How to read these notes

This book develops the mathematics of differential topology together with the quantum field theory in which it appears, following Charles Nash's *Differential Topology and Quantum Field Theory* chapter by chapter. Nash wrote a fast survey that assumes a great deal. Here every step is carried out. Every object is given explicitly, as a matrix, a transition function or a solution. Every result is traced back to a principle one already trusts: Stokes' theorem, linear algebra, Fourier analysis, gauge invariance, counting zero modes. Over some three thousand pages the aim is to understand each subject at the depth it deserves, rather than to survey it.

Structure

Part I, the Toolkit (Chapters T1–T5), builds what Nash takes for granted: differential forms and the exterior calculus; integration, Stokes' theorem and curvature; Lie groups and gauge fields; Clifford algebras, spinors and Dirac operators, with explicit gamma matrices; and the renormalisation group, from block spins and Polchinski's exact equation to fixed points, conformal invariance and the one-loop β-functions.

Part II, Following Nash (Chapters 1–12), keeps Nash's chapter numbering, so Chapter 4 here is Nash's Chapter IV. Chapter 13, on the mass gap and its topological origins, goes beyond Nash. Each chapter opens with a roadmap and closes with a summary table.

The boxes, and the whole story in seven of them

Each kind of box has one job. Rather than describe them, here is one real box of each kind, taken from the story these notes tell.

Key idea: the whole book in one line

Counting solutions is the same as integrating curvature. For an elliptic operator D (a Dirac operator in a gauge field, say),

$$\underbrace{\dim \operatorname{Ker} D - \dim \operatorname{Ker} D^\dagger}_{\text{an analyst counts zero modes}} = \underbrace{\int_M \hat{A}(M)\ \operatorname{ch}(F)}_{\text{a topologist integrates curvature}} \quad .$$

The left side depends on solving a differential equation; the right side does not change if you deform the metric or the gauge field. Instantons, anomalies, Riemann–Roch and Gauss–Bonnet are all this one equation (Chapter 4).

Key idea boxes hold the one thing to remember.

Working definition 0.1 (fibre bundle, decompressed)

Picture a space M (spacetime, a sphere, a circle). At every point x attach a copy of another space F: a line, a circle, a vector space of internal states. That copy is the **fibre** over x. All the fibres together form the **total space** E, and the projection $\pi : E \to M$ simply remembers which point each fibre hangs over. A **section** is a choice of one point in each fibre, varying smoothly with x. That is exactly what a physicist calls a field. The bundle is twisted when the fibres cannot all be labelled consistently at once: going round the space, the labels come back rotated.

Working definitions unpack every term into a picture you can compute with.

Physical picture: why charge is quantised

A magnetic monopole has no vector potential A defined on the whole sphere around it. Use one potential on the northern cap and another on the southern cap. On the equator they must differ by a gauge transformation $e^{ie\lambda(\phi)}$ of the electron's wavefunction, and going once round the equator that phase must return to itself. *The integer that counts how many times it winds is Dirac's quantisation condition*: topology, not dynamics, makes eg an integer.

Physical pictures say what is really going on.

Worked example 0.1: the monopole flux from two patches

Take $A_N = \frac{g}{2}(1-\cos\theta)\,\mathrm{d}\phi$ and $A_S = -\frac{g}{2}(1+\cos\theta)\,\mathrm{d}\phi$, so that $F = \mathrm{d}A_N = \mathrm{d}A_S = \frac{g}{2}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi$. Then

$$\int_{S^2} F \overset{(1)}{=} \int_N \mathrm{d}A_N + \int_S \mathrm{d}A_S \overset{(2)}{=} \oint_{\mathrm{eq}} A_N - \oint_{\mathrm{eq}} A_S \overset{(3)}{=} \oint_{\mathrm{eq}} g\,\mathrm{d}\phi = 2\pi g.$$

(1) Split the sphere into the two caps, and on each use the potential that is smooth there.
(2) Stokes on each cap. The southern cap's boundary is the equator traversed the other way.
(3) $A_N - A_S = g\,\mathrm{d}\phi$ is a pure gauge difference, $\mathrm{d}\lambda$ with $\lambda = g\phi$.

Single-valuedness of $e^{ie\lambda} = e^{ieg\phi}$ forces $eg \in \mathbb{Z}$, so the flux is $2\pi n/e$.

Worked examples are solved to the last line.

Watch out: pure gauge is not trivial

At infinity an instanton is "pure gauge", $A = g^{-1}\mathrm{d}g$, so its field strength vanishes there. Yet the map $g : S^3 \to \mathrm{SU}(2)$ can wrap the sphere k times, and that integer is the instanton number. Zero field strength everywhere you look does not mean nothing is there.

Pitfalls flag the confusions and sign traps.

Reading Nash (p. 32, (2.21)–(2.22))

Nash writes the symbol of $D^\alpha = (-i\partial)^\alpha$ as p^α, but with his own Fourier sign ($\mathcal{F}f = (2\pi)^{-n}\int e^{+ipx} f$) the honest answer is $(-p)^\alpha$. The slip never matters for ellipticity, which only asks where the symbol vanishes. Chapter 2 fixes the convention so his formulas hold as printed.

Reading-Nash boxes map the notes onto Nash's pages, and flag his misprints.

Recap: the dictionary this book builds

connection	gauge potential A
curvature	field strength F
section of a bundle	matter field
Chern number	monopole charge, instanton number
index of the Dirac operator	net number of fermion zero modes, the anomaly
critical points of a Morse function	classical vacua; tunnelling between them

Recaps close every section.

The labelled-equality convention

Every calculation is written as a chain. Each non-trivial equals sign carries a small label, and the labels are explained, in order, right after the chain:

$$\int_M \mathrm{d}\alpha \overset{(1)}{=} \int_{\partial M} \alpha \overset{(2)}{=} 0.$$

(1) Stokes' theorem.
(2) M is closed, so $\partial M = \varnothing$ and the integral is over nothing.

Contents

How to read these notes ii

I The Toolkit 1

T1 Differential Forms: the Working Physicist's Calculus 2

Where this chapter is going . . . 2
T1.1 Manifolds and charts: calculus without global coordinates . . . 3
T1.2 Tangent vectors, covectors and line elements . . . 10
T1.3 The wedge product and the algebra of forms . . . 17
T1.4 Metric, orientation and the Hodge star . . . 25
T1.5 The exterior derivative . . . 34
T1.6 The codifferential and the Laplace–de Rham operator . . . 43
T1.7 Maxwell's equations in the language of forms . . . 50
T1.8 Pullback and naturality . . . 62
T1.9 Interior product, Lie derivative and Cartan's formula . . . 70
T1.10 Complex coordinates and the Dolbeault operator . . . 81
Chapter summary . . . 92

T2 Integration, Stokes' Theorem, Connections and Curvature 99

Where this chapter is going . . . 99
T2.1 Integrating differential forms . . . 101
T2.2 Stokes' theorem . . . 109
T2.3 Closed and exact forms . . . 117
T2.4 A first look at de Rham cohomology . . . 127
T2.5 Connections: how a frame turns from point to point . . . 137
T2.6 Curvature . . . 150
T2.7 Geodesics: straight lines on a curved surface . . . 160
T2.8 The Gauss–Bonnet theorem: integrated curvature is topology . . . 169
T2.9 Applications: equivalence, Lagrangians, spinors and the sphere . . . 182
Chapter summary . . . 198

T3 Lie Groups, Lie Algebras and Gauge Fields 208

Where this chapter is going . . . 208
T3.1 Matrix Lie groups . . . 209
T3.2 Lie algebras: the tangent space at the identity . . . 217
T3.3 The exponential map . . . 224
T3.4 The adjoint representation and the double cover SU(2) → SO(3) . . . 231
T3.5 Representations: spin, weights and roots . . . 238
T3.6 The Maurer–Cartan form $g^{-1}\mathrm{d}g$ . . . 247
T3.7 Group actions, orbits and homogeneous spaces . . . 257
T3.8 Gauge fields: from local symmetry to curvature . . . 264
T3.9 Parallel transport, holonomy and Wilson loops . . . 278
T3.10Pure gauge, flat connections and the Chern–Simons form . . . 291
Chapter summary . . . 311

T4 Clifford Algebras, Spinors and Dirac Operators **320**
Where this chapter is going . . . 320
T4.1 Dirac's square root of the Laplacian . . . 322
T4.2 Clifford algebras: multiplying anticommuting directions . . . 329
T4.3 Gamma matrices in four dimensions . . . 336
T4.4 Gamma matrices in any dimension . . . 346
T4.5 The spin group: rotations built from reflections . . . 354
T4.6 Spin structures: putting spinors on a manifold . . . 364
T4.7 The spin connection and the Dirac operator . . . 373
T4.8 The Lichnerowicz formula, twisted Dirac operators and the index . . . 387
T4.9 Differential forms as Clifford modules . . . 402
Chapter summary . . . 437

T5 The Renormalisation Group **448**
Where this chapter is going . . . 448
T5.1 The renormalisation group: physics at a scale . . . 450
T5.2 The exact renormalisation group . . . 459
T5.3 Fixed points, linearisation and critical exponents . . . 481
T5.4 Running couplings in perturbation theory . . . 493
T5.5 Fixed points are conformal field theories . . . 509
T5.6 Quantum field theories as flows between conformal field theories . . . 521
T5.7 Beta-functions with geometry . . . 525
Reading the literature . . . 538
Chapter summary . . . 540

II Following Nash **541**

1 A Topological Preliminary **542**

Where this chapter is going . . . 542
1.1 From homeomorphism to diffeomorphism . . . 542
1.2 Some algebraic topology: homotopy . . . 554
1.3 Homotopy groups . . . 570
1.4 Cohomology and homology groups . . . 622
1.5 Fibre bundles and fibrations . . . 654
1.6 Differentiable structures for manifolds . . . 684
Chapter summary . . . 712

2 Elliptic Operators **725**
Where this chapter is going . . . 725
2.1 The meaning of ellipticity . . . 725
2.2 Ellipticity and hypo-ellipticity . . . 746
2.3 Ellipticity and vector bundles . . . 766
2.4 Pseudo-differential operators . . . 801
2.5 Pseudo-differential operators and Sobolev spaces . . . 830
2.6 Elliptic operators are Fredholm . . . 853
Chapter summary . . . 874

3 Cohomology of Sheaves and Bundles **886**
Where this chapter is going . . . 886
3.1 Sheaves . . . 886
3.2 Morphisms and exact sequences of sheaves . . . 898
3.3 Čech cohomology . . . 907
3.4 The long exact sequence . . . 919
3.5 Line bundles, $H^1(M;\mathcal{O}^*)$ and the first Chern class . . . 922
3.6 The de Rham theorem . . . 928
3.7 Complex manifolds and the Dolbeault theorem . . . 941
3.8 K-theory: why count bundles, and what we count with . . . 957
3.9 Stable equivalence: ignoring trivial junk . . . 966
3.10 The group $K(M)$: subtracting bundles . . . 973
3.11 Classifying spaces and the stable range . . . 981
3.12 Bundles over spheres: clutching functions and $\widetilde{K}(S^n)$ . . . 990
3.13 Bott periodicity . . . 1002
3.14 Real and quaternionic periodicity: the period eight . . . 1012
3.15 Characteristic classes: what they measure and where they live . . . 1026
3.16 Chern–Weil theory: characteristic classes from curvature . . . 1032
3.17 The splitting principle: pretend every bundle is a sum of lines . . . 1045
3.18 The Chern character and the Todd class . . . 1053
3.19 Real bundles, complexification and Pontryagin classes . . . 1061
3.20 The Euler class, Gauss–Bonnet–Chern, and the genera $\hat{A}$ and L . . . 1070

3.21 Fredholm operators and $K(X)$ . . . 1087
Chapter summary . . . 1110

4 Index Theory for Elliptic Operators 1118
Where this chapter is going . . . 1118
4.1 Counting solutions: the index of a linear map . . . 1118
4.2 Elliptic operators have an index . . . 1125
4.3 K-theory from complexes of bundles . . . 1133
4.4 Elliptic complexes and the rolled-up operator . . . 1141
4.5 The analytical index . . . 1150
4.6 The topological index . . . 1154
4.7 The Atiyah–Singer index theorem . . . 1161
4.8 The heat-kernel view: McKean–Singer . . . 1171
4.9 From K-theory to numbers: the index formula in characteristic classes . . . 1181
4.10 Two vanishing results: odd dimensions and operators on functions . . . 1191
4.11 Orientable manifolds: the index formula on X itself . . . 1198
4.12 The de Rham complex and the Gauss–Bonnet theorem . . . 1206
4.13 The Dolbeault complex and the Riemann–Roch theorem . . . 1214
4.14 The signature complex and the Hirzebruch signature theorem . . . 1224
4.15 The spin complex, the Dirac operator and the $\hat{A}$-genus . . . 1234
4.16 Coupling to gauge fields: counting fermion zero modes . . . 1259
4.17 Twisted complexes . . . 1270
4.18 The index theorem for families of operators . . . 1284
4.19 The index for real families . . . 1298
4.20 Index theory and fixed points . . . 1306
4.21 Index theory for manifolds with boundary . . . 1316
Chapter summary . . . 1368

5 Some Algebraic Geometry 1381
Where this chapter is going . . . 1381
5.1 Algebraic varieties . . . 1383
5.2 Riemann surfaces and divisors . . . 1414
5.3 Serre duality, line bundles and Kähler manifolds . . . 1448
5.4 The Teichmüller space $\mathcal{T}_p$ . . . 1492
5.5 The moduli space $\mathcal{M}_p$ . . . 1506
5.6 The dimension of the moduli space . . . 1518
5.7 Weierstrass gaps and Weierstrass points . . . 1546
Chapter summary . . . 1578

6 Infinite Dimensional Groups 1591
Where this chapter is going . . . 1591

6.1 Some infinite dimensional groups . . . 1593
6.2 Group extensions . . . 1620
6.3 Representations . . . 1660
Chapter summary . . . 1715

7 Morse Theory 1719
Where this chapter is going . . . 1719
7.1 Critical points, the Hessian and the index . . . 1721
7.2 Counting critical points: the Morse inequalities . . . 1730
7.3 How the topology changes at a critical point: sublevel sets, handles and gradient flow . . . 1740
7.4 Three classic calculations: $\mathbb{CP}^n$, surfaces of genus p, and degenerate critical points 1749
7.5 Critical submanifolds: Morse–Bott theory . . . 1759
7.6 Equivariant cohomology: keeping track of a symmetry . . . 1767
7.7 Equivariant Morse theory . . . 1782
7.8 Infinite dimensions: geodesics, loop spaces and Bott periodicity . . . 1789
7.9 Supersymmetric quantum mechanics and Morse theory: the plan . . . 1830
7.10 The supersymmetry algebra . . . 1834
7.11 Supersymmetry from differential forms . . . 1842
7.12 Witten's deformation of the exterior derivative . . . 1850
7.13 The deformed Laplacian: a Schrödinger operator with spin . . . 1855
7.14 Harmonic oscillators at the critical points: the weak Morse inequalities . . . 1862
7.15 Instantons: tunnelling between critical points . . . 1872
7.16 The Morse–Witten complex . . . 1886
Chapter summary . . . 1911

8 Instantons and Monopoles 1920
Where this chapter is going . . . 1920
8.1 The topology of gauge fields . . . 1920
8.2 Secondary characteristic classes . . . 1974
8.3 Instantons: the Yang–Mills action and its critical points . . . 2007
8.4 Self-duality and the Bogomolny bound . . . 2014
8.5 The BPST instanton and the 't Hooft ansatz . . . 2023
8.6 Gauge invariance, gauge fixing and ellipticity . . . 2038
8.7 The instanton moduli space and reducible connections . . . 2045
8.8 The deformation complex . . . 2055
8.9 Counting the moduli: the index theorem . . . 2065
8.10 The $k = 1$ moduli space and the ADHM construction . . . 2079
8.11 The moduli space as a global object . . . 2096
8.12 Monopoles: the Yang–Mills–Higgs system in three dimensions . . . 2108
8.13 The Bogomolny equation and the Prasad–Sommerfield monopole . . . 2119

8.14 Monopoles as symmetric instantons . . . 2129
8.15 Monopole moduli . . . 2141
8.16 Monopole dynamics: forces and the geodesic approximation . . . 2152
8.17 Two monopoles: the Atiyah–Hitchin manifold and scattering . . . 2166
8.18 Critical point theory and gauge theories . . . 2176
Chapter summary . . . 2203

9 The Elliptic Geometry of Strings **2208**
Where this chapter is going . . . 2208
9.1 The bosonic string . . . 2209
9.2 The space of metrics . . . 2236
9.3 The Weil–Petersson metric . . . 2254
Chapter summary . . . 2283

10 Anomalies **2295**
Where this chapter is going . . . 2295
10.1 Introduction: what an anomaly is . . . 2295
10.2 Anomalies and Yang–Mills theories I: chiral fermions, the index and the determinant 2302
10.3 Anomalies and Yang–Mills theories II: the anomalous Ward identity, computed 2313
10.4 Anomalies and Yang–Mills theories III: the measure, the heat kernel and the index 2341
10.5 Anomalies and Yang–Mills theories IV: non-abelian anomalies, consistency and descent . . . 2353
10.6 Anomalies and Yang–Mills theories V: the topology of the anomaly . . . 2372
10.7 Gravitational anomalies . . . 2383
10.8 The critical dimension for strings . . . 2390
10.9 Global anomalies . . . 2409
10.10 Anomalies from a Hamiltonian perspective . . . 2434
Chapter summary . . . 2489

11 Conformal Quantum Field Theories **2495**
Where this chapter is going . . . 2495
11.1 Conformal invariance and quantum field theory . . . 2496
11.2 Weyl rescalings versus conformal transformations . . . 2507
11.3 Conformal field theories in two dimensions . . . 2524
11.4 Relation to the Virasoro algebra . . . 2550
11.5 Critical phenomena and the two-dimensional Ising model . . . 2604
11.6 The Ising model as the $c = \frac{1}{2}$ conformal field theory . . . 2616
11.7 Partition functions on the torus . . . 2630
11.8 Modular forms and the modular invariance of Z . . . 2639
11.9 Operator products and correlation functions . . . 2655
11.10 Fusion rules and the Verlinde formula . . . 2671

Part I

The Toolkit

Chapter T1

Differential Forms: the Working Physicist's Calculus

Where this chapter is going

Nash writes on page 3 that he wants "to make full use of calculus on manifolds to calculate geometric and topological quantities". He then uses that calculus on every page without ever setting it up. This chapter sets it up. It is the calculus a physicist already knows (gradient, curl, divergence, line and surface integrals, Jacobians, Maxwell's equations), rewritten in a language that works in any dimension, in any signature, in any coordinates, and on curved spaces such as spheres and tori where no single coordinate system covers everything.

The language is that of **differential forms**. A differential form is, very concretely, *the thing you put under an integral sign*: $F_x\,\mathrm{d}x + F_y\,\mathrm{d}y + F_z\,\mathrm{d}z$ for a work integral, $B_x\,\mathrm{d}y\,\mathrm{d}z + \dots$ for a flux, $\rho\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z$ for a charge. We will learn to multiply such objects (the wedge product $\wedge$), to convert one kind into another using a metric (the Hodge star $\star$), to differentiate them (the exterior derivative d, which contains gradient, curl and divergence as special cases), and to transport them along maps (the pullback f^*) and along flows (the Lie derivative $\mathcal{L}_X$). Finally we complexify: on a complex manifold d splits into two halves $\partial + \bar\partial$, and $\bar\partial$ is the operator behind the Dolbeault complex that Nash uses in Chapters 3 and 4.

We follow Tevian Dray's Part III (Chapters 11–15) closely in spirit and pace: vector calculus first, then short computations, one idea at a time. Integration and Stokes' theorem are left to the next toolkit chapter (Chapter T2); here we only use them in passing. Figure T1.1 shows how the pieces of this chapter feed each other and the rest of the book.

Key idea: Conventions used in this chapter

- Manifolds are smooth, of dimension n, with local coordinates x^μ ($\mu = 1, \dots, n$). Repeated indices are summed (Einstein).
- A p-form is written $\alpha = \frac{1}{p!}\,\alpha_{\mu_1\dots\mu_p}\,\mathrm{d}x^{\mu_1}\wedge\cdots\wedge\mathrm{d}x^{\mu_p}$ with totally antisymmetric components.
- The wedge product acts on vectors by the determinant rule $(\alpha\wedge\beta)(v,w) = \alpha(v)\beta(w) - \alpha(w)\beta(v)$, so $(\mathrm{d}x\wedge\mathrm{d}y)(\partial_x,\partial_y) = 1$ (Dray's convention).
- The Hodge star is defined by $\alpha\wedge\star\beta = g(\alpha,\beta)\,\mathrm{vol}$.
- Signature s = number of minus signs in the metric. Minkowski space uses $\eta = \mathrm{diag}(-1,+1,+1,+1)$ in coordinates (t,x,y,z), orientation $\mathrm{vol} = \mathrm{d}t\wedge\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z$, $c = 1$, Heaviside–Lorentz units.
- The Laplace–de Rham operator $\Delta = \mathrm{d}\delta + \delta\mathrm{d}$ is a *positive* operator: on functions in flat

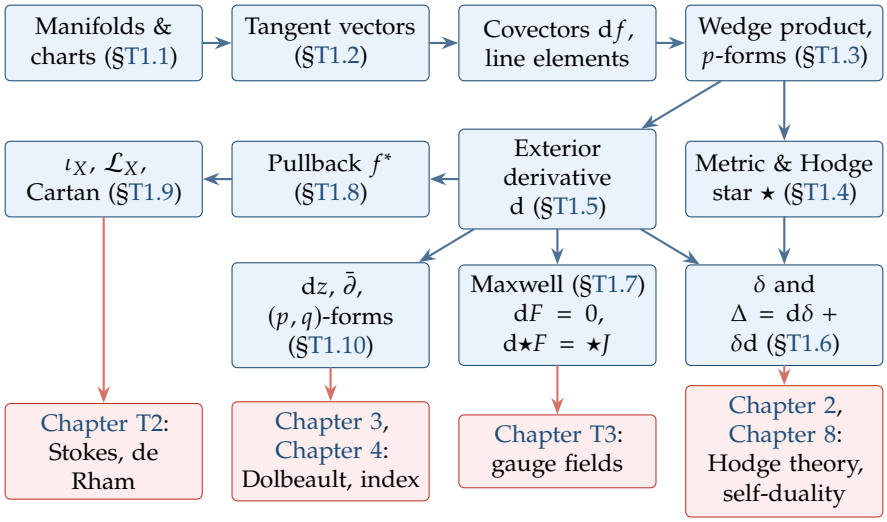

Figure T1.1: The logic of this chapter. Blue boxes are sections; red boxes are the places later in the book that lean on them. Read the top row as "where do vectors and integrands live?", the middle row as "what can we do to integrands?", and the bottom row as "what physics comes out?".

space $\Delta = -\nabla^2$. This is Nash's convention (his (2.42)).

T1.1 Manifolds and charts: calculus without global coordinates

Here is the problem. We want to do calculus (differentiate fields, write field equations, integrate densities) on spaces like the sphere S^2, the circle S^1, the torus T^2, a Euclidean space-time with the point at infinity added (S^4, the home of instantons), or the space of all gauge fields modulo gauge transformations. Calculus needs coordinates. But none of these spaces can be covered by a single coordinate system without something going wrong somewhere: the longitude on a sphere is undefined at the poles, the angle on a circle jumps by 2π somewhere.

The way out is simple, and every physicist already uses it. Cover the space with several overlapping coordinate systems, each of them good where it is defined, and write down how to translate between them on the overlaps. That is all a *manifold* is. Topology enters because the translation rules on the overlaps can carry global information (twists, windings) that no single patch can see.

T1.1.1 Charts: coordinate patches

Working definition T1.1 (chart, or coordinate patch)

A **chart** on a space M is an open region $U \subset M$ [with each of its points, U also contains all sufficiently nearby points of M] together with n functions $x^1, \dots, x^n$ on U that label the points of U one-to-one and continuously by points of an open region of $\mathbb{R}^n$. We write $\varphi : U \to \mathbb{R}^n$, $\varphi(p) = (x^1(p), \dots, x^n(p))$. *Operational test:* nearby points get nearby labels, distinct points get distinct labels, and every label near a used label is also used (the image is open).

The last condition is the one people forget. The usual polar angle $\phi \in [0, 2\pi)$ on the circle labels every point once, but it is *not* a chart on the whole circle: the points just below the positive x-axis get labels near 2π while the point on the axis gets label 0. Nearby points get distant

labels. The fix is to throw away one point, and cover it with a second chart.

Physical picture: A chart is a tracing on a paper cutout

Press a piece of paper onto the sphere, trace the curve drawn there, then lay the paper flat and read the curve off as $x^1(t), x^2(t)$ (Figure T1.2). Differentiating, integrating and parallel transport are all done on this flat tracing. It gives the same answers as embedding the sphere in $\mathbb{R}^3$ and watching how the basis vectors turn from point to point, $\nabla_a e_b = \Gamma^c{}_{ab}\, e_c$ (Example T2.27), without needing any embedding.

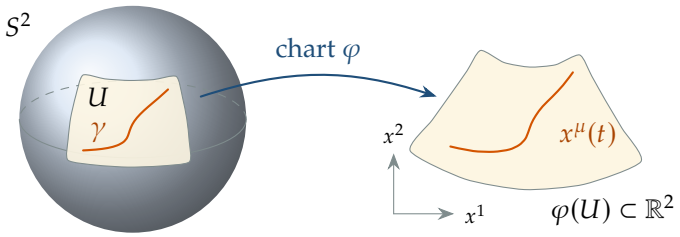

Figure T1.2: A chart as a tracing. Left: a paper cutout pressed onto the sphere covers the region U, and the curve γ is traced onto it. Right: the same cutout laid flat. The tracing is now an ordinary plane curve $x^\mu(t)$, and every derivative and integral is computed there. On the sphere the bottom edge of the cutout is a little longer than the top edge. On the table it is more than twice as long: flattening stretches the paper unevenly, and the metric remembers by how much. (The flattening drawn is the south stereographic chart of Example T1.3, turned so that north is up.)

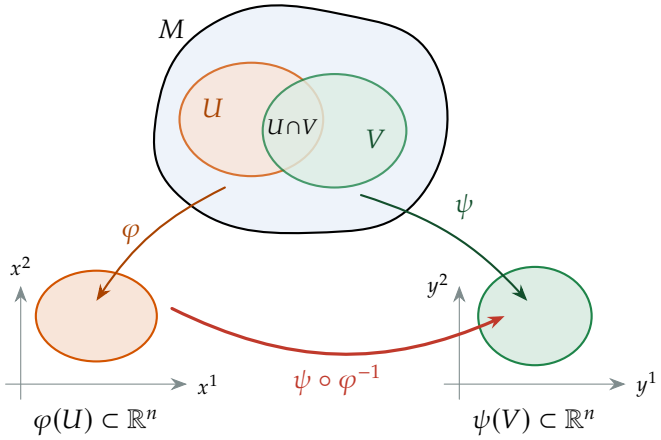

Figure T1.3: Two overlapping charts. A point in the overlap $U \cap V$ has two sets of coordinates, x^μ and y^μ. The red arrow, the *transition map* $y = \psi \circ \varphi^{-1}(x)$, is an ordinary function between regions of $\mathbb{R}^n$, and it is all we ever need to compute with.

T1.1.2 Transition maps and atlases

On the overlap $U \cap V$ of two charts, each point has two coordinate labels, x^μ from φ and y^μ from ψ. The rule converting one into the other,

$$y^\mu = y^\mu(x^1, \ldots, x^n) \qquad \text{i.e.} \qquad \psi \circ \varphi^{-1} : \ \varphi(U \cap V) \to \psi(U \cap V), \tag{T1.1}$$

is called the **transition map**. It is an ordinary map between open sets of $\mathbb{R}^n$, so it makes sense to ask whether it is differentiable.

Working definition T1.2 (smooth manifold)

A **smooth manifold** of dimension n is a space M covered by charts [open regions $U \subset M$, each labelled one-to-one by coordinates $x^1, \dots, x^n$] (a collection of charts covering M is an **atlas**) such that every transition map (T1.1) is infinitely differentiable, with infinitely differentiable inverse. *Operational test:* write down enough charts to cover every point, then compute every transition map on every overlap and check that the formulas involve no division by zero, no square roots of zero, and no absolute values on the overlap.

Formally one also asks that M be Hausdorff and second countable (two technical conditions that exclude pathological examples like "a line with two origins"); every space we meet satisfies them.

Why do we insist on smooth transition maps? Because *everything we define in one chart must mean the same thing in the other*. We will define a smooth function, a tangent vector, a differential form, by giving it in coordinates. The chain rule then converts it into any other chart. The chain rule needs derivatives of $y^\mu(x)$, and higher derivatives of fields need higher derivatives of $y^\mu(x)$. Smoothness of the transition maps is exactly what makes "smooth" a chart-independent notion.

Working definition T1.3 (smooth function on a manifold)

A function $f : M \to \mathbb{R}$ is **smooth** if in every chart the coordinate expression $f(x^1, \dots, x^n)$ is an infinitely differentiable function of the x^μ. *Test:* it suffices to check this in the charts of one atlas [a set of charts that together cover every point of M], since the transition maps [the formulas $y^\mu(x^1, \dots, x^n)$ converting one chart's coordinates into another's] are smooth.

T1.1.3 The circle

Worked example T1.1: S^1 with two angle charts

Let $S^1 = \{(x, y) \in \mathbb{R}^2 : x^2 + y^2 = 1\}$. Chart 1: $U_1 = S^1 \setminus \{(1, 0)\}$, with coordinate $\theta \in (0, 2\pi)$ defined by $(x, y) = (\cos\theta, \sin\theta)$. Chart 2: $U_2 = S^1 \setminus \{(-1, 0)\}$, with $\theta' \in (-\pi, \pi)$ defined by the same formula. Each chart misses one point, and together they cover the circle.
The overlap $U_1 \cap U_2$ is the circle minus two points, which has *two* pieces: the upper half ($y > 0$) and the lower half ($y < 0$). On the upper half both angles lie in $(0, \pi)$ and name the same point, so $\theta' = \theta$. On the lower half, $\theta \in (\pi, 2\pi)$ while $\theta' \in (-\pi, 0)$, so

$$\theta' \overset{(1)}{=} \theta - 2\pi \qquad (y < 0),$$
$$\frac{\mathrm{d}\theta'}{\mathrm{d}\theta} \overset{(2)}{=} 1 \qquad \text{on the whole overlap.}$$

(1) Both angles give the same point $(\cos\theta, \sin\theta)$, and the cosine and sine are 2π-periodic; the shift that maps $(\pi, 2\pi)$ onto $(-\pi, 0)$ is -2π.
(2) A constant shift has derivative one; the transition map is smooth (indeed linear) on both components.

So S^1 is a one-dimensional smooth manifold. Notice the constant -2π on one component of the overlap: it is invisible to derivatives, but it will make the 1-form "$\mathrm{d}\theta$" globally defined while θ itself is not. That is the first appearance of topology, and we return to it in Example T1.30 and in Chapter T2.

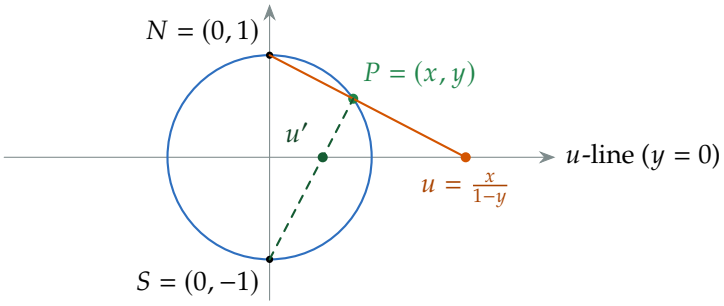

Figure T1.4: Stereographic projection of the circle. The line from the north pole N through P hits the horizontal axis at u; the line from the south pole S through P hits it at u'. Each projection covers every point except its own pole. Points near N are sent far out along the u-line, but near 0 along the u'-line: $u' = 1/u$.

Worked example T1.2: S^1 with two stereographic charts

Project from the north pole $N = (0, 1)$: the straight line through N and $P = (x, y)$ meets the line $y = 0$ at the point u (Figure T1.4). By similar triangles, $u/1 = x/(1 - y)$, so

$$u = \frac{x}{1-y} \quad \text{on } U_N = S^1 \setminus \{N\}, \qquad u' = \frac{x}{1+y} \quad \text{on } U_S = S^1 \setminus \{S\},$$

the second formula coming from projecting from $S = (0, -1)$ instead. On the overlap (the circle minus both poles, where $x \neq 0$),

$$\begin{aligned} u\,u' &\overset{(1)}{=} \frac{x^2}{(1-y)(1+y)} \\ &\overset{(2)}{=} \frac{x^2}{1-y^2} \\ &\overset{(3)}{=} 1, \qquad \text{so} \qquad u' = \frac{1}{u}. \end{aligned}$$

(1) Multiply the two definitions.
(2) Difference of squares.
(3) On the circle, $1 - y^2 = x^2$, and $x \neq 0$ on the overlap.

The transition map $u \mapsto 1/u$ is smooth on the overlap $u \neq 0$ (the two components $u > 0$ and $u < 0$ are the right and left halves of the circle). The inverse map is also useful:

$$x = \frac{2u}{1+u^2}, \qquad y = \frac{u^2-1}{u^2+1},$$

which one checks by substituting into $x^2 + y^2$ and into $x/(1 - y)$. This is the rational parametrisation of the circle behind the "$t = \tan(\theta/2)$" substitution of integral calculus.

Watch out: One chart is never enough for a compact manifold

You cannot cover all of S^1 with one chart. A chart is a continuous one-to-one map onto an *open* interval, and the image of a compact space under a continuous map is compact. A compact open subset of $\mathbb{R}$ is empty. The same argument works for S^2, T^2 and every compact manifold: at least two charts are always needed. Physicists meet this as "coordinate singularities" (the poles of spherical coordinates, $r = 2m$ in Schwarzschild coordinates),

which are artefacts of a bad chart, not of the space.

T1.1.4 The two-sphere, worked out completely

Take $S^2 = \{(X, Y, Z) \in \mathbb{R}^3 : X^2 + Y^2 + Z^2 = 1\}$. Project from the north pole $N = (0, 0, 1)$ onto the equatorial plane $Z = 0$; the image point has coordinates (u, v). Project from the south pole $S = (0, 0, -1)$ instead; call the image (u', v'). The same similar-triangles argument as for the circle gives

$$(u, v) = \left(\frac{X}{1 - Z}, \frac{Y}{1 - Z}\right), \qquad (u', v') = \left(\frac{X}{1 + Z}, \frac{Y}{1 + Z}\right). \tag{T1.2}$$

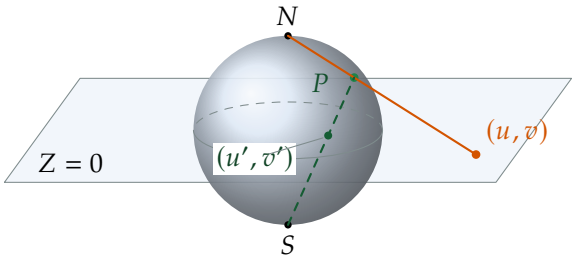

Figure T1.5: Stereographic charts on S^2. A point P in the northern hemisphere is projected from N to a point far from the origin, and from S to a point near the origin. The north chart misses only N (it goes to infinity), the south chart misses only S. The two labels are related by inversion in the unit circle, (T1.3).

Worked example T1.3: Transition map and Jacobian for S^2

First the transition map. Write $\rho^2 = u^2 + v^2$. Then

$$\begin{aligned} \rho^2 &\overset{(1)}{=} \frac{X^2 + Y^2}{(1 - Z)^2} \overset{(2)}{=} \frac{1 - Z^2}{(1 - Z)^2} \overset{(3)}{=} \frac{1 + Z}{1 - Z}, \\ u' &\overset{(4)}{=} \frac{X}{1 + Z} = \frac{X}{1 - Z} \cdot \frac{1 - Z}{1 + Z} \overset{(5)}{=} \frac{u}{\rho^2}, \qquad v' = \frac{v}{\rho^2}. \end{aligned} \tag{T1.3}$$

(1) Definition (T1.2) of u, v.
(2) On the sphere, $X^2 + Y^2 = 1 - Z^2$.
(3) Factor $1 - Z^2 = (1 - Z)(1 + Z)$ and cancel one factor.
(4) Definition of u'; multiply and divide by $1 - Z$.
(5) The first factor is u and the second is $1/\rho^2$ by the first line.

The overlap is the sphere minus both poles, i.e. $\rho \neq 0$ (and $\rho \neq \infty$), where (T1.3) is manifestly smooth: it is inversion in the unit circle. Now the Jacobian matrix:

$$\begin{aligned} \frac{\partial u'}{\partial u} &\overset{(1)}{=} \frac{\rho^2 - 2u^2}{\rho^4} = \frac{v^2 - u^2}{\rho^4}, & \frac{\partial u'}{\partial v} &\overset{(2)}{=} -\frac{2uv}{\rho^4}, \\ \frac{\partial v'}{\partial u} &= -\frac{2uv}{\rho^4}, & \frac{\partial v'}{\partial v} &= \frac{u^2 - v^2}{\rho^4}, \end{aligned}$$

$$\begin{aligned} \det \frac{\partial(u', v')}{\partial(u, v)} &\overset{(3)}{=} \frac{(v^2 - u^2)(u^2 - v^2) - 4u^2v^2}{\rho^8} \\ &\overset{(4)}{=} -\frac{(u^2 - v^2)^2 + 4u^2v^2}{\rho^8} \overset{(5)}{=} -\frac{(u^2 + v^2)^2}{\rho^8} = -\frac{1}{\rho^4}. \end{aligned}$$

(1) Quotient rule on $u/(u^2+v^2)$: $(\rho^2\cdot 1 - u\cdot 2u)/\rho^4$, and $\rho^2 - 2u^2 = v^2 - u^2$.
(2) Quotient rule with the numerator u independent of v.
(3) 2×2 determinant, $ad - bc$.
(4) Pull out the minus sign.
(5) $(a-b)^2 + 4ab = (a+b)^2$ with $a = u^2$, $b = v^2$.

The Jacobian determinant is never zero on the overlap, so the transition map is a diffeomorphism there. It is *negative*. We return to that sign immediately.

For computing, the inverse of (T1.2) is indispensable:

$$X = \frac{2u}{1+\rho^2}, \qquad Y = \frac{2v}{1+\rho^2}, \qquad Z = \frac{\rho^2-1}{\rho^2+1}. \tag{T1.4}$$

Check: $X^2+Y^2+Z^2 = \big(4\rho^2 + (\rho^2-1)^2\big)/(1+\rho^2)^2 = (\rho^2+1)^2/(\rho^2+1)^2 = 1$, and $1 - Z = 2/(1+\rho^2)$, so $X/(1-Z) = u$. The height function Z is a smooth function on S^2 because in the north chart it is the rational function $(\rho^2-1)/(\rho^2+1)$, and in the south chart it is $(1-\rho'^2)/(1+\rho'^2)$, both smooth everywhere they are defined.

T1.1.5 Orientation

A negative Jacobian determinant means the two charts disagree about handedness: a small counter-clockwise loop in the (u,v) plane is a clockwise loop in the (u',v') plane. Integrals of fluxes depend on handedness, so we need to know when a consistent choice exists.

Working definition T1.4 (orientable manifold)

An atlas is **oriented** if every transition map [the formulas $y^\mu(x)$ converting one chart's coordinates into another's on an overlap] has positive Jacobian determinant $\det(\partial y^\mu/\partial x^\nu) > 0$ on every overlap [the two charts agree there on handedness, e.g. in 2D on which small loops run counter-clockwise]. A manifold is **orientable** if it admits an oriented atlas. *Operational test:* compute the Jacobian determinants of your transition maps; if some are negative, try flipping the sign of one coordinate in some charts; if you can make all of them positive, the manifold is orientable.

For S^2 the fix is to flip one coordinate in the south chart: use $(u', -v')$. The new transition map has Jacobian determinant $(-1)\times(-1/\rho^4) = +1/\rho^4 > 0$. So S^2 is orientable.

Physical picture: The Riemann sphere is hiding here

Combine the north coordinates into one complex number $w = u + iv$, and the flipped south coordinates into $w' = u' - iv'$. Then (T1.3) says $u' + iv' = w/|w|^2 = 1/\bar{w}$, so $w' = \overline{1/\bar{w}} = 1/w$. The transition map of the oriented atlas is the holomorphic map $w \mapsto 1/w$: the sphere is the complex projective line $\mathbb{CP}^1$, the Riemann sphere. We use this in Section T1.10.

The standard non-orientable example is the Möbius band: going once around it reverses a small circle's sense of rotation, and any atlas has a transition map with negative determinant. Nash's orientability discussions (the first Stiefel–Whitney class, Chapter 1) are the topological version of this test.

Worked example T1.4: The torus T^2

Let $T^2 = \mathbb{R}^2/\mathbb{Z}^2$: points of the plane with $(x, y) \sim (x + m, y + n)$ for integers m, n. Chart: take any open square of side less than 1 in the plane; its points are pairwise inequivalent, so (x, y) restricted to it is a chart. Four such squares, say centred at $(0, 0)$, $(\frac{1}{2}, 0)$, $(0, \frac{1}{2})$, $(\frac{1}{2}, \frac{1}{2})$ with side 0.9, cover the torus. On an overlap, two labels of the same point differ by an integer vector:

$$(x', y') = (x + m,\ y + n), \qquad \frac{\partial(x', y')}{\partial(x, y)} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix},$$

with (m, n) constant on each connected piece of the overlap. All transition maps are translations: smooth, with determinant +1. So T^2 is an orientable smooth manifold, and the differentials $\mathrm{d}x$, $\mathrm{d}y$ make sense globally even though x and y do not (as with $\mathrm{d}\theta$ on S^1). This is the torus on which Nash's string theory (Chapter 9) and many index-theorem examples live.

T1.1.6 Manifolds defined by equations

Most manifolds a physicist meets are defined as the solution set of equations: the sphere $X^2 + Y^2 + Z^2 = 1$, the mass shell $p^2 = -m^2$, a group such as $\mathrm{SU}(2) = \{g : g^\dagger g = 1, \det g = 1\}$. There is a one-line test that such a set is a manifold.

Key idea: Regular level sets are manifolds

Let $f : \mathbb{R}^N \to \mathbb{R}^k$ be smooth and let $M = f^{-1}(c)$. If at every point of M the k differentials $\mathrm{d}f^1, \dots, \mathrm{d}f^k$ are linearly independent (the Jacobian matrix of f has rank k), then M is a smooth manifold of dimension $N - k$.

Why: by the implicit function theorem, near any point of M we can solve the k equations for k of the coordinates in terms of the other $N - k$, and those $N - k$ coordinates form a chart. For the sphere, $f = X^2 + Y^2 + Z^2$ has $\mathrm{d}f = 2(X\,\mathrm{d}X + Y\,\mathrm{d}Y + Z\,\mathrm{d}Z)$, which vanishes only at the origin, not on M; so S^2 is a 2-manifold. Near a point with $Z > 0$ we solve $Z = \sqrt{1 - X^2 - Y^2}$ and use (X, Y) as a chart: six such "hemisphere charts" ($Z > 0$, $Z < 0$, $X > 0$, ...) give yet another atlas of S^2.

Watch out: A manifold is not its coordinates

The same sphere carries the stereographic atlas, the hemisphere atlas and the (θ, ϕ) angles (which fail at the poles and along a line of longitude). Anything physical (a field, an integral, a curvature) must come out the same in every chart. Much of this chapter is about building objects for which that is automatic: $\mathrm{d}f$, p-forms, $\star$, d.

Reading Nash (p. 3 and p. 15)

On p. 3 Nash distinguishes topological, piecewise-linear and differentiable manifolds and then says he will "usually deal with differentiable manifolds" and simply call them manifolds. That is our convention too. On p. 15 he introduces the tangent bundle $TM = \bigcup_p T_pM$ as "one of the most basic examples" of a bundle, taking the tangent space T_pM for granted; the next section constructs it.

Recap

- A manifold is a space covered by overlapping coordinate charts whose transition maps are smooth.
- S^1: angle charts with transition $\theta' = \theta$ or $\theta - 2\pi$; stereographic charts with $u' = 1/u$.
- S^2: stereographic charts with $u' = u/\rho^2$, $v' = v/\rho^2$ and Jacobian $-1/\rho^4$; flipping v' makes the atlas oriented and the transition becomes $w' = 1/w$ (the Riemann sphere).
- Orientable = transition Jacobians can all be made positive.
- Regular level sets $f^{-1}(c)$ of maps with independent $\mathrm{d}f^i$ are manifolds.

T1.2 Tangent vectors, covectors and line elements

What is a vector on a sphere? In $\mathbb{R}^3$ we draw arrows, but an arrow at a point of S^2 sticks out of the sphere unless it happens to be tangent, and a creature living on the sphere has no "outside" to draw it in. We need a notion of vector that uses only the manifold and its charts. There are two equivalent answers, and physicists use both without noticing: a vector is the *velocity of a curve*, and a vector is a *directional derivative*. Once vectors are in place, the object dual to them, the *covector*, turns out to be the familiar differential $\mathrm{d}f$. That is the first differential form.

T1.2.1 Vectors as velocities of curves

Let $\gamma(t)$ be a curve on M passing through a point p at $t = 0$. In a chart it is described by n functions $x^\mu(t)$, and its velocity at p has components

$$v^\mu = \left.\frac{\mathrm{d}x^\mu}{\mathrm{d}t}\right|_{t=0}. \tag{T1.5}$$

In another chart with coordinates y^μ, the same curve is $y^\mu(t) = y^\mu(x(t))$ and the chain rule gives

$$\tilde{v}^\mu = \left.\frac{\mathrm{d}y^\mu}{\mathrm{d}t}\right|_0 = \frac{\partial y^\mu}{\partial x^\nu}\left.\frac{\mathrm{d}x^\nu}{\mathrm{d}t}\right|_0 = \frac{\partial y^\mu}{\partial x^\nu}\, v^\nu. \tag{T1.6}$$

This is the **contravariant** transformation law: components of a vector transform with the Jacobian matrix of the transition map.

Working definition T1.5 (tangent vector)

A **tangent vector** at p is an assignment of n numbers v^μ to each chart around p [each coordinate system x^μ defined on a region containing p], related between charts by (T1.6). Every such assignment is the velocity of some curve (take $x^\mu(t) = x^\mu(p) + tv^\mu$). The set of all tangent vectors at p is the **tangent space** T_pM, an n-dimensional vector space. A **vector field** is a smooth choice of $v \in T_pM$ at every p [in every chart the components $v^\mu(x)$ are infinitely differentiable functions of the x^ν].

T1.2.2 Vectors as directional derivatives

A velocity tells us how fast any function changes as we move along the curve. For a function f on M,

$$\left.\frac{\mathrm{d}}{\mathrm{d}t} f(\gamma(t))\right|_{t=0} \overset{(1)}{=} \frac{\partial f}{\partial x^\mu}\left.\frac{\mathrm{d}x^\mu}{\mathrm{d}t}\right|_0 \overset{(2)}{=} v^\mu \frac{\partial f}{\partial x^\mu}. \tag{T1.7}$$

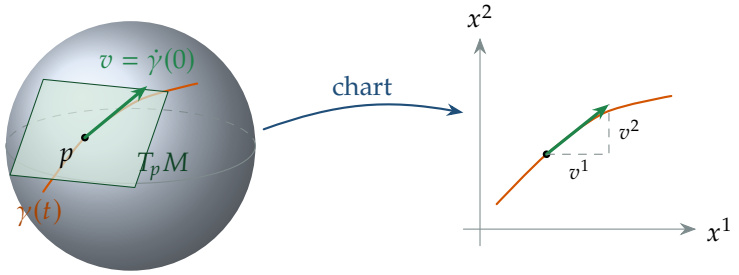

Figure T1.6: A tangent vector is the velocity of a curve through p. On the sphere we can draw it in the tangent plane T_pM; in a chart it is simply the pair of numbers $v^\mu = \dot x^\mu(0)$, read off the flattened tracing of Figure T1.2. Another chart gives other numbers, related by the Jacobian, (T1.6).

(1) Chain rule in the chart.
(2) Definition (T1.5) of the components v^μ.

The right-hand side depends on the curve only through v. So we may *identify* the vector with the differential operator it defines:

$$v = v^\mu \frac{\partial}{\partial x^\mu} \equiv v^\mu \partial_\mu, \qquad v(f) = v^\mu \partial_\mu f. \tag{T1.8}$$

The n operators $\partial_\mu = \partial/\partial x^\mu$ form a basis of T_pM, the **coordinate basis**. This is the notation of every differential geometry book, and it has a pleasant bonus: the transformation law (T1.6) is just the chain rule for partial derivatives,

$$\frac{\partial}{\partial x^\nu} = \frac{\partial y^\mu}{\partial x^\nu}\frac{\partial}{\partial y^\mu}, \qquad \text{so} \qquad v^\nu \frac{\partial}{\partial x^\nu} = \left(\frac{\partial y^\mu}{\partial x^\nu} v^\nu\right)\frac{\partial}{\partial y^\mu} = \tilde v^\mu \frac{\partial}{\partial y^\mu}.$$

The combination $v^\mu \partial_\mu$ is chart-independent: the components and the basis vectors transform oppositely and the changes cancel.

Dictionary: vectors

physicist writes	geometer writes
$\hat x, \hat y, \hat z$	$\partial_x, \partial_y, \partial_z$
$\vec v \cdot \nabla f$	$v(f)$
$\vec v = v_x \hat x + v_y \hat y$	$v = v^x \partial_x + v^y \partial_y$
$\hat r, \hat\phi$ (unit)	$\partial_r, \frac{1}{r}\partial_\phi$

Worked example T1.5: Polar coordinate basis vectors

With $x = r\cos\phi$, $y = r\sin\phi$, the chain rule gives

$$\partial_r \overset{(1)}{=} \frac{\partial x}{\partial r}\partial_x + \frac{\partial y}{\partial r}\partial_y = \cos\phi\,\partial_x + \sin\phi\,\partial_y \overset{(2)}{=} \frac{x\,\partial_x + y\,\partial_y}{r},$$
$$\partial_\phi \overset{(3)}{=} \frac{\partial x}{\partial \phi}\partial_x + \frac{\partial y}{\partial \phi}\partial_y = -r\sin\phi\,\partial_x + r\cos\phi\,\partial_y \overset{(4)}{=} -y\,\partial_x + x\,\partial_y.$$

(1) The rule $\partial/\partial r = (\partial x/\partial r)\,\partial/\partial x + (\partial y/\partial r)\,\partial/\partial y$.
(2) Substitute $\cos\phi = x/r$, $\sin\phi = y/r$.
(3) Same rule for ϕ.
(4) Substitute $r\sin\phi = y$, $r\cos\phi = x$.

So ∂_r is the unit radial vector $\hat r$, but ∂_ϕ has length r: it is $r\hat\phi$. Coordinate basis vectors are

in general *not* unit vectors. The vector field $\partial_\phi = -y\partial_x + x\partial_y$ is the generator of rotations, which we will meet again as a Killing vector and in the Lie derivative (Section T1.9). Acting on functions: $\partial_\phi(x) = -y$, $\partial_\phi(y) = x$, $\partial_\phi(x^2+y^2) = 0$.

Worked example T1.6: A latitude circle on S^2, seen in two charts

Take the circle of constant $Z = Z_0$ on the unit sphere, traversed as $X = a\cos t$, $Y = a\sin t$ with $a = \sqrt{1-Z_0^2}$. In the north stereographic chart (T1.2), $u = a\cos t/(1-Z_0)$, $v = a\sin t/(1-Z_0)$, so the velocity is

$$\dot u = -v, \quad \dot v = u, \qquad \text{i.e.} \qquad V = -v\,\partial_u + u\,\partial_v,$$

a rotation field in the (u,v) plane. Transform it to the south chart with the Jacobian of Example T1.3:

$$\tilde V^{u'} \overset{(1)}{=} \frac{v^2-u^2}{\rho^4}(-v) + \left(-\frac{2uv}{\rho^4}\right)u \overset{(2)}{=} -\frac{v(u^2+v^2)}{\rho^4} \overset{(3)}{=} -v',$$
$$\tilde V^{v'} \overset{(4)}{=} \left(-\frac{2uv}{\rho^4}\right)(-v) + \frac{u^2-v^2}{\rho^4}\,u = \frac{u(u^2+v^2)}{\rho^4} = u'.$$

(1) Contravariant law (T1.6): first row of the Jacobian times $(V^u, V^v) = (-v, u)$.
(2) Expand: $-v^3 + u^2v - 2u^2v = -v(u^2+v^2)$.
(3) $\rho^2 = u^2+v^2$ and $v' = v/\rho^2$ from (T1.3).
(4) Second row of the Jacobian.

So $V = -v'\partial_{u'} + u'\partial_{v'}$: the same rotation field in the south chart. A direct check: ρ is constant along a latitude, so $u'(t) = u(t)/\rho^2$ has velocity $\dot u/\rho^2 = -v/\rho^2 = -v'$. Both routes agree, as they must. (With the orientation-fixed chart $(u', -v')$, the rotation would appear clockwise: the charts disagree about handedness.)

T1.2.3 Covectors and the differential $\mathrm{d}f$

A vector eats a function and returns a number, $v(f)$. Turn this around: fix f and let the vector vary. We get a machine that eats vectors and returns numbers, linearly. That machine is the *differential* of f.

Working definition T1.6 (covector, differential)

A **covector** (or **1-form** at p) is a linear map $\alpha : T_pM \to \mathbb{R}$ [it eats a tangent vector v at p and returns the number $\alpha(v) = \alpha_\mu v^\mu$]. The **differential** of a function f is the covector

$$\mathrm{d}f(v) := v(f) = v^\mu \partial_\mu f. \tag{T1.9}$$

The space of covectors at p is the **cotangent space** T_p^*M. A smooth choice of covector at each point is a **1-form field**, or just a 1-form; the space of them is $\Omega^1(M)$.

Apply (T1.9) to the coordinate functions $f = x^\mu$ themselves:

$$\mathrm{d}x^\mu(\partial_\nu) = \partial_\nu x^\mu = \delta^\mu_\nu. \tag{T1.10}$$

So the $\mathrm{d}x^\mu$ are the *dual basis* to the ∂_ν, and any covector is $\alpha = \alpha_\mu \mathrm{d}x^\mu$ with $\alpha_\mu = \alpha(\partial_\mu)$. In

particular

$$(\mathrm{d}f)_\mu \overset{(1)}{=} \mathrm{d}f(\partial_\mu) \overset{(2)}{=} \partial_\mu f, \qquad \text{so} \qquad \mathrm{d}f = \frac{\partial f}{\partial x^\mu}\,\mathrm{d}x^\mu. \tag{T1.11}$$

(1) Components of a covector are its values on the basis vectors.
(2) Definition (T1.9) with $v = \partial_\mu$, whose only nonzero component is a 1 in slot μ.

This is the formula from first-year calculus, $\mathrm{d}f = f_x\mathrm{d}x + f_y\mathrm{d}y$. Now it has a precise meaning: $\mathrm{d}x$ is not a small number but the linear map "read off the x-component of a vector". Dray calls the vector-calculus version $\mathrm{d}f = \nabla f \cdot \mathrm{d}\vec{r}$ the *master formula* [Dray (13.4)].

Under a change of chart, $\mathrm{d}y^\mu = (\partial y^\mu/\partial x^\nu)\mathrm{d}x^\nu$ (this is (T1.11) applied to $f = y^\mu$), and so the components of $\alpha = \alpha_\mu \mathrm{d}x^\mu = \tilde{\alpha}_\mu \mathrm{d}y^\mu$ obey

$$\alpha_\nu = \frac{\partial y^\mu}{\partial x^\nu}\,\tilde{\alpha}_\mu. \tag{T1.12}$$

This is the **covariant** law: the Jacobian now acts from the other side (equivalently, $\tilde{\alpha}$ is obtained from α with the *inverse* Jacobian). The pairing is chart-independent:

$$\alpha(v) = \alpha_\nu v^\nu \overset{(1)}{=} \tilde{\alpha}_\mu \frac{\partial y^\mu}{\partial x^\nu} v^\nu \overset{(2)}{=} \tilde{\alpha}_\mu \tilde{v}^\mu.$$

(1) Covariant law (T1.12).
(2) Contravariant law (T1.6).

Pictures: a covector is a stack of level surfaces

Dray's picture [Dray §13.8] makes this concrete. Draw the level surfaces $f = c,\ c+1,\ c+2,\ldots$ near p; zoomed in far enough they are parallel, equally spaced planes. Then $\mathrm{d}f(v)$ is *the number of surfaces the arrow v pierces*, counted with sign. Steep functions have closely spaced surfaces and large $\mathrm{d}f$. A vector lying along a level surface pierces none: $\mathrm{d}f(v) = 0$. This is a topographic map, and a 1-form is its linearisation at each point.

Worked example T1.7: $\mathrm{d}f$ in two coordinate systems

Let $f = x^2 + y^2$ on the plane. In Cartesian coordinates $\mathrm{d}f = 2x\,\mathrm{d}x + 2y\,\mathrm{d}y$. In polar coordinates $f = r^2$, so $\mathrm{d}f = 2r\,\mathrm{d}r$. These must be the same covector. Check using $\mathrm{d}x = \cos\phi\,\mathrm{d}r - r\sin\phi\,\mathrm{d}\phi$, $\mathrm{d}y = \sin\phi\,\mathrm{d}r + r\cos\phi\,\mathrm{d}\phi$:

$$\begin{aligned} 2x\,\mathrm{d}x + 2y\,\mathrm{d}y &\overset{(1)}{=} 2r\cos\phi(\cos\phi\,\mathrm{d}r - r\sin\phi\,\mathrm{d}\phi) + 2r\sin\phi(\sin\phi\,\mathrm{d}r + r\cos\phi\,\mathrm{d}\phi) \\ &\overset{(2)}{=} 2r(\cos^2\phi + \sin^2\phi)\,\mathrm{d}r + 2r^2(-\cos\phi\sin\phi + \sin\phi\cos\phi)\,\mathrm{d}\phi \\ &= 2r\,\mathrm{d}r. \end{aligned}$$

(1) Substitute $x = r\cos\phi$, $y = r\sin\phi$ and the expressions for $\mathrm{d}x, \mathrm{d}y$ (themselves instances of (T1.11)).
(2) Collect the $\mathrm{d}r$ and $\mathrm{d}\phi$ terms.

Now evaluate on the vectors of Example T1.5: $\mathrm{d}f(\partial_r) = 2r\,\mathrm{d}r(\partial_r) = 2r$ and $\mathrm{d}f(\partial_\phi) = 0$, exactly as the contour picture (Figure T1.7) predicts.

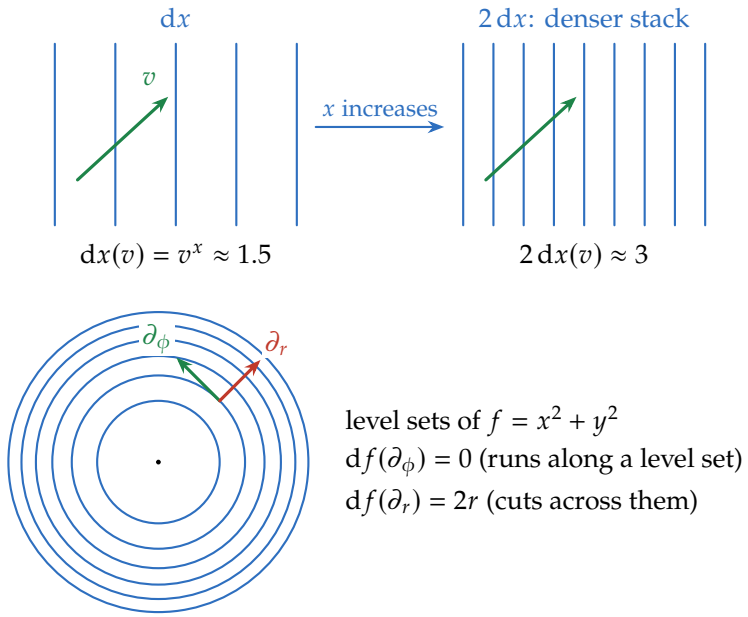

Figure T1.7: Top: the 1-form $\mathrm{d}x$ drawn as a stack of surfaces $x = \text{const}$ at unit spacing; $\mathrm{d}x(v)$ counts how many sheets v crosses. Doubling the form halves the spacing. Bottom: the 1-form $\mathrm{d}f$ for $f = x^2 + y^2$ is the linearised contour map. The rotation vector ∂_ϕ runs along a contour and gets zero; the radial vector cuts across and gets $2r$.

Worked example T1.8: $\mathrm{d}Z$ on the sphere, in both stereographic charts

The height Z is a function on S^2. In the north chart, $Z = (\rho^2-1)/(\rho^2+1) = 1-2/(1+\rho^2)$, so

$$\mathrm{d}Z \overset{(1)}{=} \frac{2\,\mathrm{d}(\rho^2)}{(1+\rho^2)^2} \overset{(2)}{=} \frac{4(u\,\mathrm{d}u + v\,\mathrm{d}v)}{(1+\rho^2)^2}.$$

(1) $\mathrm{d}(-2/w) = 2\,\mathrm{d}w/w^2$ with $w = 1+\rho^2$.
(2) $\mathrm{d}(\rho^2) = \mathrm{d}(u^2+v^2) = 2u\,\mathrm{d}u + 2v\,\mathrm{d}v$.

In the south chart, $Z = (1-\rho'^2)/(1+\rho'^2)$ by the same computation with $Z \to -Z$, so $\mathrm{d}Z = -4\rho'\,\mathrm{d}\rho'/(1+\rho'^2)^2$. On the overlap $\rho' = 1/\rho$ and $\mathrm{d}\rho' = -\mathrm{d}\rho/\rho^2$, hence

$$-\frac{4\rho'\,\mathrm{d}\rho'}{(1+\rho'^2)^2} \overset{(1)}{=} -\frac{4\rho^{-1}(-\rho^{-2}\mathrm{d}\rho)}{(1+\rho^{-2})^2} \overset{(2)}{=} \frac{4\rho^{-3}\,\rho^4\,\mathrm{d}\rho}{(\rho^2+1)^2} = \frac{4\rho\,\mathrm{d}\rho}{(1+\rho^2)^2},$$

(1) Substitute $\rho' = 1/\rho$ and $\mathrm{d}\rho' = -\mathrm{d}\rho/\rho^2$.
(2) Multiply numerator and denominator by ρ^4.

which is the north-chart answer (since $u\,\mathrm{d}u + v\,\mathrm{d}v = \rho\,\mathrm{d}\rho$). On the rotation field $V = -v\partial_u + u\partial_v$ of Example T1.6, $\mathrm{d}Z(V) = 4(u(-v)+vu)/(1+\rho^2)^2 = 0$: moving along a latitude does not change the height.

Physical picture: Wave vectors are covectors

A plane wave $e^{\mathrm{i}\theta(x)}$ has phase $\theta = k_\mu x^\mu$. Its wave "vector" is really $\mathrm{d}\theta = k_\mu \mathrm{d}x^\mu$, a covector: it counts wave crests crossed per unit displacement, exactly like the stack picture. This is why Nash writes the Fourier variable as $k = k_i\,\mathrm{d}x^i$ on p. 40, and why the symbols of differential operators live on the cotangent bundle T^*M (Chapter 2). The rule "$\partial_\mu \to \mathrm{i}k_\mu$" turns a derivative into multiplication by a covector.

T1.2.4 Line elements and the metric

The last ingredient is the one physicists write first: the line element.

$$\mathrm{d}s^2 = g_{\mu\nu}(x)\,\mathrm{d}x^\mu\,\mathrm{d}x^\nu. \tag{T1.13}$$

It is a machine that eats two vectors and returns their dot product, $g(v,w) = g_{\mu\nu}v^\mu w^\nu$, with $g_{\mu\nu} = g_{\nu\mu}$. The products $\mathrm{d}x^\mu\mathrm{d}x^\nu$ in (T1.13) are *symmetric* products ($\mathrm{d}x\,\mathrm{d}y = \mathrm{d}y\,\mathrm{d}x$), not the wedge products of the next section [Dray §6.2]. The length of a curve is $\int\sqrt{g(\dot\gamma,\dot\gamma)}\,\mathrm{d}t$.

Working definition T1.7 (metric)

A (pseudo-)**Riemannian metric** ["pseudo" allows $g(v,v) < 0$ for some nonzero v, as for time-like v in Minkowski space] is a smooth choice of symmetric, non-degenerate ($\det g_{\mu\nu} \neq 0$) bilinear form on each T_pM [the space of tangent vectors v^μ at p]. *In practice:* it is given by a line element $\mathrm{d}s^2$; read off $g_{\mu\nu}$ as the coefficient matrix, remembering that a cross term $2h\,\mathrm{d}x\,\mathrm{d}y$ contributes $g_{xy} = g_{yx} = h$.

Worked example T1.9: The round metric on S^2 in three charts

(a) *Angles.* With $X = \sin\theta\cos\phi$, $Y = \sin\theta\sin\phi$, $Z = \cos\theta$, substituting the differentials into $\mathrm{d}X^2 + \mathrm{d}Y^2 + \mathrm{d}Z^2$ gives the familiar $\mathrm{d}s^2 = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2$.
(b) *Stereographic.* Use the complex combination $w = u + \mathrm{i}v$, so that $X + \mathrm{i}Y = 2w/(1+|w|^2)$ and $Z = 1 - 2/(1+|w|^2)$ by (T1.4). Then

$$\begin{aligned}
\mathrm{d}(X+\mathrm{i}Y) &\overset{(1)}{=} \frac{2\big[(1+w\bar w)\mathrm{d}w - w(\bar w\,\mathrm{d}w + w\,\mathrm{d}\bar w)\big]}{(1+|w|^2)^2} = \frac{2(\mathrm{d}w - w^2\mathrm{d}\bar w)}{(1+|w|^2)^2},\\
\mathrm{d}Z &\overset{(2)}{=} \frac{2(\bar w\,\mathrm{d}w + w\,\mathrm{d}\bar w)}{(1+|w|^2)^2},\\
\mathrm{d}X^2+\mathrm{d}Y^2+\mathrm{d}Z^2 &\overset{(3)}{=} \big|\mathrm{d}(X+\mathrm{i}Y)\big|^2 + \mathrm{d}Z^2\\
&\overset{(4)}{=} \frac{4}{(1+|w|^2)^4}\Big[(1+|w|^4)\,\mathrm{d}w\,\mathrm{d}\bar w - \bar w^2\mathrm{d}w^2 - w^2\mathrm{d}\bar w^2\\
&\qquad + \bar w^2\mathrm{d}w^2 + 2|w|^2\mathrm{d}w\,\mathrm{d}\bar w + w^2\mathrm{d}\bar w^2\Big]\\
&= \frac{4(1+|w|^2)^2\,\mathrm{d}w\,\mathrm{d}\bar w}{(1+|w|^2)^4} \overset{(5)}{=} \frac{4(\mathrm{d}u^2+\mathrm{d}v^2)}{(1+u^2+v^2)^2}.
\end{aligned}$$

(1) Quotient rule on $2w/(1+w\bar w)$.
(2) As in Example T1.8, written with $\mathrm{d}(|w|^2) = \bar w\,\mathrm{d}w + w\,\mathrm{d}\bar w$.
(3) $\mathrm{d}X^2+\mathrm{d}Y^2 = (\mathrm{d}X+\mathrm{i}\mathrm{d}Y)(\mathrm{d}X-\mathrm{i}\mathrm{d}Y)$ for symmetric products.
(4) Multiply out $(\mathrm{d}w - w^2\mathrm{d}\bar w)(\mathrm{d}\bar w - \bar w^2\mathrm{d}w)$ and $(\bar w\,\mathrm{d}w + w\,\mathrm{d}\bar w)^2$.
(5) $\mathrm{d}w\,\mathrm{d}\bar w = (\mathrm{d}u+\mathrm{i}\mathrm{d}v)(\mathrm{d}u-\mathrm{i}\mathrm{d}v) = \mathrm{d}u^2+\mathrm{d}v^2$.

The metric is the flat metric times the *conformal factor* $4/(1+\rho^2)^2$: stereographic projection preserves angles.
(c) *Relation between (a) and (b).* In the north chart $\rho^2 = (1+Z)/(1-Z) = \cot^2(\theta/2)$ and the polar angle of (u,v) is ϕ. With $\mathrm{d}\rho = -\tfrac12\csc^2(\theta/2)\,\mathrm{d}\theta$ and $1+\rho^2 = \csc^2(\theta/2)$, $4\,\mathrm{d}\rho^2/(1+\rho^2)^2 = \mathrm{d}\theta^2$ and $4\rho^2\mathrm{d}\phi^2/(1+\rho^2)^2 = 4\cos^2(\theta/2)\sin^2(\theta/2)\,\mathrm{d}\phi^2 = \sin^2\theta\,\mathrm{d}\phi^2$. Same metric, different chart.

The metric on covectors, and raising and lowering

A metric identifies vectors with covectors. Given v, the covector $v^\flat = g(v, \cdot)$ has components $v_\mu = g_{\mu\nu} v^\nu$ ("lowering the index"). Conversely, a covector α gives a vector $\alpha^\sharp$ with components $\alpha^\mu = g^{\mu\nu}\alpha_\nu$, where $g^{\mu\nu}$ is the inverse matrix. The metric on covectors is therefore the inverse matrix:

$$g(\mathrm{d}x^\mu, \mathrm{d}x^\nu) = g^{\mu\nu}. \tag{T1.14}$$

The **gradient vector** is $\nabla f := (\mathrm{d}f)^\sharp$. The gradient is thus a vector only after a metric has been chosen; $\mathrm{d}f$ needs no metric at all.

Worked example T1.10: Why the gradient in polar coordinates has a $1/r$

In polar coordinates $g_{\mu\nu} = \mathrm{diag}(1, r^2)$, so $g^{\mu\nu} = \mathrm{diag}(1, r^{-2})$. Then

$$\nabla f = (\mathrm{d}f)^\sharp \overset{(1)}{=} g^{rr}\partial_r f\, \partial_r + g^{\phi\phi}\partial_\phi f\, \partial_\phi = \partial_r f\, \partial_r + \frac{1}{r^2}\partial_\phi f\, \partial_\phi$$
$$\overset{(2)}{=} \partial_r f\, \hat{r} + \frac{1}{r}\,\partial_\phi f\, \hat{\phi}.$$

(1) Raise the index of $(\mathrm{d}f)_\mu = \partial_\mu f$ with the diagonal inverse metric.

(2) Use the unit vectors $\hat{r} = \partial_r$, $\hat{\phi} = \frac{1}{r}\partial_\phi$ from Example T1.5.

This is the formula in every electrodynamics textbook, and now we see where the $1/r$ comes from: one power from the inverse metric, partly undone by normalising ∂_ϕ. Also, $g(\mathrm{d}r, \mathrm{d}r) = 1$, $g(\mathrm{d}\phi, \mathrm{d}\phi) = 1/r^2$, $g(\mathrm{d}r, \mathrm{d}\phi) = 0$: the *orthonormal coframe* is $\{\mathrm{d}r,\ r\,\mathrm{d}\phi\}$, the two "pieces" of $\mathrm{d}\vec{r} = \mathrm{d}r\,\hat{r} + r\,\mathrm{d}\phi\,\hat{\phi}$ [Dray (13.68)].

Watch out: Is $\mathrm{d}x$ small or not?

In calculus $\mathrm{d}x$ is "an infinitesimal change". Here $\mathrm{d}x$ is a linear map with $\mathrm{d}x(\partial_x) = 1$, not small at all. Both are right [Dray §13.9]: the 1-form lives at a single point (as zoomed-in as one can get), and at that point it behaves like a unit object. A line integral $\int_\gamma \alpha$ feeds the 1-form the velocity $\dot{\gamma}$ and multiplies by $\mathrm{d}t$; the smallness lives in $\mathrm{d}t$.

Reading Nash (p. 15 and p. 40)

Nash's tangent bundle $TM = \bigcup_p T_pM$ (p. 15) is the collection of the spaces T_pM we built above; the cotangent bundle T^*M is the collection of the T_p^*M. On p. 40 he writes the Fourier variable as $k = k_i\,\mathrm{d}x^i$ and uses it as a point of T^*M. Every time Nash says "cotangent", think "stack of level surfaces", "$\mathrm{d}f$", or "wave covector".

Recap

- A tangent vector is a velocity $v^\mu = \dot{x}^\mu$, equivalently the derivation $v = v^\mu\partial_\mu$; components transform with the Jacobian.
- A covector is a linear function on vectors. The differential $\mathrm{d}f(v) = v(f)$ has components $\partial_\mu f$; $\mathrm{d}x^\mu(\partial_\nu) = \delta^\mu_\nu$.
- Picture: a covector is a stack of level surfaces; $\alpha(v)$ counts sheets crossed.
- The line element $\mathrm{d}s^2 = g_{\mu\nu}\mathrm{d}x^\mu\mathrm{d}x^\nu$ is a metric on vectors; its inverse $g^{\mu\nu}$ is the metric on covectors.

- S^2: $\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2 = 4(\mathrm{d}u^2 + \mathrm{d}v^2)/(1+\rho^2)^2$.

T1.3 The wedge product and the algebra of forms

A 1-form is the integrand of a line integral. What is the integrand of a surface integral, or of a volume integral? In calculus we write $\mathrm{d}x\,\mathrm{d}y$ and $\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z$, and treat them as if they were ordinary products of small numbers. That turns out to be almost right. The one correction, which Dray extracts from the change-of-variables formula [Dray §11.3–11.4], is that the product must be *antisymmetric*. Once we accept that, everything else follows: oriented areas, determinants, the cross product, and a clean way to count how many independent integrands of each kind a space has.

T1.3.1 Why the product of differentials is antisymmetric

Consider a change of variables $x = x(u,v)$, $y = y(u,v)$ in the plane. The area element transforms with the Jacobian determinant,

$$\mathrm{d}x\,\mathrm{d}y = \frac{\partial(x,y)}{\partial(u,v)}\,\mathrm{d}u\,\mathrm{d}v, \qquad \frac{\partial(x,y)}{\partial(u,v)} = \det\begin{pmatrix} \partial_u x & \partial_v x \\ \partial_u y & \partial_v y \end{pmatrix}. \tag{T1.15}$$

In a first calculus course we put absolute value bars around the determinant. Let us *not* do that, and keep track of orientation instead: an integral of a flux changes sign when the orientation of the surface is reversed, so the sign carries information. Written the other way round, (T1.15) says $\mathrm{d}u\,\mathrm{d}v = \frac{\partial(u,v)}{\partial(x,y)}\,\mathrm{d}x\,\mathrm{d}y$ for *any* two functions u, v. Now make two silly choices.

$$u = y,\ v = x: \qquad \mathrm{d}y\,\mathrm{d}x \overset{(1)}{=} \frac{\partial(y,x)}{\partial(x,y)}\,\mathrm{d}x\,\mathrm{d}y \overset{(2)}{=} \det\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\mathrm{d}x\,\mathrm{d}y = -\,\mathrm{d}x\,\mathrm{d}y,$$

$$u = v = x: \qquad \mathrm{d}x\,\mathrm{d}x \overset{(3)}{=} \frac{\partial(x,x)}{\partial(x,y)}\,\mathrm{d}x\,\mathrm{d}y \overset{(4)}{=} \det\begin{pmatrix} 1 & 0 \\ 1 & 0 \end{pmatrix}\mathrm{d}x\,\mathrm{d}y = 0.$$

(1) The transformation rule with $u = y$, $v = x$.
(2) The rows of the Jacobian matrix are the gradients of $u = y$ and $v = x$: $(\partial_x y, \partial_y y) = (0,1)$ and $(1,0)$. The determinant is -1.
(3) The transformation rule with $u = v = x$.
(4) Both rows are the gradient $(1,0)$ of x; equal rows make the determinant vanish.

So if we want the change-of-variables formula to hold *with* signs, products of differentials must obey

$$\mathrm{d}y \wedge \mathrm{d}x = -\,\mathrm{d}x \wedge \mathrm{d}y, \qquad \mathrm{d}x \wedge \mathrm{d}x = 0. \tag{T1.16}$$

We use the symbol $\wedge$ ("wedge") to distinguish this product from the symmetric product $\mathrm{d}x\,\mathrm{d}y = \mathrm{d}y\,\mathrm{d}x$ that appears in line elements.

The two rules in (T1.16) are equivalent. Antisymmetry gives $\mathrm{d}x \wedge \mathrm{d}x = -\mathrm{d}x \wedge \mathrm{d}x$, so it is zero. Conversely, if every 1-form squares to zero then

$$0 \overset{(1)}{=} (\mathrm{d}x + \mathrm{d}y) \wedge (\mathrm{d}x + \mathrm{d}y) \overset{(2)}{=} \mathrm{d}x \wedge \mathrm{d}x + \mathrm{d}x \wedge \mathrm{d}y + \mathrm{d}y \wedge \mathrm{d}x + \mathrm{d}y \wedge \mathrm{d}y \overset{(3)}{=} \mathrm{d}x \wedge \mathrm{d}y + \mathrm{d}y \wedge \mathrm{d}x,$$

(1) $\mathrm{d}x + \mathrm{d}y$ is a 1-form, so its square vanishes.
(2) Distributivity.
(3) The squares $\mathrm{d}x \wedge \mathrm{d}x$ and $\mathrm{d}y \wedge \mathrm{d}y$ vanish.

which is antisymmetry. (This trick is called **polarisation**.)

T1.3.2 What a 2-form does to two vectors: oriented area

A 1-form eats one vector. A product of two 1-forms should eat two vectors, and the natural antisymmetric way to do it is a 2×2 determinant.

Working definition T1.8 (wedge product of two 1-forms)

For 1-forms α, β [covectors: each eats one vector v and returns the number $\alpha(v) = \alpha_\mu v^\mu$] the **wedge product** $\alpha \wedge \beta$ is the machine that eats an ordered pair of vectors and returns

$$(\alpha \wedge \beta)(v, w) = \det \begin{pmatrix} \alpha(v) & \alpha(w) \\ \beta(v) & \beta(w) \end{pmatrix} = \alpha(v)\beta(w) - \alpha(w)\beta(v). \tag{T1.17}$$

It is bilinear [linear in v with w held fixed, and linear in w with v held fixed] and antisymmetric in (v, w) [swapping v and w flips the sign, so $(\alpha \wedge \beta)(v, v) = 0$], and antisymmetric in (α, β).

For the basis forms of the plane, $(dx \wedge dy)(v, w) = v^x w^y - v^y w^x$. That is the signed area of the parallelogram spanned by v and w: positive if w is counter-clockwise from v, negative if clockwise, zero if they are parallel. In three dimensions, $(dx \wedge dy)(v, w)$ is the signed area of the *shadow* of the parallelogram on the xy-plane (Figure T1.8).

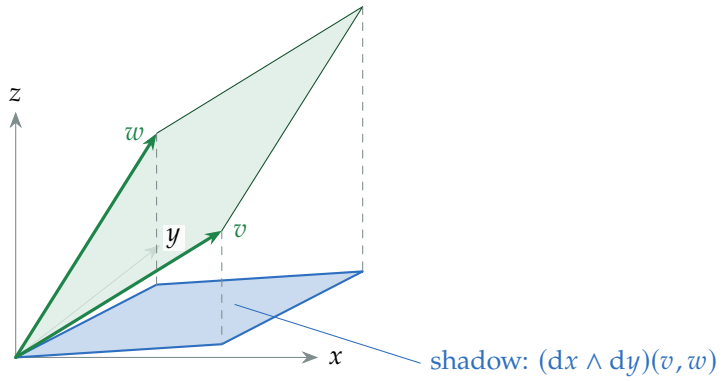

Figure T1.8: The 2-form $dx \wedge dy$ applied to two vectors v, w in $\mathbb{R}^3$ returns the signed area of the shadow (blue) of their parallelogram (green) on the xy-plane. Likewise $dy \wedge dz$ and $dz \wedge dx$ measure the shadows on the other two coordinate planes; the three numbers together are the components of $v \times w$.

Worked example T1.11: The three shadows are the cross product

Take $v = (v^x, v^y, v^z)$ and $w = (w^x, w^y, w^z)$ in $\mathbb{R}^3$. Then by (T1.17) with $dx^\mu(v) = v^\mu$,

$$\begin{aligned} (dy \wedge dz)(v, w) &= v^y w^z - v^z w^y = (v \times w)^x, \\ (dz \wedge dx)(v, w) &= v^z w^x - v^x w^z = (v \times w)^y, \\ (dx \wedge dy)(v, w) &= v^x w^y - v^y w^x = (v \times w)^z. \end{aligned}$$

With numbers: $v = (1, 0, 2)$, $w = (0, 3, 1)$ give shadows $(0 \cdot 1 - 2 \cdot 3,\ 2 \cdot 0 - 1 \cdot 1,\ 1 \cdot 3 - 0 \cdot 0) = (-6, -1, 3)$, which is $v \times w$. The cyclic order (yz, zx, xy) is what makes this match the right-hand rule; this is why Dray [Dray (12.24)] writes the flux 2-form as $F_x\, dy \wedge dz + F_y\, dz \wedge dx + F_z\, dx \wedge dy$.

T1.3.3 Changing coordinates in a 2-form

Wedge products let us change variables by pure algebra: expand each differential by the chain rule, multiply out, and use (T1.16). The Jacobian determinant appears by itself.

Worked example T1.12: $\mathrm{d}x \wedge \mathrm{d}y = r\,\mathrm{d}r \wedge \mathrm{d}\phi$

With $\mathrm{d}x = \cos\phi\,\mathrm{d}r - r\sin\phi\,\mathrm{d}\phi$ and $\mathrm{d}y = \sin\phi\,\mathrm{d}r + r\cos\phi\,\mathrm{d}\phi$,

$$\begin{aligned}\mathrm{d}x \wedge \mathrm{d}y &\overset{(1)}{=} \cos\phi\sin\phi\;\mathrm{d}r\wedge\mathrm{d}r + r\cos^2\phi\;\mathrm{d}r\wedge\mathrm{d}\phi \\ &\quad - r\sin^2\phi\;\mathrm{d}\phi\wedge\mathrm{d}r - r^2\sin\phi\cos\phi\;\mathrm{d}\phi\wedge\mathrm{d}\phi \\ &\overset{(2)}{=} r\cos^2\phi\;\mathrm{d}r\wedge\mathrm{d}\phi - r\sin^2\phi\;\mathrm{d}\phi\wedge\mathrm{d}r \\ &\overset{(3)}{=} r(\cos^2\phi+\sin^2\phi)\,\mathrm{d}r\wedge\mathrm{d}\phi = r\,\mathrm{d}r\wedge\mathrm{d}\phi. \end{aligned} \tag{T1.18}$$

(1) Distribute the product of the two brackets; four terms.
(2) $\mathrm{d}r\wedge\mathrm{d}r = 0 = \mathrm{d}\phi\wedge\mathrm{d}\phi$.
(3) $\mathrm{d}\phi\wedge\mathrm{d}r = -\mathrm{d}r\wedge\mathrm{d}\phi$.

The coefficient r is the Jacobian $\partial(x,y)/\partial(r,\phi)$, obtained without ever writing a determinant. We can also go the other way, following Dray [Dray (13.24)–(13.27)]: from $r^2 = x^2+y^2$ and $\tan\phi = y/x$ we get $r\,\mathrm{d}r = x\,\mathrm{d}x + y\,\mathrm{d}y$ and $r^2\mathrm{d}\phi = x\,\mathrm{d}y - y\,\mathrm{d}x$. Then

$$\begin{aligned} r^3\,\mathrm{d}r\wedge\mathrm{d}\phi &= (x\,\mathrm{d}x + y\,\mathrm{d}y)\wedge(x\,\mathrm{d}y - y\,\mathrm{d}x) \\ &\overset{(1)}{=} x^2\,\mathrm{d}x\wedge\mathrm{d}y - y^2\,\mathrm{d}y\wedge\mathrm{d}x \overset{(2)}{=} (x^2+y^2)\,\mathrm{d}x\wedge\mathrm{d}y = r^2\,\mathrm{d}x\wedge\mathrm{d}y, \end{aligned}$$

(1) The cross terms $-xy\,\mathrm{d}x\wedge\mathrm{d}x$ and $xy\,\mathrm{d}y\wedge\mathrm{d}y$ vanish.
(2) $-\mathrm{d}y\wedge\mathrm{d}x = +\mathrm{d}x\wedge\mathrm{d}y$.

which is (T1.18) again after dividing by r^2.

Key idea: Change of variables is automatic

For any change of coordinates $y^\mu = y^\mu(x)$ in n dimensions,

$$\mathrm{d}y^1\wedge\mathrm{d}y^2\wedge\cdots\wedge\mathrm{d}y^n = \det\!\left(\frac{\partial y^\mu}{\partial x^\nu}\right)\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\cdots\wedge\mathrm{d}x^n. \tag{T1.19}$$

The Jacobian determinant of multivariable calculus is *defined* by this equation, and its sign records whether the two coordinate systems have the same handedness.

Why: expand each $\mathrm{d}y^\mu = (\partial y^\mu/\partial x^\nu)\mathrm{d}x^\nu$ and multiply out. Every term with a repeated $\mathrm{d}x^\nu$ dies. The surviving terms have each $\mathrm{d}x^\nu$ exactly once, in some order σ; reordering them to $\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^n$ costs the sign $\operatorname{sgn}\sigma$. The coefficient is $\sum_\sigma \operatorname{sgn}\sigma \prod_\mu \partial y^\mu/\partial x^{\sigma(\mu)}$, which is the Leibniz formula for the determinant. For the S^2 stereographic charts, Example T1.3 therefore says $\mathrm{d}u'\wedge\mathrm{d}v' = -\rho^{-4}\,\mathrm{d}u\wedge\mathrm{d}v$: the two charts have opposite orientations.

Worked example T1.13: Spherical coordinates

With $x = r\sin\theta\cos\phi$, $y = r\sin\theta\sin\phi$, $z = r\cos\theta$, first write the three differentials in the orthonormal-looking combinations $\mathrm{d}r$, $r\,\mathrm{d}\theta$, $r\sin\theta\,\mathrm{d}\phi$:

$$\mathrm{d}x = \sin\theta\cos\phi\,\mathrm{d}r + \cos\theta\cos\phi\,(r\,\mathrm{d}\theta) - \sin\phi\,(r\sin\theta\,\mathrm{d}\phi),$$

$$\begin{aligned} \mathrm{d}y &= \sin\theta\sin\phi\,\mathrm{d}r + \cos\theta\sin\phi\,(r\,\mathrm{d}\theta) + \cos\phi\,(r\sin\theta\,\mathrm{d}\phi), \\ \mathrm{d}z &= \cos\theta\,\mathrm{d}r - \sin\theta\,(r\,\mathrm{d}\theta). \end{aligned}$$

The coefficient matrix R (rows: $\mathrm{d}x, \mathrm{d}y, \mathrm{d}z$; columns: $\mathrm{d}r, r\mathrm{d}\theta, r\sin\theta\mathrm{d}\phi$) is a rotation matrix: its columns are the unit vectors $\hat{r}, \hat{\theta}, \hat{\phi}$. Therefore

$$\begin{aligned} \mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z &\overset{(1)}{=} \det R\; \mathrm{d}r \wedge (r\,\mathrm{d}\theta) \wedge (r\sin\theta\,\mathrm{d}\phi) \\ &\overset{(2)}{=} r^2 \sin\theta\; \mathrm{d}r \wedge \mathrm{d}\theta \wedge \mathrm{d}\phi. \end{aligned}$$

(1) (T1.19) applied to the three 1-forms $\mathrm{d}r$, $r\mathrm{d}\theta$, $r\sin\theta\mathrm{d}\phi$ (the argument works for any three 1-forms, not only coordinate differentials).

(2) $\det R = +1$ because $(\hat{r}, \hat{\theta}, \hat{\phi})$ is a right-handed orthonormal triad (check at $\theta = \pi/2, \phi = 0$: $\hat{r} = \hat{x}$, $\hat{\theta} = -\hat{z}$, $\hat{\phi} = \hat{y}$, and $\hat{x} \times (-\hat{z}) = \hat{y}$). Pull the scalar factors r and $r\sin\theta$ out.

T1.3.4 Higher-rank forms and dimension counting

Nothing stops us from multiplying more 1-forms. Products of p of them are p-forms; they are the integrands of p-dimensional integrals.

Working definition T1.9 (p-form)

A **p-form** at a point is a linear combination of products $\mathrm{d}x^{\mu_1} \wedge \cdots \wedge \mathrm{d}x^{\mu_p}$. It eats p vectors, multilinearly and totally antisymmetrically [linear in each vector separately, and the sign flips whenever two of the p vectors are swapped], by the $p \times p$ determinant rule

$$(\alpha^1 \wedge \cdots \wedge \alpha^p)(v_1, \ldots, v_p) = \det\big[\alpha^i(v_j)\big]. \tag{T1.20}$$

A **p-form field** (or just p-form) has function coefficients [$\alpha = \sum_{\mu_1<\cdots<\mu_p} \alpha_{\mu_1\ldots\mu_p}(x)\,\mathrm{d}x^{\mu_1} \wedge \cdots \wedge \mathrm{d}x^{\mu_p}$, with smooth $\alpha_{\mu_1\ldots\mu_p}(x)$]. The space of them is $\Omega^p(M)$. By convention $\Omega^0(M)$ is the space of functions.

A basis of p-forms at a point is given by the products with *increasing* indices, $\{\mathrm{d}x^{\mu_1}\wedge\cdots\wedge\mathrm{d}x^{\mu_p} : \mu_1 < \mu_2 < \cdots < \mu_p\}$. Any other ordering is $\pm$ one of these, and any repetition is zero. So the dimension is the number of ways to choose p distinct indices out of n:

$$\dim \Omega^p_x = \binom{n}{p} = \frac{n!}{p!\,(n-p)!}, \qquad \dim \Omega^p_x = 0 \;\; (p > n). \tag{T1.21}$$

Two facts jump out of Figure T1.9. First, $\binom{n}{p} = \binom{n}{n-p}$: p-forms and $(n-p)$-forms come in equal numbers. The Hodge star of Section T1.4 is the isomorphism between them. Second, the top forms, $p = n$, form a one-dimensional space: every n-form is a function times $\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^n$. Top forms are the things we integrate over the whole manifold. The total number of independent forms of all ranks is $\sum_p \binom{n}{p} = 2^n$.

Components and the factor $1/p!$

A general p-form can be written in two ways:

$$\alpha = \sum_{\mu_1<\cdots<\mu_p} \alpha_{\mu_1\ldots\mu_p}\,\mathrm{d}x^{\mu_1} \wedge \cdots \wedge \mathrm{d}x^{\mu_p} = \frac{1}{p!}\,\alpha_{\mu_1\ldots\mu_p}\,\mathrm{d}x^{\mu_1} \wedge \cdots \wedge \mathrm{d}x^{\mu_p}, \tag{T1.22}$$

$n\backslash p$	**0**	**1**	**2**	**3**	**4**	**total**
1	1	1	0	0	0	2
2	1	2	1	0	0	4
3	1	3	3	1	0	8
4	1	4	6	4	1	16

$n = 3$: 1-forms and 2-forms both look like "vectors"
$n = 4$: six 2-forms = $\vec{E}$ and $\vec{B}$ together

Figure T1.9: Dimensions $\binom{n}{p}$ of the space of p-forms at a point. Read along a row: the numbers are symmetric under $p \leftrightarrow n-p$ (this is Hodge duality), the last nonzero entry is always 1 (top forms are multiples of a single volume form), and the row sums to 2^n. The coloured cells explain two pieces of physics: why vector calculus in $\mathbb{R}^3$ can get away with one kind of vector, and why the electromagnetic field in space-time has six components.

where in the second expression all indices are summed freely and the components $\alpha_{\mu_1\ldots\mu_p}$ are defined for all index values and taken *totally antisymmetric*. The $p!$ orderings of each index set contribute equal terms, and the $1/p!$ removes the overcounting. With this normalisation the components are the values of α on basis vectors:

$$\alpha(\partial_{\nu_1},\ldots,\partial_{\nu_p}) \overset{(1)}{=} \frac{1}{p!}\,\alpha_{\mu_1\ldots\mu_p}\,\det\!\left[\mathrm{d}x^{\mu_i}(\partial_{\nu_j})\right] \overset{(2)}{=} \frac{1}{p!}\,\alpha_{\mu_1\ldots\mu_p}\,\det\!\left[\delta^{\mu_i}_{\nu_j}\right]$$
$$\overset{(3)}{=} \frac{1}{p!}\sum_{\sigma}\operatorname{sgn}\sigma\;\alpha_{\nu_{\sigma(1)}\ldots\nu_{\sigma(p)}} \overset{(4)}{=} \frac{1}{p!}\,p!\,\alpha_{\nu_1\ldots\nu_p} = \alpha_{\nu_1\ldots\nu_p}.$$

(1) The determinant rule (T1.20) for each term.
(2) Dual basis (T1.10).
(3) The determinant of the matrix $\delta^{\mu_i}_{\nu_j}$ is nonzero only when $(\mu_1,\ldots,\mu_p)$ is a permutation σ of $(\nu_1,\ldots,\nu_p)$, and then equals $\operatorname{sgn}\sigma$.
(4) Antisymmetry of the components: each of the $p!$ terms equals $\alpha_{\nu_1\ldots\nu_p}$.

More generally, by multilinearity, $\alpha(v_1,\ldots,v_p) = \alpha_{\mu_1\ldots\mu_p}v_1^{\mu_1}\cdots v_p^{\mu_p}$. For a 2-form this reads $\alpha(v,w) = \alpha_{\mu\nu}v^\mu w^\nu$, and the antisymmetric matrix $\alpha_{\mu\nu}$ is the *representation* of the 2-form. For example $\mathrm{d}x\wedge\mathrm{d}y$ in the plane has matrix $\left(\begin{smallmatrix}0&1\\-1&0\end{smallmatrix}\right)$, and the electromagnetic field strength $F_{\mu\nu}$ is the 4×4 antisymmetric matrix of a 2-form in space-time (Section T1.7).

Watch out: Two normalisations of components

Many physics texts and Nash himself [Nash p. 39, (2.43)] write $\omega = \omega_{i_1\ldots i_p}\,\mathrm{d}x^{i_1}\wedge\cdots\wedge\mathrm{d}x^{i_p}$ with a free sum and *no* $1/p!$. Their components are then $1/p!$ times ours. Neither is wrong; but formulas with explicit factorials (the Hodge star, the inner product) must be read in the convention they were written in. We always use (T1.22).

T1.3.5 Multiplying forms of any rank

The wedge product of a p-form and a q-form is defined by multiplying out in the basis and using (T1.16). It is associative and distributive, and it is **graded commutative**:

$$\beta\wedge\alpha = (-1)^{pq}\,\alpha\wedge\beta \qquad (\alpha\in\Omega^p,\ \beta\in\Omega^q). \tag{T1.23}$$

Why: move each of the q one-form factors of β past each of the p factors of α; each swap costs a sign; there are pq swaps [Dray (13.50)]. So 1-forms anticommute with each other, but a 2-form commutes with everything.

Worked example T1.14: A 1-form times a 2-form is the dot product

In $\mathbb{R}^3$ let $v = v_x\,dx + v_y\,dy + v_z\,dz$ and $w = w_x\,dy\wedge dz + w_y\,dz\wedge dx + w_z\,dx\wedge dy$. Then

$$\begin{aligned} v\wedge w &\overset{(1)}{=} v_x w_x\,dx\wedge dy\wedge dz + v_y w_y\,dy\wedge dz\wedge dx + v_z w_z\,dz\wedge dx\wedge dy \\ &\overset{(2)}{=} (v_x w_x + v_y w_y + v_z w_z)\,dx\wedge dy\wedge dz. \end{aligned}$$

(1) Of the nine products, only those in which the 1-form supplies the differential missing from the 2-form survive; the other six contain a repeated differential.
(2) $dy\wedge dz\wedge dx$ and $dz\wedge dx\wedge dy$ are cyclic permutations of $dx\wedge dy\wedge dz$; a cyclic permutation of three objects is two swaps, so no sign.

So "vector $\wedge$ flux" is "dot product $\times$ volume" [Dray (13.46)]. And two 1-forms give the cross product as a 2-form: $v\wedge u = (v_y u_z - v_z u_y)\,dy\wedge dz + \ldots$, the content of Example T1.11. The triple product is $u\wedge v\wedge w = \det[u\,v\,w]\,dx\wedge dy\wedge dz$ for three 1-forms.

In components, the product of a p-form and a q-form is the antisymmetrised tensor product:

$$(\alpha\wedge\beta)_{\mu_1\ldots\mu_{p+q}} = \frac{(p+q)!}{p!\,q!}\,\alpha_{[\mu_1\ldots\mu_p}\,\beta_{\mu_{p+1}\ldots\mu_{p+q}]}, \tag{T1.24}$$

where the square bracket means "average over all permutations with signs". For two 1-forms this is $(\alpha\wedge\beta)_{\mu\nu} = \alpha_\mu\beta_\nu - \alpha_\nu\beta_\mu$, which agrees with (T1.17). In the language of tensors, $\alpha\wedge\beta = \alpha\otimes\beta - \beta\otimes\alpha$ for 1-forms, and more generally a p-form is exactly a totally antisymmetric covariant tensor of rank p [Dray §13.9].

Worked example T1.15: A 2-form whose square is not zero

Graded commutativity gives $\alpha\wedge\alpha = -\alpha\wedge\alpha = 0$ for odd p. For even p there is no such argument, and indeed in $\mathbb{R}^4$ with $\omega = dx^1\wedge dx^2 + dx^3\wedge dx^4$,

$$\begin{aligned} \omega\wedge\omega &\overset{(1)}{=} dx^1\wedge dx^2\wedge dx^3\wedge dx^4 + dx^3\wedge dx^4\wedge dx^1\wedge dx^2 \\ &\overset{(2)}{=} 2\,dx^1\wedge dx^2\wedge dx^3\wedge dx^4 \neq 0. \end{aligned}$$

(1) Expand; the terms $(dx^1\wedge dx^2)^{\wedge 2}$ and $(dx^3\wedge dx^4)^{\wedge 2}$ contain repeated factors.
(2) 2-forms commute (T1.23) with $pq = 4$.

A 2-form that can be written as a single product $\alpha\wedge\beta$ of 1-forms is called **decomposable**; it obviously squares to zero. For 2-forms the converse holds too (in any dimension), so "$\omega\wedge\omega = 0$" is the test for a 2-form to be decomposable. For odd forms the test is useless, since they always square to zero: in $\mathbb{R}^6$ the 3-form $dx^1\wedge dx^2\wedge dx^3 + dx^4\wedge dx^5\wedge dx^6$ squares to zero yet is not a single product, which answers the question Dray poses in [Dray §14.15]. This ω fails it. The same computation with the Maxwell field strength gives $F\wedge F \propto \vec{E}\cdot\vec{B}$ (Section T1.7), and with a Yang–Mills field it gives the instanton density $\operatorname{tr} F\wedge F$ of Chapter 8. Squares of 2-forms are where topology lives in four dimensions.

T1.3.6 Top forms and determinants

Here is Dray's elegant use of top forms [Dray §13.4]. A linear map A acting on 1-forms, $A(dx^i) = a^i{}_j\,dx^j$, extends to p-forms by $A(\alpha^1\wedge\cdots\wedge\alpha^p) = A\alpha^1\wedge\cdots\wedge A\alpha^p$. On the one-dimensional space of top forms it can only be multiplication by a number. That number is the determinant:

$$A\,(dx^1\wedge\cdots\wedge dx^n) = \det A\;dx^1\wedge\cdots\wedge dx^n. \tag{T1.25}$$

Worked example T1.16: 2×2 and 3×3 determinants by wedging

In two dimensions,

$$(a\,\mathrm{d}x + b\,\mathrm{d}y)\wedge(c\,\mathrm{d}x + d\,\mathrm{d}y) \overset{(1)}{=} ad\,\mathrm{d}x\wedge\mathrm{d}y + bc\,\mathrm{d}y\wedge\mathrm{d}x \overset{(2)}{=} (ad-bc)\,\mathrm{d}x\wedge\mathrm{d}y.$$

(1) The $ac\,\mathrm{d}x\wedge\mathrm{d}x$ and $bd\,\mathrm{d}y\wedge\mathrm{d}y$ terms vanish.
(2) Antisymmetry.

In three dimensions, with rows $(1,2,0)$, $(0,1,3)$, $(2,0,1)$:

$$\begin{aligned}(\mathrm{d}x+2\mathrm{d}y)\wedge(\mathrm{d}y+3\mathrm{d}z)\wedge(2\mathrm{d}x+\mathrm{d}z) &\overset{(1)}{=} (\mathrm{d}x\wedge\mathrm{d}y + 3\,\mathrm{d}x\wedge\mathrm{d}z + 6\,\mathrm{d}y\wedge\mathrm{d}z)\wedge(2\mathrm{d}x+\mathrm{d}z)\\ &\overset{(2)}{=} \mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z + 12\,\mathrm{d}y\wedge\mathrm{d}z\wedge\mathrm{d}x\\ &\overset{(3)}{=} 13\,\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z.\end{aligned}$$

(1) Multiply the first two factors; $2\,\mathrm{d}y\wedge\mathrm{d}y = 0$.
(2) Only terms with three different differentials survive: $\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z$ (coefficient $1\cdot1$) and $6\,\mathrm{d}y\wedge\mathrm{d}z\wedge2\mathrm{d}x$; the term $3\,\mathrm{d}x\wedge\mathrm{d}z\wedge(\dots)$ needs $\mathrm{d}y$, which the last factor does not contain.
(3) Cyclic permutation, no sign.

Indeed $\det\left(\begin{smallmatrix}1&2&0\\0&1&3\\2&0&1\end{smallmatrix}\right) = 1(1) - 2(0-6) + 0 = 13$.

The product rule for determinants is now a one-liner [Dray (13.33)]: $\det(AB)\,\omega = A(B\omega) = A(\det B\,\omega) = \det B\,\det A\,\omega$ for any top form ω. No index gymnastics, and the definition (T1.25) manifestly does not depend on the choice of basis.

T1.3.7 The three-dimensional dictionary

We can now say precisely what the "vectors" of vector calculus are. In $\mathbb{R}^3$ there are four kinds of integrand, and each corresponds to a kind of field [Dray §12.2].

Dictionary: forms in $\mathbb{R}^3$ and vector calculus

rank	form	integrand of	physicist's name
0	f	evaluation at a point	scalar
1	$\vec{F}\cdot\mathrm{d}\vec{r} = F_x\mathrm{d}x + F_y\mathrm{d}y + F_z\mathrm{d}z$	line integral (work)	(polar) vector
2	$\vec{F}\cdot\mathrm{d}\vec{A} = F_x\mathrm{d}y\wedge\mathrm{d}z + \dots$	surface integral (flux)	pseudovector
3	$f\,\mathrm{d}V = f\,\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z$	volume integral	density

Products: 1-form $\wedge$ 1-form $\leftrightarrow$ cross product; 1-form $\wedge$ 2-form $\leftrightarrow$ dot product; 1-form $\wedge$ 1-form $\wedge$ 1-form $\leftrightarrow$ triple product.

Why "pseudo"? Under the parity map $P:\vec{x}\mapsto-\vec{x}$ every $\mathrm{d}x^i$ changes sign, so a basis p-form picks up $(-1)^p$. For a field to be parity-even as a form, its components must therefore change by $(-1)^p$. A 1-form's components flip, like the components of the electric field or a velocity: a *polar* vector. A 2-form's components do not flip, like angular momentum $\vec{r}\times\vec{p}$ or the magnetic field: an *axial* or pseudo-vector. The old rule "the cross product of two vectors is a pseudovector" becomes "the wedge product of two 1-forms is a 2-form". Dimensional analysis agrees [Dray §13.5]: $|v\times w|$ is an area, not a length. The wedge product is associative while the

cross product is not, precisely because the wedge keeps track of where each product lives.

T1.3.8 Pictures of forms

Pictures of forms help enormously, and Dray draws them carefully [Dray §13.8]. We met the basic one in Figure T1.7: a 1-form at a point is an oriented *stack* of parallel surfaces, and its value on a vector is the number of sheets pierced. Two further rules make the picture a calculus.

Adding stacks. To draw $\alpha + \beta$, superimpose the stacks of α and β and draw new sheets through the points where a sheet of α meets a sheet of β with labels summing to an integer (Figure T1.10, left). For $a\,dx + b\,dy$ with constants a, b the new sheets are the lines $ax + by =$ const, spaced by $1/\sqrt{a^2+b^2}$: a steeper function has denser contours.

Fields of stacks. A 1-form field has a small stack at each point. When $\alpha = df$ the little stacks fit together into the contour map of f: for $r\,dr = x\,dx + y\,dy = \frac{1}{2}d(r^2)$ they are pieces of circles. But when α is not a differential the stacks need not fit together at all. For $r^2\,d\phi = x\,dy - y\,dx$ the sheets are radial and their spacing shrinks like $1/r^2$ as we move out; following them around the origin one comes back having crossed ever more sheets (Figure T1.10, right). There is no global contour map, because $r^2 d\phi$ is not d of any function. We will make this precise with the exterior derivative in Section T1.5.

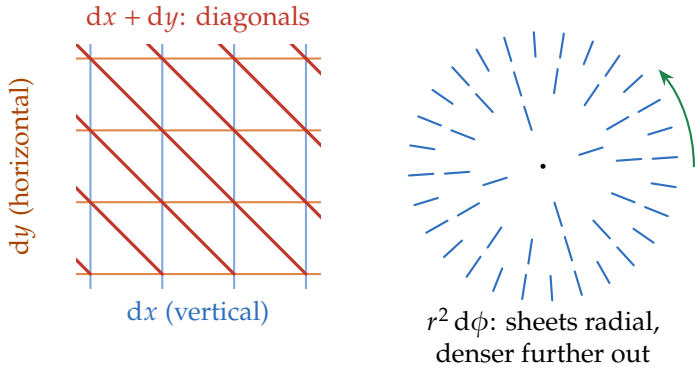

Figure T1.10: Left: adding the stacks dx and dy. The sheets of the sum (red) pass through the corners where the two old stacks cross, and are spaced by $1/\sqrt{2}$. Right: the 1-form field $r^2 d\phi = x\,dy - y\,dx$ drawn as small stacks along three circles. The number of sheets crossed per unit length along a circle grows like r: no contour map produces this pattern.

2-forms and 3-forms. A constant 2-form in the plane, such as $dx \wedge dy$, is drawn as a grid of unit cells made by the stacks of dx and dy. Its value on (v, w) counts the cells covered by the parallelogram spanned by v and w, with a sign from the orientation (Figure T1.11). In three dimensions the two stacks of dx and dy intersect in lines, so $dx \wedge dy$ is a bundle of *tubes* parallel to the z-axis: a flux 2-form literally counts flux tubes piercing a surface. A 3-form is drawn as a honeycomb of boxes, and it counts boxes inside a volume, like a charge density counts charges.

Try it: Stacks and cells

(a) Evaluate $\alpha = 2\,dx - dy$ on $v = (1, 3)$ by counting and by formula. (b) Compute $(dx \wedge dy + dy \wedge dz)(u, w)$ for $u = (1, 1, 0)$, $w = (0, 1, 1)$.
Answers: (a) $2 - 3 = -1$: the vector crosses one sheet against the orientation. (b) $(1 \cdot 1 - 1 \cdot 0) + (1 \cdot 1 - 0 \cdot 1) = 2$.

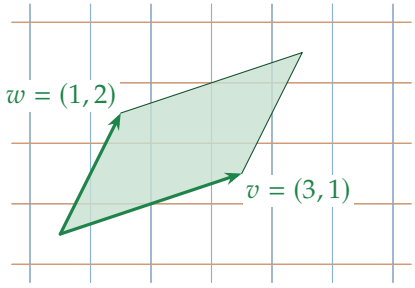

Figure T1.11: The 2-form $\mathrm{d}x \wedge \mathrm{d}y$ as a grid of unit cells. Applied to the pair (v, w) it returns the area of their parallelogram in cell units, here 5; swapping the order of the vectors reverses the orientation and the sign. The 2-form $3\,\mathrm{d}x \wedge \mathrm{d}y$ would be a grid three times finer in area.

Reading Nash (p. 14, (1.45); p. 39, (2.43)–(2.44))

Nash uses the wedge product first on p. 14, to say that the cup product on de Rham cohomology is $[\omega] \cup [\nu] = [\omega \wedge \nu]$, and he notes in (4.76) that the cup product inherits the graded symmetry $u \cup v = (-1)^{pq} v \cup u$ of forms, our (T1.23). On p. 39 he says a p-form "is a section of a bundle over M, the bundle being $\Lambda^p T^*M$, i.e. the pth anti-symmetric power of the cotangent bundle". In our language: at each point, $\Lambda^p T^*_x M$ is the $\binom{n}{p}$-dimensional space spanned by the $\mathrm{d}x^{\mu_1} \wedge \cdots \wedge \mathrm{d}x^{\mu_p}$, and a p-form field picks one element at each point. Recall that his component convention has no $1/p!$.

Recap

- The change-of-variables formula forces $\mathrm{d}y \wedge \mathrm{d}x = -\mathrm{d}x \wedge \mathrm{d}y$ and $\mathrm{d}x \wedge \mathrm{d}x = 0$.
- A p-form eats p vectors by the determinant rule; $\mathrm{d}x \wedge \mathrm{d}y$ measures oriented (shadow) area.
- $\mathrm{d}y^1 \wedge \cdots \wedge \mathrm{d}y^n = \det(\partial y/\partial x)\, \mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^n$; e.g. $\mathrm{d}x \wedge \mathrm{d}y = r\, \mathrm{d}r \wedge \mathrm{d}\phi$.
- $\dim \Omega^p_x = \binom{n}{p}$; top forms are one-dimensional; $\beta \wedge \alpha = (-1)^{pq} \alpha \wedge \beta$.
- In $\mathbb{R}^3$: 0,1,2,3-forms = scalar, vector, pseudovector, density; $\wedge$ gives cross, dot and triple products.
- Pictures: stacks (1-forms), cells or tubes (2-forms), boxes (3-forms).

T1.4 Metric, orientation and the Hodge star

In the three-dimensional dictionary of the last section, a vector field $\vec{F}$ turned into a 1-form $\vec{F} \cdot \mathrm{d}\vec{r}$ *and* into a 2-form $\vec{F} \cdot \mathrm{d}\vec{A}$. The first identification uses only the dot product. The second uses more: to turn $\hat{z}$ into $\mathrm{d}x \wedge \mathrm{d}y$ we needed to know that $\mathrm{d}x$ and $\mathrm{d}y$ are the unit 1-forms perpendicular to $\mathrm{d}z$, *and* which way round to order them. That is, we needed a metric and an orientation. The machine that uses exactly these two ingredients to convert p-forms into $(n-p)$-forms is the *Hodge star* $\star$. It is the most important operator in this chapter after d: it turns d into curl and divergence, it produces the inner product on forms that Nash uses to define adjoints and Laplacians, and in four dimensions it splits 2-forms into self-dual and anti-self-dual halves, which is where instantons live.

T1.4.1 The metric on 1-forms and orthonormal coframes

We saw in (T1.14) that a line element $\mathrm{d}s^2 = g_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu$ induces an inner product on 1-forms, $g(\mathrm{d}x^\mu, \mathrm{d}x^\nu) = g^{\mu\nu}$, the inverse matrix. Any symmetric invertible matrix can be diagonalised and the diagonal entries rescaled to ± 1. So at each point we can choose 1-forms $\sigma^1, \dots, \sigma^n$ with

$$g(\sigma^a, \sigma^b) = \pm\delta^{ab}, \qquad \mathrm{d}s^2 = \sum_a \pm(\sigma^a)^2. \tag{T1.26}$$

Such a set is an **orthonormal coframe** [Dray §14.2]. The line element tells us the coframe at a glance: whatever squares appear in $\mathrm{d}s^2$ are the σ^a.

Working definition T1.10 (signature)

The number s of minus signs in (T1.26) does not depend on the coframe (Sylvester's law of inertia [however a symmetric invertible matrix is brought to diagonal form with entries ±1, the number of -1 entries comes out the same]). We call it the **signature** [Dray §14.3]. $s = 0$ is **Riemannian** (Euclidean) geometry; $s = 1$ is **Lorentzian** geometry, the arena of relativity.

Dictionary: standard coframes

space	line element	orthonormal coframe
$\mathbb{R}^2$, polar	$\mathrm{d}r^2 + r^2\mathrm{d}\phi^2$	$\{\mathrm{d}r,\ r\,\mathrm{d}\phi\}$
$\mathbb{R}^3$, spherical	$\mathrm{d}r^2 + r^2\mathrm{d}\theta^2 + r^2\sin^2\theta\,\mathrm{d}\phi^2$	$\{\mathrm{d}r,\ r\,\mathrm{d}\theta,\ r\sin\theta\,\mathrm{d}\phi\}$
S^2, angles	$\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2$	$\{\mathrm{d}\theta,\ \sin\theta\,\mathrm{d}\phi\}$
S^2, stereographic	$\lambda^2(\mathrm{d}u^2 + \mathrm{d}v^2)$, $\lambda = \frac{2}{1+\rho^2}$	$\{\lambda\,\mathrm{d}u,\ \lambda\,\mathrm{d}v\}$
Minkowski $\mathbb{R}^{1,3}$	$-\mathrm{d}t^2 + \mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2$	$\{\mathrm{d}t, \mathrm{d}x, \mathrm{d}y, \mathrm{d}z\}$, $s = 1$

T1.4.2 Inner products of p-forms

In $\mathbb{R}^3$ we want $\mathrm{d}x \wedge \mathrm{d}y$, which "is" $\hat{z}$, to have unit length. The natural guess, which Dray arrives at by requiring bilinearity [Dray (14.17)–(14.18)], is a determinant of 1-form inner products.

Working definition T1.11 (inner product of p-forms)

On products of 1-forms,

$$g(\alpha^1 \wedge \cdots \wedge \alpha^p,\ \beta^1 \wedge \cdots \wedge \beta^p) = \det\big[g(\alpha^i, \beta^j)\big], \tag{T1.27}$$

extended bilinearly [a general p-form is a sum of such products, and g is linear in each of its two slots]; on functions $g(f, h) = fh$. In components,

$$g(\alpha, \beta) = \frac{1}{p!}\,\alpha_{\mu_1\dots\mu_p}\,\beta^{\mu_1\dots\mu_p}, \qquad \beta^{\mu_1\dots\mu_p} = g^{\mu_1\nu_1}\cdots g^{\mu_p\nu_p}\beta_{\nu_1\dots\nu_p}. \tag{T1.28}$$

In practice: in an orthonormal coframe [1-forms σ^a with $g(\sigma^a, \sigma^b) = \pm\delta^{ab}$, read off as the squares in $\mathrm{d}s^2$], the basis p-forms $\sigma^{a_1} \wedge \cdots \wedge \sigma^{a_p}$ $(a_1 < \cdots < a_p)$ are orthonormal, and each has squared length equal to the product of the signs of its factors.

The $1/p!$ in (T1.28) compensates the $p!$ equal terms in the free sum, exactly as in (T1.22).

Worked example T1.17: Lengths of area forms

(a) Polar coordinates: $g^{rr} = 1$, $g^{\phi\phi} = r^{-2}$. Then

$$g(\mathrm{d}r \wedge \mathrm{d}\phi, \mathrm{d}r \wedge \mathrm{d}\phi) \overset{(1)}{=} \det \begin{pmatrix} g(\mathrm{d}r,\mathrm{d}r) & g(\mathrm{d}r,\mathrm{d}\phi) \\ g(\mathrm{d}\phi,\mathrm{d}r) & g(\mathrm{d}\phi,\mathrm{d}\phi) \end{pmatrix} \overset{(2)}{=} \det \begin{pmatrix} 1 & 0 \\ 0 & r^{-2} \end{pmatrix} = \frac{1}{r^2}.$$

(1) Definition (T1.27).
(2) Inverse polar metric.

So the unit area form is $r\,\mathrm{d}r \wedge \mathrm{d}\phi = \mathrm{d}x \wedge \mathrm{d}y$, as it should be.
(b) Minkowski space, where $g(\mathrm{d}t, \mathrm{d}t) = -1$: time–space 2-forms have negative squared length and space–space ones positive:

$$g(\mathrm{d}t \wedge \mathrm{d}x, \mathrm{d}t \wedge \mathrm{d}x) = (-1)(+1) = -1, \qquad g(\mathrm{d}y \wedge \mathrm{d}z, \mathrm{d}y \wedge \mathrm{d}z) = (+1)(+1) = +1.$$

For the electromagnetic field $F = E_x\,\mathrm{d}x \wedge \mathrm{d}t + \cdots + B_x\,\mathrm{d}y \wedge \mathrm{d}z + \ldots$ (we set this up carefully in Section T1.7) this gives $g(F,F) = |\vec{B}|^2 - |\vec{E}|^2$, which is -2 times the Maxwell Lagrangian density $\frac{1}{2}(|\vec{E}|^2 - |\vec{B}|^2)$. The famous Lorentz invariant $E^2 - B^2$ is just the squared length of the 2-form F.

Schwarz and reverse Schwarz

Apply (T1.27) to $\alpha \wedge \beta$ with itself:

$$g(\alpha \wedge \beta, \alpha \wedge \beta) = g(\alpha,\alpha)\,g(\beta,\beta) - g(\alpha,\beta)^2. \tag{T1.29}$$

In Euclidean signature every 2-form has non-negative squared length, since in an orthonormal basis of the plane spanned by α, β we have $\alpha \wedge \beta = f\,\sigma^1 \wedge \sigma^2$ with $g(\sigma^1 \wedge \sigma^2, \sigma^1 \wedge \sigma^2) = 1$. So $g(\alpha,\beta)^2 \le g(\alpha,\alpha)g(\beta,\beta)$: the Schwarz inequality. In a Lorentzian plane containing the time direction, $g(\sigma^1 \wedge \sigma^2, \sigma^1 \wedge \sigma^2) = -1$ and the inequality reverses [Dray §14.5].

Worked example T1.18: The reverse Schwarz inequality is $\gamma \ge 1$

In Minkowski 2-space take the two unit timelike 1-forms $\alpha = \mathrm{d}t$ and $\beta = \cosh\eta\,\mathrm{d}t + \sinh\eta\,\mathrm{d}x$ (a boosted time direction with rapidity η). Then

$$g(\alpha,\beta)^2 \overset{(1)}{=} (-\cosh\eta)^2 = \cosh^2\eta,$$
$$g(\alpha,\alpha)\,g(\beta,\beta) \overset{(2)}{=} (-1)(-\cosh^2\eta + \sinh^2\eta) = 1,$$

(1) $g(\mathrm{d}t,\mathrm{d}t) = -1$, $g(\mathrm{d}t,\mathrm{d}x) = 0$.
(2) $g(\beta,\beta) = -\cosh^2\eta + \sinh^2\eta = -1$.

and the reverse inequality $\cosh^2\eta \ge 1$ is the statement that the Lorentz factor $\gamma = \cosh\eta$ is never less than one: time dilation.

T1.4.3 Orientation and the volume form

At each point the top forms make up a one-dimensional space. With an orthonormal coframe we get the unit top form

$$\omega = \sigma^1 \wedge \cdots \wedge \sigma^n, \qquad g(\omega,\omega) = g(\sigma^1,\sigma^1)\cdots g(\sigma^n,\sigma^n) = (-1)^s. \tag{T1.30}$$

There are precisely two unit top forms, $\pm\omega$.

Working definition T1.12 (orientation, volume form)

An **orientation** is a continuous choice of one of the two unit top forms at every point; the chosen one is the **volume form** vol (Dray writes ω). In coordinates x^μ that are positively oriented [$dx^1 \wedge \cdots \wedge dx^n$ is a positive multiple of the chosen unit top form],

$$\mathrm{vol} = \sqrt{|\det g_{\mu\nu}|}\, dx^1 \wedge \cdots \wedge dx^n. \tag{T1.31}$$

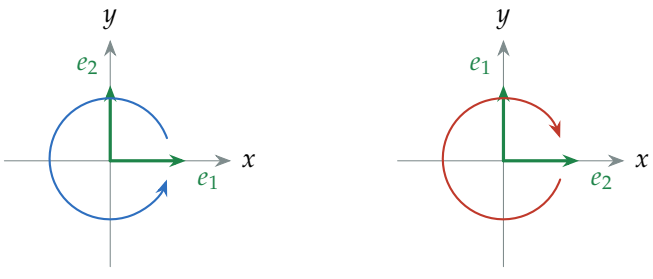
Why (T1.31): write $\sigma^a = e^a{}_\mu dx^\mu$. Then $g_{\mu\nu} = \eta_{ab} e^a{}_\mu e^b{}_\nu$ with $\eta = \mathrm{diag}(\pm 1)$, so $\det g = (\det e)^2(-1)^s$ and $|\det e| = \sqrt{|\det g|}$. By (T1.19), $\sigma^1 \wedge \cdots \wedge \sigma^n = \det e \; dx^1 \wedge \cdots \wedge dx^n$, and "positively oriented" means $\det e > 0$.

This is the same notion of orientation as in Section T1.1: two charts define the same orientation exactly when their coordinate top forms differ by a positive factor, which by (T1.19) is the statement that the transition Jacobian is positive. A manifold is orientable precisely when it admits a nowhere-vanishing top form.

Worked example T1.19: Volume forms we will keep using

$$\begin{aligned}
\mathbb{R}^2 \text{ polar:} &\quad \sqrt{\det \mathrm{diag}(1, r^2)} = r, &&\quad \mathrm{vol} = r\, dr \wedge d\phi, \\
\mathbb{R}^3 \text{ spherical:} &\quad \sqrt{r^4 \sin^2\theta} = r^2 \sin\theta, &&\quad \mathrm{vol} = r^2 \sin\theta\, dr \wedge d\theta \wedge d\phi, \\
S^2 \text{ angles:} &\quad \sqrt{\sin^2\theta} = \sin\theta, &&\quad \mathrm{vol} = \sin\theta\, d\theta \wedge d\phi, \\
S^2 \text{ stereographic:} &\quad \sqrt{\lambda^4} = \lambda^2, &&\quad \mathrm{vol} = \frac{4\, du \wedge dv}{(1+u^2+v^2)^2}, \\
\text{Minkowski:} &\quad \sqrt{|-1|} = 1, &&\quad \mathrm{vol} = dt \wedge dx \wedge dy \wedge dz.
\end{aligned}$$

Two consistency checks. The spherical result agrees with the direct computation of Example T1.13. And the stereographic area of the whole sphere is $\int_{\mathbb{R}^2} 4\, du\, dv/(1+\rho^2)^2 = \int_0^\infty 8\pi\rho\, d\rho/(1+\rho^2)^2 = 4\pi\left[-1/(1+\rho^2)\right]_0^\infty \cdot (-1) \cdot (-1) = 4\pi$, as it must be. With the north chart (u, v) the orientation of vol matches $\sin\theta\, d\theta \wedge d\phi$ only up to a sign: since $\rho = \cot(\theta/2)$ decreases as θ increases, $du \wedge dv = \rho\, d\rho \wedge d\phi$ is a *negative* multiple of $d\theta \wedge d\phi$. Choosing an orientation is a genuine choice.



$+dx \wedge dy$: counter-clockwise $\qquad$ $-dx \wedge dy$: clockwise

Figure T1.12: The two orientations of the plane. An orientation is a choice of unit top form, $+dx \wedge dy$ or $-dx \wedge dy$; equivalently a choice of which ordered bases (e_1, e_2) count as positive (those with $\mathrm{vol}(e_1, e_2) > 0$), equivalently a sense of rotation. On a Möbius band no continuous choice exists.

T1.4.4 The Hodge star

Look again at the dictionary pairs $dx \leftrightarrow dy\wedge dz, dy \leftrightarrow dz\wedge dx, dz \leftrightarrow dx\wedge dy, 1 \leftrightarrow dx\wedge dy\wedge dz$. In each pair, (form)$\wedge$(partner) $= dx \wedge dy \wedge dz$. The partner is the "orthogonal complement, ordered so as to complete the orientation". To make this linear we must let the partner scale with the form, and we arrive at Dray's definition [Dray (14.38)].

Working definition T1.13 (Hodge star)

The **Hodge star** is the linear map $\star : \Omega^p \to \Omega^{n-p}$ defined by

$$\alpha \wedge \star\beta = g(\alpha,\beta)\,\mathrm{vol} \qquad \text{for all } \alpha,\beta \in \Omega^p. \tag{T1.32}$$

Recipe on an orthonormal basis [1-forms σ^a with $g(\sigma^a,\sigma^b) = \pm\delta^{ab}$, e.g. dr, $r\,d\phi$ in polar coordinates]: for a basis p-form $\sigma^I = \sigma^{a_1}\wedge\cdots\wedge\sigma^{a_p}$, let σ^J be the wedge of the remaining σ^b's, in the order (or with the sign) that makes $\sigma^I\wedge\sigma^J = +\mathrm{vol}$ [the chosen unit top form, e.g. $dx\wedge dy\wedge dz$ in $\mathbb{R}^3$]. Then

$$\star\sigma^I = g(\sigma^I,\sigma^I)\,\sigma^J, \tag{T1.33}$$

where $g(\sigma^I,\sigma^I) = \pm 1$ is the product of the signs of the factors. For non-normalised forms, normalise first, star, then undo the normalisation using linearity [Dray §14.10].

Why the recipe works: $\sigma^I\wedge\star\sigma^I$ must equal $g(\sigma^I,\sigma^I)\mathrm{vol}$, so $\star\sigma^I$ contains σ^J with the stated coefficient. It contains nothing else, because every other basis $(n-p)$-form σ^K shares a factor with σ^I and so must satisfy $\sigma^{I'}\wedge\star\sigma^I = g(\sigma^{I'},\sigma^I)\mathrm{vol} = 0$ for the $\sigma^{I'}$ complementary to σ^K. Two immediate consequences in any dimension and signature [Dray (14.40)–(14.42)]:

$$\star 1 = \mathrm{vol}, \qquad \star\mathrm{vol} = (-1)^s. \tag{T1.34}$$

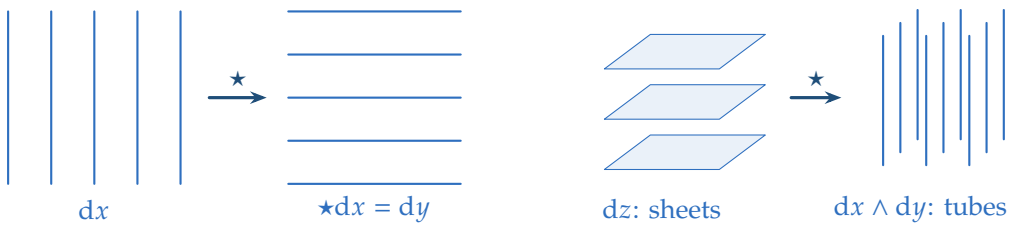


Figure T1.13: What the Hodge star does to pictures. Left: in the Euclidean plane $\star$ rotates a 1-form by 90°; the stack of vertical lines dx becomes the stack of horizontal lines dy. Doing it twice gives $\star\star\,dx = -dx$: on 1-forms in two dimensions $\star$ behaves like multiplication by i. Right: in $\mathbb{R}^3$ the horizontal sheets of dz become the vertical flux tubes of $dx\wedge dy$, which pierce those sheets at right angles.

T1.4.5 Tables of Hodge duals

We now compute $\star$ in every case we will need. Each entry follows from (T1.33); the first few are done in detail.

Worked example T1.20: Euclidean plane and polar coordinates

$\mathbb{R}^2$, $\mathrm{vol} = dx\wedge dy$. For dx the complement is dy since $dx\wedge dy = \mathrm{vol}$; for dy the complement is $-dx$ since $dy\wedge(-dx) = dx\wedge dy$. Both have $g = +1$. So

$$\star 1 = dx\wedge dy, \qquad \star dx = dy, \qquad \star dy = -dx, \qquad \star(dx\wedge dy) = 1.$$

Polar coordinates, coframe $\{\mathrm{d}r, r\,\mathrm{d}\phi\}$, vol $= r\,\mathrm{d}r \wedge \mathrm{d}\phi$: exactly the same pattern gives $\star\mathrm{d}r = r\,\mathrm{d}\phi$ and $\star(r\,\mathrm{d}\phi) = -\mathrm{d}r$. Then linearity handles the unnormalised $\mathrm{d}\phi$:

$$\star\mathrm{d}\phi \overset{(1)}{=} \star\left(\frac{1}{r}\, r\,\mathrm{d}\phi\right) \overset{(2)}{=} \frac{1}{r}\,\star\,(r\,\mathrm{d}\phi) \overset{(3)}{=} -\frac{\mathrm{d}r}{r}, \qquad \star(\mathrm{d}r \wedge \mathrm{d}\phi) \overset{(4)}{=} \frac{1}{r}\star\,(r\,\mathrm{d}r \wedge \mathrm{d}\phi) = \frac{1}{r}.$$

(1) Normalise: $\mathrm{d}\phi = \frac{1}{r}\cdot(r\,\mathrm{d}\phi)$.
(2) $\star$ is linear over functions.
(3) The orthonormal-basis result $\star(r\,\mathrm{d}\phi) = -\mathrm{d}r$.
(4) Same trick, with $\star\mathrm{vol} = 1$.

Check against Cartesian: $r^2\mathrm{d}\phi = x\,\mathrm{d}y - y\,\mathrm{d}x$ should have star $x\star\mathrm{d}y - y\star\mathrm{d}x = -x\,\mathrm{d}x - y\,\mathrm{d}y = -r\,\mathrm{d}r$; and indeed $\star(r^2\mathrm{d}\phi) = r^2(-\mathrm{d}r/r) = -r\,\mathrm{d}r$. ✓

Worked example T1.21: Euclidean $\mathbb{R}^3$ and spherical coordinates

vol $= \mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z$, all signs +. Cyclic permutations of (x, y, z) are even, so [Dray (12.30)–(12.37)]

$$\star 1 = \mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z, \quad \star\mathrm{d}x = \mathrm{d}y \wedge \mathrm{d}z, \quad \star\mathrm{d}y = \mathrm{d}z \wedge \mathrm{d}x, \quad \star\mathrm{d}z = \mathrm{d}x \wedge \mathrm{d}y,$$

$$\star(\mathrm{d}y \wedge \mathrm{d}z) = \mathrm{d}x, \quad \star(\mathrm{d}z \wedge \mathrm{d}x) = \mathrm{d}y, \quad \star(\mathrm{d}x \wedge \mathrm{d}y) = \mathrm{d}z, \quad \star(\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z) = 1.$$

In spherical coordinates the same pattern holds for the coframe $(\mathrm{d}r,\ r\,\mathrm{d}\theta,\ r\sin\theta\,\mathrm{d}\phi)$, which is right-handed (Example T1.13). Undoing the normalisations:

$$\begin{aligned}
\star\mathrm{d}r &= (r\,\mathrm{d}\theta) \wedge (r\sin\theta\,\mathrm{d}\phi) = r^2\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi,\\
\star\mathrm{d}\theta &= \tfrac{1}{r}\,(r\sin\theta\,\mathrm{d}\phi) \wedge \mathrm{d}r = \sin\theta\,\mathrm{d}\phi \wedge \mathrm{d}r,\\
\star\mathrm{d}\phi &= \tfrac{1}{r\sin\theta}\,\mathrm{d}r \wedge (r\,\mathrm{d}\theta) = \frac{1}{\sin\theta}\,\mathrm{d}r \wedge \mathrm{d}\theta.
\end{aligned}$$

The first line is the physicist's $\hat{r}\cdot\mathrm{d}\vec{A} = r^2\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi$: the flux element through a sphere. So the Coulomb field $\vec{E} = \frac{q}{4\pi r^2}\hat{r}$ as a flux 2-form is $\star\left(\frac{q}{4\pi r^2}\mathrm{d}r\right) = \frac{q}{4\pi}\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$, independent of r, and its integral over any sphere is q.

Worked example T1.22: Minkowski space $\mathbb{R}^{1,3}$

$\eta = \mathrm{diag}(-1, 1, 1, 1)$, vol $= \mathrm{d}t \wedge \mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z$, $s = 1$. Every basis form containing $\mathrm{d}t$ has $g = -1$. We do three entries in detail.

- $\star\mathrm{d}t$: the complement with $\mathrm{d}t \wedge (\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z) = \mathrm{vol}$ is $\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z$, and $g(\mathrm{d}t, \mathrm{d}t) = -1$, so $\star\mathrm{d}t = -\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z$.
- $\star\mathrm{d}x$: $\mathrm{d}x \wedge \mathrm{d}t \wedge \mathrm{d}y \wedge \mathrm{d}z = -\mathrm{vol}$ (one swap), so the complement is $-\mathrm{d}t \wedge \mathrm{d}y \wedge \mathrm{d}z$ and $\star\mathrm{d}x = -\mathrm{d}t \wedge \mathrm{d}y \wedge \mathrm{d}z$.
- $\star(\mathrm{d}t \wedge \mathrm{d}x)$: complement $\mathrm{d}y \wedge \mathrm{d}z$ (no reordering needed), $g = -1$, so $\star(\mathrm{d}t \wedge \mathrm{d}x) = -\mathrm{d}y \wedge \mathrm{d}z$.

Proceeding the same way for all sixteen basis forms (with (i, j, k) a cyclic permutation of (x, y, z)):

$\star 1$	$dt \wedge dx \wedge dy \wedge dz$	$\star(dt \wedge dx \wedge dy \wedge dz)$	-1
$\star dt$	$-dx \wedge dy \wedge dz$	$\star(dx \wedge dy \wedge dz)$	$-dt$
$\star dx^i$	$-dt \wedge dx^j \wedge dx^k$	$\star(dt \wedge dx^j \wedge dx^k)$	$-dx^i$
$\star(dt \wedge dx^i)$	$-dx^j \wedge dx^k$	$\star(dx^j \wedge dx^k)$	$dt \wedge dx^i$

The last row is the one electromagnetism uses: $\star$ swaps "electric-type" 2-forms $dt \wedge dx^i$ with "magnetic-type" ones $dx^j \wedge dx^k$, with one minus sign. That minus sign is why $\star\star = -1$ on 2-forms in Lorentzian signature, and why the duality rotation $(\vec{E}, \vec{B}) \to (-\vec{B}, \vec{E})$ of electromagnetism squares to -1.

Worked example T1.23: Euclidean $\mathbb{R}^4$: self-dual and anti-self-dual 2-forms

vol $= dx^1 \wedge dx^2 \wedge dx^3 \wedge dx^4$, all signs $+$. On 2-forms the recipe gives

$$\star(dx^1 \wedge dx^2) = dx^3 \wedge dx^4, \quad \star(dx^1 \wedge dx^3) = dx^4 \wedge dx^2, \quad \star(dx^1 \wedge dx^4) = dx^2 \wedge dx^3,$$

and conversely $\star(dx^3 \wedge dx^4) = dx^1 \wedge dx^2$, etc. (Check the middle one: $dx^1 \wedge dx^3 \wedge dx^4 \wedge dx^2$ is a cyclic permutation of the last three indices of 1234, hence even.) So $\star\star = +1$ on 2-forms, and $\star$ has eigenvalues ± 1. The eigenspaces are spanned by

$$\omega_1^{\pm} = dx^1 \wedge dx^2 \pm dx^3 \wedge dx^4, \quad \omega_2^{\pm} = dx^1 \wedge dx^3 \pm dx^4 \wedge dx^2, \quad \omega_3^{\pm} = dx^1 \wedge dx^4 \pm dx^2 \wedge dx^3,$$

with $\star\omega_i^{\pm} = \pm\omega_i^{\pm}$. The six-dimensional space of 2-forms splits as $3 + 3$: **self-dual** ($\star F = F$) and **anti-self-dual** ($\star F = -F$). A Yang–Mills field that is self-dual automatically solves the field equations; these are the instantons of Chapter 8. Note also $\omega_1^+ \wedge \omega_1^+ = 2\,\mathrm{vol}$ (Example T1.15) while $\omega_1^+ \wedge \omega_1^- = 0$: for a self-dual F, $F \wedge F = F \wedge \star F = |F|^2 \mathrm{vol} \geq 0$. Contrast Minkowski space, where $\star\star = -1$ on 2-forms and the eigenvalues are $\pm i$: real self-dual fields exist only in Euclidean signature, which is one reason Nash (and instanton physics generally) works Euclidean.

T1.4.6 The sign of $\star\star$

Apply the recipe twice. If $\sigma^I \wedge \sigma^J = \mathrm{vol}$ then moving the $(n-p)$ factors of σ^J past the p factors of σ^I gives $\sigma^J \wedge \sigma^I = (-1)^{p(n-p)}\mathrm{vol}$, so the complement of σ^J is $(-1)^{p(n-p)}\sigma^I$. Hence

$$\begin{aligned} \star\star\,\sigma^I &\overset{(1)}{=} g(\sigma^I, \sigma^I)\ \star\sigma^J \overset{(2)}{=} g(\sigma^I, \sigma^I)\, g(\sigma^J, \sigma^J)\,(-1)^{p(n-p)}\sigma^I \\ &\overset{(3)}{=} g(\omega, \omega)\,(-1)^{p(n-p)}\sigma^I \overset{(4)}{=} (-1)^{p(n-p)+s}\,\sigma^I. \end{aligned} \tag{T1.35}$$

(1) Recipe (T1.33) for σ^I.
(2) Recipe for σ^J, whose complement is $(-1)^{p(n-p)}\sigma^I$.
(3) σ^I and σ^J together contain each σ^a once, so the product of their squared lengths is the product of all n signs, $g(\omega, \omega)$.
(4) (T1.30).

Key idea: $\star\star = (-1)^{p(n-p)+s}$ on p-forms

	$p=0$	$p=1$	$p=2$	$p=3$	$p=4$
$\mathbb{R}^2$ $(n=2, s=0)$	$+$	$-$	$+$		
$\mathbb{R}^3$ $(n=3, s=0)$	$+$	$+$	$+$	$+$	
$\mathbb{R}^4$ $(n=4, s=0)$	$+$	$-$	$+$	$-$	$+$
$\mathbb{R}^{1,3}$ $(n=4, s=1)$	$-$	$+$	$-$	$+$	$-$

So $\star^{-1} = \pm\star$, and in odd dimensions with Euclidean signature $\star\star = 1$ always.

T1.4.7 The Hodge star in components

For index computations, and to read Nash, we need the component form. With $\varepsilon_{\mu_1\dots\mu_n}$ the Levi-Civita symbol ($\varepsilon_{12\dots n} = +1$ in positively oriented coordinates, totally antisymmetric),

$$(\star\alpha)_{\nu_1\dots\nu_{n-p}} = \frac{\sqrt{|g|}}{p!}\,\alpha^{\mu_1\dots\mu_p}\,\varepsilon_{\mu_1\dots\mu_p\nu_1\dots\nu_{n-p}}. \tag{T1.36}$$

Worked example T1.24: Checking the component formula

(a) $\mathbb{R}^3$, $\alpha = \mathrm{d}z$: $\alpha^z = 1$, so $(\star\alpha)_{xy} = \varepsilon_{zxy} = 1$, $(\star\alpha)_{yx} = -1$, and $\star\alpha = \frac{1}{2!}\big((\star\alpha)_{xy}\mathrm{d}x\wedge\mathrm{d}y + (\star\alpha)_{yx}\mathrm{d}y\wedge\mathrm{d}x\big) = \mathrm{d}x\wedge\mathrm{d}y$.
(b) Polar, $\alpha = \mathrm{d}\phi$: $\alpha^\phi = g^{\phi\phi}\alpha_\phi = r^{-2}$ and $\sqrt{|g|} = r$, so

$$(\star\alpha)_r \overset{(1)}{=} r\cdot r^{-2}\,\varepsilon_{\phi r} \overset{(2)}{=} -\frac{1}{r}, \qquad \star\mathrm{d}\phi = -\frac{\mathrm{d}r}{r}.$$

(1) (T1.36) with $p=1$, $n=2$, coordinates ordered (r,ϕ).
(2) $\varepsilon_{r\phi} = +1$, so $\varepsilon_{\phi r} = -1$.

This agrees with Example T1.20.
(c) Minkowski, $\alpha = \mathrm{d}t$: $\alpha^t = \eta^{tt} = -1$, so $(\star\alpha)_{xyz} = -\varepsilon_{txyz} = -1$ and $\star\mathrm{d}t = -\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z$, as in the table.

T1.4.8 Dot product, cross product, and the L^2 inner product

Since $\star$ encodes g, the vector operations can be written with it [Dray §14.11]:

$$g(\alpha,\beta) = (-1)^s\ \star(\alpha\wedge\star\beta), \qquad \alpha\times\beta = \star(\alpha\wedge\beta) \quad (\mathbb{R}^3 \text{ only}). \tag{T1.37}$$

The first is (T1.32) starred, using $\star\mathrm{vol} = (-1)^s$. The second only makes sense in three dimensions, where the star of a 2-form is again a 1-form.

Integrating the pointwise inner product over a compact oriented manifold gives the inner product on forms that the whole of Hodge theory is built on:

$$\langle\alpha,\beta\rangle = \int_M \alpha\wedge\star\beta = \int_M g(\alpha,\beta)\,\mathrm{vol}. \tag{T1.38}$$

In Riemannian signature it is positive definite: $\langle\alpha,\alpha\rangle = \int|\alpha|^2\mathrm{vol} > 0$ unless $\alpha = 0$.

Worked example T1.25: Two inner products on S^2

Let $Z = \cos\theta$, the height function. Then

$$\langle Z, Z\rangle \overset{(1)}{=} \int_0^{2\pi}\int_0^{\pi} \cos^2\theta\,\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \overset{(2)}{=} 2\pi\cdot\frac{2}{3} = \frac{4\pi}{3},$$

$$\langle \mathrm{d}Z, \mathrm{d}Z\rangle \overset{(3)}{=} \int_{S^2} g(-\sin\theta\,\mathrm{d}\theta, -\sin\theta\,\mathrm{d}\theta)\,\mathrm{vol} \overset{(4)}{=} \int_0^{2\pi}\int_0^{\pi} \sin^3\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \overset{(5)}{=} 2\pi\cdot\frac{4}{3} = \frac{8\pi}{3}.$$

(1) $g(f,h) = fh$ on functions; $\mathrm{vol} = \sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi$.
(2) Substitute $c = \cos\theta$: $\int_{-1}^{1} c^2\,\mathrm{d}c = 2/3$.
(3) $\mathrm{d}Z = -\sin\theta\,\mathrm{d}\theta$.
(4) $g(\mathrm{d}\theta,\mathrm{d}\theta) = 1$, times $\sin^2\theta$ from the coefficient, times $\sin\theta$ from vol.
(5) $\int_0^{\pi}\sin^3\theta\,\mathrm{d}\theta = \int_{-1}^{1}(1-c^2)\,\mathrm{d}c = 4/3$.

The ratio $\langle \mathrm{d}Z,\mathrm{d}Z\rangle/\langle Z,Z\rangle = 2$ is not an accident: it is the eigenvalue $\ell(\ell+1) = 2$ of the Laplacian on the $\ell = 1$ spherical harmonic Z, as we will see in Section T1.6.

Watch out: What the star depends on

$\star$ depends on the metric *and* the orientation; reversing the orientation flips the sign of every $\star$. But on p-forms in dimension $n = 2p$ it is *conformally invariant*: replacing g by $\lambda^2 g$ multiplies $g(\alpha,\beta)$ by λ^{-2p} and vol by λ^n, and these cancel when $n = 2p$. On the sphere in the stereographic chart, with coframe $\{\lambda\mathrm{d}u, \lambda\mathrm{d}v\}$, this gives $\star\mathrm{d}u = \mathrm{d}v$ and $\star\mathrm{d}v = -\mathrm{d}u$, exactly as in the flat plane, although $\star 1 = \lambda^2\mathrm{d}u\wedge\mathrm{d}v$ does feel the conformal factor. The first fact is why the Maxwell and Yang–Mills actions $\int F\wedge\star F$ are conformally invariant in four dimensions, and why a two-dimensional surface's $\star$ on 1-forms only knows its complex structure (Section T1.10).

Reading Nash (p. 39, (2.43); p. 109, (4.77))

Nash's summary list (2.43) contains exactly the objects of this section, in Riemannian signature: the inner product $\langle\omega,\nu\rangle = \int_M \omega\wedge\star\nu$ (our (T1.38)), $\star : \Omega^p \to \Omega^{n-p}$ with $\star^2 = (-1)^{p(n-p)}$ (our (T1.35) with $s = 0$), and the component formula $\star\omega = \frac{\sqrt{g}}{(n-p)!}\,\epsilon^{i_1\dots i_p}{}_{i_{p+1}\dots i_n}\,\omega_{i_1\dots i_p}\,\mathrm{d}x^{i_{p+1}}\wedge\cdots\wedge\mathrm{d}x^{i_n}$. Because his components carry no $1/p!$ (they are ours divided by $p!$), this is the same as (T1.36). He remarks that "some signs would change if the metric was Lorentzian": that is the $(-1)^s$. On p. 109 he uses the rescaled star $\tau = \mathrm{i}^{p(p-1)+n/2}\star$ on complex forms with $n = 4l$, arranged so that $\tau^2 = 1$. For $n = 4$ on 2-forms, $\tau = \mathrm{i}^{2+2}\star = \star$, and its ±1 eigenspaces are the self-dual and anti-self-dual forms of Example T1.23. On 1-forms, $\tau = \mathrm{i}^2\star = -\star$ and on 3-forms $\tau = \mathrm{i}^8\star = \star$, so $\tau^2 = -\star\star = -(-1) = 1$ there too.

Recap

- A metric gives orthonormal coframes σ^a with $g(\sigma^a,\sigma^b) = \pm\delta^{ab}$; s = number of minus signs.
- g extends to p-forms by determinants; $g(F,F) = B^2 - E^2$ in Minkowski space.
- Orientation = choice of unit top form; $\mathrm{vol} = \sqrt{|g|}\,\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^n$.
- $\alpha\wedge\star\beta = g(\alpha,\beta)\mathrm{vol}$; on an orthonormal basis $\star\sigma^I = g(\sigma^I,\sigma^I)\sigma^J$.

- $\star\star = (-1)^{p(n-p)+s}$; in $\mathbb{R}^4$ 2-forms split into self-dual and anti-self-dual.
- $\langle \alpha, \beta \rangle = \int \alpha \wedge \star\beta$ is the inner product used to define adjoints.

T1.5 The exterior derivative

We know how to differentiate a function: $f \mapsto \mathrm{d}f$, the gradient without a metric. Vector calculus has two more derivatives, the curl and the divergence, each with its own formula, its own set of identities, and its own horror-show of expressions in curvilinear coordinates. Is there one derivative, defined for forms of every rank, that contains all of them and that makes sense in any chart of any manifold? There is, and it is almost embarrassingly simple: *differentiate the coefficients and wedge the result on from the left*. This section builds that operator, the *exterior derivative* d, and shows what it measures: circulation per unit area, flux per unit volume, and in general "how much a p-form fails to integrate to zero around the boundary of a tiny $(p+1)$-dimensional box". Its single most important property, $\mathrm{d}^2 = 0$, is the seed of de Rham cohomology and hence of half of Nash's book.

T1.5.1 Why the obvious derivative is wrong

Given a 1-form $\alpha = \alpha_\nu \, \mathrm{d}x^\nu$, the obvious thing to try is the array of partial derivatives $\partial_\mu \alpha_\nu$. The trouble is that it does not mean the same thing in different charts. Change coordinates $x \to y$ and use the covariant law (T1.12), $\alpha_\nu = (\partial y^\rho / \partial x^\nu)\, \tilde{\alpha}_\rho$:

$$\begin{aligned} \frac{\partial \alpha_\nu}{\partial x^\mu} &\overset{(1)}{=} \frac{\partial}{\partial x^\mu}\left(\frac{\partial y^\rho}{\partial x^\nu}\, \tilde{\alpha}_\rho \right) \\ &\overset{(2)}{=} \frac{\partial^2 y^\rho}{\partial x^\mu \partial x^\nu}\, \tilde{\alpha}_\rho + \frac{\partial y^\rho}{\partial x^\nu} \frac{\partial y^\sigma}{\partial x^\mu} \frac{\partial \tilde{\alpha}_\rho}{\partial y^\sigma}. \end{aligned} \tag{T1.39}$$

(1) Covariant transformation law for the components of a 1-form.
(2) Product rule, and the chain rule $\partial/\partial x^\mu = (\partial y^\sigma / \partial x^\mu)\, \partial/\partial y^\sigma$ on $\tilde{\alpha}_\rho$.

The second term is what a well-behaved object with two lower indices would give. The first term, with second derivatives of the transition map, spoils it. But look: the spoiler is *symmetric* in $\mu \leftrightarrow \nu$. So the antisymmetric combination

$$\partial_\mu \alpha_\nu - \partial_\nu \alpha_\mu$$

is immune. Antisymmetric pairs of lower indices are exactly the components of 2-forms. The derivative that makes sense is therefore one that *produces forms*. This is the whole reason differential forms, and not general tensors, are the natural objects to differentiate on a bare manifold (without a metric or connection).

Worked example T1.26: The spoiler term, seen in polar coordinates

Take the constant 1-form $\alpha = \mathrm{d}x$ on the plane. In Cartesian coordinates its components are $(1, 0)$, and all partial derivatives vanish. In polar coordinates, $\alpha = \cos\phi \, \mathrm{d}r - r \sin\phi \, \mathrm{d}\phi$, so $\alpha_r = \cos\phi$ and $\alpha_\phi = -r\sin\phi$. Then

$$\partial_r \alpha_\phi = -\sin\phi \neq 0, \qquad \partial_\phi \alpha_r = -\sin\phi \neq 0,$$

$$\partial_r \alpha_\phi - \partial_\phi \alpha_r \overset{(1)}{=} -\sin\phi - (-\sin\phi) = 0.$$

(1) The two individually nonzero derivatives cancel in the antisymmetric combination.

The individual partial derivatives are artefacts of the curved coordinate lines; the antisymmetric combination agrees with the Cartesian answer 0.

T1.5.2 Definition and first examples

Working definition T1.14 (exterior derivative)

The **exterior derivative** $\mathrm{d}:\Omega^p\to\Omega^{p+1}$ is defined in any chart [every chart gives the same $(p+1)$-form, since the spoiler terms cancel in antisymmetric combinations] by

$$\mathrm{d}\big(f\,\mathrm{d}x^{\mu_1}\wedge\cdots\wedge\mathrm{d}x^{\mu_p}\big)=\mathrm{d}f\wedge\mathrm{d}x^{\mu_1}\wedge\cdots\wedge\mathrm{d}x^{\mu_p},\qquad \mathrm{d}f=\partial_\nu f\,\mathrm{d}x^\nu, \tag{T1.40}$$

extended by linearity [a general p-form is a sum of such terms, and d acts on each term separately] [Dray (15.7)]. *Recipe:* differentiate each coefficient, wedge the differential on the left, simplify with $\mathrm{d}x^\mu\wedge\mathrm{d}x^\mu=0$. In components,

$$(\mathrm{d}\alpha)_{\mu\nu}=\partial_\mu\alpha_\nu-\partial_\nu\alpha_\mu\ \ (p=1),\qquad (\mathrm{d}\alpha)_{\mu_0\mu_1\ldots\mu_p}=\sum_{i=0}^{p}(-1)^i\,\partial_{\mu_i}\alpha_{\mu_0\ldots\widehat{\mu_i}\ldots\mu_p}, \tag{T1.41}$$

where the hat means "omit this index".

Let us check the $p=1$ component formula, since it is the one we use most:

$$\mathrm{d}(\alpha_\nu\,\mathrm{d}x^\nu)\overset{(1)}{=}\partial_\mu\alpha_\nu\,\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu\overset{(2)}{=}\tfrac12\big(\partial_\mu\alpha_\nu-\partial_\nu\alpha_\mu\big)\,\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu,$$

(1) Definition (T1.40), summing over ν, and $\mathrm{d}\alpha_\nu=\partial_\mu\alpha_\nu\,\mathrm{d}x^\mu$.
(2) Split $\partial_\mu\alpha_\nu$ into symmetric and antisymmetric parts; the symmetric part dies against the antisymmetric $\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu$. What is left is in the form $\frac{1}{2!}(\mathrm{d}\alpha)_{\mu\nu}\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu$ of (T1.22).

By the argument around (T1.39), the result is the same whichever chart we compute in. (We give a chart-free formula below.)

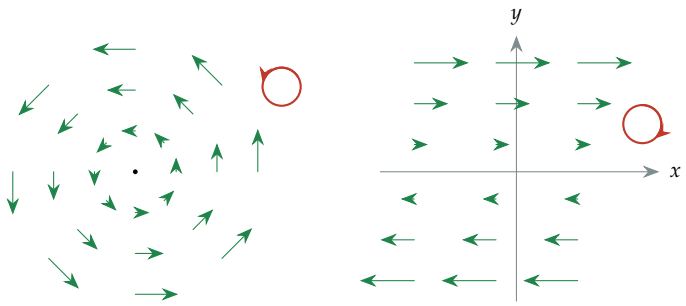
Worked example T1.27: Two flows in the plane

Think of a 1-form as a velocity field $\vec v\cdot\mathrm{d}\vec r$ of a fluid.
Rigid rotation, $\vec v=\Omega(-y,x)$: $v=\Omega(-y\,\mathrm{d}x+x\,\mathrm{d}y)$.

$$\mathrm{d}v\overset{(1)}{=}\Omega\big(-\mathrm{d}y\wedge\mathrm{d}x+\mathrm{d}x\wedge\mathrm{d}y\big)\overset{(2)}{=}2\Omega\,\mathrm{d}x\wedge\mathrm{d}y.$$

(1) (T1.40): $\mathrm{d}(-y)=-\mathrm{d}y$ wedged onto $\mathrm{d}x$, and $\mathrm{d}x$ wedged onto $\mathrm{d}y$.
(2) $\mathrm{d}y\wedge\mathrm{d}x=-\mathrm{d}x\wedge\mathrm{d}y$.

The coefficient 2Ω is the vorticity, twice the angular velocity.
Shear flow, $\vec v=(\kappa y,0)$: $v=\kappa y\,\mathrm{d}x$ and $\mathrm{d}v=\kappa\,\mathrm{d}y\wedge\mathrm{d}x=-\kappa\,\mathrm{d}x\wedge\mathrm{d}y$. Although every fluid particle moves in a straight line, the flow has vorticity: a small paddle wheel placed in it turns clockwise, because the top of the wheel is pushed harder than the bottom (Figure T1.14).
Radial flow, $\vec v=(x,y)$: $v=x\,\mathrm{d}x+y\,\mathrm{d}y$ and $\mathrm{d}v=\mathrm{d}x\wedge\mathrm{d}x+\mathrm{d}y\wedge\mathrm{d}y=0$. No vorticity; and indeed $v=\mathrm{d}(\frac12 r^2)$.



rotation: $\mathrm{d}v = 2\Omega\,\mathrm{d}x \wedge \mathrm{d}y$ shear: $\mathrm{d}v = -\kappa\,\mathrm{d}x \wedge \mathrm{d}y$

Figure T1.14: Two velocity 1-forms and their exterior derivatives. Left: rigid rotation; a small paddle wheel (red) turns counter-clockwise, and $\mathrm{d}v$ is a positive multiple of $\mathrm{d}x \wedge \mathrm{d}y$. Right: shear flow, whose streamlines are straight; the wheel still turns, clockwise here, because the flow above its centre is faster than below. $\mathrm{d}v$ detects local rotation, not curved streamlines.

T1.5.3 What $\mathrm{d}\alpha$ measures: circulation per unit area

The paddle wheel is not just a metaphor. Let us compute the circulation of a 1-form α around a small parallelogram with corner p and sides εv, εw (constant vectors in some chart), keeping terms up to order ε^2 (Figure T1.15). Along a side from q to $q + \varepsilon u$ the line integral is $\int_0^\varepsilon \alpha_\nu(q + tu)u^\nu\,\mathrm{d}t = \varepsilon\,\alpha_\nu(q)u^\nu + \tfrac{1}{2}\varepsilon^2\,\partial_\mu\alpha_\nu(q)u^\mu u^\nu + O(\varepsilon^3)$, by Taylor expansion. The four sides give

$$\begin{aligned}
\oint \alpha &\overset{(1)}{=} \left[\varepsilon\alpha_\nu v^\nu + \tfrac{1}{2}\varepsilon^2\partial_\mu\alpha_\nu v^\mu v^\nu\right] + \left[\varepsilon\alpha_\nu w^\nu + \varepsilon^2\partial_\mu\alpha_\nu v^\mu w^\nu + \tfrac{1}{2}\varepsilon^2\partial_\mu\alpha_\nu w^\mu w^\nu\right] \\
&\quad - \left[\varepsilon\alpha_\nu v^\nu + \varepsilon^2\partial_\mu\alpha_\nu w^\mu v^\nu + \tfrac{1}{2}\varepsilon^2\partial_\mu\alpha_\nu v^\mu v^\nu\right] - \left[\varepsilon\alpha_\nu w^\nu + \tfrac{1}{2}\varepsilon^2\partial_\mu\alpha_\nu w^\mu w^\nu\right] + O(\varepsilon^3) \\
&\overset{(2)}{=} \varepsilon^2\left(\partial_\mu\alpha_\nu v^\mu w^\nu - \partial_\mu\alpha_\nu w^\mu v^\nu\right) + O(\varepsilon^3) \\
&\overset{(3)}{=} \varepsilon^2\left(\partial_\mu\alpha_\nu - \partial_\nu\alpha_\mu\right)v^\mu w^\nu + O(\varepsilon^3) \overset{(4)}{=} \varepsilon^2\,\mathrm{d}\alpha(v,w) + O(\varepsilon^3).
\end{aligned} \tag{T1.42}$$

(1) The four sides, in order: bottom (from p, direction v), right (from $p + \varepsilon v$, direction w, so the Taylor expansion about p picks up an extra $\varepsilon\,v^\mu\partial_\mu$), top traversed backwards (from $p + \varepsilon w$, direction v) and left traversed backwards (from p, direction w). All α_ν and derivatives are at p.
(2) All the order-ε terms and all the "diagonal" $\tfrac{1}{2}\varepsilon^2$ terms cancel in pairs.
(3) Rename the dummy indices $\mu \leftrightarrow \nu$ in the second term.
(4) The components of $\mathrm{d}\alpha$ (T1.41), evaluated on (v, w) as in Section T1.3.

Key idea: Infinitesimal Stokes

$\mathrm{d}\alpha(v, w)$ is the circulation of α around the infinitesimal parallelogram spanned by v and w, per unit ε^2. More generally, for a p-form α, $\mathrm{d}\alpha(v_0, \ldots, v_p)$ is the integral of α over the (oriented) boundary of the small $(p+1)$-dimensional parallelepiped spanned by the v_i. Adding up many small cells, interior edges cancel and we get Stokes' theorem $\int_R \mathrm{d}\alpha = \int_{\partial R}\alpha$ (Chapter T2).

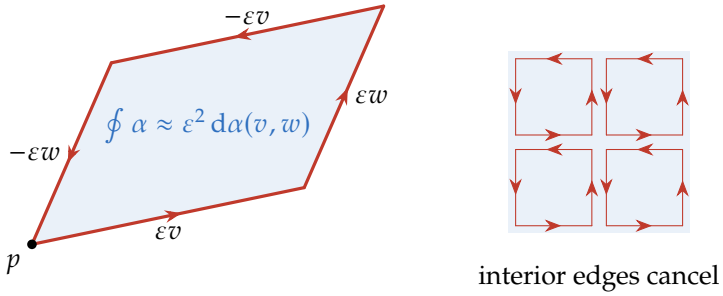


Figure T1.15: Left: the circulation of a 1-form around a small parallelogram is $\varepsilon^2 \mathrm{d}\alpha(v,w)$ to leading order, (T1.42). The order-ε contributions of opposite sides cancel; what survives is the *difference* of α between opposite sides. Right: gluing cells, each interior edge is traversed twice in opposite directions, so the sum of the small circulations is the circulation around the outer edge. That is Stokes' theorem.

T1.5.4 Gradient, curl and divergence are all d

In Euclidean $\mathbb{R}^3$ let $F = F_x\,\mathrm{d}x + F_y\,\mathrm{d}y + F_z\,\mathrm{d}z$ be the 1-form of a vector field $\vec{F}$. Following Dray [Dray (15.9)–(15.10)], first one term:

$$\begin{aligned}\mathrm{d}(F_x\,\mathrm{d}x) &\overset{(1)}{=} \left(\partial_x F_x\,\mathrm{d}x + \partial_y F_x\,\mathrm{d}y + \partial_z F_x\,\mathrm{d}z\right)\wedge \mathrm{d}x \\ &\overset{(2)}{=} \partial_z F_x\,\mathrm{d}z\wedge\mathrm{d}x - \partial_y F_x\,\mathrm{d}x\wedge\mathrm{d}y.\end{aligned}$$

(1) Definition (T1.40).
(2) $\mathrm{d}x\wedge\mathrm{d}x = 0$; $\mathrm{d}y\wedge\mathrm{d}x = -\mathrm{d}x\wedge\mathrm{d}y$.

Adding the two similar terms,

$$\mathrm{d}F = (\partial_y F_z - \partial_z F_y)\,\mathrm{d}y\wedge\mathrm{d}z + (\partial_z F_x - \partial_x F_z)\,\mathrm{d}z\wedge\mathrm{d}x + (\partial_x F_y - \partial_y F_x)\,\mathrm{d}x\wedge\mathrm{d}y. \tag{T1.43}$$

These are the components of $\nabla\times\vec{F}$, arranged as a flux 2-form. Next, a flux 2-form $G = G_x\,\mathrm{d}y\wedge\mathrm{d}z + G_y\,\mathrm{d}z\wedge\mathrm{d}x + G_z\,\mathrm{d}x\wedge\mathrm{d}y$:

$$\begin{aligned}\mathrm{d}G &\overset{(1)}{=} \partial_x G_x\,\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z + \partial_y G_y\,\mathrm{d}y\wedge\mathrm{d}z\wedge\mathrm{d}x + \partial_z G_z\,\mathrm{d}z\wedge\mathrm{d}x\wedge\mathrm{d}y \\ &\overset{(2)}{=} (\partial_x G_x + \partial_y G_y + \partial_z G_z)\,\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z.\end{aligned} \tag{T1.44}$$

(1) In $\mathrm{d}G_x\wedge\mathrm{d}y\wedge\mathrm{d}z$ only the $\mathrm{d}x$ part of $\mathrm{d}G_x$ survives; similarly for the others.
(2) Cyclic permutations of three 1-forms carry no sign.

This is the divergence, as a density. Using the Hodge star of Example T1.21 to translate back into vectors [Dray (15.12)–(15.19)]:

Dictionary: vector calculus in forms, $\mathbb{R}^3$

vector calculus	forms	ranks
∇f	$\mathrm{d}f$	$0\to 1$
$\nabla\times\vec{F}$	$\star\mathrm{d}F$ (or $\mathrm{d}F$ as a flux)	$1\to 2\,(\to 1)$
$\nabla\cdot\vec{F}$	$\star\mathrm{d}\star F$ (or $\mathrm{d}\star F$ as a density)	$1\to 2\to 3\,(\to 0)$
$\nabla^2 f$	$\star\mathrm{d}\star\mathrm{d}f$	$0\to 1\to 2\to 3\to 0$

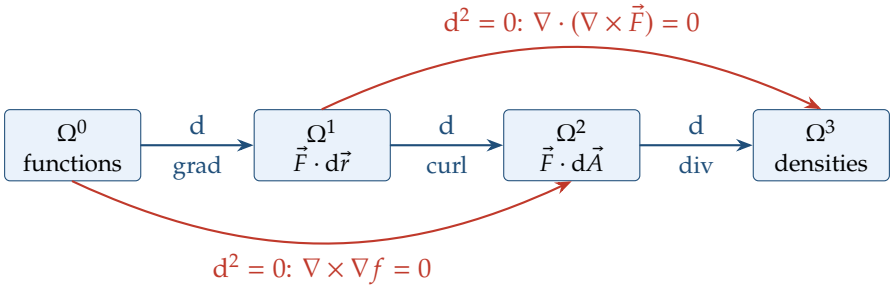

Figure T1.16: The de Rham complex of $\mathbb{R}^3$. One operator d plays the role of gradient, curl and divergence according to the rank it acts on. Two steps in a row always give zero (red arrows); these are the two classic identities of vector calculus. Nash's de Rham cohomology [Nash p. 13, (1.43)] measures how far "$d\beta = 0$" is from "$\beta = d\alpha$" in each box.

Worked example T1.28: Divergence in spherical coordinates, and the Coulomb field

Write a vector field in the orthonormal spherical basis as the 1-form $F = F_r\,dr + F_\theta\, r\,d\theta + F_\phi\, r\sin\theta\,d\phi$. Using the star of the orthonormal coframe (Example T1.21),

$$\begin{aligned} \star F &\overset{(1)}{=} F_r\,(r\,d\theta)\wedge(r\sin\theta\,d\phi) + F_\theta\,(r\sin\theta\,d\phi)\wedge dr + F_\phi\,dr\wedge(r\,d\theta) \\ &= r^2\sin\theta F_r\,d\theta\wedge d\phi + r\sin\theta F_\theta\,d\phi\wedge dr + rF_\phi\,dr\wedge d\theta, \\ d\star F &\overset{(2)}{=} \left[\partial_r(r^2\sin\theta F_r) + \partial_\theta(r\sin\theta F_\theta) + \partial_\phi(rF_\phi)\right] dr\wedge d\theta\wedge d\phi, \\ \nabla\cdot\vec{F} = \star d\star F &\overset{(3)}{=} \frac{1}{r^2}\partial_r(r^2F_r) + \frac{1}{r\sin\theta}\partial_\theta(\sin\theta F_\theta) + \frac{1}{r\sin\theta}\partial_\phi F_\phi. \end{aligned}$$

(1) $\star$ sends each element of the right-handed orthonormal coframe $(dr, r\,d\theta, r\sin\theta\,d\phi)$ to the wedge of the other two in cyclic order.
(2) For each term only the derivative along the missing coordinate survives; $d\phi\wedge dr\wedge d\theta$ and $dr\wedge d\theta\wedge d\phi$ are cyclic, so no signs.
(3) $\star(dr\wedge d\theta\wedge d\phi) = 1/(r^2\sin\theta)$, because $r^2\sin\theta\,dr\wedge d\theta\wedge d\phi = \text{vol}$ has star 1.

This is the textbook formula, obtained with no Christoffel symbols and no scale-factor lore. For the Coulomb field $F_r = q/(4\pi r^2)$, $F_\theta = F_\phi = 0$: $r^2\sin\theta F_r = q\sin\theta/4\pi$ is independent of r, so $d\star F = 0$ for $r \neq 0$. The flux 2-form $\star F = \frac{q}{4\pi}\sin\theta\,d\theta\wedge d\phi$ is closed but, as we shall see, not exact: the charge at the origin is detected by its integral, q, over any sphere.

Try it: Curl in cylindrical coordinates

With coframe $(d\rho, \rho\,d\phi, dz)$ and $F = F_\rho\,d\rho + F_\phi\,\rho\,d\phi + F_z\,dz$, compute the z-component of $\star dF$.
Answer: the $d\rho\wedge d\phi$ part of dF is $\left(\partial_\rho(\rho F_\phi) - \partial_\phi F_\rho\right)d\rho\wedge d\phi$, and $\star(d\rho\wedge d\phi) = \frac{1}{\rho}\star(d\rho\wedge\rho\,d\phi) = \frac{1}{\rho}\,dz$, giving $(\nabla\times\vec{F})_z = \frac{1}{\rho}\left(\partial_\rho(\rho F_\phi) - \partial_\phi F_\rho\right)$.

T1.5.5 $d^2 = 0$

Apply d twice to a function [Dray (15.23)]:

$$d(df) \overset{(1)}{=} d\left(\frac{\partial f}{\partial x^\nu}\right)\wedge dx^\nu \overset{(2)}{=} \frac{\partial^2 f}{\partial x^\mu\partial x^\nu}\,dx^\mu\wedge dx^\nu \overset{(3)}{=} 0. \tag{T1.45}$$

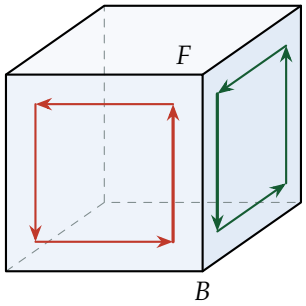
(1) Definition (T1.40) applied to the 1-form $\partial_\nu f\,dx^\nu$.

(2) Differential of the coefficient.
(3) Mixed partial derivatives are symmetric in $\mu\nu$ and $dx^\mu \wedge dx^\nu$ is antisymmetric: swapping the dummy indices shows the sum equals minus itself.

For a general form $\alpha = f\,dx^I$ (with dx^I a product of coordinate differentials), $d\alpha = df \wedge dx^I$ and $dd\alpha = ddf \wedge dx^I = 0$ by the same argument [Dray (15.26)].

Key idea: $d^2 = 0$

For every form α, $d(d\alpha) = 0$. In $\mathbb{R}^3$ this single statement is both $\nabla \times (\nabla f) = 0$ and $\nabla \cdot (\nabla \times \vec{F}) = 0$ [Dray (15.28)–(15.29)]. Geometrically it is dual to "the boundary of a boundary is empty": by Stokes, $\int_R dd\alpha = \int_{\partial R} d\alpha = \int_{\partial\partial R} \alpha = 0$ for every region R, because $\partial\partial R = \varnothing$.



edge BF is traversed upward
by the front face (red) and
downward by the right face (green)

Figure T1.17: Why $\partial\partial = \varnothing$. The boundary of a solid cube is its six faces, each oriented by the outward normal. The boundary of that closed surface is the sum of the faces' edges, but every edge is shared by two faces which traverse it in opposite directions (red and green), so the total is zero. Through Stokes, this is the same fact as $d^2 = 0$.

T1.5.6 The product rule

Working definition T1.15 (graded Leibniz rule)

For $\alpha \in \Omega^p$ [a p-form, a sum of terms $f\,dx^{\mu_1} \wedge \cdots \wedge dx^{\mu_p}$] and any form β,

$$d(\alpha \wedge \beta) = d\alpha \wedge \beta + (-1)^p\, \alpha \wedge d\beta. \tag{T1.46}$$

The sign appears because d has to be "moved past" the p one-form factors of α to act on β.

For monomials $\alpha = f\,dx^I$ (p factors) and $\beta = h\,dx^J$ [Dray (15.31)]:

$$\begin{aligned} d(\alpha \wedge \beta) &\overset{(1)}{=} d(fh) \wedge dx^I \wedge dx^J \overset{(2)}{=} (h\,df + f\,dh) \wedge dx^I \wedge dx^J \\ &\overset{(3)}{=} (df \wedge dx^I) \wedge (h\,dx^J) + (-1)^p\,(f\,dx^I) \wedge (dh \wedge dx^J) = d\alpha \wedge \beta + (-1)^p \alpha \wedge d\beta. \end{aligned}$$

(1) $\alpha \wedge \beta = fh\,dx^I \wedge dx^J$, then definition (T1.40).
(2) Ordinary product rule for functions.
(3) In the second term, move the 1-form dh past the p factors of dx^I; each swap costs -1.

Worked example T1.29: Two vector identities for free

(a) For a function f and a 1-form G in $\mathbb{R}^3$: $\star d(fG) = \star(df \wedge G) + f \star dG$. With $\star(F \wedge G) \leftrightarrow \vec{F} \times \vec{G}$ (T1.37) this is $\nabla \times (f\vec{G}) = \nabla f \times \vec{G} + f\,\nabla \times \vec{G}$.

(b) For two 1-forms F, G, the divergence of the cross product $\star(F \wedge G)$ is [Dray (15.43)]

$$\star \mathrm{d} \star \big(\star(F \wedge G)\big) \overset{(1)}{=} \star \mathrm{d}(F \wedge G) \overset{(2)}{=} \star(\mathrm{d}F \wedge G - F \wedge \mathrm{d}G)$$
$$\overset{(3)}{=} \star\big(G \wedge \mathrm{d}F\big) - \star\big(F \wedge \mathrm{d}G\big) \overset{(4)}{=} \vec{G} \cdot (\nabla \times \vec{F}) - \vec{F} \cdot (\nabla \times \vec{G}).$$

(1) $\star\star = 1$ in $\mathbb{R}^3$ (Section T1.4).
(2) Leibniz rule (T1.46) with $p = 1$.
(3) A 2-form commutes with a 1-form (T1.23).
(4) 1-form $\wedge$ flux = dot product $\times$ volume (Example T1.14), $\mathrm{d}F$ is the flux of $\nabla \times \vec{F}$, and $\star\mathrm{vol} = 1$.

So $\nabla \cdot (\vec{F} \times \vec{G}) = \vec{G} \cdot (\nabla \times \vec{F}) - \vec{F} \cdot (\nabla \times \vec{G})$, an identity that is usually proved by grinding through the ε_{ijk}'s.

T1.5.7 Uniqueness, and a chart-free formula

Key idea: d is unique

There is exactly one operator $\mathrm{d} : \Omega^p \to \Omega^{p+1}$ that (i) is linear, (ii) obeys the graded Leibniz rule (T1.46), (iii) satisfies $\mathrm{d}^2 = 0$, and (iv) gives the differential $\mathrm{d}f$ on functions [Dray §15.12].

Why: by (ii) with $p = 0$, $\mathrm{d}(f\,\mathrm{d}x^I) = \mathrm{d}f \wedge \mathrm{d}x^I + f\,\mathrm{d}(\mathrm{d}x^I)$. By (iv) and (iii), $\mathrm{d}(\mathrm{d}x^\mu) = \mathrm{d}\mathrm{d}x^\mu = 0$, and then by (ii) repeatedly $\mathrm{d}(\mathrm{d}x^{\mu_1} \wedge \cdots \wedge \mathrm{d}x^{\mu_p}) = 0$. So any operator with the four properties is given by (T1.40) in every chart. Since the four properties make no reference to coordinates, the operator defined by (T1.40) in one chart agrees with the one defined in any other chart. This is the cleanest proof that d is coordinate independent.

There is also a formula for d that uses no coordinates at all. For two vector fields X, Y define their **commutator** (or Lie bracket) as the vector field $[X, Y]f = X(Yf) - Y(Xf)$; the second derivatives cancel, so this is again a first-order operator, with components $[X, Y]^\mu = X^\nu \partial_\nu Y^\mu - Y^\nu \partial_\nu X^\mu$ (we study it in Section T1.9). Then for a 1-form α,

$$\mathrm{d}\alpha(X, Y) = X\big(\alpha(Y)\big) - Y\big(\alpha(X)\big) - \alpha([X, Y]). \tag{T1.47}$$

Check in components:

$$X(\alpha_\nu Y^\nu) - Y(\alpha_\nu X^\nu) \overset{(1)}{=} X^\mu \partial_\mu \alpha_\nu\, Y^\nu + \alpha_\nu X^\mu \partial_\mu Y^\nu - Y^\mu \partial_\mu \alpha_\nu\, X^\nu - \alpha_\nu Y^\mu \partial_\mu X^\nu$$
$$\overset{(2)}{=} (\partial_\mu \alpha_\nu - \partial_\nu \alpha_\mu) X^\mu Y^\nu + \alpha_\nu [X, Y]^\nu \overset{(3)}{=} \mathrm{d}\alpha(X, Y) + \alpha([X, Y]).$$

(1) Product rule on each term.
(2) Rename dummies in the third term; collect the terms with derivatives of X, Y into the commutator.
(3) Components of $\mathrm{d}\alpha$.

For coordinate vector fields $[\partial_\mu, \partial_\nu] = 0$ and (T1.47) reduces to the component formula. The formula (T1.47) is the one mathematicians take as the definition, and it is how curvature formulas are usually derived (Chapter T2).

T1.5.8 Closed and exact forms: a first look

Working definition T1.16 (closed, exact)

A form β is **closed** if $\mathrm{d}\beta = 0$ and **exact** if $\beta = \mathrm{d}\alpha$ for some globally defined form α [one smooth α on all of M, not a different one on each chart]. By $\mathrm{d}^2 = 0$ [applying d twice always gives zero, because mixed partial derivatives commute], every exact form is closed. *Test for closedness:* compute $\mathrm{d}\beta$. *Test for non-exactness:* find a closed curve (or surface, ...) over which β has a nonzero integral [by Stokes, $\oint_C \mathrm{d}\alpha = 0$ for every closed curve C, so an exact β integrates to zero there].

Why does a nonzero loop integral rule out exactness? If $\beta = \mathrm{d}f$ with f a smooth function everywhere, then around a closed loop γ the fundamental theorem of calculus gives $\oint_\gamma \mathrm{d}f = f(\text{end}) - f(\text{start}) = 0$.

Worked example T1.30: $\mathrm{d}\phi$ on the punctured plane: closed but not exact

On $\mathbb{R}^2 \setminus \{0\}$ consider

$$\beta = \frac{x\,\mathrm{d}y - y\,\mathrm{d}x}{x^2 + y^2}.$$

Where the angle ϕ is defined, $\beta = \mathrm{d}\phi$ (this is $r^2\mathrm{d}\phi = x\,\mathrm{d}y - y\,\mathrm{d}x$ from Example T1.12, divided by r^2). But β itself is defined on the whole punctured plane, while ϕ is not. Is it closed?

$$\mathrm{d}\beta \overset{(1)}{=} \mathrm{d}\Big(\frac{x}{r^2}\Big) \wedge \mathrm{d}y - \mathrm{d}\Big(\frac{y}{r^2}\Big) \wedge \mathrm{d}x \overset{(2)}{=} \partial_x\Big(\frac{x}{r^2}\Big)\mathrm{d}x \wedge \mathrm{d}y - \partial_y\Big(\frac{y}{r^2}\Big)\mathrm{d}y \wedge \mathrm{d}x$$
$$\overset{(3)}{=} \Big[\frac{r^2 - 2x^2}{r^4} + \frac{r^2 - 2y^2}{r^4}\Big]\mathrm{d}x \wedge \mathrm{d}y \overset{(4)}{=} \frac{2r^2 - 2(x^2+y^2)}{r^4}\,\mathrm{d}x \wedge \mathrm{d}y = 0.$$

(1) Definition (T1.40), with $r^2 = x^2 + y^2$.
(2) Only the $\mathrm{d}x$ part of $\mathrm{d}(x/r^2)$ survives against $\mathrm{d}y$, and only the $\mathrm{d}y$ part of $\mathrm{d}(y/r^2)$ against $\mathrm{d}x$.
(3) Quotient rule, $\partial_x(x/r^2) = (r^2 - 2x^2)/r^4$, and $-\mathrm{d}y \wedge \mathrm{d}x = +\mathrm{d}x \wedge \mathrm{d}y$.
(4) Add the fractions.

So β is closed. Now integrate around the unit circle $(x, y) = (\cos t, \sin t)$, $t \in [0, 2\pi]$, where $\mathrm{d}x = -\sin t\,\mathrm{d}t$, $\mathrm{d}y = \cos t\,\mathrm{d}t$ (this "substitute the curve" step is the pullback of Section T1.8):

$$\oint \beta = \int_0^{2\pi} \big(\cos t \cos t - \sin t(-\sin t)\big)\mathrm{d}t = 2\pi \neq 0.$$

So β is *not* exact on $\mathbb{R}^2 \setminus \{0\}$: there is no smooth single-valued function whose differential it is. The would-be potential ϕ jumps by 2π around the origin, exactly the jump we met in the transition map of Example T1.1. The space $\mathbb{R}^2 \setminus \{0\}$ has a hole, and the closed-but-not-exact form β detects it. This is the prototype of de Rham cohomology: $[\beta]$ is a nonzero element of $H^1_{\mathrm{dR}}(\mathbb{R}^2 \setminus \{0\})$ (Chapter T2).
Contrast $r^2\mathrm{d}\phi = x\,\mathrm{d}y - y\,\mathrm{d}x$ from Figure T1.10: its derivative is $2\,\mathrm{d}x \wedge \mathrm{d}y \neq 0$, so it is not even closed, and it is not d of anything on any region at all. That is why its stacks could not be fitted together into a contour map.

Key idea: Poincaré lemma

On a region that is *star-shaped* (every point can be joined to a fixed centre by a straight segment inside the region, e.g. $\mathbb{R}^n$ or a ball), every closed form is exact. For a closed 1-form α an explicit potential is

$$f(x) = \int_0^1 x^\mu \, \alpha_\mu(tx)\, \mathrm{d}t, \tag{T1.48}$$

the line integral of α along the straight segment from 0 to x.

Why it works:

$$\partial_\nu f(x) \overset{(1)}{=} \int_0^1 \big[\alpha_\nu(tx) + x^\mu\, t\, (\partial_\nu \alpha_\mu)(tx)\big]\mathrm{d}t \overset{(2)}{=} \int_0^1 \big[\alpha_\nu(tx) + t\, x^\mu (\partial_\mu \alpha_\nu)(tx)\big]\mathrm{d}t$$
$$\overset{(3)}{=} \int_0^1 \frac{\mathrm{d}}{\mathrm{d}t}\big[t\, \alpha_\nu(tx)\big]\mathrm{d}t \overset{(4)}{=} \alpha_\nu(x).$$

(1) Differentiate under the integral; the chain rule gives a factor t from the argument tx.
(2) α is closed: $\partial_\nu \alpha_\mu = \partial_\mu \alpha_\nu$.
(3) Product rule: $\frac{\mathrm{d}}{\mathrm{d}t}[t\, \alpha_\nu(tx)] = \alpha_\nu(tx) + t\, x^\mu (\partial_\mu \alpha_\nu)(tx)$.
(4) Fundamental theorem of calculus: $[t\, \alpha_\nu(tx)]_0^1$.

The punctured plane is not star-shaped (the segment to the centre may pass through the hole), and that is exactly where Example T1.30 escapes the lemma. Topology is the study of such escapes.

Worked example T1.31: Finding a potential with the Poincaré formula

Let $\alpha = 2xy\,\mathrm{d}x + x^2\,\mathrm{d}y$ on $\mathbb{R}^2$. It is closed: $\mathrm{d}\alpha = 2x\,\mathrm{d}y \wedge \mathrm{d}x + 2x\,\mathrm{d}x \wedge \mathrm{d}y = 0$. Then

$$f(x,y) \overset{(1)}{=} \int_0^1 \big[x \cdot 2(tx)(ty) + y \cdot (tx)^2\big]\mathrm{d}t \overset{(2)}{=} 3x^2 y \int_0^1 t^2\,\mathrm{d}t = x^2 y.$$

(1) (T1.48) with $\alpha_x(tx,ty) = 2t^2xy$ and $\alpha_y(tx,ty) = t^2x^2$.
(2) Collect: $2t^2x^2y + t^2x^2y = 3t^2x^2y$.

Check: $\mathrm{d}(x^2y) = 2xy\,\mathrm{d}x + x^2\,\mathrm{d}y$. In physics language, a curl-free force on a simply connected region is conservative, and this formula constructs its potential energy (up to sign and a constant).

Reading Nash (p. 13, (1.40)–(1.43))

Nash introduces cochain complexes abstractly, $\cdots \to E^{n-1} \to E^n \to E^{n+1} \to \dots$ with $d_n \circ d_{n-1} = 0$, and then says: take $E^n = \Omega^n(X)$ and d the exterior derivative; "the resulting complex is the de Rham complex" with cohomology $H^n_{\text{de Rham}}(X) = \ker d_n / \operatorname{Im} d_{n-1}$. Everything in that sentence is now concrete: $\Omega^n(X)$ is the space of n-forms of Section T1.3, d is (T1.40), the complex property is $\mathrm{d}^2 = 0$ (T1.45), $\ker d$ is the closed forms, $\operatorname{Im} d$ the exact ones, and Example T1.30 exhibits a nonzero class in $H^1_{\text{de Rham}}(\mathbb{R}^2 \setminus \{0\})$. On p. 14 he adds that the cup product in de Rham cohomology is $[\omega] \cup [\nu] = [\omega \wedge \nu]$; the Leibniz rule (T1.46) is what makes this well defined (closed $\wedge$ closed is closed, and closed $\wedge$ exact is exact: $\omega \wedge \mathrm{d}\alpha = \pm\mathrm{d}(\omega \wedge \alpha)$ when $\mathrm{d}\omega = 0$).

Recap

- $\mathrm{d}(f\,\mathrm{d}x^I) = \mathrm{d}f \wedge \mathrm{d}x^I$; for 1-forms $(\mathrm{d}\alpha)_{\mu\nu} = \partial_\mu\alpha_\nu - \partial_\nu\alpha_\mu$. Antisymmetry is what makes it chart independent.
- $\mathrm{d}\alpha(v,w)$ is the circulation around the small parallelogram on v, w: infinitesimal Stokes.
- In $\mathbb{R}^3$: d is grad, curl, div on 0-, 1-, 2-forms; $\nabla\cdot\vec{F} = \star\mathrm{d}\star F$, $\nabla\times\vec{F} = \star\mathrm{d}F$.
- $\mathrm{d}^2 = 0$ (curl grad = 0, div curl = 0), dual to $\partial\partial = \varnothing$.
- $\mathrm{d}(\alpha\wedge\beta) = \mathrm{d}\alpha\wedge\beta + (-1)^p\alpha\wedge\mathrm{d}\beta$; d is the unique such operator.
- Exact $\Rightarrow$ closed; the converse holds on star-shaped regions (Poincaré) but fails on $\mathbb{R}^2\setminus\{0\}$, where $\mathrm{d}\phi = (x\,\mathrm{d}y - y\,\mathrm{d}x)/r^2$ is closed and not exact.

T1.6 The codifferential and the Laplace–de Rham operator

The exterior derivative raises the rank of a form: grad takes functions to vectors, curl takes vectors to fluxes. Vector calculus also has operators that go the other way. The divergence takes a vector field to a function, and the Laplacian $\nabla^2 = \nabla\cdot\nabla$ is "go up with grad, come back with div". In the language of forms, the rank-lowering operator is the *codifferential* δ, and the Laplacian on forms of any rank is $\Delta = \mathrm{d}\delta + \delta\mathrm{d}$. Nash defines his Laplacian (2.42) exactly this way, using the adjoint d^* of d; the whole of Hodge theory, the de Rham complex as an elliptic complex, and the Euler characteristic as an index (Chapters 2 and 4 of Nash) rest on it. Our job here is to make δ and Δ completely explicit: signs, components, polar and spherical formulas, and the symbol.

T1.6.1 The adjoint of d: integration by parts

In quantum mechanics the adjoint $A^\dagger$ of an operator is defined by $\langle\psi, A\phi\rangle = \langle A^\dagger\psi, \phi\rangle$, and for $A = \mathrm{d}/\mathrm{d}x$ integration by parts gives $A^\dagger = -\mathrm{d}/\mathrm{d}x$ (the boundary terms vanish for decaying or periodic wavefunctions). We do the same with d, using the inner product (T1.38) on forms, $\langle\alpha,\beta\rangle = \int_M \alpha\wedge\star\beta$, on a compact oriented manifold M without boundary.

Working definition T1.17 (codifferential)

The **codifferential** $\delta : \Omega^p \to \Omega^{p-1}$ [it lowers the rank by one, e.g. $\delta = -\mathrm{div}$ on 1-forms in $\mathbb{R}^3$] (Nash's d^* [the adjoint of d, found by integrating by parts as $\mathrm{d}/\mathrm{d}x$ gives $-\mathrm{d}/\mathrm{d}x$]) is the operator with

$$\langle\mathrm{d}\alpha,\beta\rangle = \langle\alpha,\delta\beta\rangle \qquad \text{for all } \alpha\in\Omega^{p-1},\ \beta\in\Omega^p. \tag{T1.49}$$

It is given by

$$\delta = (-1)^{n(p+1)+1+s}\ \star\,\mathrm{d}\,\star \qquad \text{on } p\text{-forms}, \tag{T1.50}$$

with $n = \dim M$ and s the number of minus signs in the metric. By convention $\delta f = 0$ on functions.

Here is the derivation. Take $\alpha \in \Omega^{p-1}$ and $\beta \in \Omega^p$, so that $\alpha \wedge \star\beta$ is an $(n-1)$-form. Then

$$\begin{aligned} 0 &\overset{(1)}{=} \int_M \mathrm{d}(\alpha \wedge \star\beta) \overset{(2)}{=} \int_M \mathrm{d}\alpha \wedge \star\beta + (-1)^{p-1} \int_M \alpha \wedge \mathrm{d}\star\beta \\ &\overset{(3)}{=} \langle \mathrm{d}\alpha, \beta\rangle + (-1)^{p-1}\varepsilon \int_M \alpha \wedge \star\big(\star \mathrm{d}\star\beta\big) \overset{(4)}{=} \langle \mathrm{d}\alpha, \beta\rangle - (-1)^p \varepsilon\, \langle \alpha, \star \mathrm{d}\star\beta\rangle. \end{aligned} \tag{T1.51}$$

(1) Stokes' theorem: $\int_M \mathrm{d}(\cdot) = \int_{\partial M}(\cdot) = 0$ because $\partial M = \varnothing$ (Chapter T2).
(2) Leibniz rule (T1.46) with the $(p-1)$-form α in front.
(3) The first term is the inner product by definition. In the second, $\gamma = \mathrm{d}\star\beta$ is an $(n-p+1)$-form, and by (T1.35) $\gamma = \varepsilon\ \star\star\gamma$ with $\varepsilon = (-1)^{(n-p+1)(p-1)+s}$ (the sign is its own inverse).
(4) Definition (T1.38) of $\langle \alpha, \star\gamma\rangle$; $(-1)^{p-1} = -(-1)^p$.

So $\langle \mathrm{d}\alpha, \beta\rangle = \langle \alpha, (-1)^p \varepsilon\ \star \mathrm{d}\star\beta\rangle$. The sign simplifies modulo 2:

$$\begin{aligned} p + (n-p+1)(p-1) + s &\overset{(1)}{=} p + n(p-1) - (p-1)^2 + s \overset{(2)}{=} p + n(p-1) - (p-1) + s \\ &= n(p-1) + 1 + s \overset{(3)}{=} n(p+1) + 1 + s \pmod 2. \end{aligned}$$

(1) Expand $(n-(p-1))(p-1)$.
(2) $k^2 \equiv k \pmod 2$ for any integer k.
(3) $n(p+1) - n(p-1) = 2n$ is even.

This is (T1.50). For Riemannian signature ($s = 0$) it reads $\delta = (-1)^{np+n+1} \star \mathrm{d} \star$, which is precisely Nash's formula in (2.43).

Dictionary: signs of $\delta = \pm \star \mathrm{d} \star$

space	sign in $\delta = \pm \star \mathrm{d} \star$	comment
n even, Riemannian	$-$ for all p	$\mathbb{R}^2, S^2, T^2, \mathbb{R}^4, S^4$
n odd, Riemannian	$(-1)^p$	$\mathbb{R}^3$: $-$ on 1-forms, $+$ on 2-forms, $-$ on 3-forms
Minkowski $\mathbb{R}^{1,3}$	$+$ for all p	$n = 4$, $s = 1$

Key idea: δ is minus the divergence

On 1-forms in any Riemannian manifold, $\delta\alpha = -\nabla \cdot \alpha^\sharp$:

$$\delta\alpha = -\frac{1}{\sqrt{g}}\, \partial_\mu\big(\sqrt{g}\, g^{\mu\nu}\alpha_\nu\big). \tag{T1.52}$$

On p-forms, $(\delta\alpha)_{\nu_2\ldots\nu_p} = -\nabla^\mu \alpha_{\mu\nu_2\ldots\nu_p}$, "contract a derivative into the first index", where ∇ is the covariant derivative (Chapter T2); in flat Cartesian coordinates it is just $-\partial^\mu \alpha_{\mu\nu_2\ldots}$.

Why (T1.52): for $\alpha = \alpha_\nu \mathrm{d}x^\nu$ write $\alpha^\mu = g^{\mu\nu}\alpha_\nu$. The component formula (T1.36) gives $\star\alpha = \sum_\mu (-1)^{\mu-1}\sqrt{g}\,\alpha^\mu\, \mathrm{d}x^1 \wedge \cdots \wedge \widehat{\mathrm{d}x^\mu} \wedge \cdots \wedge \mathrm{d}x^n$, since $\varepsilon_{\mu 1\ldots\hat{\mu}\ldots n} = (-1)^{\mu-1}$. Then

$$\begin{aligned} \mathrm{d}\star\alpha &\overset{(1)}{=} \sum_\mu (-1)^{\mu-1}\partial_\mu(\sqrt{g}\,\alpha^\mu)\, \mathrm{d}x^\mu \wedge \mathrm{d}x^1 \wedge \cdots \wedge \widehat{\mathrm{d}x^\mu} \wedge \cdots \wedge \mathrm{d}x^n \\ &\overset{(2)}{=} \partial_\mu(\sqrt{g}\,\alpha^\mu)\, \mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^n \overset{(3)}{=} \frac{1}{\sqrt{g}}\partial_\mu(\sqrt{g}\,\alpha^\mu)\ \mathrm{vol}, \end{aligned}$$

(1) Only the derivative along the missing direction x^μ survives the wedge.

(2) Moving dx^μ into its place costs $(\mu-1)$ swaps, which cancels the sign $(-1)^{\mu-1}$.
(3) $\mathrm{vol} = \sqrt{g}\,dx^1\wedge\cdots\wedge dx^n$ (T1.31).

and $\star\mathrm{vol} = 1$, so $\star d\star\alpha = \frac{1}{\sqrt{g}}\partial_\mu(\sqrt{g}\,\alpha^\mu)$, the covariant divergence. With the sign -1 that the table gives on 1-forms (for either parity of n), (T1.52) follows.

Watch out: Why the minus sign?

It is the same minus sign as in $(d/dx)^\dagger = -d/dx$. In one dimension on the circle, $\delta(g\,d\theta) = -g'(\theta)$ and $\langle df, g\,d\theta\rangle = \int f'g\,d\theta = -\int fg'\,d\theta = \langle f, \delta(g\,d\theta)\rangle$. Keeping this sign is what makes $\Delta = d\delta+\delta d$ a *positive* operator, like $-d^2/dx^2 = p^2$ in quantum mechanics.

Two properties follow at once. First, $\delta^2 = 0$: $\delta\delta \propto \star d\star\star d\star = \pm\star dd\star = 0$, using $\star\star = \pm1$. In $\mathbb{R}^3$ this is again $\nabla\cdot(\nabla\times\vec{F}) = 0$ read backwards. Second, a form with $\delta\beta = 0$ is called **co-closed**; a form $\beta = \delta\gamma$ is **co-exact**.

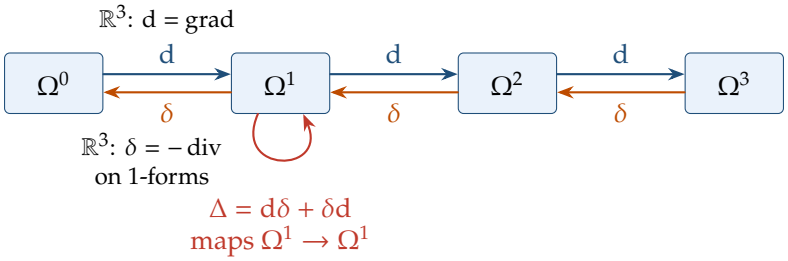


Figure T1.18: The exterior derivative d raises rank by one; its adjoint δ lowers it by one. Neither preserves rank, but the combination $\Delta = d\delta + \delta d$ does: go up and come back, or come down and go back up. On functions only the first route exists and $\Delta = \delta d = -\nabla^2$.

T1.6.2 The Laplace–de Rham operator

Working definition T1.18 (Laplace–de Rham operator)

The **Laplacian** on p-forms is

$$\Delta = d\delta + \delta d : \Omega^p \to \Omega^p \tag{T1.53}$$

(Nash's $\Delta_p = (dd^* + d^*d)_p$, (2.42)). On functions, $\Delta f = \delta df$ [$\delta f = 0$ on functions, so only the route up with d and back down with δ survives], and by (T1.52) this is the **Laplace–Beltrami operator** [the Laplacian built from the metric $g_{\mu\nu}$, with $\sqrt{g} = \sqrt{\det g_{\mu\nu}}$]

$$\Delta f = -\frac{1}{\sqrt{g}}\,\partial_\mu\big(\sqrt{g}\,g^{\mu\nu}\partial_\nu f\big), \qquad \text{flat Cartesian: } \Delta f = -\nabla^2 f. \tag{T1.54}$$

Worked example T1.32: The Laplacian in polar coordinates

Following Dray [Dray (15.22)], but keeping our sign, $\Delta f = -\star\,d\star\,df$ in $\mathbb{R}^2$. Use the orthonormal coframe $\{dr, r\,d\phi\}$ and the stars $\star dr = r\,d\phi$, $\star(r\,d\phi) = -dr$, $\star(dr\wedge d\phi) = 1/r$ from Example T1.20:

$$df \overset{(1)}{=} f_r\,dr + f_\phi\,d\phi = f_r\,dr + \frac{f_\phi}{r}\,(r\,d\phi),$$

$$\star \mathrm{d}f \overset{(2)}{=} f_r\, r\, \mathrm{d}\phi - \frac{f_\phi}{r}\,\mathrm{d}r,$$
$$\mathrm{d}\star\mathrm{d}f \overset{(3)}{=} \partial_r(r f_r)\,\mathrm{d}r\wedge\mathrm{d}\phi - \partial_\phi\Big(\frac{f_\phi}{r}\Big)\mathrm{d}\phi\wedge\mathrm{d}r \overset{(4)}{=} \Big[\partial_r(r f_r) + \frac{f_{\phi\phi}}{r}\Big]\mathrm{d}r\wedge\mathrm{d}\phi,$$
$$\Delta f = -\star\,\mathrm{d}\star\mathrm{d}f \overset{(5)}{=} -\Big[\frac{1}{r}\,\partial_r\big(r\,\partial_r f\big) + \frac{1}{r^2}\,\partial_\phi^2 f\Big].$$

(1) $\mathrm{d}f$ in coordinates; then rewrite with the unit coframe.
(2) Star each coframe element; linearity.
(3) Definition of d; in each term only the derivative along the missing coordinate survives.
(4) $\mathrm{d}\phi\wedge\mathrm{d}r = -\mathrm{d}r\wedge\mathrm{d}\phi$, and $\partial_\phi(f_\phi/r) = f_{\phi\phi}/r$.
(5) $\star(\mathrm{d}r\wedge\mathrm{d}\phi) = 1/r$; overall sign -1 from (T1.50) with $n = 2$.

The bracket is the familiar ∇^2 in polar coordinates. Checks: $\Delta(\ln r) = -\frac{1}{r}\partial_r(r\cdot\frac{1}{r}) = 0$ for $r \neq 0$ ($\ln r$ is the 2D Coulomb potential); $\Delta(r^m\cos m\phi) = -(m^2 r^{m-2} - m^2 r^{m-2})\cos m\phi = 0$ (these are $\mathrm{Re}\, z^m$, harmonic because holomorphic, see Section T1.10).

Worked example T1.33: The Laplacian on the round S^2 and spherical harmonics

On S^2 with $\mathrm{vol} = \sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi$ and coframe $\{\mathrm{d}\theta, \sin\theta\,\mathrm{d}\phi\}$ we have $\star\mathrm{d}\theta = \sin\theta\,\mathrm{d}\phi$, $\star\mathrm{d}\phi = -\mathrm{d}\theta/\sin\theta$ and $\star(\mathrm{d}\theta\wedge\mathrm{d}\phi) = 1/\sin\theta$. Exactly as above,

$$\star\mathrm{d}f \overset{(1)}{=} \sin\theta\, f_\theta\,\mathrm{d}\phi - \frac{f_\phi}{\sin\theta}\,\mathrm{d}\theta,$$
$$\mathrm{d}\star\mathrm{d}f \overset{(2)}{=} \Big[\partial_\theta(\sin\theta\, f_\theta) + \frac{f_{\phi\phi}}{\sin\theta}\Big]\mathrm{d}\theta\wedge\mathrm{d}\phi,$$
$$\Delta f \overset{(3)}{=} -\frac{1}{\sin\theta}\,\partial_\theta\big(\sin\theta\,\partial_\theta f\big) - \frac{1}{\sin^2\theta}\,\partial_\phi^2 f.$$

(1) Star of $f_\theta\mathrm{d}\theta + f_\phi\mathrm{d}\phi$.
(2) Differentiate; $\mathrm{d}\phi\wedge\mathrm{d}\theta = -\mathrm{d}\theta\wedge\mathrm{d}\phi$ turns the minus into a plus.
(3) $\Delta = -\star\,\mathrm{d}\star\mathrm{d}$ (even dimension) and $\star(\mathrm{d}\theta\wedge\mathrm{d}\phi) = 1/\sin\theta$.

This is $\hat{L}^2$, the squared angular momentum of quantum mechanics (in units $\hbar = 1$). Two eigenfunctions:
(a) $Z = \cos\theta$: $\partial_\theta Z = -\sin\theta$, so $\partial_\theta(\sin\theta\cdot(-\sin\theta)) = -2\sin\theta\cos\theta$, and $\Delta Z = 2\cos\theta = 2Z$. Eigenvalue $\ell(\ell+1) = 2$ with $\ell = 1$. This explains the ratio $\langle \mathrm{d}Z, \mathrm{d}Z\rangle/\langle Z, Z\rangle = 2$ of Example T1.25: $\langle \mathrm{d}Z, \mathrm{d}Z\rangle = \langle Z, \delta\mathrm{d}Z\rangle = \langle Z, \Delta Z\rangle = 2\langle Z, Z\rangle$.
(b) $f = \sin^2\theta\cos 2\phi = X^2 - Y^2$:

$$\frac{1}{\sin\theta}\partial_\theta\big(\sin\theta\,\partial_\theta f\big) \overset{(1)}{=} \frac{\cos 2\phi}{\sin\theta}\,\partial_\theta\big(2\sin^2\theta\cos\theta\big) \overset{(2)}{=} 2(2\cos^2\theta - \sin^2\theta)\cos 2\phi,$$
$$\Delta f \overset{(3)}{=} -\big[4\cos^2\theta - 2\sin^2\theta - 4\big]\cos 2\phi \overset{(4)}{=} 6\sin^2\theta\cos 2\phi = 6f.$$

(1) $\partial_\theta f = 2\sin\theta\cos\theta\cos 2\phi$.
(2) $\partial_\theta(\sin^2\theta\cos\theta) = 2\sin\theta\cos^2\theta - \sin^3\theta$; divide by $\sin\theta$.
(3) Add $\frac{1}{\sin^2\theta}\partial_\phi^2 f = -4\cos 2\phi$ and put in the overall minus sign.
(4) $4\cos^2\theta - 4 = -4\sin^2\theta$.

Eigenvalue $6 = \ell(\ell+1)$ with $\ell = 2$. In general the eigenvalues are $\ell(\ell+1)$ with multiplicity $2\ell+1$ (Figure T1.20).

Worked example T1.34: The Laplacian on 1-forms in $\mathbb{R}^3$

For a 1-form $F \leftrightarrow \vec{F}$ in $\mathbb{R}^3$, the table gives $\delta = -\star\mathrm{d}\star$ on 1-forms and $\delta = +\star\mathrm{d}\star$ on 2-forms. Then

$$\begin{aligned} \mathrm{d}\delta F &\overset{(1)}{=} -\mathrm{d}(\star\mathrm{d}\star F) \overset{(2)}{=} -\nabla(\nabla\cdot\vec{F})\cdot\mathrm{d}\vec{r}, \\ \delta\mathrm{d}F &\overset{(3)}{=} \star\mathrm{d}\star(\mathrm{d}F) \overset{(4)}{=} \star\mathrm{d}\big((\nabla\times\vec{F})\cdot\mathrm{d}\vec{r}\big) \overset{(5)}{=} \big(\nabla\times(\nabla\times\vec{F})\big)\cdot\mathrm{d}\vec{r}, \\ \Delta F &\overset{(6)}{=} \big(\nabla\times\nabla\times\vec{F} - \nabla(\nabla\cdot\vec{F})\big)\cdot\mathrm{d}\vec{r} \overset{(7)}{=} -(\nabla^2\vec{F})\cdot\mathrm{d}\vec{r}. \end{aligned}$$

(1) δ on the 1-form F.
(2) $\star\mathrm{d}\star F = \nabla\cdot\vec{F}$ is a function; d of it is the gradient.
(3) δ on the 2-form $\mathrm{d}F$.
(4) $\star\mathrm{d}F$ is the curl as a 1-form (dictionary of Section T1.5).
(5) $\star\mathrm{d}$ of a 1-form is its curl.
(6) Add the two pieces.
(7) The vector identity $\nabla\times(\nabla\times\vec{F}) = \nabla(\nabla\cdot\vec{F}) - \nabla^2\vec{F}$.

So on 1-forms in flat space Δ is minus the componentwise Laplacian, as on functions. In curved space the two routes differ by curvature terms (the Weitzenböck formula), which is where the Laplacian "sees" geometry. Physicists meet $\nabla\times\nabla\times\vec{A} - \nabla(\nabla\cdot\vec{A})$ as the operator of magnetostatics.

T1.6.3 Positivity, harmonic forms and Hodge's theorem

On a compact manifold without boundary, with Riemannian metric,

$$\langle\omega,\Delta\omega\rangle \overset{(1)}{=} \langle\omega,\mathrm{d}\delta\omega\rangle + \langle\omega,\delta\mathrm{d}\omega\rangle \overset{(2)}{=} \langle\delta\omega,\delta\omega\rangle + \langle\mathrm{d}\omega,\mathrm{d}\omega\rangle \overset{(3)}{=} \|\delta\omega\|^2 + \|\mathrm{d}\omega\|^2 \;\geq 0. \tag{T1.55}$$

(1) Definition (T1.53); linearity.
(2) Move d across as δ in the first term and δ across as d in the second, by (T1.49) (the inner product is symmetric).
(3) $\langle\beta,\beta\rangle = \int|\beta|^2\mathrm{vol} \geq 0$ in Riemannian signature.

This is Nash's argument (2.50). A form with $\Delta\omega = 0$ is called **harmonic**, and (T1.55) shows that

$$\Delta\omega = 0 \iff \mathrm{d}\omega = 0 \text{ and } \delta\omega = 0, \tag{T1.56}$$

since a sum of two non-negative numbers vanishes only if both do (Nash (2.51)). Harmonic forms are closed, so they define de Rham classes.

Key idea: Hodge's theorem (Nash p. 41)

On a compact oriented Riemannian manifold without boundary, every de Rham cohomology class contains *exactly one* harmonic form. Hence the Betti numbers are $b_p = \dim\mathrm{Ker}\,\Delta_p$: the number of zero modes of the Laplacian on p-forms. Moreover every p-form splits uniquely and orthogonally as

$$\omega = \mathrm{d}\alpha + \delta\beta + h, \qquad \Delta h = 0 \tag{T1.57}$$

(the **Hodge decomposition**).

Why at most one: if h_1, h_2 are harmonic and in the same class, $h_1 - h_2 = \mathrm{d}\alpha$ is exact and harmonic, so $\|\mathrm{d}\alpha\|^2 = \langle \mathrm{d}\alpha, \mathrm{d}\alpha\rangle = \langle \alpha, \delta(h_1 - h_2)\rangle = 0$. *Why the three pieces of* (T1.57) *are orthogonal:* $\langle \mathrm{d}\alpha, \delta\beta\rangle = \langle \mathrm{dd}\alpha, \beta\rangle = 0$, $\langle \mathrm{d}\alpha, h\rangle = \langle \alpha, \delta h\rangle = 0$ and $\langle \delta\beta, h\rangle = \langle \beta, \mathrm{d}h\rangle = 0$. *Existence* (that the three pieces fill everything) is the hard analytic part: it uses the ellipticity of Δ, the subject of Nash's Chapter 2 (Chapter 2). In $\mathbb{R}^3$ language (T1.57) is the Helmholtz decomposition $\vec{F} = \nabla\phi + \nabla \times \vec{A} + \vec{h}$; on a space with holes the harmonic piece $\vec{h}$ is the part that is neither a gradient nor a curl.

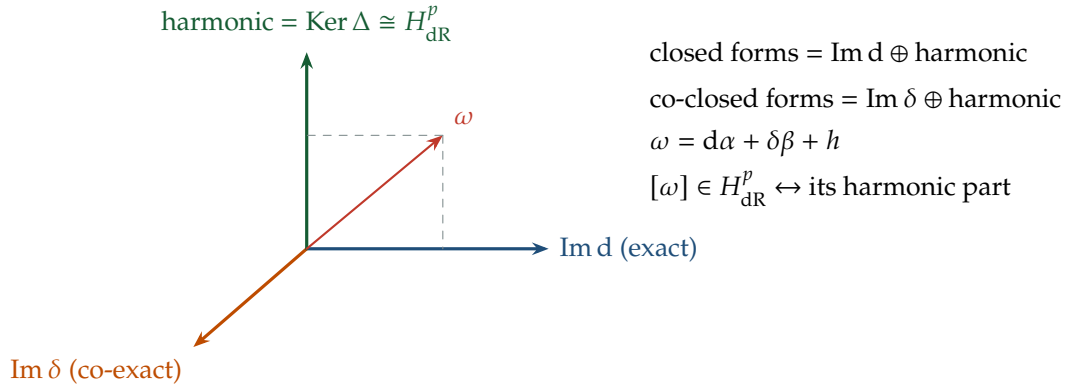

Figure T1.19: The Hodge decomposition drawn as three mutually orthogonal directions in the (infinite-dimensional) space $\Omega^p(M)$. A closed form ω has no co-exact part; its cohomology class is represented by its projection onto the harmonic axis. This is why "counting zero modes of Δ_p" computes the topological invariant b_p.

Worked example T1.35: Harmonic forms on S^1, T^2 and S^2

(a) *Circle.* On functions $\Delta = -\partial_\theta^2$ with eigenfunctions $e^{\mathrm{i}k\theta}$, eigenvalues k^2, $k \in \mathbb{Z}$. Zero modes: constants, so $b_0 = 1$. On 1-forms $f\,\mathrm{d}\theta$, $\Delta(f\,\mathrm{d}\theta) = \mathrm{d}\delta(f\,\mathrm{d}\theta) = \mathrm{d}(-f') = -f''\mathrm{d}\theta$; zero modes $c\,\mathrm{d}\theta$, so $b_1 = 1$. The harmonic representative of the class of the winding form is $\mathrm{d}\theta/2\pi$ (the form with period 1).
(b) *Torus* $T^2 = \mathbb{R}^2/\mathbb{Z}^2$, flat metric. Eigenfunctions $e^{2\pi\mathrm{i}(mx+ny)}$ with eigenvalues $4\pi^2(m^2+n^2)$. Harmonic forms: 1; $\mathrm{d}x, \mathrm{d}y$; $\mathrm{d}x \wedge \mathrm{d}y$ (constant coefficients are the only harmonic ones, since Δ acts componentwise on constant-coefficient forms in flat space). So $(b_0, b_1, b_2) = (1, 2, 1)$ and $\chi = 1 - 2 + 1 = 0$.
(c) *Sphere.* Harmonic functions: constants ($b_0 = 1$). Harmonic 2-forms: c vol, since $\star$ commutes with Δ and maps harmonic functions to harmonic 2-forms ($b_2 = 1$). Harmonic 1-forms: none. Indeed a harmonic ω is closed, and on S^2 every closed 1-form is exact (S^2 is simply connected; Chapter T2), $\omega = \mathrm{d}f$; then $0 = \delta\omega = \delta\mathrm{d}f = \Delta f$ forces f constant and $\omega = 0$. So $(b_0, b_1, b_2) = (1, 0, 1)$ and $\chi = 2$.

T1.6.4 The symbol of d, δ and Δ

How do we see that Δ is "elliptic", like $-\nabla^2$? Replace each derivative by the Fourier variable, $\partial_\mu \to \mathrm{i}k_\mu$, and keep only the highest-order terms. The result is the (principal) **symbol**, a matrix-valued function of the covector $k = k_\mu \mathrm{d}x^\mu$ (Chapter 2). For d, the recipe $\mathrm{d}\alpha = \mathrm{d}x^\mu \wedge \partial_\mu \alpha$ becomes

$$\sigma(\mathrm{d})(k)\,\omega = \mathrm{i}\,k \wedge \omega, \qquad \sigma(\delta)(k)\,\omega = -\mathrm{i}\,\iota_k\,\omega, \tag{T1.58}$$

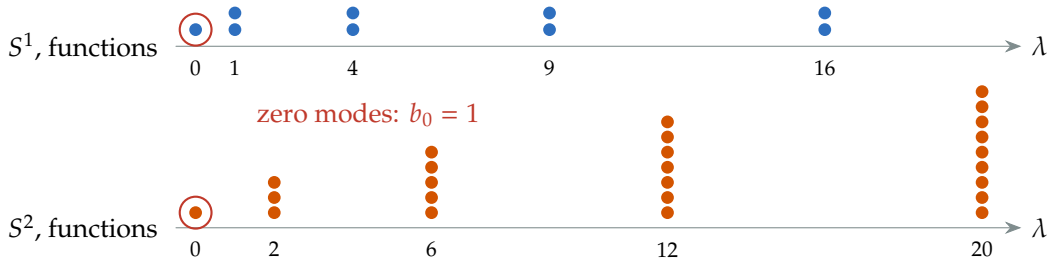

Figure T1.20: Spectra of the Laplacian on functions, each dot one eigenfunction. On S^1: $\lambda = k^2$ with multiplicity 2 (from $e^{\pm ik\theta}$) except for $k = 0$. On S^2: $\lambda = \ell(\ell+1)$ with multiplicity $2\ell+1$ (the spherical harmonics). The eigenvalues depend on the size and shape of the space; the number of zero modes (circled) does not. It is the Betti number b_0, the number of connected components.

where ι_k is the *interior product* with the vector $k^\sharp$ (insert it in the first slot, Section T1.9); the second formula follows from $(\delta\alpha)_{\nu\ldots} = -\partial^\mu \alpha_{\mu\nu\ldots}$. Then

$$\begin{aligned}\sigma(\Delta)(k) &\overset{(1)}{=} \sigma(\mathrm{d})\sigma(\delta) + \sigma(\delta)\sigma(\mathrm{d}) \overset{(2)}{=} (\mathrm{i}k\wedge)(-\mathrm{i}\iota_k) + (-\mathrm{i}\iota_k)(\mathrm{i}k\wedge)\\ &= k\wedge\iota_k + \iota_k\, k\wedge \overset{(3)}{=} |k|^2\,\mathbb{1}. \end{aligned} \tag{T1.59}$$

(1) The symbol of a product of operators is the product of the symbols (Nash (2.45)–(2.46)).
(2) (T1.58).
(3) The interior product is an antiderivation (Section T1.9): $\iota_k(k\wedge\omega) = (\iota_k k)\,\omega - k\wedge\iota_k\omega$, and $\iota_k k = g^{\mu\nu}k_\mu k_\nu = |k|^2$.

The symbol of Δ is $|k|^2$ times the identity, invertible for every $k \neq 0$: that is ellipticity. Nash states this as (2.49), $\sigma_2^{\Delta_p}(x,k) = k^2 I$.

Worked example T1.36: The symbol as explicit 4×4 matrices on $\mathbb{R}^2$

Order the basis of all forms on $\mathbb{R}^2$ as $(1,\ \mathrm{d}x,\ \mathrm{d}y,\ \mathrm{d}x\wedge\mathrm{d}y)$ and let $k = k_1\mathrm{d}x + k_2\mathrm{d}y$. Then $k\wedge$ sends $1 \mapsto k_1\mathrm{d}x + k_2\mathrm{d}y$, $\mathrm{d}x \mapsto k_2\,\mathrm{d}y\wedge\mathrm{d}x = -k_2\,\mathrm{d}x\wedge\mathrm{d}y$, $\mathrm{d}y \mapsto k_1\,\mathrm{d}x\wedge\mathrm{d}y$, $\mathrm{d}x\wedge\mathrm{d}y \mapsto 0$; and ι_k sends $1 \mapsto 0$, $\mathrm{d}x \mapsto k_1$, $\mathrm{d}y \mapsto k_2$, $\mathrm{d}x\wedge\mathrm{d}y \mapsto k_1\mathrm{d}y - k_2\mathrm{d}x$. As matrices (columns are images of basis elements):

$$E = k\wedge = \begin{pmatrix} 0 & 0 & 0 & 0\\ k_1 & 0 & 0 & 0\\ k_2 & 0 & 0 & 0\\ 0 & -k_2 & k_1 & 0 \end{pmatrix}, \qquad I = \iota_k = \begin{pmatrix} 0 & k_1 & k_2 & 0\\ 0 & 0 & 0 & -k_2\\ 0 & 0 & 0 & k_1\\ 0 & 0 & 0 & 0 \end{pmatrix}.$$

Multiplying out,

$$EI + IE \overset{(1)}{=} \begin{pmatrix} 0 & 0 & 0 & 0\\ 0 & k_1^2 & k_1k_2 & 0\\ 0 & k_1k_2 & k_2^2 & 0\\ 0 & 0 & 0 & k_1^2+k_2^2 \end{pmatrix} + \begin{pmatrix} k_1^2+k_2^2 & 0 & 0 & 0\\ 0 & k_2^2 & -k_1k_2 & 0\\ 0 & -k_1k_2 & k_1^2 & 0\\ 0 & 0 & 0 & 0 \end{pmatrix} = (k_1^2+k_2^2)\,\mathbb{1}_4.$$

(1) EI: e.g. its $(2,2)$ entry is (row 2 of E)·(column 2 of I) $= k_1\cdot k_1$, and its $(4,4)$ entry is $(-k_2)(-k_2) + k_1k_1$. IE: e.g. $(1,1)$ entry $= k_1k_1 + k_2k_2$ and $(2,2)$ entry $= (-k_2)(-k_2)$.

The off-diagonal terms cancel between the two products, exactly as the antiderivation argument promised. Notice also $E^2 = 0$ and $I^2 = 0$ (the symbols of $\mathrm{d}^2 = 0$ and $\delta^2 = 0$), so the operator $Q = E - I$ satisfies $Q^2 = -(EI + IE) = -|k|^2$. Up to the factor i, Q is the symbol of $\mathrm{d} + \delta$, a "square root" of the Laplacian. Matrices that square to $\pm|k|^2$ are Clifford algebra

generators (Chapter T4): $\mathrm{d}+\delta$ is a Dirac-type operator on forms, and it is the operator of the de Rham complex whose index Nash computes to be the Euler characteristic (Chapter 4).

Reading Nash (pp. 39–41, (2.42)–(2.53))

Nash writes $\Delta_p = (dd^* + d^*d)_p$ (2.42), gives $d^* = (-1)^{np+n+1} \star d \star$ and the inner product $\langle \omega, v \rangle = \int \omega \wedge \star v$ in (2.43), and computes the symbol $\sigma_2^{\Delta_p}(x,k) = k^2 I$ in (2.46)–(2.49) using $\sigma_1^d(x,k) : v \mapsto k \wedge v$ and its adjoint, "interior product with k". He drops the factors of i that we kept in (T1.58): they cancel in Δ, as our chain shows. His (2.50)–(2.51) is our (T1.55)–(T1.56), and his Hodge theorem and (2.53), $\dim \operatorname{Ker} \Delta_p = b_p$, is our key idea above, illustrated in Example T1.35. He also notes that Δ depends on the metric but b_p does not: in Figure T1.20 rescaling the circle moves every nonzero dot but never the zero modes.

Recap

- $\delta = (-1)^{n(p+1)+1+s} \star \mathrm{d} \star$ is the adjoint of d for $\langle \alpha, \beta \rangle = \int \alpha \wedge \star \beta$ (Stokes plus Leibniz).
- On 1-forms $\delta = -\mathrm{div}$; $\delta^2 = 0$.
- $\Delta = \mathrm{d}\delta + \delta\mathrm{d}$; on functions $\Delta f = -\frac{1}{\sqrt{g}} \partial_\mu (\sqrt{g}\, g^{\mu\nu} \partial_\nu f)$, e.g. $-\left(\frac{1}{r}\partial_r r \partial_r + \frac{1}{r^2}\partial_\phi^2\right)$ in polar coordinates.
- $\Delta \geq 0$; harmonic $\iff$ closed and co-closed; Hodge: $b_p = \dim \operatorname{Ker} \Delta_p$.
- $\sigma(\mathrm{d}) = \mathrm{i}k\wedge$, $\sigma(\delta) = -\mathrm{i}\iota_k$, $\sigma(\Delta) = |k|^2$: Δ is elliptic, and $\mathrm{d}+\delta$ is its square root.

T1.7 Maxwell's equations in the language of forms

Here is the question. Maxwell's theory is four vector equations, eight component equations, for two vector fields, with a continuity equation and a gauge freedom tacked on. Why does it have *exactly* this structure? Why are two of the equations "free" (no sources ever appear in them) and two sourced? Why does the charge have to be conserved? Why can we always introduce potentials? And why is $E^2 - B^2$ Lorentz invariant while $E^2 + B^2$ is not?

Differential forms answer all of these at once. In four-dimensional space-time Maxwell's equations become

$$\mathrm{d}F = 0, \qquad \mathrm{d} \star F = \star J.$$

The first is a statement without a metric and without sources: it is pure calculus. The second is where the metric (through $\star$) and the sources enter. Conservation of charge is $\mathrm{d}^2 = 0$. Potentials exist because of the Poincaré lemma. Gauge freedom is $\mathrm{d}^2 = 0$ again. This section is the best possible exercise in everything we have built so far, and it is also our first gauge theory: Yang–Mills theory (Chapter T3, Chapter 8) is this, with matrices.

Conventions (as stated in Chapter T1): Minkowski metric $\eta = \mathrm{diag}(-1,+1,+1,+1)$ in coordinates (t,x,y,z), orientation vol $= \mathrm{d}t \wedge \mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z$, $c = 1$, and Heaviside–Lorentz units (no 4π in the field equations, $\epsilon_0 = 1$). Dray uses Gaussian units and the orientation $\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z \wedge \mathrm{d}t$ [Dray §15.9]; his signs in intermediate steps therefore differ from ours, but the final equations agree.

T1.7.1 The starting point: vector calculus

In Heaviside–Lorentz units with $c = 1$,

$$\begin{aligned} \nabla\cdot\vec{E} &= \rho, & \nabla\times\vec{E} + \partial_t\vec{B} &= 0, \\ \nabla\cdot\vec{B} &= 0, & \nabla\times\vec{B} - \partial_t\vec{E} &= \vec{J}. \end{aligned} \tag{T1.60}$$

Two consequences are usually derived by hand. Taking the divergence of the Ampère–Maxwell law and using Gauss's law,

$$0 \overset{(1)}{=} \nabla\cdot(\nabla\times\vec{B}) = \nabla\cdot\vec{J} + \partial_t(\nabla\cdot\vec{E}) \overset{(2)}{=} \nabla\cdot\vec{J} + \partial_t\rho,$$

(1) div curl = 0, i.e. $\mathrm{d}^2 = 0$ (Section T1.5).
(2) Gauss's law.

which is the continuity equation. And the ansatz $\vec{B} = \nabla\times\vec{A}$, $\vec{E} = -\nabla\Phi - \partial_t\vec{A}$ solves the two source-free equations identically, again by div curl = 0 and curl grad = 0. Keep an eye on how often "$\mathrm{d}^2 = 0$" is doing the work.

T1.7.2 Which fields are which forms?

Before going to four dimensions, ask the question of Section T1.3: what does each field want to be integrated over?

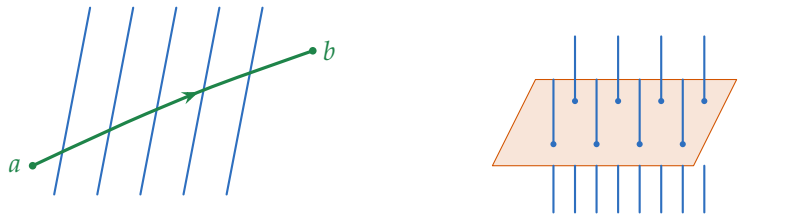
- $\vec{E}$ is integrated along curves: the EMF around a loop is $\oint \vec{E}\cdot\mathrm{d}\vec{r}$, the potential difference is $-\int_a^b \vec{E}\cdot\mathrm{d}\vec{r}$. So $\vec{E}$ wants to be the *1-form* $E = E_x\mathrm{d}x + E_y\mathrm{d}y + E_z\mathrm{d}z$.
- $\vec{B}$ is integrated over surfaces: the magnetic flux is $\int \vec{B}\cdot\mathrm{d}\vec{A}$. So $\vec{B}$ wants to be the *2-form* $\mathcal{B} = B_x\,\mathrm{d}y\wedge\mathrm{d}z + B_y\,\mathrm{d}z\wedge\mathrm{d}x + B_z\,\mathrm{d}x\wedge\mathrm{d}y = \star_3 B$, where $\star_3$ is the three-dimensional Hodge star and $B = B_x\mathrm{d}x + \dots$ is the 1-form made from $\vec{B}$.
- ρ is integrated over volumes: the charge is $\int \rho\,\mathrm{d}^3x$. So ρ wants to be the *3-form* $\rho\,\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z$.
- $\vec{J}$ is integrated over surfaces: the current through a surface. So it is the 2-form $\star_3 J$.

This is the "pseudovector" remark of Section T1.3 made physical: $\vec{B}$ is a pseudovector because it is really a 2-form, and it is only the three-dimensional Hodge star, which needs an orientation, that turns it into an arrow.

With this assignment the four equations read, in three dimensions (Dray's "Maxwell II" [Dray §15.8]),

$$\begin{aligned} \mathrm{d}_3\star_3 E &= \rho\,\mathrm{d}^3x, & \mathrm{d}_3 E + \partial_t\mathcal{B} &= 0, \\ \mathrm{d}_3\mathcal{B} &= 0, & \mathrm{d}_3 B - \partial_t\star_3 E &= \star_3 J, \end{aligned} \tag{T1.61}$$

where d_3 is the exterior derivative in x, y, z only and $\mathrm{d}^3x = \mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z$. Each follows from the dictionary of Section T1.5: $\mathrm{d}_3\star_3 E = (\nabla\cdot\vec{E})\mathrm{d}^3x$, $\mathrm{d}_3 E = \star_3(\nabla\times\vec{E})$, $\mathrm{d}_3\star_3 B = (\nabla\cdot\vec{B})\mathrm{d}^3x$ and $\mathrm{d}_3 B = \star_3(\nabla\times\vec{B})$.



E = 1-form:
stack of equipotentials;
$\int_a^b E$ counts sheets crossed

$\mathcal{B} = \star_3 B$ = 2-form:
flux tubes;
$\int_S \mathcal{B}$ counts tubes piercing S

Figure T1.21: Why $\vec{E}$ is a 1-form and $\vec{B}$ is a 2-form. On the left, the electric field is drawn as a stack of equipotential sheets (Dray's picture of a 1-form, Figure T1.7); the potential difference along the green path is the number of sheets it crosses. On the right, the magnetic field is drawn as a bundle of flux tubes (the picture of a 2-form); the flux through the orange surface is the number of tubes that pierce it. No metric is needed to count sheets or tubes.

Key idea: Where the metric enters

Look at the right-hand column of (T1.61), with $\mathcal{B}$ treated as the basic magnetic variable. The pair $\mathrm{d}_3\mathcal{B} = 0$, $\mathrm{d}_3 E + \partial_t \mathcal{B} = 0$ contains no Hodge star: it makes sense without any metric at all. The other pair needs $\star_3$ (to make the flux $\star_3 E$ from the 1-form E, and the 1-form B from the flux $\mathcal{B}$). In a material these two stars are replaced by the constitutive relations $\vec{D} = \epsilon\vec{E}$ and $\vec{H} = \vec{B}/\mu$. In four dimensions this separation becomes the cleanest statement in the subject: $\mathrm{d}F = 0$ is metric-free; $\mathrm{d} \star F = \star J$ is where the metric lives.

T1.7.3 Splitting space-time forms into space and time

To pass to four dimensions we need a bookkeeping device (Dray's "barred" quantities [Dray §15.9]). Every form on space-time can be written uniquely as

$$\omega = \bar{\omega} + \bar{\eta} \wedge \mathrm{d}t, \tag{T1.62}$$

where $\bar{\omega}$ and $\bar{\eta}$ contain no $\mathrm{d}t$ (they are "spatial" forms whose coefficients may depend on t). On spatial forms we use the spatial exterior derivative d_3 and the spatial star $\star_3$. The rules we need are these.

- *Derivative of a spatial form:* $\mathrm{d}\bar{\omega} = \mathrm{d}_3\bar{\omega} + \mathrm{d}t \wedge \partial_t \bar{\omega}$. (Split $\mathrm{d} = \mathrm{d}x^i \wedge \partial_i + \mathrm{d}t \wedge \partial_t$.)
- *Moving* $\mathrm{d}t$ *through a spatial* p*-form:* $\mathrm{d}t \wedge \bar{\omega} = (-1)^p\, \bar{\omega} \wedge \mathrm{d}t$ (T1.23).
- *The 4D star on spatial forms and on* $(\cdot) \wedge \mathrm{d}t$, read off from the Minkowski table of Example T1.22:

$$\begin{aligned} \star\mathrm{d}t &= -\mathrm{d}^3x, & \star\mathrm{d}^3x &= -\mathrm{d}t, \\ \star\bar{\alpha} &= -(\star_3\bar{\alpha}) \wedge \mathrm{d}t, & \star(\bar{\alpha} \wedge \mathrm{d}t) &= \star_3\bar{\alpha} \quad (\bar{\alpha} \text{ a spatial 1-form}), \\ \star\bar{\beta} &= -(\star_3\bar{\beta}) \wedge \mathrm{d}t & &= (\bar{\beta} \text{ a spatial 2-form}). \end{aligned} \tag{T1.63}$$

Let us check the two rules we use most, on basis elements. From the table, $\star(\mathrm{d}t \wedge \mathrm{d}x) = -\mathrm{d}y \wedge \mathrm{d}z$, so $\star(\mathrm{d}x \wedge \mathrm{d}t) = +\mathrm{d}y \wedge \mathrm{d}z = \star_3\mathrm{d}x$: that is the rule $\star(\bar{\alpha} \wedge \mathrm{d}t) = \star_3\bar{\alpha}$. And $\star(\mathrm{d}y \wedge \mathrm{d}z) = \mathrm{d}t \wedge \mathrm{d}x = -\mathrm{d}x \wedge \mathrm{d}t = -(\star_3(\mathrm{d}y \wedge \mathrm{d}z)) \wedge \mathrm{d}t$, since $\star_3(\mathrm{d}y \wedge \mathrm{d}z) = \mathrm{d}x$: that is the rule for $\bar{\beta}$. Finally $\star\mathrm{d}x = -\mathrm{d}t \wedge \mathrm{d}y \wedge \mathrm{d}z = -(\mathrm{d}y \wedge \mathrm{d}z) \wedge \mathrm{d}t$, the rule for $\bar{\alpha}$.

T1.7.4 The field strength 2-form

We have a 1-form E (3 components) and a 2-form $\mathcal{B}$ (3 components). A 2-form in four dimensions has $\binom{4}{2} = 6$ components. Combine them:

Working definition T1.19 (electromagnetic field strength)

The **field strength** (or Faraday) 2-form is

$$\begin{aligned} F &= E \wedge \mathrm{d}t + \star_3 B \\ &= E_x\,\mathrm{d}x \wedge \mathrm{d}t + E_y\,\mathrm{d}y \wedge \mathrm{d}t + E_z\,\mathrm{d}z \wedge \mathrm{d}t + B_x\,\mathrm{d}y \wedge \mathrm{d}z + B_y\,\mathrm{d}z \wedge \mathrm{d}x + B_z\,\mathrm{d}x \wedge \mathrm{d}y. \end{aligned} \tag{T1.64}$$

Its components $F = \frac{1}{2}F_{\mu\nu}\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$ [the $\frac{1}{2}$ is there because each pair $\mu \neq \nu$ appears twice in the sum] are $F_{it} = E_i$ and $F_{ij} = \varepsilon_{ijk}B_k$ [$\varepsilon_{ijk} = +1$ if (ijk) is an even permutation of (xyz), -1 if odd, 0 if an index repeats]. As an antisymmetric matrix, rows and columns ordered (t, x, y, z),

$$(F_{\mu\nu}) = \begin{pmatrix} 0 & -E_x & -E_y & -E_z \\ E_x & 0 & B_z & -B_y \\ E_y & -B_z & 0 & B_x \\ E_z & B_y & -B_x & 0 \end{pmatrix}. \tag{T1.65}$$

How to read it: $F(v, w) = F_{\mu\nu}v^\mu w^\nu$. For a charge with 4-velocity $u = \partial_t + \vec{v}\cdot\nabla$, $F(\cdot\,, u)$ is the Lorentz force 1-form (Example T1.37).

Checking a few entries: F_{xt} is the coefficient of $\mathrm{d}x \wedge \mathrm{d}t$, which is E_x, so $F_{tx} = -E_x$ (first row). The coefficient of $\mathrm{d}z \wedge \mathrm{d}x$ is B_y, so $F_{zx} = B_y$ and $F_{xz} = -B_y$ (second row, last entry). This is the 4×4 matrix every physicist has seen; here it is simply the representation of a 2-form in the basis $\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$ (Section T1.3).

Worked example T1.37: The Lorentz force from the matrix of F

Insert the velocity $u = \partial_t + v^i\partial_i$ into the second slot of F. The result is a 1-form, $f_\mu = F_{\mu\nu}u^\nu$:

$$f_t \overset{(1)}{=} F_{tt}\cdot 1 + F_{ti}v^i = -\vec{E}\cdot\vec{v},$$
$$f_x \overset{(2)}{=} F_{xt}\cdot 1 + F_{xy}v^y + F_{xz}v^z = E_x + B_z v_y - B_y v_z \overset{(3)}{=} \left(\vec{E} + \vec{v}\times\vec{B}\right)_x,$$

(1) First row of (T1.65).
(2) Second row of (T1.65).
(3) $(\vec{v}\times\vec{B})_x = v_y B_z - v_z B_y$.

and similarly for y, z. So $q\,F(\cdot\,, u) = q(\vec{E} + \vec{v}\times\vec{B})\cdot\mathrm{d}\vec{r} - q\,\vec{E}\cdot\vec{v}\,\mathrm{d}t$: the spatial part is the Lorentz force and the time part is minus the power delivered to the charge (raising the index with $\eta^{tt} = -1$ turns it into $+q\vec{E}\cdot\vec{v}$, the rate of change of energy). The whole of charged-particle dynamics is $m\,\mathrm{d}u^\mu/\mathrm{d}\tau = q\,F^\mu{}_\nu u^\nu$.

T1.7.5 The homogeneous equations: $\mathrm{d}F = 0$

Now differentiate (T1.64).

$$\mathrm{d}F \overset{(1)}{=} \mathrm{d}E \wedge \mathrm{d}t + \mathrm{d}(\star_3 B)$$

$$\overset{(2)}{=} \big(\mathrm{d}_3 E + \mathrm{d}t \wedge \partial_t E\big) \wedge \mathrm{d}t + \mathrm{d}_3 \star_3 B + \mathrm{d}t \wedge \partial_t \star_3 B$$
$$\overset{(3)}{=} \mathrm{d}_3 E \wedge \mathrm{d}t + \mathrm{d}_3 \star_3 B + \partial_t(\star_3 B) \wedge \mathrm{d}t$$
$$\overset{(4)}{=} (\nabla \cdot \vec{B})\, \mathrm{d}^3x + \star_3\big(\nabla \times \vec{E} + \partial_t \vec{B}\big) \wedge \mathrm{d}t. \tag{T1.66}$$

(1) Leibniz rule (T1.46) and $\mathrm{d}(\mathrm{d}t) = 0$.
(2) Split d on spatial forms into its space and time parts.
(3) $\mathrm{d}t \wedge \partial_t E \wedge \mathrm{d}t = 0$ because $\mathrm{d}t \wedge \mathrm{d}t = 0$; and $\mathrm{d}t \wedge$ (2-form) = (2-form) $\wedge\, \mathrm{d}t$ by (T1.23).
(4) The 3D dictionary: $\mathrm{d}_3 \star_3 B = (\nabla \cdot \vec{B})\mathrm{d}^3x$ and $\mathrm{d}_3 E = \star_3(\nabla \times \vec{E})$ (Section T1.5).

The two terms are linearly independent (one has no $\mathrm{d}t$, the other has exactly one), so

$$\boxed{\mathrm{d}F = 0 \iff \nabla \cdot \vec{B} = 0 \ \text{ and } \ \nabla \times \vec{E} + \partial_t \vec{B} = 0.} \tag{T1.67}$$

Four component equations in one line. In components, $\mathrm{d}F = \frac{1}{2}\partial_\lambda F_{\mu\nu}\mathrm{d}x^\lambda \wedge \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$, and $\mathrm{d}F = 0$ is the **Bianchi identity**

$$\partial_\lambda F_{\mu\nu} + \partial_\mu F_{\nu\lambda} + \partial_\nu F_{\lambda\mu} = 0. \tag{T1.68}$$

(For $(\lambda, \mu, \nu) = (x, y, z)$ it reads $\partial_x B_x + \partial_y B_y + \partial_z B_z = 0$; for (t, y, z) it reads $\partial_t B_x + \partial_y F_{zt} + \partial_z F_{ty} = \partial_t B_x + \partial_y E_z - \partial_z E_y = 0$, the x-component of Faraday's law.)

Physical picture: Faraday's law is Stokes' theorem

Integrate $\mathrm{d}F = 0$ over a 3-dimensional "box" in space-time: a surface S in space times a time interval $[t_1, t_2]$. By Stokes (Chapter T2) the integral of F over the boundary of the box is zero. The boundary consists of S at t_2 and at t_1 (where F restricts to $\mathcal{B}$, giving the fluxes $\Phi_B(t_2)$, $\Phi_B(t_1)$) and the "sides" $\partial S \times [t_1, t_2]$ (where F restricts to $E \wedge \mathrm{d}t$, giving $\int \oint_{\partial S} \vec{E} \cdot \mathrm{d}\vec{r}\, \mathrm{d}t$). Keeping track of orientations, $\Phi_B(t_2) - \Phi_B(t_1) = -\int_{t_1}^{t_2} \oint_{\partial S} \vec{E} \cdot \mathrm{d}\vec{r}\, \mathrm{d}t$: the integrated form of Faraday's law. "Magnetic flux changes only by EMF around the edge" is the space-time statement "F has no net flux out of any closed 3-surface".

T1.7.6 The dual field and the inhomogeneous equations

Apply the Minkowski star to F using (T1.63):

$$\star F \overset{(1)}{=} \star(E \wedge \mathrm{d}t) + \star(\star_3 B) \overset{(2)}{=} \star_3 E - \big(\star_3 \star_3 B\big) \wedge \mathrm{d}t \overset{(3)}{=} \star_3 E - B \wedge \mathrm{d}t. \tag{T1.69}$$

(1) Linearity of $\star$.
(2) The rules for $\star(\bar{\alpha} \wedge \mathrm{d}t)$ and $\star\bar{\beta}$ in (T1.63).
(3) In Euclidean $\mathbb{R}^3$, $\star_3\star_3 = +1$ (T1.35).

Compare with $F = E \wedge \mathrm{d}t + \star_3 B$: the star has made the replacement

$$(\vec{E}, \vec{B}) \xrightarrow{\star} (-\vec{B}, \vec{E}), \tag{T1.70}$$

the **electric–magnetic duality** rotation by 90°. Doing it twice gives $(\vec{E}, \vec{B}) \to (-\vec{E}, -\vec{B})$, consistent with $\star\star = -1$ on 2-forms in Lorentzian signature.

Now the current. The 4-current is the vector $J^\mu = (\rho, \vec{J})$; lowering the index with η gives the 1-form

$$J = J_\mu \mathrm{d}x^\mu = -\rho\, \mathrm{d}t + J_x \mathrm{d}x + J_y \mathrm{d}y + J_z \mathrm{d}z, \qquad \star J \overset{(1)}{=} \rho\, \mathrm{d}^3x - (\star_3 \vec{J}) \wedge \mathrm{d}t, \tag{T1.71}$$

(1) $\star \mathrm{d}t = -\mathrm{d}^3x$ and $\star\bar{\alpha} = -(\star_3\bar{\alpha}) \wedge \mathrm{d}t$ from (T1.63), with $\bar{J} = J_i \mathrm{d}x^i$.

The 3-form $\star J$ is the charge–current in its natural home: its integral over a spatial volume at fixed t (where $\mathrm{d}t = 0$) is the charge inside. Next differentiate $\star F$:

$$\begin{aligned} \mathrm{d} \star F &\overset{(1)}{=} \mathrm{d}_3 \star_3 E + \mathrm{d}t \wedge \partial_t \star_3 E - \mathrm{d}_3 B \wedge \mathrm{d}t \\ &\overset{(2)}{=} (\nabla \cdot \vec{E})\, \mathrm{d}^3x + \star_3 \big(\partial_t \vec{E} - \nabla \times \vec{B}\big) \wedge \mathrm{d}t. \end{aligned} \tag{T1.72}$$

(1) Same steps as in (T1.66): split d, drop $\mathrm{d}t \wedge \mathrm{d}t$, move $\mathrm{d}t$ past a 2-form.
(2) 3D dictionary: divergence of $\vec{E}$ and curl of $\vec{B}$.

Setting (T1.72) equal to (T1.71) and matching the parts with and without $\mathrm{d}t$:

$$\boxed{\mathrm{d} \star F = \star J \iff \nabla \cdot \vec{E} = \rho \ \text{ and } \ \nabla \times \vec{B} - \partial_t \vec{E} = \vec{J}.} \tag{T1.73}$$

Key idea: Maxwell's equations

$$\mathrm{d}F = 0, \qquad \mathrm{d} \star F = \star J. \tag{T1.74}$$

Equivalently, applying $\star$ to the second and using the codifferential of Section T1.6 ($\delta = +\star\mathrm{d}\star$ on every degree in Minkowski space, and $\star\star = +1$ on 1-forms there), $\delta F = J$. In components, $\partial_\mu F^{\nu\mu} = J^\nu$ (check $\nu = t$: $\partial_i F^{ti} = \partial_i E_i$, since raising both indices of $F_{ti} = -E_i$ gives $F^{ti} = +E_i$).

Watch out: Signs of $\partial_\mu F^{\mu\nu}$

Textbooks write $\partial_\mu F^{\mu\nu} = \pm J^\nu$ with either sign, depending on the metric signature, the definition $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ versus its negative, and whether $E_i = F_{i0}$ or F_{0i}. The form statement $\mathrm{d} \star F = \star J$ also depends on the orientation (which fixes the sign of $\star$): with Dray's orientation $\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z \wedge \mathrm{d}t = -\mathrm{vol}$, both sides flip sign and the equation is unchanged. Always check the $\nu = t$ component against Gauss's law $\nabla \cdot \vec{E} = +\rho$.

T1.7.7 Charge conservation is $\mathrm{d}^2 = 0$

$$\begin{aligned} 0 &\overset{(1)}{=} \mathrm{dd} \star F \overset{(2)}{=} \mathrm{d} \star J \overset{(3)}{=} \mathrm{d}\big(\rho\, \mathrm{d}^3x\big) - \mathrm{d}\big((\star_3 \bar{J}) \wedge \mathrm{d}t\big) \\ &\overset{(4)}{=} \partial_t \rho\, \mathrm{d}t \wedge \mathrm{d}^3x - (\nabla \cdot \vec{J})\, \mathrm{d}^3x \wedge \mathrm{d}t \overset{(5)}{=} \big(\partial_t \rho + \nabla \cdot \vec{J}\big)\, \mathrm{vol}. \end{aligned} \tag{T1.75}$$

(1) $\mathrm{d}^2 = 0$ (T1.45).
(2) Maxwell (T1.74).
(3) (T1.71).
(4) In $\mathrm{d}(\rho\, \mathrm{d}^3x)$ only $\partial_t \rho\, \mathrm{d}t$ survives (the spatial derivatives wedge to zero against d^3x); in the second term only the spatial divergence survives.
(5) $\mathrm{d}^3x \wedge \mathrm{d}t = -\mathrm{d}t \wedge \mathrm{d}^3x = -\mathrm{vol}$ (moving $\mathrm{d}t$ through a 3-form), and $\mathrm{d}t \wedge \mathrm{d}^3x = \mathrm{vol}$.

So the inhomogeneous Maxwell equation is *consistent only if* the current is conserved, $\mathrm{d} \star J = 0$. The sources cannot be chosen freely: the operator d on the left has a kernel's worth of built-in constraint, because $\mathrm{d}^2 = 0$. This is the prototype of every "anomaly" argument in Chapter 10: if a current coupled to a gauge field fails to be conserved, the gauge theory is inconsistent.

T1.7.8 Potentials and gauge freedom

The equation $\mathrm{d}F = 0$ says F is closed. On $\mathbb{R}^4$ (star-shaped) the Poincaré lemma (Section T1.5) guarantees a 1-form A with

$$F = \mathrm{d}A, \qquad A = A_\mu \mathrm{d}x^\mu = -\Phi\,\mathrm{d}t + \bar{A}, \quad \bar{A} = A_x\mathrm{d}x + A_y\mathrm{d}y + A_z\mathrm{d}z. \tag{T1.76}$$

Let us see that this is the familiar potential:

$$\begin{aligned}\mathrm{d}A &\overset{(1)}{=} -\mathrm{d}\Phi\wedge\mathrm{d}t + \mathrm{d}_3\bar{A} + \mathrm{d}t\wedge\partial_t\bar{A} \overset{(2)}{=} -\mathrm{d}_3\Phi\wedge\mathrm{d}t + \mathrm{d}_3\bar{A} - \partial_t\bar{A}\wedge\mathrm{d}t\\ &\overset{(3)}{=} \big(-\nabla\Phi - \partial_t\vec{A}\big)\cdot\mathrm{d}\vec{r}\wedge\mathrm{d}t + \star_3\big((\nabla\times\vec{A})\cdot\mathrm{d}\vec{r}\big).\end{aligned}$$

(1) Leibniz rule and the split of d on the spatial form $\bar{A}$.
(2) $\mathrm{d}\Phi\wedge\mathrm{d}t = \mathrm{d}_3\Phi\wedge\mathrm{d}t$ (the $\partial_t\Phi\,\mathrm{d}t$ part dies against $\mathrm{d}t$); $\mathrm{d}t\wedge\partial_t\bar{A} = -\partial_t\bar{A}\wedge\mathrm{d}t$ (moving $\mathrm{d}t$ past a 1-form).
(3) 3D dictionary: d_3 of a function is the gradient, d_3 of a 1-form is the flux form of the curl.

Comparing with $F = E\wedge\mathrm{d}t + \star_3 B$: $\vec{E} = -\nabla\Phi - \partial_t\vec{A}$ and $\vec{B} = \nabla\times\vec{A}$. In components, $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ (T1.41).

Working definition T1.20 (gauge transformation)

For any function λ, $A' = A + \mathrm{d}\lambda$ gives the same field strength, $\mathrm{d}A' = \mathrm{d}A + \mathrm{d}\mathrm{d}\lambda = \mathrm{d}A$. In components, $\Phi' = \Phi - \partial_t\lambda$ and $\vec{A}' = \vec{A} + \nabla\lambda$ (the $\mathrm{d}t$ coefficient of $\mathrm{d}\lambda$ is $\partial_t\lambda$, and it enters A as $-\Phi$). The potential is a *representative*; the physics is in F, or more precisely in A modulo exact forms [A and $A + \mathrm{d}\lambda$ count as the same potential, for every globally defined function λ].

This is a first taste of cohomology: the potentials giving a fixed F form an "affine copy" of the closed 1-forms, and on $\mathbb{R}^4$ all closed 1-forms are exact, so gauge transformations exhaust the ambiguity. On a space with holes (a solenoid removed, a torus) there are closed 1-forms that are not exact, and two potentials with the same F can be physically different: this is the Aharonov–Bohm effect (Chapter T2, Chapter T3).

Worked example T1.38: Lorenz gauge and the wave equation

Insert $F = \mathrm{d}A$ into $\delta F = J$. Since $\delta\mathrm{d}A = (\Delta - \mathrm{d}\delta)A$,

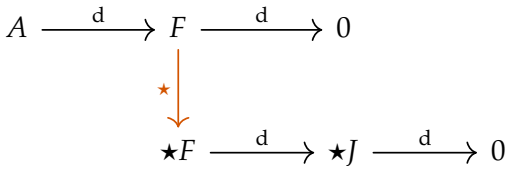
$$\Delta A - \mathrm{d}(\delta A) = J.$$

Use the gauge freedom to impose the **Lorenz gauge** $\delta A = 0$. By (T1.52), $\delta A = -\partial_\mu A^\mu$, and $A^\mu = (\Phi, \vec{A})$, so this is $\partial_t\Phi + \nabla\cdot\vec{A} = 0$. (We can always reach it: if $\delta A \neq 0$, choose λ with $\delta\mathrm{d}\lambda = \Delta\lambda = -\delta A$.) Then Maxwell becomes $\Delta A = J$. On functions in Minkowski space,

$$\Delta f \overset{(1)}{=} \delta\mathrm{d}f \overset{(2)}{=} -\partial_\mu(\eta^{\mu\nu}\partial_\nu f) \overset{(3)}{=} \partial_t^2 f - \nabla^2 f,$$

(1) $\delta f = 0$ on functions.
(2) (T1.54) with $\sqrt{|g|} = 1$.
(3) $\eta^{tt} = -1$, $\eta^{ii} = +1$.

and in Cartesian coordinates Δ acts componentwise on A_μ. So each component obeys the sourced wave equation $(\partial_t^2 - \nabla^2)A_\mu = J_\mu$. In Minkowski signature the "Laplacian" Δ is the wave operator (minus the d'Alembertian): not elliptic. This is exactly why Nash, and instanton physics, Wick-rotate to Euclidean signature, where Δ becomes $-\nabla^2_{\mathbb{R}^4}$, which is elliptic (Section T1.6, Chapter 2).



top row	no metric needed	$\mathrm{d}F = 0$ (Bianchi), $F = \mathrm{d}A$, gauge $A \to A + \mathrm{d}\lambda$
vertical arrow	metric and orientation	$(\vec{E}, \vec{B}) \mapsto (-\vec{B}, \vec{E})$
bottom row	no metric needed again	$\mathrm{d}\star F = \star J$ forces $\mathrm{d}\star J = 0$

Figure T1.22: The logical structure of Maxwell theory. Every horizontal arrow is d, and every composite of two horizontal arrows is zero: this gives the existence of potentials, gauge invariance and charge conservation. The only place the metric enters is the vertical arrow $\star$. Yang–Mills theory has the same diagram with d replaced by a covariant derivative (Chapter T3).

T1.7.9 The action and the two invariants

The two Lorentz-invariant scalars of electromagnetism are the two natural 4-forms one can build from F.

The first invariant. By the defining property of $\star$, $F \wedge \star F = g(F,F)\,\mathrm{vol}$, and $g(F,F) = |\vec{B}|^2 - |\vec{E}|^2$ was computed in Section T1.4 from the determinant formula. It is a good exercise in sign bookkeeping to get the same answer directly from the space–time split.

Worked example T1.39: Computing $F \wedge \star F$ carefully

Only terms containing all four of $\mathrm{d}t, \mathrm{d}x, \mathrm{d}y, \mathrm{d}z$ survive, so only the cross terms between the $\mathrm{d}t$ part of one factor and the spatial part of the other contribute:

$$\begin{aligned} F \wedge \star F &\overset{(1)}{=} (E \wedge \mathrm{d}t) \wedge \star_3 E + \star_3 B \wedge (-B \wedge \mathrm{d}t) \\ &\overset{(2)}{=} E \wedge \star_3 E \wedge \mathrm{d}t - \star_3 B \wedge B \wedge \mathrm{d}t \\ &\overset{(3)}{=} |\vec{E}|^2\, \mathrm{d}^3x \wedge \mathrm{d}t - |\vec{B}|^2\, \mathrm{d}^3x \wedge \mathrm{d}t \overset{(4)}{=} \left(|\vec{B}|^2 - |\vec{E}|^2\right) \mathrm{vol}. \end{aligned}$$

(1) Expand; $(E \wedge \mathrm{d}t) \wedge (B \wedge \mathrm{d}t) = 0$ (two $\mathrm{d}t$'s) and $\star_3 B \wedge \star_3 E = 0$ (a spatial 4-form in 3 dimensions).
(2) $\mathrm{d}t \wedge \star_3 E = \star_3 E \wedge \mathrm{d}t$ ($\mathrm{d}t$ past a 2-form, sign +).
(3) $E \wedge \star_3 E = |\vec{E}|^2 \mathrm{d}^3x$, and $\star_3 B \wedge B = B \wedge \star_3 B = |\vec{B}|^2 \mathrm{d}^3x$ (a 2-form and a 1-form commute).
(4) $\mathrm{d}^3x \wedge \mathrm{d}t = -\mathrm{d}t \wedge \mathrm{d}^3x = -\mathrm{vol}$ ($\mathrm{d}t$ past a 3-form costs $(-1)^3$).

This agrees with $g(F,F) = B^2 - E^2$ from Section T1.4. So the **Maxwell action** with the conventional sign is

$$S[A] = \int \left(-\tfrac{1}{2}\, F \wedge \star F + A \wedge \star J\right) = \int \left(\tfrac{1}{2}(|\vec{E}|^2 - |\vec{B}|^2) - \rho\Phi + \vec{J}\cdot\vec{A}\right) \mathrm{d}t\, \mathrm{d}^3x, \qquad \text{(T1.77)}$$

where $A \wedge \star J = g(A,J)\mathrm{vol} = A_\mu J^\mu \mathrm{vol} = (-\Phi\rho + \vec{A}\cdot\vec{J})\mathrm{vol}$.

Watch out: Moving $\mathrm{d}t$ around

The most common mistake in these computations is a wrong sign from moving $\mathrm{d}t$. The rule is (T1.23): $\mathrm{d}t$ moves past a p-form with sign $(-1)^p$. Past a 2-form it moves freely; past a 1-form or a 3-form it picks up a minus sign. Do one transposition at a time.

Varying the action. Let $A \to A + a$ with a of compact support. Using the symmetry $\alpha \wedge \star\beta = \beta \wedge \star\alpha$,

$$S[A+a] - S[A] \overset{(1)}{=} \int \left(-\mathrm{d}a \wedge \star F + a \wedge \star J\right) + O(a^2)$$
$$\overset{(2)}{=} \int \left(-\mathrm{d}(a \wedge \star F) - a \wedge \mathrm{d}\star F + a \wedge \star J\right) + O(a^2) \overset{(3)}{=} \int a \wedge \left(\star J - \mathrm{d}\star F\right) + O(a^2).$$

(1) $F \to F + \mathrm{d}a$; the cross terms of $-\frac{1}{2}(F + \mathrm{d}a) \wedge \star(F + \mathrm{d}a)$ are equal by the symmetry, giving $-\mathrm{d}a \wedge \star F$.
(2) Leibniz: $\mathrm{d}(a \wedge \star F) = \mathrm{d}a \wedge \star F - a \wedge \mathrm{d}\star F$ (a is a 1-form, sign $(-1)^1$).
(3) Stokes: the total derivative integrates to zero because a vanishes at infinity.

For this to vanish for every a we need $\mathrm{d}\star F = \star J$. The homogeneous equation $\mathrm{d}F = 0$ is not an equation of motion at all: it is automatic once $F = \mathrm{d}A$. And gauge invariance of the coupling term, $\int \mathrm{d}\lambda \wedge \star J = -\int \lambda\, \mathrm{d}\star J$, requires $\mathrm{d}\star J = 0$: again, conservation of the current.

The second invariant. The other 4-form is $F \wedge F$. Only cross terms contribute again:

$$F \wedge F \overset{(1)}{=} 2\,(E \wedge \mathrm{d}t) \wedge \star_3 B \overset{(2)}{=} 2\,E \wedge \star_3 B \wedge \mathrm{d}t \overset{(3)}{=} 2\,(\vec{E}\cdot\vec{B})\,\mathrm{d}^3x \wedge \mathrm{d}t \overset{(4)}{=} -2\,(\vec{E}\cdot\vec{B})\,\mathrm{vol}. \tag{T1.78}$$

(1) $F \wedge F$ with $F = X + Y$, $X = E \wedge \mathrm{d}t$, $Y = \star_3 B$: $X \wedge X = 0$, $Y \wedge Y = 0$ (spatial 4-form), and $X \wedge Y = Y \wedge X$ (2-forms commute).
(2) $\mathrm{d}t$ past the 2-form $\star_3 B$: no sign.
(3) $E \wedge \star_3 B = g_3(E, B)\,\mathrm{d}^3x = (\vec{E}\cdot\vec{B})\,\mathrm{d}^3x$ (definition of $\star_3$).
(4) $\mathrm{d}^3x \wedge \mathrm{d}t = -\mathrm{vol}$.

Cross-check with linear algebra: for a 4×4 antisymmetric matrix, $F\wedge F = 2\,\mathrm{Pf}(F)\,\mathrm{d}t\wedge\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z$ with the Pfaffian $\mathrm{Pf} = F_{tx}F_{yz} - F_{ty}F_{xz} + F_{tz}F_{xy}$. From (T1.65), $\mathrm{Pf} = (-E_x)B_x - (-E_y)(-B_y) + (-E_z)B_z = -\vec{E}\cdot\vec{B}$, and $\det(F_{\mu\nu}) = \mathrm{Pf}^2 = (\vec{E}\cdot\vec{B})^2$. The invariant $F \wedge F$ is also a total derivative:

$$F \wedge F \overset{(1)}{=} \mathrm{d}A \wedge \mathrm{d}A \overset{(2)}{=} \mathrm{d}(A \wedge \mathrm{d}A), \tag{T1.79}$$

(1) $F = \mathrm{d}A$.
(2) Leibniz: $\mathrm{d}(A \wedge \mathrm{d}A) = \mathrm{d}A \wedge \mathrm{d}A - A \wedge \mathrm{d}\mathrm{d}A$ and $\mathrm{d}^2 = 0$.

so adding $\theta \int F \wedge F$ to the action changes no equation of motion. Its non-abelian version $\mathrm{tr}\, F \wedge F$ is the instanton number density (Chapter 8), and $A \wedge \mathrm{d}A$ is the abelian Chern–Simons 3-form, the Lagrangian of the topological field theories of Nash's last chapter (Chapter 12).

T1.7.10 Three solutions

Worked example T1.40: The point charge: Gauss's law as a flux of $\star F$

A static charge q at the origin has $\Phi = q/(4\pi r)$ and $\vec{A} = 0$, so $A = -\Phi\,\mathrm{d}t$ and

$$F \overset{(1)}{=} \mathrm{d}A = -\mathrm{d}\Phi \wedge \mathrm{d}t \overset{(2)}{=} \frac{q}{4\pi r^2}\,\mathrm{d}r \wedge \mathrm{d}t, \qquad \star F \overset{(3)}{=} \frac{q}{4\pi r^2}\,\star_3\,\mathrm{d}r \overset{(4)}{=} \frac{q}{4\pi}\,\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi.$$

(1) (T1.76); $\mathrm{d}\mathrm{d}t = 0$.
(2) $\mathrm{d}(1/r) = -\mathrm{d}r/r^2$. So $E = \frac{q}{4\pi r^2}\mathrm{d}r$, the Coulomb field.
(3) $\star(\bar{\alpha} \wedge \mathrm{d}t) = \star_3\bar{\alpha}$ (T1.63).
(4) In spherical coordinates $\star_3\mathrm{d}r = r^2\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$ (Section T1.4): the unit coframe is $\mathrm{d}r$, $r\mathrm{d}\theta$, $r\sin\theta\mathrm{d}\phi$.

Two things to notice. First, $\star F$ does not depend on r at all, and $\mathrm{d}\star F = \frac{q}{4\pi}\cos\theta\,\mathrm{d}\theta\wedge\mathrm{d}\theta\wedge\mathrm{d}\phi = 0$ away from the origin: vacuum Maxwell. Second, its integral over any sphere around the origin is

$$\int_{S^2}\star F = \frac{q}{4\pi}\int_0^{\pi}\int_0^{2\pi}\sin\theta\,\mathrm{d}\phi\,\mathrm{d}\theta = \frac{q}{4\pi}\cdot 2\pi\cdot 2 = q.$$

This is Gauss's law. The 2-form $\star F$ restricted to $\mathbb{R}^3\setminus\{0\}$ is closed but not exact (its integral over the closed surface S^2 is nonzero, and an exact form would integrate to zero by Stokes). It is the 2-dimensional analogue of $\mathrm{d}\phi$ on the punctured plane (Example T1.30), and the charge q is the "period" that measures the hole.

Worked example T1.41: A plane wave is a null field

Take $\vec{E} = E_0\cos(z-t)\,\hat{x}$, $\vec{B} = E_0\cos(z-t)\,\hat{y}$, a wave moving in $+z$. With $u = z-t$, $\mathrm{d}u = \mathrm{d}z - \mathrm{d}t$:

$$F \overset{(1)}{=} E_0\cos u\,(\mathrm{d}x\wedge\mathrm{d}t + \mathrm{d}z\wedge\mathrm{d}x) \overset{(2)}{=} E_0\cos u\,\mathrm{d}x\wedge(\mathrm{d}t-\mathrm{d}z) \overset{(3)}{=} -E_0\cos u\,\mathrm{d}x\wedge\mathrm{d}u,$$
$$\star F \overset{(4)}{=} E_0\cos u\,(\mathrm{d}y\wedge\mathrm{d}z - \mathrm{d}y\wedge\mathrm{d}t) \overset{(5)}{=} E_0\cos u\,\mathrm{d}y\wedge\mathrm{d}u.$$

(1) (T1.64) with $E_x = B_y = E_0\cos u$.
(2) $\mathrm{d}z\wedge\mathrm{d}x = -\mathrm{d}x\wedge\mathrm{d}z$.
(3) $\mathrm{d}t - \mathrm{d}z = -\mathrm{d}u$.
(4) (T1.69): $\star_3 E = E_0\cos u\,\mathrm{d}y\wedge\mathrm{d}z$, and $B\wedge\mathrm{d}t = E_0\cos u\,\mathrm{d}y\wedge\mathrm{d}t$.
(5) $\mathrm{d}z - \mathrm{d}t = \mathrm{d}u$.

Now both Maxwell equations in vacuum are one-liners: $\mathrm{d}F = E_0\sin u\,\mathrm{d}u\wedge\mathrm{d}x\wedge\mathrm{d}u = 0$ and $\mathrm{d}\star F = -E_0\sin u\,\mathrm{d}u\wedge\mathrm{d}y\wedge\mathrm{d}u = 0$, since the only derivative is along $\mathrm{d}u$, which is already present. Both invariants vanish: $F\wedge F \propto \mathrm{d}x\wedge\mathrm{d}u\wedge\mathrm{d}x\wedge\mathrm{d}u = 0$ and $F\wedge\star F \propto \mathrm{d}x\wedge\mathrm{d}u\wedge\mathrm{d}y\wedge\mathrm{d}u = 0$. So $|\vec{E}| = |\vec{B}|$ and $\vec{E}\perp\vec{B}$ in every frame: light is **null**. The whole field is "$\mathrm{d}u$ wedge something transverse", the form-language picture of a transverse wave travelling along the light ray $u = \text{const}$.

Worked example T1.42: The Dirac monopole: a field strength with no global potential

A magnetic monopole of strength g has $\vec{B} = \frac{g}{4\pi r^2}\hat{r}$, i.e. (by the same computation as in Example T1.40)

$$F = \star_3 B = \frac{g}{4\pi}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi, \qquad \int_{S^2} F = g. \tag{T1.80}$$

It is closed on $\mathbb{R}^3\setminus\{0\}$ ($\mathrm{d}F$ contains $\mathrm{d}\theta\wedge\mathrm{d}\theta$). Could $F = \mathrm{d}A$ for a global 1-form A on the sphere? No: Stokes would give $\int_{S^2}\mathrm{d}A = \int_{\varnothing} A = 0 \neq g$. But locally there are potentials. Try $A = f(\theta)\,\mathrm{d}\phi$: then $\mathrm{d}A = f'(\theta)\,\mathrm{d}\theta\wedge\mathrm{d}\phi$, so we need $f' = \frac{g}{4\pi}\sin\theta$, $f = -\frac{g}{4\pi}\cos\theta + c$. The constant matters, because $\mathrm{d}\phi$ is singular at the poles (its length is $|\mathrm{d}\phi| = 1/(r\sin\theta)$), so A is smooth at a pole only if f vanishes there:

$$A_N = \frac{g}{4\pi}(1-\cos\theta)\,\mathrm{d}\phi \quad (\text{smooth except at } \theta=\pi),$$
$$A_S = -\frac{g}{4\pi}(1+\cos\theta)\,\mathrm{d}\phi \quad (\text{smooth except at } \theta=0). \tag{T1.81}$$

Near $\theta = 0$, $1-\cos\theta \approx \theta^2/2$, so $|A_N| \approx \frac{g}{4\pi}\frac{\theta^2/2}{r\theta} \to 0$: regular. The singular half-line of each

potential is the **Dirac string**. On the overlap (everything except the poles) the two differ by

$$A_N - A_S \overset{(1)}{=} \frac{g}{4\pi}\big[(1-\cos\theta)+(1+\cos\theta)\big]\mathrm{d}\phi = \frac{g}{2\pi}\,\mathrm{d}\phi \overset{(2)}{=} \mathrm{d}\Big(\frac{g\phi}{2\pi}\Big), \tag{T1.82}$$

(1) Subtract (T1.81).
(2) Locally $\mathrm{d}\phi$ is the differential of the angle.

a gauge transformation with $\lambda = g\phi/2\pi$, which is *not* single-valued. Is that acceptable? A charged wavefunction of charge e transforms as $\psi \to e^{ie\lambda}\psi$ (with $\hbar = 1$), so what must be single-valued on the equator is $e^{ie\lambda} = e^{ieg\phi/2\pi}$. Going once round, $\phi \to \phi + 2\pi$, it changes by e^{ieg}. So

$$eg \in 2\pi\mathbb{Z} \qquad \text{(Dirac quantization)}. \tag{T1.83}$$

The integer $n = eg/2\pi = \frac{e}{2\pi}\int_{S^2} F$ is the first Chern number of a line bundle over S^2, built exactly like the manifold S^2 itself from two charts and a transition function (Section T1.1; bundles in Chapter 1, Chapter T3). For $n = \pm 1$ it is the Hopf bundle.

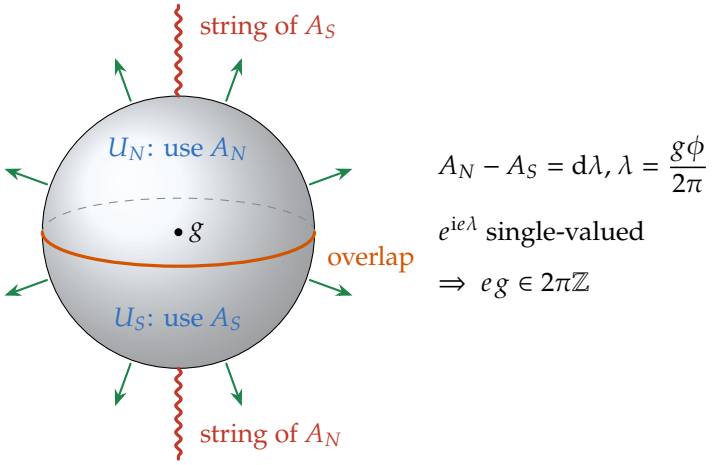


Figure T1.23: The Dirac monopole. The radial field (green) has total flux g through the sphere, so no single potential works everywhere. The potential A_N is good on the northern patch and singular along the south axis (red wavy line, its Dirac string); A_S is the reverse. On the orange overlap they differ by a gauge transformation, and requiring that transformation to be single-valued on charged fields quantizes eg. Compare the two-chart description of S^2 in Figure T1.5.

T1.7.11 Duality, Euclidean signature and self-dual fields

In vacuum ($J = 0$) the equations $\mathrm{d}F = 0$ and $\mathrm{d}\star F = 0$ are symmetric under $F \to \star F$: if F solves both, so does $\star F$, because $\mathrm{d}(\star F) = 0$ and $\mathrm{d}\star(\star F) = -\mathrm{d}F = 0$. This is the duality $(\vec{E},\vec{B}) \to (-\vec{B},\vec{E})$ of (T1.70). Since $\star\star = -1$ on Minkowski 2-forms, its eigenvalues are $\pm\mathrm{i}$: there are no real fields with $\star F = \pm F$.

Now Wick-rotate: $t = -\mathrm{i}\tau$, giving the Euclidean metric $\mathrm{d}\tau^2 + \mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2$ with $\mathrm{vol} = \mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z\wedge\mathrm{d}\tau$ (the ordering $x^1x^2x^3x^4$ of Example T1.23, with $x^4 = \tau$). Write $F = E\wedge\mathrm{d}\tau + \star_3 B$ as before. The Euclidean table Example T1.23 gives $\star(\mathrm{d}x^1\wedge\mathrm{d}x^4) = \mathrm{d}x^2\wedge\mathrm{d}x^3$ and $\star(\mathrm{d}x^2\wedge\mathrm{d}x^3) = \mathrm{d}x^1\wedge\mathrm{d}x^4$, and cyclically, so now

$$\star F = B\wedge\mathrm{d}\tau + \star_3 E: \qquad (\vec{E},\vec{B}) \xrightarrow{\star} (\vec{B},\vec{E}), \qquad \star F = \pm F \iff \vec{E} = \pm\vec{B}. \tag{T1.84}$$

Real self-dual fields exist, and they solve the vacuum equations automatically: if $F = \mathrm{d}A$ and $\star F = F$, then $\mathrm{d}\star F = \mathrm{d}F = 0$. For a single abelian field on $\mathbb{R}^4$ with finite action the only

such field is $F = 0$, but for SU(2) Yang–Mills there are nontrivial ones, the instantons, and their action is fixed by topology: $\int F \wedge \star F = \pm \int F \wedge F$ (Chapter 8). In Euclidean signature $F \wedge \star F = (|\vec{E}|^2 + |\vec{B}|^2)\mathrm{vol} \geq 0$, so the Euclidean action is positive, which is what makes the Euclidean path integral $\int e^{-S}$ sensible.

Try it: Maxwell in $1+1$ dimensions

In two-dimensional space-time with $\eta = \mathrm{diag}(-1, 1)$ and $\mathrm{vol} = \mathrm{d}t \wedge \mathrm{d}x$, let $F = E\,\mathrm{d}x \wedge \mathrm{d}t$ and $J = -\rho\,\mathrm{d}t + j\,\mathrm{d}x$. Show that $\mathrm{d}F = 0$ is empty, that $\star F = E$ (a function), and that $\mathrm{d} \star F = \star J$ gives $\partial_x E = \rho$ and $\partial_t E = -j$.
Answer: $\mathrm{d}F$ is a 3-form in 2 dimensions, so it vanishes. $F = -E\,\mathrm{vol}$ and $\star\mathrm{vol} = (-1)^s = -1$, so $\star F = E$. From $\mathrm{d}t \wedge \star \mathrm{d}t = -\mathrm{vol}$ we get $\star \mathrm{d}t = -\mathrm{d}x$, and from $\mathrm{d}x \wedge \star \mathrm{d}x = \mathrm{vol}$ we get $\star \mathrm{d}x = -\mathrm{d}t$. So $\star J = \rho\,\mathrm{d}x - j\,\mathrm{d}t$, while $\mathrm{d} \star F = \partial_t E\,\mathrm{d}t + \partial_x E\,\mathrm{d}x$. Matching coefficients gives both equations. This is the setting of the Schwinger model, the simplest anomaly computation (Chapter 10).

Reading Nash (pp. 25, 229 and Ch. 10)

Nash never writes Maxwell's equations, but he uses their structure constantly. On p. 25, (1.74)–(1.75), the Euclidean Yang–Mills action is $S = \|F\|^2 = \int_M \mathrm{tr}(F \wedge \star F)$ and the instanton equation is the self-duality condition $F = \star F$: our (T1.84) with matrices. On p. 229 he proves $\star\star = 1$ on 2-forms in four Euclidean dimensions and splits $F = \frac{1}{2}(F + \star F) + \frac{1}{2}(F - \star F)$, exactly as in Example T1.23. On p. 78 he notes that the Hopf fibration "is also the one that gives the Dirac monopole" (Example T1.42). His anomaly chapter (Chapter 10) rests on the conservation argument (T1.75) and on $F \wedge F$ being a total derivative (T1.79). Remember that Nash's gauge fields are anti-Hermitian: for U(1) his A is i times a real 1-form, $A_{\mathrm{Nash}} = -\mathrm{i}\,e A_{\mathrm{here}}$.

Recap

- $\vec{E}$ is a 1-form (integrated along lines), $\vec{B}$ a 2-form (integrated over surfaces). Together $F = E \wedge \mathrm{d}t + \star_3 B$, with matrix (T1.65).
- $\mathrm{d}F = 0$ is $\nabla \cdot \vec{B} = 0$ and Faraday; it needs no metric.
- $\star F = \star_3 E - B \wedge \mathrm{d}t$, i.e. $(\vec{E}, \vec{B}) \to (-\vec{B}, \vec{E})$; $\mathrm{d} \star F = \star J$ is Gauss and Ampère–Maxwell.
- $\mathrm{d}^2 = 0$ gives charge conservation, potentials $F = \mathrm{d}A$ locally (Poincaré), and gauge freedom $A \to A + \mathrm{d}\lambda$.
- Invariants: $F \wedge \star F = (B^2 - E^2)\mathrm{vol}$ (the action), $F \wedge F = -2\vec{E} \cdot \vec{B}\,\mathrm{vol} = \mathrm{d}(A \wedge \mathrm{d}A)$ (topological).
- The monopole needs two potentials glued by a gauge transformation; consistency gives $eg \in 2\pi\mathbb{Z}$, the first Chern number.
- In Euclidean signature $\star\star = +1$ on 2-forms and self-dual fields ($\vec{E} = \vec{B}$) solve the equations automatically.

T1.8 Pullback and naturality

We have already done the same operation many times without naming it. To get $\mathrm{d}x \wedge \mathrm{d}y = r\,\mathrm{d}r \wedge \mathrm{d}\phi$ we substituted $x = r\cos\phi$, $y = r\sin\phi$ and expanded (Example T1.12). To integrate $\mathrm{d}\phi$ around the unit circle we substituted $x = \cos t$, $y = \sin t$ and got $\mathrm{d}t$ (Example T1.30). To find the metric of the sphere we substituted $X = \sin\theta\cos\phi, \ldots$ into $\mathrm{d}X^2 + \mathrm{d}Y^2 + \mathrm{d}Z^2$ (Example T1.9). Each time a map carried points of one space (θ, ϕ or t) to another ($\mathbb{R}^3$ or $\mathbb{R}^2$), and we used it to drag a form *backwards*, from the target to the source.

That operation is the **pullback**. It is the most important operation on forms after d, for four reasons. (i) Every integral of a form is computed by pulling it back to a parameter domain in $\mathbb{R}^p$. (ii) Restricting a form to a curve or a surface is pulling it back along the inclusion. (iii) It commutes with d ("naturality"), which is why d is coordinate independent and why de Rham cohomology is a topological invariant. (iv) Nash uses it on almost every page of his Chapter 1 to move cohomology classes and bundles between spaces: $f^*\omega$, f^*E, f^*c_i.

T1.8.1 Maps between manifolds, and pushing vectors forward

Let $f : N \to M$ be a smooth map. In coordinates x^μ on N ($\mu = 1, \ldots, n$) and y^a on M ($a = 1, \ldots, m$) it is a list of m functions $y^a = f^a(x^1, \ldots, x^n)$. The dimensions need not agree, and f need not be invertible. Typical examples:

- a curve $\gamma : \mathbb{R} \to M$ ($n = 1$);
- the polar-coordinate map $(r, \phi) \mapsto (r\cos\phi, r\sin\phi)$ ($n = m = 2$);
- the embedding of the sphere $i : S^2 \to \mathbb{R}^3$, $(\theta, \phi) \mapsto (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$;
- the n-fold winding map of the circle, $\theta \mapsto n\theta$;
- a projection $\mathbb{R}^3 \to \mathbb{R}^2$, $(x, y, z) \mapsto (x, y)$.

A map carries curves to curves, hence velocities to velocities. If $x(s)$ is a curve in N with velocity $v^\mu = \mathrm{d}x^\mu/\mathrm{d}s$, its image $y^a(s) = f^a(x(s))$ has velocity, by the chain rule,

$$(f_* v)^a = \frac{\partial f^a}{\partial x^\mu}\, v^\mu. \tag{T1.85}$$

Working definition T1.21 (push-forward of a vector)

The **push-forward** (or differential) $f_* v$ of a vector v at $p \in N$ is the vector at $f(p) \in M$ obtained by multiplying the component column v^μ by the $m \times n$ Jacobian matrix $\partial f^a/\partial x^\mu$. As a derivation [a vector acting as a directional derivative, $v(g) = v^\mu \partial_\mu g$], $(f_* v)(g) = v(g \circ f)$: to differentiate a function on M along $f_* v$, pull the function back to N and differentiate it along v.

For the polar map, $f_*\partial_r = \cos\phi\,\partial_x + \sin\phi\,\partial_y$ and $f_*\partial_\phi = -r\sin\phi\,\partial_x + r\cos\phi\,\partial_y = -y\,\partial_x + x\,\partial_y$: the columns of the Jacobian, exactly as in Example T1.5.

T1.8.2 Pulling forms back

Vectors go forward. Forms go backward.

Working definition T1.22 (pullback)

For a function g on M, $f^*g = g \circ f$ [first move the point with f, then evaluate g: $(f^*g)(x) = g(f(x))$]. For a p-form ω on M, $f^*\omega$ is the p-form on N that eats vectors by pushing them forward first:

$$(f^*\omega)(v_1, \dots, v_p) = \omega(f_*v_1, \dots, f_*v_p). \tag{T1.86}$$

Recipe ("substitute and expand"): in ω, replace every coefficient $g(y)$ by $g(f(x))$ and every $\mathrm{d}y^a$ by

$$f^*\mathrm{d}y^a = \mathrm{d}f^a = \frac{\partial f^a}{\partial x^\mu}\,\mathrm{d}x^\mu, \tag{T1.87}$$

then multiply out using the wedge rules [$\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu = -\mathrm{d}x^\nu \wedge \mathrm{d}x^\mu$, so $\mathrm{d}x^\mu \wedge \mathrm{d}x^\mu = 0$].

The recipe works because pullback respects every algebraic operation:

$$f^*(\alpha + \beta) = f^*\alpha + f^*\beta, \qquad f^*(g\,\alpha) = (f^*g)\,f^*\alpha, \qquad f^*(\alpha \wedge \beta) = f^*\alpha \wedge f^*\beta. \tag{T1.88}$$

The first two are clear from (T1.86). For the third, both sides are the determinant-type expression of (T1.20) evaluated on the pushed-forward vectors. And (T1.87) is (T1.86) for $\omega = \mathrm{d}y^a$: $(f^*\mathrm{d}y^a)(\partial_\mu) = \mathrm{d}y^a(f_*\partial_\mu) = \partial f^a/\partial x^\mu$. In components, a 1-form pulls back by the *transpose* of the Jacobian,

$$(f^*\alpha)_\mu = \frac{\partial f^a}{\partial x^\mu}\,\alpha_a(f(x)), \tag{T1.89}$$

which is the covariant transformation law (T1.12) seen from a new angle: a change of coordinates is a pullback along the transition map.

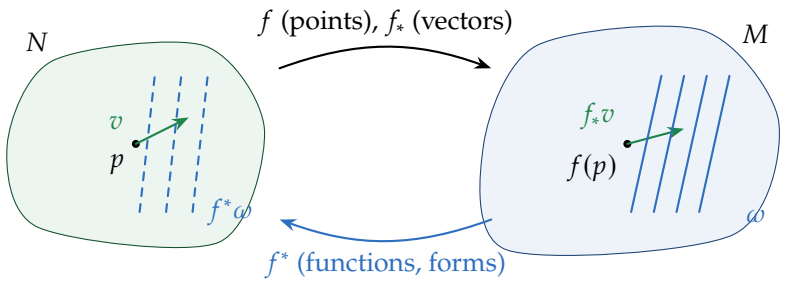

Figure T1.24: Points and vectors travel forward along $f : N \to M$; functions and forms travel backward. The pulled-back stack $f^*\omega$ at p is defined so that the number of its sheets pierced by v equals the number of sheets of ω pierced by f_*v. No inverse of f is needed, which is why we can always pull forms back but cannot, in general, push them forward.

Watch out: Why not push forms forward?

To push a form forward we would need to pull vectors back, i.e. invert the Jacobian. For the projection $(x, y, z) \mapsto (x, y)$ there is no way to say which vector upstairs a vector downstairs came from. Similarly a function on N cannot be pushed to M if two points of N land on the same point of M with different values. Pullback needs no choices; that is why it is the operation that appears in cohomology ($f^* : H^p(M) \to H^p(N)$) and in bundle theory (f^*E).

T1.8.3 Examples: curves, surfaces and top forms

Worked example T1.43: A 1-form pulled back to a curve is the line-integral integrand

Let $\alpha = -y\,dx + x\,dy + z\,dz$ on $\mathbb{R}^3$ and let $\gamma(t) = (\cos t, \sin t, t)$ be a helix. Then

$$\gamma^*\alpha \overset{(1)}{=} -\sin t\,d(\cos t) + \cos t\,d(\sin t) + t\,dt \overset{(2)}{=} \big(\sin^2 t + \cos^2 t + t\big)dt = (1+t)\,dt,$$
$$\int_\gamma \alpha \overset{(3)}{=} \int_0^{2\pi} (1+t)\,dt = 2\pi + 2\pi^2.$$

(1) Substitute $x = \cos t$, $y = \sin t$, $z = t$ in coefficients and differentials (T1.87).
(2) $d(\cos t) = -\sin t\,dt$, $d(\sin t) = \cos t\,dt$.
(3) The integral of a 1-form over an oriented curve is the ordinary integral of its pullback to the parameter interval (Chapter T2).

In vector language this is $\int \vec{F}\cdot d\vec{r} = \int \vec{F}\cdot\dot{\vec{r}}\,dt$ with $\vec{F} = (-y, x, z)$: the familiar rule "$d\vec{r} = \dot{\vec{r}}\,dt$" is the pullback. The coefficient of $\gamma^*\alpha$ is $\alpha(\gamma_*\partial_t) = \alpha(\dot\gamma)$, the form evaluated on the velocity, which is (T1.86). Note also that any 2-form pulls back to *zero* on a curve: there are no 2-forms on a 1-dimensional space.

Worked example T1.44: The flux through a graph: Dray's surface element

Let S be the graph $z = h(x,y)$, parametrised by $\sigma(x,y) = (x, y, h(x,y))$, and let $\star F = F_x\,dy\wedge dz + F_y\,dz\wedge dx + F_z\,dx\wedge dy$ be the flux 2-form of a vector field. Pull back, with $\sigma^*dz = h_x dx + h_y dy$:

$$\sigma^*(dy\wedge dz) \overset{(1)}{=} dy\wedge(h_x dx + h_y dy) = -h_x\,dx\wedge dy,$$
$$\sigma^*(dz\wedge dx) \overset{(2)}{=} (h_x dx + h_y dy)\wedge dx = -h_y\,dx\wedge dy,$$
$$\sigma^*(\star F) \overset{(3)}{=} \big(-F_x h_x - F_y h_y + F_z\big)\big|_{z=h}\,dx\wedge dy.$$

(1) $dy\wedge dy = 0$, $dy\wedge dx = -dx\wedge dy$.
(2) $dx\wedge dx = 0$.
(3) Add the three pieces; coefficients are evaluated on the surface.

This is $\vec{F}\cdot d\vec{A}$ with the upward surface element $d\vec{A} = (-h_x, -h_y, 1)\,dx\,dy$ [Dray (16.15)–(16.18)]. The vector-calculus derivation needs the cross product of two tangent vectors; the pullback does it by antisymmetry alone. For the plane $h = 0$ it gives $F_z\,dx\wedge dy$: Dray's remark "$z = 0$ on S, so $dz = 0$ there" is the statement $\sigma^*dz = 0$.

Key idea: Top forms pull back by the Jacobian determinant

If $\dim N = \dim M = n$, then

$$f^*\big(g\,dy^1\wedge\cdots\wedge dy^n\big) = (g\circ f)\,\det\!\left(\frac{\partial f^a}{\partial x^\mu}\right) dx^1\wedge\cdots\wedge dx^n, \tag{T1.90}$$

by (T1.87), (T1.88) and (T1.19). Hence, for a diffeomorphism f,

$$\int_N f^*\omega = \pm\int_M \omega, \tag{T1.91}$$

with $+$ if f preserves orientation ($\det > 0$) and $-$ if it reverses it. This is the change-of-variables formula of multivariable calculus. The measure-theory version has $|\det|$; forms

keep the sign, because an oriented integral is what flux and Stokes need.

Worked example T1.45: The area form of S^2, three ways

On $\mathbb{R}^3$ consider the 2-form

$$\omega = X\,\mathrm{d}Y\wedge\mathrm{d}Z + Y\,\mathrm{d}Z\wedge\mathrm{d}X + Z\,\mathrm{d}X\wedge\mathrm{d}Y,$$

the flux form of the position vector field $\vec{r}$. (In Section T1.9 we will recognise it as $\iota_{\vec{r}}\,\mathrm{vol}$.)
(a) Pull back along the angle map $i(\theta,\phi) = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$. The differentials are $\mathrm{d}X = \cos\theta\cos\phi\,\mathrm{d}\theta - \sin\theta\sin\phi\,\mathrm{d}\phi$, $\mathrm{d}Y = \cos\theta\sin\phi\,\mathrm{d}\theta + \sin\theta\cos\phi\,\mathrm{d}\phi$, $\mathrm{d}Z = -\sin\theta\,\mathrm{d}\theta$. Then

$$\begin{aligned}
i^*(\mathrm{d}Y\wedge\mathrm{d}Z) &\overset{(1)}{=} \sin\theta\cos\phi\,\mathrm{d}\phi\wedge(-\sin\theta\,\mathrm{d}\theta) = \sin^2\theta\cos\phi\,\mathrm{d}\theta\wedge\mathrm{d}\phi,\\
i^*(\mathrm{d}Z\wedge\mathrm{d}X) &\overset{(2)}{=} (-\sin\theta\,\mathrm{d}\theta)\wedge(-\sin\theta\sin\phi\,\mathrm{d}\phi) = \sin^2\theta\sin\phi\,\mathrm{d}\theta\wedge\mathrm{d}\phi,\\
i^*(\mathrm{d}X\wedge\mathrm{d}Y) &\overset{(3)}{=} \big(\cos\theta\cos\phi\sin\theta\cos\phi + \sin\theta\sin\phi\cos\theta\sin\phi\big)\mathrm{d}\theta\wedge\mathrm{d}\phi\\
&= \sin\theta\cos\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi,\\
i^*\omega &\overset{(4)}{=} \big(\sin^3\theta\cos^2\phi + \sin^3\theta\sin^2\phi + \cos^2\theta\sin\theta\big)\mathrm{d}\theta\wedge\mathrm{d}\phi\\
&= \sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi.
\end{aligned}$$

(1) Only the $\mathrm{d}\phi$ part of $\mathrm{d}Y$ survives against $\mathrm{d}Z\propto\mathrm{d}\theta$.
(2) Only the $\mathrm{d}\phi$ part of $\mathrm{d}X$ survives.
(3) The $\mathrm{d}\theta\wedge\mathrm{d}\phi$ term and the $\mathrm{d}\phi\wedge\mathrm{d}\theta$ term, the latter with a sign flip: $(-\sin\theta\sin\phi)(\cos\theta\sin\phi)\,\mathrm{d}\phi\wedge\mathrm{d}\theta = +\sin\theta\cos\theta\sin^2\phi\,\mathrm{d}\theta\wedge\mathrm{d}\phi$.
(4) Multiply by the coefficients X, Y, Z pulled back, and use $\cos^2\phi+\sin^2\phi = 1$, $\sin^2\theta + \cos^2\theta = 1$.

So $i^*\omega$ is the area form of the unit sphere, with total $\int_0^{\pi}\int_0^{2\pi}\sin\theta\,\mathrm{d}\phi\,\mathrm{d}\theta = 4\pi$.
(b) Pull back further, to the stereographic chart. In the north chart, $u+\mathrm{i}v = \rho\,e^{\mathrm{i}\phi}$ with $\rho = \cot(\theta/2)$ (Example T1.9(c)). Rather than substituting (T1.4) into ω (possible but long), we use $(f\circ g)^* = g^*f^*$ below and pull back $\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi$ along $(u,v)\mapsto(\theta,\phi)$. It is easier to go the other way and express $\mathrm{d}u\wedge\mathrm{d}v$ in θ,ϕ:

$$\begin{aligned}
\frac{4\,\mathrm{d}u\wedge\mathrm{d}v}{(1+\rho^2)^2} &\overset{(1)}{=} \frac{4\rho\,\mathrm{d}\rho\wedge\mathrm{d}\phi}{(1+\rho^2)^2} \overset{(2)}{=} 4\sin^4\tfrac{\theta}{2}\,\cot\tfrac{\theta}{2}\left(-\tfrac12\csc^2\tfrac{\theta}{2}\right)\mathrm{d}\theta\wedge\mathrm{d}\phi\\
&\overset{(3)}{=} -2\sin\tfrac{\theta}{2}\cos\tfrac{\theta}{2}\,\mathrm{d}\theta\wedge\mathrm{d}\phi \overset{(4)}{=} -\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi.
\end{aligned}$$

(1) Polar coordinates in the (u,v) plane: $\mathrm{d}u\wedge\mathrm{d}v = \rho\,\mathrm{d}\rho\wedge\mathrm{d}\phi$ (Example T1.12).
(2) $1+\cot^2 = \csc^2$, so $(1+\rho^2)^{-2} = \sin^4(\theta/2)$; and $\mathrm{d}\rho = \mathrm{d}\cot(\theta/2) = -\tfrac12\csc^2(\theta/2)\,\mathrm{d}\theta$.
(3) Simplify: $\sin^4\cdot\cot\cdot\csc^2 = \sin\cdot\cos$.
(4) Double-angle formula.

So on the sphere $\omega = \sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi = -\dfrac{4\,\mathrm{d}u\wedge\mathrm{d}v}{(1+u^2+v^2)^2}$. The magnitude $4/(1+\rho^2)^2$ is $\sqrt{\det g}$ for the stereographic metric of Example T1.9, as it must be. The *minus sign* says the north stereographic chart (u,v) is orientation-reversing relative to the outward normal. Check at the south pole, where $u=v=0$: there $X\approx 2u$, $Y\approx 2v$, $Z\approx -1$, so $\omega\approx Z\,\mathrm{d}X\wedge\mathrm{d}Y = -4\,\mathrm{d}u\wedge\mathrm{d}v$. Looking at the plane from above, the outward normal at the south pole points *down*. This is the orientation subtlety of Section T1.1, now visible in a single sign.

(c) The Coulomb/monopole form. On $\mathbb{R}^3 \setminus \{0\}$ the 2-form ω/r^3 is closed (it is $4\pi/g$ times the monopole field (T1.80), written in Cartesian coordinates). Pulled back to the sphere of radius R, $(X, Y, Z) = R\,(\sin\theta\cos\phi, \dots)$, it gives $R^3 \sin\theta\, \mathrm{d}\theta \wedge \mathrm{d}\phi/R^3$: independent of R, since each of X, Y, Z and each differential scale by R. The flux through every sphere is 4π, the same number, as a closed form must give on surfaces that can be deformed into each other (Chapter T2).

T1.8.4 Pullback of the metric: induced metrics

The same recipe works for symmetric products of 1-forms. For the inclusion i of a surface, $i^*(\mathrm{d}X^2 + \mathrm{d}Y^2 + \mathrm{d}Z^2)$ is the **induced metric**: the metric that measures lengths of curves drawn on the surface using the ambient ruler. That is what we computed in Example T1.9; in components,

$$(f^*g)_{\mu\nu} = \frac{\partial f^a}{\partial x^\mu}\frac{\partial f^b}{\partial x^\nu}\, g_{ab}(f(x)), \qquad \text{i.e.} \qquad f^*g = J^{\mathsf{T}} g J. \tag{T1.92}$$

Worked example T1.46: The induced metric and area of a graph

For $\sigma(x, y) = (x, y, h)$, with $\mathrm{d}z = h_x \mathrm{d}x + h_y \mathrm{d}y$:

$$\begin{aligned} \sigma^*(\mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2) &\overset{(1)}{=} \mathrm{d}x^2 + \mathrm{d}y^2 + (h_x \mathrm{d}x + h_y \mathrm{d}y)^2 \\ &= (1 + h_x^2)\,\mathrm{d}x^2 + 2h_x h_y\, \mathrm{d}x\, \mathrm{d}y + (1 + h_y^2)\,\mathrm{d}y^2, \\ \det(g_{\mu\nu}) &\overset{(2)}{=} (1 + h_x^2)(1 + h_y^2) - h_x^2 h_y^2 = 1 + h_x^2 + h_y^2. \end{aligned}$$

(1) Substitute and expand; $\mathrm{d}x\,\mathrm{d}y$ here is the *symmetric* product, so the cross term has coefficient $2h_x h_y$ and $g_{xy} = g_{yx} = h_x h_y$.
(2) 2×2 determinant.

The area form is $\sqrt{1 + h_x^2 + h_y^2}\,\mathrm{d}x \wedge \mathrm{d}y$, the familiar formula. And the unit normal flux of Example T1.44, $(-h_x, -h_y, 1)/\sqrt{1 + |\nabla h|^2}$, times this area form gives back $\mathrm{d}\vec{A} = (-h_x, -h_y, 1)\,\mathrm{d}x\,\mathrm{d}y$: the two computations agree.

Watch out: Pullback does not commute with $\star$

The Hodge star uses a metric, and f need not respect it. Take the dilation $f(x, y) = (\lambda x, \lambda y)$ of $\mathbb{R}^2$. Then $f^*(\star 1) = f^*(\mathrm{d}x \wedge \mathrm{d}y) = \lambda^2\, \mathrm{d}x \wedge \mathrm{d}y$, whereas $\star(f^*1) = \star 1 = \mathrm{d}x \wedge \mathrm{d}y$. They agree only for $\lambda = \pm 1$. In general $f^*\star = \pm \star f^*$ only when f is an *isometry* ($f^*g = g$), with the sign given by orientation. This is why $\mathrm{d}F = 0$ is invariant under every diffeomorphism while $\mathrm{d} \star F = \star J$ is only invariant under isometries (Lorentz transformations, rotations).

T1.8.5 Naturality: $\mathrm{d}f^* = f^*\mathrm{d}$

Key idea: Pullback commutes with d

For every smooth map $f : N \to M$ and every form ω on M,

$$\mathrm{d}(f^*\omega) = f^*(\mathrm{d}\omega). \tag{T1.93}$$

"Differentiate, then substitute" equals "substitute, then differentiate".

Why. For a function g this is the chain rule:

$$\mathrm{d}(f^*g) \overset{(1)}{=} \frac{\partial(g\circ f)}{\partial x^\mu}\,\mathrm{d}x^\mu \overset{(2)}{=} \frac{\partial g}{\partial y^a}\frac{\partial f^a}{\partial x^\mu}\,\mathrm{d}x^\mu \overset{(3)}{=} \frac{\partial g}{\partial y^a}\,f^*\mathrm{d}y^a \overset{(4)}{=} f^*(\mathrm{d}g).$$

(1) Definition of d on the function $g\circ f$ on N.
(2) Chain rule.
(3) (T1.87).
(4) $\mathrm{d}g = \partial_a g\,\mathrm{d}y^a$ pulled back by (T1.88).

For a p-form $\omega = g\,\mathrm{d}y^{a_1}\wedge\cdots\wedge\mathrm{d}y^{a_p}$ (and sums of such), $f^*\omega = (g\circ f)\,\mathrm{d}f^{a_1}\wedge\cdots\wedge\mathrm{d}f^{a_p}$. Differentiate with the Leibniz rule: every $\mathrm{d}(\mathrm{d}f^{a_i})$ vanishes by $\mathrm{d}^2=0$ on N, leaving $\mathrm{d}(g\circ f)\wedge\mathrm{d}f^{a_1}\wedge\ldots$, which is $f^*(\mathrm{d}g)\wedge f^*\mathrm{d}y^{a_1}\wedge\cdots = f^*(\mathrm{d}\omega)$ by the function case. Everything reduces to the chain rule plus $\mathrm{d}^2=0$.

Worked example T1.47: Checking naturality on the sphere (Dray §20.5)

Take $\beta = X\,\mathrm{d}Y$ on $\mathbb{R}^3$, so $\mathrm{d}\beta = \mathrm{d}X\wedge\mathrm{d}Y$. Pull back to the unit sphere with the angle map i of Example T1.45.
Differentiate first: $i^*(\mathrm{d}\beta) = i^*(\mathrm{d}X\wedge\mathrm{d}Y) = \sin\theta\cos\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi$, from step (3) of Example T1.45.
Pull back first:

$$\begin{aligned} i^*\beta &\overset{(1)}{=} \sin\theta\cos\phi\,(\cos\theta\sin\phi\,\mathrm{d}\theta + \sin\theta\cos\phi\,\mathrm{d}\phi) \\ &= \sin\theta\cos\theta\sin\phi\cos\phi\,\mathrm{d}\theta + \sin^2\theta\cos^2\phi\,\mathrm{d}\phi, \\ \mathrm{d}(i^*\beta) &\overset{(2)}{=} \sin\theta\cos\theta\,(\cos^2\phi - \sin^2\phi)\,\mathrm{d}\phi\wedge\mathrm{d}\theta + 2\sin\theta\cos\theta\cos^2\phi\,\mathrm{d}\theta\wedge\mathrm{d}\phi \\ &\overset{(3)}{=} \sin\theta\cos\theta\,(-\cos^2\phi + \sin^2\phi + 2\cos^2\phi)\mathrm{d}\theta\wedge\mathrm{d}\phi = \sin\theta\cos\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi. \end{aligned}$$

(1) Substitute $X = \sin\theta\cos\phi$ and $\mathrm{d}Y$ from Example T1.45.
(2) d of the $\mathrm{d}\theta$ term: only ∂_ϕ survives; d of the $\mathrm{d}\phi$ term: only ∂_θ survives.
(3) $\mathrm{d}\phi\wedge\mathrm{d}\theta = -\mathrm{d}\theta\wedge\mathrm{d}\phi$; then $\cos^2\phi+\sin^2\phi = 1$.

The two agree, as (T1.93) promised. Now use it. Integrate $\mathrm{d}X\wedge\mathrm{d}Y$ over the upper hemisphere H ($0\le\theta\le\pi/2$):

$$\int_H \sin\theta\cos\theta\,\mathrm{d}\theta\,\mathrm{d}\phi = 2\pi\cdot\tfrac{1}{2} = \pi,$$

while Stokes on the pulled-back form gives the integral of $X\,\mathrm{d}Y$ around the equator, $\int_0^{2\pi}\cos^2\phi\,\mathrm{d}\phi = \pi$. Both are the area of the unit disc: $\mathrm{d}X\wedge\mathrm{d}Y$ measures the *shadow* of the hemisphere on the XY-plane (Figure T1.25). Over the whole sphere the integral is 0: the shadows of the two hemispheres cancel, and the sphere has no boundary.

T1.8.6 Composition, winding and degree

Suppose we have two maps in a row, $P \xrightarrow{g} N \xrightarrow{f} M$. Pulling back along f first and then along g is the same as pulling back along the composite $f\circ g$ in one go:

$$(f\circ g)^* = g^*\circ f^* \qquad \text{for} \qquad P \xrightarrow{g} N \xrightarrow{f} M. \tag{T1.94}$$

The order reverses, just like $(AB)^{\mathsf{T}} = B^{\mathsf{T}}A^{\mathsf{T}}$, and for the same reason: (T1.89) is multiplication by a transposed Jacobian, and the Jacobian of a composite is the product of Jacobians (chain rule). We used this in Example T1.45(b).

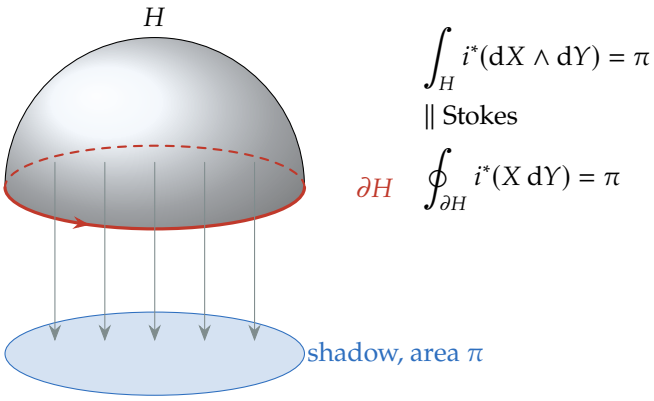

Figure T1.25: Naturality at work. The 2-form $dX \wedge dY$ pulled back to the upper hemisphere measures the area of its shadow on the XY-plane (the blue disc). Because $i^*d = di^*$, Stokes' theorem can be applied on the sphere itself, and the answer is the loop integral of $X\,dY$ around the red equator.

Naturality makes some pullbacks almost free. Here is the cleanest example.

Worked example T1.48: The squaring map pulls $d\phi$ back to $2\,d\phi$

Let $f : \mathbb{R}^2 \setminus \{0\} \to \mathbb{R}^2 \setminus \{0\}$ be $z \mapsto z^2$ in complex notation, i.e. $(x, y) \mapsto (x^2 - y^2,\ 2xy)$, and let $\beta = (x\,dy - y\,dx)/(x^2 + y^2)$ be the closed form of Example T1.30.

The quick way. In polar coordinates $f(r, \phi) = (r^2, 2\phi)$, and locally $\beta = d\phi$. By naturality, $f^*\beta = f^*d\phi = d(f^*\phi) = d(2\phi) = 2\,d\phi = 2\beta$.

The brute-force way, to see that nothing was swept under the rug. With $x' = x^2 - y^2$, $y' = 2xy$: $dx' = 2x\,dx - 2y\,dy$ and $dy' = 2y\,dx + 2x\,dy$. Then

$$\begin{aligned} x'dy' - y'dx' &\overset{(1)}{=} (x^2 - y^2)(2y\,dx + 2x\,dy) - 2xy(2x\,dx - 2y\,dy) \\ &\overset{(2)}{=} \big(2x^2y - 2y^3 - 4x^2y\big)dx + \big(2x^3 - 2xy^2 + 4xy^2\big)dy \\ &\overset{(3)}{=} 2(x^2 + y^2)\,(x\,dy - y\,dx), \\ f^*\beta &\overset{(4)}{=} \frac{2(x^2 + y^2)(x\,dy - y\,dx)}{(x^2 + y^2)^2} = 2\beta. \end{aligned}$$

(1) Substitute.
(2) Collect the dx and dy terms.
(3) $-2x^2y - 2y^3 = -2y(x^2 + y^2)$ and $2x^3 + 2xy^2 = 2x(x^2 + y^2)$.
(4) $x'^2 + y'^2 = (x^2 - y^2)^2 + 4x^2y^2 = (x^2 + y^2)^2$.

Integrating around the unit circle, $\oint f^*\beta = 2\oint \beta = 4\pi$: the image of the circle winds twice around the origin. For $z \mapsto z^n$ the same argument gives $f^*\beta = n\beta$. The number $\frac{1}{2\pi}\oint \gamma^*\beta$ is the **winding number** of a loop γ around the origin, and more generally $\int_N f^*\omega = (\deg f)\int_M \omega$ defines the **degree** of a map between closed oriented manifolds of the same dimension. For $\theta \mapsto n\theta$ on S^1, $f^*d\theta = n\,d\theta$, so $\deg f = n$.

Physical picture: Why pullbacks make cohomology a topological invariant

If $d\omega = 0$ then $d(f^*\omega) = f^*d\omega = 0$, and if $\omega = d\alpha$ then $f^*\omega = d(f^*\alpha)$. So f^* sends closed forms to closed forms and exact forms to exact forms: it gives a well-defined map

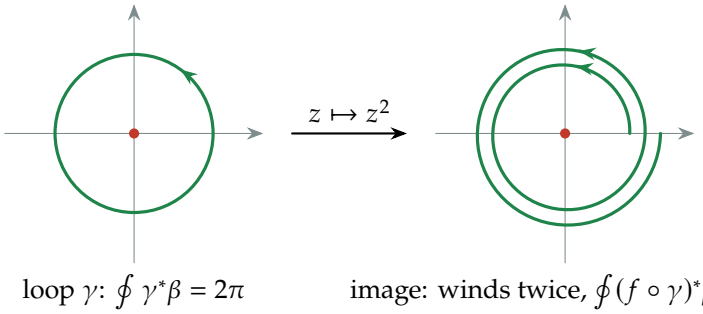

Figure T1.26: The squaring map doubles winding. The image loop (drawn slightly spread out so both turns are visible) goes around the origin twice. Algebraically this is the one-line statement $f^*\beta = 2\beta$, obtained from naturality: $f^*\mathrm{d}\phi = \mathrm{d}(f^*\phi) = \mathrm{d}(2\phi)$.

$f^* : H^p_{\mathrm{dR}}(M) \to H^p_{\mathrm{dR}}(N)$ on cohomology. Moreover, if f_t is a smooth family of maps, then $f_1^*\omega - f_0^*\omega$ is exact for closed ω (this follows from Cartan's formula of Section T1.9, integrated over t; Chapter T2). So homotopic maps induce the same map on cohomology. That is the property Nash quotes in (1.48) for bundles and uses implicitly for cohomology on p. 15.

Try it: Pullback under an orientation-reversing map

Let $r(x, y) = (x, -y)$ be the reflection of $\mathbb{R}^2$. Compute $r^*(\mathrm{d}x \wedge \mathrm{d}y)$ and $r^*\beta$, with β the angle form. What is the winding number of the reflected unit circle?
Answer: $r^*(\mathrm{d}x \wedge \mathrm{d}y) = \mathrm{d}x \wedge (-\mathrm{d}y) = -\mathrm{d}x \wedge \mathrm{d}y$ ($\det = -1$), and $r^*\beta = (x(-\mathrm{d}y) - (-y)\mathrm{d}x)/r^2 = -\beta$. The reflected circle winds -1 times: reflection reverses orientation, and the pullback records it as a sign.

Reading Nash (p. 15, (1.48)–(1.50); p. 27)

Nash introduces pullback on p. 15 in the language of cohomology: "the principal ingredient in any pullback calculation is a map $f : N \to M$, then if $\omega \in H^n(M; G)$ one can pull back ω to $f^*\omega$". For de Rham cohomology this is exactly our pullback of closed forms, which is well defined on classes because of naturality (T1.93). He then pulls back bundles, f^*E, and states that homotopic maps give isomorphic pullbacks (1.48); every bundle with group G is the pullback f^*E_G of a universal bundle, and its characteristic classes are pulled back from the classifying space, $f^* : H^*(BG) \to H^*(M)$ (1.50). All of these rest on the two properties we have established: $(f \circ g)^* = g^*f^*$ and $\mathrm{d}f^* = f^*\mathrm{d}$. His winding numbers and degrees of maps (Chapter 1, and the instanton number in Chapter 8) are the $\int f^*\omega$ of Example T1.48.

Recap

- $f : N \to M$ pushes vectors forward by the Jacobian, $(f_*v)^a = \partial_\mu f^a\, v^\mu$, and pulls forms back: $(f^*\omega)(v, \dots) = \omega(f_*v, \dots)$.
- Recipe: substitute $y = f(x)$ and $\mathrm{d}y^a = \partial_\mu f^a \mathrm{d}x^\mu$, then expand with the wedge rules. f^* respects $+$, $\wedge$ and products with functions.
- Top forms pull back by $\det J$; this is change of variables, with orientation sign. A line integral is $\int \gamma^*\alpha$; a flux is $\int \sigma^*(\star F)$; the induced metric is $f^*g = J^{\mathsf{T}} g J$.

- Naturality: $\mathrm{d}f^* = f^*\mathrm{d}$ (chain rule plus $\mathrm{d}^2 = 0$), and $(f \circ g)^* = g^* f^*$. Hence f^* acts on cohomology.
- f^* does not commute with $\star$ unless f is an isometry.
- Winding numbers and degrees: $\int f^*\omega = \deg f \int \omega$; $z \mapsto z^n$ pulls $\mathrm{d}\phi$ back to $n\,\mathrm{d}\phi$.

T1.9 Interior product, Lie derivative and Cartan's formula

Physics is full of questions of the form "how does this field change as we slide along that flow?". A fluid carries a density and a magnetic field along with it; does the magnetic flux through a comoving loop change? A Hamiltonian flow moves points of phase space; does it squeeze phase-space area? A rotation moves points of a sphere; does it change the metric? In Nash's Chapter 5 the question is: which changes of the metric g of a Riemann surface are "fake", produced merely by sliding the surface along a vector field V (a diffeomorphism), and which change its true shape?

The tool that answers all these questions is the **Lie derivative** $\mathcal{L}_X$: the rate of change of a field as it is dragged along the flow of a vector field X. It sounds complicated, since it involves solving the flow equations, but for forms it collapses to a two-term formula, *Cartan's formula* $\mathcal{L}_X = \mathrm{d}\,\iota_X + \iota_X\mathrm{d}$, which needs only d and one very simple algebraic operation ι_X, "insert X in the first slot". We start with that operation.

T1.9.1 The interior product: feeding a form one vector

A p-form eats p vectors and returns a number. If we feed it only one vector X and leave the other slots open, what remains is a machine that eats $p-1$ vectors: a $(p-1)$-form.

Working definition T1.23 (interior product)

For a vector field X and a p-form α, the **interior product** (or contraction) $\iota_X\alpha$ is the $(p-1)$-form

$$(\iota_X\alpha)(v_2,\dots,v_p) = \alpha(X, v_2,\dots,v_p), \qquad (\iota_X\alpha)_{\nu_2\dots\nu_p} = X^\mu \alpha_{\mu\nu_2\dots\nu_p}. \tag{T1.95}$$

On functions $\iota_X f = 0$. *Recipe:* for a 1-form, $\iota_X \mathrm{d}x^\mu = X^\mu$. For a wedge product, move each factor to the front in turn, with the sign of the move [each move past one 1-form factor gives -1, e.g. $\iota_X(\mathrm{d}x\wedge\mathrm{d}y) = X^x\mathrm{d}y - X^y\mathrm{d}x$], and replace it by its value on X (the antiderivation rule (T1.96) below).

The component formula follows from the $1/p!$ convention (T1.22): in $\alpha = \frac{1}{p!}\alpha_{\mu_1\dots\mu_p}\mathrm{d}x^{\mu_1}\wedge\dots$, inserting X can hit any of the p factors, and after moving each one to the front the p contributions are equal, turning $\frac{1}{p!}$ into $\frac{p}{p!} = \frac{1}{(p-1)!}$, which is the normalisation of a $(p-1)$-form.

Let us see it act. In $\mathbb{R}^2$ with $X = X^x\partial_x + X^y\partial_y$,

$$\iota_X(\mathrm{d}x\wedge\mathrm{d}y) \overset{(1)}{=} (\mathrm{d}x\wedge\mathrm{d}y)(X,\cdot) \overset{(2)}{=} \mathrm{d}x(X)\,\mathrm{d}y - \mathrm{d}y(X)\,\mathrm{d}x \overset{(3)}{=} X^x\,\mathrm{d}y - X^y\,\mathrm{d}x.$$

(1) Definition (T1.95): fill the first slot with X.
(2) The determinant rule for a wedge of two 1-forms: $(a\wedge b)(X,w) = a(X)b(w) - b(X)a(w)$.
(3) $\mathrm{d}x(X) = X^x$ and $\mathrm{d}y(X) = X^y$.

In particular $\iota_{\partial_x}(\mathrm{d}x \wedge \mathrm{d}y) = \mathrm{d}y$ and $\iota_{\partial_y}(\mathrm{d}x \wedge \mathrm{d}y) = -\mathrm{d}x$: to contract with ∂_y we first move $\mathrm{d}y$ to the front, which costs a sign.

Key idea: The interior product is an antiderivation

For a p-form α and any form β,

$$\iota_X(\alpha \wedge \beta) = (\iota_X \alpha) \wedge \beta + (-1)^p\, \alpha \wedge \iota_X \beta, \qquad \iota_X \iota_X = 0. \tag{T1.96}$$

This is the same sign rule as for d (T1.46): an operator of odd degree picks up $(-1)^p$ when it moves past a p-form.

For two 1-forms the rule is exactly step (2) above: $\iota_X(a \wedge b) = a(X)\, b - b(X)\, a = (\iota_X a)\, b - a\, (\iota_X b)$. The general case follows by writing forms as sums of wedges of 1-forms and applying the two-factor case repeatedly. And $\iota_X \iota_X \alpha = \alpha(X, X, \dots) = 0$ because α is antisymmetric; this is the algebraic twin of $\mathrm{d}^2 = 0$.

The three-dimensional dictionary for ι_X

In $\mathbb{R}^3$ with $\mathrm{vol} = \mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z$ and the dictionary of Section T1.3 (a vector $\vec{A}$ corresponds to the 1-form $A = \vec{A} \cdot \mathrm{d}\vec{r}$ and to the flux 2-form $\star A$), the interior product with $X = \vec{X} \cdot \nabla$ is:

$$\begin{aligned} \iota_X A &= \vec{X} \cdot \vec{A}, \\ \iota_X(\star B) &= (\vec{B} \times \vec{X}) \cdot \mathrm{d}\vec{r}, \\ \iota_X(\rho\, \mathrm{vol}) &= \rho \star X = \text{flux form of } \rho \vec{X}. \end{aligned} \tag{T1.97}$$

The first is (T1.95) for 1-forms. For the second, use the recipe term by term:

$$\begin{aligned} &\iota_X\big(B_x\, \mathrm{d}y \wedge \mathrm{d}z + B_y\, \mathrm{d}z \wedge \mathrm{d}x + B_z\, \mathrm{d}x \wedge \mathrm{d}y\big) \\ &\overset{(1)}{=} B_x(X^y \mathrm{d}z - X^z \mathrm{d}y) + B_y(X^z \mathrm{d}x - X^x \mathrm{d}z) + B_z(X^x \mathrm{d}y - X^y \mathrm{d}x) \\ &\overset{(2)}{=} (B_y X^z - B_z X^y)\, \mathrm{d}x + (B_z X^x - B_x X^z)\, \mathrm{d}y + (B_x X^y - B_y X^x)\, \mathrm{d}z \\ &\overset{(3)}{=} (\vec{B} \times \vec{X}) \cdot \mathrm{d}\vec{r}. \end{aligned}$$

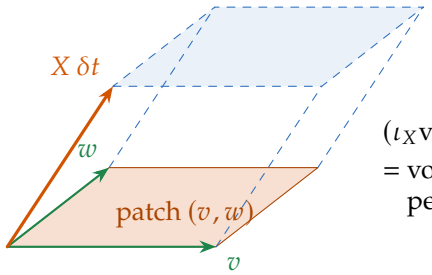
(1) $\iota_X(a \wedge b) = a(X)b - b(X)a$ on each basis 2-form.
(2) Collect the coefficients of $\mathrm{d}x$, $\mathrm{d}y$, $\mathrm{d}z$.
(3) $(\vec{B} \times \vec{X})_x = B_y X^z - B_z X^y$, and cyclically.

For the third, $\iota_X(\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z) = X^x\, \mathrm{d}y \wedge \mathrm{d}z - X^y\, \mathrm{d}x \wedge \mathrm{d}z + X^z\, \mathrm{d}x \wedge \mathrm{d}y$ (move each factor to the front: $\mathrm{d}y$ costs one sign, $\mathrm{d}z$ two), and $-\mathrm{d}x \wedge \mathrm{d}z = \mathrm{d}z \wedge \mathrm{d}x$, so this is $X^x\, \mathrm{d}y \wedge \mathrm{d}z + X^y\, \mathrm{d}z \wedge \mathrm{d}x + X^z\, \mathrm{d}x \wedge \mathrm{d}y = \star X$.

So the flux 2-form of the position vector, $\omega = X\, \mathrm{d}Y \wedge \mathrm{d}Z + Y\, \mathrm{d}Z \wedge \mathrm{d}X + Z\, \mathrm{d}X \wedge \mathrm{d}Y$ of Example T1.45, is $\iota_{\vec{r}}\, \mathrm{vol}$, as promised there. The same computation in n dimensions (Riemannian) gives

$$\iota_X \mathrm{vol} = \star X^\flat, \tag{T1.98}$$

where $X^\flat = g_{\mu\nu} X^\nu \mathrm{d}x^\mu$ is the 1-form obtained by lowering the index (Section T1.2). The third line of (T1.97) has a physical reading: a charge density ρ moving with velocity $\vec{v}$ gives $\iota_v(\rho\, \mathrm{vol}) = \star J$ with $\vec{J} = \rho \vec{v}$. *Contracting a density with a velocity gives the current.*



$(\iota_X \mathrm{vol})(v,w) = \mathrm{vol}(X,v,w)$
= volume swept by the patch per unit time

Figure T1.27: What $\iota_X \mathrm{vol}$ measures. A fluid moving with velocity X sweeps the orange patch spanned by v, w through the blue parallelepiped in time δt. Its volume, divided by δt, is $\mathrm{vol}(X,v,w)$: the amount of fluid crossing the patch per unit time. That is why $\iota_X \mathrm{vol}$ is the flux 2-form of X, and $\iota_v(\rho\,\mathrm{vol})$ is the current 2-form of a moving charge density.

Worked example T1.49: The Lorentz force as a contraction

In Example T1.37 we inserted the 4-velocity $u = \partial_t + \vec{v}\cdot\nabla$ into the *second* slot of F. With our first-slot convention that is $F(\,\cdot\,, u) = -\iota_u F$. Let us recompute it with the recipe, using $F = E\wedge \mathrm{d}t + \star_3 B$ (T1.64):

$$\iota_u(E\wedge \mathrm{d}t) \overset{(1)}{=} (\iota_u E)\,\mathrm{d}t - E\,(\iota_u \mathrm{d}t) \overset{(2)}{=} (\vec{E}\cdot\vec{v})\,\mathrm{d}t - E,$$
$$\iota_u(\star_3 B) \overset{(3)}{=} \iota_v(\star_3 B) \overset{(4)}{=} (\vec{B}\times\vec{v})\cdot \mathrm{d}\vec{r},$$
$$-q\,\iota_u F \overset{(5)}{=} q\,(\vec{E} + \vec{v}\times\vec{B})\cdot\mathrm{d}\vec{r} - q\,(\vec{E}\cdot\vec{v})\,\mathrm{d}t.$$

(1) Antiderivation rule (T1.96) with the 1-form E.
(2) E has no $\mathrm{d}t$ part, so $\iota_u E = \vec{v}\cdot\vec{E}$; and $\iota_u \mathrm{d}t = u^t = 1$.
(3) $\star_3 B$ contains no $\mathrm{d}t$, so the ∂_t part of u gives nothing.
(4) Second line of (T1.97).
(5) Add, multiply by $-q$, and use $-\vec{B}\times\vec{v} = \vec{v}\times\vec{B}$.

This is the answer of Example T1.37, obtained without writing the 4×4 matrix: the magnetic force $\vec{v}\times\vec{B}$ is literally the flux form $\star_3 B$ with the velocity inserted.

T1.9.2 Flows of vector fields

A vector field X assigns an arrow to every point. Its **integral curves** are the curves that follow the arrows,

$$\frac{\mathrm{d}x^\mu(t)}{\mathrm{d}t} = X^\mu\big(x(t)\big), \tag{T1.99}$$

a system of first-order ODEs that has a unique solution through every starting point (at least for a short time). The **flow** of X is the family of maps φ_t that sends each point to where its integral curve is after time t. Uniqueness of solutions gives the group law

$$\varphi_0 = \mathrm{id}, \qquad \varphi_s\circ\varphi_t = \varphi_{s+t}, \qquad \varphi_t^{-1} = \varphi_{-t}, \tag{T1.100}$$

and for small t,

$$\varphi_t(x)^\mu = x^\mu + t\,X^\mu(x) + O(t^2). \tag{T1.101}$$

Physicists write $\varphi_t = \exp(tX)$, and so does Nash [Nash p. 159, (5.66)]: the vector field is the infinitesimal generator of the one-parameter group of diffeomorphisms, just as the angular momentum operator generates rotations.

Worked example T1.50: Three flows in the plane

(a) Translation, $X = \partial_x$: $\dot{x} = 1$, $\dot{y} = 0$, so $\varphi_t(x, y) = (x + t, y)$.
(b) Rotation, $X = \partial_\phi = -y\,\partial_x + x\,\partial_y$ (Example T1.5):

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix} x \\ y \end{pmatrix} \overset{(1)}{=} \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} x \\ y \end{pmatrix} \quad\Longrightarrow\quad \varphi_t \begin{pmatrix} x \\ y \end{pmatrix} \overset{(2)}{=} \exp\begin{pmatrix} 0 & -t \\ t & 0 \end{pmatrix}\begin{pmatrix} x \\ y \end{pmatrix} \overset{(3)}{=} \begin{pmatrix} \cos t & -\sin t \\ \sin t & \cos t \end{pmatrix}\begin{pmatrix} x \\ y \end{pmatrix}.$$

(1) Read off $\dot{x} = -y$, $\dot{y} = x$ from the components of X.
(2) A linear ODE $\dot{\mathbf{x}} = A\mathbf{x}$ is solved by $\mathbf{x}(t) = e^{tA}\mathbf{x}(0)$.
(3) Sum the exponential series: $A^2 = -\mathbb{1}$, so $e^{tA} = \cos t\,\mathbb{1} + \sin t\,A$.

The flow is rotation by angle t; here "$\varphi_t = \exp(tX)$" is literally a matrix exponential.
(c) Dilation, $X = x\,\partial_x + y\,\partial_y = r\,\partial_r$: $\dot{x} = x$, $\dot{y} = y$, so $\varphi_t(x, y) = (e^t x, e^t y)$, scaling by e^t.

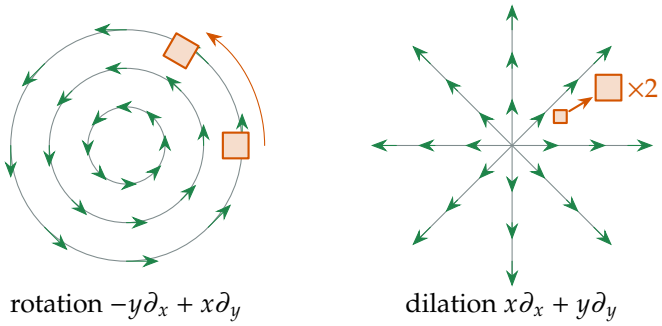


Figure T1.28: The flows of Example T1.50(b) and (c). Green arrows are the vector field; the orange square is carried along by the flow. The rotation moves the square without changing its area or shape; the dilation doubles its side and quadruples its area. The Lie derivatives $\mathcal{L}_X\mathrm{vol} = 0$ and $\mathcal{L}_X\mathrm{vol} = 2\,\mathrm{vol}$ of Example T1.51 are the infinitesimal versions of these two facts.

T1.9.3 The Lie derivative

To compare a field at $\varphi_t(p)$ with the field at p we must bring it back to p, and pullback is exactly the tool that does this without any choices (Section T1.8).

Working definition T1.24 (Lie derivative)

The **Lie derivative** of a function, form or metric T along X [along the flow φ_t of X: $\varphi_t(p)$ is where p arrives after time t following $\dot{x}^\mu = X^\mu$] is

$$\mathcal{L}_X T = \left.\frac{\mathrm{d}}{\mathrm{d}t}\right|_{t=0} \varphi_t^* T. \tag{T1.102}$$

For a vector field Y, "pull back" means push forward by the inverse, $\varphi_t^* Y = (\varphi_{-t})_* Y$. *Operationally:* use the first-order flow (T1.101), substitute, and keep the terms linear in t. The results are the component formulae (T1.103).

Functions. $\varphi_t^* f(x) = f(x + tX) = f(x) + tX^\mu \partial_\mu f + O(t^2)$, so $\mathcal{L}_X f = X(f)$: the directional derivative, nothing new.

1-forms. By the pullback rule (T1.89),

$$(\varphi_t^*\alpha)_\mu(x) \overset{(1)}{=} \frac{\partial \varphi_t^\nu}{\partial x^\mu}\,\alpha_\nu\big(\varphi_t(x)\big) \overset{(2)}{=} \big(\delta_\mu^\nu + t\,\partial_\mu X^\nu\big)\big(\alpha_\nu + t\,X^\lambda \partial_\lambda \alpha_\nu\big) + O(t^2)$$

$$\overset{(3)}{=} \alpha_\mu + t\left(X^\lambda \partial_\lambda \alpha_\mu + \alpha_\nu\, \partial_\mu X^\nu\right) + O(t^2).$$

(1) A 1-form pulls back by the transposed Jacobian.
(2) Differentiate (T1.101) for the Jacobian, and Taylor expand α_ν about x.
(3) Multiply out and keep the terms of order t.

The first term is the naive "transport the components" derivative. The second is new: it says that even a 1-form with constant components changes if the flow rotates or stretches the coordinate grid.

Vector fields. Now we need $(\varphi_{-t})_*$ applied to Y at $\varphi_t(x)$. The Jacobian of φ_{-t} is $\delta^\mu_\nu - t\,\partial_\nu X^\mu$, so

$$\begin{aligned}\left((\varphi_{-t})_* Y\right)^\mu(x) &\overset{(1)}{=} \left(\delta^\mu_\nu - t\,\partial_\nu X^\mu\right) Y^\nu(x + tX) + O(t^2)\\ &\overset{(2)}{=} Y^\mu + t\left(X^\lambda \partial_\lambda Y^\mu - Y^\nu \partial_\nu X^\mu\right) + O(t^2).\end{aligned}$$

(1) Push forward (T1.85) with the Jacobian of φ_{-t}, applied to the vector sitting at $\varphi_t(x) = x + tX$.
(2) Taylor expand $Y^\nu(x + tX)$ and keep order t.

The bracket is the commutator of Section T1.5, $[X, Y]^\mu = X^\lambda \partial_\lambda Y^\mu - Y^\lambda \partial_\lambda X^\mu$.

Metrics. A metric pulls back with two Jacobians (T1.92), and the same expansion gives one ∂X term per index.

Key idea: Lie derivatives in components

$$\begin{aligned}\mathcal{L}_X f &= X^\lambda \partial_\lambda f,\\ (\mathcal{L}_X Y)^\mu &= [X, Y]^\mu = X^\lambda \partial_\lambda Y^\mu - Y^\lambda \partial_\lambda X^\mu,\\ (\mathcal{L}_X \alpha)_\mu &= X^\lambda \partial_\lambda \alpha_\mu + \alpha_\lambda\, \partial_\mu X^\lambda,\\ (\mathcal{L}_X g)_{\mu\nu} &= X^\lambda \partial_\lambda g_{\mu\nu} + g_{\lambda\nu}\, \partial_\mu X^\lambda + g_{\mu\lambda}\, \partial_\nu X^\lambda.\end{aligned} \tag{T1.103}$$

Pattern: transport term $X^\lambda \partial_\lambda$, then one correction per index, with a + for each lower index and a − for each upper index. Only first derivatives of X appear, and no metric or connection is needed.

Watch out: The Lie derivative is not a directional derivative

$\mathcal{L}_X Y$ depends on the derivatives of X, not only on its value at the point. Example: $X = \partial_x$ and $X' = x\,\partial_x$ agree at $x = 1$, but $\mathcal{L}_X \partial_x = [\partial_x, \partial_x] = 0$ while $\mathcal{L}_{X'} \partial_x = [x\partial_x, \partial_x] = -\partial_x$. The Lie derivative asks how a field changes *relative to the flow*, and the flow near a point depends on the whole vector field nearby. A derivative that depends only on X at the point needs extra structure, a connection (Chapter T2).

The Lie derivative obeys the Leibniz rule with respect to every product, because φ_t^* respects products and $\mathrm{d}/\mathrm{d}t$ obeys the product rule:

$$\mathcal{L}_X(\alpha \wedge \beta) = \mathcal{L}_X \alpha \wedge \beta + \alpha \wedge \mathcal{L}_X \beta, \qquad \mathcal{L}_X\big(\alpha(Y)\big) = (\mathcal{L}_X \alpha)(Y) + \alpha(\mathcal{L}_X Y). \tag{T1.104}$$

Let us check the second in components, since it ties the three formulae (T1.103) together:

$$\begin{aligned}(\mathcal{L}_X \alpha)_\mu Y^\mu + \alpha_\mu [X, Y]^\mu &\overset{(1)}{=} X^\lambda \partial_\lambda \alpha_\mu\, Y^\mu + \alpha_\lambda\, \partial_\mu X^\lambda\, Y^\mu + \alpha_\mu X^\lambda \partial_\lambda Y^\mu - \alpha_\mu Y^\lambda \partial_\lambda X^\mu\\ &\overset{(2)}{=} X^\lambda \partial_\lambda \alpha_\mu\, Y^\mu + \alpha_\mu X^\lambda \partial_\lambda Y^\mu \overset{(3)}{=} X^\lambda \partial_\lambda (\alpha_\mu Y^\mu) \overset{(4)}{=} \mathcal{L}_X\big(\alpha(Y)\big).\end{aligned}$$

(1) Insert (T1.103).
(2) The second and fourth terms cancel (rename $\lambda \leftrightarrow \mu$ in one of them).
(3) Product rule.
(4) $\alpha(Y)$ is a function, and $\mathcal{L}_X$ of a function is X of it.

The correction terms of $\mathcal{L}_X\alpha$ and $\mathcal{L}_X Y$ are designed to cancel in the scalar $\alpha(Y)$: that is the meaning of "+ for lower, − for upper".

Finally, since pullback commutes with d (T1.93), differentiating $\varphi_t^*\mathrm{d}\omega = \mathrm{d}\varphi_t^*\omega$ at $t = 0$ gives

$$\mathcal{L}_X \mathrm{d} = \mathrm{d}\mathcal{L}_X. \tag{T1.105}$$

T1.9.4 Cartan's magic formula

The component formula for $\mathcal{L}_X\alpha$ on a p-form has $p + 1$ terms. There is a much better way.

Key idea: Cartan's formula

On differential forms,

$$\mathcal{L}_X = \mathrm{d}\,\iota_X + \iota_X\,\mathrm{d}. \tag{T1.106}$$

To Lie-differentiate a form: contract and differentiate, differentiate and contract, add.

Check on 1-forms. With $\iota_X\alpha = X^\nu\alpha_\nu$ and $(\mathrm{d}\alpha)_{\nu\mu} = \partial_\nu\alpha_\mu - \partial_\mu\alpha_\nu$:

$$\begin{aligned}\big(\mathrm{d}\,\iota_X\alpha + \iota_X\mathrm{d}\alpha\big)_\mu &\overset{(1)}{=} \partial_\mu(X^\nu\alpha_\nu) + X^\nu(\partial_\nu\alpha_\mu - \partial_\mu\alpha_\nu)\\ &\overset{(2)}{=} \alpha_\nu\partial_\mu X^\nu + X^\nu\partial_\mu\alpha_\nu + X^\nu\partial_\nu\alpha_\mu - X^\nu\partial_\mu\alpha_\nu\\ &\overset{(3)}{=} X^\nu\partial_\nu\alpha_\mu + \alpha_\nu\partial_\mu X^\nu \overset{(4)}{=} (\mathcal{L}_X\alpha)_\mu.\end{aligned}$$

(1) Components of $\mathrm{d}f$ and of ι_X of a 2-form (first slot).
(2) Product rule on the first term.
(3) The $X^\nu\partial_\mu\alpha_\nu$ terms cancel.
(4) (T1.103).

The cancellation in step (3) is the whole trick: $\mathrm{d}\iota_X$ produces the unwanted term $X^\nu\partial_\mu\alpha_\nu$, and $\iota_X\mathrm{d}$ removes it while supplying the transport term.

Why it holds on all forms. Call the right-hand side $K = \mathrm{d}\iota_X + \iota_X\mathrm{d}$. Three facts:

(i) K agrees with $\mathcal{L}_X$ on functions: $Kf = \iota_X\mathrm{d}f = X(f)$ (the term $\mathrm{d}\iota_X f$ vanishes since $\iota_X f = 0$).

(ii) K commutes with d: $K\mathrm{d} = \mathrm{d}\iota_X\mathrm{d} = \mathrm{d}K$, using $\mathrm{d}^2 = 0$ on both sides. So does $\mathcal{L}_X$ (T1.105).

(iii) K obeys the ordinary Leibniz rule $K(\alpha\wedge\beta) = K\alpha\wedge\beta + \alpha\wedge K\beta$. This is because d and ι_X both pick up $(-1)^p$ past a p-form, so in $\mathrm{d}\iota_X + \iota_X\mathrm{d}$ the cross terms carry opposite signs and cancel. $\mathcal{L}_X$ obeys the same rule (T1.104).

Every form is locally a sum of terms $f\,\mathrm{d}x^{\mu_1}\wedge\cdots\wedge\mathrm{d}x^{\mu_p}$, built from functions by d and $\wedge$. Two operators that agree on functions, commute with d and obey the same Leibniz rule therefore agree on everything. (This is the same uniqueness argument that pinned down d in Section T1.5.)

Worked example T1.51: Rotations preserve area, dilations do not

Take $\mathrm{vol} = \mathrm{d}x \wedge \mathrm{d}y$. Since $\mathrm{d}\,\mathrm{vol} = 0$ (a 3-form on $\mathbb{R}^2$), Cartan gives $\mathcal{L}_X \mathrm{vol} = \mathrm{d}(\iota_X \mathrm{vol})$.
Rotation $X = -y\,\partial_x + x\,\partial_y$:

$$\mathcal{L}_X \mathrm{vol} \overset{(1)}{=} \mathrm{d}\big(X^x\,\mathrm{d}y - X^y\,\mathrm{d}x\big) \overset{(2)}{=} \mathrm{d}\big(-y\,\mathrm{d}y - x\,\mathrm{d}x\big) \overset{(3)}{=} -\mathrm{d}y \wedge \mathrm{d}y - \mathrm{d}x \wedge \mathrm{d}x = 0.$$

(1) $\iota_X(\mathrm{d}x \wedge \mathrm{d}y) = X^x \mathrm{d}y - X^y \mathrm{d}x$ (computed above).
(2) $X^x = -y$, $X^y = x$. Note that this 1-form is $-\mathrm{d}(r^2/2)$, exact.
(3) $\mathrm{d}(y\,\mathrm{d}y) = \mathrm{d}y \wedge \mathrm{d}y = 0$; likewise for x.

Dilation $X = x\,\partial_x + y\,\partial_y$:

$$\mathcal{L}_X \mathrm{vol} \overset{(1)}{=} \mathrm{d}\big(x\,\mathrm{d}y - y\,\mathrm{d}x\big) \overset{(2)}{=} \mathrm{d}x \wedge \mathrm{d}y - \mathrm{d}y \wedge \mathrm{d}x \overset{(3)}{=} 2\,\mathrm{d}x \wedge \mathrm{d}y.$$

(1) Same contraction with $X^x = x$, $X^y = y$.
(2) $\mathrm{d}(x\,\mathrm{d}y) = \mathrm{d}x \wedge \mathrm{d}y$, $\mathrm{d}(y\,\mathrm{d}x) = \mathrm{d}y \wedge \mathrm{d}x$.
(3) Antisymmetry.

Check against the flow. $\varphi_t(x, y) = (e^t x, e^t y)$ pulls $\mathrm{d}x \wedge \mathrm{d}y$ back to $e^{2t}\mathrm{d}x \wedge \mathrm{d}y$ (T1.90), whose t-derivative at $t = 0$ is $2\,\mathrm{d}x \wedge \mathrm{d}y$, in agreement with Cartan. For the rotation $\varphi_t^* \mathrm{vol} = \det(\text{rotation})\,\mathrm{vol} = \mathrm{vol}$ for all t.
The numbers 0 and 2 are the divergences of the two fields. In general, on a Riemannian manifold,

$$\mathcal{L}_X \mathrm{vol} \overset{(1)}{=} \mathrm{d}(\iota_X \mathrm{vol}) \overset{(2)}{=} \mathrm{d} \star X^\flat \overset{(3)}{=} (\mathrm{div}\, X)\,\mathrm{vol}, \qquad \mathrm{div}\, X = \frac{1}{\sqrt{g}}\,\partial_\mu\big(\sqrt{g}\,X^\mu\big). \tag{T1.107}$$

(1) Cartan, with $\mathrm{d}\,\mathrm{vol} = 0$ (top form).
(2) (T1.98).
(3) $\mathrm{d}\star$ of a 1-form is the divergence times vol (Section T1.5 and (T1.52)); in coordinates, $\iota_X(\sqrt{g}\,\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^n)$ has d equal to $\partial_\mu(\sqrt{g}\,X^\mu)\,\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^n$.

In polar coordinates, $X = r\,\partial_r$ and $\mathrm{vol} = r\,\mathrm{d}r \wedge \mathrm{d}\phi$ give $\iota_X \mathrm{vol} = r^2 \mathrm{d}\phi$ and $\mathrm{d}(r^2 \mathrm{d}\phi) = 2r\,\mathrm{d}r \wedge \mathrm{d}\phi = 2\,\mathrm{vol}$: the same answer in a different chart, as it must be. *The divergence is the fractional rate at which a flow expands volume.*

Worked example T1.52: Lie derivative of a 1-form, three ways

Let $X = -y\,\partial_x + x\,\partial_y$ (rotation) and $\alpha = x\,\mathrm{d}y$.
(1) From the flow. With $\varphi_t(x, y) = (x\cos t - y\sin t,\ x\sin t + y\cos t)$ from Example T1.50,

$$\varphi_t^*(x\,\mathrm{d}y) \overset{(1)}{=} (x\cos t - y\sin t)\,(\sin t\,\mathrm{d}x + \cos t\,\mathrm{d}y),$$
$$\frac{\mathrm{d}}{\mathrm{d}t}\Big|_0 \varphi_t^* \alpha \overset{(2)}{=} (-y)\,\mathrm{d}y + x\,\mathrm{d}x = x\,\mathrm{d}x - y\,\mathrm{d}y.$$

(1) Substitute the new x in the coefficient and d of the new y in the differential (T1.87).
(2) Product rule at $t = 0$: differentiating the first factor gives $(-x\sin t - y\cos t)|_0 = -y$ times $\mathrm{d}y$; differentiating the second gives x times $(\cos t\,\mathrm{d}x - \sin t\,\mathrm{d}y)|_0 = \mathrm{d}x$.

(2) From the components (T1.103), with $\alpha_x = 0$, $\alpha_y = x$: $(\mathcal{L}_X\alpha)_x = X^\lambda \partial_\lambda \alpha_x + \alpha_y \partial_x X^y = 0 + x \cdot 1 = x$, and $(\mathcal{L}_X\alpha)_y = X^\lambda \partial_\lambda \alpha_y + \alpha_y \partial_y X^y = X^x \cdot 1 + 0 = -y$.
(3) From Cartan:

$$\mathcal{L}_X \alpha \overset{(1)}{=} \mathrm{d}(x\,X^y) + \iota_X(\mathrm{d}x \wedge \mathrm{d}y) \overset{(2)}{=} \mathrm{d}(x^2) + (-y\,\mathrm{d}y - x\,\mathrm{d}x) \overset{(3)}{=} x\,\mathrm{d}x - y\,\mathrm{d}y.$$

(1) $\iota_X(x\,\mathrm{d}y) = x\,X^y$ and $\mathrm{d}(x\,\mathrm{d}y) = \mathrm{d}x \wedge \mathrm{d}y$.
(2) $X^y = x$; the contraction of the area form was computed in Example T1.51.
(3) $\mathrm{d}(x^2) = 2x\,\mathrm{d}x$.

Three methods, one answer. The Cartan route needed neither the flow nor index gymnastics.

T1.9.5 Physics with Cartan's formula

Worked example T1.53: Liouville's theorem

Phase space of one degree of freedom has coordinates (q, p) and the **symplectic form** $\omega = \mathrm{d}q \wedge \mathrm{d}p$. A Hamiltonian $H(q,p)$ generates the flow of Hamilton's equations, with vector field $X_H = \frac{\partial H}{\partial p}\,\partial_q - \frac{\partial H}{\partial q}\,\partial_p$. Then

$$\iota_{X_H}\omega \overset{(1)}{=} X_H^q\,\mathrm{d}p - X_H^p\,\mathrm{d}q \overset{(2)}{=} \frac{\partial H}{\partial p}\,\mathrm{d}p + \frac{\partial H}{\partial q}\,\mathrm{d}q \overset{(3)}{=} \mathrm{d}H,$$

$$\mathcal{L}_{X_H}\omega \overset{(4)}{=} \mathrm{d}(\iota_{X_H}\omega) + \iota_{X_H}\mathrm{d}\omega \overset{(5)}{=} \mathrm{d}\mathrm{d}H + 0 = 0.$$

(1) $\iota_X(\mathrm{d}q \wedge \mathrm{d}p) = \mathrm{d}q(X)\,\mathrm{d}p - \mathrm{d}p(X)\,\mathrm{d}q$.
(2) Components of X_H.
(3) Definition of $\mathrm{d}H$.
(4) Cartan's formula.
(5) $\mathrm{d}^2 = 0$, and $\mathrm{d}\omega = 0$ because ω has constant coefficients.

So Hamiltonian flows preserve phase-space area: **Liouville's theorem**, in two lines. Line (3) is worth remembering on its own: Hamilton's equations *are* $\iota_{X_H}\omega = \mathrm{d}H$. Energy conservation is $\mathcal{L}_{X_H}H = \iota_{X_H}\mathrm{d}H = \iota_{X_H}\iota_{X_H}\omega = 0$, by $\iota_X^2 = 0$. For the free particle $H = p^2/2$, $X_H = p\,\partial_q$ is a shear (Figure T1.29); for the oscillator $H = \frac{1}{2}(p^2+q^2)$, $X_H = p\,\partial_q - q\,\partial_p$ is a rotation. With n degrees of freedom $\omega = \sum_i \mathrm{d}q^i \wedge \mathrm{d}p_i$ and the same two lines show $\mathcal{L}_{X_H}\omega = 0$, hence $\mathcal{L}_{X_H}(\omega^n/n!) = 0$: the phase-space volume $\omega^n/n! = \mathrm{d}q^1 \wedge \mathrm{d}p_1 \wedge \ldots$ is conserved.

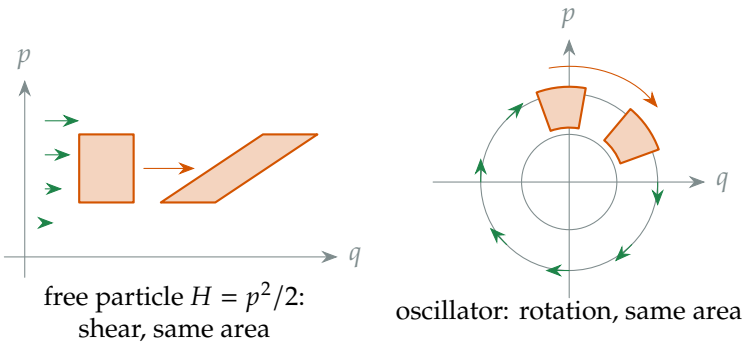

Figure T1.29: Liouville's theorem, $\mathcal{L}_{X_H}(\mathrm{d}q \wedge \mathrm{d}p) = 0$. Left: free motion shears a phase-space cell (fast particles overtake slow ones), but the area of the cell is unchanged. Right: the harmonic oscillator rotates phase space rigidly. In both cases $\iota_{X_H}\omega = \mathrm{d}H$ is exact, so $\mathcal{L}_{X_H}\omega = \mathrm{d}\mathrm{d}H = 0$.

Worked example T1.54: Faraday's flux rule for a moving loop

A wire loop C_t is carried along by a velocity field $\vec{v}$ (with flow φ_t), bounding a moving surface $S_t = \varphi_t(S_0)$. How fast does the magnetic flux $\Phi(t) = \int_{S_t} \mathcal{B}$ change? First, a general *transport rule*: for a time-dependent form ω_t,

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\varphi_t(S)} \omega_t \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}t}\int_S \varphi_t^*\omega_t \overset{(2)}{=} \int_S \varphi_t^*\big(\partial_t\omega_t + \mathcal{L}_v\omega_t\big) \overset{(3)}{=} \int_{\varphi_t(S)} \big(\partial_t\omega_t + \mathcal{L}_v\omega_t\big). \tag{T1.108}$$

(1) Integrals transform by pullback (T1.91).
(2) Product rule in t. The derivative of φ_t^* at time t is $\varphi_t^*\mathcal{L}_v$, because $\varphi_{t+h}^* = \varphi_t^*\varphi_h^*$ by the group law (T1.100) and (T1.94).
(3) Undo step (1).

Now take $\omega_t = \mathcal{B} = \star_3 B$, the magnetic flux 2-form. Then

$$\frac{\mathrm{d}\Phi}{\mathrm{d}t} \overset{(1)}{=} \int_{S_t} \big(\partial_t\mathcal{B} + \mathrm{d}_3\iota_v\mathcal{B} + \iota_v\mathrm{d}_3\mathcal{B}\big) \overset{(2)}{=} \int_{S_t} \big(-\mathrm{d}_3 E + \mathrm{d}_3\iota_v\mathcal{B}\big)$$
$$\overset{(3)}{=} -\oint_{C_t} \big(E - \iota_v\mathcal{B}\big) \overset{(4)}{=} -\oint_{C_t} \big(\vec{E} + \vec{v}\times\vec{B}\big)\cdot\mathrm{d}\vec{r}.$$

(1) Transport rule and Cartan's formula (in space; $\vec{v}$ is spatial).
(2) The metric-free Maxwell equations (T1.61): $\partial_t\mathcal{B} = -\mathrm{d}_3 E$ (Faraday) and $\mathrm{d}_3\mathcal{B} = 0$ (no monopoles).
(3) Stokes' theorem on S_t, whose boundary is C_t (Chapter T2).
(4) $\iota_v\mathcal{B} = (\vec{B}\times\vec{v})\cdot\mathrm{d}\vec{r} = -(\vec{v}\times\vec{B})\cdot\mathrm{d}\vec{r}$ by (T1.97).

The right-hand side is minus the EMF felt by charges riding on the wire: the electric force plus the magnetic Lorentz force. The "flux rule" $\mathcal{E} = -\mathrm{d}\Phi/\mathrm{d}t$, which in textbooks needs a separate argument for the motional part, is one application of Cartan's formula. Notice where each term came from: $\iota_v\mathrm{d}_3\mathcal{B}$ vanished because there are no magnetic monopoles, and $\mathrm{d}_3\iota_v\mathcal{B}$ is the motional EMF.

T1.9.6 Killing vectors: the Lie derivative of the metric

A flow is a *symmetry* of the geometry if it does not change the metric: $\varphi_t^* g = g$. Infinitesimally,

Working definition T1.25 (Killing and conformal Killing vectors)

X is a **Killing vector** if $\mathcal{L}_X g = 0$ [dragging along the flow of X leaves all lengths unchanged, e.g. a rotation of the plane]. It is a **conformal Killing vector** if $\mathcal{L}_X g = C\,g$ for some function C (its flow changes lengths but preserves angles). *Test:* compute $(\mathcal{L}_X g)_{\mu\nu}$ with (T1.103). In Cartesian coordinates on flat space, where $g_{\mu\nu} = \delta_{\mu\nu}$ is constant, this is simply $(\mathcal{L}_X g)_{\mu\nu} = \partial_\mu X_\nu + \partial_\nu X_\mu$.

Worked example T1.55: Killing vectors of the plane and of the sphere

Plane. For the rotation $X = -y\,\partial_x + x\,\partial_y$, $X_x = -y$, $X_y = x$, so $\partial_x X_y + \partial_y X_x = 1 - 1 = 0$ and the diagonal terms $2\partial_x X_x$, $2\partial_y X_y$ vanish: Killing. For the dilation $X = x\,\partial_x + y\,\partial_y$, $(\mathcal{L}_X g)_{\mu\nu} = 2\delta_{\mu\nu}$, so $\mathcal{L}_X g = 2g$: conformal Killing with $C = 2$ (scaling changes lengths uniformly and keeps angles). Translations are Killing trivially. The plane has three Killing vectors (∂_x, ∂_y, rotation) and, as we will see in Section T1.10, infinitely many conformal

Killing vectors.
Sphere. Take $g = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2$. For $X = \partial_\phi$ the components are constant and g does not depend on ϕ, so every term in (T1.103) vanishes: Killing. (Dray's slogan: a coordinate the metric does not depend on gives a Killing vector [Dray §A.1].) A less obvious one is the rotation about the X-axis of $\mathbb{R}^3$, the field $K = Z\partial_Y - Y\partial_Z$ (to avoid a clash with the Cartesian coordinate X, we call the vector field K here). On the sphere its components are $K^\theta = \sin\phi$, $K^\phi = \cot\theta\cos\phi$. To see this, differentiate $Z = \cos\theta$ and $\tan\phi = Y/X$ along the flow $\dot X = 0$, $\dot Y = Z$, $\dot Z = -Y$: $-\sin\theta\,\dot\theta = -\sin\theta\sin\phi$ gives $\dot\theta = \sin\phi$, and $\sec^2\phi\,\dot\phi = Z/X = \cos\theta/(\sin\theta\cos\phi)$ gives $\dot\phi = \cot\theta\cos\phi$. Then

$$(\mathcal{L}_K g)_{\theta\theta} \overset{(1)}{=} K^\lambda\partial_\lambda g_{\theta\theta} + 2g_{\theta\theta}\,\partial_\theta K^\theta = 0 + 2\,\partial_\theta(\sin\phi) = 0,$$

$$(\mathcal{L}_K g)_{\theta\phi} \overset{(2)}{=} g_{\phi\phi}\,\partial_\theta K^\phi + g_{\theta\theta}\,\partial_\phi K^\theta = \sin^2\theta\,\big(-\csc^2\theta\cos\phi\big) + \cos\phi = 0,$$

$$(\mathcal{L}_K g)_{\phi\phi} \overset{(3)}{=} K^\theta\partial_\theta g_{\phi\phi} + 2g_{\phi\phi}\,\partial_\phi K^\phi = \sin\phi\cdot 2\sin\theta\cos\theta + 2\sin^2\theta\,(-\cot\theta\sin\phi) = 0.$$

(1) $g_{\theta\theta} = 1$ is constant and $g_{\phi\theta} = 0$.
(2) $g_{\theta\phi} = 0$, so the transport term is absent; one correction term per index; $\partial_\theta\cot\theta = -\csc^2\theta$.
(3) $g_{\phi\phi} = \sin^2\theta$ depends on θ; $\partial_\phi(\cot\theta\cos\phi) = -\cot\theta\sin\phi$.

Each component cancels in a different way: an isometry of the round sphere that no coordinate makes obvious. The sphere has three Killing vectors, the rotations $\mathfrak{so}(3)$.

Physical picture: Killing vectors give conserved quantities

For a free particle moving on a curved space (a geodesic), the quantity $g(X,\dot x) = g_{\mu\nu}X^\mu\dot x^\nu$ is conserved whenever X is Killing. On the sphere with $X = \partial_\phi$ this is $\sin^2\theta\,\dot\phi$: the z-component of angular momentum. This is Noether's theorem in its simplest geometric form, and it is how Dray finds the conserved energy and angular momentum of orbits in Schwarzschild space-time [Dray §2.3, §A.1].

T1.9.7 Flows do not change cohomology

Here is the promise made in Section T1.8. Let ω be a closed form, $\mathrm{d}\omega = 0$, and φ_t the flow of X. Then

$$\varphi_t^*\omega - \omega \overset{(1)}{=} \int_0^t \frac{\mathrm{d}}{\mathrm{d}s}\varphi_s^*\omega\,\mathrm{d}s \overset{(2)}{=} \int_0^t \varphi_s^*\mathcal{L}_X\omega\,\mathrm{d}s \overset{(3)}{=} \int_0^t \varphi_s^*\mathrm{d}\,\iota_X\omega\,\mathrm{d}s \overset{(4)}{=} \mathrm{d}\Big(\int_0^t \varphi_s^*\iota_X\omega\,\mathrm{d}s\Big). \tag{T1.109}$$

(1) Fundamental theorem of calculus, since $\varphi_0^*\omega = \omega$.
(2) Derivative of φ_s^*, as in step (2) of (T1.108).
(3) Cartan's formula with $\mathrm{d}\omega = 0$.
(4) φ_s^* commutes with d (T1.93), and so does integration over the parameter s.

So $\varphi_t^*\omega$ and ω differ by an exact form: *sliding a closed form along any flow does not change its de Rham class*, and integrals of closed forms over closed cycles are unchanged. The same computation, done on the cylinder $[0,1]\times N$ with $X = \partial_t$, shows that any two homotopic maps $f_0, f_1 : N \to M$ satisfy $f_1^*\omega - f_0^*\omega = \mathrm{d}(K\omega)$ with $K\omega = \int_0^1 \iota_{\partial_t}F^*\omega\,\mathrm{d}t$, where F is the homotopy. This **homotopy formula** is behind the homotopy invariance of de Rham cohomology and of characteristic classes (Chapter T2, Chapter 1).

Try it: Is the angle form invariant?

With $\beta = \mathrm{d}\phi = (x\,\mathrm{d}y - y\,\mathrm{d}x)/r^2$, compute $\mathcal{L}_X\beta$ for the rotation $X = \partial_\phi$ and for the dilation $X = r\partial_r$ using Cartan.
Answer: $\mathrm{d}\beta = 0$, so $\mathcal{L}_X\beta = \mathrm{d}(\iota_X\beta)$. For the rotation $\iota_{\partial_\phi}\mathrm{d}\phi = 1$, and $\mathrm{d}1 = 0$. For the dilation $\iota_{r\partial_r}\mathrm{d}\phi = 0$. Both vanish: β is invariant under rotations and scalings, as the winding number (which it computes) should be.

T1.9.8 The Cartan calculus, collected

Dictionary: the six identities of the Cartan calculus

$\mathrm{d}^2 = 0, \quad \iota_X^2 = 0$	both odd operators square to zero
$\mathcal{L}_X = \mathrm{d}\iota_X + \iota_X\mathrm{d}$	Cartan's formula (T1.106)
$\mathcal{L}_X\mathrm{d} = \mathrm{d}\mathcal{L}_X$	flows commute with d (T1.105)
$\mathcal{L}_X\iota_Y - \iota_Y\mathcal{L}_X = \iota_{[X,Y]}$	contraction with a dragged vector
$\mathcal{L}_X\mathcal{L}_Y - \mathcal{L}_Y\mathcal{L}_X = \mathcal{L}_{[X,Y]}$	the flows represent the Lie algebra of vector fields
$(\mathrm{d} + \iota_X)^2 = \mathcal{L}_X$	equivariant d: squares to zero on X-invariant forms

The fourth identity follows from the Leibniz rule (T1.104) applied to $\alpha(Y, \dots)$. The fifth, on functions, is the definition of the commutator: $[\mathcal{L}_X, \mathcal{L}_Y]f = X(Yf) - Y(Xf) = [X, Y]f$. The last follows by squaring: $(\mathrm{d} + \iota_X)^2 = \mathrm{d}^2 + \mathrm{d}\iota_X + \iota_X\mathrm{d} + \iota_X^2 = \mathcal{L}_X$. It is the starting point of *equivariant cohomology* and of the localisation formulae used in topological field theory (Chapter 12): on forms that are invariant under the flow, $\mathrm{d}_X = \mathrm{d} + \iota_X$ is a new "differential" that squares to zero.

Watch out: Sign and slot conventions

We contract in the *first* slot. Some authors contract in the last slot, which changes ι_X by $(-1)^{p-1}$ on p-forms and moves signs around in (T1.96); Cartan's formula is the same in both conventions if the Leibniz rule is adjusted consistently. The commutator sign $[X, Y] = XY - YX$ is universal; but some books define $\mathcal{L}_X Y = -[X, Y]$ by pulling vectors with $(\varphi_t)_*$ instead of $(\varphi_{-t})_*$. Nash's footnote formula (5.71) agrees with ours.

Reading Nash (pp. 159–160, (5.66)–(5.73) and footnote 5; p. 166)

Nash needs the Lie derivative exactly once, but at a crucial point: the count of moduli of Riemann surfaces. A vector field V on the surface Σ exponentiates to a one-parameter family of diffeomorphisms $\alpha_t = \exp[tV]$ (his (5.66), our (T1.101)), which acts on metrics by $\alpha_t \cdot g$, and $g(t) = g(0) + t\mathcal{L}_V g(0) + \dots$ (5.68). So the metric perturbations that are pure diffeomorphisms are $\delta g_{ab} = \mathcal{L}_V g_{ab}$ (5.70), with the component formula (5.71),

$$\mathcal{L}_V g_{ab} = \frac{\partial g_{ab}}{\partial x^i} V^i + g_{ib}\frac{\partial V^i}{\partial x^a} + g_{ai}\frac{\partial V^i}{\partial x^b},$$

which is our (T1.103). In complex coordinates this gives $\delta\mu = 2\partial_{\bar z} V^z$ (5.72), which we derive in Example T1.61. His footnote 5 defines a conformal Killing vector by $\mathcal{L}_K g = Cg$, our working definition above; on p. 166 he uses the fact that the conformal Killing vectors of a torus form a 1-dimensional space, and (footnote 7, p. 165) that the sphere has a three-complex-parameter family, the Möbius transformations. Both counts are done explicitly in Example T1.60.

Recap

- ι_X inserts X in the first slot: $\iota_X \mathrm{d}x^\mu = X^\mu$; it is an antiderivation with $\iota_X^2 = 0$. In 3D: ι_X of a 1-form is a dot product, of a flux form a cross product, of a density a current. $\iota_X \mathrm{vol} = \star X^\flat$.
- The flow $\varphi_t = \exp(tX)$ solves $\dot{x} = X(x)$; the Lie derivative $\mathcal{L}_X T = \frac{\mathrm{d}}{\mathrm{d}t}\varphi_t^* T|_0$ measures change relative to the flow. Components: transport term plus one ∂X correction per index; $\mathcal{L}_X Y = [X, Y]$.
- Cartan: $\mathcal{L}_X = \mathrm{d}\iota_X + \iota_X \mathrm{d}$ on forms. Hence $\mathcal{L}_X \mathrm{vol} = (\operatorname{div} X)\mathrm{vol}$, Liouville's theorem, the flux rule, and invariance of cohomology under flows.
- Killing vectors: $\mathcal{L}_X g = 0$ (symmetries, conserved quantities); conformal Killing: $\mathcal{L}_X g = Cg$. These are the objects Nash counts in the moduli problem of Chapter 5.

T1.10 Complex coordinates and the Dolbeault operator

In two dimensions a physicist very often trades (x, y) for $z = x + \mathrm{i}y$ and $\bar{z} = x - \mathrm{i}y$. String theory and conformal field theory are written this way (Nash's Chapters 9 and 11), and so is the algebraic geometry of Riemann surfaces (Chapter 5). In Chapters 3 and 4 Nash uses the *Dolbeault complex*, the complex-analytic twin of the de Rham complex, as one of his four model elliptic complexes. All of it rests on one observation, which this section develops: in complex coordinates the exterior derivative splits into two halves,

$$\mathrm{d} = \partial + \bar{\partial},$$

and the half $\bar{\partial}$ is a machine for detecting holomorphic functions. The Cauchy–Riemann equations become the single equation $\bar{\partial} f = 0$, Cauchy's theorem becomes Stokes' theorem, and the Dolbeault cohomology groups measure how badly $\bar{\partial} f = g$ can fail to have global solutions.

T1.10.1 Complex-valued forms, $\mathrm{d}z$ and $\mathrm{d}\bar{z}$

Nothing we have done so far requires forms to have *real* coefficients. A **complex-valued form** is $\alpha + \mathrm{i}\beta$ with α, β real forms; $\wedge$, d, pullback and ι_X extend by linearity over $\mathbb{C}$. (Nash does exactly this on p. 103: he takes the de Rham complex "complex valued instead of real valued" so that it can be fed to the Chern character.) On $\mathbb{R}^2 = \mathbb{C}$ define

$$\mathrm{d}z = \mathrm{d}x + \mathrm{i}\,\mathrm{d}y, \qquad \mathrm{d}\bar{z} = \mathrm{d}x - \mathrm{i}\,\mathrm{d}y, \qquad \text{so} \qquad \mathrm{d}x = \tfrac{1}{2}(\mathrm{d}z + \mathrm{d}\bar{z}), \quad \mathrm{d}y = \tfrac{1}{2\mathrm{i}}(\mathrm{d}z - \mathrm{d}\bar{z}). \tag{T1.110}$$

These two complex 1-forms are a basis of complex 1-forms at each point, just as $\mathrm{d}x, \mathrm{d}y$ are.

The dual basis of (complex) vectors is fixed by $\mathrm{d}z(\partial_z) = 1$, $\mathrm{d}\bar{z}(\partial_z) = 0$, $\mathrm{d}z(\partial_{\bar{z}}) = 0$, $\mathrm{d}\bar{z}(\partial_{\bar{z}}) = 1$:

$$\partial_z = \tfrac{1}{2}\big(\partial_x - \mathrm{i}\,\partial_y\big), \qquad \partial_{\bar{z}} = \tfrac{1}{2}\big(\partial_x + \mathrm{i}\,\partial_y\big). \tag{T1.111}$$

Check one of the four conditions:

$$\mathrm{d}z(\partial_z) \overset{(1)}{=} (\mathrm{d}x + \mathrm{i}\,\mathrm{d}y)\big(\tfrac{1}{2}\partial_x - \tfrac{\mathrm{i}}{2}\partial_y\big) \overset{(2)}{=} \tfrac{1}{2} + \mathrm{i}\cdot\big(-\tfrac{\mathrm{i}}{2}\big) \overset{(3)}{=} 1.$$

(1) Definitions (T1.110) and (T1.111).
(2) Linearity, with $\mathrm{d}x(\partial_x) = \mathrm{d}y(\partial_y) = 1$ and the cross terms zero.
(3) $-\mathrm{i}^2 = 1$.

The same arithmetic gives $\mathrm{d}\bar{z}(\partial_z) = \frac{1}{2} + (-\mathrm{i})(-\frac{\mathrm{i}}{2}) = \frac{1}{2} - \frac{1}{2} = 0$. Consequently $\partial_z z = 1$, $\partial_z \bar{z} = 0$, and so on.

Watch out: Are z and $\bar{z}$ independent?

They are not independent as numbers: $\bar{z}$ is determined by z. But $\mathrm{d}z$ and $\mathrm{d}\bar{z}$ are linearly independent 1-forms, and ∂_z, $\partial_{\bar{z}}$ are independent (complex) vectors. Any smooth function of (x, y) can be written as a function of $(z, \bar{z})$ by substituting $x = (z + \bar{z})/2$, $y = (z - \bar{z})/2\mathrm{i}$, and then ∂_z, $\partial_{\bar{z}}$ act on it by the usual rules *as if* $z, \bar{z}$ were independent variables. Example: $\partial_z(z^2\bar{z}) = 2z\bar{z}$, $\partial_{\bar{z}}(z^2\bar{z}) = z^2$. This is a statement about the chain rule, not about the numbers.

Now expand the differential of a function in the new basis:

$$\mathrm{d}f \overset{(1)}{=} \partial_x f\,\mathrm{d}x + \partial_y f\,\mathrm{d}y \overset{(2)}{=} \tfrac{1}{2}(\partial_x - \mathrm{i}\partial_y)f\,\mathrm{d}z + \tfrac{1}{2}(\partial_x + \mathrm{i}\partial_y)f\,\mathrm{d}\bar{z} \overset{(3)}{=} \partial_z f\,\mathrm{d}z + \partial_{\bar{z}} f\,\mathrm{d}\bar{z}. \tag{T1.112}$$

(1) Definition of $\mathrm{d}f$.
(2) Substitute $\mathrm{d}x, \mathrm{d}y$ from (T1.110) and collect the $\mathrm{d}z$ and $\mathrm{d}\bar{z}$ terms: $\frac{1}{2}\partial_x f + \frac{1}{2\mathrm{i}}\partial_y f = \frac{1}{2}(\partial_x - \mathrm{i}\partial_y)f$, and similarly for $\mathrm{d}\bar{z}$.
(3) (T1.111).

We name the two halves:

$$\partial f = \partial_z f\,\mathrm{d}z, \qquad \bar{\partial} f = \partial_{\bar{z}} f\,\mathrm{d}\bar{z}, \qquad \mathrm{d}f = \partial f + \bar{\partial} f. \tag{T1.113}$$

Key idea: Holomorphic means $\bar{\partial} f = 0$

Write $f = u + \mathrm{i}v$. Then

$$2\,\partial_{\bar{z}} f \overset{(1)}{=} (\partial_x + \mathrm{i}\partial_y)(u + \mathrm{i}v) \overset{(2)}{=} (u_x - v_y) + \mathrm{i}\,(v_x + u_y).$$

(1) (T1.111).
(2) Multiply out; $\mathrm{i}^2 = -1$ turns $\mathrm{i}\partial_y(\mathrm{i}v)$ into $-v_y$.

So $\bar{\partial} f = 0$ is exactly the pair of Cauchy–Riemann equations $u_x = v_y$, $u_y = -v_x$: *f is holomorphic iff it does not depend on $\bar{z}$*. For holomorphic f, $\mathrm{d}f = f'(z)\,\mathrm{d}z$, and $\partial_z f$ is the complex derivative f'. This is Nash's remark after (3.25): "the familiar Cauchy–Riemann equations for a holomorphic function f are, of course, simply the statement $\bar{\partial} f = 0$".

Worked example T1.56: Four functions

(a) $f = z^2$: $\partial_{\bar{z}} f = 0$, holomorphic, $\mathrm{d}f = 2z\,\mathrm{d}z$. In real terms $z^2 = (x^2 - y^2) + 2\mathrm{i}xy$ and $\mathrm{d}(x^2 - y^2) + 2\mathrm{i}\,\mathrm{d}(xy) = 2(x + \mathrm{i}y)(\mathrm{d}x + \mathrm{i}\mathrm{d}y)$: check.
(b) $f = \bar{z}$: $\bar{\partial} f = \mathrm{d}\bar{z} \neq 0$. Complex conjugation is the basic non-holomorphic function (it reverses orientation).
(c) $f = |z|^2 = z\bar{z}$: $\mathrm{d}f = \bar{z}\,\mathrm{d}z + z\,\mathrm{d}\bar{z}$. Real, and not holomorphic; $\bar{\partial} f = z\,\mathrm{d}\bar{z}$.
(d) $f = e^z = e^x(\cos y + \mathrm{i}\sin y)$: $u_x = e^x \cos y = v_y$ and $u_y = -e^x \sin y = -v_x$, so it is holomorphic, and $\mathrm{d}f = e^z \mathrm{d}z$.

The Laplacian factorises through ∂_z and $\partial_{\bar{z}}$:

$$4\,\partial_z\partial_{\bar{z}} = (\partial_x - \mathrm{i}\partial_y)(\partial_x + \mathrm{i}\partial_y) = \partial_x^2 + \partial_y^2 = \nabla^2, \qquad \text{so} \qquad \Delta = -4\,\partial_z\partial_{\bar{z}} \tag{T1.114}$$

with our positive Δ of Section T1.6 (the cross terms $\pm\mathrm{i}\partial_x\partial_y$ cancel because partial derivatives commute). Hence *every holomorphic function is harmonic*: $\Delta f = -4\partial_z(\partial_{\bar{z}} f) = 0$, and so are its real and imaginary parts. This is why $\mathrm{Re}\, z^m = r^m \cos m\phi$ solved Laplace's equation in Example T1.32.

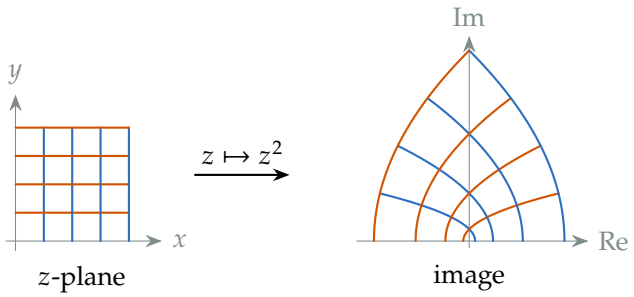

Figure T1.30: A holomorphic map preserves angles. The grid lines $x = \text{const}$ (blue) and $y = \text{const}$ (orange) in the first quadrant are carried by $z \mapsto z^2$ to two families of parabolas, $x' = a^2 - y^2$, $y' = 2ay$ and $x' = x^2 - b^2$, $y' = 2bx$, which still cross at right angles. Infinitesimally a holomorphic map is multiplication by the complex number $f'(z)$: a rotation times a scaling. This is why complex coordinates are the natural language of two-dimensional conformal geometry.

T1.10.2 Area, metric and Hodge star in complex coordinates

The area form and the metric take simple forms:

$$\mathrm{d}z \wedge \mathrm{d}\bar{z} \overset{(1)}{=} (\mathrm{d}x + \mathrm{i}\,\mathrm{d}y) \wedge (\mathrm{d}x - \mathrm{i}\,\mathrm{d}y) \overset{(2)}{=} -\mathrm{i}\,\mathrm{d}x \wedge \mathrm{d}y + \mathrm{i}\,\mathrm{d}y \wedge \mathrm{d}x \overset{(3)}{=} -2\mathrm{i}\,\mathrm{d}x \wedge \mathrm{d}y,$$
$$\mathrm{d}x \wedge \mathrm{d}y = \tfrac{\mathrm{i}}{2}\,\mathrm{d}z \wedge \mathrm{d}\bar{z}, \qquad \mathrm{d}s^2 = \mathrm{d}x^2 + \mathrm{d}y^2 = \mathrm{d}z\,\mathrm{d}\bar{z}. \tag{T1.115}$$

(1) (T1.110).
(2) $\mathrm{d}x \wedge \mathrm{d}x = \mathrm{d}y \wedge \mathrm{d}y = 0$; the cross terms are $\mathrm{d}x \wedge (-\mathrm{i}\mathrm{d}y)$ and $\mathrm{i}\,\mathrm{d}y \wedge \mathrm{d}x$.
(3) $\mathrm{d}y \wedge \mathrm{d}x = -\mathrm{d}x \wedge \mathrm{d}y$.

In the metric, $\mathrm{d}z\,\mathrm{d}\bar{z}$ is the *symmetric* product $\frac{1}{2}(\mathrm{d}z \otimes \mathrm{d}\bar{z} + \mathrm{d}\bar{z} \otimes \mathrm{d}z)$: $(\mathrm{d}x + \mathrm{i}\mathrm{d}y)(\mathrm{d}x - \mathrm{i}\mathrm{d}y) = \mathrm{d}x^2 + \mathrm{d}y^2$, the cross terms cancelling. So in the basis $(\mathrm{d}z, \mathrm{d}\bar{z})$ the metric has components $g_{zz} = g_{\bar{z}\bar{z}} = 0$, $g_{z\bar{z}} = g_{\bar{z}z} = \frac{1}{2}$, and the inverse metric has $g^{z\bar{z}} = 2$. A general metric on a surface can always be brought locally to the **conformal** (or isothermal) form $\mathrm{d}s^2 = \lambda\,\mathrm{d}z\,\mathrm{d}\bar{z}$ (Nash, p. 158).

The Hodge star on 1-forms, from the $\mathbb{R}^2$ table ($\star\mathrm{d}x = \mathrm{d}y$, $\star\mathrm{d}y = -\mathrm{d}x$, Example T1.20):

$$\star\mathrm{d}z \overset{(1)}{=} \star\mathrm{d}x + \mathrm{i} \star \mathrm{d}y \overset{(2)}{=} \mathrm{d}y - \mathrm{i}\,\mathrm{d}x \overset{(3)}{=} -\mathrm{i}\,(\mathrm{d}x + \mathrm{i}\,\mathrm{d}y) = -\mathrm{i}\,\mathrm{d}z, \qquad \star\mathrm{d}\bar{z} = +\mathrm{i}\,\mathrm{d}\bar{z}. \tag{T1.116}$$

(1) $\star$ is linear (over $\mathbb{C}$, for complex-valued forms).
(2) The $\mathbb{R}^2$ table.
(3) Factor out $-\mathrm{i}$: $-\mathrm{i} \cdot \mathrm{i}\,\mathrm{d}y = \mathrm{d}y$.

So $\mathrm{d}z$ and $\mathrm{d}\bar{z}$ are the *eigenvectors* of $\star$ on 1-forms, with eigenvalues $\mp\mathrm{i}$ (consistent with $\star\star = -1$ on 1-forms in two dimensions, (T1.35)). A 1-form $f\,\mathrm{d}z$ is called a $(1,0)$-form, and $f\,\mathrm{d}\bar{z}$ a $(0,1)$-form. Since $\star$ on 1-forms in two dimensions is conformally invariant (Section T1.4), this splitting depends only on the conformal class of the metric, i.e. on the *complex structure*. It is the two-dimensional instance of the decomposition by type that we now generalise.

Worked example T1.57: Cauchy's theorem is Stokes' theorem

Let f be any smooth complex function on a region D. Then

$$\mathrm{d}(f\,\mathrm{d}z) \overset{(1)}{=} \mathrm{d}f \wedge \mathrm{d}z \overset{(2)}{=} \partial_{\bar{z}} f\,\mathrm{d}\bar{z} \wedge \mathrm{d}z \overset{(3)}{=} 2\mathrm{i}\,\partial_{\bar{z}} f\,\mathrm{d}x \wedge \mathrm{d}y.$$

(1) Leibniz rule; $\mathrm{d}(\mathrm{d}z) = \mathrm{d}\mathrm{d}x + \mathrm{i}\,\mathrm{d}\mathrm{d}y = 0$.
(2) (T1.112); the $\mathrm{d}z \wedge \mathrm{d}z$ term vanishes.
(3) $\mathrm{d}\bar{z} \wedge \mathrm{d}z = -\mathrm{d}z \wedge \mathrm{d}\bar{z} = 2\mathrm{i}\,\mathrm{d}x \wedge \mathrm{d}y$ (T1.115).

So $f\,\mathrm{d}z$ is a closed 1-form exactly when f is holomorphic, and Stokes' theorem gives

$$\oint_{\partial D} f\,\mathrm{d}z = 2\mathrm{i}\int_D \partial_{\bar z} f\;\mathrm{d}x\,\mathrm{d}y, \tag{T1.117}$$

which vanishes for holomorphic f: **Cauchy's theorem**. The general formula (T1.117) measures the failure of holomorphy inside the loop, just as $\oint \vec{A}\cdot\mathrm{d}\vec{r}$ measures the curl inside a loop.

Worked example T1.58: $\bar\partial(1/z) = \pi\,\delta^2$ and the Cauchy integral formula

The function $1/z$ is holomorphic on $\mathbb{C}\setminus\{0\}$, so $\partial_{\bar z}(1/z) = 0$ there. What happens at 0? Test it against a smooth function φ of compact support, as one does with distributions: by definition $\int \partial_{\bar z}(1/z)\,\varphi\,\mathrm{d}^2x = -\int (1/z)\,\partial_{\bar z}\varphi\,\mathrm{d}^2x$. Remove a small disc $|z|<\varepsilon$ (its contribution is $O(\varepsilon)$, since $1/|z|$ is integrable in two dimensions):

$$-\int_{|z|>\varepsilon}\frac{\partial_{\bar z}\varphi}{z}\,\mathrm{d}^2x \overset{(1)}{=} -\int_{|z|>\varepsilon}\partial_{\bar z}\Big(\frac{\varphi}{z}\Big)\mathrm{d}^2x \overset{(2)}{=} -\frac{1}{2\mathrm{i}}\int_{|z|>\varepsilon}\mathrm{d}\Big(\frac{\varphi\,\mathrm{d}z}{z}\Big)$$
$$\overset{(3)}{=} +\frac{1}{2\mathrm{i}}\oint_{|z|=\varepsilon}\frac{\varphi\,\mathrm{d}z}{z} \overset{(4)}{=} \frac{1}{2\mathrm{i}}\int_0^{2\pi}\varphi(\varepsilon e^{\mathrm{i}\phi})\,\mathrm{i}\,\mathrm{d}\phi \xrightarrow{\varepsilon\to 0} \pi\,\varphi(0).$$

(1) $1/z$ is holomorphic on the region, so $\partial_{\bar z}$ passes through it.
(2) Example T1.57: $\mathrm{d}(g\,\mathrm{d}z) = 2\mathrm{i}\,\partial_{\bar z} g\,\mathrm{d}^2x$.
(3) Stokes. The region $|z|>\varepsilon$ has as its boundary the small circle traversed *clockwise* (φ vanishes far away), so $\int \mathrm{d}(\cdots) = -\oint_{\mathrm{ccw}}(\cdots)$.
(4) $z=\varepsilon e^{\mathrm{i}\phi}$, $\mathrm{d}z/z = \mathrm{i}\,\mathrm{d}\phi$ (this is the angle form again, Example T1.30).

Hence, as distributions,

$$\partial_{\bar z}\frac{1}{z} = \pi\,\delta^2(x,y), \qquad \partial_z\partial_{\bar z}\log|z|^2 = \pi\,\delta^2(x,y). \tag{T1.118}$$

The second follows from the first because $\partial_z \log|z|^2 = \partial_z(\log z + \log\bar z) = 1/z$. Two consequences. (i) With $\Delta = -4\partial_z\partial_{\bar z}$, the function $G = -\frac{1}{4\pi}\log|z|^2 = -\frac{1}{2\pi}\log r$ solves $\Delta G = \delta^2$: the Green function of the 2D Laplacian (the potential of a line charge). (ii) For f holomorphic on a disc D containing a, apply (T1.117) to $f(z)/(z-a)$: $\oint_{\partial D}\frac{f\,\mathrm{d}z}{z-a} = 2\mathrm{i}\int_D f\,\pi\delta^2(z-a)\,\mathrm{d}^2x = 2\pi\mathrm{i}\,f(a)$, the **Cauchy integral formula**. Similarly $\frac{1}{\pi z}$ is the Green function of $\partial_{\bar z}$: the equation $\partial_{\bar z} f = g$ is solved on $\mathbb{C}$ by

$$f(z) = \frac{1}{\pi}\int_{\mathbb{C}}\frac{g(w)}{z-w}\,\mathrm{d}^2w, \tag{T1.119}$$

for any smooth g of compact support. This is the $\bar\partial$-Poincaré lemma: *locally*, every $(0,1)$-form $g\,\mathrm{d}\bar z$ is $\bar\partial$ of something.

T1.10.3 Several complex variables: (p,q)-forms

On $\mathbb{C}^m$, with complex coordinates $z^j = x^j + \mathrm{i}y^j$ ($j=1,\dots,m$; real dimension $2m$), the complex 1-forms have the basis $\mathrm{d}z^1,\dots,\mathrm{d}z^m,\mathrm{d}\bar z^1,\dots,\mathrm{d}\bar z^m$.

Working definition T1.26 (forms of type (p,q))

A (p,q)**-form** is a sum of terms with p factors $\mathrm{d}z$ and q factors $\mathrm{d}\bar{z}$,

$$\omega = \frac{1}{p!\,q!}\,\omega_{i_1\dots i_p \bar{\jmath}_1\dots\bar{\jmath}_q}\,\mathrm{d}z^{i_1}\wedge\cdots\wedge\mathrm{d}z^{i_p}\wedge\mathrm{d}\bar{z}^{j_1}\wedge\cdots\wedge\mathrm{d}\bar{z}^{j_q} \tag{T1.120}$$

(Nash's (3.24), where as usual he omits the factorials). *Test:* rewrite the form in the basis $\mathrm{d}z^j, \mathrm{d}\bar{z}^j$ and count. Every complex k-form splits uniquely into types, $\Omega^k = \bigoplus_{p+q=k}\Omega^{p,q}$ (Nash's (3.27)) [e.g. on $\mathbb{C}$, $a\,\mathrm{d}x + b\,\mathrm{d}y = \frac{1}{2}(a-\mathrm{i}b)\,\mathrm{d}z + \frac{1}{2}(a+\mathrm{i}b)\,\mathrm{d}\bar{z}$].

Dimension count: at each point, choosing p of the m differentials $\mathrm{d}z^j$ and q of the m differentials $\mathrm{d}\bar{z}^j$ gives

$$\dim\Omega^{p,q}_x = \binom{m}{p}\binom{m}{q}, \qquad \sum_{p+q=k}\binom{m}{p}\binom{m}{q} = \binom{2m}{k}, \tag{T1.121}$$

and the second identity (Vandermonde's) says that the types add up to all k-forms on the real $2m$-dimensional space, as counted in (T1.21). For $\mathbb{C}^2$ ($m=2$) the numbers are arranged in Figure T1.31.

Working definition T1.27 (∂ and $\bar{\partial}$)

On a (p,q)-form $\omega = f\,\mathrm{d}z^I\wedge\mathrm{d}\bar{z}^J$ [$\mathrm{d}z^I = \mathrm{d}z^{i_1}\wedge\cdots\wedge\mathrm{d}z^{i_p}$ for the index list $I=(i_1,\dots,i_p)$, and likewise $\mathrm{d}\bar{z}^J$],

$$\partial\omega = \sum_{j=1}^{m}\frac{\partial f}{\partial z^j}\,\mathrm{d}z^j\wedge\mathrm{d}z^I\wedge\mathrm{d}\bar{z}^J, \qquad \bar{\partial}\omega = \sum_{j=1}^{m}\frac{\partial f}{\partial \bar{z}^j}\,\mathrm{d}\bar{z}^j\wedge\mathrm{d}z^I\wedge\mathrm{d}\bar{z}^J \tag{T1.122}$$

(Nash's (3.25), written as operators $\partial = \sum_j \mathrm{d}z^j\,\partial/\partial z^j$ and $\bar{\partial} = \sum_j \mathrm{d}\bar{z}^j\,\partial/\partial\bar{z}^j$) [$\partial/\partial z^j = \frac{1}{2}(\partial_{x^j} - \mathrm{i}\partial_{y^j})$ and $\partial/\partial\bar{z}^j = \frac{1}{2}(\partial_{x^j}+\mathrm{i}\partial_{y^j})$]. So $\partial:\Omega^{p,q}\to\Omega^{p+1,q}$ and $\bar{\partial}:\Omega^{p,q}\to\Omega^{p,q+1}$.

Key idea: The relations (3.26)

$$\mathrm{d} = \partial + \bar{\partial}, \qquad \partial^2 = 0, \qquad \bar{\partial}^2 = 0, \qquad \partial\bar{\partial} + \bar{\partial}\partial = 0. \tag{T1.123}$$

Why. The first is (T1.112) applied to each coefficient, $\mathrm{d}f = \sum_j(\partial_{z^j}f\,\mathrm{d}z^j + \partial_{\bar{z}^j}f\,\mathrm{d}\bar{z}^j)$, together with $\mathrm{d}(\mathrm{d}z^j) = \mathrm{d}(\mathrm{d}\bar{z}^j) = 0$. For the others, square it:

$$0 \overset{(1)}{=} \mathrm{d}^2 \overset{(2)}{=} \underbrace{\partial^2}_{(p+2,q)} + \underbrace{(\partial\bar{\partial}+\bar{\partial}\partial)}_{(p+1,q+1)} + \underbrace{\bar{\partial}^2}_{(p,q+2)}.$$

(1) $\mathrm{d}^2 = 0$ (T1.45).
(2) Expand $(\partial+\bar{\partial})^2$; each term changes the type by a definite amount, shown underneath.

A form is zero only if each of its type components is zero, so the three pieces vanish separately. Let us see the middle one at work on a function on $\mathbb{C}^2$:

$$\bar{\partial}\partial f + \partial\bar{\partial}f \overset{(1)}{=} \bar{\partial}\big(\partial_j f\,\mathrm{d}z^j\big) + \partial\big(\partial_{\bar{k}}f\,\mathrm{d}\bar{z}^k\big) \overset{(2)}{=} \partial_{\bar{k}}\partial_j f\,\mathrm{d}\bar{z}^k\wedge\mathrm{d}z^j + \partial_j\partial_{\bar{k}}f\,\mathrm{d}z^j\wedge\mathrm{d}\bar{z}^k \overset{(3)}{=} 0.$$

(1) (T1.122) on the function f (sum over j,k).

(2) (T1.122) again on each 1-form.
(3) Mixed partials commute, and $d\bar{z}^k \wedge dz^j = -dz^j \wedge d\bar{z}^k$.

It is the same mechanism as $d^2 = 0$ in Section T1.5: symmetric second derivatives against antisymmetric wedges.

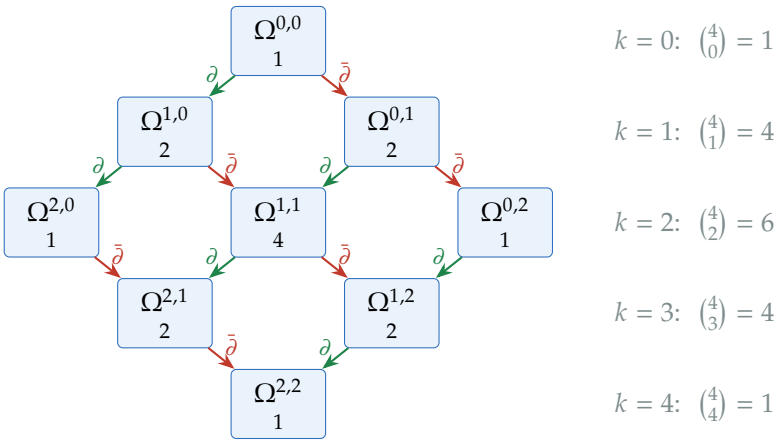

Figure T1.31: The (p, q)-forms on $\mathbb{C}^2$ with the dimension of each space at a point (small numbers). The row $p + q = k$ holds all k-forms, and the dimensions in a row add up to $\binom{4}{k}$. The green arrows are ∂ (down-left), the red arrows are $\bar{\partial}$ (down-right); d is their sum. A chain of red arrows running down to the right (fixed p) is a Dolbeault complex (T1.126).

Worked example T1.59: Computing with ∂ and $\bar{\partial}$ on $\mathbb{C}^2$; the Kähler form

(a) Let $\alpha = \bar{z}^1\, dz^2$, a $(1,0)$-form. Its coefficient depends only on $\bar{z}^1$, so $\partial\alpha = 0$ and $\bar{\partial}\alpha = d\bar{z}^1 \wedge dz^2 = -dz^2 \wedge d\bar{z}^1$, a $(1,1)$-form. Then $d\alpha = \partial\alpha + \bar{\partial}\alpha = d\bar{z}^1 \wedge dz^2$, which you can confirm by writing everything in x, y.
(b) Take the real function $K = |z|^2 = \sum_j z^j \bar{z}^j$. Then

$$\frac{i}{2}\,\partial\bar{\partial}K \overset{(1)}{=} \frac{i}{2}\,\partial\Big(\sum_j z^j\, d\bar{z}^j\Big) \overset{(2)}{=} \frac{i}{2}\sum_j dz^j \wedge d\bar{z}^j \overset{(3)}{=} \sum_j dx^j \wedge dy^j.$$

(1) $\partial_{\bar{z}^j} K = z^j$.
(2) $\partial_{z^k} z^j = \delta^j_k$.
(3) (T1.115) in each complex plane.

This $(1,1)$-form $\omega = \frac{i}{2}\partial\bar{\partial}K$ is the **Kähler form** of flat $\mathbb{C}^m$. It is real, closed ($d\omega = (\partial + \bar{\partial})\partial\bar{\partial}K = 0$ by (T1.123)), and, reading $z^j = q^j + ip_j$, it is the symplectic form $\sum dq^j \wedge dp_j$ of Example T1.53. A function K with $\omega = \frac{i}{2}\partial\bar{\partial}K$ is called a **Kähler potential**; Nash (5.29)–(5.30) defines Kähler manifolds by exactly this kind of closed $(1,1)$-form.

T1.10.4 Complex manifolds, and the Riemann sphere

A **complex manifold** of complex dimension m is a manifold with an atlas of charts valued in $\mathbb{C}^m$ whose transition maps are *holomorphic*. Holomorphic transitions are what make the type of a form chart-independent: if $w = w(z)$ is holomorphic, then $dw^j = \sum_k (\partial w^j/\partial z^k)\, dz^k$ contains no $d\bar{z}$, so a (p, q)-form in one chart is a (p, q)-form in every chart, and ∂, $\bar{\partial}$ are globally defined. (On a surface with a non-holomorphic transition, dw would pick up a $d\bar{z}$ part and the splitting would depend on the chart.)

The basic compact example is the Riemann sphere $\mathbb{CP}^1$, found in Section T1.1: two charts z (north) and w (flipped south), with $w = 1/z$ on the overlap $\mathbb{C} \setminus \{0\}$. There

$$\mathrm{d}w = -\frac{\mathrm{d}z}{z^2}, \qquad \mathrm{d}\bar{w} = -\frac{\mathrm{d}\bar{z}}{\bar{z}^2}, \qquad \partial_z = -w^2\,\partial_w. \tag{T1.124}$$

The last one is the chain rule $\partial_z = (\partial w/\partial z)\,\partial_w = -z^{-2}\partial_w = -w^2\partial_w$.

Worked example T1.60: Holomorphic 1-forms and vector fields on $\mathbb{CP}^1$ and on T^2

Holomorphic 1-forms on $\mathbb{CP}^1$. A global holomorphic $(1,0)$-form is $f(z)\,\mathrm{d}z$ in the north chart with f entire, and must also be holomorphic in the south chart:

$$f(z)\,\mathrm{d}z \overset{(1)}{=} -\frac{f(1/w)}{w^2}\,\mathrm{d}w.$$

(1) $z = 1/w$ and $\mathrm{d}z = -\mathrm{d}w/w^2$ (T1.124).

Regularity at $w = 0$ requires $f(z) = O(z^{-2})$ as $z \to \infty$. An entire function that tends to zero at infinity is bounded, hence constant (Liouville's theorem), hence zero. So $\mathbb{CP}^1$ has *no* holomorphic 1-forms: $\dim H^{1,0}(\mathbb{CP}^1) = 0$. This matches $b_1(S^2) = 0$.

Holomorphic vector fields on $\mathbb{CP}^1$. Now take $v(z)\,\partial_z$ with v entire. In the south chart it is $-w^2 v(1/w)\,\partial_w$, which is regular at $w = 0$ iff $v(z) = O(z^2)$ at infinity, i.e. iff v is a polynomial of degree at most 2:

$$v(z)\,\partial_z \in \mathrm{span}_{\mathbb{C}}\{\partial_z,\ z\,\partial_z,\ z^2\partial_z\}.$$

Their flows are the translations $z \mapsto z + a$, the dilations and rotations $z \mapsto \lambda z$, and the "special conformal" maps $z \mapsto z/(1 - cz)$: together the Möbius group $\mathrm{SL}(2,\mathbb{C})/\{\pm 1\}$, of complex dimension 3. This is Nash's footnote on p. 165: a three-complex-parameter family of conformal Killing vectors on the sphere.

The torus. $T^2 = \mathbb{C}/\Lambda$ with $\Lambda = \mathbb{Z} + \tau\mathbb{Z}$, $\mathrm{Im}\,\tau > 0$. A holomorphic vector field is $v(z)\partial_z$ with v entire and doubly periodic. Such a v is bounded (it is determined by its values on the compact fundamental parallelogram), hence constant. So the torus has exactly one (complex) holomorphic vector field, ∂_z, and by the same argument one holomorphic 1-form, $\mathrm{d}z$: Nash's "the space of conformal Killing vectors is 1-dimensional for genus one" (p. 166).

Why are holomorphic vector fields the same as conformal Killing vectors? Here is the computation Nash does on p. 160.

Worked example T1.61: Lie derivative of a metric in complex coordinates: Nash's $\delta\mu = 2\bar{\partial}V$

Take a conformal metric $g = \lambda\,\mathrm{d}z\,\mathrm{d}\bar{z}$, i.e. $g_{z\bar{z}} = g_{\bar{z}z} = \lambda/2$ and $g_{zz} = g_{\bar{z}\bar{z}} = 0$, and a real vector field $V = V^z\partial_z + V^{\bar{z}}\partial_{\bar{z}}$ with $V^{\bar{z}} = \overline{V^z}$ (for $V = V^x\partial_x + V^y\partial_y$ one has $V^z = V^x + \mathrm{i}V^y$). The component formula (T1.103) works in any basis of coordinates, including $z, \bar{z}$:

$$(\mathcal{L}_V g)_{\bar{z}\bar{z}} \overset{(1)}{=} V^\lambda\partial_\lambda g_{\bar{z}\bar{z}} + g_{\lambda\bar{z}}\,\partial_{\bar{z}}V^\lambda + g_{\bar{z}\lambda}\,\partial_{\bar{z}}V^\lambda \overset{(2)}{=} 2\,g_{z\bar{z}}\,\partial_{\bar{z}}V^z \overset{(3)}{=} \lambda\,\partial_{\bar{z}}V^z,$$

$$(\mathcal{L}_V g)_{z\bar{z}} \overset{(4)}{=} V^\lambda\partial_\lambda g_{z\bar{z}} + g_{z\bar{z}}\big(\partial_z V^z + \partial_{\bar{z}}V^{\bar{z}}\big).$$

(1) (T1.103) with $\mu = \nu = \bar{z}$; λ runs over $z, \bar{z}$.

(2) $g_{\bar{z}\bar{z}} = 0$ kills the first term; in the others only $\lambda = z$ survives, since $g_{\bar{z}\bar{z}} = 0$.

(3) $g_{z\bar{z}} = \lambda/2$ (the conformal factor; the letter λ in the summation index is unrelated).

(4) Same formula with $\mu = z$, $\nu = \bar{z}$: in the first correction term only $g_{\bar{z}\bar{z}}\ldots$ no: $g_{\lambda\bar{z}}\partial_z V^\lambda$ survives for $\lambda = z$, and $g_{z\lambda}\partial_{\bar{z}}V^\lambda$ for $\lambda = \bar{z}$.

The $(z\bar z)$ component is proportional to the metric itself: it only rescales λ. The $(\bar z\bar z)$ component, and its conjugate (zz), change the *shape*: they turn $\mathrm{d}z\,\mathrm{d}\bar z$ into $|\mathrm{d}z+\mu\,\mathrm{d}\bar z|^2$, a metric that is no longer conformal to the old one. Expanding Nash's perturbed line element $(\lambda+\delta\lambda)|\mathrm{d}z+\delta\mu\,\mathrm{d}\bar z|^2$ to first order gives $\delta g_{\bar z\bar z}=\lambda\,\delta\mu$, so a pure diffeomorphism produces

$$\delta\mu=\frac{(\mathcal{L}_V g)_{\bar z\bar z}}{\lambda}=\partial_{\bar z}V^z.$$

Nash normalises $g_{z\bar z}=\lambda$ instead of $\lambda/2$ and gets $\delta\mu=2\partial_{\bar z}V^z$ (5.72); as he says, the factor 2 is not significant. Two conclusions:

- V is a conformal Killing vector ($\mathcal{L}_V g\propto g$) iff $\partial_{\bar z}V^z=0$, i.e. iff $V^z\partial_z$ is a *holomorphic* vector field. On the plane there are infinitely many ($V^z=z^n$ for all $n\geq 0$; with the poles allowed at 0 these generate the Witt algebra of conformal field theory, Chapter 11). On $\mathbb{CP}^1$ there are three and on T^2 one (Example T1.60).
- The shape changes that are *not* fake are the Beltrami differentials $\delta\mu$ modulo those of the form $\bar\partial V$: a Dolbeault-type quotient "ker/Im $\bar\partial$". This is how Nash counts the moduli of Riemann surfaces in Chapter 5.

Worked example T1.62: The Fubini–Study form on $\mathbb{CP}^1$ has total integral 1

Define on the north chart

$$\omega_{FS}=\frac{\mathrm{i}}{2\pi}\,\partial\bar\partial\log\bigl(1+|z|^2\bigr). \tag{T1.125}$$

Compute:

$$\partial\bar\partial\log(1+z\bar z)\overset{(1)}{=}\partial\Bigl(\frac{z\,\mathrm{d}\bar z}{1+z\bar z}\Bigr)\overset{(2)}{=}\partial_z\Bigl(\frac{z}{1+z\bar z}\Bigr)\mathrm{d}z\wedge\mathrm{d}\bar z\overset{(3)}{=}\frac{(1+z\bar z)-z\bar z}{(1+z\bar z)^2}\,\mathrm{d}z\wedge\mathrm{d}\bar z=\frac{\mathrm{d}z\wedge\mathrm{d}\bar z}{(1+|z|^2)^2},$$

$$\omega_{FS}\overset{(4)}{=}\frac{\mathrm{i}}{2\pi}\cdot\frac{-2\mathrm{i}\,\mathrm{d}x\wedge\mathrm{d}y}{(1+r^2)^2}=\frac{1}{\pi}\frac{\mathrm{d}x\wedge\mathrm{d}y}{(1+r^2)^2},$$

$$\int_{\mathbb{CP}^1}\omega_{FS}\overset{(5)}{=}\frac{1}{\pi}\int_0^{2\pi}\!\!\int_0^{\infty}\frac{r\,\mathrm{d}r\,\mathrm{d}\phi}{(1+r^2)^2}\overset{(6)}{=}\frac{1}{\pi}\cdot 2\pi\cdot\frac{1}{2}=1.$$

(1) $\partial_{\bar z}\log(1+z\bar z)=z/(1+z\bar z)$.
(2) ∂ acts on the coefficient and puts $\mathrm{d}z$ in front.
(3) Quotient rule.
(4) (T1.115).
(5) The north chart covers everything except one point, which has zero area; polar coordinates.
(6) $\int_0^\infty r\,\mathrm{d}r/(1+r^2)^2=\bigl[-\frac{1}{2(1+r^2)}\bigr]_0^\infty=\frac12$.

Is ω_{FS} really a global form? In the south chart, the same formula with $w=1/z$ gives $\log(1+|w|^2)=\log(1+|z|^2)-\log|z|^2$, and $\partial\bar\partial\log|z|^2=0$ away from $z=0$ by (T1.118). So the two local definitions agree on the overlap. Comparing with the round metric in stereographic coordinates, $4\,\mathrm{d}u\,\mathrm{d}v/(1+\rho^2)^2$ (Example T1.9), ω_{FS} is the area form of the unit sphere divided by 4π. It is closed and real, and it is the first Chern form of the monopole (hyperplane) line bundle with unit charge: the "1" is the Dirac quantum of Section T1.7. Note that ω_{FS} is *locally* d-exact ($\frac{\mathrm{i}}{2\pi}\partial\bar\partial K=\mathrm{d}\bigl(\frac{\mathrm{i}}{2\pi}\bar\partial K\bigr)$) but not globally, since its integral over the closed surface $\mathbb{CP}^1$ is not zero (the exemplar argument: an exact form would integrate to zero).

Watch out: Normalisations of the Fubini–Study form

Nash (5.30) writes $\omega = \frac{\mathrm{i}}{2}\partial\bar\partial\ln(1+|z|^2)$, without the $1/\pi$; its integral over $\mathbb{CP}^1$ is π. Our ω_{FS} is normalised to integrate to 1 so that it represents the generator of $H^2(\mathbb{CP}^1;\mathbb{Z})$. Also, in (5.30) the factor $\frac{\mathrm{i}}{2}$ belongs with ω, not with the metric: the Hermitian metric coefficients are the real, positive-definite $g_{i\bar\jmath} = \partial_i\partial_{\bar\jmath}\ln(1+|z|^2) = \big[\delta_{ij}(1+|z|^2) - \bar z_i z_j\big]/(1+|z|^2)^2$.

T1.10.5 The Dolbeault complex and Dolbeault cohomology

Fix p. Since $\bar\partial^2 = 0$, the (p,q)-forms form a sequence in which each map composed with the next is zero:

$$0 \longrightarrow \Omega^{p,0} \xrightarrow{\bar\partial} \Omega^{p,1} \xrightarrow{\bar\partial} \Omega^{p,2} \xrightarrow{\bar\partial} \cdots \xrightarrow{\bar\partial} \Omega^{p,m} \longrightarrow 0. \tag{T1.126}$$

This is the **Dolbeault complex** (a chain of red arrows at fixed p in Figure T1.31), and exactly as for d one defines

Working definition T1.28 (Dolbeault cohomology)

$$H^{p,q}_{\bar\partial}(M) = \frac{\ker\big(\bar\partial : \Omega^{p,q} \to \Omega^{p,q+1}\big)}{\mathrm{Im}\big(\bar\partial : \Omega^{p,q-1} \to \Omega^{p,q}\big)}, \qquad h^{p,q} = \dim_{\mathbb{C}} H^{p,q}_{\bar\partial}(M). \tag{T1.127}$$

Operationally: a class is a $\bar\partial$-closed (p,q)-form, and two are equivalent if they differ by $\bar\partial$ of a $(p,q-1)$-form. The group $H^{0,0}$ is the space of global holomorphic functions [functions f on all of M with $\bar\partial f = 0$, i.e. $\partial f/\partial\bar z^j = 0$ for every j], and $H^{p,0}$ the space of global holomorphic p-forms [$(p,0)$-forms on all of M whose coefficient functions are holomorphic] (there is nothing to quotient by).

Locally the cohomology is trivial: (T1.119) solves $\bar\partial f = g\,\mathrm{d}\bar z$ on a disc (multiply g by a cut-off function first). So, as for de Rham cohomology, $H^{p,q}_{\bar\partial}$ is about *global* obstructions. Here is one, computed by hand.

Worked example T1.63: $\mathrm{d}\bar z$ on a torus is $\bar\partial$-closed but not $\bar\partial$-exact

On $T^2 = \mathbb{C}/(\mathbb{Z}+\tau\mathbb{Z})$ the constant form $\mathrm{d}\bar z$ is well defined (translations do not change it) and $\bar\partial$-closed (there are no $(0,2)$-forms in complex dimension 1). Suppose $\mathrm{d}\bar z = \bar\partial f$ for a smooth function f on the torus, i.e. a doubly periodic function on $\mathbb{C}$. Then:

$$\begin{aligned}
\partial_{\bar z}(f-\bar z) = 0 &\overset{(1)}{\Longrightarrow} f = \bar z + h(z),\ h \text{ entire}\\
&\overset{(2)}{\Longrightarrow} h(z+1)-h(z) = -1, \quad h(z+\tau)-h(z) = -\bar\tau\\
&\overset{(3)}{\Longrightarrow} h(z) = cz + d \ \text{ with } \ c=-1,\ c\tau = -\bar\tau\\
&\overset{(4)}{\Longrightarrow} \tau = \bar\tau,
\end{aligned}$$

(1) A function with $\partial_{\bar z} = 0$ is holomorphic.
(2) Periodicity of f under $z \mapsto z+1$ and $z \mapsto z+\tau$, with $\overline{z+\tau} = \bar z + \bar\tau$.
(3) Differentiating (2), h' is doubly periodic and entire, hence bounded, hence constant (Liouville); then read off c from (2).
(4) Combine the two conditions on c.

which contradicts $\mathrm{Im}\,\tau > 0$. So $[\mathrm{d}\bar z] \neq 0$ in $H^{0,1}(T^2)$. With a little Hodge theory (the harmonic $(0,1)$-forms on a flat torus are the constant multiples of $\mathrm{d}\bar z$) one finds $h^{0,1}(T^2) = 1$.

Together with $h^{1,0} = 1$ ($\mathrm{d}z$) this reproduces the de Rham count $b_1(T^2) = 2$: the classes $[\mathrm{d}x], [\mathrm{d}y]$ are recombined as $[\mathrm{d}z], [\mathrm{d}\bar{z}]$. Nash's (5.34)(i), $b_i = \sum_{p+q=i} h_{p,q}$, in the simplest non-trivial case.

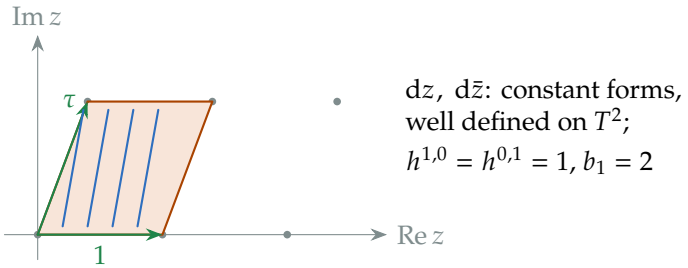

Figure T1.32: The torus $T^2 = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$: the orange parallelogram with opposite sides glued. Constant forms such as $\mathrm{d}z$ and $\mathrm{d}\bar{z}$ are invariant under the lattice translations and so live on T^2. The function $\bar{z}$ is *not* periodic, which is why $\mathrm{d}\bar{z} = \bar{\partial}\bar{z}$ is closed but not exact on the torus, the Dolbeault analogue of $\mathrm{d}x$ being closed but not exact on a circle.

Key idea: Nash's index of $\bar{\partial}$

For a compact complex manifold, Nash (4.64)–(4.65) defines the index of the Dolbeault complex with $p = 0$ as the alternating sum index $\bar{\partial} = \sum_q (-1)^q h^{0,q}$, the **arithmetic genus**. For a Riemann surface ($m = 1$) only $q = 0, 1$ occur, and $h^{0,0} = 1$ because the only global holomorphic functions on a compact surface are constants. So:

surface	$h^{0,0}$	$h^{1,0}$	$h^{0,1}$	b_1	index $\bar{\partial} = h^{0,0} - h^{0,1}$
$\mathbb{CP}^1 = S^2$	1	0	0	0	1
T^2	1	1	1	2	0
genus g	1	g	g	$2g$	$1 - g$

The entries for $\mathbb{CP}^1$ and T^2 are the hand computations of Examples T1.60 and T1.63, together with Hodge symmetry $h^{0,1} = h^{1,0}$ (Nash's (5.34)(iv)). The index $1 - g$ is what the index theorem computes from the Todd class (Chapter 4), and Riemann–Roch (Chapter 5) is its generalisation to $\bar{\partial}$ acting on sections of a line bundle.

T1.10.6 The symbol and the Laplacian of $\bar{\partial}$

Nash's index theory needs two more facts about $\bar{\partial}$: it is elliptic (as a complex), and its Laplacian is half the ordinary Laplacian on flat space. Both are quick computations on $\mathbb{C}$.

Symbol. Replacing $\partial_\mu \to \mathrm{i}k_\mu$ as in Section T1.6, write the real covector as $k = k_x\mathrm{d}x + k_y\mathrm{d}y = k_z\mathrm{d}z + k_{\bar{z}}\mathrm{d}\bar{z}$ with $k_z = \frac{1}{2}(k_x - \mathrm{i}k_y)$ and $k_{\bar{z}} = \frac{1}{2}(k_x + \mathrm{i}k_y)$. Then

$$\sigma(\bar{\partial})(k)\,\omega = \mathrm{i}\,k_{\bar{z}}\,\mathrm{d}\bar{z} \wedge \omega = \mathrm{i}\,k^{(0,1)} \wedge \omega, \tag{T1.128}$$

and $k_{\bar{z}} \neq 0$ for every real $k \neq 0$. The symbol sequence is therefore exact away from $k = 0$ (the analogue of the de Rham argument with $k\wedge$), which is Nash's statement that the symbol complex (4.66) is exact.

Adjoint and Laplacian. Use the Hermitian L^2 product $\langle \alpha, \beta \rangle = \int \alpha \wedge \star\bar{\beta}$ (the complex version of (T1.38)), for which $\langle f, h \rangle = \int f\bar{h}\,\mathrm{d}^2x$ and $\langle a\,\mathrm{d}\bar{z}, b\,\mathrm{d}\bar{z} \rangle = \int a\bar{b}\,|\mathrm{d}\bar{z}|^2\,\mathrm{d}^2x$ with $|\mathrm{d}\bar{z}|^2 =$

$|\mathrm{d}x|^2 + |\mathrm{d}y|^2 = 2$. For f and b of compact support,

$$\langle \bar\partial f,\, b\,\mathrm{d}\bar z\rangle \overset{(1)}{=} 2\int \partial_{\bar z} f\;\bar b\,\mathrm{d}^2x \overset{(2)}{=} -2\int f\,\partial_{\bar z}\bar b\,\mathrm{d}^2x \overset{(3)}{=} -2\int f\,\overline{\partial_z b}\,\mathrm{d}^2x \overset{(4)}{=} \big\langle f,\,-2\,\partial_z b\big\rangle.$$

(1) $\bar\partial f = \partial_{\bar z} f\,\mathrm{d}\bar z$ and $|\mathrm{d}\bar z|^2 = 2$.
(2) Integration by parts (no boundary terms).
(3) $\overline{\partial_z b} = \partial_{\bar z}\bar b$: conjugating swaps ∂_z and $\partial_{\bar z}$ (T1.111).
(4) Definition of $\langle f, h\rangle$.

So $\bar\partial^*(b\,\mathrm{d}\bar z) = -2\,\partial_z b$, and on functions

$$\Delta_{\bar\partial} f = \bar\partial^*\bar\partial f = -2\,\partial_z\partial_{\bar z} f = \tfrac12\Delta f, \tag{T1.129}$$

by (T1.114). This is Nash's (5.32), $\Delta_d = 2\Delta_{\bar\partial} = 2\Delta_\partial$, checked on functions on flat $\mathbb{C}$ (on a general Kähler manifold it holds on all forms). Its symbol is $(-2\mathrm{i}k_z)(\mathrm{i}k_{\bar z}) = 2k_zk_{\bar z} = \tfrac12|k|^2$, half of the symbol $|k|^2$ of Δ (T1.59). Consequently the $\bar\partial$-harmonic forms and the d-harmonic forms coincide on a compact Kähler manifold, which is what makes the Hodge numbers $h^{p,q}$ computable from harmonic forms.

Reading Nash (pp. 63–65, (3.24)–(3.31); pp. 103, 106–107, (4.49), (4.63)–(4.66); pp. 146–148, (5.29)–(5.34); pp. 158–160)

Chapter 3. Nash introduces (p,q)-forms by the local formula (3.24), the operators $\partial, \bar\partial$ by (3.25) (our (T1.122)), and the relations $\mathrm{d} = \partial + \bar\partial$, $\mathrm{d}^2 = \partial^2 = \partial\bar\partial + \bar\partial\partial = \bar\partial^2 = 0$ (3.26) (our (T1.123)). He then runs the sheaf-theoretic argument that gave de Rham's theorem with d replaced by $\bar\partial$, using the fine sheaves $\mathcal{E}^{p,q}$ and the sheaf Ω^p of holomorphic p-forms (note that Ω^p there means *holomorphic* forms, not all forms), to obtain *Dolbeault's theorem* $H^q(M;\Omega^p) \cong H^{p,q}_{\bar\partial}(M)$ (3.31). The input is the local exactness we saw in (T1.119).
Chapter 4. On p. 103 he complexifies the de Rham complex; on pp. 106–107 he writes the Dolbeault complex and its cohomology (4.63), sets $p = 0$, and defines index $\bar\partial = \sum_q (-1)^q h^{0,q}$ (4.64)–(4.65), the arithmetic genus. The symbol complex (4.66) is our (T1.128); $\Lambda^{0,q}T^*X$ is the bundle whose sections are $(0,q)$-forms.
Chapter 5. Kähler manifolds are defined by a closed $(1,1)$-form $\omega = \frac{\mathrm{i}}{2} g_{i\bar\jmath}\mathrm{d}z^i \wedge \mathrm{d}\bar z^j$ (5.29) (Example T1.59); the Fubini–Study metric is (5.30) (Example T1.62, with the caveats in the pitfall above); the three Laplacians and $\Delta_d = 2\Delta_{\bar\partial}$ are (5.31)–(5.32) (our (T1.129)). On pp. 158–160 the Beltrami differential and $\delta\mu = 2\partial_{\bar z} V^z$ appear (Example T1.61).

Recap

- $\mathrm{d}z = \mathrm{d}x + \mathrm{i}\,\mathrm{d}y$, $\mathrm{d}\bar z = \mathrm{d}x - \mathrm{i}\,\mathrm{d}y$; $\partial_z = \frac12(\partial_x - \mathrm{i}\partial_y)$, $\partial_{\bar z} = \frac12(\partial_x + \mathrm{i}\partial_y)$; $\mathrm{d}f = \partial_z f\,\mathrm{d}z + \partial_{\bar z} f\,\mathrm{d}\bar z$.
- Holomorphic $\Leftrightarrow \bar\partial f = 0$ (Cauchy–Riemann). $\nabla^2 = 4\partial_z\partial_{\bar z}$, so holomorphic functions are harmonic. $\mathrm{d}z\wedge\mathrm{d}\bar z = -2\mathrm{i}\,\mathrm{d}x\wedge\mathrm{d}y$; $\star\mathrm{d}z = -\mathrm{i}\,\mathrm{d}z$, $\star\mathrm{d}\bar z = \mathrm{i}\,\mathrm{d}\bar z$.
- Cauchy's theorem is Stokes for the closed form $f\,\mathrm{d}z$; $\partial_{\bar z}(1/z) = \pi\delta^2$ gives the Cauchy formula and the Green functions of $\bar\partial$ and Δ.
- (p,q)-forms, $\dim = \binom{m}{p}\binom{m}{q}$; $\mathrm{d} = \partial + \bar\partial$ with $\partial^2 = \bar\partial^2 = \partial\bar\partial + \bar\partial\partial = 0$. Holomorphic transition maps make types global.
- Dolbeault complex and $H^{p,q}_{\bar\partial}$. Explicitly: $\mathbb{CP}^1$ has no holomorphic 1-forms and three holomorphic vector fields; T^2 has $h^{1,0} = h^{0,1} = 1$; $\operatorname{index}\bar\partial = 1 - g$.

- $\mathcal{L}_V g$ in complex coordinates: $\delta\mu \propto \partial_{\bar{z}} V^z$; conformal Killing = holomorphic. ω_{FS} integrates to 1. $\Delta_{\bar{\partial}} = \frac{1}{2}\Delta$.

Chapter summary

We have built one calculus that replaces the grad–curl–div toolbox. Its objects are p-forms, the things we integrate over p-dimensional regions. There are six operations on them. Two need nothing but the manifold: the wedge product $\wedge$ and the exterior derivative d. One needs a map, the pullback f^*. Two need a vector field, the interior product ι_X and the Lie derivative $\mathcal{L}_X$. One needs a metric and an orientation: the Hodge star $\star$, and with it the codifferential δ and the Laplacian Δ. On a complex manifold, d splits further into $\partial + \bar{\partial}$.

The summary has three parts. Figure T1.33 is a map of the operators. Table T1.1 says what each operator needs and how it behaves. The concept tables (Tables T1.2 to T1.7) then list every concept of the chapter, with its operational meaning and where the book uses it again.

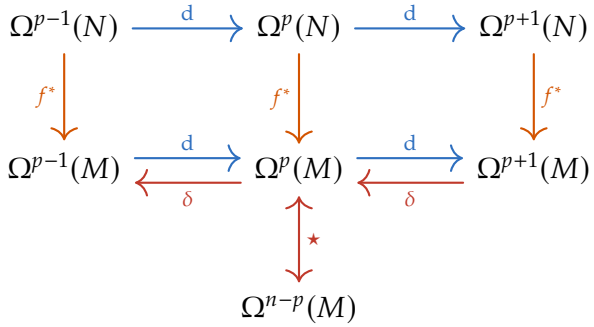

Figure T1.33: The operators of the chapter on one page. Blue arrows (d) and orange arrows (f^*) need no metric, and every square commutes: this is naturality, $\mathrm{d}f^* = f^*\mathrm{d}$ (Section T1.8). Red arrows ($\star$ and $\delta = \pm \star\, \mathrm{d} \star$) need a metric and an orientation. The interior product ι_X goes one step left along the bottom row, and the Lie derivative $\mathcal{L}_X = \mathrm{d}\iota_X + \iota_X \mathrm{d}$ stays at the same degree. See Table T1.1 for the details.

How to read the concept tables. Each row gives a concept, its *operational* meaning (what you actually compute, or how you test for it), and where it comes back later. Section references (§) are to this chapter. Chapter references are to the rest of the book, and page numbers "Nash p. x" are Nash's printed pages.

Operator	Degree	Needs	Key rules
$\alpha \wedge \beta$	$p+q$	nothing	$\alpha \wedge \beta = (-1)^{pq}\beta \wedge \alpha$; forms of degree $> n$ vanish
d	$+1$	nothing	$\mathrm{d}^2 = 0$; $\mathrm{d}(\alpha \wedge \beta) = \mathrm{d}\alpha \wedge \beta + (-1)^p \alpha \wedge \mathrm{d}\beta$
f^*	0	a map $f : M \to N$	$f^*(\alpha \wedge \beta) = f^*\alpha \wedge f^*\beta$; $\mathrm{d}f^* = f^*\mathrm{d}$; $(f \circ g)^* = g^* f^*$
ι_X	-1	a vector field	$\iota_X^2 = 0$; $\iota_X(\alpha \wedge \beta) = \iota_X\alpha \wedge \beta + (-1)^p \alpha \wedge \iota_X\beta$
$\mathcal{L}_X$	0	a vector field	$\mathcal{L}_X = \mathrm{d}\iota_X + \iota_X\mathrm{d}$; $[\mathcal{L}_X, \mathrm{d}] = 0$; $\mathcal{L}_X\mathrm{vol} = (\mathrm{div}\, X)\mathrm{vol}$
$\star$	$p \mapsto n-p$	metric, orientation	$\alpha \wedge \star\beta = g(\alpha,\beta)\mathrm{vol}$; $\star\star = (-1)^{p(n-p)+s}$
δ	-1	metric, orientation	$\delta = (-1)^{n(p+1)+1+s} \star \mathrm{d} \star$; $\langle \mathrm{d}\alpha, \beta\rangle = \langle \alpha, \delta\beta\rangle$; $\delta^2 = 0$
Δ	0	metric	$\Delta = \mathrm{d}\delta + \delta\mathrm{d} \geq 0$; $\Delta f = -\nabla^2 f$ in flat space; symbol $\lvert k\rvert^2$
∂, $\bar\partial$	$(1,0)$, $(0,1)$	complex structure	$\mathrm{d} = \partial + \bar\partial$; $\partial^2 = \bar\partial^2 = 0$; $\partial\bar\partial = -\bar\partial\partial$

Table T1.1: The operators of this chapter. "Degree" is the change in form degree; s is the number of minus signs in the metric.

Concept	Operational meaning	Used later
Chart (§T1.1)	Coordinates x^μ on a patch U, invertible onto an open set of $\mathbb{R}^n$. Write the formula and state which region it covers.	Everywhere; local trivialisations of bundles (Chapter 1)
Transition map	$x' \circ x^{-1}$ on the overlap, e.g. $u' = u/\lvert u\rvert^2$ between the two stereographic charts of S^2. It must be smooth.	Bundle transition functions (Chapters 1 and T3); monopole (§T1.7, Chapter T2)
Atlas, manifold	Enough charts to cover the space, with smooth transitions. Examples: S^1 (2 charts), S^2 (2), T^2, $\mathbb{CP}^1$.	All of the book
Orientation	All Jacobians $\det(\partial x'/\partial x)$ of the transitions are > 0. For S^2 stereographic, fix the sign by flipping one chart.	Integration and Stokes (Chapter T2); $\star$; signature (Chapter 4)
Regular level set	If $\mathrm{d}f \neq 0$ on $f = c$, then $\{f = c\}$ is a manifold of dimension $n-1$ (e.g. $S^2 \subset \mathbb{R}^3$).	Morse theory (Chapter 7)
Tangent vector (§T1.2)	The velocity of a curve, $v^\mu = \dot{x}^\mu$. It acts on functions by $v(f) = v^\mu \partial_\mu f$ and transforms by $v'^\mu = (\partial x'^\mu/\partial x^\nu)v^\nu$.	Vector fields, flows (§T1.9); gradient flows (Chapter 7)
Commutator $[X, Y]$	$[X,Y]^\mu = X^\lambda \partial_\lambda Y^\mu - Y^\lambda \partial_\lambda X^\mu$; it measures whether two flows commute.	Lie algebras (Chapter T3); diffeomorphism groups (Chapter 6)
Covector, $\mathrm{d}f$	A linear machine on vectors: $\mathrm{d}f(v) = v(f)$, $\mathrm{d}x^\mu(\partial_\nu) = \delta^\mu_\nu$. Pictured as a stack of level surfaces.	Every form; symbols of operators (Chapter 2)
Line element, metric	$\mathrm{d}s^2 = g_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu$, e.g. $\mathrm{d}r^2 + r^2\mathrm{d}\phi^2$ or $4(\mathrm{d}u^2 + \mathrm{d}v^2)/(1+\lvert u\rvert^2)^2$ on S^2. Raise and lower indices with g.	Hodge theory (Chapter 2); worldsheet metrics (Chapter 9)

Table T1.2: Summary, part 1: manifolds, vectors and covectors.

Concept	Operational meaning	Used later
Wedge product (§T1.3)	An antisymmetric product: $dx \wedge dx = 0$ and $dy \wedge dx = -dx \wedge dy$. On vectors, $(\alpha \wedge \beta)(v, w) = \alpha(v)\beta(w) - \alpha(w)\beta(v)$, the oriented area.	Cup product on cohomology (Nash p. 13–15, Chapter 1)
Change of variables	Substitute and expand; the Jacobian appears by itself: $dx \wedge dy = r\, dr \wedge d\phi$.	Integration (Chapter T2)
p-form	$\alpha = \frac{1}{p!}\alpha_{\mu_1 \ldots \mu_p} dx^{\mu_1} \wedge \cdots \wedge dx^{\mu_p}$ with antisymmetric components; the space has dimension $\binom{n}{p}$.	Throughout; Nash's convention omits the $1/p!$ (Chapter 2)
Graded commutativity	$\alpha \wedge \beta = (-1)^{pq}\beta \wedge \alpha$. So an odd form squares to zero, while $F \wedge F \neq 0$ is possible.	$\operatorname{tr} F \wedge F$ (Chapters 8 and 10)
Top form, determinant	$\alpha^1 \wedge \cdots \wedge \alpha^n = \det(\alpha^i{}_\mu)\, dx^1 \wedge \cdots \wedge dx^n$.	Volume forms; the degree of a map (§T1.8)
Decomposable form	$\alpha = \beta \wedge \gamma$ for 1-forms β, γ. For a 2-form the test is $\alpha \wedge \alpha = 0$ (e.g. $dx^1 \wedge dx^2 + dx^3 \wedge dx^4$ fails it).	Self-dual 2-forms (Chapter 8)
3D dictionary	0-, 1-, 2- and 3-forms ↔ scalar, vector (work), pseudovector (flux) and density (charge). $\wedge$ contains $\times$ and $\cdot$.	Maxwell (§T1.7)
Pictures of forms	A 1-form is a stack of surfaces (count how many you cross); a 2-form is a bundle of tubes (count how many you pierce); a 3-form is a swarm of cells.	Intuition for Stokes (Chapter T2)

Table T1.3: Summary, part 2: the algebra of forms.

Concept	Operational meaning	Used later
Inner product of forms (§T1.4)	Use $g^{\mu\nu}$ on 1-forms. On p-forms, take the determinant of the matrix of 1-form inner products; an orthonormal coframe gives an orthonormal basis of p-forms.	L^2 norms, Hodge theory (Chapter 2)
Signature s	The number of minus signs in g: $s = 0$ Euclidean, $s = 1$ Minkowski. Norms of forms can be negative when $s \neq 0$.	Signs of $\star\star$ and δ
Volume form	$\mathrm{vol} = \sqrt{\lvert g \rvert}\, dx^1 \wedge \cdots \wedge dx^n$ in an oriented chart, e.g. $r^2 \sin\theta\, dr \wedge d\theta \wedge d\phi$.	All integrals; $\mathcal{L}_X \mathrm{vol}$ (§T1.9)
Hodge star	Complete an orthonormal basis form to vol: $\alpha \wedge \star\beta = g(\alpha, \beta)\mathrm{vol}$. Tables for $\mathbb{R}^2$, polar, $\mathbb{R}^3$, spherical, $\mathbb{R}^4$, Minkowski.	Hodge theory (Nash p. 39–41); instantons; Yang–Mills action (Chapters 2, T3 and 8)
$\star\star$ sign	$\star\star = (-1)^{p(n-p)+s}$ on p-forms. It equals +1 on 2-forms in $\mathbb{R}^4$ and −1 on 2-forms in Minkowski space.	Self-duality exists only in Euclidean signature (Chapter 8)
(Anti-)self-dual 2-forms	$\star\omega = \pm\omega$ in $\mathbb{R}^4$, spanned by $dx^1 \wedge dx^2 \pm dx^3 \wedge dx^4$ and its cyclic partners; $3 + 3 = 6$.	BPST instantons (Chapter 8); signature operator (Chapter 4)
L^2 inner product	$\langle \alpha, \beta \rangle = \int_M \alpha \wedge \star\beta$, positive definite for $s = 0$.	Adjoints, δ, actions (Chapter 2)

Table T1.4: Summary, part 3: metric, orientation and the Hodge star.

Concept	Operational meaning	Used later
Exterior derivative (§T1.5)	$\mathrm{d}\alpha = \mathrm{d}x^\mu \wedge \partial_\mu \alpha$: differentiate the components and wedge on a $\mathrm{d}x$. It is chart-independent, and it is the circulation (or flux) per unit area (or volume).	de Rham cohomology (Nash (1.43), Chapter 1); Stokes (Chapter T2)
grad, curl, div	d on 0-, 1- and 2-forms in $\mathbb{R}^3$; with $\star$, it gives curl and div in any coordinates (spherical div worked out).	Maxwell; Laplacians
$\mathrm{d}^2 = 0$	Mixed partials commute. In 3D it is curl grad = 0 and div curl = 0.	Complexes: de Rham, Dolbeault, BRST (Chapters 4 and 12)
Leibniz rule	$\mathrm{d}(\alpha \wedge \beta) = \mathrm{d}\alpha \wedge \beta + (-1)^p \alpha \wedge \mathrm{d}\beta$.	Chern–Simons forms, descent (Chapter 10)
Closed, exact	Closed: $\mathrm{d}\alpha = 0$. Exact: $\alpha = \mathrm{d}\beta$. $\mathrm{d}\phi$ on $\mathbb{R}^2 \setminus 0$ is closed but not exact; its loop integral is 2π.	H^p_{dR} (Chapters 1 and T2)
Poincaré lemma	On a star-shaped region, closed implies exact. Build β by integrating along rays.	Local triviality of cohomology (Chapter 3)
Codifferential (§T1.6)	The adjoint of d: $\delta = (-1)^{n(p+1)+1+s} \star \mathrm{d} \star$. On 1-forms, $\delta = -\operatorname{div}$.	Nash's d^* (Chapter 2)
Laplace–de Rham	$\Delta = \mathrm{d}\delta + \delta\mathrm{d}$. On functions it is $-\frac{1}{\sqrt{g}}\partial_\mu(\sqrt{g}g^{\mu\nu}\partial_\nu)$, e.g. the polar form $-(f_{rr} + f_r/r + f_{\phi\phi}/r^2)$. It is positive.	Heat kernel and index (Chapters 2 and 4)
Harmonic forms, Hodge	$\Delta h = 0 \Leftrightarrow \mathrm{d}h = \delta h = 0$ on a compact M. There is one harmonic form per class, so $b_p = \dim \operatorname{Ker} \Delta_p$, and $\omega = \mathrm{d}\alpha + \delta\beta + h$.	Nash p. 41 (Chapter 2); zero modes (Chapter 4)
Symbols	Replace $\partial_\mu \to \mathrm{i}k_\mu$: $\sigma(\mathrm{d}) = \mathrm{i}k\wedge$, $\sigma(\delta) = -\mathrm{i}\iota_k$, $\sigma(\Delta) = \lvert k\rvert^2$. So Δ is elliptic.	Elliptic complexes (Nash (2.46)–(2.49), Chapter 2)

Table T1.5: Summary, part 4: the exterior derivative, the codifferential and the Laplacian.

Concept	Operational meaning	Used later
Maxwell in forms (§T1.7)	$F = E \wedge \mathrm{d}t + \star_3 B$. $\mathrm{d}F = 0$ gives $\nabla \cdot B = 0$ and Faraday's law; $\mathrm{d} \star F = \star J$ gives Gauss and Ampère.	Yang–Mills $D \star F = \star J$ (Chapters T3 and 8)
Potential, gauge	$F = \mathrm{d}A$ with $A = -\Phi\,\mathrm{d}t + \vec{A} \cdot \mathrm{d}\vec{x}$. Changing $A \to A + \mathrm{d}\lambda$ leaves F fixed because $\mathrm{d}^2 = 0$. Charge conservation is $\mathrm{d} \star J = \mathrm{d}^2 \star F = 0$.	Connections (Chapter T3); gauge orbits (Chapter 6)
Action, invariants	$S = -\frac{1}{2}\int F \wedge \star F$; $F \wedge F = \mathrm{d}(A \wedge \mathrm{d}A)$ is a total derivative ($\propto \vec{E} \cdot \vec{B}$).	θ-term, Chern–Simons, anomalies (Chapters 10 and 12)
Dirac monopole	$F = \frac{g}{4\pi} \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$ is closed but not exact on S^2. The two patch potentials differ by $\frac{g}{2\pi}\mathrm{d}\phi$, which forces $eg \in 2\pi\mathbb{Z}$.	Monopole bundle, c_1 (Chapters 1 and T2)
Push-forward, pullback (§T1.8)	f^*: substitute $y = f(x)$ and expand; vectors are pushed forward by the Jacobian. Pulling back to a curve gives the line-integral integrand.	Functoriality of H^*_{dR} (Chapter 1); gauge transformations
Top forms and Jacobians	$f^*(\mathrm{d}y^1 \wedge \cdots \wedge \mathrm{d}y^n) = \det(\partial f/\partial x)\,\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^n$: this is the change-of-variables formula.	Integration (Chapter T2); degree of a map
Induced metric	$f^*g = J^{\mathsf{T}} g J$, e.g. $S^2 \subset \mathbb{R}^3$ gets $\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2$.	Nambu–Goto and Polyakov (Chapter 9)
Naturality	$\mathrm{d}f^* = f^*\mathrm{d}$: differentiate before or after the substitution, the answer is the same.	Cohomology is a topological invariant (Chapter 1)
Degree, winding	$\deg f = \int f^*\omega \big/ \int \omega$; for $z \mapsto z^k$ on S^1 it is k.	Instanton number (Chapter 8)

Table T1.6: Summary, part 5: Maxwell's equations and the pullback.

Concept	Operational meaning	Used later
Interior product (§T1.9)	Feed X into the first slot: $(\iota_X\alpha)_{\nu\ldots} = X^\mu\alpha_{\mu\nu\ldots}$. In 3D, $\iota_{\vec v}(\star_3 B)$ is $\vec B\times\vec v$ as a 1-form: the magnetic Lorentz force.	Cartan calculus; equivariant forms (Chapter 12)
Flow	Solve $\dot x^\mu = X^\mu(x)$; the solutions form a one-parameter group ϕ_t of diffeomorphisms.	Diffeomorphism groups (Chapter 6); Morse flows (Chapter 7)
Lie derivative	$\mathcal{L}_X\alpha = \frac{\mathrm{d}}{\mathrm{d}t}\phi_t^*\alpha\big\vert_{t=0}$. In components, $(\mathcal{L}_X\alpha)_\mu = X^\lambda\partial_\lambda\alpha_\mu + \alpha_\lambda\partial_\mu X^\lambda$.	Symmetries, Noether currents
Cartan's formula	$\mathcal{L}_X = \mathrm{d}\iota_X + \iota_X\mathrm{d}$ on forms: a two-line calculation instead of components. It gives $\mathcal{L}_X\mathrm{vol} = (\mathrm{div}\,X)\mathrm{vol}$ and Liouville's theorem.	Homotopy invariance of H^*_{dR} (Chapter T2)
Killing, conformal Killing	$\mathcal{L}_X g = 0$ (isometry), or $\mathcal{L}_X g = \lambda g$ (conformal). In 2D the conformal Killing vectors are the holomorphic ones.	Moduli of Riemann surfaces, Nash (5.71) (Chapters 5 and 9)
Complex coordinates (§T1.10)	$\mathrm{d}z = \mathrm{d}x + \mathrm{i}\mathrm{d}y$, $\partial_{\bar z} = \frac12(\partial_x + \mathrm{i}\partial_y)$; holomorphic means $\bar\partial f = 0$; $\nabla^2 = 4\partial_z\partial_{\bar z}$.	Riemann surfaces, CFT (Chapters 5 and 11)
(p,q)-forms	p factors of $\mathrm{d}z$ and q of $\mathrm{d}\bar z$; the space has dimension $\binom{m}{p}\binom{m}{q}$. The type is global because the transitions are holomorphic.	Nash (3.24) (Chapter 3)
∂, $\bar\partial$	$\mathrm{d} = \partial + \bar\partial$ with $\partial^2 = \bar\partial^2 = 0$ and $\partial\bar\partial = -\bar\partial\partial$. Also $\partial_{\bar z}(1/z) = \pi\delta^2$.	Nash (3.25)–(3.26); Green functions (Chapter 11)
Dolbeault cohomology	$H^{p,q}_{\bar\partial} = \mathrm{Ker}\,\bar\partial/\mathrm{Im}\,\bar\partial$. For $\mathbb{CP}^1$, $h^{0,0} = h^{1,1} = 1$ and $h^{1,0} = h^{0,1} = 0$; for T^2 all four are 1.	Dolbeault theorem (Chapter 3); index $\bar\partial = 1 - g$ (Nash (4.63)–(4.65), Chapter 4)
Kähler, Fubini–Study	$\omega = \frac{\mathrm{i}}{2}g_{i\bar\jmath}\mathrm{d}z^i\wedge\mathrm{d}\bar z^j$ is closed; $\omega_{FS} = \frac{\mathrm{i}}{2\pi}\partial\bar\partial\log(1+\vert z\vert^2)$ integrates to 1. $\Delta_{\bar\partial} = \frac12\Delta$.	Nash (5.29)–(5.32) (Chapter 5)

Table T1.7: Summary, part 6: the Cartan calculus and complex forms.

Five calculations to be able to do from memory. If you can do these without looking, you own the chapter.

1. Show that $\mathrm{d}x \wedge \mathrm{d}y = r\,\mathrm{d}r \wedge \mathrm{d}\phi$, and that the pullback of $\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z$ to spherical coordinates is $r^2 \sin\theta\,\mathrm{d}r \wedge \mathrm{d}\theta \wedge \mathrm{d}\phi$ (§T1.3, §T1.8).
2. Write the Hodge star of $\mathrm{d}r$ and $\mathrm{d}\phi$ in the plane, and from them the polar Laplacian $\Delta f = -\star\,\mathrm{d}\star\,\mathrm{d}f = -(f_{rr} + f_r/r + f_{\phi\phi}/r^2)$ (§T1.4, §T1.6).
3. Show that $\mathrm{d}\phi = (x\,\mathrm{d}y - y\,\mathrm{d}x)/(x^2 + y^2)$ is closed, and that its integral round the unit circle is 2π, so it is not exact (§T1.5).
4. Derive all four Maxwell equations from $\mathrm{d}F = 0$ and $\mathrm{d}\star F = \star J$ with $F = E \wedge \mathrm{d}t + \star_3 B$, and derive charge conservation from $\mathrm{d}^2 = 0$ (§T1.7).
5. Compute $\mathcal{L}_X(\mathrm{d}x \wedge \mathrm{d}y)$ for $X = x\partial_x + y\partial_y$ with Cartan's formula ($= 2\,\mathrm{d}x \wedge \mathrm{d}y$), and show that ω_{FS} on $\mathbb{CP}^1$ has total integral 1 (§T1.9, §T1.10).

Reading Nash

Nash assumes this whole chapter from his first page. The places where he leans on it hardest are these. p. 13: de Rham cohomology (1.43), and the wedge product as the cup product. pp. 39–41: $\star$, d^* and Δ (2.42)–(2.53), the symbols (2.46)–(2.49), and Hodge's theorem. pp. 63–65: (p,q)-forms, ∂ and $\bar\partial$ (3.24)–(3.26), and the Dolbeault theorem. pp. 103–110: the de Rham and Dolbeault complexes in the index theorem (4.63)–(4.66), and the signature operator built from $\star$ (4.77)–(4.80). pp. 155–160: Kähler forms (5.29)–(5.32) and the Lie derivative of the metric (5.71). Chapters 8 and 10: self-dual fields and the density $\mathrm{tr}\,F \wedge F$.

Chapter T2

Integration, Stokes' Theorem, Connections and Curvature

Where this chapter is going

The previous chapter built the machinery of differential forms: the wedge product, the exterior derivative d with $\mathrm{d}^2 = 0$, the Hodge star, and pullbacks. That machinery was all *local*. It told us how to differentiate at a point. This chapter is about what happens when we *add things up* over a whole region or a whole manifold. Two very different stories come out of that, and the punchline of the chapter is that they turn out to be the same story.

The first story is **integration and topology**. Forms are exactly the objects that can be integrated without choosing coordinates. Once we can integrate, Stokes' theorem, $\int_R \mathrm{d}\alpha = \int_{\partial R} \alpha$, becomes the one tool that does everything: it contains the fundamental theorem of calculus, Green's theorem, the curl theorem and Gauss's theorem. Applied to a region with no edge it gives a detector. A form whose integral over a closed surface is non-zero cannot be exact. The forms that are closed but not exact, such as $\mathrm{d}\theta$ around a puncture or the monopole field on a sphere, measure the holes in the space. Organising them gives de Rham cohomology, the Betti numbers and the Euler characteristic.

The second story is **geometry**. To differentiate a *vector* field, rather than a function, we need to know how the basis vectors turn from point to point. That information is a matrix of 1-forms, the *connection* ω. Its failure to be "pure gauge" is the *curvature* $\Omega = \mathrm{d}\omega + \omega \wedge \omega$. This is exactly the structure of a gauge field, with $F = \mathrm{d}A + A \wedge A$; Chapter T3 makes the identification precise.

The two stories meet in the **Gauss–Bonnet theorem**. The integral of the curvature of a closed surface is 2π times its Euler characteristic,

$$\int_\Sigma K \, \mathrm{d}A = 2\pi \, \chi(\Sigma).$$

The left side needs a metric. The right side needs only a count of vertices, edges and faces. This is the first "integral of curvature equals topology" theorem. Chern–Weil theory generalises it to every gauge field, and the Atiyah–Singer index theorem (Chapter 4) turns it into a statement about zero modes of the Dirac operator. Everything later in these notes, from instanton numbers (Chapter 8) to anomalies (Chapter 10), is a descendant of the computation we do at the end of this chapter.

How to read this chapter. Sections T2.1 and T2.2 are vector calculus rewritten in forms; a physicist will recognise every formula. Sections T2.3 and T2.4 are the first genuinely topological ideas, and they are used everywhere in Nash from Chapter 1 onwards. Sections T2.5–T2.7 follow Dray's treatment of frames and connections, done entirely with forms. Section T2.8 puts

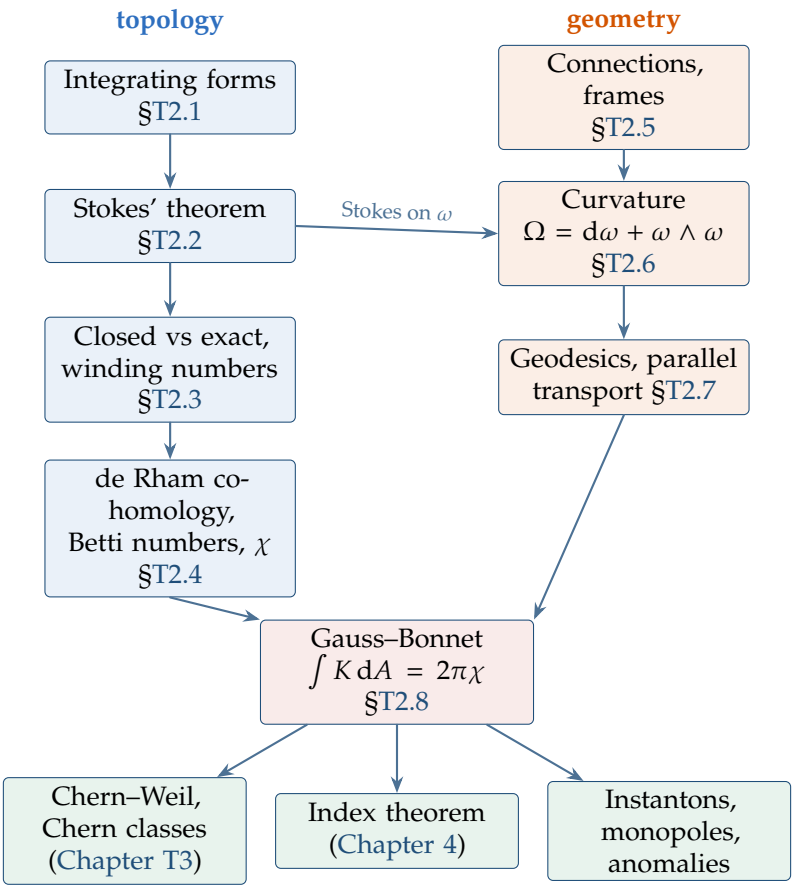

Figure T2.1: The logic of the chapter. The left column is topology: integration leads to Stokes' theorem, which detects closed-but-not-exact forms, which organise into cohomology. The right column is geometry: frames lead to connections, curvature and geodesics. Stokes' theorem applied to the connection is the bridge between them. Both columns meet in Gauss–Bonnet, the prototype of every "curvature integrates to an integer" result used later in physics.

it all together. Section T2.9 collects Dray's closing applications (spinors, the sphere puzzle, the equivalence problem).

Conventions for this chapter.

- Manifolds are smooth, of dimension n, with coordinates x^μ. Surfaces are two-dimensional and Riemannian (Euclidean signature).
- A p-form is $\alpha = \frac{1}{p!}\alpha_{\mu_1\ldots\mu_p}\mathrm{d}x^{\mu_1}\wedge\cdots\wedge\mathrm{d}x^{\mu_p}$.
- The standard orientation of $\mathbb{R}^n$ is $\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^n$. On the sphere we use $\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi$, which corresponds to the outward normal.
- Boundaries carry the "outward normal first" orientation (Section T2.2). For a planar region this means the boundary is traversed counterclockwise, with the region on the left.
- Orthonormal frames $\{e_i\}$, dual coframes $\{\sigma^i\}$ with $\mathrm{d}\vec{r} = \sigma^i e_i$. Connection 1-forms are defined by $\mathrm{d}e_j = e_i\,\omega^i{}_j$; curvature by $\Omega^i{}_j = \mathrm{d}\omega^i{}_j + \omega^i{}_k\wedge\omega^k{}_j$. These follow Dray.
- Gaussian curvature K is defined by $\Omega^1{}_2 = K\,\sigma^1\wedge\sigma^2$ on an oriented surface; the unit sphere has $K=+1$.

T2.1 Integrating differential forms

In vector calculus we meet three kinds of integral: the line integral $\int_C \vec{F}\cdot\mathrm{d}\vec{r}$, the flux integral $\iint_S \vec{F}\cdot\mathrm{d}\vec{A}$, and the volume integral $\iiint_R f\,\mathrm{d}V$. Each comes with its own little recipe for turning it into an ordinary integral over parameters. Each recipe has a Jacobian or a normal vector hidden in it. We are rarely told what the three have in common.

This section answers one question: *what kind of object is the thing under an integral sign?* The answer is that it is a differential form. A p-form is exactly the object that can be integrated over a p-dimensional oriented surface without choosing coordinates. Once we see this, the three recipes collapse into one: pull the form back to the parameter space and "drop the wedges". Everything later in the chapter, starting with Stokes' theorem, depends on this.

T2.1.1 The integrands you already know

Work in ordinary $\mathbb{R}^3$ with Cartesian coordinates (x,y,z). The **infinitesimal displacement** $\mathrm{d}\vec{r} = \mathrm{d}x\,\hat{x} + \mathrm{d}y\,\hat{y} + \mathrm{d}z\,\hat{z}$ is itself a vector-valued 1-form: feed it a direction and it returns that direction. Dray takes $\mathrm{d}\vec{r}$ as the organising object [Dray §16.1]. With it we can turn any vector field $\vec{F} = F_x\hat{x} + F_y\hat{y} + F_z\hat{z}$ into a 1-form,

$$F \coloneqq \vec{F}\cdot\mathrm{d}\vec{r} = F_x\,\mathrm{d}x + F_y\,\mathrm{d}y + F_z\,\mathrm{d}z. \tag{T2.1}$$

We use the same letter for the vector and the 1-form; the arrow tells them apart. The Hodge star (Chapter T1) turns F into a 2-form,

$$\star F = F_x\,\mathrm{d}y\wedge\mathrm{d}z + F_y\,\mathrm{d}z\wedge\mathrm{d}x + F_z\,\mathrm{d}x\wedge\mathrm{d}y, \tag{T2.2}$$

and a function f into a 3-form, $\star f = f\,\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z$.

The claim, which we will check on examples, is the dictionary

$$\int_C \vec{F}\cdot \mathrm{d}\vec{r} = \int_C F, \qquad \iint_S \vec{F}\cdot \mathrm{d}\vec{A} = \int_S \star F, \qquad \iiint_R f\,\mathrm{d}V = \int_R \star f. \tag{T2.3}$$

The circulation of $\vec{F}$ is the integral of the 1-form F. The flux of $\vec{F}$ is the integral of the 2-form $\star F$. The "amount of f" in a region is the integral of the 3-form $\star f = f\,\mathrm{d}V$.

Dictionary: vector calculus integrals as form integrals

vector calculus	form	degree
value $f(P)$ at a point	f	0
circulation $\int_C \vec{F}\cdot \mathrm{d}\vec{r}$	$F = \vec{F}\cdot \mathrm{d}\vec{r}$	1
flux $\iint_S \vec{F}\cdot \mathrm{d}\vec{A}$	$\star F = \vec{F}\cdot \mathrm{d}\vec{A}$	2
total amount $\iiint_R f\,\mathrm{d}V$	$\star f = f\,\mathrm{d}V$	3

Physical picture: a flux form counts field lines through a tile

Think of $\star F$ as a device that is handed a tiny oriented tile of surface and returns the number of field lines of $\vec{F}$ that pierce it, counted with sign. A line integral form F is handed a tiny arrow and returns the work done along it. A volume form is handed a tiny box and returns the amount of stuff inside. Integration is "chop the domain into tiles, feed each tile to the form, add up".

T2.1.2 What a form does to a tiny parallelogram

Here is the mechanism behind the intuition. A p-form at a point is a machine that eats p tangent vectors and returns a number, linearly in each slot and antisymmetrically (Chapter T1). For a 2-form built from two 1-forms,

$$(\alpha\wedge\beta)(\vec{u},\vec{v}) = \alpha(\vec{u})\,\beta(\vec{v}) - \alpha(\vec{v})\,\beta(\vec{u}). \tag{T2.4}$$

Take $\alpha = \mathrm{d}x$, $\beta = \mathrm{d}y$ and two vectors in the plane, $\vec{u} = (u_1, u_2)$ and $\vec{v} = (v_1, v_2)$. Then

$$\begin{aligned}(\mathrm{d}x\wedge\mathrm{d}y)(\vec{u},\vec{v}) &\overset{(1)}{=} \mathrm{d}x(\vec{u})\,\mathrm{d}y(\vec{v}) - \mathrm{d}x(\vec{v})\,\mathrm{d}y(\vec{u})\\ &\overset{(2)}{=} u_1v_2 - v_1u_2\\ &\overset{(3)}{=} \det\begin{pmatrix} u_1 & v_1\\ u_2 & v_2\end{pmatrix}.\end{aligned} \tag{T2.5}$$

(1) The definition (T2.4) of the wedge of two 1-forms acting on two vectors.
(2) $\mathrm{d}x$ picks out the x-component of a vector and $\mathrm{d}y$ the y-component.
(3) This is the determinant whose absolute value is the area of the parallelogram with edges $\vec{u}, \vec{v}$; its sign says whether $\vec{v}$ is counterclockwise from $\vec{u}$.

So $\mathrm{d}x\wedge\mathrm{d}y$ returns the *signed area* of the parallelogram. That is the whole reason forms are integrands: an integral is a sum of (value of the integrand) × (size of a small piece), and a form supplies both factors at once, with a sign that knows about orientation.

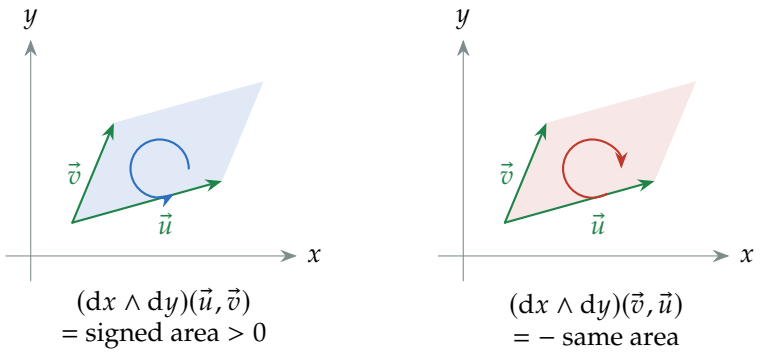

Figure T2.2: A 2-form eats the two edge vectors of a small parallelogram and returns its signed area. Swapping the edges reverses the circulation sense (the small arrow) and flips the sign. The sign is the orientation; this is why integrands must be antisymmetric.

T2.1.3 Why the wedge product does the Jacobian for you

The acid test of an integrand is how it behaves under a change of variables. In ordinary calculus we are told to insert $|\det J|$ by hand:

$$\iint f\,dx\,dy = \iint f \left|\det \frac{\partial(x,y)}{\partial(u,v)}\right| du\,dv.$$

With forms nothing has to be inserted. The Jacobian appears by itself. Write $x = x(u,v)$, $y = y(u,v)$. Then

$$\begin{aligned} dx \wedge dy &\overset{(1)}{=} \left(\frac{\partial x}{\partial u}du + \frac{\partial x}{\partial v}dv\right) \wedge \left(\frac{\partial y}{\partial u}du + \frac{\partial y}{\partial v}dv\right) \\ &\overset{(2)}{=} \frac{\partial x}{\partial u}\frac{\partial y}{\partial v}\,du \wedge dv + \frac{\partial x}{\partial v}\frac{\partial y}{\partial u}\,dv \wedge du \\ &\overset{(3)}{=} \left(\frac{\partial x}{\partial u}\frac{\partial y}{\partial v} - \frac{\partial x}{\partial v}\frac{\partial y}{\partial u}\right) du \wedge dv \\ &= \det \frac{\partial(x,y)}{\partial(u,v)}\,du \wedge dv. \end{aligned} \tag{T2.6}$$

(1) The chain rule for the differentials of x and y.
(2) Expand; the terms $du \wedge du$ and $dv \wedge dv$ vanish by antisymmetry.
(3) Antisymmetry again: $dv \wedge du = -du \wedge dv$.

The determinant is the Jacobian, and it arrives *with its sign*. The sign is what we want: it records whether the new coordinates have the same orientation as the old ones. For orientation-preserving changes of variables ($\det J > 0$) the form integral and the ordinary integral agree.

Worked example T2.1: Polar coordinates

With $x = r\cos\phi$, $y = r\sin\phi$,

$$\begin{aligned} dx \wedge dy &\overset{(1)}{=} (\cos\phi\,dr - r\sin\phi\,d\phi) \wedge (\sin\phi\,dr + r\cos\phi\,d\phi) \\ &\overset{(2)}{=} r\cos^2\phi\,dr \wedge d\phi - r\sin^2\phi\,d\phi \wedge dr \\ &\overset{(3)}{=} r(\cos^2\phi + \sin^2\phi)\,dr \wedge d\phi = r\,dr \wedge d\phi. \end{aligned}$$

(1) Differentiate x and y.
(2) Only the cross terms survive.

(3) Flip $\mathrm{d}\phi \wedge \mathrm{d}r = -\mathrm{d}r \wedge \mathrm{d}\phi$ and use $\cos^2 + \sin^2 = 1$.

The familiar "$r\,\mathrm{d}r\,\mathrm{d}\phi$" is not a rule to memorise. It is what $\mathrm{d}x \wedge \mathrm{d}y$ *is* in polar coordinates. Notice that (r, ϕ) is positively oriented relative to (x, y) since $r > 0$.

Watch out: the symbol $\mathrm{d}x\,\mathrm{d}y$ is not $\mathrm{d}x \wedge \mathrm{d}y$

In an ordinary double integral, $\mathrm{d}x\,\mathrm{d}y$ means "Lebesgue measure", which is positive and symmetric: $\mathrm{d}x\,\mathrm{d}y = \mathrm{d}y\,\mathrm{d}x$. The form $\mathrm{d}x \wedge \mathrm{d}y$ is antisymmetric. They agree only after we fix an orientation and agree to write the form with its coordinates in positive order. This is the source of every stray minus sign in flux integrals.

T2.1.4 The recipe: pull back and drop the wedges

We now state the general rule. A **parametrised p-surface** in a manifold M is a smooth map $\varphi : U \to M$ from a region $U \subset \mathbb{R}^p$ with coordinates $(u^1, \dots, u^p)$. The **pullback** $\varphi^*\alpha$ of a form (Chapter T1) is obtained by substituting $x^\mu = x^\mu(u)$ and $\mathrm{d}x^\mu = \frac{\partial x^\mu}{\partial u^a}\mathrm{d}u^a$. For a p-form on M the pullback is a top-degree form on U, so it is a single function times $\mathrm{d}u^1 \wedge \cdots \wedge \mathrm{d}u^p$.

Working definition T2.1 (integral of a p-form)

To integrate a p-form α over an oriented p-surface S [a surface on which one order of the coordinate directions has been declared positive]:

1. Choose a parametrisation $\varphi : U \to S$ whose coordinate order $(u^1, \dots, u^p)$ agrees with the orientation of S.
2. Pull back: substitute $x^\mu(u)$ and $\mathrm{d}x^\mu = \partial_a x^\mu\,\mathrm{d}u^a$, and simplify to $\varphi^*\alpha = g(u)\,\mathrm{d}u^1 \wedge \cdots \wedge \mathrm{d}u^p$.
3. Drop the wedges: $\displaystyle\int_S \alpha := \int_U g(u)\,\mathrm{d}u^1 \cdots \mathrm{d}u^p$, an ordinary multiple integral.

If the parametrisation has the wrong orientation [its coordinate order is the one declared negative, e.g. $(u^2, u^1, \dots)$], insert a minus sign. *Formally:* $\int_{\varphi(U)} \alpha = \int_U \varphi^*\alpha$.

Dray puts the whole of this in one sentence: "To integrate a differential form, simply drop the wedge products and do the integral — and check whether the orientation agrees with the one you want, inserting a minus sign if it doesn't" [Dray §20.5].

Why the answer does not depend on the parametrisation. Suppose $\varphi : U \to S$ and $\tilde\varphi : \tilde U \to S$ are two orientation-compatible parametrisations. They are related by a change of parameters $\psi : \tilde U \to U$ with $\tilde\varphi = \varphi \circ \psi$ and $\det(\partial u/\partial \tilde u) > 0$. Write $\varphi^*\alpha = g\,\mathrm{d}^p u$. Then

$$\begin{aligned}\int_{\tilde U} \tilde\varphi^*\alpha &\overset{(1)}{=} \int_{\tilde U} \psi^*\varphi^*\alpha \\ &\overset{(2)}{=} \int_{\tilde U} g(u(\tilde u))\,\det\!\left(\frac{\partial u}{\partial \tilde u}\right)\mathrm{d}^p\tilde u \\ &\overset{(3)}{=} \int_U g(u)\,\mathrm{d}^p u \;=\; \int_U \varphi^*\alpha. \end{aligned} \tag{T2.7}$$

(1) Pullbacks compose backwards: $(\varphi\circ\psi)^* = \psi^*\varphi^*$.

(2) The p-dimensional version of (T2.6): $\mathrm{d}u^1 \wedge \cdots \wedge \mathrm{d}u^p = \det(\partial u/\partial\tilde u)\,\mathrm{d}\tilde u^1 \wedge \cdots \wedge \mathrm{d}\tilde u^p$.

(3) The change-of-variables formula of ordinary calculus, which uses $|\det|$; here $\det > 0$, so $|\det| = \det$.

This is the precise sense in which forms are "the natural integrands". A function alone cannot be integrated over a surface without extra data (a measure). A vector field cannot either (it needs a normal). A p-form over a p-surface needs only an orientation.

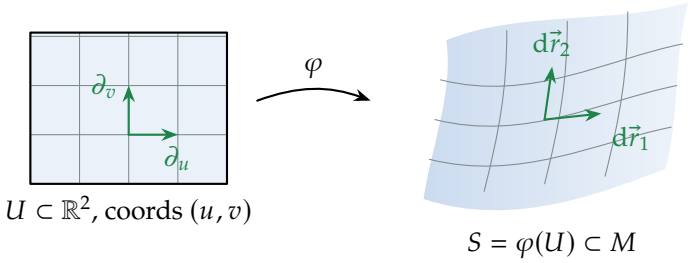

Figure T2.3: Pulling back. The parameter rectangle is chopped into little squares; φ carries each one to a little curved parallelogram on S with edges $d\vec{r}_1 = \partial_u \vec{r}\, du$ and $d\vec{r}_2 = \partial_v \vec{r}\, dv$ (Dray's Figure 16.1). The form is evaluated on those edges. The pullback $\varphi^*\alpha$ is the form on U that gives the same answer on the original little squares.

Worked example T2.2: Circulation around a circle

Let $\alpha = -y\,dx + x\,dy$ and let C be the circle of radius R, traversed counterclockwise. Parametrise by $x = R\cos t$, $y = R\sin t$, $t \in [0, 2\pi]$. Then

$$\begin{aligned}\int_C \alpha &\overset{(1)}{=} \int_0^{2\pi} \big(-R\sin t\,(-R\sin t\,dt) + R\cos t\,(R\cos t\,dt)\big) \\ &\overset{(2)}{=} \int_0^{2\pi} R^2\,dt = 2\pi R^2.\end{aligned}$$

(1) Pull back: $dx = -R\sin t\,dt$ and $dy = R\cos t\,dt$.
(2) $\sin^2 t + \cos^2 t = 1$; then drop the dt and integrate.

The answer is twice the enclosed area. That is no accident: we will see in Example T2.7 that Stokes' theorem turns it into $2\int_D dx \wedge dy$. Traversing the circle clockwise ($t \mapsto -t$) gives $-2\pi R^2$.

Worked example T2.3: Flux through a graph (Dray 16.13–16.18)

Let S be the graph $z = h(x, y)$ over a region D of the xy-plane, oriented by the upward normal. Use (x, y) as parameters. On S, $dz = h_x\,dx + h_y\,dy$ (subscripts are partial derivatives). The pullback of $\star F$ is

$$\begin{aligned}\star F\big|_S &\overset{(1)}{=} F_x\,dy \wedge (h_x dx + h_y dy) + F_y\,(h_x dx + h_y dy) \wedge dx + F_z\,dx \wedge dy \\ &\overset{(2)}{=} F_x h_x\,dy \wedge dx + F_y h_y\,dy \wedge dx + F_z\,dx \wedge dy \\ &\overset{(3)}{=} \big(-F_x h_x - F_y h_y + F_z\big)\,dx \wedge dy.\end{aligned}$$

(1) Substitute dz into (T2.2).
(2) Drop $dy \wedge dy = 0 = dx \wedge dx$.
(3) Flip $dy \wedge dx = -dx \wedge dy$.

This is exactly $\vec{F} \cdot d\vec{A}$ with the textbook area element $d\vec{A} = (-h_x, -h_y, 1)\,dx\,dy$, which one gets from $d\vec{r}_1 \times d\vec{r}_2$ with $d\vec{r}_1 = (\hat{x} + h_x\hat{z})dx$ and $d\vec{r}_2 = (\hat{y} + h_y\hat{z})dy$. The form computation did the cross product for us.

A number. Take $\vec{F} = \vec{r} = (x, y, z)$ and the paraboloid $h = 1 - x^2 - y^2$ over the unit disc. Then $h_x = -2x$, $h_y = -2y$ and

$$\begin{aligned}\int_S \star F &\overset{(1)}{=} \int_D \left(2x^2 + 2y^2 + 1 - x^2 - y^2\right) \mathrm{d}x\,\mathrm{d}y \\ &\overset{(2)}{=} \int_0^{2\pi}\int_0^1 (1+\rho^2)\,\rho\,\mathrm{d}\rho\,\mathrm{d}\phi \\ &= 2\pi\left(\tfrac{1}{2} + \tfrac{1}{4}\right) = \frac{3\pi}{2}.\end{aligned}$$

(1) The formula above with $F_x = x$, $F_y = y$, $F_z = z = 1 - x^2 - y^2$.
(2) Polar coordinates on the disc, $\mathrm{d}x \wedge \mathrm{d}y = \rho\,\mathrm{d}\rho \wedge \mathrm{d}\phi$.

We will recover $3\pi/2$ from Gauss's theorem in Example T2.9.

Worked example T2.4: Area of the sphere and volume of the 3-sphere

On the sphere of radius a with coordinates (θ, ϕ) the orthonormal coframe is $\sigma^\theta = a\,\mathrm{d}\theta$, $\sigma^\phi = a\sin\theta\,\mathrm{d}\phi$ and the area form is $\sigma^\theta \wedge \sigma^\phi$:

$$\begin{aligned}\int_{S^2_a} \sigma^\theta \wedge \sigma^\phi &\overset{(1)}{=} \int_0^{2\pi}\int_0^{\pi} a^2 \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \\ &\overset{(2)}{=} 2\pi a^2\left[-\cos\theta\right]_0^{\pi} = 4\pi a^2.\end{aligned}$$

(1) (θ, ϕ) is positively oriented (outward normal) and covers the sphere once apart from a set of zero area (the poles and one meridian).
(2) The ϕ integral is trivial.

Dray's Problem 16.1 does the same in one dimension more. The 3-sphere of radius r has line element $\mathrm{d}s^2 = r^2\left(\mathrm{d}\psi^2 + \sin^2\psi(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2)\right)$, with $\psi, \theta \in [0, \pi]$ and $\phi \in [0, 2\pi)$. The volume form is the product of the orthonormal coframe, $r\,\mathrm{d}\psi \wedge r\sin\psi\,\mathrm{d}\theta \wedge r\sin\psi\sin\theta\,\mathrm{d}\phi$, so

$$\begin{aligned}\mathrm{Vol}(S^3_r) &\overset{(1)}{=} r^3 \int_0^{\pi} \sin^2\psi\,\mathrm{d}\psi \int_0^{\pi} \sin\theta\,\mathrm{d}\theta \int_0^{2\pi} \mathrm{d}\phi \\ &\overset{(2)}{=} r^3 \cdot \frac{\pi}{2} \cdot 2 \cdot 2\pi = 2\pi^2 r^3.\end{aligned}$$

(1) Drop the wedges; the integrand factorises.
(2) $\int_0^{\pi} \sin^2\psi\,\mathrm{d}\psi = \pi/2$ (average of $\sin^2$ is $\tfrac{1}{2}$).

The number $2\pi^2$ will reappear as the volume of $\mathrm{SU}(2) \cong S^3$ when we normalise instanton numbers in Chapter 8.

T2.1.5 Orientation

Every formula above needed an orientation. We now say what that is.

Working definition T2.2 (orientation)

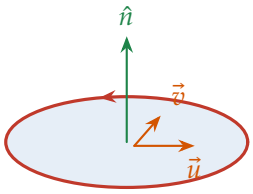
An **orientation** of an n-manifold M is a choice of nowhere-vanishing n-form vol [locally $h\,\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^n$ with $h \neq 0$ at every point], where two choices that differ by a positive

function count as the same. A chart $(x^1, \dots, x^n)$ is *positively oriented* if $\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^n = f\,\mathrm{vol}$ with $f > 0$. *Operational test:* M is orientable if you can cover it by charts whose pairwise Jacobians [the matrices $\partial\tilde{x}^\mu/\partial x^\nu$ on the overlap of two charts] all have positive determinant.

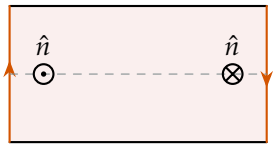
In low dimensions this is all familiar:

- A curve is oriented by a direction of travel.
- A surface in $\mathbb{R}^3$ is oriented by a continuous choice of unit normal $\hat{n}$. The two are related by the right-hand rule: a pair of tangent vectors $(\vec{u}, \vec{v})$ is positive if $\vec{u} \times \vec{v}$ points along $\hat{n}$.
- A region of $\mathbb{R}^3$ is oriented by $\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z$ (right-handed axes).
- A point is "oriented" by a sign, + or −. Integrating a 0-form over an oriented point means evaluating it and attaching the sign: $\int_{\pm P} f = \pm f(P)$ [Dray (16.23)].

Reversing the orientation of the domain reverses the sign of every integral over it. We write $-S$ for S with the opposite orientation, so $\int_{-S} \alpha = -\int_S \alpha$.



oriented surface: $\vec{u} \times \vec{v} \parallel \hat{n}$



Möbius band: glue the orange edges matching arrows (with a half twist)

Figure T2.4: Left: an orientation of a surface is a consistent choice of normal or, equivalently, of a positive order for pairs of tangent vectors. Right: a Möbius band is a strip whose ends are glued with a half twist (orange arrows). A normal pointing out of the page (⊙) carried along the core line arrives at the glued edge pointing into the page (⊗), so no consistent choice exists. Non-orientable surfaces cannot integrate 2-forms.

Watch out: the poles and the seam do not matter

The coordinates (θ, ϕ) fail at the poles and are discontinuous along the meridian $\phi = 0 \sim 2\pi$. Integrals do not care: sets of lower dimension have zero p-volume. One chart that covers everything except such a set is enough to compute an integral. (It is *not* enough to decide whether a form is globally defined; see Section T2.3.6.)

T2.1.6 Integration on a whole manifold

When no single chart covers M up to a negligible set, we cut the integrand into pieces. A **partition of unity** subordinate to an open cover $\{U_a\}$ is a family of smooth functions $\rho_a \geq 0$ with ρ_a vanishing outside U_a and $\sum_a \rho_a = 1$ everywhere. Then

$$\int_M \alpha := \sum_a \int_{U_a} \rho_a\, \alpha, \tag{T2.8}$$

and each term is computed in the chart of U_a by the recipe above. The result does not depend on the cover or the partition, by the same change-of-variables argument (T2.7).

Worked example T2.5: Two charts on the circle

Cover S^1 by $U_1 = S^1 \setminus \{(1,0)\}$ with angle $\phi_1 \in (0, 2\pi)$, and $U_2 = S^1 \setminus \{(-1,0)\}$ with angle $\phi_2 \in (-\pi, \pi)$. On the overlap, $\phi_1 = \phi_2$ on the upper half and $\phi_1 = \phi_2 + 2\pi$ on the lower half; either way $\mathrm{d}\phi_1 = \mathrm{d}\phi_2$. So there is a single, globally defined 1-form, which we call $\mathrm{d}\phi$, even though there is no global function ϕ. Choose $\rho_1 = \sin^2(\phi/2)$ and $\rho_2 = \cos^2(\phi/2)$; these are smooth on the circle, sum to 1, and ρ_1 vanishes at $(1,0)$, ρ_2 at $(-1,0)$. Then

$$\int_{S^1} \mathrm{d}\phi \overset{(1)}{=} \int_0^{2\pi} \sin^2(\phi_1/2)\,\mathrm{d}\phi_1 + \int_{-\pi}^{\pi} \cos^2(\phi_2/2)\,\mathrm{d}\phi_2 \overset{(2)}{=} \pi + \pi = 2\pi.$$

(1) Definition (T2.8); in each chart the form is $\mathrm{d}\phi_a$.
(2) Each integrand averages to $\frac{1}{2}$ over an interval of length 2π.

Of course one chart would have done. The point of the exercise is the remark in the middle: $\mathrm{d}\phi$ is a perfectly good form that is not d of any function. That observation drives Section T2.3.

Worked example T2.6: The flux of a point charge is independent of the radius

For $\vec{E} = \dfrac{q}{4\pi}\dfrac{\hat{r}}{r^2}$ the flux 2-form is $\star E = \dfrac{q}{4\pi r^2}\,\sigma^\theta \wedge \sigma^\phi$ with $\sigma^\theta \wedge \sigma^\phi = r^2 \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$ on the sphere of radius r. Thus

$$\int_{S^2_r} \star E \overset{(1)}{=} \frac{q}{4\pi}\int_0^{2\pi}\int_0^{\pi} \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \overset{(2)}{=} q.$$

(1) The r^2 in the field cancels the r^2 in the area form; in fact $\star E = \frac{q}{4\pi}\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$ everywhere on $\mathbb{R}^3 \setminus \{0\}$, with no r in it at all.
(2) The integral of $\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$ is 4π (Example T2.4 with $a = 1$).

The radius drops out. Physicists say "Gauss's law". In the language of the next sections: $\star E$ is a closed 2-form on $\mathbb{R}^3 \setminus \{0\}$ that is not exact, and its integral is the charge.

Try it: a cylinder

Integrate $\star F$ for $\vec{F} = (x, y, 0)$ over the curved side of the cylinder $x^2 + y^2 = a^2$, $0 \le z \le L$, oriented outward. *Answer:* with parameters (ϕ, z) one finds $x\,\mathrm{d}y \wedge \mathrm{d}z + y\,\mathrm{d}z \wedge \mathrm{d}x \mapsto a^2(\cos^2\phi + \sin^2\phi)\,\mathrm{d}\phi \wedge \mathrm{d}z$, so the flux is $2\pi a^2 L$. (Check the orientation: $\partial_\phi \times \partial_z$ points outward.)

Reading Nash (integrals everywhere, definitions nowhere)

Nash never explains what it means to integrate a form; he simply writes $\int_X e(X)$ [Nash p. 104, (4.53)], $\int_M \mathrm{tr}(F \wedge \mathrm{d}_A\phi)$ [Nash p. 244, (8.148)] or $\int_{S^2_\infty} \mathrm{tr}(F\phi)$ [Nash p. 245, (8.154)]. Every one of these is computed by the recipe of this section: pull back to parameters, drop the wedges, watch the orientation. When he integrates over "the two sphere at infinity" S^2_∞, he means a large sphere with the outward orientation, the one that makes Stokes' theorem (next section) hold with a plus sign.

Recap

- A p-form is the natural object to integrate over an oriented p-surface; it eats the edge vectors of small parallelograms and returns signed p-volumes.
- Circulation, flux and volume integrals are the integrals of F, $\star F$ and $\star f$ (T2.3).
- Recipe: pull back along a positively oriented parametrisation and drop the wedges. The wedge product supplies the Jacobian with its sign, so the answer is parametrisation-independent.
- Orientation reversal flips the sign. Non-orientable manifolds (Möbius band) cannot integrate top forms.
- $\mathrm{d}\phi$ on S^1 is a global 1-form with $\int_{S^1} \mathrm{d}\phi = 2\pi$, although ϕ is not a global function.

T2.2 Stokes' theorem

Vector calculus has three "big theorems": the gradient theorem, the curl theorem (usually called Stokes' theorem) and the divergence theorem. All three say the same thing: *the integral of a derivative over a region equals the integral of the undifferentiated thing over the edge of the region*. The fundamental theorem of calculus, $\int_a^b f'(x)\,\mathrm{d}x = f(b) - f(a)$, is the one-dimensional case.

With forms the three theorems, and their analogues in every dimension, become a single line. This section states that line, explains why it is true, unpacks every special case, and then draws out the consequences that physicists use daily: integration by parts, boundary terms in action principles, and the fact that some functions and fields are forced to vanish somewhere. It is the most important single formula in these notes.

T2.2.1 Boundaries and their orientation

A $(p+1)$-dimensional region R (a compact manifold with boundary) has an edge ∂R, which is a p-dimensional manifold with no edge of its own. Before Stokes' theorem can be stated we need to know how an orientation of R induces one on ∂R.

Working definition T2.3 (boundary orientation: outward normal first)

Let R be oriented and let $\hat{N}$ be a tangent vector at a point of ∂R pointing *out* of R. A list of tangent vectors $(\vec{v}_1, \ldots, \vec{v}_p)$ to ∂R is positively oriented if and only if $(\hat{N}, \vec{v}_1, \ldots, \vec{v}_p)$ is positively oriented for R [the volume form of R evaluated on this list is > 0].

Unpacking this in the cases we will use:

- $R = [a, b] \subset \mathbb{R}$, oriented left to right. At b the outward direction is $+\hat{x}$, which is positive; at a it is $-\hat{x}$, which is negative. So $\partial[a, b] = \{b\} - \{a\}$: the point b with a plus sign and a with a minus sign.
- R a region in the plane, oriented by $\mathrm{d}x \wedge \mathrm{d}y$. At the right-hand edge of a disc, $\hat{N} = \hat{x}$ and $(\hat{x}, \hat{y})$ is positive, so $\hat{y}$ (upwards) is the positive direction on the boundary. The boundary goes *counterclockwise*, keeping R on the left.
- A region with a hole (an annulus): the outer circle goes counterclockwise, the inner circle *clockwise*. Both keep the region on the left.

- R a surface in $\mathbb{R}^3$ oriented by a normal $\hat{n}$: walk along ∂R with your head along $\hat{n}$; R is on your left. This is the right-hand rule of the curl theorem.
- R a solid region in $\mathbb{R}^3$: ∂R is oriented by the outward normal.

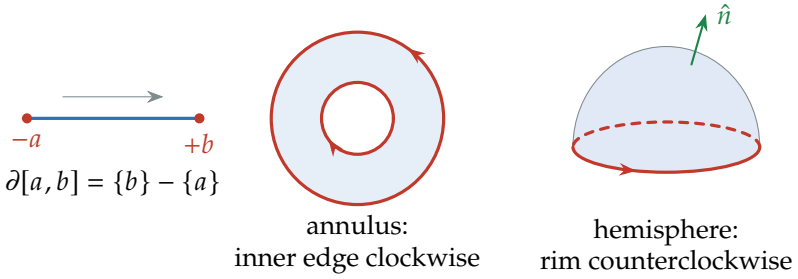


Figure T2.5: Induced boundary orientations. Left: the boundary of an interval is its endpoints with signs. Middle: the boundary of an annulus is two circles, each traversed so that the region lies to the left, so the inner one runs clockwise. Right: for a "butterfly net" surface with upward normal the rim runs counterclockwise seen from above.

T2.2.2 The theorem

Key idea: Stokes' theorem

For every p-form α and every compact oriented $(p+1)$-dimensional region R with boundary ∂R carrying the induced orientation,

$$\int_R d\alpha = \int_{\partial R} \alpha. \tag{T2.9}$$

In words: integrating a derivative over a region only sees the edge.

Dray arrives at (T2.9) by writing the three vector theorems in forms and noticing they have the same shape [Dray (16.28)–(16.33)]. He remarks that "the only real subtlety is keeping track of the relative orientations of R and its boundary", which is why we fixed that first.

T2.2.3 Why it is true: the square, then gluing

The mechanism is the fundamental theorem of calculus, applied one direction at a time. We do the case of a 1-form on a square in full; the general case is the same bookkeeping with more indices.

Let $R = [0,1] \times [0,1]$ in the (x,y)-plane and $\alpha = P\,dx + Q\,dy$. First the left side of (T2.9):

$$\begin{aligned}
\int_R d\alpha &\overset{(1)}{=} \int_R \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y}\right) dx \wedge dy \\
&\overset{(2)}{=} \int_0^1 \left[\int_0^1 \frac{\partial Q}{\partial x}\,dx\right] dy - \int_0^1 \left[\int_0^1 \frac{\partial P}{\partial y}\,dy\right] dx \\
&\overset{(3)}{=} \int_0^1 \big(Q(1,y) - Q(0,y)\big)\,dy - \int_0^1 \big(P(x,1) - P(x,0)\big)\,dx.
\end{aligned} \tag{T2.10}$$

(1) $d\alpha = \partial_y P\, dy \wedge dx + \partial_x Q\, dx \wedge dy$, and $dy \wedge dx = -dx \wedge dy$.

(2) Drop the wedge (the square is positively oriented by (x, y)) and do each term as an iterated integral, choosing the order so that the derivative is integrated first.
(3) The ordinary fundamental theorem of calculus, once in x and once in y.

Now the right side. The boundary consists of four edges, traversed counterclockwise: bottom ($y = 0$, x from 0 to 1), right ($x = 1$, y from 0 to 1), top ($y = 1$, x from 1 to 0), left ($x = 0$, y from 1 to 0). On a horizontal edge $\mathrm{d}y = 0$ and on a vertical edge $\mathrm{d}x = 0$. So

$$\begin{aligned}\int_{\partial R} \alpha &\overset{(1)}{=} \int_0^1 P(x,0)\,\mathrm{d}x + \int_0^1 Q(1,y)\,\mathrm{d}y + \int_1^0 P(x,1)\,\mathrm{d}x + \int_1^0 Q(0,y)\,\mathrm{d}y \\ &\overset{(2)}{=} \int_0^1 \big(Q(1,y) - Q(0,y)\big)\mathrm{d}y - \int_0^1 \big(P(x,1) - P(x,0)\big)\mathrm{d}x, \end{aligned} \tag{T2.11}$$

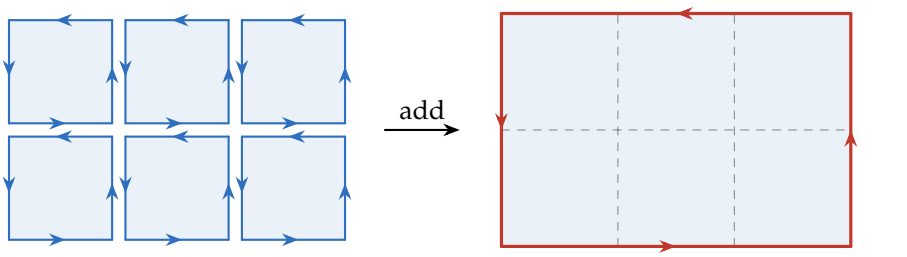
(1) Pull α back to each edge; only one of $\mathrm{d}x$, $\mathrm{d}y$ survives on each.
(2) Reverse the limits on the top and left edges, which costs a sign.

which is (T2.10). Stokes' theorem holds for the square.

Gluing. Any region can be chopped into many small squares (or, on a curved surface, small images of squares under parametrisations). Apply (T2.9) to each and add. On the left we get $\int_R \mathrm{d}\alpha$. On the right, every interior edge is shared by two squares and is traversed in opposite directions by them, so its contributions cancel. Only the outer edges survive, and together they make ∂R with its induced orientation. This is Figure T2.6.

Curved regions. For a region that is the image of a square under φ, we use that pullback commutes with d (Chapter T1), $\varphi^*\mathrm{d}\alpha = \mathrm{d}\varphi^*\alpha$, and that φ maps the boundary of the square to the boundary of the region. Then $\int_{\varphi(R)} \mathrm{d}\alpha = \int_R \mathrm{d}(\varphi^*\alpha) = \int_{\partial R} \varphi^*\alpha = \int_{\partial\varphi(R)} \alpha$.

Higher dimensions. For an $(n-1)$-form on the unit n-cube, each term looks like $f\,\mathrm{d}x^2\wedge\cdots\wedge\mathrm{d}x^n$ (up to relabelling). Its derivative is $\partial_1 f\,\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^n$. Integrating in x^1 first gives $f|_{x^1=1} - f|_{x^1=0}$, the contributions of the two faces perpendicular to x^1, with the signs dictated by "outward normal first". All other faces have some $\mathrm{d}x^j = 0$ for $j \geq 2$ and contribute nothing to this term. The rest is gluing.



each little square: counterclockwise interior edges cancel; only ∂R survives

Figure T2.6: The gluing argument. Each small square satisfies Stokes' theorem by the fundamental theorem of calculus. Adjacent squares traverse their common edge in opposite directions, so interior contributions cancel in pairs. What remains is the circulation around the outer boundary.

T2.2.4 All the special cases

We now read off the classical theorems. In $\mathbb{R}^3$ we need the translation of d into grad, curl and div (Chapter T1); we re-derive the two that matter. For $F = F_x dx + F_y dy + F_z dz$,

$$\begin{aligned} dF &\overset{(1)}{=} (\partial_y F_x\, dy + \partial_z F_x\, dz) \wedge dx + (\partial_x F_y\, dx + \partial_z F_y\, dz) \wedge dy + (\partial_x F_z\, dx + \partial_y F_z\, dy) \wedge dz \\ &\overset{(2)}{=} (\partial_y F_z - \partial_z F_y)\, dy \wedge dz + (\partial_z F_x - \partial_x F_z)\, dz \wedge dx + (\partial_x F_y - \partial_y F_x)\, dx \wedge dy \\ &\overset{(3)}{=} \star(\vec{\nabla} \times \vec{F}) = (\vec{\nabla} \times \vec{F}) \cdot d\vec{A}, \end{aligned} \tag{T2.12}$$

(1) $d(F_x\, dx) = dF_x \wedge dx$ and similarly; the $\partial_x F_x\, dx \wedge dx$ terms vanish.
(2) Collect terms, putting each 2-form in cyclic order $dy \wedge dz$, $dz \wedge dx$, $dx \wedge dy$.
(3) Compare with (T2.2): the coefficients are the Cartesian components of the curl.

and, applying d to $\star F$,

$$\begin{aligned} d\star F &\overset{(1)}{=} \partial_x F_x\, dx \wedge dy \wedge dz + \partial_y F_y\, dy \wedge dz \wedge dx + \partial_z F_z\, dz \wedge dx \wedge dy \\ &\overset{(2)}{=} (\vec{\nabla} \cdot \vec{F})\, dx \wedge dy \wedge dz = (\vec{\nabla} \cdot \vec{F})\, dV. \end{aligned} \tag{T2.13}$$

(1) Only the derivative in the missing direction survives in each term.
(2) Cyclic permutations of three 1-forms are even, so all three 3-forms equal $dx \wedge dy \wedge dz$.

Key idea: the four classical theorems are one theorem

p	α	$\int_R d\alpha = \int_{\partial R} \alpha$ reads	name
0	f	$\int_C \vec{\nabla} f \cdot d\vec{r} = f(B) - f(A)$	FTC / gradient theorem
1	$P dx + Q dy$	$\iint_D (\partial_x Q - \partial_y P)\, dx\, dy = \oint_{\partial D} P dx + Q dy$	Green
1	F	$\iint_S (\vec{\nabla} \times \vec{F}) \cdot d\vec{A} = \oint_{\partial S} \vec{F} \cdot d\vec{r}$	curl (Kelvin–Stokes)
2	$\star F$	$\iiint_V \vec{\nabla} \cdot \vec{F}\, dV = \oiint_{\partial V} \vec{F} \cdot d\vec{A}$	Gauss / divergence

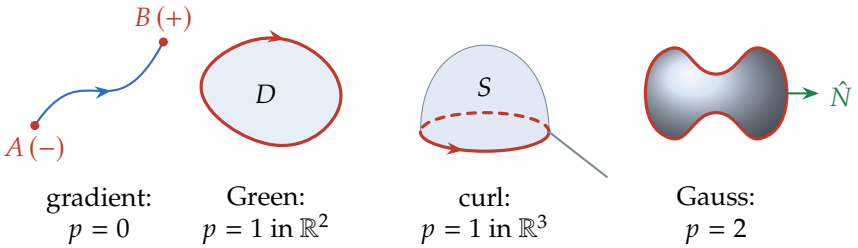


Figure T2.7: The four geometries of Stokes' theorem, in increasing dimension: a curve and its two signed endpoints; a planar region and its counterclockwise rim; Dray's "butterfly net" surface and its rim; a solid "dumbbell" and its outward-oriented surface. The boundary is always drawn in red.

Worked example T2.7: Area from a line integral (Green)

Take $\alpha = \frac{1}{2}(x\, dy - y\, dx)$. Then $d\alpha = \frac{1}{2}(dx \wedge dy - dy \wedge dx) = dx \wedge dy$, so Green's theorem says $\text{Area}(D) = \frac{1}{2}\oint_{\partial D}(x\, dy - y\, dx)$. This is how a planimeter works. For the ellipse

$x = a\cos t$, $y = b\sin t$:

$$\text{Area} \overset{(1)}{=} \tfrac{1}{2}\int_0^{2\pi} \big(a\cos t \cdot b\cos t - b\sin t \cdot (-a\sin t)\big)\,\mathrm{d}t$$
$$\overset{(2)}{=} \tfrac{1}{2}\int_0^{2\pi} ab\,\mathrm{d}t = \pi ab.$$

(1) Pull back: $\mathrm{d}x = -a\sin t\,\mathrm{d}t$, $\mathrm{d}y = b\cos t\,\mathrm{d}t$.
(2) $\cos^2 + \sin^2 = 1$.

For $a = b = R$ this is Example T2.2 divided by 2, as promised.

Worked example T2.8: The curl theorem on a hemisphere, and why the surface does not matter

Let $\alpha = -y\,\mathrm{d}x + x\,\mathrm{d}y$ in $\mathbb{R}^3$ and let S be the upper hemisphere of radius R with the outward (upward) normal. Its rim is the equator traversed counterclockwise, and Example T2.2 gave $\oint_{\partial S}\alpha = 2\pi R^2$. On the other side, $\mathrm{d}\alpha = 2\,\mathrm{d}x\wedge\mathrm{d}y$. On the sphere $x = R\sin\theta\cos\phi$, $y = R\sin\theta\sin\phi$, and the polar-coordinate computation of Section T2.1.3 with $r \to R\sin\theta$ gives $\mathrm{d}x\wedge\mathrm{d}y = R\sin\theta\,\mathrm{d}(R\sin\theta)\wedge\mathrm{d}\phi = R^2\sin\theta\cos\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi$. So

$$\int_S \mathrm{d}\alpha \overset{(1)}{=} 2R^2\int_0^{2\pi}\int_0^{\pi/2} \sin\theta\cos\theta\,\mathrm{d}\theta\,\mathrm{d}\phi$$
$$\overset{(2)}{=} 2R^2\cdot 2\pi\cdot\tfrac{1}{2} = 2\pi R^2.$$

(1) (θ,ϕ) is positively oriented for the outward normal; restrict to $\theta \le \pi/2$.
(2) $\int_0^{\pi/2}\sin\theta\cos\theta\,\mathrm{d}\theta = \tfrac{1}{2}\sin^2\theta\big|_0^{\pi/2} = \tfrac{1}{2}$.

The flat disc $x^2 + y^2 \le R^2$ with the same rim gives $\int 2\,\mathrm{d}x\wedge\mathrm{d}y = 2\pi R^2$ too. Why must any two surfaces S_1, S_2 with the same rim agree? Glue S_1 to $-S_2$: the result is a closed surface Σ (no edge), and

$$\int_{S_1}\mathrm{d}\alpha - \int_{S_2}\mathrm{d}\alpha \overset{(1)}{=} \int_\Sigma \mathrm{d}\alpha$$
$$\overset{(2)}{=} \int_{\partial\Sigma}\alpha$$
$$\overset{(3)}{=} 0.$$

(1) Reversing orientation flips the sign; the rims cancel when glued.
(2) Stokes' theorem.
(3) A closed surface has empty boundary, and an integral over the empty set is zero.

This is the argument of the model paragraph in our style guide, and we will use it again and again.

Worked example T2.9: Gauss's theorem for the paraboloid

Let V be the solid $0 \le z \le 1 - x^2 - y^2$ and $\vec{F} = \vec{r}$, so $\vec{\nabla}\cdot\vec{F} = 3$. Its boundary is the paraboloid cap S of Example T2.3 together with the unit disc B at $z = 0$ with downward normal. Then

$$\int_S \star F + \int_B \star F \overset{(1)}{=} \int_V \mathrm{d}\star F$$

$$\overset{(2)}{=} 3\int_0^{2\pi}\int_0^1 (1-\rho^2)\,\rho\,\mathrm{d}\rho\,\mathrm{d}\phi$$
$$= 3\cdot 2\pi\left(\tfrac{1}{2}-\tfrac{1}{4}\right) = \frac{3\pi}{2}.$$

(1) Stokes (Gauss) with $\partial V = S \cup B$, both outward.
(2) $\mathrm{d}{\star}F = 3\,\mathrm{d}V$ by (T2.13); the height of the solid above (ρ,ϕ) is $1-\rho^2$.

On B we have $z = 0$ and $\mathrm{d}z = 0$, so ${\star}F|_B = z\,\mathrm{d}x\wedge\mathrm{d}y = 0$. Hence $\int_S {\star}F = 3\pi/2$, agreeing with the direct computation in Example T2.3.

T2.2.5 The boundary of a boundary is empty, and $\mathrm{d}^2 = 0$

The boundary of a disc is a circle, and a circle has no boundary. The boundary of a ball is a sphere, which has no boundary. In general $\partial(\partial R) = \varnothing$. Stokes' theorem says that d and ∂ are *adjoint* under integration, $\int_R \mathrm{d}\alpha = \int_{\partial R}\alpha$. So $\mathrm{d}^2 = 0$ and $\partial^2 = \varnothing$ are two faces of one fact:

$$\int_R \mathrm{d}(\mathrm{d}\beta) \overset{(1)}{=} \int_{\partial R}\mathrm{d}\beta \overset{(2)}{=} \int_{\partial\partial R}\beta \overset{(3)}{=} 0. \tag{T2.14}$$

(1) Stokes on R.
(2) Stokes on the closed manifold ∂R.
(3) $\partial\partial R = \varnothing$.

Since this holds for every R, the form $\mathrm{d}\mathrm{d}\beta$ integrates to zero over every small region, so it vanishes identically. In vector language: $\vec{\nabla}\times\vec{\nabla}f = 0$ and $\vec{\nabla}\cdot(\vec{\nabla}\times\vec{A}) = 0$. This duality between d acting on forms and ∂ acting on regions is exactly the duality between cohomology and homology that Nash sets up in [Nash p. 13, (1.43)–(1.44)].

T2.2.6 Integration by parts

The product rule for forms (Chapter T1) is $\mathrm{d}(\alpha\wedge\beta) = \mathrm{d}\alpha\wedge\beta + (-1)^p\alpha\wedge\mathrm{d}\beta$ for a p-form α. Integrate over R and use Stokes on the total derivative [Dray (16.46)]:

$$\int_R \mathrm{d}\alpha\wedge\beta = \int_{\partial R}\alpha\wedge\beta - (-1)^p\int_R \alpha\wedge\mathrm{d}\beta. \tag{T2.15}$$

Special cases: for functions on a curve, $\int_C f\,\mathrm{d}g = [fg]_{\partial C} - \int_C g\,\mathrm{d}f$, the rule from first-year calculus. For a function f and a form α, $\int_D f\,\mathrm{d}\alpha = \int_{\partial D} f\alpha - \int_D \mathrm{d}f\wedge\alpha$ [Dray (16.48)].

The adjoint of d. On a closed Riemannian manifold (no boundary) define the inner product of two p-forms by $\langle\alpha,\beta\rangle = \int_M \alpha\wedge{\star}\beta$. Then (T2.15) with no boundary term says that moving d from one slot to the other costs only a sign and some Hodge stars. The operator that appears is the adjoint $\mathrm{d}^* = \pm{\star}\mathrm{d}{\star}$ (the sign depends on degree and dimension; Chapter T1), defined by $\langle\mathrm{d}\alpha,\beta\rangle = \langle\alpha,\mathrm{d}^*\beta\rangle$. The Hodge Laplacian $\Delta = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$ is built from it; see Section T2.4.9.

Worked example T2.10: Harmonic functions on a closed manifold are constant

This is Dray's Problems 16.3–16.4. Let M be a closed, connected, Riemannian manifold (for instance the flat torus with $\mathrm{d}s^2 = a^2\mathrm{d}\theta^2 + b^2\mathrm{d}\phi^2$, or the round S^2). Use Dray's Laplacian $\Delta f = \star\mathrm{d}\star\,\mathrm{d}f$ and suppose $\Delta f = 0$. Since $\star$ is invertible, $\mathrm{d}\star\mathrm{d}f = 0$. Then

$$\begin{aligned} 0 &\overset{(1)}{=} \int_M f\,\mathrm{d}\star\mathrm{d}f \\ &\overset{(2)}{=} \int_M \mathrm{d}\big(f\star\mathrm{d}f\big) - \int_M \mathrm{d}f\wedge\star\mathrm{d}f \\ &\overset{(3)}{=} 0 - \int_M |\mathrm{d}f|^2\ \mathrm{vol}. \end{aligned}$$

(1) $\mathrm{d}\star\mathrm{d}f = 0$ by assumption.
(2) The product rule $\mathrm{d}(f\beta) = \mathrm{d}f\wedge\beta + f\,\mathrm{d}\beta$ with $\beta = \star\mathrm{d}f$.
(3) Stokes with $\partial M = \varnothing$ kills the first term; for any 1-form γ, $\gamma\wedge\star\gamma = |\gamma|^2\,\mathrm{vol}$ (the defining property of $\star$).

In Euclidean signature $|\mathrm{d}f|^2 \geq 0$, so the integral of a non-negative function vanishes: $\mathrm{d}f = 0$ everywhere and f is constant. On the torus this says the only solutions of $a^{-2}\partial_\theta^2 f + b^{-2}\partial_\phi^2 f = 0$ are constants, as a Fourier series check confirms: $e^{i(m\theta+n\phi)}$ has eigenvalue $-(m^2/a^2 + n^2/b^2)$, which vanishes only for $m = n = 0$. In Minkowski signature the argument fails because $|\mathrm{d}f|^2$ has no sign: there are plenty of non-constant solutions of the wave equation.

T2.2.7 Corollaries: things that must vanish somewhere

Dray draws some pretty consequences from Stokes' theorem on closed manifolds [Dray §16.7]. Let M be a closed oriented n-manifold with orientation form vol, so $\int_M \mathrm{vol} > 0$.

Key idea: an exact top form must change sign or vanish

If $\mathrm{d}\alpha = h\,\mathrm{vol}$ for some $(n-1)$-form α and function h, then $\int_M h\,\mathrm{vol} = \int_{\partial M}\alpha = 0$. A continuous h with zero integral against a positive measure either vanishes identically or takes both signs; either way *h has a zero*. In particular vol itself is not exact.

- *Every smooth function on a circle has a critical point.* Take $n = 1$, $\alpha = f$, $\mathrm{d}f = f'(\phi)\,\mathrm{d}\phi$. Then f' has a zero. (Obvious from the picture: a periodic function has a maximum.)

- *Every smooth vector field on a sphere has vanishing curl (normal component) somewhere.* Take $\alpha = F = \vec{F}\cdot\mathrm{d}\vec{r}$ restricted to S^2. Then $\mathrm{d}F = (\vec{\nabla}\times\vec{F})\cdot\hat{n}\,\mathrm{vol}$, so $(\vec{\nabla}\times\vec{F})\cdot\hat{n}$ has a zero on S^2.

- *Charge neutrality on a closed universe.* On a closed spatial manifold Gauss's law $\mathrm{d}\star E = \rho\,\mathrm{vol}$ forces $\int\rho\,\mathrm{vol} = 0$: the total charge of a closed universe is zero.

T2.2.8 Boundary terms in action principles

A Lagrangian density is an n-form, and the action is its integral [Dray §20.2]. Varying the action produces a total derivative, and Stokes' theorem turns it into a boundary term. For a scalar

field Φ with $S[\Phi] = \int_R \mathrm{d}\Phi \wedge \star\mathrm{d}\Phi$, vary $\Phi \to \Phi + \delta\Phi$:

$$\begin{aligned}\delta S &\overset{(1)}{=} \int_R \left(\mathrm{d}\delta\Phi \wedge \star\mathrm{d}\Phi + \mathrm{d}\Phi \wedge \star\mathrm{d}\delta\Phi\right)\\ &\overset{(2)}{=} 2\int_R \mathrm{d}\delta\Phi \wedge \star\mathrm{d}\Phi\\ &\overset{(3)}{=} 2\int_R \mathrm{d}\left(\delta\Phi \star\mathrm{d}\Phi\right) - 2\int_R \delta\Phi\, \mathrm{d}\star\mathrm{d}\Phi\\ &\overset{(4)}{=} 2\int_{\partial R} \delta\Phi \star\mathrm{d}\Phi - 2\int_R \delta\Phi\, \mathrm{d}\star\mathrm{d}\Phi. \end{aligned} \tag{T2.16}$$

(1) Keep terms linear in $\delta\Phi$; d commutes with the variation.
(2) The inner product is symmetric: $\alpha \wedge \star\beta = \beta \wedge \star\alpha$ for forms of equal degree.
(3) Product rule, as in Example T2.10.
(4) Stokes' theorem on the total derivative.

Variations supported away from the edge give the field equation $\mathrm{d}\star\mathrm{d}\Phi = 0$, which is Laplace's equation (or the wave equation in Minkowski signature). If $\delta\Phi$ is free on ∂R as well, the boundary term forces $\star\mathrm{d}\Phi|_{\partial R} = 0$: the normal derivative of Φ vanishes (the Neumann condition), because $\star\mathrm{d}\Phi$ restricted to a surface is the flux of $\vec{\nabla}\Phi$ through it. The same computation with $L = F \wedge \star F$, $F = \mathrm{d}A$, gives the vacuum Maxwell equation $\mathrm{d}\star F = 0$; the other half, $\mathrm{d}F = 0$, is $\mathrm{d}^2 = 0$.

Reading Nash (Stokes' theorem in the Bogomolny argument)

Nash uses exactly the reasoning of Section T2.2.7 when he studies monopoles [Nash p. 244, (8.149)–(8.150)]. He shows that the cross term in the energy is a total derivative, $\mathrm{tr}(F \wedge \mathrm{d}_A\phi) = \mathrm{d}\,\mathrm{tr}(F\phi)$, and concludes: "Thus if M is compact and closed Stokes' theorem gives $\langle F, \star\mathrm{d}_A\phi\rangle = -\int_M \mathrm{d}\,\mathrm{tr}(F\phi) = 0$." On $\mathbb{R}^3$ the boundary is the sphere at infinity, and the same integral becomes $\frac{1}{4\pi}\int_{S^2_\infty} \mathrm{tr}(F\phi)$, the magnetic charge [Nash p. 245, (8.154)]. The whole topological content of the monopole lives in a boundary term, and it is Stokes' theorem that puts it there.

Recap

- $\int_R \mathrm{d}\alpha = \int_{\partial R} \alpha$, with ∂R oriented "outward normal first" (counterclockwise for planar regions).
- Mechanism: the fundamental theorem of calculus one direction at a time on a small cube; interior faces cancel when cubes are glued.
- FTC, gradient, Green, curl and divergence theorems are the cases $p = 0, 1, 1, 2$.
- $\mathrm{d}^2 = 0$ is the dual of $\partial^2 = \varnothing$.
- Integration by parts (T2.15); on closed manifolds harmonic functions are constant.
- On a closed manifold an exact top form integrates to zero, so its coefficient must vanish somewhere; the volume form is not exact.
- Varying an action gives field equations plus a boundary term.

T2.3 Closed and exact forms

Every physicist knows the curl test. If $\vec{\nabla}\times\vec{F}=0$, then $\vec{F}$ is the gradient of a potential, $\vec{F}=\vec{\nabla}f$, and the work done along a path depends only on its endpoints. Every physicist also knows that the test has a fine-print clause: "in a simply connected region". The standard counterexample is the magnetic field of a straight wire, $\vec{B}\propto\hat{\phi}/\rho$. Its curl vanishes everywhere away from the wire, yet its circulation around the wire is not zero, so it is *not* a gradient.

This section is about that fine print. In the language of forms the curl test asks: *if* $\mathrm{d}\alpha=0$, *is* $\alpha=\mathrm{d}\beta$*?* The answer is "yes, locally, always" (the Poincaré lemma) and "globally, not necessarily". The failures are not a nuisance. They are the first appearance of topology in these notes: a closed form that is not exact is a detector for a hole in the space. Stokes' theorem is the tool that detects it.

T2.3.1 Two definitions and one implication

Working definition T2.4 (closed and exact)

A p-form α on a manifold M is

- **closed** if $\mathrm{d}\alpha=0$ (test: differentiate it);
- **exact** if $\alpha=\mathrm{d}\beta$ for some $(p-1)$-form β that is smooth *on all of* M (test: find β, or use the Stokes detector below to prove none exists [a closed p-surface S, with no boundary, on which $\int_S\alpha\neq0$]).

The form β is called a **potential** for α. *Formally:* closed forms are $\ker\mathrm{d}$, exact forms are $\mathrm{im}\,\mathrm{d}$.

Exact implies closed, because $\mathrm{d}^2=0$ (Chapter T1):

$$\alpha=\mathrm{d}\beta\quad\Longrightarrow\quad\mathrm{d}\alpha=\mathrm{dd}\beta=0. \tag{T2.17}$$

Dray calls this the Poincaré lemma and its converse "the converse of the Poincaré lemma", and he notes that the converse is often *also* called the Poincaré lemma [Dray §20.4]. We will reserve the name for the converse, Section T2.3.3, as most books do.

In $\mathbb{R}^3$, with the dictionary of Section T2.1, the implication (T2.17) is two familiar identities:

degree	exact	closed	identity
0	—	$\mathrm{d}f=0$: f locally constant	—
1	$F=\mathrm{d}f$: $\vec{F}=\vec{\nabla}f$	$\mathrm{d}F=0$: $\vec{\nabla}\times\vec{F}=0$	$\vec{\nabla}\times\vec{\nabla}f=0$
2	$\star F=\mathrm{d}A$: $\vec{F}=\vec{\nabla}\times\vec{A}$	$\mathrm{d}\star F=0$: $\vec{\nabla}\cdot\vec{F}=0$	$\vec{\nabla}\cdot(\vec{\nabla}\times\vec{A})=0$
3	$\star f=\mathrm{d}\star A$: $f=\vec{\nabla}\cdot\vec{A}$	always (d of a 3-form in $\mathbb{R}^3$ is 0)	—

Physicists meet exact 1-forms as *conservative forces* and exact 2-forms as *magnetic fields with a vector potential*. The table's middle column is what we can test by differentiating. The left column is what we want.

Worked example T2.11: An exact 1-form and a closed 1-form

Let $\alpha=x\,\mathrm{d}x+y\,\mathrm{d}y$ on $\mathbb{R}^2$. It is exact: $\alpha=\mathrm{d}\left(\frac{1}{2}(x^2+y^2)\right)$, as Dray observes [Dray §20.4]. Now

let $\gamma = 2xy\,dx + (x^2 + \cos y)\,dy$. Is it closed?

$$d\gamma \overset{(1)}{=} \partial_y(2xy)\,dy \wedge dx + \partial_x(x^2 + \cos y)\,dx \wedge dy$$
$$\overset{(2)}{=} (-2x + 2x)\,dx \wedge dy = 0.$$

(1) $d(g\,dx) = dg \wedge dx = \partial_y g\,dy \wedge dx$, and similarly for the dy term.
(2) $dy \wedge dx = -dx \wedge dy$.

It is closed, and indeed $\gamma = d(x^2y + \sin y)$. We will find this potential mechanically in Example T2.12.

T2.3.2 The Stokes detector

Here is the owner's favourite argument, stated once and for all. It is the only tool we need to prove that a form is *not* exact.

Key idea: an exact form integrates to zero over anything without boundary

Let $\alpha = d\beta$ be exact and let Z be a closed (compact, boundaryless) oriented p-dimensional submanifold, or more generally any p-dimensional "cycle" with $\partial Z = \varnothing$. Then

$$\int_Z \alpha \overset{(1)}{=} \int_Z d\beta \overset{(2)}{=} \int_{\partial Z} \beta \overset{(3)}{=} \int_{\varnothing} \beta = 0. \tag{T2.18}$$

(1) α is exact, with a potential β defined on all of Z.
(2) Stokes' theorem (T2.9).
(3) Z has no boundary; an integral over the empty set is a sum with no terms.

Read backwards: *one closed cycle Z with $\int_Z \alpha \neq 0$ proves that α is not exact*, however cleverly we search for β.

Two remarks make the detector sharper.

The potential must exist on Z itself. Step (1) needs β to be smooth on all of Z. A potential that blows up somewhere on Z does not count, and this is exactly how the "paradoxes" below are resolved.

For 1-forms the detector is also sufficient. Suppose α is a 1-form on a connected manifold with $\oint_\gamma \alpha = 0$ for *every* closed loop γ. Fix a base point x_0 and define $f(x) = \int_{x_0}^{x} \alpha$ along any path. Two paths from x_0 to x together make a closed loop (go out along one, back along the other), so the answer does not depend on the path. Moving the endpoint a little in the direction $\vec{v}$ changes f by $\alpha(\vec{v})$ times the step, so $df = \alpha$. Hence

$$\alpha \text{ exact} \iff \oint_\gamma \alpha = 0 \text{ for every closed loop } \gamma \iff \text{line integrals of } \alpha \text{ are path independent.} \tag{T2.19}$$

This is the conservative-force theorem of mechanics. In higher degree the analogous statement (a closed p-form is exact if and only if all its integrals over closed p-cycles vanish) is de Rham's theorem, Section T2.4.8; for us it is enough to know that the detector (T2.18) never lies.

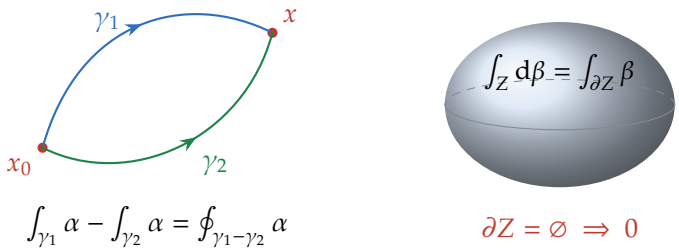

Figure T2.8: Left: two paths with the same endpoints differ by a closed loop, so path independence is the same as "zero circulation around every loop". Right: the Stokes detector. A closed surface has no edge, so an exact form has nothing to be converted into and integrates to zero.

Potentials are not unique. If $\alpha = \mathrm{d}\beta$, then also $\alpha = \mathrm{d}(\beta + \mathrm{d}\gamma)$ for any $(p-2)$-form γ, because $\mathrm{d}\mathrm{d}\gamma = 0$ [Dray (20.29)]. For $p = 1$ this is the familiar "+ constant" of an indefinite integral, $\mathrm{d}(f + c) = \mathrm{d}f$ [Dray (20.30)]. For $p = 2$ it is *gauge freedom*: the vector potential of a magnetic field is determined only up to $A \mapsto A + \mathrm{d}\lambda$, i.e. $\vec{A} \mapsto \vec{A} + \vec{\nabla}\lambda$. Physics lives in α; the potential carries redundant information. We will see in Section T2.5.10 that the connection of a surface has exactly the same redundancy.

T2.3.3 The Poincaré lemma: closed is locally exact

Now the positive result. We show that on a **star-shaped** region $U \subset \mathbb{R}^n$ (one containing a point, which we take as the origin, such that the straight segment from the origin to any point of U lies in U) every closed form is exact. The proof is constructive: it hands us the potential as an explicit integral. Balls, cubes, half-spaces and $\mathbb{R}^n$ itself are star-shaped. Every point of every manifold has a star-shaped coordinate neighbourhood, so every closed form is exact *locally*.

The idea. Shrink the region to the origin by the scaling map $\phi_t(x) = tx$, $0 \le t \le 1$. At $t = 1$ nothing has moved; at $t = 0$ everything sits at the origin, where a p-form with $p \ge 1$ pulled back along a constant map is zero. So $\alpha = \phi_1^*\alpha - \phi_0^*\alpha$ is the integral of a t-derivative. That derivative turns out to be exact when $\mathrm{d}\alpha = 0$.

The 1-form case by hand. Let $\alpha = \alpha_\mu\,\mathrm{d}x^\mu$ be closed, so $\partial_\nu\alpha_\mu = \partial_\mu\alpha_\nu$. Define f by integrating α along the ray from 0 to x, parametrised by $t \mapsto tx$ (so $\mathrm{d}x^\mu \mapsto x^\mu\,\mathrm{d}t$):

$$f(x) := \int_0^1 x^\mu\,\alpha_\mu(tx)\,\mathrm{d}t. \tag{T2.20}$$

Then

$$\begin{aligned}
\partial_\nu f(x) &\overset{(1)}{=} \int_0^1 \Big(\alpha_\nu(tx) + x^\mu\, t\,(\partial_\nu\alpha_\mu)(tx)\Big)\mathrm{d}t \\
&\overset{(2)}{=} \int_0^1 \Big(\alpha_\nu(tx) + t\,x^\mu(\partial_\mu\alpha_\nu)(tx)\Big)\mathrm{d}t \\
&\overset{(3)}{=} \int_0^1 \frac{\mathrm{d}}{\mathrm{d}t}\Big(t\,\alpha_\nu(tx)\Big)\mathrm{d}t \\
&\overset{(4)}{=} \alpha_\nu(x).
\end{aligned} \tag{T2.21}$$

(1) Differentiate under the integral: $\partial_\nu x^\mu = \delta^\mu_\nu$, and the chain rule on $\alpha_\mu(tx)$ gives a factor t.

(2) Closedness, $\partial_\nu \alpha_\mu = \partial_\mu \alpha_\nu$.
(3) Product rule: $\frac{\mathrm{d}}{\mathrm{d}t}\big(t\,\alpha_\nu(tx)\big) = \alpha_\nu(tx) + t\,x^\mu(\partial_\mu\alpha_\nu)(tx)$.
(4) Fundamental theorem of calculus; the lower limit gives $0 \cdot \alpha_\nu(0) = 0$.

So $\mathrm{d}f = \alpha$. Closedness was used exactly once, in step (2). Without it, step (3) fails and the ray integral has the wrong gradient.

All degrees: the homotopy operator. Let $E = x^\mu \partial_\mu$ be the radial (Euler) vector field; its flow is scaling. For a p-form $\alpha = \frac{1}{p!}\alpha_{\mu_1\ldots\mu_p}\mathrm{d}x^{\mu_1}\wedge\cdots\wedge\mathrm{d}x^{\mu_p}$ with $p \geq 1$ define the $(p-1)$-form

$$(K\alpha)(x) := \int_0^1 t^{p-1}\,\big(\iota_x\alpha\big)(tx)\,\mathrm{d}t = \frac{1}{(p-1)!}\int_0^1 t^{p-1}x^\mu\alpha_{\mu\nu_2\ldots\nu_p}(tx)\,\mathrm{d}t\;\mathrm{d}x^{\nu_2}\wedge\cdots\wedge\mathrm{d}x^{\nu_p}, \tag{T2.22}$$

where ι_x means "feed the position vector into the first slot". For $p = 1$ this is (T2.20). The key identity is

$$\mathrm{d}K\alpha + K\mathrm{d}\alpha = \alpha \qquad (p \geq 1), \qquad\qquad K\mathrm{d}f = f - f(0) \qquad (p = 0). \tag{T2.23}$$

Here is why. Write $t = e^s$, so ϕ_t is the flow of E for time s. The derivative of a pulled-back form along a flow is the Lie derivative (Chapter T1), and Cartan's formula gives $\mathcal{L}_E = \mathrm{d}\,\iota_E + \iota_E\,\mathrm{d}$. Then for $p \geq 1$

$$\begin{aligned}
\alpha &\overset{(1)}{=} \phi_1^*\alpha - \phi_0^*\alpha = \int_0^1 \frac{\mathrm{d}}{\mathrm{d}t}\phi_t^*\alpha\;\mathrm{d}t \\
&\overset{(2)}{=} \int_0^1 \frac{1}{t}\,\phi_t^*\big(\mathcal{L}_E\alpha\big)\,\mathrm{d}t \\
&\overset{(3)}{=} \int_0^1 \frac{1}{t}\,\phi_t^*\big(\mathrm{d}\,\iota_E\alpha\big)\,\mathrm{d}t + \int_0^1 \frac{1}{t}\,\phi_t^*\big(\iota_E\,\mathrm{d}\alpha\big)\,\mathrm{d}t \\
&\overset{(4)}{=} \mathrm{d}\Big(\int_0^1 \frac{1}{t}\,\phi_t^*\,\iota_E\alpha\,\mathrm{d}t\Big) + \int_0^1 \frac{1}{t}\,\phi_t^*\,\iota_E(\mathrm{d}\alpha)\,\mathrm{d}t \\
&\overset{(5)}{=} \mathrm{d}K\alpha + K\mathrm{d}\alpha.
\end{aligned} \tag{T2.24}$$

(1) $\phi_1 = \mathrm{id}$, and ϕ_0 maps everything to the origin, so ϕ_0^* kills every form of degree ≥ 1 (all $\mathrm{d}x^\mu$ pull back to 0).
(2) $\frac{\mathrm{d}}{\mathrm{d}t} = \frac{1}{t}\frac{\mathrm{d}}{\mathrm{d}s}$, and $\frac{\mathrm{d}}{\mathrm{d}s}\phi^*\alpha = \phi^*\mathcal{L}_E\alpha$ by the definition of the Lie derivative along a flow.
(3) Cartan's formula.
(4) Pullback commutes with d, and so does integration over the parameter t.
(5) In components, ϕ_t^* replaces x by tx in the coefficients and each $\mathrm{d}x^\nu$ by $t\,\mathrm{d}x^\nu$; $\iota_E\alpha$ has one factor x^μ (giving tx^μ) and $p-1$ differentials, so $\frac{1}{t}\phi_t^*\iota_E\alpha = t^{p-1}x^\mu\alpha_{\mu\ldots}(tx)\,\mathrm{d}x^{\nu_2}\wedge\cdots$, which is the integrand of (T2.22).

(The integrand of (T2.24) is harmless at $t = 0$: after step (5) there is no $1/t$ left.)

Key idea: Poincaré lemma

On a star-shaped region every closed p-form with $p \geq 1$ is exact, with the explicit potential $\beta = K\alpha$ of (T2.22). Every closed 0-form is constant. *Reason:* if $\mathrm{d}\alpha = 0$, the identity $\mathrm{d}K + K\mathrm{d} = 1$ reduces to $\alpha = \mathrm{d}(K\alpha)$.

Worked example T2.12: Finding a potential mechanically

For $\gamma = 2xy\,\mathrm{d}x + (x^2 + \cos y)\,\mathrm{d}y$ from Example T2.11, formula (T2.20) gives

$$\begin{aligned} f(x,y) &\overset{(1)}{=} \int_0^1 \Big(x\cdot 2(tx)(ty) + y\cdot\big((tx)^2 + \cos(ty)\big)\Big)\mathrm{d}t \\ &\overset{(2)}{=} \int_0^1 \big(3t^2x^2y + y\cos(ty)\big)\mathrm{d}t \\ &\overset{(3)}{=} x^2y + \sin y. \end{aligned}$$

(1) $f = \int_0^1 (x\,\gamma_x + y\,\gamma_y)(tx,ty)\,\mathrm{d}t$.
(2) Collect: $2t^2x^2y + t^2x^2y = 3t^2x^2y$.
(3) $\int_0^1 3t^2\mathrm{d}t = 1$ and $\int_0^1 y\cos(ty)\,\mathrm{d}t = \sin(ty)\big|_{t=0}^{t=1} = \sin y$.

Check: $\mathrm{d}(x^2y + \sin y) = 2xy\,\mathrm{d}x + (x^2+\cos y)\,\mathrm{d}y = \gamma$. In three dimensions the same recipe applied to $yz\,\mathrm{d}x + xz\,\mathrm{d}y + xy\,\mathrm{d}z$ gives $\int_0^1 3t^2xyz\,\mathrm{d}t = xyz$.

Worked example T2.13: The vector potential of a uniform magnetic field

A constant field $\vec{B}$ in $\mathbb{R}^3$ is the closed 2-form $\star B = B_x\,\mathrm{d}y\wedge\mathrm{d}z + B_y\,\mathrm{d}z\wedge\mathrm{d}x + B_z\,\mathrm{d}x\wedge\mathrm{d}y$, with components $\beta_{\mu\nu} = \varepsilon_{\mu\nu\lambda}B^\lambda$. The homotopy operator with $p=2$ gives

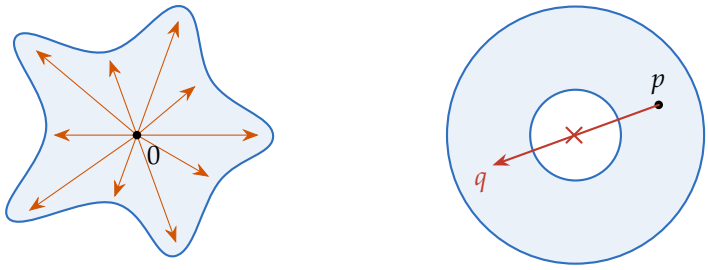
$$\begin{aligned} K(\star B) &\overset{(1)}{=} \int_0^1 t\,x^\mu\,\varepsilon_{\mu\nu\lambda}B^\lambda\,\mathrm{d}t\;\mathrm{d}x^\nu \\ &\overset{(2)}{=} \tfrac{1}{2}\,\varepsilon_{\nu\lambda\mu}B^\lambda x^\mu\,\mathrm{d}x^\nu \\ &\overset{(3)}{=} \tfrac{1}{2}\,(\vec{B}\times\vec{r})\cdot\mathrm{d}\vec{r}. \end{aligned}$$

(1) (T2.22) with $p=2$; the coefficients are constant, so $\beta(tx) = \beta(x)$.
(2) $\int_0^1 t\,\mathrm{d}t = \tfrac{1}{2}$, and $\varepsilon_{\mu\nu\lambda} = \varepsilon_{\nu\lambda\mu}$ (cyclic).
(3) $(\vec{B}\times\vec{r})_\nu = \varepsilon_{\nu\lambda\mu}B^\lambda x^\mu$.

This is the symmetric gauge $\vec{A} = \tfrac{1}{2}\vec{B}\times\vec{r}$ familiar from Landau levels. For $\vec{B} = B\hat{z}$ it reads $A = \frac{B}{2}(x\,\mathrm{d}y - y\,\mathrm{d}x)$, and $\mathrm{d}A = B\,\mathrm{d}x\wedge\mathrm{d}y$ by the computation of Example T2.7. The Landau gauge $A' = Bx\,\mathrm{d}y$ differs from it by $\mathrm{d}\lambda$ with $\lambda = \frac{B}{2}xy$: check $\mathrm{d}\lambda = \frac{B}{2}(y\,\mathrm{d}x + x\,\mathrm{d}y)$ and $A + \mathrm{d}\lambda = Bx\,\mathrm{d}y$.

Watch out: "simply connected" is only enough for 1-forms

Dray states the converse of the Poincaré lemma for simply connected regions of $\mathbb{R}^n$ [Dray §20.4]. For 1-forms that is correct (and follows from (T2.19), since every loop in a simply connected region bounds a disc). For higher forms it is false. The region $\mathbb{R}^3\setminus\{0\}$ is simply connected (every loop can be slid off the missing point), yet the Coulomb flux form $\star E$ of Example T2.6 is closed and has $\int_{S^2}\star E = q \neq 0$, so it is not exact. A 2-form sees 2-dimensional holes, which loops cannot detect. Star-shaped (or, more generally, contractible) is the right hypothesis in every degree.



star-shaped: every ray from 0 stays inside annulus: no centre works

Figure T2.9: Left: in a star-shaped region every point is joined to the centre by a straight segment inside the region; the homotopy operator K integrates the form along these rays. Right: an annulus is not star-shaped. Whatever centre p we choose, some segment pq crosses the hole. This is exactly where closed forms can fail to be exact.

T2.3.4 The angle form on the punctured plane

The punctured plane $\mathbb{R}^2 \setminus \{0\}$ is the simplest space with a hole, and it carries *the* closed-but-not-exact form. The polar angle θ is not a function on the punctured plane (it jumps by 2π somewhere), but its differential is:

$$\mathrm{d}\theta = \frac{x\,\mathrm{d}y - y\,\mathrm{d}x}{x^2 + y^2}. \tag{T2.25}$$

This expression is smooth everywhere except the origin. It is the 1-form of the wire's magnetic field, $\vec{B} \propto \hat{\phi}/\rho$.

It is closed. With $r^2 = x^2 + y^2$,

$$\begin{aligned} \mathrm{d}\left(\frac{x\,\mathrm{d}y - y\,\mathrm{d}x}{r^2}\right) &\overset{(1)}{=} \partial_x\left(\frac{x}{r^2}\right)\mathrm{d}x \wedge \mathrm{d}y - \partial_y\left(\frac{y}{r^2}\right)\mathrm{d}y \wedge \mathrm{d}x \\ &\overset{(2)}{=} \left(\frac{r^2 - 2x^2}{r^4} + \frac{r^2 - 2y^2}{r^4}\right)\mathrm{d}x \wedge \mathrm{d}y \\ &\overset{(3)}{=} \frac{2r^2 - 2(x^2 + y^2)}{r^4}\,\mathrm{d}x \wedge \mathrm{d}y = 0. \end{aligned} \tag{T2.26}$$

(1) $\mathrm{d}(g\,\mathrm{d}y) = \partial_x g\,\mathrm{d}x \wedge \mathrm{d}y$ plus a $\mathrm{d}y \wedge \mathrm{d}y = 0$ term; similarly for $\mathrm{d}x$.
(2) Quotient rule, $\partial_x(x/r^2) = (r^2 - 2x^2)/r^4$; and $\mathrm{d}y \wedge \mathrm{d}x = -\mathrm{d}x \wedge \mathrm{d}y$.
(3) $x^2 + y^2 = r^2$.

It is not exact. On the unit circle, $x = \cos t$, $y = \sin t$:

$$\begin{aligned} \oint_{S^1} \mathrm{d}\theta &\overset{(1)}{=} \int_0^{2\pi} \frac{\cos t\,(\cos t\,\mathrm{d}t) - \sin t\,(-\sin t\,\mathrm{d}t)}{1} \\ &\overset{(2)}{=} \int_0^{2\pi} \mathrm{d}t = 2\pi \neq 0. \end{aligned} \tag{T2.27}$$

(1) Pull back along the parametrisation; $r^2 = 1$ on the circle.
(2) $\cos^2 + \sin^2 = 1$.

By the detector (T2.18) (the circle has no boundary), $\mathrm{d}\theta$ is not d of any smooth function on the punctured plane. The notation is a pun: the "θ" in $\mathrm{d}\theta$ exists only on slit planes such as $\mathbb{R}^2$

minus the negative x-axis, where it is a perfectly good function. On the slit plane $\mathrm{d}\theta$ is exact, which is consistent with the detector because no loop in the slit plane goes around the origin.

Physical picture: the missing point is the source

Apply Stokes' theorem to the unit disc. The left side, $\int_D \mathrm{d}(\mathrm{d}\theta)$, would be zero if $\mathrm{d}\theta$ were smooth on the disc, but the right side is 2π. So the "curl" of $\mathrm{d}\theta$ must be a delta function at the origin: $\mathrm{d}(\mathrm{d}\theta) = 2\pi\,\delta^2(x)\,\mathrm{d}x \wedge \mathrm{d}y$ as a distribution. This is Ampère's law for a line current: $\vec{\nabla} \times \vec{B} = \mu_0 I\,\delta^2\hat{z}$ with the field zero-curl everywhere else. The hole in the space is where the source sits.

T2.3.5 Winding numbers

The period 2π is not an accident of the unit circle. For any closed loop γ in the punctured plane, define the **winding number**

$$w(\gamma) := \frac{1}{2\pi} \oint_\gamma \mathrm{d}\theta. \tag{T2.28}$$

It is an integer. Parametrise γ by $t \in [0,1]$. Along the path we can always choose the angle $\theta(t)$ of $\gamma(t)$ continuously (start with any value and follow it). The pullback of $\mathrm{d}\theta$ is then $\dot{\theta}(t)\,\mathrm{d}t$, so $\oint_\gamma \mathrm{d}\theta = \theta(1) - \theta(0)$. Since $\gamma(1) = \gamma(0)$ is the same point, the two angles differ by a multiple of 2π. So $w(\gamma) \in \mathbb{Z}$ counts the net number of times γ goes counterclockwise around the origin.

It does not change under deformation. Let γ_0 and γ_1 be two loops, and suppose γ_1 can be deformed into γ_0 without crossing the origin. The deformation sweeps out a region A (an annulus, possibly squashed) with $\partial A = \gamma_1 - \gamma_0$. Then

$$\begin{aligned} \oint_{\gamma_1} \mathrm{d}\theta - \oint_{\gamma_0} \mathrm{d}\theta &\overset{(1)}{=} \int_{\partial A} \mathrm{d}\theta \\ &\overset{(2)}{=} \int_A \mathrm{d}(\mathrm{d}\theta) \\ &\overset{(3)}{=} 0. \end{aligned} \tag{T2.29}$$

(1) The boundary of the swept region is γ_1 with its orientation and γ_0 reversed.
(2) Stokes' theorem on A, which does not contain the origin, so $\mathrm{d}\theta$ is smooth on it.
(3) $\mathrm{d}\theta$ is closed, (T2.26).

Notice the division of labour: *closedness* makes the integral a topological invariant (it cannot change under deformation), and *non-exactness* makes the invariant non-trivial.

Worked example T2.14: An ellipse, a small circle, and a double loop

Ellipse around the origin. Take $x = a\cos t$, $y = b\sin t$. Then $x\,\mathrm{d}y - y\,\mathrm{d}x = ab\,\mathrm{d}t$ and

$$\begin{aligned} \oint \mathrm{d}\theta &\overset{(1)}{=} \int_0^{2\pi} \frac{ab\,\mathrm{d}t}{a^2\cos^2 t + b^2 \sin^2 t} \\ &\overset{(2)}{=} 4\int_0^{\infty} \frac{ab\,\mathrm{d}u}{a^2 + b^2u^2} \\ &\overset{(3)}{=} 4 \cdot ab \cdot \frac{1}{ab} \cdot \frac{\pi}{2} = 2\pi. \end{aligned}$$

(1) Pull back (T2.25); as in Example T2.7, $x\,dy - y\,dx = ab(\cos^2 t + \sin^2 t)dt$.
(2) The integrand has period π and is even, so the integral is four times the integral over $[0, \pi/2]$; there substitute $u = \tan t$, $dt = du/(1+u^2)$, and divide numerator and denominator by $\cos^2 t$.
(3) $\int_0^\infty du/(a^2 + b^2u^2) = \frac{1}{ab}\arctan(bu/a)\big|_0^\infty = \frac{\pi}{2ab}$.

The answer is independent of a and b, as (T2.29) predicted: the ellipse deforms to the unit circle without touching the origin.

Circle not around the origin. Take the circle of radius 1 centred at $(3, 0)$. It lies in the half-plane $x > 0$, where $\theta = \arctan(y/x)$ is a genuine smooth function. So $d\theta$ is exact there, and $\oint d\theta = 0$ by (T2.19): $w = 0$.

Double loop. $x = \cos 2t$, $y = \sin 2t$, $t \in [0, 2\pi]$. The pullback is $2\,dt$ and the integral is 4π: $w = 2$. Reversing the direction gives $w = -2$.

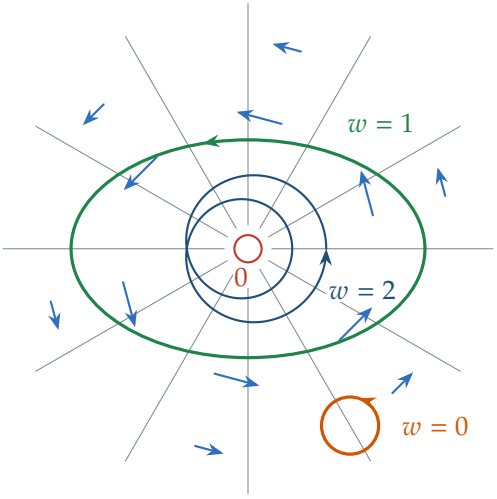


Figure T2.10: The angle form $d\theta$ on the punctured plane. Grey rays are the level sets $\theta = \text{const}$ (on any slit plane); blue arrows show the dual vector field $\hat{\theta}/r$. A loop's winding number counts how many level sets it crosses, with sign, divided by the number of rays per turn: the green ellipse crosses every ray once ($w = 1$), the orange circle crosses each ray it meets twice in opposite directions ($w = 0$), the dark spiral loop goes round twice ($w = 2$).

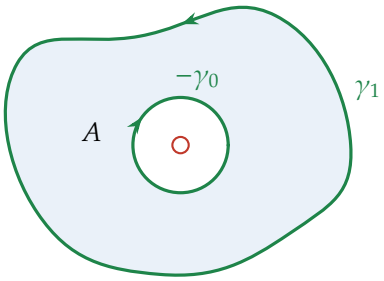


$$\partial A = \gamma_1 - \gamma_0$$
$$\oint_{\gamma_1} d\theta - \oint_{\gamma_0} d\theta = \int_A dd\theta = 0$$

Figure T2.11: Why winding numbers are deformation invariant. The region A swept out between two loops that surround the puncture is an annulus. Its boundary is the outer loop counterclockwise and the inner loop clockwise. Stokes' theorem and $d(d\theta) = 0$ on A force the two circulations to agree.

Every closed 1-form on the punctured plane. Let α be any closed 1-form on $\mathbb{R}^2 \setminus \{0\}$ and let $c = \oint_{S^1} \alpha$. Then $\alpha - \frac{c}{2\pi} d\theta$ is closed and has zero circulation around the unit circle, hence (by

deformation invariance) around every loop, since every loop is deformable to a multiple of the unit circle. By (T2.19) it is exact:

$$\alpha = \frac{c}{2\pi}\,\mathrm{d}\theta + \mathrm{d}g. \tag{T2.30}$$

So up to exact forms, the closed 1-forms are labelled by one real number. Dray makes the same argument on the circle itself [Dray (20.32)–(20.35)]. This is the statement $H^1_{\mathrm{dR}}(\mathbb{R}^2 \setminus \{0\}) \cong \mathbb{R}$ of the next section.

Worked example T2.15: The Aharonov–Bohm effect

A long thin solenoid along the z-axis carries magnetic flux Φ. Outside it, $\vec{B} = 0$, but the vector potential cannot vanish: by Stokes, its circulation around the solenoid is the enclosed flux. The natural choice outside is

$$A = \frac{\Phi}{2\pi}\,\mathrm{d}\theta, \qquad F = \mathrm{d}A = 0 \text{ outside}, \qquad \oint A = \Phi.$$

Outside the solenoid A is closed but not exact, so it cannot be gauged away: $A \mapsto A + \mathrm{d}\lambda$ never changes $\oint A$. A charged particle going around the solenoid picks up the phase $\exp\left(\frac{iq}{\hbar}\oint A\right) = \exp(iq\Phi/\hbar)$, which is observable in interference even though the particle never meets a magnetic field. The physical content of a closed-but-not-exact A is its period.

T2.3.6 The sphere puzzle and the monopole

Dray poses a puzzle that every student of forms should meet [Dray §20.5]. On the unit sphere take the area form $\omega = \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$. We computed $\int_{S^2}\omega = 4\pi \neq 0$ in Example T2.4, so by the detector ω is not exact. Yet

$$\mathrm{d}(-\cos\theta\,\mathrm{d}\phi) = \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi = \omega. \tag{T2.31}$$

What is going on?

The resolution: $\mathrm{d}\phi$ is singular at the poles. The function $\cos\theta$ is fine everywhere. The trouble is $\mathrm{d}\phi$. Near the north pole use the Cartesian coordinates x, y of the tangent plane. There ϕ is the polar angle, so $\mathrm{d}\phi$ *is* the angle form (T2.25), with its $1/r$ singularity. A smooth 1-form has circulation tending to zero around a shrinking loop; $-\cos\theta\,\mathrm{d}\phi$ has circulation tending to -2π around a tiny circle at the north pole. Dray makes the same point from $\mathbb{R}^3$: $x\,\mathrm{d}y - y\,\mathrm{d}x = r^2\sin^2\theta\,\mathrm{d}\phi$, so the orthonormal 1-form $\sigma^\phi = r\sin\theta\,\mathrm{d}\phi = \cos\phi\,\mathrm{d}y - \sin\phi\,\mathrm{d}x$ has unit length everywhere, while $\cos\theta\,\mathrm{d}\phi = \cot\theta\,\sigma^\phi/r$ blows up at the poles [Dray (20.39)–(20.41)]. So (T2.31) holds only on the sphere minus the two poles, which is a cylinder, not a sphere, and the detector does not apply there.

Two patches. We can repair one pole at a time by adding a constant times $\mathrm{d}\phi$, which does not change d of the potential:

$$A_N = (1-\cos\theta)\,\mathrm{d}\phi \quad (\theta \neq \pi), \qquad A_S = -(1+\cos\theta)\,\mathrm{d}\phi \quad (\theta \neq 0). \tag{T2.32}$$

Near the north pole $1 - \cos\theta \approx \theta^2/2$ and $\theta^2\,\mathrm{d}\phi$ equals $x\,\mathrm{d}y - y\,\mathrm{d}x$ to leading order, which is smooth. So A_N is smooth on the whole sphere except the south pole, and A_S except the north pole. Both satisfy $\mathrm{d}A_N = \mathrm{d}A_S = \omega$. On the overlap they differ by

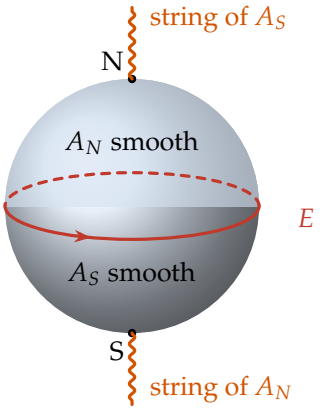
$$A_N - A_S = 2\,\mathrm{d}\phi, \tag{T2.33}$$

which is closed but not exact on the overlap (a band around the equator, topologically a punctured plane). Now compute the total integral with Stokes on each hemisphere, both bounded by the equator E (oriented counterclockwise seen from the north, the boundary orientation of the northern hemisphere N; the southern hemisphere S has boundary $-E$):

$$\begin{aligned}\int_{S^2}\omega &\overset{(1)}{=} \int_N \mathrm{d}A_N + \int_S \mathrm{d}A_S \\ &\overset{(2)}{=} \oint_E A_N - \oint_E A_S \\ &\overset{(3)}{=} \oint_E 2\,\mathrm{d}\phi = 4\pi. \end{aligned} \tag{T2.34}$$

(1) Split the sphere into hemispheres and use the potential that is smooth on each.
(2) Stokes on each hemisphere, with $\partial N = E$ and $\partial S = -E$.
(3) The transition (T2.33), and $\oint_E \mathrm{d}\phi = 2\pi$.

The total integral lives entirely in the mismatch between the two potentials. If a single global potential existed, the mismatch would be zero and so would the integral.



$A_N = (1-\cos\theta)\,\mathrm{d}\phi$
$A_S = -(1+\cos\theta)\,\mathrm{d}\phi$

on the band around E:
$A_N - A_S = 2\,\mathrm{d}\phi$

$\int_{S^2}\omega = \oint_E (A_N - A_S) = 4\pi$

Figure T2.12: The two-patch description of the monopole. A_N is smooth everywhere except the south pole, where it has a "Dirac string" singularity; A_S has its string at the north pole. On the overlap they differ by the closed, non-exact form $2\,\mathrm{d}\phi$. Stokes' theorem on the two hemispheres turns the total flux into the circulation of this mismatch around the equator.

Physical picture: Dirac's monopole

With $F = g\,\omega$ the magnetic field of a monopole of charge g (flux $4\pi g$), the two potentials are gA_N and gA_S, and they differ by the gauge transformation $g(A_N - A_S) = \mathrm{d}(2g\phi)$. A wavefunction of charge e transforms as $\psi_N = e^{2ieg\phi/\hbar}\psi_S$ on the overlap. For this to make sense as ϕ goes once around, $e^{4\pi ieg/\hbar} = 1$:

$$\frac{2eg}{\hbar} \in \mathbb{Z}.$$

That is Dirac's quantisation condition. In the language of Chapter T3 the two patches and the transition function define a nontrivial $U(1)$ bundle over S^2, and the integer is its first Chern number. Everything in this intuition box is Stokes' theorem applied to a closed-but-not-exact form.

Watch out: a formula valid on "almost all" of the space

For *integrals*, a chart missing a set of measure zero is harmless (Section T2.1.5). For *exactness*, it is fatal: a potential that is singular on a single point or a single line is not a potential. Always ask where your β is smooth before invoking Stokes' theorem.

Try it: Dray's experiment in $\mathbb{R}^3$

Take $\beta = x\,\mathrm{d}y$ in $\mathbb{R}^3$, so $\alpha = \mathrm{d}\beta = \mathrm{d}x \wedge \mathrm{d}y$. Pull α back to the unit sphere and integrate. *Answer:* in spherical coordinates the pullback is $\sin\theta\cos\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$ (as in Example T2.8), whose integral over $0 \le \theta \le \pi$ is $2\pi \cdot \frac{1}{2}\sin^2\theta\big|_0^\pi = 0$, as the detector demands: β is smooth on all of $\mathbb{R}^3$, hence on the sphere. The northern hemisphere gives $+\pi$ and the southern $-\pi$; the flux of $\hat{z}$ in through the bottom equals the flux out through the top.

Reading Nash (p. 13, (1.41))

Nash's condition "$d_n \circ d_{n-1} = 0$ implies $\operatorname{Im} d_{n-1} \subseteq \ker d_n$" [Nash p. 13, (1.41)] is exactly (T2.17): every exact form is closed. He calls a sequence *exact* when $\operatorname{Im} d_{n-1} = \ker d_n$, i.e. when every closed form is exact, and remarks that "this is false, in general". The Poincaré lemma says the de Rham sequence *is* exact on a star-shaped region; $\mathrm{d}\theta$ and the monopole form show it is not exact on the punctured plane and on S^2. The cohomology groups he defines next measure the failure; that is the subject of the next section.

Recap

- Closed: $\mathrm{d}\alpha = 0$. Exact: $\alpha = \mathrm{d}\beta$ with β smooth everywhere. Exact $\Rightarrow$ closed because $\mathrm{d}^2 = 0$.
- Stokes detector: an exact form integrates to zero over every cycle without boundary. One non-zero integral proves non-exactness. For 1-forms, zero circulation around every loop is also sufficient.
- Poincaré lemma: on a star-shaped region closed forms are exact, with potential $K\alpha = \int_0^1 t^{p-1}\iota_x\alpha(tx)\,\mathrm{d}t$ and the homotopy formula $\mathrm{d}K + K\mathrm{d} = 1$.
- $\mathrm{d}\theta = (x\,\mathrm{d}y - y\,\mathrm{d}x)/r^2$ on $\mathbb{R}^2 \setminus \{0\}$ is closed, has period 2π, and is not exact. Its periods are $2\pi\times$ integer winding numbers, invariant under deformation.
- On S^2, $\omega = \mathrm{d}(-\cos\theta\,\mathrm{d}\phi)$ only away from the poles; two patches with transition $2\,\mathrm{d}\phi$ reproduce $\int \omega = 4\pi$. This is the monopole and Dirac quantisation.

T2.4 A first look at de Rham cohomology

The last section produced a pattern. On a star-shaped region every closed form is exact. On the punctured plane the closed 1-forms are exact *except* for multiples of one form, $\mathrm{d}\theta$. On the sphere the area form is closed and not exact. In each case the "closed modulo exact" forms were labelled by a few real numbers, and those numbers were integrals over cycles that wrap around holes.

De Rham cohomology is the bookkeeping device for this pattern. It is the first topological invariant in these notes that is built out of calculus, and it is the one Nash uses throughout: Betti numbers, the Euler characteristic, Hodge theory, characteristic classes and the index theorem

are all statements about it. The goal of this section is to make it completely concrete: compute it for every space we care about, with explicit representatives, and see how to read off topology from it.

T2.4.1 The definition

Working definition T2.5 (de Rham cohomology)

The p-th **de Rham cohomology** of M is the vector space

$$H^p_{\mathrm{dR}}(M) = \frac{\{\text{closed } p\text{-forms on } M\}}{\{\text{exact } p\text{-forms on } M\}} = \frac{\mathrm{Ker}\big(\mathrm{d} : \Omega^p(M) \to \Omega^{p+1}(M)\big)}{\mathrm{Im}\big(\mathrm{d} : \Omega^{p-1}(M) \to \Omega^p(M)\big)}. \tag{T2.35}$$

An element is a **cohomology class** $[\alpha]$: a closed form α, where two closed forms count as the same class when they differ by an exact form, $[\alpha] = [\alpha + \mathrm{d}\beta]$. Its dimension $b_p = \dim H^p_{\mathrm{dR}}(M)$ is the p-th **Betti number**. *Operational recipe:* (i) find the closed p-forms; (ii) find enough closed p-cycles $Z_1, Z_2, \ldots$ [p-surfaces with no boundary, e.g. loops when $p = 1$] to separate them by their **periods** $\int_{Z_i} \alpha$; (iii) show that a closed form with all periods zero is exact. Then b_p is the number of independent periods.

The quotient in (T2.35) makes sense because exact forms are closed ((T2.17)), so the denominator sits inside the numerator. Two remarks on why this is the right object.

Periods are well defined on classes. If Z is a closed cycle and α is closed, then

$$\int_Z (\alpha + \mathrm{d}\beta) \overset{(1)}{=} \int_Z \alpha + \int_{\partial Z} \beta \overset{(2)}{=} \int_Z \alpha. \tag{T2.36}$$

(1) Linearity of the integral and Stokes' theorem on the second term.
(2) $\partial Z = \varnothing$.

So a class has well-defined periods. Conversely, deforming the cycle does not change the period either: if $Z' - Z = \partial W$ for some $(p+1)$-dimensional region W, then

$$\int_{Z'} \alpha - \int_Z \alpha \overset{(1)}{=} \int_{\partial W} \alpha \overset{(2)}{=} \int_W \mathrm{d}\alpha \overset{(3)}{=} 0. \tag{T2.37}$$

(1) $\partial W = Z' - Z$.
(2) Stokes' theorem on W.
(3) α is closed.

The winding-number argument (T2.29) was the case $p = 1$. Equations (T2.36) and (T2.37) together say that integration is a well-defined pairing between cohomology classes of forms and "homology classes" of cycles, cycles modulo boundaries. This pairing is the whole content of the duality Nash sets up between his (1.43) and (1.44) [Nash p. 13]; we return to it in Section T2.4.8.

Cohomology is a linear-algebra shadow of the space. The spaces $\Omega^p(M)$ are infinite-dimensional, but on a compact manifold the quotients $H^p_{\mathrm{dR}}(M)$ are finite-dimensional, and they vanish for $p > \dim M$ (there are no forms of that degree). All the analysis cancels out; a finite list of numbers survives.

T2.4.2 H^0 counts connected components

A closed 0-form is a function with $\mathrm{d}f = 0$, i.e. with all partial derivatives zero. Such an f is constant on each connected piece of M, but may take different constants on different pieces. There are no exact 0-forms (there are no (-1)-forms to differentiate), so nothing is divided out:

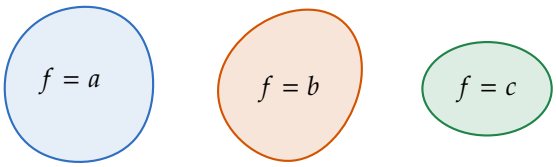
$$H^0_{\mathrm{dR}}(M) = \{\text{locally constant functions}\} \cong \mathbb{R}^{\#\text{components}}, \qquad b_0 = \text{number of connected components}. \tag{T2.38}$$

Worked example T2.16: Components

$\mathbb{R} \setminus \{0\}$. A locally constant function is one constant a on $x < 0$ and another b on $x > 0$; so $H^0_{\mathrm{dR}} \cong \mathbb{R}^2$, $b_0 = 2$. The function $\mathrm{sgn}(x)$ is closed but not constant; this is the lowest-degree cousin of $\mathrm{d}\theta$.

The orthogonal group O(3). It has two components, rotations (det $= +1$) and rotations times parity (det $= -1$). The function det is a closed 0-form taking the values ± 1, and $b_0(\mathrm{O}(3)) = 2$. The same logic applied to the Lorentz group gives $b_0 = 4$ (the signs of det and of $\Lambda^0{}_0$).

A detector for disconnectedness. For 0-forms the "cycles" are points, and the period of f at a point P is $f(P)$. The Stokes detector in degree 0 is the fundamental theorem of calculus: if a path joins P to Q then $f(Q) - f(P) = \int \mathrm{d}f = 0$. A closed f with $f(P) \neq f(Q)$ proves that no path joins them.



closed 0-forms: $\mathrm{d}f = 0$ means constant on each piece; $H^0_{\mathrm{dR}} \cong \mathbb{R}^3$

Figure T2.13: A space with three connected components. A closed function may take a different constant on each, so $H^0_{\mathrm{dR}} \cong \mathbb{R}^3$ and $b_0 = 3$. Nothing is ever divided out in degree zero.

T2.4.3 Contractible spaces have no cohomology

The Poincaré lemma (Section T2.3.3) says precisely that on a star-shaped region every closed p-form with $p \geq 1$ is exact:

$$H^p_{\mathrm{dR}}(\mathbb{R}^n) = \begin{cases} \mathbb{R}, & p = 0, \\ 0, & p \geq 1, \end{cases} \tag{T2.39}$$

and the same for balls, cubes and any star-shaped region. More generally, de Rham cohomology is a **homotopy invariant**: if one space can be continuously deformed into another (a homotopy equivalence, such as squashing a ball to a point or the punctured plane onto the unit circle), they have the same cohomology. The mechanism is the homotopy operator of (T2.23), generalised from the scaling map to any deformation; the integrals of closed forms over cycles cannot change during the deformation, by (T2.37). We shall use this in the form

$$\mathbb{R}^n \simeq \text{point}, \qquad \mathbb{R}^2 \setminus \{0\} \simeq S^1, \qquad \mathbb{R}^3 \setminus \{0\} \simeq S^2, \qquad \mathbb{R}^n \setminus \{0\} \simeq S^{n-1}. \tag{T2.40}$$

T2.4.4 The circle

Dray computes the cohomology of the circle directly [Dray (20.32)–(20.36)]; we fill in the one step he leaves out. Any 1-form on S^1 is $\alpha = f(\phi)\,\mathrm{d}\phi$ with f smooth and 2π-periodic. Every 1-form

on a 1-manifold is closed (there are no 2-forms). Define its period

$$c_\alpha := \oint_{S^1} \alpha = \int_0^{2\pi} f(\phi)\,\mathrm{d}\phi. \tag{T2.41}$$

Claim: $\alpha - \frac{c_\alpha}{2\pi}\mathrm{d}\phi$ is exact. Define $g(\phi) = \int_0^\phi \big(f(s) - \frac{c_\alpha}{2\pi}\big)\mathrm{d}s$. The only question is whether g is a function on the circle, i.e. whether $g(\phi + 2\pi) = g(\phi)$:

$$\begin{aligned} g(\phi+2\pi) - g(\phi) &\overset{(1)}{=} \int_\phi^{\phi+2\pi} \Big(f(s) - \frac{c_\alpha}{2\pi}\Big)\mathrm{d}s \\ &\overset{(2)}{=} \int_0^{2\pi} f(s)\,\mathrm{d}s - c_\alpha \\ &\overset{(3)}{=} 0. \end{aligned} \tag{T2.42}$$

(1) Subtract the two integrals from 0.
(2) f is periodic, so its integral over any interval of length 2π is the same; the constant integrates to c_α.
(3) Definition (T2.41).

So g is a smooth function on S^1 with $\mathrm{d}g = \alpha - \frac{c_\alpha}{2\pi}\mathrm{d}\phi$, i.e. $\alpha = \frac{c_\alpha}{2\pi}\mathrm{d}\phi + \mathrm{d}g$ [Dray (20.35)]. Two 1-forms are in the same class exactly when they have the same period, and the map $[\alpha] \mapsto c_\alpha$ is an isomorphism:

$$H^0_{\mathrm{dR}}(S^1) \cong \mathbb{R}, \qquad H^1_{\mathrm{dR}}(S^1) \cong \mathbb{R} \text{ (generated by } [\mathrm{d}\phi]), \qquad b_0 = b_1 = 1. \tag{T2.43}$$

Dray's summary is exactly right: the fact that this space "is one-dimensional ... turns out to imply that there is one 'hole' ".

By homotopy invariance, the punctured plane has the same answer, $H^1_{\mathrm{dR}}(\mathbb{R}^2 \setminus \{0\}) \cong \mathbb{R}$ generated by $[\mathrm{d}\theta]$, which is what we found directly in (T2.30). A plane with k punctures has $b_1 = k$: one angle form around each puncture, detected by one small loop around each.

Worked example T2.17: Fourier version

Expand $f(\phi) = \sum_{n\in\mathbb{Z}} f_n e^{in\phi}$. Then $\alpha = f_0\,\mathrm{d}\phi + \sum_{n\neq 0} f_n e^{in\phi}\mathrm{d}\phi$, and every $n \neq 0$ term is exact:

$$f_n e^{in\phi}\,\mathrm{d}\phi \overset{(1)}{=} \mathrm{d}\Big(\frac{f_n}{in} e^{in\phi}\Big).$$

(1) $\mathrm{d}e^{in\phi} = in\, e^{in\phi}\mathrm{d}\phi$, and $n \neq 0$ so we may divide.

Only the zero mode $f_0 = c_\alpha/2\pi$ cannot be integrated to a periodic function, because $\int \mathrm{d}\phi = \phi$ is not periodic. *Cohomology is the zero mode that the derivative cannot reach.* This way of thinking, where d is invertible on everything except a finite-dimensional set of modes, is exactly Hodge theory, Section T2.4.9.

T2.4.5 The sphere, and the monopole as a cohomology class

For S^2 we already know $b_0 = 1$ and that the area form ω gives a nonzero class in $H^2_{\mathrm{dR}}(S^2)$. We now show $b_1 = 0$ and $b_2 = 1$, using only two patches and the Poincaré lemma. Cover the sphere by two open caps U_N (everything except a small disc around the south pole) and U_S (everything except a small disc around the north pole). Each cap is a disc, hence star-shaped in a chart. Their overlap $U_N \cap U_S$ is a band around the equator, which deforms to a circle.

$b_1(S^2) = 0$. Let α be a closed 1-form on S^2. By the Poincaré lemma $\alpha = \mathrm{d}f_N$ on U_N and $\alpha = \mathrm{d}f_S$ on U_S. On the band $\mathrm{d}(f_N - f_S) = 0$, so $f_N - f_S$ is a constant k (the band is connected). Replace f_S by $f_S + k$; now $f_N = f_S$ on the overlap, the two glue to a global function f, and $\alpha = \mathrm{d}f$. Every closed 1-form on S^2 is exact. (In words: every loop on the sphere bounds a disc, so every circulation can be computed by Stokes as a flux of $\mathrm{d}\alpha = 0$.)

$b_2(S^2) = 1$. Let β be any 2-form on S^2 (automatically closed) with total integral $c = \int_{S^2} \beta$. Set $\beta' = \beta - \frac{c}{4\pi}\omega$, so $\int_{S^2} \beta' = 0$. We show β' is exact. By the Poincaré lemma $\beta' = \mathrm{d}A_N$ on U_N and $\beta' = \mathrm{d}A_S$ on U_S. On the band, $A_N - A_S$ is closed, hence by (T2.30) equal to $k\,\mathrm{d}\phi + \mathrm{d}g$ for a constant k and a function g on the band. The two-hemisphere computation (T2.34) gives

$$0 = \int_{S^2} \beta' = \oint_E (A_N - A_S) = 2\pi k, \tag{T2.44}$$

so $k = 0$ and $A_N - A_S = \mathrm{d}g$. Now smear g out. Take smooth functions $\rho_N, \rho_S \geq 0$ with $\rho_N + \rho_S = 1$, $\rho_N = 0$ near the south pole and $\rho_S = 0$ near the north pole (a partition of unity as in (T2.8)). Then $\rho_S g$ extends by zero to a smooth function on U_N and $\rho_N g$ to one on U_S. Define

$$A = \begin{cases} A_N - \mathrm{d}(\rho_S g) & \text{on } U_N, \\ A_S + \mathrm{d}(\rho_N g) & \text{on } U_S. \end{cases} \tag{T2.45}$$

On the overlap the two definitions agree:

$$\big(A_N - \mathrm{d}(\rho_S g)\big) - \big(A_S + \mathrm{d}(\rho_N g)\big) \overset{(1)}{=} \mathrm{d}g - \mathrm{d}\big((\rho_S + \rho_N)g\big) \overset{(2)}{=} 0.$$

(1) $A_N - A_S = \mathrm{d}g$ on the band.
(2) $\rho_N + \rho_S = 1$.

So A is a global 1-form, and $\mathrm{d}A = \beta'$ on each patch because $\mathrm{dd} = 0$. Hence $\beta = \frac{c}{4\pi}\omega + \mathrm{d}A$, and the class of a 2-form on S^2 is determined by one number, its total integral:

$$H^0_{\mathrm{dR}}(S^2) \cong \mathbb{R}, \qquad H^1_{\mathrm{dR}}(S^2) = 0, \qquad H^2_{\mathrm{dR}}(S^2) \cong \mathbb{R} \text{ (generated by } [\omega/4\pi]). \tag{T2.46}$$

Physical picture: the monopole field is the generator

Normalise the generator as $[\omega/4\pi]$, so that it integrates to 1. The field of a magnetic monopole of charge g is $F = g\,\omega$, and its class is $4\pi g$ times the generator. Every smooth deformation of the field (moving the monopole off-centre, adding smooth magnetic fields with no net flux) changes F by an exact form and leaves the class alone. The only invariant is the total flux. Dirac quantisation says this real number is actually an integer multiple of $2\pi\hbar/e$; the integer is the first Chern number of Chapter T3. The same argument, with $\mathbb{R}^3 \setminus \{0\} \simeq S^2$, shows that the closed 2-forms on $\mathbb{R}^3 \setminus \{0\}$ are classified by the enclosed charge, which is Gauss's law read as a statement about cohomology.

The pattern generalises: $H^p_{\mathrm{dR}}(S^n) \cong \mathbb{R}$ for $p = 0$ and $p = n$, and zero otherwise. The generator in top degree is the normalised volume form; on S^3 that is $\mathrm{vol}/2\pi^2$ (Example T2.4), the form whose integral counts instanton number in Chapter 8. Nash quotes this as $H^m(S^n;\mathbb{Z}) = \mathbb{Z}$ for $m = 0, n$ [Nash p. 14, (1.46)].

T2.4.6 The torus

Realise the torus as the square $[0,2\pi]\times[0,2\pi]$ with coordinates (θ,ϕ) and opposite edges identified, $T^2=\mathbb{R}^2/(2\pi\mathbb{Z})^2$. The 1-forms $\mathrm{d}\theta$ and $\mathrm{d}\phi$ are globally defined (the coordinates jump by 2π but their differentials do not), closed, and not exact. To see the last point use the two basic loops (Figure T2.14): a, along which θ runs from 0 to 2π at fixed ϕ, and b, along which ϕ runs at fixed θ. The table of periods is

$$\begin{pmatrix}\oint_a \mathrm{d}\theta & \oint_b \mathrm{d}\theta\\ \oint_a \mathrm{d}\phi & \oint_b \mathrm{d}\phi\end{pmatrix}=\begin{pmatrix}2\pi & 0\\ 0 & 2\pi\end{pmatrix}. \tag{T2.47}$$

Since this **period matrix** is invertible, no combination $x\,\mathrm{d}\theta+y\,\mathrm{d}\phi$ with $(x,y)\neq(0,0)$ has all periods zero, so no such combination is exact. Hence $b_1\geq 2$.

Every closed 1-form is $x\,\mathrm{d}\theta+y\,\mathrm{d}\phi+\mathrm{d}h$. Write a 1-form as $\alpha=f\,\mathrm{d}\theta+g\,\mathrm{d}\phi$ with f,g doubly periodic and expand $f=\sum f_{mn}e^{i(m\theta+n\phi)}$, similarly g. The condition $\mathrm{d}\alpha=0$ is $\partial_\theta g=\partial_\phi f$, i.e.

$$m\,g_{mn}=n\,f_{mn}\qquad\text{for all }(m,n)\in\mathbb{Z}^2. \tag{T2.48}$$

For each $(m,n)\neq(0,0)$ define $h_{mn}=f_{mn}/(im)$ if $m\neq 0$ and $h_{mn}=g_{mn}/(in)$ if $m=0$. Then the mode $f_{mn}\mathrm{d}\theta+g_{mn}\mathrm{d}\phi$ (times $e^{i(m\theta+n\phi)}$) equals $\mathrm{d}(h_{mn}e^{i(m\theta+n\phi)})$:

$$\begin{aligned}\mathrm{d}\big(h_{mn}e^{i(m\theta+n\phi)}\big)&\overset{(1)}{=}(im\,h_{mn}\,\mathrm{d}\theta+in\,h_{mn}\,\mathrm{d}\phi)\,e^{i(m\theta+n\phi)}\\&\overset{(2)}{=}(f_{mn}\,\mathrm{d}\theta+g_{mn}\,\mathrm{d}\phi)\,e^{i(m\theta+n\phi)}.\end{aligned}$$

(1) Differentiate the exponential.
(2) If $m\neq 0$: $im\,h_{mn}=f_{mn}$, and $in\,h_{mn}=nf_{mn}/m=g_{mn}$ by (T2.48). If $m=0$ (so $n\neq 0$): (T2.48) gives $f_{0n}=0=im\,h_{0n}$, and $in\,h_{0n}=g_{0n}$.

Summing, $\alpha=f_{00}\,\mathrm{d}\theta+g_{00}\,\mathrm{d}\phi+\mathrm{d}h$. Only the zero modes survive, and they are fixed by the periods, $f_{00}=\frac{1}{2\pi}\oint_a\alpha$ and $g_{00}=\frac{1}{2\pi}\oint_b\alpha$.

Degree 2. Every 2-form $\beta=k(\theta,\phi)\,\mathrm{d}\theta\wedge\mathrm{d}\phi$ is closed. Its non-zero Fourier modes are exact, e.g. $k_{mn}e^{i(m\theta+n\phi)}\mathrm{d}\theta\wedge\mathrm{d}\phi=\mathrm{d}\big(\frac{k_{mn}}{in}e^{i(m\theta+n\phi)}\mathrm{d}\theta\big)\cdot(-1)$ when $n\neq 0$ (check: $\mathrm{d}(e^{\cdots}\mathrm{d}\theta)=in\,e^{\cdots}\mathrm{d}\phi\wedge\mathrm{d}\theta$). The zero mode $k_{00}\,\mathrm{d}\theta\wedge\mathrm{d}\phi$ is not exact, since $\int_{T^2}\mathrm{d}\theta\wedge\mathrm{d}\phi=4\pi^2\neq 0$. So

$$H^0_{\mathrm{dR}}(T^2)\cong\mathbb{R},\qquad H^1_{\mathrm{dR}}(T^2)\cong\mathbb{R}^2\ \big([\mathrm{d}\theta],[\mathrm{d}\phi]\big),\qquad H^2_{\mathrm{dR}}(T^2)\cong\mathbb{R}\ \big([\mathrm{d}\theta\wedge\mathrm{d}\phi]\big). \tag{T2.49}$$

The Betti numbers are $(b_0,b_1,b_2)=(1,2,1)$.

Products of classes. The wedge product of two closed forms is closed, and the wedge of a closed form with an exact one is exact ($\alpha\wedge\mathrm{d}\beta=\pm\mathrm{d}(\alpha\wedge\beta)$ when $\mathrm{d}\alpha=0$). So wedge descends to classes, $[\alpha]\cup[\beta]:=[\alpha\wedge\beta]$. This is the **cup product** Nash writes in [Nash p. 14, (1.45)]. On the torus $[\mathrm{d}\theta]\cup[\mathrm{d}\phi]=[\mathrm{d}\theta\wedge\mathrm{d}\phi]$ is the generator of H^2_{dR}: the two "holes" of the torus multiply to its "volume". On S^2 there are no degree-1 classes to multiply, which is one way to see that the sphere and the torus are different spaces even though both have $b_0=b_2=1$.

T2.4.7 Betti numbers and the Euler characteristic

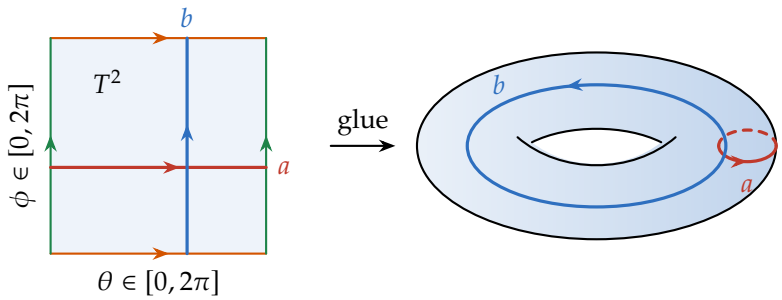


Figure T2.14: The torus as a square with opposite sides glued (orange to orange, green to green, matching arrows). The loop a goes once around in θ, the loop b once around in ϕ. The period matrix of $(\mathrm{d}\theta, \mathrm{d}\phi)$ on (a, b) is 2π times the identity, which proves that $[\mathrm{d}\theta]$ and $[\mathrm{d}\phi]$ are independent classes.

Working definition T2.6 (Euler characteristic)

For a compact manifold M of dimension n,

$$\chi(M) := \sum_{p=0}^{n} (-1)^p b_p(M). \tag{T2.50}$$

[b_p is the number of independent periods of closed p-forms, one for each independent p-dimensional hole] *Operational recipe (for a surface):* chop it into polygons [any two meet only along a whole edge or at a vertex], count
vertices V, edges E and faces F, and compute $\chi = V - E + F$. The two recipes agree (see below).

space	b_0	b_1	b_2	b_3	χ	generators
point, $\mathbb{R}^n$, disc	1	0	0	0	1	1
S^1, $\mathbb{R}^2 \setminus \{0\}$, cylinder	1	1	0	0	0	$1, \mathrm{d}\phi$
plane minus k points	1	k	0	0	$1-k$	$1, \mathrm{d}\theta_1, \ldots, \mathrm{d}\theta_k$
S^2, $\mathbb{R}^3 \setminus \{0\}$	1	0	1	0	2	$1, \omega/4\pi$
T^2	1	2	1	0	0	$1, \mathrm{d}\theta, \mathrm{d}\phi, \mathrm{d}\theta \wedge \mathrm{d}\phi$
genus-g surface Σ_g	1	$2g$	1	0	$2-2g$	$1, 2g$ loop classes, area
$S^3 \cong \mathrm{SU}(2)$	1	0	0	1	0	$1, \mathrm{vol}/2\pi^2$
T^3	1	3	3	1	0	$\mathrm{d}\theta^i, \mathrm{d}\theta^i \wedge \mathrm{d}\theta^j, \ldots$

Two patterns in the table deserve names.

- **Poincaré duality**: for a closed oriented n-manifold, $b_p = b_{n-p}$. The mechanism is that wedging a p-class with an $(n-p)$-class and integrating gives a non-degenerate pairing (on the torus: $\int \mathrm{d}\theta \wedge \mathrm{d}\phi \neq 0$). Nash uses this in Chapter 4.

- Odd-dimensional closed manifolds have $\chi = 0$, by Poincaré duality: the terms b_p and b_{n-p} enter with opposite signs.

Why $V-E+F$ equals $b_0-b_1+b_2$. Here is the linear algebra. Suppose we have any finite sequence of finite-dimensional vector spaces and linear maps with $d_p \circ d_{p-1} = 0$,

$$0 \to C^0 \xrightarrow{d_0} C^1 \xrightarrow{d_1} C^2 \xrightarrow{d_2} \cdots \xrightarrow{d_{n-1}} C^n \to 0,$$

and define its cohomology $H^p = \operatorname{Ker} d_p / \operatorname{Im} d_{p-1}$. Then

$$\begin{aligned} \sum_p (-1)^p \dim H^p &\overset{(1)}{=} \sum_p (-1)^p \left(\dim \operatorname{Ker} d_p - \dim \operatorname{Im} d_{p-1}\right) \\ &\overset{(2)}{=} \sum_p (-1)^p \dim \operatorname{Ker} d_p + \sum_p (-1)^p \dim \operatorname{Im} d_p \\ &\overset{(3)}{=} \sum_p (-1)^p \dim C^p. \end{aligned} \tag{T2.51}$$

(1) Dimension of a quotient.
(2) Shift the summation index in the second sum, $p \to p+1$, which flips the sign $(-1)^{p+1} \to -(-1)^p$.
(3) Rank–nullity for $d_p : C^p \to C^{p+1}$: $\dim \operatorname{Ker} d_p + \dim \operatorname{Im} d_p = \dim C^p$.

The alternating sum of dimensions does not care whether we take cohomology first. Now apply this twice. For a surface chopped into polygons, let C^0, C^1, C^2 be the spaces of real numbers attached to vertices, edges and faces, with d the discrete "difference across the boundary" map (value on an edge = difference of the values at its two ends, and so on). Then $\dim C^0 = V$, $\dim C^1 = E$, $\dim C^2 = F$. The theorem of de Rham (next subsection) says the cohomology of this finite complex equals H^*_{dR} of the surface. So (T2.51) gives $b_0 - b_1 + b_2 = V - E + F$. This also explains the claim, used by Dray, that $V-E+F$ does not depend on how the surface is chopped up [Dray §18.10].

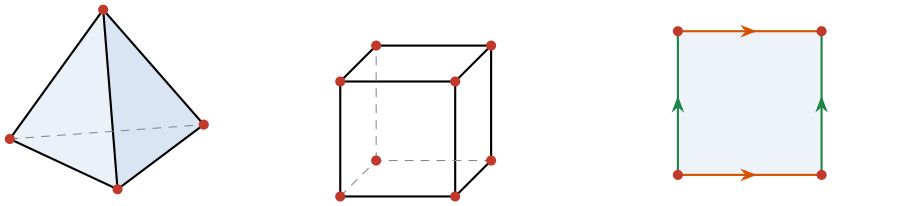
Worked example T2.18: Counting cells

Sphere. A tetrahedron: $V=4$, $E=6$, $F=4$, so $\chi = 2$. A cube: $8-12+6=2$. Dray's decomposition into four "quadrilateral" lunes plus two polar caps: $8-12+6=2$ [Dray (18.77)]. The table predicted $b_0-b_1+b_2 = 1-0+1 = 2$.
Torus. The square with identified sides: all four corners are the same point, so $V=1$; the four sides are two edges (a and b), $E=2$; one face, $F=1$. So $\chi = 1-2+1 = 0 = 1-2+1$. A finer grid of $m \times n$ squares on the torus gives $V=mn$, $E=2mn$, $F=mn$: still 0.
Adding a handle. Cut two discs out of a surface (each removes one face) and join them by a tube made of two quadrilaterals glued along two new edges [Dray Fig. 18.10]. Net change: $\Delta F = -2+2 = 0$, $\Delta E = +2$ (the vertical seams; the circles were already edges), $\Delta V = 0$. So $\Delta\chi = -2$. Starting from the sphere, g handles give $\chi(\Sigma_g) = 2-2g$.

T2.4.8 De Rham's theorem and homology

We have been using cycles freely. Here is the one-paragraph version of the dual theory that Nash writes as (1.44). A **p-chain** is a formal combination of oriented p-dimensional pieces (curves, surfaces, ...) with real coefficients; its boundary ∂ is defined piece by piece with the orientation of Section T2.2.1. Cycles are chains with $\partial Z = 0$; boundaries are chains of the form ∂W. Because $\partial\partial = 0$ (Section T2.2.5), boundaries are cycles, and the **homology** $H_p(M) = \{\text{cycles}\}/\{\text{boundaries}\}$ makes sense. Integration gives a pairing

$$H^p_{\mathrm{dR}}(M) \times H_p(M) \to \mathbb{R}, \qquad \big([\alpha],[Z]\big) \mapsto \int_Z \alpha, \tag{T2.52}$$



tetrahedron
$4 - 6 + 4 = 2$

cube
$8 - 12 + 6 = 2$

torus: $V = 1, E = 2, F = 1$
$1 - 2 + 1 = 0$

Figure T2.15: Three cell decompositions. The tetrahedron and the cube are both spheres and both give $V - E + F = 2$. The torus as a square with glued sides has one vertex (all four red corners are identified), two edges and one face, giving 0. The count never depends on the decomposition, only on the surface.

which is well defined by (T2.36) and (T2.37); Stokes' theorem is exactly the statement that d and ∂ are adjoint under this pairing.

Key idea: de Rham's theorem

The pairing (T2.52) is perfect: $H^p_{\mathrm{dR}}(M)$ is the dual of $H_p(M;\mathbb{R})$, so it is isomorphic to the topologist's real cohomology $H^p(M;\mathbb{R})$ [Nash p. 13, (1.43)]. Concretely: *a closed form is exact if and only if all of its periods vanish*, and any assignment of periods to a basis of cycles is realised by some closed form.

For 1-forms we proved the first half in (T2.19); the computations for S^1, S^2 and T^2 above are the theorem in action. The practical content for physicists: *topological charges are periods*. Winding numbers, magnetic fluxes, instanton numbers and index densities integrated over closed manifolds are all periods of closed forms, and so they cannot change under smooth deformations.

T2.4.9 Hodge theory: a best representative in each class

A cohomology class contains infinitely many forms. On a closed Riemannian manifold there is a best one. Using the inner product $\langle \alpha, \beta \rangle = \int_M \alpha \wedge \star\beta$ and the adjoint d^* of Section T2.2.6, define the **Hodge Laplacian** $\Delta_p = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$ on p-forms. A form is **harmonic** if $\Delta\omega = 0$. Nash gives a two-line argument, which we spell out [Nash p. 40, (2.50)]:

$$\begin{aligned} 0 = \langle \omega, \Delta_p \omega \rangle &\overset{(1)}{=} \langle \omega, \mathrm{d}\mathrm{d}^*\omega \rangle + \langle \omega, \mathrm{d}^*\mathrm{d}\omega \rangle \\ &\overset{(2)}{=} \langle \mathrm{d}^*\omega, \mathrm{d}^*\omega \rangle + \langle \mathrm{d}\omega, \mathrm{d}\omega \rangle \\ &\overset{(3)}{=} \|\mathrm{d}^*\omega\|^2 + \|\mathrm{d}\omega\|^2 . \end{aligned} \tag{T2.53}$$

(1) Definition of Δ_p and linearity.
(2) Move one d or d^* across using the adjoint property (integration by parts (T2.15) with no boundary term, since M is closed).
(3) Each term is the squared norm of a form, which is non-negative in Euclidean signature.

A sum of non-negative terms vanishes only if each does, so $\Delta\omega = 0 \iff \mathrm{d}\omega = 0$ and $\mathrm{d}^*\omega = 0$ [Nash (2.51)]. In particular a harmonic form is closed and defines a class [Nash (2.52)].

Key idea: Hodge's theorem (Nash p. 41)

On a compact closed Riemannian manifold there is exactly one harmonic form in each de Rham class. Hence

$$b_p = \dim H^p_{\mathrm{dR}}(M) = \dim \operatorname{Ker} \Delta_p. \tag{T2.54}$$

The left side is topological; the right side is the number of zero modes of a differential operator built from a metric. The answer does not depend on which metric we pick [Nash p. 41, (2.53)].

Worked example T2.19: Harmonic forms on the flat torus and the round sphere

On the flat torus with $\mathrm{d}s^2 = \mathrm{d}\theta^2 + \mathrm{d}\phi^2$ the Hodge Laplacian acts on the coefficients of a form as $-(\partial_\theta^2 + \partial_\phi^2)$ (the coframe is constant, so nothing mixes). On a Fourier mode,

$$\Delta\big(e^{i(m\theta+n\phi)}\mathrm{d}\theta\big) = (m^2+n^2)\, e^{i(m\theta+n\phi)}\mathrm{d}\theta,$$

which vanishes only for $m = n = 0$. So the harmonic 1-forms are exactly the constant combinations $x\,\mathrm{d}\theta + y\,\mathrm{d}\phi$: $\dim \operatorname{Ker}\Delta_1 = 2 = b_1$. Likewise $\operatorname{Ker}\Delta_0$ is the constants and $\operatorname{Ker}\Delta_2$ is spanned by $\mathrm{d}\theta \wedge \mathrm{d}\phi$, reproducing $(1, 2, 1)$. The harmonic representative of a class is its zero mode, exactly as in Example T2.17.
On the round S^2, $\operatorname{Ker}\Delta_0$ is the constants (Example T2.10); $\operatorname{Ker}\Delta_2$ is spanned by ω (because $\star\omega = 1$ and $\star$ commutes with Δ); and $\operatorname{Ker}\Delta_1 = 0$ because the spherical-harmonic eigenvalues $\ell(\ell+1)$ of $\mathrm{d}Y_\ell$ and $\star\mathrm{d}Y_\ell$ are never zero for $\ell \geq 1$. This matches $(1, 0, 1)$.

Physical picture: zero modes count topology

Equation (T2.54) is the prototype of every "index theorem" statement. Physicists count zero modes of an operator (here Δ, later the Dirac operator) and find a topological number. Combining it with the Euler characteristic gives $\chi(M) = \sum(-1)^p \dim \operatorname{Ker}\Delta_p$, which Nash rewrites as the index of the operator $\mathrm{d} + \mathrm{d}^*$ from even forms to odd forms [Nash p. 104, (4.52)]. The Gauss–Bonnet theorem of Section T2.8 computes the same number as an integral of curvature.

Reading Nash (pp. 13–14 and 40–41)

Nash defines cohomology in general, $H^n = \ker d_n / \operatorname{Im} d_{n-1}$ [Nash p. 13, (1.42)], and then specialises to the de Rham complex $\cdots \to \Omega^{n-1} \to \Omega^n \to \Omega^{n+1} \to \ldots$, asserting the isomorphism with real cohomology "of course" [Nash (1.43)]. The dual homology complex, with $\partial_{n-1} \circ \partial_n = 0$, is his (1.44); the cup product $[\omega] \cup [\nu] = [\omega \wedge \nu]$ is (1.45); the cohomology of spheres is (1.46). In Chapter 2 he returns to the Laplacian $\Delta_p = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$, proves (2.50)–(2.51) exactly as in (T2.53), and quotes Hodge's theorem to obtain $\dim \ker \Delta_p = b_p$ [Nash (2.53)]. Everything in this section is the working physicist's version of those five equations.

Recap

- H^p_{dR} = closed / exact. Classes have well-defined periods over cycles, and periods do not change when cycles are deformed.
- b_0 = number of components; $H^p_{\mathrm{dR}}(\mathbb{R}^n) = 0$ for $p \geq 1$; cohomology is homotopy invariant.

- S^1: $(1,1)$, generator $\mathrm{d}\phi$. S^2: $(1,0,1)$, generator $\omega/4\pi$, the unit monopole. T^2: $(1,2,1)$, generators $\mathrm{d}\theta$, $\mathrm{d}\phi$, $\mathrm{d}\theta\wedge\mathrm{d}\phi$. Fourier: cohomology is the zero mode d cannot reach.
- $\chi=\sum(-1)^p b_p = V-E+F$, by rank–nullity; $\chi(\Sigma_g)=2-2g$.
- de Rham: a closed form is exact iff all periods vanish.
- Hodge: one harmonic form per class; $b_p=\dim\mathrm{Ker}\,\Delta_p$ (zero modes count topology).

T2.5 Connections: how a frame turns from point to point

So far every derivative in these notes has acted on *forms*: we took d of functions, of 1-forms, of 2-forms. Physics also needs derivatives of *vectors*. Acceleration is the rate of change of velocity. The divergence of the electric field, the change of a spin as it is carried around, the equation of motion of a particle in a gravitational field: all of these differentiate a vector field.

In Cartesian coordinates this is trivial. Write $\vec{F}=F^x\hat{x}+F^y\hat{y}$ and differentiate the components, because $\hat{x}$ and $\hat{y}$ are the same at every point. In polar coordinates it is already not trivial: $\hat{r}$ and $\hat{\phi}$ point in different directions at different points, so a vector field with *constant* components $(F^r,F^\phi)=(0,1)$ is not a constant vector field. On a sphere it is worse still: there is no Cartesian frame at all, so there is nothing simple to compare with.

The question of this section is therefore:

> *How do the basis vectors change from point to point, and how do we encode that information so that we can differentiate any vector field?*

The answer is a matrix of 1-forms, the **connection**. We will find that a surface (or any Riemannian manifold) comes with a preferred one, the Levi-Civita connection, and that it can be computed by a few lines of exterior calculus. We will also find that the freedom to rotate the frame is exactly a gauge freedom, and that the connection transforms exactly like a gauge potential. That observation is the bridge from this chapter to Yang–Mills theory (Chapter T3).

We follow Dray, Chapter 17, closely [Dray §§17.1–17.10].

T2.5.1 A motivating example: the polar basis vectors rotate

Take the plane with polar coordinates (r,ϕ) and the unit vectors $\hat{r}$ (pointing away from the origin) and $\hat{\phi}$ (pointing counterclockwise). How do they change as we move?

Geometric answer. If we move radially, nothing happens: at (r,ϕ) and $(r+\mathrm{d}r,\phi)$ the vectors $\hat{r}$ and $\hat{\phi}$ are parallel copies of each other. If we move around a circle through an angle $\mathrm{d}\phi$, both vectors rotate through the same angle $\mathrm{d}\phi$ (Figure T2.16). The difference between two unit vectors separated by a small angle $\mathrm{d}\phi$ is a short chord joining their tips. In the limit the chord becomes tangent to the unit circle, so it is perpendicular to the original vector, and its length is the arc length $1\cdot\mathrm{d}\phi$. For $\hat{r}$ the chord points along $\hat{\phi}$; for $\hat{\phi}$ it points along $-\hat{r}$. So, along any path,

$$\mathrm{d}\hat{r}=\mathrm{d}\phi\;\hat{\phi},\qquad \mathrm{d}\hat{\phi}=-\mathrm{d}\phi\;\hat{r} \tag{T2.55}$$

[Dray (17.2)–(17.3)]. (Radial motion contributes nothing, so the formulae hold along an arbitrary path.)

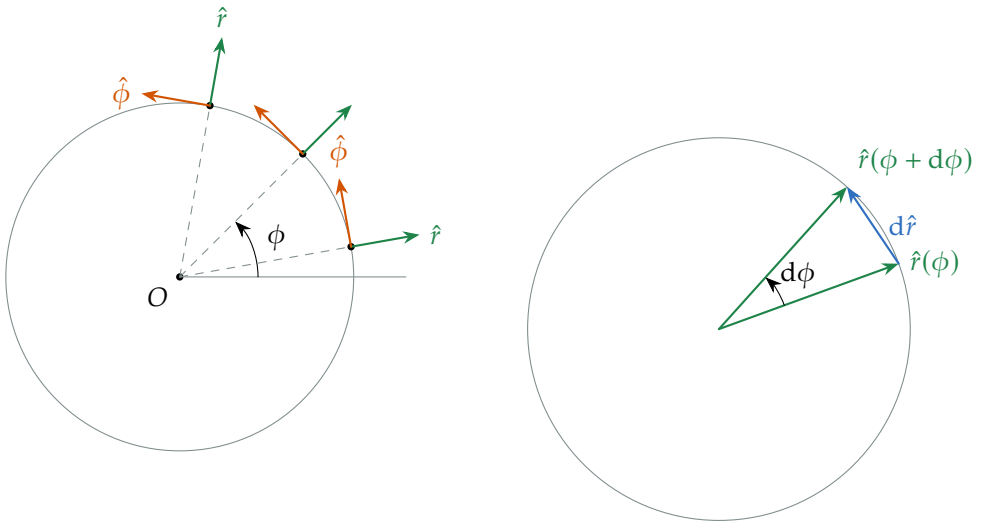


Figure T2.16: Left: the polar frame $(\hat{r}, \hat{\phi})$ at three points on a circle. Moving around the circle by $d\phi$ rotates both vectors by $d\phi$; moving radially changes nothing. Right: the change $d\hat{r}$ is the chord between the tips of two unit vectors, which in the limit is perpendicular to $\hat{r}$ (so along $\hat{\phi}$) with length $d\phi$.

Algebraic answer. Expand in the constant Cartesian frame:

$$\begin{aligned} d\hat{r} &\overset{(1)}{=} d\big(\cos\phi\,\hat{x} + \sin\phi\,\hat{y}\big) \\ &\overset{(2)}{=} -\sin\phi\,d\phi\,\hat{x} + \cos\phi\,d\phi\,\hat{y} \\ &\overset{(3)}{=} d\phi\,\hat{\phi}, \end{aligned}$$

(1) $\hat{r} = \cos\phi\,\hat{x} + \sin\phi\,\hat{y}$ and $\hat{\phi} = -\sin\phi\,\hat{x} + \cos\phi\,\hat{y}$.
(2) $\hat{x}, \hat{y}$ are constant, so only the coefficient functions are differentiated.
(3) Recognise the bracket as $\hat{\phi}$.

and in the same way $d\hat{\phi} = (-\cos\phi\,\hat{x} - \sin\phi\,\hat{y})d\phi = -d\phi\,\hat{r}$.

Watch out: a typo in Dray

Dray's (17.4)–(17.5) read $\hat{r} = r\cos\phi\,\hat{x} + r\sin\phi\,\hat{y}$, with a stray factor of r. That would be the position vector, not the unit vector. The correct expressions are the ones above, without r.

A third answer, which generalises. Differentiate the position vector $\vec{r} = r\hat{r}$:

$$d\vec{r} \overset{(1)}{=} dr\,\hat{r} + r\,d\hat{r},$$

(1) Product rule: $\vec{r}$ is a function r times the vector field $\hat{r}$.

But we also know from geometry that the infinitesimal displacement is $d\vec{r} = dr\,\hat{r} + r\,d\phi\,\hat{\phi}$ (move dr outwards and an arc $r\,d\phi$ around). Comparing gives $d\hat{r} = d\phi\,\hat{\phi}$. For $d\hat{\phi}$ we use only dot products:

$$\begin{aligned} 0 &\overset{(1)}{=} d(\hat{\phi}\cdot\hat{\phi}) \overset{(2)}{=} 2\,\hat{\phi}\cdot d\hat{\phi}, \\ 0 &\overset{(3)}{=} d(\hat{\phi}\cdot\hat{r}) \overset{(4)}{=} d\hat{\phi}\cdot\hat{r} + \hat{\phi}\cdot d\hat{r} \overset{(5)}{=} d\hat{\phi}\cdot\hat{r} + d\phi. \end{aligned}$$

(1) $\hat{\phi}$ has unit length everywhere, so $\hat{\phi}\cdot\hat{\phi}=1$ is constant.
(2) Product rule for the dot product.
(3) $\hat{\phi}\perp\hat{r}$ everywhere.
(4) Product rule again.
(5) $\mathrm{d}\hat{r}=\mathrm{d}\phi\,\hat{\phi}$ and $\hat{\phi}\cdot\hat{\phi}=1$.

The first line says $\mathrm{d}\hat{\phi}$ has no $\hat{\phi}$ component; the second says its $\hat{r}$ component is $-\mathrm{d}\phi$. Hence $\mathrm{d}\hat{\phi}=-\mathrm{d}\phi\,\hat{r}$ [Dray (17.6)–(17.10)]. This third argument never used the Cartesian frame. It used only (i) the formula for $\mathrm{d}\vec{r}$ and (ii) the fact that the frame is orthonormal. Those are exactly the two ingredients that survive on a curved surface, where there is no Cartesian frame and not even a position vector. The rest of this section turns the argument into a machine.

Key idea: derivative of a unit vector

If $\hat{u}$ has constant length, then $\hat{u}\cdot\mathrm{d}\hat{u}=\frac{1}{2}\mathrm{d}(\hat{u}\cdot\hat{u})=0$: *the change of a unit vector is always perpendicular to it.* A unit vector can only rotate. So the change of an orthonormal frame is an infinitesimal rotation, described by an antisymmetric matrix.

T2.5.2 Vector-valued forms and orthonormal coframes (vielbeins)

Vector-valued forms. The infinitesimal displacement $\mathrm{d}\vec{r}$ is both a 1-form and a vector: fed a direction of motion it returns a vector (the displacement in that direction). Dray calls such objects **vector-valued differential forms** [Dray §17.2]. In a basis $\{e_i\}$ of vector fields, a vector-valued p-form is $\alpha^i e_i$ with each α^i an ordinary p-form. A vector field $\vec{v}=v^i e_i$ is a vector-valued 0-form.

Working definition T2.7 (orthonormal frame and coframe)

An **orthonormal frame** on a Riemannian manifold [a manifold with a dot product of tangent vectors at each point, read off from $\mathrm{d}s^2$] is a set of n vector fields $e_1,\dots,e_n$ with $e_i\cdot e_j=\delta_{ij}$ at every point (of some region). The **dual coframe** is the set of 1-forms $\sigma^1,\dots,\sigma^n$ defined by

$$\mathrm{d}\vec{r}=\sigma^i\,e_i,\qquad\text{equivalently}\qquad \sigma^i(e_j)=\delta^i{}_j. \tag{T2.56}$$

How to find them in practice: write the line element as a sum of squares, $\mathrm{d}s^2=\mathrm{d}\vec{r}\cdot\mathrm{d}\vec{r}=(\sigma^1)^2+\cdots+(\sigma^n)^2$; the 1-forms being squared are an orthonormal coframe, and e_i are the unit vectors along the corresponding directions.

The metric is recovered from the coframe, because the frame is orthonormal:

$$\mathrm{d}s^2\overset{(1)}{=}\mathrm{d}\vec{r}\cdot\mathrm{d}\vec{r}\overset{(2)}{=}(\sigma^i e_i)\cdot(\sigma^j e_j)\overset{(3)}{=}\delta_{ij}\,\sigma^i\sigma^j. \tag{T2.57}$$

(1) Definition of the line element [Dray (17.21)].
(2) Expand $\mathrm{d}\vec{r}$ in the frame, (T2.56).
(3) Orthonormality, $e_i\cdot e_j=\delta_{ij}$. (In Lorentzian signature δ_{ij} becomes η_{ij}.)

The coframe as a matrix. Write $\sigma^i=E^i{}_\mu\,\mathrm{d}x^\mu$. The $n\times n$ matrix $E=(E^i{}_\mu)$ is what physicists call the **vielbein** (*zweibein* in 2D, *vierbein* in 4D) and write $e^a{}_\mu$. Its defining property is that it turns the coordinate metric into the identity:

$$g_{\mu\nu}=\delta_{ij}\,E^i{}_\mu E^j{}_\nu,\qquad\text{i.e.}\qquad g=E^{\mathsf{T}}E. \tag{T2.58}$$

The vielbein is a "square root of the metric". The inverse matrix E^{-1} gives the frame vectors in terms of coordinate derivatives, $e_i = (E^{-1})^{\mu}{}_i\,\partial_\mu$. Nash uses exactly this object, $e^a_\mu(x)e^b_\nu(x)\delta_{ab} = g_{\mu\nu}(x)$, to build the Dirac operator [Nash p. 114, (4.100)].

Worked example T2.20: Coframes of the surfaces we will use all chapter

In each case read off the coframe from the line element.
Plane, polar coordinates. $\mathrm{d}s^2 = \mathrm{d}r^2 + r^2\mathrm{d}\phi^2$, so

$$\sigma^1 = \mathrm{d}r, \quad \sigma^2 = r\,\mathrm{d}\phi, \qquad e_1 = \hat{r} = \partial_r, \quad e_2 = \hat{\phi} = \tfrac{1}{r}\partial_\phi, \qquad E = \begin{pmatrix} 1 & 0 \\ 0 & r \end{pmatrix}.$$

Sphere of radius a. $\mathrm{d}s^2 = a^2(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2)$, so

$$\sigma^1 = a\,\mathrm{d}\theta, \quad \sigma^2 = a\sin\theta\,\mathrm{d}\phi, \qquad e_1 = \hat{\theta} = \tfrac{1}{a}\partial_\theta, \quad e_2 = \hat{\phi} = \tfrac{1}{a\sin\theta}\partial_\phi, \qquad E = \begin{pmatrix} a & 0 \\ 0 & a\sin\theta \end{pmatrix}.$$

Torus of revolution. Let the tube (radius a) have its centre on a circle of radius $R > a$ in the xy-plane: $\vec{r} = \big((R + a\cos\theta)\cos\phi,\ (R + a\cos\theta)\sin\phi,\ a\sin\theta\big)$, where θ goes around the tube (starting on the outer equator) and ϕ goes around the z-axis. Moving by $\mathrm{d}\theta$ traces an arc $a\,\mathrm{d}\theta$ of the tube; moving by $\mathrm{d}\phi$ traces an arc of a horizontal circle of radius $R + a\cos\theta$. These are perpendicular, so [Dray (18.81)]

$$\mathrm{d}s^2 = a^2\mathrm{d}\theta^2 + (R + a\cos\theta)^2\mathrm{d}\phi^2, \qquad \sigma^1 = a\,\mathrm{d}\theta, \quad \sigma^2 = (R + a\cos\theta)\,\mathrm{d}\phi.$$

Euclidean $\mathbb{R}^3$, spherical coordinates. $\mathrm{d}s^2 = \mathrm{d}r^2 + r^2\mathrm{d}\theta^2 + r^2\sin^2\theta\,\mathrm{d}\phi^2$, so $(\sigma^1, \sigma^2, \sigma^3) = (\mathrm{d}r,\ r\,\mathrm{d}\theta,\ r\sin\theta\,\mathrm{d}\phi)$ and $(e_1, e_2, e_3) = (\hat{r}, \hat{\theta}, \hat{\phi})$.

The frame is not unique. At each point we may rotate the orthonormal frame by any rotation matrix, and the rotation may depend on the point. In 2D, rotating by an angle $\lambda(x)$ gives another perfectly good orthonormal frame. This freedom will turn out to be a gauge freedom (Section T2.5.10). The Cartesian frame $(\hat{x}, \hat{y})$ and the polar frame $(\hat{r}, \hat{\phi})$ of the plane are related in exactly this way, with $\lambda = \phi$.

T2.5.3 Differentiating vector fields

A vector field is a vector-valued 0-form, so its exterior derivative should be a vector-valued 1-form: fed a direction, it returns how the vector changes in that direction. In a Cartesian frame [Dray (17.11)–(17.13)],

$$\mathrm{d}\vec{F} = \mathrm{d}F^x\,\hat{x} + \mathrm{d}F^y\,\hat{y},$$

because $\mathrm{d}\hat{x} = \mathrm{d}\hat{y} = 0$. In a general frame the product rule forces

$$\mathrm{d}\vec{F} = \mathrm{d}(F^i e_i) = \mathrm{d}F^i\,e_i + F^i\,\mathrm{d}e_i, \tag{T2.59}$$

and we need to know $\mathrm{d}e_i$ [Dray (17.15)]. The properties we demand of d on vector-valued forms are [Dray (17.16)–(17.18)]:

$$\begin{aligned} \mathrm{d}(a\vec{v} + \vec{w}) &= a\,\mathrm{d}\vec{v} + \mathrm{d}\vec{w} \quad (a \text{ constant}), \\ \mathrm{d}(\alpha\,\vec{v}) &= \mathrm{d}\alpha\,\vec{v} + (-1)^p\alpha \wedge \mathrm{d}\vec{v} \quad (\alpha \text{ a } p\text{-form}), \\ \mathrm{d}(\vec{v}\,\alpha) &= \mathrm{d}\vec{v} \wedge \alpha + \vec{v}\,\mathrm{d}\alpha. \end{aligned} \tag{T2.60}$$

The sign in the middle line is the usual graded Leibniz rule: d has to move past the p-form α to reach $\vec{v}$. The last line has no sign because $\vec{v}$ is a 0-form. These rules do not determine $\mathrm{d}e_i$. That extra information is what we now name.

T2.5.4 Connection 1-forms

Working definition T2.8 (connection 1-forms)

Given a frame $\{e_j\}$ [n vector fields forming a basis at each point], the **connection 1-forms** $\omega^i{}_j$ are defined by expanding the change of each frame vector in the frame:

$$\mathrm{d}e_j = e_i\,\omega^i{}_j, \qquad \text{equivalently} \qquad \omega^i{}_j = e_i \cdot \mathrm{d}e_j \quad \text{(orthonormal frame)}. \tag{T2.61}$$

Read it as: $\omega^i{}_j(\vec{v})$ is the i-th component of the rate of change of e_j when we move with velocity $\vec{v}$. Collect them into an $n \times n$ matrix of 1-forms $\omega = (\omega^i{}_j)$ [fed a velocity $\vec{v}$, it gives an ordinary matrix, antisymmetric when the frame is orthonormal] (row i, column j).

Dray writes (T2.61) as $\mathrm{d}e_j = \omega^i{}_j\, e_i$ [Dray (17.19)]; the order does not matter because e_i is a 0-form. A compact matrix notation is useful. Arrange the frame as a *row* $\mathbf{e} = (e_1, \ldots, e_n)$ and the coframe as a *column* $\boldsymbol{\sigma} = (\sigma^1, \ldots, \sigma^n)^{\mathsf{T}}$. Then

$$\mathrm{d}\vec{r} = \mathbf{e}\,\boldsymbol{\sigma}, \qquad \mathrm{d}\mathbf{e} = \mathbf{e}\,\omega. \tag{T2.62}$$

With this, (T2.59) becomes, for $\vec{F} = F^j e_j$,

$$\mathrm{d}\vec{F} \overset{(1)}{=} \mathrm{d}F^j\, e_j + F^j\, e_i\, \omega^i{}_j \overset{(2)}{=} \left(\mathrm{d}F^i + \omega^i{}_j\, F^j\right) e_i. \tag{T2.63}$$

(1) Product rule (T2.59) and the definition (T2.61).
(2) Rename the dummy index $j \to i$ in the first term and collect the coefficient of e_i.

So the components of $\mathrm{d}\vec{F}$ are not $\mathrm{d}F^i$ but $\mathrm{d}F^i + \omega^i{}_j F^j$. The connection is the correction that accounts for the turning of the frame.

Polar coordinates. From (T2.55), with $e_1 = \hat{r}$ and $e_2 = \hat{\phi}$: $\mathrm{d}e_1 = e_2\,\mathrm{d}\phi$, so $\omega^2{}_1 = \mathrm{d}\phi$, $\omega^1{}_1 = 0$; and $\mathrm{d}e_2 = -e_1\,\mathrm{d}\phi$, so $\omega^1{}_2 = -\mathrm{d}\phi$, $\omega^2{}_2 = 0$. As a matrix,

$$\omega_{\text{polar}} = \begin{pmatrix} 0 & -\mathrm{d}\phi \\ \mathrm{d}\phi & 0 \end{pmatrix} = \mathrm{d}\phi \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}. \tag{T2.64}$$

The matrix $\left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$ is the generator of counterclockwise rotations in the plane. The connection says: "moving by $\mathrm{d}\phi$ rotates the frame by the angle $\mathrm{d}\phi$".

Worked example T2.21: Constant components, non-constant field; and the reverse

(a) The field $\vec{F} = \hat{\phi}$. Its polar components are $(F^1, F^2) = (0, 1)$, both constant. Yet by (T2.63),

$$\begin{aligned} \mathrm{d}\vec{F} &\overset{(1)}{=} \left(\mathrm{d}F^1 + \omega^1{}_2 F^2\right) e_1 + \left(\mathrm{d}F^2 + \omega^2{}_1 F^1\right) e_2 \\ &\overset{(2)}{=} (0 - \mathrm{d}\phi)\,\hat{r} + (0 + 0)\,\hat{\phi} = -\mathrm{d}\phi\,\hat{r}. \end{aligned}$$

(1) Expand (T2.63); the diagonal $\omega^i{}_i$ vanish.
(2) $F^1 = 0$, $F^2 = 1$ are constants, and $\omega^1{}_2 = -\mathrm{d}\phi$.

Feeding in the unit vector $\hat{\phi}$ (which has $\mathrm{d}\phi(\hat{\phi}) = 1/r$) gives the rate of change of $\hat{\phi}$ as we

move along a circle at unit speed: $-\hat{r}/r$. This is the centripetal acceleration v^2/r of uniform circular motion with $v = 1$, pointing inwards.
(b) The field $\vec{F} = \hat{x}$. In the polar frame, $\hat{x} = \cos\phi\,\hat{r} - \sin\phi\,\hat{\phi}$, so its components vary. But

$$\begin{aligned} \mathrm{d}\hat{x} &\overset{(1)}{=} \big(\mathrm{d}(\cos\phi) + \omega^1{}_2(-\sin\phi)\big)\hat{r} + \big(\mathrm{d}(-\sin\phi) + \omega^2{}_1\cos\phi\big)\hat{\phi} \\ &\overset{(2)}{=} \big(-\sin\phi\,\mathrm{d}\phi + \sin\phi\,\mathrm{d}\phi\big)\hat{r} + \big(-\cos\phi\,\mathrm{d}\phi + \cos\phi\,\mathrm{d}\phi\big)\hat{\phi} = 0. \end{aligned}$$

(1) (T2.63) with $F^1 = \cos\phi$, $F^2 = -\sin\phi$.
(2) $\omega^1{}_2 = -\mathrm{d}\phi$, $\omega^2{}_1 = +\mathrm{d}\phi$.
The change of the components exactly cancels the turning of the frame, as it must for a constant field.

T2.5.5 Metric compatibility: the connection is a rotation generator

We impose two conditions that single out the connection geometry gives us. The first is that differentiation respects the dot product [Dray (17.24)]:

$$\mathrm{d}(\vec{v}\cdot\vec{w}) = \mathrm{d}\vec{v}\cdot\vec{w} + \vec{v}\cdot\mathrm{d}\vec{w}. \tag{T2.65}$$

Apply it to the frame:

$$0 \overset{(1)}{=} \mathrm{d}(e_i\cdot e_j) \overset{(2)}{=} \mathrm{d}e_i\cdot e_j + e_i\cdot\mathrm{d}e_j \overset{(3)}{=} \omega^j{}_i + \omega^i{}_j. \tag{T2.66}$$

(1) $e_i\cdot e_j = \delta_{ij}$ is constant.
(2) The compatibility condition (T2.65).
(3) $\mathrm{d}e_i\cdot e_j = (e_k\,\omega^k{}_i)\cdot e_j = \omega^j{}_i$, and similarly for the second term.

So in an orthonormal frame (Euclidean signature, where indices can be raised and lowered freely) the matrix ω is *antisymmetric*: $\omega_{ij} = -\omega_{ji}$ and the diagonal vanishes [Dray (17.25)]. An antisymmetric $n\times n$ matrix is an element of the Lie algebra $\mathfrak{so}(n)$ of the rotation group. So:

Key idea: the connection is $\mathfrak{so}(n)$-valued

In an orthonormal frame the connection ω is an $\mathfrak{so}(n)$-valued 1-form: for each direction of motion it returns the infinitesimal rotation that the frame undergoes. In 2D, $\mathfrak{so}(2)$ is one-dimensional, so the whole connection is a single 1-form $\omega^1{}_2 = -\omega^2{}_1$. In 3D there are three: $\omega^1{}_2$, $\omega^1{}_3$, $\omega^2{}_3$. In 4D there are six, matching the six generators of SO(4) (or of the Lorentz group SO(3, 1)).

T2.5.6 Torsion-free: Cartan's first structure equation

The second condition concerns d^2. For forms $\mathrm{d}^2 = 0$ always. For vector-valued forms we cannot demand that in general (we will see in Section T2.6 that $\mathrm{d}^2\vec{v} \neq 0$ is precisely curvature). But for the displacement $\mathrm{d}\vec{r}$ there is a strong argument. In Euclidean space $\mathrm{d}\vec{r}$ really is d of the position vector, so $\mathrm{d}(\mathrm{d}\vec{r}) = 0$. On a sphere there is no position vector, but $\mathrm{d}\vec{r}$ still makes sense, and we *demand* [Dray (17.27)]

$$\mathrm{d}(\mathrm{d}\vec{r}) = 0. \tag{T2.67}$$

Expand it using the product rules:

$$\begin{aligned} 0 &\overset{(1)}{=} \mathrm{d}(\sigma^j e_j) \\ &\overset{(2)}{=} \mathrm{d}\sigma^j\, e_j - \sigma^j \wedge \mathrm{d}e_j \\ &\overset{(3)}{=} \mathrm{d}\sigma^i\, e_i - \sigma^j \wedge \omega^i{}_j\, e_i \\ &\overset{(4)}{=} \left(\mathrm{d}\sigma^i + \omega^i{}_j \wedge \sigma^j\right) e_i. \end{aligned} \tag{T2.68}$$

(1) (T2.67) and $\mathrm{d}\vec{r} = \sigma^j e_j$.
(2) The graded product rule (T2.60) with $p = 1$ [Dray (17.28)].
(3) Insert $\mathrm{d}e_j = e_i\, \omega^i{}_j$ and rename $j \to i$ in the first term.
(4) $\sigma^j \wedge \omega^i{}_j = -\omega^i{}_j \wedge \sigma^j$ (two 1-forms anticommute).

Each component must vanish:

$$\boxed{\mathrm{d}\sigma^i + \omega^i{}_j \wedge \sigma^j = 0} \qquad \text{or, in matrices,} \qquad \mathrm{d}\boldsymbol{\sigma} + \omega \wedge \boldsymbol{\sigma} = 0. \tag{T2.69}$$

This is **Cartan's first structure equation**. More generally the left side is the **torsion** 2-form $\Theta^i = \mathrm{d}\sigma^i + \omega^i{}_j \wedge \sigma^j$ [Dray (18.26)], and (T2.69) says the connection is **torsion free**.

Working definition T2.9 (Levi-Civita connection)

The **Levi-Civita connection** of a metric is the unique connection [a choice of the 1-forms $\omega^i{}_j$, i.e. of the rule $\mathrm{d}e_j = e_i\, \omega^i{}_j$] that is

1. metric compatible: $\omega_{ij} = -\omega_{ji}$ in an orthonormal frame [moving in any direction keeps $e_i \cdot e_j = \delta_{ij}$, so the frame only rotates], and
2. torsion free: $\mathrm{d}\sigma^i = -\omega^i{}_j \wedge \sigma^j$.

How to compute it: write down the coframe, compute each $\mathrm{d}\sigma^i$, and guess antisymmetric $\omega^i{}_j$ that reproduce them. If your guess satisfies all n equations, it is *the* answer, by uniqueness.

Why it is unique: counting. In n dimensions an antisymmetric matrix of 1-forms has $\frac{1}{2}n(n-1)$ independent entries, each with n components, so $\frac{1}{2}n^2(n-1)$ unknown functions. The torsion condition is n equations between 2-forms, each 2-form having $\frac{1}{2}n(n-1)$ components, so $\frac{1}{2}n^2(n-1)$ linear equations. The numbers match [Dray §17.6]. The explicit formula of Section T2.5.8 shows that the linear system is indeed invertible, so the solution exists and is unique.

T2.5.7 Computing Levi-Civita connections

The "educated guess" method is almost always fastest [Dray §17.7]. Here are the four cases we need; the first reproduces what we already know, the rest are new.

Worked example T2.22: Polar coordinates, from the structure equations

Coframe $\sigma^1 = \mathrm{d}r$, $\sigma^2 = r\,\mathrm{d}\phi$. The only unknown is $\omega^1{}_2 = -\omega^2{}_1$. The two structure equations are

$$\begin{aligned} 0 &\overset{(1)}{=} \mathrm{d}\sigma^1 + \omega^1{}_2 \wedge \sigma^2 = \omega^1{}_2 \wedge r\,\mathrm{d}\phi, \\ 0 &\overset{(2)}{=} \mathrm{d}\sigma^2 + \omega^2{}_1 \wedge \sigma^1 = \mathrm{d}r \wedge \mathrm{d}\phi - \omega^1{}_2 \wedge \mathrm{d}r. \end{aligned}$$

(1) $\mathrm{d}\sigma^1 = \mathrm{d}\mathrm{d}r = 0$, and $\omega^1{}_1 = 0$.

(2) $\mathrm{d}(r\,\mathrm{d}\phi) = \mathrm{d}r \wedge \mathrm{d}\phi$, and $\omega^2{}_1 = -\omega^1{}_2$, $\omega^2{}_2 = 0$.

The second equation needs $\omega^1{}_2 \wedge \mathrm{d}r = \mathrm{d}r \wedge \mathrm{d}\phi$, so $\omega^1{}_2$ must contain $-\mathrm{d}\phi$. Guess $\omega^1{}_2 = -\mathrm{d}\phi$; then the first equation, $-\mathrm{d}\phi \wedge r\,\mathrm{d}\phi = 0$, also holds. Done: $\omega^1{}_2 = -\mathrm{d}\phi$, in agreement with (T2.64) [Dray (17.32)–(17.39)]. We never used the Cartesian frame.

Worked example T2.23: The sphere of radius a

Coframe $\sigma^1 = a\,\mathrm{d}\theta$, $\sigma^2 = a\sin\theta\,\mathrm{d}\phi$. Then $\mathrm{d}\sigma^1 = 0$ and $\mathrm{d}\sigma^2 = a\cos\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$. The structure equations:

$$0 \overset{(1)}{=} \omega^1{}_2 \wedge a\sin\theta\,\mathrm{d}\phi,$$
$$a\cos\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi \overset{(2)}{=} -\omega^2{}_1 \wedge a\,\mathrm{d}\theta = \omega^1{}_2 \wedge a\,\mathrm{d}\theta.$$

(1) First structure equation for $i = 1$, with $\mathrm{d}\sigma^1 = 0$.
(2) First structure equation for $i = 2$, and antisymmetry.

Try $\omega^1{}_2 = c\,\mathrm{d}\phi$. The first equation holds. The second gives $c\,a\,\mathrm{d}\phi \wedge \mathrm{d}\theta = a\cos\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$, so $c = -\cos\theta$:

$$\omega^1{}_2 = -\cos\theta\,\mathrm{d}\phi \qquad \text{(sphere, frame } \hat\theta, \hat\phi\text{)}. \tag{T2.70}$$

Note that the radius a has dropped out. This is the potential $-\cos\theta\,\mathrm{d}\phi$ of the sphere puzzle (T2.31)! We will see why in Section T2.5.10.

Check from outside. Embed the sphere in $\mathbb{R}^3$. In spherical coordinates $\hat\phi = (-\sin\phi, \cos\phi, 0)$, so $\mathrm{d}\hat\phi = -(\cos\phi, \sin\phi, 0)\,\mathrm{d}\phi = -(\sin\theta\,\hat r + \cos\theta\,\hat\theta)\,\mathrm{d}\phi$. Then

$$\omega^1{}_2 = \hat\theta \cdot \mathrm{d}\hat\phi = -\cos\theta\,\mathrm{d}\phi,$$

the same answer. The $\hat r$ part of $\mathrm{d}\hat\phi$ sticks out of the sphere; an ant living on the sphere cannot see it, and it does not enter $\omega^1{}_2$. It will reappear as *extrinsic* curvature in Section T2.6.5.

Worked example T2.24: The torus of revolution

Coframe $\sigma^1 = a\,\mathrm{d}\theta$, $\sigma^2 = (R + a\cos\theta)\,\mathrm{d}\phi$. Then $\mathrm{d}\sigma^1 = 0$ and $\mathrm{d}\sigma^2 = -a\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$. The second structure equation reads

$$-a\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi \overset{(1)}{=} \omega^1{}_2 \wedge a\,\mathrm{d}\theta,$$

(1) As for the sphere: $\mathrm{d}\sigma^2 = -\omega^2{}_1 \wedge \sigma^1 = \omega^1{}_2 \wedge \sigma^1$.

which is solved by

$$\omega^1{}_2 = \sin\theta\,\mathrm{d}\phi \tag{T2.71}$$

(check: $\sin\theta\,\mathrm{d}\phi \wedge a\,\mathrm{d}\theta = -a\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$), and the first equation $\omega^1{}_2 \wedge \sigma^2 \propto \mathrm{d}\phi \wedge \mathrm{d}\phi = 0$ holds too [Dray (18.84)–(18.86)]. Neither R nor a appears.

Worked example T2.25: Flat $\mathbb{R}^3$ in spherical coordinates (Dray, Problem 17.1)

Now there are three connection 1-forms. Differentiate the unit vectors (from their Cartesian expressions):

$$\mathrm{d}\hat r = \mathrm{d}\theta\,\hat\theta + \sin\theta\,\mathrm{d}\phi\,\hat\phi,$$
$$\mathrm{d}\hat\theta = -\mathrm{d}\theta\,\hat r + \cos\theta\,\mathrm{d}\phi\,\hat\phi,$$

$$\mathrm{d}\hat{\phi} = -\sin\theta\,\mathrm{d}\phi\,\hat{r} - \cos\theta\,\mathrm{d}\phi\,\hat{\theta}.$$

Reading off $\omega^i{}_j = e_i \cdot \mathrm{d}e_j$ with $(e_1, e_2, e_3) = (\hat{r}, \hat{\theta}, \hat{\phi})$:

$$\omega = \begin{pmatrix} 0 & -\mathrm{d}\theta & -\sin\theta\,\mathrm{d}\phi \\ \mathrm{d}\theta & 0 & -\cos\theta\,\mathrm{d}\phi \\ \sin\theta\,\mathrm{d}\phi & \cos\theta\,\mathrm{d}\phi & 0 \end{pmatrix}. \tag{T2.72}$$

It is antisymmetric, as promised. Check the torsion equation for $i = 3$:

$$\begin{aligned} \mathrm{d}\sigma^3 + \omega^3{}_1 \wedge \sigma^1 + \omega^3{}_2 \wedge \sigma^2 &\overset{(1)}{=} \big(\sin\theta\,\mathrm{d}r \wedge \mathrm{d}\phi + r\cos\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi\big) \\ &\quad + \sin\theta\,\mathrm{d}\phi \wedge \mathrm{d}r + \cos\theta\,\mathrm{d}\phi \wedge r\,\mathrm{d}\theta \\ &\overset{(2)}{=} 0. \end{aligned}$$

(1) $\sigma^3 = r\sin\theta\,\mathrm{d}\phi$, so $\mathrm{d}\sigma^3 = \sin\theta\,\mathrm{d}r \wedge \mathrm{d}\phi + r\cos\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$; insert $\omega^3{}_1$, $\omega^3{}_2$ from (T2.72).
(2) The terms cancel in pairs after swapping the order of the wedges.

The equations for $i = 1, 2$ check the same way. Notice the $(2, 3)$ entry, $\omega^2{}_3 = -\cos\theta\,\mathrm{d}\phi$: it is exactly the sphere's connection (T2.70). Restricting to $r = \text{const}$ (so $\mathrm{d}r = 0$) keeps the tangential rotation and drops the rest [Dray (18.42)].

T2.5.8 An explicit formula: Christoffel symbols and the Koszul formula

Guessing is fast, but it is reassuring to have a formula. Expand the connection 1-forms in the coframe [Dray (17.40)]:

$$\omega^i{}_j = \Gamma^i{}_{jk}\,\sigma^k. \tag{T2.73}$$

The coefficients $\Gamma^i{}_{jk}$ are the **Christoffel symbols** (in an orthonormal frame; physicists also call ω the *spin connection* and its components *Ricci rotation coefficients*). Metric compatibility says $\Gamma_{ijk} = -\Gamma_{jik}$ [Dray (17.42)]. Next expand the derivatives of the coframe:

$$\mathrm{d}\sigma^i = \tfrac{1}{2}\,C^i{}_{jk}\,\sigma^j \wedge \sigma^k, \qquad C^i{}_{jk} = -C^i{}_{kj}. \tag{T2.74}$$

The C's are computed directly from the coframe; no connection is needed. The torsion equation, $\mathrm{d}\sigma^i = -\Gamma^i{}_{jk}\sigma^k \wedge \sigma^j = \Gamma^i{}_{jk}\sigma^j \wedge \sigma^k$, says that $C^i{}_{jk} = \Gamma^i{}_{jk} - \Gamma^i{}_{kj}$ [Dray (17.47)]. We want to invert this, using the antisymmetry in the first two indices:

$$\begin{aligned} C_{ijk} - C_{kij} + C_{jki} &\overset{(1)}{=} (\Gamma_{ijk} - \Gamma_{ikj}) - (\Gamma_{kij} - \Gamma_{kji}) + (\Gamma_{jki} - \Gamma_{jik}) \\ &\overset{(2)}{=} \Gamma_{ijk} + \Gamma_{kij} - \Gamma_{kij} - \Gamma_{jki} + \Gamma_{jki} - \Gamma_{jik} \\ &\overset{(3)}{=} \Gamma_{ijk} - \Gamma_{jik} \overset{(4)}{=} 2\,\Gamma_{ijk}. \end{aligned} \tag{T2.75}$$

(1) Substitute $C_{ijk} = \Gamma_{ijk} - \Gamma_{ikj}$ three times (indices lowered freely, Euclidean signature).
(2) Use $\Gamma_{ikj} = -\Gamma_{kij}$ and $\Gamma_{kji} = -\Gamma_{jki}$ (antisymmetry in the first pair).
(3) Four terms cancel in pairs.
(4) Antisymmetry once more: $-\Gamma_{jik} = \Gamma_{ijk}$.

So

$$\boxed{\Gamma_{ijk} = \tfrac{1}{2}\big(C_{ijk} - C_{kij} + C_{jki}\big)} \tag{T2.76}$$

which is Dray's (17.48), the **Koszul formula** in an orthonormal frame. It proves existence and uniqueness at once: the right side is determined by the coframe alone.

Commutators. The C's have a second meaning. The **commutator** of two vector fields, $[\vec{v},\vec{w}]f := \vec{v}(\vec{w}f) - \vec{w}(\vec{v}f)$, contains no second derivatives of f (they cancel), so it is again a vector field [Dray (17.60)]. For any 1-form the identity $\mathrm{d}\alpha(\vec{v},\vec{w}) = \vec{v}\big(\alpha(\vec{w})\big) - \vec{w}\big(\alpha(\vec{v})\big) - \alpha([\vec{v},\vec{w}])$ holds [Dray (17.61)] (check it on $\alpha = f\,\mathrm{d}g$ in coordinates). Apply it to $\alpha = \sigma^i$ and $\vec{v},\vec{w} = e_j, e_k$: the first two terms are derivatives of the constants $\delta^i{}_k, \delta^i{}_j$, so

$$C^i{}_{jk} = \mathrm{d}\sigma^i(e_j,e_k) = -\sigma^i\big([e_j,e_k]\big), \qquad \text{i.e.} \qquad [e_j,e_k] = -C^i{}_{jk}\,e_i. \tag{T2.77}$$

The frame vectors fail to commute exactly when the coframe fails to be closed. In 2D the Koszul formula collapses to a one-liner [Dray (17.65)–(17.66)]:

$$\omega_{12} = [e_1,e_2]\cdot \mathrm{d}\vec{r}. \tag{T2.78}$$

Worked example T2.26: The one-liner on the plane and on the sphere

Plane. $e_1 = \partial_r$, $e_2 = \frac{1}{r}\partial_\phi$. Acting on a function f,

$$[e_1,e_2]f \overset{(1)}{=} \partial_r\Big(\frac{1}{r}\partial_\phi f\Big) - \frac{1}{r}\partial_\phi\partial_r f \overset{(2)}{=} -\frac{1}{r^2}\partial_\phi f = -\frac{1}{r}\,e_2 f,$$

(1) Definition of the commutator.
(2) Product rule; the mixed second derivatives cancel.

so $[e_1,e_2] = -\frac{1}{r}e_2$ and $\omega_{12} = -\frac{1}{r}\,e_2\cdot\mathrm{d}\vec{r} = -\frac{1}{r}\sigma^2 = -\mathrm{d}\phi$.
Sphere. $e_1 = \frac{1}{a}\partial_\theta$, $e_2 = \frac{1}{a\sin\theta}\partial_\phi$. The same computation gives $[e_1,e_2] = \frac{1}{a}\partial_\theta\big(\frac{1}{a\sin\theta}\big)\partial_\phi = -\frac{\cos\theta}{a\sin\theta}\,e_2$, hence $\omega_{12} = -\frac{\cos\theta}{a\sin\theta}\,a\sin\theta\,\mathrm{d}\phi = -\cos\theta\,\mathrm{d}\phi$, matching (T2.70).

Dictionary: frame connection ↔ coordinate Christoffel symbols

Relativity textbooks use the coordinate basis ∂_μ and write $\nabla_\mu V^\nu = \partial_\mu V^\nu + \Gamma^\nu{}_{\mu\lambda}V^\lambda$ with $\Gamma^\nu{}_{\mu\lambda} = \frac{1}{2}g^{\nu\rho}(\partial_\mu g_{\rho\lambda} + \partial_\lambda g_{\rho\mu} - \partial_\rho g_{\mu\lambda})$. The orthonormal-frame connection (the *spin connection*) is related to it by changing basis with the vielbein:

$$\omega^i{}_j = \sigma^i{}_\nu\big(\partial_\mu E_j{}^\nu + \Gamma^\nu{}_{\mu\lambda}E_j{}^\lambda\big)\mathrm{d}x^\mu, \qquad e_j = E_j{}^\nu\partial_\nu,\ \sigma^i = \sigma^i{}_\nu \mathrm{d}x^\nu.$$

Check on polar coordinates: $\Gamma^r{}_{\phi\phi} = -r$, $\Gamma^\phi{}_{r\phi} = \Gamma^\phi{}_{\phi r} = \frac{1}{r}$, others zero; $e_2 = \frac{1}{r}\partial_\phi$ so $E_2{}^\phi = \frac{1}{r}$. Then $\omega^1{}_2 = \sigma^1{}_r\,\Gamma^r{}_{\phi\phi}E_2{}^\phi\,\mathrm{d}\phi = 1\cdot(-r)\cdot\frac{1}{r}\,\mathrm{d}\phi = -\mathrm{d}\phi$. Same answer, more work. The frame method needs only $n(n-1)/2$ 1-forms; the coordinate method needs $n^2(n+1)/2$ functions.

Worked example T2.27: The sphere's Christoffel symbols, seen from $\mathbb{R}^3$

Sit the unit sphere in $\mathbb{R}^3$, $\vec{r} = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$, with the coordinate basis $e_\theta = \partial_\theta\vec{r}$, $e_\phi = \partial_\phi\vec{r}$, and watch the basis turn:

$$\partial_\theta e_\phi \overset{(1)}{=} (-\cos\theta\sin\phi,\ \cos\theta\cos\phi,\ 0) \overset{(2)}{=} \cot\theta\,e_\phi,$$
$$\partial_\phi e_\phi \overset{(3)}{=} -\sin\theta(\cos\phi,\sin\phi,0) \overset{(4)}{=} -\sin\theta\cos\theta\,e_\theta - \sin^2\theta\,\hat{n}.$$

(1) Differentiate $e_\phi = (-\sin\theta\sin\phi,\ \sin\theta\cos\phi,\ 0)$ in θ.
(2) It is e_ϕ with $\sin\theta$ replaced by $\cos\theta$.
(3) Differentiate e_ϕ in ϕ.
(4) Split $(\cos\phi,\sin\phi,0) = \cos\theta\,e_\theta + \sin\theta\,\hat{n}$ into its part along the sphere and its part along the normal $\hat{n}$.

Keep only the part along the sphere, since $\nabla_a e_b = \Gamma^c{}_{ab}e_c$ is the tangent part of $\partial_a e_b$. This

gives $\Gamma^{\phi}{}_{\theta\phi} = \cot\theta$ and $\Gamma^{\theta}{}_{\phi\phi} = -\sin\theta\cos\theta$: the same numbers the metric formula in the box above gives for $ds^2 = d\theta^2 + \sin^2\theta\, d\phi^2$, and the same connection as $\omega^1{}_2 = -\cos\theta\, d\phi$ of Example T2.23, with no $\mathbb{R}^3$ needed. That is the point of the formalism (Figure T1.2).

T2.5.9 Covariant derivatives

The vector-valued 1-form $d\vec{v}$ answers "how does $\vec{v}$ change?" for every direction at once. Feeding it one direction gives the **covariant derivative**:

Working definition T2.10 (covariant derivative)

For vector fields $\vec{X}$ and $\vec{v} = v^i e_i$,

$$\nabla_{\vec{X}}\vec{v} := d\vec{v}(\vec{X}) = \left(\vec{X}(v^i) + \omega^i{}_j(\vec{X})\, v^j\right) e_i. \tag{T2.79}$$

Recipe: differentiate the components along $\vec{X}$ [$\vec{X}(v^i)$ is the ordinary directional derivative of the function v^i], then add the rotation of the frame, $\omega(\vec{X})$, acting on the column of components. In components $\nabla_k v^i = e_k(v^i) + \Gamma^i{}_{jk} v^j$ [here $\Gamma^i{}_{jk} = \omega^i{}_j(e_k)$, the connection fed the k-th frame vector].

In the physicist's language of gauge theory, $\nabla = d + \omega$ is the *covariant derivative* with gauge potential ω. Nash writes the Dirac operator as $\not{D} = \gamma^a e_a^{\mu}(\partial_\mu + \omega_\mu)$ [Nash p. 114, (4.100)], where ω_μ is this same connection, acting on spinors through the generators of Spin(n) (Chapter T4).

Worked example T2.28: Covariant derivatives on the sphere

On the unit sphere ($a = 1$), take $\vec{v} = \hat{\phi}$ and differentiate it along the latitude circle, $\vec{X} = \hat{\phi}$, and along the meridian, $\vec{X} = \hat{\theta}$. With $e_1 = \hat{\theta}$, $e_2 = \hat{\phi}$, $v^1 = 0$, $v^2 = 1$:

$$\nabla_{\hat{\phi}}\hat{\phi} \overset{(1)}{=} \omega^1{}_2(\hat{\phi})\, e_1 \overset{(2)}{=} -\cos\theta\, d\phi(\hat{\phi})\, \hat{\theta} \overset{(3)}{=} -\cot\theta\, \hat{\theta},$$

$$\nabla_{\hat{\theta}}\hat{\phi} \overset{(4)}{=} \omega^1{}_2(\hat{\theta})\, e_1 = 0.$$

(1) Constant components, so only the ω term of (T2.79) survives; $\omega^2{}_2 = 0$.
(2) (T2.70).
(3) $d\phi(\hat{\phi}) = 1/\sin\theta$, since $\hat{\phi} = \frac{1}{\sin\theta}\partial_\phi$.
(4) $d\phi(\hat{\theta}) = 0$.

So $\hat{\phi}$ does not change as we walk along a meridian, but it turns (towards the pole: $-\hat{\theta}$ points north) as we walk along a latitude circle, at a rate $\cot\theta$. At the equator, $\cot\theta = 0$: walking along the equator, $\hat{\phi}$ does not turn at all. The equator is straight as seen from inside the sphere; it is a geodesic (Section T2.7).

T2.5.10 Rotating the frame is a gauge transformation

Now we come to the observation that connects this chapter with gauge theory. Let $\mathbf{e}' = \mathbf{e}\, g$ be a rotated frame, where $g(x) \in \mathrm{SO}(n)$ is a point-dependent rotation matrix. What is the new connection?

$$d\mathbf{e}' \overset{(1)}{=} d(\mathbf{e}\, g) \overset{(2)}{=} d\mathbf{e}\, g + \mathbf{e}\, dg \overset{(3)}{=} \mathbf{e}\, \omega\, g + \mathbf{e}\, dg$$

$$\overset{(4)}{=} \mathbf{e}'\left(g^{-1}\omega\, g + g^{-1}\mathrm{d}g\right). \tag{T2.80}$$

(1) Definition of the new frame.
(2) Product rule ($\mathbf{e}$ and g are both 0-forms).
(3) $\mathrm{d}\mathbf{e} = \mathbf{e}\,\omega$.
(4) $\mathbf{e} = \mathbf{e}'g^{-1}$.

Hence, together with the coframe (which must satisfy $\mathrm{d}\vec{r} = \mathbf{e}\boldsymbol{\sigma} = \mathbf{e}'\boldsymbol{\sigma}'$),

$$\boxed{\omega' = g^{-1}\omega\, g + g^{-1}\mathrm{d}g, \qquad \boldsymbol{\sigma}' = g^{-1}\boldsymbol{\sigma}} \tag{T2.81}$$

This is *exactly* the gauge transformation law $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$ of a non-abelian gauge potential, in the convention used throughout these notes. The structure group is $\mathrm{SO}(n)$. The "matter fields" are the components v^i of vectors, which transform as $v' = g^{-1}v$.

Two dimensions: an abelian gauge field. Rotate by angle $\lambda(x)$: $g = R(\lambda) = \left(\begin{smallmatrix}\cos\lambda & -\sin\lambda \\ \sin\lambda & \cos\lambda\end{smallmatrix}\right)$, so $e_1' = \cos\lambda\, e_1 + \sin\lambda\, e_2$ and $e_2' = -\sin\lambda\, e_1 + \cos\lambda\, e_2$. Rotations in the plane commute, so $g^{-1}\omega g = \omega$, and

$$g^{-1}\mathrm{d}g \overset{(1)}{=} \begin{pmatrix}\cos\lambda & \sin\lambda \\ -\sin\lambda & \cos\lambda\end{pmatrix}\begin{pmatrix}-\sin\lambda & -\cos\lambda \\ \cos\lambda & -\sin\lambda\end{pmatrix}\mathrm{d}\lambda \overset{(2)}{=} \begin{pmatrix}0 & -1 \\ 1 & 0\end{pmatrix}\mathrm{d}\lambda.$$

(1) $g^{-1} = R(-\lambda)$, and $\mathrm{d}g = R'(\lambda)\,\mathrm{d}\lambda$.
(2) Multiply out; $\cos^2\lambda + \sin^2\lambda = 1$.

Reading off the $(1,2)$ entry:

$$\omega'^1{}_2 = \omega^1{}_2 - \mathrm{d}\lambda. \tag{T2.82}$$

This is the gauge transformation $A \mapsto A - \mathrm{d}\lambda$ of electromagnetism. Two immediate consequences:

- *Polar coordinates are a gauge transformation of Cartesian ones.* The Cartesian frame has $\omega = 0$. The polar frame is the Cartesian frame rotated by $\lambda = \phi$. So $\omega^1{}_2 = 0 - \mathrm{d}\phi$, recovering (T2.64) with no computation at all. The flat plane's connection is *pure gauge*.
- $\mathrm{d}\omega^1{}_2$ *is gauge invariant* in 2D, since $\mathrm{d}\mathrm{d}\lambda = 0$. It is the analogue of the field strength $F = \mathrm{d}A$. It is zero for the plane (pure gauge) and $\mathrm{d}(-\cos\theta\,\mathrm{d}\phi) = \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi \neq 0$ for the sphere. So no rotation of the frame can make the sphere's connection vanish, even locally. That gauge-invariant obstruction is the curvature of the next section.

Worked example T2.29: The sphere's frame, the monopole, and the hairy ball

The frame $(\hat\theta, \hat\phi)$ is singular at both poles: at the north pole $\hat\theta$ points "away from the pole" in every direction at once (Figure T2.17, left). Let us fix the north pole by a gauge transformation. Near $\theta = 0$ the sphere looks like a plane with polar coordinates (θ, ϕ), and there $\hat\theta \approx \cos\phi\,\hat x + \sin\phi\,\hat y$, $\hat\phi \approx -\sin\phi\,\hat x + \cos\phi\,\hat y$. Rotating by $\lambda = -\phi$ undoes the winding:

$$e_1^N \overset{(1)}{=} \cos\phi\,\hat\theta - \sin\phi\,\hat\phi \overset{(2)}{=} \cos\phi(\cos\phi\,\hat x + \sin\phi\,\hat y) - \sin\phi(-\sin\phi\,\hat x + \cos\phi\,\hat y) \overset{(3)}{=} \hat x,$$

(1) $e_1' = \cos\lambda\, e_1 + \sin\lambda\, e_2$ with $\lambda = -\phi$.
(2) The frame near the north pole.
(3) $\cos^2\phi + \sin^2\phi = 1$ and the $\hat y$ terms cancel.

so the new frame is smooth at the north pole. Its connection is, by (T2.82),

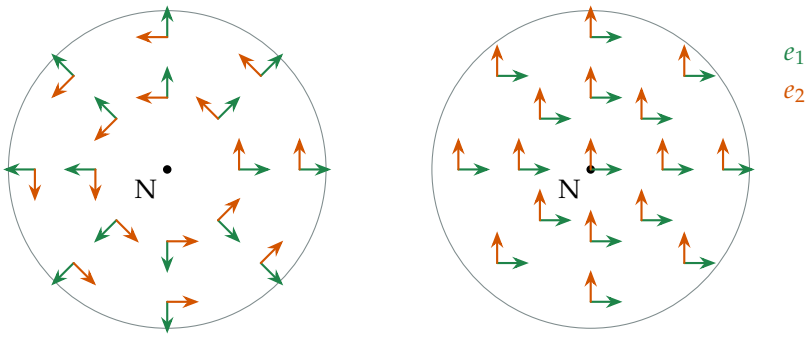
$$\omega_N = \omega^1{}_2 - \mathrm{d}(-\phi) = (1 - \cos\theta)\,\mathrm{d}\phi = A_N,$$

the north-patch monopole potential of (T2.32). Likewise rotating by $\lambda = +\phi$ gives a frame smooth at the south pole ($e_1^S \to -\hat{x}$ there) with $\omega_S = -(1 + \cos\theta)\,\mathrm{d}\phi = A_S$. On the overlap the two good frames differ by a rotation through the angle

$$\lambda_{NS} = 2\phi, \qquad \omega_N - \omega_S = 2\,\mathrm{d}\phi,$$

which winds *twice* as we go once around the equator. So:

- The Levi-Civita connection of the round sphere, written in smooth frames on two patches, *is* a magnetic monopole potential. Its flux is $\int_{S^2} \mathrm{d}\omega = 4\pi$ (Section T2.3.6).
- The transition function winds twice. In the language of Chapter T3, the tangent bundle of S^2, viewed as a complex line bundle, has first Chern number 2. The "2" is the Euler characteristic $\chi(S^2)$; this is the Gauss–Bonnet theorem in disguise (Section T2.8).
- No *single* smooth frame exists on all of S^2: if it did, its connection would be a global potential for the non-exact form $\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$. In particular there is no nowhere-vanishing smooth vector field on S^2 (take e_1 to be its normalisation). This is the *hairy ball theorem*, obtained here from the Stokes detector.



$(\hat{\theta}, \hat{\phi})$: winds once, singular at N

(e_1^N, e_2^N), rotated by $\lambda = -\phi$: smooth at N

Figure T2.17: The neighbourhood of the north pole seen from above. Left: the coordinate frame $(\hat{\theta}, \hat{\phi})$ rotates once as we go around the pole, so it has no limit at the pole; its connection $-\cos\theta\,\mathrm{d}\phi$ has a $\mathrm{d}\phi$ singularity there. Right: after the gauge rotation $\lambda = -\phi$ the frame is (to leading order) constant and smooth; its connection is $A_N = (1 - \cos\theta)\,\mathrm{d}\phi$. The analogous frame at the south pole differs from this one by a rotation through 2ϕ on the equator.

Dictionary: frames and connections ↔ gauge theory

Riemannian geometry	Gauge theory
orthonormal frame $\mathbf{e}$	choice of gauge (local trivialisation)
frame rotation $g(x) \in \mathrm{SO}(n)$	gauge transformation
connection ω, $\mathfrak{so}(n)$-valued	gauge potential A, $\mathfrak{g}$-valued
$\omega' = g^{-1}\omega g + g^{-1}\mathrm{d}g$	$A' = g^{-1}Ag + g^{-1}\mathrm{d}g$
$\nabla = \mathrm{d} + \omega$ on components	covariant derivative $D = \mathrm{d} + A$
2D: $\omega^1{}_2 \mapsto \omega^1{}_2 - \mathrm{d}\lambda$	U(1): $A_{\text{phys}} \mapsto A_{\text{phys}} - \mathrm{d}\lambda$
curvature $\Omega = \mathrm{d}\omega + \omega \wedge \omega$ (Section T2.6)	field strength $F = \mathrm{d}A + A \wedge A$

Convention check. In 2D identify the tangent plane with $\mathbb{C}$ by letting i act as rotation by $+90°$ ($i\, e_1 = e_2$). Then e_1 alone is a complex frame, $\mathrm{d}e_1 = e_2\, \omega^2{}_1 = e_1\, (i\, \omega^2{}_1)$, so the anti-Hermitian (mathematicians') U(1) potential is $A = i\, \omega^2{}_1 = -i\, \omega^1{}_2$, and the physicist's Hermitian potential ($A = -iA_{\text{phys}}$) is $A_{\text{phys}} = \omega^1{}_2$. A rotation by λ is $e_1' = e^{i\lambda} e_1$, i.e. $g = e^{i\lambda}$, and $A' = A + g^{-1}\mathrm{d}g = A + i\,\mathrm{d}\lambda$ agrees with (T2.82).

Reading Nash (pp. 86, 114; used from Chapter 3 on)

Nash never computes a Levi-Civita connection. He takes "the usual orthonormal frame (vielbein) of tangent vectors $e_a^\mu(x)$" and "the Riemannian spin connection ω" as known [Nash p. 114, (4.100)], and uses the fact that the structure group of an oriented Riemannian manifold reduces to $\mathrm{SO}(n)$ when he introduces the Euler class [Nash p. 86, (3.120)]. This section supplies all of that: the vielbein is the matrix E of (T2.58); the spin connection is ω, computed from $\mathrm{d}\boldsymbol{\sigma} + \omega \wedge \boldsymbol{\sigma} = 0$; the reduction to $\mathrm{SO}(n)$ is metric compatibility (T2.66); and the identification with gauge fields is (T2.81).

Recap

- A connection records how a frame turns: $\mathrm{d}e_j = e_i\, \omega^i{}_j$. Then $\mathrm{d}\vec{v} = (\mathrm{d}v^i + \omega^i{}_j v^j) e_i$ and $\nabla_{\vec{X}} \vec{v} = \mathrm{d}\vec{v}(\vec{X})$.
- Orthonormal coframe (vielbein): $\mathrm{d}\vec{r} = \sigma^i e_i$, $\mathrm{d}s^2 = \sum (\sigma^i)^2$, $g = E^{\mathsf{T}} E$.
- Levi-Civita: $\omega_{ij} = -\omega_{ji}$ (metric compatible, $\mathfrak{so}(n)$-valued) and $\mathrm{d}\sigma^i + \omega^i{}_j \wedge \sigma^j = 0$ (torsion free, Cartan's first structure equation). Unique, by counting or by the Koszul formula.
- Answers: plane $\omega^1{}_2 = -\mathrm{d}\phi$; sphere $-\cos\theta\, \mathrm{d}\phi$; torus $\sin\theta\, \mathrm{d}\phi$; spherical coordinates (T2.72).
- Rotating the frame, $\mathbf{e}' = \mathbf{e}g$, gives $\omega' = g^{-1}\omega g + g^{-1}\mathrm{d}g$: a gauge transformation. In 2D, $\omega^1{}_2 \mapsto \omega^1{}_2 - \mathrm{d}\lambda$. The sphere's connection in smooth frames is the monopole potential, with transition winding $2 = \chi(S^2)$.

T2.6 Curvature

The previous section ended with a question. On the plane, the connection of the polar frame is $\omega^1{}_2 = -\mathrm{d}\phi$, and a rotation of the frame (back to Cartesian) makes it vanish. On the sphere, the connection is $-\cos\theta\, \mathrm{d}\phi$, and no rotation can make it vanish, because $\mathrm{d}\omega^1{}_2$ is unchanged by rotations and is not zero. So:

What is the gauge-invariant quantity that decides whether a connection can be "gauged away", and what does it measure geometrically?

The answer is the **curvature 2-form** $\Omega = \mathrm{d}\omega + \omega \wedge \omega$. We will derive it from the failure of $\mathrm{d}^2 = 0$ on vectors, see that it measures the rotation of a vector carried around a small loop, compute it for all our examples, relate it to the bending of a surface in $\mathbb{R}^3$ (Gauss's Theorema Egregium), and extract the Riemann, Ricci and scalar curvatures that physicists use. The formula $\Omega = \mathrm{d}\omega + \omega \wedge \omega$ is word for word the Yang–Mills field strength $F = \mathrm{d}A + A \wedge A$; that is the point of this section for the rest of the book. We follow [Dray §§18.1–18.7].

T2.6.1 The second structure equation

In Section T2.5.6 we demanded $\mathrm{d}(\mathrm{d}\vec{r}) = 0$. What about $\mathrm{d}(\mathrm{d}e_j)$? Use the matrix notation $\mathrm{d}\mathbf{e} = \mathbf{e}\,\omega$ of (T2.62):

$$\mathrm{d}(\mathrm{d}\mathbf{e}) \overset{(1)}{=} \mathrm{d}(\mathbf{e}\,\omega) \overset{(2)}{=} \mathrm{d}\mathbf{e} \wedge \omega + \mathbf{e}\,\mathrm{d}\omega \overset{(3)}{=} \mathbf{e}\,\omega \wedge \omega + \mathbf{e}\,\mathrm{d}\omega \overset{(4)}{=} \mathbf{e}\,\big(\mathrm{d}\omega + \omega \wedge \omega\big). \tag{T2.83}$$

(1) Definition of the connection.
(2) Product rule (T2.60) with the vector-valued 0-form on the left: no sign.
(3) Insert $\mathrm{d}\mathbf{e} = \mathbf{e}\,\omega$ again.
(4) Factor out the frame [Dray (18.29)].

Working definition T2.11 (curvature 2-form)

The **curvature** of a connection ω is the matrix of 2-forms

$$\boxed{\Omega = \mathrm{d}\omega + \omega \wedge \omega, \qquad \Omega^i{}_j = \mathrm{d}\omega^i{}_j + \omega^i{}_k \wedge \omega^k{}_j} \tag{T2.84}$$

(**Cartan's second structure equation**, [Dray (18.30)]). Here $(\omega \wedge \omega)^i{}_j = \omega^i{}_k \wedge \omega^k{}_j$ is matrix multiplication with the entries multiplied by $\wedge$. *How to compute:* find ω from the first structure equation [$\mathrm{d}\sigma^i + \omega^i{}_j \wedge \sigma^j = 0$ with ω antisymmetric], then differentiate and add the matrix product. *How to read it:* $\Omega^i{}_j(\vec{u}, \vec{v})$ is the (i, j) entry of the infinitesimal rotation suffered by a vector carried [moved so that its covariant derivative along the path is zero] around the small parallelogram with edges $\vec{u}, \vec{v}$ (see below).

Watch out: $\omega \wedge \omega$ is not zero

For a single 1-form, $\alpha \wedge \alpha = 0$. For a *matrix* of 1-forms, $(\omega \wedge \omega)^i{}_j = \sum_k \omega^i{}_k \wedge \omega^k{}_j$ is a sum of wedges of *different* 1-forms, and it is not zero in general. It vanishes identically when the matrices commute, e.g. in 2D, where ω has only the one independent entry $\omega^1{}_2$. That is why 2D (like electromagnetism) is "abelian".

Curvature is d^2 on vectors. Let $\vec{v} = \mathbf{e}\,v$ with $v = (v^1, \dots, v^n)^{\mathsf{T}}$ a column of component functions. We showed $\mathrm{d}\vec{v} = \mathbf{e}\,(\mathrm{d}v + \omega v)$ in (T2.63). Differentiate once more:

$$\begin{aligned} \mathrm{d}(\mathrm{d}\vec{v}) &\overset{(1)}{=} \mathrm{d}\mathbf{e} \wedge (\mathrm{d}v + \omega v) + \mathbf{e}\,\mathrm{d}(\mathrm{d}v + \omega v) \\ &\overset{(2)}{=} \mathbf{e}\,\big[\omega \wedge \mathrm{d}v + \omega \wedge \omega\, v + \mathrm{d}\omega\, v - \omega \wedge \mathrm{d}v\big] \\ &\overset{(3)}{=} \mathbf{e}\,\Omega\, v. \end{aligned} \tag{T2.85}$$

(1) Product rule on $\mathbf{e}\,(\dots)$.

(2) $\mathrm{d}\mathbf{e} = \mathbf{e}\,\omega$; $\mathrm{d}\mathrm{d}v = 0$; and $\mathrm{d}(\omega v) = \mathrm{d}\omega\, v - \omega \wedge \mathrm{d}v$ (the 1-form ω is passed by d).
(3) The $\omega \wedge \mathrm{d}v$ terms cancel; what is left is (T2.84).

So on vector fields d^2 is not zero; it is *multiplication by the curvature*. There are no derivatives of $\vec{v}$ left: curvature is a tensor, an algebraic operation at each point. In coordinates this is the familiar $[\nabla_\mu, \nabla_\nu]v^i = R^i{}_{j\mu\nu}v^j$.

Physical picture: curvature = rotation around a small loop

Carry a vector around a tiny parallelogram with edges $\epsilon\vec{u}$ and $\epsilon\vec{v}$, keeping it "as constant as possible" (parallel transport, Section T2.6.8). It comes back rotated by the matrix $1 - \epsilon^2\,\Omega(\vec{u},\vec{v}) + O(\epsilon^3)$. This is the geometric content of $\mathrm{d}^2 \neq 0$: the change around a closed loop is Stokes' theorem applied to $\mathrm{d}\vec{v}$, and the integrand of the interior is $\mathrm{d}^2\vec{v} = \Omega\,\vec{v}$. In gauge theory the same statement is that the Wilson loop of a small plaquette is $1 - \epsilon^2 F_{\mu\nu} + \ldots$, which is how lattice gauge theory defines F.

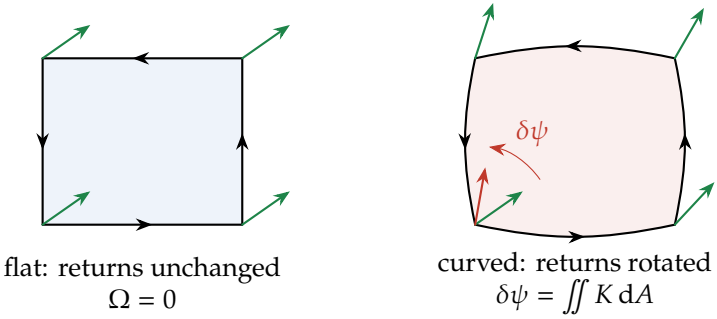


Figure T2.18: Carry a vector around a small closed loop, keeping it parallel to itself at each step. In the flat plane it comes back unchanged. On a curved surface it comes back rotated by an angle $\delta\psi$ equal to the integral of the curvature over the enclosed area. The red arrow at the start is the returned vector. Curvature is this rotation per unit area.

T2.6.2 Symmetries and counting

In an orthonormal frame $\omega_{ij} = -\omega_{ji}$. Then Ω is antisymmetric too [Dray (18.31)–(18.35)]:

$$\Omega_{ji} \overset{(1)}{=} \mathrm{d}\omega_{ji} + \omega_{jk} \wedge \omega_{ki} \overset{(2)}{=} -\mathrm{d}\omega_{ij} + \omega_{kj} \wedge \omega_{ik} \overset{(3)}{=} -\mathrm{d}\omega_{ij} - \omega_{ik} \wedge \omega_{kj} \overset{(4)}{=} -\Omega_{ij}. \tag{T2.86}$$

(1) Definition, with indices lowered (Euclidean signature, orthonormal frame).
(2) $\omega_{ji} = -\omega_{ij}$, and $\omega_{jk} \wedge \omega_{ki} = (-\omega_{kj}) \wedge (-\omega_{ik})$.
(3) Swap the order of the two 1-forms: one minus sign.
(4) Definition of Ω_{ij}.

So Ω is $\mathfrak{so}(n)$-valued, like ω: there are $\frac{1}{2}n(n-1)$ independent curvature 2-forms, each with $\frac{1}{2}n(n-1)$ components. (The first Bianchi identity below cuts the total further, to $n^2(n^2-1)/12$ independent numbers: 1 in 2D, 6 in 3D, 20 in 4D.)

Two dimensions. There is one curvature 2-form,

$$\Omega^1{}_2 \overset{(1)}{=} \mathrm{d}\omega^1{}_2 + \omega^1{}_1 \wedge \omega^1{}_2 + \omega^1{}_2 \wedge \omega^2{}_2 \overset{(2)}{=} \mathrm{d}\omega^1{}_2. \tag{T2.87}$$

(1) Expand the sum over $k = 1, 2$.

(2) The diagonal entries $\omega^1{}_1, \omega^2{}_2$ vanish by antisymmetry.

A 2-form on a surface is a function times the area form $\sigma^1 \wedge \sigma^2$, and that function is the curvature:

Working definition T2.12 (Gaussian curvature)

On a surface with orthonormal coframe σ^1, σ^2,

$$\boxed{\Omega^1{}_2 = \mathrm{d}\omega^1{}_2 = K\,\sigma^1 \wedge \sigma^2} \tag{T2.88}$$

defines the **Gaussian curvature** K [a function on the surface, e.g. $K = 1/a^2$ everywhere on a sphere of radius a] [Dray (18.45)].
Recipe: coframe $\to \omega^1{}_2 \to \mathrm{d}\omega^1{}_2 \to$ divide by the area element $\mathrm{d}A = \sigma^1 \wedge \sigma^2$. Swapping $e_1 \leftrightarrow e_2$ changes the signs of both $\Omega^1{}_2$ and $\sigma^1 \wedge \sigma^2$, so K does not depend on the orientation.

T2.6.3 Gauge covariance, and "flat means pure gauge"

Under a frame rotation $\mathbf{e}' = \mathbf{e}\,g$ we found $\omega' = g^{-1}\omega g + g^{-1}\mathrm{d}g$. The curvature is simpler:

$$\Omega' = g^{-1}\,\Omega\,g. \tag{T2.89}$$

The quickest proof uses (T2.83):

$$\mathbf{e}'\,\Omega' \overset{(1)}{=} \mathrm{d}(\mathrm{d}\mathbf{e}') \overset{(2)}{=} \mathrm{d}\big(\mathrm{d}\mathbf{e}\,g + \mathbf{e}\,\mathrm{d}g\big) \overset{(3)}{=} \mathrm{dd}\mathbf{e}\,g - \mathrm{d}\mathbf{e}\wedge\mathrm{d}g + \mathrm{d}\mathbf{e}\wedge\mathrm{d}g + \mathbf{e}\,\mathrm{dd}g \overset{(4)}{=} \mathbf{e}\,\Omega\,g \overset{(5)}{=} \mathbf{e}'\,g^{-1}\Omega\,g.$$

(1) (T2.83) for the primed frame.
(2) $\mathbf{e}' = \mathbf{e}g$ and the product rule.
(3) Product rule on each term; $\mathrm{d}\mathbf{e}$ is a 1-form so passing it costs a sign.
(4) The middle terms cancel, $\mathrm{dd}g = 0$, and $\mathrm{dd}\mathbf{e} = \mathbf{e}\,\Omega$.
(5) $\mathbf{e} = \mathbf{e}'g^{-1}$.

In 2D the rotations commute, so $\Omega^1{}_2$, and hence K, is *gauge invariant*: it does not depend on the choice of orthonormal frame. In higher dimensions Ω is gauge *covariant*; its invariants are traces of polynomials, such as $\mathrm{tr}\,\Omega\wedge\Omega$. This is the starting point of Chern–Weil theory (Chapter T3).

Key idea: flat ⇔ pure gauge

If $\Omega = 0$ on a simply connected region, there is a frame rotation g that makes $\omega' = 0$: a "Cartesian" frame exists, and the metric is flat Euclidean space in disguise. Conversely, if some frame has $\omega' = 0$ then $\Omega' = 0$ and so $\Omega = g\Omega' g^{-1} = 0$ in every frame.

Why the first direction holds: we want g with $g^{-1}\omega g + g^{-1}\mathrm{d}g = 0$, i.e. $\mathrm{d}g = -\omega g$. This is a first-order system of equations for the matrix g. Applying d to it, the integrability condition $0 = \mathrm{dd}g = -\mathrm{d}\omega\,g + \omega\wedge\mathrm{d}g = -(\mathrm{d}\omega + \omega\wedge\omega)g = -\Omega\,g$ is exactly $\Omega = 0$. In 2D it is just the Poincaré lemma: if $\mathrm{d}\omega^1{}_2 = 0$ on a star-shaped region, then $\omega^1{}_2 = \mathrm{d}\lambda$ for a function λ (Section T2.3.3), and rotating by λ gives $\omega'^1{}_2 = \omega^1{}_2 - \mathrm{d}\lambda = 0$ by (T2.82).

T2.6.4 Examples

Worked example T2.30: Plane, sphere, cylinder

Plane (polar). $\omega^1{}_2 = -\mathrm{d}\phi$, so $\Omega^1{}_2 = -\mathrm{d}\mathrm{d}\phi = 0$. Flat, as it must be.
Sphere of radius a. $\omega^1{}_2 = -\cos\theta\,\mathrm{d}\phi$ from (T2.70), and

$$\Omega^1{}_2 \overset{(1)}{=} \mathrm{d}(-\cos\theta\,\mathrm{d}\phi) \overset{(2)}{=} \sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi \overset{(3)}{=} \frac{1}{a^2}(a\,\mathrm{d}\theta)\wedge(a\sin\theta\,\mathrm{d}\phi) \overset{(4)}{=} \frac{1}{a^2}\,\sigma^1\wedge\sigma^2, \tag{T2.90}$$

(1) (T2.87).
(2) $\mathrm{d}(\cos\theta) = -\sin\theta\,\mathrm{d}\theta$.
(3) Multiply and divide by a^2.
(4) The coframe of the sphere.

so $K = 1/a^2$: constant, positive, and larger for smaller spheres.
Cylinder of radius a. $\mathrm{d}s^2 = a^2\mathrm{d}\phi^2 + \mathrm{d}z^2$, so $\sigma^1 = a\,\mathrm{d}\phi$, $\sigma^2 = \mathrm{d}z$. Both are closed, so $\omega^1{}_2 = 0$ solves the structure equations and $K = 0$. The cylinder is *intrinsically flat*: it is a sheet of paper rolled up, and an ant on it measures triangles with angle sum π. Its bending is visible only from outside (Section T2.6.5).

Worked example T2.31: The torus of revolution

From (T2.71), $\omega^1{}_2 = \sin\theta\,\mathrm{d}\phi$, so

$$\Omega^1{}_2 \overset{(1)}{=} \cos\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi \overset{(2)}{=} \frac{\cos\theta}{a(R+a\cos\theta)}\,\sigma^1\wedge\sigma^2, \qquad K = \frac{\cos\theta}{a(R+a\cos\theta)} \tag{T2.91}$$

(1) $\mathrm{d}(\sin\theta) = \cos\theta\,\mathrm{d}\theta$.
(2) $\sigma^1\wedge\sigma^2 = a(R+a\cos\theta)\,\mathrm{d}\theta\wedge\mathrm{d}\phi$ [Dray (18.87)–(18.88)].

So $K > 0$ on the outer half ($|\theta| < \pi/2$, sphere-like), $K < 0$ on the inner half (saddle-like), and $K = 0$ on the top and bottom circles $\theta = \pm\pi/2$ (Figure T2.19). The total curvature is

$$\int_{T^2} K\,\mathrm{d}A \overset{(1)}{=} \int_0^{2\pi}\!\!\int_0^{2\pi} \cos\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \overset{(2)}{=} 2\pi\left[\sin\theta\right]_0^{2\pi} = 0. \tag{T2.92}$$

(1) $K\,\mathrm{d}A = \Omega^1{}_2 = \cos\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi$; the factors $a(R+a\cos\theta)$ cancel.
(2) Nothing depends on ϕ.

The positive and negative regions cancel exactly, whatever R and a are. Gauss–Bonnet will tell us why: $\chi(T^2) = 0$.

Worked example T2.32: Negative curvature: the hyperbolic plane and the pseudosphere

Poincaré half-plane ($Y > 0$) with $\mathrm{d}s^2 = a^2(\mathrm{d}X^2 + \mathrm{d}Y^2)/Y^2$ (Dray, Problem 18.2). Coframe $\sigma^1 = a\,\mathrm{d}X/Y$, $\sigma^2 = a\,\mathrm{d}Y/Y$. Then $\mathrm{d}\sigma^2 = 0$ and

$$\mathrm{d}\sigma^1 \overset{(1)}{=} -\frac{a}{Y^2}\,\mathrm{d}Y\wedge\mathrm{d}X \overset{(2)}{=} \frac{a}{Y^2}\,\mathrm{d}X\wedge\mathrm{d}Y \overset{(3)}{=} \frac{1}{a}\,\sigma^1\wedge\sigma^2.$$

(1) $\mathrm{d}(1/Y) = -\mathrm{d}Y/Y^2$.
(2) Swap the wedge.
(3) $\sigma^1\wedge\sigma^2 = a^2\,\mathrm{d}X\wedge\mathrm{d}Y/Y^2$.

The first structure equation $\mathrm{d}\sigma^1 = -\omega^1{}_2\wedge\sigma^2$ is solved by $\omega^1{}_2 = -\sigma^1/a = -\mathrm{d}X/Y$, and the

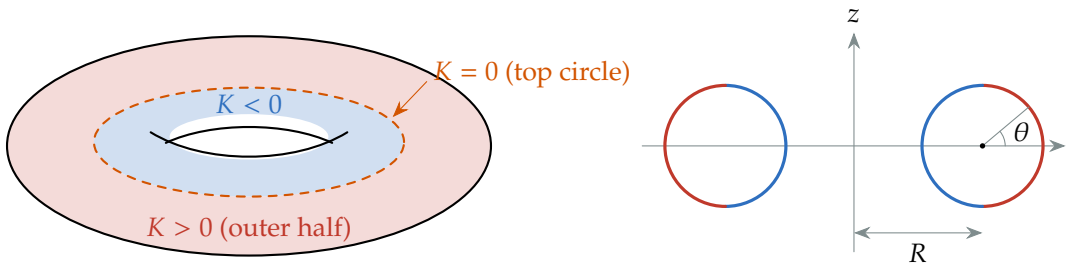

Figure T2.19: The sign of the Gaussian curvature $K = \cos\theta/(a(R + a\cos\theta))$ on a torus of revolution. The outer half (red) curves like a sphere, the inner half (blue, around the hole) like a saddle, and the dashed top circle (like the hidden bottom circle) has $K = 0$. In the cross-section, θ is measured from the outward horizontal. The two contributions to $\int K\,\mathrm{d}A$ cancel exactly, for every shape of torus.

second, $\mathrm{d}\sigma^2 = \omega^1{}_2 \wedge \sigma^1 \propto \sigma^1 \wedge \sigma^1 = 0$, holds. Then

$$\Omega^1{}_2 \overset{(1)}{=} \mathrm{d}\left(-\frac{\mathrm{d}X}{Y}\right) \overset{(2)}{=} \frac{1}{Y^2}\,\mathrm{d}Y \wedge \mathrm{d}X \overset{(3)}{=} -\frac{1}{a^2}\,\sigma^1 \wedge \sigma^2,$$

(1) (T2.87).
(2) $\mathrm{d}(-1/Y) = \mathrm{d}Y/Y^2$.
(3) $\mathrm{d}Y \wedge \mathrm{d}X = -\mathrm{d}X \wedge \mathrm{d}Y = -Y^2\sigma^1 \wedge \sigma^2/a^2$.

so $K = -1/a^2$, constant and negative.
Pseudosphere (Dray, Problem 18.1): the surface of revolution of a tractrix, $\mathrm{d}s^2 = a^2\cot^2\alpha\,\mathrm{d}\alpha^2 + a^2\sin^2\alpha\,\mathrm{d}\phi^2$, $0 < \alpha \le \pi/2$. With $\sigma^1 = a\cot\alpha\,\mathrm{d}\alpha$, $\sigma^2 = a\sin\alpha\,\mathrm{d}\phi$ one finds (try it) $\omega^1{}_2 = -\sin\alpha\,\mathrm{d}\phi$, $\Omega^1{}_2 = -\cos\alpha\,\mathrm{d}\alpha \wedge \mathrm{d}\phi = -a^{-2}\sigma^1 \wedge \sigma^2$: again $K = -1/a^2$. Its area is finite, $\int \sigma^1 \wedge \sigma^2 = \int_0^{2\pi}\int_0^{\pi/2} a^2\cos\alpha\,\mathrm{d}\alpha\,\mathrm{d}\phi = 2\pi a^2$, half that of a sphere of the same radius.

Watch out: Nash's normalisation of the hyperbolic metric

Nash states that the curvature -1 metric on the upper half plane is $\mathrm{d}s^2 = \mathrm{d}z\,\mathrm{d}\bar{z}/(z-\bar{z})^2$ [Nash p. 151, (5.40)]. With $z = X + iY$ we have $(z-\bar{z})^2 = (2iY)^2 = -4Y^2$, so this is $-\frac{1}{4}(\mathrm{d}X^2 + \mathrm{d}Y^2)/Y^2$: negative, and with $a^2 = \frac{1}{4}$ it would give $K = -4$. The curvature -1 metric is $\mathrm{d}s^2 = (\mathrm{d}X^2 + \mathrm{d}Y^2)/Y^2 = -4\,\mathrm{d}z\,\mathrm{d}\bar{z}/(z-\bar{z})^2$. Only the sign of K matters for Nash's argument there.

T2.6.5 Extrinsic curvature and Gauss's Theorema Egregium

The cylinder has $K = 0$, yet it is obviously curved. There are two kinds of curvature, and they must be kept apart: how a surface bends *in* $\mathbb{R}^3$ (extrinsic), and what an inhabitant can measure *without leaving it* (intrinsic). The structure equations make the relation between them transparent [Dray §§18.1–18.5].

Curves. The curvature of a curve is the reciprocal of the radius of its best-fitting circle, $\kappa = 1/r$. With the unit tangent $\hat{T} = \mathrm{d}\vec{r}/\mathrm{d}s$ (s the arc length), a circle has $\mathrm{d}\hat{T}/\mathrm{d}s = \hat{N}/r$ with $\hat{N}$ pointing to the centre; since this involves only first derivatives of $\hat{T}$, the same holds for any curve, $\mathrm{d}\hat{T}/\mathrm{d}s = \kappa\hat{N}$, so [Dray (18.1)–(18.5)]

$$\kappa\,\mathrm{d}s = \mathrm{d}\hat{T}\cdot\hat{N} = -\mathrm{d}\hat{N}\cdot\hat{T}. \tag{T2.93}$$

The curvature of a curve is measured by how its normal turns.

Surfaces: the shape operator. For a surface in $\mathbb{R}^3$, choose an orthonormal frame $\{e_1, e_2, e_3 = \hat{n}\}$ with e_1, e_2 tangent and $\hat{n}$ normal. The normal turns according to the connection of $\mathbb{R}^3$: $-\mathrm{d}\hat{n} \cdot e_i = \hat{n} \cdot \mathrm{d}e_i = \omega^3{}_i$ [Dray (18.6)]. On the surface $\sigma^3 = 0$ (moving within the surface has no normal displacement), so the $i = 3$ torsion equation of $\mathbb{R}^3$ reduces to $\omega^3{}_1 \wedge \sigma^1 + \omega^3{}_2 \wedge \sigma^2 = 0$. Write $\omega^3{}_i = \Gamma^3{}_{ij}\sigma^j$; the equation says $\Gamma^3{}_{12} = \Gamma^3{}_{21}$. The symmetric 2×2 matrix

$$S = -\left(\Gamma^3{}_{ij}\right)_{i,j=1,2} \tag{T2.94}$$

is the **shape operator** (or second fundamental form) [Dray (18.10)]. Being symmetric, it has real eigenvalues κ_1, κ_2, the **principal curvatures**, with orthogonal eigenvectors (the directions of maximal and minimal bending). Its trace $\kappa_1 + \kappa_2$ is the **mean curvature** and its determinant $\kappa_1\kappa_2$ is, as we are about to see, the Gaussian curvature.

Worked example T2.33: Shape operators

Plane: $\hat{n} = \hat{z}$ is constant, $S = 0$. *Cylinder* ($e_1 = \hat{\phi}$, $e_2 = \hat{z}$, $\hat{n} = \hat{r}$): $\mathrm{d}\hat{n} = \mathrm{d}\hat{r} = \mathrm{d}\phi\,\hat{\phi}$, so $\omega^3{}_1 = \hat{r} \cdot \mathrm{d}\hat{\phi} = -\mathrm{d}\phi = -\sigma^1/a$ and $\omega^3{}_2 = 0$:

$$S = \begin{pmatrix} 1/a & 0 \\ 0 & 0 \end{pmatrix}, \qquad \kappa_1\kappa_2 = 0.$$

Sphere ($e_1 = \hat{\theta}$, $e_2 = \hat{\phi}$, $\hat{n} = \hat{r}$): from (T2.72), $\omega^3{}_1 \to \omega^1{}_2$ of $\mathbb{R}^3$ in the ordering $(\hat{r}, \hat{\theta}, \hat{\phi})$, i.e. $\hat{r} \cdot \mathrm{d}\hat{\theta} = -\mathrm{d}\theta = -\sigma^1/a$, and $\hat{r} \cdot \mathrm{d}\hat{\phi} = -\sin\theta\,\mathrm{d}\phi = -\sigma^2/a$:

$$S = \begin{pmatrix} 1/a & 0 \\ 0 & 1/a \end{pmatrix}, \qquad \kappa_1\kappa_2 = \frac{1}{a^2} = K \text{[Dray (18.19)–(18.24)]}.$$

Torus: one principal curvature is $1/a$ (around the tube). The other, along the horizontal circle of radius $R + a\cos\theta$, is $\cos\theta/(R + a\cos\theta)$, not $1/(R + a\cos\theta)$: the circle bends towards the axis, but only the component of that bending along the surface normal counts, and the normal makes angle θ with the horizontal [Dray §18.11]. The product is (T2.91).

The Theorema Egregium. Now use the fact that $\mathbb{R}^3$ is flat: all nine curvature 2-forms of $\mathbb{R}^3$ vanish. Take the $(1,2)$ component and restrict to the surface:

$$\begin{aligned} 0 &\overset{(1)}{=} \Omega^1{}_2\big|_{\mathbb{R}^3} \overset{(2)}{=} \mathrm{d}\omega^1{}_2 + \omega^1{}_3 \wedge \omega^3{}_2 \\ \Longrightarrow \quad \mathrm{d}\omega^1{}_2 &\overset{(3)}{=} \omega^3{}_1 \wedge \omega^3{}_2 \overset{(4)}{=} \left(\Gamma^3{}_{11}\sigma^1 + \Gamma^3{}_{12}\sigma^2\right) \wedge \left(\Gamma^3{}_{21}\sigma^1 + \Gamma^3{}_{22}\sigma^2\right) \\ &\overset{(5)}{=} \left(\Gamma^3{}_{11}\Gamma^3{}_{22} - \Gamma^3{}_{12}\Gamma^3{}_{21}\right)\sigma^1 \wedge \sigma^2 \overset{(6)}{=} \det S\ \sigma^1 \wedge \sigma^2. \end{aligned} \tag{T2.95}$$

(1) Euclidean space is flat.
(2) The second structure equation in 3D; the terms $k = 1, 2$ vanish ($\omega^1{}_1 = 0$, $\omega^2{}_2 = 0$), leaving $k = 3$.
(3) Move to the other side: $-\omega^1{}_3 \wedge \omega^3{}_2 = \omega^3{}_1 \wedge \omega^3{}_2$ by antisymmetry.
(4) Expand in the coframe.
(5) $\sigma^1 \wedge \sigma^1 = \sigma^2 \wedge \sigma^2 = 0$ and $\sigma^2 \wedge \sigma^1 = -\sigma^1 \wedge \sigma^2$.
(6) The bracket is $\det(-S) = \det S$ for a 2×2 matrix.

But the left side, $\mathrm{d}\omega^1{}_2$, is computed from the surface's own coframe: the 3D torsion equations with $\sigma^3 = 0$ are exactly the 2D ones, so $\omega^1{}_2$ of $\mathbb{R}^3$ restricted to the surface is the surface's own Levi-Civita connection [Dray (18.41)–(18.42)]. So

Key idea: Theorema Egregium (Gauss's "remarkable theorem")

$$K = \kappa_1\kappa_2 = \det S.$$

The Gaussian curvature, defined extrinsically as the product of the principal curvatures, depends only on the metric of the surface. An ant that can only measure lengths on the surface can determine K; it cannot determine κ_1 and κ_2 separately.

That is why a sheet of paper can be rolled into a cylinder ($\kappa_1\kappa_2 = 0$ before and after) but not wrapped smoothly around a sphere without crumpling, and why every flat map of the Earth distorts distances. The computation in (T2.95) has a physical reading: the intrinsic curvature $\mathrm{d}\omega^1{}_2$ is exactly cancelled by the product of two extrinsic pieces, so the total curvature of $\mathbb{R}^3$ is zero. For the sphere, $\mathrm{d}\omega^2{}_3 + \omega^2{}_1 \wedge \omega^1{}_3 = \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi - \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi = 0$ in the ordering of (T2.72): check it.

T2.6.6 Components: Riemann, Ricci, scalar

Expand the curvature 2-forms in the coframe [Dray (18.47)–(18.51)]:

$$\Omega^i{}_j = \tfrac{1}{2} R^i{}_{jkl}\,\sigma^k \wedge \sigma^l, \qquad R^i{}_{jkl} = -R^i{}_{jlk}. \tag{T2.96}$$

The $R^i{}_{jkl}$ are the components of the **Riemann tensor**. Its traces are the **Ricci tensor** $R_{ij} = R^k{}_{ikj}$ and the **scalar curvature** $R = \delta^{ij}R_{ij}$. In 2D everything is determined by K:

$$\begin{aligned}
&\Omega^1{}_2 \overset{(1)}{=} \tfrac{1}{2}\big(R^1{}_{212}\,\sigma^1 \wedge \sigma^2 + R^1{}_{221}\,\sigma^2 \wedge \sigma^1\big) \overset{(2)}{=} R^1{}_{212}\,\sigma^1 \wedge \sigma^2 \quad\Longrightarrow\quad R^1{}_{212} = K,\\
&R_{11} \overset{(3)}{=} R^2{}_{121} \overset{(4)}{=} K, \qquad R_{22} = R^1{}_{212} = K, \qquad R_{12} = 0,\\
&R \overset{(5)}{=} R_{11} + R_{22} = 2K.
\end{aligned} \tag{T2.97}$$

(1) Only $(k,l) = (1,2), (2,1)$ contribute on a surface.
(2) $R^1{}_{221} = -R^1{}_{212}$ and $\sigma^2 \wedge \sigma^1 = -\sigma^1 \wedge \sigma^2$.
(3) $R_{11} = R^k{}_{1k1}$, and only $k = 2$ survives ($R^1{}_{111} = 0$ by antisymmetry in the last pair).
(4) $R^2{}_{121} = -R^1{}_{221}$ (antisymmetry in the first pair) $= R^1{}_{212} = K$.
(5) Trace.

So in 2D the Ricci tensor is $K\,\delta_{ij}$ and the *scalar curvature is twice the Gaussian curvature*. Keep this factor in mind: in string theory (Chapter 9) the Euler characteristic of a worldsheet is written $\chi = \frac{1}{4\pi}\int R\sqrt{g}\,\mathrm{d}^2x$, which is the same as $\frac{1}{2\pi}\int K\,\mathrm{d}A$.

T2.6.7 The Bianchi identities

Two identities follow from $\mathrm{d}^2 = 0$ on ordinary forms. In matrix notation they are two lines each.

First Bianchi identity (from $\mathrm{d}^2\boldsymbol{\sigma} = 0$):

$$0 \overset{(1)}{=} \mathrm{d}\big(\mathrm{d}\boldsymbol{\sigma} + \omega \wedge \boldsymbol{\sigma}\big) \overset{(2)}{=} \mathrm{d}\omega \wedge \boldsymbol{\sigma} - \omega \wedge \mathrm{d}\boldsymbol{\sigma} \overset{(3)}{=} \mathrm{d}\omega \wedge \boldsymbol{\sigma} + \omega \wedge \omega \wedge \boldsymbol{\sigma} \overset{(4)}{=} \Omega \wedge \boldsymbol{\sigma}. \tag{T2.98}$$

(1) The torsion vanishes identically, so its derivative does too.
(2) $\mathrm{d}\mathrm{d}\boldsymbol{\sigma} = 0$ and the graded product rule on $\omega \wedge \boldsymbol{\sigma}$.
(3) First structure equation: $\mathrm{d}\boldsymbol{\sigma} = -\omega \wedge \boldsymbol{\sigma}$.
(4) Second structure equation [Dray (18.52)].

In components, $\Omega^i{}_j \wedge \sigma^j = 0$ is the cyclic identity $R^i{}_{jkl} + R^i{}_{klj} + R^i{}_{ljk} = 0$ [Dray (18.55)]. Combined with the two antisymmetries it implies that the Ricci tensor is symmetric and that $R_{ijkl} = R_{klij}$ (Dray gives the index gymnastics in (18.58)–(18.60)). On a surface it is empty: $\Omega \wedge \sigma$ is a 3-form.

Second Bianchi identity (from $\mathrm{d}^2\omega = 0$):

$$\mathrm{d}\Omega \overset{(1)}{=} \mathrm{d}\mathrm{d}\omega + \mathrm{d}\omega \wedge \omega - \omega \wedge \mathrm{d}\omega \overset{(2)}{=} (\Omega - \omega \wedge \omega) \wedge \omega - \omega \wedge (\Omega - \omega \wedge \omega) \overset{(3)}{=} \Omega \wedge \omega - \omega \wedge \Omega,$$

(1) Differentiate $\Omega = \mathrm{d}\omega + \omega \wedge \omega$, with the graded product rule.
(2) $\mathrm{d}\mathrm{d}\omega = 0$ and $\mathrm{d}\omega = \Omega - \omega \wedge \omega$.
(3) The cubic terms $\omega \wedge \omega \wedge \omega$ cancel.

that is,

$$D\Omega := \mathrm{d}\Omega + \omega \wedge \Omega - \Omega \wedge \omega = 0 \tag{T2.99}$$

[Dray (18.53)]. In gauge theory the same computation gives $DF = \mathrm{d}F + A \wedge F - F \wedge A = 0$, the non-abelian version of the homogeneous Maxwell equations $\mathrm{d}F = 0$ (no magnetic charges, Faraday's law). In 2D, $\mathrm{d}\Omega^1{}_2$ is a 3-form and vanishes trivially. In 4D the contracted form of (T2.99) is $\nabla^\mu(R_{\mu\nu} - \frac{1}{2}R g_{\mu\nu}) = 0$, the reason Einstein's equations are consistent with energy conservation.

T2.6.8 Parallel transport and holonomy

Working definition T2.13 (parallel transport)

A vector field $\vec{v}$ along a curve $c(t)$ is **parallel transported** if $\nabla_{\dot{c}}\vec{v} = 0$, i.e. $\dot{v}^i + \omega^i{}_j(\dot{c})\, v^j = 0$ [$\dot{v}^i = \mathrm{d}v^i/\mathrm{d}t$, and $\omega(\dot{c})$ is the rate at which the frame rotates along the curve]. This is a linear first-order ODE:
given $\vec{v}$ at the start, it has a unique solution. *Meaning:* the vector is kept "as constant as the geometry allows"; in the plane it is literally constant.

On a surface write a unit vector at angle ψ from e_1, $\vec{v} = \cos\psi\, e_1 + \sin\psi\, e_2$. Then

$$\begin{aligned} \mathrm{d}\vec{v} &\overset{(1)}{=} (-\sin\psi\, e_1 + \cos\psi\, e_2)\,\mathrm{d}\psi + \cos\psi\, e_2\, \omega^2{}_1 + \sin\psi\, e_1\, \omega^1{}_2 \\ &\overset{(2)}{=} (-\sin\psi\, e_1 + \cos\psi\, e_2)\,\big(\mathrm{d}\psi - \omega^1{}_2\big). \end{aligned} \tag{T2.100}$$

(1) Product rule and $\mathrm{d}e_1 = e_2\,\omega^2{}_1$, $\mathrm{d}e_2 = e_1\,\omega^1{}_2$.
(2) $\omega^2{}_1 = -\omega^1{}_2$; collect.

So parallel transport means $\mathrm{d}\psi = \omega^1{}_2$ along the curve: the angle of the vector *relative to the frame* changes by $\omega^1{}_2$ because the frame itself turns. Around a closed curve $C = \partial D$, with a frame that is smooth on D,

$$\Delta\psi \overset{(1)}{=} \oint_C \omega^1{}_2 \overset{(2)}{=} \int_D \mathrm{d}\omega^1{}_2 \overset{(3)}{=} \int_D K\,\mathrm{d}A. \tag{T2.101}$$

(1) Integrate the transport equation $\mathrm{d}\psi = \omega^1{}_2$ around C.
(2) Stokes' theorem; this is where we need the frame (hence $\omega^1{}_2$) smooth on all of D.
(3) (T2.88).

Since the frame returns to itself, $\Delta\psi$ is the actual rotation of the transported vector: the **holonomy** of the loop. *The rotation angle equals the total curvature enclosed.* For an infinitesimal loop this is the intuition box above. It is the precise analogue of the Aharonov–Bohm phase $e^{ie\oint A} = e^{ie\Phi}$: parallel transport is the Wilson line of the connection (Chapter T3).

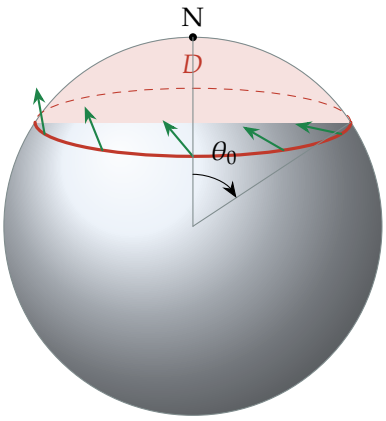
Worked example T2.34: Transport around a line of latitude; the Foucault pendulum

On the unit sphere take the latitude circle $\theta = \theta_0$, bounding the polar cap D ($0 \le \theta \le \theta_0$). The frame $(\hat\theta, \hat\phi)$ is *not* smooth on D (it is singular at the pole), but the rotated frame of Example T2.29 is, with $\omega_N = (1 - \cos\theta)\,\mathrm{d}\phi$:

$$\Delta\psi \overset{(1)}{=} \oint_{\theta=\theta_0} (1-\cos\theta_0)\,\mathrm{d}\phi \overset{(2)}{=} 2\pi(1-\cos\theta_0) \overset{(3)}{=} \int_0^{2\pi}\!\!\int_0^{\theta_0} \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi = \mathrm{area}(D).$$

(1) (T2.101) with the smooth frame.
(2) θ is constant on the curve.
(3) The same number from the right side of (T2.101), $K = 1$.

If instead we use the singular frame $(\hat\theta, \hat\phi)$ we get $\oint -\cos\theta_0\,\mathrm{d}\phi = -2\pi\cos\theta_0$, which differs by 2π: the extra turn of the frame around the pole. The rotation of the vector *relative to the local compass directions* is $-2\pi\cos\theta_0$ per circuit. This is the Foucault pendulum: carried around the latitude $90^\circ - \theta_0$ once a (sidereal) day, its swing plane turns by $2\pi\cos\theta_0 = 2\pi\sin(\text{latitude})$ clockwise relative to the ground (in the northern hemisphere). At the equator nothing happens ($\theta_0 = \pi/2$), and at the pole a full turn.



a vector transported around the circle turns relative to $\hat\theta, \hat\phi$; the cap D has area $2\pi(1-\cos\theta_0)$

Figure T2.20: Parallel transport around the latitude circle $\theta = \theta_0$ (red). The vector, kept as constant as possible along the way, returns rotated by the enclosed area $2\pi(1-\cos\theta_0)$ (for the unit sphere). Relative to the local north/east directions it has turned by $-2\pi\cos\theta_0$, the Foucault precession. Along the equator ($\theta_0 = \pi/2$) the enclosed area is a hemisphere, 2π, and the vector comes back unrotated.

Try it: Holonomy on a cone

Cut a wedge of angle β out of a paper disc and glue the edges to make a cone. Away from the tip the cone is flat ($K = 0$). What is the holonomy of a loop around the tip? *Answer:* β (in the direction that makes the total enclosed curvature β). All the curvature is concentrated at the tip, as a delta function of total weight β, the *angle deficit*. A polyhedron is a surface of this kind, with deficits at its vertices; this is Descartes' version of Gauss–Bonnet, $\sum_{\text{vertices}} \beta_v = 4\pi$ for any convex polyhedron (for a cube, $8 \times \frac{\pi}{2} = 4\pi$).

Reading Nash (pp. 129, 151–152, 226–228)

Nash writes the Gauss–Bonnet integrand as "$R/2\pi$ where R is the curvature of X" [Nash p. 129, (4.148)]: his R is our 2-form $\Omega^1{}_2 = K\,\mathrm{d}A$, not the scalar curvature $2K$. In Chapter 5 he uses $R(g)$ for the Gaussian curvature of a metric g and quotes the uniformisation theorem:

every compact Riemann surface carries a metric with $R(g) = +1, 0, -1$ for genus $0, 1, \geq 2$ [Nash pp. 151–152, (5.39)–(5.42)]; our sphere, flat torus and hyperbolic plane are the three model geometries. Parallel transport and holonomy of a general gauge field are his [Nash pp. 226–228]; the latitude circle above is the simplest nontrivial holonomy.

Recap

- $\Omega = \mathrm{d}\omega + \omega \wedge \omega$ (second structure equation) measures $\mathrm{d}^2\vec{v} = \Omega\vec{v}$: the rotation of a vector carried around a small loop. It is $\mathfrak{so}(n)$-valued and transforms covariantly, $\Omega' = g^{-1}\Omega g$.
- Flat ($\Omega = 0$) $\Leftrightarrow$ locally pure gauge $\Leftrightarrow$ a Cartesian frame exists.
- 2D: $\Omega^1{}_2 = \mathrm{d}\omega^1{}_2 = K\,\sigma^1 \wedge \sigma^2$. Sphere $K = 1/a^2$; cylinder 0; torus $\cos\theta/(a(R + a\cos\theta))$ with $\int K\,\mathrm{d}A = 0$; hyperbolic plane and pseudosphere $-1/a^2$.
- Theorema Egregium: $K = \kappa_1\kappa_2 = \det S$ is intrinsic, because $\mathbb{R}^3$ is flat.
- $\Omega^i{}_j = \frac{1}{2}R^i{}_{jkl}\sigma^k \wedge \sigma^l$; in 2D $R_{ij} = K\delta_{ij}$, $R = 2K$.
- Bianchi: $\Omega \wedge \boldsymbol{\sigma} = 0$ and $D\Omega = 0$ (cf. $DF = 0$).
- Holonomy around $\partial D = \int_D K\,\mathrm{d}A$ (Stokes); Foucault pendulum.

T2.7 Geodesics: straight lines on a curved surface

In the plane we know what a straight line is: the curve that does not turn, the path of a free particle, the shortest route between two points. On a sphere there are no straight lines in that naive sense, since every curve on a sphere bends when viewed from $\mathbb{R}^3$. Yet an aeroplane flying from one city to another does follow a preferred route, and a free particle constrained to slide on a frictionless sphere does move along a preferred family of curves. So:

> *What does "straight" mean for a curve on a curved surface, how do we compute it with the connection, and how do we find the straight curves?*

There are three answers, and they agree. A curve is straight if it does not bend to the left or to the right *within the surface* (its geodesic curvature vanishes). A curve is straight if its velocity is parallel transported along itself (no acceleration). A curve is straight if it is a stationary point of length or of energy (the free-particle action). We will see each of these in turn, solve the equations on the plane and the sphere, and then look at what happens to a family of neighbouring geodesics: they spread or focus according to the curvature. That last fact is the seed of the tidal-force equation of general relativity, and the geodesic-curvature term we meet first is exactly the boundary term of the Gauss–Bonnet theorem in the next section. We follow [Dray §18.8 and Ch. 19].

T2.7.1 Geodesic curvature

Take a curve C in an oriented surface Σ with orthonormal frame $\{e_1, e_2\}$, and let s be arc length along C. The unit tangent vector $\hat{T} = \mathrm{d}\vec{r}/\mathrm{d}s$ lies in the tangent plane, so it makes some angle α with e_1 (Figure T2.21):

$$\hat{T} = \cos\alpha\, e_1 + \sin\alpha\, e_2. \tag{T2.102}$$

The angle α is measured *relative to the frame*, so it changes for two reasons: because the curve turns, and because the frame turns. The connection knows how much of the second there is. Differentiate (T2.102) along the curve [Dray (18.61)–(18.62)]:

$$\begin{aligned} \mathrm{d}\hat{T} &\overset{(1)}{=} (-\sin\alpha\, e_1 + \cos\alpha\, e_2)\,\mathrm{d}\alpha + \cos\alpha\,\mathrm{d}e_1 + \sin\alpha\,\mathrm{d}e_2 \\ &\overset{(2)}{=} (-\sin\alpha\, e_1 + \cos\alpha\, e_2)\,\mathrm{d}\alpha + \cos\alpha\, e_2\,\omega^2{}_1 + \sin\alpha\, e_1\,\omega^1{}_2 \\ &\overset{(3)}{=} (-\sin\alpha\, e_1 + \cos\alpha\, e_2)\,(\mathrm{d}\alpha - \omega^1{}_2). \end{aligned} \tag{T2.103}$$

(1) Product rule on each term of (T2.102); $\mathrm{d}\cos\alpha = -\sin\alpha\,\mathrm{d}\alpha$ and $\mathrm{d}\sin\alpha = \cos\alpha\,\mathrm{d}\alpha$.
(2) The connection (T2.61): $\mathrm{d}e_1 = e_2\,\omega^2{}_1$ and $\mathrm{d}e_2 = e_1\,\omega^1{}_2$ (the diagonal entries vanish).
(3) $\omega^2{}_1 = -\omega^1{}_2$; then both connection terms are $-\omega^1{}_2$ times the bracket.

The bracket is the unit vector

$$\hat{N} = -\sin\alpha\, e_1 + \cos\alpha\, e_2, \tag{T2.104}$$

obtained by rotating $\hat{T}$ through $+90°$ in the tangent plane (for a surface in $\mathbb{R}^3$ with unit normal $\hat{n} = e_1 \times e_2$, it is $\hat{n} \times \hat{T}$). It points to the *left* of the direction of travel. So $\mathrm{d}\hat{T}$ is always along $\hat{N}$ (as it must be: $\hat{T}$ has unit length, so its derivative is perpendicular to it), and its size is the rate of turning to the left.

Working definition T2.14 (geodesic curvature)

The **geodesic curvature** κ_g of a curve in a surface is defined by $\mathrm{d}\hat{T} \cdot \hat{N} = \kappa_g\,\mathrm{d}s$ along the curve, i.e.

$$\boxed{\kappa_g\,\mathrm{d}s = \mathrm{d}\alpha - \omega^1{}_2} \tag{T2.105}$$

[Dray (18.64)]. *How to compute it:* write the tangent as $\cos\alpha\, e_1 + \sin\alpha\, e_2$, and subtract the connection 1-form (restricted to the curve [fed only the tangent $\hat{T}$, so it becomes $\omega^1{}_2(\hat{T})\,\mathrm{d}s$]) from the change of α.
Meaning: $\kappa_g > 0$ means the curve bends to the left as seen by an inhabitant of the surface, $\kappa_g < 0$ to the right. A curve with $\kappa_g = 0$ is a **geodesic**.

Two remarks make (T2.105) feel natural.

- *It is frame independent.* Rotate the frame by an angle λ. The tangent's angle relative to the new frame is $\alpha' = \alpha - \lambda$, and $\omega'^1{}_2 = \omega^1{}_2 - \mathrm{d}\lambda$ by (T2.82). So $\mathrm{d}\alpha' - \omega'^1{}_2 = \mathrm{d}\alpha - \mathrm{d}\lambda - \omega^1{}_2 + \mathrm{d}\lambda = \mathrm{d}\alpha - \omega^1{}_2$. The $\mathrm{d}\lambda$'s cancel: $\kappa_g\,\mathrm{d}s$ is a "gauge-invariant combination" of the matter field α and the gauge potential $\omega^1{}_2$, like the covariant derivative $\mathrm{d}\psi - A$ of a phase.
- *It compares with parallel transport.* By (T2.100), a parallel-transported vector has $\mathrm{d}\psi = \omega^1{}_2$. So $\kappa_g\,\mathrm{d}s = \mathrm{d}\alpha - \omega^1{}_2$ is the rate at which the tangent turns *relative to a parallel-transported vector*. A geodesic is a curve whose tangent is parallel transported along it.

Watch out: three different curvatures of a curve

A curve on a surface in $\mathbb{R}^3$ has an ordinary curvature κ (the bending seen in $\mathbb{R}^3$, (T2.93)) and this splits into two perpendicular pieces: the part along the surface normal $\hat{n}$, called the *normal curvature* κ_n, which the surface forces on the curve and which the shape operator measures; and the part along $\hat{N}$ within the surface, the geodesic curvature κ_g. So $\kappa^2 = \kappa_n^2 + \kappa_g^2$. A great circle on a sphere of radius a has $\kappa = 1/a$ (it is a circle of radius a in $\mathbb{R}^3$) but $\kappa_g = 0$: all its bending is forced by the sphere, none of it is chosen by the curve.

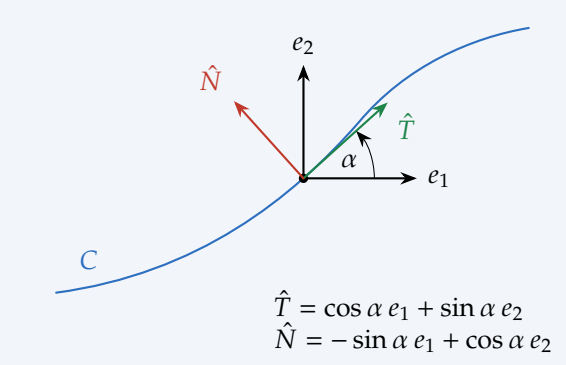


Figure T2.21: The tangent $\hat{T}$ of a curve makes an angle α with the frame vector e_1; the normal $\hat{N}$ (red) is $\hat{T}$ turned through 90° to the left, within the surface. The geodesic curvature measures how fast $\hat{T}$ swings towards $\hat{N}$. The angle α changes both because the curve bends and because the frame turns; subtracting $\omega^1{}_2$ removes the second effect.

Also do not confuse this $\hat{N}$, which depends only on the orientation of the surface, with the principal normal of the curve in $\mathbb{R}^3$ [Dray fn. 5 p. 225].

Worked example T2.35: Circles in the plane and on the sphere

A circle of radius ρ in the plane, traversed counterclockwise, in the polar frame ($e_1 = \hat{r}$, $e_2 = \hat{\phi}$). The tangent is $\hat{\phi} = e_2$, so $\alpha = \pi/2$ is constant, and $\omega^1{}_2 = -\mathrm{d}\phi$:

$$\kappa_g\, \mathrm{d}s \overset{(1)}{=} \mathrm{d}\left(\tfrac{\pi}{2}\right) - (-\mathrm{d}\phi) \overset{(2)}{=} \mathrm{d}\phi \overset{(3)}{=} \frac{\mathrm{d}s}{\rho}.$$

(1) (T2.105) with $\alpha = \pi/2$ and (T2.64).
(2) The derivative of a constant is zero.
(3) Arc length on the circle is $\mathrm{d}s = \rho\, \mathrm{d}\phi$.

So $\kappa_g = 1/\rho$, the familiar curvature of a circle, positive because the circle bends to the left. Notice where the answer came from: entirely from the connection. The tangent does not turn relative to the polar frame at all; it is the frame that turns, and the curve turns with it. *A latitude circle on a sphere of radius a*, $\theta = \theta_0$, traversed eastwards (increasing ϕ), in the frame $e_1 = \hat{\theta}$, $e_2 = \hat{\phi}$. Again $\hat{T} = \hat{\phi} = e_2$ and $\alpha = \pi/2$. With $\omega^1{}_2 = -\cos\theta\, \mathrm{d}\phi$,

$$\kappa_g\, \mathrm{d}s \overset{(1)}{=} 0 - (-\cos\theta_0\, \mathrm{d}\phi) \overset{(2)}{=} \cos\theta_0\, \frac{\mathrm{d}s}{a\sin\theta_0} \qquad \Longrightarrow \qquad \kappa_g = \frac{\cot\theta_0}{a}. \tag{T2.106}$$

(1) (T2.105) with (T2.70) evaluated at $\theta = \theta_0$.
(2) On the circle $\mathrm{d}s = a\sin\theta_0\, \mathrm{d}\phi$ (the circle has radius $a\sin\theta_0$ in $\mathbb{R}^3$).

Read the answer. In the northern hemisphere ($\theta_0 < \pi/2$), $\kappa_g > 0$: walking east, the path curves to the left, around the north pole. Near the pole, $\theta_0 \to 0$ and $\kappa_g \approx 1/(a\theta_0)$, the curvature of a small circle of radius $a\theta_0$ in a nearly flat region. In the southern hemisphere $\kappa_g < 0$. At the equator $\kappa_g = 0$: *the equator is a geodesic*, and it is the only latitude circle that is [Dray (18.65)]. Rotating the sphere, every great circle is a geodesic.

Worked example T2.36: Which circles on the torus are geodesics?

On the torus of revolution, with $\sigma^1 = a\,\mathrm{d}\theta$, $\sigma^2 = (R + a\cos\theta)\,\mathrm{d}\phi$ and $\omega^1{}_2 = \sin\theta\,\mathrm{d}\phi$ (T2.71), there are two families of circles.
Meridians (ϕ = const, going around the tube). The tangent is e_1, so $\alpha = 0$, and $\mathrm{d}\phi = 0$ along the curve:

$$\kappa_g\,\mathrm{d}s \overset{(1)}{=} 0 - \sin\theta\,\mathrm{d}\phi\big|_{\phi=\text{const}} \overset{(2)}{=} 0.$$

(1) (T2.105) with $\alpha = 0$.
(2) $\mathrm{d}\phi$ restricted to a curve of constant ϕ is zero.

Every meridian is a geodesic. (Symmetry says so too: reflection in the plane containing the meridian and the axis maps the torus to itself and fixes the meridian, so the meridian cannot prefer to bend left or right.)
Parallels ($\theta = \theta_0$, going around the axis). The tangent is e_2, so $\alpha = \pi/2$:

$$\kappa_g\,\mathrm{d}s \overset{(1)}{=} -\sin\theta_0\,\mathrm{d}\phi \overset{(2)}{=} -\frac{\sin\theta_0}{R + a\cos\theta_0}\,\mathrm{d}s.$$

(1) (T2.105) with $\alpha = \pi/2$ constant.
(2) $\mathrm{d}s = (R + a\cos\theta_0)\,\mathrm{d}\phi$ along the parallel.

So $\kappa_g = -\sin\theta_0/(R + a\cos\theta_0)$. It vanishes exactly for the *outer equator* $\theta_0 = 0$ and the *inner equator* $\theta_0 = \pi$: these two parallels are geodesics. The top circle $\theta_0 = \pi/2$ has $|\kappa_g| = 1/R$: it is a circle of radius R lying in a horizontal tangent plane, so all its bending is within the surface. Compare with Figure T2.19: the top circle is where $K = 0$, and there the torus looks locally like a plane.

T2.7.2 The geodesic equation

The geodesic-curvature definition is special to surfaces. Here is the definition that works in any dimension [Dray §19.1]. A free particle has zero acceleration. Let $\vec{v} = \mathrm{d}\vec{r}/\mathrm{d}t$ be the velocity of a curve with parameter t. Along the curve, $\mathrm{d}\vec{r} = \vec{v}\,\mathrm{d}t$, so

$$\sigma^i = v^i\,\mathrm{d}t \qquad \text{(restricted to the curve)}, \tag{T2.107}$$

where v^i are the frame components of $\vec{v}$. Differentiate the velocity:

$$\mathrm{d}\vec{v} \overset{(1)}{=} \mathrm{d}(v^j e_j) \overset{(2)}{=} \big(\mathrm{d}v^j + \omega^j{}_i\,v^i\big)e_j \overset{(3)}{=} \big(\mathrm{d}v^j + \Gamma^j{}_{ik}\,v^i\sigma^k\big)e_j \overset{(4)}{=} \big(\dot{v}^j + \Gamma^j{}_{ik}\,v^i v^k\big)\mathrm{d}t\;e_j. \tag{T2.108}$$

(1) Expand in the frame.
(2) The covariant derivative formula (T2.63).
(3) Expand the connection in the coframe, (T2.73).
(4) Along the curve $\mathrm{d}v^j = \dot{v}^j\,\mathrm{d}t$ and (T2.107).

Dividing by $\mathrm{d}t$ gives the acceleration $\dot{\vec{v}} = \nabla_{\vec{v}}\vec{v} = (\dot{v}^j + \Gamma^j{}_{ik}v^i v^k)\,e_j$ [Dray (19.4)–(19.6)].

Working definition T2.15 (geodesic)

A curve is a **geodesic** if its velocity is parallel transported [its frame components change only to undo the rotation of the frame] along it, $\nabla_{\vec{v}}\vec{v} = 0$:

$$\boxed{\dot{v}^j + \Gamma^j{}_{ik}\,v^i v^k = 0} \quad \text{(frame form)}, \qquad \ddot{x}^\mu + \Gamma^\mu{}_{\nu\rho}\,\dot{x}^\nu\dot{x}^\rho = 0 \quad \text{(coordinate form)}. \tag{T2.109}$$

[in the coordinate form, $\Gamma^\mu{}_{\nu\rho}$ are the Christoffel symbols of the basis ∂_μ, built from $g_{\mu\nu}$]

Recipe: write $\vec{v}$ in the frame, compute $\mathrm{d}\vec{v}$ using the derivatives of the frame vectors, divide by $\mathrm{d}t$ and set each component to zero. *Meaning:* the path of a free particle, the "straightest" curve.

How does this compare with $\kappa_g = 0$? Write $\vec{v} = v\,\hat{T}$ with speed $v = |\vec{v}|$. Then $\dot{\vec{v}} = \dot{v}\,\hat{T} + v\,\dot{\hat{T}}$, and $\dot{\hat{T}}$ is perpendicular to $\hat{T}$ (it is along $\hat{N}$, by (T2.103)). The two pieces are perpendicular, so $\dot{\vec{v}} = 0$ exactly when $\dot{v} = 0$ *and* $\dot{\hat{T}} = 0$. On a surface $\dot{\hat{T}} = \kappa_g v\,\hat{N}$, so

$$\nabla_{\vec{v}}\vec{v} = 0 \iff \kappa_g = 0 \text{ and the speed is constant}$$

[Dray (19.9)–(19.15)]. The two definitions pick out the same curves; the acceleration definition also fixes the parametrisation up to $t \mapsto at + b$.

Worked example T2.37: Polar coordinates: the geodesic equation, and why it gives straight lines

Write $\vec{v} = \dot{r}\,\hat{r} + r\dot{\phi}\,\hat{\phi}$ (from $\mathrm{d}\vec{r} = \mathrm{d}r\,\hat{r} + r\,\mathrm{d}\phi\,\hat{\phi}$). Differentiate, using $\mathrm{d}\hat{r} = \mathrm{d}\phi\,\hat{\phi}$ and $\mathrm{d}\hat{\phi} = -\mathrm{d}\phi\,\hat{r}$ (T2.55):

$$\begin{aligned}\mathrm{d}\vec{v} &\overset{(1)}{=} \mathrm{d}\dot{r}\,\hat{r} + \dot{r}\,\mathrm{d}\hat{r} + \mathrm{d}(r\dot{\phi})\,\hat{\phi} + r\dot{\phi}\,\mathrm{d}\hat{\phi}\\ &\overset{(2)}{=} \big(\mathrm{d}\dot{r} - r\dot{\phi}\,\mathrm{d}\phi\big)\hat{r} + \big(\mathrm{d}(r\dot{\phi}) + \dot{r}\,\mathrm{d}\phi\big)\hat{\phi}\\ &\overset{(3)}{=} \Big[\big(\ddot{r} - r\dot{\phi}^2\big)\hat{r} + \big(r\ddot{\phi} + 2\dot{r}\dot{\phi}\big)\hat{\phi}\Big]\mathrm{d}t. \end{aligned} \tag{T2.110}$$

(1) Product rule on each term.
(2) Insert the derivatives of $\hat{r}, \hat{\phi}$ and collect.
(3) Along the curve $\mathrm{d}f = \dot{f}\,\mathrm{d}t$; $\frac{\mathrm{d}}{\mathrm{d}t}(r\dot{\phi}) = \dot{r}\dot{\phi} + r\ddot{\phi}$.

These are the radial and transverse accelerations every mechanics student knows (centripetal $-r\dot{\phi}^2$, Coriolis $2\dot{r}\dot{\phi}$). The geodesic equations are [Dray (19.20)]

$$\ddot{r} - r\dot{\phi}^2 = 0, \qquad r\ddot{\phi} + 2\dot{r}\dot{\phi} = 0.$$

Solving them [Dray §§19.4–19.5]. Multiply the second by r: it says $\frac{\mathrm{d}}{\mathrm{d}t}(r^2\dot{\phi}) = 0$, so $r^2\dot{\phi} = \ell$ is conserved (angular momentum per unit mass). Multiply the first by $\dot{r}$ and use $\dot{\phi} = \ell/r^2$: $\dot{r}\ddot{r} - \ell^2\dot{r}/r^3 = \frac{\mathrm{d}}{\mathrm{d}t}\big(\frac{1}{2}\dot{r}^2 + \frac{1}{2}\ell^2/r^2\big) = 0$, so $\dot{r}^2 + r^2\dot{\phi}^2 = |\vec{v}|^2$ is conserved (energy). Choose unit speed, $t = \lambda$ the arc length. Then

$$\dot{r}^2 = 1 - \frac{\ell^2}{r^2} \quad\Longrightarrow\quad r^2 = \lambda^2 + \ell^2,$$
$$\dot{\phi} = \frac{\ell}{\lambda^2 + \ell^2} \quad\Longrightarrow\quad \phi - \alpha_0 = \arctan\frac{\lambda}{\ell},$$

(check the first: $\dot{r} = \lambda/r$, so $\dot{r}^2 = \lambda^2/r^2 = (r^2 - \ell^2)/r^2$; the origin of λ is chosen at the point of closest approach). Eliminate λ:

$$r\cos(\phi - \alpha_0) \overset{(1)}{=} r\cos\Big(\arctan\frac{\lambda}{\ell}\Big) \overset{(2)}{=} \sqrt{\lambda^2 + \ell^2}\,\frac{\ell}{\sqrt{\lambda^2 + \ell^2}} = \ell,$$

(1) The solution for ϕ.
(2) $\cos(\arctan u) = 1/\sqrt{1 + u^2}$ and $r = \sqrt{\lambda^2 + \ell^2}$.

that is, $x\cos\alpha_0 + y\sin\alpha_0 = \ell$: a straight line at distance ℓ from the origin [Dray (19.53)]. The angular momentum of a unit-speed particle is its impact parameter. We never used Cartesian coordinates, yet the connection $\omega^1{}_2 = -\mathrm{d}\phi$ knew that the plane is flat and produced straight lines.

T2.7.3 Geodesics from an action principle

Physicists usually meet geodesics as the paths of free particles, derived from a Lagrangian. For a curve $x^\mu(t)$, $0 \le t \le 1$, in a manifold with metric $g_{\mu\nu}$, define the **length** and the **energy**

$$L(\gamma) = \int_0^1 \sqrt{g_{\mu\nu}\dot{x}^\mu \dot{x}^\nu}\, \mathrm{d}t, \qquad E(\gamma) = \int_0^1 g_{\mu\nu}\dot{x}^\mu \dot{x}^\nu\, \mathrm{d}t. \tag{T2.111}$$

The energy is the free-particle action (twice the kinetic energy, integrated). Its Euler–Lagrange equations, with $\mathcal{L} = g_{\mu\nu}\dot{x}^\mu\dot{x}^\nu$, are

$$\begin{aligned} 0 &\overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial \mathcal{L}}{\partial \dot{x}^\rho} - \frac{\partial \mathcal{L}}{\partial x^\rho} \overset{(2)}{=} \frac{\mathrm{d}}{\mathrm{d}t}\left(2g_{\rho\nu}\dot{x}^\nu\right) - \partial_\rho g_{\mu\nu}\dot{x}^\mu\dot{x}^\nu \\ &\overset{(3)}{=} 2g_{\rho\nu}\ddot{x}^\nu + 2\partial_\mu g_{\rho\nu}\dot{x}^\mu\dot{x}^\nu - \partial_\rho g_{\mu\nu}\dot{x}^\mu\dot{x}^\nu \\ &\overset{(4)}{=} 2g_{\rho\nu}\ddot{x}^\nu + \left(\partial_\mu g_{\rho\nu} + \partial_\nu g_{\rho\mu} - \partial_\rho g_{\mu\nu}\right)\dot{x}^\mu\dot{x}^\nu \\ &\overset{(5)}{=} 2g_{\rho\sigma}\left(\ddot{x}^\sigma + \Gamma^\sigma{}_{\mu\nu}\dot{x}^\mu\dot{x}^\nu\right). \end{aligned} \tag{T2.112}$$

(1) Euler–Lagrange equation for the coordinate x^ρ.
(2) $\partial\mathcal{L}/\partial\dot{x}^\rho = 2g_{\rho\nu}\dot{x}^\nu$ by the symmetry of g.
(3) Chain rule: $\frac{\mathrm{d}}{\mathrm{d}t}g_{\rho\nu} = \partial_\mu g_{\rho\nu}\,\dot{x}^\mu$.
(4) Split $2\partial_\mu g_{\rho\nu}\dot{x}^\mu\dot{x}^\nu$ into two equal halves and relabel $\mu \leftrightarrow \nu$ in one of them.
(5) The coordinate Christoffel symbol $\Gamma^\sigma{}_{\mu\nu} = \frac{1}{2}g^{\sigma\rho}(\partial_\mu g_{\rho\nu} + \partial_\nu g_{\rho\mu} - \partial_\rho g_{\mu\nu})$ (the dictionary box of Section T2.5.8).

So the stationary curves of E are exactly the geodesics (T2.109). This is usually the fastest way to *get* the geodesic equations: write down the kinetic energy and turn the crank.

Energy versus length. The length does not depend on how the curve is parametrised; the energy does. They are related by the Cauchy–Schwarz inequality:

$$L(\gamma)^2 \overset{(1)}{=} \left(\int_0^1 1\cdot|\dot{\gamma}|\,\mathrm{d}t\right)^2 \overset{(2)}{\le} \int_0^1 1^2\,\mathrm{d}t \int_0^1 |\dot{\gamma}|^2\,\mathrm{d}t \overset{(3)}{=} E(\gamma), \tag{T2.113}$$

(1) Definition of L, with $|\dot{\gamma}| = \sqrt{g_{\mu\nu}\dot{x}^\mu\dot{x}^\nu}$.
(2) Cauchy–Schwarz for the functions 1 and $|\dot{\gamma}|$; equality holds exactly when $|\dot{\gamma}|$ is constant.
(3) $\int_0^1 \mathrm{d}t = 1$ and the definition of E.

So minimising E does two things at once: it minimises the length, and it forces constant speed. That is why the geodesic equation automatically conserves speed (we saw it in polar coordinates), and why the energy is the better functional for Morse theory (Chapter 7).

Worked example T2.38: The sphere from its Lagrangian; conserved angular momentum

On the sphere of radius a, $\mathcal{L} = a^2(\dot{\theta}^2 + \sin^2\theta\,\dot{\phi}^2)$. The Euler–Lagrange equations are

$$\begin{aligned} \theta: &\quad \frac{\mathrm{d}}{\mathrm{d}t}\left(2a^2\dot{\theta}\right) - 2a^2\sin\theta\cos\theta\,\dot{\phi}^2 = 0 &&\iff \quad \ddot{\theta} - \sin\theta\cos\theta\,\dot{\phi}^2 = 0, \\ \phi: &\quad \frac{\mathrm{d}}{\mathrm{d}t}\left(2a^2\sin^2\theta\,\dot{\phi}\right) = 0 &&\iff \quad \ddot{\phi} + 2\cot\theta\,\dot{\theta}\dot{\phi} = 0, \end{aligned}$$

which are Dray's (19.29), obtained there from the frame computation ($\vec{v} = a\dot{\theta}\,\hat{\theta} + a\sin\theta\,\dot{\phi}\,\hat{\phi}$ and $\mathrm{d}\hat{\theta} = \cos\theta\,\mathrm{d}\phi\,\hat{\phi}$, $\mathrm{d}\hat{\phi} = -\cos\theta\,\mathrm{d}\phi\,\hat{\theta}$ on the sphere; try it). The equator ($\theta = \pi/2$, $\dot{\phi}$

constant) solves both, since $\cos\frac{\pi}{2} = 0$.
The ϕ equation is a conservation law: ϕ does not appear in $\mathcal{L}$, so its conjugate momentum

$$\ell = \sin^2\theta\,\dot\phi \qquad \text{(unit sphere)}$$

is conserved [Dray (19.39)]. It is the z-component of angular momentum, $x\dot y - y\dot x = (\sin\theta)^2\dot\phi$. The θ equation, multiplied by $\dot\theta$, integrates to conservation of $\dot\theta^2 + \sin^2\theta\,\dot\phi^2$, the speed squared [Dray (19.41)].
The quick way to all solutions. A particle sliding freely on a frictionless sphere feels only the normal force, which is radial, so it exerts no torque about the centre. Hence the full angular-momentum vector $\vec L = \vec r \times \vec v$ is constant. Since $\vec r \perp \vec L$ at all times, the particle stays in the plane through the centre perpendicular to $\vec L$: *geodesics on the sphere are great circles*. The z-component $L_z = \ell$ is Dray's constant, and for a unit-speed geodesic on the unit sphere $\left|\vec L\right| = 1$, so $\ell = \cos i$ where i is the angle between the plane of the great circle and the equatorial plane. Dray reaches the same conclusion by integrating $\mathrm{d}\phi/\mathrm{d}\theta$ directly, obtaining $\ell\cot\theta = \sqrt{1-\ell^2}\,\sin(\alpha_0 - \phi)$, which after multiplying by $\sin\theta$ is the equation of a plane through the origin [Dray (19.54)–(19.61)].

Worked example T2.39: Flying between two cities at latitude 45°

Two cities on the unit sphere at colatitude $\theta = \pi/4$, with longitudes 0 and $\pi/2$: $\vec u = \left(\frac{1}{\sqrt2}, 0, \frac{1}{\sqrt2}\right)$, $\vec w = \left(0, \frac{1}{\sqrt2}, \frac{1}{\sqrt2}\right)$. The great-circle distance is the angle between the position vectors:

$$\cos d \overset{(1)}{=} \vec u\cdot\vec w \overset{(2)}{=} 0 + 0 + \tfrac12 \quad\Longrightarrow\quad d = \frac{\pi}{3} \approx 1.047.$$

(1) Arc length on a unit circle equals the angle subtended; the great circle lies in the plane of $\vec u$ and $\vec w$.
(2) Multiply componentwise.

Along the latitude circle the distance is $\sin\frac{\pi}{4}\cdot\frac{\pi}{2} = \frac{\pi}{2\sqrt2} \approx 1.111$. On the Earth ($a = 6371$ km) the two routes are about 6670 km and 7080 km. Where does the great circle go? Its plane has normal $\vec u\times\vec w = \left(-\frac12, -\frac12, \frac12\right)$, of length $\sqrt3/2$, so $\ell = L_z = \pm 1/\sqrt3$. At the highest point $\dot\theta = 0$, so conservation of speed gives $\sin^2\theta\,\dot\phi^2 = 1$, and with $\ell = \sin^2\theta\,\dot\phi$ this means $\sin\theta_{\min} = |\ell| = 1/\sqrt3$: $\theta_{\min} \approx 35.3^\circ$, i.e. latitude 54.7°. The shortest route bulges *towards the pole*, which is why flights from Europe to North America pass over Greenland. The explicit parametrisation is $\vec r(\beta) = \vec u\cos\beta + \hat m\sin\beta$, $0 \le \beta \le d$, with $\hat m$ the unit vector in the plane perpendicular to $\vec u$ (Dray's construction, [Dray Fig. 19.1]).

Try it: Clairaut's relation

On any surface of revolution, $\mathrm{d}s^2 = \mathrm{d}u^2 + \rho(u)^2\mathrm{d}\phi^2$ (with u arc length along a meridian and ρ the distance from the axis), the Lagrangian does not depend on ϕ. Show that along a unit-speed geodesic $\rho\sin\psi = \text{const}$, where ψ is the angle between the geodesic and the meridian. *Answer:* the conserved momentum is $\rho^2\dot\phi$, and the e_2 component of the unit velocity is $\rho\dot\phi = \sin\psi$. On the torus this says that a geodesic starting on the outer equator at a small angle to it can never reach the inner equator (where ρ is smallest) unless $\rho_{\text{out}}\sin\psi \le \rho_{\text{in}}$: some geodesics wind forever around the outside.

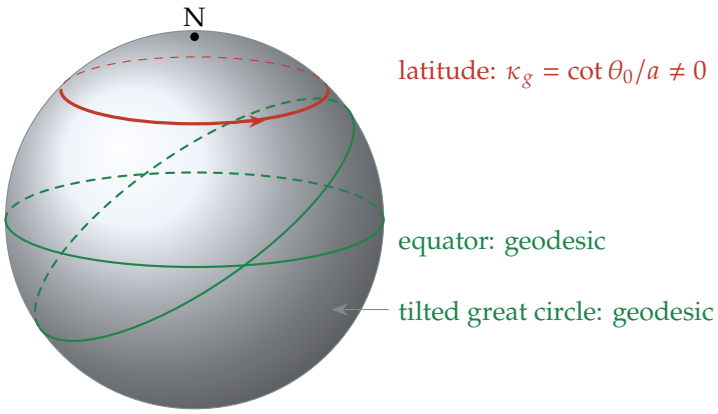

Figure T2.22: Geodesics and non-geodesics on a sphere. Great circles (green), such as the equator and any tilted circle through the centre, do not bend to either side within the sphere. The latitude circle (red) bends to the left, towards the north pole, with geodesic curvature $\cot\theta_0/a$; an inhabitant walking along it must keep turning left.

T2.7.4 Neighbouring geodesics: focusing, spreading and curvature

Two particles leave the north pole along neighbouring meridians. On a plane their separation would grow linearly forever. On a sphere they separate at first, then come together again and meet at the south pole. On a saddle they separate faster than linearly. Curvature is exactly the rate at which neighbouring geodesics accelerate towards or away from each other. The cleanest way to see it uses coordinates adapted to geodesics.

Geodesic polar coordinates. Pick a point p and send out unit speed geodesics in every direction ϕ. Label a point by the direction ϕ of the geodesic that reaches it and the distance r travelled. Near p this is an honest coordinate system (this is Gauss's lemma, which we accept), and the metric takes the form

$$\mathrm{d}s^2 = \mathrm{d}r^2 + G(r,\phi)^2\,\mathrm{d}\phi^2, \qquad G(0,\phi) = 0, \quad \partial_r G(0,\phi) = 1. \tag{T2.114}$$

The conditions at $r = 0$ say that very close to p the metric is the flat polar metric $\mathrm{d}r^2 + r^2\mathrm{d}\phi^2$. The function G has a direct meaning: two radial geodesics at angles ϕ and $\phi + \delta\phi$ are a distance $J = G\,\delta\phi$ apart at radius r. Now compute the curvature with the structure equations. The coframe is $\sigma^1 = \mathrm{d}r$, $\sigma^2 = G\,\mathrm{d}\phi$, and

$$\begin{aligned} \mathrm{d}\sigma^2 &\overset{(1)}{=} \partial_r G\;\mathrm{d}r\wedge\mathrm{d}\phi \overset{(2)}{=} \omega^1{}_2\wedge\sigma^1 \qquad\Longrightarrow\qquad \omega^1{}_2 = -\partial_r G\,\mathrm{d}\phi, \\ \Omega^1{}_2 &\overset{(3)}{=} \mathrm{d}\big(-\partial_r G\,\mathrm{d}\phi\big) \overset{(4)}{=} -\partial_r^2 G\;\mathrm{d}r\wedge\mathrm{d}\phi \overset{(5)}{=} -\frac{\partial_r^2 G}{G}\;\sigma^1\wedge\sigma^2. \end{aligned} \tag{T2.115}$$

(1) $\mathrm{d}(G\,\mathrm{d}\phi) = \partial_r G\,\mathrm{d}r\wedge\mathrm{d}\phi + \partial_\phi G\,\mathrm{d}\phi\wedge\mathrm{d}\phi$, and the second term vanishes.
(2) The first structure equation for $i = 2$, $\mathrm{d}\sigma^2 = -\omega^2{}_1\wedge\sigma^1 = \omega^1{}_2\wedge\sigma^1$. The guess $\omega^1{}_2 = -\partial_r G\,\mathrm{d}\phi$ gives $-\partial_r G\,\mathrm{d}\phi\wedge\mathrm{d}r = \partial_r G\,\mathrm{d}r\wedge\mathrm{d}\phi$; it also satisfies the $i = 1$ equation, $0 = \mathrm{d}\sigma^1 = -\omega^1{}_2\wedge\sigma^2 \propto \mathrm{d}\phi\wedge\mathrm{d}\phi$.
(3) The curvature in 2D is $\mathrm{d}\omega^1{}_2$, (T2.87).
(4) $\mathrm{d}(\partial_r G) = \partial_r^2 G\,\mathrm{d}r + \partial_\phi\partial_r G\,\mathrm{d}\phi$; the $\mathrm{d}\phi$ part dies against $\mathrm{d}\phi$.
(5) $\mathrm{d}r\wedge\mathrm{d}\phi = \sigma^1\wedge\sigma^2/G$.

So $K = -\partial_r^2 G/G$, which we write as the **Jacobi equation**

$$\boxed{\frac{\partial^2 J}{\partial r^2} + K\,J = 0}, \qquad J = G\,\delta\phi. \tag{T2.116}$$

The separation of neighbouring geodesics obeys a harmonic-oscillator equation whose "spring constant" is the Gaussian curvature. (The radial lines really are geodesics: along ϕ = const the tangent is e_1, $\alpha = 0$, and $\omega^1{}_2 \propto \mathrm{d}\phi$ vanishes on the curve, so $\kappa_g = 0$.)

Worked example T2.40: Constant curvature: sin, linear, sinh

With $J(0) = 0$, $J'(0) = \delta\phi$, the Jacobi equation for constant K has the solutions

$$K = +1 : \; G = \sin r, \qquad K = 0 : \; G = r, \qquad K = -1 : \; G = \sinh r.$$

These are the round sphere $\mathrm{d}r^2 + \sin^2 r\,\mathrm{d}\phi^2$ (with $r = \theta$), the flat plane in polar coordinates, and the hyperbolic plane $\mathrm{d}r^2 + \sinh^2 r\,\mathrm{d}\phi^2$. On the sphere the meridians reconverge at $r = \pi$: every geodesic from the north pole passes through the south pole. The south pole is a **conjugate point** of the north pole. Past a conjugate point a geodesic is no longer the shortest path (go from N past S to a point beyond: the other way round is shorter).

An ant's curvature meter. The circumference of the geodesic circle of radius r is $C(r) = \int_0^{2\pi} G\,\mathrm{d}\phi$. Expanding the solution of (T2.116) with K approximately constant near p, $G = r - \frac{1}{6}Kr^3 + O(r^4)$, so

$$C(r) \overset{(1)}{=} 2\pi\Big(r - \frac{K(p)}{6}\,r^3 + O(r^4)\Big) \quad\Longrightarrow\quad K(p) \overset{(2)}{=} \lim_{r\to 0} \frac{3}{\pi}\,\frac{2\pi r - C(r)}{r^3}.$$

(1) Insert the Taylor series of G, which follows from $G(0) = 0$, $G'(0) = 1$, $G''(0) = 0$ and $G'''(0) = -K(p)$ by differentiating (T2.116).

(2) Solve for $K(p)$.

On the unit sphere $C(r) = 2\pi \sin r$ and the limit is $\frac{3}{\pi} \cdot 2\pi \cdot \frac{1}{6} = 1$. An inhabitant who measures that circles are *shorter* than $2\pi r$ knows that $K > 0$, without ever leaving the surface: the Theorema Egregium again.

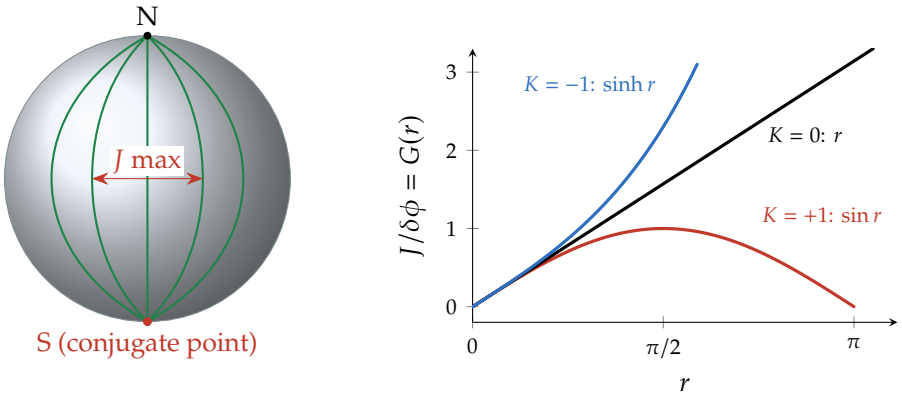

Figure T2.23: Left: geodesics leaving the north pole of a sphere spread apart, reach maximal separation at the equator, and refocus at the south pole, the conjugate point. Right: the separation $J = G(r)\,\delta\phi$ of two neighbouring geodesics solves $J'' + KJ = 0$. Positive curvature focuses ($\sin r$), zero curvature gives linear spreading, negative curvature defocuses exponentially ($\sinh r$).

Physical picture: tidal forces, and why gravity is curvature

In general relativity freely falling bodies follow geodesics of spacetime, and two nearby freely falling bodies drift apart or together according to the *geodesic deviation equation* $\frac{D^2 J^\mu}{\mathrm{d}\tau^2} = -R^\mu{}_{\nu\rho\sigma} u^\nu J^\rho u^\sigma$, the higher-dimensional version of (T2.116). Two apples dropped

side by side above the Earth approach each other: that relative acceleration is a tidal effect, it cannot be removed by choosing a freely falling frame, and it is curvature. The focusing of geodesics by positive curvature is also the mechanism behind the singularity theorems (Raychaudhuri's equation). In Morse theory (Chapter 7) the number of conjugate points along a geodesic is its *index* as a critical point of the energy E: each conjugate point is a direction in which the geodesic can be shortened.

Reading Nash (pp. 205–206, (7.55)–(7.59))

Nash introduces geodesics only in his Morse theory chapter, as the critical points of the energy functional $E(\gamma) = \int_0^1 |\mathrm{d}\gamma/\mathrm{d}t|^2 \,\mathrm{d}t$ on the space of paths from p to q. He writes the geodesic equation $\frac{\mathrm{d}^2\gamma^i}{\mathrm{d}t^2} + \Gamma^i{}_{jk}\frac{\mathrm{d}x^j}{\mathrm{d}t}\frac{\mathrm{d}x^k}{\mathrm{d}t} = 0$ [Nash p. 206, (7.56)]: this is our (T2.109), derived in (T2.112). He states that $E(\gamma) = L^2(\gamma)$ for a geodesic and $E(\gamma) \geq L^2(\gamma)$ in general [Nash (7.57)–(7.58)]: that is the Cauchy–Schwarz computation (T2.113). His remark that "there exist infinitely many geodesics joining a pair of points on a sphere" [Nash p. 192] is visible in Figure T2.22: go round the great circle through the two points once, twice, ..., in either direction. Each winding is a critical point of E with a larger index (more conjugate points passed), and Morse theory uses these to compute the topology of the loop space.

Recap

- Geodesic curvature: $\kappa_g\,\mathrm{d}s = \mathrm{d}\alpha - \omega^1{}_2$, the turning of the tangent relative to a parallel-transported vector. It is gauge invariant. Geodesics have $\kappa_g = 0$.
- Examples: circles in the plane $\kappa_g = 1/\rho$; latitude circles $\kappa_g = \cot\theta_0/a$ (only the equator is a geodesic); on the torus all meridians and the outer and inner equators are geodesics.
- Geodesic equation: $\nabla_{\vec v}\vec v = 0$, i.e. $\dot v^j + \Gamma^j{}_{ik}v^i v^k = 0$. Equivalent to $\kappa_g = 0$ at constant speed. It is the Euler–Lagrange equation of the energy $E = \int g_{\mu\nu}\dot x^\mu \dot x^\nu \,\mathrm{d}t$, and $E \geq L^2$.
- Plane: $r\cos(\phi - \alpha_0) = \ell$, straight lines. Sphere: great circles, by conservation of $\vec L = \vec r \times \vec v$; the shortest route bulges towards the pole.
- Jacobi equation $J'' + KJ = 0$: positive curvature focuses geodesics (conjugate points), negative curvature spreads them; $C(r) = 2\pi(r - Kr^3/6 + \dots)$.

T2.8 The Gauss–Bonnet theorem: integrated curvature is topology

We have computed the total curvature $\int K\,\mathrm{d}A$ of two closed surfaces. For a sphere of radius a it is $\frac{1}{a^2}\cdot 4\pi a^2 = 4\pi$, whatever a is. For a torus of revolution it is 0, whatever the radii R and a are (T2.92). In both cases the metric details dropped out completely. That is suspicious. So:

> *Is the total curvature of a closed surface independent of the metric? If so, what topological number is it?*

The answer is the **Gauss–Bonnet theorem**: $\int_\Sigma K\,\mathrm{d}A = 2\pi\chi(\Sigma)$, where χ is the Euler characteristic of Section T2.4.7. We will prove it in the physicist's way, with nothing but Stokes' theorem applied to the connection 1-form and some careful bookkeeping of angles. Along the way we get the angle sum of a triangle on a curved surface, the version with boundary that Nash quotes,

a second proof of metric independence by the "exact form over a closed surface" argument, the Gauss map and its degree, the Poincaré–Hopf theorem on zeros of vector fields, and finally the reading of Gauss–Bonnet as the first example of Chern–Weil theory and of the index theorem. We follow [Dray §§18.9–18.11].

T2.8.1 The turning tangent

Walk once around the edge of a region, counterclockwise. How much does your heading turn in total? In the plane, for the boundary of a disc, the answer is one full turn, 2π. For a circle this is obvious. For any other simple closed curve, deform it continuously into a circle through simple closed curves: the total turning is always an integer multiple of 2π (the heading returns to where it started), it changes continuously during the deformation, so it cannot change at all. This is Hopf's **turning tangent theorem** (the *Umlaufsatz*).

If the curve has corners, the heading jumps at each corner by the **exterior angle** ε_k (positive for a left turn), and the smooth parts supply the rest (Figure T2.24):

$$\oint_{\text{smooth parts}} \mathrm{d}\alpha + \sum_k \varepsilon_k = 2\pi. \tag{T2.117}$$

The exterior angle is $\varepsilon_k = \pi - \eta_k$, with η_k the interior angle. For a square, $4 \times \frac{\pi}{2} = 2\pi$ comes entirely from the corners.

The same statement holds for a region D on a curved surface, provided D is a topological disc and we measure the heading α relative to a frame that is smooth on all of D. The argument is the same: shrink D continuously to a tiny disc around one of its points. Throughout, the total turning of α is a multiple of 2π and varies continuously, and at the end the region is so small that the surface is flat to any desired accuracy and the frame is constant across it, so we are back in the plane with answer 2π.

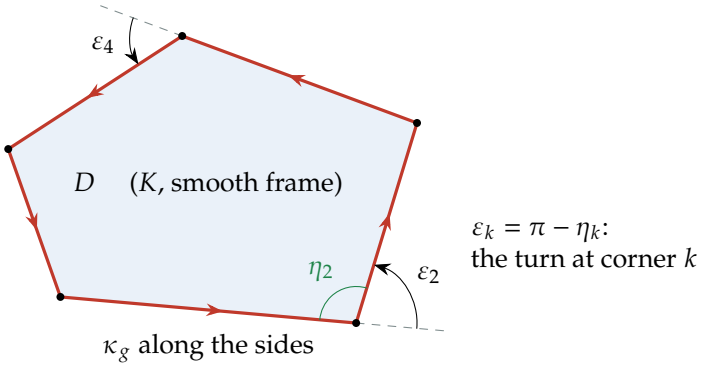

Figure T2.24: A region D with a piecewise smooth boundary, traversed counterclockwise (red). At each corner the heading jumps by the exterior angle ε_k, the angle between the continuation of the incoming side (dashed) and the outgoing side; the interior angle is $\eta_k = \pi - \varepsilon_k$. Along the smooth sides the heading turns at the rate κ_g relative to parallel transport. The sides need not be straight or geodesic.

T2.8.2 Local Gauss–Bonnet

Let D be a topological disc on an oriented surface, with a piecewise smooth boundary $C = \partial D$ traversed in the boundary orientation (region on the left), exterior angles ε_k at the corners, and let $\{e_1, e_2\}$ be an orthonormal frame that is smooth on D. Integrate the geodesic curvature

around the smooth parts of C [Dray (18.66)–(18.70)]:

$$\begin{aligned}\oint_C \kappa_g \,\mathrm{d}s &\overset{(1)}{=} \oint_C \mathrm{d}\alpha - \oint_C \omega^1{}_2 \\ &\overset{(2)}{=} \Big(2\pi - \sum_k \varepsilon_k\Big) - \oint_C \omega^1{}_2 \\ &\overset{(3)}{=} 2\pi - \sum_k \varepsilon_k - \int_D \mathrm{d}\omega^1{}_2 \\ &\overset{(4)}{=} 2\pi - \sum_k \varepsilon_k - \int_D K\,\mathrm{d}A. \end{aligned} \tag{T2.118}$$

(1) The definition (T2.105) of κ_g, integrated along the smooth pieces.
(2) The turning tangent theorem (T2.117); this is where we need D to be a disc and the frame to be smooth on it.
(3) Stokes' theorem for the 1-form $\omega^1{}_2$, which is smooth on D because the frame is. (The corners do not matter: Stokes holds for piecewise smooth boundaries.)
(4) The curvature 2-form, (T2.88): $\mathrm{d}\omega^1{}_2 = K\,\sigma^1 \wedge \sigma^2 = K\,\mathrm{d}A$.

Rearranging:

Key idea: local Gauss–Bonnet

For a disc-shaped region D with piecewise smooth boundary,

$$\boxed{\int_D K\,\mathrm{d}A + \oint_{\partial D} \kappa_g \,\mathrm{d}s + \sum_k \varepsilon_k = 2\pi} \tag{T2.119}$$

[Dray (18.69)–(18.70)]. The three ways a walker's heading can turn (bending of the path, kinks at the corners, and curvature of the surface enclosed) always add up to exactly one full turn.

Notice what happened to the frame: it appears in the middle of the derivation and has disappeared from the result. Every term in (T2.119) is gauge invariant. Compare (T2.101): the curvature term is the holonomy of the boundary loop. So local Gauss–Bonnet also says: *the rotation of a vector parallel transported around ∂D equals 2π minus the total turning of the path.* For a geodesic polygon that is $2\pi - \sum \varepsilon_k$, a purely angular quantity.

Worked example T2.41: Four checks

A flat polygon. $K = 0$, straight sides ($\kappa_g = 0$), so $\sum \varepsilon_k = 2\pi$. For a triangle, $\sum(\pi - \eta_k) = 2\pi$, i.e. $\eta_1 + \eta_2 + \eta_3 = \pi$.
A disc of radius ρ in the plane. $K = 0$, no corners, and $\kappa_g = 1/\rho$ from Example T2.35: $\oint \kappa_g \,\mathrm{d}s = \frac{1}{\rho} \cdot 2\pi\rho = 2\pi$.
A polar cap on the unit sphere, $0 \le \theta \le \theta_0$. The three terms are:

$$\int_D K\,\mathrm{d}A + \oint \kappa_g \,\mathrm{d}s \overset{(1)}{=} 2\pi(1 - \cos\theta_0) + \cot\theta_0 \cdot 2\pi \sin\theta_0 \overset{(2)}{=} 2\pi - 2\pi\cos\theta_0 + 2\pi\cos\theta_0 = 2\pi.$$

(1) $K = 1$ and the area of the cap from Example T2.34; $\kappa_g = \cot\theta_0$ from (T2.106) times the length $2\pi\sin\theta_0$ of the circle.
(2) $\cot\theta_0 \sin\theta_0 = \cos\theta_0$.

As the cap grows, the area term grows and the boundary term shrinks, in exact compensa-

tion. For $\theta_0 > \pi/2$ the cap is more than a hemisphere, $\kappa_g < 0$ (the boundary bends to the right, seen from inside the cap), and the formula still holds.
The hemisphere. $\theta_0 = \pi/2$: the equator is a geodesic, and all 2π comes from the enclosed curvature. (Compare Figure T2.20: a vector carried around the equator returns unrotated relative to the tangent of the equator, but rotated by 2π relative to a frame smooth on the hemisphere; both statements say the same thing.)

T2.8.3 Geodesic triangles and the angle excess

A **geodesic triangle** has three geodesic sides ($\kappa_g = 0$) and interior angles η_1, η_2, η_3. Local Gauss–Bonnet with $\varepsilon_k = \pi - \eta_k$ gives

$$\int_T K \, \mathrm{d}A \overset{(1)}{=} 2\pi - \sum_{k=1}^{3} (\pi - \eta_k) \overset{(2)}{=} \eta_1 + \eta_2 + \eta_3 - \pi. \tag{T2.120}$$

(1) (T2.119) with no κ_g term.
(2) $2\pi - 3\pi = -\pi$.

The angle excess of a geodesic triangle equals the total curvature inside it [Dray (18.71)]. On a sphere of radius a ($K = 1/a^2$) this is Girard's theorem,

$$\mathrm{Area}(T) = a^2 \, (\eta_1 + \eta_2 + \eta_3 - \pi), \tag{T2.121}$$

so spherical triangles always have angle sum larger than π. On the hyperbolic plane ($K = -1/a^2$) the sum is smaller: the *angle deficit* $\pi - \sum \eta_k$ is Area/a^2. Since the deficit cannot exceed π, no hyperbolic triangle has area larger than πa^2, however long its sides; the "ideal triangle" with all three vertices at infinity and all angles zero has exactly that area.

Worked example T2.42: The octant and the lune

The octant. The triangle on the unit sphere with vertices at the north pole and at the equator points of longitude 0 and $\pi/2$ has three right angles (Figure T2.25). Its area is one eighth of the sphere, $4\pi/8 = \pi/2$, and (T2.121) gives $\frac{\pi}{2} + \frac{\pi}{2} + \frac{\pi}{2} - \pi = \frac{\pi}{2}$. It checks.
A thinner triangle. Keep the north pole and put the two equator vertices at longitudes 0 and β. The angles are β (at the pole) and $\frac{\pi}{2}, \frac{\pi}{2}$. Directly:

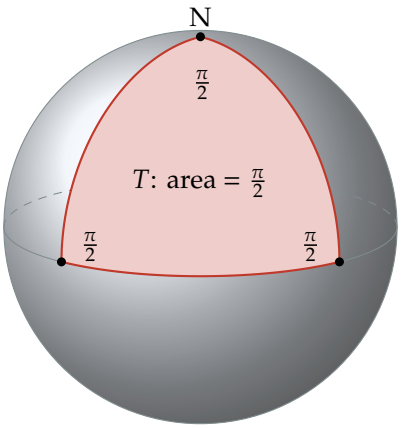
$$\mathrm{Area} \overset{(1)}{=} \int_0^{\beta} \int_0^{\pi/2} \sin\theta \, \mathrm{d}\theta \, \mathrm{d}\phi \overset{(2)}{=} \beta \big[-\cos\theta \big]_0^{\pi/2} = \beta,$$

(1) The area form of the unit sphere over the region $0 \le \theta \le \frac{\pi}{2}, 0 \le \phi \le \beta$.
(2) The ϕ integral gives β.

and (T2.121) gives $\beta + \frac{\pi}{2} + \frac{\pi}{2} - \pi = \beta$.
Girard's own argument, without calculus. Two great circles meeting at angle η cut out a **lune** of area 2η (it is the fraction $\eta/2\pi$ of the total area 4π). The three great circles through the sides of a triangle T make, at each vertex, a lune and its antipodal copy, of total area $2 \cdot 2\eta_k$. The six lunes cover the sphere, covering T and its antipodal copy T' three times each and everything else once. So

$$\sum_{k=1}^{3} 4\eta_k = 4\pi + 2\,\mathrm{Area}(T) + 2\,\mathrm{Area}(T') = 4\pi + 4\,\mathrm{Area}(T),$$

which is (T2.121) with $a = 1$. Two completely different arguments give the same answer, one using only areas and the other only the connection.



angle sum $= \frac{3\pi}{2}$
excess $= \frac{\pi}{2} = \int_T K\,\mathrm{d}A$

Figure T2.25: A geodesic triangle on the unit sphere with three right angles: two meridians from the north pole and a quarter of the equator. Its angle sum exceeds π by $\pi/2$, which is exactly its area, one eighth of 4π. A vector parallel transported around its edge comes back rotated by $\pi/2$.

Physical picture: measuring the curvature of space with triangles

Gauss is said to have measured the angles of the triangle formed by three mountain peaks near Göttingen, looking for an excess. Modern cosmology does the same on a vastly larger scale: the angular size of the hot and cold spots in the cosmic microwave background is a triangle whose apex is at us and whose base is a known physical length at the last scattering surface. The observed size agrees with a Euclidean angle sum to about one percent, which is the statement that the universe is spatially flat.

Try it: carrying a spear around the octant

Stand at the north pole holding a spear pointing along the meridian $\phi = \pi/2$. Walk down the meridian $\phi = 0$ to the equator, keeping the spear parallel (never rotating it relative to your path, which is a geodesic). Walk east along the equator to $\phi = \pi/2$, then back up to the pole. Which way does the spear point? *Answer:* it has turned by $\pi/2$, the enclosed curvature. Along a geodesic the angle between the spear and the path is constant; the path turns by $\varepsilon_k = \pi/2$ at each of the three corners, a total of $3\pi/2$, while a full circuit of the heading would need 2π: the missing $\pi/2$ is the holonomy.

T2.8.4 Global Gauss–Bonnet

Now let Σ be a closed, oriented surface. Chop it into polygons, each a small topological disc with a smooth frame on it, meeting edge to edge: V vertices, E edges, F faces. Apply local Gauss–Bonnet to every face f and add up [Dray (18.72)–(18.76)]. Face f has n_f corners with interior angles $\eta_{f,k}$, and

$$\int_f K\,\mathrm{d}A + \oint_{\partial f} \kappa_g\,\mathrm{d}s + \sum_{k=1}^{n_f} (\pi - \eta_{f,k}) = 2\pi. \tag{T2.122}$$

Sum (T2.122) over all faces, term by term:

$$\begin{aligned} 2\pi F &\overset{(1)}{=} \sum_f \int_f K\,\mathrm{d}A + \sum_f \oint_{\partial f} \kappa_g\,\mathrm{d}s + \pi \sum_f n_f - \sum_{f,k} \eta_{f,k} \\ &\overset{(2)}{=} \int_\Sigma K\,\mathrm{d}A + \sum_f \oint_{\partial f} \kappa_g\,\mathrm{d}s + \pi \sum_f n_f - \sum_{f,k} \eta_{f,k} \end{aligned}$$

$$\overset{(3)}{=} \int_\Sigma K\,\mathrm{d}A + 0 + \pi \sum_f n_f - \sum_{f,k} \eta_{f,k}$$
$$\overset{(4)}{=} \int_\Sigma K\,\mathrm{d}A + 2\pi E - \sum_{f,k} \eta_{f,k}$$
$$\overset{(5)}{=} \int_\Sigma K\,\mathrm{d}A + 2\pi E - 2\pi V. \tag{T2.123}$$

(1) The right side of (T2.122) is 2π for each of the F faces; on the left, split the corner sum.
(2) The faces tile Σ, so the curvature integrals add up to the integral over Σ.
(3) Every edge borders exactly two faces, and their boundary orientations traverse it in opposite directions. Reversing the direction turns a left bend into a right bend, so $\kappa_g\,\mathrm{d}s$ is a 1-form on the edge whose two integrals cancel. All edge terms cancel in pairs (Figure T2.26).
(4) Count corner-edge incidences: each face has as many corners as edges, n_f, and every edge belongs to two faces, so $\sum_f n_f = 2E$.
(5) The interior angles of all faces meeting at a vertex fill the full angle 2π around it, so the sum of all interior angles is $2\pi V$.

Rearranging, we have proved:

Key idea: Gauss–Bonnet theorem

For a closed oriented surface Σ with any Riemannian metric,

$$\boxed{\int_\Sigma K\,\mathrm{d}A = 2\pi\,(V - E + F) = 2\pi\,\chi(\Sigma)} \tag{T2.124}$$

[Dray (18.76)]. The left side needs a metric and two derivatives of it. The right side needs only a count of cells, and by Section T2.4.7 it equals $2\pi(b_0 - b_1 + b_2)$, a statement about closed and exact forms.

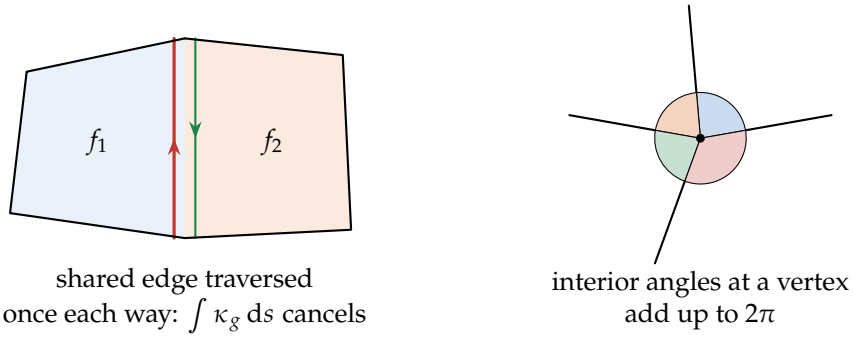


Figure T2.26: The two cancellations behind global Gauss–Bonnet. Left: an edge shared by two faces is traversed in opposite directions by their boundary orientations, so the geodesic-curvature integrals cancel. Right: the interior angles of all the faces meeting at a vertex fill out a full turn. What survives the sum is $2\pi(V - E + F)$.

Two consequences for free.

- *χ does not depend on the decomposition.* Fix a metric. The left side of (T2.124) does not know about the decomposition, so every decomposition gives the same $V - E + F$. (Dray derives

(T2.124) with quadrilaterals only; the derivation above works for arbitrary polygons, which settles his remark that χ does not depend on the shape of the faces.)

- $\int K\,\mathrm{d}A$ *does not depend on the metric.* The right side does not know about the metric. Deform the surface however you like, stretch it, dent it: the total curvature stays fixed.

Worked example T2.43: Sphere, torus, and surfaces of higher genus

Sphere. The cube decomposition gives $\chi = 8 - 12 + 6 = 2$, and the round sphere gives $\int K\,\mathrm{d}A = 4\pi = 2\pi \cdot 2$. Any other metric on S^2 (an ellipsoid, a potato, a dented ping-pong ball) also has total curvature 4π. In particular *no metric on the sphere has $K \le 0$ everywhere*.
Torus. The square with glued sides gives $\chi = 1 - 2 + 1 = 0$, and the torus of revolution gave $\int K\,\mathrm{d}A = 0$ in (T2.92) [Dray (18.89)]. So *no torus has $K > 0$ everywhere*: the positively curved outer half must always be compensated by negative curvature somewhere. The flat torus has $K = 0$ everywhere. It cannot be built in $\mathbb{R}^3$, but it exists in $\mathbb{R}^4$ as $(r\cos\theta, r\sin\theta, s\cos\phi, s\sin\phi)$ [Dray (18.90)–(18.93)]: its line element is $\mathrm{d}s^2 = r^2\mathrm{d}\theta^2 + s^2\mathrm{d}\phi^2$, the coframe $r\,\mathrm{d}\theta$, $s\,\mathrm{d}\phi$ is closed, so $\omega^1{}_2 = 0$ and $K = 0$, consistent with $\chi = 0$. It is the "wrap-around" screen of a video game.
Genus g. Each handle lowers χ by 2 (Example T2.18, [Dray Fig. 18.10]), so $\chi(\Sigma_g) = 2 - 2g$ and

$$\int_{\Sigma_g} K\,\mathrm{d}A = 4\pi(1 - g).$$

For $g \ge 2$ the total curvature is negative. By the uniformisation theorem quoted by Nash (Section T2.6, Reading Nash box), every such surface carries a metric with constant $K = -1$, and then Gauss–Bonnet fixes its area: Area $= -\int K\,\mathrm{d}A = 4\pi(g - 1)$. A hyperbolic surface of genus 2 has area 4π, whatever its shape.

surface	$V - E + F$	χ	$\int K\,\mathrm{d}A$	model metric	K
sphere S^2	$8 - 12 + 6$	2	4π	round	$+1$
torus T^2	$1 - 2 + 1$	0	0	flat (in $\mathbb{R}^4$)	0
genus $g \ge 2$	$1 - 2g + 1$	$2 - 2g$	$4\pi(1 - g)$	hyperbolic	-1
disc (with boundary)	$1 - 1 + 1$	1	$2\pi - \oint \kappa_g\,\mathrm{d}s$	flat or cap	any
annulus, cylinder	$2 - 3 + 1$	0	$-\oint \kappa_g\,\mathrm{d}s$	flat	0

(The genus-g count uses the standard $4g$-gon with its sides glued in pairs: one vertex, $2g$ edges, one face. The disc is one vertex on its boundary circle, one edge, one face. The annulus has a vertex on each boundary circle, the two circles and one radial cut as edges, and one face.)

T2.8.5 Gauss–Bonnet with boundary

If Σ has a boundary, redo the sum (T2.123) with a decomposition in which the boundary is made of edges. The interior edges still cancel in pairs, but the boundary edges belong to only one face and survive. The vertex count changes too: at a boundary vertex the interior angles add up to π (a straight angle) if the boundary is smooth there, or to η at a genuine corner. Redoing the bookkeeping (try it) gives

$$\boxed{\int_\Sigma K\,\mathrm{d}A + \oint_{\partial\Sigma} \kappa_g\,\mathrm{d}s + \sum_{\text{corners}} \varepsilon_k = 2\pi\,\chi(\Sigma)} \tag{T2.125}$$

For a disc, $\chi = 1$, and this is local Gauss–Bonnet (T2.119).

Worked example T2.44: Annulus, cylinder, and a test tube

A flat annulus $\rho_1 \le r \le \rho_2$ in the plane, $\chi = 0$. $K = 0$. The boundary orientation (region on the left) goes counterclockwise around the outer circle and *clockwise* around the inner circle. The outer circle bends left with $\kappa_g = 1/\rho_2$; the inner circle, traversed clockwise, bends right with $\kappa_g = -1/\rho_1$:

$$\oint_{\partial\Sigma} \kappa_g \, \mathrm{d}s = \frac{2\pi\rho_2}{\rho_2} - \frac{2\pi\rho_1}{\rho_1} = 0 = 2\pi\chi.$$

A finite cylinder. $K = 0$, and the boundary circles are geodesics (the cylinder is a rolled-up strip and the circles are the rolled-up straight edges). So both sides of (T2.125) vanish.
A test tube: a hemisphere of radius a with a cylinder of radius a attached along the equator, cut off at some height. $\chi = 1$ (it is a disc). The cylinder and the boundary contribute nothing ($K = 0$, $\kappa_g = 0$), and the hemisphere contributes $\frac{1}{a^2} \cdot 2\pi a^2 = 2\pi$. The boundary term is absent because the metric near the boundary is a product, circle × interval. That is Nash's (4.149).

Reading Nash (p. 129, (4.148)–(4.149))

Nash quotes Gauss–Bonnet for a surface with boundary as

$$\int_X \frac{R}{2\pi} + \int_{\partial X} \frac{R_g}{2\pi} = \chi(X)$$

[Nash p. 129, (4.148)], "where R is the curvature of X and R_g is the geodesic curvature of ∂X in X". In our notation $R = K\,\mathrm{d}A$ (a 2-form) and $R_g = \kappa_g\,\mathrm{d}s$ (a 1-form on the boundary); his boundary is smooth, so there are no corner terms. This is (T2.125) divided by 2π. He then notes that if X is isometric to $\partial X \times \mathbb{R}^+$ near its boundary the boundary integral vanishes and $\int_X R/2\pi = \chi(X)$ [Nash (4.149)]. Why: a product metric near the boundary is $\mathrm{d}s^2 = \mathrm{d}u^2 + \mathrm{d}t^2$ with u the arc length along the boundary and t the distance from it; the coframe $\mathrm{d}u, \mathrm{d}t$ is closed, so $\omega^1{}_2 = 0$ there, the boundary tangent is the constant frame vector e_1, and (T2.105) gives $\kappa_g = 0$. The test tube above is an example. Nash uses this as the warm-up for the Atiyah–Patodi–Singer index theorem, where the boundary correction is not a local integral but the spectral η-invariant.

T2.8.6 Why the metric drops out: an exact form on a closed surface

The polygon argument proves metric independence by comparison with a count. Here is a direct proof that uses nothing but the chapter's favourite fact, $\int_M \mathrm{d}\beta = 0$ when $\partial M = \varnothing$. Change the metric by a **conformal factor**: $g' = e^{2u} g$ for a smooth function u on Σ. (In two dimensions this is no loss of generality: every metric on a closed surface is, after a diffeomorphism, conformal to any other one of the constant curvature metrics listed above, by the uniformisation theorem.) The new coframe is $\sigma'^i = e^u \sigma^i$. Write $\mathrm{d}u = u_1\sigma^1 + u_2\sigma^2$, and recall the Hodge star $\star\sigma^1 = \sigma^2$, $\star\sigma^2 = -\sigma^1$, so $\star\mathrm{d}u = u_1\sigma^2 - u_2\sigma^1$. Guess $\omega'^1{}_2 = \omega^1{}_2 - \star\mathrm{d}u$ and check the first structure equation for $i = 1$:

$$\mathrm{d}\sigma'^1 \overset{(1)}{=} e^u\,\mathrm{d}u \wedge \sigma^1 + e^u\,\mathrm{d}\sigma^1 \overset{(2)}{=} e^u\left(-u_2\,\sigma^1 \wedge \sigma^2 - \omega^1{}_2 \wedge \sigma^2\right)$$
$$\overset{(3)}{=} -e^u\left(\omega^1{}_2 + u_2\sigma^1 - u_1\sigma^2\right) \wedge \sigma^2 \overset{(4)}{=} -\omega'^1{}_2 \wedge \sigma'^2.$$

(1) Product rule.
(2) $\mathrm{d}u \wedge \sigma^1 = u_2\,\sigma^2 \wedge \sigma^1 = -u_2\,\sigma^1 \wedge \sigma^2$, and the old structure equation $\mathrm{d}\sigma^1 = -\omega^1{}_2 \wedge \sigma^2$.
(3) Factor out $\wedge\sigma^2$; the added $-u_1\sigma^2 \wedge \sigma^2$ is zero.
(4) $\omega^1{}_2 + u_2\sigma^1 - u_1\sigma^2 = \omega^1{}_2 - \star\mathrm{d}u$ is the guess, and $e^u\sigma^2 = \sigma'^2$.

The $i = 2$ equation, $\mathrm{d}\sigma'^2 = \omega'^1{}_2 \wedge \sigma'^1$, checks the same way. By uniqueness of the Levi-Civita connection the guess is right:

$$\omega'^1{}_2 = \omega^1{}_2 - \star\mathrm{d}u, \qquad K'\,\mathrm{d}A' = \mathrm{d}\omega'^1{}_2 = K\,\mathrm{d}A - \mathrm{d}\star\mathrm{d}u. \tag{T2.126}$$

Now $\star\mathrm{d}u$ is a *globally defined* 1-form (it is built from the function u and the metric, with no frame choices), so

$$\int_\Sigma K'\,\mathrm{d}A' \overset{(1)}{=} \int_\Sigma K\,\mathrm{d}A - \int_\Sigma \mathrm{d}(\star\mathrm{d}u) \overset{(2)}{=} \int_\Sigma K\,\mathrm{d}A - \int_{\partial\Sigma} \star\mathrm{d}u \overset{(3)}{=} \int_\Sigma K\,\mathrm{d}A. \tag{T2.127}$$

(1) Integrate (T2.126).
(2) Stokes' theorem, legitimate because $\star\mathrm{d}u$ is smooth on all of Σ.
(3) Σ is closed: $\partial\Sigma = \varnothing$, and an integral over the empty set is zero.

The change of total curvature is the integral of an exact form over a closed surface, which vanishes. This is the same mechanism as the monopole computation (T2.34), run in reverse: there the curvature was locally exact but no global potential existed, and the integral was non-zero; here the *change* of curvature has a global potential, and the integral of the change is zero.

Since $\mathrm{d}\star\mathrm{d}u = (\Delta u)\,\mathrm{d}A$ with Δ the Laplacian ($\partial_x^2 + \partial_y^2$ in flat Cartesian coordinates), and $\mathrm{d}A' = e^{2u}\mathrm{d}A$, (T2.126) also gives the useful formula

$$K' = e^{-2u}\big(K - \Delta u\big). \tag{T2.128}$$

Worked example T2.45: The round sphere from the flat plane

Stereographic projection writes the unit sphere as the plane with metric $\mathrm{d}s^2 = \frac{4(\mathrm{d}x^2+\mathrm{d}y^2)}{(1+r^2)^2}$, i.e. $K = 0$ and $u = \ln 2 - \ln(1 + r^2)$. For a radial function $\Delta u = u'' + u'/r$:

$$u' = -\frac{2r}{1+r^2}, \qquad u'' = -\frac{2}{1+r^2} + \frac{4r^2}{(1+r^2)^2},$$
$$\Delta u \overset{(1)}{=} -\frac{4}{1+r^2} + \frac{4r^2}{(1+r^2)^2} \overset{(2)}{=} -\frac{4}{(1+r^2)^2},$$
$$K' \overset{(3)}{=} \frac{(1+r^2)^2}{4}\cdot\frac{4}{(1+r^2)^2} = 1.$$

(1) Add u'' and $u'/r = -2/(1 + r^2)$.
(2) Common denominator: $-4(1 + r^2) + 4r^2 = -4$.
(3) (T2.128) with $K = 0$ and $e^{-2u} = (1 + r^2)^2/4$.

The plane has total curvature 0, the sphere 4π, yet (T2.127) says conformal changes preserve the total. There is no contradiction: the plane is not closed, and $u \to -\infty$ at infinity, so $\star\mathrm{d}u$ is not smooth on the compactified plane (the point at infinity is the north pole). The whole 4π sits in the boundary term at infinity: $-\oint_{r=\Lambda} \star\mathrm{d}u = -2\pi\Lambda\,u'(\Lambda) = 4\pi\Lambda^2/(1 + \Lambda^2) \to 4\pi$.

T2.8.7 The Gauss map: total curvature as a degree

For a surface in $\mathbb{R}^3$ there is a third way to see that total curvature is an integer multiple of something. The **Gauss map** sends each point $p \in \Sigma$ to its unit normal, $\hat{n}(p) \in S^2$. In the adapted frame $\{e_1, e_2, e_3 = \hat{n}\}$ of Section T2.6.5 we had $\mathrm{d}\hat{n} \cdot e_i = -\omega^3{}_i = S_{ij}\sigma^j$, where S is the shape operator. The area form of the unit sphere, evaluated at the point $\hat{n}$, is $\frac{1}{2}\,\hat{n} \cdot (\mathrm{d}\hat{n} \times \mathrm{d}\hat{n})$ (the 2-form that eats two displacements of $\hat{n}$ and returns the area of the parallelogram they span). Pulling it back along the Gauss map:

$$\hat{n}^*\big(\mathrm{d}A_{S^2}\big) \overset{(1)}{=} \tfrac{1}{2}\,\hat{n} \cdot (\mathrm{d}\hat{n} \times \mathrm{d}\hat{n}) \overset{(2)}{=} \tfrac{1}{2}\big[(S_{1j}\sigma^j) \wedge (S_{2k}\sigma^k) - (S_{2k}\sigma^k) \wedge (S_{1j}\sigma^j)\big]$$
$$\overset{(3)}{=} (S_{1j}\sigma^j) \wedge (S_{2k}\sigma^k) \overset{(4)}{=} \det S\ \sigma^1 \wedge \sigma^2 \overset{(5)}{=} K\,\mathrm{d}A. \tag{T2.129}$$

(1) The area form of S^2 written with the embedding; the cross product is taken on the vector parts and the wedge on the form parts.
(2) $\mathrm{d}\hat{n} = (S_{1j}\sigma^j)e_1 + (S_{2k}\sigma^k)e_2$ has no normal part (since $\hat{n} \cdot \hat{n} = 1$), and $\hat{n} \cdot (e_1 \times e_2) = 1 = -\hat{n} \cdot (e_2 \times e_1)$.
(3) Two 1-forms anticommute, so the two terms are equal.
(4) Expand: only $\sigma^1 \wedge \sigma^2$ and $\sigma^2 \wedge \sigma^1$ survive, with coefficient $S_{11}S_{22} - S_{12}S_{21}$.
(5) The Theorema Egregium (T2.95).

The curvature form is the pullback of the area form of the sphere by the Gauss map. (Check on a sphere of radius a: $\hat{n} = \vec{r}/a$ shrinks everything by a, so areas by a^2, and $K = 1/a^2$.) Integrating, $\int_\Sigma K\,\mathrm{d}A$ is the signed area swept out on S^2 by the normal. A map between closed oriented surfaces covers the target an integer number of times, counted with orientation: its **degree**. So

$$\int_\Sigma K\,\mathrm{d}A = 4\pi\,\deg\hat{n}, \qquad \text{and by Gauss–Bonnet} \qquad \deg\hat{n} = \tfrac{1}{2}\chi(\Sigma) = 1 - g. \tag{T2.130}$$

For a convex surface (an ellipsoid, a potato) every direction is the normal at exactly one point, $\deg\hat{n} = 1$, and $\int K\,\mathrm{d}A = 4\pi$ with no calculation at all.

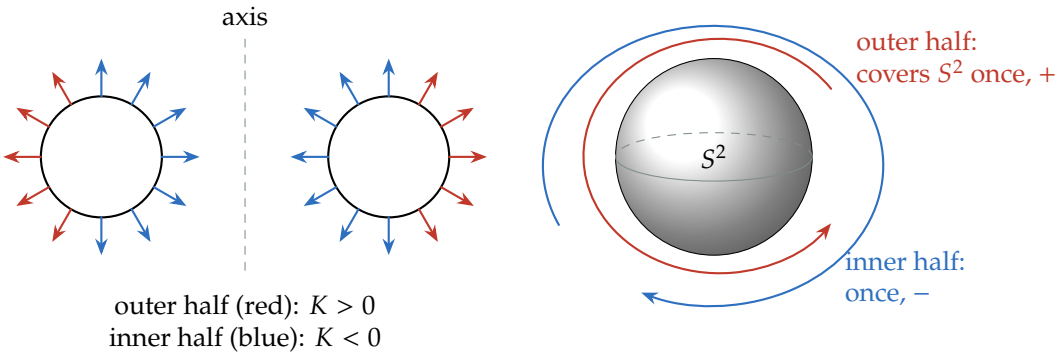

Figure T2.27: The Gauss map of a torus. Every direction in space is the outward normal at exactly one point of the outer half (red) and at exactly one point of the inner half (blue). On the outer half the normal turns the same way as the surface ($K > 0$), on the inner half the opposite way ($K < 0$). The two coverings cancel: $\deg\hat{n} = 0$ and $\int K\,\mathrm{d}A = 0$.

Reading Nash (p. 245, (8.153)–(8.155))

The magnetic charge of a Yang–Mills–Higgs monopole is exactly such a degree. At infinity the Higgs field has unit length, so its direction $\hat{\phi}$ is a map from the sphere at infinity S^2_∞ to the unit sphere in $\mathfrak{su}(2) \cong \mathbb{R}^3$, and Nash writes $k = -\frac{1}{2\pi}\int_{S^2_\infty} \mathrm{tr}\big(\hat{\phi}\,\mathrm{d}\hat{\phi} \wedge \mathrm{d}\hat{\phi}\big)$ [Nash (8.155)].

With the anti-Hermitian basis $T_a = -\frac{i}{2}\sigma_a$ of $\mathfrak{su}(2)$, $\hat\phi = n^a T_a$ with $n \cdot n = 1$:

$$-\frac{1}{2\pi}\operatorname{tr}\big(\hat\phi\,\mathrm{d}\hat\phi \wedge \mathrm{d}\hat\phi\big) \overset{(1)}{=} -\frac{1}{2\pi}\Big(-\frac{i}{2}\Big)^3 \operatorname{tr}(\sigma_a\sigma_b\sigma_c)\, n^a \mathrm{d}n^b \wedge \mathrm{d}n^c \overset{(2)}{=} -\frac{1}{2\pi}\cdot\frac{i}{8}\cdot 2i\,\varepsilon_{abc}\, n^a \mathrm{d}n^b \wedge \mathrm{d}n^c$$
$$\overset{(3)}{=} \frac{1}{8\pi}\,\varepsilon_{abc}\, n^a \mathrm{d}n^b \wedge \mathrm{d}n^c \overset{(4)}{=} \frac{1}{4\pi}\,\hat n^*\big(\mathrm{d}A_{S^2}\big).$$

(1) Insert $\hat\phi = n^a T_a$; the trace is linear.
(2) $(-i/2)^3 = i/8$ and $\operatorname{tr}(\sigma_a\sigma_b\sigma_c) = 2i\,\varepsilon_{abc}$ (from $\sigma_a\sigma_b = \delta_{ab} + i\varepsilon_{abd}\sigma_d$ and $\operatorname{tr}\sigma_d\sigma_c = 2\delta_{dc}$).
(3) $i \cdot i = -1$.
(4) $\frac{1}{2}\varepsilon_{abc} n^a \mathrm{d}n^b \wedge \mathrm{d}n^c = \frac{1}{2}\hat n \cdot (\mathrm{d}\hat n \times \mathrm{d}\hat n)$ is the pulled-back area form, as in (T2.129).

So $k = \frac{1}{4\pi}\int \hat n^*(\mathrm{d}A_{S^2}) = \deg \hat n$: Nash's monopole number is the degree of the Higgs direction field, computed exactly like the Gauss map of a surface. (The unit-length normalisation corresponds to $-2\operatorname{tr}\hat\phi^2 = n \cdot n = 1$.)

T2.8.8 Zeros of vector fields: the Poincaré–Hopf theorem

Why must the wind on the Earth vanish somewhere, while on a doughnut planet it need not? Let $\vec v$ be a vector field on a closed surface with isolated zeros $p_1, \dots, p_m$.

Working definition T2.16 (index of a zero)

Draw a small counterclockwise circle around the zero p [small enough to enclose no other zero] and use a frame that is smooth near p. The **index** of p is the number of times $\vec v$ turns [net number of full counterclockwise turns, a clockwise turn counts -1] as we go once around the circle:

$$\operatorname{ind}_p \vec v = \frac{1}{2\pi}\oint \mathrm{d}\lambda,$$

where λ is the angle of $\vec v$ relative to the frame. It is the winding number (T2.28) of the component map $(v^1, v^2) : \text{circle} \to \mathbb{R}^2 \setminus \{0\}$. *Examples:* a source (x, y), a sink $(-x, -y)$ and a vortex $(-y, x)$ all have index $+1$; a saddle $(x, -y)$ has index -1 (Figure T2.28). In complex notation $v = z^n$ has index n and $v = \bar z^n$ has index $-n$.

Away from its zeros, $\vec v$ defines a frame: $e_1 = \vec v/|\vec v|$, and e_2 the rotation of e_1 by $+90°$. Let ω_v be its connection form. Cut out small discs D_k around the zeros, and let $\Sigma' = \Sigma \setminus \bigcup_k D_k$; its boundary is $\bigcup_k \partial D_k$ with the *opposite* (clockwise) orientation. On each D_k choose a smooth frame $\tilde e$ with connection $\tilde\omega$; on ∂D_k the frame of $\vec v$ is $\tilde e$ rotated by λ, so $\omega_v = \tilde\omega - \mathrm{d}\lambda$ by (T2.82). Then

$$\int_{\Sigma'} K\,\mathrm{d}A \overset{(1)}{=} \int_{\Sigma'} \mathrm{d}\omega_v \overset{(2)}{=} -\sum_k \oint_{\partial D_k} \omega_v \overset{(3)}{=} -\sum_k \oint_{\partial D_k} (\tilde\omega - \mathrm{d}\lambda)$$
$$\overset{(4)}{=} -\sum_k \int_{D_k} K\,\mathrm{d}A + 2\pi \sum_k \operatorname{ind}_{p_k} \vec v. \tag{T2.131}$$

(1) On Σ' the frame of $\vec v$ is smooth, so $K\,\mathrm{d}A = \mathrm{d}\omega_v$ holds on all of Σ'.
(2) Stokes' theorem on Σ', whose boundary circles carry the clockwise orientation (the minus sign).
(3) The change of frame on each circle.
(4) Stokes' theorem for $\tilde\omega$ on the disc D_k (where $\tilde e$ is smooth), and the definition of the index.

Move the D_k integrals to the left: $\int_\Sigma K\,\mathrm{d}A = 2\pi\sum_k \mathrm{ind}_{p_k}\vec{v}$. Combined with Gauss–Bonnet:

Key idea: Poincaré–Hopf theorem

For any vector field with isolated zeros on a closed oriented surface,

$$\sum_{\text{zeros } p} \mathrm{ind}_p\,\vec{v} = \chi(\Sigma). \tag{T2.132}$$

In particular, if $\chi \neq 0$ every vector field has a zero.

Worked example T2.46: Sphere and torus

Sphere, rotation field ∂_ϕ. It vanishes at the two poles. Near the north pole, in local Cartesian coordinates, it is the vortex $(-y, x)$, index +1. Near the south pole, looking from outside (which is the orientation of the sphere there), the rotation appears clockwise, $(y, -x)$: still index +1 (a vortex turned by $-90°$). Total $2 = \chi(S^2)$. *The height function's gradient* on the sphere has a source at the south pole and a sink at the north pole, again $1 + 1 = 2$. This is the hairy ball theorem: you cannot comb a hairy ball flat, and at any moment there is a point on the Earth with no horizontal wind.
Torus. The field ∂_ϕ (around the axis) has no zeros: consistent with $\chi(T^2) = 0$. The gradient of the height of a torus standing on its edge has four zeros: a maximum and a minimum (index +1 each) and two saddles on the rim of the hole (index −1 each). Total 0. Counting critical points of a function with signs is the starting point of Morse theory (Chapter 7).

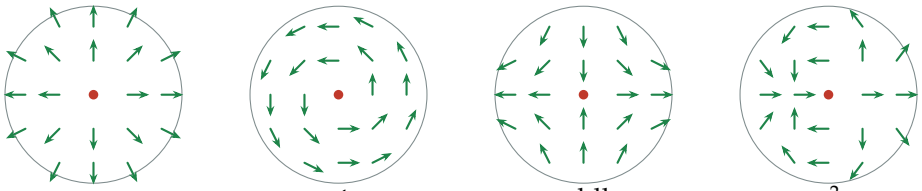

Figure T2.28: Zeros of vector fields and their indices: the number of turns the arrow makes as we go once counterclockwise around the zero. A source and a vortex turn once with the circle (+1), a saddle turns once against it (−1), and the field $z^2 = (x^2 - y^2, 2xy)$ turns twice (+2). On a closed surface the indices of all zeros add up to χ.

T2.8.9 The seed of Chern–Weil theory and of the index theorem

Gauss–Bonnet is the prototype for most of the topology in the rest of these notes. Three readings of it point in three directions.

1. It is a characteristic class (Chern–Weil). Define the **Euler form** of an oriented surface,

$$e := \frac{\Omega^1{}_2}{2\pi} = \frac{K\,\mathrm{d}A}{2\pi}. \tag{T2.133}$$

It is a closed 2-form (every 2-form on a surface is), it is built algebraically from the curvature, it is gauge invariant, and by (T2.127) its cohomology class does not depend on the metric. Gauss–Bonnet says $\int_\Sigma e = \chi(\Sigma)$. Now use the dictionary of Section T2.5.10, which views the

tangent plane as $\mathbb{C}$ and the frame rotation as a U(1) gauge transformation: the anti-Hermitian U(1) potential is $A = -i\,\omega^1{}_2$. Its field strength and first Chern form are

$$c_1 \overset{(1)}{=} \frac{i}{2\pi} F \overset{(2)}{=} \frac{i}{2\pi}\,\mathrm{d}A \overset{(3)}{=} \frac{i}{2\pi}\,(-i)\,\mathrm{d}\omega^1{}_2 \overset{(4)}{=} \frac{\Omega^1{}_2}{2\pi} = e. \tag{T2.134}$$

(1) The convention for the first Chern form used throughout these notes.
(2) For U(1) the term $A \wedge A$ vanishes, so $F = \mathrm{d}A$.
(3) The dictionary $A = -i\,\omega^1{}_2$.
(4) $i \cdot (-i) = 1$, and $\Omega^1{}_2 = \mathrm{d}\omega^1{}_2$ in 2D.

So *the Euler class of a surface is the first Chern class of its tangent bundle*, and Gauss–Bonnet reads $c_1(T\Sigma)[\Sigma] = \chi(\Sigma)$. For the sphere this is the 2 we found as the winding of the transition function between the north and south frames in Example T2.29. Chern–Weil theory (Chapter T3) does the same for any gauge field: invariant polynomials in F (such as $\mathrm{tr}\,F$, $\mathrm{tr}\,F \wedge F$) are closed forms whose integrals are topological, and the monopole charge and the instanton number of Chapter 8 are the next two examples.

2. It generalises to all even dimensions (Chern–Gauss–Bonnet). In dimension $n = 2m$ the Euler form is the **Pfaffian** of the curvature matrix, $e = \mathrm{Pf}(\Omega/2\pi)$, and $\int_M e = \chi(M)$. In four dimensions

$$e = \frac{1}{32\pi^2}\,\varepsilon_{abcd}\,\Omega^{ab} \wedge \Omega^{cd}. \tag{T2.135}$$

Check it on the unit four-sphere, where constant curvature $K = 1$ means $\Omega^{ab} = \sigma^a \wedge \sigma^b$ (the 4D analogue of $\Omega^1{}_2 = \sigma^1 \wedge \sigma^2$):

$$\int_{S^4} e \overset{(1)}{=} \frac{1}{32\pi^2} \int_{S^4} \varepsilon_{abcd}\,\sigma^a \wedge \sigma^b \wedge \sigma^c \wedge \sigma^d \overset{(2)}{=} \frac{24}{32\pi^2} \int_{S^4} \sigma^1 \wedge \sigma^2 \wedge \sigma^3 \wedge \sigma^4 \overset{(3)}{=} \frac{3}{4\pi^2} \cdot \frac{8\pi^2}{3} = 2.$$

(1) Insert the constant-curvature form of Ω into (T2.135).
(2) Each of the $4! = 24$ orderings (a, b, c, d) of $(1, 2, 3, 4)$ contributes $\varepsilon_{abcd} \cdot \varepsilon_{abcd}\,\sigma^1 \wedge \cdots \wedge \sigma^4 = +\sigma^{1234}$.
(3) The volume of the unit S^4 is $8\pi^2/3$.

And $\chi(S^4) = b_0 + b_4 = 2$. In odd dimensions there is no Pfaffian and $\chi = 0$, consistent with Poincaré duality (Section T2.4.7). The same combination $\varepsilon_{abcd} R^{ab}{}_{ef} R^{cd}{}_{gh} \varepsilon^{efgh}$ is the Gauss–Bonnet term of four-dimensional gravity, which is a total derivative and therefore does not change the classical equations of motion.

3. It is an index theorem. By Hodge's theorem (Section T2.4.9) b_p is the number of harmonic p-forms. Group the forms into even ($p = 0, 2$) and odd ($p = 1$) and consider the operator $\mathrm{d} + \mathrm{d}^*$ from even forms to odd forms. Since $(\mathrm{d} + \mathrm{d}^*)^2 = \mathrm{dd}^* + \mathrm{d}^*\mathrm{d} = \Delta$ (the cross terms are $\mathrm{d}^2 = 0$ and $(\mathrm{d}^*)^2 = 0$), its zero modes are exactly the harmonic forms, and

$$\mathrm{index}(\mathrm{d} + \mathrm{d}^*) \overset{(1)}{=} \dim \mathrm{Ker}_{\mathrm{even}} - \dim \mathrm{Ker}_{\mathrm{odd}} \overset{(2)}{=} (b_0 + b_2) - b_1 \overset{(3)}{=} \chi(\Sigma) \overset{(4)}{=} \int_\Sigma e. \tag{T2.136}$$

(1) The index of an operator from even to odd forms: zero modes on the even side minus zero modes of its adjoint on the odd side (the adjoint is again $\mathrm{d} + \mathrm{d}^*$).
(2) Zero modes are harmonic forms, counted by the Betti numbers.
(3) Definition of χ.
(4) Gauss–Bonnet.

The left end is analytic (it counts solutions of a differential equation), the right end is the integral of a local curvature density. This is the Atiyah–Singer index theorem for the de Rham complex. For the Dirac operator the same structure holds with the Euler form replaced by the $\hat{A}$-form (Chapter 4), and in physics that equation computes the chiral anomaly (Chapter 10).

Reading Nash (pp. 104–106, (4.50)–(4.62))

Nash obtains Gauss–Bonnet in the opposite direction. He takes the de Rham complex as an elliptic complex, forms the operator $\mathrm{d}+\mathrm{d}^*$ from even to odd forms, and writes $\operatorname{index}\mathrm{d} = \sum_i (-1)^i \dim H^i_{\text{de Rham}}(X) = \sum (-1)^i b_i = \chi(X)$ [Nash p. 104, (4.52)]. He then evaluates the same index with the general index formula, manipulating Chern characters and the Todd class by the splitting principle, and finds $\operatorname{index}\mathrm{d} = \int_X e(X)$ [Nash (4.53), (4.61)–(4.62)], "the famous Gauss–Bonnet theorem" $\int_X e(X) = \chi(X)$ [Nash (4.54)]. Our derivation used only Stokes' theorem and angle counting, and is special to surfaces; his works in every even dimension but needs the whole machinery of Chapter 4. In two dimensions his $e(X)$ is our $K\,\mathrm{d}A/2\pi$, and (T2.136) is his (4.52)–(4.54) spelled out.

Recap

- Local Gauss–Bonnet: $\int_D K\,\mathrm{d}A + \oint \kappa_g\,\mathrm{d}s + \sum \varepsilon_k = 2\pi$ for a disc; proof: $\kappa_g\,\mathrm{d}s = \mathrm{d}\alpha - \omega^1{}_2$, the turning tangent theorem, and Stokes on $\omega^1{}_2$.
- Geodesic triangles: angle excess $= \int_T K\,\mathrm{d}A$; Girard's area formula on the sphere; angle deficit on the hyperbolic plane.
- Global: $\int_\Sigma K\,\mathrm{d}A = 2\pi\chi$; edges cancel in pairs, angles at vertices sum to 2π. Sphere 4π, torus 0, genus g: $4\pi(1-g)$.
- With boundary (Nash 4.148): $\int K\,\mathrm{d}A + \oint \kappa_g\,\mathrm{d}s = 2\pi\chi$; the boundary term vanishes for a product metric near the boundary (Nash 4.149).
- Metric independence: $K'\mathrm{d}A' = K\,\mathrm{d}A - \mathrm{d}{\star}\mathrm{d}u$; exact form over a closed surface integrates to zero.
- Gauss map: $K\,\mathrm{d}A = \hat{n}^*\mathrm{d}A_{S^2}$, $\deg\hat{n} = 1-g$; the monopole charge is the same kind of degree.
- Poincaré–Hopf: $\sum \mathrm{ind} = \chi$; hairy ball theorem.
- Seed: $e = K\,\mathrm{d}A/2\pi = c_1(T\Sigma)$ (Chern–Weil); Pfaffian in higher dimension ($\int_{S^4} e = 2$); $\operatorname{index}(\mathrm{d}+\mathrm{d}^*) = \chi = \int e$ (index theorem).

T2.9 Applications: equivalence, Lagrangians, spinors and the sphere

We now own a complete toolkit: integration and Stokes' theorem, closed and exact forms, frames, connections, curvature and Gauss–Bonnet. Dray ends his book with a chapter of applications that use the whole kit at once [Dray Ch. 20]. We do the same, with a physicist's eye on what comes next in Nash. Five questions organise the section.

1. Two metrics are written in different coordinates. *Are they the same geometry?* Curvature answers this locally, and holonomy and topology answer it globally (Section T2.9.1).
2. An action is the integral of a top form. *What is the Einstein–Hilbert action in form language,*

and why is gravity in two dimensions pure topology? (Section T2.9.2).

3. Forms of mixed degree can be multiplied with a new product. *Why does this reproduce the Pauli and Dirac matrices, and what is a spinor in this language?* (Sections T2.9.3 and T2.9.4).
4. *Which first-order operator on forms squares to the Laplacian?* The answer, $\mathrm{d}-\delta$, is a Dirac operator in disguise, and its even/odd splitting is the operator whose index is the Euler characteristic (Section T2.9.5).
5. *What does "no holes" really mean, and what happens when we integrate a form from $\mathbb{R}^3$ over a sphere?* Here we correct one statement in Dray and do his closing exercise explicitly (Sections T2.9.6 and T2.9.7).

T2.9.1 The equivalence problem: are two metrics the same?

General relativity is full of rediscovered solutions: a metric is found, published, and later recognised as an old one in new coordinates [Dray §20.1]. The underlying question is:

> *Given two line elements $\mathrm{d}s^2$ and $\mathrm{d}s'^2$, is there a change of coordinates turning one into the other?*

This is the **equivalence problem**. Christoffel introduced connections to attack it.

The flat case is easy. If all the curvature 2-forms vanish, $\Omega^i{}_j = 0$, then by Section T2.6.3 the connection is pure gauge. We can rotate to a frame with $\omega = 0$. In that frame $\mathrm{d}\sigma^i = 0$, so by the Poincaré lemma $\sigma^i = \mathrm{d}X^i$ locally, and $\mathrm{d}s^2 = \sum_i (\mathrm{d}X^i)^2$. The X^i are Cartesian coordinates. So *a metric is locally flat exactly when its curvature vanishes*, and the proof tells us how to find the flat coordinates.

Working definition T2.17 (Flatness test)

Given a line element: (i) choose an orthonormal coframe; (ii) solve $\mathrm{d}\sigma^i = -\omega^i{}_j \wedge \sigma^j$ for the connection; (iii) compute $\Omega = \mathrm{d}\omega + \omega \wedge \omega$. *If* $\Omega = 0$, the metric is locally Euclidean (or Minkowski), and the flat coordinates are found by integrating $\mathrm{d}X^i = \sigma'^i$ in a frame where $\omega' = 0$ [the original frame rotated by a position-dependent angle, which exists locally when $\Omega = 0$]. *If* $\Omega \neq 0$ *anywhere*, no coordinate change can make it flat there.

Worked example T2.47: A flat metric in disguise

Is $\mathrm{d}s^2 = e^{2y}(\mathrm{d}x^2 + \mathrm{d}y^2)$ flat? It does not look it: the coefficients grow exponentially. Take the coframe $\sigma^1 = e^y \mathrm{d}x$, $\sigma^2 = e^y \mathrm{d}y$. Then

$$\mathrm{d}\sigma^1 \overset{(1)}{=} e^y\, \mathrm{d}y \wedge \mathrm{d}x = -e^y\, \mathrm{d}x \wedge \mathrm{d}y, \qquad \mathrm{d}\sigma^2 \overset{(2)}{=} e^y\, \mathrm{d}y \wedge \mathrm{d}y = 0.$$

(1) $\mathrm{d}(e^y \mathrm{d}x) = \mathrm{d}(e^y) \wedge \mathrm{d}x$ and $\mathrm{d}(e^y) = e^y \mathrm{d}y$.
(2) $\mathrm{d}y \wedge \mathrm{d}y = 0$.

Guess $\omega^1{}_2 = c\, \mathrm{d}x$. The structure equations are

$$\mathrm{d}\sigma^1 \overset{(1)}{=} -\omega^1{}_2 \wedge \sigma^2 = -c\, e^y\, \mathrm{d}x \wedge \mathrm{d}y,$$
$$\mathrm{d}\sigma^2 \overset{(2)}{=} -\omega^2{}_1 \wedge \sigma^1 = c\, e^y\, \mathrm{d}x \wedge \mathrm{d}x = 0.$$

(1) First structure equation for $i = 1$.

(2) First structure equation for $i = 2$, with $\omega^2{}_1 = -\omega^1{}_2$.

The second holds for any c, and the first needs $c = 1$. So $\omega^1{}_2 = \mathrm{d}x$ and

$$\Omega^1{}_2 = \mathrm{d}\omega^1{}_2 = \mathrm{d}\mathrm{d}x = 0.$$

The metric is flat. To find the flat coordinates, notice that $\mathrm{d}(e^y) = e^y \mathrm{d}y = \sigma^2$ and $\sigma^1 = e^y \mathrm{d}x$. With $\rho = e^y$ and $\varphi = x$,

$$\mathrm{d}s^2 \overset{(1)}{=} (\sigma^1)^2 + (\sigma^2)^2 \overset{(2)}{=} \rho^2 \,\mathrm{d}\varphi^2 + \mathrm{d}\rho^2.$$

(1) Orthonormal coframe.

(2) $\sigma^1 = \rho \,\mathrm{d}\varphi$ and $\sigma^2 = \mathrm{d}\rho$.

These are polar coordinates, with the frame order swapped: $(e_1, e_2) = (\hat{\varphi}, \hat{\rho})$. (Swapping the frame flips the sign of $\omega^1{}_2$, so $\omega^1{}_2 = +\mathrm{d}\varphi = \mathrm{d}x$ agrees with the polar result $-\mathrm{d}\phi$ of Example T2.22.) The Cartesian coordinates are $X + iY = \rho e^{i\varphi} = e^{y+ix}$. Check: $\left|\mathrm{d}(e^{y+ix})\right|^2 = e^{2y}\,|\mathrm{d}y + i\,\mathrm{d}x|^2 = e^{2y}(\mathrm{d}x^2 + \mathrm{d}y^2)$.

The example has a sting in its tail. The coordinate x runs over all of $\mathbb{R}$, but the angle $\varphi = x$ on the plane is only defined modulo 2π. So the map $(x, y) \mapsto e^{y+ix}$ wraps the (x, y) plane infinitely many times around the punctured plane $\mathbb{R}^2 \setminus \{0\}$. The metric $e^{2y}(\mathrm{d}x^2 + \mathrm{d}y^2)$ is locally flat everywhere, but globally it is the infinite spiral staircase that covers $\mathbb{R}^2 \setminus \{0\}$ (its **universal cover**), not the Euclidean plane. *Curvature decides local equivalence. Global equivalence also needs topology.* The next example shows the difference in its sharpest form.

Worked example T2.48: The cone: flat everywhere except where it isn't

Cut a wedge out of a sheet of paper and glue the edges: you get a cone. In coordinates,

$$\mathrm{d}s^2 = \mathrm{d}r^2 + \beta^2 r^2 \,\mathrm{d}\phi^2, \qquad 0 < \beta \le 1, \quad \phi \sim \phi + 2\pi,$$

where $2\pi\beta$ is the angle of paper that is left. The coframe $\sigma^1 = \mathrm{d}r$, $\sigma^2 = \beta r \,\mathrm{d}\phi$ is the polar one with $\phi \to \beta\phi$, so $\omega^1{}_2 = -\beta \,\mathrm{d}\phi$ and $\Omega^1{}_2 = -\beta \,\mathrm{d}\mathrm{d}\phi = 0$ for $r > 0$. The cone is flat away from the tip. Now apply local Gauss–Bonnet (T2.119) to the disc $D = \{r \le r_0\}$, whose boundary circle has no corners. In the frame $(e_1, e_2) = (\hat{r}, \hat{\phi})$ the tangent of the counterclockwise circle is e_2, so its angle is the constant $\alpha = \pi/2$, and

$$\int_D K \,\mathrm{d}A \overset{(1)}{=} 2\pi - \oint_{r=r_0} \kappa_g \,\mathrm{d}s \overset{(2)}{=} 2\pi - \oint \left(\mathrm{d}\alpha - \omega^1{}_2\right) \overset{(3)}{=} 2\pi - \oint \beta \,\mathrm{d}\phi \overset{(4)}{=} 2\pi(1 - \beta). \quad \text{(T2.137)}$$

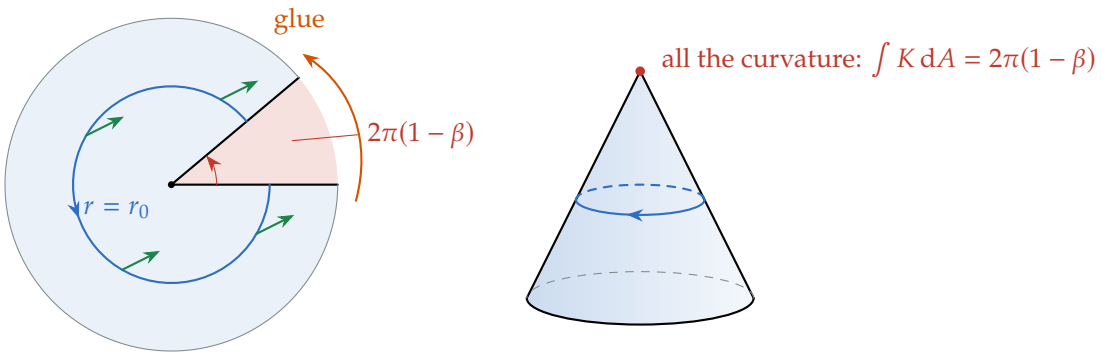
(1) Local Gauss–Bonnet for a disc with smooth boundary: $\sum_k \varepsilon_k = 0$.

(2) The definition (T2.105) of geodesic curvature.

(3) α is constant, so $\mathrm{d}\alpha = 0$; and $-\omega^1{}_2 = \beta \,\mathrm{d}\phi$.

(4) $\oint \mathrm{d}\phi = 2\pi$.

The answer does not depend on r_0. Since $K = 0$ at every $r > 0$, the whole of $2\pi(1 - \beta)$ sits at the tip: $K \,\mathrm{d}A = 2\pi(1 - \beta)\,\delta^2(\text{tip})$. The number $2\pi(1 - \beta)$ is the **deficit angle**, the angle of the wedge we cut out. A vector carried once around the tip by parallel transport comes back rotated by exactly this angle (T2.101). And if we round off the tip by any smooth cap, the cap carries total curvature $2\pi(1 - \beta)$, whatever its shape.



flat paper, wedge removed:
vectors parallel in the plane

$K = 0$ on the sides,
holonomy $2\pi(1-\beta)$ around the tip

Figure T2.29: The cone of Example T2.48. Left: the paper is flat, and a vector field that is parallel in the plane (green) is parallel on the cone. But after gluing the red wedge shut, a vector carried around the circle $r = r_0$ comes back rotated by the missing angle. Right: the cone is flat on its sides, and Gauss–Bonnet puts the whole deficit $2\pi(1-\beta)$ at the tip.

Physical picture: Deficit angles in physics

Descartes' version of Gauss–Bonnet (Section T2.8) is the polyhedral case of (T2.137): each vertex of a polyhedron is a cone point with deficit $2\pi - \sum(\text{face angles})$, and the deficits add up to 4π. The space around a straight cosmic string in general relativity is a cone times a line, with deficit angle $8\pi G\mu$ set by the string tension μ. The orbifold $\mathbb{C}/\mathbb{Z}_N$ of string theory is the cone with $\beta = 1/N$. Regge's lattice gravity builds curved space out of flat simplices and puts all curvature into deficit angles at the hinges.

How hard is the general problem? When the curvature does not vanish, comparing two metrics means comparing their curvature components *and their covariant derivatives*, up to some finite order, after bringing both lists into a canonical form. How many numbers is that? In an orthonormal frame the $\frac{1}{2}n(n-1)$ curvature 2-forms Ω_{ij} each have $N = \frac{1}{2}n(n-1)$ components, giving R_{ijkl} antisymmetric in ij and in kl. Counting,

$$\#R_{ijkl} \overset{(1)}{=} \tfrac{1}{2}N(N+1) - \binom{n}{4} \overset{(2)}{=} \frac{n^2(n^2-1)}{12}, \qquad \text{e.g. } n=4:\ \tfrac{1}{2}\cdot 6\cdot 7 - 1 = 20. \tag{T2.138}$$

(1) The pair symmetry $R_{ijkl} = R_{klij}$ makes R a symmetric $N \times N$ matrix, with $\frac{1}{2}N(N+1)$ entries. The first Bianchi identity (T2.98), $\Omega^i{}_j \wedge \sigma^j = 0$, then removes one more condition for each set of four distinct indices (the totally antisymmetric part $R_{[ijkl]}$ must vanish).

(2) Algebra; the values are $1, 6, 20$ for $n = 2, 3, 4$.

Each derivative adds n more index values. Dray quotes the practical outcome for four-dimensional spacetimes [Dray §20.1], summarised in Table T2.1.

T2.9.2 Lagrangians are top forms: gravity in two dimensions is topology

A Lagrangian density is an n-form, and the action is its integral [Dray §20.2]. We varied the scalar-field and Maxwell actions in Section T2.2.8. Dray lists a third Lagrangian, for gravity [Dray (20.18)]:

$$L_{\mathrm{EH}} = \Omega_{ij} \wedge \star(\sigma^i \wedge \sigma^j), \tag{T2.139}$$

summed over i, j, with the frame index of Ω lowered ($\Omega_{ij} = \Omega^i{}_j$ in Euclidean signature). Let us check that this is the familiar Einstein–Hilbert density $R\,\mathrm{d}V$. Write $\Omega_{ij} = \frac{1}{2}R_{ijkl}\,\sigma^k \wedge \sigma^l$ (T2.96)

Method	highest derivative needed	independent components
naive coordinate components	20	79 310
orthonormal frame (Cartan)	10	8 690
spinor (two-component) formalism	7	3 156
every known exact solution so far	3	430

Table T2.1: The cost of the equivalence problem in four dimensions, as quoted by Dray. Orthonormal frames, the method of this chapter, cut the work by a factor of about ten. Spinors, the "square roots of vectors" of Section T2.9.4, cut it again.

and use $\alpha \wedge \star\beta = \langle \alpha, \beta \rangle \, \mathrm{d}V$ with $\langle \sigma^k \wedge \sigma^l, \sigma^i \wedge \sigma^j \rangle = \delta^{ki}\delta^{lj} - \delta^{kj}\delta^{li}$:

$$\begin{aligned} L_{\mathrm{EH}} &\overset{(1)}{=} \tfrac{1}{2} R_{ijkl}\, \sigma^k \wedge \sigma^l \wedge \star(\sigma^i \wedge \sigma^j) \\ &\overset{(2)}{=} \tfrac{1}{2} R_{ijkl} \big(\delta^{ki}\delta^{lj} - \delta^{kj}\delta^{li}\big)\, \mathrm{d}V \\ &\overset{(3)}{=} \tfrac{1}{2} \big(R_{ijij} - R_{ijji}\big)\, \mathrm{d}V \overset{(4)}{=} R_{ijij}\, \mathrm{d}V \overset{(5)}{=} R\, \mathrm{d}V. \end{aligned} \tag{T2.140}$$

(1) Insert the components of Ω_{ij}.
(2) $\alpha \wedge \star\beta = \langle \alpha, \beta \rangle \, \mathrm{d}V$, and the inner product of basis 2-forms is $+1$ for the same pair in the same order, -1 in the opposite order, 0 otherwise.
(3) Contract the Kronecker deltas.
(4) $R_{ijji} = -R_{ijij}$ (antisymmetry in the last pair).
(5) The scalar curvature is the full contraction $R = R^{ij}{}_{ij}$ (T2.97).

Varying $\int L_{\mathrm{EH}}$ with respect to the coframe gives Einstein's equation in vacuum. That calculation is longer than the scalar one but uses nothing new: the variation of Ω is $\mathrm{d}\,\delta\omega + [\omega, \delta\omega]$, and a Stokes-theorem integration by parts moves the d.

Worked example T2.49: The Einstein–Hilbert action of a closed surface

In two dimensions $\star(\sigma^1 \wedge \sigma^2) = 1$ and $\star(\sigma^2 \wedge \sigma^1) = -1$. Then

$$\int_\Sigma L_{\mathrm{EH}} \overset{(1)}{=} \int_\Sigma \big(\Omega_{12} \cdot 1 + \Omega_{21} \cdot (-1)\big) \overset{(2)}{=} 2 \int_\Sigma \Omega^1{}_2 \overset{(3)}{=} 2 \int_\Sigma K \, \mathrm{d}A \overset{(4)}{=} 4\pi\, \chi(\Sigma). \tag{T2.141}$$

(1) Only $i \neq j$ contributes, since $\Omega_{11} = \Omega_{22} = 0$.
(2) $\Omega_{21} = -\Omega_{12}$ (T2.86).
(3) $\Omega^1{}_2 = K\, \sigma^1 \wedge \sigma^2 = K\, \mathrm{d}A$ (T2.88).
(4) Global Gauss–Bonnet (T2.124).

(Consistently with (T2.140), $R = 2K$ in two dimensions.) The action is the same number for *every* metric on Σ. Its variation with respect to the metric is identically zero, so it produces no field equation at all. *Two-dimensional Einstein gravity has no dynamics; its action is a topological invariant.*

Dictionary: the string coupling counts handles

In string theory the world sheet is a surface Σ and the Polyakov path integral contains exactly this term: $\frac{\lambda}{4\pi} \int_\Sigma R \, \mathrm{d}A = \lambda\, \chi(\Sigma)$. In the sum over world sheets it contributes a weight $e^{-\lambda\chi} = e^{-\lambda(2-2g)} = g_s^{2g-2}$ with $g_s = e^{\lambda}$. So a surface with g handles is suppressed by g_s^{2g-2}: the genus expansion of string perturbation theory is a Gauss–Bonnet expansion (Chapter 9). The four-dimensional analogue, the Pfaffian (T2.135), is likewise a total derivative that can

be added to the gravitational action without changing the field equations.

T2.9.3 The Clifford product of forms

Quantum mechanics hands us objects that the wedge product cannot produce: the Pauli matrices, which square to one, and the Dirac matrices. Dray shows that differential forms already contain them, if we allow ourselves to add forms of different degrees and to multiply them with a new product [Dray §20.3].

Working definition T2.18 (Clifford product)

For functions f and 1-forms α, β define [Dray (20.19)–(20.20)]

$$f \vee \alpha = f\alpha, \qquad \alpha \vee \beta = \alpha \wedge \beta + g(\alpha, \beta), \tag{T2.142}$$

[$g(\alpha,\beta)$ is the metric's dot product of 1-forms, $g(\sigma^i, \sigma^j) = \delta^{ij}$ for an orthonormal Euclidean coframe] and extend to sums of forms of all degrees by requiring the product to be associative and distributive. The symbol $\vee$ is read "vee". The space of mixed-degree forms with this product is the **Clifford algebra** $\mathrm{Cl}(V)$ of the cotangent space V [the 1-forms at one point].

How to compute: in an orthonormal coframe $\{e^i\}$, a product of basis 1-forms is simplified by two rules: distinct ones anticommute and combine into a wedge, $e^i \vee e^j = e^i \wedge e^j = -e^j \vee e^i$ for $i \neq j$; a repeated one cancels in pairs, $e^i \vee e^i = g(e^i, e^i) = \pm 1$ (always +1 in Euclidean signature).

The two rules follow from (T2.142): for $i \neq j$ the metric term $g(e^i, e^j)$ is zero, and for $i = j$ the wedge $e^i \wedge e^i$ is zero. The symmetric and antisymmetric parts of $\vee$ are

$$\alpha \vee \beta + \beta \vee \alpha = 2g(\alpha,\beta), \qquad \alpha \vee \beta - \beta \vee \alpha = 2\,\alpha \wedge \beta. \tag{T2.143}$$

The first of these is the defining relation of the Pauli and Dirac matrices, $\{\gamma^i, \gamma^j\} = 2g^{ij}$. That is the whole secret.

Worked example T2.50: Dray's triple product

Dray states [Dray (20.21)]

$$\alpha \vee \beta \vee \gamma = \alpha \wedge \beta \wedge \gamma + g(\alpha,\beta)\,\gamma - g(\alpha,\gamma)\,\beta + g(\beta,\gamma)\,\alpha. \tag{T2.144}$$

Both sides are linear in each of α, β, γ, so it is enough to check them on orthonormal basis 1-forms in Euclidean signature. There are five cases, up to renaming.

$$e^1 \vee e^2 \vee e^3 \overset{(1)}{=} e^1 \wedge e^2 \wedge e^3 \qquad \text{RHS: } e^{123} + 0 - 0 + 0,$$

$$e^1 \vee e^1 \vee e^2 \overset{(2)}{=} (e^1 \vee e^1) \vee e^2 = e^2 \qquad \text{RHS: } 0 + e^2 - 0 + 0,$$

$$e^1 \vee e^2 \vee e^1 \overset{(3)}{=} -e^1 \vee e^1 \vee e^2 = -e^2 \qquad \text{RHS: } 0 + 0 - e^2 + 0,$$

$$e^2 \vee e^1 \vee e^1 \overset{(4)}{=} e^2 \vee (e^1 \vee e^1) = e^2 \qquad \text{RHS: } 0 + 0 - 0 + e^2,$$

$$e^1 \vee e^1 \vee e^1 \overset{(5)}{=} (e^1 \vee e^1) \vee e^1 = e^1 \qquad \text{RHS: } 0 + e^1 - e^1 + e^1.$$

(1) Distinct basis forms: the product is the wedge. On the right only the wedge survives, since all inner products vanish.
(2) Associativity and $e^1 \vee e^1 = 1$. On the right only $g(\alpha,\beta)\gamma = g(e^1, e^1)e^2$ survives.

(3) Anticommute the middle e^2 past the last e^1. On the right only $-g(\alpha,\gamma)\beta = -e^2$ survives.
(4) Associativity. On the right only $g(\beta,\gamma)\alpha = e^2$ survives.
(5) Associativity. On the right all three metric terms are e^1, with signs $+,-,+$.

All five agree, so (T2.144) holds. Read it as a rule: *the Clifford product is the wedge product plus all possible contractions*, each contraction carrying the sign needed to bring the contracted pair next to each other.

The same bookkeeping gives the product of a 1-form with a p-form, which we need below:

$$\alpha \vee \omega = \alpha \wedge \omega + \iota_{\alpha^\sharp}\omega, \tag{T2.145}$$

where $\alpha^\sharp$ is the vector dual to α and ι is the interior product (Chapter T1). Check it on basis forms in $\mathbb{R}^2$: $e^1 \vee e^{12} = e^1 \vee e^1 \vee e^2 = e^2$, while $e^1 \wedge e^{12} + \iota_{e_1}(e^1 \wedge e^2) = 0 + e^2$; and $e^2 \vee e^{12} = e^2 \vee e^1 \vee e^2 = -e^1 \vee e^2 \vee e^2 = -e^1$, while $e^2 \wedge e^{12} + \iota_{e_2}(e^1 \wedge e^2) = 0 - e^1$. (Here $e^{12} := e^1 \wedge e^2$.)

Worked example T2.51: The Clifford algebra of the plane is the Pauli algebra

On $\mathbb{R}^2$ with coframe $e^1 = \mathrm{d}x$, $e^2 = \mathrm{d}y$, a general element is

$$\Phi = f + a\,e^1 + b\,e^2 + h\,e^{12},$$

so $\mathrm{Cl}(\mathbb{R}^2)$ is four-dimensional. The full multiplication table is shown in Figure T2.30. The only entry needing thought is

$$e^{12} \vee e^{12} \overset{(1)}{=} e^1 \vee e^2 \vee e^1 \vee e^2 \overset{(2)}{=} -e^1 \vee e^1 \vee e^2 \vee e^2 \overset{(3)}{=} -1.$$

(1) $e^{12} = e^1 \wedge e^2 = e^1 \vee e^2$ (distinct factors).
(2) Anticommute the middle pair.
(3) $e^1 \vee e^1 = e^2 \vee e^2 = 1$.

The area element squares to -1: it is a square root of -1 made of geometry. The even part $\{f + h\,e^{12}\}$ is a copy of the complex numbers, with e^{12} playing i. And e^{12} rotates 1-forms by a right angle: $e^1 \vee e^{12} = e^2$ and $e^2 \vee e^{12} = -e^1$.
Now compare the Pauli matrices. The assignment

$$1 \mapsto \mathbb{1}, \qquad e^1 \mapsto \sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad e^2 \mapsto \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \qquad e^{12} \mapsto \sigma_1\sigma_2 = \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix} = i\sigma_3 \tag{T2.146}$$

respects every product: $\sigma_1^2 = \sigma_2^2 = \mathbb{1}$ matches $e^i \vee e^i = 1$; $\sigma_1\sigma_2 = -\sigma_2\sigma_1$ matches anticommutation; and $(i\sigma_3)^2 = -\mathbb{1}$ matches $e^{12} \vee e^{12} = -1$. The four matrices $\mathbb{1}, \sigma_1, \sigma_2, i\sigma_3$ are linearly independent and span all 2×2 complex matrices over $\mathbb{C}$, so $\mathrm{Cl}(\mathbb{R}^2) \otimes \mathbb{C}$ is the algebra of 2×2 complex matrices. *Mixed-degree forms on the plane, multiplied with $\vee$, are 2×2 matrices.*

Worked example T2.52: Three dimensions: Pauli matrices and a central i

On $\mathbb{R}^3$ the Clifford algebra has dimension $1+3+3+1 = 8 = 2^3$, one basis element for each subset of $\{1,2,3\}$. The assignment $e^k \mapsto \sigma_k$ works again, since $\sigma_j\sigma_k + \sigma_k\sigma_j = 2\delta_{jk}$. Then the volume element becomes

$$e^{123} = e^1 \vee e^2 \vee e^3 \;\mapsto\; \sigma_1\sigma_2\sigma_3 \overset{(1)}{=} (i\sigma_3)\sigma_3 \overset{(2)}{=} i\,\mathbb{1}.$$

$\vee$	1	e^1	e^2	e^{12}
1	1	e^1	e^2	e^{12}
e^1	e^1	1	e^{12}	e^2
e^2	e^2	$-e^{12}$	1	$-e^1$
e^{12}	e^{12}	$-e^2$	e^1	-1

Pauli image

$\longrightarrow \mathbb{1}$

$\longrightarrow \sigma_1$

$\longrightarrow \sigma_2$

$\longrightarrow \sigma_1\sigma_2 = i\sigma_3$

Figure T2.30: The multiplication table of $\mathrm{Cl}(\mathbb{R}^2)$: the entry in row A, column B is $A \vee B$. Scalars are white, 1-forms blue, the area element orange. The table is not symmetric: distinct 1-forms anticommute. The red entry says the area element squares to -1. On the right, the Pauli matrices reproduce the table exactly.

(1) $\sigma_1\sigma_2 = i\sigma_3$.
(2) $\sigma_3^2 = \mathbb{1}$.

So in three dimensions the volume element commutes with everything and squares to -1: it is "the" i of quantum mechanics. The bivectors become $e^{23} \mapsto i\sigma_1$, $e^{31} \mapsto i\sigma_2$, $e^{12} \mapsto i\sigma_3$, which are (2×) the anti-Hermitian generators of SU(2): the even part of $\mathrm{Cl}(\mathbb{R}^3)$ is the quaternions, and the rotation generators of spin-$\frac{1}{2}$ are 2-forms. This is the start of the Spin(3) = SU(2) story of Chapter T4.

In four-dimensional spacetime with coframe $\{\sigma^\mu\}$, the same construction with $g(\sigma^\mu, \sigma^\nu) = g^{\mu\nu}$ gives $\sigma^\mu \vee \sigma^\nu + \sigma^\nu \vee \sigma^\mu = 2g^{\mu\nu}$. This is the Dirac algebra, under Dray's identification [Dray (20.22)]

$$\gamma^\mu \longleftrightarrow \sigma^\mu.$$

In rectangular coordinates $\sigma^\mu = \mathrm{d}x^\mu$, so *the gamma matrices are the coordinate differentials*, multiplied with $\vee$. The algebra has dimension $2^4 = 16$, the number of independent 4×4 matrices built from $\mathbb{1}, \gamma^\mu, \gamma^{\mu\nu}, \gamma^{\mu\nu\rho}, \gamma^5$: the familiar $1 + 4 + 6 + 4 + 1$ of the Fierz basis is the $1 + 4 + 6 + 4 + 1$ of forms of degree $0, 1, 2, 3, 4$.

T2.9.4 Spinors live inside the Clifford algebra

If the gamma matrices are forms, what does a gamma matrix act *on*? A spinor is a column vector, but the Clifford algebra acts on itself by left multiplication, and that is too big: in 2D it is a four-component space, while a spinor has two. The fix is to keep only a subspace preserved by left multiplication. "Spinors actually live in certain subspaces of Clifford algebras" [Dray §20.3]. Here is that subspace, written down.

Worked example T2.53: Two-component spinors as forms on the plane

In $\mathrm{Cl}(\mathbb{R}^2)$ take

$$P = \tfrac{1}{2}(1 + e^1).$$

It is a projector:

$$P \vee P \overset{(1)}{=} \tfrac{1}{4}(1 + 2e^1 + e^1 \vee e^1) \overset{(2)}{=} \tfrac{1}{4}(2 + 2e^1) = P.$$

(1) Expand; 1 commutes with everything.
(2) $e^1 \vee e^1 = 1$.

The set $S = \mathrm{Cl}(\mathbb{R}^2) \vee P$ of all left multiples of P is closed under left multiplication, since $A \vee (B \vee P) = (A \vee B) \vee P$. Such a subspace is called a **left ideal**. It is two-dimensional, spanned by

$$u_1 = P = \tfrac{1}{2}(1 + e^1), \qquad u_2 = e^2 \vee P = \tfrac{1}{2}(e^2 - e^{12}),$$

because the other two left multiples are not new: $e^1 \vee P = \tfrac{1}{2}(e^1 + 1) = u_1$ and $e^{12} \vee P = \tfrac{1}{2}(e^{12} + e^1 \vee e^2 \vee e^1) = \tfrac{1}{2}(e^{12} - e^2) = -u_2$. Now let the generators act:

$$e^1 \vee u_1 \overset{(1)}{=} u_1, \qquad e^1 \vee u_2 \overset{(2)}{=} -e^2 \vee e^1 \vee P = -e^2 \vee P = -u_2,$$
$$e^2 \vee u_1 \overset{(3)}{=} u_2, \qquad e^2 \vee u_2 \overset{(4)}{=} e^2 \vee e^2 \vee P = u_1.$$

(1) Computed above.
(2) Anticommute e^1 past e^2, then use $e^1 \vee P = P$.
(3) Definition of u_2.
(4) $e^2 \vee e^2 = 1$.

In the basis (u_1, u_2) the left action of the generators is therefore

$$e^1 \mapsto \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = \sigma_3, \qquad e^2 \mapsto \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \sigma_1. \tag{T2.147}$$

These two matrices square to $\mathbb{1}$ and anticommute, so they satisfy the same algebra as e^1, e^2. So a **spinor** on the plane is a form in the ideal S,

$$\psi = \psi_1 u_1 + \psi_2 u_2 = \tfrac{1}{2}\psi_1 + \tfrac{1}{2}\psi_1\,\mathrm{d}x + \tfrac{1}{2}\psi_2\,\mathrm{d}y - \tfrac{1}{2}\psi_2\,\mathrm{d}x \wedge \mathrm{d}y,$$

with components (ψ_1, ψ_2), and the gamma matrices act on it by the Pauli matrices (T2.147). (These are σ_3, σ_1 rather than σ_1, σ_2. The two sets are related by a unitary change of basis; any two irreducible representations of the Clifford algebra are equivalent.) The complementary projector $P' = \tfrac{1}{2}(1 - e^1)$ gives a second ideal S', and since $P + P' = 1$ every form is uniquely the sum of a piece in S and a piece in S': $\mathrm{Cl}(\mathbb{R}^2) = S \oplus S'$, *four form components are two two-component spinors*.

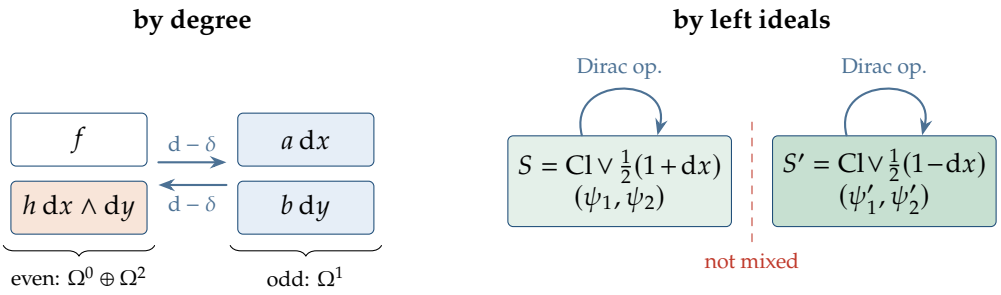


Figure T2.31: Two ways to cut the four components of a form on the plane. Left: by degree parity. The operator $\mathrm{d} - \delta$ always changes degree by one, so it swaps even and odd forms; this is the grading whose index is the Euler characteristic. Right: by left ideals. Left Clifford multiplication preserves each ideal, so $\mathrm{d} - \delta$ acts inside each one as an ordinary two-component Dirac operator.

T2.9.5 The Kähler–Dirac operator: a square root of the Laplacian

Dirac wanted a first-order operator whose square is the wave operator. The gamma matrices were invented for that. We now have gamma matrices made of forms, so we should look for

the corresponding first-order operator on forms. Dray's answer is the **Kähler operator** $\mathrm{d}-\delta$ with [Dray (20.23)]

$$\delta\omega = (-1)^p \star^{-1}\mathrm{d}\star\omega \qquad (\omega \text{ a } p\text{-form}). \tag{T2.148}$$

(This δ has nothing to do with the variational δ of Section T2.9.2.) It lowers the degree by one. In Riemannian signature, using $\star\star = (-1)^{k(n-k)}$ on k-forms, a short sign count shows $\delta = (-1)^{n(p+1)+1}\star\mathrm{d}\star$, which is exactly the adjoint d^* of Sections T2.2.6 and T2.4.9. So $\delta = \mathrm{d}^*$, and $\delta^2 = \pm\star\mathrm{d}\mathrm{d}\star = 0$.

The square. Because $\mathrm{d}^2 = 0$ and $\delta^2 = 0$,

$$(\mathrm{d}-\delta)^2 = \mathrm{d}^2 - \mathrm{d}\delta - \delta\mathrm{d} + \delta^2 = -(\mathrm{d}\delta + \delta\mathrm{d}) \tag{T2.149}$$

[Dray (20.24)]. On a function f we have $\delta f = 0$ (there are no (-1)-forms), so

$$(\mathrm{d}-\delta)^2 f \overset{(1)}{=} -\mathrm{d}\delta f - \delta\mathrm{d}f \overset{(2)}{=} 0 - (-1)^1\star^{-1}\mathrm{d}\star\mathrm{d}f \overset{(3)}{=} \Delta f. \tag{T2.150}$$

(1) (T2.149).
(2) $\delta f = 0$; and $\mathrm{d}f$ is a 1-form, so $p = 1$ in (T2.148).
(3) $\star\mathrm{d}f$ is the flux form of $\vec{\nabla}f$, its d is $(\nabla^2 f)\,\mathrm{d}V$, and $\star^{-1}$ strips off $\mathrm{d}V$: the result is $\nabla^2 f = \Delta f$ [Dray (20.25)].

So $\mathrm{d}-\delta$ is a square root of the Laplacian (and, in Minkowski signature, of the wave operator). That is exactly the job of the Dirac operator.

Watch out: Two Laplacians with opposite signs

Dray's Δ is the physicist's $\nabla^2 = \partial_x^2 + \partial_y^2 + \dots$, whose eigenvalues on a closed manifold are ≤ 0. The Hodge Laplacian $\Delta_{\text{Hodge}} = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$ of Section T2.4.9 and of Nash is $-\nabla^2$ on functions in $\mathbb{R}^n$, with eigenvalues ≥ 0. The two are related by (T2.149): $(\mathrm{d}-\delta)^2 = -\Delta_{\text{Hodge}}$. Always check which sign a book means.

It really is $\gamma^i\partial_i$. On $\mathbb{R}^n$ with Cartesian coordinates, $\mathrm{d}\omega = e^i \wedge \partial_i\omega$ (the derivative acts on the coefficients), and the adjoint is minus the contraction, $\delta\omega = -\iota_{e_i}\partial_i\omega$ (checked below in 2D). Then by (T2.145)

$$e^i \vee \partial_i\omega \overset{(1)}{=} e^i \wedge \partial_i\omega + \iota_{e_i}\partial_i\omega \overset{(2)}{=} \mathrm{d}\omega - \delta\omega. \tag{T2.151}$$

(1) The Clifford product of a 1-form with a p-form (T2.145); e^i is constant, so ∂_i passes through it.
(2) The Cartesian formulas for d and δ.

So $\mathrm{d}-\delta = e^i \vee \partial_i$, which under $e^i \leftrightarrow \gamma^i$ is the Dirac operator $\gamma^i\partial_i$. Its square is $e^i \vee e^j\,\partial_i\partial_j = \frac{1}{2}(e^i\vee e^j + e^j \vee e^i)\,\partial_i\partial_j = \delta^{ij}\partial_i\partial_j = \nabla^2$, by (T2.143), the same computation Dirac did with matrices.

Worked example T2.54: The Kähler–Dirac equation on the plane, component by component

Let $\Phi = f + a\,\mathrm{d}x + b\,\mathrm{d}y + h\,\mathrm{d}x\wedge\mathrm{d}y$ on $\mathbb{R}^2$. With $\star 1 = \mathrm{d}x\wedge\mathrm{d}y$, $\star\mathrm{d}x = \mathrm{d}y$, $\star\mathrm{d}y = -\mathrm{d}x$, $\star(\mathrm{d}x\wedge\mathrm{d}y) = 1$, and $\star^{-1} = -\star$ on 1-forms, $\star^{-1} = \star$ on 0- and 2-forms:

$$\mathrm{d}\Phi \overset{(1)}{=} f_x\,\mathrm{d}x + f_y\,\mathrm{d}y + (b_x - a_y)\,\mathrm{d}x\wedge\mathrm{d}y,$$
$$\delta(a\,\mathrm{d}x + b\,\mathrm{d}y) \overset{(2)}{=} -\star^{-1}\mathrm{d}(a\,\mathrm{d}y - b\,\mathrm{d}x) = -(a_x + b_y),$$

$$\delta(h\,\mathrm{d}x\wedge\mathrm{d}y)\overset{(3)}{=}\star^{-1}\mathrm{d}h=-\star(h_x\,\mathrm{d}x+h_y\,\mathrm{d}y)=h_y\,\mathrm{d}x-h_x\,\mathrm{d}y.$$

(1) $\mathrm{d}f=f_x\mathrm{d}x+f_y\mathrm{d}y$; $\mathrm{d}(a\,\mathrm{d}x+b\,\mathrm{d}y)=(b_x-a_y)\,\mathrm{d}x\wedge\mathrm{d}y$; d of a 2-form on $\mathbb{R}^2$ is zero.
(2) $p=1$: sign -1; $\star$ of the 1-form; $\mathrm{d}(a\,\mathrm{d}y-b\,\mathrm{d}x)=(a_x+b_y)\mathrm{d}x\wedge\mathrm{d}y$; $\star^{-1}$ of that is a_x+b_y. This is minus the divergence, as for d^*.
(3) $p=2$: sign $+1$; $\star(h\,\mathrm{d}x\wedge\mathrm{d}y)=h$; then $\star^{-1}=-\star$ on the 1-form $\mathrm{d}h$.

(Items (2) and (3) confirm $\delta=-\iota_{e_i}\partial_i$: e.g. $-\iota_{\partial_x}\partial_x(h\,\mathrm{d}x\wedge\mathrm{d}y)-\iota_{\partial_y}\partial_y(h\,\mathrm{d}x\wedge\mathrm{d}y)=-h_x\,\mathrm{d}y+h_y\,\mathrm{d}x$.) Collecting by degree,

$$(\mathrm{d}-\delta)\Phi=(a_x+b_y)+(f_x-h_y)\,\mathrm{d}x+(f_y+h_x)\,\mathrm{d}y+(b_x-a_y)\,\mathrm{d}x\wedge\mathrm{d}y. \tag{T2.152}$$

Read off two facts.
(i) Even and odd are swapped. The even data (f,h) appear only in the odd (1-form) part of the result, and the odd data (a,b) only in the even part. Zero modes satisfy two separate systems:

$$f_x=h_y,\quad f_y=-h_x\qquad\text{and}\qquad a_x=-b_y,\quad a_y=b_x.$$

These are the Cauchy–Riemann equations: $f+ih$ and $a-ib$ are holomorphic functions of $z=x+iy$. *The zero modes of the Kähler–Dirac operator on the plane are pairs of holomorphic functions.*
(ii) Each ideal carries a Dirac equation. Insert the spinor of Example T2.53, $f=a=\frac{1}{2}\psi_1$, $b=-h=\frac{1}{2}\psi_2$, into (T2.152):

$$\begin{aligned}(\mathrm{d}-\delta)\psi&\overset{(1)}{=}\tfrac{1}{2}(\partial_x\psi_1+\partial_y\psi_2)(1+\mathrm{d}x)+\tfrac{1}{2}(\partial_y\psi_1-\partial_x\psi_2)(\mathrm{d}y-\mathrm{d}x\wedge\mathrm{d}y)\\&\overset{(2)}{=}(\partial_x\psi_1+\partial_y\psi_2)\,u_1+(\partial_y\psi_1-\partial_x\psi_2)\,u_2.\end{aligned}$$

(1) Substitute: the scalar and $\mathrm{d}x$ coefficients are both $\frac{1}{2}(\partial_x\psi_1+\partial_y\psi_2)$, and the $\mathrm{d}y$ and $\mathrm{d}x\wedge\mathrm{d}y$ coefficients are $\pm\frac{1}{2}(\partial_y\psi_1-\partial_x\psi_2)$.
(2) $u_1=\frac{1}{2}(1+\mathrm{d}x)$ and $u_2=\frac{1}{2}(\mathrm{d}y-\mathrm{d}x\wedge\mathrm{d}y)$.

The result is again in the ideal S, and in components

$$\begin{pmatrix}\psi_1\\\psi_2\end{pmatrix}\longmapsto\begin{pmatrix}\partial_x&\partial_y\\\partial_y&-\partial_x\end{pmatrix}\begin{pmatrix}\psi_1\\\psi_2\end{pmatrix}=\left(\sigma_3\partial_x+\sigma_1\partial_y\right)\begin{pmatrix}\psi_1\\\psi_2\end{pmatrix},$$

the two-dimensional Dirac operator in the representation (T2.147). Its square is $(\partial_x^2+\partial_y^2)\mathbb{1}$, since σ_3 and σ_1 anticommute.

Physical picture: Four tastes on the lattice

In n dimensions forms have 2^n components and a Dirac spinor has $2^{n/2}$ (for n even), so the Kähler–Dirac field is $2^{n/2}$ copies of a Dirac field. In four dimensions that is four copies. Lattice QCD knows this well: the Kogut–Susskind ("staggered") lattice fermion is a discretised Kähler–Dirac field, with one field component per lattice cell of each dimension (sites, links, plaquettes, cubes, hypercubes), and it describes four "tastes" of quark. The forms-to-spinors dictionary of this section is how one untangles them.

The index connection. Nash's operator for the Euler characteristic (Section T2.8.9) is $\mathrm{d}+\mathrm{d}^*$ from even to odd forms. On the plane, (T2.152) shows $\mathrm{d}-\delta$ does the same even→odd swap, and $\mathrm{d}+\delta$ differs from it only by the sign of δ (they have the same kernel on a closed manifold,

the harmonic forms, since $\ker(\mathrm{d}\pm\delta)=\ker\mathrm{d}\cap\ker\delta$ there). So

$$\operatorname{index}\bigl(\mathrm{d}+\mathrm{d}^{*}:\Omega^{\text{even}}\to\Omega^{\text{odd}}\bigr)=\chi(M)=\int_{M}e$$

is an index theorem for the Kähler–Dirac operator with the even/odd grading. Replace the grading by chirality inside one spinor ideal, and the same operator becomes the chiral Dirac operator, whose index is the $\hat{A}$-genus instead of the Euler number (Chapter 4). The Euler characteristic and the Dirac index are two readings of one Clifford module.

Reading Nash (p. 114, (4.99)–(4.101))

Nash introduces the Dirac matrices through their anticommutator, $\gamma_a\gamma_b+\gamma_b\gamma_a=-2\delta_{ab}\mathbb{1}$, and the chirality operator $\gamma_5=i^{n(n+1)/2}\gamma_1\cdots\gamma_n$ with $\gamma_5^2=\mathbb{1}$ [Nash (4.99)]. The minus sign is the anti-Hermitian convention of these notes: Nash's γ_a is i times a Hermitian gamma matrix, and in the language of this section it corresponds to replacing $+g$ by $-g$ in (T2.142). The Dirac operator is $\not{D}=\gamma^a e_a^\mu(x)(\partial_\mu+\omega_\mu)$ with $e_\mu^a e_\nu^b\delta_{ab}=g_{\mu\nu}$ [Nash (4.100)]. Every ingredient is now familiar: e_μ^a is the vielbein of Section T2.5.2, the coframe $\sigma^a=e_\mu^a\mathrm{d}x^\mu$; ω_μ is the connection of Section T2.5 acting on spinors through the rotation generators $\frac{1}{4}\omega_{ab}\gamma^a\gamma^b$ (the 2-forms of Example T2.52); and $\gamma^a e_a^\mu\partial_\mu$ is the flat-space $e^i\vee\partial_i$ of (T2.151). Check the 2D chirality: with $\gamma_a=i\sigma_a$, $\gamma_5=i^3\gamma_1\gamma_2=(-i)(i\sigma_1)(i\sigma_2)=(-i)(-i\sigma_3)=-\sigma_3$, which squares to $\mathbb{1}$ and anticommutes with both γ_a. The splitting $E=E^+\oplus E^-$ by γ_5 [Nash (4.101)] is the chiral analogue of the even/odd splitting of Figure T2.31.

T2.9.6 Topology revisited: what "no holes" means

Dray's topology section [Dray §20.4] restates the facts of Sections T2.3 and T2.4: exact implies closed because $\mathrm{d}^2=0$, which contains $\vec{\nabla}\times\vec{\nabla}f=0$ and $\vec{\nabla}\cdot\vec{\nabla}\times\vec{A}=0$; potentials are unique only up to adding an exact form [Dray (20.29)–(20.30)]; and $\mathrm{d}\phi$ on the circle is closed, has period 2π, and so is not exact, which organises into $H^1_{\mathrm{dR}}(S^1)=\mathbb{R}$ [Dray (20.31)–(20.36)]. We did all of this in detail. Two remarks remain.

Watch out: Naming, and a wrong converse

Naming. "Exact implies closed" is sometimes called the Poincaré lemma (Dray does this), and the converse "closed implies locally exact" is *also* called the Poincaré lemma (we did this in Section T2.3.3). Dray warns about the ambiguity. In these notes *Poincaré lemma* means the converse, on star-shaped regions.
A wrong converse. Dray states that on a simply connected region of $\mathbb{R}^n$ all closed p-forms are exact. That is true for $p=1$ only. Simple connectivity says every loop can be shrunk to a point, so every period of a closed 1-form vanishes and the line-integral construction of the potential works. It says nothing about spheres. The region $\mathbb{R}^3\setminus\{0\}$ is simply connected, since a loop can always slide off the missing point, yet the Coulomb 2-form is closed and not exact (Example T2.6 and Section T2.4.5):

$$E=\frac{x\,\mathrm{d}y\wedge\mathrm{d}z+y\,\mathrm{d}z\wedge\mathrm{d}x+z\,\mathrm{d}x\wedge\mathrm{d}y}{r^3},\qquad \mathrm{d}E=0,\qquad \int_{S^2}E=4\pi\neq0.$$

The correct hypotheses are: contractible (for example star-shaped) regions have *all* closed forms exact; simply connected regions have closed *1-forms* exact.

Which closed-but-not-exact forms a region carries is a fingerprint of the region, and each one is a familiar field. Table T2.2 collects the basic cases in $\mathbb{R}^3$. The most instructive is the last row.

Region	simply conn.?	b_1	b_2	closed, non-exact field
$\mathbb{R}^3$ or a ball	yes	0	0	none: every curl-free field is a gradient, every divergence-free field is a curl
$\mathbb{R}^3 \setminus \{\text{point}\}$	yes	0	1	Coulomb/monopole flux 2-form (flux through an enclosing sphere)
$\mathbb{R}^3 \setminus \{\text{line}\}$	no	1	0	magnetic field of a straight wire, $B \propto \mathrm{d}\phi$ (circulation around the wire)
$\mathbb{R}^3 \setminus \{\text{circle}\}$	no	1	1	field of a current loop (circulation through the ring) and electric field of a charged ring (flux through an enclosing sphere)

Table T2.2: Closed but not exact forms detect holes of different dimensions. A removed point is a hole that a sphere can surround (b_2); a removed line is a hole that a loop can go around (b_1); a removed circle is both.

Worked example T2.55: Ampère's law is the Stokes detector

A steady current I runs along the z-axis. Outside the wire the magnetic field is $\vec{B} = \frac{\mu_0 I}{2\pi\rho}\,\hat{\phi}$ (cylindrical coordinates ρ, ϕ, z). Its 1-form is

$$B \overset{(1)}{=} B_\phi\, \sigma^\phi \overset{(2)}{=} \frac{\mu_0 I}{2\pi\rho}\,\rho\,\mathrm{d}\phi \overset{(3)}{=} \frac{\mu_0 I}{2\pi}\,\mathrm{d}\phi.$$

(1) The 1-form of a vector field is $\vec{B}\cdot\mathrm{d}\vec{r}$, and only the $\hat{\phi}$ component is non-zero.
(2) $\sigma^\phi = \rho\,\mathrm{d}\phi$ is the orthonormal coframe element dual to $\hat{\phi}$.
(3) The factors of ρ cancel.

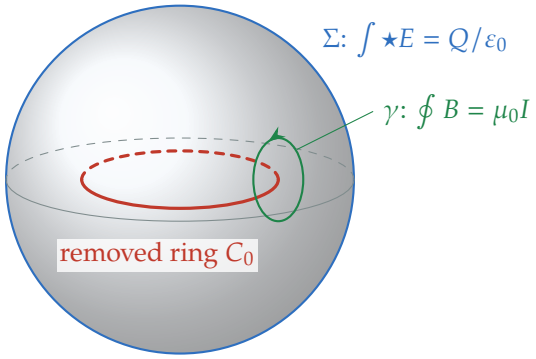
So B is a constant multiple of the angle form: $\mathrm{d}B = 0$ (no current outside the wire, $\vec{\nabla}\times\vec{B} = 0$), and for any loop C

$$\oint_C B = \frac{\mu_0 I}{2\pi}\oint_C \mathrm{d}\phi = \mu_0 I \cdot \mathrm{wind}(C),$$

by (T2.28). That is Ampère's law, with the winding number made explicit. Since $\oint B \neq 0$ around the wire, B is not exact: there is no single-valued magnetic scalar potential Φ_M with $\vec{B} = -\vec{\nabla}\Phi_M$ on $\mathbb{R}^3 \setminus \{\text{wire}\}$. There is a multivalued one, $\Phi_M = -\frac{\mu_0 I}{2\pi}\phi$, which jumps by $\mu_0 I$ across any half-plane $\phi = \text{const}$.

Worked example T2.56: The two holes of a removed circle

Remove the unit circle $C_0 = \{x^2 + y^2 = 1,\ z = 0\}$ from $\mathbb{R}^3$. *Loops:* a small loop γ threading the ring cannot be shrunk to a point in the complement. A current I around C_0 produces a curl-free field outside the wire whose circulation around γ is $\mu_0 I$, by Ampère's law and Stokes' theorem on a small disc pierced by the wire. So $b_1 \geq 1$. *Spheres:* a sphere Σ of radius 2 encloses C_0 and cannot be shrunk to a point either, because it would have to pass through the ring. Spread a charge Q uniformly along C_0. Outside C_0 its electric field is divergence-free, so its flux 2-form $\star E$ is closed on the complement, and Gauss's law gives $\int_\Sigma \star E = Q/\varepsilon_0 \neq 0$. So $b_2 \geq 1$. (In fact $\mathbb{R}^3 \setminus C_0$ can be shrunk onto a sphere with a diameter attached, and $b_1 = b_2 = 1$ exactly.) A thin torus hugging C_0 is homologous to Σ: the region between them has boundary $\Sigma - T$, so by Stokes the flux through the small torus is also Q/ε_0.



$b_1 = 1$: loops that link the ring; $b_2 = 1$: spheres that enclose it

Figure T2.32: The complement of a ring in $\mathbb{R}^3$ has two independent kinds of hole. A loop γ threading the ring (green) detects a closed 1-form, the magnetic field of a current in the ring. A sphere Σ enclosing the ring (blue) detects a closed 2-form, the electric flux of a charge on the ring. Neither loop nor sphere can be shrunk to a point without crossing the ring.

T2.9.7 Integration on the sphere: Dray's exercise, done

Dray closes with an exercise [Dray §20.5]. Pick a 1-form β on $\mathbb{R}^3$ in rectangular coordinates, with $\alpha = \mathrm{d}\beta \neq 0$. Restrict α to the unit sphere and integrate. Then restrict β first and take d of the result. Do the two agree? What must the integral be? We carry this out with two choices of β, and then look at a 2-form that is *not* the restriction of an exact form.

Restricting a form to a surface is the **pullback** ι^* along the inclusion $\iota : S^2 \hookrightarrow \mathbb{R}^3$: substitute $x = \sin\theta\cos\phi$, $y = \sin\theta\sin\phi$, $z = \cos\theta$ and expand, exactly as in Section T2.1.4. The general fact (Chapter T1) is that pullback commutes with d:

$$\iota^*(\mathrm{d}\beta) = \mathrm{d}(\iota^*\beta). \tag{T2.153}$$

$$\begin{array}{ccccc} \beta \in \Omega^1(\mathbb{R}^3) & \xrightarrow{\ \mathrm{d}\ } & \mathrm{d}\beta \in \Omega^2(\mathbb{R}^3) & & \\ \Big\downarrow{\scriptstyle \iota^*} & & \Big\downarrow{\scriptstyle \iota^*} & & \\ \iota^*\beta \in \Omega^1(S^2) & \xrightarrow[\ \mathrm{d}\ ]{} & \iota^*\mathrm{d}\beta = \mathrm{d}\,\iota^*\beta \in \Omega^2(S^2) & \xrightarrow{\int_{S^2}} & 0 \quad (\text{Stokes, } \partial S^2 = \varnothing) \end{array}$$

Figure T2.33: Dray's exercise as a commutative square. Going right then down (differentiate in $\mathbb{R}^3$, then restrict) equals going down then right (restrict, then differentiate on the sphere). Since the bottom-right form is exact on the sphere, its integral over the closed sphere is zero.

Worked example T2.57: $\beta = \frac{1}{2}(x\,\mathrm{d}y - y\,\mathrm{d}x)$: projected area

Here $\mathrm{d}\beta = \frac{1}{2}(\mathrm{d}x\wedge\mathrm{d}y - \mathrm{d}y\wedge\mathrm{d}x) = \mathrm{d}x\wedge\mathrm{d}y$. *Route 1, differentiate then restrict.* On the sphere,

$$\mathrm{d}x = \cos\theta\cos\phi\,\mathrm{d}\theta - \sin\theta\sin\phi\,\mathrm{d}\phi, \qquad \mathrm{d}y = \cos\theta\sin\phi\,\mathrm{d}\theta + \sin\theta\cos\phi\,\mathrm{d}\phi,$$

$$\iota^*(\mathrm{d}x\wedge\mathrm{d}y) \overset{(1)}{=} \big(\cos\theta\cos\phi\cdot\sin\theta\cos\phi + \sin\theta\sin\phi\cdot\cos\theta\sin\phi\big)\,\mathrm{d}\theta\wedge\mathrm{d}\phi$$
$$\overset{(2)}{=} \sin\theta\cos\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi.$$

(1) Keep the $\mathrm{d}\theta\wedge\mathrm{d}\phi$ terms: (coefficient of $\mathrm{d}\theta$ in $\mathrm{d}x$)(coefficient of $\mathrm{d}\phi$ in $\mathrm{d}y$) minus (coefficient of $\mathrm{d}\phi$ in $\mathrm{d}x$)(coefficient of $\mathrm{d}\theta$ in $\mathrm{d}y$).
(2) $\cos^2\phi + \sin^2\phi = 1$.

Route 2, restrict then differentiate. By Dray's formula $x\,dy - y\,dx = r^2 \sin^2\theta\,d\phi$ [Dray (20.40)] with $r = 1$,

$$d(\iota^*\beta) \overset{(1)}{=} d\left(\tfrac{1}{2}\sin^2\theta\,d\phi\right) \overset{(2)}{=} \sin\theta\cos\theta\,d\theta \wedge d\phi.$$

(1) $\iota^*\beta = \frac{1}{2}\sin^2\theta\,d\phi$.
(2) $d(\frac{1}{2}\sin^2\theta) = \sin\theta\cos\theta\,d\theta$.

The routes agree, as (T2.153) promises. Now integrate over the sphere with the orientation $\sin\theta\,d\theta \wedge d\phi$:

$$\int_{S^2} dx \wedge dy \overset{(1)}{=} \int_0^{2\pi}\int_0^{\pi} \sin\theta\cos\theta\,d\theta\,d\phi \overset{(2)}{=} 2\pi\left[\tfrac{1}{2}\sin^2\theta\right]_0^{\pi} = 0.$$

(1) Drop the wedge; the orientation of $d\theta \wedge d\phi$ agrees with the chosen one.
(2) The ϕ integral gives 2π.

Zero, as Stokes demands. But the hemispheres separately are not zero. Over the northern hemisphere N ($0 \le \theta \le \pi/2$),

$$\int_N dx \wedge dy \overset{(1)}{=} \oint_{\text{equator}} \beta \overset{(2)}{=} \int_0^{2\pi} \tfrac{1}{2}\sin^2\tfrac{\pi}{2}\,d\phi \overset{(3)}{=} \pi,$$

(1) Stokes, with the equator traversed counterclockwise seen from above (the boundary orientation of N).
(2) $\iota^*\beta = \frac{1}{2}\sin^2\theta\,d\phi$ at $\theta = \pi/2$.
(3) Arithmetic.

and the southern hemisphere gives $-\pi$. The geometric meaning: $dx \wedge dy$ restricted to a surface measures the area of its shadow on the xy-plane, with a sign that records whether the outward normal points up or down. Each hemisphere casts a unit-disc shadow of area π, and the two signs cancel (Figure T2.34).

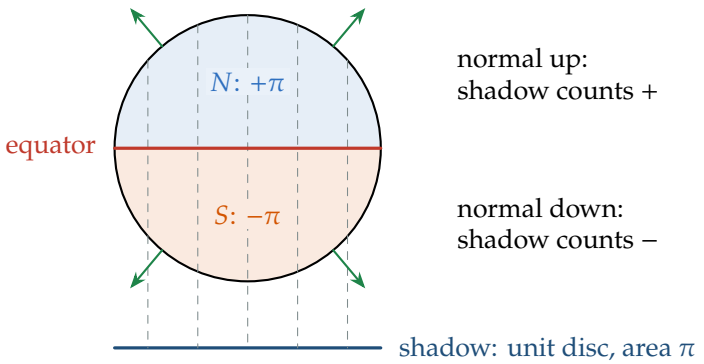


Figure T2.34: The meaning of $\int dx \wedge dy$ over a surface: the signed area of its shadow on the xy-plane. The northern hemisphere (normal up) contributes $+\pi$, the southern (normal down) $-\pi$, and the closed sphere 0. Stokes turns each hemisphere integral into the equator integral of $\beta = \frac{1}{2}(x\,dy - y\,dx)$, which is the area-sweeping form of Kepler's second law.

Worked example T2.58: $\beta = z\,dx$: a less symmetric check

Now $d\beta = dz \wedge dx$. *Route 1.* With $dz = -\sin\theta\,d\theta$,

$$\iota^*(dz \wedge dx) \overset{(1)}{=} (-\sin\theta\,d\theta) \wedge (-\sin\theta\sin\phi\,d\phi) \overset{(2)}{=} \sin^2\theta\sin\phi\,d\theta \wedge d\phi.$$

(1) Only the $d\phi$ part of dx survives the wedge with $d\theta$.
(2) Multiply out.

Route 2. $\iota^*\beta = \cos\theta(\cos\theta\cos\phi\,d\theta - \sin\theta\sin\phi\,d\phi)$, so

$$\begin{aligned} d(\iota^*\beta) &\overset{(1)}{=} d\big(\cos^2\theta\cos\phi\big) \wedge d\theta - d\big(\sin\theta\cos\theta\sin\phi\big) \wedge d\phi \\ &\overset{(2)}{=} -\cos^2\theta\sin\phi\,d\phi \wedge d\theta - \big(\cos^2\theta - \sin^2\theta\big)\sin\phi\,d\theta \wedge d\phi \\ &\overset{(3)}{=} \big(\cos^2\theta - \cos^2\theta + \sin^2\theta\big)\sin\phi\,d\theta \wedge d\phi = \sin^2\theta\sin\phi\,d\theta \wedge d\phi. \end{aligned}$$

(1) $d(f\,d\theta) = df \wedge d\theta$, and similarly for $d\phi$.
(2) In the first term only the ϕ-derivative survives; in the second only the θ-derivative, with $\partial_\theta(\sin\theta\cos\theta) = \cos^2\theta - \sin^2\theta$.
(3) $d\phi \wedge d\theta = -d\theta \wedge d\phi$; collect.

Again the routes agree, and $\int_{S^2}\sin^2\theta\sin\phi\,d\theta\,d\phi = \big(\int_0^\pi \sin^2\theta\,d\theta\big)\big(\int_0^{2\pi}\sin\phi\,d\phi\big) = \frac{\pi}{2}\cdot 0 = 0$. (Geometrically: $dz \wedge dx$ is the signed shadow on the zx-plane, and the halves $y > 0$ and $y < 0$ cancel.)

Worked example T2.59: The area form is a restriction, but not of an exact form

Why does the area form $\omega = \sin\theta\,d\theta \wedge d\phi$ escape this argument? It *is* the restriction of a 2-form on $\mathbb{R}^3$, namely

$$\Omega_0 = x\,dy \wedge dz + y\,dz \wedge dx + z\,dx \wedge dy = \iota_{\vec r}\,(dx \wedge dy \wedge dz),$$

the flux form of the position field $\vec r$ (T2.2). On the unit sphere $\vec r = \hat n$ is the unit normal, so the flux form of $\vec r$ is the area form: $\iota^*\Omega_0 = \omega$. But Ω_0 is not closed, let alone exact:

$$d\Omega_0 \overset{(1)}{=} (\vec\nabla\cdot\vec r)\,dx \wedge dy \wedge dz \overset{(2)}{=} 3\,dV, \qquad \int_{S^2}\omega \overset{(3)}{=} \int_B 3\,dV = 3\cdot\tfrac{4}{3}\pi = 4\pi.$$

(1) d of a flux form is the divergence times the volume form (T2.13).
(2) $\vec\nabla\cdot\vec r = 3$.
(3) Stokes (Gauss) on the unit ball B, whose boundary is S^2.

We can make the extension closed, at a price. Divide by r^3: $E = \Omega_0/r^3$ still restricts to ω on the unit sphere, and

$$dE \overset{(1)}{=} \frac{d\Omega_0}{r^3} + d\big(r^{-3}\big) \wedge \Omega_0 \overset{(2)}{=} \frac{3\,dV}{r^3} - \frac{3}{r^5}(x\,dx + y\,dy + z\,dz) \wedge \Omega_0 \overset{(3)}{=} \frac{3\,dV}{r^3} - \frac{3r^2\,dV}{r^5} = 0.$$

(1) Product rule for d of a function times a form.
(2) $d\Omega_0 = 3\,dV$, and $d(r^{-3}) = -3r^{-4}\,dr = -3r^{-5}(x\,dx + y\,dy + z\,dz)$.
(3) $dx \wedge \Omega_0 = x\,dV$, and similarly for y, z, so the wedge gives $(x^2 + y^2 + z^2)\,dV = r^2\,dV$.

So E is the Coulomb form, closed on $\mathbb{R}^3 \setminus \{0\}$ and singular at the origin. Either way, there is no conflict with Stokes. An extension of ω to all of $\mathbb{R}^3$ cannot be closed (its d must integrate to 4π over the ball), and a closed extension must be singular somewhere inside the sphere. This is the three-dimensional version of the sphere puzzle (T2.31): the non-exactness of ω on S^2 is the charge sitting inside.

Try it: Your own β

Take $\beta = xz\,dy$. Compute $\alpha = d\beta$, restrict it to the unit sphere both ways, and integrate over the sphere and over the northern hemisphere. *Answer:* $\alpha = z\,dx \wedge dy - x\,dy \wedge dz$. On the sphere $\iota^*\beta = \sin\theta\cos\theta\cos\phi\,(\cos\theta\sin\phi\,d\theta + \sin\theta\cos\phi\,d\phi)$. The sphere integral is 0. The hemisphere integral is the equator integral of $\iota^*\beta$ at $\theta = \pi/2$, where $\cos\theta = 0$, so it is also 0. (Check with the shadow picture: $z\,dx \wedge dy$ and $-x\,dy \wedge dz$ each integrate to zero over the northern hemisphere by symmetry in $x \to -x$ and a direct θ integral: $\int_N z\,dx \wedge dy = 2\pi\int_0^{\pi/2}\cos^2\theta\sin\theta\,d\theta = 2\pi/3$ and $\int_N x\,dy \wedge dz = \int_N \sin^3\theta\cos^2\phi\,d\theta\,d\phi = 2\pi/3$, which cancel.)

Reading Nash (where these tools reappear)

Nash never pauses on the material of this section, but he uses all of it. The Clifford algebra and the spin connection are the input to the Dirac operator [Nash p. 114, (4.99)–(4.100)], and the even/odd splitting of forms is his route to the Euler characteristic [Nash p. 104, (4.52)]. The flux of a field through a sphere at infinity is his monopole charge [Nash p. 245, (8.154)], the same Stokes argument as in Example T2.59 with Ω_0/r^3 replaced by $\mathrm{tr}(F\phi)$. Deficit angles and the Euler characteristic of the world sheet return in the string chapter (Chapter 9).

Recap

- *Equivalence:* $\Omega = 0$ iff locally flat; flat coordinates come from integrating a parallel coframe. $e^{2y}(dx^2 + dy^2)$ is flat (polar coordinates with $\rho = e^y$) but globally a covering space. The cone is flat except at its tip, which carries the deficit $2\pi(1-\beta)$. R_{ijkl} has $n^2(n^2-1)/12$ components.
- *Lagrangians:* $\Omega_{ij} \wedge \star(\sigma^i \wedge \sigma^j) = R\,dV$; in 2D its integral is $4\pi\chi$, so 2D gravity is topological and weights string world sheets by g_s^{2g-2}.
- *Clifford product:* $\alpha \vee \beta = \alpha \wedge \beta + g(\alpha,\beta)$; wedge plus all contractions. $\mathrm{Cl}(\mathbb{R}^2)$ is the Pauli algebra with $e^{12} \mapsto i\sigma_3$; in $\mathbb{R}^3$, $e^{123} \mapsto i\mathbb{1}$; in spacetime $\gamma^\mu \leftrightarrow dx^\mu$.
- *Spinors:* a left ideal such as $\mathrm{Cl} \vee \frac{1}{2}(1+e^1)$; in 2D, two components with $e^1 \mapsto \sigma_3$, $e^2 \mapsto \sigma_1$.
- *Kähler–Dirac:* $d - \delta = e^i \vee \partial_i$ squares to ∇^2; on the plane its zero modes are pairs of holomorphic functions; it is $2^{n/2}$ Dirac fields; with the even/odd grading its index is χ.
- *Topology:* simply connected kills H^1, not H^2 ($\mathbb{R}^3 \setminus \{0\}$); Ampère's law is the Stokes detector for $d\phi$; a removed ring has $b_1 = b_2 = 1$.
- *Sphere exercise:* pullback commutes with d; restrictions of exact forms integrate to zero on S^2; $dx \wedge dy$ is signed shadow area; the area form extends to $\mathbb{R}^3$ only as a non-closed form or as the singular Coulomb form.

Chapter summary

The chapter told two stories and then showed they were one. The first story was about *adding up*: forms are the things we can integrate, and Stokes' theorem $\int_R d\alpha = \int_{\partial R}\alpha$ (T2.9) turns the

local statement $d^2 = 0$ into global information. The second story was about *turning*: a frame that is carried across a curved space rotates, the rate of rotation is the connection ω, and the failure of that rotation to be undone around a loop is the curvature $\Omega = d\omega + \omega \wedge \omega$. The stories met in Gauss–Bonnet, $\int_\Sigma K\, dA = 2\pi\chi(\Sigma)$ (T2.124), where a curvature integral turned out to be a count of holes.

If we had to keep a single sentence from the chapter, it would be the owner's favourite: *an exact form integrates to zero over anything without boundary, because the boundary is empty.* That one argument did four different jobs, shown side by side in Figure T2.35. It detected non-exact forms (T2.18). It made periods of cohomology classes well defined (T2.36). It made the total curvature of a closed surface independent of the metric (T2.127). And, as we previewed in §T2.8.9, it is exactly why Chern numbers and instanton numbers are topological in Chapter 4 and Chapter 8.

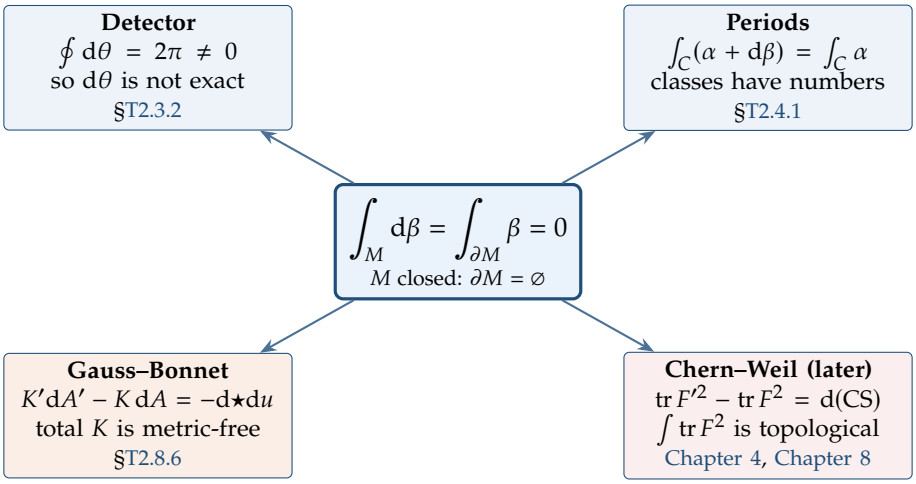

Figure T2.35: One argument, four uses. The hub is Stokes' theorem on a manifold with no boundary. Upper left: a single non-zero loop integral proves a closed form is not exact. Upper right: adding an exact form does not change any period, so a cohomology class carries well-defined numbers. Lower left: a change of metric changes $K\, dA$ by an exact form, so $\int K\, dA$ cannot change. Lower right: the same mechanism, with ω replaced by a gauge potential, makes $\int \mathrm{tr}\, F \wedge F$ topological.

The rest of this summary has five parts: a table of every concept with its operational meaning and where it returns; a catalogue of the spaces we computed; a dictionary between the geometry of this chapter and gauge theory; a list of conventions; and a short self-test.

Every concept, how to use it, and where it returns

The middle column is the *operational* meaning: what you actually do to compute or test the thing. The right column says where in the book the idea comes back. References such as §T2.3.3 point to this chapter.

§T2.1: integrating forms

Concept	Operational meaning	Returns in
p-form as integrand	eats the p edge vectors of a tiny parallelogram and returns its signed p-volume; circulation, flux and volume are $\int F$, $\int \star F$, $\int \star f$ (T2.3)	every action and every topological charge
pull back and drop the wedges	parametrise, substitute $x^\mu(u)$, expand, write $\mathrm{d}u^1 \wedge \cdots \wedge \mathrm{d}u^p \to \mathrm{d}u^1 \cdots \mathrm{d}u^p$; the wedge supplies the Jacobian (T2.6)	all explicit integrals; Chapter 8
orientation	a consistent choice of "positive" ordering of bases; reversing it flips every integral; Möbius band has none	signs of indices, Chapter 4
partition of unity	chop M into chart-sized pieces with weights ρ_a, $\sum \rho_a = 1$, and add (T2.8)	gluing arguments, Chapter 3

§T2.2: Stokes' theorem

Concept	Operational meaning	Returns in
Stokes' theorem	$\int_R \mathrm{d}\alpha = \int_{\partial R} \alpha$; boundary oriented "outward normal first" (T2.9)	everywhere
special cases	FTC ($p = 0$), gradient, Green and curl ($p = 1$), Gauss ($p = 2$ in $\mathbb{R}^3$); Figure T2.7	electromagnetism, Chapter T3
$\partial^2 = \varnothing \leftrightarrow \mathrm{d}^2 = 0$	a boundary has no boundary; dual statement is $\mathrm{dd} = 0$ (T2.14)	chain complexes, Chapter 1
integration by parts	$\int_M \mathrm{d}\alpha \wedge \beta = \int_{\partial M} \alpha \wedge \beta - (-1)^p \int_M \alpha \wedge \mathrm{d}\beta$ (T2.15); gives the adjoint d^*	Hodge theory, Chapter 2
boundary terms	varying $S = \int \mathcal{L}$ gives field equations plus $\int_{\partial M}(\dots)\,\delta\phi$ (T2.16)	anomalies, Chapter 10; TQFT, Chapter 12

§T2.3: closed and exact forms

Concept	Operational meaning	Returns in
closed, exact	closed: compute $\mathrm{d}\alpha$ and get 0; exact: exhibit a global smooth β with $\alpha = \mathrm{d}\beta$; exact $\Rightarrow$ closed (T2.17)	gauge potentials, Chapter T3
Stokes detector	integrate over a cycle without boundary; any non-zero answer proves non-exactness (T2.18)	monopoles and instantons, Chapter 8
Poincaré lemma	on a star-shaped region, $\beta = K\alpha = \int_0^1 t^{p-1} \iota_x \alpha(tx)\,\mathrm{d}t$ solves $\mathrm{d}\beta = \alpha$; $\mathrm{d}K + K\mathrm{d} = 1$ (T2.23)	local gauge potentials; Čech–de Rham, Chapter 3
angle form $\mathrm{d}\theta$	$(x\,\mathrm{d}y - y\,\mathrm{d}x)/r^2$ on $\mathbb{R}^2 \setminus \{0\}$: closed, period 2π, not exact (T2.25)	Aharonov–Bohm; vortices; Chapter 1
winding number	$\frac{1}{2\pi}\oint_C \mathrm{d}\theta \in \mathbb{Z}$; unchanged by deformations that avoid the puncture (T2.28)	degree of maps, π_1, Chapter 1; Chapter 6
sphere puzzle	$\omega = \mathrm{d}(-\cos\theta\,\mathrm{d}\phi)$ fails at the poles; two patches with transition $2\,\mathrm{d}\phi$ give $\int \omega = 4\pi$ (T2.33)	Dirac monopole, Chapter 8

§T2.4: first look at de Rham cohomology

Concept	Operational meaning	Returns in
$H^p_{\mathrm{dR}}(M)$	closed p-forms modulo exact ones (T2.35); label a class by its periods over a basis of cycles	Chapter 1; Chapter 2
H^0 and $H^p(\mathbb{R}^n)$	b_0 = number of components (T2.38); contractible spaces have nothing above degree 0 (T2.39)	homotopy invariance, Chapter 1
Betti numbers	$b_p = \dim H^p_{\mathrm{dR}}$: $S^1\,(1,1)$, $S^2\,(1,0,1)$, $T^2\,(1,2,1)$	Chapter 1; Chapter 7
Euler characteristic	$\chi = \sum_p (-1)^p b_p = V - E + F$ (T2.50); $\chi(\Sigma_g) = 2 - 2g$	index theorem, Chapter 4; strings, Chapter 9
de Rham's theorem	a closed form is exact iff all its periods vanish (T2.52)	Chapter 1
Hodge's theorem	one harmonic representative per class; $b_p = \dim \mathrm{Ker}\,\Delta_p$ (T2.54): zero modes count topology	Chapter 2; Chapter 4

§T2.5: connections

Concept	Operational meaning	Returns in
orthonormal coframe (vielbein)	write $\mathrm{d}\vec{r} = \sigma^i e_i$, i.e. $\mathrm{d}s^2 = \sum_i (\sigma^i)^2$; $g = E^{\mathsf{T}} E$ (T2.58)	spinors on curved space, Chapter T4
connection 1-forms	differentiate the frame: $\mathrm{d}e_j = e_i\,\omega^i{}_j$ (T2.61); then $\mathrm{d}\vec{v} = (\mathrm{d}v^i + \omega^i{}_j v^j) e_i$	gauge potential A, Chapter T3
metric compatibility	$\omega_{ij} = -\omega_{ji}$: ω is $\mathfrak{so}(n)$-valued (T2.66)	structure group of TM, Chapter T3
Cartan's first structure equation	solve $\mathrm{d}\sigma^i + \omega^i{}_j \wedge \sigma^j = 0$ for ω; in 2D read off $\omega^1{}_2$ from $\mathrm{d}\sigma^1, \mathrm{d}\sigma^2$ (T2.69)	spin connection, Chapter T4
Levi-Civita answers	plane (polar) $\omega^1{}_2 = -\mathrm{d}\phi$; sphere $-\cos\theta\,\mathrm{d}\phi$; torus $\sin\theta\,\mathrm{d}\phi$ (T2.70), (T2.71)	examples throughout
Christoffel symbols, Koszul formula	Γ from derivatives of g; frame version via structure constants (T2.75)	geodesics; Chapter 7
frame rotation	$\omega' = g^{-1}\omega g + g^{-1}\mathrm{d}g$; in 2D $\omega^1{}_2 \mapsto \omega^1{}_2 - \mathrm{d}\lambda$ (T2.81)	gauge transformations, Chapter T3

§T2.6: curvature

Concept	Operational meaning	Returns in
curvature 2-form	$\Omega = \mathrm{d}\omega + \omega \wedge \omega$ (T2.84); $\mathrm{d}^2\vec{v} = \Omega\vec{v}$	$F = \mathrm{d}A + A \wedge A$, Chapter T3
Gaussian curvature	in 2D, $\mathrm{d}\omega^1{}_2 = K\,\sigma^1 \wedge \sigma^2$ (T2.87); sphere $1/a^2$, torus (T2.91), hyperbolic $-1/a^2$	Gauss–Bonnet; Chapter 9
flat ⇔ pure gauge	$\Omega = 0$ iff locally $\omega = g^{-1}\mathrm{d}g$ iff a Cartesian frame exists	flat connections, Chapter 12
Theorema Egregium	$K = \kappa_1\kappa_2 = \det S$ (T2.95) yet computable from g alone	intrinsic geometry
Riemann, Ricci, scalar	$\Omega^i{}_j = \frac{1}{2}R^i{}_{jkl}\sigma^k \wedge \sigma^l$ (T2.96); in 2D $R = 2K$	Einstein–Hilbert, Chapter 9
Bianchi identities	$\Omega \wedge \boldsymbol{\sigma} = 0$, $D\Omega = \mathrm{d}\Omega + [\omega, \Omega] = 0$ (T2.98), (T2.99)	$DF = 0$, Chapter T3; Chern–Weil, Chapter 4
holonomy	rotation angle after transport around ∂D equals $\int_D K\,\mathrm{d}A$ (T2.101)	Wilson loops, Chapter T3; Chapter 12

§T2.7: geodesics

Concept	Operational meaning	Returns in
geodesic curvature	$\kappa_g\,\mathrm{d}s = \mathrm{d}\alpha - \omega^1{}_2$ (T2.105): turning of the tangent relative to a transported vector	Gauss–Bonnet with boundary, Chapter 4
geodesic equation	$\ddot{x}^j + \Gamma^j{}_{ik}\dot{x}^i\dot{x}^k = 0$ (T2.109); Euler–Lagrange equation of $E = \int g_{\mu\nu}\dot{x}^\mu\dot{x}^\nu\,\mathrm{d}t$	Morse theory on path space, Chapter 7
Jacobi equation	$J'' + KJ = 0$ (T2.116): $K > 0$ focuses, $K < 0$ spreads	conjugate points and Morse index, Chapter 7

§T2.8: Gauss–Bonnet

Concept	Operational meaning	Returns in
local Gauss–Bonnet	$\int_D K\,\mathrm{d}A + \oint \kappa_g\,\mathrm{d}s + \sum \varepsilon_k = 2\pi$ (T2.119)	Chapter 4
angle excess	geodesic triangle: $\alpha + \beta + \gamma - \pi = \int_T K\,\mathrm{d}A$ (T2.120)	deficit angles, Chapter 9
global Gauss–Bonnet	$\int_\Sigma K\,\mathrm{d}A = 2\pi\chi(\Sigma)$ (T2.124); with boundary add $\oint \kappa_g\,\mathrm{d}s$ (T2.125)	Nash (4.148), Chapter 4
Gauss map degree	$K\,\mathrm{d}A = \hat{n}^*(\mathrm{d}A_{S^2})$, so $\frac{1}{4\pi}\int K\,\mathrm{d}A = \deg\hat{n} = 1 - g$ (T2.130)	monopole charge as degree, Chapter 8
Poincaré–Hopf	sum the indices of the zeros of any vector field; the answer is χ (T2.132)	Morse inequalities, Chapter 7
Euler class	$e = K\,\mathrm{d}A/2\pi = c_1(T\Sigma)$ (T2.133); Pfaffian in 4D (T2.135); $\mathrm{index}(\mathrm{d} + \mathrm{d}^*) = \chi$ (T2.136)	Chern–Weil and the index theorem, Chapter 4

§T2.9: applications

Concept	Operational meaning	Returns in
equivalence problem	compute Ω; if it vanishes, integrate a parallel coframe to find flat coordinates; cones hide curvature at the tip (T2.137)	orbifolds, Chapter 9
2D gravity is topological	$\int R\,\mathrm{d}V = 4\pi\chi$ (T2.141); world sheets weighted by g_s^{2g-2}	string perturbation theory, Chapter 9
Clifford product	$\alpha \vee \beta = \alpha \wedge \beta + g(\alpha,\beta)$ for 1-forms (T2.142); $\mathrm{Cl}(\mathbb{R}^2)$ is the Pauli algebra (T2.146)	gamma matrices, Chapter T4
Kähler–Dirac operator	$\mathrm{d} - \delta = e^i \vee \partial_i$ squares to the Laplacian (T2.149); index with even/odd grading is χ	Dirac operators, Chapter T4; Chapter 4

A catalogue of the spaces we computed

The same handful of spaces appeared in every section. Table T2.3 collects everything we learned about each of them. Read a row from left to right and you replay the chapter: cohomology first (topology only), then a frame and its connection (geometry), then the curvature, and finally the check that total curvature is $2\pi\chi$.

Space	(b_0, b_1, b_2), χ	Generators of H^1_{dR}, H^2_{dR}	Frame data	$\int K\,\mathrm{d}A$
$\mathbb{R}^2$	$(1,0,0)$, 1	none (Poincaré lemma)	polar: $\omega^1{}_2 = -\mathrm{d}\phi$, $K = 0$	–
$\mathbb{R}^2 \setminus \{0\}$	$(1,1,0)$, 0	$\mathrm{d}\theta$, period 2π	polar, $K = 0$	–
S^1	$(1,1)$, 0	$\mathrm{d}\phi$, $\int_{S^1}\mathrm{d}\phi = 2\pi$	–	–
S^2, radius a	$(1,0,1)$, 2	$\omega/4\pi$ (unit monopole)	$\omega^1{}_2 = -\cos\theta\,\mathrm{d}\phi$, $K = 1/a^2$	4π
T^2 in $\mathbb{R}^3$	$(1,2,1)$, 0	$\mathrm{d}\theta$, $\mathrm{d}\phi$; $\mathrm{d}\theta \wedge \mathrm{d}\phi$	$\omega^1{}_2 = \sin\theta\,\mathrm{d}\phi$, $K = \frac{\cos\theta}{a(R + a\cos\theta)}$	0
Σ_g	$(1, 2g, 1)$, $2 - 2g$	$2g$ loop classes; area form	any metric	$4\pi(1-g)$
$\mathbb{R}^3 \setminus \{0\}$	$(1,0,1)$, 2	Coulomb flux $\hat{r}\cdot\mathrm{d}\vec{A}/r^2$	–	–
$\mathbb{R}^3 \setminus$ ring	$(1,1,1)$, 1	linking form (Ampère); flux	–	–

Table T2.3: The chapter's spaces in one table. Betti numbers and χ need only topology; the connection and K need a metric; the last column shows that their integral forgets the metric and remembers χ. For the three-dimensional spaces, χ is the alternating sum of the listed Betti numbers (all higher ones vanish).

The "curvature budget" of Figure T2.36 is the same content for closed surfaces in picture form. Adding a handle costs 4π of total curvature: the metric can move curvature around the surface as it pleases, but it cannot change the total.

Dictionary: the geometry of this chapter as a gauge theory

§T2.5.10 and §T2.6.3 showed that the Levi-Civita connection of a surface is a gauge field whose gauge group is the rotation group $\mathrm{SO}(2) \cong \mathrm{U}(1)$ of the frame. We collect the translation here,

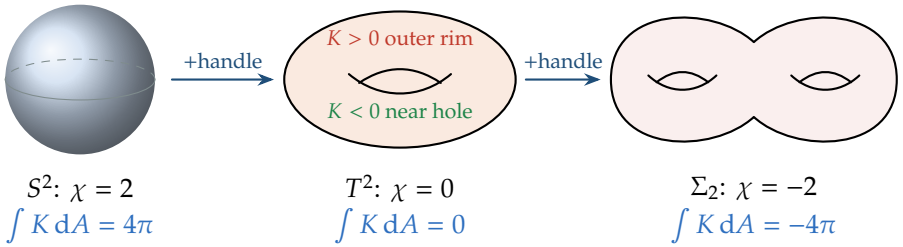

Figure T2.36: The curvature budget. On the sphere the total curvature is 4π however the sphere is dented. On the torus the positive curvature on the outer rim ($K > 0$, red) is cancelled exactly by the negative curvature near the hole ($K < 0$, green), as we checked in (T2.92). Each extra handle adds a saddle-shaped region worth -4π, so $\int_{\Sigma_g} K\,\mathrm{d}A = 4\pi(1-g) = 2\pi\chi$.

because the chapters on gauge theory (Chapter T3) and on instantons (Chapter 8) use it in the other direction.

Dictionary: surface geometry ↔ U(1) gauge theory

Surface geometry	Gauge theory
choice of orthonormal frame (e_1, e_2)	choice of gauge
rotation of frame by angle $\lambda(x)$	gauge transformation $g = e^{i\lambda}$
connection 1-form $\omega^1{}_2$	gauge potential A (with $A_{\text{math}} = -i\,\omega^1{}_2$ in anti-Hermitian form, §T2.5.10)
$\omega^1{}_2 \mapsto \omega^1{}_2 - \mathrm{d}\lambda$	$A \mapsto A + g^{-1}\mathrm{d}g$
$\Omega^1{}_2 = \mathrm{d}\omega^1{}_2 = K\,\mathrm{d}A$	field strength $F = \mathrm{d}A$ (abelian)
$\Omega \mapsto g^{-1}\Omega g$; Bianchi $D\Omega = 0$	$F \mapsto g^{-1}Fg$; Bianchi $DF = 0$
holonomy around a loop $= \int K\,\mathrm{d}A$	Aharonov–Bohm phase, Wilson loop $= \exp \oint A$
sphere: frames smooth on two caps, transition winding 2	monopole of charge 2 in units of Dirac's $\frac{1}{2}$
$\frac{1}{2\pi}\int K\,\mathrm{d}A = \chi$	first Chern number $c_1 = \frac{i}{2\pi}\int F$
geodesic ($\kappa_g = 0$)	path of a charged particle feeling no force
$R\,\mathrm{d}V$ in 2D is a total-derivative density	$\mathrm{tr}\,F \wedge F$ in 4D is locally d(Chern–Simons)
Gauss–Bonnet $\int K\,\mathrm{d}A = 2\pi\chi$	Chern–Weil; index theorem index $= \int$(char. class)

Conventions used in this chapter

- Boundary orientation: *outward normal first*. For a planar region the boundary runs counterclockwise (§T2.2.1).
- A p-form is $\alpha = \frac{1}{p!}\alpha_{\mu_1\ldots\mu_p}\mathrm{d}x^{\mu_1}\wedge\cdots\wedge\mathrm{d}x^{\mu_p}$.
- Frames: $\mathrm{d}e_j = e_i\,\omega^i{}_j$; first structure equation $\mathrm{d}\sigma^i = -\omega^i{}_j\wedge\sigma^j$; curvature $\Omega = \mathrm{d}\omega + \omega\wedge\omega$.
- On the unit sphere in the frame $(\hat\theta, \hat\phi)$ we have $\omega^1{}_2 = -\cos\theta\,\mathrm{d}\phi$ and $\Omega^1{}_2 = \sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi = K\,\sigma^1\wedge\sigma^2$ with $K = +1$. The sign of K is fixed so that spheres are positive.

- Gauss–Bonnet corner terms use the *exterior* (turning) angles $\varepsilon_k = \pi -$ (interior angle).
- Riemannian (Euclidean) signature throughout, except for the remarks on action principles and Maxwell theory, where we stated the signature locally.

Self-test

Each question can be answered in a few lines with the tools of the chapter. The answers follow.

Try it: six quick questions

(a) Without computing any potential, show that $\alpha = \frac{x\,dy\wedge dz + y\,dz\wedge dx + z\,dx\wedge dy}{r^3}$ is not exact on $\mathbb{R}^3 \setminus \{0\}$.

(b) Is $\beta = 2xy\,dx + x^2\,dy$ exact on $\mathbb{R}^2$? If so, find the potential with the homotopy operator K.

(c) A geodesic triangle on the unit sphere has all three angles equal to $\pi/2$. What is its area?

(d) Why can the Gaussian curvature of a closed surface in $\mathbb{R}^3$ of genus 2 not be everywhere positive?

(e) A vector is parallel-transported once around the latitude circle $\theta = \theta_0$ of the unit sphere. By what angle does it come back rotated?

(f) Find the potential for $dx \wedge dy$ on $\mathbb{R}^2$ given by the Poincaré lemma, and check it.

Answers.

(a) It is closed (it is the Coulomb flux form, $d\alpha = 0$ away from the origin), and its integral over the unit sphere is the solid angle:

$$\int_{S^2} \alpha \overset{(1)}{=} \int_{S^2} \sin\theta\, d\theta \wedge d\phi \overset{(2)}{=} 4\pi \neq 0.$$

(1) On the unit sphere $r = 1$, and α restricts to the area form, as in §T2.4.5.

(2) $\int_0^{\pi} \sin\theta\, d\theta = 2$ and $\int_0^{2\pi} d\phi = 2\pi$.

If α were $d\gamma$, Stokes would give $\int_{S^2} \alpha = \int_{\partial S^2} \gamma = 0$, because $\partial S^2 = \varnothing$. The Stokes detector fires.

(b) First test closedness, then build the potential by integrating along rays from the origin:

$$d\beta \overset{(1)}{=} \frac{\partial(2xy)}{\partial y}\,dy\wedge dx + \frac{\partial(x^2)}{\partial x}\,dx\wedge dy \overset{(2)}{=} (-2x + 2x)\,dx\wedge dy = 0,$$

$$K\beta \overset{(3)}{=} \int_0^1 \big(2(tx)(ty)\,x + (tx)^2\,y\big)\,dt \overset{(4)}{=} 3x^2y \int_0^1 t^2\,dt = x^2y.$$

(1) Only the cross derivatives survive in d of a 1-form in the plane.

(2) $dy \wedge dx = -dx \wedge dy$.

(3) The homotopy operator for a 1-form, $K\beta(x) = \int_0^1 \beta_\mu(tx)\,x^\mu\,dt$ (T2.20).

(4) Collect: $2x^2y + x^2y = 3x^2y$, and $\int_0^1 t^2\,dt = \frac{1}{3}$.

Check: $d(x^2y) = 2xy\,dx + x^2\,dy = \beta$. So β is exact, as it must be on a star-shaped region.

(c) By the angle excess formula (T2.120) with $K = 1$, the area is $\frac{\pi}{2} + \frac{\pi}{2} + \frac{\pi}{2} - \pi = \frac{\pi}{2}$. This is the octant of Figure T2.25: one eighth of 4π.

(d) If $K > 0$ everywhere then $\int K \, \mathrm{d}A > 0$. But Gauss–Bonnet gives $\int K \, \mathrm{d}A = 2\pi\chi(\Sigma_2) = 2\pi(2 - 2 \cdot 2) = -4\pi < 0$. So K must be negative somewhere; in fact the negative part must outweigh the positive part by 4π.

(e) The holonomy is the curvature of the enclosed cap (T2.101):

$$\Delta\psi \overset{(1)}{=} \int_{\mathrm{cap}} K \, \mathrm{d}A \overset{(2)}{=} \int_0^{2\pi} \int_0^{\theta_0} \sin\theta \, \mathrm{d}\theta \, \mathrm{d}\phi \overset{(3)}{=} 2\pi(1 - \cos\theta_0).$$

(1) Stokes on $\omega^1{}_2$: the rotation after one circuit is the flux of $\Omega^1{}_2 = K \, \mathrm{d}A$ through the cap.
(2) $K = 1$ and $\mathrm{d}A = \sin\theta \, \mathrm{d}\theta \wedge \mathrm{d}\phi$.
(3) $\int_0^{\theta_0} \sin\theta \, \mathrm{d}\theta = 1 - \cos\theta_0$.

At the equator ($\theta_0 = \pi/2$) this is 2π, the same as no rotation: the equator is a geodesic, so its tangent is itself parallel. This is the Foucault pendulum at co-latitude θ_0.

(f) Apply the homotopy operator $K\alpha = \int_0^1 t^{p-1} \, \iota_x \alpha(tx) \, \mathrm{d}t$ (T2.22), where ι_x inserts the position vector:

$$K(\mathrm{d}x \wedge \mathrm{d}y) \overset{(1)}{=} \int_0^1 t \, \mathrm{d}t \, (x \, \mathrm{d}y - y \, \mathrm{d}x) \overset{(2)}{=} \tfrac{1}{2}(x \, \mathrm{d}y - y \, \mathrm{d}x),$$

$$\mathrm{d}\big(\tfrac{1}{2}(x \, \mathrm{d}y - y \, \mathrm{d}x)\big) \overset{(3)}{=} \tfrac{1}{2}(\mathrm{d}x \wedge \mathrm{d}y - \mathrm{d}y \wedge \mathrm{d}x) = \mathrm{d}x \wedge \mathrm{d}y.$$

(1) Here $p = 2$, so the weight is $t^{p-1} = t$. The coefficient of $\mathrm{d}x \wedge \mathrm{d}y$ is the constant 1, so evaluating it at tx changes nothing. Inserting the position vector $x \, \partial_x + y \, \partial_y$ into the first slot gives $\iota_x(\mathrm{d}x \wedge \mathrm{d}y) = x \, \mathrm{d}y - y \, \mathrm{d}x$.
(2) $\int_0^1 t \, \mathrm{d}t = \frac{1}{2}$.
(3) $\mathrm{d}(x \, \mathrm{d}y) = \mathrm{d}x \wedge \mathrm{d}y$ and $\mathrm{d}(y \, \mathrm{d}x) = \mathrm{d}y \wedge \mathrm{d}x$.

This is the familiar "area $= \frac{1}{2} \oint (x \, \mathrm{d}y - y \, \mathrm{d}x)$" of Green's theorem, now obtained as the Poincaré-lemma potential of the area form.

Where the chapter leads

- Chapter T3 replaces the rotation group $\mathrm{SO}(n)$ of the frame by any Lie group G. Every formula of §T2.5 and §T2.6 survives with $\omega \to A$ and $\Omega \to F$; holonomy becomes the Wilson loop.
- Chapter T4 lifts the frame rotation to spinors. The spin connection is our ω written in the Clifford algebra of §T2.9.3, and the Dirac operator is the honest version of the Kähler–Dirac operator of §T2.9.5.
- Chapter 1 makes cohomology precise, adds integer coefficients and torsion, and proves the invariance we used.
- Chapter 2 develops the Hodge theory previewed in §T2.4.9: harmonic forms as zero modes of the Laplacian.
- Chapter 4 states Gauss–Bonnet as the index theorem for $\mathrm{d} + \mathrm{d}^*$ (Nash (4.52)–(4.54), (4.148)–(4.149)) and generalises the Euler class to all characteristic classes by Chern–Weil.
- Chapter 8 computes monopole and instanton numbers by exactly the two-patch argument of §T2.3.6.

- Chapter 9 sums over surfaces of every genus, weighted by the topological Einstein–Hilbert action of §T2.9.2.

Recap: the whole chapter

- Forms are integrands; Stokes, $\int_R \mathrm{d}\alpha = \int_{\partial R} \alpha$, is the one theorem of integral calculus.
- Exact forms integrate to zero over closed cycles; closed forms that do not are cohomology classes, and they count holes: $b_p = \dim H^p_{\mathrm{dR}}$, $\chi = \sum (-1)^p b_p$.
- A connection is how a frame turns, $\mathrm{d}e = e\,\omega$; the curvature $\Omega = \mathrm{d}\omega + \omega \wedge \omega$ is what does not cancel around a loop. Frame rotation is a gauge transformation.
- Gauss–Bonnet: $\int_\Sigma K\,\mathrm{d}A = 2\pi\chi$. The first "integral of curvature = topology" theorem, and the seed of Chern–Weil theory and the Atiyah–Singer index theorem.

Chapter T3

Lie Groups, Lie Algebras and Gauge Fields

Where this chapter is going

Almost everything in Nash that has a physicist's name attached to it – Yang–Mills fields, instantons, monopoles, anomalies, Chern–Simons theory, Wilson loops, current algebras – is built from two ingredients. The first is a *group of symmetries* that can be described by a finite number of continuous parameters: a Lie group such as U(1), SU(2) or SU(3). The second is the idea of making that symmetry *local*, allowing the symmetry transformation to vary from point to point in spacetime. Once we do that, ordinary derivatives stop making sense and must be replaced by covariant derivatives. The correction term in the covariant derivative is the gauge field A. Geometrically it is a connection, and its curvature $F = \mathrm{d}A + A \wedge A$ is the field strength.

This chapter builds both ingredients from scratch, with explicit matrices at every step. We start with groups of matrices (Section T3.1), look at their infinitesimal versions, the Lie algebras (Section T3.2), and connect the two with the exponential map (Section T3.3). We then meet the most important single example in physics, the two-to-one map $\mathrm{SU}(2) \to \mathrm{SO}(3)$ that is responsible for spin $\frac{1}{2}$ (Section T3.4), and the representation theory that labels particles by spin, weights and roots (Section T3.5). The Maurer–Cartan form $g^{-1}\mathrm{d}g$ (Section T3.6) is the bridge between groups and differential forms: it is the prototype of every gauge field, and its cube counts windings. Group actions and homogeneous spaces (Section T3.7) tell us how spheres and projective spaces arise as quotients of groups. With this toolkit in hand we derive gauge theory (Section T3.8): the transformation law of A, the field strength, the Bianchi identity and the Yang–Mills equations. Finally we look at what a connection does to a particle carried around a loop – parallel transport, holonomy, Wilson loops and the Aharonov–Bohm effect (Section T3.9) – and at connections with zero curvature and the Chern–Simons form, whose derivative is $\operatorname{tr} F \wedge F$ (Section T3.10). That last identity is the doorway to instantons (Chapter 8) and anomalies (Chapter 10).

Conventions for the whole chapter. We use the mathematicians' (and Nash's) conventions. Lie algebra elements of unitary groups are *anti-Hermitian* matrices, a gauge field is a Lie-algebra-valued 1-form $A = A_\mu \, \mathrm{d}x^\mu$, the covariant derivative is $D = \mathrm{d} + A$, and

$$F = \mathrm{d}A + A \wedge A, \qquad A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g, \qquad F \mapsto g^{-1}Fg.$$

Physicists usually pull out a factor of $-i$ and a coupling constant and use Hermitian generators; the translation is $A_{\text{math}} = -i\, g\, A^a_{\text{phys}} T^a$, and we give a full dictionary in Section T3.8. Spacetime is Euclidean unless we say otherwise. Wedge products of matrix-valued forms multiply the matrices *and* wedge the forms, keeping the order.

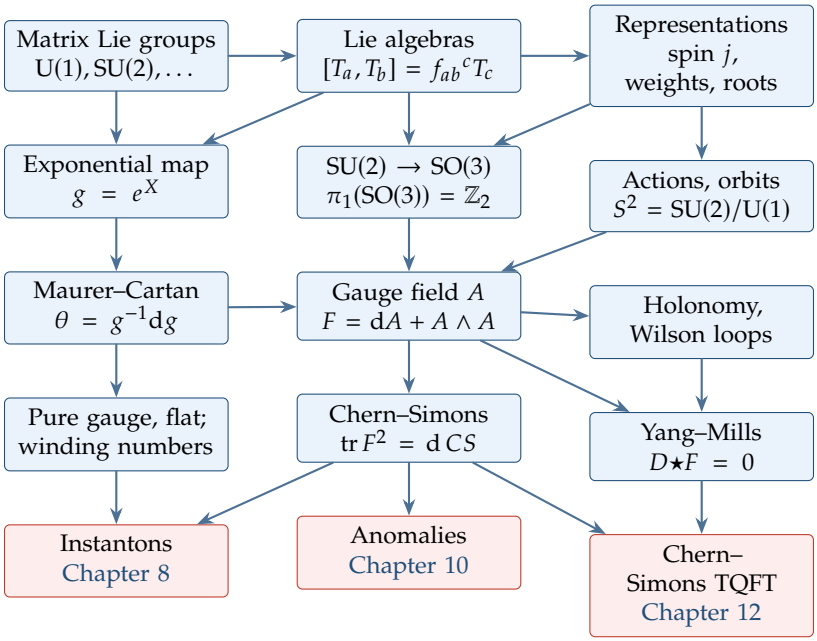

Figure T3.1: The logic of this chapter. Read it top to bottom. The first row is pure algebra: groups, their infinitesimal versions, and the ways they act on vectors. The middle rows turn algebra into geometry: the Maurer–Cartan form $g^{-1}\mathrm{d}g$ is the seed from which the gauge field grows. The red boxes at the bottom are where Nash uses the results.

T3.1 Matrix Lie groups

A symmetry is a transformation that leaves something unchanged: a rotation leaves lengths unchanged, a phase rotation $\psi \mapsto e^{i\alpha}\psi$ leaves $|\psi|^2$ unchanged, an SU(3) colour rotation leaves the strong interactions unchanged. Two symmetries done one after the other give another symmetry, and every symmetry can be undone. That is all a *group* is. When the symmetries can be labelled by a finite number of continuous real parameters (an angle, three Euler angles, eight colour angles) we have a *Lie group*. In physics these groups almost always come to us as groups of matrices acting on a vector space of states or fields. So we start with matrices and never leave them.

T3.1.1 Symmetries as matrices

Working definition T3.1 (group)

A **group** is a set G with a product $g \cdot h$ such that (i) the product of two elements is again in G, (ii) there is an identity e with $e \cdot g = g \cdot e = g$, (iii) every g has an inverse g^{-1} with $g\,g^{-1} = g^{-1}g = e$, and (iv) the product is associative [$(g \cdot h) \cdot k = g \cdot (h \cdot k)$, so a long product needs no brackets]. *Operational test for a set of matrices:* check that it contains $\mathbb{1}$, and that it is closed under matrix multiplication and matrix inversion. Associativity is automatic for matrices.

Working definition T3.2 (matrix Lie group)

A **matrix Lie group** is a set of invertible $n \times n$ real or complex matrices which is a group, and which is cut out of the space of all matrices by smooth equations (such as $R^T R = \mathbb{1}$ or $\det U = 1$), so that it is a smooth manifold [near every element the group looks like a

piece of $\mathbb{R}^d$, so nearby elements are labelled by d real coordinates]. Its **dimension** is the number of independent real parameters needed to describe an element near the identity. *How to compute the dimension:* count the real entries of the matrix, then subtract the number of independent real equations in the defining condition.

Almost every group we need is defined by a sentence of the form *"the matrices that preserve a certain structure."* The structure is an inner product, a volume, an orientation or a symplectic form. The defining equation then says that the structure is unchanged. For example, a real matrix R preserves the dot product if $(Rx)\cdot(Ry) = x\cdot y$ for all x, y. Writing the dot product as $x^T y$,

$$(Rx)\cdot(Ry) \overset{(1)}{=} x^T R^T R\, y \overset{(2)}{=} x^T y \quad \text{for all } x,y \quad \Longleftrightarrow \quad R^T R = \mathbb{1}.$$

(1) The transpose of a product reverses the order: $(Rx)^T = x^T R^T$.
(2) This is the requirement. Taking x, y to be basis vectors picks out each entry of $R^T R$, so the requirement holds for all x, y exactly when $R^T R$ is the identity matrix.

T3.1.2 The catalogue of classical groups

Table T3.1 lists the groups we shall meet, with their defining conditions. We now go through them one at a time and count dimensions, because the counting method is the same every time and it is worth doing once slowly.

Group	Matrices	Condition	Preserves	Real dim.
$\mathrm{GL}(n,\mathbb{R})$	real $n\times n$	$\det M \neq 0$	nothing (all invertible)	n^2
$\mathrm{GL}(n,\mathbb{C})$	complex $n\times n$	$\det M \neq 0$	nothing	$2n^2$
$\mathrm{SL}(n,\mathbb{R})$	real	$\det M = 1$	volume and orientation	n^2-1
$\mathrm{O}(n)$	real	$R^T R = \mathbb{1}$	dot product $x\cdot y$	$\frac{1}{2}n(n-1)$
$\mathrm{SO}(n)$	real	$R^T R = \mathbb{1}$, $\det R = 1$	dot product, orientation	$\frac{1}{2}n(n-1)$
$\mathrm{U}(n)$	complex	$U^\dagger U = \mathbb{1}$	$\langle\xi,\chi\rangle = \xi^\dagger\chi$	n^2
$\mathrm{SU}(n)$	complex	$U^\dagger U = \mathbb{1}$, $\det U = 1$	$\xi^\dagger\chi$ and complex volume	n^2-1
$\mathrm{Sp}(2n,\mathbb{R})$	real $2n\times 2n$	$M^T J M = J$	symplectic form $x^T J y$	$n(2n+1)$
$\mathrm{Sp}(n)$	complex $2n\times 2n$	$U^\dagger U = \mathbb{1}$, $U^T J U = J$	both of the above	$n(2n+1)$

Table T3.1: The classical matrix groups. Here $J = \left(\begin{smallmatrix} 0 & \mathbb{1}_n \\ -\mathbb{1}_n & 0 \end{smallmatrix}\right)$. The last column is the number of real parameters. The compact ones are $\mathrm{O}(n)$, $\mathrm{SO}(n)$, $\mathrm{U}(n)$, $\mathrm{SU}(n)$ and $\mathrm{Sp}(n)$.

$\mathrm{GL}(n)$ and $\mathrm{SL}(n)$. The **general linear group** $\mathrm{GL}(n,\mathbb{R})$ is all invertible real matrices. The condition $\det M \neq 0$ is an inequality, not an equation, so it removes no parameters: $\dim \mathrm{GL}(n,\mathbb{R}) = n^2$. The **special linear group** $\mathrm{SL}(n,\mathbb{R})$ imposes one real equation $\det M = 1$, so its dimension is n^2-1. Geometrically, $\det M$ is the factor by which M scales volumes, so $\mathrm{SL}(n)$ is the group of volume-preserving, orientation-preserving linear maps.

$\mathrm{O}(n)$ and $\mathrm{SO}(n)$. The **orthogonal group** preserves the dot product, $R^T R = \mathbb{1}$. Counting:

$$\begin{aligned}\dim \mathrm{O}(n) &\overset{(1)}{=} n^2 - \#\{\text{independent equations in } R^T R = \mathbb{1}\} \\ &\overset{(2)}{=} n^2 - \tfrac{1}{2}n(n+1) \\ &= \tfrac{1}{2}n(n-1).\end{aligned}$$

(1) Start from the n^2 real entries of R and subtract one parameter per independent real equation.
(2) The matrix $R^T R$ is automatically symmetric, $(R^T R)^T = R^T R$, so the equation $R^T R = \mathbb{1}$ has only as many independent components as a symmetric matrix: n on the diagonal plus $\frac{1}{2}n(n-1)$ above it, total $\frac{1}{2}n(n+1)$.

Taking the determinant of $R^T R = \mathbb{1}$ gives $(\det R)^2 = 1$, so $\det R = \pm 1$. The **special orthogonal group** $\mathrm{SO}(n)$ keeps only $\det R = +1$: the rotations, which also preserve orientation. Because det is continuous and can only take the values ± 1, no continuous path in $\mathrm{O}(n)$ joins a rotation to a reflection. So $\mathrm{O}(n)$ has two *connected components*, and $\mathrm{SO}(n)$ is the one containing $\mathbb{1}$. Adding the discrete condition $\det R = 1$ does not change the dimension.

$\mathrm{U}(n)$ and $\mathrm{SU}(n)$. The **unitary group** preserves the complex inner product $\langle \xi, \chi \rangle = \xi^\dagger \chi = \sum_a \bar{\xi}_a \chi_a$: exactly as for $\mathrm{O}(n)$, this means $U^\dagger U = \mathbb{1}$. It is the group of symmetries of quantum mechanics, because it preserves transition amplitudes.

$$\begin{aligned}\dim \mathrm{U}(n) &\overset{(1)}{=} 2n^2 - \#\{\text{real equations in } U^\dagger U = \mathbb{1}\} \\ &\overset{(2)}{=} 2n^2 - n^2 = n^2.\end{aligned}$$

(1) A complex $n \times n$ matrix has n^2 complex, so $2n^2$ real, entries.
(2) $U^\dagger U$ is automatically Hermitian. A Hermitian matrix has n real diagonal entries and $\frac{1}{2}n(n-1)$ complex entries above the diagonal, so $n + n(n-1) = n^2$ real components.

For a unitary matrix, $|\det U|^2 = \det U^\dagger \det U = \det(U^\dagger U) = 1$, so $\det U = e^{i\varphi}$ is a phase. Requiring $\det U = 1$ is therefore *one* real condition (on φ), and the **special unitary group** has $\dim \mathrm{SU}(n) = n^2 - 1$. So $\dim \mathrm{SU}(2) = 3$ (the three components of isospin or spin) and $\dim \mathrm{SU}(3) = 8$ (the eight gluons).

The symplectic groups. Classical mechanics lives on phase space with coordinates (q, p). The Poisson bracket is built from the antisymmetric form $\omega(x, y) = x^T J y$ with $J = \begin{pmatrix} 0 & \mathbb{1}_n \\ -\mathbb{1}_n & 0 \end{pmatrix}$. Linear canonical transformations preserve it: $M^T J M = J$. They form the real symplectic group $\mathrm{Sp}(2n, \mathbb{R})$.

$$\begin{aligned}\dim \mathrm{Sp}(2n, \mathbb{R}) &\overset{(1)}{=} (2n)^2 - \tfrac{1}{2}(2n)(2n-1) \\ &= n(2n+1).\end{aligned}$$

(1) $M^T J M$ is automatically antisymmetric, because $(M^T J M)^T = M^T J^T M = -M^T J M$. An antisymmetric $2n \times 2n$ matrix has $\frac{1}{2}(2n)(2n-1)$ independent entries, and that is the number of equations.

The *compact* symplectic group $\mathrm{Sp}(n)$ consists of the $2n \times 2n$ complex matrices that are both unitary and symplectic. It has the same dimension $n(2n+1)$. It is also the group of $n \times n$ *quaternionic* matrices preserving the quaternionic inner product; we will see in a moment that $\mathrm{Sp}(1) = \mathrm{SU}(2)$.

Watch out: Two names for the same symplectic group

Some books (including the QFT notes, [QFT notes §31.1]) write $\mathrm{Sp}(2N)$ for the group we call $\mathrm{Sp}(N)$, labelling it by the size of the matrices rather than by the quaternionic dimension. Both conventions give the same Lie algebra, of dimension $N(2N+1)$. Always check which is meant by computing the dimension: Sp(1) in our convention ("Sp(2)" in the other) is 3-dimensional.

U(1). The simplest of all is $\mathrm{U}(1) = \{e^{i\alpha}\}$, the 1×1 unitary matrices. It is the symmetry group of electromagnetism: the phase of a charged field.

T3.1.3 U(1) is a circle, and so is SO(2)

Worked example T3.1: $\mathrm{U}(1) \cong \mathrm{SO}(2) \cong S^1$

A 1×1 complex matrix u is unitary when $\bar{u}u = |u|^2 = 1$. So U(1) is the unit circle in the complex plane, $u = e^{i\alpha}$ with $\alpha \in [0, 2\pi)$. Now look at rotations of the plane. Write $R(\alpha) = \left(\begin{smallmatrix}\cos\alpha & -\sin\alpha \\ \sin\alpha & \cos\alpha\end{smallmatrix}\right)$; every element of SO(2) has this form (the first column is a unit vector $(\cos\alpha, \sin\alpha)$, and the second column must be the unit vector perpendicular to it that gives det = +1). The map $e^{i\alpha} \mapsto R(\alpha)$ respects products:

$$R(\alpha)R(\beta) \overset{(1)}{=} \begin{pmatrix}\cos\alpha\cos\beta - \sin\alpha\sin\beta & -(\sin\alpha\cos\beta + \cos\alpha\sin\beta) \\ \sin\alpha\cos\beta + \cos\alpha\sin\beta & \cos\alpha\cos\beta - \sin\alpha\sin\beta\end{pmatrix}$$
$$\overset{(2)}{=} R(\alpha+\beta),$$

(1) Matrix multiplication, row times column.
(2) The addition formulas for $\cos(\alpha+\beta)$ and $\sin(\alpha+\beta)$.

which is the image of $e^{i\alpha}e^{i\beta} = e^{i(\alpha+\beta)}$. So the two groups are the same group written differently. A map between groups that respects products is called a **homomorphism**; a bijective one is an **isomorphism**. Physically, a charged scalar field $\phi = \phi_1 + i\phi_2$ can be written either as one complex number rotating by $e^{i\alpha}$ or as a real 2-vector (ϕ_1, ϕ_2) rotating by $R(\alpha)$.

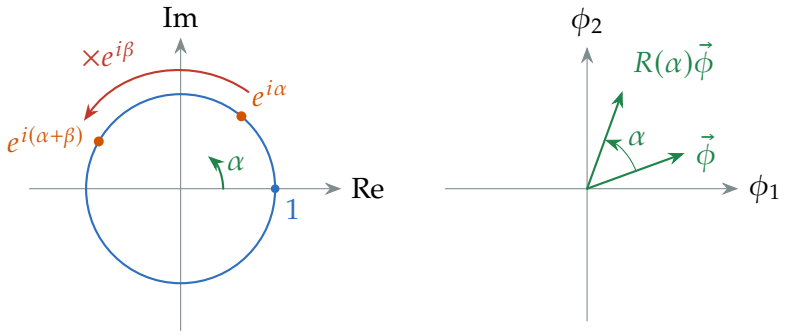

Figure T3.2: Left: U(1) is the unit circle in $\mathbb{C}$; multiplying by $e^{i\beta}$ moves a point a further angle β round the circle, so the group product is addition of angles. Right: the same group acting as SO(2) rotations of a real 2-vector (ϕ_1, ϕ_2).

T3.1.4 SU(2) is the three-sphere

This is the most useful explicit fact in the chapter. Let $U = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ be in SU(2). Because $\det U = 1$, the inverse is given by the familiar 2×2 formula, and because U is unitary the inverse is also $U^\dagger$:

$$\begin{pmatrix} d & -b \\ -c & a \end{pmatrix} \overset{(1)}{=} U^{-1} \overset{(2)}{=} U^\dagger = \begin{pmatrix} \bar a & \bar c \\ \bar b & \bar d \end{pmatrix}.$$

(1) For a 2×2 matrix, $U^{-1} = \frac{1}{\det U}\left(\begin{smallmatrix} d & -b \\ -c & a \end{smallmatrix}\right)$, and $\det U = 1$.
(2) Unitarity: $U^\dagger U = \mathbb{1}$ means $U^{-1} = U^\dagger$.

Comparing entries, $d = \bar a$ and $c = -\bar b$. So

$$U = \begin{pmatrix} a & -\bar b \\ b & \bar a \end{pmatrix}, \qquad \det U = |a|^2 + |b|^2 = 1. \tag{T3.1}$$

Write $a = x^4 + ix^3$ and $b = -x^2 + ix^1$ with four real numbers x^μ. Then

$$\begin{aligned} U &= \begin{pmatrix} x^4 + ix^3 & x^2 + ix^1 \\ -x^2 + ix^1 & x^4 - ix^3 \end{pmatrix} \\ &\overset{(1)}{=} x^4\,\mathbb{1} + i\left(x^1\sigma_1 + x^2\sigma_2 + x^3\sigma_3\right) = x^4\,\mathbb{1} + i\,\vec{x}\cdot\vec{\sigma}, \end{aligned} \tag{T3.2}$$

(1) Using the Pauli matrices

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

we have $ix^1\sigma_1 = \left(\begin{smallmatrix} 0 & ix^1 \\ ix^1 & 0 \end{smallmatrix}\right)$, $ix^2\sigma_2 = \left(\begin{smallmatrix} 0 & x^2 \\ -x^2 & 0 \end{smallmatrix}\right)$, $ix^3\sigma_3 = \mathrm{diag}(ix^3, -ix^3)$; add these to $x^4\mathbb{1}$.

and the condition $\det U = 1$ reads

$$(x^1)^2 + (x^2)^2 + (x^3)^2 + (x^4)^2 = 1. \tag{T3.3}$$

Key idea: SU(2) $\cong S^3$

Every element of SU(2) is $U = x^4\mathbb{1} + i\,\vec{x}\cdot\vec{\sigma}$ for a unique point (x^1, x^2, x^3, x^4) of the unit three-sphere $S^3 \subset \mathbb{R}^4$, and every point of S^3 gives an element of SU(2). The identity is the "north pole" $x^4 = 1$; the element $-\mathbb{1}$ is the "south pole" $x^4 = -1$.

Because S^3 is simply connected (any loop on it can be shrunk to a point), so is SU(2). This fact will be the whole reason spin $\frac{1}{2}$ exists (Section T3.4).

Worked example T3.2: Unit quaternions and Sp(1) = SU(2)

Set $\mathbf{I} = -i\sigma_1$, $\mathbf{J} = -i\sigma_2$, $\mathbf{K} = -i\sigma_3$. Then

$$\begin{aligned} \mathbf{IJ} &\overset{(1)}{=} (-i)^2\sigma_1\sigma_2 \overset{(2)}{=} -i\sigma_3 = \mathbf{K}, \\ \mathbf{I}^2 &\overset{(3)}{=} (-i)^2\sigma_1^2 = -\mathbb{1}, \end{aligned}$$

(1) Definition of $\mathbf{I}, \mathbf{J}$.
(2) The Pauli product rule $\sigma_a\sigma_b = \delta_{ab}\mathbb{1} + i\varepsilon_{abc}\sigma_c$ gives $\sigma_1\sigma_2 = i\sigma_3$, and $(-i)^2\cdot i = -i$.
(3) $\sigma_1^2 = \mathbb{1}$.

and similarly $\mathbf{J}^2 = \mathbf{K}^2 = -\mathbb{1}$, $\mathbf{JK} = \mathbf{I}$, $\mathbf{KI} = \mathbf{J}$. These are Hamilton's quaternion relations. So (T3.2) says $U = x^4 - x^1\mathbf{I} - x^2\mathbf{J} - x^3\mathbf{K}$: SU(2) is the group of *unit quaternions* under multiplication. Unit quaternions are the 1×1 quaternionic unitary matrices, that is Sp(1). The dimension check agrees: $\dim \mathrm{Sp}(1) = 1 \cdot (2+1) = 3 = \dim \mathrm{SU}(2)$.

Worked example T3.3: Conjugacy classes of SU(2) are 2-spheres of latitude

Two group elements U and VUV^{-1} are called **conjugate**; in physics, they are the "same" transformation seen in a rotated frame. Which elements of SU(2) are conjugate? The trace is unchanged by conjugation, $\mathrm{tr}(VUV^{-1}) = \mathrm{tr}(U)$, and from (T3.2) $\mathrm{tr}\, U = 2x^4$ because the Pauli matrices are traceless. So conjugation moves U only within the slice $x^4 = \text{const}$ of S^3. That slice is the 2-sphere $|\vec{x}|^2 = 1 - (x^4)^2$. In fact conjugation moves U over the *whole* slice: writing $\vec{x} = |\vec{x}|\,\hat{n}$, $U = x^4 + i|\vec{x}|\,\hat{n}\cdot\vec{\sigma}$, and we will see in Section T3.4 that $V(\hat{n}\cdot\vec{\sigma})V^{-1} = (R\hat{n})\cdot\vec{\sigma}$ with R an arbitrary rotation. Writing $x^4 = \cos(\theta/2)$ and $|\vec{x}| = \sin(\theta/2)$, the eigenvalues of U are $x^4 \pm i|\vec{x}| = e^{\pm i\theta/2}$, and each conjugacy class is labelled by one angle $\theta \in [0, 2\pi]$. The two poles $\pm\mathbb{1}$ are classes on their own: they commute with everything. They form the **centre** $Z(\mathrm{SU}(2)) = \{\pm\mathbb{1}\} \cong \mathbb{Z}_2$.

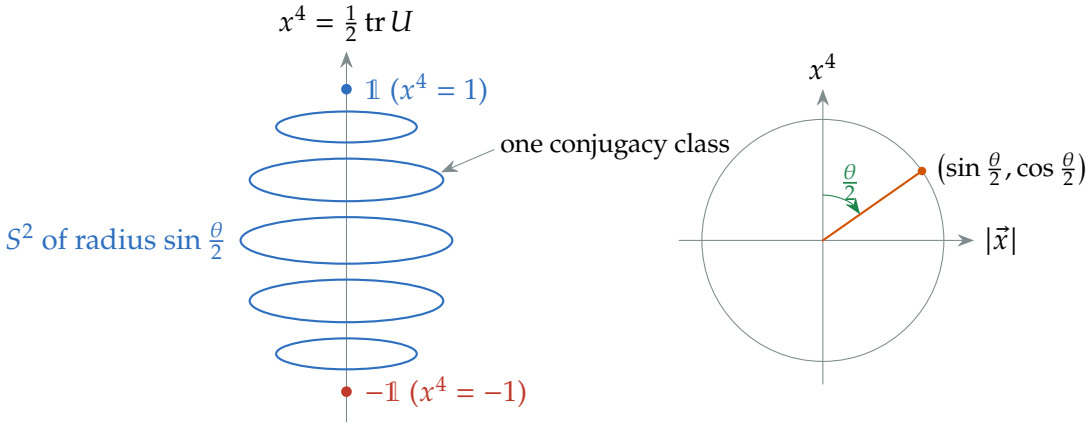

Figure T3.3: SU(2) = S^3 drawn as a stack of 2-spheres, one for each value of $x^4 = \frac{1}{2}\,\mathrm{tr}\, U = \cos\frac{\theta}{2}$. Each 2-sphere is a conjugacy class (all elements with eigenvalues $e^{\pm i\theta/2}$). The stack shrinks to a point at the two poles $\pm\mathbb{1}$, which form the centre. Right: the angle θ that labels the slice.

T3.1.5 SO(3) is a solid ball with its surface glued

Every rotation of $\mathbb{R}^3$ is a rotation by some angle about some axis. This is Euler's theorem, and its proof is a one-line determinant calculation showing that $R \in \mathrm{SO}(3)$ always has eigenvalue 1:

$$\det(R - \mathbb{1}) \overset{(1)}{=} \det(R - RR^T) \overset{(2)}{=} \det R\, \det(\mathbb{1} - R^T) \overset{(3)}{=} \det(\mathbb{1} - R)$$
$$\overset{(4)}{=} (-1)^3 \det(R - \mathbb{1}),$$

(1) $RR^T = \mathbb{1}$ for an orthogonal matrix.
(2) Factor out R on the left; the determinant of a product is the product of determinants.
(3) $\det R = 1$, and a matrix and its transpose have the same determinant.
(4) Pull the factor -1 out of each of the three rows.

so $\det(R-\mathbb{1}) = -\det(R-\mathbb{1}) = 0$. The eigenvector $\hat{n}$ with $R\hat{n} = \hat{n}$ is the axis. In the plane perpendicular to $\hat{n}$, R is an SO(2) rotation by some angle θ. Choosing coordinates with $\hat{n} = \hat{z}$,

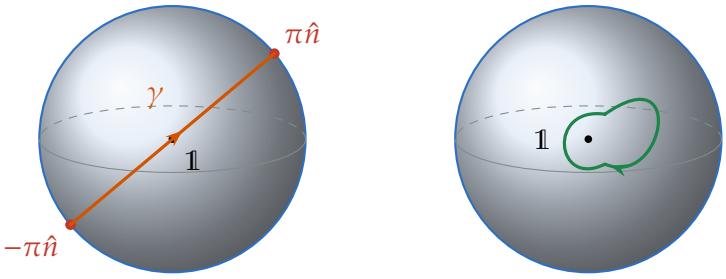
$$R_z(\theta) = \begin{pmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \operatorname{tr} R = 1 + 2\cos\theta. \tag{T3.4}$$

The trace is basis independent, so $\operatorname{tr} R = 1 + 2\cos\theta$ gives the rotation angle of any rotation matrix.

We can now draw SO(3). Represent the rotation by angle $\theta \in [0, \pi]$ about $\hat{n}$ by the vector $\theta\hat{n}$. These vectors fill a solid ball of radius π. Rotations by angles in $(\pi, 2\pi)$ are not new: rotation by θ about $\hat{n}$ equals rotation by $2\pi - \theta$ about $-\hat{n}$. But at the surface there is a double counting: rotation by π about $\hat{n}$ is the same as rotation by π about $-\hat{n}$. So

Key idea: SO(3) as a ball

SO(3) is the solid ball of radius π in which each pair of antipodal points on the surface is identified. This space is the real projective space $\mathbb{RP}^3$.



a closed loop in SO(3) that cannot be shrunk

a loop inside the ball shrinks to $\mathbb{1}$

Figure T3.4: SO(3) as the ball of radius π with antipodal surface points identified: the two red points $\pm\pi\hat{n}$ are the same rotation. Left: the straight path γ from $-\pi\hat{n}$ to $\pi\hat{n}$ (a full 2π rotation about $\hat{n}$) is a *closed* loop, because its endpoints are the same rotation. Moving the endpoints moves both at once (they must stay antipodal), so this loop can never be shrunk. Right: an ordinary loop that stays inside can be shrunk. We show in Section T3.4 that going round γ *twice* can be shrunk.

Worked example T3.4: Axis and angle of a permutation matrix

Take the matrix that cycles the axes, $R\,\hat{x} = \hat{y}$, $R\,\hat{y} = \hat{z}$, $R\,\hat{z} = \hat{x}$:

$$R = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

It is orthogonal (its columns are orthonormal) and $\det R = +1$. Then

$$1 + 2\cos\theta \overset{(1)}{=} \operatorname{tr} R \overset{(2)}{=} 0 \quad \Longrightarrow \quad \cos\theta = -\tfrac{1}{2}, \;\; \theta = \tfrac{2\pi}{3},$$

(1) The trace formula (T3.4), valid in any basis.
(2) All diagonal entries of R vanish.

The axis is the fixed vector: $R(1,1,1)^T = (1,1,1)^T$, so $\hat{n} = (1,1,1)/\sqrt{3}$. Geometrically: a rotation by 120° about the body diagonal of a cube permutes the three axes. Note that $R^3 = \mathbb{1}$, consistent with $3 \times 120° = 360°$.

T3.1.6 Topology at a glance

Several global properties of these groups matter in gauge theory. A group is **compact** if it is closed and bounded as a set of matrices; $\mathrm{U}(n)$ is bounded because each column of a unitary matrix is a unit vector. Compact groups have unitary finite-dimensional representations and positive-definite invariant inner products on their Lie algebras, which is why gauge groups are compact: the kinetic energy must be positive. The **fundamental group** $\pi_1(G)$ classifies loops in G up to deformation, and $\pi_3(G)$ classifies maps $S^3 \to G$ up to deformation. Table T3.2 collects the facts.

G	compact	π_0 (components)	π_1	π_3
$\mathrm{U}(1) = S^1$	yes	0	$\mathbb{Z}$	0
$\mathrm{SU}(2) = S^3$	yes	0	0	$\mathbb{Z}$
$\mathrm{SO}(3) = \mathbb{RP}^3$	yes	0	$\mathbb{Z}_2$	$\mathbb{Z}$
$\mathrm{SU}(n)$, $n \geq 2$	yes	0	0	$\mathbb{Z}$
$\mathrm{U}(n)$	yes	0	$\mathbb{Z}$	$\mathbb{Z}$ $(n \geq 2)$
$\mathrm{SO}(n)$, $n \geq 3$	yes	0	$\mathbb{Z}_2$	$\mathbb{Z}$ $(n = 3, n \geq 5)$, $\mathbb{Z} \oplus \mathbb{Z}$ $(n = 4)$
$\mathrm{O}(n)$	yes	$\mathbb{Z}_2$	as $\mathrm{SO}(n)$	as $\mathrm{SO}(n)$

$\mathrm{SL}(2, \mathbb{R})$	no	0	$\mathbb{Z}$	0

Table T3.2: Topological data of the common Lie groups. Two entries matter most for physics. $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$ is the winding number of a phase, which gives Dirac monopoles and vortices. $\pi_3(G) = \mathbb{Z}$ for every compact simple G is the winding number of a gauge transformation at infinity in four dimensions, which gives instantons.

Three entries can be understood right now. $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$: a loop $\alpha \mapsto e^{in\alpha}$ in the circle winds n times, and loops with different n cannot be deformed into each other. $\pi_1(\mathrm{SU}(2)) = 0$ and $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$: $\mathrm{SU}(2)$ is S^3, loops on S^3 shrink, and maps $S^3 \to S^3$ have an integer degree (we compute it with an integral in Section T3.6). $\pi_1(\mathrm{U}(n)) = \mathbb{Z}$: the map $\det : \mathrm{U}(n) \to \mathrm{U}(1)$ sends a loop in $\mathrm{U}(n)$ to a loop in the circle, and its winding number is the invariant. The entry $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$ is explained in Section T3.4.

Try it: The Lorentz group has dimension 6

The Lorentz group $\mathrm{O}(1,3)$ consists of real 4×4 matrices with $\Lambda^T \eta \Lambda = \eta$, $\eta = \mathrm{diag}(-1,1,1,1)$. Count its dimension.
Answer: $\Lambda^T \eta \Lambda$ is symmetric, so there are 10 equations and $16 - 10 = 6$ parameters: three rotations and three boosts. It is not compact, since boosts can be arbitrarily large.

Reading Nash (where these groups appear)

Nash takes Lie groups for granted. His structure groups are "G a compact simple Lie group", typically $\mathrm{SU}(2)$ for instantons [Nash p. 25, (1.74)] and $\mathrm{U}(N)$ or $\mathrm{SU}(N)$ when he computes the cohomology of the gauge group [Nash p. 223, (8.38)]. The fact $\pi_3(G) = \mathbb{Z}$ that we quoted in Table T3.2 is what he uses to count the components of the gauge group in three dimensions [Nash p. 227, (8.59)]: $\pi_0(\mathcal{G}) = \pi_3(G) = \mathbb{Z}$. The 3-sphere picture of $\mathrm{SU}(2)$ is used silently throughout Chapter 8.

Recap

- A matrix Lie group is a group of matrices defined by smooth equations; its dimension is the number of entries minus the number of independent equations.
- $\dim \mathrm{SO}(n) = \frac{1}{2}n(n-1)$, $\dim \mathrm{U}(n) = n^2$, $\dim \mathrm{SU}(n) = n^2 - 1$, $\dim \mathrm{Sp}(n) = n(2n+1)$.
- $\mathrm{U}(1) = \mathrm{SO}(2) = S^1$; $\mathrm{SU}(2) = \{x^4 + i\vec{x}\cdot\vec{\sigma}\} = S^3$ = unit quaternions = $\mathrm{Sp}(1)$.
- $\mathrm{SO}(3)$ is a ball of radius π with antipodal surface points glued, $\mathbb{RP}^3$; $\mathrm{tr}\, R = 1 + 2\cos\theta$.
- Topological data: $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$, $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$, $\pi_3(G) = \mathbb{Z}$ for compact simple G.

T3.2 Lie algebras: the tangent space at the identity

A Lie group is a curved space: U(1) is a circle and SU(2) is a 3-sphere. Curved spaces are hard to work with, but near any point they look flat. Near the identity, a group element is "the identity plus something small", and the small somethings form an ordinary vector space. Physicists call its elements *infinitesimal generators*: angular momentum generates rotations, charge generates phase rotations, momentum generates translations. The question of this section is: *what is left of the group structure once we zoom in to the identity?* The answer is a vector space together with one extra operation, the commutator, and that is a Lie algebra.

T3.2.1 Infinitesimal transformations

Take a smooth curve $g(t)$ in the group with $g(0) = \mathbb{1}$. Its velocity at $t = 0$,

$$X = \left.\frac{\mathrm{d}g}{\mathrm{d}t}\right|_{t=0}, \qquad g(\varepsilon) = \mathbb{1} + \varepsilon X + O(\varepsilon^2),$$

is a matrix: a tangent vector to the group at the identity.

Working definition T3.3 (Lie algebra of a matrix group)

The **Lie algebra** $\mathfrak{g}$ of a matrix group G is the set of all velocities $X = \dot{g}(0)$ of curves through the identity. It is a real vector space [if X and Y are velocities, so is every real combination $aX + bY$] of the same dimension as G. *How to find it:* substitute $g = \mathbb{1} + \varepsilon X$ into the defining equations of G and keep the terms of first order in ε. The resulting *linear* equations on X define $\mathfrak{g}$. We write the Lie algebra of a group with the same letters in lower-case Fraktur: $\mathfrak{su}(2)$, $\mathfrak{so}(3)$, $\mathfrak{u}(1)$.

Orthogonal groups. Put $R = \mathbb{1} + \varepsilon X$ in $R^T R = \mathbb{1}$:

$$\mathbb{1} \overset{(1)}{=} (\mathbb{1} + \varepsilon X)^T(\mathbb{1} + \varepsilon X) \overset{(2)}{=} \mathbb{1} + \varepsilon\,(X^T + X) + O(\varepsilon^2) \quad\Longrightarrow\quad X^T = -X.$$

(1) The defining equation of $\mathrm{O}(n)$ with $R = \mathbb{1} + \varepsilon X$.
(2) Multiply out; the $\varepsilon^2 X^T X$ term is second order. The first-order term must vanish on its own.

So $\mathfrak{so}(n) = \mathfrak{o}(n)$ is the space of real *antisymmetric* matrices. An antisymmetric $n \times n$ matrix has $\frac{1}{2}n(n-1)$ free entries, matching $\dim \mathrm{SO}(n)$.

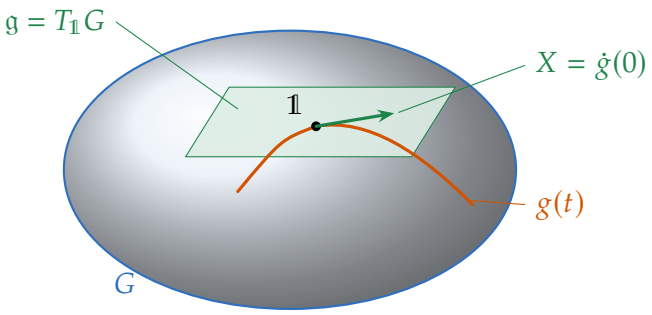

Figure T3.5: A curve $g(t)$ in the group passes through the identity at $t = 0$. Its velocity X lives in the flat tangent plane at $\mathbb{1}$. The set of all such velocities is the Lie algebra $\mathfrak{g}$. Near $\mathbb{1}$, $g(\varepsilon) \approx \mathbb{1} + \varepsilon X$.

Unitary groups. The same calculation with $U^\dagger U = \mathbb{1}$ gives $X^\dagger = -X$: $\mathfrak{u}(n)$ is the space of *anti-Hermitian* matrices, of real dimension n^2. For $\mathrm{SU}(n)$ we also need $\det U = 1$. For small ε,

$$\det(\mathbb{1} + \varepsilon X) \overset{(1)}{=} \prod_{i=1}^{n}(1 + \varepsilon\lambda_i) \overset{(2)}{=} 1 + \varepsilon \sum_i \lambda_i + O(\varepsilon^2) = 1 + \varepsilon\ \mathrm{tr}\, X + O(\varepsilon^2),$$

(1) The determinant is the product of the eigenvalues, and the eigenvalues of $\mathbb{1} + \varepsilon X$ are $1 + \varepsilon\lambda_i$ where λ_i are those of X.
(2) Expand the product to first order; the sum of eigenvalues is the trace.

so $\det U = 1$ linearises to $\mathrm{tr}\, X = 0$. Hence $\mathfrak{su}(n)$ is the space of *traceless anti-Hermitian* matrices, of dimension $n^2 - 1$. The same argument gives $\mathfrak{sl}(n) = \{\mathrm{tr}\, X = 0\}$ and $\mathfrak{gl}(n) =$ all matrices.

Symplectic groups. $M^T J M = J$ linearises to $X^T J + J X = 0$.

Group G	Lie algebra $\mathfrak{g}$	Condition on X	dim
$\mathrm{GL}(n,\mathbb{R})$	$\mathfrak{gl}(n,\mathbb{R})$	none	n^2
$\mathrm{SL}(n,\mathbb{R})$	$\mathfrak{sl}(n,\mathbb{R})$	$\mathrm{tr}\, X = 0$	$n^2 - 1$
$\mathrm{SO}(n)$	$\mathfrak{so}(n)$	$X^T = -X$	$\frac{1}{2}n(n-1)$
$\mathrm{U}(n)$	$\mathfrak{u}(n)$	$X^\dagger = -X$	n^2
$\mathrm{SU}(n)$	$\mathfrak{su}(n)$	$X^\dagger = -X$, $\mathrm{tr}\, X = 0$	$n^2 - 1$
$\mathrm{Sp}(2n,\mathbb{R})$	$\mathfrak{sp}(2n,\mathbb{R})$	$X^T J + J X = 0$	$n(2n+1)$
$\mathrm{Sp}(n)$	$\mathfrak{sp}(n)$	$X^\dagger = -X$, $X^T J + J X = 0$	$n(2n+1)$

Table T3.3: Lie algebras of the classical groups, obtained by linearising the defining equations. The dimensions agree with Table T3.1, as they must: a manifold and its tangent space have the same dimension.

T3.2.2 What survives of the product: the commutator

A vector space cannot know whether the group was commutative. U(1) and $\mathbb{R}$ both have one-dimensional Lie algebras, but so would a hypothetical non-commutative group. The information that survives is *how badly group elements fail to commute*, measured to second order. Take two curves

$$g = \mathbb{1} + \varepsilon X + \varepsilon^2 A + O(\varepsilon^3), \qquad h = \mathbb{1} + \varepsilon Y + \varepsilon^2 B + O(\varepsilon^3).$$

Their inverses are, to the same order, $g^{-1} = \mathbb{1} - \varepsilon X + \varepsilon^2(X^2 - A)$ and $h^{-1} = \mathbb{1} - \varepsilon Y + \varepsilon^2(Y^2 - B)$; multiply out $g\,g^{-1}$ to check. Now compute the **group commutator** $ghg^{-1}h^{-1}$, which is $\mathbb{1}$ exactly when g and h commute:

$$\begin{aligned} gh &\overset{(1)}{=} \mathbb{1} + \varepsilon(X+Y) + \varepsilon^2(A + B + XY), \\ g^{-1}h^{-1} &\overset{(2)}{=} \mathbb{1} - \varepsilon(X+Y) + \varepsilon^2(X^2 + Y^2 - A - B + XY), \\ ghg^{-1}h^{-1} &\overset{(3)}{=} \mathbb{1} + \varepsilon^2\big[(A + B + XY) + (X^2 + Y^2 - A - B + XY) - (X+Y)^2\big] \\ &\overset{(4)}{=} \mathbb{1} + \varepsilon^2\,(XY - YX) + O(\varepsilon^3). \end{aligned} \tag{T3.5}$$

(1) Multiply the two expansions, keeping terms up to ε^2.
(2) The same for the inverses; the cross term is $(-\varepsilon X)(-\varepsilon Y) = \varepsilon^2 XY$.
(3) Multiply $(gh)(g^{-1}h^{-1})$. The ε terms cancel. At order ε^2 we get the two ε^2 coefficients plus the product of the two first-order terms, $(X+Y)(-(X+Y))$.
(4) Expand $(X+Y)^2 = X^2 + XY + YX + Y^2$. Everything cancels except $2XY - XY - YX$. Notice that the arbitrary second-order terms A, B have dropped out.

So the first sign of non-commutativity is the **commutator** $[X,Y] = XY - YX$ of the two generators. It is again in $\mathfrak{g}$: the curve $t \mapsto g(\sqrt{t})h(\sqrt{t})g(\sqrt{t})^{-1}h(\sqrt{t})^{-1}$ lies in G and by (T3.5) has velocity $[X,Y]$ at $t = 0$. You can also check it directly; for example, for X, Y anti-Hermitian, $[X,Y]^\dagger = [Y^\dagger, X^\dagger] = [-Y, -X] = -[X,Y]$, and $\mathrm{tr}[X,Y] = 0$ always.

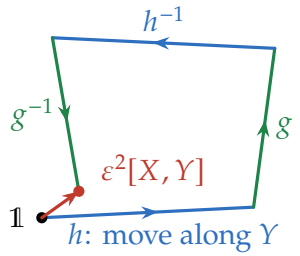

Figure T3.6: Reading right to left, $ghg^{-1}h^{-1}$ is: step along Y, step along X, step back along Y, step back along X. In a commutative group the path would close. In general it misses by $\varepsilon^2[X,Y]$: the commutator is the "gap" left by an infinitesimal rectangle. We will meet the same picture again when the curvature F appears as the failure of a small loop of parallel transports to close (Section T3.9).

Working definition T3.4 (abstract Lie algebra)

A **Lie algebra** is a real (or complex) vector space $\mathfrak{g}$ with a bracket $[\cdot,\cdot] : \mathfrak{g} \times \mathfrak{g} \to \mathfrak{g}$ [for matrices, the commutator $[X,Y] = XY - YX$] which is

1. bilinear [linear in each slot, e.g. $[aX + bY, Z] = a[X,Z] + b[Y,Z]$];
2. antisymmetric, $[X,Y] = -[Y,X]$;
3. obeys the **Jacobi identity** $[X,[Y,Z]] + [Y,[Z,X]] + [Z,[X,Y]] = 0$.

In practice: every Lie algebra we meet is a space of matrices closed under the commutator, and (1)–(3) are then automatic.

For matrices, Jacobi is a direct check:

$$\begin{aligned} [X,[Y,Z]] + \text{cyclic} &\overset{(1)}{=} (XYZ - XZY - YZX + ZYX) + (YZX - YXZ - ZXY + XZY) \\ &\quad + (ZXY - ZYX - XYZ + YXZ) \\ &\overset{(2)}{=} 0. \end{aligned}$$

(1) Expand each double commutator, $[X,[Y,Z]] = X(YZ-ZY)-(YZ-ZY)X$, and likewise for the cyclic permutations $X\to Y\to Z\to X$.
(2) Each of the six words $XYZ, XZY, \dots$ appears once with each sign.

T3.2.3 Structure constants

Choose a basis $T_1,\dots,T_N$ of $\mathfrak{g}$ ($N=\dim\mathfrak{g}$). The commutator of two basis elements is again in $\mathfrak{g}$, so it is a combination of basis elements:

$$[T_a,T_b] = f_{ab}{}^{c}\,T_c. \tag{T3.6}$$

The real numbers $f_{ab}{}^{c}$ are the **structure constants**. By bilinearity they determine every commutator: $[X,Y]=X^aY^b f_{ab}{}^{c}T_c$ for $X=X^aT_a$, $Y=Y^bT_b$. They are antisymmetric in a,b. Inserting (T3.6) into the Jacobi identity for T_a,T_b,T_c gives the component form

$$f_{bc}{}^{d}f_{ad}{}^{e}+f_{ca}{}^{d}f_{bd}{}^{e}+f_{ab}{}^{d}f_{cd}{}^{e}=0. \tag{T3.7}$$

For compact groups one can always choose the basis so that f_{abc} (index lowered with δ_{ab}) is totally antisymmetric; we will see why in Section T3.4.

Key idea: The structure constants are the group, to second order

Two groups with the same structure constants look identical near the identity. The Lie algebra captures everything *local* about the group. It misses only global information, such as whether SU(2) or SO(3) is meant (Section T3.4).

T3.2.4 The two most important examples: $\mathfrak{su}(2)$ and $\mathfrak{so}(3)$

Worked example T3.5: $\mathfrak{su}(2)$ from the Pauli matrices

A traceless anti-Hermitian 2×2 matrix is $X=-\tfrac{i}{2}(X^1\sigma_1+X^2\sigma_2+X^3\sigma_3)$ with real X^a (the Pauli matrices span the traceless Hermitian matrices, and $-i$ times Hermitian is anti-Hermitian). So a basis of $\mathfrak{su}(2)$ is

$$T_a=-\tfrac{i}{2}\sigma_a,\qquad a=1,2,3. \tag{T3.8}$$

Their commutators:

$$[T_a,T_b]\overset{(1)}{=}\left(-\tfrac{i}{2}\right)^2[\sigma_a,\sigma_b]\overset{(2)}{=}-\tfrac{1}{4}\cdot 2i\varepsilon_{abc}\sigma_c\overset{(3)}{=}\varepsilon_{abc}\left(-\tfrac{i}{2}\sigma_c\right)=\varepsilon_{abc}T_c.$$

(1) Bilinearity: numerical factors come out of the bracket.
(2) The Pauli matrices obey $\sigma_a\sigma_b=\delta_{ab}\mathbb{1}+i\varepsilon_{abc}\sigma_c$, so $[\sigma_a,\sigma_b]=2i\varepsilon_{abc}\sigma_c$. For instance $\sigma_1\sigma_2=\left(\begin{smallmatrix}0&1\\1&0\end{smallmatrix}\right)\left(\begin{smallmatrix}0&-i\\i&0\end{smallmatrix}\right)=\left(\begin{smallmatrix}i&0\\0&-i\end{smallmatrix}\right)=i\sigma_3$.
(3) Rearrange: $-\tfrac{1}{4}\cdot 2i=-\tfrac{i}{2}$.

So the structure constants of $\mathfrak{su}(2)$ in this basis are $f_{abc}=\varepsilon_{abc}$: $[T_1,T_2]=T_3$ and cyclic permutations.

Worked example T3.6: $\mathfrak{so}(3)$: rotation generators

An antisymmetric real 3×3 matrix has three free entries. A convenient basis is $(L_a)_{bc} = -\varepsilon_{abc}$:

$$L_1 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}, \quad L_2 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix}, \quad L_3 = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Each L_a acts on a vector by a cross product with the a-th axis:

$$(L_a v)_b \overset{(1)}{=} -\varepsilon_{abc} v_c \overset{(2)}{=} \varepsilon_{bac} v_c \overset{(3)}{=} (\hat{e}_a \times v)_b,$$

(1) Definition of L_a and matrix multiplication (sum over c).
(2) ε is antisymmetric under swapping two indices.
(3) The cross product in components is $(u \times v)_b = \varepsilon_{bdc} u_d v_c$, and for $u = \hat{e}_a$ only $d = a$ contributes.

so L_3 generates rotations about $\hat{z}$: $L_3(x, y, z)^T = (-y, x, 0)^T$, the velocity of a point rotating anticlockwise about the z-axis. Multiplying out,

$$L_1 L_2 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

$$L_2 L_1 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

$$[L_1, L_2] \overset{(1)}{=} \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = L_3.$$

(1) Subtract the two products and compare with L_3 above.

By cyclic symmetry $[L_a, L_b] = \varepsilon_{abc} L_c$. *These are the same structure constants as* $\mathfrak{su}(2)$. The linear map $T_a \mapsto L_a$ is an isomorphism of Lie algebras, $\mathfrak{su}(2) \cong \mathfrak{so}(3)$. The groups are nevertheless different, as we will see in Section T3.4.

T3.2.5 Mathematicians' and physicists' generators

Physicists prefer Hermitian generators, because Hermitian operators are observables. They write a group element near the identity as $U = \mathbb{1} + i\varepsilon^a J_a$ with $J_a = J_a^\dagger$, and the Lie algebra as

$$[J_a, J_b] = i\, f_{abc}\, J_c. \tag{T3.9}$$

For spin $\frac{1}{2}$, $J_a = \frac{1}{2}\sigma_a$, and (T3.9) with $f_{abc} = \varepsilon_{abc}$ is the angular momentum algebra. The two conventions are related by $T_a = -iJ_a$:

$$[T_a, T_b] \overset{(1)}{=} (-i)^2 [J_a, J_b] \overset{(2)}{=} -i f_{abc} J_c \overset{(3)}{=} f_{abc} T_c,$$

(1) Substitute $T_a = -iJ_a$.
(2) Use (T3.9): $(-1) \cdot i f_{abc} J_c$.
(3) $-iJ_c = T_c$.

so *the real structure constants are the same* in both conventions.

Dictionary: generators

Mathematics (Nash, these notes)	**Physics (QFT notes)**
$X \in \mathfrak{su}(n)$ anti-Hermitian	$J = iX$ Hermitian
$[T_a, T_b] = f_{abc} T_c$	$[J_a, J_b] = i f_{abc} J_c$
$g = e^X$, $X = \alpha^a T_a$	$U = e^{i\alpha^a J_a}$
$T_a = -\frac{i}{2}\sigma_a$	$J_a = \frac{1}{2}\sigma_a$
$\operatorname{tr}(T_a T_b) = -\frac{1}{2}\delta_{ab}$	$\operatorname{tr}(J_a J_b) = \frac{1}{2}\delta_{ab}$

Watch out: Factors of i and signs of f

Some physics texts use $U = e^{-i\alpha^a J_a}$, which flips the sign of α but not of f_{abc}. When comparing formulas, always check one commutator, such as $[J_1, J_2] = iJ_3$ or $[T_1, T_2] = T_3$, in the source you are reading. Nash himself switches to the physicists' form for Kac–Moody algebras, writing if^{abc} [Nash p. 182, (6.9)].

T3.2.6 $\mathfrak{su}(3)$ and the Gell-Mann matrices

$\mathfrak{su}(3)$ has dimension $3^2 - 1 = 8$. The physicists' Hermitian basis is $J_a = \frac{1}{2}\lambda_a$, with the **Gell-Mann matrices**

$$\lambda_1 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad \lambda_2 = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad \lambda_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad \lambda_4 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix},$$

$$\lambda_5 = \begin{pmatrix} 0 & 0 & -i \\ 0 & 0 & 0 \\ i & 0 & 0 \end{pmatrix}, \quad \lambda_6 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \quad \lambda_7 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{pmatrix}, \quad \lambda_8 = \frac{1}{\sqrt{3}} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{pmatrix}.$$

They are traceless, Hermitian, and normalised as $\operatorname{tr}(\lambda_a \lambda_b) = 2\delta_{ab}$. The first three are the Pauli matrices sitting in the upper-left 2×2 block, so they generate an SU(2) subgroup ("isospin"). The pairs (λ_4, λ_5) and (λ_6, λ_7) do the same for the $(1,3)$ and $(2,3)$ blocks. The two diagonal ones, λ_3 and λ_8, commute with each other.

The nonzero structure constants $[J_a, J_b] = i f_{abc} J_c$ are, up to antisymmetry,

$$f_{123} = 1, \quad f_{147} = f_{246} = f_{257} = f_{345} = \tfrac{1}{2}, \quad f_{156} = f_{367} = -\tfrac{1}{2}, \quad f_{458} = f_{678} = \tfrac{\sqrt{3}}{2}. \tag{T3.10}$$

Worked example T3.7: Computing two $\mathfrak{su}(3)$ structure constants

Write E_{ij} for the matrix with a 1 in row i, column j and zeros elsewhere, so $E_{ij}E_{kl} = \delta_{jk}E_{il}$. Then $\lambda_4 = E_{13} + E_{31}$ and $\lambda_5 = -iE_{13} + iE_{31}$, and

$$\lambda_4\lambda_5 \overset{(1)}{=} (E_{13} + E_{31})(-iE_{13} + iE_{31}) \overset{(2)}{=} iE_{11} - iE_{33},$$

$$\lambda_5\lambda_4 \overset{(3)}{=} -iE_{11} + iE_{33},$$

$$[\lambda_4, \lambda_5] = 2i(E_{11} - E_{33}) \overset{(4)}{=} 2i\left(\tfrac{1}{2}\lambda_3 + \tfrac{\sqrt{3}}{2}\lambda_8\right).$$

(1) Substitute.
(2) Only $E_{13}E_{31} = E_{11}$ and $E_{31}E_{13} = E_{33}$ survive; the products $E_{13}E_{13}$ and $E_{31}E_{31}$ vanish.
(3) The same computation in the other order.
(4) $\frac{1}{2}\lambda_3 + \frac{\sqrt{3}}{2}\lambda_8 = \operatorname{diag}(\frac{1}{2}, -\frac{1}{2}, 0) + \operatorname{diag}(\frac{1}{2}, \frac{1}{2}, -1) = \operatorname{diag}(1, 0, -1) = E_{11} - E_{33}$.

Dividing by 4 to convert to $J_a = \frac{1}{2}\lambda_a$: $[J_4, J_5] = i\left(\frac{1}{2}J_3 + \frac{\sqrt{3}}{2}J_8\right)$, so $f_{453} = f_{345} = \frac{1}{2}$ and $f_{458} = \frac{\sqrt{3}}{2}$, as in (T3.10). Similarly $[\lambda_1, \lambda_2] = 2i\lambda_3$ is just the Pauli algebra, giving $f_{123} = 1$.

T3.2.7 Abelian, simple and semisimple

A Lie algebra is **abelian** if all brackets vanish ($\mathfrak{u}(1)$, or $\mathbb{R}^n$). A subspace $\mathfrak{h} \subset \mathfrak{g}$ with $[\mathfrak{g}, \mathfrak{h}] \subset \mathfrak{h}$ is an **ideal**; it generates a normal subgroup. A non-abelian $\mathfrak{g}$ with no ideals other than 0 and itself is **simple** ($\mathfrak{su}(n)$, $\mathfrak{so}(n)$ for $n \neq 2, 4$, $\mathfrak{sp}(n)$, and five exceptional algebras); a direct sum of simple algebras is **semisimple**. Two decompositions come up constantly:

- $\mathfrak{u}(n) = \mathfrak{u}(1) \oplus \mathfrak{su}(n)$: split an anti-Hermitian X as $X = \frac{\operatorname{tr} X}{n}\mathbb{1} + \left(X - \frac{\operatorname{tr} X}{n}\mathbb{1}\right)$. The first piece commutes with everything. (The Standard Model gauge algebra $\mathfrak{su}(3) \oplus \mathfrak{su}(2) \oplus \mathfrak{u}(1)$ is of this "semisimple plus abelian" kind.)
- $\mathfrak{so}(4) = \mathfrak{su}(2) \oplus \mathfrak{su}(2)$, which is behind the split of 2-forms in four dimensions into self-dual and anti-self-dual parts (see the next box).

Try it: $\mathfrak{so}(4) \cong \mathfrak{su}(2) \oplus \mathfrak{su}(2)$

Let L_a ($a = 1, 2, 3$) be the rotations of the first three coordinates of $\mathbb{R}^4$ (the matrices L_a above, padded with a zero fourth row and column), and let B_a be the rotation in the $(a, 4)$ plane, $B_a = E_{4a} - E_{a4}$. Multiplying 4×4 matrices one finds $[L_a, L_b] = \varepsilon_{abc}L_c$, $[L_a, B_b] = \varepsilon_{abc}B_c$ and $[B_a, B_b] = \varepsilon_{abc}L_c$. Show that $N_a^{\pm} = \frac{1}{2}(L_a \pm B_a)$ satisfy $[N_a^{\pm}, N_b^{\pm}] = \varepsilon_{abc}N_c^{\pm}$ and $[N_a^{+}, N_b^{-}] = 0$. *Answer:* $[N_a^{+}, N_b^{+}] = \frac{1}{4}\varepsilon_{abc}(L_c + B_c + B_c + L_c) = \varepsilon_{abc}N_c^{+}$, and $[N_a^{+}, N_b^{-}] = \frac{1}{4}([L_a, L_b] - [L_a, B_b] + [B_a, L_b] - [B_a, B_b]) = \frac{1}{4}\varepsilon_{abc}(L_c - B_c + B_c - L_c) = 0$, using $[B_a, L_b] = -[L_b, B_a] = \varepsilon_{abc}B_c$. The N^{+} and N^{-} generate the self-dual and anti-self-dual rotations of $\mathbb{R}^4$ (Chapter 8).

Reading Nash (infinite-dimensional Lie algebras)

Nash's chapter 6 applies the idea "Lie algebra = tangent space at the identity" to infinite-dimensional groups [Nash pp. 173–178]. The recipe is exactly our working definition. For the group $\mathrm{Map}(X, G)$ of G-valued functions, a curve through the identity is $g_t(x)$ with $g_0(x) = \mathbb{1}$, so its velocity is a $\mathfrak{g}$-valued function: the Lie algebra is $\mathrm{Map}(X, \mathfrak{g})$ with the pointwise commutator. For the loop group $LG = \mathrm{Map}(S^1, G)$, expanding in Fourier modes $T_n^a = T^a e^{in\theta}$ gives $[T_m^a, T_n^b] = f_{ab}{}^c T_{m+n}^c$, which Nash then centrally extends to a Kac–Moody algebra. For $\mathrm{Diff}(X)$, a curve of diffeomorphisms through the identity has a velocity vector field, so the Lie algebra is the space of vector fields with the Lie bracket.

Recap

- $\mathfrak{g} = T_{\mathbb{1}}G$: linearise the defining equations. $\mathfrak{so}(n)$ is antisymmetric, $\mathfrak{u}(n)$ anti-Hermitian, $\mathfrak{su}(n)$ traceless anti-Hermitian matrices.
- The group commutator $ghg^{-1}h^{-1} = \mathbb{1} + \varepsilon^2[X, Y] + \ldots$, so $\mathfrak{g}$ is closed under $[X, Y] = XY - YX$, which obeys Jacobi.
- Structure constants: $[T_a, T_b] = f_{ab}{}^c T_c$. For $\mathfrak{su}(2)$ with $T_a = -\frac{i}{2}\sigma_a$ and for $\mathfrak{so}(3)$ with $(L_a)_{bc} = -\varepsilon_{abc}$, $f_{abc} = \varepsilon_{abc}$.
- Physicists use $J_a = iT_a$ Hermitian, $[J_a, J_b] = if_{abc}J_c$; the f's agree.
- $\mathfrak{su}(3)$: Gell-Mann matrices, eight generators, two commuting diagonal ones.

T3.3 The exponential map

The Lie algebra is the set of infinitesimal transformations. But physics needs finite ones: a rotation by 90°, a time evolution over one second, a gauge transformation that winds once around a circle. How do we get from a generator X to a finite group element? The physicist's answer is to compose a huge number of tiny steps. Rotating by θ is the same as rotating N times by θ/N, and for large N each small rotation is $\mathbb{1} + \frac{\theta}{N}X$. So

$$g = \lim_{N\to\infty}\left(\mathbb{1} + \frac{\theta X}{N}\right)^N = e^{\theta X}.$$

This is the same limit that turns compound interest into e^{rt}. The matrix exponential is the bridge from the algebra back to the group. This section computes it explicitly for the groups we care about, finds out how far it reaches, and finds out what happens to products.

T3.3.1 Definition and first properties

Working definition T3.5 (matrix exponential)

For any square matrix X,

$$e^X = \exp X := \sum_{k=0}^{\infty} \frac{X^k}{k!} = \mathbb{1} + X + \tfrac{1}{2}X^2 + \tfrac{1}{6}X^3 + \cdots .$$

The series always converges, because each entry of X^k is bounded by $(n\|X\|)^k$ with $\|X\|$ the largest entry, and $\sum c^k/k! = e^c$ is finite. *How to compute it in practice:* find a polynomial relation that X satisfies (for example $X^2 = -\mathbb{1}$ or $X^3 = -X$), use it to reduce every power X^k to a few low powers, and sum the resulting scalar series, which are usually cos, sin, cosh, sinh. Alternatively, diagonalise [possible when X has n independent eigenvectors, which form the columns of P]: if $X = P\,\mathrm{diag}(\lambda_i)P^{-1}$ then $e^X = P\,\mathrm{diag}(e^{\lambda_i})P^{-1}$.

The diagonalisation recipe works because conjugation passes through every power, $(PDP^{-1})^k = PD^kP^{-1}$, and hence through the whole series. The same argument gives a formula we shall use over and over:

$$g\,e^X g^{-1} = e^{gXg^{-1}} \qquad \text{for any invertible } g. \tag{T3.11}$$

One-parameter subgroups. Fix X and let t vary. Since sX and tX commute, the exponential series multiplies like the ordinary exponential (the binomial theorem needs only commutativity):

$$e^{sX}e^{tX} = e^{(s+t)X}, \qquad e^{0X} = \mathbb{1}, \qquad \left(e^{tX}\right)^{-1} = e^{-tX}. \tag{T3.12}$$

So $t \mapsto e^{tX}$ is a homomorphism from the additive group $\mathbb{R}$ into matrices. It is called the **one-parameter subgroup** generated by X. Differentiating the series term by term,

$$\frac{\mathrm{d}}{\mathrm{d}t}e^{tX} \overset{(1)}{=} \sum_{k=1}^{\infty}\frac{k\,t^{k-1}X^k}{k!} \overset{(2)}{=} X\sum_{k=1}^{\infty}\frac{t^{k-1}X^{k-1}}{(k-1)!} \overset{(3)}{=} X\,e^{tX} = e^{tX}X. \tag{T3.13}$$

(1) Differentiate t^k; the $k = 0$ term is constant and drops out.
(2) Cancel k against $k!$ and pull out one factor of X.
(3) Relabel $k - 1 \to k$; the remaining sum is e^{tX} again. X commutes with every power of itself, so it can stand on either side.

So $g(t) = e^{tX}$ is *the* solution of the linear ODE $\dot{g} = Xg$ with $g(0) = \mathbb{1}$. Its velocity at $t = 0$ is X, as it should be.

Physical picture: Exponentials are everywhere in physics

Time evolution in quantum mechanics is $U(t) = e^{-iHt}$, the solution of $i\dot{U} = HU$. A rotation of a quantum state by θ about $\hat{n}$ is $e^{-i\theta\,\hat{n}\cdot\vec{J}}$. A spatial translation is $e^{-ia\hat{p}}$. In each case a Hermitian generator (an observable) exponentiates to a unitary one-parameter group. In the mathematicians' convention we absorb the $-i$ into an anti-Hermitian generator $X = -iH$ and just write e^{tX}.

The exponential lands in the group. We should check that $e^X \in G$ whenever $X \in \mathfrak{g}$. For the unitary groups:

$$\left(e^X\right)^\dagger e^X \overset{(1)}{=} e^{X^\dagger} e^X \overset{(2)}{=} e^{-X} e^X \overset{(3)}{=} \mathbb{1}.$$

(1) Take the dagger of the series term by term: $(X^k)^\dagger = (X^\dagger)^k$.
(2) $X \in \mathfrak{u}(n)$ is anti-Hermitian.
(3) $-X$ and X commute, so (T3.12) applies with $s = -1, t = 1$.

The orthogonal case is identical with T in place of $\dagger$. For the determinant condition we need one more formula.

T3.3.2 $\det e^X = e^{\operatorname{tr} X}$

Key idea: Determinant of an exponential

For every square matrix X,

$$\det e^X = e^{\operatorname{tr} X}. \tag{T3.14}$$

In particular, traceless generators exponentiate to matrices of determinant one: $e^{\mathfrak{su}(n)} \subset \mathrm{SU}(n)$ and $e^{\mathfrak{sl}(n)} \subset \mathrm{SL}(n)$.

Here is a derivation that works for every X, diagonalisable or not. Let $f(t) = \det e^{tX}$. Then

$$f'(t) \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}s}\Big|_{s=0} \det\left(e^{tX}e^{sX}\right) \overset{(2)}{=} \det\left(e^{tX}\right) \frac{\mathrm{d}}{\mathrm{d}s}\Big|_{s=0} \det e^{sX}$$
$$\overset{(3)}{=} f(t) \frac{\mathrm{d}}{\mathrm{d}s}\Big|_{s=0} \det(\mathbb{1} + sX + O(s^2)) \overset{(4)}{=} f(t)\ \operatorname{tr} X.$$

(1) Write $e^{(t+s)X} = e^{tX}e^{sX}$ using (T3.12), and differentiate in s at $s = 0$.
(2) The determinant of a product is the product of the determinants; the first factor does not depend on s.
(3) Expand e^{sX} to first order.
(4) We showed in Section T3.2 that $\det(\mathbb{1} + sX) = 1 + s \operatorname{tr} X + O(s^2)$.

So $f' = (\operatorname{tr} X) f$ with $f(0) = 1$, whose unique solution is $f(t) = e^{t \operatorname{tr} X}$. Setting $t = 1$ gives (T3.14).

Worked example T3.8: The $\mathrm{U}(1)$ part of a unitary matrix

Any $X \in \mathfrak{u}(n)$ has purely imaginary trace (its eigenvalues are imaginary). Write $\operatorname{tr} X = i\varphi$. Then $\det e^X = e^{i\varphi}$. The overall phase of the unitary matrix is carried entirely by the trace of the generator: this is the $\mathfrak{u}(n) = \mathfrak{u}(1) \oplus \mathfrak{su}(n)$ split of Section T3.2, seen at the level of the

group. For example, with $X = \mathrm{diag}(i\alpha, i\beta)$, $e^X = \mathrm{diag}(e^{i\alpha}, e^{i\beta})$ and $\det e^X = e^{i(\alpha+\beta)} = e^{\mathrm{tr}\, X}$.

T3.3.3 U(1), SO(2) and boosts

Worked example T3.9: Exponentiating the SO(2) generator

The Lie algebra $\mathfrak{so}(2)$ is spanned by $L = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$. Multiplying, $L^2 = -\mathbb{1}$, so $L^{2k} = (-1)^k \mathbb{1}$ and $L^{2k+1} = (-1)^k L$. Then

$$e^{\alpha L} \overset{(1)}{=} \sum_k \frac{\alpha^{2k}(-1)^k}{(2k)!}\,\mathbb{1} + \sum_k \frac{\alpha^{2k+1}(-1)^k}{(2k+1)!}\,L$$
$$\overset{(2)}{=} \cos\alpha\ \mathbb{1} + \sin\alpha\ L = \begin{pmatrix} \cos\alpha & -\sin\alpha \\ \sin\alpha & \cos\alpha \end{pmatrix} = R(\alpha).$$

(1) Split the series into even and odd powers and reduce them with $L^2 = -\mathbb{1}$.
(2) Recognise the Taylor series of cos and sin.

This is Euler's formula $e^{i\alpha} = \cos\alpha + i\sin\alpha$ in disguise: L plays the role of i, since $L^2 = -\mathbb{1}$. In U(1) itself the generator is the 1×1 matrix i and $e^{i\alpha}$ is literally the exponential.

Notice that $e^{2\pi L} = \mathbb{1}$. The exponential map $\mathfrak{u}(1) = i\mathbb{R} \to \mathrm{U}(1)$ wraps the line around the circle infinitely many times (Figure T3.7). Its *kernel*, the set of generators that map to the identity, is the lattice $2\pi i\mathbb{Z}$. This innocent-looking lattice is behind charge quantisation: a U(1) gauge transformation $e^{i\alpha(x)}$ on a circle must come back to itself, so α can jump by $2\pi n$ but the winding number n must be an integer.

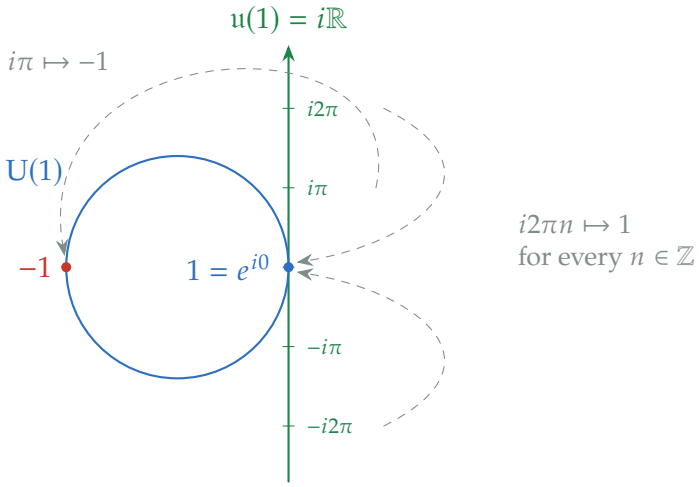

Figure T3.7: The exponential map $i\alpha \mapsto e^{i\alpha}$ rolls the Lie algebra (the green tangent line at 1) around the group circle. Every point of the circle is reached, infinitely often: all the generators $2\pi i n$ land on the identity. The integer n that is lost is exactly the winding number that labels maps $S^1 \to \mathrm{U}(1)$.

Worked example T3.10: Lorentz boosts: rapidities add

A boost along x acts on (t, x) by the generator $K = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, which preserves $-t^2 + x^2$ to first

order. Now $K^2 = +\mathbb{1}$, so

$$e^{\eta K} \overset{(1)}{=} \Big(\sum_k \frac{\eta^{2k}}{(2k)!}\Big)\mathbb{1} + \Big(\sum_k \frac{\eta^{2k+1}}{(2k+1)!}\Big)K \overset{(2)}{=} \begin{pmatrix} \cosh\eta & \sinh\eta \\ \sinh\eta & \cosh\eta \end{pmatrix}.$$

(1) Reduce the powers using $K^2 = \mathbb{1}$ (no alternating signs this time).
(2) The even and odd parts of the exponential series are cosh and sinh.

With $\cosh\eta = \gamma$ and $\sinh\eta = \gamma v$ this is the familiar boost matrix, and (T3.12) says that *rapidities add*: $e^{\eta_1 K} e^{\eta_2 K} = e^{(\eta_1+\eta_2)K}$. The velocity-addition formula $v = \frac{v_1+v_2}{1+v_1 v_2}$ is just $\tanh(\eta_1+\eta_2)$ written out. The one-parameter group of boosts never returns to the identity: this is the non-compact cousin of the rotation group.

T3.3.4 The SU(2) exponential

This is the calculation we use most. Let $\hat{n}$ be a unit vector and θ a real number. With the basis $T_a = -\frac{i}{2}\sigma_a$ of (T3.8), a general element of $\mathfrak{su}(2)$ is

$$X = \theta\, \hat{n}\cdot\vec{T} = -\tfrac{i\theta}{2}\, \hat{n}\cdot\vec{\sigma}.$$

The key fact is that $\hat{n}\cdot\vec{\sigma}$ squares to the identity:

$$(\hat{n}\cdot\vec{\sigma})^2 \overset{(1)}{=} n_a n_b\, \sigma_a\sigma_b \overset{(2)}{=} n_a n_b\big(\delta_{ab}\mathbb{1} + i\varepsilon_{abc}\sigma_c\big) \overset{(3)}{=} |\hat{n}|^2\,\mathbb{1} = \mathbb{1}.$$

(1) Expand the product (sum over a and b).
(2) The Pauli product rule.
(3) $n_a n_b$ is symmetric in a, b and ε_{abc} is antisymmetric, so their contraction vanishes.

Hence $X^2 = -\frac{\theta^2}{4}\mathbb{1}$, and exactly as for SO(2) the series splits into cos and sin:

$$\begin{aligned} e^{-\frac{i\theta}{2}\hat{n}\cdot\vec{\sigma}} &\overset{(1)}{=} \sum_k \frac{(-1)^k(\theta/2)^{2k}}{(2k)!}\mathbb{1} + \sum_k \frac{(-1)^k(\theta/2)^{2k+1}}{(2k+1)!}\big(-i\hat{n}\cdot\vec{\sigma}\big) \\ &\overset{(2)}{=} \cos\tfrac{\theta}{2}\,\mathbb{1} - i\sin\tfrac{\theta}{2}\,\hat{n}\cdot\vec{\sigma} \\ &= \begin{pmatrix} \cos\frac{\theta}{2} - in_3\sin\frac{\theta}{2} & -(in_1+n_2)\sin\frac{\theta}{2} \\ -(in_1-n_2)\sin\frac{\theta}{2} & \cos\frac{\theta}{2} + in_3\sin\frac{\theta}{2} \end{pmatrix}. \end{aligned} \tag{T3.15}$$

(1) Reduce $X^{2k} = (-1)^k(\theta/2)^{2k}\mathbb{1}$ and $X^{2k+1} = (-1)^k(\theta/2)^{2k}X$, and write $X = (\theta/2)(-i\hat{n}\cdot\vec{\sigma})$.
(2) Recognise the cos and sin series in the variable $\theta/2$.

Compare with the parametrisation $U = x^4\mathbb{1} + i\vec{x}\cdot\vec{\sigma}$ of $\mathrm{SU}(2) = S^3$ in (T3.2):

$$x^4 = \cos\tfrac{\theta}{2}, \qquad \vec{x} = -\sin\tfrac{\theta}{2}\,\hat{n}. \tag{T3.16}$$

Indeed $(x^4)^2 + |\vec{x}|^2 = \cos^2 + \sin^2 = 1$. Three consequences follow at once.

1. *The exponential is onto.* Given any $U \in \mathrm{SU}(2)$, i.e. any point $(\vec{x}, x^4)$ of S^3, choose $\theta \in [0, 2\pi]$ with $\cos\frac{\theta}{2} = x^4$, and $\hat{n} = -\vec{x}/|\vec{x}|$ (any $\hat{n}$ if $\vec{x} = 0$). Then $U = e^{\theta\hat{n}\cdot\vec{T}}$.

2. *The angle θ is the conjugacy class.* The eigenvalues are $e^{\mp i\theta/2}$ and $\operatorname{tr} U = 2\cos\frac{\theta}{2}$, in agreement with Example T3.3.

3. *A 2π rotation is $-\mathbb{1}$.* Setting $\theta = 2\pi$ gives $e^{-i\pi\hat{n}\cdot\vec{\sigma}} = \cos\pi\,\mathbb{1} = -\mathbb{1}$ for *every* axis $\hat{n}$. Only $\theta = 4\pi$ gives back $\mathbb{1}$. We will see in Section T3.4 that θ is the rotation angle of the corresponding element of SO(3). So a spin-$\frac{1}{2}$ wavefunction changes sign under a 360° rotation.

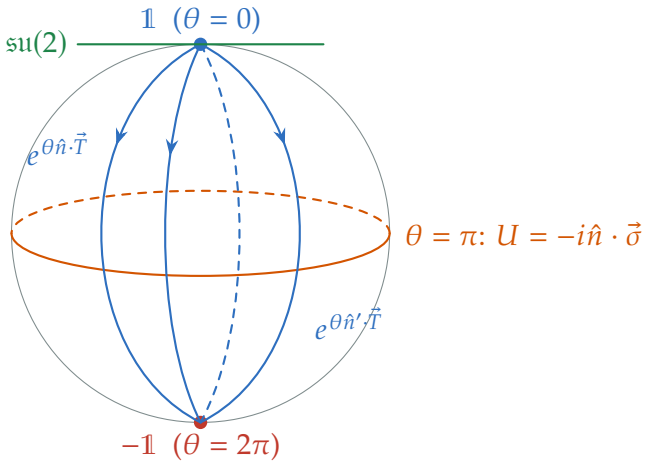

Figure T3.8: SU(2) = S^3 drawn as in Figure T3.3. Each one-parameter subgroup $\theta \mapsto e^{\theta\hat{n}\cdot\vec{T}}$ is a great circle that leaves the identity in the direction $\hat{n}$ (a point of the green tangent space), crosses the equatorial 2-sphere of elements $-i\hat{n}\cdot\vec{\sigma}$ at $\theta = \pi$, and arrives at $-\mathbb{1}$ at $\theta = 2\pi$, *whatever the direction* $\hat{n}$. It then returns to $\mathbb{1}$ at $\theta = 4\pi$ along the opposite half of the same great circle.

Worked example T3.11: A spin-$\frac{1}{2}$ rotation about $\hat{z}$

For $\hat{n} = \hat{z}$, (T3.15) is diagonal: $e^{-\frac{i\theta}{2}\sigma_3} = \mathrm{diag}(e^{-i\theta/2}, e^{i\theta/2})$. Acting on the spin-up state it gives $|\uparrow\rangle \mapsto e^{-i\theta/2}|\uparrow\rangle$. In the physicists' language this is $e^{-i\theta J_3}$ with $J_3 = \frac{1}{2}\sigma_3$ and eigenvalue $m = +\frac{1}{2}$. The phase $e^{-im\theta}$ is the general rule, and $m = \pm\frac{1}{2}$ is what makes $\theta = 2\pi$ give -1. This sign has been measured directly: rotating a beam of neutrons by 2π in a magnetic field and interfering it with an unrotated beam flips the interference pattern (Rauch et al. and Werner et al., 1975).

T3.3.5 Rotations: the Rodrigues formula

For SO(3) we exponentiate θK with $K = \hat{n}\cdot\vec{L}$. From Example T3.6, K acts on a vector by $Kv = \hat{n}\times v$. We need the polynomial relation that K satisfies:

$$K^2 v \overset{(1)}{=} \hat{n}\times(\hat{n}\times v) \overset{(2)}{=} \hat{n}(\hat{n}\cdot v) - v,$$
$$K^3 v \overset{(3)}{=} \hat{n}\times\big(\hat{n}(\hat{n}\cdot v) - v\big) \overset{(4)}{=} -\hat{n}\times v = -Kv.$$

(1) Apply K twice.
(2) The "BAC–CAB" rule $a\times(b\times c) = b(a\cdot c) - c(a\cdot b)$ and $\hat{n}\cdot\hat{n} = 1$.
(3) Apply K to the previous line.
(4) $\hat{n}\times\hat{n} = 0$.

So $K^3 = -K$, hence $K^{2k+1} = (-1)^k K$ and $K^{2k} = (-1)^{k+1}K^2$ for $k \geq 1$. Therefore

$$e^{\theta K} \overset{(1)}{=} \mathbb{1} + \Big(\theta - \frac{\theta^3}{3!} + \cdots\Big)K + \Big(\frac{\theta^2}{2!} - \frac{\theta^4}{4!} + \cdots\Big)K^2$$
$$\overset{(2)}{=} \mathbb{1} + \sin\theta\, K + (1-\cos\theta)\, K^2. \tag{T3.17}$$

(1) Separate the $k = 0$ term, the odd powers and the even powers ≥ 2, and reduce them.
(2) $\theta - \theta^3/3! + \cdots = \sin\theta$ and $\theta^2/2! - \theta^4/4! + \cdots = 1 - \cos\theta$.

Acting on a vector and using the formulas for Kv and $K^2 v$,

$$e^{\theta K} v = \cos\theta\, v + \sin\theta\, (\hat{n} \times v) + (1 - \cos\theta)\, \hat{n}(\hat{n} \cdot v). \tag{T3.18}$$

This is the **Rodrigues rotation formula**: the component of v along $\hat{n}$ is untouched, and the perpendicular part rotates by θ in the plane perpendicular to $\hat{n}$.

Worked example T3.12: Rodrigues reproduces $R_z(\theta)$

Take $\hat{n} = \hat{z}$, $K = L_3$. Then $K^2 = L_3^2 = \mathrm{diag}(-1, -1, 0)$ and

$$e^{\theta L_3} \overset{(1)}{=} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} + \sin\theta \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} + (1 - \cos\theta) \begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$
$$= \begin{pmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix} \overset{(2)}{=} R_z(\theta).$$

(1) Insert $K = L_3$ into (T3.17).
(2) Compare with (T3.4).

The trace of (T3.17) for general $\hat{n}$ is $3 + 0 + (1 - \cos\theta)\,\mathrm{tr}\, K^2 = 3 - 2(1 - \cos\theta) = 1 + 2\cos\theta$, using $\mathrm{tr}\, K^2 = -2$. This confirms that θ is the rotation angle. Unlike the SU(2) case, $e^{2\pi K} = \mathbb{1}$.

T3.3.6 Products of exponentials: Baker–Campbell–Hausdorff

For numbers $e^x e^y = e^{x+y}$. For matrices this fails as soon as X and Y do not commute, and the correction is controlled by the commutator.

Key idea: BCH formula

For small X, Y,

$$e^X e^Y = \exp\Big(X + Y + \tfrac{1}{2}[X,Y] + \tfrac{1}{12}[X,[X,Y]] - \tfrac{1}{12}[Y,[X,Y]] + \cdots \Big), \tag{T3.19}$$

where every omitted term is a nested commutator. So the group product near the identity is *determined by the bracket*: this is the precise sense in which the Lie algebra knows the group locally.

We check the first two orders. Expand both sides up to terms of total degree two in X, Y:

$$e^X e^Y \overset{(1)}{=} \big(\mathbb{1} + X + \tfrac{1}{2}X^2\big)\big(\mathbb{1} + Y + \tfrac{1}{2}Y^2\big) = \mathbb{1} + X + Y + \tfrac{1}{2}X^2 + XY + \tfrac{1}{2}Y^2,$$
$$e^{X+Y+\frac{1}{2}[X,Y]} \overset{(2)}{=} \mathbb{1} + X + Y + \tfrac{1}{2}[X,Y] + \tfrac{1}{2}(X+Y)^2$$
$$\overset{(3)}{=} \mathbb{1} + X + Y + \tfrac{1}{2}(XY - YX) + \tfrac{1}{2}(X^2 + XY + YX + Y^2)$$
$$= \mathbb{1} + X + Y + \tfrac{1}{2}X^2 + XY + \tfrac{1}{2}Y^2.$$

(1) Truncate each series at second order and multiply.
(2) Truncate $e^Z = \mathbb{1} + Z + \frac{1}{2}Z^2$ with $Z = X + Y + \frac{1}{2}[X,Y]$; in Z^2 only $(X+Y)^2$ is of degree two.
(3) Expand the commutator and the square, keeping the order of factors.

The two agree. Without the $\frac{1}{2}[X,Y]$ term the XY coefficient would be $\frac{1}{2}$ on the right instead of 1. Two consequences:

- If $[X,Y]=0$ then $e^X e^Y = e^{X+Y}$ exactly. (Every nested commutator vanishes.)
- If $[X,Y]$ commutes with both X and Y (as for $\hat{x}$ and $\hat{p}$ in quantum mechanics, $[\hat{x},\hat{p}]=i$), the series stops: $e^X e^Y = e^{X+Y+\frac{1}{2}[X,Y]}$. This is the formula behind coherent states and the Weyl form of the canonical commutation relations.

Try it: Group commutator from BCH

Use (T3.19) to show that $e^{\varepsilon X}e^{\varepsilon Y}e^{-\varepsilon X}e^{-\varepsilon Y} = e^{\varepsilon^2[X,Y]+O(\varepsilon^3)}$, reproducing (T3.5).
Answer: $e^{\varepsilon X}e^{\varepsilon Y} = e^{\varepsilon(X+Y)+\frac{\varepsilon^2}{2}[X,Y]+\cdots}$ and $e^{-\varepsilon X}e^{-\varepsilon Y} = e^{-\varepsilon(X+Y)+\frac{\varepsilon^2}{2}[X,Y]+\cdots}$. Combining these two with BCH once more, the ε terms cancel, the commutator of the two exponents is $O(\varepsilon^3)$, and the ε^2 terms add to $\varepsilon^2[X,Y]$.

T3.3.7 How far does the exponential reach?

For U(1), SU(2) and SO(3) we found that every group element is an exponential. This is true for every *compact connected* Lie group: every element can be conjugated into a maximal torus (a maximal commuting subgroup, such as the diagonal matrices in $\mathrm{U}(n)$), where it is $\mathrm{diag}(e^{i\varphi_1},\dots) = e^{\mathrm{diag}(i\varphi_1,\dots)}$, and conjugation commutes with exp by (T3.11). For non-compact groups it can fail, even when the group is connected.

Worked example T3.13: $\mathrm{SL}(2,\mathbb{R})$: an element that is not an exponential

Let $X \in \mathfrak{sl}(2,\mathbb{R})$, a real traceless 2×2 matrix. For 2×2 matrices the Cayley–Hamilton theorem says $X^2 - (\operatorname{tr}X)X + (\det X)\mathbb{1} = 0$, so $X^2 = \delta\,\mathbb{1}$ with $\delta = -\det X$ real. Three cases:

$$\begin{aligned}
\delta = s^2 > 0: &\quad e^X \overset{(1)}{=} \cosh s\,\mathbb{1} + \tfrac{\sinh s}{s}X, &&\operatorname{tr}e^X \overset{(2)}{=} 2\cosh s \;\geq 2,\\
\delta = 0: &\quad e^X = \mathbb{1} + X, &&\operatorname{tr}e^X = 2,\\
\delta = -s^2 < 0: &\quad e^X \overset{(3)}{=} \cos s\,\mathbb{1} + \tfrac{\sin s}{s}X, &&\operatorname{tr}e^X = 2\cos s \;\geq -2.
\end{aligned}$$

(1) As for boosts: $X^{2k} = s^{2k}\mathbb{1}$, $X^{2k+1} = s^{2k}X$.
(2) $\operatorname{tr}X = 0$, so only the $\mathbb{1}$ term contributes to the trace.
(3) As for rotations: $X^{2k} = (-1)^k s^{2k}\mathbb{1}$.

So *every* exponential has $\operatorname{tr}e^X \geq -2$. But $M = \mathrm{diag}(-2,-\frac{1}{2})$ has $\det M = 1$, so $M \in \mathrm{SL}(2,\mathbb{R})$, and $\operatorname{tr}M = -\frac{5}{2} < -2$. Hence M is not e^X for any X. (It is a product of two exponentials, $M = e^{\pi L}\,e^{\ln 2\,\sigma_3}$, since $e^{\pi L} = -\mathbb{1}$.)

Watch out: The exponential is neither one-to-one nor always onto

Even for compact groups, exp is not injective: $e^{2\pi L} = e^0$ in SO(2), and all of $\{4\pi\hat{n}\cdot\vec{T}\}$ goes to $\mathbb{1}$ in SU(2). It is a diffeomorphism only from a small neighbourhood of 0 in $\mathfrak{g}$ onto a neighbourhood of $\mathbb{1}$ in G. This is why a local calculation (in $\mathfrak{g}$) cannot see global facts such as π_1.

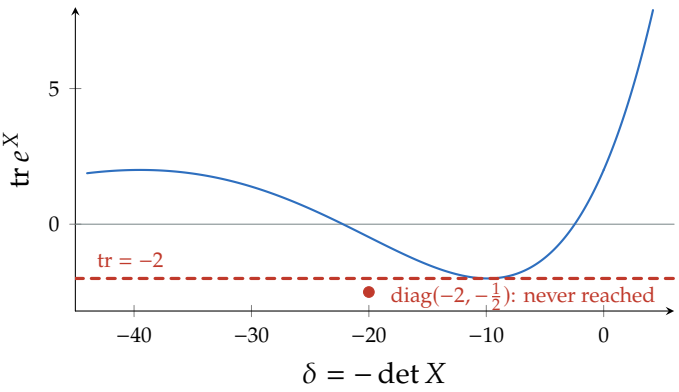

Figure T3.9: The trace of e^X for $X \in \mathfrak{sl}(2,\mathbb{R})$ depends only on $\delta = -\det X$. For $\delta < 0$ (elliptic, rotation-like X) it oscillates between -2 and 2; for $\delta > 0$ (hyperbolic, boost-like X) it grows like $2\cosh\sqrt{\delta}$. It never drops below -2, so group elements with trace below -2 (red dot) are not exponentials.

Reading Nash (where the exponential hides)

Nash rarely writes exp explicitly, but it is behind two of his formulas. The parallel transport equation $\frac{dg}{dt} + A(\dot\gamma)\,g = 0$ [Nash p. 217, (8.4)] is the ODE (T3.13) with the constant generator replaced by a time-dependent one; when $A(\dot\gamma)$ is constant along the path its solution is $g(t) = e^{-tA(\dot\gamma)}g(0)$. We develop this in Section T3.9. And the Fourier modes $T^a e^{in\theta}$ of the loop algebra [Nash p. 182] exponentiate to loops $e^{\alpha T^a e^{in\theta}}$ in LG; for U(1) the loop $\theta \mapsto e^{in\theta}$ is exactly the winding-n loop of Figure T3.7.

Recap

- $e^X = \sum X^k/k!$; $t \mapsto e^{tX}$ is the one-parameter subgroup solving $\dot g = Xg$, $g(0) = \mathbb{1}$.
- $\det e^X = e^{\operatorname{tr} X}$; $ge^Xg^{-1} = e^{gXg^{-1}}$.
- SO(2): $e^{\alpha L} = \cos\alpha + L\sin\alpha$. Boosts: cosh, sinh, rapidities add.
- SU(2): $e^{-\frac{i\theta}{2}\hat n\cdot\vec\sigma} = \cos\frac{\theta}{2} - i\sin\frac{\theta}{2}\,\hat n\cdot\vec\sigma$; onto S^3; $\theta = 2\pi$ gives $-\mathbb{1}$.
- SO(3): Rodrigues $e^{\theta K} = \mathbb{1} + \sin\theta K + (1-\cos\theta)K^2$.
- BCH: $e^Xe^Y = e^{X+Y+\frac12[X,Y]+\cdots}$; the bracket fixes the product locally.
- exp is onto for compact connected groups, but not for $\mathrm{SL}(2,\mathbb{R})$.

T3.4 The adjoint representation and the double cover SU(2) → SO(3)

A rotation acts on vectors. But it also acts on *other rotations*: if h is a rotation about the z-axis and g is some other rotation, then ghg^{-1} is a rotation by the same angle about the rotated axis $g\hat z$. Infinitesimally, a rotation generator is an angular-momentum vector, and a rotation turns one angular-momentum vector into another. So every Lie group acts on its own Lie algebra. This action is the *adjoint representation*. It is the single most important representation in gauge theory, because gauge fields and field strengths transform in it ($F \mapsto g^{-1}Fg$). For SU(2) it produces the famous two-to-one map onto SO(3), which is why electrons have spin $\frac12$ and why a 360° rotation of a spinor gives a minus sign.

T3.4.1 Ad: the group acting on its algebra

Working definition T3.6 (adjoint action)

For $g \in G$ and $X \in \mathfrak{g}$ [a generator, i.e. the velocity $\dot{h}(0)$ of a curve $h(t)$ in G with $h(0) = \mathbb{1}$] define

$$\mathrm{Ad}_g X := g X g^{-1}.$$

It is again in $\mathfrak{g}$: the curve $t \mapsto g\, e^{tX} g^{-1}$ lies in G and by (T3.11) equals $e^{t\, gXg^{-1}}$, whose velocity at $t = 0$ is gXg^{-1}. *How to compute its matrix:* choose a basis T_a, conjugate each basis element, and expand the result in the basis,

$$g\, T_a\, g^{-1} = T_b\, (\mathrm{Ad}_g)_{ba}. \tag{T3.20}$$

The numbers $(\mathrm{Ad}_g)_{ba}$ form a $\dim G \times \dim G$ matrix.

Ad is a **representation**, meaning that it turns the group product into matrix multiplication:

$$\mathrm{Ad}_{gh} X \overset{(1)}{=} (gh)X(gh)^{-1} \overset{(2)}{=} g\big(hXh^{-1}\big)g^{-1} \overset{(3)}{=} \mathrm{Ad}_g\big(\mathrm{Ad}_h X\big).$$

(1) Definition.
(2) $(gh)^{-1} = h^{-1}g^{-1}$ and associativity.
(3) Definition twice.

It also preserves brackets, $\mathrm{Ad}_g[X,Y] = g(XY - YX)g^{-1} = [gXg^{-1}, gYg^{-1}]$, because the $g^{-1}g$ in the middle cancels.

T3.4.2 ad: the algebra acting on itself

Differentiate Ad along a one-parameter subgroup $g = e^{tY}$:

$$\frac{\mathrm{d}}{\mathrm{d}t}\Big|_{t=0} e^{tY} X e^{-tY} \overset{(1)}{=} YX - XY = [Y, X].$$

(1) Product rule with $\frac{\mathrm{d}}{\mathrm{d}t} e^{\pm tY}|_0 = \pm Y$, from (T3.13).

Working definition T3.7 (adjoint representation of the algebra)

$\mathrm{ad}_Y X := [Y, X]$. In a basis, the matrix of ad_{T_a} [a $\dim G \times \dim G$ matrix acting on the components of X] is built from the structure constants:

$$\mathrm{ad}_{T_a} T_b = [T_a, T_b] = f_{ab}{}^c T_c, \qquad \text{so} \qquad (\mathrm{ad}_{T_a})_{cb} = f_{ab}{}^c. \tag{T3.21}$$

That ad respects brackets, $\mathrm{ad}_{[X,Y]} = [\mathrm{ad}_X, \mathrm{ad}_Y]$, is *exactly* the Jacobi identity:

$$[\mathrm{ad}_X, \mathrm{ad}_Y]Z \overset{(1)}{=} [X,[Y,Z]] - [Y,[X,Z]] \overset{(2)}{=} [X,[Y,Z]] + [Y,[Z,X]]$$
$$\overset{(3)}{=} -[Z,[X,Y]] \overset{(4)}{=} [[X,Y],Z] = \mathrm{ad}_{[X,Y]} Z.$$

(1) Definition of the commutator of two linear maps.
(2) Antisymmetry of the inner bracket.
(3) Jacobi: the three cyclic terms sum to zero.
(4) Antisymmetry once more.

The physicists' version of (T3.21) is $(R^b_A)_{ac} = -if^{bac}$ in [QFT notes (31.2.9)], up to their index placement and the factor of i from Hermitian generators.

Key idea: $\mathrm{Ad} = e^{\mathrm{ad}}$

Conjugation by an exponential is the exponential of the commutator:

$$e^Y X e^{-Y} = e^{\mathrm{ad}_Y} X = X + [Y,X] + \tfrac{1}{2!}[Y,[Y,X]] + \tfrac{1}{3!}[Y,[Y,[Y,X]]] + \cdots . \tag{T3.22}$$

Why: let $Z(t) = e^{tY} X e^{-tY}$. Then $\dot{Z} = YZ - ZY = \mathrm{ad}_Y Z$, a linear ODE with constant coefficients and $Z(0) = X$. Its solution is $Z(t) = e^{t\,\mathrm{ad}_Y} X$, by (T3.13) applied to the linear map ad_Y. Set $t = 1$. This is the formula the QFT notes work out order by order in [QFT notes (19.3.16)].

Worked example T3.14: The adjoint representation of $\mathfrak{su}(2)$ is $\mathfrak{so}(3)$

With $f_{ab}{}^c = \varepsilon_{abc}$, (T3.21) gives $(\mathrm{ad}_{T_a})_{cb} = \varepsilon_{abc}$. Compare with the rotation generators of Example T3.6, $(L_a)_{cb} = -\varepsilon_{acb} = \varepsilon_{abc}$. They are equal:

$$\mathrm{ad}_{T_a} = L_a .$$

The adjoint representation of $\mathfrak{su}(2)$ is the vector representation of $\mathfrak{so}(3)$. In physics language: *the generators of isospin themselves carry isospin 1.* The $W^\pm, W^3$ bosons of SU(2) gauge theory form an isospin triplet; the eight gluons of SU(3) form an octet, the adjoint of SU(3).

Worked example T3.15: Using (T3.22) to rotate a Pauli matrix

Take $Y = -\frac{i\theta}{2}\sigma_3 = \theta T_3$ and $X = \sigma_1$. Then $\mathrm{ad}_Y \sigma_1 = -\frac{i\theta}{2}[\sigma_3, \sigma_1] = -\frac{i\theta}{2}(2i\sigma_2) = \theta\sigma_2$ and $\mathrm{ad}_Y \sigma_2 = -\frac{i\theta}{2}[\sigma_3, \sigma_2] = -\frac{i\theta}{2}(-2i\sigma_1) = -\theta\sigma_1$. So ad_Y acts on the pair (σ_1, σ_2) like the SO(2) generator, and

$$e^{-\frac{i\theta}{2}\sigma_3}\,\sigma_1\, e^{\frac{i\theta}{2}\sigma_3} \overset{(1)}{=} \sigma_1 + \theta\sigma_2 - \tfrac{\theta^2}{2!}\sigma_1 - \tfrac{\theta^3}{3!}\sigma_2 + \tfrac{\theta^4}{4!}\sigma_1 + \cdots$$
$$\overset{(2)}{=} \cos\theta\,\sigma_1 + \sin\theta\,\sigma_2 .$$

(1) Apply ad_Y repeatedly: $\sigma_1 \to \theta\sigma_2 \to -\theta^2\sigma_1 \to -\theta^3\sigma_2 \to \cdots$.
(2) Collect the cos and sin series.

The Pauli "vector" $\vec{\sigma}$ is rotated by the angle θ, not $\theta/2$. Keep this in mind for the double cover below.

T3.4.3 The Killing form: a built-in inner product

A Yang–Mills Lagrangian needs a way to square the field strength $F = F^a T_a$ and get a number that does not change under gauge transformations. We need an inner product on $\mathfrak{g}$ that is invariant under Ad. Every Lie algebra carries a canonical candidate.

Working definition T3.8 (Killing form)

The **Killing form** is

$$B(X,Y) := \mathrm{tr}\big(\mathrm{ad}_X\,\mathrm{ad}_Y\big), \qquad B_{ab} = B(T_a, T_b) = f_{ac}{}^d f_{bd}{}^c .$$

In practice: for matrix algebras it is proportional to the trace in the defining representation [the $N \times N$ matrices that define the group], $B(X,Y) = c\ \mathrm{tr}(XY)$, with $c = 2N$ for $\mathfrak{su}(N)$

(derived below). Either one serves as "the" invariant inner product [unchanged when both X and Y are conjugated by the same g]; physicists use tr in the fundamental and normalise $\operatorname{tr}(J_a J_b) = \frac{1}{2}\delta_{ab}$.

The component formula follows from (T3.21): $\operatorname{tr}(\mathrm{ad}_{T_a}\mathrm{ad}_{T_b}) = (\mathrm{ad}_{T_a})_{dc}(\mathrm{ad}_{T_b})_{cd} = f_{ac}{}^{d} f_{bd}{}^{c}$.

Invariance. Both B and $\operatorname{tr}(XY)$ are invariant, because conjugation cancels inside a trace:

$$\operatorname{tr}\big(\mathrm{Ad}_g X\, \mathrm{Ad}_g Y\big) \overset{(1)}{=} \operatorname{tr}\big(gXg^{-1}gYg^{-1}\big) \overset{(2)}{=} \operatorname{tr}\big(XYg^{-1}g\big) = \operatorname{tr}(XY). \tag{T3.23}$$

(1) Definition of Ad.
(2) Cancel $g^{-1}g$ in the middle and move g from the front to the back using cyclicity of the trace, $\operatorname{tr}(AB) = \operatorname{tr}(BA)$.

Differentiating along $g = e^{tZ}$ gives the infinitesimal form, $\operatorname{tr}([Z,X]Y) + \operatorname{tr}(X[Z,Y]) = 0$. In components (with an orthonormal basis, tr or B proportional to δ_{ab}) this says that $f_{abc} \coloneqq f_{ab}{}^{d}\,\delta_{dc}$ is antisymmetric in b and c as well as in a, b: it is *totally antisymmetric*, as promised in Section T3.2.

Worked example T3.16: Killing form of $\mathfrak{su}(N)$ is $2N$ tr

For $X, Y \in \mathfrak{su}(N)$, the map $Z \mapsto \mathrm{ad}_X\mathrm{ad}_Y Z = [X,[Y,Z]]$ can be extended to all $N \times N$ matrices Z. We need one fact: the map $Z \mapsto AZC$ on the N^2-dimensional space of matrices has trace $\operatorname{tr} A\ \operatorname{tr} C$ (check it on the basis E_{ij}: the coefficient of E_{ij} in $AE_{ij}C$ is $A_{ii}C_{jj}$). Then

$$\begin{aligned}\operatorname{tr}_{\text{all } Z}\big(\mathrm{ad}_X\mathrm{ad}_Y\big) &\overset{(1)}{=} \operatorname{tr}_Z\big(Z \mapsto XYZ - XZY - YZX + ZYX\big)\\ &\overset{(2)}{=} N\operatorname{tr}(XY) - \operatorname{tr}X\operatorname{tr}Y - \operatorname{tr}Y\operatorname{tr}X + N\operatorname{tr}(YX)\\ &\overset{(3)}{=} 2N\operatorname{tr}(XY).\end{aligned}$$

(1) Expand the double commutator.
(2) Use the fact for each term: $Z \mapsto (XY)Z\mathbb{1}$ has trace $\operatorname{tr}(XY)\operatorname{tr}\mathbb{1} = N\operatorname{tr}(XY)$, and so on.
(3) X, Y are traceless, and $\operatorname{tr}(YX) = \operatorname{tr}(XY)$.

The space of all matrices is $\mathfrak{sl}(N,\mathbb{C}) \oplus \mathbb{C}\mathbb{1}$, and ad kills the $\mathbb{1}$ direction, so this is also the trace over the Lie algebra. Hence $B(X,Y) = 2N\operatorname{tr}(XY)$. For $\mathfrak{su}(2)$: $B(T_a,T_b) = 4\operatorname{tr}(T_aT_b) = 4\cdot(-\frac{1}{2}\delta_{ab}) = -2\delta_{ab}$. Directly from $\mathrm{ad}_{T_a} = L_a$: $\operatorname{tr}(L_aL_b) = -2\delta_{ab}$ (e.g. $L_3^2 = \mathrm{diag}(-1,-1,0)$). The two computations agree.

Key idea: Compact ⇔ negative-definite Killing form

For anti-Hermitian $X \neq 0$, $\operatorname{tr}(X^2) = -\operatorname{tr}(X^\dagger X) = -\sum_{ij}|X_{ij}|^2 < 0$. So on $\mathfrak{su}(N)$, and on the Lie algebra of any compact semisimple group, $-B$ and $-\operatorname{tr}$ are *positive-definite* invariant inner products. This is why Yang–Mills actions carry a minus sign in the maths convention: $-\operatorname{tr}(F_{\mu\nu}F^{\mu\nu}) = \frac{1}{2}F^a_{\mu\nu}F^{a\,\mu\nu} \geq 0$. For a non-compact group the Killing form is indefinite: in $\mathfrak{sl}(2,\mathbb{R})$, $B(\sigma_3,\sigma_3) = 4\operatorname{tr}\sigma_3^2 = 8 > 0$ while $B(L,L) = 4\operatorname{tr}L^2 = -8 < 0$. A Yang–Mills theory with such a gauge group would have negative-energy (ghost) gluons.

T3.4.4 The double cover SU(2) → SO(3) built explicitly

Now apply Ad to SU(2). Identify a vector $\vec{x} \in \mathbb{R}^3$ with the traceless Hermitian matrix

$$\vec{x}\cdot\vec{\sigma} = \begin{pmatrix} x_3 & x_1 - ix_2 \\ x_1 + ix_2 & -x_3 \end{pmatrix}, \qquad \det(\vec{x}\cdot\vec{\sigma}) = -|\vec{x}|^2.$$

For $U \in \mathrm{SU}(2)$, the matrix $U(\vec{x}\cdot\vec{\sigma})U^\dagger$ is again Hermitian ($(UMU^\dagger)^\dagger = UM^\dagger U^\dagger$) and traceless (cyclicity), so it equals $\vec{x}\,'\cdot\vec{\sigma}$ for some new vector $\vec{x}\,'$, which depends linearly on $\vec{x}$: $\vec{x}\,' = R(U)\vec{x}$. And

$$-|R(U)\vec{x}|^2 \overset{(1)}{=} \det\big(U(\vec{x}\cdot\vec{\sigma})U^\dagger\big) \overset{(2)}{=} \det U\,\det(\vec{x}\cdot\vec{\sigma})\,\det U^\dagger \overset{(3)}{=} -|\vec{x}|^2.$$

(1) The determinant formula above, applied to $\vec{x}\,'$.
(2) Determinant of a product.
(3) $\det U = \det U^\dagger = 1$.

So $R(U)$ preserves lengths: $R(U) \in \mathrm{O}(3)$. To extract its entries, use $\mathrm{tr}(\sigma_i\sigma_k) = 2\delta_{ik}$. From $U\sigma_j U^\dagger = \sigma_k R_{kj}$, multiply by σ_i and take the trace:

Key idea: The covering map

$$R_{ij}(U) = \tfrac{1}{2}\,\mathrm{tr}\big(\sigma_i\, U\sigma_j U^\dagger\big), \qquad U\sigma_j U^\dagger = \sigma_i\, R_{ij}(U). \tag{T3.24}$$

$U \mapsto R(U)$ is a homomorphism SU(2) → SO(3), onto, and exactly two-to-one: $R(U) = R(-U)$.

It is a homomorphism because it is Ad (on the basis $T_a = -\frac{i}{2}\sigma_a$, which is proportional to σ_a). The rest we verify by explicit computation.

Worked example T3.17: The rotation matrix of a general U

Write $U = a\mathbb{1} + i\vec{x}\cdot\vec{\sigma}$ with $a^2 + |\vec{x}|^2 = 1$, as in (T3.2) (here $a = x^4$). We need two Pauli identities: $[\vec{x}\cdot\vec{\sigma}, \sigma_j] = 2i\varepsilon_{kjl}x_k\sigma_l$ and $(\vec{x}\cdot\vec{\sigma})\sigma_j = 2x_j\mathbb{1} - \sigma_j(\vec{x}\cdot\vec{\sigma})$ (from $\sigma_k\sigma_j + \sigma_j\sigma_k = 2\delta_{jk}$). Then

$$\begin{aligned} U\sigma_j U^\dagger &\overset{(1)}{=} (a + i\vec{x}\cdot\vec{\sigma})\,\sigma_j\,(a - i\vec{x}\cdot\vec{\sigma}) \\ &\overset{(2)}{=} a^2\sigma_j + ia\,[\vec{x}\cdot\vec{\sigma}, \sigma_j] + (\vec{x}\cdot\vec{\sigma})\sigma_j(\vec{x}\cdot\vec{\sigma}) \\ &\overset{(3)}{=} a^2\sigma_j - 2a\,\varepsilon_{kjl}x_k\sigma_l + 2x_j(\vec{x}\cdot\vec{\sigma}) - |\vec{x}|^2\sigma_j \\ &\overset{(4)}{=} \sigma_i\Big[(a^2 - |\vec{x}|^2)\delta_{ij} + 2x_ix_j + 2a\,\varepsilon_{ijk}x_k\Big]. \end{aligned}$$

(1) $U^\dagger = a - i\vec{x}\cdot\vec{\sigma}$ since $a, \vec{x}$ are real.
(2) Multiply out; the two cross terms combine into a commutator.
(3) The commutator identity; and for the last term, move σ_j to the right using the anticommutator, then $(\vec{x}\cdot\vec{\sigma})^2 = |\vec{x}|^2$.
(4) Rename the free index $l \to i$ in the second term and use $\varepsilon_{kji} = -\varepsilon_{ijk}$ (an odd permutation), then read off the coefficient of σ_i.

So

$$R_{ij}(U) = (a^2 - |\vec{x}|^2)\,\delta_{ij} + 2x_ix_j + 2a\,\varepsilon_{ijk}x_k. \tag{T3.25}$$

Every term is *quadratic* in $(a, \vec{x})$, so $R(-U) = R(U)$: two antipodal points of S^3 give the

same rotation. Now insert the exponential (T3.16), $a = \cos\frac{\theta}{2}$, $\vec{x} = -\sin\frac{\theta}{2}\,\hat{n}$:

$$R_{ij} \overset{(1)}{=} \left(\cos^2\tfrac{\theta}{2} - \sin^2\tfrac{\theta}{2}\right)\delta_{ij} + 2\sin^2\tfrac{\theta}{2}\, n_i n_j - 2\sin\tfrac{\theta}{2}\cos\tfrac{\theta}{2}\,\varepsilon_{ijk} n_k$$
$$\overset{(2)}{=} \cos\theta\,\delta_{ij} + (1-\cos\theta)\, n_i n_j - \sin\theta\,\varepsilon_{ijk} n_k .$$

(1) Substitute.
(2) Double-angle formulas: $\cos^2 - \sin^2 = \cos\theta$, $2\sin^2\frac{\theta}{2} = 1 - \cos\theta$, $2\sin\frac{\theta}{2}\cos\frac{\theta}{2} = \sin\theta$.

Acting on v, the last term is $-\sin\theta\,\varepsilon_{ijk} n_k v_j = \sin\theta\,(\hat{n}\times v)_i$. This is precisely the Rodrigues formula (T3.18). So

$$R\left(e^{\theta\hat{n}\cdot\vec{T}}\right) = e^{\theta\hat{n}\cdot\vec{L}} :$$

the SU(2) element with parameter θ maps to the rotation by angle θ about $\hat{n}$. Every rotation is hit (onto), and θ and $\theta + 2\pi$, i.e. U and $-U$, hit the same one.

Why exactly two-to-one. $R(U) = \mathbb{1}$ means $U\sigma_j U^\dagger = \sigma_j$ for all j, i.e. U commutes with all three Pauli matrices and hence with every 2×2 matrix. Such a U is a multiple of $\mathbb{1}$, and $\det U = 1$ forces $U = \pm\mathbb{1}$. The kernel is the centre $\{\pm\mathbb{1}\} \cong \mathbb{Z}_2$. And $\det R(U) = +1$ (not -1) because $\det R$ is continuous on the connected space S^3, only takes values ± 1, and equals 1 at $U = \mathbb{1}$. Therefore

$$\mathrm{SO}(3) \cong \mathrm{SU}(2)/\{\pm\mathbb{1}\} = S^3/(\text{antipodal map}) = \mathbb{RP}^3. \tag{T3.26}$$

This matches the ball picture of Section T3.1.5: the upper hemisphere $a \geq 0$ of S^3 (i.e. $\theta \in [0,\pi]$) is a solid ball, and on its boundary $a = 0$ the antipodal identification $\vec{x} \sim -\vec{x}$ is exactly the gluing of $\pi\hat{n}$ to $-\pi\hat{n}$.

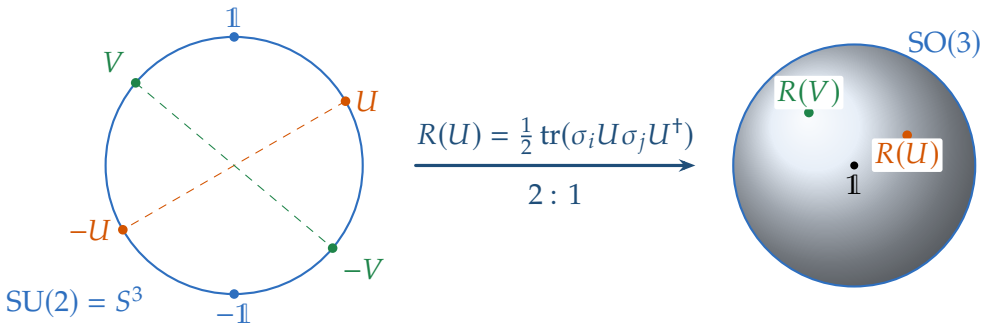

Figure T3.10: The covering map sends each antipodal pair $\{U, -U\}$ of the 3-sphere to a single rotation. Both $\mathbb{1}$ and $-\mathbb{1}$ go to the identity rotation. Locally the map is a diffeomorphism (the Lie algebras agree, Example T3.14); globally it folds S^3 onto $\mathbb{RP}^3$ twice.

T3.4.5 $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$ and the belt trick

The double cover explains the loop we met in Figure T3.4. Consider the loop in SO(3) of rotations about $\hat{z}$ by angle θ running from 0 to 2π: $\gamma(\theta) = R_z(\theta)$. Where does it come from in SU(2)? By Example T3.17, $\gamma(\theta) = R(\tilde{\gamma}(\theta))$ with $\tilde{\gamma}(\theta) = e^{-\frac{i\theta}{2}\sigma_3}$. But $\tilde{\gamma}(0) = \mathbb{1}$ and $\tilde{\gamma}(2\pi) = -\mathbb{1}$: the **lift** of the closed loop γ is an *open* path in S^3, from the north pole to the south pole.

Key idea: Why $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$

Every loop in SO(3) based at $\mathbb{1}$ lifts uniquely (given the starting point $\mathbb{1}$) to a path in SU(2) that ends at $+\mathbb{1}$ or at $-\mathbb{1}$. If we deform the loop continuously, the endpoint of the lift moves continuously in the two-point set $\{\pm\mathbb{1}\}$, so it cannot change. Hence:

- loops whose lift ends at $+\mathbb{1}$ are closed loops in S^3, and every loop in S^3 can be shrunk; so these loops are contractible;
- loops whose lift ends at $-\mathbb{1}$ (such as one full 2π rotation) can never be shrunk;
- going round γ twice lifts to $\theta \in [0, 4\pi]$, which ends at $e^{-2\pi i\sigma_3} = +\mathbb{1}$: a closed loop in S^3, hence contractible.

So there are exactly two classes of loops, and "twice = nothing": $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$.

The same argument works whenever a simply connected group covers another: $\pi_1(G/\Gamma) = \Gamma$ for a discrete central subgroup Γ. Thus $\pi_1(\mathrm{SO}(n)) = \mathbb{Z}_2$ for $n \geq 3$, using the simply connected double cover $\mathrm{Spin}(n) \to \mathrm{SO}(n)$ built from Clifford algebras in Chapter T4, and SU(2) = Spin(3).

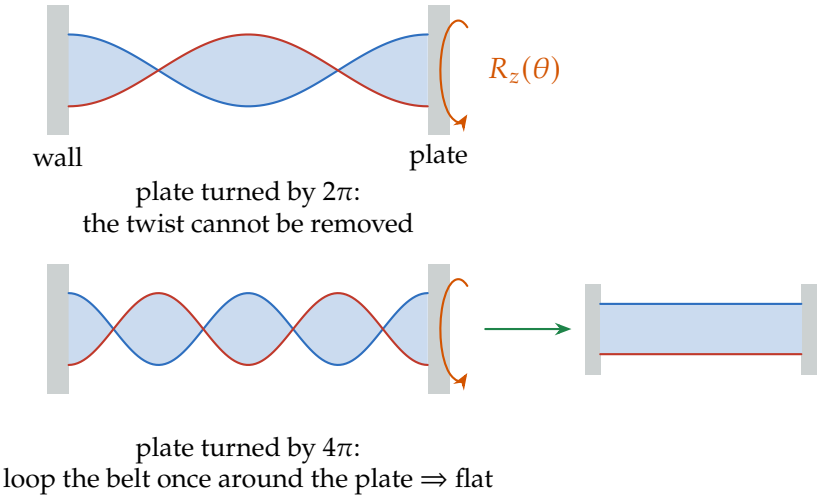

Figure T3.11: The belt trick (Dirac's scissors). A belt joins a fixed wall to a plate. Turning the plate by θ about the belt's axis traces the loop $\theta \mapsto R_z(\theta)$ in SO(3); the orientation of each cross-section of the belt is a path from $\mathbb{1}$ (at the wall) to the plate's rotation. After a 2π turn (top) the belt has a full twist, and no motion of the belt that keeps the plate's orientation fixed can remove it: this is the non-trivial element of $\pi_1(\mathrm{SO}(3))$. After a 4π turn (bottom), passing the belt once around the plate undoes the twist entirely: twice the generator is trivial.

Physical picture: Spin $\frac{1}{2}$

Quantum states are rays: ψ and $e^{i\alpha}\psi$ are the same physical state. So a symmetry need only be represented up to a phase. For rotations, this lets the group SU(2) act instead of SO(3). On a spin-$\frac{1}{2}$ state the 2π rotation is $-\mathbb{1}$: invisible on its own (a phase), but visible in interference, as in the neutron experiment. Topologically, the sign records which class in $\pi_1(\mathrm{SO}(3))$ the rotation path belongs to. Particles whose wavefunction picks up -1 are fermions; that is the origin of the need for spin structures on curved spacetimes (Chapter T4).

Try it: $\mathrm{SO}(4) = (\mathrm{SU}(2) \times \mathrm{SU}(2))/\mathbb{Z}_2$

Identify $\mathbb{R}^4$ with 2×2 matrices $q = x^4\mathbb{1} + i\vec{x}\cdot\vec{\sigma}$ (real multiples of SU(2) matrices, $\det q = |x|^2$). For $(U, V) \in \mathrm{SU}(2) \times \mathrm{SU}(2)$, show that $q \mapsto UqV^\dagger$ preserves $|x|^2$, and that (U, V) and

$(-U,-V)$ give the same map.
Answer: $\det(UqV^\dagger) = \det U \det q \det V^\dagger = \det q$, and the product $UqV^\dagger$ is still of the form $y^4 + i\vec{y}\cdot\vec{\sigma}$ (the quaternions are closed under multiplication). The signs cancel in $(-U)q(-V)^\dagger$. The Lie algebra version is the decomposition $\mathfrak{so}(4) = \mathfrak{su}(2) \oplus \mathfrak{su}(2)$ of Section T3.2.

Reading Nash (the adjoint action in Nash)

Nash uses Ad constantly without naming it. The gauge group $\mathcal{G}$ is the group of sections of the bundle $\mathrm{Ad}\, P = P \times_G G$ built from conjugation, and its Lie algebra is the space of sections of $\mathrm{ad}\, P = P \times_G \mathfrak{g}$ [Nash pp. 176–177, (6.19)–(6.24)]. Both bundles are glued together using Ad from this section, applied point by point in spacetime. His invariant polynomials such as $\det\left(t\mathbb{1} + \frac{iF}{2\pi}\right)$ [Nash p. 87, (3.125)] are the functions on $\mathfrak{g}$ that are unchanged by Ad, exactly like $\mathrm{tr}(XY)$ in (T3.23). The inner product $\langle F, F\rangle = -\int \mathrm{tr}(F \wedge \star F)$ in his Yang–Mills action [Nash p. 227, (8.63)] is the negative trace, which by the key idea above is positive for compact G.

Recap

- $\mathrm{Ad}_g X = gXg^{-1}$ (group on algebra), $\mathrm{ad}_Y X = [Y, X]$ (algebra on algebra), $(\mathrm{ad}_{T_a})_{cb} = f_{ab}{}^c$, $e^Y X e^{-Y} = e^{\mathrm{ad}_Y} X$.
- Killing form $B(X,Y) = \mathrm{tr}(\mathrm{ad}_X \mathrm{ad}_Y) = 2N\,\mathrm{tr}(XY)$ on $\mathfrak{su}(N)$; invariant; negative definite for compact groups.
- $R_{ij}(U) = \frac{1}{2}\mathrm{tr}(\sigma_i U \sigma_j U^\dagger) = (a^2 - |\vec{x}|^2)\delta_{ij} + 2x_i x_j + 2a\varepsilon_{ijk}x_k$ is a $2:1$ homomorphism $\mathrm{SU}(2) \to \mathrm{SO}(3)$ with kernel $\pm\mathbb{1}$; $e^{\theta\hat{n}\cdot\vec{T}} \mapsto$ rotation by θ.
- The 2π rotation lifts to a path from $\mathbb{1}$ to $-\mathbb{1}$; hence $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$ and the belt trick.

T3.5 Representations: spin, weights and roots

In quantum mechanics a symmetry group does not act on points of space; it acts on the Hilbert space of states, by unitary matrices. The same group can act on different spaces in different ways: rotations act on a scalar trivially, on a vector by 3×3 matrices, on an electron's spin by 2×2 matrices. Each such action is a *representation*, and the particles of a theory are sorted into *irreducible* representations, the multiplets: the isospin doublet (p, n), the pion triplet, the quark triplet (u, d, s), the gluon octet. This section answers the question *what are all the ways a given Lie group can act on states, and how do we label them?* The answer for SU(2) is the spin j; for bigger groups it is a *highest weight*, drawn as a point in a lattice decorated by *roots*.

Convention for this section. Representation theory is traditionally done with Hermitian generators, because their eigenvalues (the weights) are real and are the quantum numbers physicists measure. So in this section we use $J_a = iT_a$, with $[J_a, J_b] = if_{abc}J_c$, as in Section T3.2.5. For SU(2), $J_a = \frac{1}{2}\sigma_a$ in the defining representation.

T3.5.1 What a representation is

Working definition T3.9 (representation)

A **representation** of a group G on a vector space V is an assignment $g \mapsto D(g)$ of an invertible matrix to each group element with $D(gh) = D(g)D(h)$ and $D(\mathbb{1}) = \mathbb{1}$. A representation of a Lie algebra is a linear assignment $X \mapsto \rho(X)$ [each generator X gets a matrix $\rho(X)$ acting on the same V, and $\rho(aX + bY) = a\rho(X) + b\rho(Y)$] with $\rho([X, Y]) = [\rho(X), \rho(Y)]$. The two are related by $D(e^X) = e^{\rho(X)}$. *Operational test:* given matrices R_a for each generator, check $[R_a, R_b] = i f_{abc} R_c$ with the *same* structure constants as the group. Then $D(e^{-i\alpha^a J_a}) = e^{-i\alpha^a R_a}$ is (at least near the identity [far from $\mathbb{1}$ one g can equal e^X for several different X, and the formula may then give different matrices]) a representation.

The relation $\rho([X, Y]) = [\rho X, \rho Y]$ follows from $D(gh) = D(g)D(h)$ by the group-commutator computation of (T3.5): the ε^2 term of $D(ghg^{-1}h^{-1})$ is $\varepsilon^2\rho([X, Y])$ on one side and $\varepsilon^2[\rho X, \rho Y]$ on the other.

The representations we already know.

- *Trivial:* $D(g) = 1$ on $V = \mathbb{C}$, $R_a = 0$. (A singlet.)
- *Defining* or *fundamental*: $D(g) = g$ itself, on $\mathbb{C}^N$ for SU(N), on $\mathbb{R}^n$ for SO(n).
- *Adjoint:* $D(g) = \mathrm{Ad}_g$ on $V = \mathfrak{g}$, with $\rho = \mathrm{ad}$ (Section T3.4); dimension $\dim G$.
- *Conjugate:* $D(g) = \overline{g}$ (complex conjugate matrix). If $D(e^{-i\alpha R}) = e^{-i\alpha R}$, then $\overline{D} = e^{+i\alpha\bar{R}} = e^{-i\alpha(-\bar{R})}$, so the generators are $\bar{R}_a \to -R_a^* = -R_a^T$, exactly [QFT notes (31.2.7)]. Antiparticles transform in the conjugate representation.

New representations from old. Given representations D_1 on V_1 and D_2 on V_2, the **direct sum** acts block-diagonally on $V_1 \oplus V_2$, and the **tensor product** acts on $V_1 \otimes V_2$ by $D_1(g) \otimes D_2(g)$. For the generators of the tensor product, put $g = e^{\varepsilon X}$:

$$\begin{aligned} D_1(g) \otimes D_2(g) &\overset{(1)}{=} \big(\mathbb{1} + \varepsilon\rho_1(X)\big) \otimes \big(\mathbb{1} + \varepsilon\rho_2(X)\big) + O(\varepsilon^2) \\ &\overset{(2)}{=} \mathbb{1} \otimes \mathbb{1} + \varepsilon\big(\rho_1(X) \otimes \mathbb{1} + \mathbb{1} \otimes \rho_2(X)\big) + O(\varepsilon^2). \end{aligned} \tag{T3.27}$$

(1) Expand each factor to first order.
(2) The tensor product is bilinear; the ε^2 cross term is dropped.

So generators of a tensor product *add*: $R_a^{(1\otimes 2)} = R_a^{(1)} \otimes \mathbb{1} + \mathbb{1} \otimes R_a^{(2)}$ [QFT notes (31.3.13)]. This is the rule "total angular momentum $\vec{J} = \vec{J}^{(1)} + \vec{J}^{(2)}$" from quantum mechanics.

Working definition T3.10 (irreducible representation)

A representation is **irreducible** if no proper subspace $0 \neq W \subsetneq V$ is mapped into itself by all $D(g)$ [every $D(g)$ sends each vector of W to a vector of W]. *Operational test for unitary representations* [every $D(g)$ satisfies $D(g)^\dagger D(g) = \mathbb{1}$]: it is reducible exactly when some basis change puts all the R_a simultaneously into the same block-diagonal form. For a compact group [a closed and bounded set of matrices, like SU(N) or SO(N)] every representation can be made unitary (average an inner product over the group), and every representation is then a direct sum of irreducible ones.

Key idea: Schur's lemma, physicist's form

If a matrix C commutes with all the generators R_a of an irreducible representation, then $C = c\,\mathbb{1}$.

Why: an eigenspace of C is mapped into itself by every R_a (if $Cv = cv$ then $C(R_a v) = R_a C v = c\,R_a v$). By irreducibility the eigenspace is all of V. In physics: an observable that commutes with all the symmetry generators takes a single value on a whole multiplet. That is why all members of a multiplet have the same mass, and why the Casimir operator below is a number.

T3.5.2 The irreducible representations of SU(2): spin j

We construct every irreducible representation of $[J_a, J_b] = i\varepsilon_{abc}J_c$ by the ladder method. Suppose the J_a are Hermitian operators on a finite-dimensional space V. Define

$$J_\pm = J_1 \pm iJ_2, \qquad J_\pm^\dagger = J_\mp.$$

Their brackets with J_3 and with each other are

$$[J_3, J_\pm] \overset{(1)}{=} [J_3, J_1] \pm i[J_3, J_2] \overset{(2)}{=} iJ_2 \pm i(-iJ_1) = \pm(J_1 \pm iJ_2) = \pm J_\pm,$$
$$[J_+, J_-] \overset{(3)}{=} -i[J_1, J_2] + i[J_2, J_1] \overset{(4)}{=} -i(iJ_3) + i(-iJ_3) = 2J_3.$$

(1) Bilinearity.
(2) $[J_3, J_1] = i\varepsilon_{312}J_2 = iJ_2$ and $[J_3, J_2] = i\varepsilon_{321}J_1 = -iJ_1$.
(3) Expand $[J_1 + iJ_2, J_1 - iJ_2]$; the $[J_1, J_1]$ and $[J_2, J_2]$ terms vanish.
(4) $[J_1, J_2] = iJ_3$.

The first relation says $J_\pm$ are **ladder operators**: if $J_3 v = mv$ then

$$J_3(J_\pm v) \overset{(1)}{=} J_\pm J_3 v + [J_3, J_\pm]v \overset{(2)}{=} (m \pm 1)\,J_\pm v.$$

(1) Write $J_3 J_\pm = J_\pm J_3 + [J_3, J_\pm]$.
(2) $J_3 v = mv$ and $[J_3, J_\pm] = \pm J_\pm$.

So J_+ raises the J_3 eigenvalue by one and J_- lowers it by one. The **Casimir operator** $\vec{J}^2 = J_1^2 + J_2^2 + J_3^2$ commutes with all J_a [QFT notes (31.3.2)], so by Schur it is a number on an irreducible representation. Two rewritings are useful:

$$\vec{J}^2 = J_-J_+ + J_3^2 + J_3 = J_+J_- + J_3^2 - J_3, \tag{T3.28}$$

since $J_\mp J_\pm = J_1^2 + J_2^2 \pm i[J_1, J_2] = J_1^2 + J_2^2 \mp J_3$.

Building the multiplet. V is finite-dimensional, so J_3 has a largest eigenvalue j, with eigenvector $|j, j\rangle$. Then $J_+|j, j\rangle = 0$ (it would have eigenvalue $j + 1$). From (T3.28), $\vec{J}^2|j, j\rangle = (0 + j^2 + j)|j, j\rangle$, so $\vec{J}^2 = j(j + 1)$ on the whole irreducible representation. Now lower repeatedly. The norm of each lowered state is

$$\big\|J_-|j, m\rangle\big\|^2 \overset{(1)}{=} \langle j, m|J_+J_-|j, m\rangle \overset{(2)}{=} \langle j, m|\big(\vec{J}^2 - J_3^2 + J_3\big)|j, m\rangle$$
$$\overset{(3)}{=} j(j + 1) - m^2 + m = (j + m)(j - m + 1). \tag{T3.29}$$

(1) $J_-^\dagger = J_+$.

(2) The second form of (T3.28).
(3) Eigenvalues, with $|j,m\rangle$ normalised.

Starting from $m = j$ and stepping down by one, the right-hand side $(j+m)(j-m+1)$ stays positive until $m = -j$, where it vanishes. If the sequence $j, j-1, j-2, \ldots$ skipped over $-j$, the next norm would be negative, which is impossible. So the ladder must land exactly on $m = -j$: $j-(-j) = 2j$ is a non-negative integer.

Key idea: Irreducible representations of $\mathfrak{su}(2)$

For each $j \in \{0, \frac{1}{2}, 1, \frac{3}{2}, \ldots\}$ there is exactly one irreducible representation, of dimension $2j+1$, with orthonormal basis $|j,m\rangle$, $m = -j, -j+1, \ldots, j$, and

$$J_3|j,m\rangle = m|j,m\rangle, \quad J_\pm|j,m\rangle = \sqrt{(j\mp m)(j\pm m+1)}\,|j,m\pm1\rangle, \quad \vec{J}^{\,2} = j(j+1). \tag{T3.30}$$

The eigenvalues m of J_3 are the **weights**; j is the **highest weight**.

Worked example T3.18: Explicit matrices for $j = \frac{1}{2}$ and $j = 1$

For $j = \frac{1}{2}$, basis $(|\frac{1}{2},\frac{1}{2}\rangle, |\frac{1}{2},-\frac{1}{2}\rangle)$: (T3.30) gives $J_+|\frac{1}{2},-\frac{1}{2}\rangle = \sqrt{1\cdot1}|\frac{1}{2},\frac{1}{2}\rangle$, so

$$J_3 = \tfrac{1}{2}\begin{pmatrix}1&0\\0&-1\end{pmatrix}, \quad J_+ = \begin{pmatrix}0&1\\0&0\end{pmatrix}, \quad J_1 = \tfrac{1}{2}(J_+ + J_-) = \tfrac{1}{2}\sigma_1, \quad J_2 = \tfrac{1}{2i}(J_+ - J_-) = \tfrac{1}{2}\sigma_2.$$

This is the defining representation. For $j = 1$, basis $m = 1, 0, -1$: $J_+|1,0\rangle = \sqrt{1\cdot2}|1,1\rangle$ and $J_+|1,-1\rangle = \sqrt{2\cdot1}|1,0\rangle$, so

$$J_3 = \begin{pmatrix}1&0&0\\0&0&0\\0&0&-1\end{pmatrix}, \quad J_+ = \sqrt{2}\begin{pmatrix}0&1&0\\0&0&1\\0&0&0\end{pmatrix}, \quad J_1 = \tfrac{1}{\sqrt{2}}\begin{pmatrix}0&1&0\\1&0&1\\0&1&0\end{pmatrix}.$$

Check the Casimir on $|1,0\rangle$: $J_3^2|1,0\rangle = 0$ and $J_+J_-|1,0\rangle = J_+(\sqrt{2}|1,-1\rangle) = 2|1,0\rangle$, so $\vec{J}^{\,2} = J_+J_- + J_3^2 - J_3 = 2 = 1\cdot(1+1)$. This representation is the adjoint one, iL_a of Example T3.6, written in a different basis: iL_3 has eigenvalues $+1, 0, -1$ with eigenvectors $(\hat{x}+i\hat{y})/\sqrt{2}$, $\hat{z}$, $(\hat{x}-i\hat{y})/\sqrt{2}$, the "spherical basis" of vectors.

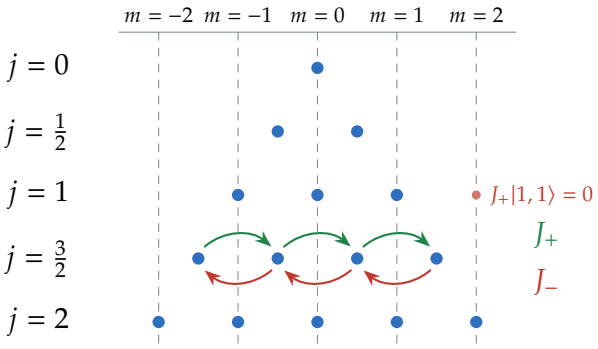

Figure T3.12: Weight diagrams of the spin-j representations of SU(2). Each dot is a state $|j,m\rangle$ at position m (its J_3 eigenvalue). The raising operator J_+ moves one step right, J_- one step left, and the ladder must stop symmetrically at $\pm j$. The difference between neighbouring weights, ±1, is the *root* of $\mathfrak{su}(2)$. Integer j has a weight at $m = 0$; half-integer j does not.

Which representations are representations of SO(3)? A rotation by 2π about $\hat{z}$ is $e^{-2\pi i J_3}$. On $|j,m\rangle$ it is $e^{-2\pi i m} = (-1)^{2m} = (-1)^{2j}$, since m and j differ by an integer. It is the identity for integer j and $-\mathbb{1}$ for half-integer j. So integer spins are genuine representations of SO(3) (orbital angular momentum, $Y_{\ell m}$), while half-integer spins are representations of SU(2) only, in which the element $-\mathbb{1}$ of Section T3.4 acts as -1.

Worked example T3.19: Two spin-$\frac{1}{2}$ particles: $\frac{1}{2}\otimes\frac{1}{2} = 0\oplus 1$

The tensor product has the four states $|\uparrow\uparrow\rangle, |\uparrow\downarrow\rangle, |\downarrow\uparrow\rangle, |\downarrow\downarrow\rangle$ with total weights $m = m_1 + m_2 = 1, 0, 0, -1$ (generators add, so weights add). The highest weight is 1, carried by $|\uparrow\uparrow\rangle$; lower it with the total $J_- = J_-^{(1)} + J_-^{(2)}$:

$$J_-|\uparrow\uparrow\rangle \overset{(1)}{=} (J_-|\uparrow\rangle)\otimes|\uparrow\rangle + |\uparrow\rangle\otimes(J_-|\uparrow\rangle) \overset{(2)}{=} |\downarrow\uparrow\rangle + |\uparrow\downarrow\rangle \overset{(3)}{=} \sqrt{2}\,|1,0\rangle.$$

(1) The tensor-product generator (T3.27).
(2) For $j=\frac{1}{2}$, $J_-|\frac{1}{2},\frac{1}{2}\rangle = \sqrt{1\cdot 1}|\frac{1}{2},-\frac{1}{2}\rangle$.
(3) (T3.30) for $j=1$, $m=1$: $J_-|1,1\rangle = \sqrt{2}|1,0\rangle$.

So the triplet is $|\uparrow\uparrow\rangle$, $\frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle)$, $|\downarrow\downarrow\rangle$. The orthogonal combination $\frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle)$ has $m=0$ and is annihilated by J_+ (check: J_+ gives $\frac{1}{\sqrt{2}}(|\uparrow\uparrow\rangle - |\uparrow\uparrow\rangle) = 0$), so it is a highest weight with $j=0$: the singlet. Dimensions: $2\times 2 = 1+3$. In general $j_1\otimes j_2 = |j_1-j_2|\oplus\cdots\oplus(j_1+j_2)$; the dimension check is $\sum_{j=|j_1-j_2|}^{j_1+j_2}(2j+1) = (2j_1+1)(2j_2+1)$.

Real, pseudoreal and complex. Is the conjugate of the spin-$\frac{1}{2}$ representation new? The Pauli matrices obey $\sigma_2\sigma_a^*\sigma_2 = -\sigma_a$ (check: $\sigma_1^* = \sigma_1$, $\sigma_3^* = \sigma_3$ anticommute with σ_2; $\sigma_2^* = -\sigma_2$ commutes with it). So $-\sigma_a^* = \sigma_2\sigma_a\sigma_2^{-1}$: the conjugate generators are equivalent to the original ones, $\bar{\mathbf{2}}\cong\mathbf{2}$. The intertwiner $\varepsilon = i\sigma_2$ is antisymmetric, and the invariant $\varepsilon_{\alpha\beta}\xi^\alpha\eta^\beta$ is the spin singlet above. A representation equivalent to its conjugate with an antisymmetric invariant is **pseudoreal**; with a symmetric one (like $\vec{v}\cdot\vec{w}$ for $j=1$) it is **real** [QFT notes §31.2]. For SU(3) the $\mathbf{3}$ and $\bar{\mathbf{3}}$ are genuinely different (*complex*), which is why quarks and antiquarks are distinguishable.

T3.5.3 Cartan subalgebra, weights and roots

For SU(2) we singled out one generator, J_3, diagonalised it, and used the others as ladders. For a bigger group we diagonalise as many generators as possible at once.

Working definition T3.11 (Cartan subalgebra, weights, roots)

A **Cartan subalgebra** is a maximal [no generator outside their span commutes with all of them] set of mutually commuting Hermitian generators $H_1,\dots,H_\ell$. The number ℓ is the **rank**. Commuting Hermitian matrices can be diagonalised together; a common eigenvector $|\mu\rangle$ has an eigenvalue vector

$$H_i|\mu\rangle = \mu_i|\mu\rangle, \qquad \mu = (\mu_1,\dots,\mu_\ell)\in\mathbb{R}^\ell,$$

called its **weight**. The weights of the adjoint representation [the generators themselves form the vector space, and H_i acts by $[H_i,\cdot\,]$] (other than 0) are the **roots**. The corresponding generators E_α satisfy $[H_i,E_\alpha] = \alpha_i E_\alpha$ [QFT notes (31.4.1)]. *How to find them:* for $\mathfrak{su}(N)$ take H_i to be the traceless diagonal matrices; the weights of the fundamental representation are the diagonal entries; the roots are the differences of these weights, carried by the matrix units E_{jk} [the matrix with 1 in row j, column k and zeros elsewhere].

Roots act as ladders on weights, in every representation:

$$H_i\big(E_\alpha|\mu\rangle\big) \overset{(1)}{=} E_\alpha H_i|\mu\rangle + [H_i, E_\alpha]|\mu\rangle \overset{(2)}{=} (\mu_i + \alpha_i)\, E_\alpha|\mu\rangle.$$

(1) Move H_i through E_α.
(2) Eigenvalue equation and the defining property of a root.

So E_α shifts the weight by α. For SU(2): rank 1, $H = J_3$, roots ± 1 with $E_{\pm 1} = J_\pm$. The weight diagrams of Figure T3.12 are one-dimensional because the rank is one.

Weights as characters of the torus. Exponentiating the Cartan generators gives the **maximal torus** $T = \{e^{-i\theta^i H_i}\} \cong \mathrm{U}(1)^\ell$. On a weight vector, $e^{-i\theta\cdot H}$ acts by the phase $e^{-i\theta\cdot\mu}$. So a weight is the same thing as a homomorphism $T \to \mathrm{U}(1)$, $e^{-i\theta\cdot H} \mapsto e^{-i\theta\cdot\mu}$. This is how Nash defines weights [Nash p. 188]. For SU(2), the torus is $\{e^{-i\theta J_3}\}$ with $\theta \in [0, 4\pi)$ and the weight m is the homomorphism $\theta \mapsto e^{-im\theta}$; single-valuedness on the torus forces $2m \in \mathbb{Z}$, the same integrality we found from the ladder.

T3.5.4 SU(3): triangles and a hexagon

In the Gell-Mann basis of Section T3.2.6, the diagonal generators $H_1 = J_3 = \frac{1}{2}\lambda_3$ and $H_2 = J_8 = \frac{1}{2}\lambda_8$ commute, and no other generator commutes with both. So $\mathfrak{su}(3)$ has rank 2 and its weights are points in a plane:

$$H_1 = \begin{pmatrix} \frac{1}{2} & 0 & 0 \\ 0 & -\frac{1}{2} & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad H_2 = \frac{1}{2\sqrt{3}} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{pmatrix}.$$

The fundamental 3. The standard basis vectors e_1, e_2, e_3 of $\mathbb{C}^3$ are common eigenvectors. Reading off the diagonal entries,

$$\mu^{(1)} = \Big(\tfrac{1}{2}, \tfrac{1}{2\sqrt{3}}\Big), \qquad \mu^{(2)} = \Big(-\tfrac{1}{2}, \tfrac{1}{2\sqrt{3}}\Big), \qquad \mu^{(3)} = \Big(0, -\tfrac{1}{\sqrt{3}}\Big).$$

Each has length squared $\frac{1}{4} + \frac{1}{12} = \frac{1}{3}$: the three weights form an equilateral triangle centred at the origin. In the quark model these are u, d, s, with isospin $I_3 = \mu_1$ and hypercharge $Y = \frac{2}{\sqrt{3}}\mu_2$: u, d have $Y = \frac{1}{3}$, s has $Y = -\frac{2}{3}$. The electric charge $Q = I_3 + \frac{Y}{2}$ gives $\frac{2}{3}, -\frac{1}{3}, -\frac{1}{3}$. The conjugate representation $\bar{\mathbf{3}}$ has generators $-R_a^*$, so for the diagonal ones $-H_i$: its weights are $-\mu^{(k)}$, the inverted triangle (the antiquarks).

The roots. For any diagonal matrix $D = \mathrm{diag}(d_1, d_2, d_3)$ and matrix unit E_{jk},

$$[D, E_{jk}] \overset{(1)}{=} \sum_l d_l \big(E_{ll}E_{jk} - E_{jk}E_{ll}\big) \overset{(2)}{=} d_j E_{jk} - d_k E_{jk} = (d_j - d_k)\, E_{jk}.$$

(1) Write $D = \sum_l d_l E_{ll}$.
(2) $E_{ll}E_{jk} = \delta_{lj}E_{lk}$ and $E_{jk}E_{ll} = \delta_{kl}E_{jl}$.

Applying this to H_1, H_2: E_{jk} (for $j \neq k$) is a root vector with root $\alpha = \mu^{(j)} - \mu^{(k)}$. The six roots are

$$\pm(1, 0), \qquad \pm\Big(\tfrac{1}{2}, \tfrac{\sqrt{3}}{2}\Big), \qquad \pm\Big(-\tfrac{1}{2}, \tfrac{\sqrt{3}}{2}\Big),$$

from E_{12}, E_{13}, E_{23} and their transposes. All have length 1 and neighbouring roots are 60° apart: a regular hexagon. The adjoint representation has these six weights plus the weight 0 twice (H_1 and H_2 themselves), $6 + 2 = 8 = \dim \mathrm{SU}(3)$: the gluon (or meson) octet. In terms of Gell-Mann matrices, $E_{12} = \frac{1}{2}(\lambda_1 + i\lambda_2)$ is the isospin raising operator (root $(1, 0)$), $E_{13} = \frac{1}{2}(\lambda_4 + i\lambda_5)$ and $E_{23} = \frac{1}{2}(\lambda_6 + i\lambda_7)$ are the "V-spin" and "U-spin" raising operators.

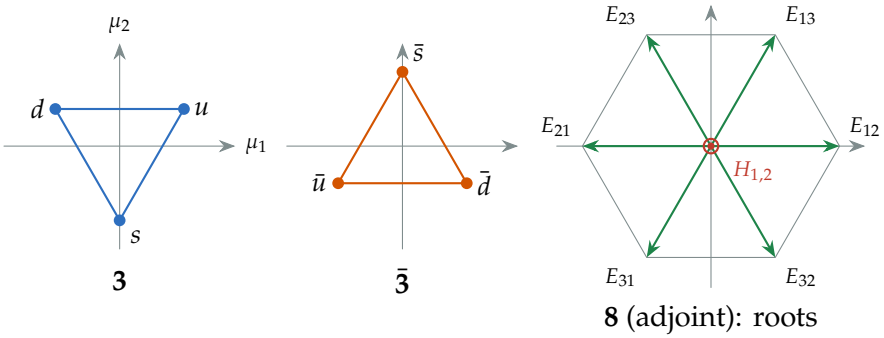

Figure T3.13: Weight diagrams of SU(3) in the (μ_1, μ_2) plane, the eigenvalues of $(H_1, H_2) = (\frac{1}{2}\lambda_3, \frac{1}{2}\lambda_8)$. Left: the quark triplet. Middle: the antiquark triplet, the negative of the first. Right: the adjoint representation: six roots (green arrows) forming a hexagon, each carried by a matrix unit E_{jk}, plus a doubly occupied weight 0 (the two Cartan generators). Each root is the difference of two weights of the **3**: e.g. E_{12} turns d into u.

Worked example T3.20: Checking one root with Gell-Mann matrices

Take $E_{13} = \frac{1}{2}(\lambda_4 + i\lambda_5)$, which is the matrix with a single 1 in position $(1, 3)$. By the formula above, $[H_1, E_{13}] = (\frac{1}{2} - 0)E_{13}$ and $[H_2, E_{13}] = (\frac{1}{2\sqrt{3}} + \frac{2}{2\sqrt{3}})E_{13} = \frac{\sqrt{3}}{2}E_{13}$. So its root is $(\frac{1}{2}, \frac{\sqrt{3}}{2})$. Acting on the s quark e_3: $E_{13}e_3 = e_1$, the u quark, and indeed $\mu^{(3)} + (\frac{1}{2}, \frac{\sqrt{3}}{2}) = (\frac{1}{2}, \frac{\sqrt{3}}{2} - \frac{1}{\sqrt{3}}) = (\frac{1}{2}, \frac{1}{2\sqrt{3}}) = \mu^{(1)}$. Its commutator with its adjoint is $[E_{13}, E_{31}] = E_{11} - E_{33} = \mathrm{diag}(1, 0, -1) = H_1 + \sqrt{3}H_2 = 2\,\alpha \cdot H$, a Cartan element in the direction of the root, as in [QFT notes (31.4.1)].

T3.5.5 Why roots are so rigid: integrality and the rank-two list

Every root α comes with its own copy of $\mathfrak{su}(2)$. Normalise the root vectors so that $[E_\alpha, E_{-\alpha}] = \alpha \cdot H$, and define

$$\mathcal{J}_3^{(\alpha)} = \frac{\alpha \cdot H}{(\alpha, \alpha)}, \qquad (\alpha, \beta) = \sum_i \alpha_i \beta_i .$$

Then $[\mathcal{J}_3^{(\alpha)}, E_{\pm\alpha}] = \pm\frac{(\alpha,\alpha)}{(\alpha,\alpha)}E_{\pm\alpha} = \pm E_{\pm\alpha}$, the $\mathfrak{su}(2)$ relation $[J_3, J_\pm] = \pm J_\pm$. (We use the Euclidean inner product in the orthonormal basis $\mathrm{tr}(H_i H_j) \propto \delta_{ij}$; the QFT notes allow a general Killing metric $g^{ij} = \mathrm{tr}\, H^i H^j$ [QFT notes (31.4.2)].) Any representation of $\mathfrak{g}$ is in particular a representation of this $\mathfrak{su}(2)$, so by Section T3.5.2 the eigenvalues of $\mathcal{J}_3^{(\alpha)}$ are half-integers. Apply this to the adjoint representation and the state E_β of weight β:

$$[\mathcal{J}_3^{(\alpha)}, E_\beta] \overset{(1)}{=} \frac{\alpha_i [H_i, E_\beta]}{(\alpha, \alpha)} \overset{(2)}{=} \frac{(\alpha, \beta)}{(\alpha, \alpha)} E_\beta \quad \Longrightarrow \quad 2\,\frac{(\alpha, \beta)}{(\alpha, \alpha)} \in \mathbb{Z}.$$

(1) Definition of $\mathcal{J}_3^{(\alpha)}$.
(2) $[H_i, E_\beta] = \beta_i E_\beta$; the eigenvalue must be in $\frac{1}{2}\mathbb{Z}$.

The same holds with α and β swapped. Multiplying the two integers $n = 2(\alpha,\beta)/(\alpha,\alpha)$ and $m = 2(\alpha,\beta)/(\beta,\beta)$,

$$\cos^2\theta_{\alpha\beta} = \frac{(\alpha,\beta)^2}{(\alpha,\alpha)(\beta,\beta)} = \frac{mn}{4} \in \{0, \tfrac14, \tfrac12, \tfrac34, 1\}$$

[QFT notes (31.4.6)]. So the angle between two roots can only be 90°, 60° (or 120°), 45° (or 135°), 30° (or 150°), with length ratios $\sqrt{m/n}$ equal to 1, 1, $\sqrt2$, $\sqrt3$ respectively. The **Weyl reflection** $s_\alpha(\beta) = \beta - 2\frac{(\alpha,\beta)}{(\alpha,\alpha)}\alpha$, the mirror image of β in the plane perpendicular to α, maps roots to roots (it is the $\mathrm{SU}(2)^{(\alpha)}$ rotation by π, which exchanges m and $-m$). For SU(3) the Weyl reflections permute the three weights of the triangle: the Weyl group is S_3.

$A_1 \times A_1$: 90° $\mathfrak{so}(4)$, dim 2 + 4 | A_2: 60° $\mathfrak{su}(3)$, dim 2 + 6 | $B_2 = C_2$: 45° $\mathfrak{so}(5) \cong \mathfrak{sp}(2)$, dim 2 + 8 | G_2: 30° dim 2 + 12

Figure T3.14: The four root systems of rank two, one for each allowed angle between simple roots. Green: short roots; orange: long roots (length ratio $\sqrt2$ for B_2, $\sqrt3$ for G_2). The dimension of the Lie algebra is the rank plus the number of roots. Nothing else is possible: the integrality of $2(\alpha,\beta)/(\alpha,\alpha)$ forbids every other angle.

Watch out: A misprint in the QFT notes

In the list of rank-two algebras the QFT notes call the 45° case "$\mathfrak{so}(8) \equiv \mathfrak{sp}(4)$" [QFT notes §31.4, item 3]. The correct statement is $\mathfrak{so}(5) \cong \mathfrak{sp}(4)$ in their convention (our $\mathfrak{sp}(2)$): dimension 10, as the count 2 + 8 shows. ($\mathfrak{so}(8)$ has dimension 28 and rank 4.)

Simple roots, the Cartan matrix and Dynkin diagrams. Call a root **positive** if its first nonzero component is positive. A positive root that is not a sum of two positive roots is **simple**; there are exactly ℓ of them, and every positive root is a combination of simple roots with non-negative integer coefficients. The **Cartan matrix** $A_{ij} = 2(\alpha_i,\alpha_j)/(\alpha_j,\alpha_j)$ of the simple roots determines the whole algebra.

Worked example T3.21: Simple roots and Cartan matrix of $\mathfrak{su}(3)$

By our rule the positive roots are $(1,0)$, $(\frac12, \frac{\sqrt3}{2})$ and $(\frac12, -\frac{\sqrt3}{2})$; the root $(-\frac12, \frac{\sqrt3}{2})$ counts as negative because its first component is negative. The first is the sum of the other two, $(1,0) = (\frac12, \frac{\sqrt3}{2}) + (\frac12, -\frac{\sqrt3}{2})$, so it is not simple, and the simple roots are $\alpha_1 = (\frac12, \frac{\sqrt3}{2})$, $\alpha_2 = (\frac12, -\frac{\sqrt3}{2})$. Then

$$(\alpha_1,\alpha_1) = (\alpha_2,\alpha_2) = 1, \quad (\alpha_1,\alpha_2) \overset{(1)}{=} \tfrac14 - \tfrac34 = -\tfrac12, \quad A \overset{(2)}{=} \begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}.$$

(1) Dot product of the two vectors.
(2) $A_{12} = 2(-\frac12)/1 = -1 = A_{21}$, and $A_{ii} = 2$ always.

The angle between the simple roots is 120°. The Weyl reflection of α_2 in α_1 is $s_{\alpha_1}(\alpha_2) = \alpha_2 - (-1)\alpha_1 = \alpha_1 + \alpha_2 = (1,0)$, the third positive root.

The Dynkin diagram encodes the Cartan matrix: one node per simple root, and $A_{ij}A_{ji} \in$

$\{0,1,2,3\}$ lines between nodes i and j, with an arrow pointing to the shorter root when the lengths differ. The classification of possible diagrams gives the complete list of compact simple Lie algebras (Figure T3.15).

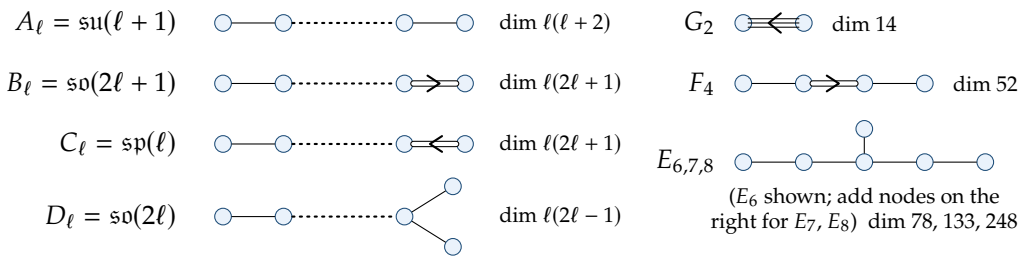

Figure T3.15: Dynkin diagrams of all compact simple Lie algebras. Nodes are simple roots; no line means 90°, one line 120°, two lines 135°, three lines 150°; arrows point to the shorter root. The four infinite families are the classical algebras of Table T3.3; five exceptional algebras complete the list.

T3.5.6 Casimirs and the index of a representation

Two numbers attached to each irreducible representation R appear in every loop calculation in gauge theory. With Hermitian generators R_a normalised so that $\mathrm{tr}_{\text{fund}}(J_a J_b) = \frac{1}{2}\delta_{ab}$:

$$\sum_a R_a R_a = C_2(R)\,\mathbb{1}_{\dim R}, \qquad \mathrm{tr}(R_a R_b) = C(R)\,\delta_{ab}. \tag{T3.31}$$

The first is Schur's lemma applied to the Casimir; the second holds because $\mathrm{tr}(R_a R_b)$ is an invariant symmetric form on a simple algebra and hence proportional to the Killing form. They are related by taking the trace of the first and contracting the second with δ_{ab}:

$$C_2(R)\dim R \overset{(1)}{=} \mathrm{tr}\sum_a R_a R_a \overset{(2)}{=} \sum_a C(R)\,\delta_{aa} = C(R)\dim G. \tag{T3.32}$$

(1) Trace of the first equation in (T3.31).
(2) Set $a = b$ in the second and sum over a; $\delta_{aa} = \dim G$.

Worked example T3.22: Casimirs of $\mathrm{SU}(N)$

Fundamental: $C(\mathbf{N}) = \frac{1}{2}$ by normalisation, so (T3.32) gives $C_2(\mathbf{N}) = \frac{N^2-1}{2N}$. For SU(2) that is $\frac{3}{4} = \frac{1}{2}(\frac{1}{2}+1)$, the spin-$\frac{1}{2}$ value of $\vec{J}^2$. For SU(3) it is $\frac{4}{3}$, the "colour factor" C_F of a quark. *Adjoint:* the adjoint generators are $J^A_a = i\,\mathrm{ad}_{T_a}$, so

$$\mathrm{tr}\big(J^A_a J^A_b\big) \overset{(1)}{=} -\mathrm{tr}\big(\mathrm{ad}_{T_a}\mathrm{ad}_{T_b}\big) \overset{(2)}{=} -B(T_a,T_b) \overset{(3)}{=} -2N\,\mathrm{tr}(T_a T_b) \overset{(4)}{=} 2N\,\mathrm{tr}(J_a J_b) = N\,\delta_{ab}.$$

(1) $i^2 = -1$.
(2) Definition of the Killing form.
(3) Example T3.16.
(4) $T_a = -iJ_a$, so $\mathrm{tr}(T_a T_b) = -\mathrm{tr}(J_a J_b) = -\frac{1}{2}\delta_{ab}$.

So $C(A) = N$, and since $\dim A = \dim G$, also $C_2(A) = N$ [QFT notes (31.3.22)]. For SU(2), $C_2(A) = 2 = 1\cdot(1+1)$, the spin-1 value. For QCD, $C_A = 3$. The one-loop beta function coefficient $b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f$ (with $T_F = C(\mathbf{N}) = \frac{1}{2}$) is built from exactly these numbers; $b_0 > 0$ is asymptotic freedom.

Try it: $\mathbf{N}\otimes\bar{\mathbf{N}} = \mathbf{1}\oplus$ adjoint

A quark–antiquark pair $\psi^i\bar{\chi}_j$ is an $N\times N$ matrix $M^i{}_j$ transforming as $M\mapsto UMU^\dagger$. Split $M = \frac{\operatorname{tr}M}{N}\mathbb{1} + (M - \frac{\operatorname{tr}M}{N}\mathbb{1})$ and identify the two pieces.
Answer: the trace is invariant ($\operatorname{tr}UMU^\dagger = \operatorname{tr}M$): a singlet, the colour-neutral meson. The traceless part transforms by conjugation, i.e. in the adjoint representation, of dimension N^2-1. So $N^2 = 1 + (N^2-1)$ [QFT notes (31.3.20)].

Reading Nash (weights, roots and highest weights in Nash)

Nash's account of the Borel–Weil theorem [Nash pp. 188–190, (6.63)–(6.70)] uses exactly the objects of this section. The weights of a representation are homomorphisms $\lambda_i : T\to \mathrm{U}(1)$ from the maximal torus; an irreducible representation is labelled by its highest weight λ and written V_λ. His decomposition $\mathfrak{g} = \mathfrak{t}\oplus\mathfrak{h}$ [Nash (6.66)] splits the Lie algebra into the Cartan subalgebra $\mathfrak{t}$ and the sum $\mathfrak{h}$ of root spaces; after complexifying, $\mathfrak{h}_{\mathbb{C}} = \mathfrak{h}^+_{\mathbb{C}}\oplus\mathfrak{h}^-_{\mathbb{C}}$ [Nash (6.68)] is our split into positive and negative root vectors $E_{\pm\alpha}$, the "step operators". For SU(2) these are $J_\pm$. The Casimir operator he uses for Kac–Moody algebras [Nash p. 182, (6.39)] is the $\sum_a R_aR_a$ of (T3.31).

Recap

- A representation turns group products into matrix products; its generators satisfy the same commutation relations. Tensor products add generators; conjugates use $-R^*$.
- Schur: anything commuting with an irrep is a number. Hence Casimirs are constants on multiplets.
- SU(2) irreps: spin $j\in\frac12\mathbb{Z}_{\geq0}$, weights $m = -j,\dots,j$, $J_\pm$ ladders with norms $(j\mp m)(j\pm m+1)$. Integer j only for SO(3).
- Cartan subalgebra = maximal commuting set; weights = simultaneous eigenvalues; roots = weights of the adjoint, acting as ladders.
- SU(3): rank 2, $\mathbf{3}$ is a triangle, $\bar{\mathbf{3}}$ the inverted triangle, roots form a hexagon.
- $2(\alpha,\beta)/(\alpha,\alpha)\in\mathbb{Z}$ fixes the allowed angles and leads to the Dynkin classification.
- $C_2(R)\dim R = C(R)\dim G$; SU($N$): $C(\mathbf{N}) = \frac12$, $C_2(\mathbf{N}) = \frac{N^2-1}{2N}$, $C_2(A) = N$.

T3.6 The Maurer–Cartan form $g^{-1}\mathrm{d}g$

So far a group element has been a fixed matrix. In gauge theory it becomes a *field*: a matrix $g(x)$ that depends on the point x of spacetime. The first thing a physicist wants to do with a field is differentiate it. Here we hit a small but important snag. The derivative $\mathrm{d}g$ of a group-valued function is not in the Lie algebra: for $g(x)\in\mathrm{SU}(2)$, the matrix $\partial_\mu g$ is neither anti-Hermitian nor traceless in general. It is a tangent vector to the group at the point g, not at the identity. The question of this section is: *how do we turn the derivative of a group-valued field into something that lives in the Lie algebra, so that we can expand it in generators T_a?* The answer, $g^{-1}\mathrm{d}g$, is the single most important formula connecting Lie groups to differential forms. It is the prototype of every gauge field (it is "pure gauge"), its structure equation is the prototype of $F = \mathrm{d}A + A\wedge A$, and the trace of its cube counts how many times a map wraps around the group.

T3.6.1 Pulling a velocity back to the identity

Take a curve $g(t)$ in a matrix group, passing through $g_0 = g(0)$. Its velocity $\dot{g}(0)$ is a tangent vector at g_0. Multiply it on the left by g_0^{-1}. The curve $t \mapsto g_0^{-1} g(t)$ lies in the group (it is a product of group elements) and passes through $\mathbb{1}$ at $t = 0$. So its velocity $g_0^{-1}\dot{g}(0)$ is in $\mathfrak{g}$, by the working definition of Section T3.2. Left multiplication by g_0^{-1} has carried the tangent vector from g_0 back to the identity.

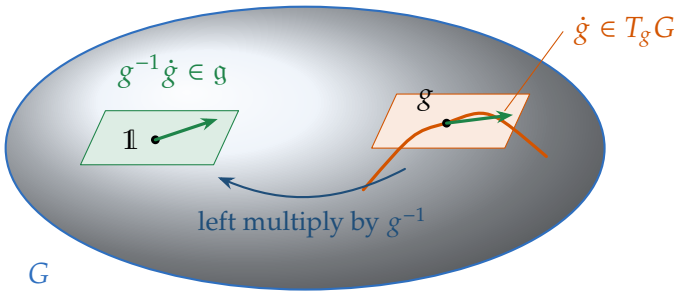

Figure T3.16: The velocity $\dot{g}$ of a curve through g is a tangent vector at g (orange plane), not in the Lie algebra. Left multiplication by g^{-1} maps a neighbourhood of g to a neighbourhood of $\mathbb{1}$ and carries $\dot{g}$ to $g^{-1}\dot{g}$, which lies in the tangent plane at the identity: the Lie algebra (green plane). Doing this at every point at once is the Maurer–Cartan form.

Now let g depend on several variables x^μ, the coordinates of a manifold M (spacetime, or the group itself). Doing the same thing for each partial derivative gives a Lie-algebra-valued 1-form.

Working definition T3.12 (Maurer–Cartan form)

For a group-valued function $g : M \to G$, its **Maurer–Cartan form** is the matrix of 1-forms [it turns a small step δx^μ in M into the generator $g^{-1}\delta g = g^{-1}\partial_\mu g\, \delta x^\mu$]

$$\theta \coloneqq g^{-1}\mathrm{d}g = g^{-1}\partial_\mu g\, \mathrm{d}x^\mu .$$

Each component $g^{-1}\partial_\mu g$ lies in $\mathfrak{g}$, so we may expand $\theta = \theta^a T_a$ with ordinary real 1-forms θ^a. *How to compute it:* differentiate the matrix entry by entry, multiply on the left by g^{-1}, and read off the coefficient of each generator T_a (for $\mathfrak{su}(N)$, $\theta^a = -2\,\mathrm{tr}(T_a\theta)$ when $\mathrm{tr}(T_aT_b) = -\frac{1}{2}\delta_{ab}$). When $M = G$ and g is the identity map, θ is called *the* Maurer–Cartan form of the group.

Let us check that the components really are in $\mathfrak{u}(n)$ when g is unitary:

$$(g^{-1}\partial_\mu g)^\dagger \overset{(1)}{=} (\partial_\mu g)^\dagger\, g \overset{(2)}{=} -g^\dagger\,\partial_\mu g\, g^\dagger g \overset{(3)}{=} -g^{-1}\partial_\mu g .$$

(1) The dagger of a product reverses the order, and $(g^{-1})^\dagger = g$ for unitary g.
(2) Differentiate $g^\dagger g = \mathbb{1}$: $(\partial_\mu g^\dagger)g = -g^\dagger\partial_\mu g$; multiply on the right by $g^\dagger$ and use $gg^\dagger = \mathbb{1}$, so $(\partial_\mu g)^\dagger = -g^\dagger(\partial_\mu g)g^\dagger$.
(3) $g^\dagger g = \mathbb{1}$ and $g^\dagger = g^{-1}$.

For $\mathrm{SU}(n)$ it is also traceless, because $\mathrm{tr}(g^{-1}\partial_\mu g) = \partial_\mu \log\det g = 0$ when $\det g = 1$ (a consequence of $\det e^X = e^{\mathrm{tr}\,X}$, Section T3.3).

Worked example T3.23: U(1): the Maurer–Cartan form is $i\,\mathrm{d}\alpha$

Let $g = e^{i\alpha(x)}$ be a phase field. Then

$$g^{-1}\mathrm{d}g \overset{(1)}{=} e^{-i\alpha}\,\mathrm{d}\big(e^{i\alpha}\big) \overset{(2)}{=} e^{-i\alpha}\,e^{i\alpha}\,i\,\mathrm{d}\alpha = i\,\mathrm{d}\alpha.$$

(1) Definition.
(2) Chain rule: $\mathrm{d}(e^{i\alpha}) = e^{i\alpha}\,i\,\mathrm{d}\alpha$.

The answer is in $\mathfrak{u}(1) = i\mathbb{R}$, as it must be. On the group $\mathrm{U}(1) = S^1$ itself, with the angle α as coordinate, $\theta = i\,\mathrm{d}\alpha$. Note that $\mathrm{d}\alpha$ is a perfectly good 1-form on the circle even though α is not a function there (it jumps by 2π): this is the standard closed-but-not-exact form of Chapter T2. The Maurer–Cartan form of U(1) is i times the angle form.

Worked example T3.24: SO(2) written as matrices

With $R(\alpha) = \left(\begin{smallmatrix}\cos\alpha & -\sin\alpha\\ \sin\alpha & \cos\alpha\end{smallmatrix}\right)$,

$$R^{-1}\mathrm{d}R \overset{(1)}{=} \begin{pmatrix}\cos\alpha & \sin\alpha\\ -\sin\alpha & \cos\alpha\end{pmatrix}\begin{pmatrix}-\sin\alpha & -\cos\alpha\\ \cos\alpha & -\sin\alpha\end{pmatrix}\mathrm{d}\alpha$$
$$\overset{(2)}{=} \begin{pmatrix}0 & -1\\ 1 & 0\end{pmatrix}\mathrm{d}\alpha = L\,\mathrm{d}\alpha.$$

(1) $R^{-1} = R^T$ for a rotation; differentiate each entry of R.
(2) Multiply out: the $(1,1)$ entry is $-\cos\alpha\sin\alpha + \sin\alpha\cos\alpha = 0$, the $(1,2)$ entry is $-\cos^2\alpha - \sin^2\alpha = -1$, and so on.

The α-dependence has disappeared: θ is the constant generator L times $\mathrm{d}\alpha$. This is the matrix version of Example T3.23, and it is the connection 1-form of polar coordinates in disguise. Dray computes $\mathrm{d}\hat{r} = \mathrm{d}\phi\,\hat{\phi}$, $\mathrm{d}\hat{\phi} = -\mathrm{d}\phi\,\hat{r}$ [Dray (17.2)–(17.3)]. Put the frame in a row, $(\hat{r},\hat{\phi}) = (\hat{x},\hat{y})R(\phi)$: then $\mathrm{d}(\hat{r},\hat{\phi}) = (\hat{x},\hat{y})\mathrm{d}R = (\hat{r},\hat{\phi})\,R^{-1}\mathrm{d}R$, and $R^{-1}\mathrm{d}R = L\,\mathrm{d}\phi$ reproduces exactly Dray's two formulas. The connection 1-forms of a rotating frame *are* a Maurer–Cartan form. We return to this in Section T3.8.

T3.6.2 Left invariance

Why multiply on the left and not on the right? Either works, and each gives a form with a symmetry. For a constant group element h,

$$(hg)^{-1}\mathrm{d}(hg) \overset{(1)}{=} g^{-1}h^{-1}\,h\,\mathrm{d}g \overset{(2)}{=} g^{-1}\mathrm{d}g, \tag{T3.33}$$
$$(gh)^{-1}\mathrm{d}(gh) \overset{(3)}{=} h^{-1}g^{-1}\,\mathrm{d}g\,h \overset{(4)}{=} h^{-1}\,\theta\,h = \mathrm{Ad}_{h^{-1}}\theta. \tag{T3.34}$$

(1) $(hg)^{-1} = g^{-1}h^{-1}$, and $\mathrm{d}(hg) = h\,\mathrm{d}g$ because h is constant.
(2) $h^{-1}h = \mathbb{1}$.
(3) Similarly, $\mathrm{d}(gh) = \mathrm{d}g\,h$.
(4) Definition of θ and of the adjoint action (Section T3.4).

So θ is **left-invariant**: it does not change if we rotate the field from the left by a constant. Under a constant rotation from the right it rotates in the adjoint representation. The other choice, $\Theta \coloneqq \mathrm{d}g\,g^{-1}$, is **right-invariant** and rotates by Ad_h under $g \mapsto hg$. The two are related by $\Theta = g\,\theta\,g^{-1} = \mathrm{Ad}_g\theta$.

Physical picture: Body frame and space frame

Think of $g(t) \in \mathrm{SO}(3)$ as the orientation of a spinning top. Then $g^{-1}\dot{g}$ is the angular velocity measured in the *body* frame (what an observer riding on the top sees), and $\dot{g}\,g^{-1}$ is the angular velocity in the *space* frame. Rotating the laboratory (left multiplication) does not change what the rider sees: that is left invariance. Euler's equations for the rigid body are written in the body frame precisely because $g^{-1}\dot{g}$ does not care where the laboratory is.

T3.6.3 The structure equation $\mathrm{d}\theta + \theta \wedge \theta = 0$

The Maurer–Cartan form is not an arbitrary Lie-algebra-valued 1-form. It is the "derivative" of something, so its own derivative is constrained, just as a gradient field has zero curl. First we need the derivative of an inverse. Differentiating $g^{-1}g = \mathbb{1}$ gives $\mathrm{d}(g^{-1})\,g + g^{-1}\mathrm{d}g = 0$, so

$$\mathrm{d}(g^{-1}) = -g^{-1}\,\mathrm{d}g\,g^{-1}. \tag{T3.35}$$

This is the matrix version of $\mathrm{d}(1/x) = -\mathrm{d}x/x^2$. Now

$$\begin{aligned} \mathrm{d}\theta &\overset{(1)}{=} \mathrm{d}(g^{-1}) \wedge \mathrm{d}g + g^{-1}\,\mathrm{d}\mathrm{d}g \\ &\overset{(2)}{=} -g^{-1}\mathrm{d}g\,g^{-1} \wedge \mathrm{d}g \\ &\overset{(3)}{=} -(g^{-1}\mathrm{d}g) \wedge (g^{-1}\mathrm{d}g) = -\theta \wedge \theta. \end{aligned} \tag{T3.36}$$

(1) Product rule for the exterior derivative. The first factor g^{-1} is a (matrix-valued) 0-form, so no sign appears.
(2) Equation (T3.35), and $\mathrm{d}\mathrm{d} = 0$ applied to each matrix entry of g.
(3) Regroup the matrix product; the order of the matrices is kept, and the only wedge is between the two $\mathrm{d}g$'s.

Key idea: Maurer–Cartan structure equation

$$\mathrm{d}\theta + \theta \wedge \theta = 0, \qquad \text{in components} \qquad \mathrm{d}\theta^a + \tfrac{1}{2} f_{bc}{}^a\, \theta^b \wedge \theta^c = 0. \tag{T3.37}$$

It says that the "curvature" $\mathrm{d}A + A \wedge A$ of the special gauge field $A = g^{-1}\mathrm{d}g$ vanishes. We will see in Section T3.10 that this is exactly what "pure gauge" means.

The component form needs one small calculation, because $\theta \wedge \theta$ looks as if it should vanish (a 1-form wedged with itself). It does not, because the matrix coefficients do not commute:

$$\begin{aligned} \theta \wedge \theta &\overset{(1)}{=} \theta^b \wedge \theta^c\, T_b T_c \\ &\overset{(2)}{=} \tfrac{1}{2}\,\theta^b \wedge \theta^c\, \left(T_b T_c - T_c T_b\right) \\ &\overset{(3)}{=} \tfrac{1}{2}\,\theta^b \wedge \theta^c\, f_{bc}{}^a\, T_a. \end{aligned} \tag{T3.38}$$

(1) Expand $\theta = \theta^b T_b$ in both factors. The θ^b are ordinary 1-forms, so they can be moved past the constant matrices.
(2) $\theta^b \wedge \theta^c$ is antisymmetric in b, c, so only the antisymmetric part of $T_b T_c$ survives: write $T_b T_c = \tfrac{1}{2}[T_b, T_c] + \tfrac{1}{2}\{T_b, T_c\}$ and drop the symmetric anticommutator.
(3) Structure constants, (T3.6).

We often write this as $\theta \wedge \theta = \tfrac{1}{2}[\theta, \theta]$, where the bracket of two Lie-algebra-valued 1-forms means $[\alpha, \beta] = \alpha^b \wedge \beta^c\,[T_b, T_c]$. For an abelian group $\theta \wedge \theta = 0$ and the structure equation is just $\mathrm{d}\theta = 0$: for $\mathrm{U}(1)$, $\mathrm{d}(i\,\mathrm{d}\alpha) = 0$.

Watch out: Signs for matrix-valued forms

For matrix-valued forms, $\alpha \wedge \beta \neq \pm\beta \wedge \alpha$ in general, because the matrices do not commute. Two rules replace graded commutativity. (i) Under a trace, the *graded* cyclic rule holds: $\mathrm{tr}(\alpha \wedge \beta) = (-1)^{pq}\,\mathrm{tr}(\beta \wedge \alpha)$ for a p-form α and a q-form β. (ii) The product rule is $\mathrm{d}(\alpha \wedge \beta) = \mathrm{d}\alpha \wedge \beta + (-1)^p \alpha \wedge \mathrm{d}\beta$, with the matrices kept in order. Every calculation in the rest of this chapter uses only these two rules. For the right-invariant form $\Theta = \mathrm{d}g\, g^{-1}$ the same steps give $\mathrm{d}\Theta - \Theta \wedge \Theta = 0$: note the opposite sign.

The dual picture: left-invariant vector fields. For each generator T_a there is a vector field e_a on the group whose value at g is gT_a (the velocity of $t \mapsto g\, e^{tT_a}$). These are the vector fields dual to the θ^a: $\theta(e_a) = g^{-1}gT_a = T_a$, i.e. $\theta^b(e_a) = \delta^b_a$. Their Lie bracket is $[e_a, e_b] = f_{ab}{}^c e_c$, and the component equation (T3.37) is the same statement written with forms. (Use Cartan's formula $\mathrm{d}\theta^c(e_a, e_b) = e_a\big(\theta^c(e_b)\big) - e_b\big(\theta^c(e_a)\big) - \theta^c([e_a, e_b])$: the first two terms vanish because $\theta^c(e_b)$ is constant, leaving $\mathrm{d}\theta^c(e_a, e_b) = -f_{ab}{}^c$, which is what $-\frac{1}{2} f_{de}{}^c \theta^d \wedge \theta^e$ gives on (e_a, e_b).) So a Lie algebra is "the algebra of left-invariant vector fields", and this is how Nash thinks of $\mathfrak{g}$ for infinite-dimensional groups like $\mathrm{Diff}(X)$ [Nash p. 178].

T3.6.4 SU(2) in Euler angles: the forms written out

Let us compute the three 1-forms θ^a on $\mathrm{SU}(2) = S^3$ explicitly, and check the structure equation by hand. Parametrise

$$g(\phi, \vartheta, \psi) = e^{\phi T_3}\, e^{\vartheta T_2}\, e^{\psi T_3}, \qquad 0 \le \vartheta \le \pi, \quad 0 \le \phi < 2\pi, \quad 0 \le \psi < 4\pi, \tag{T3.39}$$

with $T_a = -\frac{i}{2}\sigma_a$. (The range 4π for ψ is needed because $e^{2\pi T_3} = -\mathbb{1}$: we are covering SU(2), not SO(3).) We need how conjugation by an exponential rotates the generators. From $[T_a, T_b] = \varepsilon_{abc} T_c$, ad_{T_a} acts on the components of $X = X^b T_b$ exactly as the rotation generator L_a acts on a 3-vector (Example T3.14), so $\mathrm{Ad}_{e^{\beta T_a}} = e^{\beta\,\mathrm{ad}_{T_a}}$ is the rotation by β about the a-th axis ((T3.22)):

$$e^{-\psi T_3}\, T_1\, e^{\psi T_3} = \cos\psi\, T_1 - \sin\psi\, T_2, \qquad e^{-\psi T_3}\, T_2\, e^{\psi T_3} = \sin\psi\, T_1 + \cos\psi\, T_2,$$
$$e^{-\vartheta T_2}\, T_3\, e^{\vartheta T_2} = \cos\vartheta\, T_3 - \sin\vartheta\, T_1.$$

(These are rotations by $-\psi$ about the 3-axis and $-\vartheta$ about the 2-axis applied to the unit vectors $\hat{e}_1, \hat{e}_2, \hat{e}_3$. Check one: to first order in ψ, $e^{-\psi T_3} T_1 e^{\psi T_3} = T_1 - \psi[T_3, T_1] = T_1 - \psi T_2$.) Now differentiate the product (T3.39) with the product rule:

$$\begin{aligned} g^{-1}\mathrm{d}g &\overset{(1)}{=} e^{-\psi T_3} e^{-\vartheta T_2}\,(T_3\,\mathrm{d}\phi)\, e^{\vartheta T_2} e^{\psi T_3} + e^{-\psi T_3}\,(T_2\,\mathrm{d}\vartheta)\, e^{\psi T_3} + T_3\,\mathrm{d}\psi \\ &\overset{(2)}{=} \mathrm{d}\phi\; e^{-\psi T_3}\big(\cos\vartheta\, T_3 - \sin\vartheta\, T_1\big) e^{\psi T_3} + \mathrm{d}\vartheta\,\big(\sin\psi\, T_1 + \cos\psi\, T_2\big) + \mathrm{d}\psi\, T_3 \\ &\overset{(3)}{=} \big(\sin\psi\,\mathrm{d}\vartheta - \sin\vartheta\cos\psi\,\mathrm{d}\phi\big) T_1 + \big(\cos\psi\,\mathrm{d}\vartheta + \sin\vartheta\sin\psi\,\mathrm{d}\phi\big) T_2 \\ &\qquad + \big(\mathrm{d}\psi + \cos\vartheta\,\mathrm{d}\phi\big) T_3. \end{aligned}$$

(1) $\mathrm{d}(e^{\phi T_3}) = e^{\phi T_3} T_3\,\mathrm{d}\phi$ and similarly for the other factors; after multiplying by $g^{-1} = e^{-\psi T_3} e^{-\vartheta T_2} e^{-\phi T_3}$ on the left, each derivative is sandwiched between the factors to its right and their inverses.

(2) The conjugation formulas for T_3 by $e^{\vartheta T_2}$ and for T_2 by $e^{\psi T_3}$; T_3 commutes with $e^{\psi T_3}$.

(3) Conjugate T_1 by $e^{\psi T_3}$ with the first formula and collect the coefficients of T_1, T_2, T_3.

So the left-invariant forms of SU(2) are

$$\begin{aligned}\theta^1 &= \sin\psi\,\mathrm{d}\vartheta - \sin\vartheta\cos\psi\,\mathrm{d}\phi,\\ \theta^2 &= \cos\psi\,\mathrm{d}\vartheta + \sin\vartheta\sin\psi\,\mathrm{d}\phi,\\ \theta^3 &= \mathrm{d}\psi + \cos\vartheta\,\mathrm{d}\phi.\end{aligned} \tag{T3.40}$$

Worked example T3.25: Checking the structure equation by hand

With $f_{bc}{}^{a} = \varepsilon_{abc}$, (T3.37) reads $\mathrm{d}\theta^3 + \theta^1\wedge\theta^2 = 0$ and cyclic permutations. For the third component:

$$\begin{aligned}\theta^1\wedge\theta^2 &\overset{(1)}{=} \sin^2\psi\,\sin\vartheta\,\mathrm{d}\vartheta\wedge\mathrm{d}\phi - \sin\vartheta\cos^2\psi\,\mathrm{d}\phi\wedge\mathrm{d}\vartheta\\ &\overset{(2)}{=} \sin\vartheta\left(\sin^2\psi+\cos^2\psi\right)\mathrm{d}\vartheta\wedge\mathrm{d}\phi = \sin\vartheta\,\mathrm{d}\vartheta\wedge\mathrm{d}\phi,\\ \mathrm{d}\theta^3 &\overset{(3)}{=} \mathrm{d}(\cos\vartheta)\wedge\mathrm{d}\phi = -\sin\vartheta\,\mathrm{d}\vartheta\wedge\mathrm{d}\phi.\end{aligned}$$

(1) Multiply out; the terms $\mathrm{d}\vartheta\wedge\mathrm{d}\vartheta$ and $\mathrm{d}\phi\wedge\mathrm{d}\phi$ vanish, leaving the two cross terms.
(2) $\mathrm{d}\phi\wedge\mathrm{d}\vartheta = -\mathrm{d}\vartheta\wedge\mathrm{d}\phi$.
(3) $\mathrm{dd}\psi = 0$ and $\mathrm{dd}\phi = 0$.

The sum is zero. For the first component, $\mathrm{d}\theta^1 = \cos\psi\,\mathrm{d}\psi\wedge\mathrm{d}\vartheta - \cos\vartheta\cos\psi\,\mathrm{d}\vartheta\wedge\mathrm{d}\phi + \sin\vartheta\sin\psi\,\mathrm{d}\psi\wedge\mathrm{d}\phi$ and $\theta^2\wedge\theta^3 = \cos\psi\,\mathrm{d}\vartheta\wedge\mathrm{d}\psi + \cos\psi\cos\vartheta\,\mathrm{d}\vartheta\wedge\mathrm{d}\phi + \sin\vartheta\sin\psi\,\mathrm{d}\phi\wedge\mathrm{d}\psi$; the three pairs cancel term by term. The Maurer–Cartan equation is not an abstract identity: it is a statement about these trigonometric functions.

The metric and the volume. Because the θ^a are left-invariant, anything built from them with constant coefficients is left-invariant too. Two things are especially useful.

- The metric $\mathrm{d}s^2 = (\theta^1)^2 + (\theta^2)^2 + (\theta^3)^2 = -2\,\mathrm{tr}(\theta\otimes\theta)$ is invariant under both left and right multiplication (right multiplication rotates θ^a by Ad, an orthogonal matrix). From (T3.40),
$$\mathrm{d}s^2 = \mathrm{d}\vartheta^2 + \mathrm{d}\phi^2 + \mathrm{d}\psi^2 + 2\cos\vartheta\,\mathrm{d}\phi\,\mathrm{d}\psi,$$
which is the round metric on the 3-sphere of radius 2. (The radius is 2 rather than 1 because $T_a = -\frac{i}{2}\sigma_a$ carries a $\frac{1}{2}$: going once round the group takes ψ from 0 to 4π.)

- The volume form $\theta^1\wedge\theta^2\wedge\theta^3$. Using the first part of Example T3.25,
$$\begin{aligned}\theta^1\wedge\theta^2\wedge\theta^3 &\overset{(1)}{=} \sin\vartheta\,\mathrm{d}\vartheta\wedge\mathrm{d}\phi\wedge(\mathrm{d}\psi+\cos\vartheta\,\mathrm{d}\phi) \overset{(2)}{=} \sin\vartheta\,\mathrm{d}\vartheta\wedge\mathrm{d}\phi\wedge\mathrm{d}\psi,\\ \int_{\mathrm{SU}(2)}\theta^1\wedge\theta^2\wedge\theta^3 &\overset{(3)}{=} \int_0^{\pi}\sin\vartheta\,\mathrm{d}\vartheta\int_0^{2\pi}\mathrm{d}\phi\int_0^{4\pi}\mathrm{d}\psi = 2\cdot 2\pi\cdot 4\pi = 16\pi^2.\end{aligned}$$
(1) $\theta^1\wedge\theta^2 = \sin\vartheta\,\mathrm{d}\vartheta\wedge\mathrm{d}\phi$.
(2) $\mathrm{d}\phi\wedge\mathrm{d}\phi = 0$.
(3) The ranges (T3.39), with the orientation $\mathrm{d}\vartheta\wedge\mathrm{d}\phi\wedge\mathrm{d}\psi$.

This is $2^3\times 2\pi^2$, the volume of a 3-sphere of radius 2 (the unit S^3 has volume $2\pi^2$), as the metric predicted.

Physical picture: Haar measure

The normalised volume $\mathrm{d}\mu = \theta^1 \wedge \theta^2 \wedge \theta^3/16\pi^2$ is the **Haar measure**: the unique way of "averaging over the group" that is unchanged by left and right multiplication, $\int f(hg)\,\mathrm{d}\mu(g) = \int f(g)\,\mathrm{d}\mu(g)$. It is the measure used for the link variables of lattice gauge theory, and for the "average over the group" that makes every representation of a compact group unitary (Section T3.5). For a function of the conjugacy class only (a function of the rotation angle θ, like a character), the Haar measure reduces to $\frac{1}{\pi}\sin^2\frac{\theta}{2}\,\mathrm{d}\theta$ on $[0, 2\pi]$: the classes near $\pm\mathbb{1}$ are small 2-spheres (Figure T3.3) and carry little weight.

T3.6.5 The cube of θ counts windings

Here is the promised topological use. Consider first a map from a circle into U(1), $g(\varphi) = e^{i\alpha(\varphi)}$ with $\alpha(2\pi) = \alpha(0) + 2\pi n$. By Example T3.23,

$$\frac{1}{2\pi i}\oint_{S^1} g^{-1}\mathrm{d}g = \frac{1}{2\pi}\oint \mathrm{d}\alpha = \frac{\alpha(2\pi) - \alpha(0)}{2\pi} = n. \tag{T3.41}$$

The integral of the Maurer–Cartan form counts how many times the loop winds around the group: it is the element of $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$ of Table T3.2.

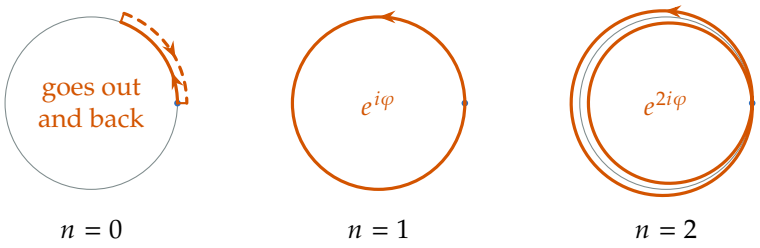

Figure T3.17: Loops $\varphi \mapsto g(\varphi)$ in U(1) (drawn slightly off the circle when they overlap). The left loop can be pulled back to a point; the others wind once and twice and cannot. The number n is computed by the integral $\frac{1}{2\pi i}\oint g^{-1}\mathrm{d}g$, which is unchanged by any continuous deformation of the loop.

For maps from a 3-sphere into SU(2) (or any compact simple group) the analogue is built from the cube of θ. We need the trace of three generators. For $\mathfrak{su}(2)$, only the part antisymmetric in a, b, c survives when contracted with $\theta^a \wedge \theta^b \wedge \theta^c$, and

$$\mathrm{tr}\big(T_a\,[T_b, T_c]\big) \overset{(1)}{=} \varepsilon_{bcd}\ \mathrm{tr}(T_a T_d) \overset{(2)}{=} -\tfrac{1}{2}\,\varepsilon_{bca} = -\tfrac{1}{2}\,\varepsilon_{abc}.$$

(1) $[T_b, T_c] = \varepsilon_{bcd} T_d$.
(2) $\mathrm{tr}(T_a T_d) = -\frac{1}{2}\delta_{ad}$; and $\varepsilon_{bca} = \varepsilon_{abc}$ (cyclic).

Therefore

$$\begin{aligned}\mathrm{tr}(\theta \wedge \theta \wedge \theta) &\overset{(1)}{=} \theta^a \wedge \theta^b \wedge \theta^c\ \mathrm{tr}(T_a T_b T_c)\\ &\overset{(2)}{=} \tfrac{1}{2}\,\theta^a \wedge \theta^b \wedge \theta^c\ \mathrm{tr}\big(T_a [T_b, T_c]\big)\\ &\overset{(3)}{=} -\tfrac{1}{4}\,\varepsilon_{abc}\,\theta^a \wedge \theta^b \wedge \theta^c \overset{(4)}{=} -\tfrac{3}{2}\,\theta^1 \wedge \theta^2 \wedge \theta^3.\end{aligned} \tag{T3.42}$$

(1) Expand each θ in the basis; the scalar 1-forms come out of the trace.
(2) Antisymmetry of $\theta^b \wedge \theta^c$ in b, c keeps only $\frac{1}{2}[T_b, T_c]$, as in (T3.38).
(3) The trace just computed.

(4) The sum over a, b, c has $3! = 6$ nonzero terms, each equal to $+\theta^1 \wedge \theta^2 \wedge \theta^3$ (both ε and the wedge change sign under a swap).

Integrating over the group with the volume computed above,

$$\int_{\mathrm{SU}(2)} \operatorname{tr}(\theta \wedge \theta \wedge \theta) = -\tfrac{3}{2} \cdot 16\pi^2 = -24\pi^2. \tag{T3.43}$$

Working definition T3.13 (winding number of a map $S^3 \to \mathrm{SU}(2)$)

For a map $g : S^3 \to \mathrm{SU}(2)$ (or into $\mathrm{SU}(N)$), the **winding number** (degree) [how many times g covers SU(2), each covering counted $+1$ or -1 according to orientation] is

$$w(g) = -\frac{1}{24\pi^2} \int_{S^3} \operatorname{tr}\big(g^{-1}\mathrm{d}g\big)^3, \tag{T3.44}$$

where $(g^{-1}\mathrm{d}g)^3$ means the triple wedge product. *How to compute it:* pull back, i.e. substitute $g(x)$, compute the 3×3 determinant-like combination $\varepsilon^{ijk} \operatorname{tr}(g^{-1}\partial_i g\, g^{-1}\partial_j g\, g^{-1}\partial_k g)$ in coordinates on S^3 and integrate. It is an integer, it is unchanged by continuous deformations of g, and it labels $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$ [maps that can be continuously deformed into each other count as one class, and the classes are labelled by one integer].

The normalisation is fixed by (T3.43): for the identity map $S^3 \to \mathrm{SU}(2)$, with S^3 oriented by $\theta^1 \wedge \theta^2 \wedge \theta^3$ (which, at the north pole $\mathbb{1}$, is the standard orientation of S^3 as the boundary of the unit ball in $\mathbb{R}^4$), $w = 1$. For a map that covers the group k times, the integral is k times as big.

Watch out: The sign in front

Many books write $w = +\frac{1}{24\pi^2}\int \operatorname{tr}(g^{-1}\mathrm{d}g)^3$. The difference is a choice of orientation of S^3 or of Hermitian versus anti-Hermitian generators. With anti-Hermitian θ and the orientation above, the minus sign is needed for the identity map to have $w = +1$. The advantage of our sign is that the instanton number $k = \frac{1}{8\pi^2}\int \operatorname{tr} F \wedge F$ then equals w of the gauge transformation at infinity, with no extra sign (Section T3.10).

Why is w unchanged by deformations? Deform g to $g\, e^{\varepsilon X}$ with $X(x) \in \mathfrak{g}$ small. To first order the Maurer–Cartan form changes by

$$\delta\theta \overset{(1)}{=} \big(g(1+\varepsilon X)\big)^{-1}\mathrm{d}\big(g(1+\varepsilon X)\big) - g^{-1}\mathrm{d}g \overset{(2)}{=} \varepsilon\,\big(\mathrm{d}X + \theta X - X\theta\big) + O(\varepsilon^2),$$

(1) Definition; $e^{\varepsilon X} = 1 + \varepsilon X + O(\varepsilon^2)$.
(2) $(g(1+\varepsilon X))^{-1} = (1-\varepsilon X)g^{-1}$; expand $(1-\varepsilon X)g^{-1}(\mathrm{d}g + \varepsilon\,\mathrm{d}g\,X + \varepsilon\, g\,\mathrm{d}X)$ to first order.

and the change of the integrand is exact:

$$\begin{aligned}\delta \operatorname{tr}\theta^3 &\overset{(1)}{=} 3\operatorname{tr}\big(\theta^2\,\delta\theta\big) \overset{(2)}{=} 3\varepsilon\,\operatorname{tr}\big(\theta^2\mathrm{d}X\big) + 3\varepsilon\,\operatorname{tr}\big(\theta^3 X - \theta^2 X\theta\big)\\ &\overset{(3)}{=} 3\varepsilon\,\operatorname{tr}\big(\theta^2\mathrm{d}X\big) \overset{(4)}{=} 3\varepsilon\,\mathrm{d}\operatorname{tr}\big(\theta^2 X\big).\end{aligned}$$

(1) Vary each of the three factors; graded cyclicity of the trace brings each varied factor to the end with sign $+1$ (a 1-form moved past a 2-form).
(2) Substitute $\delta\theta$.
(3) $\operatorname{tr}(\theta^2 X\theta) = \operatorname{tr}(\theta\,\theta^2 X) = \operatorname{tr}(\theta^3 X)$ by graded cyclicity (moving the 1-form θ past the 2-form $\theta^2 X$ costs $(-1)^2 = +1$).

(4) $\mathrm{d}\,\mathrm{tr}(\theta^2 X) = \mathrm{tr}(\mathrm{d}(\theta^2)X) + \mathrm{tr}(\theta^2 \mathrm{d}X)$, and $\mathrm{d}(\theta^2) = \mathrm{d}\theta\,\theta - \theta\,\mathrm{d}\theta = -\theta^3 + \theta^3 = 0$ by the structure equation.

By Stokes' theorem an exact 3-form integrates to zero on the closed manifold S^3, so $\delta w = 0$. This is the exemplar argument of the style guide in a new setting: *topological invariance is Stokes' theorem applied to an exact variation.*

Worked example T3.26: Windings add: $w(gh) = w(g) + w(h)$

Let $g, h : S^3 \to \mathrm{SU}(2)$ and multiply them pointwise. Write $a = g^{-1}\mathrm{d}g$ and $b = \mathrm{d}h\,h^{-1}$ (the right-invariant form of h). Then

$$(gh)^{-1}\mathrm{d}(gh) \overset{(1)}{=} h^{-1}g^{-1}(\mathrm{d}g\,h + g\,\mathrm{d}h) = h^{-1}a\,h + h^{-1}\mathrm{d}h \overset{(2)}{=} h^{-1}(a+b)\,h,$$
$$\mathrm{tr}\big((gh)^{-1}\mathrm{d}(gh)\big)^3 \overset{(3)}{=} \mathrm{tr}(a+b)^3 \overset{(4)}{=} \mathrm{tr}\,a^3 + \mathrm{tr}\,b^3 + 3\,\mathrm{tr}(a^2b) + 3\,\mathrm{tr}(ab^2).$$

(1) Product rule.
(2) $h^{-1}\mathrm{d}h = h^{-1}(\mathrm{d}h\,h^{-1})h = h^{-1}bh$.
(3) Conjugation by h cancels inside the trace.
(4) Expand the cube keeping the order of factors; graded cyclicity for three 1-forms has no sign, so e.g. $\mathrm{tr}(aba) = \mathrm{tr}(a^2b)$.

The cross terms are exact. Using $\mathrm{d}a = -a^2$ and $\mathrm{d}b = +b^2$ (the two structure equations), $\mathrm{d}\,\mathrm{tr}(ab) = \mathrm{tr}(\mathrm{d}a\,b) - \mathrm{tr}(a\,\mathrm{d}b) = -\mathrm{tr}(a^2b) - \mathrm{tr}(ab^2)$. So $3\,\mathrm{tr}(a^2b) + 3\,\mathrm{tr}(ab^2) = -3\,\mathrm{d}\,\mathrm{tr}(ab)$, which integrates to zero. And $\mathrm{tr}\,b^3 = \mathrm{tr}(h\,h^{-1}\mathrm{d}h\,h^{-1}\mathrm{d}h\,h^{-1}\mathrm{d}h\,h^{-1}) = \mathrm{tr}(h^{-1}\mathrm{d}h)^3$. Integrating,

$$w(gh) = w(g) + w(h), \qquad \text{and in particular} \qquad w(g^{-1}) = -w(g), \quad w(g^k) = k\,w(g).$$

The winding number turns pointwise multiplication of maps into addition of integers: it is the group isomorphism $\pi_3(\mathrm{SU}(2)) \cong \mathbb{Z}$.

Worked example T3.27: The basic winding-one map on $\mathbb{R}^3$ and on S^3_∞

Two versions of the identity map $S^3 \to \mathrm{SU}(2)$ appear constantly. *On the 3-sphere at infinity of* $\mathbb{R}^4$: for $x = (x^1, x^2, x^3, x^4)$ with $|x| = r$,

$$g(x) = \frac{x^4 \mathbb{1} + i\,\vec{x}\cdot\vec{\sigma}}{r}.$$

On the sphere $|x| = r$ this is (T3.2) with a rescaled radius, so it covers SU(2) exactly once: $w = 1$. This is the gauge transformation at infinity of the BPST instanton (Chapter 8). *On* $\mathbb{R}^3$ *compactified to* S^3: stereographic projection sends $\vec{y} \in \mathbb{R}^3$ to the point $\big(\frac{2\vec{y}}{1+|\vec{y}|^2}, \frac{|\vec{y}|^2-1}{|\vec{y}|^2+1}\big)$ of the unit S^3, and

$$g(\vec{y}) = \frac{(|\vec{y}|^2 - 1)\mathbb{1} + 2i\,\vec{y}\cdot\vec{\sigma}}{|\vec{y}|^2 + 1}$$

tends to $\mathbb{1}$ as $|\vec{y}| \to \infty$ and equals $-\mathbb{1}$ at the origin. As $\vec{y}$ ranges over $\mathbb{R}^3$ it covers S^3 once, so $w = \pm 1$ (the sign depends on the orientation of $\mathbb{R}^3$). Such "large" gauge transformations, which cannot be deformed to the identity, are what split the gauge group in three dimensions into components labelled by $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$ [Nash p. 227, (8.59)].

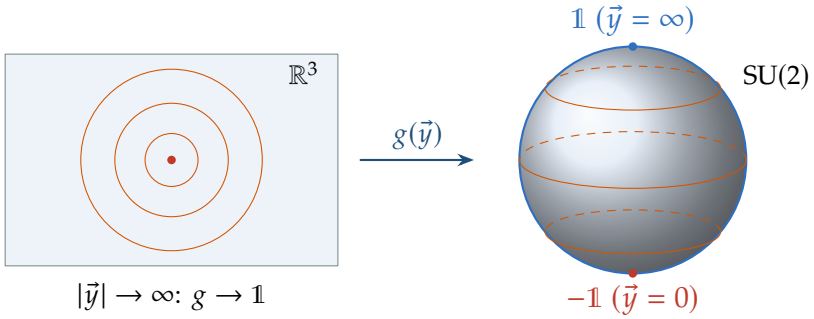

Figure T3.18: The winding-one map of Example T3.27. Spheres $|\vec{y}| = \text{const}$ in $\mathbb{R}^3$ (orange rings) go to the 2-spheres of latitude of SU(2) = S^3 (conjugacy classes, Figure T3.3); the origin goes to the south pole $-\mathbb{1}$ and infinity to the north pole $\mathbb{1}$. Every point of the group is hit exactly once, so $\frac{1}{24\pi^2}\left|\int \mathrm{tr}(g^{-1}\mathrm{d}g)^3\right| = 1$.

Try it: Winding number of a map that misses a point

Suppose $g : S^3 \to \mathrm{SU}(2)$ never takes the value $-\mathbb{1}$. Show that $w(g) = 0$.
Answer: SU(2) minus a point is a 3-sphere minus a point, which can be contracted to $\mathbb{1}$ (slide everything away from $-\mathbb{1}$ along the great circles through it). So g can be deformed to the constant map, whose Maurer–Cartan form vanishes, and w is deformation invariant. A nonzero winding number means the map is *onto*.

Reading Nash (Maurer–Cartan forms in Nash)

Nash never names $g^{-1}\mathrm{d}g$, but it runs through chapter 8. His gauge transformation law $g^{-1}(A+\mathrm{d})g = A$ for a fixed point [Nash p. 232, (8.88)] reads, once expanded, $g^{-1}Ag + g^{-1}\mathrm{d}g = A$: the Maurer–Cartan form is the inhomogeneous term. The "transgression" formulas [Nash p. 224, (8.41)–(8.42)] applied to the pure-gauge connection $A = g^{-1}\mathrm{d}g$ produce, up to normalisation, $\mathrm{tr}(g^{-1}\mathrm{d}g)^3$; his forms μ_{2j-1} on the gauge group [Nash pp. 225–226, (8.48)–(8.58)] are generalisations of our winding number density to families of maps. The statement $\pi_0(\mathcal{G}) = \pi_3(G) = \mathbb{Z}$ [Nash p. 227, (8.59)] is the fact that w of (T3.44) labels the components of the group of gauge transformations of S^3.

Recap

- $\theta = g^{-1}\mathrm{d}g$ carries the derivative of a group-valued field back to the identity; it is a $\mathfrak{g}$-valued 1-form, $\theta = \theta^a T_a$.
- Left-invariant: $(hg)^{-1}\mathrm{d}(hg) = \theta$; under $g \mapsto gh$ it rotates by $\mathrm{Ad}_{h^{-1}}$. U(1): $\theta = i\,\mathrm{d}\alpha$.
- Structure equation $\mathrm{d}\theta + \theta \wedge \theta = 0$, i.e. $\mathrm{d}\theta^a + \frac{1}{2} f_{bc}{}^a \theta^b \wedge \theta^c = 0$ (from $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\, g^{-1}$).
- SU(2) in Euler angles: (T3.40); the metric $\sum(\theta^a)^2$ is the round S^3 of radius 2, volume $16\pi^2$.
- $\mathrm{tr}\,\theta^3 = -\frac{3}{2}\theta^1\theta^2\theta^3$, $\int_{\mathrm{SU}(2)} \mathrm{tr}\,\theta^3 = -24\pi^2$; winding number $w = -\frac{1}{24\pi^2}\int \mathrm{tr}(g^{-1}\mathrm{d}g)^3 \in \mathbb{Z}$, invariant under deformation (the variation is exact) and additive.

T3.7 Group actions, orbits and homogeneous spaces

A group is interesting because of what it *does*. Rotations move points of space; SU(2) moves spin states; gauge transformations move gauge fields. Very often the thing being moved is itself a curved space: the direction of a spin is a point on a 2-sphere, the vacuum of a Higgs field is a point on a sphere, a quantum state up to phase is a point of a complex projective space. The question of this section is: *how do we describe a space on which a group acts, and how do we build such spaces out of groups?* The answer is the orbit–stabiliser principle, which says that a space on which G acts transitively is a quotient G/H. This one idea produces spheres, projective spaces and flag manifolds from matrices, gives the Hopf fibration $S^3 \to S^2$ that underlies the Dirac monopole, and prepares the language of principal bundles and of the gauge group acting on the space of connections.

T3.7.1 Actions

Working definition T3.14 (group action)

An **action** of a group G on a space X is a rule that assigns to each $g \in G$ a map $x \mapsto g \cdot x$ of X to itself, such that

$$\mathbb{1} \cdot x = x, \qquad g \cdot (h \cdot x) = (gh) \cdot x.$$

Operational test: check that the identity does nothing and that doing h then g is the same as doing gh. A representation (Section T3.5) is the special case in which X is a vector space and each $x \mapsto g \cdot x$ is linear [$g \cdot (av + bw) = a\, g \cdot v + b\, g \cdot w$, so each g acts by a matrix].

Examples we already know, and some new ones:

- SO(3) acts on $\mathbb{R}^3$ by $R \cdot \vec{x} = R\vec{x}$; SU(2) acts on $\mathbb{C}^2$ by $U \cdot \psi = U\psi$.
- G acts on itself by *left multiplication* $g \cdot h = gh$ and by *conjugation* $g \cdot h = ghg^{-1}$, and on its Lie algebra by Ad (Section T3.4).
- SU(2) acts on the unit 2-sphere through SO(3): $U \cdot \hat{n}$ is defined by $(U \cdot \hat{n}) \cdot \vec{\sigma} = U(\hat{n} \cdot \vec{\sigma})U^\dagger$.
- U(1) acts on $\mathbb{C}^{n+1}$ by an overall phase, $e^{i\alpha} \cdot z = e^{i\alpha} z$.
- The group $\mathcal{G}$ of gauge transformations $g(x)$ acts on gauge fields by $g \cdot A = g^{-1}Ag + g^{-1}\mathrm{d}g$ (Section T3.8). (Strictly this is a right action: $(gh) \cdot A = h \cdot (g \cdot A)$. Nothing below depends on the difference.)

T3.7.2 Orbits and stabilisers

Working definition T3.15 (orbit and stabiliser)

The **orbit** of a point x_0 is the set of all points it can be moved to, $G \cdot x_0 = \{g \cdot x_0 : g \in G\}$. The **stabiliser** (or isotropy group, or little group [the physicist's name when x_0 is a momentum p and G is the Lorentz group]) of x_0 is the set of group elements that do not move it, $H = G_{x_0} = \{g : g \cdot x_0 = x_0\}$. It is a subgroup: if g and h fix x_0, so do gh and g^{-1}. The action is **transitive** if there is only one orbit (every point can be reached from every other), and **free** if every stabiliser is trivial ($g \cdot x = x$ only for $g = \mathbb{1}$).

Worked example T3.28: Rotations of $\mathbb{R}^3$: spheres and axes

Take SO(3) acting on $\mathbb{R}^3$ and a point $\vec{x}_0 \neq 0$. A rotation preserves length, so the orbit lies in the sphere $|\vec{x}| = |\vec{x}_0|$; and any point of that sphere can be reached by rotating about the axis $\vec{x}_0 \times \vec{x}$. So the orbit is the whole 2-sphere of radius $|\vec{x}_0|$. The stabiliser of $\vec{x}_0 = r\hat{z}$ consists of the rotations that fix $\hat{z}$, which are the rotations $R_z(\alpha)$ about the z-axis: $H \cong \mathrm{SO}(2)$. Dimensions:

$$\dim(\text{orbit}) = 2 = 3 - 1 = \dim \mathrm{SO}(3) - \dim \mathrm{SO}(2).$$

The origin is a special orbit on its own, a single point, with stabiliser the whole group. So $\mathbb{R}^3$ is sliced into orbits: concentric spheres plus one point (Figure T3.19). The orbits are labelled by one number, the radius, which is the *invariant* of the action.

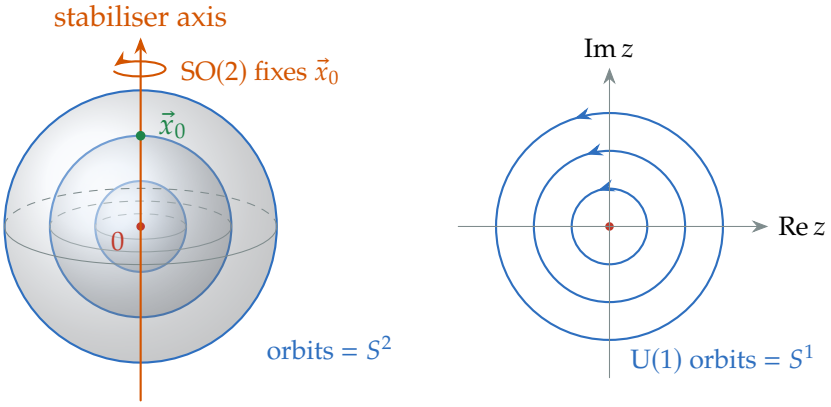

Figure T3.19: Left: SO(3) acting on $\mathbb{R}^3$. The orbits are concentric spheres (blue) and the single point 0 (red). A point $\vec{x}_0$ on the z-axis is fixed by the SO(2) of rotations about that axis. Right: U(1) acting on $\mathbb{C}$ by phases: orbits are circles, and the action is free except at the origin. In both pictures the orbit through x_0 is a copy of G/H.

T3.7.3 Cosets and the orbit–stabiliser principle

Two group elements g and gh with $h \in H$ move x_0 to the same place, because $gh \cdot x_0 = g \cdot (h \cdot x_0) = g \cdot x_0$. So points of the orbit correspond not to single group elements but to whole families $gH = \{gh : h \in H\}$, called **left cosets** of H. The set of left cosets is written G/H.

Key idea: Orbit–stabiliser

The map $G/H \to G \cdot x_0$, $gH \mapsto g \cdot x_0$, is well defined and a one-to-one correspondence. So every orbit is a quotient G/H of the group by the stabiliser, and

$$\dim(G \cdot x_0) = \dim G - \dim H.$$

A space on which G acts transitively is called a **homogeneous space**; it is G/H for the stabiliser H of any of its points.

Why one-to-one: *well defined*, because different representatives g, gh of the same coset give the same point (just shown); *onto*, by the definition of the orbit; *injective*, because

$$g_1 \cdot x_0 = g_2 \cdot x_0 \overset{(1)}{\Longleftrightarrow} g_2^{-1} g_1 \cdot x_0 = x_0 \overset{(2)}{\Longleftrightarrow} g_2^{-1} g_1 \in H \overset{(3)}{\Longleftrightarrow} g_1 H = g_2 H.$$

(1) Act on both sides with g_2^{-1} and use the action rule $g_2^{-1} \cdot (g_1 \cdot x_0) = (g_2^{-1} g_1) \cdot x_0$.

(2) Definition of the stabiliser.
(3) $g_1 = g_2 h$ with $h \in H$ means exactly that g_1 lies in the coset of g_2.

The dimension formula follows by differentiating: near x_0 the orbit is swept out by $e^{tX} \cdot x_0$, $X \in \mathfrak{g}$, and the directions $X \in \mathfrak{h}$ do not move x_0, so the tangent space of the orbit is $\mathfrak{g}/\mathfrak{h}$.

Watch out: G/H is usually not a group

G/H is a space, not a group, unless H is a *normal* subgroup ($gHg^{-1} = H$ for all g). $\mathrm{SO}(3) = \mathrm{SU}(2)/\{\pm\mathbb{1}\}$ is a group because $\{\pm\mathbb{1}\}$ is central. $S^2 = \mathrm{SU}(2)/\mathrm{U}(1)$ is not: the $\mathrm{U}(1)$ of diagonal matrices is not normal, and the 2-sphere has no continuous group structure.

T3.7.4 Spheres as homogeneous spaces

Worked example T3.29: $S^{n-1} = \mathrm{SO}(n)/\mathrm{SO}(n-1)$

$\mathrm{SO}(n)$ acts on the unit sphere $S^{n-1} \subset \mathbb{R}^n$ transitively (the first column of a rotation can be any unit vector: complete it to an oriented orthonormal basis). The stabiliser of the north pole e_n is the set of R with $Re_n = e_n$. Such an R has last column e_n, and because its rows are orthonormal its last row is e_n^T as well:

$$R = \begin{pmatrix} R' & 0 \\ 0 & 1 \end{pmatrix}, \qquad R' \in \mathrm{SO}(n-1).$$

So $S^{n-1} = \mathrm{SO}(n)/\mathrm{SO}(n-1)$. Dimension check: $\frac{1}{2}n(n-1) - \frac{1}{2}(n-1)(n-2) = n-1$. ✓ In the same way $\mathrm{U}(n)$ and $\mathrm{SU}(n)$ act transitively on the unit sphere $S^{2n-1} \subset \mathbb{C}^n$ with stabiliser $\mathrm{U}(n-1)$ and $\mathrm{SU}(n-1)$: $S^{2n-1} = \mathrm{SU}(n)/\mathrm{SU}(n-1)$. For $n = 2$ the stabiliser $\mathrm{SU}(1)$ is trivial and we recover $S^3 = \mathrm{SU}(2)$.

T3.7.5 The 2-sphere as $\mathrm{SU}(2)/\mathrm{U}(1)$, and the Hopf map

This is the example to know by heart. Let $\mathrm{SU}(2)$ act on traceless Hermitian matrices of unit "length" $\hat{n} \cdot \vec{\sigma}$ by conjugation. Every such matrix has eigenvalues ± 1 and so is conjugate to σ_3: the action is transitive on the 2-sphere of unit vectors $\hat{n}$. Define

$$\pi : \mathrm{SU}(2) \to S^2, \qquad \pi(U) \cdot \vec{\sigma} = U \sigma_3 U^\dagger. \tag{T3.45}$$

The stabiliser of σ_3 is the set of U commuting with σ_3, which is the diagonal subgroup $\{e^{i\chi\sigma_3} = \mathrm{diag}(e^{i\chi}, e^{-i\chi})\} \cong \mathrm{U}(1)$. By orbit–stabiliser, $S^2 = \mathrm{SU}(2)/\mathrm{U}(1)$, and the dimensions agree: $3 - 1 = 2$.

Let us write π out. With $U = \left(\begin{smallmatrix} a & -\bar{b} \\ b & \bar{a} \end{smallmatrix}\right)$, $|a|^2 + |b|^2 = 1$, as in (T3.1), call the columns $u_1 = (a, b)^T$ and $u_2 = (-\bar{b}, \bar{a})^T$. Then

$$\begin{aligned} U\sigma_3 U^\dagger &\overset{(1)}{=} u_1 u_1^\dagger - u_2 u_2^\dagger \\ &\overset{(2)}{=} \begin{pmatrix} |a|^2 & a\bar{b} \\ \bar{a}b & |b|^2 \end{pmatrix} - \begin{pmatrix} |b|^2 & -a\bar{b} \\ -\bar{a}b & |a|^2 \end{pmatrix} = \begin{pmatrix} |a|^2 - |b|^2 & 2a\bar{b} \\ 2\bar{a}b & |b|^2 - |a|^2 \end{pmatrix}. \end{aligned}$$

(1) $U\sigma_3 U^\dagger = U\,\mathrm{diag}(1,-1)\,U^\dagger = \sum_k (\sigma_3)_{kk} u_k u_k^\dagger$, the spectral decomposition with eigenvectors the columns of U.
(2) Outer products: $(u_1 u_1^\dagger)_{ij} = (u_1)_i \overline{(u_1)_j}$, and likewise for u_2.

Comparing with $\hat{n}\cdot\vec{\sigma} = \begin{pmatrix} n_3 & n_1 - in_2 \\ n_1 + in_2 & -n_3 \end{pmatrix}$:

$$n_1 + in_2 = 2\bar{a}\,b, \qquad n_3 = |a|^2 - |b|^2. \tag{T3.46}$$

Check that it lands on the sphere:

$$n_1^2 + n_2^2 + n_3^2 \overset{(1)}{=} 4|a|^2|b|^2 + \left(|a|^2 - |b|^2\right)^2 \overset{(2)}{=} \left(|a|^2 + |b|^2\right)^2 \overset{(3)}{=} 1.$$

(1) $|n_1 + in_2|^2 = |2\bar{a}b|^2$.
(2) $(p-q)^2 + 4pq = (p+q)^2$ with $p = |a|^2$, $q = |b|^2$.
(3) $\det U = 1$.

The map (T3.46) depends only on the first column $(a, b) \in S^3 \subset \mathbb{C}^2$. It is the **Hopf map** $S^3 \to S^2$. Its fibres are the cosets $U\,\mathrm{U}(1)$: multiplying on the right by $\mathrm{diag}(e^{i\chi}, e^{-i\chi})$ sends $(a, b) \mapsto e^{i\chi}(a, b)$, which leaves $\bar{a}b$ and $|a|^2 - |b|^2$ unchanged. So above each point of S^2 sits a circle in S^3.

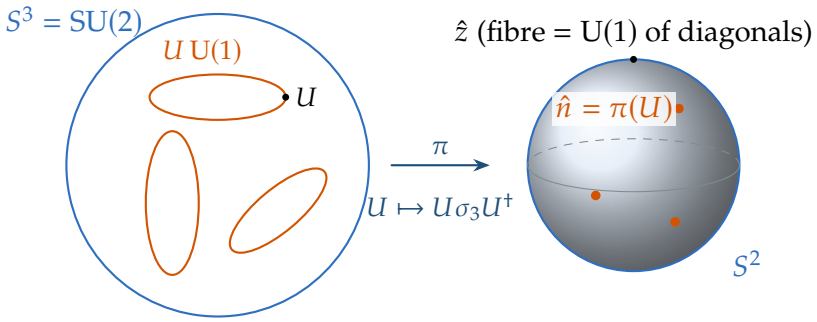

Figure T3.20: The Hopf fibration $S^3 \to S^2$ as the quotient $\mathrm{SU}(2) \to \mathrm{SU}(2)/\mathrm{U}(1)$. Each orange circle in S^3 is a coset $U\,\mathrm{U}(1) = \{Ue^{i\chi\sigma_3}\}$ and is collapsed to a single point of S^2. Any two fibres are linked circles in S^3 (the drawing only suggests this). The fibre over the north pole is the subgroup of diagonal matrices itself.

Worked example T3.30: The Bloch sphere

A spin-$\frac{1}{2}$ state is a unit vector $\psi = (a, b)^T \in \mathbb{C}^2$, a point of S^3. Physically, ψ and $e^{i\chi}\psi$ are the same state. The expectation value of spin is

$$\langle\sigma_1\rangle + i\langle\sigma_2\rangle \overset{(1)}{=} \psi^\dagger(\sigma_1 + i\sigma_2)\psi \overset{(2)}{=} 2\bar{a}\,b,$$
$$\langle\sigma_3\rangle \overset{(3)}{=} |a|^2 - |b|^2,$$

(1) Linearity of the expectation value.
(2) $\sigma_1 + i\sigma_2 = \left(\begin{smallmatrix} 0 & 0 \\ 2 & 0 \end{smallmatrix}\right)$, so $\psi^\dagger(\sigma_1 + i\sigma_2)\psi = \bar{a}\cdot 2b$.
(3) $\sigma_3 = \mathrm{diag}(1, -1)$.

This is (T3.46): the Hopf map *is* the map from a normalised spinor to its spin direction, and the fibre is the unobservable overall phase. The Bloch sphere of physical states is $S^3/\mathrm{U}(1) = S^2 = \mathbb{CP}^1$. The state with $\hat{n} = \hat{z}$ is spin-up $(1, 0)$; spin-down $(0, 1)$ goes to $\hat{n} = -\hat{z}$; and $(1, 1)/\sqrt{2}$ goes to $\hat{x}$.

Physical picture: Why the Hopf fibration is the monopole

A section of the Hopf map would be a smooth choice of phase for the spinor $\psi(\hat{n})$ over the whole sphere. There is none: the phase must wind once around the equator when we compare the choices made near the north and south poles. This winding is the Dirac monopole of charge one, and the natural connection on the Hopf fibration (Example T3.37) is the monopole vector potential. Berry's phase for a spin-$\frac{1}{2}$ in a slowly rotating magnetic field is the holonomy of the same connection (Section T3.9).

T3.7.6 Complex projective space $\mathbb{CP}^n = \mathrm{SU}(n+1)/\mathrm{U}(n)$

$\mathbb{CP}^n$ is the set of complex lines through the origin of $\mathbb{C}^{n+1}$, or equivalently of nonzero vectors z modulo $z \sim \lambda z$, $\lambda \in \mathbb{C}^\times$. Normalising $|z| = 1$ leaves the phase freedom $z \sim e^{i\alpha} z$, so

$$\mathbb{CP}^n = S^{2n+1}/\mathrm{U}(1), \qquad \dim_{\mathbb{R}} \mathbb{CP}^n = 2n.$$

In quantum mechanics, $\mathbb{CP}^n$ is the space of pure states of an $(n+1)$-level system. $\mathrm{SU}(n+1)$ acts on it by $[z] \mapsto [Uz]$, and the action is transitive because it is already transitive on S^{2n+1}.

Worked example T3.31: The stabiliser of a line

Take the line through $e_0 = (1, 0, \ldots, 0)$. A matrix $U \in \mathrm{U}(n+1)$ fixes this line if $Ue_0 = e^{i\alpha} e_0$. Then its first column is $e^{i\alpha} e_0$, and unitarity (orthonormal rows) forces its first row to be $(e^{i\alpha}, 0, \ldots, 0)$:

$$U = \begin{pmatrix} e^{i\alpha} & 0 \\ 0 & V \end{pmatrix}, \qquad V \in \mathrm{U}(n).$$

The stabiliser in $\mathrm{U}(n+1)$ is $\mathrm{U}(1) \times \mathrm{U}(n)$. Inside $\mathrm{SU}(n+1)$ we need in addition $\det U = e^{i\alpha} \det V = 1$, which fixes $e^{i\alpha} = (\det V)^{-1}$. So the stabiliser in $\mathrm{SU}(n+1)$ is $\{\mathrm{diag}((\det V)^{-1}, V) : V \in \mathrm{U}(n)\} \cong \mathrm{U}(n)$, and

$$\mathbb{CP}^n = \mathrm{SU}(n+1)/\mathrm{U}(n) = \mathrm{U}(n+1)/\big(\mathrm{U}(1) \times \mathrm{U}(n)\big),$$

$$\dim \mathbb{CP}^n \overset{(1)}{=} \big((n+1)^2 - 1\big) - n^2 = 2n.$$

(1) $\dim \mathrm{SU}(n+1) - \dim \mathrm{U}(n)$, from Table T3.1.

For $n = 1$: $\mathbb{CP}^1 = \mathrm{SU}(2)/\mathrm{U}(1) = S^2$, the Hopf case again. For $n = 2$: $\mathbb{CP}^2 = \mathrm{SU}(3)/\mathrm{U}(2)$ is four-dimensional; it is a favourite compact 4-manifold for instantons (Chapter 8) and algebraic geometry (Chapter 5).

T3.7.7 Flag manifolds G/T

Take the stabiliser to be as small as a commutative subgroup can reasonably be: a maximal torus T, the group $e^{\mathfrak{t}}$ generated by a Cartan subalgebra (Section T3.5.3). For $\mathrm{SU}(N)$, T is the diagonal matrices $\mathrm{diag}(e^{i\phi_1}, \ldots, e^{i\phi_N})$ with $\sum \phi_k = 0$, of dimension $N - 1$. The homogeneous space G/T is the orbit of a *generic* diagonal Hermitian matrix $D = \mathrm{diag}(d_1, \ldots, d_N)$ (all d_k different) under conjugation:

$$\mathrm{SU}(N)/T \cong \{UDU^\dagger\}, \qquad \dim = (N^2 - 1) - (N - 1) = N(N-1).$$

Such a matrix is the same thing as an ordered set of N orthogonal eigenlines in $\mathbb{C}^N$, a "flag". For SU(2), $G/T = S^2$ (again); for SU(3), G/T is six-dimensional. The dimension $N(N-1)$ is the number of roots (Section T3.5): the tangent space of G/T at the identity coset is $\mathfrak{g}/\mathfrak{t}$, which is spanned by the root vectors. This is the space on which Nash's Borel–Weil construction lives.

T3.7.8 Free actions and a first look at bundles

When an action is *free*, every orbit is a copy of G itself ($H = \{\mathbb{1}\}$). The space X is then sliced into copies of G, one for each point of the quotient X/G:

$$G \longrightarrow X \longrightarrow X/G.$$

This is the shape of a **principal G-bundle**: a total space X, a base X/G, and fibres that are copies of the group. Examples:

- U(1) acts freely on $S^3 \subset \mathbb{C}^2$ by phases, with quotient S^2: the Hopf bundle $\mathrm{U}(1) \to S^3 \to S^2$ of Section T3.7.5.
- U(1) acts freely on S^{2n+1} with quotient $\mathbb{CP}^n$.
- Any subgroup H acts freely on G by right multiplication, with quotient G/H: $H \to G \to G/H$. For example $\mathrm{SO}(n-1) \to \mathrm{SO}(n) \to S^{n-1}$ and $T \to G \to G/T$ ("G forms a principal T-bundle over the homogeneous space G/T", [Nash p. 189]).
- $\{\pm\mathbb{1}\}$ acts freely on SU(2) with quotient SO(3): a principal $\mathbb{Z}_2$-bundle, which is exactly the double cover.

When the action is not free, the quotient is singular at points with larger stabilisers: the orbit space of SO(3) on $\mathbb{R}^3$ is the half-line $r \geq 0$, with an "edge" at $r = 0$ where the stabiliser jumps from SO(2) to SO(3).

Worked example T3.32: Vacuum manifolds of Higgs fields

A Higgs potential $V(\phi) = \lambda(|\phi|^2 - v^2)^2$ is minimised on an orbit of the gauge group, the **vacuum manifold** $\mathcal{V} = G/H$, where H is the unbroken subgroup (the stabiliser of one vacuum).

- SU(2) *doublet* (the electroweak Higgs without hypercharge): $\phi \in \mathbb{C}^2$ with $|\phi| = v$. SU(2) acts freely and transitively on this S^3, so $H = \{\mathbb{1}\}$, $\mathcal{V} = S^3$: all three generators are broken, giving three massive vector bosons.
- SU(2) *adjoint* (the Georgi–Glashow model): $\phi = \phi^a \sigma_a$ with $|\vec{\phi}| = v$, acted on by conjugation. By Section T3.7.5, $\mathcal{V} = S^2 = \mathrm{SU}(2)/\mathrm{U}(1)$: one generator survives (the photon) and two are broken ($W^\pm$).

Counting: the number of broken generators is $\dim G - \dim H = \dim \mathcal{V}$, the number of Goldstone directions. Topology of $\mathcal{V}$ then classifies defects: a field configuration that tends to the vacuum at spatial infinity S^2_∞ defines a map $S^2_\infty \to \mathcal{V}$, and for $\mathcal{V} = S^2$ these are classified by $\pi_2(S^2) = \mathbb{Z}$: the charge of the 't Hooft–Polyakov monopole.

T3.7.9 The gauge group acting on connections

The most important action in Nash is infinite-dimensional: the gauge group $\mathcal{G}$ acting on the space $\mathcal{A}$ of all connections. Two gauge fields on the same orbit, $A' = g^{-1}Ag + g^{-1}\mathrm{d}g$, describe the same physics, so the physical configuration space is the orbit space $\mathcal{A}/\mathcal{G}$. Three facts from this section carry over directly.

- *Stabilisers.* The stabiliser of a connection A is the set of gauge transformations with $g^{-1}Ag + g^{-1}\mathrm{d}g = A$, i.e. with $\mathrm{d}g + [A, g] = 0$: covariantly constant g's. Constant elements

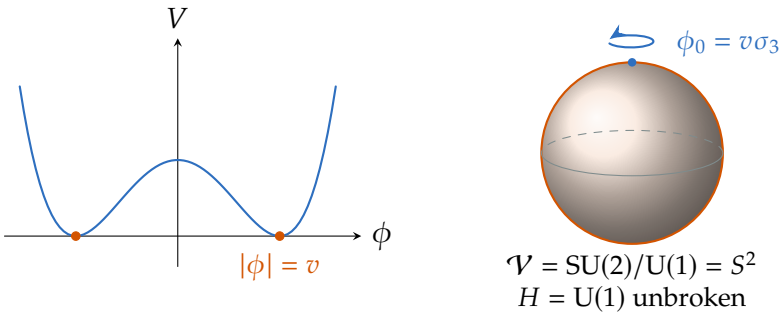

Figure T3.21: Left: a slice of the Higgs potential; its minima form one orbit of the gauge group. Right: for an adjoint SU(2) Higgs the orbit is a 2-sphere, $\mathcal{V} = G/H$. The vacuum $v\sigma_3$ is fixed by the diagonal U(1) (the electromagnetic gauge group), and moving along $\mathcal{V}$ costs no energy: these are the two Goldstone directions, eaten by $W^{\pm}$.

of the centre $Z(G)$ always qualify. A connection with a bigger stabiliser is called *reducible*; its holonomy (Section T3.9) is smaller than G. The orbit space $\mathcal{A}/\mathcal{G}$ is singular at reducible connections, exactly as the orbit space $r \geq 0$ of SO(3) on $\mathbb{R}^3$ is singular at $r = 0$.

- *Freeness.* If we use the *based* gauge group (gauge transformations equal to $\mathbb{1}$ at a chosen point x_0), the action is free, so $\mathcal{G} \to \mathcal{A} \to \mathcal{A}/\mathcal{G}$ is a principal bundle.

- *Dimension counting.* Orbit dimensions subtract stabiliser dimensions; this is how the dimension of the instanton moduli space is computed in Chapter 8.

Reading Nash (actions in Nash)

Nash proves that the gauge group $\mathcal{G}$ acts freely on $\mathcal{A}$ [Nash pp. 216–218, (8.7)–(8.11)] by showing that gauge transformations commute with parallel transport, $\alpha_b \circ PT_{\gamma_{ab}}(A) = PT_{\gamma_{ab}}(\alpha \cdot A) \circ \alpha_a$: a gauge transformation fixing A and equal to $\mathbb{1}$ at one point is then $\mathbb{1}$ everywhere. The quotient bundle $\mathcal{G} \to \mathcal{A} \to \mathcal{A}/\mathcal{G}$ [Nash (8.11)] is the "free action gives a principal bundle" of this section. The stabiliser of a connection under constant gauge transformations is the centraliser of its holonomy group [Nash p. 232, (8.88)–(8.90)], which is why he cuts down to irreducible connections and to $\mathrm{Ad}\, G = G/Z(G)$. The homogeneous space G/T and the bundle $T \to G \to G/T$ are the setting of the Borel–Weil theorem [Nash pp. 188–190].

Recap

- An action is a rule $g \cdot x$ with $\mathbb{1} \cdot x = x$ and $g \cdot (h \cdot x) = (gh) \cdot x$. Orbit $G \cdot x_0$; stabiliser $H = G_{x_0}$.
- Orbit–stabiliser: $G \cdot x_0 \cong G/H$, dim = dim G − dim H; homogeneous space = single orbit = G/H.
- $S^{n-1} = \mathrm{SO}(n)/\mathrm{SO}(n-1)$, $S^{2n-1} = \mathrm{SU}(n)/\mathrm{SU}(n-1)$, $S^2 = \mathrm{SU}(2)/\mathrm{U}(1) = \mathbb{CP}^1$, $\mathbb{CP}^n = \mathrm{SU}(n+1)/\mathrm{U}(n)$, flags G/T of dimension #roots.
- Hopf map $(a, b) \mapsto (2\bar{a}b, |a|^2 - |b|^2)$: spinor ↦ spin direction; fibre = phase. Free actions give principal bundles $G \to X \to X/G$.
- Vacuum manifolds G/H, broken generators = dim G/H; $\mathcal{A}/\mathcal{G}$ is singular at reducible connections.

T3.8 Gauge fields: from local symmetry to curvature

Everything so far has been about groups on their own. Now we let a group act on *fields*, and we let the group element depend on the point of spacetime. The question of this section is: *if a theory is invariant under $\psi(x) \mapsto g^{-1}(x)\psi(x)$ with $g(x)$ an arbitrary G-valued function, what must its derivatives look like?* The answer is forced on us. Ordinary derivatives fail, and the repair is a new field A, a Lie-algebra-valued 1-form: the gauge field. Its transformation law $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$, its curvature $F = \mathrm{d}A + A \wedge A$, the Bianchi identity and the Yang–Mills equations all follow from this one demand, and we derive each of them line by line. Geometrically, A is a *connection*, the same object as the connection 1-forms of Dray's Chapter 17 (reviewed in Chapter T2), now with an internal symmetry group in place of rotations of tangent vectors.

T3.8.1 Global versus local symmetry

Take a field $\psi(x)$ with n complex components, a column vector in $\mathbb{C}^n$ at every point x of spacetime M (coordinates x^μ, $\mu = 1, \dots, \dim M$). A group $G \subset \mathrm{U}(n)$ acts on $\mathbb{C}^n$ by matrix multiplication: SU(2) on an isospin doublet $(u, d)^T$, SU(3) on a colour triplet, U(1) on a single charged field by a phase. A typical kinetic term,

$$\mathcal{L} = \partial_\mu \psi^\dagger \, \partial_\mu \psi \qquad \text{or} \qquad \mathcal{L} = \bar{\psi} \gamma^\mu \partial_\mu \psi,$$

is invariant under $\psi \mapsto g^{-1}\psi$ for a *constant* unitary g, because $\partial_\mu(g^{-1}\psi) = g^{-1}\partial_\mu\psi$ and $(g^{-1})^\dagger g^{-1} = \mathbb{1}$. This is a **global symmetry**.

Why g^{-1}? We write the transformation as $\psi \mapsto g^{-1}\psi$ rather than $\psi \mapsto g\psi$ to match Nash and the mathematicians. The reason is the frame picture of Section T3.8.4: if we rotate the *basis* of $\mathbb{C}^n$ by g, the *components* of a fixed vector change by g^{-1}, just as rotating your axes by $+30^\circ$ rotates the coordinates of a fixed arrow by -30°. Physicists usually write $\psi \mapsto V\psi$; then simply $V = g^{-1}$ (see the dictionary in Section T3.8.9).

Now let g depend on x. The mass term $\psi^\dagger\psi$ is still invariant, but the derivative is not:

$$\begin{aligned} \mathrm{d}\big(g^{-1}\psi\big) &\overset{(1)}{=} \mathrm{d}(g^{-1})\,\psi + g^{-1}\mathrm{d}\psi \\ &\overset{(2)}{=} -g^{-1}\mathrm{d}g\, g^{-1}\psi + g^{-1}\mathrm{d}\psi \\ &\overset{(3)}{=} g^{-1}\mathrm{d}\psi - \theta\,\big(g^{-1}\psi\big), \qquad \theta := g^{-1}\mathrm{d}g. \end{aligned} \tag{T3.47}$$

(1) Product rule; d acts on each matrix entry, and the order of the matrix factors is kept.
(2) The derivative of an inverse, (T3.35).
(3) Name the Maurer–Cartan form $\theta = g^{-1}\mathrm{d}g$ of the map $x \mapsto g(x)$ (Section T3.6) and regroup.

If $\mathrm{d}\psi$ transformed like ψ we would have only the first term. The unwanted second term is the Maurer–Cartan form of the gauge transformation. It vanishes when g is constant and only then.

Physical picture: A derivative compares two different vector spaces

$\partial_\mu\psi = \lim_{\varepsilon\to 0} \frac{1}{\varepsilon}\big[\psi(x + \varepsilon\hat{\mu}) - \psi(x)\big]$ subtracts a vector in the copy of $\mathbb{C}^n$ at $x + \varepsilon\hat{\mu}$ from a vector in the copy at x. With a local symmetry, the basis of each copy can be rotated independently, so "the same components" at two different points means nothing. It is like subtracting the velocity of a ship measured in one harbour's coordinates from one

measured in another harbour's coordinates, without being told how the two sets of axes are related. We need an extra piece of data that tells us how to carry a vector from one copy to the next. That piece of data is the gauge field (Figure T3.22).

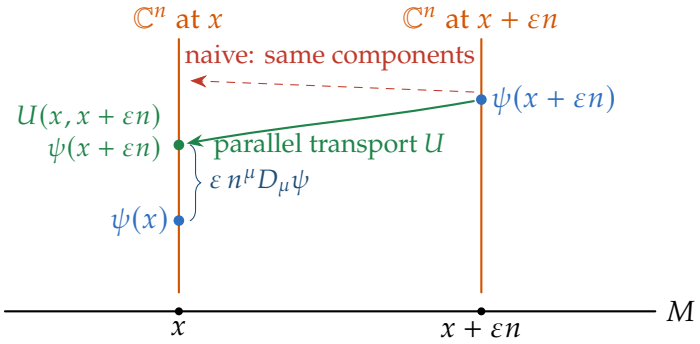

Figure T3.22: The covariant derivative. Above each point of spacetime M sits a copy of $\mathbb{C}^n$ (orange). Comparing $\psi(x + \varepsilon n)$ with $\psi(x)$ by "keeping the components fixed" (red dashed) depends on arbitrary choices of basis at the two points. Instead we carry $\psi(x+\varepsilon n)$ back to x with the comparator $U(x, x + \varepsilon n)$ (green) and subtract there. The difference, divided by ε, is $n^\mu D_\mu \psi$.

T3.8.2 The comparator and the covariant derivative

Following the QFT notes [QFT notes §19.2–19.3], introduce a matrix $U(y, x)$ that carries a vector in the copy of $\mathbb{C}^n$ at x to the copy at y. We want $U(y, x)\psi(x)$ to transform like a field at y. Since $\psi(x) \mapsto g(x)^{-1}\psi(x)$ and $\psi(y) \mapsto g(y)^{-1}\psi(y)$, this requires

$$U(y, x) \;\longmapsto\; g(y)^{-1}\, U(y, x)\, g(x). \tag{T3.48}$$

Check: $U(y, x)\psi(x) \mapsto g(y)^{-1}U(y, x)g(x)\, g(x)^{-1}\psi(x) = g(y)^{-1}\big(U(y, x)\psi(x)\big)$.

Working definition T3.16 (comparator and connection components)

A **comparator** (or parallel transporter) assigns to each pair of nearby points a matrix $U(y, x) \in G$ with $U(x, x) = \mathbb{1}$ and the transformation law (T3.48). Its first-order Taylor coefficients define the **connection components** $A_\mu(x)$:

$$U(x, x + \varepsilon n) = \mathbb{1} + \varepsilon\, n^\mu A_\mu(x) + O(\varepsilon^2). \tag{T3.49}$$

How to read it: A_μ is "the rotation of internal space [the copy of $\mathbb{C}^n$ at x in which $\psi(x)$ lives] you must apply per unit length in the μ direction to bring a vector back to x".

Now define the derivative by carrying the neighbouring value back before subtracting (Figure T3.22):

$$\begin{aligned} n^\mu D_\mu \psi(x) &\overset{(1)}{=} \lim_{\varepsilon \to 0} \frac{1}{\varepsilon}\Big[U(x, x + \varepsilon n)\, \psi(x + \varepsilon n) - \psi(x)\Big] \\ &\overset{(2)}{=} \lim_{\varepsilon \to 0} \frac{1}{\varepsilon}\Big[\big(\mathbb{1} + \varepsilon n^\mu A_\mu\big)\big(\psi + \varepsilon n^\mu \partial_\mu \psi\big) - \psi\Big] \\ &\overset{(3)}{=} n^\mu \big(\partial_\mu + A_\mu\big)\psi. \end{aligned} \tag{T3.50}$$

(1) Definition: transport the value at $x + \varepsilon n$ back to x, then subtract. Both terms now live in the copy of $\mathbb{C}^n$ at x.

(2) Expand U by (T3.49) and ψ by Taylor's theorem, everything evaluated at x.
(3) The zeroth-order terms $\psi - \psi$ cancel; the $O(\varepsilon)$ terms are $\varepsilon n^\mu(\partial_\mu\psi + A_\mu\psi)$; the $O(\varepsilon^2)$ terms vanish in the limit.

So the **covariant derivative** is $D_\mu = \partial_\mu + A_\mu$, or, as a 1-form,

$$D\psi = \mathrm{d}\psi + A\psi, \qquad A = A_\mu\,\mathrm{d}x^\mu. \tag{T3.51}$$

What kind of matrix is A_μ? U lies in G and $U(x,x) = \mathbb{1}$, so $\varepsilon \mapsto U(x, x+\varepsilon n)$ is a curve in G through the identity, and its velocity $n^\mu A_\mu$ lies in the Lie algebra $\mathfrak{g} = T_{\mathbb{1}}G$ (Section T3.2). For $G = \mathrm{U}(n)$: differentiating $U^\dagger U = \mathbb{1}$ gives $A_\mu^\dagger + A_\mu = 0$, anti-Hermitian. For $G = \mathrm{SU}(n)$: differentiating $\det U = 1$ gives $\operatorname{tr} A_\mu = 0$ as well. For $G = \mathrm{U}(1)$: $A_\mu = ia_\mu$ with a_μ real.

Working definition T3.17 (gauge field = connection)

A **gauge field** (or **connection**) with gauge group G on a region of M is a $\mathfrak{g}$-valued 1-form [at each x, one generator $A_\mu(x) \in \mathfrak{g}$ for each direction μ]

$$A = A_\mu(x)\,\mathrm{d}x^\mu = A_\mu^a(x)\,T_a\,\mathrm{d}x^\mu,$$

where T_a is a basis of $\mathfrak{g}$ (for SU(2), $T_a = -\frac{i}{2}\sigma_a$). *How to count it:* $\dim G \times \dim M$ real functions $A_\mu^a(x)$; for SU(3) in four dimensions, $8 \times 4 = 32$ fields (eight gluons, four components each). *How to use it:* $D\psi = \mathrm{d}\psi + A\psi$, where A acts on ψ in whatever representation ψ carries, i.e. T_a is replaced by its representation matrix.

T3.8.3 The transformation law $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$

Derivation 1: from the comparator. Put the expansion (T3.49) into the law (T3.48) with $y = x$ and the second point $x + \varepsilon n$:

$$\begin{aligned}
\mathbb{1} + \varepsilon n^\mu A'_\mu &\overset{(1)}{=} g(x)^{-1}\big(\mathbb{1} + \varepsilon n^\mu A_\mu\big)\, g(x+\varepsilon n) \\
&\overset{(2)}{=} g^{-1}\big(\mathbb{1} + \varepsilon n^\mu A_\mu\big)\big(g + \varepsilon n^\mu \partial_\mu g\big) + O(\varepsilon^2) \\
&\overset{(3)}{=} \mathbb{1} + \varepsilon n^\mu\big(g^{-1}A_\mu g + g^{-1}\partial_\mu g\big) + O(\varepsilon^2).
\end{aligned}$$

(1) The transformed comparator is $g(x)^{-1}U(x, x+\varepsilon n)g(x+\varepsilon n)$ by (T3.48), with the roles $y \to x$, $x \to x + \varepsilon n$.
(2) Taylor-expand $g(x+\varepsilon n)$; now everything is evaluated at x.
(3) Multiply out; $g^{-1}g = \mathbb{1}$, and keep the terms of order ε.

Comparing the coefficients of εn^μ:

$$\boxed{A \longmapsto A' = g^{-1}Ag + g^{-1}\mathrm{d}g} \tag{T3.52}$$

The first term rotates A like an element of the Lie algebra (it is $\mathrm{Ad}_{g^{-1}}A$, Section T3.4). The second, inhomogeneous term is the Maurer–Cartan form of g.

Derivation 2: demand that $D\psi$ transforms like ψ. We want $D'\psi' = g^{-1}D\psi$, where $\psi' = g^{-1}\psi$ and $D' = \mathrm{d} + A'$. Using (T3.47),

$$\begin{aligned} D'\psi' &\overset{(1)}{=} \mathrm{d}(g^{-1}\psi) + A'g^{-1}\psi \overset{(2)}{=} g^{-1}\mathrm{d}\psi - g^{-1}\mathrm{d}g\, g^{-1}\psi + A'g^{-1}\psi \\ &\overset{(3)}{=} g^{-1}\mathrm{d}\psi - g^{-1}\mathrm{d}g\, g^{-1}\psi + \big(g^{-1}Ag + g^{-1}\mathrm{d}g\big)g^{-1}\psi \\ &\overset{(4)}{=} g^{-1}\big(\mathrm{d}\psi + A\psi\big) = g^{-1}D\psi. \end{aligned}$$

(1) Definition of D' acting on ψ'.
(2) Equation (T3.47).
(3) Insert the proposed law (T3.52).
(4) $g\,g^{-1} = \mathbb{1}$ in both brackets: the two $g^{-1}\mathrm{d}g\,g^{-1}\psi$ terms cancel, and $g^{-1}Agg^{-1}\psi = g^{-1}A\psi$.

So (T3.52) is exactly what is needed, and it is the *only* choice: if A' had any other value, the difference $(A' - g^{-1}Ag - g^{-1}\mathrm{d}g)g^{-1}\psi$ would spoil the result for some ψ. With $D\psi$ covariant, the Lagrangian $(D_\mu\psi)^\dagger D_\mu\psi$ is gauge invariant, because $(g^{-1}D\psi)^\dagger(g^{-1}D\psi) = (D\psi)^\dagger D\psi$ for unitary g.

Key idea: Gauge principle

Promoting a global symmetry $\psi \mapsto g^{-1}\psi$ to a local one forces the replacement $\mathrm{d} \to D = \mathrm{d} + A$, with A a $\mathfrak{g}$-valued 1-form transforming as $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$. Then $D\psi \mapsto g^{-1}D\psi$, and any globally invariant Lagrangian built with D in place of d is locally invariant.

Try it: The law is a right action

Show that doing g and then h is the same as doing gh: $(A^g)^h = A^{gh}$, where $A^g := g^{-1}Ag + g^{-1}\mathrm{d}g$.
Answer: $(A^g)^h = h^{-1}(g^{-1}Ag + g^{-1}\mathrm{d}g)h + h^{-1}\mathrm{d}h = (gh)^{-1}A(gh) + (gh)^{-1}(\mathrm{d}g\,h + g\,\mathrm{d}h) = (gh)^{-1}A(gh) + (gh)^{-1}\mathrm{d}(gh)$. This is the "right action" remarked on in Section T3.7.

T3.8.4 The frame picture: a connection is a rotating basis

Dray's Chapter 17 [Dray §17.1–17.5] gives a third derivation, and the most geometric one. In the plane with polar coordinates, the basis vectors $\hat{r}, \hat{\phi}$ change from point to point, and Dray records how they change with *connection 1-forms*: $\mathrm{d}\hat{e}_j = \omega^i{}_j\,\hat{e}_i$. For polar coordinates he finds $\mathrm{d}\hat{r} = \mathrm{d}\phi\,\hat{\phi}$ and $\mathrm{d}\hat{\phi} = -\mathrm{d}\phi\,\hat{r}$, i.e. $\omega^r{}_\phi = -\mathrm{d}\phi$ [Dray (17.2)–(17.3), (17.38)].

Do the same in the internal space. Choose at every point x a basis ("frame") $e_1(x), \dots, e_n(x)$ of the copy of $\mathbb{C}^n$, and write a field as $\Psi = e_i\,\psi^i$, where $\psi = (\psi^1, \dots, \psi^n)^T$ are its components. Record how the frame changes by a matrix of 1-forms A:

$$\mathrm{d}e_j = e_i\,A^i{}_j.$$

Then the derivative of the (frame-independent) field Ψ is

$$\mathrm{d}\Psi \overset{(1)}{=} \mathrm{d}e_j\,\psi^j + e_i\,\mathrm{d}\psi^i \overset{(2)}{=} e_i\big(\mathrm{d}\psi^i + A^i{}_j\psi^j\big) = e_i\,(D\psi)^i,$$

(1) Product rule (Dray's (17.15)).
(2) Substitute $\mathrm{d}e_j = e_iA^i{}_j$ and rename the dummy index.

so the components of the derivative are exactly $D\psi = \mathrm{d}\psi + A\psi$. Now change frame, $e'_j = e_i\,g^i{}_j$, with $g(x)$ an invertible matrix (unitary if both frames are orthonormal). A fixed field has

$\Psi = e'\psi' = e\, g\, \psi'$, so $\psi' = g^{-1}\psi$: *components transform by g^{-1} when the frame transforms by g*. The new connection matrix is read off from

$$\mathrm{d}e'_j \overset{(1)}{=} \mathrm{d}e_i\, g^i{}_j + e_i\, \mathrm{d}g^i{}_j \overset{(2)}{=} e_k \big(A^k{}_i\, g^i{}_j + \mathrm{d}g^k{}_j\big) \overset{(3)}{=} e'_l\, \big(g^{-1}\big)^l{}_k \big(Ag + \mathrm{d}g\big)^k{}_j,$$

(1) Product rule applied to $e'_j = e_i g^i{}_j$.

(2) $\mathrm{d}e_i = e_k A^k{}_i$; rename $i \to k$ in the second term.

(3) Express the old frame in terms of the new one, $e_k = e'_l (g^{-1})^l{}_k$.

so $A' = g^{-1}Ag + g^{-1}\mathrm{d}g$ once more. A gauge transformation is nothing but a change of frame in the internal space, and the gauge field records how the chosen frames twist from point to point.

Worked example T3.33: Polar coordinates as a pure-gauge connection

In the plane, the Cartesian frame $(\hat{x}, \hat{y})$ is constant, so its connection is $A = 0$. The polar frame is the Cartesian frame rotated by the angle ϕ (Figure T3.23):

$$(\hat{r}, \hat{\phi}) = (\hat{x}, \hat{y})\, g, \qquad g = \begin{pmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{pmatrix} \in \mathrm{SO}(2).$$

(Column j of g holds the Cartesian components of the j-th new basis vector: $\hat{r} = \cos\phi\, \hat{x} + \sin\phi\, \hat{y}$ and $\hat{\phi} = -\sin\phi\, \hat{x} + \cos\phi\, \hat{y}$.) By (T3.52) with $A = 0$, the polar connection is

$$A' = g^{-1}\mathrm{d}g \overset{(1)}{=} \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} -\sin\phi & -\cos\phi \\ \cos\phi & -\sin\phi \end{pmatrix} \mathrm{d}\phi \overset{(2)}{=} \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \mathrm{d}\phi.$$

(1) $g^{-1} = g^T$ for a rotation; differentiate each entry of g.

(2) Multiply: the $(1,1)$ entry is $-\cos\phi\sin\phi + \sin\phi\cos\phi = 0$, the $(1,2)$ entry is $-\cos^2\phi - \sin^2\phi = -1$, and so on.

So $A'^r{}_\phi = -\mathrm{d}\phi$ and $A'^\phi{}_r = +\mathrm{d}\phi$, exactly Dray's $\omega^r{}_\phi = -\mathrm{d}\phi$. The polar connection is not zero, but it is *pure gauge*: it comes from the trivial connection by a change of frame. That is why the plane is flat even though $\omega \neq 0$ in polar coordinates. Its curvature, computed below, vanishes (Section T3.10 develops this).

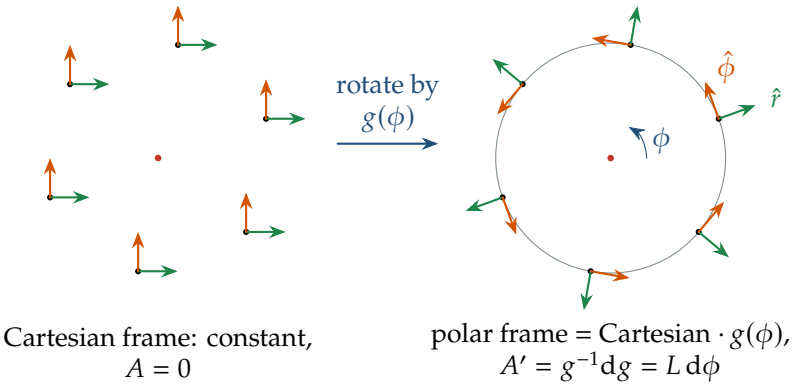

Figure T3.23: Dray's polar-coordinate example as a gauge transformation. Left: the Cartesian frame is the same at every point, so it has zero connection. Right: the polar frame $(\hat{r}, \hat{\phi})$ is the Cartesian one rotated by $g(\phi) \in \mathrm{SO}(2)$. Its connection $A' = g^{-1}\mathrm{d}g$ is nonzero, with $L = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$, but it is pure gauge. The polar frame is ill defined at the origin (red), where ϕ has no value.

T3.8.5 Infinitesimal gauge transformations

Take $g = e^{\varepsilon X}$ with $X(x) \in \mathfrak{g}$ and ε small. To first order,

$$\begin{aligned} A' &\overset{(1)}{=} (\mathbb{1} - \varepsilon X)\, A\, (\mathbb{1} + \varepsilon X) + (\mathbb{1} - \varepsilon X)\, \mathrm{d}(\mathbb{1} + \varepsilon X) + O(\varepsilon^2) \\ &\overset{(2)}{=} A + \varepsilon\big(\mathrm{d}X + AX - XA\big) + O(\varepsilon^2) = A + \varepsilon\big(\mathrm{d}X + [A, X]\big) + O(\varepsilon^2). \end{aligned} \tag{T3.53}$$

(1) Insert $g = \mathbb{1} + \varepsilon X + O(\varepsilon^2)$ and $g^{-1} = \mathbb{1} - \varepsilon X + O(\varepsilon^2)$ into (T3.52).
(2) Multiply out and keep the terms of order ε; $\mathrm{d}\mathbb{1} = 0$.

The combination $\mathrm{d}X + [A, X]$ is the **covariant derivative in the adjoint representation**, written $D_A X$ or DX. So

$$\delta A = DX = \mathrm{d}X + [A, X].$$

Why this combination? A Lie-algebra-valued field X transforms by conjugation, $X \mapsto g^{-1} X g$, because it acts on ψ like a matrix: $X\psi \mapsto g^{-1} X g\, g^{-1}\psi$. The covariant derivative of X must obey the Leibniz rule $D(X\psi) = (DX)\psi + X\, D\psi$. Solving for DX,

$$(DX)\psi \overset{(1)}{=} D(X\psi) - X\, D\psi \overset{(2)}{=} \mathrm{d}X\, \psi + X\mathrm{d}\psi + AX\psi - X\mathrm{d}\psi - XA\psi = \big(\mathrm{d}X + [A, X]\big)\psi.$$

(1) The Leibniz rule we demand.
(2) Expand $D(X\psi) = \mathrm{d}(X\psi) + AX\psi$ and $D\psi = \mathrm{d}\psi + A\psi$.

In components, with $X = X^a T_a$, $A = A^b_\mu T_b\, \mathrm{d}x^\mu$ and $[T_b, T_c] = f_{bc}{}^a T_a$:

$$\delta A^a_\mu = \partial_\mu X^a + f_{bc}{}^a\, A^b_\mu X^c. \tag{T3.54}$$

The first term is the abelian gauge transformation; the second, new for non-abelian G, rotates A in the adjoint representation (the ad matrices of (T3.21)). This is the QFT notes' [QFT notes (19.3.19)–(19.3.20)] in our conventions.

Worked example T3.34: QED as the $\mathrm{U}(1)$ case

For $G = \mathrm{U}(1)$ acting on a charged field, write $g = e^{-i\alpha(x)}$, so that $\psi \mapsto g^{-1}\psi = e^{i\alpha}\psi$, the physicists' convention of [QFT notes (19.2.1)]. A $\mathfrak{u}(1)$-valued 1-form is $A = i\, e\, a_\mu \mathrm{d}x^\mu$ with a_μ real (e is a constant, the charge, pulled out for convenience). Then

$$A' \overset{(1)}{=} A + g^{-1}\mathrm{d}g \overset{(2)}{=} A - i\, \mathrm{d}\alpha, \qquad \text{i.e.} \qquad a'_\mu = a_\mu - \tfrac{1}{e}\partial_\mu \alpha,$$
$$D_\mu \psi = (\partial_\mu + ie\, a_\mu)\psi.$$

(1) Everything commutes in U(1), so $g^{-1} A g = A$.
(2) $g^{-1}\mathrm{d}g = e^{i\alpha}\mathrm{d}(e^{-i\alpha}) = -i\, \mathrm{d}\alpha$.

These are the QED formulas [QFT notes (19.2.9), (19.2.11)]. Nothing rotates: the abelian gauge field only shifts by a gradient.

Worked example T3.35: Gauge transformations of a constant $\mathrm{SU}(2)$ potential

Take $G = \mathrm{SU}(2)$, $T_a = -\frac{i}{2}\sigma_a$, and the constant potential $A = a\, T_1\, \mathrm{d}x$ on $\mathbb{R}^2$ with coordinates (x, y).
(i) A constant gauge transformation $g = e^{\beta T_3}$. From the Pauli-matrix rotation of Section T3.4,

$e^{\beta T_3} T_1 e^{-\beta T_3} = \cos\beta\, T_1 + \sin\beta\, T_2$, and replacing $\beta \to -\beta$,

$$A' \overset{(1)}{=} g^{-1} A g \overset{(2)}{=} a\big(\cos\beta\, T_1 - \sin\beta\, T_2\big)\mathrm{d}x.$$

(1) g is constant, so $g^{-1}\mathrm{d}g = 0$.
(2) $g^{-1} T_1 g = e^{-\beta T_3} T_1 e^{\beta T_3}$, the rotation of the "colour vector" $(1,0,0)$ by $-\beta$ about the 3-axis.

A constant gauge transformation just rotates the colour components A^a as a vector in the adjoint (isospin-1) representation.
(ii) A position-dependent one, $g = e^{\beta x\, T_3}$. Now $g^{-1}\mathrm{d}g = \beta\, T_3\, \mathrm{d}x$, and

$$A' = a\big(\cos\beta x\, T_1 - \sin\beta x\, T_2\big)\mathrm{d}x + \beta\, T_3\, \mathrm{d}x.$$

The colour direction of A' now twists as we move along x, and a new component along T_3 has appeared. Both A and A' describe the same physics. Since A is constant and has only an x-component, its field strength (Section T3.8.6) is $F = \mathrm{d}A + A \wedge A = a^2 T_1^2\, \mathrm{d}x \wedge \mathrm{d}x = 0$; so A' must have $F' = 0$ too. Check it yourself with (T3.57): $F'_{xy} = 0$ trivially because nothing depends on y and there is no $\mathrm{d}y$ component.

T3.8.6 Curvature from the commutator of covariant derivatives

Ordinary derivatives commute: $\mathrm{dd} = 0$. Covariant derivatives need not. To see what replaces $\mathrm{dd} = 0$, extend D to vector-valued *forms*: for a $\mathbb{C}^n$-valued p-form ϕ (such as $D\psi$, a $\mathbb{C}^n$-valued 1-form) set $D\phi = \mathrm{d}\phi + A \wedge \phi$. Then

$$\begin{aligned} D(D\psi) &\overset{(1)}{=} \mathrm{d}\big(\mathrm{d}\psi + A\psi\big) + A \wedge \big(\mathrm{d}\psi + A\psi\big) \\ &\overset{(2)}{=} \mathrm{d}A\,\psi - A \wedge \mathrm{d}\psi + A \wedge \mathrm{d}\psi + A \wedge A\,\psi \\ &\overset{(3)}{=} \big(\mathrm{d}A + A \wedge A\big)\psi. \end{aligned} \tag{T3.55}$$

(1) Apply $D = \mathrm{d} + A\wedge$ to the 1-form $D\psi = \mathrm{d}\psi + A\psi$.
(2) $\mathrm{dd}\psi = 0$; the product rule for the 1-form A times the 0-form ψ gives $\mathrm{d}(A\psi) = \mathrm{d}A\,\psi - A \wedge \mathrm{d}\psi$ (a minus sign for moving d past a 1-form).
(3) The two $A \wedge \mathrm{d}\psi$ terms cancel.

All derivatives of ψ have dropped out: D^2 is not a differential operator at all, but multiplication by a matrix-valued 2-form.

Working definition T3.18 (curvature / field strength)

The **curvature** (field strength) of A is the $\mathfrak{g}$-valued 2-form [for each pair of directions μ, ν, a generator $F_{\mu\nu} = -F_{\nu\mu}$ in $\mathfrak{g}$]

$$F := \mathrm{d}A + A \wedge A, \qquad D^2\psi = F\psi. \tag{T3.56}$$

How to compute it in components: write $F = \frac{1}{2} F_{\mu\nu} \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$; then

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + [A_\mu, A_\nu], \qquad F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + f_{bc}{}^a A^b_\mu A^c_\nu. \tag{T3.57}$$

How to recognise it: $F_{\mu\nu} = [D_\mu, D_\nu]$, the failure of covariant derivatives to commute.

The component formula comes from

$$\begin{aligned} \mathrm{d}A + A \wedge A &\overset{(1)}{=} \partial_\mu A_\nu \, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu + A_\mu A_\nu \, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu \\ &\overset{(2)}{=} \tfrac{1}{2}\big(\partial_\mu A_\nu - \partial_\nu A_\mu\big)\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu + \tfrac{1}{2}\big(A_\mu A_\nu - A_\nu A_\mu\big)\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu, \end{aligned}$$

(1) $\mathrm{d}(A_\nu \mathrm{d}x^\nu) = \partial_\mu A_\nu \, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$ and $A \wedge A = A_\mu \mathrm{d}x^\mu \wedge A_\nu \mathrm{d}x^\nu$ (the matrices stay in order; the scalar forms $\mathrm{d}x^\mu$ pass through them).
(2) $\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$ is antisymmetric, so only the antisymmetric part of each coefficient survives; write it with the factor $\frac{1}{2}$.

and from $[A_\mu, A_\nu] = A_\mu^b A_\nu^c [T_b, T_c] = f_{bc}{}^a A_\mu^b A_\nu^c T_a$. The commutator version: acting on ψ,

$$\begin{aligned} [D_\mu, D_\nu]\psi &\overset{(1)}{=} (\partial_\mu + A_\mu)(\partial_\nu \psi + A_\nu \psi) - (\mu \leftrightarrow \nu) \\ &\overset{(2)}{=} \partial_\mu \partial_\nu \psi + (\partial_\mu A_\nu)\psi + A_\nu \partial_\mu \psi + A_\mu \partial_\nu \psi + A_\mu A_\nu \psi - (\mu \leftrightarrow \nu) \\ &\overset{(3)}{=} \big(\partial_\mu A_\nu - \partial_\nu A_\mu + A_\mu A_\nu - A_\nu A_\mu\big)\psi = F_{\mu\nu}\psi. \end{aligned}$$

(1) Definition of the commutator of two operators.
(2) Expand, using the product rule on $\partial_\mu(A_\nu \psi)$.
(3) Subtracting the $\mu \leftrightarrow \nu$ terms cancels $\partial_\mu \partial_\nu \psi$ (partial derivatives commute) and the symmetric pair $A_\nu \partial_\mu \psi + A_\mu \partial_\nu \psi$.

For electromagnetism this is the QFT notes' $[D_\mu, D_\nu] = ieF_{\mu\nu}$ [QFT notes (19.2.26)]; for Yang–Mills it is [QFT notes (19.3.22)–(19.3.25)].

How F transforms. Since $D\psi \mapsto g^{-1}D\psi$ for every ψ, applying the rule twice gives $D'^2\psi' = g^{-1}D^2\psi$, i.e. $F' g^{-1}\psi = g^{-1}F\psi$ for every ψ, so

$$\boxed{F \longmapsto F' = g^{-1} F g} \tag{T3.58}$$

It is instructive to check this directly, because it shows the inhomogeneous terms cancelling. Write $\tilde{A} = g^{-1}Ag$ and $\theta = g^{-1}\mathrm{d}g$, so $A' = \tilde{A} + \theta$. We need two derivatives:

$$\begin{aligned} \mathrm{d}\tilde{A} &\overset{(1)}{=} \mathrm{d}(g^{-1}) \wedge Ag + g^{-1}\mathrm{d}A\, g - g^{-1}A \wedge \mathrm{d}g \\ &\overset{(2)}{=} -\theta \wedge \tilde{A} + g^{-1}\mathrm{d}A\, g - \tilde{A} \wedge \theta, \\ \mathrm{d}\theta &\overset{(3)}{=} -\theta \wedge \theta. \end{aligned} \tag{T3.59}$$

(1) Product rule on the triple product $g^{-1} \cdot A \cdot g$; the last term has a minus sign because d moves past the 1-form A.
(2) $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\, g^{-1}$ gives $-g^{-1}\mathrm{d}g\, g^{-1}Ag = -\theta \wedge \tilde{A}$; and $g^{-1}A \wedge \mathrm{d}g = (g^{-1}Ag) \wedge (g^{-1}\mathrm{d}g)$ after inserting gg^{-1}.
(3) The Maurer–Cartan structure equation (T3.36).

Then

$$\begin{aligned} F' &\overset{(1)}{=} \mathrm{d}\tilde{A} + \mathrm{d}\theta + (\tilde{A} + \theta) \wedge (\tilde{A} + \theta) \\ &\overset{(2)}{=} \big(-\theta\tilde{A} + g^{-1}\mathrm{d}A\, g - \tilde{A}\theta\big) - \theta\theta + \tilde{A}\tilde{A} + \tilde{A}\theta + \theta\tilde{A} + \theta\theta \\ &\overset{(3)}{=} g^{-1}\mathrm{d}A\, g + \tilde{A} \wedge \tilde{A} \overset{(4)}{=} g^{-1}\big(\mathrm{d}A + A \wedge A\big)g = g^{-1}Fg. \end{aligned}$$

(1) Definition of F' with $A' = \tilde{A} + \theta$.
(2) Insert (T3.59) and expand the square, keeping the order (wedges suppressed).
(3) Every term containing θ cancels against a partner.
(4) $\tilde{A} \wedge \tilde{A} = g^{-1}Ag\,g^{-1} \wedge Ag = g^{-1}A \wedge A\,g$.

Key idea: Field strength is covariant, not invariant

$F = \mathrm{d}A + A \wedge A$ transforms by conjugation, $F \mapsto g^{-1}Fg$: it lives in the adjoint representation and carries colour. For U(1) conjugation does nothing, so the electromagnetic field is gauge *invariant*. For non-abelian G only conjugation-invariant combinations are physical: $\operatorname{tr} F \wedge F$, $\operatorname{tr} F \wedge \star F$, $\operatorname{tr} F_{\mu\nu}F_{\mu\nu}$, $\det(\mathbb{1} + \frac{i}{2\pi}F)$. These are the gauge-invariant polynomials that build the Yang–Mills action and the characteristic classes (Chapter 1, [Nash p. 87, (3.125)]).

Worked example T3.36: A constant potential with nonzero field strength

On $\mathbb{R}^2$ take the SU(2) potential $A = a\,T_1\,\mathrm{d}x + b\,T_2\,\mathrm{d}y$ with constants a, b. In electromagnetism a constant potential has zero field. Here

$$F \overset{(1)}{=} A \wedge A \overset{(2)}{=} ab\,(T_1T_2\,\mathrm{d}x \wedge \mathrm{d}y + T_2T_1\,\mathrm{d}y \wedge \mathrm{d}x) \overset{(3)}{=} ab\,[T_1, T_2]\,\mathrm{d}x \wedge \mathrm{d}y \overset{(4)}{=} ab\,T_3\,\mathrm{d}x \wedge \mathrm{d}y.$$

(1) A is constant, so $\mathrm{d}A = 0$.
(2) Multiply out; the $\mathrm{d}x \wedge \mathrm{d}x$ and $\mathrm{d}y \wedge \mathrm{d}y$ terms vanish.
(3) $\mathrm{d}y \wedge \mathrm{d}x = -\mathrm{d}x \wedge \mathrm{d}y$.
(4) $[T_1, T_2] = T_3$.

So $F_{xy} = ab\,T_3 \neq 0$. It is not a gauge artefact: $\operatorname{tr}(F_{xy}F_{xy}) = a^2b^2\operatorname{tr}(T_3^2) = -\frac{1}{2}a^2b^2 \neq 0$ is invariant. A non-abelian field can be "magnetic" purely through the self-interaction $[A_\mu, A_\nu]$. Its holonomy is computed in Example T3.41.

Worked example T3.37: The Dirac monopole: one connection, two patches

Here is a gauge field that *cannot* be written with a single potential on its whole domain, the prototype of every topologically nontrivial gauge field in Nash. Recall the Hopf map of Section T3.7.5: the unit spinor $\psi = (a, b)^T$ has spin direction $\hat{n}$ with $n_1 + in_2 = 2\bar{a}b$, $n_3 = |a|^2 - |b|^2$. A *choice* of spinor for each direction $\hat{n}$, in spherical angles (ϑ, ϕ), is

$$\psi_N(\vartheta,\phi) = \begin{pmatrix} \cos\frac{\vartheta}{2} \\ e^{i\phi}\sin\frac{\vartheta}{2} \end{pmatrix}, \qquad \psi_S(\vartheta,\phi) = e^{-i\phi}\psi_N = \begin{pmatrix} e^{-i\phi}\cos\frac{\vartheta}{2} \\ \sin\frac{\vartheta}{2} \end{pmatrix}.$$

Check: $2\bar{a}b = 2\cos\frac{\vartheta}{2}\sin\frac{\vartheta}{2}e^{i\phi} = \sin\vartheta\,e^{i\phi}$ and $|a|^2 - |b|^2 = \cos\vartheta$, the point $\hat{n}(\vartheta,\phi)$. At the north pole $\vartheta = 0$ we get $\psi_N = (1, 0)$ whatever ϕ is, so ψ_N is smooth there; at the south pole $\psi_N = (0, e^{i\phi})$ depends on the direction of approach, so ψ_N is singular. For ψ_S it is the other way round. Each is a good choice of phase on one patch: $U_N = S^2 \setminus \{\text{south pole}\}$, $U_S = S^2 \setminus \{\text{north pole}\}$.
The **Berry connection** of a family of states is $A = \psi^\dagger \mathrm{d}\psi$. It is imaginary, i.e. $\mathfrak{u}(1)$-valued, because $0 = \mathrm{d}(\psi^\dagger\psi) = \mathrm{d}\psi^\dagger\,\psi + \psi^\dagger\mathrm{d}\psi = 2\operatorname{Re}(\psi^\dagger\mathrm{d}\psi)$. Changing the phase, $\psi \mapsto \psi\,h$ with $h = e^{i\chi}$, gives $A \mapsto A + h^{-1}\mathrm{d}h$, the gauge law. On the two patches:

$$\begin{aligned} A_N = \psi_N^\dagger \mathrm{d}\psi_N &\overset{(1)}{=} \cos\tfrac{\vartheta}{2}\,\mathrm{d}\big(\cos\tfrac{\vartheta}{2}\big) + \sin\tfrac{\vartheta}{2}\,e^{-i\phi}\,\mathrm{d}\big(e^{i\phi}\sin\tfrac{\vartheta}{2}\big) \\ &\overset{(2)}{=} \tfrac{1}{2}\mathrm{d}\big(\cos^2\tfrac{\vartheta}{2} + \sin^2\tfrac{\vartheta}{2}\big) + i\sin^2\tfrac{\vartheta}{2}\,\mathrm{d}\phi \overset{(3)}{=} \tfrac{i}{2}\,(1 - \cos\vartheta)\,\mathrm{d}\phi, \\ A_S = \psi_S^\dagger \mathrm{d}\psi_S &\overset{(4)}{=} A_N + e^{i\phi}\mathrm{d}e^{-i\phi} = A_N - i\,\mathrm{d}\phi \overset{(5)}{=} -\tfrac{i}{2}\,(1 + \cos\vartheta)\,\mathrm{d}\phi. \end{aligned}$$

(1) Write out $\bar{a}\,\mathrm{d}a + \bar{b}\,\mathrm{d}b$ with the components of ψ_N.
(2) $\mathrm{d}(e^{i\phi}\sin\frac{\vartheta}{2}) = e^{i\phi}(\mathrm{d}\sin\frac{\vartheta}{2} + i\sin\frac{\vartheta}{2}\mathrm{d}\phi)$; the real terms combine to half the derivative of $\cos^2 + \sin^2$.
(3) That derivative is $\mathrm{d}(1) = 0$, and $\sin^2\frac{\vartheta}{2} = \frac{1}{2}(1-\cos\vartheta)$.
(4) $\psi_S = \psi_N h$ with $h = e^{-i\phi}$: the gauge law with $h^{-1}\mathrm{d}h = -i\,\mathrm{d}\phi$.
(5) Substitute A_N: $\frac{i}{2}(1-\cos\vartheta) - i = -\frac{i}{2}(1+\cos\vartheta)$.

A_N is smooth on U_N: near the north pole $1-\cos\vartheta \approx \vartheta^2/2$ kills the bad behaviour of $\mathrm{d}\phi$. At the south pole it is singular (a Dirac string). A_S is the mirror image. Both give the *same* field strength,

$$F = \mathrm{d}A_N = \mathrm{d}A_S = \tfrac{i}{2}\sin\vartheta\,\mathrm{d}\vartheta\wedge\mathrm{d}\phi,$$

(abelian, so $A\wedge A = 0$) which is smooth on the whole sphere: it is $\frac{i}{2}$ times the area form. The total flux is

$$\int_{S^2} F = \tfrac{i}{2}\cdot 4\pi = 2\pi i, \qquad c_1 = \frac{i}{2\pi}\int_{S^2} F = -1.$$

The transition function $h = e^{-i\phi}$ on the overlap (a band around the equator) winds once around U(1) as we go once around the equator (Figure T3.24). This is not an accident. If one smooth A existed on all of S^2, Stokes' theorem would give $\int_{S^2} F = \int_{S^2}\mathrm{d}A = 0$. The nonzero flux *forces* two patches, and the winding of the transition function measures the flux:

$$\int_{S^2} F \overset{(1)}{=} \int_{\text{north cap}} \mathrm{d}A_N + \int_{\text{south cap}} \mathrm{d}A_S \overset{(2)}{=} \oint_{\text{equator}} (A_N - A_S) \overset{(3)}{=} \oint i\,\mathrm{d}\phi = 2\pi i.$$

(1) Split the sphere along the equator and use the potential that is smooth on each half.
(2) Stokes on each cap. The equator bounds the north cap with the orientation of increasing ϕ and the south cap with the opposite orientation.
(3) $A_N - A_S = i\,\mathrm{d}\phi$ from the computation above.

In physics units, a monopole of magnetic charge g_m has $A_N^{\text{phys}} = g_m(1-\cos\vartheta)\mathrm{d}\phi$, flux $4\pi g_m$, and a particle of charge e sees $A = -ie\,A^{\text{phys}}$ (Section T3.8.9). The transition function is then $h = e^{-2ieg_m\phi}$, which is single-valued on the equator only if $2eg_m \in \mathbb{Z}$. That is the **Dirac quantisation condition**. The Hopf connection above is the case $2eg_m = -1$: the magnetic field seen by the phase of a spin-$\frac{1}{2}$ state.

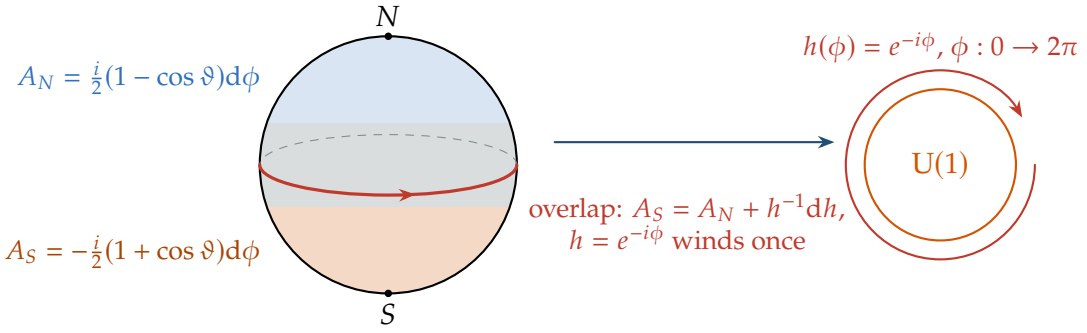

Figure T3.24: The monopole connection of Example T3.37. The sphere is covered by two patches, each missing one pole (blue north, orange south), overlapping in a band around the equator (grey). On each patch the potential is smooth; on the overlap they differ by the gauge transformation $h = e^{-i\phi}$, which goes once around U(1) as ϕ goes once around the equator. That winding number is the magnetic charge, $c_1 = -1$.

Watch out: A singular potential is not a singular field

A_N blows up at the south pole, but F does not. Singularities of a potential that disappear under a gauge transformation (Dirac strings) are artefacts of a bad choice of frame, like the singularity of the polar frame at the origin in Example T3.33. Only F and gauge-invariant quantities built from it are physical. The topological statement is that the underlying bundle is nontrivial: Chapter 1 and Chapter 8 treat the monopole as the Hopf bundle with $c_1 = \pm 1$.

T3.8.7 The Bianchi identity

The covariant derivative extends to Lie-algebra-valued p-forms ω (which transform by conjugation, like F) by

$$D\omega = \mathrm{d}\omega + A \wedge \omega - (-1)^p\, \omega \wedge A \;=:\; \mathrm{d}\omega + [A, \omega]. \tag{T3.60}$$

For $p = 0$ this is $\mathrm{d}X + [A, X]$ from above; the sign $(-1)^p$ makes the graded Leibniz rule $D(\omega\,\phi) = (D\omega)\phi + (-1)^p \omega \wedge D\phi$ hold for a $\mathbb{C}^n$-valued form ϕ. For a 2-form such as F the sign is +: $DF = \mathrm{d}F + A \wedge F - F \wedge A$.

Key idea: Bianchi identity

Every curvature satisfies $DF = \mathrm{d}F + [A, F] = 0$ identically.

Direct check:

$$\begin{aligned} \mathrm{d}F &\overset{(1)}{=} \mathrm{d}\mathrm{d}A + \mathrm{d}A \wedge A - A \wedge \mathrm{d}A \overset{(2)}{=} \mathrm{d}A \wedge A - A \wedge \mathrm{d}A, \\ A \wedge F - F \wedge A &\overset{(3)}{=} A \wedge \mathrm{d}A + A \wedge A \wedge A - \mathrm{d}A \wedge A - A \wedge A \wedge A = A \wedge \mathrm{d}A - \mathrm{d}A \wedge A, \\ DF &\overset{(4)}{=} 0. \end{aligned} \tag{T3.61}$$

(1) $\mathrm{d}(A \wedge A) = \mathrm{d}A \wedge A - A \wedge \mathrm{d}A$ (the product rule for a 1-form in front).
(2) $\mathrm{d}\mathrm{d} = 0$.
(3) Substitute $F = \mathrm{d}A + A \wedge A$ in both products; the cubic terms cancel.
(4) Add the two lines.

There is a slicker reason. Associativity says $D(D^2\psi) = D^2(D\psi)$, i.e. $D(F\psi) = F \wedge D\psi$. By the Leibniz rule the left side is $(DF)\psi + F \wedge D\psi$ (sign + for the 2-form F). So $(DF)\psi = 0$ for every ψ. In components, $DF = 0$ reads

$$D_\lambda F_{\mu\nu} + D_\mu F_{\nu\lambda} + D_\nu F_{\lambda\mu} = 0,$$

which is the Jacobi identity $[D_\lambda, [D_\mu, D_\nu]] + \text{cyclic} = 0$ for the operators D_μ.

Physical picture: Half of Maxwell's equations for free

For U(1) the commutator term vanishes and the Bianchi identity is $\mathrm{d}F = 0$. With F the electromagnetic field 2-form, $\mathrm{d}F = 0$ is $\nabla \cdot \vec{B} = 0$ together with Faraday's law $\nabla \times \vec{E} + \partial_t \vec{B} = 0$ (Chapter T1). These two equations are not dynamics: they say only that F comes from a potential. The other half, which contains the sources, comes from the action.

T3.8.8 The Yang–Mills action and field equations

We want a Lagrangian for A itself: gauge invariant, Lorentz (or rotation) invariant, and quadratic in first derivatives so that A propagates. The natural candidate uses the Hodge star

$\star$ of Chapter T1. In d Euclidean dimensions, $\alpha \wedge \star\beta = \langle \alpha, \beta \rangle$ vol for p-forms, with $\langle \cdot, \cdot \rangle$ the pointwise inner product; for 2-forms $\langle F, G \rangle = \frac{1}{2} F_{\mu\nu} G_{\mu\nu}$ (sum over all μ, ν). In four Euclidean dimensions, for example, $\star(\mathrm{d}x^1 \wedge \mathrm{d}x^2) = \mathrm{d}x^3 \wedge \mathrm{d}x^4$.

Working definition T3.19 (Yang–Mills action)

$$S_{\mathrm{YM}}[A] = -\frac{1}{g_{\mathrm{YM}}^2} \int_M \mathrm{tr}\big(F \wedge \star F\big) = -\frac{1}{2g_{\mathrm{YM}}^2} \int_M \mathrm{tr}\big(F_{\mu\nu} F_{\mu\nu}\big)\, \mathrm{d}^d x. \tag{T3.62}$$

Nash absorbs the coupling [the constant g_{YM} that sets the strength of the gluon self-interaction] ($g_{\mathrm{YM}} = 1$) and writes $S = \|F\|^2 = -\int \mathrm{tr}(F \wedge \star F)$ [Nash p. 227, (8.63)]. *Why the minus sign:* for anti-Hermitian X [$X^\dagger = -X$, as every $F_{\mu\nu}$ is for $G = \mathrm{U}(n)$ or $\mathrm{SU}(n)$], $\mathrm{tr}(X^2) = -\mathrm{tr}(X^\dagger X) = -\sum_{ij} |X_{ij}|^2 \le 0$, so the minus makes the action positive. With $\mathrm{tr}(T_a T_b) = -\frac{1}{2}\delta_{ab}$,

$$-\mathrm{tr}(F_{\mu\nu} F_{\mu\nu}) = \tfrac{1}{2} F^a_{\mu\nu} F^a_{\mu\nu}, \qquad S_{\mathrm{YM}} = \frac{1}{4g_{\mathrm{YM}}^2} \int F^a_{\mu\nu} F^a_{\mu\nu}\, \mathrm{d}^d x,$$

a sum of squares, the non-abelian version of $\frac{1}{2}(\vec{E}^2 + \vec{B}^2)$.

It is gauge invariant: $\mathrm{tr}(g^{-1} F g \wedge \star g^{-1} F g) = \mathrm{tr}(g^{-1} F \wedge \star F\, g) = \mathrm{tr}(F \wedge \star F)$, since $\star$ acts on the form part only and the trace is cyclic.

The field equations. Vary $A \to A_t = A + t\,a$ with a an arbitrary $\mathfrak{g}$-valued 1-form of compact support (Nash's (8.64)). First the curvature:

$$\begin{aligned} F(A + ta) &\overset{(1)}{=} \mathrm{d}A + t\,\mathrm{d}a + (A + ta) \wedge (A + ta) \\ &\overset{(2)}{=} F + t\big(\mathrm{d}a + A \wedge a + a \wedge A\big) + t^2 a \wedge a \overset{(3)}{=} F + t\,Da + t^2\, a \wedge a. \end{aligned} \tag{T3.63}$$

(1) Definition of F for the connection $A + ta$.
(2) Expand the product keeping the order of factors.
(3) For the 1-form a, (T3.60) with $p = 1$ gives $Da = \mathrm{d}a + A \wedge a + a \wedge A$.

We also need integration by parts under a trace. For $\mathfrak{g}$-valued forms ω (degree p) and η (degree q),

$$\mathrm{d}\ \mathrm{tr}(\omega \wedge \eta) = \mathrm{tr}(D\omega \wedge \eta) + (-1)^p\, \mathrm{tr}(\omega \wedge D\eta). \tag{T3.64}$$

Proof: the d terms are the ordinary product rule, so we must show the A terms cancel:

$$\begin{aligned} &\mathrm{tr}\big([A, \omega] \wedge \eta\big) + (-1)^p\, \mathrm{tr}\big(\omega \wedge [A, \eta]\big) \\ &\overset{(1)}{=} \mathrm{tr}(A\omega\eta) - (-1)^p\, \mathrm{tr}(\omega A \eta) + (-1)^p\, \mathrm{tr}(\omega A \eta) - (-1)^{p+q}\, \mathrm{tr}(\omega \eta A) \\ &\overset{(2)}{=} \mathrm{tr}(A\omega\eta) - (-1)^{p+q}(-1)^{p+q}\, \mathrm{tr}(A\omega\eta) = 0. \end{aligned}$$

(1) Expand $[A, \omega] = A\omega - (-1)^p \omega A$ and $[A, \eta] = A\eta - (-1)^q \eta A$ (wedges suppressed).
(2) The middle terms cancel. Graded cyclicity moves the 1-form A from the back past the $(p+q)$-form $\omega\eta$: $\mathrm{tr}(\omega\eta A) = (-1)^{p+q}\, \mathrm{tr}(A\omega\eta)$.

Now vary the action (with $g_{\mathrm{YM}} = 1$; the constant just multiplies everything):

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\Big|_{t=0} S[A + ta] &\overset{(1)}{=} -\int \mathrm{tr}\big(Da \wedge \star F\big) - \int \mathrm{tr}\big(F \wedge \star Da\big) \overset{(2)}{=} -2 \int \mathrm{tr}\big(Da \wedge \star F\big) \\ &\overset{(3)}{=} -2 \int \mathrm{d}\,\mathrm{tr}\big(a \wedge \star F\big) - 2 \int \mathrm{tr}\big(a \wedge D \star F\big) \overset{(4)}{=} -2 \int \mathrm{tr}\big(a \wedge D \star F\big). \end{aligned}$$

(1) Insert (T3.63); the t^2 term does not contribute at $t = 0$.
(2) $\alpha \wedge \star\beta = \beta \wedge \star\alpha$ for two forms of the same degree (both equal $\langle\alpha, \beta\rangle \mathrm{vol}$), applied entry by entry inside the trace.
(3) Equation (T3.64) with $\omega = a$ ($p = 1$) and $\eta = \star F$: $\mathrm{tr}(Da \wedge \star F) = \mathrm{d}\,\mathrm{tr}(a \wedge \star F) + \mathrm{tr}(a \wedge D \star F)$.
(4) Stokes: a has compact support (or M is closed), so the exact term integrates to zero.

This vanishes for every a exactly when

$$\boxed{D \star F = \mathrm{d} \star F + A \wedge \star F - (-1)^{d-2} \star F \wedge A = 0} \qquad \Longleftrightarrow \qquad D_\mu F_{\mu\nu} = \partial_\mu F_{\mu\nu} + [A_\mu, F_{\mu\nu}] = 0. \tag{T3.65}$$

These are the **Yang–Mills equations**. Nash writes them as $d_A^* F = 0$ with $d_A^* = - \star d_A \star$ [Nash pp. 228–229, (8.69)–(8.75)]; the extra $\star$'s do not change the content. Together with the Bianchi identity,

$$DF = 0, \qquad D \star F = 0,$$

they are the non-abelian Maxwell equations. With matter the right-hand side of the second equation becomes the colour current, $D_\mu F^a_{\mu\nu} \propto j^a_\nu$ [QFT notes (19.3.36)].

Physical picture: Non-linearity: gluons carry colour

For U(1), $\mathrm{d} \star F = 0$ is linear in A: light passes through light. For non-abelian G, $[A_\mu, F_{\mu\nu}]$ contains A^2 and A^3 terms, and the action $\mathrm{tr}\, F^2$ contains cubic and quartic self-couplings:

$$\tfrac{1}{2} F^a_{\mu\nu} F^a_{\mu\nu} = \underbrace{(\partial_\mu A^a_\nu - \partial_\nu A^a_\mu)\partial_\mu A^a_\nu}_{\text{free}} + \underbrace{2 f_{bc}{}^a\, \partial_\mu A^a_\nu\, A^b_\mu A^c_\nu}_{\text{3-gluon vertex}} + \underbrace{\tfrac{1}{2} f_{bc}{}^a f_{de}{}^a\, A^b_\mu A^c_\nu A^d_\mu A^e_\nu}_{\text{4-gluon vertex}}.$$

(Square (T3.57); the cross term doubles because $\partial_\mu A_\nu - \partial_\nu A_\mu$ and $f A_\mu A_\nu$ are both anti-symmetric in $\mu\nu$.) The gauge field is itself charged under the group, which is why gluons interact with each other, and why Yang–Mills theory is asymptotically free.

Worked example T3.38: Self-duality solves the Yang–Mills equations

In four Euclidean dimensions $\star\star = +1$ on 2-forms, so a 2-form splits into self-dual and anti-self-dual parts, $F = F^+ + F^-$ with $\star F^\pm = \pm F^\pm$. If $F = \pm \star F$ then

$$D \star F = \pm DF = 0$$

by the Bianchi identity: a first-order equation implies the second-order Yang–Mills equation (Nash's (8.75)–(8.76)). Moreover such fields minimise the action in their topological class. Using $\star F \wedge \star\star F = \star F \wedge F$ and $\alpha \wedge \star\beta = \beta \wedge \star\alpha$,

$$\begin{aligned} 0 &\overset{(1)}{\leq} -\tfrac{1}{2} \int \mathrm{tr}\big((F \mp \star F) \wedge \star (F \mp \star F)\big) \\ &\overset{(2)}{=} -\tfrac{1}{2} \int \mathrm{tr}\big(F \wedge \star F \mp F \wedge F \mp \star F \wedge \star F + \star F \wedge F\big) \overset{(3)}{=} -\int \mathrm{tr}(F \wedge \star F) \pm \int \mathrm{tr}(F \wedge F), \end{aligned}$$

(1) $-\mathrm{tr}(X \wedge \star X) \geq 0$ pointwise for any $\mathfrak{su}(N)$-valued 2-form X (the positivity above).
(2) Expand; $\star\star F = F$.
(3) $\star F \wedge \star\star F = \star F \wedge F = F \wedge \star F$.

so $S \geq \mp \int \mathrm{tr}\, F \wedge F$ for either sign, i.e. $S \geq \left| \int \mathrm{tr}\, F \wedge F \right|$, with equality exactly when $F = \pm \star F$. We will see in Section T3.10 that $\int \mathrm{tr}\, F \wedge F = 8\pi^2 k$ with k an integer; so $S_{\mathrm{YM}} \geq 8\pi^2 |k| / g^2_{\mathrm{YM}}$, the instanton bound, and $e^{-S} \leq e^{-8\pi^2|k|/g^2_{\mathrm{YM}}}$ is the non-perturbative factor of the QFT notes [QFT notes (4.13.12)–(4.13.14)]. Instantons are the subject of Chapter 8.

T3.8.9 Mathematicians' and physicists' conventions

The QFT notes (like most physics texts) write the covariant derivative as $D_\mu = \partial_\mu - ig\,\mathcal{A}^a_\mu R_a$ with Hermitian generators R_a of the representation of ψ, $[R_a, R_b] = i f_{abc} R_c$ and $\mathrm{tr}(R_a R_b) = C(R)\delta_{ab}$ ($= \frac{1}{2}\delta_{ab}$ in the fundamental), and $\psi \mapsto V\psi$ with $V = e^{i\alpha^a R_a}$ [QFT notes (19.3.1)–(19.3.10)]. To avoid a clash with the group element g, we write their coupling as g_{YM} and their Hermitian gauge field as $\mathcal{A}$. Matching $D = \mathrm{d} + A$:

$$A_{\mathrm{math}} = -i\, g_{\mathrm{YM}}\, \mathcal{A}^a_\mu R_a\, \mathrm{d}x^\mu, \qquad V = g^{-1}. \tag{T3.66}$$

Then:

$$\begin{aligned} F_{\mathrm{math},\mu\nu} &\overset{(1)}{=} -ig_{\mathrm{YM}}\big(\partial_\mu \mathcal{A}^a_\nu - \partial_\nu \mathcal{A}^a_\mu\big)R_a + (-ig_{\mathrm{YM}})^2 \mathcal{A}^b_\mu \mathcal{A}^c_\nu [R_b, R_c] \\ &\overset{(2)}{=} -ig_{\mathrm{YM}}\Big(\partial_\mu \mathcal{A}^a_\nu - \partial_\nu \mathcal{A}^a_\mu + g_{\mathrm{YM}} f_{bca}\mathcal{A}^b_\mu \mathcal{A}^c_\nu\Big)R_a = -ig_{\mathrm{YM}}\,\mathcal{F}^a_{\mu\nu} R_a, \end{aligned}$$

(1) Insert (T3.66) into (T3.57).
(2) $(-ig)^2[R_b, R_c] = -g^2\, i f_{bca} R_a = -ig\,(g f_{bca})R_a$.

which is the QFT notes' field strength [QFT notes (19.3.25)]. The gauge law with $g = V^{-1}$ becomes $A' = VAV^{-1} - (\mathrm{d}V)V^{-1}$, i.e. $\mathcal{A}' = V\mathcal{A}V^{-1} - \frac{i}{g_{\mathrm{YM}}}(\mathrm{d}V)V^{-1}$, which is [QFT notes (19.3.14)].

Dictionary: gauge fields

Mathematics (Nash, these notes)	**Physics (QFT notes)**
$A = A_\mu \mathrm{d}x^\mu$, anti-Hermitian	$\mathcal{A}_\mu = \mathcal{A}^a_\mu R_a$, Hermitian
$A = -ig_{\mathrm{YM}}\mathcal{A}$	$\mathcal{A} = \frac{i}{g_{\mathrm{YM}}}A$
$D = \mathrm{d} + A$	$D_\mu = \partial_\mu - ig_{\mathrm{YM}}\mathcal{A}^a_\mu R_a$
$\psi \mapsto g^{-1}\psi$	$\psi \mapsto V\psi$, $V = e^{i\alpha^a R_a}$
$A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$	$\mathcal{A} \mapsto V\mathcal{A}V^\dagger - \frac{i}{g_{\mathrm{YM}}}(\partial V)V^\dagger$
$\delta A = \mathrm{d}X + [A, X]$	$\delta\mathcal{A}^a_\mu = \frac{1}{g_{\mathrm{YM}}}\partial_\mu \alpha^a + f_{abc}\mathcal{A}^b_\mu \alpha^c$
$F = \mathrm{d}A + A \wedge A$	$\mathcal{F}^a = \partial\mathcal{A}^a - \partial\mathcal{A}^a + g_{\mathrm{YM}} f_{abc}\mathcal{A}^b\mathcal{A}^c$
$F_{\mu\nu} = [D_\mu, D_\nu]$	$[D_\mu, D_\nu] = -ig_{\mathrm{YM}}\mathcal{F}^a_{\mu\nu}R_a$
$F \mapsto g^{-1}Fg$	$\mathcal{F} \mapsto V\mathcal{F}V^\dagger$
$-\frac{1}{g^2_{\mathrm{YM}}}\int \mathrm{tr}\, F \wedge \star F$	$\frac{1}{4}\int \mathcal{F}^a_{\mu\nu}\mathcal{F}^a_{\mu\nu}$ (Euclidean)
$D \star F = 0$	$\partial_\mu \mathcal{F}^a_{\mu\nu} + g_{\mathrm{YM}} f_{abc}\mathcal{A}^b_\mu \mathcal{F}^c_{\mu\nu} = 0$
QED: $A = ie\,a$, $g = e^{-i\alpha}$	$D = \partial + iea$, $\psi \mapsto e^{i\alpha}\psi$

(For the $\delta\mathcal{A}$ line, take $X = -i\alpha^a R_a$, which is $g = V^{-1} = e^X$ to first order in the sign convention $V = e^{i\alpha R}$, so the table's α is minus the α of (T3.53); always check one line against the source you are reading.) The QED line uses the QFT notes' convention $D = \partial + iea$ [QFT notes (19.2.9)], which is the U(1) case with $R = -1$ and $g_{\mathrm{YM}} = e$.

Watch out: Minkowski signature

The dictionary above is Euclidean. In Minkowski signature the physics Lagrangian is $-\frac{1}{4}\mathcal{F}^a_{\mu\nu}\mathcal{F}^{a\,\mu\nu}$ and $\star\star = -1$ on 2-forms in four dimensions, so there are no real self-dual solutions: $F = \star F$ would give $F = \star\star F = -F$ [QFT notes §4.13.4]. This is why instantons live in Euclidean space.

Reading Nash (gauge fields in Nash)

Nash uses the mathematicians' conventions throughout: A is a $\mathfrak{g}$-valued 1-form (anti-Hermitian for unitary G), $F = \mathrm{d}A + A\wedge A$, and gauge transformations act by $A \mapsto g^{-1}(A+\mathrm{d})g$ [Nash p. 232, (8.88)]. The action appears first as $S = -\int \mathrm{tr}(F \wedge \star F)$ with self-dual solutions $F = \star F$ [Nash p. 25, (1.74)–(1.75)], and in detail in [Nash pp. 227–229, (8.63)–(8.76)]: the family $A_t = A + ta$, the expansion $F(A_t) = F(A) + t\, d_A a + t^2 a \wedge a$ (our (T3.63)), the critical-point equation $d_A^* F = 0$, the Bianchi identity $d_A F = 0$, and the split $S = \|F^+\|^2 + \|F^-\|^2$. Nash's gauge group is the group of gauge transformations $g(x)$ (sections of $\mathrm{Ad}\, P$) and its Lie algebra is the space of $X(x)$ (sections of $\mathrm{ad}\, P$) [Nash pp. 176–177, (6.19)–(6.24)]; our infinitesimal law $\delta A = DX$ is the action of that Lie algebra on $\mathcal{A}$.

Recap

- Local symmetry $\psi \mapsto g^{-1}(x)\psi$ spoils $\mathrm{d}\psi$ by the Maurer–Cartan term $-g^{-1}\mathrm{d}g$; the cure is $D = \mathrm{d} + A$.
- $A = A_\mu^a T_a \mathrm{d}x^\mu$ is a $\mathfrak{g}$-valued 1-form (the linearised comparator); $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$, derived three ways (comparator, covariance of $D\psi$, change of frame). Infinitesimally $\delta A = \mathrm{d}X + [A, X]$.
- $D^2 = F = \mathrm{d}A + A\wedge A$, $F_{\mu\nu} = [D_\mu, D_\nu] = \partial_\mu A_\nu - \partial_\nu A_\mu + [A_\mu, A_\nu]$, $F \mapsto g^{-1}Fg$; constant non-abelian potentials can have $F \neq 0$.
- Monopole: $A_N = \frac{i}{2}(1-\cos\vartheta)\mathrm{d}\phi$, $A_S = -\frac{i}{2}(1+\cos\vartheta)\mathrm{d}\phi$, glued by $e^{-i\phi}$; flux $2\pi i$, $c_1 = -1$; Dirac quantisation.
- Bianchi $DF = 0$; Yang–Mills $S = -\frac{1}{g^2}\int \mathrm{tr}\, F \wedge \star F$, field equation $D \star F = 0$; self-dual fields solve it and saturate $S \geq |\int \mathrm{tr}\, F \wedge F|$.
- Physics dictionary: $A_{\text{math}} = -ig_{\text{YM}}\mathcal{A}^a R_a$, $V = g^{-1}$.

T3.9 Parallel transport, holonomy and Wilson loops

In Section T3.8 the gauge field entered as the first Taylor coefficient of a comparator $U(x, x+\varepsilon n)$ that carries a vector between two *infinitely close* copies of $\mathbb{C}^n$. The question of this section is: *how do we carry a vector along a finite path, and what do we learn when the path is closed?* The answer is an ordinary differential equation along the path, whose solution is a path-ordered exponential of A. For a closed loop the result is a group element, the **holonomy**, and its trace, the **Wilson loop**, is the simplest gauge-invariant observable there is. Small loops measure the curvature F. Large loops can see gauge fields that have no curvature at all where the particle travels, which is the Aharonov–Bohm effect. The whole of lattice gauge theory, and much of Nash's Chapter 12, is written in terms of these objects.

T3.9.1 Parallel transport along a curve

Let $\gamma : [0,1] \to M$, $t \mapsto x^\mu(t)$, be a smooth path from $a = \gamma(0)$ to $b = \gamma(1)$, with velocity $\dot\gamma^\mu = \mathrm{d}x^\mu/\mathrm{d}t$. Break the path into many short steps of duration Δt. Over each step the comparator of (T3.49) tells us how to move a vector, and we simply chain the steps together.

A field ψ along the path is **parallel transported** if it is "covariantly constant along γ": at every step, the value at the new point is what the comparator produces from the value at the

old point. By the derivation of (T3.50), that means the covariant derivative in the direction of motion vanishes:

$$0 = \dot\gamma^\mu D_\mu\psi \overset{(1)}{=} \dot\gamma^\mu\partial_\mu\psi + \dot\gamma^\mu A_\mu\psi \overset{(2)}{=} \frac{\mathrm{d}\psi}{\mathrm{d}t} + A(\dot\gamma)\,\psi, \qquad A(\dot\gamma) \coloneqq A_\mu\big(x(t)\big)\,\dot\gamma^\mu(t). \tag{T3.67}$$

(1) $D_\mu = \partial_\mu + A_\mu$, (T3.51).
(2) Chain rule: $\dot\gamma^\mu\partial_\mu\psi = \frac{\mathrm{d}}{\mathrm{d}t}\psi(x(t))$. $A(\dot\gamma)$ is the 1-form A evaluated on the velocity vector: a matrix-valued function of t alone.

This is a linear, first-order ODE for the column vector $\psi(t)$, with a time-dependent matrix coefficient $-A(\dot\gamma)$. It has a unique solution for every initial value $\psi(0)$, and the solution depends linearly on $\psi(0)$. So there is a matrix $W_\gamma(t)$ with

$$\psi(t) = W_\gamma(t)\,\psi(0), \qquad \frac{\mathrm{d}W_\gamma}{\mathrm{d}t} + A(\dot\gamma)\,W_\gamma = 0, \qquad W_\gamma(0) = \mathbb{1}.$$

The matrix $W_\gamma \coloneqq W_\gamma(1)$ is the **parallel transport** (or **Wilson line**) along γ.

Working definition T3.20 (parallel transport)

Given a gauge field A and a path γ from a to b, solve

$$\frac{\mathrm{d}W(t)}{\mathrm{d}t} = -A\big(\dot\gamma(t)\big)\,W(t), \qquad W(0) = \mathbb{1}, \tag{T3.68}$$

and set $W_\gamma = W(1)$. It maps the copy of $\mathbb{C}^n$ at a to the copy at b. *Operational check:* $W_\gamma \in G$ (for A valued in $\mathfrak{g}$), it does not depend on how the path is parametrised [how fast γ is traversed, i.e. replacing t by an increasing $s(t)$ with $s(0) = 0$, $s(1) = 1$], and it is the identity if $A(\dot\gamma) = 0$ along the path.

Two of the claims in the box deserve a line each. $W_\gamma \in G$: for $G = \mathrm{U}(n)$,

$$\frac{\mathrm{d}}{\mathrm{d}t}(W^\dagger W) \overset{(1)}{=} \dot W^\dagger W + W^\dagger\dot W \overset{(2)}{=} -W^\dagger A(\dot\gamma)^\dagger W - W^\dagger A(\dot\gamma)W \overset{(3)}{=} 0,$$

(1) Product rule.
(2) The ODE (T3.68) and its Hermitian conjugate $\dot W^\dagger = -W^\dagger A(\dot\gamma)^\dagger$.
(3) A is anti-Hermitian: $A^\dagger = -A$.

so $W^\dagger W$ stays equal to its initial value $\mathbb{1}$. (For $\mathrm{SU}(n)$, $\frac{\mathrm{d}}{\mathrm{d}t}\det W = -\operatorname{tr}A(\dot\gamma)\det W = 0$ as well.) The ODE is a curve in G whose velocity, translated back to the identity, lies in $\mathfrak{g}$: it is the ODE $\dot g = Xg$ of the one-parameter subgroups (T3.13) with a generator that changes along the way. *Reparametrisation:* if $t = t(s)$, then $A(\mathrm{d}\gamma/\mathrm{d}s) = A(\dot\gamma)\,\mathrm{d}t/\mathrm{d}s$ and $\mathrm{d}W/\mathrm{d}s = (\mathrm{d}W/\mathrm{d}t)(\mathrm{d}t/\mathrm{d}s)$, so the equation keeps its form; W depends only on the geometric path and its direction.

The abelian case. For $G = \mathrm{U}(1)$ everything commutes, and the ODE is solved by an ordinary exponential:

$$W_\gamma = \exp\Big(-\int_0^1 A(\dot\gamma)\,\mathrm{d}t\Big) = \exp\Big(-\int_\gamma A\Big). \tag{T3.69}$$

Check: differentiating $\exp(-\int_0^t A(\dot\gamma)\mathrm{d}t')$ with respect to t brings down $-A(\dot\gamma(t))$, which commutes with the exponential. With $A = ie\,a$ (the QED convention of Example T3.34) this is the phase $e^{-ie\int_\gamma a}$, the QFT notes' Wilson line [QFT notes (19.4.1)].

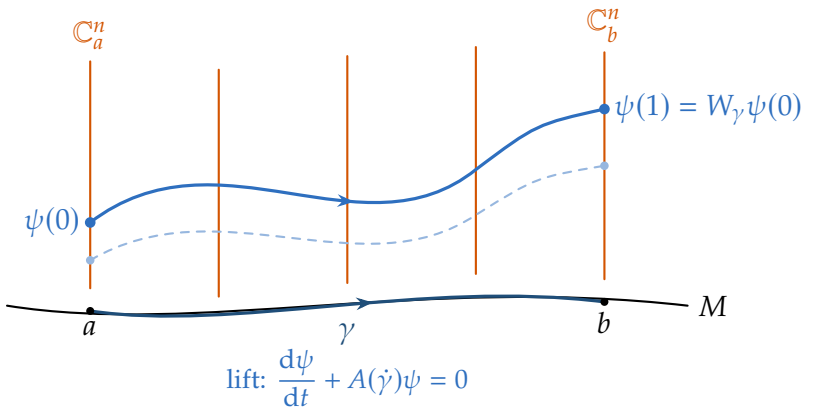

Figure T3.25: Parallel transport. Over each point of the path γ sits a copy of $\mathbb{C}^n$ (orange). Starting from any vector $\psi(0)$ in the copy over a, the ODE (T3.67) produces a unique lifted curve (blue) ending over b. A different starting vector (faint) gives a different lift. The map $\psi(0) \mapsto \psi(1)$ is linear: it is the matrix W_γ, Nash's $PT_{\gamma_{ab}}(A) : P_a \to P_b$.

T3.9.2 Path ordering

For non-abelian G the matrices $A(\dot\gamma(t))$ at different times do not commute and (T3.69) is wrong. The cure is the same one used for time-dependent Hamiltonians in quantum mechanics. Write $\mathcal{A}(t) := A(\dot\gamma(t))$ and turn the ODE into an integral equation, then iterate:

$$\begin{aligned} W(t) &\overset{(1)}{=} \mathbb{1} - \int_0^t dt_1\, \mathcal{A}(t_1)\, W(t_1) \\ &\overset{(2)}{=} \mathbb{1} - \int_0^t dt_1\, \mathcal{A}(t_1) + \int_0^t dt_1 \int_0^{t_1} dt_2\, \mathcal{A}(t_1)\mathcal{A}(t_2)\, W(t_2) \\ &\overset{(3)}{=} \sum_{k=0}^{\infty} (-1)^k \int_{t>t_1>t_2>\cdots>t_k>0} \mathcal{A}(t_1)\mathcal{A}(t_2)\cdots\mathcal{A}(t_k)\, dt_1 \cdots dt_k. \end{aligned} \tag{T3.70}$$

(1) Integrate (T3.68) from 0 to t and use $W(0) = \mathbb{1}$.
(2) Substitute the same equation for $W(t_1)$ inside the integral.
(3) Keep going. The k-th term has k factors of $-\mathcal{A}$, ordered with the *latest time on the left*.

In the k-th term the region $t > t_1 > \cdots > t_k > 0$ is one of the $k!$ orderings of the cube $[0,t]^k$. If we define the **path-ordering** symbol $\mathcal{P}$ to rearrange any product so that later times stand to the left, then each of the $k!$ orderings contributes the same, and

$$\boxed{W_\gamma = \mathcal{P}\exp\Big(-\int_\gamma A\Big) := \sum_{k=0}^{\infty} \frac{(-1)^k}{k!} \int_0^1 \cdots \int_0^1 \mathcal{P}\big[\mathcal{A}(t_1)\cdots\mathcal{A}(t_k)\big]\, dt_1 \cdots dt_k} \tag{T3.71}$$

This is the QFT notes' [QFT notes (19.4.6)–(19.4.8)], where the ordering is written with step functions $\theta(\sigma_1 - \sigma_2)$.

Physical picture: It is the Dyson series

In the interaction picture of quantum mechanics, $i\,dU/dt = H_I(t)U$ is solved by $U = \mathcal{T}\exp(-i\int H_I\,dt)$, with the time-ordering symbol $\mathcal{T}$ putting later Hamiltonians to the left. Parallel transport is the same mathematics with $iH_I(t) \to A(\dot\gamma(t))$ and "time" $\to$ "position along the path". The Wilson line is the time-evolution operator of the internal degrees of freedom (colour, isospin) of a very heavy particle dragged along γ.

The most useful way to *compute* a path-ordered exponential is to chop the path into pieces on which $\mathcal{A}$ is (nearly) constant. The ODE is then solved exactly on each piece, $W_{\text{piece}} = e^{-\Delta t\,\mathcal{A}}$, and the pieces multiply in order:

$$W_\gamma = \lim_{N\to\infty} e^{-\Delta t\,\mathcal{A}(t_N)} \cdots e^{-\Delta t\,\mathcal{A}(t_2)}\, e^{-\Delta t\,\mathcal{A}(t_1)}, \qquad \Delta t = 1/N. \tag{T3.72}$$

This is exactly how lattice gauge theory defines things, with one group element per link (Section T3.9.8).

Composition and reversal. Two facts follow directly from the ODE. If γ_1 runs from a to b and γ_2 from b to c, then $\gamma_2 * \gamma_1$ (first γ_1, then γ_2) has

$$W_{\gamma_2*\gamma_1} = W_{\gamma_2}\, W_{\gamma_1}, \qquad W_{\gamma^{-1}} = W_\gamma^{-1}, \tag{T3.73}$$

where γ^{-1} is γ run backwards. The first holds because the solution on the second leg starts from the value reached at the end of the first. The second holds because running backwards, the transported vector retraces its steps: the composite $\gamma^{-1} * \gamma$ transports $\psi(0)$ to $\psi(1)$ and back to $\psi(0)$. Note the order: *the first path taken stands on the right*, just as in (T3.72).

Worked example T3.39: A path with two straight legs

Take $G = \mathrm{SU}(2)$ with $T_a = -\frac{i}{2}\sigma_a$, and the constant potential $A = \alpha\, T_1\, \mathrm{d}x + \beta\, T_3\, \mathrm{d}y$ on $\mathbb{R}^2$. Go from $(0,0)$ to $(1,0)$ along x (γ_1), then from $(1,0)$ to $(1,1)$ along y (γ_2). On γ_1, $\dot\gamma = \partial_x$ and $A(\dot\gamma) = \alpha T_1$; on γ_2, $A(\dot\gamma) = \beta T_3$. Both are constant, so each leg is a single exponential and

$$\begin{aligned} W_{\gamma_2*\gamma_1} &\overset{(1)}{=} e^{-\beta T_3}\, e^{-\alpha T_1} \overset{(2)}{=} \Big(\cos\tfrac{\beta}{2} + i\sin\tfrac{\beta}{2}\,\sigma_3\Big)\Big(\cos\tfrac{\alpha}{2} + i\sin\tfrac{\alpha}{2}\,\sigma_1\Big) \\ &\overset{(3)}{=} \cos\tfrac{\alpha}{2}\cos\tfrac{\beta}{2}\,\mathbb{1} + i\sin\tfrac{\alpha}{2}\cos\tfrac{\beta}{2}\,\sigma_1 - i\sin\tfrac{\alpha}{2}\sin\tfrac{\beta}{2}\,\sigma_2 + i\cos\tfrac{\alpha}{2}\sin\tfrac{\beta}{2}\,\sigma_3. \end{aligned}$$

(1) Composition (T3.73): the first leg on the right; on a leg with constant $\mathcal{A}$ the ODE gives $e^{-\mathcal{A}}$.
(2) The SU(2) exponential (T3.15): $e^{-\alpha T_1} = e^{\frac{i\alpha}{2}\sigma_1} = \cos\frac{\alpha}{2} + i\sin\frac{\alpha}{2}\sigma_1$.
(3) Multiply out, using $\sigma_3\sigma_1 = i\sigma_2$, so $(i\sigma_3)(i\sigma_1) = -i\sigma_2$.

Going the other way round, first along y and then along x via $(0,1)$, gives $e^{-\alpha T_1}e^{-\beta T_3}$, which differs only in the sign of the σ_2 term (because $\sigma_1\sigma_3 = -i\sigma_2$). *Parallel transport depends on the path.* The two results agree only if $\sin\frac{\alpha}{2}\sin\frac{\beta}{2} = 0$. For comparison, this constant potential has $F = \alpha\beta\,[T_1, T_3]\,\mathrm{d}x\wedge\mathrm{d}y = -\alpha\beta\, T_2\,\mathrm{d}x\wedge\mathrm{d}y \neq 0$, as in Example T3.36. We return to the precise relation between path dependence and F below.

T3.9.3 Gauge covariance of parallel transport

Under a gauge transformation, $\psi \mapsto g^{-1}\psi$ and $A \mapsto A^g = g^{-1}Ag + g^{-1}\mathrm{d}g$. A vector transported along γ should still be transported after we change all the frames, so we expect

$$W_\gamma(A^g) = g(b)^{-1}\, W_\gamma(A)\, g(a), \tag{T3.74}$$

the finite version of the comparator law (T3.48). Here is the check, following the QFT notes' argument [QFT notes (19.4.9)–(19.4.24)]. Write $g_t = g(\gamma(t))$ and $V(t) \coloneqq g_t^{-1}W(t)g_0$, with $W(t)$ the

solution for A. Then

$$\begin{aligned}\frac{\mathrm{d}V}{\mathrm{d}t} &\overset{(1)}{=} -g_t^{-1}\dot g_t\, g_t^{-1}\, W(t)g_0 + g_t^{-1}\dot W(t)g_0\\ &\overset{(2)}{=} -g_t^{-1}\dot g_t\, g_t^{-1} W(t)g_0 - g_t^{-1}\mathcal{A}(t)W(t)g_0\\ &\overset{(3)}{=} -\big(g_t^{-1}\mathcal{A}(t)g_t + g_t^{-1}\dot g_t\big)\, g_t^{-1}W(t)g_0 \overset{(4)}{=} -A^g(\dot\gamma)\,V(t).\end{aligned}$$

(1) Product rule and (T3.35); $\dot g_t = \frac{\mathrm{d}}{\mathrm{d}t}g(\gamma(t)) = (\mathrm{d}g)(\dot\gamma)$.
(2) The ODE for W.
(3) Insert $\mathbb{1} = g_t g_t^{-1}$ between $\mathcal{A}(t)$ and $W(t)$ and factor out $g_t^{-1}Wg_0 = V$.
(4) The bracket is A^g evaluated on $\dot\gamma$.

So V solves the transport equation for A^g, and $V(0) = g_0^{-1}g_0 = \mathbb{1}$. By uniqueness of solutions, $V(t)$ *is* the transport for A^g, which is (T3.74).

Reading Nash (p. 217, (8.2)–(8.9))

Nash sets up parallel transport on the principal bundle P: in local coordinates (x, g) a path γ_{ab} is lifted to $\hat\gamma_{ab}(t) = (\gamma_{ab}(t), g(t))$ with $\frac{\mathrm{d}g}{\mathrm{d}t} + A\dot\gamma_{ab}\, g = 0$ [Nash (8.4)] – our (T3.68) with W renamed g. The map $PT_{\gamma_{ab}}(A) : P_a \to P_b$, $g(0) \mapsto g(1)$ [Nash (8.7)] is our W_γ. His commutation relation $\alpha_b \circ PT_{\gamma_{ab}}(A) = PT_{\gamma_{ab}}(\alpha\cdot A)\circ\alpha_a$ [Nash (8.8)] is (T3.74), written as $g(b)^{-1}W_\gamma(A) = W_\gamma(A^g)g(a)^{-1}$ with his $\alpha = g^{-1}$ acting on fibres. From it he proves that the based gauge group acts freely on $\mathcal{A}$: if $A^g = A$ and $g(a) = \mathbb{1}$, then $g(b)^{-1}W_\gamma = W_\gamma$ for every path from a, so $g(b) = \mathbb{1}$ for every b [Nash (8.9)].

T3.9.4 Holonomy and the Wilson loop

Now close the path: γ is a loop based at a, $\gamma(0) = \gamma(1) = a$. Parallel transport maps the copy of $\mathbb{C}^n$ at a to *itself*, so W_γ is simply an element of G, acting on one vector space.

Working definition T3.21 (holonomy and Wilson loop)

The **holonomy** of A around a loop γ based at a is

$$\mathrm{Hol}_\gamma(A) = W_\gamma = \mathcal{P}\exp\Big(-\oint_\gamma A\Big) \in G$$

[$\mathcal{P}$ is path ordering: the product of the short-step transports $\mathbb{1} - A(\dot\gamma)\Delta t$, with later steps standing to the left]. Under a gauge transformation it is conjugated, $\mathrm{Hol}_\gamma(A^g) = g(a)^{-1}\,\mathrm{Hol}_\gamma(A)\,g(a)$ (put $b = a$ in (T3.74)). Its trace in a representation R,

$$W_R(\gamma) := \mathrm{tr}_R\ \mathcal{P}\exp\Big(-\oint_\gamma A\Big), \tag{T3.75}$$

is therefore *gauge invariant*: the **Wilson loop**. *How to compute it:* chop γ into legs, multiply the leg transports right to left in the order travelled, and take the trace.

The gauge invariance of the trace is one line, as in [QFT notes (19.4.25)]: $\mathrm{tr}(g^{-1}Wg) = \mathrm{tr}(Wgg^{-1}) = \mathrm{tr}\,W$. More generally, any conjugation-invariant function of the holonomy (its eigenvalues, its conjugacy class) is gauge invariant, and for SU(2) the trace in the fundamental already determines the conjugacy class (Example T3.3).

Changing the base point. If we move the base point from a to c along a path σ from a to c, the loop $\sigma * \gamma * \sigma^{-1}$ based at c has holonomy $W_\sigma \operatorname{Hol}_\gamma W_\sigma^{-1}$ by (T3.73). Again only the conjugacy class matters: the trace does not care where on the loop we start.

Working definition T3.22 (holonomy group; reducible and irreducible)

As γ ranges over all loops based at a, the holonomies form a subgroup $\operatorname{Hol}_a(A) \subset G$: loops compose by (T3.73), and the reversed loop gives the inverse. This is the **holonomy group**. For a connected [any two points are joined by a path] M the groups at different base points are conjugate. If $\operatorname{Hol}_a(A) = G$, the connection is **irreducible**; if it is a proper subgroup, A is **reducible**. *Test:* a connection is reducible if there is a gauge in which all its components $A_\mu(x)$ lie in a proper subalgebra of $\mathfrak{g}$ [a smaller space of generators closed under commutators, e.g. the multiples of T_3 inside $\mathfrak{su}(2)$] (then every transport lies in the corresponding subgroup).

Worked example T3.40: A reducible SU(2) connection and its stabiliser

Let $A = a_\mu(x)\, T_3\, \mathrm{d}x^\mu$ with arbitrary real functions a_μ. Every $A(\dot\gamma)$ is a multiple of T_3, and multiples of T_3 commute, so

$$\operatorname{Hol}_\gamma(A) = \exp\Big(-T_3 \oint_\gamma a\Big) = \begin{pmatrix} e^{\frac{i}{2}\Phi} & 0 \\ 0 & e^{-\frac{i}{2}\Phi} \end{pmatrix}, \qquad \Phi = \oint_\gamma a .$$

The holonomy group lies in the maximal torus $\mathrm{U}(1) = \{e^{sT_3}\} \subset \mathrm{SU}(2)$: A is reducible. Which constant gauge transformations fix A? We need $g^{-1}T_3 g = T_3$, i.e. g commutes with T_3: $g = e^{sT_3}$. So the stabiliser is the whole U(1), not just the centre $\{\pm\mathbb{1}\}$. This is the general rule quoted in Section T3.7: the stabiliser of a connection is the centraliser of its holonomy group [Nash p. 232, (8.88)–(8.90)]. An irreducible connection has holonomy group SU(2), whose centraliser is the centre $\{\pm\mathbb{1}\}$.

Reading Nash (p. 218, (8.10))

Nash closes the path to a loop γ_a and obtains $PT_{\gamma_a}(A) : P_a \to P_a$ [Nash (8.10)]. "As γ_a varies over all the loops based at a the set of all the $PT_{\gamma_a}(A)$ form a group known as the holonomy group of A at a." If it is all of G, A is irreducible; otherwise reducible. This is exactly the working definition above. Reducible connections are where the space of gauge orbits $\mathcal{A}/\mathcal{G}$ is singular, which matters for instanton moduli spaces (Chapter 8) and for Floer theory (Chapter 12).

T3.9.5 Small loops measure the curvature

We now make precise the statement, made pictorially in Figure T3.6, that curvature is the failure of a small loop of transports to close. Put the base point at x and go around a small parallelogram spanned by $\varepsilon\, e_1$ and $\delta\, e_2$ (two coordinate directions $\mu = 1, 2$), counterclockwise: along e_1, then e_2, then back along $-e_1$, then $-e_2$ (Figure T3.26).

Write $a = A_1(x)$, $b = A_2(x)$. With each potential evaluated at the midpoint of its leg (which is accurate to the order we need) the four leg exponents are

$$X_1 = -\varepsilon\big(a + \tfrac{\varepsilon}{2}\partial_1 a\big), \qquad X_2 = -\delta\big(b + \varepsilon\,\partial_1 b + \tfrac{\delta}{2}\partial_2 b\big),$$
$$X_3 = +\varepsilon\big(a + \tfrac{\varepsilon}{2}\partial_1 a + \delta\,\partial_2 a\big), \qquad X_4 = +\delta\big(b + \tfrac{\delta}{2}\partial_2 b\big),$$

up to third-order terms, and the holonomy is $e^{X_4}e^{X_3}e^{X_2}e^{X_1}$. The Baker–Campbell–Hausdorff

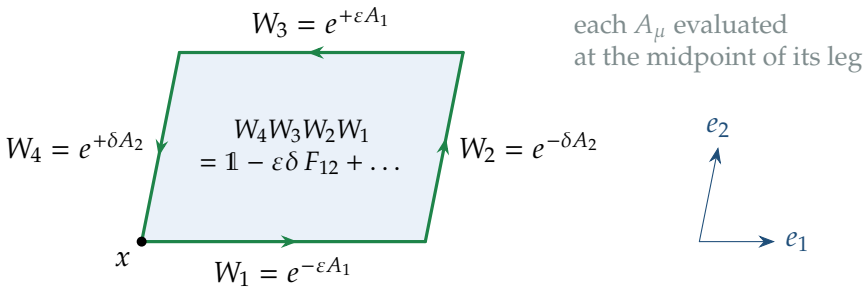

Figure T3.26: A small loop, travelled counterclockwise from x. Each leg contributes the exponential of $\mp$(length)$\times A_\mu$ at its midpoint. The four factors would cancel if the A_μ were the same on opposite legs and commuted with each other. The first failure is the change of A across the loop ($\partial_1 A_2 - \partial_2 A_1$); the second is non-commutativity ($[A_1, A_2]$). Together they are F_{12}. In lattice gauge theory this loop is a plaquette.

formula (T3.19), to second order, gives $\log(e^{X_4}e^{X_3}e^{X_2}e^{X_1}) = \sum_i X_i + \frac{1}{2}\sum_{i>j}[X_i, X_j] + O(3)$. First the linear terms:

$$X_1 + X_2 + X_3 + X_4 \overset{(1)}{=} \varepsilon\delta\,\partial_2 a - \varepsilon\delta\,\partial_1 b = -\varepsilon\delta\left(\partial_1 A_2 - \partial_2 A_1\right).$$

(1) In $X_1 + X_3$ everything cancels except $\varepsilon\delta\,\partial_2 a$: the potential on the top leg exceeds the one on the bottom leg by the change of A_1 over the height δ. In $X_2 + X_4$ everything cancels except $-\varepsilon\delta\,\partial_1 b$ from the change of A_2 over the width ε.

Then the commutators, where only the leading parts $X_1 \approx -\varepsilon a$, $X_2 \approx -\delta b$, $X_3 \approx \varepsilon a$, $X_4 \approx \delta b$ matter:

$$\tfrac{1}{2}\sum_{i>j}[X_i, X_j] \overset{(1)}{=} \tfrac{1}{2}\Big([X_2, X_1] + [X_3, X_2] + [X_4, X_1] + [X_4, X_3]\Big)$$
$$\overset{(2)}{=} \tfrac{1}{2}\,\varepsilon\delta\Big([b, a] - [a, b] + [a, b] + [b, a]\Big) \overset{(3)}{=} -\varepsilon\delta\,[A_1, A_2].$$

(1) $[X_3, X_1]$ and $[X_4, X_2]$ vanish at this order (opposite legs have proportional leading exponents).
(2) $[X_2, X_1] = \varepsilon\delta[b, a]$, $[X_3, X_2] = -\varepsilon\delta[a, b]$, $[X_4, X_1] = -\varepsilon\delta[b, a] = \varepsilon\delta[a, b]$, $[X_4, X_3] = \varepsilon\delta[b, a]$.
(3) $[b, a] = -[a, b]$, so the bracket is $-2[a, b]$.

Adding, and exponentiating,

$$\boxed{\mathrm{Hol}_\square(A) = \mathbb{1} - \varepsilon\delta\, F_{12}(x) + O(3), \qquad F_{12} = \partial_1 A_2 - \partial_2 A_1 + [A_1, A_2]} \tag{T3.76}$$

which is the component formula (T3.57). More invariantly: for a small loop spanning the tangent 2-plane of vectors u, v at x, $\mathrm{Hol} = \mathbb{1} - F(u, v) + \ldots$, where $F(u, v) = F_{\mu\nu}u^\mu v^\nu$ is the curvature 2-form evaluated on the two vectors.

Key idea: Curvature is holonomy per unit area

$F_{\mu\nu}(x)$ is (minus) the rotation of internal space picked up by going around an infinitesimal loop in the $\mu\nu$ plane at x, per unit area. Zero curvature means small loops have trivial holonomy; nonzero curvature means parallel transport is path dependent. The Wilson loop of a small loop is

$$\mathrm{tr}_R\ \mathrm{Hol}_\square = \dim R - \varepsilon\delta\ \mathrm{tr}_R\, F_{12} + \tfrac{1}{2}\varepsilon^2\delta^2\ \mathrm{tr}_R(F_{12}F_{12}) + \ldots,$$

and for $\mathfrak{su}(N)$ the linear term is zero ($\operatorname{tr} F = 0$), so the first gauge-invariant information is $\operatorname{tr} F_{12}^2$: exactly the Yang–Mills Lagrangian density.

Abelian Stokes, and why there is no simple non-abelian Stokes. For U(1) the path ordering is irrelevant, and Stokes' theorem turns the line integral into a flux: if $\gamma = \partial S$,

$$\mathrm{Hol}_\gamma(A) = \exp\Big(-\oint_{\partial S} A\Big) = \exp\Big(-\int_S F\Big), \tag{T3.77}$$

the QFT notes' [QFT notes (19.4.4)–(19.4.5)]. In QED this is the phase $e^{-ie\Phi_B}$ with Φ_B the magnetic flux through S. For non-abelian G there is no formula this simple: the local contributions $\mathbb{1} - F\,\mathrm{d}\sigma$ from the little plaquettes tiling S must each be transported back to the base point before they are multiplied, and they do not commute. The small-loop formula (T3.76) is the only piece that survives unchanged. The next example shows what happens for a finite loop.

Worked example T3.41: Wilson loop of a constant non-abelian field

Return to Example T3.36: $G = \mathrm{SU}(2)$, $A = a\,T_1\,\mathrm{d}x + b\,T_2\,\mathrm{d}y$ with constants a, b, so $F = ab\,T_3\,\mathrm{d}x \wedge \mathrm{d}y$ is constant too. Go counterclockwise around the rectangle $[0, L_1] \times [0, L_2]$ from the origin, and write $\alpha = aL_1$, $\beta = bL_2$. Each leg has constant $A(\dot\gamma)$, so

$$\mathrm{Hol} \overset{(1)}{=} e^{+\beta T_2}\, e^{+\alpha T_1}\, e^{-\beta T_2}\, e^{-\alpha T_1} \overset{(2)}{=} \big(PQP^{-1}\big)\, Q^{-1}, \qquad P = e^{\beta T_2},\ Q = e^{\alpha T_1}.$$

(1) Legs in order: $+x$ ($e^{-\alpha T_1}$), $+y$ ($e^{-\beta T_2}$), $-x$ ($e^{+\alpha T_1}$), $-y$ ($e^{+\beta T_2}$); the first leg stands on the right.

(2) Group the factors: the holonomy is a *group commutator* (T3.5).

Now use the SU(2) exponential. $Q = \cos\frac{\alpha}{2} - i \sin\frac{\alpha}{2}\,\sigma_1$, and $PQP^{-1} = \cos\frac{\alpha}{2} - i \sin\frac{\alpha}{2}\,P\sigma_1 P^{-1}$, where conjugating by $P = e^{-\frac{i\beta}{2}\sigma_2}$ rotates σ_1 about the 2-axis: $P\sigma_1 P^{-1} = \cos\beta\,\sigma_1 - \sin\beta\,\sigma_3$ (Section T3.4). The trace of a product of two SU(2) elements $c - i\,s\,\hat m \cdot \vec\sigma$ and $c' + i\,s'\,\hat n \cdot \vec\sigma$ is $2(cc' + ss'\,\hat m \cdot \hat n)$, since $\operatorname{tr}(\sigma_i\sigma_j) = 2\delta_{ij}$. Hence

$$\operatorname{tr}\mathrm{Hol} \overset{(1)}{=} 2\Big(\cos^2\tfrac{\alpha}{2} + \sin^2\tfrac{\alpha}{2}\,\cos\beta\Big) \overset{(2)}{=} 2 - 2\sin^2\tfrac{\alpha}{2}\,(1 - \cos\beta) \overset{(3)}{=} 2 - 4\sin^2\tfrac{aL_1}{2}\,\sin^2\tfrac{bL_2}{2}.$$

(1) $Q^{-1} = \cos\frac{\alpha}{2} + i\sin\frac{\alpha}{2}\,\sigma_1$, so $\hat n = \hat e_1$; and $\hat m = (\cos\beta, 0, -\sin\beta)$, so $\hat m \cdot \hat n = \cos\beta$.

(2) $\cos^2 + \sin^2 = 1$.

(3) $1 - \cos\beta = 2\sin^2\frac{\beta}{2}$.

Small loop check. For small L_1, L_2, $\operatorname{tr}\mathrm{Hol} \approx 2 - 4\cdot\frac{\alpha^2}{4}\cdot\frac{\beta^2}{4} = 2 - \frac{1}{4}(ab\,L_1L_2)^2$. The small-loop formula predicts $\operatorname{tr}\big(\mathbb{1} - L_1L_2F_{12} + \frac{1}{2}L_1^2L_2^2F_{12}^2\big) = 2 + \frac{1}{2}(abL_1L_2)^2\operatorname{tr}T_3^2 = 2 - \frac{1}{4}(abL_1L_2)^2$, using $\operatorname{tr}T_3 = 0$ and $\operatorname{tr}T_3^2 = -\frac{1}{2}$. They agree. *Large loop.* The naive guess "exp(−area × F)" would give $\operatorname{tr} e^{-L_1L_2\,ab\,T_3} = 2\cos\frac{abL_1L_2}{2}$, which depends only on the area L_1L_2. The true answer does not: at fixed area it depends on the shape, and it is periodic in L_1 and L_2 separately. The non-abelian field is not "flux through the loop".

T3.9.6 The Aharonov–Bohm effect: holonomy without field

Everything so far suggests that holonomy is a way of measuring F. The Aharonov–Bohm effect shows it is more: a gauge field can have *zero* field strength everywhere a particle goes and still produce a measurable holonomy. The physical set-up (Figure T3.28): an infinitely long thin

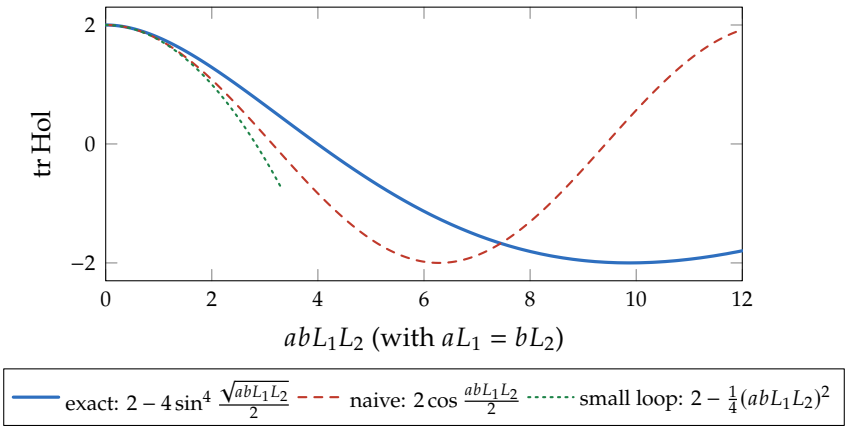

Figure T3.27: The Wilson loop of Example T3.41 for square loops ($aL_1 = bL_2$), as a function of the "flux" abL_1L_2. All three curves agree for small loops (the green small-loop formula (T3.76)). For larger loops the exact answer (blue) never goes below -2 and oscillates at a different rate from the naive abelian guess (red): non-abelian holonomy is not the exponential of a flux.

solenoid along the z-axis carries magnetic flux Φ, confined inside it. Electrons are kept out of the solenoid by a wall, so they live in the plane with a disc removed, $M = \mathbb{R}^2 \setminus \{r < r_0\}$. Outside the solenoid $\vec{B} = 0$, yet the vector potential cannot vanish: Stokes' theorem around any circle enclosing the solenoid gives $\oint \vec{a} \cdot \mathrm{d}\vec{l} = \Phi$. The symmetric choice is

$$\vec{a} = \frac{\Phi}{2\pi r}\,\hat{\phi}, \qquad a = \frac{\Phi}{2\pi}\,\mathrm{d}\phi \quad (r > r_0),$$

since the 1-form dual to $\hat{\phi}/r$ is $\mathrm{d}\phi$ (Chapter T1). Its field strength is $\mathrm{d}a = \frac{\Phi}{2\pi}\mathrm{d}\mathrm{d}\phi = 0$ on M. (The "$\mathrm{d}\phi$" is closed but not exact on M: ϕ is not a single-valued function there.)

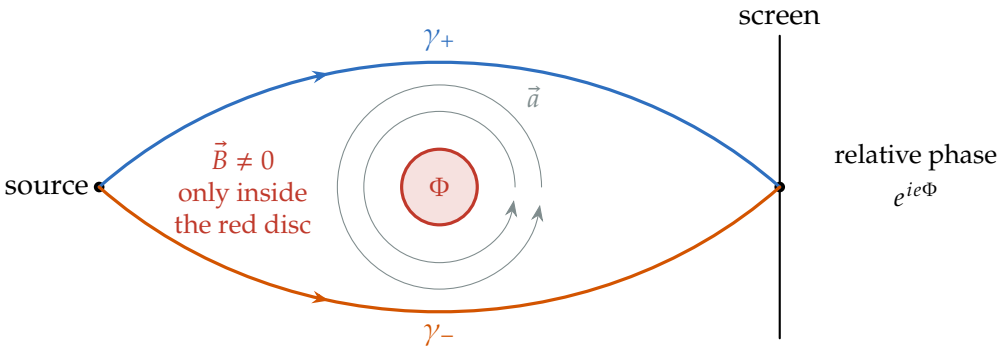

Figure T3.28: The Aharonov–Bohm experiment. The flux Φ is confined inside the solenoid (red), so electrons on either path $\gamma_\pm$ see $\vec{B} = 0$. But the vector potential (grey circles) circulates around the solenoid, and the two paths together form a loop $\gamma_-^{-1} * \gamma_+$ enclosing it. The relative phase at the screen is the holonomy $e^{ie\Phi}$ of that (clockwise) loop.

In the language of this chapter the electron's covariant derivative is $D = \mathrm{d} + A$ with $A = ie\,a$ (Example T3.34). The amplitude to reach a point on the screen along $\gamma_\pm$ is the field-free amplitude multiplied by the parallel transport, the phase $W_{\gamma_\pm} = e^{-ie\int_{\gamma_\pm} a}$ (in the semiclassical, or path-integral, picture each path carries its Wilson line). The interference depends on the ratio:

$$W_{\gamma_-}^{-1} W_{\gamma_+} \overset{(1)}{=} W_{\gamma_-^{-1}*\gamma_+} \overset{(2)}{=} \exp\Big(-ie \oint_{\gamma_-^{-1}*\gamma_+} a\Big) \overset{(3)}{=} \exp\big(+ie\Phi\big). \tag{T3.78}$$

(1) Composition and reversal (T3.73): go out along γ_+ and come back along γ_- reversed. For U(1) the order of the factors does not matter.
(2) Abelian transport (T3.69) around the closed loop.
(3) The loop goes once around the solenoid *clockwise* as drawn (over the top from left to right, back underneath), so $\oint \frac{\Phi}{2\pi} \mathrm{d}\phi = -\Phi$. Any loop winding once around the solenoid gives the same, however it is deformed: a is closed, so by Stokes the integral depends only on the winding number.

The interference pattern shifts by $e\Phi$ in phase: the fringe intensity goes like $\cos(\delta_0 + e\Phi)$, where δ_0 is the field-free path difference. The shift is periodic: it vanishes when $e\Phi \in 2\pi\mathbb{Z}$, i.e. when the flux is a multiple of the flux quantum $2\pi/e$ (which is h/e in SI units).

Key idea: Aharonov–Bohm = holonomy of a flat connection

On $M = \mathbb{R}^2 \setminus \text{disc}$ the connection $A = ie\frac{\Phi}{2\pi}\mathrm{d}\phi$ is *flat*, $F = 0$, yet its holonomy once counterclockwise around the hole is $e^{-ie\Phi} \neq 1$ (unless $e\Phi \in 2\pi\mathbb{Z}$). Locally it is pure gauge, $A = g^{-1}\mathrm{d}g$ with $g = e^{ie\Phi\phi/2\pi}$, but this g is not single-valued around the hole. Holonomy detects gauge fields that curvature cannot see; it needs a loop that cannot be shrunk, i.e. $\pi_1(M) \neq 0$. This is Nash's remark that a flat connection's "only departure from triviality lies in its holonomy, which relies on $\pi_1(M)$ to be non-vanishing" [Nash p. 244].

Watch out: Is the potential physical?

The Aharonov–Bohm effect does not make A itself observable: A can still be changed by any single-valued gauge transformation. What is observable is the gauge-invariant holonomy $e^{-ie\oint a}$, a non-local quantity. The lesson is that the complete gauge-invariant content of a connection is its set of Wilson loops, not its field strength alone. (Knowing all Wilson loops determines the connection up to gauge; knowing F does not, as this example shows.)

T3.9.7 Holonomy on the 2-sphere and Berry's phase

Two more classic holonomies are both computed on a circle of latitude $\vartheta = \vartheta_0$ of the unit sphere, traversed once in the direction of increasing ϕ. They are two faces of the same fact: on a curved space the holonomy of a small-ish loop is the enclosed curvature.

Worked example T3.42: A tangent vector carried around a latitude

Parallel transport of tangent vectors on S^2 (the Levi-Civita connection of Dray's Chapters 17–18, Chapter T2) is an SO(2) gauge field. In the orthonormal frame $(\hat{e}_\vartheta, \hat{e}_\phi)$, the tangential parts of the frame derivatives are [Dray Ch. 17–18]

$$\mathrm{d}\hat{e}_\vartheta = \cos\vartheta\,\mathrm{d}\phi\;\hat{e}_\phi, \qquad \mathrm{d}\hat{e}_\phi = -\cos\vartheta\,\mathrm{d}\phi\;\hat{e}_\vartheta,$$

so, in the convention $\mathrm{d}e_j = e_i A^i{}_j$ of Section T3.8.4,

$$A = \begin{pmatrix} 0 & -\cos\vartheta \\ \cos\vartheta & 0 \end{pmatrix}\mathrm{d}\phi = \cos\vartheta\, L\,\mathrm{d}\phi, \qquad L = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix},$$

where e^{sL} is the rotation by angle s (Example T3.9). Along the latitude $\phi \mapsto (\vartheta_0, \phi)$ we have $A(\dot\gamma) = \cos\vartheta_0\, L$, constant, so

$$\mathrm{Hol} \overset{(1)}{=} \exp\!\big(-2\pi\cos\vartheta_0\, L\big) \overset{(2)}{=} \text{rotation by } -2\pi\cos\vartheta_0 \overset{(3)}{=} \text{rotation by } 2\pi(1-\cos\vartheta_0).$$

(1) Constant $A(\dot\gamma)$ on a path of parameter length 2π.
(2) e^{sL} is the rotation by s.
(3) Add 2π: a full turn is the identity in SO(2).

The angle $2\pi(1-\cos\vartheta_0)$ is the area of the polar cap enclosed by the latitude. A vector carried around a small circle near the north pole comes back almost unrotated; carried around the equator it comes back rotated by 2π, i.e. unrotated, and the equator is a geodesic, along which the tangent vector is transported without turning relative to the curve. The curvature is $F = \mathrm{d}A = -\sin\vartheta\,\mathrm{d}\vartheta\wedge\mathrm{d}\phi\;L$, so $-F$ is L times the area form, and the small-loop formula gives rotation by (area) × (Gaussian curvature = 1), in agreement. For a cap, abelian Stokes (T3.77) gives the same answer exactly, because SO(2) is abelian: this is the local Gauss–Bonnet theorem.

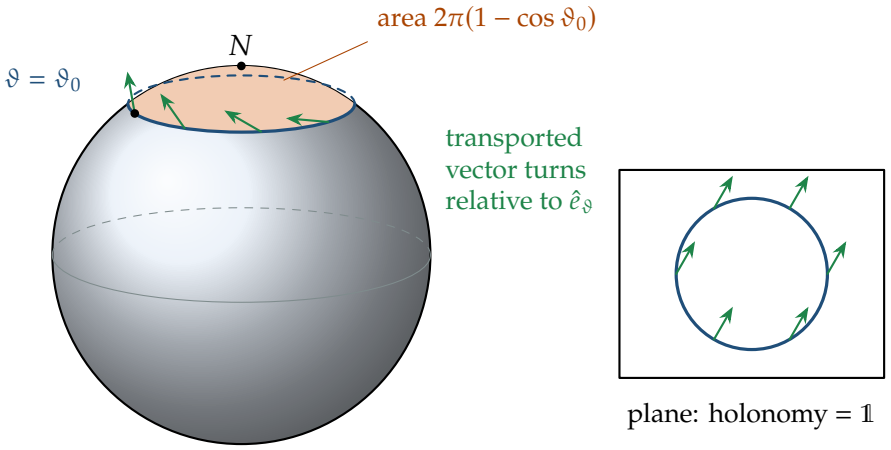

Figure T3.29: Left: on the sphere a tangent vector carried around the latitude $\vartheta=\vartheta_0$ comes back rotated by the enclosed area $2\pi(1-\cos\vartheta_0)$ (orange cap), because the Levi-Civita connection has curvature. Right: in the flat plane the same experiment returns every vector unchanged; the polar-frame connection of Example T3.33 is nonzero but pure gauge, so its holonomy is trivial.

Worked example T3.43: Berry's phase of a spin-$\frac12$

A spin-$\frac12$ in a magnetic field $\vec B = B\hat n$ has ground state $\psi_N(\hat n)$ of Example T3.37, up to a phase. If the direction $\hat n$ is turned slowly around a closed loop γ on S^2, the adiabatic theorem says the state follows $\psi_N(\hat n(t))$ up to a phase $e^{i\chi(t)}$ (apart from the dynamical phase $e^{-i\int E\,\mathrm{d}t}$, which we drop), and the phase is fixed by the condition that no component of $\frac{\mathrm{d}}{\mathrm{d}t}\psi$ lies along ψ: $\psi^\dagger\frac{\mathrm{d}\psi}{\mathrm{d}t}=0$. With $\psi = e^{i\chi}\psi_N$,

$$0 = \psi^\dagger\frac{\mathrm{d}\psi}{\mathrm{d}t} \overset{(1)}{=} i\dot\chi + \psi_N^\dagger\frac{\mathrm{d}\psi_N}{\mathrm{d}t} \overset{(2)}{=} i\dot\chi + A_N(\dot\gamma),$$

(1) Product rule and $\psi_N^\dagger\psi_N = 1$.
(2) The Berry connection $A_N = \psi_N^\dagger\mathrm{d}\psi_N$.

so $\frac{\mathrm{d}}{\mathrm{d}t}e^{i\chi} = -A_N(\dot\gamma)e^{i\chi}$: the phase is parallel transported with the monopole connection. For the latitude ϑ_0,

$$e^{i\chi(1)} \overset{(1)}{=} \exp\Big(-\oint A_N\Big) \overset{(2)}{=} \exp\Big(-\tfrac{i}{2}(1-\cos\vartheta_0)\cdot 2\pi\Big) = e^{-\frac{i}{2}\Omega}, \qquad \Omega = 2\pi(1-\cos\vartheta_0),$$

(1) Abelian parallel transport (T3.69) with $\chi(0)=0$.

(2) $A_N = \frac{i}{2}(1-\cos\vartheta)\mathrm{d}\phi$, constant along the latitude.

The **Berry phase** is $-\frac{1}{2}\Omega$, minus half the solid angle swept out by the spin. It is the holonomy of the monopole (Hopf) connection, and by abelian Stokes it equals $\exp(-\int_{\text{cap}} F)$ with $F = \frac{i}{2}\sin\vartheta\,\mathrm{d}\vartheta\wedge\mathrm{d}\phi$, the monopole field of strength $\frac{1}{2}$ sitting at the degeneracy point $\vec{B}=0$. Using A_S instead (i.e. the other patch) gives $e^{-\frac{i}{2}\Omega}e^{2\pi i}$, the same number: the Dirac quantisation of Example T3.37 is what makes the Berry phase independent of the patch. For $\vartheta_0 = \pi/2$ (spin rotated once around the equator) the phase is $e^{-i\pi} = -1$: the same sign as a 2π rotation of a spinor (Section T3.4.5).

T3.9.8 Lattice gauge theory: Wilson's action

Wilson's formulation of gauge theory on a lattice takes holonomy as the *fundamental* variable. Replace spacetime by a hypercubic lattice of spacing ℓ (we write ℓ rather than the usual a to avoid a clash). A matter field lives on the sites x. The gauge field lives on the links: to each link from x to $x+\ell\hat{\mu}$ we attach the group element

$$U_{x,\mu} := W_{\text{link}} \approx e^{-\ell A_\mu(x+\frac{\ell}{2}\hat{\mu})} \in G,$$

which carries vectors from x to $x+\ell\hat{\mu}$. Gauge transformations act on sites, $U_{x,\mu} \mapsto g(x+\ell\hat{\mu})^{-1}\,U_{x,\mu}\,g(x)$, which is (T3.74) for one link. The smallest gauge-invariant object is the Wilson loop of an elementary square, a **plaquette** (Figure T3.30):

$$U_p = U_{x,\nu}^{-1}\,U_{x+\ell\hat{\nu},\mu}^{-1}\,U_{x+\ell\hat{\mu},\nu}\,U_{x,\mu}, \qquad \operatorname{tr} U_p \text{ gauge invariant.}$$

(Right to left: along μ, then along ν, then back along μ, then back along ν.)

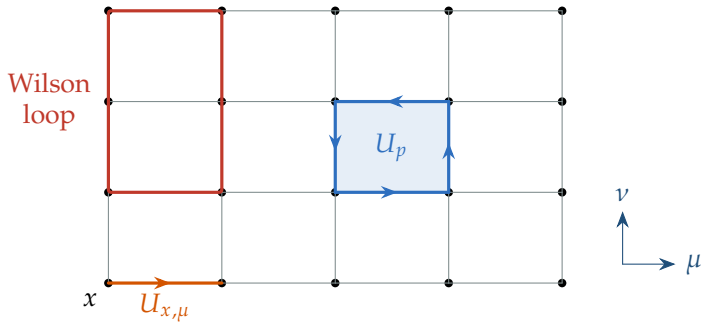

Figure T3.30: Lattice gauge theory. Group elements $U_{x,\mu}$ live on the links (orange); gauge transformations act at the sites (dots). The trace of the product around an elementary square is the plaquette variable $\operatorname{tr} U_p$ (blue), whose continuum limit is $\operatorname{tr} F_{\mu\nu}^2$. Larger Wilson loops (red) are the order parameters of confinement.

Worked example T3.44: Wilson's action becomes Yang–Mills

Wilson's action for $G=\mathrm{SU}(N)$ is $S_W = \beta\sum_p\big(1-\frac{1}{N}\operatorname{Re}\operatorname{tr}U_p\big)$, a sum over all plaquettes. By (T3.76) with $\varepsilon=\delta=\ell$, $U_p = \exp\big(-\ell^2 F_{\mu\nu} + O(\ell^3)\big)$, and for an $\mathfrak{su}(N)$ matrix X (traceless, anti-Hermitian) $\operatorname{tr}e^X = N + \frac{1}{2}\operatorname{tr}X^2 + O(X^3)$. For the symmetric plaquette the $O(\ell^3)$ terms drop out of the real part, and

$$1-\tfrac{1}{N}\operatorname{Re}\operatorname{tr}U_p \overset{(1)}{=} -\tfrac{\ell^4}{2N}\operatorname{tr}\big(F_{\mu\nu}F_{\mu\nu}\big) + O(\ell^6) \qquad \text{(no sum)},$$

$$S_W \overset{(2)}{=} \beta \sum_x \sum_{\mu<\nu} \left(-\tfrac{\ell^4}{2N}\right) \operatorname{tr} F_{\mu\nu}^2 \overset{(3)}{=} -\frac{\beta}{2N} \int \mathrm{d}^4x \sum_{\mu<\nu} \operatorname{tr} F_{\mu\nu}^2 \overset{(4)}{=} -\frac{\beta}{4N} \int \mathrm{d}^4x \, \operatorname{tr}\big(F_{\mu\nu}F_{\mu\nu}\big).$$

(1) $\operatorname{tr} F_{\mu\nu} = 0$, and the quadratic term of the exponential.
(2) Each plaquette is labelled by its corner x and a pair $\mu < \nu$.
(3) $\sum_x \ell^4 \to \int \mathrm{d}^4x$ as $\ell \to 0$.
(4) $\sum_{\mu<\nu}$ is half the sum over all μ, ν (diagonal terms vanish).

Comparing with $S_{\mathrm{YM}} = -\frac{1}{2g_{\mathrm{YM}}^2} \int \operatorname{tr}(F_{\mu\nu}F_{\mu\nu})$ of (T3.62), the lattice coupling is

$$\beta = \frac{2N}{g_{\mathrm{YM}}^2}.$$

Both terms are positive: $-\operatorname{tr} F^2 \geq 0$ for anti-Hermitian F, and $\operatorname{Re} \operatorname{tr} U \leq N$ for unitary U. The lattice theory is gauge invariant exactly, at every spacing, with no gauge fixing: only holonomies appear.

Physical picture: Wilson loops and confinement

A large rectangular Wilson loop of time extent T and spatial width R is the amplitude for creating a static quark–antiquark pair at separation R, holding it for time T, and annihilating it. Hence $\langle W(\gamma)\rangle \sim e^{-V(R)\,T}$ with $V(R)$ the static potential. If $\langle W\rangle$ falls like $e^{-\sigma RT}$, the *area law*, the potential is linear, $V = \sigma R$: quarks are confined by a string of tension σ. If it falls only like the perimeter, $e^{-c(R+T)}$, they are not. The Wilson loop is therefore the order parameter of confinement, and it is a holonomy.

Watch out: Signs and orders in the literature

Our transport solves $\dot{W} = -A(\dot{\gamma})W$, so $W = \mathcal{P}\exp(-\int A)$ with later points on the left. The QFT notes write $\mathcal{P}\exp(+ig\int \mathcal{A}^a R_a)$ [QFT notes (19.4.26)], which is the same thing under the dictionary $A = -ig_{\mathrm{YM}}\mathcal{A}$ of Section T3.8.9. Nash writes the Wilson line of Chern–Simons theory as $W(R, C) = \operatorname{tr} \mathcal{P}\exp\big[\oint_C A\big]$ [Nash p. 343, (12.84)], without the minus sign. That is the holonomy of the loop run the other way (or with the opposite ordering convention), and for a trace in a unitary representation it is the complex conjugate of ours. When comparing formulas, fix which end of the path is on the left and the sign in the exponent; nothing physical depends on the choice.

Reading Nash (holonomy and Wilson lines in Nash)

Holonomy appears three times in Nash. (i) In the proof that the based gauge group acts freely and in the definition of irreducible connections [Nash pp. 216–218, (8.2)–(8.10)]; (ii) in the statement that a flat connection is detected only by its holonomy, which requires $\pi_1(M) \neq 0$ [Nash p. 244, after (8.151)], and its use in Floer theory, where flat SU(2) connections on a homology 3-sphere are identified with representations $\operatorname{Hom}(\pi_1(M), \mathrm{SU}(2))/\operatorname{Ad}\mathrm{SU}(2)$ [Nash p. 325, (12.9)–(12.10)]; (iii) in Witten's Chern–Simons theory, where the observables are products of Wilson lines $W(R_i, C_i)$ along the components of a knot or link, and their expectation values give the Jones polynomial [Nash pp. 343–344, (12.84)–(12.85)]. The global anomaly discussion also computes a holonomy, of a determinant line bundle [Nash pp. 289–290] (Chapter 10).

Recap

- Parallel transport along γ: $\dot{W} = -A(\dot{\gamma})W$, $W(0) = \mathbb{1}$; solution $W_\gamma = \mathcal{P}\exp(-\int_\gamma A)$ (Dyson series, later points on the left), $W_\gamma \in G$. Abelian: $e^{-\int_\gamma A}$.
- $W_{\gamma_2 * \gamma_1} = W_{\gamma_2} W_{\gamma_1}$, $W_{\gamma^{-1}} = W_\gamma^{-1}$; gauge law $W_\gamma \mapsto g(b)^{-1} W_\gamma\, g(a)$.
- Holonomy of a loop: conjugated by $g(a)$; Wilson loop $W_R(\gamma) = \operatorname{tr}_R \operatorname{Hol}_\gamma$ is gauge invariant. Holonomy group; irreducible if it is all of G.
- Small loop: $\operatorname{Hol} = \mathbb{1} - \varepsilon\delta F_{12} + \ldots$; curvature is holonomy per unit area. Abelian Stokes $e^{-\oint A} = e^{-\int F}$; no simple non-abelian version (constant SU(2) field example).
- Aharonov–Bohm: flat connection, holonomy $e^{\mp ie\Phi}$; needs $\pi_1 \neq 0$. Sphere: rotation by enclosed area; Berry phase $-\Omega/2$ is the monopole holonomy.
- Lattice: $U_{x,\mu}$ on links, $S_W = \beta \sum_p (1 - \frac{1}{N}\operatorname{Re}\operatorname{tr} U_p) \to S_{\mathrm{YM}}$ with $\beta = 2N/g_{\mathrm{YM}}^2$; area law = confinement.

T3.10 Pure gauge, flat connections and the Chern–Simons form

Two questions close the chapter. The first: *when is a gauge field "nothing at all"?* Clearly $A = 0$ describes no field. But so does anything gauge equivalent to it, $A = g^{-1}\mathrm{d}g$, and such an A can look very complicated. Is $F = 0$ the test? The Aharonov–Bohm effect of Section T3.9.6 already warns us that the answer is "locally yes, globally no": a curvature-free field can have holonomy. We shall see that the gap between "flat" and "pure gauge" is measured exactly by the holonomy around non-contractible loops, i.e. by the topology of spacetime.

The second question: *the density* $\operatorname{tr} F \wedge F$ *is gauge invariant and closed; can we write it as* d *of something?* The answer is the **Chern–Simons form**

$$CS(A) = \operatorname{tr}\Big(A \wedge \mathrm{d}A + \tfrac{2}{3}\, A \wedge A \wedge A\Big), \qquad \mathrm{d}\, CS(A) = \operatorname{tr}(F \wedge F).$$

This one identity has three consequences that run through the rest of Nash. By Stokes' theorem the four-dimensional integral $\int \operatorname{tr} F \wedge F$ becomes a three-dimensional integral at infinity, where the field is pure gauge; there CS reduces to the winding-number density $\operatorname{tr}(g^{-1}\mathrm{d}g)^3$ of Section T3.6.5, so the instanton number is an integer. The form $CS(A)$ is itself a Lagrangian in three dimensions, the Chern–Simons action of Witten's knot theory (Chapter 12), whose critical points are flat connections. And the failure of CS to be gauge invariant, computed below, is the first step of the descent equations that produce anomalies (Chapter 10).

Throughout, $\theta = g^{-1}\mathrm{d}g$ is the Maurer–Cartan form of a map g into G, satisfying $\mathrm{d}\theta = -\theta \wedge \theta$ (T3.36). We write θ^2 for $\theta \wedge \theta$, A^3 for $A \wedge A \wedge A$, and so on: powers of matrix-valued forms always mean wedge products in order.

Graded cyclicity. We will use one trace rule over and over, so we state it once. If α is a matrix-valued p-form and β a matrix-valued q-form, then

$$\operatorname{tr}(\alpha \wedge \beta) = (-1)^{pq}\, \operatorname{tr}(\beta \wedge \alpha). \tag{T3.79}$$

It is ordinary cyclicity of the trace, $\operatorname{tr}(MN) = \operatorname{tr}(NM)$, combined with the sign $(-1)^{pq}$ from moving the q one-forms of β past the p one-forms of α. Three consequences we need:

- $\operatorname{tr}(\theta^2) = 0$ for any matrix-valued 1-form θ (take $p = q = 1$: $\operatorname{tr}(\theta \wedge \theta) = -\operatorname{tr}(\theta \wedge \theta)$). More generally $\operatorname{tr}(\alpha^{2m}) = 0$ for an odd form α; in particular $\operatorname{tr}(A^4) = 0$.

- A 1-form may be moved cyclically past a 2-form without a sign: $\operatorname{tr}(A \wedge \omega) = \operatorname{tr}(\omega \wedge A)$ for a 2-form ω.

- A product of three 1-forms is cyclic without a sign: $\operatorname{tr}(abc) = \operatorname{tr}(bca)$ (move the 1-form a past the 2-form bc).

T3.10.1 Pure gauge connections

Start from the trivial connection $A = 0$ and gauge transform it with an arbitrary $g(x)$. By the law $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$ (T3.52),

$$0 \;\longmapsto\; g^{-1}\,0\,g + g^{-1}\mathrm{d}g = \theta.$$

Working definition T3.23 (pure gauge)

A connection is **pure gauge** on a region U if there is a map $g : U \to G$ with

$$A = g^{-1}\mathrm{d}g \qquad \text{on } U. \tag{T3.80}$$

It is then gauge equivalent to $A = 0$ on U, and has no physical effect there [every gauge-invariant quantity on U, such as F or a Wilson loop inside U, takes its $A = 0$ value]. *Test:* try to solve $\mathrm{d}g = g\,A$ for g (a linear first-order PDE for the matrix g); pure gauge means a solution exists on all of U.

The field strength of a pure-gauge connection vanishes. This had better be so, because F transforms covariantly and $F(0) = 0$; but it is worth seeing the cancellation directly, because it is exactly the Maurer–Cartan structure equation:

$$\begin{aligned} F(g^{-1}\mathrm{d}g) &\overset{(1)}{=} \mathrm{d}\theta + \theta \wedge \theta \\ &\overset{(2)}{=} -g^{-1}\mathrm{d}g \wedge g^{-1}\mathrm{d}g + g^{-1}\mathrm{d}g \wedge g^{-1}\mathrm{d}g \\ &= 0. \end{aligned} \tag{T3.81}$$

(1) $F = \mathrm{d}A + A \wedge A$ (T3.56) with $A = \theta$.
(2) $\mathrm{d}\theta = \mathrm{d}(g^{-1}) \wedge \mathrm{d}g = -g^{-1}\mathrm{d}g\, g^{-1} \wedge \mathrm{d}g$, by $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\, g^{-1}$ (T3.35).

So the Maurer–Cartan equation $\mathrm{d}\theta + \theta^2 = 0$ *is* the statement "pure gauge fields are flat". Its content is not new; its interpretation is.

What does parallel transport do in a pure-gauge field? Transport for $A = 0$ is $W_\gamma(0) = \mathbb{1}$, and the gauge law (T3.74) gives

$$W_\gamma\big(g^{-1}\mathrm{d}g\big) = g(b)^{-1}\,\mathbb{1}\,g(a) = g(b)^{-1}g(a), \tag{T3.82}$$

for a path γ from a to b. The answer depends only on the end points, not on the path. For a closed loop, $b = a$, the holonomy is $g(a)^{-1}g(a) = \mathbb{1}$. So: *pure gauge* $\Rightarrow$ *path-independent transport* $\Rightarrow$ *trivial holonomy around every loop in* U.

Worked example T3.45: Checking (T3.82) by solving the ODE

Let $W(t) = g(\gamma(t))^{-1} g(a)$ and write $g_t = g(\gamma(t))$. Then

$$\frac{\mathrm{d}W}{\mathrm{d}t} \overset{(1)}{=} -g_t^{-1}\dot{g}_t\, g_t^{-1}\, g(a) \overset{(2)}{=} -\theta(\dot\gamma)\, W(t),$$

(1) Derivative of an inverse, $\frac{\mathrm{d}}{\mathrm{d}t} g_t^{-1} = -g_t^{-1}\dot{g}_t\, g_t^{-1}$.
(2) $g_t^{-1}\dot{g}_t = (g^{-1}\mathrm{d}g)(\dot\gamma) = \theta(\dot\gamma)$, and $g_t^{-1} g(a) = W(t)$.

and $W(0) = g(a)^{-1} g(a) = \mathbb{1}$. So W solves the transport equation (T3.68) for $A = \theta$, and by uniqueness it is the transport. Concretely, for U(1) with $g = e^{i\alpha(x)}$ we get $A = i\,\mathrm{d}\alpha$ and $W_\gamma = e^{-i(\alpha(b)-\alpha(a))}$, which is $e^{-\int_\gamma A}$ by the fundamental theorem of calculus.

Worked example T3.46: A pure-gauge SU(2) field that looks complicated

Take $g(x) = e^{\phi(x)T_3}\, e^{\chi(x)T_1}$ with $T_a = -\frac{i}{2}\sigma_a$ and two arbitrary functions ϕ, χ on $\mathbb{R}^2$. Then

$$\begin{aligned} A = g^{-1}\mathrm{d}g &\overset{(1)}{=} e^{-\chi T_1} e^{-\phi T_3}\left(\mathrm{d}\phi\, T_3\, e^{\phi T_3} e^{\chi T_1} + e^{\phi T_3}\,\mathrm{d}\chi\, T_1\, e^{\chi T_1}\right) \\ &\overset{(2)}{=} \mathrm{d}\phi\; e^{-\chi T_1} T_3\, e^{\chi T_1} + \mathrm{d}\chi\, T_1 \\ &\overset{(3)}{=} \mathrm{d}\phi\,\left(\cos\chi\, T_3 + \sin\chi\, T_2\right) + \mathrm{d}\chi\, T_1. \end{aligned}$$

(1) Product rule on g; $\mathrm{d}e^{\phi T_3} = \mathrm{d}\phi\, T_3 e^{\phi T_3}$ because T_3 commutes with its own exponential.
(2) $e^{-\phi T_3} T_3 e^{\phi T_3} = T_3$ and $e^{-\phi T_3} e^{\phi T_3} = \mathbb{1}$.
(3) $e^{-\chi T_1} T_3 e^{\chi T_1} = \mathrm{Ad}_{e^{-\chi T_1}} T_3$ is the adjoint action of $e^{-\chi T_1}$ on T_3 (Example T3.14), a rotation of the 2–3 plane by the angle χ; with $[T_1, T_3] = -T_2$ the Hadamard series (T3.22) gives $T_3 - \chi[T_1, T_3] + \cdots = \cos\chi\, T_3 + \sin\chi\, T_2$.

So $A^1 = \mathrm{d}\chi$, $A^2 = \sin\chi\,\mathrm{d}\phi$, $A^3 = \cos\chi\,\mathrm{d}\phi$. Check flatness in components. With $F^a = \mathrm{d}A^a + \frac{1}{2}\varepsilon_{abc} A^b \wedge A^c$ (the $\mathfrak{su}(2)$ form of $F = \mathrm{d}A + A \wedge A$):

$$\begin{aligned} F^1 &= 0 + A^2 \wedge A^3 = \sin\chi\cos\chi\,\mathrm{d}\phi \wedge \mathrm{d}\phi = 0, \\ F^2 &= \cos\chi\,\mathrm{d}\chi \wedge \mathrm{d}\phi + A^3 \wedge A^1 = \cos\chi\,\mathrm{d}\chi \wedge \mathrm{d}\phi + \cos\chi\,\mathrm{d}\phi \wedge \mathrm{d}\chi = 0, \\ F^3 &= -\sin\chi\,\mathrm{d}\chi \wedge \mathrm{d}\phi + A^1 \wedge A^2 = -\sin\chi\,\mathrm{d}\chi \wedge \mathrm{d}\phi + \sin\chi\,\mathrm{d}\chi \wedge \mathrm{d}\phi = 0. \end{aligned}$$

Each component of $\mathrm{d}A$ is non-zero but is cancelled exactly by the commutator term. A single component taken alone, say A^3, is *not* a flat abelian field ($\mathrm{d}A^3 \neq 0$): non-abelian flatness is a collective property of all the components together.

T3.10.2 Flat means locally pure gauge

We showed pure gauge ⇒ flat. Now the converse, which is the real content of this subsection.

Working definition T3.24 (flat connection)

A connection is **flat** if its curvature vanishes identically, $F = \mathrm{d}A + A \wedge A = 0$. *Test:* compute $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + [A_\mu, A_\nu]$ for every pair $\mu < \nu$. *Physical meaning:* parallel transport around every small loop is trivial [it returns every vector unchanged, $W_\gamma = \mathbb{1}$], by (T3.76).

Key idea: flat = locally pure gauge

If $F = 0$ on a simply connected region U (every loop in U can be shrunk to a point inside U), then $A = g^{-1}\mathrm{d}g$ on U for some $g : U \to G$, unique up to $g \mapsto h\,g$ with h a constant. On a region that is *not* simply connected this can fail, and the failure is measured by the holonomies around the non-contractible loops.

Here is why, in three steps.

Step 1: the equation for g and its integrability condition. We want g with $g^{-1}\mathrm{d}g = A$, i.e. $\mathrm{d}g = g\,A$, i.e. $\partial_\mu g = g\,A_\mu$ for each μ. That is n first-order equations for one unknown matrix, so it is overdetermined: the mixed partials must agree, $\partial_\nu\partial_\mu g = \partial_\mu\partial_\nu g$. Compute:

$$\begin{aligned}\partial_\nu(\partial_\mu g) - \partial_\mu(\partial_\nu g) &\overset{(1)}{=} \partial_\nu(gA_\mu) - \partial_\mu(gA_\nu)\\ &\overset{(2)}{=} (\partial_\nu g)A_\mu + g\,\partial_\nu A_\mu - (\partial_\mu g)A_\nu - g\,\partial_\mu A_\nu\\ &\overset{(3)}{=} g\,A_\nu A_\mu + g\,\partial_\nu A_\mu - g\,A_\mu A_\nu - g\,\partial_\mu A_\nu\\ &\overset{(4)}{=} -g\left(\partial_\mu A_\nu - \partial_\nu A_\mu + [A_\mu, A_\nu]\right) = -g\,F_{\mu\nu}.\end{aligned}$$

(1) Insert the equation $\partial_\mu g = gA_\mu$.
(2) Product rule.
(3) Use the equation again for $\partial_\nu g$ and $\partial_\mu g$.
(4) Collect terms; the bracket is the component formula (T3.57).

So the equations are consistent only if $F_{\mu\nu} = 0$. In form language: if $\mathrm{d}g = gA$ then $0 = \mathrm{d}\mathrm{d}g = \mathrm{d}g \wedge A + g\,\mathrm{d}A = g(A \wedge A + \mathrm{d}A) = gF$. This is the non-abelian version of "a vector field with zero curl is locally a gradient".

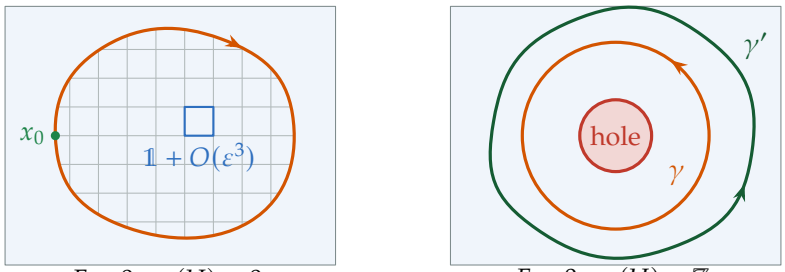
Step 2: construct g by parallel transport. Pick a base point $x_0 \in U$. For each $x \in U$ choose a path γ_x from x_0 to x and let $h(x) = W_{\gamma_x}$ be the parallel transport along it. *If* $h(x)$ does not depend on the choice of path, then extending the path by a small step εn at the end gives, by (T3.49) and (T3.73), $h(x + \varepsilon n) = (\mathbb{1} - \varepsilon\, n^\mu A_\mu)h(x) + O(\varepsilon^2)$, i.e. $\mathrm{d}h = -A\,h$. Then $g := h^{-1}$ does the job:

$$\mathrm{d}g \overset{(1)}{=} -h^{-1}\,\mathrm{d}h\,h^{-1} \overset{(2)}{=} -h^{-1}(-A\,h)h^{-1} = h^{-1}A = g\,A.$$

(1) Derivative of an inverse.
(2) $\mathrm{d}h = -Ah$.

Step 3: path independence is flatness plus simple connectivity. Two paths γ, γ' from x_0 to x give the same transport if and only if the loop $\gamma'^{-1} * \gamma$ has trivial holonomy (by (T3.73)). If U is simply connected, this loop can be shrunk to a point. Shrinking it sweeps out a surface, which we can tile by a fine grid of small plaquettes. The holonomy of the big loop is a product of conjugated plaquette holonomies (each plaquette is visited by a "lollipop": out along a tail, around, and back along the same tail, and the tails cancel in pairs), and each plaquette holonomy is $\mathbb{1} - \varepsilon^2 F_{12} + \cdots = \mathbb{1} + O(\varepsilon^3)$ when $F = 0$, by (T3.76). There are about $1/\varepsilon^2$ plaquettes, so the total error is $O(\varepsilon) \to 0$: the holonomy is exactly $\mathbb{1}$. (Figure T3.31 shows the picture.)

The same plaquette argument, applied to the strip between two loops that can be deformed into one another, gives a result we will use constantly.



$F = 0$, $\pi_1(U) = 0$: every holonomy $= \mathbb{1}$

$F = 0$, $\pi_1(U) = \mathbb{Z}$: $\mathrm{Hol}_\gamma = \mathrm{Hol}_{\gamma'}$ may be $\neq \mathbb{1}$

Figure T3.31: Left: in a flat connection on a simply connected region, a loop can be filled in by small plaquettes, each with holonomy $\mathbb{1} + O(\varepsilon^3)$; so the loop's holonomy is $\mathbb{1}$ and transport is path independent. Right: around a hole, the orange and green loops, both running counterclockwise, can be deformed into each other (so they have the same holonomy, up to conjugation when G is non-abelian), but neither can be filled in. Their common holonomy is the only information a flat connection carries.

Key idea: holonomy of a flat connection is topological

For a flat connection, the holonomy around a loop based at x_0 depends only on the *homotopy class* of the loop. It therefore defines a map

$$\rho_A : \pi_1(M, x_0) \longrightarrow G, \qquad [\gamma] \longmapsto \mathrm{Hol}_\gamma(A),$$

which is a group homomorphism (a **representation of the fundamental group**) because holonomies compose, (T3.73). A gauge transformation conjugates it, $\rho_{A^g} = g(x_0)^{-1}\rho_A g(x_0)$. Conversely every homomorphism $\pi_1(M) \to G$ arises from some flat connection (possibly on a non-trivial bundle). So

$$\{\text{flat connections on } M\}/\{\text{gauge}\} \;\cong\; \mathrm{Hom}\big(\pi_1(M), G\big)/\text{conjugation}. \tag{T3.83}$$

A small bookkeeping remark about homomorphism order: with the convention "first path on the right" of (T3.73), the holonomy of "γ_1 then γ_2" is $\mathrm{Hol}_{\gamma_2}\mathrm{Hol}_{\gamma_1}$, so ρ_A respects products if we also write loop composition right to left. Nothing below depends on this.

Watch out: flat is not trivial

On $\mathbb{R}^n$, or on any simply connected M such as S^2, S^3 or S^4, (T3.83) says that the only flat connection up to gauge is $A = 0$: flat $\Leftrightarrow$ pure gauge. On a circle, a torus, a punctured plane, a knot complement or a lens space, there are many inequivalent flat connections. They carry no field strength and no energy, yet they are physically distinct: they are detected by Wilson loops, as in Aharonov–Bohm.

Worked example T3.47: Flat connections on a circle

On $M = S^1$ with coordinate $\phi \in [0, 2\pi)$ there are no 2-forms, so every connection is flat. Any connection can be gauge transformed to a constant one, $A = X\,\mathrm{d}\phi$ with $X \in \mathfrak{g}$ constant (transport around the circle gives a group element W; write $W = e^{-2\pi X}$ and gauge away the rest). Its holonomy is found by solving $\mathrm{d}W/\mathrm{d}\phi = -XW$:

$$\mathrm{Hol}(A) = e^{-2\pi X}.$$

U(1): $X = ia$ with $a \in \mathbb{R}$; the holonomy is $e^{-2\pi i a}$. The gauge transformation $g = e^{in\phi}$ ($n \in \mathbb{Z}$,

single valued) gives $g^{-1}\mathrm{d}g = in\,\mathrm{d}\phi$, so

$$A^g \overset{(1)}{=} g^{-1}(ia\,\mathrm{d}\phi)g + g^{-1}\mathrm{d}g \overset{(2)}{=} i(a+n)\,\mathrm{d}\phi.$$

(1) Gauge law (T3.52).
(2) U(1) is abelian so $g^{-1}(\cdot)g$ does nothing; $g^{-1}\mathrm{d}g = e^{-in\phi}\,in\,e^{in\phi}\,\mathrm{d}\phi$.

So a and $a+n$ are gauge equivalent: the space of flat U(1) connections on S^1 is $\mathbb{R}/\mathbb{Z}$, a circle, labelled faithfully by the holonomy $e^{-2\pi ia} \in \mathrm{U}(1)$. The transformations $e^{in\phi}$ with $n \neq 0$ cannot be deformed to the identity (they wind n times, $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$); they are the simplest **large gauge transformations**.
SU(2): conjugate X into the Cartan subalgebra, $X = ia\sigma_3$, holonomy $\mathrm{diag}(e^{-2\pi ia}, e^{2\pi ia})$. Large gauge transformations $e^{in\phi\sigma_3}$ shift $a \mapsto a+n$, and the Weyl reflection (conjugation by $i\sigma_2$) sends $a \mapsto -a$. A fundamental domain is $a \in [0, \frac{1}{2}]$: the flat SU(2) connections on S^1 form an *interval*, the space of conjugacy classes of SU(2) (the latitudes of Figure T3.3). At the endpoints the holonomy is central ($\pm\mathbb{1}$) and the stabiliser is all of SU(2); in the interior it is the U(1) of diagonal matrices (compare Example T3.40).

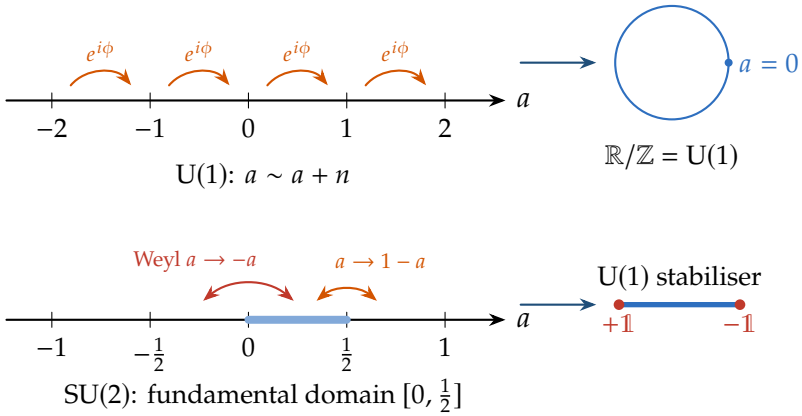


Figure T3.32: Flat connections on a circle, $A = ia\sigma\,\mathrm{d}\phi$. Top: for U(1) the large gauge transformations $e^{in\phi}$ shift a by integers, and the moduli space is a circle. Bottom: for SU(2) we also quotient by the Weyl reflection; the moduli space is the interval $[0, \frac{1}{2}]$, whose endpoints (holonomy $\pm\mathbb{1}$, red) have the largest stabiliser.

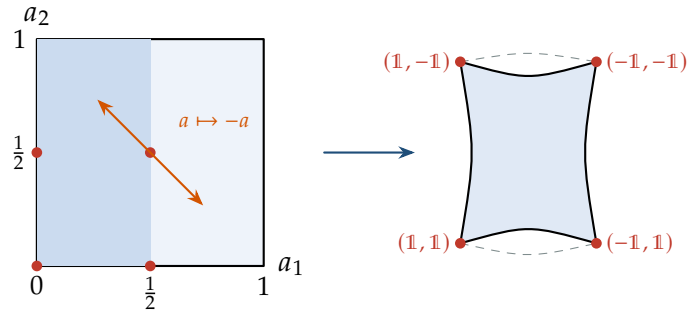
Worked example T3.48: Flat connections on a torus: the pillowcase

On T^2 with angles (ϕ_1, ϕ_2), $\pi_1(T^2) = \mathbb{Z}^2$ is generated by the two cycles γ_1, γ_2, with the single relation $\gamma_1\gamma_2\gamma_1^{-1}\gamma_2^{-1} = 1$ (the boundary of the square in the usual picture of the torus). So a flat connection is a pair of *commuting* holonomies (U_1, U_2), up to simultaneous conjugation.

- U(1): $A = i(a_1\mathrm{d}\phi_1 + a_2\mathrm{d}\phi_2)$ with constants a_1, a_2; $F = \mathrm{d}A = 0$. Large gauge transformations $e^{i(n_1\phi_1 + n_2\phi_2)}$ shift (a_1, a_2) by integers. The moduli space is the torus $\mathbb{R}^2/\mathbb{Z}^2$ (the "dual torus", or Jacobian, of Chapter 5).
- SU(2): two commuting elements of SU(2) can be simultaneously diagonalised, so $A = i(a_1\mathrm{d}\phi_1 + a_2\mathrm{d}\phi_2)\sigma_3$, again with $(a_1, a_2) \in \mathbb{R}^2/\mathbb{Z}^2$, but now also identified under the Weyl reflection $(a_1, a_2) \mapsto (-a_1, -a_2)$. The quotient of a torus by this reflection is a sphere with four corner points, the **pillowcase** (Figure T3.33). The corners are the four pairs $(\pm\mathbb{1}, \pm\mathbb{1})$ of central holonomies.

Check that $F = 0$ in the SU(2) case: $\mathrm{d}A = 0$ (constant coefficients) and $A \wedge A = -(a_1 \mathrm{d}\phi_1 + a_2 \mathrm{d}\phi_2)^2 \sigma_3^2 = 0$ since the scalar 1-form squares to zero. The flatness is "abelian" because the components commute.



$T^2 = \mathbb{R}^2/\mathbb{Z}^2$, shaded half is a fundamental domain

pillowcase: flat SU(2) connections on T^2

Figure T3.33: The moduli space of flat SU(2) connections on a torus. Commuting holonomies are conjugated to $(e^{-2\pi i a_1 \sigma_3}, e^{-2\pi i a_2 \sigma_3})$ with (a_1, a_2) on a torus (left). The Weyl reflection $a \mapsto -a$ folds the torus in half and sews the edges, giving a sphere with four singular corners (right). The corners, marked in red, are the four flat connections with central holonomy, where the stabiliser jumps to all of SU(2).

Try it: Flat connections on $\mathbb{RP}^3$ and on S^3

(a) $\pi_1(S^3) = 0$. What are the flat SU(2) connections on S^3? (b) $\pi_1(\mathbb{RP}^3) = \mathbb{Z}_2$. Classify flat SU(2) connections on $\mathbb{RP}^3$.
Answer: (a) Only $A = 0$ up to gauge: the trivial representation. (b) A homomorphism $\mathbb{Z}_2 \to \mathrm{SU}(2)$ sends the generator to U with $U^2 = \mathbb{1}$. In SU(2) the only such elements are $\pm\mathbb{1}$ (an element $\cos\alpha + i \sin\alpha\, \hat{n} \cdot \vec{\sigma}$ squares to $\mathbb{1}$ only for $\alpha \in \{0, \pi\}$). So there are exactly two flat connections, both with central holonomy. The non-trivial one is the "$-\mathbb{1}$ around the non-contractible loop" connection, the gauge-theory cousin of the spin-$\frac{1}{2}$ sign of Section T3.4.5.

Reading Nash (flat connections in Nash)

Nash meets flat connections three times. In the monopole chapter, energy $E = \frac{1}{2}(\|F\|^2 + \|d_A\phi\|^2) = 0$ forces $F = 0$, and he remarks that the connection's "only departure from triviality lies in its holonomy, which relies on $\pi_1(M)$ to be non-vanishing" [Nash p. 244, (8.150)–(8.151)]: that is our (T3.83). In Floer theory the critical points of the Chern–Simons function are the flat connections, identified with $\mathrm{Hom}(\pi_1(M), \mathrm{SU}(2))/\mathrm{Ad}\,\mathrm{SU}(2)$ [Nash p. 325, (12.8)–(12.10)]; on a homology 3-sphere they are automatically irreducible, because a reducible one would give an abelian representation of π_1, which factors through $H_1(M;\mathbb{Z}) = 0$. And in Chern–Simons theory the semiclassical expansion of the partition function is a sum over flat connections [Nash pp. 346–348].

T3.10.3 The Chern–Simons form: $\mathrm{tr}\, F \wedge F = \mathrm{d}\, CS$

Consider the 4-form $\mathrm{tr}(F \wedge F)$. It has two properties that make it special.

- *Gauge invariant:* $\mathrm{tr}(g^{-1}Fg \wedge g^{-1}Fg) = \mathrm{tr}(g^{-1}F \wedge F\, g) = \mathrm{tr}(F \wedge F)$.

- *Closed:* $\mathrm{d}\,\mathrm{tr}(F\wedge F) = \mathrm{tr}(\mathrm{d}F\wedge F)+\mathrm{tr}(F\wedge \mathrm{d}F) = 2\,\mathrm{tr}(\mathrm{d}F\wedge F)$, and by Bianchi $\mathrm{d}F = F\wedge A - A\wedge F$, so $\mathrm{d}\,\mathrm{tr}(F^2) = 2\,\mathrm{tr}(FAF - AF^2) = 0$, since $\mathrm{tr}(FAF) = \mathrm{tr}(AF^2)$ by (T3.79) (move the 2-form F at the front to the back, past the 3-form AF: sign $(-1)^{2\cdot 3} = +1$).

Closed forms are locally exact (Poincaré lemma, Chapter T2). So there should be a 3-form whose derivative is $\mathrm{tr}\,F\wedge F$. In the abelian case it is easy to guess, since $F = \mathrm{d}A$:

$$F\wedge F = \mathrm{d}A\wedge \mathrm{d}A = \mathrm{d}(A\wedge \mathrm{d}A).$$

For non-abelian A we need a correction cubic in A.

Key idea: the Chern–Simons 3-form

For any $\mathfrak{g}$-valued 1-form A with curvature $F = \mathrm{d}A + A\wedge A$,

$$CS(A) := \mathrm{tr}\Big(A\wedge \mathrm{d}A + \tfrac{2}{3}\,A\wedge A\wedge A\Big) \qquad \text{satisfies} \qquad \mathrm{d}\,CS(A) = \mathrm{tr}(F\wedge F). \tag{T3.84}$$

Equivalently $CS(A) = \mathrm{tr}\big(A\wedge F - \tfrac{1}{3}A\wedge A\wedge A\big)$.

Derivation, line by line. First expand the right-hand side:

$$\begin{aligned}\mathrm{tr}(F\wedge F) &\overset{(1)}{=} \mathrm{tr}\big((\mathrm{d}A + A^2)\wedge(\mathrm{d}A + A^2)\big)\\ &\overset{(2)}{=} \mathrm{tr}(\mathrm{d}A\,\mathrm{d}A) + \mathrm{tr}(\mathrm{d}A\,A^2) + \mathrm{tr}(A^2\,\mathrm{d}A) + \mathrm{tr}(A^4)\\ &\overset{(3)}{=} \mathrm{tr}(\mathrm{d}A\,\mathrm{d}A) + 2\,\mathrm{tr}(\mathrm{d}A\,A^2).\end{aligned} \tag{T3.85}$$

(1) Definition of F.
(2) Multiply out, keeping the order of the factors.
(3) $\mathrm{tr}(A^2\mathrm{d}A) = \mathrm{tr}(\mathrm{d}A\,A^2)$ by (T3.79) with $p = q = 2$; and $\mathrm{tr}(A^4) = 0$ since $A^4 = A\wedge A^3$ and $\mathrm{tr}(A\wedge A^3) = (-1)^{1\cdot 3}\,\mathrm{tr}(A^3\wedge A) = -\,\mathrm{tr}(A^4)$.

Now differentiate the two terms of CS separately:

$$\mathrm{d}\,\mathrm{tr}(A\,\mathrm{d}A) \overset{(1)}{=} \mathrm{tr}(\mathrm{d}A\,\mathrm{d}A) - \mathrm{tr}(A\,\mathrm{d}\mathrm{d}A) \overset{(2)}{=} \mathrm{tr}(\mathrm{d}A\,\mathrm{d}A), \tag{T3.86}$$

$$\begin{aligned}\mathrm{d}\,\mathrm{tr}(A^3) &\overset{(3)}{=} \mathrm{tr}(\mathrm{d}A\,A^2) - \mathrm{tr}(A\,\mathrm{d}A\,A) + \mathrm{tr}(A^2\,\mathrm{d}A)\\ &\overset{(4)}{=} \mathrm{tr}(\mathrm{d}A\,A^2) + \mathrm{tr}(\mathrm{d}A\,A^2) + \mathrm{tr}(\mathrm{d}A\,A^2) = 3\,\mathrm{tr}(\mathrm{d}A\,A^2).\end{aligned} \tag{T3.87}$$

(1) Leibniz rule $\mathrm{d}(\alpha\wedge\beta) = \mathrm{d}\alpha\wedge\beta + (-1)^p\alpha\wedge\mathrm{d}\beta$ with $\alpha = A$ a 1-form; d commutes with the trace.
(2) $\mathrm{dd} = 0$.
(3) Leibniz on the triple product: the sign alternates each time d passes a 1-form.
(4) Middle term: $\mathrm{tr}(A\wedge(\mathrm{d}A\,A)) = (-1)^{1\cdot 3}\,\mathrm{tr}(\mathrm{d}A\,A\wedge A)$, so $-\,\mathrm{tr}(A\,\mathrm{d}A\,A) = +\,\mathrm{tr}(\mathrm{d}A\,A^2)$. Last term: move the 2-form A^2 past the 2-form $\mathrm{d}A$, no sign.

Putting them together,

$$\mathrm{d}\,CS(A) \overset{(1)}{=} \mathrm{tr}(\mathrm{d}A\,\mathrm{d}A) + \tfrac{2}{3}\cdot 3\,\mathrm{tr}(\mathrm{d}A\,A^2) \overset{(2)}{=} \mathrm{tr}(F\wedge F).$$

(1) (T3.86) and (T3.87).
(2) Compare with (T3.85).

The coefficient $\frac{2}{3}$ is forced: it is the only number that makes the $\mathrm{tr}(\mathrm{d}A\,A^2)$ terms match. The alternative form follows from $\mathrm{tr}(A\,\mathrm{d}A) = \mathrm{tr}(A(F - A^2)) = \mathrm{tr}(AF) - \mathrm{tr}(A^3)$, so $CS = \mathrm{tr}(AF) - \mathrm{tr}\,A^3 + \frac{2}{3}\,\mathrm{tr}\,A^3 = \mathrm{tr}(AF) - \frac{1}{3}\,\mathrm{tr}\,A^3$.

In components. On a 3-manifold with coordinates x^1, x^2, x^3, write $A = A_\mu \mathrm{d}x^\mu$ and use $\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu \wedge \mathrm{d}x^\rho = \varepsilon^{\mu\nu\rho}\,\mathrm{d}^3x$:

$$CS(A) \overset{(1)}{=} \operatorname{tr}\big(A_\mu \partial_\nu A_\rho + \tfrac{2}{3} A_\mu A_\nu A_\rho\big)\,\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu \wedge \mathrm{d}x^\rho$$
$$\overset{(2)}{=} \varepsilon^{\mu\nu\rho}\,\operatorname{tr}\Big(A_\mu \partial_\nu A_\rho + \tfrac{2}{3} A_\mu A_\nu A_\rho\Big)\,\mathrm{d}^3x. \tag{T3.88}$$

(1) $\mathrm{d}A = \partial_\nu A_\rho\,\mathrm{d}x^\nu \wedge \mathrm{d}x^\rho$; the matrix coefficients stay in order.
(2) The wedge of three coordinate differentials is $\varepsilon^{\mu\nu\rho}$ times the coordinate volume form.

This is the form found in the physics literature, e.g. as the Lagrangian of 2+1-dimensional Chern–Simons theory. Note what is *missing*: there is no metric anywhere, no $\star$, no $g_{\mu\nu}$. This is why Chern–Simons theory is topological.

Worked example T3.49: CS for SU(2) in components

Write $A = A^a T_a$ with $T_a = -\frac{i}{2}\sigma_a$, so $\operatorname{tr}(T_a T_b) = -\frac{1}{2}\delta_{ab}$ and $\operatorname{tr}(T_a[T_b, T_c]) = -\frac{1}{2}\varepsilon_{abc}$ (computed before (T3.42)). Then

$$\operatorname{tr}(A \wedge \mathrm{d}A) \overset{(1)}{=} A^a \wedge \mathrm{d}A^b\ \operatorname{tr}(T_a T_b) = -\tfrac{1}{2}\,A^a \wedge \mathrm{d}A^a,$$
$$\operatorname{tr}(A \wedge A \wedge A) \overset{(2)}{=} -\tfrac{1}{4}\,\varepsilon_{abc}\,A^a \wedge A^b \wedge A^c = -\tfrac{3}{2}\,A^1 \wedge A^2 \wedge A^3,$$
$$CS(A) \overset{(3)}{=} -\tfrac{1}{2}\Big(A^a \wedge \mathrm{d}A^a + \tfrac{1}{3}\varepsilon_{abc}\,A^a \wedge A^b \wedge A^c\Big) = -\tfrac{1}{2}A^a \wedge \mathrm{d}A^a - A^1 \wedge A^2 \wedge A^3.$$

(1) Scalar 1-forms come out of the trace.
(2) Exactly the computation (T3.42) with θ replaced by A.
(3) $\frac{2}{3}\cdot(-\frac{1}{4}) = -\frac{1}{6} = -\frac{1}{2}\cdot\frac{1}{3}$; and $\varepsilon_{abc}A^aA^bA^c = 6A^1A^2A^3$.

In physicists' Hermitian variables ($A^a = -g_{\mathrm{YM}}\mathcal{A}^a$, see Section T3.8.9) this is, up to normalisation, $\mathcal{A}^a \wedge \mathrm{d}\mathcal{A}^a + \frac{g}{3}\varepsilon_{abc}\mathcal{A}^a\mathcal{A}^b\mathcal{A}^c$, the form in which it is usually quoted.

Worked example T3.50: CS of a pure-gauge field is the winding density

Put $A = \theta = g^{-1}\mathrm{d}g$. Then $F = 0$ by (T3.81), and

$$CS(\theta) \overset{(1)}{=} \operatorname{tr}\big(\theta \wedge F - \tfrac{1}{3}\theta^3\big) \overset{(2)}{=} -\tfrac{1}{3}\operatorname{tr}\big(g^{-1}\mathrm{d}g\big)^3. \tag{T3.89}$$

(1) The alternative form of (T3.84).
(2) $F(\theta) = 0$.

So on pure-gauge configurations the Chern–Simons form *is* the winding-number density of (T3.44), up to a constant. Integrating over a 3-sphere and using $\int \operatorname{tr}(g^{-1}\mathrm{d}g)^3 = -24\pi^2 w(g)$:

$$\frac{1}{8\pi^2}\int_{S^3} CS\big(g^{-1}\mathrm{d}g\big) = \frac{1}{8\pi^2}\cdot\Big(-\frac{1}{3}\Big)\cdot\big(-24\pi^2\,w(g)\big) = w(g). \tag{T3.90}$$

For the identity map of SU(2) (the Maurer–Cartan form on the group itself), $\frac{1}{8\pi^2}\int CS = 1$. The normalisation $\frac{1}{8\pi^2}$ is the one that makes Chern–Simons integrals integers on pure-gauge fields.

T3.10.4 Transgression: where the Chern–Simons form comes from

Guessing the $\frac{2}{3}$ worked, but it does not generalise. Nash uses a systematic construction, **transgression**, that produces a Chern–Simons form for any invariant polynomial [Nash p. 224,

(8.41)–(8.42)]. The idea is to switch the connection on gradually.

Let $A_t = tA$ for $t \in [0,1]$, interpolating between $A_0 = 0$ and $A_1 = A$. Its curvature is

$$F_t = \mathrm{d}(tA) + tA \wedge tA = t\,\mathrm{d}A + t^2 A \wedge A, \tag{T3.91}$$

Nash's (8.41). At $t = 0$, $F_0 = 0$; at $t = 1$, $F_1 = F$. So

$$\operatorname{tr}(F \wedge F) = \int_0^1 \frac{\mathrm{d}}{\mathrm{d}t} \operatorname{tr}(F_t \wedge F_t)\,\mathrm{d}t.$$

We compute the integrand. First, the t-derivative of F_t is the covariant derivative of A with respect to the connection A_t:

$$\frac{\mathrm{d}F_t}{\mathrm{d}t} \overset{(1)}{=} \mathrm{d}A + 2t\,A \wedge A \overset{(2)}{=} \mathrm{d}A + A_t \wedge A + A \wedge A_t \overset{(3)}{=} D_t A, \tag{T3.92}$$

(1) Differentiate (T3.91).
(2) $A_t = tA$, so $A_t \wedge A + A \wedge A_t = 2tA \wedge A$.
(3) $D_t\omega = \mathrm{d}\omega + A_t \wedge \omega - (-1)^p \omega \wedge A_t$ is the covariant derivative (T3.60) built from A_t; for the 1-form $\omega = A$ the sign is $+$.

Second, the trace of a covariant derivative against F_t is an ordinary derivative, because of Bianchi. For any $\mathfrak{g}$-valued 1-form a and any connection B with curvature F_B,

$$\begin{aligned}
\mathrm{d}\operatorname{tr}(a \wedge F_B) &\overset{(1)}{=} \operatorname{tr}(\mathrm{d}a \wedge F_B) - \operatorname{tr}(a \wedge \mathrm{d}F_B) \\
&\overset{(2)}{=} \operatorname{tr}(\mathrm{d}a \wedge F_B) - \operatorname{tr}(a \wedge F_B \wedge B) + \operatorname{tr}(a \wedge B \wedge F_B) \\
&\overset{(3)}{=} \operatorname{tr}(\mathrm{d}a \wedge F_B) + \operatorname{tr}(B \wedge a \wedge F_B) + \operatorname{tr}(a \wedge B \wedge F_B) \\
&\overset{(4)}{=} \operatorname{tr}\big(D_B a \wedge F_B\big).
\end{aligned} \tag{T3.93}$$

(1) Leibniz rule; a is a 1-form.
(2) Bianchi identity $\mathrm{d}F_B = F_B \wedge B - B \wedge F_B$ (T3.61).
(3) Move the 1-form B from the back to the front past the 3-form $a \wedge F_B$: sign $(-1)^3 = -1$.
(4) $D_B a = \mathrm{d}a + B \wedge a + a \wedge B$.

Now put the pieces together:

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}t} \operatorname{tr}(F_t \wedge F_t) &\overset{(1)}{=} 2 \operatorname{tr}\Big(\frac{\mathrm{d}F_t}{\mathrm{d}t} \wedge F_t\Big) \overset{(2)}{=} 2 \operatorname{tr}\big(D_t A \wedge F_t\big) \overset{(3)}{=} 2\,\mathrm{d}\operatorname{tr}\big(A \wedge F_t\big), \\
\operatorname{tr}(F \wedge F) &\overset{(4)}{=} \mathrm{d}\Big[\,2\int_0^1 \operatorname{tr}(A \wedge F_t)\,\mathrm{d}t\,\Big].
\end{aligned} \tag{T3.94}$$

(1) Product rule; the two terms are equal because 2-forms commute inside the trace, (T3.79) with $p = q = 2$.
(2) (T3.92).
(3) (T3.93) with $a = A$, $B = A_t$.
(4) Integrate over t from 0 to 1 (with $F_0 = 0$) and pull d, which acts on x only, outside the t-integral.

The bracket is the Chern–Simons form. Evaluating the t-integral:

$$2\int_0^1 \operatorname{tr}(A \wedge F_t)\,\mathrm{d}t \overset{(1)}{=} 2\int_0^1 \big(t\,\operatorname{tr}(A\,\mathrm{d}A) + t^2 \operatorname{tr}(A^3)\big)\mathrm{d}t \overset{(2)}{=} \operatorname{tr}(A\,\mathrm{d}A) + \tfrac{2}{3}\operatorname{tr}(A^3) = CS(A).$$

(1) (T3.91).
(2) $\int_0^1 2t\,\mathrm{d}t = 1$, $\int_0^1 2t^2\,\mathrm{d}t = \frac{2}{3}$.

The mysterious $\frac{2}{3}$ is $\int_0^1 2t^2\,\mathrm{d}t$.

Working definition T3.25 (transgression formula)

For an invariant polynomial P_j of degree j (symmetric, multilinear in j matrix arguments, and invariant under simultaneous conjugation [replacing every argument X by gXg^{-1} with the same g], such as $P_2(X,Y) = \mathrm{tr}(XY)$ or $P_3(X,Y,Z) = \frac{1}{2}\,\mathrm{tr}(X\{Y,Z\})$) set

$$TP_j(A) = j\int_0^1 P_j\big(A, F_t, \dots, F_t\big)\,\mathrm{d}t, \qquad F_t = t\,\mathrm{d}A + t^2 A\wedge A \tag{T3.95}$$

[F_t is the curvature of the scaled connection tA]. Then $\mathrm{d}\,TP_j(A) = P_j(F,\dots,F)$ [Nash (8.42)]. *How to use it:* substitute F_t, expand in powers of t, integrate each power. TP_2 with $P_2 = \mathrm{tr}$ is $CS(A)$.

The proof is the one just given: $\frac{\mathrm{d}}{\mathrm{d}t}P_j(F_t,\dots,F_t) = j\,P_j(D_tA, F_t,\dots,F_t)$ by symmetry, and invariance plus Bianchi turn $P_j(D_tA,F_t,\dots)$ into $\mathrm{d}P_j(A,F_t,\dots)$.

Worked example T3.51: The five-dimensional Chern–Simons form

In six dimensions the relevant invariant is $\mathrm{tr}(F\wedge F\wedge F)$; its Chern–Simons form governs anomalies of four-dimensional chiral fermions (Chapter 10). By (T3.95) with $j=3$:

$$\begin{aligned} CS_5(A) &\overset{(1)}{=} 3\int_0^1 \mathrm{tr}\big(A\wedge F_t\wedge F_t\big)\mathrm{d}t \\ &\overset{(2)}{=} 3\int_0^1 \Big[t^2\,\mathrm{tr}\big(A(\mathrm{d}A)^2\big) + t^3\,\mathrm{tr}\big(A\,\mathrm{d}A\,A^2 + A^3\,\mathrm{d}A\big) + t^4\,\mathrm{tr}(A^5)\Big]\mathrm{d}t \\ &\overset{(3)}{=} \mathrm{tr}\big(A(\mathrm{d}A)^2\big) + \tfrac{3}{4}\cdot 2\,\mathrm{tr}\big(A^3\,\mathrm{d}A\big) + \tfrac{3}{5}\,\mathrm{tr}(A^5) \\ &= \mathrm{tr}\Big(A(\mathrm{d}A)^2 + \tfrac{3}{2}A^3\,\mathrm{d}A + \tfrac{3}{5}A^5\Big). \end{aligned}$$

(1) Transgression with $P_3(X,Y,Z)$ symmetrised; for $\mathrm{tr}(AF_tF_t)$ the symmetrisation is automatic because the two F_t are equal.
(2) $F_t^2 = t^2(\mathrm{d}A)^2 + t^3(\mathrm{d}A\,A^2 + A^2\,\mathrm{d}A) + t^4A^4$.
(3) $\int_0^1 3t^2 = 1$, $\int_0^1 3t^3 = \frac{3}{4}$, $\int_0^1 3t^4 = \frac{3}{5}$; and $\mathrm{tr}(A\,\mathrm{d}A\,A^2) = \mathrm{tr}(A^2\,A\,\mathrm{d}A) = \mathrm{tr}(A^3\mathrm{d}A)$ by moving the 2-form A^2 from the back to the front past a 4-form (no sign).

So $\mathrm{d}\,CS_5 = \mathrm{tr}\,F^3$. Checking this directly takes a page of algebra; the transgression formula does it for us.

Chern–Weil: characteristic classes do not depend on the connection. The same computation with $A_t = A_0 + t(A_1 - A_0)$ interpolating between two arbitrary connections (each A_t is again a connection, because the difference $A_1 - A_0$ transforms homogeneously, $a \mapsto g^{-1}ag$: the inhomogeneous terms $g^{-1}\mathrm{d}g$ cancel) gives, with $a = A_1 - A_0$ and $\frac{\mathrm{d}F_t}{\mathrm{d}t} = D_t a$,

$$\mathrm{tr}(F_1\wedge F_1) - \mathrm{tr}(F_0\wedge F_0) = \mathrm{d}\Big[2\int_0^1 \mathrm{tr}\big(a\wedge F_t\big)\mathrm{d}t\Big]. \tag{T3.96}$$

The difference of the two 4-forms is exact. On a closed 4-manifold its integral vanishes by Stokes, so $\int_M \operatorname{tr} F\wedge F$ is the same for *every* connection on a given bundle: it is a topological invariant of the bundle, a characteristic number (Chapter 1). The Chern–Simons form is the special case $A_0 = 0$, which is available only where the bundle is trivial, i.e. locally, or on all of $\mathbb{R}^4$.

Reading Nash (secondary characteristic classes, pp. 223–224)

Nash's §8.2 is this subsection in general form. He writes a characteristic class as an invariant polynomial, $c_j(F) = P_j(F,\dots,F)$ [Nash (8.40)]; he pulls it back to the total space P of the bundle, where it becomes exact, $\pi^* c_j(F) = \mathrm{d}\,TP_j(A)$, with TP_j given by (T3.95) using $A_t = tA$, $F_t = t\,\mathrm{d}A + t^2 A\wedge A$ [Nash (8.41)–(8.42)]. (Working on P is the mathematicians' way of saying "in a local trivialisation, where $A_0 = 0$ makes sense".) If $c_j(F)$ happens to vanish as a form, then $\mathrm{d}\,TP_j(A) = 0$ and TP_j defines a cohomology class of odd degree, a **secondary characteristic class** [Nash (8.43)–(8.45)]; it is only defined modulo integers on the base, because changing gauge shifts it by an integral class, as we compute next. With $P_2(F) = -\frac{1}{8\pi^2}\operatorname{tr}(F\wedge F)$ he obtains $TP_2(A) = -\frac{1}{8\pi^2}\operatorname{tr}(A\wedge \mathrm{d}A + \frac{2}{3}A\wedge A\wedge A)$ [Nash (8.61)], which is $-\frac{1}{8\pi^2}CS(A)$ in our notation. The same transgression with $j=3$, pulled back to the gauge group, gives his formula for the generator μ_1 of $H^1(\mathcal{G})$ [Nash (8.56)–(8.58)], which is the anomaly (Chapter 10).

Watch out: the sign of P_2

With the Chern class convention $c(F) = \det\!\left(\mathbb{1} + \frac{i}{2\pi}F\right)$ of this book, $c_2(F) = \frac{1}{8\pi^2}\left[\operatorname{tr}(F\wedge F) - \operatorname{tr}F\wedge \operatorname{tr}F\right]$, which for $\mathfrak{su}(N)$ ($\operatorname{tr}F = 0$) is $+\frac{1}{8\pi^2}\operatorname{tr}(F\wedge F)$. Nash's (8.61) writes $P_2(F) = -\frac{1}{8\pi^2}\operatorname{tr}(F\wedge F)$ for $\mathrm{SU}(N)$. The overall sign is a convention (it flips with the orientation, or with the sign of i in $c(F)$) and does not affect anything in this section except the sign of the integer. The structure $\operatorname{tr}(A\,\mathrm{d}A + \frac{2}{3}A^3)$ is the same in every convention.

T3.10.5 How the Chern–Simons form changes under a gauge transformation

$\operatorname{tr}F\wedge F$ is gauge invariant, but $CS(A)$ is built from A itself and is not. Since $\mathrm{d}\,CS(A^g) = \operatorname{tr}F^g\wedge F^g = \operatorname{tr}F\wedge F = \mathrm{d}\,CS(A)$, the difference $CS(A^g) - CS(A)$ is a *closed* 3-form. We now compute it exactly. Write

$$A^g = \tilde{A} + \theta, \qquad \tilde{A} := g^{-1}Ag, \qquad \theta := g^{-1}\mathrm{d}g, \qquad \rho := \mathrm{d}g\,g^{-1},$$

so that $F^g = g^{-1}Fg =: \tilde{F}$, and note two facts about the right-invariant form ρ: it is θ conjugated, $\theta = g^{-1}\rho\,g$, and it obeys the structure equation with the opposite sign,

$$\mathrm{d}\rho = -\mathrm{d}g\wedge \mathrm{d}(g^{-1}) = \mathrm{d}g\wedge g^{-1}\mathrm{d}g\,g^{-1} = \rho\wedge\rho. \tag{T3.97}$$

Then, using the alternative form $CS = \operatorname{tr}(AF) - \frac{1}{3}\operatorname{tr}A^3$,

$$\begin{aligned}
CS(A^g) &\overset{(1)}{=} \operatorname{tr}\big((\tilde{A}+\theta)\tilde{F}\big) - \tfrac{1}{3}\operatorname{tr}(\tilde{A}+\theta)^3 \\
&\overset{(2)}{=} \operatorname{tr}(AF) + \operatorname{tr}(\rho F) - \tfrac{1}{3}\Big[\operatorname{tr}A^3 + 3\operatorname{tr}(A^2\rho) + 3\operatorname{tr}(A\rho^2) + \operatorname{tr}\theta^3\Big] \\
&\overset{(3)}{=} CS(A) + \operatorname{tr}(\rho F) - \operatorname{tr}(A^2\rho) - \operatorname{tr}(A\rho^2) - \tfrac{1}{3}\operatorname{tr}\theta^3 \\
&\overset{(4)}{=} CS(A) + \operatorname{tr}(\rho\,\mathrm{d}A) - \operatorname{tr}(A\rho^2) - \tfrac{1}{3}\operatorname{tr}\theta^3 \\
&\overset{(5)}{=} CS(A) - \mathrm{d}\operatorname{tr}(\rho\wedge A) - \tfrac{1}{3}\operatorname{tr}\theta^3.
\end{aligned} \tag{T3.98}$$

(1) Definition, with $A^g = \tilde{A} + \theta$ and $F^g = \tilde{F}$.
(2) Conjugation drops out of traces: $\operatorname{tr}(\tilde{A}\tilde{F}) = \operatorname{tr}(AF)$. Also $\operatorname{tr}(\theta\tilde{F}) = \operatorname{tr}(g^{-1}\mathrm{d}g\, g^{-1}Fg) = \operatorname{tr}(\mathrm{d}g\, g^{-1}F) = \operatorname{tr}(\rho F)$. In the cube, the three terms with two $\tilde{A}$'s and one θ are equal by cyclicity of three 1-forms, and $\operatorname{tr}(\tilde{A}^2\theta) = \operatorname{tr}(g^{-1}A^2g\, g^{-1}\mathrm{d}g) = \operatorname{tr}(A^2\rho)$; likewise the three terms with one $\tilde{A}$ give $3\operatorname{tr}(\tilde{A}\theta^2) = 3\operatorname{tr}(A\rho^2)$.
(3) Collect $\operatorname{tr}(AF) - \frac{1}{3}\operatorname{tr}A^3 = CS(A)$.
(4) $\operatorname{tr}(\rho F) = \operatorname{tr}(\rho\,\mathrm{d}A) + \operatorname{tr}(\rho A^2)$ and $\operatorname{tr}(\rho A^2) = \operatorname{tr}(A^2\rho)$ (a 1-form past a 2-form, no sign).
(5) $\mathrm{d}\operatorname{tr}(\rho\wedge A) = \operatorname{tr}(\mathrm{d}\rho\wedge A) - \operatorname{tr}(\rho\wedge \mathrm{d}A) = \operatorname{tr}(\rho^2A) - \operatorname{tr}(\rho\,\mathrm{d}A)$ by (T3.97), and $\operatorname{tr}(\rho^2A) = \operatorname{tr}(A\rho^2)$.

Key idea: gauge variation of the Chern–Simons form

$$CS(A^g) = CS(A) - \mathrm{d}\operatorname{tr}\big(\mathrm{d}g\, g^{-1}\wedge A\big) - \tfrac{1}{3}\operatorname{tr}\big(g^{-1}\mathrm{d}g\big)^3. \tag{T3.99}$$

The change is an exact term plus the winding density. On a closed oriented 3-manifold M the exact term integrates to zero, and by (T3.90)

$$\frac{1}{8\pi^2}\int_M CS(A^g) = \frac{1}{8\pi^2}\int_M CS(A) + w(g), \qquad w(g)\in\mathbb{Z}. \tag{T3.100}$$

So $\frac{1}{8\pi^2}\int_M CS(A)$ is gauge invariant *modulo integers*: it is a well-defined element of $\mathbb{R}/\mathbb{Z}$ on the space of gauge orbits.

Two special cases are worth isolating.

- $A = 0$. Then $A^g = \theta$ and (T3.99) gives $CS(\theta) = -\frac{1}{3}\operatorname{tr}\theta^3$, which is (T3.89) again.
- *Small gauge transformations.* Put $g = e^{\varepsilon X}$ with $X(x)\in\mathfrak{g}$. Then $\rho = \varepsilon\,\mathrm{d}X + O(\varepsilon^2)$ and $\operatorname{tr}\theta^3 = O(\varepsilon^3)$, so to first order

$$\delta_X CS(A) = -\varepsilon\,\mathrm{d}\operatorname{tr}(\mathrm{d}X\wedge A) = \varepsilon\,\mathrm{d}\operatorname{tr}(X\,\mathrm{d}A), \tag{T3.101}$$

where the last step uses $\operatorname{tr}(\mathrm{d}X\wedge A) = \mathrm{d}\operatorname{tr}(XA) - \operatorname{tr}(X\mathrm{d}A)$ and $\mathrm{dd} = 0$. The change is exact, and $\int_M CS$ is invariant under every gauge transformation that can be reached from the identity: $w(e^{\varepsilon X}) = 0$.

The general variation. For the equations of motion we need the change of CS under an arbitrary small change $A\to A+\delta A$:

$$\begin{aligned}\delta\, CS(A) &\overset{(1)}{=} \operatorname{tr}(\delta A\,\mathrm{d}A) + \operatorname{tr}(A\,\mathrm{d}\delta A) + \tfrac{2}{3}\cdot 3\operatorname{tr}(\delta A\, A^2)\\ &\overset{(2)}{=} \operatorname{tr}(\delta A\,\mathrm{d}A) + \operatorname{tr}(\delta A\,\mathrm{d}A) - \mathrm{d}\operatorname{tr}(A\wedge\delta A) + 2\operatorname{tr}(\delta A\, A^2)\\ &\overset{(3)}{=} 2\operatorname{tr}(\delta A\wedge F) - \mathrm{d}\operatorname{tr}(A\wedge\delta A).\end{aligned} \tag{T3.102}$$

(1) Vary each factor; the three variations of $\operatorname{tr}A^3$ are equal by cyclicity of three 1-forms.
(2) $\mathrm{d}\operatorname{tr}(A\wedge\delta A) = \operatorname{tr}(\mathrm{d}A\,\delta A) - \operatorname{tr}(A\,\mathrm{d}\delta A)$. So $\operatorname{tr}(A\,\mathrm{d}\delta A) = \operatorname{tr}(\mathrm{d}A\,\delta A) - \mathrm{d}\operatorname{tr}(A\,\delta A)$, and $\operatorname{tr}(\mathrm{d}A\,\delta A) = \operatorname{tr}(\delta A\,\mathrm{d}A)$.
(3) $\mathrm{d}A + A^2 = F$.

(For $\delta A = DX$ one can check that this reproduces (T3.101), using $\operatorname{tr}(DX\wedge F) = \mathrm{d}\operatorname{tr}(XF)$, which is Bianchi again.)

T3.10.6 The instanton number is a winding number

Here is the payoff. Consider a gauge field on $\mathbb{R}^4$ with finite action. Finite action needs $F \to 0$ at infinity faster than $1/r^2$, so on a large 3-sphere S^3_R the field is *flat*, and since S^3 is simply connected it is *pure gauge* there:

$$A \xrightarrow{r\to\infty} g^{-1}\mathrm{d}g, \qquad g : S^3_\infty \to G.$$

The map g is a map from a 3-sphere to the group, and it has a winding number $w(g) \in \pi_3(G) = \mathbb{Z}$.

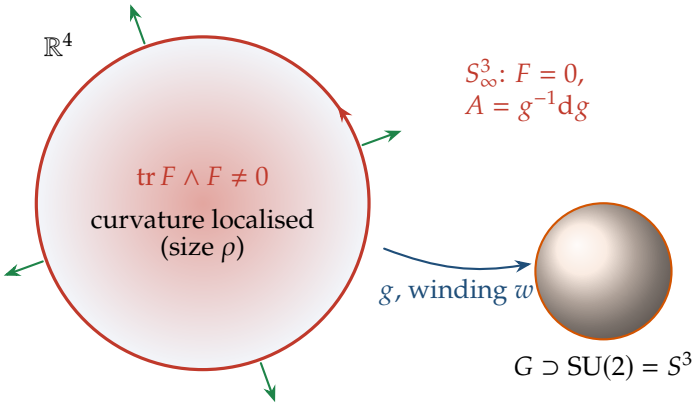


Figure T3.34: An instanton on $\mathbb{R}^4$. The action density (red) is concentrated in a region of size ρ. Far away the field is pure gauge, $A = g^{-1}\mathrm{d}g$, so it defines a map g from the 3-sphere at infinity to the group. Stokes' theorem converts $\int \mathrm{tr}\, F \wedge F$ over the whole of $\mathbb{R}^4$ into $\int CS$ over this sphere, where CS is the winding density of g.

Key idea: instanton number = winding at infinity

With $\mathbb{R}^4$ oriented by $\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4$ and S^3_∞ oriented as its boundary (outward normal first),

$$k := \frac{1}{8\pi^2}\int_{\mathbb{R}^4} \mathrm{tr}(F \wedge F) = w(g) \in \mathbb{Z}. \tag{T3.103}$$

The derivation is four lines:

$$\int_{\mathbb{R}^4} \mathrm{tr}(F\wedge F) \overset{(1)}{=} \lim_{R\to\infty}\int_{B_R} \mathrm{d}\,CS(A) \overset{(2)}{=} \lim_{R\to\infty}\int_{S^3_R} CS(A)$$
$$\overset{(3)}{=} \int_{S^3_\infty} CS\big(g^{-1}\mathrm{d}g\big) \overset{(4)}{=} 8\pi^2\, w(g).$$

(1) $\mathrm{tr}\, F \wedge F = \mathrm{d}\, CS(A)$ (T3.84); on $\mathbb{R}^4$ the gauge field is a single globally defined 1-form, so $CS(A)$ is defined everywhere. B_R is the ball of radius R.
(2) Stokes' theorem.
(3) On S^3_R, $A = g^{-1}\mathrm{d}g + o(1/R)$; CS is cubic in A and its derivatives, which are $O(1/R)$ and $O(1/R^2)$, while the area of S^3_R grows like R^3, so the corrections vanish in the limit.
(4) (T3.90).

This is the exemplar argument of the style guide again, one level up: the integral of an exact form sees only the boundary, and on the boundary the field is pure gauge and carries only topological information. The integrality $\int \mathrm{tr}\, F \wedge F \in 8\pi^2\mathbb{Z}$ quoted in the QFT notes [QFT notes (4.13.13)] is exactly this.

Worked example T3.52: Every radial ansatz has $k = 1$

Let $g(x) = (x^4\mathbb{1} + i\vec{x}\cdot\vec{\sigma})/r$, the winding-one map of Example T3.27, and $\theta = g^{-1}\mathrm{d}g$. Since g depends only on the direction x/r, θ has no $\mathrm{d}r$ component. Take

$$A = f(r)\,\theta, \qquad f(0) = 0, \quad f(\infty) = 1,$$

with f smooth and $f \sim r^2$ near 0 (so that A, which behaves like f/r times a smooth angular form, is smooth at the origin). Then:

$$\begin{aligned} F &\overset{(1)}{=} \mathrm{d}f\wedge\theta + f\,\mathrm{d}\theta + f^2\theta\wedge\theta \overset{(2)}{=} f'\,\mathrm{d}r\wedge\theta + (f^2 - f)\,\theta^2, \\ \operatorname{tr}(F\wedge F) &\overset{(3)}{=} (f^2-f)f'\left[\operatorname{tr}(\mathrm{d}r\wedge\theta\wedge\theta^2) + \operatorname{tr}(\theta^2\wedge\mathrm{d}r\wedge\theta)\right] + (f^2-f)^2\operatorname{tr}\theta^4 \\ &\overset{(4)}{=} 2(f^2-f)f'\,\mathrm{d}r\wedge\operatorname{tr}\theta^3. \end{aligned}$$

(1) $\mathrm{d}(f\theta) = \mathrm{d}f\wedge\theta + f\,\mathrm{d}\theta$, and $A\wedge A = f^2\theta^2$.
(2) $\mathrm{d}f = f'\mathrm{d}r$ and the structure equation $\mathrm{d}\theta = -\theta^2$.
(3) Expand the square; the term $(f'\mathrm{d}r\wedge\theta)^2$ vanishes because it contains $\mathrm{d}r\wedge\mathrm{d}r = 0$.
(4) $\operatorname{tr}\theta^4 = 0$ (graded cyclicity); $\theta^2\wedge\mathrm{d}r = \mathrm{d}r\wedge\theta^2$ (a 2-form commutes with a 1-form), so both cross terms equal $\mathrm{d}r\wedge\operatorname{tr}\theta^3$.

Now integrate, using $\mathbb{R}^4\setminus\{0\} = (0,\infty)\times S^3$ with orientation $\mathrm{d}r\wedge$ (boundary orientation of S^3):

$$\begin{aligned} \int_{\mathbb{R}^4}\operatorname{tr}(F\wedge F) &\overset{(1)}{=} \int_0^\infty 2(f^2-f)f'\,\mathrm{d}r\int_{S^3}\operatorname{tr}\theta^3 \overset{(2)}{=} \left[\tfrac{2}{3}f^3 - f^2\right]_{f=0}^{f=1}\cdot(-24\pi^2) \\ &= \left(-\tfrac{1}{3}\right)(-24\pi^2) = 8\pi^2. \end{aligned}$$

(1) Fubini; the S^3 factor is the same on every sphere since θ depends only on the direction.
(2) Substitute $u = f(r)$: $\int(2u^2-2u)\,\mathrm{d}u$; and $\int_{S^3}\operatorname{tr}\theta^3 = -24\pi^2 w(g) = -24\pi^2$ (T3.43).

So $k = 1$, for *every* profile f. The shape of f decides where the topological charge density sits (Figure T3.35), but not how much there is. The choice $f = r^2/(r^2+\rho^2)$ is the one for which F is (anti-)self-dual and the action is minimal, $S = 8\pi^2/g_{\mathrm{YM}}^2$: the BPST instanton of Chapter 8 in "regular gauge". Check with (T3.103): at infinity $A\to\theta$ with $w = 1$. Also check the CS form directly: $CS(f\theta) = \operatorname{tr}\big(f\theta(f'\mathrm{d}r\wedge\theta - f\theta^2)\big) + \frac{2}{3}f^3\operatorname{tr}\theta^3 = (\frac{2}{3}f^3 - f^2)\operatorname{tr}\theta^3$ (the $\mathrm{d}r$ term is $-ff'\mathrm{d}r\wedge\operatorname{tr}\theta^2 = 0$), which at $f = 1$ is $-\frac{1}{3}\operatorname{tr}\theta^3$, as it must be.

Watch out: which sign of duality has $k > 0$?

In Example T3.38 we found $S_{\mathrm{YM}} \geq \mp\int\operatorname{tr}F\wedge F$ with equality iff $F = \pm\star F$. With our conventions ($\operatorname{tr}(X^2)\leq 0$ for anti-Hermitian X, and $k = \frac{1}{8\pi^2}\int\operatorname{tr}F\wedge F$), a self-dual field has $\int\operatorname{tr}F\wedge F = \int\operatorname{tr}F\wedge\star F = -g_{\mathrm{YM}}^2 S \leq 0$, i.e. $k\leq 0$; the fields with $k > 0$ that saturate the bound are anti-self-dual. Many books define $k = -\frac{1}{8\pi^2}\int\operatorname{tr}F\wedge F$ (or use the opposite orientation) so that instantons are self-dual with $k > 0$. Nothing physical depends on this, but it is the most common source of stray minus signs. Always check one example, such as Example T3.52.

The same argument on S^4: transition functions. On the compact S^4 a gauge field with $k\neq 0$ cannot be written as a single globally defined 1-form (if it could, $k = \frac{1}{8\pi^2}\int_{S^4}\mathrm{d}\,CS = 0$

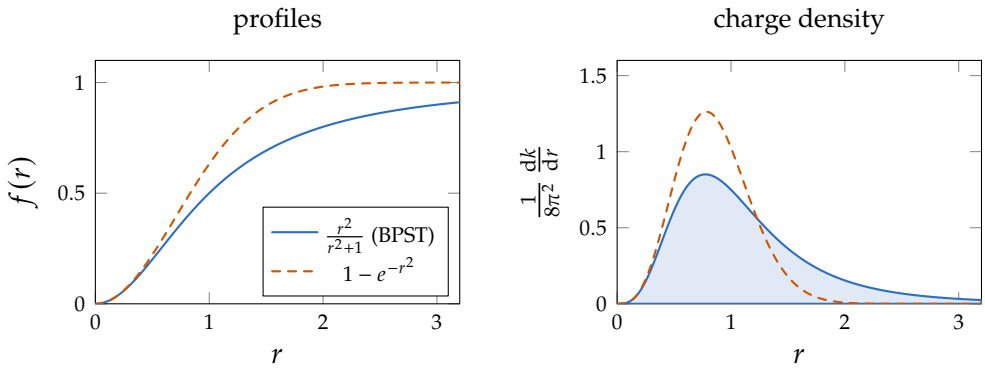

Figure T3.35: Two radial profiles $f(r)$ (left) and the corresponding radial density of topological charge $6(f-f^2)f'$ (right; the $\frac{1}{8\pi^2}$ and the S^3 integral are included). The curves have different shapes but both enclose area exactly 1: the charge is fixed by $f(0)=0$, $f(\infty)=1$ and the winding of θ, not by the details.

by Stokes). Instead, as for the monopole of Example T3.37, we use two patches: A_N on the northern hemisphere D_N and A_S on the southern D_S, glued on the equator S^3 by a transition function, $A_N = A_S^g = g^{-1}A_S g + g^{-1}\mathrm{d}g$. Then

$$\int_{S^4} \operatorname{tr} F\wedge F \overset{(1)}{=} \int_{D_N} \mathrm{d}\,CS(A_N) + \int_{D_S} \mathrm{d}\,CS(A_S) \overset{(2)}{=} \int_{S^3}\big[CS(A_N) - CS(A_S)\big]$$
$$\overset{(3)}{=} \int_{S^3}\Big[-\mathrm{d}\operatorname{tr}(\mathrm{d}g\,g^{-1}\wedge A_S) - \tfrac{1}{3}\operatorname{tr}(g^{-1}\mathrm{d}g)^3\Big] \overset{(4)}{=} 8\pi^2\, w(g).$$

(1) Split the sphere; on each hemisphere A is a genuine 1-form, so $\operatorname{tr}F\wedge F = \mathrm{d}\,CS$ there.
(2) Stokes on each hemisphere; the equator is the boundary of both, with opposite orientations. We orient S^3 as ∂D_N.
(3) (T3.99) with $A = A_S$.
(4) The exact term integrates to zero on the closed S^3; (T3.90) for the rest.

So *the instanton number is the winding number of the transition function on the equator*, exactly as the monopole charge was the winding of the U(1) transition function $e^{-i\phi}$ on the equator of S^2. On $\mathbb{R}^4$ the "southern patch" is the point at infinity, and g is the gauge transformation at infinity. This is the statement, used throughout Chapter 8, that SU(2) bundles over S^4 are classified by $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$, with $k = c_2$ up to sign.

T3.10.7 Chern–Simons number and the vacua of Yang–Mills theory

The same identity has a Hamiltonian reading. Split Euclidean $\mathbb{R}^4$ into time and space, $\mathbb{R}_t\times\mathbb{R}^3$, oriented by $\mathrm{d}t\wedge\mathrm{d}^3x$, and consider the slab $[-T,T]\times\mathbb{R}^3$. Suppose $A\to 0$ fast enough at spatial infinity that the sides of the slab contribute nothing. Define the **Chern–Simons number** of a spatial configuration

$$N_{\mathrm{CS}}[A] \coloneqq \frac{1}{8\pi^2}\int_{\mathbb{R}^3} CS(A). \tag{T3.104}$$

Then Stokes' theorem on the slab gives (the top face has the orientation d^3x, the bottom face the opposite)

$$k = \frac{1}{8\pi^2}\int_{[-T,T]\times\mathbb{R}^3} \operatorname{tr}F\wedge F = N_{\mathrm{CS}}[A(T)] - N_{\mathrm{CS}}[A(-T)]. \tag{T3.105}$$

The instanton number is the change in Chern–Simons number.

Now look at the classical vacua, the spatial configurations with zero energy: $F = 0$ on $\mathbb{R}^3$, hence $A = h^{-1}\mathrm{d}h$ with $h : \mathbb{R}^3 \to G$. If we require $h \to \mathbb{1}$ at spatial infinity, h is a map from $\mathbb{R}^3 \cup \{\infty\} = S^3$ to G, and by (T3.90)

$$N_{\mathrm{CS}}\left[h^{-1}\mathrm{d}h\right] = w(h) \in \mathbb{Z}.$$

So there is not one classical vacuum but a whole $\mathbb{Z}$'s worth, $|n\rangle$ with $N_{\mathrm{CS}} = n$, related by the large gauge transformations of Example T3.27. They cannot be connected by a path of zero-energy configurations, because N_{CS} is an integer on vacua and changes continuously along a path. A path from $|n\rangle$ to $|n+1\rangle$ must climb over an energy barrier, and in Euclidean time the tunnelling event is an instanton with $k = 1$ (Figure T3.36). Its amplitude is suppressed by $e^{-S} = e^{-8\pi^2/g_{\mathrm{YM}}^2}$ [QFT notes (4.13.14)]: invisible in perturbation theory, but not zero.

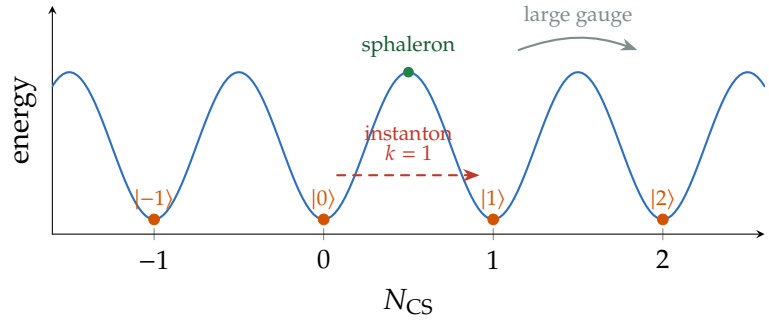

Figure T3.36: Schematic energy of static gauge fields as a function of the Chern–Simons number. The classical vacua (orange) sit at the integers and are pure gauge, $A = h^{-1}\mathrm{d}h$ with winding $w(h) = N_{\mathrm{CS}}$; large gauge transformations shift between them. An instanton is the Euclidean tunnelling path from $|n\rangle$ to $|n+k\rangle$ under the barrier; the lowest point on the barrier (green) is the sphaleron. (Energy is not literally a function of N_{CS} alone: the picture is a one-dimensional slice.)

Physical picture: θ-vacua in one paragraph

Because the large gauge transformation U maps $|n\rangle \to |n+1\rangle$ and commutes with the Hamiltonian, the true energy eigenstates are its eigenstates, the Bloch-wave combinations $|\vartheta\rangle = \sum_n e^{in\vartheta}|n\rangle$, exactly as for an electron in a periodic potential. The angle ϑ is a new parameter of the theory. In the Euclidean path integral it appears as a weight $e^{i\vartheta k}$ for each sector of instanton number k, i.e. as an extra term $\frac{i\vartheta}{8\pi^2}\int \mathrm{tr}\, F \wedge F$ in the exponent, which is a total derivative and so invisible in the classical equations of motion. The analogous statement in electroweak theory, combined with the anomaly (Chapter 10), is that baryon number changes by the number of generations times ΔN_{CS}.

T3.10.8 The Chern–Simons action in three dimensions

In three dimensions $CS(A)$ is a 3-form, so it can be integrated over the spacetime itself. Witten's Chern–Simons theory, the subject of the last part of Nash (Chapter 12), takes it as the entire action. In Nash's normalisation the path-integral weight is [Nash p. 343, (12.85)]

$$e^{iS_k[A]}, \qquad S_k[A] = -\frac{k}{4\pi}\int_M \mathrm{tr}\left(A \wedge \mathrm{d}A + \tfrac{2}{3}A \wedge A \wedge A\right) = -\frac{k}{4\pi}\int_M CS(A), \tag{T3.106}$$

with M a closed oriented 3-manifold and k a constant, the **level**.

The level is quantised. Under a gauge transformation g, (T3.100) gives

$$S_k[A^g] \overset{(1)}{=} -\frac{k}{4\pi}\Big(\int_M CS(A) + 8\pi^2 w(g)\Big) = S_k[A] - 2\pi k\, w(g),$$
$$e^{iS_k[A^g]} \overset{(2)}{=} e^{iS_k[A]}\, e^{-2\pi i\, k\, w(g)}.$$

(1) (T3.100).
(2) Exponentiate.

The action itself is not gauge invariant, but the weight is, for every g, if and only if

$$k \in \mathbb{Z}.$$

(On S^3 there are maps g with $w(g) = 1$, so the condition is necessary.) This is the first example of a phenomenon we will meet again: a quantum theory can be consistent even though its classical action is not invariant, provided the non-invariance is an integer multiple of 2π. Nash's version for the topologically massive theory of Deser–Jackiw–Templeton and Schonfeld is the action

$$S = \|F\|^2 + \alpha\, TP_2(A) = -\operatorname{tr}\int_M \Big\{F\wedge\star F + \frac{\alpha}{8\pi^2}\Big(\mathrm{d}A\wedge A + \tfrac{2}{3}A\wedge A\wedge A\Big)\Big\}$$

[Nash p. 227, (8.60)–(8.62)], with $TP_2(A) = -\frac{1}{8\pi^2}CS(A)$. Under g, $\alpha\int TP_2$ shifts by $-\alpha\, w(g)$, so e^{iS} is gauge invariant iff $\alpha \in 2\pi\mathbb{Z}$, his quantisation condition. (Note $\operatorname{tr}(\mathrm{d}A\wedge A) = \operatorname{tr}(A\wedge \mathrm{d}A)$.) The Chern–Simons term gives the gauge field a mass without a Higgs field, and the mass is quantised in units set by the Yang–Mills coupling; this is why the $\pi_0(\mathcal{G}) = \pi_3(G) = \mathbb{Z}$ of [Nash (8.59)] has physical consequences.

Physicists' normalisation. With the dictionary $A = -i\mathcal{A}$ of Section T3.8.9 (coupling absorbed into $\mathcal{A}$),

$$CS(A) \overset{(1)}{=} \operatorname{tr}\big((-i)^2\mathcal{A}\,\mathrm{d}\mathcal{A} + \tfrac{2}{3}(-i)^3\mathcal{A}^3\big) \overset{(2)}{=} -\operatorname{tr}\Big(\mathcal{A}\,\mathrm{d}\mathcal{A} - \tfrac{2i}{3}\mathcal{A}^3\Big),$$

(1) Substitute; the factors of $-i$ are scalars.
(2) $(-i)^2 = -1$ and $(-i)^3 = i$.

so $S_k = \frac{k}{4\pi}\int \operatorname{tr}(\mathcal{A}\,\mathrm{d}\mathcal{A} - \frac{2i}{3}\mathcal{A}^3)$, the form in which Witten writes it, with Hermitian $\mathcal{A}$ and tr in the fundamental.

The equations of motion are flatness. Vary $A \to A + \delta A$ in (T3.106). By (T3.102) the exact term integrates to zero on the closed M, and

$$\delta S_k = -\frac{k}{4\pi}\int_M 2\operatorname{tr}(\delta A\wedge F) = -\frac{k}{2\pi}\int_M \operatorname{tr}(\delta A\wedge F).$$

This vanishes for every δA iff $F = 0$. *The classical solutions of Chern–Simons theory are the flat connections*, which by (T3.83) are the representations of $\pi_1(M)$ in G. There are no propagating degrees of freedom; everything is topological. The same computation is Nash's derivation that the critical points of the Chern–Simons function $f(A) = -\frac{1}{8\pi^2}\int_M CS(A)$ used in Floer theory are the flat connections: $\delta f = -\frac{1}{4\pi^2}\int_M \operatorname{tr}(\delta A\wedge F)$, i.e. "$\mathrm{d}f(A) = -F(A)/4\pi^2$" [Nash p. 324–325, (12.4)–(12.8)], and $f(A^g) = f(A) - w(g)$ is his (12.5).

Key idea: why Chern–Simons theory is topological

The action (T3.106) is built from d, $\wedge$ and tr only. None of these uses a metric. So the classical theory, and (with care about the gauge fixing, which does need a metric and leaves a framing dependence) the quantum theory, depend only on the topology of M and of any Wilson loops inserted in it. The Wilson loop expectation values are knot invariants.

Worked example T3.53: Abelian Chern–Simons: magnetic helicity and linking

For $G = \mathrm{U}(1)$ write $A = ia$ with a a real 1-form (the electromagnetic potential, $b = \mathrm{d}a$ the magnetic field 2-form). Then $A \wedge A = 0$ and

$$CS(A) = (i)^2\, a \wedge \mathrm{d}a = -a \wedge \mathrm{d}a, \qquad \int_{\mathbb{R}^3} a \wedge \mathrm{d}a = \int \vec{a} \cdot \vec{b}\, \mathrm{d}^3x =: H,$$

the **magnetic helicity** of plasma physics. Its value for two thin, closed, untwisted flux tubes along curves C_1, C_2 carrying fluxes Φ_1, Φ_2 (Figure T3.37) is

$$H \overset{(1)}{=} \int_{\mathbb{R}^3} a \wedge b \overset{(2)}{=} \Phi_1 \oint_{C_1} a + \Phi_2 \oint_{C_2} a \overset{(3)}{=} \Phi_1 \int_{\Sigma_1} b + \Phi_2 \int_{\Sigma_2} b$$
$$\overset{(4)}{=} \Phi_1\, \Phi_2\, \mathrm{Lk}(C_1, C_2) + \Phi_2\, \Phi_1\, \mathrm{Lk}(C_2, C_1) \overset{(5)}{=} 2\, \Phi_1 \Phi_2\, \mathrm{Lk}(C_1, C_2).$$

(1) $b = \mathrm{d}a$.
(2) For a thin tube along C with flux Φ (field pointing along C), $\int \alpha \wedge b = \Phi \oint_C \alpha$ for any 1-form α: in local coordinates with C along z, $b = \Phi\, \delta^2(x, y)\, \mathrm{d}x \wedge \mathrm{d}y$ and $\alpha \wedge b = \Phi\, \alpha_z\, \delta^2(x, y)\, \mathrm{d}^3x$.
(3) Stokes, with Σ_i a surface bounded by C_i (a Seifert surface).
(4) The flux through Σ_1 comes only from tube 2, which pierces Σ_1 a net $\mathrm{Lk}(C_1, C_2)$ times; tube 1 contributes nothing because it is untwisted (its own field lines do not cross Σ_1).
(5) The linking number is symmetric.

So the Chern–Simons integral of a pair of flux tubes counts how many times they link. The linking number has Gauss's integral formula [Nash p. 344, (12.90)]

$$\mathrm{Lk}(C_1, C_2) = \frac{1}{4\pi} \oint_{C_1} \mathrm{d}x^i \oint_{C_2} \mathrm{d}y^j\, \varepsilon_{ijk} \frac{(x - y)^k}{|x - y|^3},$$

which is the Biot–Savart law: $\oint_{C_1} a$ with a the potential of a unit current along C_2. In the U(1) Chern–Simons path integral with Wilson lines $W = e^{in \oint_C a}$, the Gaussian integral over a produces exactly this double integral, and Nash obtains $\langle W(n_1, C_1) \cdots \rangle = \exp\left[\frac{i\pi}{k} \sum n_l n_m \mathrm{Lk}(C_l, C_m)\right]$ [Nash (12.92)]: a knot invariant computed by a quantum field theory. The self-linking terms $l = m$ need a framing ("untwisted" above), which is the framing dependence mentioned in the key idea.

T3.10.9 Descent: a preview of anomalies

Look again at the chain of identities we have derived:

$$\mathrm{tr}(F \wedge F) = \mathrm{d}\, CS(A),$$
$$\delta_X CS(A) = \mathrm{d}\ \mathrm{tr}(X\, \mathrm{d}A) \qquad (\text{with } \varepsilon = 1). \tag{T3.107}$$

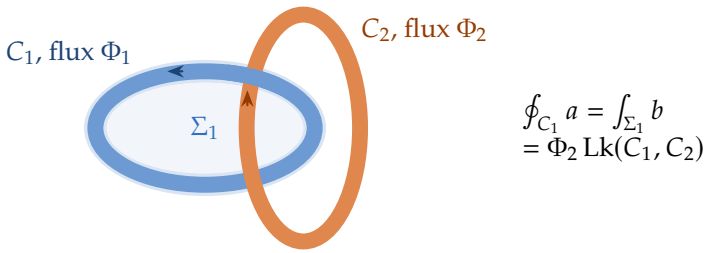

Figure T3.37: Two linked flux tubes (a Hopf link). Tube 2 (orange) threads the surface Σ_1 spanning tube 1 (blue) once, so the circulation of the vector potential around C_1 is Φ_2. The magnetic helicity $\int a \wedge \mathrm{d}a$, the abelian Chern–Simons integral, is $2\Phi_1\Phi_2\,\mathrm{Lk}(C_1, C_2)$.

A gauge-invariant closed 4-form determines a 3-form, which is not gauge invariant; its gauge variation is exact and determines a 2-form linear in the gauge parameter X. Writing $\omega_4 = \operatorname{tr} F^2$, $\omega_3 = CS$, $\omega_2^1 = \operatorname{tr}(X\mathrm{d}A)$,

$$\omega_4 = \mathrm{d}\omega_3, \qquad \delta_X \omega_3 = \mathrm{d}\omega_2^1.$$

These are the first two of the **descent equations**. Their importance is this. In Chapter 10 we will find that a chiral fermion in two dimensions, coupled to A, has an effective action $\Gamma[A]$ that fails to be gauge invariant, and that the failure is

$$\delta_X \Gamma[A] \;\propto\; \int_{M^2} \operatorname{tr}(X\,\mathrm{d}A) = \int_{M^2} \omega_2^1,$$

the bottom of the descent from $\operatorname{tr} F^2$ in four dimensions. Because ω_2^1 comes from descent, it automatically satisfies the Wess–Zumino consistency condition (two successive gauge variations commute in the right way). In four dimensions the same construction starts from $\operatorname{tr} F^3$ in six dimensions: $\operatorname{tr} F^3 = \mathrm{d}\,CS_5$ (Example T3.51), and the variation of CS_5 is $\mathrm{d}\omega_4^1$ with $\omega_4^1 = \operatorname{tr}\big(X\,\mathrm{d}(A\,\mathrm{d}A + \tfrac{1}{2}A^3)\big)$ (a standard result which we quote here and derive in Chapter 10). That 4-form is the non-abelian anomaly, and Nash's μ_1 of [Nash (8.58)] is the same object seen as a cohomology class on the gauge group.

Try it: Abelian descent

For $G = \mathrm{U}(1)$, check (T3.107) directly: $CS = A \wedge \mathrm{d}A$, and under $A \to A + \mathrm{d}X$ (with X imaginary), $\delta CS = \mathrm{d}X \wedge \mathrm{d}A = \mathrm{d}(X\,\mathrm{d}A)$.
Answer: $\delta(A \wedge \mathrm{d}A) = \mathrm{d}X \wedge \mathrm{d}A + A \wedge \mathrm{d}\mathrm{d}X = \mathrm{d}X \wedge \mathrm{d}A$, and $\mathrm{d}(X\mathrm{d}A) = \mathrm{d}X \wedge \mathrm{d}A + X\,\mathrm{d}\mathrm{d}A = \mathrm{d}X \wedge \mathrm{d}A$. In two dimensions this gives the abelian anomaly $\propto \int X\,F$, the $\epsilon^{\mu\nu}F_{\mu\nu}$ of the Schwinger model [QFT notes Ch. 22].

Reading Nash (the Chern–Simons form throughout Nash)

The Chern–Simons form appears in Nash in five guises, all covered in this section. (i) As the transgression $TP_2(A)$ of the second Chern class, $\operatorname{tr} F \wedge F = \mathrm{d}(\cdots)$ [Nash pp. 223–224, (8.39)–(8.45)], with $A_t = tA$, $F_t = t\,\mathrm{d}A + t^2 A \wedge A$ [Nash (8.41)]; our (T3.94). (ii) As an $\mathbb{R}/\mathbb{Z}$-valued secondary class, because a gauge transformation shifts it by an integer [Nash (8.45)]; our (T3.100). (iii) As a term in the 3D gauge theory action with quantised coefficient [Nash p. 227, (8.59)–(8.62)]. (iv) As the Morse function of Floer theory, whose critical points are flat connections [Nash pp. 324–325, (12.4)–(12.10)]. (v) As the action of Witten's topological field theory, whose Wilson-loop correlators give linking numbers and the Jones polynomial [Nash pp. 342–348, (12.84)–(12.94)]. Nash also writes the instanton number as $\frac{1}{8\pi^2}\int \operatorname{tr} F \wedge F$ and uses $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$ to classify SU(2) bundles on S^4 and the components of the 3D gauge group; our (T3.103) and its two-patch version are the reason these are the same

integer.

Recap

- Pure gauge $A = g^{-1}\mathrm{d}g$: $F = 0$ is the Maurer–Cartan equation; transport $W_\gamma = g(b)^{-1}g(a)$, trivial holonomy.
- Flat $\Rightarrow$ locally pure gauge (integrability of $\mathrm{d}g = gA$ is $F = 0$; construct g by parallel transport). Globally, flat connections up to gauge = $\mathrm{Hom}(\pi_1(M), G)$/conjugation. Circle: conjugacy classes ($\mathbb{R}/\mathbb{Z}$ for U(1), $[0, \frac{1}{2}]$ for SU(2)); torus: commuting pairs, the pillowcase.
- $CS(A) = \mathrm{tr}(A\,\mathrm{d}A + \frac{2}{3}A^3) = \mathrm{tr}(AF - \frac{1}{3}A^3)$, $\mathrm{d}\,CS = \mathrm{tr}\,F \wedge F$; transgression $CS = 2\int_0^1 \mathrm{tr}(A \wedge F_t)\,\mathrm{d}t$, $\frac{2}{3} = \int_0^1 2t^2$; $CS_5 = \mathrm{tr}(A(\mathrm{d}A)^2 + \frac{3}{2}A^3\mathrm{d}A + \frac{3}{5}A^5)$; Chern–Weil.
- $CS(A^g) = CS(A) - \mathrm{d}\,\mathrm{tr}(\mathrm{d}g\,g^{-1}A) - \frac{1}{3}\,\mathrm{tr}(g^{-1}\mathrm{d}g)^3$; $\frac{1}{8\pi^2}\int_{M^3} CS$ shifts by $w(g) \in \mathbb{Z}$; infinitesimally $\delta CS = \mathrm{d}\,\mathrm{tr}(X\mathrm{d}A)$; general variation $2\,\mathrm{tr}(\delta A\,F)$+exact.
- $k = \frac{1}{8\pi^2}\int_{\mathbb{R}^4} \mathrm{tr}\,F \wedge F = w(g_\infty)$; every radial ansatz $f\,\theta$ has $k = 1$; on S^4, $k = w$(transition function); $k = \Delta N_{\mathrm{CS}}$, vacua $|n\rangle$, ϑ-vacua.
- 3D Chern–Simons action $-\frac{k}{4\pi}\int CS$: level $k \in \mathbb{Z}$, equations of motion $F = 0$, metric independent; abelian case = helicity = $2\Phi_1\Phi_2\mathrm{Lk}$.
- Descent $\mathrm{tr}\,F^2 \to CS \to \mathrm{tr}(X\mathrm{d}A)$: the seed of the anomaly.

Chapter summary

The chapter had one job: to take the physicist's two words "symmetry" and "gauge" and turn them into objects we can compute with. The first half built the symmetry side. A Lie group is a set of matrices closed under multiplication and cut out by smooth equations; its Lie algebra is the set of velocities at the identity, closed under the commutator; the exponential map goes back from the algebra to the group; and a representation lets the group act on the fields. The second half made the symmetry local. A field $g : M \to G$ has a derivative $g^{-1}\mathrm{d}g$ that lives in the Lie algebra. A covariant derivative needs a Lie-algebra-valued 1-form A that absorbs such terms, and the curvature of A is the field strength. Once there is a connection we can ask what it does around loops (holonomy, Wilson loops), when it is trivial (pure gauge versus flat), and how its topology is measured (the Chern–Simons form and the winding number).

The summary has four parts. Figures T3.38 and T3.39 put the two halves of the chapter on one page each. The concept tables (Tables T3.4 to T3.10) list every concept, what it means operationally, and where the rest of the book uses it. Table T3.11 collects the numbers worth knowing by heart. The chapter closes with the calculations a reader should be able to do without looking, and a map from Nash's pages back to the sections of this chapter.

The two halves on one page

Concept tables

In each table the last column says where the idea is used again. References to chapters are to the rest of the book; references to sections are to this chapter.

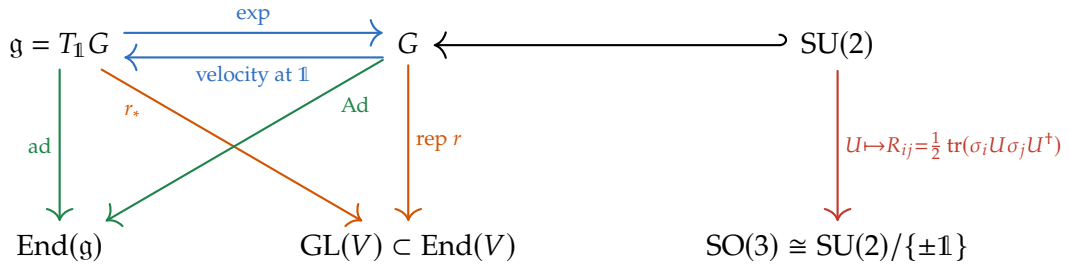

Figure T3.38: The algebraic half of the chapter. The exponential map (blue) goes from the Lie algebra to the group, and "velocity at the identity" comes back. A representation r of the group (orange) differentiates to a representation r_* of the algebra with the same structure constants. The group acts on its own algebra by $\mathrm{Ad}_g X = gXg^{-1}$ and the algebra by $\mathrm{ad}_Y X = [Y, X]$ (green). On the right is the most important example in physics: the adjoint representation of SU(2) is the double cover of SO(3) (red), with kernel $\pm\mathbb{1}$, which is why spin $\frac{1}{2}$ exists (Section T3.4).

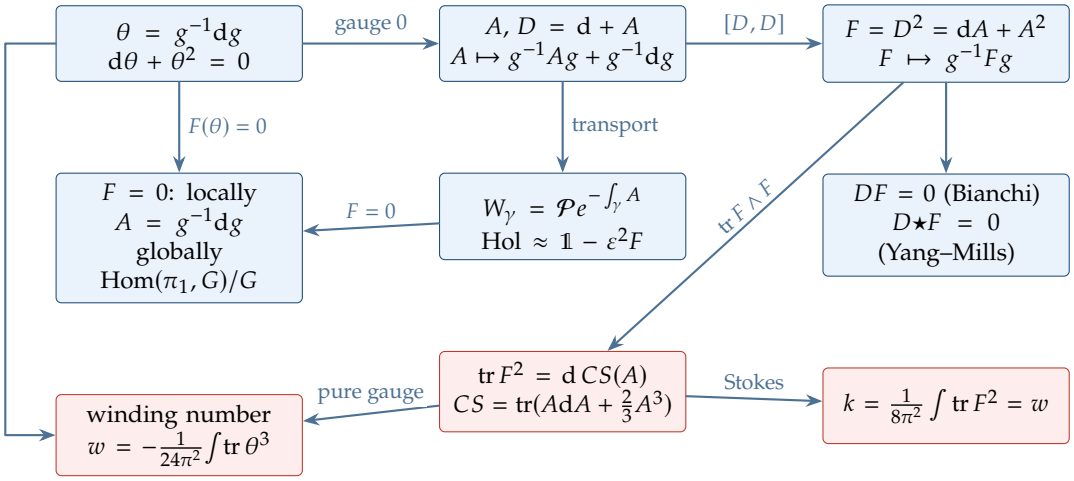

Figure T3.39: The geometric half of the chapter. The Maurer–Cartan form (top left) is what you get by gauge transforming $A = 0$; the gauge field A is its generalisation, and its curvature F is the commutator of covariant derivatives. Parallel transport measures F around small loops. When $F = 0$ only the topology of the loops is left. The red boxes are the topological numbers: the Chern–Simons form turns $\int \mathrm{tr}\,F \wedge F$ into a boundary term, which for a pure-gauge boundary is the winding number of g.

Concept	Operational meaning	Used later in
Matrix Lie group	A group of $n \times n$ matrices cut out by smooth equations ($R^T R = \mathbb{1}$, $U^\dagger U = \mathbb{1}$, $\det = 1, \dots$). Dimension = number of entries minus number of independent equations (Section T3.1).	Every gauge group; Chapters 6 and 8
Classical groups	$\mathrm{GL}(n)$, $\mathrm{SL}(n)$, $\mathrm{O}(n)$, $\mathrm{SO}(n)$, $\mathrm{U}(n)$, $\mathrm{SU}(n)$, $\mathrm{Sp}(n)$; test which equations a matrix satisfies (Table T3.1).	Structure groups of bundles, Chapters 1 and 4
$\mathrm{U}(1) = S^1$	$e^{i\alpha}$, $\alpha \sim \alpha + 2\pi$; the same as SO(2).	Electromagnetism, monopoles, Chapter 8
$\mathrm{SU}(2) = S^3$	$U = x^4\mathbb{1} + i\vec{x}\cdot\vec{\sigma}$ with $\sum x_\mu^2 = 1$ (T3.1); unit quaternions = Sp(1).	Instantons, $\pi_3 = \mathbb{Z}$, Chapter 8
$\mathrm{SO}(3) = \mathbb{RP}^3$	Ball of radius π (axis × angle) with antipodal surface points identified; $\mathrm{tr}\, R = 1 + 2\cos\theta$.	Spin, Chapter T4
Topological data	π_0 (components), π_1 (non-contractible loops), π_3 (winding of $S^3 \to G$) of each group (Table T3.2).	Instanton sectors, θ-vacua, anomalies

Table T3.4: Groups (Section T3.1).

Numbers worth knowing by heart

Group	dim	rank	π_1	π_3	$\mathfrak{g}$
U(1)	1	1	$\mathbb{Z}$	0	$i\mathbb{R}$
$\mathrm{SU}(2) = S^3$	3	1	0	$\mathbb{Z}$	traceless anti-Hermitian 2×2
$\mathrm{SO}(3) = \mathbb{RP}^3$	3	1	$\mathbb{Z}_2$	$\mathbb{Z}$	antisymmetric real 3×3
$\mathrm{SU}(N)$	N^2-1	$N-1$	0	$\mathbb{Z}$	traceless anti-Hermitian
$\mathrm{U}(N)$	N^2	N	$\mathbb{Z}$	$\mathbb{Z}$ $(N \geq 2)$	anti-Hermitian
$\mathrm{SO}(n)$, $n \geq 3$	$\frac{1}{2}n(n-1)$	$\lfloor n/2 \rfloor$	$\mathbb{Z}_2$	$\mathbb{Z}$ $(n \neq 4)$, $\mathbb{Z}^2$ $(n = 4)$	antisymmetric
$\mathrm{Sp}(n)$	$n(2n+1)$	n	0	$\mathbb{Z}$	quaternionic anti-Hermitian

Quantity	Value
$\mathfrak{su}(2)$ structure constants ($T_a = -\frac{i}{2}\sigma_a$)	$f_{abc} = \varepsilon_{abc}$
Killing form on $\mathfrak{su}(N)$	$B(X,Y) = 2N\,\mathrm{tr}(XY)$
Index and Casimirs of $\mathrm{SU}(N)$	$C(\mathbf{N}) = \frac{1}{2}$, $C_2(\mathbf{N}) = \frac{N^2-1}{2N}$, $C_2(\mathrm{adj}) = N$
Spin j	$\dim = 2j+1$, $C_2 = j(j+1)$
Volume of SU(2) in the metric $\sum(\theta^a)^2$	$16\pi^2$ (round S^3 of radius 2)
$\int_{\mathrm{SU}(2)} \mathrm{tr}(g^{-1}\mathrm{d}g)^3$	$-24\pi^2$
Instanton number normalisation	$k = \frac{1}{8\pi^2}\int \mathrm{tr}\, F \wedge F \in \mathbb{Z}$
Minimal instanton action	$S = 8\pi^2\lvert k\rvert/g_{\mathrm{YM}}^2$
Chern–Simons level	e^{iS_k} gauge invariant iff $k \in \mathbb{Z}$
Lattice coupling	$\beta = 2N/g_{\mathrm{YM}}^2$

Table T3.11: Dimensions, ranks and homotopy groups of the groups used in the book (top), and the constants that recur (bottom). The π_3 column is where instantons live: a finite-action field on $\mathbb{R}^4$ defines a map from S^3_∞ into G, and $\pi_3(G) = \mathbb{Z}$ is its winding number.

Concept	Operational meaning	Used later in
Lie algebra $\mathfrak{g}$	Linearise the defining equations at $\mathbb{1}$: write $g = \mathbb{1} + \varepsilon X$ and keep $O(\varepsilon)$. $\mathfrak{su}(n)$: traceless anti-Hermitian; $\mathfrak{so}(n)$: antisymmetric.	Values of gauge fields; Chapter 6
Commutator	$[X, Y] = XY - YX$, the $O(\varepsilon^2)$ part of the group commutator (T3.5); obeys Jacobi.	F contains $[A_\mu, A_\nu]$
Structure constants	$[T_a, T_b] = f_{ab}{}^c T_c$ (T3.6); for $\mathfrak{su}(2)$, $f_{abc} = \varepsilon_{abc}$.	Kac–Moody algebras, Chapter 6; $F^a_{\mu\nu}$
Maths vs physics generators	T_a anti-Hermitian, $J_a = iT_a$ Hermitian, $[J_a, J_b] = i f_{abc} J_c$ (Section T3.2.5).	Every comparison with QFT texts
Gell-Mann matrices	Eight Hermitian traceless 3×3 matrices, λ_3, λ_8 diagonal (Section T3.2.6).	QCD examples
Exponential map	$e^X = \sum X^k/k!$; e^{tX} solves $\dot{g} = Xg$; $\det e^X = e^{\operatorname{tr} X}$ (T3.14).	Gauge transformations $g = e^X$, path ordering
SU(2) exponential	$e^{-\frac{i\theta}{2}\hat{n}\cdot\vec{\sigma}} = \cos\frac{\theta}{2} - i \sin\frac{\theta}{2}\, \hat{n}\cdot\vec{\sigma}$ (T3.15); $\theta = 2\pi$ gives $-\mathbb{1}$.	Spinor sign under 2π, Chapter T4
Rodrigues formula	$e^{\theta K} = \mathbb{1} + \sin\theta\, K + (1 - \cos\theta) K^2$ for rotations (T3.17).	Explicit rotations
BCH	$e^X e^Y = e^{X+Y+\frac{1}{2}[X,Y]+\cdots}$ (T3.19): the bracket determines the product near $\mathbb{1}$.	Non-abelian Stokes, lattice
Ad, ad	$\mathrm{Ad}_g X = gXg^{-1}$; $\mathrm{ad}_Y X = [Y, X]$, matrix $(\mathrm{ad}_{T_a})_{cb} = f_{ab}{}^c$ (T3.21).	$F \mapsto g^{-1} F g$; adjoint bundle, Chapter 6
Killing form	$B(X, Y) = \operatorname{tr}(\mathrm{ad}_X \mathrm{ad}_Y) = 2N \operatorname{tr}(XY)$ on $\mathfrak{su}(N)$; invariant; negative definite $\Leftrightarrow$ compact semisimple (Section T3.4.3).	The metric in $\operatorname{tr} F \wedge \star F$
Double cover	$R_{ij} = \frac{1}{2}\operatorname{tr}(\sigma_i U \sigma_j U^\dagger)$ (T3.24); $2:1$, kernel $\pm\mathbb{1}$.	Spin groups, Chapter T4
$\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$	The 2π rotation lifts to a path from $\mathbb{1}$ to $-\mathbb{1}$; 4π is contractible (belt trick, Section T3.4.5).	Spin structures, Chapter T4

Table T3.5: Lie algebras, the exponential map and the adjoint representation (Sections T3.2 to T3.4).

Concept	Operational meaning	Used later in
Representation	Matrices $r(g)$ with $r(gh) = r(g)r(h)$; generators R_a satisfy the same commutation relations as T_a.	Matter fields, twisted Dirac operators, Chapter 4
Irreducible, Schur	No invariant subspace; anything commuting with every $r(g)$ is a multiple of $\mathbb{1}$. Hence Casimirs are numbers on a multiplet.	Peter–Weyl, Borel–Weil, Chapter 6
Tensor product, conjugate	Generators add, $R \otimes \mathbb{1} + \mathbb{1} \otimes R'$ (T3.27); conjugate generators $-R^*$ (or R^* in anti-Hermitian form).	Coupling of multiplets
Spin j	J_3 eigenvalues $m = -j, \dots, j$; ladders $J_\pm$ with $\|J_\pm \|j, m\rangle\|^2 = (j \mp m)(j \pm m + 1)$ (T3.29); explicit matrices (T3.30).	Angular momentum, index of Dirac on S^2
Cartan subalgebra, rank	A maximal set of commuting generators (diagonal ones); rank = how many (Section T3.5.3).	Maximal torus T, G/T
Weights	Simultaneous eigenvalues of the Cartan generators on a representation; plot them.	Borel–Weil, character formulae
Roots	Weights of the adjoint; root vectors are ladder operators $[H_i, E_\alpha] = \alpha_i E_\alpha$.	Kac–Moody, Chapter 6
SU(3) diagrams	**3** triangle, $\bar{\mathbf{3}}$ inverted triangle, adjoint hexagon plus two zeros (Figure T3.13).	Quark model; anomaly cancellation
Simple roots, Dynkin	$2(\alpha, \beta)/(\alpha, \alpha) \in \mathbb{Z}$ allows only $90°, 120°, 135°, 150°$; classify by diagrams (Figure T3.15).	Choice of gauge group
Casimir and index	$C_2(R)\mathbb{1} = \sum_a R_a R_a$, $\operatorname{tr} R_a R_b = C(R)\delta_{ab}$, $C_2(R) \dim R = C(R) \dim G$ (T3.32).	Anomaly coefficients, β-functions, Chapter 10

Table T3.6: Representations (Section T3.5).

Concept	Operational meaning	Used later in
Maurer–Cartan form	$\theta = g^{-1}\mathrm{d}g$: differentiate the group-valued field and carry the result back to $\mathbb{1}$; a $\mathfrak{g}$-valued 1-form.	Pure gauge fields; WZW models, Chapter 11
Left invariance	$(hg)^{-1}\mathrm{d}(hg) = g^{-1}\mathrm{d}g$ for constant h (T3.33); right translation rotates it by $\mathrm{Ad}_{h^{-1}}$.	Global vs local symmetry
Structure equation	$\mathrm{d}\theta + \theta \wedge \theta = 0$ (T3.36), from $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\, g^{-1}$; in components $\mathrm{d}\theta^a = -\frac{1}{2} f_{bc}{}^a \theta^b \wedge \theta^c$.	"Pure gauge is flat"
Euler-angle forms	Explicit θ^a on SU(2) (T3.40); metric $\sum(\theta^a)^2$ is the round S^3 of radius 2.	Instanton computations
Winding number	$w(g) = -\frac{1}{24\pi^2}\int_{S^3} \mathrm{tr}(g^{-1}\mathrm{d}g)^3 \in \mathbb{Z}$ (T3.44); U(1): $\frac{1}{2\pi i}\oint g^{-1}\mathrm{d}g$.	Instanton number, CS level, Chapters 8 and 12
Group action	A rule $x \mapsto g \cdot x$ with $\mathbb{1} \cdot x = x$, $g \cdot (h \cdot x) = (gh) \cdot x$.	Gauge group on $\mathcal{A}$, Chapter 6
Orbit, stabiliser	Everything x_0 can reach; everything fixing it. $G \cdot x_0 \cong G/H$, $\dim = \dim G - \dim H$.	Reducible connections, moduli singularities
Homogeneous spaces	$S^{n-1} = \mathrm{SO}(n)/\mathrm{SO}(n-1)$, $S^2 = \mathrm{SU}(2)/\mathrm{U}(1) = \mathbb{CP}^1$ (Hopf map (T3.45)), $\mathbb{CP}^n = \mathrm{SU}(n+1)/\mathrm{U}(n)$, flags G/T.	Borel–Weil, σ-models, Chapters 5 and 6
Free actions	Every stabiliser trivial; then $G \to X \to X/G$ is a principal bundle.	Principal bundles, Chapter 1

Table T3.7: The Maurer–Cartan form, group actions and homogeneous spaces (Sections T3.6 and T3.7).

Concept	Operational meaning	Used later in
Local symmetry	$\psi \mapsto g^{-1}(x)\psi$; then $\mathrm{d}\psi$ picks up $-g^{-1}\mathrm{d}g\, g^{-1}\psi$ (T3.47) and is no longer covariant.	Motivation for all gauge theory
Comparator	$U(y,x)$ transports the internal frame from x to y; expanding it gives A (T3.49).	Lattice links; Wilson lines
Connection A	$A = A^a_\mu T_a\,\mathrm{d}x^\mu$, a $\mathfrak{g}$-valued 1-form; $D = \mathrm{d} + A$ (T3.51).	Every Nash chapter from 6 on
Gauge law	$A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$ (T3.52); infinitesimally $\delta A = \mathrm{d}X + [A, X] = DX$ (T3.53).	Gauge orbits, Faddeev–Popov, BRST
Frame picture	A is the rate of rotation of a chosen basis; change of basis gives the same law (Section T3.8.4, after Dray).	Levi-Civita and spin connections, Chapters T2 and T4
Curvature F	$F = D^2 = \mathrm{d}A + A \wedge A$ (T3.56); $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + [A_\mu, A_\nu]$; $F \mapsto g^{-1}Fg$.	Characteristic classes, Chapters 4 and 8
Monopole connection	$A_N = \frac{i}{2}(1-\cos\vartheta)\mathrm{d}\phi$, $A_S = -\frac{i}{2}(1+\cos\vartheta)\mathrm{d}\phi$, glued by $e^{-i\phi}$; $c_1 = -1$.	Hopf bundle, index on S^2
Bianchi identity	$DF = \mathrm{d}F + [A, F] = 0$ (T3.61), automatic.	Closedness of $\operatorname{tr} F^k$
Yang–Mills	$S = -\frac{1}{g^2}\int \operatorname{tr} F \wedge \star F$ (T3.62); $D \star F = 0$ (T3.65); self-dual fields solve it.	Instantons, monopoles, Chapter 8
Dictionary	$A_{\text{math}} = -ig_{\text{YM}}\mathcal{A}^a R_a$, $V = g^{-1}$ (T3.66) (Section T3.8.9).	Comparing with the QFT notes

Table T3.8: Gauge fields (Section T3.8).

Concept	Operational meaning	Used later in
Parallel transport	Solve $\dot{W} = -A(\dot\gamma)W$, $W(0) = \mathbb{1}$ (T3.67); $W_\gamma = \mathcal{P}\exp(-\int_\gamma A)$ (T3.71), later points on the left.	Nash §8.1; holonomy of moduli
Gauge covariance	$W_\gamma \mapsto g(b)^{-1}W_\gamma\, g(a)$ (T3.74): only the endpoints feel the gauge.	Gauge-invariant observables
Holonomy, Wilson loop	Transport round a closed loop; $W_R(\gamma) = \operatorname{tr}_R \mathrm{Hol}_\gamma$ (T3.75) is gauge invariant.	Chern–Simons TQFT, knot invariants, Chapter 12
Holonomy group	All holonomies at a point; the connection is irreducible if it is all of G.	Smooth points of the moduli space
Small loops	$\mathrm{Hol} = \mathbb{1} - \varepsilon\delta F_{12} + \cdots$ (T3.76): curvature is holonomy per unit area.	Lattice action; flatness test
Aharonov–Bohm	$F = 0$ on the electron's region, holonomy $e^{\mp ie\Phi}$ (T3.78); needs a non-contractible loop.	Flat connections, Chapter 12
Berry phase	Holonomy of the monopole connection round a loop on S^2: $-\Omega/2$.	Geometric phases, anomalies
Lattice gauge theory	Links $U_{x,\mu} \in G$, $S_W = \beta\sum_p(1 - \frac{1}{N}\operatorname{Re}\operatorname{tr} U_p) \to S_{\text{YM}}$, $\beta = 2N/g^2_{\text{YM}}$ (Section T3.9.8).	Non-perturbative intuition

Table T3.9: Parallel transport, holonomy and Wilson loops (Section T3.9).

Concept	Operational meaning	Used later in
Pure gauge	$A = g^{-1}\mathrm{d}g$ (T3.80); $F = 0$ is the Maurer–Cartan equation; $W_\gamma = g(b)^{-1}g(a)$.	Vacua, boundary conditions at ∞
Flat connection	$F = 0$. Locally pure gauge (construct g by transport); globally classified by $\mathrm{Hom}(\pi_1(M), G)/G$ (T3.83).	Floer theory, CS theory, Chapter 12
Flat on S^1, T^2	Conjugacy classes of one holonomy (circle; interval $[0, \frac{1}{2}]$ for SU(2)); commuting pairs on T^2 (the pillowcase, Figure T3.33).	Moduli spaces, Chapter 12
Chern–Simons form	$CS(A) = \mathrm{tr}(A\,\mathrm{d}A + \frac{2}{3}A^3)$ with $\mathrm{d}\,CS = \mathrm{tr}\,F \wedge F$ (T3.84); check by expanding both sides.	Instantons, anomalies, TQFT
Transgression	$CS = 2\int_0^1 \mathrm{tr}(A \wedge F_t)\,\mathrm{d}t$ with $A_t = tA$ (T3.94); same recipe gives CS_5; Chern–Weil.	Nash (8.39)–(8.45); Chapter 10
Gauge variation of CS	$CS(A^g) = CS(A) - \mathrm{d}\,\mathrm{tr}(\mathrm{d}g\,g^{-1}A) - \frac{1}{3}\mathrm{tr}(g^{-1}\mathrm{d}g)^3$ (T3.99); $\frac{1}{8\pi^2}\int CS$ shifts by $w(g)$.	Level quantisation
Instanton number	$k = \frac{1}{8\pi^2}\int_{\mathbb{R}^4} \mathrm{tr}\,F \wedge F = w(g_\infty)$ (T3.103) (Stokes plus pure gauge at infinity).	Chapters 4 and 8
CS number, θ-vacua	N_{CS} labels classical vacua; $k = \Delta N_{\mathrm{CS}}$ (T3.105); $\lvert\vartheta\rangle = \sum e^{in\vartheta}\lvert n\rangle$.	Strong CP, baryon number violation
3D CS action	$S_k = -\frac{k}{4\pi}\int CS$ (T3.106); $k \in \mathbb{Z}$; field equations $F = 0$; no metric; abelian case = linking.	Witten's knot theory, Chapter 12
Descent	$\mathrm{tr}\,F^2 = \mathrm{d}\,CS$, $\delta_X CS = \mathrm{d}\,\mathrm{tr}(X\mathrm{d}A)$ (T3.107): the bottom form is the anomaly.	Chapter 10

Table T3.10: Pure gauge, flat connections and the Chern–Simons form (Section T3.10).

Calculations to be able to do without looking

A toolkit chapter has done its job when its core calculations become reflexes. These are the ones the rest of the book assumes.

1. *Exponentiate a Pauli matrix.* Use $(\hat{n}\cdot\vec{\sigma})^2 = \mathbb{1}$ to split the series into even and odd parts: $e^{-\frac{i\theta}{2}\hat{n}\cdot\vec{\sigma}} = \cos\frac{\theta}{2}\,\mathbb{1} - i\sin\frac{\theta}{2}\,\hat{n}\cdot\vec{\sigma}$ (Section T3.3.4).

2. *Build the rotation of a spinor matrix.* $R_{ij} = \frac{1}{2}\mathrm{tr}(\sigma_i U \sigma_j U^\dagger)$; for $U = e^{-\frac{i\theta}{2}\sigma_3}$ this is the rotation by θ about z, and U and $-U$ give the same R (Section T3.4.4).

3. *Build spin j.* Start from the highest weight, lower with J_-, and use $\|J_-|j,m\rangle\|^2 = (j+m)(j-m+1)$ to fix the matrix entries (Section T3.5.2).

4. *Derive the gauge law.* Demand $D(g^{-1}\psi) = g^{-1}D\psi$ and solve for the new A: $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$ (Section T3.8).

5. *Compute F from D^2.* $D^2\psi = (\mathrm{d}A)\psi + A\wedge A\,\psi$, the $\mathrm{d}\psi$ terms cancelling by the graded Leibniz rule (Section T3.8.6).

6. *Check that pure gauge is flat.* $\mathrm{d}(g^{-1}\mathrm{d}g) = -g^{-1}\mathrm{d}g \wedge g^{-1}\mathrm{d}g$, which cancels $A\wedge A$ exactly (Section T3.10.1).

7. *Derive* $\mathrm{tr}\,F\wedge F = \mathrm{d}\,CS$. Expand both sides; use $\mathrm{dd} = 0$, graded cyclicity (T3.79) and $\mathrm{tr}\,A^4 = 0$; the coefficient $\frac{2}{3}$ is forced (Section T3.10.3).

8. *Turn $\int \mathrm{tr}\,F\wedge F$ into a winding number.* Stokes' theorem on a large ball, $A \to g^{-1}\mathrm{d}g$ on the boundary, and $CS(g^{-1}\mathrm{d}g) = -\frac{1}{3}\mathrm{tr}(g^{-1}\mathrm{d}g)^3$ (Section T3.10.6).

9. *Compute an Aharonov–Bohm phase.* Holonomy of a flat abelian connection round the solenoid is $e^{-\oint A}$, fixed by the enclosed flux (Section T3.9.6).

Table T3.12: Where Nash relies on this toolkit chapter, with the section of this chapter that supplies the background.

Recap: the chapter in five sentences

- A Lie group is a smooth family of matrices; its Lie algebra is the set of its velocities at $\mathbb{1}$, and exp goes back.
- Representations are the ways the group acts on fields; for SU(2) they are labelled by spin j, and in general by weights, whose differences are roots.
- $g^{-1}\mathrm{d}g$ is what a local symmetry does to a derivative; the gauge field A is introduced to cancel it, and transforms as $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$.
- The curvature $F = \mathrm{d}A + A \wedge A$ is the commutator of covariant derivatives and the holonomy per unit area; a flat connection sees only π_1.
- $\operatorname{tr} F \wedge F = \mathrm{d}\, CS(A)$ makes the instanton number a winding number, the Chern–Simons action a topological field theory, and its gauge variation the seed of anomalies.

Chapter T4

Clifford Algebras, Spinors and Dirac Operators

Where this chapter is going

Every fermion in the Standard Model is described by a field ψ that obeys a *first-order* wave equation, the Dirac equation. Dirac found it by asking a naive question: can we take the square root of the wave operator $\partial_t^2 - \nabla^2$? The answer is yes, but only if the coefficients are matrices that *anticommute*. That single requirement is the seed of everything in this chapter.

Here is the chain of ideas we will follow.

- The anticommutation rule $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$ defines an algebra, the **Clifford algebra**. We never leave it abstract. In every dimension we write down the matrices (Pauli matrices, quaternions, the 4×4 Dirac and Weyl matrices, and tensor products of Pauli matrices in general) and check the relations by multiplying them out.
- Inside the Clifford algebra lives a group, $\mathrm{Spin}(n)$, which is a double cover of the rotation group. Rotating a spinor by 2π multiplies it by -1. This sign is the reason spinors are subtle on curved manifolds.
- Transporting spinors around a manifold requires lifting the rotation matrices that glue coordinate patches to $\mathrm{Spin}(n)$ consistently. When this is possible we have a **spin structure**. On a circle there are two (the Ramond and Neveu–Schwarz sectors of string theory); on $\mathbb{CP}^2$ there are none.
- With a spin structure and a metric we build the **Dirac operator** D. We compute its spectrum on $\mathbb{R}^n$, S^1, T^2 and S^2 by hand. The Lichnerowicz formula $D^2 = \nabla^*\nabla + R/4$ ties its zero modes to curvature.
- Splitting spinors by chirality turns D into a map $D^+ : S^+ \to S^-$. The number $\dim \ker D^+ - \dim \ker D^-$ is the *index*. It is the central object of Nash's Chapter 4 (Chapter 4) and the source of the anomalies of Chapter 10 (Chapter 10).
- Finally, differential forms themselves form a Clifford module, and $\mathrm{d} + \mathrm{d}^*$ is a Dirac-type operator. This is how de Rham theory, the signature and the Dolbeault operator all fit into one pattern.

Conventions used in this chapter

Signs and factors of i in the spinor literature are a notorious mess. Every source in the bibliography uses a different convention. We fix ours once and for all here, and give a

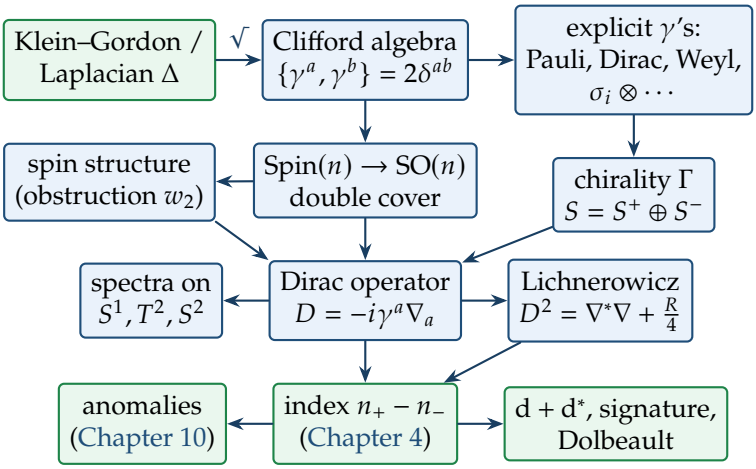

Figure T4.1: The logic of this chapter. Green boxes are the physics that goes in and comes out; blue boxes are the tools we build. Read it top to bottom: square-rooting the Laplacian forces the Clifford algebra; the algebra contains the spin group and chirality; spin structures let us transport spinors on a manifold; the Dirac operator and its index are the payoff.

translation table.

Dictionary: our conventions and the sources'

- **Euclidean gamma matrices (our default).** $\gamma_1, \dots, \gamma_n$ are *Hermitian* matrices with

$$\gamma_a \gamma_b + \gamma_b \gamma_a = 2\delta_{ab}\,\mathbf{1}, \qquad \text{so } \gamma_a^2 = \mathbf{1}.$$

  Indices $a, b, c, \dots$ refer to an orthonormal frame; they are raised and lowered with δ_{ab}, so $\gamma^a = \gamma_a$.

- **Dirac operator.** $D = -i\gamma^a \nabla_a$ (sum over a). It is formally self-adjoint and $D^2 = -\nabla^a \nabla_a + \dots$ is a *positive* Laplacian.

- **Mathematicians' Clifford multiplication** (Bär). Bär writes $e_a \cdot e_a = -1$ and $D = \sum_a e_a \cdot \nabla_{e_a}$. The translation is $c(e_a) = -i\gamma_a$: indeed $(-i\gamma_a)^2 = -\mathbf{1}$. With this dictionary Bär's D is exactly our D.

- **Nash** [Nash p. 114, (4.99)] uses anti-Hermitian matrices with $\{\gamma_a, \gamma_b\} = -2\delta_{ab}$, i.e. $\gamma_a^{\text{Nash}} = i\gamma_a^{\text{ours}}$, and $\not{D} = \gamma^a_{\text{Nash}}(\partial_a + \omega_a)$, which is $-D$ in our notation. Spectra are symmetric in all our examples, so nothing physical changes.

- **Minkowski space** (following the QFT notes [QFT notes §3.5]). $\eta^{\mu\nu} = \text{diag}(+1, -1, -1, -1)$, $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$, γ^0 Hermitian, γ^i anti-Hermitian, $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$, Dirac equation $(i\gamma^\mu \partial_\mu - m)\psi = 0$.

- **Clifford algebras.** $\text{Cl}_{p,q}$ is generated by p vectors squaring to $+1$ and q vectors squaring to -1. Bär's Cl_n is our $\text{Cl}_{0,n}$. (Warning: Lawson–Michelsohn use the opposite order.)

- **Gauge fields** follow the house convention: A is anti-Hermitian, $\nabla = \mathrm{d} + A$, $F = \mathrm{d}A + A \wedge A$. The physicists' Hermitian field is a with $A = -ia$ for U(1) (and $A = -ig\, A^a_{\text{phys}} T^a$ in general).

T4.1 Dirac's square root of the Laplacian

In 1928 Dirac wanted a relativistic wave equation that was *first order* in time, like the Schrödinger equation. The obvious relativistic equation, the Klein–Gordon equation $(\partial_t^2 - \nabla^2 + m^2)\phi = 0$, is second order. So he asked: is there a first-order operator whose square is the Klein–Gordon operator? This section answers that question. The answer forces on us a new kind of algebra, and it is worth seeing it appear with no input except "take a square root".

T4.1.1 Trying to factorise a second-order operator

We start in Euclidean space $\mathbb{R}^n$ with coordinates $x^1, \dots, x^n$, because there the signs are simplest. The (positive) Laplacian is

$$\Delta := -\sum_{a=1}^{n} \partial_a \partial_a = -\partial_1^2 - \cdots - \partial_n^2 .$$

On a plane wave $e^{ik\cdot x}$ it acts as multiplication by $|k|^2 \geq 0$. We look for a first-order operator with constant coefficients,

$$D = -i \sum_a \gamma^a \partial_a \qquad \text{(coefficients } \gamma^a \text{ to be found)},$$

such that $D^2 = \Delta$. (The factor $-i$ is only there to make D Hermitian later; it plays no role in the algebra.) Square it:

$$\begin{aligned} D^2 &\overset{(1)}{=} (-i)^2 \sum_{a,b} \gamma^a \gamma^b \, \partial_a \partial_b \\ &\overset{(2)}{=} -\frac{1}{2} \sum_{a,b} \left(\gamma^a \gamma^b + \gamma^b \gamma^a \right) \partial_a \partial_b \\ &\overset{(3)}{=} -\sum_a (\gamma^a)^2 \partial_a^2 - \sum_{a<b} \left(\gamma^a \gamma^b + \gamma^b \gamma^a \right) \partial_a \partial_b . \end{aligned} \tag{T4.1}$$

(1) The coefficients are constants, so they pass through the derivatives; we just multiply out the two sums.

(2) Partial derivatives commute, $\partial_a \partial_b = \partial_b \partial_a$, so only the symmetric part of $\gamma^a \gamma^b$ survives the double sum.

(3) Split the double sum into diagonal terms $a = b$ and off-diagonal pairs $a < b$ (each unordered pair appears twice in the sum, which cancels the $\frac{1}{2}$).

For this to equal $-\sum_a \partial_a^2$ *for every function*, the coefficients of ∂_a^2 and of $\partial_a \partial_b$ must match:

$$(\gamma^a)^2 = 1, \qquad \gamma^a \gamma^b + \gamma^b \gamma^a = 0 \ (a \neq b), \qquad \text{i.e.} \qquad \boxed{\{\gamma^a, \gamma^b\} = 2\delta^{ab}} \tag{T4.2}$$

where $\{A, B\} := AB + BA$ is the **anticommutator**.

Key idea: the square root forces anticommutation

A first-order operator $-i\gamma^a \partial_a$ squares to the Laplacian if and only if the coefficients satisfy $\{\gamma^a, \gamma^b\} = 2\delta^{ab}$. For $n \geq 2$ ordinary numbers cannot do this: if $\gamma^1 \gamma^2 + \gamma^2 \gamma^1 = 2\gamma^1 \gamma^2 = 0$ then one of them vanishes, contradicting $(\gamma^a)^2 = 1$. The coefficients must be *matrices*, and the wave function they act on must have several components.

Now repeat the computation in Minkowski space. We use the metric of the QFT notes, $\eta^{\mu\nu} = \mathrm{diag}(+1, -1, -1, -1)$, and the d'Alembertian

$$\partial^2 = \eta^{\mu\nu}\partial_\mu\partial_\nu = \partial_t^2 - \nabla^2,$$

gives the Minkowski version. Suppose $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$. Then

$$\begin{aligned}(-i\gamma^\mu\partial_\mu - m)(i\gamma^\nu\partial_\nu - m)\psi &\overset{(1)}{=} \left(\gamma^\mu\gamma^\nu\partial_\mu\partial_\nu + im\gamma^\mu\partial_\mu - im\gamma^\nu\partial_\nu + m^2\right)\psi \\ &\overset{(2)}{=} \left(\tfrac{1}{2}\{\gamma^\mu, \gamma^\nu\}\partial_\mu\partial_\nu + m^2\right)\psi \\ &\overset{(3)}{=} (\partial^2 + m^2)\psi. \end{aligned} \tag{T4.3}$$

(1) Multiply out; $(-i)(i) = 1$ and the two cross terms carry $+im$ and $-im$.
(2) The two cross terms are the same operator with a renamed dummy index, so they cancel; and only the symmetric part of $\gamma^\mu\gamma^\nu$ survives against $\partial_\mu\partial_\nu$.
(3) Use $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$.

So every solution of the **Dirac equation** $(i\gamma^\mu\partial_\mu - m)\psi = 0$ solves the Klein–Gordon equation component by component [QFT notes (3.5.30)]. The Dirac equation is a first-order "square root" of Klein–Gordon.

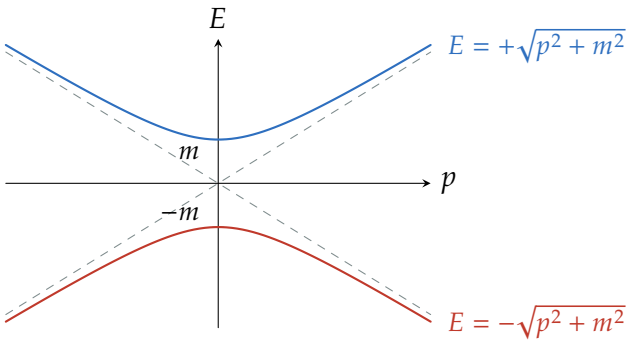

Figure T4.2: The Klein–Gordon dispersion relation $E^2 = p^2 + m^2$ has two branches. A first-order equation $E\psi = (\alpha \cdot p + \beta m)\psi$ reproduces both only if $(\alpha \cdot p + \beta m)^2 = p^2 + m^2$ as a *matrix* identity; its eigenvalues are then exactly $\pm\sqrt{p^2 + m^2}$. The negative branch (red) is the one Dirac later reinterpreted as antiparticles.

T4.1.2 Solving the anticommutation relations in low dimensions

Now we find the matrices. The goal is the smallest matrices that work.

Dimension 1. Take $\gamma^1 = 1$. Then $D = -i\,\mathrm{d}/\mathrm{d}x$ and $D^2 = -\mathrm{d}^2/\mathrm{d}x^2$. Nothing new: a first derivative is already the square root of a second derivative.

Dimension 2. We need two anticommuting matrices, each squaring to $\mathbf{1}$. The **Pauli matrices**

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \qquad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \tag{T4.4}$$

will do. Let us multiply them out once and for all.

$$\sigma_1\sigma_2 \overset{(1)}{=} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} = \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix} \overset{(2)}{=} i\sigma_3,$$
$$\sigma_2\sigma_1 \overset{(3)}{=} \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} -i & 0 \\ 0 & i \end{pmatrix} = -i\sigma_3. \tag{T4.5}$$

(1) Row times column: the $(1,1)$ entry is $0\cdot 0 + 1\cdot i = i$, the $(2,2)$ entry is $1\cdot(-i) + 0\cdot 0 = -i$, and the off-diagonal entries vanish.
(2) Compare with $\sigma_3 = \operatorname{diag}(1,-1)$.
(3) Same computation in the other order.

So $\sigma_1\sigma_2 + \sigma_2\sigma_1 = 0$. The same kind of multiplication gives the complete set of Pauli relations,

$$\sigma_j\sigma_k = \delta_{jk}\mathbf{1} + i\,\varepsilon_{jkl}\,\sigma_l, \qquad \{\sigma_j,\sigma_k\} = 2\delta_{jk}, \qquad [\sigma_j,\sigma_k] = 2i\varepsilon_{jkl}\sigma_l. \tag{T4.6}$$

In two dimensions we take $\gamma^1 = \sigma_1$, $\gamma^2 = \sigma_2$.

Worked example T4.1: the 2D Dirac operator is the Cauchy–Riemann operator

With $\gamma^1 = \sigma_1$, $\gamma^2 = \sigma_2$ and the complex coordinate $z = x^1 + ix^2$, put $\partial_z = \tfrac{1}{2}(\partial_1 - i\partial_2)$ and $\partial_{\bar z} = \tfrac{1}{2}(\partial_1 + i\partial_2)$. Then

$$D \overset{(1)}{=} -i\begin{pmatrix} 0 & \partial_1 \\ \partial_1 & 0 \end{pmatrix} - i\begin{pmatrix} 0 & -i\partial_2 \\ i\partial_2 & 0 \end{pmatrix}$$
$$\overset{(2)}{=} -i\begin{pmatrix} 0 & \partial_1 - i\partial_2 \\ \partial_1 + i\partial_2 & 0 \end{pmatrix}$$
$$\overset{(3)}{=} \begin{pmatrix} 0 & -2i\,\partial_z \\ -2i\,\partial_{\bar z} & 0 \end{pmatrix}.$$

(1) Insert the Pauli matrices into $D = -i(\sigma_1\partial_1 + \sigma_2\partial_2)$.
(2) Add the two matrices entry by entry.
(3) Recognise $\partial_1 \mp i\partial_2 = 2\partial_z,\ 2\partial_{\bar z}$.

Squaring,

$$D^2 \overset{(1)}{=} \begin{pmatrix} (-2i)^2\partial_z\partial_{\bar z} & 0 \\ 0 & (-2i)^2\partial_{\bar z}\partial_z \end{pmatrix} \overset{(2)}{=} -4\partial_z\partial_{\bar z}\,\mathbf{1} \overset{(3)}{=} -(\partial_1^2 + \partial_2^2)\,\mathbf{1}.$$

(1) The product of two off-diagonal matrices is diagonal: $(1,1)$ entry is $(-2i\partial_z)(-2i\partial_{\bar z})$ and so on.
(2) $(-2i)^2 = -4$, and $\partial_z, \partial_{\bar z}$ commute.
(3) $4\partial_z\partial_{\bar z} = (\partial_1 - i\partial_2)(\partial_1 + i\partial_2) = \partial_1^2 + \partial_2^2$.

So $D^2 = \Delta$ as promised. And the equation $D\psi = 0$ for $\psi = (\psi_+, \psi_-)^{\mathsf T}$ says $\partial_{\bar z}\psi_+ = 0$ and $\partial_z\psi_- = 0$: the upper component is *holomorphic* and the lower one *antiholomorphic*. Zero modes of the 2D Dirac operator are solutions of the Cauchy–Riemann equations. We will meet this again when we count zero modes on surfaces.

Dimension 3. Now all three Pauli matrices anticommute, so $\gamma^a = \sigma_a$, $a = 1,2,3$, works. This is the familiar operator $\sigma\cdot p$ of the Pauli equation.

Worked example T4.2: the Pauli identity and $(\sigma \cdot p)^2 = p^2$

For any two vectors $\vec{a}, \vec{b}$ (whose components commute with the σ's),

$$\begin{aligned}(\sigma \cdot \vec{a})(\sigma \cdot \vec{b}) &\overset{(1)}{=} \sum_{j,k} a_j b_k \, \sigma_j \sigma_k \\ &\overset{(2)}{=} \sum_{j,k} a_j b_k \left(\delta_{jk} + i \varepsilon_{jkl} \sigma_l\right) \\ &\overset{(3)}{=} \vec{a} \cdot \vec{b} + i \, \sigma \cdot (\vec{a} \times \vec{b}).\end{aligned}$$

(1) Expand both sums.
(2) Use the product rule (T4.6).
(3) $\sum_{j,k} \varepsilon_{jkl} a_j b_k = (\vec{a} \times \vec{b})_l$.

With $\vec{a} = \vec{b} = \vec{p}$ the cross product vanishes, so $(\sigma \cdot \vec{p})^2 = |\vec{p}|^2$: the operator $-i\sigma \cdot \nabla$ is a square root of the three-dimensional Laplacian. With $\vec{p} \to \vec{p} - e\vec{A}$ the cross product no longer vanishes, because the components of $\vec{p} - e\vec{A}$ do not commute; one finds $(\sigma \cdot \vec{\pi})^2 = \vec{\pi}^2 - e\hbar \, \sigma \cdot \vec{B}$, the Pauli Hamiltonian with $g = 2$. This is our first "twisted" Dirac operator; we return to it in Section T4.8.

Dimension 4: the 2×2 matrices run out. In four dimensions (Euclidean or Minkowski) we need *four* mutually anticommuting matrices. Can they still be 2×2? No. Any 2×2 matrix can be written $M = m_0 \mathbf{1} + \vec{m} \cdot \sigma$. If M anticommutes with all three Pauli matrices, then

$$0 = \{\sigma_j, M\} \overset{(1)}{=} 2m_0 \sigma_j + \sum_k m_k \{\sigma_j, \sigma_k\} \overset{(2)}{=} 2m_0 \sigma_j + 2m_j \mathbf{1},$$

(1) σ_j commutes with $m_0 \mathbf{1}$, so $\{\sigma_j, m_0 \mathbf{1}\} = 2m_0 \sigma_j$.
(2) $\{\sigma_j, \sigma_k\} = 2\delta_{jk}$.

and since $\mathbf{1}, \sigma_j$ are linearly independent, $m_0 = m_j = 0$. So at most three 2×2 matrices can anticommute pairwise. There is also a size argument valid in any dimension $n \geq 2$: each γ^a is traceless, because

$$\operatorname{tr} \gamma^1 \overset{(1)}{=} \operatorname{tr}(\gamma^1 \gamma^2 \gamma^2) \overset{(2)}{=} \operatorname{tr}(\gamma^2 \gamma^1 \gamma^2) \overset{(3)}{=} -\operatorname{tr}(\gamma^1 \gamma^2 \gamma^2) = -\operatorname{tr} \gamma^1,$$

(1) Insert $(\gamma^2)^2 = \mathbf{1}$.
(2) Cyclicity of the trace moves the last γ^2 to the front.
(3) Anticommute $\gamma^2 \gamma^1 = -\gamma^1 \gamma^2$.

and $(\gamma^a)^2 = \mathbf{1}$ means its eigenvalues are ± 1. Traceless with eigenvalues ± 1 forces equally many $+1$'s and -1's, so the matrix size is *even*. In four dimensions the smallest size turns out to be 4×4; Dirac found the matrices, and in Section T4.3 we write them down in two standard forms. The general pattern (Section T4.4) is that in n dimensions the smallest size is $2^{\lfloor n/2 \rfloor}$.

Watch out: why not just use $\sqrt{\Delta}$?

One can define $\sqrt{\Delta}$ by Fourier transform: it multiplies $e^{ik \cdot x}$ by $|k|$. But $|k| = \sqrt{k_1^2 + \cdots + k_n^2}$ is not a polynomial in k, so $\sqrt{\Delta}$ is not a differential operator; it is non-local (its kernel spreads over all of space). Dirac's trick makes $|k|$ polynomial at the price of matrices:

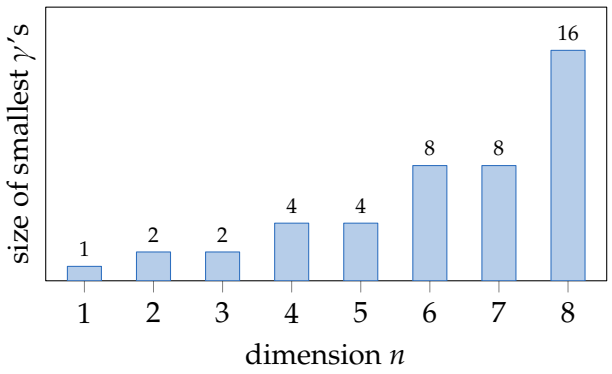

Figure T4.3: How big the gamma matrices must be. Each time we add *two* dimensions the size doubles: $2^{\lfloor n/2 \rfloor}$. In odd dimension the extra matrix is "free": it is the product of all the others (for $n = 3$, $\sigma_3 \propto \sigma_1\sigma_2$). This staircase is why Dirac spinors in 4D have four components.

$(\gamma^a k_a)^2 = |k|^2$, and $\gamma^a k_a$ is linear in k.

T4.1.3 Symbols: Laplace-type and Dirac-type operators

On a curved manifold, or with a gauge field, the operators we care about have variable coefficients and lower-order terms. What survives of Dirac's computation is the *leading* part. We need a way to talk about it.

Working definition T4.1 (principal symbol)

Let $P = \sum_{|\alpha| \le k} A^\alpha(x)\,\partial_\alpha$ [α lists which partial derivatives are taken, and $|\alpha|$ counts them, so $\partial_\alpha = \partial_1\partial_1\partial_3$ has $|\alpha| = 3$] be a differential operator of order k acting on vector-valued functions, with matrix coefficients A^α. Its **principal symbol** at the covector $\xi = \xi_\mu \mathrm{d}x^\mu$ [one number ξ_μ per coordinate, playing the role of the wave vector k_μ of $e^{ik\cdot x}$] is obtained by keeping only the k-th order terms and replacing each ∂_μ by $i\xi_\mu$:

$$\sigma_P(x,\xi) = \sum_{|\alpha|=k} A^\alpha(x)\,(i\xi)^\alpha .$$

Operationally: it is the matrix you get by letting P act on a rapidly oscillating wave $e^{i\lambda\,\xi\cdot x}u$ and keeping the leading power λ^k. It is a matrix-valued polynomial in ξ, and it changes under coordinate changes like a function of a covector.

Worked example T4.3: symbols of the basic operators

- Laplacian on a Riemannian manifold, $\Delta = -g^{\mu\nu}\partial_\mu\partial_\nu$ + (first order):

$$\sigma_\Delta(\xi) \overset{(1)}{=} -g^{\mu\nu}(i\xi_\mu)(i\xi_\nu) \overset{(2)}{=} g^{\mu\nu}\xi_\mu\xi_\nu = |\xi|^2 .$$

  (1) Replace each ∂ by $i\xi$; the first-order terms drop.
  (2) $i^2 = -1$ cancels the minus sign.

- Our Dirac operator $D = -i\gamma^a\partial_a$ on $\mathbb{R}^n$: $\sigma_D(\xi) = -i\gamma^a(i\xi_a) = \gamma^a\xi_a =: \not{\xi}$.
- The exterior derivative on functions, $\mathrm{d}f = \partial_\mu f\,\mathrm{d}x^\mu$: $\sigma_{\mathrm{d}}(\xi)f = i\xi\, f$, i.e. "multiply by $i\xi$". On p-forms, $\sigma_{\mathrm{d}}(\xi)\alpha = i\,\xi\wedge\alpha$.

The whole content of (T4.1) is then a statement about symbols: $\sigma_{D^2} = \sigma_D^2$ (symbols of compositions multiply), so D^2 has the symbol of the Laplacian exactly when $\not{\xi}^2 = |\xi|^2$ for all ξ. This suggests the following definitions, which are Bär's [Bär Def. 1.3.1, 1.3.7] (Bär omits the factors of i in the symbol, so his Laplace-type condition reads $\sigma_2 = -|\xi|^2$).

Working definition T4.2 (Laplace-type and Dirac-type)

A second-order operator P on sections of a vector bundle E [fields with several components at each point, such as spinor fields or forms] is of **Laplace type** if $\sigma_P(\xi) = |\xi|^2\,\mathbf{1}_E$. In local coordinates: $P = -g^{\mu\nu}\partial_\mu\partial_\nu\,\mathbf{1} +$ (first and zeroth order).
A first-order operator $D : \Gamma(E) \to \Gamma(F)$ is of **Dirac type** if both D^*D and DD^* are of Laplace type [D^* is the adjoint, fixed by $\langle D\psi, \chi\rangle = \langle \psi, D^*\chi\rangle$ for all ψ, χ]. If $E = F$ and $D = D^*$ this just says D^2 is of Laplace type [Bär Rem. 1.3.8].
Test: compute the symbol $\sigma_D(\xi)$, a matrix linear in ξ, and check whether $\sigma_D(\xi)^\dagger\sigma_D(\xi) = |\xi|^2$.

Now comes the key observation [Bär Rem. 1.3.14]. Let D be a formally self-adjoint Dirac-type operator. Then $\sigma_D(\xi)^2 = |\xi|^2$ for every ξ. Apply this to $\xi + \eta$:

$$\begin{aligned} |\xi|^2 + 2\langle\xi,\eta\rangle + |\eta|^2 &\overset{(1)}{=} |\xi+\eta|^2 \\ &\overset{(2)}{=} \big(\sigma_D(\xi) + \sigma_D(\eta)\big)^2 \\ &\overset{(3)}{=} |\xi|^2 + \sigma_D(\xi)\sigma_D(\eta) + \sigma_D(\eta)\sigma_D(\xi) + |\eta|^2. \end{aligned} \tag{T4.7}$$

(1) Expand the squared norm of a sum.
(2) D is of Dirac type and σ_D is linear in ξ.
(3) Expand the square of a sum of (non-commuting) matrices and use the Dirac-type condition on each of the two squares.

Comparing both sides:

$$\sigma_D(\xi)\sigma_D(\eta) + \sigma_D(\eta)\sigma_D(\xi) = 2\langle\xi,\eta\rangle\,\mathbf{1}. \tag{T4.8}$$

Key idea: every Dirac-type operator carries a Clifford algebra

At each point x, the symbol matrices $\sigma_D(\xi)$ of a self-adjoint Dirac-type operator satisfy the same anticommutation relations as Dirac's γ's. So the fibre E_x is automatically a representation space of the Clifford algebra of T^*_xM. Clifford algebras are not an optional decoration: they are forced on us the moment we ask for a first-order square root of a Laplacian. This is Bär's (1.18), and it is why "it is much more difficult to construct Dirac-type operators than Laplace-type operators".

Worked example T4.4: the gradient is *not* of Dirac type

Take $D = \mathrm{grad}$ from functions to vector fields on $\mathbb{R}^n$. Its adjoint is $D^* = -\mathrm{div}$ (integrate by parts). Then $D^*D = -\mathrm{div}\,\mathrm{grad} = \Delta$, which is of Laplace type. But $DD^* = -\mathrm{grad}\,\mathrm{div}$ acts on a vector field v as

$$(-\mathrm{grad}\,\mathrm{div}\,v)_j \overset{(1)}{=} -\partial_j \sum_k \partial_k v_k, \qquad \sigma_{DD^*}(\xi)_{jk} \overset{(2)}{=} -(i\xi_j)(i\xi_k) = \xi_j\xi_k.$$

(1) Definitions of divergence and gradient.
(2) Replace $\partial \to i\xi$.

The matrix $\xi\xi^{\mathsf T}$ is a projector onto ξ times $|\xi|^2$; it is not $|\xi|^2\mathbf{1}$ (it kills vectors perpendicular to ξ). So grad fails the test [Bär Ex. 1.3.9]. The fix, as we will see in Section T4.9, is to enlarge

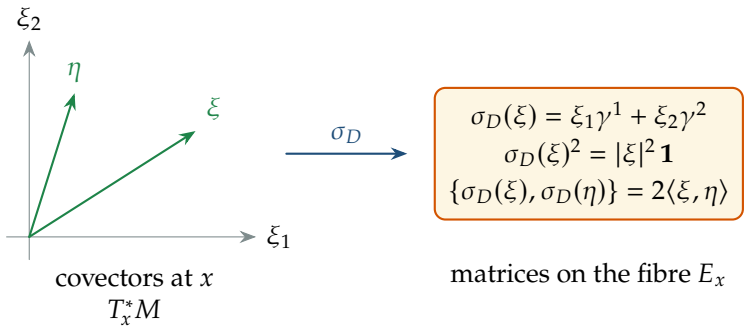

Figure T4.4: The principal symbol of a Dirac-type operator sends each covector ξ to a matrix whose square is $|\xi|^2$. Polarising (feeding in $\xi + \eta$) turns this into the Clifford relation, so the fibre is a Clifford module.

the bundles: $\mathrm{d} + \mathrm{d}^*$ acting on *all* forms is of Dirac type.

Worked example T4.5: Dray's Kähler operator

Dray [Dray §20.3, (20.23)–(20.25)] considers $\mathrm{d} - \delta$ acting on formal sums of forms, where $\delta = (-1)^p \star^{-1} \mathrm{d} \star$ is (minus) the codifferential. Since $\mathrm{d}^2 = 0$ and $\delta^2 = 0$,

$$(\mathrm{d} - \delta)^2 \overset{(1)}{=} \mathrm{d}^2 - \mathrm{d}\delta - \delta\mathrm{d} + \delta^2 \overset{(2)}{=} -(\mathrm{d}\delta + \delta\mathrm{d}),$$

(1) Expand the square keeping the order of the operators.
(2) $\mathrm{d}^2 = 0 = \delta^2$.

and on a function f this is $-\delta\mathrm{d}f$, which is the Laplacian of f (Dray's sign conventions make it the positive or negative Laplacian depending on signature). So Dray's $\mathrm{d} - \delta$ is "a sort of square root of the Laplacian" built without any matrices, because the forms themselves provide the anticommuting objects: $\mathrm{d}x^1 \wedge \mathrm{d}x^2 = -\mathrm{d}x^2 \wedge \mathrm{d}x^1$. We make this precise in Section T4.9.

Try it: a first-order root of the harmonic oscillator

Show that $Q = \sigma_1 p + \sigma_2 x$, with $p = -i\,\mathrm{d}/\mathrm{d}x$, satisfies $Q^2 = p^2 + x^2 + \sigma_3$. *Answer:* $Q^2 = \sigma_1^2 p^2 + \sigma_2^2 x^2 + \sigma_1\sigma_2\, px + \sigma_2\sigma_1\, xp = p^2 + x^2 + i\sigma_3[p, x] = p^2 + x^2 + \sigma_3$, using $[p, x] = -i$. The extra term is the "spin" part; this is the simplest supersymmetric quantum mechanics, and we meet it again with Witten's approach to Morse theory (Chapter 7).

Reading Nash (p. 114–115, (4.99)–(4.100))

Nash introduces the Dirac matrices in one sentence: "a set of n anti-commuting $2^{n/2} \times 2^{n/2}$ matrices which generate the Clifford algebra". His relation is $\gamma_a\gamma_b + \gamma_b\gamma_a = -2\delta_{ab}$ (anti-Hermitian γ's; ours times i). On p. 115 he notes that the Dirac operator is elliptic "because its symbol is given locally by the matrix $\sigma_1(x, p) = i\gamma^a e_a^\mu p_\mu$ and the inverse of this matrix is $i\gamma^a e_a^\mu p_\mu / p^2$". That is exactly the statement $\sigma_D(\xi)^2 = |\xi|^2$ above (with his signs), and it is the reason for the whole construction.

Recap

- Demanding $(-i\gamma^a\partial_a)^2 = \Delta$ forces $\{\gamma^a, \gamma^b\} = 2\delta^{ab}$; in Minkowski space $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$ and Dirac $\Rightarrow$ Klein–Gordon.
- Solutions: 1 in 1D; σ_1, σ_2 in 2D (the Cauchy–Riemann operator); $\sigma_1, \sigma_2, \sigma_3$ in 3D (the Pauli operator); 4×4 matrices in 4D. Sizes grow like $2^{\lfloor n/2 \rfloor}$.
- The principal symbol of a Dirac-type operator satisfies the Clifford relation, so every Dirac-type operator acts on a Clifford module. The gradient alone is not of Dirac type; $\mathrm{d} + \mathrm{d}^*$ is.

T4.2 Clifford algebras: multiplying anticommuting directions

Once we have matrices $\gamma^1, \dots, \gamma^n$ obeying $\{\gamma^a, \gamma^b\} = 2\delta^{ab}$, we can multiply them together: $\gamma^1\gamma^2$, $\gamma^1\gamma^2\gamma^3$, and so on. These products are not decorations. $\gamma^1\gamma^2$ will turn out to generate rotations of spinors in the 12-plane, and the product of all the γ's will be the chirality operator γ^5. The set of all linear combinations of all products is an algebra, the Clifford algebra. In this section we find out what it looks like, dimension by dimension, and we always identify it with a concrete algebra of matrices.

T4.2.1 The working definition

Working definition T4.3 (Clifford algebra $\mathrm{Cl}_{p,q}$)

Let $n = p + q$. The **Clifford algebra** $\mathrm{Cl}_{p,q}$ is the real algebra generated by a unit 1 and n symbols $e_1, \dots, e_n$ [its elements are real linear combinations of products $e_{i_1}e_{i_2}\cdots$, multiplied associatively] subject only to

$$e_ie_j + e_je_i = 2\eta_{ij}, \qquad \eta = \mathrm{diag}(\underbrace{+1, \dots, +1}_{p}, \underbrace{-1, \dots, -1}_{q}). \tag{T4.9}$$

So $e_i^2 = +1$ for the first p generators, $e_i^2 = -1$ for the last q, and distinct generators anticommute. *Operationally*: an element of $\mathrm{Cl}_{p,q}$ is a polynomial in the e_i; to simplify a product, reorder the factors using $e_je_i = -e_ie_j$ ($i \neq j$) and replace e_i^2 by ± 1. A **representation** (or Clifford module) is a choice of matrices γ_i [square matrices, all of the same size, real or complex] with $\gamma_i\gamma_j + \gamma_j\gamma_i = 2\eta_{ij}\mathbf{1}$.

Two remarks make the definition less arbitrary.

(1) It is really a statement about all vectors. Put $v = v^ie_i$ for any real numbers v^i. Then

$$v\,v \overset{(1)}{=} \sum_{i,j} v^iv^je_ie_j \overset{(2)}{=} \frac{1}{2}\sum_{i,j} v^iv^j(e_ie_j + e_je_i) \overset{(3)}{=} \sum_{i,j}\eta_{ij}v^iv^j =: Q(v). \tag{T4.10}$$

(1) Multiply out; the v^i are numbers and commute with everything.
(2) v^iv^j is symmetric in i, j, so only the symmetric part of e_ie_j contributes.
(3) The relation (T4.9).

So "the square of a vector is its length squared" (with signature η). Conversely, if $v\,v = Q(v)$ for all v, then applying it to $v + w$ and subtracting the squares gives $vw + wv = 2\langle v, w\rangle_\eta$. This

is the same polarisation trick as (T4.7). Bär's definition [Bär Def. 2.1.1] is exactly this, with the opposite sign: $v \cdot v = -\beta(v,v)$.

(2) "Only" these relations. The phrase "subject only to" means we impose no further relations: the algebra is as big as it can be. (Formally, $\mathrm{Cl}(V,Q)$ is the tensor algebra $\bigoplus_k V^{\otimes k}$ divided by the ideal generated by $v \otimes v - Q(v)1$; equivalently it is characterised by a universal property: any linear map $f : V \to A$ into an algebra with $f(v)^2 = Q(v)$ extends uniquely to an algebra map $\mathrm{Cl}(V,Q) \to A$ [Bär Prop. 2.1.5].) A representation may be smaller than the algebra, as we will see with $\mathrm{Cl}_{0,3}$ below.

Watch out: which sign?

Physicists write $\{\gamma^a, \gamma^b\} = 2\delta^{ab}$ (vectors square to $+1$, that is $\mathrm{Cl}_{n,0}$); many mathematicians, including Bär and Nash, use $\{e_a, e_b\} = -2\delta_{ab}$ (vectors square to -1, $\mathrm{Cl}_{0,n}$). Over the real numbers these are *different algebras* (we will see $\mathrm{Cl}_{1,0} \neq \mathrm{Cl}_{0,1}$ and $\mathrm{Cl}_{2,0} \neq \mathrm{Cl}_{0,2}$). Over the complex numbers they are the same: if $\gamma_a^2 = 1$ then $(i\gamma_a)^2 = -1$. Since spinors are complex in almost all of physics, the sign is usually a harmless convention, but it matters for real (Majorana) spinors.

T4.2.2 Basis and dimension: 2^n

Any product of generators can be reordered, at the cost of signs, so that the indices increase, and repeated indices cancel in pairs ($e_i^2 = \pm 1$). So every element is a combination of the **basis monomials**

$$e_I \coloneqq e_{i_1} e_{i_2} \cdots e_{i_k}, \qquad I = \{i_1 < i_2 < \cdots < i_k\} \subseteq \{1, \dots, n\}, \tag{T4.11}$$

with $e_\varnothing = 1$. There is one monomial for each subset I, so 2^n of them, and $\binom{n}{k}$ of degree k. That they are linearly independent (so $\dim \mathrm{Cl}_{p,q} = 2^n$ exactly) follows from the matrix representations below, where we will simply see 2^n independent matrices [Bär Cor. 2.1.13]. The number $k = |I|$ is the **degree** or grade of e_I.

Worked example T4.6: multiplying two monomials

In $\mathrm{Cl}_{3,0}$ compute $(e_1e_2)(e_2e_3)$ and $(e_1e_2)(e_1e_3)$:

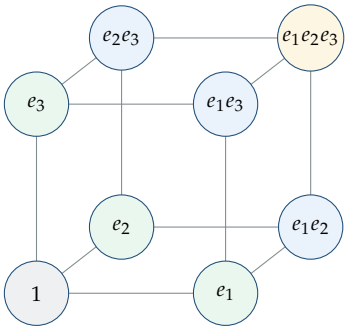
$$(e_1e_2)(e_2e_3) \overset{(1)}{=} e_1(e_2e_2)e_3 \overset{(2)}{=} e_1e_3,$$
$$(e_1e_2)(e_1e_3) \overset{(3)}{=} -e_2e_1e_1e_3 \overset{(4)}{=} -e_2e_3.$$

(1) Associativity.
(2) $e_2^2 = +1$.
(3) Anticommute $e_1e_2 = -e_2e_1$.
(4) $e_1^2 = +1$.

General rule: $e_I e_J = \pm e_{I \triangle J}$ (times ± 1 from the squares), where $I \triangle J$ is the symmetric difference: indices in both sets cancel. The product of monomials of degrees k and l has degree $k + l - 2|I \cap J|$, which has the same *parity* as $k + l$. The degree itself is not preserved, only its parity.

T4.2.3 One dimension: $\mathbb{C}$ and $\mathbb{R} \oplus \mathbb{R}$

With a single generator e the algebra has basis $\{1, e\}$.



degree k: number $\binom{3}{k}$

$k = 0$: 1 scalar

$k = 1$: 3 vectors

$k = 2$: 3 bivectors

$k = 3$: 1 trivector

$1 + 3 + 3 + 1 = 2^3$

Figure T4.5: The basis of Cl_3 drawn as the vertices of a cube: a monomial e_I is a vertex, and I records which of the three directions you have moved along. Multiplying by e_i moves you along edge i (with a sign). The number of monomials of degree k is a row of Pascal's triangle, and the total is $2^3 = 8$. Even monomials (grey, blue) and odd ones (green, yellow) alternate around the cube.

Worked example T4.7: $\mathrm{Cl}_{0,1} \cong \mathbb{C}$

If $e^2 = -1$, then e behaves exactly like i: the map $a + be \mapsto a + bi$ is an algebra isomorphism [Bär Ex. 2.1.9]. As a real 2×2 matrix, $e \mapsto \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$, the rotation by $90°$, whose square is $-\mathbf{1}$.

Worked example T4.8: $\mathrm{Cl}_{1,0} \cong \mathbb{R} \oplus \mathbb{R}$

If $e^2 = +1$, the elements $P_\pm := \frac{1}{2}(1 \pm e)$ satisfy

$$P_\pm^2 \overset{(1)}{=} \tfrac{1}{4}(1 \pm 2e + e^2) \overset{(2)}{=} \tfrac{1}{4}(2 \pm 2e) = P_\pm,$$
$$P_+P_- \overset{(3)}{=} \tfrac{1}{4}(1 - e^2) \overset{(4)}{=} 0, \qquad P_+ + P_- = 1.$$

(1) Expand the square.
(2) $e^2 = 1$.
(3) $(1 + e)(1 - e) = 1 - e + e - e^2$.
(4) $e^2 = 1$ again.

So $P_\pm$ are complementary projectors, and $a + be = (a + b)P_+ + (a - b)P_-$. Multiplication is componentwise in the $P_\pm$ basis: the algebra is two copies of $\mathbb{R}$ side by side [Bär Ex. 2.1.10]. Concretely, $e \mapsto \sigma_3 = \mathrm{diag}(1, -1)$ and $a + be \mapsto \mathrm{diag}(a + b,\ a - b)$. Note the difference from $\mathbb{C}$: $\mathbb{R} \oplus \mathbb{R}$ has zero divisors ($P_+P_- = 0$), while $\mathbb{C}$ is a field. This is the simplest instance of the "$\oplus$" that appears in odd dimensions throughout the classification.

T4.2.4 Two dimensions: real matrices and quaternions

Worked example T4.9: $\mathrm{Cl}_{2,0} \cong \mathbb{R}(2)$, the real 2×2 matrices

We need two anticommuting matrices squaring to $+1$. We could use σ_1, σ_2, but σ_2 is imaginary; the *real* choice $e_1 \mapsto \sigma_1$, $e_2 \mapsto \sigma_3$ also works because $\sigma_1\sigma_3 = -\sigma_3\sigma_1$. The fourth basis element is

$$e_1e_2 \mapsto \sigma_1\sigma_3 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix},$$

the 90° rotation, which squares to $-\mathbf{1}$ (check: $(e_1e_2)^2 = e_1e_2e_1e_2 = -e_1e_1e_2e_2 = -1$). The four matrices

$$\mathbf{1} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad \sigma_1\sigma_3 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$

are linearly independent and span all real 2×2 matrices: $\begin{pmatrix} a & b \\ c & d \end{pmatrix} = \frac{a+d}{2}\mathbf{1} + \frac{a-d}{2}\sigma_3 + \frac{b+c}{2}\sigma_1 + \frac{c-b}{2}\sigma_1\sigma_3$. So $\mathrm{Cl}_{2,0} \cong \mathbb{R}(2)$, where $\mathbb{R}(m)$ denotes the algebra of real $m \times m$ matrices.

Worked example T4.10: $\mathrm{Cl}_{0,2} \cong \mathbb{H}$, the quaternions

Now $e_1^2 = e_2^2 = -1$. The monomial e_1e_2 also squares to -1: $(e_1e_2)^2 = -e_1^2e_2^2 = -1$. So all three of e_1, e_2, e_1e_2 square to -1, and they anticommute pairwise; for instance $e_1(e_1e_2) = e_1^2e_2 = -e_2$ while $(e_1e_2)e_1 = -e_1^2e_2 = e_2$. Writing $\mathbf{i} = e_1$, $\mathbf{j} = e_2$, $\mathbf{k} = e_1e_2$ we get Hamilton's rules

$$\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = \mathbf{ijk} = -1, \qquad \mathbf{ij} = -\mathbf{ji} = \mathbf{k}, \quad \mathbf{jk} = -\mathbf{kj} = \mathbf{i}, \quad \mathbf{ki} = -\mathbf{ik} = \mathbf{j}. \tag{T4.12}$$

So $\mathrm{Cl}_{0,2} \cong \mathbb{H}$ [Bär Ex. 2.1.14]. A matrix representation uses the Pauli matrices times $-i$:

$$\mathbf{i} \mapsto -i\sigma_1, \qquad \mathbf{j} \mapsto -i\sigma_2, \qquad \mathbf{k} \mapsto -i\sigma_3. \tag{T4.13}$$

Check one relation: $\mathbf{ij} \mapsto (-i\sigma_1)(-i\sigma_2) \overset{(1)}{=} -\sigma_1\sigma_2 \overset{(2)}{=} -i\sigma_3 \leftrightarrow \mathbf{k}$.

(1) $(-i)^2 = -1$.

(2) $\sigma_1\sigma_2 = i\sigma_3$ from (T4.5).

A general quaternion $q = a + b\mathbf{i} + c\mathbf{j} + d\mathbf{k}$ becomes

$$q \mapsto \begin{pmatrix} a - id & -c - ib \\ c - ib & a + id \end{pmatrix} = \begin{pmatrix} \alpha & -\bar{\beta} \\ \beta & \bar{\alpha} \end{pmatrix}, \qquad \alpha = a - id,\ \beta = c - ib, \tag{T4.14}$$

and $\det = |\alpha|^2 + |\beta|^2 = a^2 + b^2 + c^2 + d^2 = |q|^2$. The unit quaternions are exactly the matrices of this form with determinant 1, i.e. the group SU(2). This is the first appearance of the spin group: Spin(3) = SU(2) (Section T4.5).

$\times$	1	$\mathbf{i} = e_1$	$\mathbf{j} = e_2$	$\mathbf{k} = e_1e_2$
1	1	$\mathbf{i}$	$\mathbf{j}$	$\mathbf{k}$
$\mathbf{i}$	$\mathbf{i}$	-1	$\mathbf{k}$	$-\mathbf{j}$
$\mathbf{j}$	$\mathbf{j}$	$-\mathbf{k}$	-1	$\mathbf{i}$
$\mathbf{k}$	$\mathbf{k}$	$\mathbf{j}$	$-\mathbf{i}$	-1

$\times$	1	e_1	e_2	e_1e_2
1	1	e_1	e_2	e_1e_2
e_1	e_1	$+1$	e_1e_2	e_2
e_2	e_2	$-e_1e_2$	$+1$	$-e_1$
e_1e_2	e_1e_2	$-e_2$	e_1	-1

Table T4.1: Multiplication tables (row $\times$ column) of $\mathrm{Cl}_{0,2} = \mathbb{H}$ (left) and $\mathrm{Cl}_{2,0} = \mathbb{R}(2)$ (right). The only difference is the sign of the squares of the generators, yet the left algebra is a division algebra and the right one is not (it contains the non-invertible matrix $\frac{1}{2}(1 + e_1)$). In both, the bivector e_1e_2 squares to -1: that is the rotation generator.

T4.2.5 Three dimensions: the Pauli algebra

Worked example T4.11: $\mathrm{Cl}_{3,0} \cong \mathbb{C}(2)$: the algebra of Pauli matrices

Take $e_a \mapsto \sigma_a$. The eight basis monomials become

$$1 \mapsto \mathbf{1}; \qquad e_1, e_2, e_3 \mapsto \sigma_1, \sigma_2, \sigma_3;$$

$$e_1e_2 \mapsto i\sigma_3, \quad e_2e_3 \mapsto i\sigma_1, \quad e_3e_1 \mapsto i\sigma_2; \qquad e_1e_2e_3 \mapsto \sigma_1\sigma_2\sigma_3 \overset{(1)}{=} i\sigma_3\sigma_3 \overset{(2)}{=} i\mathbf{1}.$$

(1) $\sigma_1\sigma_2 = i\sigma_3$.
(2) $\sigma_3^2 = \mathbf{1}$.

As a *real* vector space, the span of $\{\mathbf{1}, \sigma_a, i\sigma_a, i\mathbf{1}\}$ is all of $\mathbb{C}(2)$, the complex 2×2 matrices (real dimension 8). So the map is onto an 8-dimensional algebra, hence injective: $\mathrm{Cl}_{3,0} \cong \mathbb{C}(2)$ and the eight monomials are linearly independent, confirming dim $= 2^3$.
The **volume element** $\omega := e_1e_2e_3$ is special:

- it commutes with every e_a (moving e_a through ω passes two other generators and one copy of itself: $(-1)^2 = 1$), hence it is central;
- $\omega^2 = e_1e_2e_3e_1e_2e_3 = (e_1e_2)^2e_3^2 \cdot (+1) = -1$ (moving e_3 past e_1e_2 costs $(-1)^2$).

A central element squaring to -1 acts as $\pm i$; in the Pauli representation it is exactly $i\mathbf{1}$. This is why the "real" Clifford algebra of three-space secretly contains the complex numbers.

Physical picture: geometric algebra of space

In $\mathrm{Cl}_{3,0}$ the four grades have a direct geometric meaning. Vectors $v = v^a e_a$ are arrows. Bivectors e_1e_2, e_2e_3, e_3e_1 are oriented plane elements; since $e_1e_2 = i\sigma_3$, a bivector is "i times the normal vector", which is the Clifford version of the fact that an axial vector (angular momentum, magnetic field) is really an oriented plane. The trivector $e_1e_2e_3$ is an oriented volume, the pseudoscalar. The product of two vectors is scalar plus bivector: $ab = a \cdot b + i\,\sigma \cdot (a \times b)$, which is the Pauli identity of Example T4.2 read geometrically.

Worked example T4.12: $\mathrm{Cl}_{0,3} \cong \mathbb{H} \oplus \mathbb{H}$: a representation can be smaller than the algebra

With $e_a^2 = -1$ try $e_a \mapsto -i\sigma_a$ (the quaternions of (T4.13)). The relations hold, but

$$e_1e_2e_3 \mapsto (-i)^3\sigma_1\sigma_2\sigma_3 \overset{(1)}{=} i \cdot i\mathbf{1} = -\mathbf{1}.$$

(1) $(-i)^3 = i$ and $\sigma_1\sigma_2\sigma_3 = i\mathbf{1}$.

So the degree-3 monomial is represented by a multiple of the identity: the eight monomials are *not* independent in this representation, which has only real dimension 4. What happened? Now the volume element $\omega = e_1e_2e_3$ is central with $\omega^2 = +1$ (same computation as before with $e_3^2 = -1$ and $(e_1e_2)^2 = -1$). Exactly as in $\mathrm{Cl}_{1,0}$, the elements $\frac{1}{2}(1 \pm \omega)$ are central complementary projectors, and they split the algebra into two pieces, each a copy of $\mathbb{H}$. The representation $e_a \mapsto -i\sigma_a$ has $\omega = -1$, so it sees only one piece; the other representation $e_a \mapsto +i\sigma_a$ has $\omega = +1$ and sees the other. The faithful representation is block diagonal, $e_a \mapsto \mathrm{diag}(-i\sigma_a, i\sigma_a)$, and $\mathrm{Cl}_{0,3} \cong \mathbb{H} \oplus \mathbb{H}$. The lesson: in odd dimensions a central volume element with square $+1$ splits the algebra, and there are two inequivalent irreducible representations.

T4.2.6 Clifford algebra versus exterior algebra

The basis monomials e_I look exactly like the basis $e_{i_1} \wedge \cdots \wedge e_{i_k}$ of the exterior algebra $\Lambda^\bullet V$. The difference is only in what happens when an index repeats: in Λ, $e_i \wedge e_i = 0$; in Cl, $e_i e_i = \pm 1$. Dray [Dray §20.3] makes this precise with his "vee" product on forms: for 1-forms α, β,

$$\alpha \vee \beta = \alpha \wedge \beta + g(\alpha, \beta) \tag{T4.15}$$

(Dray's (20.20); we use the + convention). The Clifford product of two vectors is their wedge product plus their dot product. Let us derive Dray's formula (20.21) for three 1-forms. We need the product of a 2-form with a 1-form, $(\alpha \wedge \beta) \vee \gamma$. Write $\alpha \wedge \beta = \alpha \vee \beta - g(\alpha, \beta)$ and use associativity; for orthonormal e_1, e_2, e_3 we check directly:

$$e_1 \vee e_2 \vee e_1 \overset{(1)}{=} -e_1 \vee e_1 \vee e_2 \overset{(2)}{=} -e_2,$$

$$\text{formula (20.21):} \quad e_1 \wedge e_2 \wedge e_1 + g(e_1, e_2)e_1 - g(e_1, e_1)e_2 + g(e_2, e_1)e_1 \overset{(3)}{=} 0 + 0 - e_2 + 0 = -e_2.$$

(1) Anticommute the first two factors ($e_1 \perp e_2$).
(2) $e_1 \vee e_1 = g(e_1, e_1) = 1$.
(3) A wedge with a repeated factor vanishes, and $g(e_1, e_2) = 0$.

Checking all orderings of orthonormal triples (with repeats) proves

$$\alpha \vee \beta \vee \gamma = \alpha \wedge \beta \wedge \gamma + g(\alpha, \beta)\gamma - g(\alpha, \gamma)\beta + g(\beta, \gamma)\alpha \tag{T4.16}$$

by linearity. We will use exactly this identity (with γ matrices) in the Lichnerowicz computation of Section T4.8.

Key idea: Clifford = exterior, deformed by the metric

The linear map $\Lambda^\bullet V \to \mathrm{Cl}(V)$, $e_{i_1} \wedge \cdots \wedge e_{i_k} \mapsto e_{i_1} \cdots e_{i_k}$ (for an orthonormal basis) is an isomorphism of *vector spaces* but not of algebras [Bär Rem. 2.1.15]. Under it, the Clifford product of a vector with anything is

$$v \cdot \phi = v \wedge \phi + \iota_v \phi \qquad (\text{with } v^2 = +|v|^2),$$

wedge plus contraction. Every Clifford algebra is the exterior algebra with its product "corrected" by the inner product. This is the bridge that lets differential forms carry a Clifford action (Section T4.9).

T4.2.7 Even and odd parts

Because every relation (T4.9) involves only even-degree terms ($e_i e_j + e_j e_i$ and 1), the parity of the degree is well defined, even though the degree itself is not (Example T4.6). So the algebra splits

$$\mathrm{Cl}_{p,q} = \mathrm{Cl}^0_{p,q} \oplus \mathrm{Cl}^1_{p,q}, \qquad \mathrm{Cl}^i \cdot \mathrm{Cl}^j \subseteq \mathrm{Cl}^{i+j \bmod 2}, \tag{T4.17}$$

where Cl^0 (the **even part**) is spanned by monomials of even degree and Cl^1 (the odd part) by those of odd degree. Each has dimension 2^{n-1}. The even part is a subalgebra; the odd part is not. A slick way to say this [Bär p. 71]: the map $e_i \mapsto -e_i$ preserves the relations, so it extends to an automorphism α with $\alpha^2 = 1$; Cl^0 and Cl^1 are its ± 1 eigenspaces.

Worked example T4.13: the even part of $\mathrm{Cl}_{3,0}$ is the quaternions

$\mathrm{Cl}^0_{3,0}$ is spanned by $1, e_2e_3, e_3e_1, e_1e_2 \mapsto \mathbf{1}, i\sigma_1, i\sigma_2, i\sigma_3$. Each bivector squares to -1, and $(e_2e_3)(e_3e_1) = e_2e_1 = -e_1e_2$. So with $\mathbf{i} = -e_2e_3$, $\mathbf{j} = -e_3e_1$, $\mathbf{k} = -e_1e_2$ (matrices $-i\sigma_a$) we recover Hamilton's rules: $\mathrm{Cl}^0_{3,0} \cong \mathbb{H} \cong \mathrm{Cl}_{0,2}$. The even part of the 3D algebra is the 2D algebra with the opposite sign. This is a general phenomenon [Bär Lemma 2.3.12]:

$$\mathrm{Cl}^0_{p,q+1} \cong \mathrm{Cl}_{p,q}, \qquad \text{via } e_i \mapsto e_ie_{n+1}\ (i \le n), \tag{T4.18}$$

where e_{n+1} is the extra generator with $e_{n+1}^2 = -1$. The check: $(e_ie_{n+1})^2 = -e_i^2e_{n+1}^2 = e_i^2$, and for $i \neq j$, $(e_ie_{n+1})(e_je_{n+1}) = -e_ie_je_{n+1}^2 = e_ie_j$ anticommutes with $(e_je_{n+1})(e_ie_{n+1}) = e_je_i$. So the elements e_ie_{n+1} satisfy the relations of $\mathrm{Cl}_{p,q}$, and a dimension count (2^n on both sides) gives the isomorphism.

Physical picture: why physicists care about the even part

Rotations are built from products of an *even* number of vectors (Section T4.5), so the spin group and its Lie algebra live in Cl^0. The Lie algebra is spanned by the bivectors e_ie_j: in 3D these are $i\sigma_a$, the generators $-\frac{i}{2}\sigma_a$ of SU(2) up to a factor. The isomorphism (T4.18) is the algebraic reason why the spinors of $n+1$ dimensions, restricted to rotations, look like the spinors of n dimensions (e.g. a 4D Weyl spinor restricted to spatial rotations is a 3D Pauli spinor).

T4.2.8 Building big algebras from small ones

If $V = V_1 \oplus V_2$ is an orthogonal splitting, then generators from V_1 anticommute with generators from V_2. So $\mathrm{Cl}(V)$ is built from $\mathrm{Cl}(V_1)$ and $\mathrm{Cl}(V_2)$, but with a twist: we must remember that odd elements of the two factors anticommute. Bär [Bär Def. 2.1.11, Prop. 2.1.12] calls this the **graded tensor product**:

$$\mathrm{Cl}(V_1 \oplus V_2) \cong \mathrm{Cl}(V_1) \hat{\otimes} \mathrm{Cl}(V_2), \qquad (a \otimes b)(a' \otimes b') = (-1)^{|b|\,|a'|}\, aa' \otimes bb', \tag{T4.19}$$

with $v_1 + v_2 \mapsto v_1 \otimes 1 + 1 \otimes v_2$. The sign is exactly what is needed: $(v_1 \otimes 1)(1 \otimes v_2) = v_1 \otimes v_2$ while $(1 \otimes v_2)(v_1 \otimes 1) = -v_1 \otimes v_2$. Taking dimensions gives $\dim \mathrm{Cl}(V) = \dim \mathrm{Cl}(V_1) \cdot \dim \mathrm{Cl}(V_2)$, and induction from the one-dimensional case gives $\dim \mathrm{Cl}(V) = 2^{\dim V}$ [Bär Cor. 2.1.13]. For computing *which* matrix algebra we get, the ungraded tensor product is more useful; we use it in Section T4.4.5. In physics this sign rule is the familiar one: fermionic operators from independent subsystems anticommute.

Watch out: "the Clifford algebra of $\mathrm{Spin}(n)$"

Nash [Nash p. 114] says the γ-matrices "generate the Clifford algebra of $\mathrm{Spin}(n)$". Strictly, the Clifford algebra belongs to the vector space $\mathbb{R}^n$ with its inner product; $\mathrm{Spin}(n)$ is a group sitting *inside* it (Section T4.5). The phrase is a harmless shorthand, but do not look for a Clifford algebra "of a group" in general.

Recap

- $\mathrm{Cl}_{p,q}$: generators with $e_ie_j + e_je_i = 2\eta_{ij}$; equivalently $v^2 = Q(v)$. Basis e_I indexed by subsets; $\dim = 2^n$.
- Low dimensions: $\mathrm{Cl}_{0,1} = \mathbb{C}$, $\mathrm{Cl}_{1,0} = \mathbb{R} \oplus \mathbb{R}$, $\mathrm{Cl}_{0,2} = \mathbb{H}$ (matrices $-i\sigma_a$), $\mathrm{Cl}_{2,0} = \mathbb{R}(2)$

(matrices σ_1, σ_3), $\mathrm{Cl}_{3,0} = \mathbb{C}(2)$ (Pauli), $\mathrm{Cl}_{0,3} = \mathbb{H} \oplus \mathbb{H}$.

- $\mathrm{Cl} \cong \Lambda^\bullet$ as vector spaces; Clifford product of a vector = wedge + contraction (Dray's vee product).
- $\mathbb{Z}_2$-grading $\mathrm{Cl} = \mathrm{Cl}^0 \oplus \mathrm{Cl}^1$; $\mathrm{Cl}^0_{p,q+1} \cong \mathrm{Cl}_{p,q}$; rotations live in the even part.
- In odd dimensions a central volume element can split the algebra into two pieces, giving two inequivalent irreducible representations.

T4.3 Gamma matrices in four dimensions

We saw in Section T4.1.2 that three anticommuting 2×2 matrices exist but four do not. Four dimensions is where physics lives, so we need four anticommuting matrices, and they must be at least 4×4. This section writes them down in the representations that appear in the literature, checks every relation by block multiplication, and then uses them: chirality γ^5, Weyl spinors, the Lorentz generators, and the sixteen bilinears $\bar\psi \Gamma \psi$. Everything later in the book (the index of the Dirac operator in Chapter 4, the chiral anomaly in Chapter 10) is written in terms of these matrices.

The one trick we use over and over is **block multiplication**. Write a 4×4 matrix as a 2×2 array of 2×2 blocks. Then

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix} \begin{pmatrix} A' & B' \\ C' & D' \end{pmatrix} = \begin{pmatrix} AA' + BC' & AB' + BD' \\ CA' + DC' & CB' + DD' \end{pmatrix},$$

exactly as for numbers, except that the order of the blocks in each product must be kept, because 2×2 matrices do not commute. With Pauli matrices in the blocks, every computation reduces to the Pauli product rule (T4.6).

T4.3.1 Euclidean signature: the chiral representation

In Euclidean $\mathbb{R}^4$ we want Hermitian $\gamma_1, \dots, \gamma_4$ with $\{\gamma_a, \gamma_b\} = 2\delta_{ab}$. The idea is to put 2×2 blocks off the diagonal. Define the four 2×2 matrices

$$\tau_a = (\tau_1, \tau_2, \tau_3, \tau_4) \coloneqq (i\sigma_1,\ i\sigma_2,\ i\sigma_3,\ \mathbf{1}), \qquad \tau_a^\dagger = (-i\sigma_1,\ -i\sigma_2,\ -i\sigma_3,\ \mathbf{1}), \tag{T4.20}$$

and set

$$\gamma_a \coloneqq \begin{pmatrix} 0 & \tau_a \\ \tau_a^\dagger & 0 \end{pmatrix}, \qquad a = 1, 2, 3, 4. \tag{T4.21}$$

Written out, $\gamma_4 = \begin{pmatrix} 0 & \mathbf{1} \\ \mathbf{1} & 0 \end{pmatrix}$ and $\gamma_j = \begin{pmatrix} 0 & i\sigma_j \\ -i\sigma_j & 0 \end{pmatrix}$ for $j = 1, 2, 3$. Each γ_a is Hermitian, because the lower-left block is the Hermitian conjugate of the upper-right block.

The four τ_a are the *quaternion units* (up to sign) from (T4.13), and the relation we need is

$$\tau_a \tau_b^\dagger + \tau_b \tau_a^\dagger = 2\delta_{ab}\mathbf{1}, \qquad \tau_a^\dagger \tau_b + \tau_b^\dagger \tau_a = 2\delta_{ab}\mathbf{1}. \tag{T4.22}$$

Check it case by case. For $a = b = 4$: $2 \cdot \mathbf{1} \cdot \mathbf{1} = 2$. For $a = j$, $b = 4$: $\tau_j \tau_4^\dagger + \tau_4 \tau_j^\dagger = i\sigma_j - i\sigma_j = 0$. For $a = j, b = k$ spatial:

$$\tau_j \tau_k^\dagger + \tau_k \tau_j^\dagger \overset{(1)}{=} (i\sigma_j)(-i\sigma_k) + (i\sigma_k)(-i\sigma_j) \overset{(2)}{=} \sigma_j\sigma_k + \sigma_k\sigma_j \overset{(3)}{=} 2\delta_{jk}.$$

(1) Insert (T4.20).
(2) $(i)(-i) = 1$.
(3) The Pauli anticommutator.

The second relation in (T4.22) is checked the same way.

Worked example T4.14: the Euclidean Clifford relations by block multiplication

Using the block rule,

$$\gamma_a\gamma_b + \gamma_b\gamma_a \overset{(1)}{=} \begin{pmatrix} \tau_a\tau_b^\dagger & 0 \\ 0 & \tau_a^\dagger\tau_b \end{pmatrix} + \begin{pmatrix} \tau_b\tau_a^\dagger & 0 \\ 0 & \tau_b^\dagger\tau_a \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} 2\delta_{ab}\mathbf{1} & 0 \\ 0 & 2\delta_{ab}\mathbf{1} \end{pmatrix} = 2\delta_{ab}\mathbf{1}_4.$$

(1) Product of two block-off-diagonal matrices: the upper-left block is (upper right)×(lower left) $= \tau_a\tau_b^\dagger$, and the lower-right block is (lower left)×(upper right) $= \tau_a^\dagger\tau_b$.
(2) The relations (T4.22).

So (T4.21) is a representation of the Euclidean Clifford algebra on $\mathbb{C}^4$. Note what the computation shows in passing: the product of *two* gamma matrices is block *diagonal*. This fact is behind everything that follows about chirality.

The chirality matrix. Multiply all four:

$$\begin{aligned} \gamma_1\gamma_2 &\overset{(1)}{=} \begin{pmatrix} \tau_1\tau_2^\dagger & 0 \\ 0 & \tau_1^\dagger\tau_2 \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} \sigma_1\sigma_2 & 0 \\ 0 & \sigma_1\sigma_2 \end{pmatrix} = \begin{pmatrix} i\sigma_3 & 0 \\ 0 & i\sigma_3 \end{pmatrix}, \\ \gamma_3\gamma_4 &\overset{(3)}{=} \begin{pmatrix} \tau_3 & 0 \\ 0 & \tau_3^\dagger \end{pmatrix} = \begin{pmatrix} i\sigma_3 & 0 \\ 0 & -i\sigma_3 \end{pmatrix}, \\ \gamma_1\gamma_2\gamma_3\gamma_4 &\overset{(4)}{=} \begin{pmatrix} (i\sigma_3)(i\sigma_3) & 0 \\ 0 & (i\sigma_3)(-i\sigma_3) \end{pmatrix} = \begin{pmatrix} -\mathbf{1} & 0 \\ 0 & \mathbf{1} \end{pmatrix}. \end{aligned} \tag{T4.23}$$

(1) Block rule for two off-diagonal matrices.
(2) $(i\sigma_1)(-i\sigma_2) = \sigma_1\sigma_2$ and $(-i\sigma_1)(i\sigma_2) = \sigma_1\sigma_2$.
(3) Same rule with $\tau_4 = \mathbf{1}$.
(4) Multiply the two diagonal matrices block by block; $\sigma_3^2 = \mathbf{1}$.

We define the Euclidean **chirality operator** in four dimensions by

$$\Gamma := (-i)^2\gamma_1\gamma_2\gamma_3\gamma_4 = -\gamma_1\gamma_2\gamma_3\gamma_4 = \begin{pmatrix} \mathbf{1} & 0 \\ 0 & -\mathbf{1} \end{pmatrix}. \tag{T4.24}$$

The phase $(-i)^2$ is part of a general rule, $\Gamma = (-i)^k\gamma_1\cdots\gamma_{2k}$, that we justify in Section T4.4; it is chosen so that Γ is Hermitian with $\Gamma^2 = 1$. In this representation Γ is diagonal: the upper two components of a spinor have chirality $+1$ and the lower two have chirality -1. That is why this is called the **chiral representation**.

T4.3.2 Minkowski signature: Dirac and Weyl representations

We now follow the QFT notes [QFT notes §3.5]. The metric is $\eta^{\mu\nu} = \mathrm{diag}(+1,-1,-1,-1)$, so we need

$$(\gamma^0)^2 = \mathbf{1}, \qquad (\gamma^i)^2 = -\mathbf{1}\ (i=1,2,3), \qquad \gamma^\mu\gamma^\nu = -\gamma^\nu\gamma^\mu\ (\mu \neq \nu).$$

Since $(\gamma^i)^2 = -1$, the γ^i cannot be Hermitian (a Hermitian matrix has real eigenvalues, so its square is positive). The standard choice is γ^0 Hermitian and γ^i anti-Hermitian. All the representations below share the spatial matrices

$$\gamma^i = \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix}, \qquad i = 1,2,3, \tag{T4.25}$$

and differ in γ^0.

Working definition T4.4 (Dirac and Weyl (chiral) representations)

The **Dirac representation** has $\gamma^0_{\mathrm{D}} = \begin{pmatrix} \mathbf{1} & 0 \\ 0 & -\mathbf{1} \end{pmatrix}$ and (T4.25). The **Weyl** or **chiral representation** [the basis of $\mathbb{C}^4$ in which γ^5 is diagonal, so the upper two and lower two components have opposite chirality] [QFT notes (3.5.13)] has $\gamma^0_{\mathrm{W}} = \begin{pmatrix} 0 & \mathbf{1} \\ \mathbf{1} & 0 \end{pmatrix}$ and (T4.25). With

$$\sigma^\mu := (\mathbf{1}, \sigma^1, \sigma^2, \sigma^3), \qquad \bar\sigma^\mu := (\mathbf{1}, -\sigma^1, -\sigma^2, -\sigma^3), \tag{T4.26}$$

the Weyl representation is compactly $\gamma^\mu = \begin{pmatrix} 0 & \sigma^\mu \\ \bar\sigma^\mu & 0 \end{pmatrix}$ [QFT notes (3.5.51)]. *Test for any proposed set:* check $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$ on all ten pairs, e.g. by block multiplication as below.

Worked example T4.15: verifying the Weyl representation

Exactly as in Example T4.14,

$$\{\gamma^\mu, \gamma^\nu\} \overset{(1)}{=} \begin{pmatrix} \sigma^\mu\bar\sigma^\nu + \sigma^\nu\bar\sigma^\mu & 0 \\ 0 & \bar\sigma^\mu\sigma^\nu + \bar\sigma^\nu\sigma^\mu \end{pmatrix}.$$

(1) Block rule for off-diagonal matrices.

Now evaluate the upper-left block on each type of pair:

$$\begin{aligned} \mu = \nu = 0: &\quad \sigma^0\bar\sigma^0 + \sigma^0\bar\sigma^0 \overset{(1)}{=} 2\mathbf{1} = 2\eta^{00}, \\ \mu = 0, \nu = i: &\quad \sigma^0\bar\sigma^i + \sigma^i\bar\sigma^0 \overset{(2)}{=} -\sigma^i + \sigma^i = 0 = 2\eta^{0i}, \\ \mu = i, \nu = j: &\quad \sigma^i\bar\sigma^j + \sigma^j\bar\sigma^i \overset{(3)}{=} -(\sigma^i\sigma^j + \sigma^j\sigma^i) \overset{(4)}{=} -2\delta^{ij} = 2\eta^{ij}. \end{aligned}$$

(1) $\sigma^0 = \bar\sigma^0 = \mathbf{1}$.
(2) $\bar\sigma^i = -\sigma^i$ and $\bar\sigma^0 = \mathbf{1}$.
(3) Again $\bar\sigma^j = -\sigma^j$.
(4) Pauli anticommutator; and $\eta^{ij} = -\delta^{ij}$.

The lower-right block is the same computation with $\sigma \leftrightarrow \bar\sigma$ and gives the same answers. So $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbf{1}_4$. The Dirac representation is checked the same way; the only new products are $\gamma^0_{\mathrm{D}}\gamma^i + \gamma^i\gamma^0_{\mathrm{D}} = \begin{pmatrix} 0 & \sigma^i \\ \sigma^i & 0 \end{pmatrix} + \begin{pmatrix} 0 & -\sigma^i \\ -\sigma^i & 0 \end{pmatrix} = 0$.

Why two representations, and how they are related. Both sets of matrices satisfy the same algebra. In Section T4.4.3 we will see that any two irreducible representations of the complex Clifford algebra in even dimensions are *equivalent*: there is an invertible U with $\gamma^\mu_{\mathrm{W}} = U\gamma^\mu_{\mathrm{D}}U^{-1}$ for all μ. Here it is explicitly.

Worked example T4.16: the change of basis from Dirac to Weyl

Let $U = \frac{1}{\sqrt{2}}\begin{pmatrix} \mathbf{1} & -\mathbf{1} \\ \mathbf{1} & \mathbf{1} \end{pmatrix}$, which is unitary with $U^\dagger = \frac{1}{\sqrt{2}}\begin{pmatrix} \mathbf{1} & \mathbf{1} \\ -\mathbf{1} & \mathbf{1} \end{pmatrix}$. Then

$$U\gamma^0_{\mathrm{D}}U^\dagger \overset{(1)}{=} \tfrac{1}{2}\begin{pmatrix} \mathbf{1} & \mathbf{1} \\ \mathbf{1} & -\mathbf{1} \end{pmatrix}\begin{pmatrix} \mathbf{1} & \mathbf{1} \\ -\mathbf{1} & \mathbf{1} \end{pmatrix} \overset{(2)}{=} \tfrac{1}{2}\begin{pmatrix} 0 & 2\cdot\mathbf{1} \\ 2\cdot\mathbf{1} & 0 \end{pmatrix} = \gamma^0_{\mathrm{W}},$$

$$U\gamma^i U^\dagger \overset{(3)}{=} \tfrac{1}{2}\begin{pmatrix} \sigma^i & \sigma^i \\ -\sigma^i & \sigma^i \end{pmatrix}\begin{pmatrix} \mathbf{1} & \mathbf{1} \\ -\mathbf{1} & \mathbf{1} \end{pmatrix} \overset{(4)}{=} \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix} = \gamma^i.$$

(1) $U\gamma^0_{\mathrm{D}}$: multiplying by $\mathrm{diag}(\mathbf{1}, -\mathbf{1})$ on the right flips the sign of the second block column of U.

(2) Block multiplication: upper-left $\mathbf{1} - \mathbf{1} = 0$, upper-right $\mathbf{1} + \mathbf{1}$, and so on.

(3) $U\gamma^i = \frac{1}{\sqrt{2}}\left(\begin{smallmatrix} \sigma^i & \sigma^i \\ -\sigma^i & \sigma^i \end{smallmatrix}\right)$ by block multiplication.

(4) Upper-left $\sigma^i - \sigma^i = 0$, upper-right $\sigma^i + \sigma^i$, lower-left $-\sigma^i - \sigma^i$, lower-right $-\sigma^i + \sigma^i$; then divide by 2.

So a Dirac-representation spinor ψ_{D} corresponds to the Weyl-representation spinor $\psi_{\mathrm{W}} = U\psi_{\mathrm{D}}$. The physics is identical; only the basis of $\mathbb{C}^4$ has changed. The Dirac representation is convenient near rest (then γ^0 is diagonal and separates particle from antiparticle components); the Weyl representation is convenient for massless particles and for chirality.

Hermiticity in one line. In both representations

$$(\gamma^\mu)^\dagger = \gamma^0\gamma^\mu\gamma^0. \tag{T4.27}$$

For $\mu = 0$ this says γ^0 is Hermitian (using $(\gamma^0)^2 = 1$). For $\mu = i$: $\gamma^0\gamma^i\gamma^0 = -\gamma^i(\gamma^0)^2 = -\gamma^i = (\gamma^i)^\dagger$. Since U is unitary, (T4.27) survives any unitary change of basis. We will use it for the Dirac conjugate $\bar\psi = \psi^\dagger\gamma^0$.

T4.3.3 The chirality matrix γ^5

Working definition T4.5 (γ^5 in Minkowski space)

$\gamma^5 := i\gamma^0\gamma^1\gamma^2\gamma^3$ [QFT notes (3.5.122)]. It satisfies

$$(\gamma^5)^\dagger = \gamma^5, \qquad (\gamma^5)^2 = \mathbf{1}, \qquad \{\gamma^5, \gamma^\mu\} = 0. \tag{T4.28}$$

Its eigenvalues are ± 1, each twice. The **chiral projectors** [$P_L\psi$ keeps only the part of ψ with $\gamma^5 = -1$, and $P_R\psi$ only the part with $\gamma^5 = +1$] are $P_L = \frac{1}{2}(1 - \gamma^5)$ and $P_R = \frac{1}{2}(1 + \gamma^5)$.

Let us derive the three properties. The factor i is there to make the square positive:

$$\begin{aligned}(\gamma^5)^2 &\overset{(1)}{=} i^2\,\gamma^0\gamma^1\gamma^2\gamma^3\gamma^0\gamma^1\gamma^2\gamma^3 \\ &\overset{(2)}{=} -(-1)^3\,\gamma^0\gamma^0\,\gamma^1\gamma^2\gamma^3\gamma^1\gamma^2\gamma^3 \\ &\overset{(3)}{=} \gamma^1\gamma^2\gamma^3\gamma^1\gamma^2\gamma^3 \overset{(4)}{=} (-1)^2\gamma^1\gamma^1\,\gamma^2\gamma^3\gamma^2\gamma^3 \\ &\overset{(5)}{=} -\gamma^2\gamma^3\gamma^2\gamma^3 \overset{(6)}{=} \gamma^2\gamma^2\gamma^3\gamma^3 \overset{(7)}{=} \mathbf{1}.\end{aligned}$$

(1) Write out the product.

(2) Move the second γ^0 to the left past $\gamma^3, \gamma^2, \gamma^1$: three anticommutations.
(3) $(\gamma^0)^2 = 1$ and $-(-1)^3 = 1$.
(4) Move the second γ^1 left past γ^3, γ^2: two signs.
(5) $(\gamma^1)^2 = -1$.
(6) Anticommute $\gamma^3\gamma^2 = -\gamma^2\gamma^3$ in the middle.
(7) $(\gamma^2)^2(\gamma^3)^2 = (-1)(-1) = 1$.

For the anticommutation: γ^μ anticommutes with the three factors of $\gamma^0\gamma^1\gamma^2\gamma^3$ different from it and commutes with the one equal to it, so moving it through the product costs $(-1)^3 = -1$. For Hermiticity:

$$(\gamma^5)^\dagger \overset{(1)}{=} -i(\gamma^3)^\dagger(\gamma^2)^\dagger(\gamma^1)^\dagger(\gamma^0)^\dagger \overset{(2)}{=} -i(-1)^3\gamma^3\gamma^2\gamma^1\gamma^0 \overset{(3)}{=} i\,(-1)^6\gamma^0\gamma^1\gamma^2\gamma^3 = \gamma^5.$$

(1) The dagger reverses the order and conjugates i.
(2) γ^0 is Hermitian, the three γ^i are anti-Hermitian.
(3) Reversing four objects takes $3 + 2 + 1 = 6$ transpositions.

Worked example T4.17: γ^5 in the two representations

In the Weyl representation,

$$\gamma^0\gamma^1 \overset{(1)}{=} \begin{pmatrix} 0 & \mathbf{1} \\ \mathbf{1} & 0 \end{pmatrix}\begin{pmatrix} 0 & \sigma^1 \\ -\sigma^1 & 0 \end{pmatrix} = \begin{pmatrix} -\sigma^1 & 0 \\ 0 & \sigma^1 \end{pmatrix},$$

$$\gamma^2\gamma^3 \overset{(2)}{=} \begin{pmatrix} -\sigma^2\sigma^3 & 0 \\ 0 & -\sigma^2\sigma^3 \end{pmatrix} \overset{(3)}{=} \begin{pmatrix} -i\sigma^1 & 0 \\ 0 & -i\sigma^1 \end{pmatrix},$$

$$\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3 \overset{(4)}{=} i\begin{pmatrix} (-\sigma^1)(-i\sigma^1) & 0 \\ 0 & \sigma^1(-i\sigma^1) \end{pmatrix} = \begin{pmatrix} -\mathbf{1} & 0 \\ 0 & \mathbf{1} \end{pmatrix}.$$

(1) Block multiplication.
(2) Two off-diagonal blocks: upper-left is $\sigma^2(-\sigma^3)$, lower-right is $(-\sigma^2)\sigma^3$.
(3) $\sigma^2\sigma^3 = i\sigma^1$.
(4) Multiply the diagonal blocks and use $(\sigma^1)^2 = \mathbf{1}$; then $i \cdot i = -1$ and $i \cdot (-i) = 1$.

So $\gamma^5_{\mathrm{W}} = \mathrm{diag}(-\mathbf{1}, \mathbf{1})$ [QFT notes (3.5.128)], and $P_L = \mathrm{diag}(\mathbf{1}, 0)$, $P_R = \mathrm{diag}(0, \mathbf{1})$. In the Dirac representation $\gamma^5_{\mathrm{D}} = U^\dagger\gamma^5_{\mathrm{W}}U = \begin{pmatrix} 0 & \mathbf{1} \\ \mathbf{1} & 0 \end{pmatrix}$: chirality is *not* diagonal there, which is why the Weyl basis is used for chiral physics.

Watch out: the sign of γ^5 and a typo in the QFT notes

With $\gamma^5_{\mathrm{W}} = \mathrm{diag}(-\mathbf{1}, \mathbf{1})$, the left-handed spinor $\psi = (\psi_L, 0)$ has $\gamma^5\psi = -\psi$, and $P_L = \frac{1}{2}(1-\gamma^5)$ picks it out. The QFT notes say (just after (3.5.128)) that a left-handed spinor has eigenvalue $+1$; that is a slip, as their own projector $P_L = \frac{1}{2}(1 - \gamma^5)$ shows. Other books (Srednicki, some older texts) use $\gamma^5 = -i\gamma^0\gamma^1\gamma^2\gamma^3$ or put ψ_L in the lower components. Always check which components P_L projects onto.

T4.3.4 Lorentz transformations of spinors

Why do anticommuting matrices have anything to do with relativity? Because their commutators generate Lorentz transformations. The QFT notes define

$$S^{\mu\nu} := \frac{i}{4}[\gamma^\mu, \gamma^\nu] \tag{T4.29}$$

[QFT notes (3.5.2)] and show, using only $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$, that these obey the commutation relations of the Lorentz algebra [QFT notes (3.5.5)]. The spinor transformation with parameters $\omega_{\mu\nu} = -\omega_{\nu\mu}$ is

$$\psi \longmapsto \Lambda_{1/2}\psi, \qquad \Lambda_{1/2} = \exp\Big(-\frac{i}{2}\omega_{\mu\nu}S^{\mu\nu}\Big). \tag{T4.30}$$

Let us compute the generators in the Weyl representation.

Worked example T4.18: boosts and rotations as block-diagonal matrices

For $\mu \neq \nu$, $[\gamma^\mu, \gamma^\nu] = 2\gamma^\mu\gamma^\nu$, so $S^{\mu\nu} = \frac{i}{2}\gamma^\mu\gamma^\nu$. Then

$$S^{0i} \overset{(1)}{=} \frac{i}{2}\begin{pmatrix}0 & \mathbf{1}\\ \mathbf{1} & 0\end{pmatrix}\begin{pmatrix}0 & \sigma^i\\ -\sigma^i & 0\end{pmatrix} \overset{(2)}{=} \frac{i}{2}\begin{pmatrix}-\sigma^i & 0\\ 0 & \sigma^i\end{pmatrix} = -\frac{i}{2}\begin{pmatrix}\sigma^i & 0\\ 0 & -\sigma^i\end{pmatrix},$$
$$S^{ij} \overset{(3)}{=} \frac{i}{2}\begin{pmatrix}-\sigma^i\sigma^j & 0\\ 0 & -\sigma^i\sigma^j\end{pmatrix} \overset{(4)}{=} \frac{1}{2}\varepsilon^{ijk}\begin{pmatrix}\sigma^k & 0\\ 0 & \sigma^k\end{pmatrix} \quad (i \neq j).$$

(1) $S^{0i} = \frac{i}{2}\gamma^0\gamma^i$ with the Weyl matrices.
(2) Block multiplication (as in Example T4.17).
(3) Two off-diagonal matrices multiply to a diagonal one with blocks $\sigma^i(-\sigma^j)$ and $(-\sigma^i)\sigma^j$.
(4) For $i \neq j$, $\sigma^i\sigma^j = i\varepsilon^{ijk}\sigma^k$, and $\frac{i}{2}\cdot(-i) = \frac{1}{2}$.

These agree with [QFT notes (3.5.15), (3.5.17)]. All six generators are block diagonal, so Lorentz transformations never mix the upper and lower pairs of components. The rotation generators S^{ij} are Hermitian; the boost generators S^{0i} are anti-Hermitian, so boosts act by non-unitary matrices. This is unavoidable: the Lorentz group is non-compact, and a non-compact simple group has no faithful finite-dimensional unitary representations.

Worked example T4.19: finite rotations and the minus sign at 2π

A rotation by angle θ about the z-axis has $\omega_{12} = -\omega_{21} = \theta$ and all other parameters zero, so $-\frac{i}{2}\omega_{\mu\nu}S^{\mu\nu} = -i\theta S^{12}$. Thus

$$\Lambda_{1/2}(\theta) \overset{(1)}{=} \exp\Big(-\frac{i\theta}{2}\begin{pmatrix}\sigma^3 & 0\\ 0 & \sigma^3\end{pmatrix}\Big) \overset{(2)}{=} \operatorname{diag}\big(e^{-i\theta/2}, e^{i\theta/2}, e^{-i\theta/2}, e^{i\theta/2}\big).$$

(1) The two terms $\omega_{12}S^{12} + \omega_{21}S^{21} = 2\theta S^{12}$, and $S^{12} = \frac{1}{2}\operatorname{diag}(\sigma^3, \sigma^3)$ from the previous example.
(2) The exponent is diagonal, so exponentiate entry by entry.

At $\theta = 2\pi$ every entry is $e^{\pm i\pi} = -1$:

$$\Lambda_{1/2}(2\pi) = -\mathbf{1}_4.$$

A rotation by 2π, which is the identity on vectors, multiplies every Dirac spinor by -1. Only at $\theta = 4\pi$ do we return to $+\mathbf{1}$. This is the first appearance of the double cover Spin $\to$ SO (Section T4.5).

Worked example T4.20: a finite boost stretches spinors

A boost with rapidity β along z has $\omega_{03} = -\omega_{30} = \beta$, so the exponent is $-i\beta S^{03} = -i\beta\cdot(-\frac{i}{2})\operatorname{diag}(\sigma^3, -\sigma^3) = -\frac{\beta}{2}\operatorname{diag}(\sigma^3, -\sigma^3)$ and

$$\Lambda_{1/2} = \operatorname{diag}\big(e^{-\beta/2},\, e^{\beta/2},\, e^{\beta/2},\, e^{-\beta/2}\big).$$

The entries are real and not of modulus one: boosts rescale the components. On the upper (left-handed) block the boost is $e^{-\beta\sigma^3/2}$, on the lower (right-handed) block it is $e^{+\beta\sigma^3/2}$. The two blocks transform *inequivalently*; this is the content of [QFT notes (3.5.43)],

$$\psi_L \mapsto \big(1 - i\vec{\theta}\cdot\tfrac{\vec{\sigma}}{2} - \vec{\beta}\cdot\tfrac{\vec{\sigma}}{2}\big)\psi_L, \qquad \psi_R \mapsto \big(1 - i\vec{\theta}\cdot\tfrac{\vec{\sigma}}{2} + \vec{\beta}\cdot\tfrac{\vec{\sigma}}{2}\big)\psi_R.$$

Gammas are invariant tensors. The key identity that makes the Dirac equation Lorentz covariant is

$$[\gamma^\mu, S^{\rho\sigma}] = i\big(\eta^{\mu\rho}\gamma^\sigma - \eta^{\mu\sigma}\gamma^\rho\big). \tag{T4.31}$$

It follows from the identity $[A, BC] = \{A, B\}C - B\{A, C\}$:

$$\begin{aligned}
[\gamma^\mu, S^{\rho\sigma}] &\overset{(1)}{=} \frac{i}{4}\big([\gamma^\mu, \gamma^\rho\gamma^\sigma] - [\gamma^\mu, \gamma^\sigma\gamma^\rho]\big) \\
&\overset{(2)}{=} \frac{i}{4}\big(\{\gamma^\mu, \gamma^\rho\}\gamma^\sigma - \gamma^\rho\{\gamma^\mu, \gamma^\sigma\} - \{\gamma^\mu, \gamma^\sigma\}\gamma^\rho + \gamma^\sigma\{\gamma^\mu, \gamma^\rho\}\big) \\
&\overset{(3)}{=} \frac{i}{4}\big(4\eta^{\mu\rho}\gamma^\sigma - 4\eta^{\mu\sigma}\gamma^\rho\big) = i\big(\eta^{\mu\rho}\gamma^\sigma - \eta^{\mu\sigma}\gamma^\rho\big).
\end{aligned}$$

(1) Definition (T4.29), expanding the commutator.
(2) $[A, BC] = ABC - BCA = (AB + BA)C - B(AC + CA)$.
(3) $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$; the numbers commute with the matrices, so the four terms combine in pairs.

The right-hand side of (T4.31) is exactly an infinitesimal Lorentz transformation acting on the vector index of γ^μ. Exponentiating gives [QFT notes (3.5.26)]

$$\Lambda_{1/2}^{-1}\gamma^\mu\Lambda_{1/2} = \Lambda^\mu{}_\nu\gamma^\nu, \tag{T4.32}$$

where $\Lambda^\mu{}_\nu$ is the vector Lorentz matrix with the same parameters. In words: rotating the spinor indices of γ^μ is the same as rotating its vector index. With this, if ψ solves the Dirac equation then so does $\psi'(x) = \Lambda_{1/2}\psi(\Lambda^{-1}x)$ [QFT notes (3.5.29)]: the operator $i\gamma^\mu\partial_\mu$ transforms into $\Lambda_{1/2}\, i\gamma^\nu\partial_\nu\Lambda_{1/2}^{-1}$ because the change of γ^μ cancels the change of ∂_μ. The same identity in Euclidean signature is the statement that $v \mapsto uvu^{-1}$ is a rotation, which we make the definition of the spin group in Section T4.5.

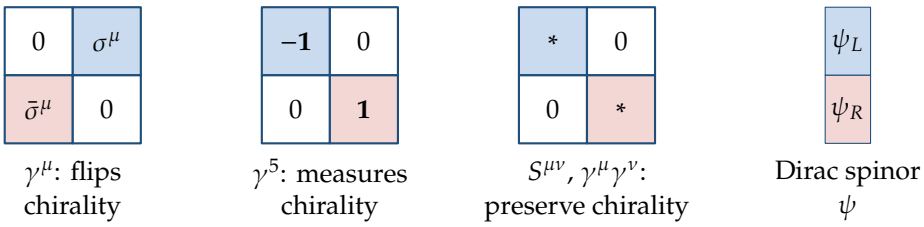


Figure T4.6: Block structure in the Weyl representation. A single γ^μ is off-diagonal, so it exchanges the left-handed (blue) and right-handed (red) halves of a Dirac spinor. Products of an even number of γ's, in particular the Lorentz generators, are block diagonal: Lorentz transformations never mix ψ_L and ψ_R. γ^5 is diagonal with entries ∓ 1 and simply reads off which half we are in.

T4.3.5 Weyl spinors

Because every Lorentz generator is block diagonal, the four-component Dirac spinor splits into two two-component pieces that transform separately:

$$\psi = \begin{pmatrix} \psi_L \\ \psi_R \end{pmatrix}, \qquad P_L\psi = \begin{pmatrix} \psi_L \\ 0 \end{pmatrix}, \quad P_R\psi = \begin{pmatrix} 0 \\ \psi_R \end{pmatrix}.$$

ψ_L and ψ_R are **Weyl spinors**. They are the two inequivalent two-dimensional representations of the Lorentz group, often written $(\frac{1}{2}, 0)$ and $(0, \frac{1}{2})$.

Worked example T4.21: the Dirac equation in chiral components

With the Weyl matrices,

$$(i\gamma^\mu\partial_\mu - m)\psi \overset{(1)}{=} \begin{pmatrix} -m & i\sigma^\mu\partial_\mu \\ i\bar\sigma^\mu\partial_\mu & -m \end{pmatrix}\begin{pmatrix} \psi_L \\ \psi_R \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} i\sigma^\mu\partial_\mu\psi_R - m\psi_L \\ i\bar\sigma^\mu\partial_\mu\psi_L - m\psi_R \end{pmatrix}.$$

(1) Insert $\gamma^\mu = \left(\begin{smallmatrix} 0 & \sigma^\mu \\ \bar\sigma^\mu & 0 \end{smallmatrix}\right)$; the mass term is $m\mathbf{1}_4$.
(2) Multiply the block matrix into the column.

The mass couples ψ_L to ψ_R. For $m = 0$ the equations decouple into the **Weyl equations** [QFT notes (3.5.52)]

$$\bar\sigma^\mu\partial_\mu\psi_L = (\partial_0 - \vec\sigma\cdot\nabla)\psi_L = 0, \qquad \sigma^\mu\partial_\mu\psi_R = (\partial_0 + \vec\sigma\cdot\nabla)\psi_R = 0.$$

Try a plane wave $\psi_L = \xi\, e^{-iEt + i\vec p\cdot\vec x}$ with a constant two-spinor ξ:

$$0 = (\partial_0 - \vec\sigma\cdot\nabla)\psi_L \overset{(1)}{=} (-iE - i\vec\sigma\cdot\vec p)\psi_L \quad\Longrightarrow\quad (\vec\sigma\cdot\hat p)\,\xi \overset{(2)}{=} -\frac{E}{|\vec p|}\,\xi.$$

(1) $\partial_0 \to -iE$ and $\nabla \to i\vec p$ on the plane wave.
(2) Divide by $-i|\vec p|$; here $\hat p = \vec p/|\vec p|$.

Since $(\vec\sigma\cdot\hat p)^2 = 1$, its eigenvalues are ±1, so $E = \pm|\vec p|$ (massless dispersion). For positive energy $\vec\sigma\cdot\hat p\,\xi = -\xi$: the spin points *opposite* to the momentum. The **helicity** $\frac{1}{2}\vec\sigma\cdot\hat p$ is $-\frac{1}{2}$, and the particle is left-handed. The same computation gives helicity $+\frac{1}{2}$ for ψ_R. This is where the names come from.

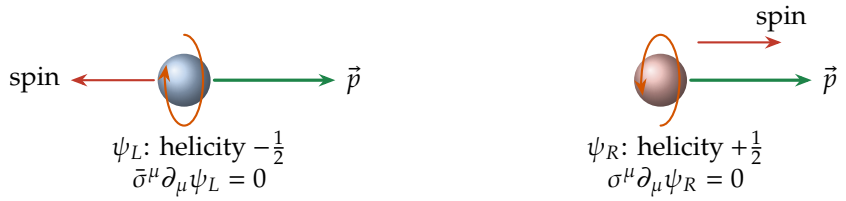

Figure T4.7: Massless Weyl particles. A positive-energy solution of the left-handed Weyl equation has its spin anti-parallel to its momentum; a right-handed one has it parallel. For a massless particle this is Lorentz invariant, because no boost can overtake a particle moving at the speed of light and reverse its momentum.

Worked example T4.22: $\sigma^2\psi_L^*$ is right-handed

We need the identity $\sigma^2(\sigma^i)^* = -\sigma^i\sigma^2$. For $i = 2$: $(\sigma^2)^* = -\sigma^2$, so $\sigma^2(\sigma^2)^* = -(\sigma^2)^2 = -\sigma^2\sigma^2$. For $i = 1, 3$: σ^1, σ^3 are real, and they anticommute with σ^2. Now take the complex conjugate

of the left-handed transformation law:

$$\sigma^2\psi_L^* \overset{(1)}{=} \sigma^2\Big(1 + i\vec{\theta}\cdot\frac{\vec{\sigma}^*}{2} - \vec{\beta}\cdot\frac{\vec{\sigma}^*}{2}\Big)\psi_L^* \overset{(2)}{=} \Big(1 - i\vec{\theta}\cdot\frac{\vec{\sigma}}{2} + \vec{\beta}\cdot\frac{\vec{\sigma}}{2}\Big)\sigma^2\psi_L^*.$$

(1) Complex conjugate of $\big(1 - i\vec{\theta}\cdot\frac{\vec{\sigma}}{2} - \vec{\beta}\cdot\frac{\vec{\sigma}}{2}\big)\psi_L$; θ, β are real.
(2) Move σ^2 to the right using $\sigma^2\sigma^{i*} = -\sigma^i\sigma^2$; this flips the sign of both the rotation and boost terms.

This is exactly the right-handed law [QFT notes (3.5.46)]. So the complex conjugate of a left-handed spinor, rotated by σ^2 = "$i\times$ the SU(2)-invariant antisymmetric tensor", is right-handed. One Weyl spinor therefore contains the same information as the other: a Majorana fermion can be built from ψ_L alone, and the charge conjugation matrix of the Dirac theory is built from σ^2.

T4.3.6 Bilinears, currents and traces

Observables are built from pairs of spinors. Because boosts are not unitary, $\psi^\dagger\psi$ is not Lorentz invariant (it is the time component of a current). The fix is the **Dirac conjugate** $\bar\psi := \psi^\dagger\gamma^0$ [QFT notes (3.5.32)], which transforms as $\bar\psi \mapsto \bar\psi\Lambda_{1/2}^{-1}$. Then $\bar\psi\psi$ is a scalar, and $\bar\psi\gamma^\mu\psi$ is a vector by (T4.32).

A general bilinear is $\bar\psi\Gamma\psi$ with Γ any 4×4 matrix. The 4×4 matrices form a 16-dimensional space, and the 16 basis monomials of the Clifford algebra (Section T4.2.2) are a basis. It is convenient to trade the three- and four-index monomials for $\gamma^\mu\gamma^5$ and γ^5, via [QFT notes (3.5.131)] $\gamma^{[\mu}\gamma^\nu\gamma^{\rho]} = i\varepsilon^{\mu\nu\rho\sigma}\gamma_\sigma\gamma^5$ (with $\varepsilon^{0123} = +1$).

basis matrix Γ	grade in Cl	number	$\bar\psi\Gamma\psi$ transforms as
$\mathbf{1}$	0	1	scalar
γ^μ	1	4	vector
$\sigma^{\mu\nu} = \frac{i}{2}[\gamma^\mu,\gamma^\nu] = 2S^{\mu\nu}$	2	6	antisymmetric tensor
$\gamma^\mu\gamma^5$	3	4	axial vector
γ^5	4	1	pseudoscalar
total		$16 = 2^4$	

Table T4.2: The sixteen Dirac bilinears [QFT notes Table 3.5.1]. The grade is the number of γ's in the corresponding Clifford monomial; the numbers are the binomial coefficients $\binom{4}{k}$. "Pseudo" and "axial" mean an extra sign under parity, which comes from the γ^5.

Worked example T4.23: vector and axial currents

Let ψ solve the Dirac equation, so $\gamma^\mu\partial_\mu\psi = -im\psi$ and (taking the Dirac conjugate) $\partial_\mu\bar\psi\gamma^\mu = im\bar\psi$. Then for $j^\mu = \bar\psi\gamma^\mu\psi$ and $j^{\mu5} = \bar\psi\gamma^\mu\gamma^5\psi$:

$$\partial_\mu j^\mu \overset{(1)}{=} (\partial_\mu\bar\psi)\gamma^\mu\psi + \bar\psi\gamma^\mu\partial_\mu\psi \overset{(2)}{=} im\bar\psi\psi - im\bar\psi\psi = 0,$$
$$\partial_\mu j^{\mu5} \overset{(3)}{=} (\partial_\mu\bar\psi)\gamma^\mu\gamma^5\psi - \bar\psi\gamma^5\gamma^\mu\partial_\mu\psi \overset{(4)}{=} im\bar\psi\gamma^5\psi + im\bar\psi\gamma^5\psi = 2im\,\bar\psi\gamma^5\psi.$$

(1) Product rule.
(2) The Dirac equation and its conjugate.

(3) Product rule, and move γ^5 to the left past γ^μ with a sign.
(4) The Dirac equation and its conjugate again.

So the vector current is always conserved, and the axial current is conserved when $m = 0$ [QFT notes (3.5.136)–(3.5.137)]. They are the Noether currents of $\psi \mapsto e^{i\alpha}\psi$ and $\psi \mapsto e^{i\alpha\gamma^5}\psi$. The second conservation law is classical only: in the quantum theory it fails by a term proportional to $\varepsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$, the chiral anomaly, and Nash's Chapter 10 (Chapter 10) explains it as the index of a Dirac operator.

Worked example T4.24: trace identities from the Clifford relation alone

We already know $\operatorname{tr}\gamma^\mu = 0$ (Section T4.1.2). The same argument with γ^5 inserted shows that the trace of any *odd* number of γ's vanishes: $\operatorname{tr}(\gamma^{\mu_1}\cdots\gamma^{\mu_{2j+1}}) = \operatorname{tr}(\gamma^5\gamma^5\gamma^{\mu_1}\cdots) = -\operatorname{tr}(\gamma^5\gamma^{\mu_1}\cdots\gamma^5) = -\operatorname{tr}(\cdots)$ (move one γ^5 through $2j+1$ gammas, then use cyclicity). For two:

$$\operatorname{tr}(\gamma^\mu\gamma^\nu) \overset{(1)}{=} \tfrac{1}{2}\operatorname{tr}\{\gamma^\mu,\gamma^\nu\} \overset{(2)}{=} \tfrac{1}{2}\cdot 2\eta^{\mu\nu}\operatorname{tr}\mathbf{1}_4 = 4\eta^{\mu\nu}.$$

(1) Cyclicity: $\operatorname{tr}(\gamma^\mu\gamma^\nu) = \operatorname{tr}(\gamma^\nu\gamma^\mu)$.
(2) The Clifford relation.

For four, anticommute γ^μ all the way to the right, then use cyclicity:

$$\begin{aligned}\operatorname{tr}(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) &\overset{(1)}{=} 2\eta^{\mu\nu}\operatorname{tr}(\gamma^\rho\gamma^\sigma) - 2\eta^{\mu\rho}\operatorname{tr}(\gamma^\nu\gamma^\sigma) + 2\eta^{\mu\sigma}\operatorname{tr}(\gamma^\nu\gamma^\rho) - \operatorname{tr}(\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^\mu)\\ &\overset{(2)}{=} 4\big(\eta^{\mu\nu}\eta^{\rho\sigma} - \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho}\big).\end{aligned}$$

(1) Each step $\gamma^\mu\gamma^\alpha = 2\eta^{\mu\alpha} - \gamma^\alpha\gamma^\mu$ moves γ^μ one place right, leaving a term with the pair removed.
(2) The last trace equals the left-hand side by cyclicity; bring it over, divide by 2, and use the two-gamma trace.

Finally the trace with γ^5: $\operatorname{tr}(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma)$ is totally antisymmetric (repeated indices reduce it to $\operatorname{tr}(\gamma^5\gamma^\alpha\gamma^\beta)$, which vanishes by the same kind of argument), so it is a multiple of $\varepsilon^{\mu\nu\rho\sigma}$. The multiple is fixed by one component: $\gamma^0\gamma^1\gamma^2\gamma^3 = -i\gamma^5$, so $\operatorname{tr}(\gamma^5\gamma^0\gamma^1\gamma^2\gamma^3) = -i\operatorname{tr}(\gamma^5)^2 = -4i$, i.e.

$$\operatorname{tr}(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = -4i\,\varepsilon^{\mu\nu\rho\sigma} \qquad (\varepsilon^{0123} = +1).$$

This is the trace that produces the $\varepsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$ of the anomaly (and the $\hat{A}$ and ch forms of the index theorem) in the heat-kernel calculation of Chapter 10.

Physical picture: why the trace with γ^5 needs four gammas

In $n = 2k$ dimensions the chirality operator is proportional to the product of all $2k$ gammas. A trace of Γ times fewer than $2k$ gammas vanishes, because such a product is a Clifford monomial of the wrong grade and all non-trivial monomials are traceless. So the first non-zero trace $\operatorname{tr}(\Gamma\gamma^{a_1}\cdots\gamma^{a_{2k}}) \propto \varepsilon^{a_1\ldots a_{2k}}$ needs exactly one of each direction. In the index theorem this is why, among all the terms of a heat-kernel expansion, only the top-degree form (the one you can integrate over M^{2k}) survives the supertrace.

T4.3.7 The $\mathrm{SL}(2,\mathbb{C})$ picture

There is a neat way to see all of this at once. To a four-vector x^μ associate the Hermitian 2×2 matrix

$$X := x^0\mathbf{1} + \vec{x}\cdot\vec{\sigma} = \begin{pmatrix} x^0+x^3 & x^1 - ix^2 \\ x^1+ix^2 & x^0-x^3 \end{pmatrix}. \tag{T4.33}$$

Its determinant is the Minkowski norm: $\det X = (x^0)^2 - (x^3)^2 - (x^1-ix^2)(x^1+ix^2) = (x^0)^2 - |\vec{x}|^2$. Any $A \in \mathrm{SL}(2,\mathbb{C})$ acts by $X \mapsto AXA^\dagger$. The result is again Hermitian, and $\det(AXA^\dagger) = |\det A|^2 \det X = \det X$. So each A gives a Lorentz transformation, and A and $-A$ give the same one. This is the Lorentzian analogue of $\mathrm{Spin}(3) = \mathrm{SU}(2) \to \mathrm{SO}(3)$, and it says $\mathrm{Spin}(1,3) \cong \mathrm{SL}(2,\mathbb{C})$; we return to it in Section T4.5.7. One Weyl spinor transforms by A and the other by $(A^\dagger)^{-1}$; for A unitary (a rotation, $A = e^{-i\vec{\theta}\cdot\vec{\sigma}/2}$) these agree, while for A Hermitian (a boost, $A = e^{\mp\vec{\beta}\cdot\vec{\sigma}/2}$) they are inverse to each other, matching Example T4.20.

Reading Nash (p. 114, (4.99)–(4.101))

Nash works in Euclidean signature throughout, and uses anti-Hermitian $\gamma_a^{\text{Nash}} = i\gamma_a$ with $\{\gamma_a,\gamma_b\} = -2\delta_{ab}$. His chirality operator is $\gamma_5 = i^{n(n+1)/2}\gamma_1\cdots\gamma_n$. For $n=4$, $i^{10} = -1$ and $\gamma_1^{\text{Nash}}\cdots\gamma_4^{\text{Nash}} = i^4\gamma_1\cdots\gamma_4$, so $\gamma_5^{\text{Nash}} = -\gamma_1\gamma_2\gamma_3\gamma_4 = \Gamma$, exactly our (T4.24); and his (4.101), $\gamma_5 = \mathrm{diag}(I,-I)$, is our Euclidean chiral representation. Note that this Euclidean Γ is not the Minkowski $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$: the two are related by the Wick rotation $\gamma^0 \leftrightarrow \gamma_4$, $\gamma^j \leftrightarrow i\gamma_j$ (up to convention-dependent signs). Nash's remark on p. 115 that "in a space of Lorentzian signature the Dirac operator is not elliptic" is visible here: the Minkowski symbol $\gamma^\mu p_\mu$ squares to $p^\mu p_\mu$, which vanishes on the light cone.

Recap

- Euclidean 4D: $\gamma_a = \left(\begin{smallmatrix} 0 & \tau_a \\ \tau_a^\dagger & 0 \end{smallmatrix}\right)$ with $\tau_a = (i\vec{\sigma},\mathbf{1})$; $\Gamma = -\gamma_1\gamma_2\gamma_3\gamma_4 = \mathrm{diag}(\mathbf{1},-\mathbf{1})$.
- Minkowski 4D: Dirac rep (γ^0 diagonal) and Weyl rep ($\gamma^\mu = \left(\begin{smallmatrix} 0 & \sigma^\mu \\ \bar{\sigma}^\mu & 0 \end{smallmatrix}\right)$), related by an explicit unitary U.
- $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ is Hermitian, squares to 1, anticommutes with all γ^μ; in the Weyl rep it is $\mathrm{diag}(-\mathbf{1},\mathbf{1})$ and $\psi = (\psi_L,\psi_R)$.
- $S^{\mu\nu} = \frac{i}{4}[\gamma^\mu,\gamma^\nu]$ generate Lorentz transformations; they are block diagonal, so ψ_L,ψ_R do not mix; a 2π rotation gives -1.
- Sixteen bilinears $= 2^4$ Clifford monomials; the axial current is classically conserved only for $m=0$; $\mathrm{tr}(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = -4i\varepsilon^{\mu\nu\rho\sigma}$.

T4.4 Gamma matrices in any dimension

Nash's index theorem for the Dirac operator is stated on a manifold of any even dimension $n = 2k$; the anomalies of Chapter 10 appear in QED in $2k$ dimensions; superstrings live in ten. So we need gamma matrices in every dimension, and we need to know how big they are, what the chirality operator is, and whether they can be chosen real. The answer is a construction so simple that it fits on one line (tensor products of Pauli matrices), plus a classification with a surprising period of eight.

T4.4.1 The tensor product construction

Recall that the tensor (Kronecker) product of matrices is $A \otimes B = (a_{ij}B)$, a block matrix whose (i,j) block is $a_{ij}B$. Its two properties we need are

$$(A \otimes B)(C \otimes D) = AC \otimes BD, \qquad (A \otimes B)^\dagger = A^\dagger \otimes B^\dagger. \tag{T4.34}$$

So two tensor products anticommute exactly when an *odd* number of their factors anticommute (and the rest commute).

Working definition T4.6 (gamma matrices in dimension $2k$)

For $j = 1, \dots, k$ put

$$\begin{aligned} \gamma_{2j-1} &:= \underbrace{\sigma_3 \otimes \cdots \otimes \sigma_3}_{j-1} \otimes \sigma_1 \otimes \underbrace{\mathbf{1} \otimes \cdots \otimes \mathbf{1}}_{k-j}, \\ \gamma_{2j} &:= \underbrace{\sigma_3 \otimes \cdots \otimes \sigma_3}_{j-1} \otimes \sigma_2 \otimes \underbrace{\mathbf{1} \otimes \cdots \otimes \mathbf{1}}_{k-j}. \end{aligned} \tag{T4.35}$$

[each is a tensor product of k Pauli-type factors, and the j-th factor is where σ_1 or σ_2 sits]. These are $2^k \times 2^k$ Hermitian matrices with $\{\gamma_a, \gamma_b\} = 2\delta_{ab}$. The **chirality operator** [a Hermitian matrix with $\Gamma^2 = \mathbf{1}$ that anticommutes with every γ_a, so its eigenvalues ± 1 split spinors into two halves] is

$$\Gamma := (-i)^k \gamma_1 \gamma_2 \cdots \gamma_{2k} = \sigma_3 \otimes \sigma_3 \otimes \cdots \otimes \sigma_3. \tag{T4.36}$$

Let us verify the claims.

Squares. Each factor in (T4.35) squares to $\mathbf{1}$, so by (T4.34) $\gamma_a^2 = \mathbf{1} \otimes \cdots \otimes \mathbf{1}$.

Anticommutation. Compare γ_{2j-1} with γ_{2j}: they differ only in slot j, where σ_1 and σ_2 anticommute; all other slots are equal and commute. One anticommuting slot: they anticommute. Now compare γ_a in "pair" j with γ_b in a later pair $l > j$. In slot j, γ_a has σ_1 or σ_2 while γ_b has σ_3: these anticommute. In every other slot at least one of the two has $\mathbf{1}$ or both have σ_3: these commute. Again exactly one anticommuting slot. The string of σ_3's is there precisely to produce this one sign.

Chirality. Group the product in pairs:

$$-i\gamma_{2j-1}\gamma_{2j} \overset{(1)}{=} -i\,(\sigma_3^2)^{\otimes(j-1)} \otimes \sigma_1\sigma_2 \otimes \mathbf{1}^{\otimes(k-j)} \overset{(2)}{=} \mathbf{1}^{\otimes(j-1)} \otimes \sigma_3 \otimes \mathbf{1}^{\otimes(k-j)},$$

$$\Gamma \overset{(3)}{=} \prod_{j=1}^{k} (-i\gamma_{2j-1}\gamma_{2j}) \overset{(4)}{=} \sigma_3 \otimes \sigma_3 \otimes \cdots \otimes \sigma_3.$$

(1) Multiply slot by slot using (T4.34).
(2) $\sigma_3^2 = \mathbf{1}$ and $-i\sigma_1\sigma_2 = -i \cdot i\sigma_3 = \sigma_3$.
(3) $\gamma_1\gamma_2\cdots\gamma_{2k}$ is already ordered in consecutive pairs; the k factors of $-i$ are distributed one per pair.
(4) Each pair contributes a σ_3 in its own slot.

In general (for *any* Hermitian representation) Γ is Hermitian and $\Gamma^2 = 1$. Indeed, reversing $2k$ anticommuting factors takes $\binom{2k}{2} = k(2k-1)$ transpositions, so

$$(\gamma_1 \cdots \gamma_{2k})^2 \overset{(1)}{=} (-1)^{k(2k-1)} \gamma_1 \cdots \gamma_{2k}\gamma_{2k} \cdots \gamma_1 \overset{(2)}{=} (-1)^k,$$

$$\Gamma^2 \overset{(3)}{=} (-i)^{2k}(-1)^k = (-1)^k(-1)^k = 1,$$

(1) Reverse the order of the second copy.
(2) The middle pairs $\gamma_{2k}\gamma_{2k}$, then $\gamma_{2k-1}\gamma_{2k-1}, \dots$ cancel one by one; and $k(2k-1) \equiv k \pmod 2$.
(3) The phase $(-i)^k$ was chosen for exactly this.

and $\Gamma^\dagger = i^k\gamma_{2k}\cdots\gamma_1 = i^k(-1)^k\gamma_1\cdots\gamma_{2k} = \Gamma$. Finally, Γ anticommutes with each γ_a: moving γ_a through $\gamma_1\cdots\gamma_{2k}$ passes $2k-1$ other gammas.

Worked example T4.25: dimensions 2, 4 and 6 explicitly

$d = 2$ ($k = 1$): $\gamma_1 = \sigma_1$, $\gamma_2 = \sigma_2$, $\Gamma = -i\sigma_1\sigma_2 = \sigma_3$. This is Example T4.1: chirality ± 1 are the holomorphic and antiholomorphic components.
$d = 4$ ($k = 2$):

$$\gamma_1 = \sigma_1 \otimes \mathbf{1} = \begin{pmatrix} 0 & \mathbf{1} \\ \mathbf{1} & 0 \end{pmatrix}, \quad \gamma_2 = \sigma_2 \otimes \mathbf{1} = \begin{pmatrix} 0 & -i\mathbf{1} \\ i\mathbf{1} & 0 \end{pmatrix},$$
$$\gamma_3 = \sigma_3 \otimes \sigma_1 = \begin{pmatrix} \sigma_1 & 0 \\ 0 & -\sigma_1 \end{pmatrix}, \quad \gamma_4 = \sigma_3 \otimes \sigma_2 = \begin{pmatrix} \sigma_2 & 0 \\ 0 & -\sigma_2 \end{pmatrix},$$
$$\Gamma = \sigma_3 \otimes \sigma_3 = \operatorname{diag}(1, -1, -1, 1).$$

Check one mixed pair by blocks: $\gamma_1\gamma_3 = \left(\begin{smallmatrix} 0 & -\sigma_1 \\ \sigma_1 & 0 \end{smallmatrix}\right)$ and $\gamma_3\gamma_1 = \left(\begin{smallmatrix} 0 & \sigma_1 \\ -\sigma_1 & 0 \end{smallmatrix}\right)$, so they anticommute. Here Γ is diagonal but its $+1$ eigenvectors are the first and fourth basis vectors, not the first two. Permuting the basis to $(1, 4, 2, 3)$ brings it to $\operatorname{diag}(1, 1, -1, -1)$ and the gammas to block-off-diagonal form, like (T4.21); by the uniqueness result below, the two sets are unitarily equivalent.
$d = 6$ ($k = 3$): 8×8 matrices

$$\gamma_1 = \sigma_1 \otimes \mathbf{1} \otimes \mathbf{1}, \qquad \gamma_2 = \sigma_2 \otimes \mathbf{1} \otimes \mathbf{1},$$
$$\gamma_3 = \sigma_3 \otimes \sigma_1 \otimes \mathbf{1}, \qquad \gamma_4 = \sigma_3 \otimes \sigma_2 \otimes \mathbf{1},$$
$$\gamma_5 = \sigma_3 \otimes \sigma_3 \otimes \sigma_1, \qquad \gamma_6 = \sigma_3 \otimes \sigma_3 \otimes \sigma_2,$$

with $\Gamma = (-i)^3\gamma_1\cdots\gamma_6 = \sigma_3 \otimes \sigma_3 \otimes \sigma_3 = \operatorname{diag}(1, -1, -1, 1, -1, 1, 1, -1)$. Four $+1$'s and four -1's: $S^\pm$ are each four-dimensional.

Watch out: the recursion in the QFT notes

The QFT notes [QFT notes (3.5.9)–(3.5.10)] give the same construction recursively: from $2n$-dimensional gammas $\gamma_i^{(n)}$ build $\gamma_i^{(n+1)} = \gamma_i^{(n)} \otimes \tau_3$ ($i \le 2n$), $\gamma_{2n+1}^{(n+1)} = \mathbf{1} \otimes \tau_1$, $\gamma_{2n+2}^{(n+1)} = \mathbf{1} \otimes \tau_2$. Two things to watch. First, they write $\tau_i = \frac{1}{2}\sigma_i$, but then $\tau_i^2 = \frac{1}{4}$ and the Clifford relation fails; read $\tau_i = \sigma_i$. Second, their explicit block matrices, e.g. $\gamma_i^{(n)} \otimes \tau_3 = \operatorname{diag}(\gamma_i^{(n)}, -\gamma_i^{(n)})$, use the opposite ordering of the Kronecker product from ours ($A \otimes B$ with B as the *outer* block matrix). Either ordering works; just be consistent.

T4.4.2 Spinors as a fermionic Fock space

The tensor-product structure has a physical meaning that makes the whole theory transparent. Pair the gammas into complex combinations

$$b_j := \tfrac{1}{2}(\gamma_{2j-1} + i\gamma_{2j}), \qquad b_j^\dagger = \tfrac{1}{2}(\gamma_{2j-1} - i\gamma_{2j}), \qquad j = 1, \dots, k. \tag{T4.37}$$

Then the Clifford relations become the canonical anticommutation relations of k fermionic modes:

$$\{b_j, b_l^\dagger\} \overset{(1)}{=} \tfrac{1}{4}\big(\{\gamma_{2j-1}, \gamma_{2l-1}\} + \{\gamma_{2j}, \gamma_{2l}\} - i\{\gamma_{2j-1}, \gamma_{2l}\} + i\{\gamma_{2j}, \gamma_{2l-1}\}\big) \overset{(2)}{=} \tfrac{1}{4}(2\delta_{jl} + 2\delta_{jl}) = \delta_{jl},$$

$$\{b_j, b_l\} \overset{(3)}{=} \tfrac{1}{4}\big(\{\gamma_{2j-1},\gamma_{2l-1}\} - \{\gamma_{2j},\gamma_{2l}\} + i\{\gamma_{2j-1},\gamma_{2l}\} + i\{\gamma_{2j},\gamma_{2l-1}\}\big) \overset{(4)}{=} 0. \tag{T4.38}$$

(1) Expand the bilinear anticommutator.
(2) $\{\gamma_a,\gamma_b\} = 2\delta_{ab}$; the mixed terms involve an odd and an even index, which are never equal.
(3) Same expansion without the conjugation.
(4) The two diagonal terms cancel and the mixed ones vanish.

In the representation (T4.35), $b_j = \sigma_3^{\otimes(j-1)} \otimes \sigma^+ \otimes \mathbf{1}^{\otimes(k-j)}$ with $\sigma^+ = \tfrac{1}{2}(\sigma_1 + i\sigma_2) = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$. This is the **Jordan–Wigner** representation of fermions on a chain of k spins. Let $|\uparrow\rangle = (1,0)^{\mathsf{T}}$ and $|\downarrow\rangle = (0,1)^{\mathsf{T}}$; then $\sigma^+|\uparrow\rangle = 0$. So:

- The *vacuum* $|0\rangle = |\uparrow\uparrow\cdots\uparrow\rangle$ is killed by every b_j.
- $b_j^\dagger$ flips spin j down (with a sign from the σ_3 string): it creates a fermion in mode j.
- The 2^k states $b_{j_1}^\dagger \cdots b_{j_r}^\dagger|0\rangle$ ($j_1 < \cdots < j_r$) form a basis: spinor space is the fermionic Fock space $S \cong \Lambda^\bullet \mathbb{C}^k$, of dimension 2^k.
- $\Gamma = \sigma_3^{\otimes k}$ is $+1$ on $|\uparrow\rangle$ and -1 on $|\downarrow\rangle$ in each slot, so $\Gamma = (-1)^F$ where F is the number of fermions (down spins).

Thus the chirality splitting is the split into even and odd fermion number:

$$S = S^+ \oplus S^-, \qquad S^+ = \Lambda^{\text{even}}\mathbb{C}^k, \quad S^- = \Lambda^{\text{odd}}\mathbb{C}^k, \qquad \dim S^\pm = 2^{k-1}. \tag{T4.39}$$

A single γ_a is linear in b's and $b^\dagger$'s, so it changes the fermion number by one and maps $S^\pm \to S^\mp$; a product of two gammas preserves the parity. Bär's construction [Bär pp. 85–88] is exactly this: his $z_j = \tfrac{1}{2}(e_{2j-1} - ie_{2j})$ are the b's (his e_a square to -1; with $e_a = -i\gamma_a$ one gets $z_j = -\tfrac{i}{2}(\gamma_{2j-1} - i\gamma_{2j}) = -ib_j^\dagger$), his relations $z_j^2 = \bar z_j^2 = 0$ are (T4.38), his basis $z(j_1,\dots,j_r)$ is our Fock basis, and his $\Sigma_n^\pm = \{i^m\omega\cdot z = \pm z\}$ [Bär (2.9)] is our $\Gamma = \pm 1$ (since $i^m\omega = i^m(-i)^{2m}\gamma_1\cdots\gamma_{2m} = \Gamma$).

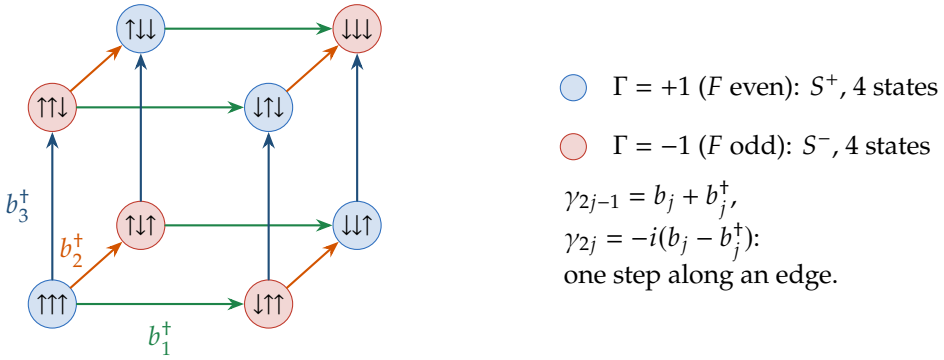

Figure T4.8: The 8-dimensional spinor space in $d = 6$ as the Fock space of three fermionic modes, drawn as a cube. Each vertex is a basis state; a gamma matrix moves along one edge (creating or destroying one fermion), so it always connects a blue vertex (S^+) to a red one (S^-). Chirality is fermion parity.

T4.4.3 Uniqueness: all irreducible representations are equivalent

We have used the word "the" spinor representation. Here is why that is justified in even dimensions.

Key idea: uniqueness of the spinor representation, $n = 2k$

Any set of Hermitian matrices $\gamma'_1, \dots, \gamma'_{2k}$ on $\mathbb{C}^N$ with $\{\gamma'_a, \gamma'_b\} = 2\delta_{ab}$ is unitarily equivalent to a direct sum of copies of (T4.35). In particular N is a multiple of 2^k, and an irreducible set ($N = 2^k$) is unique up to a change of basis.

Why (a Fock-space argument). Form $b'_j = \frac{1}{2}(\gamma'_{2j-1} + i\gamma'_{2j})$; they obey (T4.38). The operators $n_j = b'^\dagger_j b'_j$ are commuting projectors (from the CAR, $n_j^2 = b'^\dagger_j(1 - b'^\dagger_j b'_j)b'_j = n_j$), so they can be diagonalised together. Take a joint eigenvector and apply b'_j to it wherever $n_j = 1$: since $b'_j n_j = b'_j$ and $b'^2_j = 0$, this produces a non-zero vector $|0'\rangle$ with $b'_j|0'\rangle = 0$ for all j, a "vacuum". Then the 2^k vectors $b'^\dagger_{j_1} \cdots b'^\dagger_{j_r}|0'\rangle$ are orthonormal (compute their inner products with the CAR, exactly as for a harmonic oscillator) and span a subspace on which the γ''s act by the *same* matrices as in (T4.35). The orthogonal complement is again invariant, so repeat. The map sending one Fock basis to the other is the unitary equivalence.

A second, more algebraic way to say it: the 2^{2k} matrices γ_I (products over subsets I) of (T4.35) are orthogonal for the trace inner product, $\mathrm{tr}(\gamma_I^\dagger \gamma_J) = 2^k \delta_{IJ}$ (for $I \neq J$ the product is $\pm\gamma_{I\triangle J}$, which is traceless). So they are linearly independent and span all $2^k \times 2^k$ matrices: the complexified Clifford algebra is a full matrix algebra,

$$\mathrm{Cl}_{2k} \otimes \mathbb{C} \cong \mathbb{C}(2^k), \tag{T4.40}$$

which is Bär's Prop. 2.3.11. A full matrix algebra has only one irreducible module, the column vectors. This is the fact we used in Example T4.16 to relate the Dirac and Weyl representations.

T4.4.4 Odd dimensions

In dimension $2k + 1$ we need one more matrix anticommuting with $\gamma_1, \dots, \gamma_{2k}$ and squaring to one. We already have it: Γ. So

$$\gamma_{2k+1} := \pm\Gamma \tag{T4.41}$$

gives a representation of the $(2k + 1)$-dimensional Clifford algebra on the same 2^k-dimensional space. For $k = 1$ this is $\sigma_1, \sigma_2, \pm\sigma_3$: the Pauli matrices in 3D.

The two signs give two representations that are *not* equivalent. The reason is the volume element $\omega = \gamma_1 \cdots \gamma_{2k+1}$. In odd dimensions ω commutes with every generator (moving γ_a through it passes $2k$ other gammas), so it is central, and it is represented by a multiple of the identity: with $\gamma_{2k+1} = \pm\Gamma$,

$$\gamma_1 \cdots \gamma_{2k}\gamma_{2k+1} \overset{(1)}{=} \pm i^k \Gamma \cdot \Gamma \overset{(2)}{=} \pm i^k \mathbf{1}.$$

(1) $\gamma_1 \cdots \gamma_{2k} = i^k \Gamma$ by (T4.36).
(2) $\Gamma^2 = 1$.

A change of basis cannot change a multiple of the identity, so the sign is an invariant. This is the $\mathrm{Cl}_{0,3} = \mathbb{H} \oplus \mathbb{H}$ phenomenon of Example T4.12 in general: in odd dimensions the complex Clifford algebra is $\mathbb{C}(2^k) \oplus \mathbb{C}(2^k)$ and has two irreducible representations, one for each value of ω. Either one restricts to the *same* representation of the spin group, because the spin group lies in the even part, which does not see the sign of γ_{2k+1}. Bär realises the odd-dimensional spinor space as $\Sigma_{2k+1} := \Sigma^+_{2k+2}$, using $\mathrm{Cl}_{2k+1} \cong \mathrm{Cl}^0_{2k+2}$ [Bär Lemma 2.3.12].

Key idea: size of spinors

In dimension n the irreducible complex spinor space has dimension $2^{\lfloor n/2 \rfloor}$ [Nash (4.97)]: $1, 2, 2, 4, 4, 8, 8, 16, \ldots$ for $n = 1, 2, 3, \ldots$ In even dimensions it splits into $S^+ \oplus S^-$, each of dimension $2^{n/2-1}$; in odd dimensions it does not split.

T4.4.5 Real Clifford algebras and the period eight

Over $\mathbb{C}$ the story is now complete: period two, with a full matrix algebra in even dimension and two copies in odd dimension. Over $\mathbb{R}$, and for mixed signatures, the algebra can be a matrix algebra over $\mathbb{R}$, $\mathbb{C}$ or $\mathbb{H}$, and the answer repeats with period eight. This matters in physics for one reason: *real* (Majorana) spinors exist exactly when the relevant Clifford algebra is a real matrix algebra.

We have computed the first few cases by hand: $\mathrm{Cl}_{1,0} = \mathbb{R} \oplus \mathbb{R}$, $\mathrm{Cl}_{0,1} = \mathbb{C}$, $\mathrm{Cl}_{2,0} = \mathbb{R}(2)$, $\mathrm{Cl}_{0,2} = \mathbb{H}$, $\mathrm{Cl}_{3,0} = \mathbb{C}(2)$, $\mathrm{Cl}_{0,3} = \mathbb{H} \oplus \mathbb{H}$ (Section T4.2). The rest follows from two shifting rules.

Key idea: shifting by two dimensions

$$\mathrm{Cl}_{0,n+2} \cong \mathrm{Cl}_{n,0} \otimes \mathrm{Cl}_{0,2} = \mathrm{Cl}_{n,0} \otimes \mathbb{H}, \qquad \mathrm{Cl}_{n+2,0} \cong \mathrm{Cl}_{0,n} \otimes \mathrm{Cl}_{2,0} = \mathrm{Cl}_{0,n} \otimes \mathbb{R}(2). \tag{T4.42}$$

Adding two dimensions tensors with $\mathbb{H}$ or $\mathbb{R}(2)$, *and flips the sign* of the original generators.

The generators, explicitly. Let $e_1, \ldots, e_n$ generate $\mathrm{Cl}_{n,0}$ ($e_i^2 = +1$) and f_1, f_2 generate $\mathrm{Cl}_{0,2}$ ($f^2 = -1$). Inside $\mathrm{Cl}_{n,0} \otimes \mathrm{Cl}_{0,2}$ (ordinary, ungraded tensor product: the two factors commute) define

$$E_i \coloneqq e_i \otimes f_1 f_2 \ (i \le n), \qquad E_{n+1} \coloneqq 1 \otimes f_1, \qquad E_{n+2} \coloneqq 1 \otimes f_2.$$

Then

$$E_i^2 \overset{(1)}{=} e_i^2 \otimes (f_1 f_2)^2 \overset{(2)}{=} (+1)(-1) = -1, \qquad E_{n+1}^2 = E_{n+2}^2 = -1,$$
$$E_i E_{n+1} \overset{(3)}{=} e_i \otimes f_1 f_2 f_1 \overset{(4)}{=} -e_i \otimes f_1 f_1 f_2 = -E_{n+1} E_i,$$
$$E_i E_j \overset{(5)}{=} e_i e_j \otimes (f_1 f_2)^2 = -e_i e_j \otimes 1, \text{ which anticommutes with } E_j E_i \ (i \neq j).$$

(1) Rule (T4.34) for tensor products.
(2) $e_i^2 = 1$ and $(f_1 f_2)^2 = -f_1^2 f_2^2 = -1$.
(3) Multiply in each factor.
(4) $f_2 f_1 = -f_1 f_2$.
(5) Same rule; then $e_i e_j = -e_j e_i$.

The case $E_i E_{n+2}$ is identical. So the E's are $n+2$ anticommuting elements squaring to -1: they generate a copy of $\mathrm{Cl}_{0,n+2}$, and comparing dimensions ($2^{n+2} = 2^n \cdot 4$) gives the isomorphism. The second rule is the same computation with all signs reversed. (This is why the ungraded tensor product is the useful one here: the "twist" by $f_1 f_2$ supplies the anticommutation by hand.)

Now iterate, using $\mathbb{H} \otimes \mathbb{R}(2) = \mathbb{H}(2)$, $\mathbb{C} \otimes \mathbb{H} = \mathbb{C}(2)$, $\mathbb{H} \otimes \mathbb{H} = \mathbb{R}(4)$ (the last two can be checked by writing down the obvious actions on $\mathbb{C}^2$ and on $\mathbb{H} \cong \mathbb{R}^4$, $x \mapsto p x \bar{q}$). For example

$$\mathrm{Cl}_{0,4} \overset{(1)}{=} \mathrm{Cl}_{2,0} \otimes \mathbb{H} = \mathbb{R}(2) \otimes \mathbb{H} \overset{(2)}{=} \mathbb{H}(2),$$
$$\mathrm{Cl}_{0,6} \overset{(3)}{=} \mathrm{Cl}_{4,0} \otimes \mathbb{H} = \big(\mathrm{Cl}_{0,2} \otimes \mathbb{R}(2)\big) \otimes \mathbb{H} = \mathbb{H}(2) \otimes \mathbb{H} \overset{(4)}{=} \mathbb{R}(8),$$

$$\mathrm{Cl}_{0,n+8} \overset{(5)}{=} \mathrm{Cl}_{0,n} \otimes \big(\mathbb{R}(2) \otimes \mathbb{H} \otimes \mathbb{R}(2) \otimes \mathbb{H}\big) \overset{(6)}{=} \mathrm{Cl}_{0,n} \otimes \mathbb{R}(16).$$

(1) First rule of (T4.42) with $n = 2$.
(2) A 2×2 matrix with quaternion entries.
(3) First rule with $n = 4$, then the second rule for $\mathrm{Cl}_{4,0}$.
(4) $\mathbb{H} \otimes \mathbb{H} \cong \mathbb{R}(4)$, and $\mathbb{R}(2) \otimes \mathbb{R}(4) = \mathbb{R}(8)$.
(5) Apply the two rules alternately four times; the signs flip back after an even number of steps.
(6) $\mathbb{H} \otimes \mathbb{H} = \mathbb{R}(4)$ and $\mathbb{R}(2) \otimes \mathbb{R}(2) \otimes \mathbb{R}(4) = \mathbb{R}(16)$.

The last line is **Bott periodicity** for Clifford algebras: $\mathrm{Cl}_{0,n+8} \cong \mathrm{Cl}_{0,n} \otimes \mathbb{R}(16)$, so the *type* of the algebra depends only on n mod 8. Complexifying kills the distinction between $\mathbb{R}$, $\mathbb{C}$ and $\mathbb{H}$ and leaves period two.

n	$\mathrm{Cl}_{0,n}$ ($e^2 = -1$, Bär)	$\mathrm{Cl}_{n,0}$ ($\gamma^2 = +1$)	$\mathrm{Cl}_n \otimes \mathbb{C}$	spinor dim $2^{\lfloor n/2 \rfloor}$
0	$\mathbb{R}$	$\mathbb{R}$	$\mathbb{C}$	1
1	$\mathbb{C}$	$\mathbb{R} \oplus \mathbb{R}$	$\mathbb{C} \oplus \mathbb{C}$	1

Table T4.3: The classification of Clifford algebras. $\mathbb{R}(m), \mathbb{C}(m), \mathbb{H}(m)$ are $m \times m$ matrices over the reals, complexes and quaternions. The pattern of the real columns repeats with period 8 (with matrix sizes multiplied by 16); the complex column repeats with period 2. A "$\oplus$" appears exactly when the volume element is central with square $+1$ (odd n of the right sign), as in $\mathrm{Cl}_{1,0}$ and $\mathrm{Cl}_{0,3}$.

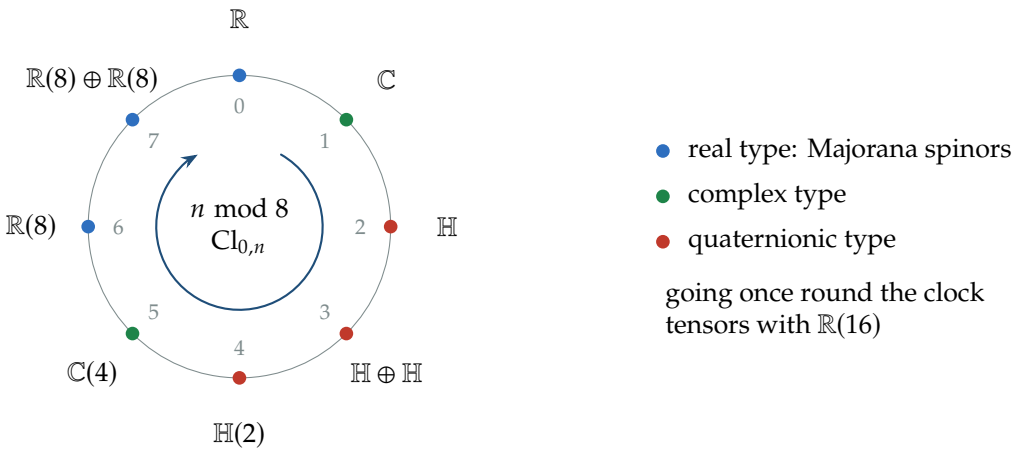

Figure T4.9: The Bott clock for $\mathrm{Cl}_{0,n}$ (vectors square to -1). Reading clockwise: real, complex, quaternionic, quaternionic, quaternionic, complex, real, real, and back to real at $n = 8$. The same eightfold pattern reappears in the real K-theory of spheres, $KO^{-n}(\mathrm{pt}) = \mathbb{Z}, \mathbb{Z}_2, \mathbb{Z}_2, 0, \mathbb{Z}, 0, 0, 0$, and it is why dimensions $8m + 1$ and $8m + 2$ carry mod-2 indices.

Mixed signature and Majorana spinors. One more rule, $\mathrm{Cl}_{p+1,q+1} \cong \mathrm{Cl}_{p,q} \otimes \mathbb{R}(2)$ (same proof, with the extra pair $f_1^2 = +1$, $f_2^2 = -1$, so $(f_1 f_2)^2 = +1$ and no sign flip), handles any signature.

In four-dimensional spacetime:

$$\mathrm{Cl}_{1,3} \cong \mathrm{Cl}_{0,2} \otimes \mathbb{R}(2) = \mathbb{H}(2), \qquad \mathrm{Cl}_{3,1} \cong \mathrm{Cl}_{2,0} \otimes \mathbb{R}(2) = \mathbb{R}(4).$$

With the QFT notes' mostly-minus metric, $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$ is $\mathrm{Cl}_{1,3} = \mathbb{H}(2)$: there are no *real* 4×4 gammas. But $\tilde\gamma^\mu := i\gamma^\mu$ satisfy $\{\tilde\gamma^\mu, \tilde\gamma^\nu\} = -2\eta^{\mu\nu}$, which is $\mathrm{Cl}_{3,1} = \mathbb{R}(4)$: *real* 4×4 matrices exist. The next example finds them.

Worked example T4.26: a Majorana representation in four dimensions

We want real 4×4 matrices with $(\tilde\gamma^0)^2 = -1$, $(\tilde\gamma^i)^2 = +1$, all anticommuting. Real symmetric matrices square to positive matrices, and $\epsilon := i\sigma_2 = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ is real antisymmetric with $\epsilon^2 = -1$. Try

$$\tilde\gamma^0 = \epsilon \otimes \sigma_3, \quad \tilde\gamma^1 = \sigma_1 \otimes \mathbf{1}, \quad \tilde\gamma^2 = \sigma_3 \otimes \mathbf{1}, \quad \tilde\gamma^3 = \epsilon \otimes \epsilon.$$

All are real. Squares: $(\epsilon \otimes \sigma_3)^2 = \epsilon^2 \otimes \sigma_3^2 = -1$; $(\epsilon \otimes \epsilon)^2 = (-1)(-1) = +1$; the middle two square to $+1$. Anticommutation, by counting anticommuting slots (Section T4.4.1): ϵ anticommutes with σ_1 and σ_3, and σ_1 anticommutes with σ_3, so every pair among $\tilde\gamma^0, \tilde\gamma^1, \tilde\gamma^2$ and every pair $(\tilde\gamma^{1,2}, \tilde\gamma^3)$ has exactly one anticommuting slot (the first). For $(\tilde\gamma^0, \tilde\gamma^3)$ the first slots ϵ, ϵ commute and the second slots σ_3, ϵ anticommute: again one. So these are real gammas for $\mathrm{Cl}_{3,1}$, and $\gamma^\mu = -i\tilde\gamma^\mu$ are purely imaginary gammas for the QFT notes' convention. In this basis $i\gamma^\mu\partial_\mu = \tilde\gamma^\mu\partial_\mu$ is a real operator and $\Lambda_{1/2} = \exp\left(-\frac{1}{8}\omega_{\mu\nu}[\tilde\gamma^\mu, \tilde\gamma^\nu]\right)$ is a real matrix, so the condition "ψ is real" is Lorentz invariant and compatible with the massless and massive Dirac equations. That is a **Majorana** spinor: four real components instead of four complex ones.

Dictionary: which dimensions have which spinors

- Weyl (chiral) spinors: even dimension n (Euclidean or Lorentzian).
- Majorana spinors in Lorentzian signature $(1, n-1)$ exist for $n \equiv 2, 3, 4 \pmod 8$ (with the appropriate sign convention; e.g. $n = 4$ above); Majorana–Weyl for $n \equiv 2 \pmod 8$, e.g. $n = 2$ and $n = 10$. This is why the heterotic and type I superstrings live in ten dimensions with sixteen real supercharges (Chapter 9).
- Euclidean signature (Nash's setting) typically has no real structure compatible with chirality in $n = 4$: $\mathrm{Cl}_{0,4} = \mathrm{Cl}_{4,0} = \mathbb{H}(2)$ is quaternionic, and $S^\pm$ are quaternionic ($\cong \mathbb{H}$) rather than real. This is the origin of the "SU(2) = Sp(1)" structures of instanton theory.

Reading Nash (p. 113–114, (4.97), (4.99))

Nash quotes: "S has dimensions $2^{n/2}$ and $2^{(n-1)/2}$ for n even and odd respectively. For odd n the representation S is irreducible but for n even S is reducible into two irreducible components of equal dimension" (4.97). Here we have seen why: S is a fermionic Fock space of $\lfloor n/2 \rfloor$ modes, and in even dimension chirality is fermion parity. His chirality operator $\gamma_5 = i^{n(n+1)/2}\gamma_1 \cdots \gamma_n$ (in his anti-Hermitian gammas) equals $i^{n/2}\gamma_1 \cdots \gamma_n$ in ours, which is our $\Gamma = (-i)^{n/2}\gamma_1 \cdots \gamma_n$ when $n \equiv 0 \pmod 4$ and $-\Gamma$ when $n \equiv 2 \pmod 4$. So in two dimensions Nash's E^+ is our S^-; the index changes sign, which is harmless but worth knowing when comparing with Chapter 4.

Recap

- In dimension $2k$: $\gamma_{2j-1} = \sigma_3^{\otimes(j-1)} \otimes \sigma_1 \otimes \mathbf{1}^{\otimes(k-j)}$, $\gamma_{2j} = \sigma_3^{\otimes(j-1)} \otimes \sigma_2 \otimes \mathbf{1}^{\otimes(k-j)}$; $\Gamma = (-i)^k \gamma_1 \cdots \gamma_{2k} = \sigma_3^{\otimes k}$.
- $b_j = \frac{1}{2}(\gamma_{2j-1} + i\gamma_{2j})$ are fermion annihilators; spinors = Fock space $\Lambda^\bullet \mathbb{C}^k$; $\Gamma = (-1)^F$, $S^\pm$ = even/odd.
- The irreducible representation is unique in even dimensions ($\mathrm{Cl}_{2k} \otimes \mathbb{C} = \mathbb{C}(2^k)$); in odd dimensions add $\gamma_{2k+1} = \pm\Gamma$, giving two inequivalent representations. Dimension $2^{\lfloor n/2 \rfloor}$.
- Real Clifford algebras: explicit shift rules $\mathrm{Cl}_{0,n+2} = \mathrm{Cl}_{n,0} \otimes \mathbb{H}$, $\mathrm{Cl}_{n+2,0} = \mathrm{Cl}_{0,n} \otimes \mathbb{R}(2)$ give period 8 (Bott); Majorana spinors exist when the algebra is real, e.g. $\mathrm{Cl}_{3,1} = \mathbb{R}(4)$.

T4.5 The spin group: rotations built from reflections

We have met the minus sign twice already. In Example T4.19 a rotation by 2π multiplied a Dirac spinor by -1, and in Example T4.10 the unit quaternions turned out to be SU(2), which is "twice as big" as SO(3). This section explains both facts with one construction. The question it answers is:

Which matrices act on spinors when we rotate the coordinate axes?

For vectors the answer is $\mathrm{SO}(n)$. For spinors the answer is a group $\mathrm{Spin}(n)$ that lives *inside the Clifford algebra* and covers $\mathrm{SO}(n)$ twice. The recipe is surprisingly geometric: a unit vector u, viewed as the Clifford element $u = u^a \gamma_a$, acts on vectors by a reflection; two reflections make a rotation; so products of an *even* number of unit vectors are "square roots" of rotations. Everything in this section is a consequence of the one identity $u^2 = |u|^2$.

Throughout, $\gamma_1, \dots, \gamma_n$ are Hermitian with $\{\gamma_a, \gamma_b\} = 2\delta_{ab}$ (our convention, Chapter T4), and we identify a vector $x \in \mathbb{R}^n$ with the matrix

$$\not{x} := x^a \gamma_a, \qquad \not{x}\not{y} + \not{y}\not{x} = 2\langle x, y\rangle \mathbf{1}, \qquad \not{x}^2 = |x|^2 \mathbf{1}. \tag{T4.43}$$

When no confusion is possible we drop the slash and write x for $\not{x}$.

T4.5.1 A unit vector acts by a reflection

Let u be a unit vector, so $u^2 = 1$ and $u^{-1} = u$. Conjugate an arbitrary vector x by u:

$$\begin{aligned} u\, x\, u^{-1} &\overset{(1)}{=} u\, x\, u \\ &\overset{(2)}{=} u\big(-u\, x + 2\langle x, u\rangle\big) \\ &\overset{(3)}{=} -x + 2\langle x, u\rangle\, u \\ &\overset{(4)}{=} -\big(x - 2\langle x, u\rangle u\big) \;=\; -R_u(x). \end{aligned} \tag{T4.44}$$

(1) $u^2 = |u|^2 = 1$, so u is its own inverse.
(2) The Clifford relation (T4.43) in the form $xu = -ux + 2\langle x, u\rangle$.
(3) $u^2 = 1$ again, and the number $\langle x, u\rangle$ commutes with everything.

(4) $R_u(x) \coloneqq x - 2\langle x, u\rangle u$ is the **reflection** in the hyperplane $u^\perp$ perpendicular to u: it flips the component of x along u and leaves the perpendicular part alone.

So conjugation by a unit vector is a reflection followed by the total inversion $x \mapsto -x$. The result is again a vector (a linear combination of the γ_a), which is not obvious in advance: conjugating a vector by a general element of the Clifford algebra produces higher-degree junk.

Worked example T4.27: reflections with Pauli matrices

In three dimensions $\gamma_a = \sigma_a$, and a vector is the Hermitian traceless matrix $X = \vec{x}\cdot\vec{\sigma}$. Take $u = \sigma_3$ (the unit vector along z). Then

$$\sigma_3\,(x^1\sigma_1 + x^2\sigma_2 + x^3\sigma_3)\,\sigma_3 \overset{(1)}{=} -x^1\sigma_1 - x^2\sigma_2 + x^3\sigma_3,$$

(1) $\sigma_3\sigma_1\sigma_3 = -\sigma_1\sigma_3\sigma_3 = -\sigma_1$, likewise for σ_2, and $\sigma_3\sigma_3\sigma_3 = \sigma_3$.

which is $-(x^1, x^2, -x^3)$: minus the reflection in the xy-plane, exactly as (T4.44) says. In three dimensions $-R_u$ is a rotation by π about the axis u, so it has determinant $+1$; but that is an accident of odd dimension. The honest statement is that $x \mapsto uxu^{-1}$ has determinant $(-1)^n \cdot (-1) = (-1)^{n+1}$, and we will only ever use it in pairs, where the signs cancel.

T4.5.2 Two reflections make a rotation

Composing two reflections in hyperplanes that meet at angle α gives a rotation by 2α in the plane spanned by the two normals. This is the kaleidoscope principle (Figure T4.10). In the Clifford algebra it becomes a computation. Let u_1, u_2 be unit vectors. Then

$$(u_2u_1)\,x\,(u_2u_1)^{-1} \overset{(1)}{=} u_2\,(u_1xu_1^{-1})\,u_2^{-1} \overset{(2)}{=} u_2\big(-R_{u_1}x\big)u_2^{-1} \overset{(3)}{=} R_{u_2}R_{u_1}(x). \tag{T4.45}$$

(1) $(u_2u_1)^{-1} = u_1^{-1}u_2^{-1}$.
(2) (T4.44) for u_1.
(3) (T4.44) for u_2, applied to the vector $-R_{u_1}x$; the two minus signs cancel.

So the *even* product u_2u_1 acts on vectors by the rotation $R_{u_2}R_{u_1} \in \mathrm{SO}(n)$.

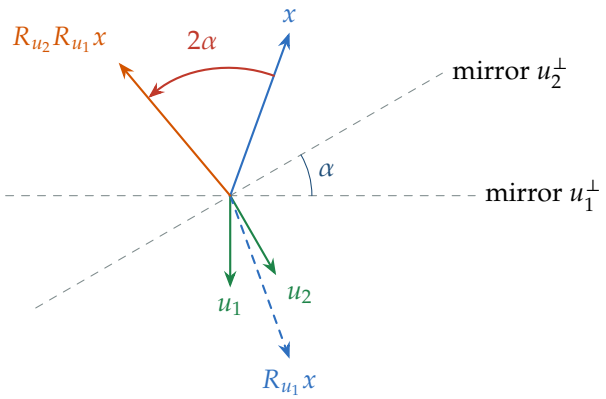

Figure T4.10: Two reflections make a rotation. Reflect x in the mirror $u_1^\perp$ (dashed image), then in the mirror $u_2^\perp$. The result is x rotated by *twice* the angle α between the mirrors. In the Clifford algebra the rotation is implemented by the product u_2u_1, which "knows" only the angle α: this factor of two is the origin of the half-angles in spinor rotations.

Worked example T4.28: the lift of a plane rotation

Take $u_1 = \gamma_1$ and $u_2 = \cos\frac{\theta}{2}\,\gamma_1 + \sin\frac{\theta}{2}\,\gamma_2$, two unit vectors at angle $\theta/2$. Their product is

$$a(\theta) := u_2 u_1 \overset{(1)}{=} \cos\tfrac{\theta}{2}\,\gamma_1\gamma_1 + \sin\tfrac{\theta}{2}\,\gamma_2\gamma_1 \overset{(2)}{=} \cos\tfrac{\theta}{2} - \sin\tfrac{\theta}{2}\,\gamma_1\gamma_2 \overset{(3)}{=} \exp\!\Big(-\frac{\theta}{2}\,\gamma_1\gamma_2\Big). \tag{T4.46}$$

(1) Multiply out.
(2) $\gamma_1^2 = 1$ and $\gamma_2\gamma_1 = -\gamma_1\gamma_2$.
(3) $(\gamma_1\gamma_2)^2 = -\gamma_1^2\gamma_2^2 = -1$, so $\gamma_1\gamma_2$ behaves like the imaginary unit and $e^{-\phi\gamma_1\gamma_2} = \cos\phi - \gamma_1\gamma_2\sin\phi$ (Euler's formula; expand the exponential series and separate even and odd powers).

Let us check directly that it rotates the 12-plane by θ. The element $\gamma_1\gamma_2$ anticommutes with γ_1 and γ_2 and commutes with $\gamma_3, \dots, \gamma_n$. Therefore $a(\theta)\gamma_1 = \gamma_1 a(-\theta)$, and

$$a(\theta)\,\gamma_1\,a(\theta)^{-1} \overset{(1)}{=} \gamma_1\,a(-\theta)\,a(-\theta) \overset{(2)}{=} \gamma_1\,e^{\theta\gamma_1\gamma_2} \overset{(3)}{=} \gamma_1(\cos\theta + \sin\theta\,\gamma_1\gamma_2) = \cos\theta\,\gamma_1 + \sin\theta\,\gamma_2,$$

$$a(\theta)\,\gamma_2\,a(\theta)^{-1} \overset{(4)}{=} \gamma_2\,e^{\theta\gamma_1\gamma_2} = \cos\theta\,\gamma_2 - \sin\theta\,\gamma_1, \qquad a(\theta)\,\gamma_j\,a(\theta)^{-1} = \gamma_j\ (j \geq 3).$$

(1) Move γ_1 to the left through $a(\theta)$; $a(\theta)^{-1} = a(-\theta)$ because the exponents add.
(2) $a(-\theta)^2 = e^{\theta\gamma_1\gamma_2}$.
(3) Euler's formula again, and $\gamma_1\gamma_1\gamma_2 = \gamma_2$.
(4) Same steps, with $\gamma_2\gamma_1\gamma_2 = -\gamma_1$.

So $\rho(a(\theta))$ is the rotation by θ taking e_1 towards e_2. Now the punchline:

$$a(2\pi) = \cos\pi - \sin\pi\,\gamma_1\gamma_2 = -\mathbf{1}, \qquad a(4\pi) = +\mathbf{1}. \tag{T4.47}$$

The rotation by 2π is the identity on vectors, but its lift through the Clifford algebra is $-\mathbf{1}$. This is the same sign as Example T4.19, now derived without any Lorentz group theory.

T4.5.3 The groups $\mathrm{Pin}(n)$ and $\mathrm{Spin}(n)$

Working definition T4.7 (spin group)

Inside the Clifford algebra (concretely: inside the algebra of $2^{\lfloor n/2\rfloor}$ dimensional gamma-matrix products) let

$$\mathrm{Pin}(n) := \{u_1 u_2 \cdots u_m \ :\ u_j \in S^{n-1} \text{ unit vectors},\ m \geq 0\},$$
$$\mathrm{Spin}(n) := \{u_1 u_2 \cdots u_m \ :\ u_j \in S^{n-1},\ m \text{ even}\}.$$

[a unit vector u is used as the matrix $u^a\gamma_a$, which squares to $\mathbf{1}$]. The **spin group** acts on vectors by

$$\rho(a)x := a\,x\,a^{-1}, \qquad a \in \mathrm{Spin}(n), \tag{T4.48}$$

and on spinors simply by matrix multiplication, $\psi \mapsto a\psi$. *To test whether a matrix a is in* $\mathrm{Spin}(n)$*:* it must be even [a sum of products of an even number of γ's], it must satisfy $a\,x\,a^{-1} \in \mathbb{R}^n$ for all vectors x (i.e. a combination of γ's), and it must have "unit norm", $a\,a^{\dagger} = 1$, where † reverses the order of the factors. For Hermitian gammas and real u_j this says a is unitary.

Bär's definitions [Bär Def. 2.2.3, 2.2.5] are identical, with his convention $v^2 = -|v|^2$; since u and $-u$ are both unit vectors, the sign convention changes nothing in the group. Three facts

make Spin(n) useful.

1. It is a group. The product of two even products of unit vectors is again one. The inverse of $u_1 \cdots u_m$ is $u_m \cdots u_1$, because the factors cancel from the middle out ($u_m u_m = 1$, then $u_{m-1}u_{m-1} = 1, \dots$). With Hermitian γ's every unit vector $u = u^a \gamma_a$ is Hermitian and unitary, so $(u_1 \cdots u_m)^\dagger = u_m \cdots u_1 = (u_1 \cdots u_m)^{-1}$: *the spinor representation of* Spin(n) *is unitary*.

2. ρ lands in SO(n) and hits all of it. By (T4.45), $\rho(u_1 \cdots u_{2k})$ is a product of $2k$ reflections, hence orthogonal with determinant $(-1)^{2k} = 1$. Conversely, the theorem of Cartan and Dieudonné says every element of O(n) is a product of at most n reflections; an element of SO(n) needs an even number. So every rotation is $\rho(a)$ for some a [Bär Prop. 2.2.10]. For a physicist the proof in the case that matters is Example T4.28: any rotation is a product of rotations in commuting planes (the normal form of an orthogonal matrix), and each plane rotation lifts as $a(\theta)$.

3. The kernel is $\{\pm 1\}$. If $\rho(a) = \mathrm{id}$ then a commutes with every γ_a, hence with the whole algebra; an even element with this property is a multiple of $\mathbf{1}$ (this is the "exercise" in Bär's proof: an even monomial $\gamma_I \neq 1$ contains some γ_a and anticommutes with a suitable γ_b). So $a = \alpha\mathbf{1}$. Reversing the order of the factors does nothing to a multiple of $\mathbf{1}$, so $a^\dagger = \alpha\mathbf{1}$ too, while $a\,a^\dagger = u_1 \cdots u_m\, u_m \cdots u_1 = 1$. Hence $\alpha^2 = 1$ and $a = \pm\mathbf{1}$. Both are in Spin(n): $-1 = \gamma_1(-\gamma_1)$.

Key idea: the spin group is a double cover

The sequence

$$1 \longrightarrow \{\pm 1\} \longrightarrow \mathrm{Spin}(n) \xrightarrow{\rho} \mathrm{SO}(n) \longrightarrow 1 \tag{T4.49}$$

is exact [Bär Prop. 2.2.10]: every rotation R has exactly two lifts $\pm a$, and they act on spinors with opposite signs. A spinor "knows" not just the rotation R but also which of the two lifts was used.

Watch out: spinors are not a representation of SO(n)

If a representation of Spin(n) came from a representation λ' of SO(n), then $-1 \in \mathrm{Spin}(n)$ would act as $\lambda'(\rho(-1)) = \lambda'(\mathrm{id}) = \mathrm{id}$ [Bär Rem. 2.3.4]. On spinors -1 acts as $-\mathrm{id}$. So the spinor representation is *not* a representation of the rotation group, only of its double cover. Tensors (vectors, forms, metrics) are the representations on which -1 acts trivially; spinors are the ones on which it acts as -1. Physicists say "spinors are double valued representations of SO(n)".

T4.5.4 Small cases, completely explicitly

Worked example T4.29: Spin(1) = $\mathbb{Z}_2$ and Spin(2) = U(1)

$n = 1$. The unit vectors are $\pm\gamma_1$, so even products are ± 1: Spin(1) = $\{\pm 1\} = \mathbb{Z}_2$, covering the trivial group SO(1) [Bär Ex. 2.2.7]. This tiny group is what distinguishes the two spin structures on a circle (Section T4.6).
$n = 2$. Every unit vector is $u(\phi) = \cos\phi\,\gamma_1 + \sin\phi\,\gamma_2$, and

$$u(\phi_2)\,u(\phi_1) \overset{(1)}{=} \cos\phi_2\cos\phi_1 + \sin\phi_2\sin\phi_1 + (\cos\phi_2\sin\phi_1 - \sin\phi_2\cos\phi_1)\gamma_1\gamma_2$$
$$\overset{(2)}{=} \cos(\phi_2 - \phi_1) - \sin(\phi_2 - \phi_1)\gamma_1\gamma_2 \overset{(3)}{=} a\big(2(\phi_2 - \phi_1)\big).$$

(1) Expand; use $\gamma_1^2 = \gamma_2^2 = 1$ and $\gamma_2\gamma_1 = -\gamma_1\gamma_2$.
(2) Angle-difference formulas.
(3) Compare with (T4.46).

Products of such pairs multiply like $a(\theta)a(\theta') = a(\theta+\theta')$, so $\mathrm{Spin}(2) = \{a(\theta)\}$ is a circle, parametrised by $\theta \in [0, 4\pi)$ [Bär Ex. 2.2.8]. In the representation $\gamma_1 = \sigma_1$, $\gamma_2 = \sigma_2$ of Example T4.1, $\gamma_1\gamma_2 = i\sigma_3$ and

$$a(\theta) = e^{-i\theta\sigma_3/2} = \begin{pmatrix} e^{-i\theta/2} & 0 \\ 0 & e^{i\theta/2} \end{pmatrix}. \tag{T4.50}$$

The two chiral components of a 2D spinor carry "spin" $\mp\frac{1}{2}$: they pick up the phases $e^{\mp i\theta/2}$ under a rotation by θ, while a vector $v^1 + iv^2$ picks up $e^{i\theta}$. The lower entry $w = e^{i\theta/2}$ of $a(\theta)$ squares to the rotation $z = e^{i\theta}$, so ρ is the squaring map $\mathrm{U}(1) \to \mathrm{U}(1)$ (Bär writes $z \mapsto z^2$).

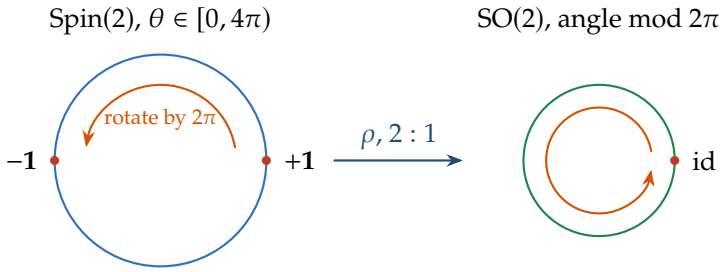

Figure T4.11: $\mathrm{Spin}(2) \to \mathrm{SO}(2)$ is the double cover of a circle by a circle. Going once around SO(2) (a full 2π rotation, orange loop on the right) lifts to going *half* way around Spin(2), from $+\mathbf{1}$ to $-\mathbf{1}$. Only a 4π rotation closes the loop upstairs.

Worked example T4.30: Spin(3) = SU(2)

Now $\gamma_a = \sigma_a$ and a unit vector is $\hat{u}\cdot\vec{\sigma}$. By the Pauli product rule (T4.6),

$$(\hat{u}\cdot\vec{\sigma})(\hat{w}\cdot\vec{\sigma}) = (\hat{u}\cdot\hat{w})\mathbf{1} + i(\hat{u}\times\hat{w})\cdot\vec{\sigma}, \tag{T4.51}$$

and $(\hat{u}\cdot\hat{w})^2 + |\hat{u}\times\hat{w}|^2 = 1$. So a product of two unit vectors has the form $a_0\mathbf{1} + i\vec{a}\cdot\vec{\sigma}$ with $a_0^2 + |\vec{a}|^2 = 1$. These matrices are exactly

$$\begin{pmatrix} a_0 + ia_3 & ia_1 + a_2 \\ ia_1 - a_2 & a_0 - ia_3 \end{pmatrix} = \begin{pmatrix} \alpha & -\bar{\beta} \\ \beta & \bar{\alpha} \end{pmatrix}, \qquad |\alpha|^2 + |\beta|^2 = 1,$$

the group SU(2), topologically the 3-sphere S^3 (the unit quaternions, (T4.14)). Every element can be written

$$U(\theta, \hat{n}) = \exp\!\left(-\frac{i\theta}{2}\,\hat{n}\cdot\vec{\sigma}\right) = \cos\frac{\theta}{2}\,\mathbf{1} - i\sin\frac{\theta}{2}\,\hat{n}\cdot\vec{\sigma}, \tag{T4.52}$$

and $\rho(U)$ is the rotation by θ about $\hat{n}$. Let us verify this for $\hat{n} = \hat{z}$ by explicit multiplication. With $X = \vec{x}\cdot\vec{\sigma}$ and $U = \mathrm{diag}(e^{-i\theta/2}, e^{i\theta/2})$:

$$UXU^\dagger \overset{(1)}{=} \begin{pmatrix} e^{-i\theta/2} & 0 \\ 0 & e^{i\theta/2} \end{pmatrix} \begin{pmatrix} x^3 & x^1 - ix^2 \\ x^1 + ix^2 & -x^3 \end{pmatrix} \begin{pmatrix} e^{i\theta/2} & 0 \\ 0 & e^{-i\theta/2} \end{pmatrix}$$
$$\overset{(2)}{=} \begin{pmatrix} x^3 & e^{-i\theta}(x^1 - ix^2) \\ e^{i\theta}(x^1 + ix^2) & -x^3 \end{pmatrix}.$$

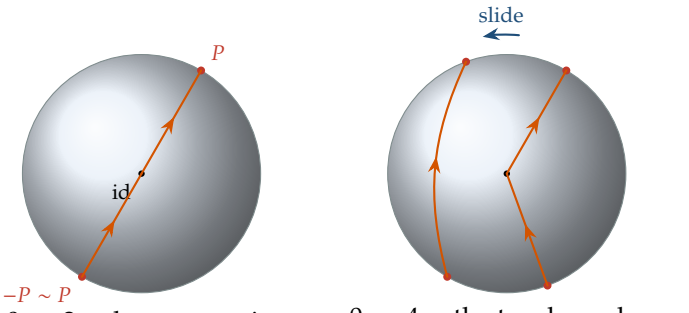
(1) Write out X and $U^\dagger = U^{-1}$.
(2) Multiplying by diagonal matrices on both sides scales entry (j,k) by $U_{jj}\bar{U}_{kk}$: the diagonal is unchanged and the off-diagonal entries acquire $e^{\mp i\theta}$.

So $x^1 + ix^2 \mapsto e^{i\theta}(x^1 + ix^2)$ and $x^3 \mapsto x^3$: a rotation by θ about z. The rotation matrix in general is read off as $R_{ab} = \frac{1}{2}\operatorname{tr}(\sigma_a U \sigma_b U^\dagger)$. The kernel is visible too: $U(2\pi, \hat{n}) = -\mathbf{1}$ for every axis, and $\pm U$ give the same R.

The topology of SO(3)**.** Since $\mathrm{SU}(2) = S^3$ and ρ identifies U with $-U$, the rotation group is the 3-sphere with antipodal points identified: $\mathrm{SO}(3) \cong \mathbb{RP}^3$. A more visual model [Bär proof of Prop. 2.2.13]: represent the rotation by angle $\theta \in [0, \pi]$ about the axis $\hat{n}$ by the point $\theta\hat{n}/\pi$ of the closed unit ball. Rotations by π about $\hat{n}$ and $-\hat{n}$ coincide, so antipodal points of the boundary sphere are identified. A path that starts at the centre, runs out to the boundary, reappears at the antipodal point and returns to the centre is a closed loop (the family of rotations by $0 \to 2\pi$ about a fixed axis). It cannot be shrunk to a point: shrinking would require pulling the two ends of the chord off the boundary together, but they are stuck at antipodal points. Traversing it twice gives a loop that *can* be shrunk (Figure T4.12). Hence

$$\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2, \qquad \pi_1(\mathrm{SU}(2)) = \pi_1(S^3) = 0.$$

The 2π loop is exactly the loop whose lift to SU(2) ends at $-\mathbf{1}$ instead of $+\mathbf{1}$: a lift of a loop in SO(3) closes in SU(2) precisely when the loop is contractible.



$0 \to 2\pi$ about one axis: not contractible

$0 \to 4\pi$: the two boundary pairs slide together and cancel

Figure T4.12: SO(3) as a ball of radius π with antipodal boundary points identified. Left: the 2π rotation loop leaves through P and re-enters at $-P$; it cannot be contracted. Right: the 4π loop crosses the boundary twice; moving the second crossing point around the sphere until it meets the first lets the two crossings annihilate, and the loop shrinks to the identity. This is the geometry behind Dirac's belt trick: a belt twisted by 4π can be untwisted without rotating its ends, one twisted by 2π cannot.

Physical picture: the belt trick

Hold one end of a belt fixed and rotate the buckle by 2π. The belt is twisted and you cannot untwist it without rotating the buckle back. Rotate by 4π instead: now, keeping the buckle's orientation fixed, you can loop the belt around the buckle and the twist disappears. The state of the belt records an element of SU(2), not just of SO(3). Neutron interferometry measured the -1 directly in 1975: a neutron beam rotated by 2π in a magnetic field interferes destructively with an unrotated one.

Connectedness in general. For $n \geq 2$, $\mathrm{Spin}(n)$ is connected: the path $c(t) = (\cos t\, \gamma_1 + \sin t\, \gamma_2)\gamma_1 = \cos t - \sin t\, \gamma_1\gamma_2$ joins $c(0) = 1$ to $c(\pi) = -1$, and every other element is joined to

one of them by lifting a path in the connected group $\mathrm{SO}(n)$. For $n \geq 3$ it is simply connected: $\pi_1(\mathrm{SO}(n)) = \mathbb{Z}_2$ for all $n \geq 3$ (adding dimensions does not change π_1, since $\mathrm{SO}(n+1)/\mathrm{SO}(n) = S^n$ is simply connected), and the nontrivial loop is the 2π rotation in one plane, whose lift is the *open* path from 1 to -1. So $\mathrm{Spin}(n)$ is the **universal cover** of $\mathrm{SO}(n)$ for $n \geq 3$ [Bär Prop. 2.2.13]; this is how Nash introduces it.

T4.5.5 The Lie algebra: $\gamma_a\gamma_b/4$

Infinitesimal rotations are antisymmetric matrices $A \in \mathfrak{so}(n)$, $A_{ab} = -A_{ba}$, acting as $x \mapsto Ax$. Which infinitesimal element of the Clifford algebra implements them? Differentiating (T4.46) at $\theta = 0$ gives $-\frac{1}{2}\gamma_1\gamma_2$ for the rotation generator of the 12-plane. So we expect bivectors. The key commutator is

$$\begin{aligned}[\gamma_a\gamma_b, \gamma_c] &\overset{(1)}{=} \gamma_a\gamma_b\gamma_c - \gamma_c\gamma_a\gamma_b \overset{(2)}{=} \gamma_a(2\delta_{bc} - \gamma_c\gamma_b) - \gamma_c\gamma_a\gamma_b \\ &\overset{(3)}{=} 2\delta_{bc}\gamma_a - \{\gamma_a, \gamma_c\}\gamma_b \overset{(4)}{=} 2\delta_{bc}\gamma_a - 2\delta_{ac}\gamma_b. \end{aligned} \tag{T4.53}$$

(1) Definition of the commutator.
(2) $\gamma_b\gamma_c = 2\delta_{bc} - \gamma_c\gamma_b$.
(3) Collect the two terms ending in γ_b.
(4) Clifford relation.

Now contract with $\frac{1}{4}A_{ab}$ and apply to a vector $x = x^c\gamma_c$:

$$\begin{aligned}\left[\tfrac{1}{4}A_{ab}\gamma_a\gamma_b,\ x^c\gamma_c\right] &\overset{(1)}{=} \tfrac{1}{4}A_{ab}x^c(2\delta_{bc}\gamma_a - 2\delta_{ac}\gamma_b) \overset{(2)}{=} \tfrac{1}{2}(A_{ab}x^b\gamma_a - A_{ab}x^a\gamma_b) \\ &\overset{(3)}{=} \tfrac{1}{2}(A_{ab}x^b\gamma_a + A_{ba}x^a\gamma_b) \overset{(4)}{=} (Ax)^a\gamma_a. \end{aligned} \tag{T4.54}$$

(1) (T4.53).
(2) Do the c sums with the deltas.
(3) A is antisymmetric.
(4) Rename $a \leftrightarrow b$ in the second term; the two terms are equal.

Since the derivative of $x \mapsto axa^{-1}$ at $a = 1$ in the direction X is $x \mapsto [X, x]$, this says:

Key idea: spin generators

The Lie algebra $\mathfrak{spin}(n)$ is spanned by the $\binom{n}{2}$ bivectors $\gamma_a\gamma_b$ $(a < b)$, and the infinitesimal rotation $A \in \mathfrak{so}(n)$ lifts to

$$\rho_*^{-1}(A) = \frac{1}{4}A_{ab}\gamma_a\gamma_b = \frac{1}{2}A_{ab}\Sigma_{ab}, \qquad \Sigma_{ab} := \frac{1}{4}[\gamma_a, \gamma_b]. \tag{T4.55}$$

A finite rotation e^A acts on spinors by $\exp\left(\frac{1}{4}A_{ab}\gamma_a\gamma_b\right)$.

The Σ_{ab} satisfy the commutation relations of $\mathfrak{so}(n)$. From (T4.53), $[\Sigma_{ab}, \gamma_c] = \delta_{bc}\gamma_a - \delta_{ac}\gamma_b$ (for $a \neq b$, $\Sigma_{ab} = \frac{1}{2}\gamma_a\gamma_b$), and then for $c \neq d$

$$\begin{aligned}[\Sigma_{ab}, \Sigma_{cd}] &\overset{(1)}{=} \tfrac{1}{2}[\Sigma_{ab}, \gamma_c]\gamma_d + \tfrac{1}{2}\gamma_c[\Sigma_{ab}, \gamma_d] \\ &\overset{(2)}{=} \delta_{bc}\Sigma_{ad} - \delta_{ac}\Sigma_{bd} + \delta_{bd}\Sigma_{ca} - \delta_{ad}\Sigma_{cb}, \end{aligned}$$

(1) Leibniz rule for commutators, $[X, YZ] = [X, Y]Z + Y[X, Z]$.

(2) Insert $[\Sigma_{ab}, \gamma_c]$ and use $\frac{1}{2}\gamma_x\gamma_y = \Sigma_{xy}$ for $x \neq y$ (when an index coincidence produces $\frac{1}{2}\gamma_x\gamma_x = \frac{1}{2}$, the two such constants appear with opposite signs and cancel).

which is the familiar $\mathfrak{so}(n)$ algebra of the generators $L_{ab} = E_{ab} - E_{ba}$. Bär computes the same thing as $\rho_*(e_ie_j) = 2(E_{ji} - E_{ij})$ [Bär p. 82]; with $e_a = -i\gamma_a$, $e_ie_j = -\gamma_i\gamma_j$, and our (T4.54) gives $\rho_*(-\gamma_i\gamma_j) = -4(E_{ij} - E_{ji})$, in agreement.

Dictionary: Euclidean Σ_{ab} versus Lorentz $S^{\mu\nu}$

- Mathematicians use the anti-Hermitian $\Sigma_{ab} = \frac{1}{4}[\gamma_a, \gamma_b]$; group elements are $\exp(\frac{1}{2}\omega_{ab}\Sigma_{ab})$ with real ω.
- Physicists use Hermitian generators $J_{ab} = i\Sigma_{ab}$ and write $\exp(-\frac{i}{2}\omega_{ab}J_{ab})$. In Minkowski space the QFT notes' $S^{\mu\nu} = \frac{i}{4}[\gamma^\mu, \gamma^\nu]$ (T4.29) is this J.
- In 3D: $\Sigma_{ab} = \frac{1}{2}\sigma_a\sigma_b = \frac{i}{2}\varepsilon_{abc}\sigma_c$ for $a \neq b$, so $J_{12} = i\Sigma_{12} = -\frac{1}{2}\sigma_3$, and cyclically: the Hermitian spin operators are $\pm\frac{1}{2}\vec{\sigma}$, the overall sign being a convention. "Spin $\frac{1}{2}$" is the statement that the rotation generators are *half* the Pauli matrices, which is the infinitesimal version of the half-angle in $a(\theta)$.

T4.5.6 $\mathrm{Spin}(4) = \mathrm{SU}(2) \times \mathrm{SU}(2)$ and self-duality

Four dimensions is special: the rotation group splits into two commuting pieces. The chiral representation (T4.21) shows this at once. Write a vector $x \in \mathbb{R}^4$ as the 2×2 matrix

$$X := x^a\tau_a = x^4\mathbf{1} + i\,\vec{x}\cdot\vec{\sigma} = \begin{pmatrix} x^4 + ix^3 & ix^1 + x^2 \\ ix^1 - x^2 & x^4 - ix^3 \end{pmatrix}, \qquad \det X = |x|^2, \tag{T4.56}$$

a quaternion (Example T4.10). Then $\not{x} = x^a\gamma_a = \left(\begin{smallmatrix} 0 & X \\ X^\dagger & 0 \end{smallmatrix}\right)$. Since even products of γ's are block diagonal, a spin element has the form $a = \mathrm{diag}(p, q)$, and

$$a\not{x}a^{-1} \overset{(1)}{=} \begin{pmatrix} p & 0 \\ 0 & q \end{pmatrix}\begin{pmatrix} 0 & X \\ X^\dagger & 0 \end{pmatrix}\begin{pmatrix} p^\dagger & 0 \\ 0 & q^\dagger \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} 0 & pXq^\dagger \\ qX^\dagger p^\dagger & 0 \end{pmatrix}. \tag{T4.57}$$

(1) a is unitary (fact 1 above), so $a^{-1} = a^\dagger$.
(2) Block multiplication.

The result is again of the form $\not{x}'$, with $X' = pXq^\dagger$, because $(pXq^\dagger)^\dagger = qX^\dagger p^\dagger$. For this to be a vector for every X, $pXq^\dagger$ must again be a real combination of $\mathbf{1}, i\sigma_j$, which holds for $p, q \in \mathrm{SU}(2)$; and $\det(pXq^\dagger) = \det X$, so the map is a rotation.

Worked example T4.31: $\mathrm{Spin}(4) \to \mathrm{SO}(4)$ via quaternions

The map $(p, q) \mapsto \big(X \mapsto pXq^\dagger\big)$ sends $\mathrm{SU}(2) \times \mathrm{SU}(2)$ onto $\mathrm{SO}(4)$. Its kernel: if $pXq^\dagger = X$ for all X, then $X = \mathbf{1}$ gives $p = q$, and then p commutes with every quaternion, so $p = \pm\mathbf{1}$. The kernel is $\{(\mathbf{1}, \mathbf{1}), (-\mathbf{1}, -\mathbf{1})\}$, the $\{\pm 1\}$ of (T4.49). So

$$\mathrm{Spin}(4) = \mathrm{SU}(2)_+ \times \mathrm{SU}(2)_-, \qquad \mathrm{SO}(4) = \big(\mathrm{SU}(2) \times \mathrm{SU}(2)\big)/\mathbb{Z}_2.$$

The positive-chirality spinors S^+ (upper block) transform under p only, the negative ones S^- under q only. In particle-physics language: a Euclidean Weyl spinor is a doublet of one SU(2) and a singlet of the other, the Euclidean shadow of the $(\frac{1}{2}, 0)$ and $(0, \frac{1}{2})$ representations of the Lorentz group.

Self-dual and anti-self-dual generators. Which rotations does S^+ see? Compute the blocks of $\Sigma_{ab} = \frac{1}{2}\gamma_a\gamma_b$ ($a \neq b$). The upper block is $\frac{1}{2}\tau_a\tau_b^\dagger$ and the lower block is $\frac{1}{2}\tau_a^\dagger\tau_b$ (Example T4.14). For the two "opposite" planes 12 and 34:

$$\Sigma_{12} \overset{(1)}{=} \tfrac{1}{2}\,\mathrm{diag}\big((i\sigma_1)(-i\sigma_2),\ (-i\sigma_1)(i\sigma_2)\big) \overset{(2)}{=} \tfrac{i}{2}\,\mathrm{diag}(\sigma_3,\ \sigma_3),$$
$$\Sigma_{34} \overset{(3)}{=} \tfrac{1}{2}\,\mathrm{diag}\big((i\sigma_3)\mathbf{1},\ (-i\sigma_3)\mathbf{1}\big) = \tfrac{i}{2}\,\mathrm{diag}(\sigma_3,\ -\sigma_3).$$

(1) Insert $\tau_1 = i\sigma_1$, $\tau_2 = i\sigma_2$ from (T4.20).
(2) $\sigma_1\sigma_2 = i\sigma_3$.
(3) $\tau_3 = i\sigma_3$, $\tau_4 = \mathbf{1}$.

So on S^+, $\Sigma_{12} = \Sigma_{34}$, while on S^-, $\Sigma_{12} = -\Sigma_{34}$. The same holds for the pairs $(13, 42)$ and $(14, 23)$. The combinations $\Sigma_{12} - \Sigma_{34}$ etc. vanish on S^+. Recall that the Hodge star in $\mathbb{R}^4$ exchanges $\mathrm{d}x^1 \wedge \mathrm{d}x^2 \leftrightarrow \mathrm{d}x^3 \wedge \mathrm{d}x^4$. A two-form $F = \frac{1}{2}F_{ab}\mathrm{d}x^a \wedge \mathrm{d}x^b$ acts on spinors through $\frac{1}{2}F_{ab}\Sigma_{ab}$, and the computation shows

$$\tfrac{1}{2}F_{ab}\Sigma_{ab}\big|_{S^+} \text{ depends only on } F^+ = \tfrac{1}{2}(F + \star F), \qquad \tfrac{1}{2}F_{ab}\Sigma_{ab}\big|_{S^-} \text{ only on } F^- = \tfrac{1}{2}(F - \star F). \quad \text{(T4.58)}$$

This is the algebra behind the splitting $\Lambda^2\mathbb{R}^4 = \Lambda^2_+ \oplus \Lambda^2_-$, $\mathfrak{so}(4) = \mathfrak{su}(2)_+ \oplus \mathfrak{su}(2)_-$, and it is why instantons (self-dual fields, Chapter 8) couple to one chirality in a special way.

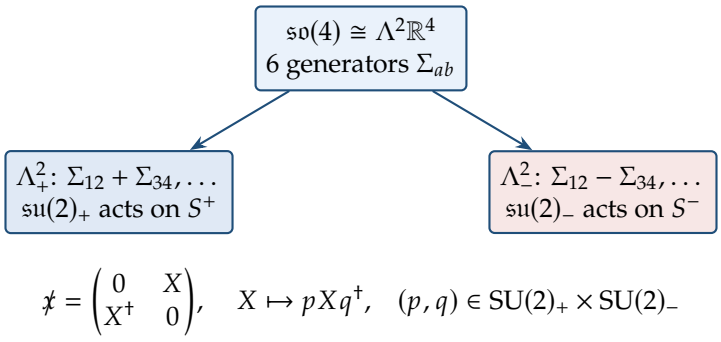


Figure T4.13: The four-dimensional miracle. The six rotation generators split into three self-dual and three anti-self-dual combinations that commute with each other. The first three act only on positive-chirality spinors, the last three only on negative ones. At the group level, a vector is a quaternion X and a rotation is $X \mapsto pXq^\dagger$.

T4.5.7 Lorentzian signature

The same construction works for any signature [Bär §6.1]. A vector v with $\langle v, v\rangle = \pm 1$ is invertible in the Clifford algebra, $v\,x\,v^{-1}$ is (minus) the reflection in $v^\perp$, and even products of such v form $\mathrm{Spin}(p, q)$, a double cover of $\mathrm{SO}(p, q)$. Two new features appear.

Worked example T4.32: $\mathrm{Spin}(1, 1)$: boosts in two dimensions

Take a timelike γ^0 with $(\gamma^0)^2 = 1$ and a spacelike γ^1 with $(\gamma^1)^2 = -1$, e.g. $\gamma^0 = \sigma_1$, $\gamma^1 = i\sigma_2$. The bivector $\gamma^0\gamma^1 = \sigma_1\, i\sigma_2 = -\sigma_3$ now squares to $+1$, so exponentials give hyperbolic functions:

$$b(\beta) := \exp\Big(\frac{\beta}{2}\gamma^0\gamma^1\Big) = \cosh\frac{\beta}{2} + \sinh\frac{\beta}{2}\,\gamma^0\gamma^1 = \mathrm{diag}\big(e^{-\beta/2}, e^{\beta/2}\big).$$

Since $\gamma^0\gamma^1$ anticommutes with γ^0, $b(\beta)\gamma^0 = \gamma^0 b(-\beta)$, and

$$b\gamma^0 b^{-1} \overset{(1)}{=} \gamma^0\, b(-\beta)^2 \overset{(2)}{=} \gamma^0\big(\cosh\beta - \sinh\beta\,\gamma^0\gamma^1\big) \overset{(3)}{=} \cosh\beta\,\gamma^0 - \sinh\beta\,\gamma^1,$$

(1) Move γ^0 through $b(\beta)$; $b(\beta)^{-1} = b(-\beta)$.
(2) $b(-\beta)^2 = \exp(-\beta\gamma^0\gamma^1)$, and $(\gamma^0\gamma^1)^2 = +1$ gives cosh and sinh instead of cos and sin.
(3) $\gamma^0\gamma^0\gamma^1 = \gamma^1$.

a boost with rapidity β (the sign depends on which way we call "forward"). The two components of the spinor are rescaled by $e^{\mp\beta/2}$: they are the left- and right-movers, and boosts, unlike rotations, are not unitary. SO(1, 1) has two components and Spin(1, 1) has four [Bär Ex. 6.1.11], because the non-compact direction does not close up.

Spin(1, 3) = SL(2, $\mathbb{C}$). In four-dimensional Minkowski space the identity component $\mathrm{Spin}_0(1,3)$ is $\mathrm{SL}(2,\mathbb{C})$ acting by $X \mapsto AXA^\dagger$ on Hermitian matrices $X = x^0\mathbf{1} + \vec{x}\cdot\vec{\sigma}$ (Section T4.3.7). The proof that this is a double cover of the proper orthochronous Lorentz group mirrors Example T4.30: $\det(AXA^\dagger) = \det X$ shows it is a Lorentz transformation; $AXA^\dagger = X$ for all X forces $A = \pm\mathbf{1}$; and the Lie algebra $\mathfrak{sl}(2,\mathbb{C})$ is spanned by $\frac{i}{2}\sigma_j$ (rotations) and $\frac{1}{2}\sigma_j$ (boosts), matching the block-diagonal $S^{\mu\nu}$ of Example T4.18. The Weyl spinors are the defining representation A and its conjugate-inverse $(A^\dagger)^{-1}$. As in Euclidean signature, $\mathrm{Spin}_0(1,3)$ is simply connected while $\mathrm{SO}_0(1,3)$ has $\pi_1 = \mathbb{Z}_2$ [Bär Prop. 6.1.17]; but $\mathrm{SL}(2,\mathbb{C})$ is not compact, so these spinor representations are not unitary.

Try it: the rotation matrix from SU(2)

Compute $R_{ab} = \frac{1}{2}\operatorname{tr}(\sigma_a U \sigma_b U^\dagger)$ for $U = e^{-i\theta\sigma_1/2}$ and check that it is the rotation by θ about the x-axis. *Answer:* $U\sigma_1U^\dagger = \sigma_1$, $U\sigma_2U^\dagger = \cos\theta\,\sigma_2 + \sin\theta\,\sigma_3$, $U\sigma_3U^\dagger = \cos\theta\,\sigma_3 - \sin\theta\,\sigma_2$, so R has columns $(1,0,0)$, $(0,\cos\theta,\sin\theta)$, $(0,-\sin\theta,\cos\theta)$.

Reading Nash (p. 113)

Nash's whole treatment of the spin group is one sentence: "Spinors first arise when one encounters the universal cover Spin(n) of the orthogonal group SO(n)." We have now seen what that cover is concretely: even products of unit vectors $u = u^a\gamma_a$, acting on vectors by $x \mapsto axa^{-1}$ and on spinors by matrix multiplication; it is universal (simply connected) for $n \geq 3$, and the two lifts $\pm a$ of each rotation differ in their action on spinors. The "spin representation" Nash quotes on the same page is the restriction of the Clifford representation of Section T4.4 to Spin(n); since $\mathrm{Spin}(n) \subset \mathrm{Cl}^0$ and even elements commute with Γ, it splits as $S^+ \oplus S^-$ in even dimensions (his (4.97)).

Recap

- A unit vector u acts by $x \mapsto uxu^{-1} = -R_u(x)$; two of them give a rotation by twice the angle between them.
- $\mathrm{Spin}(n) = \{\text{even products of unit vectors}\}$, $\rho(a)x = axa^{-1}$; $1 \to \mathbb{Z}_2 \to \mathrm{Spin}(n) \to \mathrm{SO}(n) \to 1$; spinors are acted on by a itself.
- Plane rotation lift $a(\theta) = \exp(-\frac{\theta}{2}\gamma_1\gamma_2)$, and $a(2\pi) = -1$. Spin(2) = U(1) (squaring map), Spin(3) = SU(2), Spin(4) = SU(2) × SU(2), $\mathrm{Spin}_0(1,3) = \mathrm{SL}(2,\mathbb{C})$.
- $\mathfrak{spin}(n)$ is spanned by $\Sigma_{ab} = \frac{1}{4}[\gamma_a,\gamma_b]$; $A \in \mathfrak{so}(n)$ lifts to $\frac{1}{4}A_{ab}\gamma_a\gamma_b$ (T4.55).

- In 4D, S^+ sees only self-dual rotations/field strengths, S^- only anti-self-dual ones.

T4.6 Spin structures: putting spinors on a manifold

On $\mathbb{R}^n$ a spinor field is simply a function $\psi : \mathbb{R}^n \to \mathbb{C}^{2^{\lfloor n/2 \rfloor}}$. On a curved manifold we must say what the components of ψ *mean*. The components of a vector field are meaningful only relative to a frame; change the frame by a rotation R and the components change by R. The components of a spinor are also meaningful only relative to a frame, but a change of frame acts on them by a *lift* $\pm a$ of R to $\mathrm{Spin}(n)$, and there are two lifts. The question of this section is:

Can we choose the signs of the lifts consistently over the whole manifold?

When the answer is yes, and we have made a choice, we have a **spin structure**. The answer is sometimes "yes, in several inequivalent ways" (the circle has two, the torus four) and sometimes "no" ($\mathbb{CP}^2$). Both answers have physical consequences. On a circle, the two spin structures are periodic and antiperiodic fermions: the Ramond and Neveu–Schwarz sectors of string theory, or the $(-1)^F$-twisted and untwisted thermal traces. On $\mathbb{CP}^2$, the impossibility means there is no Dirac equation at all unless we couple the fermion to an extra gauge field.

T4.6.1 Frames, transition functions and associated bundles

We first recall how vectors and forms are glued together on a manifold, written so that the spinor case becomes a small modification.

Let M be an oriented Riemannian manifold of dimension n. Cover M by open sets U_α on each of which we have chosen an oriented orthonormal frame $h_\alpha = (e_1^{(\alpha)}, \dots, e_n^{(\alpha)})$ (for instance by applying Gram–Schmidt to the coordinate vectors ∂_μ). On an overlap $U_\alpha \cap U_\beta$ two frames are available, and since both are oriented and orthonormal they differ by a rotation:

$$e_b^{(\beta)} = e_a^{(\alpha)} \left(g_{\alpha\beta}\right)_{ab}, \qquad g_{\alpha\beta} : U_\alpha \cap U_\beta \to \mathrm{SO}(n). \tag{T4.59}$$

We write this compactly as $h_\beta = h_\alpha\, g_{\alpha\beta}$. The functions $g_{\alpha\beta}$ are the **transition functions** of the frame bundle.

Components of a vector. A vector v has components $v_\alpha \in \mathbb{R}^n$ in the frame h_α, meaning $v = e_a^{(\alpha)} v_\alpha^a$. Comparing the two expansions on an overlap:

$$e_a^{(\alpha)} v_\alpha^a \overset{(1)}{=} v \overset{(2)}{=} e_b^{(\beta)} v_\beta^b \overset{(3)}{=} e_a^{(\alpha)} (g_{\alpha\beta})_{ab} v_\beta^b,$$

(1) Expansion of v in the frame h_α.
(2) Expansion of the same vector in the frame h_β.
(3) Insert (T4.59).

so $v_\alpha = g_{\alpha\beta}\, v_\beta$. On a triple overlap $U_\alpha \cap U_\beta \cap U_\gamma$ we can go from γ to α directly or through β, and consistency requires the **cocycle condition**

$$g_{\alpha\beta}\, g_{\beta\gamma} = g_{\alpha\gamma}, \qquad \text{equivalently} \qquad g_{\alpha\beta}\, g_{\beta\gamma}\, g_{\gamma\alpha} = \mathbf{1}, \qquad g_{\beta\alpha} = g_{\alpha\beta}^{-1}. \tag{T4.60}$$

For frames this is automatic, because it is literally the statement $h_\gamma = h_\alpha g_{\alpha\gamma} = h_\beta g_{\beta\gamma} = h_\alpha g_{\alpha\beta} g_{\beta\gamma}$.

Associated bundles. Every other tensor field is glued with the same $g_{\alpha\beta}$, fed through a representation. A k-form has components $\omega_\alpha \in \Lambda^k\mathbb{R}^n$ with $\omega_\alpha = \Lambda^k(g_{\alpha\beta})\,\omega_\beta$; a metric-type tensor has $T_\alpha = g_{\alpha\beta}T_\beta g_{\alpha\beta}^{\mathsf{T}}$; and so on. In general, a representation $\lambda : \mathrm{SO}(n) \to \mathrm{GL}(V)$ gives a vector bundle whose sections are collections $\phi_\alpha : U_\alpha \to V$ with $\phi_\alpha = \lambda(g_{\alpha\beta})\phi_\beta$. The cocycle condition for the $\lambda(g_{\alpha\beta})$ follows from (T4.60) because λ is a homomorphism. Bär calls this the **associated vector bundle** $P_{\mathrm{SO}}(M) \times_\lambda V$ [Bär Def. 2.4.2]; his table is:

fibre V	representation of $\mathrm{SO}(n)$	bundle
$\mathbb{R}$	trivial	functions, $M \times \mathbb{R}$
$\mathbb{R}^n$	defining, $v \mapsto gv$	TM
$(\mathbb{R}^n)^*$	dual, $\xi \mapsto \xi g^{-1}$	T^*M
$\Lambda^k(\mathbb{R}^n)^*$	Λ^k of the dual	$\Lambda^k T^*M$ (k-forms)
$\otimes^k\mathbb{R}^n \otimes \otimes^l(\mathbb{R}^n)^*$	tensor products	(k,l) tensors

Formally, $P_{\mathrm{SO}}(M)$ is the **oriented orthonormal frame bundle**: the space of all pairs (point, oriented orthonormal frame at that point), on which $\mathrm{SO}(n)$ acts by rotating frames [Bär Def. 2.4.1]. Everything we need is captured by the transition functions $g_{\alpha\beta}$.

Watch out: orientability comes first

If M is not orientable we can only arrange $g_{\alpha\beta} \in \mathrm{O}(n)$, and $\det g_{\alpha\beta} = \pm 1$ is a $\mathbb{Z}_2$-valued cocycle. Its class $w_1(M) \in H^1(M;\mathbb{Z}_2)$ is the **first Stiefel–Whitney class**; it vanishes exactly when the signs can be removed by flipping some frames, i.e. when M is orientable. This is the first of Nash's two conditions (4.96). The Möbius band and $\mathbb{RP}^2$ fail it.

T4.6.2 Lifting the transition functions

A spinor field should be a collection of local spinor-valued functions $\psi_\alpha : U_\alpha \to \mathbb{C}^N$ ($N = 2^{\lfloor n/2 \rfloor}$) glued by matrices that rotate spinors the way $g_{\alpha\beta}$ rotates vectors. From Section T4.5 we know which matrices those are: elements $\hat g_{\alpha\beta} \in \mathrm{Spin}(n)$ with $\rho(\hat g_{\alpha\beta}) = g_{\alpha\beta}$. So we try

$$\psi_\alpha = \hat g_{\alpha\beta}\,\psi_\beta, \qquad \rho(\hat g_{\alpha\beta}) = g_{\alpha\beta}, \qquad \hat g_{\beta\alpha} = \hat g_{\alpha\beta}^{-1}. \tag{T4.61}$$

Two things must be checked.

(i) Local lifts exist. On a contractible overlap (we may always refine the cover so that all overlaps are contractible), $g_{\alpha\beta}$ is a map from a contractible set into $\mathrm{SO}(n)$, and such a map can always be lifted continuously through the double cover ρ; the only freedom is an overall sign $\pm\hat g_{\alpha\beta}$ on each overlap, because a continuous choice of sign is constant on a connected set.

(ii) The cocycle condition. On a triple overlap,

$$\rho\big(\hat g_{\alpha\beta}\hat g_{\beta\gamma}\hat g_{\gamma\alpha}\big) \overset{(1)}{=} \rho(\hat g_{\alpha\beta})\,\rho(\hat g_{\beta\gamma})\,\rho(\hat g_{\gamma\alpha}) \overset{(2)}{=} g_{\alpha\beta}g_{\beta\gamma}g_{\gamma\alpha} \overset{(3)}{=} \mathbf{1},$$

$$\text{hence} \quad \hat g_{\alpha\beta}\,\hat g_{\beta\gamma}\,\hat g_{\gamma\alpha} \overset{(4)}{=} \varepsilon_{\alpha\beta\gamma}\,\mathbf{1}, \qquad \varepsilon_{\alpha\beta\gamma} \in \{+1,-1\}. \tag{T4.62}$$

(1) ρ is a group homomorphism.
(2) The $\hat g$'s are lifts.
(3) The cocycle condition (T4.60) for frames.
(4) The kernel of ρ is $\{\pm\mathbf{1}\}$ (T4.49); by continuity the sign is constant on the (connected) triple overlap.

If some $\varepsilon_{\alpha\beta\gamma} = -1$, the rule (T4.61) is inconsistent: going around the three patches, a spinor comes back as $-\psi$. We are allowed to flip the sign of any $\hat g_{\alpha\beta}$ (with $\hat g_{\beta\alpha}$ flipped too), which flips

the three signs ε of the triple overlaps containing $U_\alpha \cap U_\beta$. The question is whether all signs can be made $+1$.

Working definition T4.8 (spin structure)

A **spin structure** on an oriented Riemannian manifold is a choice of lifts $\hat{g}_{\alpha\beta} \in \mathrm{Spin}(n)$ of the frame transition functions [at each point, one of the two elements $\pm\hat{g}$ with $\rho(\hat{g}) = g_{\alpha\beta}$, the rotation converting frame components on U_β into those on U_α], continuous on each overlap, such that

$$\hat{g}_{\alpha\beta}\,\hat{g}_{\beta\gamma}\,\hat{g}_{\gamma\alpha} = +\mathbf{1} \qquad \text{on every triple overlap.}$$

Two choices $\hat{g}$ and $\hat{g}'$ are **equivalent** if $\hat{g}'_{\alpha\beta} = s_\alpha\,\hat{g}_{\alpha\beta}\,s_\beta$ for some signs $s_\alpha = \pm 1$, one per patch (this is just flipping the sign convention for the spinor components on U_α, $\psi_\alpha \to s_\alpha\psi_\alpha$).
How to test existence: pick any lifts, compute the signs $\varepsilon_{\alpha\beta\gamma}$, and ask whether they can all be removed by sign flips. *How to count:* if one spin structure exists, the others are obtained by multiplying the lifts by signs $\eta_{\alpha\beta}$ with $\eta_{\alpha\beta}\eta_{\beta\gamma}\eta_{\gamma\alpha} = 1$; in practice, by choosing independently the sign acquired around each non-contractible loop.
Formal definition [Bär Def. 2.4.3]: a principal $\mathrm{Spin}(n)$-bundle $P_{\mathrm{Spin}}(M)$ [a copy of $\mathrm{Spin}(n)$ over each point, glued between patches by multiplying with $\hat{g}_{\alpha\beta}$] with a two-to-one map $\bar{\rho} : P_{\mathrm{Spin}}(M) \to P_{\mathrm{SO}}(M)$ compatible with ρ. Its transition functions are our $\hat{g}_{\alpha\beta}$.

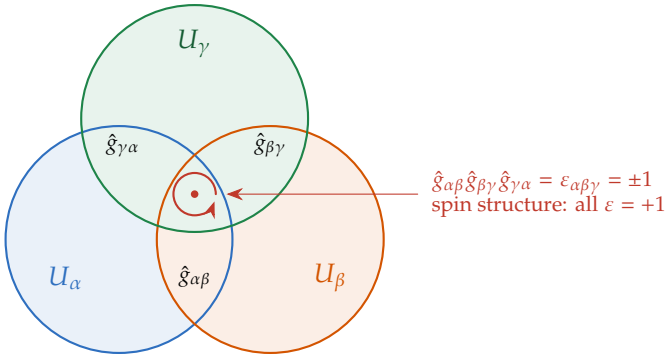

Figure T4.14: Three patches and their overlaps. On each pairwise overlap the frame rotation $g_{\alpha\beta}$ has two lifts $\pm\hat{g}_{\alpha\beta}$. Going once around the triple overlap (red loop) the product of the chosen lifts is a sign $\varepsilon_{\alpha\beta\gamma}$. A spin structure is a choice of lifts for which every such sign is $+1$; the collection of signs, modulo flips, is the obstruction w_2.

The obstruction w_2 and the counting by H^1. The pattern of signs $\varepsilon_{\alpha\beta\gamma}$ is a $\mathbb{Z}_2$-valued Čech 2-cocycle, and changing the lifts changes it by a coboundary. Its class

$$w_2(M) := [\varepsilon] \in H^2(M;\mathbb{Z}_2)$$

is the **second Stiefel–Whitney class**. It is independent of every choice we made, and

$$M \text{ admits a spin structure} \iff w_1(M) = 0 \text{ and } w_2(M) = 0. \tag{T4.63}$$

When a spin structure exists, any other differs from it by signs $\eta_{\alpha\beta}$ forming a $\mathbb{Z}_2$ Čech 1-cocycle, and equivalent ones differ by coboundaries. So spin structures are counted by $H^1(M;\mathbb{Z}_2)$. For a connected M, $H^1(M;\mathbb{Z}_2) = \mathrm{Hom}(\pi_1(M),\mathbb{Z}_2)$: a spin structure difference is a rule assigning a sign to every loop, multiplicative under composition of loops. For the rest of this chapter the operational content is:

Key idea: spin structures, operationally

- Existence: all triple-overlap signs can be made $+1$ ($w_2 = 0$). On a 2-sphere inside M this reduces to a parity check on a single winding number (below).
- Choice: once one exists, we may still choose independently whether spinors pick up $+1$ or -1 around each independent non-contractible loop. The number of spin structures is $|H^1(M;\mathbb{Z}_2)|$; if M is simply connected the spin structure is unique.

Watch out: a torsor, not a group

Nash says "each choice of a spin structure determines an element of $H^1(X;\mathbb{Z}_2)$, and vice versa" [Nash p. 113]. More precisely, the *difference* of two spin structures is an element of $H^1(X;\mathbb{Z}_2)$. The set of spin structures is in bijection with H^1, but there is in general no preferred "zero" spin structure. (On the circle, calling the periodic one "trivial" is natural because it is the product cover, but it is the other one that extends over the disc, as we see next.)

T4.6.3 The circle: periodic and antiperiodic spinors

Worked example T4.33: the two spin structures on S^1

On the circle, $n = 1$, $\mathrm{SO}(1) = \{1\}$ and $\mathrm{Spin}(1) = \{\pm 1\}$ (Example T4.29). The unit tangent vector $e_1 = \partial_\theta/|\partial_\theta|$ is a global frame, so we may take all $g_{\alpha\beta} = 1$. Its lifts are $\hat{g}_{\alpha\beta} = \pm 1$, and the cocycle condition just says the product of the signs is consistent. Cover S^1 by two arcs U_1, U_2 whose overlap consists of *two* disjoint intervals I and I'. On each interval we choose a sign. Flipping the sign convention on U_2 flips both, so only the product

$$\varepsilon = \hat{g}_{12}\big|_I \cdot \hat{g}_{12}\big|_{I'} = \pm 1$$

matters. This is the sign a spinor acquires when transported once around the circle. Unwrapping the circle to the real line, a spinor field is a function $\psi(\theta)$ with

$$\psi(\theta + 2\pi) = +\psi(\theta) \quad \text{(periodic)}, \qquad \text{or} \qquad \psi(\theta + 2\pi) = -\psi(\theta) \quad \text{(antiperiodic)}. \tag{T4.64}$$

These are Bär's trivial and non-trivial spin structures [Bär Ex. 2.4.6, 2.4.8]. As spaces, the two double covers $P_{\mathrm{Spin}}(S^1) \to P_{\mathrm{SO}}(S^1) = S^1$ are the disconnected cover $S^1 \sqcup S^1$ and the connected cover $z \mapsto z^2$ (Figure T4.15). They are inequivalent because one total space is connected and the other is not. And $H^1(S^1;\mathbb{Z}_2) = \mathbb{Z}_2$: two spin structures.

Which of the two is "natural"? A circle usually appears as the boundary of a disc, and then the answer is forced.

Worked example T4.34: the circle bounding a disc carries the antiperiodic structure

The plane $\mathbb{R}^2$ has the global frame (∂_x, ∂_y) and is simply connected, so it has exactly one spin structure: spinors are ordinary functions $\psi_{\mathrm{cart}}(x, y)$. Restrict to the unit circle, but now use the frame adapted to the circle, $e_r = \cos\theta\,\partial_x + \sin\theta\,\partial_y$, $e_\theta = -\sin\theta\,\partial_x + \cos\theta\,\partial_y$. This polar frame is the Cartesian one rotated by the angle θ:

$$h_{\mathrm{polar}} = h_{\mathrm{cart}}\,R(\theta), \qquad R(\theta) = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}.$$

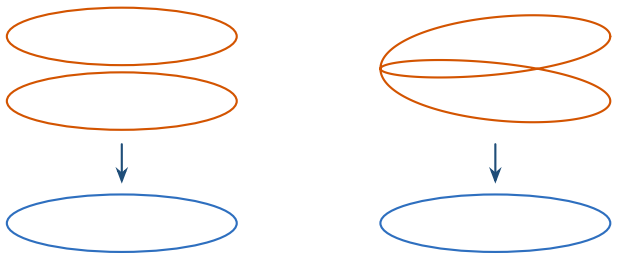

Figure T4.15: The two spin structures on a circle, drawn as double covers of the circle of frames (blue). Left: two separate copies; following a lift once around brings you back to the same sheet, so spinors are periodic. Right: a single curve that winds twice; once around the base takes you to the *other* sheet, which is the sign flip -1: spinors are antiperiodic.

By (T4.61) the spinor components in the two frames are related by a lift of $R(\theta)$, and the continuous lift is $a(\theta)$ of (T4.50):

$$\psi_{\text{polar}}(\theta) \overset{(1)}{=} a(\theta)^{-1}\,\psi_{\text{cart}} \overset{(2)}{=} \begin{pmatrix} e^{i\theta/2} & 0 \\ 0 & e^{-i\theta/2} \end{pmatrix} \psi_{\text{cart}},$$

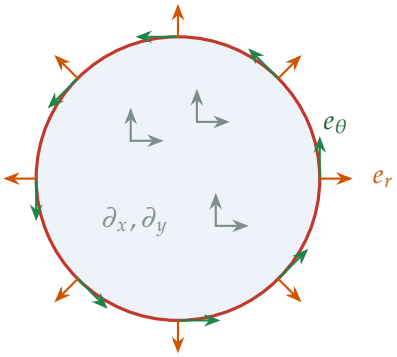
$$\psi_{\text{polar}}(\theta + 2\pi) \overset{(3)}{=} \begin{pmatrix} e^{i\theta/2}e^{i\pi} & 0 \\ 0 & e^{-i\theta/2}e^{-i\pi} \end{pmatrix} \psi_{\text{cart}} = -\psi_{\text{polar}}(\theta).$$

(1) $\psi_{\text{cart}} = \hat{g}\,\psi_{\text{polar}}$ with $\hat{g} = a(\theta)$ lifting $R(\theta)$; $a(\theta)$ must vary continuously with θ because the frames do.

(2) $a(\theta) = \operatorname{diag}(e^{-i\theta/2}, e^{i\theta/2})$ in the representation $\gamma_1 = \sigma_1$, $\gamma_2 = \sigma_2$.

(3) ψ_{cart} is a genuine single-valued function of the point, so only the half-angle phases change, each by $e^{\pm i\pi} = -1$.

So a perfectly smooth spinor on the disc, written in the frame tangent to its boundary, is *antiperiodic* around the boundary. The Neveu–Schwarz structure is the one that "bounds"; the Ramond structure does not extend over a disc. (Bär's general statement: a spin structure on M induces one on every oriented hypersurface [Bär §2.6, (2.45)]; the frame of the hypersurface is completed by the normal ν, here e_r.)



polar frame turns by 2π
relative to (∂_x, ∂_y);
its lift $a(\theta)$ ends at -1:
boundary spinors antiperiodic

Figure T4.16: Why the boundary of a disc carries the antiperiodic spin structure. The grey Cartesian frame is global on the disc. The frame adapted to the boundary (green tangent e_θ, orange normal e_r) rotates once as we go around. Spinor components in the adapted frame pick up the half-angle phase $e^{\pm i\theta/2}$, which is -1 after one circuit.

Dictionary: spin structures on a circle in physics

- **String theory.** A closed-string worldsheet fermion on the spatial circle is either periodic (**Ramond**, R) or antiperiodic (**Neveu–Schwarz**, NS). R-sector fermions have zero modes (Example T4.44), which is why the Ramond ground state is a spinor of spacetime; the NS sector contains the graviton. Under the conformal map from the cylinder to the plane (radial quantisation, Chapter 11), the NS sector is the one that extends smoothly over the origin: Example T4.34.
- **Thermal field theory.** The partition function $\operatorname{Tr} e^{-\beta H}$ is a path integral over Euclidean time $\tau \in [0, \beta]$ with fermions *antiperiodic* in τ (the Matsubara frequencies $(2k+1)\pi/\beta$). Inserting $(-1)^F$ flips the boundary condition: $\operatorname{Tr}(-1)^F e^{-\beta H}$ has *periodic* fermions. This twisted trace is the Witten index, a first physical appearance of the index of a Dirac operator (Chapter 4).

T4.6.4 Tori and surfaces

Worked example T4.35: the four spin structures on T^2

Let $T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$ with the flat metric. The coordinate frame (∂_x, ∂_y) is global and orthonormal, so the frame bundle is trivial and all $g_{\alpha\beta} = \mathbf{1}$. Every choice of lifts is a choice of sign around each of the two independent loops ($x \to x + 2\pi$ and $y \to y + 2\pi$). A spinor field is a function on $\mathbb{R}^2$ with

$$\psi(x + 2\pi, y) = \varepsilon_1\, \psi(x, y), \qquad \psi(x, y + 2\pi) = \varepsilon_2\, \psi(x, y), \qquad \varepsilon_1, \varepsilon_2 \in \{\pm 1\}. \tag{T4.65}$$

The loop $x \to x + 2\pi$ followed by $y \to y + 2\pi$ is homotopic to the opposite order, and the signs commute, so there is no further condition. We get

$$(\varepsilon_1, \varepsilon_2) \in \{(+,+), (+,-), (-,+), (-,-)\}, \qquad |H^1(T^2; \mathbb{Z}_2)| = |\mathbb{Z}_2 \oplus \mathbb{Z}_2| = 4.$$

In string language: (R,R), (R,NS), (NS,R), (NS,NS). The three structures with at least one antiperiodic direction are called **even** and the fully periodic one **odd**; the modular group of the torus permutes the three even ones among themselves and fixes the odd one (the parity is the Arf invariant). Only the odd structure $(+,+)$ will have zero modes of the Dirac operator (Example T4.45).

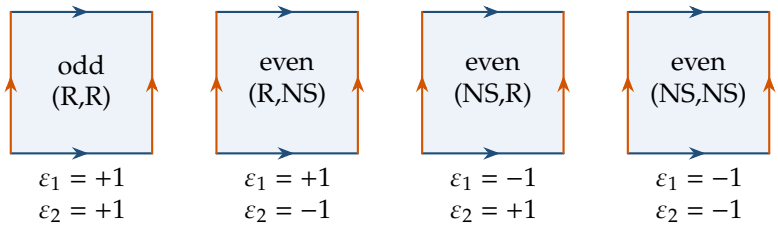


Figure T4.17: The four spin structures on the torus. Opposite edges of each square are glued. Crossing an orange edge (going once around in x) multiplies a spinor by ε_1; crossing a blue edge (going once around in y) multiplies it by ε_2. Only the fully periodic choice (far left) admits constant spinors.

The same reasoning gives 2^n spin structures on the flat n-torus T^n (one sign per circle), and more generally 2^{b_1} on any parallelisable manifold with $H^1(M; \mathbb{Z}_2) = \mathbb{Z}_2^{b_1}$ (for instance every Lie group, whose tangent bundle is trivialised by left-invariant vector fields). A closed oriented

surface of genus g has $H^1 = \mathbb{Z}_2^{2g}$, hence 2^{2g} spin structures; it always has at least one, because w_2 of a surface is the Euler characteristic mod 2, and $\chi = 2 - 2g$ is even. (This parity statement is exactly the computation we now do for the sphere.)

T4.6.5 The sphere S^2: one spin structure, found by a winding number

The sphere is simply connected, so $H^1(S^2;\mathbb{Z}_2) = 0$ and there is at most one spin structure. Does it exist? We compute.

Worked example T4.36: the clutching function of TS^2 and its lift

Cover $S^2 = \mathbb{C} \cup \{\infty\}$ by $U_0 = S^2 \setminus \{\infty\}$ with complex coordinate z and $U_\infty = S^2 \setminus \{0\}$ with $w = 1/z$. The round metric is $ds^2 = 4|dz|^2/(1+|z|^2)^2$, conformal to the flat one, so on U_0 the rescaled coordinate vectors $e_1^{(0)} \propto \partial_x$, $e_2^{(0)} \propto \partial_y$ are an oriented orthonormal frame; similarly on U_∞ using w. Identify a tangent vector at a point of U_0 with the complex number δz describing its direction. The frame vector $e_1^{(\infty)}$ points in the direction $\delta w = 1$. Since $\delta w = -\delta z/z^2$ (the derivative of $w = 1/z$), in the z-picture

$$\delta z\big|_{e_1^{(\infty)}} \overset{(1)}{=} -z^2\,\delta w \overset{(2)}{=} -z^2 \overset{(3)}{=} |z|^2 e^{i(\pi+2\phi)} \qquad (z = |z|e^{i\phi}).$$

(1) Invert $\delta w = -\delta z/z^2$.
(2) $e_1^{(\infty)}$ has δw real and positive; only the direction matters.
(3) $-1 = e^{i\pi}$ and $z^2 = |z|^2 e^{2i\phi}$.

So on the overlap the frame h_∞ is h_0 rotated by the angle $\pi + 2\phi$:

$$g_{0\infty}(z) = R(\pi + 2\phi), \qquad \phi = \arg z.$$

Going once around the equator ($\phi : 0 \to 2\pi$) the rotation angle increases by 4π: the **clutching function** has winding number 2. (This is the Euler number $\chi(S^2) = 2$: the frames h_0 and h_∞ each extend over one hemisphere, and their relative winding counts the zeros of a vector field.) Now lift. With two patches there are no triple overlaps, so a spin structure is just a continuous lift of $g_{0\infty}$ on the overlap $\mathbb{C}^\times$. Try

$$\hat{g}_{0\infty}(z) = a(\pi + 2\phi) = \exp\!\left(-\frac{\pi + 2\phi}{2}\,\gamma_1\gamma_2\right).$$

As $\phi \to \phi + 2\pi$ the argument of a increases by 4π, and $a(\theta + 4\pi) = a(\theta)$ by (T4.47). So $\hat{g}_{0\infty}$ is single valued: the lift exists and S^2 is spin, with a unique spin structure. In the representation $\gamma_j = \sigma_j$, $\hat{g}_{0\infty} = \mathrm{diag}(e^{-i(\pi+2\phi)/2}, e^{i(\pi+2\phi)/2}) = \mathrm{diag}(-i\,e^{-i\phi},\ i\,e^{i\phi})$, visibly single valued.

Key idea: the parity test on a sphere

For an oriented rank-2 bundle over S^2, glued by a clutching function of winding number d, the lift of the clutching function to Spin(2) closes up exactly when d is even: the lift of a rotation by total angle $2\pi d$ is $a(2\pi d) = (-1)^d$. The same holds for higher-rank bundles over S^2, with d the class of the clutching loop in $\pi_1(\mathrm{SO}(r)) = \mathbb{Z}_2$ ($r \geq 3$). So

$$\langle w_2(E), [S^2] \rangle = d \bmod 2.$$

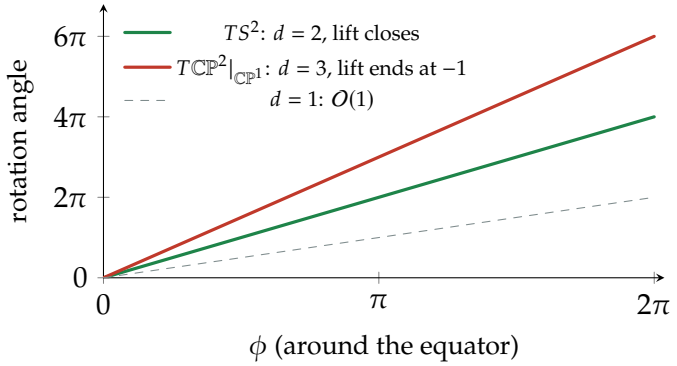

Figure T4.18: Clutching functions over a 2-sphere, drawn as the total rotation angle of the frame as we go once around the equator. A rotation by total angle $2\pi d$ lifts to $a(2\pi d) = (-1)^d$. For the tangent bundle of S^2 the angle grows by 4π ($d = 2$) and the lifted transition function is single valued. For $\mathbb{CP}^2$ restricted to a line the total is $d = 3$, odd, and no consistent sign exists.

T4.6.6 $\mathbb{CP}^2$: a manifold with no spin structure

Nash states that $\mathbb{CP}^n$ is spin exactly when n is odd [Nash p. 113]. The first failure is $\mathbb{CP}^2$, and the parity test shows why.

Worked example T4.37: $\mathbb{CP}^2$ is not spin

Inside $\mathbb{CP}^2$ sits the line $\mathbb{CP}^1 = \{[z_0 : z_1 : 0]\} \cong S^2$. Along it the tangent bundle of $\mathbb{CP}^2$ splits into directions along the line and directions normal to it:

$$T\mathbb{CP}^2\big|_{\mathbb{CP}^1} = T\mathbb{CP}^1 \oplus N = O(2) \oplus O(1).$$

Here $O(k)$ denotes the complex line bundle over S^2 whose clutching function winds k times. We found $T\mathbb{CP}^1 = TS^2$ has $k = 2$. The normal bundle of a line in $\mathbb{CP}^2$ has $k = 1$: in the chart $z_0 = 1$ the normal direction is the coordinate $u = z_2/z_0$, in the chart $z_1 = 1$ it is $u' = z_2/z_1$, and on the overlap $u = (z_1/z_0)\,u' = z\,u'$ with $z = z_1/z_0$: one winding. So the rank-4 real bundle $T\mathbb{CP}^2|_{\mathbb{CP}^1}$ is glued by

$$g(\phi) = \mathrm{diag}\big(R(2\phi + \mathrm{const}),\, R(\phi)\big) \in \mathrm{SO}(2) \times \mathrm{SO}(2) \subset \mathrm{SO}(4).$$

Its would-be lift is a product of lifts in the two commuting planes,

$$\hat{g}(\phi) \overset{(1)}{=} a_{12}(2\phi + c)\, a_{34}(\phi),$$
$$\hat{g}(\phi + 2\pi) \overset{(2)}{=} a_{12}(2\phi + c + 4\pi)\, a_{34}(\phi + 2\pi) \overset{(3)}{=} (+1)(-1)\, \hat{g}(\phi) = -\hat{g}(\phi),$$

(1) $a_{12}(\theta) = \exp(-\frac{\theta}{2}\gamma_1\gamma_2)$ and $a_{34}(\theta) = \exp(-\frac{\theta}{2}\gamma_3\gamma_4)$ commute and lift the two plane rotations; any other continuous lift differs by an overall sign.

(2) Go once around the equator.

(3) $a(\theta + 4\pi) = a(\theta)$ but $a(\theta + 2\pi) = -a(\theta)$ (T4.47).

No continuous single-valued lift exists, so $w_2(\mathbb{CP}^2)$ is nonzero on the line: $\mathbb{CP}^2$ has no spin structure. (Restricting a spin structure of $\mathbb{CP}^2$ to the line would produce such a lift.) For $\mathbb{CP}^n$ the same computation gives $T\mathbb{CP}^n|_{\mathbb{CP}^1} = O(2) \oplus O(1)^{\oplus(n-1)}$, total winding $n + 1$: spin iff n is odd, in agreement with Nash. In characteristic-class language, w_2 of a complex manifold is c_1 mod 2, and $c_1(\mathbb{CP}^n) = (n + 1)h$.

Physical picture: what goes wrong physically, and the way out

On $\mathbb{CP}^2$ one cannot write the Dirac equation for an uncharged fermion. But the obstruction is "half a unit of monopole flux" through the line: the sign -1 that spoils the lift is the same sign a charged particle picks up going around half a Dirac string. So if the fermion carries charge under a U(1) gauge field whose flux through the line is *half-integral*, the two signs cancel and the combined object is well defined. This is a **spin^c structure**; every complex manifold (indeed every oriented 4-manifold) has one, and it is how Seiberg–Witten theory and the Dolbeault operator (Section T4.9) handle $\mathbb{CP}^2$.

Watch out: a useful test in four dimensions

For a closed oriented 4-manifold, $w_2(M)$ evaluated on a surface Σ equals the self-intersection $\Sigma \cdot \Sigma \bmod 2$ (the Wu formula). So a spin 4-manifold has an *even* intersection form. $\mathbb{CP}^2$ has intersection form (1) (the line meets a displaced copy once), so it is not spin. S^4, $S^2 \times S^2$ (form $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$) and the K3 surface are spin. We use this in the instanton and index chapters.

T4.6.7 The spinor bundle and Clifford multiplication

With a spin structure in hand, spinor fields are defined by (T4.61): a spinor field is a collection $\psi_\alpha : U_\alpha \to \mathbb{C}^N$ with $\psi_\alpha = \hat{g}_{\alpha\beta}\psi_\beta$. The bundle they are sections of is the **spinor bundle** $S = P_{\mathrm{Spin}}(M) \times_\sigma \mathbb{C}^N$ [Bär Def. 2.4.7]; Nash calls it E [Nash (4.98)]. Three structures carry over from a single fibre to the whole bundle, each for a one-line reason.

Hermitian metric. Define $\langle \psi, \chi \rangle := \psi_\alpha^\dagger \chi_\alpha$ in any patch. It does not depend on the patch because $\hat{g}_{\alpha\beta}$ is unitary (Section T4.5.3, fact 1): $\psi_\alpha^\dagger \chi_\alpha = \psi_\beta^\dagger \hat{g}_{\alpha\beta}^\dagger \hat{g}_{\alpha\beta} \chi_\beta = \psi_\beta^\dagger \chi_\beta$.

Clifford multiplication. A tangent vector v acts on spinors by $v \cdot \psi := \not{v}_\alpha \psi_\alpha = v_\alpha^a \gamma_a \psi_\alpha$ in the patch U_α [Bär Def. 2.4.9]. This is patch independent:

$$\not{v}_\alpha \, \psi_\alpha \overset{(1)}{=} \gamma(g_{\alpha\beta} v_\beta)\, \hat{g}_{\alpha\beta} \psi_\beta \overset{(2)}{=} \hat{g}_{\alpha\beta}\, \gamma(v_\beta)\, \hat{g}_{\alpha\beta}^{-1}\, \hat{g}_{\alpha\beta} \psi_\beta \overset{(3)}{=} \hat{g}_{\alpha\beta} \big(\not{v}_\beta \psi_\beta \big),$$

(1) Vector components glue with g, spinor components with $\hat{g}$; write $\gamma(v) := v^a \gamma_a$.
(2) $\rho(\hat{g})v = \hat{g}\, \gamma(v)\, \hat{g}^{-1}$ is the definition of ρ (T4.48).
(3) Cancel $\hat{g}^{-1}\hat{g}$.

so $v \cdot \psi$ glues like a spinor. The Clifford relation $v \cdot w \cdot \psi + w \cdot v \cdot \psi = 2\langle v, w \rangle \psi$ holds pointwise because it holds for the γ's, and $v\cdot$ is Hermitian (Bär's skew-symmetry, with his $v = -i\gamma(v)$).

Chirality. In even dimension $n = 2k$, $\hat{g}_{\alpha\beta}$ is even, so it commutes with the chirality matrix Γ (T4.36). Hence the eigenspaces of Γ are glued separately and $S = S^+ \oplus S^-$, with rank $S^\pm = 2^{k-1}$: Nash's (4.97)–(4.98). Clifford multiplication by a vector anticommutes with Γ and so swaps $S^+ \leftrightarrow S^-$.

Worked example T4.38: the spinor bundle of S^2 in the two charts

With $\hat{g}_{0\infty} = \mathrm{diag}(-ie^{-i\phi},\ ie^{i\phi})$ from Example T4.36, the positive-chirality component (upper entry, $\Gamma = \sigma_3$) is glued by $\psi_0^+ = -ie^{-i\phi}\psi_\infty^+$ and the negative one by $\psi_0^- = ie^{i\phi}\psi_\infty^-$. Each is a complex line bundle over S^2 with clutching winding ∓ 1. Compare TS^2, a complex line bundle with winding $+2$ (Example T4.36): the spinor bundles are its "square roots" $S^\pm \cong (TS^2)^{\mp 1/2}$, in holomorphic language $S^+ \cong \mathcal{O}(-1)$ and $S^- \cong \mathcal{O}(1)$ (up to the orientation

convention). This is the concrete meaning of "spinors are square roots of vectors", and it only makes sense because the winding 2 is even.

Reading Nash (p. 113, (4.96)–(4.98))

Nash compresses this section into one paragraph: a spin structure is a lift of the structure group from $\mathrm{SO}(n)$ to $\mathrm{Spin}(n)$; it exists iff $w_1(X) = 0$ (orientability) and $w_2(X) = 0$ ("spinors are globally defined"), (4.96); spin structures are parametrised by $H^1(X;\mathbb{Z}_2)$ (read: form a torsor over it); simply connected manifolds have at most one; and $\mathbb{CP}^n$ is spin iff n is odd. His (4.98), $E^\pm = \tilde{P} \times_{\mathrm{Spin}(n)} S^\pm$, is our spinor bundle glued by $\hat{g}_{\alpha\beta}$ acting on the two chiral halves. We have made each claim concrete: (T4.62) is the w_2 cocycle, Example T4.33 and Example T4.35 are the H^1 counts, Example T4.36 and Example T4.37 are the parity test.

Recap

- Frame transition functions $g_{\alpha\beta} \in \mathrm{SO}(n)$ glue vectors and tensors. Spinors need lifts $\hat{g}_{\alpha\beta} \in \mathrm{Spin}(n)$ satisfying the cocycle condition; the obstruction is the sign pattern $\varepsilon_{\alpha\beta\gamma}$, whose class is $w_2(M)$.
- When spin structures exist, they are counted by $H^1(M;\mathbb{Z}_2)$: a free choice of sign around each independent loop. S^1: two (R and NS); T^2: four; genus g: 2^{2g}; S^n ($n \geq 2$): one.
- Over a 2-sphere the test is the parity of a winding number: TS^2 winds twice (spin), $T\mathbb{CP}^2|_{\mathbb{CP}^1}$ three times (not spin). $\mathbb{CP}^n$ is spin iff n is odd.
- The circle bounding a disc inherits the antiperiodic (NS) structure.
- The spinor bundle carries a Hermitian metric, Clifford multiplication by vectors, and (in even dimensions) a chiral splitting $S = S^+ \oplus S^-$.

T4.7 The spin connection and the Dirac operator

We now have spinor fields on a spin manifold: local functions ψ_α glued by the lifted transition functions $\hat{g}_{\alpha\beta}$. To write a wave equation for them we must *differentiate* them. On $\mathbb{R}^n$ we would write $-i\gamma^a\partial_a\psi$. On a curved manifold $\partial_a\psi_\alpha$ is not a spinor: the gluing matrices $\hat{g}_{\alpha\beta}$ depend on the point, so $\partial(\hat{g}\psi) \neq \hat{g}\,\partial\psi$. This is the same problem as for vectors, where the cure is the Levi-Civita connection, and the same problem as for charged fields, where the cure is a gauge field. For spinors the cure is a connection built out of the Levi-Civita one, and the recipe is fixed completely by the spin generators $\frac{1}{4}\gamma_a\gamma_b$ of Section T4.5.5.

The questions of this section are:

- How do we differentiate a spinor field? (Answer: the **spin connection** $\nabla = \mathrm{d} + \frac{1}{4}\omega_{ab}\gamma^a\gamma^b$.)
- What is the Dirac operator on a curved manifold, and what are its properties? (Answer: $D = -i\gamma^a\nabla_a$; it is self-adjoint and swaps chiralities.)
- What does its spectrum look like? We compute it by hand on $\mathbb{R}^n$, S^1, T^2 and S^2, and watch the spin structure decide whether there are zero modes.

T4.7.1 Reminder: the Levi-Civita connection in an orthonormal frame

Everything in this section is done in a local oriented orthonormal frame $e_1, \dots, e_n$ with dual coframe $e^1, \dots, e^n$ (so $e^a(e_b) = \delta^a_b$ and the metric is $g = \sum_a e^a \otimes e^a$). The Levi-Civita connection is encoded in the matrix of **connection 1-forms** $\omega^a{}_b$, defined by how the frame vectors turn as we move:

$$\nabla_X e_b = e_a\, \omega^a{}_b(X), \qquad \omega_{ab} \coloneqq \omega^a{}_b = -\omega_{ba}. \tag{T4.66}$$

Indices are raised and lowered with δ_{ab}, so the position of frame indices does not matter. Antisymmetry is metric compatibility: differentiating $\langle e_a, e_b\rangle = \delta_{ab}$ gives $0 = \langle \nabla e_a, e_b\rangle + \langle e_a, \nabla e_b\rangle = \omega_{ba} + \omega_{ab}$. So ω is an $\mathfrak{so}(n)$-valued 1-form, an infinitesimal rotation per unit displacement. The fastest way to compute it is **Cartan's first structure equation** (torsion-freeness written in the frame; see Chapter T2):

$$\mathrm{d}e^a + \omega^a{}_b \wedge e^b = 0. \tag{T4.67}$$

Its curvature is the matrix of 2-forms

$$R^a{}_b = \mathrm{d}\omega^a{}_b + \omega^a{}_c \wedge \omega^c{}_b, \qquad R_{ab} = \tfrac{1}{2} R_{abcd}\, e^c \wedge e^d, \qquad R(X,Y)e_b = e_a\, R^a{}_b(X,Y), \tag{T4.68}$$

so that $R_{abcd} = \langle R(e_c, e_d)e_b, e_a\rangle$. With this convention the sectional curvature of the plane $e_a \wedge e_b$ is R_{abab} (no sum), the Ricci tensor is $\mathrm{Ric}_{bd} = \sum_a R_{abad}$ and the scalar curvature is $R = \sum_{a,b} R_{abab}$. The unit sphere has $R_{abab} = 1$ for $a \neq b$ and $R = n(n-1)$.

In coordinates, with vielbein components $e_b = e_b{}^\nu \partial_\nu$, the connection forms are $\omega^a{}_{b\mu} = e^a{}_\nu \big(\partial_\mu e_b{}^\nu + \Gamma^\nu_{\mu\lambda} e_b{}^\lambda\big)$, which is just (T4.66) with $X = \partial_\mu$. Bär writes $\nabla_{b_i} b_j = \sum_k \Gamma^k_{ij} b_k$ for the same thing, so his "Christoffel symbols of the frame" are $\Gamma^k_{ij} = \omega_{kj}(b_i)$ [Bär (2.19)].

Worked example T4.39: the round sphere S^2: frame, connection and curvature

Use polar coordinates, $g = \mathrm{d}\theta^2 + \sin^2\theta\, \mathrm{d}\phi^2$, and the frame

$$e_1 = \partial_\theta, \qquad e_2 = \frac{1}{\sin\theta}\,\partial_\phi, \qquad e^1 = \mathrm{d}\theta, \qquad e^2 = \sin\theta\, \mathrm{d}\phi.$$

It is oriented ($e^1 \wedge e^2 = \sin\theta\, \mathrm{d}\theta \wedge \mathrm{d}\phi$ is the area form) and orthonormal, but singular at the two poles, where ∂_ϕ vanishes. Apply (T4.67):

$$\mathrm{d}e^2 \overset{(1)}{=} \cos\theta\, \mathrm{d}\theta \wedge \mathrm{d}\phi \overset{(2)}{=} -\omega^2{}_1 \wedge e^1 = \mathrm{d}\theta \wedge \omega^2{}_1 \quad \Longrightarrow \quad \omega^2{}_1 = \cos\theta\, \mathrm{d}\phi,$$
$$\mathrm{d}e^1 \overset{(3)}{=} 0 \overset{(4)}{=} -\omega^1{}_2 \wedge e^2 = \cos\theta\, \mathrm{d}\phi \wedge \sin\theta\, \mathrm{d}\phi = 0.$$

(1) Differentiate $\sin\theta\, \mathrm{d}\phi$.
(2) Cartan's equation for $a = 2$; $\omega^2{}_2 = 0$ by antisymmetry, and $\alpha \wedge \beta = -\beta \wedge \alpha$ for 1-forms.
(3) $e^1 = \mathrm{d}\theta$ is exact.
(4) Consistency check of the $a = 1$ equation with $\omega^1{}_2 = -\cos\theta\, \mathrm{d}\phi$: $\mathrm{d}\phi \wedge \mathrm{d}\phi = 0$.

So $\omega_{12} = -\cos\theta\, \mathrm{d}\phi$. The curvature:

$$R_{12} = \mathrm{d}\omega_{12} + \underbrace{\omega_{1c} \wedge \omega_{c2}}_{=0\ (c\in\{1,2\})} = \sin\theta\, \mathrm{d}\theta \wedge \mathrm{d}\phi = e^1 \wedge e^2,$$

so $R_{1212} = 1$: Gauss curvature 1, scalar curvature $R = R_{1212} + R_{2121} = 2$. (The quadratic term vanishes because $\omega_{11} = \omega_{22} = 0$.)

T4.7.2 The spin connection

Working definition T4.9 (spin connection)

In a local orthonormal frame [vector fields $e_1, \dots, e_n$ on a patch U with $g(e_a, e_b) = \delta_{ab}$], with spinor components $\psi : U \to \mathbb{C}^N$ and constant gamma matrices γ_a, the **spin connection** is

$$\nabla\psi := \mathrm{d}\psi + \Omega\,\psi, \qquad \Omega := \frac{1}{4}\,\omega_{ab}\,\gamma^a\gamma^b = \frac{1}{2}\sum_{a<b}\omega_{ab}\,\gamma^a\gamma^b, \tag{T4.69}$$

where ω_{ab} are the connection 1-forms of the frame [fixed by $\mathrm{d}e^a = -\omega^a{}_b \wedge e^b$ and $\omega_{ab} = -\omega_{ba}$], i.e. $\nabla_X\psi = \partial_X\psi + \frac{1}{4}\omega_{ab}(X)\gamma^a\gamma^b\psi$. In coordinates, $\nabla_\mu\psi = \partial_\mu\psi + \frac{1}{4}\omega_{ab\mu}\gamma^a\gamma^b\psi$. *Recipe:* (1) choose a frame; (2) find ω_{ab} from (T4.67); (3) replace each infinitesimal rotation ω_{ab} by its spin generator: $\Omega = \rho_*^{-1}(\omega)$ from (T4.55). Bär's formula [Bär (2.21)] is identical after $e_a \to -i\gamma_a$.

Where does the $\frac{1}{4}$ come from? There are three ways to see that (T4.69) is forced, and each teaches something.

1. The Leibniz rule for Clifford multiplication. We want the spin connection to be compatible with everything we already have, and in particular with Clifford multiplication by vectors: for a vector field $Y = Y^c e_c$ we demand

$$\nabla_X\big(\gamma(Y)\psi\big) = \gamma(\nabla_X Y)\,\psi + \gamma(Y)\,\nabla_X\psi, \qquad \gamma(Y) := Y^c\gamma_c. \tag{T4.70}$$

Try $\nabla = \mathrm{d} + \Omega$ with an unknown matrix-valued 1-form Ω. Then

$$\begin{aligned}\nabla\big(\gamma(Y)\psi\big) - \gamma(\nabla Y)\psi - \gamma(Y)\nabla\psi &\overset{(1)}{=} (\mathrm{d}Y^c)\gamma_c\psi + Y^c\gamma_c\,\mathrm{d}\psi + \Omega\,Y^c\gamma_c\psi \\ &\quad - (\mathrm{d}Y^a + \omega_{ac}Y^c)\gamma_a\psi - Y^c\gamma_c(\mathrm{d}\psi + \Omega\psi) \\ &\overset{(2)}{=} Y^c\big([\Omega, \gamma_c] - \omega_{ac}\gamma_a\big)\psi.\end{aligned}$$

(1) The γ_c are constant matrices in our trivialisation; the covariant derivative of Y is $\nabla Y = e_a(\mathrm{d}Y^a + \omega_{ac}Y^c)$ by (T4.66).

(2) The $\mathrm{d}Y$ and $\mathrm{d}\psi$ terms cancel; what is left is a commutator.

So (T4.70) holds iff $[\Omega, \gamma_c] = \omega_{ac}\gamma_a$ for every c: *conjugation by Ω must rotate the gammas by the infinitesimal rotation ω.* That is precisely the property (T4.54) of $\frac{1}{4}A_{ab}\gamma_a\gamma_b$, with $A = \omega$ and $x = e_c$:

$$\Big[\tfrac{1}{4}\omega_{ab}\gamma_a\gamma_b,\ \gamma_c\Big] \overset{(1)}{=} (\omega\,e_c)^a\gamma_a \overset{(2)}{=} \omega_{ac}\gamma_a.$$

(1) (T4.54), which holds for any antisymmetric A, here the (form-valued) matrix ω.

(2) The a-th component of the column c of the matrix ω.

Is the answer unique? If Ω' also works, then $\Omega' - \Omega$ commutes with every γ_c, hence with the whole Clifford algebra, and so is a multiple of $\mathbf{1}$ (in even dimensions the γ's generate all matrices). The spin connection is therefore unique *up to adding a* U(1) *gauge field* $A\,\mathbf{1}$. Keeping that freedom is exactly what "twisting by a line bundle" means (Section T4.8.4); forbidding it gives (T4.69).

2. The half-angle. In two dimensions, $\Omega = \frac{1}{2}\omega_{12}\gamma^1\gamma^2$. If the frame turns by an angle $\vartheta(x)$ relative to a fixed one, then $\omega_{12} = -\mathrm{d}\vartheta$ (see the next example), and $\Omega = -\frac{1}{2}\mathrm{d}\vartheta\,\gamma_1\gamma_2 = a^{-1}\mathrm{d}a$ with $a = \exp(-\frac{\vartheta}{2}\gamma_1\gamma_2)$ the lift (T4.46). One factor $\frac{1}{2}$ counts ω_{12} and ω_{21} once; the other is the *half-angle* of the spinor lift. Spinors turn at half the rate of the frame.

3. Gluing. On an overlap, frames are related by $h' = h\,g$ with $g : U \cap U' \to \mathrm{SO}(n)$, the connection matrix transforms like a gauge field, $\omega' = g^{-1}\omega g + g^{-1}\mathrm{d}g$ (Chapter T3), and spinor components are related by $\psi = \hat{g}\,\psi'$ with $\rho(\hat{g}) = g$. For $\nabla\psi$ to glue like a spinor we need

$$\nabla\psi = \mathrm{d}(\hat{g}\psi') + \Omega\,\hat{g}\psi' \overset{(1)}{=} \hat{g}\big(\mathrm{d}\psi' + (\hat{g}^{-1}\mathrm{d}\hat{g} + \hat{g}^{-1}\Omega\hat{g})\psi'\big) \overset{(2)}{=} \hat{g}\,(\mathrm{d} + \Omega')\psi',$$

(1) Leibniz rule for $\mathrm{d}(\hat{g}\psi')$ and factor out $\hat{g}$.
(2) This is the requirement: the bracket must be the spin connection $\Omega' = \rho_*^{-1}(\omega')$ built from the primed frame.

It holds because ρ_*^{-1} converts each piece correctly: $\rho_*^{-1}(g^{-1}\omega g) = \hat{g}^{-1}\rho_*^{-1}(\omega)\hat{g}$ (conjugating a rotation generator by g corresponds to conjugating its spin generator by the lift $\hat{g}$, by the definition $\rho(\hat{g})x = \hat{g}x\hat{g}^{-1}$), and $\rho_*^{-1}(g^{-1}\mathrm{d}g) = \hat{g}^{-1}\mathrm{d}\hat{g}$ (differentiate $\rho(\hat{g}) = g$). Note that only the *lift* $\hat{g}$ enters: this is where the spin structure is used. Nash's one line "ω denotes the Riemannian spin connection on X" [Nash p. 114] hides all of this.

Worked example T4.40: flat space in polar coordinates: the spin connection is pure gauge

On $\mathbb{R}^2$ take the polar frame $e_1 = \partial_r$, $e_2 = \frac{1}{r}\partial_\phi$, $e^1 = \mathrm{d}r$, $e^2 = r\,\mathrm{d}\phi$. Then

$$\mathrm{d}e^2 \overset{(1)}{=} \mathrm{d}r \wedge \mathrm{d}\phi \overset{(2)}{=} \mathrm{d}r \wedge \omega^2{}_1 \implies \omega_{21} = \mathrm{d}\phi,\ \ \omega_{12} = -\mathrm{d}\phi,$$
$$\Omega \overset{(3)}{=} \tfrac{1}{2}\omega_{12}\gamma_1\gamma_2 \overset{(4)}{=} -\tfrac{i}{2}\,\sigma_3\,\mathrm{d}\phi \overset{(5)}{=} a(\phi)^{-1}\mathrm{d}a(\phi), \qquad a(\phi) = \mathrm{diag}(e^{-i\phi/2}, e^{i\phi/2}).$$

(1) Differentiate $r\,\mathrm{d}\phi$.
(2) Cartan's equation, as in Example T4.39.
(3) (T4.69); the two terms $ab = 12, 21$ are equal.
(4) $\gamma_1\gamma_2 = \sigma_1\sigma_2 = i\sigma_3$ in the representation $\gamma_j = \sigma_j$.
(5) $a^{-1}\mathrm{d}a = \mathrm{diag}(-\frac{i}{2}, \frac{i}{2})\mathrm{d}\phi$; $a(\phi)$ is the lift (T4.50) of the rotation $R(\phi)$ relating the polar frame to the Cartesian one.

The curvature $\mathrm{d}\Omega + \Omega \wedge \Omega = 0$, as it must be in flat space, but Ω is not zero: it is the Maurer–Cartan form of the frame rotation. Its holonomy around the origin is $\exp(-\oint \Omega) = a(2\pi)^{-1}a(0) = -\mathbf{1}$. This is the antiperiodicity of polar-frame spinors from Example T4.34 seen by the connection: a covariantly constant spinor, written in the rotating frame, comes back with a minus sign.

Three properties. The spin connection inherits three properties, each in one line.

1. *Leibniz rule for Clifford multiplication*, (T4.70) [Bär (2.23)]: shown above.

2. *Metric compatibility* [Bär (2.22)]. For $a \neq b$, $(\gamma_a\gamma_b)^\dagger = \gamma_b\gamma_a = -\gamma_a\gamma_b$, so Ω is anti-Hermitian, and

$$\mathrm{d}(\psi^\dagger\chi) \overset{(1)}{=} (\mathrm{d}\psi)^\dagger\chi + \psi^\dagger\mathrm{d}\chi \overset{(2)}{=} (\mathrm{d}\psi + \Omega\psi)^\dagger\chi + \psi^\dagger(\mathrm{d}\chi + \Omega\chi) = \langle\nabla\psi, \chi\rangle + \langle\psi, \nabla\chi\rangle.$$

   (1) Product rule.
   (2) Add $(\Omega\psi)^\dagger\chi + \psi^\dagger\Omega\chi = \psi^\dagger(\Omega^\dagger + \Omega)\chi = 0$.

3. *Chirality is preserved* [Bär Rem. 2.4.11]. In even dimension Ω is a sum of products of *two* gammas, which commute with Γ. So ∇ maps S^+-valued fields to S^+-valued forms, and likewise for S^-.

Curvature of the spin connection. Since $\Omega = \rho_*^{-1}(\omega)$ and ρ_*^{-1} is a Lie algebra homomorphism (it preserves commutators, as we checked for the Σ_{ab} in Section T4.5.5), the curvature of ∇ is the image of the Riemann curvature:

$$\begin{aligned} R^S := \mathrm{d}\Omega + \Omega\wedge\Omega &\overset{(1)}{=} \rho_*^{-1}(\mathrm{d}\omega) + \tfrac{1}{2}[\Omega\wedge\Omega] \overset{(2)}{=} \rho_*^{-1}(\mathrm{d}\omega) + \rho_*^{-1}\big(\tfrac{1}{2}[\omega\wedge\omega]\big) \\ &\overset{(3)}{=} \rho_*^{-1}(\mathrm{d}\omega + \omega\wedge\omega) \overset{(4)}{=} \frac{1}{4}R_{ab}\,\gamma^a\gamma^b = \frac{1}{8}R_{abcd}\,\gamma^a\gamma^b\,e^c\wedge e^d. \end{aligned} \tag{T4.71}$$

(1) ρ_*^{-1} is linear and x-independent, so it commutes with d. For a matrix-valued 1-form, $\Omega\wedge\Omega = \frac{1}{2}[\Omega\wedge\Omega]$, where $[\alpha\wedge\beta] := \alpha\wedge\beta + \beta\wedge\alpha$ is the graded commutator (write $\Omega = \Omega_\mu \mathrm{d}x^\mu$: $\Omega\wedge\Omega = \frac{1}{2}[\Omega_\mu,\Omega_\nu]\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu$).
(2) ρ_*^{-1} preserves commutators.
(3) Undo step 1 for ω.
(4) Definition (T4.68) of the curvature matrix, and $\rho_*^{-1}(A) = \frac{1}{4}A_{ab}\gamma^a\gamma^b$ once more.

Evaluated on two vectors, $R^S(e_c,e_d) = \frac{1}{4}R_{abcd}\gamma^a\gamma^b$; this is Bär's (2.24),

$$R^\Sigma(X,Y)\phi = -\tfrac{1}{4}\textstyle\sum_i (R(X,Y)b_i)\cdot b_i\cdot\phi,$$

after the translation $b\to -i\gamma$.

Worked example T4.41: spin connection and spinor curvature on S^2

From Example T4.39, $\omega_{12} = -\cos\theta\,\mathrm{d}\phi$ and $R_{12} = e^1\wedge e^2$. With $\gamma_1=\sigma_1$, $\gamma_2=\sigma_2$, $\gamma_1\gamma_2 = i\sigma_3$:

$$\begin{aligned} \Omega &\overset{(1)}{=} \tfrac{1}{2}\omega_{12}\gamma_1\gamma_2 = -\tfrac{i}{2}\cos\theta\,\sigma_3\,\mathrm{d}\phi, \\ R^S &\overset{(2)}{=} \tfrac{1}{2}R_{12}\gamma_1\gamma_2 = \tfrac{i}{2}\,\sigma_3\,e^1\wedge e^2 = \begin{pmatrix} \frac{i}{2} & 0 \\ 0 & -\frac{i}{2}\end{pmatrix}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi. \end{aligned}$$

(1) (T4.69) in two dimensions.
(2) (T4.71); check directly: $\mathrm{d}\Omega = \frac{i}{2}\sin\theta\,\sigma_3\,\mathrm{d}\theta\wedge\mathrm{d}\phi$ and $\Omega\wedge\Omega = 0$ because Ω is a multiple of the single form $\mathrm{d}\phi$.

The chirality $\Gamma = \sigma_3$ is diagonal, so S^+ and S^- are two complex line bundles, each carrying a U(1) connection with curvature $F^\pm = \pm\frac{i}{2}\,\mathrm{vol}$. Their first Chern numbers are

$$c_1(S^\pm) \overset{(1)}{=} \frac{i}{2\pi}\int_{S^2} F^\pm \overset{(2)}{=} \frac{i}{2\pi}\Big(\pm\frac{i}{2}\Big)4\pi = \mp 1.$$

(1) The house convention $c_1 = \frac{i}{2\pi}\operatorname{tr}F$ (Chapter T3).
(2) The area of the unit sphere is 4π.

This agrees with the clutching computation of Example T4.38 (windings ∓1). So *on S^2 the chiral spinors are monopoles of charge $\mp\frac{1}{2}$ relative to the tangent bundle, which has $c_1 = \chi(S^2) = 2$.* We will see the charge again in the spectrum.

T4.7.3 The Dirac operator on a spin manifold

Working definition T4.10 (Dirac operator)

On a Riemannian spin manifold [one on which a spin structure has been chosen, so that spinor fields are defined], in a local orthonormal frame [$e_a = e_a{}^\mu \partial_\mu$ with $g(e_a, e_b) = \delta_{ab}$],

$$D\psi := -i\gamma^a \nabla_{e_a}\psi = -i\gamma^a e_a{}^\mu \Big(\partial_\mu + \frac{1}{4}\omega_{bc\mu}\gamma^b\gamma^c\Big)\psi. \tag{T4.72}$$

Recipe: compute Ω, then contract the covariant derivative with the gammas. The result does not depend on the frame: under $h' = hg$ both γ^a and ∇_{e_a} rotate, and $\gamma^a\nabla_{e_a}$ is a contraction. (In Clifford-module language, D is "Clifford multiplication composed with the connection", $D = -i\,c \circ \nabla$, Bär's (2.25) with $c(e_a) = -i\gamma_a$.)

Reading Nash (p. 114, (4.99)–(4.101))

Nash writes $\not{D} = \gamma^a e_a^\mu(x)(\partial_\mu + \omega_\mu)$ with anti-Hermitian gammas $\{\gamma_a, \gamma_b\} = -2\delta_{ab}$ and the vielbein relation $e_a^\mu e_b^\nu\, g_{\mu\nu} = \delta_{ab}$ written in (4.100) with the indices placed the other way. His ω_μ is our $\Omega_\mu = \frac{1}{4}\omega_{ab\mu}\gamma^a\gamma^b$ (the product of two of his gammas is minus the product of two of ours, and his ω_{ab} is our $-\omega_{ab}$ or ours depending on the index order; only the combination Ω_μ matters). His $\gamma_5 = i^{n(n+1)/2}\gamma_1\cdots\gamma_n$ is our Γ up to the change $\gamma^{\text{Nash}} = i\gamma$: in $n = 4$, $i^{10}(i)^4\gamma_1\gamma_2\gamma_3\gamma_4 = -\gamma_1\gamma_2\gamma_3\gamma_4 = \Gamma$. Since $\gamma_a^{\text{Nash}} = i\gamma_a$, his $\not{D}$ is $i\gamma^a\nabla_a = -D$. Nothing depends on the overall sign.

The symbol, and ellipticity. Replacing ∂_μ by $i\xi_\mu$ in the top-order part:

$$\sigma_D(x,\xi) = -i\gamma^a e_a{}^\mu(i\xi_\mu) = \gamma^a\xi_a = \not{\xi}, \qquad \not{\xi}^2 = |\xi|^2\,\mathbf{1}.$$

So D is of Dirac type (Section T4.1.3); the connection term is zeroth order and does not appear. The symbol is invertible for every $\xi \neq 0$, with $\not{\xi}^{-1} = \not{\xi}/|\xi|^2$: D is **elliptic**. Nash makes the same point [Nash p. 115]: the symbol of the chiral operator is $i\gamma^a e_a^\mu p_\mu$ with inverse $-i\gamma^a e_a^\mu p_\mu/p^2$, and this needs Euclidean signature: in Lorentzian signature $\not{p}^2 = p^2$ vanishes on the light cone and the Dirac operator is *not* elliptic (it is hyperbolic, which is why it propagates waves instead of having a discrete spectrum).

Formal self-adjointness. On a closed manifold (compact, no boundary)

$$(D\psi, \chi) := \int_M \langle D\psi, \chi\rangle \,\mathrm{vol} = (\psi, D\chi)$$

[Bär Lemma 2.5.5]. The proof is Stokes' theorem applied to a current. Define the complex vector field V by $V(Y) := \psi^\dagger\gamma(Y)\chi$ for all vectors Y, i.e. $V = V^a e_a$ with $V^a = \psi^\dagger\gamma^a\chi$. (In Minkowski physics this is the current $\bar\psi\gamma^\mu\chi$.) Compute its divergence in a frame with $(\nabla e_a)(x) = 0$ at the point x under consideration (such a **synchronous frame** always exists: parallel transport a frame out radially from x):

$$\begin{aligned}\operatorname{div} V &\overset{(1)}{=} \sum_a e_a\big(V^a\big) \overset{(2)}{=} \sum_a \Big[(\nabla_a\psi)^\dagger\gamma^a\chi + \psi^\dagger\gamma^a\nabla_a\chi\Big] \\ &\overset{(3)}{=} \big(i\,D\psi\big)^\dagger\chi + \psi^\dagger\big(i\,D\chi\big) \overset{(4)}{=} -i\big(\langle D\psi,\chi\rangle - \langle\psi, D\chi\rangle\big).\end{aligned} \tag{T4.73}$$

(1) $\operatorname{div} V = \sum_a \langle \nabla_{e_a} V, e_a\rangle = \sum_a \big[e_a(V^a) - \langle V, \nabla_{e_a} e_a\rangle\big]$, and the last term vanishes at x.

(2) Metric compatibility of ∇ and the Leibniz rule (T4.70); the extra term $\gamma(\nabla_{e_a} e_a)$ vanishes at x.
(3) $\gamma^a \nabla_a \psi = iD\psi$ by definition (T4.72), and $(\nabla_a \psi)^\dagger \gamma^a = (\gamma^a \nabla_a \psi)^\dagger$ since γ^a is Hermitian.
(4) $(iD\psi)^\dagger = -i(D\psi)^\dagger$.

Both sides of (T4.73) are frame independent, so it holds everywhere. Integrating over a closed M and using $\int_M \operatorname{div} V \operatorname{vol} = 0$ (the divergence theorem, i.e. Stokes for the $(n-1)$-form $\iota_V \operatorname{vol}$ on a manifold with empty boundary) gives $(D\psi, \chi) = (\psi, D\chi)$. On a manifold with boundary the same computation leaves a flux,

$$(D\psi, \chi) - (\psi, D\chi) = i \int_{\partial M} \psi^\dagger \, \gamma(\nu) \, \chi \, \mathrm{d}A, \tag{T4.74}$$

with ν the outward unit normal (Bär's (2.27) in his conventions). The boundary term is the flux of the fermion-number current through the boundary; choosing boundary conditions that kill it is the subject of the Atiyah–Patodi–Singer problem in Chapter 4.

Key idea: the Dirac operator and chirality

In even dimension $n = 2k$, γ^a anticommutes with Γ and ∇ commutes with it, so $D\Gamma = -\Gamma D$. In the basis $S = S^+ \oplus S^-$ in which $\Gamma = \operatorname{diag}(\mathbf{1}, -\mathbf{1})$,

$$D = \begin{pmatrix} 0 & D^- \\ D^+ & 0 \end{pmatrix}, \qquad D^\pm : \Gamma(S^\pm) \to \Gamma(S^\mp), \qquad D^- = (D^+)^*. \tag{T4.75}$$

The last statement is self-adjointness of D written in blocks [Bär Rem. 2.5.3]. Nash's chiral operator $\not{D}(1+\gamma_5)/2$ is D^+ [Nash (4.102)]. Its **index** $\dim \operatorname{Ker} D^+ - \dim \operatorname{Ker} D^-$ is the topic of Section T4.8.5.

Watch out: chirality is not a symmetry of D

Because D *anticommutes* with Γ, an eigenspinor of D with $\lambda \neq 0$ never has definite chirality: if $D\psi = \lambda\psi$ then $D(\Gamma\psi) = -\lambda\,\Gamma\psi$. Only zero modes can be chosen chiral. In Minkowski language: the massless Dirac equation preserves chirality, but a mass term (a nonzero eigenvalue in the Euclidean problem) mixes the two.

T4.7.4 Flat space: plane waves and holomorphic functions

Worked example T4.42: the Dirac operator on $\mathbb{R}^n$

With the Cartesian frame $\omega = 0$, so $D = -i\gamma^a \partial_a$. Try a plane wave $\psi = u\, e^{ik\cdot x}$ with a constant spinor u:

$$D\psi \overset{(1)}{=} -i\gamma^a (ik_a) u\, e^{ik\cdot x} = \not{k}\, u\, e^{ik\cdot x},$$
$$\not{k}^2 \overset{(2)}{=} \tfrac{1}{2} k_a k_b \{\gamma^a, \gamma^b\} = |k|^2.$$

(1) $\partial_a e^{ik\cdot x} = ik_a e^{ik\cdot x}$.
(2) Only the symmetric part of $\gamma^a \gamma^b$ survives the symmetric sum; Clifford relation.

So $\not{k}$ is a Hermitian matrix squaring to $|k|^2$: its eigenvalues are $\pm|k|$. For $n \geq 2$ it is traceless ($\operatorname{tr} \gamma^a = 0$, Example T4.24), so the two eigenvalues have equal multiplicity $\frac{1}{2} \cdot 2^{\lfloor n/2 \rfloor}$. The spectrum of D on $\mathbb{R}^n$ is all of $\mathbb{R}$, continuous, and $D^2 = -\partial_a \partial_a$ is the Laplacian. This is Dirac's square root again (Section T4.1), now reinterpreted: *each Fourier mode splits into a positive and a negative "energy" branch*, $\lambda = \pm|k|$.

In two dimensions with $\gamma_1 = \sigma_1$, $\gamma_2 = \sigma_2$ and $k = |k|(\cos\beta, \sin\beta)$,

$$\not{k} = \begin{pmatrix} 0 & k_1 - ik_2 \\ k_1 + ik_2 & 0 \end{pmatrix} = |k| \begin{pmatrix} 0 & e^{-i\beta} \\ e^{i\beta} & 0 \end{pmatrix}, \qquad u_\pm = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ \pm e^{i\beta} \end{pmatrix}, \quad \not{k}\, u_\pm = \pm|k|\, u_\pm.$$

Rotating k by 2π ($\beta \to \beta + 2\pi$) returns $u_\pm$ to itself, but the *relative* phase between the components winds once: this is the "Berry phase π" of massless Dirac fermions in graphene.

Worked example T4.43: in two dimensions D is the Cauchy–Riemann operator

Let $z = x + iy$, $\partial_z = \tfrac{1}{2}(\partial_x - i\partial_y)$, $\partial_{\bar z} = \tfrac{1}{2}(\partial_x + i\partial_y)$. Then

$$D \overset{(1)}{=} -i \begin{pmatrix} 0 & \partial_x - i\partial_y \\ \partial_x + i\partial_y & 0 \end{pmatrix} \overset{(2)}{=} -2i \begin{pmatrix} 0 & \partial_z \\ \partial_{\bar z} & 0 \end{pmatrix}, \qquad D^+ = -2i\,\partial_{\bar z}, \quad D^- = -2i\,\partial_z. \tag{T4.76}$$

(1) $\sigma_1\partial_x + \sigma_2\partial_y$ written out.
(2) Definitions of $\partial_z, \partial_{\bar z}$.

So a positive-chirality zero mode, $D^+\psi_+ = 0$, is exactly a *holomorphic* function, and a negative-chirality zero mode is an antiholomorphic one. This is the first place where the Dirac operator meets complex geometry; it is the seed of the statement that on a Riemann surface D^+ is the Dolbeault operator $\bar\partial$ acting on $S^+ = K^{1/2}$ (Section T4.9.8). On all of $\mathbb{R}^2$ there are no normalisable holomorphic functions (a bounded entire function is constant, and a nonzero constant is not square integrable), so D has no L^2 zero modes. The same equation with a magnetic field will have many (Example T4.52).

T4.7.5 The circle

Worked example T4.44: the Dirac operator on S^1 for both spin structures

Take the circle of length L, coordinate $t \in [0, L)$. In one dimension the Clifford algebra has a single generator with $\gamma_1^2 = 1$; we take $\gamma_1 = 1$ on spinors $\mathbb{C}^1$. The frame $e_1 = \partial_t$ is global and $\omega = 0$, so

$$D = -i\frac{\mathrm{d}}{\mathrm{d}t}.$$

It acts on functions with the boundary condition (T4.64) of the spin structure.

- **Periodic (Ramond, Bär's "trivial").** $\psi(t + L) = \psi(t)$. Fourier modes $\psi_k = e^{2\pi i k t/L}$, $k \in \mathbb{Z}$:
$$D\psi_k \overset{(1)}{=} -i \cdot \frac{2\pi i k}{L}\psi_k = \frac{2\pi k}{L}\psi_k, \qquad \operatorname{spec} D = \frac{2\pi}{L}\mathbb{Z}.$$
- **Antiperiodic (Neveu–Schwarz).** $\psi(t+L) = -\psi(t)$. The function $e^{i\pi t/L}\psi(t)$ is periodic (the factor contributes the missing -1), so $\psi_k = e^{2\pi i(k-\frac{1}{2})t/L}$, and
$$D\psi_k = \frac{2\pi}{L}\Big(k - \frac{1}{2}\Big)\psi_k, \qquad \operatorname{spec} D = \frac{2\pi}{L}\Big(\mathbb{Z} + \frac{1}{2}\Big).$$

(1) $\dfrac{\mathrm{d}}{\mathrm{d}t}e^{2\pi i k t/L} = \dfrac{2\pi i k}{L}e^{2\pi i k t/L}$ and $(-i)(i) = 1$.

All multiplicities are 1 [Bär Ex. 2.5.8]. The periodic structure has exactly one zero mode, the constant spinor; the antiperiodic one has none. Both spectra are symmetric under $\lambda \to -\lambda$.

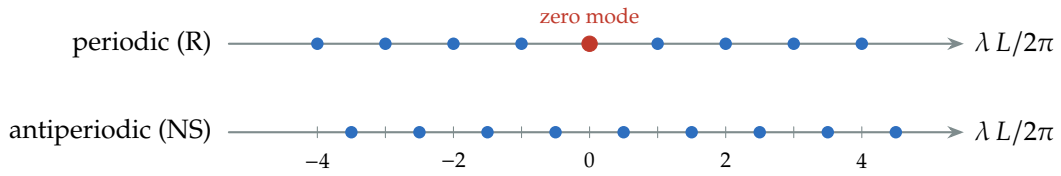

Figure T4.19: Spectrum of $D = -i\,\mathrm{d}/\mathrm{d}t$ on a circle of length L. Top: the periodic spin structure gives the integers, including a single zero mode (red, the constant spinor). Bottom: the antiperiodic structure shifts every eigenvalue by $\frac{1}{2}$ and there is no zero mode. The spin structure changes the spectrum, not just the bookkeeping.

The two spin structures as a flat gauge field. The two spin structures differ by a sign around the circle, and a sign is the holonomy of a flat U(1) connection. Let us make this precise, since it is the simplest example of *spectral flow*. Couple the periodic spinor to a constant gauge field $A = -i\,a\,\mathrm{d}t$ (anti-Hermitian, house convention; the physicist's field is a, with charge 1). The twisted operator is

$$D_a = -i\Big(\frac{\mathrm{d}}{\mathrm{d}t} - ia\Big) = -i\frac{\mathrm{d}}{\mathrm{d}t} - a, \qquad D_a e^{2\pi i k t/L} = \Big(\frac{2\pi k}{L} - a\Big)e^{2\pi i k t/L}.$$

The holonomy of the gauge field is $e^{-\oint A} = e^{iaL}$. At $a = 0$ we have the Ramond spectrum; at $a = \pi/L$ (holonomy -1) the spectrum is $\frac{2\pi}{L}(\mathbb{Z} - \frac{1}{2})$, the Neveu–Schwarz spectrum; indeed $e^{-i\pi t/L}$ times a periodic function is antiperiodic, and $D_{\pi/L}$ acting on periodic functions is unitarily equivalent to D_0 acting on antiperiodic ones. At $a = 2\pi/L$ the spectrum is back to itself, but *every eigenvalue has moved down by one step* (Figure T4.20). The net number of eigenvalues crossing zero from above, here 1, is the **spectral flow**. It is a topological number (it only depends on the winding of the holonomy e^{iaL} around U(1)) and it is the one-dimensional origin of the chiral anomaly: in Chapter 10 the adiabatic change of a background field pumps one unit of charge out of the Dirac sea.

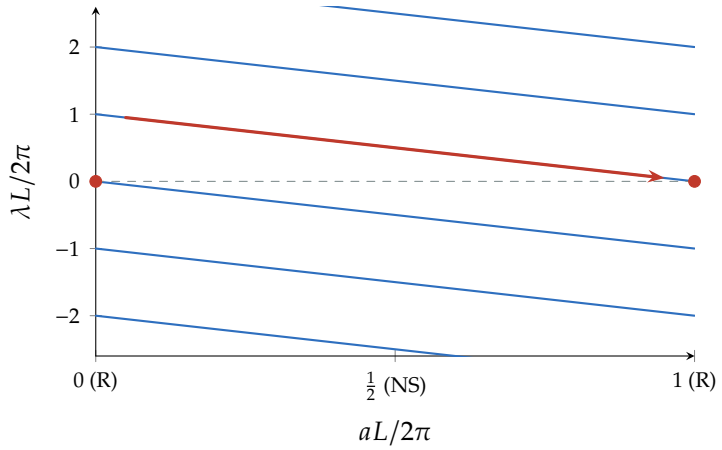

Figure T4.20: Spectral flow on the circle. As the flat gauge field a increases from 0 to $2\pi/L$, every eigenvalue $\frac{2\pi k}{L} - a$ slides down one step. Half way, at holonomy -1, we pass through the Neveu–Schwarz spectrum. One eigenvalue (red) crosses zero: the spectral flow is 1. The spectrum returns to itself as a set, but the eigenvalues have been relabelled.

Dictionary: the circle spectrum in physics

- **Ramond zero mode.** A fermion zero mode on the spatial circle is a Grassmann variable ψ_0 with no energy cost; quantising it gives a two-fold degenerate ground

state (the Clifford algebra of one fermionic zero mode). With many worldsheet fermions the zero modes form a Clifford algebra and the Ramond ground state is a *spacetime spinor* (Chapter 9).

- **Zero-point energies.** Formally the vacuum energy is a sum of eigenvalues. With ζ-function regularisation, $\sum_{k\geq 1} k = \zeta(-1) = -\frac{1}{12}$ and $\sum_{k\geq 1}(k-\frac{1}{2}) = \zeta(-1,\frac{1}{2}) = +\frac{1}{24}$ (Hurwitz zeta). These are the numbers behind the different normal-ordering constants of the R and NS sectors.
- **Thermal fermions.** With $L=\beta$ the antiperiodic spectrum is the set of fermionic Matsubara frequencies $(2k+1)\pi/\beta$.

T4.7.6 The torus

Worked example T4.45: the Dirac operator on T^2 for the four spin structures

Let $T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$, flat, with the global frame (∂_x, ∂_y), so $\omega = 0$ and D is (T4.76). A spinor field obeys the boundary conditions (T4.65) with signs $(\varepsilon_1, \varepsilon_2)$. Plane waves $u\, e^{i(px+qy)}$ satisfy them iff

$$p \in \mathbb{Z} \text{ if } \varepsilon_1 = +1, \quad p \in \mathbb{Z} + \tfrac{1}{2} \text{ if } \varepsilon_1 = -1; \qquad \text{and the same for } q \text{ and } \varepsilon_2.$$

For each allowed (p,q), Example T4.42 gives two eigenvalues

$$\lambda = \pm\sqrt{p^2+q^2},$$

each with multiplicity one, except that when $(p,q)=(0,0)$ the matrix $\not{k}=0$ and both spinors $u=(1,0)^{\mathsf{T}}$ and $(0,1)^{\mathsf{T}}$ are zero modes. The momentum $(0,0)$ is allowed only for $(\varepsilon_1,\varepsilon_2)=(+,+)$. So:

spin structure $(\varepsilon_1,\varepsilon_2)$	$(+,+)$	$(+,-)$	$(-,+)$	$(-,-)$
allowed (p,q)	$\mathbb{Z}\times\mathbb{Z}$	$\mathbb{Z}\times(\mathbb{Z}+\frac{1}{2})$	$(\mathbb{Z}+\frac{1}{2})\times\mathbb{Z}$	$(\mathbb{Z}+\frac{1}{2})^2$
zero modes (n_+,n_-)	$(1,1)$	$(0,0)$	$(0,0)$	$(0,0)$
smallest $\lvert\lambda\rvert>0$	1 (mult. 4 each sign)	$\frac{1}{2}$ (mult. 2)	$\frac{1}{2}$ (mult. 2)	$\frac{1}{\sqrt{2}}$ (mult. 4)
index n_+-n_-	0	0	0	0

In the $(+,+)$ case the zero modes are the constants: $D^+\psi_+ = -2i\partial_{\bar z}\psi_+ = 0$ means ψ_+ is a holomorphic doubly periodic function, hence constant (Liouville on the compact torus), and similarly for ψ_-. In the other cases a constant does not satisfy the antiperiodic condition, and neither does any other holomorphic function. The index vanishes in every case, as it must by the index theorem in two dimensions without a gauge field ($\hat A = 1$ has no 2-form part; Section T4.8.5).

Try it: a torus with a flat twist

Couple the $(+,+)$ spinor on T^2 to a constant gauge field $A = -i(a_1\mathrm{d}x + a_2\mathrm{d}y)$. Show that the eigenvalues become $\pm\sqrt{(p-a_1)^2+(q-a_2)^2}$, $p,q\in\mathbb{Z}$, so that zero modes exist only when $(a_1,a_2)\in\mathbb{Z}^2$, and that $(a_1,a_2)=(\frac{1}{2},0)$ reproduces the $(-,+)$ spectrum. *Answer:* $D_A = -i\gamma^a(\partial_a - ia_a)$ acts on $u\,e^{i(px+qy)}$ as $\gamma^a(k_a-a_a)$ with $k=(p,q)$; square it. The shift by

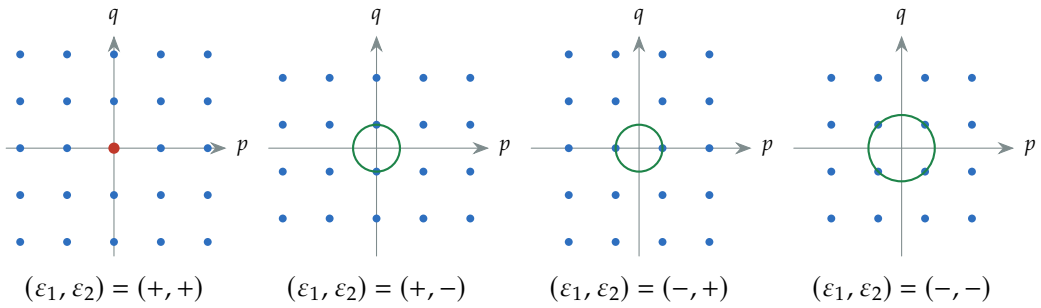

Figure T4.21: Allowed momenta (p, q) on the square torus for the four spin structures. Each dot gives the eigenvalues $\pm\sqrt{p^2+q^2}$. Only the periodic–periodic lattice contains the origin (red), which gives the two constant zero modes. For the other three, the lattice is shifted by half a step and the green circle shows the resulting gap $|\lambda| \geq \frac{1}{2}$ or $\frac{1}{\sqrt{2}}$.

$\frac{1}{2}$ in p is the same as the shift of the allowed momenta from $\mathbb{Z}$ to $\mathbb{Z}+\frac{1}{2}$ (the minus sign is irrelevant since the lattice is symmetric).

T4.7.7 The round two-sphere

The sphere is the first example where the spin connection is not removable, and the answer is beautiful: the eigenvalues are $\pm1, \pm2, \pm3, \ldots$ with multiplicities $2, 4, 6, \ldots$. We derive the operator, find the lowest eigenspinors explicitly, check that they are smooth, and then obtain the whole spectrum by recognising an old friend from the hydrogen atom.

Worked example T4.46: the Dirac operator on S^2 in polar coordinates

With the frame of Example T4.39 and Ω of Example T4.41:

$$D \overset{(1)}{=} -i\Big[\sigma_1\nabla_{e_1} + \sigma_2\nabla_{e_2}\Big] \overset{(2)}{=} -i\Big[\sigma_1\partial_\theta + \sigma_2\frac{1}{\sin\theta}\Big(\partial_\phi - \frac{i}{2}\cos\theta\,\sigma_3\Big)\Big]$$
$$\overset{(3)}{=} -i\Big[\sigma_1\Big(\partial_\theta + \frac{1}{2}\cot\theta\Big) + \frac{\sigma_2}{\sin\theta}\,\partial_\phi\Big]. \tag{T4.77}$$

(1) (T4.72) with $\gamma_1 = \sigma_1$, $\gamma_2 = \sigma_2$.
(2) $\Omega(e_1) = \Omega(\partial_\theta) = 0$ and $\Omega(e_2) = \frac{1}{\sin\theta}\Omega(\partial_\phi) = -\frac{i}{2}\frac{\cos\theta}{\sin\theta}\sigma_3$.
(3) $\sigma_2\sigma_3 = i\sigma_1$, so $\sigma_2\big(-\frac{i}{2}\cot\theta\,\sigma_3\big) = -\frac{i}{2}\cot\theta\,(i\sigma_1) = \frac{1}{2}\cot\theta\,\sigma_1$.

The spin connection has become the term $\frac{1}{2}\cot\theta$. It has a simple meaning: $\partial_\theta + \frac{1}{2}\cot\theta = (\sin\theta)^{-1/2}\,\partial_\theta\,(\sin\theta)^{1/2}$, i.e. it makes ∂_θ antisymmetric with respect to the measure $\sin\theta\,\mathrm{d}\theta$ (the one-dimensional version of formal self-adjointness).
Because the frame rotates once around each pole, spinor components in this frame are *antiperiodic* in ϕ (Example T4.34), so we separate variables with half-integer m:

$$\psi = \begin{pmatrix} f(\theta) \\ g(\theta) \end{pmatrix} e^{im\phi}, \qquad m \in \mathbb{Z} + \tfrac{1}{2}.$$

Using $\sigma_1 = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, $\sigma_2 = \left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right)$ and $\partial_\phi \to im$,

$$D\begin{pmatrix} f \\ g \end{pmatrix} e^{im\phi} = -i\begin{pmatrix} \big(\partial_\theta + \frac{1}{2}\cot\theta + \frac{m}{\sin\theta}\big)g \\ \big(\partial_\theta + \frac{1}{2}\cot\theta - \frac{m}{\sin\theta}\big)f \end{pmatrix} e^{im\phi}. \tag{T4.78}$$

(The upper entry: σ_2 contributes $-i\cdot im/\sin\theta = m/\sin\theta$ acting on g; the lower entry: $+i\cdot im/\sin\theta = -m/\sin\theta$ acting on f.) The lower-left block is D^+, the upper-right is D^-, as in (T4.75).

Worked example T4.47: the lowest eigenspinors on S^2: $\lambda = \pm 1$

Take $m = \frac{1}{2}$ and try $f = \cos\frac{\theta}{2}$, $g = c\,\sin\frac{\theta}{2}$ with a constant c. We need two derivatives. Writing $\sin\theta = 2\sin\frac{\theta}{2}\cos\frac{\theta}{2}$:

$$\Big(\partial_\theta + \tfrac{1}{2}\cot\theta + \tfrac{1}{2\sin\theta}\Big)\sin\tfrac{\theta}{2} \overset{(1)}{=} \tfrac{1}{2}\cos\tfrac{\theta}{2} + \frac{\cos\theta+1}{2\sin\theta}\sin\tfrac{\theta}{2} \overset{(2)}{=} \tfrac{1}{2}\cos\tfrac{\theta}{2} + \frac{2\cos^2\frac{\theta}{2}}{4\cos\frac{\theta}{2}} = \cos\tfrac{\theta}{2},$$

$$\Big(\partial_\theta + \tfrac{1}{2}\cot\theta - \tfrac{1}{2\sin\theta}\Big)\cos\tfrac{\theta}{2} \overset{(3)}{=} -\tfrac{1}{2}\sin\tfrac{\theta}{2} + \frac{\cos\theta-1}{2\sin\theta}\cos\tfrac{\theta}{2} \overset{(4)}{=} -\tfrac{1}{2}\sin\tfrac{\theta}{2} - \frac{2\sin^2\frac{\theta}{2}}{4\sin\frac{\theta}{2}} = -\sin\tfrac{\theta}{2}.$$

(1) Differentiate, and combine $\frac{1}{2}\cot\theta + \frac{1}{2\sin\theta} = \frac{\cos\theta+1}{2\sin\theta}$.
(2) $1+\cos\theta = 2\cos^2\frac{\theta}{2}$ and $\sin\theta = 2\sin\frac{\theta}{2}\cos\frac{\theta}{2}$.
(3) Same steps with the opposite sign of the m term.
(4) $\cos\theta - 1 = -2\sin^2\frac{\theta}{2}$.

Insert into (T4.78): $D\psi = -i\big(c\cos\frac{\theta}{2},\ -\sin\frac{\theta}{2}\big)^{\mathsf T}e^{i\phi/2}$. For this to be $\lambda\psi = \lambda(\cos\frac{\theta}{2},\ c\sin\frac{\theta}{2})^{\mathsf T}e^{i\phi/2}$ we need $-ic = \lambda$ (upper components) and $i = \lambda c$ (lower components). The first gives $c = i\lambda$; inserting it into the second gives $i = i\lambda^2$, so $\lambda^2 = 1$ and $c = \pm i$:

$$\psi_\pm^{(1/2)} = \begin{pmatrix}\cos\frac{\theta}{2}\\ \pm i\sin\frac{\theta}{2}\end{pmatrix}e^{i\phi/2}, \qquad D\psi_\pm^{(1/2)} = \pm\psi_\pm^{(1/2)}. \tag{T4.79}$$

The same computation with $m = -\frac{1}{2}$ gives $\psi_\pm^{(-1/2)} = \big(\sin\frac{\theta}{2},\ \mp i\cos\frac{\theta}{2}\big)^{\mathsf T}e^{-i\phi/2}$, also with $D = \pm 1$. So $\lambda = +1$ and $\lambda = -1$ each occur (at least) twice.

Are these genuine smooth spinors? The polar frame is singular at the poles, so we must re-express ψ in a frame that is smooth there. Near the north pole, (e_1, e_2) is the polar frame of a small disc with polar angle ϕ, and by Example T4.34 components in a smooth (Cartesian-like) frame are $\psi_{\text{cart}} = a(\phi)\psi = \operatorname{diag}(e^{-i\phi/2}, e^{i\phi/2})\psi$:

$$\psi_{\text{cart}} = \begin{pmatrix}\cos\frac{\theta}{2}\\ \pm i\sin\frac{\theta}{2}\,e^{i\phi}\end{pmatrix} \approx \begin{pmatrix}1\\ \pm\frac{i}{2}\,\theta e^{i\phi}\end{pmatrix} = \begin{pmatrix}1\\ \pm\frac{i}{2}(x+iy)\end{pmatrix} \quad (\theta\to 0),$$

with local Cartesian coordinates $x + iy = \theta e^{i\phi}$: smooth. Near the south pole the oriented polar angle is $-\phi$ and $e_1 = \partial_\theta$ points *towards* the pole, so (e_1, e_2) is the smooth frame rotated by $\pi - \phi$; multiplying by $a(\pi-\phi) = \operatorname{diag}(-ie^{i\phi/2}, ie^{-i\phi/2})$ gives components $\big(-ie^{i\phi}\cos\frac{\theta}{2},\ \mp\sin\frac{\theta}{2}\big)$, which with $\theta' = \pi - \theta$ and $x' - iy' = \theta' e^{i\phi}$ behave as $\big(-\frac{i}{2}(x'-iy'),\ \mp 1\big)$: smooth again. The half-integer m was essential: an integer m would leave a factor $e^{\pm i\phi/2}$ that is discontinuous at the poles.

The whole spectrum: the spin–orbit operator of the hydrogen atom. The eigenvalues ± 1 look like the start of a pattern. To see it, embed $S^2 \subset \mathbb{R}^3$ and use the flat Dirac operator of $\mathbb{R}^3$, $-i\vec\sigma\cdot\nabla$. Recall the Pauli identity $(\vec\sigma\cdot\vec a)(\vec\sigma\cdot\vec b) = \vec a\cdot\vec b + i\vec\sigma\cdot(\vec a\times\vec b)$ (Example T4.2), valid as long as $\vec a$ stands to the left of the derivatives in $\vec b$. With $\hat r = \vec r/r$ and the orbital angular momentum

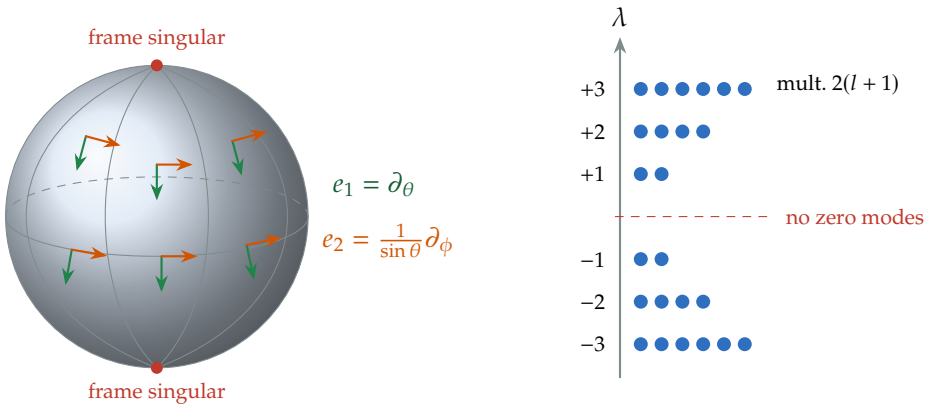

Figure T4.22: Left: the polar frame on S^2 (green along meridians, orange along parallels). It is smooth except at the poles, where it rotates once around each pole; hence spinor components in this frame have half-integer angular momentum m. Right: the spectrum of the Dirac operator on the unit sphere, $\lambda = \pm(l+1)$ with multiplicity $2(l+1)$ for each sign (dots count eigenspinors). It is symmetric and has a gap: $|\lambda| \geq 1$.

$\vec{L} = -i\,\vec{r}\times\nabla$:

$$(\vec{\sigma}\cdot\hat{r})(\vec{\sigma}\cdot\nabla) \overset{(1)}{=} \hat{r}\cdot\nabla + i\vec{\sigma}\cdot(\hat{r}\times\nabla) \overset{(2)}{=} \partial_r + \frac{i}{r}\,\vec{\sigma}\cdot(i\vec{L}) = \partial_r - \frac{\vec{\sigma}\cdot\vec{L}}{r},$$
$$-i\vec{\sigma}\cdot\nabla \overset{(3)}{=} -i(\vec{\sigma}\cdot\hat{r})\Big(\partial_r - \frac{\vec{\sigma}\cdot\vec{L}}{r}\Big) = -i(\vec{\sigma}\cdot\hat{r})\Big(\partial_r + \frac{1}{r}\Big) + \frac{i(\vec{\sigma}\cdot\hat{r})}{r}\,K, \qquad K \coloneqq \vec{\sigma}\cdot\vec{L} + 1. \tag{T4.80}$$

(1) Pauli identity with $\vec{a} = \hat{r}$, $\vec{b} = \nabla$.
(2) $\hat{r}\cdot\nabla = \partial_r$, and $\vec{r}\times\nabla = i\vec{L}$.
(3) Multiply on the left by $\vec{\sigma}\cdot\hat{r}$, which squares to 1; add and subtract $1/r$.

The first term differentiates in the normal direction (the $1/r$ is the mean curvature term that makes ∂_r antisymmetric with respect to $r^2\mathrm{d}r$). The second term involves only derivatives along the sphere. The general hypersurface formula of Bär's §2.6 identifies it: *the intrinsic Dirac operator of the unit S^2, with its unique spin structure induced from $\mathbb{R}^3$, is unitarily equivalent to* $K = \vec{\sigma}\cdot\vec{L} + 1$, acting on two-component functions on the sphere. (Clifford multiplication by the normal, $\vec{\sigma}\cdot\hat{r}$, anticommutes with K and exchanges its $\pm$ eigenspaces, which is the same pairing as Γ in Section T4.7.3.) We accept this identification and check it against what we computed. The eigenvalues of K follow from angular momentum addition. With $\vec{J} = \vec{L} + \frac{1}{2}\vec{\sigma}$,

$$\vec{J}^2 \overset{(1)}{=} \vec{L}^2 + \vec{\sigma}\cdot\vec{L} + \tfrac{3}{4} \quad\Longrightarrow\quad K = j(j+1) - l(l+1) + \tfrac{1}{4},$$
$$j = l + \tfrac{1}{2}:\ K \overset{(2)}{=} l + 1 = j + \tfrac{1}{2}, \qquad j = l - \tfrac{1}{2}:\ K \overset{(3)}{=} -l = -(j + \tfrac{1}{2}).$$

(1) $(\vec{L} + \frac{1}{2}\vec{\sigma})^2 = \vec{L}^2 + \vec{L}\cdot\vec{\sigma} + \frac{1}{4}\vec{\sigma}^2$ (the components of $\vec{L}$ and $\vec{\sigma}$ commute) and $\vec{\sigma}^2 = 3$.
(2) $(l+\frac{1}{2})(l+\frac{3}{2}) - l(l+1) + \frac{1}{4} = l + 1$.
(3) $(l-\frac{1}{2})(l+\frac{1}{2}) - l(l+1) + \frac{1}{4} = -l$.

For each $j = \frac{1}{2}, \frac{3}{2}, \ldots$ the multiplet has $2j+1$ states, and $K = +(j+\frac{1}{2})$ (from $l = j - \frac{1}{2}$) and $K = -(j+\frac{1}{2})$ (from $l = j + \frac{1}{2}$) each occur once per state. Writing $j + \frac{1}{2} = l + 1$:

$$\operatorname{spec} D_{S^2} = \{\pm(l+1) :\ l = 0, 1, 2, \ldots\}, \qquad \text{multiplicity } 2(l+1) \text{ for each sign.} \tag{T4.81}$$

For a sphere of radius r every eigenvalue is divided by r (D has dimensions of inverse length).

Checks. (i) $l = 0$: $\lambda = \pm 1$ with multiplicity 2 each: the four eigenspinors (T4.79). (In the $\mathbb{R}^3$ picture, $K = +1$ is the constant spinors χ, which have $\vec{L}\chi = 0$, and $K = -1$ is $(\vec{\sigma}\cdot\hat{r})\chi$.) (ii) The m values: for the multiplet j the angular momentum J_3 takes the $2j+1$ half-integer values $-j, \dots, j$, which matches the half-integer m we were forced to use in the polar frame; for $j = \frac{1}{2}$ these are the two values $m = \pm\frac{1}{2}$ we found. (iii) There is no zero mode, consistent with the Lichnerowicz argument of Section T4.8 ($R = 2 > 0$). (iv) The spectrum is symmetric, as it must be in even dimension: Γ anticommutes with D and maps the λ-eigenspace onto the $(-\lambda)$-eigenspace (in the $\mathbb{R}^3$ picture this role is played by $\vec{\sigma}\cdot\hat{r}$).

Dictionary: the sphere spectrum in physics

- **Relativistic hydrogen.** K is Dirac's spin–orbit operator; its eigenvalue $-\kappa = \pm(j+\frac{1}{2})$ is the quantum number that labels the $s_{1/2}, p_{1/2}, p_{3/2}, \dots$ levels. The Dirac operator on the unit sphere *is* the angular part of the Dirac Hamiltonian.
- **Radial quantisation.** On $\mathbb{R}\times S^2$ (or on S^2 as the celestial sphere) free massless fermions have energies $\pm(l+1)/r$: the conformal dimensions $l+1 = \frac{3}{2} - \frac{1}{2} + l$ of the free-fermion operators $\psi, \partial\psi, \dots$ shifted by the curvature of the sphere.
- **The gap** $|\lambda| \geq 1$ is a curvature effect: on a flat torus of the same area there can be zero modes. Positive curvature pushes spinor eigenvalues away from zero. The next section explains why.

Reading Nash (p. 113–115)

Nash defines the Dirac operator in one line, (4.100), and moves directly to its index. Everything in this section is background he assumes: the spin connection ω ("the Riemannian spin connection on X") and its curvature, ellipticity of the symbol $i\gamma^a e_a^\mu p_\mu$, self-adjointness, and the chiral splitting (4.101)–(4.102). Nash never computes a Dirac spectrum; the examples S^1, T^2 and S^2 are there so that the index $n_+ - n_-$ of (4.106) has concrete meaning: on all of them it is 0, for different reasons (no zero modes at all, or zero modes that come in chiral pairs).

Recap

- The spin connection is $\nabla = \mathrm{d} + \frac{1}{4}\omega_{ab}\gamma^a\gamma^b$: each infinitesimal frame rotation ω is replaced by its spin generator. It is forced by the Leibniz rule for Clifford multiplication, it encodes the half-angle, and it glues correctly only because the transition functions are lifted to $\mathrm{Spin}(n)$.
- Its curvature is $R^S = \frac{1}{4}R_{ab}\gamma^a\gamma^b$; on S^2 the chiral halves are line bundles with $c_1 = \mp 1$.
- The Dirac operator $D = -i\gamma^a\nabla_a$ is elliptic (symbol $\not{\xi}$), formally self-adjoint (divergence of the current $\psi^\dagger\gamma^a\chi$), and anticommutes with Γ, so $D = \left(\begin{smallmatrix} 0 & D^- \\ D^+ & 0 \end{smallmatrix}\right)$.
- Spectra: $\mathbb{R}^n$: $\pm|k|$. S^1: $\frac{2\pi}{L}\mathbb{Z}$ (R, one zero mode) or $\frac{2\pi}{L}(\mathbb{Z}+\frac{1}{2})$ (NS, none). T^2: $\pm\sqrt{p^2+q^2}$ with zero modes only for $(+,+)$. S^2: $\pm(l+1)$ with multiplicity $2(l+1)$, no zero modes.
- In two dimensions $D^+ = -2i\partial_{\bar{z}}$: chiral zero modes are holomorphic.

T4.8 The Lichnerowicz formula, twisted Dirac operators and the index

In Section T4.7 we computed three spectra by hand and noticed a pattern. On the flat torus with periodic boundary conditions there were zero modes: the constant spinors. On the round sphere there were none, and the eigenvalues kept a respectful distance $|\lambda| \geq 1$ from zero. Is this an accident of the examples, or is curvature *forcing* the spinors away from zero?

It is forced, and the mechanism is one identity: the square of the Dirac operator is a positive "kinetic" term plus a quarter of the scalar curvature,

$$D^2 = \nabla^*\nabla + \frac{R}{4}.$$

This is the **Lichnerowicz formula**. It is the spinor analogue of the statement that the Pauli Hamiltonian $(\sigma \cdot \vec{\pi})^2$ is the kinetic energy $\vec{\pi}^2$ plus the magnetic moment term $-\sigma \cdot \vec{B}$: squaring a first-order operator produces a second-order kinetic term *plus a curvature term*, and the curvature term is where all the physics sits. With a gauge field in addition, the curvature term acquires exactly the Pauli coupling $-\frac{1}{2}\gamma^a\gamma^b F_{ab}$.

The questions of this section are:

- What is $\nabla^*\nabla$, and why can every Laplace-type operator be written as $\nabla^*\nabla$ plus a potential?
- Why is the potential for D^2 exactly $R/4$? (A two-line computation with the Clifford relation and the Bianchi identity.)
- What does it imply? (No harmonic spinors when $R > 0$; lower bounds on $|\lambda|$; the bound is attained on round spheres.)
- What happens when spinors are also charged? (Twisted Dirac operators, Landau levels, the Aharonov–Casher zero modes, monopoles on S^2.)
- Why is $\dim \operatorname{Ker} D^+ - \dim \operatorname{Ker} D^-$ so robust, and what formula computes it? (A preview of the index theorem of Nash's Chapter 4.)

Throughout, M is a Riemannian spin manifold of dimension n, γ_a are our Hermitian gamma matrices with $\{\gamma_a, \gamma_b\} = 2\delta_{ab}$, and $D = -i\gamma^a\nabla_a$ with the spin connection of Section T4.7.2.

T4.8.1 The connection Laplacian

On functions on $\mathbb{R}^n$ the Laplacian is $-\sum_a \partial_a^2$, and integrating by parts gives $\int \bar{f}(-\partial_a^2 f) = \int |\partial f|^2 \geq 0$. For sections of any bundle with a connection there is a direct analogue.

Working definition T4.11 (connection Laplacian)

Let $E \to M$ be a bundle with a Hermitian metric [an inner product $\langle\psi, \chi\rangle$ on the components at each point] and a metric connection ∇ [one that obeys $\partial_X\langle\psi, \chi\rangle = \langle\nabla_X\psi, \chi\rangle + \langle\psi, \nabla_X\chi\rangle$] (for us: spinors with the spin connection, or spinors tensored with a gauge bundle). The **connection Laplacian** (or **rough Laplacian**) is the operator $\nabla^*\nabla$ defined by

$$(\nabla^*\nabla\psi, \chi) = (\nabla\psi, \nabla\chi) := \int_M \sum_a \langle\nabla_a\psi, \nabla_a\chi\rangle \,\mathrm{vol}$$

for all compactly supported χ [χ vanishes outside a bounded region, so boundary terms drop]. *Recipe* [Bär Lemma 2.5.10, (2.33)]: in a local orthonormal frame

$$\nabla^*\nabla = -\sum_{a=1}^{n}\Big(\nabla_{e_a}\nabla_{e_a} - \nabla_{\nabla_{e_a}e_a}\Big), \tag{T4.82}$$

and at a point where the frame is synchronous ($\nabla e_a = 0$ there) it is simply $-\sum_a \nabla_a\nabla_a$.

The second term in (T4.82) is there because the frame vectors themselves turn. Let us see why the recipe is right. The argument is the same divergence trick we used for self-adjointness of D in (T4.73). Define the complex vector field X by $\langle X, Y\rangle = \langle\psi, \nabla_Y\chi\rangle$ for all vectors Y, i.e. $X^a = \langle\psi, \nabla_a\chi\rangle$. At a point x with a synchronous frame,

$$\begin{aligned}\operatorname{div} X &\overset{(1)}{=} \sum_a e_a\big(\langle\psi, \nabla_a\chi\rangle\big) \overset{(2)}{=} \sum_a\Big(\langle\nabla_a\psi, \nabla_a\chi\rangle + \langle\psi, \nabla_a\nabla_a\chi\rangle\Big)\\ &\overset{(3)}{=} \langle\nabla\psi, \nabla\chi\rangle - \big\langle\psi, \nabla^*\nabla\chi\big\rangle.\end{aligned}$$

(1) Divergence in an orthonormal frame; the term $\langle X, \nabla_{e_a}e_a\rangle$ vanishes at x.
(2) The connection is metric: $e_a\langle\psi,\phi\rangle = \langle\nabla_a\psi,\phi\rangle + \langle\psi,\nabla_a\phi\rangle$.
(3) At x, (T4.82) reduces to $-\sum_a \nabla_a\nabla_a$.

Both ends of the chain are frame-independent, so the identity holds everywhere. Integrating over a closed M kills the divergence (Stokes), and what remains is $(\nabla\psi, \nabla\chi) = (\psi, \nabla^*\nabla\chi)$: the recipe computes the adjoint. Setting $\chi = \psi$ gives the one property we will use again and again:

$$(\nabla^*\nabla\psi, \psi) = \|\nabla\psi\|^2 \geq 0, \qquad \text{with equality iff } \nabla\psi = 0. \tag{T4.83}$$

So $\nabla^*\nabla$ is a *non-negative* operator whose kernel is the parallel sections. It is the "kinetic energy" of the field.

Worked example T4.48: the rough Laplacian of functions in polar coordinates

On $\mathbb{R}^2$ with the polar frame $e_1 = \partial_r$, $e_2 = \frac{1}{r}\partial_\phi$ of Example T4.40, $\omega_{12} = -\mathrm{d}\phi$. By (T4.66), $\nabla_X e_2 = e_1\,\omega_{12}(X) = -\mathrm{d}\phi(X)\,e_1$ and $\nabla_X e_1 = e_2\,\omega_{21}(X) = \mathrm{d}\phi(X)\,e_2$. Hence

$$\nabla_{e_1}e_1 = \mathrm{d}\phi(\partial_r)\,e_2 = 0, \qquad \nabla_{e_2}e_2 = -\mathrm{d}\phi\big(\tfrac{1}{r}\partial_\phi\big)\,e_1 = -\tfrac{1}{r}\,e_1.$$

For a function f (trivial bundle, $\nabla = \mathrm{d}$):

$$\begin{aligned}\nabla^*\nabla f &\overset{(1)}{=} -\Big(e_1e_1f - (\nabla_{e_1}e_1)f + e_2e_2f - (\nabla_{e_2}e_2)f\Big)\\ &\overset{(2)}{=} -\Big(\partial_r^2 f + \frac{1}{r^2}\partial_\phi^2 f + \frac{1}{r}\partial_r f\Big).\end{aligned}$$

(1) (T4.82) with $n = 2$.
(2) $e_1e_1f = \partial_r^2 f$, $e_2e_2f = r^{-2}\partial_\phi^2 f$, $-(\nabla_{e_2}e_2)f = +\frac{1}{r}\partial_r f$.

This is the familiar polar Laplacian. The $\frac{1}{r}\partial_r$ term, which students usually memorise, is the correction for the turning frame.

Every Laplace-type operator is a rough Laplacian plus a potential. Bär proves a small but important structural fact [Bär Lemma 1.3.5]: if P is a formally self-adjoint operator of Laplace

type on E (symbol $|\xi|^2\mathbf{1}$), there is *exactly one* metric connection ∇ on E and one Hermitian endomorphism field K with

$$P = \nabla^*\nabla + K. \tag{T4.84}$$

The mechanism is simple. The second-order part of P is fixed by the symbol. The first-order part $B^a\partial_a$ can be absorbed by choosing the connection $\nabla_a = \partial_a - \frac{1}{2}B^a + \dots$, exactly as one completes the square $x^2 + bx = (x + \frac{b}{2})^2 - \frac{b^2}{4}$. What is left over has order zero: it is K. Any formula of the type (T4.84) with an explicit K is called a **Weitzenböck formula**. The Lichnerowicz formula identifies the connection and the potential for $P = D^2$: the connection is the spin connection and the potential is $R/4$.

Physical picture: completing the square

In quantum mechanics $H = (\vec{p} - \vec{a})^2 + V$ is "kinetic energy with a gauge field, plus a potential". (T4.84) says every Laplace-type operator can be put in this form in exactly one way. The gauge field is the connection ∇, and the potential K is what the operator "feels" at each point beyond kinetic energy. For D^2, the potential is curvature.

T4.8.2 Deriving the Lichnerowicz formula

Key idea: Lichnerowicz formula [Bär Thm. 2.5.11]

On any Riemannian spin manifold, with R the scalar curvature,

$$D^2 = \nabla^*\nabla + \frac{R}{4}. \tag{T4.85}$$

The derivation has three steps. Each is short, and each uses one idea.

Step 1: square D and split into symmetric and antisymmetric parts. Work at a point x in a synchronous frame, so that $\nabla e_a = 0$ at x. Then $\gamma(e_b) = \gamma_b$ is covariantly constant at x by the Leibniz rule (T4.70), and $[e_a, e_b] = \nabla_{e_a}e_b - \nabla_{e_b}e_a = 0$ at x, so the commutator of covariant derivatives is pure curvature: $[\nabla_a, \nabla_b] = R^S(e_a, e_b) =: R^S_{ab}$. Now

$$\begin{aligned} D^2\psi &\overset{(1)}{=} (-i\gamma^a\nabla_a)(-i\gamma^b\nabla_b\psi) \overset{(2)}{=} -\gamma^a\gamma^b\,\nabla_a\nabla_b\psi \\ &\overset{(3)}{=} -\sum_a \nabla_a\nabla_a\psi - \sum_{a\neq b}\gamma^a\gamma^b\,\nabla_a\nabla_b\psi \\ &\overset{(4)}{=} -\sum_a \nabla_a\nabla_a\psi - \frac{1}{2}\sum_{a\neq b}\gamma^a\gamma^b\,[\nabla_a, \nabla_b]\psi \\ &\overset{(5)}{=} \nabla^*\nabla\psi - \frac{1}{2}\,\gamma^a\gamma^b\,R^S_{ab}\,\psi. \end{aligned} \tag{T4.86}$$

(1) Definition (T4.72).
(2) $(-i)^2 = -1$, and ∇_a passes through γ^b because γ^b is parallel at x.
(3) Separate $a = b$ (where $\gamma^a\gamma^a = \mathbf{1}$) from $a \neq b$.
(4) For $a \neq b$, $\gamma^b\gamma^a = -\gamma^a\gamma^b$, so the sum over ordered pairs only sees the antisymmetric part of $\nabla_a\nabla_b$: $\sum_{a\neq b}\gamma^a\gamma^b\nabla_a\nabla_b = \frac{1}{2}\sum_{a\neq b}\gamma^a\gamma^b(\nabla_a\nabla_b - \nabla_b\nabla_a)$.
(5) (T4.82) at x; $[\nabla_a, \nabla_b] = R^S_{ab}$ at x, and the $a = b$ terms may be added back since $R^S_{aa} = 0$.

This step is pure Clifford algebra and holds for *any* connection compatible with Clifford multiplication. It is the curved-space version of the Pauli computation $(\sigma\cdot\vec{\pi})^2 = \vec{\pi}^{\,2} + i\sigma_3[\pi_1, \pi_2]$.

Step 2: insert the spinor curvature. By (T4.71), $R^S_{ab} = R^S(e_a, e_b) = \frac{1}{4} R_{cdab}\gamma^c\gamma^d$. So

$$D^2 = \nabla^*\nabla - \frac{1}{8}\, R_{cdab}\, \gamma^a\gamma^b\gamma^c\gamma^d = \nabla^*\nabla - \frac{1}{8}\, R_{abcd}\, \gamma^a\gamma^b\gamma^c\gamma^d, \tag{T4.87}$$

using the pair symmetry $R_{cdab} = R_{abcd}$ of the Riemann tensor.

Step 3: a four-gamma identity. We need $X := R_{abcd}\gamma^a\gamma^b\gamma^c\gamma^d$. Hold a fixed and look at the last three gammas. The gamma-matrix version of Dray's triple product (T4.16) is

$$\gamma^b\gamma^c\gamma^d = \gamma^{[bcd]} + \delta^{bc}\gamma^d - \delta^{bd}\gamma^c + \delta^{cd}\gamma^b, \tag{T4.88}$$

where $\gamma^{[bcd]}$ is the totally antisymmetric part (equal to $\gamma^b\gamma^c\gamma^d$ when b, c, d are distinct and zero otherwise). (Check one case: $b = d = 1$, $c = 2$ gives $\gamma^1\gamma^2\gamma^1 = -\gamma^2$ on the left and $0 + 0 - \gamma^2 + 0$ on the right.) Contract with R_{abcd}, using the symmetries $R_{abcd} = -R_{bacd} = -R_{abdc} = R_{cdab}$, the first Bianchi identity $R_{abcd} + R_{acdb} + R_{adbc} = 0$, and $\mathrm{Ric}_{bd} = \sum_a R_{abad}$ (Section T4.7.1):

$$\begin{aligned} R_{abcd}\gamma^b\gamma^c\gamma^d &\overset{(1)}{=} R_{abcd}\gamma^{[bcd]} + R_{abbd}\gamma^d - R_{abcb}\gamma^c + R_{abcc}\gamma^b \\ &\overset{(2)}{=} 0 + R_{abbd}\gamma^d - R_{abcb}\gamma^c + 0 \\ &\overset{(3)}{=} -\mathrm{Ric}_{ad}\gamma^d - \mathrm{Ric}_{ac}\gamma^c = -2\,\mathrm{Ric}_{ad}\gamma^d. \end{aligned} \tag{T4.89}$$

(1) Insert (T4.88) and do the δ contractions (repeated indices summed).
(2) The antisymmetrisation of R_{abcd} over b, c, d is one third of the cyclic sum in the Bianchi identity, so it vanishes. $R_{abcc} = 0$ by antisymmetry in the last pair.
(3) $\sum_b R_{abbd} = -\sum_b R_{babd} = -\mathrm{Ric}_{ad}$, and $\sum_b R_{abcb} = \sum_b R_{babc} = \mathrm{Ric}_{ac}$ (swap both pairs' entries).

Equation (T4.89) is Bär's Lemma 2.5.9 in our language ($\sum_j \gamma^j R^S(e_j, X) = -\frac{1}{2}\gamma(\mathrm{Ric}\, X)$ up to his sign conventions). Now multiply by γ^a and sum:

$$X = \gamma^a\left(R_{abcd}\gamma^b\gamma^c\gamma^d\right) \overset{(1)}{=} -2\,\mathrm{Ric}_{ad}\,\gamma^a\gamma^d \overset{(2)}{=} -2\,\mathrm{Ric}_{ad}\,\tfrac{1}{2}\{\gamma^a, \gamma^d\} \overset{(3)}{=} -2\,\mathrm{Ric}_{aa} = -2R.$$

(1) (T4.89).
(2) Ric is symmetric, so only the symmetric part of $\gamma^a\gamma^d$ survives.
(3) Clifford relation; the trace of the Ricci tensor is the scalar curvature.

Insert into (T4.87): $D^2 = \nabla^*\nabla - \frac{1}{8}(-2R) = \nabla^*\nabla + \frac{R}{4}$. That is (T4.85).

Worked example T4.49: checking the four-gamma identity on a round sphere

The unit sphere S^n has $R_{abcd} = \delta_{ac}\delta_{bd} - \delta_{ad}\delta_{bc}$ (sectional curvature 1). Then, with $\gamma^b\gamma^b = n$ and $\gamma^a\gamma^b\gamma^a = (2-n)\gamma^b$ (anticommute γ^b past γ^a for the $n-1$ values $a \neq b$),

$$X \overset{(1)}{=} \gamma^a\gamma^b\gamma^a\gamma^b - \gamma^a\gamma^b\gamma^b\gamma^a \overset{(2)}{=} (2-n)\gamma^b\gamma^b - n\,\gamma^a\gamma^a \overset{(3)}{=} (2-n)n - n^2 = -2n(n-1).$$

(1) Insert R_{abcd}; the two δ terms give the two orderings.
(2) $\gamma^a\gamma^b\gamma^a = (2-n)\gamma^b$ in the first term, $\gamma^b\gamma^b = n$ in the second.
(3) $\gamma^b\gamma^b = n$ again.

Since $R = n(n-1)$ for the unit sphere, $X = -2R$ as claimed. So on S^n, $D^2 = \nabla^*\nabla + \frac{n(n-1)}{4}$; on the unit S^2, $D^2 = \nabla^*\nabla + \frac{1}{2}$.

Worked example T4.50: the S^2 ground state: splitting $\lambda^2 = 1$ into kinetic and curvature parts

Take the eigenspinor $\psi = \left(\cos\frac{\theta}{2},\ i\sin\frac{\theta}{2}\right)^{\mathsf{T}} e^{i\phi/2}$ of (T4.79) with $\lambda = +1$, and compute its covariant derivatives with the spin connection $\Omega = -\frac{i}{2}\cos\theta\,\sigma_3\,\mathrm{d}\phi$ of Example T4.41. Along $e_1 = \partial_\theta$, $\Omega(e_1) = 0$:

$$\nabla_{e_1}\psi \overset{(1)}{=} \left(-\tfrac{1}{2}\sin\tfrac{\theta}{2},\ \tfrac{i}{2}\cos\tfrac{\theta}{2}\right)^{\mathsf{T}} e^{i\phi/2} \overset{(2)}{=} \tfrac{i}{2}\,\gamma_1\psi.$$

(1) Differentiate the components.

(2) $\gamma_1 = \sigma_1$ swaps the components: $\frac{i}{2}\sigma_1\psi = \frac{i}{2}\left(i\sin\frac{\theta}{2}, \cos\frac{\theta}{2}\right)^{\mathsf{T}} e^{i\phi/2}$.

Along $e_2 = \frac{1}{\sin\theta}\partial_\phi$, $\partial_\phi \to \frac{i}{2}$ and $\Omega(\partial_\phi) = -\frac{i}{2}\cos\theta\,\sigma_3$:

$$\nabla_{e_2}\psi \overset{(1)}{=} \frac{1}{\sin\theta}\left[\frac{i}{2}\begin{pmatrix}\cos\frac{\theta}{2}\\ i\sin\frac{\theta}{2}\end{pmatrix} - \frac{i}{2}\cos\theta\begin{pmatrix}\cos\frac{\theta}{2}\\ -i\sin\frac{\theta}{2}\end{pmatrix}\right]e^{i\phi/2} \overset{(2)}{=} \frac{1}{\sin\theta}\begin{pmatrix}\frac{i}{2}(1-\cos\theta)\cos\frac{\theta}{2}\\ -\frac{1}{2}(1+\cos\theta)\sin\frac{\theta}{2}\end{pmatrix}e^{i\phi/2}$$
$$\overset{(3)}{=} \begin{pmatrix}\frac{i}{2}\sin\frac{\theta}{2}\\ -\frac{1}{2}\cos\frac{\theta}{2}\end{pmatrix}e^{i\phi/2} \overset{(4)}{=} \tfrac{i}{2}\,\gamma_2\psi.$$

(1) $\nabla_{e_2} = \frac{1}{\sin\theta}(\partial_\phi + \Omega(\partial_\phi))$ and $\sigma_3 = \mathrm{diag}(1,-1)$.

(2) Collect terms; $\frac{i}{2}\cdot i = -\frac{1}{2}$.

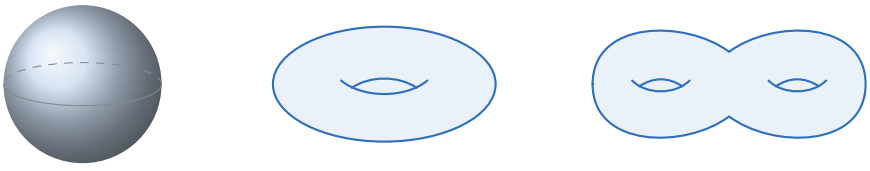
(3) $1-\cos\theta = 2\sin^2\frac{\theta}{2}$, $1+\cos\theta = 2\cos^2\frac{\theta}{2}$, $\sin\theta = 2\sin\frac{\theta}{2}\cos\frac{\theta}{2}$.

(4) $\sigma_2(a,b)^{\mathsf{T}} = (-ib, ia)^{\mathsf{T}}$, so $\frac{i}{2}\sigma_2\psi = \frac{i}{2}\left(\sin\frac{\theta}{2},\ i\cos\frac{\theta}{2}\right)^{\mathsf{T}} e^{i\phi/2}$.

So $\nabla_X\psi = \frac{i}{2}\gamma(X)\psi$ for every X: ψ is a **Killing spinor**. Consistency: $D\psi = -i\gamma^a\cdot\frac{i}{2}\gamma_a\psi = \frac{1}{2}\gamma^a\gamma_a\psi = \frac{n}{2}\psi = \psi$. ✓ Its kinetic energy density is $|\nabla\psi|^2 = \sum_a |\frac{i}{2}\gamma_a\psi|^2 = 2\cdot\frac{1}{4}|\psi|^2 = \frac{1}{2}|\psi|^2$ (each γ_a is unitary). Hence

$$\lambda^2\|\psi\|^2 = \|D\psi\|^2 = \underbrace{\|\nabla\psi\|^2}_{\frac{1}{2}\|\psi\|^2} + \underbrace{\int \tfrac{R}{4}|\psi|^2}_{\frac{1}{2}\|\psi\|^2} = \|\psi\|^2,$$

and the Lichnerowicz formula is verified on a nontrivial eigenspinor: half of $\lambda^2 = 1$ is kinetic, half is curvature.



S^2: $R = 2 > 0$
$D^2 \geq \frac{R}{4} > 0$
no zero modes

T^2: $R = 0$
$D^2 = \nabla^*\nabla$
zero modes = parallel spinors

genus 2: $R = -2 < 0$
no constraint from R
zero modes may exist

Figure T4.23: What the Lichnerowicz formula $D^2 = \nabla^*\nabla + R/4$ says for surfaces of constant curvature. For positive R both terms are non-negative and the curvature term strictly positive, so D cannot vanish on a nonzero spinor. For $R = 0$ a zero mode must be parallel ($\nabla\psi = 0$): the constant spinors of the $(+,+)$ torus. For negative R the curvature term pulls the other way and the formula gives no obstruction; whether harmonic spinors exist then depends on the conformal structure and the spin structure.

Watch out: which Laplacian?

D^2 is *not* the rough Laplacian $\nabla^*\nabla$, and neither of them is the Hodge Laplacian of forms. Three different "Laplacians" act on three different bundles, and each Weitzenböck formula relates two of them: $D^2 = \nabla^*\nabla + \frac{R}{4}$ on spinors, $\Delta = \nabla^*\nabla + \mathrm{Ric}$ on 1-forms (Section T4.9.5), and $D_A^2 = \nabla^*\nabla + \frac{R}{4} - \gamma(F)$ on charged spinors (Section T4.8.4). On flat space with no gauge field all of them reduce to $-\sum \partial_a^2$ acting componentwise.

T4.8.3 Consequences: harmonic spinors and positive curvature

A **harmonic spinor** is a solution of $D\psi = 0$, a zero mode. The Lichnerowicz formula gives two quick results, both obtained by pairing (T4.85) with ψ and integrating.

Key idea: no harmonic spinors in positive scalar curvature [Bär Cor. 2.5.12–2.5.13]

Let M be closed and connected.

1. If $R \geq 0$, every harmonic spinor is parallel, $\nabla\psi = 0$. Hence $\dim \ker D \leq 2^{\lfloor n/2 \rfloor}$, the rank of the spinor bundle.
2. If moreover $R > 0$ somewhere, there are no harmonic spinors at all.

Here is the whole argument. Let $D\psi = 0$. Then

$$0 \overset{(1)}{=} \|D\psi\|^2 \overset{(2)}{=} (D^2\psi, \psi) \overset{(3)}{=} (\nabla^*\nabla\psi, \psi) + \int_M \frac{R}{4}|\psi|^2 \,\mathrm{vol} \overset{(4)}{=} \|\nabla\psi\|^2 + \int_M \frac{R}{4}|\psi|^2 \,\mathrm{vol}. \tag{T4.90}$$

(1) $D\psi = 0$.
(2) D is formally self-adjoint (Section T4.7.3).
(3) Lichnerowicz (T4.85).
(4) (T4.83).

If $R \geq 0$ both terms on the right are ≥ 0 and they add to zero, so each vanishes: $\nabla\psi = 0$. A parallel section is determined by its value at one point (solve the transport equation along paths from that point), which gives the dimension bound. For part 2: $\nabla\psi = 0$ implies $\mathrm{d}|\psi|^2 = 2\,\mathrm{Re}\langle\nabla\psi, \psi\rangle = 0$, so $|\psi|$ is a constant c, and the second term is $\frac{c^2}{4}\int_M R \,\mathrm{vol}$. It vanishes only if $c = 0$, because $\int_M R > 0$ when $R \geq 0$ everywhere and $R > 0$ on some open set.

Checks. The $(+,+)$ torus has $R = 0$ and two harmonic spinors, the constants: parallel, and $2 = 2^{\lfloor 2/2 \rfloor}$ saturates the bound. The other three torus spin structures have no parallel spinors (a constant is not antiperiodic), hence no zero modes, as found in Example T4.45. The round S^2 has $R = 2$ and no zero modes, as found in (T4.81).

A spectral gap. The same computation with $D\psi = \lambda\psi$ and $R \geq s_0 > 0$ gives [Bär (2.36)]

$$\lambda^2\|\psi\|^2 = \|\nabla\psi\|^2 + \int_M \tfrac{R}{4}|\psi|^2 \;\geq\; \tfrac{s_0}{4}\|\psi\|^2 \quad\Longrightarrow\quad |\lambda| \geq \tfrac{1}{2}\sqrt{s_0}.$$

On the unit S^2 this says $|\lambda| \geq 1/\sqrt{2} \approx 0.71$, but the true answer is $|\lambda| \geq 1$. The estimate throws away $\|\nabla\psi\|^2$ entirely, and we saw in Example T4.50 that half of λ^2 is kinetic. A better estimate keeps part of it.

Friedrich's inequality. The trick is to bound the kinetic term from below *by D itself*. At each point, with $\psi_a := \nabla_a \psi$,

$$|D\psi|^2 = \Big|\sum_a \gamma^a \psi_a\Big|^2 \overset{(1)}{\leq} \Big(\sum_a |\gamma^a \psi_a|\Big)^2 \overset{(2)}{=} \Big(\sum_a |\psi_a|\Big)^2 \overset{(3)}{\leq} n \sum_a |\psi_a|^2 = n\,|\nabla\psi|^2. \tag{T4.91}$$

(1) Triangle inequality (the $-i$ in D does not change norms).
(2) Each γ^a is Hermitian with square $\mathbf{1}$, hence unitary: $|\gamma^a \phi| = |\phi|$ [Bär (2.38)].
(3) Cauchy–Schwarz for the vectors $(1,\dots,1)$ and $(|\psi_1|,\dots,|\psi_n|)$ in $\mathbb{R}^n$.

Now let $D\psi = \lambda\psi$ and $R \geq s_0 > 0$:

$$\lambda^2 \|\psi\|^2 = \|D\psi\|^2 \overset{(1)}{=} \|\nabla\psi\|^2 + \int_M \tfrac{R}{4}|\psi|^2 \overset{(2)}{\geq} \tfrac{1}{n}\|D\psi\|^2 + \tfrac{s_0}{4}\|\psi\|^2 = \tfrac{\lambda^2}{n}\|\psi\|^2 + \tfrac{s_0}{4}\|\psi\|^2.$$

(1) (T4.90) without setting $D\psi = 0$.
(2) Integrate (T4.91), and $R \geq s_0$.

Rearranging gives **Friedrich's inequality** [Bär Thm. 2.5.15, (2.37)]:

$$\lambda^2 \;\geq\; \frac{n}{n-1}\,\frac{s_0}{4}. \tag{T4.92}$$

When is it sharp? Equality needs equality in both steps of (T4.91): all $\gamma^a\psi_a$ must be parallel vectors of the same length. The solutions are exactly the Killing spinors, $\nabla_X\psi = \mu\,\gamma(X)\psi$ with constant μ; then $D\psi = -i\mu\gamma^a\gamma_a\psi = -in\mu\,\psi$, so $\mu = i\lambda/n$. On the unit S^2 we found such a spinor in Example T4.50 with $\mu = \frac{i}{2}$, $\lambda = 1$, and indeed (T4.92) with $n = 2$, $s_0 = 2$ gives $\lambda^2 \geq 1$: *equality*. On the unit S^n, $s_0 = n(n-1)$ and Friedrich gives $|\lambda| \geq n/2$, which is exactly the smallest eigenvalue of the round sphere (the full spectrum is $\pm(\frac{n}{2}+k)$, $k = 0,1,2,\dots$, generalising $\pm(l+1)$ for $n = 2$) [Bär Rem. 2.5.16].

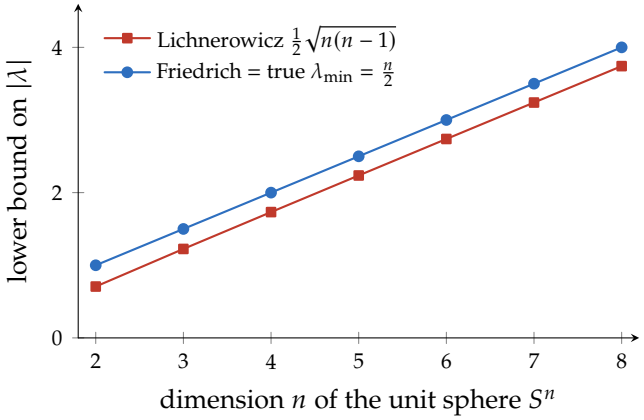


Figure T4.24: Two lower bounds for the smallest Dirac eigenvalue on the unit sphere S^n. The Lichnerowicz gap $\frac{1}{2}\sqrt{s_0}$ (red) discards all kinetic energy and is never attained. Friedrich's bound (blue) keeps a fraction $\frac{1}{n}$ of it and coincides with the true lowest eigenvalue $n/2$, attained by Killing spinors.

A bound with no curvature assumption. On a two-sphere something even stronger holds. Bär proved [Bär Thm. 2.5.17, (2.40)] that for *every* Riemannian metric on S^2,

$$\lambda^2 \;\geq\; \frac{4\pi}{\operatorname{area}(S^2, g)}. \tag{T4.93}$$

Check on the round sphere of radius r: $\lambda_{\min} = 1/r$ and the area is $4\pi r^2$, so $\lambda_{\min}^2 = 1/r^2 = 4\pi/(4\pi r^2)$, equality. Bär also shows that equality characterises constant curvature. Unlike Friedrich's bound this needs no sign of R; it reflects the topology (a two-sphere has a unique spin structure, and its spinor bundle is "twisted" by $c_1(S^\pm) = \mp 1$). By contrast, every closed orientable surface of genus ≥ 1, and S^3, admit metrics with harmonic spinors [Bär Rem. 2.5.18], so no such estimate can hold there. (Hitchin showed that in dimensions $n \equiv 0, 1, 7 \pmod 8$ there are metrics with harmonic spinors on many spin manifolds; this is where the mod-8 periodicity of Section T4.4.5 reappears in geometry.)

Dictionary: the Lichnerowicz term in physics

- **Fermion masses from curvature.** On $\mathbb{R} \times M$ a massless Dirac field has frequencies $\omega = \pm\lambda$, $\lambda \in \operatorname{spec} D_M$. Positive curvature gives a gap: fermions on a sphere of radius r cannot have energy below $1/r$. In a Kaluza–Klein compactification on a positively curved internal space there are therefore no massless fermions, a classic no-go argument (Witten, 1981) that pushes model builders towards Ricci-flat or gauge-twisted internal spaces.
- **Positive energy.** Witten's spinorial proof of the positive energy theorem in general relativity uses the Lichnerowicz formula on a spacelike slice: the ADM energy is written as $\|\nabla\psi\|^2$ plus $\frac{R}{4}|\psi|^2$, and the dominant energy condition makes the curvature term non-negative.

T4.8.4 Twisted Dirac operators

Physical fermions carry charges. An electron is a spinor *and* a section of a U(1) bundle; a quark is a spinor and a colour triplet. Mathematically the field lives in the tensor product $S \otimes E$ of the spinor bundle with a gauge bundle E (rank r, with a connection A). Locally ψ is a $2^{\lfloor n/2 \rfloor} \times r$ array: a spinor index and a gauge index.

Working definition T4.12 (twisted Dirac operator)

Let E carry a Hermitian metric and a unitary connection $\nabla^E = \mathrm{d} + A$ [parallel transport along any path preserves the inner product on the gauge index] with anti-Hermitian A_μ (house convention; for U(1) with charge 1, $A = -ia$ with the physicists' real potential a). On $S \otimes E$ use the product connection $\nabla_a = \nabla_a^S \otimes \mathbf{1} + \mathbf{1} \otimes \nabla_a^E$, i.e. in components

$$\nabla_\mu \psi = \partial_\mu \psi + \tfrac{1}{4}\omega_{ab\mu}\gamma^a\gamma^b\psi + A_\mu\psi,$$

with the gammas acting on the spinor index and A_μ on the gauge index. The **twisted Dirac operator** is

$$D_A\psi := -i\gamma^a\nabla_a\psi = -i\gamma^a e_a{}^\mu\big(\partial_\mu + \Omega_\mu + A_\mu\big)\psi. \tag{T4.94}$$

This is Bär's D^{∇^C} [Bär Def. 2.5.4, (2.26)] with $C = E$, and Nash's $\not{D}_F = \gamma^a e_a^\mu(\partial_\mu + \omega_\mu + A_\mu)$ [Nash p. 118].

Three properties carry over from D with no work.

1. *Same symbol.* A has no derivatives, so $\sigma_{D_A}(\xi) = \not{\xi} \otimes \mathbf{1}_E$ [Bär (1.34)]. Hence D_A is elliptic and of Dirac type [Bär Cor. 1.3.22]. The gauge field is "invisible to the symbol", which is why the index can depend on E only through topology.
2. *Self-adjoint.* If A is anti-Hermitian (a unitary connection), the proof of (T4.73) goes through

with $\langle\cdot,\cdot\rangle$ the metric of $S\otimes E$ [Bär Cor. 2.5.6].

3. *Chirality.* A commutes with Γ (it acts on the other index), so D_A still anticommutes with Γ and splits as $D_A^{\pm}:\Gamma(S^{\pm}\otimes E)\to\Gamma(S^{\mp}\otimes E)$. Nash's $\not{D}_F(1+\gamma_5)/2$ is D_A^+.

The square. Step 1 of the Lichnerowicz derivation used only Clifford algebra and $[\nabla_a,\nabla_b]=$ curvature. For the product connection the curvature is the sum, $[\nabla_a,\nabla_b]=R^S_{ab}\otimes\mathbf{1}+\mathbf{1}\otimes F_{ab}$, with $F=\mathrm{d}A+A\wedge A$ and $F_{ab}=F(e_a,e_b)$. So (T4.86) and Steps 2–3 give at once

$$D_A^2=\nabla^*\nabla+\frac{R}{4}-\gamma(F),\qquad \gamma(F):=\frac{1}{2}F_{ab}\,\gamma^a\gamma^b=\sum_{a<b}F_{ab}\,\gamma^a\gamma^b. \tag{T4.95}$$

Here $\gamma(F)$ is the Clifford action of the curvature 2-form: the gammas act on the spinor index, F_{ab} on the gauge index. This is Bär's formula $D^2=\nabla^*\nabla+\frac{\mathrm{scal}}{4}+\mathfrak{F}^E$ [Bär §5], with $\mathfrak{F}^E=\frac{1}{2}\sum e_ie_jF_{ij}=-\gamma(F)$ after $e_i\to -i\gamma_i$.

Dictionary: the Pauli term

With $A=-ia$, $F=-if$ ($f=\mathrm{d}a$ the physicists' field strength),

$$-\gamma(F)=\tfrac{i}{2}f_{ab}\gamma^a\gamma^b=-\tfrac{1}{2}f_{ab}\,\Sigma^{ab}_{\text{phys}},\qquad \Sigma^{ab}_{\text{phys}}:=-\tfrac{i}{2}[\gamma^a,\gamma^b]\ (a\neq b).$$

In three dimensions with $\gamma_j=\sigma_j$, $\gamma^1\gamma^2=i\sigma_3$ etc., this is $-\vec\sigma\cdot\vec B$: (T4.95) on flat $\mathbb{R}^3$ *is* the Pauli Hamiltonian $(\vec\sigma\cdot\vec\pi)^2=\vec\pi^{\,2}-\vec\sigma\cdot\vec B$ with gyromagnetic ratio $g=2$ (Example T4.2). In Minkowski QFT the same term is $\frac{e}{2}F_{\mu\nu}\sigma^{\mu\nu}$, obtained by squaring $i\not{D}$ [QFT notes §3.5]. The value $g=2$ is not an input: it is forced by the Clifford algebra.

Worked example T4.51: Landau levels of a Dirac fermion

Flat $\mathbb{R}^2$, $\gamma_1=\sigma_1$, $\gamma_2=\sigma_2$, $\Gamma=\sigma_3$, and a constant magnetic field $f_{12}=B>0$. Write $\pi_a=p_a-a_a$ with $p_a=-i\partial_a$, so that $D_A=\sigma_1\pi_1+\sigma_2\pi_2$. First the commutator:

$$[\pi_1,\pi_2]\overset{(1)}{=}-[p_1,a_2]-[a_1,p_2]\overset{(2)}{=}i\,\partial_1a_2-i\,\partial_2a_1=iB.$$

(1) $[p_1,p_2]=0=[a_1,a_2]$.
(2) $[p_a,g]=-i\,\partial_a g$ for a function g.

So π_1,π_2 are like x,p of a harmonic oscillator. With $b:=(\pi_1+i\pi_2)/\sqrt{2B}$ one checks $[b,b^\dagger]=\frac{1}{2B}\big(-i[\pi_1,\pi_2]+i[\pi_2,\pi_1]\big)=1$ and $\pi_1^2+\pi_2^2=B(2b^\dagger b+1)$. Now square D_A:

$$D_A^2\overset{(1)}{=}\pi_1^2+\pi_2^2+\sigma_1\sigma_2\pi_1\pi_2+\sigma_2\sigma_1\pi_2\pi_1\overset{(2)}{=}\pi_1^2+\pi_2^2+i\sigma_3[\pi_1,\pi_2]\overset{(3)}{=}B(2b^\dagger b+1)-B\sigma_3.$$

(1) Expand; $\sigma_1^2=\sigma_2^2=\mathbf{1}$.
(2) $\sigma_1\sigma_2=i\sigma_3=-\sigma_2\sigma_1$.
(3) $i\cdot iB=-B$, and the oscillator form of π^2.

This is (T4.95) with $R=0$ and $-\gamma(F)=-B\sigma_3$. With $N=b^\dagger b=0,1,2,\ldots$:

$$\operatorname{spec}D_A^2=\begin{cases}2NB & \text{on } S^+\ (\sigma_3=+1),\\ 2(N+1)B & \text{on } S^-\ (\sigma_3=-1),\end{cases}\qquad \operatorname{spec}D_A=\{0\}\cup\{\pm\sqrt{2mB}:m=1,2,\ldots\}.$$

The zero modes are the lowest Landau level of the spin-up component: $D_A^-D_A^+$ has the Landau spectrum shifted *down* by B, so its bottom lands exactly on zero. Every nonzero

level $2mB$ appears once in S^+ (with $N = m$) and once in S^- (with $N = m-1$): they pair up. Each Landau level has degeneracy $B/2\pi$ per unit area, i.e. one state per flux quantum. This is the relativistic Landau problem of graphene, where the zero-energy level is responsible for the anomalous half-integer quantum Hall effect.

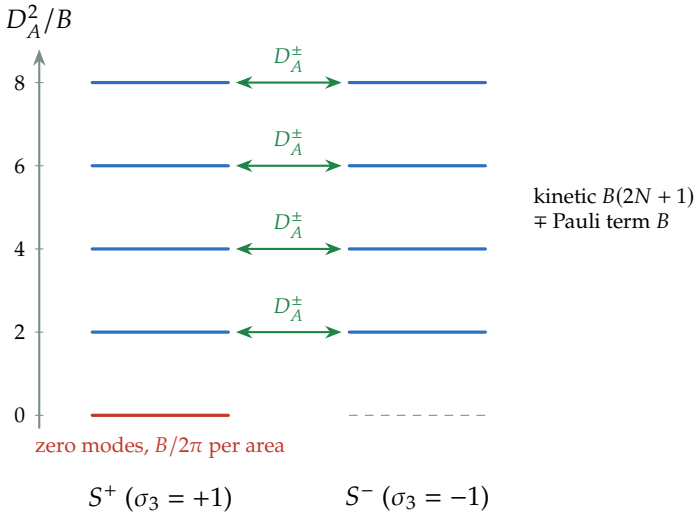

Figure T4.25: Landau levels of $D_A^2 = B(2b^\dagger b + 1) - B\sigma_3$ on $\mathbb{R}^2$. The Pauli term shifts the spin-up tower down and the spin-down tower up by B. Nonzero levels pair up between S^+ and S^- (green arrows: $D_A^\pm$ maps one onto the other). The bottom of the S^+ tower sits exactly at zero and has no partner: these unpaired zero modes are what the index counts.

Worked example T4.52: Aharonov–Casher: the number of zero modes is the flux

Now let $B(x,y) = f_{12}$ be any smooth field on $\mathbb{R}^2$ with compact support and total flux $\Phi = \int B\,\mathrm{d}x\,\mathrm{d}y > 0$. Choose the potential in Coulomb gauge through a scalar φ:

$$a_1 = -\partial_2\varphi, \quad a_2 = \partial_1\varphi \quad\Longrightarrow\quad f_{12} = \partial_1 a_2 - \partial_2 a_1 = \Delta_0\varphi := (\partial_1^2 + \partial_2^2)\varphi = B.$$

The solution is $\varphi(x) = \frac{1}{2\pi}\int \ln|x-y|\,B(y)\,\mathrm{d}^2y$ (the 2D Green's function), so far away $\varphi \approx \frac{\Phi}{2\pi}\ln r$. In complex notation (Example T4.43), $D_A^+ = -2i(\partial_{\bar z} - i a_{\bar z})$ with $a_{\bar z} = \frac{1}{2}(a_1 + i a_2)$. Then

$$-i a_{\bar z} \overset{(1)}{=} -\tfrac{i}{2}\big(-\partial_2\varphi + i\partial_1\varphi\big) = \tfrac{1}{2}(\partial_1 + i\partial_2)\varphi \overset{(2)}{=} \partial_{\bar z}\varphi,$$
$$D_A^+ \overset{(3)}{=} -2i\,(\partial_{\bar z} + \partial_{\bar z}\varphi) \overset{(4)}{=} -2i\,e^{-\varphi}\,\partial_{\bar z}\,e^{\varphi}.$$

(1) Insert the Coulomb-gauge potential.
(2) $\partial_{\bar z} = \frac{1}{2}(\partial_1 + i\partial_2)$.
(3) Substitute.
(4) $e^{-\varphi}\partial_{\bar z}(e^{\varphi}\psi) = \partial_{\bar z}\psi + (\partial_{\bar z}\varphi)\psi$.

So $D_A^+\psi_+ = 0$ iff $e^{\varphi}\psi_+$ is holomorphic: $\psi_+ = e^{-\varphi}h(z)$. The same steps give $D_A^- = -2i\,e^{\varphi}\partial_z e^{-\varphi}$, whose zero modes $e^{\varphi}\bar h(\bar z)$ grow like $r^{\Phi/2\pi}$ and are never normalisable. For ψ_+ normalisability decides everything. At large r, $|\psi_+| \approx r^{-\Phi/2\pi}|h|$, and for $h = z^k$

$$\int^\infty |\psi_+|^2\, r\,\mathrm{d}r \sim \int^\infty r^{2k-\Phi/\pi+1}\,\mathrm{d}r < \infty \iff 2k - \frac{\Phi}{\pi} + 1 < -1 \iff k < \frac{\Phi}{2\pi} - 1.$$

(Any h growing faster than a polynomial is excluded, and polynomials of degree k behave like z^k.) So the zero modes are $e^{-\varphi}z^k$ with $0 \le k < \Phi/2\pi - 1$, all of positive chirality:

$$n_+ = \left\lceil \frac{\Phi}{2\pi} \right\rceil - 1, \qquad n_- = 0. \tag{T4.96}$$

Up to the rounding, *the number of zero modes is the number of flux quanta*. For a uniform field this reproduces the lowest Landau level: $\varphi = \frac{B}{4}r^2$, $\psi_+ = z^k e^{-Br^2/4}$. For $\Phi < 0$ the roles of $S^\pm$ are exchanged. This is the Aharonov–Casher theorem (1979); it is the simplest non-trivial instance of the index theorem, whose answer here is $\frac{1}{2\pi}\int f = \Phi/2\pi$ (the rounding comes from $\mathbb{R}^2$ not being compact).

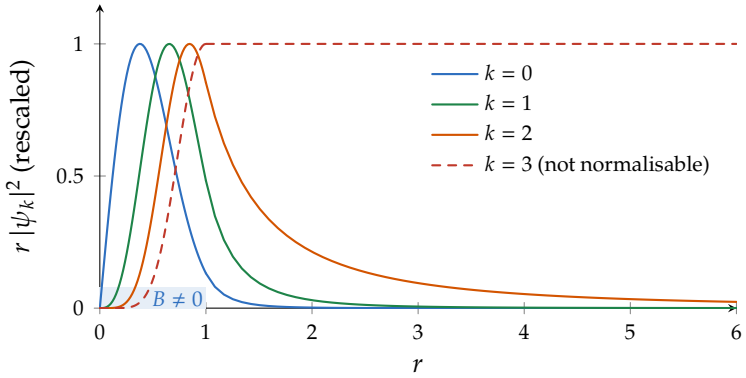

Figure T4.26: Aharonov–Casher zero modes $\psi_k = z^k e^{-\varphi}$ for a uniform flux tube of radius 1 carrying $\Phi/2\pi = 3.5$ flux quanta. Outside the tube $r|\psi_k|^2 \propto r^{2k+1-\Phi/\pi} = r^{2k-6}$. For $k = 0, 1, 2$ the density decays and the mode is normalisable; for $k = 3$ it tends to a constant (red, dashed) and the norm diverges. Three flux quanta (rounded down), three zero modes.

Worked example T4.53: a monopole on S^2: twisting the sphere

Let $L_k \to S^2$ be the line bundle of Chern number k (the Dirac monopole of charge $k/2$ in units where the minimal Dirac charge is $\frac{1}{2}$; see Chapter T3), with the rotationally invariant connection. Its curvature is a constant multiple of the area form, fixed by the Chern number:

$$\frac{i}{2\pi}\int_{S^2} F = k \implies F = -\frac{ik}{2}\, e^1 \wedge e^2, \qquad F_{12} = -\frac{ik}{2}.$$

(Check: $\frac{i}{2\pi}\cdot(-\frac{ik}{2})\cdot 4\pi = k$.) The Clifford action is $\gamma(F) = F_{12}\gamma^1\gamma^2 = (-\frac{ik}{2})(i\sigma_3) = \frac{k}{2}\sigma_3$, and $R/4 = \frac{1}{2}$ on the unit sphere, so (T4.95) reads

$$D_A^2 = \nabla^*\nabla + \frac{1}{2} - \frac{k}{2}\,\sigma_3 = \begin{cases} \nabla^*\nabla + \frac{1-k}{2} & \text{on } S^+ \otimes L_k, \\ \nabla^*\nabla + \frac{1+k}{2} & \text{on } S^- \otimes L_k. \end{cases} \tag{T4.97}$$

Read off, for $k \ge 0$:

- On $S^- \otimes L_k$ the potential is $\ge \frac{1}{2} > 0$, so there are *no* negative-chirality zero modes, by the argument (T4.90).
- $k = 0$: both potentials are $\frac{1}{2}$; no zero modes at all, as in (T4.81).
- $k = 1$: the potential vanishes on $S^+ \otimes L_1$. In fact $S^+ \otimes L_1$ is *flat*: its curvature is $\frac{i}{2}\mathrm{vol}$ (from S^+, Example T4.41) plus $-\frac{i}{2}\mathrm{vol}$ (from L_1). A flat line bundle on the simply connected S^2 has a parallel section, and that section is the unique zero mode: $n_+ = 1$.

- $k \geq 2$: the potential on $S^+ \otimes L_k$ is negative and zero modes are allowed. Their number is $n_+ = k$. The cleanest way to see it is holomorphic: on $S^2 = \mathbb{CP}^1$, D_A^+ is (a multiple of) $\bar\partial$ acting on sections of $S^+ \otimes L_k$, a line bundle of degree $-1 + k$ (Section T4.9.8). Holomorphic sections of the degree-$(k-1)$ bundle $\mathcal{O}(k-1)$ are the polynomials of degree $\leq k-1$ in the affine coordinate z: $1, z, \dots, z^{k-1}$, which is k of them.

The complete spectrum is known in closed form (Wu–Yang monopole harmonics): the eigenvalues are $\pm\sqrt{(j+\frac{1}{2})^2 - \frac{k^2}{4}}$ with $j = \frac{|k|-1}{2}, \frac{|k|+1}{2}, \dots$, each with multiplicity $2j+1$, and the value $j = \frac{|k|-1}{2}$ gives $|k|$ zero modes. For $k = 0$ this is $\pm(j+\frac{1}{2}) = \pm 1, \pm 2, \dots$ with multiplicities $2, 4, \dots$, our (T4.81).

Try it: the Pauli term on S^2

Show that for $k < 0$ the roles are reversed: $n_+ = 0$ and $n_- = |k|$. *Answer:* in (T4.97) the S^+ potential $\frac{1-k}{2} = \frac{1+|k|}{2}$ is now positive, and the S^- potential $\frac{1-|k|}{2}$ can be negative; the holomorphic count applies to the antiholomorphic side. In all cases $n_+ - n_- = k$.

T4.8.5 Chirality and the index: a preview

Every example so far had the same structure. The nonzero eigenvalues of D came in pairs, one in each chirality sector of D^2, and only the zero modes could be lopsided. Nash's Chapter 4 is about the number that measures the lopsidedness.

Working definition T4.13 (index of the Dirac operator)

In even dimension n, with $D^+ : \Gamma(S^+ \otimes E) \to \Gamma(S^- \otimes E)$ [D restricted to fields of chirality $\Gamma = +1$, which it maps to chirality -1] and its adjoint D^- (T4.75), let $n_\pm := \dim \operatorname{Ker} D^\pm$ be the numbers of positive and negative chirality harmonic spinors [independent solutions of $D\psi = 0$, i.e. zero modes]. The **index** is

$$\operatorname{index} D^+ := \dim \operatorname{Ker} D^+ - \dim \operatorname{Ker} D^- = n_+ - n_-. \tag{T4.98}$$

How to compute it in examples: find the zero modes and sort them by chirality. *How to compute it in general:* the Atiyah–Singer formula (T4.103) below.

Nash packages this as the **spin complex**, a two-term sequence $0 \to \Gamma(X, E^+) \xrightarrow{\not{D}} \Gamma(X, E^-) \to 0$ together with its symbol sequence [Nash (4.102)]; "elliptic complex" just means that the symbol $\sigma(\xi) = \not{\xi}$ is an isomorphism $S^+ \to S^-$ for $\xi \neq 0$, which is our $\not{\xi}^2 = |\xi|^2$. Since $D^- = (D^+)^*$ and $\operatorname{Ker} D = \operatorname{Ker} D^+ \oplus \operatorname{Ker} D^-$, the index is also $\dim \operatorname{Ker} D^+ - \dim \operatorname{Coker} D^+$.

Why the index is robust. The key fact is that nonzero eigenvalues pair. Write $D^2 = \operatorname{diag}(D^-D^+, D^+D^-)$ on $S^+ \oplus S^-$. Let $D^-D^+\psi = \mu\psi$ with $\psi \in \Gamma(S^+)$ and $\mu \neq 0$, and put $\chi := D^+\psi$. Then

$$D^+D^-\chi \overset{(1)}{=} D^+(D^-D^+\psi) = \mu\, D^+\psi = \mu\,\chi,$$
$$\|\chi\|^2 \overset{(2)}{=} (D^+\psi, D^+\psi) \overset{(3)}{=} (D^-D^+\psi, \psi) = \mu\|\psi\|^2 \neq 0.$$

(1) Associativity of composition and the eigenvalue equation.
(2) Definition of χ.

(3) D^- is the adjoint of D^+.

So D^+ maps the μ-eigenspace of D^-D^+ injectively into the μ-eigenspace of D^+D^-; by the same argument D^- maps back, and $\frac{1}{\mu}D^-D^+ = \mathbf{1}$ on the first space. The two eigenspaces are isomorphic for every $\mu \neq 0$. (This is the spectral pairing $\lambda \leftrightarrow -\lambda$ of Section T4.7.3, seen through D^2.) Only $\mu = 0$ can be unbalanced. Consequences:

- *Deformation invariance.* If we change the metric or the gauge field continuously, eigenvalues of D^2 move continuously. An eigenvalue can reach zero only together with its partner, so n_+ and n_- can jump only by the same amount. The difference is constant.
- *McKean–Singer formula.* For every $t > 0$

$$\operatorname{Tr}\big(\Gamma\, e^{-tD^2}\big) \overset{(1)}{=} \sum_{\mu} e^{-t\mu}\big(\dim E^+_\mu - \dim E^-_\mu\big) \overset{(2)}{=} n_+ - n_-. \tag{T4.99}$$

  (1) Diagonalise D^2 on S^+ and S^-; $\Gamma = \pm 1$ on the two sectors.
  (2) All terms with $\mu \neq 0$ cancel by the pairing.

  The left side can be computed as $t \to 0$ from purely local data (the short-time heat kernel), which is how the index theorem is proved in Chapter 4. In physics, $\operatorname{Tr}(-1)^F e^{-\beta H}$ with $H = D^2$ is the **Witten index** of supersymmetric quantum mechanics.

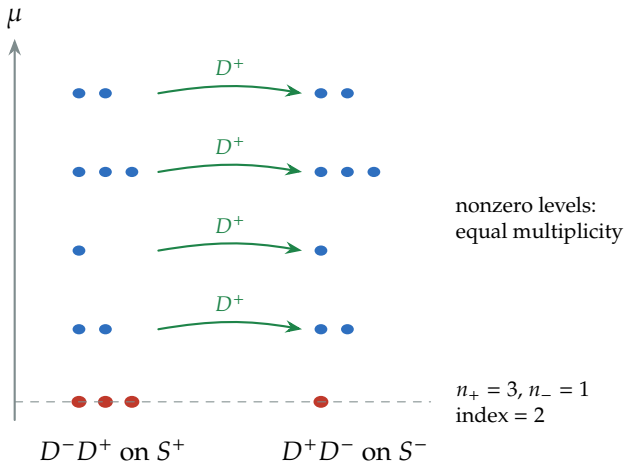

Figure T4.27: Why only zero modes count. For $\mu \neq 0$, D^+ is an isomorphism from the μ-eigenspace of D^-D^+ to that of D^+D^-, so the blue levels always have equal multiplicities on the two sides. Under deformations, levels may descend to zero, but only in pairs (one from each side), so $n_+ - n_-$ (red) cannot change.

The indices we have already computed.

manifold	twisting	n_+	n_-	index
T^2, $(+,+)$	none	1	1	0
T^2, other three	none	0	0	0
S^2	none	0	0	0
S^2	monopole L_k, $k > 0$	k	0	k
$\mathbb{R}^2$	flux Φ	$\lceil \Phi/2\pi \rceil - 1$	0	$\approx \Phi/2\pi$

The pattern is striking: in two dimensions the index is zero without a gauge field, and equal to the number of flux quanta $\frac{i}{2\pi}\int F = c_1(E)$ with one. The index theorem explains this and gives the answer in every dimension.

The index formula. Nash states the result in three steps [Nash (4.107)–(4.111)]. We follow them and fill in the algebra. Write the Pontryagin (or Chern) roots of TM as $\pm x_1, \dots, \pm x_k$ ($n = 2k$): formally, $TM \otimes \mathbb{C}$ splits into line bundles with first Chern classes $\pm x_i$, and $p_1 = \sum_i x_i^2$, $p_2 = \sum_{i<j} x_i^2 x_j^2$, $e(TM) = \prod_i x_i$.

Step 1: the Chern character of the spinor symbol. The weights of the spin representation are $\frac{1}{2}(\pm x_1 \pm \cdots \pm x_k)$: this is the Fock-space description of Section T4.4.2, where each of the k fermion modes is empty or full and a rotation by θ_i in the i-th plane acts with phases $e^{\pm i\theta_i/2}$. The even states make S^+, the odd ones S^-. So

$$\operatorname{ch} S^+ - \operatorname{ch} S^- = \prod_{i=1}^{k} \left(e^{x_i/2} - e^{-x_i/2}\right) \tag{T4.100}$$

up to an overall sign $(-1)^k$ fixed by which half is called S^+ (Nash's (4.107)). Check in $n = 2$: $S^\pm$ are line bundles with $c_1 = \mp\frac{x}{2}$, $x = e(TS^2)$. On S^2, $\int x = \chi = 2$ and $c_1(S^\pm) = \mp 1$, matching Example T4.41.

Step 2: divide by the Euler class and multiply by the Todd class. The general Atiyah–Singer recipe [Nash (4.108)] is index $= (-1)^k \{\operatorname{ch}(\sigma)\, e(TM)^{-1} \operatorname{td}(TM\otimes\mathbb{C})\}[M]$, with $\operatorname{td}(TM\otimes\mathbb{C}) = \prod_i \frac{x_i}{1-e^{-x_i}}\cdot\frac{-x_i}{1-e^{x_i}}$ (roots $\pm x_i$). For one root:

$$\begin{aligned} \frac{e^{x/2}-e^{-x/2}}{x}\cdot\frac{x}{1-e^{-x}}\cdot\frac{-x}{1-e^{x}} &\overset{(1)}{=} \frac{-x\left(e^{x/2}-e^{-x/2}\right)}{2-e^{x}-e^{-x}} \overset{(2)}{=} \frac{-x\left(e^{x/2}-e^{-x/2}\right)}{-\left(e^{x/2}-e^{-x/2}\right)^2} \\ &\overset{(3)}{=} \frac{x}{e^{x/2}-e^{-x/2}} = \frac{x/2}{\sinh(x/2)}. \end{aligned} \tag{T4.101}$$

(1) Cancel x against x, and multiply out $(1-e^{-x})(1-e^{x}) = 2 - e^{x} - e^{-x}$.
(2) $(e^{x/2}-e^{-x/2})^2 = e^{x} - 2 + e^{-x}$.
(3) Cancel one factor; $e^{y} - e^{-y} = 2\sinh y$.

Step 3: the $\hat{A}$ genus. So the index is the integral of

$$\hat{A}(M) := \prod_{i=1}^{k} \frac{x_i/2}{\sinh(x_i/2)} = 1 - \frac{p_1}{24} + \frac{7p_1^2 - 4p_2}{5760} + \cdots \tag{T4.102}$$

[Nash (4.109)–(4.110)]. The expansion is a two-line exercise. From $\frac{\sinh y}{y} = 1 + \frac{y^2}{6} + \frac{y^4}{120} + \dots$ with $y = x/2$:

$$\begin{aligned} \frac{x/2}{\sinh(x/2)} &\overset{(1)}{=} \left(1 + \frac{x^2}{24} + \frac{x^4}{1920}\right)^{-1} \overset{(2)}{=} 1 - \frac{x^2}{24} + \left(\frac{1}{576} - \frac{1}{1920}\right)x^4 = 1 - \frac{x^2}{24} + \frac{7x^4}{5760}, \\ \prod_i \left(1 - \frac{x_i^2}{24} + \frac{7x_i^4}{5760}\right) &\overset{(3)}{=} 1 - \frac{\sum x_i^2}{24} + \frac{7\sum x_i^4}{5760} + \frac{\sum_{i<j} x_i^2 x_j^2}{576} \overset{(4)}{=} 1 - \frac{p_1}{24} + \frac{7(p_1^2 - 2p_2) + 10p_2}{5760}. \end{aligned}$$

(1) $y^2/6 = x^2/24$ and $y^4/120 = x^4/1920$.
(2) $(1+u)^{-1} = 1 - u + u^2 - \dots$ with $u = \frac{x^2}{24} + \frac{x^4}{1920}$; the x^4 terms are $\frac{x^4}{576} - \frac{x^4}{1920}$, and $\frac{1}{576} - \frac{1}{1920} = \frac{10-3}{5760}$.
(3) Multiply out to fourth order.
(4) $\sum x_i^4 = p_1^2 - 2p_2$, $\sum_{i<j} x_i^2 x_j^2 = p_2$, and $\frac{1}{576} = \frac{10}{5760}$.

The last numerator is $7p_1^2 - 4p_2$, which is Nash's (4.110).

Key idea: the index theorem for Dirac operators [Nash (4.111), (4.122)]

On a closed even-dimensional spin manifold, with E a gauge bundle with connection,

$$\operatorname{index} D_A^+ = \int_M \hat{A}(M)\, \operatorname{ch}(E)\Big|_{\text{top degree}} \tag{T4.103}$$

(up to the orientation sign $(-1)^{n/2}$ that Nash keeps explicitly). With no twisting ($\operatorname{ch} E = 1$) only the degree-n part of $\hat{A}$ contributes, and since $\hat{A}$ has components only in degrees $0, 4, 8, \ldots$, *the untwisted index vanishes unless* $4 \mid n$.

Worked example T4.54: the index formula in two and four dimensions

$n = 2$. $\hat{A} = 1 + (\text{degree} \geq 4)$, so $\hat{A}$ contributes only its 1, and $\operatorname{ch} E = \operatorname{rk} E + c_1(E) + \ldots$ contributes its 2-form part:

$$\operatorname{index} D_A^+ \overset{(1)}{=} \int_M c_1(E) \overset{(2)}{=} \frac{i}{2\pi} \int_M \operatorname{tr} F.$$

(1) The top-degree part of $\hat{A} \operatorname{ch} E$ in two dimensions.
(2) House convention for c_1.

Untwisted: 0 on every surface (torus and sphere, as found). Monopole L_k on S^2: k. Flux on $\mathbb{R}^2$: $\Phi/2\pi$, which Aharonov–Casher confirmed up to the boundary rounding.
$n = 4$, **untwisted.** $\operatorname{index} D^+ = -\frac{1}{24}\int_M p_1$. The Hirzebruch signature theorem (Section T4.9.7) gives $\int p_1 = 3\sigma(M)$, so

$$\operatorname{index} D^+ = -\frac{\sigma(M)}{8}. \tag{T4.104}$$

The K3 surface has $\sigma = -16$, so $\hat{A} = 2$: two harmonic spinors (in fact parallel ones, since K3 carries a Ricci-flat metric). For $\mathbb{CP}^2$, $\sigma = 1$ and the formula would give $-\frac{1}{8}$, *not an integer*. There is no contradiction: $\mathbb{CP}^2$ is not spin (Example T4.37), so there is no Dirac operator whose index this could be. The fractional answer is the index theorem's own way of detecting $w_2 \neq 0$.
$n = 4$, **twisted by an** SU(2) **bundle.** $\operatorname{ch} E = 2 + \operatorname{ch}_2(E)$ with $\operatorname{ch}_2 = \frac{1}{2}\operatorname{tr}\left(\frac{iF}{2\pi}\right)^2 = -\frac{1}{8\pi^2}\operatorname{tr} F \wedge F$ (and $c_1 = 0$). So

$$\operatorname{index} D_A^+ \overset{(1)}{=} \int_M \operatorname{ch}_2(E) + 2\int_M \left(-\frac{p_1}{24}\right) \overset{(2)}{=} -\frac{1}{8\pi^2}\int_M \operatorname{tr} F \wedge F - \frac{\sigma(M)}{4}.$$

(1) Degree-4 part of $(1 - \frac{p_1}{24})(2 + \operatorname{ch}_2)$.
(2) Definitions, and $\int p_1 = 3\sigma$.

On S^4 ($\sigma = 0$) the index is minus the instanton number $k = \frac{1}{8\pi^2}\int \operatorname{tr} F \wedge F$ of the house convention: an instanton of charge k has $|k|$ fermion zero modes of one chirality in the fundamental representation. These are 't Hooft's zero modes, the source of instanton-induced fermion interactions and of the anomaly (Chapter 8, Chapter 10).

Key idea: Lichnerowicz meets Atiyah–Singer

Combine Section T4.8.3 with (T4.103). If a closed spin manifold carries *some* metric with $R > 0$, then $\operatorname{Ker} D = 0$ for that metric, hence $\operatorname{index} D^+ = 0$; but the index does not depend

on the metric. So

$$\hat{A}(M) \neq 0 \quad \Longrightarrow \quad M \text{ admits no metric of positive scalar curvature.}$$

Example: the K3 surface ($\hat{A} = 2$). A differential-geometric question (can the curvature be positive?) has been answered by a topological invariant computed from zero modes. This is the prototype of every argument in Nash's book: *count zero modes analytically, compute them topologically, and compare*.

Reading Nash (pp. 113–118, (4.96)–(4.122))

Nash's treatment of the Dirac operator as an index problem occupies pp. 113–116, and the twisted version is on p. 118. The correspondences are: spinor bundles $E^{\pm}$ (4.98) = our $S^{\pm}$; $\not{D}$ (4.100) = $-D$; chiral operator $\not{D}(1+\gamma_5)/2$ (4.102) = our D^+ (up to sign); harmonic spinors $\Psi^{\pm}$ (4.104) = our $\operatorname{Ker} D^{\pm}$; $\operatorname{index}\not{D} = n^+ - n^-$ (4.106) = (T4.98); the character formula (4.107) = (T4.100); the passage (4.108) from $\operatorname{ch}/e \cdot \operatorname{td}$ to $\prod \frac{x_i/2}{\sinh(x_i/2)}$ = our chain (T4.101); $\hat{A}$ and its expansion (4.109)–(4.110) = (T4.102); (4.111) and the twisted (4.122) = (T4.103). The sign $(-1)^{n/2}$ in Nash depends on his choice of γ_5 and orientation; in our conventions (with $\Gamma = \sigma_3$ in two dimensions and positive flux) (T4.103) holds with a plus sign, as the Aharonov–Casher and monopole examples confirm. Nash does not discuss the Lichnerowicz formula; it is the standard route to the vanishing results he uses implicitly.

Recap

- The rough Laplacian $\nabla^*\nabla = -\sum(\nabla_a\nabla_a - \nabla_{\nabla_a e_a})$ is non-negative with kernel the parallel sections. Every Laplace-type operator is $\nabla^*\nabla + K$.
- Lichnerowicz: $D^2 = \nabla^*\nabla + \frac{R}{4}$. Proof: split $\gamma^a\gamma^b\nabla_a\nabla_b$ into symmetric part (rough Laplacian) and antisymmetric part (curvature), then $R_{abcd}\gamma^a\gamma^b\gamma^c\gamma^d = -2R$ by the three-gamma identity and Bianchi.
- $R \geq 0$: harmonic spinors are parallel; $R > 0$ somewhere: none. Gap $|\lambda| \geq \frac{1}{2}\sqrt{s_0}$, improved by Friedrich to $\lambda^2 \geq \frac{n}{n-1}\frac{s_0}{4}$, sharp on round spheres (Killing spinors). On S^2, $\lambda^2 \geq 4\pi/\text{area}$ for every metric.
- Twisted: $D_A = -i\gamma^a(\nabla^S_a + A_a)$, $D_A^2 = \nabla^*\nabla + \frac{R}{4} - \gamma(F)$: the Pauli term with $g = 2$. Landau levels, Aharonov–Casher ($n_+ \approx \Phi/2\pi$) and the monopole on S^2 ($n_+ - n_- = k$).
- Nonzero modes pair between chiralities, so $\operatorname{index} D^+ = n_+ - n_-$ is deformation invariant and equals $\operatorname{Tr}\Gamma e^{-tD^2}$. Formula: $\int \hat{A}\,\operatorname{ch} E$, $\hat{A} = 1 - \frac{p_1}{24} + \dots$. Positive scalar curvature forces $\hat{A} = 0$.

T4.9 Differential forms as Clifford modules

Everything so far needed a spin structure. On $\mathbb{CP}^2$ there is none (Example T4.37), so on $\mathbb{CP}^2$ there is no Dirac operator D acting on spinors. And yet $\mathbb{CP}^2$ has a perfectly good Laplacian on differential forms, a Hodge theory, an Euler characteristic ($\chi = 3$), a signature ($\sigma = 1$) and Nash computes all of these as indices of elliptic operators [Nash pp. 103–112]. Where do those operators come from, if there are no spinors?

The answer is the observation we made at the end of Section T4.2.6: the exterior algebra

already carries an action of the Clifford algebra. Wedging with a 1-form and contracting with it are a creation and an annihilation operator, and their sum and difference obey the Clifford relations. So the bundle of all forms $\Lambda^\bullet T^*M$ is a Clifford module on *every* Riemannian manifold, and the operator $\mathrm{d} + \mathrm{d}^*$ is a Dirac-type operator on it. The questions of this section are:

- What exactly is the Clifford action on forms? Can we write it as explicit matrices and check the relations?
- How are forms related to spinors? (Answer: a form is a spinor with an extra spinor index; in two dimensions, a 2×2 matrix whose columns are spinors.)
- Why is $\mathrm{d} + \mathrm{d}^*$ of Dirac type, and what are its zero modes? (Answer: harmonic forms, which are de Rham cohomology.)
- Which gradings of $\Lambda^\bullet$ anticommute with $\mathrm{d} + \mathrm{d}^*$, and what indices do they produce? (Answer: the Euler characteristic, the signature and, on complex manifolds, the arithmetic genus.)

These are the three "classical elliptic complexes" that Nash treats as examples of the index theorem before he reaches the spin complex. Here we build the operators; Chapter 4 computes their indices.

Notation. V is an oriented Euclidean space of dimension n (later $V = T^*_x M$) with orthonormal basis $e^1, \dots, e^n$. We identify vectors and covectors with the metric, so we write e^a and e_a interchangeably. For an increasing multi-index $I = (i_1 < \cdots < i_k)$ we write $e^I = e^{i_1} \wedge \cdots \wedge e^{i_k}$; these 2^n forms are an orthonormal basis of $\Lambda^\bullet V$. The degree operator N multiplies a k-form by k. Forms are complex-valued when we need eigenvalues, with the Hermitian inner product in which the e^I are orthonormal.

T4.9.1 Wedge and contraction: creation and annihilation operators

There are two natural linear maps on $\Lambda^\bullet V$ attached to a vector v.

Working definition T4.14 (exterior and interior multiplication)

For $v \in V$ define, on every form α,

$$\varepsilon(v)\alpha := v \wedge \alpha, \qquad \iota(v)\alpha := \iota_v \alpha,$$

[$\varepsilon(v)$ raises the degree of a form by one and $\iota(v)$ lowers it by one, like fermion creation and annihilation operators], where ι_v is the interior product ("feed v into the first slot", Chapter T1). *Operationally*, on a basis form: $\varepsilon(e^j)e^I$ is 0 if $j \in I$ and otherwise $\pm e^{I \cup \{j\}}$; $\iota(e^j)e^I$ is 0 if $j \notin I$ and otherwise $\pm e^{I \setminus \{j\}}$. The sign is $(-1)^s$ where s is the number of indices in I smaller than j (the number of swaps needed to move e^j to the front).

For example, in $\mathbb{R}^3$: $\varepsilon(e^2)e^{13} = e^2 \wedge e^1 \wedge e^3 = -e^{123}$ and $\iota(e^2)e^{123} = \iota_{e_2}(e^1 \wedge e^2 \wedge e^3) = -e^{13}$: in both cases one swap past e^1.

Physical picture: forms are a fermionic Fock space

Think of the n basis directions as n fermionic modes. The form $e^{i_1} \wedge \cdots \wedge e^{i_k}$ is the state with modes $i_1, \dots, i_k$ occupied; the function 1 is the vacuum. Wedging with e^j *creates* a fermion in mode j (and gives zero if it is already there: Pauli exclusion is $e^j \wedge e^j = 0$).

Contracting with e_j *annihilates* it. The degree N is the fermion number. This is the same Fock space we met for spinors in Section T4.4.2, but with n modes instead of $n/2$, which is why forms have 2^n components and spinors only $2^{n/2}$.

The three anticommutators are the whole algebra.

Key idea: canonical anticommutation relations on forms

For all $u, v \in V$,

$$\{\varepsilon(u), \varepsilon(v)\} = 0, \qquad \{\iota(u), \iota(v)\} = 0, \qquad \{\varepsilon(u), \iota(v)\} = \langle u, v\rangle\, \mathbf{1}. \tag{T4.105}$$

Moreover $\iota(v)$ is the adjoint of $\varepsilon(v)$: $\varepsilon(v)^\dagger = \iota(v)$.

The first relation is the antisymmetry of the wedge product: $u \wedge v \wedge \alpha = -v \wedge u \wedge \alpha$. The second is the same statement for contractions, $\iota_u \iota_v \alpha = \alpha(v, u, \dots) = -\alpha(u, v, \dots) = -\iota_v \iota_u \alpha$. The third is the only one with content. We need the graded Leibniz rule for the interior product (Chapter T1): for a 1-form u and any form α, $\iota_v(u \wedge \alpha) = (\iota_v u)\,\alpha - u \wedge \iota_v \alpha$. Then

$$\begin{aligned} \{\varepsilon(u), \iota(v)\}\alpha &\overset{(1)}{=} u \wedge \iota_v \alpha + \iota_v(u \wedge \alpha) \\ &\overset{(2)}{=} u \wedge \iota_v \alpha + \langle u, v\rangle\, \alpha - u \wedge \iota_v \alpha \\ &\overset{(3)}{=} \langle u, v\rangle\, \alpha. \end{aligned} \tag{T4.106}$$

(1) Definition of the anticommutator: $\varepsilon(u)\iota(v) + \iota(v)\varepsilon(u)$.
(2) Graded Leibniz rule; $\iota_v u = u(v) = \langle u, v\rangle$ for a 1-form u.
(3) The two wedge terms cancel.

For the adjoint statement take $j \notin I$. Moving e^j to its place in $e^j \wedge e^I$ and moving it back out of $e^{I\cup\{j\}}$ to contract it take the same number s of swaps, so

$$\langle e^{I\cup\{j\}}, \varepsilon(e^j) e^I\rangle = (-1)^s = \langle \iota(e^j) e^{I\cup\{j\}}, e^I\rangle,$$

and all other matrix elements of both operators vanish. So in the orthonormal basis e^I the matrix of $\iota(e^j)$ is the transpose of the (real) matrix of $\varepsilon(e^j)$. Bär gives a basis-free version of the same argument [Bär Ex. 1.3.10]: split every form as $\alpha = \xi \wedge \alpha_\xi + \alpha_{\xi^\perp}$ with no ξ in $\alpha_\xi, \alpha_{\xi^\perp}$, and compare $\langle \xi \wedge \alpha, \beta\rangle$ with $\langle \alpha, \iota_\xi \beta\rangle$.

Now the Clifford algebra appears. From one creation and one annihilation operator we can form two Hermitian-or-anti-Hermitian combinations.

Working definition T4.15 (the two Clifford actions on forms)

For $v \in V$ put

$$c(v) := \varepsilon(v) - \iota(v), \qquad \hat{c}(v) := \varepsilon(v) + \iota(v). \tag{T4.107}$$

Then

$$\{c(u), c(v)\} = -2\langle u, v\rangle, \qquad \{\hat{c}(u), \hat{c}(v)\} = +2\langle u, v\rangle, \qquad \{c(u), \hat{c}(v)\} = 0. \tag{T4.108}$$

$c(v)$ is anti-Hermitian [$c(v)^\dagger = -c(v)$, because $\iota(v)$ is the adjoint of $\varepsilon(v)$] and squares to $-|v|^2$: it is Bär's Clifford multiplication (Chapter T4, conventions box). $\hat{c}(v)$ is Hermitian and squares to $+|v|^2$: it is a gamma matrix in our convention. The Hermitian gamma matrices that go with c are

$$\gamma(v) := i\, c(v) = i\big(\varepsilon(v) - \iota(v)\big), \qquad \gamma(v)^2 = |v|^2. \tag{T4.109}$$

Test: to check that a family of operators is a Clifford action, compute the three anticommutators in (T4.108) using only (T4.105) [ε's anticommute among themselves, ι's likewise, and $\{\varepsilon(u), \iota(v)\} = \langle u, v\rangle$].

Here is the computation of the first relation; the other two are identical in structure.

$$\{c(u), c(v)\} \overset{(1)}{=} \{\varepsilon(u), \varepsilon(v)\} - \{\varepsilon(u), \iota(v)\} - \{\iota(u), \varepsilon(v)\} + \{\iota(u), \iota(v)\}$$
$$\overset{(2)}{=} 0 - \langle u, v\rangle - \langle v, u\rangle + 0 = -2\langle u, v\rangle.$$

(1) The anticommutator is bilinear; expand $c = \varepsilon - \iota$ in both slots.
(2) (T4.105), and the inner product is symmetric.

For $\hat{c}$ the two middle terms come with + signs, giving $+2\langle u, v\rangle$. For the mixed one, $\{c(u), \hat{c}(v)\} = \{\varepsilon, \varepsilon\} + \{\varepsilon(u), \iota(v)\} - \{\iota(u), \varepsilon(v)\} - \{\iota, \iota\} = \langle u, v\rangle - \langle v, u\rangle = 0$. Anti-Hermiticity of c: $c(v)^\dagger = \iota(v) - \varepsilon(v) = -c(v)$ by the adjoint relation.

Watch out: two actions, not one

$\Lambda^\bullet V$ carries *two* anticommuting Clifford actions, c and $\hat{c}$. Together they give $2n$ anticommuting generators acting on a space of dimension 2^n, which is exactly the size of the irreducible spinor representation in $2n$ dimensions (Section T4.4). So $\Lambda^\bullet V$ is *the spinor space of* $V \oplus V$. As a module over one copy of $\mathrm{Cl}(V)$ it is far from irreducible: it is $2^{n/2}$ copies of the spinor space (for even n), as we will see in Section T4.9.2. When a formula says "Clifford multiplication on forms", check which of the two is meant.

Worked example T4.55: the Clifford action on $\Lambda^\bullet\mathbb{R}^2$ as 4×4 matrices

Order the basis of $\Lambda^\bullet\mathbb{R}^2$ as $(1,\ e^1,\ e^2,\ e^{12})$ and write a form as the column $(f, a_1, a_2, b)^{\mathsf{T}}$ for $\alpha = f + a_1 e^1 + a_2 e^2 + b\, e^{12}$. Read off the action of the four basic operators on the basis:

	1	e^1	e^2	e^{12}
$\varepsilon(e^1)$	e^1	0	e^{12}	0
$\iota(e^1)$	0	1	0	e^2
$\varepsilon(e^2)$	e^2	$-e^{12}$	0	0
$\iota(e^2)$	0	0	1	$-e^1$

(for instance $\varepsilon(e^2)e^1 = e^2 \wedge e^1 = -e^{12}$ and $\iota(e^2)e^{12} = \iota_{e_2}(e^1 \wedge e^2) = -e^1$). The columns of the matrices are the images of the basis vectors, so

$$c(e^1) = \begin{pmatrix} 0 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{pmatrix}, \quad c(e^2) = \begin{pmatrix} 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{pmatrix},$$

$$\hat{c}(e^1) = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}, \quad \hat{c}(e^2) = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{pmatrix}.$$

These are 2×2 block matrices, so they are Kronecker products. With $A \otimes B = \left(\begin{smallmatrix} a_{11}B & a_{12}B \\ a_{21}B & a_{22}B \end{smallmatrix}\right)$ and $J := -i\sigma_2 = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$,

$$c(e^1) = \mathbf{1} \otimes J, \qquad c(e^2) = J \otimes \sigma_3, \qquad \hat{c}(e^1) = \mathbf{1} \otimes \sigma_1, \qquad \hat{c}(e^2) = \sigma_1 \otimes \sigma_3. \tag{T4.110}$$

Now every relation is a one-line check with the rule $(A\otimes B)(C\otimes D)=AC\otimes BD$ of (T4.34). Using $J^2=-\mathbf{1}$, $\sigma_1 J=-J\sigma_1=\sigma_3$ and $\sigma_3 J=-J\sigma_3$:

$$c(e^2)c(e^1)+c(e^1)c(e^2)\overset{(1)}{=}J\otimes\sigma_3 J+J\otimes J\sigma_3\overset{(2)}{=}J\otimes(\sigma_3 J+J\sigma_3)=0,$$

$$c(e^1)^2\overset{(3)}{=}\mathbf{1}\otimes J^2=-\mathbf{1},\qquad c(e^2)^2\overset{(4)}{=}J^2\otimes\sigma_3^2=-\mathbf{1},$$

$$c(e^1)\hat{c}(e^1)+\hat{c}(e^1)c(e^1)\overset{(5)}{=}\mathbf{1}\otimes(J\sigma_1+\sigma_1 J)=0.$$

(1) Multiply slot by slot.
(2) Collect the common first factor J.
(3) $J^2=-\mathbf{1}$.
(4) $J^2=-\mathbf{1}$, $\sigma_3^2=\mathbf{1}$.
(5) J and σ_1 anticommute ($J=-i\sigma_2$).

The Hermitian gammas (T4.109) are $\gamma(e^1)=ic(e^1)=\mathbf{1}\otimes\sigma_2$ and $\gamma(e^2)=\sigma_2\otimes\sigma_3$, since $iJ=\sigma_2$. The parity of the degree is $(-1)^N=\mathrm{diag}(1,-1,-1,1)=\sigma_3\otimes\sigma_3$, and it anticommutes with all four generators. This is a Jordan–Wigner representation of the kind in (T4.35), with the σ_3 string on the other side (the sign in $e^2\wedge e^1=-e^{12}$ is what puts it there).

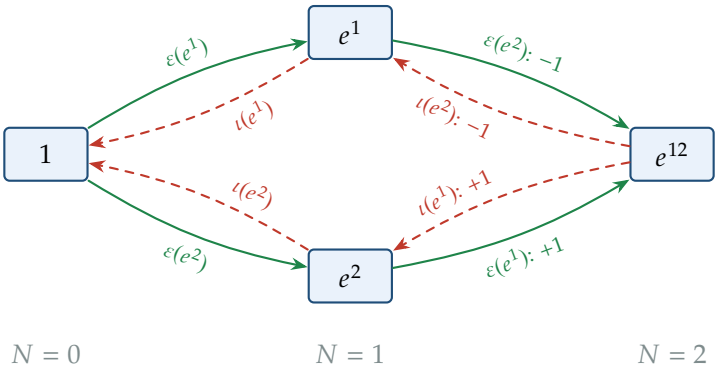

Figure T4.28: The exterior algebra of $\mathbb{R}^2$ as a two-mode fermionic Fock space. Green arrows are wedge products (creation operators), red dashed arrows are contractions (annihilation operators); the labels on the right-hand arrows are the signs. Following $\varepsilon(e^1)$ then $\varepsilon(e^2)$ from 1 gives $-e^{12}$ (top route), following them in the other order gives $+e^{12}$ (bottom route): that is $\{\varepsilon(e^1),\varepsilon(e^2)\}=0$. Going out and back along one mode, in either order, returns the state once: that is $\{\varepsilon(e^j),\iota(e^j)\}=1$.

T4.9.2 Forms are spinors with an extra spinor index

Dray says it in words [Dray §20.3]: "the space of formal sums of differential forms under the Clifford product is a Clifford algebra … spinors actually live in certain subspaces of Clifford algebras". Let us make the statement concrete.

Working definition T4.16 (the quantisation map)

Let $\gamma_1,\dots,\gamma_n$ be Hermitian gamma matrices, $\{\gamma_a,\gamma_b\}=2\delta_{ab}$. The **quantisation map** (or **symbol map** read backwards) sends a form to a matrix by replacing wedge products of basis 1-forms by products of gammas:

$$Q\big(e^{i_1}\wedge\cdots\wedge e^{i_k}\big):=\gamma_{i_1}\gamma_{i_2}\cdots\gamma_{i_k}\qquad(i_1<\cdots<i_k),\tag{T4.111}$$

extended linearly. It is a linear isomorphism $\Lambda^\bullet V \otimes \mathbb{C} \to \mathrm{Cl}(V) \otimes \mathbb{C}$ [$\mathrm{Cl}(V) \otimes \mathbb{C}$ is all complex linear combinations of products of the γ's] [Bär Rem. 2.1.15], but not an algebra map [it does not satisfy $Q(\alpha \wedge \beta) = Q(\alpha)Q(\beta)$ in general]: $Q(e^1 \wedge e^1) = 0 \neq \gamma_1\gamma_1 = \mathbf{1}$.

The point of Q is that it turns the action $\hat{c}$ into ordinary matrix multiplication from the left, and c into multiplication from the right:

$$Q\big(\hat{c}(v)\alpha\big) = \gamma(v)\,Q(\alpha), \qquad Q\big(c(v)\alpha\big) = (-1)^k\,Q(\alpha)\,\gamma(v) \quad (\alpha \in \Lambda^k), \tag{T4.112}$$

where on the right $\gamma(v) = v^a\gamma_a$. To check the first, take $v = e^j$ and a basis form e^I, with j in position p of $I \cup \{j\}$. If $j \notin I$, then $\gamma_j\gamma_{i_1}\cdots\gamma_{i_k}$ can be reordered into increasing order by moving γ_j past the $p-1$ smaller indices, each move costing a sign, which is exactly the sign in $e^j \wedge e^I$. If $j \in I$ (in position p), then

$$\gamma_j\,Q(e^I) \overset{(1)}{=} (-1)^{p-1}\,\gamma_{i_1}\cdots\gamma_{i_{p-1}}\,\gamma_j\gamma_j\,\gamma_{i_{p+1}}\cdots\gamma_{i_k} \overset{(2)}{=} (-1)^{p-1}\,Q\big(e^{I\setminus\{j\}}\big) \overset{(3)}{=} Q\big(\iota(e^j)e^I\big).$$

(1) Move γ_j to the right past the $p-1$ smaller gammas; they anticommute.
(2) $\gamma_j^2 = \mathbf{1}$.
(3) The contraction $\iota_{e_j}e^I$ has the same sign $(-1)^{p-1}$ (move e^j to the front).

In both cases $\gamma_j Q(e^I) = Q(\varepsilon(e^j)e^I + \iota(e^j)e^I) = Q(\hat{c}(e^j)e^I)$. The right multiplication rule is checked the same way; the extra $(-1)^k$ comes from moving γ_j past all k factors instead of the ones on its left.

Worked example T4.56: a form on $\mathbb{R}^2$ is a 2×2 matrix whose columns are spinors

Take $\gamma_1 = \sigma_1$, $\gamma_2 = \sigma_2$, so $\gamma_1\gamma_2 = \sigma_1\sigma_2 = i\sigma_3$. For $\alpha = f + a_1e^1 + a_2e^2 + b\,e^{12}$,

$$Q(\alpha) \overset{(1)}{=} f\,\mathbf{1} + a_1\sigma_1 + a_2\sigma_2 + b\,i\sigma_3 \overset{(2)}{=} \begin{pmatrix} f + ib & a_1 - ia_2 \\ a_1 + ia_2 & f - ib \end{pmatrix}. \tag{T4.113}$$

(1) Definition (T4.111).
(2) Write out the Pauli matrices.

The four real (or complex) components of α fill the four entries of a 2×2 matrix, and Q is invertible: $f = \frac{1}{2}\operatorname{tr} Q$, $b = -\frac{i}{2}\operatorname{tr}(\sigma_3 Q)$, and so on. Left multiplication by $\gamma(v)$ acts on each *column* separately, as a gamma matrix acts on a two-component spinor. So

$$\Lambda^\bullet\mathbb{R}^2 \otimes \mathbb{C} \;\cong\; \{2\times 2 \text{ matrices}\} \;=\; S \oplus S \;=\; S \otimes \mathbb{C}^2,$$

two copies of the spinor space $S = \mathbb{C}^2$, one per column. Check with $v = e^1$ and $\alpha = 1$: $\hat{c}(e^1)1 = e^1$ and indeed $\sigma_1 \cdot \mathbf{1} = \sigma_1 = Q(e^1)$. Check with $\alpha = e^{12}$: $\hat{c}(e^1)e^{12} = \iota_{e_1}e^{12} = e^2$, and $\sigma_1\,(i\sigma_3) = i\sigma_1\sigma_3 = i(-i\sigma_2) = \sigma_2 = Q(e^2)$.

The general statement follows from the classification of Section T4.4.3: for even n, $\mathrm{Cl}(V)\otimes\mathbb{C}$ is the full matrix algebra $\mathrm{End}(S)$ with $\dim S = 2^{n/2}$.

Key idea: forms are bispinors

For n even,

$$\Lambda^\bullet V \otimes \mathbb{C} \;\cong\; \mathrm{Cl}(V)\otimes\mathbb{C} \;\cong\; \mathrm{End}(S) \;=\; S \otimes S^*, \qquad 2^n = 2^{n/2}\cdot 2^{n/2}, \tag{T4.114}$$

with $\hat{c}$ acting on the S factor and c on the S^* factor. On a spin manifold this holds bundle-wise: $\Lambda^\bullet T^*M \otimes \mathbb{C} \cong S \otimes S^*$.

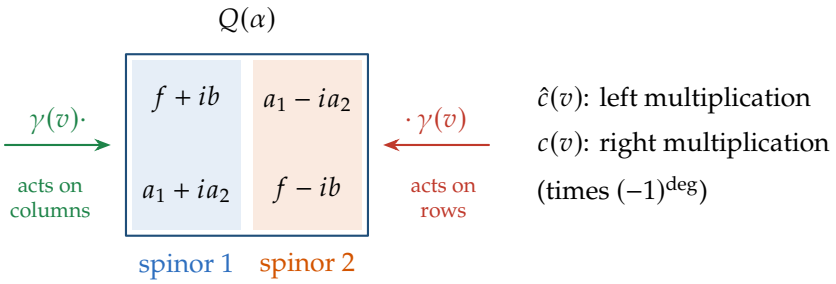

Figure T4.29: The quantisation map turns a form on $\mathbb{R}^2$ into a 2×2 matrix. The Clifford action $\hat{c}$ multiplies from the left and so acts on each column, which is therefore a spinor. The other action c multiplies from the right and acts on the row index. A form is a spinor with an extra (dual) spinor index: $\Lambda^\bullet \otimes \mathbb{C} \cong S \otimes S^*$.

Physical picture: why forms never need a spin structure

On a spin manifold the spinor bundle is glued with lifted transition functions $\tilde{g}_{\alpha\beta} \in \mathrm{Spin}(n)$, each defined only up to a sign, and the signs must be chosen consistently (Section T4.6.2). A bispinor $S \otimes S^*$ transforms with $\tilde{g} \otimes (\tilde{g}^{-1})^{\mathsf{T}}$, in which the sign appears *twice* and cancels. So the bundle $S \otimes S^*$ can be glued on any manifold, spin or not, and it is just $\Lambda^\bullet T^*M \otimes \mathbb{C}$. The same cancellation is why a vector ($\cong$ a traceless bispinor, cf. $X = x^\mu \sigma_\mu$ in Section T4.3.7) never notices the 2π sign. Every operator built on forms, in particular $\mathrm{d} + \mathrm{d}^*$, exists on every Riemannian manifold.

Dictionary: forms and fermions

- *Kähler–Dirac fermions.* The equation $(\mathrm{d} + \mathrm{d}^*)\Phi = 0$ for an inhomogeneous form Φ is equivalent to $2^{n/2}$ Dirac equations, one per column of $Q(\Phi)$ (Example T4.57 below). In four dimensions a form has 16 components: four Dirac spinors.
- *Staggered lattice fermions.* Lattice QCD exploits exactly this: placing the 2^4 components of a form on the corners of a hypercube gives a lattice Dirac operator with four "tastes" of quark, because a form is four spinors.
- *Supersymmetric quantum mechanics.* On the Fock space of forms, ε and ι are fermion creation and annihilation operators, and d and d^* are supercharges (Section T4.9.6, Chapter 7).

T4.9.3 The operator $\mathrm{d} + \mathrm{d}^*$ is of Dirac type

Now differentiate. Let M be an oriented Riemannian manifold, d the exterior derivative on $\Omega^\bullet(M)$ and d^* its formal adjoint, the **codifferential**, defined by $(\mathrm{d}\alpha, \beta) = (\alpha, \mathrm{d}^*\beta)$ for compactly supported forms, with $(\alpha, \beta) = \int_M \langle \alpha, \beta \rangle$ vol. In terms of the Hodge star (defined by $\alpha \wedge \star\beta = \langle \alpha, \beta \rangle$ vol, Chapter T1) it is [Bär Lemma 1.3.17]

$$\mathrm{d}^* = (-1)^{n(k+1)+1} \star \mathrm{d} \star \quad \text{on } k\text{-forms}, \qquad \text{so } \mathrm{d}^* = - \star \mathrm{d} \star \quad \text{for } n \text{ even}. \tag{T4.115}$$

For our purposes the more useful form is in terms of ε and ι.

Key idea: d and d^* in a frame

In any local orthonormal frame, with ∇ the Levi-Civita connection on forms,

$$\mathrm{d} = \sum_a \varepsilon(e^a)\,\nabla_{e_a}, \qquad \mathrm{d}^* = -\sum_a \iota(e^a)\,\nabla_{e_a}, \qquad \mathrm{d}+\mathrm{d}^* = \sum_a c(e^a)\,\nabla_{e_a} = -i\,\gamma^a\nabla_a. \tag{T4.116}$$

So $\mathrm{d}+\mathrm{d}^*$ has *exactly* the form of our Dirac operator $D = -i\gamma^a\nabla_a$ of (T4.72), with the spinor bundle replaced by $\Lambda^\bullet T^*M$ and the gammas by $\gamma(e^a) = ic(e^a)$ of (T4.109).

Why (T4.116) is true. In flat space with Cartesian coordinates, $\alpha = \frac{1}{k!}\alpha_{a_1\ldots a_k}e^{a_1}\wedge\cdots\wedge e^{a_k}$ with constant $e^a = \mathrm{d}x^a$, and $\mathrm{d}\alpha = \mathrm{d}x^a\wedge\partial_a\alpha$: this is the definition of d in components. The adjoint of a product is the product of adjoints in reverse order, so

$$\mathrm{d}^* \overset{(1)}{=} \Big(\sum_a \varepsilon(e^a)\,\partial_a\Big)^\dagger \overset{(2)}{=} \sum_a (\partial_a)^\dagger\,\varepsilon(e^a)^\dagger \overset{(3)}{=} \sum_a(-\partial_a)\,\iota(e^a) \overset{(4)}{=} -\sum_a \iota(e^a)\,\partial_a.$$

(1) The flat-space formula for d; d^* is its adjoint.
(2) $(AB)^\dagger = B^\dagger A^\dagger$.
(3) Integration by parts, $(\partial_a)^\dagger = -\partial_a$; and $\varepsilon^\dagger = \iota$ from (T4.105).
(4) $\iota(e^a)$ has constant coefficients, so it commutes with ∂_a.

On a curved manifold replace ∂_a by ∇_a. For d this is allowed because the Levi-Civita connection is torsion-free: the Christoffel symbols $\Gamma^\lambda_{\mu\nu}$ are symmetric in $\mu\nu$ and drop out when antisymmetrised by the wedge. For d^* the same integration by parts works with the divergence theorem, exactly as in the self-adjointness argument for D (T4.73). On a 1-form $\alpha = \alpha_a e^a$ the formula gives $\mathrm{d}^*\alpha = -\nabla_a\alpha_a = -\operatorname{div}\alpha$, which is the familiar statement that the adjoint of grad is $-\operatorname{div}$ (Example T4.4).

The symbol. Replacing ∇_a by $i\xi_a$ (Section T4.1.3) in (T4.116),

$$\sigma_{\mathrm{d}}(\xi) = i\,\varepsilon(\xi), \qquad \sigma_{\mathrm{d}^*}(\xi) = -i\,\iota(\xi), \qquad \sigma_{\mathrm{d}+\mathrm{d}^*}(\xi) = i\,c(\xi) = \gamma(\xi). \tag{T4.117}$$

The Dirac-type test of Section T4.1.3 is Bär's computation (1.15) in our language:

$$\begin{aligned}\sigma_{\mathrm{dd}^*+\mathrm{d}^*\mathrm{d}}(\xi) &\overset{(1)}{=} \sigma_{\mathrm{d}}(\xi)\sigma_{\mathrm{d}^*}(\xi) + \sigma_{\mathrm{d}^*}(\xi)\sigma_{\mathrm{d}}(\xi)\\ &\overset{(2)}{=} (i\varepsilon(\xi))(-i\iota(\xi)) + (-i\iota(\xi))(i\varepsilon(\xi))\\ &\overset{(3)}{=} \{\varepsilon(\xi),\iota(\xi)\} \overset{(4)}{=} |\xi|^2\,\mathbf{1}.\end{aligned} \tag{T4.118}$$

(1) Symbols of compositions multiply.
(2) (T4.117).
(3) $i\cdot(-i) = 1$.
(4) (T4.105) with $u = v = \xi$.

So $\Delta := \mathrm{dd}^* + \mathrm{d}^*\mathrm{d}$, the **Hodge Laplacian**, is of Laplace type, and since $(\mathrm{d}+\mathrm{d}^*)^2 = \mathrm{dd}^* + \mathrm{d}^*\mathrm{d}$ (because $\mathrm{d}^2 = 0 = (\mathrm{d}^*)^2$), the operator $\mathrm{d}+\mathrm{d}^*$ on $\Lambda^\bullet T^*M$ is a formally self-adjoint operator of Dirac type [Bär Ex. 1.3.10, Rem. 1.3.13]. This is how the gradient's failure (Example T4.4) is repaired: add the curl and the divergence and act on all degrees at once.

Worked example T4.57: $\mathrm{d}+\mathrm{d}^*$ on $\mathbb{R}^2$: the Cauchy–Riemann operator twice

Use the basis and matrices of Example T4.55. Then $\mathrm{d}+\mathrm{d}^* = c(e^1)\partial_1 + c(e^2)\partial_2$ acts on (f, a_1, a_2, b) as

$$(\mathrm{d}+\mathrm{d}^*)\begin{pmatrix} f \\ a_1 \\ a_2 \\ b \end{pmatrix} \overset{(1)}{=} \begin{pmatrix} -\partial_1 a_1 \\ \partial_1 f \\ -\partial_1 b \\ \partial_1 a_2 \end{pmatrix} + \begin{pmatrix} -\partial_2 a_2 \\ \partial_2 b \\ \partial_2 f \\ -\partial_2 a_1 \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} -(\partial_1 a_1 + \partial_2 a_2) \\ \partial_1 f + \partial_2 b \\ \partial_2 f - \partial_1 b \\ \partial_1 a_2 - \partial_2 a_1 \end{pmatrix}. \tag{T4.119}$$

(1) Multiply the columns by the matrices $c(e^1)$ and $c(e^2)$.
(2) Add.

Read the rows: the 0-form part is $-\operatorname{div} a$ (d^* of the 1-form), the 1-form part is grad f plus $\mathrm{d}^*(b\,e^{12}) = \partial_2 b\,e^1 - \partial_1 b\,e^2$, and the 2-form part is $\mathrm{d}a = (\partial_1 a_2 - \partial_2 a_1)e^{12}$, the curl. Applying the operator twice gives $-(\partial_1^2 + \partial_2^2)$ on every component (try it: the first row becomes $-\partial_1(\partial_1 f + \partial_2 b) - \partial_2(\partial_2 f - \partial_1 b) = -\nabla^2 f$).
The zero modes: $(\mathrm{d}+\mathrm{d}^*)\alpha = 0$ splits into an even part (rows 2 and 3 involve only f, b) and an odd part (rows 1 and 4 involve only a_1, a_2):

$$\partial_1 f = -\partial_2 b, \quad \partial_2 f = \partial_1 b \qquad \text{and} \qquad \partial_1 a_1 = -\partial_2 a_2, \quad \partial_1 a_2 = \partial_2 a_1.$$

The first pair is the Cauchy–Riemann system for $f - ib$; the second for $a_1 - ia_2$. So harmonic forms on $\mathbb{R}^2$ are *two* holomorphic functions, one for each column of $Q(\alpha)$: compare Example T4.43, where one harmonic spinor was one holomorphic function.
Finally, the columns. Under Q the operator $\sum_a \hat{c}(e^a)\partial_a = \mathrm{d} - \mathrm{d}^*$ becomes left multiplication $\sigma_1\partial_1 Q + \sigma_2\partial_2 Q = i\,D_{\mathrm{col}}Q$, where $D_{\mathrm{col}} = -i(\sigma_1\partial_1 + \sigma_2\partial_2)$ is our Dirac operator acting on each column. The two operators $\mathrm{d} \pm \mathrm{d}^*$ are unitarily equivalent: with $U := i^N$ (i^k on k-forms),

$$U\mathrm{d}U^{-1}\alpha \overset{(1)}{=} i^{k+1}\,\mathrm{d}(i^{-k}\alpha) = i\,\mathrm{d}\alpha, \qquad U\mathrm{d}^*U^{-1}\alpha \overset{(2)}{=} i^{k-1}\,\mathrm{d}^*(i^{-k}\alpha) = -i\,\mathrm{d}^*\alpha,$$

(1) d raises the degree by one.
(2) d^* lowers the degree by one; $i^{-1} = -i$.

so $U(\mathrm{d}+\mathrm{d}^*)U^{-1} = i(\mathrm{d}-\mathrm{d}^*)$, which under Q is $-D_{\mathrm{col}}$. Hence $\mathrm{d}+\mathrm{d}^*$ *on forms is unitarily equivalent to (minus) the Dirac operator acting on two spinors side by side.* This is the precise version of Dray's "the Dirac equation can be rewritten in terms of differential forms".

Worked example T4.58: $\mathrm{d}+\mathrm{d}^*$ on $\mathbb{R}^3$: grad, curl and div are one operator

On $\mathbb{R}^3$ identify a form with a quadruple of scalar and vector fields,

$$\alpha = f + A\cdot\mathrm{d}x + B_1\,e^{23} + B_2\,e^{31} + B_3\,e^{12} + g\,e^{123} \;\longleftrightarrow\; (f, \vec{A}, \vec{B}, g).$$

Then $\mathrm{d}f = \nabla f\cdot\mathrm{d}x$, $\mathrm{d}(A\cdot\mathrm{d}x) \leftrightarrow \nabla\times\vec{A}$, $\mathrm{d}(B) = (\nabla\cdot\vec{B})\,e^{123}$, and from $\mathrm{d}^* = -\sum_a \iota(e^a)\partial_a$:

$$\mathrm{d}^*(A\cdot\mathrm{d}x) \overset{(1)}{=} -\partial_a A_a = -\nabla\cdot\vec{A},$$
$$\mathrm{d}^*B \overset{(2)}{=} -\big[\partial_1(B_3e^2 - B_2e^3) + \partial_2(B_1e^3 - B_3e^1) + \partial_3(B_2e^1 - B_1e^2)\big] \overset{(3)}{=} (\nabla\times\vec{B})\cdot\mathrm{d}x,$$
$$\mathrm{d}^*(g\,e^{123}) \overset{(4)}{=} -\big(\partial_1 g\,e^{23} + \partial_2 g\,e^{31} + \partial_3 g\,e^{12}\big) \;\leftrightarrow\; -\nabla g.$$

(1) $\iota(e^a)e^b = \delta^{ab}$.
(2) $\iota_{e_1}B = B_3e^2 - B_2e^3$ (from $\iota_{e_1}e^{31} = -e^3$, $\iota_{e_1}e^{12} = e^2$), and cyclically.

(3) Collect the coefficient of each e^a: e.g. of e^1, $\partial_2 B_3 - \partial_3 B_2$.
(4) $\iota_{e_1} e^{123} = e^{23}$, $\iota_{e_2} e^{123} = -e^{13} = e^{31}$, $\iota_{e_3} e^{123} = e^{12}$.

So

$$(\mathrm{d} + \mathrm{d}^*)(f, \vec{A}, \vec{B}, g) = \big(-\nabla \cdot \vec{A},\ \ \nabla f + \nabla \times \vec{B},\ \ \nabla \times \vec{A} - \nabla g,\ \ \nabla \cdot \vec{B}\big). \tag{T4.120}$$

All of first-order vector calculus is one Dirac-type operator. Now square it. The 1-form component of $(\mathrm{d} + \mathrm{d}^*)^2$ is

$$\nabla(-\nabla \cdot \vec{A}) + \nabla \times (\nabla \times \vec{A} - \nabla g) \overset{(1)}{=} -\nabla(\nabla \cdot \vec{A}) + \nabla \times \nabla \times \vec{A} \overset{(2)}{=} -\nabla^2 \vec{A},$$

(1) $\nabla \times \nabla g = 0$ (this is $\mathrm{d}^2 = 0$).
(2) The identity $\nabla \times \nabla \times \vec{A} = \nabla(\nabla \cdot \vec{A}) - \nabla^2 \vec{A}$.

Read backwards, *the vector identity "curl curl = grad div − Laplacian" is the statement* $(\mathrm{d} + \mathrm{d}^*)^2 = \mathrm{d}^*\mathrm{d} + \mathrm{d}\mathrm{d}^* = -\nabla^2$ *on 1-forms*. The other components work the same way ($\nabla \cdot \nabla \times = 0$ kills the cross terms).

Physical picture: Maxwell's equations are a Dirac equation

Let F be the electromagnetic field strength 2-form. Maxwell's equations are $\mathrm{d}F = 0$ (no monopoles, Faraday) and $\mathrm{d}^*F = J$ (Gauss and Ampère, with the current 1-form J; the sign depends on conventions and, in Lorentzian signature, on the metric used to define d^*). Because $\mathrm{d}F$ is a 3-form and d^*F a 1-form, the two equations are the components of the single equation

$$(\mathrm{d} + \mathrm{d}^*)F = J.$$

In Lorenz gauge $\mathrm{d}^*A = 0$ we have $F = \mathrm{d}A = (\mathrm{d} + \mathrm{d}^*)A$, and then $(\mathrm{d} + \mathrm{d}^*)^2 A = \Delta A = J$: the wave equation for the potential is the square of the Dirac-type equation, exactly as Klein–Gordon is the square of Dirac (Section T4.1).

Watch out: $\mathrm{d} + \mathrm{d}^*$ mixes degrees

$\mathrm{d} + \mathrm{d}^*$ does not map k-forms to k-forms; it maps Λ^k to $\Lambda^{k+1} \oplus \Lambda^{k-1}$. Its square $\Delta = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$ does preserve the degree. So "the Dirac operator on forms" only makes sense on all of $\Lambda^\bullet$, just as the spinor Dirac operator only makes sense on all of $S = S^+ \oplus S^-$ and exchanges the two halves.

T4.9.4 Hodge theory: harmonic forms are the zero modes

For the Dirac operator the interesting objects were the zero modes. For $\mathrm{d} + \mathrm{d}^*$ the zero modes turn out to be cohomology classes.

Working definition T4.17 (harmonic forms)

A form h on a closed manifold [compact and without boundary, so integration by parts produces no boundary terms] is **harmonic** if $\Delta h = 0$ [$\Delta = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$, the Hodge Laplacian]. *Test:* h is harmonic iff it is both closed and coclosed,

$$\Delta h = 0 \iff (\mathrm{d} + \mathrm{d}^*)h = 0 \iff \mathrm{d}h = 0 \text{ and } \mathrm{d}^* h = 0.$$

The test follows from positivity, as for the rough Laplacian (T4.83):

$$(\Delta\alpha, \alpha) \overset{(1)}{=} (\mathrm{d}\mathrm{d}^*\alpha, \alpha) + (\mathrm{d}^*\mathrm{d}\alpha, \alpha) \overset{(2)}{=} (\mathrm{d}^*\alpha, \mathrm{d}^*\alpha) + (\mathrm{d}\alpha, \mathrm{d}\alpha) = \|\mathrm{d}^*\alpha\|^2 + \|\mathrm{d}\alpha\|^2,$$

$$\|(\mathrm{d}+\mathrm{d}^*)\alpha\|^2 \overset{(3)}{=} \|\mathrm{d}\alpha\|^2 + \|\mathrm{d}^*\alpha\|^2 + 2\,\mathrm{Re}\,(\mathrm{d}\alpha, \mathrm{d}^*\alpha) \overset{(4)}{=} \|\mathrm{d}\alpha\|^2 + \|\mathrm{d}^*\alpha\|^2. \tag{T4.121}$$

(1) Definition of Δ.
(2) Move one factor to the other side of the inner product; d and d^* are adjoint.
(3) Expand the norm of a sum.
(4) $(\mathrm{d}\alpha, \mathrm{d}^*\alpha) = (\mathrm{dd}\alpha, \alpha) = 0$ since $\mathrm{d}^2 = 0$.

All three quantities vanish together, which is the test. The kernel of $\mathrm{d}+\mathrm{d}^*$ on $\Omega^\bullet$ is therefore the direct sum over degrees of the harmonic k-forms $\mathcal{H}^k$, since Δ preserves degree.

Key idea: Hodge's theorem

On a closed oriented Riemannian manifold every de Rham class contains exactly one harmonic form:

$$H^k_{\mathrm{dR}}(M) \;\cong\; \mathcal{H}^k = \operatorname{Ker}\Delta\big|_{\Omega^k}, \qquad \operatorname{Ker}(\mathrm{d}+\mathrm{d}^*) = \bigoplus_k \mathcal{H}^k, \qquad \dim \mathcal{H}^k = b_k. \tag{T4.122}$$

Equivalently, every form splits orthogonally as $\Omega^k = \mathcal{H}^k \oplus \mathrm{d}\Omega^{k-1} \oplus \mathrm{d}^*\Omega^{k+1}$ (the **Hodge decomposition**).

Two parts of this are elementary and worth seeing. *Orthogonality* of the three pieces: for h harmonic, $(\mathrm{d}\beta, \mathrm{d}^*\gamma) = (\mathrm{dd}\beta, \gamma) = 0$, $(h, \mathrm{d}\beta) = (\mathrm{d}^*h, \beta) = 0$ and $(h, \mathrm{d}^*\gamma) = (\mathrm{d}h, \gamma) = 0$. *Uniqueness and meaning* of the harmonic representative: if α is closed and coclosed, then for every β

$$\|\alpha + \mathrm{d}\beta\|^2 \overset{(1)}{=} \|\alpha\|^2 + 2\,\mathrm{Re}(\alpha, \mathrm{d}\beta) + \|\mathrm{d}\beta\|^2 \overset{(2)}{=} \|\alpha\|^2 + 2\,\mathrm{Re}(\mathrm{d}^*\alpha, \beta) + \|\mathrm{d}\beta\|^2 \overset{(3)}{=} \|\alpha\|^2 + \|\mathrm{d}\beta\|^2.$$

(1) Expand the norm.
(2) Adjointness.
(3) $\mathrm{d}^*\alpha = 0$.

So the harmonic form is the *unique shortest element* of its cohomology class $\alpha + \mathrm{d}\Omega^{k-1}$, and two harmonic forms in the same class differ by an exact form $\mathrm{d}\beta$ that is itself harmonic, so $\|\mathrm{d}\beta\|^2 = (\mathrm{d}^*\mathrm{d}\beta, \beta) = 0$. In physics language, choosing the harmonic representative is choosing the *Coulomb gauge* $\mathrm{d}^*\alpha = 0$ in the class of α under gauge transformations $\alpha \to \alpha + \mathrm{d}\beta$: it minimises the energy $\|\alpha\|^2$. Existence (that the minimum is attained) is analysis: it is the statement that Δ is elliptic, proved in Chapter 2.

Worked example T4.59: harmonic forms on the flat torus and on the round sphere

Flat $T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$**.** By (T4.119) and Fourier series, a form is harmonic iff each component function is harmonic, $-\nabla^2 f = 0$, and on a torus that means constant (expand $f = \sum f_{pq} e^{i(px+qy)}$: $-\nabla^2$ multiplies by p^2+q^2). So

$$\mathcal{H}^0 = \langle 1 \rangle, \quad \mathcal{H}^1 = \langle \mathrm{d}x, \mathrm{d}y \rangle, \quad \mathcal{H}^2 = \langle \mathrm{d}x \wedge \mathrm{d}y \rangle, \qquad (b_0, b_1, b_2) = (1, 2, 1).$$

Under Q these four constant forms become the constant matrices $\mathbf{1}, \sigma_1, \sigma_2, i\sigma_3$, whose columns are constant spinors. On the torus with the periodic spin structure there are 2 constant (harmonic) spinors (Example T4.45); two columns of two harmonic spinors each give $4 = 2 \times 2$ harmonic forms, as (T4.114) predicts. (For the other spin structures there are no harmonic spinors, but the forms do not care: the two sign choices in $S \otimes S^*$ cancel.)
Round S^2**.** $b_0 = b_2 = 1$, $b_1 = 0$: the harmonic forms are the constants and multiples of the area form $\mathrm{vol} = \sin\theta\, \mathrm{d}\theta \wedge \mathrm{d}\phi$. The constant is harmonic trivially. For the area form, $\mathrm{d}\,\mathrm{vol} = 0$ (top degree) and $\mathrm{d}^*\mathrm{vol} = -\star\,\mathrm{d}\star\,\mathrm{vol} = -\star\,\mathrm{d}1 = 0$. There are no harmonic 1-forms:

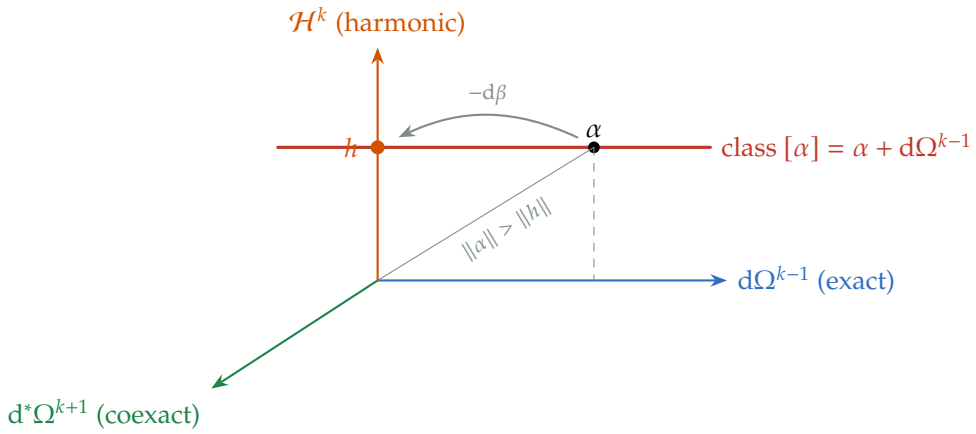

Figure T4.30: The Hodge decomposition. The three subspaces are mutually orthogonal. A closed form has no coexact part, so its cohomology class is a line parallel to the exact axis (red). The harmonic representative h is the point of the line closest to the origin: subtracting the exact part $\mathrm{d}\beta$ of α lowers the squared norm by $\|\mathrm{d}\beta\|^2$.

a harmonic 1-form h would be closed, hence $h = \mathrm{d}f$ on the simply connected S^2, and then $0 = \mathrm{d}^*\mathrm{d}f = \Delta f$ forces f constant and $h = 0$.

Watch out: harmonic forms exist where harmonic spinors cannot

The round S^2 has no harmonic spinors at all (positive scalar curvature, Section T4.8.3), yet it has the two harmonic forms 1 and vol. No contradiction: forms are $S \otimes S^*$, i.e. spinors *twisted* by the bundle S^*, and the twisted Lichnerowicz formula of Section T4.8.4 has an extra curvature term from the twisting bundle that can be negative. Positivity of R alone does not kill harmonic forms. What *does* kill some of them is positivity of Ricci, as we now show.

T4.9.5 The Bochner formula

The first step of the Lichnerowicz derivation (T4.86) used nothing but the Clifford relations and a parallel Clifford action. So it applies verbatim to $\mathrm{d} + \mathrm{d}^* = \sum_a c(e^a)\nabla_a$, with the only change that $c(e^a)^2 = -1$ where $\gamma_a^2 = +1$.

Key idea: Weitzenböck formula for a Dirac-type operator

If $D = \sum_a c(e^a)\nabla_a$ with $\{c(e^a), c(e^b)\} = -2\delta^{ab}$ and $\nabla c = 0$, then

$$D^2 = \nabla^*\nabla + \frac{1}{2}\sum_{a,b} c(e^a)c(e^b)\, R^{\nabla}(e_a, e_b), \tag{T4.123}$$

where $R^{\nabla}(e_a, e_b) = [\nabla_a, \nabla_b]$ (in a synchronous frame) is the curvature of the bundle.

The derivation at a point with a synchronous frame:

$$D^2 \overset{(1)}{=} \sum_{a,b} c(e^a)c(e^b)\nabla_a\nabla_b \overset{(2)}{=} \sum_{a,b} \tfrac{1}{2}\{c(e^a), c(e^b)\}\nabla_a\nabla_b + \sum_{a,b} \tfrac{1}{2}[c(e^a), c(e^b)]\nabla_a\nabla_b$$
$$\overset{(3)}{=} -\sum_a \nabla_a\nabla_a + \tfrac{1}{2}\sum_{a,b} c(e^a)c(e^b)\,[\nabla_a, \nabla_b] \overset{(4)}{=} \nabla^*\nabla + \tfrac{1}{2}\sum_{a,b} c(e^a)c(e^b)R^{\nabla}(e_a, e_b).$$

(1) $c(e^b)$ is parallel at the point, so ∇_a passes through it.
(2) Split $c^a c^b$ into its symmetric and antisymmetric parts.
(3) Clifford relation $\{c^a, c^b\} = -2\delta^{ab}$; the antisymmetric part $\frac{1}{2}[c^a, c^b]$ pairs with the antisymmetric part of $\nabla_a \nabla_b$, and for $a \neq b$ it equals $c^a c^b$ (for $a = b$ the commutator $[\nabla_a, \nabla_a] = 0$ anyway).
(4) (T4.82) at the point, and $[\nabla_a, \nabla_b] = R^{\nabla}(e_a, e_b)$ since $[e_a, e_b] = 0$ there.

For spinors ($c \to -i\gamma$) the curvature term is $\frac{R}{4}$, the Lichnerowicz formula. For forms the curvature R^{∇} is the Riemann tensor acting on forms as a derivation. On 1-forms it acts by $R^{\nabla}(e_a, e_b)e^d = \sum_c R_{cdab}\, e^c$ in the convention $R_{abcd} = \langle R(e_c, e_d)e_b, e_a\rangle$ of (T4.68).

Key idea: Bochner formula [Bär Prop. 1.3.12, (1.17)]

On 1-forms,

$$\Delta = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d} = \nabla^*\nabla + \mathrm{Ric}, \tag{T4.124}$$

where Ric acts on a 1-form $\theta = \theta_d e^d$ by $(\mathrm{Ric}\,\theta)_b = \mathrm{Ric}_{bd}\theta_d$.

To derive it we evaluate the curvature term of (T4.123) on $\theta = \theta_d e^d$. First the Clifford algebra: using $c = \varepsilon - \iota$ twice,

$$c(e^b)e^c \overset{(1)}{=} e^b \wedge e^c - \delta^{bc},$$
$$c(e^a)c(e^b)e^c \overset{(2)}{=} e^a \wedge e^b \wedge e^c - \delta^{ab}e^c + \delta^{ac}e^b - \delta^{bc}e^a.$$

(1) $\varepsilon(e^b)e^c = e^b \wedge e^c$ and $\iota(e^b)e^c = \delta^{bc}$.
(2) Apply $c(e^a)$: $\iota_{e_a}(e^b \wedge e^c) = \delta^{ab}e^c - \delta^{ac}e^b$, and $c(e^a)1 = e^a$.

Now contract with the curvature (all indices summed):

$$\begin{aligned}\tfrac{1}{2}\, c(e^a)c(e^b)R^{\nabla}(e_a, e_b)\theta &\overset{(1)}{=} \tfrac{1}{2}\,\theta_d R_{cdab}\, c(e^a)c(e^b)e^c \\ &\overset{(2)}{=} \tfrac{1}{2}\,\theta_d\big(R_{cdab}\, e^a \wedge e^b \wedge e^c - R_{cdaa}e^c + R_{adab}e^b - R_{bdab}e^a\big) \\ &\overset{(3)}{=} \tfrac{1}{2}\,\theta_d\big(0 - 0 + R_{adab}e^b + R_{adab}e^b\big) \overset{(4)}{=} \mathrm{Ric}_{bd}\,\theta_d\, e^b.\end{aligned}$$

(1) $R^{\nabla}(e_a, e_b)e^d = R_{cdab}e^c$.
(2) Insert the Clifford computation.
(3) The first term is the antisymmetrisation of R_{cdab} over a, b, c, which vanishes by the first Bianchi identity; $R_{cdaa} = 0$; in the last term rename $a \leftrightarrow b$ and use $R_{adba} = -R_{adab}$.
(4) $\mathrm{Ric}_{bd} = \sum_a R_{abad} = \sum_a R_{adab}$ (pair symmetry).

With (T4.123) and $D^2 = \Delta$ this is (T4.124). The calculation is the same three-gamma identity (T4.88) that produced $-2\,\mathrm{Ric}$ in the Lichnerowicz derivation; there it was contracted once more to give the scalar curvature, here the free index is the form index.

Key idea: Bochner's vanishing theorem

On a closed manifold, integrate $(\Delta h, h) = 0$ for a harmonic 1-form h:

$$0 = \|\nabla h\|^2 + \int_M \mathrm{Ric}(h, h)\,\mathrm{vol}. \tag{T4.125}$$

If $\mathrm{Ric} \geq 0$, both terms vanish, so every harmonic 1-form is parallel and $b_1 \leq n$. If moreover $\mathrm{Ric} > 0$ somewhere, then $h = 0$ there, hence everywhere (it is parallel), and $b_1(M) = 0$.

Worked example T4.60: Bochner on spheres, tori and $S^1 \times S^2$

- *Round* S^n ($n \geq 2$): Ric $= (n-1)g > 0$, so $b_1 = 0$, as we found directly for S^2. Quantitatively $\Delta \geq n-1$ on 1-forms. On S^2 the lowest 1-form eigenvalue is 2 (the forms $\mathrm{d}Y_{1m}$, since $\Delta \mathrm{d}f = \mathrm{d}\Delta f$ and $\Delta Y_{1m} = 2Y_{1m}$), which respects the bound ≥ 1.
- *Flat* T^n: Ric $= 0$, harmonic 1-forms are parallel, and indeed they are the constant forms $\mathrm{d}x^1, \ldots, \mathrm{d}x^n$: $b_1 = n$, saturating the bound.
- $S^1 \times S^2$ with the product metric: Ric ≥ 0 (zero along S^1, positive along S^2). The parallel 1-form $\mathrm{d}\theta$ along the circle is harmonic, and $b_1 = 1$.
- *Surfaces of genus* $g \geq 2$ with constant curvature -1: Ric < 0, no obstruction, and indeed $b_1 = 2g$.

bundle	Dirac-type operator	Weitzenböck potential K	vanishing result
spinors S	$D = -i\gamma^a \nabla_a$	$\frac{R}{4}$	$R > 0 \Rightarrow$ no harmonic spinors
$S \otimes E$	D_A	$\frac{R}{4} - \gamma(F)$	needs F small
1-forms	$\mathrm{d} + \mathrm{d}^*$	Ric	Ric $> 0 \Rightarrow b_1 = 0$
functions	$\mathrm{d} + \mathrm{d}^*$	0	harmonic $\Rightarrow$ constant

T4.9.6 The Euler operator: the index is the Euler characteristic

We now have a Dirac-type operator $\mathrm{d} + \mathrm{d}^*$ on $\Lambda^\bullet T^*M$ on every Riemannian manifold. For the spinor Dirac operator the interesting number was not the kernel itself but the *index*, the difference of zero modes in two sectors exchanged by D (Section T4.8.5). To imitate that we need a grading: a splitting $\Lambda^\bullet = E^+ \oplus E^-$ such that $\mathrm{d} + \mathrm{d}^*$ maps E^+ to E^- and back. In the language of Section T4.3.3, we need an operator that squares to $\mathbf{1}$ and *anticommutes* with every Clifford generator $c(e^a)$, and that is parallel. Differential forms carry two such operators. The first one is obvious.

Working definition T4.18 (the Euler grading and the Euler operator)

Let $(-1)^N$ be $+1$ on even forms and -1 on odd forms. The **Euler operator** (Nash's $\mathbf{d}$, [Nash (4.51)]) is the restriction of $\mathrm{d} + \mathrm{d}^*$ to even forms [sums of forms of degree $0, 2, 4, \ldots$],

$$D_{\mathrm{E}} := (\mathrm{d} + \mathrm{d}^*)\big|_{\Omega^{\mathrm{even}}} : \Omega^{\mathrm{even}}(M) \longrightarrow \Omega^{\mathrm{odd}}(M), \tag{T4.126}$$

with adjoint $D_{\mathrm{E}}^* = (\mathrm{d} + \mathrm{d}^*)|_{\Omega^{\mathrm{odd}}}$. *Test* that it is well defined: $(-1)^N$ must anticommute with $\mathrm{d} + \mathrm{d}^*$.

The test is one line per operator. Since $\varepsilon(v)$ raises the degree by one and $\iota(v)$ lowers it by one, on a k-form α

$$(-1)^N c(v)\,\alpha \overset{(1)}{=} (-1)^{k+1}\varepsilon(v)\alpha - (-1)^{k-1}\iota(v)\alpha \overset{(2)}{=} -(-1)^k\big(\varepsilon(v) - \iota(v)\big)\alpha \overset{(3)}{=} -c(v)\,(-1)^N\alpha,$$

(1) $\varepsilon(v)\alpha$ has degree $k+1$ and $\iota(v)\alpha$ has degree $k-1$.
(2) $(-1)^{k+1} = (-1)^{k-1} = -(-1)^k$.
(3) $(-1)^N\alpha = (-1)^k\alpha$.

so $\{(-1)^N, c(v)\} = 0$, and the same computation gives $\{(-1)^N, \hat{c}(v)\} = 0$. The Levi-Civita

connection preserves degrees, so ∇_a commutes with $(-1)^N$, and therefore, from (T4.116),

$$(-1)^N(\mathrm{d}+\mathrm{d}^*) \overset{(1)}{=} \sum_a (-1)^N c(e^a)\nabla_a \overset{(2)}{=} -\sum_a c(e^a)(-1)^N\nabla_a \overset{(3)}{=} -(\mathrm{d}+\mathrm{d}^*)(-1)^N.$$

(1) (T4.116).
(2) $(-1)^N$ anticommutes with $c(e^a)$.
(3) $(-1)^N$ commutes with ∇_a.

Of course one sees this directly: d and d^* each change the degree by one. The Clifford version is worth having because it is the template for the second grading below, where "directly" is much less obvious.

Key idea: the index of the Euler operator [Nash (4.52)]

On a closed oriented Riemannian manifold,

$$\operatorname{index} D_{\mathrm{E}} = \sum_k (-1)^k b_k(M) = \chi(M). \tag{T4.127}$$

The derivation is just Hodge theory:

$$\operatorname{index} D_{\mathrm{E}} \overset{(1)}{=} \dim\operatorname{Ker}\big((\mathrm{d}+\mathrm{d}^*)|_{\text{even}}\big) - \dim\operatorname{Ker}\big((\mathrm{d}+\mathrm{d}^*)|_{\text{odd}}\big) \overset{(2)}{=} \sum_{k\ \text{even}} \dim\mathcal{H}^k - \sum_{k\ \text{odd}} \dim\mathcal{H}^k$$
$$\overset{(3)}{=} \sum_k (-1)^k b_k \overset{(4)}{=} \chi(M).$$

(1) Definition of the index, with $\operatorname{Coker} D_{\mathrm{E}} = \operatorname{Ker} D_{\mathrm{E}}^*$ (as for D^+ in Section T4.8.5).
(2) The kernel of $\mathrm{d}+\mathrm{d}^*$ is the direct sum of the harmonic forms of each degree, by the test (T4.121); sort them by parity.
(3) Hodge's theorem (T4.122): $\dim\mathcal{H}^k = b_k$.
(4) Euler–Poincaré: the alternating sum of Betti numbers is the Euler characteristic (the alternating count of cells, $V - E + F$ for a surface, Chapter T2).

The index theorem computes the same number as the integral of a curvature expression, the Euler form: that is the Gauss–Bonnet–Chern theorem $\int_M e(TM) = \chi(M)$ [Nash (4.53)–(4.54)]. In two dimensions $e = \frac{1}{2\pi}K\,\mathrm{vol}$ and this is the Gauss–Bonnet theorem of Chapter T2. We will see in Section T4.9.9 how the Euler form arises from the $\hat{A}$ genus.

Worked example T4.61: the Euler operator on the circle: every level pairs, including zero

On S^1 with coordinate $\theta \in [0, 2\pi)$ and metric $\mathrm{d}\theta^2$, an even form is a function f and an odd form is $g\,\mathrm{d}\theta$. From $\mathrm{d}f = f'\,\mathrm{d}\theta$ and $\mathrm{d}^*(g\,\mathrm{d}\theta) = -\iota(\mathrm{d}\theta)\partial_\theta(g\,\mathrm{d}\theta) = -g'$,

$$(\mathrm{d}+\mathrm{d}^*)\begin{pmatrix} f \\ g \end{pmatrix} = \begin{pmatrix} -g' \\ f' \end{pmatrix} = \begin{pmatrix} 0 & -\partial_\theta \\ \partial_\theta & 0 \end{pmatrix}\begin{pmatrix} f \\ g \end{pmatrix}. \tag{T4.128}$$

On a Fourier mode $(f, g) = (a, b)\,e^{in\theta}$ the operator is the 2×2 matrix

$$\begin{pmatrix} 0 & -in \\ in & 0 \end{pmatrix} = n\,\sigma_2, \qquad \text{eigenvalues } \pm n, \quad n \in \mathbb{Z}.$$

So the spectrum of $\mathrm{d}+\mathrm{d}^*$ is $\{\pm n\}$, the spectrum of the *periodic* (Ramond) Dirac operator of Example T4.44, doubled. It is never the half-integer spectrum of the antiperiodic spin

structure, because $S \otimes S^*$ does not see the sign of the spin structure (Section T4.9.2). The Laplacian $\Delta = (\mathrm{d} + \mathrm{d}^*)^2 = -\partial_\theta^2$ has eigenvalue n^2 on both sides:

$\lambda = n^2$	even (functions)	odd (1-forms)	D_{E} maps
0	1	$\mathrm{d}\theta$	$1 \mapsto 0$
$n^2,\ n \geq 1$	$e^{\pm in\theta}$	$e^{\pm in\theta}\mathrm{d}\theta$	$e^{in\theta} \mapsto in\, e^{in\theta}\mathrm{d}\theta$

Every nonzero level has the same multiplicity (2) on both sides, as the pairing argument of Section T4.8.5 requires, and at $\lambda = 0$ there is one zero mode on each side:

$$\operatorname{index} D_{\mathrm{E}} = \dim \mathcal{H}^0 - \dim \mathcal{H}^1 = 1 - 1 = 0 = \chi(S^1).$$

Worked example T4.62: the Euler operator on the round S^2

The eigenfunctions of $\Delta = -\nabla^2$ on functions are the spherical harmonics Y_{lm}, with eigenvalue $l(l+1)$ and multiplicity $2l+1$. We build all other eigenforms from them.

- *2-forms.* $\star$ commutes with Δ (because $\mathrm{d}^* = -\star\,\mathrm{d}\star$ in even dimensions), so $Y_{lm}\,\mathrm{vol} = \star Y_{lm}$ has the same eigenvalue.
- *1-forms.* Δ commutes with d ($\Delta\mathrm{d} = \mathrm{d}\mathrm{d}^*\mathrm{d} = \mathrm{d}\Delta$), so $\mathrm{d}Y_{lm}$ is an eigenform with eigenvalue $l(l+1)$, and so is $\star\mathrm{d}Y_{lm}$. They are nonzero for $l \geq 1$: $\|\mathrm{d}Y_{lm}\|^2 = (\mathrm{d}^*\mathrm{d}Y_{lm}, Y_{lm}) = l(l+1)$. By the Hodge decomposition, with $\mathcal{H}^1 = 0$, every 1-form is exact plus coexact, so these exhaust the 1-forms.

Sorting by parity:

λ	even: Y_{lm} and $Y_{lm}\mathrm{vol}$	odd: $\mathrm{d}Y_{lm}$ and $\star\mathrm{d}Y_{lm}$	difference
0	$1 + 1 = 2$	0	2
$l(l+1),\ l \geq 1$	$(2l+1) + (2l+1)$	$(2l+1) + (2l+1)$	0

The pairing map is explicit: for $l \geq 1$,

$$D_{\mathrm{E}}\big(Y_{lm}\big) \overset{(1)}{=} \mathrm{d}Y_{lm}, \qquad D_{\mathrm{E}}\big(Y_{lm}\mathrm{vol}\big) \overset{(2)}{=} \mathrm{d}^\star \star Y_{lm} \overset{(3)}{=} -\star\,\mathrm{d}Y_{lm},$$

(1) d^* of a function is zero.
(2) d of a top form is zero, and $Y\mathrm{vol} = \star Y$.
(3) $\mathrm{d}^* = -\star\,\mathrm{d}\star$ and $\star\star = 1$ on functions.

so the even eigenspace at $l(l+1)$ is mapped isomorphically onto the odd one. Only the two harmonic even forms 1 and vol are unpaired, and index $D_{\mathrm{E}} = 2 = \chi(S^2)$.
Compare with the spinor Dirac operator on the same sphere (Example T4.47): there the spectrum was $\pm(l+1)$ with *no* zero modes. The forms have D_{E}^2-eigenvalues $l(l+1)$ and two zero modes. Positive curvature kills harmonic spinors; it does not kill the Euler characteristic.

Worked example T4.63: Euler characteristics as indices

With the Betti numbers found by Hodge theory in Example T4.59 and in Chapter T2:

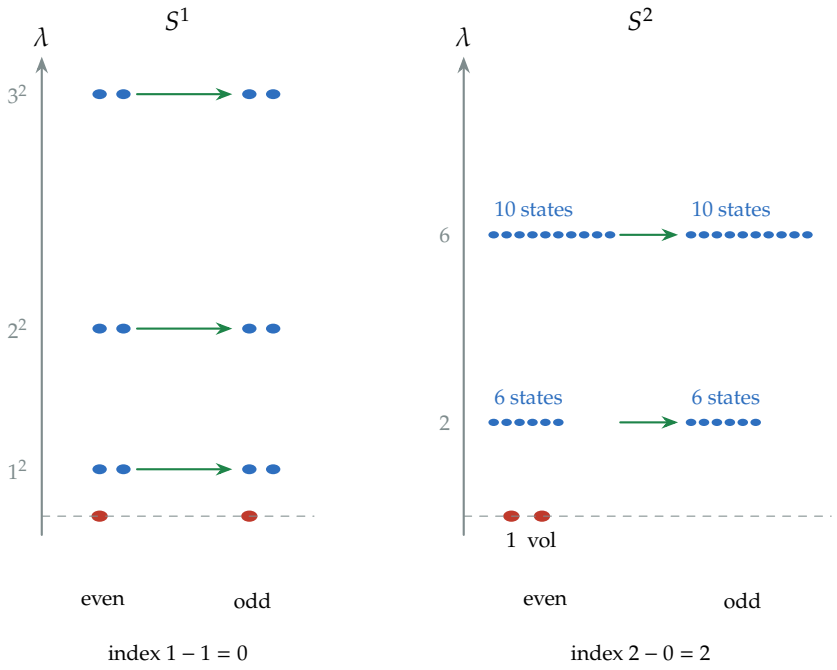

Figure T4.31: Spectrum of the Hodge Laplacian $\Delta = D_{\mathrm{E}}^* D_{\mathrm{E}} \oplus D_{\mathrm{E}} D_{\mathrm{E}}^*$ on even and odd forms. Left: the circle, levels n^2; right: the round sphere, levels $l(l+1)$ with $2(2l+1)$ states on each side. The green arrows are D_{E}, an isomorphism between the two sides at every nonzero level. The red dots are the harmonic forms. Only they can be unbalanced, and their imbalance is χ.

M	$(b_0, b_1, \ldots, b_n)$	$\chi = \operatorname{index} D_{\mathrm{E}}$	spin?
S^1	$(1,1)$	0	yes (two)
S^2	$(1,0,1)$	2	yes (one)
T^2	$(1,2,1)$	0	yes (four)
Σ_g	$(1,2g,1)$	$2-2g$	yes (2^{2g})
S^4	$(1,0,0,0,1)$	2	yes
$S^2 \times S^2$	$(1,0,2,0,1)$	4	yes
$\mathbb{CP}^2$	$(1,0,1,0,1)$	3	**no**

The last line is the reason for this whole section: $\mathbb{CP}^2$ has no Dirac operator on spinors, but its Euler operator is perfectly well defined and has index 3. In odd dimensions $\chi = 0$ always (Poincaré duality pairs b_k with b_{n-k}, which enter with opposite signs), consistent with the vanishing of the index of every differential operator in odd dimensions [Nash p. 103].

Physical picture: supersymmetric quantum mechanics on forms

The Fock-space picture of Section T4.9.1 turns the Euler operator into a quantum system. The Hilbert space is $\Omega^\bullet(M)$, the fermion number is the degree N, and

$$Q := \mathrm{d}, \qquad Q^\dagger = \mathrm{d}^*, \qquad H := \{Q, Q^\dagger\} = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d} = \Delta, \qquad Q^2 = 0.$$

This is **supersymmetric quantum mechanics**: Q changes fermion number by one, commutes with H, and squares to zero. The Hamiltonian is the Laplacian, a particle moving on M with fermionic partners $\varepsilon(e^a)$, $\iota(e^a)$. Every state with $E > 0$ has a partner of opposite fermion parity (namely Q or $Q^\dagger$ of it), exactly the pairing of Figure T4.31. Supersymmetric

ground states ($E = 0$) are harmonic forms, i.e. cohomology. The **Witten index** is

$$\operatorname{Tr}\big((-1)^N e^{-tH}\big) \overset{(1)}{=} \sum_{\lambda} e^{-t\lambda}\big(\dim \Omega^{\text{even}}_{\lambda} - \dim \Omega^{\text{odd}}_{\lambda}\big) \overset{(2)}{=} \chi(M), \tag{T4.129}$$

(1) Diagonalise Δ in each parity sector.
(2) Only $\lambda = 0$ survives the pairing, and there the count is (T4.127).

independent of t and of the metric: the McKean–Singer formula (T4.99) for forms. Witten's deformation $Q_s = e^{-sf}\,\mathrm{d}\,e^{sf}$ by a function f still squares to zero, so it leaves the index unchanged, and for large s the ground states localise at the critical points of f. That is the physicist's proof of the Morse inequalities (Chapter 7).

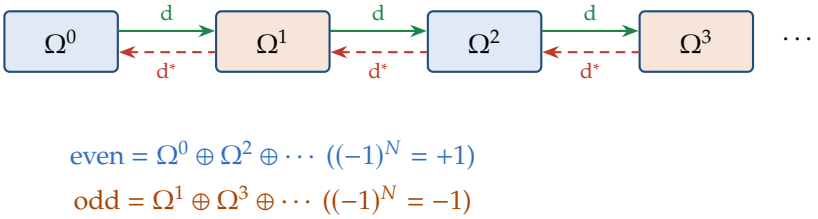

Figure T4.32: The de Rham complex as a ladder of fermion numbers. Both d (green) and d* (red, dashed) move one rung, so each maps even forms to odd forms and vice versa. That is why $(-1)^N$ anticommutes with $\mathrm{d} + \mathrm{d}^*$, and why the Euler operator D_{E} (all arrows, starting from the blue boxes) is a map from even to odd forms.

T4.9.7 The signature operator

The Euler grading uses only the degree. A four-manifold has a finer invariant that the degree cannot see. On H^2 the wedge product gives a quadratic form, $q(u,v) = \int_M u \wedge v$, and a symmetric real form has a signature: the number of positive minus the number of negative eigenvalues. For $\mathbb{CP}^2$ it is $+1$, for $S^2 \times S^2$ it is 0, for the K3 surface it is -16. Is this number also the index of a Dirac-type operator? It is, and the grading that does it is the *chirality operator of the Clifford action* c, which turns out to be a multiple of the Hodge star.

The intersection form and the signature. Let $n = 2m$. The middle cohomology $H^m(M)$ carries the pairing [Nash (4.74)]

$$q(u,v) := \int_M u \wedge v \qquad (u, v \in H^m(M;\mathbb{R})), \tag{T4.130}$$

which is well defined on classes by Stokes ($\int (u + \mathrm{d}\alpha)\wedge v = \int u\wedge v + \int \mathrm{d}(\alpha \wedge v)$ for closed v) and nondegenerate by Poincaré duality. Since $u \wedge v = (-1)^{m^2} v \wedge u$ [Nash (4.76)], q is antisymmetric when m is odd, and a real antisymmetric form has no real eigenvalues. So the **signature**

$$\sigma(M) := b^+ - b^- \qquad (\text{Nash's Sign}(X), \text{[Nash (4.75)]}) \tag{T4.131}$$

is interesting only when m is even, i.e. $4 \mid n$. Reversing the orientation flips the sign of $\int$, hence of σ.

Working definition T4.19 (the involution τ [Nash (4.77)], [Bär Ex. 1.3.19])

On complex-valued k-forms on an oriented Riemannian manifold of dimension $n = 2m$, put

$$\tau\alpha := i^{\,k(k-1)+m} \star \alpha \qquad (\alpha \in \Omega^k). \tag{T4.132}$$

[$\star$ is the Hodge star, sending a k-form to an $(n-k)$-form, e.g. $\star e^1 = e^2$ on $\mathbb{R}^2$] Then $\tau^2 = 1$, so $\Lambda^\bullet T^*M \otimes \mathbb{C} = \Lambda^+ \oplus \Lambda^-$ splits into the ± 1 eigenbundles [at each point, the forms with $\tau\alpha = +\alpha$ and those with $\tau\alpha = -\alpha$] [Nash (4.79)]. *How to compute:* apply $\star$ and multiply by the phase; the table for $n = 4$ is below.

The phase is chosen precisely to make τ an involution. Using $\star^2 = (-1)^{k(n-k)} = (-1)^k$ on k-forms in even dimension ([Bär Lemma 1.3.16], and $k(n-k) = 2mk - k^2 \equiv k \bmod 2$):

$$\tau^2\alpha \overset{(1)}{=} i^{k(k-1)+m}\,\tau(\star\alpha) \overset{(2)}{=} i^{k(k-1)+m}\,i^{(n-k)(n-k-1)+m}\,\star^2\alpha \overset{(3)}{=} i^{2k^2}\,\star^2\alpha \overset{(4)}{=} (-1)^k(-1)^k\alpha = \alpha. \tag{T4.133}$$

(1) Definition (T4.132) on the k-form α.
(2) $\star\alpha$ is an $(n-k)$-form, so τ acts on it with the phase for degree $n-k$.
(3) Exponent: $k^2 - k + (n-k)^2 - (n-k) + 2m = 2k^2 + n^2 - 2nk$ with $n = 2m$; the terms $n^2 = 4m^2$ and $2nk = 4mk$ are multiples of 4 and drop out of a power of i.
(4) $i^{2k^2} = (-1)^{k^2} = (-1)^k$, and $\star^2 = (-1)^k$.

This is Nash's (4.78), with every exponent spelled out. For $n = 4$ ($m = 2$), the phases $i^{k(k-1)+2}$ for $k = 0, \dots, 4$ are $-1, -1, +1, +1, -1$:

degree k	0	1	2	3	4
τ	$-\star$	$-\star$	$\star$	$\star$	$-\star$
$+1$ eigenforms	$f - f\,\mathrm{vol}$	$\theta - \star\theta$	self-dual	(paired with degrees 1, 0)	

In the middle degree $\tau = \star$ *exactly* whenever $4 \mid n$: the phase is $i^{m(m-1)+m} = i^{m^2} = 1$ for m even. So on 2-forms in four dimensions Λ^+ is the bundle of *self-dual* forms and Λ^- the anti-self-dual ones: the same splitting $\Lambda^2 = \Lambda^2_+ \oplus \Lambda^2_-$ that underlies instantons and $\mathrm{Spin}(4) = \mathrm{SU}(2) \times \mathrm{SU}(2)$ (Section T4.5.6, Chapter 8).

τ is the chirality operator. Why this odd phase? Because τ is the Clifford volume element. Recall that for Hermitian gammas the chirality operator is $\Gamma = (-i)^m \gamma_1 \cdots \gamma_n$ (Section T4.4.1). With the gammas $\gamma(e^a) = i\,c(e^a)$ of (T4.109) this is

$$\Gamma_\Lambda \overset{(1)}{=} (-i)^m\, i^n\, c(e^1)\cdots c(e^n) \overset{(2)}{=} i^m\, c(e^1)c(e^2)\cdots c(e^n) \;=\; \tau. \tag{T4.134}$$

(1) $\gamma(e^a) = i\,c(e^a)$, and there are n factors.
(2) $(-i)^m i^{2m} = (-i)^m(-1)^m = i^m$.

The last equality, $\tau = i^m c(e^1)\cdots c(e^n)$, is the content; it is a sign count on basis forms, and it is quickest to check it on examples.

- *On the function* 1, *any* n: each $c(e^a) = \varepsilon(e^a) - \iota(e^a)$ acting on a form not containing e^a just wedges, so $c(e^1)\cdots c(e^n)1 = e^1 \wedge \cdots \wedge e^n = \mathrm{vol}$, and $i^m \mathrm{vol} = i^{0+m} \star 1 = \tau 1$.
- *On* $\Lambda^\bullet\mathbb{R}^2$, *all four basis forms.* With the matrices of Example T4.55, $c(e^1)c(e^2) = (\mathbf{1} \otimes J)(J \otimes \sigma_3) = J \otimes J\sigma_3$ and $J\sigma_3 = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right) = \sigma_1$, so

$$i\,c(e^1)c(e^2) = i\,J \otimes \sigma_1 = \begin{pmatrix} 0 & 0 & 0 & -i \\ 0 & 0 & -i & 0 \\ 0 & i & 0 & 0 \\ i & 0 & 0 & 0 \end{pmatrix}.$$

Its columns say $1 \mapsto i\,e^{12}$, $e^1 \mapsto i\,e^2$, $e^2 \mapsto -i\,e^1$, $e^{12} \mapsto -i$. Directly from (T4.132) with $m = 1$: $\tau 1 = i \star 1 = i\,e^{12}$; $\tau e^1 = i \star e^1 = ie^2$; $\tau e^2 = i \star e^2 = -ie^1$; $\tau e^{12} = i^{2+1} \star e^{12} = -i$. They agree.

- *On e^{12} in $\mathbb{R}^4$.* Working from the right, $c(e^4)e^{12} = e^{412} = e^{124}$, $c(e^3)e^{124} = e^{3124} = e^{1234}$, $c(e^2)e^{1234} = -\iota_{e_2}e^{1234} = e^{134}$, $c(e^1)e^{134} = -e^{34}$. So $i^2 c(e^1)\cdots c(e^4)e^{12} = e^{34} = \star e^{12} = \tau e^{12}$.

Key idea: τ anticommutes with $\mathrm{d} + \mathrm{d}^*$ [Nash p. 110]

Since τ is the chirality operator of the Clifford module $(\Lambda^\bullet, c)$, it anticommutes with every $c(e^a)$; being built from the metric and orientation it is parallel. Hence

$$\tau(\mathrm{d} + \mathrm{d}^*) = -(\mathrm{d} + \mathrm{d}^*)\tau, \qquad D_S := (\mathrm{d} + \mathrm{d}^*)\big|_{\Omega^+} : \Omega^+(M) \longrightarrow \Omega^-(M), \tag{T4.135}$$

where $\Omega^\pm = \Gamma(\Lambda^\pm)$. D_S is the **signature operator** (Nash's d_+, [Nash (4.80)–(4.81)]); its adjoint is the restriction of $\mathrm{d} + \mathrm{d}^*$ to Ω^-.

It is reassuring to see the anticommutation without Clifford algebra. Separately, τ turns d into $-\mathrm{d}^*$. For $\alpha \in \Omega^k$ (so $\mathrm{d}\alpha \in \Omega^{k+1}$ and $\star\alpha \in \Omega^{n-k}$), with $\mathrm{d}^* = -\star\,\mathrm{d}\star$ in even dimension:

$$\mathrm{d}^*\tau\alpha \overset{(1)}{=} i^{k(k-1)+m}\,\mathrm{d}^* \star \alpha \overset{(2)}{=} -i^{k(k-1)+m} \star \mathrm{d} \star \star\alpha \overset{(3)}{=} -(-1)^k\, i^{k(k-1)+m} \star \mathrm{d}\alpha$$
$$\overset{(4)}{=} -i^{2k}\, i^{k(k-1)+m} \star \mathrm{d}\alpha \overset{(5)}{=} -i^{(k+1)k+m} \star \mathrm{d}\alpha \overset{(6)}{=} -\tau\mathrm{d}\alpha.$$

(1) Definition of τ on the k-form α.
(2) $\mathrm{d}^* = -\star\,\mathrm{d}\star$ on forms of any degree when n is even (T4.115).
(3) $\star\star\alpha = (-1)^k\alpha$.
(4) $(-1)^k = i^{2k}$.
(5) $2k + k(k-1) = (k+1)k$.
(6) $\mathrm{d}\alpha$ has degree $k+1$, and the phase of τ in degree $k+1$ is $i^{(k+1)k+m}$.

So $\tau\mathrm{d} = -\mathrm{d}^*\tau$; conjugating by τ (using $\tau^2 = 1$) gives $\tau\mathrm{d}^* = -\mathrm{d}\tau$, and adding, $\tau(\mathrm{d}+\mathrm{d}^*) = -(\mathrm{d}+\mathrm{d}^*)\tau$. Note that τ does *not* anticommute with d alone: it exchanges d and $-\mathrm{d}^*$. Only the Dirac-type combination is graded.

Key idea: the index of the signature operator [Nash (4.84)–(4.89)]

If $4 \mid n$,

$$\operatorname{index} D_S = h_+ - h_- = \sigma(M). \tag{T4.136}$$

Here $h_\pm$ is the dimension of the space of harmonic forms in $\Omega^\pm$.

The argument is linear algebra on harmonic forms. Since τ anticommutes with $\mathrm{d} + \mathrm{d}^*$, it commutes with $\Delta = (\mathrm{d} + \mathrm{d}^*)^2$ and maps harmonic forms to harmonic forms, taking $\mathcal{H}^p$ to $\mathcal{H}^{n-p}$. The kernel of D_S is $\mathcal{H}^\bullet \cap \Omega^+$ and the kernel of its adjoint is $\mathcal{H}^\bullet \cap \Omega^-$. Group the harmonic forms as Nash does [Nash (4.85)]:

$$\mathcal{H}^\bullet = \underbrace{\left(\mathcal{H}^0 \oplus \mathcal{H}^n\right)}_{I^0} \oplus \underbrace{\left(\mathcal{H}^1 \oplus \mathcal{H}^{n-1}\right)}_{I^1} \oplus \cdots \oplus \underbrace{\left(\mathcal{H}^{m-1} \oplus \mathcal{H}^{m+1}\right)}_{I^{m-1}} \oplus \mathcal{H}^m.$$

- *The pairs I^p ($p < m$) contribute nothing.* τ swaps the two summands. For every $h \in \mathcal{H}^p$ the forms $h \pm \tau h$ are eigenforms with eigenvalue ± 1 (as $\tau^2 = 1$), and every element of I^p is a combination of these. So $I^p = I^p_+ \oplus I^p_-$ with $\dim I^p_+ = \dim I^p_- = b_p$, and the contributions to $h_+ - h_-$ cancel.

- *The middle degree contributes $b^+ - b^-$.* On $\mathcal{H}^m$, $\tau = \star$ (the phase is 1 when m is even), which is real. Its ± 1 eigenspaces $\mathcal{H}^m_\pm$ are complexifications of real spaces of self-dual and anti-self-dual harmonic forms. For a real h with $\star h = \pm h$,

$$q(h,h) \overset{(1)}{=} \int_M h \wedge h \overset{(2)}{=} \pm \int_M h \wedge \star h \overset{(3)}{=} \pm \|h\|^2. \tag{T4.137}$$

  (1) Definition (T4.130).
  (2) $h = \pm \star h$.
  (3) Defining property of the Hodge star, $\alpha \wedge \star\beta = \langle \alpha, \beta \rangle \mathrm{vol}$.

  And $q(h_+, h_-) = \int h_+ \wedge \star h_- \cdot (-1) = -(h_+, h_-)$ while also $q(h_+, h_-) = \int \star h_+ \wedge h_- = (h_-, h_+)$, so $(h_-, h_+) = -(h_+, h_-)$; the real inner product is symmetric, so both vanish and $q(h_+, h_-) = 0$. Thus q is positive definite on $\mathcal{H}^m_+$, negative definite on $\mathcal{H}^m_-$, and the two are q-orthogonal: $\dim \mathcal{H}^m_\pm = b^\pm$.

Adding up,

$$h_+ - h_- \overset{(1)}{=} \sum_{p<m} \left(\dim I^p_+ - \dim I^p_-\right) + \dim \mathcal{H}^m_+ - \dim \mathcal{H}^m_- \overset{(2)}{=} 0 + b^+ - b^- \overset{(3)}{=} \sigma(M).$$

(1) Decompose $\mathcal{H}^\bullet$ as above; each piece is τ-invariant.
(2) The pairs cancel; the middle degree gives $b^\pm$.
(3) Definition (T4.131).

When m is odd the same bookkeeping applies, but on $\mathcal{H}^m$ we have $\tau = \pm i\star$ with $\star^2 = -1$, and complex conjugation exchanges the two eigenspaces, so $h_+ = h_-$ and the index is 0, as it should be for an antisymmetric q.

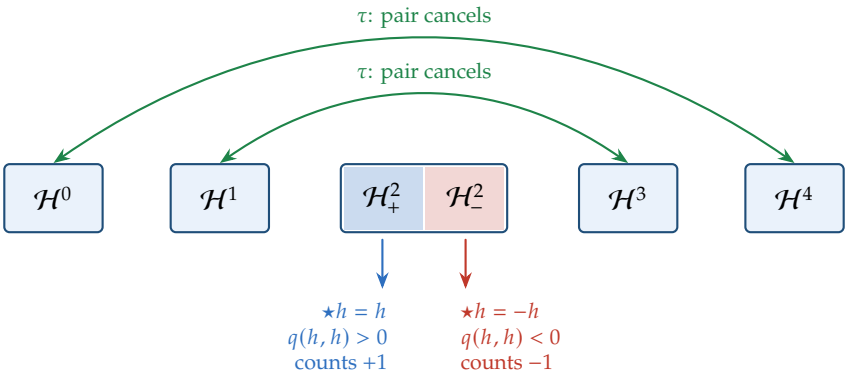

Figure T4.33: Why the signature operator counts $b^+ - b^-$ ($n = 4$). τ exchanges $\mathcal{H}^p$ and $\mathcal{H}^{4-p}$, so each such pair contains as many $\tau = +1$ as $\tau = -1$ forms and drops out of $h_+ - h_-$. In the middle degree $\tau = \star$, and a self-dual harmonic form has positive intersection with itself, an anti-self-dual one negative. The index sees only the middle.

Worked example T4.64: signatures of four-manifolds from harmonic forms

- S^4: $b_2 = 0$, so $\sigma = 0$.
- T^4 with flat coordinates $x^1, \dots, x^4$: $\mathcal{H}^2$ is spanned by the six constant forms e^{ij}. Since $\star e^{12} = e^{34}$, $\star e^{13} = -e^{24}$, $\star e^{14} = e^{23}$, the combinations

$$e^{12} \pm e^{34}, \qquad e^{13} \mp e^{24}, \qquad e^{14} \pm e^{23}$$

are self-dual (upper signs) and anti-self-dual (lower signs): $b^+ = b^- = 3$ and $\sigma(T^4) = 0$. Check with q: $\int (e^{12} + e^{34}) \wedge (e^{12} + e^{34}) = 2 \int e^{1234} > 0$.

- $S^2 \times S^2$ with the product of round metrics: $\mathcal{H}^2$ is spanned by the two area forms ω_1, ω_2 (normalised to $\int_{S^2} \omega_i = 1$). Here $\star\omega_1 = \omega_2$ (the Hodge star of the area form of one factor is the area form of the other, for equal radii), so $\omega_1 + \omega_2$ is self-dual and $\omega_1 - \omega_2$ anti-self-dual. In the basis ω_1, ω_2, $q = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ (since $\omega_i \wedge \omega_i = 0$ and $\int \omega_1 \wedge \omega_2 = 1$), with eigenvalues ± 1: $\sigma = 0$.
- $\mathbb{CP}^2$ with the Fubini–Study metric: $b_2 = 1$, and $\mathcal{H}^2$ is spanned by the Kähler form ω. On a Kähler surface ω is self-dual (in local unitary coordinates $\omega = e^{12} + e^{34}$), so $b^+ = 1$, $b^- = 0$, $\sigma(\mathbb{CP}^2) = 1$. With the opposite orientation, $\overline{\mathbb{CP}}^2$ has $\sigma = -1$.
- **K3** (quoted): $b_2 = 22$ with $b^+ = 3$, $b^- = 19$, so $\sigma = -16$.

The index formula: Hirzebruch's theorem. The Atiyah–Singer theorem computes index D_S as the integral of a characteristic class. Nash does it with the general recipe [Nash (4.90)–(4.93)]; in Section T4.9.9 we will see a shorter route through the spinor index formula. The answer, in terms of the Pontryagin roots $\pm x_i$ of Section T4.8.5, is

$$\sigma(M) = \int_M L(M), \qquad L(M) = \prod_{i=1}^{m} \frac{x_i}{\tanh x_i}\Big|_{\text{degree } n} = \left(1 + \frac{p_1}{3} + \frac{7p_2 - p_1^2}{45} + \cdots\right)_{\text{degree } n}. \tag{T4.138}$$

This is the **Hirzebruch signature theorem** [Nash (4.94)–(4.95)]. The expansion follows from $\frac{y}{\tanh y} = 1 + \frac{y^2}{3} - \frac{y^4}{45} + \cdots$ and the same symmetric-function manipulation as for $\hat{A}$ in Section T4.8.5. In four dimensions

$$\sigma(M) = \frac{1}{3} \int_M p_1(M).$$

Check on $\mathbb{CP}^2$: $p_1(\mathbb{CP}^2) = 3h^2$ with $\int h^2 = 1$ (h the hyperplane class), so $\sigma = 1$, matching Example T4.64. *Check on $S^2 \times S^2$:* the tangent bundle is a sum of two bundles pulled back from S^2, whose Pontryagin classes live in $H^4(S^2) = 0$, so $p_1 = 0$ and $\sigma = 0$. Since index $D^+ = -\frac{1}{24} \int p_1$ for spinors, this is what gave index $D^+ = -\sigma/8$ in (T4.104).

Watch out: two normalisations of the L-polynomial

Nash writes the result as index $d_+ = 2^{n/2} \mathfrak{L}(X)[X]$ with $\mathfrak{L} = \prod_i \frac{x_i/2}{\tanh(x_i/2)}$ [Nash (4.93)], and remarks that Hirzebruch's $\prod_i x_i/\tanh x_i$ gives the same top-degree term. The reason: a homogeneous polynomial of form-degree n in the x_i has polynomial degree $n/2$, so substituting $x_i \to x_i/2$ multiplies it by $2^{-n/2}$, which the prefactor $2^{n/2}$ undoes. Check in $n = 4$: $\frac{x/2}{\tanh(x/2)} = 1 + \frac{x^2}{12} + \cdots$, so $2^2 \cdot \frac{x_1^2 + x_2^2}{12} = \frac{p_1}{3}$. The lower-degree terms of the two polynomials differ, so they are not interchangeable in formulas (such as the twisted index, or the η-invariant corrections of Chapter 10) that use them.

Physical picture: why a physicist meets the signature

In four dimensions Λ^+ contains the self-dual 2-forms. The deformation theory of instantons (Chapter 8) uses exactly the complex $\Omega^0 \xrightarrow{\mathrm{d}_A} \Omega^1 \xrightarrow{\mathrm{d}_A^+} \Omega^2_+$. Untwisted, its alternating sum of cohomology dimensions is $b_0 - b_1 + b^+ = \frac{1}{2}(\chi + \sigma)$, built from the Euler and signature indices of this section; this is the term $-3(1 - b_1 + b^+)$ in the instanton moduli space dimension

$8k - 3(1 - b_1 + b^+)$. The gravitational contribution to the axial anomaly is proportional to $\int p_1$, i.e. to the signature (Chapter 10).

T4.9.8 The Dolbeault operator: holomorphic sections as zero modes

In Example T4.43 we found that a harmonic spinor on $\mathbb{R}^2$ is a pair of a holomorphic and an antiholomorphic function. On a complex manifold the natural first-order operator is $\bar\partial$, whose kernel on functions is the holomorphic functions. Is $\bar\partial$ (suitably completed) of Dirac type, and how is it related to the spinor Dirac operator? It is, and on a Kähler manifold the two are the same operator in disguise: spinors *are* $(0,q)$-forms, up to a square root of a line bundle. This explains why spin structures on a Riemann surface are counted by square roots of the canonical bundle, and why the monopole zero modes of Example T4.53 are holomorphic polynomials.

Complex forms in one line each. On a complex manifold with local holomorphic coordinates $z^j = x^j + iy^j$ ($j = 1, \dots, m$, real dimension $n = 2m$) put

$$\mathrm{d}z^j = \mathrm{d}x^j + i\,\mathrm{d}y^j, \quad \mathrm{d}\bar z^j = \mathrm{d}x^j - i\,\mathrm{d}y^j, \quad \frac{\partial}{\partial z^j} = \tfrac12\Big(\frac{\partial}{\partial x^j} - i\frac{\partial}{\partial y^j}\Big), \quad \frac{\partial}{\partial \bar z^j} = \tfrac12\Big(\frac{\partial}{\partial x^j} + i\frac{\partial}{\partial y^j}\Big).$$

Then $\mathrm{d}f = \sum_j \partial_{z^j} f\,\mathrm{d}z^j + \sum_j \partial_{\bar z^j} f\,\mathrm{d}\bar z^j =: \partial f + \bar\partial f$ [Bär (1.23)], and $\bar\partial f = 0$ is the Cauchy–Riemann system: f is holomorphic. A form with p factors $\mathrm{d}z$ and q factors $\mathrm{d}\bar z$ is a **(p,q)-form**; $\Lambda^k T^*M \otimes \mathbb{C} = \bigoplus_{p+q=k} \Lambda^{p,q}$. The exterior derivative splits as $\mathrm{d} = \partial + \bar\partial$ with $\partial : \Lambda^{p,q} \to \Lambda^{p+1,q}$ and $\bar\partial : \Lambda^{p,q} \to \Lambda^{p,q+1}$ (differentiate the coefficients; $\mathrm{d}(\mathrm{d}z^j) = \mathrm{d}(\mathrm{d}\bar z^j) = 0$). Sorting $0 = \mathrm{d}^2$ by bidegree,

$$0 = \mathrm{d}^2 = \underbrace{\partial^2}_{(p+2,q)} + \underbrace{(\partial\bar\partial + \bar\partial\partial)}_{(p+1,q+1)} + \underbrace{\bar\partial^2}_{(p,q+2)} \quad\Longrightarrow\quad \partial^2 = 0,\ \ \partial\bar\partial = -\bar\partial\partial,\ \ \bar\partial^2 = 0 \tag{T4.139}$$

[Bär (1.24)–(1.26)], because the three pieces lie in different bidegrees and must vanish separately. So each $(\Omega^{p,\bullet}, \bar\partial)$ is a complex, the **Dolbeault complex** [Nash (4.63)], with cohomology $H^{p,q}_{\bar\partial}(M)$ and **Hodge numbers** $h^{p,q} = \dim H^{p,q}_{\bar\partial}$. We take $p = 0$ as Nash does.

Metric conventions: with the Euclidean metric, $|\mathrm{d}z|^2 = |\mathrm{d}\bar z|^2 = 2$ and $\mathrm{d}z \perp \mathrm{d}\bar z$. For a real covector v write $v = v^{1,0} + v^{0,1}$; then $v^{1,0} = \overline{v^{0,1}}$ and, for real u, v,

$$\langle u, v\rangle = \langle u^{1,0}, v^{1,0}\rangle + \langle u^{0,1}, v^{0,1}\rangle = 2\,\mathrm{Re}\,\langle u^{0,1}, v^{0,1}\rangle. \tag{T4.140}$$

For example $\mathrm{d}x^{0,1} = \tfrac12 \mathrm{d}\bar z$ has $|\tfrac12 \mathrm{d}\bar z|^2 = \tfrac12 = \tfrac12 |\mathrm{d}x|^2$.

Working definition T4.20 (Clifford action on $(0,q)$-forms and the Dolbeault–Dirac operator)

On $\Lambda^{0,\bullet} = \bigoplus_q \Lambda^{0,q}$ let a real covector v act by

$$c(v) := \sqrt{2}\,\big(\varepsilon(v^{0,1}) - \iota(v^{0,1})\big), \tag{T4.141}$$

where $\iota(w) := \varepsilon(w)^\dagger$ is contraction with the metric dual of w. The **Dolbeault–Dirac operator** [Bär Ex. 1.3.20] is

$$D_{\bar\partial} := \sqrt{2}\,\big(\bar\partial + \bar\partial^*\big) : \ \Omega^{0,\mathrm{even}} \longrightarrow \Omega^{0,\mathrm{odd}}. \tag{T4.142}$$

[$\bar\partial^*$ is the adjoint of $\bar\partial$ and lowers the number of $\mathrm{d}\bar z$'s by one. $\Omega^{0,\mathrm{even}}$ holds forms built

from an even number of $\mathrm{d}\bar z$'s and no $\mathrm{d}z$] *Test:* check $\{c(u),c(v)\} = -2\langle u,v\rangle$, and that $D_{\bar\partial} = \sum_a c(e^a)\nabla_a$.

The Clifford relation follows from the canonical anticommutators, now with complex vectors. For $a,b \in \Lambda^{0,1}$ we have $\{\varepsilon(a),\varepsilon(b)\} = 0$, $\{\iota(a),\iota(b)\} = 0$ and $\{\iota(b),\varepsilon(a)\} = \langle a,b\rangle$ (the Hermitian inner product, linear in a), exactly as in (T4.105). So, with $a = u^{0,1}$ and $b = v^{0,1}$,

$$\{c(u),c(v)\} \overset{(1)}{=} 2\big(-\{\varepsilon(a),\iota(b)\} - \{\iota(a),\varepsilon(b)\}\big) \overset{(2)}{=} -2\big(\langle a,b\rangle + \langle b,a\rangle\big)$$
$$\overset{(3)}{=} -4\,\mathrm{Re}\langle u^{0,1},v^{0,1}\rangle \overset{(4)}{=} -2\langle u,v\rangle.$$

(1) Expand; the $\varepsilon\varepsilon$ and $\iota\iota$ anticommutators vanish.
(2) The mixed anticommutators are inner products.
(3) $\langle b,a\rangle = \overline{\langle a,b\rangle}$.
(4) (T4.140).

And the operator: on flat $\mathbb{C}^m$, $\mathrm{d} = \sum_a \varepsilon(e^a)\partial_a$ (T4.116); its $(0,1)$ part is $\bar\partial = \sum_a \varepsilon(e^{a\,(0,1)})\partial_a$, the adjoint is $\bar\partial^* = -\sum_a \iota(e^{a\,(0,1)})\partial_a$ (as for d^*), and so $\sqrt{2}(\bar\partial + \bar\partial^*) = \sum_a c(e^a)\partial_a$. On a curved *Kähler* manifold the same holds with $\partial_a \to \nabla_a$, because there the Levi-Civita connection preserves the splitting into (p,q) types. Squaring, using $\bar\partial^2 = 0 = (\bar\partial^*)^2$,

$$D_{\bar\partial}^2 = 2\big(\bar\partial\bar\partial^* + \bar\partial^*\bar\partial\big) = 2\Delta_{\bar\partial}, \tag{T4.143}$$

so $2\Delta_{\bar\partial}$ is of Laplace type [Bär (1.27)]; on a Kähler manifold $2\Delta_{\bar\partial} = \Delta$, the Hodge Laplacian.

Worked example T4.65: the Dolbeault–Dirac operator on $\mathbb{C}$ is the Dirac operator

On $\mathbb{C}$ with $z = x+iy$, $\Lambda^{0,\bullet}$ has orthonormal basis $(1,\ \mathrm{d}\bar z/\sqrt{2})$. Write a section as $f + h\,\mathrm{d}\bar z/\sqrt{2}$, i.e. as the column (f,h). First the adjoint of $\bar\partial$: for $g\,\mathrm{d}\bar z$,

$$(\bar\partial f, g\,\mathrm{d}\bar z) \overset{(1)}{=} \int \partial_{\bar z} f\ \bar g\ \langle \mathrm{d}\bar z, \mathrm{d}\bar z\rangle\,\mathrm{d}x\,\mathrm{d}y \overset{(2)}{=} 2\int \partial_{\bar z} f\ \bar g \overset{(3)}{=} -2\int f\ \partial_{\bar z}\bar g \overset{(4)}{=} \int f\ \overline{(-2\partial_z g)},$$

(1) $\bar\partial f = \partial_{\bar z} f\,\mathrm{d}\bar z$ and the L^2 inner product.
(2) $|\mathrm{d}\bar z|^2 = 2$.
(3) Integrate by parts (compact support).
(4) $\overline{\partial_z g} = \partial_{\bar z}\bar g$.

so $\bar\partial^*(g\,\mathrm{d}\bar z) = -2\partial_z g$. In the orthonormal basis $(g = h/\sqrt{2})$:

$$D_{\bar\partial}\begin{pmatrix} f \\ h\end{pmatrix} \overset{(1)}{=} \sqrt{2}\begin{pmatrix} -2\partial_z(h/\sqrt{2}) \\ \sqrt{2}\,\partial_{\bar z} f\end{pmatrix} \overset{(2)}{=} \begin{pmatrix} 0 & -2\partial_z \\ 2\partial_{\bar z} & 0\end{pmatrix}\begin{pmatrix} f \\ h\end{pmatrix} = \begin{pmatrix} 0 & -(\partial_x - i\partial_y) \\ \partial_x + i\partial_y & 0\end{pmatrix}\begin{pmatrix} f \\ h\end{pmatrix}. \tag{T4.144}$$

(1) $\bar\partial f = \partial_{\bar z} f\,\mathrm{d}\bar z = \sqrt{2}\,\partial_{\bar z} f\cdot(\mathrm{d}\bar z/\sqrt{2})$, and the $\bar\partial^*$ just computed.
(2) Collect.

Compare with our Dirac operator with $\gamma_1 = \sigma_1$, $\gamma_2 = \sigma_2$: $D = -i(\sigma_1\partial_x + \sigma_2\partial_y) = \left(\begin{smallmatrix} 0 & -2i\partial_z \\ -2i\partial_{\bar z} & 0\end{smallmatrix}\right)$. With the constant unitary $U = \mathrm{diag}(1,i)$,

$$UDU^{-1} = \begin{pmatrix} 0 & -2i\partial_z\cdot\frac{1}{i} \\ i\cdot(-2i)\partial_{\bar z} & 0\end{pmatrix} = \begin{pmatrix} 0 & -2\partial_z \\ 2\partial_{\bar z} & 0\end{pmatrix} = D_{\bar\partial}.$$

So on $\mathbb{C}$ the Dolbeault–Dirac operator *is* the Dirac operator, with $S^+ = \Lambda^{0,0}$ (functions) and $S^- = \Lambda^{0,1}$. Its symbol is $\gamma(\xi)$ with $\gamma(e^1) = \sigma_2$, $\gamma(e^2) = -\sigma_1$, which one checks from (T4.141)

($\gamma = ic$): $c(\mathrm{d}x) = \sqrt{2}(\varepsilon - \iota)(\frac{1}{2}\mathrm{d}\bar{z})$ sends $1 \mapsto \mathrm{d}\bar{z}/\sqrt{2}$ and $\mathrm{d}\bar{z}/\sqrt{2} \mapsto -1$, i.e. $c(\mathrm{d}x) = J$ and $ic(\mathrm{d}x) = \sigma_2$. The zero modes: $D_{\bar\partial}(f, h) = 0$ says $\partial_{\bar z} f = 0$ and $\partial_z h = 0$: f holomorphic and h antiholomorphic, the result of Example T4.43.

Worked example T4.66: $\Lambda^{0,\bullet}\mathbb{C}^2$ is the four-dimensional spinor space

On $\mathbb{C}^2$ the bundle $\Lambda^{0,\bullet}$ has basis 1, $\mathrm{d}\bar{z}^1$, $\mathrm{d}\bar{z}^2$, $\mathrm{d}\bar{z}^1 \wedge \mathrm{d}\bar{z}^2$ (normalised by powers of $\sqrt{2}$): dimension $4 = 2^{4/2}$, the size of Dirac spinors in four dimensions. The operators $\frac{1}{\sqrt{2}}\varepsilon(\mathrm{d}\bar{z}^j)$ and their adjoints obey the canonical anticommutation relations of two fermionic modes; they are the $b_j^\dagger$, b_j of Section T4.4.2, and $\Lambda^{0,\bullet}\mathbb{C}^2$ is the Fock space $\Lambda^\bullet\mathbb{C}^2$ of (T4.39). The chirality $\Gamma = (-1)^F$ is the parity of q:

$$S^+ \cong \Lambda^{0,0} \oplus \Lambda^{0,2} = \langle 1,\ \mathrm{d}\bar{z}^1 \wedge \mathrm{d}\bar{z}^2 \rangle, \qquad S^- \cong \Lambda^{0,1} = \langle \mathrm{d}\bar{z}^1,\ \mathrm{d}\bar{z}^2 \rangle.$$

In general $\dim \Lambda^{0,\bullet}\mathbb{C}^m = 2^m = 2^{n/2}$: *the Fock-space construction of spinors is the statement that spinors on $\mathbb{C}^m$ are $(0,q)$-forms.* Compare the forms of Section T4.9.1: all of $\Lambda^\bullet\mathbb{R}^{2m}$ is the Fock space of $2m$ modes; the $(0,q)$-forms use only the m antiholomorphic ones.

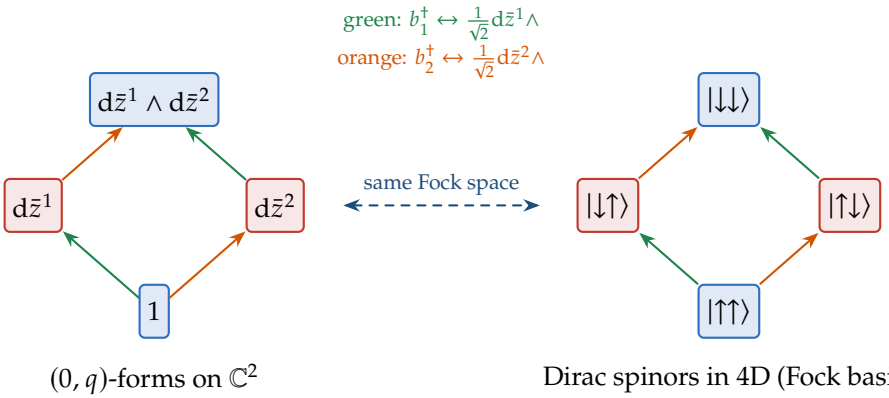

Figure T4.34: Spinors on $\mathbb{C}^2$ are $(0,q)$-forms. Left: the four basic $(0,q)$-forms, with wedging by $\mathrm{d}\bar{z}^1$ and $\mathrm{d}\bar{z}^2$ as the arrows. Right: the Fock basis of four-dimensional spinors of Section T4.4.2, with the creation operators $b_1^\dagger, b_2^\dagger$. The two squares are the same. Blue boxes are even (S^+), red boxes odd (S^-).

The global statement: spinors are $(0,q)$-forms twisted by $K^{1/2}$. Flat $\mathbb{C}^m$ hides a subtlety: under rotations, spinors and $(0,q)$-forms do *not* transform in the same way. We compute on $\mathbb{C}$. Let R_θ rotate the plane by θ (from e_1 towards e_2).

- *Spinors.* By Example T4.28 the lift is $a(\theta) = \exp(-\frac{\theta}{2}\gamma_1\gamma_2)$, and with $\gamma_1\gamma_2 = \sigma_1\sigma_2 = i\sigma_3$ this is $\mathrm{diag}(e^{-i\theta/2}, e^{i\theta/2})$: S^+ has weight $-\frac{1}{2}$, S^- weight $+\frac{1}{2}$.
- *Forms.* A rotation moves covectors like vectors, $e^1 \mapsto \cos\theta\, e^1 + \sin\theta\, e^2$, $e^2 \mapsto -\sin\theta\, e^1 + \cos\theta\, e^2$. Hence

$$\mathrm{d}z = e^1 + ie^2 \overset{(1)}{=} (\cos\theta - i\sin\theta)\, e^1 + (\sin\theta + i\cos\theta)\, e^2 \overset{(2)}{=} e^{-i\theta}\big(e^1 + ie^2\big) = e^{-i\theta}\mathrm{d}z,$$

  (1) Substitute the rotated covectors and collect.
  (2) $\sin\theta + i\cos\theta = i(\cos\theta - i\sin\theta) = ie^{-i\theta}$.

  and $\mathrm{d}\bar{z} \mapsto e^{i\theta}\mathrm{d}\bar{z}$. So $\Lambda^{0,0}$ has weight 0 and $\Lambda^{0,1}$ weight +1.

The weights of the forms are those of the spinors shifted by $+\frac{1}{2}$. The line bundle $K \coloneqq \Lambda^{m,0}$ (the **canonical bundle**; on $\mathbb{C}$ it is spanned by $\mathrm{d}z$, weight -1) has a square root of weight $-\frac{1}{2}$, and $(0, \frac{1}{2}-\frac{1}{2},\ 1-\frac{1}{2}) = (-\frac{1}{2}, \frac{1}{2})$. Globally:

Key idea: spinors on a Kähler manifold

On a Kähler manifold of complex dimension m,

$$S \ \cong\ \Lambda^{0,\bullet}T^*M \otimes K^{1/2}, \qquad S^+ \cong \Lambda^{0,\mathrm{even}} \otimes K^{1/2}, \quad S^- \cong \Lambda^{0,\mathrm{odd}} \otimes K^{1/2}, \tag{T4.145}$$

and under this isomorphism D is the Dolbeault–Dirac operator $\sqrt{2}(\bar\partial + \bar\partial^*)$ acting on $(0,q)$-forms with values in $K^{1/2}$. *Spin structures are the same thing as holomorphic square roots $K^{1/2}$ of K*; one exists iff $c_1(K)$ is even, which is $w_2 = 0$ for a complex manifold. Harmonic spinors of positive chirality are holomorphic sections of $K^{1/2}$ (in real dimension two; in general, $\bar\partial$-cohomology of $K^{1/2}$).

Worked example T4.67: Riemann surfaces: spin structures are square roots of K

On a compact Riemann surface Σ_g, $K = T^*\Sigma$ (the $(1,0)$-forms) has degree

$$\deg K \overset{(1)}{=} -\deg T\Sigma \overset{(2)}{=} -\chi(\Sigma_g) = 2g-2,$$

(1) K is dual to the holomorphic tangent bundle, and dualising flips the degree.
(2) The degree (first Chern number) of the tangent bundle is the Euler number (Gauss–Bonnet, or the Poincaré–Hopf count of zeros of a vector field).

which is even, so square roots exist: every orientable surface is spin, as we found by hand.

- $S^2 = \mathbb{CP}^1$: $K = \mathcal{O}(-2)$ (spanned by $\mathrm{d}z$, which has a double pole at $z=\infty$: $\mathrm{d}z = -w^{-2}\mathrm{d}w$ with $w = 1/z$). The square root $K^{1/2} = \mathcal{O}(-1)$ is unique, and so is the spin structure (Example T4.36). $S^+ = \mathcal{O}(-1)$ has no holomorphic sections (a negative-degree bundle has none). The negative-chirality zero modes are the Dolbeault cohomology $H^{0,1}(K^{1/2})$, and Serre duality ($H^1(L) \cong H^0(K\otimes L^{-1})^*$) turns this into $H^0(K^{1/2})^*$, which is zero again: *no harmonic spinors*, as Lichnerowicz said. Twisting by the monopole bundle $L_k = \mathcal{O}(k)$ gives $S^+ \otimes L_k = \mathcal{O}(k-1)$, with the k holomorphic sections $1, z, \ldots, z^{k-1}$ (Example T4.53).

- $T^2 = \mathbb{C}/\Lambda$: K is trivial ($\mathrm{d}z$ is a global nowhere-zero section). Its square roots are the flat line bundles whose holonomy around each of the two cycles is ±1: $2^2 = 4$ of them, the four spin structures of Example T4.35. Only the trivial root (periodic–periodic) has a holomorphic section (the constant), matching the two zero modes, one of each chirality, of Example T4.45.

- **Genus** g: $K^{1/2}$ has degree $g-1$, and the square roots differ by the 2^{2g} flat bundles with holonomies ±1: $2^{2g} = |H^1(\Sigma_g;\mathbb{Z}_2)|$ spin structures, Nash's count [Nash p. 113]. Algebraic geometers call them **theta characteristics**. The number of harmonic spinors $h^0(K^{1/2})$ depends on the choice (and the complex structure), but its parity does not: $2^{g-1}(2^g+1)$ spin structures are "even" and $2^{g-1}(2^g-1)$ "odd". String theorists sum over all of them (Chapter 9).

- $\mathbb{CP}^2$: $K = \mathcal{O}(-3)$, of odd degree on a line, has no square root: $\mathbb{CP}^2$ is not spin (Example T4.37). But $\Lambda^{0,\bullet}$ is still a perfectly good Clifford module and $D_{\bar\partial}$ exists. Formally $\Lambda^{0,\bullet} = S \otimes K^{-1/2}$: neither factor exists alone, but the sign ambiguities of the two cancel in the product, as they did for $S\otimes S^*$. Such a pair is a **spin^c structure**; every complex manifold has one.

Watch out: the index of $\bar\partial$ on $K^{1/2}$ is always zero on a surface

Riemann–Roch for a holomorphic line bundle L on Σ_g says $h^0(L) - h^1(L) = \deg L + 1 - g$. For $L = K^{1/2}$ this is $(g-1) + 1 - g = 0$, whatever the spin structure. This is the statement index $D^+ = \int \hat A = 0$ in two dimensions (Example T4.54): zero modes can occur, but always in chirality pairs.

Key idea: the index of the Dolbeault operator: Riemann–Roch [Nash (4.64)–(4.72)]

On a compact complex manifold,

$$\operatorname{index} D_{\bar\partial} = \sum_q (-1)^q\, h^{0,q} =: \chi(M,\mathcal{O}) = \int_M \operatorname{td}(M), \tag{T4.146}$$

$$\operatorname{td} = \prod_i \frac{x_i}{1-e^{-x_i}} = 1 + \frac{c_1}{2} + \frac{c_1^2 + c_2}{12} + \cdots$$

where now $x_1, \dots, x_m$ are the Chern roots of the holomorphic tangent bundle. The integer $\chi(M,\mathcal{O})$ is the **arithmetic genus** [Nash (4.65)]; the equality with $\int \operatorname{td}$ is the Hirzebruch–Riemann–Roch theorem [Nash (4.72)].

The first equality is again Hodge theory: $\operatorname{Ker} D_{\bar\partial}$ on $\Omega^{0,q}$ is the space of $\Delta_{\bar\partial}$-harmonic $(0,q)$-forms, which represents $H^{0,q}_{\bar\partial}$ (the Dolbeault version of (T4.122)), and the even and odd q are separated by the grading.

Worked example T4.68: arithmetic genera

- Σ_g. $h^{0,0} = 1$ (holomorphic functions on a compact surface are constant) and $h^{0,1} = g$. So
$$\operatorname{index} D_{\bar\partial} \overset{(1)}{=} 1 - g \overset{(2)}{=} \int_\Sigma \frac{c_1}{2} \overset{(3)}{=} \frac{\chi(\Sigma_g)}{2} = \frac{2-2g}{2}.$$
  (1) Hodge numbers.
  (2) The degree-2 part of td.
  (3) $c_1(T\Sigma)$ is the Euler class; its integral is χ.

- $\mathbb{CP}^2$. The total Chern class is $c(T\mathbb{CP}^2) = (1+h)^3$, so $c_1 = 3h$, $c_2 = 3h^2$, with $\int h^2 = 1$:
$$\int_{\mathbb{CP}^2} \operatorname{td} \overset{(1)}{=} \int \frac{c_1^2 + c_2}{12} \overset{(2)}{=} \frac{9+3}{12} = 1 \overset{(3)}{=} h^{0,0} - h^{0,1} + h^{0,2} = 1 - 0 + 0.$$
  (1) Degree-4 part of td.
  (2) $c_1^2 = 9h^2$, $c_2 = 3h^2$.
  (3) Hodge numbers of $\mathbb{CP}^2$: only $h^{0,0} = h^{1,1} = h^{2,2} = 1$ are nonzero.

  A non-spin manifold with a perfectly integral Dirac-type index.

- **K3.** K is trivial, so $K^{1/2}$ is trivial and $S = \Lambda^{0,\bullet}$ exactly. The Hodge numbers $h^{0,0} = 1$, $h^{0,1} = 0$, $h^{0,2} = 1$ give index $D_{\bar\partial} = 2$, which must equal index $D^+ = \hat A(\mathrm{K3}) = -\sigma/8 = 2$ (Example T4.54). The two harmonic spinors are the constant function 1 and the holomorphic 2-form (the conjugate of the harmonic $(0,2)$-form $\overline{\Omega}$).

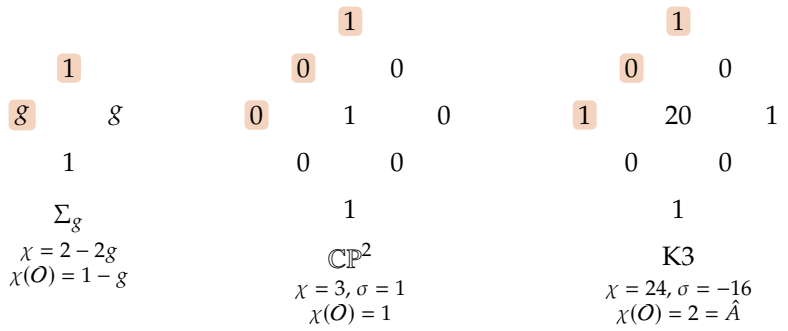

Figure T4.35: Hodge diamonds: $h^{p,q}$ sits in row $p+q$ (top row $p+q=0$), with $h^{0,q}$ on the upper-left edge (shaded). Row sums are Betti numbers, so the alternating sum of all entries is χ [Nash (4.73)]. The alternating sum along the shaded edge is the arithmetic genus $\chi(\mathcal{O}) = \operatorname{index} D_{\bar\partial}$. For K3 the shaded edge is $1, 0, 1$, which is the number $\hat A = 2$ of harmonic spinors.

T4.9.9 One Dirac operator, four indices

Nash computes the indices of the Euler, Dolbeault and signature operators by three separate manipulations of characteristic classes [Nash (4.55)–(4.62), (4.67)–(4.72), (4.90)–(4.93)], and the spinor index by a fourth [Nash (4.107)–(4.111)]. Each of them needs a "standard linear-algebraic fact" about exterior powers, and for the signature he quotes the key identity (4.91) with the words "this computation requires the combining of the splitting principle with a little group theory for SO(n)". The bispinor picture of Section T4.9.2 supplies that group theory in a few lines, and does more: it shows that, on a spin manifold, *all four operators are the one spin Dirac operator, twisted by different bundles*. Then the single formula $\operatorname{index} D^+_W = \int \hat A \operatorname{ch} W$ of (T4.103) produces the Euler class, the L-polynomial and the Todd class by one-line algebra. The questions are: which twisting bundle W, and which grading?

Step 1: a second Clifford action that commutes with the first. The two actions c and $\hat c$ on forms *anticommute*. A tensor product $S \otimes W$ has two actions that *commute*, one on each factor. To see $\Lambda^\bullet$ as a tensor product we must turn one anticommuting family into a commuting one. The chirality τ does it.

Working definition T4.21 (the twisting Clifford action)

Let $n = 2m$ and let $\tau = i^m\, c(e^1)\cdots c(e^n)$ be the chirality operator (T4.134) [$\tau^2 = 1$, and τ anticommutes with every $c(u)$ but commutes with every $\hat c(u)$]. For $v \in V$ put

$$w(v) := \hat c(v)\,\tau. \tag{T4.147}$$

[$\hat c(v) = \varepsilon(v) + \iota(v)$, the Hermitian Clifford action on forms] *Test:* $w(v)$ must commute with every $c(u)$, be Hermitian, and obey $\{w(u), w(v)\} = 2\langle u, v\rangle$.

First, τ commutes with every $\hat c(v)$: it is a product of an even number n of operators $c(e^a)$, each of which anticommutes with $\hat c(v)$ by (T4.108), so moving $\hat c(v)$ through it costs $(-1)^n = 1$. It anticommutes with every $c(u)$: that is what a chirality operator does (Section T4.9.7). With these two facts,

$$\begin{aligned} c(u)\,w(v) &\overset{(1)}{=} c(u)\,\hat c(v)\,\tau \overset{(2)}{=} -\hat c(v)\,c(u)\,\tau \overset{(3)}{=} \hat c(v)\,\tau\,c(u) = w(v)\,c(u), \\ w(u)w(v) + w(v)w(u) &\overset{(4)}{=} \hat c(u)\hat c(v)\,\tau^2 + \hat c(v)\hat c(u)\,\tau^2 \overset{(5)}{=} \{\hat c(u), \hat c(v)\} \overset{(6)}{=} 2\langle u, v\rangle. \end{aligned} \tag{T4.148}$$

(1) Definition (T4.147).

(2) $\{c(u), \hat{c}(v)\} = 0$.
(3) τ anticommutes with $c(u)$: the second sign cancels the first.
(4) Move the middle τ to the right through $\hat{c}(v)$ (they commute).
(5) $\tau^2 = 1$ (T4.133).
(6) (T4.108).

Hermiticity: $c(e^a)$ is anti-Hermitian with $c(e^a)^2 = -1$, so it is unitary, and so is τ; a unitary involution is Hermitian. Then $w(v)^\dagger = \tau^\dagger \hat{c}(v)^\dagger = \tau\, \hat{c}(v) = \hat{c}(v)\, \tau = w(v)$.

So on forms we now have *two commuting sets of Hermitian gamma matrices*,

$$\gamma(v) = i\, c(v) \quad \text{and} \quad w(v) = \hat{c}(v)\, \tau, \qquad [\gamma(u), w(v)] = 0,$$

each generating a copy of $\mathrm{Cl}(V) \otimes \mathbb{C} \cong \mathrm{End}(\mathbb{C}^{2^m})$ (Section T4.4.3). Their chirality operators are

$$\Gamma_S := (-i)^m \gamma(e^1) \cdots \gamma(e^n) = \tau, \qquad \Gamma_W := (-i)^m\, w(e^1) \cdots w(e^n) = (-i)^m\, \hat{c}(e^1) \cdots \hat{c}(e^n). \tag{T4.149}$$

The first is (T4.134). For the second, move all the τ's to the right through the $\hat{c}$'s (they commute) and use $\tau^n = 1$.

Key idea: forms are spinors tensor spinors

For $n = 2m$ there is an isomorphism

$$\Lambda^\bullet V \otimes \mathbb{C} \;\cong\; S \otimes W, \qquad \gamma(v) \leftrightarrow \gamma_S(v) \otimes \mathbf{1}, \qquad w(v) \leftrightarrow \mathbf{1} \otimes \gamma_W(v), \tag{T4.150}$$

where S and W are two copies of the 2^m-dimensional spinor space. The chirality of the first factor is τ and that of the second is Γ_W.

Why it is true. Pick a joint eigenvector-type decomposition: as a module for the γ's alone, $\Lambda^\bullet$ is a sum of copies of the unique irreducible module S (Section T4.4.3); there are $2^n/2^m = 2^m$ copies. The operators that commute with all the γ's are then exactly the $2^m \times 2^m$ matrices that mix the copies (Schur's lemma), an algebra of dimension 4^m. The w's commute with the γ's and generate an algebra of that dimension, so they generate *all* of it. Labelling the copies by a vector space W, the w's act on W, and a 2^m-dimensional module of $\mathrm{Cl}(V) \otimes \mathbb{C}$ is the spinor module. This is the precise form of "a form is a spinor with an extra spinor index".

Step 2: the Euler grading in the new language. The degree parity $(-1)^N$ anticommutes with all $2n$ generators $c, \hat{c}$. So does the product $\Gamma_S \Gamma_W$, since Γ_S anticommutes with the γ's and commutes with the w's, and vice versa. They are proportional, and the constant is found from a one-mode identity. Write $n_a := \varepsilon(e^a)\iota(e^a)$ for the occupation number of mode a (1 on forms containing e^a, 0 otherwise). Then

$$c(e^a)\, \hat{c}(e^a) \overset{(1)}{=} \big(\varepsilon_a - \iota_a\big)\big(\varepsilon_a + \iota_a\big) \overset{(2)}{=} \varepsilon_a \iota_a - \iota_a \varepsilon_a \overset{(3)}{=} n_a - (1 - n_a) = -(-1)^{n_a}, \tag{T4.151}$$

(1) Abbreviate $\varepsilon_a = \varepsilon(e^a)$, $\iota_a = \iota(e^a)$; use (T4.107).
(2) $\varepsilon_a^2 = 0$ and $\iota_a^2 = 0$ (Pauli exclusion).
(3) $\iota_a \varepsilon_a = 1 - \varepsilon_a \iota_a$ by the anticommutation relation (T4.105).

since $2n_a - 1$ is $+1$ on an occupied mode and -1 on an empty one. Now multiply over all modes:

$$\begin{aligned} \Gamma_S \Gamma_W &\overset{(1)}{=} i^m (-i)^m\, c_1 c_2 \cdots c_n\, \hat{c}_1 \hat{c}_2 \cdots \hat{c}_n \overset{(2)}{=} (-1)^{n(n-1)/2}\, (c_1 \hat{c}_1)(c_2 \hat{c}_2) \cdots (c_n \hat{c}_n) \\ &\overset{(3)}{=} (-1)^m \prod_{a=1}^{n} \big(-(-1)^{n_a}\big) \overset{(4)}{=} (-1)^m\, (-1)^N. \end{aligned} \tag{T4.152}$$

(1) (T4.149), with $c_a = c(e^a)$, $\hat{c}_a = \hat{c}(e^a)$.
(2) Move $\hat{c}_1$ left past $c_n, \dots, c_2$ ($n-1$ swaps), then $\hat{c}_2$ past $c_n, \dots, c_3$ ($n-2$ swaps), and so on: $n(n-1)/2$ swaps, each a sign.
(3) $n(n-1)/2 = m(2m-1) \equiv m \pmod 2$, and (T4.151) for each pair.
(4) There are n (an even number of) minus signs, and $\sum_a n_a = N$.

So

$$(-1)^N = (-1)^m \, \Gamma_S \, \Gamma_W, \qquad \tau = \Gamma_S. \tag{T4.153}$$

The signature grading is the chirality of the *first* factor alone; the Euler grading is the product of the chiralities of *both* factors, up to the sign $(-1)^m$. This single line contains the whole difference between the two complexes.

Worked example T4.69: $\Lambda^\bullet \mathbb{R}^2 = S \otimes W$ with explicit matrices

Use the Kronecker forms (T4.110): $c(e^1) = \mathbf{1} \otimes J$, $c(e^2) = J \otimes \sigma_3$, $\hat{c}(e^1) = \mathbf{1} \otimes \sigma_1$, $\hat{c}(e^2) = \sigma_1 \otimes \sigma_3$, with $J = -i\sigma_2$, and recall $\tau = ic(e^1)c(e^2) = \sigma_2 \otimes \sigma_1$ (Section T4.9.7). The twisting gammas are

$$w(e^1) \overset{(1)}{=} (\mathbf{1} \otimes \sigma_1)(\sigma_2 \otimes \sigma_1) \overset{(2)}{=} \sigma_2 \otimes \mathbf{1},$$
$$w(e^2) \overset{(3)}{=} (\sigma_1 \otimes \sigma_3)(\sigma_2 \otimes \sigma_1) \overset{(4)}{=} \sigma_1\sigma_2 \otimes \sigma_3\sigma_1 \overset{(5)}{=} (i\sigma_3) \otimes (i\sigma_2) = -\sigma_3 \otimes \sigma_2.$$

(1) Definition (T4.147) with $v = e^1$.
(2) $(A \otimes B)(C \otimes D) = AC \otimes BD$ and $\sigma_1^2 = \mathbf{1}$.
(3) Definition with $v = e^2$.
(4) Multiply slot by slot.
(5) $\sigma_1\sigma_2 = i\sigma_3$ and $\sigma_3\sigma_1 = i\sigma_2$.

Check against the gammas $\gamma(e^1) = \mathbf{1} \otimes \sigma_2$, $\gamma(e^2) = \sigma_2 \otimes \sigma_3$ of Example T4.55. Two Kronecker products commute when the number of slots in which the factors anticommute is even. $w(e^1) = \sigma_2 \otimes \mathbf{1}$ against $\mathbf{1} \otimes \sigma_2$: zero slots; against $\sigma_2 \otimes \sigma_3$: zero slots. $w(e^2) = -\sigma_3 \otimes \sigma_2$ against $\mathbf{1} \otimes \sigma_2$: zero slots; against $\sigma_2 \otimes \sigma_3$: two slots. All four commute. And $w(e^1)$, $w(e^2)$ anticommute with each other (one slot, σ_2 against σ_3) and square to $\mathbf{1}$.
The two chiralities are $\Gamma_S = \tau = \sigma_2 \otimes \sigma_1$ and

$$\Gamma_W \overset{(1)}{=} -i \, w(e^1)w(e^2) \overset{(2)}{=} i \, \sigma_2\sigma_3 \otimes \sigma_2 \overset{(3)}{=} i(i\sigma_1) \otimes \sigma_2 = -\sigma_1 \otimes \sigma_2,$$

(1) (T4.149) with $m = 1$.
(2) $w(e^1)w(e^2) = -(\sigma_2 \otimes \mathbf{1})(\sigma_3 \otimes \sigma_2) = -\sigma_2\sigma_3 \otimes \sigma_2$.
(3) $\sigma_2\sigma_3 = i\sigma_1$.

and $\Gamma_S\Gamma_W = -(\sigma_2\sigma_1) \otimes (\sigma_1\sigma_2) = -(-i\sigma_3) \otimes (i\sigma_3) = -\sigma_3 \otimes \sigma_3$. Since $(-1)^N = \mathrm{diag}(1,-1,-1,1) = \sigma_3 \otimes \sigma_3$, this is $(-1)^N = -\Gamma_S\Gamma_W$: (T4.153) with $m = 1$.
Now find the four joint eigenvectors. On even forms $\Gamma_W = -\Gamma_S(-1)^N = -\tau$, and on odd forms $\Gamma_W = +\tau$. The eigenvectors of τ were found in Section T4.9.7: $\tau(1 \pm i\,e^{12}) = \pm(1 \pm i\,e^{12})$ and $\tau(e^1 \pm i\,e^2) = \pm(e^1 \pm i\,e^2)$. With $\mathrm{d}z = e^1 + ie^2$ and $\mathrm{d}\bar{z} = e^1 - ie^2$:

form	$\mathrm{d}z$	$1 + i\,e^{12}$	$1 - i\,e^{12}$	$\mathrm{d}\bar{z}$
$\Gamma_S = \tau$	$+1$	$+1$	-1	-1
Γ_W	$+1$	-1	$+1$	-1
sits in	$S^+ \otimes W^+$	$S^+ \otimes W^-$	$S^- \otimes W^+$	$S^- \otimes W^-$
$(-1)^N$	-1	$+1$	$+1$	-1

Every one of the four lines $S^\pm \otimes W^\pm$ is spanned by one explicit form. The Euler grading picks the anti-diagonal ($S^+ \otimes W^- \oplus S^- \otimes W^+$ are the even forms); the signature grading picks the top row ($S^+ \otimes W$). See Figure T4.36.

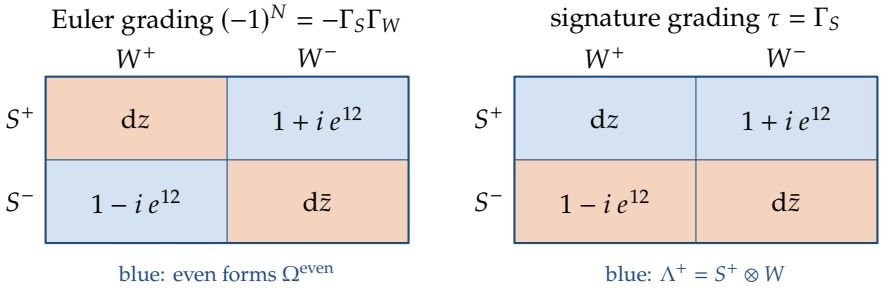

Figure T4.36: The four forms on $\mathbb{R}^2$ that diagonalise both chiralities, placed in the grid $S^\pm \otimes W^\pm$. Left: the degree parity is a *checkerboard*, because it is the product of the row and column chiralities (with a sign). Right: the signature grading τ sees only the row. So the Euler operator is the Dirac operator twisted by the *graded* bundle $W^+ \ominus W^-$, and the signature operator is the Dirac operator twisted by the whole of W.

Step 3: the connection splits too. To identify $\mathrm{d} + \mathrm{d}^*$ with a twisted Dirac operator we need more than algebra at a point: the Levi-Civita connection on forms must be the product of spin connections on S and W. An infinitesimal rotation $A_{ab} = -A_{ba}$ acts on forms by the derivation

$$\mathcal{D}_A := \sum_{a,b} A_{ab}\, \varepsilon(e^a)\, \iota(e^b),$$

which rotates each 1-form, $\mathcal{D}_A e^c = \sum_a A_{ac} e^a$, and obeys the Leibniz rule on wedge products (because ι is an antiderivation and $\varepsilon(e^a)$ moves past a k-form with the sign $(-1)^k$). The Levi-Civita connection on forms is $\nabla = \mathrm{d} + \mathcal{D}_\omega$ in an orthonormal coframe, since $\nabla e^c = -\omega^c{}_b e^b = \omega_{bc} e^b$ by (T4.66). Now rewrite $\mathcal{D}_A$ with $\varepsilon = \tfrac{1}{2}(\hat{c} + c)$ and $\iota = \tfrac{1}{2}(\hat{c} - c)$:

$$\begin{aligned}\mathcal{D}_A &\overset{(1)}{=} \frac{1}{4}\sum_{a,b} A_{ab}\big(\hat{c}^a + c^a\big)\big(\hat{c}^b - c^b\big) \overset{(2)}{=} \frac{1}{4}\sum_{a,b} A_{ab}\big(\hat{c}^a\hat{c}^b - c^a c^b\big) + \frac{1}{4}\sum_{a,b} A_{ab}\big(c^a\hat{c}^b - \hat{c}^a c^b\big)\\ &\overset{(3)}{=} \frac{1}{4}\sum_{a,b} A_{ab}\big(\hat{c}^a\hat{c}^b - c^a c^b\big) \overset{(4)}{=} \frac{1}{4}\sum_{a,b} A_{ab}\,\gamma^a\gamma^b + \frac{1}{4}\sum_{a,b} A_{ab}\,w^a w^b. \end{aligned} \tag{T4.154}$$

(1) Write $c^a = c(e^a)$, $\hat{c}^a = \hat{c}(e^a)$ and substitute.
(2) Multiply out and group.
(3) $\hat{c}^a c^b = -c^b\hat{c}^a$, so $c^a\hat{c}^b - \hat{c}^a c^b = c^a\hat{c}^b + c^b\hat{c}^a$ is symmetric in a, b, and its contraction with the antisymmetric A_{ab} vanishes.
(4) $\gamma = ic$ gives $-c^a c^b = \gamma^a\gamma^b$; and $w^a w^b = \hat{c}^a\tau\hat{c}^b\tau = \hat{c}^a\hat{c}^b\tau^2 = \hat{c}^a\hat{c}^b$.

With $A = \omega$ the first term is exactly the spin connection $\Omega = \frac{1}{4}\omega_{ab}\gamma^a\gamma^b$ of (T4.69), acting on S; the second is the same expression in the w's, the spin connection of W. So

$$\nabla^\Lambda = \nabla^S \otimes \mathbf{1} + \mathbf{1} \otimes \nabla^W, \qquad \mathrm{d} + \mathrm{d}^* = \sum_a c(e^a)\nabla_a = -i\gamma^a\nabla_a = D_W,$$

the Dirac operator of S twisted by W with its own spin connection (T4.94). On a spin manifold W is glued with the same lifted transition functions as S, so as bundles with connection and grading $W \cong S$, and

$$\Lambda^\bullet T^*M \otimes \mathbb{C} \;\cong\; S \otimes S, \qquad \mathrm{d} + \mathrm{d}^* = D_S \;\text{(Dirac twisted by spinors)}. \tag{T4.155}$$

Step 4: read off the indices. Everything now follows from $\operatorname{index} D_W^+ = \int \hat{A}\,\operatorname{ch} W$ and the spinor character $\operatorname{ch} S^+ - \operatorname{ch} S^- = (-1)^m \prod_i (e^{x_i/2} - e^{-x_i/2})$, where the sign is the one left open in (T4.100): in our conventions $c_1(S^\pm) = \mp\frac{x}{2}$ in two dimensions, so the sign is -1 per plane. Also $\operatorname{ch} S = \operatorname{ch} S^+ + \operatorname{ch} S^- = \prod_i (e^{x_i/2} + e^{-x_i/2})$ (all 2^m weights $\frac{1}{2}(\pm x_1 \pm \cdots \pm x_m)$ with a plus sign).

The Euler operator. By (T4.153) the even forms are $S^+ \otimes W^\epsilon \oplus S^- \otimes W^{-\epsilon}$ with $\epsilon = (-1)^m$, and D_W acts only on the S factor. So

$$\begin{aligned}\operatorname{index} D_{\mathrm{E}} &\overset{(1)}{=} \big(n_+(W^\epsilon) - n_-(W^{-\epsilon})\big) - \big(n_-(W^\epsilon) - n_+(W^{-\epsilon})\big) \overset{(2)}{=} \operatorname{index} D^+_{W^\epsilon} - \operatorname{index} D^+_{W^{-\epsilon}} \\ &\overset{(3)}{=} (-1)^m \int_M \hat{A}(M)\,\big(\operatorname{ch} W^+ - \operatorname{ch} W^-\big) \overset{(4)}{=} \int_M \prod_{i=1}^m \frac{x_i/2}{\sinh(x_i/2)}\big(e^{x_i/2} - e^{-x_i/2}\big) \\ &\overset{(5)}{=} \int_M \prod_{i=1}^m x_i \overset{(6)}{=} \int_M e(TM). \end{aligned} \tag{T4.156}$$

(1) The index counts zero modes on even forms minus zero modes on odd forms; $n_\pm(W^{\pm\epsilon})$ is the number of zero modes of D_W on $S^\pm \otimes W^{\pm\epsilon}$, and the odd forms are $S^- \otimes W^\epsilon \oplus S^+ \otimes W^{-\epsilon}$.
(2) Regroup by twisting bundle: $n_+(W^\epsilon) - n_-(W^\epsilon) = \operatorname{index} D^+_{W^\epsilon}$, and likewise for $W^{-\epsilon}$.
(3) The twisted index formula (T4.103) for each; the difference is ϵ times $(\operatorname{ch} W^+ - \operatorname{ch} W^-)$.
(4) $W \cong S$ as graded bundles, so $\operatorname{ch} W^+ - \operatorname{ch} W^- = (-1)^m \prod (e^{x_i/2} - e^{-x_i/2})$, and $(-1)^m(-1)^m = 1$; $\hat{A}$ from (T4.102).
(5) $\frac{x/2}{\sinh(x/2)} \cdot 2\sinh(x/2) = x$, one plane at a time.
(6) $\prod_i x_i$ is the Euler class in terms of the Pontryagin roots (Section T4.8.5).

This is the Gauss–Bonnet–Chern theorem $\chi(M) = \int_M e(TM)$ [Nash (4.53)–(4.54)], obtained without Nash's detour through $c_n(TX_{\mathbb{C}}) = (-1)^{n/2} e^2$ [Nash (4.61)–(4.62)]. The mechanism is visible: the sinh in the denominator of $\hat{A}$, which comes from the spinors, is cancelled by the sinh in the character of the *graded* twisting spinors. Every trace of the spin structure disappears from the answer, as it must, because χ is defined on every manifold.

The signature operator. Now the grading is $\tau = \Gamma_S \otimes \mathbf{1}$, so $\Omega^+ = \Gamma(S^+ \otimes W)$ and $D_{\mathrm{S}} = D^+_W$ with the *whole* of W:

$$\begin{aligned}\operatorname{index} D_{\mathrm{S}} &\overset{(1)}{=} \int_M \hat{A}(M)\,\operatorname{ch} W \overset{(2)}{=} \int_M \prod_{i=1}^m \frac{x_i/2}{\sinh(x_i/2)}\, 2\cosh(x_i/2) \overset{(3)}{=} \int_M \prod_{i=1}^m \frac{x_i}{\tanh(x_i/2)} \\ &\overset{(4)}{=} 2^m \int_M \prod_{i=1}^m \frac{x_i/2}{\tanh(x_i/2)} \overset{(5)}{=} \int_M \prod_{i=1}^m \frac{x_i}{\tanh x_i} = \sigma(M). \end{aligned} \tag{T4.157}$$

(1) The twisted index formula (T4.103) with the ungraded twist W.
(2) $\operatorname{ch} W = \operatorname{ch} S = \prod_i (e^{x_i/2} + e^{-x_i/2})$ and $e^y + e^{-y} = 2\cosh y$.
(3) $\cosh/\sinh = 1/\tanh$, and $\frac{x}{2} \cdot 2 = x$.
(4) Pull a factor 2 out of each of the m numerators.
(5) In top degree $n = 2m$ (polynomial degree m in the x_i) the substitution $x_i \to x_i/2$ multiplies by 2^{-m}, which cancels the prefactor (the pitfall after (T4.138)); then Hirzebruch's theorem.

The penultimate expression is Nash's $2^{n/2}\mathfrak{L}(X)[X]$ [Nash (4.92)–(4.93)] exactly. Two bonuses come for free. First, $x/\tanh(x/2)$ is an *even* function of x, so only degrees divisible by 4 survive, and the index vanishes when $n \equiv 2 \pmod 4$: the analytic shadow of the antisymmetry of the intersection form [Nash (4.76)]. Second, in four dimensions, one plane gives $\frac{x}{\tanh(x/2)} = 2 + \frac{x^2}{6} + \cdots$, so the degree-4 part of the product of two is $2 \cdot \frac{x_1^2 + x_2^2}{6} = \frac{p_1}{3}$: $\sigma = \frac{1}{3}\int p_1$, as in Section T4.9.7.

The Dolbeault operator. On a Kähler manifold, (T4.145) says $\Lambda^{0,\bullet} = S \otimes K^{-1/2}$ with the grading $\Gamma_S \otimes \mathbf{1}$, and $D_{\bar\partial}$ is D twisted by the line bundle $K^{-1/2}$. Its first Chern class is $-\frac12 c_1(K) = \frac12 c_1(M) = \frac12 \sum_i x_i$, where the x_i are the Chern roots of the holomorphic tangent bundle (and also the Pontryagin roots, since $TM \otimes \mathbb{C} = T^{1,0} \oplus T^{0,1}$ has roots $\pm x_i$). So

$$\operatorname{index} D_{\bar\partial} \overset{(1)}{=} \int_M \hat A(M)\, e^{c_1(M)/2} \overset{(2)}{=} \int_M \prod_{i=1}^m \frac{x_i/2}{\sinh(x_i/2)}\, e^{x_i/2} \overset{(3)}{=} \int_M \prod_{i=1}^m \frac{x_i\, e^{x_i/2}}{e^{x_i/2} - e^{-x_i/2}}$$
$$\overset{(4)}{=} \int_M \prod_{i=1}^m \frac{x_i}{1 - e^{-x_i}} \overset{(5)}{=} \int_M \operatorname{td}(M). \tag{T4.158}$$

(1) The twisted index formula with $\operatorname{ch} K^{-1/2} = e^{c_1(K^{-1/2})}$.
(2) $e^{\sum x_i/2} = \prod e^{x_i/2}$, and (T4.102).
(3) $2\sinh(x/2) = e^{x/2} - e^{-x/2}$.
(4) Divide numerator and denominator by $e^{x/2}$.
(5) The Todd class (T4.146).

This is Hirzebruch–Riemann–Roch [Nash (4.71)–(4.72)], again as a consequence of the spinor formula. The identity behind it, $\operatorname{td} = \hat A\, e^{c_1/2}$, holds as an identity of characteristic classes on *every* complex manifold, spin or not.

Worked example T4.70: non-integers that add up: $\mathbb{CP}^2$ and $\operatorname{td} = \hat A\, e^{c_1/2}$

On $\mathbb{CP}^2$, with h the hyperplane class, $c_1 = 3h$ and $p_1 = 3h^2$, and $\int h^2 = 1$. Then

$$\int_{\mathbb{CP}^2} \hat A\, e^{c_1/2} \overset{(1)}{=} \int \Big(1 - \frac{3h^2}{24}\Big)\Big(1 + \frac{3h}{2} + \frac{9h^2}{8}\Big) \overset{(2)}{=} \frac98 - \frac18 = 1 \overset{(3)}{=} \int_{\mathbb{CP}^2} \operatorname{td}.$$

(1) $\hat A = 1 - \frac{p_1}{24}$ and $e^{3h/2} = 1 + \frac{3h}{2} + \frac12\big(\frac{3h}{2}\big)^2 + \cdots$.
(2) Keep the h^2 terms: $\frac98 h^2$ from the second factor alone, $-\frac18 h^2$ from the first alone.
(3) Example T4.68.

Each factor on its own gives a non-integer: $\int \hat A = -\frac18$ (there is no spinor bundle, Example T4.54) and "$\int e^{c_1/2} = \frac98$" (there is no line bundle $K^{-1/2}$, since $c_1 = 3h$ is odd). The product bundle $S \otimes K^{-1/2} = \Lambda^{0,\bullet}$ exists, and its index is the integer 1. This is the spin^c mechanism of Example T4.67 seen in the characteristic classes.

Worked example T4.71: Nash's character identities from bispinors

Nash needs two characters of exterior powers. Both are one line from $\Lambda^\bullet \otimes \mathbb{C} \cong S \otimes W$ and (T4.153).

The signature character [Nash (4.91)]. With $\Lambda^\pm = S^\pm \otimes W$:

$$\operatorname{ch}\Lambda^+ - \operatorname{ch}\Lambda^- \overset{(1)}{=} \big(\operatorname{ch} S^+ - \operatorname{ch} S^-\big)\operatorname{ch} W \overset{(2)}{=} (-1)^m \prod_i \big(e^{x_i/2} - e^{-x_i/2}\big)\big(e^{x_i/2} + e^{-x_i/2}\big)$$
$$\overset{(3)}{=} (-1)^m \prod_i \big(e^{x_i} - e^{-x_i}\big) = \prod_{i=1}^m \big(e^{-x_i} - e^{x_i}\big),$$

(1) The Chern character is multiplicative on tensor products and additive on sums.
(2) The spinor characters above, with $W \cong S$.
(3) $(a-b)(a+b) = a^2 - b^2$ with $a = e^{x/2}$, $b = e^{-x/2}$.

which is (4.91) including Nash's sign. *Direct check on a surface:* from Example T4.69, Λ^+ is

spanned by $1 + i\,\mathrm{vol}$ (a trivial line) and dz (the canonical line $K = \Lambda^{1,0}$, with $c_1(K) = -x$), and Λ^- by $1 - i\,\mathrm{vol}$ and $d\bar{z}$ (the line $\bar{K} \cong K^{-1}$). So $\mathrm{ch}\,\Lambda^+ - \mathrm{ch}\,\Lambda^- = e^{-x} - e^{x}$.
The de Rham character [Nash (4.59)], for the real bundle $TX \otimes \mathbb{C}$ with roots $\pm x_i$:

$$\sum_p (-1)^p \,\mathrm{ch}\,\Lambda^p \overset{(1)}{=} (-1)^m \big(\mathrm{ch}\,S^+ - \mathrm{ch}\,S^-\big)\big(\mathrm{ch}\,W^+ - \mathrm{ch}\,W^-\big) \overset{(2)}{=} (-1)^m \prod_i \big(e^{x_i/2} - e^{-x_i/2}\big)^2$$
$$\overset{(3)}{=} (-1)^m \prod_i \big(e^{x_i} - 2 + e^{-x_i}\big) \overset{(4)}{=} \prod_i (1 - e^{x_i})(1 - e^{-x_i}),$$

(1) (T4.153): the even-minus-odd forms are $(-1)^m(S^+ - S^-)\otimes(W^+ - W^-)$ as virtual bundles.
(2) Both factors equal $(-1)^m \prod(e^{x_i/2} - e^{-x_i/2})$; $(-1)^{3m} = (-1)^m$.
(3) Square out.
(4) $(1 - e^{x})(1 - e^{-x}) = 2 - e^{x} - e^{-x} = -(e^{x} - 2 + e^{-x})$, one minus sign per plane.

which is Nash's (4.59) with the $2m$ roots $x_1, \ldots, x_m, -x_1, \ldots, -x_m$. The "standard linear-algebraic fact" (4.56) and the $\mathrm{SO}(n)$ group theory behind (4.91) are the same statement: a form is a product of two spinors.

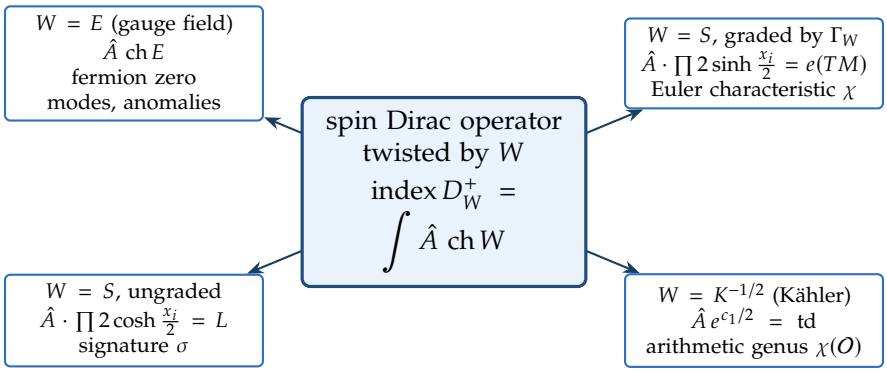

Figure T4.37: One index formula, four classical theorems. Each classical elliptic operator is the spin Dirac operator twisted by a bundle W; the integrand is $\hat{A}$ times the character of W. The twisting by spinors turns $\hat{A}$ into the Euler class (graded twist) or the L-class (ungraded twist); the twisting by $K^{-1/2}$ turns it into the Todd class. The three right-hand and lower answers make sense on non-spin manifolds, because $S \otimes W$ exists even when S does not.

operator	bundle	as D_W	integrand	index
Dirac D^+	S^+	$W = \mathbb{C}$	$\hat{A}$	$\hat{A}(M)$
twisted Dirac D^+_A	$S^+ \otimes E$	$W = E$	$\hat{A}\,\mathrm{ch}\,E$	$n_+ - n_-$ of D_A
Euler $d + d^*$	Λ^{even}	$W = S$, graded	$e(TM)$	$\chi(M)$
signature $d + d^*$	Λ^+ (via τ)	$W = S$	$L(M)$	$\sigma(M)$
Dolbeault $\sqrt{2}(\bar{\partial} + \bar{\partial}^*)$	$\Lambda^{0,\mathrm{even}}$	$W = K^{-1/2}$	$\mathrm{td}(M)$	$\chi(M, \mathcal{O})$

Physical picture: the supersymmetric quantum mechanics picture

In the path-integral proof of the index theorem (Chapter 4), $\mathrm{index}\,D = \mathrm{Tr}\,\Gamma e^{-tD^2}$ is the Witten index of a particle moving on M with fermions: one real fermion ψ^a per direction for the Dirac operator (these are the γ^a), *two* per direction for $d + d^*$ (these are c^a and $\hat{c}^a$). In the limit $t \to 0$ each rotation plane contributes a bosonic factor $\frac{x/2}{\sinh(x/2)}$ (this is $\hat{A}$) and each extra fermion pair contributes the fermionic factor $2\sinh(x/2)$ with periodic boundary

conditions (graded) or $2\cosh(x/2)$ with antiperiodic ones (ungraded). The Euler class is what remains when the extra fermions exactly cancel the bosons: $e(TM) = \mathrm{Pf}(R/2\pi)$ is a pure Berezin integral. The periodic/antiperiodic choice is the Ramond/Neveu–Schwarz choice of Section T4.6.3 in time.

Watch out: signs and orientations in the four formulas

The sign $(-1)^m$ appears twice in the Euler computation (in (T4.153) and in $\mathrm{ch}\, S^+ - \mathrm{ch}\, S^-$) and cancels. Nash's version has the same cancellation in the form $(-1)^{n/2}(-1)^{n/2}$ [Nash (4.62)]. If a different convention for Γ or for the orientation flips one of them, it flips the other too: χ does not depend on the orientation. The signature does: reversing the orientation flips τ and hence σ. The check that fixes all conventions at once is S^2: $\chi = 2 = \int e$, with $\int x = 2$.

Try it

Twist the Euler operator by a gauge bundle E, i.e. let $\mathrm{d}_A + \mathrm{d}_A^*$ act on $\Lambda^\bullet \otimes E$. Show that its index is $\mathrm{rk}(E)\,\chi(M)$ for every connection. *Answer:* the integrand is $\hat{A}\,(\mathrm{ch}\, W^+ - \mathrm{ch}\, W^-)(-1)^m\ \mathrm{ch}\, E = e(TM)\ \mathrm{ch}\, E$; since $e(TM)$ already has top degree, only $\mathrm{ch}_0 E = \mathrm{rk}\, E$ contributes. The twisted *signature* operator is different: its index $\int \prod_i \frac{x_i}{\tanh(x_i/2)}\ \mathrm{ch}\, E$ picks up $\mathrm{ch}_2 E$ in four dimensions, and it is the operator Atiyah and Singer used in their original proof.

Reading Nash (pp. 103–112, (4.47)–(4.95))

Nash treats the classical complexes as examples of his second index formula (4.48), $\mathrm{index}\, D = (-1)^{n/2}\{\mathrm{ch}(\sum(-1)^p[E^p])\, e(X)^{-1}\, \mathrm{td}(TX_{\mathbb{C}})\}[X]$, valid on even-dimensional oriented manifolds. The correspondences with this section are:

- *De Rham complex* (4.49)–(4.51): our $\mathrm{d} + \mathrm{d}^*$ on Ω^{even}, the Euler operator D_{E} (T4.126). Its index (4.52) is χ by Hodge theory (T4.127). Nash's characteristic class manipulations (4.55)–(4.62) giving Gauss–Bonnet (4.53)–(4.54) are our (T4.156); the identity (4.59) is derived in Example T4.71. His footnote that $b_i = \dim_{\mathbb{C}} H^i(X;\mathbb{C})$ is why we complexify forms throughout.
- *Dolbeault complex* (4.63)–(4.72): our $D_{\bar\partial}$ of Section T4.9.8 with index $\sum(-1)^q h^{0,q}$ (4.64)–(4.65), the arithmetic genus. Riemann–Roch (4.71)–(4.72) is (T4.158). The relation (4.73) between Betti and Hodge numbers is Figure T4.35. Nash uses only the $p = 0$ row, as we do; the general p is the twist by $\Lambda^{p,0}$.
- *Signature complex* (4.74)–(4.95): intersection form (4.74), signature (4.75), its vanishing for $n \equiv 2 \pmod 4$ (4.76), $\tau = i^{p(p-1)+n/2}\star$ (4.77) and $\tau^2 = 1$ (4.78) are our (T4.130)–(T4.133). The splitting (4.79), d_+ (4.80)–(4.82) and the Hodge-theoretic count (4.83)–(4.89) are (T4.135)–(T4.136). The character (4.90)–(4.91) is in Example T4.71, and (4.92)–(4.93) is (T4.157). The two normalisations of the L-polynomial (p. 112) are in the pitfall after (T4.138); (4.94)–(4.95) is Hirzebruch's theorem.

Nash writes the eigenvalues of τ as "∓ 1" in (4.79) but uses Ω^+ for the $+1$ eigenspace, as we do. He does not mention the Clifford structure on forms: in his treatment the three complexes are unrelated to the Dirac operator of pp. 113–118. The bispinor identification (T4.155) is what links them, and is the route taken in [Bär §1.3] and in Atiyah–Singer's later papers.

Recap

- Wedge $\varepsilon(v)$ and contraction $\iota(v)$ are fermion creation and annihilation operators on $\Lambda^\bullet$. The combinations $c = \varepsilon - \iota$ and $\hat{c} = \varepsilon + \iota$ are two anticommuting Clifford actions ($c^2 = -|v|^2$, $\hat{c}^2 = +|v|^2$). On $\Lambda^\bullet\mathbb{R}^2$ they are explicit 4×4 Kronecker products.
- The quantisation map Q turns a form into a matrix: forms are bispinors, $\Lambda^\bullet \otimes \mathbb{C} \cong S \otimes S^*$ (even n), which is why forms never need a spin structure.
- $\mathrm{d} + \mathrm{d}^* = \sum_a c(e^a)\nabla_a = -i\gamma^a\nabla_a$ is of Dirac type; its square is the Hodge Laplacian, and its zero modes are the harmonic forms, which represent de Rham cohomology (Hodge). Bochner: $\Delta = \nabla^*\nabla + \mathrm{Ric}$ on 1-forms, so $\mathrm{Ric} > 0 \Rightarrow b_1 = 0$.
- Gradings that anticommute with $\mathrm{d} + \mathrm{d}^*$: the degree parity (Euler operator, index χ) and the Clifford chirality $\tau = i^{k(k-1)+m}\star$ (signature operator, index σ, $\tau = \star$ on middle forms when $4 \mid n$). On Kähler manifolds $\sqrt{2}(\bar{\partial} + \bar{\partial}^*)$ on $\Lambda^{0,\bullet}$ is Dirac type too (index $\chi(M, \mathcal{O})$), and $S = \Lambda^{0,\bullet} \otimes K^{1/2}$: spin structures are square roots of K.
- Unification: $w(v) = \hat{c}(v)\tau$ commutes with c, so $\Lambda^\bullet \otimes \mathbb{C} = S \otimes W$ with $W \cong S$; the Levi-Civita connection splits; $\mathrm{d} + \mathrm{d}^* = D_W$. The Euler grading is $(-1)^m\Gamma_S\Gamma_W$ and the signature grading is Γ_S. From $\int \hat{A}\,\mathrm{ch}\,W$: $e(TM)$, $L(M)$ and $\mathrm{td}(M) = \hat{A}\,e^{c_1/2}$.

Chapter summary

The chapter started from one question: can the wave operator be written as the square of a first-order operator? Dirac's answer was yes, provided the coefficients anticommute, $\{\gamma^a, \gamma^b\} = 2\delta^{ab}$. Everything else followed from taking that relation seriously. The relation defines the Clifford algebra. Its matrix solutions are the gamma matrices, which we built in every dimension from tensor products of Pauli matrices, and whose size $2^{\lfloor n/2 \rfloor}$ is forced. Inside the algebra sit products of unit vectors. These act on vectors by reflections, and pairs of them act by rotations, so they form the spin group, a double cover of $\mathrm{SO}(n)$ in which a 2π rotation is -1.

The second half of the chapter moved the algebra onto a curved manifold. To do this we had to lift the frame transition functions from $\mathrm{SO}(n)$ to $\mathrm{Spin}(n)$ with consistent signs. When this is possible we have a spin structure, and there may be several of them: two on S^1, four on T^2, one on S^2 and none on $\mathbb{CP}^2$. On a spin manifold the Levi-Civita connection lifts to the spin connection $\nabla = \mathrm{d} + \frac{1}{4}\omega_{ab}\gamma^a\gamma^b$, and $D = -i\gamma^a\nabla_a$ is the Dirac operator. We computed its spectrum by hand on $\mathbb{R}^n$, S^1, T^2 and S^2. The Lichnerowicz formula $D^2 = \nabla^*\nabla + R/4$ explained the gaps we found, and the chirality splitting $D^+ : S^+ \to S^-$ produced the index $n_+ - n_-$. Finally the exterior algebra turned out to be a Clifford module too, so $\mathrm{d} + \mathrm{d}^*$ is a Dirac operator in disguise and the Euler characteristic, the signature and the arithmetic genus all come out of the same index formula.

The summary has five parts. Figures T4.38 and T4.39 put the algebra and the spectra on one page each. The concept tables (Tables T4.4 to T4.10) list every concept, what it means operationally, and where the rest of the book uses it. Tables T4.11 and T4.12 collect the numbers worth knowing by heart. The chapter closes with the calculations a reader should be able to do without looking, and a map from Nash's pages back to the sections of this chapter.

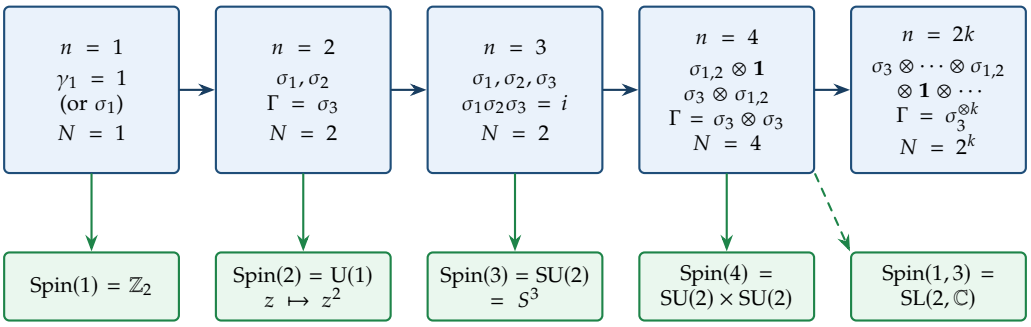

Figure T4.38: The algebraic half of the chapter in one picture. Top row: explicit Hermitian gamma matrices with $\{\gamma_a, \gamma_b\} = 2\delta_{ab}$, and the spinor dimension $N = 2^{\lfloor n/2 \rfloor}$. Each arrow is one step of the construction. Going from $n = 2k$ to $2k+1$ adds the chirality matrix Γ as the last gamma. Going from $2k+1$ to $2k+2$ doubles the size: the first $2k$ gammas become $\gamma_a \otimes \mathbf{1}$, and the last one ($\Gamma$) becomes $\Gamma \otimes \sigma_1$ and $\Gamma \otimes \sigma_2$ (Section T4.4.1). Starting from $\gamma_1 = 1$ at $n = 1$, this reproduces every box. Bottom row: the spin groups, generated by the even products of unit vectors, $\exp(-\frac{\theta}{2}\gamma_1\gamma_2)$ in each plane (Section T4.5). Each is a double cover of the rotation group, with kernel ± 1. The dashed arrow is the change to Minkowski signature, where the same four matrices generate Spin(1, 3) = SL(2, $\mathbb{C}$).

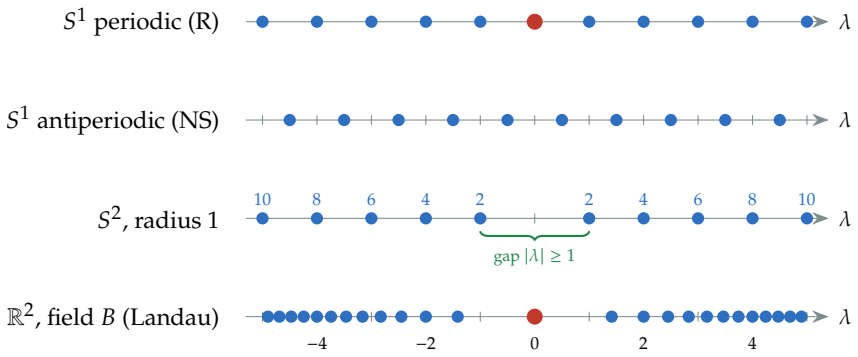

Figure T4.39: The Dirac spectra computed in this chapter, as dots on the λ axis (red: zero modes). The two circle spectra (length 2π) differ only by the spin structure: integers with one zero mode (Ramond), half-integers with none (Neveu–Schwarz) (Section T4.7.5). On the unit sphere the eigenvalues are $\pm(l+1)$ with multiplicity $2(l+1)$ (Section T4.7.7); the gap $|\lambda| \geq 1$ is Friedrich's bound $\lambda^2 \geq \frac{n}{n-1}\frac{R}{4}$ with $R = 2$, saturated (Section T4.8.3). In a magnetic field on $\mathbb{R}^2$ (here $B = 1$) the levels are $\pm\sqrt{2mB}$ plus a zero-energy level with one state per flux quantum, all of positive chirality (Section T4.8.4). Every spectrum is symmetric under $\lambda \to -\lambda$, because Γ anticommutes with D.

The algebra and the spectra on one page

Concept tables

In each table the last column says where the idea is used again. References to chapters are to the rest of the book; references to sections are to this chapter.

Concept	Operational meaning	Used later in
Square root of Δ	Demand $(-i\gamma^a\partial_a)^2 = -\partial^a\partial_a$; the cross terms cancel iff $\{\gamma^a, \gamma^b\} = 2\delta^{ab}$ (T4.2); no numbers do it, so γ^a are matrices (Section T4.1.1).	Every Dirac operator; $\sqrt{\text{Laplacian}}$ in Chapter 2
Klein–Gordon from Dirac	$(i\gamma^\mu\partial_\mu + m)(i\gamma^\nu\partial_\nu - m) = -(\partial^2 + m^2)$ with $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$ (T4.3).	Fermions in Chapter 10
Symbol	Replace $\partial_a \to i\xi_a$ and keep the top order. Laplace type: $\sigma(\xi) = \lvert\xi\rvert^2$; Dirac type: $\sigma(\xi)^2 = \lvert\xi\rvert^2$, i.e. $\sigma(\xi)$ is Clifford multiplication by ξ (T4.7) (Section T4.1.3).	Ellipticity, Chapter 2; symbol class in $K(T^*X)$, Chapter 4
Clifford algebra $\mathrm{Cl}_{p,q}$	Polynomials in anticommuting generators with $e_i^2 = +1$ (p of them) or -1 (q of them); reduce any word using $vw + wv = 2\langle v, w\rangle$ (T4.9).	Everything in this chapter
Basis, dimension 2^n	Ordered monomials $e_{i_1}\cdots e_{i_k}$, $i_1 < \cdots < i_k$: one per subset, so 2^n (T4.11); picture as the vertices of a cube (Figure T4.5).	Counting spinor components
Low dimensions	$\mathrm{Cl}_{0,1} = \mathbb{C}$, $\mathrm{Cl}_{1,0} = \mathbb{R}\oplus\mathbb{R}$, $\mathrm{Cl}_{0,2} = \mathbb{H}$ (quaternions, $ij = k$), $\mathrm{Cl}_{2,0} = \mathbb{R}(2)$, $\mathrm{Cl}_{3,0} = \mathbb{C}(2)$ (Pauli), $\mathrm{Cl}_{0,3} = \mathbb{H}\oplus\mathbb{H}$ (Sections T4.2.3 to T4.2.5).	Spin groups, instantons ($\mathbb{H}$), Chapter 8
Clifford vs exterior	$vw = v\wedge w + \langle v, w\rangle$: the same vector space $\Lambda^\bullet V$ with a deformed product (Dray's $\vee$ product, (T4.15)).	Forms as Clifford modules, Section T4.9
Even and odd parts	$\mathrm{Cl} = \mathrm{Cl}^0 \oplus \mathrm{Cl}^1$ by word length mod 2 (T4.17); $\mathrm{Cl}^0_{p,q} \cong \mathrm{Cl}_{p,q-1}$ (T4.18), e.g. $\mathrm{Cl}^0_{3,0} = \mathbb{H}$.	$\mathrm{Spin}(n) \subset \mathrm{Cl}^0$; supersymmetry gradings
Graded tensor product	$\mathrm{Cl}(V\oplus W) = \mathrm{Cl}(V)\hat{\otimes}\mathrm{Cl}(W)$, with a sign when two odd elements pass (T4.19).	Building gammas in higher n

Table T4.4: The Dirac square root and Clifford algebras (Sections T4.1 and T4.2).

Numbers worth knowing by heart

The first table is the dimension count behind every spinor calculation. Read across a row: in dimension n the gamma matrices are $N \times N$ with $N = 2^{\lfloor n/2\rfloor}$, a chirality matrix exists only for even n, and then the Weyl spinors have half the components.

Calculations to be able to do without looking

A toolkit chapter has done its job when its core calculations become reflexes. These are the ones the rest of the book assumes.

1. *Square the Dirac operator on $\mathbb{R}^n$.* Split $\gamma^a\gamma^b\partial_a\partial_b$ into its symmetric part, which is $\delta^{ab}\partial_a\partial_b$, and its antisymmetric part, which vanishes because partial derivatives commute (Section T4.1.1).

Concept	Operational meaning	Used later in
Euclidean chiral gammas ($n = 4$)	$\gamma_a = \left(\begin{smallmatrix} 0 & \tau_a \\ \tau_a^\dagger & 0 \end{smallmatrix}\right)$ with $\tau = (\vec{\sigma}, \pm i\mathbf{1})$ (T4.21); $\Gamma = \mathrm{diag}(\mathbf{1}, -\mathbf{1})$ (T4.24) (Section T4.3.1).	Instantons, Chapter 8; Nash (4.99)
Dirac and Weyl representations	Minkowski γ^0 Hermitian, γ^i anti-Hermitian; Weyl: $\gamma^\mu = \left(\begin{smallmatrix} 0 & \sigma^\mu \\ \bar{\sigma}^\mu & 0 \end{smallmatrix}\right)$ (T4.26); related by a unitary change of basis (Example T4.16).	QFT notes; Chapter 10
Chirality γ^5, Γ	$\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$; squares to $\mathbf{1}$, anticommutes with every γ^μ (T4.28); projectors $\frac{1}{2}(1 \pm \gamma^5)$.	Chiral fermions, Nash (10.1); index
Lorentz generators	$S^{\mu\nu} = \frac{i}{4}[\gamma^\mu, \gamma^\nu]$ (T4.29) obey the $\mathfrak{so}(1,3)$ algebra; $\Lambda_{1/2} = \exp(-\frac{i}{2}\omega_{\mu\nu}S^{\mu\nu})$ (T4.30).	Spin connection, Section T4.7
2π rotation	$\exp(-i\theta S^{12})$ at $\theta = 2\pi$ is $-\mathbf{1}$ (Example T4.19); boosts are not unitary (Example T4.20).	Spin structures
Weyl spinors	$\psi = (\psi_L, \psi_R)$, $\gamma^5 = \mp 1$; massless Dirac equation decouples; helicity (Section T4.3.5 and Figure T4.7).	Chiral anomalies, Chapter 10
Bilinears, traces	$\bar{\psi}\Gamma\psi$ for $\Gamma \in \{\mathbf{1}, \gamma^\mu, \sigma^{\mu\nu}, \gamma^\mu\gamma^5, \gamma^5\}$ (Table T4.2); $\mathrm{tr}\,\gamma^\mu\gamma^\nu = 4\eta^{\mu\nu}$, $\mathrm{tr}\,\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma = -4i\varepsilon^{\mu\nu\rho\sigma}$ (Example T4.24).	Triangle diagram, Chapter 10
SL$(2,\mathbb{C})$ picture	$X = x^\mu\sigma_\mu$, $\det X = x^\mu x_\mu$; $X \mapsto AXA^\dagger$ is a Lorentz transformation (T4.33) (Section T4.3.7).	Spin$(1,3)$
Gammas in $n = 2k$	Jordan–Wigner tensor products (T4.35); $\Gamma = (-i)^k\gamma_1\cdots\gamma_{2k} = \sigma_3^{\otimes k}$ (T4.36); explicit $n = 2, 4, 6$ (Example T4.25).	D in any dimension; $d = 6, 10, 12$ anomalies
Fock space	$b_j = \frac{1}{2}(\gamma_{2j-1} - i\gamma_{2j})$ obey the CAR (T4.38); spinors = states of k fermion modes, $\Gamma = (-1)^F$ (Section T4.4.2).	Forms as fermions, Chapter 7; Dolbeault
Uniqueness	Every irreducible representation in even n is equivalent to the one built here; odd n has two, $\Gamma \to \pm$ (Sections T4.4.3 and T4.4.4).	Well-defined spinor bundle
Classification	$\mathrm{Cl}_{0,n}$, $\mathrm{Cl}_{n,0}$, $\mathrm{Cl}_n \otimes \mathbb{C}$ as matrix algebras over $\mathbb{R}, \mathbb{C}, \mathbb{H}$ (Table T4.3); period 8 (real) and 2 (complex) from $\mathrm{Cl}_{0,n+2} = \mathrm{Cl}_{n,0} \otimes \mathbb{H}$ (T4.42).	Bott periodicity, KO, Chapter 3; real families, Chapter 4
Majorana spinors	Real representations exist when the algebra is of real type; $\mathrm{Cl}_{3,1} = \mathbb{R}(4)$ (Example T4.26).	Free Majorana fermion, Chapter 11

Table T4.5: Gamma matrices in four and in general dimensions (Sections T4.3 and T4.4).

Concept	Operational meaning	Used later in
Reflection	For a unit vector u, $x \mapsto uxu^{-1} = -R_u(x)$ (T4.44): conjugation by u is (minus) the mirror image in the plane $\perp u$.	Parity; Pin groups
Two reflections	Mirrors at angle $\theta/2$ compose to a rotation by θ (T4.45); the lift is $\exp(-\frac{\theta}{2}\gamma_1\gamma_2)$ (T4.46) (Figure T4.10).	Every spinor rotation
$\mathrm{Pin}(n)$, $\mathrm{Spin}(n)$	Products of unit vectors; Spin: an even number of them (Section T4.5.3).	Structure group of S
Double cover	$1 \to \{\pm 1\} \to \mathrm{Spin}(n) \to \mathrm{SO}(n) \to 1$ (T4.49); $a(2\pi) = -1$ (T4.47); the spinor representation is not a representation of $\mathrm{SO}(n)$.	Spin structures, w_2
Spin(2), Spin(3)	$\mathrm{Spin}(2) = \mathrm{U}(1)$ covering $\mathrm{SO}(2)$ by $z \mapsto z^2$ (T4.50); $\mathrm{Spin}(3) = \mathrm{SU}(2)$ with $R_{ij} = \frac{1}{2}\operatorname{tr}(\sigma_i U \sigma_j U^\dagger)$ (T4.52); $\mathrm{SO}(3) = \mathbb{RP}^3$, belt trick (Figure T4.12).	Monopoles, Chapter 8
$\mathfrak{spin}(n)$	Spanned by $\gamma_a\gamma_b$ $(a < b)$; an infinitesimal rotation A_{ab} lifts to $\frac{1}{4}A_{ab}\gamma_a\gamma_b = \frac{1}{2}A_{ab}\Sigma_{ab}$, $\Sigma_{ab} = \frac{1}{4}[\gamma_a, \gamma_b]$ (T4.55).	Spin connection $\frac{1}{4}\omega_{ab}\gamma^a\gamma^b$
Spin(4)	Unit quaternions (p, q) acting on $x \in \mathbb{H}$ by $x \mapsto pxq$ (T4.57); $\mathfrak{so}(4) = \mathfrak{su}(2) \oplus \mathfrak{su}(2)$, and $S^\pm$ carry the two factors; self-dual 2-forms act on S^+ only (T4.58).	Instantons, ADHM, Chapters 8 and 12
Lorentzian signature	$\mathrm{Spin}(1,3) = \mathrm{SL}(2,\mathbb{C})$; $\mathrm{Spin}(1,1)$ as the boosts (Example T4.32); Lorentz group has two components beyond Spin (Section T4.5.7).	Worldsheet fermions, Chapter 11

Table T4.6: The spin group (Section T4.5).

Concept	Operational meaning	Used later in
Frame bundle	Orthonormal frames glued by $g_{\alpha\beta} : U_\alpha \cap U_\beta \to \mathrm{SO}(n)$ with the cocycle rule (T4.60) (Section T4.6.1).	Every associated bundle, Chapter 1
Spin structure	Choose lifts $\hat{g}_{\alpha\beta} \in \mathrm{Spin}(n)$; the triple-overlap signs $\varepsilon_{\alpha\beta\gamma} = \hat{g}_{\alpha\beta}\hat{g}_{\beta\gamma}\hat{g}_{\gamma\alpha}$ (T4.62) must all be made $+1$ (Section T4.6.2).	All fermions on curved space
w_1, w_2	w_1: orientability; $w_2 = [\varepsilon_{\alpha\beta\gamma}] \in H^2(M;\mathbb{Z}_2)$ is the obstruction (T4.63); spin iff $w_1 = w_2 = 0$.	Nash (10.1) requirement; Chapters 1 and 10
Counting	If spin, the structures are counted by $H^1(M;\mathbb{Z}_2) = \mathrm{Hom}(\pi_1 M, \mathbb{Z}_2)$: a sign for each loop.	Nash p. 113; string sectors
S^1	Two: periodic (Ramond) and antiperiodic (Neveu–Schwarz) (T4.64); only the NS one bounds the disc (Example T4.34).	Superstrings, Chapter 11
T^2, T^n	Signs $(\varepsilon_1, \varepsilon_2)$ around the two cycles (T4.65): four; T^n has 2^n.	Fermions on the torus, Chapter 11
S^2	One; the clutching map $S^1 \to \mathrm{SO}(2)$ has degree 2, which is even, so it lifts (Figure T4.18).	Monopoles, S^{2m} in Nash (10.3)
$\mathbb{CP}^2$	None: $T\mathbb{CP}^2\big\|_{\mathbb{CP}^1} = \mathcal{O}(2) \oplus \mathcal{O}(1)$ has odd total degree 3 (Example T4.37); $\mathbb{CP}^n$ spin iff n odd.	index would be $-\frac{1}{8}$; Spin^c
Spinor bundle	$S = P_{\mathrm{Spin}} \times_{\mathrm{Spin}} \mathbb{C}^N$: components glued by $\hat{g}_{\alpha\beta}$ (T4.61); Clifford multiplication $TM \otimes S \to S$ (Section T4.6.7).	$E^\pm$ in Nash (4.100)

Table T4.7: Spin structures (Section T4.6).

Concept	Operational meaning	Used later in
Connection 1-forms	Solve $de^a + \omega^a{}_b \wedge e^b = 0$, $\omega_{ab} = -\omega_{ba}$ (T4.67); e.g. $\omega_{12} = -\cos\theta\, d\phi$ on S^2 (Example T4.39).	Gravitational anomalies, Chapter 10
Spin connection	$\nabla\psi = d\psi + \frac{1}{4}\omega_{ab}\gamma^a\gamma^b\psi$ (T4.69); Leibniz for Clifford multiplication (T4.70); preserves $S^{\pm}$.	Γ^μ in Nash (10.1)
Spin curvature	$R^S = \frac{1}{4}R_{ab}\gamma^a\gamma^b$ (T4.71).	Lichnerowicz; $\hat{A}$
Dirac operator	$D = -i\gamma^a\nabla_{e_a}$ (T4.72); formally self-adjoint by a divergence (T4.73); $D = \left(\begin{smallmatrix} 0 & D^- \\ D^+ & 0 \end{smallmatrix}\right)$ (T4.75).	Chapters 4 and 10
$\mathbb{R}^n$	Plane waves $u\, e^{ik\cdot x}$, $\lambda = \pm\lvert k\rvert$; in $n = 2$, $D^+ = -2i\partial_{\bar z}$ so zero modes are holomorphic (T4.76) (Example T4.43).	Riemann surfaces, Chapter 5
S^1	spec $D = \frac{2\pi}{L}\mathbb{Z}$ (R, one zero mode) or $\frac{2\pi}{L}(\mathbb{Z} + \frac{1}{2})$ (NS, none); spectral flow under a flat U(1) twist (Figure T4.20).	η-invariant, global anomalies, Chapter 10
T^2	$\lambda = \pm\sqrt{p^2 + q^2}$ on the shifted lattices of Figure T4.21; only $(+,+)$ has zero modes, $(n_+, n_-) = (1, 1)$, index 0.	Torus partition functions, Chapter 11
S^2	$\pm(l+1)$ with multiplicity $2(l+1)$ (T4.81), via $K = \vec{\sigma}\cdot\vec{L} + 1$ (T4.80); no zero modes.	Monopole harmonics, Chapter 8

Table T4.8: The spin connection and the Dirac operator (Section T4.7).

Concept	Operational meaning	Used later in
Connection Laplacian	$\nabla^*\nabla = -\sum_a(\nabla_a\nabla_a - \nabla_{\nabla_a e_a})$ (T4.82); $\langle\psi, \nabla^*\nabla\psi\rangle = \lVert\nabla\psi\rVert^2 \geq 0$ (T4.83).	Heat kernels, Chapter 4
Lichnerowicz	$D^2 = \nabla^*\nabla + \frac{R}{4}$ (T4.85): expand $\gamma^a\gamma^b\nabla_a\nabla_b$ into symmetric and antisymmetric parts; $\gamma^a\gamma^b\gamma^c R_{abcd}$ collapses to $-2\,\mathrm{Ric}$ by the Bianchi identity (Section T4.8.2).	Vanishing theorems, Chapters 4 and 12
Positive curvature	$R > 0 \Rightarrow \ker D = 0$ (T4.90), hence $\hat{A}(M) = 0$; Friedrich $\lambda^2 \geq \frac{n}{n-1}\frac{\min R}{4}$ (T4.92); on S^2, $\lambda^2 \geq 4\pi/\mathrm{area}$ (T4.93).	Obstructions to psc metrics
Twisted Dirac	$D_A = -i\gamma^a(\nabla_a + A_a)$ on $S \otimes E$ (T4.94); $D_A^2 = \nabla^*\nabla + \frac{R}{4} - \frac{1}{2}F_{ab}\gamma^a\gamma^b$ (T4.95).	Nash (4.122), (10.2)
Landau levels	On $\mathbb{R}^2$ with field B: $D_A^2 = B(2b^\dagger b + 1) - B\sigma_3$, spectrum $0, \pm\sqrt{2mB}$ (Example T4.51).	Graphene; spectral asymmetry
Aharonov–Casher	Zero modes $e^{-\varphi}z^k$ with $\nabla^2\varphi = B$: $n_+ = \lceil\Phi/2\pi\rceil - 1$, $n_- = 0$ (T4.96).	"Zero modes = flux"
Monopole on S^2	Twist by L_k: $n_+ - n_- = k$ (Example T4.53), holomorphic sections of $\mathcal{O}(k-1)$.	Nash (10.3) with $m = 1$
Index	$\mathrm{index}\, D^+ = n_+ - n_-$ (T4.98); nonzero modes pair up; $\mathrm{Tr}\,\Gamma e^{-tD^2}$ is independent of t (McKean–Singer, (T4.99)).	Central object of Chapter 4; anomalies
$\hat{A}$ and ch	$\mathrm{index}\, D_A^+ = \int \hat{A}(M)\,\mathrm{ch}(E)$ (T4.103), $\hat{A} = \prod \frac{x_i/2}{\sinh(x_i/2)} = 1 - \frac{p_1}{24} + \cdots$ (T4.102); $n = 4$: $\mathrm{index}\, D^+ = -\sigma/8$ (T4.104).	Nash (4.107)–(4.111), Chapters 4 and 10

Table T4.9: The Lichnerowicz formula, twisted Dirac operators and the index (Section T4.8).

Concept	Operational meaning	Used later in
Wedge and contraction	$\varepsilon(v) = v\wedge$, $\iota(v)$; $\{\varepsilon(v), \iota(w)\} = \langle v, w\rangle$ (T4.105): fermion creation and annihilation on $\Lambda^\bullet$.	SUSY QM, Nash (7.64)–(7.69), Chapter 7
Clifford actions on forms	$c = \varepsilon - \iota$, $\hat{c} = \varepsilon + \iota$ (T4.107): $c^2 = -\lvert v\rvert^2$, $\hat{c}^2 = +\lvert v\rvert^2$, $\{c, \hat{c}\} = 0$; explicit 4×4 on $\Lambda^\bullet\mathbb{R}^2$ (T4.110).	Witten's Q_1, Q_2
Forms = bispinors	$Q(e^{a_1}\wedge\cdots) = \gamma^{a_1}\cdots$ (T4.111); $\Lambda^\bullet\otimes\mathbb{C} \cong S\otimes S^*$ (T4.114); forms need no spin structure.	Twisting in TQFT, Chapter 12
$\mathrm{d} + \mathrm{d}^*$	$= \sum_a c(e^a)\nabla_a$ (T4.116); on $\mathbb{R}^2$ it is Cauchy–Riemann, on $\mathbb{R}^3$ grad, curl, div (T4.120); its square is the Hodge Laplacian.	Nash (4.49)–(4.52); Morse, Chapter 7
Hodge theory	Harmonic forms = zero modes of $\mathrm{d} + \mathrm{d}^*$ = de Rham classes (T4.122) (Figure T4.30).	H^p computations throughout
Bochner	On 1-forms $\Delta = \nabla^*\nabla + \mathrm{Ric}$ (T4.124); $\mathrm{Ric} > 0 \Rightarrow b_1 = 0$.	Vanishing theorems
Euler operator	Grade by degree parity: index $= \sum(-1)^p b_p = \chi(M)$ (T4.127); Witten index $\mathrm{Tr}(-1)^F e^{-tH}$ (T4.129).	Gauss–Bonnet, Morse inequalities, Chapter 7
Signature operator	Grade by $\tau = i^{k(k-1)+m}\star$ (T4.132); index $= \sigma(M) = b^+ - b^-$ (T4.136); Hirzebruch $\sigma = \int L = \frac{1}{3}\int p_1$ (T4.138).	Nash (4.74)–(4.95); gravitational anomalies
Dolbeault operator	$\sqrt{2}(\bar\partial + \bar\partial^*)$ on $\Lambda^{0,\bullet}$ (T4.142); index $= \sum(-1)^q h^{0,q}$; $S = \Lambda^{0,\bullet}\otimes K^{1/2}$ (T4.145).	Riemann–Roch, theta characteristics, Chapter 5
Unification	$\Lambda^\bullet\otimes\mathbb{C} = S\otimes W$, $\mathrm{d} + \mathrm{d}^* = D_W$ (T4.155); e, L, td all from $\int \hat{A}\,\mathrm{ch}\,W$ (Figure T4.37).	Nash (4.48)

Table T4.10: Differential forms as Clifford modules (Section T4.9).

n	$\dim \mathrm{Cl}$	$N = 2^{\lfloor n/2 \rfloor}$	chirality Γ	$\dim S^{\pm}$	$\mathrm{Spin}(n)$
1	2	1	no	–	$\mathbb{Z}_2$
2	4	2	σ_3	1	U(1)
3	8	2	no	–	SU(2)
4	16	4	$\sigma_3 \otimes \sigma_3$	2	$\mathrm{SU}(2) \times \mathrm{SU}(2)$
5	32	4	no	–	(double cover of SO(5))
6	64	8	$\sigma_3^{\otimes 3}$	4	(double cover of SO(6))
10	2^{10}	32	$\sigma_3^{\otimes 5}$	16	(superstring spacetime)

Quantity	Value
Clifford relation (ours)	$\{\gamma_a, \gamma_b\} = 2\delta_{ab}$, $\gamma_a^\dagger = \gamma_a$
Translation to Bär and Nash	$c(e_a) = -i\gamma_a$; $\gamma_a^{\mathrm{Nash}} = i\gamma_a$, $\not{D}_{\mathrm{Nash}} = -D$
Spinor rotation in the 12-plane	$\exp(-\frac{\theta}{2}\gamma_1\gamma_2) = \cos\frac{\theta}{2} - \sin\frac{\theta}{2}\,\gamma_1\gamma_2$
Spin generator	$\Sigma_{ab} = \frac{1}{4}[\gamma_a, \gamma_b]$; Minkowski $S^{\mu\nu} = \frac{i}{4}[\gamma^\mu, \gamma^\nu]$
Spin connection	$\Omega = \frac{1}{4}\omega_{ab}\gamma^a\gamma^b$
Lichnerowicz	$D^2 = \nabla^*\nabla + \frac{R}{4}$; twisted: $-\frac{1}{2}F_{ab}\gamma^a\gamma^b$ extra
Unit S^n	$R = n(n-1)$; unit S^2: $R = 2$, $\lambda_{\min}^2 = 1$
$\hat{A}$ expansion	$1 - \frac{p_1}{24} + \frac{7p_1^2 - 4p_2}{5760} + \cdots$
Four-dimensional index	$\mathrm{index}\, D^+ = -\frac{\sigma}{8}$; twisted by SU(2): $-k - \frac{\sigma}{4}$
Spin structures	$\lvert H^1(M;\mathbb{Z}_2)\rvert$: S^1: 2, T^2: 4, Σ_g: 2^{2g}, simply connected: ≤ 1

Table T4.11: Dimensions of Clifford algebras, spinors and spin groups (top), and the constants that recur (bottom). The $n = 10$ row is the superstring's: the Weyl condition halves 32 complex components to 16, and in signature $(1, 9)$ a Majorana condition can be imposed as well, leaving 16 real components.

Manifold	spin str.	spectrum of D	zero modes (n_+, n_-)	index
S^1, length 2π	2	R: $\mathbb{Z}$; NS: $\mathbb{Z} + \frac{1}{2}$	R: 1; NS: 0 (no chirality)	–
$T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$	4	$\pm\sqrt{p^2+q^2}$, (p, q) in $\mathbb{Z}$ or $\mathbb{Z} + \frac{1}{2}$ per cycle	$(+,+)$: $(1,1)$; else $(0,0)$	0
S^2, radius 1	1	$\pm(l+1)$, mult. $2(l+1)$	$(0,0)$	0
S^2 with L_k	1	k zero modes, the rest in $\pm$ pairs	$(k,0)$ for $k \ge 0$	k
$\mathbb{R}^2$, flux Φ	1	$0, \pm\sqrt{2mB}$ (uniform B)	$(\lceil \frac{\Phi}{2\pi} \rceil - 1, 0)$	$\approx \frac{\Phi}{2\pi}$
K3	1	(not computed)	$(2,0)$	$2 = -\frac{\sigma}{8}$
$\mathbb{CP}^2$	0	no Dirac operator	–	$-\frac{1}{8} \notin \mathbb{Z}$

Table T4.12: The manifolds of this chapter and their Dirac data. The index column vanishes on every untwisted surface because $\hat{A}$ has no 2-form part; it becomes nonzero only when a gauge field (the monopole, the flux) or four-dimensional topology (K3) supplies a top-degree class.

2. *Check a Clifford relation by multiplying matrices.* For example $(\sigma_3 \otimes \sigma_1)(\sigma_1 \otimes \mathbf{1}) = \sigma_3\sigma_1 \otimes \sigma_1 = -\sigma_1\sigma_3 \otimes \sigma_1$: the σ_3 prefix is what makes different slots anticommute (T4.34).

3. *Build the gammas in dimension $2k$ and the chirality matrix.* Use (T4.35), then $\gamma_{2j-1}\gamma_{2j} = \mathbf{1} \otimes \cdots \otimes i\sigma_3 \otimes \cdots$, so $\Gamma = (-i)^k \prod \gamma_a = \sigma_3^{\otimes k}$ (Example T4.25).

4. *Lift a rotation.* Two reflections in unit vectors at angle $\theta/2$ give $\exp(-\frac{\theta}{2}\gamma_1\gamma_2)$; at $\theta = 2\pi$ this is -1 (T4.46).

5. *Compute the rotation of a spin matrix.* $R_{ij} = \frac{1}{2}\operatorname{tr}(\sigma_i U \sigma_j U^\dagger)$ for $U \in \mathrm{SU}(2)$, and see that $\pm U$ give the same R (Example T4.30).

6. *Count spin structures.* Pick a sign for each generator of π_1 (on S^1, T^2, Σ_g); on simply connected manifolds decide whether the clutching winding number is even (Sections T4.6.5 and T4.6.6).

7. *Find the spin connection.* Solve Cartan's equation $\mathrm{d}e^a = -\omega^a{}_b \wedge e^b$ in an orthonormal frame, then $\Omega = \frac{1}{4}\omega_{ab}\gamma^a\gamma^b$ (Example T4.41).

8. *Compute a spectrum on a flat manifold.* Plane waves with momenta on the lattice fixed by the spin structure; $\lambda = \pm|k|$ (Examples T4.44 and T4.45).

9. *Derive the Lichnerowicz formula.* Split $\gamma^a\gamma^b\nabla_a\nabla_b$ as in item 1, but now the antisymmetric part is $\frac{1}{2}\gamma^a\gamma^b R^S_{ab} = \frac{R}{4}$ by the three-gamma identity (Section T4.8.2); add F for a twisted operator.

10. *Run the vanishing argument.* $\|D\psi\|^2 = \|\nabla\psi\|^2 + \int \frac{R}{4}|\psi|^2$, so $R > 0$ and $D\psi = 0$ force $\psi = 0$ (T4.90).

11. *Count zero modes by holomorphy.* In two dimensions $D^+ \propto \partial_{\bar z}$ (twisted: $\partial_{\bar z} + A_{\bar z}$), so zero modes are holomorphic sections; count them (Examples T4.52 and T4.53).

12. *Write $\mathrm{d} + \mathrm{d}^*$ as a Dirac operator.* $\mathrm{d} = \sum \varepsilon(e^a)\nabla_a$, $\mathrm{d}^* = -\sum \iota(e^a)\nabla_a$, add them (Section T4.9.3).

Where Nash uses this chapter

Nash has no chapter on Clifford algebras; he uses the material in passing, mostly in his Chapters 4, 7 and 10. The table lists the places, with the section of this chapter that supplies the background. Page numbers are Nash's printed pages.

Nash	What he uses	Here
p. 16	Stiefel–Whitney classes as $\mathbb{Z}_2$ characteristic classes	Section T4.6.2

Table T4.13: Where Nash relies on this toolkit chapter.

Recap: the chapter in five sentences

- Square-rooting the Laplacian forces $\{\gamma^a, \gamma^b\} = 2\delta^{ab}$, and the solutions are explicit matrices: Pauli matrices, the 4×4 Dirac and Weyl matrices, and tensor products $\sigma_3 \otimes \cdots \otimes \sigma_{1,2} \otimes \mathbf{1}\cdots$ of size $2^{\lfloor n/2\rfloor}$, with chirality $\Gamma = \sigma_3^{\otimes k}$ in even dimensions.
- Even products of unit vectors form Spin(n), which double covers SO(n) through reflections; its Lie algebra is spanned by $\frac{1}{4}[\gamma_a, \gamma_b]$, and a 2π rotation is -1 on spinors.
- Spinors live on a manifold only after the frame transition functions are lifted with consistent signs; the obstruction is w_2 and the choices are counted by $H^1(M;\mathbb{Z}_2)$ (Ramond and Neveu–Schwarz on S^1).
- The Dirac operator $D = -i\gamma^a\nabla_a = -i\gamma^a e_a{}^\mu(\partial_\mu + \frac{1}{4}\omega_{bc\mu}\gamma^b\gamma^c)$ has computable spectra, obeys $D^2 = \nabla^*\nabla + \frac{R}{4} - \gamma(F)$, and has no zero modes when $R > 0$ and $F = 0$.

- Chirality splits D into $D^{\pm}$ and defines the index $n_+ - n_- = \int \hat{A}\ \mathrm{ch}\, E$; with forms as a Clifford module, $\mathrm{d} + \mathrm{d}^*$ is a twisted Dirac operator whose indices are χ, σ and the arithmetic genus.

Chapter T5

The Renormalisation Group

Where this chapter is going

Quantum field theories come with a scale. A lattice has a spacing, a regularised path integral has a cutoff, a scattering experiment has an energy. The **renormalisation group** (RG) is the systematic answer to the question "how does the description of a system change when we change the scale at which we look at it?". The answer is a flow on the space of all possible couplings. Its fixed points are theories without any scale, which turn out to be conformal field theories, and every quantum field theory can be viewed as a trajectory of this flow running from one fixed point at short distances to another at long distances.

The logic has seven steps. Coarse graining on a lattice and in momentum space defines the flow (Section T5.1). Polchinski's exact flow equation makes it a differential equation, which can be solved in the local potential approximation (Section T5.2). Near a fixed point the flow is linear, its eigenvalues are the critical exponents, and the Wilson–Fisher fixed point in $4-\varepsilon$ dimensions gives them explicitly (Section T5.3). The same running can be computed with ordinary Feynman diagrams. The Callan–Symanzik equation turns the freedom to choose the renormalisation scale into power laws, and one-loop diagrams give the β-functions of φ^4 theory and of Yang–Mills theory, whose sign is asymptotic freedom (Section T5.4). A fixed point is conformally invariant under a condition on the stress tensor that always holds for unitary theories in two dimensions. Away from a fixed point the trace of the stress tensor is the β-function, which is the scale anomaly (Section T5.5). Put together, these facts give a dictionary between quantum field theories and conformal field theories (Section T5.6). Finally, two β-functions carry geometry. For a sigma model with a curved target it is the Ricci tensor, so fixed points solve Einstein's vacuum equations and the flow is Ricci flow. For Chern–Simons theory the one-loop correction shifts the level k to $k + h^\vee$ (Section T5.7). Figure T5.1 shows the logic and where each piece is used later.

Dictionary: the words of this chapter

RG language	what it means physically
coupling g_i, theory space	the numbers in the action; the space of all actions
RG flow, $\beta_i(g)$	how the effective couplings change as we zoom out
fixed point	a theory with no length scale (critical point, CFT)
relevant / irrelevant	grows / dies away at long distances
RG eigenvalue y	d minus the scaling dimension of the operator
critical surface	theories that flow into the fixed point
Wilsonian action S_Λ	the action that reproduces all physics below Λ

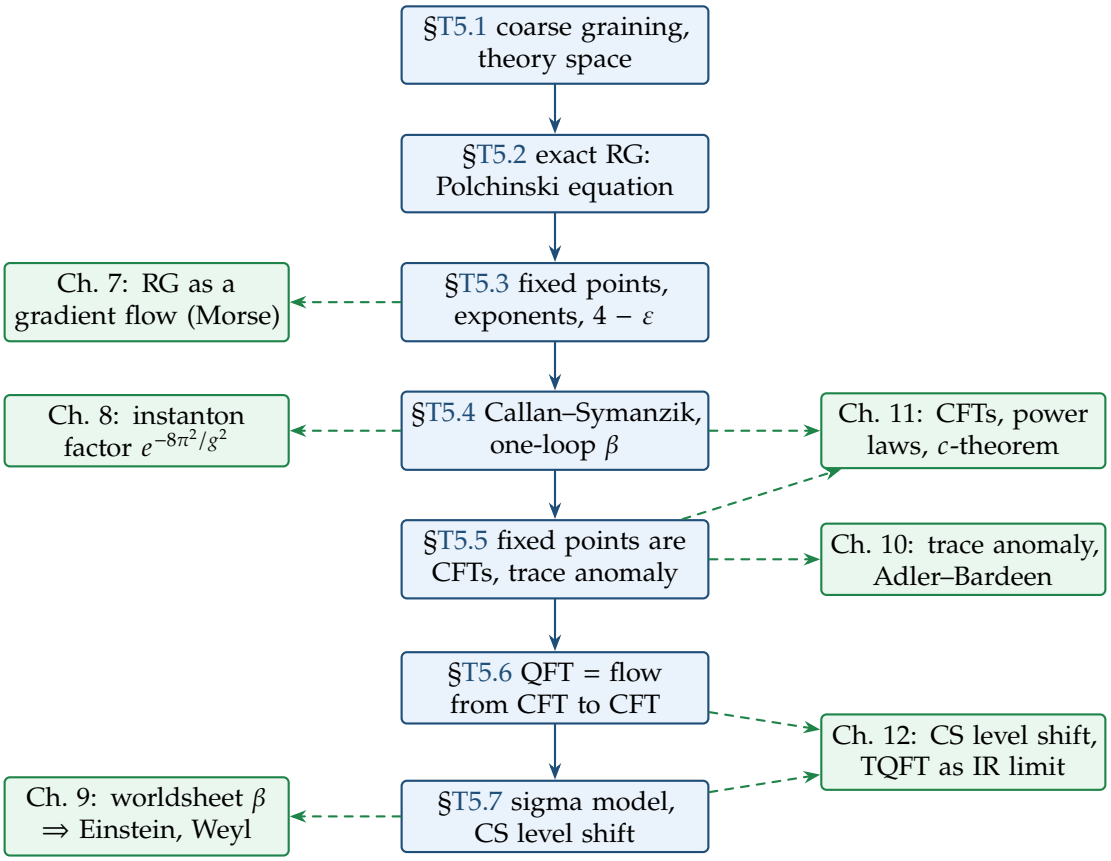

Figure T5.1: The logic of this chapter (blue) and the later chapters that use it (green). The main line runs from coarse graining to the statement that a quantum field theory is an RG trajectory between two conformal field theories, and ends with two β-functions that carry geometry. What to see: every Nash chapter from 7 to 12 uses one piece of this line.

T5.1 The renormalisation group: physics at a scale

Two puzzles sit behind everything in this chapter. The first comes from particle physics. Nobody knows what happens at distances of 10^{-35} m, yet quantum electrodynamics predicts the magnetic moment of the electron to twelve digits using only two measured numbers, e and m_e. Why does ignorance of the shortest distances not spoil predictions at long ones? The second comes from statistical mechanics. The critical exponents of a liquid–gas transition, of a uniaxial magnet and of a binary alloy are the same numbers (in three dimensions $\nu \approx 0.630$, $\eta \approx 0.036$), although the microscopic physics could hardly be more different. Why?

Both puzzles have the same answer, the **renormalisation group** (RG). The same machinery gives the Callan–Symanzik equation and anomalous dimensions (Chapter 11), the β-functions of the string worldsheet (Chapter 9) and the scale anomaly (Chapter 10). Its end point is the statement that makes conformal field theory relevant to ordinary quantum field theory: *a QFT is an RG flow from one CFT to another.*

Physical picture: a camera with finite resolution

Photograph a magnet near its critical point, then zoom out by a factor of two and photograph it again with the same camera. Each pixel of the new picture averages four pixels of the old one. Fine detail is lost, but the picture is still a picture of a magnet, described by the same kind of rules with slightly different numbers (a different effective temperature and field). The RG is the map "old numbers $\mapsto$ new numbers". Iterating it is zooming out further and further. What survives many iterations is what we see in the laboratory.

T5.1.1 Coarse graining a lattice: block spins

Kadanoff's version of the idea is the easiest to draw. Take the Ising model, the simplest model of a uniaxial magnet (its two-dimensional version is solved exactly by conformal field theory in Chapter 11): spins $s_i = \pm 1$ on a square lattice with spacing a, weight e^{-H} with

$$-H = K \sum_{\langle ij \rangle} s_i s_j + h \sum_i s_i$$

($K = J/k_B T$ and h is the magnetic field in units of $k_B T$). Group the spins into $b \times b$ blocks and give each block a single **block spin** $s'_I = \pm 1$, for example by majority rule (Figure T5.2). Then sum the Boltzmann weight over all configurations of the original spins that are compatible with a given configuration of block spins. What is left is a Boltzmann weight $e^{-H'}$ for the block spins alone.

Working definition T5.1 (RG transformation)

The **couplings** $\{K_1, K_2, \dots\}$ [the numbers in the Boltzmann weight: nearest-neighbour coupling, four-spin coupling, field] specify a statistical system. An **RG transformation** R_b [one step of zooming out by a factor b] is the rule $\{K_i\} \mapsto \{K'_i\}$ obtained by

1. summing the Boltzmann weight over the degrees of freedom on length scales between a and ba [the spins inside each block of Figure T5.2],
2. rescaling lengths by $1/b$ [so that the new lattice spacing is again called a],
3. reading off the new couplings K'_i from the Boltzmann weight of the block spins that is left.

Operational test: the partition function is unchanged, $Z(K') = Z(K)$ up to a spin-independent factor, and every long-distance quantity is the same function of the new couplings, measured in the new units. In particular the correlation length [the size of a typical patch of aligned

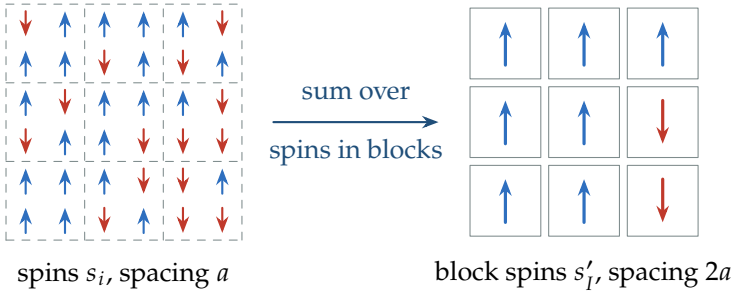

Figure T5.2: One block-spin step with $b = 2$. Left: a configuration of 36 Ising spins; the dashed lines cut the lattice into 2×2 blocks. Right: each block is replaced by one spin, here by majority rule (a tie is broken upwards). The new lattice has spacing $2a$ and 9 spins. What to see: the new picture has the same kind of variables as the old one, so it can be described by the same kind of Hamiltonian with new couplings (K', h').

spins, in units of the lattice spacing] obeys

$$\xi(K') = \frac{\xi(K)}{b}. \tag{T5.1}$$

Equation (T5.1) is worth pausing on. The physical correlation length (in metres) does not change, because nothing physical has been done. But we now measure it in units of the new lattice spacing ba, so the number ξ drops by b. Two consequences follow at once.

- A **fixed point** $K^* = R_b(K^*)$ has $\xi(K^*) = \xi(K^*)/b$, so $\xi = 0$ or $\xi = \infty$. The first kind are trivial (zero or infinite temperature). The second kind are *critical points*. A fixed point with $\xi = \infty$ has no length scale at all: it is a scale-invariant theory, the subject of Chapter 11.

- Couplings that approach a fixed point under repeated RG steps describe systems that look, at long distances, exactly like the fixed point. All such systems share the same long-distance physics. This is **universality**.

Working definition T5.2 (correlation length, scaling dimension, critical exponents)

Take the connected correlation $G(r) = \langle s(x)s(0)\rangle - \langle s\rangle^2$ [how much a spin at x still "knows" about the spin at 0, a distance r away]. Away from a critical point it dies exponentially, $G \sim e^{-r/\xi}$, and ξ is the **correlation length** [the size of a typical correlated patch]. As the reduced temperature $t = (T - T_c)/T_c$ goes to zero, ξ diverges as $\xi \propto |t|^{-\nu}$. At $t = 0$ no length is left, so G is a pure power,

$$G(r) \propto \frac{1}{r^{2\Delta}},$$

and Δ is the **scaling dimension** of the local operator [the power of length it carries once all scales are gone, read off from how fast its correlations fall]. For the order parameter one writes $2\Delta = d - 2 + \eta$. The numbers ν and η are the first two **critical exponents** [the powers that describe the singular behaviour near T_c]. *Operational test:* on a log–log plot of $G(r)$ at T_c, the slope is -2Δ; on a log–log plot of ξ against $|t|$, the slope is $-\nu$. (For the two-dimensional Ising model $\nu = 1$ and $\eta = \frac{1}{4}$ exactly; the full list of exponents is derived from conformal field theory in Chapter 11.)

T5.1.2 An exact RG step: the one-dimensional Ising chain

In one dimension we can do a block-spin step exactly. Instead of majority rule we use **decimation**: sum over every second spin and keep the others.

Worked example T5.1: Decimating the Ising chain

Take $h = 0$ and the Boltzmann weight $\prod_i e^{K s_i s_{i+1}}$. A spin s_2 sitting between s_1 and s_3 appears in exactly two factors. Summing over it,

$$\sum_{s_2=\pm 1} e^{K s_1 s_2} e^{K s_2 s_3} \overset{(1)}{=} \sum_{s_2=\pm 1} e^{K s_2 (s_1+s_3)} \overset{(2)}{=} 2\cosh\bigl(K(s_1+s_3)\bigr).$$

(1) Combine the exponents.
(2) $e^{x} + e^{-x} = 2\cosh x$.

We want this to have the old form, $A\, e^{K' s_1 s_3}$, with a new coupling K' and a spin-independent factor A. There are only two cases:

$$\begin{aligned} s_1 = s_3 &: \quad 2\cosh 2K = A\, e^{K'}, \\ s_1 = -s_3 &: \quad 2 = A\, e^{-K'}. \end{aligned}$$

Dividing and multiplying the two lines,

$$e^{2K'} \overset{(1)}{=} \cosh 2K, \qquad A^2 \overset{(2)}{=} 4\cosh 2K. \tag{T5.2}$$

(1) Divide the first line by the second.
(2) Multiply the two lines.

An equivalent and nicer form uses tanh:

$$\tanh K' \overset{(1)}{=} \frac{e^{2K'}-1}{e^{2K'}+1} \overset{(2)}{=} \frac{\cosh 2K - 1}{\cosh 2K + 1} \overset{(3)}{=} \frac{2\sinh^2 K}{2\cosh^2 K} = \tanh^2 K.$$

(1) Definition of tanh, multiplied top and bottom by $e^{K'}$.
(2) (T5.2).
(3) $\cosh 2K = 1 + 2\sinh^2 K = 2\cosh^2 K - 1$.

So one RG step with $b = 2$ is the map $\tanh K \mapsto \tanh^2 K$.

The map has two fixed points, $\tanh K = 0$ and $\tanh K = 1$. Between them, $\tanh^2 K < \tanh K$, so every finite coupling decreases under coarse graining (Figure T5.3). The $K = \infty$ fixed point is *unstable*: start near it and you are pushed away. The $K = 0$ fixed point is *stable*: everything ends there. Let us check (T5.1) with the exact correlation length.

Worked example T5.2: The correlation length of the chain obeys $\xi' = \xi/2$

First rewrite each bond factor. Since $s s' = \pm 1$,

$$e^{K s s'} \overset{(1)}{=} \cosh K + s s' \sinh K \overset{(2)}{=} \cosh K \,\bigl(1 + s s' \tanh K\bigr).$$

(1) For $s s' = +1$ both sides are $e^{K} = \cosh K + \sinh K$; for $s s' = -1$ both are $e^{-K} = \cosh K - \sinh K$.
(2) Take out the factor $\cosh K$ and use $\tanh K = \sinh K / \cosh K$.

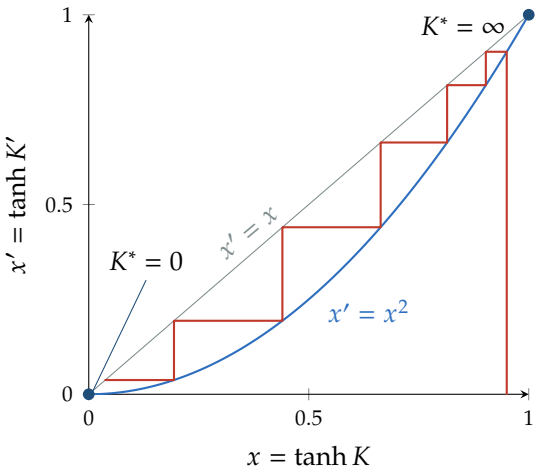

Figure T5.3: The decimation map of the 1D Ising chain, $\tanh K' = \tanh^2 K$ (blue), and a "cobweb" of repeated RG steps (red) starting from $\tanh K = 0.95$. Each step goes up to the curve and across to the diagonal. What to see: the only fixed points are the ends, $K = 0$ (infinite temperature) and $K = \infty$ (zero temperature). Every finite K flows to $K = 0$: at long distances a 1D magnet at any $T > 0$ looks disordered, so there is no phase transition at finite temperature.

For an open chain of N spins $s_0, \dots, s_{N-1}$ with $0 < r < N$,

$$\langle s_0 s_r \rangle \overset{(1)}{=} \frac{\sum_{\{s\}} s_0 s_r \prod_i (1 + s_i s_{i+1} \tanh K)}{\sum_{\{s\}} \prod_i (1 + s_i s_{i+1} \tanh K)} \overset{(2)}{=} \frac{2^N \tanh^r K}{2^N} = \tanh^r K.$$

(1) The factors $\cosh K$ cancel between numerator and denominator.

(2) Expand the product. Summing $s_j = \pm 1$ kills every term in which some spin appears an odd number of times, since $\sum_{s=\pm 1} s = 0$. In the denominator only the term 1 survives. In the numerator, s_0 and s_r must be paired by the bonds $(0,1), (1,2), \dots, (r-1, r)$, each contributing $\tanh K$; this chain of bonds is the only surviving term. Each surviving term gives 2^N (N spins, each summed over two values).

Since $\tanh^r K = e^{r \ln \tanh K}$ and $\ln \tanh K < 0$ for $0 < K < \infty$, this is $\langle s_0 s_r \rangle = e^{-r/\xi}$ with $\xi(K) = -1/\ln \tanh K$, measured in lattice spacings. After one decimation step,

$$\xi(K') \overset{(1)}{=} \frac{-1}{\ln \tanh K'} \overset{(2)}{=} \frac{-1}{\ln \tanh^2 K} = \frac{1}{2} \frac{-1}{\ln \tanh K} = \frac{\xi(K)}{2},$$

(1) The formula for ξ applied to the new coupling.

(2) $\tanh K' = \tanh^2 K$ from Example T5.1.

exactly (T5.1) with $b = 2$. How large is ξ at low temperature, where $K = J/k_B T$ is large? Write $q := e^{-2K} \ll 1$:

$$\tanh K \overset{(1)}{=} \frac{1 - e^{-2K}}{1 + e^{-2K}} \overset{(2)}{=} (1 - q)(1 - q + q^2 - \cdots) \overset{(3)}{=} 1 - 2q + O(q^2),$$
$$\xi \overset{(4)}{=} \frac{-1}{\ln(1 - 2q + O(q^2))} \overset{(5)}{=} \frac{1}{2q + O(q^2)} \approx \tfrac{1}{2} e^{2K} = \tfrac{1}{2} e^{2J/k_B T}.$$

(1) Multiply numerator and denominator of $\sinh K / \cosh K$ by e^{-K}.

(2) Geometric series $1/(1+q) = 1 - q + q^2 - \cdots$.

(3) Multiply out and keep the first order in q.

(4) $\xi = -1/\ln \tanh K$.

(5) $\ln(1-x) = -x + O(x^2)$.

The correlation length is finite at every $T > 0$ and diverges only as $T \to 0$.

Watch out: the RG is a semigroup, not a group

Decimation can be iterated but not undone: from K' we cannot recover the configurations of the spins we summed over. So R_b has no inverse in general, and the "group" in renormalisation group is a historical misnomer (only the composition law $R_b R_{b'} = R_{bb'}$ holds). In continuum language we will still run the flow both ways, $\Lambda \to \Lambda e^{\pm \delta t}$, but only the direction towards long distances has the meaning "integrate out".

T5.1.3 Integrating out modes in a field theory

In a continuum field theory the analogue of "summing over the spins inside a block" is Wilson's **integrating out**. Work in Euclidean signature: after the Wick rotation $t = -i\tau$ the weight e^{iS} becomes a Boltzmann weight e^{-S_E}, so a Euclidean field theory in d dimensions is a statistical system in d dimensions. Fourier transform the field, $\varphi(x) = \int \frac{\mathrm{d}^d p}{(2\pi)^d}\, e^{ip\cdot x} \varphi(p)$. A theory with an ultraviolet cutoff Λ contains only the modes with $|p| < \Lambda$; the cutoff plays the role of the inverse lattice spacing, $\Lambda \sim 1/a$. Split

$$\varphi = \varphi_< + \varphi_>, \qquad \varphi_< : \ |p| < \Lambda/b, \qquad \varphi_> : \ \Lambda/b < |p| < \Lambda, \tag{T5.3}$$

and define the new action of the slow modes by doing the path integral over the fast ones:

$$e^{-S_{\Lambda/b}[\varphi_<]} := \int \mathcal{D}\varphi_>\, e^{-S_\Lambda[\varphi_< + \varphi_>]}. \tag{T5.4}$$

By construction $\int \mathcal{D}\varphi_<\, e^{-S_{\Lambda/b}[\varphi_<]} = \int \mathcal{D}\varphi\, e^{-S_\Lambda[\varphi]}$: the partition function, and every correlation function of slow modes, is unchanged. The functional S_Λ is the **Wilsonian effective action** at scale Λ. Figure T5.4 shows the shell of modes that is removed.

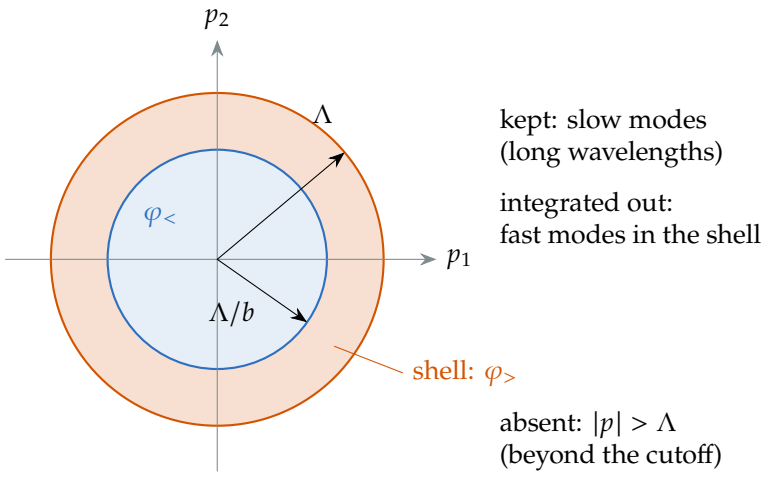

Figure T5.4: Wilson's momentum shell in $d = 2$. The theory with cutoff Λ contains the modes inside the orange circle. One RG step integrates out the orange annulus $\Lambda/b < |p| < \Lambda$ and keeps the blue disc. Then momenta are rescaled by b so that the blue disc becomes a disc of radius Λ again. What to see: this is the block-spin step of Figure T5.2 in Fourier space; short wavelengths are thrown away and their effect is absorbed into new couplings.

What does the integral over fast modes do to the couplings? The simplest possible model shows it: a "field theory in zero dimensions", in which the path integral is an ordinary integral over two numbers.

Worked example T5.3: Integrating out a heavy variable generates a new coupling

Let x be a light variable and y a heavy one, with action

$$S(x,y) = \tfrac{1}{2}x^2 + \tfrac{1}{2}M^2y^2 + g\,x^2y, \qquad M \gg 1.$$

Integrate out y. The y dependence is quadratic, so complete the square:

$$\tfrac{1}{2}M^2y^2 + gx^2y \overset{(1)}{=} \tfrac{1}{2}M^2\Big(y + \frac{gx^2}{M^2}\Big)^2 - \frac{g^2x^4}{2M^2},$$

$$\int_{-\infty}^{\infty} \mathrm{d}y\, e^{-S(x,y)} \overset{(2)}{=} e^{-\frac{1}{2}x^2 + \frac{g^2x^4}{2M^2}} \int_{-\infty}^{\infty} \mathrm{d}y'\, e^{-\frac{1}{2}M^2y'^2} \overset{(3)}{=} \sqrt{\frac{2\pi}{M^2}}\; e^{-\frac{1}{2}x^2 + \frac{g^2}{2M^2}x^4}.$$

(1) Expand the square: $\frac{1}{2}M^2(y^2 + 2gx^2y/M^2 + g^2x^4/M^4)$; the last term is subtracted again.
(2) Shift $y' = y + gx^2/M^2$; the shift does not change $\int \mathrm{d}y$ over the whole line.
(3) Gaussian integral $\int \mathrm{d}y\, e^{-\frac{1}{2}Ay^2} = \sqrt{2\pi/A}$.

The effective action of the light variable is defined, as in (T5.4), by $e^{-S_{\text{eff}}(x)} = \int \mathrm{d}y\, e^{-S(x,y)}$:

$$S_{\text{eff}}(x) \overset{(1)}{=} -\ln \int \mathrm{d}y\, e^{-S(x,y)} \overset{(2)}{=} \tfrac{1}{2}x^2 - \frac{g^2}{2M^2}x^4 - \ln\sqrt{\frac{2\pi}{M^2}}$$

$$\overset{(3)}{=} \tfrac{1}{2}x^2 + \frac{\lambda_{\text{eff}}}{4!}x^4 + \text{const}, \qquad \lambda_{\text{eff}} \overset{(4)}{=} -\frac{12\,g^2}{M^2}.$$

(1) Take $-\ln$ of the definition.
(2) The result of the previous chain; $-\ln e^X = -X$.
(3) Name the x^4 coefficient $\lambda_{\text{eff}}/4!$, the usual normalisation of a quartic coupling. The constant does not depend on x, so it drops out of every average.
(4) $\lambda_{\text{eff}}/24 = -g^2/(2M^2)$, so $\lambda_{\text{eff}} = -24g^2/(2M^2)$.

Three lessons. (i) Integrating out *generates* a coupling (x^4) that was not in the original action. (ii) The new coupling is suppressed by $1/M^2$, a power of the heavy scale. (iii) Its value is fixed by the old couplings, g and M.

Fermi's four-fermion interaction arises in exactly this way from W-boson exchange. At momenta far below M_W the kinetic term of the W is negligible, and the terms of the (Minkowski) Lagrangian that contain it are $\mathcal{L}_W = M_W^2 W_\mu^+ W^{-\mu} - \frac{g_W}{2\sqrt{2}}\big(W_\mu^+ J^{-\mu} + W_\mu^- J^{+\mu}\big)$, where g_W is the weak coupling and $J^{\pm\mu}$ are the charged currents built from the lepton and quark fields. With $a := g_W/(2\sqrt{2}M_W^2)$,

$$\mathcal{L}_W \overset{(1)}{=} M_W^2\big(W_\mu^+ - aJ_\mu^+\big)\big(W^{-\mu} - aJ^{-\mu}\big) - M_W^2 a^2 J_\mu^+ J^{-\mu} \;\longrightarrow\; \mathcal{L}_{\text{eff}} \overset{(2)}{=} -\frac{g_W^2}{8M_W^2}\, J_\mu^+ J^{-\mu}.$$

(1) Complete the square, as for y above: the cross terms of the product are $-M_W^2 a(W_\mu^+ J^{-\mu} + J_\mu^+ W^{-\mu})$ and $M_W^2 a = g_W/(2\sqrt{2})$; the a^2 term of the product is subtracted again.
(2) Shift W and integrate it out; the shifted Gaussian integral is a constant. What is left is $-M_W^2 a^2 = -g_W^2/(8M_W^2)$.

Fermi wrote this interaction as $-\frac{G_F}{\sqrt{2}} J_\mu^+ J^{-\mu}$, so $G_F/\sqrt{2} = g_W^2/(8M_W^2)$: a coupling of negative mass dimension, suppressed by the heavy mass, exactly as λ_{eff}.

In a real field theory the fast modes are not a single heavy variable but a whole shell, and the integral cannot be done exactly unless the theory is free. Two cases can nevertheless be handled. A shell of infinitesimal thickness can be integrated out exactly (Section T5.2), and a thin shell at weak coupling can be integrated out in perturbation theory (Section T5.3). The three lessons of Example T5.3 hold in both.

T5.1.4 Theory space, running couplings and power counting

The heavy-variable example shows that the RG does not stay inside any finite family of actions: it generates every coupling that the symmetries allow. So the arena of the RG is large.

Working definition T5.3 (theory space and RG flow)

List all local operators $O_i(x)$ allowed by the symmetries [for a $\mathbb{Z}_2$-symmetric scalar: φ^2, φ^4, $(\partial\varphi)^2$, φ^6, $\varphi^2(\partial\varphi)^2$, …]. A general Wilsonian action [the action that reproduces all physics below the cutoff Λ] is

$$S_\Lambda[\varphi] = \sum_i g_i(\Lambda) \int \mathrm{d}^d x \, O_i(x).$$

The **theory space** [one axis for each coupling g_i, so one point for each possible action] is the space of coupling vectors $\{g_i\}$. Lowering the cutoff moves the point. The **RG flow** [an arrow at every point saying where it moves as we zoom out] is this vector field. We parametrise it by the **RG time** [the number of e-folds by which we have zoomed out]

$$t = \ln \frac{\Lambda_0}{\Lambda}, \qquad \frac{\mathrm{d}\hat{g}_i}{\mathrm{d}t} = \beta_i(\hat{g}), \tag{T5.5}$$

where Λ_0 is the cutoff we started with and $\hat{g}_i = g_i \Lambda^{-[g_i]}$ are the **dimensionless couplings** [each coupling measured in units of the current cutoff]. Only these can have fixed points, since a dimensionful coupling changes under any change of units.

Rewriting in dimensionless couplings has an immediate consequence even without any interaction. Suppose g_i has mass dimension $[g_i]$ and does not change at all when modes are integrated out. Then

$$\frac{\mathrm{d}\hat{g}_i}{\mathrm{d}t} \overset{(1)}{=} -\Lambda \frac{\mathrm{d}}{\mathrm{d}\Lambda}\left(g_i \Lambda^{-[g_i]}\right) \overset{(2)}{=} [g_i]\, g_i \Lambda^{-[g_i]} = [g_i]\, \hat{g}_i. \tag{T5.6}$$

(1) $\mathrm{d}t = -\mathrm{d}\Lambda/\Lambda$ from (T5.5).

(2) g_i is constant by assumption; differentiate the power of Λ.

So $\hat{g}_i(t) = \hat{g}_i(0)\, e^{[g_i]t}$: a coupling of positive mass dimension grows towards the infrared, one of negative dimension dies away. This is the **classical** (or **canonical**) part of every β-function. The number $[g_i]$ is the RG eigenvalue y_i (defined in general in Section T5.3.1) at the free (Gaussian) fixed point.

Working definition T5.4 (relevant, marginal, irrelevant)

Near a fixed point a coupling grows or shrinks like e^{yt}, with y its RG eigenvalue [the growth rate per e-fold of zooming out]. It is **relevant** if $y > 0$ [it matters more and more at long distances, like the temperature deviation of a magnet], **irrelevant** if $y < 0$ [its effect dies off as a power of the length scale, like the x^4 coupling suppressed by $1/M^2$ in Example T5.3], and **marginal** if $y = 0$ [whether it grows or shrinks is decided by the β_i

beyond linear order]. *Test:* $y_i = d - \Delta_i$, where Δ_i is the scaling dimension of the operator $\mathcal{O}_i$ that the coupling multiplies (derived in Section T5.3.1, (T5.48)).

Worked example T5.4: Power counting at the Gaussian fixed point

Count mass dimensions, with $\hbar = c = 1$: a length has dimension -1, so $[\mathrm{d}^d x] = -d$ and $[\partial_\mu] = +1$. At the free massless point the action $\frac{1}{2}\int \mathrm{d}^d x (\partial\varphi)^2$ is a pure number, so

$$0 \overset{(1)}{=} [\mathrm{d}^d x] + 2[\partial] + 2[\varphi] = -d + 2 + 2[\varphi] \quad \Longrightarrow \quad [\varphi] = \tfrac{d-2}{2}.$$

(1) Dimensions of a product add; the integrand has two derivatives and two fields.

An operator with n fields and k derivatives therefore has $\Delta = n\frac{d-2}{2} + k$. The action $g\int \mathrm{d}^d x\, \mathcal{O}$ is dimensionless, so

$$y = [g] \overset{(1)}{=} d - \Delta \overset{(2)}{=} d - n\,\frac{d-2}{2} - k.$$

(1) $[\mathrm{d}^d x] = -d$, and the three dimensions must add to zero.
(2) Count the fields and derivatives.

For $\mathcal{O} = \varphi^n$ ($k = 0$):

	φ^2	φ^4	φ^6	φ^8
$d = 4$	2	0	-2	-4
$d = 3$	2	1	0	-1
$d = 2$	2	2	2	2

In four dimensions the mass is relevant, φ^4 is marginal, and everything else is irrelevant: this is why $\lambda\varphi^4$ is the most general renormalisable scalar theory. In three dimensions φ^4 is relevant (and φ^6 marginal). In two dimensions $[\varphi] = 0$, every φ^n is relevant, and the Gaussian counting is useless; this is one reason two-dimensional critical points need the exact methods of conformal field theory (Chapter 11). The derivative operator $(\partial\varphi)^2$ has $y = 0$ in every d: it is the kinetic term, which is marginal by construction (we use it to define the normalisation of φ).

Figure T5.5 is the picture to keep in mind. It explains both puzzles at the start of this section. Universality: magnets with very different microscopic couplings sit at different points of theory space, but all are pushed onto the same flow line near the fixed point, so they share its exponents. Predictivity: a QFT with an unknown ultraviolet completion starts somewhere unknown, but by the time the flow reaches accessible energies it has been squeezed onto a low-dimensional surface labelled by the few relevant and marginal couplings (here, e and m_e). We make the squeezing precise in Section T5.2.6.

Watch out: two sign conventions for β

The Callan–Symanzik treatment of Chapter 11 (and [QFT notes §15.4]) writes $\beta(g) = M\,\mathrm{d}g/\mathrm{d}M$, with M a renormalisation scale that *increases* towards the ultraviolet. Here the RG time $t = \ln(\Lambda_0/\Lambda)$ increases towards the *infrared*, and $\mathrm{d}\hat{g}/\mathrm{d}t = \beta(\hat{g})$. Identify the two

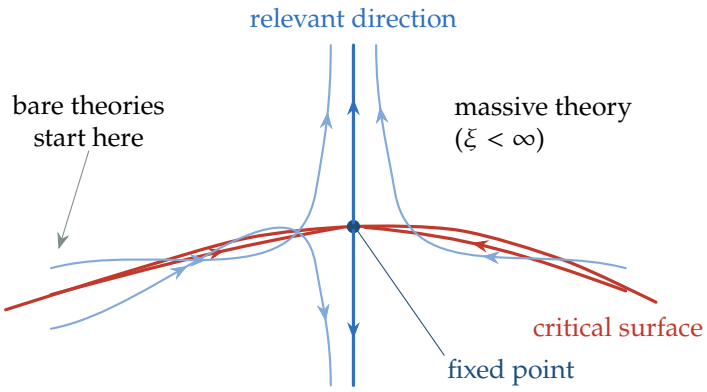

Figure T5.5: A cartoon of theory space. The red curve stands for the **critical surface**: all theories that flow into the fixed point. Its directions are the irrelevant couplings. The blue arrow leaving the fixed point is a relevant coupling (for a magnet: the temperature deviation). A theory that starts slightly off the critical surface (thin blue curves) first approaches the fixed point, lingers near it, and is then expelled along the relevant direction. What to see: the long-distance physics of all such theories is controlled by the fixed point and by one number, how far off the surface they started.

scales, $M = \Lambda$ (this is exact at the leading order where the two schemes agree). Then

$$\frac{\mathrm{d}\hat{g}}{\mathrm{d}t} \overset{(1)}{=} \frac{\mathrm{d}\Lambda}{\mathrm{d}t}\,\frac{\mathrm{d}\hat{g}}{\mathrm{d}\Lambda} \overset{(2)}{=} -\Lambda\,\frac{\mathrm{d}\hat{g}}{\mathrm{d}\Lambda} \overset{(3)}{=} -M\,\frac{\mathrm{d}\hat{g}}{\mathrm{d}M}.$$

(1) Chain rule.
(2) $\Lambda = \Lambda_0 e^{-t}$, so $\mathrm{d}\Lambda/\mathrm{d}t = -\Lambda$.
(3) $M = \Lambda$.

So the two β's differ by a sign. Relevant couplings have $\mathrm{d}\hat{g}/\mathrm{d}t > 0$ here, and $M\,\mathrm{d}g/\mathrm{d}M < 0$ in the other convention. For example, φ^4 in $d = 4 - \varepsilon$ has $M\,\mathrm{d}g/\mathrm{d}M = -\varepsilon g + 3g^2/16\pi^2$ (the form used in Chapter 11), which is $\mathrm{d}g/\mathrm{d}t = \varepsilon g - 3g^2/16\pi^2$ here; this β-function is derived by a shell integration in Section T5.3.3, (T5.54).

Reading Nash (p. 301, Ch. XI §1)

Nash devotes one sentence to the RG, in his chapter on conformal field theory: "the renormalisation properties of correlation functions are constrained by the need to obey the Callan–Symanzik renormalisation group equations", and then states that a zero of $\beta(g)$ is "necessary, but insufficient" for conformal invariance. The Callan–Symanzik equation and its consequence at a fixed point are unpacked in Chapter 11. Behind Nash's sentence lie three facts he takes for granted: the flow comes from integrating out short distances (Sections T5.1 and T5.2), its fixed points carry the critical exponents (Section T5.3), and the "insufficient" condition becomes sufficient for unitary two-dimensional theories (Section T5.5).

Recap

- An RG step removes the degrees of freedom between two length scales and rescales lengths; the couplings move, $K \mapsto R_b(K)$, and $\xi \mapsto \xi/b$.
- Fixed points have $\xi = 0$ or $\xi = \infty$; the latter are the scale-invariant critical theories.
- Exact example: decimating the 1D Ising chain gives $\tanh K' = \tanh^2 K$; every finite

coupling flows to $K = 0$, and $\xi(K') = \xi(K)/2$ exactly.

- Integrating out generates new couplings, suppressed by powers of the heavy scale and fixed by the old couplings ($\lambda_{\text{eff}} = -12g^2/M^2$).
- Near the Gaussian point a coupling of O scales with $y = d - \Delta_O$; $y > 0$ relevant, $y < 0$ irrelevant, $y = 0$ marginal.

T5.2 The exact renormalisation group

The definition (T5.4) integrates out a shell of finite thickness. For an interacting theory that integral cannot be done in closed form. But a shell of *infinitesimal* thickness can be integrated out exactly, because in a very thin shell the fast modes are almost free: their propagator is tiny, so only the first order in it matters. Doing this step after step turns (T5.4) into a differential equation for the Wilsonian action, the **exact renormalisation group equation**. Several versions exist (Wilson 1974, Wegner and Houghton 1973, Wetterich 1993). The one due to Polchinski has the simplest form, and it gives a short proof that $\lambda\varphi^4$ theory in four dimensions is renormalisable. Two questions organise this section. What equation does the Wilsonian action obey as the cutoff is lowered? And why does the answer at low energies forget almost everything about the theory we started with?

T5.2.1 A smooth cutoff

A sharp cutoff (keep $|p| < \Lambda$, drop the rest) produces awkward non-local effects in position space, because the Fourier transform of a step function decays only slowly. It is cleaner to suppress high momenta smoothly.

Working definition T5.5 (regularised propagator and shell propagator)

Choose a **cutoff function** $K(x)$ [a dial that is 1 for modes we keep and 0 for modes we have removed, with $x = p^2/\Lambda^2$] with $K(0) = 1$, decreasing, and falling to zero faster than any power as $x \to \infty$. The standard example is $K(x) = e^{-x}$. The **regularised propagator** at scale Λ [the propagator of only those modes that are still present at cutoff Λ] is

$$C_\Lambda(p) = \frac{K(p^2/\Lambda^2)}{p^2}. \tag{T5.7}$$

Picture it as the ordinary massless propagator $1/p^2$ for $|p| \ll \Lambda$, killed off for $|p| \gg \Lambda$. (The massive version $K/(p^2 + m^2)$ works equally well; nothing below depends on the choice.) The **shell propagator** [the propagator of the thin layer of modes removed when Λ is lowered a little] is the logarithmic derivative with respect to the cutoff,

$$\Delta_\Lambda(p) := \Lambda\frac{\partial C_\Lambda(p)}{\partial\Lambda} = -\frac{2}{\Lambda^2}\,K'\!\left(\frac{p^2}{\Lambda^2}\right) \geq 0. \tag{T5.8}$$

Operational meaning: lowering the cutoff from Λ to $\Lambda - \delta\Lambda$ removes from C_Λ exactly the propagator of the modes near $|p| \sim \Lambda$,

$$C_\Lambda - C_{\Lambda-\delta\Lambda} = \Delta_\Lambda\,\frac{\delta\Lambda}{\Lambda} + O(\delta\Lambda^2). \tag{T5.9}$$

Let us check (T5.8). With $x = p^2/\Lambda^2$,

$$\Lambda\frac{\partial}{\partial\Lambda}\frac{K(p^2/\Lambda^2)}{p^2} \overset{(1)}{=} \frac{1}{p^2}K'(x)\,\Lambda\frac{\partial x}{\partial\Lambda} \overset{(2)}{=} \frac{1}{p^2}K'(x)\left(-\frac{2p^2}{\Lambda^2}\right) = -\frac{2}{\Lambda^2}K'(x).$$

(1) Chain rule; $1/p^2$ does not depend on Λ.
(2) $\Lambda\,\partial_\Lambda(p^2\Lambda^{-2}) = -2p^2\Lambda^{-2}$.

Because K is decreasing, $K' \le 0$ and $\Delta_\Lambda \ge 0$: a larger cutoff contains more modes. For $K(x) = e^{-x}$, $K'(x) = -e^{-x}$ and so $\Delta_\Lambda(p) = 2e^{-p^2/\Lambda^2}/\Lambda^2$. Which modes does it describe? In d dimensions the modes with $|p|$ between p and $p + \mathrm{d}p$ fill a spherical shell of volume $S_{d-1}p^{d-1}\mathrm{d}p$ (with S_{d-1} the area of the unit sphere), so their weight is $p^{d-1}\Delta_\Lambda(p)$. Its maximum is at

$$0 = \frac{\mathrm{d}}{\mathrm{d}p}\left(p^{d-1}e^{-p^2/\Lambda^2}\right) \overset{(1)}{=} \left(\frac{d-1}{p} - \frac{2p}{\Lambda^2}\right)p^{d-1}e^{-p^2/\Lambda^2} \quad\Longrightarrow\quad p \overset{(2)}{=} \sqrt{\tfrac{d-1}{2}}\,\Lambda,$$

(1) Product rule.
(2) Set the bracket to zero and solve for $p > 0$.

which is $1.22\,\Lambda$ in $d = 4$: the removed modes sit near $|p| \approx \Lambda$ (Figure T5.6).

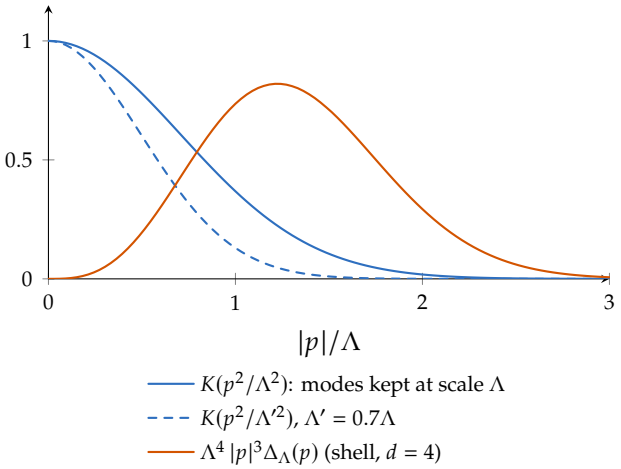

Figure T5.6: The smooth cutoff $K(x) = e^{-x}$. Solid blue: the fraction of each mode kept at scale Λ. Dashed blue: the same at a lower scale Λ'; the modes between the two curves have been integrated out. Orange: the radial weight of the shell propagator in four dimensions, $\Lambda^4|p|^3\Delta_\Lambda = 2(|p|/\Lambda)^3e^{-p^2/\Lambda^2}$. What to see: a thin RG step removes a smeared shell of modes centred near $|p| \approx \Lambda$, the smooth version of the annulus in Figure T5.4.

We write the Wilsonian action at scale Λ as a regularised kinetic term plus everything else,

$$S_\Lambda[\varphi] = \tfrac{1}{2}\,\varphi\cdot C_\Lambda^{-1}\cdot\varphi + S_\Lambda^{\mathrm{I}}[\varphi], \qquad \varphi\cdot A\cdot\varphi \coloneqq \int\frac{\mathrm{d}^dp}{(2\pi)^d}\,\varphi(-p)A(p)\varphi(p). \tag{T5.10}$$

The **interaction action** S_Λ^{I} contains all interactions, and may also contain mass terms and corrections to the kinetic term. In position space A becomes a kernel $A(x-y)$ and $\varphi\cdot A\cdot\varphi = \int \mathrm{d}^dx\,\mathrm{d}^dy\,\varphi(x)A(x-y)\varphi(y)$. We use the same dot notation for functional derivatives, for example

$$\frac{\delta}{\delta\varphi}\cdot A\cdot\frac{\delta}{\delta\varphi} \coloneqq \int \mathrm{d}^dx\,\mathrm{d}^dy\,A(x-y)\,\frac{\delta}{\delta\varphi(x)}\frac{\delta}{\delta\varphi(y)}.$$

T5.2.2 Two facts about Gaussian integrals

Everything in the derivation rests on two properties of Gaussian integrals. We state them for N real variables $\chi = (\chi_1, \dots, \chi_N)$; a field is the case $N \to \infty$ with the index i replaced by x (or p). For a positive symmetric matrix D write

$$\langle F \rangle_D := \frac{\int \mathrm{d}^N\chi \; e^{-\frac{1}{2}\chi\cdot D^{-1}\cdot\chi}\, F(\chi)}{\int \mathrm{d}^N\chi \; e^{-\frac{1}{2}\chi\cdot D^{-1}\cdot\chi}} \tag{T5.11}$$

for the Gaussian average with covariance D (the name is justified by (T5.13) below: $\langle \chi_i\chi_j\rangle_D = D_{ij}$).

Fact 1 (the generating function). For any vector J,

$$\left\langle e^{J\cdot\chi}\right\rangle_D \overset{(1)}{=} \frac{\int \mathrm{d}^N\chi \; e^{-\frac{1}{2}(\chi-DJ)\cdot D^{-1}\cdot(\chi-DJ)+\frac{1}{2}J\cdot D\cdot J}}{\int \mathrm{d}^N\chi \; e^{-\frac{1}{2}\chi\cdot D^{-1}\cdot\chi}} \overset{(2)}{=} e^{\frac{1}{2}J\cdot D\cdot J}. \tag{T5.12}$$

(1) Complete the square: $-\frac{1}{2}\chi D^{-1}\chi + J\chi = -\frac{1}{2}(\chi - DJ)D^{-1}(\chi - DJ) + \frac{1}{2}JDJ$. To check it, expand the right side: $-\frac{1}{2}\chi D^{-1}\chi + \frac{1}{2}\chi D^{-1}DJ + \frac{1}{2}JDD^{-1}\chi - \frac{1}{2}JDD^{-1}DJ + \frac{1}{2}JDJ$. With $D^{-1}D = \mathbb{1}$ and $D = D^{\mathsf{T}}$ the second and third terms add up to $J\cdot\chi$, and the last two cancel.

(2) Shift the integration variable $\chi \to \chi + DJ$; the numerator becomes $e^{\frac{1}{2}JDJ}$ times the denominator.

Expanding both sides of (T5.12) to second order in J identifies D as the covariance:

$$\left\langle \chi_i\chi_j\right\rangle_D \overset{(1)}{=} \frac{\partial^2}{\partial J_i \partial J_j}\left\langle e^{J\cdot\chi}\right\rangle_D\Big|_{J=0} \overset{(2)}{=} \frac{\partial^2}{\partial J_i \partial J_j} e^{\frac{1}{2}J\cdot D\cdot J}\Big|_{J=0} \overset{(3)}{=} D_{ij}. \tag{T5.13}$$

(1) Each $\partial/\partial J_i$ brings down one factor χ_i; then set $J = 0$.

(2) (T5.12).

(3) $\partial_{J_j} e^{\frac{1}{2}JDJ} = (DJ)_j e^{\frac{1}{2}JDJ}$, and the second derivative at $J = 0$ keeps only $\partial_{J_i}(DJ)_j = D_{ji} = D_{ij}$.

A second consequence: if χ_1 and χ_2 are independent Gaussians with covariances A and B, then $\langle e^{J\cdot(\chi_1+\chi_2)}\rangle = e^{\frac{1}{2}J\cdot A\cdot J} e^{\frac{1}{2}J\cdot B\cdot J} = e^{\frac{1}{2}J\cdot(A+B)\cdot J}$, so $\chi_1 + \chi_2$ *is Gaussian with covariance* $A + B$*: covariances add.* (A distribution is fixed by its generating function.) This is the statement "the propagator of all modes is the propagator of the slow modes plus the propagator of the fast modes".

Fact 2 (Gaussian smearing is a heat operator). For any polynomial (or analytic) function F and any fixed vector φ,

$$\left\langle F(\varphi+\chi)\right\rangle_D \overset{(1)}{=} \left\langle e^{\chi\cdot\partial_\varphi}\right\rangle_D F(\varphi) \overset{(2)}{=} \exp\!\left(\tfrac{1}{2}\,\partial_\varphi\cdot D\cdot\partial_\varphi\right)F(\varphi). \tag{T5.14}$$

(1) Taylor's theorem in N variables: $F(\varphi+\chi) = \sum_n \frac{1}{n!}(\chi\cdot\partial_\varphi)^n F(\varphi) = e^{\chi\cdot\partial_\varphi}F(\varphi)$ (in one variable this is the familiar $e^{a\,\mathrm{d}/\mathrm{d}x}f(x) = f(x+a)$).

(2) Fact 1 with $J = \partial_\varphi$. This is legitimate because the components of ∂_φ commute with each other, so every algebraic step in (T5.12) goes through term by term in the power series.

In words: averaging a function over Gaussian jitter of size D is the same as running the heat equation $\partial_s F = \frac{1}{2}\partial\cdot D\cdot\partial F$ for unit time. Heat flow smooths; so does integrating out.

Worked example T5.5: Checking the heat-operator formula on φ^4

Take $N = 1$, D a number, $F(\varphi) = \varphi^4$. Directly, using $\langle\chi\rangle = \langle\chi^3\rangle = 0$, $\langle\chi^2\rangle = D$ and $\langle\chi^4\rangle = 3D^2$ (Wick's theorem: three ways to pair four χ's),

$$\langle(\varphi+\chi)^4\rangle_D \overset{(1)}{=} \varphi^4 + 6\varphi^2\langle\chi^2\rangle + \langle\chi^4\rangle = \varphi^4 + 6D\varphi^2 + 3D^2.$$

(1) Binomial expansion; the odd powers of χ average to zero.

With the heat operator,

$$e^{\frac{D}{2}\partial^2}\varphi^4 \overset{(1)}{=} \Big(1 + \frac{D}{2}\partial^2 + \frac{D^2}{8}\partial^4\Big)\varphi^4 \overset{(2)}{=} \varphi^4 + \frac{D}{2}\cdot 12\varphi^2 + \frac{D^2}{8}\cdot 24 = \varphi^4 + 6D\varphi^2 + 3D^2.$$

(1) Exponential series; $\partial^6\varphi^4 = 0$, so it stops.
(2) $\partial^2\varphi^4 = 12\varphi^2$ and $\partial^4\varphi^4 = 24$.

The two agree. The $6D\varphi^2$ term is the "tadpole": two of the four legs of φ^4 are joined by the propagator D of the jitter.

T5.2.3 Deriving the Polchinski equation

Now the derivation. The partition function at cutoff Λ is

$$Z = \int \mathcal{D}\varphi\; e^{-\frac{1}{2}\varphi\cdot C_\Lambda^{-1}\cdot\varphi}\, e^{-S^{\mathrm{I}}_\Lambda[\varphi]}. \tag{T5.15}$$

Read the first factor as a Gaussian measure with covariance C_Λ: Z is (up to a constant) the average $\langle e^{-S^{\mathrm{I}}_\Lambda}\rangle_{C_\Lambda}$. Let $\Lambda' = \Lambda - \delta\Lambda$ and write $C_\Lambda = C_{\Lambda'} + \delta C$, with $\delta C = \Delta_\Lambda\,\delta\Lambda/\Lambda$ by (T5.9). Then

$$Z \overset{(1)}{=} \mathcal{N}\big\langle e^{-S^{\mathrm{I}}_\Lambda[\varphi]}\big\rangle_{C_\Lambda} \overset{(2)}{=} \mathcal{N}\Big\langle\big\langle e^{-S^{\mathrm{I}}_\Lambda[\varphi'+\chi]}\big\rangle_{\delta C}\Big\rangle_{C_{\Lambda'}} \overset{(3)}{=} \mathcal{N}\big\langle e^{-S^{\mathrm{I}}_{\Lambda'}[\varphi']}\big\rangle_{C_{\Lambda'}}, \tag{T5.16}$$

where we have *defined*

$$e^{-S^{\mathrm{I}}_{\Lambda'}[\varphi]} := \big\langle e^{-S^{\mathrm{I}}_\Lambda[\varphi+\chi]}\big\rangle_{\delta C} = \exp\Big(\tfrac{1}{2}\frac{\delta}{\delta\varphi}\cdot\delta C\cdot\frac{\delta}{\delta\varphi}\Big)e^{-S^{\mathrm{I}}_\Lambda[\varphi]}. \tag{T5.17}$$

(1) (T5.15) with the normalisation $\mathcal{N} = \int\mathcal{D}\varphi\, e^{-\frac{1}{2}\varphi C_\Lambda^{-1}\varphi}$ pulled out; it does not depend on the fields, so it never affects correlation functions.
(2) Fact 1: a Gaussian with covariance $C_{\Lambda'} + \delta C$ is the sum $\varphi' + \chi$ of independent Gaussians with covariances $C_{\Lambda'}$ (the slow modes) and δC (the thin shell). The average over φ becomes an average over both.
(3) Do the inner (shell) average first, and call the result $e^{-S^{\mathrm{I}}_{\Lambda'}}$. The second form in (T5.17) is Fact 2.

The last expression in (T5.16) is again of the form (T5.15), with the lower cutoff Λ' and the new interaction $S^{\mathrm{I}}_{\Lambda'}$. So (T5.17) is one exact RG step. It is Wilson's (T5.4) for a thin shell, with the kinetic term of the slow modes automatically correct.

Now expand to first order in δC. Write $S_x := \delta S^{\mathrm{I}}_\Lambda/\delta\varphi(x)$ and $S_{xy} := \delta^2 S^{\mathrm{I}}_\Lambda/\delta\varphi(x)\delta\varphi(y)$.

$$\begin{aligned} e^{-S^{\mathrm{I}}_{\Lambda'}} &\overset{(1)}{=} \Big(1 + \tfrac{1}{2}\int_{x,y}\delta C(x-y)\,\frac{\delta}{\delta\varphi(x)}\frac{\delta}{\delta\varphi(y)}\Big)e^{-S^{\mathrm{I}}_\Lambda} + O(\delta C^2) \\ &\overset{(2)}{=} e^{-S^{\mathrm{I}}_\Lambda}\Big(1 + \tfrac{1}{2}\int_{x,y}\delta C(x-y)\big[S_xS_y - S_{xy}\big]\Big) + O(\delta C^2). \end{aligned} \tag{T5.18}$$

(1) First two terms of the exponential series in (T5.17).
(2) Chain rule twice: $\frac{\delta}{\delta\varphi(y)}e^{-S} = -S_y\, e^{-S}$, and then $\frac{\delta}{\delta\varphi(x)}\big(-S_y e^{-S}\big) = (-S_{xy} + S_x S_y)\, e^{-S}$.

Now take $-\ln$ of both sides and compare with a Taylor expansion of the left side in $\delta\Lambda$:

$$\begin{aligned} S^{\mathrm{I}}_\Lambda - \delta\Lambda\,\partial_\Lambda S^{\mathrm{I}}_\Lambda + O(\delta\Lambda^2) &\overset{(1)}{=} S^{\mathrm{I}}_{\Lambda-\delta\Lambda} \overset{(2)}{=} S^{\mathrm{I}}_\Lambda - \ln\Big(1 + \tfrac{1}{2}\int_{x,y} \delta C(x-y)\big[S_xS_y - S_{xy}\big]\Big) \\ &\overset{(3)}{=} S^{\mathrm{I}}_\Lambda - \tfrac{1}{2}\int_{x,y} \delta C(x-y)\big[S_xS_y - S_{xy}\big] + O(\delta\Lambda^2) \\ &\overset{(4)}{=} S^{\mathrm{I}}_\Lambda - \frac{\delta\Lambda}{\Lambda}\,\tfrac{1}{2}\int_{x,y} \Delta_\Lambda(x-y)\big[S_xS_y - S_{xy}\big] + O(\delta\Lambda^2). \end{aligned}$$

(1) Taylor expansion of $S^{\mathrm{I}}_{\Lambda'}$ in its label Λ' about Λ.
(2) $-\ln$ of (T5.18); $-\ln e^{-S} = S$ and the log of a product is the sum of the logs.
(3) $\ln(1+\epsilon) = \epsilon + O(\epsilon^2)$, and $\epsilon \propto \delta C = O(\delta\Lambda)$.
(4) $\delta C = \Delta_\Lambda\, \delta\Lambda/\Lambda$ by (T5.9).

Cancel S^{I}_Λ, divide by $-\delta\Lambda/\Lambda$ and let $\delta\Lambda \to 0$.

Key idea: the Polchinski equation

The interaction action obeys

$$\Lambda\frac{\partial S^{\mathrm{I}}_\Lambda}{\partial\Lambda} = \frac{1}{2}\int \mathrm{d}^dx\,\mathrm{d}^dy\;\Delta_\Lambda(x-y)\left[\frac{\delta S^{\mathrm{I}}_\Lambda}{\delta\varphi(x)}\frac{\delta S^{\mathrm{I}}_\Lambda}{\delta\varphi(y)} - \frac{\delta^2 S^{\mathrm{I}}_\Lambda}{\delta\varphi(x)\,\delta\varphi(y)}\right], \tag{T5.19}$$

or, in the dot notation and with the RG time $t = \ln(\Lambda_0/\Lambda)$,

$$\partial_t S^{\mathrm{I}} = -\tfrac{1}{2}\frac{\delta S^{\mathrm{I}}}{\delta\varphi}\cdot\Delta\cdot\frac{\delta S^{\mathrm{I}}}{\delta\varphi} + \tfrac{1}{2}\frac{\delta}{\delta\varphi}\cdot\Delta\cdot\frac{\delta S^{\mathrm{I}}}{\delta\varphi}, \qquad \text{equivalently} \qquad \partial_t\, e^{-S^{\mathrm{I}}} = \tfrac{1}{2}\frac{\delta}{\delta\varphi}\cdot\Delta\cdot\frac{\delta}{\delta\varphi}\, e^{-S^{\mathrm{I}}}. \tag{T5.20}$$

The equation is exact: no expansion in a coupling was made. It says that $e^{-S^{\mathrm{I}}}$ diffuses in field space, with the shell propagator as the diffusion constant.

Both forms of (T5.20) follow from (T5.19). With $\partial_t = -\Lambda\partial_\Lambda$ (because $t = \ln(\Lambda_0/\Lambda)$),

$$\begin{aligned} \partial_t S^{\mathrm{I}} &\overset{(1)}{=} -\tfrac{1}{2}\int_{x,y}\Delta(x-y)\big[S_xS_y - S_{xy}\big] \overset{(2)}{=} -\tfrac{1}{2}\frac{\delta S^{\mathrm{I}}}{\delta\varphi}\cdot\Delta\cdot\frac{\delta S^{\mathrm{I}}}{\delta\varphi} + \tfrac{1}{2}\frac{\delta}{\delta\varphi}\cdot\Delta\cdot\frac{\delta S^{\mathrm{I}}}{\delta\varphi}, \\ \partial_t\, e^{-S^{\mathrm{I}}} &\overset{(3)}{=} -(\partial_t S^{\mathrm{I}})\, e^{-S^{\mathrm{I}}} \overset{(4)}{=} \tfrac{1}{2}\int_{x,y}\Delta(x-y)\big[S_xS_y - S_{xy}\big]e^{-S^{\mathrm{I}}} \overset{(5)}{=} \tfrac{1}{2}\frac{\delta}{\delta\varphi}\cdot\Delta\cdot\frac{\delta}{\delta\varphi}\, e^{-S^{\mathrm{I}}}. \end{aligned}$$

(1) Multiply (T5.19) by -1.
(2) The dot notation of (T5.10): $\int_{x,y}\Delta(x-y)S_xS_y$ is $\frac{\delta S}{\delta\varphi}\cdot\Delta\cdot\frac{\delta S}{\delta\varphi}$, and $\int_{x,y}\Delta(x-y)S_{xy}$ is $\frac{\delta}{\delta\varphi}\cdot\Delta\cdot\frac{\delta S}{\delta\varphi}$.
(3) Chain rule for the exponential.
(4) The first line.
(5) Step (2) of (T5.18) read backwards: $\frac{\delta}{\delta\varphi(x)}\frac{\delta}{\delta\varphi(y)}e^{-S} = (S_xS_y - S_{xy})e^{-S}$.

The exponential form shows the structure at a glance: a linear equation (heat flow) for $\psi = e^{-S^{\mathrm{I}}}$, which becomes the non-linear equation (T5.19) for $S^{\mathrm{I}} = -\ln\psi$. The same substitution turns the Schrödinger-like heat equation into the Hamilton–Jacobi-like equation of a classical action, and that is exactly what the two terms mean.

T5.2.4 Polchinski's derivation: the partition function does not move

The same equation can be reached from the opposite direction (Polchinski 1984, eqs. (16)–(19)). Instead of integrating out a shell, ask: if we lower the cutoff in the propagator, how must the interaction change so that the generating functional $Z[J]$, and hence every correlation function, stays exactly the same? Put a source J into (T5.15) that only couples to low momenta, $J(p) = 0$ wherever $\Delta_\Lambda(p) \neq 0$. To keep the bookkeeping transparent, treat the momentum modes as a discrete list φ_i (so $\varphi \cdot C^{-1} \cdot \varphi = \sum_i C_i^{-1}\varphi_i^2$, the propagator being diagonal in momentum), and write $\partial_i = \partial/\partial\varphi_i$, $S_i = \partial_i S^{\mathrm{I}}$, $S_{ii} = \partial_i^2 S^{\mathrm{I}}$ and

$$E \coloneqq \exp\Big(-\tfrac{1}{2}\sum_i C_i^{-1}\varphi_i^2 - S^{\mathrm{I}} + \sum_i J_i\varphi_i\Big), \qquad Z = \int \prod_i \mathrm{d}\varphi_i \; E.$$

Differentiating under the integral,

$$\Lambda\frac{\mathrm{d}Z}{\mathrm{d}\Lambda} \overset{(1)}{=} \int \prod_i \mathrm{d}\varphi_i \Big[-\tfrac{1}{2}\sum_i \varphi_i^2\, \Lambda\partial_\Lambda C_i^{-1} - \Lambda\partial_\Lambda S^{\mathrm{I}}\Big] E \overset{(2)}{=} \int \prod_i \mathrm{d}\varphi_i \Big[\tfrac{1}{2}\sum_i \Delta_i C_i^{-2}\varphi_i^2 - \Lambda\partial_\Lambda S^{\mathrm{I}}\Big] E. \tag{T5.21}$$

(1) Only C_Λ and S^{I}_Λ depend on Λ; J does not.
(2) $\Lambda\partial_\Lambda C^{-1} = -C^{-2}\Lambda\partial_\Lambda C = -C^{-2}\Delta$.

The integral of a total derivative $\partial_i(\cdots)$ vanishes (the integrand falls off at large φ_i). So we look for a total derivative that reproduces the bracket. Try $Y \coloneqq \sum_i \partial_i\big[(a_i\varphi_i + b_i\partial_i)E\big]$ with numbers a_i, b_i to be chosen. Using $\partial_i E = w_i E$ with $w_i = -C_i^{-1}\varphi_i - S_i$ on the shell modes (where $J_i = 0$),

$$\begin{aligned} Y &\overset{(1)}{=} \sum_i \big[a_i + a_i\varphi_i w_i + b_i(\partial_i w_i + w_i^2)\big]E \\ &\overset{(2)}{=} \sum_i \Big[a_i - b_i C_i^{-1} + (b_i C_i^{-2} - a_i C_i^{-1})\varphi_i^2 + (2b_i C_i^{-1} - a_i)\varphi_i S_i + b_i\big(S_i^2 - S_{ii}\big)\Big]E. \end{aligned}$$

(1) Product rule: $\partial_i(\varphi_i E) = E + \varphi_i w_i E$ and $\partial_i^2 E = \partial_i(w_i E) = (\partial_i w_i + w_i^2)E$.
(2) $\partial_i w_i = -C_i^{-1} - S_{ii}$ and $w_i^2 = C_i^{-2}\varphi_i^2 + 2C_i^{-1}\varphi_i S_i + S_i^2$; collect powers of φ_i.

Choose $a_i = 2b_i C_i^{-1}$ to kill the mixed term $\varphi_i S_i$, which has no counterpart in (T5.21). The φ_i^2 coefficient becomes $b_i C_i^{-2} - 2b_i C_i^{-2} = -b_i C_i^{-2}$ and the constant becomes $2b_i C_i^{-1} - b_i C_i^{-1} = b_i C_i^{-1}$ (field independent; its effect is worked out below). Matching the φ^2 term of (T5.21) requires $b_i = -\tfrac{1}{2}\Delta_i$. Then

$$Y = \Big[\tfrac{1}{2}\sum_i \Delta_i C_i^{-2}\varphi_i^2 - \tfrac{1}{2}\sum_i \Delta_i\big(S_i^2 - S_{ii}\big)\Big]E - \tfrac{1}{2}\sum_i \Delta_i C_i^{-1}E, \qquad Y = -\sum_i \Delta_i\,\partial_i\Big[\Big(C_i^{-1}\varphi_i + \tfrac{1}{2}\partial_i\Big)E\Big]. \tag{T5.22}$$

(The sums run only over shell modes, since a_i and b_i are proportional to Δ_i.) Now subtract Y from the integrand of (T5.21) and write $c \coloneqq \tfrac{1}{2}\sum_i \Delta_i C_i^{-1}$ for the field-independent constant:

$$\begin{aligned} \Lambda\frac{\mathrm{d}Z}{\mathrm{d}\Lambda} &\overset{(1)}{=} \int \prod_i \mathrm{d}\varphi_i \; Y + \int \prod_i \mathrm{d}\varphi_i \Big[\tfrac{1}{2}\sum_i \Delta_i\big(S_i^2 - S_{ii}\big) - \Lambda\partial_\Lambda S^{\mathrm{I}} + c\Big]E \\ &\overset{(2)}{=} \int \prod_i \mathrm{d}\varphi_i \Big[\tfrac{1}{2}\sum_i \Delta_i\big(S_i^2 - S_{ii}\big) - \Lambda\partial_\Lambda S^{\mathrm{I}}\Big]E + c\,Z. \end{aligned}$$

(1) Add and subtract Y, using the first form of (T5.22) with the constant written out: the φ_i^2 terms cancel.

(2) The integral of the total derivative Y vanishes (second form of (T5.22)); c does not depend on the fields, so $\int cE = cZ$.

The bracket vanishes exactly when $\Lambda\partial_\Lambda S^{\mathrm{I}} = \frac{1}{2}\sum_i \Delta_i(S_i^2 - S_{ii})$, which is (T5.19) written for discrete modes. So if S^{I} obeys the Polchinski equation, $\Lambda\,\mathrm{d}Z/\mathrm{d}\Lambda = cZ$: Z changes only by a field-independent and J-independent factor, which cancels in every normalised correlation function $\langle\varphi\cdots\varphi\rangle = Z^{-1}\partial_J\cdots\partial_J Z$. All n-point functions at low momenta are cutoff independent.

Watch out: why the source must avoid the shell

The step "$J_i = 0$ on the shell" is not a technicality. If J reached into the modes being removed, the correlators of those modes would change, since they are no longer in the theory. In practice one fixes a low scale Λ_R [the lowest cutoff we will ever use, where measurements are made], takes $J(p) = 0$ for $p^2 > \Lambda_R^2$, and lowers the cutoff only down to Λ_R. With a cutoff function that is exactly 1 for $p^2 < \Lambda^2$, as in Section T5.2.7, $\Delta_\Lambda(p)$ vanishes for $p^2 < \Lambda^2$, so the shell never reaches the source. Then we only ask questions at momenta below Λ_R.

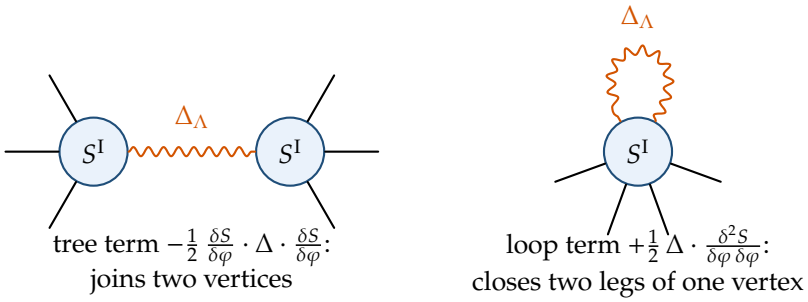

Figure T5.7: The two terms of the Polchinski equation as Feynman diagrams. A blob is a vertex of S^{I}_Λ; black lines are external legs (slow fields φ); the wavy orange line is the shell propagator Δ_Λ of the modes being integrated out. Left: two vertices are joined by one shell line, which generates a new vertex with the legs of both, as in Example T5.3. Right: two legs of one vertex are joined, which lowers the number of legs by two, as the tadpole $6D\varphi^2$ of Example T5.5. What to see: iterating these two moves builds every Feynman diagram, with internal lines made of the modes already integrated out.

Watch out: what is and is not approximated

The Polchinski equation is exact, but to use it we must truncate the infinite set of couplings in S^{I}. The truncation is the approximation, not the equation. Two standard truncations are perturbation theory (expand in the couplings, Example T5.6 below and Section T5.3) and the derivative expansion, whose lowest order is the local potential approximation of Section T5.2.5.

Since (T5.20) is a heat equation, its solution is the heat kernel: integrating from the bare scale Λ_0 down to Λ,

$$e^{-S^{\mathrm{I}}_\Lambda[\varphi]} = \exp\Big(\tfrac{1}{2}\frac{\delta}{\delta\varphi}\cdot(C_{\Lambda_0} - C_\Lambda)\cdot\frac{\delta}{\delta\varphi}\Big)e^{-S^{\mathrm{I}}_{\Lambda_0}[\varphi]} = \big\langle e^{-S^{\mathrm{I}}_{\Lambda_0}[\varphi+\chi]}\big\rangle_{C_{\Lambda_0}-C_\Lambda}. \tag{T5.23}$$

Why is this the solution? Write $\mathsf{H}_t := \frac{1}{2}\frac{\delta}{\delta\varphi}\cdot\Delta_{\Lambda(t)}\cdot\frac{\delta}{\delta\varphi}$, so that (T5.20) reads $\partial_t\psi = \mathsf{H}_t\psi$ for $\psi = e^{-S^{\mathrm{I}}}$. The operators H_t at different times commute (each is a second derivative in φ with a field-independent kernel, and partial derivatives commute), so they can be integrated like

numbers:

$$\psi(t) \overset{(1)}{=} \exp\Big(\int_0^t \mathrm{d}s\ \mathsf{H}_s\Big)\psi(0), \qquad \int_0^t \mathrm{d}s\ \Delta_{\Lambda(s)} \overset{(2)}{=} \int_\Lambda^{\Lambda_0} \frac{\mathrm{d}\Lambda'}{\Lambda'}\,\Lambda' \frac{\partial C_{\Lambda'}}{\partial \Lambda'} \overset{(3)}{=} C_{\Lambda_0} - C_\Lambda .$$

(1) Differentiate in t: since the H_s commute, the derivative of the exponential is H_t times the exponential, as for $e^{\int_0^t a(s)\mathrm{d}s}$ with a number $a(s)$.
(2) $s = \ln(\Lambda_0/\Lambda')$, so $\mathrm{d}s = -\mathrm{d}\Lambda'/\Lambda'$, and s from 0 to t means Λ' from Λ_0 down to Λ; the minus sign flips the limits. Then (T5.8).
(3) The integral of a derivative.

This is the first form of (T5.23): the "diffusion time" is the propagator $C_{\Lambda_0} - C_\Lambda$. The second form is Fact 2 (T5.14) with $D = C_{\Lambda_0} - C_\Lambda$. So *the Wilsonian interaction at scale Λ is the sum of all connected Feynman diagrams built from the bare vertices, with internal lines $C_{\Lambda_0} - C_\Lambda$* (the propagator of the modes between Λ and Λ_0) and with the slow field φ on the external legs. The minus sign and the logarithm pick out the connected diagrams, as always. Here is the simplest case, solved exactly.

Worked example T5.6: A mass term as an exact solution

Try $S^{\mathrm{I}}_\Lambda = \frac{1}{2}\varphi\cdot M_\Lambda\cdot\varphi + E_\Lambda$, a quadratic interaction with kernel $M_\Lambda(p)$ and a field-independent constant E_Λ. In the dot notation its derivatives are $\frac{\delta S^{\mathrm{I}}}{\delta\varphi} = M_\Lambda\cdot\varphi$ and $\frac{\delta^2 S^{\mathrm{I}}}{\delta\varphi\,\delta\varphi} = M_\Lambda$ (the kernel itself). Insert them into the first form of (T5.20):

$$\begin{aligned}\tfrac{1}{2}\,\varphi\cdot\partial_t M_\Lambda\cdot\varphi + \partial_t E_\Lambda &\overset{(1)}{=} -\tfrac{1}{2}\,(M_\Lambda\cdot\varphi)\cdot\Delta_\Lambda\cdot(M_\Lambda\cdot\varphi) + \tfrac{1}{2}\,\mathrm{Tr}\big(\Delta_\Lambda M_\Lambda\big)\\ &\overset{(2)}{=} -\tfrac{1}{2}\,\varphi\cdot M_\Lambda\Delta_\Lambda M_\Lambda\cdot\varphi + \tfrac{1}{2}\,\mathrm{Tr}\big(\Delta_\Lambda M_\Lambda\big).\end{aligned}$$

(1) Left: only M and E depend on t. Right: the tree term, and the loop term $\frac{1}{2}\int_{x,y}\Delta(x-y)M(x-y)$, which is a number (the trace of the product of kernels).
(2) In momentum space all kernels are diagonal (functions of p), so $M\cdot\varphi$ is $M(p)\varphi(p)$ and the product of kernels is the product of functions, $M(p)\Delta(p)M(p)$.

The φ^2 terms give $\partial_t M = -M\Delta M$, and the field-independent terms only fix E_Λ. Since $\partial_t = -\Lambda\partial_\Lambda$,

$$\Lambda\partial_\Lambda M_\Lambda = M_\Lambda\,\Delta_\Lambda\,M_\Lambda \quad\Longrightarrow\quad \Lambda\partial_\Lambda\Big(\frac{1}{M_\Lambda}\Big) \overset{(1)}{=} -\frac{\Lambda\partial_\Lambda M_\Lambda}{M_\Lambda^2} \overset{(2)}{=} -\Delta_\Lambda \overset{(3)}{=} -\Lambda\partial_\Lambda C_\Lambda .$$

(1) Derivative of $1/M$.
(2) The flow equation just derived.
(3) Definition (T5.8).

So $1/M_\Lambda + C_\Lambda$ is independent of Λ. Start at Λ_0 with a plain mass, $M_{\Lambda_0} = m^2$, and write $D = C_{\Lambda_0} - C_\Lambda$:

$$M_\Lambda(p) \overset{(1)}{=} \frac{m^2}{1 + m^2 D(p)} \overset{(2)}{=} m^2 - m^2 D m^2 + m^2 D m^2 D m^2 - \cdots$$

(1) $1/M_\Lambda = 1/m^2 + C_{\Lambda_0} - C_\Lambda$.
(2) Geometric series.

This is the diagrammatic statement: a chain of mass insertions (crosses) joined by propagators D of the modes already integrated out, with the sign (-1) per extra insertion from e^{-S}. It is the tree term of Figure T5.7 iterated.

As a check, let $\Lambda \to 0$ with Λ_0 finite, so that all modes are integrated out ($C_\Lambda = K(\infty)/p^2 = 0$). Write $C \coloneqq C_{\Lambda_0} = K_0/p^2$ with $K_0 \coloneqq K(p^2/\Lambda_0^2)$. Then

$$M_{\Lambda\to 0} \overset{(1)}{=} \frac{m^2}{1+m^2 C} \overset{(2)}{=} \frac{m^2 p^2}{p^2 + m^2 K_0}.$$

(1) $D = C_{\Lambda_0} - 0 = C$.
(2) Multiply top and bottom by p^2 and use $p^2 C = K_0$.

What should it be? Put $\Lambda = 0$ in the second form of (T5.23) and change variables to $\chi' = \varphi + \chi$, the full field:

$$e^{-S_0^{\mathrm{I}}[\varphi]} \overset{(1)}{=} \frac{\int \mathcal{D}\chi'\, e^{-\frac{1}{2}(\chi'-\varphi)\cdot C^{-1}\cdot(\chi'-\varphi)} e^{-S^{\mathrm{I}}_{\Lambda_0}[\chi']}}{\int \mathcal{D}\chi\, e^{-\frac{1}{2}\chi\cdot C^{-1}\cdot\chi}} \overset{(2)}{=} e^{-\frac{1}{2}\varphi\cdot C^{-1}\cdot\varphi}\, \frac{Z[J]}{Z_{\mathrm{free}}}, \qquad J \coloneqq C^{-1}\cdot\varphi,$$

(1) The definition (T5.11) of the average; the shift does not change the measure.
(2) Expand the square: $-\frac{1}{2}\chi' C^{-1}\chi' + J\cdot\chi' - \frac{1}{2}\varphi C^{-1}\varphi$. What remains is the full partition function of the bare theory with source J, $Z[J] = \int \mathcal{D}\chi'\, e^{-\frac{1}{2}\chi' C^{-1}\chi' - S^{\mathrm{I}}_{\Lambda_0}[\chi'] + J\cdot\chi'}$, divided by its free value at $J = 0$.

So $-S_0^{\mathrm{I}}[\varphi] = W[J] - \frac{1}{2}J\cdot C\cdot J$ with $W = \ln(Z/Z_{\mathrm{free}})$ the connected generating functional (we used $\varphi\cdot C^{-1}\cdot\varphi = J\cdot C\cdot J$). For our bare theory, a free field with propagator $G \coloneqq (C^{-1}+m^2)^{-1} = K_0/(p^2+m^2K_0)$, the Gaussian integral gives $W = \frac{1}{2}J\cdot G\cdot J$. Compare the two sides, working at each momentum p:

$$W - \tfrac{1}{2}J\cdot C\cdot J \overset{(1)}{=} \tfrac{1}{2}J\cdot(G-C)\cdot J \overset{(2)}{=} -\tfrac{1}{2}J\cdot\frac{m^2C^2}{1+m^2C}\cdot J \overset{(3)}{=} -\tfrac{1}{2}\varphi\cdot\frac{m^2}{1+m^2C}\cdot\varphi \overset{(4)}{=} -S_0^{\mathrm{I}}[\varphi].$$

(1) Combine the two quadratic forms.
(2) $G = C/(1+m^2C)$, so $G - C = \big(C - C - m^2C^2\big)/(1+m^2C)$.
(3) $J = C^{-1}\varphi$ cancels the two factors of C.
(4) $S_0^{\mathrm{I}} = \frac{1}{2}\varphi\cdot M_{\Lambda\to 0}\cdot\varphi$ with $M_{\Lambda\to 0}$ found above (up to the constant E).

The flow reproduces the full massive propagator $K_0/(p^2+m^2K_0)$.

T5.2.5 The local potential approximation

The most useful truncation keeps an arbitrary function of the field but throws away all momentum dependence of the vertices:

$$S_\Lambda^{\mathrm{I}}[\varphi] \approx \int \mathrm{d}^d x\; V_\Lambda\big(\varphi(x)\big). \tag{T5.24}$$

This is the **local potential approximation** (LPA). It keeps every φ^n coupling at once (all the couplings in the Taylor series of V_Λ) and drops the derivative couplings such as $\varphi^2(\partial\varphi)^2$. It is the lowest order of an expansion in derivatives, and it is good when the anomalous dimension is small, since the anomalous dimension lives in the $(\partial\varphi)^2$ term.

To get the flow of V_Λ, insert (T5.24) into (T5.19) and evaluate both sides on a *constant* field $\varphi(x) = \varphi$ in a large volume $\mathcal{V}$. (On a non-constant field the tree term generates momentum-dependent vertices, so the ansatz is not exactly preserved. The LPA keeps only what a constant

field sees.) The ingredients are

$$\frac{\delta S^{\mathrm{I}}}{\delta\varphi(x)} \overset{(1)}{=} V'(\varphi), \qquad \frac{\delta^2 S^{\mathrm{I}}}{\delta\varphi(x)\delta\varphi(y)} \overset{(2)}{=} V''(\varphi)\,\delta^d(x-y),$$

$$\int_{x,y} \Delta(x-y)\,V'V' \overset{(3)}{=} \mathcal{V}\,\Delta_\Lambda(p{=}0)\,V'^2, \qquad \int_{x,y} \Delta(x-y)\,V''\delta^d(x-y) \overset{(4)}{=} \mathcal{V}\,V''\int \frac{\mathrm{d}^d p}{(2\pi)^d}\Delta_\Lambda(p).$$

(1) Changing φ at the single point x changes $\int \mathrm{d}^d z\, V(\varphi(z))$ only through the integrand at $z = x$, by $V'(\varphi(x))$.
(2) Differentiate $V'(\varphi(x))$ once more; it depends on $\varphi(y)$ only if $y = x$, which gives $\delta^d(x-y)$.
(3) V' is constant, $\int \mathrm{d}^d x = \mathcal{V}$, and $\int \mathrm{d}^d y\,\Delta(x-y) = \int \mathrm{d}^d z\,\Delta(z)e^{-i0\cdot z}$ is the Fourier transform at zero momentum.
(4) The delta function sets $y = x$, leaving $\mathcal{V}\,V''\,\Delta(z{=}0)$, and $\Delta(z{=}0) = \int \frac{\mathrm{d}^d p}{(2\pi)^d} e^{ip\cdot 0}\Delta(p)$ is the integral over all momenta.

The left side of (T5.19) is $\Lambda\partial_\Lambda \int \mathrm{d}^d x\, V = \mathcal{V}\,\Lambda\partial_\Lambda V$. Insert the four ingredients and divide by $\mathcal{V}$:

$$\Lambda\frac{\partial V_\Lambda}{\partial\Lambda} = \tfrac{1}{2}\Delta_\Lambda(0)\,V'^2 - \tfrac{1}{2}V''\int \frac{\mathrm{d}^d p}{(2\pi)^d}\,\Delta_\Lambda(p). \tag{T5.25}$$

For the exponential cutoff both numbers are elementary. Setting $p = 0$ in $\Delta_\Lambda(p) = 2e^{-p^2/\Lambda^2}/\Lambda^2$ gives $\Delta_\Lambda(0) = 2/\Lambda^2$, and

$$\int \frac{\mathrm{d}^d p}{(2\pi)^d}\,\frac{2}{\Lambda^2}e^{-p^2/\Lambda^2} \overset{(1)}{=} \frac{2}{\Lambda^2}\,\frac{(\pi\Lambda^2)^{d/2}}{(2\pi)^d} \overset{(2)}{=} \frac{2\,\Lambda^{d-2}}{(4\pi)^{d/2}}.$$

(1) The Gaussian integral $\int \mathrm{d}^d p\, e^{-p^2/\Lambda^2} = (\pi\Lambda^2)^{d/2}$: since $p^2 = p_1^2 + \cdots + p_d^2$, it is the product of d one-dimensional integrals $\int \mathrm{d}p_1\, e^{-p_1^2/\Lambda^2} = \sqrt{\pi}\,\Lambda$.
(2) $(2\pi)^d = (4\pi^2)^{d/2}$, so $\pi^{d/2}/(4\pi^2)^{d/2} = (4\pi)^{-d/2}$.

So, with $\alpha_d := (4\pi)^{-d/2}$, the two terms of (T5.25) are $\frac{1}{2}\cdot\frac{2}{\Lambda^2}V'^2$ and $\frac{1}{2}V''\cdot 2\alpha_d\Lambda^{d-2}$:

$$\Lambda\frac{\partial V_\Lambda}{\partial\Lambda} = \frac{V'^2}{\Lambda^2} - \alpha_d\,\Lambda^{d-2}\,V''. \tag{T5.26}$$

Dimensionless variables. Fixed points need dimensionless quantities. Measure the field and the potential in units of the cutoff,

$$\varphi = \Lambda^{\frac{d-2}{2}}\,\hat{\varphi}, \qquad V_\Lambda(\varphi) = \Lambda^d\,v_t(\hat{\varphi}), \qquad t = \ln\frac{\Lambda_0}{\Lambda}. \tag{T5.27}$$

Primes on v mean $\mathrm{d}/\mathrm{d}\hat{\varphi}$. Since $\hat{\varphi} = \Lambda^{-\frac{d-2}{2}}\varphi$, each $\mathrm{d}/\mathrm{d}\varphi$ acting on $V = \Lambda^d v(\hat{\varphi})$ brings a factor $\Lambda^{-\frac{d-2}{2}}$:

$$V' = \Lambda^{d-\frac{d-2}{2}}v' = \Lambda^{\frac{d+2}{2}}v', \qquad V'' = \Lambda^{d-(d-2)}v'' = \Lambda^2 v''.$$

Differentiating at fixed $\hat{\varphi}$,

$$\begin{aligned}
\partial_t v &\overset{(1)}{=} -\Lambda\partial_\Lambda\big(\Lambda^{-d}V_\Lambda(\Lambda^{\frac{d-2}{2}}\hat{\varphi})\big) \\
&\overset{(2)}{=} d\,v - \Lambda^{-d}\Big[\Lambda\partial_\Lambda V\big|_\varphi + V'\cdot\tfrac{d-2}{2}\Lambda^{\frac{d-2}{2}}\hat{\varphi}\Big] \\
&\overset{(3)}{=} d\,v - \tfrac{d-2}{2}\,\hat{\varphi}\,v' - v'^2 + \alpha_d\,v''.
\end{aligned} \tag{T5.28}$$

(1) $\partial_t = -\Lambda\partial_\Lambda$ and (T5.27).
(2) Product rule: the Λ^{-d} gives $d\,v$; the Λ inside the argument gives the chain-rule term.
(3) Insert (T5.26): $\Lambda^{-d}V'^2/\Lambda^2 = v'^2$ and $\Lambda^{-d}\alpha_d\Lambda^{d-2}V'' = \alpha_d v''$; and $\Lambda^{-d}V'\Lambda^{(d-2)/2}\hat\varphi = \hat\varphi v'$.

The first two terms are pure dimensional analysis (they are there even with no interactions, as in (T5.6)); the last two are the tree and loop terms.

Worked example T5.7: The LPA flow of the mass, the quartic and the sextic coupling

Expand the dimensionless potential of a $\mathbb{Z}_2$-symmetric theory,

$$v = \frac{r}{2}\hat\varphi^2 + \frac{u}{4!}\hat\varphi^4 + \frac{w}{6!}\hat\varphi^6 + \cdots,$$

so that $r = m^2/\Lambda^2$ is the dimensionless mass, u the quartic and w the sextic coupling. We need

$$v' = r\hat\varphi + \tfrac{u}{6}\hat\varphi^3 + \tfrac{w}{120}\hat\varphi^5 + \cdots, \qquad v'' = r + \tfrac{u}{2}\hat\varphi^2 + \tfrac{w}{24}\hat\varphi^4 + \cdots,$$
$$\hat\varphi v' = r\hat\varphi^2 + \tfrac{u}{6}\hat\varphi^4 + \tfrac{w}{120}\hat\varphi^6 + \cdots, \qquad v'^2 = r^2\hat\varphi^2 + \tfrac{ru}{3}\hat\varphi^4 + \left(\tfrac{u^2}{36} + \tfrac{rw}{60}\right)\hat\varphi^6 + \cdots.$$

The first three lines differentiate the series term by term. For v'^2, square v' and collect: the $\hat\varphi^4$ term is $2\cdot r\cdot\frac{u}{6} = \frac{ru}{3}$, and the $\hat\varphi^6$ term is $(\frac{u}{6})^2 + 2\cdot r\cdot\frac{w}{120} = \frac{u^2}{36} + \frac{rw}{60}$. Now match powers of $\hat\varphi$ in (T5.28). On the left, $\partial_t v = \frac{\partial_t r}{2}\hat\varphi^2 + \frac{\partial_t u}{4!}\hat\varphi^4 + \frac{\partial_t w}{6!}\hat\varphi^6 + \cdots$, so we multiply the coefficient of $\hat\varphi^2$ by 2, of $\hat\varphi^4$ by 4! and of $\hat\varphi^6$ by 6!. On the right each coefficient collects four pieces: from $d\,v$, from $-\frac{d-2}{2}\hat\varphi v'$, from $-v'^2$ and from $\alpha_d v''$:

$$\begin{aligned}
\partial_t r &\overset{(1)}{=} d\,r - (d-2)r - 2r^2 + \alpha_d u = 2r - 2r^2 + \alpha_d u,\\
\partial_t u &\overset{(2)}{=} d\,u - 2(d-2)u - 8ru + \alpha_d w = (4-d)u - 8ru + \alpha_d w,\\
\partial_t w &\overset{(3)}{=} d\,w - 3(d-2)w - 20u^2 - 12rw + \alpha_d w_8 = (6-2d)w - 20u^2 - 12rw + \alpha_d w_8.
\end{aligned} \tag{T5.29}$$

(1) $2\cdot\left[\frac{d}{2}r - \frac{d-2}{2}r - r^2 + \alpha_d\frac{u}{2}\right]$.
(2) $24\cdot\left[\frac{d}{24}u - \frac{d-2}{2}\frac{u}{6} - \frac{ru}{3} + \alpha_d\frac{w}{24}\right]$.
(3) $720\cdot\left[\frac{d}{720}w - \frac{d-2}{2}\frac{w}{120} - \frac{u^2}{36} - \frac{rw}{60} + \alpha_d\frac{w_8}{720}\right]$, where w_8 is the $\hat\varphi^8$ coupling ($v \supset w_8\hat\varphi^8/8!$, so $v'' \supset w_8\hat\varphi^6/6!$).

The linear terms $2, 4-d, 6-2d$ are the Gaussian eigenvalues of Example T5.4, as they must be. The constant α_d can be absorbed into the couplings. Define $\tilde u := \alpha_d u$, $\tilde w := \alpha_d^2 w$ and $\tilde w_8 := \alpha_d^3 w_8$. Multiply the second line by α_d and the third by α_d^2:

$$\partial_t r = 2r - 2r^2 + \tilde u, \qquad \partial_t\tilde u \overset{(1)}{=} (4-d)\tilde u - 8r\tilde u + \tilde w,$$
$$\partial_t\tilde w \overset{(2)}{=} (6-2d)\tilde w - 20\tilde u^2 - 12r\tilde w + \tilde w_8.$$

(1) $\alpha_d\cdot\alpha_d w = \alpha_d^2 w = \tilde w$.
(2) $\alpha_d^2 u^2 = \tilde u^2$ and $\alpha_d^2\cdot\alpha_d w_8 = \tilde w_8$.

This is (T5.29) with $\alpha_d = 1$. We use these variables from now on and drop the tildes.

Three features of (T5.29) deserve comment.

- The loop term (α_d) feeds each coupling from the next higher one: u into r, w into u. The tree term (v'^2) feeds from lower ones: u^2 into w, as in Example T5.3. So the tower does

not close; in practice one truncates it.

- In $d = 4 - \varepsilon$ the sextic coupling has eigenvalue $6 - 2d = -2 + 2\varepsilon$: strongly irrelevant. It relaxes quickly to the value where $\partial_t w \approx 0$. Dropping $12rw$ and w_8, which are of higher order in the small couplings,

$$0 \overset{(1)}{=} (-2 + 2\varepsilon)w - 20u^2 \implies w \overset{(2)}{=} -\frac{20u^2}{2(1-\varepsilon)} \overset{(3)}{=} -10u^2\big(1 + O(\varepsilon)\big).$$

  (1) The third line of (T5.29) with $d = 4 - \varepsilon$ and $\alpha_d = 1$.
  (2) Solve for w.
  (3) $1/(1-\varepsilon) = 1 + \varepsilon + \cdots$.

  Section T5.2.6 shows why the flow really lands there. Substituting $w = -10u^2$ into the second line, where $(4-d)u = \varepsilon u$, gives a closed system for (r, u):

$$\partial_t r = 2r - 2r^2 + u, \qquad \partial_t u = \varepsilon u - 8ru - 10u^2. \tag{T5.30}$$

- Fixed points of (T5.30): the **Gaussian** point $r = u = 0$, and, for $\varepsilon > 0$, a second one, the **Wilson–Fisher** point, computed in the next example.

Worked example T5.8: The Wilson–Fisher fixed point in the LPA

Set both right sides of (T5.30) to zero with $u \neq 0$ and keep the leading order in ε (we will see $r^*, u^* = O(\varepsilon)$, so r^2 and ru corrections are $O(\varepsilon^2)$):

$$0 = 2r^* - 2r^{*2} + u^* \implies r^* \overset{(1)}{=} -\tfrac{1}{2}u^* + O(\varepsilon^2),$$
$$0 = \varepsilon - 8r^* - 10u^* \implies \varepsilon + 4u^* - 10u^* \overset{(2)}{=} 0 \implies u^* = \frac{\varepsilon}{6}, \quad r^* = -\frac{\varepsilon}{12}.$$

(1) Drop $r^{*2} = O(\varepsilon^2)$.
(2) Divide the second equation by $u^* \neq 0$ and insert r^*.

The **stability matrix** $M_{ij} = \partial(\partial_t g_i)/\partial g_j$ at the fixed point, with $g = (r, u)$, is

$$M \overset{(1)}{=} \begin{pmatrix} 2 - 4r^* & 1 \\ -8u^* & \varepsilon - 8r^* - 20u^* \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} 2 + \frac{\varepsilon}{3} & 1 \\ -\frac{4\varepsilon}{3} & -\frac{5\varepsilon}{3} \end{pmatrix} + O(\varepsilon^2).$$

(1) Differentiate (T5.30).
(2) Insert $r^* = -\varepsilon/12$, $u^* = \varepsilon/6$: $\varepsilon + \frac{2\varepsilon}{3} - \frac{10\varepsilon}{3} = -\frac{5\varepsilon}{3}$.

Its eigenvalues y solve the characteristic equation $\det(M - y\mathbb{1}) = y^2 - (\operatorname{tr} M)\, y + \det M = 0$. First the two coefficients:

$$\operatorname{tr} M \overset{(1)}{=} 2 + \tfrac{\varepsilon}{3} - \tfrac{5\varepsilon}{3} = 2 - \tfrac{4\varepsilon}{3},$$
$$\det M \overset{(2)}{=} \big(2 + \tfrac{\varepsilon}{3}\big)\big(-\tfrac{5\varepsilon}{3}\big) - 1 \cdot \big(-\tfrac{4\varepsilon}{3}\big) = -\tfrac{10\varepsilon}{3} + \tfrac{4\varepsilon}{3} + O(\varepsilon^2) = -2\varepsilon + O(\varepsilon^2).$$

(1) Sum of the diagonal entries.
(2) $\det \begin{pmatrix} a & b \\ c & e \end{pmatrix} = ae - bc$; the product $\frac{\varepsilon}{3} \cdot \frac{5\varepsilon}{3}$ is $O(\varepsilon^2)$.

Then the roots, using that $\det M$ is small compared with $(\operatorname{tr} M)^2 \approx 4$:

$$y_{1,2} \overset{(1)}{=} \tfrac{1}{2}\Big(\operatorname{tr} M \pm \sqrt{(\operatorname{tr} M)^2 - 4\det M}\Big) \overset{(2)}{=} \tfrac{1}{2}\operatorname{tr} M\Big(1 \pm \Big(1 - \frac{2\det M}{(\operatorname{tr} M)^2}\Big)\Big) + O(\varepsilon^2),$$
$$y_1 \overset{(3)}{=} \operatorname{tr} M - \frac{\det M}{\operatorname{tr} M} = 2 - \tfrac{4\varepsilon}{3} + \varepsilon + O(\varepsilon^2), \qquad y_2 \overset{(4)}{=} \frac{\det M}{\operatorname{tr} M} = \frac{-2\varepsilon}{2} + O(\varepsilon^2).$$

(1) Quadratic formula.
(2) Take $\operatorname{tr} M$ out of the root and use $\sqrt{1-x} = 1 - \frac{x}{2} + O(x^2)$ with $x = 4 \det M/(\operatorname{tr} M)^2 = O(\varepsilon)$.
(3) Upper sign; $\det M/\operatorname{tr} M = -2\varepsilon/2 + O(\varepsilon^2) = -\varepsilon + O(\varepsilon^2)$.
(4) Lower sign; only $\operatorname{tr} M = 2$ is needed at this order.

So

$$y_1 = 2 - \frac{\varepsilon}{3} + O(\varepsilon^2), \qquad y_2 = -\varepsilon + O(\varepsilon^2). \tag{T5.31}$$

One relevant direction (the temperature) and one irrelevant one. By the relation $\nu = 1/y_t$ derived in Section T5.3.1, $\nu = 1/y_1 = \frac{1}{2}(1 - \frac{\varepsilon}{6})^{-1} = \frac{1}{2} + \frac{\varepsilon}{12} + O(\varepsilon^2)$. (A numerical solution of the untruncated three-coupling system (T5.29) at $\varepsilon = 10^{-3}$ gives $y_1 = 1.99967$ and $y_2 = -0.00100$, as predicted.)

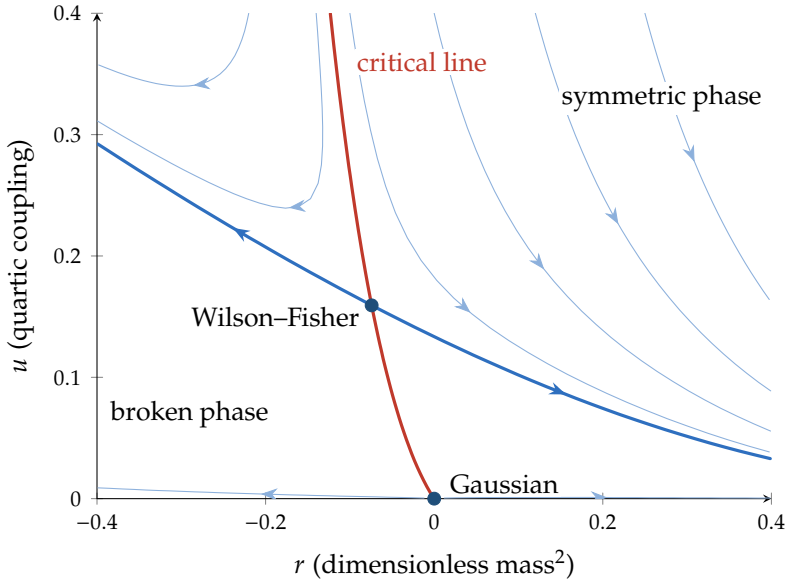

Figure T5.8: The LPA flow (T5.30) in the (r, u) plane for $\varepsilon = 1$ ($d = 3$), computed numerically; arrows point towards the infrared. Red: the critical line, the set of theories that flow into the Wilson–Fisher point (from the Gaussian point below and from large u above). Thick blue: the relevant direction leaving the Wilson–Fisher point. Theories to the right of the red line flow to large positive r (a massive, disordered theory); theories to the left flow to negative r (the ordered phase). What to see: the geometry of Figure T5.5 in an honest calculation. (For $\varepsilon = 1$ the $O(\varepsilon)$ formulas are only rough: the numerical fixed point is at $(r^*, u^*) = (-0.074, 0.159)$ with eigenvalues 1.94 and −1.23.)

Watch out: fixed-point coordinates are not physical; eigenvalues are

The location $u^* = \varepsilon/6$ depends on the cutoff function K and on the truncation. In Section T5.3 a different scheme (a sharp momentum shell, keeping only one-loop diagrams) gives $u^* = \varepsilon/3$ in the same units, twice the LPA value, and dimensional regularisation gives yet another number. What does *not* depend on the scheme are the eigenvalues of the stability matrix: a change of scheme is a smooth change of coordinates $g \mapsto \tilde{g}(g)$ on theory space, with Jacobian $J_{ij} = \partial \tilde{g}_i/\partial g_j$. Near the fixed point write $\delta\tilde{g} = J\,\delta g + O(\delta g^2)$. Then

$$\partial_t\, \delta\tilde{g} \overset{(1)}{=} J\, \partial_t\, \delta g \overset{(2)}{=} JM\, \delta g \overset{(3)}{=} JMJ^{-1}\, \delta\tilde{g},$$

(1) J is evaluated at the fixed point, so it is constant along the linearised flow.

(2) Linearised flow $\partial_t \delta g = M \delta g$.
(3) $\delta g = J^{-1} \delta \tilde{g}$.

so $\tilde{M} = JMJ^{-1}$. If $Me = ye$ then $\tilde{M}(Je) = JMe = y\,(Je)$: the eigenvalues are unchanged. This is why critical exponents are universal while coupling constants at fixed points are not.

T5.2.6 Polchinski's toy flow: one relevant and one irrelevant coupling

We can now make the "squeezing" of Figure T5.5 quantitative. The mechanism is clearest in a model with just two couplings (Polchinski 1984, §2), chosen to mimic the φ^4 and φ^6 couplings of a four-dimensional scalar: g_4, dimensionless, and g_6, of mass dimension -2. Their flow is

$$\Lambda \frac{\mathrm{d}g_4}{\mathrm{d}\Lambda} = \beta_4\big(g_4, \Lambda^2 g_6\big), \qquad \Lambda \frac{\mathrm{d}g_6}{\mathrm{d}\Lambda} = \Lambda^{-2}\beta_6\big(g_4, \Lambda^2 g_6\big),$$

with β_4, β_6 dimensionless functions. The powers of Λ are fixed by dimensional analysis: the only scale is Λ, so g_6 can enter only through the dimensionless $\Lambda^2 g_6$, and the left side of the second equation has dimension -2, which the factor Λ^{-2} supplies. (In this subsection we use $\Lambda\,\mathrm{d}/\mathrm{d}\Lambda$, which points towards the ultraviolet, the opposite of $\partial_t = -\Lambda\,\mathrm{d}/\mathrm{d}\Lambda$.) In the dimensionless variables $\lambda_4 = g_4$, $\lambda_6 = \Lambda^2 g_6$,

$$\Lambda \frac{\mathrm{d}\lambda_6}{\mathrm{d}\Lambda} \overset{(1)}{=} 2\Lambda^2 g_6 + \Lambda^2 \Lambda \frac{\mathrm{d}g_6}{\mathrm{d}\Lambda} \overset{(2)}{=} 2\lambda_6 + \beta_6(\lambda_4, \lambda_6) \quad \Longrightarrow \quad \Lambda \frac{\mathrm{d}\lambda_4}{\mathrm{d}\Lambda} = \beta_4, \qquad \Lambda \frac{\mathrm{d}\lambda_6}{\mathrm{d}\Lambda} - 2\lambda_6 = \beta_6. \tag{T5.32}$$

(1) Product rule on $\Lambda^2 g_6$.
(2) The flow of g_6: $\Lambda^2 \cdot \Lambda^{-2}\beta_6 = \beta_6$.

The $-2\lambda_6$ says that λ_6 is irrelevant: with β_6 switched off, $\lambda_6 \propto \Lambda^2$, so it dies like $(\Lambda/\Lambda_0)^2$ on the way from Λ_0 down to Λ.

Two neighbouring trajectories. Take one solution $\bar{\lambda}_i(\Lambda)$ and a nearby one, $\lambda_i = \bar{\lambda}_i + \epsilon_i$. Taylor expand the right sides of (T5.32) about $\bar{\lambda}$ and subtract the equations for $\bar{\lambda}$; to first order in ϵ,

$$\Lambda \frac{\mathrm{d}\epsilon}{\mathrm{d}\Lambda} = J\epsilon, \qquad J = \begin{pmatrix} \bar{\partial}_4\beta_4 & \bar{\partial}_6\beta_4 \\ \bar{\partial}_4\beta_6 & 2 + \bar{\partial}_6\beta_6 \end{pmatrix}, \tag{T5.33}$$

where $\bar{\partial}_a\beta_b = \partial\beta_b/\partial\lambda_a$ at $\bar{\lambda}(\Lambda)$. Part of ϵ is uninteresting: the second trajectory may be the *same* curve in the (λ_4, λ_6) plane, just run a little ahead of the first. Such a displacement points along the tangent vector $\tau_a := \Lambda\,\mathrm{d}\bar{\lambda}_a/\mathrm{d}\Lambda$, with $\tau_4 = \bar{\beta}_4$ and $\tau_6 = 2\bar{\lambda}_6 + \bar{\beta}_6$ by (T5.32). The tangent itself solves (T5.33):

$$\Lambda \frac{\mathrm{d}\tau_a}{\mathrm{d}\Lambda} \overset{(1)}{=} \Lambda \frac{\mathrm{d}}{\mathrm{d}\Lambda} F_a\big(\bar{\lambda}(\Lambda)\big) \overset{(2)}{=} \sum_b \frac{\partial F_a}{\partial \lambda_b}\Big|_{\bar{\lambda}} \Lambda \frac{\mathrm{d}\bar{\lambda}_b}{\mathrm{d}\Lambda} \overset{(3)}{=} \sum_b J_{ab}\tau_b,$$

(1) Write the right sides of (T5.32) as $F_4 = \beta_4$ and $F_6 = 2\lambda_6 + \beta_6$, so $\tau_a = F_a(\bar{\lambda})$.
(2) Chain rule along the trajectory.
(3) $\partial F_a/\partial\lambda_b = J_{ab}$ is exactly the matrix of (T5.33), and $\Lambda\,\mathrm{d}\bar{\lambda}_b/\mathrm{d}\Lambda = \tau_b$.

Split ϵ into a piece along the tangent and a purely vertical piece:

$$\epsilon = a\,\tau + \begin{pmatrix} 0 \\ \xi_6 \end{pmatrix}, \qquad a = \frac{\epsilon_4}{\tau_4}. \tag{T5.34}$$

The number ξ_6 is the genuine vertical distance between the two trajectories, measured at the same λ_4. Insert (T5.34) into (T5.33), with $e_6 := (0,1)$ the vertical unit vector:

$$\Big(\Lambda\frac{\mathrm{d}a}{\mathrm{d}\Lambda}\Big)\tau + a\,J\tau + \Lambda\frac{\mathrm{d}\xi_6}{\mathrm{d}\Lambda}\,e_6 \overset{(1)}{=} \Lambda\frac{\mathrm{d}\epsilon}{\mathrm{d}\Lambda} \overset{(2)}{=} J\epsilon \overset{(3)}{=} a\,J\tau + \xi_6\,Je_6.$$

(1) Product rule on $a\tau + \xi_6 e_6$, and $\Lambda\,\mathrm{d}\tau/\mathrm{d}\Lambda = J\tau$.
(2) (T5.33).
(3) Linearity of J.

The terms $aJ\tau$ cancel. With $Je_6 = (\bar\partial_6\beta_4,\ 2+\bar\partial_6\beta_6)$, the second column of J, the two components read

$$\begin{aligned}\text{row 4:}\quad & (\Lambda\,\mathrm{d}a/\mathrm{d}\Lambda)\,\tau_4 = \bar\partial_6\beta_4\,\xi_6,\\ \text{row 6:}\quad & (\Lambda\,\mathrm{d}a/\mathrm{d}\Lambda)\,\tau_6 + \Lambda\frac{\mathrm{d}\xi_6}{\mathrm{d}\Lambda} = (2+\bar\partial_6\beta_6)\,\xi_6.\end{aligned}$$

Eliminate $\Lambda\,\mathrm{d}a/\mathrm{d}\Lambda$ between them:

$$\Lambda\frac{\mathrm{d}\xi_6}{\mathrm{d}\Lambda} - 2\xi_6 \overset{(1)}{=} \Big(\bar\partial_6\beta_6 - \frac{\tau_6}{\tau_4}\bar\partial_6\beta_4\Big)\xi_6 \overset{(2)}{=} \Big(\bar\partial_6\beta_6 + \bar\partial_4\beta_4 - \Lambda\frac{\mathrm{d}}{\mathrm{d}\Lambda}\ln\bar\beta_4\Big)\xi_6. \tag{T5.35}$$

(1) Row 4 gives $\Lambda\,\mathrm{d}a/\mathrm{d}\Lambda = \bar\partial_6\beta_4\,\xi_6/\tau_4$; put it in row 6.
(2) Chain rule along the trajectory: $\Lambda\,\mathrm{d}\bar\beta_4/\mathrm{d}\Lambda = \bar\partial_4\beta_4\,\tau_4 + \bar\partial_6\beta_4\,\tau_6$; divide by $\tau_4 = \bar\beta_4$, so $-\frac{\tau_6}{\tau_4}\bar\partial_6\beta_4 = \bar\partial_4\beta_4 - \Lambda\frac{\mathrm{d}}{\mathrm{d}\Lambda}\ln\bar\beta_4$.

This is a linear first-order equation for one function, so it integrates directly:

$$\begin{aligned}\ln\frac{\xi_6(\Lambda)}{\xi_6(\Lambda_0)} &\overset{(1)}{=} \int_{\Lambda_0}^{\Lambda}\frac{\mathrm{d}\Lambda'}{\Lambda'}\Big(2+\bar\partial_6\beta_6+\bar\partial_4\beta_4\Big) - \ln\frac{\bar\beta_4(\Lambda)}{\bar\beta_4(\Lambda_0)}\\ \xi_6(\Lambda) &\overset{(2)}{=} \xi_6(\Lambda_0)\,\frac{\Lambda^2}{\Lambda_0^2}\,\frac{\bar\beta_4(\Lambda_0)}{\bar\beta_4(\Lambda)}\,\exp\int_{\Lambda_0}^{\Lambda}\frac{\mathrm{d}\Lambda'}{\Lambda'}\Big(\bar\partial_6\beta_6+\bar\partial_4\beta_4\Big)(\Lambda').\end{aligned} \tag{T5.36}$$

(1) Divide (T5.35) by ξ_6 and integrate $\mathrm{d}\ln\xi_6 = \frac{\mathrm{d}\Lambda}{\Lambda}(\cdots)$ from Λ_0 to Λ; the total-derivative term integrates to a logarithm.
(2) Exponentiate; $\int_{\Lambda_0}^{\Lambda} 2\,\mathrm{d}\Lambda'/\Lambda' = \ln(\Lambda^2/\Lambda_0^2)$.

At weak coupling the integrand of the exponential is small (these are anomalous dimensions, of order the couplings), and the ratio of β_4's varies slowly. So ξ_6 is dominated by Λ^2/Λ_0^2: *two neighbouring trajectories approach each other like* $(\Lambda/\Lambda_0)^2$ *in the infrared.* The infrared theory lies very close to a one-dimensional curve in the (λ_4,λ_6) plane, and the one remaining parameter only says where on that curve we are: it is "transmuted into a scale".

Why this is renormalisability. Start at the bare cutoff Λ_0 with a bare theory $\lambda_4 = \lambda_4^0$, $\lambda_6 = 0$, and flow down to a low scale Λ_R, where λ_4 is *defined* to have the measured value λ_4^R. For a larger bare cutoff Λ_0' choose the bare coupling so that the flow again reaches λ_4^R at Λ_R. This defines a function $\lambda_4^0(\lambda_4^R,\Lambda_R,\Lambda_0)$. The two flows end at the same λ_4, so their difference at Λ_R is purely vertical, and its size is the ξ_6 of (T5.36):

$$\big|\lambda_6(\Lambda_R;\Lambda_0') - \lambda_6(\Lambda_R;\Lambda_0)\big| \overset{(1)}{=} |\xi_6(\Lambda_R)| \overset{(2)}{=} |\xi_6(\Lambda_0)|\,\frac{\Lambda_R^2}{\Lambda_0^2}\,\big(1+O(\lambda)\big) \overset{(3)}{=} O\Big(\frac{\Lambda_R^2}{\Lambda_0^2}\Big).$$

(1) Both flows are trajectories of (T5.32) passing through the same λ_4^R at Λ_R; for Λ_0' close to Λ_0 the difference is small and the linear analysis applies (for a large change of cutoff, add up small steps).

(2) (T5.36) with $\Lambda = \Lambda_R$; at weak coupling λ the exponential and the ratio of β_4's are $1 + O(\lambda)$ up to slowly varying logarithms.
(3) At Λ_0 the first flow has $\lambda_6 = 0$, while the second has already run from Λ_0' to Λ_0, so it has some $\lambda_6 = O(1)$ in cutoff units. So $|\xi_6(\Lambda_0)|$ is a pure number of order one at most.

So as $\Lambda_0 \to \infty$ with Λ_R and λ_4^R held fixed, $\lambda_6(\Lambda_R)$ approaches a limit, with corrections that are inverse powers of the cutoff. That is exactly the definition of a renormalisable theory: *holding the renormalised couplings fixed, everything else has a limit as the cutoff goes to infinity*. The same statement can be packaged in a vector that generalises to infinitely many couplings:

$$v_i(\Lambda) := \Lambda_0 \frac{\partial \lambda_i}{\partial \Lambda_0} - \frac{\partial \lambda_i}{\partial \lambda_4^0}\Big(\frac{\partial \lambda_4}{\partial \lambda_4^0}\Big)^{-1} \Lambda_0 \frac{\partial \lambda_4}{\partial \Lambda_0} = \Lambda_0 \frac{\mathrm{d}}{\mathrm{d}\Lambda_0} \lambda_i\big(\Lambda, \Lambda_0, \lambda_4^0(\Lambda, \lambda_4, \Lambda_0)\big), \tag{T5.37}$$

the change of the couplings at Λ when the bare cutoff moves while $\lambda_4(\Lambda)$ is held fixed. (The two forms agree by the chain rule: the derivative $\Lambda_0\,\mathrm{d}/\mathrm{d}\Lambda_0$ acts both on the explicit Λ_0 and, through λ_4^0, on the bare coupling, and $\Lambda_0\,\partial\lambda_4^0/\partial\Lambda_0$ is fixed by demanding $v_4 = 0$.) By construction $v_4 = 0$, so v is purely vertical, and $v_6(\Lambda)$ is the vertical distance computed above per unit change of $\ln \Lambda_0$: $v_6(\Lambda) = O(\Lambda^2/\Lambda_0^2)$. Now integrate over the cutoff, from Λ_0 to ∞, at $\Lambda = \Lambda_R$:

$$\big|\lambda_6(\Lambda_R;\infty) - \lambda_6(\Lambda_R;\Lambda_0)\big| \overset{(1)}{=} \Big|\int_{\Lambda_0}^{\infty} \frac{\mathrm{d}\Lambda_0'}{\Lambda_0'}\, v_6(\Lambda_R;\Lambda_0')\Big| \overset{(2)}{\le} c \int_{\Lambda_0}^{\infty} \frac{\mathrm{d}\Lambda_0'}{\Lambda_0'} \frac{\Lambda_R^2}{\Lambda_0'^2} \overset{(3)}{=} \frac{c}{2}\frac{\Lambda_R^2}{\Lambda_0^2},$$

(1) $\Lambda_0\,\mathrm{d}\lambda_6/\mathrm{d}\Lambda_0 = v_6$, integrated in $\ln\Lambda_0$.
(2) The bound on v_6, with c a pure number.
(3) $\int_{\Lambda_0}^{\infty} x^{-3}\mathrm{d}x = 1/(2\Lambda_0^2)$.

so the limit $\lambda_6(\Lambda_R;\infty)$ exists and is approached like Λ_R^2/Λ_0^2.

The LPA flow provides a concrete toy of exactly this kind. Stay in $d = 4$ and look at the sextic coupling w of (T5.29), irrelevant with eigenvalue -2 (with α_d absorbed, and in the infrared time t):

$$\partial_t w = -2w - 20u^2 + R_w, \qquad \partial_t u = -8ru + w =: \beta_u, \tag{T5.38}$$

where $R_w = -12rw + w_8$ collects terms of higher order in the small couplings. Instead of the vertical distance to a neighbouring trajectory, we measure w relative to the value it would have if it had relaxed completely.

Worked example T5.9: A concrete toy: the bare value of w is forgotten

Define the deviation $\delta := w + 10u^2$. Then

$$\partial_t \delta \overset{(1)}{=} \partial_t w + 20u\,\partial_t u \overset{(2)}{=} -2w - 20u^2 + R_w + 20u\beta_u \overset{(3)}{=} -2\delta + \underbrace{R_w + 20u\beta_u}_{=:R}.$$

(1) Chain rule.
(2) (T5.38).
(3) $-2w - 20u^2 = -2(w + 10u^2) = -2\delta$.

This linear equation is solved by an integrating factor:

$$\delta(t) \overset{(1)}{=} e^{-2t}\delta(0) + \int_0^t \mathrm{d}s\; e^{-2(t-s)} R(s),$$

$$|\delta(t)| \overset{(2)}{\le} e^{-2t}|\delta(0)| + \max_{s\le t}|R(s)| \int_0^t \mathrm{d}s\; e^{-2(t-s)} \overset{(3)}{\le} \Big(\frac{\Lambda}{\Lambda_0}\Big)^2 |\delta(0)| + \tfrac{1}{2}\max|R|.$$

(1) $\partial_t(e^{2t}\delta) = e^{2t}R$; integrate from 0 to t.

(2) Triangle inequality, and bound $|R|$ by its maximum.
(3) $e^{-2t} = (\Lambda/\Lambda_0)^2$ by the definition of t, and $\int_0^t e^{-2(t-s)}\mathrm{d}s = \frac{1}{2}(1-e^{-2t}) \le \frac{1}{2}$.

Now R is cubic in the small couplings. Near the critical surface the mass is tied to u ($\partial_t r = 0$ in (T5.29) gives $r \approx -u/2$), so $r = O(u)$, $w = O(u^2)$ and $w_8 = O(u^3)$, and term by term

$$R \overset{(1)}{=} -12rw + w_8 + 20u(-8ru + w) \overset{(2)}{=} O(u\cdot u^2) + O(u^3) + O(u\cdot u\cdot u) + O(u\cdot u^2) = O(u^3).$$

(1) $R = R_w + 20u\beta_u$ with R_w and β_u from (T5.38).
(2) Insert the orders of magnitude of r, w, w_8.

Since $\delta = w + 10u^2$, the bound gives, at the low scale Λ_R,

$$w(\Lambda_R) = -10\,u(\Lambda_R)^2 + O(u^3) + O\Big(\frac{\Lambda_R^2}{\Lambda_0^2}\Big) \times (\text{bare data}).$$

The first two terms are fixed by the marginal coupling u at the low scale. All memory of the bare value $w(\Lambda_0)$ sits in the last term, which vanishes as $\Lambda_0 \to \infty$.

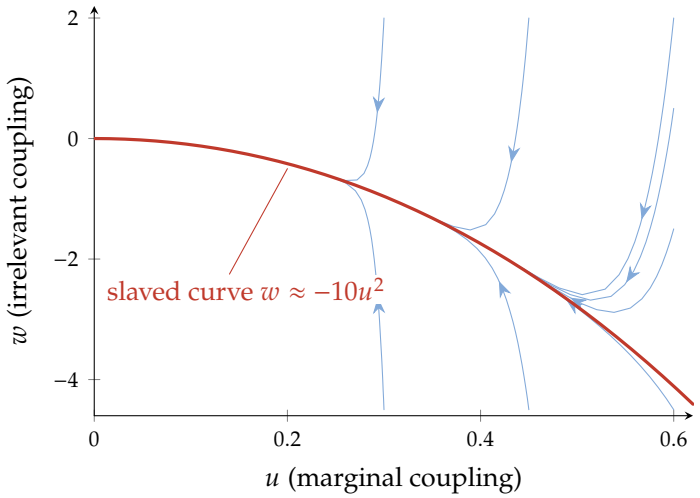

Figure T5.9: Slaving of an irrelevant coupling, computed for the model flow $\partial_t u = -u^2/5$, $\partial_t w = -2w - 20u^2$ (blue curves; arrows towards the infrared). Trajectories start (top and bottom edges) at a few values of the marginal coupling u and with very different irrelevant couplings w; within a few units of RG time they all land on the red curve $w = -10u^2 - 2u^3 - 0.6u^4$ (the attracting solution, computed as a power series), and then move slowly along it. What to see: at low energies the irrelevant coupling is a function of the marginal one. The theory space is squeezed onto a surface whose dimension is the number of relevant and marginal couplings.

T5.2.7 The exact equation in components, and the bound

For $\lambda\varphi^4$ theory in four dimensions the same logic has to control infinitely many couplings with full momentum dependence. The signs are tidier for the **effective interaction** $L(\varphi,\Lambda) := -S^{\mathrm{I}}_{\Lambda}$ [the interaction as it appears in the exponent of e^{+L}], and we use it in this subsection. The bare interaction at Λ_0 is

$$L_{\mathrm{int}} = \int \mathrm{d}^4x \Big(-\tfrac{1}{2}\rho_1^0\varphi^2 - \tfrac{1}{2}\rho_2^0(\partial_\mu\varphi)^2 - \tfrac{1}{4!}\rho_3^0\varphi^4\Big),$$

with the bare mass counterterm $\rho_1^0 = \delta m^2$, the wave-function counterterm $\rho_2^0 = Z - 1$ and the bare quartic coupling $\rho_3^0 = \lambda^0$. The propagator is the massive one, $K(p^2/\Lambda^2)/(p^2 + m^2)$, so the shell propagator is $\Delta_\Lambda = \Lambda\partial_\Lambda K/(p^2 + m^2)$. Put $S^{\mathrm{I}} = -L$ into (T5.19) and go to momentum space:

$$-\Lambda\frac{\partial L}{\partial\Lambda} \overset{(1)}{=} \frac{1}{2}\int_{x,y}\Delta_\Lambda(x-y)\Big[\frac{\delta L}{\delta\varphi(x)}\frac{\delta L}{\delta\varphi(y)} + \frac{\delta^2 L}{\delta\varphi(x)\,\delta\varphi(y)}\Big]$$
$$\overset{(2)}{=} \frac{1}{2}\int\frac{\mathrm{d}^4p}{(2\pi)^4}\,\Delta_\Lambda(p)\Big[\frac{\delta L}{\delta\varphi(-p)}\frac{\delta L}{\delta\varphi(p)} + \frac{\delta^2 L}{\delta\varphi(p)\,\delta\varphi(-p)}\Big].$$

(1) The product of two first derivatives does not change sign under $S^{\mathrm{I}} \to -L$; the left side and the second derivative do.

(2) Insert $\Delta(x-y) = \int_p e^{ip\cdot(x-y)}\Delta(p)$ and $\frac{\delta}{\delta\varphi(x)} = \int_p e^{-ip\cdot x}\frac{\delta}{\delta\varphi(p)}$. This is normalised so that $\delta\varphi(q)/\delta\varphi(p) = (2\pi)^4\delta^4(p-q)$. The x and y integrals give delta functions that set the two momenta to p and $-p$.

Multiplying by -1:

$$\Lambda\frac{\partial L}{\partial\Lambda} = -\frac{1}{2}\int\frac{\mathrm{d}^4p}{(2\pi)^4}\,\Delta_\Lambda(p)\Big[\frac{\delta L}{\delta\varphi(-p)}\frac{\delta L}{\delta\varphi(p)} + \frac{\delta^2 L}{\delta\varphi(p)\,\delta\varphi(-p)}\Big] \tag{T5.39}$$

Its two terms are the tree and loop diagrams of Figure T5.7.

Vertices and relevant coordinates. Expand the effective interaction in vertex functions,

$$L(\varphi,\Lambda) = \sum_{m\geq 1}\frac{1}{(2m)!}\int\prod_{i=1}^{2m}\frac{\mathrm{d}^4p_i}{(2\pi)^4}\,(2\pi)^4\delta^4\Big(\sum_i p_i\Big)\,L_{2m}(p_1,\dots,p_{2m};\Lambda)\,\varphi(p_1)\cdots\varphi(p_{2m}), \tag{T5.40}$$

with each L_{2m} symmetric in its momenta (only even m-point functions, since we keep $\varphi \to -\varphi$). The three **relevant parameters** are

$$\rho_1(\Lambda) = -L_2(0,0;\Lambda), \qquad \rho_2(\Lambda) = -\frac{1}{8}\,\frac{\partial^2}{\partial p_1^\mu\partial p_1^\mu}L_2(p_1,-p_1;\Lambda)\Big|_{p_1=0}, \qquad \rho_3(\Lambda) = -L_4(0,0,0,0;\Lambda). \tag{T5.41}$$

To see where the $\frac{1}{8}$ comes from, read off L_2 for the bare interaction:

$$-\tfrac{1}{2}\int\mathrm{d}^4x\,(\rho_1^0\varphi^2 + \rho_2^0(\partial_\mu\varphi)^2) \overset{(1)}{=} -\tfrac{1}{2}\int\frac{\mathrm{d}^4p}{(2\pi)^4}(\rho_1^0 + \rho_2^0p^2)\varphi(p)\varphi(-p),$$
$$\Longrightarrow \quad L_2(p,-p) \overset{(2)}{=} -\rho_1^0 - \rho_2^0p^2.$$

(1) Fourier transform: $\int\mathrm{d}^4x\,\varphi^2 = \int_p\varphi(p)\varphi(-p)$, and each ∂_μ becomes ip_μ, so $(\partial\varphi)^2 \to (ip)\cdot(-ip) = p^2$.

(2) Compare with the $m = 1$ term of (T5.40),

$$\frac{1}{2!}\int_{p_1,p_2}(2\pi)^4\delta^4(p_1+p_2)\,L_2\,\varphi(p_1)\varphi(p_2) = \tfrac{1}{2}\int_p L_2(p,-p)\,\varphi(p)\varphi(-p).$$

The four-dimensional Laplacian of p^2 is $\partial_\mu\partial_\mu(p_\nu p_\nu) = 2\delta_{\mu\mu} = 8$, so the $\frac{1}{8}$ in ρ_2 returns ρ_2^0. These are the mass, the wave-function normalisation and the quartic coupling, read off at zero momentum: the coordinates on the three-dimensional surface of Figure T5.5. Every other piece of L (the L_{2m} with $m \geq 3$, and the momentum dependence of L_2 and L_4 beyond these three numbers) is irrelevant.

Worked example T5.10: The component equation

Insert (T5.40) into (T5.39) and read off the coefficient of $\varphi(p_1)\cdots\varphi(p_{2m})/(2m)!$. We use $\delta\varphi(q)/\delta\varphi(p) = (2\pi)^4\delta^4(p-q)$, so a derivative removes one field and its momentum integral.

- *Loop term.* $\delta^2/\delta\varphi(p)\delta\varphi(-p)$ acting on the $(2m+2)$-point term removes two fields in $(2m+2)(2m+1)$ ways, which cancels $(2m+2)!$ down to $(2m)!$. It leaves $-\frac{1}{2}\int_p \Delta_\Lambda(p)\, L_{2m+2}(p_1,\dots,p_{2m},p,-p)$.
- *Tree term.* $\delta L/\delta\varphi(p)$ from the $2l$-point term is $\frac{1}{(2l-1)!}\int L_{2l}(q_1,\dots,q_{2l-1},p)\varphi^{2l-1}$. The product of the $2l$ and the $2l'$ terms has $2l-1+2l'-1$ fields, which is $2m$ for $l' = m+1-l$, with $l = 1,\dots,m$. Symmetrising over which $2l-1$ of the $2m$ external legs sit on the first vertex gives $\frac{(2m)!}{(2l-1)!(2m+1-2l)!} = \binom{2m}{2l-1}$ distinct terms, and the factorials cancel against $1/(2m)!$. The shell line carries the momentum P equal to the sum of the momenta on the first vertex, by momentum conservation at that vertex. Both terms carry the prefactor $-\frac{1}{2}$ of (T5.39).

Now measure everything in units of Λ. The vertex L_{2m} has mass dimension $4-2m$: the term (T5.40) is dimensionless, $\varphi(p)$ has dimension $[\varphi(x)] - 4 = 1-4 = -3$, each d^4p has dimension 4 and δ^4 has -4, so

$$0 \overset{(1)}{=} 2m\cdot 4 - 4 + [L_{2m}] + 2m\cdot(-3) \quad\Longrightarrow\quad [L_{2m}] = 4-2m.$$

(1) Add the dimensions of the $2m$ measures, the delta function, the vertex and the $2m$ fields.

So define the dimensionless vertices $A_{2m} := \Lambda^{2m-4}L_{2m}$ and the dimensionless shell factor $Q(p,\Lambda,m^2) := \Lambda^2\Delta_\Lambda(p)$ (recall $[\Delta] = -2$). By the product rule $\Lambda\partial_\Lambda A_{2m} = (2m-4)A_{2m} + \Lambda^{2m-4}\Lambda\partial_\Lambda L_{2m}$, so the left side below is $\Lambda^{2m-4}\Lambda\partial_\Lambda L_{2m}$:

$$\Big(\Lambda\frac{\partial}{\partial\Lambda} + 4 - 2m\Big)A_{2m}(p_1,\dots,p_{2m}) \overset{(1)}{=} -\frac{1}{2}\sum_{l=1}^{m}\sum_{\binom{2m}{2l-1}\text{ splits}} Q(P)\,A_{2l}(\dots,P)\,A_{2m+2-2l}(\dots,-P) - \frac{1}{2}\int\frac{\mathrm{d}^4p}{(2\pi\Lambda)^4}\,A_{2m+2}(p_1,\dots,p_{2m},p,-p)\,Q(p). \tag{T5.42}$$

(1) The two bullets, multiplied by Λ^{2m-4}. The powers of Λ work out: in the tree term $\Delta L_{2l}L_{2m+2-2l} = (Q/\Lambda^2)\Lambda^{4-2l}\Lambda^{2-2m+2l}AA = Q\Lambda^{4-2m}AA$; in the loop term $\Delta L_{2m+2} = (Q/\Lambda^2)\Lambda^{2-2m}A$, and $\Lambda^{2m-4}\cdot\Lambda^{-2m}\int\mathrm{d}^4p/(2\pi)^4 = \int\mathrm{d}^4p/(2\pi\Lambda)^4$.

This is the component form of the exact RG equation (Polchinski 1984, eq. (34)).

The left side of (T5.42) is pure dimensional analysis: with the right side switched off, $A_{2m}\propto\Lambda^{2m-4}$, so the $2m$-point vertices with $m\geq 3$ die like $(\Lambda/\Lambda_0)^{2m-4}$ as Λ decreases. The right side is where the interactions feed one vertex into another.

The bound. Choose K to be exactly 1 for $p^2\leq\Lambda^2$ and exactly 0 for $p^2\geq 4\Lambda^2$, smooth in between. With $x = p^2/\Lambda^2$, $\Lambda\partial_\Lambda K(x) = -2xK'(x)$ (as in (T5.8)), which is non-zero only on the shell $1<x<4$. Let $k_1 := \max_{1\leq x\leq 4}|2xK'(x)|$, a pure number fixed by the choice of K, and assume $|m^2|\leq\frac{1}{2}\Lambda_R^2$, with $\Lambda\geq\Lambda_R$ throughout. Two elementary estimates follow. On the shell,

$$|Q(p,\Lambda,m^2)| \overset{(1)}{=} \frac{\Lambda^2\,|\Lambda\partial_\Lambda K|}{p^2+m^2} \overset{(2)}{\leq} \frac{\Lambda^2\,k_1}{\Lambda^2-\frac{1}{2}\Lambda^2} \overset{(3)}{=} 2k_1 =: D_0,$$

$$\int \frac{\mathrm{d}^4p}{(2\pi\Lambda)^4}\,|Q| \overset{(4)}{\le} D_0\,\frac{\mathrm{vol}\{\Lambda^2<p^2<4\Lambda^2\}}{(2\pi\Lambda)^4} \overset{(5)}{=} D_0\,\frac{\frac{\pi^2}{2}(16-1)\Lambda^4}{16\pi^4\Lambda^4} = \frac{15}{32\pi^2}\,D_0 =: C.$$

(1) Definition $Q=\Lambda^2\Delta_\Lambda$ with $\Delta_\Lambda=\Lambda\partial_\Lambda K/(p^2+m^2)$.
(2) On the shell $p^2>\Lambda^2$ and $|m^2|\le\frac12\Lambda_R^2\le\frac12\Lambda^2$, so $p^2+m^2\ge\frac12\Lambda^2$; and $|\Lambda\partial_\Lambda K|\le k_1$.
(3) Arithmetic.
(4) Q vanishes off the shell, and $|Q|\le D_0$ on it.
(5) The volume of a ball of radius R in four dimensions is $\frac{\pi^2}{2}R^4$; subtract the ball of radius Λ from the ball of radius 2Λ.

Write $\|f\|:=\max_{p_i^2<4\Lambda^2}|f(p_1,\dots)|$, the largest value on the momenta that are still present. Taking absolute values in (T5.42) and replacing every factor by its maximum,

$$\Big\|\Big(\Lambda\frac{\partial}{\partial\Lambda}+4-2m\Big)A_{2m}\Big\| \;\le\; \sum_{l=1}^{m}\frac12\binom{2m}{2l-1}D_0\,\|A_{2l}\|\,\|A_{2m+2-2l}\|+\frac12 C\,\|A_{2m+2}\|. \tag{T5.43}$$

(Each tree term is bounded by $\frac12 D_0\|A_{2l}\|\|A_{2m+2-2l}\|$ and there are $\binom{2m}{2l-1}$ of them; the loop term is bounded by $\|A_{2m+2}\|$ times the integral of $|Q|$.) This bound is the heart of the proof: because every momentum integral runs over a bounded range, the momentum dependence can be estimated naively, and the infinite system becomes as simple as the toy flow.

Integrating the bound. For an irrelevant vertex ($m\ge3$), write the right side of (T5.42) as $R_{2m}(\Lambda)$ and solve the linear equation by an integrating factor, from the bare scale down:

$$\begin{aligned}
&\Lambda\frac{\partial}{\partial\Lambda}\big(\Lambda^{4-2m}A_{2m}\big)=\Lambda^{4-2m}R_{2m} \quad\Longrightarrow\\
&A_{2m}(\Lambda)\overset{(1)}{=}\Big(\frac{\Lambda}{\Lambda_0}\Big)^{2m-4}A_{2m}(\Lambda_0)-\int_\Lambda^{\Lambda_0}\frac{\mathrm{d}\Lambda'}{\Lambda'}\Big(\frac{\Lambda}{\Lambda'}\Big)^{2m-4}R_{2m}(\Lambda'),\\
&\|A_{2m}(\Lambda)\|\overset{(2)}{\le}\max_{\Lambda\le\Lambda'\le\Lambda_0}\|R_{2m}(\Lambda')\|\int_\Lambda^{\Lambda_0}\frac{\mathrm{d}\Lambda'}{\Lambda'}\Big(\frac{\Lambda}{\Lambda'}\Big)^{2m-4}\\
&\qquad\overset{(3)}{\le}\frac{\max\|R_{2m}\|}{2m-4}.
\end{aligned} \tag{T5.44}$$

(1) The first equation holds because $\Lambda\partial_\Lambda\Lambda^{4-2m}=(4-2m)\Lambda^{4-2m}$. Integrate it in $\ln\Lambda'$ from Λ to Λ_0: $\Lambda_0^{4-2m}A_{2m}(\Lambda_0)-\Lambda^{4-2m}A_{2m}(\Lambda)=\int_\Lambda^{\Lambda_0}\frac{\mathrm{d}\Lambda'}{\Lambda'}\Lambda'^{4-2m}R_{2m}(\Lambda')$, then solve for $A_{2m}(\Lambda)$ by multiplying by Λ^{2m-4}.
(2) The bare vertices with $m\ge3$ vanish, $A_{2m}(\Lambda_0)=0$, since L_{int} has only φ^2, $(\partial\varphi)^2$ and φ^4.
(3) $\int_\Lambda^{\Lambda_0}(\Lambda/\Lambda')^{2m-4}\mathrm{d}\Lambda'/\Lambda'=\frac{1-(\Lambda/\Lambda_0)^{2m-4}}{2m-4}\le\frac{1}{2m-4}$.

So an irrelevant vertex is bounded by its sources, uniformly in Λ_0. The relevant parts ($m=1$ and $m=2$ at zero momentum) must *not* be integrated down from Λ_0. For $m=1$ the first term of (T5.44) is $(\Lambda/\Lambda_0)^{-2}A_2(\Lambda_0)=(\Lambda_0/\Lambda)^2A_2(\Lambda_0)$: a mass integrated down grows like $(\Lambda_0/\Lambda)^2$, and for $m=2$ the factor $(\Lambda/\Lambda_0)^0=1$ gives no suppression either. Instead the relevant parts are fixed at the low scale by **renormalisation conditions** [the measured mass, normalisation and coupling at the scale Λ_R],

$$\rho_1(\Lambda_R)=0,\qquad \rho_2(\Lambda_R)=0,\qquad \rho_3(\Lambda_R)=\lambda^R, \tag{T5.45}$$

and integrates *up* from Λ_R. The fact that the mass must be fixed at the bottom, by a finely tuned bare ρ_1^0, is the naturalness problem of light scalars.

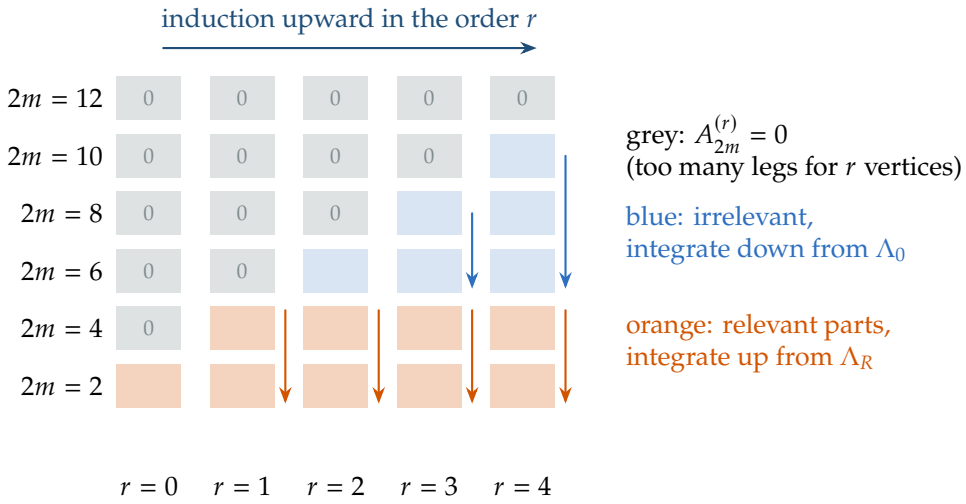

Figure T5.10: The order in which Polchinski's bounds are proved. Each cell is one vertex A_{2m} at order r in the renormalised coupling λ^R. At order r a tree of r vertices has at most $2r+2$ legs, so the grey cells vanish. Within a column the proof goes down in m (arrows), because the bound (T5.43) on A_{2m} only needs A_{2m+2} at the same order and products of lower orders. The two lowest rows hold the relevant parameters; they come last in each column, and they are anchored at Λ_R and integrated upwards in Λ (orange) instead of down from Λ_0. What to see: at every step only quantities already bounded appear on the right side.

Key idea: Polchinski's theorem (1984)

Fix $\rho_a(\Lambda_R)$ by (T5.45) and let $\tilde{L}(\varphi, \Lambda_R, \lambda^R, \Lambda_0)$ be the effective interaction at Λ_R. Then, order by order in λ^R, the limit $\Lambda_0 \to \infty$ of $\tilde{L}$ exists, and at order r (Polchinski 1984, eq. (47))

$$\big\|\tilde{L}^{(r)}_{2m}(\Lambda_R, \Lambda_0) - \tilde{L}^{(r)}_{2m}(\Lambda_R, \infty)\big\| \le \Lambda_R^{4-2m}\Big(\frac{\Lambda_R}{\Lambda_0}\Big)^2 P\big(\ln(\Lambda_0/\Lambda_R)\big),$$

with P a polynomial with pure-number coefficients (and zero if $m > r+1$). The correlation functions at momenta below Λ_R therefore depend on the cutoff only through inverse powers: $\lambda\varphi^4$ theory in four dimensions is perturbatively renormalisable.

The proof is the induction of Figure T5.10, run twice. Write $A^{(r)}_{2m}$ for the part of A_{2m} of order r in λ^R, and $\ell := \ln(\Lambda_0/\Lambda_R)$.

Step 1: the vertices are bounded by polynomials in ℓ. At order r a tree of r quartic vertices has at most $2r+2$ external legs, so $A^{(r)}_{2m} = 0$ for $m > r+1$. Assume the bound for all orders below r, and at order r for all $m' > m$. On the right side of (T5.43) for $A^{(r)}_{2m}$ the tree terms are products $A^{(r_1)}A^{(r_2)}$ with $r_1 + r_2 = r$ and $r_1, r_2 \ge 1$ (lower orders), and the loop term is $A^{(r)}_{2m+2}$ (same order, more legs). All are already bounded, so $\|R^{(r)}_{2m}\| \le P(\ell)$ for some polynomial P. Now integrate:

- $m \ge 3$ (irrelevant): (T5.44) gives $\|A^{(r)}_{2m}\| \le \max \|R^{(r)}_{2m}\|/(2m-4)$.
- $m = 2$ at zero momentum (ρ_3, marginal): integrate $\Lambda\partial_\Lambda A_4 = R_4$ *up* from Λ_R, where $A_4 = -\lambda^R$: $|A_4(\Lambda)| \le \lambda^R + \max|R_4|\,\ln(\Lambda/\Lambda_R)$. This is where the powers of ℓ come from.
- $m = 1$ at zero momentum (ρ_1, relevant): integrate $\Lambda\partial_\Lambda(\Lambda^2 A_2) = \Lambda^2 R_2$ up from Λ_R, where $A_2 = 0$: $|A_2(\Lambda)| \le \Lambda^{-2}\int_{\Lambda_R}^{\Lambda} \frac{\mathrm{d}\Lambda'}{\Lambda'}\Lambda'^2 \max|R_2| \le \frac{1}{2}\max|R_2|$.

(The momentum dependence of A_2 and A_4, and ρ_2, are handled in the same way, by Taylor

expanding in the external momenta.) So every $\|A^{(r)}_{2m}\|$ is bounded by a polynomial in ℓ, uniformly in Λ_0.

Step 2: the cutoff dependence is $(\Lambda_R/\Lambda_0)^2$. Define the analogue of (T5.37),

$$V(\Lambda) = \Lambda_0 \frac{\partial L}{\partial \Lambda_0} - \sum_{a,b} \frac{\partial L}{\partial \rho^0_a} \frac{\partial \rho^0_a}{\partial \rho_b(\Lambda)} \Lambda_0 \frac{\partial \rho_b(\Lambda)}{\partial \Lambda_0},$$

the change of the effective interaction when Λ_0 moves with the three relevant parameters held fixed. By construction V has no relevant component. Differentiating (T5.39) with respect to Λ_0 gives an equation *linear* in V: its left side is the operator $\Lambda\partial_\Lambda + 4 - 2m$ of (T5.42) acting on V_{2m}, and its right side has one factor V in each term (the other factor is an A, already bounded in step 1). The dimensionless V_{2m} start at Λ_0 with values of order one (times powers of ℓ). Running the same induction, the integrating factor $(\Lambda/\Lambda_0)^{2m-4} \le (\Lambda/\Lambda_0)^2$ for $m \ge 3$ makes every component of V at Λ_R at most $\Lambda_R^{4-2m}(\Lambda_R/\Lambda_0)^2 P(\ell)$ in dimensionful units (Polchinski 1984 carries out this estimate in detail). Finally integrate $\Lambda_0\,\partial\tilde{L}/\partial\Lambda_0 = V$ over the cutoff. For a term ℓ^k of P,

$$\int_{\Lambda_0}^{\infty} \frac{\mathrm{d}\Lambda_0'}{\Lambda_0'} \Big(\frac{\Lambda_R}{\Lambda_0'}\Big)^2 \Big(\ln\frac{\Lambda_0'}{\Lambda_R}\Big)^k \overset{(1)}{=} \Big(\frac{\Lambda_R}{\Lambda_0}\Big)^2 \int_0^{\infty} \mathrm{d}s\; e^{-2s}(s+\ell)^k \overset{(2)}{=} \Big(\frac{\Lambda_R}{\Lambda_0}\Big)^2 \sum_{j=0}^{k} \binom{k}{j} \frac{j!}{2^{j+1}}\, \ell^{k-j}.$$

(1) Substitute $s = \ln(\Lambda_0'/\Lambda_0)$, so $\Lambda_0' = \Lambda_0 e^s$ and $\ln(\Lambda_0'/\Lambda_R) = s + \ell$.

(2) Binomial expansion and $\int_0^\infty s^j e^{-2s}\mathrm{d}s = j!/2^{j+1}$.

The result is again $(\Lambda_R/\Lambda_0)^2$ times a polynomial in ℓ, which is the bound of the theorem. The proof never mentions divergent integrals, counterterms or overlapping subdivergences; it is a statement about the attraction of a three-dimensional surface in theory space.

Two remarks complete the picture. First, the relevant coupling behaves the opposite way. By (T5.29) the dimensionless mass has eigenvalue 2: near the critical surface, at the critical value r_c of the bare mass, the linearised flow is $\partial_t(r - r_c) = 2(r - r_c)$. Then

$$r(t_R) - r_c \overset{(1)}{=} \big(r(0) - r_c\big) e^{2t_R} \overset{(2)}{=} \big(r(0) - r_c\big) \frac{\Lambda_0^2}{\Lambda_R^2} \quad\Longrightarrow\quad r(0) \overset{(3)}{=} r_c + \big(r(t_R) - r_c\big) \frac{\Lambda_R^2}{\Lambda_0^2}.$$

(1) Solve the linear equation from $t = 0$ (the scale Λ_0) to $t_R = \ln(\Lambda_0/\Lambda_R)$.

(2) $e^{t_R} = \Lambda_0/\Lambda_R$.

(3) Solve for the bare value.

A finite mass at Λ_R, $r(t_R) - r_c = O(1)$, needs a bare value tuned to the critical surface with ever greater precision, $r(\Lambda_0) = r_c + O(\Lambda_R^2/\Lambda_0^2)$. This is the fine-tuning (or hierarchy) problem of scalar masses ([QFT notes §15.9.4]). Second, a theory with an irrelevant coupling of its own (Fermi theory, gravity) is not thereby useless: at energies $E \ll \Lambda_0$ it is an **effective field theory**, predictive order by order in E/Λ_0 ([QFT notes §15.9.5]).

Recap

- A smooth cutoff $C_\Lambda = K(p^2/\Lambda^2)/p^2$; its derivative $\Delta_\Lambda = \Lambda\partial_\Lambda C_\Lambda \ge 0$ is the propagator of a thin shell.
- Covariances of independent Gaussians add, and Gaussian smearing is the heat operator $e^{\frac{1}{2}\partial\cdot D\cdot\partial}$.
- Together they give the exact Polchinski equation $\partial_t e^{-S^{\mathrm{I}}} = \frac{1}{2}\frac{\delta}{\delta\varphi}\cdot\Delta\cdot\frac{\delta}{\delta\varphi}e^{-S^{\mathrm{I}}}$: a tree term

joining vertices and a loop term closing legs.

- Its solution is the sum of Feynman diagrams with internal lines $C_{\Lambda_0} - C_\Lambda$; a mass insertion is resummed exactly.
- The LPA gives $\partial_t v = dv - \frac{d-2}{2}\hat{\varphi}v' - v'^2 + v''$; in $d = 4 - \varepsilon$ it has a Wilson–Fisher fixed point with eigenvalues $2 - \varepsilon/3$ and $-\varepsilon$.
- Polchinski's toy flow: neighbouring trajectories converge like $(\Lambda/\Lambda_0)^2$, so irrelevant couplings become functions of the relevant ones.
- For $\lambda\varphi^4$ the dimensionless vertices obey $(\Lambda\partial_\Lambda + 4 - 2m)A_{2m} = (\text{tree}) + (\text{loop})$, bounded as in (T5.43); induction in the order and in m gives cutoff dependence $(\Lambda_R/\Lambda_0)^2$: renormalisability.

T5.3 Fixed points, linearisation and critical exponents

A fixed point is a theory without a scale. Near it the flow is almost linear, and a linear flow is characterised by the eigenvalues of a matrix. Those eigenvalues are the critical exponents, and they are also the scaling dimensions of the operators of the fixed-point theory. How do we compute them? The most important example in statistical physics shows the whole procedure: the Wilson–Fisher fixed point of φ^4 theory in $d = 4 - \varepsilon$ dimensions, which describes the Ising universality class (magnets with one preferred axis, the liquid–gas critical point, binary alloys).

T5.3.1 The linearised flow and scaling fields

Let g^* be a fixed point of (T5.5), $\beta_i(g^*) = 0$, and write $g_i = g_i^* + \delta g_i$. Taylor expanding the β-functions to first order,

$$\frac{\mathrm{d}\,\delta g_i}{\mathrm{d}t} \overset{(1)}{=} \beta_i(g^* + \delta g) \overset{(2)}{=} \sum_j M_{ij}\,\delta g_j + O(\delta g^2), \qquad M_{ij} := \left.\frac{\partial \beta_i}{\partial g_j}\right|_{g^*}. \tag{T5.46}$$

(1) g^* is constant, so $\mathrm{d}g/\mathrm{d}t = \mathrm{d}\,\delta g/\mathrm{d}t$.
(2) First-order Taylor expansion; $\beta_i(g^*) = 0$.

Suppose the **stability matrix** M has a basis of eigenvectors, $Me_a = y_a e_a$ (this is the generic case; the eigenvalues are real in every unitary example we meet). Expand $\delta g = \sum_a u_a\, e_a$. Then

$$\sum_a \frac{\mathrm{d}u_a}{\mathrm{d}t} e_a \overset{(1)}{=} M \sum_a u_a e_a \overset{(2)}{=} \sum_a y_a u_a e_a \quad\Longrightarrow\quad u_a(t) = u_a(0)\, e^{y_a t} = u_a(0)\left(\frac{\Lambda_0}{\Lambda}\right)^{y_a}. \tag{T5.47}$$

(1) Insert the expansion into (T5.46).
(2) $Me_a = y_a e_a$; then compare coefficients of the independent e_a.

Working definition T5.6 (scaling fields and RG eigenvalues)

Near a fixed point, replace the couplings g_i [the numbers we write in a Lagrangian] by the **scaling fields** u_a [the components of δg along the eigenvectors e_a of the stability matrix M]. In these coordinates the flow is diagonal: each u_a is multiplied by e^{y_a} per unit of RG time, and the y_a are the **RG eigenvalues** [the eigenvalues of M]. Picture the fixed point as a saddle in a landscape: downhill directions ($y_a > 0$, relevant, the flow runs away), uphill directions ($y_a < 0$, irrelevant, the flow comes in) and possibly flat ones ($y_a = 0$, marginal).

Operational recipe: compute β_i, find g^*, differentiate to get M, diagonalise.

Each scaling field multiplies a definite operator. If the Wilsonian action near the fixed point is $S = S^* + \sum_a u_a \int \mathrm{d}^d x\, \mathcal{O}_a(x)$, the operator $\mathcal{O}_a$ has a definite scaling dimension Δ_a at the fixed point: measured in the rescaled units $x' = x/b$ it becomes $\mathcal{O}_a(x) = b^{-\Delta_a}\mathcal{O}'_a(x')$, with $\mathcal{O}'_a$ normalised in the new units exactly as $\mathcal{O}_a$ was in the old. Follow one RG step with factor b, which is RG time $\ln b$:

$$u_a \int \mathrm{d}^d x\, \mathcal{O}_a(x) \overset{(1)}{=} u_a \int b^d\, \mathrm{d}^d x'\; b^{-\Delta_a}\mathcal{O}'_a(x') \overset{(2)}{=} \left(b^{d-\Delta_a} u_a\right) \int \mathrm{d}^d x'\, \mathcal{O}'_a(x'),$$
$$u'_a \overset{(3)}{=} b^{y_a} u_a \quad \Longrightarrow \quad y_a = d - \Delta_a. \tag{T5.48}$$

(1) Substitute $x = bx'$, so $\mathrm{d}^d x = b^d \mathrm{d}^d x'$, and the scaling of the operator.
(2) Collect the powers of b: in the new units the coupling of $\mathcal{O}'_a$ is $u'_a = b^{d-\Delta_a} u_a$.
(3) (T5.47) with $t = \ln b$: $e^{y_a \ln b} = b^{y_a}$. Comparing the two expressions for u'_a gives the result.

The *spectrum of the linearised RG* and the *spectrum of scaling dimensions of the fixed-point theory* are the same list of numbers.

The correlation length follows from (T5.1). Let there be one relevant scaling field u_t (the temperature) with eigenvalue y_t. After RG time t, lengths in the new units are e^t times shorter, so

$$\xi\big(u_t(0)\big) \overset{(1)}{=} e^t\, \xi\big(u_t(0) e^{y_t t}\big) \overset{(2)}{=} u_t(0)^{-1/y_t}\, \xi(1),$$

(1) (T5.1) with $b = e^t$ and (T5.47).
(2) Stop the flow when $u_t = 1$, that is at $e^t = u_t(0)^{-1/y_t}$; from there on the system is far from criticality and $\xi(1)$ is a number of order one.

So $\xi \propto u_t^{-1/y_t}$, and since $u_t \propto T - T_c$ close to the critical point, $\nu = 1/y_t$. (Chapter 11 applies the same argument to the two-dimensional Ising model.)

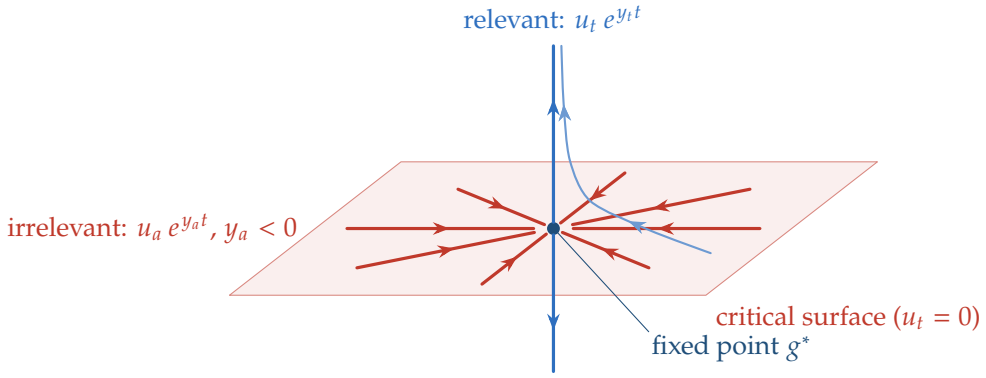

Figure T5.11: The linearised flow near a fixed point with one relevant and two irrelevant directions. Inside the critical surface (red plane) all flow lines converge on the fixed point, each component shrinking like $e^{y_a t}$. The relevant scaling field (blue axis) grows like $e^{y_t t}$. A theory starting slightly above the surface (thin blue curve) first slides in towards g^*, then leaves along the relevant axis. What to see: the number of relevant directions is the number of parameters one must tune to reach the critical point (one, the temperature, for the Ising class at zero field; two if the field is counted).

Worked example T5.11: The scaling operators of the Gaussian fixed point

Linearise the LPA (T5.28) (with $\alpha_d = 1$) about the Gaussian point $v = 0$. The quadratic term v'^2 drops, leaving the linear operator

$$\partial_t\, \delta v = \mathsf{L}\, \delta v, \qquad \mathsf{L} \coloneqq d - \tfrac{d-2}{2}\, \hat\varphi\, \frac{\mathrm{d}}{\mathrm{d}\hat\varphi} + \frac{\mathrm{d}^2}{\mathrm{d}\hat\varphi^2}.$$

On a monomial,

$$\mathsf{L}\, \hat\varphi^n \overset{(1)}{=} \Big(d - n\, \frac{d-2}{2}\Big)\hat\varphi^n + n(n-1)\hat\varphi^{n-2}. \tag{T5.49}$$

(1) $\hat\varphi\, \mathrm{d}\hat\varphi^n/\mathrm{d}\hat\varphi = n\hat\varphi^n$ (the degree counter of a monomial) and $\mathrm{d}^2\hat\varphi^n/\mathrm{d}\hat\varphi^2 = n(n-1)\hat\varphi^{n-2}$.

So L lowers the degree or keeps it: in the basis $1, \hat\varphi^2, \hat\varphi^4, \ldots$ it is an upper-triangular matrix, and its eigenvalues are the diagonal entries $y_n = d - n\frac{d-2}{2}$, the power-counting values of Example T5.4. The eigenfunctions are polynomials $\hat\varphi^n$ + (lower). For $n = 2$ try $\hat\varphi^2 + c$:

$$\mathsf{L}(\hat\varphi^2 + c) \overset{(1)}{=} 2\hat\varphi^2 + 2 + dc \overset{(2)}{=} 2(\hat\varphi^2 + c) \quad\Longleftrightarrow\quad c = -\frac{2}{d-2}.$$

(1) (T5.49) with $n = 2$ and $n = 0$.

(2) Demand the eigenvalue $y_2 = 2$ and solve $2 + dc = 2c$.

For $n = 4$ try $\hat\varphi^4 + a\hat\varphi^2 + b$, with eigenvalue $y_4 = d - 2(d-2) = 4 - d$:

$$\begin{aligned}\mathsf{L}(\hat\varphi^4 + a\hat\varphi^2 + b) &\overset{(1)}{=} (4-d)\hat\varphi^4 + 12\hat\varphi^2 + a\big(2\hat\varphi^2 + 2\big) + d\,b \\ &\overset{(2)}{=} (4-d)\hat\varphi^4 + (12 + 2a)\hat\varphi^2 + (2a + d\,b).\end{aligned}$$

(1) (T5.49) with $n = 4$ (diagonal entry $d - 2(d-2) = 4 - d$, lower term $4 \cdot 3\,\hat\varphi^2$), with $n = 2$ and with $n = 0$.

(2) Collect powers of $\hat\varphi$.

Demand that this equal $(4-d)(\hat\varphi^4 + a\hat\varphi^2 + b)$ and match the two lower powers:

$$\begin{aligned}\hat\varphi^2 &: \; 12 + 2a = (4-d)a \;\Longrightarrow\; a \overset{(1)}{=} \frac{12}{2-d}, \\ \hat\varphi^0 &: \; 2a + d\,b = (4-d)b \;\Longrightarrow\; b \overset{(2)}{=} \frac{2a}{4-2d} = \frac{a}{2-d} = \frac{12}{(2-d)^2}.\end{aligned}$$

(1) $a(4 - d - 2) = 12$.

(2) $b(4 - d - d) = 2a$, then insert a.

In $d = 4$: $c = -1$, $a = -6$, $b = 3$, and the two eigenfunctions are

$$\hat\varphi^2 - 1, \qquad \hat\varphi^4 - 6\hat\varphi^2 + 3,$$

the Hermite polynomials He_2 and He_4. Physically they are the normal-ordered operators $:\varphi^2:$ and $:\varphi^4:$: subtracting the self-contractions (the tadpoles of Example T5.5) is exactly what makes φ^n an eigenoperator of the RG. The "lower" terms are the mixing of φ^n with operators of lower dimension.

Worked example T5.12: A marginal coupling runs logarithmically

At $d = 4$ the quartic coupling has $y = 0$; its flow starts at second order, $\mathrm{d}u/\mathrm{d}t = -bu^2$ with

$b > 0$ (we find b in Example T5.13). Separate variables:

$$-\frac{\mathrm{d}u}{u^2} = b\,\mathrm{d}t \implies \frac{1}{u(t)} - \frac{1}{u(0)} \overset{(1)}{=} bt \implies u(t) \overset{(2)}{=} \frac{u(0)}{1 + b\,u(0)\ln(\Lambda_0/\Lambda)}.$$

(1) Integrate from 0 to t; $\int u^{-2}\mathrm{d}u = -u^{-1}$.
(2) Solve for $u(t)$ and use $t = \ln(\Lambda_0/\Lambda)$.

The coupling dies off towards the infrared, but only logarithmically: it is **marginally irrelevant**. Run backwards (towards the ultraviolet), it grows and blows up at $\ln(\Lambda_0/\Lambda) = -1/(bu(0))$, the Landau pole. QCD is the opposite case, **marginally relevant** ($b < 0$): weak at short distances and strong at long ones.

T5.3.2 From two eigenvalues to all six exponents

A magnet near its critical point has two relevant directions: the reduced temperature t (eigenvalue y_t, operator the energy density ε) and the magnetic field h (eigenvalue y_h, operator the spin σ). The **singular free energy density** $f(t,h)$ (the non-analytic part of $-\ln Z$ per unit volume) has dimension (length)$^{-d}$. One RG step with factor b leaves Z unchanged but shrinks the volume in new units by b^{-d}, and moves the couplings to $(b^{y_t}t, b^{y_h}h)$, so

$$f(t,h) = b^{-d}\,f\left(b^{y_t}t,\; b^{y_h}h\right). \tag{T5.50}$$

The standard thermodynamic quantities are derivatives of f: the specific heat $C \propto \partial^2 f/\partial t^2$, the magnetisation $M = -\partial f/\partial h$ and the susceptibility $\chi = \partial^2 f/\partial h^2$. Their exponents are defined by $C \sim |t|^{-\alpha}$, $M \sim (-t)^{\beta}$ at $h = 0$, $\chi \sim |t|^{-\gamma}$, and $M \sim h^{1/\delta}$ at $t = 0$. Choosing b cleverly gives each of them.

$$\begin{aligned}
f(t,0) &\overset{(1)}{=} |t|^{d/y_t} f(\pm 1, 0) && \implies C \propto |t|^{d/y_t - 2}, \quad \alpha = 2 - \frac{d}{y_t},\\
M(t) &\overset{(2)}{=} b^{y_h - d} M(b^{y_t}t, 0) = |t|^{(d-y_h)/y_t} M(-1,0) && \implies \beta = \frac{d - y_h}{y_t},\\
\chi(t) &\overset{(3)}{=} b^{2y_h - d}\chi(b^{y_t}t, 0) && \implies \gamma = \frac{2y_h - d}{y_t},\\
M(0,h) &\overset{(4)}{=} b^{y_h - d} M(0, b^{y_h}h) = h^{(d-y_h)/y_h} M(0,1) && \implies \delta = \frac{y_h}{d - y_h}.
\end{aligned}$$

(1) Put $h = 0$ and $b = |t|^{-1/y_t}$ in (T5.50), so that the rescaled temperature is ± 1 and $b^{-d} = |t|^{d/y_t}$; differentiate twice in t.
(2) Differentiate (T5.50) once in h (chain rule gives b^{y_h}), then choose $b = |t|^{-1/y_t}$ with $t < 0$.
(3) Differentiate twice in h (factor b^{2y_h}), same choice of b.
(4) Put $t = 0$ and choose $b = h^{-1/y_h}$.

Together with $\nu = 1/y_t$ and, from the power law of the spin correlation at T_c, $2\Delta_\sigma = d - 2 + \eta$ with $\Delta_\sigma = d - y_h$ by (T5.48):

Key idea: critical exponents from two scaling dimensions

With $\Delta_\varepsilon = d - y_t$ and $\Delta_\sigma = d - y_h$,

$$\nu = \frac{1}{d - \Delta_\varepsilon}, \qquad \eta = 2\Delta_\sigma + 2 - d, \qquad \alpha = 2 - \frac{d}{d - \Delta_\varepsilon},$$

$$\beta = \frac{\Delta_\sigma}{d-\Delta_\varepsilon}, \qquad \gamma = \frac{d-2\Delta_\sigma}{d-\Delta_\varepsilon}, \qquad \delta = \frac{d-\Delta_\sigma}{\Delta_\sigma}.$$

Six exponents from two numbers imply four **scaling relations**, for example $\alpha + 2\beta + \gamma = 2$ and $\gamma = \nu(2-\eta)$, which hold for every universality class. Chapter 11 uses this table with the exact two-dimensional values $\Delta_\sigma = \frac{1}{8}$, $\Delta_\varepsilon = 1$.

The four relations follow by inserting the table. Write $y_t = d - \Delta_\varepsilon$:

$$\alpha + 2\beta + \gamma \overset{(1)}{=} \frac{2y_t - d + 2\Delta_\sigma + d - 2\Delta_\sigma}{y_t} = 2, \qquad \nu(2-\eta) \overset{(2)}{=} \frac{2 - 2\Delta_\sigma - 2 + d}{y_t} = \gamma,$$

$$\beta(\delta - 1) \overset{(3)}{=} \frac{\Delta_\sigma}{y_t} \cdot \frac{d - 2\Delta_\sigma}{\Delta_\sigma} = \gamma, \qquad d\,\nu \overset{(4)}{=} \frac{d}{y_t} = 2 - \alpha.$$

(1) Put everything over the common denominator y_t: $\alpha = (2y_t - d)/y_t$.
(2) $\nu = 1/y_t$ and $2 - \eta = 2 - (2\Delta_\sigma + 2 - d) = d - 2\Delta_\sigma$.
(3) $\delta - 1 = (d - 2\Delta_\sigma)/\Delta_\sigma$ (Widom's relation).
(4) Hyperscaling (Josephson's relation), which involves d explicitly.

As a check, the Gaussian fixed point in $d = 4$ has $\Delta_\sigma = \Delta_\varphi = 1$ and $\Delta_\varepsilon = \Delta_{\varphi^2} = 2$, so $y_t = 2$, which gives the mean-field values $\nu = \frac{1}{2}$, $\eta = 2 + 2 - 4 = 0$, $\alpha = 2 - \frac{4}{2} = 0$, $\beta = \frac{1}{2}$, $\gamma = \frac{4-2}{2} = 1$, $\delta = \frac{4-1}{1} = 3$.

T5.3.3 The Wilson–Fisher fixed point at one loop

We now compute the flow of φ^4 theory perturbatively, in the way Wilson did it: integrate out a thin shell with a sharp cutoff, keeping all diagrams with one loop of shell modes. The action is

$$S = \int \mathrm{d}^d x \left[\tfrac{1}{2}(\partial\varphi)^2 + \tfrac{1}{2} m^2 \varphi^2 + \frac{\lambda}{4!}\varphi^4 \right], \qquad |p| < \Lambda. \tag{T5.51}$$

Split $\varphi = \varphi_< + \varphi_>$ with $\varphi_>$ in the shell $\Lambda e^{-\delta t} < |p| < \Lambda$. The shell modes are Gaussian with propagator $G_>(k) = 1/(k^2 + m^2)$ restricted to the shell (the mass is kept in the propagator; only the interaction is treated as a perturbation).

The shell integral. Every loop over a thin shell is the same kind of integral. Let S_{d-1} be the area of the unit sphere in $\mathbb{R}^d$. For any function f of $|k|$, use spherical coordinates, $\mathrm{d}^d k = k^{d-1}\mathrm{d}k\,\mathrm{d}\Omega$ with $\int \mathrm{d}\Omega = S_{d-1}$:

$$\int_{\text{shell}} \frac{\mathrm{d}^d k}{(2\pi)^d} f(|k|) \overset{(1)}{=} \frac{S_{d-1}}{(2\pi)^d} \int_{\Lambda e^{-\delta t}}^{\Lambda} \mathrm{d}k\; k^{d-1} f(k) \overset{(2)}{=} \frac{S_{d-1}}{(2\pi)^d}\, \Lambda^{d-1}\, (\Lambda\,\delta t)\, f(\Lambda)$$
$$= K_d\, \Lambda^d\, f(\Lambda)\, \delta t, \qquad K_d := \frac{S_{d-1}}{(2\pi)^d}. \tag{T5.52}$$

(1) The integrand does not depend on the direction, so the angular integral gives S_{d-1}.
(2) The shell is thin: the integrand is $\Lambda^{d-1} f(\Lambda)$ up to $O(\delta t)$, and its thickness is $\Lambda - \Lambda e^{-\delta t} = \Lambda\,\delta t + O(\delta t^2)$.

To find S_{d-1}, compute the Gaussian integral $\int \mathrm{d}^d k\, e^{-k^2}$ in two ways:

$$\pi^{d/2} \overset{(1)}{=} \int \mathrm{d}^d k\, e^{-k^2} \overset{(2)}{=} S_{d-1} \int_0^\infty \mathrm{d}k\, k^{d-1} e^{-k^2} \overset{(3)}{=} \tfrac{1}{2} S_{d-1}\, \Gamma(d/2),$$

$$\Longrightarrow \quad S_{d-1} = \frac{2\pi^{d/2}}{\Gamma(d/2)}, \qquad K_d \overset{(4)}{=} \frac{2}{(4\pi)^{d/2}\Gamma(d/2)}.$$

(1) Product of d one-dimensional integrals $\int \mathrm{d}k_i\, e^{-k_i^2} = \sqrt{\pi}$.
(2) Spherical coordinates.
(3) Substitute $s = k^2$, so $k^{d-1}\mathrm{d}k = \frac{1}{2}s^{d/2-1}\mathrm{d}s$, and use $\int_0^\infty s^{d/2-1}e^{-s}\mathrm{d}s = \Gamma(d/2)$.
(4) Divide S_{d-1} by $(2\pi)^d = 2^d\pi^d$, and $2^d\pi^{d/2} = (4\pi)^{d/2}$.

So $S_1 = 2\pi$, $S_2 = 4\pi$, $S_3 = 2\pi^2$ (with $\Gamma(1) = 1$, $\Gamma(\frac{3}{2}) = \frac{\sqrt{\pi}}{2}$, $\Gamma(2) = 1$), and in $d = 4$, $K_4 = 2\pi^2/(2\pi)^4 = 1/(8\pi^2)$.

The effective action to second order. Write $S = S_0[\varphi_<] + S_0[\varphi_>] + S_{\mathrm{int}}[\varphi_< + \varphi_>]$, where S_0 is the Gaussian part (it does not couple slow and fast modes, since they live at different momenta). Then

$$e^{-S_{\mathrm{eff}}[\varphi_<]} \overset{(1)}{=} e^{-S_0[\varphi_<]}\big\langle e^{-S_{\mathrm{int}}[\varphi_< + \varphi_>]}\big\rangle_>$$
$$S_{\mathrm{eff}} \overset{(2)}{=} S_0[\varphi_<] + \langle S_{\mathrm{int}}\rangle_> - \tfrac{1}{2}\Big(\langle S_{\mathrm{int}}^2\rangle_> - \langle S_{\mathrm{int}}\rangle_>^2\Big) + \cdots \tag{T5.53}$$

(1) Definition (T5.4), with the (normalised) Gaussian average $\langle\cdot\rangle_>$ over the shell modes.
(2) The **cumulant expansion**: expand $\ln\langle e^{-X}\rangle = \ln\big(1 - \langle X\rangle + \frac{1}{2}\langle X^2\rangle - \cdots\big) = -\langle X\rangle + \frac{1}{2}(\langle X^2\rangle - \langle X\rangle^2) + O(X^3)$ using $\ln(1+\epsilon) = \epsilon - \frac{1}{2}\epsilon^2 + \cdots$.

The variance $\langle S^2\rangle - \langle S\rangle^2$ keeps only the terms in which the two copies of S_{int} are connected by at least one shell propagator: the *connected* diagrams, as in (T5.23).

Worked example T5.13: One-loop shell integration of φ^4

Mass. In $\langle S_{\mathrm{int}}\rangle_>$ expand $(\varphi_< + \varphi_>)^4$ and keep the term with two slow and two fast fields (odd numbers of fast fields average to zero; the term with four fast fields is a constant):

$$\frac{\lambda}{4!}\int \mathrm{d}^dx \binom{4}{2}\varphi_<^2\langle\varphi_>^2\rangle \overset{(1)}{=} \frac{\lambda}{4}\int \mathrm{d}^dx\,\varphi_<^2 \int_{\mathrm{shell}} \frac{\mathrm{d}^dk}{(2\pi)^d}\,\frac{1}{k^2+m^2} \overset{(2)}{=} \frac{1}{2}\Big[\frac{\lambda}{2}\,\frac{K_d\Lambda^d}{\Lambda^2+m^2}\,\delta t\Big]\int \mathrm{d}^dx\,\varphi_<^2.$$

(1) $\binom{4}{2} = 6$ ways to choose the two fast fields; $\langle\varphi_>(x)^2\rangle$ is the shell propagator at coincident points, the integral of $G_>(k)$ over the shell.
(2) (T5.52); written as $\frac{1}{2}\,\delta m^2\int\varphi^2$.

So $\delta m^2 = \frac{\lambda}{2}K_d\Lambda^d\delta t/(\Lambda^2+m^2)$: the tadpole of Example T5.5. Integrating out adds positive mass.

Quartic coupling. In the variance, take from each copy of S_{int} the term with two slow and two fast fields, and contract the two fast fields of one vertex with the two of the other (a loop of two shell propagators). The number of ways is $\binom{4}{2}\cdot\binom{4}{2}\cdot 2 = 72$ (choose the fast pair at each vertex, then two ways to pair them across). So

$$-\tfrac{1}{2}\big(\langle S_{\mathrm{int}}^2\rangle - \langle S_{\mathrm{int}}\rangle^2\big) \overset{(1)}{=} -\frac{1}{2}\Big(\frac{\lambda}{4!}\Big)^2\cdot 72\int_{x,y}\varphi_<^2(x)\,G_>(x-y)^2\,\varphi_<^2(y)$$
$$\overset{(2)}{=} -\frac{\lambda^2}{16}\Big(\int_{\mathrm{shell}}\frac{\mathrm{d}^dk}{(2\pi)^d}\,\frac{1}{(k^2+m^2)^2}\Big)\int\mathrm{d}^dx\,\varphi_<^4 + \cdots$$
$$\overset{(3)}{=} \frac{1}{4!}\Big[-\frac{3\lambda^2}{2}\,\frac{K_d\Lambda^d}{(\Lambda^2+m^2)^2}\,\delta t\Big]\int\mathrm{d}^dx\,\varphi_<^4.$$

(1) Wick's theorem for the shell modes; each contraction of a fast field at x with one at y gives $G_>(x-y)$.
(2) $\frac{1}{2}\cdot\frac{72}{576} = \frac{1}{16}$. The slow fields vary slowly on the scale $1/\Lambda$ over which $G_>(x-$

$y)^2$ is concentrated, so set $\varphi_<^2(y) \approx \varphi_<^2(x)$ (the dots are derivative terms). Then $\int \mathrm{d}^d z\, G_>(z)^2 = \int_k G_>(k)G_>(-k)$ by Parseval; both k and $-k$ lie in the shell.

(3) (T5.52), and $\frac{24}{16} = \frac{3}{2}$.

So $\delta\lambda = -\frac{3}{2}\lambda^2 K_d \Lambda^d \delta t/(\Lambda^2 + m^2)^2$. There are three more second-order terms, and none of them contributes: (i) the term with one fast field at each vertex (a single shell line between two vertices) needs the shell momentum to equal the sum of the three slow momenta at one vertex; for small external momenta this sum is far below Λ, not in the shell, so the term vanishes (at larger momenta it builds a six-leg vertex, which is irrelevant); (ii) the terms with three fast fields at a vertex give higher-order corrections to the mass; (iii) the kinetic term $(\partial\varphi)^2$ is not corrected at one loop, because the tadpole does not depend on the external momentum. Point (iii) means *the anomalous dimension vanishes at one loop*: $\eta = O(\lambda^2)$.

Rescaling. After the integration the slow field lives on $|p| < \Lambda' := \Lambda e^{-\delta t}$, with couplings $m^2 + \delta m^2$ and $\lambda + \delta\lambda$, and the kinetic term still has coefficient $\frac{1}{2}$ (point (iii)). Rescaling momenta by $e^{\delta t}$ so that the cutoff is again called Λ is the same as measuring every coupling in units of the new cutoff Λ'. So use the dimensionless couplings

$$r := \frac{m^2}{\Lambda^2}, \qquad \bar{u} := K_d\, \lambda\, \Lambda^{d-4},$$

and compare them before and after the step. With $\Lambda'^{-2} = \Lambda^{-2}(1+2\delta t)$ and $\Lambda'^{d-4} = \Lambda^{d-4}(1+\varepsilon\,\delta t)$ to first order, where $\varepsilon := 4 - d$,

$$\begin{aligned} r' - r &\overset{(1)}{=} \frac{m^2 + \delta m^2}{\Lambda^2}(1 + 2\delta t) - \frac{m^2}{\Lambda^2} \overset{(2)}{=} 2r\,\delta t + \frac{\lambda}{2}\,\frac{K_d \Lambda^{d-4}}{1+r}\,\delta t \\ &\overset{(3)}{=} \Big(2r + \frac{\bar{u}}{2(1+r)}\Big)\delta t, \\ \bar{u}' - \bar{u} &\overset{(4)}{=} K_d(\lambda + \delta\lambda)\Lambda^{d-4}(1 + \varepsilon\,\delta t) - K_d\lambda\Lambda^{d-4} \overset{(5)}{=} \varepsilon\,\bar{u}\,\delta t - \frac{3}{2}\,\frac{K_d^2\lambda^2\Lambda^{2d-8}}{(1+r)^2}\,\delta t \\ &\overset{(6)}{=} \Big(\varepsilon\,\bar{u} - \frac{3}{2}\,\frac{\bar{u}^2}{(1+r)^2}\Big)\delta t. \end{aligned}$$

(1) Definition of r at the new cutoff, $r' = (m^2 + \delta m^2)/\Lambda'^2$.
(2) Keep first order in δt; insert δm^2 and write $\Lambda^d/(\Lambda^2(\Lambda^2 + m^2)) = \Lambda^{d-4}/(1 + r)$.
(3) $K_d\lambda\Lambda^{d-4} = \bar{u}$.
(4) Definition of $\bar{u}$ at the new cutoff.
(5) First order in δt; insert $\delta\lambda$ and write $K_d\Lambda^{d-4} \cdot K_d\Lambda^d/(\Lambda^2 + m^2)^2 = K_d^2\Lambda^{2d-8}/(1 + r)^2$.
(6) $K_d^2\lambda^2\Lambda^{2d-8} = \bar{u}^2$.

The first terms, $2r$ and $\varepsilon\bar{u}$, are the canonical factors $e^{[g]\delta t}$ of (T5.6). Dividing by δt,

$$\frac{\mathrm{d}r}{\mathrm{d}t} = 2r + \frac{\bar{u}}{2(1+r)}, \qquad \frac{\mathrm{d}\bar{u}}{\mathrm{d}t} = \varepsilon\,\bar{u} - \frac{3}{2}\,\frac{\bar{u}^2}{(1+r)^2}, \qquad \varepsilon = 4 - d. \tag{T5.54}$$

In $d = 4$ ($\varepsilon = 0$) and at $r = 0$, $\bar{u} = K_4\lambda = \lambda/8\pi^2$, and the second equation becomes

$$\frac{1}{8\pi^2}\,\frac{\mathrm{d}\lambda}{\mathrm{d}t} \overset{(1)}{=} -\frac{3}{2}\,\frac{\lambda^2}{(8\pi^2)^2} \quad\Longrightarrow\quad \frac{\mathrm{d}\lambda}{\mathrm{d}t} \overset{(2)}{=} -\frac{3\lambda^2}{16\pi^2},$$

(1) Insert $\bar{u} = \lambda/8\pi^2$.

(2) Multiply by $8\pi^2$: $\frac{3}{2}\cdot\frac{1}{8\pi^2}=\frac{3}{16\pi^2}$.

the familiar one-loop β-function of φ^4 theory ([QFT notes (15.7.56)]), with the sign convention of the pitfall in Section T5.1.4. In Example T5.12, $b=3/16\pi^2$. For $d=4-\varepsilon$ the same substitution, with $K_d=K_4+O(\varepsilon)$, gives $\mathrm{d}\hat\lambda/\mathrm{d}t=\varepsilon\hat\lambda-3\hat\lambda^2/16\pi^2$ at leading order for the dimensionless coupling $\hat\lambda:=\lambda\Lambda^{d-4}$.

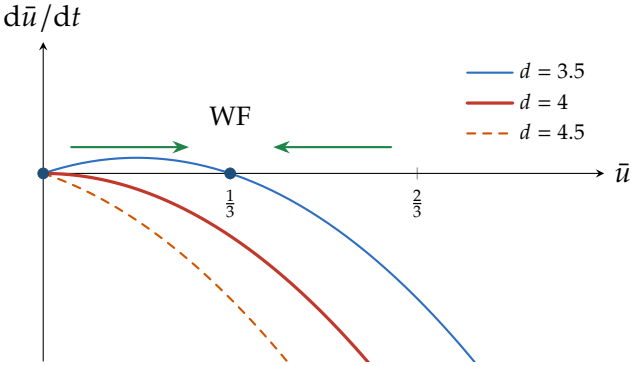

Figure T5.12: The one-loop flow of the quartic coupling at $r=0$, $\mathrm{d}\bar u/\mathrm{d}t=\varepsilon\bar u-\frac{3}{2}\bar u^2$, for $d=3.5$ ($\varepsilon=\frac12$, blue), $d=4$ (red) and $d=4.5$ (orange, dashed). Green arrows: the direction of flow towards the infrared for $d=3.5$. What to see: below four dimensions a second zero appears at $\bar u^*=\frac{2}{3}\varepsilon$ (here $\frac13$), and it attracts the flow from both sides; this is the Wilson–Fisher point. At $d=4$ it merges with the Gaussian point, and the coupling decays logarithmically (Example T5.12). Chapter 11 draws the same curve with the opposite sign convention.

Worked example T5.14: Fixed point and exponents to first order in ε

Setting the right sides of (T5.54) to zero with $\bar u\neq0$, at leading order in ε:

$$\bar u^*\overset{(1)}{=}\tfrac{2}{3}\varepsilon,\qquad r^*\overset{(2)}{=}-\tfrac14\bar u^*=-\tfrac{\varepsilon}{6}.$$

(1) $\varepsilon=\frac{3}{2}\bar u^*/(1+r^*)^2$ and $(1+r^*)^2=1+O(\varepsilon)$.
(2) $2r^*+\frac12\bar u^*=0$ at leading order.

The stability matrix at this point is

$$M\overset{(1)}{=}\begin{pmatrix}2-\dfrac{\bar u^*}{2(1+r^*)^2} & \dfrac{1}{2(1+r^*)}\\ \dfrac{3\bar u^{*2}}{(1+r^*)^3} & \varepsilon-\dfrac{3\bar u^*}{(1+r^*)^2}\end{pmatrix}\overset{(2)}{=}\begin{pmatrix}2-\dfrac{\varepsilon}{3} & \dfrac12\\ O(\varepsilon^2) & -\varepsilon\end{pmatrix}+O(\varepsilon^2).$$

(1) Differentiate (T5.54) with respect to r and $\bar u$.
(2) Insert $\bar u^*=\frac23\varepsilon$: $\frac12\bar u^*=\frac{\varepsilon}{3}$ and $\varepsilon-3\bar u^*=\varepsilon-2\varepsilon=-\varepsilon$.

The matrix is triangular up to $O(\varepsilon^2)$. Write it as $\left(\begin{smallmatrix}a & b\\ c & e\end{smallmatrix}\right)$ with $a=2-\varepsilon/3$, $b=\frac12$, $c=O(\varepsilon^2)$, $e=-\varepsilon$. Its characteristic polynomial is

$$(a-y)(e-y)-bc\overset{(1)}{=}(a-y)(e-y)+O(\varepsilon^2),$$

(1) $bc=\frac12\cdot O(\varepsilon^2)$.

so its roots are a and e up to corrections $bc/(a-e)=O(\varepsilon^2)$:

$$y_t=2-\frac{\varepsilon}{3},\qquad y_{\mathrm{irr}}=-\varepsilon.$$

These agree with the LPA result (T5.31), although the fixed point sits elsewhere ($\bar{u}^* = \frac{2}{3}\varepsilon$ here, which is $\tilde{u}^* = \frac{\varepsilon}{3}$ in the LPA units since $\bar{u} = K_4\lambda = 2\alpha_4\lambda$; the LPA had $\tilde{u}^* = \frac{\varepsilon}{6}$). Now use Section T5.3.2:

$$\nu \overset{(1)}{=} \frac{1}{y_t} = \frac{1}{2-\varepsilon/3} \overset{(2)}{=} \frac{1}{2} + \frac{\varepsilon}{12} + O(\varepsilon^2),$$

$$\eta \overset{(3)}{=} 0 + O(\varepsilon^2), \qquad \Delta_\varphi = \frac{d-2+\eta}{2} = 1 - \frac{\varepsilon}{2} + O(\varepsilon^2), \qquad \Delta_{\varphi^2} = d - y_t = 2 - \frac{2\varepsilon}{3} + O(\varepsilon^2).$$

(1) The relation $\nu = 1/y_t$ derived above.
(2) $\frac{1}{2}(1-\frac{\varepsilon}{6})^{-1} = \frac{1}{2}(1+\frac{\varepsilon}{6}+\cdots)$.
(3) No field renormalisation at one loop (Example T5.13, point (iii)).

The first non-zero anomalous dimension comes from a two-loop diagram, $\eta = \varepsilon^2/54$; Example T5.15 below computes it. The other exponents follow from the key idea of Section T5.3.2 with $\Delta_\sigma = \Delta_\varphi = 1 - \frac{\varepsilon}{2}$, $\Delta_\varepsilon = \Delta_{\varphi^2}$ and $y_t = d - \Delta_\varepsilon = 2 - \frac{\varepsilon}{3}$, expanding each ratio to first order with $(2-\frac{\varepsilon}{3})^{-1} = \frac{1}{2}(1+\frac{\varepsilon}{6}) + O(\varepsilon^2)$:

$$\alpha \overset{(1)}{=} 2 - \frac{4-\varepsilon}{2-\varepsilon/3} = 2 - \left(2-\tfrac{\varepsilon}{2}\right)\left(1+\tfrac{\varepsilon}{6}\right) = \frac{\varepsilon}{6}, \qquad \beta \overset{(2)}{=} \frac{1-\varepsilon/2}{2-\varepsilon/3} = \tfrac{1}{2}\left(1-\tfrac{\varepsilon}{2}\right)\left(1+\tfrac{\varepsilon}{6}\right) = \frac{1}{2} - \frac{\varepsilon}{6},$$

$$\gamma \overset{(3)}{=} \frac{4-\varepsilon-2+\varepsilon}{2-\varepsilon/3} = \frac{2}{2-\varepsilon/3} = 1 + \frac{\varepsilon}{6}, \qquad \delta \overset{(4)}{=} \frac{3-\varepsilon/2}{1-\varepsilon/2} = \left(3-\tfrac{\varepsilon}{2}\right)\left(1+\tfrac{\varepsilon}{2}\right) = 3 + \varepsilon,$$

(1) $\alpha = 2 - d/y_t$; drop ε^2: $2 - \frac{\varepsilon}{2} + \frac{\varepsilon}{3} = 2 - \frac{\varepsilon}{6}$.
(2) $\beta = \Delta_\sigma/y_t$; $\frac{1}{2}(1 - \frac{\varepsilon}{2} + \frac{\varepsilon}{6}) = \frac{1}{2} - \frac{\varepsilon}{6}$.
(3) $\gamma = (d - 2\Delta_\sigma)/y_t$ with $2\Delta_\sigma = 2 - \varepsilon$.
(4) $\delta = (d - \Delta_\sigma)/\Delta_\sigma$ and $(1 - \frac{\varepsilon}{2})^{-1} = 1 + \frac{\varepsilon}{2} + \cdots$; then $\frac{3\varepsilon}{2} - \frac{\varepsilon}{2} = \varepsilon$.

all to $O(\varepsilon^2)$. At $\varepsilon = 0$ these are the mean-field values.

Worked example T5.15: The sunset diagram gives $\eta = \varepsilon^2/54$

The field is not renormalised at one loop, so η starts at order λ^2. We compute it at the massless critical point, in **dimensional regularisation** [do the loop integrals in $d = 4 - \varepsilon$ dimensions, where they are finite, and read off the divergences as poles in $1/\varepsilon$]. Exponents are scheme independent (Section T5.2.5, last pitfall), so any scheme will do. To keep the coupling dimensionless write $\lambda = \mu^\varepsilon g$, with μ an arbitrary mass scale. The one-loop flow derived above, rewritten in the convention of the pitfall in Section T5.1.4, is $\mu\,\mathrm{d}g/\mathrm{d}\mu = -\varepsilon g + 3g^2/16\pi^2$, with fixed point $g^* = 16\pi^2\varepsilon/3$.
(a) The diagram. At order λ^2 the correction to $\langle\varphi\varphi\rangle$ that depends on the external momentum p is the **sunset** diagram: the two external legs attach to two vertices, which are joined by three propagators. Its weight is

$$\frac{1}{2!}\left(\frac{\lambda}{4!}\right)^2 \cdot 2\cdot 4\cdot 4\cdot 3! \overset{(1)}{=} \frac{\lambda^2\cdot 192}{2\cdot 576} \overset{(2)}{=} \frac{\lambda^2}{6}.$$

(1) Second order of $e^{-S_{\text{int}}}$ gives $\frac{1}{2!}\langle S_{\text{int}}^2\rangle$ (the two minus signs cancel). Choose which vertex the first external leg joins (2), which of its four legs (4), which leg of the other vertex the second external leg joins (4), and pair the remaining three legs at one vertex with the three at the other (3!).
(2) Arithmetic.

So the self-energy is $\Sigma(p) = \frac{\lambda^2}{6} I(p)$ with

$$I(p) \coloneqq \int \frac{\mathrm{d}^d k}{(2\pi)^d} \frac{\mathrm{d}^d q}{(2\pi)^d} \frac{1}{k^2\, q^2\, (p-k-q)^2},$$

and, since the correction adds to the free propagator as $G_0 + G_0 \Sigma G_0 + \cdots = 1/(p^2 - \Sigma)$, the inverse propagator is $\Gamma^{(2)}(p) = p^2 - \Sigma(p)$.
(b) The key integral. Every one-loop integral we need is of the form

$$J(a,b) \coloneqq \int \frac{\mathrm{d}^d k}{(2\pi)^d} \frac{1}{(k^2)^a \left((p-k)^2\right)^b}.$$

With Schwinger parameters,

$$\begin{aligned}
J(a,b) &\overset{(1)}{=} \frac{1}{\Gamma(a)\Gamma(b)} \int_0^\infty \mathrm{d}s\, \mathrm{d}t\; s^{a-1} t^{b-1} \int \frac{\mathrm{d}^d k}{(2\pi)^d}\, e^{-sk^2 - t(p-k)^2} \\
&\overset{(2)}{=} \frac{1}{\Gamma(a)\Gamma(b)} \int_0^\infty \mathrm{d}s\, \mathrm{d}t\; \frac{s^{a-1} t^{b-1}}{(4\pi(s+t))^{d/2}}\, e^{-\frac{st}{s+t} p^2} \\
&\overset{(3)}{=} \frac{1}{\Gamma(a)\Gamma(b)(4\pi)^{d/2}} \int_0^1 \mathrm{d}x\, x^{a-1}(1-x)^{b-1} \int_0^\infty \mathrm{d}\rho\; \rho^{a+b-1-d/2} e^{-\rho x(1-x)p^2} \\
&\overset{(4)}{=} \frac{\Gamma(a+b-\frac{d}{2})}{\Gamma(a)\Gamma(b)(4\pi)^{d/2}}\, (p^2)^{\frac{d}{2}-a-b} \int_0^1 \mathrm{d}x\, x^{\frac{d}{2}-b-1}(1-x)^{\frac{d}{2}-a-1} \\
&\overset{(5)}{=} \frac{(p^2)^{\frac{d}{2}-a-b}}{(4\pi)^{d/2}}\, \frac{\Gamma(a+b-\frac{d}{2})\,\Gamma(\frac{d}{2}-a)\,\Gamma(\frac{d}{2}-b)}{\Gamma(a)\,\Gamma(b)\,\Gamma(d-a-b)}.
\end{aligned}$$

(1) $A^{-a} = \frac{1}{\Gamma(a)} \int_0^\infty \mathrm{d}s\, s^{a-1} e^{-sA}$ for $A > 0$, once for each denominator.
(2) Complete the square, $sk^2 + t(p-k)^2 = (s+t)\big(k - \frac{t}{s+t} p\big)^2 + \frac{st}{s+t} p^2$, and use $\int \frac{\mathrm{d}^d k}{(2\pi)^d} e^{-ck^2} = (4\pi c)^{-d/2}$ (Section T5.2.5).
(3) $s = \rho x$, $t = \rho(1-x)$ with $\mathrm{d}s\, \mathrm{d}t = \rho\, \mathrm{d}\rho\, \mathrm{d}x$.
(4) $\int_0^\infty \mathrm{d}\rho\, \rho^{z-1} e^{-\rho c} = \Gamma(z) c^{-z}$ with $z = a + b - \frac{d}{2}$, $c = x(1-x)p^2$; collect the powers of x and $1-x$.
(5) The Beta integral $\int_0^1 x^{\alpha-1}(1-x)^{\beta-1} \mathrm{d}x = \Gamma(\alpha)\Gamma(\beta)/\Gamma(\alpha+\beta)$, with $\alpha + \beta = d - a - b$.

(c) The sunset as two nested loops. Do the q integral first, at fixed $P \coloneqq p - k$: it is $J(1,1)$ with external momentum P. The result is a power of P^2, so the k integral is again of the form $J(a,b)$:

$$I(p) \overset{(1)}{=} \frac{\Gamma(2-\frac{d}{2})\Gamma(\frac{d}{2}-1)^2}{(4\pi)^{d/2}\Gamma(d-2)} \int \frac{\mathrm{d}^d k}{(2\pi)^d} \frac{1}{k^2\, ((p-k)^2)^{2-d/2}} \overset{(2)}{=} \frac{(p^2)^{d-3}}{(4\pi)^d} \frac{\Gamma(\frac{d}{2}-1)^3\, \Gamma(3-d)}{\Gamma(\frac{3d}{2}-3)}.$$

(1) $J(1,1) = \frac{(P^2)^{d/2-2}}{(4\pi)^{d/2}} \frac{\Gamma(2-\frac{d}{2})\Gamma(\frac{d}{2}-1)^2}{\Gamma(d-2)}$.
(2) $J(1, 2-\frac{d}{2})$: here $a + b - \frac{d}{2} = 3 - d$, $\frac{d}{2} - a = \frac{d}{2} - 1$, $\frac{d}{2} - b = d - 2$, $d - a - b = \frac{3d}{2} - 3$, and the power is $(p^2)^{d-3}$; the factors $\Gamma(2 - \frac{d}{2})$ and $\Gamma(d-2)$ cancel.

(d) The pole. Put $d = 4 - \varepsilon$. Then $\Gamma(\frac{d}{2}-1) = \Gamma(1-\frac{\varepsilon}{2}) = 1 + O(\varepsilon)$, $\Gamma(\frac{3d}{2}-3) = \Gamma(3-\frac{3\varepsilon}{2}) = 2 + O(\varepsilon)$, and $\Gamma(3-d) = \Gamma(-1+\varepsilon) = \frac{\Gamma(\varepsilon)}{-1+\varepsilon} = -\frac{1}{\varepsilon} + O(1)$ (from $\Gamma(z+1) = z\Gamma(z)$ and $\Gamma(\varepsilon) = \frac{1}{\varepsilon} + O(1)$). So

$$I(p) = -\frac{p^2}{2\varepsilon\,(4\pi)^4} + (\text{finite}) \cdot p^2.$$

The divergence multiplies p^2: the sunset renormalises the kinetic term, which the one-loop tadpole could not do.
(e) The anomalous dimension. Insert into $\Gamma^{(2)}$, with $\lambda^2 = \mu^{2\varepsilon} g^2$ (the factor $\mu^{2\varepsilon}(p^2)^{-\varepsilon}$ is finite and only changes the finite part):

$$\Gamma^{(2)}(p) \overset{(1)}{=} p^2 - \frac{g^2}{6} I(p) \overset{(2)}{=} p^2\left(1 + \frac{g^2}{12\varepsilon(4\pi)^4}\right) + (\text{finite}) \cdot p^2.$$

(1) $\Gamma^{(2)} = p^2 - \Sigma$ with $\Sigma = \frac{\lambda^2}{6} I$.
(2) $-\frac{1}{6} \cdot \left(-\frac{1}{2\varepsilon}\right) = \frac{1}{12\varepsilon}$.

A rescaled field $\varphi = Z^{1/2}\varphi_R$ has $\Gamma^{(2)}_R = Z\,\Gamma^{(2)}$, which is finite if $Z = 1 - g^2/(12\varepsilon(4\pi)^4)$. The **anomalous dimension** of the field is $\gamma_\varphi := \frac{1}{2}\mu\,\mathrm{d}\ln Z/\mathrm{d}\mu$ at fixed bare coupling. At a fixed point the Callan–Symanzik equation (Chapter 11) makes the propagator a power, $\langle\varphi(x)\varphi(0)\rangle \propto |x|^{-(d-2)-2\gamma_\varphi}$, so $\Delta_\varphi = \frac{d-2}{2} + \gamma_\varphi$ and, comparing with $2\Delta_\varphi = d - 2 + \eta$, $\eta = 2\gamma_\varphi(g^*)$. Now

$$\gamma_\varphi \overset{(1)}{=} \frac{1}{2} \cdot \left(-\frac{2g}{12\varepsilon(4\pi)^4}\right)\mu\frac{\mathrm{d}g}{\mathrm{d}\mu} \overset{(2)}{=} \frac{1}{2} \cdot \left(-\frac{2g}{12\varepsilon(4\pi)^4}\right)(-\varepsilon g) = \frac{g^2}{12(4\pi)^4},$$
$$\eta \overset{(3)}{=} 2\gamma_\varphi(g^*) \overset{(4)}{=} \frac{2}{12(4\pi)^4}\left(\frac{(4\pi)^2\varepsilon}{3}\right)^2 = \frac{2\varepsilon^2}{108} = \frac{\varepsilon^2}{54}.$$

(1) $\ln Z = -g^2/(12\varepsilon(4\pi)^4) + O(g^4)$; differentiate with the chain rule.
(2) $\mu\,\mathrm{d}g/\mathrm{d}\mu = -\varepsilon g + O(g^2)$; the $O(g^2)$ term gives $O(g^3)$ in γ_φ. The $1/\varepsilon$ cancels: the anomalous dimension is finite.
(3) The relation just derived.
(4) $g^* = 16\pi^2\varepsilon/3 = (4\pi)^2\varepsilon/3$.

For the N-component model the same steps give $\eta = (N+2)\varepsilon^2/(2(N+8)^2)$ ([QFT notes (16.2.81)–(16.2.82)]), which is $3\varepsilon^2/(2\cdot 81) = \varepsilon^2/54$ at $N = 1$.

Watch out: η comes from the field, not from φ^2

Two anomalous dimensions appear at the Wilson–Fisher point and are easily confused. The field anomalous dimension γ_φ gives $\eta = 2\gamma_\varphi(g^*)$, which starts at $O(\varepsilon^2)$. The anomalous dimension γ_m of the operator φ^2 is already $O(\varepsilon)$: from $\Delta_{\varphi^2} = d - 2 + \gamma_m$ and $\Delta_{\varphi^2} = 2 - \frac{2\varepsilon}{3}$ we get $\gamma_m = \frac{\varepsilon}{3}$, and it controls $\nu = 1/y_t = (2 - \gamma_m)^{-1}$, not η.

T5.3.4 How good is the ε-expansion, and where the CFTs come in

Set $\varepsilon = 1$ and $\varepsilon = 2$ in the first-order formulas and compare with what is known in $d = 3$ (from the conformal bootstrap and Monte Carlo) and in $d = 2$ (Onsager's solution, and the $c = \frac{1}{2}$ CFT of Chapter 11).

	ν	η	α	β	γ	δ
mean field ($d \geq 4$)	0.5	0	0	0.5	1	3
$O(\varepsilon)$ at $\varepsilon = 1$	0.583	0	0.167	0.333	1.167	4
3D Ising (bootstrap)	0.630	0.036	0.110	0.326	1.237	4.79
$O(\varepsilon)$ at $\varepsilon = 2$	0.667	0	0.333	0.167	1.333	5
2D Ising (exact)	1	0.25	0	0.125	1.75	15

In three dimensions first order is already within about 10%; higher orders, resummed, give three or four digits. In two dimensions the expansion is hopeless ($\delta = 5$ against 15). That is not a failure of the RG but of perturbation theory about the Gaussian point: at $\varepsilon = 2$ the fixed point is far from free. The exact answer comes from the other end: the fixed point is a CFT, and in two dimensions CFTs can be classified. In Chapter 11 we will find that the two-dimensional Ising critical point is the "minimal model" $\mathcal{M}_3$, the CFT with central charge $c = \frac{1}{2}$ whose two non-trivial primary operators σ and ε have conformal weights $h = \bar{h} = \frac{1}{16}$ and $\frac{1}{2}$, so $\Delta_\sigma = \frac{1}{8}$ and $\Delta_\varepsilon = 1$. The RG eigenvalues $y_t = 2 - 1 = 1$ and $y_h = 2 - \frac{1}{8} = \frac{15}{8}$ then reproduce the last line of the table through Section T5.3.2. More generally, Zamolodchikov identified the multicritical fixed point of $\varphi^{2(m-1)}$ theory in two dimensions with the minimal model $\mathcal{M}_m$ of central charge $c_m = 1 - 6/(m(m+1))$: $\varphi^4 \leftrightarrow$ Ising ($m = 3$), $\varphi^6 \leftrightarrow$ tricritical Ising ($m = 4$), and so on. This identification drives the flows between minimal models in the c-theorem section of Chapter 11 (Section 11.13.4).

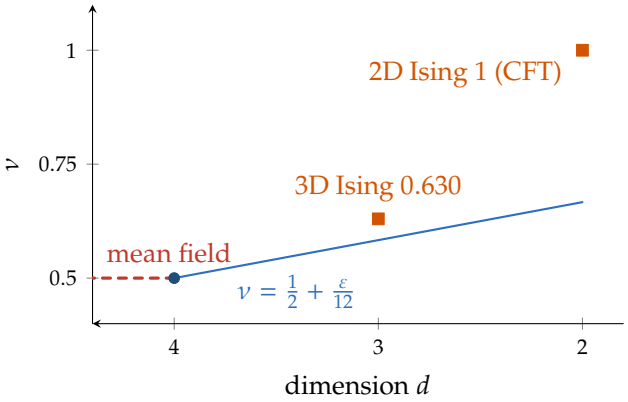

Figure T5.13: The correlation-length exponent against dimension (read from right to left, starting at $d = 4$). Blue: the first-order ε-expansion. Orange squares: the known values in $d = 3$ and $d = 2$. What to see: the expansion about the Gaussian point is good near $d = 4$ and poor at $d = 2$, where the exact value comes instead from the Ising CFT of Chapter 11.

Recap

- Linearising $\mathrm{d}g/\mathrm{d}t = \beta(g)$ at a fixed point gives a stability matrix M; its eigenvectors define scaling fields $u_a \propto e^{y_a t}$.
- RG eigenvalues and scaling dimensions are the same data: $y_a = d - \Delta_a$; $\nu = 1/y_t$.
- At the Gaussian point the eigenoperators are the normal-ordered $:\varphi^n:$ (Hermite polynomials) with $y_n = d - n\frac{d-2}{2}$.
- One-loop shell integration of φ^4 gives $\mathrm{d}r/\mathrm{d}t = 2r + \bar{u}/2(1+r)$, $\mathrm{d}\bar{u}/\mathrm{d}t = \varepsilon\bar{u} - \frac{3}{2}\bar{u}^2/(1+r)^2$; the Wilson–Fisher point $\bar{u}^* = \frac{2}{3}\varepsilon$ has $y_t = 2 - \varepsilon/3$, so $\nu = \frac{1}{2} + \frac{\varepsilon}{12}$, $\eta = \varepsilon^2/54$.

- Fixed-point locations are scheme dependent; eigenvalues are not.
- Scaling of the free energy turns (y_t, y_h) into all six exponents.
- In $d = 2$ the Wilson–Fisher point is the Ising CFT $\mathcal{M}_3$, whose exact weights give the exact exponents (Chapter 11).

T5.4 Running couplings in perturbation theory

Wilson's RG removes shells of momenta below a cutoff Λ and follows the couplings as Λ is lowered. A particle physicist usually works differently. The cutoff is removed (or replaced by dimensional regularisation), and the coupling is *defined* by a measurement at some chosen momentum scale μ. Nothing physical can depend on that choice. This section asks what that requirement says about correlation functions, and it computes the first coefficient of the β-function in the two theories that matter most in this book: φ^4 theory and Yang–Mills theory. The answers are the Callan–Symanzik equation (Section T5.4.1), $\beta = 3\lambda^2/16\pi^2$ (Section T5.4.2) and $\beta = -(g^3/16\pi^2)(\frac{11N}{3} - \frac{2n_f}{3})$ (Section T5.4.3).

Throughout, $\beta(g) \coloneqq \mu\, \mathrm{d}g/\mathrm{d}\mu$ with μ increasing towards the ultraviolet. This is minus the $\mathrm{d}g/\mathrm{d}t$ of (T5.5) (the pitfall in Section T5.1.4).

T5.4.1 The Callan–Symanzik equation

[Callan 1970, Symanzik 1970] Take massless φ^4 theory in $d = 4 - \varepsilon$ Euclidean dimensions, with the **bare** action

$$S = \int \mathrm{d}^d x \left[\tfrac{1}{2}(\partial\varphi_0)^2 + \frac{\lambda_0}{4!}\varphi_0^4 \right].$$

The field φ_0 and coupling λ_0 are the ones that appear in the path integral. The **bare correlators** $G_0^{(n)}(x_1, \dots, x_n) = \langle \varphi_0(x_1) \cdots \varphi_0(x_n) \rangle$ depend on λ_0 and on ε (which plays the role of the cutoff), and on nothing else. Their poles at $\varepsilon \to 0$ are removed by rescaling the field and the coupling.

Working definition T5.7 (renormalised coupling and anomalous dimension)

Pick a **renormalisation scale** μ [the momentum at which we agree to call the strength of the interaction λ] and write

$$\varphi_0 = Z^{1/2}\varphi, \qquad \lambda_0 = \mu^{\varepsilon} Z_\lambda\, \lambda, \tag{T5.55}$$

with Z and Z_λ chosen so that the **renormalised correlators** $G^{(n)} \coloneqq Z^{-n/2} G_0^{(n)}$ are finite as $\varepsilon \to 0$ [Z absorbs the part of the field's normalisation that the loops make infinite]. The factor μ^ε keeps λ dimensionless, since $[\lambda_0] = 4 - d = \varepsilon$. Holding λ_0 fixed and changing μ changes λ and Z. The two rates are the **β-function** and the **anomalous dimension**

$$\beta(\lambda) \coloneqq \mu \frac{\mathrm{d}\lambda}{\mathrm{d}\mu}\bigg|_{\lambda_0}, \qquad \gamma(\lambda) \coloneqq \frac{1}{2}\,\mu \frac{\mathrm{d}\ln Z}{\mathrm{d}\mu}\bigg|_{\lambda_0}. \tag{T5.56}$$

Here γ [how fast the field's normalisation must be readjusted as μ moves] is the anomalous dimension. *Operational test:* compute a finite quantity in terms of $\lambda(\mu)$, demand that it does not change with μ, and read off β (this is done in Example T5.18).

The renormalised correlators depend on μ and λ, but the bare ones do not know about μ at

all. That single fact gives a differential equation.

$$
\begin{aligned}
0 &\overset{(1)}{=} \mu \frac{\mathrm{d}}{\mathrm{d}\mu}\Big|_{\lambda_0} G_0^{(n)} \overset{(2)}{=} \mu \frac{\mathrm{d}}{\mathrm{d}\mu}\Big|_{\lambda_0} \left[Z^{n/2}\, G^{(n)}\big(x_i; \mu, \lambda(\mu)\big) \right] \\
&\overset{(3)}{=} Z^{n/2} \left[\frac{n}{2}\, \mu \frac{\mathrm{d} \ln Z}{\mathrm{d}\mu} + \mu \frac{\partial}{\partial \mu} + \mu \frac{\mathrm{d}\lambda}{\mathrm{d}\mu} \frac{\partial}{\partial \lambda} \right] G^{(n)} \\
&\overset{(4)}{=} Z^{n/2} \left[\mu \frac{\partial}{\partial \mu} + \beta(\lambda) \frac{\partial}{\partial \lambda} + n\, \gamma(\lambda) \right] G^{(n)}.
\end{aligned}
\tag{T5.57}
$$

(1) $G_0^{(n)}$ is a function of x_i, λ_0 and ε only.
(2) $G_0^{(n)} = Z^{n/2} G^{(n)}$, the definition of $G^{(n)}$.
(3) Product rule, and the chain rule for the μ-dependence that enters through $\lambda(\mu)$. The factor $Z^{n/2}$ gives $\mu\, \mathrm{d}Z^{n/2}/\mathrm{d}\mu = Z^{n/2}\, \frac{n}{2}\, \mu\, \mathrm{d} \ln Z/\mathrm{d}\mu$.
(4) The definitions (T5.56).

Dividing by $Z^{n/2}$ gives the result.

Key idea: the Callan–Symanzik equation

Renormalised correlators obey

$$
\left[\mu \frac{\partial}{\partial \mu} + \beta(\lambda) \frac{\partial}{\partial \lambda} + n\, \gamma(\lambda) \right] G^{(n)}(x_1, \ldots, x_n; \mu, \lambda) = 0. \tag{T5.58}
$$

A change of the arbitrary scale μ is compensated by a change of the coupling (rate β) and of the normalisation of each field (rate γ).

What does (T5.58) say physically? Combine it with dimensional analysis. The field has classical dimension $\Delta_{\mathrm{cl}} = \frac{d-2}{2}$ (Example T5.4), so the two-point function must have the form

$$
G^{(2)}(x; \mu, \lambda) = |x|^{-2\Delta_{\mathrm{cl}}}\, F(\mu\, |x|\,, \lambda), \tag{T5.59}
$$

with F a dimensionless function of the only two dimensionless numbers available. Write $r = |x|$ and $u = \mu r$. Then

$$
r \frac{\partial G^{(2)}}{\partial r} \overset{(1)}{=} -2\Delta_{\mathrm{cl}}\, G^{(2)} + r^{-2\Delta_{\mathrm{cl}}}\, u\, \partial_u F \overset{(2)}{=} -2\Delta_{\mathrm{cl}}\, G^{(2)} + \mu \frac{\partial G^{(2)}}{\partial \mu},
$$

(1) Product rule; $r\, \partial_r F(\mu r) = u\, \partial_u F$.
(2) $\mu\, \partial_\mu F(\mu r) = u\, \partial_u F$ as well.

so $\mu \partial_\mu = r \partial_r + 2\Delta_{\mathrm{cl}}$ on $G^{(2)}$, and (T5.58) becomes

$$
\left[r \frac{\partial}{\partial r} + 2\Delta_{\mathrm{cl}} + \beta(\lambda) \frac{\partial}{\partial \lambda} + 2\gamma(\lambda) \right] G^{(2)} = 0. \tag{T5.60}
$$

Read it as a statement about zooming out: moving the two points apart ($r\partial_r$) has the same effect as changing the coupling at the rate β and the normalisation at the rate γ. This is Wilson's picture again, now written for correlators.

Solving it: the method of characteristics. Equation (T5.58) is a first-order linear partial differential equation in the two variables (μ, λ). Such an equation is solved along the curves

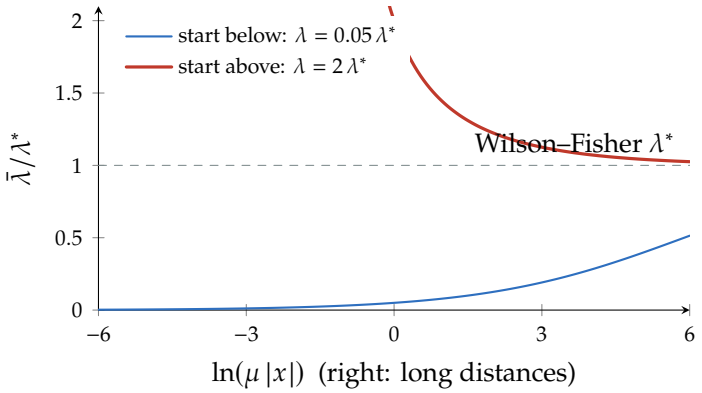

Figure T5.14: The running coupling $\bar\lambda$ of Example T5.17 in $d = 4 - \varepsilon$ ($\varepsilon = \frac{1}{2}$), as a function of the distance at which the two-point function is probed. Both curves are fixed by $\bar\lambda = \lambda$ at $\mu\,|x| = 1$. What to see: at long distances (right) every starting value is drawn to the Wilson–Fisher value λ^*, so the correlator becomes the pure power of the fixed point; at short distances (left) the coupling from below dies away (the theory is free in the ultraviolet), while the one from above grows and runs out of the region of validity of one loop.

on which its derivative part is an ordinary derivative. Define the **running coupling** $\bar\lambda(\ell)$ [the coupling we would have to use if we renormalised at the scale μe^{ℓ} instead of μ] by

$$\frac{\mathrm{d}\bar\lambda}{\mathrm{d}\ell} = \beta(\bar\lambda), \qquad \bar\lambda(0) = \lambda, \tag{T5.61}$$

and follow the curve $\ell \mapsto (\mu e^{\ell}, \bar\lambda(\ell))$ in the (μ, λ) plane. Along it,

$$\frac{\mathrm{d}}{\mathrm{d}\ell}\, G^{(2)}\big(x; \mu e^{\ell}, \bar\lambda(\ell)\big) \overset{(1)}{=} \Big[\mu' \frac{\partial}{\partial \mu'} + \frac{\mathrm{d}\bar\lambda}{\mathrm{d}\ell}\,\frac{\partial}{\partial \lambda}\Big] G^{(2)} \overset{(2)}{=} -2\gamma\big(\bar\lambda(\ell)\big)\, G^{(2)},$$

(1) Chain rule with $\mu' = \mu e^{\ell}$, so $\mathrm{d}\mu'/\mathrm{d}\ell = \mu'$.
(2) (T5.61), then (T5.58) with $n = 2$, evaluated at $(\mu', \bar\lambda)$.

This is an ordinary linear equation in ℓ, solved by an exponential: $G^{(2)}(x; \mu e^{\ell}, \bar\lambda(\ell)) = G^{(2)}(x; \mu, \lambda) \exp\big(-2\int_0^{\ell} \gamma(\bar\lambda(\ell'))\mathrm{d}\ell'\big)$. Now choose ℓ so that the new scale is the inverse distance, $\mu e^{\ell_x} = 1/r$, that is $\ell_x = -\ln(\mu r)$. At that scale the dimensionless function in (T5.59) is evaluated at $\mu' r = 1$, and

$$G^{(2)}(x; \mu, \lambda) = \frac{F\big(1, \bar\lambda(\ell_x)\big)}{r^{2\Delta_{\mathrm{cl}}}}\, \exp\Big(2\int_0^{\ell_x} \gamma\big(\bar\lambda(\ell')\big)\,\mathrm{d}\ell'\Big), \qquad \ell_x = -\ln(\mu r). \tag{T5.62}$$

Everything about the distance dependence is now carried by the running coupling at the scale $1/r$ and by the accumulated anomalous dimension. If $\bar\lambda(\ell_x)$ is small, $F(1, \bar\lambda)$ can be computed in perturbation theory even when $\ln(\mu r)$ is large: the solution *resums* the large logarithms that spoil a naive expansion in λ.

At a fixed point: a pure power law. Suppose $\beta(\lambda^*) = 0$ and start at $\lambda = \lambda^*$. Then $\bar\lambda(\ell) = \lambda^*$ for all ℓ (the right side of (T5.61) vanishes), $\gamma(\bar\lambda) = \gamma^* := \gamma(\lambda^*)$ is constant, and

$$G^{(2)}(x) \overset{(1)}{=} \frac{F(1, \lambda^*)}{r^{2\Delta_{\mathrm{cl}}}}\, e^{2\gamma^* \ell_x} \overset{(2)}{=} \frac{F(1, \lambda^*)}{r^{2\Delta_{\mathrm{cl}}}}\, (\mu r)^{-2\gamma^*} = \frac{F(1, \lambda^*)\, \mu^{-2\gamma^*}}{r^{2(\Delta_{\mathrm{cl}} + \gamma^*)}}. \tag{T5.63}$$

(1) (T5.62) with a constant integrand.

(2) $\ell_x = -\ln(\mu r)$, so $e^{2\gamma^*\ell_x} = (\mu r)^{-2\gamma^*}$.

The correlator is a pure power, $G \propto r^{-2\Delta}$, with

$$\Delta = \Delta_{\mathrm{cl}} + \gamma(\lambda^*). \tag{T5.64}$$

The anomalous dimension at the fixed point is exactly the shift of the scaling dimension away from its classical value. This is the scaling dimension of the workdef in Section T5.1.1, the Δ of $y = d - \Delta$ ((T5.48)), and, in two dimensions, the conformal weight $\Delta = h + \bar{h}$ of the primary field that the conformal field theory of Chapter 11 assigns to φ. The same steps for any local operator $\mathcal{O}$ with its own anomalous dimension $\gamma_{\mathcal{O}}$ give $\Delta_{\mathcal{O}} = \Delta_{\mathcal{O},\mathrm{cl}} + \gamma_{\mathcal{O}}(\lambda^*)$.

Near, rather than at, the fixed point, expand $\beta(\lambda) \approx \beta'(\lambda^*)(\lambda - \lambda^*)$. Then (T5.61) gives $\bar{\lambda}(\ell) - \lambda^* \propto e^{\beta'(\lambda^*)\ell} = (\mu r)^{-\beta'(\lambda^*)}$. If $\beta'(\lambda^*) > 0$ this dies away at long distances: the coupling is irrelevant at λ^*, and its RG eigenvalue in the language of Section T5.3.1 is $y = -\beta'(\lambda^*)$ (the minus sign is the change from t to $\ln \mu$).

Worked example T5.16: Massless φ^4 in $d = 4$: logarithms instead of powers

At one loop in $d = 4$, $\beta = b\lambda^2$ with $b = 3/16\pi^2$ (derived in Section T5.4.2), and at two loops $\gamma = c\lambda^2$ with $c = 1/(12(4\pi)^4)$ (Example T5.15). The running coupling and the exponent in (T5.62) are

$$\bar{\lambda}(\ell) \overset{(1)}{=} \frac{\lambda}{1 - b\lambda\ell},$$
$$\int_0^\ell \gamma\big(\bar{\lambda}(\ell')\big)\mathrm{d}\ell' \overset{(2)}{=} \int_0^\ell \frac{c\,\bar{\lambda}^2}{b\,\bar{\lambda}^2}\frac{\mathrm{d}\bar{\lambda}}{\mathrm{d}\ell'}\,\mathrm{d}\ell' \overset{(3)}{=} \frac{c}{b}\big(\bar{\lambda}(\ell) - \lambda\big).$$

(1) Separate variables in $\mathrm{d}\bar{\lambda}/\mathrm{d}\ell = b\bar{\lambda}^2$: $1/\lambda - 1/\bar{\lambda} = b\ell$.
(2) Insert $1 = \beta(\bar{\lambda})^{-1}\mathrm{d}\bar{\lambda}/\mathrm{d}\ell'$ with $\beta = b\bar{\lambda}^2$.
(3) The integrand is $\frac{c}{b}\,\mathrm{d}\bar{\lambda}/\mathrm{d}\ell'$, a total derivative.

With $\ell_x = -\ln(\mu r)$ the two-point function is therefore

$$G^{(2)}(x) = \frac{F(1, \bar{\lambda}_x)}{r^2}\,\exp\!\Big[\frac{2c}{b}\big(\bar{\lambda}_x - \lambda\big)\Big], \qquad \bar{\lambda}_x = \frac{\lambda}{1 + b\lambda\ln(\mu r)}.$$

At long distances $\ln(\mu r) \to \infty$, so $\bar{\lambda}_x \approx 1/(b\ln(\mu r)) \to 0$ and $F(1, \bar{\lambda}_x) \to F(1,0) = 1/(4\pi^2)$, the free massless propagator. The correlator tends to $\frac{1}{4\pi^2 r^2}e^{-2c\lambda/b}$: a *free* power law with no anomalous exponent, approached only logarithmically. (Numerically $2c/b = 1/(18\cdot 16\pi^2) \approx 3.5 \times 10^{-4}$, so the constant is very close to 1.) This is the statement that four-dimensional φ^4 theory is trivial at long distances, the marginally irrelevant flow of Example T5.12. At short distances $\bar{\lambda}_x$ grows and reaches the Landau pole at $r = \mu^{-1}e^{-1/(b\lambda)}$, where one loop can no longer be trusted.

Worked example T5.17: $d = 4 - \varepsilon$: crossover to the Wilson–Fisher power law

Now $\beta = -\varepsilon\lambda + b\lambda^2$, with fixed point $\lambda^* = \varepsilon/b = 16\pi^2\varepsilon/3$. For $u := 1/\bar{\lambda}$ the flow equation becomes linear:

$$\frac{\mathrm{d}u}{\mathrm{d}\ell} \overset{(1)}{=} -\frac{1}{\bar{\lambda}^2}\frac{\mathrm{d}\bar{\lambda}}{\mathrm{d}\ell} \overset{(2)}{=} \frac{\varepsilon}{\bar{\lambda}} - b = \varepsilon\,u - b \quad\Longrightarrow\quad u(\ell) \overset{(3)}{=} \frac{b}{\varepsilon} + \Big(\frac{1}{\lambda} - \frac{b}{\varepsilon}\Big)e^{\varepsilon\ell},$$

(1) Chain rule for $u = \bar{\lambda}^{-1}$.
(2) Insert $\beta(\bar{\lambda}) = -\varepsilon\bar{\lambda} + b\bar{\lambda}^2$.

(3) The general solution of $u' = \varepsilon u - b$ is the constant solution b/ε plus $Ce^{\varepsilon\ell}$; $u(0) = 1/\lambda$ fixes C.

so, with $e^{\varepsilon \ell_x} = (\mu r)^{-\varepsilon}$ and $b/\varepsilon = 1/\lambda^*$,

$$\bar\lambda_x = \frac{\lambda^*}{1 + \left(\frac{\lambda^*}{\lambda} - 1\right)(\mu r)^{-\varepsilon}}.$$

Figure T5.14 plots it. As $r \to \infty$, $(\mu r)^{-\varepsilon} \to 0$ and $\bar\lambda_x \to \lambda^*$ from either side, and (T5.63) applies: $G \propto r^{-2\Delta_\varphi}$ with $\Delta_\varphi = 1 - \frac{\varepsilon}{2} + \gamma(\lambda^*) = 1 - \frac{\varepsilon}{2} + \frac{\varepsilon^2}{108}$, which is $\eta = 2\gamma(\lambda^*) = \varepsilon^2/54$ of Example T5.15. As $r \to 0$, $\bar\lambda_x \approx \lambda(\mu r)^\varepsilon \to 0$: below four dimensions the theory is free at short distances. The crossover happens where the two terms in the denominator are equal; for $\lambda \ll \lambda^*$ this is at $\mu r_\times \approx (\lambda^*/\lambda)^{1/\varepsilon}$. The approach to the fixed point is $\bar\lambda_x - \lambda^* \propto (\mu r)^{-\varepsilon}$, the power $\beta'(\lambda^*) = -\varepsilon + 2b\lambda^* = \varepsilon$, which is the irrelevant eigenvalue $y_{\rm irr} = -\varepsilon$ of Example T5.14.

Watch out: which γ, which sign

Three conventions coexist. (i) Some books define γ with $\mu\,\mathrm{d}/\mathrm{d}\mu$ acting on $\ln Z^{-1}$, or write the equation with $-n\gamma$; then $\Delta = \Delta_{\rm cl} - \gamma^*$. Check with (T5.64): in a unitary theory the field's dimension is raised by interactions, so $\gamma^* > 0$ in the convention used here. (ii) The exponent η is $2\gamma^*$, not γ^*, because the two-point function contains two fields. (iii) With the RG time t of (T5.5) the β-function changes sign but γ does not.

Reading Nash (p. 301, Ch. XI §1)

"The renormalisation properties of correlation functions are constrained by the need to obey the Callan–Symanzik renormalisation group equations." Equation (T5.58) is that constraint, and (T5.63) is Nash's remark that at a zero of β the scale dimension differs from the canonical one by the anomalous dimension.

T5.4.2 The one-loop β-function of φ^4 theory

Section T5.3.3 found $\mathrm{d}\lambda/\mathrm{d}t = -3\lambda^2/16\pi^2$ in $d = 4$ by integrating out a shell. We now get the same number from the scattering amplitude, with dimensional regularisation, as it is done in particle physics. The calculation is short, but it uses four standard tools (Feynman parameters, the Wick rotation, the d-dimensional loop integral and the expansion of Γ near its pole), and we derive each of them.

For this subsection only we work in Minkowski space, with metric $\eta = \mathrm{diag}(+1,-1,-1,-1)$, $k^2 = k_0^2 - \vec{k}^2$, Lagrangian $\mathcal{L} = \frac12 \partial_\mu\varphi\,\partial^\mu\varphi - \frac12 m^2\varphi^2 - \frac{\lambda_0}{4!}\varphi^4$, and the Feynman rules: vertex $-i\lambda_0$, propagator $i/(k^2 - m^2 + i0)$, a factor $\int \mathrm{d}^dk/(2\pi)^d$ per loop. For $2 \to 2$ scattering with incoming momenta p_1, p_2 and outgoing p_3, p_4, the Mandelstam variables are $s = (p_1+p_2)^2$, $t = (p_1 - p_3)^2$, $u = (p_1 - p_4)^2$. The tree amplitude is $i\mathcal{M} = -i\lambda_0$.

Step 1: the diagrams and their weight. At order λ_0^2 the amplitude comes from the three diagrams of Figure T5.15. For the s-channel, expand $e^{i\int\mathcal{L}}$ to second order and count the Wick contractions that attach p_1, p_2 to one vertex and p_3, p_4 to the other:

$$\frac{1}{2!}\left(\frac{-i\lambda_0}{4!}\right)^2 \times \underbrace{2\cdot(4\cdot3)\cdot(4\cdot3)\cdot2}_{576} \overset{(1)}{=} \frac{(-i\lambda_0)^2}{2}.$$

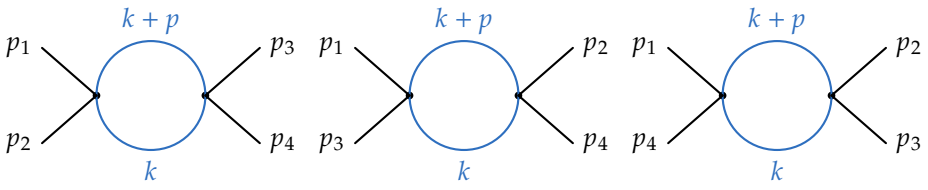

Figure T5.15: The three one-loop corrections to $2 \to 2$ scattering in φ^4 theory. In each, two external lines meet at one vertex and two at the other, and the two vertices are joined by a loop of two propagators; p is the momentum flowing through the loop ($p = p_1 + p_2$, $p_1 - p_3$ or $p_1 - p_4$). What to see: the three diagrams are the same integral evaluated at $p^2 = s, t$ and u, and each has the same logarithmic divergence, which is why the β-function has a factor 3.

(1) Choose the vertex for p_1, p_2 (2 ways), the legs there for p_1 and p_2 ($4 \cdot 3$), the legs at the other vertex for p_3, p_4 ($4 \cdot 3$), and pair the two leftover legs of one vertex with those of the other (2); $576/(2 \cdot 576) = \frac{1}{2}$.

So, with $p = p_1 + p_2$,

$$i\mathcal{M}_s = \frac{(-i\lambda_0)^2}{2} \int \frac{\mathrm{d}^d k}{(2\pi)^d} \frac{i}{k^2 - m^2 + i0} \frac{i}{(k+p)^2 - m^2 + i0} = \frac{\lambda_0^2}{2} I(p^2), \tag{T5.65}$$

where $I(p^2) := \int \frac{\mathrm{d}^d k}{(2\pi)^d} \frac{1}{(k^2-m^2+i0)((k+p)^2-m^2+i0)}$ and $(-i)^2 \cdot i^2 = +1$. The factor $\frac{1}{2}$ is the **symmetry factor** of the bubble: exchanging its two internal lines gives the same diagram.

Step 2: Feynman parameters. Two denominators are combined into one with

$$\frac{1}{AB} = \int_0^1 \frac{\mathrm{d}x}{\big[xA + (1-x)B\big]^2}. \tag{T5.66}$$

To check it, write the denominator as $B + x(A - B)$:

$$\int_0^1 \frac{\mathrm{d}x}{\big[B + x(A-B)\big]^2} \overset{(1)}{=} \Big[-\frac{1}{(A-B)\big(B + x(A-B)\big)}\Big]_0^1 \overset{(2)}{=} \frac{1}{A-B}\Big(\frac{1}{B} - \frac{1}{A}\Big) = \frac{1}{AB}.$$

(1) $\int \mathrm{d}x\,(B + cx)^{-2} = -1/(c(B + cx))$ with $c = A - B$.
(2) Upper limit gives A, lower limit gives B; $\frac{1}{B} - \frac{1}{A} = \frac{A-B}{AB}$.

Take $A = (k+p)^2 - m^2$ and $B = k^2 - m^2$:

$$xA + (1-x)B \overset{(1)}{=} k^2 + 2x\,k \cdot p + x\,p^2 - m^2 \overset{(2)}{=} (k + xp)^2 - \Delta, \qquad \Delta := m^2 - x(1-x)p^2.$$

(1) Expand $(k+p)^2 = k^2 + 2k \cdot p + p^2$ and collect.
(2) $(k + xp)^2 = k^2 + 2xk \cdot p + x^2 p^2$, and $xp^2 - x^2 p^2 = x(1-x)p^2$.

Shift the loop momentum to $\ell = k + xp$ (a shift does not change $\int \mathrm{d}^d k$ over all of momentum space):

$$I(p^2) = \int_0^1 \mathrm{d}x \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \frac{1}{(\ell^2 - \Delta + i0)^2}. \tag{T5.67}$$

Step 3: the Wick rotation. For fixed $\vec{\ell}$ the integrand, as a function of ℓ_0, has double poles where $\ell_0^2 = \vec{\ell}^2 + \Delta - i0$, that is at $\ell_0 = +E - i0$ and $\ell_0 = -E + i0$ with $E = \sqrt{\vec{\ell}^2 + \Delta}$ (take $\Delta > 0$ first). The first lies just below the positive real axis, the second just above the negative real axis (Figure T5.16). So the first and third quadrants contain no poles, and the integration contour along the real axis can be rotated anticlockwise onto the imaginary axis, $\ell_0 = i\ell_E^0$ with ℓ_E^0 real. The arcs at infinity contribute nothing, because the integrand falls like $|\ell_0|^{-4}$. With $\mathrm{d}\ell_0 = i\,\mathrm{d}\ell_E^0$ and $\ell^2 = -(\ell_E^0)^2 - \vec{\ell}^2 := -\ell_E^2$,

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta)^2} \overset{(1)}{=} i\int \frac{\mathrm{d}^d\ell_E}{(2\pi)^d}\,\frac{1}{(-\ell_E^2-\Delta)^2} = i\int \frac{\mathrm{d}^d\ell_E}{(2\pi)^d}\,\frac{1}{(\ell_E^2+\Delta)^2}. \tag{T5.68}$$

(1) Rotate the ℓ_0 contour; the other $d-1$ components are untouched, and together with ℓ_E^0 they form a Euclidean vector ℓ_E.

For $\Delta < 0$ (above threshold) the result is defined by analytic continuation in Δ, which is what the $+i0$ prescription instructs.

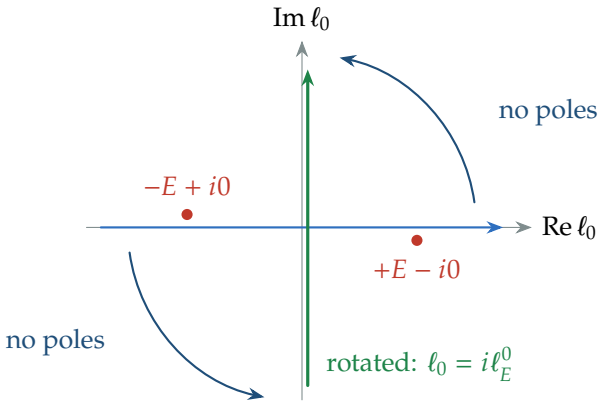

Figure T5.16: The Wick rotation. The poles of the propagators (red) sit just below the positive real axis and just above the negative one. What to see: turning the real contour (blue) anticlockwise by 90° sweeps only through the first and third quadrants, where there are no poles, so the integral along the imaginary axis (green) equals the original one.

Step 4: the d-dimensional integral. For $n > d/2$ and $\Delta > 0$,

$$\int \frac{\mathrm{d}^d\ell_E}{(2\pi)^d}\,\frac{1}{(\ell_E^2+\Delta)^n} \overset{(1)}{=} \frac{1}{\Gamma(n)}\int_0^\infty \mathrm{d}s\; s^{n-1}e^{-s\Delta}\int \frac{\mathrm{d}^d\ell_E}{(2\pi)^d}\,e^{-s\ell_E^2} \overset{(2)}{=} \frac{1}{\Gamma(n)}\int_0^\infty \mathrm{d}s\;\frac{s^{n-1}e^{-s\Delta}}{(4\pi s)^{d/2}}$$
$$\overset{(3)}{=} \frac{\Gamma(n-\frac{d}{2})}{(4\pi)^{d/2}\,\Gamma(n)}\,\Delta^{\frac{d}{2}-n}. \tag{T5.69}$$

(1) $X^{-n} = \frac{1}{\Gamma(n)}\int_0^\infty \mathrm{d}s\; s^{n-1}e^{-sX}$ for $X > 0$ (substitute $s' = sX$ to see it), with $X = \ell_E^2 + \Delta$; then exchange the order of integration.

(2) The Gaussian $\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}e^{-s\ell^2} = (4\pi s)^{-d/2}$ (Section T5.2.5).

(3) $\int_0^\infty \mathrm{d}s\; s^{z-1}e^{-s\Delta} = \Gamma(z)\Delta^{-z}$ with $z = n - \frac{d}{2}$.

The right side makes sense for any complex d with $n - d/2$ not a non-positive integer. **Dimensional regularisation** [evaluate the loop in a dimension where it converges, then continue in d] *defines* the loop integral by this formula. For $n = 2$ and $d = 4$ it has a pole: the logarithmic divergence of the bubble.

Step 5: the pole. Put $d = 4 - \varepsilon$ and $n = 2$. Three expansions are needed:

$$\Gamma\!\left(\tfrac{\varepsilon}{2}\right) \overset{(1)}{=} \frac{2}{\varepsilon} - \gamma_E + O(\varepsilon), \qquad (4\pi)^{-d/2} \overset{(2)}{=} \frac{1}{16\pi^2}\Big(1 + \frac{\varepsilon}{2}\ln 4\pi + O(\varepsilon^2)\Big),$$
$$\left(\frac{\Delta}{\mu^2}\right)^{-\varepsilon/2} \overset{(3)}{=} 1 - \frac{\varepsilon}{2}\ln\frac{\Delta}{\mu^2} + O(\varepsilon^2).$$

(1) $\Gamma(z) = \Gamma(z+1)/z$ and $\Gamma(1+z) = 1 - \gamma_E z + O(z^2)$, with $\gamma_E = 0.5772\ldots$ the Euler constant.
(2) $(4\pi)^{-2+\varepsilon/2} = (4\pi)^{-2} e^{\frac{\varepsilon}{2}\ln 4\pi}$.
(3) $a^{-\varepsilon/2} = e^{-\frac{\varepsilon}{2}\ln a}$. Here μ is an arbitrary mass, inserted to make the argument of the logarithm dimensionless; it will be the renormalisation scale.

Combining (T5.67), (T5.68) and (T5.69), and multiplying and dividing by $\mu^{-\varepsilon}$,

$$I(p^2) \overset{(1)}{=} i\,\mu^{-\varepsilon}\int_0^1 \mathrm{d}x\;\frac{\Gamma(\frac{\varepsilon}{2})}{(4\pi)^{d/2}}\left(\frac{\Delta}{\mu^2}\right)^{-\varepsilon/2}$$
$$\overset{(2)}{=} \frac{i\,\mu^{-\varepsilon}}{16\pi^2}\left[\frac{2}{\varepsilon} - \gamma_E + \ln 4\pi - \int_0^1 \mathrm{d}x\;\ln\frac{m^2 - x(1-x)p^2}{\mu^2}\right] + O(\varepsilon). \tag{T5.70}$$

(1) $\Delta^{d/2-2} = \Delta^{-\varepsilon/2} = \mu^{-\varepsilon}(\Delta/\mu^2)^{-\varepsilon/2}$, and $\Gamma(2) = 1$.
(2) Multiply the three expansions and keep terms up to $O(\varepsilon^0)$: the $\frac{2}{\varepsilon}$ times each $O(\varepsilon)$ correction gives the finite terms.

Step 6: renormalise and read off β. Add the three channels. The pole is the same in each, and the amplitude is

$$\mathcal{M} \overset{(1)}{=} -\lambda_0 + \frac{\lambda_0^2}{2i}\big[I(s) + I(t) + I(u)\big] \overset{(2)}{=} -\lambda_0 + \frac{3\lambda_0^2\mu^{-\varepsilon}}{16\pi^2\,\varepsilon} + (\text{finite}). \tag{T5.71}$$

(1) Divide $i\mathcal{M}$ by i; tree plus (T5.65) for each channel.
(2) Each I contributes $\frac{i\mu^{-\varepsilon}}{16\pi^2}\frac{2}{\varepsilon}$; three channels and the prefactor $\frac{1}{2}$ give $3\cdot\frac{1}{2}\cdot\frac{2}{\varepsilon} = \frac{3}{\varepsilon}$.

In terms of the renormalised coupling of (T5.55), written as $\lambda_0 = \mu^\varepsilon\big(\lambda + a\lambda^2/\varepsilon + O(\lambda^3)\big)$ (the field is not renormalised at one loop, Example T5.13), (T5.71) is

$$\mu^{-\varepsilon}\mathcal{M} = -\lambda - \frac{a\lambda^2}{\varepsilon} + \frac{3\lambda^2}{16\pi^2\varepsilon} + (\text{finite}) + O(\lambda^3),$$

which is finite exactly when $a = 3/16\pi^2$. Now hold λ_0 fixed:

$$0 \overset{(1)}{=} \mu\frac{\mathrm{d}\lambda_0}{\mathrm{d}\mu} \overset{(2)}{=} \mu^\varepsilon\left[\varepsilon\left(\lambda + \frac{a\lambda^2}{\varepsilon}\right) + \left(1 + \frac{2a\lambda}{\varepsilon}\right)\beta(\lambda)\right]$$
$$\Longrightarrow \quad \beta(\lambda) \overset{(3)}{=} -\varepsilon\left(\lambda + \frac{a\lambda^2}{\varepsilon}\right)\left(1 - \frac{2a\lambda}{\varepsilon} + O(\lambda^2)\right) \overset{(4)}{=} -\varepsilon\lambda + a\lambda^2 + O(\lambda^3). \tag{T5.72}$$

(1) The bare coupling does not know about μ.
(2) Differentiate μ^ε (giving $\varepsilon\mu^\varepsilon$) and the bracket (giving $(1 + 2a\lambda/\varepsilon)\,\mu\,\mathrm{d}\lambda/\mathrm{d}\mu$).
(3) Solve for β and expand $(1 + 2a\lambda/\varepsilon)^{-1}$ to first order in λ.
(4) Multiply out: $-\varepsilon\lambda - a\lambda^2 + 2a\lambda^2$. The poles in $1/\varepsilon$ cancel, as they must for a finite β.

Key idea: one-loop β-function of φ^4

$$\beta(\lambda) = \mu\frac{\mathrm{d}\lambda}{\mathrm{d}\mu} = -\varepsilon\lambda + \frac{3\lambda^2}{16\pi^2} + O(\lambda^3), \qquad \text{so in } d=4: \quad \beta = \frac{3\lambda^2}{16\pi^2}. \tag{T5.73}$$

Check against Wilson's shell integration. In the convention of (T5.5) this is $\mathrm{d}\lambda/\mathrm{d}t = \varepsilon\lambda - 3\lambda^2/16\pi^2$, the same coefficient that the sharp-cutoff shell calculation gave in (T5.54). The fixed point $\lambda^* = 16\pi^2\varepsilon/3$ is the Wilson–Fisher point: in Wilson's variable $\bar{u} = K_4\lambda = \lambda/8\pi^2$ it is $\bar{u}^* = \frac{2}{3}\varepsilon$, as in Example T5.14, and its slope $\beta'(\lambda^*) = -\varepsilon + 2\cdot\frac{3}{16\pi^2}\lambda^* = \varepsilon$ is the eigenvalue $y_{\mathrm{irr}} = -\varepsilon$ with the sign flipped. Why do two quite different schemes agree? For a marginal coupling the one-loop coefficient is scheme independent. If a second scheme uses $\lambda' = \lambda + c\lambda^2 + \cdots$, then

$$\beta'(\lambda') \overset{(1)}{=} \mu\frac{\mathrm{d}\lambda'}{\mathrm{d}\mu} \overset{(2)}{=} (1+2c\lambda)\,b\lambda^2 + O(\lambda^4) \overset{(3)}{=} b\lambda'^2 + O(\lambda'^3),$$

(1) Definition of β in the new scheme.
(2) Chain rule, $\mathrm{d}\lambda'/\mathrm{d}\lambda = 1 + 2c\lambda$, and $\beta(\lambda) = b\lambda^2 + O(\lambda^3)$ in $d = 4$.
(3) $\lambda^2 = \lambda'^2 + O(\lambda'^3)$; the change starts at order λ^3.

so b is the same in every scheme (the location of a fixed point in $d < 4$ is not, as the LPA showed, but its eigenvalues are).

Worked example T5.18: The β-function from μ-independence of the amplitude

Take $m = 0$ and Euclidean momenta, so $s, t, u < 0$ and every logarithm is real. From (T5.70), $\int_0^1 \mathrm{d}x\,\ln\!\big(x(1-x)(-s)/\mu^2\big) = \ln(-s/\mu^2) - 2$ (use $\int_0^1 \ln x\,\mathrm{d}x = -1$ twice). After the pole is removed, at $\varepsilon \to 0$,

$$\mathcal{M} = -\lambda(\mu) + \frac{\lambda^2}{32\pi^2}\sum_{q^2=s,t,u}\left[2 - \gamma_E + \ln 4\pi - \ln\frac{-q^2}{\mu^2}\right] + O(\lambda^3).$$

A physical amplitude cannot depend on the bookkeeping scale μ:

$$0 = \mu\frac{\mathrm{d}\mathcal{M}}{\mathrm{d}\mu} \overset{(1)}{=} -\beta(\lambda) + \frac{\lambda^2}{32\pi^2}\cdot 3\cdot 2 + O(\lambda^3) \quad\Longrightarrow\quad \beta(\lambda) \overset{(2)}{=} \frac{3\lambda^2}{16\pi^2}.$$

(1) $\mu\,\partial_\mu$ acting on $-\ln(-q^2/\mu^2)$ gives $+2$ for each of the three channels; $\mu\,\mathrm{d}\lambda/\mathrm{d}\mu = \beta$ acts on the tree term. The derivative of the λ^2 prefactor gives $O(\lambda^3)$.
(2) $6/32\pi^2 = 3/16\pi^2$.

The same logarithms say what "running" means: at large momentum transfer $Q^2 = -s$ the one-loop amplitude grows like $\lambda + \frac{3\lambda^2}{16\pi^2}\ln\frac{Q}{\mu}$, which is the first term of $\bar{\lambda}(\ln\frac{Q}{\mu}) = \lambda/(1 - \frac{3\lambda}{16\pi^2}\ln\frac{Q}{\mu})$. For $\lambda = 1$ at μ the Landau pole sits at $\ln(Q/\mu) = 16\pi^2/3 \approx 52.6$, some 10^{22} times higher: harmless in practice, but a sign that φ^4 theory in $d = 4$ needs new physics at some short distance.

Worked example T5.19: The $O(N)$ model: $\beta = (N+8)\lambda^2/48\pi^2$

Take N scalars φ_a with potential $\frac{\lambda}{4!}(\varphi_a\varphi_a)^2$. Its fourth derivative is the vertex $-i\lambda\,S_{abcd}/3$ with $S_{abcd} := \delta_{ab}\delta_{cd} + \delta_{ac}\delta_{bd} + \delta_{ad}\delta_{bc}$ (check at $N = 1$: $S = 3$, vertex $-i\lambda$). The s-channel

bubble carries the internal sum

$$\sum_{e,f} S_{abef} S_{efcd} \overset{(1)}{=} N\,\delta_{ab}\delta_{cd} + 4\,\delta_{ab}\delta_{cd} + 2\,\delta_{ac}\delta_{bd} + 2\,\delta_{ad}\delta_{bc}$$
$$\overset{(2)}{=} (N+4)\,\delta_{ab}\delta_{cd} + 2\,\delta_{ac}\delta_{bd} + 2\,\delta_{ad}\delta_{bc}.$$

(1) Multiply out the nine products. The product $\delta_{ab}\delta_{ef}\cdot\delta_{ef}\delta_{cd}$ has a free sum $\delta_{ee}=N$. The four products that contain exactly one of $\delta_{ab}\delta_{ef}$ and $\delta_{ef}\delta_{cd}$ each give $\delta_{ab}\delta_{cd}$. Of the four remaining products, two give $\delta_{ac}\delta_{bd}$ and two give $\delta_{ad}\delta_{bc}$.
(2) Collect the $\delta_{ab}\delta_{cd}$ terms.

The t- and u-channels are the same with (b,c) and (b,d) exchanged. Adding the three channels,

$$\sum_{\text{channels}} \overset{(1)}{=} (N+4+2+2)\left(\delta_{ab}\delta_{cd}+\delta_{ac}\delta_{bd}+\delta_{ad}\delta_{bc}\right) \overset{(2)}{=} (N+8)\,S_{abcd}.$$

(1) Each structure gets $N+4$ from the channel in which it is the "$\delta_{ab}\delta_{cd}$" structure and 2 from each of the other two.
(2) The definition of S_{abcd}.

At $N=1$ the same sum is $9\,S_{abcd}$, so the one-loop pole of the four-point vertex is $\frac{N+8}{9}$ times its $N=1$ value. Hence

$$\beta(\lambda) = -\varepsilon\lambda + \frac{N+8}{9}\cdot\frac{3\lambda^2}{16\pi^2} = -\varepsilon\lambda + \frac{(N+8)\lambda^2}{48\pi^2}, \qquad \lambda^* = \frac{48\pi^2\varepsilon}{N+8}.$$

At $N=1$ this is (T5.73). The factor $N+8$ is the one that appears in the $O(N)$ exponents, for example $\eta=(N+2)\varepsilon^2/(2(N+8)^2)$ quoted after Example T5.15.

T5.4.3 Yang–Mills theory at one loop: the background-field method

The β-function of Yang–Mills theory is the most consequential number in this chapter. Its sign decides that quarks are almost free at short distances and confined at long ones, it produces Λ_{QCD} by dimensional transmutation (Example T5.28), and it sets the size of the trace anomaly (Section T5.5.3). We compute it with the **background-field method**, which reduces the problem to a single two-point function [Abbott 1981].

Conventions. Euclidean signature. Hermitian generators T^a in a representation r, with $[T^a,T^b]=if^{abc}T^c$ and $\mathrm{tr}(T^aT^b)=T(r)\,\delta^{ab}$. For SU($N$) the fundamental has $T(\mathrm{fund})=\frac12$, and the adjoint, with matrices $(T^a_{\mathrm{adj}})_{bc}=-if^{abc}$, has $T(\mathrm{adj})=N$, which is the identity $\sum_{c,d} f^{acd}f^{bcd}=N\delta^{ab}$. The gauge field is $A_\mu=A^a_\mu T^a$ with the coupling absorbed, so that

$$S_{\mathrm{YM}} = \frac{1}{4g^2}\int \mathrm{d}^4x\; F^a_{\mu\nu}F^a_{\mu\nu}, \qquad F^a_{\mu\nu}=\partial_\mu A^a_\nu - \partial_\nu A^a_\mu + f^{abc}A^b_\mu A^c_\nu, \tag{T5.74}$$

matter in r has $D_\mu=\partial_\mu - iA_\mu$ and $[D_\mu,D_\nu]=-iF_{\mu\nu}$ with $F_{\mu\nu}=F^a_{\mu\nu}T^a$, and an adjoint field X^a has $(D_\mu X)^a=\partial_\mu X^a + f^{abc}A^b_\mu X^c$. (In the anti-Hermitian convention of Chapter T3, $A_{\mathrm{math}}=-iA$ and $F_{\mathrm{math}}=-iF$. Rescaling $A=gA_c$ gives the canonical normalisation $\frac14 F_cF_c$, with g in the commutator.)

Worked example T5.20: SU(2): the adjoint is the vector representation

For SU(2), $f^{abc} = \epsilon^{abc}$ and $T^a = \sigma^a/2$ in the fundamental, so $\mathrm{tr}(T^3T^3) = \frac{1}{4}\,\mathrm{tr}(\sigma^3)^2 = \frac{1}{2}$. The adjoint matrices $(T^a)_{bc} = -i\epsilon^{abc}$ are

$$T^3_{\text{adj}} = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad \mathrm{tr}\big(T^3_{\text{adj}} T^3_{\text{adj}}\big) \overset{(1)}{=} (-i)(i) + (i)(-i) = 2 = N.$$

(1) The only non-zero entries are $(T^3)_{12} = -i\epsilon^{312} = -i$ and $(T^3)_{21} = -i\epsilon^{321} = i$; the trace of the square is $\sum_{b,c}(T^3)_{bc}(T^3)_{cb} = (T^3)_{12}(T^3)_{21} + (T^3)_{21}(T^3)_{12}$.

T^3_{adj} has eigenvalues $+1, 0, -1$: the three gluons of SU(2) carry charges ± 1 and 0 under the T^3 direction. The ratio $T(\text{adj})/T(\text{fund}) = 2N = 4$ is used again in Section T5.7.2.

Step 1: the background field and its gauge invariance. Split the gauge field into a fixed classical background and a fluctuation,

$$A_\mu = \bar{A}_\mu + a_\mu,$$

and integrate over a only. Write $\bar{D}$ and $\bar{F}$ for the covariant derivative and curvature of $\bar{A}$. Expanding (T5.74),

$$F^a_{\mu\nu} \overset{(1)}{=} \bar{F}^a_{\mu\nu} + (\bar{D}_\mu a_\nu)^a - (\bar{D}_\nu a_\mu)^a + f^{abc} a^b_\mu a^c_\nu,$$

(1) The terms linear in a are $\partial_\mu a^a_\nu - \partial_\nu a^a_\mu + f^{abc}(\bar{A}^b_\mu a^c_\nu + a^b_\mu \bar{A}^c_\nu)$; in the last one relabel $b \leftrightarrow c$ and use $f^{acb} = -f^{abc}$ to get $-f^{abc}\bar{A}^b_\nu a^c_\mu$. Grouping gives $(\bar{D}_\mu a_\nu)^a - (\bar{D}_\nu a_\mu)^a$.

We fix the gauge of the fluctuation with the **background-field gauge** $(\bar{D}_\mu a_\mu)^a = 0$, imposed by adding $\frac{1}{2g^2}\int (\bar{D}_\mu a_\mu)^a (\bar{D}_\nu a_\nu)^a$ to the action (Feynman gauge). Here is the point of the method. Under a gauge transformation of the *background*, $\bar{A} \mapsto U\bar{A}U^{-1} + iU\partial U^{-1}$ together with $a \mapsto UaU^{-1}$, the total A transforms as a gauge field, the action is invariant, and $\bar{D}_\mu a_\mu$ rotates covariantly, so the gauge-fixing term is invariant too. Hence the effective action $\Gamma[\bar{A}]$ obtained by integrating out a is a gauge-invariant functional of $\bar{A}$. Its divergent part must be a local, gauge-invariant functional of dimension four, and there is only one:

$$\Gamma[\bar{A}] = \frac{1}{4}\Big(\frac{1}{g_0^2} + \delta\Big)\int \bar{F}^a_{\mu\nu}\bar{F}^a_{\mu\nu} + (\text{finite}).$$

So the renormalisation of g is read off from the coefficient of $\bar{F}^2$, and that coefficient can be found from the part of Γ that is quadratic in $\bar{A}$, where $\bar{F}^2$ reduces to $(\partial_\mu \bar{A}^a_\nu - \partial_\nu \bar{A}^a_\mu)^2$. The quadratic part is a two-point function of the background: the **vacuum polarisation**.

Step 2: the quadratic action of the fluctuations. Keep the terms of $\frac{1}{4}F^aF^a$ quadratic in a, add the gauge-fixing term, and integrate by parts.

$$\tfrac{1}{4}F^aF^a\big|_{a^2} \overset{(1)}{=} \tfrac{1}{2}(\bar{D}_\mu a_\nu)^a(\bar{D}_\mu a_\nu)^a - \tfrac{1}{2}(\bar{D}_\mu a_\nu)^a(\bar{D}_\nu a_\mu)^a + \tfrac{1}{2}\bar{F}^a_{\mu\nu} f^{abc} a^b_\mu a^c_\nu,$$

$$-\tfrac{1}{2}\int (\bar{D}_\mu a_\nu)^a(\bar{D}_\nu a_\mu)^a \overset{(2)}{=} \tfrac{1}{2}\int a^a_\nu\big(\bar{D}_\mu\bar{D}_\nu a_\mu\big)^a \overset{(3)}{=} \tfrac{1}{2}\int a^a_\nu\big(\bar{D}_\nu\bar{D}_\mu a_\mu + [\bar{D}_\mu,\bar{D}_\nu]a_\mu\big)^a$$

$$\overset{(4)}{=} -\tfrac{1}{2}\int (\bar{D}_\mu a_\mu)^a(\bar{D}_\nu a_\nu)^a + \tfrac{1}{2}\int a^a_\nu f^{abc}\bar{F}^b_{\mu\nu}a^c_\mu,$$

$$\tfrac{1}{2}\,a^a_\nu f^{abc}\bar{F}^b_{\mu\nu}a^c_\mu \overset{(5)}{=} \tfrac{1}{2}\,\bar{F}^a_{\mu\nu}f^{abc}a^b_\mu a^c_\nu.$$

(1) Square the linear term, $(\bar D_\mu a_\nu - \bar D_\nu a_\mu)^2 = 2(\bar D_\mu a_\nu)^2 - 2(\bar D_\mu a_\nu)(\bar D_\nu a_\mu)$ summed over μ,ν, and keep the cross term $2\bar F^a_{\mu\nu} f^{abc} a^b_\mu a^c_\nu$ between $\bar F$ and the quadratic part of F.
(2) Integrate by parts; for adjoint fields $\int X^a (\bar D_\mu Y)^a = -\int (\bar D_\mu X)^a Y^a$ because f^{abc} is antisymmetric.
(3) Commute the two derivatives.
(4) Integrate the first term by parts again. For adjoint fields $([\bar D_\mu, \bar D_\nu]X)^a = f^{abc}\bar F^b_{\mu\nu} X^c$ (the adjoint case of $[D_\mu, D_\nu] = -iF_{\mu\nu}$, with $-iT^b_{\text{adj}}$ having entries $-f^{bac} = f^{abc}$).
(5) Rename $a \to b$, $b \to a$ (using $f^{bac} = -f^{abc}$), then swap $\mu \leftrightarrow \nu$ (using $\bar F_{\nu\mu} = -\bar F_{\mu\nu}$).

The $-\frac12(\bar D\cdot a)^2$ cancels the gauge-fixing term exactly, the two $\frac12 \bar F f a a$ terms add, and one more integration by parts turns $\frac12(\bar D a)^2$ into $\frac12 a(-\bar D^2 a)$:

$$S_2 = \frac{1}{2g^2}\int a^b_\mu \Big[(-\bar D^2)^{bc}\,\delta_{\mu\nu} + 2f^{abc}\bar F^a_{\mu\nu}\Big] a^c_\nu \coloneqq \frac{1}{2g^2}\int a\,\big(-\bar D^2 + X\big)a, \qquad X^{bc}_{\mu\nu} = 2f^{abc}\bar F^a_{\mu\nu}. \tag{T5.75}$$

The operator has two parts. $-\bar D^2$ is the kinetic operator of four adjoint scalars $a_1,\dots,a_4$: it describes how a charged particle's *orbit* responds to the field. X mixes the Lorentz index μ with ν in proportion to $\bar F_{\mu\nu}$: it is the coupling of the gluon's *spin* to the field, a magnetic-moment term. (With the spin-1 generators $(J_{\rho\sigma})_{\mu\nu} = \delta_{\rho\mu}\delta_{\sigma\nu} - \delta_{\sigma\mu}\delta_{\rho\nu}$ one has $X = \bar F^a_{\rho\sigma}(J_{\rho\sigma})\otimes(\cdots)$ with gyromagnetic factor 2.)

Step 3: the one-loop effective action. The Faddeev–Popov operator of the gauge $\bar D_\mu a_\mu = 0$ is $\bar D_\mu D_\mu$, which is $\bar D^2$ at one loop, so the ghosts are two anticommuting adjoint scalars with action $\int \bar c^a(-\bar D^2)^{ab}c^b$. Add n_f Dirac fermions in the fundamental, with action $\int \bar\psi\gamma_\mu D_\mu\psi$. Doing the three Gaussian integrals (a real bosonic Gaussian gives $\det^{-1/2}$, a pair of Grassmann variables gives $\det^{+1}$),

$$\Gamma_1[\bar A] = \tfrac12 \ln\det\big(-\bar D^2 + X\big)_{\text{adj, vector}} - \ln\det\big(-\bar D^2\big)_{\text{adj}} - n_f \ln\det\big(\gamma_\mu \bar D_\mu\big)_{\text{fund}}. \tag{T5.76}$$

For the fermions use $\det \vec{\not D} = \det(-\vec{\not D}^2)^{1/2}$ (the eigenvalues of the anti-Hermitian $\vec{\not D}$ come in pairs $\pm i\lambda$) and

$$\vec{\not D}^2 \overset{(1)}{=} \tfrac12\{\gamma_\mu,\gamma_\nu\}\bar D_\mu\bar D_\nu + \tfrac14[\gamma_\mu,\gamma_\nu][\bar D_\mu,\bar D_\nu] \overset{(2)}{=} \bar D^2 - \tfrac{i}{2}\gamma_{\mu\nu}\bar F_{\mu\nu}, \qquad \gamma_{\mu\nu} \coloneqq \tfrac12[\gamma_\mu,\gamma_\nu], \tag{T5.77}$$

(1) Write $\gamma_\mu\gamma_\nu$ as its symmetric plus antisymmetric part, and do the same for $\bar D_\mu\bar D_\nu$; the mixed products vanish when summed.
(2) $\{\gamma_\mu,\gamma_\nu\} = 2\delta_{\mu\nu}$ (Euclidean, Chapter T4) and $[\bar D_\mu,\bar D_\nu] = -i\bar F_{\mu\nu}$.

so $-\vec{\not D}^2 = -\bar D^2 + X_f$ with $X_f = \frac{i}{2}\gamma_{\mu\nu}\bar F_{\mu\nu}$, the spin coupling of the fermion. Every term in (T5.76) is now of the form $\ln\det(-\bar D^2 + \text{spin term})$, and we need only two master calculations.

Step 4 (master calculation A): the orbital part. Let $\Gamma_s[\bar A] \coloneqq \ln\det(-\bar D^2)$ for one *complex* scalar in a representation r (this is minus the log of $\int \mathcal{D}\phi^\dagger\mathcal{D}\phi\, e^{-\int\phi^\dagger(-\bar D^2)\phi}$). Expand $-\bar D^2 = -\partial^2 + V_1 + V_2$ in powers of $\bar A$, with $V_1 = i(\partial_\mu\bar A_\mu + \bar A_\mu\partial_\mu)$ (an operator: first multiply by $\bar A_\mu$, then differentiate, plus the other order) and $V_2 = \bar A_\mu\bar A_\mu$. With $G = (-\partial^2)^{-1}$ and $\ln\det = \operatorname{Tr}\ln$,

$$\Gamma_s\big|_{\bar A^2} \overset{(1)}{=} \operatorname{Tr}\big(GV_2\big) - \tfrac12\operatorname{Tr}\big(GV_1GV_1\big) \overset{(2)}{=} \frac12\int_p \bar A^a_\mu(-p)\bar A^b_\nu(p)\,T(r)\,\delta^{ab}\,\Pi_{\mu\nu}(p),$$

$$\Pi_{\mu\nu}(p) \overset{(3)}{=} 2\delta_{\mu\nu}\int_k \frac{1}{k^2} - \int_k \frac{(2k+p)_\mu(2k+p)_\nu}{k^2\,(k+p)^2},$$

(1) $\operatorname{Tr}\ln(G^{-1}+V)=\operatorname{Tr}\ln G^{-1}+\operatorname{Tr}(GV)-\frac12\operatorname{Tr}(GVGV)+\cdots$, the matrix identity $\ln(1+Y)=Y-\frac12Y^2+\cdots$ with $Y=GV$; keep the terms with two powers of $\bar A$.
(2) In momentum space V_1 takes a plane wave e^{ikx} to one of momentum $k+p$ with amplitude $i\cdot i(2k+p)_\mu\bar A_\mu(p)=-(2k+p)_\mu\bar A_\mu(p)$; the colour trace gives $\operatorname{tr}(T^aT^b)=T(r)\delta^{ab}$; we write $\int_k$ for $\int\frac{\mathrm{d}^dk}{(2\pi)^d}$.
(3) The first term is the "seagull" V_2, the second the loop with two V_1 vertices.

In dimensional regularisation $\int_k k^{-2}=0$ (it has no scale to depend on). The second integral is done exactly as the bubble: Feynman parameter x, shift $\ell=k+xp$ so that $2k+p=2\ell+(1-2x)p$ and the denominator is $(\ell^2+\Delta)^2$ with $\Delta=x(1-x)p^2$, then (T5.69). The term linear in ℓ vanishes by symmetry and $\ell_\mu\ell_\nu\to\delta_{\mu\nu}\ell^2/d$:

$$\begin{aligned}\Pi_{\mu\nu}&\overset{(1)}{=}-\int_0^1\mathrm{d}x\Big[\frac{4\delta_{\mu\nu}}{d}\int_\ell\frac{\ell^2}{(\ell^2+\Delta)^2}+(1-2x)^2p_\mu p_\nu\int_\ell\frac{1}{(\ell^2+\Delta)^2}\Big]\\&\overset{(2)}{=}-\frac{\Gamma(2-\frac d2)}{(4\pi)^{d/2}}\int_0^1\mathrm{d}x\,\Delta^{\frac d2-2}\Big[\frac{2\Delta}{1-\frac d2}\,\delta_{\mu\nu}+(1-2x)^2p_\mu p_\nu\Big]\\&\overset{(3)}{=}\frac{\Gamma(2-\frac d2)}{(4\pi)^{d/2}}\,(p^2)^{\frac d2-2}\,C_d\,\big(p^2\delta_{\mu\nu}-p_\mu p_\nu\big),\qquad C_d:=\int_0^1\mathrm{d}x\,(1-2x)^2\big(x(1-x)\big)^{\frac d2-2}.\end{aligned}$$

(1) Insert the numerator $4\ell_\mu\ell_\nu+(1-2x)^2p_\mu p_\nu$ and average $\ell_\mu\ell_\nu$ over directions.
(2) Write $\ell^2=(\ell^2+\Delta)-\Delta$ and use (T5.69) with $n=1,2$: $\frac4d\big[\frac{\Gamma(1-\frac d2)}{(4\pi)^{d/2}}\Delta^{\frac d2-1}-\frac{\Gamma(2-\frac d2)}{(4\pi)^{d/2}}\Delta^{\frac d2-1}\big]$, and $\Gamma(1-\frac d2)=\Gamma(2-\frac d2)/(1-\frac d2)$, so the bracket is $\frac{\Gamma(2-\frac d2)}{(4\pi)^{d/2}}\Delta^{\frac d2-1}\frac{d/2}{1-d/2}$; times $\frac4d$ this is $\frac{2\Delta}{1-d/2}$.
(3) Integration by parts in x: $0=\int_0^1\mathrm{d}x\,\frac{\mathrm{d}}{\mathrm{d}x}\big[(x(1-x))^{\frac d2-1}(1-2x)\big]=(\frac d2-1)\int(1-2x)^2(x(1-x))^{\frac d2-2}-2\int(x(1-x))^{\frac d2-1}$, so $\int\frac{2\Delta^{d/2-1}}{1-d/2}\mathrm{d}x=-(p^2)^{\frac d2-1}C_d$.

The result is exactly *transverse*, $p_\mu\Pi_{\mu\nu}=0$, as background gauge invariance demands. At $d=4-\varepsilon$: $\Gamma(\frac\varepsilon2)=\frac2\varepsilon+\cdots$ and $C_4=\int_0^1(1-2x)^2\mathrm{d}x=\frac13$. Since $\frac12\int_p\bar A^a_\mu(-p)\big(p^2\delta_{\mu\nu}-p_\mu p_\nu\big)\bar A^a_\nu(p)=\frac14\int(\partial_\mu\bar A^a_\nu-\partial_\nu\bar A^a_\mu)^2$, we get

$$\Gamma_s\big|_{\bar F^2}=\frac14\cdot\frac{T(r)}{3}\,L(p)\int\bar F^a_{\mu\nu}\bar F^a_{\mu\nu},\qquad L(p):=\frac{1}{16\pi^2}\Big(\frac2\varepsilon-\ln\frac{p^2}{\mu^2}+\text{const}\Big).\tag{T5.78}$$

(With a momentum cutoff instead, $L(p)=\frac{1}{16\pi^2}\ln\frac{\Lambda^2}{p^2}$.) A charged scalar *increases* the coefficient of $\bar F^2$ at long distances: it screens the charge, like the electron–positron pairs of QED. This is the magnetic response of the orbital motion of charges: Landau diamagnetism.

Step 5 (master calculation B): the spin part. For an operator $-\bar D^2+X$ with X linear in $\bar F$, the new terms quadratic in the background come from two insertions of X (a cross term of X with the orbital vertex V_1 has a vanishing Lorentz trace, because $X_{\mu\nu}$ is antisymmetric in the gluon case and $\operatorname{tr}\gamma_{\mu\nu}=0$ in the fermion case):

$$\begin{aligned}\ln\det\big(-\bar D^2+X\big)-\ln\det\big(-\bar D^2\big)&\overset{(1)}{=}-\tfrac12\operatorname{Tr}\big(GXGX\big)+\cdots\overset{(2)}{=}-\frac12\int_p\operatorname{tr}X(-p)X(p)\int_k\frac{1}{k^2(k+p)^2}\\&\overset{(3)}{=}-\frac12\,L(p)\int\operatorname{tr}X^2.\end{aligned}\tag{T5.79}$$

(1) The second-order term of $\operatorname{Tr}\ln(G^{-1}+X)$, as in step 4.

(2) X has no derivatives, so each insertion just transfers momentum; the trace tr is over colour and spin (or Lorentz) indices.

(3) The loop is (T5.70) at $m = 0$ in Euclidean form, $\int_k \frac{1}{k^2(k+p)^2} = \frac{1}{16\pi^2}\big(\frac{2}{\varepsilon} - \ln\frac{p^2}{\mu^2} + \cdots\big) = L(p)$; in position space $\int_p \operatorname{tr} X(-p)X(p) = \int \mathrm{d}^4x\ \operatorname{tr} X^2$.

The two traces we need are:

$$\text{gluon:}\quad \operatorname{tr} X^2 \overset{(1)}{=} 4 f^{abc} f^{dcb} \bar F^a_{\mu\nu} \bar F^d_{\nu\mu} \overset{(2)}{=} 4 f^{abc} f^{dbc} \bar F^a_{\mu\nu} \bar F^d_{\mu\nu} \overset{(3)}{=} 4N\, \bar F^a_{\mu\nu} \bar F^a_{\mu\nu},$$

$$\text{fermion:}\quad \operatorname{tr} X_f^2 \overset{(4)}{=} -\tfrac14 \operatorname{tr}\big(\gamma_{\mu\nu}\gamma_{\rho\sigma}\big)\ \operatorname{tr}\big(\bar F_{\mu\nu}\bar F_{\rho\sigma}\big) \overset{(5)}{=} -T(r)\big(\delta_{\mu\sigma}\delta_{\nu\rho} - \delta_{\mu\rho}\delta_{\nu\sigma}\big)\bar F^a_{\mu\nu}\bar F^a_{\rho\sigma} \overset{(6)}{=} 2T(r)\, \bar F^a_{\mu\nu}\bar F^a_{\mu\nu}.$$

(1) $\operatorname{tr} X^2 = \sum X^{bc}_{\mu\nu} X^{cb}_{\nu\mu}$ with $X^{bc}_{\mu\nu} = 2 f^{abc} \bar F^a_{\mu\nu}$ from (T5.75).

(2) $f^{dcb} = -f^{dbc}$ and $\bar F^d_{\nu\mu} = -\bar F^d_{\mu\nu}$.

(3) $\sum_{b,c} f^{abc} f^{dbc} = N\delta^{ad}$.

(4) $X_f = \frac{i}{2}\gamma_{\mu\nu}\bar F_{\mu\nu}$, so $X_f^2 = -\frac14 \gamma_{\mu\nu}\gamma_{\rho\sigma}\bar F_{\mu\nu}\bar F_{\rho\sigma}$; the trace factorises into a spinor trace and a colour trace.

(5) $\operatorname{tr}(\gamma_{\mu\nu}\gamma_{\rho\sigma}) = 4(\delta_{\mu\sigma}\delta_{\nu\rho} - \delta_{\mu\rho}\delta_{\nu\sigma})$ for 4×4 Euclidean gamma matrices (from $\operatorname{tr}\gamma_\mu\gamma_\nu\gamma_\rho\gamma_\sigma = 4(\delta_{\mu\nu}\delta_{\rho\sigma} - \delta_{\mu\rho}\delta_{\nu\sigma} + \delta_{\mu\sigma}\delta_{\nu\rho})$ with $\mu\neq\nu$, $\rho\neq\sigma$), and $\operatorname{tr}(\bar F_{\mu\nu}\bar F_{\rho\sigma}) = T(r)\bar F^a_{\mu\nu}\bar F^a_{\rho\sigma}$.

(6) The first term gives $\bar F^a_{\mu\nu}\bar F^a_{\nu\mu} = -\bar F^a_{\mu\nu}\bar F^a_{\mu\nu}$.

Both are positive. Inserted in (T5.79) with the minus sign, a spin coupling *decreases* the coefficient of $\bar F^2$ for bosons: the spins line up with the field and lower its energy, which is Pauli paramagnetism. For fermions the overall sign of the determinant is reversed.

Step 6: add up. Write each contribution to Γ_1 as $\frac14 c\, L(p) \int \bar F^a \bar F^a$. A real field in a real representation gives half of a complex one; the vector a_μ has four components and the Dirac spinor four.

term of (T5.76)	origin	c	how
gluon, orbital	$\frac12 \cdot 4\,\Gamma_s(\text{adj})$	$+\frac{2N}{3}$	(T5.78), four real adjoint scalars
gluon, spin	$\frac12\cdot\big(-\frac12\big)\operatorname{tr} X^2$	$-4N$	(T5.79): $\frac12\cdot\frac12\cdot 4N\cdot 4 = 4N$
ghosts	$-\Gamma_s(\text{adj})$	$-\frac{N}{3}$	(T5.78), Grassmann sign
quarks, orbital	$-n_f\cdot\frac12\cdot 4\,\Gamma_s(\text{fund})$	$-\frac{n_f}{3}$	$2n_f\cdot\frac{T_F}{3}$ with $T_F=\frac12$
quarks, spin	$-n_f\cdot\frac12\cdot\big(-\frac12\big)\operatorname{tr} X_f^2$	$+n_f$	$\frac14\cdot 2T_F\cdot 4\,n_f$
total		$\frac{2N}{3} - 4N - \frac{N}{3} - \frac{n_f}{3} + n_f = -\big(\frac{11N}{3} - \frac{2n_f}{3}\big)$	

(In the "how" column the spin entries convert $-\frac12 L\int \operatorname{tr} X^2$ into the form $\frac14 cL\int \bar F^2$: for the gluon, $\frac12\cdot(-\frac12)\cdot 4N = -N = \frac14\cdot(-4N)$.) So

$$\Gamma[\bar A] = \frac14\Big[\frac{1}{g_0^2} - b_0\, L(p)\Big]\int \bar F^a_{\mu\nu}\bar F^a_{\mu\nu}, \qquad b_0 := \frac{11N}{3} - \frac{2n_f}{3}. \tag{T5.80}$$

In minimal subtraction the bare coupling absorbs the pole, $\frac{1}{g_0^2} = \mu^{-\varepsilon}\big[\frac{1}{g^2(\mu)} + \frac{b_0}{16\pi^2}\frac{2}{\varepsilon}\big]$, and what is left is the finite *effective coupling at momentum* p,

$$\frac{1}{g^2_{\text{eff}}(p)} = \frac{1}{g^2(\mu)} + \frac{b_0}{16\pi^2}\ln\frac{p^2}{\mu^2} + \text{const.} \tag{T5.81}$$

It cannot depend on μ, so

$$0 = \mu\frac{\mathrm{d}}{\mathrm{d}\mu}\frac{1}{g_{\text{eff}}^2} \overset{(1)}{=} -\frac{2}{g^3}\beta(g) - \frac{2b_0}{16\pi^2} \quad\Longrightarrow\quad \beta(g) \overset{(2)}{=} -\frac{b_0\, g^3}{16\pi^2}. \tag{T5.82}$$

(1) $\mu\,\mathrm{d}(g^{-2})/\mathrm{d}\mu = -2g^{-3}\beta$, and $\mu\,\partial_\mu \ln(p^2/\mu^2) = -2$.
(2) Solve for β.

Key idea: the one-loop Yang–Mills β-function

For gauge group SU(N) with n_f Dirac fermions in the fundamental,

$$\beta(g) = \mu\frac{\mathrm{d}g}{\mathrm{d}\mu} = -\frac{g^3}{16\pi^2}\left(\frac{11N}{3} - \frac{2n_f}{3}\right) + O(g^5). \tag{T5.83}$$

[Gross and Wilczek 1973, Politzer 1973] The $\frac{11}{3}$ is $4 - \frac{1}{3}$: the gluon's spin (paramagnetic, antiscreening) gives 4, its orbital motion (diamagnetic, screening, with the ghosts removing the two unphysical polarisations) gives $-\frac{1}{3}$. For a quark the signs flip and $(2s)^2 = 1$ replaces 4: $-(1 - \frac{1}{3})\cdot 2T_F = -\frac{2}{3}$ per flavour.

Physical picture: the vacuum as a paramagnet (Nielsen and Hughes)

[Nielsen 1981, Hughes 1981] In a medium, a static charge is screened if the dielectric constant $\epsilon > 1$. A relativistic vacuum must have $\epsilon\,\mu_{\mathrm{m}} = 1$ (the product sets the speed of light), so a vacuum that is *paramagnetic*, $\mu_{\mathrm{m}} > 1$, has $\epsilon < 1$: it antiscreens, and the effective charge grows with distance. The magnetic susceptibility of free charged particles has two parts: Pauli paramagnetism of the spin magnetic moment, $\propto (g_L s_z)^2$, and Landau diamagnetism of the orbits, $\propto -\frac{1}{3}$ relative to it. For a particle of spin s with $g_L = 2$, the combination is $(2s)^2 - \frac{1}{3}$, times $(-1)^{2s}$ because fermion loops have the opposite sign. Spin-1 gluons give $4 - \frac{1}{3} > 0$: the Yang–Mills vacuum is a paramagnet, and that is asymptotic freedom. Charged scalars give $-\frac{1}{3}$ and quarks $-(1 - \frac{1}{3})$: both screen. QED has no charged spin-1 particles, which is why its coupling grows at short distances.

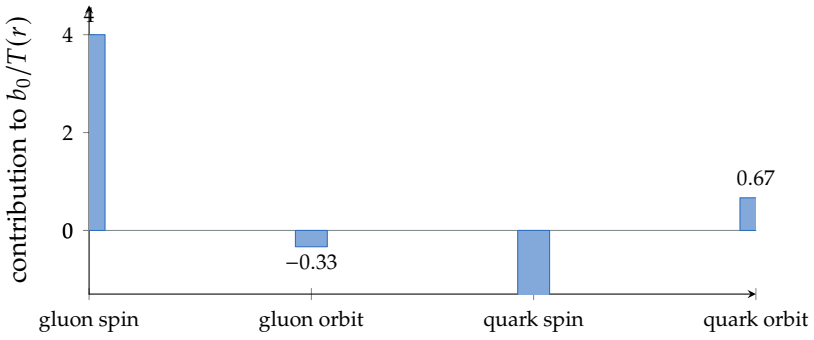

Figure T5.17: The four pieces of the one-loop coefficient b_0, each divided by the group factor $T(r)$ of the particle in the loop (N for gluons, $\frac{1}{2}$ per quark flavour). Positive bars antiscreen (drive asymptotic freedom), negative bars screen. What to see: the gluon spin term 4 dominates everything; the orbital terms are the small $\mp\frac{1}{3}$ corrections. For quarks the bars are the gluon-like values $(2s)^2 = 1$ and $-\frac{1}{3}$, reversed in sign by Fermi statistics and doubled for the four components of a Dirac spinor: -2 and $+\frac{2}{3}$, so $T_F(-2 + \frac{2}{3}) = -\frac{2}{3}$ per flavour.

Worked example T5.21: QCD numbers: α_s from M_Z to 1 TeV, and $\Lambda_{\rm QCD}$

For $N = 3$: $b_0 = 11 - \frac{2}{3}n_f$, positive for $n_f \le 16$; with all six quarks $b_0 = 7$. In terms of $\alpha_s = g^2/4\pi$,

$$\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\frac{1}{\alpha_s} \overset{(1)}{=} 4\pi\,\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\frac{1}{g^2} \overset{(2)}{=} 4\pi\cdot\frac{b_0}{8\pi^2} = \frac{b_0}{2\pi} \quad\Longrightarrow\quad \frac{1}{\alpha_s(Q)} = \frac{1}{\alpha_s(\mu)} + \frac{b_0}{2\pi}\ln\frac{Q}{\mu}.$$

(1) $1/\alpha_s = 4\pi/g^2$.
(2) From (T5.82), $\mu\,\mathrm{d}(g^{-2})/\mathrm{d}\mu = -2\beta/g^3 = 2b_0/16\pi^2$.

Between m_b and m_t five quarks are light, $b_0 = \frac{23}{3}$ and $b_0/2\pi = 1.220$. Starting from the measured $\alpha_s(M_Z) = 0.118$ at $M_Z = 91.2\,\mathrm{GeV}$, so $1/\alpha_s = 8.47$:

Q	$\ln(Q/M_Z)$	$1/\alpha_s(Q)$	$\alpha_s(Q)$
10 GeV	−2.21	8.47 − 2.70 = 5.77	0.173
1 TeV	+2.39	8.47 + 2.92 = 11.39	0.088

close to the measured 0.18 and 0.088. The coupling blows up where $1/\alpha_s = 0$, at $\Lambda = M_Z\exp(-2\pi/(b_0\alpha_s(M_Z))) = 91.2\,\mathrm{GeV}\times e^{-6.95} \approx 0.09\,\mathrm{GeV}$. Two-loop running and quark thresholds move this to the familiar $\Lambda_{\rm QCD} \approx 0.2\,\mathrm{GeV}$, but the order of magnitude is already right.

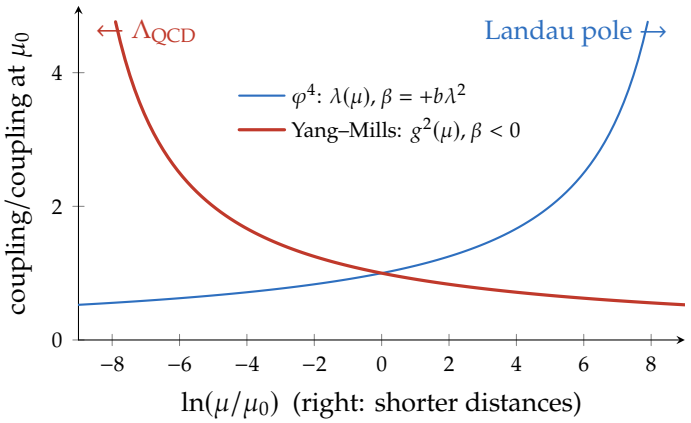

Figure T5.18: One-loop running in four dimensions, with the same strength of running 0.1 per e-fold for both. Blue: φ^4 theory, $\lambda(\mu) = \lambda_0/(1 - 0.1\ln(\mu/\mu_0))$, grows towards short distances and has a Landau pole in the ultraviolet. Red: Yang–Mills, $g^2(\mu) = g_0^2/(1 + 0.1\ln(\mu/\mu_0))$, shrinks towards short distances (asymptotic freedom) and blows up in the infrared, at the scale Λ of dimensional transmutation. What to see: the two curves are mirror images, and the sign of β alone decides at which end the theory is weakly coupled.

Worked example T5.22: Dimensional transmutation and the instanton factor

For g^2 the flow is $\mathrm{d}g^2/\mathrm{d}t = -\mu\,\mathrm{d}g^2/\mathrm{d}\mu = -2g\beta = \frac{b_0}{8\pi^2}g^4$, which is Example T5.28 with $b = b_0/8\pi^2$. So the RG-invariant mass is

$$\Lambda = \mu\, e^{-8\pi^2/(b_0\, g^2(\mu))}. \tag{T5.84}$$

Check that it does not depend on μ:

$$\mu\frac{\mathrm{d}\ln\Lambda}{\mathrm{d}\mu} \overset{(1)}{=} 1 - \frac{8\pi^2}{b_0}\,\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\frac{1}{g^2} \overset{(2)}{=} 1 - \frac{8\pi^2}{b_0}\cdot\frac{b_0}{8\pi^2} = 0.$$

(1) Take the logarithm of (T5.84) and differentiate.
(2) $\mu\,\mathrm{d}(g^{-2})/\mathrm{d}\mu = b_0/8\pi^2$ from (T5.82).

Now raise (T5.84) to the power b_0:

$$e^{-8\pi^2/g^2(\mu)} \overset{(1)}{=} \left(\frac{\Lambda}{\mu}\right)^{b_0}.$$

(1) $(\Lambda/\mu)^{b_0} = e^{-b_0\cdot 8\pi^2/(b_0 g^2)}$.

The left side is the weight e^{-S} of a Yang–Mills instanton, whose action is $8\pi^2/g^2$ in the normalisation (T5.74) (Chapter 8). The coupling in it should be the one at the instanton's own scale, $\mu = 1/\rho$ for an instanton of size ρ. So the tunnelling amplitude of a size-ρ instanton is $(\rho\Lambda)^{b_0}$, which is $(\rho\Lambda)^{22/3}$ for pure SU(2): small instantons are exponentially rare, large ones are not suppressed at all, and the dilute instanton gas breaks down at $\rho \sim 1/\Lambda$, the same scale at which the coupling becomes strong.

Watch out: the background-field shortcut and the Ward identity

In a covariant gauge without a background, g appears in the three- and four-gluon vertices and in the quark–gluon vertex, and each renormalises differently; the β-function comes out only after combining the gluon, ghost and vertex renormalisations ($Z_g = Z_1/Z_3^{3/2}$). The background field gauge avoids this because background gauge invariance forces $Z_g Z_{\bar{A}}^{1/2} = 1$: the coupling renormalises only through the normalisation of $\bar{A}$, which is the single coefficient b_0 computed above. The answer (T5.83) is the same in both methods, as it must be for a one-loop coefficient of a marginal coupling.

Recap

- The Callan–Symanzik equation $[\mu\partial_\mu + \beta\partial_\lambda + n\gamma]G^{(n)} = 0$ says that bare correlators do not know the renormalisation scale.
- Its solution by characteristics expresses $G^{(2)}(x)$ through the running coupling at $\mu = 1/|x|$ and $\exp(2\int\gamma)$; at a zero of β it is a pure power with $\Delta = \Delta_{\mathrm{cl}} + \gamma(\lambda^*)$.
- φ^4: the s, t, u bubbles give $\beta = -\varepsilon\lambda + 3\lambda^2/16\pi^2$, the same as Wilson's shell integration; $O(N)$: $(N+8)\lambda^2/48\pi^2$.
- Yang–Mills in the background-field gauge: orbital (diamagnetic) and spin (paramagnetic) parts of $\ln\det(-\bar{D}^2 + X)$ give $\beta = -\frac{g^3}{16\pi^2}(\frac{11N}{3} - \frac{2n_f}{3})$, with $\frac{11}{3} = 4 - \frac{1}{3}$.
- $\Lambda = \mu e^{-8\pi^2/(b_0 g^2)}$ and $e^{-8\pi^2/g^2(1/\rho)} = (\rho\Lambda)^{b_0}$: the instanton factor is a power of the transmuted scale.

T5.5 Fixed points are conformal field theories

A fixed point of the RG has no length scale, so it is scale invariant. Nash calls this "necessary, but insufficient" for conformal invariance [Nash p. 301]. Conformal invariance is invariance under maps that rescale lengths by a *position-dependent* factor while preserving angles. In two dimensions these maps are all holomorphic functions $z \mapsto f(z)$, infinitely many, and that infinite symmetry is what makes two-dimensional CFTs solvable (Chapter 11). So it matters whether a fixed point is merely scale invariant or fully conformal. Which extra condition

upgrades scale invariance to conformal invariance? The answer is a condition on the trace of the stress tensor. In two dimensions it always holds for unitary theories with a discrete spectrum (the Zamolodchikov–Polchinski theorem), while in higher dimensions a free unitary theory shows how it can fail. The same trace turns out to *be* the list of β-functions, the fact behind the scale anomaly of Chapter 10.

T5.5.1 Conformal maps and the stress tensor

Working definition T5.8 (conformal transformation)

A change of coordinates $x \mapsto x'$ is **conformal** if it changes the metric only by an overall factor, $\mathrm{d}x'^{\mu}\mathrm{d}x'^{\mu} = \Omega(x)^2\,\mathrm{d}x^{\mu}\mathrm{d}x^{\mu}$ [near each point it is a rotation times a stretch, and the stretch Ω may differ from point to point]. Such maps preserve angles but not lengths. Infinitesimally, $x'^{\mu} = x^{\mu} + v^{\mu}(x)$ with v a **conformal Killing vector** [a vector field whose flow stretches every small square into a bigger or smaller square, never a rectangle or a rhombus]. *Test:* v is conformal Killing exactly when

$$\partial_{\mu}v_{\nu} + \partial_{\nu}v_{\mu} = \frac{2}{d}\,(\partial\cdot v)\,\delta_{\mu\nu}. \tag{T5.85}$$

Here is where (T5.85) comes from. Under $x' = x + v$,

$$\mathrm{d}x'^{\mu}\mathrm{d}x'^{\mu} \overset{(1)}{=} (\mathrm{d}x^{\mu} + \partial_{\nu}v^{\mu}\,\mathrm{d}x^{\nu})(\mathrm{d}x^{\mu} + \partial_{\rho}v^{\mu}\,\mathrm{d}x^{\rho}) \overset{(2)}{=} \mathrm{d}x^{\mu}\mathrm{d}x^{\mu} + (\partial_{\mu}v_{\nu} + \partial_{\nu}v_{\mu})\,\mathrm{d}x^{\mu}\mathrm{d}x^{\nu} + O(v^2).$$

(1) $\mathrm{d}x'^{\mu} = \mathrm{d}x^{\mu} + \partial_{\nu}v^{\mu}\mathrm{d}x^{\nu}$ by the chain rule.
(2) Expand to first order in v and rename dummy indices.

This is $\Omega^2\mathrm{d}x\cdot\mathrm{d}x$ only if the symmetric matrix $\partial_{\mu}v_{\nu} + \partial_{\nu}v_{\mu}$ is a multiple of $\delta_{\mu\nu}$, say $c\,\delta_{\mu\nu}$. Taking the trace of both sides, $2\,\partial\cdot v = c\,d$, so $c = \frac{2}{d}\partial\cdot v$, which is (T5.85). The solutions in d dimensions are: translations $v = a$; rotations $v_{\mu} = \omega_{\mu\nu}x_{\nu}$ with ω antisymmetric (for both the left side of (T5.85) vanishes, and so does $\partial\cdot v$); the dilatation $v = x$, with $\partial_{\mu}x_{\nu} + \partial_{\nu}x_{\mu} = 2\delta_{\mu\nu} = \frac{2}{d}(d)\delta_{\mu\nu}$; and the special conformal fields $v_{\nu} = 2(b\cdot x)x_{\nu} - x^2 b_{\nu}$ for a constant vector b:

$$\begin{aligned}\partial_{\mu}v_{\nu} + \partial_{\nu}v_{\mu} &\overset{(1)}{=} \big(2b_{\mu}x_{\nu} + 2(b\cdot x)\delta_{\mu\nu} - 2x_{\mu}b_{\nu}\big) + \big(2b_{\nu}x_{\mu} + 2(b\cdot x)\delta_{\mu\nu} - 2x_{\nu}b_{\mu}\big)\\ &\overset{(2)}{=} 4(b\cdot x)\,\delta_{\mu\nu} \overset{(3)}{=} \frac{2}{d}\,(\partial\cdot v)\,\delta_{\mu\nu}.\end{aligned}$$

(1) $\partial_{\mu}(b\cdot x) = b_{\mu}$, $\partial_{\mu}x_{\nu} = \delta_{\mu\nu}$ and $\partial_{\mu}x^2 = 2x_{\mu}$; the second bracket is the first with $\mu \leftrightarrow \nu$.
(2) The terms $2b_{\mu}x_{\nu}$ and $2x_{\mu}b_{\nu}$ cancel against their partners.
(3) $\partial\cdot v = 2d\,(b\cdot x)$, computed in (T5.87) below.

In $d = 2$ write $v = v^1 + iv^2$ and $z = x^1 + ix^2$. The (11) component of (T5.85) is $2\partial_1 v^1 = \partial_1 v^1 + \partial_2 v^2$, that is $\partial_1 v^1 = \partial_2 v^2$, and the (12) component is $\partial_1 v^2 + \partial_2 v^1 = 0$. These are the Cauchy–Riemann equations for $v^1 + iv^2$ as a function of $x^1 + ix^2$. So in two dimensions *every* holomorphic $v(z)$ is conformal Killing, which is the infinite-dimensional symmetry of Chapter 11.

Working definition T5.9 (stress tensor)

The **stress tensor** $T^{\mu\nu}$ [the local density and flux of energy and momentum] is the response of the action to a position-dependent translation $\delta\varphi = v^{\mu}(x)\partial_{\mu}\varphi$ [moving the fields by an amount that varies from place to place]:

$$\delta S = \int \mathrm{d}^d x\; T^{\mu\nu}\,\partial_{\mu}v_{\nu}.$$

A constant v is a symmetry, so only ∂v can appear. For a rotation-invariant theory $T^{\mu\nu}$ can be chosen symmetric. *Recipe:* vary the action with $\delta\varphi = v^\mu \partial_\mu \varphi$, integrate by parts until only ∂v appears, read off the coefficient.

Two consequences. First, conservation: integrating by parts, $\delta S = -\int v_\nu \, \partial_\mu T^{\mu\nu}$ for v vanishing at infinity. On shell the action is stationary under *every* small change of the fields, including this one, so $\delta S = 0$ for every v, and therefore $\partial_\mu T^{\mu\nu} = 0$ on shell. Second, the recipe at work on the free scalar $S = \frac{1}{2}\int (\partial\varphi)^2$:

$$\delta S \overset{(1)}{=} \int \partial_\nu\varphi \, \partial_\nu\big(v^\mu \partial_\mu \varphi\big) \overset{(2)}{=} \int (\partial_\nu v^\mu)\, \partial_\nu\varphi \, \partial_\mu\varphi + \int v^\mu \, \partial_\mu\big(\tfrac{1}{2}(\partial\varphi)^2\big)$$
$$\overset{(3)}{=} \int (\partial_\nu v_\mu)\Big[\partial_\nu\varphi \, \partial_\mu\varphi - \tfrac{1}{2}\delta_{\mu\nu}(\partial\varphi)^2\Big].$$

(1) $\delta\frac{1}{2}(\partial\varphi)^2 = \partial_\nu\varphi \, \partial_\nu\delta\varphi$.
(2) Product rule on $\partial_\nu(v^\mu\partial_\mu\varphi)$; in the second term $\partial_\nu\varphi \, \partial_\mu\partial_\nu\varphi = \partial_\mu\big(\frac{1}{2}(\partial\varphi)^2\big)$.
(3) Integrate the second term by parts, which puts the derivative on v^μ: $-\int(\partial_\mu v^\mu)\frac{1}{2}(\partial\varphi)^2 = -\int(\partial_\nu v_\mu)\frac{1}{2}\delta_{\mu\nu}(\partial\varphi)^2$.

So $T_{\mu\nu} = \partial_\mu\varphi\partial_\nu\varphi - \frac{1}{2}\delta_{\mu\nu}(\partial\varphi)^2$, which is symmetric.

For a conformal v the change of the action involves only the trace:

$$\delta S \overset{(1)}{=} \int T^{\mu\nu}\,\tfrac{1}{2}\big(\partial_\mu v_\nu + \partial_\nu v_\mu\big) \overset{(2)}{=} \int T^{\mu\nu}\,\tfrac{1}{d}(\partial\cdot v)\,\delta_{\mu\nu} = \frac{1}{d}\int (\partial\cdot v)\, T^\mu{}_\mu.$$

(1) $T^{\mu\nu}$ is symmetric, so only the symmetric part of $\partial_\mu v_\nu$ contributes.
(2) (T5.85).

So a theory with $T^\mu{}_\mu = 0$ is invariant under every conformal map. When does scale invariance, which only needs the *integrated* trace to vanish, already imply that?

T5.5.2 Currents from vector fields

Let $T^{\mu\nu}$ be the symmetric conserved stress tensor of a Euclidean field theory in d dimensions, $\partial_\mu T^{\mu\nu} = 0$ (on shell, away from other operator insertions). For any vector field $v^\nu(x)$ build the current $J_v^\mu := T^{\mu\nu}v_\nu$. Its divergence is

$$\partial_\mu J_v^\mu \overset{(1)}{=} (\partial_\mu T^{\mu\nu})v_\nu + T^{\mu\nu}\partial_\mu v_\nu \overset{(2)}{=} \tfrac{1}{2}T^{\mu\nu}\big(\partial_\mu v_\nu + \partial_\nu v_\mu\big). \tag{T5.86}$$

(1) Product rule.
(2) Conservation kills the first term; $T^{\mu\nu}$ is symmetric, so only the symmetric part of $\partial_\mu v_\nu$ survives.

So J_v is conserved whenever $\partial_\mu v_\nu + \partial_\nu v_\mu = 0$, that is, for translations and rotations (the Killing vectors of flat space). For the other two kinds of vector field in Figure T5.19 the right side is not zero:

- *Dilatation*, $v_\nu = x_\nu$: $\partial_\mu x_\nu = \delta_{\mu\nu}$, so $\partial_\mu(T^{\mu\nu}x_\nu) = T^\mu{}_\mu$.
- *Conformal Killing vectors*, $\partial_\mu v_\nu + \partial_\nu v_\mu = \frac{2}{d}(\partial\cdot v)\delta_{\mu\nu}$ by (T5.85): then $\partial_\mu J_v^\mu = \frac{1}{d}(\partial\cdot v)\,T^\mu{}_\mu$. The typical example is the **special conformal** field $v_\nu = 2(b\cdot x)x_\nu - x^2 b_\nu$ for a constant vector b, for which

$$\partial\cdot v \overset{(1)}{=} 2(b\cdot x) + 2d\,(b\cdot x) - 2(b\cdot x) = 2d\,(b\cdot x). \tag{T5.87}$$

(1) $\partial_\mu[(b\cdot x)x_\mu] = b_\mu x_\mu + (b\cdot x)\,d$ and $\partial_\mu(x^2 b_\mu) = 2x_\mu b_\mu$.

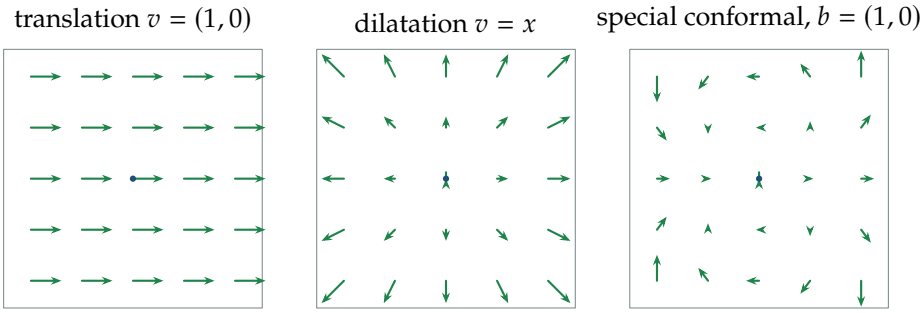

Figure T5.19: Three vector fields on the plane. Left: a translation, a Killing vector; its current $T^{\mu\nu}v_\nu$ is conserved in every theory. Middle: the dilatation $v = x$; its current has divergence $T^\mu{}_\mu$. Right: the special conformal field $v = 2(b\cdot x)x - x^2 b$ with $b = (1,0)$, whose components are $(x^2 - y^2,\, 2xy)$: the holomorphic field $v(z) = z^2$. It stretches by the position-dependent amount $\partial\cdot v = 4(b\cdot x)$, so its current has divergence $2(b\cdot x)T^\mu{}_\mu$. What to see: the middle and right fields rescale lengths, uniformly and non-uniformly; both are symmetries only if the trace of T is under control.

Working definition T5.10 (virial current)

A theory is **scale invariant** if it has a conserved dilatation current [a current whose charge generates $x \mapsto \lambda x$ and does not change in time]. The natural candidate $x_\nu T^{\mu\nu}$ has divergence $T^\mu{}_\mu$ [how the energy responds to a uniform stretch of all lengths]. It may be corrected by subtracting a local operator $K^\mu(x)$ [built from the fields at x, with no explicit x in it]:

$$D^\mu := x_\nu T^{\mu\nu} - K^\mu, \qquad \partial_\mu D^\mu = T^\mu{}_\mu - \partial_\mu K^\mu. \tag{T5.88}$$

So scale invariance means precisely $T^\mu{}_\mu = \partial_\mu K^\mu$ for some local K^μ, the **virial current** [the flux whose divergence is the trace, so that the trace integrates to zero over all space]. (The name is from Clausius' virial $\sum \vec{r}\cdot\vec{F}$, which plays the same role for a gas.) *Test:* compute $T^\mu{}_\mu$ on shell and try to write it as a divergence of a local current.

Now try to build a conserved current for a special conformal transformation. With $T^\mu{}_\mu = \partial_\mu K^\mu$,

$$\partial_\mu\big(v_\nu T^{\mu\nu}\big) \overset{(1)}{=} \tfrac{1}{d}(\partial\cdot v)\,T^\mu{}_\mu \overset{(2)}{=} 2(b\cdot x)\,\partial_\mu K^\mu \overset{(3)}{=} \partial_\mu\big(2(b\cdot x)K^\mu\big) - 2\,b_\mu K^\mu. \tag{T5.89}$$

(1) (T5.86) with the conformal Killing equation.
(2) (T5.87) and the virial current.
(3) Product rule backwards: $\partial_\mu(2(b\cdot x)K^\mu) = 2b_\mu K^\mu + 2(b\cdot x)\partial_\mu K^\mu$.

The first term can be moved into the current. The second, $-2b\cdot K$, can also be written as a divergence for every b exactly when $K_\mu = \partial_\mu L$ for some local scalar L (then $b\cdot K = \partial_\mu(b^\mu L)$). In that case $C^\mu_b = v_\nu T^{\mu\nu} - 2(b\cdot x)K^\mu + 2b^\mu L$ is conserved. So:

Key idea: when scale invariance becomes conformal invariance

A scale-invariant theory with $T^\mu{}_\mu = \partial_\mu K^\mu$ is conformally invariant if and only if the virial current is a gradient, $K_\mu = \partial_\mu L$ (up to a separately conserved current, which does not contribute to the trace). In that case the **improved** stress tensor

$$\Theta_{\mu\nu} := T_{\mu\nu} + \frac{1}{d-1}\big(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2\big)L \tag{T5.90}$$

is symmetric, conserved, has the same charges as $T_{\mu\nu}$, and is traceless.

The claims about (T5.90) are each one line:

$$\partial^\mu\big(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2\big)L \overset{(1)}{=} \partial^2\partial_\nu L - \partial_\nu\partial^2 L = 0,$$
$$\Theta^\mu{}_\mu \overset{(2)}{=} T^\mu{}_\mu + \frac{1}{d-1}\big(\partial^2 - d\,\partial^2\big)L \overset{(3)}{=} \partial_\mu K^\mu - \partial^2 L \overset{(4)}{=} 0.$$

(1) Partial derivatives commute: the added term is conserved identically, without using any equation of motion.
(2) $\delta^\mu{}_\mu = d$.
(3) $(1-d)/(d-1) = -1$ and $T^\mu{}_\mu = \partial_\mu K^\mu$.
(4) $K_\mu = \partial_\mu L$.

The charges do not change because the added term in $\Theta_{0\nu}$ is $(\partial_0\partial_\nu - \delta_{0\nu}\partial^2)L$; for $\nu = 0$ this is $-\partial_i\partial_i L$, and for $\nu = j$ it is $\partial_j(\partial_0 L)$. Both are spatial divergences, which integrate to zero over a time slice.

Worked example T5.23: The free scalar: scale invariant and conformal in every d

For $S = \frac{1}{2}\int(\partial\varphi)^2$ the canonical tensor is $T_{\mu\nu} = \partial_\mu\varphi\partial_\nu\varphi - \frac{1}{2}\delta_{\mu\nu}(\partial\varphi)^2$ (Section T5.5.1). Its trace, on shell ($\partial^2\varphi = 0$), is

$$T^\mu{}_\mu \overset{(1)}{=} \Big(1 - \frac{d}{2}\Big)(\partial\varphi)^2 \overset{(2)}{=} \frac{2-d}{4}\,\partial^2(\varphi^2) = \partial_\mu\Big[\frac{2-d}{4}\,\partial^\mu(\varphi^2)\Big],$$

(1) $\delta^\mu{}_\mu = d$.
(2) $\partial^2(\varphi^2) = 2(\partial\varphi)^2 + 2\varphi\,\partial^2\varphi = 2(\partial\varphi)^2$ on shell.

so the virial current is $K^\mu = \frac{2-d}{4}\partial^\mu(\varphi^2)$, a gradient with $L = \frac{2-d}{4}\varphi^2$. The theory is conformal in every dimension, and (T5.90) gives the improvement term $-\frac{d-2}{4(d-1)}(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2)\varphi^2$. In $d = 4$ the coefficient is $-\frac{1}{6}$: the classic "improved" stress tensor of Callan, Coleman and Jackiw. In $d = 2$ the trace vanishes already, without any improvement.

Worked example T5.24: Free Maxwell theory in $d \neq 4$: scale but not conformal

Take $S = \frac{1}{4}\int F_{\mu\nu}F^{\mu\nu}$ in d dimensions. The recipe of Section T5.5.1 applied to A_μ gives a tensor that is not gauge invariant, so use instead the metric definition of the stress tensor, $\delta S = \frac{1}{2}\int\sqrt{g}\,T_{\mu\nu}\,\delta g^{\mu\nu}$ (introduced in Section T5.5.3; for the scalar it reproduces the same tensor). With $S = \frac{1}{4}\int\sqrt{g}\,g^{\mu\alpha}g^{\nu\beta}F_{\mu\nu}F_{\alpha\beta}$,

$$\delta S \overset{(1)}{=} \frac{1}{4}\int\sqrt{g}\Big[2\,\delta g^{\mu\alpha}\,F_{\mu\nu}F_\alpha{}^\nu - \tfrac{1}{2}g_{\mu\alpha}\,\delta g^{\mu\alpha}\,F^2\Big] \overset{(2)}{=} \frac{1}{2}\int\sqrt{g}\Big[F_{\mu\rho}F_\nu{}^\rho - \tfrac{1}{4}g_{\mu\nu}F^2\Big]\delta g^{\mu\nu},$$

(1) $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ does not involve the metric. The two inverse metrics give two equal terms, and $\delta\sqrt{g} = -\frac{1}{2}\sqrt{g}\,g_{\mu\nu}\delta g^{\mu\nu}$.
(2) Take out $\frac{1}{2}$ and rename indices.

so in flat space $T_{\mu\nu} = F_{\mu\rho}F_\nu{}^\rho - \frac{1}{4}\delta_{\mu\nu}F^2$, which is gauge invariant. On shell ($\partial_\mu F^{\mu\nu} = 0$),

$$T^\mu{}_\mu \overset{(1)}{=} \Big(1 - \frac{d}{4}\Big)F^2 \overset{(2)}{=} \frac{4-d}{2}\,\partial_\mu\big(A_\nu F^{\mu\nu}\big),$$

(1) $F_{\mu\rho}F^{\mu\rho} = F^2$ and $\delta^\mu{}_\mu = d$.

(2) $\partial_\mu(A_\nu F^{\mu\nu}) = (\partial_\mu A_\nu)F^{\mu\nu} + A_\nu \partial_\mu F^{\mu\nu} = \frac{1}{2}(\partial_\mu A_\nu - \partial_\nu A_\mu)F^{\mu\nu} = \frac{1}{2}F^2$, using the equation of motion and the antisymmetry of $F^{\mu\nu}$.

So the theory is scale invariant with virial current $K^\mu = \frac{4-d}{2}A_\nu F^{\mu\nu}$. Is it a gradient $\partial^\mu L$ of a local *gauge-invariant* scalar? $T^\mu{}_\mu$ has dimension d, so $\partial_\mu K^\mu$ does too, $[K] = d-1$, and L would need dimension $d-2$. But $[A] = \frac{d-2}{2}$ and $[F] = \frac{d}{2}$, and every gauge-invariant local scalar is built from F and its derivatives, the lowest being F^2 of dimension d. There is none of dimension $d-2$. So for $d \neq 4$ the virial current cannot be removed and the free Maxwell field is scale invariant but *not* conformally invariant. For $d > 4$ the representation theory of the conformal group gives an independent check: in a unitary CFT a primary 2-form must have $\Delta \geq d-2$ (the unitarity bound, Mack 1977), and $\Delta_F = \frac{d}{2} < d-2$ when $d > 4$. (In $d = 3$ the photon is dual to a free scalar, $F_{\mu\nu} = \epsilon_{\mu\nu\rho}\partial^\rho\phi$, and the theory sits inside the conformal free-scalar theory; the subtlety there is the gauge non-invariance of K^μ, not unitarity.)

Watch out: what the Maxwell example does and does not show

Maxwell theory in $d \neq 4$ is unitary, so it shows that "unitary + scale invariant $\Rightarrow$ conformal" is false as stated in general dimension. The loophole is that its virial current is not gauge invariant, so it is not a genuine local operator of the theory. Theories that are scale but not conformally invariant with a genuine virial current are known only when unitarity (reflection positivity) fails; the standard example is the Riva–Cardy theory of elasticity, $\int\left[\frac{1}{4}(\partial_\mu v_\nu - \partial_\nu v_\mu)^2 + \frac{\alpha}{2}(\partial\cdot v)^2\right]$ for a displacement vector v_μ with no gauge symmetry, which is conformal only for $\alpha = (d-4)/d$ (Riva and Cardy 2005). Scale invariance for every α is quick to see. Any Lagrangian $\mathcal{L}$ quadratic in the first derivatives of free fields v_ρ has the conserved canonical tensor $T_c^{\mu\nu} = \pi^{\mu\rho}\partial^\nu v_\rho - \delta^{\mu\nu}\mathcal{L}$, with $\pi^{\mu\rho} := \partial\mathcal{L}/\partial(\partial_\mu v_\rho)$, and on shell

$$T_c{}^\mu{}_\mu \overset{(1)}{=} \pi^{\mu\rho}\partial_\mu v_\rho - d\,\mathcal{L} \overset{(2)}{=} (2-d)\,\mathcal{L} \overset{(3)}{=} \frac{2-d}{2}\,\partial_\mu\big(\pi^{\mu\rho}v_\rho\big).$$

(1) $\delta^\mu{}_\mu = d$.
(2) Euler's theorem for a function of degree 2 in ∂v: $\pi^{\mu\rho}\partial_\mu v_\rho = 2\mathcal{L}$.
(3) $\partial_\mu(\pi^{\mu\rho}v_\rho) = (\partial_\mu\pi^{\mu\rho})v_\rho + \pi^{\mu\rho}\partial_\mu v_\rho = 0 + 2\mathcal{L}$, using the equation of motion $\partial_\mu\pi^{\mu\rho} = 0$.

So $\partial_\mu(x_\nu T_c^{\mu\nu}) = T_c{}^\mu{}_\mu$ is a total derivative, and a conserved dilatation current exists. (For the free scalar, $\pi^\mu = \partial^\mu\varphi$, this gives $\frac{2-d}{4}\partial^2\varphi^2$, as in Example T5.23.) Whether the virial current can be made a gradient is decided by the symmetric stress tensor, and that is where α matters.

T5.5.3 The trace of the stress tensor measures the β-functions

Away from a fixed point the trace is not a total derivative, and it is worth knowing exactly what it is. Near a fixed point write $S = S^* + \sum_i g^i \int \mathrm{d}^d x\, \mathcal{O}_i$, with $\mathcal{O}_i$ of scaling dimension Δ_i at the fixed point, so that g^i has mass dimension $y_i = d - \Delta_i$. Define the stress tensor equivalently as the response to the metric, $\delta S = \frac{1}{2}\int \sqrt{g}\, T_{\mu\nu}\,\delta g^{\mu\nu}$ (for the free scalar this reproduces the tensor of Section T5.5.1). A uniform stretch of all lengths, $g_{\mu\nu} \to (1+2\sigma)g_{\mu\nu}$, has $\delta g^{\mu\nu} = -2\sigma g^{\mu\nu}$, so $\delta S = \frac{1}{2}\int T_{\mu\nu}(-2\sigma\delta^{\mu\nu}) = -\sigma\int T^\mu{}_\mu$. On the other hand the fixed-point action does not respond (it has no scale), the volume element grows, $\sqrt{g} = \sqrt{\det g} \to (1+2\sigma)^{d/2}\sqrt{g} = (1+d\sigma)\sqrt{g}$, and each operator shrinks by its dimension, $\mathcal{O}_i \to (1-\Delta_i\sigma)\mathcal{O}_i$:

$$-\sigma\int T^\mu{}_\mu \overset{(1)}{=} \sigma\sum_i (d-\Delta_i)\,g^i\int \mathcal{O}_i \quad\Longrightarrow\quad T^\mu{}_\mu \overset{(2)}{=} -\sum_i y_i\,g^i\,\mathcal{O}_i \overset{(3)}{=} -\sum_i \beta^i(g)\,\mathcal{O}_i + \partial_\mu K^\mu. \tag{T5.91}$$

(1) Collect the factors of $1+\sigma$ from the measure and from each operator, to first order in σ.
(2) The coefficient of each $\int \mathcal{O}_i$ must agree; $d-\Delta_i = y_i$.
(3) $y_i g^i$ is the classical β-function (T5.6). In the quantum theory, stretching all lengths by $1+\sigma$ is one RG step of RG time σ: the theory with couplings g in the stretched metric is the theory with couplings $g+\sigma\beta(g)$ in the old one, by the definition (T5.5) of β. So the change of the action is $\sigma\sum_i \beta^i \int \mathcal{O}_i$, and the full β^i replaces $y_i g^i$ (this is the operator form of the Callan–Symanzik equation). Terms whose integral vanishes, a divergence $\partial_\mu K^\mu$ and contact terms, are not fixed by this argument and may be added.

At a fixed point all $\beta^i = 0$ and only the virial term is left, which is the starting point of Section T5.5.2.

Worked example T5.25: The massive scalar and the scale anomaly of Yang–Mills

Massive scalar. For $S = \int \sqrt{g}\,[\frac{1}{2}g^{\mu\nu}\partial_\mu\varphi\partial_\nu\varphi + \frac{1}{2}m^2\varphi^2]$,

$$\delta S \overset{(1)}{=} \int \sqrt{g}\,\tfrac{1}{2}\partial_\mu\varphi\partial_\nu\varphi\,\delta g^{\mu\nu} - \int \tfrac{1}{2}\sqrt{g}\,g_{\mu\nu}\delta g^{\mu\nu}\left[\tfrac{1}{2}(\partial\varphi)^2 + \tfrac{1}{2}m^2\varphi^2\right]$$
$$\overset{(2)}{=} \frac{1}{2}\int \sqrt{g}\left[\partial_\mu\varphi\partial_\nu\varphi - g_{\mu\nu}\left(\tfrac{1}{2}(\partial\varphi)^2 + \tfrac{1}{2}m^2\varphi^2\right)\right]\delta g^{\mu\nu},$$

(1) Vary the inverse metric in the kinetic term, and use $\delta\sqrt{g} = -\frac{1}{2}\sqrt{g}\,g_{\mu\nu}\delta g^{\mu\nu}$.
(2) Take out $\frac{1}{2}$.

so in flat space $T_{\mu\nu} = \partial_\mu\varphi\partial_\nu\varphi - \delta_{\mu\nu}\left(\frac{1}{2}(\partial\varphi)^2 + \frac{1}{2}m^2\varphi^2\right)$ (at $m=0$ this is the tensor found in Section T5.5.1). On shell, $\partial^2\varphi = m^2\varphi$, so $\partial^2(\varphi^2) = 2(\partial\varphi)^2 + 2m^2\varphi^2$, and

$$T^\mu{}_\mu \overset{(1)}{=} \left(1-\frac{d}{2}\right)(\partial\varphi)^2 - \frac{d}{2}m^2\varphi^2 \overset{(2)}{=} \frac{2-d}{4}\,\partial^2(\varphi^2) - m^2\varphi^2.$$

(1) $\delta^\mu{}_\mu = d$.
(2) Replace $(\partial\varphi)^2 = \frac{1}{2}\partial^2(\varphi^2) - m^2\varphi^2$; then $-\frac{2-d}{2}m^2 - \frac{d}{2}m^2 = -m^2$.

The last term is $-y\,g\,\mathcal{O}$ with $\mathcal{O}=\varphi^2$, $g=\frac{1}{2}m^2$, $y=2$, exactly as (T5.91) predicts; the first is a virial term.

Yang–Mills. Write $S = \frac{1}{4g^2}\int F^a_{\mu\nu}F^a_{\mu\nu}$ in $d=4$. Classically F^2 has dimension 4, so the theory is scale invariant ($y=0$). Quantum mechanically the coupling $\kappa = 1/g^2$ of $\mathcal{O} = \frac{1}{4}F^aF^a$ runs, with $\beta_\kappa = \mathrm{d}(1/g^2)/\mathrm{d}t = -\frac{2}{g^3}\frac{\mathrm{d}g}{\mathrm{d}t}$. So (T5.91) gives

$$T^\mu{}_\mu \overset{(1)}{=} -\beta_\kappa\,\tfrac{1}{4}F^aF^a \overset{(2)}{=} \frac{1}{2g^3}\frac{\mathrm{d}g}{\mathrm{d}t}\,F^a_{\mu\nu}F^a_{\mu\nu}$$

(1) (T5.91) with the single coupling κ; there is no classical term since $y=0$.
(2) $-\left(-\frac{2}{g^3}\right)\cdot\frac{1}{4} = \frac{1}{2g^3}$.

(the overall sign depends on the sign convention for T). A classically scale invariant theory has a non-zero trace because the coupling runs: the **scale (trace) anomaly**. Insert the one-loop running of SU(N) Yang–Mills, $\mathrm{d}g/\mathrm{d}t = \frac{11N}{3}\frac{g^3}{16\pi^2}$ (asymptotic freedom: g grows towards the infrared):

$$T^\mu{}_\mu \overset{(1)}{=} \frac{1}{2g^3}\cdot\frac{11N}{3}\frac{g^3}{16\pi^2}\,F^aF^a \overset{(2)}{=} \frac{11N}{96\pi^2}\,F^aF^a.$$

(1) The previous line with the one-loop $\mathrm{d}g/\mathrm{d}t$.
(2) g^3 cancels and $2\cdot3\cdot16 = 96$.

Unlike the chiral anomaly, whose coefficient is fixed at one loop (the Adler–Bardeen theorem), the trace anomaly follows the full β-function; Chapter 10 compares the two.

The Yang–Mills trace anomaly in particle-physics form. The example used the infrared-ward flow $\mathrm{d}g/\mathrm{d}t$ and the normalisation with $1/g^2$ in front of the action. The formula usually quoted uses $\beta(g) = \mu\,\mathrm{d}g/\mathrm{d}\mu$ of (T5.83) and canonically normalised fields $A = gA_c$ (Section T5.4.3). Then $F = gF_c$ exactly, because the commutator term of F_c carries one factor of g, and

$$T^{\mu}{}_{\mu} \overset{(1)}{=} \frac{1}{2g^3}\frac{\mathrm{d}g}{\mathrm{d}t}\,F^aF^a \overset{(2)}{=} -\frac{\beta(g)}{2g^3}\,F^aF^a \overset{(3)}{=} -\frac{\beta(g)}{2g}\,F^a_cF^a_c \overset{(4)}{=} \frac{b_0\,g^2}{32\pi^2}\,F^a_cF^a_c. \tag{T5.92}$$

(1) The Yang–Mills part of Example T5.25.
(2) t increases towards the infrared, so $\mathrm{d}g/\mathrm{d}t = -\mu\,\mathrm{d}g/\mathrm{d}\mu = -\beta$ (the pitfall in Section T5.1.4).
(3) $F^a = gF^a_c$, so $F^aF^a = g^2F^a_cF^a_c$.
(4) $\beta = -b_0g^3/16\pi^2$ from (T5.83), so $-\beta/2g = b_0g^2/32\pi^2$. At $n_f = 0$, $b_0g^2F_cF_c/32\pi^2 = \frac{11N}{96\pi^2}F^aF^a$, the value found in the example.

Quark masses. A quark mass m multiplies $\bar\psi\psi$, of dimension 3, so $y = 1$ and the classical part of (T5.91) is $-m\bar\psi\psi$, exactly as for $\frac12 m^2\varphi^2$ above. The mass also runs. Write $\mu\,\mathrm{d}m/\mathrm{d}\mu = -\gamma_m\,m$, which defines the mass anomalous dimension γ_m. The coupling that enters (T5.91) is the dimensionless $\hat m = m/\mu$, and

$$\frac{\mathrm{d}\ln\hat m}{\mathrm{d}t} \overset{(1)}{=} -\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\big(\ln m - \ln\mu\big) \overset{(2)}{=} \gamma_m + 1.$$

(1) $t = -\ln\mu$ and $\ln\hat m = \ln m - \ln\mu$.
(2) $\mu\,\mathrm{d}\ln m/\mathrm{d}\mu = -\gamma_m$ and $\mu\,\mathrm{d}\ln\mu/\mathrm{d}\mu = 1$.

So each quark adds $-(1+\gamma_m)\,m\,\bar\psi\psi$ to $T^{\mu}{}_{\mu}$.

Minkowski signature. The tensor of this chapter is Euclidean, with $\delta S = \frac12\int\sqrt{g}\,T_{\mu\nu}\delta g^{\mu\nu}$. The physical tensor $\theta_{\mu\nu}$ in signature $(+,-,-,-)$ has θ_{00} = energy density. For the scalar of the example, with Euclidean time $\tau = it$ and $V = \frac12 m^2\varphi^2$,

$$T_{\tau\tau} \overset{(1)}{=} (\partial_\tau\varphi)^2 - \tfrac12(\partial_\tau\varphi)^2 - \tfrac12(\nabla\varphi)^2 - V \overset{(2)}{=} -\tfrac12(\partial_t\varphi)^2 - \tfrac12(\nabla\varphi)^2 - V \overset{(3)}{=} -\theta_{00}.$$

(1) The flat-space $T_{\mu\nu}$ of the example at $\mu = \nu = \tau$.
(2) $\partial_\tau = -i\partial_t$, so $(\partial_\tau\varphi)^2 = -(\partial_t\varphi)^2$.
(3) $\theta_{00} = \frac12(\partial_t\varphi)^2 + \frac12(\nabla\varphi)^2 + V$ is the energy density.

The same substitution gives $T_{ij} = \theta_{ij}$ for the spatial components. The Euclidean trace is $T_{\tau\tau} + \sum_i T_{ii} = -\theta_{00} + \sum_i \theta_{ii}$, and the Minkowski trace is $\theta^{\mu}{}_{\mu} = \theta_{00} - \sum_i \theta_{ii}$. So $\theta^{\mu}{}_{\mu} = -T^{\mu}{}_{\mu}$. Both tensors come from the same metric variation, so this holds for every field. Finally $F^a_{c\,\mu\nu}F^{a\,\mu\nu}_c$ (Euclidean) equals $F^a_{c\,\mu\nu}F^{a\,\mu\nu}_c = 2(\vec B^2 - \vec E^2)$ (Minkowski), since $A_\tau = -iA_0$ makes $F_{\tau i}F_{\tau i} = -F_{0i}F_{0i}$.

Key idea: the QCD trace anomaly

In Minkowski signature, with θ^{00} the energy density and canonically normalised fields,

$$\theta^{\mu}{}_{\mu} = \frac{\beta(g)}{2g}\,F^a_{c\,\mu\nu}F^{a\,\mu\nu}_c + \sum_q(1+\gamma_m)\,m_q\,\bar\psi_q\psi_q, \qquad \frac{\beta(g)}{2g} = -\frac{b_0\,\alpha_s}{8\pi} + O(\alpha_s^2), \tag{T5.93}$$

with $\alpha_s = g^2/4\pi$ and $b_0 = \frac{11N}{3} - \frac{2n_f}{3}$ [Collins, Duncan, Joglekar 1977]. A theory with no scale in its classical action acquires one, and the operator that measures it is F^2 times the β-function. Chapter 10 compares it with the chiral anomaly.

Worked example T5.26: where the proton mass and the vacuum energy come from

Proton mass. Normalise one-particle states as $\langle p'|p\rangle = 2E(2\pi)^3\delta^3(\vec{p}-\vec{p}')$. The four-momentum is $P^\nu = \int \mathrm{d}^3x\, \theta^{0\nu}$, and $\theta(x) = e^{iPx}\theta(0)e^{-iPx}$. Then

$$p^\nu\, 2E(2\pi)^3\delta^3(\vec{p}-\vec{p}') \overset{(1)}{=} \langle p'|P^\nu|p\rangle \overset{(2)}{=} \int \mathrm{d}^3x\; e^{i(\vec{p}-\vec{p}')\cdot\vec{x}}\,\langle p'|\theta^{0\nu}(0)|p\rangle$$
$$\overset{(3)}{=} (2\pi)^3\delta^3(\vec{p}-\vec{p}')\,\langle p|\theta^{0\nu}(0)|p\rangle.$$

(1) $P^\nu|p\rangle = p^\nu|p\rangle$ and the normalisation.
(2) Translate $\theta^{0\nu}(x)$ to the origin. At equal times the phase is $e^{i(\vec{p}-\vec{p}')\cdot\vec{x}}$.
(3) $\int \mathrm{d}^3x\, e^{i\vec{k}\cdot\vec{x}} = (2\pi)^3\delta^3(\vec{k})$.

So $\langle p|\theta^{0\nu}|p\rangle = 2Ep^\nu$. The only symmetric tensors built from p are $p^\mu p^\nu$ and $M^2 g^{\mu\nu}$, so $\langle p|\theta^{\mu\nu}|p\rangle = a\,p^\mu p^\nu + b\,M^2 g^{\mu\nu}$. The component $\nu = i$ gives $2Ep^i = aEp^i$, so $a = 2$. The component $\nu = 0$ gives $2E^2 = 2E^2 + bM^2$, so $b = 0$. Taking the trace with $p^\mu p_\mu = M^2$,

$$2M^2 \overset{(1)}{=} \langle p|\theta^\mu{}_\mu|p\rangle \overset{(2)}{=} \frac{\beta(g)}{2g}\,\langle p|F^a_c F^a_c|p\rangle \qquad (m_q = 0).$$

(1) $\langle p|\theta^{\mu\nu}|p\rangle = 2p^\mu p^\nu$ contracted with $g_{\mu\nu}$.
(2) (T5.93) with massless quarks.

With massless quarks the entire mass of the proton is the matrix element of the anomaly. Classically the theory has no scale, and M must be a pure number times the transmuted scale Λ of (T5.84). The physical u, d masses add the quark term, the pion–nucleon sigma term, which is of order 50 MeV, about 5% of M [Gasser, Leutwyler, Sainio 1991].
Vacuum energy. Lorentz invariance of the vacuum forces $\langle 0|\theta^{\mu\nu}|0\rangle = \epsilon\, g^{\mu\nu}$, and θ^{00} gives ϵ as the energy density. With $g^\mu{}_\mu = 4$ and massless quarks,

$$\epsilon \overset{(1)}{=} \tfrac{1}{4}\langle\theta^\mu{}_\mu\rangle \overset{(2)}{=} \frac{\beta(g)}{8g}\,\langle F^a_c F^a_c\rangle \overset{(3)}{=} -\frac{b_0}{32}\left\langle\frac{\alpha_s}{\pi}F^a_c F^a_c\right\rangle.$$

(1) Trace of $\epsilon\, g^{\mu\nu}$.
(2) (T5.93).
(3) $\beta/8g = -b_0 g^2/128\pi^2$ and $g^2/4\pi^2 = \alpha_s/\pi$.

The gluon condensate, the non-perturbative part of $\langle\frac{\alpha_s}{\pi}F_cF_c\rangle$, is about $0.012\ \mathrm{GeV}^4$ [Shifman, Vainshtein, Zakharov 1979]. With $n_f = 3$ light flavours, $b_0 = 9$ and $\epsilon \approx -\frac{9}{32}\cdot 0.012\ \mathrm{GeV}^4 \approx -(0.24\,\mathrm{GeV})^4$. The confining vacuum lies below the perturbative one. This energy difference is the bag constant of bag models of hadrons.

T5.5.4 Two dimensions: the Zamolodchikov–Polchinski argument

In two dimensions the upgrade is a theorem. Use complex coordinates $z = x^1 + ix^2$, $\partial = \frac{1}{2}(\partial_1 - i\partial_2)$, $\bar\partial = \frac{1}{2}(\partial_1 + i\partial_2)$, metric $\mathrm{d}s^2 = \mathrm{d}z\,\mathrm{d}\bar z$, so $g_{z\bar z} = \frac{1}{2}$ and $g^{z\bar z} = 2$. Define

$$T := -2\pi T_{zz}, \qquad \Theta := -2\pi T_{z\bar z} = -\frac{\pi}{2}\,T^\mu{}_\mu. \tag{T5.94}$$

The factor -2π is the standard normalisation of two-dimensional CFT (used throughout Chapter 11): at a conformal fixed point $T = T(z)$ is holomorphic, and its operator product with itself is $T(w)T(z) \sim \frac{c/2}{(w-z)^4} + \cdots$, where the number c, the **central charge**, counts degrees of freedom ($c = 1$ for a free boson, $c = \frac{1}{2}$ for a free Majorana fermion). The second form of

Θ uses $T^{\mu}{}_{\mu} = g^{z\bar z}T_{z\bar z} + g^{\bar z z}T_{\bar z z} = 4T_{z\bar z}$. Away from a fixed point T is no longer holomorphic; conservation now reads

$$0 = \partial^{\mu}T_{\mu z} \overset{(1)}{=} g^{z\bar z}\partial_{\bar z}T_{zz} + g^{\bar z z}\partial_z T_{\bar z z} \overset{(2)}{=} 2\big(\bar\partial T_{zz} + \partial T_{z\bar z}\big) \quad\Longrightarrow\quad \bar\partial T + \partial\Theta \overset{(3)}{=} 0. \tag{T5.95}$$

(1) Raise the index with the inverse metric, whose only entries are $g^{z\bar z} = g^{\bar z z}$.
(2) $g^{z\bar z} = 2$, and T is symmetric.
(3) Multiply by $-\pi$ and use (T5.94).

At a conformal point $\Theta = 0$ and this says $\bar\partial T = 0$: T is holomorphic (Nash's (11.13)).

The three two-point functions. Rotation $z \mapsto e^{i\alpha}z$ acts on T as a spin-2 object ($T \mapsto e^{-2i\alpha}T$, since T_{zz} carries two lower z indices) and leaves the scalar Θ unchanged. Translation and rotation invariance therefore force

$$\langle T(z,\bar z)T(0)\rangle = \frac{F(z\bar z)}{z^4}, \qquad \langle T(z,\bar z)\Theta(0)\rangle = \frac{G(z\bar z)}{z^3\bar z}, \qquad \langle \Theta(z,\bar z)\Theta(0)\rangle = \frac{H(z\bar z)}{z^2\bar z^2}, \tag{T5.96}$$

with F, G, H functions of $r^2 = z\bar z$ only: under the rotation each prefactor z^{-4}, $z^{-3}\bar z^{-1}$, $z^{-2}\bar z^{-2}$ picks up exactly the phase of the operators ($e^{-4i\alpha}$, $e^{-2i\alpha}$, 1), so F, G, H must be invariant. (Also $\langle\Theta(z)T(0)\rangle = \langle T(z)\Theta(0)\rangle$: translate by $-z$ and note $(-z)^3(-\bar z) = z^3\bar z$.) At a conformal fixed point $F = \frac{c}{2}$ and $G = H = 0$.

What conservation says about F, G, H. Put (T5.95) inside correlators with $T(0)$ and with $\Theta(0)$, at $z \neq 0$. Write $\dot X := \mathrm{d}X/\mathrm{d}\ln(z\bar z) = u\,\mathrm{d}X/\mathrm{d}u$ with $u = z\bar z$, and note $\bar\partial X(u) = zX'(u)$, $\partial X(u) = \bar z X'(u)$.

$$\bar\partial\frac{F}{z^4} = -\partial\frac{G}{z^3\bar z} \overset{(1)}{=} \frac{F'}{z^3} = -\frac{G'}{z^3} + \frac{3G}{z^4\bar z} \overset{(2)}{=} \dot F = -\dot G + 3G, \tag{T5.97}$$

$$\bar\partial\frac{G}{z^3\bar z} = -\partial\frac{H}{z^2\bar z^2} \overset{(3)}{=} \frac{G'}{z^2\bar z} - \frac{G}{z^3\bar z^2} = -\frac{H'}{z^2\bar z} + \frac{2H}{z^3\bar z^2} \overset{(4)}{=} \dot G - G = -\dot H + 2H. \tag{T5.98}$$

(1) $\bar\partial(Fz^{-4}) = zF'z^{-4}$; $\partial(Gz^{-3}\bar z^{-1}) = \bar z G' z^{-3}\bar z^{-1} - 3Gz^{-4}\bar z^{-1}$.
(2) Multiply by z^3, which gives $F' = -G' + 3G/u$, then by $u = z\bar z$, using $uF' = \dot F$.
(3) $\bar\partial(Gz^{-3}\bar z^{-1}) = zG'z^{-3}\bar z^{-1} - Gz^{-3}\bar z^{-2}$; $\partial(Hz^{-2}\bar z^{-2}) = \bar z H' z^{-2}\bar z^{-2} - 2Hz^{-3}\bar z^{-2}$.
(4) Multiply by $z^3\bar z^2$, which turns $G'z\bar z$ into $\dot G$.

These two equations are the whole content of energy–momentum conservation for the two-point functions.

Key idea: Zamolodchikov and Polchinski: scale invariance implies conformal invariance in 2D

Assume a two-dimensional Euclidean field theory that is (i) local, with a symmetric conserved $T_{\mu\nu}$; (ii) reflection positive (unitary after continuation); (iii) scale invariant; (iv) with a discrete spectrum of scaling dimensions, in particular no operator of dimension zero other than the identity. Then $\Theta = 0$ as an operator, and the theory is conformally invariant.

Here is the argument, in three steps.

Step 1: F, G, H are constants. In a scale-invariant theory the dilatations act on local operators, and a conserved $T_{\mu\nu}$ has engineering dimension $d = 2$. It could fail to be a scaling operator only by mixing with another symmetric, identically conserved operator of the same dimension, and the only such operators are the improvement terms $(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2)\mathcal{O}$ of (T5.90). These have dimension $2 + \Delta_{\mathcal O}$, so they need $\Delta_{\mathcal O} = 0$, which (iv) excludes (Polchinski 1988). So T and Θ have

dimension exactly 2, and each two-point function in (T5.96) obeys $\langle X(\lambda x)Y(0)\rangle = \lambda^{-4}\langle X(x)Y(0)\rangle$. For the first one,

$$\frac{F(\lambda^2 z\bar z)}{\lambda^4 z^4} \overset{(1)}{=} \lambda^{-4}\,\frac{F(z\bar z)}{z^4} \quad\Longrightarrow\quad F(\lambda^2 u) \overset{(2)}{=} F(u) \text{ for all } \lambda > 0,$$

(1) Replace $z \to \lambda z$, $\bar z \to \lambda \bar z$ on the left, and use the scaling law on the right.
(2) Cancel $\lambda^{-4} z^{-4}$, with $u = z\bar z$.

so F is a constant; the same argument applies to G and H.

Step 2: $G = H = 0$. With $\dot F = \dot G = \dot H = 0$, (T5.97) gives $0 = 3G$, and then (T5.98) gives $0 = -G + 0 = 2H$. So

$$\langle \Theta(x)\Theta(0)\rangle = 0 \qquad \text{for all } x \neq 0.$$

Step 3: $\Theta = 0$. Take x along the Euclidean time direction, $x = (\tau, 0)$ with $\tau > 0$, and insert a complete set of energy eigenstates $|n\rangle$ (with $H|0\rangle = 0$). Since $\Theta(\tau) = e^{H\tau}\Theta(0)e^{-H\tau}$ and Θ is Hermitian,

$$0 = \langle \Theta(\tau)\Theta(0)\rangle \overset{(1)}{=} \sum_n \langle 0|\Theta(0)|n\rangle\langle n|\Theta(0)|0\rangle\, e^{-E_n\tau} \overset{(2)}{=} \sum_n \big|\langle n|\Theta(0)|0\rangle\big|^2 e^{-E_n\tau}. \tag{T5.99}$$

(1) Insert $\sum_n |n\rangle\langle n| = 1$; $e^{-H\tau}|0\rangle = |0\rangle$ and $\langle 0|e^{H\tau} = \langle 0|$, while $e^{-H\tau}$ acting on $|n\rangle$ gives $e^{-E_n\tau}$.
(2) $\langle 0|\Theta|n\rangle = \overline{\langle n|\Theta^\dagger|0\rangle} = \overline{\langle n|\Theta|0\rangle}$.

Every term is non-negative, so every term vanishes: $\langle n|\Theta|0\rangle = 0$ for all n, that is, $\Theta|0\rangle = 0$. A local operator that annihilates the vacuum is zero (the Reeh–Schlieder theorem; physically, a local operator acting on the vacuum always creates *something* unless it is the zero operator). So $\Theta = T^\mu{}_\mu \cdot (-\pi/2) = 0$, $\bar\partial T = 0$, and the full infinite-dimensional (Virasoro) symmetry of two-dimensional CFT follows (Chapter 11).

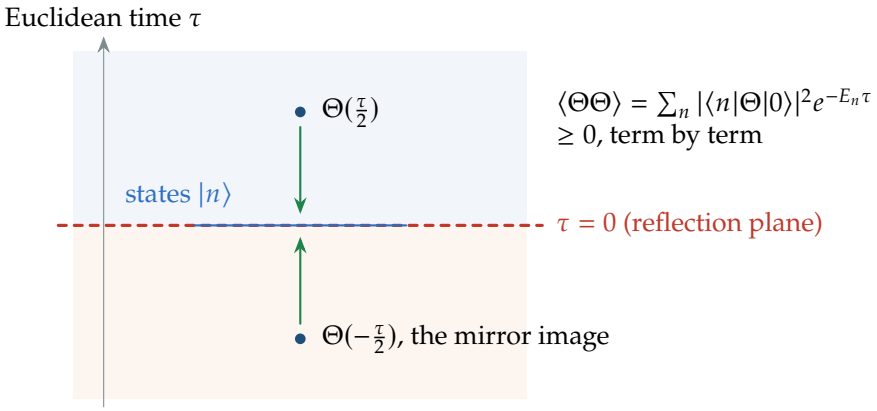

Figure T5.20: Reflection positivity. A two-point function of a Hermitian operator at Euclidean times $\pm\tau/2$ is the norm of the state $e^{-H\tau/2}\Theta|0\rangle$ that the upper operator creates on the slice $\tau = 0$; the lower operator is its mirror image. What to see: such a correlator is a sum of squares, so it can vanish only if the operator annihilates the vacuum. This is the step that needs unitarity, and it fails for the non-unitary Riva–Cardy theory.

The role of each assumption. Unitarity enters only in step 3. The discrete spectrum enters only in step 1. When a dimension-zero operator $\mathcal{O}$ is allowed, T can mix with $(\partial\partial - \delta\partial^2)\mathcal{O}$, the correlator of $\mathcal{O}$ with itself grows like $\ln r$ instead of being a power, and F, G, H acquire powers of $\ln r$. Then $\dot F, \dot G, \dot H \neq 0$, the conservation equations no longer force $H = 0$, and the theorem fails (Nakayama 2013, §5.3.1). This is not academic: the string worldsheet theory for a

non-compact target space has such operators (and is not unitary either), which is why string theory must check conformal, not just scale, invariance [Nash Ch. 9] (Chapter 9).

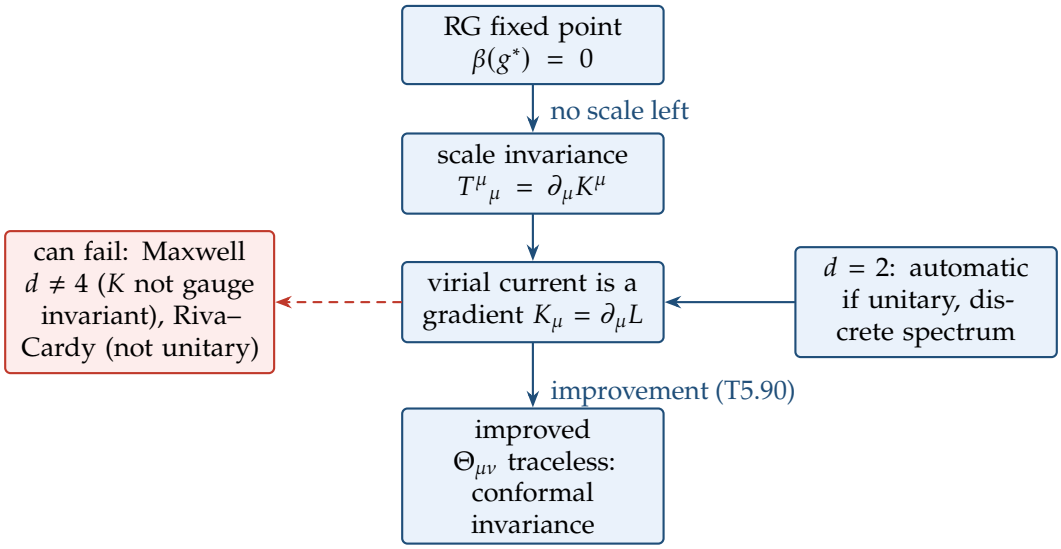

Figure T5.21: The logic of this section. Each downward arrow is one step of Section T5.5.2. The box on the right is the Zamolodchikov–Polchinski theorem; the red box on the left lists the ways the middle step can fail. What to see: the only non-trivial condition between a fixed point and a CFT is whether the virial current is a gradient.

Higher dimensions. In $d = 4$, Luty, Polchinski and Rattazzi (2012) and Fortin, Grinstein and Stergiou showed that scale invariance implies conformal invariance in perturbation theory, using the four-dimensional a-function of Section 11.13.6; non-perturbatively the question is open, and no unitary interacting counterexample is known in any d. For the fixed points met in practice (critical lattice models, Wilson–Fisher points, minimal models) conformal invariance is established.

Reading Nash (p. 301, Ch. XI §1)

"A necessary, but insufficient, condition for a theory to possess conformal invariance is that the renormalisation group flow has a fixed point." The fixed point gives scale invariance. The extra condition is that the virial current be a gradient (Section T5.5.2), and in two dimensions, for the unitary theories with discrete spectra that Nash has in mind (critical statistical models, unitary minimal models), it is automatic (Section T5.5.4). So for Nash's purposes the "insufficient" condition is in fact sufficient; in string theory, where the worldsheet theory is not unitary, it is not.

Recap

- For a vector field v, $\partial_\mu(T^{\mu\nu}v_\nu) = \frac{1}{2}T^{\mu\nu}(\partial_\mu v_\nu + \partial_\nu v_\mu)$: dilatations and conformal maps see only the trace $T^\mu{}_\mu$.
- Scale invariance $\Leftrightarrow T^\mu{}_\mu = \partial_\mu K^\mu$ (virial current). Conformal invariance $\Leftrightarrow$ in addition $K_\mu = \partial_\mu L$; then $\Theta_{\mu\nu} = T_{\mu\nu} + \frac{1}{d-1}(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2)L$ is traceless.
- Free scalar: $L = \frac{2-d}{4}\varphi^2$, conformal in all d. Free Maxwell in $d \neq 4$: $K^\mu = \frac{4-d}{2}A_\nu F^{\mu\nu}$, scale but not conformal.

- In 2D, conservation gives $\dot{F} = -\dot{G} + 3G$, $\dot{G} - G = -\dot{H} + 2H$; scale invariance makes F, G, H constant, so $G = H = 0$; reflection positivity then forces $\Theta = 0$.

T5.6 Quantum field theories as flows between conformal field theories

Fixed points of the RG are scale invariant, and (under the conditions of Section T5.5) conformal. Near a fixed point the flow is controlled by a finite list of relevant operators. Far from it, irrelevant couplings are slaved to relevant ones (Section T5.2.6). Now turn the picture around. Instead of asking what the RG does to a given theory, ask what a quantum field theory *is* from the RG point of view. The answer is short ([QFT notes §15.9.5]): *a quantum field theory is an RG trajectory, starting at a conformal field theory in the ultraviolet and ending at another one (possibly empty) in the infrared*.

T5.6.1 A QFT is a trajectory

Working definition T5.11 (relevant deformation of a CFT)

Start from a conformal field theory $\mathrm{CFT}_{\mathrm{UV}}$ [a theory with no length scale, such as a free massless field or a critical point] and add relevant operators [operators $\mathcal{O}_i$ of scaling dimension $\Delta_i < d$, so that their couplings grow towards long distances]:

$$S = S_{\mathrm{CFT}_{\mathrm{UV}}} + \sum_i \lambda_i \int \mathrm{d}^d x \, \mathcal{O}_i(x), \qquad [\lambda_i] = y_i = d - \Delta_i > 0. \tag{T5.100}$$

The result is a **relevant deformation** [a QFT whose short-distance limit is the CFT we started from]. Each λ_i carries a positive mass dimension y_i, so λ_i^{1/y_i} is a mass and it defines a length $\ell_i = \lambda_i^{-1/y_i}$. At distances $r \ll \ell_i$ the deformation is invisible; at $r \gg \ell_i$ it dominates. *Test:* the correlation functions at $r \to 0$ are those of $\mathrm{CFT}_{\mathrm{UV}}$; the RG trajectory leaves the UV fixed point along the relevant directions of Figure T5.11.

Where does the trajectory end? There are only two possibilities for a unitary theory at long distances.

- *A gapped phase.* All correlations die exponentially beyond some length ξ. The infrared fixed point is "empty" (a trivial theory, $c = 0$ in two dimensions) or a **topological field theory** [a theory with no local degrees of freedom whose correlators depend only on topology]. The latter is how Chern–Simons theory arises in Chapter 12.
- *A massless phase.* The trajectory ends at a non-trivial $\mathrm{CFT}_{\mathrm{IR}}$, which it approaches along its *irrelevant* directions.

Limit cycles are excluded in two dimensions by the c-theorem, and in four by the a-theorem (Section 11.13 in Chapter 11).

Key idea: the RG definition of a quantum field theory

A renormalisable quantum field theory is a relevant (or marginally relevant) deformation of a UV conformal field theory, with the couplings of (T5.100) as its parameters. Its number of free parameters is the number of relevant operators allowed by the symmetries. An effective field theory is the reverse: an infrared CFT (often free) deformed by *irrelevant*

operators, valid below the scale where they become strong.

Two examples make this concrete. Massive $\lambda\varphi^4$ theory in $d = 4$ is the free massless scalar (a CFT) deformed by φ^2 ($y = 2$) and the marginally irrelevant φ^4; it flows to the empty theory beyond the Compton wavelength. In $d = 3$ the same Lagrangian flows from the free scalar in the UV, past the Wilson–Fisher point (Figure T5.8), to a gapped phase: the theory is "super-renormalisable", its UV end is free and its long-distance physics near the critical line is the 3D Ising CFT.

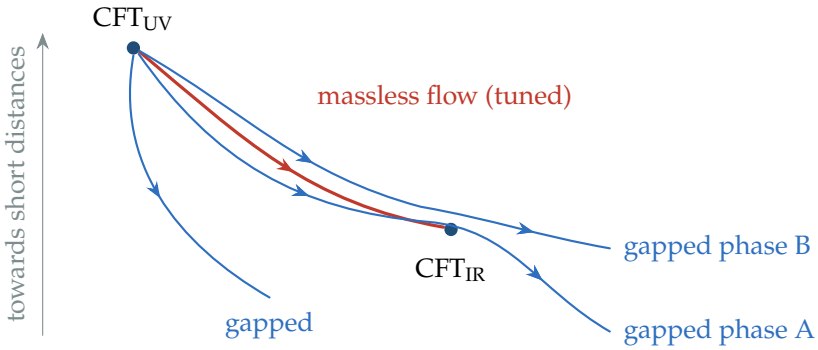

Figure T5.22: Quantum field theories as RG trajectories. Every trajectory leaves the UV fixed point along a relevant direction. The red one, tuned to lie on the critical surface of the IR fixed point, ends there: a massless theory interpolating between two CFTs. The blue ones pass close to CFT$_{\mathrm{IR}}$ (their physics at intermediate scales is governed by it) and are then pushed off into gapped phases. What to see: a QFT is the whole curve, its two ends are CFTs, and its parameters say which curve it is.

T5.6.2 Masses, correlation lengths and dimensional transmutation

With a single relevant coupling λ of dimension y, dimensional analysis alone fixes every mass in the theory up to pure numbers:

$$m = (\text{number}) \times \lambda^{1/y}, \qquad \xi \propto \lambda^{-1/y} = \lambda^{-\nu}, \qquad \nu = \frac{1}{y}. \tag{T5.101}$$

There is nothing else with the dimension of a mass. This is the continuum form of $\nu = 1/y_t$ (Section T5.3.1).

Worked example T5.27: The two-dimensional Ising field theory

Near its critical point the 2D Ising model is the $c = \frac{1}{2}$ CFT perturbed by the energy operator ε ($\Delta_\varepsilon = 1$) with coupling $\propto t$, and by the spin σ ($\Delta_\sigma = \frac{1}{8}$) with coupling $\propto h$ (these dimensions are derived in Chapter 11). By (T5.101),

$$\begin{aligned} h = 0: &\quad y_t = 2 - 1 = 1 \implies m \propto |t|, \\ t = 0: &\quad y_h = 2 - \tfrac{1}{8} = \tfrac{15}{8} \implies m \propto h^{8/15}. \end{aligned}$$

The first is Onsager's $\nu = 1$: the thermal perturbation is a free Majorana fermion of mass $\propto |t|$. The second is the celebrated $h^{8/15}$ law of the Ising model in a field at T_c, whose particle spectrum Zamolodchikov found to be organised by the exceptional Lie algebra E_8.

A *marginally* relevant coupling has $y = 0$ and defines no length by dimensional analysis. It still produces one, through its running.

Worked example T5.28: Dimensional transmutation

Let $\mathrm{d}g/\mathrm{d}t = +b\,g^2$ with $b > 0$ (towards the infrared the coupling grows; for Yang–Mills g^2 plays this role, cf. Example T5.25). Then

$$\frac{1}{g(t)} \overset{(1)}{=} \frac{1}{g_0} - bt, \qquad \Lambda_* := \Lambda\, e^{-1/(b\,g(\Lambda))},$$
$$\frac{\mathrm{d}\ln\Lambda_*}{\mathrm{d}t} \overset{(2)}{=} \frac{\mathrm{d}\ln\Lambda}{\mathrm{d}t} + \frac{1}{b\,g^2}\frac{\mathrm{d}g}{\mathrm{d}t} \overset{(3)}{=} -1 + 1 = 0.$$

(1) Separate variables as in Example T5.12, with the opposite sign.
(2) Differentiate $\ln\Lambda_* = \ln\Lambda - 1/(bg)$.
(3) $t = \ln(\Lambda_0/\Lambda)$ gives $\mathrm{d}\ln\Lambda/\mathrm{d}t = -1$; and $\mathrm{d}g/\mathrm{d}t = bg^2$.

So Λ_* is the same at every scale: an RG-invariant mass built from a dimensionless coupling. Where does the coupling become strong? Start at Λ_0 with g_0:

$$\frac{1}{g(\Lambda)} \overset{(1)}{=} \frac{1}{g_0} - b\ln\frac{\Lambda_0}{\Lambda} = 0 \quad\Longleftrightarrow\quad \Lambda \overset{(2)}{=} \Lambda_0\, e^{-1/(bg_0)} \overset{(3)}{=} \Lambda_*.$$

(1) The first line of the chain above with $t = \ln(\Lambda_0/\Lambda)$; $1/g = 0$ means $g = \infty$.
(2) Solve for $\ln(\Lambda_0/\Lambda) = 1/(bg_0)$.
(3) The definition of Λ_* evaluated at Λ_0 (it has the same value at every scale).

So the coupling blows up at $\Lambda = \Lambda_*$ (at one loop; in practice it becomes of order one near there), and every mass of the theory is a pure number times Λ_*. In QCD this is $\Lambda_{\mathrm{QCD}} \approx 200\,\mathrm{MeV}$, which sets the proton mass. A dimensionless parameter has been traded for a scale: this is **dimensional transmutation** ([QFT notes §15.9.4]).

T5.6.3 Crossover

Between the two ends of a trajectory a correlation function interpolates. Dimensional analysis gives it the **scaling form**

$$G(r) = \frac{1}{r^{2\Delta_{\mathrm{UV}}}}\,\Phi\!\left(\frac{r}{\xi}\right), \qquad \Phi(0) = \text{const}, \tag{T5.102}$$

with Δ_{UV} the dimension at the UV fixed point and Φ a universal function. For $r \ll \xi$ we see the UV CFT; for $r \gg \xi$ we see the IR end (Φ decays exponentially in a gapped phase, or as a power $(r/\xi)^{2\Delta_{\mathrm{UV}}-2\Delta_{\mathrm{IR}}}$ if the flow ends at a CFT). A good diagnostic is the **effective dimension**

$$\Delta_{\mathrm{eff}}(r) := -\frac{1}{2}\frac{\mathrm{d}\ln G}{\mathrm{d}\ln r}, \tag{T5.103}$$

which equals Δ on any stretch where G is a pure power.

Worked example T5.29: Crossover of a free massive field in three dimensions

The propagator of a free field of mass m in $d = 3$ is the Fourier transform of $1/(p^2+m^2)$. With $r = |x|$ and spherical coordinates around the direction of x,

$$G(r) \overset{(1)}{=} \int \frac{\mathrm{d}^3p}{(2\pi)^3}\,\frac{e^{ip\cdot x}}{p^2+m^2} \overset{(2)}{=} \frac{1}{4\pi^2}\int_0^\infty \mathrm{d}p\,\frac{p^2}{p^2+m^2}\int_{-1}^{1}\mathrm{d}c\; e^{iprc}$$
$$\overset{(3)}{=} \frac{1}{2\pi^2 r}\int_0^\infty \mathrm{d}p\,\frac{p\sin pr}{p^2+m^2} \overset{(4)}{=} \frac{e^{-mr}}{4\pi r}.$$

(1) Definition of the propagator.
(2) $\mathrm{d}^3p = p^2\mathrm{d}p\,\mathrm{d}c\,\mathrm{d}\phi$ with $c = \cos\theta$; the ϕ integral gives 2π, and $2\pi/(2\pi)^3 = 1/(4\pi^2)$.
(3) $\int_{-1}^{1} e^{iprc}\mathrm{d}c = 2\sin(pr)/(pr)$.
(4) The integrand is even in p, so the integral is $\frac{1}{2}\int_{-\infty}^{\infty}$ of $\mathrm{Im}\; pe^{ipr}/(p^2+m^2)$. Close the contour in the upper half plane, where e^{ipr} decays; the pole at $p = im$ has residue $\frac{im\,e^{-mr}}{2im} = \frac{1}{2}e^{-mr}$, so $\int_{-\infty}^{\infty}\frac{pe^{ipr}}{p^2+m^2}\mathrm{d}p = 2\pi i\cdot\frac{1}{2}e^{-mr}$, and the original integral is $\frac{\pi}{2}e^{-mr}$.

It has the scaling form with $\Delta_{\mathrm{UV}} = \frac{1}{2}$ (at $m = 0$, $G = 1/(4\pi r)$), $\xi = 1/m$ and $\Phi(x) = e^{-x}/4\pi$. Its effective dimension is

$$\Delta_{\mathrm{eff}}(r) \overset{(1)}{=} -\frac{1}{2}\,r\frac{\mathrm{d}}{\mathrm{d}r}\left(-mr - \ln r - \ln 4\pi\right) \overset{(2)}{=} \frac{1}{2} + \frac{mr}{2}.$$

(1) $\ln G = -mr - \ln r - \ln 4\pi$ and $\mathrm{d}/\mathrm{d}\ln r = r\,\mathrm{d}/\mathrm{d}r$.
(2) $r\,\mathrm{d}(mr)/\mathrm{d}r = mr$ and $r\,\mathrm{d}\ln r/\mathrm{d}r = 1$.

It starts at the free-field value $\frac{1}{2}$ and grows without bound once $r \gtrsim 1/m$: the signature of a gapped phase.

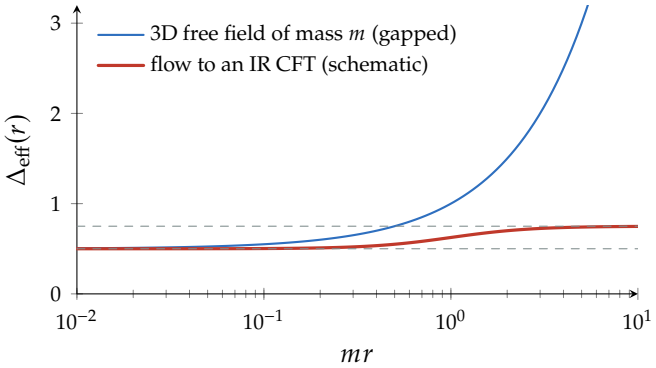

Figure T5.23: The effective dimension (T5.103) along two RG trajectories. Blue: the free massive field of Example T5.29, which starts at the UV value $\frac{1}{2}$ and then shoots up as correlations die exponentially. Red (a schematic interpolation, not a computed flow): a massless flow from $\Delta_{\mathrm{UV}} = \frac{1}{2}$ to a different IR dimension, here $\frac{3}{4}$, with a plateau at each end. What to see: the crossover happens around $r \sim \xi$, and the plateaus are the two CFTs at the ends of the trajectory.

Theory space can be a space of functions. Consider a two-dimensional sigma model

$$S = \frac{1}{4\pi\alpha'}\int \mathrm{d}^2x\, G_{\mu\nu}(X)\,\partial_a X^\mu \partial_a X^\nu.$$

Here the "coupling" is a whole metric $G_{\mu\nu}$ on the target space, one coupling for every point, and $R_{\mu\nu}$ below is its Ricci tensor. Its β-function is, at one loop and in the convention $\beta = \mu\,\mathrm{d}G/\mathrm{d}\mu$, $\beta^G_{\mu\nu} = \alpha' R_{\mu\nu}$ (Friedan 1980). It comes from the one-loop tadpole of the fluctuations of X around a point, whose coupling to the background is the curvature of G in Riemann normal coordinates; Chapter 9 takes this up. By (T5.91), with the operator $\mathcal{O} = \frac{1}{4\pi\alpha'}\partial_a X^\mu \partial_a X^\nu$ multiplying the coupling $G_{\mu\nu}$, the trace of the worldsheet stress tensor is proportional to $\beta^G_{\mu\nu}\,\partial_a X^\mu \partial_a X^\nu$. So conformal invariance of the worldsheet, which string theory requires, is $R_{\mu\nu} = 0$ at this order: *Einstein's equations in vacuum are an RG fixed-point condition*. The flow itself is $\partial_t G_{\mu\nu} = -\mu\,\mathrm{d}G_{\mu\nu}/\mathrm{d}\mu = -\alpha' R_{\mu\nu}$ (the sign flip of the pitfall in Section T5.1.4): Ricci flow.

T5.6.4 The dictionary

quantum field theory	RG / conformal field theory
renormalisable QFT	relevant deformation of a UV CFT, (T5.100)
effective field theory	IR CFT deformed by irrelevant operators
number of free parameters	number of relevant (and marginal) operators
mass m, correlation length ξ	$\lambda^{1/y}$, $\lambda^{-1/y}$, (T5.101)
running coupling $g(\mu)$	position along the trajectory
β-function	the RG vector field, (T5.5)
anomalous dimension γ	$\Delta - \Delta_{\text{canonical}}$ at a fixed point
asymptotic freedom	UV end is the Gaussian (free) fixed point
Λ_{QCD}	dimensional transmutation of a marginally relevant coupling
trace anomaly $T^{\mu}{}_{\mu} \neq 0$	$T^{\mu}{}_{\mu} = -\beta^i \mathcal{O}_i$, (T5.91)
critical point, universality class	fixed point, its CFT
critical exponents	scaling dimensions, $y = d - \Delta$
phase of matter	basin of attraction of an IR fixed point
gapped phase	trivial or topological IR theory
irreversibility of coarse graining	c- and a-theorems (Chapter 11)

Recap

- A QFT is an RG trajectory: a UV CFT deformed by relevant operators, ending in a gapped phase or at an IR CFT.
- Masses follow from dimensional analysis, $m \propto \lambda^{1/y}$; for the 2D Ising model $m \propto |t|$ and $m \propto h^{8/15}$.
- A marginally relevant coupling generates the RG-invariant scale $\Lambda_* = \Lambda e^{-1/bg(\Lambda)}$.
- Correlators cross over between the UV and IR dimensions; the effective dimension shows the plateaus.
- For a sigma model the fixed-point condition is $R_{\mu\nu} = 0$.

T5.7 Beta-functions with geometry

In Section T5.4 the couplings were numbers, λ and g. Two theories that matter later in the book have couplings of a different kind. In the two-dimensional sigma model of string theory the coupling is a whole Riemannian metric, and its β-function turns out to be the Ricci tensor (Section T5.7.1). In three-dimensional Chern–Simons theory the coupling is an integer, the level k, which cannot run at all, and yet one loop shifts it by a fixed integer (Section T5.7.2). Both answers are one-loop calculations of the kind done in Section T5.4. What is new is that the answer is a geometric object: a curvature in the first case, a spectral invariant in the second.

We keep the convention of Section T5.4: $\beta := \mu\, \mathrm{d}(\text{coupling})/\mathrm{d}\mu$, with the scale μ increasing towards the ultraviolet.

T5.7.1 The sigma model: the coupling is a metric

The string worldsheet of Chapter 9 is a surface Σ with D scalar fields $X^\mu(\sigma)$ on it, the position of the string in space-time. In flat space-time they are free fields. In a curved space-time the flat metric is replaced by a metric $G_{\mu\nu}(X)$, and the theory is no longer free. Is it still scale invariant, as string theory requires? This subsection computes the answer: only if G is Ricci flat, to first order in the curvature.

Working definition T5.12 (nonlinear sigma model)

A **nonlinear sigma model** is a field theory whose field is a map $X : \Sigma \to M$ [each point σ of the surface is sent to a point $X(\sigma)$ of a space M] from a surface Σ with metric g_{ab} into a **target** M with metric $G_{\mu\nu}(x)$ [a matrix at each point x of M that measures lengths there, and changes from point to point]. In Euclidean signature, with weight e^{-S}, the action is

$$S[X] = \frac{1}{4\pi\alpha'} \int_\Sigma \mathrm{d}^2\sigma \, \sqrt{g}\, g^{ab}\, G_{\mu\nu}(X)\, \partial_a X^\mu \partial_b X^\nu . \tag{T5.104}$$

It is the energy of the map [how much X stretches the surface, with lengths measured by G] divided by $2\pi\alpha'$, where α' is a constant of dimension length^2 (the string length squared). *How to use it:* expand X about a background map, and read the Taylor coefficients of G as coupling constants.

For $G_{\mu\nu} = \delta_{\mu\nu}$ and $T = 1/2\pi\alpha'$ this is the Polyakov action of Chapter 9. On a flat worldsheet ($g_{ab} = \delta_{ab}$) we write $\partial_a X^\mu \partial_a X^\nu$ with a summed.

Why the metric is a coupling. Choose coordinates x on M centred at a point x_0 in which $G_{\mu\nu}(x_0) = \delta_{\mu\nu}$ and $\partial_\rho G_{\mu\nu}(x_0) = 0$ (Riemann normal coordinates, Chapter T2). Put $X = x_0 + y$ and Taylor expand. The first non-trivial coefficient is the second derivative of G, whose size is $1/r_c^2$ for a curvature radius r_c. Rescale $y = \sqrt{\alpha'}\,\tilde{y}$ so that the kinetic term is $\frac{1}{4\pi}(\partial\tilde{y})^2$:

$$\begin{aligned} S &\overset{(1)}{=} \frac{1}{4\pi\alpha'} \int \mathrm{d}^2\sigma \Big[\delta_{\mu\nu} + \tfrac{1}{2}\,\partial_\alpha\partial_\beta G_{\mu\nu}(x_0)\, y^\alpha y^\beta + \dots \Big] \partial_a y^\mu \partial_a y^\nu \\ &\overset{(2)}{=} \frac{1}{4\pi} \int \mathrm{d}^2\sigma \Big[\partial_a \tilde{y}^\mu \partial_a \tilde{y}^\mu + \tfrac{1}{2}\,\alpha'\,\partial_\alpha\partial_\beta G_{\mu\nu}(x_0)\, \tilde{y}^\alpha \tilde{y}^\beta\, \partial_a \tilde{y}^\mu \partial_a \tilde{y}^\nu + \dots \Big] . \end{aligned}$$

(1) Taylor expansion of $G_{\mu\nu}(x_0 + y)$; the linear term is absent because $\partial G(x_0) = 0$, and $\partial_a X = \partial_a y$ because x_0 is constant.

(2) $y^\alpha y^\beta \partial y^\mu \partial y^\nu = \alpha'^2\, \tilde{y}^\alpha \tilde{y}^\beta \partial\tilde{y}^\mu \partial\tilde{y}^\nu$, and $\alpha'^2/\alpha' = \alpha'$.

The quartic vertex has the dimensionless strength $\alpha'\,\partial\partial G \sim \alpha'/r_c^2$. Perturbation theory in the sigma model is an expansion in (string length/curvature radius)^2. The Taylor coefficients at every point are couplings, so "the coupling" is the whole function $G_{\mu\nu}(x)$, and its β-function is a symmetric tensor field $\beta^G_{\mu\nu}(x)$ on M.

Worked example T5.30: The sphere: the $O(n)$ model

Take $M = S^{n-1}$ of radius r, written as $X = r\,\mathbf{n}$ with a unit vector $\mathbf{n} \in \mathbb{R}^n$, $\mathbf{n}\cdot\mathbf{n} = 1$. The induced metric is $G = r^2 \hat{G}$, where $\hat{G}$ is the metric of the unit sphere, and

$$S \overset{(1)}{=} \frac{r^2}{4\pi\alpha'} \int \mathrm{d}^2\sigma\, \partial_a\mathbf{n}\cdot\partial_a\mathbf{n} \overset{(2)}{=} \frac{1}{2g^2} \int \mathrm{d}^2\sigma\, \partial_a\mathbf{n}\cdot\partial_a\mathbf{n}, \qquad g^2 := \frac{2\pi\alpha'}{r^2}.$$

(1) $G_{\mu\nu}\partial_a X^\mu \partial_a X^\nu$ is the squared length of $\partial_a X = r\,\partial_a\mathbf{n}$ in $\mathbb{R}^n$.

(2) Definition of g^2: $\frac{r^2}{4\pi\alpha'} = \frac{1}{2g^2}$.

This is the $O(n)$ model of statistical mechanics (for $n = 3$, the continuum Heisenberg ferromagnet). A large sphere is weak coupling. Its Ricci tensor (sign conventions in (T5.105) below) follows from the Riemann tensor of a sphere of radius r, $R_{\rho\sigma\mu\nu} = r^{-2}(G_{\rho\mu}G_{\sigma\nu} - G_{\rho\nu}G_{\sigma\mu})$, which for $n = 3$ is the statement that the Gauss curvature is $1/r^2$ (Chapter T2):

$$R_{\sigma\nu} = G^{\rho\mu}R_{\rho\sigma\mu\nu} \overset{(1)}{=} \frac{1}{r^2}\big((n-1)G_{\sigma\nu} - G_{\sigma\nu}\big) = \frac{n-2}{r^2}\,G_{\sigma\nu} = (n-2)\,\hat{G}_{\sigma\nu}.$$

(1) $G^{\rho\mu}G_{\rho\mu} = \dim M = n - 1$ and $G^{\rho\mu}G_{\rho\nu}G_{\sigma\mu} = G_{\sigma\nu}$.

The Ricci tensor of a round sphere does not depend on its radius.

Step 1: expand along geodesics. To integrate out short-wavelength fluctuations we split X into a slowly varying background $x(\sigma)$ and a fluctuation. The naive split $X = x + y$ is coordinate dependent: y is a difference of coordinates, not a vector, and the coefficients ∂G, $\partial\partial G$ of its expansion are not tensors. The cure is to describe the fluctuation by a tangent vector $\xi(\sigma) \in T_{x(\sigma)}M$ and to reach $X(\sigma)$ by following the geodesic that leaves $x(\sigma)$ with velocity $\xi(\sigma)$ for unit time (Figure T5.24). Then every coefficient of the expansion is a tensor at x [Alvarez-Gaumé, Freedman and Mukhi 1981].

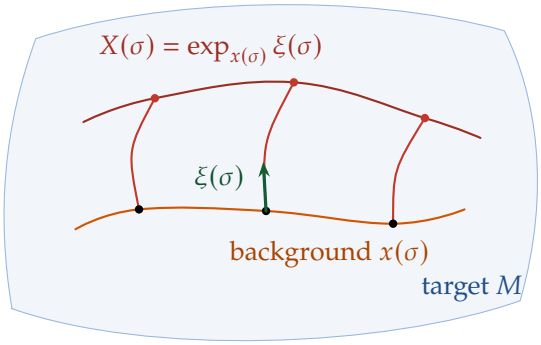

Figure T5.24: The geodesic split of the field. The orange curve is the background map $x(\sigma)$ (one line of the worldsheet drawn in the target). From each of its points a geodesic (red) leaves with initial velocity $\xi(\sigma)$ (green), a tangent vector at $x(\sigma)$; after unit time it arrives at the point $X(\sigma)$ on the full field (upper red curve). Because ξ is a vector at x, the expansion of the action in powers of ξ has tensors as coefficients, and the first one that matters is the Riemann tensor.

Write $X_s(\sigma)$ for the point reached at time s, so $X_0 = x$, $X_1 = X$, $\partial_s X_s|_{s=0} = \xi$, and $\nabla_s\partial_s X_s = 0$ (each curve $s \mapsto X_s(\sigma)$ is a geodesic). Let $E(s) = \frac{1}{2}\int \mathrm{d}^2\sigma\, G(\partial_a X_s, \partial_a X_s)$, so that $S[X_s] = E(s)/2\pi\alpha'$ on a flat worldsheet. Our curvature convention is

$$[\nabla_\mu, \nabla_\nu]W^\rho = R^\rho{}_{\sigma\mu\nu}W^\sigma, \qquad R_{\sigma\nu} = R^\rho{}_{\sigma\rho\nu}, \tag{T5.105}$$

for which a round sphere has positive Ricci tensor (Example T5.30). Along the two-parameter family $X_s(\sigma)$ the covariant derivatives ∇_s and ∇_a of vector fields along the map obey $\nabla_s\partial_a X = \nabla_a\partial_s X$ (the Levi-Civita connection has no torsion and $[\partial_s, \partial_a] = 0$) and $\nabla_s\nabla_a W - \nabla_a\nabla_s W = R(\partial_s X, \partial_a X)W$, which is (T5.105) with W^ρ carried along the map. Then

$$E'(s) \overset{(1)}{=} \int \mathrm{d}^2\sigma\, G\big(\partial_a X_s, \nabla_s\partial_a X_s\big) \overset{(2)}{=} \int \mathrm{d}^2\sigma\, G\big(\partial_a X_s, \nabla_a\partial_s X_s\big),$$

$$
\begin{aligned}
E''(s) &\overset{(3)}{=} \int \mathrm{d}^2\sigma \Big[G\big(\nabla_s \partial_a X_s, \nabla_a \partial_s X_s\big) + G\big(\partial_a X_s, \nabla_s \nabla_a \partial_s X_s\big) \Big] \\
&\overset{(4)}{=} \int \mathrm{d}^2\sigma \Big[G\big(\nabla_a \partial_s X_s, \nabla_a \partial_s X_s\big) + G\big(\partial_a X_s, R(\partial_s X_s, \partial_a X_s)\partial_s X_s\big) \Big], \\
E''(0) &\overset{(5)}{=} \int \mathrm{d}^2\sigma \Big[G_{\mu\nu} \nabla_a \xi^\mu \nabla_a \xi^\nu + R_{\mu\alpha\beta\nu}\, \xi^\alpha \xi^\beta\, \partial_a x^\mu \partial_a x^\nu \Big].
\end{aligned}
$$

(1) The metric is covariantly constant, so $\partial_s G(V,V) = 2G(V, \nabla_s V)$; the $\frac{1}{2}$ cancels the 2.
(2) No torsion: $\nabla_s \partial_a X = \nabla_a \partial_s X$.
(3) Differentiate the first line of E' again with the same product rule.
(4) In the first term use (2) again. In the second, swap ∇_s and ∇_a at the price of a curvature term; the swapped term $\nabla_a \nabla_s \partial_s X$ vanishes because the curves $s \mapsto X_s$ are geodesics.
(5) At $s = 0$: $\partial_s X = \xi$ and $X = x$. In components $G(\partial_a x, R(\xi, \partial_a x)\xi) = G_{\mu\rho} \partial_a x^\mu R^\rho{}_{\alpha\beta\nu} \xi^\alpha \xi^\beta \partial_a x^\nu$, with $R(U,V)W^\rho = R^\rho{}_{\sigma\mu\nu} W^\sigma U^\mu V^\nu$; lowering ρ gives $R_{\mu\alpha\beta\nu}$.

Here $\nabla_a \xi^\mu = \partial_a \xi^\mu + \Gamma^\mu_{\nu\rho}(x)\, \partial_a x^\nu\, \xi^\rho$ is the covariant derivative of ξ along the background. Taylor's theorem, $S[X_1] = \frac{1}{2\pi\alpha'}\big(E(0) + E'(0) + \frac{1}{2}E''(0) + \dots\big)$, gives

$$
\begin{aligned}
S[X] = S[x] &+ \frac{1}{2\pi\alpha'} \int \mathrm{d}^2\sigma\, G_{\mu\nu}\, \partial_a x^\mu \nabla_a \xi^\nu \\
&+ \frac{1}{4\pi\alpha'} \int \mathrm{d}^2\sigma \Big[G_{\mu\nu} \nabla_a \xi^\mu \nabla_a \xi^\nu + R_{\mu\alpha\beta\nu}\, \xi^\alpha \xi^\beta\, \partial_a x^\mu \partial_a x^\nu \Big] + O(\xi^3).
\end{aligned}
\tag{T5.106}
$$

On the round sphere the curvature term is $r^{-2}\big[(\xi \cdot \partial_a x)^2 - |\xi|^2\, |\partial_a x|^2\big] \le 0$, by the Riemann tensor of Example T5.30. Pushing a stretched map sideways on a sphere lowers its energy, because neighbouring geodesics converge. This focusing is what will make the sphere shrink under the RG.

Step 2: integrate out a shell. Take the background $x(\sigma)$ to contain only wavelengths longer than $1/\Lambda'$, and the fluctuation ξ only wave numbers in the shell $\Lambda' < |k| < \Lambda$, as in Wilson's calculation of Section T5.3.3. Three simplifications make the one-loop calculation short.

- The term linear in ξ is $E'(0)/2\pi\alpha'$. Integrating by parts, $E'(0) = -\int G(\nabla_a \partial_a x, \xi)$, and $\nabla_a \partial_a x^\mu = \partial^2 x^\mu + \Gamma^\mu_{\nu\rho} \partial_a x^\nu \partial_a x^\rho = 0$ is the classical equation of motion. We expand about a classical solution, so this term is absent.
- Only terms quadratic in ξ enter at one loop, because the one-loop integral is the Gaussian integral over ξ. Each extra power of ξ costs a factor $\sqrt{\alpha'}$, by the rescaling $y = \sqrt{\alpha'}\,\tilde{y}$ above.
- Use an orthonormal frame $e^i{}_\mu(x)$ [D perpendicular unit vectors at each point of M] and write $\xi^i = e^i{}_\mu \xi^\mu$. Then $G_{\mu\nu} \nabla_a \xi^\mu \nabla_a \xi^\nu = (\partial_a \xi^i + \omega_a{}^i{}_j \xi^j)^2$, where $\omega_a = \omega_\mu(x) \partial_a x^\mu$ is the spin connection pulled back to the worldsheet. It acts on ξ^i like a two-dimensional $\mathrm{SO}(D)$ gauge field, and rotating the frame is a gauge transformation of it. As in the background-field gauge of Section T5.4.3, the divergences it produces must be gauge invariant. In two dimensions the only gauge-invariant local term of dimension two is $\mathrm{tr}(\epsilon^{ab} \mathcal{F}_{ab})$, with $\mathcal{F}_{ab}$ the curvature of ω_a. It is the trace of an antisymmetric $\mathfrak{so}(D)$ matrix, which is zero. So ω produces no divergence, and the free kinetic term $\frac{1}{4\pi\alpha'}(\partial \xi^i)^2$ is all we need.

The shell average of two fluctuations at the same point is

$$
\big\langle \xi^i(\sigma) \xi^j(\sigma) \big\rangle_{\text{shell}} \overset{(1)}{=} \delta^{ij} \int_{\Lambda' < |k| < \Lambda} \frac{\mathrm{d}^2 k}{(2\pi)^2} \frac{2\pi\alpha'}{k^2} \overset{(2)}{=} \delta^{ij} \frac{2\pi\alpha'}{(2\pi)^2} 2\pi \int_{\Lambda'}^{\Lambda} \frac{\mathrm{d}k}{k} = \delta^{ij}\, \alpha' \ln \frac{\Lambda}{\Lambda'}. \tag{T5.107}
$$

(1) In Fourier space $\frac{1}{4\pi\alpha'}\int(\partial\xi)^2 = \frac{1}{2}\int\frac{\mathrm{d}^2k}{(2\pi)^2}\,\tilde\xi(-k)\,\frac{k^2}{2\pi\alpha'}\,\tilde\xi(k)$. A Gaussian $e^{-\frac{1}{2}Av^2}$ has $\langle v^2\rangle = 1/A$, so the propagator is $2\pi\alpha'/k^2$.
(2) Polar coordinates, $\mathrm{d}^2k = 2\pi k\,\mathrm{d}k$.

To first order in the curvature vertex, integrating out the shell replaces $\xi^\alpha\xi^\beta$ in (T5.106) by its average, so the action of the slow field becomes

$$\begin{aligned} S_{\Lambda'}[x] &\overset{(1)}{=} \frac{1}{4\pi\alpha'}\int \mathrm{d}^2\sigma\Big[G_{\mu\nu} + R_{\mu\alpha\beta\nu}\big\langle\xi^\alpha\xi^\beta\big\rangle_{\text{shell}}\Big]\partial_a x^\mu\partial_a x^\nu \\ &\overset{(2)}{=} \frac{1}{4\pi\alpha'}\int \mathrm{d}^2\sigma\Big[G_{\mu\nu} + \alpha'\ln\frac{\Lambda}{\Lambda'}\,G^{\alpha\beta}R_{\mu\alpha\beta\nu}\Big]\partial_a x^\mu\partial_a x^\nu \\ &\overset{(3)}{=} \frac{1}{4\pi\alpha'}\int \mathrm{d}^2\sigma\Big[G_{\mu\nu} - \alpha'\ln\frac{\Lambda}{\Lambda'}\,R_{\mu\nu}\Big]\partial_a x^\mu\partial_a x^\nu. \end{aligned} \tag{T5.108}$$

(1) $\int\mathcal{D}\xi\,e^{-S_0-V} = e^{-\langle V\rangle+\cdots}$ times a constant, with V the curvature vertex (the cumulant expansion used in Section T5.3.3).
(2) (T5.107) with $\xi^\alpha = e_i{}^\alpha\xi^i$ and $\sum_i e_i{}^\alpha e_i{}^\beta = G^{\alpha\beta}$.
(3) $G^{\alpha\beta}R_{\mu\alpha\beta\nu} = -G^{\alpha\beta}R_{\alpha\mu\beta\nu} = -R^\beta{}_{\mu\beta\nu} = -R_{\mu\nu}$: antisymmetry in the first pair of indices, then (T5.105).

So the metric seen at scale Λ' is $G_{\mu\nu}(\Lambda') = G_{\mu\nu}(\Lambda) - \alpha'\ln(\Lambda/\Lambda')R_{\mu\nu}$. Calling the lower scale μ,

$$\mu\frac{\mathrm{d}G_{\mu\nu}}{\mathrm{d}\mu} \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}\ln\Lambda'}\Big[G_{\mu\nu}(\Lambda) - \alpha'(\ln\Lambda - \ln\Lambda')R_{\mu\nu}\Big] = \alpha' R_{\mu\nu}. \tag{T5.109}$$

(1) $\mu = \Lambda'$, with Λ and the bare metric held fixed; the change of $R_{\mu\nu}$ is of order α' and contributes at two loops.

Key idea: the sigma-model β-function is the Ricci tensor

For the sigma model (T5.104), at one loop,

$$\beta^G_{\mu\nu} := \mu\frac{\mathrm{d}G_{\mu\nu}}{\mathrm{d}\mu} = \alpha' R_{\mu\nu} + O(\alpha'^2). \tag{T5.110}$$

Positive curvature shrinks the target towards the infrared; negative curvature expands it. The next term is $\frac{1}{2}\alpha'^2 R_{\mu\kappa\lambda\tau}R_\nu{}^{\kappa\lambda\tau}$ [Friedan 1980].

Worked example T5.31: Asymptotic freedom of the $O(n)$ model

For the sphere of Example T5.30, $G = r^2\hat G$ and $R_{\mu\nu} = (n-2)\hat G_{\mu\nu}$. So (T5.110) is a flow of the radius alone, and of $g^2 = 2\pi\alpha'/r^2$:

$$\mu\frac{\mathrm{d}r^2}{\mathrm{d}\mu}\,\hat G_{\mu\nu} \overset{(1)}{=} \alpha'(n-2)\,\hat G_{\mu\nu} \quad\Longrightarrow\quad \mu\frac{\mathrm{d}r^2}{\mathrm{d}\mu} = \alpha'(n-2),$$
$$\mu\frac{\mathrm{d}g^2}{\mathrm{d}\mu} \overset{(2)}{=} -\frac{2\pi\alpha'}{r^4}\,\mu\frac{\mathrm{d}r^2}{\mathrm{d}\mu} \overset{(3)}{=} -\frac{(n-2)}{2\pi}\,g^4.$$

(1) $\beta^G = \mu\,\mathrm{d}(r^2\hat G)/\mathrm{d}\mu$, and $\hat G$ does not change.
(2) Differentiate $g^2 = 2\pi\alpha'/r^2$.
(3) First line, and $(2\pi\alpha'/r^2)^2 = g^4$.

For $n \geq 3$ the coupling decreases at short distances: the $O(n)$ model is asymptotically free [Polyakov 1975], like Yang–Mills theory (compare $\beta(g) = -b_0 g^3/16\pi^2$ in (T5.83)). As there,

the coupling transmutes into a scale (Example T5.28): $\mu\,\mathrm{d}(g^{-2})/\mathrm{d}\mu = (n-2)/2\pi$ integrates to

$$\Lambda_{O(n)} \overset{(1)}{=} \mu\,\exp\!\Big(-\frac{2\pi}{(n-2)\,g^2(\mu)}\Big),$$

(1) $\ln(\mu/\Lambda_{O(n)}) = \frac{2\pi}{n-2}g^{-2}(\mu)$ makes $\mu\,\mathrm{d}(g^{-2})/\mathrm{d}\mu = (n-2)/2\pi$ hold, and $\Lambda_{O(n)}$ is then μ-independent, exactly as for (T5.84).

and the model has a mass gap of order $\Lambda_{O(n)}$ (Chapter 13). For $n = 2$ the target is a circle, $R_{\mu\nu} = 0$, and the radius does not run: the free compact boson.

Worked example T5.32: The linearised check: the graviton is massless

Near flat space, $G_{\mu\nu} = \delta_{\mu\nu} + \chi_{\mu\nu}$ with χ small, the sigma model is the free string perturbed by a graviton vertex operator. Its Weyl anomaly can be computed directly from the operator product of two ∂X's, and Polchinski finds, to first order in χ, $\beta^G_{\mu\nu} = -\frac{\alpha'}{2}\big(\partial^2\chi_{\mu\nu} - \partial_\nu\partial^\omega\chi_{\mu\omega} - \partial_\mu\partial^\omega\chi_{\omega\nu} + \partial_\mu\partial_\nu\chi^\omega{}_\omega\big)$ [Polchinski, *String Theory* I, (3.7.13)]. Linearising the Ricci tensor reproduces this. To first order, $\Gamma^\rho_{\mu\nu} = \frac{1}{2}(\partial_\mu\chi^\rho{}_\nu + \partial_\nu\chi^\rho{}_\mu - \partial^\rho\chi_{\mu\nu})$, and

$$\begin{aligned} R_{\mu\nu} &\overset{(1)}{=} \partial_\rho\Gamma^\rho_{\nu\mu} - \partial_\nu\Gamma^\rho_{\rho\mu} \\ &\overset{(2)}{=} \tfrac{1}{2}\big(\partial_\rho\partial_\nu\chi^\rho{}_\mu + \partial_\rho\partial_\mu\chi^\rho{}_\nu - \partial^2\chi_{\mu\nu}\big) - \tfrac{1}{2}\partial_\nu\partial_\mu\chi^\rho{}_\rho \\ &\overset{(3)}{=} -\tfrac{1}{2}\big(\partial^2\chi_{\mu\nu} - \partial_\nu\partial^\omega\chi_{\mu\omega} - \partial_\mu\partial^\omega\chi_{\omega\nu} + \partial_\mu\partial_\nu\chi^\omega{}_\omega\big). \end{aligned}$$

(1) $R^\rho{}_{\mu\rho\nu}$ from (T5.105), $R^\rho{}_{\sigma\mu\nu} = \partial_\mu\Gamma^\rho_{\nu\sigma} - \partial_\nu\Gamma^\rho_{\mu\sigma} + \Gamma\Gamma$, dropping $\Gamma\Gamma = O(\chi^2)$.
(2) Insert Γ; in $\Gamma^\rho_{\rho\mu}$ the first and third terms cancel, leaving $\frac{1}{2}\partial_\mu\chi^\rho{}_\rho$.
(3) Rename $\rho \to \omega$ and use the symmetry of χ.

So $\alpha' R_{\mu\nu}$ is exactly the vertex-operator answer. In the gauge $\partial^\omega\chi_{\omega\mu} = \frac{1}{2}\partial_\mu\chi^\omega{}_\omega$ it is $-\frac{\alpha'}{2}\partial^2\chi_{\mu\nu}$, and $\beta^G = 0$ becomes the massless wave equation for a plane wave $\chi \propto e^{ik\cdot X}$: $k^2 = 0$, the graviton is massless.

Step 3: the Weyl anomaly and the string. String theory needs the worldsheet theory to be invariant under local rescalings $g_{ab} \to e^{2\omega(\sigma)}g_{ab}$ (Chapter 9). The general statement (T5.91) says that the trace of the stress tensor measures the β-functions. We translate it into the string normalisation, in which $T^{ab} := (4\pi/\sqrt{g})\,\delta S/\delta g_{ab}$ [Polchinski, §2.3], so that $\delta S = \frac{1}{2\pi}\int\sqrt{g}\,\delta\omega\,T^a{}_a$ for $\delta g_{ab} = 2\delta\omega\,g_{ab}$:

$$T^a{}_a \overset{(1)}{=} -2\pi\,T^\mu{}_\mu\big|_{(\mathrm{T5.91})} \overset{(2)}{=} 2\pi\sum_i \frac{\mathrm{d}g^i}{\mathrm{d}t}\,\mathcal{O}_i \overset{(3)}{=} -2\pi\sum_i \mu\frac{\mathrm{d}g^i}{\mathrm{d}\mu}\,\mathcal{O}_i \overset{(4)}{=} -\frac{1}{2\alpha'}\,\beta^G_{\mu\nu}\,g^{ab}\partial_a X^\mu\partial_b X^\nu. \quad \text{(T5.111)}$$

(1) (T5.91) uses $\delta S = \frac{1}{2}\int\sqrt{g}\,T_{ab}\,\delta g^{ab}$. Since $\delta g^{ab} = -g^{ac}g^{bd}\delta g_{cd}$, the string definition gives $\delta S = -\frac{1}{4\pi}\int\sqrt{g}\,T_{ab}\,\delta g^{ab}$; comparing, $T_{\text{string}} = -2\pi\,T$.
(2) (T5.91), $T^\mu{}_\mu = -\sum_i\beta^i\mathcal{O}_i$, whose β^i is the flow $\mathrm{d}g^i/\mathrm{d}t$ towards the infrared.
(3) $\mathrm{d}/\mathrm{d}t = -\mu\,\mathrm{d}/\mathrm{d}\mu$ (the pitfall in Section T5.1.4).
(4) The couplings are the values $G_{\mu\nu}(x)$ at every target point, and the operator multiplying $G_{\mu\nu}(X(\sigma))$ in (T5.104) is $\frac{1}{4\pi\alpha'}g^{ab}\partial_a X^\mu\partial_b X^\nu$.

So the worldsheet is Weyl invariant exactly when $\beta^G_{\mu\nu} = 0$. The string can move consistently only through a space-time whose metric is a fixed point of the sigma-model RG.

Strings also couple to the antisymmetric tensor $B_{\mu\nu}$ and to the dilaton Φ, the other two

massless closed-string fields:

$$S = \frac{1}{4\pi\alpha'}\int \mathrm{d}^2\sigma\,\sqrt{g}\Big[\big(g^{ab}G_{\mu\nu} + i\epsilon^{ab}B_{\mu\nu}\big)\partial_a X^\mu \partial_b X^\nu + \alpha' R^{(2)}\Phi(X)\Big], \tag{T5.112}$$

with $R^{(2)}$ the worldsheet curvature and $\sqrt{g}\,\epsilon^{12} = 1$. The field strength $H_{\omega\mu\nu} = \partial_\omega B_{\mu\nu} + \partial_\mu B_{\nu\omega} + \partial_\nu B_{\omega\mu}$ is invariant under $\delta B_{\mu\nu} = \partial_\mu\zeta_\nu - \partial_\nu\zeta_\mu$, which changes the action by a total derivative. The dilaton term is *classically* not Weyl invariant, and its failure is of the same order in α' as the one-loop effect of G. Under $g \to e^{2\delta\omega}g$ in two dimensions $\sqrt{g}\,R^{(2)} \to \sqrt{g}\,(R^{(2)} - 2\nabla^2\delta\omega)$ (Chapter 9), and

$$\delta S_\Phi \overset{(1)}{=} \frac{1}{4\pi}\int \mathrm{d}^2\sigma\,\sqrt{g}\,\big(-2\nabla^2\delta\omega\big)\,\Phi(X) \overset{(2)}{=} \frac{1}{2\pi}\int \mathrm{d}^2\sigma\,\sqrt{g}\,\delta\omega\,\big(-\nabla^2\Phi(X)\big),$$

$$\nabla^2\Phi(X) \overset{(3)}{=} \partial_\mu\partial_\nu\Phi\,\partial_a X^\mu\partial^a X^\nu + \partial_\rho\Phi\,\nabla^2 X^\rho \overset{(4)}{=} \nabla_\mu\nabla_\nu\Phi\,\partial_a X^\mu\partial^a X^\nu + \partial_\rho\Phi\big(\nabla^2 X^\rho + \Gamma^\rho_{\mu\nu}\partial_a X^\mu\partial^a X^\nu\big)$$
$$\overset{(5)}{=} \nabla_\mu\nabla_\nu\Phi\,\partial_a X^\mu\partial^a X^\nu + O(\alpha').$$

(1) The $\frac{1}{4\pi\alpha'}\cdot\alpha' = \frac{1}{4\pi}$ term of (T5.112) and the variation of $\sqrt{g}R^{(2)}$.
(2) Integrate ∇^2 by parts twice (the worldsheet is closed).
(3) Chain rule twice: $\partial_a\Phi(X) = \partial_\mu\Phi\,\partial_a X^\mu$, then ∇^a of that.
(4) Target covariant derivative, $\partial_\mu\partial_\nu\Phi = \nabla_\mu\nabla_\nu\Phi + \Gamma^\rho_{\mu\nu}\partial_\rho\Phi$.
(5) The bracket is the classical equation of motion of X at $B = \Phi = 0$ (step 2); the B and Φ corrections to it are of higher order.

So the dilaton adds $-\nabla_\mu\nabla_\nu\Phi\,\partial X^\mu\partial X^\nu$ to $T^a{}_a$, which in the form (T5.111) is a shift $\beta^G_{\mu\nu} \to \beta^G_{\mu\nu} + 2\alpha'\nabla_\mu\nabla_\nu\Phi$. The complete one-loop result has the same structure for all three fields.

Key idea: the string's β-functions

With the conventions of (T5.112) and $T^{ab} = (4\pi/\sqrt{g})\,\delta S/\delta g_{ab}$,

$$T^a{}_a = -\frac{1}{2\alpha'}\beta^G_{\mu\nu}g^{ab}\partial_a X^\mu\partial_b X^\nu - \frac{i}{2\alpha'}\beta^B_{\mu\nu}\epsilon^{ab}\partial_a X^\mu\partial_b X^\nu - \frac{1}{2}\beta^\Phi R^{(2)},$$

and [Polchinski, (3.7.14)]

$$\beta^G_{\mu\nu} = \alpha' R_{\mu\nu} + 2\alpha'\nabla_\mu\nabla_\nu\Phi - \tfrac{\alpha'}{4}H_{\mu\lambda\omega}H_\nu{}^{\lambda\omega} + O(\alpha'^2),$$
$$\beta^B_{\mu\nu} = -\tfrac{\alpha'}{2}\nabla^\omega H_{\omega\mu\nu} + \alpha'\nabla^\omega\Phi\,H_{\omega\mu\nu} + O(\alpha'^2),$$
$$\beta^\Phi = \frac{D-26}{6} - \tfrac{\alpha'}{2}\nabla^2\Phi + \alpha'\nabla_\omega\Phi\nabla^\omega\Phi - \tfrac{\alpha'}{24}H_{\mu\nu\lambda}H^{\mu\nu\lambda} + O(\alpha'^2).$$

Weyl invariance, $\beta^G = \beta^B = \beta^\Phi = 0$, is Einstein's equation with sources, a Maxwell equation for B, and a condition that fixes the number of dimensions. The $R_{\mu\nu}$ and $\nabla\nabla\Phi$ terms are derived above; the $\frac{D-26}{6}$ is the flat-space conformal anomaly of D scalars and the ghosts (Chapters 9 and 10); the H terms come from the same tadpole with the connection $\Gamma^\mu_{\nu\rho} \pm \frac{1}{2}H^\mu{}_{\nu\rho}$.

Worked example T5.33: The linear dilaton: $D \neq 26$ with a tilted string coupling

Take $G_{\mu\nu} = \delta_{\mu\nu}$, $B = 0$ and $\Phi(X) = V_\mu X^\mu$ with a constant vector V. Then $\nabla\nabla\Phi = 0$, so

$\beta^G = \beta^B = 0$, and

$$\beta^\Phi \overset{(1)}{=} \frac{D-26}{6} + \alpha' V_\mu V^\mu = 0 \quad \Longleftrightarrow \quad V_\mu V^\mu = \frac{26-D}{6\alpha'}.$$

(1) $\nabla^2\Phi = 0$, $\nabla_\omega \Phi = V_\omega$, $H = 0$ in the keyidea.

The background is exact (the action is still Gaussian in X), and it is a consistent string background in any D: the dilaton gradient supplies the missing central charge, $c = D + 6\alpha' V^2 = 26$ [Polchinski, (3.7.18)].

Step 4: fixed points and Ricci flow. At a fixed point with $B = 0$ and constant Φ, (T5.110) says $R_{\mu\nu} = 0$: the target is Ricci flat. Flat tori are fixed points for every choice of radii, a whole manifold of fixed points (the radii are exactly marginal couplings). Curved Ricci-flat examples are the K3 surface and the Calabi–Yau spaces of string compactification. Away from a fixed point, in the RG time $t = \ln(\mu_0/\mu)$ of (T5.5) that runs towards the infrared,

$$\frac{\partial G_{\mu\nu}}{\partial t} \overset{(1)}{=} -\mu \frac{\mathrm{d}G_{\mu\nu}}{\mathrm{d}\mu} = -\alpha' R_{\mu\nu} \qquad \Longleftrightarrow \qquad \frac{\partial G_{\mu\nu}}{\partial \tau} \overset{(2)}{=} -2R_{\mu\nu}, \quad \tau = \tfrac{1}{2}\alpha' t. \tag{T5.113}$$

(1) The pitfall in Section T5.1.4, and (T5.110).
(2) Chain rule, $\partial_t = \frac{1}{2}\alpha' \partial_\tau$.

The second form is Hamilton's **Ricci flow** [Hamilton 1982], the equation Perelman used to prove the Poincaré conjecture. The RG of the sigma model coarse-grains the geometry of its target: bumps of positive curvature shrink, regions of negative curvature grow, and flat directions stay put (Figure T5.25).

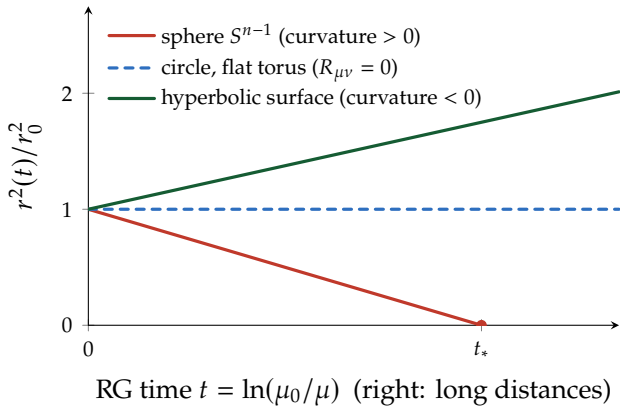

Figure T5.25: Ricci flow as the sigma-model RG, drawn for targets whose shape does not change, so only the size r flows. From Example T5.31, r^2 of a sphere decreases linearly and reaches zero at the finite RG time $t_* = r_0^2/\alpha'(n-2)$: there the coupling $g^2 = 2\pi\alpha'/r^2$ has become strong and perturbation theory stops, at the scale $\mu_0 e^{-t_*} = \Lambda_{O(n)}$. A flat target does not flow. A target of negative curvature grows, so its sigma model is weakly coupled at long distances and strongly coupled at short ones.

Worked example T5.34: The collapse time is the transmuted scale

For S^{n-1}, $\partial_t r^2 = -\mu\, \mathrm{d}r^2/\mathrm{d}\mu = -\alpha'(n-2)$ by Example T5.31, so $r^2(t) = r_0^2 - \alpha'(n-2)t$ reaches

zero at

$$t_* \overset{(1)}{=} \frac{r_0^2}{\alpha'(n-2)} \overset{(2)}{=} \frac{2\pi}{(n-2)\,g_0^2}, \qquad \mu_0 e^{-t_*} \overset{(3)}{=} \mu_0 \exp\!\left(-\frac{2\pi}{(n-2)g_0^2}\right) = \Lambda_{O(n)}.$$

(1) Solve $r^2(t_*) = 0$.
(2) $r_0^2 = 2\pi\alpha'/g_0^2$ with $g_0 = g(\mu_0)$.
(3) $t = \ln(\mu_0/\mu)$, and the formula for $\Lambda_{O(n)}$ in Example T5.31.

The finite-time singularity of Ricci flow on a round sphere and the dynamically generated mass of the $O(n)$ model are the same event. For a two-dimensional target, $R_{\mu\nu} = KG_{\mu\nu}$ with K the Gauss curvature, and the same computation with $n = 3$ shows that the area $4\pi r^2$ decreases at the constant rate $4\pi\alpha'$: the rate is $\alpha' \int K\,\mathrm{d}A = 2\pi\alpha'\chi(S^2)$ by Gauss–Bonnet (Chapter T2).

Watch out: what is and is not fixed about β^G

- β^G is defined only up to a change of coordinates on the target. A field redefinition $X^\mu \to X^\mu + \epsilon v^\mu(X)$ changes G by $\nabla_\mu v_\nu + \nabla_\nu v_\mu$ and describes the same theory, so $\beta^G_{\mu\nu}$ and $\beta^G_{\mu\nu} + \nabla_\mu v_\nu + \nabla_\nu v_\mu$ are equivalent flows. The dilaton term is of this form, $2\alpha'\nabla_\mu\nabla_\nu\Phi = \nabla_\mu v_\nu + \nabla_\nu v_\mu$ with $v = \alpha'\nabla\Phi$, which is why Perelman's version of Ricci flow carries an extra function that plays the role of the dilaton.
- Two signs are easy to lose when deriving (T5.111) in dimensional regularisation instead. In $d = 2-\varepsilon$, $\sqrt{g}\,g^{ab} \to e^{(d-2)\delta\omega}\sqrt{g}\,g^{ab}$, so the classical Weyl variation is $-\varepsilon\,\delta\omega$ times the action. And $\int \mathrm{d}^d\sigma\,\partial X\partial X$ has mass dimension $-\varepsilon$, so the bare coupling $\lambda_0 = G_0/\alpha'_0$ carries $\mu^{-\varepsilon}$, $\lambda_0 = \mu^{-\varepsilon}(\lambda + \text{poles})$, which gives $\varepsilon\lambda_0 = \beta\,\partial\lambda_0/\partial\lambda$. Together, $T^a{}_a = -2\pi\varepsilon\lambda_0 O = -2\pi\beta\,[O]$, in agreement with (T5.111). A derivative with respect to g^{ab} instead of g_{ab} in the definition of T flips the overall sign.

Recap

- The sigma-model coupling is the target metric; the dimensionless expansion parameter is α'/r_c^2.
- Expanding along geodesics, $S_2 = \frac{1}{4\pi\alpha'}\int[(\nabla\xi)^2 + R_{\mu\alpha\beta\nu}\xi^\alpha\xi^\beta\partial x^\mu\partial x^\nu]$; the shell tadpole $\langle\xi\xi\rangle = \alpha'\ln(\Lambda/\Lambda')$ gives $\beta^G_{\mu\nu} = \alpha' R_{\mu\nu}$.
- The worldsheet trace is $T^a{}_a = -\frac{1}{2\alpha'}\beta^G\partial X\partial X + \ldots$, so Weyl invariance is $R_{\mu\nu} = 0$ (plus dilaton and H terms), Einstein's equation.
- Towards the infrared the flow is Ricci flow; the sphere collapses at the transmuted scale of the asymptotically free $O(n)$ model.

T5.7.2 The Chern–Simons level shift

Chern–Simons theory on a closed oriented three-manifold M with gauge group $G = \mathrm{SU}(N)$ has the partition function

$$Z(M) = \int \mathcal{D}A\; e^{2\pi i k\,\mathrm{CS}(A)}, \qquad \mathrm{CS}(A) := -\frac{1}{8\pi^2}\int_M \mathrm{tr}\!\left(A\wedge\mathrm{d}A + \tfrac{2}{3}A\wedge A\wedge A\right), \qquad \text{(T5.114)}$$

with A an anti-Hermitian matrix-valued 1-form and tr the trace in the N-dimensional representation. This is the weight $e^{-ikS(A)/4\pi}$ of Chapter 12, since $2\pi/8\pi^2 = 1/4\pi$. A large gauge transformation changes $\mathrm{CS}(A)$ by an integer (Chapter 12), so $e^{2\pi i k\,\mathrm{CS}}$ is gauge invariant only for integer k. The coupling $1/k$ is *quantised*. It cannot run: a β-function would move it continuously. Yet every semiclassical formula of Chapter 12 for SU(2) contains $k+2$, not k. This subsection derives the shift $k \to k + h^\vee\,\mathrm{sgn}(k)$ from the phase of the one-loop determinant.

Working definition T5.13 (dual Coxeter number)

The **dual Coxeter number** $h^\vee$ of a simple Lie group is the number with

$$\mathrm{tr}_{\mathrm{adj}}(XY) = 2h^\vee\,\mathrm{tr}(XY) \qquad \text{for all } X, Y \text{ in the Lie algebra,}$$

where $\mathrm{tr}_{\mathrm{adj}}$ is the trace in the adjoint representation [the matrices by which X acts on the Lie algebra itself, $Y \mapsto [X,Y]$, the representation of the gluons] and tr the trace in the fundamental one [the $N \times N$ matrices, the representation of the quarks]. It measures how strongly the gauge field acts on itself, compared with how strongly it acts on a quark. *Recipe:* compute both traces for one generator and divide. For SU(N), $h^\vee = N$. The values for the other groups are in the table of Chapter 8.

For SU(2), Example T5.20 found $\mathrm{tr}(T^3_{\mathrm{adj}}T^3_{\mathrm{adj}}) = 2$ and $\mathrm{tr}(T^3T^3) = \frac{1}{2}$, a ratio $4 = 2h^\vee$, so $h^\vee = 2$.

Step 1: the one-loop phase. Around a flat connection A_f the gauge-fixed quadratic action of Chapter 12 packages the fluctuation a and the Lagrange multiplier ϕ into $v = (a, \phi)$, with exponent $\frac{ik}{4\pi}\langle v, D_{A_f} v\rangle$. Here

$$D_A = \begin{pmatrix} \star\mathrm{d}_A & \mathrm{d}_A \\ \mathrm{d}_A^\dagger & 0 \end{pmatrix} \qquad \text{on } \Omega^1(M,\mathfrak{g}) \oplus \Omega^0(M,\mathfrak{g}) \tag{T5.115}$$

is the self-adjoint **odd signature operator** [curl on the Lie-algebra-valued 1-forms, glued to gradient and divergence]. A single Fresnel integral has the phase $\int \mathrm{d}x\, e^{i\lambda x^2/2} = \sqrt{2\pi/|\lambda|}\, e^{i\pi\,\mathrm{sgn}(\lambda)/4}$. So

$$\text{phase of } \int \mathcal{D}v\, e^{\frac{ik}{4\pi}\langle v, Dv\rangle} \overset{(1)}{=} \text{phase of } \int \mathcal{D}v\, e^{\frac{i}{2}\langle v, \frac{k}{2\pi} Dv\rangle}$$
$$\overset{(2)}{=} \prod_j e^{\frac{i\pi}{4}\,\mathrm{sgn}(k\lambda_j)} \overset{(3)}{=} \exp\!\left(\frac{i\pi}{4}\,\mathrm{sgn}(k)\,\eta(A_f)\right). \tag{T5.116}$$

(1) $\frac{k}{4\pi} = \frac{1}{2}\cdot\frac{k}{2\pi}$.
(2) Expand v in eigenvectors of D, with eigenvalues λ_j; each mode is a Fresnel integral with $\lambda = k\lambda_j/2\pi$.
(3) $\sum_j \mathrm{sgn}(k\lambda_j) = \mathrm{sgn}(k)\sum_j \mathrm{sgn}(\lambda_j)$, regularised as the eta invariant $\eta(A) := \eta_{D_A}(0)$, $\eta_D(s) = \sum_j \mathrm{sgn}(\lambda_j)\,|\lambda_j|^{-s}$ (Chapter 12).

The ghosts contribute the determinant of the positive operator $\mathrm{d}_A^\dagger \mathrm{d}_A$, which has no phase. So each flat connection enters Z as $e^{2\pi i k\,\mathrm{CS}(A_f)}\, e^{i\pi\,\mathrm{sgn}(k)\eta(A_f)/4}$ times a positive modulus. Everything now depends on how $\eta(A)$ depends on A.

Worked example T5.35: The circle: η is linear in the connection, and jumps by 2

Chapter 12 computed the eta invariant of $-i\,\mathrm{d}/\mathrm{d}x$ on a circle with holonomy $e^{2\pi i\alpha}$. The eigenvalues are $n + \alpha$, $n \in \mathbb{Z}$, and $\eta = 1 - 2\alpha$ for $0 < \alpha < 1$. The number $\alpha = \frac{1}{2\pi i}\oint A$ is the

one-dimensional Chern–Simons functional of the U(1) connection, and like CS it is defined only modulo integers. So

$$\eta(\alpha+\delta)-\eta(\alpha)\overset{(1)}{=}-2\delta \quad (0<\alpha<\alpha+\delta<1), \qquad \lim_{\alpha\to 0^+}\eta-\lim_{\alpha\to 1^-}\eta\overset{(2)}{=}1-(-1)=2.$$

(1) $\eta=1-2\alpha$ on the interval.
(2) $\alpha=0^+$ and $\alpha=1^-$ are the same holonomy approached from the two sides. In between, the eigenvalue $\alpha-1$ has crossed zero from below.

Two features (Figure T5.26): away from zero crossings η changes linearly with the Chern–Simons functional, with a slope fixed by the local index density; at a crossing it jumps by 2. The three-dimensional statement below has the same shape, with slope $8h^\vee$.

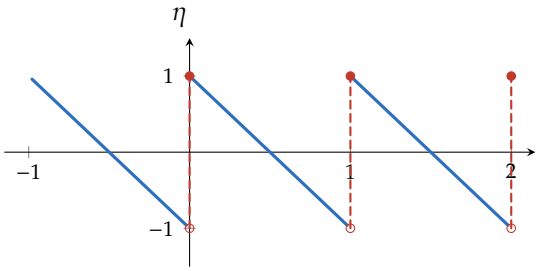

Figure T5.26: Spectral asymmetry of $-i\,\mathrm{d}/\mathrm{d}x$ on a circle as the connection is changed. Between integers, $\eta=1-2\alpha$ falls linearly (blue): this is the part fixed by the local index density. At each integer one eigenvalue crosses zero and η jumps up by 2 (red dashes), which multiplies the phase $e^{i\pi\eta/4}$ by i. The Chern–Simons case has the same shape: a linear rise $8h^\vee\,\mathrm{CS}(A)$ interrupted by jumps of ±2.

Step 2: $\eta(A)$ from the Atiyah–Patodi–Singer theorem. Recall the APS theorem (Chapter 4): if a first-order elliptic operator on a compact X has the form $\sigma\,(\partial_n+L)$ near ∂X, with n the inward normal, σ an invertible bundle map and L self-adjoint on ∂X, then with APS boundary conditions

$$\text{index}=\int_X P-\sum_{\text{boundary pieces}}\tfrac{1}{2}\big(h(L)+\eta_L(0)\big), \tag{T5.117}$$

with P the same local index density as on a closed manifold and $h(L)=\dim\ker L$. Apply it to the cylinder $X=[0,1]\times M$ (Figure T5.27), with the product metric, orientation $\mathrm{d}t\wedge\mathrm{vol}_M$, and the connection $\mathbb{A}=A_t$ that has no $\mathrm{d}t$ component and interpolates from $A_0=0$ to $A_1=A$ (constant in t near both ends). The operator is the one whose index counts instantons (Chapter 8),

$$\mathcal{D}=(-\mathrm{d}_{\mathbb{A}}^\dagger)\oplus\mathrm{d}_{\mathbb{A}}^+:\ \Omega^1(X,\mathfrak{g})\to\Omega^0(X,\mathfrak{g})\oplus\Omega^2_+(X,\mathfrak{g}),$$

where d^+ is the self-dual part of d. On a closed four-manifold its index is $4h^\vee c_2-\dim G\,(1-b_1+b_+)$, with $c_2=\frac{1}{8\pi^2}\int\mathrm{tr}(F\wedge F)$ (positive for anti-self-dual instantons); for SU(2) on S^4 this is $8k-3$. So P is $4h^\vee\cdot\frac{1}{8\pi^2}\,\mathrm{tr}(\mathbb{F}\wedge\mathbb{F})$ plus densities built from the curvature of X.

(a) The boundary operator is $\pm D$. Write a 1-form on X as $a=a_0\,\mathrm{d}t+b$, with $b(t)$ a 1-form on M. We show the computation for $\mathbb{A}=0$; with $\mathbb{A}\neq0$ every d becomes d_{A_t}. A self-dual 2-form is $\mathrm{d}t\wedge\beta+\star_M\beta$ for a 1-form β on M, because $\star(\mathrm{d}t\wedge\beta)=\star_M\beta$ in this orientation; so

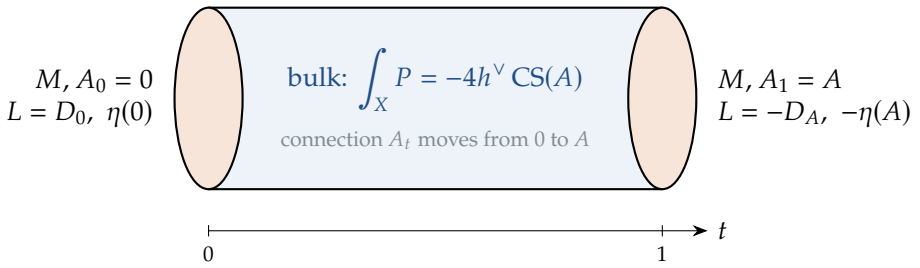

Figure T5.27: The cylinder that compares $\eta(A)$ with $\eta(0)$. The two ends are copies of M carrying the trivial connection and A. Seen from inside, the normal at the right end points backwards in t, so the boundary operator there is $-D_A$ and contributes $-\eta(A)$. The index density in between is local and integrates to a Chern–Simons functional. The index is an integer, so the difference of the two eta invariants is that local integral up to integers.

$\Omega^2_+(X) \cong \Omega^1(M)$ at each t. Then

$$
\begin{aligned}
-\mathrm{d}^\dagger a &\overset{(1)}{=} \partial_t a_0 - \mathrm{d}^\dagger_M b, \\
\mathrm{d}a &\overset{(2)}{=} \mathrm{d}t \wedge (\partial_t b - \mathrm{d}_M a_0) + \mathrm{d}_M b, \\
\mathrm{d}^+ a &\overset{(3)}{=} \tfrac{1}{2}\big[\mathrm{d}t \wedge \beta + \star_M \beta\big], \qquad \beta = \partial_t b - \mathrm{d}_M a_0 + \star_M \mathrm{d}_M b.
\end{aligned}
$$

(1) $\mathrm{d}^\dagger a = -\nabla^\mu a_\mu = -\partial_t a_0 - \nabla^i b_i$, and $-\nabla^i b_i = \mathrm{d}^\dagger_M b$.
(2) $\mathrm{d}(a_0 \mathrm{d}t) = \mathrm{d}_M a_0 \wedge \mathrm{d}t = -\mathrm{d}t \wedge \mathrm{d}_M a_0$ and $\mathrm{d}b = \mathrm{d}t \wedge \partial_t b + \mathrm{d}_M b$.
(3) For $F = \mathrm{d}t \wedge E + B$: $\star F = \star_M E + \mathrm{d}t \wedge \star_M B$, so $\frac{1}{2}(F + \star F) = \frac{1}{2}[\mathrm{d}t \wedge \beta + \star_M \beta]$ with $\beta = E + \star_M B$ (using $\star_M \star_M = 1$).

Identifying $\mathrm{d}^+ a$ with β (an invertible bundle map, the σ of (T5.117)),

$$
\mathcal{D}\begin{pmatrix} a_0 \\ b \end{pmatrix} \cong \partial_t \begin{pmatrix} a_0 \\ b \end{pmatrix} + L \begin{pmatrix} a_0 \\ b \end{pmatrix}, \qquad L = \begin{pmatrix} 0 & -\mathrm{d}^\dagger_M \\ -\mathrm{d}_M & \star_M \mathrm{d}_M \end{pmatrix}.
$$

Changing the sign of a_0 turns L into $\begin{pmatrix} 0 & \mathrm{d}^\dagger_M \\ \mathrm{d}_M & \star_M \mathrm{d}_M \end{pmatrix}$, which is D of (T5.115) with the two components of v listed in the other order. A change of basis does not change eigenvalues, so $\eta_L = \eta_D$.

(b) APS on the cylinder. At $t = 0$ the inward normal is ∂_t and $L = D_0$. At $t = 1$ it is $-\partial_t$, and $\partial_t + D_A = -(\partial_n - D_A)$, so the boundary operator is $-D_A$, whose eta invariant is $-\eta(A)$. With $h_0 = \dim \mathrm{Ker}\, D_0$ and $h_1 = \dim \mathrm{Ker}\, D_A$,

$$
\begin{aligned}
\operatorname{index} \mathcal{D} &\overset{(1)}{=} \int_X P - \tfrac{1}{2}\big(h_0 + \eta(0)\big) - \tfrac{1}{2}\big(h_1 - \eta(A)\big), \\
\tfrac{1}{2}\big(\eta(A) - \eta(0)\big) &\overset{(2)}{=} \operatorname{index} \mathcal{D} - \int_X P + \tfrac{1}{2}(h_0 + h_1).
\end{aligned}
$$

(1) (T5.117) with the two boundary operators; $\eta_{-D} = -\eta_D$.
(2) Rearrange.

(c) The bulk integral. For the product metric every curvature 2-form of X has legs only along M, and a 4-form built from them would need four independent directions in the three-dimensional M; so the gravitational part of P vanishes. The gauge part is a total derivative, $\mathrm{tr}(\mathbb{F} \wedge \mathbb{F}) = \mathrm{d}\,\mathrm{tr}(\mathbb{A} \wedge \mathrm{d}\mathbb{A} + \frac{2}{3}\mathbb{A} \wedge \mathbb{A} \wedge \mathbb{A})$ (Chapter 12), and

$$
\int_X P \overset{(1)}{=} \frac{4h^\vee}{8\pi^2} \int_X \mathrm{tr}(\mathbb{F} \wedge \mathbb{F}) \overset{(2)}{=} \frac{4h^\vee}{8\pi^2}\Big[\int_M \mathrm{tr}\big(A \wedge \mathrm{d}A + \tfrac{2}{3}A^3\big) - 0\Big] \overset{(3)}{=} -4h^\vee \mathrm{CS}(A).
$$

(1) The gravitational part vanishes.
(2) Stokes. With outward normal first, ∂X is M at $t = 1$ with its own orientation and M at $t = 0$ with the opposite one; the Chern–Simons form of $A_0 = 0$ is zero.
(3) Definition (T5.114).

(d) Put together. Steps (b) and (c) give

$$\eta(A) = \eta(0) + 8h^\vee \,\mathrm{CS}(A) + \big(2\,\mathrm{index}\,\mathcal{D} + h_0 + h_1\big). \tag{T5.118}$$

The bracket is an integer. It depends on the path from 0 to A only through integers, and $\eta(A)$ does not depend on it at all: a large gauge transformation shifts $\mathrm{CS}(A)$ by an integer m and the index by $-4h^\vee m$ (the instanton number of the path changes by $-m$), and $8h^\vee m - 2\cdot 4h^\vee m = 0$.

Key idea: the level shift

Inserting (T5.118) into the one-loop phase (T5.116),

$$e^{2\pi i k\,\mathrm{CS}(A_f)}\, e^{\frac{i\pi}{4}\,\mathrm{sgn}(k)\eta(A_f)} \overset{(1)}{=} e^{\frac{i\pi}{4}\,\mathrm{sgn}(k)\eta(0)}\; e^{\frac{i\pi}{4}\,\mathrm{sgn}(k)(2\,\mathrm{index}\,\mathcal{D}+h_0+h_1)}\; e^{2\pi i\,(k+h^\vee\,\mathrm{sgn}\,k)\,\mathrm{CS}(A_f)}.$$

(1) $\frac{i\pi}{4}\cdot 8h^\vee\,\mathrm{CS} = 2\pi i h^\vee\,\mathrm{CS}$, combined with $e^{2\pi i k\,\mathrm{CS}}$.

At one loop the level multiplying the Chern–Simons invariant of every flat connection is

$$k \;\longrightarrow\; k + h^\vee\,\mathrm{sgn}(k), \qquad k \to k+2 \;\text{ for SU(2)},\; k > 0.$$

The shift is an integer, so the renormalised weight is still gauge invariant. The other two factors do not depend on the level. The integer bracket gives an eighth root of unity for each flat connection (Witten's spectral-flow phase). $\eta(0)$ does not depend on A but depends on the metric of M; APS applied to a family of metrics shows that its variation is the gravitational Chern–Simons form, and cancelling it with a counterterm is the framing dependence of Chapter 12 [Witten 1989, §2].

Worked example T5.36: SU(2): the exact answers know about $k+2$

With $h^\vee = 2$ the one-loop answer for S^3 is a function of $k+2$. The exact result of Chapter 12 is $Z(S^3) = \sqrt{2/(k+2)}\,\sin(\pi/(k+2))$. Expanding,

$$Z(S^3) \overset{(1)}{=} \sqrt{\frac{2}{k+2}}\left(\frac{\pi}{k+2} + O\big((k+2)^{-3}\big)\right) = \sqrt{2}\,\pi\,(k+2)^{-3/2}\big(1 + O(k^{-2})\big).$$

(1) $\sin x = x - x^3/6 + \ldots$ with $x = \pi/(k+2)$.

The power $k^{-3/2}$ is the one-loop count of the three zero modes of the trivial connection, and the +2 is the level shift: at $k = 10$ the exact value is 0.1057, while $\sqrt{2}\pi(k+2)^{-3/2} = 0.1069$ and $\sqrt{2}\pi k^{-3/2} = 0.1405$. The same denominator appears in the $\mathrm{SU}(2)_k$ WZW model of Chapter 11: the central charge $c = 3k/(k+2)$ and the conformal weights $j(j+1)/(k+2)$ come from the Sugawara construction, whose normalisation is $k + h^\vee$.

Worked example T5.37: U(1): no shift

For U(1) the structure constants vanish, so the adjoint representation is trivial: $\mathrm{tr}_{\mathrm{adj}}(XY) = 0$ and $h^\vee = 0$. In (T5.118) the gauge field drops out of the index density, $\eta(A) = \eta(0)+$ integer, and the level is not shifted. This fits the fact that the abelian theory is Gaussian: CS is quadratic in A, the stationary-phase evaluation is exact, and there is nothing for a loop to renormalise except the metric-dependent phase. For SU(N) the shift is $k \to k + N$.

Physical picture: a quantised coupling can only jump

A coupling that must be an integer cannot run logarithmically, since a β-function would move it through non-integer values. What it can do is change by a finite integer when heavy modes are integrated out. If Chern–Simons theory is regularised by adding a Yang–Mills term, the gluons become massive, and integrating them out at their mass scale shifts the Chern–Simons coefficient by $h^\vee \operatorname{sgn}(k)$ [Pisarski and Rao 1985]. In the language of Section T5.6, three-dimensional Yang–Mills theory with a Chern–Simons term is a trajectory whose infrared end is a topological theory (Chapter 12), and the level shift is the one-loop threshold effect along it. Here the same number came out of a gauge-invariant regularisation (the eta invariant) with no heavy fields at all.

Watch out: which η, which power

Books write the one-loop phase as $e^{i\pi\eta/4}$, $e^{i\pi\eta/2}$ or $e^{-i\pi\eta/4}$, depending on whether η is taken for D on $\Omega^1 \oplus \Omega^0$ (as here), for the operator on all odd forms, or for $\star\mathrm{d}$ on 1-forms alone, and on the sign of the exponent. The statement that does not depend on these choices is the coefficient of $\mathrm{CS}(A)$ in the logarithm of the phase, $2\pi i h^\vee \operatorname{sgn}(k)$. A check of any convention: it must reproduce $\sqrt{2}\pi(k+2)^{-3/2}$ for $Z(S^3)$ at $G = \mathrm{SU}(2)$.

Recap

- The Chern–Simons level is quantised, so it cannot run; the one-loop Gaussian contributes the phase $e^{i\pi \operatorname{sgn}(k)\eta(A)/4}$.
- APS on $[0,1]\times M$ with the instanton-counting operator gives $\eta(A) = \eta(0) + 8h^\vee \mathrm{CS}(A) +$ integer.
- Hence $e^{2\pi i k\,\mathrm{CS}} \to e^{2\pi i(k+h^\vee \operatorname{sgn} k)\mathrm{CS}}$: $k \to k+2$ for SU(2), $k \to k+N$ for SU(N), no shift for U(1).
- The leftover $\eta(0)$ is metric dependent; removing it is the framing choice of Chapter 12.

Reading the literature

Sources. The exact RG equation, the two-coupling toy flow and the renormalisability bound follow J. Polchinski, "Renormalization and effective Lagrangians", Nucl. Phys. B231 (1984) 269. The Gaussian-smearing derivation of the same equation is in O. Rosten, "Fundamentals of the exact renormalization group", arXiv:1003.1366, §III; the exponential form also appears in [QFT notes §15.9.1, (15.9.19)]. Effective field theory from this point of view is developed in J. Polchinski, "Effective field theory and the Fermi surface", hep-th/9210046. The relation between scale and conformal invariance, including the Maxwell and Riva–Cardy examples and the two-dimensional theorem (J. Polchinski, Nucl. Phys. B303 (1988) 226), is reviewed in Y. Nakayama, "Scale invariance vs conformal invariance", arXiv:1302.0884, §§2.5, 4.1, 5.1–5.3 and 5–6.

Dictionary: notation in the original papers

Polchinski (1984)	here
weight e^S, interaction $L(\varphi,\Lambda)$	weight e^{-S}, $S^{\mathrm{I}}_\Lambda = -L$
propagator $K(p^2/\Lambda^2)/(p^2+m^2)$	$C_\Lambda(p)$, massless in most examples
$\Lambda\,\partial_\Lambda K/(p^2+m^2)$	shell propagator $\Delta_\Lambda(p)$
$Q = \Lambda^3\partial_\Lambda K/(p^2+m^2)$	$\Lambda^2\Delta_\Lambda(p)$
$\Lambda\,\mathrm{d}/\mathrm{d}\Lambda$ (towards the UV)	$\partial_t = -\Lambda\,\partial_\Lambda$ (towards the IR)
eqs. (1)–(10), (18), (20)–(21), (34), (35), (45), (47)	(T5.32)–(T5.37), (T5.39), (T5.40)–(T5.41), (T5.42), (T5.43), (T5.45), theorem

Rosten writes the flow in terms of $\dot{C} = -\Delta$. In [QFT notes Ch. 16], eqs. (16.2.24) and (16.2.84) state $\eta = 2\gamma_m(\lambda^*)$ with γ_m the anomalous dimension of φ^2; the relation (16.2.23) there shows that the correct statement is $\eta = 2\gamma(\lambda^*)$ with the field anomalous dimension (Example T5.15), while $\nu = [2-\gamma_m(\lambda^*)]^{-1}$ in (16.2.84) is correct.

Sources for Section T5.4. The Callan–Symanzik equation is C. G. Callan, Phys. Rev. D2 (1970) 1541, and K. Symanzik, Commun. Math. Phys. 18 (1970) 227. The Yang–Mills β-function is D. J. Gross and F. Wilczek, Phys. Rev. Lett. 30 (1973) 1343, and H. D. Politzer, *ibid.* 1346. The background-field method used here is L. F. Abbott, Nucl. Phys. B185 (1981) 189. The spin-versus-orbital split of $\frac{11}{3}$ is N. K. Nielsen, Am. J. Phys. 49 (1981) 1171, and R. J. Hughes, Nucl. Phys. B186 (1981) 376.

Sources for the trace anomaly (Section T5.5.3). The operator equation for $T^\mu{}_\mu$ in gauge theories is J. C. Collins, A. Duncan and S. D. Joglekar, Phys. Rev. D16 (1977) 438. The pion–nucleon σ-term is from J. Gasser, H. Leutwyler and M. E. Sainio, Phys. Lett. B253 (1991) 252. The gluon condensate is from M. A. Shifman, A. I. Vainshtein and V. I. Zakharov, Nucl. Phys. B147 (1979) 385.

Sources for Section T5.7. The sigma-model β-function is D. Friedan, Phys. Rev. Lett. 45 (1980) 1057, with the full treatment in Ann. Phys. 163 (1985) 318. The $O(N)$ case is A. M. Polyakov, Phys. Lett. 59B (1975) 79. The covariant (Riemann-normal-coordinate) expansion is L. Alvarez-Gaumé, D. Z. Freedman and S. Mukhi, Ann. Phys. 134 (1981) 85. The Weyl-anomaly route and the string β-functions follow J. Polchinski, *String Theory* I, §3.7, eqs. (3.7.13)–(3.7.18). Ricci flow is R. S. Hamilton, J. Diff. Geom. 17 (1982) 255, and G. Perelman, arXiv:math/0211159. The level shift is in E. Witten, Commun. Math. Phys. 121 (1989) 351, §2. It uses the η-invariant theorem of M. F. Atiyah, V. K. Patodi and I. M. Singer, Math. Proc. Camb. Phil. Soc. 77 (1975) 43. The perturbative shift is R. D. Pisarski and S. Rao, Phys. Rev. D32 (1985) 2081.

Chapter summary

concept	operational meaning	used later in
RG step, $\xi' = \xi/b$	integrate out short scales, rescale; fixed points have $\xi = 0, \infty$	Chapter 11 (critical points)
Wilsonian action S_Λ	action reproducing all physics below Λ	Chapters 9 and 10
Polchinski equation	$\partial_t e^{-S^{\mathrm{I}}} = \frac{1}{2}\frac{\delta}{\delta\varphi}\cdot\Delta\cdot\frac{\delta}{\delta\varphi}e^{-S^{\mathrm{I}}}$	Chapter 9 (worldsheet β)
relevant / irrelevant	$y = d - \Delta > 0 \,/\, < 0$	every chapter with a cutoff
Polchinski's theorem	irrelevant couplings slaved, cutoff effects $(\Lambda_R/\Lambda_0)^2$	Chapter 10 (regulator independence)
stability matrix, y_a	linearised flow at g^*; $\nu = 1/y_t$	Chapter 11 (Ising exponents)
six exponents from (y_t, y_h)	scaling of the free energy	Chapter 11
Wilson–Fisher point	$\bar{u}^* = \frac{2}{3}\varepsilon$, $\nu = \frac{1}{2} + \frac{\varepsilon}{12}$	Chapter 11
Callan–Symanzik equation	$[\mu\partial_\mu + \beta\partial_\lambda + n\gamma]G^{(n)} = 0$; at $\beta(\lambda^*) = 0$, $\Delta = \Delta_{\mathrm{cl}} + \gamma(\lambda^*)$	Chapter 11 (power laws)
one-loop φ^4	$\beta = 3\lambda^2/16\pi^2$ in $d = 4$; $-\varepsilon\lambda$ added gives Wilson–Fisher	Chapter 11 (Ising exponents)
one-loop Yang–Mills	$\beta = -\frac{g^3}{16\pi^2}(\frac{11N}{3} - \frac{2n_f}{3})$, $\frac{11}{3} = 4 - \frac{1}{3}$ (spin, orbit)	Chapter 8 ($e^{-8\pi^2/g^2}$), Chapter 13
virial current, improvement	scale $\Rightarrow$ conformal iff $K_\mu = \partial_\mu L$	Chapters 9 and 11
$T^\mu{}_\mu = -\beta^i O_i$	trace measures running	Chapter 9 (Weyl anomaly, Einstein eqs), Chapter 10 (scale anomaly, Adler–Bardeen)
QCD trace anomaly	$\theta^\mu{}_\mu = \frac{\beta}{2g}F_c F_c + \sum_q (1+\gamma_m) m_q \bar{\psi}_q \psi_q$; the proton mass	Chapter 10 (scale versus chiral anomaly)
2D scale $\Rightarrow$ conformal	$G = H = 0$, reflection positivity	Chapter 11
C-function, gradient flow	C decreases, Morse index = number of relevant operators	Chapter 11 (Section 11.13), Chapter 7
QFT = trajectory	UV CFT + relevant operators $\to$ IR CFT or gapped	Chapter 12 (TQFT as IR limit, CS level shift)
dimensional transmutation	$\Lambda_* = \Lambda e^{-1/bg}$	Chapters 8 and 10
sigma-model β	$\beta^G_{\mu\nu} = \alpha' R_{\mu\nu}$ (+ dilaton, H); fixed point $R_{\mu\nu} = 0$; flow is Ricci flow	Chapter 9 (Einstein equations from Weyl invariance)
Chern–Simons level shift	$\eta(A) = \eta(0) + 8h^\vee \mathrm{CS}(A)+$ integer, so $k \to k + h^\vee$ ($k+2$ for SU(2))	Chapter 12 ($Z(S^3)$, $q = e^{2\pi i/(k+2)}$)

Two uses deserve a sentence each. In Chapter 7 the RG reappears as a gradient flow: in two dimensions $\beta^i = -\mathsf{G}^{ij}\partial_j(C/6\pi^2)$, and the Morse index of C at a fixed point is its number of relevant operators (Section 11.13.5). In Chapter 12 a gapped phase is described at long distances by a topological theory; Chern–Simons theory is the infrared end of three-dimensional Yang–Mills with a Chern–Simons term (the Yang–Mills coupling $1/g^2$ has negative mass dimension there, so it is irrelevant), and the famous shift of the level $k \to k+2$ for SU(2) is a one-loop renormalisation of a quantised coupling (Section T5.7.2).

Part II

Following Nash

Chapter 1

A Topological Preliminary

Where this chapter is going

Nash's first chapter is a guided tour of the topologist's toolbox. Nothing in it is quantum field theory yet. But every later chapter leans on it. When a physicist says "the instanton number is an integer", "this anomaly is topological", "the vortex cannot unwind" or "the Dirac monopole needs two patches", a piece of this chapter is doing the work. The chapter answers one question in a sequence of increasingly clever ways: *how can we tell two spaces apart, or two field configurations apart, without solving any equations?*

The answer comes in layers. First (§1) we decide what "the same space" means: homeomorphic, piecewise-linearly equivalent, or diffeomorphic. Then (§2) we relax "the same" to "deformable into each other": homotopy. Homotopy classes of loops and spheres give the *homotopy groups* (§3), which classify vortices, monopoles and instantons. They are hard to compute, so (§4) we trade them for the more computable *cohomology groups*, which de Rham's theorem ties to differential forms and hence to field strengths. We then (§5) study spaces that are locally products, the *fibre bundles*: these are the arenas of gauge theory. Finally (§6) we return to the surprising fact from §1 that one topological manifold may carry several inequivalent calculus structures. That fact reappears in Donaldson theory and in global gravitational anomalies. This part of the notes covers §1–§3. Figure 1.1 shows how the pieces feed into each other and into physics.

Throughout the chapter we keep one physical question in mind. A field configuration is a map from space (or spacetime) into some target space of field values. Two configurations with finite energy can often be deformed into one another continuously, and then they are "in the same sector". If they cannot, some integer (a winding number, a magnetic charge, an instanton number) is conserved for purely topological reasons. The mathematics of this chapter is the systematic theory of such integers.

1.1 From homeomorphism to diffeomorphism

Physicists usually meet "space" already equipped with coordinates, a metric and derivatives. Topology asks what survives if we throw almost all of that away and keep only the notion of *nearness*. When are two spaces the same in this weak sense? When are they the same in the stronger sense needed for calculus? And, surprisingly, can these two notions of sameness disagree? This section answers these questions informally. It also introduces the three kinds of manifold (topological, piecewise-linear, differentiable) that Nash distinguishes on his first two pages.

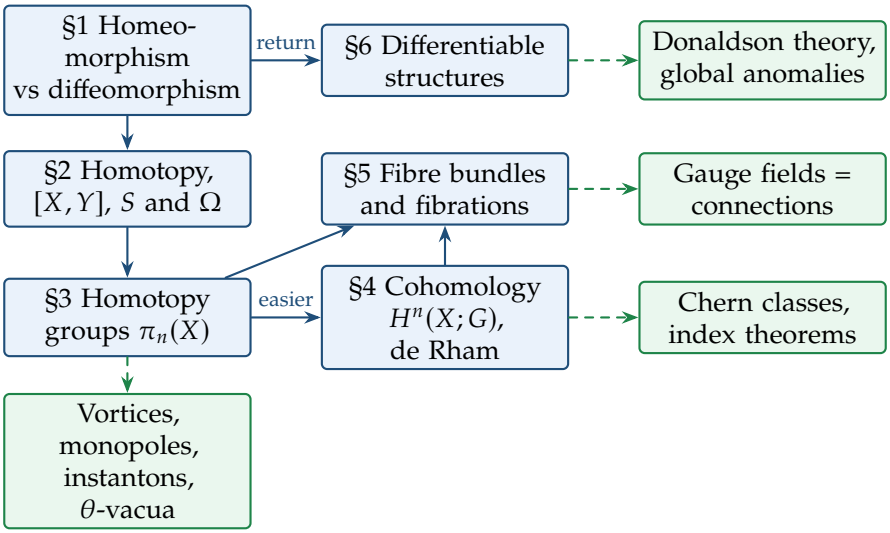

Figure 1.1: The logic of Chapter I. Blue boxes are Nash's sections; green boxes are the physics they feed. Homotopy groups (§3) classify topological defects directly; cohomology (§4) is the computable shadow of homotopy and becomes Chern classes; bundles (§5) are where gauge fields live. This part covers the left column.

1.1.1 Continuity and homeomorphism

Start with the notion of nearness. In $\mathbb{R}^n$ we know what it means for a function to be continuous: points that are close go to points that are close. In ϵ–δ language, f is continuous at x if for every $\epsilon > 0$ there is a $\delta > 0$ with $|y - x| < \delta \Rightarrow |f(y) - f(x)| < \epsilon$. Topologists rephrase this without distances, using **open sets**: sets U such that every point of U has a small ball around it that is still inside U. Then:

Working definition 1.1 (continuous map)

A map $f : X \to Y$ is **continuous** if the preimage $f^{-1}(V)$ [the set of all points of X that f sends into V] of every open set $V \subset Y$ is open in X. *Operational test in practice:* if X and Y sit inside Euclidean spaces and f is given by formulas, check that small changes in the input produce small changes in the output (no jumps, no tearing). Compositions of continuous maps are continuous; polynomials, sin, exp, $\sqrt{\ }$ on its domain, and quotients with nonvanishing denominators are continuous.

A **topological space** is a set together with a declared collection of "open" subsets (closed under arbitrary unions and finite intersections, and containing $\varnothing$ and the whole set). For everything in this book, the spaces are subsets of some $\mathbb{R}^N$, or spaces glued out of such pieces, and "open" means what it means in $\mathbb{R}^N$. So the abstract definition will never bite us.

Working definition 1.2 (homeomorphism)

Two spaces X and Y are **homeomorphic**, written $X \cong Y$, if there are maps

$$\alpha : X \to Y, \qquad \alpha^{-1} : Y \to X, \qquad \alpha \circ \alpha^{-1} = \mathrm{id}_Y, \quad \alpha^{-1} \circ \alpha = \mathrm{id}_X, \tag{1.1}$$

with *both* α and α^{-1} continuous. *Operational test:* exhibit an explicit formula for α, check it is a bijection [each point of Y is hit by exactly one point of X] by writing down the inverse formula, and check that both formulas are continuous.

A homeomorphism is a "rubber-sheet" equivalence: stretch, bend, squash, but do not cut

and do not glue. The coffee cup and the doughnut are the standard cartoon. Here are honest calculations.

Worked example 1.1: An open interval is homeomorphic to the whole line

Let $X = (-1, 1)$ and $Y = \mathbb{R}$. Define $\alpha(x) = \tan(\pi x/2)$. We claim $\alpha^{-1}(y) = \frac{2}{\pi}\arctan y$. Check both compositions:

$$\alpha\big(\alpha^{-1}(y)\big) \overset{(1)}{=} \tan\Big(\frac{\pi}{2}\cdot\frac{2}{\pi}\arctan y\Big) \overset{(2)}{=} y,$$
$$\alpha^{-1}\big(\alpha(x)\big) \overset{(3)}{=} \frac{2}{\pi}\arctan\big(\tan(\pi x/2)\big) \overset{(4)}{=} x.$$

(1) Substitute the candidate inverse into α.
(2) $\tan(\arctan y) = y$ for every real y.
(3) Substitute α into the candidate inverse.
(4) For $x \in (-1, 1)$ the angle $\pi x/2$ lies in $(-\pi/2, \pi/2)$, which is exactly the range of arctan, so $\arctan(\tan\theta) = \theta$ there.

Both tan (away from $\pm\pi/2$) and arctan are continuous, so $(-1, 1) \cong \mathbb{R}$. Length is *not* a topological notion: a finite interval and an infinite line are the same space.

Worked example 1.2: The boundary of a square is homeomorphic to a circle

Let X be the boundary of the square $\max(|x|, |y|) = 1$ and Y the unit circle $x^2 + y^2 = 1$. Radial projection $\alpha(\vec{r}) = \vec{r}/|\vec{r}|$ sends X to Y; its inverse is $\alpha^{-1}(\vec{u}) = \vec{u}/\max(|u_x|, |u_y|)$. Check:

$$\alpha^{-1}\big(\alpha(\vec{r})\big) \overset{(1)}{=} \frac{\vec{r}/|\vec{r}|}{\max(|x|, |y|)/|\vec{r}|} \overset{(2)}{=} \frac{\vec{r}}{\max(|x|, |y|)} \overset{(3)}{=} \vec{r}.$$

(1) The components of $\vec{u} = \vec{r}/|\vec{r}|$ are $x/|\vec{r}|$ and $y/|\vec{r}|$, so $\max(|u_x|, |u_y|) = \max(|x|, |y|)/|\vec{r}|$.
(2) Cancel the positive number $|\vec{r}|$.
(3) On the square, $\max(|x|, |y|) = 1$.

The other composition is checked the same way. Both maps are continuous (neither denominator vanishes on its domain), so the square's corners are invisible to topology (Figure 1.2). A physicist's version: a Wilson loop around a square path and around a circular path detect the same enclosed flux.

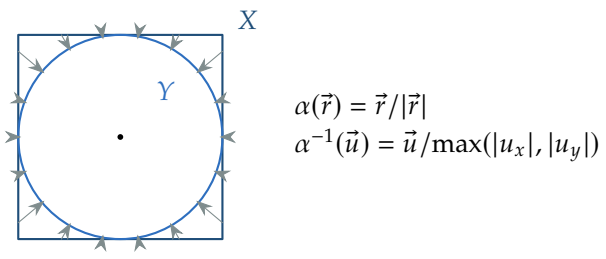

Figure 1.2: Radial projection is a homeomorphism from the square to the circle. Each grey arrow moves a point of the square along its ray from the origin; no two points collide and nothing is torn. Corners are not topological features.

Watch out: A continuous bijection need not be a homeomorphism

Wrap the half-open interval $X = [0, 1)$ onto the circle by $\alpha(t) = (\cos 2\pi t, \sin 2\pi t)$. This is continuous and bijective. But the inverse is *not* continuous: points on the circle just below $(1, 0)$ come from $t \approx 1$, points just above come from $t \approx 0$, so α^{-1} jumps at $(1, 0)$. That is why (1.1) demands continuity of α^{-1} separately. And indeed $[0, 1) \not\cong S^1$: removing the point $t = \frac{1}{2}$ disconnects $[0, 1)$, while removing any single point leaves the circle connected.

That last argument is typical: to prove two spaces are *not* homeomorphic, we find a property preserved by homeomorphisms that one space has and the other lacks. Such a property is a **topological invariant**. The simplest ones are:

- *Connectedness* and the number of connected pieces.
- *Compactness*: for subsets of $\mathbb{R}^N$, being closed and bounded. S^1 is compact, $\mathbb{R}$ is not, so $S^1 \not\cong \mathbb{R}$.
- *What happens when you remove a point.* $\mathbb{R}$ minus a point has two pieces; $\mathbb{R}^2$ minus a point has one. So $\mathbb{R} \not\cong \mathbb{R}^2$.
- *Dimension.* $\mathbb{R}^n \cong \mathbb{R}^m$ only if $n = m$ (Brouwer's "invariance of domain"; easy for $n = 1$ by the previous item, hard in general).
- *Numbers built by counting*, such as the Euler characteristic below, and *algebraic objects* such as the homotopy groups of §1.3.

Reading Nash (p. 1, (1.1))

Nash's (1.1) is exactly our (1.1); his I is the identity map. He announces the goal of topology as "classifying all topological spaces up to homeomorphism" and immediately says that this goal is not reached except in special cases. The rest of the chapter is about retreating to more modest but achievable goals.

1.1.2 The one great success: closed surfaces

The classification problem *is* solved in dimension two, for surfaces that are compact, have no boundary ("closed") and are orientable (they have two sides; no Möbius strips inside). The answer:

Key idea: Classification of closed orientable surfaces

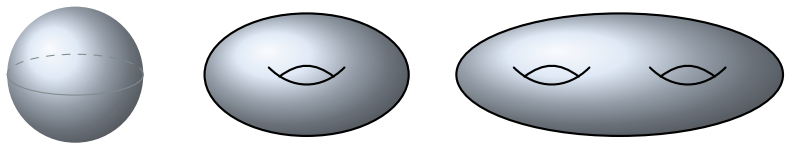
Every closed orientable surface is homeomorphic to a sphere with g handles attached, for exactly one $g \in \{0, 1, 2, \dots\}$, called the **genus**. Two such surfaces are homeomorphic if and only if they have the same genus. The genus is read off from the Euler characteristic by

$$\chi = 2 - 2g. \tag{1.2}$$

Working definition 1.3 (Euler characteristic)

Cut the surface into polygons (faces) meeting along edges and vertices, in any way you like, as long as the pieces are glued edge to edge. Count V vertices, E edges and F faces. Then

$$\chi := V - E + F.$$



$g = 0, \chi = 2$ $g = 1, \chi = 0$ $g = 2, \chi = -2$

Figure 1.3: The first three closed orientable surfaces. Each handle lowers the Euler characteristic by 2. As Riemann surfaces these are the Riemann sphere $\mathbb{CP}^1$, the complex tori $\mathbb{C}/\Lambda$, and the genus-2 curves; string perturbation theory sums over exactly this list (Chapter 9).

The number does not depend on how you cut, so it is a topological invariant [homeomorphic surfaces always give the same χ].

Why is χ independent of the cutting? Any two cuttings have a common refinement, and refining changes nothing: adding a vertex in the middle of an edge adds one vertex and one edge ($\Delta\chi = 1 - 1 = 0$); adding an edge across a face that joins two existing vertices adds one edge and one face ($\Delta\chi = -1 + 1 = 0$). Dray gives the physicist's reason [Dray §18.10]: the Gauss–Bonnet theorem

$$\int_{\Sigma} K \, \mathrm{d}A = 2\pi\chi(\Sigma) \tag{1.3}$$

expresses χ as an integral of the Gaussian curvature K. Deforming the surface changes K locally, but the total is pinned to 2π times an integer, so it cannot change continuously. (We return to Gauss–Bonnet in Chapter T2.) This "an integral that must be an integer is deformation-invariant" argument will recur all through the book.

Worked example 1.3: Euler characteristics of the sphere and the torus

Sphere. Inflate a cube into a sphere. It has $V = 8$ corners, $E = 12$ edges and $F = 6$ faces:

$$\chi(S^2) = 8 - 12 + 6 = 2, \qquad \text{so } g = \tfrac{1}{2}(2 - \chi) = 0.$$

Torus. A torus is a square with opposite edges glued (Figure 1.4). Cut the square into a 3×3 grid of small squares, and then each small square into two triangles by a diagonal. After gluing, the grid points form a 3×3 array (the points on the right and top edges are identified with those on the left and bottom), so

$$V \overset{(1)}{=} 3 \cdot 3 = 9,$$
$$F \overset{(2)}{=} 2 \cdot 9 = 18,$$
$$E \overset{(3)}{=} \tfrac{3}{2}F = 27,$$
$$\chi(T^2) = 9 - 27 + 18 = 0, \qquad g = 1.$$

(1) Gluing identifies the 4×4 lattice of grid points to 3×3.
(2) Nine small squares, two triangles each.
(3) Each triangle has three edges and each edge is shared by exactly two triangles after gluing.

The crudest possible cutting (one square, with its four edges glued in pairs and all four corners glued to one point) gives $V = 1$, $E = 2$, $F = 1$ and the same $\chi = 0$, as it must.

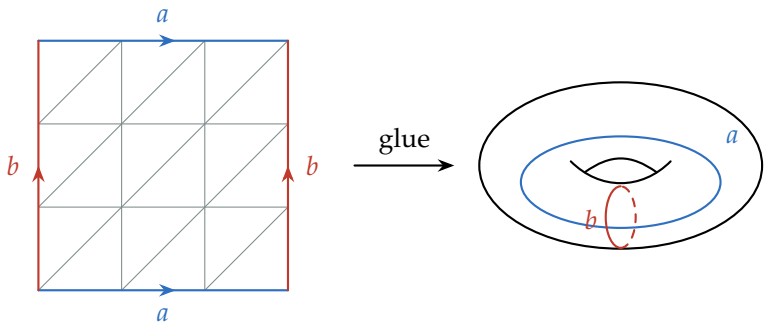


Figure 1.4: The torus as a square with opposite edges glued: a to a and b to b, respecting the arrows. The 3×3 triangulated grid on the left counts $V = 9$, $E = 27$, $F = 18$ after gluing, so $\chi = 0$. The two edge classes become the two basic loops a and b on the torus; they return in §1.3 as generators of $\pi_1(T^2) = \mathbb{Z} \times \mathbb{Z}$.

Try it: A genus-g surface

A closed genus-g surface can be made from a $4g$-gon by gluing its edges in the pattern $a_1 b_1 a_1^{-1} b_1^{-1} \cdots a_g b_g a_g^{-1} b_g^{-1}$ (read around the boundary; a^{-1} means edge a traversed backwards). All $4g$ corners end up glued to a single point. Compute χ. *Answer:* $V = 1$, $E = 2g$ (edges are glued in pairs), $F = 1$, so $\chi = 2 - 2g$, in agreement with (1.2).

Nash adds that these surfaces are "the celebrated Riemann surfaces". The reason: every closed orientable surface can be given a **complex structure**, i.e. an atlas of charts to $\mathbb{C}$ whose transition functions are holomorphic. Then it becomes a one-dimensional complex manifold, a **Riemann surface**. The genus is then the number of holes, and also the number of independent holomorphic 1-forms (we will meet that in Chapter 5). What topology does *not* fix is which complex structure: a torus can be $\mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$ for any τ in the upper half plane. The space of such choices is a moduli space, central in string theory (Chapter 9).

Watch out: Orientability matters

If we drop orientability, there are more closed surfaces: the projective plane $\mathbb{RP}^2$ (a disc with antipodal boundary points glued, $\chi = 1$), the Klein bottle ($\chi = 0$), and connected sums of these. The Klein bottle and the torus both have $\chi = 0$ but are not homeomorphic; the full classification needs χ *and* orientability. This is why Nash restricts to "compact closed orientable surfaces".

1.1.3 Why dimension two is special: room to move

In higher dimensions, no list like "sphere with g handles" exists. Nash gives a heuristic for why low and high dimensions behave differently. The heuristic rests on one counting rule, which is worth making explicit.

Key idea: General position: a dimension count

In an n-dimensional space, a p-dimensional and a q-dimensional object in "general position" (wiggled slightly at random) meet in a set of dimension

$$p + q - n. \tag{1.4}$$

If $p + q - n < 0$, a small wiggle makes them miss each other entirely.

The reason is linear algebra. Locally, a p-dimensional object is cut out by $n-p$ equations and a q-dimensional one by $n-q$ equations. Their intersection solves all $(n-p)+(n-q)$ equations in n unknowns. Generically the solution set has dimension $n-(n-p)-(n-q) = p+q-n$, and if that number is negative, generic equations have no common solution. Two random lines in a plane ($1+1-2=0$) meet in a point; two random lines in space ($1+1-3=-1$) miss.

Now Nash's point. Suppose we want to deform something inside a 2-dimensional manifold M, and a submanifold N is in the way. N has dimension 1 or 2. A path of the deformation is 1-dimensional, and $1+1-2=0$: a curve generically *hits* a curve in a surface, and there is no room to go around. In a manifold of large dimension n, a 1- or 2-dimensional obstacle is hit by a 2-dimensional family of paths only if $2+2-n \geq 0$, i.e. only if $n \leq 4$. For $n \geq 5$ there is room to push the deformation off the obstacle (Figure 1.5).

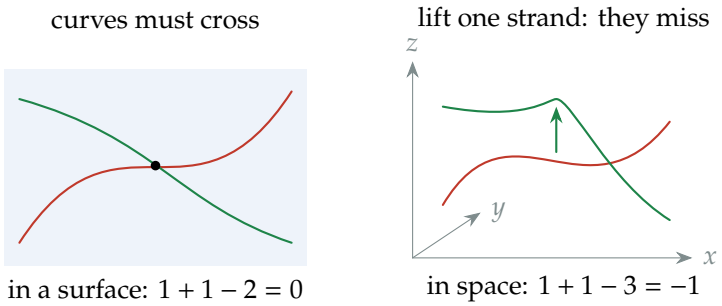

Figure 1.5: General position. In a surface, two curves that cross cannot be pulled apart by a small wiggle: the crossing point is stable because $1+1-2=0$. With one extra dimension, one strand lifts over the other, and the count $1+1-3<0$ says they generically miss. High dimensions are "roomy"; low dimensions are "cramped".

1.1.4 Knots, and the dimension at which things become easy

Nash's second illustration is knot theory.

Working definition 1.4 (knot)

A **knot** is a smooth [K can be differentiated any number of times] one-to-one map $K : S^1 \to \mathbb{R}^3$ (a closed loop of string with no self-intersections). Two knots are **equivalent** if one can be deformed into the other through knots, i.e. without ever passing the string through itself. A knot is **trivial** (the **unknot**) if it is equivalent to a round circle.

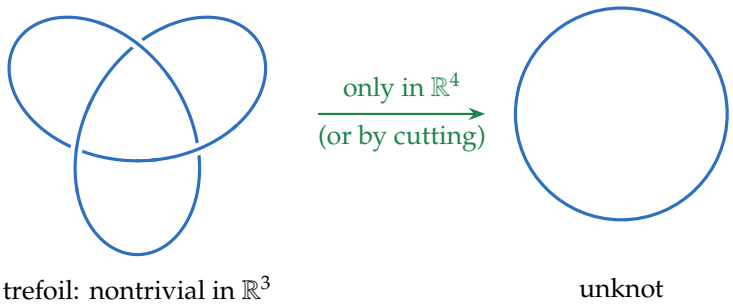

Figure 1.6: The trefoil cannot be deformed into the round circle inside $\mathbb{R}^3$ without the string passing through itself. In $\mathbb{R}^4$ it can: at each crossing one strand is pushed into the fourth direction, slid past, and brought back.

Many knots are non-trivial: the trefoil (Figure 1.6) is the simplest. Proving it is non-trivial

needs an invariant (for example the number of ways of colouring its three arcs with three colours so that at each crossing either all colours agree or all differ: the trefoil has 9 such colourings, the unknot only 3). But, as Nash says, *every* knot unties in $\mathbb{R}^4$.

Worked example 1.4: Why every knot unties in four dimensions

Think of a deformation of a knot as a movie: at each moment $s \in [0,1]$ of deformation time we have a closed curve in $\mathbb{R}^n$. A crossing change happens when two points of the string collide at some moment. Count the dimension of the set of collisions with (1.4): at fixed s, take two separate arcs of the string, then let s vary:

$$\dim\{\text{collisions}\} \overset{(1)}{=} \underbrace{(1+1-n)}_{\text{two arcs at fixed time}} + \underbrace{1}_{\text{time}}$$

$$= 3-n \begin{cases} = 0 & n=3: \text{ isolated collisions, cannot be avoided,} \\ = -1 & n=4: \text{ generically no collisions at all.} \end{cases}$$

(1) At a fixed time, two arcs in $\mathbb{R}^n$ meet in dimension $1+1-n$ by (1.4); letting time vary adds one dimension to the family.

So in $\mathbb{R}^4$ any homotopy of a loop (any deformation allowed to pass the string through itself) can be wiggled into one that never self-intersects. Every loop in $\mathbb{R}^4$ can be shrunk to a round circle by a homotopy, hence by an isotopy: every knot in $\mathbb{R}^4$ is trivial.

The general lesson: interesting knotting happens in codimension two (S^1 in $\mathbb{R}^3$, S^2 in $\mathbb{R}^4$, S^n in $\mathbb{R}^{n+2}$). Higher codimension gives too much room.

Physical picture: Knots in physics

Knots are not a mathematical curiosity for physicists. A Wilson loop $\operatorname{tr} P \exp \oint_K A$ is a function of a closed curve K; in Chern–Simons theory its expectation value depends only on the knot type of K, and it computes the Jones polynomial. This is one of the founding examples of a topological quantum field theory (Chapter 12). Knotted vortex lines in fluids and superfluids, and knotted flux tubes, are also real objects.

Nash then asks: if $\dim M = n$, from what n onwards does M behave like a "space of higher dimension", with enough room for general-position arguments? The answer is about $n = 5$. The technical reason is the **Whitney trick**: to cancel two intersection points of two submanifolds of complementary dimensions, one pushes across an embedded 2-disc. The 2-disc can be made embedded by general position when $2+2-n < 0$, i.e. $n \geq 5$. Dimensions 3 and 4 are the hard ones: in dimension 3 the geometry of 3-manifolds is special (Thurston, Perelman), and dimension 4 is where the gauge theory of this book (instantons, Seiberg–Witten) discovered completely unexpected phenomena. Nash returns to this in §6 of this chapter and in Chapter 8.

1.1.5 Topological manifolds

Since classifying all topological spaces is hopeless, Nash "lowers his sights" to spaces that look locally like $\mathbb{R}^n$.

Working definition 1.5 (topological manifold of dimension n)

A space M is a **topological manifold** of dimension n if

(i) it is covered by open sets (**patches** or **charts**) U_α, each equipped with a homeomorphism [a continuous bijection whose inverse is also continuous] $\phi_\alpha : U_\alpha \to \phi_\alpha(U_\alpha) \subset \mathbb{R}^n$ onto an open subset of $\mathbb{R}^n$ (the **coordinates** on U_α);

(ii) it is **Hausdorff**: any two distinct points have disjoint neighbourhoods [open sets containing them, with no point in common].

On an overlap $U_\alpha \cap U_\beta$ the two coordinate systems are related by the **transition function**

$$g_{\alpha\beta} := \phi_\alpha \circ \phi_\beta^{-1} : \phi_\beta(U_\alpha \cap U_\beta) \to \phi_\alpha(U_\alpha \cap U_\beta), \tag{1.5}$$

a map between open subsets of $\mathbb{R}^n$. For a topological manifold, the $g_{\alpha\beta}$ are homeomorphisms (automatically, being composites of homeomorphisms). A collection of charts covering M is an **atlas**.

The transition functions are the whole story. They say how to glue flat pieces of $\mathbb{R}^n$ together. The gluing idea returns in §5 of this chapter, where the transition functions take values in a gauge group and describe how to glue a fibre bundle: a gauge field on a non-trivial bundle is exactly a collection of local gauge potentials related by gauge transformations $g_{\alpha\beta}$ on overlaps.

Watch out: Why "Hausdorff"?

Without condition (ii) strange things can happen. Take two copies of the real line and glue them along every point except 0. The result, the "line with two origins", is covered by two charts (each copy of $\mathbb{R}$), so it is locally Euclidean. But the two origins cannot be separated: every neighbourhood of one meets every neighbourhood of the other. A sequence like $x_k = 1/k$ converges to both origins. Physics needs limits to be unique, so we exclude this. (Usually one also asks that M be covered by countably many charts; this is automatic for everything we meet.)

Worked example 1.5: An atlas for the circle

Let $S^1 = \{(x, y) : x^2 + y^2 = 1\}$. Use **stereographic projection**: from the north pole $N = (0, 1)$ draw the line through a point $P = (x, y) \neq N$ and record where it hits the x-axis. Similarly from the south pole $S = (0, -1)$. This gives two charts,

$$U_N = S^1 \setminus \{N\}, \quad u = \phi_N(x, y) = \frac{x}{1 - y}; \qquad U_S = S^1 \setminus \{S\}, \quad v = \phi_S(x, y) = \frac{x}{1 + y}.$$

On the overlap (the circle minus both poles), $u \neq 0$ and

$$u\, v \overset{(1)}{=} \frac{x^2}{1 - y^2} \overset{(2)}{=} 1, \qquad \text{so} \qquad g_{SN}(u) = \phi_S \circ \phi_N^{-1}(u) = \frac{1}{u}.$$

(1) Multiply the two formulas: $(1 - y)(1 + y) = 1 - y^2$.
(2) On the circle, $x^2 = 1 - y^2$.

The transition function $u \mapsto 1/u$ is a homeomorphism of $\mathbb{R} \setminus \{0\}$ to itself, so this is an atlas of a topological manifold of dimension 1. It is even infinitely differentiable, which will matter shortly. The same construction for $S^2 \subset \mathbb{R}^3$ gives charts $\vec{u}_N = (x, y)/(1 - z)$ and $\vec{u}_S = (x, y)/(1 + z)$ with $\vec{u}_S = \vec{u}_N/|\vec{u}_N|^2$; in complex form $\zeta_N = (x + iy)/(1 - z)$, $\zeta_S = (x - iy)/(1 + z)$ and $\zeta_S = 1/\zeta_N$, which is holomorphic: S^2 is the Riemann sphere $\mathbb{CP}^1$.

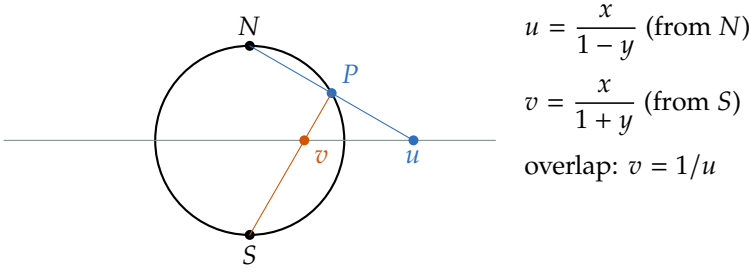

Figure 1.7: Two stereographic charts cover the circle. A point P gets the coordinate u (blue line from N) and v (orange line from S). Neither chart alone covers the whole circle, since each misses its own pole. On the overlap the coordinates are related by the smooth transition function $v = 1/u$.

1.1.6 Piecewise-linear manifolds

Topological manifolds are very general and "sparsely provided with concrete mathematical structures", as Nash puts it: we cannot differentiate on them, and we cannot count anything on them directly. The first way to add structure is combinatorial.

A **triangulation** of a space cuts it into simplices (points, edges, triangles, tetrahedra and their higher analogues) glued face to face. The sphere is triangulated by the surface of a tetrahedron or an octahedron. A map is **piecewise-linear** (PL) if, after subdividing into small enough simplices, it is affine (linear plus constant) on each simplex.

Working definition 1.6 (PL manifold)

A **piecewise-linear manifold** is a topological manifold with an atlas whose transition functions $g_{\alpha\beta}$ [the maps $\phi_\alpha \circ \phi_\beta^{-1}$ converting one chart's coordinates into another's] and their inverses are piecewise-linear. Equivalently, it is a manifold built from a triangulation in which the simplices around every vertex fit together like the simplices of a triangulated ball in $\mathbb{R}^n$. *Operational meaning:* you can *count*. Invariants such as $\chi = \sum_k (-1)^k (\#k\text{-simplices})$ and the simplicial homology groups [groups counting independent holes of each dimension] are computed by finite linear algebra on the triangulation.

Worked example 1.6: Euler characteristic of S^2 from two triangulations

Tetrahedron: $V = 4$, $E = 6$, $F = 4$, so $\chi = 4 - 6 + 4 = 2$. Octahedron: $V = 6$, $E = 12$, $F = 8$, so $\chi = 6 - 12 + 8 = 2$. The octahedron triangulation is a subdivision-equivalent refinement of the same PL structure: a PL homeomorphism (radial projection followed by straightening edges) carries one to the other. Lattice field theorists meet PL manifolds constantly: a lattice discretisation of spacetime *is* a triangulation (or cubulation), and lattice gauge theory lives on its edges (link variables) and faces (plaquettes).

1.1.7 Differentiable manifolds

The physicist, and the differential topologist, want calculus. Calculus needs the notion of a differentiable function, and on a manifold "differentiable" only makes sense if it means the same thing in every chart. That forces the transition functions to be differentiable.

Working definition 1.7 (differentiable manifold, diffeomorphism)

A **differentiable** (or **smooth**) manifold is a topological manifold with an atlas whose transition functions $g_{\alpha\beta}$ (and hence their inverses $g_{\beta\alpha} = g_{\alpha\beta}^{-1}$) are infinitely differentiable (C^∞). A function $f : M \to \mathbb{R}$ is smooth if $f \circ \phi_\alpha^{-1}$ is smooth on $\phi_\alpha(U_\alpha) \subset \mathbb{R}^n$ for every α. A map $h : M \to N$ between smooth manifolds is a **diffeomorphism** if it is a homeomorphism and both h and h^{-1} are smooth when written in charts. *Operational test:* write h in local coordinates, check that all partial derivatives of all orders exist and are continuous, and check the Jacobian $\det(\partial h^i/\partial x^j)$ never vanishes (then the inverse is smooth too, by the inverse function theorem [a smooth map with nonzero Jacobian at a point has a smooth inverse near that point]).

Why does "smooth in one chart" imply "smooth in every chart"? Because on an overlap

$$f \circ \phi_\beta^{-1} \overset{(1)}{=} f \circ \phi_\alpha^{-1} \circ \phi_\alpha \circ \phi_\beta^{-1} \overset{(2)}{=} \left(f \circ \phi_\alpha^{-1}\right) \circ g_{\alpha\beta},$$

(1) Insert $\phi_\alpha^{-1} \circ \phi_\alpha = \mathrm{id}$ on $U_\alpha \cap U_\beta$.
(2) Definition (1.5) of the transition function.

and a composite of smooth maps is smooth (chain rule). This is exactly why the $g_{\alpha\beta}$ must be C^∞. The circle atlas of Example 1.5 has $g_{SN}(u) = 1/u$, smooth on $u \neq 0$, so S^1 is a smooth manifold; likewise S^2, and every sphere S^n. Tori $T^n = S^1 \times \cdots \times S^1$, the projective spaces $\mathbb{RP}^n$ and $\mathbb{CP}^n$, and all the matrix Lie groups (U(1), SU(2), SO(3), ...) are smooth manifolds. The toolkit chapter Chapter T1 builds forms and derivatives on such manifolds.

Worked example 1.7: Homeomorphic but not a diffeomorphism; different atlases but the same manifold

Consider $h : \mathbb{R} \to \mathbb{R}$, $h(x) = x^3$. It is a homeomorphism: its inverse $h^{-1}(y) = y^{1/3}$ (real cube root) is continuous. It is smooth. But h^{-1} is not differentiable at 0:

$$\frac{\mathrm{d}}{\mathrm{d}y}\, y^{1/3} = \frac{1}{3}\, y^{-2/3} \xrightarrow{y \to 0} \infty.$$

So h is a homeomorphism but not a diffeomorphism. (In the Jacobian language: $h'(0) = 0$.) Now use h to define a new atlas on the set $\mathbb{R}$: the single chart $\psi(x) = x^3$. Call the resulting smooth manifold $\mathbb{R}'$. The standard atlas $\{\mathrm{id}\}$ and the new atlas $\{\psi\}$ are *not compatible*: the transition function $\mathrm{id} \circ \psi^{-1}(y) = y^{1/3}$ is not smooth. So they are different smooth structures on the same set. Are $\mathbb{R}$ and $\mathbb{R}'$ different smooth manifolds? No. The map $f : \mathbb{R} \to \mathbb{R}'$, $f(x) = x^{1/3}$, is a diffeomorphism. To see this, write it in the charts (id on the source, ψ on the target):

$$\psi \circ f \circ \mathrm{id}^{-1}(x) \overset{(1)}{=} \left(x^{1/3}\right)^3 \overset{(2)}{=} x,$$

(1) Apply f, then the chart $\psi(t) = t^3$ of $\mathbb{R}'$.
(2) Real cube roots cube back to the original number.

which is the identity, smooth with smooth inverse. So different atlases can give diffeomorphic manifolds. When mathematicians count "smooth structures" on a topological manifold, they count them *up to diffeomorphism*, and this example counts as one structure, not two.

1.1.8 Three kinds of manifold, and why the distinction matters

We now have three levels of structure: M_{TOP} (transition functions homeomorphisms), M_{PL} (piecewise-linear) and M_{DIFF} (smooth). Every smooth manifold can be triangulated in an essentially unique way compatible with its smooth structure (Whitehead), and every PL manifold is a topological manifold. So there are forgetful arrows

$$\mathrm{DIFF} \longrightarrow \mathrm{PL} \longrightarrow \mathrm{TOP}.$$

One might guess that these arrows can always be reversed: that any topological manifold has, uniquely, a PL structure and a smooth structure. Nash stresses that this is false in both respects.

Key idea: Existence and uniqueness both fail

- *Existence can fail.* There are topological manifolds that admit no PL structure, and topological or PL manifolds that admit no smooth structure.
- *Uniqueness can fail.* A topological manifold can carry several smooth structures that are homeomorphic but *not* diffeomorphic to each other.

This is the *raison d'être* of **differential topology** as a separate subject: smoothness is genuinely extra information.

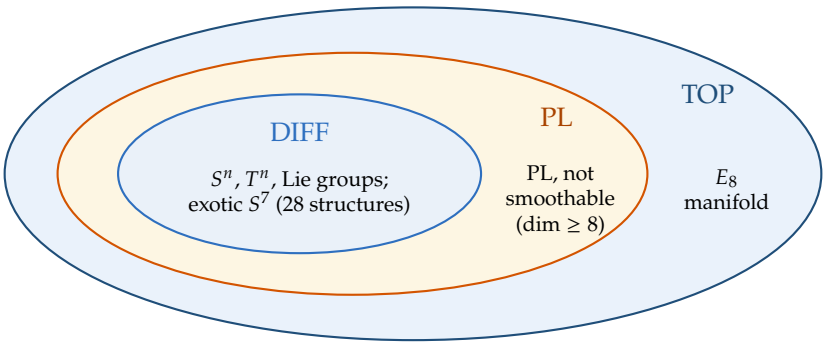

Figure 1.8: Three nested worlds. Every smooth manifold is PL, and every PL manifold is topological, but not conversely. Freedman's E_8 manifold is a closed topological 4-manifold with no PL and no smooth structure. Inside DIFF, one topological sphere S^7 carries 28 inequivalent smooth structures (counting orientation).

Some landmark facts, to make these statements concrete (we only name them here; Nash develops some of them in §6 of this chapter):

dimension	what happens	name
$n \le 3$	TOP = PL = DIFF: every topological manifold has a unique smooth structure	Radó, Moise
$n = 4$	topological 4-manifolds with no smooth structure	Freedman, Donaldson
	$\mathbb{R}^4$ has uncountably many smooth structures	Taubes, Gompf
$n \ge 5$	TOP manifolds with no PL structure	Kirby–Siebenmann
$n = 7$	S^7 has 28 smooth structures (oriented)	Milnor, Kervaire–Milnor
$n = 11$	S^{11} has 992 smooth structures, i.e. 991 exotic ones	Kervaire–Milnor

Physical picture: Why a physicist should care

Nash anticipates the objection that "the particular properties of manifolds described here might be thought unlikely to have any relevance for quantum field theory", and says the opposite is true. Two examples we will meet:

- *Donaldson theory* (Chapter 8): moduli spaces of instantons, solutions of the Yang–Mills self-duality equations, are sensitive to the smooth structure of a 4-manifold. Gauge theory is how exotic 4-dimensional smooth structures were discovered.
- *Global gravitational anomalies* (Chapter 10): the 991 exotic 11-spheres enter the check that ten-dimensional superstring theories are free of global anomalies, because a large diffeomorphism of S^{10} can be used to glue an exotic S^{11}.

More simply: a path integral over metrics or fields uses derivatives, so it needs a smooth structure. If a spacetime topology admits several, the "sum over geometries" has a choice to make.

Reading Nash (pp. 1–3)

Nash's order is: goal of topology (1.1); surfaces solved by genus; dimension 2 restricted by obstacles; knots untie in $\mathbb{R}^4$; "higher dimension" starts around $n = 5$ (pointer to his §6); topological manifolds with transition functions $g_{\alpha\beta}$; PL manifolds ($g_{\alpha\beta}$, $g_{\alpha\beta}^{-1}$ piecewise-linear); differentiable manifolds ($g_{\alpha\beta}$, $g_{\alpha\beta}^{-1}$ of class C^∞); M_{TOP}, M_{PL}, M_{DIFF} may fail to exist or to be unique. He closes by adopting the convention that "manifold" means differentiable manifold unless stated otherwise. We adopt the same convention from now on.

Recap

- A homeomorphism is a continuous bijection with continuous inverse (1.1); homeomorphic spaces are topologically identical. Length, corners and curvature are not topological.
- Closed orientable surfaces are classified by the genus g, read off from $\chi = V - E + F = 2 - 2g$.
- General position (1.4): objects of dimensions p, q in $\mathbb{R}^n$ generically miss if $p + q < n$. Low dimensions are cramped, dimension ≥ 5 is roomy; knots untie in $\mathbb{R}^4$.
- A manifold is glued from patches of $\mathbb{R}^n$ by transition functions $g_{\alpha\beta} = \phi_\alpha \circ \phi_\beta^{-1}$. Their regularity (homeomorphism, PL, C^∞) defines TOP, PL, DIFF manifolds.
- Smooth structures may fail to exist or to be unique: exotic spheres, exotic $\mathbb{R}^4$. This matters for instantons and anomalies.

1.2 Some algebraic topology: homotopy

Homeomorphism is too fine a relation to be useful in general: we cannot classify spaces up to homeomorphism. Algebraic topology therefore changes the question. Instead of deciding whether two spaces are *the same*, it attaches to each space some **invariants**, quantities that do not change under homeomorphism, and compares those. If the invariants differ, the spaces differ. Nash lists the two kinds:

- *numbers*: the dimension, the Euler–Poincaré characteristic χ we met in §1.1.2;
- *algebraic objects*: groups such as the homotopy groups (this section and the next) and the homology and cohomology groups (§4 of this chapter).

The most powerful single idea for building invariants is *homotopy*: continuous deformation of maps. A physicist already thinks this way. A field configuration is a map $\phi : X \to Y$ from space X to a space Y of field values. Time evolution with finite energy deforms ϕ continuously. So anything that cannot change under continuous deformation is a *conserved topological charge*. This section builds the language for such charges.

1.2.1 Maps and homotopies

Fix two spaces X and Y. Write

$$\mathrm{Map}(X, Y) := \{\alpha : X \to Y \text{ continuous}\} \tag{1.6}$$

for the set of all continuous maps from X to Y. For a physicist, $\mathrm{Map}(\mathbb{R}^3, \mathbb{C})$ is the space of (continuous) complex scalar field configurations, and $\mathrm{Map}(S^1, Y)$ is the space of closed strings moving in a target space Y.

Working definition 1.8 (homotopy)

Two maps $\alpha, \beta \in \mathrm{Map}(X, Y)$ are **homotopic**, written $\alpha \simeq \beta$, if there is a continuous map [small changes in the pair (t, x) give small changes in $F(t, x)$]

$$F : [0,1] \times X \to Y \qquad \text{with} \qquad F(0, x) = \alpha(x), \quad F(1, x) = \beta(x) \quad \text{for all } x \in X. \tag{1.7}$$

F is called a **homotopy** from α to β. Think of the first variable $t \in [0,1]$ as time: $F_t := F(t, \cdot)$ is a one-parameter family of maps (a "movie") that starts at α and ends at β. *Operational test:* to show $\alpha \simeq \beta$, write down a formula $F(t, x)$, check it is continuous in both variables jointly, check it lands in Y for all t, and check the endpoints.

The condition "lands in Y for all t" is where all the content is. Writing down *some* interpolation between α and β is easy; keeping it inside Y may be impossible.

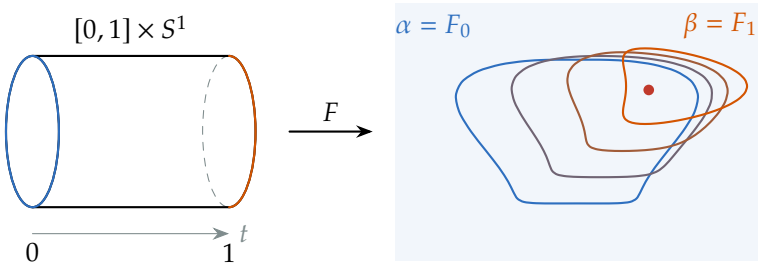

Figure 1.9: A homotopy is a map from the cylinder $[0,1] \times X$ (here $X = S^1$) into Y. Its left end is the loop α and its right end the loop β; the intermediate slices are a movie of loops (colours interpolating). In the plane with a hole (the red dot), the movie is legal only if no intermediate loop passes through the hole. Here every slice keeps the hole inside, so this is a genuine homotopy in $\mathbb{R}^2 \setminus \{\text{hole}\}$. Sliding the loop off the hole would require crossing it, and we will see in §1.3.2 that no homotopy can do that.

Worked example 1.8: Everything is homotopic in $\mathbb{R}^n$: the straight-line homotopy

Let $Y = \mathbb{R}^n$ and let $\alpha, \beta \in \mathrm{Map}(X, \mathbb{R}^n)$ be *any* two maps. Define $F(t,x) = (1-t)\,\alpha(x) + t\,\beta(x)$. Then

$$F(0,x) \overset{(1)}{=} \alpha(x), \qquad F(1,x) \overset{(1)}{=} \beta(x),$$

(1) Set $t = 0$ or $t = 1$ in the formula.

and F is continuous because it is built from continuous functions by multiplication and addition. It lands in $\mathbb{R}^n$ trivially. So any two maps into $\mathbb{R}^n$ are homotopic. The same formula works for maps into any **convex** set (one containing the straight segment between any two of its points), such as a ball. It fails in $\mathbb{R}^2 \setminus \{0\}$, where the straight segment from $\alpha(x)$ to $\beta(x)$ may pass through the origin.

Worked example 1.9: The antipodal map of an odd-dimensional sphere

Let $X = Y = S^{2k-1}$, viewed as the unit sphere in $\mathbb{C}^k$: $S^{2k-1} = \{z = (z_1, \dots, z_k) : |z_1|^2 + \cdots + |z_k|^2 = 1\}$. The **antipodal map** is $a(z) = -z$. Claim: $a \simeq \mathrm{id}$. Take $F(t,z) = e^{i\pi t} z$. Then

$$|F(t,z)|^2 \overset{(1)}{=} \sum_{j=1}^{k} |e^{i\pi t} z_j|^2 \overset{(2)}{=} \sum_{j=1}^{k} |z_j|^2 \overset{(3)}{=} 1,$$

$$F(0,z) = z = \mathrm{id}(z), \qquad F(1,z) \overset{(4)}{=} -z = a(z).$$

(1) Definition of the length in $\mathbb{C}^k$.
(2) $|e^{i\pi t}| = 1$, so each term is unchanged.
(3) z was on the unit sphere.
(4) $e^{i\pi} = -1$.

So F stays on the sphere for all t: it is the rotation by angle πt simultaneously in each complex plane. For $k = 1$ this is just the rotation of a circle by 180°. On even-dimensional spheres, such as S^2, the antipodal map is *not* homotopic to the identity (it has degree -1, §1.3.8); this is the hairy-ball phenomenon.

Worked example 1.10: Homotopy is an equivalence relation

We check the three properties, since everything below depends on them.

- *Reflexive:* $\alpha \simeq \alpha$ via the "do nothing" homotopy $F(t,x) = \alpha(x)$.
- *Symmetric:* if F goes from α to β, then $\bar{F}(t,x) := F(1-t,x)$ goes from β to α (run the movie backwards).
- *Transitive:* if F goes from α to β and G from β to γ, play the two movies in succession at double speed:

$$H(t,x) = \begin{cases} F(2t,x) & 0 \le t \le \tfrac{1}{2}, \\ G(2t-1,x) & \tfrac{1}{2} \le t \le 1. \end{cases}$$

The only thing to check is that H is well defined and continuous at $t = \frac{1}{2}$, where both formulas apply:

$$F(2\cdot\tfrac{1}{2}, x) = F(1,x) \overset{(1)}{=} \beta(x) \overset{(2)}{=} G(0,x) = G(2\cdot\tfrac{1}{2} - 1, x).$$

(1) F ends at β.
(2) G starts at β.

Two continuous functions on the closed pieces $[0, \frac{1}{2}] \times X$ and $[\frac{1}{2}, 1] \times X$ that agree on the common edge glue to a continuous function (the "gluing lemma"). This double-speed concatenation reappears as the product of loops in §1.3.

Because homotopy is an equivalence relation, it divides $\mathrm{Map}(X, Y)$ into equivalence classes.

Working definition 1.9 (homotopy classes)

The set of homotopy classes [one class for each collection of maps that can all be deformed into one another] of maps from X to Y is written

$$[X, Y] := \mathrm{Map}(X, Y)/\simeq . \tag{1.8}$$

The class of a map α is written $[\alpha]$. *Physics reading:* $[X, Y]$ is the set of *topological sectors* of field configurations $X \to Y$: two configurations are in the same sector iff one can be continuously deformed into the other.

Some first examples, all of which we justify in this part:

$[X, Y]$	answer	reason
$[X, \mathbb{R}^n]$	one element	straight-line homotopy, Example 1.8
$[\{\mathrm{pt}\}, Y]$	path components of Y, written $\pi_0(Y)$	a map from a point is a point of Y; a homotopy is a path between points
$[S^1, S^1]$	$\mathbb{Z}$	winding number, §1.3.2
$[S^1, S^2]$	one element	loops slide off a point of S^2, §1.3.7
$[S^2, S^2]$	$\mathbb{Z}$	degree, §1.3.8
$[S^3, \mathrm{SU}(2)]$	$\mathbb{Z}$	instanton number, §1.3.14

Dictionary: homotopy language

mathematics	physics
map $\alpha : X \to Y$	field configuration on space X with values in Y
homotopy $F : [0, 1] \times X \to Y$	continuous evolution / deformation of the field
class $[\alpha] \in [X, Y]$	topological sector, "charge" of the configuration
homotopy invariant	topologically conserved quantity
$[X, Y]$ has one element	no topological sectors (everything deforms to vacuum)

$[X, Y]$ is a topological invariant of Y

Nash observes that if X is fixed and Y is replaced by a homeomorphic space Y', the set $[X, Y]$ does not change. Let $h : Y \to Y'$ be a homeomorphism. Send each map $\alpha : X \to Y$ to $h \circ \alpha : X \to Y'$. If F is a homotopy from α to β, then $h \circ F$ is a homotopy from $h \circ \alpha$ to $h \circ \beta$:

$$(h \circ F)(0, x) \overset{(1)}{=} h\big(F(0, x)\big) \overset{(2)}{=} h\big(\alpha(x)\big), \qquad (h \circ F)(1, x) = h\big(\beta(x)\big),$$

(1) Definition of composition.
(2) F starts at α; the same argument at $t = 1$ gives β.

and $h \circ F$ is continuous as a composite of continuous maps. So $[\alpha] \mapsto [h \circ \alpha]$ is a well-defined map $[X, Y] \to [X, Y']$. Doing the same with h^{-1} gives the inverse map. Hence $[X, Y]$ and

$[X, Y']$ are canonically identified. The same argument, with h acting on X by precomposition, shows $[X, Y]$ is also a topological invariant of X.

The argument used much less than a homeomorphism. It only used that composition with a fixed continuous map carries homotopies to homotopies:

$$\alpha \simeq \beta \implies h \circ \alpha \simeq h \circ \beta \quad \text{and} \quad \alpha \circ k \simeq \beta \circ k \tag{1.9}$$

for any continuous $h : Y \to Y'$ and $k : X' \to X$ (use $h \circ F$ and $F(t, k(x'))$ respectively). That observation leads to the next notion.

1.2.2 Homotopy type

Homeomorphism asks for maps $\alpha : X \to Y$ and $\beta : Y \to X$ that are exact inverses. Homotopy theory asks only that they be inverses up to homotopy.

Working definition 1.10 (homotopy equivalence)

Spaces X and Y have the same **homotopy type** (are **homotopy equivalent**), written $X \simeq Y$, if there are continuous maps

$$\alpha : X \to Y, \qquad \beta : Y \to X, \qquad \alpha \circ \beta \simeq \mathrm{id}_Y, \qquad \beta \circ \alpha \simeq \mathrm{id}_X. \tag{1.10}$$

[here $\simeq$ between maps means homotopic, i.e. deformable into each other, not equal]. β is a **homotopy inverse** of α. A space homotopy equivalent to a single point is **contractible**. *Operational test:* guess a "shrinking" map α onto a simpler space and the inclusion β back [each point of the simpler space sent to itself inside the original one]; one composite is usually the identity on the nose; write down an explicit homotopy for the other.

Homotopy equivalence is an equivalence relation. Transitivity uses (1.9): if $X \simeq Y$ via (α, β) and $Y \simeq Z$ via (γ, δ), then

$$(\gamma \circ \alpha) \circ (\beta \circ \delta) \overset{(1)}{=} \gamma \circ (\alpha \circ \beta) \circ \delta \overset{(2)}{\simeq} \gamma \circ \mathrm{id}_Y \circ \delta = \gamma \circ \delta \overset{(3)}{\simeq} \mathrm{id}_Z,$$

(1) Composition of maps is associative.
(2) $\alpha \circ \beta \simeq \mathrm{id}_Y$, and composing on both sides with fixed maps preserves homotopy, (1.9).
(3) $\gamma \circ \delta \simeq \mathrm{id}_Z$ by assumption.

and similarly $(\beta \circ \delta) \circ (\gamma \circ \alpha) \simeq \mathrm{id}_X$.

Worked example 1.11: $\mathbb{R}^n$ is contractible

Let $\alpha : \mathbb{R}^n \to \{0\}$ send everything to the origin and let $\beta : \{0\} \to \mathbb{R}^n$ be the inclusion. Then $\alpha \circ \beta = \mathrm{id}_{\{0\}}$ exactly. The other composite $\beta \circ \alpha$ is the constant map $x \mapsto 0$. Use $F(t, x) = t\,x$:

$$F(0, x) = 0 = (\beta \circ \alpha)(x), \qquad F(1, x) = x = \mathrm{id}_{\mathbb{R}^n}(x).$$

So $\beta \circ \alpha \simeq \mathrm{id}$ and $\mathbb{R}^n \simeq \{\mathrm{pt}\}$. The homotopy is the movie in which space is uniformly shrunk to the origin (Figure 1.10, left).
Nash draws the moral. $\mathbb{R}^n$ $(n > 0)$ is *not* homeomorphic to a point (it is not even the same size as a set), and $\mathbb{R}^n \cong \mathbb{R}^m$ only if $n = m$. But all $\mathbb{R}^n$ have the homotopy type of a point. So dimension is a topological invariant which is *not* a homotopy invariant, and every homotopy invariant (homotopy groups, homology groups) of $\mathbb{R}^n$ equals that of a point, i.e. is trivial.

Worked example 1.12: The punctured plane has the homotopy type of a circle

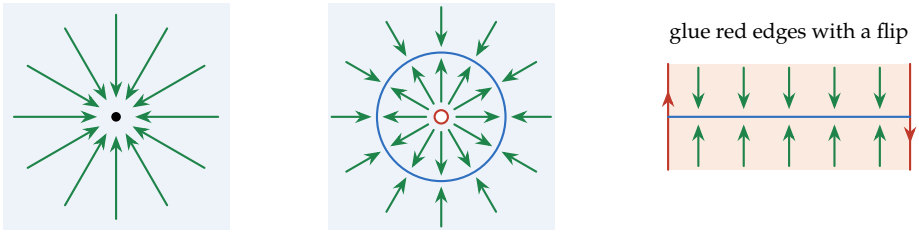
Let $X = \mathbb{R}^2 \setminus \{0\}$ and $Y = S^1$. Take $\alpha(x) = x/|x|$ (radial projection) and $\beta : S^1 \hookrightarrow X$ the inclusion. Then $\alpha \circ \beta = \mathrm{id}_{S^1}$ since unit vectors are already unit. For the other composite use the straight-line homotopy $F(t, x) = (1 - t)\,\frac{x}{|x|} + t\,x$. The danger is that F might hit the origin, which is not in X. It does not:

$$F(t,x) \overset{(1)}{=} \Big(\frac{1-t}{|x|} + t\Big)x, \qquad \text{and} \qquad \frac{1-t}{|x|} + t \overset{(2)}{>} 0,$$

(1) Factor out the vector x.

(2) For $t \in [0, 1]$ both terms are ≥ 0, and they cannot both vanish ($t = 0$ makes the first term $1/|x| > 0$).

So $F(t, x)$ is a positive multiple of $x \neq 0$: it slides each point along its own ray, never through the origin. $F(0, \cdot) = \beta \circ \alpha$ and $F(1, \cdot) = \mathrm{id}_X$. Hence $\mathbb{R}^2 \setminus \{0\} \simeq S^1$. In the same way $\mathbb{R}^n \setminus \{0\} \simeq S^{n-1}$, which is why the field of a point charge in $\mathbb{R}^3$ is "measured" by a sphere S^2 around it.



$\mathbb{R}^2 \simeq \{0\}$: $F(t, x) = tx$ $\quad$ $\mathbb{R}^2 \setminus \{0\} \simeq S^1$ $\quad$ Möbius band $\simeq S^1$

Figure 1.10: Three deformation retractions (green arrows show where points move as t runs from 1 down to 0). Left: the plane shrinks to a point. Middle: the punctured plane retracts onto the unit circle, points outside moving in and points inside moving out, never crossing the hole. Right: a Möbius band (a strip whose ends are glued with a flip) retracts onto its central circle, shown in blue.

Worked example 1.13: More spaces with the homotopy type of a circle

Each of the following retracts onto a circle by squashing the "thick" directions, exactly as in Figure 1.10:

- the cylinder $S^1 \times [0, 1]$ (squash $[0, 1]$ to a point) and $S^1 \times \mathbb{R}^k$ (use $F(t, (z, y)) = (z, ty)$);
- the Möbius band (squash each vertical segment to its midpoint);
- the solid torus $S^1 \times D^2$ (squash each disc to its centre);
- $\mathbb{R}^3$ minus a straight line, for instance the space around an infinitely long solenoid or a straight vortex line (project onto a plane perpendicular to the line and use Example 1.12);
- the thickened letters O, D, P, A, Q, R (one hole each). The letter B is homotopy equivalent to the figure eight $S^1 \vee S^1$ (two holes), and C, E, T, ... are contractible.

The cylinder and the Möbius band have the same homotopy type but are not homeomorphic (the Möbius band has only one boundary circle). Homotopy type forgets orientability.

Key idea: Invariants of homotopy type

If $Y \simeq Y'$ then $[X, Y] = [X, Y']$ for every X; if $X \simeq X'$ then $[X, Y] = [X', Y]$ for every Y. In Nash's form,

$$[X, Y] = [X, Y'] \quad \text{for } Y \text{ homeomorphic to } Y', \tag{1.11}$$
$$[X, Y] = [X, Y'] \quad \text{for } Y \text{ of the same homotopy type as } Y'. \tag{1.12}$$

The second is stronger. Most invariants of algebraic topology (homotopy groups, homology and cohomology groups, the Euler characteristic) are invariants of homotopy type.

Why does (1.12) hold? Let $\alpha : Y \to Y'$, $\beta : Y' \to Y$ be a homotopy equivalence. Define $\alpha_* : [X, Y] \to [X, Y']$ by $[f] \mapsto [\alpha \circ f]$ and β_* similarly. By (1.9) these are well defined, and

$$\beta_*\alpha_*[f] \overset{(1)}{=} [\beta \circ \alpha \circ f] \overset{(2)}{=} [\mathrm{id}_Y \circ f] = [f],$$

(1) Apply the definitions of α_* and then β_*.
(2) $\beta \circ \alpha \simeq \mathrm{id}_Y$; compose on the right with f using (1.9).

and likewise $\alpha_*\beta_* = \mathrm{id}$. So α_* is a bijection.

Watch out: Asking for a homotopy invariant is asking for less

Nash warns: an invariant of homotopy type is a *coarser* invariant than an invariant of the homeomorphism class. Homotopy invariants cannot tell $\mathbb{R}^3$ from a point, a Möbius band from a cylinder, or a solid torus from a circle. That is the price of computability. When we need finer information (dimension, smooth structure) we must use other tools.

1.2.3 Retracts and deformation retracts

All the examples above have the same shape: a big space X is squashed onto a subspace A that it contains, without moving the points of A. This pattern has a name.

Working definition 1.11 (retract, deformation retract)

Let $A \subset X$ and let $i : A \hookrightarrow X$ be the inclusion [each point of A sent to itself, now regarded as a point of X].

- A is a **retract** of X if there is a continuous $r : X \to A$ with $r(a) = a$ for all $a \in A$ (i.e. $r \circ i = \mathrm{id}_A$).
- A is a **deformation retract** of X if moreover $i \circ r \simeq \mathrm{id}_X$ [the squashing map $X \to A \subset X$ can be deformed continuously into doing nothing] by a homotopy that keeps A fixed at all times.

A deformation retract is automatically a homotopy equivalence ($\alpha = r$, $\beta = i$). *Operational test:* find a "squashing" formula $F(t, x)$, equal to x at $t = 1$, landing in A at $t = 0$, and fixing points of A.

Worked example 1.14: The circle is not a retract of the disc; Brouwer's fixed-point theorem

The punctured plane retracts onto S^1. The full disc D^2 does not. Suppose $r : D^2 \to S^1$ were a retraction. Consider the loop $\gamma(s) = (\cos 2\pi s, \sin 2\pi s)$ on the boundary circle, and

the homotopy $\Gamma(t,s) = r\big(t\,\gamma(s)\big)$ (shrink the loop into the disc, then apply r). Then

$$\Gamma(1,s) \overset{(1)}{=} r(\gamma(s)) \overset{(2)}{=} \gamma(s), \qquad \Gamma(0,s) = r(0) = \text{a constant point of } S^1.$$

(1) Set $t = 1$.
(2) r fixes the points of S^1, and $\gamma(s) \in S^1$.

So Γ would be a homotopy *in* S^1 from the loop that winds once around the circle to a constant loop. We will prove in §1.3.2 that the winding number is a homotopy invariant, and these two loops have winding numbers 1 and 0. Contradiction: no retraction exists.
A famous consequence is **Brouwer's fixed-point theorem**: every continuous $f : D^2 \to D^2$ has a fixed point. If not, $f(x) \neq x$ for all x, and we could define $r(x)$ as the point where the ray from $f(x)$ through x leaves the disc. This r is continuous and fixes the boundary, so it is a retraction $D^2 \to S^1$, which does not exist. Stir a cup of coffee (continuously, without splashing) and some point of the surface ends where it started.

Try it: Retracts of the torus

Show that the circle $S^1 \times \{1\}$ is a retract of the torus $T^2 = S^1 \times S^1$ but not a deformation retract. *Answer:* $r(z,w) = (z,1)$ is a retraction. It is not a deformation retract, since then $T^2 \simeq S^1$; but $\pi_1(T^2) = \mathbb{Z}\times\mathbb{Z}$ while $\pi_1(S^1) = \mathbb{Z}$ (§1.3.3), and π_1 is a homotopy invariant.

1.2.4 Base points: why loops need a common point

The most important choice of X in $[X,Y]$ is the circle: $[S^1,Y]$ is the set of deformation classes of closed loops in Y. We would like these classes to form a *group*, with the product "go around one loop, then the other". But two arbitrary loops in Y need not meet, so there is no obvious way to follow one by the other. The cure is simple and, as Nash says, "powerful": make all loops start and end at one agreed point.

Working definition 1.12 (pointed spaces and based maps)

A **pointed space** $\{X,*\}$ is a space X with a chosen **base point** $* = x_0 \in X$. A **based map** $\alpha : \{X,x_0\} \to \{Y,y_0\}$ is a continuous map with $\alpha(x_0) = y_0$. We write

$$\mathrm{Map}_0(X,Y) := \{\alpha \in \mathrm{Map}(X,Y) : \alpha(x_0) = y_0\}. \tag{1.13}$$

A **based homotopy** is a homotopy F [a continuous $F : [0,1]\times X \to Y$ deforming one map, $F(0,\cdot)$, into another, $F(1,\cdot)$] with $F(t,x_0) = y_0$ for all t: the base point is pinned throughout the movie. The set of based homotopy classes is

$$[X,Y]_0 := \mathrm{Map}_0(X,Y)/\!\simeq_{\text{based}}. \tag{1.14}$$

By contrast $[X,Y]$ is the set of **free** homotopy classes: neither the maps nor the homotopies need respect base points.

Every based class determines a free class (forget that the base point was pinned), giving a map $[X,Y]_0 \to [X,Y]$. It need not be one-to-one: two based maps can be freely homotopic without being based homotopic. We work out exactly how the two differ in §1.3.5.

Worked example 1.15: π_0: path components as based classes

Let $S^0 = \{-1, +1\}$, the "zero-sphere" (the solutions of $x^2 = 1$), with base point $+1$. A based map $\alpha : S^0 \to Y$ is determined by the single point $\alpha(-1) \in Y$, since $\alpha(+1) = y_0$ is forced. A based homotopy is a path $t \mapsto F(t, -1)$ moving that point around. So

$$[S^0, Y]_0 = \{\text{path components of } Y\} =: \pi_0(Y).$$

For example $\pi_0(\mathrm{O}(3))$ has two elements (rotations and reflections, $\det R = \pm 1$), and $\pi_0(\text{Lorentz group})$ has four. A space is **path-connected** if $\pi_0(Y)$ has one element: any two points can be joined by a path. π_0 has no group structure in general (it does if Y is a group: $\pi_0(\mathrm{O}(3)) \cong \mathbb{Z}_2$). In physics, π_0 of the vacuum manifold classifies domain walls (§1.3.13).

1.2.5 Maps into mapping spaces: the exponential law

We now drop base points for a moment. Nash records a simple but very useful bijection: for spaces X, Y, Z,

$$i : \mathrm{Map}\big(X, \mathrm{Map}(Y, Z)\big) \longrightarrow \mathrm{Map}(X \times Y, Z). \tag{1.15}$$

A map that assigns to each x a map $Y \to Z$ is the same thing as a map of two variables $(x, y) \mapsto Z$. Programmers call this *currying*. The formula is

$$i(g)(x, y) \coloneqq g(x)(y), \qquad \text{with inverse} \qquad i^{-1}(f)(x) \coloneqq f(x, \cdot).$$

Where does the name "exponential law" come from? Write Y^X for the set of all functions (continuous or not) from X to Y. If X and Y are finite sets, there are exactly $|Y|^{|X|}$ such functions (for each of the $|X|$ inputs choose one of $|Y|$ outputs), so the notation is honest:

$$|Y^X| = |Y|^{|X|}. \tag{1.16}$$

Then the set-theoretic version of (1.15) is the familiar law of exponents,

$$Z^{(Y \times X)} \cong Z^{(X \times Y)} \cong \left(Z^X\right)^Y, \tag{1.17}$$

and for finite sets we can check it by counting:

$$\left|(Z^X)^Y\right| \overset{(1)}{=} |Z^X|^{|Y|} \overset{(2)}{=} \left(|Z|^{|X|}\right)^{|Y|} \overset{(3)}{=} |Z|^{|X|\,|Y|} \overset{(4)}{=} \left|Z^{(X \times Y)}\right|.$$

(1) (1.16) with Z^X in place of Y and Y in place of X.
(2) (1.16) again.
(3) The ordinary law of exponents for numbers.
(4) $|X \times Y| = |X|\,|Y|$ and (1.16).

Nash's remark is that to establish (1.15) one only needs to check that the set-theoretic bijection (1.17) respects continuity. It does, provided we give $\mathrm{Map}(Y, Z)$ the natural topology in which "$g(x)$ close to $g(x')$" means the two maps are uniformly close on compact pieces of Y (the *compact-open topology*), and Y is a reasonable space (locally compact, as all manifolds are).

Worked example 1.16: A homotopy is a path in the space of maps

Apply (1.15) with $X = [0, 1]$: a homotopy $F : [0, 1] \times Y \to Z$ is the same as a path

$$t \longmapsto F_t = F(t, \cdot) \in \mathrm{Map}(Y, Z)$$

in the space of maps. Two maps are homotopic exactly when they lie in the same path

component of $\mathrm{Map}(Y,Z)$. Therefore

$$[Y,Z] = \pi_0\big(\mathrm{Map}(Y,Z)\big). \tag{1.18}$$

This is precisely the physicist's picture: $\mathrm{Map}(Y,Z)$ is the configuration space of a field theory on space Y with target Z; a finite-energy time evolution is a path in configuration space; and topological sectors are the disconnected pieces of configuration space. For instance, the configuration space of a U(1)-valued field on a circle, $\mathrm{Map}(S^1,\mathrm{U}(1))$, falls into pieces labelled by the winding number $n \in \mathbb{Z}$.

1.2.6 Wedge and smash products

We want a based version of (1.15). In it, X, Y and Z are pointed, and all maps are based. $\mathrm{Map}_0(Y,Z)$ has a natural base point: the constant map $y \mapsto z_0$. The one space in (1.15) with no natural base point is the product $X \times Y$: the obvious candidate is (x_0, y_0), but that turns out to be the wrong answer. Nash describes the right construction in two steps.

Working definition 1.13 (wedge and smash)

- The **wedge** (one-point union) $X \vee Y$ is the disjoint union [a copy of X and a copy of Y side by side, sharing no point] of X and Y with the two base points identified:

$$X \vee Y := (X \sqcup Y)/(x_0 \sim y_0). \tag{1.19}$$

  Inside $X \times Y$ it sits as the "axes" $(X \times \{y_0\}) \cup (\{x_0\} \times Y)$.

- The **smash product** (reduced product) collapses those axes to a single point, which becomes the base point:

$$X \wedge Y := \frac{X \times Y}{X \vee Y}. \tag{1.20}$$

Here A/B (for $B \subset A$) means: identify all points of B with each other, leave the rest alone. *Operational picture:* draw $X \times Y$, draw the two axes through the base point, and shrink both axes to one point.

Worked example 1.17: The figure eight, and $S^1 \wedge S^1 = S^2$

Take $X = Y = S^1$. Then $S^1 \vee S^1$ is the figure eight: two circles touching at one point. In the torus $S^1 \times S^1$ drawn as a square with opposite edges glued (Figure 1.4), the wedge $S^1 \vee S^1$ is exactly the union of the edges a and b, i.e. the whole boundary of the square. Collapsing it to a point leaves the *open* square plus one extra point. The open square is homeomorphic to $\mathbb{R}^2$ (use the map of Example 1.1 in each coordinate), and adding one point "at infinity" to $\mathbb{R}^2$ gives the sphere S^2 (inverse stereographic projection, Example 1.5). So

$$S^1 \wedge S^1 \cong S^2.$$

Think of pulling a drawstring bag closed around the boundary of the square (Figure 1.11).

Now the based exponential law. A based map $g : X \to \mathrm{Map}_0(Y,Z)$ gives, by currying, $f(x,y) = g(x)(y)$ on $X \times Y$. Which points of $X \times Y$ are automatically sent to z_0?

$$f(x,y_0) \overset{(1)}{=} g(x)(y_0) \overset{(2)}{=} z_0,$$

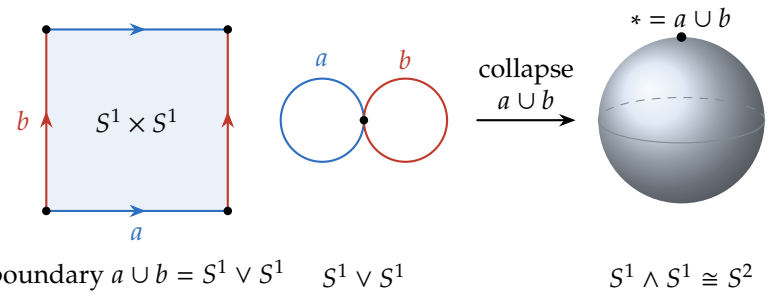


Figure 1.11: The smash product of two circles. The torus is a square with glued edges; the glued edges form the wedge $S^1 \vee S^1$ (a figure eight, middle). Collapsing the wedge to a single point closes the square up like a drawstring bag into a sphere, with the collapsed boundary as the base point.

$$f(x_0, y) \overset{(3)}{=} g(x_0)(y) \overset{(4)}{=} z_0.$$

(1) Definition of currying.
(2) Each $g(x)$ lies in $\mathrm{Map}_0(Y, Z)$, so it is a based map.
(3) Definition of currying.
(4) g is based, so $g(x_0)$ is the base point of $\mathrm{Map}_0(Y, Z)$, the constant map at z_0.

So f sends the whole wedge $X \vee Y = (X \times \{y_0\}) \cup (\{x_0\} \times Y)$ to z_0, and therefore descends to a based map on the quotient $X \wedge Y$. Conversely, any based map on $X \wedge Y$ uncurries to a based g. This is Nash's based exponential law:

$$i_* : \mathrm{Map}_0\big(X, \mathrm{Map}_0(Y, Z)\big) \xrightarrow{\cong} \mathrm{Map}_0(X \wedge Y, Z). \tag{1.21}$$

That is why the smash product, and not $X \times Y$ with base point (x_0, y_0), is the correct "product" of pointed spaces.

1.2.7 Suspension and loop space

Two special cases of the smash product and of based mapping spaces are used constantly.

Working definition 1.14 (suspension and loop space)

- The (reduced) **suspension** of a pointed space X is

$$SX \coloneqq S^1 \wedge X$$

[the smash product: $S^1 \times X$ with the axes $S^1 \vee X$ collapsed to one point]. Concretely: take the cylinder $[0, 1] \times X$, collapse the top $\{1\} \times X$, the bottom $\{0\} \times X$ and the vertical line $[0, 1] \times \{x_0\}$ all to one point.

- The **loop space** of X is the space of based loops,

$$\Omega X \coloneqq \mathrm{Map}_0(S^1, X) \tag{1.22}$$

[continuous maps $S^1 \to X$ sending the base point of S^1 to x_0]. We parametrise S^1 as $[0, 1]$ with $0 \sim 1$ the base point, so a point of ΩX is a path $\gamma : [0, 1] \to X$ with $\gamma(0) = \gamma(1) = x_0$.

The suspension is a "double cone" on X (Figure 1.12): each point x of X becomes a meridian running from the south pole ($t = 0$) to the north pole ($t = 1$). Suspending raises dimension by

one. The key example (Nash's (1.20)):

$$S^1 \wedge S^n = SS^n \cong S^{n+1}. \tag{1.23}$$

Worked example 1.18: Why $S^m \wedge S^n \cong S^{m+n}$

Use the fact (stereographic projection) that S^n is $\mathbb{R}^n$ plus one point at infinity: $S^n \cong (\mathbb{R}^n)^+$, where W^+ means "W with one point ∞ added", and we choose ∞ as the base point. Then

$$\begin{aligned} S^m \wedge S^n &\overset{(1)}{=} (\mathbb{R}^m)^+ \wedge (\mathbb{R}^n)^+ \\ &\overset{(2)}{=} \frac{(\mathbb{R}^m \cup \infty) \times (\mathbb{R}^n \cup \infty)}{(\mathbb{R}^m \cup \infty) \times \{\infty\} \ \cup \ \{\infty\} \times (\mathbb{R}^n \cup \infty)} \\ &\overset{(3)}{=} (\mathbb{R}^m \times \mathbb{R}^n) \cup \{\text{one point}\} \\ &\overset{(4)}{=} (\mathbb{R}^{m+n})^+ \overset{(5)}{=} S^{m+n}. \end{aligned}$$

(1) Stereographic projection, with the base point at ∞.
(2) Definition (1.20): the wedge consists of all pairs in which at least one entry is the base point ∞.
(3) The product of the two sets consists of the pairs (x, y) with both finite, which form $\mathbb{R}^m \times \mathbb{R}^n$, plus the pairs with at least one entry infinite, which is the wedge; the wedge is collapsed to one point.
(4) $\mathbb{R}^m \times \mathbb{R}^n = \mathbb{R}^{m+n}$, and the collapsed point is the new point at infinity (a sequence leaves every compact set of $\mathbb{R}^{m+n}$ exactly when one of its two components runs off to infinity).
(5) Stereographic projection in dimension $m + n$.

With $m = 1$ this is (1.23); with $m = n = 1$ it is Example 1.17 again. Iterating, $S^n \cong S^1 \wedge S^1 \wedge \cdots \wedge S^1$ (n factors) is the n-cube with its whole boundary collapsed to a point: $S^n \cong [0,1]^n/\partial[0,1]^n$. We use this cube picture of the sphere for the higher homotopy groups in §1.3.6.

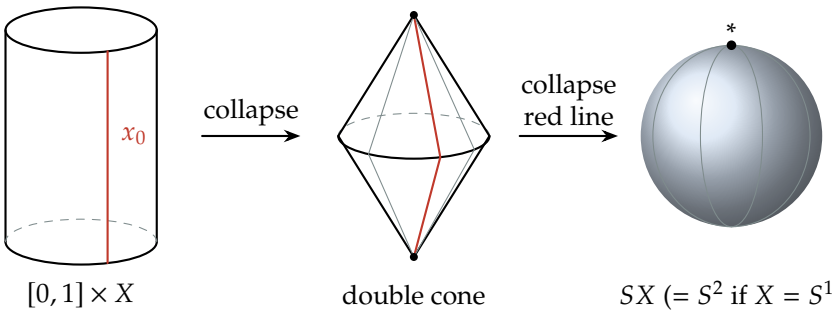

Figure 1.12: Building the reduced suspension $SX = S^1 \wedge X$. Start with the cylinder over X, collapse top and bottom (the double cone, or unreduced suspension), then collapse the red meridian through the base point x_0. For $X = S^1$ the result is the sphere S^2, drawn with meridians (grey), one for each point of X, all starting and ending at the base point.

The loop space ΩX is the space of closed strings pinned at one point of X. It is an infinite-dimensional space even when X is a finite manifold. Loop spaces of Lie groups, ΩG, are the loop groups of Chapter 6, which appear in two-dimensional conformal field theory and string theory.

S and Ω are adjoint

Take $Y = S^1$ in the based exponential law (1.21), and rename:

$$\mathrm{Map}_0(X, \Omega Z) \overset{(1)}{=} \mathrm{Map}_0\big(X, \mathrm{Map}_0(S^1, Z)\big) \overset{(2)}{=} \mathrm{Map}_0(X \wedge S^1, Z)$$
$$\overset{(3)}{=} \mathrm{Map}_0(S^1 \wedge X, Z) = \mathrm{Map}_0(SX, Z).$$

(1) Definition (1.22) of ΩZ.
(2) The based exponential law (1.21) with $Y = S^1$.
(3) $X \wedge S^1 \cong S^1 \wedge X$ by swapping the two factors.

Concretely, a based map $f : SX \to Z$, $f(s, x)$, corresponds to the map $g : X \to \Omega Z$ that sends x to the loop $s \mapsto f(s, x)$. This bijection (Nash's (1.21)) is compatible with homotopies (a homotopy is just one more parameter), so it passes to classes:

$$\mathrm{Map}_0(SX, Y) \cong \mathrm{Map}_0(X, \Omega Y), \tag{1.24}$$
$$[SX, Y]_0 \cong [X, \Omega Y]_0. \tag{1.25}$$

Physical picture: Adjoint, as in Hilbert space

Nash calls S and Ω *functors*: operations that act on spaces, and on maps between spaces, compatibly with composition. They are **adjoint**: (1.25) has exactly the shape of the definition of the adjoint of an operator,

$$\langle Sx, y\rangle = \langle x, \Omega\, y\rangle,$$

with the "inner product" $\langle A, B\rangle$ replaced by the set $[A, B]_0$. You can move S from the first slot to the second slot, where it becomes Ω. Suspension raises the dimension of the source; looping lowers the dimension of the target. The two effects cancel in $[\cdot, \cdot]_0$.

Worked example 1.19: A sphere of maps is a loop of loops

Take $X = S^1$ in (1.25): since $SS^1 = S^2$,

$$[S^2, Y]_0 \cong [S^1, \Omega Y]_0.$$

A based map of the sphere into Y is a based loop in the space of based loops. To see it, use the meridian picture of Figure 1.12: each meridian of S^2 (labelled by a point x of the equator S^1) is mapped to a loop in Y through y_0. As x goes once around the equator, we get a closed family of loops, starting and ending at the constant loop (the meridian through the base point is collapsed). Physically: a static configuration of a field on a sphere is the same as a periodic "movie" of field configurations on a line segment with fixed ends. This is how Nash will compute (1.44) below: $\pi_n(Y) = \pi_{n-1}(\Omega Y)$.

1.2.8 Group structures on $[X, Y]_0$: H-spaces and coH-spaces

Groups are extremely valuable, so we want the sets $[X, Y]_0$ to be groups. There are two ways this can happen, dual to each other: a structure on the target Y (Nash's "P"), or a structure on the source X (Nash's "P'").

Structure on the target: H-spaces

Suppose first that $Y = G$ is a group (a topological group: multiplication and inversion are continuous), with base point the identity e. Then maps into G can be multiplied pointwise.

Working definition 1.15 (pointwise product)

For $\alpha, \beta \in \mathrm{Map}_0(X, G)$ [continuous maps $X \to G$ sending the base point of X to the identity e] define

$$\alpha \bullet \beta : X \to G, \qquad x \longmapsto \alpha(x) * \beta(x), \tag{1.26}$$

where $*$ is the product in G. *Physics reading:* if X is space and G a gauge group, $\mathrm{Map}(X, G)$ is the group of gauge transformations $g(x)$, and $\bullet$ is how two gauge transformations compose. This is the gauge group $\mathcal{G}$.

This makes $\mathrm{Map}_0(X, G)$ itself a group: $\alpha \bullet \beta$ is based since $e * e = e$, the identity element is the constant map e, and the inverse of α is $x \mapsto \alpha(x)^{-1}$. It passes to homotopy classes: if F is a based homotopy from α to α' and H one from β to β', then $(t, x) \mapsto F(t, x) * H(t, x)$ is a based homotopy from $\alpha \bullet \beta$ to $\alpha' \bullet \beta'$. So

$$[\alpha] \bullet [\beta] \coloneqq [\alpha \bullet \beta]$$

is well defined, and $[X, G]_0$ is a group, for *any* X.

Worked example 1.20: $[S^1, \mathrm{U}(1)]_0$ with the pointwise product

Let $G = \mathrm{U}(1) = \{e^{i\theta}\}$ and $X = S^1$, parametrised by $s \in [0, 1]$. The maps $\alpha_n(s) = e^{2\pi i n s}$ ($n \in \mathbb{Z}$) are based ($\alpha_n(0) = 1$) and wind n times around $\mathrm{U}(1)$. Their pointwise product is

$$(\alpha_m \bullet \alpha_n)(s) \overset{(1)}{=} e^{2\pi i m s}\, e^{2\pi i n s} \overset{(2)}{=} e^{2\pi i (m+n) s} = \alpha_{m+n}(s).$$

(1) Definition (1.26), with $*$ ordinary multiplication of complex numbers.
(2) $e^a e^b = e^{a+b}$.

So under $\bullet$, winding numbers *add*. We will see in §1.3.2 that every based loop in $\mathrm{U}(1)$ is homotopic to exactly one α_n, so $([S^1, \mathrm{U}(1)]_0, \bullet) \cong (\mathbb{Z}, +)$. In gauge theory on a circle (or on the S^1 at the edge of a vortex), α_n is a *large* gauge transformation when $n \neq 0$: it cannot be deformed to the identity.

Nash's next observation: nothing in this argument used that G is a group on the nose. We only needed a continuous multiplication $* : Y \times Y \to Y$ whose group axioms hold *up to homotopy*, because we only ever look at homotopy classes.

Working definition 1.16 (H-space)

A pointed space Y is a (homotopy associative) **H-space** if it has a continuous multiplication $* : Y \times Y \to Y$ such that, up to based homotopy [the two sides need not be equal, only deformable into each other with the base point held fixed],

- the base point is a two-sided identity: $y * y_0 \simeq y \simeq y_0 * y$;
- $*$ is associative: $(y * y') * y'' \simeq y * (y' * y'')$ (as maps $Y \times Y \times Y \to Y$);
- there is an inverse map $\nu : Y \to Y$ with $y * \nu(y) \simeq y_0$.

Then $[X, Y]_0$ is a group for every X, under the pointwise product. *Examples:* every

topological group; every loop space ΩX [based loops in X, multiplied by running one loop and then the other] (we check this in §1.3.1).

The phrase "homotopy associative" is the whole point. On $\mathrm{Map}_0(X,Y)$ itself the product need not be associative; only on the classes $[X,Y]_0$ is it associative.

Structure on the source: coH-spaces

Now the dual idea. Instead of a multiplication $Y \times Y \to Y$ on the target, put a *comultiplication* on the source.

Working definition 1.17 (coH-space)

A pointed space X is a (homotopy associative) **coH-space** if it has a continuous based map

$$*' : X \longrightarrow X \vee X \tag{1.27}$$

[$X \vee X$ is two copies of X joined at their base points] (a "comultiplication") satisfying the duals of the H-space axioms [for example, $*'$ followed by squashing the second copy to its base point is homotopic to id_X] up to homotopy. Given $\alpha, \beta \in \mathrm{Map}_0(X,Y)$, define $\alpha \vee \beta : X \vee X \to Y$ to be α on the first copy and β on the second (consistent at the shared base point since both send it to y_0), and

$$\bullet' : [X,Y]_0 \times [X,Y]_0 \to [X,Y]_0, \qquad [\alpha] \bullet' [\beta] := \big[(\alpha \vee \beta) \circ *'\big]. \tag{1.28}$$

Then $[X,Y]_0$ is a group for every Y.

Watch out: Why $X \vee X$ and not $X \times X$?

Nash notes that $X \vee X$ appears "where one would expect $X \times X$". The reason is concrete. To combine α and β on the target of $*'$ we need a map out of it built from α and β alone. On $X \vee X$ this is $\alpha \vee \beta$: each point lies in one copy or the other. On $X \times X$ we would have to assign a single value to a pair (x, x') using both $\alpha(x)$ and $\beta(x')$, which requires multiplying points of Y: exactly the H-space structure we are trying not to assume. (Also, $X \vee X$ is where base points behave: $\alpha \vee \beta$ is automatically based.)

Worked example 1.21: Suspensions are coH-spaces: the pinch map

Let $X = SZ$, with points written (t,z), $t \in [0,1]$ (Figure 1.12; all of $t=0$, $t=1$ and $z = z_0$ is the base point). Define the **pinch map**: squeeze the "equator" $t = \frac{1}{2}$ to the base point, which splits SZ into two copies of itself glued at the base point:

$$*'(t,z) = \begin{cases} (2t,z) \text{ in the first copy of } SZ, & 0 \le t \le \tfrac{1}{2}, \\ (2t-1,z) \text{ in the second copy of } SZ, & \tfrac{1}{2} \le t \le 1. \end{cases}$$

At $t = \frac{1}{2}$ the two formulas give $(1,z)$ and $(0,z)$, both the base point, so $*'$ is continuous. The induced product (1.28) is

$$(\alpha \bullet' \beta)(t,z) = \begin{cases} \alpha(2t,z), & 0 \le t \le \tfrac{1}{2}, \\ \beta(2t-1,z), & \tfrac{1}{2} \le t \le 1, \end{cases}$$

"do α on the southern half, β on the northern half". For $Z = S^0$ we have $SZ = S^1$ and this is the concatenation of loops, Nash's (1.27), the product in the fundamental group. For

$Z = S^{n-1}$ we get $SZ = S^n$ and the product of the higher homotopy groups (Figure 1.13).

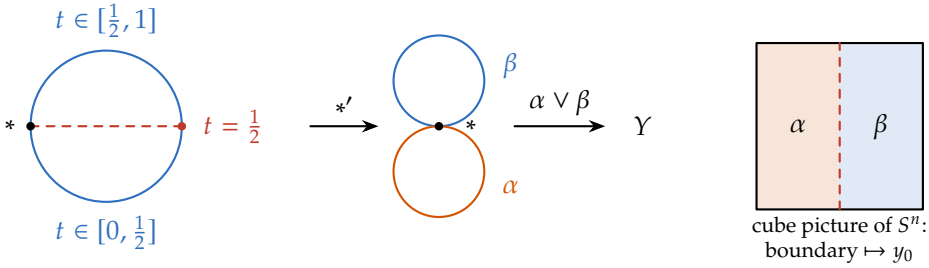

Figure 1.13: The pinch map. Squeezing the point $t = \frac{1}{2}$ of the loop parameter to the base point (the red point meets $*$) gives a figure eight $S^1 \vee S^1$; then $\alpha \vee \beta$ runs α on one lobe and β on the other. This is loop concatenation. In the cube picture of S^n (right), the pinch splits the cube in half along the first coordinate: α fills one half, β the other, and the whole boundary goes to y_0.

When both structures are present

Nash ends §2 with an "elementary calculation": if Y is an H-space *and* X is a coH-space, then the two group structures $\bullet$ and $\bullet'$ on $[X, Y]_0$ coincide, and the resulting group is *commutative*. Since the calculation is short and is the reason why higher homotopy groups are abelian, we do it. It is known as the **Eckmann–Hilton argument**.

The one fact we need is the *interchange law*:

$$(\alpha \bullet' \beta) \bullet (\gamma \bullet' \delta) = (\alpha \bullet \gamma) \bullet' (\beta \bullet \delta). \tag{1.29}$$

Both sides are the same map: take $X = SZ$ with the pinch map for concreteness. On the southern half ($t \le \frac{1}{2}$) the left side is $\alpha(2t, z) * \gamma(2t, z)$ and on the northern half $\beta(2t-1, z) * \delta(2t-1, z)$; the right side is literally the same. Write e for the constant map at the base point; it is the identity for both products (up to homotopy). Then for any α, δ:

$$\alpha \bullet \delta \overset{(1)}{=} (\alpha \bullet' e) \bullet (e \bullet' \delta) \overset{(2)}{=} (\alpha \bullet e) \bullet' (e \bullet \delta) \overset{(3)}{=} \alpha \bullet' \delta,$$
$$\alpha \bullet \delta \overset{(4)}{=} (e \bullet' \alpha) \bullet (\delta \bullet' e) \overset{(5)}{=} (e \bullet \delta) \bullet' (\alpha \bullet e) \overset{(6)}{=} \delta \bullet' \alpha \overset{(7)}{=} \delta \bullet \alpha.$$

(1) e is the identity for $\bullet'$ (in homotopy classes).
(2) The interchange law (1.29) with $\beta = \gamma = e$.
(3) e is the identity for $\bullet$.
(4) e is the identity for $\bullet'$, now inserted on the other side.
(5) The interchange law with $(\alpha, \beta, \gamma, \delta) \to (e, \alpha, \delta, e)$.
(6) e is the identity for $\bullet$.
(7) The first line, with α and δ swapped: $\bullet' = \bullet$.

The first line says the two products agree; the second says the product is commutative. All equalities are of homotopy classes.

Key idea: Consequence

If Y is an H-space and X a coH-space (for example $Y = G$ a group and $X = SZ$ a suspension), then $[X, Y]_0$ has a single natural group structure, and it is abelian. In particular $[SZ, G]_0$ is always an abelian group.

Reading Nash (pp. 3–9, (1.2)–(1.25))

Nash's §2 runs: invariants (numbers, groups); $\mathrm{Map}(X,Y)$ (1.2), homotopy (1.3)–(1.5); classes $[X,Y]$ (1.6) and their invariance under homeomorphism of Y; homotopy type (1.7), (1.8); invariants of homotopy type (1.9), (1.10) (our (1.11), (1.12)); $\mathbb{R}^n$ versus a point; base points, Map_0 (1.11), $[X,Y]_0$ (1.12); exponential law (1.13)–(1.15); wedge (1.16), smash (1.17), based exponential law (1.18); $SX = S^1 \wedge X$, ΩX (1.19), $SS^n \cong S^{n+1}$ (1.20); adjunction (1.21), (1.22); pointwise product (1.23), H-spaces; comultiplication (1.24) and product (1.25), coH-spaces; coincidence and commutativity when both are present. He cites Whitehead for (1.20), Husemoller for coH-spaces and Spanier for the "elementary calculation", which is our Eckmann–Hilton chain. Nash writes $\cong$ for bijections and $\simeq$ for homotopy, as we do. Note that his (1.9) contains the misprint "$[X,Y]$".

Recap

- A homotopy is a continuous movie of maps; $[X,Y]$ is the set of topological sectors, $[X,Y] = \pi_0(\mathrm{Map}(X,Y))$.
- $X \simeq Y$ (homotopy equivalence) means maps both ways whose composites are homotopic to identities. $\mathbb{R}^n \simeq$ point, $\mathbb{R}^n \setminus 0 \simeq S^{n-1}$, Möbius band $\simeq S^1$. $[X,Y]$ depends only on homotopy types.
- A deformation retract squashes X onto $A \subset X$ keeping A fixed. S^1 is not a retract of D^2, which gives Brouwer's theorem.
- Based maps and based homotopies give $[X,Y]_0$. The correct product of pointed spaces is the smash $X \wedge Y = X \times Y / X \vee Y$, with $S^m \wedge S^n = S^{m+n}$.
- $SX = S^1 \wedge X$ and $\Omega X = \mathrm{Map}_0(S^1, X)$ are adjoint: $[SX,Y]_0 = [X,\Omega Y]_0$.
- A group (H-space) target or a suspension (coH-space) source makes $[X,Y]_0$ a group; with both, the group is abelian (Eckmann–Hilton).

1.3 Homotopy groups

We now have all the machinery of §1.2: based maps, homotopy classes $[X,Y]_0$, suspensions, loop spaces, and two ways of making $[X,Y]_0$ a group. Nash's §3 applies this machinery to the simplest possible sources, the spheres. The questions are concrete:

- How many essentially different ways are there to draw a closed loop in a space X? (The fundamental group $\pi_1(X)$.)
- How many essentially different ways are there to wrap a sphere S^n around X? (The higher homotopy groups $\pi_n(X)$.)

For a physicist these are the questions "which vortices can exist?", "which monopoles?", "which instantons?". A vortex line in three-space is surrounded by a circle, so its charge is a class of loops in the space of field values. A point defect is surrounded by a sphere S^2. A finite-action gauge field on $\mathbb{R}^4$ is controlled by what happens on the sphere S^3 at infinity. We will compute the basic examples by hand, using nothing more than the winding-number integral $\oint \mathrm{d}\theta/2\pi$ and some 2×2 matrices. At the end of the section we collect the physics.

1.3.1 The fundamental group

Recall that we parametrise the circle by $t \in [0,1]$ with the ends glued, $0 \sim 1$, and take the glued point as the base point (the circle has unit circumference, as in Nash). A based map $S^1 \to X$ is therefore the same thing as a path that starts and ends at the base point.

Working definition 1.18 (fundamental group)

Let $\{X, x_0\}$ be a pointed space. A **loop at** x_0 is a continuous $\alpha : [0,1] \to X$ with $\alpha(0) = \alpha(1) = x_0$. The **fundamental group** of X is the set of based homotopy classes of such loops,

$$\pi_1(X) \coloneqq [S^1, X]_0. \tag{1.30}$$

Two loops define the same element iff one can be deformed into the other through loops at x_0, keeping the base point pinned at all times. *Operational test:* to show $[\alpha] = [\beta]$, write down $F(s,t)$ with $F(0,t) = \alpha(t)$, $F(1,t) = \beta(t)$ and $F(s,0) = F(s,1) = x_0$; to show $[\alpha] \neq [\beta]$, find an invariant (for example a winding number [the net number of times the loop goes around a hole, counted with sign]) that takes different values on them.

Because $\pi_1(X)$ consists of classes, we never distinguish between two homotopic loops. What makes π_1 a *group* is the product: first run around α, then around β, each at double speed.

Working definition 1.19 (product of loops)

For loops α, β at x_0, the product $\alpha \cdot \beta$ is the loop

$$(\alpha \cdot \beta)(t) \coloneqq \begin{cases} \alpha(2t), & 0 \le t \le \tfrac{1}{2}, \\ \beta(2t-1), & \tfrac{1}{2} \le t \le 1, \end{cases} \qquad [\alpha][\beta] \coloneqq [\alpha \cdot \beta]. \tag{1.31}$$

[$[\alpha]$ is the class of all loops at x_0 that can be deformed into α with x_0 held fixed]

This is Nash's (1.27). Let us check that $\alpha \cdot \beta$ really is a loop, i.e. continuous at the junction and based:

$$\alpha(2 \cdot \tfrac{1}{2}) \overset{(1)}{=} \alpha(1) \overset{(2)}{=} x_0 \overset{(3)}{=} \beta(0) = \beta(2 \cdot \tfrac{1}{2} - 1),$$
$$(\alpha \cdot \beta)(0) = \alpha(0) \overset{(4)}{=} x_0, \qquad (\alpha \cdot \beta)(1) = \beta(1) \overset{(4)}{=} x_0.$$

(1) Substitute $t = \frac{1}{2}$ into the first branch.
(2) α is a loop at x_0, so it ends at x_0.
(3) β is a loop at x_0, so it starts at x_0; the second branch at $t = \frac{1}{2}$ gives the same point, so the two halves join up (gluing lemma).
(4) Both loops start and end at the base point.

We saw in Example 1.21 that (1.31) is precisely the coH-space product $\bullet'$ coming from the pinch map of $S^1 = SS^0$ (Figure 1.13). The product is also well defined on classes: if F deforms α to α' and G deforms β to β', then running $F(s,2t)$ on the first half and $G(s,2t-1)$ on the second deforms $\alpha \cdot \beta$ to $\alpha' \cdot \beta'$.

The group axioms hold up to homotopy

On the nose, the product (1.31) is *not* associative: $(\alpha \cdot \beta) \cdot \gamma$ spends a quarter of the time on α, a quarter on β and a half on γ, while $\alpha \cdot (\beta \cdot \gamma)$ spends a half on α. The two loops trace the same

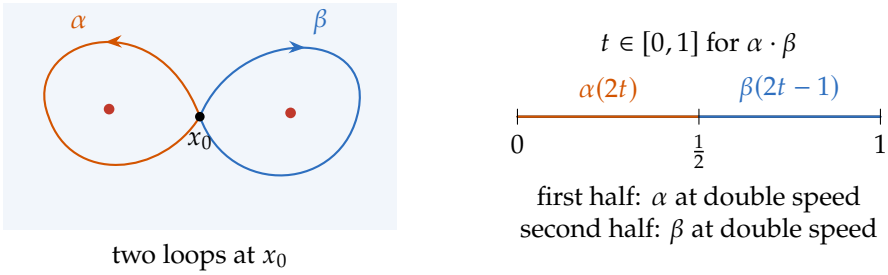

Figure 1.14: The product of loops in the plane with two holes (red). Both loops start and end at x_0, so we can run one after the other. The product $\alpha \cdot \beta$ spends the first half of its time on α and the second half on β. Neither loop can be shrunk to x_0 without crossing a hole.

route at different speeds. Nash calls checking the axioms up to homotopy "the well known process". It rests on a single fact, which we state and prove.

Key idea: Reparametrisation does not change the class

Let $\phi : [0,1] \to [0,1]$ be continuous with $\phi(0) = 0$ and $\phi(1) = 1$. Then for every loop α, $\alpha \circ \phi \simeq \alpha$ as based loops.

The homotopy slides the time variable linearly from $\phi(t)$ to t: $F(s,t) = \alpha\big((1-s)\phi(t) + st\big)$. The argument $(1-s)\phi(t) + st$ is a weighted average of two numbers in $[0,1]$, so it lies in $[0,1]$ and F makes sense. Check the ends:

$$F(0,t) = \alpha(\phi(t)), \qquad F(1,t) = \alpha(t),$$

$$F(s,0) \overset{(1)}{=} \alpha\big((1-s)\cdot 0 + 0\big) = \alpha(0) = x_0, \qquad F(s,1) \overset{(2)}{=} \alpha\big((1-s)+s\big) = \alpha(1) = x_0.$$

(1) $\phi(0) = 0$.
(2) $\phi(1) = 1$.

So the base point stays pinned. Now the axioms follow.

- *Associativity.* $(\alpha \cdot \beta) \cdot \gamma = \big(\alpha \cdot (\beta \cdot \gamma)\big) \circ \phi$, where ϕ is the piecewise-linear map with $\phi(\frac{1}{4}) = \frac{1}{2}$, $\phi(\frac{1}{2}) = \frac{3}{4}$:
$$\phi(t) = \begin{cases} 2t, & 0 \le t \le \frac{1}{4}, \\ t + \frac{1}{4}, & \frac{1}{4} \le t \le \frac{1}{2}, \\ \frac{t+1}{2}, & \frac{1}{2} \le t \le 1. \end{cases}$$
Check on the first quarter: $\big(\alpha \cdot (\beta \cdot \gamma)\big)(\phi(t)) = \big(\alpha \cdot (\beta \cdot \gamma)\big)(2t) = \alpha(4t)$, which is what $(\alpha \cdot \beta) \cdot \gamma$ does for $t \in [0, \frac{1}{4}]$. The other two pieces are checked the same way. The keyidea gives $[(\alpha \cdot \beta) \cdot \gamma] = [\alpha \cdot (\beta \cdot \gamma)]$.
- *Identity.* Let e be the constant loop, $e(t) = x_0$. Then $e \cdot \alpha = \alpha \circ \phi$ with $\phi(t) = 0$ for $t \le \frac{1}{2}$ and $\phi(t) = 2t - 1$ for $t \ge \frac{1}{2}$. So $[e][\alpha] = [\alpha]$, and similarly $[\alpha][e] = [\alpha]$.
- *Inverse.* Let $\bar{\alpha}(t) := \alpha(1-t)$ be α run backwards. Then $\alpha \cdot \bar{\alpha} \simeq e$ via "go out along α only as far as $1-s$, then come back":
$$H(s,t) = \begin{cases} \alpha\big(2t(1-s)\big), & 0 \le t \le \frac{1}{2}, \\ \alpha\big((2-2t)(1-s)\big), & \frac{1}{2} \le t \le 1. \end{cases}$$
At $s = 0$ this is $\alpha(2t)$ followed by $\alpha(2-2t) = \bar{\alpha}(2t-1)$, i.e. $\alpha \cdot \bar{\alpha}$. At $s = 1$ it is $\alpha(0) = x_0$ throughout, i.e. e. At $t = \frac{1}{2}$ both branches give $\alpha(1-s)$, so H is continuous, and $H(s,0) = H(s,1) = \alpha(0) = x_0$.

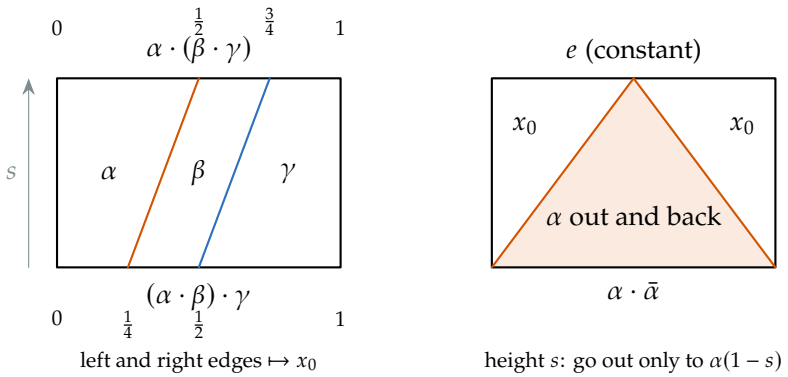

Figure 1.15: The group axioms as pictures of homotopies. Each square is the (t, s) domain of a based homotopy: the bottom edge is the starting loop, the top edge the final loop, and the vertical edges go to x_0. Left: the associativity homotopy just slides the break points $\frac{1}{4}, \frac{1}{2}$ to $\frac{1}{2}, \frac{3}{4}$. Right: the loop $\alpha \cdot \bar{\alpha}$ is reeled in; at height s it goes out along α only as far as $\alpha(1-s)$ and retraces its steps. The white regions map to x_0.

Key idea: $\pi_1(X)$ is a group, and ΩX is an H-space

With the product (1.31), identity $[e]$ and inverse $[\alpha]^{-1} = [\bar{\alpha}]$, the set $\pi_1(X)$ is a group. In Nash's words, checking this "is precisely the verification that ΩX is (another example of) a H-space": the loop product is a multiplication $\Omega X \times \Omega X \to \Omega X$ that is associative, unital and invertible up to homotopy.

A space whose fundamental group is trivial (every loop contracts to the base point) is called **simply connected**.

Worked example 1.22: Convex sets are simply connected

Let $X \subset \mathbb{R}^n$ be convex (for example $\mathbb{R}^n$ itself or a ball) and α a loop at x_0. The straight-line homotopy to the constant loop is $F(s,t) = (1-s)\,\alpha(t) + s\,x_0$. It stays in X by convexity, and it is based:

$$F(s,0) \overset{(1)}{=} (1-s)\,x_0 + s\,x_0 = x_0, \qquad F(s,1) \overset{(1)}{=} x_0.$$

(1) $\alpha(0) = \alpha(1) = x_0$.

So $\pi_1(X) = 0$. (We write 0 or 1 for the trivial group.) The same argument with $x_0 = 0$ works for any *star-shaped* set, one containing the segment from the origin to each of its points.

Maps induce homomorphisms

A based map $f : \{X, x_0\} \to \{Y, y_0\}$ sends loops in X to loops in Y, and by (1.9) homotopic loops to homotopic loops. So it defines $f_* : \pi_1(X) \to \pi_1(Y)$, $f_*[\alpha] = [f \circ \alpha]$. It respects products, because applying f commutes with running two loops in succession:

$$f \circ (\alpha \cdot \beta)(t) \overset{(1)}{=} \begin{cases} f(\alpha(2t)) & t \le \tfrac{1}{2} \\ f(\beta(2t-1)) & t \ge \tfrac{1}{2} \end{cases} \overset{(2)}{=} \big((f \circ \alpha) \cdot (f \circ \beta)\big)(t).$$

(1) Apply f to each branch of (1.31).
(2) This is the definition of the product of the loops $f \circ \alpha$ and $f \circ \beta$.

So f_* is a group homomorphism. Clearly $(g \circ f)_* = g_* \circ f_*$ and $(\mathrm{id})_* = \mathrm{id}$. If f is a based

homotopy equivalence, f_* is therefore an isomorphism, by the same argument we gave for (1.12). The fundamental group is an invariant of homotopy type.

1.3.2 The circle: $\pi_1(S^1) = \mathbb{Z}$ and the winding number

Everything else in this section rests on one computation: the fundamental group of the circle. Physicists know the answer in their bones. The phase $e^{i\theta(\vec{x})}$ of a superfluid order parameter, or of a single-valued wavefunction, can wind around the circle an integer number of times as $\vec{x}$ goes around a closed path, and that integer cannot change under small deformations. We make this precise.

Unwrapping the circle

Write $S^1 = \mathrm{U}(1) = \{z \in \mathbb{C} : |z| = 1\}$ with base point 1, and let

$$p : \mathbb{R} \to S^1, \qquad p(\theta) = e^{i\theta}$$

be the map that wraps the real line around the circle, once every 2π (Figure 1.16). Draw $\mathbb{R}$ as a helix sitting above the circle: p is the vertical projection. Above each point $z \in S^1$ sits a whole ladder of points $\theta, \theta \pm 2\pi, \theta \pm 4\pi, \dots$, all the possible values of "arg z".

Key idea: Path lifting

Every continuous path $\gamma : [0,1] \to S^1$ has a **lift**: a continuous $\tilde{\theta} : [0,1] \to \mathbb{R}$ with $e^{i\tilde{\theta}(t)} = \gamma(t)$. Once $\tilde{\theta}(0)$ is chosen from the ladder above $\gamma(0)$, the lift is unique.

Why: over any arc of the circle shorter than a half-turn, the argument function has a continuous branch (for instance $\arg z = \arctan(y/x)$ plus a constant). Chop $[0,1]$ into many short pieces on each of which γ moves by less than a half-turn (possible since γ is uniformly continuous on the compact interval). On the first piece use the branch that matches $\tilde{\theta}(0)$; on each next piece use the branch that agrees with the previous one at the junction. Uniqueness holds because two lifts differ by a continuous function with values in $2\pi\mathbb{Z}$, hence by a constant, and that constant is zero at $t = 0$. Physically: to follow the phase of a wavefunction continuously, you are never allowed to jump by 2π.

Working definition 1.20 (winding number)

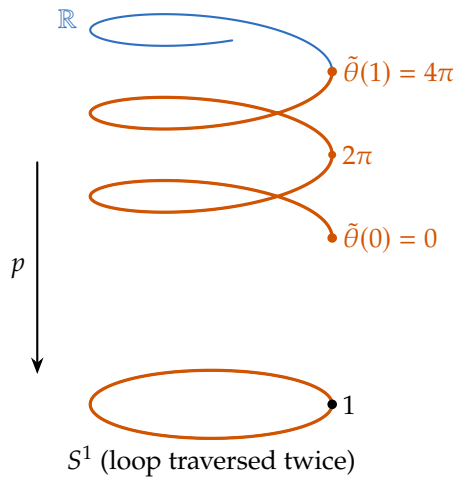
For a loop γ in S^1 based at 1, let $\tilde{\theta}$ be its lift [a continuous real-valued angle $\tilde{\theta}(t)$ with $\gamma(t) = e^{i\tilde{\theta}(t)}$, not reduced mod 2π] with $\tilde{\theta}(0) = 0$. Since $e^{i\tilde{\theta}(1)} = \gamma(1) = 1$, the endpoint $\tilde{\theta}(1)$ is a multiple of 2π. The **winding number** (or **degree**) is

$$W[\gamma] := \frac{\tilde{\theta}(1) - \tilde{\theta}(0)}{2\pi} \in \mathbb{Z}. \tag{1.32}$$

For a smooth loop it is an integral. Writing $\gamma(t) = e^{i\tilde{\theta}(t)}$,

$$W[\gamma] = \frac{1}{2\pi}\oint_\gamma \mathrm{d}\theta = \frac{1}{2\pi i}\oint_\gamma \frac{\mathrm{d}z}{z} = \frac{1}{2\pi i}\int_0^1 \frac{\dot{\gamma}(t)}{\gamma(t)}\,\mathrm{d}t. \tag{1.33}$$

For a loop in $\mathbb{C} \setminus \{0\}$ that is not on the unit circle, use the same integral: it measures the winding of $\gamma/|\gamma|$.



A loop γ in S^1 (orange, below) lifts to a path $\tilde\theta$ on the helix (orange, above). The lift need not close up: it ends at $\tilde\theta(1) = 2\pi W$, and

$$W = \frac{\tilde\theta(1) - \tilde\theta(0)}{2\pi} = \frac{1}{2\pi}\oint_\gamma d\theta$$

counts the turns. Here $\gamma(t) = e^{4\pi i t}$ runs twice around the circle and its lift climbs two storeys: $W = 2$.

Figure 1.16: Unwrapping the circle. The real line (blue helix) covers the circle by vertical projection p. A path on the circle lifts uniquely to the helix once a starting storey is chosen. A closed loop on the circle lifts to a path that ends an integer number of storeys (2π each) above where it started. That integer is the winding number.

The equalities in (1.33) are a two-line computation:

$$\frac{1}{2\pi i}\int_0^1 \frac{\dot\gamma}{\gamma}\,dt \overset{(1)}{=} \frac{1}{2\pi i}\int_0^1 \frac{i\dot{\tilde\theta}\,e^{i\tilde\theta}}{e^{i\tilde\theta}}\,dt \overset{(2)}{=} \frac{1}{2\pi}\int_0^1 \dot{\tilde\theta}\,dt \overset{(3)}{=} \frac{\tilde\theta(1)-\tilde\theta(0)}{2\pi}.$$

(1) Chain rule: $\dot\gamma = \frac{d}{dt}e^{i\tilde\theta} = i\dot{\tilde\theta}\,e^{i\tilde\theta}$.
(2) Cancel $e^{i\tilde\theta} \neq 0$ and the factor i.
(3) The fundamental theorem of calculus.

Here "$d\theta$" is the familiar 1-form $d\theta = (x\,dy - y\,dx)/(x^2+y^2)$ on the punctured plane. It is closed but not exact: there is no global function θ (the angle jumps by 2π somewhere), which is exactly why its integral around a loop can be nonzero. We return to this in Chapter T2 and in §4 of this chapter (de Rham cohomology).

Worked example 1.23: The standard loops α_n

Let $\alpha_n(t) = e^{2\pi i n t}$, $n \in \mathbb{Z}$. Then

$$W[\alpha_n] \overset{(1)}{=} \frac{1}{2\pi i}\int_0^1 \frac{2\pi i n\, e^{2\pi i n t}}{e^{2\pi i n t}}\,dt \overset{(2)}{=} n\int_0^1 dt = n.$$

(1) Formula (1.33) with $\dot\alpha_n = 2\pi i n\, e^{2\pi i n t}$.
(2) Cancel.

Equivalently, the lift is $\tilde\theta(t) = 2\pi n t$, which climbs n storeys. For $n < 0$ the loop runs clockwise.

Worked example 1.24: An off-centre circle: winding by Fourier analysis

Let $\gamma_a(\phi) = a + e^{i\phi}$, $\phi \in [0, 2\pi]$, with real $a \neq \pm 1$: the unit circle centred at a. It avoids 0, and we ask how often it winds around 0. Here $dz = ie^{i\phi}d\phi$.

Case $|a| < 1$. Expand $1/z$ in a geometric series in $ae^{-i\phi}$:

$$W \overset{(1)}{=} \frac{1}{2\pi i}\int_0^{2\pi} \frac{ie^{i\phi}}{e^{i\phi}(1+ae^{-i\phi})}\,\mathrm{d}\phi \overset{(2)}{=} \frac{1}{2\pi}\int_0^{2\pi}\sum_{k\geq 0}(-a)^k e^{-ik\phi}\,\mathrm{d}\phi \overset{(3)}{=} \frac{1}{2\pi}\cdot 2\pi = 1.$$

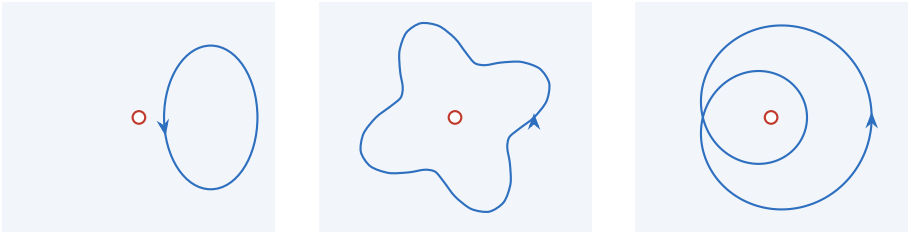
(1) Formula (1.33); factor $z = e^{i\phi}(1+ae^{-i\phi})$.
(2) $\frac{1}{1+w} = \sum_k (-w)^k$ with $|w| = |a| < 1$; the series converges uniformly, so we may integrate term by term.
(3) $\int_0^{2\pi} e^{-ik\phi}\mathrm{d}\phi = 2\pi\delta_{k0}$: only the constant Fourier mode survives.

Case $|a| > 1$. Now expand in $e^{i\phi}/a$ instead:

$$W \overset{(1)}{=} \frac{1}{2\pi i}\int_0^{2\pi} \frac{ie^{i\phi}}{a(1+e^{i\phi}/a)}\,\mathrm{d}\phi \overset{(2)}{=} \frac{1}{2\pi a}\int_0^{2\pi}\sum_{k\geq 0}(-a)^{-k} e^{i(k+1)\phi}\,\mathrm{d}\phi \overset{(3)}{=} 0.$$

(1) Factor $z = a(1+e^{i\phi}/a)$.
(2) Geometric series with $|e^{i\phi}/a| < 1$.
(3) Every term has frequency $k+1 \geq 1$, so it integrates to zero.

So the circle winds once around the origin when it encloses it and zero times when it does not, as the picture suggests (Figure 1.17). The jump from 1 to 0 happens only at $|a| = 1$, where the loop passes through the origin and leaves the space $\mathbb{C}\setminus\{0\}$.



$W = 0$ $W = 1$ $W = 2$

Figure 1.17: Loops in the punctured plane $\mathbb{C}\setminus\{0\}$ and their winding numbers. Wiggles do not matter (middle); only the net number of times the loop goes around the hole counts. The right-hand loop, $z(t) = 0.95e^{2it} + 0.45e^{it}$, goes around the origin twice, crossing itself once. In a superfluid these are the possible circulations $\oint \nabla\theta\cdot\mathrm{d}\vec{l} = 2\pi W$ around a vortex at the hole.

The winding number cannot change under homotopy

This is the heart of the matter. Here is the physicist's proof, for a smooth based homotopy $F(s,t)$ of loops in $\mathbb{C}\setminus\{0\}$. Write $W(s) = \frac{1}{2\pi i}\int_0^1 \frac{\partial_t F}{F}\,\mathrm{d}t$ for the winding number of the loop $F(s,\cdot)$. Then

$$\frac{\mathrm{d}W}{\mathrm{d}s} \overset{(1)}{=} \frac{1}{2\pi i}\int_0^1 \partial_s\Big(\frac{\partial_t F}{F}\Big)\mathrm{d}t \overset{(2)}{=} \frac{1}{2\pi i}\int_0^1 \frac{F\,\partial_s\partial_t F - \partial_s F\,\partial_t F}{F^2}\,\mathrm{d}t$$
$$\overset{(3)}{=} \frac{1}{2\pi i}\int_0^1 \partial_t\Big(\frac{\partial_s F}{F}\Big)\mathrm{d}t \overset{(4)}{=} \frac{1}{2\pi i}\Big[\frac{\partial_s F}{F}\Big]_{t=0}^{t=1} \overset{(5)}{=} 0.$$

(1) Differentiate under the integral sign (everything is smooth and $F \neq 0$).
(2) Quotient rule.
(3) Quotient rule in the other order: $\partial_t(\partial_s F/F) = (F\partial_t\partial_s F - \partial_t F\partial_s F)/F^2$, and mixed partials commute.

(4) Fundamental theorem of calculus in t.
(5) The base point is pinned, $F(s,0) = F(s,1) = x_0$ for all s, so $\partial_s F = 0$ at both ends. (For a free homotopy of closed loops, $F(s,0) = F(s,1)$ and the two boundary terms are equal and cancel.)

So $W(s)$ is constant. Even without this computation, $W(s)$ is a continuous function of s with values in the integers, and a continuous integer-valued function on an interval is constant. (For merely continuous homotopies one lifts the whole homotopy to $\mathbb{R}$, square by small square, by the same patching argument as for paths.)

Key idea: Nash's (1.32), first line: $\pi_1(S^1) \cong \mathbb{Z}$

The winding number is a group isomorphism

$$W : \pi_1(S^1) \xrightarrow{\cong} \mathbb{Z}, \qquad [\gamma] \mapsto W[\gamma].$$

Every loop in the circle is homotopic to exactly one standard loop α_n, and $n = W[\gamma]$.

We check the four things this says.

(a) *Well defined:* homotopic loops have equal W, by the computation above.

(b) *Homomorphism:* the lift of $\alpha \cdot \beta$ is the lift of α (at double speed) followed by the lift of β shifted up to start where the first one ended, so

$$W[\alpha \cdot \beta] \overset{(1)}{=} \frac{1}{2\pi i}\int_0^{1/2} \frac{2\dot\alpha(2t)}{\alpha(2t)}\mathrm{d}t + \frac{1}{2\pi i}\int_{1/2}^{1} \frac{2\dot\beta(2t-1)}{\beta(2t-1)}\mathrm{d}t \overset{(2)}{=} W[\alpha] + W[\beta].$$

(1) Formula (1.33) on the two halves of (1.31), with the chain rule giving the factor 2.
(2) Substitute $u = 2t$ in the first integral and $u = 2t-1$ in the second.

(c) *Onto:* $W[\alpha_n] = n$ (Example 1.23).

(d) *One-to-one:* suppose $W[\alpha] = W[\beta] = n$, with lifts $\tilde\theta_\alpha$, $\tilde\theta_\beta$ from 0 to $2\pi n$. Average the *lifts*, not the loops:

$$F(s,t) = \exp\big(i\,[(1-s)\tilde\theta_\alpha(t) + s\,\tilde\theta_\beta(t)]\big).$$

This is on the circle for all s,t; at $s = 0,1$ it is α,β; and at $t = 0$ and $t = 1$ the exponent is 0 and $2\pi i n$, so $F(s,0) = F(s,1) = 1$. Hence $\alpha \simeq \beta$ as based loops.

Step (d) is the whole trick: on the helix $\mathbb{R}$ we may interpolate linearly (it is contractible), and projecting down gives a homotopy on the circle.

Worked example 1.25: The fundamental theorem of algebra

Winding numbers prove that every polynomial $P(z) = z^n + c_{n-1}z^{n-1} + \cdots + c_0$ with $n \geq 1$ has a complex root. Suppose not: $P(z) \neq 0$ for all z. For $r \geq 0$ consider the loop $\gamma_r(t) = P(re^{2\pi i t})$ in $\mathbb{C} \setminus \{0\}$.

- As r goes from 0 to R, the loops γ_r form a homotopy in $\mathbb{C} \setminus \{0\}$ from the constant loop $\gamma_0 = P(0)$ (winding 0) to γ_R. (It is a free homotopy of loops, so the free version of the invariance argument applies.) So $W[\gamma_R] = 0$.
- For large R the leading term dominates. Put $Q(z) = c_{n-1}z^{n-1} + \cdots + c_0$ and deform

z^n into $P(z)$ by $H_s(z) = z^n + sQ(z)$, $s \in [0,1]$, on the circle $|z| = R$. It never vanishes:

$$|H_s(z)| \overset{(1)}{\geq} |z|^n - s|Q(z)| \overset{(2)}{\geq} R^n - \left(|c_{n-1}|R^{n-1} + \cdots + |c_0|\right) \overset{(3)}{>} 0.$$

(1) Reverse triangle inequality $|a+b| \geq |a| - |b|$.
(2) $s \leq 1$ and the triangle inequality on Q.
(3) True for $R > 1 + \sum_k |c_k|$, since then the bracket is at most $R^{n-1}\sum_k |c_k| < R^n$.

So γ_R is homotopic in $\mathbb{C} \setminus \{0\}$ to $t \mapsto R^n e^{2\pi i n t}$, which has winding number n (Example 1.23).

Thus $0 = W[\gamma_R] = n \geq 1$, a contradiction. So P has a root.

Physical picture: Flux quantisation and the Aharonov–Bohm effect

In a superconducting ring the Cooper-pair condensate is $\psi = |\psi|e^{i\theta}$, with charge $q = 2e$. Deep inside the ring the current vanishes, which forces $\hbar\nabla\theta = q\vec{A}$. Integrating around a loop C inside the ring,

$$\Phi = \oint_C \vec{A}\cdot \mathrm{d}\vec{l} \overset{(1)}{=} \frac{\hbar}{q}\oint_C \nabla\theta \cdot \mathrm{d}\vec{l} \overset{(2)}{=} \frac{\hbar}{q} 2\pi W \overset{(3)}{=} W\,\frac{h}{2e}.$$

(1) Zero current in the bulk: $\vec{J} \propto \hbar\nabla\theta - q\vec{A} = 0$; the first equality is Stokes' theorem for the enclosed flux.
(2) ψ is single valued, so θ changes by $2\pi W$ around C, where W is the winding number of the loop $\psi/|\psi| : C \to S^1$.
(3) $2\pi\hbar = h$ and $q = 2e$.

Flux comes in integer multiples of $h/2e$ because $\pi_1(S^1) = \mathbb{Z}$. Similarly, an electron moving in $\mathbb{R}^3$ minus an infinitely long solenoid lives in a space homotopy equivalent to S^1 (Example 1.13). Its paths fall into classes labelled by $\pi_1 = \mathbb{Z}$, and the Aharonov–Bohm phase $e^{iqW\Phi/\hbar}$ weights them in the path integral.

Now we can finish the argument of Example 1.14: the identity loop of S^1 has $W = 1$ and a constant loop has $W = 0$, so they are not homotopic, and S^1 is not a retract of the disc. Brouwer's fixed-point theorem is proved.

1.3.3 Computing more fundamental groups

With $\pi_1(S^1) = \mathbb{Z}$ in hand, homotopy invariance and a few simple rules give the fundamental groups of most spaces a physicist meets.

Homotopy invariance

Since π_1 depends only on the homotopy type, Examples 1.12 and 1.13 give at once

$$\pi_1(\mathbb{R}^2 \setminus \{0\}) = \pi_1(\text{Möbius band}) = \pi_1(S^1 \times D^2) = \pi_1(\mathbb{R}^3 \setminus \text{line}) = \mathbb{Z},$$

and $\pi_1(\mathbb{R}^n) = 0$. In each case a generator is "go once around the hole". The winding number around the z-axis of a loop in $\mathbb{R}^3 \setminus \{z\text{-axis}\}$ is computed by the same integral $\frac{1}{2\pi}\oint \mathrm{d}\phi$, with ϕ the azimuthal angle.

Products

A loop in $X \times Y$ is a pair of loops, one in each factor, run simultaneously, and a based homotopy is a pair of based homotopies. So

$$\pi_1(X \times Y) \cong \pi_1(X) \times \pi_1(Y), \qquad [(\alpha, \beta)] \mapsto ([\alpha], [\beta]). \tag{1.34}$$

The product of loops is computed componentwise:

$$(\alpha, \beta) \cdot (\alpha', \beta') \overset{(1)}{=} (\alpha \cdot \alpha',\ \beta \cdot \beta'),$$

(1) Both sides run (α, β) at double speed on $[0, \frac{1}{2}]$ and (α', β') on $[\frac{1}{2}, 1]$, component by component.

so (1.34) is a group isomorphism. (The same argument works for all the higher π_n.)

Worked example 1.26: The torus: $\pi_1(T^2) = \mathbb{Z} \times \mathbb{Z}$

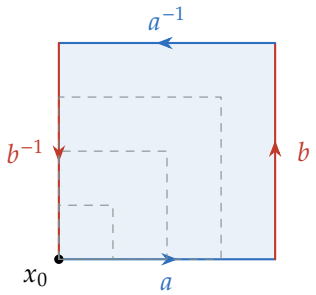
Let $T^2 = S^1 \times S^1$ with angles (θ, ϕ). By (1.34) and $\pi_1(S^1) = \mathbb{Z}$, a loop on the torus is classified by two winding numbers,

$$(m, n) = \left(\frac{1}{2\pi} \oint \mathrm{d}\theta,\ \frac{1}{2\pi} \oint \mathrm{d}\phi \right) \in \mathbb{Z} \times \mathbb{Z}.$$

The loop $t \mapsto (e^{2\pi i p t}, e^{2\pi i q t})$ has class (p, q); for coprime p, q it is a (p, q) torus knot when the torus is drawn in $\mathbb{R}^3$ (the trefoil of Figure 1.6 is $(2, 3)$). The group is abelian. In terms of the generators $a = (1, 0)$ and $b = (0, 1)$ (the edges of the square in Figure 1.4),

$$aba^{-1}b^{-1} \simeq e.$$

Geometrically: the loop $aba^{-1}b^{-1}$ runs around the boundary of the square, and the square itself provides the contraction: shrink the boundary of the square through the interior to a corner (Figure 1.18).



$aba^{-1}b^{-1}$ bounds the square

Figure 1.18: On the torus (a square with opposite sides glued), the loop $aba^{-1}b^{-1}$ is the boundary of the square traversed once. The square itself is a disc filling it in, so the loop shrinks (grey dashed squares) to the corner x_0. Hence $ab = ba$ in $\pi_1(T^2)$.

Spheres of dimension at least two are simply connected

Worked example 1.27: $\pi_1(S^n) = 0$ for $n \geq 2$

Take a loop α in S^n. First deform it slightly to a smooth loop (any continuous loop is homotopic to a smooth one by smoothing, e.g. by convolution followed by projection back onto the sphere). A smooth loop is 1-dimensional, and by the general-position count (1.4) it meets a chosen point $P \neq x_0$ of S^n in a set of dimension $1 + 0 - n < 0$, i.e. generically not at all. (If it happens to pass through P, choose another point: the image of a smooth curve has zero area in S^n when $n \geq 2$.) So α lies in $S^n \setminus \{P\}$, which is homeomorphic to $\mathbb{R}^n$ by stereographic projection from P, and there α contracts by Example 1.22. Hence every loop contracts: $\pi_1(S^n) = 0$ for $n \geq 2$.
The smoothing step is not pedantry: there are continuous surjections $[0,1] \to S^2$ (space-filling curves), which do not miss any point. They are still contractible, but only because they can first be smoothed.

Wedges: the figure eight and the plane with two holes

For wedges, the rule is different: loops in the two pieces do not commute. The general statement is the Seifert–van Kampen theorem, which Nash assumes silently (it is behind his remark on Riemann surfaces).

Key idea: Seifert–van Kampen, in the form we need

- $\pi_1(X \vee Y)$ is the **free product** $\pi_1(X) * \pi_1(Y)$: its elements are words $g_1 h_1 g_2 h_2 \cdots$ alternating between elements of $\pi_1(X)$ and $\pi_1(Y)$, multiplied by juxtaposition, with no relations between the two factors.
- Gluing a disc onto a space along a loop λ adds the relation $\lambda = 1$.

A consequence: any assignment of the generators to elements of a group G that respects the relations defines a homomorphism $\pi_1 \to G$.

So $\pi_1(S^1 \vee S^1) = \mathbb{Z} * \mathbb{Z} = F_2$, the free group on two generators a, b. The plane with two punctures deformation retracts onto a figure eight (Figure 1.14), so it has the same π_1.

Worked example 1.28: The figure eight has a non-abelian π_1

We show $ab \neq ba$ in $F_2 = \pi_1(S^1 \vee S^1)$. It is enough to find a homomorphism $\rho : F_2 \to G$ into some group with $\rho(a)\rho(b) \neq \rho(b)\rho(a)$. Take $G = S_3$, the permutations of $\{1,2,3\}$, and $\rho(a) = \sigma = (12)$, $\rho(b) = \tau = (23)$; since F_2 has no relations this is allowed. (Geometrically, ρ is the monodromy of a three-sheeted covering of the figure eight: going around a swaps sheets $1,2$, going around b swaps sheets $2,3$.) Compose permutations right to left and follow the element 1 through the commutator:

$$\sigma\tau\sigma^{-1}\tau^{-1}(1) \overset{(1)}{=} \sigma\tau\sigma\tau(1) \overset{(2)}{=} \sigma\tau\sigma(1) \overset{(3)}{=} \sigma\tau(2) \overset{(4)}{=} \sigma(3) = 3 \neq 1.$$

(1) Transpositions are their own inverses.
(2) $\tau = (23)$ fixes 1.
(3) $\sigma = (12)$ sends 1 to 2.
(4) τ sends 2 to 3; then σ fixes 3.

So $\rho(aba^{-1}b^{-1}) \neq 1$, hence $aba^{-1}b^{-1} \neq e$ and π_1 is non-abelian. Physically: an electron

encircling first flux tube a then flux tube b, versus the reverse order, follows paths in different homotopy classes. For abelian (ordinary) fluxes the Aharonov–Bohm phases still commute; for non-abelian fluxes (holonomies in a non-abelian gauge group) the order is observable.

Worked example 1.29: Riemann surfaces of genus $g \geq 2$: Nash's non-abelian π_1

A genus-g surface Σ_g is a $4g$-gon with edges glued as in the Try-it of §1.1.2 (Figure 1.19). After gluing, the boundary of the polygon becomes a wedge of $2g$ circles $a_1, b_1, \ldots, a_g, b_g$, and the interior is a disc glued along the loop $a_1 b_1 a_1^{-1} b_1^{-1} \cdots a_g b_g a_g^{-1} b_g^{-1}$. By van Kampen,

$$\pi_1(\Sigma_g) = \langle a_1, b_1, \ldots, a_g, b_g \mid [a_1, b_1][a_2, b_2] \cdots [a_g, b_g] = 1 \rangle, \qquad [a, b] := aba^{-1}b^{-1}. \tag{1.35}$$

For $g = 1$ this is $\langle a, b \mid aba^{-1}b^{-1} = 1 \rangle = \mathbb{Z} \times \mathbb{Z}$, the torus again. For $g = 2$, Nash says π_1 is non-commutative. To see it, map to S_3 again: $a_1 \mapsto \sigma = (12)$, $b_1 \mapsto \tau = (23)$, $a_2 \mapsto \tau$, $b_2 \mapsto \sigma$. The relation is respected: with $c := \sigma\tau$ (a 3-cycle, so $c^3 = 1$) and $\tau\sigma = c^{-1}$,

$$[\sigma, \tau][\tau, \sigma] \overset{(1)}{=} (\sigma\tau\sigma\tau)(\tau\sigma\tau\sigma) \overset{(2)}{=} c^2 c^{-2} = 1.$$

(1) Transpositions are self-inverse, so $[\sigma, \tau] = \sigma\tau\sigma\tau$ and $[\tau, \sigma] = \tau\sigma\tau\sigma$.

(2) $\sigma\tau\sigma\tau = (\sigma\tau)^2 = c^2$ and $\tau\sigma\tau\sigma = (\tau\sigma)^2 = c^{-2}$, where $\tau\sigma = (\sigma\tau)^{-1}$ because both are self-inverse.

So this defines a homomorphism $\pi_1(\Sigma_2) \to S_3$, and a_1, b_1 map to non-commuting permutations (Example 1.28). Hence $a_1 b_1 \neq b_1 a_1$ in $\pi_1(\Sigma_2)$. The same trick (with the extra generators sent to 1) works for all $g \geq 2$.

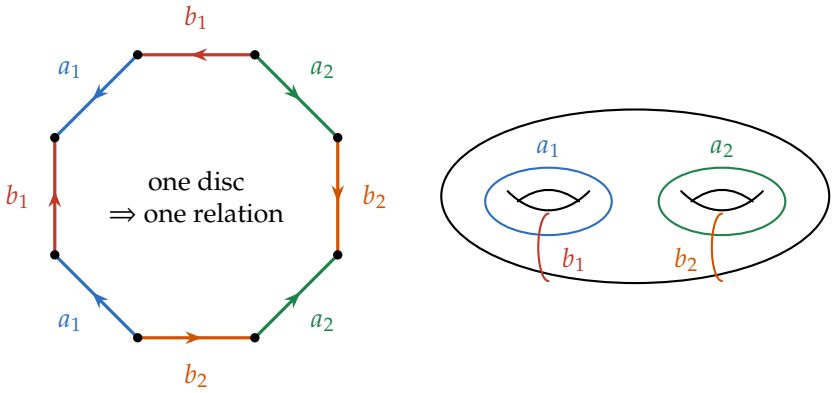


Figure 1.19: A genus-2 surface as an octagon with edges glued in the pattern $a_1 b_1 a_1^{-1} b_1^{-1} a_2 b_2 a_2^{-1} b_2^{-1}$ (reading clockwise from the bottom left). All eight corners become one point. The glued edges are four loops on the surface (right). The interior of the octagon is a single disc glued along the boundary word, which gives the single relation $[a_1, b_1][a_2, b_2] = 1$ in (1.35).

Worked example 1.30: The projective plane: $\pi_1(\mathbb{RP}^2) = \mathbb{Z}_2$

$\mathbb{RP}^2$ is the sphere S^2 with antipodal points identified, $\vec{n} \sim -\vec{n}$ (the space of lines through the origin in $\mathbb{R}^3$, or of unoriented directions: the order-parameter space of a nematic liquid crystal). Let γ be a path on S^2 from the north pole N to the south pole $S = -N$ along a meridian. Since $N \sim S$ in $\mathbb{RP}^2$, γ becomes a closed loop there. It is not contractible: a homotopy of loops in $\mathbb{RP}^2$ lifts to a homotopy of paths in S^2 starting at N, and the lifted

endpoint can only be N or $-N$; by continuity it stays $-N$, whereas the constant loop lifts to a path ending at N. But $\gamma\cdot\gamma$ lifts to a path from N to S and back to N along the antipodal meridian: a closed loop on S^2, which contracts because $\pi_1(S^2)=0$. So $\pi_1(\mathbb{RP}^2)=\{e,[\gamma]\}\cong\mathbb{Z}_2$. The same argument gives $\pi_1(\mathbb{RP}^n)=\mathbb{Z}_2$ for all $n\geq 2$. In a nematic this is why there are line defects of "half-integer" strength: the director rotates by π, not 2π, around the defect.

1.3.4 Topological groups, $\mathrm{SO}(3)$ and the belt trick

Nash promised at the end of §2 that "the fundamental group of a topological group G (e.g. G is some Lie group) is always commutative". In §3 he proves it by writing

$$\pi_1(G)=[S^1,G]_0=[SS^0,G]_0, \tag{1.36}$$

where $S^0=\{x_1 : x_1^2=1\}=\{\pm1\}$ is the zero-sphere (Nash's footnote) and $S^1=SS^0$ by (1.23) with $n=0$. So $\pi_1(G)$ has the form $[X,Y]_0$ with $Y=G$ an H-space and $X=SS^0$ a coH-space, and the Eckmann–Hilton argument of §1.2.8 applies.

It is instructive to see the argument with actual loops. Let α,β be loops in G at the identity e, write e also for the constant loop, and let $\bullet$ be the pointwise product. Then

$$\alpha\cdot\beta \overset{(1)}{=} (\alpha\cdot e)\bullet(e\cdot\beta) \overset{(2)}{\simeq} (e\cdot\alpha)\bullet(\beta\cdot e) \overset{(3)}{=} \beta\cdot\alpha.$$

(1) For $t\leq\frac12$ the right side is $\alpha(2t)\,e=\alpha(2t)$; for $t\geq\frac12$ it is $e\,\beta(2t-1)=\beta(2t-1)$. This is literally $\alpha\cdot\beta$.

(2) $\alpha\cdot e\simeq e\cdot\alpha$ and $e\cdot\beta\simeq\beta\cdot e$ (both sides are reparametrisations of the same loop), and pointwise products of homotopies are homotopies.

(3) For $t\leq\frac12$ the middle expression is $e\,\beta(2t)=\beta(2t)$, for $t\geq\frac12$ it is $\alpha(2t-1)\,e$; this is $\beta\cdot\alpha$.

The picture: slide the loop α "through" β, using the group multiplication to let them pass each other. So $\pi_1(G)$ is abelian. For instance, the figure eight is not a topological group, and no group structure can be put on it.

$\mathrm{SU}(2)$ is the three-sphere

Every 2×2 matrix of the form

$$U=a_0\,\mathbf{1}+i\,\vec a\cdot\vec\sigma=\begin{pmatrix}a_0+ia_3 & ia_1+a_2\\ ia_1-a_2 & a_0-ia_3\end{pmatrix},\qquad (a_0,\vec a)\in\mathbb{R}^4, \tag{1.37}$$

with the Pauli matrices $\sigma_1=\left(\begin{smallmatrix}0&1\\1&0\end{smallmatrix}\right)$, $\sigma_2=\left(\begin{smallmatrix}0&-i\\i&0\end{smallmatrix}\right)$, $\sigma_3=\left(\begin{smallmatrix}1&0\\0&-1\end{smallmatrix}\right)$, satisfies

$$U^\dagger U \overset{(1)}{=} (a_0-i\,\vec a\cdot\vec\sigma)(a_0+i\,\vec a\cdot\vec\sigma) \overset{(2)}{=} a_0^2+(\vec a\cdot\vec\sigma)^2 \overset{(3)}{=} (a_0^2+|\vec a|^2)\,\mathbf{1},$$

$$\det U \overset{(4)}{=} (a_0+ia_3)(a_0-ia_3)-(ia_1+a_2)(ia_1-a_2)=a_0^2+a_3^2+a_1^2+a_2^2.$$

(1) The Pauli matrices are Hermitian, so $U^\dagger=a_0-i\,\vec a\cdot\vec\sigma$.

(2) The cross terms $\pm ia_0\,\vec a\cdot\vec\sigma$ cancel.

(3) $\sigma_j\sigma_k+\sigma_k\sigma_j=2\delta_{jk}$, so $(\vec a\cdot\vec\sigma)^2=|\vec a|^2\,\mathbf{1}$.

(4) Determinant of the explicit matrix; $(ia_1)^2=-a_1^2$.

So $U\in\mathrm{SU}(2)$ iff $a_0^2+|\vec a|^2=1$, and conversely every element of $\mathrm{SU}(2)$ has this form. Hence

$$\mathrm{SU}(2)\cong S^3\subset\mathbb{R}^4,$$

and in particular $\pi_1(\mathrm{SU}(2))=0$ by Example 1.27.

The double cover $\mathrm{SU}(2) \to \mathrm{SO}(3)$

SU(2) acts on traceless Hermitian matrices $\vec{x}\cdot\vec{\sigma}$ by conjugation, $\vec{x}\cdot\vec{\sigma} \mapsto U(\vec{x}\cdot\vec{\sigma})U^\dagger$. The result is again traceless and Hermitian, so equals $\vec{x}'\cdot\vec{\sigma}$ for a unique $\vec{x}'$, and det is preserved, so $|\vec{x}'|^2 = -\det(\vec{x}'\cdot\vec{\sigma}) = |\vec{x}|^2$. Thus $\vec{x}' = R(U)\vec{x}$ with $R(U) \in \mathrm{SO}(3)$; explicitly

$$U(\vec{x}\cdot\vec{\sigma})U^\dagger = \big(R(U)\vec{x}\big)\cdot\vec{\sigma}, \qquad R(U)_{jk} = \tfrac{1}{2}\operatorname{tr}\big(\sigma_j U \sigma_k U^\dagger\big). \tag{1.38}$$

Since U and $-U$ give the same conjugation, $R(-U) = R(U)$: the map $U \mapsto R(U)$ is two-to-one. (One can check it is onto and that $\pm U$ are the only elements with the same image.)

Worked example 1.31: Rotating by 2π gives -1 in SU(2)

Let $U_\theta = e^{-i\theta\sigma_3/2} = \operatorname{diag}(e^{-i\theta/2}, e^{i\theta/2})$. Its action on σ_1:

$$U_\theta\sigma_1 U_\theta^\dagger \overset{(1)}{=} \begin{pmatrix} e^{-i\theta/2} & 0 \\ 0 & e^{i\theta/2}\end{pmatrix}\begin{pmatrix} 0 & 1 \\ 1 & 0\end{pmatrix}\begin{pmatrix} e^{i\theta/2} & 0 \\ 0 & e^{-i\theta/2}\end{pmatrix} \overset{(2)}{=} \begin{pmatrix} 0 & e^{-i\theta} \\ e^{i\theta} & 0\end{pmatrix}$$
$$\overset{(3)}{=} \begin{pmatrix} 0 & \cos\theta - i\sin\theta \\ \cos\theta + i\sin\theta & 0\end{pmatrix} \overset{(4)}{=} \cos\theta\,\sigma_1 + \sin\theta\,\sigma_2.$$

(1) $U_\theta^\dagger = \operatorname{diag}(e^{i\theta/2}, e^{-i\theta/2})$.
(2) Multiply out: the $(1,2)$ entry is $e^{-i\theta/2}\cdot 1\cdot e^{-i\theta/2}$ and the $(2,1)$ entry is $e^{i\theta/2}\cdot 1\cdot e^{i\theta/2}$.
(3) Euler's formula.
(4) Read off the coefficients of $\sigma_1 = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0\end{smallmatrix}\right)$ and $\sigma_2 = \left(\begin{smallmatrix} 0 & -i \\ i & 0\end{smallmatrix}\right)$.

The same computation gives $U_\theta\sigma_2 U_\theta^\dagger = -\sin\theta\,\sigma_1 + \cos\theta\,\sigma_2$, and σ_3 commutes with U_θ. So

$$R(U_\theta) = \begin{pmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1\end{pmatrix},$$

the rotation by angle θ about the z-axis. As θ goes from 0 to 2π, the rotation goes once around a closed loop in SO(3), from $\mathbb{1}$ back to $\mathbf{1}$. But the matrix U_θ goes from $U_0 = \mathbf{1}$ to

$$U_{2\pi} = \operatorname{diag}(e^{-i\pi}, e^{i\pi}) = -\mathbf{1}.$$

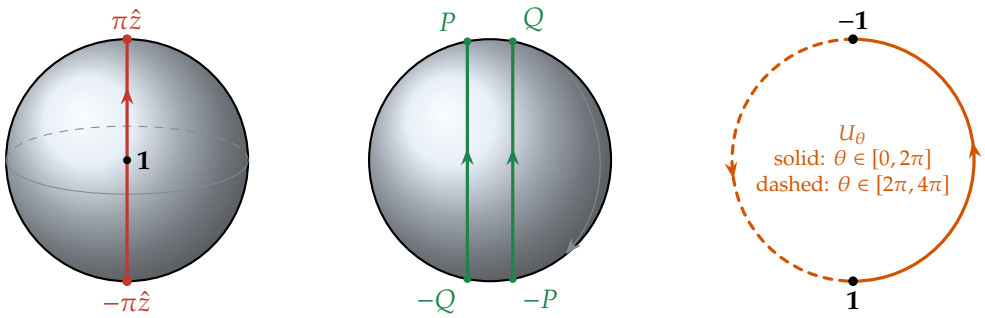
The lift of the closed loop is *not* closed. Only at $\theta = 4\pi$ does U_θ return to $\mathbf{1}$.

Key idea: $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$

Let γ be the loop $\theta \mapsto R(U_\theta)$, $\theta \in [0, 2\pi]$.

- γ is *not* contractible. Any loop in SO(3) at $\mathbf{1}$ lifts uniquely to a path in SU(2) starting at $\mathbf{1}$ (the same patching argument as for $\mathbb{R} \to S^1$, since the map is locally a homeomorphism). Its endpoint is $+\mathbf{1}$ or $-\mathbf{1}$. Under a based homotopy of the loop, the endpoint of the lift moves continuously in the two-point set $\{\pm\mathbf{1}\}$, so it cannot change. The constant loop lifts to a path ending at $+\mathbf{1}$; γ lifts to one ending at $-\mathbf{1}$.
- $\gamma\cdot\gamma$ (rotation by 4π) *is* contractible. Its lift U_θ, $\theta \in [0, 4\pi]$, is a closed loop in $\mathrm{SU}(2) \cong S^3$, which contracts since $\pi_1(S^3) = 0$. Projecting the contraction by R contracts $\gamma\cdot\gamma$.

Every loop lifts to a path ending at $\pm\mathbf{1}$, and loops with the same endpoint are homotopic (project a homotopy of lifts in the simply connected S^3). So $\pi_1(\mathrm{SO}(3)) = \{[e], [\gamma]\} \cong \mathbb{Z}_2$.



SO(3): ball of radius π, antipodes on the surface glued

4π: move the two surface crossings around and cancel

lift to SU(2) $\cong S^3$

Figure 1.20: Three views of $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$. Left: a rotation is a vector $\theta\hat{n}$ with $|\theta| \le \pi$, so SO(3) is a solid ball whose antipodal surface points $\pm\pi\hat{n}$ are the same rotation. The 2π loop runs up the z-axis, leaves at $\pi\hat{z}$ and re-enters at $-\pi\hat{z}$; it cannot be shrunk. Middle: the 4π loop crosses the surface twice; the pair of crossings can be moved round the sphere until they meet and cancel. Right: in SU(2) the 2π rotation lifts to a path from $\mathbf{1}$ to $-\mathbf{1}$ (solid), and only the 4π rotation closes up (solid plus dashed).

Physical picture: The belt trick, and why electrons have spin $\frac{1}{2}$

Hold one end of a belt fixed and rotate the buckle by 2π about the belt's axis. The belt is twisted, and no amount of moving the buckle around (without rotating it) will untwist it. Rotate by another 2π: now the belt can be untwisted by looping it around the buckle. This is Dirac's demonstration of $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$: the family of orientations along the belt is a path in SO(3), and the 2π loop is non-contractible while the 4π loop is contractible.

Quantum mechanics represents rotations on states up to phase, and it is really the simply connected group SU(2) = Spin(3) that acts. A spin-$\frac{1}{2}$ state picks up $U_{2\pi} = -\mathbf{1}$ under a 2π rotation. The sign was measured directly in neutron interferometry (1975): a neutron beam passed through a magnetic field that precesses its spin by 2π interferes destructively with the unrotated beam. The generalisation, $\pi_1(\mathrm{SO}(n)) = \mathbb{Z}_2$ for $n \ge 3$ with universal cover $\mathrm{Spin}(n)$, is the subject of Chapter T4.

Worked example 1.32: $\pi_1(\mathrm{U}(n)) = \mathbb{Z}$ via the determinant

$\mathrm{SU}(n)$ is simply connected for all n (for $n = 2$ we just showed it; in general it follows from the exact sequences of §1.3.11). The map

$$\mathrm{SU}(n) \times \mathrm{U}(1) \to \mathrm{U}(n), \qquad (V, z) \mapsto V\,\mathrm{diag}(z, 1, \dots, 1)$$

is a homeomorphism (inverse: $z = \det M$, $V = M\,\mathrm{diag}(z^{-1}, 1, \dots, 1)$), though not a group isomorphism. So $\pi_1(\mathrm{U}(n)) \cong \pi_1(\mathrm{SU}(n)) \times \pi_1(\mathrm{U}(1)) = \mathbb{Z}$, and the isomorphism is the winding number of the determinant. For example, in U(2):

$$W\left[\det \mathrm{diag}(e^{2\pi i t}, 1)\right] = W[e^{2\pi i t}] \overset{(1)}{=} 1, \qquad W\left[\det(e^{2\pi i t}\mathbf{1}_2)\right] \overset{(2)}{=} W[e^{4\pi i t}] \overset{(1)}{=} 2.$$

(1) Example 1.23.
(2) $\det(\lambda \mathbf{1}_2) = \lambda^2$.

So the loop of overall phases $e^{2\pi i t}\mathbf{1}_2$ is twice the generator. Summary for the groups we use most:

G	U(1)	U(n)	SU(n)	SO(2)	SO(n), $n \ge 3$	Sp(n), Spin(n) ($n \ge 3$)
$\pi_1(G)$	$\mathbb{Z}$	$\mathbb{Z}$	0	$\mathbb{Z}$	$\mathbb{Z}_2$	0

All are abelian, as Nash's argument requires.

1.3.5 Free versus based homotopy classes

In §1.2.4 we introduced base points for convenience. Now we pay the bill: how much does the answer depend on them? Nash summarises the answer in one line,

$$[X, Y]_0/\pi_1(Y) \cong [X, Y], \tag{1.39}$$

which says: $\pi_1(Y)$ acts on the based classes, and the free classes are the orbits of this action. We unpack it.

Changing the base point

Temporarily write $[X, x_0; Y, y_0]_0$ to show the base points. Keep x_0 fixed and move y_0 to y_1. Choose a path γ from y_0 to y_1 (here we need Y path-connected, or at least y_0, y_1 in the same path component). For loops ($X = S^1$) the translation is explicit:

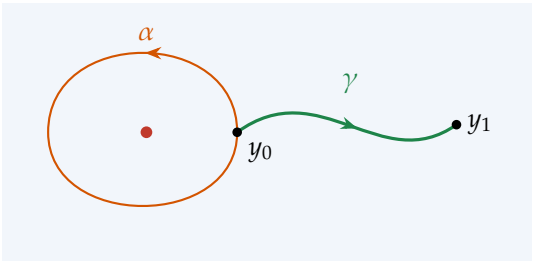
$$i_\gamma : \pi_1(Y, y_0) \to \pi_1(Y, y_1), \qquad i_\gamma[\alpha] := [\bar\gamma \cdot \alpha \cdot \gamma], \tag{1.40}$$

"walk back from y_1 to y_0 along γ, do α, return along γ" (Figure 1.21). (The products of paths are defined as for loops, whenever the end of one is the start of the next.) This is a group isomorphism: its inverse is $i_{\bar\gamma}$, and

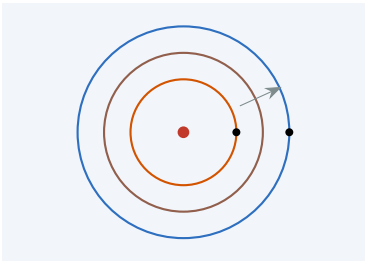
$$i_\gamma[\alpha]\, i_\gamma[\beta] \overset{(1)}{=} [\bar\gamma \cdot \alpha \cdot \gamma \cdot \bar\gamma \cdot \beta \cdot \gamma] \overset{(2)}{=} [\bar\gamma \cdot \alpha \cdot \beta \cdot \gamma] = i_\gamma[\alpha\beta].$$

(1) Definition (1.40) and associativity up to homotopy.
(2) $\gamma \cdot \bar\gamma$ is homotopic (with endpoints fixed) to the constant path at y_0, by the "reel it in" homotopy of §1.3.1.

For general X one uses the same idea: a based map α is dragged along γ by a homotopy that moves only a neighbourhood of the base point.



$i_\gamma[\alpha] = [\bar\gamma \cdot \alpha \cdot \gamma]$: a loop at y_1



free homotopy: base point may move

Figure 1.21: Left: translating a loop from base point y_0 to y_1 along a path γ. Right: a free homotopy of loops is allowed to move the base point; if the base point travels around a closed loop δ during the homotopy, the based class changes by conjugation, $[\alpha] \mapsto [\delta]^{-1}[\alpha][\delta]$.

The isomorphism depends only on the class of the path

If $\gamma \simeq \gamma'$ with endpoints fixed, then $\bar\gamma \cdot \alpha \cdot \gamma \simeq \bar\gamma' \cdot \alpha \cdot \gamma'$, so $i_\gamma = i_{\gamma'}$. If γ and γ' are *not* homotopic, they differ by a loop: $\mu := \bar\gamma \cdot \gamma'$ (back from y_1 to y_0 along γ, then out again along γ') is a loop at y_1, with inverse $\bar\mu = \bar\gamma' \cdot \gamma$. Then

$$i_{\gamma'}[\alpha] \overset{(1)}{=} [\bar\gamma' \cdot \alpha \cdot \gamma'] \overset{(2)}{=} [\bar\gamma' \cdot \gamma \cdot \bar\gamma \cdot \alpha \cdot \gamma \cdot \bar\gamma \cdot \gamma'] \overset{(3)}{=} [\bar\mu]\; i_\gamma[\alpha]\; [\mu] = [\mu]^{-1}\, i_\gamma[\alpha]\, [\mu].$$

(1) Definition (1.40).
(2) Insert $\gamma \cdot \bar{\gamma}$ (out to y_1 and back), which is homotopic to the constant path at y_0, on both sides of α.
(3) Group the six factors as $(\bar{\gamma}' \cdot \gamma) \cdot (\bar{\gamma} \cdot \alpha \cdot \gamma) \cdot (\bar{\gamma} \cdot \gamma')$: the outer pieces are $\bar{\mu}$ and μ, the middle is $i_\gamma[\alpha]$.

So two different paths give identifications that differ by conjugation by a loop, i.e. by the action of $\pi_1(Y)$ on itself. In words: the ambiguity in identifying based classes at different base points is exactly the action of $\pi_1(Y)$, by conjugation for π_1 itself. If $\pi_1(Y) = 0$ there is no ambiguity. This is Nash's argument.

Free loops are conjugacy classes

Now take $X = S^1$. A free homotopy of loops may drag the base point around. If the base point travels around a loop δ at y_0 during the homotopy, then the starting and final loops α, α' are related by $[\alpha'] = [\delta]^{-1}[\alpha][\delta]$. Conversely, α and $\bar{\delta} \cdot \alpha \cdot \delta$ are always freely homotopic (slide the base point back along δ). Hence (1.39) for $X = S^1$ reads

$$[S^1, Y] \cong \{\text{conjugacy classes of } \pi_1(Y)\}. \tag{1.41}$$

Worked example 1.33: Free and based loops in the figure eight

In $F_2 = \pi_1(S^1 \vee S^1)$, the loops a and bab^{-1} are conjugate, so they are freely homotopic. They are not based homotopic: under the homomorphism ρ of Example 1.28,

$$\rho(bab^{-1})(1) \overset{(1)}{=} \tau\sigma\tau(1) \overset{(2)}{=} \tau\sigma(1) \overset{(3)}{=} \tau(2) = 3, \qquad \text{while} \qquad \rho(a)(1) = \sigma(1) = 2.$$

(1) $\rho(b) = \tau = (23) = \tau^{-1}$, $\rho(a) = \sigma = (12)$, applied right to left.
(2) τ fixes 1.
(3) $\sigma(1) = 2$.

So $\rho(bab^{-1}) = (13) \neq (12) = \rho(a)$, and $a \neq bab^{-1}$ in π_1. In the abelian case (circle, torus, any Lie group) conjugation does nothing, and free and based classes of loops coincide: the winding number of a loop in S^1 needs no base point.

Worked example 1.34: When Y is simply connected, base points can be ignored

If $\pi_1(Y) = 0$, (1.39) says $[X, Y]_0 = [X, Y]$. Two important cases: $[S^2, S^2] = \pi_2(S^2)$, the degree of a map of spheres (§1.3.8), and $[S^3, \mathrm{SU}(2)] = \pi_3(\mathrm{SU}(2))$, the instanton number (§1.3.14). Physically this is a relief. A field configuration on space has no preferred base point, so it is the *free* class that is physical; when the target is simply connected the free class equals the based class, which is what we can compute. For $Y = \mathbb{RP}^2$ (nematics, $\pi_1 = \mathbb{Z}_2$), π_1 acts on $\pi_2(\mathbb{RP}^2) = \mathbb{Z}$ by $n \mapsto -n$, and free classes of point defects are labelled by $|n|$ only: a hedgehog and an anti-hedgehog in a nematic are the same defect.

Watch out: Path-connectedness

Nash notes that we "must assume that Y is path-connected, otherwise such γ's need not exist". For example $Y = \mathrm{O}(3)$ has two components (det $= \pm 1$). Based classes at the identity only see SO(3); maps into the other component are not related to them by any change of base point.

Physical picture: Non-abelian vortices

In a biaxial nematic liquid crystal the order-parameter space has $\pi_1 = Q_8 = \{\pm 1, \pm i, \pm j, \pm k\}$, the quaternion group. Line defects are labelled by *conjugacy classes*, $\{1\}, \{-1\}, \{\pm i\}, \{\pm j\}, \{\pm k\}$, by (1.41). Moreover, two defect lines labelled by non-commuting elements cannot cross each other without leaving a connecting line behind, labelled by their commutator. The algebra of π_1 becomes the mechanics of defect lines.

1.3.6 Higher homotopy groups

A vortex line in three-dimensional space is detected by a loop around it. A *point* defect in three-dimensional space, such as a magnetic monopole or the hedgehog in a ferromagnet, is not: any loop around a point in $\mathbb{R}^3$ can be slipped off the point. To detect a point defect we must surround it by a sphere S^2 and ask how the field on that sphere wraps around the space of field values. In four Euclidean dimensions the object that surrounds everything is the three-sphere at infinity. So we need to replace the circle in $\pi_1(X) = [S^1, X]_0$ by higher spheres. That is Nash's next step.

Working definition 1.21 (higher homotopy groups)

For $n \geq 1$ the **n-th homotopy group** of a pointed space $\{X, x_0\}$ is

$$\pi_n(X) \coloneqq [S^n, X]_0, \qquad n = 1, 2, \ldots \tag{1.42}$$

the set of based homotopy classes of based maps $S^n \to X$ [maps sending the base point of S^n to x_0, counted as the same when deformable into each other with the base point held fixed]. *Cube picture:* since $S^n \cong [0,1]^n/\partial[0,1]^n$ [the cube with its whole boundary squashed to a single point] (Example 1.18), an element is represented by a map $f(t_1, \ldots, t_n)$ of the unit cube I^n into X that sends the *whole boundary* of the cube to x_0. A homotopy is a family $F(s, t_1, \ldots, t_n)$ of such maps, with the boundary kept at x_0 for every s. The product is concatenation in the first coordinate:

$$(f+g)(t_1, t_2, \ldots, t_n) \coloneqq \begin{cases} f(2t_1, t_2, \ldots, t_n), & 0 \leq t_1 \leq \tfrac{1}{2}, \\ g(2t_1 - 1, t_2, \ldots, t_n), & \tfrac{1}{2} \leq t_1 \leq 1. \end{cases} \tag{1.43}$$

For $n = 1$ this is the loop product (1.31). We write the product as "+" because we shall shortly see that for $n \geq 2$ it is commutative. As for loops, $f + g$ is continuous on the wall $t_1 = \frac{1}{2}$: there the first branch gives $f(1, t_2, \ldots)$ and the second $g(0, t_2, \ldots)$, and both are x_0 because $t_1 = 1$ and $t_1 = 0$ are faces of the cube. Also $f + g$ sends every face of the cube to x_0, so it is again an element of π_n. The identity is the constant map $e \equiv x_0$, and the inverse of f is f run backwards in t_1, $(-f)(t_1, \ldots) = f(1 - t_1, \ldots)$. The associativity, identity and inverse homotopies are those of §1.3.1, acting on the variable t_1 and carried along trivially in $t_2, \ldots, t_n$.

$\pi_n(X)$ is π_{n-1} of the loop space

The right-hand panel of Figure 1.22 is Nash's (1.29). Read a map of the cube one row at a time: for each fixed $(t_2, \ldots, t_n)$ the function $t_1 \mapsto f(t_1, t_2, \ldots, t_n)$ is a loop at x_0, because the faces $t_1 = 0$ and $t_1 = 1$ go to x_0. So f is a map from the $(n-1)$-cube into the loop space ΩX. When $(t_2, \ldots, t_n)$ is on the boundary of the $(n-1)$-cube, the whole row lies in a face of I^n, so the loop is constant: the boundary of I^{n-1} goes to the base point of ΩX (the constant loop). In terms of

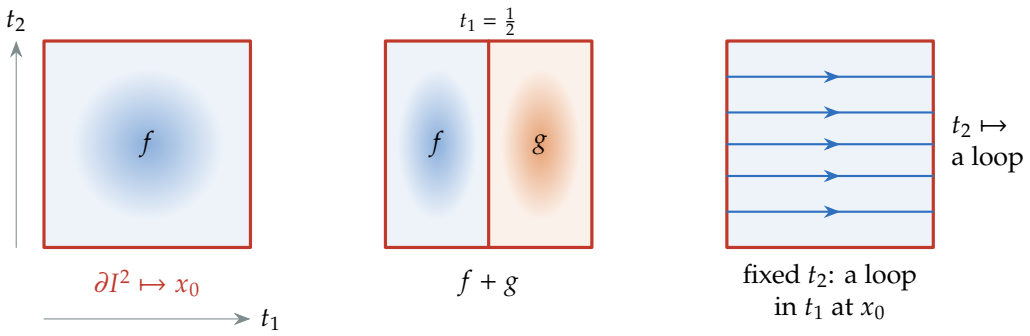


Figure 1.22: The cube picture of π_2. Left: an element is a map of the square whose whole boundary (red) goes to the base point x_0; only the interior (shaded) is doing anything. Middle: the product $f + g$ squeezes f into the left half and g into the right half. Right: read row by row, the same map is a one-parameter family of loops (horizontal lines), beginning and ending with the constant loop. This is (1.44): $\pi_2(X) = \pi_1(\Omega X)$.

the adjunction of §1.2.7:

$$\pi_n(X) \overset{(1)}{=} [S^n, X]_0 \overset{(2)}{=} [SS^{n-1}, X]_0 \overset{(3)}{=} [S^{n-1}, \Omega X]_0 \overset{(4)}{=} \pi_{n-1}(\Omega X). \tag{1.44}$$

(1) Definition (1.42).
(2) $S^n \cong S^1 \wedge S^{n-1} = SS^{n-1}$, (1.23).
(3) The adjunction $[SZ, X]_0 \cong [Z, \Omega X]_0$, (1.25), with $Z = S^{n-1}$; concretely the row-by-row reading above.
(4) Definition (1.42) again, now for the pointed space $\{\Omega X, \text{constant loop}\}$.

Iterating, $\pi_n(X) = \pi_{n-2}(\Omega^2 X) = \cdots = \pi_1(\Omega^{n-1} X) = \pi_0(\Omega^n X)$: an element of $\pi_n(X)$ is a path component of the n-fold loop space. The last form is how physicists often meet it. For instance, $\pi_3(G) = \pi_0(\Omega^3 G)$, and $\Omega^3 G$ is the space of gauge transformations on $\mathbb{R}^3$ that go to 1 at infinity. Its path components are the "large gauge transformations" of §1.3.14.

Why π_n is a group, and abelian for $n \geq 2$

By (1.44), $\pi_n(X) = [S^{n-1}, \Omega X]_0$. Since ΩX is an H-space (loops can be multiplied), $[Z, \Omega X]_0$ is a group for any Z (§1.2.8). So $\pi_n(X)$ is a group, and the group law coming from ΩX is exactly the concatenation (1.43) in t_1. For $n \geq 2$ we may peel off one more suspension, which is Nash's (1.30):

$$\pi_n(X) \overset{(1)}{=} [S^{n-1}, \Omega X]_0 \overset{(2)}{=} [SS^{n-2}, \Omega X]_0, \qquad n \geq 2. \tag{1.45}$$

(1) Equation (1.44).
(2) $S^{n-1} \cong SS^{n-2}$ by (1.23); for $n = 2$ this is $S^1 = SS^0$ with $S^0 = \{\pm 1\}$.

Now the target ΩX is an H-space *and* the source SS^{n-2} is a coH-space. By the Eckmann–Hilton argument (§1.2.8) the two group structures coincide and are commutative. So:

Key idea: Higher homotopy groups are abelian

For $n \geq 2$, $\pi_n(X)$ is an abelian group, and its product can be computed by concatenating in *any* of the n cube coordinates: all these products agree. The fundamental group $\pi_1(X)$, by contrast, can be non-abelian (the figure eight, genus $g \geq 2$ surfaces: Examples 1.28 and 1.29).

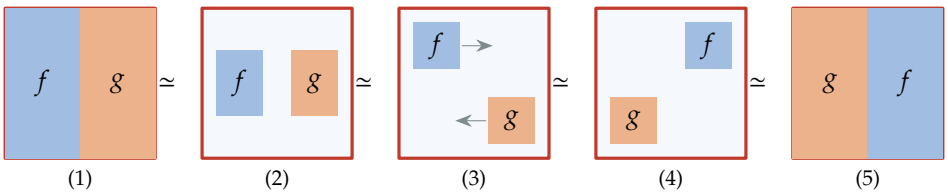

Figure 1.23: Why π_2 is abelian: $f + g \simeq g + f$. (1) The product $f + g$. (2) Shrink each map into a smaller box, filling the rest of the square with the base point (this is a reparametrisation, hence a homotopy). (3) Slide f up and g down, using the second direction. (4) Move them past each other horizontally. (5) Expand again: this is $g + f$. Every intermediate map still sends the boundary to x_0. In π_1 there is no second direction, the two blocks meet head-on, and the argument fails: like two particles on a line, which cannot exchange without colliding, while in the plane they can.

Figure 1.23 is the Eckmann–Hilton argument drawn in the cube. Each step is an explicit homotopy. For example, the step (1)→(2) is $F(s, t_1, t_2) = (f + g)\big(\phi_s(t_1), \psi_s(t_2)\big)$, where ϕ_s and ψ_s are piecewise-linear maps of $[0, 1]$ that squeeze the middle part of the interval onto the whole interval and send the edges to the ends; the parts of the square that are sent to the boundary get the value x_0.

Watch out: Abelian does not mean "free of structure"

For $n \geq 2$ the group $\pi_n(X)$ is abelian, but $\pi_1(X)$ still acts on it (by dragging the base point around a loop, §1.3.5). For $\mathbb{RP}^2$ the action on $\pi_2(\mathbb{RP}^2) = \mathbb{Z}$ is $n \mapsto -n$. For simply connected spaces, and for topological groups, the action is trivial.

First properties

The following facts are proved exactly as for π_1; we use them freely.

- *Functoriality.* A based map $h : X \to Y$ induces a homomorphism $h_* : \pi_n(X) \to \pi_n(Y)$, $h_*[f] = [h \circ f]$, with $(h \circ k)_* = h_* \circ k_*$.
- *Homotopy invariance.* A homotopy equivalence induces isomorphisms on all π_n. In particular a contractible space has $\pi_n = 0$ for all n: $\pi_n(\mathbb{R}^k) = 0$, $\pi_n(\text{ball}) = 0$.
- *Products.* $\pi_n(X \times Y) \cong \pi_n(X) \times \pi_n(Y)$, as in (1.34).
- *Topological groups.* For a topological group G the pointwise product also gives $\pi_n(G)$ a group law, and by Eckmann–Hilton it agrees with (1.43). This is often the easiest way to add two elements of $\pi_3(\mathrm{SU}(2))$: multiply the matrices.

Coverings do not see higher homotopy

We found $\pi_1(S^1)$ by unwrapping the circle onto the line $\mathbb{R}$. The same unwrapping shows that the circle has *no* higher homotopy: Nash's (1.32), second line. The mechanism is general.

Key idea: Lifting spheres through a covering

Let $p : \tilde{X} \to X$ be a **covering map**: every point of X has a neighbourhood U such that $p^{-1}(U)$ is a disjoint union of copies of U, each mapped homeomorphically onto U by p (examples: $\mathbb{R} \to S^1$, $S^2 \to \mathbb{RP}^2$, $\mathrm{SU}(2) \to \mathrm{SO}(3)$, $\mathbb{R}^2 \to T^2$). Then for $n \geq 2$

$$p_* : \pi_n(\tilde{X}) \xrightarrow{\cong} \pi_n(X).$$

Reason: a based map $f : S^n \to X$ lifts to $\tilde f : S^n \to \tilde X$ because S^n is simply connected (below), and so does every homotopy of such maps (the cylinder $[0,1] \times S^n$ is simply connected too). Lifts of homotopic maps are homotopic, and p of a lift gives back the map.

Worked example 1.35: $\pi_n(S^1) = 0$ for $n \geq 2$, by an explicit lift

Let $f : S^n \to S^1$ be based, $f(x_0) = 1$, with $n \geq 2$. We build a lift $\tilde f : S^n \to \mathbb{R}$ with $e^{i\tilde f} = f$ and $\tilde f(x_0) = 0$. For any point $x \in S^n$ choose a path c from x_0 to x, lift the path $f \circ c$ in S^1 to $\mathbb{R}$ starting at 0 (the path lifting of §1.3.2), and let $\tilde f(x)$ be its endpoint.

- *The answer does not depend on the path.* If c' is another path from x_0 to x, then $c \cdot \bar c'$ is a loop in S^n at x_0. The difference of the two lifted endpoints is

$$\widetilde{f \circ c}(1) - \widetilde{f \circ c'}(1) \overset{(1)}{=} 2\pi\, W\big[f \circ (c \cdot \bar c')\big] \overset{(2)}{=} 2\pi\, W[\text{const}] \overset{(3)}{=} 0.$$

  (1) Lifting $f \circ c$ and then $f \circ \bar c'$ (which walks the second lift backwards) gives the lift of the loop $f \circ (c \cdot \bar c')$, whose total climb is 2π times its winding number (1.32).
  (2) $\pi_1(S^n) = 0$ (Example 1.27), so $c \cdot \bar c'$ contracts in S^n, hence $f \circ (c \cdot \bar c')$ contracts in S^1, and W is a homotopy invariant.
  (3) The constant loop has winding number 0.

- *The lift is null-homotopic, hence so is f.* On $\mathbb{R}$ we may interpolate linearly. Define

$$F(s,x) = \exp\big(i(1-s)\tilde f(x)\big), \qquad s \in [0,1].$$

  Then $F(0,x) = f(x)$, $F(1,x) = 1$, and $F(s,x_0) = e^0 = 1$ for all s: a based homotopy from f to the constant map.

So $\pi_n(S^1) = 0$ for $n \geq 2$. Together with $\pi_1(S^1) = \mathbb{Z}$ this is Nash's

$$\pi_m(S^1) = \begin{cases} \mathbb{Z}, & m = 1, \\ 0, & m > 1. \end{cases} \tag{1.46}$$

The same lift works for any simply connected source: every map from a simply connected space into S^1 is null-homotopic. For $n = 1$ the argument fails precisely at step (2), and the failure is measured by the winding number.

Worked example 1.36: Consequences of the lifting principle

- $T^k = \mathbb{R}^k/\mathbb{Z}^k$ is covered by $\mathbb{R}^k$, so $\pi_n(T^k) = \pi_n(\mathbb{R}^k) = 0$ for $n \geq 2$. A torus has only $\pi_1 = \mathbb{Z}^k$.
- Every closed orientable surface of genus $g \geq 1$ is covered by the plane (flat for $g = 1$, hyperbolic for $g \geq 2$), so $\pi_n(\Sigma_g) = 0$ for $n \geq 2$. Such spaces, with only one nonzero homotopy group, are the Eilenberg–MacLane spaces of Nash §4: S^1 is a $K(\mathbb{Z},1)$ and Σ_g is a $K(\pi_1(\Sigma_g),1)$.
- $S^2 \to \mathbb{RP}^2$ is a two-sheeted covering, so $\pi_n(\mathbb{RP}^2) = \pi_n(S^2)$ for $n \geq 2$; in particular $\pi_2(\mathbb{RP}^2) = \mathbb{Z}$ (point defects in nematics).
- $\mathrm{SU}(2) \to \mathrm{SO}(3)$ is a two-sheeted covering (§1.3.4), so $\pi_n(\mathrm{SO}(3)) = \pi_n(S^3)$ for $n \geq 2$. In particular $\pi_3(\mathrm{SO}(3)) = \pi_3(S^3) = \mathbb{Z}$.

1.3.7 Spheres in spheres, I: $\pi_m(S^n) = 0$ for $m < n$

Nash now turns to the most basic question: what are the homotopy groups of the spheres themselves? He quotes (from Bott and Tu) the answer for $m \le n$,

$$\pi_m(S^n) = \begin{cases} 0, & m < n, \\ \mathbb{Z}, & m = n, \end{cases} \tag{1.47}$$

and calls it "relatively easy". We now give the reasons. The first line is the argument of Example 1.27 in higher dimension.

Key idea: A lower-dimensional sphere slides off

If $m < n$, every map $f : S^m \to S^n$ misses a point after a small deformation, and a map into S^n minus a point is null-homotopic because S^n minus a point is $\mathbb{R}^n$.

The steps are these.

(a) *Smooth it.* Any continuous f is homotopic to a smooth map, through maps close to f (smooth the components of f in $\mathbb{R}^{n+1}$ by averaging over small balls, then divide by the length to project back onto S^n). Close maps are homotopic by the straight-line homotopy followed by projection, which never passes through 0 if the maps are less than a distance 1 apart.

(b) *Count dimensions.* The image of a smooth map from an m-dimensional manifold has zero n-dimensional volume when $m < n$ (locally it is the image of a small m-cube, which fits in an ε-neighbourhood of an m-dimensional patch: volume $\sim \varepsilon^{n-m} \to 0$). So there is a point $P \in S^n$ not in the image, and we can choose $P \neq x_0$.

(c) *Contract through the complement.* Let $\sigma : S^n \setminus \{P\} \to \mathbb{R}^n$ be stereographic projection from P, and $c = \sigma(x_0)$. Set

$$F(s, x) = \sigma^{-1}\Big((1 - s)\,\sigma\big(f(x)\big) + s\,c\Big). \tag{1.48}$$

We check that (1.48) is a based null-homotopy:

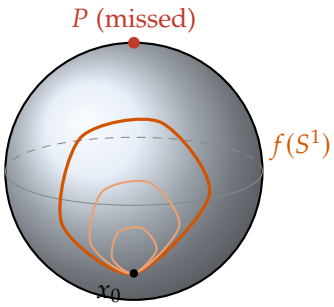
$$F(0, x) \overset{(1)}{=} \sigma^{-1}\big(\sigma(f(x))\big) = f(x), \qquad F(1, x) \overset{(2)}{=} \sigma^{-1}(c) = x_0,$$
$$F(s, x_0) \overset{(3)}{=} \sigma^{-1}\big((1 - s)\,c + s\,c\big) = \sigma^{-1}(c) = x_0.$$

(1) $f(x) \neq P$, so $\sigma(f(x))$ is defined; $\sigma^{-1} \circ \sigma = \mathrm{id}$.
(2) At $s = 1$ only the constant c survives.
(3) $f(x_0) = x_0$, so $\sigma(f(x_0)) = c$.

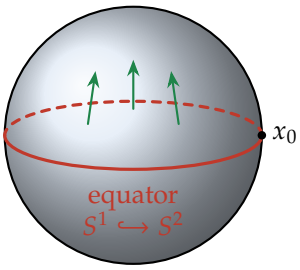
The straight line in $\mathbb{R}^n$ never reaches the "point at infinity" P, so F is continuous. Hence $[f] = 0$ and $\pi_m(S^n) = 0$ for $m < n$.

Watch out: Why the smoothing step is needed

Without step (a), step (b) fails: there are continuous surjections $S^1 \to S^2$ (Peano curves). The conclusion is still true, but only because every continuous map is homotopic to a smooth one. The whole of differential topology is full of this move: approximate a continuous object by a smooth one, then count dimensions.



a loop on S^2 misses P
and shrinks through $S^2 \setminus P \cong \mathbb{R}^2$



$m = n$ is different: the identity
$S^2 \to S^2$ hits every point

Figure 1.24: Left: for $m < n$ a (smoothed) map $S^m \to S^n$ leaves a point P uncovered. Stereographic projection from P turns the rest of the sphere into the plane, where the loop contracts to the base point (fainter copies). Right: the equator can be slid up (green arrows) over the north pole and shrunk, while the identity map of S^2, which covers every point, has no uncovered point to project from. That is why $\pi_2(S^2)$ can be nonzero.

1.3.8 Spheres in spheres, II: the degree and $\pi_n(S^n) = \mathbb{Z}$

For $m = n$ the dimension count gives nothing: an n-sphere can cover an n-sphere. The question becomes: *how many times* does it cover it? For $n = 1$ the answer was the winding number. For general n it is the **degree**. We give three equivalent working definitions. They are the same number seen by a counter, by an integrator, and by a topologist.

Working definition 1.22 (degree of a map $f : S^n \to S^n$)

(i) *Counting.* Pick a point y of the target that is a **regular value**: at every preimage $x \in f^{-1}(y)$ the Jacobian $\det(\mathrm{d}f_x)$ (computed in oriented local coordinates) is nonzero. Then there are finitely many preimages, and

$$\deg f = \sum_{x \in f^{-1}(y)} \operatorname{sgn} \det(\mathrm{d}f_x). \tag{1.49}$$

[each preimage counts $+1$ if f keeps orientation near it, -1 if it reverses it]

(ii) *Integrating.* Let ω be any n-form [an integrand $\rho(y)\,\mathrm{d}y^1 \cdots \mathrm{d}y^n$ in local coordinates] on the target with $\int_{S^n} \omega = 1$ (for instance the normalised volume form). Then

$$\deg f = \int_{S^n} f^*\omega. \tag{1.50}$$

[$f^*\omega$ is ω with $y = f(x)$ substituted, so $\mathrm{d}y$ becomes the Jacobian times $\mathrm{d}x$]

(iii) *For fields* $\vec{n} : S^2 \to S^2$ (unit vectors, $\vec{n} \cdot \vec{n} = 1$) in local coordinates (u^1, u^2) on the source:

$$\deg \vec{n} = \frac{1}{4\pi} \int \vec{n} \cdot \left(\partial_1 \vec{n} \times \partial_2 \vec{n}\right) \mathrm{d}u^1\,\mathrm{d}u^2. \tag{1.51}$$

The first definition makes it obvious that $\deg f$ is an integer; the second and third make it obvious that it is a homotopy invariant [unchanged when f is deformed continuously]; it is a theorem (below) that they agree, and that the answer does not depend on the choices of y or ω.

The integrand of (1.51) has a simple meaning. The small coordinate rectangle $\mathrm{d}u^1\,\mathrm{d}u^2$ in the source is mapped to a small parallelogram on the target sphere, spanned by the tangent vectors $\partial_1\vec{n}\,\mathrm{d}u^1$ and $\partial_2\vec{n}\,\mathrm{d}u^2$. Its area, with a sign telling whether its orientation agrees with the outward normal $\vec{n}$, is the triple product $\vec{n}\cdot(\partial_1\vec{n}\times\partial_2\vec{n})\,\mathrm{d}u^1\mathrm{d}u^2$. So (1.51) is "total signed area swept out on the target, divided by the area 4π of the unit sphere". It is (1.50) with ω the area form divided by 4π. For $n=1$ the analogue is the winding number (1.33): total signed angle swept, divided by 2π.

Worked example 1.37: The identity and the k-fold wrapping of S^2

Use spherical coordinates (θ,ϕ) on the source, oriented so that $\mathrm{d}\theta\,\mathrm{d}\phi$ is positive (this is the outward orientation, since $\hat\theta\times\hat\phi=\hat r$). For an integer k let

$$\vec{n}_k(\theta,\phi)=\big(\sin\theta\cos k\phi,\ \sin\theta\sin k\phi,\ \cos\theta\big),$$

which wraps each circle of latitude k times around itself; $\vec{n}_1$ is the identity. Then

$$\begin{aligned}\partial_\theta\vec{n}_k\times\partial_\phi\vec{n}_k &\overset{(1)}{=}(\cos\theta\cos k\phi,\ \cos\theta\sin k\phi,\ -\sin\theta)\times(-k\sin\theta\sin k\phi,\ k\sin\theta\cos k\phi,\ 0)\\ &\overset{(2)}{=}k\sin\theta\,\big(\sin\theta\cos k\phi,\ \sin\theta\sin k\phi,\ \cos\theta\big)=k\sin\theta\,\vec{n}_k,\end{aligned}$$

(1) Differentiate each component.

(2) Call the two vectors $\vec{a}$ and $\vec{b}$. The components of $\vec{a}\times\vec{b}$ are x: $\cos\theta\sin k\phi\cdot 0-(-\sin\theta)(k\sin\theta\cos k\phi)=k\sin^2\theta\cos k\phi$; y: $(-\sin\theta)(-k\sin\theta\sin k\phi)-\cos\theta\cos k\phi\cdot 0=k\sin^2\theta\sin k\phi$; z: $\cos\theta\cos k\phi\cdot k\sin\theta\cos k\phi+\cos\theta\sin k\phi\cdot k\sin\theta\sin k\phi=k\sin\theta\cos\theta$.

and therefore

$$\deg\vec{n}_k\overset{(1)}{=}\frac{1}{4\pi}\int_0^{2\pi}\!\!\int_0^{\pi}k\sin\theta\,(\vec{n}_k\cdot\vec{n}_k)\,\mathrm{d}\theta\,\mathrm{d}\phi\overset{(2)}{=}\frac{k}{4\pi}\cdot 2\cdot 2\pi=k.$$

(1) Formula (1.51) with the cross product just computed.

(2) $\vec{n}_k\cdot\vec{n}_k=1$, $\int_0^\pi\sin\theta\,\mathrm{d}\theta=2$, $\int_0^{2\pi}\mathrm{d}\phi=2\pi$.

Check by counting: take the regular value $y=(1,0,0)$. Its preimages have $\theta=\pi/2$ and $\cos k\phi=1$, i.e. $\phi=2\pi j/k$, $j=0,\dots,|k|-1$: exactly $|k|$ points. At each, the Jacobian is $\partial(\theta,k\phi)/\partial(\theta,\phi)=k$, with sign $\operatorname{sgn}k$. So (1.49) gives $|k|\operatorname{sgn}k=k$ as well. Every integer is the degree of some map.

In complex language: stereographic projection identifies S^2 with the Riemann sphere $\mathbb{C}\cup\{\infty\}$, $z=e^{i\phi}\tan(\theta/2)$, and $\vec{n}_k$ becomes (after a harmless reparametrisation of θ) $z\mapsto z^k$. More generally a rational map $z\mapsto P(z)/Q(z)$ with no common factors has degree $\max(\deg P,\deg Q)$: a generic point has that many preimages, all counted $+1$ because holomorphic maps preserve orientation.

Worked example 1.38: Reflections and the antipodal map

The reflection $r(x_1,x_2,\dots,x_{n+1})=(-x_1,x_2,\dots,x_{n+1})$ of S^n has degree -1. By counting: the point $y=(0,\dots,0,1)$ has the single preimage y itself, and near it r in the local coordinates $(x_1,\dots,x_n)$ is $\operatorname{diag}(-1,1,\dots,1)$, with determinant -1.

The antipodal map $a(x)=-x$ is the composition of $n+1$ reflections, one for each coordinate. Degrees multiply under composition (the preimage count of a composition is the product

of counts, signs included), so

$$\deg a = (-1)^{n+1}. \tag{1.52}$$

On S^2 we can confirm with (1.51):

$$\deg(-\vec{n}) \overset{(1)}{=} \frac{1}{4\pi}\int (-\vec{n})\cdot\big((-\partial_1\vec{n})\times(-\partial_2\vec{n})\big)\,\mathrm{d}^2u \overset{(2)}{=} -\frac{1}{4\pi}\int \vec{n}\cdot(\partial_1\vec{n}\times\partial_2\vec{n})\,\mathrm{d}^2u = -\deg\vec{n}.$$

(1) Replace $\vec{n}$ by $-\vec{n}$ in (1.51).
(2) Three minus signs make one.

With $\vec{n}$ the identity, the antipodal map of S^2 has degree -1, so it is *not* homotopic to the identity. On odd spheres it is: on S^1 it is the rotation by π, and on $S^{2k-1}\subset\mathbb{C}^k$ it is the end point of the rotation $x\mapsto e^{i\pi s}x$, $s\in[0,1]$.

Worked example 1.39: The hairy ball theorem

Claim: every continuous tangent vector field on S^{2k} vanishes somewhere. ("You cannot comb a hairy ball flat"; there is always a point on Earth where the horizontal wind speed is zero.)
Suppose $\vec{v}(x)$ is tangent, $\vec{v}(x)\cdot x = 0$, and never zero. Normalise, $\hat{v} = \vec{v}/|\vec{v}|$, and rotate each point x towards $\hat{v}(x)$ along a great circle:

$$F(s,x) = \cos(\pi s)\,x + \sin(\pi s)\,\hat{v}(x), \qquad s\in[0,1].$$

This stays on the sphere:

$$|F(s,x)|^2 \overset{(1)}{=} \cos^2(\pi s)\,|x|^2 + 2\cos(\pi s)\sin(\pi s)\,x\cdot\hat{v} + \sin^2(\pi s)\,|\hat{v}|^2 \overset{(2)}{=} \cos^2(\pi s)+\sin^2(\pi s) = 1.$$

(1) Expand the square.
(2) $|x| = |\hat{v}| = 1$ and $x\cdot\hat{v} = 0$ (tangency).

At $s=0$, F is the identity; at $s=1$, $F(1,x) = -x$ is the antipodal map. So the identity would be homotopic to the antipodal map. But their degrees are 1 and $(-1)^{2k+1} = -1$ by (1.52), and the degree is a homotopy invariant (below). Contradiction. On odd spheres there is no contradiction, and indeed $\vec{v}(x_1,x_2,\dots) = (-x_2,x_1,-x_4,x_3,\dots)$ is a nowhere-zero tangent field on S^{2k-1}.
This is the promised explanation of the remark in Example 1.9 that the antipodal map of S^2 is not homotopic to the identity. It is also our first "index theorem": the zeros of a vector field on S^2, counted with their indices, add up to the Euler characteristic $\chi(S^2) = 2$ (the Poincaré–Hopf theorem; the index of a zero is the degree of $\hat{v}$ on a small circle around it).

Why the degree is an integer and a homotopy invariant

We give the argument for fields $\vec{n}: S^2\to S^2$, where everything is explicit. Two facts carry it.

Fact 1: the degree integral does not change under deformations. Let $\vec{n}$ depend smoothly on a deformation parameter, and write $\delta\vec{n}$ for its derivative. Since $\vec{n}\cdot\vec{n} = 1$, the three vectors $\delta\vec{n}$, $\partial_1\vec{n}$, $\partial_2\vec{n}$ are all orthogonal to $\vec{n}$, so they lie in one plane and any triple product of them vanishes. With the density $q := \vec{n}\cdot(\partial_1\vec{n}\times\partial_2\vec{n})$,

$$\begin{aligned}\delta q &\overset{(1)}{=} \delta\vec{n}\cdot(\partial_1\vec{n}\times\partial_2\vec{n}) + \vec{n}\cdot(\partial_1\delta\vec{n}\times\partial_2\vec{n}) + \vec{n}\cdot(\partial_1\vec{n}\times\partial_2\delta\vec{n})\\ &\overset{(2)}{=} \vec{n}\cdot(\partial_1\delta\vec{n}\times\partial_2\vec{n}) + \vec{n}\cdot(\partial_1\vec{n}\times\partial_2\delta\vec{n})\end{aligned}$$

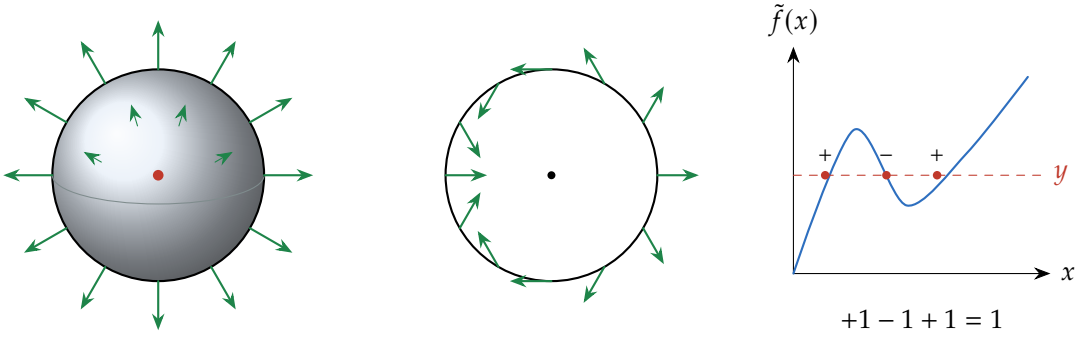


Figure 1.25: Pictures of degree. Left: the hedgehog field $\vec n(\vec x) = \hat r$ on a sphere surrounding a point defect (red) is the identity map $S^2 \to S^2$, of degree 1. Middle: the equator of $\vec n_2$ of Example 1.37: as we go once around, the arrow turns twice. Right: counting preimages, drawn for S^1 via the lift $\tilde f$. The horizontal line y is crossed three times, twice going up (+) and once going down (−). The net count 1 is the same for every regular value y: moving the line creates or destroys crossings in ± pairs.

$$\overset{(3)}{=} \partial_1\big[\vec n \cdot (\delta\vec n \times \partial_2\vec n)\big] + \partial_2\big[\vec n \cdot (\partial_1\vec n \times \delta\vec n)\big].$$

(1) Product rule on the triple product; δ commutes with ∂_i.
(2) The first term is a triple product of three vectors tangent to the sphere at $\vec n$: zero.
(3) Expand the right side by the product rule. The terms where ∂_i hits $\vec n$ outside the bracket are $\partial_1\vec n \cdot (\delta\vec n \times \partial_2\vec n)$ and $\partial_2\vec n \cdot (\partial_1\vec n \times \delta\vec n)$: triple products of tangent vectors, zero. The terms with second derivatives are $\vec n \cdot (\delta\vec n \times \partial_1\partial_2\vec n) + \vec n \cdot (\partial_2\partial_1\vec n \times \delta\vec n) = 0$ by antisymmetry of $\times$. What is left is the line above.

So δq is a total divergence, and its integral over the closed sphere vanishes (Stokes, or the divergence theorem, with no boundary). Hence $\delta(\deg \vec n) = 0$: the integral (1.51) is constant along any smooth homotopy. The same holds for (1.50) in general, in one line: a homotopy changes $f^*\omega$ by an exact form $\mathrm{d}\eta$, and $\int_{S^n} \mathrm{d}\eta = \int_\varnothing \eta = 0$. (This is the fact "the integral of an exact form over a closed manifold vanishes" of Chapter T2; de Rham cohomology in Nash §4 turns it into a theory.)

Fact 2: the integral equals the signed count. By Fact 1 applied to the *target* form, $\int f^*\omega$ depends on ω only through $\int \omega = 1$: if ω' is another n-form with total integral 1, then $\omega' - \omega = \mathrm{d}\eta$ (on S^n a top form with zero integral is exact; this is $H^n_{\mathrm{dR}}(S^n) = \mathbb{R}$), and $\int f^*\mathrm{d}\eta = \int \mathrm{d}f^*\eta = 0$. Now choose ω to be a bump form concentrated in a tiny disc D around a regular value y. Then $f^*\omega$ lives only on $f^{-1}(D)$, which (by the inverse function theorem at each regular preimage) is a disjoint union of small discs $D_1, \dots, D_N$ around the preimages $x_1, \dots, x_N$, each mapped diffeomorphically onto D. So

$$\int_{S^n} f^*\omega \overset{(1)}{=} \sum_{j=1}^{N} \int_{D_j} f^*\omega \overset{(2)}{=} \sum_{j=1}^{N} \operatorname{sgn}\det(\mathrm{d}f_{x_j}) \int_D \omega \overset{(3)}{=} \sum_{j=1}^{N} \operatorname{sgn}\det(\mathrm{d}f_{x_j}).$$

(1) $f^*\omega = 0$ outside $f^{-1}(D) = D_1 \cup \cdots \cup D_N$.
(2) Change of variables $x \mapsto f(x)$ on each D_j: the integral of a pulled-back form is the integral of the form, times +1 if f preserves orientation there and -1 if it reverses it.
(3) $\int_D \omega = \int_{S^n} \omega = 1$.

This proves that (1.49) and (1.50) agree, that the count is independent of the regular value y,

and that the integral is an integer. (Regular values exist, in fact almost every y is one: this is Sard's theorem.)

Key idea: Nash's (1.33), second line: $\pi_n(S^n) \cong \mathbb{Z}$ (Hopf)

The degree defines a group isomorphism

$$\deg : \pi_n(S^n) \xrightarrow{\cong} \mathbb{Z}.$$

It is well defined by Fact 1; it is onto because the maps $\vec{n}_k$ (and their analogues, suspensions of $z \mapsto z^k$) realise every integer; it is a homomorphism because the preimages of y under $f + g$ are those of f (squeezed into one half of the cube) together with those of g. That it is one-to-one, i.e. *maps of equal degree are homotopic*, is Hopf's theorem: the one genuinely hard step, which we take on trust. Since S^n is simply connected for $n \geq 2$, base points do not matter and $[S^n, S^n] = \pi_n(S^n) = \mathbb{Z}$ (Example 1.34).

Physical picture: Baby skyrmions and the Belavin–Polyakov bound

In a two-dimensional ferromagnet the magnetisation direction is a unit vector field $\vec{n}(x, y)$. Finite energy requires $\vec{n} \to \hat{z}$ at infinity, so we may add the point at infinity and regard $\vec{n}$ as a map from $\mathbb{R}^2 \cup \{\infty\} \cong S^2$ to S^2. Its degree $Q = \frac{1}{4\pi} \int q \, \mathrm{d}x \, \mathrm{d}y$ is the **skyrmion number**; it is conserved by any smooth time evolution, by Fact 1. It also bounds the exchange energy $E = \frac{1}{2} \int |\partial_i \vec{n}|^2 \, \mathrm{d}^2x$ from below. Since a square is non-negative,

$$\begin{aligned} 0 &\overset{(1)}{\leq} \int \left|\partial_i \vec{n} \pm \varepsilon_{ij}\, \vec{n} \times \partial_j \vec{n}\right|^2 \mathrm{d}^2x \\ &\overset{(2)}{=} \int \Big(|\partial_i \vec{n}|^2 + |\vec{n} \times \partial_j \vec{n}|^2 \pm 2\varepsilon_{ij}\, \partial_i \vec{n} \cdot (\vec{n} \times \partial_j \vec{n}) \Big) \mathrm{d}^2x \\ &\overset{(3)}{=} \int \left(2|\partial_i \vec{n}|^2 \mp 4\, q\right) \mathrm{d}^2x \overset{(4)}{=} 4E \mp 16\pi Q, \end{aligned}$$

(1) The integrand is a sum of squares (sum over $i = 1, 2$; $\varepsilon_{12} = -\varepsilon_{21} = 1$).
(2) Expand; $\varepsilon_{ij}\varepsilon_{ik} = \delta_{jk}$ in two dimensions turns the second square into $\sum_j |\vec{n} \times \partial_j \vec{n}|^2$.
(3) $|\vec{n} \times \partial_j \vec{n}| = |\partial_j \vec{n}|$ because $\partial_j \vec{n} \perp \vec{n}$ and $|\vec{n}| = 1$; and the cross term is $\varepsilon_{ij}\, \vec{n} \cdot (\partial_j \vec{n} \times \partial_i \vec{n})$ (cyclic triple product), which for $(i, j) = (1, 2)$ and $(2, 1)$ gives $-q$ twice.
(4) $\int |\partial_i \vec{n}|^2 = 2E$ and $\int q = 4\pi Q$.

So $E \geq 4\pi|Q|$, with equality exactly when $\partial_i \vec{n} = \mp \varepsilon_{ij}\, \vec{n} \times \partial_j \vec{n}$, a first-order "self-duality" equation. Topology forces a minimum energy in each sector. This is the two-dimensional model of the instanton bound $S_{\mathrm{YM}} \geq 8\pi^2|k|/g^2$ of Chapter 8.

Try it: Degree of a map given by a formula

Compute the degree of $f : \mathbb{C} \cup \{\infty\} \to \mathbb{C} \cup \{\infty\}$, $f(z) = \bar{z}^3$, by counting the preimages of $y = 1$ with signs.
Answer: the preimages are the three cube roots of unity. Near each, f is the composition of the holomorphic map $z \mapsto z^3$ (orientation preserving, Jacobian $|3z^2|^2 > 0$) with complex conjugation (a reflection, Jacobian -1). So each counts -1 and $\deg f = -3$.

1.3.9 Spheres in spheres, III: the Hopf map and $\pi_3(S^2) = \mathbb{Z}$

So far the pattern is tidy: $\pi_m(S^n) = 0$ below the dimension and $\mathbb{Z}$ at the dimension. One might guess that $\pi_m(S^n) = 0$ for $m > n$ as well, as it is for S^1. It is not. The first counterexample, found by Hopf in 1931, is a map from S^3 onto S^2 that cannot be deformed to a constant. Every physicist already knows it: it is the map from a spin-$\frac{1}{2}$ state to its Bloch vector.

Working definition 1.23 (the Hopf map)

Write $S^3 = \{(z_1, z_2) \in \mathbb{C}^2 : |z_1|^2 + |z_2|^2 = 1\}$, i.e. normalised spinors $\psi = \binom{z_1}{z_2}$. The **Hopf map** $h : S^3 \to S^2$ sends a spinor to the expectation value of the Pauli matrices:

$$h(\psi) = \vec{n}, \qquad n_a = \psi^\dagger \sigma_a \psi, \qquad \vec{n} = \big(2\,\mathrm{Re}(\bar{z}_1 z_2),\ 2\,\mathrm{Im}(\bar{z}_1 z_2),\ |z_1|^2 - |z_2|^2\big). \tag{1.53}$$

[$\vec{n}$ is the Bloch vector. It has unit length, since $|\vec{n}| = |z_1|^2 + |z_2|^2 = 1$]

The components follow from the Pauli matrices of (1.37): $\psi^\dagger\sigma_1\psi = \bar{z}_1 z_2 + \bar{z}_2 z_1 = 2\,\mathrm{Re}(\bar{z}_1 z_2)$, $\psi^\dagger\sigma_2\psi = -i\bar{z}_1 z_2 + i\bar{z}_2 z_1 = 2\,\mathrm{Im}(\bar{z}_1 z_2)$ and $\psi^\dagger\sigma_3\psi = |z_1|^2 - |z_2|^2$. The image really is on the unit sphere:

$$|\vec{n}|^2 \overset{(1)}{=} 4\,|\bar{z}_1 z_2|^2 + \big(|z_1|^2 - |z_2|^2\big)^2 \overset{(2)}{=} \big(|z_1|^2 + |z_2|^2\big)^2 \overset{(3)}{=} 1.$$

(1) $(2\,\mathrm{Re}\,w)^2 + (2\,\mathrm{Im}\,w)^2 = 4|w|^2$ with $w = \bar{z}_1 z_2$.
(2) $4ab + (a-b)^2 = (a+b)^2$ with $a = |z_1|^2$, $b = |z_2|^2$.
(3) ψ is normalised.

The fibres are circles: the global phase

Multiplying ψ by a phase does not change $\vec{n}$, because $(e^{i\alpha}\psi)^\dagger\sigma_a(e^{i\alpha}\psi) = e^{-i\alpha}e^{i\alpha}\psi^\dagger\sigma_a\psi$. Conversely, if $h(\psi) = h(\psi')$ then $\psi' = e^{i\alpha}\psi$ for some α. Indeed $\vec{n}$ fixes $|z_1|^2 = \frac{1}{2}(1 + n_3)$ and $|z_2|^2 = \frac{1}{2}(1 - n_3)$ and the product $\bar{z}_1 z_2 = \frac{1}{2}(n_1 + i n_2)$. If $z_1 \neq 0$, write $z_1' = e^{i\alpha} z_1$ (same modulus); then $\bar{z}_1' z_2' = \bar{z}_1 z_2$ gives $z_2' = e^{i\alpha} z_2$. If $z_1 = 0$ then $z_1' = 0$, and z_2, z_2' are two unit complex numbers, so again $z_2' = e^{i\alpha} z_2$. So

$$h^{-1}(\vec{n}) = \{e^{i\alpha}\psi : \alpha \in [0, 2\pi)\} \cong S^1.$$

The three-sphere is a union of disjoint circles, one over each point of S^2:

$$S^1 \longrightarrow S^3 \xrightarrow{\ h\ } S^2. \tag{1.54}$$

This is the **Hopf fibration**, our first nontrivial fibre bundle (Nash §5, next part). In quantum-mechanical language: the space of normalised spinors is S^3, the space of physical states (rays) is the Bloch sphere $S^2 = \mathbb{CP}^1$, and the fibre is the unobservable global phase U(1). The same bundle, viewed over S^2 as a U(1) bundle, is the Dirac monopole of charge one.

Dictionary: the Hopf fibration

normalised spinor $\psi \in \mathbb{C}^2$	point of S^3
Bloch vector $\langle\vec{\sigma}\rangle$, or the ray $[z_1 : z_2] \in \mathbb{CP}^1$	point of S^2
global phase $e^{i\alpha}$	fibre $S^1 = \mathrm{U}(1)$
Berry connection $i\psi^\dagger \mathrm{d}\psi$	connection on the bundle
Berry phase of a loop on the Bloch sphere	holonomy; $-\frac{1}{2}\times$ solid angle

Why h is not null-homotopic: linked fibres

Pick two different points $\vec{n}, \vec{n}'$ of S^2. Their preimages are two disjoint circles in S^3. The claim is that they are *linked*, and that the linking number cannot change under homotopy.

Take the north and south poles. With $z_1 = x_1 + ix_2$, $z_2 = x_3 + ix_4$:

- $h^{-1}(0,0,1)$: $n_3 = 1$ forces $|z_1| = 1$, $z_2 = 0$: the circle $C_N = \{x_1^2 + x_2^2 = 1,\ x_3 = x_4 = 0\}$.
- $h^{-1}(0,0,-1)$: $z_1 = 0$, $|z_2| = 1$: the circle $C_S = \{x_3^2 + x_4^2 = 1,\ x_1 = x_2 = 0\}$.

To see them, project S^3 stereographically from the point $(0,0,0,1)$ onto $\mathbb{R}^3$: $(x_1, x_2, x_3, x_4) \mapsto (x_1, x_2, x_3)/(1 - x_4)$. Then C_N (where $x_4 = 0$) becomes the unit circle in the (x_1, x_2) plane, and C_S becomes $\{(0, 0, x_3/(1 - x_4))\}$, which runs over the entire x_3-axis as the point moves around C_S (through ∞ at $x_4 = 1$). The axis pierces the disc bounded by the unit circle exactly once: the linking number is 1 (Figure 1.26). Any two fibres of h are linked once in the same way.

Key idea: The Hopf invariant

For a smooth map $f : S^3 \to S^2$ and two regular values $y \neq y'$, the **Hopf invariant** $H(f)$ is the linking number of the curves $f^{-1}(y)$ and $f^{-1}(y')$ in S^3. It is a homotopy invariant, and

$$H : \pi_3(S^2) \xrightarrow{\cong} \mathbb{Z}, \qquad H(h) = 1.$$

So $\pi_3(S^2) = \mathbb{Z}$, generated by the Hopf map. A constant map has $H = 0$ (the preimage of $y' \neq$ the constant value is empty), so h is not null-homotopic.

There is also an integral formula, due to Whitehead, which makes the Hopf invariant look like physics. Let ω be the area form of S^2 divided by 4π, and $F := f^*\omega$, a closed 2-form on S^3. Since every closed 2-form on S^3 is exact (Nash §4: $H^2_{\mathrm{dR}}(S^3) = 0$), $F = \mathrm{d}A$ for some 1-form A, and

$$H(f) = \int_{S^3} A \wedge F. \tag{1.55}$$

Read F as a magnetic field $\vec{B}$ on (compactified) $\mathbb{R}^3$ and A as its vector potential: (1.55) is the **magnetic helicity** $\int \vec{A} \cdot \vec{B}\, \mathrm{d}^3x$ of plasma physics, which measures how much the lines of $\vec{B}$ are linked. Here the field lines of $\vec{B}$ are exactly the fibres $f^{-1}(y)$, and each pair links H times. Knotted solitons in the Faddeev–Skyrme model ("hopfions"), and knotted vortex configurations in some magnets, are classified by exactly this integer.

Worked example 1.40: The Hopf map in the language of spinors: its degree on a slice

A consistency check that ties $\pi_3(S^2)$ to $\pi_2(S^2)$. Restrict h to the set $\Sigma = \{(z_1, z_2) \in S^3 : z_2 \in \mathbb{R},\ z_2 \geq 0\}$ where z_2 is real and non-negative. Every fibre $\{e^{i\alpha}\psi\}$ meets Σ exactly once if $z_2 \neq 0$ (choose α to make z_2 real positive), and the fibre over the north pole ($z_2 = 0$) lies entirely in the boundary circle $z_2 = 0$ of Σ. So Σ is a disc $\{|z_1| \leq 1\}$ (with $z_2 = \sqrt{1 - |z_1|^2}$), and h maps its interior one-to-one onto S^2 minus the north pole, and its boundary circle to the north pole. Explicitly, with $z_1 = re^{i\phi}$, $z_2 = \sqrt{1 - r^2}$:

$$\vec{n} \overset{(1)}{=} \left(2r\sqrt{1 - r^2}\cos\phi,\ -2r\sqrt{1 - r^2}\sin\phi,\ 2r^2 - 1\right) \overset{(2)}{=} \left(\sin\theta\cos\phi,\ -\sin\theta\sin\phi,\ -\cos\theta\right),$$

(1) (1.53): $\bar{z}_1 z_2 = r\sqrt{1 - r^2}\, e^{-i\phi}$ and $|z_1|^2 - |z_2|^2 = r^2 - (1 - r^2)$.

(2) Put $r = \sin(\theta/2)$, so $2r\sqrt{1 - r^2} = \sin\theta$ and $2r^2 - 1 = -\cos\theta$, with $\theta \in [0, \pi]$ as $r \in [0, 1]$.

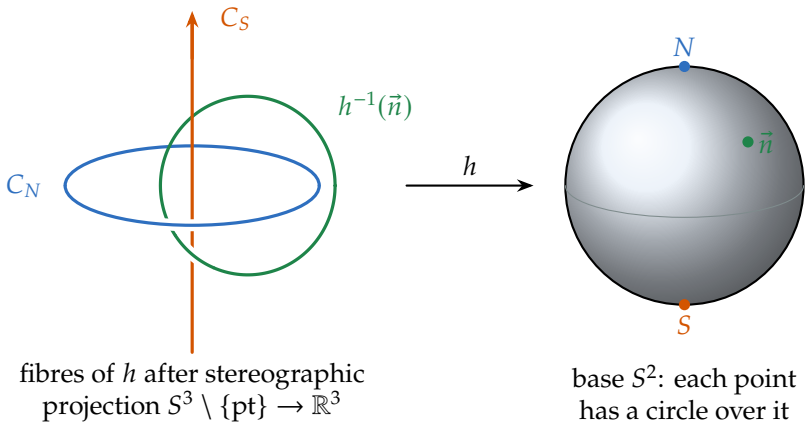

Figure 1.26: The Hopf fibration. Left: in S^3 (drawn in $\mathbb{R}^3$ by stereographic projection) the fibre over the north pole is the unit circle C_N (blue), the fibre over the south pole is the vertical axis C_S closed up through infinity (orange), and the fibre over any other point is a circle (green) that links both. Every pair of fibres links exactly once: the Hopf invariant of h is 1. Right: the base.

This is the disc, with its boundary collapsed, wrapped once over the sphere: a degree ± 1 map $D^2/\partial D^2 \cong S^2 \to S^2$. So the Hopf map "contains" the generator of $\pi_2(S^2)$. Read in reverse, this is the boundary map $\partial : \pi_2(S^2) \to \pi_1(S^1)$ of the exact sequence of §1.3.11: the boundary circle of Σ, which is a whole fibre, is the loop of phases that the generator of $\pi_2(S^2)$ is sent to.

1.3.10 The table of $\pi_m(S^n)$

Nash states the general situation for $m > n$, quoting Serre's theorem (1951):

$$\pi_m(S^n) = \begin{cases} \text{a finite group}, & m > n,\ n \text{ odd}, \\ \text{a finite group}, & m > n,\ n \text{ even},\ m \neq 2n-1, \\ \mathbb{Z} \times F, & m > n,\ n \text{ even},\ m = 2n-1, \end{cases} \tag{1.56}$$

with F some finite group. In words: apart from $\pi_n(S^n) = \mathbb{Z}$, the only infinite homotopy groups of spheres are $\pi_{2n-1}(S^n)$ for even n, and each of these contains exactly one copy of $\mathbb{Z}$. The extra $\mathbb{Z}$ is detected by the Hopf invariant, defined for maps $S^{2n-1} \to S^n$ as the linking number of two $(n-1)$-dimensional preimages in S^{2n-1}. (For odd n the linking number of two preimages is antisymmetric under exchanging them, so the Hopf invariant vanishes.) Maps of Hopf invariant 1 exist only for $n = 2, 4, 8$; they are built exactly like (1.53) from the complex numbers, the quaternions and the octonions ($S^3 \to S^2$, $S^7 \to S^4$, $S^{15} \to S^8$). This is Adams' theorem, and it is why there are only four normed division algebras $\mathbb{R}, \mathbb{C}, \mathbb{H}, \mathbb{O}$.

The actual groups are known only in a range. Nash remarks that "$\pi_m(S^2)$ is not known for all m"; that is still true. Figure 1.27 tabulates the beginning, arranged so that its structure is visible: row k lists $\pi_{n+k}(S^n)$, the maps that go up in dimension by k.

Stability: the Freudenthal suspension theorem

Look along a row of Figure 1.27. The entries change for small n and then settle down. Nash's (1.35)–(1.36) record this:

$$\pi_{m+n}(S^n) = \pi_{m+n+1}(S^{n+1}) = \cdots =: G_m \quad \text{for } n \geq m+2, \qquad G_m = \pi_{2m+2}(S^{m+2}). \tag{1.57}$$

	S^1	S^2	S^3	S^4	S^5	S^6	S^7	S^8	G_k
$k=0$	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}$
$k=1$	0	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$
$k=2$	0	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$
$k=3$	0	$\mathbb{Z}_2$	$\mathbb{Z}_{12}$	$\mathbb{Z}\times\mathbb{Z}_{12}$	$\mathbb{Z}_{24}$	$\mathbb{Z}_{24}$	$\mathbb{Z}_{24}$	$\mathbb{Z}_{24}$	$\mathbb{Z}_{24}$
$k=4$	0	$\mathbb{Z}_{12}$	$\mathbb{Z}_2$	$\mathbb{Z}_2^2$	$\mathbb{Z}_2$	0	0	0	0
$k=5$	0	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2^2$	$\mathbb{Z}_2$	$\mathbb{Z}$	0	0	0
$k=6$	0	$\mathbb{Z}_2$	$\mathbb{Z}_3$	$\mathbb{Z}_{24}\times\mathbb{Z}_3$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_2$
$k=7$	0	$\mathbb{Z}_3$	$\mathbb{Z}_{15}$	$\mathbb{Z}_{15}$	$\mathbb{Z}_{30}$	$\mathbb{Z}_{60}$	$\mathbb{Z}_{120}$	$\mathbb{Z}\times\mathbb{Z}_{120}$	$\mathbb{Z}_{240}$

Figure 1.27: Homotopy groups of spheres: row k, column S^n contains $\pi_{n+k}(S^n)$. The diagonal $k=0$ is $\pi_n(S^n)=\mathbb{Z}$ (the degree). The red boxes are the infinite groups $\pi_{2n-1}(S^n)$, n even, predicted by Serre (1.56) and detected by the Hopf invariant. In the shaded region $n \geq k+2$ each row is constant: this is the stability (1.57) of Nash's (1.35), and the constant value is the stable group G_k of (1.36), listed on the right. Column S^1 is (1.46); column S^2 is column S^3 shifted down by one row (Example 1.45).

(Nash's m is our row label k.) The mechanism is suspension. A map $f : S^p \to S^n$ gives a map of suspensions

$$Sf : S^{p+1} = S^1 \wedge S^p \to S^1 \wedge S^n = S^{n+1}, \qquad (t,x) \mapsto (t, f(x)),$$

which "does f on every meridian" (Figure 1.12). A homotopy of f gives a homotopy of Sf, so this defines the **suspension homomorphism** $E : \pi_p(S^n) \to \pi_{p+1}(S^{n+1})$.

Key idea: Freudenthal (1937)

$E : \pi_p(S^n) \to \pi_{p+1}(S^{n+1})$ is an isomorphism for $p < 2n-1$ and onto for $p = 2n-1$. With $p = n+k$ the condition $p < 2n-1$ is $n \geq k+2$, which gives (1.57).

Why a bound like $p < 2n-1$? By the adjunction (1.25), $\pi_{p+1}(S^{n+1}) = [S^1 \wedge S^p, S^{n+1}]_0 = [S^p, \Omega S^{n+1}]_0 = \pi_p(\Omega S^{n+1})$, and under this identification E is induced by the inclusion

$$j : S^n \hookrightarrow \Omega S^{n+1}, \qquad x \mapsto \big(\text{the meridian loop of } S^{n+1} \text{ through } x\big).$$

So E is an isomorphism exactly when the loop space ΩS^{n+1} "looks like" S^n as far as p-spheres can tell. James showed that ΩS^{n+1} is built from S^n by attaching further cells of dimensions $2n, 3n, 4n, \ldots$ (roughly: loops that pass over the north pole twice, three times, ...). Now the general-position count (1.4) does the rest. A p-sphere in a space can be pushed off the interior of a $2n$-cell if $p < 2n$, so every element of $\pi_p(\Omega S^{n+1})$ comes from S^n (this is "onto" for $p \leq 2n-1$); a homotopy between two p-spheres is a $(p+1)$-dimensional object, which can be pushed off if $p+1 < 2n$ (this is "one-to-one" for $p < 2n-1$). Beyond that range the $2n$-cell makes itself felt, and it is precisely there that the Hopf invariant lives.

Worked example 1.41: Stability at work: from $\pi_3(S^2)=\mathbb{Z}$ to $\pi_4(S^3)=\mathbb{Z}_2$

Take $n=2$, $p=3=2n-1$. Freudenthal says $E : \pi_3(S^2) \to \pi_4(S^3)$ is onto but need not be one-to-one. Indeed $\pi_3(S^2) = \mathbb{Z}$ (generated by the Hopf map h) while $\pi_4(S^3) = \mathbb{Z}_2$

(generated by the suspension $\eta = Sh$), so

$$E(k\,[h]) = k\,[\eta] = \begin{cases} 0, & k \text{ even}, \\ [\eta], & k \text{ odd}. \end{cases}$$

The linking-number invariant dies on suspension: in S^4 two circles can be unlinked, and only a mod-2 remnant survives. From $n = 3$ on, E is an isomorphism, and the row $k = 1$ is constant: $G_1 = \mathbb{Z}_2$. Physics: since $\mathrm{SU}(2) \cong S^3$, this says $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$, and that is the origin of Witten's global SU(2) anomaly: a theory with an odd number of Weyl fermion doublets is inconsistent (Chapter 10).

Watch out: Homotopy groups do not stop at the dimension

S^2 is two-dimensional, yet $\pi_m(S^2) \neq 0$ for every $m \geq 2$ that has been computed. Maps of big spheres into small spheres can wrap in intricate, knotted ways (the fibres of the Hopf map are linked circles). By contrast, the cohomology groups of Nash §4 vanish above the dimension of the space. This is the main reason Nash calls homotopy groups "very difficult to calculate" and turns to cohomology.

1.3.11 Exact sequences

How were the entries of Figure 1.27 computed, and how do we know that $\pi_1(\mathrm{SU}(n)) = 0$ or $\pi_3(\mathrm{SU}(3)) = \mathbb{Z}$? The main tool is the exact sequence. Nash introduces exact sequences in §4 (for complexes) and uses the exact homotopy sequence of a fibre bundle in §5; since these tools are behind much of what we have just stated, we give a working introduction now.

Working definition 1.24 (exact sequence)

A sequence of groups and homomorphisms [maps respecting the group law, $f(aa') = f(a)f(a')$]

$$\cdots \longrightarrow A \xrightarrow{f} B \xrightarrow{g} C \longrightarrow \cdots$$

is **exact at** B if $\mathrm{Im}\, f = \mathrm{Ker}\, g$: what f produces is exactly what g kills. It is **exact** if it is exact at every place. Operational consequences (with 0 the trivial group):

- $0 \to A \xrightarrow{f} B$ exact $\iff$ f is one-to-one;
- $B \xrightarrow{g} C \to 0$ exact $\iff$ g is onto;
- $0 \to A \xrightarrow{f} B \to 0$ exact $\iff$ f is an isomorphism;
- $0 \to A \xrightarrow{f} B \xrightarrow{g} C \to 0$ exact (a **short exact sequence**) $\iff$ A is a subgroup of B and $C \cong B/A$ [B with any two elements differing by an element of A counted as the same].

Worked example 1.42: Short exact sequences a physicist knows

- $0 \to \mathbb{Z} \xrightarrow{\times 2} \mathbb{Z} \to \mathbb{Z}_2 \to 0$: doubling is one-to-one, its image is the even integers, and the quotient is "even or odd".

- $0 \to \mathbb{Z} \to \mathbb{R} \xrightarrow{\theta \mapsto e^{i\theta}} \mathrm{U}(1) \to 1$ with the first map $n \mapsto 2\pi n$: the kernel of $\theta \mapsto e^{i\theta}$ is $2\pi\mathbb{Z}$. This is the helix of Figure 1.16 as algebra.
- $1 \to \mathbb{Z}_2 \to \mathrm{SU}(2) \xrightarrow{R} \mathrm{SO}(3) \to 1$, with $\mathbb{Z}_2 = \{\pm\mathbf{1}\}$: the kernel of $U \mapsto R(U)$ in (1.38) is $\pm\mathbf{1}$, and R is onto.

The exact homotopy sequence of a fibration

Let $p : E \to B$ be a fibre bundle with fibre $F = p^{-1}(b_0)$ over the base point b_0, with base point $e_0 \in F$. Examples: the covering $\mathbb{R} \to S^1$ (fibre $\mathbb{Z}$, a discrete set); $\mathrm{SU}(2) \to \mathrm{SO}(3)$ (fibre $\{\pm\mathbf{1}\}$); the Hopf fibration (1.54) (fibre S^1). The essential property, which Nash takes as the definition of a *fibration* in §5, is *homotopy lifting*: a homotopy in B can be lifted to a homotopy in E, once the lift of its starting map is given. For coverings this is the path lifting of §1.3.2.

Key idea: The long exact homotopy sequence

For a fibration $F \xrightarrow{i} E \xrightarrow{p} B$ there is an exact sequence

$$\cdots \to \pi_n(F) \xrightarrow{i_*} \pi_n(E) \xrightarrow{p_*} \pi_n(B) \xrightarrow{\partial} \pi_{n-1}(F) \xrightarrow{i_*} \pi_{n-1}(E) \to \cdots \to \pi_0(E) \to \pi_0(B). \quad (1.58)$$

Here i_* and p_* are induced by inclusion and projection, and ∂ is the **boundary map**: lift a sphere in the base to a disc in the total space and look at the boundary of the disc, which lies in the fibre (Figure 1.28).

Let us see ∂ concretely in the cube picture. An element of $\pi_n(B)$ is a map $f : I^n \to B$ with $f(\partial I^n) = b_0$. Regard it as a homotopy, in the last variable t_n, of maps of the $(n-1)$-cube, starting at the constant map. Lift it, starting from the constant map at e_0: we get $\tilde{f} : I^n \to E$ with $p \circ \tilde{f} = f$. All faces of the cube except the top one ($t_n = 1$) still go to e_0 (they are lifts of constant maps that start at e_0, and such a lift can be chosen constant). The top face goes into $p^{-1}(b_0) = F$, and its boundary goes to e_0. So the top face is an element of $\pi_{n-1}(F)$: that is $\partial[f]$.

For $n = 1$ this is exactly the lift of a loop: a loop γ in B at b_0 lifts to a path in E from e_0 to some point $\tilde{\gamma}(1)$ of the fibre, and $\partial[\gamma]$ is the component of F containing that endpoint.

Why exactness holds, in two representative places.

- *At $\pi_n(E)$:* $\mathrm{Im}\, i_* = \mathrm{Ker}\, p_*$. If g is a sphere in the fibre, then $p \circ g$ is the constant map b_0, so $p_* i_* = 0$. Conversely, if $g : S^n \to E$ has $p \circ g$ null-homotopic, lift the null-homotopy of $p \circ g$ to a homotopy of g; at its end g has been deformed to a map whose projection is constant, i.e. a sphere in F.
- *At $\pi_n(B)$:* $\mathrm{Im}\, p_* = \mathrm{Ker}\, \partial$. If $f = p \circ g$ comes from E, then g itself is a lift with all faces at e_0, so the top face is constant: $\partial[f] = 0$. Conversely, if the top face is null-homotopic in F, use that null-homotopy to push the top face of $\tilde{f}$ to e_0 as well; the result is a sphere in E lying over f.

The remaining places are similar. We now use (1.58) as a machine. The recurring pattern: if the two neighbours of a group are zero, the map between them is an isomorphism.

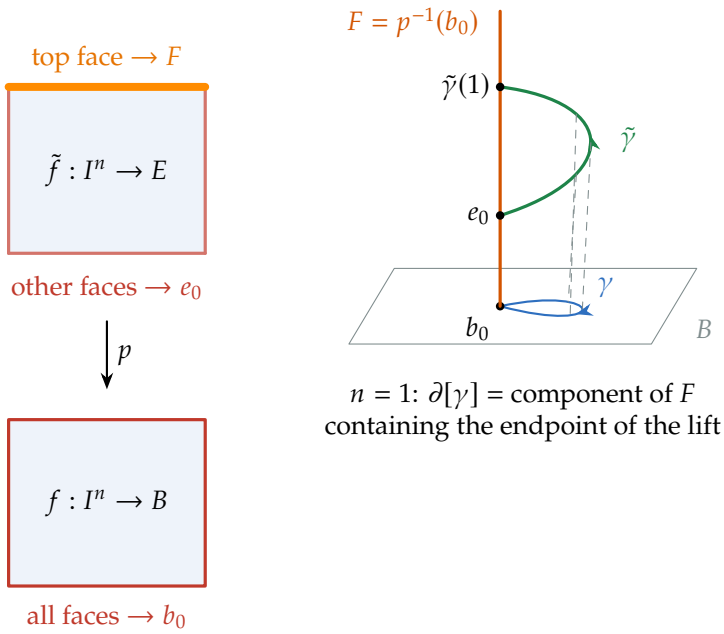

Figure 1.28: The boundary map $\partial : \pi_n(B) \to \pi_{n-1}(F)$. Left: an element of $\pi_n(B)$ (all faces to b_0) lifts to a map of the cube into E with all faces but the top one at e_0. The top face (orange) lies in the fibre over b_0 and defines $\partial[f] \in \pi_{n-1}(F)$. Right: for $n = 1$, a loop in the base lifts to a path that ends somewhere in the fibre. For $\mathbb{R} \to S^1$ the endpoint is $2\pi W$: the boundary map is the winding number.

Worked example 1.43: The circle again: $\mathbb{Z} \to \mathbb{R} \to S^1$

Here $F = 2\pi\mathbb{Z}$ is discrete, so $\pi_k(F) = 0$ for $k \geq 1$ and $\pi_0(F) = \mathbb{Z}$ (one component per point), and $E = \mathbb{R}$ is contractible, so $\pi_k(\mathbb{R}) = 0$. The segments of (1.58) read

$$\underbrace{\pi_n(\mathbb{R})}_{0} \to \pi_n(S^1) \xrightarrow{\partial} \underbrace{\pi_{n-1}(\mathbb{Z})}_{0\ (n\geq 2)} \qquad \Longrightarrow \quad \pi_n(S^1) = 0 \ \ (n \geq 2),$$

$$\underbrace{\pi_1(\mathbb{R})}_{0} \to \pi_1(S^1) \xrightarrow{\partial} \pi_0(\mathbb{Z}) \to \underbrace{\pi_0(\mathbb{R})}_{\text{one point}} \qquad \Longrightarrow \quad \pi_1(S^1) \cong \pi_0(\mathbb{Z}) = \mathbb{Z}.$$

The boundary map is the endpoint of the lift divided by 2π: the winding number (1.32). So (1.46) drops out of the machine in one line.

Worked example 1.44: $\pi_1(\mathrm{SO}(3))$ again: $\mathbb{Z}_2 \to \mathrm{SU}(2) \to \mathrm{SO}(3)$

Fibre $\{\pm\mathbf{1}\}$, total space $\mathrm{SU}(2) \cong S^3$ with $\pi_1 = \pi_2 = 0$:

$$\underbrace{\pi_1(\mathrm{SU}(2))}_{0} \to \pi_1(\mathrm{SO}(3)) \xrightarrow{\partial} \underbrace{\pi_0(\{\pm\mathbf{1}\})}_{\mathbb{Z}_2} \to \underbrace{\pi_0(\mathrm{SU}(2))}_{\text{one point}} \quad \Longrightarrow \quad \pi_1(\mathrm{SO}(3)) \cong \mathbb{Z}_2,$$

and $\partial[\gamma]$ is the endpoint $\pm\mathbf{1}$ of the lift, exactly as in §1.3.4. For $n \geq 2$ the fibre has no homotopy and $\pi_n(\mathrm{SO}(3)) \cong \pi_n(\mathrm{SU}(2)) = \pi_n(S^3)$.

Worked example 1.45: The Hopf fibration: $\pi_2(S^2)$ and $\pi_3(S^2)$

For $S^1 \to S^3 \to S^2$ we know $\pi_k(S^1)$ ((1.46)) and $\pi_k(S^3) = 0$ for $k = 1, 2$ (§1.3.7). Then:

$$\underbrace{\pi_2(S^3)}_{0} \to \pi_2(S^2) \xrightarrow{\partial} \underbrace{\pi_1(S^1)}_{\mathbb{Z}} \to \underbrace{\pi_1(S^3)}_{0} \qquad \Longrightarrow \quad \pi_2(S^2) \cong \mathbb{Z},$$

$$\underbrace{\pi_n(S^1)}_{0} \to \pi_n(S^3) \xrightarrow{h_*} \pi_n(S^2) \xrightarrow{\partial} \underbrace{\pi_{n-1}(S^1)}_{0\ (n\geq 3)} \qquad \Longrightarrow \quad \pi_n(S^2) \cong \pi_n(S^3) \quad (n \geq 3).$$

The first line recovers $\pi_2(S^2) = \mathbb{Z}$ without the degree: the boundary map sends the generator of $\pi_2(S^2)$ (the identity) to the loop of phases in the fibre, which is Example 1.40 read backwards. The second line with $n = 3$ gives

$$\pi_3(S^2) \cong \pi_3(S^3) = \mathbb{Z}, \qquad \text{generated by } h_*[\mathrm{id}_{S^3}] = [h].$$

For larger n it explains why the column S^2 of Figure 1.27 is the column S^3 shifted by one row: $\pi_4(S^2) = \pi_4(S^3) = \mathbb{Z}_2$, $\pi_5(S^2) = \pi_5(S^3) = \mathbb{Z}_2$, $\pi_6(S^2) = \pi_6(S^3) = \mathbb{Z}_{12}$, and so on.

$$\cdots \to \underset{0}{\pi_3(S^1)} \to \underset{\mathbb{Z}}{\pi_3(S^3)} \xrightarrow{h_*} \underset{\mathbb{Z}}{\pi_3(S^2)} \xrightarrow{\partial} \underset{0}{\pi_2(S^1)} \to \underset{0}{\pi_2(S^3)} \to \underset{\mathbb{Z}}{\pi_2(S^2)} \xrightarrow{\partial} \underset{\mathbb{Z}}{\pi_1(S^1)} \to \underset{0}{\pi_1(S^3)}$$

Figure 1.29: The long exact sequence of the Hopf fibration $S^1 \to S^3 \to S^2$, with the value of each group written underneath. Between two zeros (red) the map is an isomorphism, so the unknowns (blue) are forced: $\pi_3(S^2) \cong \pi_3(S^3) = \mathbb{Z}$ and $\pi_2(S^2) \cong \pi_1(S^1) = \mathbb{Z}$.

Worked example 1.46: The unitary and orthogonal groups, by induction

Let $\mathrm{SU}(n)$ act on unit vectors $v \in \mathbb{C}^n$, i.e. on S^{2n-1}. The map

$$p : \mathrm{SU}(n) \to S^{2n-1}, \qquad U \mapsto Ue_1 \ \text{ (the first column of } U)$$

is onto (any unit vector can be completed to a unitary matrix with determinant 1 by Gram–Schmidt). The fibre over e_1 consists of the U with first column e_1; unitarity forces the first row to be e_1^T as well, so

$$p^{-1}(e_1) = \left\{ \begin{pmatrix} 1 & 0 \\ 0 & V \end{pmatrix} : V \in \mathrm{SU}(n-1) \right\} \cong \mathrm{SU}(n-1).$$

So there is a fibration $\mathrm{SU}(n-1) \to \mathrm{SU}(n) \to S^{2n-1}$. (For $n = 2$ the fibre is trivial and p is the homeomorphism $\mathrm{SU}(2) \cong S^3$ of (1.37).) The segment

$$\underbrace{\pi_{k+1}(S^{2n-1})}_{0\ (k+1<2n-1)} \xrightarrow{\partial} \pi_k(\mathrm{SU}(n-1)) \xrightarrow{i_*} \pi_k(\mathrm{SU}(n)) \xrightarrow{p_*} \underbrace{\pi_k(S^{2n-1})}_{0\ (k<2n-1)}$$

shows $\pi_k(\mathrm{SU}(n-1)) \cong \pi_k(\mathrm{SU}(n))$ for $k \leq 2n-3$. Running up from $\mathrm{SU}(2) \cong S^3$:

- $k = 1$: $\pi_1(\mathrm{SU}(n)) = \pi_1(\mathrm{SU}(2)) = 0$ for all n (this was used in Example 1.32);
- $k = 2$: $\pi_2(\mathrm{SU}(n)) = \pi_2(S^3) = 0$;

- $k = 3$ (needs $n \geq 3$): $\pi_3(\mathrm{SU}(n)) = \pi_3(\mathrm{SU}(2)) = \pi_3(S^3) = \mathbb{Z}$. The generator is the SU(2) winding embedded in the top-left corner.

The same argument with $\mathrm{SO}(n)$ acting on $S^{n-1} \subset \mathbb{R}^n$ gives a fibration $\mathrm{SO}(n-1) \to \mathrm{SO}(n) \to S^{n-1}$ and $\pi_k(\mathrm{SO}(n-1)) \cong \pi_k(\mathrm{SO}(n))$ for $k \leq n-3$. With $k = 1$: $\pi_1(\mathrm{SO}(n)) = \pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$ for all $n \geq 3$, the fact behind spinors in every dimension (Chapter T4). With $\mathrm{U}(n)$: $\pi_1(\mathrm{U}(n)) = \pi_1(\mathrm{U}(1)) = \mathbb{Z}$.

Worked example 1.47: Homogeneous spaces: $\pi_2(G/H) = \pi_1(H)$

If a group G acts transitively on a space M and H is the stabiliser of a point, then $M = G/H$ and $H \to G \to G/H$ is a fibration. If G is a compact simply connected Lie group, then $\pi_1(G) = \pi_2(G) = 0$ (the vanishing of π_2 holds for every compact Lie group, a theorem of É. Cartan), and

$$\underbrace{\pi_2(G)}_{0} \to \pi_2(G/H) \xrightarrow{\partial} \pi_1(H) \to \underbrace{\pi_1(G)}_{0} \quad \Longrightarrow \quad \pi_2(G/H) \cong \pi_1(H).$$

For $G = \mathrm{SU}(2)$ acting on the Bloch sphere by rotations, the stabiliser of the north pole is the diagonal U(1), $G/H = S^2$, and $\pi_2(S^2) = \pi_1(\mathrm{U}(1)) = \mathbb{Z}$: this is the Hopf fibration once more. This formula is the backbone of the classification of magnetic monopoles in grand unified theories (§1.3.13): a symmetry breaking $G \to H$ admits monopoles labelled by $\pi_1(H)$, which is nonzero whenever H contains an unbroken U(1) factor, such as electromagnetism.

1.3.12 Homotopy groups of Lie groups and Bott periodicity

Nash remarks that the homotopy groups of the classical compact Lie groups are "somewhat better known" than those of spheres. The fibrations of Example 1.46 explain why. Including $\mathrm{U}(n) \subset \mathrm{U}(n+1)$ as the top-left block, we found $\pi_k(\mathrm{U}(n)) \cong \pi_k(\mathrm{U}(n+1))$ as soon as $k \leq 2n-1$. So for fixed k the groups $\pi_k(\mathrm{U}(n))$ stop changing once n is large, and we may define the **stable** groups

$$\pi_k(\mathrm{U}) := \pi_k(\mathrm{U}(n)) \ \ (2n > k), \qquad \pi_k(\mathrm{O}) := \pi_k(\mathrm{O}(n)) \ \ (n \geq k+2),$$
$$\pi_k(\mathrm{Sp}) := \pi_k(\mathrm{Sp}(n)) \ \ (4n \geq k-1).$$

The ranges come from the fibrations $\mathrm{O}(n) \to \mathrm{O}(n+1) \to S^n$ and $\mathrm{Sp}(n) \to \mathrm{Sp}(n+1) \to S^{4n+3}$ in the same way.

Key idea: Bott periodicity (1959)

The stable homotopy groups of the classical groups are periodic:

$$\pi_{k+2}(\mathrm{U}) \cong \pi_k(\mathrm{U}), \qquad \pi_{k+8}(\mathrm{O}) \cong \pi_k(\mathrm{O}), \qquad \pi_{k+4}(\mathrm{Sp}) \cong \pi_k(\mathrm{O}),$$

with the values

$k \bmod 8$	0	1	2	3	4	5	6	7
$\pi_k(\mathrm{U})$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$
$\pi_k(\mathrm{O})$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	0	$\mathbb{Z}$	0	0	0	$\mathbb{Z}$
$\pi_k(\mathrm{Sp})$	0	0	0	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	0	$\mathbb{Z}$

We can check the first few entries against what we already computed: $\pi_1(\mathrm{U}) = \pi_1(\mathrm{U}(1)) = \mathbb{Z}$ (winding of the determinant), $\pi_0(\mathrm{O}) = \mathbb{Z}_2$ (the two components $\det = \pm 1$), $\pi_1(\mathrm{O}) = \pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$, $\pi_3(\mathrm{U}) = \pi_3(\mathrm{SU}(n)) = \mathbb{Z}$ and $\pi_3(\mathrm{Sp}) = \pi_3(\mathrm{Sp}(1)) = \pi_3(\mathrm{SU}(2)) = \mathbb{Z}$ (since Sp(1), the unit quaternions, is SU(2)). The pattern is astonishing: an infinite list of hard computations reduced to period two and period eight. Nash returns to it in Chapter 3, where it becomes the periodicity of K-theory, and the period eight is the same period eight as that of the real Clifford algebras (Chapter T4).

Outside the stable range the groups are not periodic, but the first few are known for every group we need.

G	π_1	π_2	π_3	π_4	π_5	π_6
U(1)	$\mathbb{Z}$	0	0	0	0	0
SU(2) $\cong S^3$	0	0	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_{12}$
SO(3)	$\mathbb{Z}_2$	0	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_{12}$
SU(3)	0	0	$\mathbb{Z}$	0	$\mathbb{Z}$	$\mathbb{Z}_6$
SU(n), $n \geq 4$	0	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0

Physical picture: Which homotopy group does which physics

- $\pi_2(G) = 0$ for every compact Lie group: there are no "monopoles" valued in a group; monopoles need a coset G/H (Example 1.47).
- $\pi_3(G) = \mathbb{Z}$ for every compact simple Lie group: Yang–Mills instantons exist for every simple gauge group, labelled by one integer (§1.3.14).
- $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$: Witten's global anomaly (Example 1.41).
- $\pi_5(\mathrm{SU}(3)) = \mathbb{Z}$: the coefficient of the Wess–Zumino–Witten term of the chiral Lagrangian must be an integer, which turns out to be the number of colours N_c.
- $\pi_{2n+1}(\mathrm{U}) = \mathbb{Z}$ in general: the non-abelian anomalies in $2n$ dimensions (Chapter 10).

1.3.13 Physics I: topological defects

We now have enough homotopy theory to answer a question that runs through condensed matter, particle physics and cosmology: *which stable "lumps" can a field form?* A domain wall in a magnet, a vortex in a superfluid, a flux tube in a superconductor, a magnetic monopole in a grand unified theory, a skyrmion in nuclear physics: each is a configuration that cannot be removed by any smooth, finite-energy change of the field. In every case the reason is that a certain map of a sphere into a certain space is not null-homotopic. Nash does not discuss this; it is the most direct physical use of §3, and we give it in full.

The space of vacua

Let ϕ be a field (real, complex, vector or matrix valued) with a potential energy $V(\phi) \geq 0$. The set of field values that minimise V is the **vacuum manifold** (or **order-parameter space**)

$$\mathcal{M}_0 := \{\phi : V(\phi) = \min V\}.$$

Finite energy forces the field to lie in $\mathcal{M}_0$ wherever it is far from the "core" of a defect, because a region of volume $\mathcal{V}$ outside $\mathcal{M}_0$ costs energy of order $\mathcal{V} \cdot (V - \min V)$. When a symmetry group G acts on the fields, leaves V invariant and acts transitively on the minima, and $H \subset G$ is

the stabiliser (the **unbroken subgroup**) of one minimum ϕ_0, then every minimum is $g\phi_0$ for some g, and $g\phi_0 = g'\phi_0$ exactly when $g^{-1}g' \in H$. So

$$\mathcal{M}_0 \cong G/H.$$

Dictionary: vacuum manifolds

system	order parameter	$\mathcal{M}_0$
Ising magnet, ϕ^4 kink	real ϕ, $V = \frac{\lambda}{4}(\phi^2 - v^2)^2$	$\{+v, -v\} = S^0$
superfluid, superconductor, cosmic string	complex ψ, $V = \frac{\lambda}{4}(\lvert\psi\rvert^2 - v^2)^2$	$\mathrm{U}(1)/1 = S^1$
Heisenberg ferromagnet	unit magnetisation $\vec{n}$	$\mathrm{SO}(3)/\mathrm{SO}(2) = S^2$
nematic liquid crystal	director $\pm\vec{n}$	$S^2/\mathbb{Z}_2 = \mathbb{RP}^2$
Georgi–Glashow SO(3) model	real triplet $\vec{\phi}$, $\lvert\vec{\phi}\rvert = v$	$\mathrm{SO}(3)/\mathrm{SO}(2) = S^2$
chiral pions	$U \in \mathrm{SU}(2)$	$\frac{\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R}{\mathrm{SU}(2)_V} = S^3$
electroweak Higgs	doublet Φ, $\Phi^\dagger\Phi = v^2/2$	$\frac{\mathrm{SU}(2)\times\mathrm{U}(1)}{\mathrm{U}(1)} = S^3$

The codimension rule

Suppose the field is allowed to leave $\mathcal{M}_0$ only in a small region of space, the core. What matters is the **codimension** d of the core: the number of directions in which one can move away from it. In D-dimensional space, a wall has $d = 1$, a line has $d = 2$, a point has $d = 3$ (for $D = 3$). The set of points at a fixed small distance from the core, in the d transverse directions, is a sphere S^{d-1}: two points for a wall, a circle for a line, a two-sphere for a point (Figure 1.30). On that sphere the field lies in $\mathcal{M}_0$, so it defines a map

$$\phi\big|_{S^{d-1}} : S^{d-1} \longrightarrow \mathcal{M}_0.$$

Working definition 1.25 (topological charge of a defect)

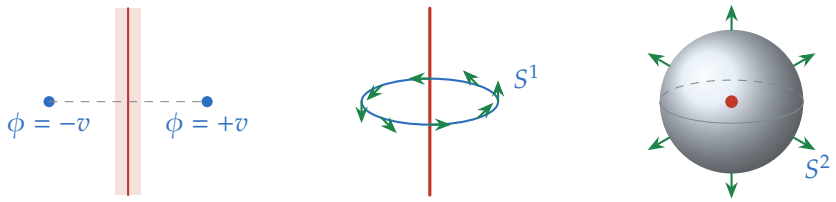
Surround the core by a sphere S^{d-1} in the transverse directions. The **topological charge** of the defect is the homotopy class [all maps from the sphere into the vacuum manifold $\mathcal{M}_0$ that can be deformed into this one]

$$[\phi|_{S^{d-1}}] \in [S^{d-1}, \mathcal{M}_0] \;=\; \pi_{d-1}(\mathcal{M}_0)\big/\pi_1(\mathcal{M}_0).$$

The quotient by π_1 is Nash's (1.31), (1.39): space has no preferred base point, so the physical charge is a *free* homotopy class. When $\mathcal{M}_0$ is simply connected [every loop in $\mathcal{M}_0$ can be shrunk to a point, $\pi_1(\mathcal{M}_0) = 0$] the charge is simply an element of $\pi_{d-1}(\mathcal{M}_0)$. *Operational test:* compute the relevant winding number ((1.33) for $d = 2$, the degree integral (1.51) for $d = 3$) of the field on a sphere far from the core. If it is nonzero, the defect is topologically stable.

Key idea: Why the charge is conserved

Any smooth time evolution of the field that keeps the energy finite keeps the field in $\mathcal{M}_0$ on the surrounding sphere (as long as the core does not cross it). So the map $\phi_t|_{S^{d-1}}$, $t \in [0, 1]$, is a homotopy, and its class cannot change. *Topological charges are conserved because homotopy classes are discrete and time evolution is continuous.* No equation of motion is needed. The only ways to change the charge are discontinuous: pay an infinite energy, or bring in another defect through the sphere.



wall, $d = 1$
S^0 = two points
charge in $\pi_0(\mathcal{M}_0)$

line, $d = 2$
loop around it
charge in $\pi_1(\mathcal{M}_0)$

point, $d = 3$
sphere around it
charge in $\pi_2(\mathcal{M}_0)$

Figure 1.30: The codimension rule. The core of a defect (red) is surrounded, in the directions transverse to it, by a sphere S^{d-1} (blue): two points on either side of a wall, a loop around a line, a two-sphere around a point. On that sphere the field sits in the vacuum manifold, and its homotopy class in $\pi_{d-1}(\mathcal{M}_0)$ is the charge. The green arrows show the field on the sphere: winding once around a vortex, pointing outward on a hedgehog.

Charges also add, in the sense of the group law. Two vortices of windings n_1 and n_2, enclosed together by a big loop, have total winding $n_1 + n_2$: deform the big loop into the product of two small loops, one around each (Figure 1.14). For point defects the same squeezing of a big sphere into two small spheres touching at a point is the cube-picture sum (1.43). A defect and an anti-defect can annihilate; two defects of charge +1 cannot.

Dictionary: defects and homotopy groups

defect	codim. d	classified by	examples
domain wall	1	$\pi_0(\mathcal{M}_0)$	Ising walls, ϕ^4 kink, axion walls
vortex, string	2	$\pi_1(\mathcal{M}_0)$	superfluid vortex, Abrikosov flux tube, cosmic string
monopole, hedgehog	3	$\pi_2(\mathcal{M}_0)$	't Hooft–Polyakov monopole, hedgehog in a magnet
texture, skyrmion	(whole space)	$\pi_D(\mathcal{M}_0)$	skyrmion (π_3), baby skyrmion (π_2 in $D = 2$)
instanton	(all of spacetime)	$\pi_3(G)$	Yang–Mills instanton (§1.3.14)

The last two rows are a different kind of object: **textures** have no core at all. The field stays in $\mathcal{M}_0$ everywhere, and tends to one fixed value ϕ_∞ at spatial infinity. Adding the point at infinity turns $\mathbb{R}^D$ into S^D (stereographic projection, Figure 1.7), so the whole field is a map $S^D \to \mathcal{M}_0$ and has a class in $\pi_D(\mathcal{M}_0)$. We now work through one example of each type.

Worked example 1.48: The ϕ^4 kink: $\pi_0(S^0)$ and a Bogomolny bound

Take a real scalar in one space dimension with energy

$$E[\phi] = \int_{-\infty}^{\infty} \Big(\tfrac{1}{2}\phi'^2 + V(\phi) \Big) \mathrm{d}x, \qquad V(\phi) = \tfrac{\lambda}{4}(\phi^2 - v^2)^2.$$

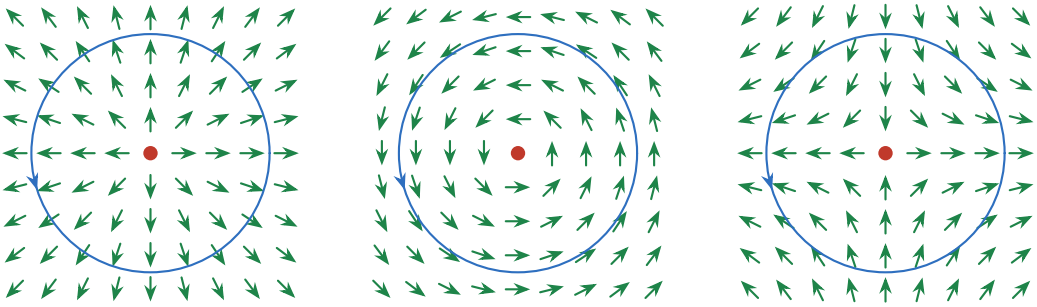
Here $\mathcal{M}_0 = \{\pm v\} = S^0$, and $\pi_0(\mathcal{M}_0)$ is the set of its two points (Example 1.15). Finite energy forces $\phi(\pm\infty) \in \{\pm v\}$, so there are four sectors labelled by $(\phi(-\infty), \phi(+\infty))$. The sectors with $\phi(-\infty) \neq \phi(+\infty)$ contain a wall. To find the lowest energy in the sector $(-v, +v)$, set $W(\phi) := \sqrt{\lambda/2}\,(v^2\phi - \phi^3/3)$, so that $W'(\phi) = \sqrt{\lambda/2}\,(v^2 - \phi^2)$ and $\frac{1}{2}W'^2 = V$. Then

$$E[\phi] \overset{(1)}{=} \int \Big(\tfrac{1}{2}\phi'^2 + \tfrac{1}{2}W'(\phi)^2 \Big) \mathrm{d}x$$

$$\overset{(2)}{=} \int \tfrac{1}{2}\big(\phi' - W'(\phi)\big)^2 \mathrm{d}x + \int W'(\phi)\,\phi'\,\mathrm{d}x$$
$$\overset{(3)}{=} \int \tfrac{1}{2}\big(\phi' - W'(\phi)\big)^2 \mathrm{d}x + W(v) - W(-v)$$
$$\overset{(4)}{\geq} W(v) - W(-v) = \tfrac{4}{3}\sqrt{\tfrac{\lambda}{2}}\,v^3.$$

(1) $V = \frac{1}{2}W'^2$ by construction.
(2) Complete the square: $\frac{1}{2}a^2 + \frac{1}{2}b^2 = \frac{1}{2}(a-b)^2 + ab$.
(3) Chain rule, $W'(\phi)\phi' = \mathrm{d}W(\phi(x))/\mathrm{d}x$, and the fundamental theorem of calculus with $\phi(\pm\infty) = \pm v$. The result depends only on the boundary values: it is topological.
(4) A square is non-negative; $W(v) - W(-v) = 2\sqrt{\lambda/2}\,(v^3 - v^3/3)$.

Equality holds when $\phi' = W'(\phi) = \sqrt{\lambda/2}\,(v^2 - \phi^2)$, a first-order equation. Its solution is the **kink** $\phi(x) = v\tanh(mx)$ with $m = v\sqrt{\lambda/2}$: indeed $\phi' = vm\,\mathrm{sech}^2(mx)$ and $\sqrt{\lambda/2}\,(v^2 - v^2\tanh^2 mx) = \sqrt{\lambda/2}\,v^2\,\mathrm{sech}^2(mx) = vm\,\mathrm{sech}^2(mx)$. The kink cannot decay into the vacuum $\phi \equiv v$: that would change $\phi(-\infty)$ from $-v$ to $+v$ through values outside $\mathcal{M}_0$, at infinite cost. Its energy is fixed by the boundary data. This is the pattern of every **Bogomolny bound**: energy $\geq$ constant $\times$|topological charge|, saturated by a first-order equation. We met it for the baby skyrmion (the Belavin–Polyakov bound of §1.3.8), and will meet it again for instantons.



$\psi \propto e^{i\theta}$: $W = +1$ (hedgehog in the plane)
$\psi \propto ie^{i\theta}$: $W = +1$ (circulating flow)
$\psi \propto e^{-i\theta}$: $W = -1$ (anti-vortex)

Figure 1.31: The phase of ψ drawn as an arrow at angle $\arg\psi$. Walk around the blue loop and count how many times the arrow turns: that is the winding number $W \in \pi_1(S^1) = \mathbb{Z}$. The left and middle fields differ by a constant rotation of every arrow, a homotopy, and have the same $W = +1$; the right one has $W = -1$ (the arrow turns backwards as we walk forwards). In each case the phase is undefined at the red core, where $|\psi|$ must vanish.

Worked example 1.49: Vortices and quantised flux: $\pi_1(S^1) = \mathbb{Z}$

Global vortex. A complex order parameter in the plane, far from the core, has the form $\psi = v\,e^{i\chi(x,y)}$, with χ defined modulo 2π. On a circle C_R of radius R around the core, ψ/v is a loop in S^1, with winding number $W = \frac{1}{2\pi}\oint_{C_R}\mathrm{d}\chi$ ((1.33)). The simplest representative is $\chi = W\theta$ (Figure 1.31). Its gradient energy between the core radius a and R is

$$\int_{a<r<R} |\nabla\psi|^2\,\mathrm{d}^2x \overset{(1)}{=} \int_a^R\int_0^{2\pi} v^2\left|\frac{1}{r}\frac{\partial\chi}{\partial\theta}\right|^2 r\,\mathrm{d}\theta\,\mathrm{d}r \overset{(2)}{=} 2\pi W^2v^2\int_a^R\frac{\mathrm{d}r}{r} \overset{(3)}{=} 2\pi W^2v^2\ln\frac{R}{a}.$$

(1) $|\nabla\psi|^2 = v^2|\nabla\chi|^2$ and, for $\chi = W\theta$, only the angular component $\frac{1}{r}\partial_\theta\chi$ of the gradient is nonzero.

(2) $\partial_\theta \chi = W$; the θ integral gives 2π.
(3) Elementary integral.

The energy grows logarithmically with the size of the system. The vortex cannot unwind (that would change W), but it costs a lot: this is why superfluid vortices appear only when the container rotates, which makes the winding energetically favourable, and why the $W = 2$ vortex, with energy $\propto W^2 = 4$, prefers to split into two $W = 1$ vortices ($1 + 1 = 2 < 4$).

Gauged vortex. In a superconductor ψ has charge q and couples to $\vec{A}$ through $\vec{D}\psi = (\nabla - iq\vec{A})\psi$ (physicists' convention, $\hbar = 1$). Finite energy now needs $\vec{D}\psi \to 0$ at large r, not $\nabla\psi \to 0$. For $\psi \to v e^{iW\theta}$ this fixes the gauge field at large r, and the magnetic flux through the plane follows:

$$\Phi \overset{(1)}{=} \oint_{C_R} \vec{A} \cdot \mathrm{d}\vec{l} \overset{(2)}{=} \frac{1}{q} \oint_{C_R} \nabla\chi \cdot \mathrm{d}\vec{l} \overset{(3)}{=} \frac{2\pi W}{q}.$$

(1) Stokes' theorem: $\int \vec{B} \cdot \mathrm{d}\vec{S} = \oint \vec{A} \cdot \mathrm{d}\vec{l}$ for C_R large enough to enclose all the flux.
(2) $\vec{D}\psi = iv\, e^{i\chi}(\nabla\chi - q\vec{A}) = 0$ at large r, so $\vec{A} = \frac{1}{q}\nabla\chi$ there.
(3) $\oint \nabla\chi \cdot \mathrm{d}\vec{l} = \oint \mathrm{d}\chi = 2\pi W$.

So each Abrikosov flux tube carries an integer number of flux quanta $\Phi_0 = 2\pi\hbar/q = h/2e$ (Cooper pairs have $q = 2e$), the same quantisation we found for a ring (§1.3.2), now for a tube of flux in the bulk. The gradient energy at large r is gone, since $\vec{D}\psi \to 0$ there, so the gauged vortex has finite energy per unit length. In a relativistic theory the same object is a **cosmic string** (Nielsen–Olesen vortex), with $\mathcal{M}_0 = S^1$ and charge in $\pi_1(S^1) = \mathbb{Z}$.

Watch out: Topology gives stability, not existence

A nonzero homotopy class says that the field *cannot be deformed to the vacuum*. It does not say that a static solution of minimum energy exists in that class. The energy may be lowered forever by shrinking or spreading the configuration. Derrick's theorem makes this precise: for a scalar field with only two-derivative terms in $D \geq 3$ space dimensions, rescaling $\phi(x) \mapsto \phi(\lambda x)$ always lowers the energy of a static configuration, so no static texture exists. Stabilisation requires something extra: gauge fields (vortices, monopoles), four-derivative terms (the Skyrme term), or $D = 2$ where the gradient energy is scale invariant (baby skyrmions).

Worked example 1.50: The hedgehog: $\pi_2(S^2) = \mathbb{Z}$

In the Georgi–Glashow model a real triplet $\vec{\phi} = (\phi^1, \phi^2, \phi^3)$ has $V = \frac{\lambda}{4}(\vec{\phi}\cdot\vec{\phi} - v^2)^2$ and $\mathcal{M}_0$ is the sphere $|\vec{\phi}| = v$. Point defects in $\mathbb{R}^3$ are labelled by $\pi_2(S^2) = \mathbb{Z}$ (S^2 is simply connected, so free and based classes agree, Example 1.34). The **hedgehog**

$$\vec{\phi}(\vec{x}) = v\, h(r)\, \hat{\vec{x}}, \qquad h(0) = 0, \quad h(\infty) = 1,$$

points radially outward (Figure 1.30, right). On a large sphere of radius R with coordinates (θ, φ) its direction is $\hat{\vec{\phi}} = \hat{\vec{x}} = (\sin\theta\cos\varphi, \sin\theta\sin\varphi, \cos\theta)$, which is the map $\vec{n}_1$ of Example 1.37. So

$$N \overset{(1)}{=} \frac{1}{4\pi} \int \hat{\vec{\phi}} \cdot \left(\partial_\theta \hat{\vec{\phi}} \times \partial_\varphi \hat{\vec{\phi}}\right) \mathrm{d}\theta\, \mathrm{d}\varphi \overset{(2)}{=} \frac{1}{4\pi} \int_0^{2\pi} \int_0^{\pi} \sin\theta\, \mathrm{d}\theta\, \mathrm{d}\varphi \overset{(3)}{=} 1.$$

(1) The degree integral (1.51) on the sphere $r = R$.

(2) The computation of Example 1.37 with $k = 1$: $\partial_\theta \hat{\vec{x}} \times \partial_\varphi \hat{\vec{x}} = \sin\theta\, \hat{\vec{x}}$.
(3) $\int_0^\pi \sin\theta \, \mathrm{d}\theta = 2$ and $\int_0^{2\pi} \mathrm{d}\varphi = 2\pi$.

Since $N \neq 0$ the field cannot be combed flat: $\vec{\phi}$ must vanish somewhere inside every sphere, which is the core. (If $\vec{\phi}$ had no zero inside the ball, $\hat{\vec{\phi}}$ would be defined on the whole ball, and shrinking the sphere to a point would be a null-homotopy.) With the SO(3) gauge field included, the hedgehog is the **'t Hooft–Polyakov monopole**. Far from the core the unbroken gauge group is the U(1) of rotations about $\hat{\vec{\phi}}$, which plays the role of electromagnetism, and its magnetic flux through the large sphere is

$$\oint \vec{B} \cdot \mathrm{d}\vec{S} = \frac{4\pi}{e} N,$$

with e the gauge coupling: the magnetic charge is the degree. We do not derive this (it needs 't Hooft's gauge-invariant field strength); Chapter 8 returns to monopoles.

The monopole charge can also be read in a second way, which prepares for fibre bundles (Nash §5, next part) and makes contact with the exact sequence of Example 1.47. For SU(2) → U(1) that sequence says $\pi_2(S^2) \cong \pi_1(\mathrm{U}(1))$: the degree of the Higgs field on the sphere equals the winding of a U(1) gauge transformation around the equator. The Dirac monopole shows that winding directly.

Worked example 1.51: The Dirac monopole: π_2 of the sphere becomes $\pi_1(\mathrm{U}(1))$

A point magnetic charge g has $\vec{B} = \frac{g}{4\pi}\frac{\hat{\vec{r}}}{r^2}$, i.e. the 2-form $F = \frac{g}{4\pi}\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\varphi$ on each sphere around the origin. It is closed but not exact on S^2 (its integral is $g \neq 0$; see the exemplar argument in Chapter T2). So no single vector potential works. Two do:

$$A_N = \frac{g}{4\pi}(1-\cos\theta)\,\mathrm{d}\varphi \ \ (\theta < \pi), \qquad A_S = -\frac{g}{4\pi}(1+\cos\theta)\,\mathrm{d}\varphi \ \ (\theta > 0).$$

A_N is smooth at the north pole because its coefficient vanishes there ($1-\cos\theta \to 0$ as $\theta \to 0$, where $\mathrm{d}\varphi$ is singular); likewise A_S at the south pole. Both have $\mathrm{d}A = \frac{g}{4\pi}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\varphi = F$. On the overlap they differ by

$$A_N - A_S \overset{(1)}{=} \frac{g}{4\pi}\big[(1-\cos\theta)+(1+\cos\theta)\big]\mathrm{d}\varphi \overset{(2)}{=} \frac{g}{2\pi}\,\mathrm{d}\varphi \overset{(3)}{=} \frac{1}{q}\,\mathrm{d}\chi, \qquad \chi \coloneqq \frac{qg}{2\pi}\varphi.$$

(1) Subtract the two formulas.
(2) The $\cos\theta$ terms cancel.
(3) Define χ; this has the form of a gauge transformation $\vec{A} \mapsto \vec{A} + \frac{1}{q}\nabla\chi$, under which a charge-$q$ wavefunction changes as $\psi \mapsto e^{i\chi}\psi$.

A charged particle's wavefunctions in the two patches must be related by $\psi_N = e^{i\chi}\psi_S$. For this to make sense on the whole overlap the **transition function** $e^{i\chi} = e^{iqg\varphi/2\pi}$ must be single valued around the equator, which is **Dirac's quantisation condition**

$$\frac{qg}{2\pi} = N \in \mathbb{Z}.$$

Now look at what N is: the transition function is a loop $\varphi \mapsto e^{iN\varphi}$ in U(1), and N is its winding number, an element of $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$. And the total flux is (by Stokes on each

hemisphere, whose common boundary is the equator, traversed in opposite directions)

$$\int_{S^2} F \overset{(1)}{=} \int_{\text{north}} \mathrm{d}A_N + \int_{\text{south}} \mathrm{d}A_S \overset{(2)}{=} \oint_{\text{eq}} A_N - \oint_{\text{eq}} A_S \overset{(3)}{=} \oint_{\text{eq}} \frac{1}{q}\mathrm{d}\chi \overset{(4)}{=} \frac{2\pi N}{q}.$$

(1) Split the sphere into hemispheres and use the potential that is smooth on each.
(2) Stokes. The equator is the boundary of the northern hemisphere with the direction of increasing φ and of the southern hemisphere with the opposite direction.
(3) The difference of the potentials, computed above.
(4) χ increases by $2\pi N$ once around the equator.

Magnetic charge = winding of the transition function. The degree of a map $S^2 \to S^2$ has become the winding of a map $S^1 \to \mathrm{U}(1)$ on the equator. This is our first glimpse of how bundles over S^2 are classified by π_1 of their structure group: the "clutching" construction of Nash §5.

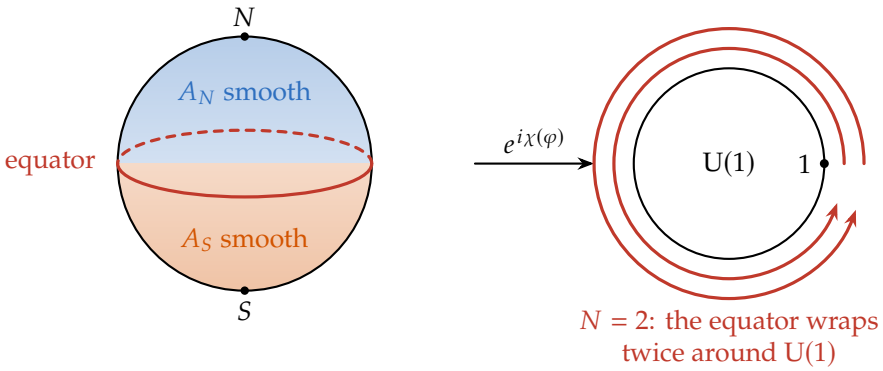


Figure 1.32: The Dirac monopole. Each hemisphere carries its own smooth vector potential. On the equator (red) they are glued by a gauge transformation $e^{i\chi}$, $\chi = N\varphi$, a loop in U(1). Its winding number $N \in \pi_1(\mathrm{U}(1)) = \mathbb{Z}$ is the magnetic charge in units of $2\pi/q$. The picture on the right shows $N = 2$.

Worked example 1.52: The skyrmion: a texture in $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$

In the low-energy theory of pions the field is a matrix $U(\vec{x}) \in \mathrm{SU}(2)$, with $U \to \mathbf{1}$ at spatial infinity. So U is a map $\mathbb{R}^3 \cup \{\infty\} \cong S^3 \to \mathrm{SU}(2) \cong S^3$, with a class in $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$. Skyrme's insight (1961) was that this integer is the *baryon number*: nucleons are textures of the pion field. The integer is computed by the winding integral that we set up in the next subsection, (1.60); here we evaluate it for the **hedgehog skyrmion**

$$U(\vec{x}) = \cos f(r)\,\mathbf{1} + i \sin f(r)\,\hat{\vec{x}} \cdot \vec{\sigma}, \qquad f(0) = \pi, \quad f(\infty) = 0.$$

Under the identification $\mathrm{SU}(2) \cong S^3$ of (1.37), $U = x^0\mathbf{1} + i\,x^a\sigma_a$ with $(x^0, \vec{x}') = (\cos f,\ \sin f\,\hat{\vec{x}})$. In hyperspherical coordinates (χ, θ, φ) on S^3, $x^0 = \cos\chi$, $\vec{x}' = \sin\chi\,(\sin\theta\cos\varphi, \sin\theta\sin\varphi, \cos\theta)$, the map U is simply

$$(r, \theta, \varphi) \longmapsto (\chi, \theta, \varphi) = (f(r), \theta, \varphi).$$

The volume form of the unit S^3 in these coordinates is $\sin^2\chi\,\sin\theta\,\mathrm{d}\chi \wedge \mathrm{d}\theta \wedge \mathrm{d}\varphi$ (the round metric is $\mathrm{d}\chi^2 + \sin^2\chi\,(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2)$), and its total is $2\pi^2$. The degree of U is the

pulled-back volume divided by the total volume:

$$\deg U \overset{(1)}{=} \frac{1}{2\pi^2}\int_{\mathbb{R}^3} \sin^2 f(r)\, f'(r)\, \sin\theta \, \mathrm{d}r\, \mathrm{d}\theta\, \mathrm{d}\varphi$$
$$\overset{(2)}{=} \frac{4\pi}{2\pi^2}\int_0^\infty \sin^2 f \,\frac{\mathrm{d}f}{\mathrm{d}r}\,\mathrm{d}r \overset{(3)}{=} \frac{2}{\pi}\int_{f(0)}^{f(\infty)} \sin^2 f \,\mathrm{d}f$$
$$\overset{(4)}{=} \frac{2}{\pi}\left[\frac{f}{2} - \frac{\sin 2f}{4}\right]_\pi^0 \overset{(5)}{=} -1.$$

(1) (1.50) with $\omega = \mathrm{vol}_{S^3}/2\pi^2$: substitute $\chi = f(r)$, so $\mathrm{d}\chi = f'\,\mathrm{d}r$, and keep θ, φ.
(2) The angular integral is 4π.
(3) Change variables from r to f; the limits are $f(0) = \pi$ and $f(\infty) = 0$.
(4) $\sin^2 f = \frac{1}{2}(1 - \cos 2f)$.
(5) $\frac{2}{\pi}\left(0 - \frac{\pi}{2}\right) = -1$.

The answer depends only on the boundary values $f(0) = \pi$, $f(\infty) = 0$, not on the profile, as a homotopy invariant must. Geometrically: as r runs from 0 to ∞, $\chi = f(r)$ runs from the south pole $-\mathbf{1}$ of S^3 to the north pole $\mathbf{1}$, and each sphere $r = \text{const}$ is mapped to the latitude sphere $\chi = f(r)$ of S^3: U covers S^3 exactly once. The sign is an orientation convention: here $\mathbb{R}^3$ has its standard orientation and S^3 the one fixed in (1.60) below. With these conventions the skyrmion has $\deg U = -1$, and the Skyrme-model literature defines the baryon number as $B = -\deg U$ so that it is $+1$. (Equivalently, $f(0) = -\pi$ gives $\deg U = +1$.) Derrick's theorem (the pitfall above) forbids a static skyrmion in the two-derivative pion Lagrangian; Skyrme added a four-derivative term that stabilises it.

Recap: defects

- Finite energy puts the field in the vacuum manifold $\mathcal{M}_0 = G/H$ away from the core.
- A defect of codimension d is surrounded by S^{d-1}; its charge is the (free) class in $\pi_{d-1}(\mathcal{M}_0)$. Walls: π_0; vortices: π_1; monopoles: π_2. Textures with a fixed value at infinity: $\pi_D(\mathcal{M}_0)$.
- Charges are conserved because homotopy classes are discrete; they add by the group law; topology gives stability, not existence.
- Examples: kink ($\pi_0(S^0)$, Bogomolny bound), vortex and flux quantum $2\pi/q$ ($\pi_1(S^1)$), hedgehog and Dirac monopole ($\pi_2(S^2) = \pi_1(\mathrm{U}(1))$), skyrmion ($\pi_3(S^3)$).

1.3.14 Physics II: instantons and $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$

The Euclidean path integral of a gauge theory is a sum over gauge fields on $\mathbb{R}^4$ weighted by e^{-S}. Semiclassically it is dominated by configurations of finite action. The question of this subsection is: *do the finite-action gauge fields on $\mathbb{R}^4$ fall into disconnected classes?* If so, the path integral splits into a sum over sectors, and the sectors cannot be reached from each other by perturbation theory. The answer is yes, the classes are labelled by $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$, and the label is the **instanton number**. This is the physics that the whole of Nash's book is building towards (Chapter 8), and we can already see its topological core.

Dictionary: conventions for gauge fields in this part

We use Nash's (mathematicians') convention. The gauge field $A = A_\mu \mathrm{d}x^\mu$ is a 1-form with values in anti-Hermitian 2×2 matrices ($\mathfrak{su}(2)$),

$$F = \mathrm{d}A + A\wedge A, \qquad A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g, \qquad F \mapsto g^{-1}Fg.$$

The physicists' Hermitian fields are related by $A = -ig\,A^a_{\text{phys}}T^a$, $F = -ig\,F^a_{\text{phys}}T^a$, with $T^a = \sigma^a/2$ and $\operatorname{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$, where g is the coupling constant (context distinguishes it from a gauge transformation $g(x)$). Euclidean $\mathbb{R}^4$ has coordinates (x^0,x^1,x^2,x^3), orientation $\mathrm{d}x^0\wedge\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3$, and the three-sphere S^3_R of radius R carries the boundary orientation (outward normal first). See Chapter T3 for connections and curvature.

Finite action forces a map $S^3 \to \mathrm{SU}(2)$

The Yang–Mills action is

$$S = \frac{1}{4}\int F^a_{\mu\nu}F^a_{\mu\nu}\,\mathrm{d}^4x = -\frac{1}{2g^2}\int \operatorname{tr}(F_{\mu\nu}F_{\mu\nu})\,\mathrm{d}^4x.$$

For it to be finite, F must fall off faster than $1/r^2$ as $r=|x|\to\infty$. So on a large sphere S^3_R the field is *flat*, $F\approx 0$. A flat connection on a simply connected region is *pure gauge*: parallel transport is path independent (its holonomy around small loops is $1+O(F)$, and every loop can be shrunk), so transporting from a fixed point defines a gauge g in which $A=0$, i.e. $A = g^{-1}\mathrm{d}g$ in the original gauge. On the region $r>R$, which is homotopic to S^3 and hence simply connected (Example 1.27), we therefore have

$$A \xrightarrow{\;r\to\infty\;} g^{-1}\mathrm{d}g, \qquad g : S^3_\infty \to \mathrm{SU}(2). \tag{1.59}$$

The finite-action field thus defines a class $[g]\in[S^3,\mathrm{SU}(2)]$. Since $\mathrm{SU}(2)\cong S^3$ is simply connected, free and based classes coincide (Example 1.34), and

$$[S^3,\mathrm{SU}(2)] = \pi_3(\mathrm{SU}(2)) = \pi_3(S^3) = \mathbb{Z}$$

by the degree (§1.3.8). Figure 1.33 shows the picture.

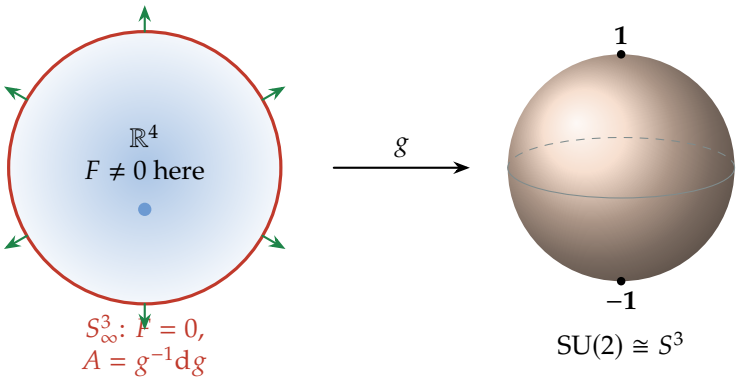

Figure 1.33: Why instantons are classified by π_3. Finite action forces the field strength to vanish on the three-sphere at infinity (red), so there the gauge field is a pure gauge $g^{-1}\mathrm{d}g$. The gauge transformation g maps S^3_∞ to the group SU(2), which is itself a three-sphere. How many times it wraps around, $n(g)\in\pi_3(\mathrm{SU}(2))=\mathbb{Z}$, is the instanton number. The energy density (blue) sits in a lump inside.

Why can we not simply undo the winding by a gauge transformation? A gauge transformation h that is smooth on the whole of $\mathbb{R}^4$ restricts on S^3_R to a null-homotopic map: $h_t(x) = h(tx)$, $t \in [0,1]$, is a homotopy from the constant map $h(0)$ to $h|_{S^3_R}$. So it changes g to gh with $[gh] = [g]$ (this uses the additivity (1.62) proved below). The winding at infinity is gauge invariant.

The winding number as an integral

For $\pi_1(S^1)$ the winding number was $\frac{1}{2\pi}\oint \mathrm{d}\theta = \frac{1}{2\pi i}\oint g^{-1}\mathrm{d}g$ for $g = e^{i\theta}$. The three-dimensional analogue uses the matrix-valued 1-form $g^{-1}\mathrm{d}g$ cubed.

Working definition 1.26 (winding number of $g : S^3 \to \mathrm{SU}(2)$)

$$n(g) = \frac{1}{24\pi^2}\int_{S^3} \mathrm{tr}\big[(g^{-1}\mathrm{d}g)^3\big] = \frac{1}{24\pi^2}\int \varepsilon^{ijk}\,\mathrm{tr}\big(L_iL_jL_k\big)\,\mathrm{d}^3u, \qquad L_i := g^{-1}\partial_i g, \tag{1.60}$$

where u^i are oriented local coordinates on S^3, $(g^{-1}\mathrm{d}g)^3$ means $g^{-1}\mathrm{d}g \wedge g^{-1}\mathrm{d}g \wedge g^{-1}\mathrm{d}g$ with matrix multiplication [$\wedge$ antisymmetrises in the three directions, which is where ε^{ijk} comes from], and $\varepsilon^{123} = 1$. *Operational meaning:* $n(g)$ is the degree of g [the number of times g covers S^3, counted with orientation signs] as a map $S^3 \to S^3$ (shown below), so it is an integer, and it can be computed either by the integral or by counting signed preimages of a point.

Worked example 1.53: The identity map has winding number one

Let $g_1 : S^3 \to \mathrm{SU}(2)$ be the identification (1.37), $g_1(a_0, \vec{a}) = a_0\mathbf{1} + i\,\vec{a}\cdot\vec{\sigma}$. We evaluate the integrand in two steps: first at the point $\mathbf{1} = (1,0,0,0)$, then everywhere by symmetry.

At $\mathbf{1}$. Near $(1,\vec{0})$ we may use a^1, a^2, a^3 as coordinates on S^3; there $g_1 = \mathbf{1}$ and $\mathrm{d}g_1 = i\sigma_a\,\mathrm{d}a^a$. Then

$$\mathrm{tr}\big[(g_1^{-1}\mathrm{d}g_1)^3\big]\Big|_{\mathbf{1}} \overset{(1)}{=} i^3\,\mathrm{tr}(\sigma_a\sigma_b\sigma_c)\,\mathrm{d}a^a\wedge\mathrm{d}a^b\wedge\mathrm{d}a^c \overset{(2)}{=} -i\cdot 2i\,\varepsilon_{abc}\,\mathrm{d}a^a\wedge\mathrm{d}a^b\wedge\mathrm{d}a^c$$
$$\overset{(3)}{=} 2\cdot 6\,\mathrm{d}a^1\wedge\mathrm{d}a^2\wedge\mathrm{d}a^3 = 12\,\mathrm{d}a^1\wedge\mathrm{d}a^2\wedge\mathrm{d}a^3.$$

(1) $g_1^{-1}\mathrm{d}g_1 = i\sigma_a\mathrm{d}a^a$ at $\mathbf{1}$; the wedge product of three copies, with the matrices multiplied in order.

(2) $\mathrm{tr}(\sigma_a\sigma_b\sigma_c) = 2i\,\varepsilon_{abc}$: from $\sigma_a\sigma_b = \delta_{ab}\mathbf{1} + i\varepsilon_{abd}\sigma_d$ and $\mathrm{tr}\,\sigma_c = 0$, $\mathrm{tr}(\sigma_d\sigma_c) = 2\delta_{dc}$.

(3) $\varepsilon_{abc}\,\mathrm{d}a^a\wedge\mathrm{d}a^b\wedge\mathrm{d}a^c$ has $3! = 6$ nonzero terms, each equal to $+\mathrm{d}a^1\wedge\mathrm{d}a^2\wedge\mathrm{d}a^3$ after reordering.

At $\mathbf{1}$ the outward normal of $S^3 \subset \mathbb{R}^4$ is e_0, and (e_0, e_1, e_2, e_3) is the standard frame, so (e_1, e_2, e_3) is positively oriented on S^3 there. Hence $\mathrm{d}a^1\wedge\mathrm{d}a^2\wedge\mathrm{d}a^3 = \mathrm{vol}_{S^3}$ at $\mathbf{1}$, and the integrand equals $12\,\mathrm{vol}_{S^3}$ at $\mathbf{1}$.

Everywhere. The 3-form $\mathrm{tr}[(g^{-1}\mathrm{d}g)^3]$ on the group is *bi-invariant*. Under $g \mapsto hg$ with h constant, $(hg)^{-1}\mathrm{d}(hg) = g^{-1}h^{-1}h\,\mathrm{d}g = g^{-1}\mathrm{d}g$; under $g \mapsto gh$, $g^{-1}\mathrm{d}g \mapsto h^{-1}(g^{-1}\mathrm{d}g)h$, and the trace of a product is unchanged by conjugation. Left multiplication by a unit quaternion h is a rotation of $\mathbb{R}^4$ (it preserves $a_0^2 + |\vec{a}|^2 = \det$, and it is connected to the identity), so it also preserves vol_{S^3}. Two left-invariant 3-forms that agree at $\mathbf{1}$ agree everywhere, so

$\operatorname{tr}[(g_1^{-1}\mathrm{d}g_1)^3] = 12\,\mathrm{vol}_{S^3}$ on all of S^3, and

$$n(g_1) \overset{(1)}{=} \frac{12}{24\pi^2}\operatorname{Vol}(S^3) \overset{(2)}{=} \frac{12}{24\pi^2}\int_0^{\pi}\!\!\int_0^{\pi}\!\!\int_0^{2\pi} \sin^2\chi\,\sin\theta\,\mathrm{d}\varphi\,\mathrm{d}\theta\,\mathrm{d}\chi \overset{(3)}{=} \frac{12}{24\pi^2}\cdot\frac{\pi}{2}\cdot 2\cdot 2\pi \overset{(4)}{=} 1.$$

(1) The integrand is $12\,\mathrm{vol}_{S^3}$.
(2) Hyperspherical coordinates, as in Example 1.52.
(3) $\int_0^{\pi}\sin^2\chi\,\mathrm{d}\chi = \frac{\pi}{2}$, $\int_0^{\pi}\sin\theta\,\mathrm{d}\theta = 2$.
(4) So $\operatorname{Vol}(S^3) = 2\pi^2$, and $12\cdot 2\pi^2 = 24\pi^2$.

This explains the strange normalisation $1/24\pi^2$: it is $1/(12\cdot\operatorname{Vol}(S^3))$. For a general map g, $\operatorname{tr}[(g^{-1}\mathrm{d}g)^3]$ is the pullback by g of the same form on the group, i.e. $12\,g^*\mathrm{vol}_{S^3}$, so $n(g) = \int g^*(\mathrm{vol}/2\pi^2) = \deg g$ by (1.50). In particular $n(g)\in\mathbb{Z}$ and it is a homotopy invariant. (The skyrmion of Example 1.52 has $n(U) = \deg U = -1$.)

Worked example 1.54: Winding numbers add under pointwise multiplication

Let $g = g_1g_2$ (pointwise matrix product) and write $a := g_1^{-1}\mathrm{d}g_1$, $b := \mathrm{d}g_2\,g_2^{-1}$. Then $g^{-1}\mathrm{d}g = g_2^{-1}g_1^{-1}(\mathrm{d}g_1\,g_2 + g_1\mathrm{d}g_2) = g_2^{-1}(a+b)g_2$, and

$$\begin{aligned}\operatorname{tr}\big[(g^{-1}\mathrm{d}g)^3\big] &\overset{(1)}{=} \operatorname{tr}\big[(a+b)^3\big]\\ &\overset{(2)}{=} \operatorname{tr}a^3 + \operatorname{tr}b^3 + 3\operatorname{tr}(a^2b) + 3\operatorname{tr}(ab^2)\\ &\overset{(3)}{=} \operatorname{tr}\big[(g_1^{-1}\mathrm{d}g_1)^3\big] + \operatorname{tr}\big[(g_2^{-1}\mathrm{d}g_2)^3\big] - 3\,\mathrm{d}\,\operatorname{tr}(ab).\end{aligned} \tag{1.61}$$

(1) The conjugation by g_2 drops out of the trace.
(2) Expand the eight terms. For 1-forms, $\operatorname{tr}(xyz) = \operatorname{tr}(yzx)$ (moving a 1-form past a 2-form costs no sign), so $\operatorname{tr}(aab) = \operatorname{tr}(aba) = \operatorname{tr}(baa)$, and similarly for the terms with two b's.
(3) $\operatorname{tr}b^3 = \operatorname{tr}[g_2(g_2^{-1}\mathrm{d}g_2)^3g_2^{-1}] = \operatorname{tr}[(g_2^{-1}\mathrm{d}g_2)^3]$. For the cross terms: $\mathrm{d}a = \mathrm{d}(g_1^{-1})\wedge\mathrm{d}g_1 = -g_1^{-1}\mathrm{d}g_1\,g_1^{-1}\wedge\mathrm{d}g_1 = -a^2$ and similarly $\mathrm{d}b = b^2$, so $\mathrm{d}\operatorname{tr}(ab) = \operatorname{tr}(\mathrm{d}a\,b) - \operatorname{tr}(a\,\mathrm{d}b) = -\operatorname{tr}(a^2b) - \operatorname{tr}(ab^2)$.

The last term is exact, and an exact form integrates to zero over the closed manifold S^3 (Stokes, $\partial S^3 = \varnothing$). Therefore

$$n(g_1g_2) = n(g_1) + n(g_2), \qquad n(g^{-1}) = -n(g), \qquad n(g^k) = k\,n(g). \tag{1.62}$$

The second follows from the first with $g_1g_2 = \mathbf{1}$ and $n(\mathbf{1}) = 0$. This is the Eckmann–Hilton statement of §1.2.8 made concrete: the pointwise product of maps into a group gives the same group law on π_3 as the cube-picture concatenation. An explicit map of winding k is g_1^k. In the polar form $g_1 = \cos\chi + i\sin\chi\,\hat{\vec{n}}\cdot\vec{\sigma} = \exp(i\chi\,\hat{\vec{n}}\cdot\vec{\sigma})$ it is $g_1^k = \exp(ik\chi\,\hat{\vec{n}}\cdot\vec{\sigma})$: the same hedgehog shape, turning k times as fast.

From the field strength to the winding: Chern–Simons and Stokes

The winding at infinity can be written as a volume integral of the field strength, exactly as the magnetic charge was an integral of $\vec{B}$.

Key idea: $\operatorname{tr} F \wedge F$ is a total derivative

With the **Chern–Simons form** $\mathrm{CS}(A) := \operatorname{tr}\big(A \wedge \mathrm{d}A + \frac{2}{3} A \wedge A \wedge A\big)$,

$$\operatorname{tr}(F \wedge F) = \mathrm{d}\,\mathrm{CS}(A). \tag{1.63}$$

Here is the verification, using only graded cyclicity $\operatorname{tr}(\alpha \wedge \beta) = (-1)^{pq} \operatorname{tr}(\beta \wedge \alpha)$ for matrix-valued p- and q-forms.

$$\mathrm{d}\,\mathrm{CS} \overset{(1)}{=} \operatorname{tr}(\mathrm{d}A \wedge \mathrm{d}A) + \tfrac{2}{3} \operatorname{tr}\big(\mathrm{d}A\, A^2 - A\, \mathrm{d}A\, A + A^2 \mathrm{d}A\big) \overset{(2)}{=} \operatorname{tr}(\mathrm{d}A \wedge \mathrm{d}A) + 2 \operatorname{tr}(\mathrm{d}A \wedge A^2),$$

$$\operatorname{tr}(F \wedge F) \overset{(3)}{=} \operatorname{tr}(\mathrm{d}A\, \mathrm{d}A) + \operatorname{tr}(\mathrm{d}A\, A^2) + \operatorname{tr}(A^2 \mathrm{d}A) + \operatorname{tr}(A^4) \overset{(4)}{=} \operatorname{tr}(\mathrm{d}A \wedge \mathrm{d}A) + 2 \operatorname{tr}(\mathrm{d}A \wedge A^2).$$

(1) Leibniz rule; $\mathrm{d}(\mathrm{d}A) = 0$; a minus sign each time d passes a 1-form.
(2) $\operatorname{tr}(A\, \mathrm{d}A\, A) = (-1)^{1\cdot 3} \operatorname{tr}(\mathrm{d}A\, A\, A) = -\operatorname{tr}(\mathrm{d}A\, A^2)$ and $\operatorname{tr}(A^2 \mathrm{d}A) = (-1)^{2\cdot 2} \operatorname{tr}(\mathrm{d}A\, A^2)$; so the bracket is $3 \operatorname{tr}(\mathrm{d}A\, A^2)$.
(3) Expand $F \wedge F = (\mathrm{d}A + A^2) \wedge (\mathrm{d}A + A^2)$.
(4) $\operatorname{tr}(A^2 \mathrm{d}A) = \operatorname{tr}(\mathrm{d}A\, A^2)$ as before, and $\operatorname{tr}(A^4) = \operatorname{tr}(A \cdot A^3) = (-1)^{1\cdot 3} \operatorname{tr}(A^3 \cdot A) = -\operatorname{tr}(A^4)$, so it vanishes.

Now integrate over a large ball B_R and use Stokes' theorem. Assume A is smooth on all of $\mathbb{R}^4$ and becomes the pure gauge (1.59) at large r.

$$\begin{aligned} \int_{\mathbb{R}^4} \operatorname{tr}(F \wedge F) &\overset{(1)}{=} \lim_{R\to\infty} \int_{S^3_R} \mathrm{CS}(A) \overset{(2)}{=} \int_{S^3_\infty} \operatorname{tr}\big(-A^3 + \tfrac{2}{3} A^3\big) \\ &\overset{(3)}{=} -\frac{1}{3} \int_{S^3_\infty} \operatorname{tr}\big[(g^{-1}\mathrm{d}g)^3\big] \overset{(4)}{=} -8\pi^2\, n(g). \end{aligned} \tag{1.64}$$

(1) (1.63) and Stokes on the ball, whose boundary is S^3_R with the outward orientation.
(2) On S^3_∞, $F = 0$, so $\mathrm{d}A = -A \wedge A$.
(3) Collect terms; $A = g^{-1}\mathrm{d}g$ there.
(4) The definition (1.60): $\frac{1}{3} \cdot 24\pi^2 = 8\pi^2$.

Working definition 1.27 (instanton number)

$$k := -\frac{1}{8\pi^2} \int_{\mathbb{R}^4} \operatorname{tr}(F \wedge F) = \frac{g^2}{32\pi^2} \int F^a_{\mu\nu} \tilde{F}^a_{\mu\nu}\, \mathrm{d}^4x = n(g) \in \mathbb{Z}, \qquad \tilde{F}^a_{\mu\nu} := \tfrac{1}{2} \varepsilon_{\mu\nu\rho\sigma} F^a_{\rho\sigma}$$

[$n(g)$ is the winding number of the gauge transformation g for which $A = g^{-1}\mathrm{d}g$ on the sphere at infinity]. The minus sign in the first expression is the price of anti-Hermitian fields [$A^\dagger = -A$, as for $A = g^{-1}\mathrm{d}g$ with g unitary]: in Hermitian conventions it is $+\frac{1}{8\pi^2} \int \operatorname{tr}(F_{\text{phys}} \wedge F_{\text{phys}})$ (with g absorbed). *Operational meaning:* either integrate the "topological charge density" $\frac{g^2}{32\pi^2} F\tilde{F}$ over spacetime, or read off the winding of the gauge transformation at infinity.

The middle expression follows by substituting the dictionary:

$$-\frac{1}{8\pi^2} \operatorname{tr}(F \wedge F) \overset{(1)}{=} -\frac{1}{8\pi^2} (-ig)^2 \operatorname{tr}(T^a T^b)\, F^a \wedge F^b \overset{(2)}{=} \frac{g^2}{16\pi^2} F^a \wedge F^a \overset{(3)}{=} \frac{g^2}{32\pi^2} F^a_{\mu\nu} \tilde{F}^a_{\mu\nu}\, \mathrm{d}^4x.$$

(1) $F = -igF^aT^a$, where $F^a = \frac{1}{2} F^a_{\mu\nu} \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$.
(2) $(-ig)^2 = -g^2$ and $\operatorname{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$.
(3) $F^a \wedge F^a = \frac{1}{4} F^a_{\mu\nu} F^a_{\rho\sigma}\, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu \wedge \mathrm{d}x^\rho \wedge \mathrm{d}x^\sigma = \frac{1}{4} \varepsilon_{\mu\nu\rho\sigma} F^a_{\mu\nu} F^a_{\rho\sigma}\, \mathrm{d}^4x = \frac{1}{2} F^a_{\mu\nu} \tilde{F}^a_{\mu\nu}\, \mathrm{d}^4x$.

Physical picture: Integral of a local density = integer

$F\tilde{F}$ is a local density built from the fields, and in general it has no reason to integrate to anything special. Yet its integral is always $32\pi^2/g^2$ times an integer. The mechanism is the same as for the monopole's flux: the density is a total derivative, so the integral only sees the boundary, where the field is a map between spheres, and maps between spheres are counted by integers. The same mechanism will produce the index theorem's integrality (Chapter 4).

The action bound and the tunnelling amplitude

Topology also bounds the action from below, exactly as in the kink and the baby skyrmion. In four Euclidean dimensions $\tilde{\tilde{F}} = F$ and $\tilde{F}^a_{\mu\nu}\tilde{F}^a_{\mu\nu} = F^a_{\mu\nu}F^a_{\mu\nu}$. So

$$S \overset{(1)}{=} \frac{1}{4}\int F^a_{\mu\nu}F^a_{\mu\nu}\,\mathrm{d}^4x \overset{(2)}{=} \frac{1}{8}\int \left(F^a_{\mu\nu} \mp \tilde{F}^a_{\mu\nu}\right)^2 \mathrm{d}^4x \pm \frac{1}{4}\int F^a_{\mu\nu}\tilde{F}^a_{\mu\nu}\,\mathrm{d}^4x$$
$$\overset{(3)}{=} \frac{1}{8}\int \left(F \mp \tilde{F}\right)^2 \mathrm{d}^4x \pm \frac{8\pi^2}{g^2}\,k \overset{(4)}{\geq} \frac{8\pi^2}{g^2}\,|k|.$$

(1) The Yang–Mills action in Hermitian components.
(2) $(F \mp \tilde{F})^2 = FF + \tilde{F}\tilde{F} \mp 2F\tilde{F} = 2FF \mp 2F\tilde{F}$, so $\frac{1}{8}(F \mp \tilde{F})^2 = \frac{1}{4}FF \mp \frac{1}{4}F\tilde{F}$.
(3) The instanton number: $\int F\tilde{F} = 32\pi^2 k/g^2$.
(4) Choose the sign equal to the sign of k; a square is non-negative.

Equality holds exactly for **self-dual** ($F = \tilde{F}$, $k > 0$) or **anti-self-dual** ($F = -\tilde{F}$, $k < 0$) fields: first-order equations, whose solutions are automatically solutions of the second-order Yang–Mills equations (by the Bianchi identity). These are the **instantons**. In the path integral each contributes a weight $e^{-S} = e^{-8\pi^2|k|/g^2}$. As a function of g this has a vanishing Taylor series at $g = 0$: instanton effects are invisible to every order of perturbation theory [QFT notes §4.13.4, p. 403].

Worked example 1.55: The BPST instanton has $k = 1$ without computing F

Belavin, Polyakov, Schwarz and Tyupkin (1975) found the solution, in the **regular gauge**,

$$A = \frac{r^2}{r^2+\rho^2}\,g_1^{-1}\mathrm{d}g_1, \qquad g_1(x) = \frac{x^0\mathbf{1} + i\,x^a\sigma_a}{r}, \qquad r^2 = \sum_\mu (x^\mu)^2,$$

with an arbitrary size $\rho > 0$ (and an arbitrary centre, here the origin). Two properties decide its instanton number.

- *It is smooth at the origin.* $g_1^{-1}\mathrm{d}g_1$ behaves like $1/r$ near $r = 0$ (it is homogeneous of degree -1), but the prefactor behaves like r^2/ρ^2. In fact $g_1^{-1}\mathrm{d}g_1 = r^{-2}(x^0 - ix^a\sigma_a)(\mathrm{d}x^0 + i\sigma_b\mathrm{d}x^b) + (\text{a term} \propto \mathrm{d}r)$, and $A = (r^2+\rho^2)^{-1} \times (\text{polynomial in } x)$ is smooth. So Stokes on $\mathbb{R}^4$ is legitimate.
- *At infinity it is pure gauge with $g = g_1$.* As $r \to \infty$, $r^2/(r^2+\rho^2) \to 1$. And g_1 restricted to S^3_R is the map of Example 1.53 after rescaling by $1/R$, so $n(g_1) = 1$.

By (1.64), $k = n(g_1) = 1$. One checks by direct computation (done in Chapter 8) that F is (anti-)self-dual, the sign being fixed by the orientation conventions, so $S = 8\pi^2/g^2$: the instanton saturates the bound. Its field strength is concentrated in a region of size ρ around the centre, as in Figure 1.33. With g_1^{-1} in place of g_1 the same construction gives $k = -1$, the anti-instanton, by (1.62).

The vacuum is not unique: winding vacua and θ

There is a Hamiltonian version of the same topology. Work in the temporal gauge $A_0 = 0$ and consider static field configurations of zero energy on space $\mathbb{R}^3$. They have $F = 0$, so $A_i = g^{-1}\partial_i g$ with $g : \mathbb{R}^3 \to \mathrm{SU}(2)$. Require $g \to \mathbf{1}$ at spatial infinity (gauge transformations that do not change the state at infinity). Adding the point at infinity, $\mathbb{R}^3 \cup \{\infty\} \cong S^3$, so each classical vacuum has a winding number $n(g) \in \pi_3(\mathrm{SU}(2)) = \mathbb{Z}$, computed by (1.60) over $\mathbb{R}^3$. We get infinitely many classical vacua $|n\rangle$, $n \in \mathbb{Z}$. Their winding is the **Chern–Simons number** $N_{\mathrm{CS}}[A] := -\frac{1}{8\pi^2}\int_{\mathbb{R}^3} \mathrm{CS}(A)$, which on a pure gauge equals $n(g)$ by steps (2)–(4) of (1.64).

A gauge transformation of winding one maps $|n\rangle$ to $|n+1\rangle$: it is a symmetry of the Hamiltonian, but it cannot be deformed to the identity (it is a **large gauge transformation**). So the vacua $|n\rangle$ are physically equivalent but distinct as states. Between them the energy functional has barriers (Figure 1.34): to go from $|n\rangle$ to $|n+1\rangle$ continuously the field must pass through configurations with $F \neq 0$. Quantum mechanically it can tunnel, and the tunnelling path in Euclidean time is an instanton. Apply Stokes to the slab $\mathbb{R}^3 \times [-T, T]$:

$$k \overset{(1)}{=} -\frac{1}{8\pi^2}\int_{\mathbb{R}^3\times[-T,T]} \mathrm{d}\,\mathrm{CS} \overset{(2)}{=} -\frac{1}{8\pi^2}\left(\int_{x^0=T} \mathrm{CS} - \int_{x^0=-T} \mathrm{CS}\right) \overset{(3)}{=} N_{\mathrm{CS}}(T) - N_{\mathrm{CS}}(-T) \xrightarrow{T\to\infty} n_+ - n_-.$$

(1) (1.63), with T large enough to contain the instanton.
(2) Stokes. The outward normal is $+e_0$ on the top face and $-e_0$ on the bottom face, hence the relative sign; the sides at spatial infinity contribute nothing because $A \to 0$ there fast enough (we have required $g \to \mathbf{1}$).
(3) Definition of N_{CS} with the standard orientation of $\mathbb{R}^3$.

An instanton of charge k is a tunnelling event from $|n\rangle$ to $|n+k\rangle$.

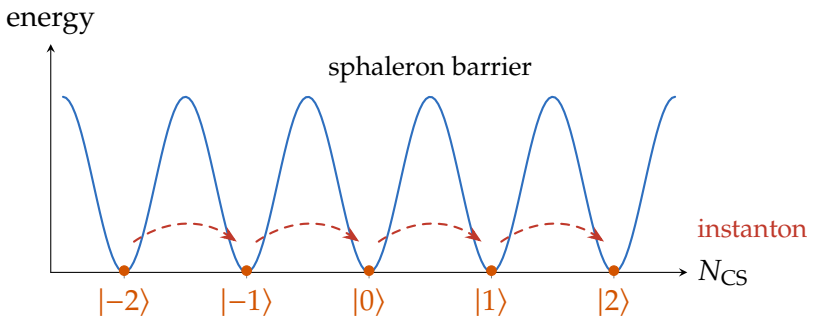

Figure 1.34: Schematic energy of gauge-field configurations as a function of the Chern–Simons number. The classical vacua $|n\rangle$ (orange) sit at the integers and are related by large gauge transformations. Classically they are separated by barriers; quantum mechanically an instanton (red) tunnels from $|n\rangle$ to $|n+1\rangle$. The true vacuum is a Bloch wave over this "crystal": the θ-vacuum.

This is the quantum mechanics of a particle in a periodic potential, and the answer is the same: the energy eigenstates are Bloch waves. Let $\mathcal{T}$ be the operator of the winding-one large gauge transformation, $\mathcal{T}|n\rangle = |n+1\rangle$. It commutes with the Hamiltonian, so we may diagonalise them together. Its eigenstates are the θ-vacua

$$|\theta\rangle := \sum_{n\in\mathbb{Z}} e^{-in\theta}|n\rangle, \qquad \theta \in [0, 2\pi),$$

because

$$\mathcal{T}|\theta\rangle \overset{(1)}{=} \sum_n e^{-in\theta}|n+1\rangle \overset{(2)}{=} \sum_m e^{-i(m-1)\theta}|m\rangle \overset{(3)}{=} e^{i\theta}|\theta\rangle.$$

(1) Linearity and $\mathcal{T}|n\rangle = |n+1\rangle$.
(2) Relabel $m = n + 1$; the sum over all integers is unchanged.
(3) Pull out $e^{i\theta}$.

Since $\mathcal{T}$ commutes with every gauge-invariant observable, different θ's never mix: θ is a new constant of nature, like a superselection label. What does it do to the path integral? The amplitude $\langle m|e^{-HT}|n\rangle$ is the path integral over fields that interpolate from $|n\rangle$ to $|m\rangle$, i.e. over the sector $k = m - n$; call it I_{m-n}. Then

$$\langle\theta'|e^{-HT}|\theta\rangle \overset{(1)}{=} \sum_{m,n} e^{im\theta'} e^{-in\theta}\, I_{m-n} \overset{(2)}{=} \sum_{n} e^{in(\theta'-\theta)} \sum_{k} e^{ik\theta'} I_k$$
$$\overset{(3)}{=} 2\pi\,\delta(\theta'-\theta) \sum_{k\in\mathbb{Z}} e^{ik\theta} \int_{[k]} \mathcal{D}A\; e^{-S[A]}.$$

(1) Expand both θ-states in the $|n\rangle$; $\langle\theta'| = \sum_m e^{im\theta'}\langle m|$.
(2) Put $m = n + k$ and sum over n and k independently.
(3) $\sum_n e^{in\alpha} = 2\pi\delta(\alpha)$ for $\alpha \in (-\pi, \pi]$; and I_k is the path integral over the sector of instanton number k.

So the θ-vacuum is the same as adding to the Euclidean action the term $-i\theta k = -i\theta\frac{g^2}{32\pi^2}\int F\tilde{F}\,\mathrm{d}^4x$. It is a total derivative, so it changes neither the classical equations nor perturbation theory, yet it is physical. In QCD it violates CP, and the bound on the neutron electric dipole moment forces $|\theta| \lesssim 10^{-10}$: the **strong CP problem**. We return to all of this, and to the counting of instanton moduli, in Chapter 8.

Dictionary: the θ-vacuum as a crystal

particle in a periodic potential	Yang–Mills vacuum
lattice site n	classical vacuum $\lvert n\rangle$, winding $n \in \pi_3(\mathrm{SU}(2))$
translation by one lattice spacing	large gauge transformation $\mathcal{T}$
tunnelling through a barrier	instanton, weight $e^{-8\pi^2/g^2}$
Bloch momentum × lattice spacing	θ
Bloch wave $\sum_n e^{-in\theta}\lvert n\rangle$	θ-vacuum $\lvert\theta\rangle$

1.3.15 Why Nash now turns to cohomology

Nash closes §3 with a warning: homotopy groups, "though simple and intuitive to describe, can be very difficult to calculate", and "a much more calculable set of invariants … are the cohomology groups". After this section we can say precisely what goes wrong and what cohomology will fix.

	homotopy groups $\pi_m(X)$	cohomology groups $H^m(X)$ (Nash §4)
definition	maps *into* X from spheres	(for de Rham) closed forms *on* X modulo exact ones
above dim X	usually nonzero ($\pi_3(S^2) = \mathbb{Z}$, Figure 1.27)	always zero
cutting and gluing	no simple rule (van Kampen only for π_1)	Mayer–Vietoris exact sequence
computed by	exact sequences, much ingenuity; unknown in general	linear algebra; integrals of forms
algebra	non-abelian π_1, abelian $\pi_{m\geq 2}$	abelian groups, with a ring structure (wedge product)
physics	defect and instanton charges	fluxes, characteristic classes, anomalies

The two are closely related, and Nash's first definition of cohomology uses homotopy. The circle has only one nonzero homotopy group, $\pi_1(S^1) = \mathbb{Z}$ (Nash's (1.32)): it is an **Eilenberg–MacLane space** $K(\mathbb{Z}, 1)$. Nash defines $H^n(X; G) = [X, K(G, n)]_0$, so in particular $H^1(X; \mathbb{Z}) = [X, S^1]_0$: the first integral cohomology of X is the set of ways of mapping X to a circle, and these are counted by winding numbers.

Worked example 1.56: $H^1(T^2;\mathbb{Z}) = [T^2, S^1] = \mathbb{Z}^2$ by winding numbers

A map $f : T^2 \to S^1$, restricted to the two basic circles of the torus (Example 1.26 picture), has two winding numbers

$$(m, n) = \left(\frac{1}{2\pi} \oint_a f^* \mathrm{d}\theta,\ \frac{1}{2\pi} \oint_b f^* \mathrm{d}\theta \right) \in \mathbb{Z}^2.$$

Every pair occurs: $f_{m,n}(\theta, \phi) = e^{i(m\theta + n\phi)}$ has windings (m, n), since $f_{m,n}^* \mathrm{d}\theta = m\,\mathrm{d}\theta + n\,\mathrm{d}\phi$. Conversely, if f has windings (m, n), then $f \cdot f_{m,n}^{-1}$ has windings $(0, 0)$, so it lifts to a real function $\tilde{h}$ on T^2 with $f = f_{m,n}\, e^{i\tilde{h}}$, and $f_{m,n} e^{it\tilde{h}}$, $t \in [0, 1]$, is a homotopy from $f_{m,n}$ to f. So $[T^2, S^1] = \mathbb{Z}^2$ (and base points do not matter since S^1 is abelian). The answer is the pair of periods of the closed 1-form $f^*\mathrm{d}\theta/2\pi$: an element of $H^1(T^2;\mathbb{Z})$. The de Rham version of this, $H^1_{\mathrm{dR}}(T^2) = \mathbb{R}^2$, is where the next part starts.

Reading Nash (pp. 9–12, (1.26)–(1.36))

- *(1.26)–(1.27)*: $\pi_1(X) = [S^1, X]_0$ with the product "first α at double speed, then β"; the group axioms hold up to homotopy, i.e. ΩX is an H-space. Our §1.3.1, with the homotopies written out.
- *(1.28)–(1.30)*: $\pi_n(X) = [S^n, X]_0 = [S^{n-1}, \Omega X]_0 = [SS^{n-2}, \Omega X]_0$; the last form has an H-space target and a coH-space source, so by the remark at the end of Nash §2 (our Eckmann–Hilton argument) π_n is abelian for $n \geq 2$. Our §1.3.6, with the cube picture of Figure 1.23.
- $\pi_1(G)$ *abelian*: $\pi_1(G) = [SS^0, G]_0$, G an H-space; the footnote explains $S^0 = \{x_1^2 = 1\}$, two points. Our §1.3.4; the example $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$ and the belt trick are our additions.
- *Genus $g \geq 2$ Riemann surfaces* have non-abelian π_1: our Figure 1.19 and the presentation (1.35).
- *(1.31)*: $[X, Y]_0/\pi_1(Y) \cong [X, Y]$ via change of base point along paths γ, depending

only on the homotopy class of γ, and requiring Y path-connected. Our §1.3.5. Nash's notation $[X, x_0; Y, y_0]_0$ is our $[X, Y]_0$ with the base points shown.
