- *(1.32)–(1.34)*: $\pi_m(S^1)$, $\pi_m(S^n)$ for $m \leq n$, and Serre's result for $m > n$. Nash cites Bott and Tu; we computed (1.32) by lifting, (1.33) by general position and the degree, and illustrated (1.34) by the Hopf map and Figure 1.27.
- *(1.35)–(1.36)*: stability, $G_m = \pi_{2m+2}(S^{m+2})$. Our (1.57) and the Freudenthal theorem; note Nash's m is the row index k of our table.
- *Lie groups and Bott periodicity*, deferred by Nash to his chapter 3 (K-theory): our §1.3.12.
- *Cohomology is more calculable*: our §1.3.15.

Everything in §§1.3.11, 1.3.13 and 1.3.14 (exact homotopy sequences, defects, instantons, θ) goes beyond Nash's text in this section; it anticipates his §5 and chapters 8 and 10.

Recap: homotopy groups (Nash §3)

- $\pi_1(X) = [S^1, X]_0$: based loops up to homotopy, multiplied by concatenation. $\pi_1(S^1) = \mathbb{Z}$ by the winding number $\frac{1}{2\pi}\oint \mathrm{d}\theta$; $\pi_1(T^2) = \mathbb{Z}^2$; π_1 of the figure eight and of genus $g \geq 2$ surfaces is non-abelian; $\pi_1(\mathbb{RP}^2) = \pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$ (the belt trick, spin $\frac{1}{2}$).
- $\pi_n(X) = [S^n, X]_0$: maps of cubes with boundary at the base point; abelian for $n \geq 2$ (Eckmann–Hilton); coverings do not change $\pi_{n\geq 2}$.
- Spheres: $\pi_m(S^n) = 0$ for $m < n$ (general position), $\pi_n(S^n) = \mathbb{Z}$ (degree $= \frac{1}{\mathrm{Vol}}\int f^*\mathrm{vol}$), $\pi_3(S^2) = \mathbb{Z}$ (Hopf map, linking number), finite otherwise except $\pi_{2n-1}(S^n)$ for even n (Serre); stable along diagonals (Freudenthal).
- Free classes are based classes modulo the action of π_1: conjugacy classes for loops.
- The long exact sequence of a fibration computes π_*: $\pi_2(S^2) = \pi_1(S^1)$, $\pi_3(S^2) = \pi_3(S^3)$, $\pi_k(\mathrm{SU}(n))$ stable, $\pi_2(G/H) = \pi_1(H)$. Stable groups of classical groups are periodic (Bott).
- Physics: defects of codimension d carry charges in π_{d-1} of the vacuum manifold; textures in π_D. Instantons carry $k = -\frac{1}{8\pi^2}\int \mathrm{tr}\, F \wedge F = n(g) \in \pi_3(\mathrm{SU}(2)) = \mathbb{Z}$, the winding of the gauge transformation at infinity; $S \geq 8\pi^2|k|/g^2$; the vacuum is a θ-vacuum.
- Homotopy groups are hard to compute; cohomology (next) is easier.

1.4 Cohomology and homology groups

Homotopy groups are the most natural invariants we have met so far. A loop that cannot be shrunk, a sphere that cannot be collapsed: these are things we can picture. Their weakness is that they are *hard to compute*. Nobody knows all the groups $\pi_m(S^2)$. Even the sphere, the simplest non-trivial space there is, defeats us.

This section is about a second family of invariants, the **cohomology groups** $H^n(X; G)$ and their duals, the **homology groups** $H_n(X; G)$. They are coarser than homotopy groups: they see

less. In exchange they are *computable*, in the most literal sense. For a space built out of finitely many triangles, computing homology is a matter of writing down a few integer matrices and finding their ranks. For a manifold, computing real cohomology is a matter of asking which closed differential forms fail to be exact.

For a physicist there are three reasons to care.

- Cohomology classes are what *topological charges* are. Magnetic charge, instanton number and winding number are all integrals of a closed form over a closed surface. Those integrals only depend on the cohomology class of the form.

- Cohomology counts *zero modes*. By Hodge theory (Chapter 2) the dimension of $H^p_{\mathrm{dR}}(M)$ equals the number of harmonic p-forms. These are the zero modes of the Laplacian on p-forms.

- The alternating sum of these dimensions, the Euler characteristic, is the simplest *index*. The whole of Chapter 4 generalises it.

Nash gives two definitions of cohomology in quick succession. One uses maps into special spaces (Eilenberg–MacLane spaces). The other uses complexes, meaning sequences of linear maps whose consecutive composites vanish. We follow him, and then spend most of our time on the second definition, because that is the one we can compute with. Figure 1.35 shows how the pieces fit together.

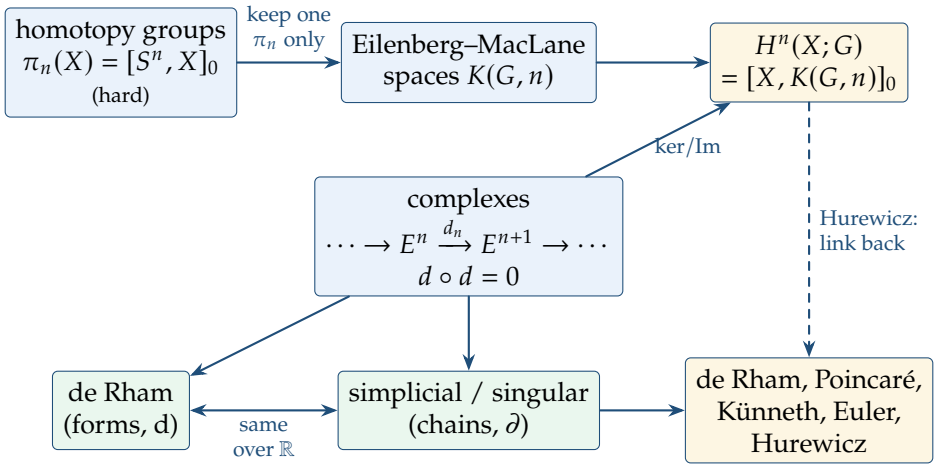

Figure 1.35: Roadmap of Section 1.4. Nash's first definition (top row) makes it obvious that cohomology depends only on homotopy type. The second (middle) turns cohomology into linear algebra, with two concrete realisations (bottom row): differential forms and triangulations. The theorems at the bottom right let us compute.

1.4.1 Eilenberg–MacLane spaces: one homotopy group and nothing else

Recall from earlier in the chapter that for a pointed space X the m-th homotopy group is $\pi_m(X) = [S^m, X]_0$. This is the set of based homotopy classes of maps from the m-sphere into X. A general space has many non-zero homotopy groups, all tangled together. Eilenberg and MacLane asked a simple question: what if a space had *only one*?

Working definition 1.28 (Eilenberg–MacLane space)

Let G be a group and $n \geq 1$ an integer. A $K(G,n)$ is a path-connected [any two points can be joined by a path in K] space K with

$$\pi_m\big(K(G,n)\big) = \begin{cases} G & m = n, \\ 0 & m \neq n. \end{cases} \tag{1.65}$$

Operational test: list the homotopy groups of your candidate space. Exactly one of them must be non-zero. For $n \geq 2$, G must be abelian [$gh = hg$ for all $g, h \in G$], because π_n is always abelian for $n \geq 2$.

Such spaces exist for every G (abelian when $n \geq 2$). Up to homotopy equivalence there is only one of each. So we can speak of *the* $K(G,n)$, just as we speak of *the* circle without fixing a radius.

Here is the idea behind existence. Start with a bunch of n-spheres glued at a point. Their π_n is a free group on the spheres. Glue on $(n+1)$-dimensional discs to impose the relations of G. Now π_n is exactly G, but the gluing has created unwanted higher homotopy groups. Kill each class of π_{n+1} by gluing in an $(n+2)$-disc along it. Then kill π_{n+2} by $(n+3)$-discs, and so on for ever. The result is usually infinite-dimensional, and we will see that this cannot be avoided.

Worked example 1.57: The circle is a $K(\mathbb{Z},1)$

We already know $\pi_1(S^1) = \mathbb{Z}$: a loop is classified by how many times it winds. The higher groups vanish. To see why, unroll the circle onto its universal cover $\mathbb{R} \to S^1$, $t \mapsto e^{2\pi i t}$. A map $S^m \to S^1$ with $m \geq 2$ lifts to a map $S^m \to \mathbb{R}$, because S^m is simply connected. The lift can be shrunk to a point, since $\mathbb{R}$ is contractible. Push the shrinking back down to S^1 and the original map becomes null-homotopic. Hence

$$\begin{aligned} \pi_m(S^1) &\overset{(1)}{=} \pi_m(\mathbb{R}) \\ &\overset{(2)}{=} 0 \qquad (m \geq 2), \end{aligned}$$

(1) Every map (and every homotopy) from a simply connected S^m lifts through the covering, and lifts of homotopic maps are homotopic.

(2) $\mathbb{R}$ is contractible, so all its homotopy groups vanish.

Therefore $S^1 = K(\mathbb{Z},1)$, which is the example Nash gives. In Section 1.5.13 we will get the same result from the exact homotopy sequence of the fibration $\mathbb{Z} \to \mathbb{R} \to S^1$.

Worked example 1.58: More Eilenberg–MacLane spaces

- *Torus.* $T^k = S^1 \times \cdots \times S^1$ has universal cover $\mathbb{R}^k$, which is contractible. Therefore $T^k = K(\mathbb{Z}^k, 1)$.
- *Surfaces.* A closed orientable surface Σ_g of genus $g \geq 1$ has the contractible plane (for $g = 1$) or the hyperbolic disc (for $g \geq 2$) as universal cover. So $\Sigma_g = K(\pi_1(\Sigma_g), 1)$. The sphere $\Sigma_0 = S^2$ is *not* a $K(G,n)$, since π_2 and π_3 are both $\mathbb{Z}$.
- *Infinite real projective space.* Let $S^\infty = \bigcup_N S^N$ be the unit sphere in $\mathbb{R}^\infty$. It is contractible. The antipodal map $x \mapsto -x$ acts freely, and the quotient is $\mathbb{RP}^\infty$. It has $\pi_1 = \mathbb{Z}_2$ and nothing else: $\mathbb{RP}^\infty = K(\mathbb{Z}_2, 1)$.

- *Infinite complex projective space.* $U(1)$ acts freely on the unit sphere $S^\infty \subset \mathbb{C}^\infty$ by $z \mapsto e^{i\alpha}z$. The quotient $\mathbb{CP}^\infty$ has $\pi_2 = \mathbb{Z}$ and nothing else: $\mathbb{CP}^\infty = K(\mathbb{Z}, 2)$. We prove this in Example 1.101 with the exact homotopy sequence.

Notice that the finite-dimensional versions fail. $\mathbb{RP}^2$ has $\pi_2(\mathbb{RP}^2) = \pi_2(S^2) = \mathbb{Z}$, and $\mathbb{CP}^1 = S^2$ has $\pi_3 = \mathbb{Z}$. Only in the infinite-dimensional limit do the unwanted groups die.

Watch out: $K(G, n)$ is almost never a manifold

Apart from $K(\mathbb{Z}, 1) = S^1$, the tori, the surfaces and similar aspherical manifolds, Eilenberg–MacLane spaces are infinite-dimensional. You should not try to picture $K(\mathbb{Z}, 2)$ as something smooth and finite. Picture it as the receptacle for a certain kind of map. It is a tool, not an object of study.

1.4.2 Nash's first definition: cohomology as maps into $K(G, n)$

We can now state Nash's first definition. The n-th cohomology group of a pointed space X with coefficients in G is

$$H^n(X; G) \coloneqq [X, K(G, n)]_0. \tag{1.66}$$

This is the set of based homotopy classes of maps from X into the Eilenberg–MacLane space. Compare it with homotopy groups. There we map a *fixed* simple space (a sphere) *into* X. Here we map X *into* a fixed simple space. Cohomology is "homotopy the other way round".

Key idea: Cohomology is an invariant of homotopy type

If $X \simeq X'$ are homotopy equivalent, then $[X, Y]_0 = [X', Y]_0$ for any Y (this was shown for $[X, Y]$ earlier in the chapter). Taking $Y = K(G, n)$ gives

$$X \simeq X' \quad \Longrightarrow \quad H^n(X; G) \cong H^n(X'; G).$$

So a contractible space, such as $\mathbb{R}^k$ or a disc, has the cohomology of a point.

The definition becomes concrete when $n = 1$ and $G = \mathbb{Z}$, because then $K(\mathbb{Z}, 1) = S^1$ and

$$H^1(X; \mathbb{Z}) = [X, S^1]_0. \tag{1.67}$$

A degree-one integral cohomology class *is* a homotopy class of maps into the circle. Equivalently, since $S^1 = U(1)$, it is a homotopy class of $U(1)$-valued functions. Physicists call these *gauge transformations up to deformation*, and label them by winding numbers.

Worked example 1.59: $H^1(S^1; \mathbb{Z}) = \mathbb{Z}$ and the winding number

A based map $f : S^1 \to S^1 \subset \mathbb{C}$ is a phase $f(e^{i\theta})$ with $f(1) = 1$. Its homotopy class is fixed by its **winding number**, or **degree**,

$$\deg f = \frac{1}{2\pi i} \oint_{S^1} f^{-1} \mathrm{d}f. \tag{1.68}$$

For $f_k(e^{i\theta}) = e^{ik\theta}$ we get

$$\deg f_k \overset{(1)}{=} \frac{1}{2\pi i} \int_0^{2\pi} e^{-ik\theta} \frac{\mathrm{d}}{\mathrm{d}\theta}\left(e^{ik\theta}\right) \mathrm{d}\theta$$

$$\overset{(2)}{=} \frac{1}{2\pi i}\int_0^{2\pi} e^{-ik\theta}\,(ik)\,e^{ik\theta}\,\mathrm{d}\theta$$
$$= \frac{ik\cdot 2\pi}{2\pi i} = k.$$

(1) Pull the 1-form $f^{-1}\mathrm{d}f$ back to the parameter $\theta \in [0, 2\pi]$.
(2) Chain rule.

The integrand $f^{-1}\mathrm{d}f = i\,\mathrm{d}(\arg f)$ changes by an exact form under a small deformation of f. So $\deg f$ is a homotopy invariant, and it is always an integer, because $\arg f$ must come back to itself modulo 2π. Conversely, two maps with the same degree are homotopic: interpolate their lifts $\arg f_0$ and $\arg f_1$ linearly. The group law on $[S^1, U(1)]_0$ is pointwise multiplication of phases, and

$$\deg(fg) \overset{(1)}{=} \frac{1}{2\pi i}\oint (fg)^{-1}(\mathrm{d}f\,g + f\,\mathrm{d}g)$$
$$\overset{(2)}{=} \frac{1}{2\pi i}\oint f^{-1}\mathrm{d}f + \frac{1}{2\pi i}\oint g^{-1}\mathrm{d}g = \deg f + \deg g.$$

(1) Leibniz rule for $\mathrm{d}(fg)$.
(2) $U(1)$ is abelian, so $(fg)^{-1} = f^{-1}g^{-1}$ and the factors cancel term by term.

So $H^1(S^1;\mathbb{Z}) \cong \mathbb{Z}$ *as a group*, with pointwise multiplication of maps becoming addition of integers.

Worked example 1.60: $H^1(T^2;\mathbb{Z}) = \mathbb{Z}^2$

Put angles (θ_1, θ_2) on the torus. For every pair of integers (m, n) there is a map

$$f_{m,n} : T^2 \to S^1, \qquad f_{m,n}(\theta_1, \theta_2) = e^{i(m\theta_1 + n\theta_2)}.$$

Restricted to the loop $a = \{\theta_2 = 0\}$ it has degree m. Restricted to the loop $b = \{\theta_1 = 0\}$ it has degree n. Both degrees are homotopy invariants, so different pairs give non-homotopic maps. Every map $T^2 \to S^1$ is homotopic to exactly one $f_{m,n}$: lift the phase to $\mathbb{R}$ after subtracting $m\theta_1 + n\theta_2$, and the remainder is a genuine periodic function, which can be shrunk to zero. Hence

$$H^1(T^2;\mathbb{Z}) = [T^2, S^1]_0 \cong \mathbb{Z}^2, \qquad [f_{m,n}] \mapsto (m, n).$$

Figure 1.36 shows the picture.

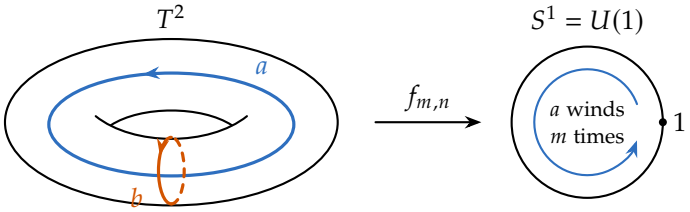

Figure 1.36: A map from the torus to the circle is fixed, up to homotopy, by two integers: how many times the image of the loop a (blue) winds around S^1, and how many times the image of b (orange) does. This is $H^1(T^2;\mathbb{Z}) = \mathbb{Z}^2$, read off as "one integer per independent loop".

Worked example 1.61: $H^1(S^2;\mathbb{Z}) = 0$

Any map $f : S^2 \to S^1$ lifts to $\tilde{f} : S^2 \to \mathbb{R}$, because S^2 is simply connected. Now $t\tilde{f}$, $t \in [0,1]$, shrinks the lift to 0, and $e^{2\pi i t\tilde{f}}$ shrinks f to the constant map. So $[S^2, S^1]_0$ has one element. The sphere has no "winding-number sectors" for $U(1)$-valued fields.

Physical picture: Large gauge transformations

In a $U(1)$ gauge theory on a spatial manifold X, a gauge transformation is a map $g : X \to U(1)$. The ones that can be deformed to the identity are "small". The rest are "large", and they fall into sectors labelled by $[X, U(1)] = H^1(X;\mathbb{Z})$. On a spatial circle these are the winding numbers $k \in \mathbb{Z}$ of $g = e^{ik\theta}$. On a spatial torus they are pairs (m, n), as above. On a sphere there are none.

What about $n = 2$? We will see in Section 1.5.11 that $K(\mathbb{Z}, 2) = \mathbb{CP}^\infty$ is also the *classifying space* of the group $U(1)$. Then (1.66) says

$$H^2(X;\mathbb{Z}) = [X, \mathbb{CP}^\infty]_0 = \{U(1) \text{ bundles over } X\}/\text{iso}.$$

This is the mathematical statement of Dirac quantisation: the magnetic flux through a closed surface is an integer.

1.4.3 Why $[X, K(G,n)]_0$ is a group: loop spaces of $K(G,n)$

A set of homotopy classes is only a group if something supplies a multiplication. Earlier in the chapter we saw the two ways this can happen. Either the *target* is an H-space (it has a product $Y \times Y \to Y$ that is associative and invertible up to homotopy), or the *source* is a coH-space (for example a suspension). For cohomology the source X is arbitrary, so the product must come from the target. Nash's argument is that $K(G,n)$ is itself a loop space, and loop spaces are H-spaces.

The key fact, recalled from the discussion of (1.29), is that looping shifts homotopy groups down by one:

$$\pi_m(\Omega Y) = [S^m, \Omega Y]_0 = [SS^m, Y]_0 = [S^{m+1}, Y]_0 = \pi_{m+1}(Y). \tag{1.69}$$

Apply this to $Y = K(G, n+1)$:

$$\pi_m\big(\Omega K(G,n+1)\big) \overset{(1)}{=} \pi_{m+1}\big(K(G,n+1)\big) \overset{(2)}{=} \begin{cases} G & m+1 = n+1, \\ 0 & \text{otherwise} \end{cases} = \begin{cases} G & m = n, \\ 0 & \text{otherwise.} \end{cases} \tag{1.70}$$

(1) Looping lowers the index by one, (1.69).
(2) Definition (1.65) of $K(G, n+1)$.

So $\Omega K(G, n+1)$ has exactly the homotopy groups of a $K(G,n)$. By uniqueness up to homotopy equivalence,

$$\Omega K(G,n+1) \simeq K(G,n), \qquad \text{and more generally} \qquad \Omega^m K(G,n+m) \simeq K(G,n). \tag{1.71}$$

Now $K(G,n)$ is (up to homotopy) the loop space ΩY with $Y = K(G,n+1)$. Loops can be concatenated, and concatenation is an H-space product. This makes $[X, K(G,n)]_0 = [X, \Omega K(G,n+1)]_0$ a group: two maps $f, g : X \to \Omega Y$ multiply to the map sending x to the loop "first $f(x)$, then $g(x)$". Because $K(G,n)$ is even a *double* loop space, $\Omega^2 K(G,n+2)$, this group is abelian. This is the same argument that made π_n abelian for $n \geq 2$.

Worked example 1.62: Checking (1.71) in the two simplest cases

- $\Omega S^1 = \Omega K(\mathbb{Z},1)$ should be a "$K(\mathbb{Z},0)$", meaning a space whose path components are labelled by $\mathbb{Z}$ and are each contractible. Indeed, a based loop in S^1 lies, up to homotopy, in exactly one winding sector $k \in \mathbb{Z}$, and each sector deforms to the single loop $e^{ik\theta}$.
- $\Omega\mathbb{CP}^\infty = \Omega K(\mathbb{Z},2) \simeq K(\mathbb{Z},1) = S^1$. A loop in $\mathbb{CP}^\infty$ is "the same as" an element of $U(1)$. This reflects the fibration $U(1) \to S^\infty \to \mathbb{CP}^\infty$ of Section 1.5.11: the fibre of the path fibration over a classifying space BG is $\Omega BG \simeq G$.

Physical picture: Spectra and generalised cohomology

A sequence of spaces K_n with $\Omega K_{n+1} \simeq K_n$ is called a **spectrum**. Ordinary cohomology comes from the spectrum $K_n = K(G,n)$. Replace it by the Bott spectrum $\mathbb{Z}\times BU,\ U,\ \mathbb{Z}\times BU,\ U,\dots$ (which obeys $\Omega^2 BU \simeq \mathbb{Z}\times BU$, Bott periodicity) and you get *K-theory*, the cohomology theory of vector bundles that drives the index theorem (Chapters 3 and 4). This is why Nash insists on the $[X,K(G,n)]_0$ viewpoint: it generalises.

1.4.4 Complexes: cohomology by linear algebra

The definition $[X,K(G,n)]_0$ is conceptually clean but hard to compute with: the target is an infinite-dimensional monster. The second definition is built from linear algebra, and it is the one we actually use.

Working definition 1.29 (cochain complex and its cohomology)

A **cochain complex** is a sequence of abelian groups (or vector spaces) E^n and homomorphisms (or linear maps) $d_n : E^n \to E^{n+1}$,

$$\cdots \xrightarrow{d_{n-2}} E^{n-1} \xrightarrow{d_{n-1}} E^n \xrightarrow{d_n} E^{n+1} \xrightarrow{d_{n+1}} \cdots \tag{1.72}$$

with the one crucial property

$$d_n \circ d_{n-1} = 0 \qquad \text{for all } n. \tag{1.73}$$

Elements of $\operatorname{Ker} d_n$ [the $e \in E^n$ with $d_n e = 0$] are **cocycles** ("closed"). Elements of $\operatorname{Im} d_{n-1}$ [those of the form $d_{n-1}f$ with $f \in E^{n-1}$] are **coboundaries** ("exact"). The **n-th cohomology** of the complex is

$$H^n_E = \frac{\operatorname{Ker} d_n}{\operatorname{Im} d_{n-1}} = \frac{\{\text{closed elements of } E^n\}}{\{\text{exact elements of } E^n\}}. \tag{1.74}$$

[two closed elements count as the same class when they differ by an exact one]. *Operational recipe* (finite dimensions, real coefficients): write each d_n as a matrix D_n and compute its rank r_n. Then $\dim H^n_E = \dim E^n - r_n - r_{n-1}$.

The quotient in (1.74) makes sense because every exact element is closed. If $e = d_{n-1}f$ then

$$\begin{aligned} d_n e &\overset{(1)}{=} d_n(d_{n-1}f) \\ &\overset{(2)}{=} 0, \qquad \text{so} \qquad \operatorname{Im} d_{n-1} \subseteq \operatorname{Ker} d_n. \end{aligned} \tag{1.75}$$

(1) e is exact: $e = d_{n-1}f$ for some $f \in E^{n-1}$.

(2) The defining property $d \circ d = 0$, (1.73).

If equality holds, $\operatorname{Im} d_{n-1} = \operatorname{Ker} d_n$, at every n, the sequence is called **exact**. In general it is not, and H^n_E measures by how much exactness fails at the n-th spot. "Cohomology is the obstruction to exactness" is the slogan.

The rank formula in the box follows from rank–nullity:

$$\begin{aligned} \dim H^n_E &\overset{(1)}{=} \dim \operatorname{Ker} d_n - \dim \operatorname{Im} d_{n-1} \\ &\overset{(2)}{=} (\dim E^n - r_n) - r_{n-1}. \end{aligned}$$

(1) The dimension of a quotient of vector spaces is the difference of dimensions.
(2) Rank–nullity for $d_n : E^n \to E^{n+1}$ gives $\dim \operatorname{Ker} d_n = \dim E^n - r_n$. The image of d_{n-1} has dimension r_{n-1} by definition of rank.

Worked example 1.63: A discrete circle: cohomology of a triangle

Take three vertices v_0, v_1, v_2 joined in a loop by edges e_{01}, e_{12}, e_{20}. Let $E^0 = \mathbb{R}^3$ be the functions on vertices and $E^1 = \mathbb{R}^3$ the functions on edges. Define the "discrete gradient" $(d_0 f)(e_{ij}) = f(v_j) - f(v_i)$. All other E^n are zero. In the bases of vertices and edges,

$$D_0 = \begin{pmatrix} -1 & 1 & 0 \\ 0 & -1 & 1 \\ 1 & 0 & -1 \end{pmatrix} \begin{matrix} \leftarrow e_{01} \\ \leftarrow e_{12} \\ \leftarrow e_{20} \end{matrix}$$

The rows add up to zero, so $r_0 \le 2$; the first two rows are independent, so $r_0 = 2$. Then

$$\begin{aligned} \dim H^0 &\overset{(1)}{=} \dim E^0 - r_0 - r_{-1} = 3 - 2 - 0 = 1, \\ \dim H^1 &\overset{(2)}{=} \dim E^1 - r_1 - r_0 = 3 - 0 - 2 = 1. \end{aligned}$$

(1) Rank formula. There is no map into E^0, so $r_{-1} = 0$.
(2) $d_1 : E^1 \to E^2 = 0$ is the zero map, so $r_1 = 0$.

Interpretation: H^0 is spanned by the constant function (gradient zero). H^1 is detected by the "discrete line integral" $a \mapsto a(e_{01}) + a(e_{12}) + a(e_{20})$. Every gradient has zero total, because the sum telescopes around the loop. An edge function with non-zero total is *not* a gradient: it is a discrete $\mathrm{d}\theta$. This is the lattice-gauge-theory picture of a Wilson loop.

Key idea: Euler characteristic of a complex

For a finite complex of finite-dimensional spaces,

$$\sum_n (-1)^n \dim E^n = \sum_n (-1)^n \dim H^n_E. \tag{1.76}$$

The alternating sum is the same before and after taking cohomology.

This follows from the rank formula:

$$\begin{aligned} \sum_n (-1)^n \dim H^n_E &\overset{(1)}{=} \sum_n (-1)^n \dim E^n - \sum_n (-1)^n r_n - \sum_n (-1)^n r_{n-1} \\ &\overset{(2)}{=} \sum_n (-1)^n \dim E^n - \sum_n (-1)^n r_n + \sum_m (-1)^m r_m \end{aligned}$$

$$= \sum_n (-1)^n \dim E^n .$$

(1) Insert $\dim H^n_E = \dim E^n - r_n - r_{n-1}$.
(2) Rename $m = n - 1$ in the last sum, so $(-1)^n = -(-1)^m$.

For the triangle, $3 - 3 = 0 = 1 - 1$. This small identity is the seed of the index theorem. The left side is "combinatorial" (count cells). The right side is "analytic" (count solutions of $\mathrm{d}f = 0$ modulo gauge). In Chapter 4 the complex will be a complex of differential operators, and the right side becomes an index.

1.4.5 The de Rham complex

The most important example for us takes $E^n = \Omega^n(X)$, the smooth n-forms on a manifold X, and $d_n = \mathrm{d}$, the exterior derivative (Chapter T1). We recall the two facts we need.

- In coordinates, d of a p-form $\alpha = \frac{1}{p!}\alpha_{\mu_1\dots\mu_p}\mathrm{d}x^{\mu_1}\wedge\cdots\wedge\mathrm{d}x^{\mu_p}$ is $\mathrm{d}\alpha = \frac{1}{p!}\partial_\nu\alpha_{\mu_1\dots\mu_p}\,\mathrm{d}x^\nu\wedge\mathrm{d}x^{\mu_1}\wedge\cdots$.
- $\mathrm{d}\circ\mathrm{d} = 0$, because mixed partial derivatives are symmetric while $\mathrm{d}x^\nu\wedge\mathrm{d}x^\lambda$ is antisymmetric.

So the de Rham complex

$$0 \to \Omega^0(X) \xrightarrow{\mathrm{d}} \Omega^1(X) \xrightarrow{\mathrm{d}} \Omega^2(X) \xrightarrow{\mathrm{d}} \cdots \xrightarrow{\mathrm{d}} \Omega^{\dim X}(X) \to 0 \tag{1.77}$$

is a cochain complex. Its cohomology

$$H^p_{\mathrm{dR}}(X) = \frac{\{\alpha \in \Omega^p(X) : \mathrm{d}\alpha = 0\}}{\{\mathrm{d}\beta : \beta \in \Omega^{p-1}(X)\}} \tag{1.78}$$

is the **de Rham cohomology** of X. In $\mathbb{R}^3$ the complex is vector calculus in disguise (Figure 1.37).

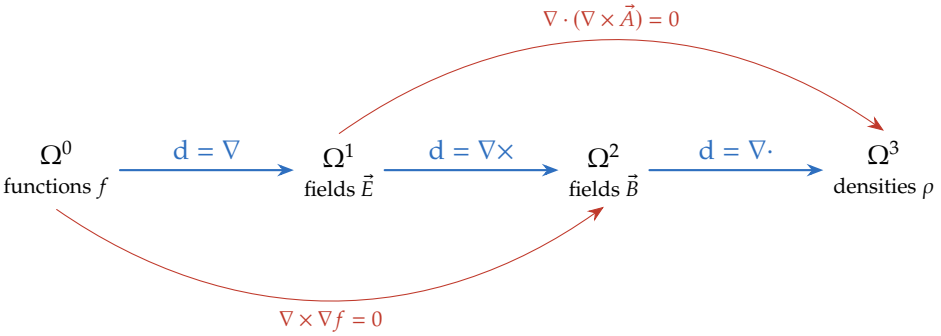

Figure 1.37: The de Rham complex of $\mathbb{R}^3$ is grad, curl, div. The two identities of vector calculus (red) are $\mathrm{d}\circ\mathrm{d} = 0$. On all of $\mathbb{R}^3$ the complex is exact: curl-free fields are gradients and divergence-free fields are curls. On a region with holes it is not, and the failure is the cohomology.

Worked example 1.64: H^0_{dR} counts connected components

There is nothing before Ω^0, so nothing is exact in degree 0, and $H^0_{\mathrm{dR}}(X) = \{f : \mathrm{d}f = 0\}$. A function with zero gradient is constant on each connected piece. So $H^0_{\mathrm{dR}}(X) = \mathbb{R}^c$, where c is the number of connected components. For $X = \mathbb{R}\setminus\{0\}$, $c = 2$ and $H^0_{\mathrm{dR}} = \mathbb{R}^2$.

Worked example 1.65: The Poincaré lemma: $\mathbb{R}^n$ has no cohomology in degree ≥ 1

Let $\alpha = \alpha_\mu \mathrm{d}x^\mu$ be a closed 1-form on $\mathbb{R}^n$: $\partial_\mu \alpha_\nu = \partial_\nu \alpha_\mu$. We construct a potential explicitly by integrating along the straight ray from the origin:

$$f(x) = \int_0^1 x^\mu \, \alpha_\mu(tx) \, \mathrm{d}t.$$

Then

$$\begin{aligned}
\partial_\nu f(x) &\overset{(1)}{=} \int_0^1 \Big[\alpha_\nu(tx) + x^\mu \, t \, (\partial_\nu \alpha_\mu)(tx) \Big] \mathrm{d}t \\
&\overset{(2)}{=} \int_0^1 \Big[\alpha_\nu(tx) + t \, x^\mu (\partial_\mu \alpha_\nu)(tx) \Big] \mathrm{d}t \\
&\overset{(3)}{=} \int_0^1 \frac{\mathrm{d}}{\mathrm{d}t} \Big[t \, \alpha_\nu(tx) \Big] \mathrm{d}t \\
&\overset{(4)}{=} \alpha_\nu(x).
\end{aligned}$$

(1) Differentiate under the integral. The product rule acts on x^μ and on $\alpha_\mu(tx)$, and the chain rule supplies the factor t.
(2) α is closed: $\partial_\nu \alpha_\mu = \partial_\mu \alpha_\nu$.
(3) Product rule: $\frac{\mathrm{d}}{\mathrm{d}t}[t \alpha_\nu(tx)] = \alpha_\nu(tx) + t \, x^\mu (\partial_\mu \alpha_\nu)(tx)$.
(4) Fundamental theorem of calculus: the bracket is $\alpha_\nu(x)$ at $t = 1$ and 0 at $t = 0$.

So $\alpha = \mathrm{d}f$ and $H^1_{\mathrm{dR}}(\mathbb{R}^n) = 0$. The same "integrate along rays" construction works in every degree (and on any star-shaped region), giving $H^p_{\mathrm{dR}}(\mathbb{R}^n) = 0$ for $p \geq 1$. This is the curl test for conservative fields, made precise. It fits the keyidea above: $\mathbb{R}^n$ is contractible, so it has the cohomology of a point.

Worked example 1.66: $H^1_{\mathrm{dR}}(S^1) = \mathbb{R}$

This follows [Dray §20.4]. Every 1-form on S^1 is $\alpha = f(\phi)\,\mathrm{d}\phi$ with f 2π-periodic, and every such form is closed (there are no 2-forms on S^1). Set $c_\alpha = \oint \alpha = \int_0^{2\pi} f \, \mathrm{d}\phi$. If $c_\alpha = 0$, the function

$$g(\phi) = \int_0^\phi f(\phi') \, \mathrm{d}\phi'$$

is periodic, because $g(2\pi) = c_\alpha = 0 = g(0)$. It satisfies $\mathrm{d}g = \alpha$, so α is exact. In general $\alpha - \frac{c_\alpha}{2\pi}\mathrm{d}\phi$ has zero integral, so

$$\alpha = \frac{c_\alpha}{2\pi} \, \mathrm{d}\phi + \mathrm{d}g,$$

and the class of α is fixed by the single number c_α. The form $\mathrm{d}\phi$ is closed but not exact, even though it is written as "d of ϕ". There is no single-valued smooth function ϕ on the whole circle. So $H^1_{\mathrm{dR}}(S^1) = \mathbb{R}$, spanned by $[\mathrm{d}\phi]$.

Worked example 1.67: The punctured plane and Aharonov–Bohm

On $X = \mathbb{R}^2 \setminus \{0\}$ consider

$$\alpha = \frac{x \, \mathrm{d}y - y \, \mathrm{d}x}{x^2 + y^2} \quad (= \mathrm{d}\theta \text{ locally}).$$

With $\alpha_x = -y/r^2$, $\alpha_y = x/r^2$ and $r^2 = x^2 + y^2$,

$$\begin{aligned} \mathrm{d}\alpha &\overset{(1)}{=} (\partial_x \alpha_y - \partial_y \alpha_x)\,\mathrm{d}x \wedge \mathrm{d}y \\ &\overset{(2)}{=} \left(\frac{r^2 - 2x^2}{r^4} + \frac{r^2 - 2y^2}{r^4}\right)\mathrm{d}x \wedge \mathrm{d}y \\ &\overset{(3)}{=} \frac{2r^2 - 2(x^2+y^2)}{r^4}\,\mathrm{d}x \wedge \mathrm{d}y = 0. \end{aligned}$$

(1) d of a 1-form in two dimensions; $\mathrm{d}y \wedge \mathrm{d}x = -\mathrm{d}x \wedge \mathrm{d}y$.
(2) Quotient rule: $\partial_x(x/r^2) = (r^2 - 2x^2)/r^4$ and $\partial_y(-y/r^2) = -(r^2 - 2y^2)/r^4$.
(3) $x^2 + y^2 = r^2$.

So α is closed. On the unit circle, $x = \cos\theta$, $y = \sin\theta$, it pulls back to $\mathrm{d}\theta$, so $\oint \alpha = 2\pi \neq 0$ and α is not exact (exemplar logic: an exact form integrates to zero on a closed curve). Therefore $H^1_{\mathrm{dR}}(\mathbb{R}^2 \setminus \{0\}) \neq 0$. In fact it is $\mathbb{R}$: the punctured plane deformation-retracts onto the circle, and cohomology is a homotopy invariant.

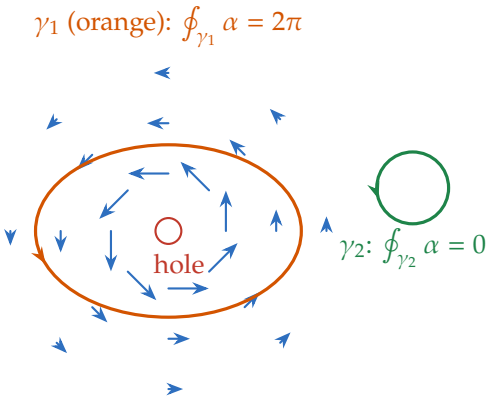

Figure 1.38: The closed form $\alpha = \mathrm{d}\theta$ on the punctured plane (blue arrows show the dual vector field, of strength $1/r$). The loop γ_1 encircles the hole and picks up 2π. The loop γ_2 does not, and picks up 0. The loop integral depends only on the *homology class* of the loop, which is "how many times it encircles the hole". For a solenoid carrying flux Φ, the vector potential outside is $A = \frac{\Phi}{2\pi}\alpha$: closed ($B = 0$) but not exact, and a charge going around γ_1 picks up the Aharonov–Bohm phase $e^{iq\Phi/\hbar}$.

Worked example 1.68: $H^2_{\mathrm{dR}}(S^2) \neq 0$

The area form $\omega = \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$ is closed (it is a top form) and $\int_{S^2} \omega = 4\pi \neq 0$, so it is not exact. This is the magnetic field of a monopole. We will show in Example 1.79 that $H^2_{\mathrm{dR}}(S^2) = \mathbb{R}$, spanned by $[\omega]$: *every* closed 2-form on S^2 is $\frac{c}{4\pi}\omega + \mathrm{d}\beta$, where c is its total flux.

Watch out: Closed does not mean exact, and "$\mathrm{d}\phi$" is a lie

The notation $\mathrm{d}\phi$, $\mathrm{d}\theta$ suggests exactness. On the circle, the punctured plane or the sphere, these forms are closed but not exact, because the would-be potential (ϕ, or the Dirac potential) is multivalued or singular somewhere. Cohomology is precisely the bookkeeping of such "potentials that exist locally but not globally".

Reading Nash (pp. 12–13, (1.37)–(1.43))

Nash's §4 opens with Eilenberg–MacLane spaces (1.37), the example $S^1 = K(\mathbb{Z}, 1)$ and the definition $H^n(X; G) = [X, K(G, n)]_0$ (1.38). He notes that $\Omega K(G, n+1)$ is a $K(G, n)$ (1.39), which makes $K(G, n)$ an H-space and $[X, K(G, n)]_0$ a group. He then switches to complexes $\{E^n(X), d_n\}$ with $d_n \circ d_{n-1} = 0$ (1.40), $\operatorname{Im} d_{n-1} \subseteq \operatorname{Ker} d_n$ (1.41), $H_E^n = \operatorname{Ker} d_n / \operatorname{Im} d_{n-1}$ (1.42), and the de Rham complex (1.43), whose cohomology is "of course" isomorphic to $H^n(X; \mathbb{R})$. That "of course" is de Rham's theorem, which we explain in Section 1.4.8. Everything in our examples above (winding numbers, discrete circle, Poincaré lemma, $\mathrm{d}\theta$) is background that Nash assumes.

1.4.6 Homology: the things we integrate over

So far cohomology has been built from things we *integrate*: forms, or functions on edges. The dual objects are the things we integrate *over*: points, curves, surfaces, and formal combinations of them. Stokes' theorem already tells us how the two sides talk to each other:

$$\int_c \mathrm{d}\alpha = \int_{\partial c} \alpha. \tag{1.79}$$

The exterior derivative d on forms is "adjoint" to the boundary operator ∂ on regions. Nash says this in one line: "passing to the dual will generate the corresponding homology groups". In this subsection we build the region side properly and compute with it.

Simplices and their orientation

A **simplex** is the simplest convex shape in each dimension:

- a 0-simplex is a point $[v_0]$;
- a 1-simplex is a segment $[v_0, v_1]$;
- a 2-simplex is a filled triangle $[v_0, v_1, v_2]$;
- a 3-simplex is a solid tetrahedron $[v_0, v_1, v_2, v_3]$.

In general $[v_0, \dots, v_n]$ is the convex hull of $n+1$ points in general position. The **standard n-simplex** is $\Delta^n = \{(t_0, \dots, t_n) \in \mathbb{R}^{n+1} : t_i \geq 0,\ \sum t_i = 1\}$.

The order in which we list the vertices carries an *orientation*. Swapping two vertices reverses it:

$$[v_0, v_1] = -[v_1, v_0], \qquad [v_0, v_1, v_2] = -[v_1, v_0, v_2] = [v_1, v_2, v_0].$$

An even permutation of the vertices gives back the same oriented simplex. An odd one gives its negative. For a triangle, "$v_0 \to v_1 \to v_2$ counterclockwise" is one orientation and clockwise is the other. This is exactly the sign rule of $\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^n$, and it is no accident: we will integrate n-forms over oriented n-simplices.

The boundary operator

Working definition 1.30 (boundary of a simplex)

$$\partial[v_0, \dots, v_n] = \sum_{i=0}^{n} (-1)^i \, [v_0, \dots, \widehat{v_i}, \dots, v_n], \tag{1.80}$$

where the hat means "omit this vertex". *In words:* the boundary is the sum of the faces [the $(n-1)$-simplices obtained by dropping one vertex], each taken with the orientation it inherits from the simplex [for a triangle, the three edges then run round in the same sense as $v_0 \to v_1 \to v_2$].

The first cases are exactly what our intuition wants:

$$\begin{aligned} \partial[v_0, v_1] &= [v_1] - [v_0] \qquad \text{(end minus start)}, \\ \partial[v_0, v_1, v_2] &= [v_1, v_2] - [v_0, v_2] + [v_0, v_1] \\ &= [v_0, v_1] + [v_1, v_2] + [v_2, v_0] \qquad \text{(walk around the triangle)}. \end{aligned}$$

The second line uses $-[v_0, v_2] = [v_2, v_0]$. Figure 1.39 shows these.

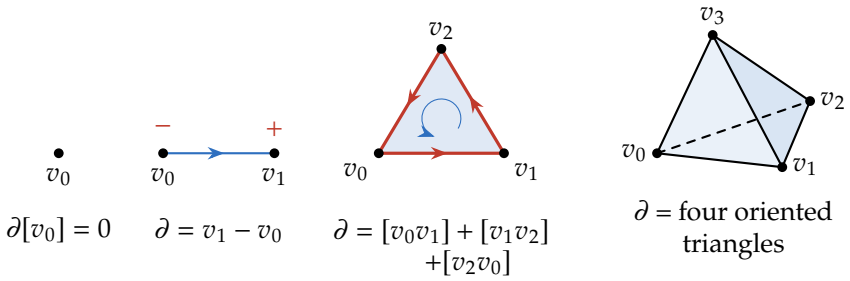

Figure 1.39: Oriented simplices in dimensions 0 to 3 and their boundaries. The boundary of a segment is "end minus start". The boundary of a triangle is the loop around its edge (red), traversed in the direction the orientation (blue circular arrow) dictates. The boundary of a tetrahedron is its four faces, all oriented outward.

Key idea: The boundary of a boundary is zero: $\partial \circ \partial = 0$

Apply ∂ twice to the triangle:

$$\begin{aligned} \partial\partial[v_0, v_1, v_2] &\overset{(1)}{=} \partial[v_1, v_2] - \partial[v_0, v_2] + \partial[v_0, v_1] \\ &\overset{(2)}{=} (v_2 - v_1) - (v_2 - v_0) + (v_1 - v_0) \\ &= 0. \end{aligned}$$

(1) (1.80) with $n = 2$, and linearity of ∂.
(2) (1.80) with $n = 1$ on each edge.

In general, $\partial\partial[v_0, \dots, v_n]$ is a sum over pairs $i < j$ of the face with v_i and v_j both removed. Each such face arises twice: remove v_i first, or remove v_j first. The two terms carry signs $(-1)^i(-1)^{j-1}$ and $(-1)^j(-1)^i$, which are opposite, so they cancel. Geometrically, a closed loop has no endpoints, and the surface of a solid has no edge.

Chains, cycles and boundaries

Let K be a space cut into simplices (a **simplicial complex**): the simplices meet only along whole common faces. An **n-chain** is a formal integer combination $c = \sum_i m_i \sigma_i$ of oriented n-simplices of K. Negative coefficients mean "reversed orientation". Coefficient 2 means "counted twice". The n-chains form an abelian group $C_n(K) \cong \mathbb{Z}^{N_n}$, where N_n is the number of n-simplices. The boundary operator extends linearly to maps $\partial_n : C_n \to C_{n-1}$, and we get a **chain complex**, with arrows pointing *down* in degree:

$$\cdots \xleftarrow{\partial_{n-1}} C_{n-1} \xleftarrow{\partial_n} C_n \xleftarrow{\partial_{n+1}} C_{n+1} \xleftarrow{\partial_{n+2}} \cdots, \qquad \partial_{n-1} \circ \partial_n = 0. \tag{1.81}$$

Working definition 1.31 (simplicial homology)

Cycles are chains with no boundary, $Z_n = \operatorname{Ker} \partial_n$. **Boundaries** are chains that bound something, $B_n = \operatorname{Im} \partial_{n+1}$. Since $\partial\partial = 0$, $B_n \subseteq Z_n$, and the **homology** is

$$H_n(K;\mathbb{Z}) = \frac{Z_n}{B_n} = \frac{\operatorname{Ker} \partial_n}{\operatorname{Im} \partial_{n+1}}. \tag{1.82}$$

[two cycles count as the same class when their difference is a boundary]. *Recipe:* write each ∂_n as an $N_{n-1} \times N_n$ integer matrix. Then

- the **Betti number** is $b_n = \operatorname{rank} H_n$ [the number of independent copies of $\mathbb{Z}$ in H_n], $b_n = N_n - \operatorname{rank} \partial_n - \operatorname{rank} \partial_{n+1}$;
- the **torsion** in H_n is $\mathbb{Z}_{d_1} \oplus \mathbb{Z}_{d_2} \oplus \cdots$, where the $d_i > 1$ are the non-unit diagonal entries (**elementary divisors**) in the Smith normal form of ∂_{n+1}. That form is a diagonalisation by integer row and column operations.

Physically, a cycle is a closed curve or surface, possibly with multiplicities. It is homologous to zero when it is the edge of something. H_1 asks: "which closed loops are not the edge of any surface?" H_2 asks the same for closed surfaces and solids.

Worked example 1.69: Homology of the circle (a hollow triangle)

Let K be the three vertices and three edges of a triangle, with no face. Use the edges $e_{01} = [v_0, v_1]$, $e_{12} = [v_1, v_2]$, $e_{20} = [v_2, v_0]$. Then $\partial e_{ij} = v_j - v_i$, and in the bases (e_{01}, e_{12}, e_{20}) and (v_0, v_1, v_2)

$$\partial_1 = \begin{pmatrix} -1 & 0 & 1 \\ 1 & -1 & 0 \\ 0 & 1 & -1 \end{pmatrix}.$$

This is the *transpose* of the matrix D_0 of Example 1.63. The boundary is the adjoint of the discrete gradient, as the Stokes pairing (1.79) predicts. The rank is 2, and there are no 2-simplices, so

$$b_0 = N_0 - \operatorname{rank} \partial_0 - \operatorname{rank} \partial_1 = 3 - 0 - 2 = 1,$$
$$b_1 = N_1 - \operatorname{rank} \partial_1 - \operatorname{rank} \partial_2 = 3 - 2 - 0 = 1.$$

The kernel of ∂_1 is spanned by $z = e_{01} + e_{12} + e_{20}$: the loop once around. Nothing bounds it, since there are no triangles. Hence $H_1(S^1;\mathbb{Z}) = \mathbb{Z}$, generated by the fundamental loop, and $H_0 = \mathbb{Z}$.

Worked example 1.70: Homology of S^2 as the surface of a tetrahedron

The hollow tetrahedron on vertices $0,1,2,3$ is a triangulated sphere. It has $N_0 = 4$ vertices, $N_1 = 6$ edges $e_{01}, e_{02}, e_{03}, e_{12}, e_{13}, e_{23}$, and $N_2 = 4$ triangles $f_{012}, f_{013}, f_{023}, f_{123}$ (vertices always listed in increasing order). From (1.80),

$$\partial f_{012} = e_{12} - e_{02} + e_{01}, \qquad \partial f_{013} = e_{13} - e_{03} + e_{01},$$
$$\partial f_{023} = e_{23} - e_{03} + e_{02}, \qquad \partial f_{123} = e_{23} - e_{13} + e_{12}.$$

Reading off columns, the boundary matrices are

$$\partial_2 = \begin{pmatrix} 1 & 1 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ 0 & -1 & -1 & 0 \\ 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & 1 \end{pmatrix} \begin{matrix} e_{01} \\ e_{02} \\ e_{03} \\ e_{12}, \\ e_{13} \\ e_{23} \end{matrix} \qquad \partial_1 = \begin{pmatrix} -1 & -1 & -1 & 0 & 0 & 0 \\ 1 & 0 & 0 & -1 & -1 & 0 \\ 0 & 1 & 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & 0 & 1 & 1 \end{pmatrix} \begin{matrix} v_0 \\ v_1 \\ v_2 \\ v_3 \end{matrix}.$$

Kernel of ∂_2. Put $c = af_{012} + bf_{013} + c'f_{023} + df_{123}$. The rows give $a + b = 0$, $-a + c' = 0$, $-b - c' = 0$, $a + d = 0$, $b - d = 0$, $c' + d = 0$. Hence $b = -a$, $c' = a$, $d = -a$, and all six equations hold. So

$$\operatorname{Ker} \partial_2 = \mathbb{Z} \cdot \big(f_{012} - f_{013} + f_{023} - f_{123}\big), \qquad \operatorname{rank} \partial_2 = 3.$$

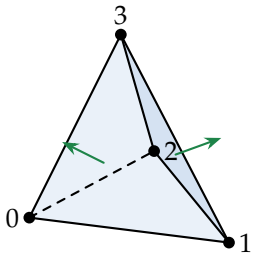
This cycle is (minus) the boundary of the solid tetrahedron $[0,1,2,3]$: all four faces, coherently oriented. That is the sphere itself, the **fundamental class**.
Rank of ∂_1. The graph of edges is connected, with 4 vertices, so $\operatorname{rank} \partial_1 = 4 - 1 = 3$. (The rows sum to zero, and any three are independent.)
Betti numbers.

$$b_0 = 4 - 0 - 3 = 1, \qquad b_1 = 6 - 3 - 3 = 0, \qquad b_2 = 4 - 3 - 0 = 1.$$

Torsion. The 3×3 minor of ∂_2 in rows e_{01}, e_{02}, e_{13} and columns $f_{012}, f_{013}, f_{023}$ is $\det\left(\begin{smallmatrix} 1 & 1 & 0 \\ -1 & 0 & 1 \\ 0 & 1 & 0 \end{smallmatrix}\right) = -1$. So the gcd of the 3×3 minors is 1, all elementary divisors are 1, and there is no torsion. Therefore

$$H_0(S^2;\mathbb{Z}) = \mathbb{Z}, \qquad H_1(S^2;\mathbb{Z}) = 0, \qquad H_2(S^2;\mathbb{Z}) = \mathbb{Z}.$$

Every closed loop on the sphere bounds (it is the edge of a cap), but the sphere as a whole bounds nothing inside itself. Check: $N_0 - N_1 + N_2 = 4 - 6 + 4 = 2 = b_0 - b_1 + b_2$.



$[S^2] = \pm\big(f_{012} - f_{013} + f_{023} - f_{123}\big)$
all faces oriented outward: a 2-cycle bounding nothing

Figure 1.40: The surface of a tetrahedron is a triangulated sphere. The alternating sum of its four faces, oriented so that the normals (green) all point outward, is the unique (up to sign) 2-cycle. It generates $H_2(S^2;\mathbb{Z}) = \mathbb{Z}$. Integrating a 2-form over this cycle is integrating over the sphere.

The torus by boundary matrices

For the torus it pays to relax the rules slightly. We allow a triangle's vertices to be glued to each other, as happens when we build the torus from a square by identifying opposite sides. Such a decomposition is called a **Δ-complex**. The recipe (1.80) and all the linear algebra are unchanged.

Worked example 1.71: Homology of T^2 from two triangles

Take the unit square with bottom and top edges identified (both called a, pointing right) and left and right edges identified (both called b, pointing up). Draw the diagonal c from the bottom-left to the top-right corner. All four corners become *one* vertex v. There are three edges a, b, c and two triangles

$$L = [(0,0),(1,0),(1,1)] \text{ (lower right)}, \qquad U = [(0,0),(0,1),(1,1)] \text{ (upper left)}.$$

(Figure 1.41.) Apply (1.80), reading off which edge each face is:

$$\partial L \overset{(1)}{=} [(1,0),(1,1)] - [(0,0),(1,1)] + [(0,0),(1,0)] = b - c + a,$$
$$\partial U \overset{(2)}{=} [(0,1),(1,1)] - [(0,0),(1,1)] + [(0,0),(0,1)] = a - c + b,$$
$$\partial a \overset{(3)}{=} v - v = 0, \qquad \partial b = \partial c = 0.$$

(1) The right side of the square is b, the diagonal is c, the bottom is a.
(2) The top side is a (identified with the bottom), the diagonal is c, the left side is b.
(3) Every edge starts and ends at the single vertex v.

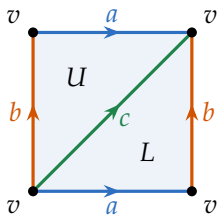
So, in the bases (U, L), (a, b, c) and (v),

$$\partial_2 = \begin{pmatrix} 1 & 1 \\ 1 & 1 \\ -1 & -1 \end{pmatrix}, \qquad \partial_1 = \begin{pmatrix} 0 & 0 & 0 \end{pmatrix}.$$

Now read off the homology.

- H_0: $\operatorname{Ker}\partial_0 = \mathbb{Z}v$ and $\operatorname{Im}\partial_1 = 0$, so $H_0 = \mathbb{Z}$.
- H_1: $\operatorname{Ker}\partial_1 = \mathbb{Z}^3$ (everything) and $\operatorname{Im}\partial_2 = \mathbb{Z}\cdot(a+b-c)$. Change basis of $\mathbb{Z}^3$ to $\{a,\ b,\ a+b-c\}$. This is allowed, since the matrix taking (a,b,c) to it has determinant -1. Then
$$H_1(T^2;\mathbb{Z}) = \frac{\mathbb{Z}a \oplus \mathbb{Z}b \oplus \mathbb{Z}(a+b-c)}{\mathbb{Z}(a+b-c)} \cong \mathbb{Z}a \oplus \mathbb{Z}b = \mathbb{Z}^2.$$
The diagonal c is homologous to $a+b$: going diagonally is the same, up to a boundary, as going along a and then b.
- H_2: $\operatorname{Ker}\partial_2 = \{xU + yL : x + y = 0\} = \mathbb{Z}(L-U)$, so $H_2(T^2;\mathbb{Z}) = \mathbb{Z}$, generated by the fundamental class $[T^2] = L - U$. Checking orientations directly from the vertex order (the cross product of consecutive edge vectors), $L = [(0,0),(1,0),(1,1)]$ is counterclockwise but $U = [(0,0),(0,1),(1,1)]$ is clockwise; to combine the two triangles into one consistently counterclockwise-oriented cycle we must flip U, giving $L + (-U) = L - U$ rather than $U - L$. (Either sign generates the same $\mathbb{Z}$; we fix this one because it is the sign used consistently in Example 1.81, where $(\alpha \cup \beta)[T^2] = +1$ matches $\int_{T^2} \omega_1 \wedge \omega_2 = +1$.)

Euler characteristic check: $N_0 - N_1 + N_2 = 1 - 3 + 2 = 0 = 1 - 2 + 1$.



$$\partial_2 = \begin{pmatrix} 1 & 1 \\ 1 & 1 \\ -1 & -1 \end{pmatrix}$$

$$\partial_1 = (0\ 0\ 0)$$

$$H_* = \mathbb{Z},\ \mathbb{Z}^2,\ \mathbb{Z}$$

Figure 1.41: The torus as a square with opposite sides glued (same letter, same arrow). The diagonal c cuts it into two triangles L and U. All four corners are one vertex. The two small boundary matrices give the whole homology of the torus. The generators of H_1 are the two loops a and b of Figure 1.36.

Watch out: A real triangulation needs more simplices

In a genuine simplicial complex, two different simplices cannot have the same vertex set. The two-triangle torus violates this badly. The smallest honest triangulation of T^2 (Möbius, Császár) has 7 vertices, 21 edges and 14 triangles. The obvious one, a 3×3 grid of squares each cut by a diagonal, has 9 vertices, 27 edges and 18 triangles. Its boundary matrices are 9×27 and 27×18. That is fine for a computer, and it gives the same homology: $9 - 27 + 18 = 0$, $\operatorname{rank} \partial_1 = 8$, $\operatorname{rank} \partial_2 = 17$, so $b_0 = 1$, $b_1 = 27 - 8 - 17 = 2$, $b_2 = 18 - 17 = 1$. The answer does not depend on the triangulation. That is the content of the statement that homology is a topological invariant.

Cells instead of simplices: T^2, $\mathbb{RP}^2$ and the Klein bottle in three lines

The torus computation suggests a further shortcut. Why cut the square into triangles at all? A **CW** or **cell complex** is built by gluing discs ("cells") of increasing dimension. The **cellular chain complex** has one generator per cell. The boundary of a 2-cell is the word you read walking around its edge, written additively: each edge counts +1 if you traverse it along its arrow and -1 against it. Cellular homology agrees with simplicial homology, and it is usually far quicker.

Worked example 1.72: Three surfaces from a square

Each surface below has one 2-cell D (the square) and 1-cells a, b.

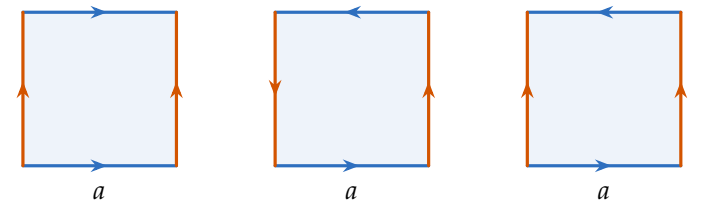
- *Torus.* Boundary word $aba^{-1}b^{-1}$, one vertex. Then $\partial D = a + b - a - b = 0$ and $\partial a = \partial b = 0$. So $H_0 = \mathbb{Z}$, $H_1 = \mathbb{Z}^2$, $H_2 = \mathbb{Z}$, as before.
- *Real projective plane* $\mathbb{RP}^2$ (the disc with antipodal boundary points identified). Boundary word aa (the square with a along the bottom and a reversed along the top, b likewise, collapses to one 1-cell). One vertex, one edge a, one face D, with $\partial D = 2a$ and $\partial a = 0$. Then

$$H_2 \overset{(1)}{=} \operatorname{Ker}(\partial_2 : \mathbb{Z} \to \mathbb{Z},\ 1 \mapsto 2) = 0,$$
$$H_1 \overset{(2)}{=} \mathbb{Z}a/2\mathbb{Z}a = \mathbb{Z}_2,$$
$$H_0 = \mathbb{Z}.$$

  (1) Multiplication by 2 on $\mathbb{Z}$ is injective. No 2-cycle exists, because $\mathbb{RP}^2$ is not orientable.
  (2) Every 1-chain is a cycle. The boundaries are the even multiples of a.

  The loop a is not a boundary, but *twice* it is. This is **torsion**.

- *Klein bottle* K. Boundary word $aba^{-1}b$, one vertex. $\partial D = a + b - a + b = 2b$, so $H_2 = 0$ and $H_1 = (\mathbb{Z}a \oplus \mathbb{Z}b)/\langle 2b \rangle = \mathbb{Z} \oplus \mathbb{Z}_2$.



torus T^2 $H_1 = \mathbb{Z}^2$, $H_2 = \mathbb{Z}$ | $\mathbb{RP}^2$ $H_1 = \mathbb{Z}_2$, $H_2 = 0$ | Klein bottle $H_1 = \mathbb{Z} \oplus \mathbb{Z}_2$, $H_2 = 0$

Figure 1.42: Three surfaces from one square, differing only in the arrows (blue sides are identified with each other, and so are orange sides). The torus keeps both pairs parallel. $\mathbb{RP}^2$ reverses both. The Klein bottle reverses one. A reversed pair makes the boundary of the square count an edge twice instead of zero times. That produces $\mathbb{Z}_2$ torsion in H_1 and kills H_2: the surface is non-orientable.

Coefficients and torsion

We can use coefficients other than $\mathbb{Z}$. Allow chains $\sum g_i \sigma_i$ with g_i in any abelian group G, such as $\mathbb{R}$, $\mathbb{Q}$ or $\mathbb{Z}_2$. The same matrices now act on G^{N_n}, and we get $H_n(K; G)$.

- Over $\mathbb{R}$ (or any field of characteristic zero) torsion disappears, because 2 is invertible, and $H_n(K; \mathbb{R}) = \mathbb{R}^{b_n}$. For $\mathbb{RP}^2$: $H_1(\mathbb{RP}^2; \mathbb{R}) = \mathbb{R}/2\mathbb{R} = 0$.
- Over $\mathbb{Z}_2$, signs do not matter and orientation is irrelevant. For $\mathbb{RP}^2$ the map $\partial D = 2a = 0$ vanishes, so $H_1(\mathbb{RP}^2; \mathbb{Z}_2) = \mathbb{Z}_2$ and $H_2(\mathbb{RP}^2; \mathbb{Z}_2) = \mathbb{Z}_2$. Non-orientable surfaces still have a $\mathbb{Z}_2$ fundamental class.

The general rule is the **universal coefficient theorem**: integral homology determines homology with any coefficients. In particular $b_n = \dim_{\mathbb{R}} H_n(K; \mathbb{R})$ is the rank of $H_n(K; \mathbb{Z})$, and torsion is invisible to real numbers, hence to differential forms. This is why de Rham cohomology cannot see $\mathbb{Z}_2$ phenomena such as spin structures or the Kirby–Siebenmann class of Section 1.6.

Singular homology

Simplicial homology needs a triangulation, and it is not obvious that the answer is independent of the triangulation chosen. **Singular homology** removes the choice by brute force.

Working definition 1.32 (singular homology)

A **singular n-simplex** in a space X is *any* continuous map $\sigma : \Delta^n \to X$ [Δ^n is the standard n-simplex, a point, segment, triangle, ...]. It can be crumpled, degenerate or self-intersecting. Singular n-chains are finite integer combinations $\sum m_i \sigma_i$. The boundary is $\partial\sigma = \sum_i (-1)^i \, \sigma|_{i\text{-th face}}$, with the faces parametrised as in (1.80). Then $\partial\partial = 0$ as before, and $H_n(X; \mathbb{Z}) = \operatorname{Ker} \partial_n / \operatorname{Im} \partial_{n+1}$. *Use:* never compute with this directly. Use it to know that homology is defined for every space, is a topological invariant, and is homotopy invariant [homotopy equivalent spaces have the same H_n]. Then compute simplicially or cellularly [from a decomposition into balls glued along their boundaries].

Three facts make singular homology the right foundation:

1. *Functoriality.* A continuous map $f : X \to Y$ pushes singular simplices forward, $\sigma \mapsto f \circ \sigma$. This commutes with ∂, so it induces $f_* : H_n(X) \to H_n(Y)$. A homeomorphism therefore induces an isomorphism.
2. *Homotopy invariance.* If $f \simeq g$ via $F : [0,1] \times X \to Y$, then the "prism" $F \circ (\mathrm{id} \times \sigma)$ swept out by a simplex has boundary $g \circ \sigma - f \circ \sigma$ plus the prism over $\partial\sigma$. So a cycle is moved to a homologous cycle, and $f_* = g_*$. Hence homology, like cohomology, is an invariant of homotopy type.
3. *Agreement.* For a simplicial (or cell) complex, singular, simplicial and cellular homology coincide.

Worked example 1.73: H_0 counts path components

A singular 1-simplex is a path $\sigma : [0,1] \to X$ with $\partial\sigma = \sigma(1) - \sigma(0)$. So two points joined by a path are homologous 0-chains. Conversely, the "total coefficient in each path component" is unchanged by adding boundaries. Hence $H_0(X;\mathbb{Z}) = \mathbb{Z}^c$, where c is the number of path components. This is the homology twin of Example 1.64.

Worked example 1.74: A loop is a 1-cycle

A based loop $\gamma : [0,1] \to X$ with $\gamma(0) = \gamma(1)$ is a singular 1-simplex with $\partial\gamma = \gamma(1) - \gamma(0) = 0$, so it is a cycle and defines a class $[\gamma] \in H_1(X;\mathbb{Z})$. Homotopic loops give the same class. Concatenation gives the sum, because the triangle "γ_1, then γ_2, back along $\gamma_1 \cdot \gamma_2$" is a singular 2-simplex with boundary $\gamma_2 - \gamma_1 \cdot \gamma_2 + \gamma_1$. This defines the **Hurewicz map** $h : \pi_1(X) \to H_1(X;\mathbb{Z})$, which we study in Section 1.4.10.

Physical picture: Integration is the pairing between chains and forms

For a smooth p-form α and a (smooth) singular p-chain $c = \sum m_i \sigma_i$, define

$$\langle \alpha, c \rangle = \int_c \alpha = \sum_i m_i \int_{\Delta^p} \sigma_i^* \alpha.$$

Stokes' theorem for each simplex gives $\langle \mathrm{d}\alpha, c \rangle = \langle \alpha, \partial c \rangle$. In other words, d is the transpose of ∂. Consequences:

- closed form, boundary chain: $\langle \alpha, \partial b \rangle = \langle \mathrm{d}\alpha, b \rangle = 0$;
- exact form, cycle: $\langle \mathrm{d}\beta, z \rangle = \langle \beta, \partial z \rangle = 0$.

So integration descends to a well-defined pairing $H^p_{\mathrm{dR}}(X) \times H_p(X;\mathbb{R}) \to \mathbb{R}$. De Rham's theorem says this pairing is perfect.

Watch out: Homology is not cohomology

Nash writes that singular homology "is isomorphic to the integral cohomology group $H_n(X;\mathbb{Z})$". Read this as "is the integral *homology* group $H_n(X;\mathbb{Z})$". It is a naming, not a theorem. Homology and cohomology are genuinely different in general. For $\mathbb{RP}^2$:

$$H_0, H_1, H_2 = \mathbb{Z},\ \mathbb{Z}_2,\ 0, \qquad \text{but} \qquad H^0, H^1, H^2 = \mathbb{Z},\ 0,\ \mathbb{Z}_2.$$

The torsion moves up one degree. (This is the universal coefficient theorem for cohomology: $H^n \cong \mathrm{free}(H_n) \oplus \mathrm{torsion}(H_{n-1})$.) The two are related by Poincaré duality on closed oriented manifolds, $H^n(M;\mathbb{Z}) \cong H_{\dim M - n}(M;\mathbb{Z})$. For real coefficients the distinction is just vector-

space duality, $H^n(X;\mathbb{R}) = H_n(X;\mathbb{R})^*$.

1.4.7 Cochains: cohomology from a triangulation

We now have two complexes that look like mirror images. Forms with d raise degree. Chains with ∂ lower it. Stokes' theorem (1.79) says d is the transpose of ∂. We can turn this around and *define* a cohomology from a triangulation by transposing the boundary matrices. This is what Nash means when he says the two complexes are dual.

Working definition 1.33 (simplicial cochains and coboundary)

Let K be a simplicial (or Δ-, or cell) complex [a space glued from simplices, or from balls, along their faces] and G an abelian group. An **n-cochain** with values in G is a function that assigns an element of G to each oriented n-simplex, extended linearly to chains: $C^n(K;G) = \mathrm{Hom}(C_n(K), G) \cong G^{N_n}$ [one value in G for each of the N_n simplices, and $\varphi(c + c') = \varphi(c) + \varphi(c')$ on chains]. The **coboundary** $\delta : C^n \to C^{n+1}$ is defined by

$$(\delta\varphi)(\sigma) = \varphi(\partial\sigma) \qquad \text{for every } (n+1)\text{-simplex } \sigma. \tag{1.83}$$

In matrix form, *the matrix of δ_n is the transpose of the matrix of ∂_{n+1}*. The **simplicial cohomology** is $H^n(K;G) = \mathrm{Ker}\,\delta_n / \mathrm{Im}\,\delta_{n-1}$ [cochains with $\delta\varphi = 0$, counted as the same when they differ by some $\delta\psi$]. *Recipe:* transpose the boundary matrices you already have, and compute kernels and images again.

Because δ is a transpose, $\delta \circ \delta = 0$ is automatic:

$$\begin{aligned}(\delta\delta\varphi)(\tau) &\overset{(1)}{=} (\delta\varphi)(\partial\tau)\\ &\overset{(2)}{=} \varphi(\partial\partial\tau)\\ &\overset{(3)}{=} 0.\end{aligned}$$

(1) Definition (1.83), applied to $\delta\varphi$.
(2) Definition (1.83) again, applied to each simplex in the chain $\partial\tau$ (linearity).
(3) The boundary of a boundary is zero.

We already met the simplest case without saying so: the discrete gradient of Example 1.63 is exactly δ_0 on the hollow triangle, and its matrix D_0 is the transpose of ∂_1 in Example 1.69.

Worked example 1.75: Integral cohomology of the torus by transposing

Use the two-triangle torus of Example 1.71, with bases (v), (a,b,c), (U,L). Transposing $\partial_1 = (0\ 0\ 0)$ and ∂_2 gives

$$\delta_0 = \begin{pmatrix}0\\0\\0\end{pmatrix}, \qquad \delta_1 = \partial_2^T = \begin{pmatrix}1 & 1 & -1\\ 1 & 1 & -1\end{pmatrix}.$$

A 1-cochain is a triple $\varphi = (\varphi(a), \varphi(b), \varphi(c)) = (x,y,z)$. Then

$$\begin{aligned}H^0(T^2;\mathbb{Z}) &\overset{(1)}{=} \mathrm{Ker}\,\delta_0 = \mathbb{Z},\\ H^1(T^2;\mathbb{Z}) &\overset{(2)}{=} \{(x,y,z) \in \mathbb{Z}^3 : x + y - z = 0\}/0 \cong \mathbb{Z}^2,\\ H^2(T^2;\mathbb{Z}) &\overset{(3)}{=} \mathbb{Z}^2/\mathrm{Im}\,\delta_1 = \mathbb{Z}^2/\mathbb{Z}(1,1) \cong \mathbb{Z}.\end{aligned}$$

(1) $\delta_0 = 0$, so every 0-cochain (a single integer on the single vertex) is a cocycle.
(2) The cocycle condition is $(\delta_1\varphi)(U) = (\delta_1\varphi)(L) = x + y - z = 0$, so $z = x + y$ and (x, y) are free integers. Nothing is exact, because $\delta_0 = 0$.
(3) Every 2-cochain is a cocycle (there are no 3-simplices). The image of δ_1 is spanned by $(1, 1)$, and $(p, q) \mapsto p + q$ identifies the quotient with $\mathbb{Z}$.

A 1-cocycle is a rule "how much phase do I pick up along a, along b, and along the diagonal c". The cocycle condition says the phase around the edge of each triangle vanishes: *zero flux through each plaquette*, in lattice-gauge language. The two free integers are the two holonomies around the two non-contractible loops. They match $H^1(T^2;\mathbb{Z}) = [T^2, S^1]_0 = \mathbb{Z}^2$ of Example 1.60, where the pair (m, n) were the windings along a and b.

Worked example 1.76: Torsion moves up: the cohomology of $\mathbb{RP}^2$

The cell complex of $\mathbb{RP}^2$ in Example 1.72 has one cell in each dimension, with $\partial_2 = (2)$ and $\partial_1 = (0)$. Transposing, $\delta_0 = (0)$ and $\delta_1 = (2)$. Hence

$$H^0 = \mathbb{Z}, \qquad H^1 = \mathrm{Ker}(\times 2) = 0, \qquad H^2 = \mathbb{Z}/2\mathbb{Z} = \mathbb{Z}_2.$$

Compare $H_1 = \mathbb{Z}_2$, $H_2 = 0$. This is the "torsion moves up one degree" of the pitfall at the end of the homology subsection, now seen as nothing more than the difference between the kernel and the cokernel of the 1×1 matrix (2).

1.4.8 The de Rham theorem: forms know the real topology

Nash asserts that de Rham cohomology is "of course" isomorphic to $H^n(X;\mathbb{R})$. This is **de Rham's theorem**. It is the reason a physicist can do topology with differential forms. Here is what it says and why it is true.

The de Rham map

Triangulate the manifold X by smooth simplices. Given a p-form α, build a real p-cochain by integrating:

$$I(\alpha)(\sigma) = \int_\sigma \alpha \qquad \text{for each oriented } p\text{-simplex } \sigma. \tag{1.84}$$

The map $I : \Omega^p(X) \to C^p(K;\mathbb{R})$ is the **de Rham map**. It intertwines the two differentials:

$$\begin{aligned} I(\mathrm{d}\alpha)(\tau) &\overset{(1)}{=} \int_\tau \mathrm{d}\alpha \\ &\overset{(2)}{=} \int_{\partial\tau} \alpha \\ &\overset{(3)}{=} I(\alpha)(\partial\tau) \\ &\overset{(4)}{=} (\delta I(\alpha))(\tau). \end{aligned} \tag{1.85}$$

(1) Definition (1.84), for a $(p+1)$-simplex τ.
(2) Stokes' theorem on the simplex τ.
(3) The integral over the chain $\partial\tau$ is the sum of integrals over its faces with their signs, which is the linear extension of $I(\alpha)$.
(4) Definition (1.83) of the coboundary.

So $I \circ \mathrm{d} = \delta \circ I$. A map between complexes that commutes with the differentials is called a **chain map**. It sends closed to closed and exact to exact, so it induces a map on cohomology.

Key idea: de Rham's theorem

For a smooth manifold X the de Rham map induces an isomorphism

$$I_* : H^p_{\mathrm{dR}}(X) \xrightarrow{\cong} H^p(X;\mathbb{R}) \qquad \text{for all } p. \tag{1.86}$$

Equivalently, in terms of the integration pairing with cycles:

1. a closed p-form is exact *if and only if* all its **periods** $\oint_z \alpha$ over p-cycles z vanish;
2. any assignment of real periods to a basis of $H_p(X;\mathbb{Z})$ is realised by some closed p-form.

Half of statement 1 is the exemplar argument: exact forms have zero periods by Stokes. The other half is the real content. Here is why it is true, in the style of the Poincaré lemma.

- *Locally* there is nothing to prove. On a small ball every closed form is exact (Example 1.65), and the ball's cohomology is that of a point. So both theories agree on each simplex's star.
- *Gluing* works the same way in both theories: both satisfy the Mayer–Vietoris sequence of Section 1.4.9 below.
- Build X up one open set at a time. At each stage the two long exact sequences are compared by I. The "five lemma" of linear algebra then transfers the isomorphism from the pieces to the union.

So de Rham's theorem is "the Poincaré lemma plus gluing". Weil's proof via Čech cohomology makes this into an honest argument, and we will meet that machinery in Chapter 3.

$$\begin{array}{ccccccc}
\cdots & \xrightarrow{\mathrm{d}} & \Omega^p(X) & \xrightarrow{\mathrm{d}} & \Omega^{p+1}(X) & \xrightarrow{\mathrm{d}} & \cdots \\
 & & \downarrow{\scriptstyle I=\int} & & \downarrow{\scriptstyle I=\int} & & \\
\cdots & \xrightarrow[\delta]{} & C^p(K;\mathbb{R}) & \xrightarrow[\delta=\partial^T]{} & C^{p+1}(K;\mathbb{R}) & \xrightarrow[\delta]{} & \cdots
\end{array}$$

Figure 1.43: The de Rham map is a ladder between two complexes. Going across then down (differentiate, then integrate over a simplex) equals going down then across (integrate over the faces of the simplex). That square is Stokes' theorem, (1.85). De Rham's theorem says the ladder induces an isomorphism on cohomology: the smooth and the combinatorial pictures of real topology are the same.

Worked example 1.77: The period matrix of the torus

On T^2 with angles $\theta_1, \theta_2 \in [0, 2\pi)$, take the closed forms $\omega_1 = \mathrm{d}\theta_1/2\pi$ and $\omega_2 = \mathrm{d}\theta_2/2\pi$, and the cycles a ($\theta_2 = 0$, θ_1 running from 0 to 2π) and b ($\theta_1 = 0$). The periods are

$$\oint_a \omega_1 \overset{(1)}{=} \frac{1}{2\pi}\int_0^{2\pi} \mathrm{d}\theta_1 = 1, \qquad \oint_b \omega_1 \overset{(2)}{=} 0,$$
$$\oint_a \omega_2 = 0, \qquad \oint_b \omega_2 = 1.$$

(1) Parametrise a by θ_1.

(2) Along b, θ_1 is constant, so $\mathrm{d}\theta_1$ pulls back to zero.

The **period matrix** $\left(\oint_{z_j} \omega_i\right)$ is the identity. By statement 1 of de Rham's theorem, ω_1 and ω_2 are linearly independent in cohomology (a combination $x\omega_1 + y\omega_2$ with x, y not both zero has a non-zero period). By statement 2 they span: any closed 1-form α with periods $A = \oint_a \alpha$, $B = \oint_b \alpha$ satisfies

$$\alpha = A\,\omega_1 + B\,\omega_2 + \mathrm{d}f$$

for a periodic function f. So $H^1_{\mathrm{dR}}(T^2) = \mathbb{R}^2$. Its *integral lattice*, the forms with integer periods, is $\mathbb{Z}\omega_1 \oplus \mathbb{Z}\omega_2$. This is $H^1(T^2;\mathbb{Z})$ sitting inside $H^1(T^2;\mathbb{R})$, and it is exactly the set of forms $\frac{1}{2\pi i} f^{-1}\mathrm{d}f$ coming from maps $f_{m,n} : T^2 \to U(1)$ in Example 1.60.

Worked example 1.78: A form on the punctured plane is fixed by one number

On $\mathbb{R}^2 \setminus \{0\}$, $H_1 = \mathbb{Z}$ is generated by the unit circle γ. De Rham's theorem says: a closed 1-form β is exact exactly when $\oint_\gamma \beta = 0$, and in general $\beta - \frac{1}{2\pi}\left(\oint_\gamma \beta\right)\alpha$ is exact, with α the angle form of Example 1.67. For a static magnetic field confined to a solenoid, β is the vector potential outside, and the only gauge-invariant information it carries in the field-free region is the single period $\oint_\gamma A = \Phi$, the enclosed flux.

Watch out: What de Rham cannot see

De Rham cohomology is cohomology with *real* coefficients. It sees the Betti numbers and nothing else. The $\mathbb{Z}_2$ in $H^2(\mathbb{RP}^2;\mathbb{Z})$ is invisible to forms, since $H^2_{\mathrm{dR}}(\mathbb{RP}^2) = 0$. So are all the $\mathbb{Z}_2$-valued invariants of Section 1.6 (Stiefel–Whitney classes, the Kirby–Siebenmann class). Integrality, too, is extra information. De Rham tells you that $[F/2\pi] \in H^2_{\mathrm{dR}}(S^2)$, but the fact that its period is an integer (Dirac quantisation) comes from $H^2(S^2;\mathbb{Z})$ and the bundle structure, not from the forms.

1.4.9 Gluing: the Mayer–Vietoris sequence

How do we compute cohomology of a space we cannot triangulate by hand, like S^n for large n? We cut it into simple pieces and glue. The bookkeeping of gluing is an exact sequence.

Let $X = U \cup V$ with U, V open. There are two natural maps of forms:

$$0 \to \Omega^p(X) \xrightarrow{\ r\ } \Omega^p(U) \oplus \Omega^p(V) \xrightarrow{\ s\ } \Omega^p(U \cap V) \to 0, \tag{1.87}$$
$$r(\omega) = (\omega|_U, \omega|_V), \qquad s(\alpha,\beta) = \beta|_{U\cap V} - \alpha|_{U\cap V}.$$

This short sequence is exact. r is injective, since a form that vanishes on U and on V vanishes. $\operatorname{Im} r = \operatorname{Ker} s$, since two forms that agree on the overlap glue to a global form. s is surjective: this is where a **partition of unity** enters. Choose smooth functions $\rho_U, \rho_V \geq 0$ with $\rho_U + \rho_V = 1$, $\operatorname{supp}\rho_U \subset U$ and $\operatorname{supp}\rho_V \subset V$. Given ω on $U \cap V$, set

$$\alpha = -\rho_V\,\omega \ \text{ on } U, \qquad \beta = \rho_U\,\omega \ \text{ on } V. \tag{1.88}$$

(Here $\rho_V\omega$ extends by zero to all of U, because ρ_V vanishes near the edge of V.) Then $s(\alpha,\beta) = \rho_U\omega + \rho_V\omega = \omega$.

Key idea: Mayer–Vietoris

A short exact sequence of complexes gives a long exact sequence of cohomology:

$$\begin{aligned} 0 \to H^0(X) &\xrightarrow{r^*} H^0(U)\oplus H^0(V) \xrightarrow{s^*} H^0(U\cap V) \\ &\xrightarrow{\mathrm{d}^*} H^1(X) \xrightarrow{r^*} H^1(U)\oplus H^1(V) \xrightarrow{s^*} H^1(U\cap V) \\ &\xrightarrow{\mathrm{d}^*} H^2(X) \xrightarrow{r^*} H^2(U)\oplus H^2(V) \xrightarrow{s^*} \cdots \end{aligned} \tag{1.89}$$

The **connecting map** d^* sends a closed p-form ω on $U\cap V$ to the closed $(p+1)$-form on X

$$\mathrm{d}^*\omega = \mathrm{d}\rho_U \wedge \omega, \tag{1.90}$$

which is supported inside $U\cap V$ and extended by zero.

Let us check that (1.90) is the right recipe. Lift ω to (α,β) by (1.88) and differentiate:

$$\begin{aligned} \mathrm{d}\beta &\overset{(1)}{=} \mathrm{d}\rho_U\wedge\omega + \rho_U\,\mathrm{d}\omega = \mathrm{d}\rho_U\wedge\omega \quad \text{on } V, \\ \mathrm{d}\alpha &\overset{(2)}{=} -\mathrm{d}\rho_V\wedge\omega \overset{(3)}{=} \mathrm{d}\rho_U\wedge\omega \quad \text{on } U. \end{aligned}$$

(1) Leibniz rule, and $\mathrm{d}\omega = 0$.
(2) The same, for $\alpha = -\rho_V\omega$.
(3) $\rho_U + \rho_V = 1$, so $\mathrm{d}\rho_V = -\mathrm{d}\rho_U$.

The two pieces agree on $U\cap V$, so they glue to one global closed form. It is not in general exact on X, although it is exact on U (as $\mathrm{d}\alpha$) and on V (as $\mathrm{d}\beta$). This is exactly the monopole situation: a field strength that has a potential on each patch but not globally. Exactness of the long sequence is then a (tedious but routine) exercise in chasing definitions.

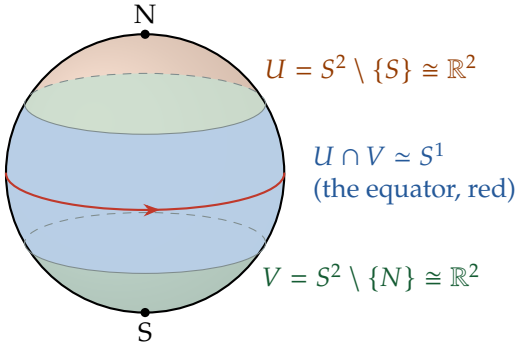


Figure 1.44: The Mayer–Vietoris cover of the sphere. Each cap is contractible, so all the topology of S^2 lives in how the caps overlap, along a band that retracts onto the equator. The class $[\mathrm{d}\phi/2\pi]$ on the band is sent by the connecting map to the generator of $H^2_{\mathrm{dR}}(S^2)$. In physics the same cover carries the Wu–Yang monopole: A_N on U, A_S on V, and a gauge transformation $e^{in\phi}$ on the band.

Worked example 1.79: Mayer–Vietoris computes the cohomology of S^2

Take U and V as in Figure 1.44. Both are contractible, so $H^0=\mathbb{R}$ and $H^p=0$ for $p\geq 1$ on each (Poincaré lemma). The overlap retracts onto the equator, so $H^0(U\cap V)=H^1(U\cap V)=\mathbb{R}$ (Example 1.66). The sequence (1.89) becomes

$$0\to H^0(S^2)\xrightarrow{r^*}\mathbb{R}\oplus\mathbb{R}\xrightarrow{s^*}\mathbb{R}\xrightarrow{\mathrm{d}^*}H^1(S^2)\to 0\oplus 0\to\mathbb{R}\xrightarrow{\mathrm{d}^*}H^2(S^2)\to 0\oplus 0.$$

Read it from the left.

$$\begin{aligned} H^0(S^2) &\overset{(1)}{=} \mathbb{R}, \\ \operatorname{Im} s^* &\overset{(2)}{=} \{b-a : (a,b) \in \mathbb{R}^2\} = \mathbb{R}, \\ H^1(S^2) &\overset{(3)}{=} 0, \\ H^2(S^2) &\overset{(4)}{=} \mathrm{d}^*\big(H^1(U \cap V)\big) \cong \mathbb{R}. \end{aligned}$$

(1) S^2 is connected, so its closed 0-forms are the constants.
(2) On H^0, s^* takes the constant a on U and b on V to the constant $b-a$ on the overlap. Every constant arises.
(3) Exactness at $H^0(U \cap V)$: since s^* is onto, $\operatorname{Ker} \mathrm{d}^* = \mathbb{R}$ and $\mathrm{d}^* = 0$. Then exactness at $H^1(S^2)$: the next map lands in 0, so its kernel is all of $H^1(S^2)$, which must equal $\operatorname{Im} \mathrm{d}^* = 0$.
(4) Exactness at $H^1(U \cap V)$ and at $H^2(S^2)$: the map into $H^1(U \cap V)$ comes from 0, so d^* is injective, and the map out of $H^2(S^2)$ goes to 0, so d^* is surjective.

The explicit generator. Let $\rho_U = \rho(\theta)$ depend only on the polar angle, with $\rho = 1$ for $\theta < \pi/3$ and $\rho = 0$ for $\theta > 2\pi/3$. Using the orientation $\mathrm{d}\theta \wedge \mathrm{d}\phi$ (the one in which $\sin\theta\, \mathrm{d}\theta \wedge \mathrm{d}\phi$ is positive),

$$\begin{aligned} \int_{S^2} \mathrm{d}^*\Big(\frac{\mathrm{d}\phi}{2\pi}\Big) &\overset{(1)}{=} \int_{S^2} \rho'(\theta)\, \mathrm{d}\theta \wedge \frac{\mathrm{d}\phi}{2\pi} \\ &\overset{(2)}{=} \int_0^{\pi} \rho'(\theta)\, \mathrm{d}\theta \\ &\overset{(3)}{=} \rho(\pi) - \rho(0) = -1. \end{aligned}$$

(1) (1.90) with $\mathrm{d}\rho_U = \rho'(\theta)\, \mathrm{d}\theta$.
(2) The ϕ integral gives 2π.
(3) Fundamental theorem of calculus.

So $-\mathrm{d}\rho_U \wedge \mathrm{d}\phi/2\pi$ is a closed 2-form, a "band of flux" concentrated between latitudes, with total flux 1. Every closed 2-form on S^2 is a multiple of it plus an exact form. In particular, the monopole's $\frac{1}{4\pi} \sin\theta\, \mathrm{d}\theta \wedge \mathrm{d}\phi$ and this band are cohomologous: they have the same total flux.

Worked example 1.80: All spheres at once: Nash's (1.46)

Cover S^n by $U = S^n \setminus \{S\}$ and $V = S^n \setminus \{N\}$, both $\cong \mathbb{R}^n$, with $U \cap V \simeq S^{n-1}$. For $p \geq 1$ the groups $H^p(U) \oplus H^p(V)$ vanish, so the segment

$$0 = H^{p-1}(U) \oplus H^{p-1}(V) \to H^{p-1}(U \cap V) \xrightarrow{\mathrm{d}^*} H^p(S^n) \to H^p(U) \oplus H^p(V) = 0 \qquad (p \geq 2)$$

shows $H^p(S^n) \cong H^{p-1}(S^{n-1})$ for $p \geq 2$. The low degrees are handled as in Example 1.79: $H^0(S^n) = \mathbb{R}$, and $H^1(S^n) = 0$ for $n \geq 2$. Iterating the shift,

$$\begin{aligned} H^n(S^n) &\overset{(1)}{=} H^{n-1}(S^{n-1}) \overset{(1)}{=} \cdots \overset{(1)}{=} H^1(S^1) \overset{(2)}{=} \mathbb{R}, \\ H^p(S^n) &\overset{(3)}{=} H^{p-1}(S^{n-1}) \overset{(3)}{=} \cdots \overset{(3)}{=} H^1(S^{n-p+1}) \overset{(4)}{=} 0 \qquad (2 \leq p < n), \end{aligned}$$

(1) The shift isomorphism, applied $n-1$ times; each step lowers a degree that is still ≥ 2.

(2) Example 1.66.
(3) The shift applied $p-1$ times. Degree and dimension drop together, so we end in degree 1 on a sphere of dimension $n-p+1 \geq 2$.
(4) The low-degree result: $H^1(S^m) = 0$ for $m \geq 2$.

So $H^m(S^n) = \mathbb{R}$ for $m = 0, n$ and 0 otherwise. The same argument with integer coefficients (Mayer–Vietoris holds for singular cohomology too) gives Nash's

$$H^m(S^n;\mathbb{Z}) \cong H_m(S^n;\mathbb{Z}) = \begin{cases} \mathbb{Z} & m = 0 \text{ or } m = n, \\ 0 & \text{otherwise.} \end{cases} \tag{1.91}$$

The generator of $H^n(S^n)$ is "a bump of unit total integral", for example the normalised volume form. Compare this three-line answer with the homotopy groups of spheres, which fill tables and are still not all known.

Try it: The torus by Mayer–Vietoris

Cut T^2 into two cylinders U and V (each $\simeq S^1$) whose intersection is two disjoint cylinders ($\simeq S^1 \sqcup S^1$). Show that the sequence forces $b_0 = 1$, $b_1 = 2$, $b_2 = 1$. *Answer sketch:* H^0: $\mathbb{R}^2 \to \mathbb{R}^2$, $(a,b) \mapsto (b-a, b-a)$ has rank 1, so the cokernel $\mathbb{R}$ injects into $H^1(T^2)$. H^1: $\mathbb{R} \oplus \mathbb{R} \to \mathbb{R} \oplus \mathbb{R}$ sends $(a,b) \mapsto (b-a, b-a)$, kernel $\mathbb{R}$ and cokernel $\mathbb{R}$. So $b_1 = 1+1 = 2$ and $b_2 = \dim \operatorname{coker} = 1$.

1.4.10 Four facts Nash lists

Nash closes §4 by recalling "a few well known and useful facts". Each deserves its own explanation.

Finiteness: cohomology stops at the dimension

Key idea: Finiteness

For a manifold X of dimension n, $H^p(X) = 0$ for $p > n$ (and trivially for $p < 0$). If X is compact, each $H^p(X;\mathbb{Z})$ is finitely generated, so each $H^p_{\mathrm{dR}}(X)$ is finite-dimensional.

The first statement is obvious for forms: a p-form with $p > n$ is a totally antisymmetric tensor with more indices than there are directions, so it is zero. For triangulations: an n-manifold needs no simplices of dimension above n. The second statement follows from the existence of a finite triangulation for a compact smooth manifold: then all the chain groups are $\mathbb{Z}^{N_n}$ with finite N_n. Contrast homotopy: $\pi_3(S^2) = \mathbb{Z} \neq 0$, even though $3 > \dim S^2$. Homotopy groups do not stop at the dimension.

The cohomology ring and the cup product

Cohomology classes can be multiplied. For forms the product is the wedge product. If $\mathrm{d}\omega = 0$ and $\mathrm{d}\nu = 0$, then

$$\mathrm{d}(\omega \wedge \nu) \overset{(1)}{=} \mathrm{d}\omega \wedge \nu + (-1)^p\, \omega \wedge \mathrm{d}\nu \overset{(2)}{=} 0,$$
$$(\omega + \mathrm{d}\lambda) \wedge \nu \overset{(3)}{=} \omega \wedge \nu + \mathrm{d}(\lambda \wedge \nu). \tag{1.92}$$

(1) Graded Leibniz rule for a p-form ω.

(2) Both forms are closed.
(3) $\mathrm{d}(\lambda \wedge \nu) = \mathrm{d}\lambda \wedge \nu \pm \lambda \wedge \mathrm{d}\nu = \mathrm{d}\lambda \wedge \nu$, because ν is closed.

So closed $\wedge$ closed is closed, and changing ω by an exact form changes $\omega \wedge \nu$ by an exact form. The product of classes, Nash's (1.45),

$$\cup : H^m(X;\mathbb{R}) \times H^n(X;\mathbb{R}) \to H^{m+n}(X;\mathbb{R}), \qquad [\omega] \cup [\nu] = [\omega \wedge \nu], \tag{1.93}$$

is therefore well defined. It makes $H^*(X;\mathbb{R}) = \bigoplus_{n\geq 0} H^n(X;\mathbb{R})$ into a **graded-commutative ring**: $[\omega] \cup [\nu] = (-1)^{mn}[\nu] \cup [\omega]$. The **cup product** exists for any coefficient ring (for example $\mathbb{Z}$ or $\mathbb{Z}_2$), where forms are not available. On simplicial cochains it is the "front face times back face" formula

$$(\varphi \cup \psi)[v_0, \dots, v_{m+n}] = \varphi[v_0, \dots, v_m]\, \psi[v_m, \dots, v_{m+n}]. \tag{1.94}$$

Worked example 1.81: The cohomology ring of the torus, two ways

With forms. $x = [\mathrm{d}\theta_1/2\pi]$ and $y = [\mathrm{d}\theta_2/2\pi]$ span $H^1(T^2)$. Then $x \cup x = 0$ (since $\mathrm{d}\theta_1 \wedge \mathrm{d}\theta_1 = 0$), $y \cup y = 0$, $y \cup x = -x \cup y$, and

$$\int_{T^2} x \cup y = \frac{1}{4\pi^2} \int_0^{2\pi} \int_0^{2\pi} \mathrm{d}\theta_1\, \mathrm{d}\theta_2 = 1.$$

So $x \cup y$ generates $H^2(T^2;\mathbb{Z})$, and $H^*(T^2) = \Lambda[x, y]$ is the exterior algebra on two generators.
With cochains. On the two-triangle torus, take the cocycles of Example 1.75

$$\alpha : (a,b,c) \mapsto (1,0,1), \qquad \beta : (a,b,c) \mapsto (0,1,1)$$

(both satisfy $x + y - z = 0$). The triangle $L = [(0,0),(1,0),(1,1)]$ has front edge a and back edge b. The triangle $U = [(0,0),(0,1),(1,1)]$ has front edge b and back edge a. With the standard (counterclockwise) orientation the fundamental class is $[T^2] = L - U$. By (1.94),

$$(\alpha \cup \beta)[T^2] \overset{(1)}{=} \alpha(a)\beta(b) - \alpha(b)\beta(a) = 1 \cdot 1 - 0 \cdot 0 = 1,$$
$$(\beta \cup \alpha)[T^2] \overset{(1)}{=} \beta(a)\alpha(b) - \beta(b)\alpha(a) = 0 \cdot 0 - 1 \cdot 1 = -1.$$

(1) Front edge times back edge on L, minus the same on U.

The combinatorial formula reproduces $\int \omega_1 \wedge \omega_2 = 1$ and the antisymmetry $y \cup x = -x \cup y$. (At the cochain level $\cup$ is not graded-commutative; only on cohomology is it.)

Worked example 1.82: Same numbers, different rings

T^2 and the wedge $S^1 \vee S^1 \vee S^2$ (two circles and a sphere glued at a point) both have Betti numbers $1, 2, 1$. In T^2 the product of the two degree-one generators is the degree-two generator. In the wedge it is zero: the circles and the sphere touch at a single point, and a 1-form supported on one circle wedged with one on the other circle vanishes. So the cohomology *ring* tells them apart when the groups cannot. The ring structure is also the origin of the intersection form of 4-manifolds, (1.162) below.

Poincaré duality

On a closed oriented n-manifold M we can pair a p-form with an $(n-p)$-form by wedging and integrating.

Key idea: Poincaré duality

If M is closed (compact, no boundary) and oriented, the pairing

$$H^p_{\mathrm{dR}}(M) \times H^{n-p}_{\mathrm{dR}}(M) \to \mathbb{R}, \qquad ([\omega],[\nu]) \mapsto \int_M \omega \wedge \nu \tag{1.95}$$

is well defined and non-degenerate. Hence $b_p = b_{n-p}$. With integer coefficients, $H^p(M;\mathbb{Z}) \cong H_{n-p}(M;\mathbb{Z})$.

Well defined: shifting ω by $\mathrm{d}\lambda$ changes the integral by $\int_M \mathrm{d}(\lambda \wedge \nu) = \int_{\partial M} \lambda \wedge \nu = 0$, by (1.92) and Stokes. Non-degenerate is the real content. It is most transparent with Hodge theory (Chapter 2): each class has a harmonic representative ω, and $\star\omega$ is again harmonic, so

$$\int_M \omega \wedge \star\omega = \|\omega\|^2_{L^2} > 0 \quad \text{for } \omega \neq 0.$$

The class $[\star\omega] \in H^{n-p}_{\mathrm{dR}}$ therefore pairs non-trivially with $[\omega]$.

The geometric meaning is *intersection*. A closed oriented $(n-p)$-dimensional submanifold $S \subset M$ has a **Poincaré dual** form η_S, a closed p-form concentrated near S, with $\int_S \nu = \int_M \nu \wedge \eta_S$ for every closed $(n-p)$-form ν. It is a smeared delta function transverse to S. Two such submanifolds of complementary dimension then have

$$\int_M \eta_S \wedge \eta_{S'} = \#(S \cap S') \quad \text{(counted with signs)}.$$

Worked example 1.83: Duality on the torus

On T^2 the loops a ($\theta_2 = 0$) and b ($\theta_1 = 0$) cross once. Their Poincaré duals are bump forms across them: $\eta_a = \delta_\epsilon(\theta_2)\,\mathrm{d}\theta_2$ and $\eta_b = -\delta_\epsilon(\theta_1)\,\mathrm{d}\theta_1$, where δ_ϵ is a narrow bump of unit area. (Check: $\int_a \nu = \int_{T^2} \nu \wedge \eta_a$ for $\nu = \mathrm{d}\theta_1/2\pi$ gives $1 = 1$. The sign in η_b is fixed the same way, since $\mathrm{d}\theta_2 \wedge \mathrm{d}\theta_1 = -\mathrm{d}\theta_1 \wedge \mathrm{d}\theta_2$.) In cohomology $\eta_a \sim \mathrm{d}\theta_2/2\pi = y$ and $\eta_b \sim -\mathrm{d}\theta_1/2\pi = -x$. The pairing matrix on H^1 in the basis (x, y) is

$$Q = \begin{pmatrix} \int x\wedge x & \int x\wedge y \\ \int y\wedge x & \int y\wedge y \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \qquad \det Q = 1 \neq 0.$$

It is antisymmetric because $p = n - p = 1$ is odd, and unimodular (determinant ± 1) because Poincaré duality holds over $\mathbb{Z}$. In dimension 4 with $p = 2$ the same construction gives a *symmetric* unimodular matrix: the intersection form of Section 1.6.8.

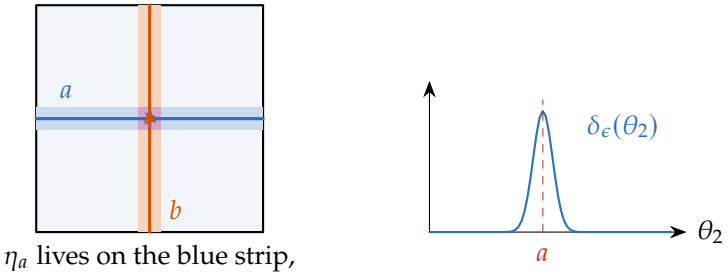
Künneth: cohomology of products

Key idea: Künneth formula

With field coefficients (for example $\mathbb{R}$),

$$H^k(X \times Y) \cong \bigoplus_{p+q=k} H^p(X) \otimes H^q(Y), \tag{1.96}$$

where $[\omega] \otimes [\nu] \mapsto [\pi_X^*\omega \wedge \pi_Y^*\nu]$. In terms of the **Poincaré polynomial** $P_X(t) = \sum_p b_p(X)\, t^p$, this says $P_{X\times Y} = P_X\, P_Y$.



η_a lives on the blue strip, η_b on the orange strip

profile of η_a across a: unit area

Figure 1.45: Poincaré duality as smeared delta functions. The dual of the loop a is a 1-form supported in a thin strip around a, with unit integral across it (right). The wedge of the two duals is supported only where the strips cross (purple square), so $\int \eta_a \wedge \eta_b = \pm 1$ counts the single crossing point of a and b.

The mechanism is separation of variables. A closed form on $X \times Y$ is cohomologous to a sum of products of closed forms on the factors, just as a function on a product is expanded in products of eigenfunctions. (With Hodge theory, harmonic forms on $X \times Y$ are exactly the sums of products of harmonic forms on X and Y.)

Worked example 1.84: Tori, and products of spheres

$$P_{T^n}(t) \overset{(1)}{=} (1+t)^n = \sum_{p=0}^{n} \binom{n}{p} t^p,$$

$$P_{S^2\times S^2}(t) \overset{(2)}{=} (1+t^2)^2 = 1 + 2t^2 + t^4,$$

$$P_{S^1\times S^3}(t) \overset{(3)}{=} (1+t)(1+t^3) = 1 + t + t^3 + t^4.$$

(1) $P_{S^1} = 1 + t$. A basis of $H^p(T^n)$ is $\mathrm{d}\theta_{i_1} \wedge \cdots \wedge \mathrm{d}\theta_{i_p}$ with $i_1 < \cdots < i_p$, and there are $\binom{n}{p}$ of these: the exterior algebra on n generators.

(2) $P_{S^2} = 1 + t^2$. $H^2(S^2 \times S^2)$ is spanned by the area forms ω_1, ω_2 of the two factors.

(3) $S^1 \times S^3$ has $b_1 = 1$ but $b_2 = 0$. It is a compact complex manifold (a Hopf surface) that cannot be Kähler, because Kähler manifolds have even b_1.

For $S^2 \times S^2$ the ring gives the intersection matrix on H^2 in the basis $(\omega_1/4\pi, \omega_2/4\pi)$: $\int (\omega_1/4\pi)^2 = 0$, $\int \omega_1 \wedge \omega_2/16\pi^2 = 1$, so $Q = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. It is even, of signature zero. We will need it in Section 1.6.8.

The Euler characteristic

Working definition 1.34 (Euler characteristic)

$$\chi(X) = \sum_p (-1)^p\, b_p(X) = \sum_p (-1)^p\, N_p,$$

where b_p is the Betti number [$\dim H^p(X;\mathbb{R})$, the number of independent p-dimensional holes] and N_p is the number of p-cells [pieces that are p-dimensional balls, e.g. vertices, edges, faces] in any cell decomposition of X. *Recipe:* count vertices minus edges plus faces minus ..., or take $P_X(-1)$ [the Poincaré polynomial $\sum_p b_p t^p$ at $t = -1$].

The equality of the two sums is (1.76) applied to the cellular chain complex. So the alternating count of cells does not depend on how you cut the space up. That is the content of Euler's polyhedron formula.

Worked example 1.85: Euler characteristics you should know

$$\chi(\text{cube surface}) \overset{(1)}{=} 8 - 12 + 6 = 2 = \chi(S^2),$$
$$\chi(\Sigma_g) \overset{(2)}{=} 1 - 2g + 1 = 2 - 2g,$$
$$\chi(S^n) \overset{(3)}{=} 1 + (-1)^n,$$
$$\chi(X \times Y) \overset{(4)}{=} \chi(X)\,\chi(Y).$$

(1) Vertices, edges, faces of a cube; any convex polyhedron gives 2.
(2) The genus-g surface is a $4g$-gon with edges identified in pairs $(a_1 b_1 a_1^{-1} b_1^{-1} \cdots a_g b_g a_g^{-1} b_g^{-1})$: one vertex, $2g$ edges, one face.
(3) From (1.91): $b_0 = b_n = 1$.
(4) Künneth: $\chi = P(-1)$ and $P_{X\times Y} = P_X P_Y$.

So $\chi(T^2) = 0$ and $\chi(S^2 \times S^2) = 4$. Every closed odd-dimensional manifold has $\chi = 0$, because Poincaré duality pairs b_p with b_{n-p} and they enter with opposite signs.

Physical picture: Three faces of one number

The Euler characteristic of a closed surface appears in three guises that look unrelated.

- *Combinatorics:* $V - E + F$.
- *Curvature (Gauss–Bonnet, Chapter T2):* $\frac{1}{2\pi}\int_\Sigma K\,\mathrm{d}A = \chi(\Sigma)$.
- *Zeros of vector fields (Poincaré–Hopf):* the sum of indices of the zeros of any vector field is χ. This forces a zero on S^2: the hairy ball theorem of Section 1.5.8.

And in the analytic guise $\chi = \sum(-1)^p \dim\{\text{harmonic } p\text{-forms}\}$ it is the index of the operator $\mathrm{d} + \mathrm{d}^\dagger$ from even to odd forms. The Atiyah–Singer theorem (Chapter 4) is the grand generalisation of "combinatorics = curvature = zero modes".

Hurewicz: where homotopy and homology meet

Homotopy groups and homology groups are both built from maps of spheres or simplices into X. There is a natural map between them. A based map $f : S^n \to X$ pushes forward the fundamental class of the sphere:

$$h : \pi_n(X) \to H_n(X;\mathbb{Z}), \qquad [f] \mapsto f_*[S^n]. \tag{1.97}$$

This is the **Hurewicz map**. For $n = 1$ it is Example 1.74: a loop, viewed as a 1-cycle.

Key idea: The Hurewicz theorem

Let X be path connected.

1. If $\pi_k(X) = 0$ for all $1 \le k < n$, with $n \ge 2$, then $H_k(X;\mathbb{Z}) = 0$ for $1 \le k < n$ and $h : \pi_n(X) \to H_n(X;\mathbb{Z})$ is an isomorphism. The first non-vanishing homotopy and homology groups occur in the same dimension and agree.

2. For $n = 1$: h is onto, and its kernel is the commutator subgroup, so

$$H_1(X;\mathbb{Z}) \cong \pi_1(X)/[\pi_1(X), \pi_1(X)]. \tag{1.98}$$

Why is H_1 the *abelianised* π_1? Homology adds chains, and addition is commutative: $a+b = b+a$. So whatever π_1 records about the *order* of loops is lost. Concretely, the commutator loop $aba^{-1}b^{-1}$ is the boundary of a surface: it is the edge of the square that becomes a punctured torus when a and b are glued (Figure 1.46). As a 1-chain it is $a + b - a - b = 0$ anyway. The theorem says that this is *all* that is lost.

Worked example 1.86: Hurewicz at work

- *Spheres.* S^n is $(n-1)$-connected, so $\pi_n(S^n) \cong H_n(S^n;\mathbb{Z}) = \mathbb{Z}$. The degree of a map $S^n \to S^n$ can therefore be computed homologically: $f_*[S^n] = (\deg f)[S^n]$, or with forms, $\deg f = \int_{S^n} f^*\mathrm{vol}/\int_{S^n} \mathrm{vol}$.
- *Only the first group.* $\pi_3(S^2) = \mathbb{Z}$ but $H_3(S^2) = 0$. Beyond the first non-vanishing group, homotopy and homology part company. The Hopf map (Section 1.5.7) generates a homotopy class that homology cannot see at all.
- *The figure eight* $S^1 \vee S^1$: one vertex and two edges a, b with $\partial = 0$, so $H_1 = \mathbb{Z}^2$. But π_1 is the free group on a, b, in which $ab \neq ba$. Abelianising the free group on two letters gives $\mathbb{Z}^2$.
- *Genus two.* $\pi_1(\Sigma_2) = \langle a_1, b_1, a_2, b_2 \mid a_1 b_1 a_1^{-1} b_1^{-1} a_2 b_2 a_2^{-1} b_2^{-1} = 1\rangle$, a non-abelian group (Nash's example). Abelianising turns the relation into $a_1+b_1-a_1-b_1+a_2+b_2-a_2-b_2 = 0$, which is empty. So $H_1(\Sigma_2;\mathbb{Z}) = \mathbb{Z}^4$.
- $\mathbb{RP}^2$: $\pi_1 = \mathbb{Z}_2$ is already abelian, and $H_1 = \mathbb{Z}_2$, as computed cellularly.

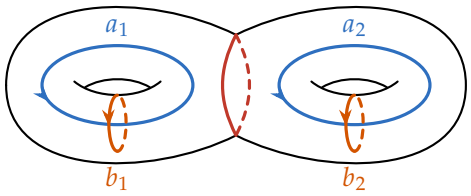


Figure 1.46: The genus-2 surface. The red loop cuts it into two punctured tori. As an element of π_1 it equals the commutator $a_1 b_1 a_1^{-1} b_1^{-1}$, which is not the identity: the loop cannot be shrunk. As a 1-cycle it is the boundary of the left half, so it is zero in H_1. This is the content of $H_1 = \pi_1/[\pi_1, \pi_1]$: homology forgets exactly the commutators.

Dictionary: cohomology in physics

mathematics	physics
closed but not exact 1-form	vector potential of a flux tube (Aharonov–Bohm)
period $\oint_\gamma A$	enclosed magnetic flux, holonomy phase
$H^1(X;\mathbb{Z}) = [X, U(1)]$	sectors of large $U(1)$ gauge transformations
$H^2(X;\mathbb{Z})$	magnetic charges; $U(1)$ bundles (Section 1.5.11)
Mayer–Vietoris connecting map	Wu–Yang patching of the monopole
Poincaré dual form η_S	delta-function source (current) on S
$b_p = \dim H^p_{\mathrm{dR}}$	number of harmonic p-form zero modes
$\chi = \sum(-1)^p b_p$	index of $\mathrm{d} + \mathrm{d}^\dagger$; Witten index of SUSY QM

Reading Nash (pp. 13–14, (1.44)–(1.46) and Hurewicz)

Nash dualises the complex (1.44) to get homology, $\partial_{n-1} \circ \partial_n = 0$ and $H^E_n = \operatorname{Ker} \partial_{n-1} / \operatorname{Im} \partial_n$. (His indexing names each map by its target; ours names it by its source, $\partial_n : C_n \to C_{n-1}$; the content is identical.) He takes the singular chain complex and says its homology "is isomorphic to the integral cohomology group $H_n(X;\mathbb{Z})$"; read "homology" (see the pitfall in the homology subsection). He then lists: finiteness ($0 \le n \le \dim X$); the ring $H^*_E(X)$ with cup product equal to the wedge product for de Rham (1.45); the sphere result (1.46), which we derived by Mayer–Vietoris in Example 1.80; the Hurewicz isomorphism; and $H_1 = \pi_1/[\pi_1, \pi_1]$ with the genus-2 example. Poincaré duality, Künneth and the Euler characteristic are not in Nash's §4. We added them because Nash uses them freely later: Poincaré duality in the definition of the intersection form (1.72), and the Euler characteristic throughout the index theorem chapters.

Recap: §1.4 Cohomology and homology

- $K(G, n)$ has one homotopy group, G in degree n. Cohomology is $H^n(X;G) = [X, K(G,n)]_0$, a group because $K(G,n) = \Omega K(G, n+1)$. Examples: $H^1(X;\mathbb{Z}) = [X, S^1]_0$ (winding numbers).
- A complex is a sequence with $d \circ d = 0$. Its cohomology $\operatorname{Ker} d / \operatorname{Im} d$ measures failure of exactness. The Euler characteristic of the complex survives passage to cohomology.
- de Rham: forms and d. Homology: chains and ∂, computed by integer boundary matrices (torus: $\partial_2 = (1, 1, -1)^T$ twice, $\partial_1 = 0$). Cochains: transpose. Torsion ($\mathbb{RP}^2$) sits in H_1 but in H^2.
- de Rham's theorem: $H^p_{\mathrm{dR}}(X) \cong H^p(X;\mathbb{R})$; a closed form is exact iff all periods vanish.
- Mayer–Vietoris glues: it gives $H^*(S^n)$ in three lines, and its connecting map is the monopole's patching.
- Cup product = wedge; Poincaré duality $b_p = b_{n-p}$ and intersection numbers; Künneth $P_{X\times Y} = P_X P_Y$; $\chi = \sum(-1)^p b_p = V - E + F$.
- Hurewicz: first non-zero π_n equals first non-zero H_n; $H_1 = \pi_1^{\mathrm{ab}}$.

1.5 Fibre bundles and fibrations

A field in physics is a rule that attaches a value to each point of space. For a scalar field the value is a number. For a vector field it is a vector in the tangent space at that point. For a charged field it is a complex number defined *only up to a phase convention*, and the convention may be changed from point to point by a gauge transformation. In every case there is a *space of possible values* sitting over each point, and a field picks one value from each.

When all these value spaces can be identified with one fixed space F in a single global way, the field is just a function $M \to F$. Often they cannot be. The tangent planes of a sphere cannot be identified with $\mathbb{R}^2$ smoothly everywhere at once. The phases of a charged field around a magnetic monopole cannot be fixed smoothly on the whole sphere surrounding it. A **fibre bundle** is the structure that describes value spaces that are *locally* a product but *globally* twisted. This section builds bundles concretely, from transition functions, then turns to the homotopy theory Nash needs: pullbacks, classifying spaces, the exact homotopy sequence and fibrations.

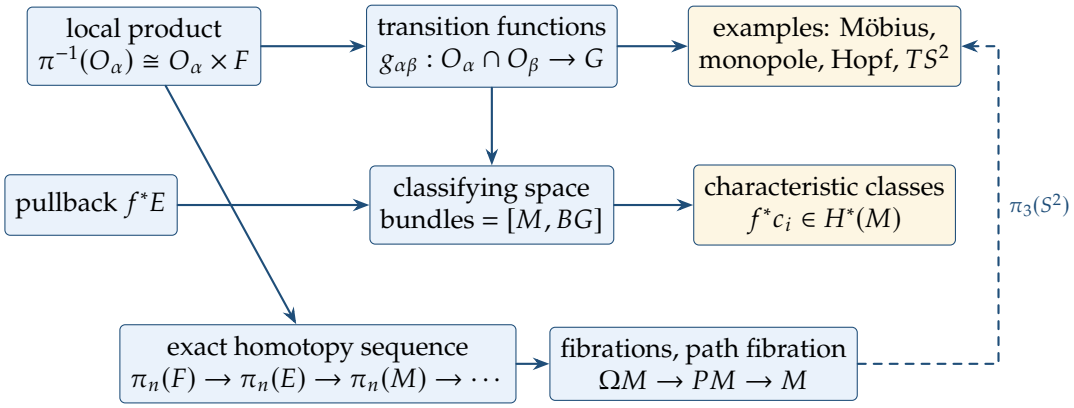

Figure 1.47: Roadmap of Section 1.5. The top row is geometry: bundles are glued from products by transition functions. The middle row is classification: every bundle is pulled back from a universal one, and its characteristic classes are pulled back cohomology. The bottom row is homotopy theory: the exact sequence of a bundle or fibration, which (among other things) computes $\pi_3(S^2) = \mathbb{Z}$ from the Hopf fibration.

1.5.1 The first example: the tangent bundle

Nash starts with the tangent bundle of a manifold M,

$$TM = \bigcup_{p \in M} T_pM, \tag{1.99}$$

the collection of all tangent spaces, one for each point. It comes with a **projection** $\pi : TM \to M$ that sends a tangent vector to the point where it is attached. The vocabulary for every bundle is already here.

- The **base space** is M.
- The **total space** is TM.
- The **fibre** over p is $\pi^{-1}(p) = T_pM$, a copy of $\mathbb{R}^n$, $n = \dim M$.

When the fibres are vector spaces, and the gluing respects the linear structure, we speak of a **vector bundle**. Its **rank** is the dimension of the fibre. TM is a vector bundle of rank n.

Concretely. On $S^2 \subset \mathbb{R}^3$ the tangent plane at p is $T_pS^2 = \{v \in \mathbb{R}^3 : v \cdot p = 0\}$. So

$$TS^2 = \{(p, v) \in \mathbb{R}^3 \times \mathbb{R}^3 : \ |p| = 1, \ v \cdot p = 0\}, \qquad \pi(p, v) = p.$$

It is a 4-dimensional manifold: 2 dimensions of base plus 2 of fibre.

In coordinates. On a chart with coordinates x^μ, a tangent vector is $v = v^\mu \partial_\mu$, and the chart identifies $\pi^{-1}(\text{chart})$ with $(\text{chart}) \times \mathbb{R}^n$ via (x^μ, v^μ). On an overlap with a second chart x'^μ, the chain rule gives

$$v'^\mu = \frac{\partial x'^\mu}{\partial x^\nu} v^\nu. \tag{1.100}$$

The *Jacobian matrix* $\partial x'/\partial x$, an element of $\mathrm{GL}(n, \mathbb{R})$ at each point of the overlap, tells us how to glue the local pieces $(\text{chart}) \times \mathbb{R}^n$ together. That is the entire content of a bundle, as we now explain.

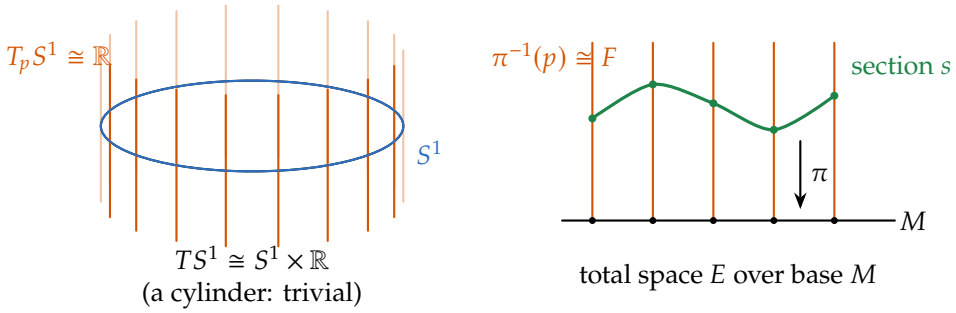

Figure 1.48: Left: the tangent bundle of the circle is a cylinder, one tangent line (orange) over each point of S^1. Right: the general picture of a bundle. Each point p of the base M carries a fibre $\pi^{-1}(p)$, a copy of F. The projection π collapses each fibre to its point. A section (green) picks one point in each fibre: it is a field.

1.5.2 Local triviality and transition functions

Working definition 1.35 (fibre bundle)

A **fibre bundle** with fibre F over M is a space E with a map $\pi : E \to M$ such that M has an open cover $\{O_\alpha\}$ [open sets whose union is all of M] with **local trivialisations**

$$\phi_\alpha : \ \pi^{-1}(O_\alpha) \xrightarrow{\cong} O_\alpha \times F, \qquad \phi_\alpha(e) = (\pi(e), \ f_\alpha(e)). \tag{1.101}$$

[$\pi^{-1}(O_\alpha)$ is the part of E lying over O_α, and $\cong$ means homeomorphic]. Over each patch the bundle is a product. On an overlap $O_\alpha \cap O_\beta$ the two identifications of the fibre differ by a map

$$f_\alpha(e) = g_{\alpha\beta}(\pi(e)) \cdot f_\beta(e), \qquad g_{\alpha\beta} : O_\alpha \cap O_\beta \to G, \tag{1.102}$$

where G is a group acting on F [each $g \in G$ moves the points of F, with $(gh)\cdot f = g\cdot(h\cdot f)$], the **structure group**, and the $g_{\alpha\beta}$ are the **transition functions**. *Operational form:* a bundle *is* a cover, a group G acting on F, and a set of G-valued functions on the overlaps obeying the cocycle conditions (1.104) [$g_{\alpha\beta}\, g_{\beta\gamma} = g_{\alpha\gamma}$ wherever three patches overlap].

The transition functions are not arbitrary. On any point of a triple overlap $O_\alpha \cap O_\beta \cap O_\gamma$ we

can change coordinates $\gamma \to \beta \to \alpha$ or go directly $\gamma \to \alpha$, and the answers must agree:

$$\begin{aligned} g_{\alpha\gamma}\, f_\gamma &\overset{(1)}{=} f_\alpha \\ &\overset{(2)}{=} g_{\alpha\beta}\, f_\beta \\ &\overset{(3)}{=} g_{\alpha\beta}\, g_{\beta\gamma}\, f_\gamma . \end{aligned} \tag{1.103}$$

(1) (1.102) for the pair (α, γ).
(2) (1.102) for the pair (α, β).
(3) (1.102) for the pair (β, γ).

Since this holds for every point of the fibre (and we take G to act faithfully), we get the **cocycle conditions**

$$g_{\alpha\alpha} = 1, \qquad g_{\beta\alpha} = g_{\alpha\beta}^{-1}, \qquad g_{\alpha\beta}\, g_{\beta\gamma}\, g_{\gamma\alpha} = 1 \ \text{ on } O_\alpha \cap O_\beta \cap O_\gamma . \tag{1.104}$$

Key idea: A bundle is its transition functions

Conversely, given a cover $\{O_\alpha\}$ and functions $g_{\alpha\beta}$ obeying (1.104), we can *build* the bundle:

$$E = \Big(\bigsqcup_\alpha O_\alpha \times F \Big) \Big/ \sim, \qquad (x, f)_\beta \sim (x,\ g_{\alpha\beta}(x) f)_\alpha \ \text{ for } x \in O_\alpha \cap O_\beta . \tag{1.105}$$

The cocycle conditions are exactly what makes $\sim$ an equivalence relation (reflexive, symmetric, transitive). Changing the trivialisations by G-valued functions h_α on each patch replaces

$$g_{\alpha\beta} \longmapsto h_\alpha\, g_{\alpha\beta}\, h_\beta^{-1}, \tag{1.106}$$

and gives an isomorphic bundle. A bundle is **trivial**, $E \cong M \times F$, exactly when its transition functions can be written as $g_{\alpha\beta} = h_\alpha h_\beta^{-1}$.

Notice the resemblance with cohomology. "Cocycle" modulo "coboundary" $h_\alpha h_\beta^{-1}$ is a cohomology in which the cochains are functions on overlaps: Čech cohomology, the subject of Chapter 3. For $G = U(1)$ this is literal. Write $g_{\alpha\beta} = e^{i\lambda_{\alpha\beta}}$. The cocycle condition says $\lambda_{\alpha\beta} + \lambda_{\beta\gamma} + \lambda_{\gamma\alpha} \in 2\pi\mathbb{Z}$, and the integers $n_{\alpha\beta\gamma} = (\lambda_{\alpha\beta} + \lambda_{\beta\gamma} + \lambda_{\gamma\alpha})/2\pi$ form a class in $H^2(M;\mathbb{Z})$: the first Chern class of the bundle. We will compute it for the monopole below.

Physical picture: Transition functions are gauge transformations on the overlaps

In a gauge theory with gauge group G, a choice of trivialisation over a patch is a choice of gauge. On the overlap of two patches two gauges are in use, and they are related by a gauge transformation: that is $g_{\alpha\beta}$. The replacement (1.106) is a change of gauge on each patch. A bundle is *non-trivial* when no choice of gauges makes all the patch-to-patch transformations disappear. The magnetic monopole is the prototype.

Worked example 1.87: Cylinder and Möbius band: the simplest twist

Take the base S^1, with angle ϕ, covered by two arcs $O_1 = \{-\frac{\pi}{2} - \epsilon < \phi < \frac{\pi}{2} + \epsilon\}$ and $O_2 = \{\frac{\pi}{2} - \epsilon < \phi < \frac{3\pi}{2} + \epsilon\}$. Their overlap has two pieces: A near $\phi = \pi/2$ and B near $\phi = -\pi/2$. Take fibre $F = \mathbb{R}$ and structure group $G = \mathbb{Z}_2 = \{\pm 1\} = \mathrm{O}(1)$.

- $g_{12} = +1$ on A and $+1$ on B: the cylinder $S^1 \times \mathbb{R}$.

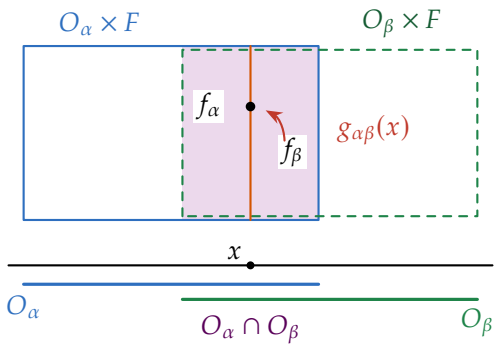

Figure 1.49: Gluing a bundle. Over O_α the bundle is the product $O_\alpha \times F$ (blue box), over O_β it is $O_\beta \times F$ (green). Over the overlap (purple) a single point of the fibre above x has two names, f_α and f_β, related by the transition function: $f_\alpha = g_{\alpha\beta}(x) f_\beta$. A twisted bundle arises when these relabellings cannot all be undone.

- $g_{12} = +1$ on A and -1 on B: the **Möbius band**.

There are no triple overlaps, so the cocycle conditions hold trivially. Can we untwist the Möbius band by (1.106)? The new transition function is $h_1 g_{12} h_2^{-1}$ with $h_i : O_i \to \{\pm 1\}$ continuous, hence constant on each (connected) arc. So

$$h_1 g_{12} h_2^{-1}\big|_A = h_1 h_2^{-1}, \qquad h_1 g_{12} h_2^{-1}\big|_B = -h_1 h_2^{-1}.$$

The product of the values on A and B is -1 for every choice. It is an invariant, so the band cannot be made trivial. Allowing $G = \mathrm{GL}(1,\mathbb{R}) = \mathbb{R}^\times$ does not help: h_i must be nowhere zero, hence of constant sign, and the same argument applies.

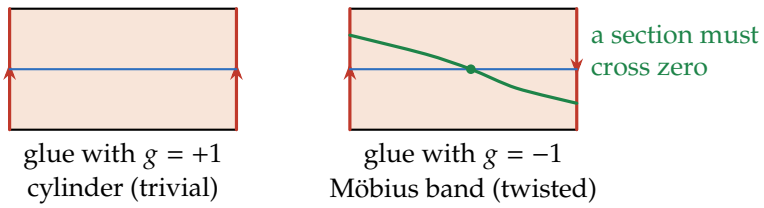

Figure 1.50: The two line bundles over the circle. Both are a strip $[0, 2\pi] \times \mathbb{R}$ with the ends glued. Gluing with $+1$ gives the cylinder. Gluing with -1 (arrows reversed) gives the Möbius band. The blue line is the zero section. A section of the Möbius band (green) must take value $s(2\pi) = -s(0)$, so by the intermediate value theorem it vanishes somewhere.

1.5.3 Sections: fields as bundle maps

Working definition 1.36 (section)

A **section** of $\pi : E \to M$ is a map $s : M \to E$ with $\pi \circ s = \mathrm{id}_M$: it picks one point in each fibre [the copy $\pi^{-1}(x)$ of F sitting over the point x]. *Operationally*, it is a collection of local functions $s_\alpha : O_\alpha \to F$ that obey

$$s_\alpha(x) = g_{\alpha\beta}(x)\, s_\beta(x) \qquad \text{on } O_\alpha \cap O_\beta. \tag{1.107}$$

[$g_{\alpha\beta}$ are the transition functions, converting the β description of a point of F into the α one]

A physical field of a given type is a section of the appropriate bundle. On a trivial bundle sections are just functions $M \to F$. On a twisted bundle the local functions must be patched with the transition functions, and this can force zeros.

Worked example 1.88: Every section of the Möbius band has a zero

Cut the circle at $\phi = 0$ and describe a section by a continuous function $s(\phi)$, $\phi \in [0, 2\pi]$. Going around once, the fibre coordinate comes back multiplied by the product of the transition functions encountered, which is -1. So $s(2\pi) = -s(0)$. If $s(0) > 0$ then $s(2\pi) < 0$, and by the intermediate value theorem s vanishes somewhere. The zero section is a section, but there is no nowhere-vanishing one. Consequently the Möbius band has no global frame: it is not trivial. (A nowhere-zero section s of a line bundle would give a trivialisation $\lambda s(x) \mapsto (x, \lambda)$.)

Key idea: Sections detect triviality

A vector bundle of rank k is trivial exactly when it has k sections that are linearly independent at every point (a global frame). A principal bundle (below) is trivial exactly when it has a single global section.

1.5.4 New vector bundles from old

Nash notes that we can build new bundles "by carrying out the standard operations of linear algebra on the fibres". In terms of transition functions this is mechanical. Let E and E' have transition functions $g_{\alpha\beta}$ and $g'_{\alpha\beta}$ (matrices, on a common cover).

bundle	fibre over x	transition functions
direct sum $E \oplus E'$	$E_x \oplus E'_x$	$\begin{pmatrix} g_{\alpha\beta} & 0 \\ 0 & g'_{\alpha\beta} \end{pmatrix}$
tensor product $E \otimes E'$	$E_x \otimes E'_x$	$g_{\alpha\beta} \otimes g'_{\alpha\beta}$ (Kronecker product)
dual E^*	$(E_x)^*$	$(g_{\alpha\beta}^T)^{-1}$
determinant $\Lambda^k E$	$\Lambda^k E_x$	$\det g_{\alpha\beta}$
exterior power $\Lambda^p E$	$\Lambda^p E_x$	$\Lambda^p g_{\alpha\beta}$ ($p \times p$ minors)

Each line is checked in the same way: apply the rule to the fibres, and verify that the new transition functions still satisfy the cocycle condition. For the dual, a covector ξ pairs with vectors to give numbers, and this pairing must be gauge invariant. If $v_\alpha = g_{\alpha\beta} v_\beta$, then

$$\xi_\alpha^T v_\alpha \overset{(1)}{=} \xi_\alpha^T g_{\alpha\beta} v_\beta$$

$$\overset{(2)}{=} \xi_\beta^T v_\beta \qquad \Longleftrightarrow \qquad \xi_\alpha = (g_{\alpha\beta}^T)^{-1}\xi_\beta.$$

(1) Transform the vector.
(2) Require invariance of the pairing for every v_β; this forces $g_{\alpha\beta}^T \xi_\alpha = \xi_\beta$.

Worked example 1.89: Forms are sections of bundles built from TM

The cotangent bundle T^*M is the dual of TM. Its transition functions are the inverse transpose of the Jacobian (1.100), which is the familiar covector rule $\xi'_\mu = \frac{\partial x^\nu}{\partial x'^\mu}\xi_\nu$. The p-forms of Chapter T1 are sections of $\Lambda^p T^*M$. The top power $\Lambda^n T^*M$ has transition functions $\det(\partial x/\partial x') = 1/\det(\partial x'/\partial x)$, which is the Jacobian factor in the change of variables of an integral. M is **orientable** exactly when we can choose charts with all Jacobian determinants positive. Then $\Lambda^n T^*M$ has transition functions in $\mathbb{R}_{>0}$, which can be gauged to 1, so it is trivial and has a nowhere-zero section: a volume form. For the Möbius band the Jacobians of the obvious charts have determinants of both signs, and no choice fixes it.

1.5.5 Principal bundles and associated bundles

Underneath every vector bundle Nash places a **principal bundle**, one whose fibre is the structure group itself.

Working definition 1.37 (principal bundle)

A **principal G-bundle** $P \to M$ is a bundle with fibre $F = G$, transition functions acting on the fibre by *left* multiplication, $f_\alpha = g_{\alpha\beta} f_\beta$. Because left and right multiplications commute [$(gf)h = g(fh)$ in G], G also acts on P from the *right*, $p \mapsto p \cdot h$, fibre by fibre, without reference to any trivialisation [a choice of patch identification $\pi^{-1}(O_\alpha) \cong O_\alpha \times G$]. *Operationally*: a principal bundle is just the set of transition functions $g_{\alpha\beta}$, regarded as data on their own, with no particular fibre in mind.

Given P and a representation $\rho : G \to \mathrm{GL}(V)$, the **associated vector bundle** $E = P \times_\rho V$ is the bundle with fibre V and transition functions $\rho(g_{\alpha\beta})$. The same principal bundle gives many vector bundles, one for each representation.

Worked example 1.90: The frame bundle of a manifold

A **frame** at $p \in M$ is an ordered basis $(e_1, \dots, e_n)$ of T_pM. The set of all frames at p is a copy of $\mathrm{GL}(n,\mathbb{R})$: fix one frame, and every other is obtained from it by a unique invertible matrix. The **frame bundle** $F(M)$ is the principal $\mathrm{GL}(n,\mathbb{R})$ bundle of all frames. Its transition functions are the Jacobians (1.100). The tangent bundle is associated to it via the defining representation of $\mathrm{GL}(n,\mathbb{R})$ on $\mathbb{R}^n$, the cotangent bundle via the dual representation, and tensor bundles via tensor representations. This is Nash's "underlying principal bundle with fibre $G = \mathrm{GL}(n,\mathbb{R})$".
A metric lets us restrict to orthonormal frames. Then the transition functions can be chosen in $\mathrm{O}(n)$, and with an orientation in $\mathrm{SO}(n)$. This **reduction of the structure group** will be important in Section 1.6 and Chapter T4, where lifting from $\mathrm{SO}(n)$ to $\mathrm{Spin}(n)$ defines spinors.

Dictionary: bundles and gauge theory

bundle language	physics language
principal G-bundle P	gauge group G, with topological sector fixed
local trivialisation over O_α	choice of gauge on O_α
transition function $g_{\alpha\beta}$	gauge transformation relating two gauges
associated bundle $P \times_\rho V$	matter field in the representation ρ
section of $P \times_\rho V$	matter field configuration $\psi(x)$
connection on P	gauge potential A_μ
curvature	field strength $F_{\mu\nu}$
non-trivial bundle	topologically non-trivial sector (monopole, instanton)

Gauge potentials on a patched bundle. We use the convention stated in Chapter T3: A is a Lie-algebra-valued 1-form with anti-Hermitian values, the covariant derivative on sections is $D = \mathrm{d} + A$, and $F = \mathrm{d}A + A \wedge A$. (The physicists' Hermitian field is related by $A_{\text{math}} = -ig\, A^a_{\text{phys}} T^a$; for electromagnetism with charge e, $A_{\text{math}} = -ie\, A_{\text{phys}}$.) Each patch carries its own local potential A_α. For D to be a well-defined operation on sections (1.107), we need $D_\alpha s_\alpha = g_{\alpha\beta} D_\beta s_\beta$. Writing $g = g_{\alpha\beta}$,

$$\begin{aligned} D_\alpha s_\alpha &\overset{(1)}{=} \mathrm{d}(g\, s_\beta) + A_\alpha\, g\, s_\beta \\ &\overset{(2)}{=} g\, \mathrm{d}s_\beta + (\mathrm{d}g)\, s_\beta + A_\alpha\, g\, s_\beta \\ &\overset{(3)}{=} g\big(\mathrm{d}s_\beta + (g^{-1} A_\alpha g + g^{-1}\mathrm{d}g)\, s_\beta\big). \end{aligned} \tag{1.108}$$

(1) Definition of D_α and the patching rule $s_\alpha = g s_\beta$.
(2) Leibniz rule.
(3) Factor out g on the left.

This equals $g\, D_\beta s_\beta$ exactly when

$$A_\beta = g_{\alpha\beta}^{-1} A_\alpha\, g_{\alpha\beta} + g_{\alpha\beta}^{-1} \mathrm{d} g_{\alpha\beta} \qquad \text{on } O_\alpha \cap O_\beta, \tag{1.109}$$

which is the gauge transformation law. The potentials are not global objects; they are local representatives glued by (1.109).

1.5.6 Clutching: bundles over spheres

For a sphere S^n there is a very economical description. Cover S^n by two caps O_N and O_S, each contractible, overlapping in a band around the equator S^{n-1}. Over a contractible set every bundle is trivial (we will see why in Section 1.5.10), so a bundle over S^n is completely described by one transition function on the band, and up to homotopy that is a map from the equator,

$$g_{NS} : S^{n-1} \longrightarrow G. \tag{1.110}$$

Deforming g_{NS} continuously deforms the bundle, and homotopic transition functions give isomorphic bundles. Changing trivialisations on the caps multiplies g_{NS} by maps that extend over the caps, which are null-homotopic. The result is the **clutching construction**: for connected G,

$$\{\text{principal } G\text{-bundles over } S^n\}/\text{iso} \;\cong\; \pi_{n-1}(G). \tag{1.111}$$

base	group	classified by	physics
S^2	$U(1)$	$\pi_1(U(1)) = \mathbb{Z}$	Dirac monopole of charge n
S^2	SO(3)	$\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$	't Hooft–Polyakov sectors mod 2
S^4	SU(2)	$\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$	BPST instantons of charge k (Chapter 8)
S^3	any Lie G	$\pi_2(G) = 0$	every bundle over S^3 is trivial

The monopole bundle

Worked example 1.91: The Dirac monopole as a $U(1)$ bundle over S^2

Cover S^2 by $O_N = \{0 \le \theta < \frac{\pi}{2} + \epsilon\}$ and $O_S = \{\frac{\pi}{2} - \epsilon < \theta \le \pi\}$. Take $G = U(1)$ and the transition function on the band

$$g_{NS}(\phi) = e^{in\phi}. \tag{1.112}$$

For this to be a continuous function on the band, $e^{in\cdot 2\pi} = 1$: *n must be an integer*. On the two patches choose the potentials

$$A_N = -\frac{in}{2}(1 - \cos\theta)\,\mathrm{d}\phi, \qquad A_S = +\frac{in}{2}(1 + \cos\theta)\,\mathrm{d}\phi. \tag{1.113}$$

Each is smooth on its own patch. A_N has a coefficient that vanishes at $\theta = 0$, where $\mathrm{d}\phi$ is singular, like $(1 - \cos\theta) \sim \theta^2/2$; in Cartesian coordinates near the north pole $\theta^2\mathrm{d}\phi \approx x\,\mathrm{d}y - y\,\mathrm{d}x$ is smooth. Likewise A_S at $\theta = \pi$.
They are glued correctly. For abelian G, (1.109) reads $A_S = A_N + g^{-1}\mathrm{d}g$:

$$\begin{aligned} A_N + g_{NS}^{-1}\mathrm{d}g_{NS} &\overset{(1)}{=} -\frac{in}{2}(1 - \cos\theta)\,\mathrm{d}\phi + in\,\mathrm{d}\phi \\ &= \frac{in}{2}(1 + \cos\theta)\,\mathrm{d}\phi = A_S. \end{aligned}$$

(1) $g^{-1}\mathrm{d}g = e^{-in\phi}\,(in)\,e^{in\phi}\mathrm{d}\phi = in\,\mathrm{d}\phi$.

The curvature is global. On both patches

$$F = \mathrm{d}A_N \overset{(1)}{=} -\frac{in}{2}\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi, \qquad \mathrm{d}A_S \overset{(2)}{=} -\frac{in}{2}\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi,$$

(1) $\mathrm{d}\big((1 - \cos\theta)\mathrm{d}\phi\big) = \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$.
(2) $\mathrm{d}\big((1 + \cos\theta)\mathrm{d}\phi\big) = -\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$.

so F is a single, smooth, closed 2-form on S^2: a radial magnetic field of constant strength.
The first Chern number. With $c_1 = \frac{i}{2\pi}F$ (orientation $\mathrm{d}\theta \wedge \mathrm{d}\phi$),

$$\begin{aligned} \int_{S^2} c_1 &\overset{(1)}{=} \frac{i}{2\pi}\Big(-\frac{in}{2}\Big)\int_0^{2\pi}\!\!\int_0^{\pi} \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \\ &\overset{(2)}{=} \frac{n}{4\pi}\cdot 4\pi = n. \end{aligned} \tag{1.114}$$

(1) Insert F.
(2) $i\cdot(-i) = 1$, and the area of the unit sphere is 4π.

We can also get this without any curvature, by Stokes on the two hemispheres H_N, H_S with common boundary the equator γ (oriented as the boundary of H_N):

$$\begin{aligned}\int_{S^2} F &\overset{(1)}{=} \int_{H_N} \mathrm{d}A_N + \int_{H_S} \mathrm{d}A_S \\ &\overset{(2)}{=} \oint_\gamma A_N - \oint_\gamma A_S \\ &\overset{(3)}{=} -\oint_\gamma g_{NS}^{-1}\mathrm{d}g_{NS} = -2\pi i\, n.\end{aligned}$$

(1) Split the sphere; on each hemisphere use the potential that is smooth there.
(2) Stokes. The equator is $+\gamma$ as the boundary of H_N and $-\gamma$ as the boundary of H_S.
(3) $A_S - A_N = g^{-1}\mathrm{d}g$, and $\oint in\,\mathrm{d}\phi = 2\pi i n$.

So $\frac{i}{2\pi}\int F = n$ again: *the total flux is the winding number of the transition function*.

Physical picture: Dirac quantisation is topology

In physical units, $A_{\text{math}} = -ie\,A_{\text{phys}}$ (with $\hbar = c = 1$), so the magnetic flux is $\Phi = \int B = \frac{i}{e}\int F = \frac{2\pi n}{e}$. That is Dirac's condition $e\Phi \in 2\pi\mathbb{Z}$, or $eg = n/2$ for a monopole of flux $4\pi g$. In Dirac's original picture, the "string" is where A_N would be singular if we insisted on using it on the whole sphere ($\theta = \pi$). The string is invisible exactly when $e^{ie\Phi} = 1$. Wu and Yang's patching removes the string altogether. The integer n is the clutching class in $\pi_1(U(1)) = \mathbb{Z}$, it is the first Chern number, and it is the class $[F/2\pi]$ in $H^2(S^2;\mathbb{Z}) = \mathbb{Z}$.

1.5.7 The Hopf fibration

The most famous non-trivial bundle is a principal $U(1)$ bundle over S^2 whose total space is the 3-sphere. Nash uses it (via the exact sequence) to compute $\pi_3(S^2)$. Let us build it by hand.

The map

Write $S^3 = \{(z_1, z_2) \in \mathbb{C}^2 : |z_1|^2 + |z_2|^2 = 1\}$ and think of $z = (z_1, z_2)^T$ as a normalised two-component spinor. Define

$$\pi(z_1, z_2) = z^\dagger \vec{\sigma} z = \big(2\,\mathrm{Re}(\bar z_1 z_2),\ 2\,\mathrm{Im}(\bar z_1 z_2),\ |z_1|^2 - |z_2|^2\big), \tag{1.115}$$

with the Pauli matrices $\sigma_1 = \left(\begin{smallmatrix}0&1\\1&0\end{smallmatrix}\right)$, $\sigma_2 = \left(\begin{smallmatrix}0&-i\\i&0\end{smallmatrix}\right)$, $\sigma_3 = \left(\begin{smallmatrix}1&0\\0&-1\end{smallmatrix}\right)$. The image lies on the unit sphere:

$$\begin{aligned}|\pi(z)|^2 &\overset{(1)}{=} 4|\bar z_1 z_2|^2 + \big(|z_1|^2 - |z_2|^2\big)^2 \\ &\overset{(2)}{=} \big(|z_1|^2 + |z_2|^2\big)^2 = 1.\end{aligned}$$

(1) $(2\,\mathrm{Re}\,w)^2 + (2\,\mathrm{Im}\,w)^2 = 4|w|^2$ with $w = \bar z_1 z_2$.
(2) $4ab + (a-b)^2 = (a+b)^2$ with $a = |z_1|^2$, $b = |z_2|^2$.

Physically, $\pi(z)$ is the *Bloch vector* $\langle\vec\sigma\rangle$ of the spin-$\frac12$ state z.

The fibres are circles

Multiplying the spinor by a phase does not change the Bloch vector: $\pi(e^{i\alpha}z) = (e^{i\alpha}z)^\dagger\vec\sigma(e^{i\alpha}z) = z^\dagger\vec\sigma z$. Conversely, if $\pi(z) = \pi(z')$ then $z' = e^{i\alpha}z$ (a spin state is fixed by its Bloch vector up to

phase). So

$$\pi^{-1}(\text{point}) = \{e^{i\alpha}z : \alpha \in [0, 2\pi)\} \cong U(1),$$

and $U(1)$ acts on S^3 from the right by $z \mapsto ze^{i\alpha}$, freely and preserving fibres. This is a principal $U(1)$ bundle

$$U(1) = S^1 \longrightarrow S^3 \xrightarrow{\pi} S^2, \tag{1.116}$$

the **Hopf fibration**. Equivalently $S^2 = \mathbb{CP}^1$, the space of complex lines in $\mathbb{C}^2$, and $\pi(z_1, z_2) = [z_1 : z_2]$.

Coordinates, trivialisations and the transition function

Parametrise S^3 by **Hopf coordinates**

$$z_1 = \cos\tfrac{\theta}{2}\, e^{i\xi_1}, \qquad z_2 = \sin\tfrac{\theta}{2}\, e^{i\xi_2}, \qquad 0 \le \theta \le \pi. \tag{1.117}$$

Then

$$\begin{aligned}\pi(z) &\overset{(1)}{=} \Big(2\cos\tfrac{\theta}{2}\sin\tfrac{\theta}{2}\cos(\xi_2-\xi_1),\ 2\cos\tfrac{\theta}{2}\sin\tfrac{\theta}{2}\sin(\xi_2-\xi_1),\ \cos^2\tfrac{\theta}{2}-\sin^2\tfrac{\theta}{2}\Big)\\ &\overset{(2)}{=} \big(\sin\theta\cos\phi,\ \sin\theta\sin\phi,\ \cos\theta\big), \qquad \phi = \xi_2 - \xi_1.\end{aligned}$$

(1) $\bar z_1 z_2 = \cos\frac{\theta}{2}\sin\frac{\theta}{2}\, e^{i(\xi_2-\xi_1)}$.
(2) Double-angle formulas.

So θ is the polar angle on the base, the azimuth is $\phi = \xi_2 - \xi_1$, and the overall phase $(\xi_1 + \xi_2)/2$ moves along the fibre.

Cover S^2 by $O_N = \{\theta < \pi\}$ (where $z_1 \neq 0$) and $O_S = \{\theta > 0\}$ (where $z_2 \neq 0$), and trivialise

$$\phi_N(z) = \Big(\pi(z),\ \frac{z_1}{|z_1|}\Big), \qquad \phi_S(z) = \Big(\pi(z),\ \frac{z_2}{|z_2|}\Big) \in S^2 \times U(1). \tag{1.118}$$

Each is a bijection from $\pi^{-1}(O_{N,S})$ to $O_{N,S} \times U(1)$, compatible with the $U(1)$ action. On the overlap the fibre coordinates are related by

$$\frac{z_2/|z_2|}{z_1/|z_1|} = e^{i(\xi_2-\xi_1)} = e^{i\phi} \qquad \Longrightarrow \qquad g_{SN}(\phi) = e^{i\phi}. \tag{1.119}$$

The transition function winds once around $U(1)$ as we go once around the equator. Comparing with (1.112): *the Hopf bundle is the monopole bundle with* $|n| = 1$. (Whether one calls it $n = +1$ or $n = -1$ depends on orientation conventions; the magnitude is what matters here.)

The natural connection is the monopole potential

The spinor z carries a natural $U(1)$ connection, the *Berry connection* $\mathcal{A} = z^\dagger \mathrm{d}z$. It is anti-Hermitian (purely imaginary), since $0 = \mathrm{d}(z^\dagger z) = z^\dagger \mathrm{d}z + (z^\dagger \mathrm{d}z)^*$. Pull it back to the base with the local sections

$$s_N(\theta,\phi) = \big(\cos\tfrac{\theta}{2},\ \sin\tfrac{\theta}{2}\, e^{i\phi}\big), \qquad s_S(\theta,\phi) = \big(\cos\tfrac{\theta}{2}\, e^{-i\phi},\ \sin\tfrac{\theta}{2}\big), \tag{1.120}$$

($\xi_1 = 0$ and $\xi_2 = 0$ respectively). s_N is smooth at $\theta = 0$ because $\sin\frac{\theta}{2}$ kills the ill-defined phase there, and s_S is smooth at $\theta = \pi$. Then

$$\begin{aligned}s_N^*\mathcal{A} &\overset{(1)}{=} \cos\tfrac{\theta}{2}\,\mathrm{d}\cos\tfrac{\theta}{2} + \sin\tfrac{\theta}{2}\, e^{-i\phi}\,\mathrm{d}\big(\sin\tfrac{\theta}{2}\, e^{i\phi}\big)\\ &\overset{(2)}{=} \tfrac{1}{2}\mathrm{d}\big(\cos^2\tfrac{\theta}{2} + \sin^2\tfrac{\theta}{2}\big) + i\sin^2\tfrac{\theta}{2}\,\mathrm{d}\phi\\ &\overset{(3)}{=} \frac{i}{2}(1-\cos\theta)\,\mathrm{d}\phi,\end{aligned}$$

(1) $\mathcal{A} = \bar{z}_1 \mathrm{d}z_1 + \bar{z}_2 \mathrm{d}z_2$ evaluated on s_N.
(2) Leibniz rule on the second term; the real parts combine into a total derivative.
(3) $\cos^2 + \sin^2 = 1$ has zero derivative, and $\sin^2 \frac{\theta}{2} = \frac{1}{2}(1 - \cos\theta)$.

and similarly $s_S^* \mathcal{A} = -\frac{i}{2}(1 + \cos\theta)\,\mathrm{d}\phi$. These are the monopole potentials (1.113) with $n = -1$. The curvature $\mathrm{d}\mathcal{A} = \frac{i}{2}\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$ integrates to $\int \frac{i}{2\pi} F = -1$. So in our conventions the Hopf bundle, with the Berry connection, has first Chern number -1. (Using $\bar{z}$ instead of z gives the conjugate bundle, with $+1$.)

Physical picture: Berry phase of a spin

Carry a spin-$\frac{1}{2}$ state adiabatically around a loop C of Bloch vectors, always choosing the state aligned with the instantaneous direction. The state returns with an extra phase $e^{-\oint_C s^* \mathcal{A}}$, which by Stokes is $e^{-\int_\Sigma F}$ over a cap Σ bounded by C: minus one half of the solid angle, $e^{-i\Omega/2}$ (the sign depends on the direction of travel and on the convention for $\mathcal{A}$). This is Berry's phase. The "monopole in parameter space" Berry found is the curvature of the Hopf bundle, and the fact that its total flux is an integer is the fact that the Hopf bundle is a genuine (non-trivial) $U(1)$ bundle.

Every two fibres link

Stereographic projection from $(0, 1) \in S^3$ sends $S^3 \setminus \{\mathrm{pt}\}$ to $\mathbb{R}^3$. The fibre over the south pole ($z_1 = 0$) passes through the projection point and becomes the vertical axis. The fibre over the north pole ($z_2 = 0$) becomes the unit circle in the horizontal plane. Every other fibre becomes a circle that winds once around the axis and once through the unit circle. *Any two fibres are linked exactly once* (Figure 1.51). The linking number is the **Hopf invariant**. It cannot change under deformation, which is the geometric reason the Hopf map is not homotopic to a constant: $\pi_3(S^2) \neq 0$.

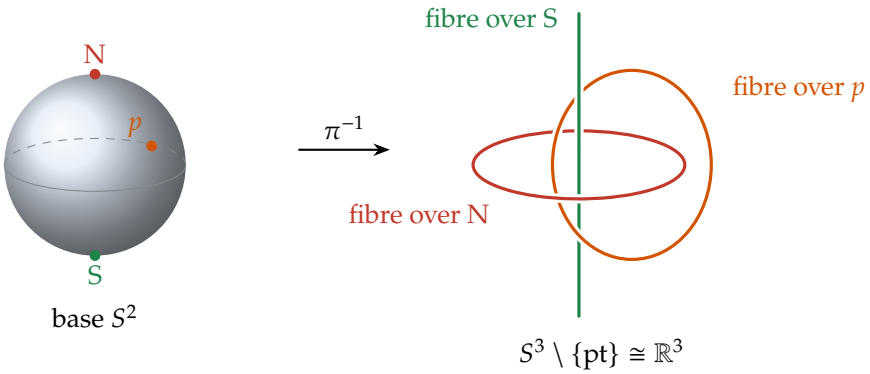

Figure 1.51: The Hopf fibration seen in $\mathbb{R}^3$ after stereographic projection of S^3. Each point of the base S^2 (left) has a circle as its fibre (right). The fibre over the south pole is the vertical axis (closed up through the point at infinity), the fibre over the north pole is the horizontal unit circle, and the fibre over a generic point p is a circle threading both. Any two fibres are linked once. The whole of S^3 is filled by such circles, nested on tori.

Watch out: Locally a product, globally not

Locally S^3 looks like $S^2 \times S^1$. Globally it is not: S^3 is simply connected, while $\pi_1(S^2 \times S^1) = \mathbb{Z}$. If the Hopf bundle were trivial, $\pi_1(S^3)$ would be $\mathbb{Z}$. So the Hopf bundle is non-trivial, and it has no global section. (A global section would be a global choice of phase for spin states:

impossible, as every physicist who has tried to write a spin coherent state without a Dirac string knows.)

Try it: The quaternionic Hopf fibration

Replace $\mathbb{C}$ by the quaternions $\mathbb{H}$. The unit sphere $S^7 \subset \mathbb{H}^2$ maps to $\mathbb{H}P^1 = S^4$ with fibre the unit quaternions $S^3 = \mathrm{SU}(2)$. The clutching function on the equator S^3 of S^4 is $q \mapsto q$ (or its inverse), which has degree one. What bundle over S^4 is this? *Answer:* the principal SU(2) bundle of instanton number ± 1, generating $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$ in the clutching table above. Its natural connection is the BPST instanton of Chapter 8.

1.5.8 The tangent bundle of S^2 and the hairy ball

We return to Nash's first example and show that TS^2 is not trivial. Use the complex stereographic coordinates of the sphere: z on $O_0 = S^2 \setminus \{N\}$ and w on $O_1 = S^2 \setminus \{S\}$, related by $w = 1/z$ on the overlap. The real 2-dimensional tangent plane at each point is a complex line, spanned by ∂_z (we identify $v = v^x \partial_x + v^y \partial_y$ with the complex number $v^z = v^x + i v^y$).

The transition function. A tangent vector $v = v^z \partial_z = v^w \partial_w$ has components related by the chain rule (1.100):

$$\begin{aligned} v^w &\overset{(1)}{=} \frac{\mathrm{d}w}{\mathrm{d}z}\, v^z \\ &\overset{(2)}{=} -\frac{1}{z^2}\, v^z. \end{aligned} \tag{1.121}$$

(1) The 1×1 complex Jacobian of the holomorphic change of coordinates.
(2) $w = 1/z$, so $\mathrm{d}w/\mathrm{d}z = -1/z^2$.

On the equator $z = e^{i\phi}$ this is $g_{10}(\phi) = -e^{-2i\phi}$: the transition function winds *twice* around $U(1)$ (the sign -1 is a constant and can be deformed away). By the clutching construction, TS^2 is the $U(1)$ bundle, or complex line bundle, of charge $|n| = 2$. It is not trivial, and $2 = \chi(S^2)$.

Key idea: The hairy ball theorem

Every continuous tangent vector field on S^2 vanishes somewhere. "You cannot comb a hairy ball flat."

Suppose v were a nowhere-vanishing vector field. On the closed disc $|z| \le 1$ (the southern hemisphere in the z chart) its component v^z is a nowhere-zero complex function. The winding number of $v^z(e^{i\phi})$ around 0, as ϕ goes from 0 to 2π, is therefore zero: the loop $\phi \mapsto v^z(re^{i\phi})$ can be shrunk to the constant $v^z(0)$ by letting $r \to 0$, without passing through zero. By the same argument on the disc $|w| \le 1$, the winding of v^w around the equator is zero. (On the equator $w = e^{-i\phi}$, so ϕ runs the opposite way around the w disc; this reverses the sign of a winding number but does not change zero.) But (1.121) gives

$$\begin{aligned} \mathrm{wind}_\phi\big(v^w\big) &\overset{(1)}{=} \mathrm{wind}_\phi\big(-e^{-2i\phi}\big) + \mathrm{wind}_\phi\big(v^z\big) \\ &\overset{(2)}{=} -2 + 0 = -2 \neq 0, \end{aligned}$$

(1) Winding numbers add under multiplication of non-vanishing functions (Example 1.59: $\deg(fg) = \deg f + \deg g$).
(2) The factor $-e^{-2i\phi}$ winds -2 times; v^z winds 0 times.

a contradiction. So v must vanish somewhere. The same argument shows TS^2 has no nowhere-zero section, hence is not trivial.

Worked example 1.92: Two combings of the sphere and their zeros

Rotation field $v = \partial_\phi$ (the velocity field of a rigid rotation about the z axis). It vanishes at the two poles. Near each pole it circulates, like $-y\partial_x + x\partial_y$, which has index +1 (the vector turns once as we go once around the zero). Total index $1 + 1 = 2$.
Dipole field v = the projection onto TS^2 of the constant vector $\hat{e}_3$ *rotated* so that it flows out of the north pole, around, and back in. The standard example is the pushforward of ∂_x on the plane under inverse stereographic projection from the north pole: on the z chart it is $v^z = 1$ (no zeros there), and in the w chart (1.121) gives $v^w = -1/z^2 = -w^2$, a double zero at $w = 0$, of index 2. Total index 2 again.
In both cases the indices add to $\chi(S^2) = 2$. This is the Poincaré–Hopf theorem: for any vector field with isolated zeros on a closed manifold, the sum of the indices is χ. For the torus $\chi = 0$, and indeed ∂_{θ_1} combs the torus with no zeros.

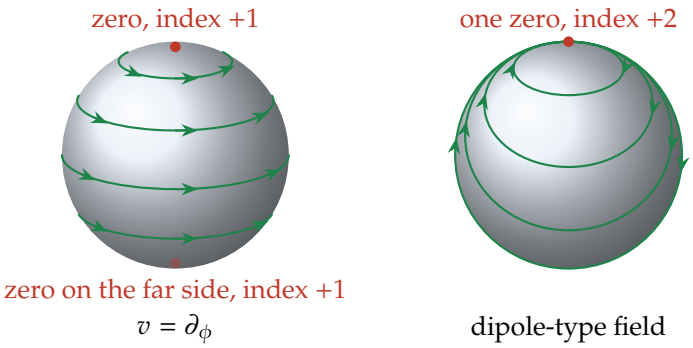

Figure 1.52: Two attempts to comb the sphere. Left: circulation around the axis leaves a zero at each pole, each of index +1. Right: flowing from a single point around the sphere and back into it gives one zero of index +2. However the vector field is chosen, the indices of its zeros sum to $\chi(S^2) = 2$, the winding of the transition function of TS^2.

Physical picture: Where hairy balls appear in physics

- There is always a point on Earth with no horizontal wind.
- The transverse polarisation vectors $\vec{\epsilon}(\hat{k})$ of a photon, as $\hat{k}$ ranges over the sphere of directions, are tangent vectors to S^2. They cannot be chosen continuously for all directions. The helicity basis $\vec{\epsilon}_\pm$ lives in two line bundles with Chern numbers ± 2, the photon's "monopole charge" in momentum space.
- Only S^1, S^3 and S^7 among spheres have trivial tangent bundles (Adams). S^1 and S^3 are the Lie groups $U(1)$ and SU(2), and a Lie group always has a global frame of left-invariant vector fields.

1.5.9 Pulling back cohomology

So far we have built bundles by hand. Nash now turns to the question every physicist asks of a new object: *how do we tell two of them apart?* The tool is a very simple operation, the pullback, applied first to cohomology and then to bundles.

Let $f : N \to M$ be a smooth map. A differential form on M can be *pulled back* to N: evaluate

it on the pushed-forward vectors. In coordinates y^a on N and x^μ on M, with $x^\mu = f^\mu(y)$, we substitute and use the chain rule,

$$f^*\big(\omega_\mu(x)\,\mathrm{d}x^\mu\big) = \omega_\mu(f(y))\,\frac{\partial f^\mu}{\partial y^a}\,\mathrm{d}y^a. \tag{1.122}$$

(This is the "change of variables" of Chapter T1.) Two facts make f^* pass to cohomology.

- f^* commutes with d: $\mathrm{d}(f^*\omega) = f^*(\mathrm{d}\omega)$. So closed forms go to closed forms and exact forms to exact forms, $f^*(\mathrm{d}\alpha) = \mathrm{d}(f^*\alpha)$.
- f^* respects the wedge product: $f^*(\omega \wedge \nu) = f^*\omega \wedge f^*\nu$.

Hence we get a well-defined map

$$f^* : H^p(M;G) \longrightarrow H^p(N;G), \qquad f^*(a \cup b) = f^*a \cup f^*b, \tag{1.123}$$

a **ring homomorphism** of cohomology rings. Notice the direction: f goes from N to M, but f^* goes from M to N. Cohomology is *contravariant*. (With the definition $H^n(X;G) = [X, K(G,n)]_0$ of Section 1.4.2 this is even simpler: a class on M is a map $c : M \to K(G,n)$, and f^*c is the composite $c \circ f : N \to K(G,n)$.)

Worked example 1.93: Pulling back the angle form along $z \mapsto z^k$

Let $f_k : S^1 \to S^1$, $e^{i\theta} \mapsto e^{ik\theta}$, so in the angle coordinate $\theta \mapsto k\theta$. The generator of $H^1(S^1;\mathbb{Z})$ is represented by the form $x = \mathrm{d}\theta/2\pi$, whose integral is 1. Then

$$\int_{S^1} f_k^* x \overset{(1)}{=} \int_0^{2\pi} \frac{1}{2\pi}\,\frac{\mathrm{d}(k\theta)}{\mathrm{d}\theta}\,\mathrm{d}\theta \overset{(2)}{=} k.$$

(1) Apply (1.122): the coefficient of $\mathrm{d}\theta$ picks up the derivative of $\theta \mapsto k\theta$.
(2) The integrand is the constant $k/2\pi$.

So $f_k^* x = k\,x$: on $H^1(S^1;\mathbb{Z}) = \mathbb{Z}$ the pullback is multiplication by the winding number k. In the same way a map $f : S^2 \to S^2$ of degree k multiplies the class of the area form by k. Pullback turns "how many times does the map wrap" into linear algebra.

Key idea: Homotopic maps pull back equally

If $f_0 \simeq f_1 : N \to M$, then $f_0^* = f_1^*$ on cohomology. So f^* depends only on the homotopy class $[f]$, and cohomology is an invariant of homotopy type (as Nash said in §4).

Here is the de Rham reason. Let $F : N \times [0,1] \to M$ be the homotopy, with $F(y,0) = f_0(y)$ and $F(y,1) = f_1(y)$, and let ω be a closed form on M. Split the pulled-back form on the cylinder $N \times [0,1]$ into the part without $\mathrm{d}t$ and the part with it, $F^*\omega = \alpha(t) + \mathrm{d}t \wedge \beta(t)$, where $\alpha(t), \beta(t)$ are forms on N depending on t. Write d_N for the exterior derivative in the N directions. Then

$$\begin{aligned} 0 &\overset{(1)}{=} F^*(\mathrm{d}\omega) = \mathrm{d}(F^*\omega) \\ &\overset{(2)}{=} \mathrm{d}_N\alpha + \mathrm{d}t \wedge \partial_t\alpha - \mathrm{d}t \wedge \mathrm{d}_N\beta = \mathrm{d}_N\alpha + \mathrm{d}t \wedge \big(\partial_t\alpha - \mathrm{d}_N\beta\big). \end{aligned}$$

(1) ω is closed, and d commutes with pullback.
(2) The full d on $N \times [0,1]$ is $\mathrm{d}_N + \mathrm{d}t \wedge \partial_t$; moving d_N past $\mathrm{d}t$ costs a sign.

The part with $\mathrm{d}t$ must vanish on its own, so $\partial_t \alpha = \mathrm{d}_N \beta$. Now

$$\begin{aligned} f_1^*\omega - f_0^*\omega &\overset{(1)}{=} \alpha(1) - \alpha(0) \\ &\overset{(2)}{=} \int_0^1 \partial_t \alpha \, \mathrm{d}t \\ &\overset{(3)}{=} \mathrm{d}_N \Big(\int_0^1 \beta(t) \, \mathrm{d}t \Big). \end{aligned} \tag{1.124}$$

(1) At $t = 0$ and $t = 1$ the $\mathrm{d}t$ part of $F^*\omega$ does not contribute to the restriction to $N \times \{t\}$, which is $f_t^*\omega$.
(2) Fundamental theorem of calculus in t.
(3) $\partial_t \alpha = \mathrm{d}_N \beta$, and d_N commutes with the t integral.

The difference is exact, so $[f_1^*\omega] = [f_0^*\omega]$. This single identity is behind Nash's remark that "two homotopic maps produce identical pullbacks".

1.5.10 Pullback bundles

Bundles can be pulled back too, and this is the operation that will classify them.

Working definition 1.38 (pullback bundle)

Given a bundle $\pi : E \to M$ and a map $f : N \to M$, the **pullback bundle** $f^*E \to N$ has as its fibre over $y \in N$ the fibre of E over $f(y)$:

$$f^*E = \{(y, e) \in N \times E : \ f(y) = \pi(e)\}, \qquad (f^*E)_y = E_{f(y)}. \tag{1.125}$$

Operationally: if E has transition functions $g_{\alpha\beta}$ on the cover $\{O_\alpha\}$ of M, then f^*E has transition functions $g_{\alpha\beta} \circ f$ [at $y \in N$, use the gluing $g_{\alpha\beta}(f(y))$ of E at the point $f(y)$] on the cover $\{f^{-1}(O_\alpha)\}$ [the points of N that f sends into O_α] of N.

The cocycle conditions (1.104) for $g_{\alpha\beta} \circ f$ are those of $g_{\alpha\beta}$, evaluated at $f(y)$, so they hold automatically. The pullback of a section s of E is the section $y \mapsto s(f(y))$ of f^*E.

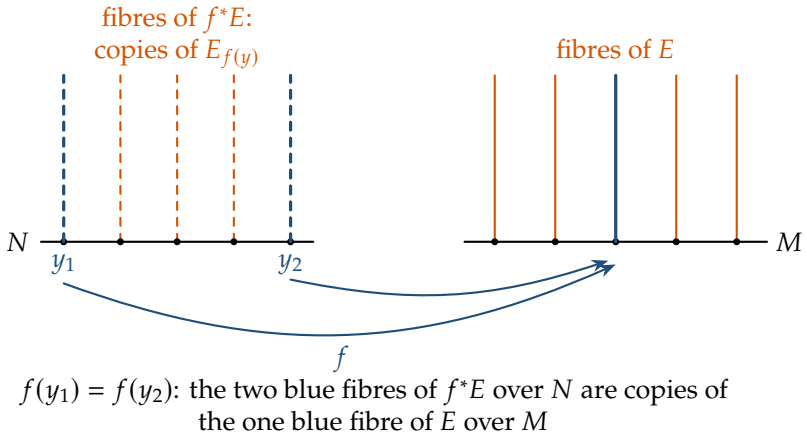

Figure 1.53: The pullback bundle. Each point y of N is assigned a copy of the fibre of E at its image $f(y)$. If f is not injective, several fibres of f^*E are copies of one fibre of E. If f is constant, every fibre of f^*E is the same fibre, and f^*E is the trivial bundle $N \times F$.

Worked example 1.94: Three pullbacks you can do in your head

1. *Restriction.* If $i : S \hookrightarrow M$ is a submanifold, $i^*E = E|_S$. For example TS^2 restricted to the equator S^1 is $TS^1 \oplus$ (normal line), a trivial rank-2 bundle.

2. *Constant maps.* If $f(y) = x_0$ for all y, then $g_{\alpha\beta} \circ f$ is constant on each connected overlap, and it can be gauged away by constant h_α in (1.106). So $f^*E \cong N \times F$ is trivial.

3. *The Möbius band along f_k.* Pull back the Möbius band Mb along $f_k : S^1 \to S^1$ of Example 1.93. Going once around the source circle, f_k goes k times around the target, and the fibre coordinate comes back multiplied by the product of the transition functions met on the way:

$$\begin{aligned} s(2\pi) &\overset{(1)}{=} \big((-1)\cdot\ldots\cdot(-1)\big)\, s(0) \quad (k \text{ factors}) \\ &\overset{(2)}{=} (-1)^k\, s(0). \end{aligned}$$

   (1) Each passage through the twisted overlap B of Example 1.87 contributes -1.
   (2) There are k such passages.

   So f_k^*Mb is the Möbius band for k odd and the cylinder for k even. (The double cover of a Möbius band's core circle untwists it: cut a paper Möbius band down the middle and see.)

Worked example 1.95: Pulling back the monopole bundle

Let $P_n \to S^2$ be the monopole bundle of Example 1.91, with clutching function $g_{NS}(\phi) = e^{in\phi}$. Let $f : S^2 \to S^2$ be the map that, in polar angles, sends $(\theta, \phi) \mapsto (\theta, k\phi)$. It has degree k and preserves the two caps. Then f^*P_n has clutching function

$$\begin{aligned} (g_{NS} \circ f)(\phi) &\overset{(1)}{=} g_{NS}(k\phi) \\ &\overset{(2)}{=} e^{ink\phi}, \end{aligned}$$

(1) Rule for pullback transition functions, restricted to the equator.
(2) Insert (1.112).

so $f^*P_n = P_{nk}$. The charge multiplies by the degree. In terms of characteristic classes, $c_1(f^*P) = f^*c_1(P)$, and f^* on $H^2(S^2;\mathbb{Z}) = \mathbb{Z}$ is multiplication by k (Example 1.93). The bundle and its cohomology class pull back together. This compatibility is the whole point of (1.129) below.

Key idea: Nash's (1.48): homotopic maps give isomorphic pullbacks

If $f_0 \simeq f_1 : N \to M$, then $f_0^*E \cong f_1^*E$.

There is a transparent physicist's argument. Let $F : N \times [0,1] \to M$ be the homotopy, and consider the single bundle F^*E over the cylinder $N \times [0,1]$. Its restrictions to the two ends are f_0^*E and f_1^*E. Choose any connection on F^*E (a partition of unity always provides one) and *parallel transport* along the segments $\{y\} \times [0,1]$. Parallel transport is a linear (or G-equivariant) isomorphism from the fibre at $(y,0)$ to the fibre at $(y,1)$, it depends smoothly on y, and it has an inverse (transport back). So it is a bundle isomorphism $f_0^*E \to f_1^*E$ (Figure 1.54).

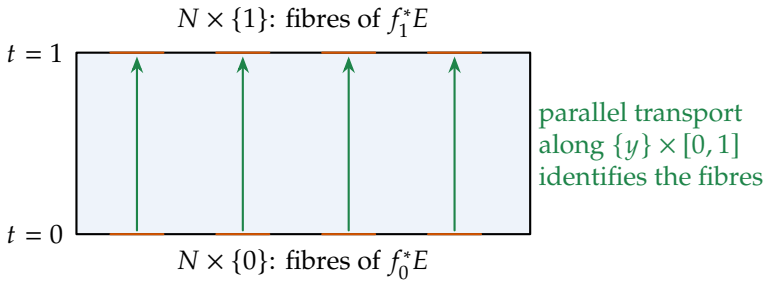

Figure 1.54: Why homotopic maps pull back isomorphic bundles. The homotopy F gives one bundle over the cylinder $N \times [0,1]$. Parallel transport along the vertical segments (green) carries each fibre at the bottom isomorphically to the fibre above it at the top, smoothly in y. That is an isomorphism $f_0^*E \cong f_1^*E$.

Two consequences are used constantly.

- *Every bundle over a contractible space is trivial.* If M is contractible, $\mathrm{id}_M \simeq c$, a constant map. Then $E = \mathrm{id}_M^* E \cong c^*E$, which is trivial by Example 1.94. This is what allowed us to trivialise the bundle over each cap in the clutching construction (Section 1.5.6), and it is why local potentials A_α always exist on contractible patches.

- *Topological sectors are discrete.* A continuous deformation of a gauge field configuration cannot change the bundle it lives on. The bundle can only jump, and the possible jumps are counted by homotopy classes of maps, as we now see.

1.5.11 Universal bundles and classifying spaces

Nash's next point is striking: for each group G there is *one* bundle from which all others are pulled back.

Working definition 1.39 (universal bundle, classifying space)

A principal G-bundle [a bundle whose fibres are copies of G, with G acting on them by right multiplication] $E_G \to BG$ is **universal** if its total space E_G is contractible [it can be shrunk continuously to one of its points] (and G acts freely on it [only the identity of G fixes any point]). The base $BG = E_G/G$ is the **classifying space** of G. *Operationally*: find a contractible space with a free G action; its quotient is BG.

Key idea: Nash's (1.49): bundles are maps into BG

Every principal G-bundle over M is isomorphic to f^*E_G for some map $f : M \to BG$, the **classifying map**, and $f^*E_G \cong f'^*E_G$ exactly when $f \simeq f'$. So

$$\{\text{principal } G\text{-bundles over } M\}/\text{iso} \;\cong\; [M, BG]. \tag{1.126}$$

Why contractibility of E_G? A classifying map for $P \to M$ is the same thing as a G-equivariant map $P \to E_G$ (it then descends to $M = P/G \to E_G/G = BG$). Such maps are sections of the bundle $P \times_G E_G$ over M with fibre E_G. When the fibre is contractible, the obstruction theory of Section 1.6.4 says a section always exists and any two sections are homotopic: all the obstruction groups $H^{k+1}(M; \pi_k(E_G))$ vanish. Existence gives the map f; uniqueness up to homotopy gives (1.126).

How to build a classifying map: the Grassmannian

For vector bundles the construction is completely concrete. Let $E \to M$ be a complex vector bundle of rank k over a compact M, with local trivialisations $\phi_\alpha(e) = (\pi(e), f_\alpha(e))$, $f_\alpha(e) \in \mathbb{C}^k$, on finitely many patches $\alpha = 1, \dots, m$, and a partition of unity ρ_α (smooth functions with $\operatorname{supp}\rho_\alpha \subset O_\alpha$ and $\sum_\alpha \rho_\alpha = 1$). Define

$$\Phi : E \to \mathbb{C}^{km}, \qquad \Phi(e) = \big(\rho_1(\pi e) f_1(e),\ \dots,\ \rho_m(\pi e) f_m(e)\big). \tag{1.127}$$

On each fibre Φ is linear, and it is injective because at least one ρ_α is positive there. So each fibre E_x becomes a k-dimensional subspace $\Phi(E_x) \subset \mathbb{C}^{km}$, and

$$f : M \to \mathrm{Gr}_k(\mathbb{C}^{km}), \qquad x \mapsto \Phi(E_x),$$

is a map into the **Grassmannian** of k-planes. By construction $E = f^*\gamma$, where γ is the **tautological bundle** whose fibre over a plane is the plane itself. Letting $m \to \infty$, the universal case is $BU(k) = \mathrm{Gr}_k(\mathbb{C}^\infty)$.

Worked example 1.96: The tautological line bundle over $\mathbb{CP}^1$ is the Hopf bundle

Over $[z_1 : z_2] \in \mathbb{CP}^1 = S^2$ the tautological line is $\ell = \mathbb{C}\cdot(z_1, z_2) \subset \mathbb{C}^2$. On $U_1 = \{z_1 \neq 0\}$ use the inhomogeneous coordinate $w = z_2/z_1$ and the frame $e_1 = (1, w)$; on $U_2 = \{z_2 \neq 0\}$ use $e_2 = (1/w, 1)$. On the overlap

$$\begin{aligned} e_1 &\overset{(1)}{=} (1, w) = w\,(1/w,\ 1) \\ &\overset{(2)}{=} w\, e_2, \end{aligned}$$

(1) Factor w out of both components.
(2) Definition of e_2.

so the transition function is $w = z_2/z_1$. On the equator $|z_1| = |z_2|$ it is the phase $e^{i(\xi_2 - \xi_1)} = e^{i\phi}$ of (1.119): it winds once. The unit vectors in the tautological lines form $\{(\ell, v) : v \in \ell,\ |v| = 1\} = S^3$, and the projection $v \mapsto \ell$ is exactly the Hopf map. So:

- the Hopf fibration is the unit circle bundle of the tautological line bundle over $\mathbb{CP}^1$;
- the Berry connection of Section 1.5.7 is the connection the tautological bundle inherits from the flat $\mathbb{C}^2$ (project the derivative of a section back onto the line), and its Chern number -1 is the Chern number of the tautological bundle, often written $\mathcal{O}(-1)$;
- its classifying map is the inclusion $\mathbb{CP}^1 \hookrightarrow \mathbb{CP}^\infty = BU(1)$, covered by $S^3 \hookrightarrow S^\infty = EU(1)$.

A table of classifying spaces

G	E_G (contractible)	BG	bundles classified
$\mathbb{Z}$	$\mathbb{R}$	S^1	$\mathbb{Z}$-covers; $[M, S^1] = H^1(M;\mathbb{Z})$
$\mathbb{Z}_2$	$S^\infty \subset \mathbb{R}^\infty$	$\mathbb{RP}^\infty = K(\mathbb{Z}_2, 1)$	double covers, real line bundles; $H^1(M;\mathbb{Z}_2)$
$U(1)$	$S^\infty \subset \mathbb{C}^\infty$	$\mathbb{CP}^\infty = K(\mathbb{Z}, 2)$	complex line bundles; $H^2(M;\mathbb{Z})$
SU(2)	$S^\infty \subset \mathbb{H}^\infty$	$\mathbb{H}P^\infty$	SU(2) gauge sectors; c_2 on 4-manifolds
$U(k)$	k-frames in $\mathbb{C}^\infty$	$\mathrm{Gr}_k(\mathbb{C}^\infty)$	rank-k complex vector bundles
O(k)	k-frames in $\mathbb{R}^\infty$	$\mathrm{Gr}_k(\mathbb{R}^\infty)$	rank-k real vector bundles

Here $S^\infty = \bigcup_N S^N$ is contractible: any sphere mapped into it lies in some S^N of higher dimension, where it can be shrunk (see Example 1.101). The $U(1)$ row is Nash's link between §4 and §5: $\mathbb{CP}^\infty$ is at the same time $K(\mathbb{Z},2)$ and $BU(1)$, so

$$\{\text{complex line bundles over } M\}/\text{iso} = [M, \mathbb{CP}^\infty] = [M, K(\mathbb{Z},2)] = H^2(M;\mathbb{Z}), \tag{1.128}$$

and the isomorphism is $L \mapsto c_1(L)$. Every magnetic charge is realised by a bundle, and the charge determines the bundle.

Physical picture: Topological sectors of a gauge theory

In a gauge theory with group G on a compact Euclidean spacetime M, the field configurations split into sectors labelled by $[M, BG]$. For $U(1)$ on a closed surface Σ the sectors are $H^2(\Sigma;\mathbb{Z}) = \mathbb{Z}$, the total flux. For SU(2) on a closed simply connected 4-manifold they are labelled by the instanton number $c_2 \in \mathbb{Z}$. The path integral is a sum over sectors, each an integral over connections on one fixed bundle.

1.5.12 Characteristic classes

We now have a way to detect non-triviality. If $E = f^*E_G$, pull back the cohomology of BG along the same map:

$$f^* : H^*(BG) \longrightarrow H^*(M), \qquad c_i \longmapsto c_i(E) := f^* c_i. \tag{1.129}$$

The generators c_i of the ring $H^*(BG)$ are the **universal characteristic classes**; their pullbacks are the **characteristic classes** of E. Because f is determined up to homotopy, and homotopic maps pull back equally, $c_i(E)$ depends only on the isomorphism class of E.

Working definition 1.40 (characteristic class)

A characteristic class assigns to each bundle $E \to M$ a class $c(E) \in H^*(M)$ [a cohomology class, e.g. a closed form up to exact ones] that is *natural*: $c(f^*E) = f^*c(E)$ [computing c for the pulled-back bundle gives the pullback of $c(E)$ along f]. *Operational test for non-triviality:* a trivial bundle [one isomorphic to $M \times F$] is pulled back from a point, so all its characteristic classes of positive degree vanish. One non-zero characteristic class proves the bundle is twisted.

Which groups, which classes

For vector bundles over a manifold we can always simplify the structure group. A real vector bundle has structure group $\mathrm{GL}(n,\mathbb{R})$, but a fibre metric (which exists by a partition of unity) lets us use orthonormal frames, with transition functions in $\mathrm{O}(n)$. Nothing topological is lost, because $\mathrm{GL}(n,\mathbb{R})$ deformation retracts onto $\mathrm{O}(n)$. Write $A \in \mathrm{GL}(n,\mathbb{R})$ in polar form $A = OP$ with $O \in \mathrm{O}(n)$ and $P = (A^TA)^{1/2}$ symmetric positive definite, and set $A_t = OP^t$. Then

$$\det A_t \overset{(1)}{=} \det O\,(\det P)^t \overset{(2)}{=} \pm(\det P)^t \neq 0,$$

(1) det is multiplicative, and P^t has eigenvalues λ_i^t where $\lambda_i > 0$ are those of P.
(2) $\det O = \pm 1$ and $\det P > 0$.

so A_t is a path in $\mathrm{GL}(n,\mathbb{R})$ from $A_1 = A$ to $A_0 = O \in \mathrm{O}(n)$, fixing $\mathrm{O}(n)$ throughout. Likewise $\mathrm{GL}(n,\mathbb{C})$ retracts onto $U(n)$. This is Nash's remark that the structure group is "naturally" $\mathrm{O}(n)$ or $U(n)$.

group	$H^*(BG)$	classes	degree	Chern–Weil formula
$U(n)$	$\mathbb{Z}[c_1,\dots,c_n]$	Chern c_i	$2i$	$\det(1+\frac{i}{2\pi}F)=1+c_1+c_2+\cdots$
$\mathrm{O}(n)$	$\mathbb{Z}_2[w_1,\dots,w_n]$ (mod 2)	Stiefel–Whitney w_i	i	none (mod 2)
$\mathrm{O}(n)$	from $H^*(BO(n);\mathbb{Z})$	Pontryagin p_i	$4i$	$\det(1-\frac{F}{2\pi})=1+p_1+\cdots$
$\mathrm{SO}(n)$, n even	extra generator	Euler e	n	$\mathrm{Pf}(F/2\pi)$, $e^2=p_{n/2}$

The Pontryagin classes are defined by complexifying, $p_i(E)=(-1)^i c_{2i}(E\otimes\mathbb{C})$. The Chern–Weil formulas express each class by the curvature F of any connection. That these forms are closed and that their classes do not depend on the connection is the subject of Chapter T2 and Chapter 4.

Expanding the determinant with $X=\frac{i}{2\pi}F$ gives the first two Chern classes, which are the ones a physicist meets most:

$$\begin{aligned}\det(1+X) &\overset{(1)}{=} 1+\operatorname{tr}X+\tfrac{1}{2}\big[(\operatorname{tr}X)^2-\operatorname{tr}(X^2)\big]+\cdots\\ &\overset{(2)}{=} 1+\frac{i}{2\pi}\operatorname{tr}F+\frac{1}{8\pi^2}\big[\operatorname{tr}(F\wedge F)-\operatorname{tr}F\wedge\operatorname{tr}F\big]+\cdots .\end{aligned}\tag{1.130}$$

(1) For a diagonalisable X with eigenvalues x_i, $\det(1+X)=\prod(1+x_i)=1+\sum x_i+\sum_{i<j}x_ix_j+\cdots$, and $\sum_{i<j}x_ix_j=\frac{1}{2}[(\sum x_i)^2-\sum x_i^2]$.

(2) Insert $X=\frac{i}{2\pi}F$; $(\frac{i}{2\pi})^2=-\frac{1}{4\pi^2}$, and the $\frac{1}{2}$ makes $\frac{1}{8\pi^2}$.

So $c_1=\frac{i}{2\pi}\operatorname{tr}F$ and, for $\mathrm{SU}(n)$ where $\operatorname{tr}F=0$, $c_2=\frac{1}{8\pi^2}\operatorname{tr}(F\wedge F)$. These are the monopole charge and the instanton number.

Worked example 1.97: Characteristic classes of the bundles we have met

1. *Monopole.* $c_1(P_n)[S^2]=n$, computed in (1.114).
2. *Möbius band.* $w_1(\mathrm{Mb})\in H^1(S^1;\mathbb{Z}_2)=\mathbb{Z}_2$ is the product of the signs of the transition functions around the circle, the invariant -1 found in Example 1.87. It is the non-zero element. For a manifold, $w_1(TM)=0$ exactly when M is orientable (Example 1.89).
3. *Tangent bundle of S^2.* As a complex line bundle, its transition function winds twice (1.121), so $c_1(TS^2)[S^2]=2$. As an oriented real rank-2 bundle, its Euler class is the same number, $e(TS^2)[S^2]=2=\chi(S^2)$. The Gauss–Bonnet theorem is the Chern–Weil form of this: $\frac{1}{2\pi}\int_{S^2}K\,\mathrm{d}A=2$.
4. *Tautological bundle.* $c_1(\mathcal{O}(-1))[\mathbb{CP}^1]=-1$, the Berry-phase computation of Section 1.5.7.

Worked example 1.98: The universal class for line bundles

The cohomology ring of $\mathbb{CP}^\infty$ is a polynomial ring, $H^*(\mathbb{CP}^\infty;\mathbb{Z})=\mathbb{Z}[c]$ with c in degree 2. Here is why. $\mathbb{CP}^N$ is built from one cell in each even dimension $0,2,\dots,2N$: $\mathbb{CP}^N=\mathbb{CP}^{N-1}\cup(\text{a }2N\text{-cell }\{[z_0:\cdots:z_{N-1}:1]\}\cong\mathbb{C}^N)$. With cells only in even dimensions, every cellular boundary map goes from an even degree to an odd one, where there are no cells, so all boundary maps vanish and

$$H^{2j}(\mathbb{CP}^N;\mathbb{Z})=\mathbb{Z}\quad(0\le j\le N),\qquad H^{\mathrm{odd}}=0.$$

The ring structure: the class $c\in H^2$ is Poincaré dual to a hyperplane $\mathbb{CP}^{N-1}$, and c^j is dual to the intersection of j generic hyperplanes, a $\mathbb{CP}^{N-j}$. For $j=N$ that is a single point, so c^N

generates H^{2N} and $H^*(\mathbb{CP}^N) = \mathbb{Z}[c]/(c^{N+1})$. Letting $N \to \infty$ removes the relation. For $\mathbb{CP}^2$ the pairing on H^2 is $\int c \cup c = 1$: two lines in the projective plane meet in exactly one point. This 1×1 matrix (1) is the intersection form of $\mathbb{CP}^2$ that we meet again in Section 1.6.8. The first Chern class of a line bundle L with classifying map f is $c_1(L) = f^*c$.

Watch out: Characteristic classes detect, but need not classify

A non-zero class proves non-triviality. The converse can fail: there are non-trivial bundles with all characteristic classes zero (for example non-trivial SU(2) bundles over S^5, classified by $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$, which no cohomology class of S^5 in degree 2 or 4 can see). For $U(1)$ bundles, however, c_1 is a complete invariant, by (1.128).

1.5.13 The exact homotopy sequence of a bundle

We now turn from cohomology to homotopy. A bundle is written

$$F \xrightarrow{i} E \xrightarrow{\pi} M, \tag{1.131}$$

where i is the inclusion of the fibre $F = \pi^{-1}(*)$ over the base point. Its homotopy groups are tied together by Nash's "valuable" long exact sequence

$$\cdots \to \pi_n(F) \xrightarrow{i_*} \pi_n(E) \xrightarrow{\pi_*} \pi_n(M) \xrightarrow{\partial} \pi_{n-1}(F) \xrightarrow{i_*} \pi_{n-1}(E) \to \cdots \to \pi_0(E) \to \pi_0(M) \to 0. \tag{1.132}$$

Recall from Section 1.4.4 that *exact* means: at every spot the image of the incoming map equals the kernel of the outgoing one. The maps i_* and π_* are just composition with i and π. The interesting map is ∂.

The boundary map: lift a disc and look at its edge

An element of $\pi_n(M)$ can be represented by a map $\sigma : D^n \to M$ from the n-disc which sends the whole boundary sphere $\partial D^n = S^{n-1}$ to the base point $*$ (collapsing the boundary of a disc gives a sphere). The disc is contractible, so σ *lifts*: there is $\tilde{\sigma} : D^n \to E$ with $\pi \circ \tilde{\sigma} = \sigma$. (Over a contractible domain the pulled-back bundle σ^*E is trivial, by Section 1.5.10, and a trivial bundle has sections.) On the boundary, $\pi(\tilde{\sigma}(x)) = *$, so $\tilde{\sigma}$ maps S^{n-1} into the fibre F. Define

$$\partial[\sigma] = \left[\tilde{\sigma}|_{S^{n-1}} : S^{n-1} \to F\right] \in \pi_{n-1}(F). \tag{1.133}$$

With the three maps defined, exactness can be checked by the same lifting idea at each spot.

- *At* $\pi_n(E)$. A sphere in F projects to the point $*$, so $\pi_* i_* = 0$. Conversely, if a sphere τ in E projects to a contractible sphere in M, lift the contraction (homotopy lifting, Section 1.5.15); it deforms τ into a sphere lying over $*$, that is, in F.
- *At* $\pi_n(M)$. If $\sigma = \pi \circ \tau$ comes from E, we may lift with $\tilde{\sigma} = \tau$, whose edge is a point: $\partial \pi_* = 0$. Conversely, if the edge of the lift can be contracted in F, we can use the contraction to close up the lifted disc into a sphere in E projecting to σ.
- *At* $\pi_{n-1}(F)$. An edge $\partial[\sigma]$ bounds the disc $\tilde{\sigma}$ in E, so it is contractible in E: $i_* \partial = 0$. Conversely, a sphere in F that bounds a disc in E is the edge of that disc, whose projection is a sphere in M.

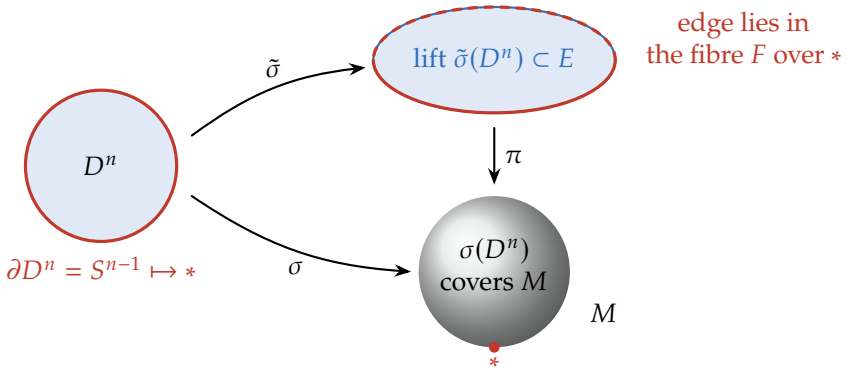

Figure 1.55: The boundary map $\partial : \pi_n(M) \to \pi_{n-1}(F)$. A sphere in the base is a disc whose edge is sent to the base point. Lift the disc into the total space. The lifted disc's edge must lie over $*$, that is, in the fibre F (red). That edge is an $(n-1)$-sphere in F, and its class is $\partial[\sigma]$. If the bundle were trivial we could lift with a constant fibre coordinate and the edge would be a point.

Key idea: The boundary map of a bundle over a sphere is its clutching function

For a principal G-bundle over S^n with clutching function $g : S^{n-1} \to G$ (1.110), the boundary map sends the generator of $\pi_n(S^n) = \mathbb{Z}$ to the class of the clutching function:

$$\partial\,[\mathrm{id}_{S^n}] = [g] \in \pi_{n-1}(G). \tag{1.134}$$

To see it, put the base point at the south pole and view S^n as a disc D^n whose boundary is squashed to the south pole: the meridians from the north pole are the radii of the disc, and all their end points go to S. Lift as follows. Over the northern cap use the constant section $f_N = 1$ of the northern trivialisation. At a point x of the equator this reads, in the southern trivialisation, $f_S = g_{SN}(x)$. Continue down each meridian to the south pole keeping f_S constant, equal to $g_{SN}(x)$. The lift is continuous, and at the south pole the meridian through x arrives at the point $g_{SN}(x)$ of the fibre G. So the edge of the lifted disc is the map $x \mapsto g_{SN}(x)$ from S^{n-1} to the fibre: that is the clutching function (up to the inverse, which only changes an overall sign in $\pi_{n-1}(G)$). A trivial bundle has null-homotopic clutching function and $\partial = 0$; the more the bundle twists, the more the edge winds.

Computations

Worked example 1.99: The trivial bundle, and the covering $\mathbb{Z} \to \mathbb{R} \to S^1$

Trivial bundle. For $E = M \times F$ the section $x \mapsto (x, f_0)$ lifts every sphere in M with a point as edge, so $\partial = 0$. The sequence breaks into short exact pieces $0 \to \pi_n(F) \to \pi_n(M \times F) \to \pi_n(M) \to 0$, and in fact $\pi_n(M \times F) = \pi_n(M) \oplus \pi_n(F)$ (a sphere in a product is a pair of spheres). This is Nash's remark; for a non-trivial bundle the sequence does not split like this, and it carries information.

The covering $\exp : \mathbb{R} \to S^1$, $t \mapsto e^{2\pi i t}$, with fibre $\mathbb{Z}$. The total space $\mathbb{R}$ is contractible, so $\pi_n(\mathbb{R}) = 0$ and the sequence reads

$$\underbrace{\pi_n(\mathbb{R})}_{0} \to \pi_n(S^1) \xrightarrow{\partial} \pi_{n-1}(\mathbb{Z}) \to \underbrace{\pi_{n-1}(\mathbb{R})}_{0}.$$

Hence $\pi_n(S^1) \cong \pi_{n-1}(\mathbb{Z})$. A discrete space has $\pi_0 =$ its set of points and no higher homotopy,

so

$$\pi_1(S^1) \overset{(1)}{=} \pi_0(\mathbb{Z}) = \mathbb{Z},$$
$$\pi_n(S^1) \overset{(2)}{=} \pi_{n-1}(\mathbb{Z}) = 0 \qquad (n \geq 2).$$

(1) Exactness with zeros on both sides. The boundary map is completely explicit: the loop $t \mapsto e^{2\pi i k t}$, $t \in [0,1]$, lifts to the path $t \mapsto kt$ in $\mathbb{R}$ starting at 0, whose end point $k \in \mathbb{Z}$ lies in the fibre. ∂ is the winding number.

(2) For $n \geq 2$, π_{n-1} of a discrete space is trivial.

This recovers $S^1 = K(\mathbb{Z}, 1)$ (Section 1.4.1) from the exact sequence, as promised.

Worked example 1.100: The Hopf fibration gives $\pi_3(S^2) = \mathbb{Z}$

Apply (1.132) to $S^1 \to S^3 \to S^2$:

$$\cdots \to \pi_n(S^1) \to \pi_n(S^3) \xrightarrow{\pi_*} \pi_n(S^2) \xrightarrow{\partial} \pi_{n-1}(S^1) \to \pi_{n-1}(S^3) \to \cdots$$

We know $\pi_k(S^1) = 0$ for $k \geq 2$ (Example 1.99) and $\pi_k(S^3) = 0$ for $k = 1, 2$ (Chapter 1, §3).

- $n \geq 3$. Both neighbours $\pi_n(S^1)$ and $\pi_{n-1}(S^1)$ vanish, since $n - 1 \geq 2$:

$$\pi_3(S^2) \overset{(1)}{=} \pi_3(S^3) \overset{(2)}{=} \mathbb{Z}. \tag{1.135}$$

  (1) $0 \to \pi_3(S^3) \xrightarrow{\pi_*} \pi_3(S^2) \to 0$ is exact, so π_* is an isomorphism.

  (2) $\pi_n(S^n) = \mathbb{Z}$, generated by the identity (the degree).

  The generator of $\pi_3(S^2)$ is $\pi_*[\mathrm{id}_{S^3}] = [\pi]$: *the Hopf map itself*. Its multiples are detected by the Hopf invariant, the linking number of two fibres (Figure 1.51). The same step gives $\pi_n(S^2) = \pi_n(S^3)$ for every $n \geq 3$: for example $\pi_4(S^2) = \pi_4(S^3) = \mathbb{Z}_2$ and $\pi_6(S^2) = \pi_6(S^3) = \mathbb{Z}_{12}$, entries of the table in Chapter 1.

- $n = 2$. $\underbrace{\pi_2(S^3)}_{0} \to \pi_2(S^2) \xrightarrow{\partial} \pi_1(S^1) \to \underbrace{\pi_1(S^3)}_{0}$, so $\pi_2(S^2) \cong \pi_1(S^1) = \mathbb{Z}$. By (1.134), ∂ sends the identity of S^2 to the clutching function $e^{i\phi}$ of (1.119), which winds once: ∂ is an isomorphism, as it must be.

Physical picture: Hopf solitons and skyrmions

Maps $\mathbb{R}^3 \cup \{\infty\} = S^3 \to S^2$ are the field configurations of a unit 3-vector field $\vec{n}(x)$ (a Heisenberg ferromagnet, or the Faddeev–Skyrme model) that tends to a constant at infinity. The sectors are $\pi_3(S^2) = \mathbb{Z}$. The integer is the linking number of the preimages of two target points, the Hopf invariant. Knotted solitons ("hopfions") carry it. The formula $H = \frac{1}{16\pi^2}\int_{S^3} a \wedge \mathrm{d}a$, where a is any real 1-form with $\mathrm{d}a = f^*\omega$ the pullback of the area form ω of S^2 (total area 4π), is an abelian Chern–Simons integral: the first appearance of Chern–Simons theory, Chapter 12.

Worked example 1.101: $\mathbb{CP}^\infty = K(\mathbb{Z},2)$ and $\pi_n(BG) = \pi_{n-1}(G)$

First, S^∞ is contractible. A map $S^k \to S^\infty$ has compact image, so it lies in some S^N; enlarge N so that $N > k$; then $\pi_k(S^N) = 0$ and the map is null-homotopic. So $\pi_k(S^\infty) = 0$ for all k (and with a little more work S^∞ contracts to a point). Apply (1.132) to $U(1) \to S^\infty \to \mathbb{CP}^\infty$:

$$\pi_n(\mathbb{CP}^\infty) \overset{(1)}{=} \pi_{n-1}(U(1)) \overset{(2)}{=} \begin{cases} \mathbb{Z} & n = 2, \\ 0 & n \neq 2. \end{cases}$$

(1) $\pi_n(S^\infty) = \pi_{n-1}(S^\infty) = 0$ on both sides of ∂.
(2) $U(1) = S^1$, whose only non-zero homotopy group is $\pi_1 = \mathbb{Z}$ (Example 1.99).

So $\mathbb{CP}^\infty$ is a $K(\mathbb{Z},2)$, as claimed in Example 1.58. The finite stages show how the higher groups die: $S^1 \to S^{2N+1} \to \mathbb{CP}^N$ gives $\pi_2(\mathbb{CP}^N) = \mathbb{Z}$ and $\pi_k(\mathbb{CP}^N) = \pi_k(S^{2N+1})$ for $k \geq 3$, which is zero for $k \leq 2N$. As $N \to \infty$ nothing survives above degree 2.
The same argument for any universal bundle $G \to E_G \to BG$, with E_G contractible, gives

$$\pi_n(BG) \cong \pi_{n-1}(G). \tag{1.136}$$

For connected G this matches the clutching construction: bundles over S^n are $[S^n, BG] = \pi_n(BG) = \pi_{n-1}(G)$, as in (1.111). It also matches $\Omega BG \simeq G$ from Section 1.4.3.

Worked example 1.102: Two fibrations of $\mathrm{SO}(3)$ and the belt trick

Route 1: the double cover. $\mathrm{SU}(2) = S^3$ double covers $\mathrm{SO}(3)$, with fibre $\{\pm 1\} = \mathbb{Z}_2$ (Chapter 1, belt trick). The sequence $\underbrace{\pi_1(S^3)}_{0} \to \pi_1(\mathrm{SO}(3)) \xrightarrow{\partial} \pi_0(\mathbb{Z}_2) \to \underbrace{\pi_0(S^3)}_{\mathrm{pt}}$ gives $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$.
For $n \geq 2$, $\pi_n(\mathrm{SO}(3)) = \pi_n(S^3)$: $\pi_2(\mathrm{SO}(3)) = 0$, $\pi_3(\mathrm{SO}(3)) = \mathbb{Z}$.
Route 2: the unit tangent bundle of S^2. A rotation R is fixed by where it sends the frame $(\hat{e}_3, \hat{e}_1)$: the point $p = R\hat{e}_3 \in S^2$ and the unit tangent vector $R\hat{e}_1 \perp p$. So $\mathrm{SO}(3)$ is the bundle of unit tangent vectors of S^2, a principal $\mathrm{SO}(2)$ bundle $\mathrm{SO}(2) \to \mathrm{SO}(3) \to S^2$ whose clutching function is that of TS^2, winding twice (1.121). The sequence reads

$$\underbrace{\pi_2(\mathrm{SO}(3))}_{0} \to \underbrace{\pi_2(S^2)}_{\mathbb{Z}} \xrightarrow{\partial} \underbrace{\pi_1(\mathrm{SO}(2))}_{\mathbb{Z}} \to \pi_1(\mathrm{SO}(3)) \to \underbrace{\pi_1(S^2)}_{0}.$$

By (1.134), ∂ is multiplication by the winding of the clutching function, 2. Exactness then gives

$$\pi_1(\mathrm{SO}(3)) \overset{(1)}{=} \pi_1(\mathrm{SO}(2))/\operatorname{Im}\partial \overset{(2)}{=} \mathbb{Z}/2\mathbb{Z} = \mathbb{Z}_2.$$

(1) The map $\pi_1(\mathrm{SO}(2)) \to \pi_1(\mathrm{SO}(3))$ is onto (the next group $\pi_1(S^2)$ is zero) with kernel $\operatorname{Im}\partial$.
(2) ∂ is multiplication by 2.

The two routes agree. The second shows something remarkable: *the belt trick and the hairy ball theorem are the same number* $2 = \chi(S^2)$. A 4π rotation is contractible because the tangent bundle of the sphere twists twice.

Try it: Homotopy groups of $\mathrm{SU}(n)$ by induction

$\mathrm{SU}(n)$ acts transitively on the unit sphere $S^{2n-1} \subset \mathbb{C}^n$, and the stabiliser of e_n is $\mathrm{SU}(n-1)$. So $\mathrm{SU}(n-1) \to \mathrm{SU}(n) \to S^{2n-1}$ is a bundle. Show that $\pi_1(\mathrm{SU}(n)) = 0$ and $\pi_3(\mathrm{SU}(n)) = \mathbb{Z}$ for all $n \geq 2$. *Answer:* for $k \leq 2n-3$ the groups $\pi_k(S^{2n-1})$ and $\pi_{k+1}(S^{2n-1})$ vanish, so $\pi_k(\mathrm{SU}(n-1)) \cong \pi_k(\mathrm{SU}(n))$. Starting from $\mathrm{SU}(2) = S^3$: $\pi_1 = 0$ and $\pi_3 = \mathbb{Z}$ are passed up for $n \geq 3$ (for $k = 3$ we need $3 \leq 2n-3$, true for $n \geq 3$). Physically: every $\mathrm{SU}(n)$ instanton sector has an integer charge, and the minimal instanton is an SU(2) instanton sitting in an SU(2) subgroup.

1.5.14 Cohomology of a bundle: no simple rule

Nash warns that "there is no simple relation between the cohomology groups of E, F and M". A trivial bundle obeys Künneth, $P_{M\times F} = P_M P_F$ (Example 1.84). A twisted one does not. The cleanest demonstration is the family of all circle bundles over S^2.

Worked example 1.103: The homology of the charge-n circle bundle over S^2

Let $E_n \to S^2$ be the circle bundle with clutching function $e^{in\phi}$, so that $f_N = e^{in\phi} f_S$ on the equator (Example 1.91). Cover E_n by $E_N = \pi^{-1}(O_N) \cong D^2 \times S^1$ and $E_S = \pi^{-1}(O_S) \cong D^2 \times S^1$. Their intersection is the circle bundle over the equatorial band, $\simeq S^1 \times S^1 = T^2$. On $H_1(T^2) = \mathbb{Z}^2$ use the basis

- b: the fibre circle over a point of the equator;
- a: the equator traced at fixed northern fibre coordinate, $\phi \mapsto (\phi, f_N = 1)$.

In $E_N \cong D^2 \times S^1$, $H_1 = \mathbb{Z}\beta_N$ (the fibre); $b \mapsto \beta_N$, and $a \mapsto 0$ because a bounds the disc $D^2 \times \{1\}$. In E_S, $H_1 = \mathbb{Z}\beta_S$; $b \mapsto \beta_S$, but a has southern fibre coordinate $f_S = e^{-in\phi}$, which winds $-n$ times around the fibre, so $a \mapsto -n\beta_S$. The Mayer–Vietoris sequence (Section 1.4.9, in its homology form)

$$H_1(T^2) \xrightarrow{\Phi} H_1(E_N) \oplus H_1(E_S) \to H_1(E_n) \to \tilde{H}_0(T^2) = 0$$

gives $H_1(E_n) = \operatorname{Coker}\Phi$. In the bases (a, b) and (β_N, β_S),

$$\begin{aligned} H_1(E_n) &\overset{(1)}{=} \mathbb{Z}^2 \Big/ \operatorname{Im}\begin{pmatrix} 0 & 1 \\ -n & 1 \end{pmatrix} \\ &\overset{(2)}{=} \mathbb{Z}^2/\langle (0,-n), (1,1)\rangle \\ &\overset{(3)}{=} \mathbb{Z}/n\mathbb{Z}. \end{aligned}$$

(1) The columns are the images of a and b.
(2) The image is spanned by the columns.
(3) The relation $(1,1)$ sets $\beta_N = -\beta_S$, leaving one generator β_S subject to $n\beta_S = 0$.

Also $H_2(E_n) = \operatorname{Ker}\Phi$ (since $H_2(E_N) = H_2(E_S) = 0$), which is 0 for $n \neq 0$ because $\det\Phi = n \neq 0$. So:

n	E_n	$H_1(E_n)$	$H_2(E_n)$
0	$S^2 \times S^1$	$\mathbb{Z}$	$\mathbb{Z}$
± 1	S^3 (Hopf)	0	0
± 2	$\mathrm{SO}(3) = \mathbb{RP}^3$ (unit tangent bundle of S^2)	$\mathbb{Z}_2$	0
n	lens space $L(n,1) = S^3/\mathbb{Z}_n$	$\mathbb{Z}_n$	0

Same fibre, same base, different total spaces with different homology. The twist n enters as a matrix entry.

Physical picture: The spectral sequence in one sentence

The tool Nash names is the **Serre spectral sequence**. One starts from the "Künneth guess" $E_2^{p,q} = H^p(M; H^q(F))$, laid out on a grid, and corrects it by differentials $d_r : E_r^{p,q} \to E_r^{p+r,q-r+1}$ that encode the twisting. For a circle bundle over S^2 the grid has four entries, at $(p,q) = (0,0), (2,0), (0,1), (2,1)$, and the only differential is $d_2 : E_2^{0,1} = \mathbb{Z} \to E_2^{2,0} = \mathbb{Z}$, which is multiplication by the Euler class n. Its kernel is $H^1(E_n)$ and its cokernel is $H^2(E_n) = \mathbb{Z}_n$, in agreement with the example (torsion in H_1 reappears in H^2, Example 1.76).

One number is insensitive to the twist: the Euler characteristic.

Key idea: χ is multiplicative in bundles

For a bundle $F \to E \to M$ with compact fibre and base, $\chi(E) = \chi(F)\,\chi(M)$.

Triangulate M so finely that E is trivial over each simplex. Each k-simplex σ of M, together with a cell decomposition of F, contributes cells $\sigma \times (\text{cell of } F)$ to E. Counting with signs,

$$\chi(E) \overset{(1)}{=} \sum_{\sigma} \sum_{c} (-1)^{\dim \sigma + \dim c} \overset{(2)}{=} \sum_{\sigma} (-1)^{\dim \sigma}\, \chi(F) = \chi(M)\,\chi(F).$$

(1) χ is the alternating count of cells (Section 1.4.10), and the cells of E are products.
(2) The inner sum over cells c of F is $\chi(F)$; the outer sum is $\chi(M)$.

Checks: the Hopf fibration, $\chi(S^3) = 0 = 0 \cdot 2$; the unit tangent bundle $\mathbb{RP}^3$ of S^2, $0 = 0 \cdot 2$; the Möbius band, which retracts to its core circle, $0 = 1 \cdot 0$.

1.5.15 Fibrations and the homotopy lifting property

Every argument in the last two subsections used one property of a bundle: *maps into the base can be lifted, and so can their deformations*. Nash promotes this property to a definition.

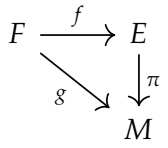
Working definition 1.41 (fibration)

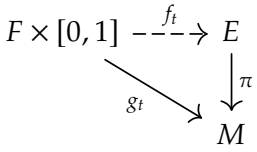
A map $\pi : E \to M$ is a **fibration** if it has the **homotopy lifting property**: for every space F, every map $f : F \to E$ and every homotopy $g_t : F \to M$ [a family of maps depending continuously on $t \in [0,1]$] of its projection $g_0 = \pi \circ f$ [f followed by π, i.e. f pushed down to M], there is a homotopy $f_t : F \to E$ with

$$f_0 = f \qquad \text{and} \qquad \pi \circ f_t = g_t \ \text{ for all } t.$$

Operationally: "whenever you move the shadow, you can move the object so that it casts that shadow."

In diagrams, Nash's (1.53)–(1.55) are





$$g = \pi \circ f, \quad f_0 = f, \quad g_t = \pi \circ f_t. \tag{1.137}$$

The dashed arrow is what the property guarantees.

Worked example 1.104: Bundles and coverings are fibrations

Fibre bundles. Over a single patch $O_\alpha \times F'$ lifting is trivial: keep the fibre coordinate fixed, $f_t(y) = (g_t(y),\ f_\alpha(f(y)))$. For a general homotopy, cut $[0,1]$ into short time steps during which each point stays within one patch, and lift step by step, re-expressing the fibre coordinate with $g_{\alpha\beta}$ when crossing to a new patch. (With a connection there is an even simpler lift: parallel transport along the paths $t \mapsto g_t(y)$.) Nash calls these "locally trivial" fibrations.
Coverings. For $\mathbb{R} \to S^1$ the lift of a path is unique once the starting point is chosen: this is the lifting that computed $\pi_1(S^1)$. Coverings are the fibrations with discrete fibre.

The fibre of a fibration is $F = \pi^{-1}(*)$. The fibres over different points of a path-connected base need not be homeomorphic, but they all have the same homotopy type. The reason is transport: lifting a path γ from x to y for every point of $\pi^{-1}(x)$ at once gives a map $\pi^{-1}(x) \to \pi^{-1}(y)$, and the reversed path gives a map back, whose composites are homotopic to the identities.

Worked example 1.105: A fibration whose fibres are not all homeomorphic

Let $E = \{(x,t) \in \mathbb{R}^2 : 0 \le t \le 1,\ 0 \le x \le t\}$, a closed triangle, and $\pi(x,t) = t$. The fibre over $t > 0$ is the interval $[0,t]$; over $t = 0$ it is a single point. These are not homeomorphic, but all are contractible. Homotopy lifting holds. Given $f(y) = (x_0(y), t_0(y))$ and a homotopy $t_s(y)$ of t_0, define

$$f_s(y) = \big(\min\{x_0(y), t_s(y)\},\ t_s(y)\big),$$

$$\text{check:}\quad f_0(y) \overset{(1)}{=} \big(x_0(y), t_0(y)\big) = f(y), \qquad \pi f_s(y) \overset{(2)}{=} t_s(y).$$

(1) $x_0 \le t_0$ because $f(y) \in E$, so the minimum is x_0.
(2) By construction; and $0 \le \min\{x_0, t_s\} \le t_s$, so $f_s(y) \in E$.

The minimum of continuous functions is continuous, so f_s is a lift. A fibre bundle could never behave like this; a fibration can. This extra flexibility is exactly what makes fibrations useful: every map can be replaced, up to homotopy, by a fibration, and the most important example arises this way.

Nash's next statement is that fibrations have the *same* exact homotopy sequence (1.132). Indeed, our derivation of ∂ and of exactness used only lifting of discs and of homotopies. The spectral sequence relating the cohomology of F, E and M also carries over.

1.5.16 The path fibration

Take as total space the based paths in M:

$$PM = \mathrm{Map}_0([0,1], M) = \{p : [0,1] \to M \text{ continuous},\ p(0) = *\}, \tag{1.138}$$

and let $\pi : PM \to M$ send a path to its end point, $\pi(p) = p(1)$. The fibre over $*$ is the set of paths starting and ending at $*$: the loop space ΩM of Chapter 1. Nash's picture is

$$\Omega M \longrightarrow PM \xrightarrow{\pi} M, \qquad \pi(p) = p(1). \tag{1.139}$$

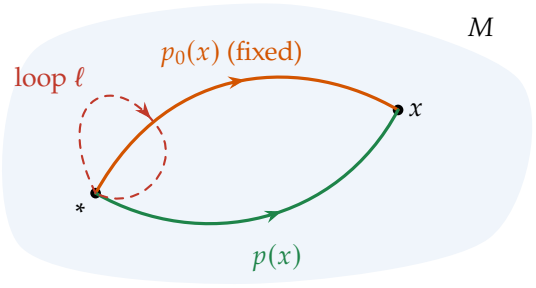


Figure 1.56: The path fibration. The fibre over x consists of all paths from $*$ to x. Fix one of them, $p_0(x)$ (orange). Any other path $p(x)$ (green) differs from it by the loop $p(x) \cdot \overline{p_0(x)}$ at $*$ (go out along p, come back along p_0). Conversely a loop ℓ (red) followed by $p_0(x)$ is a path to x. This identifies the fibre over x with ΩM up to homotopy.

Every fibre is a loop space. Nash's argument, made explicit: fix a path $p_0(x)$ from $*$ to x. Define maps

$$\Omega M \to \pi^{-1}(x), \ \ \ell \mapsto \ell \cdot p_0(x), \qquad \pi^{-1}(x) \to \Omega M, \ \ p \mapsto p \cdot \overline{p_0(x)},$$

where $\cdot$ is concatenation and the bar reverses a path. The composites send $\ell \mapsto \ell \cdot p_0 \cdot \overline{p_0}$ and $p \mapsto p \cdot \overline{p_0} \cdot p_0$, which are homotopic to ℓ and p by retracting the back-and-forth excursion (the same homotopies that make π_1 a group, Chapter 1). So $\pi^{-1}(x) \simeq \Omega M$, and in particular the fibre over $*$ is ΩM itself.

The total space is contractible. Shrink every path back along itself:

$$H_u(p)(t) = p(ut), \qquad u \in [0,1],$$
$$H_1(p) \overset{(1)}{=} p, \qquad H_0(p) \overset{(2)}{=} \text{the constant path at } *.$$

(1) $p(1 \cdot t) = p(t)$.
(2) $p(0 \cdot t) = p(0) = *$ for every t.

Each $H_u(p)$ still starts at $*$, so it lies in PM. Hence PM has the homotopy type of a point.

Homotopy lifting. Suppose p is a path from $*$ to x_0 and the end point moves along a path $s \mapsto x_s$. Lift by *extending* the path: follow p, then follow the motion of the end point.

$$p_s(t) = \begin{cases} p\big((1+s)t\big), & 0 \le t \le \frac{1}{1+s}, \\ x_{(1+s)t-1}, & \frac{1}{1+s} \le t \le 1. \end{cases} \tag{1.140}$$

At the junction $t = \frac{1}{1+s}$ both lines give $p(1) = x_0$; at $t = 1$ the end point is x_s; at $s = 0$ the second line is empty and $p_0 = p$. Doing this for a whole family of paths at once (the $y \in F$ of the definition) is the same formula. So π is a fibration.

Key idea: Loop space shifts homotopy down by one

The exact sequence of $\Omega M \to PM \to M$, with $\pi_n(PM) = 0$ for all n, gives

$$\pi_n(M) \cong \pi_{n-1}(\Omega M). \tag{1.141}$$

This is the isomorphism $[S^n, M]_0 = [S^{n-1}, \Omega M]_0$ of Chapter 1 (Nash's (1.29)), now as a

consequence of a fibration. With $M = K(G, n+1)$ it says $\Omega K(G, n+1)$ has a single homotopy group G in degree n, which is Nash's (1.39). With $M = BG$ and (1.136) it says $\Omega BG \simeq G$.

Why Nash cares: computing the cohomology of ΩM

Loop spaces are infinite dimensional, and there is no direct way to triangulate them. But in the path fibration the total space is a point up to homotopy, so its cohomology is known: $\mathbb{Z}$ in degree 0 and nothing else. The spectral sequence must turn the grid $E_2^{p,q} = H^p(M) \otimes H^q(\Omega M)$ into that, and this is a very strong constraint.

Worked example 1.106: The cohomology of ΩS^n

Take $M = S^n$, $n \geq 2$. The grid has only two non-zero columns, $p = 0$ and $p = n$, each a copy of $H^q(\Omega S^n)$. A differential d_r moves r steps right and $r-1$ steps down, so the only one that can connect the two columns is $d_n : E^{0,q} \to E^{n,q-n+1}$. Everything except $E^{0,0} = \mathbb{Z}$ must be killed, so each d_n must be an isomorphism:

$$H^q(\Omega S^n) \overset{(1)}{=} E_2^{0,q} \overset{(2)}{=} E_2^{n,q-n+1} = H^{q-n+1}(\Omega S^n) \qquad (q \geq 1).$$

(1) The column $p = 0$ is $H^0(S^n) \otimes H^q(\Omega S^n) = H^q(\Omega S^n)$.

(2) d_n must be an isomorphism for everything to cancel, and the column $p = n$ is another copy of $H^*(\Omega S^n)$.

Starting from $H^0 = \mathbb{Z}$ and $H^q = 0$ for $0 < q < n-1$, the recursion gives

$$H^q(\Omega S^n; \mathbb{Z}) = \begin{cases} \mathbb{Z}, & q = 0,\ n-1,\ 2(n-1),\ 3(n-1), \dots \\ 0, & \text{otherwise.} \end{cases}$$

For $n = 2$, ΩS^2 has $\mathbb{Z}$ in every degree. The infinite-dimensional loop space has cohomology in infinitely many degrees, which is characteristic of loop spaces and of the loop groups of Chapter 6.

Reading Nash (pp. 14–19, (1.47)–(1.58))

Nash's §5 is a rapid tour; we have filled in each stop.

- (1.47) is local triviality, our (1.101). Nash does not write transition functions at this point; we made them the working definition because every computation runs through them.
- The pullback of cohomology, $f^* : H^n(M; G) \to H^n(N; G)$, and of bundles, f^*E, and (1.48) $f_1^*E \cong f_2^*E$ for $f_1 \simeq f_2$: our Sections 1.5.9 and 1.5.10, with the homotopy operator and the parallel-transport argument added.
- (1.49) bundles $\leftrightarrow [M, BG]$ and (1.50) $c_i \mapsto f^*c_i$: Sections 1.5.11 and 1.5.12. Nash names Chern, Pontryagin, Stiefel–Whitney and Euler classes without formulas; we added the Chern–Weil expressions and the explicit classes of our examples.
- (1.51)–(1.52): the fibre sequence and the exact homotopy sequence, with "$\pi_n(E) \cong \pi_n(M) + \pi_n(F)$" for a trivial bundle (read + as direct sum). Nash gives no examples

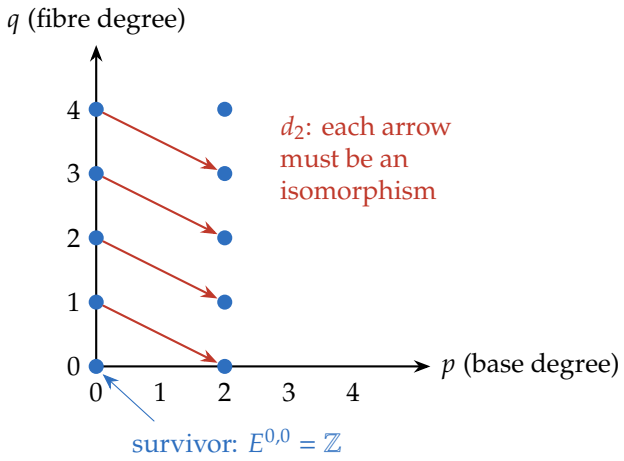

Figure 1.57: The spectral sequence of $\Omega S^2 \to PS^2 \to S^2$. Dots are the groups $H^p(S^2) \otimes H^q(\Omega S^2)$, in the columns $p = 0$ and $p = 2$. The differential d_2 (red) goes two steps right and one step down. The total space is contractible, so every dot except the bottom-left one must be cancelled by an arrow. This forces $H^q(\Omega S^2) \cong H^{q-1}(\Omega S^2)$, so $\mathbb{Z}$ appears in every degree.

of the sequence in use; we computed $\pi_n(S^1)$, $\pi_3(S^2)$, $\pi_n(\mathbb{CP}^\infty)$, $\pi_1(\mathrm{SO}(3))$ (two ways) and $\pi_3(\mathrm{SU}(n))$.

- (1.53)–(1.55): fibrations and the homotopy lifting property, Nash's diagrams being our (1.137). His remarks that fibres need only share a homotopy type and that the same exact sequence holds are Example 1.105 and the discussion after it.
- (1.56)–(1.58): the path fibration $\Omega M \to PM \to M$, with Nash's fixed-path argument that $\pi^{-1}(x) \simeq \Omega M$. We added the explicit contraction of PM, the lifting formula (1.140), and the computation of $H^*(\Omega S^n)$ that shows why "this encoding of ΩM as the fibre of a fibration" is a "crucial step".

Recap: §1.5 Fibre bundles and fibrations

- A bundle is local products $O_\alpha \times F$ glued by transition functions $g_{\alpha\beta} \in G$ obeying the cocycle condition; changing trivialisations is a gauge transformation $h_\alpha g_{\alpha\beta} h_\beta^{-1}$.
- Fields are sections. Twisting can force zeros: Möbius band, hairy ball (TS^2 has clutching winding 2).
- Principal bundles carry the transition functions; associated bundles $P \times_\rho V$ carry matter in representation ρ; gauge potentials glue as $A_\beta = g^{-1} A_\alpha g + g^{-1} \mathrm{d} g$.
- Bundles over S^n are classified by $\pi_{n-1}(G)$ (clutching). The monopole is $e^{in\phi}$; its charge is $c_1 = n$. The Hopf fibration $S^1 \to S^3 \to S^2$ is the $|n| = 1$ case, and it is the unit circle bundle of the tautological line bundle.
- Pullback f^* is contravariant and homotopy invariant. Bundles are pullbacks of a universal bundle, $\{\text{bundles}\} = [M, BG]$; characteristic classes are pullbacks of $H^*(BG)$. Line bundles are $H^2(M; \mathbb{Z})$.
- Exact sequence $\cdots \to \pi_n(F) \to \pi_n(E) \to \pi_n(M) \xrightarrow{\partial} \pi_{n-1}(F) \to \cdots$; ∂ is "lift a disc, take its edge", and over a sphere it is the clutching class. Hopf gives $\pi_3(S^2) = \mathbb{Z}$.

- Fibrations need only homotopy lifting. The path fibration $\Omega M \to PM \to M$ has contractible total space, so $\pi_n(M) = \pi_{n-1}(\Omega M)$, and it computes $H^*(\Omega S^n)$.

1.6 Differentiable structures for manifolds

In §1.1 we met three kinds of manifold: topological (M_{TOP}), piecewise-linear (M_{PL}) and smooth (M_{DIFF}). They differ only in what we demand of the transition functions $g_{\alpha\beta}$ that glue the coordinate patches: homeomorphisms, piecewise-linear homeomorphisms, or diffeomorphisms. Two questions follow at once.

- *Existence.* Given a topological manifold, can we choose the atlas so that all the $g_{\alpha\beta}$ are piecewise-linear ("straighten" it)? Given a PL manifold, can we make them smooth ("smooth" it)?
- *Uniqueness.* If we can, in how many essentially different ways?

Why should a physicist care? Every action we write, $\int \left(\frac{1}{2}\partial_\mu\phi\,\partial^\mu\phi - V(\phi)\right)$ or $-\int \mathrm{tr}(F \wedge \star F)$, needs derivatives, and derivatives need a smooth structure. If one topological space carried two inequivalent smooth structures, "the same" spacetime would carry two inequivalent sets of smooth fields and two different field theories. This really happens: on S^7 there are 28 smooth structures, and on $\mathbb{R}^4$, the most important space in physics, there are uncountably many. And the most spectacular result in the subject, Donaldson's theorem, was proved by solving the Yang–Mills equations. Physics was used to answer a question about smoothness.

The pleasant surprise is that most of the answer can be computed with the tools of the previous two sections. The plan is:

1. turn the three kinds of transition function into three groups $TOP_n \supset PL_n \supset DIFF_n$;
2. use their classifying spaces (Section 1.5.11) to say what a "topological tangent bundle" is;
3. recast "can M be straightened or smoothed?" as a *lifting problem* through a fibration (Section 1.5.15);
4. solve lifting problems cell by cell with *obstruction theory*, whose answers are cohomology classes (Section 1.4);
5. feed in the homotopy groups of the fibres TOP/PL and $PL/DIFF$, which are known.

The result works beautifully in dimension ≥ 5 and fails spectacularly in dimension 4. Figure 1.58 shows the whole section on one page.

1.6.1 Three groups of transition functions

A transition function $g_{\alpha\beta}$ is a map from an open subset of $\mathbb{R}^n$ to another open subset of $\mathbb{R}^n$. To turn these into a *group*, we look at invertible maps of $\mathbb{R}^n$ to itself, and (as for vector bundles) only care about what happens near one point, which we may put at the origin. So we define:

- TOP_n: homeomorphisms $f : \mathbb{R}^n \to \mathbb{R}^n$ with $f(0) = 0$;
- PL_n: piecewise-linear homeomorphisms with $f(0) = 0$ ("piecewise-linear": there is a triangulation of $\mathbb{R}^n$ on each simplex of which f is affine; the inverse is then automatically PL too);

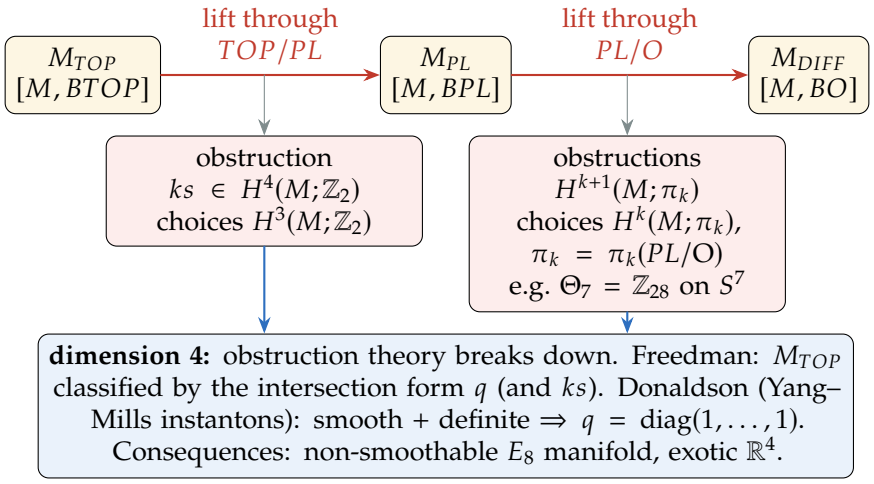

Figure 1.58: Road map of Section 1.6. Going from left to right adds structure. Each arrow is a lifting problem through a fibration, answered by obstruction theory: the red boxes list the cohomology group that contains the obstruction and the group that counts the answers. In dimension ≥ 5 that is the whole story. In dimension 4 (blue box) it is replaced by Freedman's and Donaldson's theorems.

- $DIFF_n$: diffeomorphisms with $f(0) = 0$.

Each is a group under composition, and each is a topological group (we can say when two homeomorphisms are close). The **structure group** of a manifold's tangent bundle is then TOP_n, PL_n or $DIFF_n$ according to its type.

Worked example 1.107: Elements of one group that are not in the next

Work in $n = 1$.

- $f(x) = x^3$ is a homeomorphism of $\mathbb{R}$ (continuous, bijective, with continuous inverse $x^{1/3}$). It is smooth, but its inverse is not differentiable at 0. So $f \in TOP_1$, $f \notin DIFF_1$. It is not PL either: no finite collection of straight pieces reproduces a cubic.
- $f(x) = x$ for $x \leq 0$ and $f(x) = 2x$ for $x \geq 0$ is PL (two linear pieces), a homeomorphism, but has a kink at 0. So $f \in PL_1$, $f \notin DIFF_1$.
- $f(x) = x + x^3$ is a diffeomorphism ($f' = 1 + 3x^2 > 0$), but it is not affine on any interval. So $f \in DIFF_1$, $f \notin PL_1$.

The last example shows that $DIFF_n \subset PL_n$ is *not* a literal inclusion of sets; see the pitfall below.

These groups are huge (infinite-dimensional), but for the smooth one there is an enormous simplification: $DIFF_n$ can be squashed down, without changing its homotopy type, onto a finite-dimensional Lie group.

Key idea: A diffeomorphism is homotopic to its derivative

Every $f \in DIFF_n$ is joined to the linear map $\mathrm{d}f_0 \in \mathrm{GL}(n,\mathbb{R})$ by the path

$$f_t(x) = \frac{f(tx)}{t} \quad (0 < t \leq 1), \qquad f_0(x) = \mathrm{d}f_0(x). \tag{1.142}$$

Consequently $DIFF_n \simeq \mathrm{GL}(n,\mathbb{R}) \simeq \mathrm{O}(n)$, and $BDIFF_n \simeq BO(n)$: a smooth tangent bundle is, up to homotopy, just an ordinary vector bundle.

Let us check that the path really ends at the derivative. Expand f around 0:

$$\begin{aligned} f_t(x) &\overset{(1)}{=} \frac{1}{t}\Big(f(0) + t\,\mathrm{d}f_0(x) + \tfrac{t^2}{2}\,\mathrm{d}^2 f_0(x,x) + O(t^3)\Big) \\ &\overset{(2)}{=} \mathrm{d}f_0(x) + \tfrac{t}{2}\,\mathrm{d}^2 f_0(x,x) + O(t^2) \\ &\xrightarrow{t\to 0} \mathrm{d}f_0(x). \end{aligned}$$

(1) Taylor's theorem for $f(tx)$ in powers of t; $\mathrm{d}f_0$ is the Jacobian matrix at the origin and $\mathrm{d}^2 f_0$ the Hessian.

(2) $f(0) = 0$ because elements of $DIFF_n$ fix the origin; divide through by t.

Each f_t is a diffeomorphism (a rescaled copy of f), so this is a path inside $DIFF_n$ that shrinks the whole group onto its linear part. The second step, $\mathrm{GL}(n,\mathbb{R}) \simeq \mathrm{O}(n)$, is Gram–Schmidt: write $A = O\,P$ with O orthogonal and $P = (A^T A)^{1/2}$ positive definite (the polar decomposition), and slide P to the identity along P^s, $s \in [0,1]$. Physicists know this from the vielbein: any frame can be deformed to an orthonormal one.

The trick fails for TOP_n and PL_n, because a homeomorphism has no derivative to shrink onto. That is the whole difference between the three theories: TOP_n and PL_n are genuinely bigger than $\mathrm{O}(n)$, and the "extra" homotopy is measured by the quotients TOP_n/PL_n and $PL_n/\mathrm{O}(n)$.

Watch out: "$DIFF \subset PL$" is an inclusion only up to homotopy

Nash writes the inclusions $DIFF_n \subset PL_n \subset TOP_n$ [Nash p. 19, (1.59)]. The second is literal. The first is not, by Example 1.107. What is true is J. H. C. Whitehead's theorem: every smooth manifold has a triangulation compatible with its smooth structure, unique up to PL homeomorphism. So each smooth structure determines a PL structure, and on the level of groups one gets a map $\mathrm{O}(n) \simeq DIFF_n \to PL_n$ defined up to homotopy. That is all the theory uses, and it is why topologists often write O instead of $DIFF$, as in PL/O.

Letting $n \to \infty$: direct limits

Each group sits inside the next one: a map f of $\mathbb{R}^n$ extends to $\mathbb{R}^{n+1} = \mathbb{R}^n \times \mathbb{R}$ by doing nothing to the last coordinate, $f \mapsto f \times \mathrm{id}_{\mathbb{R}}$. This gives Nash's three towers

$$\begin{array}{ccccccccc} TOP_1 & \subset & TOP_2 & \subset & \cdots & \subset & TOP_n & \subset & \cdots \\ PL_1 & \subset & PL_2 & \subset & \cdots & \subset & PL_n & \subset & \cdots \\ DIFF_1 & \subset & DIFF_2 & \subset & \cdots & \subset & DIFF_n & \subset & \cdots \end{array} \tag{1.143}$$

Working definition 1.42 (direct limit)

Given a sequence $O_1 \xrightarrow{\phi_1} O_2 \xrightarrow{\phi_2} O_3 \to \cdots$, the **direct limit** $\varinjlim O_i$ is "the union of all of them, with each O_i identified with its image in the next" [$\phi_i(O_i) \subset O_{i+1}$]. An element is an element of some O_i; two elements are equal if they become equal further along [$x \in O_i$ and $x' \in O_j$ are equal when their images in some later O_k coincide]. For groups and spaces the operations and the topology are inherited from the finite stages. *Operationally*: a statement about the limit is a statement about O_i for all sufficiently large i. For example $\pi_k(\varinjlim O_i) = \varinjlim \pi_k(O_i)$, which is $\pi_k(O_i)$ for i large once these groups stabilise [the maps $\pi_k(O_i) \to \pi_k(O_{i+1})$ are isomorphisms from some i on]. The dual notion, for maps going the other way $O_1 \leftarrow O_2 \leftarrow \cdots$, is the **inverse limit** $\varprojlim O_i$: sequences $(x_1, x_2, \dots)$ with

$x_i \in O_i$ compatible under the maps [the map $O_{i+1} \to O_i$ sends each x_{i+1} to x_i].

Worked example 1.108: Three direct limits

- $\mathbb{R}^\infty = \varinjlim \mathbb{R}^n$, with $\mathbb{R}^n \subset \mathbb{R}^{n+1}$ as $(x_1, \dots, x_n, 0)$: the space of real sequences with finitely many nonzero entries.
- $S^\infty = \varinjlim S^n$, the unit sphere in $\mathbb{R}^\infty$. It is contractible (every sphere S^n is contractible inside S^{n+1}), and $\mathbb{Z}_2 = \{\pm 1\}$ acts freely on it, so it is $E_{\mathbb{Z}_2}$ and $S^\infty/\mathbb{Z}_2 = \mathbb{RP}^\infty = B\mathbb{Z}_2$ (Section 1.5.11).
- $\mathrm{O} = \varinjlim \mathrm{O}(n)$, with $A \mapsto \left(\begin{smallmatrix} A & 0 \\ 0 & 1 \end{smallmatrix}\right)$: infinite orthogonal matrices that differ from the identity in a finite block. Its homotopy groups are the stable ones, $\pi_k(\mathrm{O}) = \pi_k(\mathrm{O}(n))$ for $n > k+1$; Bott periodicity (§1.3, Chapter 3) says they repeat with period 8: $\mathbb{Z}_2, \mathbb{Z}_2, 0, \mathbb{Z}, 0, 0, 0, \mathbb{Z}$ for $k = 0, 1, \dots, 7$.

The limits of (1.143) are the three groups

$$TOP = \varinjlim TOP_n, \qquad PL = \varinjlim PL_n, \qquad DIFF = \varinjlim DIFF_n \simeq \mathrm{O}. \tag{1.144}$$

Why go to the limit? Because the questions we ask are *stable*. Replacing M by $M \times \mathbb{R}^k$ adds a trivial bundle to its tangent bundle, $T(M \times \mathbb{R}^k) = TM \oplus \underline{\mathbb{R}}^k$, and does not change whether M can be smoothed (in the range of dimensions where the theory works). Stable questions are governed by the limit groups, whose homotopy groups are simpler and are known.

1.6.2 Classifying spaces and the three tangent bundles

Each of the groups TOP, PL, $DIFF$ has a classifying space, $BTOP$, BPL, $BDIFF \simeq BO$, built exactly as in Section 1.5.11: a contractible space with a free action of the group, divided by that action. By (1.126), a bundle with structure group G over M is the same thing as a homotopy class of maps $M \to BG$.

What bundle? The tangent bundle. For a smooth manifold this is the ordinary TM, glued by the Jacobians. For a PL or a topological manifold there are no Jacobians, but there is still a "tangent bundle" whose transition functions are the $g_{\alpha\beta}$ themselves, germs of homeomorphisms near a point.

Working definition 1.43 (topological tangent bundle)

For a topological manifold M, take a small neighbourhood U of the diagonal $\{(x,x)\}$ in $M \times M$ and project to the first factor, $(x,y) \mapsto x$. The fibre over x is a neighbourhood of x in M, a copy of $\mathbb{R}^n$ with a marked point x (the "origin"). Changing coordinates near x changes this $\mathbb{R}^n$ by an element of TOP_n [a homeomorphism of $\mathbb{R}^n$ fixing the origin]. This bundle with fibre $\mathbb{R}^n$ and structure group TOP_n is the **tangent microbundle** TM_{TOP} (Milnor). For a smooth M, the exponential map [a tangent vector v at x goes to the point reached by the geodesic from x with velocity v after unit time] identifies it with TM. *Operationally*: it is recorded by its classifying map $\tau_M : M \to BTOP_n$ [the map, unique up to homotopy, along which this bundle is pulled back from the universal one], stabilised to $M \to BTOP$.

Physical picture: The tangent space of a manifold without derivatives

Zoom in on a point of a smooth manifold and it looks like a vector space: that is T_xM. Zoom in on a topological manifold and you still see $\mathbb{R}^n$, but you have lost the linear structure, so "tangent vectors" can be added only up to homeomorphism. The microbundle keeps exactly the part of the tangent bundle that survives: the local copy of $\mathbb{R}^n$ and how these copies are glued.

So each type of manifold comes with a map, and the type of M is encoded in which space the map lands in:

$$TM_{TOP} \leftrightarrow [M, BTOP], \qquad TM_{PL} \leftrightarrow [M, BPL], \qquad TM_{DIFF} \leftrightarrow [M, BDIFF]. \tag{1.145}$$

A PL manifold is in particular topological, so its tangent map $M \to BPL$ can be composed with $BPL \to BTOP$ to give the topological tangent map. The question "does the topological manifold M admit a PL structure?" therefore has a *necessary condition* that is pure homotopy theory: $\tau_M : M \to BTOP$ must factor through BPL.

The fibre of $BH \to BG$ is G/H

Nash states that $BPL \to BTOP$ can be made into a fibration with fibre TOP/PL. This is an instance of a general and very useful fact. Let $H \subset G$ be a subgroup, and let E_G be the contractible space with free G action. Then H also acts freely on E_G, so E_G serves as E_H too, and

$$BH \overset{(1)}{=} E_G/H \xrightarrow{\ \pi\ } E_G/G \overset{(2)}{=} BG, \qquad \pi^{-1}\big([e]\big) \overset{(3)}{=} \{[eg]_H : g \in G\} \overset{(4)}{=} G/H. \tag{1.146}$$

(1) E_G is contractible with a free H action, which is all a universal H-bundle needs.
(2) The definition of BG.
(3) π sends an H-orbit to the G-orbit containing it. The H-orbits inside the G-orbit of a point e are the classes $[eg]_H$.
(4) eg and eg' lie in the same H-orbit iff $g' \in Hg$, since the action is free. So the fibre is the coset space (right or left cosets, depending on the side on which the group acts).

So for every inclusion of groups there is a fibration

$$G/H \longrightarrow BH \xrightarrow{\ \pi\ } BG, \tag{1.147}$$

and Nash's (1.148) below is the case $H = PL$, $G = TOP$.

Worked example 1.109: Fibres we already know

- $H = \mathrm{O}(n-1) \subset G = \mathrm{O}(n)$. The group $\mathrm{O}(n)$ moves the unit vector e_n to any unit vector, and the matrices fixing e_n form $\mathrm{O}(n-1)$. So $\mathrm{O}(n)/\mathrm{O}(n-1) = S^{n-1}$, and $S^{n-1} \to BO(n-1) \to BO(n)$. Lifting the tangent map of M from $BO(n)$ to $BO(n-1)$ means splitting $TM = L \oplus \xi$ with L a trivial line: it means finding a *nowhere-vanishing vector field*.
- $H = \mathrm{SO}(n) \subset G = \mathrm{O}(n)$. Here $\mathrm{O}(n)/\mathrm{SO}(n) = \{\pm 1\}$ via the determinant. Lifting from $BO(n)$ to $BSO(n)$ means choosing an *orientation*.
- $\mathrm{Spin}(n) \to \mathrm{SO}(n)$ is not an inclusion but a double cover with kernel $\mathbb{Z}_2$ (Chapter T4). The same argument with G/H replaced by B(kernel) gives the fibration $B\mathbb{Z}_2 \to$

$B\mathrm{Spin}(n) \to BSO(n)$, with fibre $B\mathbb{Z}_2 = \mathbb{RP}^\infty = K(\mathbb{Z}_2, 1)$. Lifting means choosing a *spin structure*.

Vector fields, orientations and spinors are all lifting problems of exactly the same type as straightening and smoothing. We shall solve these three first, because we can check the answers by hand.

1.6.3 Straightening and smoothing as lifting problems

Apply (1.147) to $PL \subset TOP$:

$$\begin{array}{ccc} TOP/PL & \longrightarrow & BPL \\ & & \downarrow{\scriptstyle \pi} \\ & & BTOP \end{array} \tag{1.148}$$

A topological manifold M gives its tangent map $\alpha = \tau_M : M \to BTOP$. If M carries a PL structure, its PL tangent bundle gives $\beta : M \to BPL$ with $\pi \circ \beta = \alpha$. Nash's proposal is to run this backwards: *try to factorise α through BPL; if you succeed, M acquires a PL structure.*

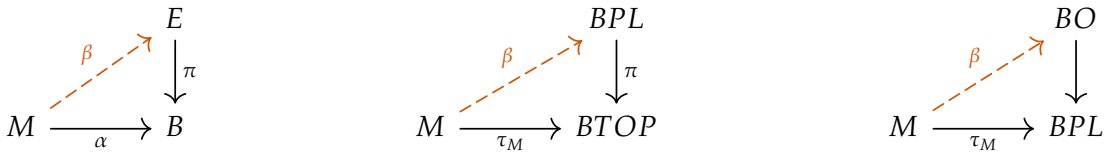

Figure 1.59: Three lifting problems. Left: the general problem (1.149) for a fibration $F \to E \to B$. Middle: "can the topological manifold M be straightened?" Right: "can the PL manifold M be smoothed?" In each case we are given the solid arrow and ask for the dashed (orange) one making the triangle commute, $\pi \circ \beta = \alpha$.

The general form of the question is [Nash p. 20, (1.61)]: given a fibration $F \to E \xrightarrow{\pi} B$ and a map $\alpha : M \to B$, find

$$\beta : M \to E \qquad \text{with} \qquad \alpha = \pi \circ \beta. \tag{1.149}$$

There is an equivalent way to say this that will make the solution transparent. Pull the fibration back along α (Section 1.5.10): $\alpha^*E = \{(m, e) \in M \times E : \alpha(m) = \pi(e)\}$ is a fibration over M with the same fibre F. A lift β is the same thing as a *section* $m \mapsto (m, \beta(m))$ of α^*E. So

lifting α through E = finding a section of a bundle over M with fibre F.

We know from the Möbius band and the hairy ball (Sections 1.5.3 and 1.5.8) that sections of twisted bundles can fail to exist. Obstruction theory measures exactly how.

Watch out: A lift is not yet a structure

Every PL structure gives a lift, but the converse "every lift comes from a PL structure" is a theorem, not a tautology. It is the content of the work of Kirby and Siebenmann, and it holds when $\dim M \geq 5$ ($\dim M \geq 6$ if M has a boundary) [Nash p. 20, footnote 5]. The dimension restriction is the same "room to move" we met in §1.1: the proof needs the Whitney trick, which separates two intersecting discs by sliding one over a third disc, and that disc can be pushed off everything else only when $\dim M \geq 5$. In dimension 4 the lifting problem is still well posed but its answer no longer decides the geometric question; see Section 1.6.7. The smoothing theory of Hirsch and Mazur plays the same role for

$PL \to DIFF$.

1.6.4 Obstruction theory: extending a section cell by cell

We want a section of a bundle $F \to \alpha^*E \to M$. Build M out of cells: points (0-cells), then segments glued along their end points (1-cells), then discs glued along their boundary circles (2-cells), and so on. This is a triangulation, or more economically a cell decomposition like those of Section 1.4.6. The union of the cells of dimension $\leq k$ is the **k-skeleton** $M^{(k)}$. We build the section one skeleton at a time.

- *0-cells.* Over each vertex choose any point of the fibre. Possible as long as $F \neq \varnothing$.
- *1-cells.* Over each edge, the section is already given at its two end points, two points of F. We need a path in F joining them. Possible for every edge if F is path-connected, $\pi_0(F) = 0$.
- *k-cells.* Over each cell e^k the bundle is trivial (e^k is contractible), so a section over e^k is a map $e^k \to F$. The section is already defined on the boundary $\partial e^k \cong S^{k-1}$. That boundary map $S^{k-1} \to F$ extends over the disc iff it is null-homotopic, that is, iff its class in $\pi_{k-1}(F)$ vanishes.

Working definition 1.44 (obstruction cocycle and obstruction class)

Suppose a section s has been built on the $(k-1)$-skeleton. For each k-cell e^k let

$$c(s)(e^k) = \left[\, s|_{\partial e^k} : S^{k-1} \to F \,\right] \in \pi_{k-1}(F). \tag{1.150}$$

This assigns an element of the group $\pi_{k-1}(F)$ to every k-cell: it is a k-cochain with coefficients in $\pi_{k-1}(F)$ (Section 1.4.7). It is a cocycle [$\delta c(s) = 0$: summed over the boundary of any $(k+1)$-cell, $c(s)$ gives 0], and changing s on the $(k-1)$-cells changes $c(s)$ by a coboundary [a cochain of the form δd]. Its class

$$\mathfrak{o}_k \in H^k\big(M; \pi_{k-1}(F)\big) \tag{1.151}$$

is the **obstruction class**. *Operationally*: s extends over the k-skeleton (after possibly changing it on the $(k-1)$-skeleton) iff $\mathfrak{o}_k = 0$. Writing $k = n+1$ gives Nash's form $H^{n+1}(M; \pi_n(F))$ [Nash p. 21, (1.62)].

Two facts make this practical.

- *Only the homotopy groups of F enter.* If $\pi_j(F) = 0$ for all $j < n$, there are no obstructions until $k = n+1$: the first possibly non-zero one is the **primary obstruction** in $H^{n+1}(M; \pi_n(F))$. If F is contractible there are no obstructions at all, which is why every bundle has a classifying map (Section 1.5.11).
- *Counting answers.* Two sections that agree on the $(n-1)$-skeleton differ on each n-cell by an element of $\pi_n(F)$ (glue the two discs along their common boundary to get an n-sphere in F). This **difference cochain** is an n-cochain with values in $\pi_n(F)$, and the two sections are homotopic iff its class in $H^n(M; \pi_n(F))$ vanishes. When F has a single homotopy group $\pi_n(F)$, that is when $F = K(\pi, n)$ (Section 1.4.1), homotopy classes of lifts, if there are any, are counted exactly by $H^n(M; \pi_n(F))$ [Nash p. 21, (1.66)].

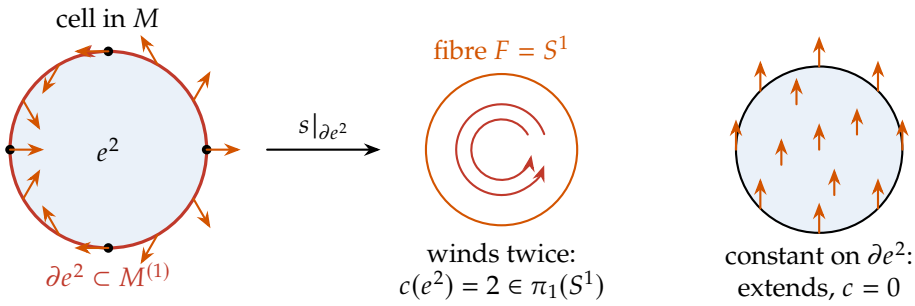

Figure 1.60: Obstruction theory for a section with fibre S^1 (a unit vector field on a surface). The section is known on the boundary of a 2-cell. Left: the arrows turn twice as we go once round the boundary, so the boundary map $S^1 \to F = S^1$ has degree 2, and no continuous choice of arrows fills the disc: the obstruction cochain takes the value 2 on this cell. Right: if the boundary arrows do not turn, we just continue them inwards, and the section extends.

Why is the obstruction cochain a cocycle? Look at the case $k = 2$ with fibre S^1 of the figure, and at a 3-cell e^3. Its boundary is a 2-sphere tiled by 2-cells (faces), and over the whole of e^3 the bundle is trivial, so the section on the edges of the tiling is just an angle ϑ attached to each point of each edge. The obstruction on a face is its winding number, $\frac{1}{2\pi}$ times the total change of ϑ as we run once round the edges of that face. Now add up over all faces of the 2-sphere. Each edge lies on exactly two faces, and is traversed in opposite directions by them, so its change of ϑ enters once with each sign:

$$\begin{aligned}(\delta c)(e^3) &\overset{(1)}{=} \sum_{\text{faces } f \subset \partial e^3} \pm c(f) \\ &\overset{(2)}{=} \frac{1}{2\pi} \sum_{f} \sum_{\text{edges } \ell \subset \partial f} \pm \Delta_\ell \vartheta \\ &\overset{(3)}{=} 0.\end{aligned}$$

(1) The coboundary of a cochain evaluates it on the boundary of the cell, with incidence signs (Section 1.4.7).
(2) The winding number of a face is the sum of the angle changes $\Delta_\ell \vartheta$ along its edges; the signs record the direction in which the face runs along each edge.
(3) Every edge appears twice, with opposite signs: this is $\partial\partial = 0$ for the tiled sphere.

So $\delta c = 0$. In higher degree the argument is the same with "angle changes" replaced by homotopy classes: it is the discrete Stokes theorem of Section 1.4.7, which is why obstructions are *cohomology* classes.

Worked examples of lifting problems

Worked example 1.110: Nowhere-vanishing vector fields on surfaces: the obstruction is χ

A nowhere-zero vector field on an oriented surface M is (after normalising it) a section of the unit tangent bundle $S^1 \to UTM \to M$. The fibre S^1 is connected, and $\pi_1(S^1) = \mathbb{Z}$. So the first obstruction lies in

$$H^2\big(M; \pi_1(S^1)\big) = H^2(M; \mathbb{Z}) \cong \mathbb{Z},$$

the last step for closed oriented M by Poincaré duality (1.95).
The sphere. Use the two patches of Section 1.5.8: $O_0 = S^2 \setminus \{N\}$ with coordinate z and

$O_1 = S^2 \setminus \{S\}$ with coordinate $w = 1/z$. Take the section $v = \partial_z$ on O_0. It is constant in the z-trivialisation, so it is a perfectly good nowhere-zero section over everything except the north pole. What is left is to extend it over one 2-cell, the northern cap $D_N = \{|w| \le 1\}$. In the w-trivialisation its component is, by (1.121),

$$v^w = \frac{\mathrm{d}w}{\mathrm{d}z} \cdot 1 = -\frac{1}{z^2} = -w^2.$$

The obstruction on D_N is the winding number of this map from the boundary circle $w = e^{i\psi}$ to the fibre (directions in the tangent plane):

$$\begin{aligned} c(D_N) &\overset{(1)}{=} \frac{1}{2\pi i} \oint_{|w|=1} \frac{\mathrm{d}v^w}{v^w} \\ &\overset{(2)}{=} \frac{1}{2\pi i} \int_0^{2\pi} 2i \, \mathrm{d}\psi \\ &\overset{(3)}{=} 2. \end{aligned}$$

(1) The degree of a map $S^1 \to S^1$, $\psi \mapsto u(\psi)$, is $\frac{1}{2\pi i} \oint \mathrm{d} \log u$ (§1.3). Only the direction of v matters, and d log ignores the modulus.
(2) $\mathrm{d}\log(-w^2) = 2\,\mathrm{d}w/w = 2i\,\mathrm{d}\psi$ on $w = e^{i\psi}$.
(3) The integrand is constant.

So $\mathfrak{v}_2 = 2 \neq 0$ and v cannot be extended without a zero: the hairy ball theorem again. Indeed the obvious extension $v^w = -w^2$ has a double zero, of index 2, at the north pole, exactly as in Figure 1.60 (left). The number is $2 = \chi(S^2)$.
The torus. $T^2 = \mathbb{R}^2/\mathbb{Z}^2$ has the global field ∂_{θ_1}, so the obstruction must vanish, and $\chi(T^2) = 0$.
In general the obstruction class, evaluated on $[M]$, is the sum of the indices of the zeros of any vector field (each zero is a 2-cell over which the field failed to extend), and by the Poincaré–Hopf theorem that sum is $\chi(M) = 2 - 2g$. The obstruction class is the **Euler class** of TM (Section 1.5.12). We will derive Poincaré–Hopf from Morse theory in Chapter 7.

Worked example 1.111: Orientation and spin structures

Let M be a Riemannian manifold with tangent map $\tau : M \to BO(n)$.
Orientation. The fibration $\mathrm{O}(n)/\mathrm{SO}(n) = \mathbb{Z}_2 \to BSO(n) \to BO(n)$ has discrete fibre, $\pi_0(\mathbb{Z}_2) = \mathbb{Z}_2$ (two points, thought of as the group $\mathbb{Z}_2$) and no higher homotopy. The only obstruction is to extending over 1-cells:

$$w_1(M) \in H^1(M; \mathbb{Z}_2).$$

On a closed loop γ, $w_1[\gamma]$ records whether an orthonormal frame carried round γ comes back with the same or the opposite orientation, i.e. the sign of det of the holonomy of the frame bundle. For the Möbius band and for $\mathbb{RP}^2$ it is 1 on the core loop, so they are non-orientable. If $w_1 = 0$ the choices are counted by $H^0(M; \mathbb{Z}_2) = \mathbb{Z}_2$ for connected M: the two orientations.
Spin structure. Now let M be oriented, and use $B\mathbb{Z}_2 \to B\mathrm{Spin}(n) \to BSO(n)$. The fibre is $K(\mathbb{Z}_2, 1)$, whose only homotopy group is $\pi_1 = \mathbb{Z}_2$. So the obstruction is the second Stiefel–Whitney class and the choices form a group:

$$\text{obstruction } w_2(M) \in H^2(M; \mathbb{Z}_2), \qquad \text{spin structures} \;\leftrightarrow\; H^1(M; \mathbb{Z}_2) \;\; (\text{if } w_2 = 0). \quad (1.152)$$

For the torus T^2 (which has a global frame, so $w_2 = 0$),

$$\#\{\text{spin structures on } T^2\} \overset{(1)}{=} \left|H^1(T^2;\mathbb{Z}_2)\right| \overset{(2)}{=} |\mathbb{Z}_2 \oplus \mathbb{Z}_2| = 4.$$

(1) (1.152); the fibre is a $K(\mathbb{Z}_2,1)$, so lifts are counted by H^1.
(2) $H^1(T^2;\mathbb{Z}) = \mathbb{Z}^2$ and there is no torsion, so reducing mod 2 gives $\mathbb{Z}_2^2$ (universal coefficients, Section 1.4.7).

These four are the four choices of periodic or antiperiodic boundary conditions for a fermion around the two cycles of the torus: $(P,P),(P,A),(A,P),(A,A)$, the Ramond and Neveu–Schwarz sectors of string theory (Chapter 9). A class in $H^1(M;\mathbb{Z}_2)$ is precisely a choice of sign ± 1 for each loop: the sign a spinor picks up when transported around it.

structure	fibration	fibre	obstruction	choices
vector field $\neq 0$	$BO(n-1) \to BO(n)$	S^{n-1}	$e(M) \in H^n(M;\mathbb{Z})$	(harder)
orientation	$BSO(n) \to BO(n)$	$\mathbb{Z}_2 = K(\mathbb{Z}_2,0)$	$w_1 \in H^1(M;\mathbb{Z}_2)$	$H^0(M;\mathbb{Z}_2)$
spin structure	$B\mathrm{Spin}(n) \to BSO(n)$	$K(\mathbb{Z}_2,1)$	$w_2 \in H^2(M;\mathbb{Z}_2)$	$H^1(M;\mathbb{Z}_2)$
PL structure	$BPL \to BTOP$	$K(\mathbb{Z}_2,3)$	$ks \in H^4(M;\mathbb{Z}_2)$	$H^3(M;\mathbb{Z}_2)$
smooth structure	$BO \to BPL$	PL/O	$H^{k+1}(M;\pi_k)$	$H^k(M;\pi_k)$, $\pi_k = \pi_k(PL/\mathrm{O})$

The table is the point of this subsection: *straightening and smoothing are the same kind of problem as choosing an orientation or a spin structure.* The only new input is the homotopy of the fibres TOP/PL and PL/O, to which we now turn.

Watch out: Local coefficients

In $H^{n+1}(M;\pi_n(F))$ the coefficient group is really a family of groups $\pi_n(F_b)$, one for each fibre F_b over $b \in B$. They are all isomorphic, since all fibres have the same homotopy type, but not canonically: carrying F_b around a loop in B can act on $\pi_n(F_b)$ by a non-trivial automorphism. When π_1 acts non-trivially, one must use **cohomology with local coefficients**, a twisted version in which the coefficients themselves form a bundle of groups [Nash p. 21, footnote 6]. Example: the Euler class of a non-orientable surface lives in H^2 with $\mathbb{Z}$ twisted by the orientation character, because going round an orientation-reversing loop sends the winding number $w \in \pi_1(S^1)$ to $-w$. For TOP/PL the coefficients are $\mathbb{Z}_2$, which has no non-trivial automorphism, so no twisting can occur, and Nash may safely write $\pi_n(TOP/PL)$.

1.6.5 From topological to PL: the Kirby–Siebenmann class

For the lifting (1.148) the obstructions lie in [Nash p. 21, (1.63)]

$$H^{n+1}\big(M;\pi_n(TOP/PL)\big), \tag{1.153}$$

and Kirby and Siebenmann computed the coefficients [Nash p. 21, (1.64)]:

$$\pi_n(TOP/PL) = \begin{cases} \mathbb{Z}_2 & n = 3, \\ 0 & \text{otherwise.} \end{cases} \tag{1.154}$$

A space with exactly one non-zero homotopy group is an Eilenberg–MacLane space (Section 1.4.1), so $TOP/PL \simeq K(\mathbb{Z}_2, 3)$. Everything now follows from the table above.

Key idea: Straightening a topological manifold, $\dim M \geq 5$

- There is exactly one obstruction, the **Kirby–Siebenmann class**

$$ks(M) \in H^4(M; \mathbb{Z}_2). \tag{1.155}$$

  M admits a PL structure iff $ks(M) = 0$.

- If $ks(M) = 0$, the PL structures (up to concordance, i.e. up to deformation) are in one-to-one correspondence with

$$H^3(M; \mathbb{Z}_2). \tag{1.156}$$

Both lines come from (1.151) and the difference-cochain count, with the single non-zero coefficient group:

$$\text{obstructions} \overset{(1)}{=} \bigoplus_n H^{n+1}\big(M; \pi_n(TOP/PL)\big) \overset{(2)}{=} H^{3+1}(M; \mathbb{Z}_2),$$

$$\text{choices} \overset{(3)}{=} H^n\big(M; \pi_n(TOP/PL)\big)\big|_{n=3} = H^3(M; \mathbb{Z}_2).$$

(1) The possible obstructions, one for each homotopy group of the fibre.
(2) By (1.154) only $n = 3$ survives.
(3) The fibre is $K(\mathbb{Z}_2, 3)$, so lifts are counted by H^3 with coefficients in its one homotopy group.

Nash calls the class $e(M)$. We write $ks(M)$ to avoid a clash with the Euler class. As Nash notes [Nash p. 21, footnote 7], it is a characteristic class: there is a *universal* class $d \in H^4(BTOP; \mathbb{Z}_2)$, the obstruction for the universal bundle, and $ks(M) = \tau_M^* d$ is its pullback by the tangent map. So ks is to topological manifolds what w_1 is to orientability and w_2 to spin.

Worked example 1.112: How many PL structures?

Spheres. For $n \geq 5$, $H^4(S^n; \mathbb{Z}_2) = 0$ and $H^3(S^n; \mathbb{Z}_2) = 0$ by (1.91) (with $\mathbb{Z}_2$ in place of $\mathbb{Z}$; the same Mayer–Vietoris argument works). So S^n has a PL structure and it is unique.
Tori. For the torus T^n, $n \geq 5$, the obstruction vanishes because T^n is smooth. The count is

$$\#\{\text{PL structures on } T^n\} \overset{(1)}{=} \left|H^3(T^n; \mathbb{Z}_2)\right| \overset{(2)}{=} \left|\mathbb{Z}_2^{\binom{n}{3}}\right| = 2^{\binom{n}{3}},$$

(1) (1.156).
(2) The Künneth theorem (Section 1.4.10): $H^*(T^n)$ is the exterior algebra on n generators of degree 1, so H^3 has a basis $\mathrm{d}\theta_i \wedge \mathrm{d}\theta_j \wedge \mathrm{d}\theta_k$, $i < j < k$, one for each of the $\binom{n}{3}$ triples. There is no torsion, so the same holds mod 2.

For T^5 that is $2^{10} = 1024$ PL structures up to concordance. Some of them give PL manifolds that are homeomorphic to T^5 but not PL-homeomorphic to it: the "fake tori" of Hsiang–Shaneson and Wall, which played a central role in Kirby's proof.

Physical picture: The Hauptvermutung

The *Hauptvermutung* ("main conjecture", Steinitz and Tietze, 1908) said that two triangulations of the same space always have a common subdivision: triangulations are unique up to refinement, so "PL" adds nothing to "TOP". For polyhedra Milnor disproved it in 1961. For manifolds, (1.156) disproves it whenever $H^3(M;\mathbb{Z}_2)$ produces genuinely different PL manifolds, as for the fake tori. Nash's two consequences [Nash p. 22]:

- there are PL manifolds that are homeomorphic but admit no PL homeomorphism between them;
- if $ks(M) \neq 0$, the topological manifold M has no PL structure at all, i.e. it cannot be triangulated by a triangulation that is a PL manifold.

In low dimension the question is empty: Radó (1925) proved that every surface has a unique PL structure, and Moise (1952) did the same for 3-manifolds. So $TOP = PL$ for $\dim M \leq 3$. Dimension 4 is the interesting case; Nash postpones it and so do we, to Section 1.6.7.

1.6.6 From PL to smooth, and the exotic 7-spheres

Smoothing a PL manifold M with $\dim M \geq 5$ is the same kind of problem, with the fibration [Nash p. 22, (1.68)]

$$\begin{array}{ccc} PL/DIFF & \longrightarrow & BDIFF \\ & & \downarrow{\scriptstyle \pi} \\ & & BPL \end{array} \tag{1.157}$$

The difference is in the fibre. Its homotopy groups are much richer [Nash p. 22, (1.69)]. We complete Nash's table:

n	≤ 6	7	8	9	10	11	12	13	14	15	16
$\pi_n(PL/\mathrm{O})$	0	$\mathbb{Z}_{28}$	$\mathbb{Z}_2$	$\mathbb{Z}_2^3$	$\mathbb{Z}_6$	$\mathbb{Z}_{992}$	0	$\mathbb{Z}_3$	$\mathbb{Z}_2$	$\mathbb{Z}_{8128} \oplus \mathbb{Z}_2$	$\mathbb{Z}_2$

(1.158)

For $n \geq 7$ (in fact for $n \geq 5$) these groups are the groups Θ_n of Kervaire and Milnor: the set of smooth structures on the topological n-sphere, up to orientation-preserving diffeomorphism, made into an abelian group by connected sum.

Key idea: Smoothing, $\dim M \geq 5$

Obstructions to smoothing a PL manifold lie in $H^{k+1}(M;\pi_k(PL/\mathrm{O}))$, and when they vanish the smooth structures (up to concordance) are counted by the groups $H^k(M;\pi_k(PL/\mathrm{O}))$, in the sense of obstruction theory. Since $\pi_k(PL/\mathrm{O}) = 0$ for $k \leq 6$, *every PL manifold of dimension* ≤ 7 *is smoothable, and in dimension* ≤ 6 *the smoothing is unique.*

Worked example 1.113: The 28 smooth structures on S^7

Take $M = S^7$ with its PL structure. The first non-zero coefficient group is $\pi_7(PL/\mathrm{O}) = \mathbb{Z}_{28}$.

$$\begin{aligned} \text{obstruction} &\overset{(1)}{=} H^8\big(S^7;\pi_7(PL/\mathrm{O})\big) \overset{(2)}{=} 0, \\ \text{smoothings} &\overset{(3)}{=} H^7\big(S^7;\pi_7(PL/\mathrm{O})\big) \overset{(4)}{=} \mathbb{Z}_{28}. \end{aligned} \tag{1.159}$$

(1) The first possibly non-zero obstruction: $k = 7$ in $H^{k+1}(M;\pi_k)$ [Nash (1.70)].

(2) A 7-dimensional space has no cohomology in degree 8: there are no 8-cells.
(3) The first possibly non-zero choice group [Nash (1.71)]. The groups $H^k(S^7;\pi_k)$ for other k vanish, either because $\pi_k = 0$ ($k \le 6$) or because $H^k(S^7) = 0$ ($k \ge 8$).
(4) $H^7(S^7;G) = G$ for any coefficient group G, by (1.91).

So S^7 can be smoothed (we knew that: the round sphere is smooth), and there are 28 smoothings. One is the standard one; the other 27 are **exotic spheres**: smooth manifolds homeomorphic, but not diffeomorphic, to S^7 (Milnor 1956, Kervaire–Milnor 1963).

Watch out: 28 or 15?

The 28 counts oriented smooth structures up to *orientation-preserving* diffeomorphism. Reversing orientation sends the class $x \in \Theta_7 = \mathbb{Z}_{28}$ to $-x$. If we allow orientation-reversing diffeomorphisms too, x and $-x$ are identified, leaving 15 classes (0, 14, and thirteen pairs $\pm x$). Nash's "27 exotic spheres" is the oriented count.

Obstruction theory tells us there are 28 smoothings, but it does not show us one. Milnor's original construction is explicit, and it is a beautiful application of everything in Section 1.5: clutching, characteristic classes and the signature. We give it in full, because it is the prototype of every exotic structure.

Worked example 1.114: Milnor's exotic spheres as S^3 bundles over S^4

The bundles. By clutching (1.111), vector bundles of rank 4 over S^4 are classified by $\pi_3(\mathrm{SO}(4)) \cong \mathbb{Z} \oplus \mathbb{Z}$. Explicit representatives: identify $\mathbb{R}^4$ with the quaternions $\mathbb{H}$ and S^3 with the unit quaternions, and for integers h, j let

$$g_{h,j} : S^3 \to \mathrm{SO}(4), \qquad g_{h,j}(u)\,v = u^h\, v\, u^j \qquad (u \in S^3,\ v \in \mathbb{H}). \tag{1.160}$$

(Left and right multiplication by unit quaternions preserve $|v|$, so $g_{h,j}(u) \in \mathrm{SO}(4)$.) Let $\xi_{h,j}$ be the rank-4 bundle with this clutching function, $W_{h,j}$ its unit disc bundle (an 8-manifold with boundary) and $M_{h,j} = \partial W_{h,j}$ its unit sphere bundle, a 7-manifold fibred as $S^3 \to M_{h,j} \to S^4$. The two characteristic numbers of $\xi_{h,j}$ are (Milnor)

$$e(\xi_{h,j})[S^4] = h + j, \qquad p_1(\xi_{h,j})[S^4] = \pm 2(h - j). \tag{1.161}$$

For $h = 1, j = 0$ this is the quaternionic Hopf bundle, whose sphere bundle is $S^7 \to S^4$ (the quaternionic analogue of $S^3 \to S^2$, Section 1.5.7).

They are topological spheres. Take $h + j = 1$ and put $k = h - j$ (an odd integer). Milnor wrote down a smooth function on $M_{h,j}$ with exactly two critical points, a maximum and a minimum. A closed manifold with such a function is homeomorphic to a sphere (Reeb's theorem: it is two discs glued along their boundary; Chapter 7). So each $M_k = M_{h,j}$ is homeomorphic to S^7.

Some are not diffeomorphic to S^7. For a closed smooth oriented 8-manifold X, the Hirzebruch signature theorem (Chapter 4) gives

$$\sigma(X) = \frac{7p_2 - p_1^2}{45}[X], \qquad \text{so} \qquad 45\,\sigma(X) + p_1^2[X] = 7\,p_2[X] \equiv 0 \pmod 7.$$

Since $45 \equiv 3$, multiplying by 2 gives $6\sigma + 2p_1^2 \equiv -\sigma + 2p_1^2 \equiv 0 \pmod 7$. Now suppose M_k were diffeomorphic to S^7. Then we could glue an 8-disc onto $W = W_{h,j}$ along M_k and get a closed smooth 8-manifold X with the same H^4, the same p_1 and the same signature as W.

Compute:

$$\begin{aligned} 0 &\overset{(1)}{=} 2p_1^2[X] - \sigma(X) \pmod 7 \\ &\overset{(2)}{=} 2(2k)^2 - 1 \\ &\overset{(3)}{=} 8k^2 - 1 \;\equiv\; k^2 - 1 \pmod 7. \end{aligned}$$

(1) The mod-7 consequence of the signature theorem derived above, applied to the closed manifold X.

(2) $H^4(X) = H^4(W) = H^4(S^4) = \mathbb{Z}$ (the disc bundle retracts onto its zero section, and the 8-disc adds nothing in degree 4), generated by a class x. The tangent bundle of W is $\pi^*(TS^4 \oplus \xi)$ and TS^4 is stably trivial, so $p_1(X) = p_1(\xi) = \pm 2k\,x$ by (1.161). The self-intersection of the zero section $S^4 \subset W$ is the Euler number $h + j = 1$, so $x^2[X] = 1$: the intersection form is the 1×1 matrix (1). Hence $p_1^2[X] = 4k^2$ and $\sigma(X) = 1$.

(3) $8 \equiv 1 \pmod 7$.

So if $k^2 \not\equiv 1 \pmod 7$, M_k is *not* diffeomorphic to S^7. For $k = 1$ ($h = 1, j = 0$) we get 0: consistent, it is the Hopf S^7. For $k = 3$ ($h = 2, j = -1$) we get $k^2 - 1 = 8 \equiv 1 \neq 0$: M_3 *is an exotic 7-sphere.* Milnor's invariant $\lambda(M_k) = k^2 - 1 \bmod 7$ takes the values $0, 1, 3, 6$ for $k = 1, 3, 5, \ldots$ (as $k^2 \bmod 7 \in \{1, 2, 4, 0\}$), so it already detects several distinct exotic spheres.

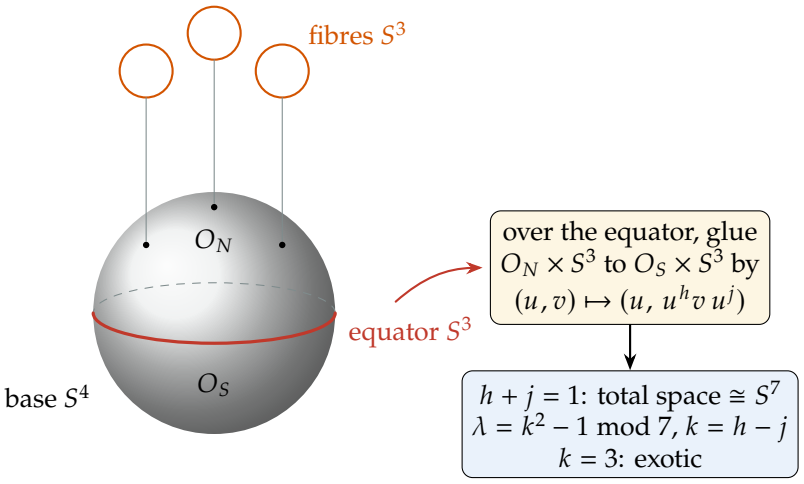

Figure 1.61: Milnor's construction. A 7-manifold is built as a bundle of 3-spheres over S^4, glued over the equatorial S^3 by the quaternionic clutching function (1.160). When $h + j = 1$ the result is always a topological 7-sphere, but the mod-7 invariant computed from p_1 and the signature shows that for $h - j = \pm 3$ it cannot be the standard smooth sphere.

Physical picture: Where are the exotic spheres "hidden"?

Every exotic 7-sphere is obtained from two standard 7-discs by gluing their boundary 6-spheres with a diffeomorphism $\phi : S^6 \to S^6$ that is not isotopic to the identity (Smale). Topologically every such ϕ can be straightened (the Alexander trick: cone it off, $x \mapsto |x|\ \phi(x/|x|)$, which is a homeomorphism of the disc but not smooth at the centre). Smoothly it cannot. So an exotic sphere is a "twisted double" whose twist is invisible to continuity and visible to derivatives: the smooth analogue of a non-trivial transition function. Another

model, due to Brieskorn, sits inside $\mathbb{C}^5$:

$$\Sigma_k = \{z \in \mathbb{C}^5 : \ z_1^{6k-1} + z_2^3 + z_3^2 + z_4^2 + z_5^2 = 0, \ |z| = 1\}, \qquad k = 1, \dots, 28,$$

and Σ_k represents k times a generator of $\Theta_7 = \mathbb{Z}_{28}$, so these 28 algebraic links run through all the smooth structures on S^7, with Σ_{28} standard.

n	1	2	3	4	5	6	7	8	9	10	11
smooth structures on S^n	1	1	1	?	1	1	28	2	8	6	992
smooth structures on $\mathbb{R}^n$	1	1	1	$2^{\aleph_0}$	1	1	1	1	1	1	1

The table (oriented counts) shows how odd dimension 4 is. For S^4 nobody knows whether there is an exotic structure: that is the *smooth 4-dimensional Poincaré conjecture*, still open. For $\mathbb{R}^4$ there are uncountably many (Section 1.6.12). In every other dimension $\mathbb{R}^n$ has exactly one.

Finally, PL and DIFF agree in low dimension: by the work of Kirby–Siebenmann and Kuiper cited by Nash [Nash p. 23], and in fact because $\pi_k(PL/\mathrm{O}) = 0$ for all $k \leq 6$, a PL manifold of dimension ≤ 6 has a unique smooth structure. (Nash states the bijection for dim $M \leq 3$; it holds in dimension 4 too, by Cerf's theorem, which is why Nash says a PL 4-manifold has a unique smooth structure.) So in dimension 4 the only gap is between TOP and PL=DIFF, and that is where we now go.

Reading Nash (pp. 19–23, (1.59)–(1.71))

Nash introduces TOP_n, PL_n, $DIFF_n$ and their direct limits in half a page (1.59), and the classifying spaces and $[M, BTOP]$, $[M, BPL]$, $[M, BDIFF]$ in a paragraph. We added: the linearisation (1.142) showing $DIFF_n \simeq \mathrm{O}(n)$; the tangent microbundle; the general fibre G/H of $BH \to BG$ (1.146), of which his (1.60) and (1.68) are instances; and the cell-by-cell construction behind the obstruction groups (1.62). His "one can check that the fibre is TOP/PL" is (1.146). His $e(M)$ is our $ks(M)$. His (1.66)–(1.67) ("the answer is just the whole cohomology group") is the difference-cochain count, valid because TOP/PL is a $K(\mathbb{Z}_2, 3)$. His (1.69) is our (1.158); his (1.70)–(1.71) are (1.159). The explicit Milnor spheres, the worked examples of vector fields, orientations and spin structures, and the fake tori are additions.

1.6.7 Why dimension four is different

In dimension 4, Nash says [Nash p. 23], "there are phenomena which have no counterpart in any other dimension":

- there are topological 4-manifolds with no smooth structure (although a PL 4-manifold has a unique smooth structure, so the whole difficulty is between TOP and PL=DIFF);
- the obstruction to smoothing is not of the type met in Section 1.6.4: it is not the pullback of a class from a classifying space, i.e. not a characteristic class. The Kirby–Siebenmann class $ks(M) \in H^4(M; \mathbb{Z}_2)$ is still defined, and $ks \neq 0$ still forbids smoothing, but $ks = 0$ is no longer enough.

Why does the machine break exactly here? The homotopy theory of the lifting problem is the same in every dimension. What fails is the step "a lift gives a structure", which rests on the geometric **Whitney trick**.

Physical picture: The Whitney trick needs five dimensions

In an n-manifold, a p-dimensional and a q-dimensional submanifold in general position meet in a set of dimension $p + q - n$ (count equations: each surface is cut out by $n - p$ and $n - q$ equations). When $p + q = n$ they meet in isolated points, each with a sign $\pm$ from orientations. The algebraic count is a homological invariant, the intersection number. Suppose two intersection points have opposite signs. Join them by an arc in each submanifold; the two arcs form a loop, and if the manifold is simply connected the loop bounds a disc D, the **Whitney disc**. Pushing one submanifold across D removes both intersection points (Figure 1.62), so the geometric count becomes the algebraic count.
The catch is that D must be embedded and must not meet the submanifolds in its interior. A 2-disc meets a p-dimensional submanifold in dimension $2 + p - n$, and meets itself in dimension $2 + 2 - n$. For $n \geq 5$ (with $p, q \geq 3$, or after the standard manipulations) these are negative, so generic position gives a clean disc. For $n = 4$ and $p = q = 2$ they are 0: *the Whitney disc itself generically has intersection points*, and the trick needs another Whitney disc to remove those, and so on forever. Casson made that infinite tower of discs precise (Casson handles), and Freedman proved, by an extraordinary piece of point-set topology, that the tower always contains a *topological* disc. It does not contain a smooth one in general. That is the gap between TOP and DIFF in dimension 4.

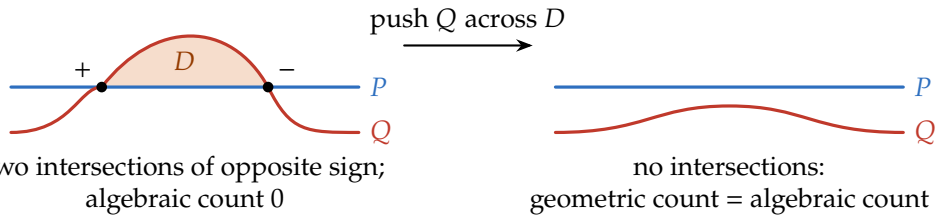

Figure 1.62: The Whitney trick, drawn one dimension down. Two submanifolds P and Q of complementary dimension cross twice with opposite signs. The arcs between the crossings bound the Whitney disc D (orange). Pushing Q across D removes both crossings. In dimension $n \geq 5$ the disc can be chosen embedded and disjoint from everything else; in dimension 4 it generically hits P, Q and itself in points, and the trick fails smoothly.

So in dimension 4 we need a new invariant, one that captures "how 2-dimensional surfaces intersect" directly. That is the intersection form.

1.6.8 The intersection form of a 4-manifold

Let M be a closed, oriented, simply connected 4-manifold. Its interesting cohomology is $H^2(M;\mathbb{Z})$: we have $H^0 = H^4 = \mathbb{Z}$, and $H^1 = H^3 = 0$ because $\pi_1 = 0$ (Hurewicz and Poincaré duality, Section 1.4.10). Two classes of degree 2 multiply to a class of degree 4, which we can evaluate on the fundamental class. Nash's definition [Nash p. 23, (1.72)]:

$$q(\alpha, \beta) = (\alpha \cup \beta)[M] \in \mathbb{Z}, \qquad \alpha, \beta \in H^2(M;\mathbb{Z}). \tag{1.162}$$

Working definition 1.45 (intersection form)

Three equivalent ways to compute q:

- *Forms.* Represent α, β by closed 2-forms with integer periods [$\int_\Sigma \alpha \in \mathbb{Z}$ for every closed surface Σ in M]; then $q(\alpha, \beta) = \int_M \alpha \wedge \beta$.
- *Surfaces.* By Poincaré duality (1.95) each class is dual to an oriented surface Σ_α.

Make $\Sigma_\alpha, \Sigma_\beta$ transverse [meeting at isolated points, where their two tangent planes together span all four directions]; then $q(\alpha,\beta) = \#(\Sigma_\alpha \cap \Sigma_\beta)$, counted with signs. For $q(\alpha,\alpha)$ push Σ_α off itself along a normal vector field and count the zeros of that field: the **self-intersection** number.

- *Matrix.* Choose a basis $e_1, \dots, e_n$ of $H^2(M;\mathbb{Z}) \cong \mathbb{Z}^n$ and write $Q_{ij} = q(e_i, e_j)$. A change of basis $P \in \mathrm{GL}(n,\mathbb{Z})$ [an integer matrix whose inverse is also an integer matrix, so $\det P = \pm 1$] gives $Q \mapsto P^T Q P$.

Its basic properties, each with a one-line reason:

- *Symmetric*: $\alpha \wedge \beta = (-1)^{2\cdot 2}\beta \wedge \alpha = \beta \wedge \alpha$ for 2-forms.
- *Unimodular*: $\det Q = \pm 1$. Poincaré duality over $\mathbb{Z}$ says every homomorphism $H^2(M;\mathbb{Z}) \to \mathbb{Z}$ is $q(\alpha,\cdot)$ for exactly one α, i.e. Q is invertible over the integers. (Simple connectivity ensures $H^2(M;\mathbb{Z})$ is free, with no torsion to spoil this.) Note $\det(P^T Q P) = \det Q$ since $\det P = \pm 1$.
- *Invariants*: the **rank** $n = b_2$; the **signature** $\sigma(q) = b_+ - b_-$, the number of positive minus the number of negative eigenvalues of Q [Nash p. 24, footnote 8]; the **type**, *even* if $q(\alpha,\alpha)$ is even for all α (equivalently all diagonal entries Q_{ii} are even) and *odd* otherwise; and *definite* ($b_+ = 0$ or $b_- = 0$) or *indefinite*.

Why the diagonal entries decide the type: for $x = \sum x_i e_i$,

$$q(x,x) \overset{(1)}{=} \sum_i Q_{ii}x_i^2 + \sum_{i\neq j} Q_{ij}x_i x_j$$
$$\overset{(2)}{=} \sum_i Q_{ii}x_i^2 + 2\sum_{i<j} Q_{ij}x_i x_j \;\equiv\; \sum_i Q_{ii}x_i^2 \pmod 2.$$

(1) Bilinearity.
(2) Symmetry $Q_{ij} = Q_{ji}$ pairs the off-diagonal terms, which contribute an even number.

Worked example 1.115: The basic intersection forms

- S^4: $H^2 = 0$, so q is the empty form, $q = \varnothing$. Rank 0, even.
- $\mathbb{CP}^2$: $H^2 = \mathbb{Z}c$, with c dual to a line $\mathbb{CP}^1$; two lines meet in one point, so $Q = (1)$ (Section 1.5.12). Odd, positive definite, $\sigma = 1$. Reversing the orientation, $\overline{\mathbb{CP}^2}$ has $Q = (-1)$.
- $S^2 \times S^2$: in the basis dual to $S^2 \times \{pt\}$ and $\{pt\} \times S^2$, $Q = H := \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ (Section 1.4.10). Each sphere can be pushed off itself (to a parallel copy), so its self-intersection is 0; the two spheres meet once. Even, indefinite, and since the eigenvalues of H are ± 1, $\sigma = 0$.
- Connected sums: removing a ball from each of M_1, M_2 and gluing along the boundary spheres gives $M_1 \# M_2$ with $H^2(M_1\#M_2) = H^2(M_1) \oplus H^2(M_2)$ and $q = q_1 \oplus q_2$. For example $\mathbb{CP}^2 \# \overline{\mathbb{CP}^2}$ has $Q = \mathrm{diag}(1,-1)$, and $\#^k \mathbb{CP}^2$ has $Q = I_k$.
- The K3 surface (a smooth quartic $\{z_0^4 + z_1^4 + z_2^4 + z_3^4 = 0\} \subset \mathbb{CP}^3$) has $b_2 = 22$ and $q = (-E_8) \oplus (-E_8) \oplus H \oplus H \oplus H$, of signature -16; it is even. We meet E_8 in (1.164).

Worked example 1.116: $S^2 \times S^2$ and $\mathbb{CP}^2\#\overline{\mathbb{CP}^2}$ are different

Both forms have rank 2 and signature 0. Over $\mathbb{R}$ they are equivalent (both are $\mathrm{diag}(1,-1)$ after diagonalising H by $(e_1 \pm e_2)/\sqrt{2}$). Over $\mathbb{Z}$ they are not. For $x = (a, b)$:

$$H(x,x) \overset{(1)}{=} 2ab \ \in 2\mathbb{Z},$$
$$\mathrm{diag}(1,-1)(x,x) \overset{(2)}{=} a^2 - b^2, \qquad \text{which is 1 for } x = (1,0).$$

(1) $x^T H x = a \cdot b + b \cdot a$.
(2) $x^T \mathrm{diag}(1,-1) x = a^2 - b^2$.

Parity of $q(x,x)$ does not depend on the basis, so H is even and $\mathrm{diag}(1,-1)$ is odd, and no $P \in \mathrm{GL}(2,\mathbb{Z})$ relates them. (The real change of basis needed the non-integer $1/\sqrt{2}$.) The two manifolds have the same Betti numbers and the same signature but are not homotopy equivalent. The integers matter.

Dictionary: the intersection form in physics

- A U(1) gauge field on M is a connection on a line bundle L, and line bundles are classified by $m = c_1(L) = [F/2\pi] \in H^2(M;\mathbb{Z})$ (1.128): the magnetic fluxes through the 2-cycles, quantised by Dirac's argument. (Here $F = \mathrm{d}A$ is the real field strength.)
- The θ-term is then $\frac{\theta}{8\pi^2}\int_M F \wedge F = \frac{\theta}{2}\, q(m,m)$. If q is even, $e^{i\frac{\theta}{2}q(m,m)}$ is invariant under $\theta \to \theta + 2\pi$; if q is odd, only under $\theta \to \theta + 4\pi$. The parity of the intersection form is a physical property of the spacetime.
- The lattice $(H^2(M;\mathbb{Z}), q)$ is the lattice of electric and magnetic fluxes in the Euclidean path integral of Maxwell theory; electromagnetic duality acts on it.

Unimodular forms: what exists

Because they are so central, it is worth knowing the classification of unimodular symmetric forms over $\mathbb{Z}$ (Serre, *A Course in Arithmetic*).

- *Indefinite, odd*: always diagonalisable, $q \cong m(1) \oplus n(-1)$. Determined by rank and signature.
- *Indefinite, even*: $q \cong a\,E_8 \oplus b\,H$ (with $a \in \mathbb{Z}$, and $-E_8$ meaning E_8 with the sign reversed). Again determined by rank and signature, and $\sigma = 8a$.
- *Definite*: a zoo. In each rank there are finitely many, but their number grows fast. Even positive definite forms exist only in ranks divisible by 8: E_8 in rank 8; $E_8 \oplus E_8$ and D_{16}^+ in rank 16; the 24 Niemeier lattices in rank 24 (one of them the Leech lattice). Odd ones include I_n and, for example, $E_8 \oplus (1)$ in rank 9.

The signature of an even form is always divisible by 8. The reason is a neat mod-8 identity. Call w **characteristic** if $q(w,x) \equiv q(x,x) \pmod 2$ for all x. Characteristic vectors always exist (reduce mod 2: $x \mapsto q(x,x)$ is linear mod 2, so by unimodularity it is $q(w,\cdot)$ for some w), and van der Blij's lemma says

$$q(w,w) \equiv \sigma(q) \pmod 8 \qquad \text{for every characteristic } w. \tag{1.163}$$

Checks: for (1), $w = 1$ is characteristic and $q(w,w) = 1 = \sigma$. For $\mathrm{diag}(1,-1)$, $w = (1,1)$ gives $1 - 1 = 0 = \sigma$. For an *even* form, $w = 0$ is characteristic, so $\sigma \equiv 0 \pmod 8$. The E_8 form, with $\sigma = 8$, is the smallest possibility.

1.6.9 Freedman's theorem

That the intersection form is important is old news: Whitehead and Milnor showed (1949–58) that q determines the *homotopy type* of a closed simply connected 4-manifold. Freedman (1982) showed that it almost determines the *homeomorphism type*.

Key idea: Freedman's theorem [Nash p. 23–24]

Let M be a closed, simply connected topological 4-manifold with intersection form q.

- If q is even, M is unique up to homeomorphism.
- If q is odd, there are exactly two non-homeomorphic M with this q. They are distinguished by the Kirby–Siebenmann class $ks(M) \in H^4(M;\mathbb{Z}_2) = \mathbb{Z}_2$, and the one with $ks \neq 0$ has no smooth structure.
- Every unimodular form is the intersection form of some such M.

Compare with dimension ≥ 5, where the classification of simply connected manifolds needs far more data: here a single integer matrix, up to change of basis, together with one bit, is everything.

Worked example 1.117: The topological Poincaré conjecture in dimension 4

The Poincaré conjecture in dimension 4 says: a closed 4-manifold S^4_h with the homotopy type of S^4 is homeomorphic to S^4. Nash's proof from Freedman's theorem [Nash p. 24] is a chain of implications:

$$\begin{aligned} S^4_h \simeq S^4 &\overset{(1)}{\Longrightarrow} \pi_1(S^4_h) = 0 \text{ and } H^2(S^4_h;\mathbb{Z}) = H^2(S^4;\mathbb{Z}) = 0 \\ &\overset{(2)}{\Longrightarrow} q_{S^4_h} = \varnothing = q_{S^4}, \text{ which is even} \\ &\overset{(3)}{\Longrightarrow} S^4_h \cong S^4. \end{aligned}$$

(1) Homotopy groups and cohomology are homotopy invariants (§1.2 and Section 1.4).
(2) With no classes of degree 2, the intersection form is the empty form, and it has no odd diagonal entry.
(3) Freedman: an even form determines a unique homeomorphism class, and S^4 is in it.

The Poincaré conjecture had been proved for $n \geq 5$ by Smale (1961). Nash wrote that it remained open only for $n = 3$, the case Poincaré himself proposed; Perelman settled that in 2003, using Ricci flow. The *smooth* Poincaré conjecture in dimension 4 (is every smooth homotopy 4-sphere *diffeomorphic* to S^4?) is still open.

Worked example 1.118: Two manifolds with $q = (1)$

The form (1) is odd, so Freedman gives two homeomorphism classes. One is $\mathbb{CP}^2$, with $ks = 0$. The other is the **Chern manifold** (or "fake $\mathbb{CP}^2$") $*\mathbb{CP}^2$, with $ks = 1$. It is homotopy equivalent to $\mathbb{CP}^2$ (same q) but not homeomorphic to it, and it has no smooth or PL structure

at all. Its existence shows that in dimension 4 the Kirby–Siebenmann class is a genuine obstruction, as in higher dimensions.

The E_8 form and the E_8 manifold

The most famous unimodular form is [Nash p. 24, (1.73)]

$$q = \begin{pmatrix} 2 & -1 & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 2 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 2 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 2 & -1 & 0 & -1 \\ 0 & 0 & 0 & 0 & -1 & 2 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & 2 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 & 0 & 2 \end{pmatrix} = E_8. \tag{1.164}$$

It is the Cartan matrix of the exceptional Lie algebra $\mathfrak{e}_8$ (Chapter T3): the diagonal entries are 2 and the entry -1 appears exactly when two nodes of the Dynkin diagram are joined. Reading off the -1's, node i is joined to node $i+1$ for $i = 1, \dots, 6$, and node 8 is joined to node 5 (Figure 1.63).

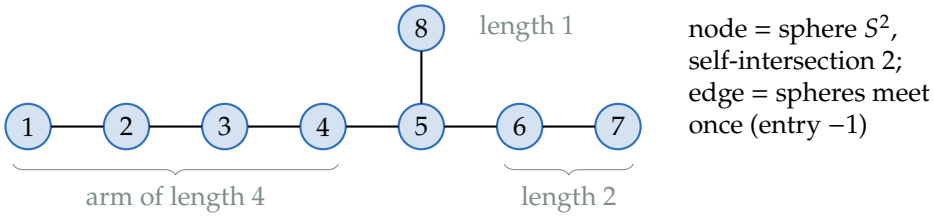

Figure 1.63: The E_8 Dynkin diagram with Nash's numbering of (1.164). Node 5 is the branch point; the three arms have lengths 4, 2 and 1. To build a 4-manifold with this intersection form, take one copy of the tangent disc bundle of S^2 (self-intersection $\chi(S^2) = 2$) for each node and *plumb* two of them (glue them so that their zero sections cross once) for each edge.

Worked example 1.119: E_8 is even, unimodular, positive definite, of signature 8

Even. All diagonal entries are 2. Explicitly $q(x,x) = 2\sum_i x_i^2 - 2\sum_{\text{edges } ij} x_i x_j \in 2\mathbb{Z}$.
Determinant and definiteness by Gaussian elimination. Eliminate the nodes of the arms from the tips inwards. Removing a node i with current diagonal entry (pivot) d_i, joined by an entry -1 to a neighbour j, replaces Q_{jj} by $Q_{jj} - (-1)^2/d_i$ (the Schur complement). Along an arm starting at the tip,

$$d^{(1)} = 2, \quad d^{(2)} = 2 - \tfrac{1}{2} = \tfrac{3}{2}, \quad d^{(3)} = 2 - \tfrac{2}{3} = \tfrac{4}{3}, \quad d^{(4)} = 2 - \tfrac{3}{4} = \tfrac{5}{4}, \qquad d^{(m)} = \tfrac{m+1}{m}.$$

So the arm $1,2,3,4$ gives pivots $2, \frac{3}{2}, \frac{4}{3}, \frac{5}{4}$; the arm $7,6$ gives $2, \frac{3}{2}$; the arm 8 gives 2. The branch node 5 is joined to the last node of each arm, so its pivot is

$$\begin{aligned} d_5 &\overset{(1)}{=} 2 - \frac{1}{d_4} - \frac{1}{d_6} - \frac{1}{d_8} \\ &\overset{(2)}{=} 2 - \frac{4}{5} - \frac{2}{3} - \frac{1}{2} \\ &\overset{(3)}{=} \frac{60 - 24 - 20 - 15}{30} = \frac{1}{30}. \end{aligned}$$

(1) Three Schur-complement corrections, one from each arm.

(2) The last pivots of the arms: $d_4 = \frac{5}{4}$ (arm of length 4), $d_6 = \frac{3}{2}$ (length 2), $d_8 = 2$ (length 1).
(3) Common denominator 30.

The determinant is the product of the pivots:

$$\det E_8 \overset{(1)}{=} \left(2 \cdot \tfrac{3}{2} \cdot \tfrac{4}{3} \cdot \tfrac{5}{4}\right)\left(2 \cdot \tfrac{3}{2}\right)(2)\left(\tfrac{1}{30}\right)$$
$$\overset{(2)}{=} 5 \cdot 3 \cdot 2 \cdot \tfrac{1}{30} = 1.$$

(1) Gaussian elimination $Q = LDL^T$ with L unit lower triangular, so $\det Q = \det D$.
(2) Each arm's product telescopes: $\prod_{m=1}^{\ell} \frac{m+1}{m} = \ell + 1$.

So E_8 is unimodular. All eight pivots are positive, so (Sylvester's criterion, in its LDL^T form) E_8 is positive definite: $b_+ = 8$, $b_- = 0$, $\sigma = 8$. Being even, it has no vectors with $q(x, x) = 1$; its 240 vectors with $q(x, x) = 2$ are the roots of $\mathfrak{e}_8$.

By Freedman's theorem there is a closed, simply connected topological 4-manifold M_{E_8} with $q = E_8$, unique up to homeomorphism. Concretely: the plumbing of Figure 1.63 is a smooth 4-manifold with boundary whose intersection form is E_8; its boundary is the Poincaré homology sphere $\Sigma(2, 3, 5)$ (a 3-manifold with the homology of S^3 but π_1 the binary icosahedral group of order 120). Freedman proved that every homology 3-sphere bounds a contractible *topological* 4-manifold. Capping off with it gives M_{E_8}. The cap cannot be chosen smooth, and the next result shows why.

1.6.10 Rohlin's theorem

Key idea: Rohlin's theorem [Nash p. 24]

If M is a closed, smooth, simply connected 4-manifold with even intersection form, then $\sigma(q)$ is divisible by 16.

For simply connected M, "q even" is the same as "M is spin" ($w_2 = 0$, Example 1.111). Indeed Wu's formula says $w_2 \cup x = x \cup x \bmod 2$ for every $x \in H^2(M; \mathbb{Z}_2)$, so w_2 is the mod-2 reduction of a characteristic vector, and it vanishes iff 0 is characteristic, i.e. iff q is even. The purely algebraic bound (1.163) gives $8 \mid \sigma$; smoothness buys one more factor of 2. There is a beautiful physicist's explanation, through the index of the Dirac operator.

Physical picture: Rohlin from fermion zero modes

On a smooth spin 4-manifold the Dirac operator $\not{D}$ exists (Chapter T4), and its chiral part $\not{D}^+ : S^+ \to S^-$ has an index, index $\not{D}^+ = n_+ - n_-$, the number of positive-chirality minus negative-chirality zero modes. The Atiyah–Singer index theorem (Chapter 4) computes it:

$$\operatorname{index} \not{D}^+ \overset{(1)}{=} \hat{A}(M) = -\frac{1}{24}\, p_1[M]$$
$$\overset{(2)}{=} -\frac{\sigma(M)}{8}.$$

(1) The index theorem for the Dirac operator in 4 dimensions: the $\hat{A}$ genus is $1 - \frac{p_1}{24} + \cdots$.
(2) The Hirzebruch signature theorem in 4 dimensions, $\sigma = \frac{1}{3} p_1[M]$.

In 4 Euclidean dimensions $\mathrm{Spin}(4) = \mathrm{SU}(2) \times \mathrm{SU}(2)$, and each chiral spinor is a doublet of one SU(2): a *pseudo-real* (quaternionic) representation. The antilinear map $\psi \mapsto \epsilon \psi^*$

(with $\epsilon = i\sigma_2$, $\epsilon^2 = -1$) commutes with $\not{D}$ and squares to -1, like time reversal for a spin-$\frac{1}{2}$ particle. So zero modes come in Kramers pairs, $n_\pm$ are even, and index $\not{D}^+$ is even. Then $\sigma/8$ is even: $16 \mid \sigma$.

Worked example 1.120: The E_8 manifold cannot be smoothed

M_{E_8} is simply connected with even form and $\sigma = 8$ (Example 1.119). If it were smooth, Rohlin would force $16 \mid 8$. So M_{E_8} has no smooth structure. In fact it has no PL structure either: for simply connected topological spin 4-manifolds $ks(M) \equiv \sigma(M)/8 \pmod 2$, so $ks(M_{E_8}) = 1$.
For comparison: $E_8 \oplus E_8$ has $\sigma = 16$ and *passes* Rohlin's test; the K3 surface, with $q = -2E_8 \oplus 3H$ and $\sigma = -16$, passes it and is indeed smooth, with index $\not{D}^+ = -\sigma/8 = 2$. Rohlin cannot decide whether the manifold $M_{E_8 \oplus E_8}$ is smoothable. Donaldson can.

1.6.11 Donaldson's theorem

Key idea: Donaldson's theorem [Nash p. 25]

If M is a closed, smooth, simply connected 4-manifold with positive definite intersection form (always achievable for a definite form by choosing the orientation), then q is diagonalisable over the integers:

$$q \cong \mathrm{diag}(1, 1, \ldots, 1) = I_n.$$

The consequences are immediate and dramatic.

- *No smooth manifold has an even definite form* (other than the empty one): I_n has $q(e_1, e_1) = 1$, so it is odd. So M_{E_8} (already excluded by Rohlin) and $M_{E_8 \oplus E_8}$ (not excluded by Rohlin) are not smoothable. Before Donaldson, surgery theorists had tried hard to construct a smooth $M_{E_8 \oplus E_8}$; the attempts were doomed.
- *Odd forms are not safe either*: $E_8 \oplus (1)$ is odd and positive definite of rank 9 but not diagonalisable (it has only two vectors of square 1, $\pm e_9$, while I_9 has eighteen), so it is not smooth either.
- Freedman: *every* unimodular form is realised topologically. Donaldson: among the positive definite ones, only *one* per rank is realised smoothly. The gap between topological and smooth 4-manifolds is enormous.

What makes the theorem so striking is its proof. It uses the Yang–Mills equations. We now sketch it, following Nash.

Yang–Mills and instantons

Let $P \to M$ be a principal SU(2) bundle (Section 1.5.5) and A a connection on it, locally a 1-form with values in anti-Hermitian traceless 2×2 matrices, with curvature $F = \mathrm{d}A + A \wedge A$ (Chapter T3). Its size is measured by the Euclidean Yang–Mills action [Nash p. 25, (1.74)]

$$S(A) = \|F\|^2 = -\int_M \mathrm{tr}(F \wedge \star F). \tag{1.165}$$

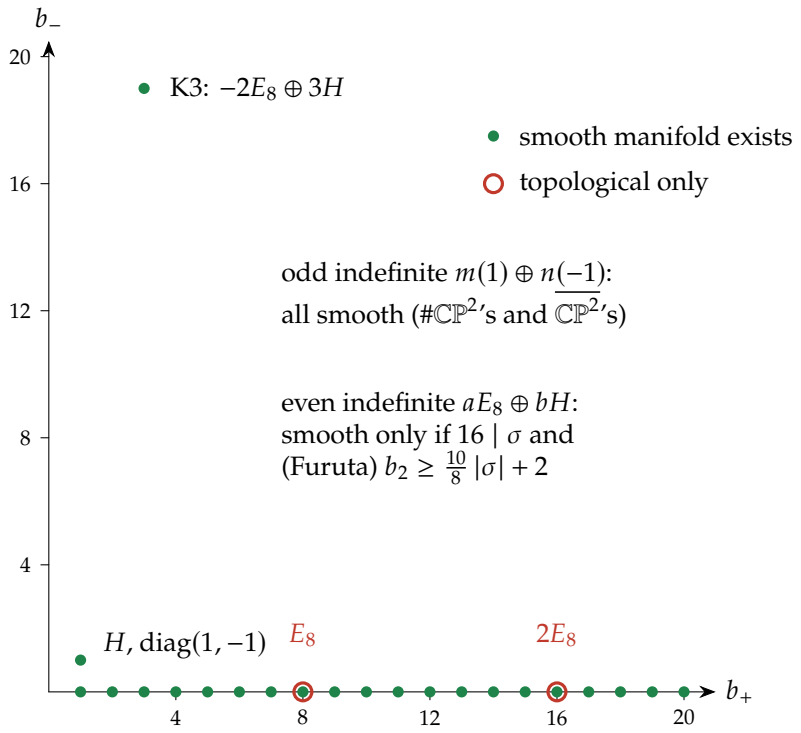

Figure 1.64: The landscape of closed simply connected 4-manifolds, by (b_+, b_-). Freedman realises every unimodular form topologically. Along the positive-definite axis $b_- = 0$, Donaldson allows only I_n (green dots); the even definite forms E_8, $E_8 \oplus E_8$ (red circles) and every other non-diagonal definite form exist only as topological manifolds. The same holds on the negative-definite axis by reversing orientation.

The minus sign makes $S \geq 0$. With $F = \frac{1}{2}F_{\mu\nu}\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$ in an orthonormal frame,

$$-\operatorname{tr}(F \wedge \star F) \overset{(1)}{=} -\tfrac{1}{2}\sum_{\mu,\nu} \operatorname{tr}\big(F_{\mu\nu}F_{\mu\nu}\big)\,\mathrm{vol}$$
$$\overset{(2)}{=} \tfrac{1}{2}\sum_{\mu,\nu} \operatorname{tr}\big(F^\dagger_{\mu\nu}F_{\mu\nu}\big)\,\mathrm{vol} \overset{(3)}{\geq} 0.$$

(1) For 2-forms $\alpha \wedge \star\beta = \frac{1}{2}\alpha_{\mu\nu}\beta_{\mu\nu}\,\mathrm{vol}$ (Chapter T1); the trace acts on the matrix values.
(2) Each $F_{\mu\nu}$ is anti-Hermitian, $F^\dagger_{\mu\nu} = -F_{\mu\nu}$.
(3) $\operatorname{tr}(X^\dagger X) = \sum_{ab}|X_{ab}|^2 \geq 0$.

Dictionary: mathematicians' and physicists' Yang–Mills

With $A_{\text{math}} = -ig\,A^a_\mu T^a \mathrm{d}x^\mu$, $T^a = \sigma^a/2$ Hermitian with $\operatorname{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$, the same computation gives $S_{\text{math}} = \frac{g^2}{4}\int F^a_{\mu\nu}F^a_{\mu\nu}\,\mathrm{d}^4x = g^2 S_{\text{phys}}$. So the Euclidean path-integral weight is $e^{-S_{\text{phys}}} = e^{-S_{\text{math}}/g^2}$, and the bound below becomes the famous instanton action $8\pi^2|k|/g^2$.

The Hodge star on 2-forms in 4 dimensions squares to +1, so every F splits into self-dual and anti-self-dual parts, $F = F_+ + F_-$ with $\star F_\pm = \pm F_\pm$. The topological charge is the second Chern class (Section 1.5.12), and with Nash's choice of self-dual instantons we fix the sign of the instanton number as

$$k := -c_2(P)[M] = -\frac{1}{8\pi^2}\int_M \operatorname{tr}(F \wedge F). \tag{1.166}$$

(It is an integer independent of A, by Chern–Weil.) Then

$$\begin{aligned} S &\overset{(1)}{=} -\int \operatorname{tr}\big((F_+ + F_-) \wedge (F_+ - F_-)\big) \\ &\overset{(2)}{=} -\int \operatorname{tr}(F_+ \wedge F_+) + \int \operatorname{tr}(F_- \wedge F_-) = \|F_+\|^2 + \|F_-\|^2 , \\ 8\pi^2 k &\overset{(3)}{=} -\int \operatorname{tr}(F_+ \wedge F_+) - \int \operatorname{tr}(F_- \wedge F_-) = \|F_+\|^2 - \|F_-\|^2 , \end{aligned}$$

(1) $\star F = F_+ - F_-$.
(2) The cross terms $F_+ \wedge F_- = -F_+ \wedge \star F_-$ vanish, because self-dual and anti-self-dual forms are orthogonal ($\alpha \wedge \star\beta = \langle \alpha, \beta \rangle \mathrm{vol}$ and $\langle F_+, F_- \rangle = \langle \star F_+, \star F_- \rangle = -\langle F_+, F_- \rangle$). Then use $F_\pm \wedge F_\pm = \pm F_\pm \wedge \star F_\pm$ and $\|F_\pm\|^2 = -\int \operatorname{tr}(F_\pm \wedge \star F_\pm)$.
(3) Definition (1.166) and the same splitting.

Subtracting, $S - 8\pi^2 k = 2\|F_-\|^2 \geq 0$. So in the sector with instanton number $k \geq 0$,

$$S \geq 8\pi^2 k, \qquad \text{with equality iff} \qquad F = \star F. \tag{1.167}$$

The absolute minima of the action in each sector are the **instantons**, the solutions of the self-duality equations [Nash p. 25, (1.75)] $F = \star F$. (A self-dual connection automatically solves the Yang–Mills equations $\mathrm{d}_A \star F = 0$, by the Bianchi identity $\mathrm{d}_A F = 0$.)

The moduli space

Two connections related by a gauge transformation are physically the same. The **moduli space** is

$$\mathcal{M} = \{A : F_A = \star F_A\} / \mathcal{G},$$

self-dual connections modulo gauge. Perturbing an instanton, $A \to A + a$, and linearising $F = \star F$ modulo gauge gives an elliptic system of equations for a (Chapter 2), so $\mathcal{M}$ is finite-dimensional, and its dimension is computed by an index theorem (Chapters 4 and 8). For SU(2), instanton number k and M simply connected with positive definite form,

$$\dim \mathcal{M} = 8k - 3, \qquad \text{so for } k = 1 : \quad \dim \mathcal{M} = 5.$$

On S^4 the 5 parameters of the minimal ($k = 1$) instanton are visible in the BPST solution: 4 for its centre $x_0 \in S^4$ and 1 for its size $\lambda > 0$. So $\mathcal{M}_{S^4}$ is an open 5-ball, with the centre of the ball the round, maximally spread-out instanton and the boundary sphere reached as $\lambda \to 0$: an instanton shrunk to a point of S^4. *The boundary of the moduli space is a copy of the manifold itself.*

Donaldson's analysis of $\mathcal{M}$ for $k = 1$ on a general M (smooth, simply connected, positive definite, with a generic metric) gives four facts.

1. *The collar.* Very concentrated instantons are labelled by a point $x \in M$ and a small size λ (Taubes constructed them by gluing a tiny BPST instanton into M). So $\mathcal{M}$ contains a collar $M \times (0, \lambda_0)$ and is non-compact, but compactness fails *only* there (Uhlenbeck). This shows $\mathcal{M} \neq \varnothing$.

2. *Smoothness.* Away from finitely many special points $\mathcal{M}$ is a smooth, orientable 5-manifold (Freed and Uhlenbeck for generic metrics; Donaldson for the orientation).

3. *Reducible connections.* The special points are connections whose structure group reduces from SU(2) to U(1): $P = L \oplus L^{-1}$ for a line bundle L with $e = c_1(L)$, with a self-dual U(1) connection. For these

$$c(L \oplus L^{-1}) \overset{(1)}{=} (1 + e)(1 - e) \overset{(2)}{=} 1 - e^2 \quad \Rightarrow \quad k = -c_2[M] \overset{(3)}{=} q(e, e).$$

(1) The total Chern class is multiplicative on direct sums, and $c_1(L^{-1}) = -e$.
(2) Expand; the degree-4 part is $c_2 = -e^2$.
(3) Definition (1.166) and $e^2[M] = q(e,e)$ (1.162).

So for $k = 1$ the reducibles correspond to classes with $q(e,e) = 1$, with e and $-e$ giving the same connection (swap L and L^{-1}). (A self-dual U(1) connection exists for each such e: its curvature is the harmonic representative of $-2\pi i e$, which is self-dual because q is positive definite, so all harmonic 2-forms are self-dual.) Let

$$p = \#\{\pm e \in H^2(M;\mathbb{Z}) : \; q(e,e) = 1\} \tag{1.168}$$

be the number of such pairs.

4. *Cones.* A reducible connection is fixed by a U(1) of gauge transformations, not just by the centre ±1. Near it, $\mathcal{M}$ is modelled on (deformations)/U(1). The deformation space has real dimension $\dim \mathcal{M} + \dim \mathrm{U}(1) = 6$, i.e. it is $\mathbb{C}^3$, and U(1) acts on it by phases. So $\mathcal{M}$ looks like $\mathbb{C}^3/\mathrm{U}(1)$ near the point: a cone on $(\mathbb{C}^3 \setminus 0)/\mathrm{U}(1)$ restricted to the unit sphere, $S^5/\mathrm{U}(1) = \mathbb{CP}^2$. *Each reducible is a cone point whose link is* $\mathbb{CP}^2$ [Nash p. 26].

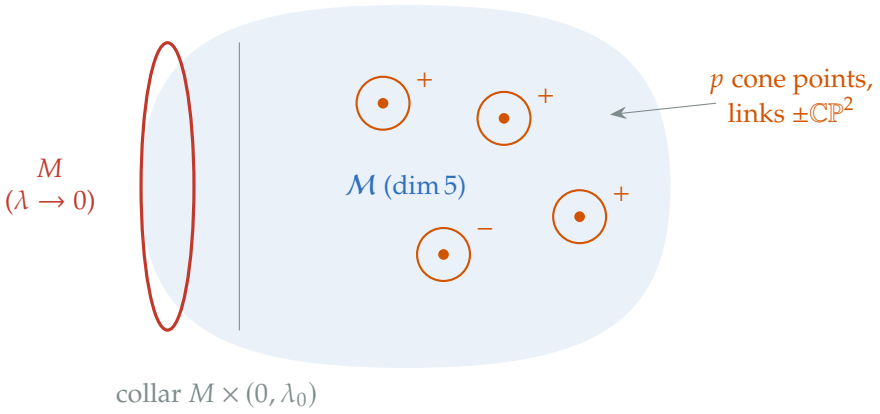

Figure 1.65: Donaldson's moduli space of $k = 1$ instantons on a smooth, simply connected, positive definite M. At one end (red) the instantons shrink to points of M, and the moduli space looks like $M \times (0, \lambda_0)$. Inside there are p singular points (orange), the reducible connections, each a cone on $\mathbb{CP}^2$. Removing small neighbourhoods of both gives a cobordism between M and p copies of $\mathbb{CP}^2$ with various orientations.

Signature is a cobordism invariant

The last ingredient is topological. If a closed oriented 4-manifold X is the boundary of a compact oriented 5-manifold W, then $\sigma(X) = 0$. Here is the mechanism. Let $L \subset H^2(X;\mathbb{R})$ be the classes that extend to closed forms on W. For $a = [\alpha|_X]$, $b = [\beta|_X]$ in L,

$$\begin{aligned} q_X(a,b) &\overset{(1)}{=} \int_X \alpha \wedge \beta \\ &\overset{(2)}{=} \int_W \mathrm{d}(\alpha \wedge \beta) \\ &\overset{(3)}{=} \int_W (\mathrm{d}\alpha \wedge \beta + \alpha \wedge \mathrm{d}\beta) = 0. \end{aligned}$$

(1) The de Rham form of the intersection form, using the restrictions of the extensions.
(2) Stokes' theorem, $\partial W = X$.
(3) Leibniz rule for d (the sign in front of the second term is $(-1)^2 = +1$); α, β are closed on W.

So q vanishes identically on L. Poincaré–Lefschetz duality shows $\dim L = \frac{1}{2}b_2(X)$ ("half the cycles of the boundary bound in the interior"). Now a non-degenerate form that vanishes on a half-dimensional subspace has signature zero: a subspace V_+ on which q is positive definite meets L only in 0, so $b_+ = \dim V_+ \le b_2 - \dim L = \frac{1}{2}b_2$; likewise $b_- \le \frac{1}{2}b_2$; and $b_+ + b_- = b_2$ forces $b_+ = b_-$, i.e. $\sigma(X) = 0$.

Donaldson's argument

Apply this to $W = \mathcal{M}_0$. Its boundary is M together with the p links, a of them oriented like $\mathbb{CP}^2$ and b like $\overline{\mathbb{CP}^2}$, with $a + b = p$. As inner boundary components they enter with the orientation opposite to M's, so $0 = \sigma(\partial\mathcal{M}_0) = \sigma(M) - (a - b)$. Let $n = b_2(M)$. The chain of Nash [Nash p. 26, (1.76)–(1.79)]:

$$\begin{aligned} n &\overset{(1)}{=} \sigma(M) \\ &\overset{(2)}{=} a - b \\ &\overset{(3)}{\le} a + b \\ &\overset{(4)}{=} p \\ &\overset{(5)}{\le} n. \end{aligned}$$

(1) q is positive definite of rank n, so all n eigenvalues are positive [Nash (1.77)].
(2) Cobordism invariance of the signature applied to $\mathcal{M}_0$, with $\sigma(\mathbb{CP}^2) = 1$ and $\sigma(\overline{\mathbb{CP}^2}) = -1$ [Nash (1.76)].
(3) $b \ge 0$.
(4) Each reducible gives exactly one cone point [Nash (1.78)].
(5) The lattice argument below: a positive definite unimodular form of rank n has at most n pairs $\pm e$ with $q(e, e) = 1$.

So $n \le p \le n$, hence $p = n$ [Nash (1.79)]: *there are exactly n pairs of classes with square* 1. It remains to see that this forces $q \cong I_n$.

Worked example 1.121: Vectors of square 1 in a positive definite lattice

Let e, f satisfy $q(e, e) = q(f, f) = 1$ with $f \ne \pm e$. Then

$$\begin{aligned} |q(e,f)| &\overset{(1)}{<} \sqrt{q(e,e)\,q(f,f)} \\ &\overset{(2)}{=} 1, \qquad \text{so} \qquad q(e,f) \overset{(3)}{=} 0. \end{aligned}$$

(1) Cauchy–Schwarz for the positive definite inner product q, strict because e and f are not parallel (the only multiples of e with square 1 are $\pm e$).
(2) Both have square 1.
(3) $q(e, f)$ is an integer of absolute value less than 1.

So one representative from each of the p pairs gives an *orthonormal* set $e_1, \dots, e_p$. Orthonormal vectors are linearly independent, so $p \le n$: this is step (5) above. If $p = n$ they span a sublattice $\Lambda' \subset \Lambda = H^2(M; \mathbb{Z})$ of full rank with Gram matrix I_n. For a sublattice of index d

the Gram determinants satisfy $\det(I_n) = d^2 \det(q)$, i.e. $1 = d^2 \cdot 1$, so $d = 1$ and $\Lambda' = \Lambda$: in the basis $e_1, \dots, e_n$, $q = I_n$. That is Donaldson's theorem.
Test cases for the count p: I_n has $p = n$ (the pairs $\pm e_i$); E_8 has $p = 0 < 8$ (it is even); $E_8 \oplus (1)$ has $p = 1 < 9$. The last two cannot be the forms of smooth manifolds.

Watch out: Nash's "p unit eigenvalues"

Nash phrases step (5) as "q regarded as an $n \times n$ matrix with precisely p unit eigenvalues (clearly $p \leq n$)" [Nash p. 26]. Read literally this is not right: the eigenvalues of a matrix change under $Q \mapsto P^T Q P$, and E_8 has no eigenvalue equal to 1 in any sense relevant here. The correct statement is the lattice one: p is the number of pairs of *integral* classes of square 1, which is basis-independent, is at most n by Example 1.121, and equals n exactly when $q \cong I_n$.

Physical picture: Why a physicist should be amazed

The moduli space of solutions of a classical field equation, the self-duality equation, is a 5-dimensional space that remembers the 4-manifold: one of its ends *is* M, and its singularities count the square-one classes. Field theory turned into a cobordism. Donaldson went on to extract numerical invariants of smooth 4-manifolds from these moduli spaces (Donaldson invariants), and Witten showed they are the correlation functions of a topological quantum field theory, a twisted version of $N = 2$ super Yang–Mills (Chapter 12). The Seiberg–Witten equations later reproduced all of this with a U(1) monopole equation and compact moduli spaces. We return to instantons in Chapter 8.

1.6.12 Non-compact manifolds and exotic $\mathbb{R}^4$

For non-compact manifolds, Nash reports [Nash p. 26]:

- *Quinn*: every non-compact connected 4-manifold is smoothable. (No closed 4-manifold phenomenon like M_{E_8} occurs.)
- *Uniqueness fails badly.* For $n \neq 4$, $\mathbb{R}^n$ has exactly one smooth structure up to diffeomorphism (Stallings, for $n \geq 5$; Moise for $n \leq 3$). For $n = 4$ there is an **exotic** (or *fake*) $\mathbb{R}^4$: a smooth manifold homeomorphic to $\mathbb{R}^4$ but not diffeomorphic to it. This follows from Freedman's and Donaldson's work.
- *Gompf* (and Taubes): there is a continuum, i.e. uncountably many, of pairwise non-diffeomorphic smooth structures on $\mathbb{R}^4$.

This is in sharp contrast with the compact case, where obstruction theory produced a finite, discrete set of structures (28 on S^7).

Physical picture: How an exotic $\mathbb{R}^4$ arises

The logic, stripped of its (formidable) technicalities, is a proof by contradiction that uses both theorems.

1. Take a smooth 4-manifold whose intersection form splits algebraically as a definite non-diagonal piece plus hyperbolic pieces; the K3 surface, $q = (-E_8 \oplus -E_8) \oplus 3H$, is the standard choice.
2. Freedman's topological methods split the manifold *topologically* along this decom-

position, into a piece carrying $-E_8 \oplus -E_8$ and a piece carrying $3H$. The splitting is controlled by a certain open subset that is *homeomorphic* to $\mathbb{R}^4$. Being an open subset of a smooth manifold, it inherits a smooth structure.

3. If that smooth $\mathbb{R}^4$ were the standard one, a smooth ball could be found where the topological theory needs it, and the splitting could be carried out *smoothly*, producing a closed smooth manifold with definite form $-E_8 \oplus -E_8$.

4. Donaldson forbids that. So the inherited smooth structure on this $\mathbb{R}^4$ is exotic.

Exotic $\mathbb{R}^4$'s of this kind cannot even be smoothly embedded in the standard $\mathbb{R}^4$. Others ("small" ones) arise from Donaldson's discovery that the smooth h-cobordism theorem fails in dimension 4.

Watch out: What an exotic $\mathbb{R}^4$ is not

An exotic $\mathbb{R}^4$ is not a curved metric on $\mathbb{R}^4$, nor a non-trivial topology. It is homeomorphic to $\mathbb{R}^4$ and, locally, every smooth manifold looks like standard $\mathbb{R}^4$ in a small chart. The difference is global and lies in *which functions count as smooth*: there is no homeomorphism $\mathbb{R}^4_{\text{exotic}} \to \mathbb{R}^4$ that is smooth with smooth inverse. Physicists have speculated (Brans, Asselmeyer-Maluga and others) that exotic smoothness of spacetime might have physical consequences, e.g. in the gravitational path integral, but this remains speculation.

Reading Nash (pp. 23–26, (1.72)–(1.79))

Nash's treatment of dimension 4 is a guided tour. He *defines* the intersection form (1.72), states Freedman's theorem, deduces the 4-dimensional Poincaré conjecture (our Example 1.117), states Rohlin, writes down E_8 (1.73) "by inspection even and, by calculation, of signature 8" (our Example 1.119 does the calculation), states Donaldson, and sketches the proof through (1.74)–(1.79). We added: the Whitney-trick explanation of why dimension 4 is special; the three ways to compute q and its invariants; the list of basic forms and the H versus $\mathrm{diag}(1,-1)$ example; the classification of unimodular forms and the mod-8 theorem; the fake $\mathbb{CP}^2$; the E_8 plumbing; the Dirac-operator explanation of Rohlin; the positivity of S and the bound $S \geq 8\pi^2 k$; the dimension count, the reducibles $L \oplus L^{-1}$ and the cone structure of $\mathcal{M}$; the Stokes proof that signature is a cobordism invariant; and the lattice argument that turns $p = n$ into $q \cong I_n$, correcting Nash's "unit eigenvalues". His last paragraph (Quinn, exotic $\mathbb{R}^4$, Gompf) is our Section 1.6.12. Note that Nash's book predates Perelman (2003) and Seiberg–Witten theory (1994).

Recap: §1.6 Differentiable structures

- Transition functions come in three kinds, forming groups $TOP_n \supset PL_n \supset DIFF_n \simeq \mathrm{O}(n)$, with direct limits TOP, PL, O. The type of a manifold is the lift of its tangent map $M \to BTOP$ to BPL or BO.
- Lifting through a fibration with fibre F is finding a section; obstructions lie in $H^{k+1}(M;\pi_k(F))$ and choices in $H^k(M;\pi_k(F))$. The same pattern gives the Euler class (vector fields), w_1 (orientation) and w_2 (spin structures; four on T^2).
- $TOP/PL = K(\mathbb{Z}_2,3)$: for $\dim M \geq 5$ the only obstruction to a PL structure is $ks(M) \in H^4(M;\mathbb{Z}_2)$, and PL structures are counted by $H^3(M;\mathbb{Z}_2)$. The Hauptvermutung is false.

- $\pi_k(PL/\mathrm{O}) = \Theta_k$ is 0 for $k \le 6$ and $\mathbb{Z}_{28}$ for $k = 7$: S^7 has 28 smooth structures. Milnor's S^3-bundles over S^4 realise them, detected by $2p_1^2 - \sigma \bmod 7$.
- In dimension 4 the Whitney trick fails. The invariant is the intersection form $q(\alpha, \beta) = (\alpha \cup \beta)[M]$, symmetric and unimodular. Freedman: q (plus ks if odd) classifies simply connected topological 4-manifolds, and all forms occur; hence the 4-dimensional topological Poincaré conjecture.
- Rohlin: smooth + even $\Rightarrow 16 \mid \sigma$, so the E_8 manifold is not smooth. Donaldson: smooth + positive definite $\Rightarrow q \cong I_n$, proved by the moduli space of self-dual SU(2) instantons, a 5-dimensional cobordism from M to p copies of $\pm\mathbb{CP}^2$.
- $\mathbb{R}^n$ has a unique smooth structure except for $n = 4$, where there are uncountably many.

Chapter summary

The chapter asked one question: *how can we tell two spaces, or two field configurations, apart without solving any equations?* We answered it with a ladder of invariants. At the top of the ladder sit the finest notions of "the same" (diffeomorphic, PL homeomorphic, homeomorphic). They are what we would really like to decide, and they are almost never decidable by hand. Lower down sit coarser notions (homotopy equivalent, same cohomology ring, same Betti numbers, same Euler characteristic). Each rung sees less than the one above it, but is easier to compute. The art of topology is to climb down only as far as necessary. The whole of Figure 1.66 is the chapter in one picture: each downward arrow is an implication, and each red example on the right shows that the arrow cannot be reversed.

The rungs "isomorphic groups" and "same Betti numbers" are separated by *torsion*. Real coefficients, and hence differential forms, see only the ranks b_k of the homology groups and forget every finite cyclic summand $\mathbb{Z}_k$. The red box between them ($\mathbb{RP}^3$ against S^3) is the reason the chapter needed integer (simplicial and singular) homology as well as de Rham cohomology.

The rest of this summary has four parts: a table of every concept of the chapter with its operational meaning and where it returns; a catalogue of the spaces we computed; a dictionary to physics; and a self-test.

Every concept, how to use it, and where it returns

The tables follow Nash's sections. The middle column is the *operational* meaning: what you actually do to compute or test the thing. The right column says where in the book the idea comes back. References of the form §1.4 point to our own sections; Nash §1–§3 are Sections 1.1–1.3 of these notes.

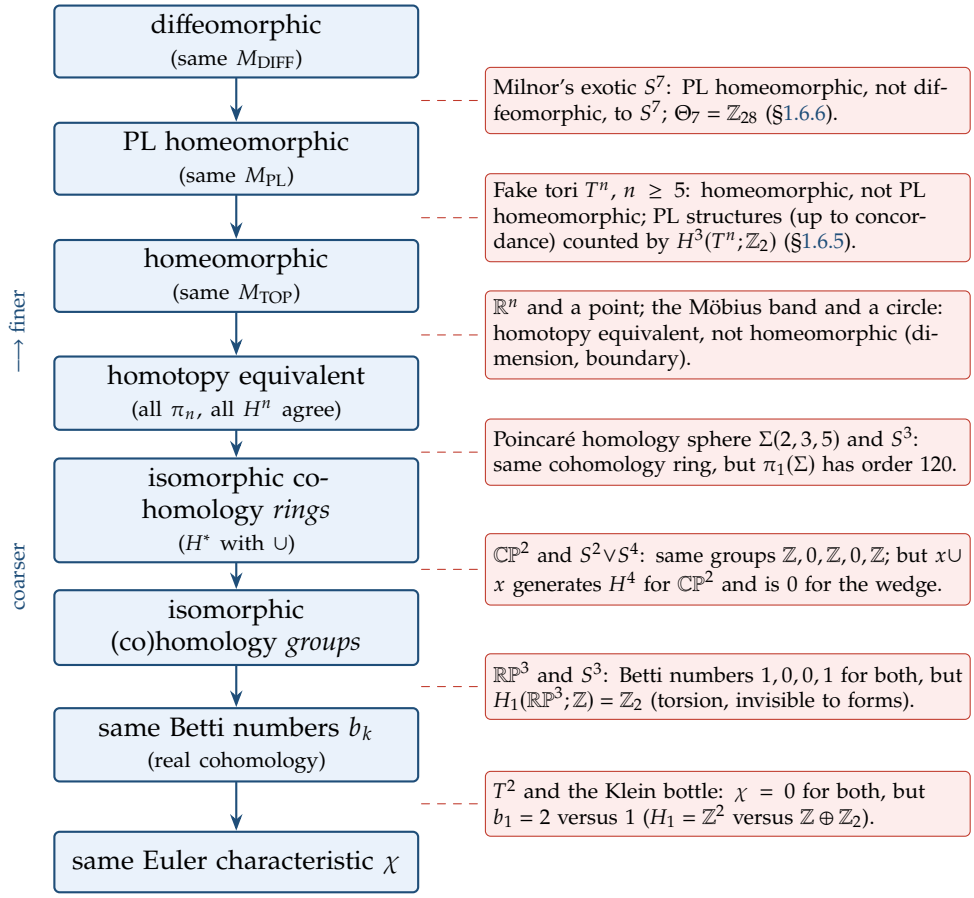

Figure 1.66: The ladder of "sameness" built in this chapter. Read downwards: each notion implies the next. Read the red boxes: each is a pair of spaces that agree on the lower rung but differ on the upper one, so no arrow can be reversed. Nash §1 and §6 live on the top three rungs; §2–§4 build the lower ones.

Nash §1: from homeomorphism to diffeomorphism

Concept	Operational meaning	Returns in
homeomorphism	a continuous bijection with continuous inverse; to *show* two spaces differ, find an invariant (dimension, compactness, connectedness, χ, π_n, H^n) that differs	everywhere
classification of surfaces	closed orientable surfaces are classified by the genus g; compute g from $\chi = 2 - 2g = V - E + F$ of any triangulation	Chapter 5, Chapter 9, Chapter 11
general position	submanifolds of dimensions p, q in M^n generically miss each other if $p + q < n$ and meet in a $(p + q - n)$-manifold otherwise; the reason low dimensions are hard	§1.6.7, Chapter 12
knots	embeddings $S^1 \hookrightarrow \mathbb{R}^3$ up to isotopy; all knots untie in $\mathbb{R}^4$ $(1 + 1 < 4)$	Chapter 12 (Jones polynomial)
topological manifold	cover by charts $U_\alpha \to \mathbb{R}^n$; transition functions $g_{\alpha\beta}$ are homeomorphisms	§1.6.1
PL manifold	transition functions are piecewise linear; equivalently a nice triangulation	§1.4.6, §1.6.5
smooth manifold	transition functions are C^∞ with C^∞ inverse (check the Jacobian is invertible)	all of Chapter T1–Chapter T4
M_{TOP}, M_{PL}, M_{DIFF}	the same set with three kinds of atlas; existence and uniqueness of the finer ones can fail	§1.6, Chapter 10, Chapter 12

Nash §2: some algebraic topology: homotopy

Concept	Operational meaning	Returns in
homotopy $F : [0,1] \times X \to Y$	a continuous one-parameter family of maps; write one down explicitly (straight line $F_t = (1-t)f + tg$ in a convex target, or a radial shrink)	everywhere
$[X, Y]$	the set of maps modulo homotopy; a field configuration's *topological sector*	Chapter 8, Chapter 10
homotopy equivalence, contractible	maps $f : X \to Y$, $g : Y \to X$ with $gf \simeq \mathrm{id}$, $fg \simeq \mathrm{id}$; contractible = homotopy equivalent to a point (e.g. $\mathbb{R}^n$, a disc, a vector space)	Poincaré lemma (Example 1.65), Chapter 2
retract, deformation retract	a continuous projection $r : X \to A$ with $r\|_A = \mathrm{id}$; a deformation retract is a homotopy from id_X to r (punctured plane → circle)	Example 1.67, §1.4.9
base point, $[X, Y]_0$	maps and homotopies that keep $* \mapsto *$; needed to make loops composable	§1.4.2
exponential law	$\mathrm{Map}(X \times Y, Z) = \mathrm{Map}(X, \mathrm{Map}(Y, Z))$: a family of maps is a map into a space of maps	path fibration (§1.5.16), Chapter 6
wedge $X \vee Y$, smash $X \wedge Y$	glue at the base point; collapse $X \vee Y$ inside $X \times Y$; $S^m \wedge S^n = S^{m+n}$	Example 1.82
suspension SX, loop space ΩX	$SX = S^1 \wedge X$; ΩX = based loops; adjoint: $[SX, Y]_0 = [X, \Omega Y]_0$	§1.4.3, §1.5.16, Chapter 7, Chapter 6
H-space, coH-space	a target with a product up to homotopy (ΩY, a group G) or a source with a coproduct (SX) makes $[X, Y]_0$ a group	§1.4.3
Eckmann–Hilton	when both structures exist they agree and are commutative (slide squares past each other)	$\pi_{n \geq 2}$ abelian

Nash §3: homotopy groups

Concept	Operational meaning	Returns in
$\pi_1(X) = [S^1, X]_0$	based loops up to homotopy, composed by "first one, then the other"; compute by van Kampen (glue along simply connected overlaps) or by coverings	§1.4.10, Chapter 8
winding number	$\frac{1}{2\pi}\oint f^*\mathrm{d}\theta = \frac{1}{2\pi i}\oint \frac{\mathrm{d}f}{f} \in \mathbb{Z}$: the isomorphism $\pi_1(S^1) \to \mathbb{Z}$	§1.4.2, §1.5.6
π_1 examples	$\pi_1(T^2) = \mathbb{Z}^2$; genus g: $\langle a_i, b_i \mid \prod[a_i, b_i]\rangle$; $\pi_1(\mathbb{RP}^2) = \mathbb{Z}_2$; $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$ (belt trick, spin $\frac{1}{2}$)	Example 1.86, Chapter T4
$\pi_n(X) = [S^n, X]_0$	based maps of spheres; $= [S^{n-1}, \Omega X]_0$; abelian for $n \geq 2$	§1.5.13
free vs based classes	$[X, Y] = [X, Y]_0/\pi_1(Y)$; for simply connected Y base points do not matter	§1.4.2
degree	$\deg f = \int_{S^n} f^*\omega$ with $\int \omega = 1$, or count preimages with Jacobian signs; gives $\pi_n(S^n) = \mathbb{Z}$	§1.5.8, Chapter 4
$\pi_m(S^n) = 0$ for $m < n$	a (smoothed) map from a lower-dimensional sphere misses a point, and $S^n \setminus \{\mathrm{pt}\} = \mathbb{R}^n$ is contractible	§1.4.1
Hopf map, $\pi_3(S^2) = \mathbb{Z}$	$S^3 \to S^2$, $(z_1, z_2) \mapsto z_1/z_2$; Hopf invariant = linking number of two fibres	§1.5.7, Example 1.100
table, stability	$\pi_{n+k}(S^n)$ depends only on k once $n > k + 1$ (Freudenthal)	§1.6.6
exact sequences	"image = kernel" at every step; a zero on each side of a term makes a map an isomorphism	§1.5.13, §1.4.9
Lie groups, Bott	$\pi_1(\mathrm{U}(n)) = \mathbb{Z}$, $\pi_3(\mathrm{SU}(n)) = \mathbb{Z}$, $\pi_1(\mathrm{SO}(n \geq 3)) = \mathbb{Z}_2$; Bott periodicity: $\pi_k(\mathrm{U})$ has period 2, $\pi_k(\mathrm{O})$ period 8	Chapter 3, Chapter 10
defects	a defect of codimension $k + 1$ with vacuum manifold $\mathcal{V}$ is classified by $\pi_k(\mathcal{V})$: walls (π_0), vortices (π_1), monopoles (π_2), textures (π_3)	Chapter 8
instantons, θ	$k = \frac{1}{8\pi^2}\int \mathrm{tr}\, F \wedge F \in \pi_3(\mathrm{SU}(2)) = \mathbb{Z}$; vacua labelled by k, superposed into θ-vacua	§1.6.11, Chapter 8

Nash §4: cohomology and homology groups (§1.4)

Concept	Operational meaning	Returns in
$K(G,n)$	a space with $\pi_n = G$ and all other $\pi_m = 0$; $S^1 = K(\mathbb{Z},1)$, $\mathbb{RP}^\infty = K(\mathbb{Z}_2,1)$, $\mathbb{CP}^\infty = K(\mathbb{Z},2)$	§1.5.11
$H^n(X;G) = [X, K(G,n)]_0$	e.g. $H^1(X;\mathbb{Z})$ = maps to a circle up to homotopy, counted by winding numbers around the 1-cycles	Example 1.60, §1.5.12
$\Omega K(G,n+1) = K(G,n)$	shifting degree by looping; makes $[X, K(G,n)]_0$ an abelian group	Chapter 3
complex, $H = \mathrm{Ker}/\mathrm{Im}$	a sequence of linear maps with $d \circ d = 0$; its cohomology is *rank arithmetic*: $\dim H^n = \dim \mathrm{Ker}\, d_n - \mathrm{rank}\, d_{n-1}$	every complex in Chapter 2, Chapter 4
de Rham cohomology	closed p-forms modulo exact ones; to find a class, integrate over cycles; to kill one, find a primitive	Chapter T2, Chapter 4
simplicial homology	chains = integer combinations of oriented simplices; write the boundary matrices ∂_k, then $H_k = \mathrm{Ker}\,\partial_k/\mathrm{Im}\,\partial_{k+1}$ (Smith normal form gives torsion)	§1.4.6, Chapter 7
singular homology	the same with all continuous simplices; manifestly a topological invariant; agrees with simplicial	§1.4.6
cochains, coboundary	functions on simplices; $\delta = \partial^{\mathsf{T}}$; Stokes $\langle \delta c, \sigma\rangle = \langle c, \partial\sigma\rangle$	§1.4.7
universal coefficients	$H^n(X;\mathbb{Z}) \cong \mathrm{free}(H_n) \oplus \mathrm{tors}(H_{n-1})$; with $\mathbb{R}$ coefficients torsion disappears	Example 1.76
de Rham theorem	$H^p_{\mathrm{dR}}(M) \cong H^p(M;\mathbb{R})$, the map being "integrate the form over chains"; periods determine the class	§1.4.8, Chapter 3
Mayer–Vietoris	a long exact sequence for $M = U \cup V$; compute $H^*(S^n)$ from two discs	§1.4.9, Chapter 3
finiteness	$H^n = 0$ for $n > \dim M$ and $n < 0$ (unlike π_n)	
cup product, ring	wedge of representatives, $[\alpha] \cup [\beta] = [\alpha \wedge \beta]$; graded commutative	§1.6.8
Poincaré duality	closed oriented M^n: $H^p \cong H_{n-p}$, $b_p = b_{n-p}$; the pairing $\int_M \alpha \wedge \beta$ is non-degenerate	§1.6.8, Chapter 4
Künneth	$H^*(X \times Y) = H^*(X) \otimes H^*(Y)$ (field coefficients); Poincaré polynomials multiply	Example 1.84
Euler characteristic	$\chi = \sum(-1)^k b_k = \sum(-1)^k N_k$ (count simplices) = index of $\mathrm{d} + \mathrm{d}^\dagger$	Chapter 4, Chapter 7
Hurewicz	for simply connected X the first non-zero π_n equals the first non-zero H_n; $H_1 = \pi_1/[\pi_1, \pi_1]$	§1.4.10

Nash §5: fibre bundles and fibrations (§1.5)

Concept	Operational meaning	Returns in
fibre bundle $F \to E \xrightarrow{\pi} M$	locally $\pi^{-1}(O_\alpha) \cong O_\alpha \times F$; to specify one, give a cover and transition functions	Chapter 2 onwards
transition functions, cocycle	$g_{\alpha\beta} : O_\alpha \cap O_\beta \to G$ with $g_{\alpha\beta} g_{\beta\gamma} = g_{\alpha\gamma}$; the structure group G is where they take values	§1.5.2, Chapter 3
change of trivialisation	$g_{\alpha\beta} \mapsto h_\alpha^{-1} g_{\alpha\beta} h_\beta$: a gauge transformation; the bundle is trivial iff one can reach $g_{\alpha\beta} = 1$	Chapter T3, Chapter 8
section	a map $s : M \to E$ with $\pi \circ s = \mathrm{id}$; locally a F-valued function, patched by $s_\alpha = g_{\alpha\beta} s_\beta$; a matter field	§1.5.3, Chapter 2
vector bundle, rank	fibre $\mathbb{R}^k$ or $\mathbb{C}^k$, $g_{\alpha\beta} \in \mathrm{GL}(k)$; TM has $g_{\alpha\beta} =$ Jacobian	§1.5.1
$\oplus$, $\otimes$, dual, Λ^p	do the linear algebra fibrewise, and apply it to the transition matrices ($g \oplus h$, $g \otimes h$, $(g^{\mathsf{T}})^{-1}$)	Chapter 2, Chapter 3
principal bundle P, associated bundle $P \times_\rho V$	fibre G acting on itself; associated bundles use the same $g_{\alpha\beta}$ acting through a representation ρ; frame bundle of TM	§1.5.5, Chapter T3, Chapter T4
Möbius band	the simplest non-trivial bundle, $g = -1$ on one overlap; every section vanishes	Example 1.87
clutching	bundles over $S^n \leftrightarrow [S^{n-1}, G] = \pi_{n-1}(G)$ (connected G)	§1.5.6, Chapter 3, Chapter 8
monopole bundle	$g_{NS} = e^{in\phi}$ on the equator; $\int_{S^2} \frac{i}{2\pi} F = n$: Dirac quantisation	§1.5.6, Chapter 8
Hopf fibration	$S^1 \to S^3 \to S^2$, the $n = 1$ monopole bundle; fibres are linked circles	§1.5.7
TS^2, hairy ball	transition $-1/z^2$ winds twice; $c_1 = \chi(S^2) = 2$; every vector field on S^2 vanishes	§1.5.8, Chapter 7
pullback f^*	pull back forms (substitute), classes, and bundles ($g_{\alpha\beta} \circ f$); homotopic maps pull back isomorphic bundles	§1.5.10, Chapter 4
$EG \to BG$	bundles over $M \leftrightarrow [M, BG]$; $B\mathrm{U}(1) = \mathbb{CP}^\infty$, $B\mathrm{O}(1) = \mathbb{RP}^\infty$; $\pi_n(BG) = \pi_{n-1}(G)$	§1.5.11, Chapter 3
characteristic classes	pull back universal classes: c_i ($\mathrm{U}(n)$), p_i ($\mathrm{O}(n)$), w_i (mod 2), e ($\mathrm{SO}(2m)$); in practice $c_1 = [\frac{i}{2\pi} \operatorname{tr} F]$, $c_2 = \frac{1}{8\pi^2}[\operatorname{tr} F \wedge F]$	§1.5.12, Chapter 3, Chapter 4
homotopy exact sequence	$\cdots \to \pi_n(F) \to \pi_n(E) \to \pi_n(M) \xrightarrow{\partial} \pi_{n-1}(F) \to \cdots$; computes $\pi_3(S^2)$, $\pi_2(G/H)$	§1.5.13, Chapter 8
cohomology of a bundle	no simple rule; the spectral sequence; $\chi(E) = \chi(F)\chi(M)$ survives	§1.5.14, Chapter 7
fibration, homotopy lifting	a map along which homotopies lift; all fibres homotopy equivalent, not necessarily homeomorphic	§1.5.15
path fibration	$\Omega M \to PM \to M$ with PM contractible; gives $\pi_n(\Omega M) = \pi_{n+1}(M)$	§1.5.16, Chapter 7, Chapter 6

Nash §6: differentiable structures for manifolds (§1.6)

Concept	Operational meaning	Returns in
$TOP_n \supset PL_n \supset DIFF_n$	the three groups of local transition functions; $DIFF_n \simeq \mathrm{O}(n)$; direct limits TOP, PL, O	§1.6.1
$BTOP$, BPL, $B\mathrm{O}$	the tangent bundle is a map $M \to BTOP$; a PL or smooth structure is a lift to BPL or $B\mathrm{O}$	§1.6.2
lifting problem	a lift through $F \to E \to B$ is a section of a pulled-back bundle with fibre F	§1.6.3
obstruction theory	extend a section cell by cell; the obstruction to the next step lies in $H^{k+1}(M;\pi_k(F))$, choices in $H^k(M;\pi_k(F))$	§1.6.4, Chapter 10
Euler class, w_1, w_2	obstructions to a non-vanishing vector field, to orientation, to a spin structure; spin structures counted by $H^1(M;\mathbb{Z}_2)$	Example 1.110, Example 1.111, Chapter T4
Kirby–Siebenmann class	$TOP/PL = K(\mathbb{Z}_2,3)$; for $\dim M \geq 5$ a PL structure exists iff $ks(M) = 0 \in H^4(M;\mathbb{Z}_2)$; count by $H^3(M;\mathbb{Z}_2)$	§1.6.5
Hauptvermutung	"homeomorphic triangulated spaces are PL homeomorphic"; false	§1.6.5
PL/O, Θ_n	$\pi_k(PL/\mathrm{O}) = \Theta_k$: 0 for $k \leq 6$, $\mathbb{Z}_{28}$ for $k = 7$; smooth structures on S^7	§1.6.6, Chapter 10
Milnor spheres	S^3-bundles over S^4 with Euler number 1, told apart by $2p_1^2 - \sigma \bmod 7$	Example 1.114
Whitney trick	cancel intersection points across an embedded disc; works for $n \geq 5$, fails for $n = 4$	§1.6.7
intersection form q	$q(\alpha,\beta) = \int_M \alpha \wedge \beta$ on $H^2(M;\mathbb{Z})$; symmetric unimodular matrix; rank, signature, type	§1.6.8, Chapter 4, Chapter 12
Freedman	q (and ks if odd) classifies simply connected closed topological 4-manifolds; all forms occur	§1.6.9
E_8	the Cartan matrix of $\mathfrak{e}_8$: even, positive definite, $\sigma = 8$; the E_8 manifold is not smoothable	Example 1.119, Example 1.120
Rohlin	smooth + spin $\Rightarrow 16 \mid \sigma$; from the quaternionic zero modes of the Dirac operator	§1.6.10, Chapter 4
Donaldson	smooth + simply connected + definite $\Rightarrow q \cong \pm I_n$; proof via the 5-dimensional moduli space of $k = 1$ instantons	§1.6.11, Chapter 8, Chapter 12
exotic $\mathbb{R}^4$	$\mathbb{R}^n$ has one smooth structure for $n \neq 4$ and uncountably many for $n = 4$	§1.6.12

A catalogue of the spaces we met

Most statements in this chapter were tested on the same dozen spaces. Table 1.1 collects what we know about them. Knowing this table by heart is the best single preparation for the rest of the book. The integral homology column lists $H_0, H_1, H_2, \ldots$ up to the dimension; cohomology follows from the universal coefficient rule (torsion moves up one degree).

A few entries deserve a line of justification, since not all were computed in the text.

- *Aspherical surfaces.* T^2, $\Sigma_{g\geq 2}$ and K have contractible universal cover $\mathbb{R}^2$ (or the hyperbolic plane). A covering map induces isomorphisms on π_n for $n \geq 2$, so all their higher homotopy groups vanish.
- $\mathbb{RP}^2$. Its universal cover is S^2, so $\pi_n(\mathbb{RP}^2) = \pi_n(S^2)$ for $n \geq 2$: in particular $\pi_3(\mathbb{RP}^2) = \mathbb{Z}$, although $\mathbb{RP}^2$ is only 2-dimensional.
- $\mathbb{CP}^2$. The fibration $S^1 \to S^5 \to \mathbb{CP}^2$ (the Hopf construction one dimension up) gives

space X	π_1	π_2	π_3	$H_0, H_1, H_2, \dots$	χ
point, $\mathbb{R}^n$, disc	0	0	0	$\mathbb{Z}$	1
$S^1 = \mathrm{U}(1)$	$\mathbb{Z}$	0	0	$\mathbb{Z}, \mathbb{Z}$	0
$S^2 = \mathbb{CP}^1$	0	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}, 0, \mathbb{Z}$	2
$S^3 = \mathrm{SU}(2)$	0	0	$\mathbb{Z}$	$\mathbb{Z}, 0, 0, \mathbb{Z}$	0
S^n, $n \geq 4$	0	0	0	$\mathbb{Z}$ in degrees $0, n$	$1 + (-1)^n$
T^2	$\mathbb{Z}^2$	0	0	$\mathbb{Z}, \mathbb{Z}^2, \mathbb{Z}$	0
Σ_g, $g \geq 2$	$\langle a_i, b_i \mid \prod_i [a_i, b_i] \rangle$	0	0	$\mathbb{Z}, \mathbb{Z}^{2g}, \mathbb{Z}$	$2 - 2g$
Klein bottle K	$\langle a, b \mid abab^{-1} \rangle$	0	0	$\mathbb{Z}, \mathbb{Z} \oplus \mathbb{Z}_2, 0$	0
$\mathbb{RP}^2$	$\mathbb{Z}_2$	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}, \mathbb{Z}_2, 0$	1
$\mathbb{RP}^3 = \mathrm{SO}(3)$	$\mathbb{Z}_2$	0	$\mathbb{Z}$	$\mathbb{Z}, \mathbb{Z}_2, 0, \mathbb{Z}$	0
$\mathbb{CP}^2$	0	$\mathbb{Z}$	0	$\mathbb{Z}, 0, \mathbb{Z}, 0, \mathbb{Z}$	3
$S^2 \times S^2$	0	$\mathbb{Z}^2$	$\mathbb{Z}^2$	$\mathbb{Z}, 0, \mathbb{Z}^2, 0, \mathbb{Z}$	4
$\mathrm{SU}(3)$	0	0	$\mathbb{Z}$	$\mathbb{Z}$ in degrees $0, 3, 5, 8$	0
$\mathbb{CP}^\infty = B\mathrm{U}(1) = K(\mathbb{Z}, 2)$	0	$\mathbb{Z}$	0	$\mathbb{Z}$ in every even degree	–
$\mathbb{RP}^\infty = B\mathrm{O}(1) = K(\mathbb{Z}_2, 1)$	$\mathbb{Z}_2$	0	0	$\mathbb{Z}, \mathbb{Z}_2, 0, \mathbb{Z}_2, 0, \dots$	–

Table 1.1: The spaces of the chapter. Read the columns against each other: π_1 abelianises to H_1 (Hurewicz); the first non-zero π_n of a simply connected space equals H_n; the higher π_n carry information that homology throws away (compare $\pi_3(S^2) = \mathbb{Z}$ with $H_3(S^2) = 0$); χ is the alternating sum of the ranks.

$\pi_n(\mathbb{CP}^2) = \pi_n(S^5) = 0$ for $3 \leq n \leq 4$ and $\pi_2(\mathbb{CP}^2) = \pi_1(S^1) = \mathbb{Z}$, by the same argument as Example 1.100.

- $S^2 \times S^2$. Homotopy groups of products are products; homology by Künneth (Example 1.84).
- $\mathrm{SU}(3)$. The fibration $\mathrm{SU}(2) \to \mathrm{SU}(3) \to S^5$ gives $\pi_3(\mathrm{SU}(3)) = \pi_3(\mathrm{SU}(2)) = \mathbb{Z}$; its cohomology is an exterior algebra on generators of degrees 3 and 5, so the Poincaré polynomial is $(1 + t^3)(1 + t^5)$ and $\chi = 0$, as for every compact Lie group of positive dimension.

One space, every tool: the chapter on S^2

The best test of a toolbox is to use every tool on the same object. We do it for the two-sphere, the space on which the chapter's ideas were most often illustrated.

Worked example 1.122: Everything about S^2, in one place

Homotopy. $\pi_1(S^2) = 0$ because a loop can be moved off a point and then shrunk in $S^2 \setminus \{\mathrm{pt}\} \cong \mathbb{R}^2$. $\pi_2(S^2) = \mathbb{Z}$ by the degree. $\pi_3(S^2) = \mathbb{Z}$ by the Hopf fibration:

$$\pi_3(S^2) \overset{(1)}{=} \pi_3(S^3) \overset{(2)}{=} \mathbb{Z}.$$

(1) The exact sequence of $S^1 \to S^3 \to S^2$ reads $\pi_3(S^1) \to \pi_3(S^3) \to \pi_3(S^2) \to \pi_2(S^1)$, and both ends vanish because the universal cover of S^1 is the contractible line $\mathbb{R}$ (Example 1.100).

(2) The degree of maps $S^3 \to S^3$.

Homology from a triangulation. The hollow tetrahedron (Example 1.70) has 4 vertices, 6 edges and 4 faces, and its boundary matrices give $H_0 = \mathbb{Z}$, $H_1 = 0$, $H_2 = \mathbb{Z}$. Its Euler characteristic

is

$$\begin{aligned}\chi(S^2) &\overset{(1)}{=} N_0 - N_1 + N_2 \\ &= 4 - 6 + 4 = 2 \\ &\overset{(2)}{=} b_0 - b_1 + b_2 = 1 - 0 + 1.\end{aligned}$$

(1) The Euler characteristic of the simplicial chain complex is the alternating count of simplices (Example 1.85).
(2) The Euler–Poincaré formula: the same alternating sum computed from the homology, since rank arithmetic cancels in pairs.

De Rham. The area form $\omega = \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$ is closed (it is a top form) and is not exact, because

$$\begin{aligned}\int_{S^2} \omega &\overset{(1)}{=} \int_0^{2\pi}\int_0^{\pi} \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi = 4\pi \\ &\overset{(2)}{\neq} 0 = \int_{S^2} \mathrm{d}\alpha.\end{aligned}$$

(1) Direct integration in spherical coordinates.
(2) Stokes: $\int_{S^2} \mathrm{d}\alpha = \int_{\partial S^2} \alpha = 0$ since $\partial S^2 = \varnothing$.

So $H^2_{\mathrm{dR}}(S^2) = \mathbb{R}$, spanned by $[\omega/4\pi]$; Mayer–Vietoris with two discs gives the same answer (Example 1.79), as the de Rham theorem demands.

Bundles. By clutching, U(1) bundles on S^2 are classified by $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$: the transition function on the equator is $e^{in\phi}$ and the Chern number is $\int_{S^2} \frac{i}{2\pi} F = n$ (Example 1.91). The case $n = 1$ is the Hopf bundle. The tangent bundle, viewed as a complex line bundle, has transition function $-1/z^2$, which winds twice, and its Chern number equals the Euler characteristic, as Gauss–Bonnet (Chapter T2) confirms for the round sphere of radius r:

$$\begin{aligned}\frac{1}{2\pi}\int_{S^2} K\,\mathrm{d}A &\overset{(1)}{=} \frac{1}{2\pi}\cdot\frac{1}{r^2}\cdot 4\pi r^2 \\ &= 2 = \chi(S^2).\end{aligned}$$

(1) The Gaussian curvature of the round sphere is the constant $1/r^2$ and its area is $4\pi r^2$.

Since $\chi \neq 0$, TS^2 has no nowhere-zero section: the hairy ball theorem (§1.5.8).

Smooth structures. In dimension 2 every topological manifold has exactly one smooth structure (Radó; §1.6). So for S^2 the top three rungs of Figure 1.66 coincide, and the coarse invariants above say everything: a closed simply connected surface is S^2.

The formulas of the chapter

Key idea: Formulas to know by heart

winding number / degree: $\deg f = \dfrac{1}{2\pi i}\oint \dfrac{\mathrm{d}f}{f}$, $\deg f = \displaystyle\int_{S^n} f^*\omega \ \left(\int_{S^n}\omega = 1\right)$

homology of a complex: $H^n = \dfrac{\operatorname{Ker} d_n}{\operatorname{Im} d_{n-1}}$, $d_n \circ d_{n-1} = 0$

Euler characteristic:	$\chi = \sum_k (-1)^k N_k = \sum_k (-1)^k b_k, \qquad \chi(\Sigma_g) = 2 - 2g$
products:	$P_{X\times Y}(t) = P_X(t)\,P_Y(t), \qquad \chi(X \times Y) = \chi(X)\chi(Y)$
Poincaré duality:	$b_p(M) = b_{n-p}(M) \quad (M^n$ closed, oriented$)$
Hurewicz:	$H_1(X;\mathbb{Z}) = \pi_1(X)/[\pi_1(X), \pi_1(X)]$
cocycle condition:	$g_{\alpha\beta}\, g_{\beta\gamma} = g_{\alpha\gamma}$ on $O_\alpha \cap O_\beta \cap O_\gamma$
gauge change:	$g_{\alpha\beta} \mapsto h_\alpha^{-1} g_{\alpha\beta} h_\beta, \qquad A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$
clutching:	$\{G$-bundles on $S^n\} \leftrightarrow \pi_{n-1}(G) \quad (G$ connected$)$
classifying spaces:	$\{G$-bundles on $M\} \leftrightarrow [M, BG], \qquad \pi_n(BG) = \pi_{n-1}(G)$
Chern numbers:	$c_1 = \left[\frac{i}{2\pi}\operatorname{tr} F\right], \qquad k = \frac{1}{8\pi^2}\int_M \operatorname{tr} F \wedge F$
fibration sequence:	$\cdots \to \pi_n(F) \to \pi_n(E) \to \pi_n(M) \to \pi_{n-1}(F) \to \cdots$
obstructions:	$\mathfrak{o} \in H^{k+1}(M;\pi_k(F)), \qquad$ choices $\in H^k(M;\pi_k(F))$
intersection form:	$q(\alpha,\beta) = \int_M \alpha \wedge \beta, \qquad \sigma = b_+ - b_-$
Rohlin:	smooth, closed, spin 4-manifold $\Rightarrow 16 \mid \sigma$
Donaldson:	smooth, $\pi_1 = 0$, definite $\Rightarrow q \cong \pm I$
Yang–Mills bound:	$S = \|F\|^2 \geq 8\pi^2\,\lvert k\rvert$, equality iff $F = \pm \star F$

And the numbers: $\pi_3(S^2) = \mathbb{Z}$, $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$, $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$, $\pi_3(TOP/PL) = \mathbb{Z}_2$, $\Theta_7 = \mathbb{Z}_{28}$, $\dim \mathcal{M}_k = 8k-3$ for SU(2) instantons on S^4 or in Donaldson's set-up (simply connected, definite form; $= 5$ for $k = 1$), and $\sigma(E_8) = 8$.

Dictionary: topology and physics

The dictionary below translates each tool of the chapter into the physics it describes. It is the table to consult when a physics paper uses a topological word without explaining it.

Dictionary: The chapter's mathematics and its physical avatars

$[X, Y]$, **homotopy class:** topological sector of a field $\phi : X \to Y$; conserved because finite action forbids jumps

$\pi_0, \pi_1, \pi_2, \pi_3$ **of the vacuum manifold:** domain walls, vortices / flux tubes, monopoles, textures and skyrmions

$\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$**:** spin $\frac{1}{2}$: a 2π rotation is not homotopic to the identity, a 4π rotation is

$\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$**:** instanton number, large gauge transformations, θ-vacua, baryon number of skyrmions

$\pi_3(S^2) = \mathbb{Z}$ **(Hopf invariant):** Hopf solitons; linking of flux lines; the Hopf term in $2+1$ dimensions

closed form modulo exact, $H^2(M;\mathbb{Z})$**:** quantised flux: magnetic charge, $\oint F/2\pi \in \mathbb{Z}$

$H^1(M;\mathbb{R})$**:** Aharonov–Bohm phases, flat connections, Wilson lines around non-contractible loops

de Rham theorem, periods: a field strength is determined, up to gauge, by its fluxes through cycles

Betti numbers, harmonic forms: zero modes of the Laplacian on forms

$\chi(M)$**:** index of $\mathrm{d} + \mathrm{d}^\dagger$; Gauss–Bonnet; number of zeros of a vector field, with signs

fibre bundle, transition functions: gauge field configuration defined patch by patch; $g_{\alpha\beta}$ are gauge transformations on overlaps

principal bundle P: the gauge structure itself; G the gauge group

section of an associated bundle: a matter field in the representation ρ

monopole bundle, Hopf fibration: Dirac monopole, Wu–Yang patches, Dirac quantisation

c_1, c_2: magnetic charge, instanton number

w_2: obstruction to having fermions (a spin structure) at all

obstruction theory: "can this field configuration be extended inside?"; the answer is a topological charge

loop space ΩG, path fibration: loop groups, Kac–Moody symmetry, Wilson loops, strings

intersection form, E_8: lattice of electric and magnetic fluxes; θ periodicity; even lattices in string theory

instanton moduli space $\mathcal{M}_k$: collective coordinates of instantons; Donaldson invariants as correlation functions of a topological field theory

smooth structure: a choice hidden in every path integral over metrics; exotic spheres enter global gravitational anomalies

Where Chapter 1 goes next

Figure 1.67 shows how the chapter's five main tools feed the rest of the book. Nothing in Chapter 1 was analysis: there were no differential equations, only their topological shadows. The next chapter supplies the analysis. An elliptic operator acts on sections of vector bundles (§1.5); its kernel is the analytic incarnation of a cohomology group (§1.4); and its index turns out to be a characteristic number (§1.5.12). The simplest case is already in hand: the index of the de Rham operator $\mathrm{d} + \mathrm{d}^\dagger$ is $\chi(M)$.

Watch out: Five confusions to leave behind in Chapter 1

- *Homotopy groups are not homology groups.* They agree in the lowest non-trivial degree (Hurewicz) and then diverge: $\pi_3(S^2) = \mathbb{Z}$ but $H_3(S^2) = 0$. Homology vanishes above the dimension; homotopy does not.
- *H_n and H^n are not simply "isomorphic".* With integer coefficients torsion shifts up a degree: $H_1(\mathbb{RP}^2) = \mathbb{Z}_2$ but $H^1(\mathbb{RP}^2;\mathbb{Z}) = 0$ and $H^2(\mathbb{RP}^2;\mathbb{Z}) = \mathbb{Z}_2$ (Example 1.76). Only with field coefficients are they dual vector spaces.
- *De Rham cohomology is blind to torsion.* It computes $H^*(M;\mathbb{R})$, which forgets every $\mathbb{Z}_k$. Spin structures, w_2 and the Kirby–Siebenmann class all live in torsion, so they are invisible to forms.
- *The fibres of a fibration need not be homeomorphic*, only homotopy equivalent; those of a bundle are homeomorphic to F.
- *Homeomorphic does not mean diffeomorphic.* In dimension 7 there are 28 smooth spheres; on $\mathbb{R}^4$ uncountably many smooth structures. Physics done "on a manifold" silently picks one.

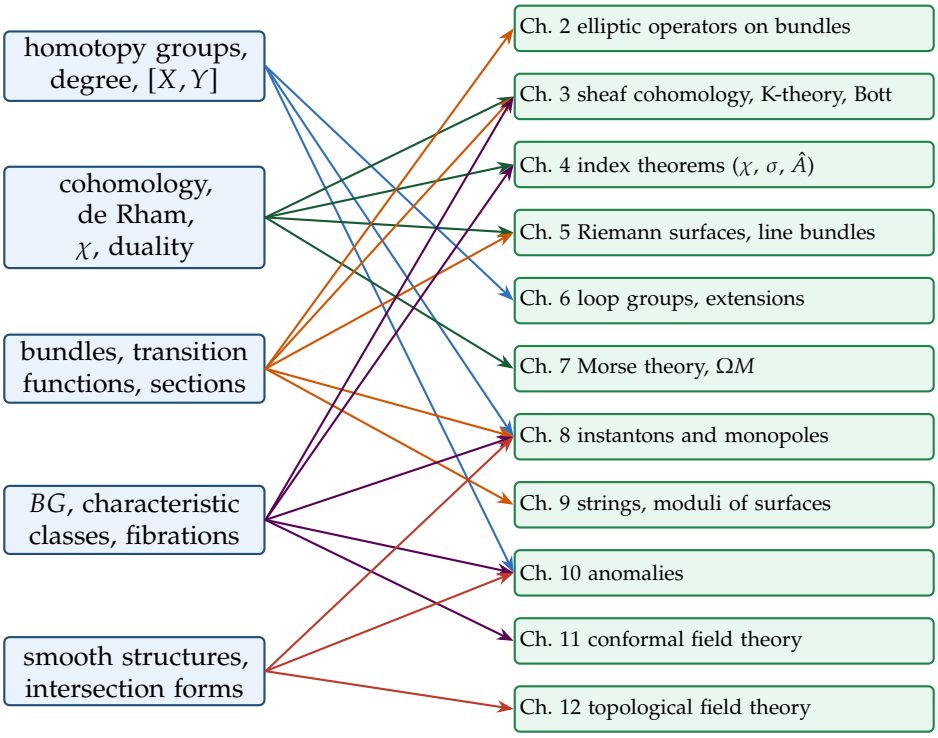

Figure 1.67: How Chapter 1 feeds the book. Each tool (left) is drawn with its own colour of arrow, so one can follow, for example, the red arrows of smooth structures to instantons (Donaldson), anomalies (exotic spheres and global gravitational anomalies) and topological field theory (Donaldson invariants). Cohomology and bundles are used almost everywhere; the arrows show only where they are the main actors.

Self-test

Try it: Ten questions on Chapter 1

(1) Compute χ of the octahedron and of a triangulated torus with 9 vertices.

(2) Why is every map $S^2 \to T^2$ null-homotopic?

(3) What is $[T^2, S^1]$, and what are the classes' representatives?

(4) Use Mayer–Vietoris to show $H^1_{\mathrm{dR}}(S^1 \vee S^1) = \mathbb{R}^2$ (cover by two thickened circles).

(5) How many U(1) bundles are there on S^2? On S^3? On S^4 with structure group SU(2)?

(6) Does T^2 admit a nowhere-vanishing vector field? Does Σ_2?

(7) How many spin structures does Σ_g have?

(8) Check that the exact sequence of $\mathrm{SO}(2) \to \mathrm{SO}(3) \to S^2$ is consistent with $\pi_2(S^2) = \mathbb{Z}$, and find the image of the generator of $\pi_2(S^2)$ in $\pi_1(\mathrm{SO}(2))$.

(9) Is $S^2 \times S^2$ spin? What does Rohlin say about it?

(10) Which of the forms I_3, E_8, $E_8 \oplus E_8$, $H \oplus H$ are intersection forms of smooth closed simply connected 4-manifolds?

Answers.

(1) Octahedron: $6-12+8=2$. Torus: 9 vertices, 27 edges, 18 triangles, $\chi = 9-27+18 = 0$.

(2) The universal cover of T^2 is the contractible $\mathbb{R}^2$, and S^2 is simply connected, so every map lifts to $\mathbb{R}^2$ and contracts there.

(3) $\mathbb{Z}^2$, represented by $e^{i(m\theta+n\phi)}$, detected by the two winding numbers (Example 1.60).

(4) Each piece retracts to a circle and the overlap (a neighbourhood of the wedge point) is contractible, so the sequence is $0 \to H^0 \to \mathbb{R}^2 \to \mathbb{R} \xrightarrow{\mathrm{d}^*} H^1 \to \mathbb{R}^2 \to 0$. The difference map $\mathbb{R}^2 \to \mathbb{R}$ is onto, so $\mathrm{d}^* = 0$ and $H^1 \cong \mathbb{R}^2$.

(5) On S^2: $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$, one for each monopole charge. On S^3: $\pi_2(\mathrm{U}(1)) = 0$, only the trivial one. On S^4: $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$, one for each instanton number.

(6) Yes: $\chi(T^2) = 0$ and ∂_θ works. No: $\chi(\Sigma_2) = -2 \neq 0$.

(7) $|H^1(\Sigma_g; \mathbb{Z}_2)| = 2^{2g}$ (orientable surfaces have $w_2 = 0$).

(8) $\pi_2(\mathrm{SO}(3)) = 0 \to \pi_2(S^2) \to \pi_1(\mathrm{SO}(2)) = \mathbb{Z} \to \pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2 \to \pi_1(S^2) = 0$. The map $\mathbb{Z} \to \mathbb{Z}_2$ is onto, so its kernel $2\mathbb{Z} \cong \mathbb{Z}$ is the image of $\pi_2(S^2)$; and ∂ is injective because $\pi_2(\mathrm{SO}(3)) = 0$, so $\pi_2(S^2) \cong 2\mathbb{Z} \cong \mathbb{Z}$ (a degree-one class maps to twice the generator: the frame of a sphere turns twice around the equator, as for TS^2).

(9) Yes: $q = H$ is even and $S^2 \times S^2$ is simply connected, so $w_2 = 0$. Rohlin requires $16 \mid \sigma$, and indeed $\sigma = 0$.

(10) I_3 ($\#^3\mathbb{CP}^2$) and $H \oplus H$ ($\#^2 S^2 \times S^2$) yes. E_8 no (Rohlin). $E_8 \oplus E_8$ no (Donaldson: it is definite but not diagonal).

With these tools in hand we can turn from topology to analysis. The next chapter asks what makes a differential operator "elliptic", and why elliptic operators on compact manifolds have finite-dimensional kernels whose difference of dimensions, the index, is a topological invariant of exactly the kind this chapter taught us to compute.

Chapter 2

Elliptic Operators

Where this chapter is going

Physics is full of differential operators: the Laplacian of electrostatics, the d'Alembertian of wave propagation, the heat operator of diffusion, the Schrödinger operator, the Dirac operator. They do not all behave alike. The Laplacian is "kind": feed it a smooth source and every solution is smooth, and on a compact space it has finitely many zero modes. The wave operator is "unkind": a kink in the initial data travels along light rays forever and never smooths out. This chapter isolates the property that makes the Laplacian kind. It is called **ellipticity**, and it can be read off from a single polynomial, the *principal symbol*, obtained by Fourier transforming the highest derivatives. Once we know how to recognise ellipticity, we can carry it to operators acting on sections of vector bundles, such as the Hodge Laplacian on p-forms and the Dirac operator. That leads to Hodge's theorem: the zero modes of the Laplacian on p-forms count the p-dimensional holes of the manifold. The chapter then widens the class of operators to pseudo-differential operators and Sobolev spaces (part 2b), which is the analytic engine behind the index theorem of Chapter 4.

In this part (Nash §1–§3) we build the core ideas: the symbol, ellipticity, hypo-ellipticity, elliptic regularity, the bundle version of ellipticity, the symbol calculus of d, d^* and Δ_p, and the Hodge theorem. Figure 2.1 shows how these ideas feed into each other and into the physics used later in the book.

Conventions for this part. We work on $\mathbb{R}^n$ with coordinates $x = (x_1, \dots, x_n)$ and on smooth manifolds M of dimension n. Unless we say otherwise, everything is Euclidean (signature $+\cdots+$). When we need Minkowski space we write $(t, x_1, \dots, x_n)$ and use the wave operator $\partial_t^2 - \nabla^2$, so the metric is $(+, -, \dots, -)$ in the "∂_t^2 first" sense. We write p (Nash's notation in §1–§2) or k (Nash's notation in §3) for the Fourier variable. Our Fourier convention is fixed in Section 2.1.2; it differs from Nash's footnote by a sign, and we explain why in the "Watch out" box on page 728.

2.1 The meaning of ellipticity

Here is the question this section answers. We have three famous second-order operators in two variables:

$$-\Big(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\Big) \text{ (Laplace)}, \qquad \frac{\partial^2}{\partial t^2} - \frac{\partial^2}{\partial x^2} \text{ (wave)}, \qquad \frac{\partial}{\partial t} - \frac{\partial^2}{\partial x^2} \text{ (heat)}.$$

They look almost the same: each is a combination of second derivatives, the first two differ only by a sign. Yet their solutions behave completely differently. Solutions of Laplace's equation are

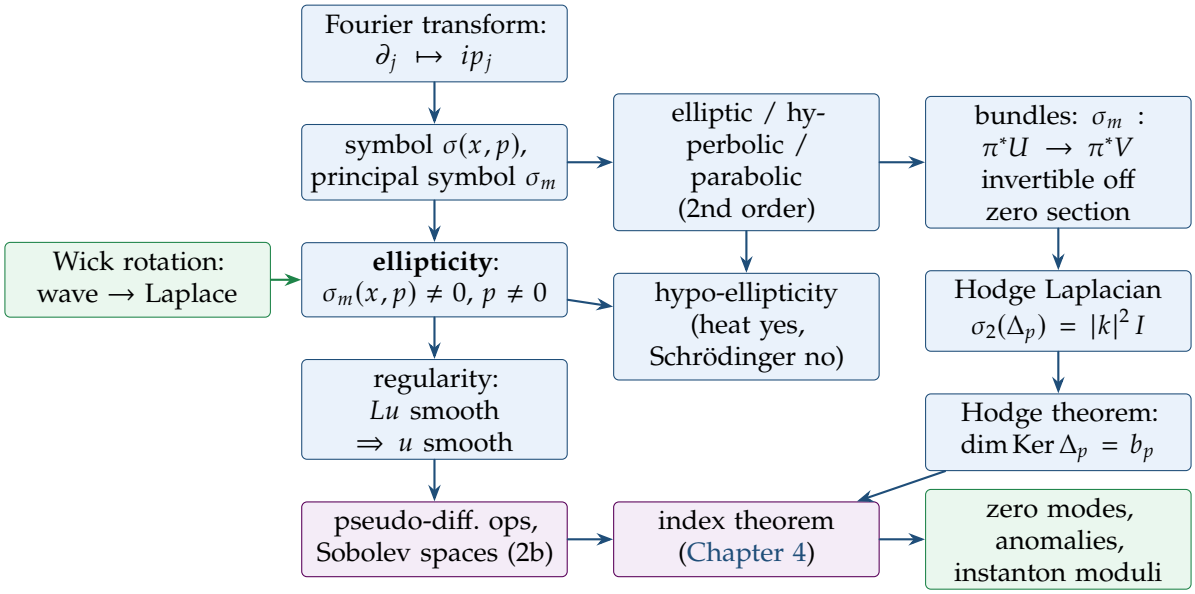

Figure 2.1: The logic of Chapter 2. Read it top to bottom. The Fourier transform turns derivatives into polynomials. The top-degree part of the polynomial (the principal symbol) decides whether the operator is elliptic. Ellipticity gives smoothness of solutions, survives the passage to vector bundles, and powers Hodge theory. Hodge theory and the pseudo-differential machinery (purple, part 2b) together feed the index theorem, which is what physics uses (green) to count zero modes.

as smooth as can be. Solutions of the wave equation can carry a kink forever. Solutions of the heat equation become smooth instantly, but only forwards in time. *What feature of the operator decides this?* Nash's answer, which we develop here, is: *Fourier transform the operator, keep only the highest-order terms, and look at where the resulting polynomial vanishes.*

Before we start, it helps to know why a book on topology and physics cares.

2.1.1 Why ellipticity matters for topology and physics

Take a compact Riemannian manifold M (a sphere, a torus, a Calabi–Yau space, Euclidean space-time compactified to S^4). On it there is a Laplacian Δ_p acting on p-forms. We will define it carefully in Section 2.3.7; for now think of it as the operator $-\nabla^2$ applied component by component. The celebrated **Hodge–de Rham theorem**, which we reach in Section 2.3.12, says

$$\dim \operatorname{Ker} \Delta_p \;=\; \dim H^p(M;\mathbb{R}) \;=\; b_p, \tag{2.1}$$

where $H^p(M;\mathbb{R})$ is the p-th de Rham cohomology group (closed p-forms modulo exact ones, see Chapter T2) and b_p is the p-th Betti number, the number of independent p-dimensional "holes" of M.

Read (2.1) as a physicist. The left side counts **zero modes**: solutions of $\Delta_p \omega = 0$, the static, source-free field configurations. The right side is topology, so it does not change when we deform the metric. Something analytic (a count of solutions of a PDE) equals something topological (a count of holes). Three things are needed to make sense of the left side:

1. the kernel must be *finite-dimensional*, or the count means nothing;
2. the solutions must be *smooth*, so that they really are differential forms and represent de Rham classes;
3. the count must be *stable* under deformations.

All three are consequences of ellipticity. The index theorem of Chapter 4 generalises (2.1) from Δ_p to any elliptic operator, and in physics it counts fermion zero modes in an instanton background, computes anomalies, and gives the dimension of instanton moduli spaces. So ellipticity is the entry ticket to everything that follows.

Physical picture: Elliptic = "no preferred direction of propagation"

An elliptic equation describes *equilibrium*: a soap film, an electrostatic potential, a static field. Every point feels every other point, and there is no direction along which disturbances run away. A hyperbolic equation describes *propagation*: signals move along special directions (light rays), and a sharp front stays sharp. A parabolic equation describes *diffusion*: there is a preferred time direction, and sharp features melt away as time goes forwards.

2.1.2 The Fourier transform: derivatives become multiplication

The one tool behind everything in this chapter is the Fourier transform. We recall it now and fix conventions.

Working definition 2.1 (Fourier transform)

For a function $u(x)$ on $\mathbb{R}^n$ that decays fast enough [fast enough for the integral below to converge, e.g. $\int |u| \, \mathrm{d}^n x < \infty$], its **Fourier transform** is

$$\hat{u}(p) \;=\; \mathcal{F}(u)(p) \;=\; \frac{1}{(2\pi)^{n/2}} \int_{\mathbb{R}^n} e^{-ip\cdot x}\, u(x)\, \mathrm{d}^n x, \tag{2.2}$$

and u is recovered by the **inverse transform**

$$u(x) \;=\; \frac{1}{(2\pi)^{n/2}} \int_{\mathbb{R}^n} e^{ip\cdot x}\, \hat{u}(p)\, \mathrm{d}^n p. \tag{2.3}$$

Here $p \cdot x = p_1 x_1 + \cdots + p_n x_n$. *Operationally*: u is a superposition of plane waves $e^{ip\cdot x}$, and $\hat{u}(p)$ is the amplitude of the wave with wave-vector p.

The key property is what a derivative does. Differentiate the inverse transform (2.3) under the integral sign:

$$\begin{aligned} \frac{\partial u}{\partial x_j}(x) &\overset{(1)}{=} \frac{1}{(2\pi)^{n/2}} \int_{\mathbb{R}^n} \frac{\partial}{\partial x_j}\left(e^{ip\cdot x}\right) \hat{u}(p)\, \mathrm{d}^n p \\ &\overset{(2)}{=} \frac{1}{(2\pi)^{n/2}} \int_{\mathbb{R}^n} e^{ip\cdot x}\, \big(i p_j\, \hat{u}(p)\big)\, \mathrm{d}^n p. \end{aligned} \tag{2.4}$$

(1) Only the plane wave depends on x; $\hat{u}(p)$ does not.
(2) $\partial_{x_j} e^{ip\cdot x} = i p_j\, e^{ip\cdot x}$, since $p \cdot x$ contains x_j only in the term $p_j x_j$.

Comparing with (2.3), the function $\partial_j u$ has Fourier transform $i p_j \hat{u}(p)$. So

$$\boxed{\frac{\partial}{\partial x_j} \;\longleftrightarrow\; \text{multiplication by } i p_j} \qquad \text{and} \qquad -i\frac{\partial}{\partial x_j} \;\longleftrightarrow\; \text{multiplication by } p_j. \tag{2.5}$$

The second form is why Nash (and quantum mechanics) like the operator $D_j := -i\,\partial/\partial x_j$: it is the momentum operator (with $\hbar = 1$), and on a plane wave it just reads off the momentum, $D_j e^{ip\cdot x} = p_j e^{ip\cdot x}$.

Applying (2.5) twice, a second derivative becomes $\partial_j \partial_k \leftrightarrow (ip_j)(ip_k) = -p_j p_k$. Any linear differential operator with constant coefficients therefore becomes *multiplication by a polynomial*. Solving a constant-coefficient PDE becomes division by that polynomial. Everything difficult about the PDE is hidden in *where the polynomial vanishes*, because that is where we cannot divide.

Watch out: Nash's Fourier convention

Nash's footnote on p. 28 defines $\mathcal{F}(f) = (2\pi)^{-n} \int e^{+ipx} f \, \mathrm{d}^n x$ (note: the full $(2\pi)^{-n}$, not our symmetric $(2\pi)^{-n/2}$), and in (2.21) he writes the inverse transform with e^{-ipx} and *no* extra 2π factor. So Nash's pair is asymmetric: all of $(2\pi)^{-n}$ sits on the forward transform, none on the inverse. Ours (2.2)–(2.3) splits it symmetrically, $(2\pi)^{-n/2}$ each way, and uses the opposite sign convention for which map is "forward". With Nash's sign, $-i\partial_j$ becomes multiplication by $-p_j$, not p_j, so his formula (2.21) is off by a factor $(-1)^{|\alpha|}$ in each term compared with ours. None of this matters for ellipticity, which only asks whether the top-order polynomial *vanishes*: a sign or a real constant prefactor never changes a zero set. It also never matters for second-order operators, where $(-1)^2 = 1$. We use (2.2)–(2.3) throughout, which makes $D_j \leftrightarrow p_j$ exactly and Nash's symbol formulas correct as written.

Two more facts we will use repeatedly:

- **The delta function is the flat spectrum.** Formally $\hat{\delta}(p) = (2\pi)^{-n/2}$, so
$$\delta(x) \;=\; \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} e^{ip\cdot x} \, \mathrm{d}^n p. \tag{2.6}$$
A point source contains every wavelength with equal weight.
- **Smoothness is decay in p.** If $|\hat{u}(p)| \le C(1+|p|)^{-N}$ with $N > n + k$, then we may differentiate (2.3) k times under the integral: each derivative brings down a factor of size $|p|$, and the integral of $|p|^k (1+|p|)^{-N}$ still converges. So *fast decay of $\hat{u}$ means many derivatives of u*; decay faster than every power means u is C^∞. Conversely a jump or a kink in u produces a slowly decaying tail in $\hat{u}$ (a step gives $\hat{u} \sim 1/p$, a kink gives $\sim 1/p^2$).

Worked example 2.1: Fourier transforming the Laplacian

Nash multiplies the Laplacian by -1 so that it is a *positive* operator:
$$\Delta \;=\; -\frac{\partial^2}{\partial x_1^2} - \cdots - \frac{\partial^2}{\partial x_n^2}. \tag{2.7}$$
Apply it to a plane wave:
$$\Delta\, e^{ip\cdot x} \overset{(1)}{=} -\sum_{j=1}^{n} \frac{\partial^2}{\partial x_j^2} e^{ip\cdot x} \overset{(2)}{=} -\sum_{j=1}^{n} (ip_j)^2 \, e^{ip\cdot x} \overset{(3)}{=} \left(p_1^2 + \cdots + p_n^2\right) e^{ip\cdot x}.$$
(1) Definition (2.7).
(2) Each ∂_j brings down ip_j, by (2.4).
(3) $(ip_j)^2 = -p_j^2$, and the minus signs cancel.

So under Fourier transformation Δ is multiplication by
$$\sigma(\Delta)(p) \;=\; p_1^2 + \cdots + p_n^2 \;=\; |p|^2, \tag{2.8}$$
Nash's (2.3). This is a quadratic form in p. It is *positive*, which is the point of Nash's sign:

for a real function u that decays at infinity,

$$\int_{\mathbb{R}^n} u\,\Delta u\,\mathrm{d}^n x \overset{(1)}{=} -\sum_j \int_{\mathbb{R}^n} u\,\partial_j^2 u\,\mathrm{d}^n x \overset{(2)}{=} \sum_j \int_{\mathbb{R}^n} (\partial_j u)^2\,\mathrm{d}^n x \;\geq\; 0.$$

(1) Definition (2.7).
(2) Integrate by parts in x_j; the boundary term vanishes because u decays.

In quantum mechanics Δ is (twice the mass times) the kinetic energy operator $\hat{\vec{p}}^{\,2}$, and positivity is the statement that kinetic energy is never negative.

2.1.3 Quadratic forms, level sets and the word "elliptic"

Where does the word *elliptic* come from? Nash's answer is geometric. Set the symbol (2.8) equal to a positive constant c: the set $|p|^2 = c$ is a sphere of radius $\sqrt{c}$ in p-space. Now stretch the coordinates. Replace the Laplacian by

$$L \;=\; -\sum_{i=1}^{n} a_i \frac{\partial^2}{\partial x_i^2}, \qquad a_i \in \mathbb{R} \text{ constants}, \tag{2.9}$$

Nash's (2.4). Exactly as in Example 2.1, Fourier transformation turns L into multiplication by

$$\sigma(L)(p) \;=\; \sum_{i=1}^{n} a_i\, p_i^2, \tag{2.10}$$

Nash's (2.5), and the level set $\sigma(L) = c$ is

$$a_1 p_1^2 + \cdots + a_n p_n^2 \;=\; c, \tag{2.11}$$

Nash's (2.6). If every $a_i > 0$ this is an *ellipsoid* with semi-axes $\sqrt{c/a_i}$. That is the origin of the name.

A word about **signature**. A real quadratic form $\sigma(p) = \sum_{ij} a_{ij} p_i p_j$ (with a_{ij} symmetric) can be diagonalised by a rotation of p-space; the diagonal entries are the eigenvalues of the matrix (a_{ij}). If n_+ of them are positive, n_- negative and n_0 zero, the signature is often quoted as the single number $n_+ - n_-$, and that is how Nash uses the word. "Signature $+n$" means all n eigenvalues are positive: the form is **positive definite**. "Signature $n-2$" with $\det \neq 0$ means $n_+ = n-1$, $n_- = 1$: the form is Lorentzian.

Working definition 2.2 (elliptic, constant-coefficient second-order case)

The operator $L = -\sum_i a_i \partial_i^2$ is **elliptic** if its Fourier polynomial [what L becomes after Fourier transform, with each ∂_j replaced by ip_j] $\sigma(L) = \sum_i a_i p_i^2$ is positive definite (signature $+n$), or negative definite (signature $-n$; then $-L$ is positive definite). *Test:* all a_i nonzero and of the same sign. *Equivalent test:* $\sigma(L)(p) \neq 0$ for every real $p \neq 0$; the level sets $\sigma = c$ are ellipsoids, which are bounded.

The last reformulation is the one that generalises. An ellipsoid is *bounded*: if $\sigma(L)(p) = c$ then $|p|$ is at most $\sqrt{c/\min a_i}$. Put differently, $|\sigma(L)(p)|$ grows like $|p|^2$ in *every* direction. For the wave or heat operators the level sets are hyperbolae or parabolae, which run off to infinity: there are directions in p-space along which the symbol does *not* grow. Figure 2.2 shows the three pictures side by side.

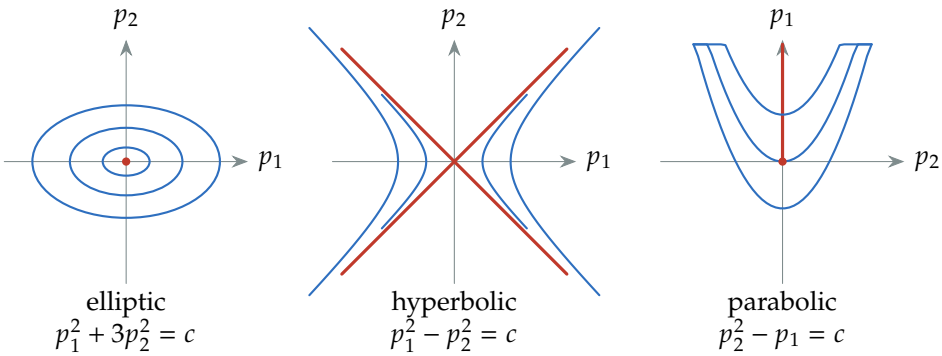

Figure 2.2: Level sets $\sigma(p) = c$ of the Fourier polynomial for the three archetypes (blue), and the directions where the *top-order* part of σ vanishes (red). Elliptic: closed ellipses, the top-order part vanishes only at $p = 0$. Hyperbolic (wave operator): the curves run to infinity along the red light cone $p_1 = \pm p_2$, where σ does not grow. Parabolic (heat or Schrödinger operator): the parabolas open along the p_1-axis. There the second-order part p_2^2 vanishes, and σ grows only linearly.

2.1.4 The payoff: smooth sources give smooth solutions

Why is the ellipsoid picture so important? Because of the following property, which is the main theme of the chapter.

Key idea: Elliptic regularity (Nash's first statement, (2.7))

If L is elliptic and f is a C^∞ function, then every solution u of

$$Lu = f \tag{2.12}$$

is automatically C^∞. More precisely, and this is the useful form, if f is smooth on an open set Ω, then u is smooth on Ω, whatever f does elsewhere.

This is surprising at first. The equation $Lu = f$ only constrains a particular *combination* of second derivatives of u. Why should it control *all* derivatives of all orders? For example, $-\partial_x^2 u - \partial_y^2 u = 0$ says nothing directly about $\partial_x \partial_y u$. The answer is that for an elliptic operator the combination is "fat enough" in Fourier space: it controls $|p|^2\,\hat{u}$, hence every $p_i p_j \hat{u}$. Compare the wave operator: the combination $p_1^2 - p_2^2$ vanishes on the light cone, and $\hat{u}$ can be as large as it likes there without Lu noticing. We now make this precise with Green's functions, following Nash.

Green's functions

Working definition 2.3 (Green's function / fundamental solution)

A **Green's function** (mathematicians say **fundamental solution**) of a constant-coefficient operator L on $\mathbb{R}^n$ is a function or distribution [a generalised function such as δ, known only through its integrals against smooth functions] G with

$$L\,G(x) = \delta(x). \tag{2.13}$$

Operationally: G is the field produced by a unit point source at the origin. *How to compute it*: Fourier transform. Since L becomes multiplication by $\sigma(L)(p)$ and δ has flat spectrum

[$\hat{\delta}(p) = (2\pi)^{-n/2}$, the same for every p] (2.6),

$$G(x) \;=\; \frac{1}{(2\pi)^n}\int_{\mathbb{R}^n} \frac{e^{ip\cdot x}}{\sigma(L)(p)}\,\mathrm{d}^n p, \tag{2.14}$$

which is Nash's (2.9) (Nash drops the $(2\pi)^{-n}$ and uses the opposite sign in the exponent; neither affects the argument).

Once we have G, we can solve $Lu = f$ for any source by superposing point sources:

$$u(x) \;=\; (G * f)(x) \;=\; \int_{\mathbb{R}^n} G(x-y)\,f(y)\,\mathrm{d}^n y, \tag{2.15}$$

Nash's (2.8). Let us check that this works:

$$Lu(x) \overset{(1)}{=} \int_{\mathbb{R}^n} \big(L_x G(x-y)\big)\,f(y)\,\mathrm{d}^n y \overset{(2)}{=} \int_{\mathbb{R}^n} \delta(x-y)\,f(y)\,\mathrm{d}^n y \overset{(3)}{=} f(x).$$

(1) L acts on x; only $G(x-y)$ depends on x.
(2) L has constant coefficients, so $L_x G(x-y) = (LG)(x-y) = \delta(x-y)$ by (2.13).
(3) The defining property of the delta function.

This is the principle of superposition familiar from electrostatics: the potential of a charge distribution ρ is the sum of Coulomb potentials of its point charges.

Worked example 2.2: The Coulomb potential as the Green's function of Δ on $\mathbb{R}^3$

We compute (2.14) for $L = \Delta$ in $\mathbb{R}^3$, where $\sigma = |p|^2$. Put $r = |x|$ and use spherical polar coordinates in p-space with the polar axis along x, so $p\cdot x = pr\cos\theta$ with $p = |p|$.

$$\begin{aligned} G(x) &\overset{(1)}{=} \frac{1}{(2\pi)^3}\int_0^\infty\!\!\int_0^\pi\!\!\int_0^{2\pi} \frac{e^{ipr\cos\theta}}{p^2}\,p^2\sin\theta\,\mathrm{d}\phi\,\mathrm{d}\theta\,\mathrm{d}p \\ &\overset{(2)}{=} \frac{1}{(2\pi)^2}\int_0^\infty\!\!\int_{-1}^1 e^{iprs}\,\mathrm{d}s\,\mathrm{d}p \overset{(3)}{=} \frac{1}{(2\pi)^2}\int_0^\infty \frac{2\sin(pr)}{pr}\,\mathrm{d}p \\ &\overset{(4)}{=} \frac{1}{(2\pi)^2}\,\frac{2}{r}\,\frac{\pi}{2} \;=\; \frac{1}{4\pi r}. \end{aligned}$$

(1) Formula (2.14) in spherical coordinates; the volume element is $p^2\sin\theta\,\mathrm{d}p\,\mathrm{d}\theta\,\mathrm{d}\phi$.
(2) The p^2 cancels, the ϕ integral gives 2π, and we substitute $s = \cos\theta$, $\mathrm{d}s = -\sin\theta\,\mathrm{d}\theta$.
(3) $\int_{-1}^1 e^{iprs}\mathrm{d}s = (e^{ipr} - e^{-ipr})/(ipr) = 2\sin(pr)/(pr)$.
(4) Substitute $q = pr$ and use the Dirichlet integral $\int_0^\infty (\sin q/q)\,\mathrm{d}q = \pi/2$.

So the Green's function of the positive Laplacian in $\mathbb{R}^3$ is the Coulomb potential $G = 1/(4\pi r)$. Notice two things. It is singular only at $r = 0$, where the source sits. Away from $r = 0$ it is C^∞, indeed real analytic.

Worked example 2.3: The same result from Gauss's law

We can confirm $\Delta(1/4\pi r) = \delta$ without Fourier transforms, using only Stokes' theorem in its Gauss form (Chapter T2). Away from the origin, with $G = 1/(4\pi r)$,

$$\Delta G \overset{(1)}{=} -\frac{1}{r^2}\frac{\partial}{\partial r}\Big(r^2\frac{\partial G}{\partial r}\Big) \overset{(2)}{=} -\frac{1}{r^2}\frac{\partial}{\partial r}\Big(r^2\cdot\frac{-1}{4\pi r^2}\Big) \overset{(3)}{=} 0 \qquad (r \neq 0).$$

(1) For a radial function, $\nabla^2 G = r^{-2}\partial_r(r^2\partial_r G)$, and $\Delta = -\nabla^2$.
(2) $\partial_r(1/4\pi r) = -1/(4\pi r^2)$.
(3) $r^2 \cdot (-1/4\pi r^2) = -1/4\pi$ is constant, so its r-derivative is zero.

So ΔG is concentrated at the origin. Its total strength is the integral over a ball B_R of radius R:

$$\int_{B_R} \Delta G \, \mathrm{d}^3x \overset{(1)}{=} -\int_{B_R} \nabla\cdot\nabla G \, \mathrm{d}^3x \overset{(2)}{=} -\oint_{\partial B_R} \nabla G \cdot \mathrm{d}\vec{A} \overset{(3)}{=} -\Big(\frac{-1}{4\pi R^2}\Big) 4\pi R^2 \;=\; 1.$$

(1) $\Delta = -\nabla\cdot\nabla$.
(2) Gauss's divergence theorem (Stokes for the 2-form $\star \mathrm{d}G$).
(3) $\nabla G = -\hat{r}/(4\pi r^2)$ is radial and of constant size on the sphere of area $4\pi R^2$.

A distribution concentrated at a point with total integral 1 is δ. Physically: the electric field of a unit charge has unit flux through any sphere around it.

For later use, here are the Green's functions of Δ in all dimensions. Write $\omega_{n-1} = 2\pi^{n/2}/\Gamma(n/2)$ for the area of the unit sphere S^{n-1} (so $\omega_1 = 2\pi$, $\omega_2 = 4\pi$). The same Gauss's-law argument, with flux $-\partial_r G \cdot \omega_{n-1} r^{n-1} = 1$, gives

$$G_n(x) \;=\; \begin{cases} -\dfrac{1}{2\pi}\ln|x|\,, & n = 2, \\[2ex] \dfrac{1}{(n-2)\,\omega_{n-1}\,|x|^{n-2}}, & n \geq 3. \end{cases} \tag{2.16}$$

Every one of them is singular only at $x = 0$ and real analytic elsewhere.

Why the Green's function of an elliptic operator is smooth away from the source

Now we can see the mechanism behind elliptic regularity. It has two steps.

Step 1: G is smooth for $x \neq 0$. This is where ellipticity enters. We want to show that $G(x)$ in (2.14) has derivatives of all orders away from the origin. Recall the principle "smoothness is decay in p". The function $1/\sigma(p)$ only decays like $|p|^{-2}$, which is not enough to differentiate (2.14) even once in $n \geq 2$ dimensions. That is fine: G really is singular at $x = 0$. The trick is to multiply by powers of x, which kill the singularity at 0, and to see that this improves the decay in p. Since $\partial_{p_j} e^{ip\cdot x} = i x_j e^{ip\cdot x}$, integration by parts gives

$$\begin{aligned} x_j\, G(x) &\overset{(1)}{=} \frac{1}{(2\pi)^n}\int_{\mathbb{R}^n}\Big(-i\frac{\partial}{\partial p_j}e^{ip\cdot x}\Big)\frac{1}{\sigma(p)}\,\mathrm{d}^n p \\ &\overset{(2)}{=} \frac{1}{(2\pi)^n}\int_{\mathbb{R}^n} e^{ip\cdot x}\, i\frac{\partial}{\partial p_j}\Big(\frac{1}{\sigma(p)}\Big)\,\mathrm{d}^n p. \end{aligned} \tag{2.17}$$

(1) $x_j e^{ip\cdot x} = -i\,\partial_{p_j} e^{ip\cdot x}$.
(2) Integrate by parts in p_j (ignoring for the moment the point $p = 0$; see below). The boundary terms at $|p| \to \infty$ vanish because $1/\sigma \to 0$.

So *multiplying G by x_j is the same as differentiating $1/\sigma$ with respect to p_j*. Now use ellipticity. Because σ is a positive definite quadratic form, it is bounded below on the unit sphere, $\sigma(p) \geq \lambda\,|p|^2$ with $\lambda = \min_i a_i > 0$. Differentiating $1/\sigma$ produces terms like $\partial_j\sigma/\sigma^2$, each of which is homogeneous of degree -3, and in general

$$\Big|\partial_p^\gamma\Big(\frac{1}{\sigma(p)}\Big)\Big| \;\leq\; C_\gamma\,|p|^{-2-|\gamma|}\,, \tag{2.18}$$

where ∂_p^γ is any combination of $|\gamma|$ derivatives. *Each p-derivative improves the decay at infinity by one power.* Therefore, for any number k of x-derivatives, the function $|x|^{2N}\,\partial_x^\beta G$ with $|\beta| = k$ has a Fourier transform bounded by a constant times $|p|^{k-2-2N}$ at large $|p|$, which is integrable once $2N > k - 2 + n$. So $|x|^{2N}\,\partial_x^\beta G$ is a continuous function, and dividing by $|x|^{2N}$ (allowed for $x \neq 0$) shows that $\partial_x^\beta G$ exists and is continuous for $x \neq 0$. Since k was arbitrary, G is C^∞ away from the origin.

There is a technical point we skipped: the extra p-derivatives make the singularity of $1/\sigma$ at $p = 0$ worse. It is handled by splitting $1/\sigma = \chi(p)/\sigma + (1 - \chi(p))/\sigma$, where χ is a smooth bump equal to 1 near $p = 0$. The first piece has compact support in p, so its inverse Fourier transform is automatically smooth in x (for $n \geq 3$, where $1/|p|^2$ is integrable near 0; for $n = 2$ one subtracts a constant, which is where the logarithm comes from). The second piece is smooth everywhere in p, so the decay argument applies to it without any trouble at $p = 0$.

Key idea: Where exactly ellipticity was used

The whole argument rests on (2.18), and that estimate holds only because σ *has no zeros except* $p = 0$. If σ vanished on some ray $p = s\,\hat{p}_0$ going to infinity, then $1/\sigma$ would be singular all along that ray. Differentiating would make it more singular, not more decaying, and the argument would collapse. Nash puts it this way: "had the quadratic form $\sigma(L)$ vanished away from the origin the whole argument would have failed."

Nash phrases Step 1 slightly differently. He rescales $p_i \to \tilde{p}_i = \sqrt{a_i}\,p_i$ so that σ becomes $|\tilde{p}|^2$, passes to spherical polar coordinates in $\tilde{p}$-space so that the only nontrivial integral is over the radius $|\tilde{p}|$, and deforms that radial contour in the complex plane (Cauchy's theorem) to make the integral converge absolutely when $x \neq 0$. That is the same mechanism in different clothing: the integrand has no poles for real $\tilde{p} \neq 0$ precisely because σ vanishes only at the origin.

Step 2: from smooth G to smooth u. Suppose $Lu = f$ and f is smooth on an open set Ω. Fix a point $x_0 \in \Omega$ and a small ball B around it with $\bar{B} \subset \Omega$. The following narrative argument shows that u is smooth near x_0.

1. Choose a smooth cutoff χ equal to 1 on a smaller ball B' around x_0 and 0 outside B. The function χu has compact support, so it equals $G * L(\chi u)$ (a compactly supported solution is determined by its source, because $G*$ inverts L on such functions).

2. Compute the source using the product rule: $L(\chi u) = \chi\,Lu + [L, \chi]u = \chi f + [L, \chi]u$. The commutator $[L, \chi]u$ involves derivatives of χ, so it vanishes on B' and outside B: it lives in the shell $B \setminus B'$.

3. Hence near x_0, $\chi u = G*(\chi f) + G*([L, \chi]u)$. The first term is smooth because χf is smooth with compact support: we may move all derivatives onto χf, $\partial^\beta(G * \chi f) = G * \partial^\beta(\chi f)$. The second term is smooth near x_0 because it only uses $G(x - y)$ with x near x_0 and y in the shell. Then $x - y \neq 0$, and G is smooth there by Step 1.

So $u = \chi u$ is smooth near x_0. Only *two* properties of G were used: it inverts L, and it is smooth off the origin. In the language of distributions this is the statement

$$\operatorname{sing\,supp}(u) \;\subseteq\; \operatorname{sing\,supp}(Lu) \qquad \text{whenever} \qquad \operatorname{sing\,supp}(G) = \{0\}, \tag{2.19}$$

where the **singular support** of a function is the closure of the set of points where it fails to be C^∞.

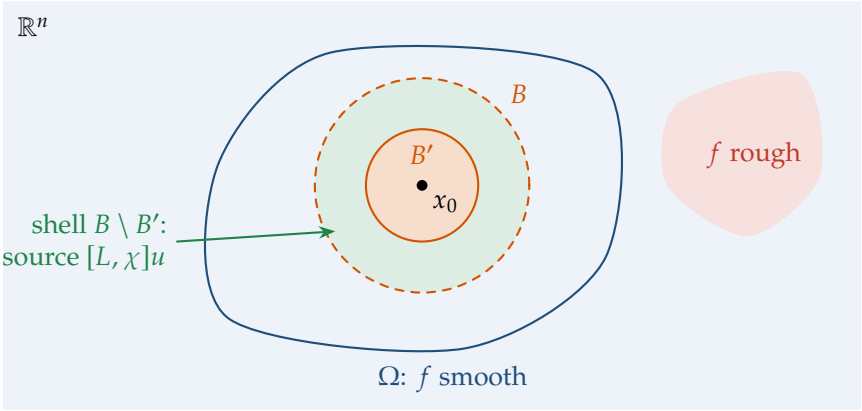

Figure 2.3: The localisation argument of Step 2. The source f is smooth on Ω but may be rough elsewhere (red). Near x_0 we cut u off with χ ($\chi = 1$ on the inner ball B', $\chi = 0$ outside B). The price is a new source $[L, \chi]u$ living only in the shell $B \setminus B'$. Its effect on points near x_0 is felt through G at nonzero separation, where G is smooth. Roughness far away cannot spoil smoothness near x_0.

Weyl's lemma: harmonic means smooth

The simplest instance of elliptic regularity is the case $f = 0$: solutions of Laplace's equation $\Delta u = 0$ (**harmonic functions**) are C^∞, and in fact real analytic. Historically this is **Weyl's lemma**. It says more: even a *distribution* u, a priori just a "generalised function" that need not have any derivatives at all, is a smooth function if $\Delta u = 0$. There is a beautifully physical proof in two dimensions, through the mean value property.

Worked example 2.4: Mean value property of harmonic functions

Let u be harmonic on a region of $\mathbb{R}^2$ containing the closed disc of radius R about x_0. Define the circle average

$$A(r) \;=\; \frac{1}{2\pi}\int_0^{2\pi} u(x_0 + r\cos\phi,\; y_0 + r\sin\phi)\,\mathrm{d}\phi.$$

Then, writing ∂_r for the radial derivative and D_r for the disc of radius r,

$$\frac{\mathrm{d}A}{\mathrm{d}r} \overset{(1)}{=} \frac{1}{2\pi}\int_0^{2\pi} \partial_r u\,\mathrm{d}\phi \overset{(2)}{=} \frac{1}{2\pi r}\oint_{\partial D_r} \nabla u\cdot\hat{n}\,\mathrm{d}s \overset{(3)}{=} \frac{1}{2\pi r}\int_{D_r} \nabla^2 u\,\mathrm{d}^2x \overset{(4)}{=} 0.$$

(1) Differentiate under the integral; ∂_r at fixed ϕ is the radial derivative.
(2) On the circle, $\partial_r u = \nabla u\cdot\hat{n}$ with $\hat{n}$ the outward normal, and arc length is $\mathrm{d}s = r\,\mathrm{d}\phi$.
(3) Divergence theorem in the plane (Stokes).
(4) u is harmonic: $\nabla^2 u = -\Delta u = 0$.

So $A(r)$ is constant, and letting $r \to 0$ gives $A(r) = u(x_0)$: *a harmonic function equals its average over every circle around a point.* The same argument in $\mathbb{R}^n$ uses spheres.

Here is why this gives smoothness. Let $\phi_\varepsilon(x)$ be a smooth radial bump of total integral 1 supported in the disc of radius ε. Averaging the mean-value identity over radii with weight ϕ_ε gives

$$u \;=\; u * \phi_\varepsilon \qquad \text{near any point at distance} > \varepsilon \text{ from the edge of the region.}$$

But a convolution with a smooth function is smooth, since all derivatives can be moved onto ϕ_ε: $\partial^\beta(u * \phi_\varepsilon) = u * \partial^\beta\phi_\varepsilon$. So u is C^∞. The argument used *only* integrals of u, so it works even

for merely integrable u, which is Weyl's lemma. Harmonic functions are self-smoothing: each is its own local average.

Worked example 2.5: Harmonic polynomials are smooth, and every harmonic function in the plane is a real part

In $\mathbb{R}^2$ write $z = x + iy$. For any integer $k \geq 0$ the functions $u_k = \operatorname{Re} z^k$ and $v_k = \operatorname{Im} z^k$ are harmonic. For $k = 2$: $z^2 = (x^2 - y^2) + 2ixy$, and

$$\Delta(x^2 - y^2) \overset{(1)}{=} -(2) - (-2) = 0, \qquad \Delta(2xy) \overset{(2)}{=} -0 - 0 = 0.$$

(1) $\partial_x^2(x^2 - y^2) = 2$ and $\partial_y^2(x^2 - y^2) = -2$.
(2) $2xy$ is linear in each variable separately.

More generally, if $F(z)$ is complex analytic then $\operatorname{Re} F$ and $\operatorname{Im} F$ are harmonic, by the Cauchy–Riemann equations. Conversely, every harmonic function on a disc is the real part of an analytic function. So in two dimensions *elliptic regularity for Δ is the smoothness of analytic functions*. We will see this again when we meet the Cauchy–Riemann operator in Section 2.2.10.

Watch out: Elliptic regularity is local and needs smooth coefficients

Elliptic regularity does not say solutions exist, and it does not say solutions are bounded or decay: $u = e^x \cos y$ is harmonic on all of $\mathbb{R}^2$ and grows exponentially. It says only that solutions have as many derivatives as the source allows. It is also local: $\Delta u = f$ with f rough on a region K gives a u that is smooth outside K but may be rough on K. For example, the potential of a uniformly charged ball has a discontinuous second derivative on the surface of the ball, where f jumps.

2.1.5 Hyperbolic operators: the wave equation

Now we look at what goes wrong when the quadratic form is *not* definite. Nash takes the quadratic form $\sum_i a_i p_i^2$ with signature $n - 2$: $n - 1$ positive eigenvalues and one negative. The associated operator is called **hyperbolic**. The simplest case is $n = 2$ with

$$L = \frac{\partial^2}{\partial x_1^2} - \frac{\partial^2}{\partial x_2^2}, \qquad \sigma(L)(p) = -p_1^2 + p_2^2. \tag{2.20}$$

(Each ∂_j^2 becomes $(ip_j)^2 = -p_j^2$. Nash writes $p_1^2 - p_2^2$; the overall sign is irrelevant for everything that follows.) The level curves $\sigma = c$ are now *hyperbolae* (Figure 2.2), and the symbol vanishes on the two lines $p_1 = \pm p_2$, which extend to infinity. Our Step 1 argument now fails, and we expect that solutions of $Lu = f$ with smooth f may be singular. We shall see that they are, and that the singularities can be traced to the Green's function.

Rename the variables $(x_1, x_2) \to (x, t)$, so $L = \partial_x^2 - \partial_t^2$. The key to the whole analysis is a change of variables to **light-cone coordinates**

$$\xi = x + t, \qquad \eta = x - t. \tag{2.21}$$

By the chain rule $\partial_x = \partial_\xi + \partial_\eta$ and $\partial_t = \partial_\xi - \partial_\eta$, so

$$\begin{aligned} L &\overset{(1)}{=} (\partial_\xi + \partial_\eta)^2 - (\partial_\xi - \partial_\eta)^2 \\ &\overset{(2)}{=} \left(\partial_\xi^2 + 2\partial_\xi\partial_\eta + \partial_\eta^2\right) - \left(\partial_\xi^2 - 2\partial_\xi\partial_\eta + \partial_\eta^2\right) = 4\,\partial_\xi\partial_\eta. \end{aligned} \tag{2.22}$$

(1) Substitute the chain-rule expressions for ∂_x and ∂_t.
(2) Expand the squares; partial derivatives commute, so the cross terms are $2\partial_\xi\partial_\eta$.

So the wave operator is just a mixed second derivative. Its solutions with $f = 0$ are therefore

$$u(x,t) \;=\; F(x+t) + H(x-t) \tag{2.23}$$

for *arbitrary* functions F and H of one variable (d'Alembert). Here is the problem in one line: F and H can be as rough as we like, and u still solves $Lu = 0$. Nothing smooths them out. Roughness travels along the lines $x + t = \text{const}$ and $x - t = \text{const}$, the **characteristics** or light rays.

Worked example 2.6: Nash's Green's function for the wave operator, (2.10)

Nash claims that

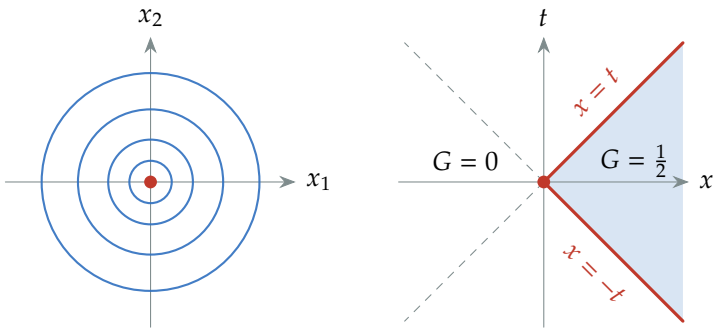
$$G(x,t) \;=\; \tfrac{1}{2}\,\theta(x+t)\,\theta(x-t), \qquad \theta(s) = \begin{cases} 1, & s \geq 0, \\ 0, & s < 0, \end{cases} \tag{2.24}$$

satisfies $LG = \delta(x)\delta(t)$ for $L = \partial_x^2 - \partial_t^2$. We check this in light-cone coordinates, where $G = \frac{1}{2}\theta(\xi)\theta(\eta)$:

$$LG \overset{(1)}{=} 4\,\partial_\xi\partial_\eta\big(\tfrac{1}{2}\theta(\xi)\theta(\eta)\big) \overset{(2)}{=} 2\,\delta(\xi)\,\delta(\eta) \overset{(3)}{=} \delta(x)\,\delta(t).$$

(1) The factorisation (2.22).
(2) The derivative of a step function is a delta function, $\theta' = \delta$, and the two factors depend on different variables.
(3) The Jacobian of $(x,t) \mapsto (\xi,\eta)$ is $|\partial(\xi,\eta)/\partial(x,t)| = \left|\det\left(\begin{smallmatrix} 1 & 1 \\ 1 & -1 \end{smallmatrix}\right)\right| = 2$, so $\mathrm{d}\xi\,\mathrm{d}\eta = 2\,\mathrm{d}x\,\mathrm{d}t$. Hence $\int \delta(\xi)\delta(\eta)\,\mathrm{d}x\,\mathrm{d}t = \frac{1}{2}$, that is, $\delta(\xi)\delta(\eta) = \frac{1}{2}\delta(x)\delta(t)$.

So G is a Green's function. It equals $\frac{1}{2}$ on the wedge $x \geq |t|$ and 0 elsewhere. It is *discontinuous across the whole of the two half-lines* $x = \pm t$, $x \geq 0$, not just at the origin (Figure 2.4). Compare the Laplacian, whose Green's function is singular only at the source. This is the Green's-function face of non-ellipticity.



Laplace: $G = -\frac{1}{2\pi}\ln r$
singular only at 0

wave: $G = \frac{1}{2}\theta(x+t)\theta(x-t)$
singular on two whole half-lines

Figure 2.4: Where the Green's function is singular (red). Left: for the (elliptic) Laplacian in the plane, only at the source; the blue level curves of G are smooth circles. Right: for the (hyperbolic) wave operator $\partial_x^2 - \partial_t^2$, Nash's Green's function (2.10) jumps from 0 to $\frac{1}{2}$ across the two characteristic half-lines $x = \pm t$. Every point of these lines is in the singular support.

Worked example 2.7: A solution of $Lu = 0$ that is only C^2, Nash's (2.11)

Take $F(s) = s^{5/2}$ and $H = 0$ in (2.23):

$$u(x,t) \;=\; (x+t)^{5/2}. \tag{2.25}$$

For $s = x + t < 0$ we need to say what $s^{5/2}$ means. Nash takes the principal branch: $s^{5/2} = |s|^{5/2}$ for $s > 0$ and $s^{5/2} = i\,|s|^{5/2}$ for $s < 0$ (the positive-imaginary choice). Either way u is a function of $x + t$ alone, so $Lu = 4\partial_\xi\partial_\eta u = 0$ wherever u is twice differentiable. Now differentiate along s for $s > 0$:

$$\frac{\mathrm{d}}{\mathrm{d}s}s^{5/2} = \tfrac{5}{2}s^{3/2}, \qquad \frac{\mathrm{d}^2}{\mathrm{d}s^2}s^{5/2} = \tfrac{15}{4}s^{1/2}, \qquad \frac{\mathrm{d}^3}{\mathrm{d}s^3}s^{5/2} = \tfrac{15}{8}s^{-1/2} \xrightarrow{\;s\to 0^+\;} \infty.$$

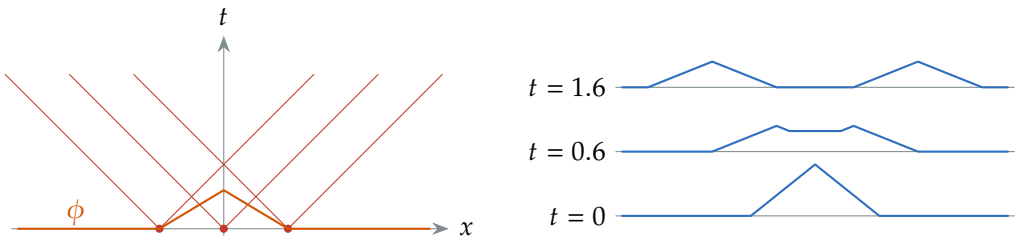
The same happens for $s < 0$ with an extra factor i. So u has two continuous derivatives across the line $x = -t$ (the first and second derivatives tend to 0 from both sides), but its third derivative blows up there. The data were smooth (zero source), yet the solution is only C^2. This cannot happen for an elliptic operator.

Worked example 2.8: A kink that never heals

Solve $(\partial_t^2 - \partial_x^2)u = 0$ with initial data $u(x,0) = \phi(x)$, $\partial_t u(x,0) = 0$. From (2.23), $u(x,0) = F(x) + H(x) = \phi(x)$ and $\partial_t u(x,0) = F'(x) - H'(x) = 0$, so $F = H = \frac{1}{2}\phi$ (up to a constant that cancels), and

$$u(x,t) \;=\; \tfrac{1}{2}\big[\phi(x+t) + \phi(x-t)\big]. \tag{2.26}$$

Take a "tent" $\phi(x) = \max(0, 1 - |x|)$, which has kinks at $x = 0, \pm 1$. Then $u(\cdot, t)$ consists of two half-height tents moving left and right at unit speed. The kinks never smooth out: at time t they sit at $x = \pm t, \pm t \pm 1$. The singular support of u is the union of the characteristic lines through the kinks of the initial data (Figure 2.5). Contrast the heat equation, where the same tent would become C^∞ at any $t > 0$ (Section 2.2.8).



kinks of the data travel on characteristics — snapshots $u(\cdot, t)$: kinks stay sharp

Figure 2.5: Hyperbolic equations propagate singularities. Left: the tent-shaped initial data ϕ has kinks at $x = -1, 0, 1$; each sends a kink along both light rays $x = \text{const} \pm t$ (red). Right: d'Alembert's solution $u = \frac{1}{2}[\phi(x+t) + \phi(x-t)]$ at three times; the profile splits into two half-height tents with permanently sharp corners. At $t = 0.6$ the two tents still overlap, and between their peaks they add up to a flat plateau.

2.1.6 The Cauchy problem, light cones and Huygens' principle

The natural question for a hyperbolic equation is not "solve $Lu = f$ on all of space" but an **initial value problem**, also called a **Cauchy problem**: given u and $\partial_t u$ at an initial time t_0 (the

Cauchy data), find u at later times. Nash states it for the wave operator in n space dimensions,

$$Lu = f, \qquad L = \frac{\partial^2}{\partial t^2} - \frac{\partial^2}{\partial x_1^2} - \cdots - \frac{\partial^2}{\partial x_n^2}, \tag{2.27}$$

Nash's (2.12). This is the d'Alembertian $\Box$ of $(n+1)$-dimensional Minkowski space, and the characteristic lines $x = \pm t$ of the $1+1$ case become **light cones** $|x - x_0| = |t - t_0|$.

Recall that the **support** of a function is the closure of the set where it is non-zero (Nash's footnote 2). The **singular support** is the closure of the set where it fails to be C^∞. Nash's description of how singularities propagate is:

Key idea: Propagation of singularities for the wave equation

Suppose the Cauchy data at time t_0 is singular on a set S (its singular support), and f is smooth. Then the solution $u(x,t)$ at a later time can be singular at a point (x,t) only if the backward light cone from (x,t) meets S at time t_0. In other words: singularities move at the speed of light, along light rays, and nowhere else.

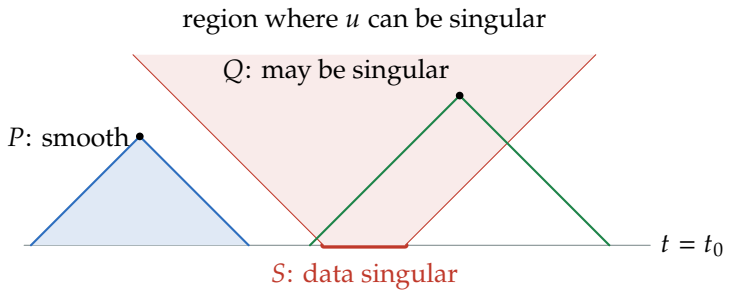


Figure 2.6: The Cauchy problem for the wave equation. The Cauchy data at $t = t_0$ is singular on S (thick red). At a later point P whose backward light cone (blue) misses S, the solution is smooth. At Q the backward cone (green) meets S, so u may be singular there. In odd space dimensions $n \geq 3$ only the *edges* of the shaded region (the light cones through ∂S) carry the singularities that started on ∂S; this is Huygens' principle.

How do we see this? Once again, through the Green's function. The solution of the Cauchy problem is built from the **retarded Green's function** G_{ret}, the field of a flash of light emitted at the origin at $t = 0$ ($LG_{\text{ret}} = \delta$, $G_{\text{ret}} = 0$ for $t < 0$). The data at time t_0 is propagated to time t by convolution with $G_{\text{ret}}(\cdot, t - t_0)$ and its time derivative. Singularities of u come from singularities of the data, carried along by the singularities of G_{ret}, exactly as in (2.19). So the whole question is where G_{ret} is singular.

Worked example 2.9: The retarded Green's function in three space dimensions

Fourier transform in x only. For each wave-vector p, the equation $(\partial_t^2 + |p|^2)g = \delta(t)$ with $g = 0$ for $t < 0$ is solved by $g(t) = \theta(t)\sin(|p|\,t)/|p|$. (Check: g is continuous at $t = 0$ and g' jumps by 1 there, which produces the $\delta(t)$ when we differentiate twice; for $t > 0$, g solves the harmonic-oscillator equation.) So, with $r = |x|$, $k = |p|$ and $t > 0$,

$$\begin{aligned} G_{\text{ret}}(x,t) &\overset{(1)}{=} \frac{1}{(2\pi)^3}\int_{\mathbb{R}^3} e^{ip\cdot x}\,\frac{\sin(kt)}{k}\,\mathrm{d}^3p \overset{(2)}{=} \frac{1}{(2\pi)^2}\int_0^\infty k^2\,\frac{2\sin(kr)}{kr}\,\frac{\sin(kt)}{k}\,\mathrm{d}k \\ &\overset{(3)}{=} \frac{1}{2\pi^2 r}\int_0^\infty \sin(kr)\sin(kt)\,\mathrm{d}k \overset{(4)}{=} \frac{1}{2\pi^2 r}\cdot\frac{\pi}{2}\big[\delta(r-t) - \delta(r+t)\big] \\ &\overset{(5)}{=} \frac{\delta(t-r)}{4\pi r}. \end{aligned}$$

(1) Inverse Fourier transform in the three space variables.
(2) Angular integration exactly as in Example 2.2.
(3) Simplify: $k^2 \cdot 2/(kr) \cdot 1/k = 2/r$, and $2/(2\pi)^2 = 1/(2\pi^2)$.
(4) $\sin a \sin b = \frac{1}{2}[\cos(a-b) - \cos(a+b)]$ and $\int_0^\infty \cos(ks)\,\mathrm{d}k = \pi\delta(s)$.
(5) For $t > 0$ and $r \geq 0$, $r + t > 0$, so $\delta(r + t) = 0$.

The retarded Green's function in three dimensions is supported *exactly on the forward light cone* $r = t$: a flash of light is seen once, as a sharp shell, and then it is dark again.

Doing the same calculation in other dimensions gives (with $r = |x|$)

$$G_{\mathrm{ret}}(x,t) \;=\; \begin{cases} \frac{1}{2}\,\theta(t-|x|), & n=1, \\ \dfrac{\theta(t-r)}{2\pi\sqrt{t^2-r^2}}, & n=2, \\ \dfrac{\delta(t-r)}{4\pi r}, & n=3. \end{cases} \tag{2.28}$$

In every case the *singular support* is the light cone $r = t$. But the *support* differs. For $n = 3$ (and, it turns out, all odd $n \geq 3$) the support is the cone itself. For $n = 1, 2$ (and all even n) the support is the whole solid interior of the cone. This is Nash's remark that "for $n = 3, 5, \ldots$ the support and the singular support of the Green's function actually coincide" (he cites Treves). The physical name is **Huygens' principle**: in three space dimensions a sharp signal stays sharp and leaves no wake. In two dimensions it does leave a wake: drop a stone in a pond and the water keeps rippling inside the expanding circle.

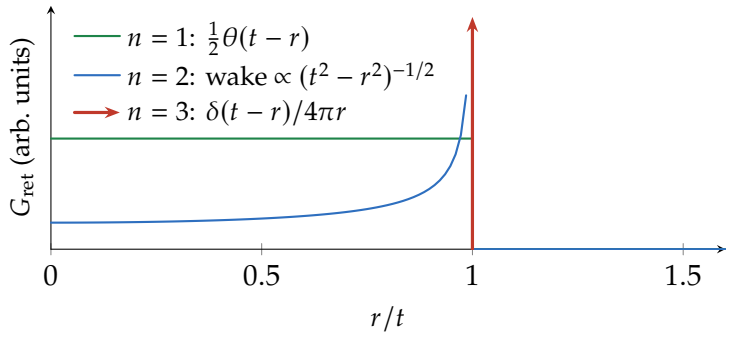

Figure 2.7: The retarded Green's function at a fixed time t, as a function of distance r. In $n = 1$ (green) the signal fills the interior of the light cone with a constant. In $n = 2$ (blue) there is a wake inside the cone, singular at the front $r = t$. In $n = 3$ (red arrow) everything is concentrated on the front: Huygens' principle. In all three cases the singularities sit on the light cone $r = t$.

2.1.7 Wick rotation: turning the wave operator into the Laplacian

The wave operator $\partial_x^2 - \partial_t^2$ and the Laplacian $-\partial_x^2 - \partial_y^2$ differ only in a sign. Substituting $t = iy$ gives $\partial_t = -i\partial_y$, hence $\partial_t^2 = -\partial_y^2$, and

$$\frac{\partial^2}{\partial x^2} - \frac{\partial^2}{\partial t^2} \;\xrightarrow{\;t=iy\;}\; \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \;=\; -\Delta. \tag{2.29}$$

Physicists call this kind of substitution a **Wick rotation**, and it is the bridge between Minkowski and Euclidean field theory. Nash uses it to make a subtle point.

Nash's puzzle: is $z^{5/2}$ a non-smooth harmonic function?

Apply the substitution to the C^2 solution (2.25):

$$u(x,t) = (x+t)^{5/2} \xrightarrow{\;t=iy\;} u(x,y) = (x+iy)^{5/2} = z^{5/2}.$$

One might claim that $z^{5/2}$ solves Laplace's equation and is singular at the origin (its third derivatives blow up there), contradicting elliptic regularity. It does not, and the reason is instructive.

In the real (x,t)-plane, $x+t$ is a real number, and Nash's rule for $(x+t)^{5/2}$ (principal branch) gives a single-valued function on the whole plane. In the complex z-plane, $z^{5/2}$ is *multi-valued*. To make it a function we must cut the plane along a ray from 0 to ∞, say the negative real axis. Write $z = re^{i\theta}$ with $-\pi < \theta \le \pi$, so $z^{5/2} = r^{5/2}e^{5i\theta/2}$. Approaching the negative real axis from above and from below,

$$\lim_{\theta\to\pi^-} z^{5/2} \;=\; r^{5/2}e^{5i\pi/2} \;=\; i\,r^{5/2}, \qquad \lim_{\theta\to-\pi^+} z^{5/2} \;=\; r^{5/2}e^{-5i\pi/2} \;=\; -i\,r^{5/2}.$$

So $z^{5/2}$ *jumps by* $2ir^{5/2}$ *across the cut*. It is not continuous there, let alone differentiable, so it does not satisfy Laplace's equation on any open set that meets the cut. Every neighbourhood of the origin meets the cut, so $z^{5/2}$ is not a solution of $\Delta u = 0$ near the origin at all, and elliptic regularity has nothing to say about it. On any open set that avoids the cut, $z^{5/2}$ is complex analytic, hence harmonic *and* C^∞, exactly as elliptic regularity predicts (Figure 2.8).

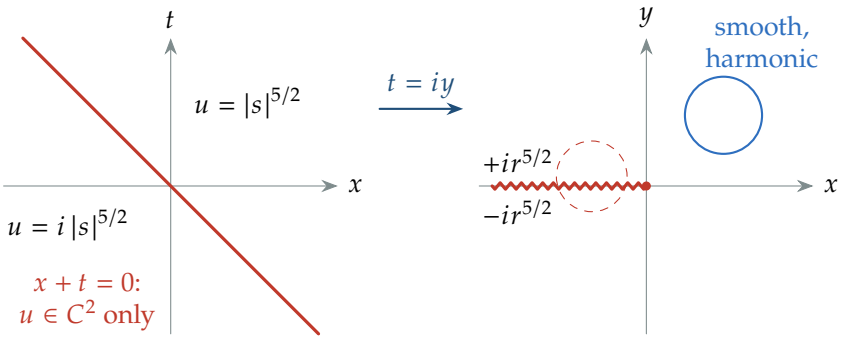

Figure 2.8: Nash's warning about Wick rotation. Left: $(x+t)^{5/2}$ is single valued on the real (x,t)-plane and solves the wave equation, but it is only C^2 across the characteristic $x+t=0$. Right: after $t \to iy$ it becomes $z^{5/2}$, which needs a branch cut (zigzag). On any disc away from the cut (blue) it is analytic and smooth. On a disc crossing the cut (dashed red) it is discontinuous, so it does not solve Laplace's equation there. Elliptic regularity survives.

Wick rotation in quantum field theory

The same mechanism is why quantum field theorists love to Wick rotate. Take the Klein–Gordon operator in $3+1$ dimensions with metric $(+,-,-,-)$:

$$L_{\mathrm{M}} \;=\; \frac{\partial^2}{\partial t^2} - \nabla^2 + m^2. \tag{2.30}$$

Using (2.5) with Fourier variables $(p_0, \vec{p})$ for $(t, \vec{x})$, its symbol is

$$\sigma(L_{\mathrm{M}}) \;=\; -p_0^2 + |\vec{p}|^2 + m^2, \tag{2.31}$$

which vanishes on the **mass shell** $p_0 = \pm\sqrt{|\vec{p}|^2 + m^2}$: a two-sheeted hyperboloid running off to infinity. The Green's function $\int e^{ip\cdot x}/\sigma \, \mathrm{d}^4p$ is ill-defined until we say how to go around the poles. That is the $i\varepsilon$ prescription, and each choice (retarded, advanced, Feynman) gives a different Green's function, all singular on the light cone.

Now set $t = -i\tau$ ("imaginary time"). Then $\partial_t = i\partial_\tau$, $\partial_t^2 = -\partial_\tau^2$, and

$$L_{\mathrm{M}} \overset{(1)}{=} -\frac{\partial^2}{\partial\tau^2} - \nabla^2 + m^2 \overset{(2)}{=} \Delta_{\mathbb{R}^4} + m^2 \;=:\; L_{\mathrm{E}}, \tag{2.32}$$

(1) $\partial_t^2 = (i\partial_\tau)^2 = -\partial_\tau^2$.
(2) The positive Laplacian of $\mathbb{R}^4$ with coordinates $(\tau, \vec{x})$.

The Euclidean operator has symbol $p_4^2 + |\vec{p}|^2 + m^2 \geq m^2 > 0$. It never vanishes: L_{E} is elliptic, its Green's function

$$G_{\mathrm{E}}(x) \;=\; \frac{1}{(2\pi)^4} \int_{\mathbb{R}^4} \frac{e^{ip\cdot x}}{|p|^2 + m^2} \, \mathrm{d}^4p$$

is unique (no pole prescription needed), decays like $e^{-m|x|}$, and is smooth everywhere except at $x = 0$. In momentum space the Wick rotation is the rotation of the p_0 integration contour onto the imaginary axis, $p_0 = ip_4$ (Figure 2.9). The poles of the Feynman propagator sit at $p_0 = \pm(\omega_{\vec{p}} - i\varepsilon)$ with $\omega_{\vec{p}} = \sqrt{|\vec{p}|^2 + m^2}$, in the fourth and second quadrants, so the rotation through the first and third quadrants crosses no poles:

$$\int_{-\infty}^{\infty} \frac{\mathrm{d}p_0}{-p_0^2 + \omega_{\vec{p}}^2 - i\varepsilon} \overset{(1)}{=} \int_{-i\infty}^{i\infty} \frac{\mathrm{d}p_0}{-p_0^2 + \omega_{\vec{p}}^2} \overset{(2)}{=} i \int_{-\infty}^{\infty} \frac{\mathrm{d}p_4}{p_4^2 + \omega_{\vec{p}}^2} \;=\; \frac{i\pi}{\omega_{\vec{p}}}.$$

(1) Rotate the contour anticlockwise by 90°. The arcs at infinity contribute nothing because the integrand falls off like p_0^{-2}, and no poles are crossed. The $i\varepsilon$ may then be dropped.
(2) Substitute $p_0 = ip_4$, so $\mathrm{d}p_0 = i\,\mathrm{d}p_4$ and $-p_0^2 = p_4^2$.

(The last integral is $\pi/\omega_{\vec{p}}$ by $\int \mathrm{d}s/(s^2 + a^2) = \pi/a$.) A Minkowski integral with delicate poles has become a Euclidean integral with a strictly positive, elliptic denominator.

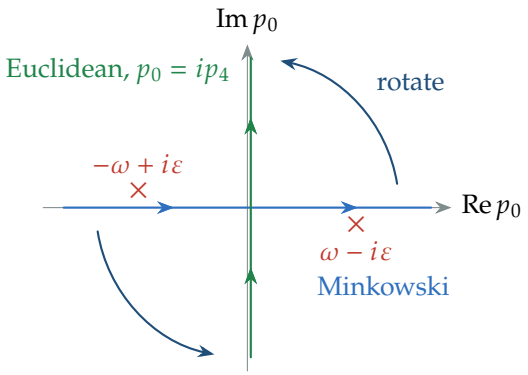

Figure 2.9: Wick rotation in the complex p_0-plane. The Feynman poles (red crosses) sit just below the positive real axis and just above the negative real axis. The real-axis contour (blue) can be swung anticlockwise onto the imaginary axis (green) without crossing them. On the imaginary axis the denominator $p_4^2 + \omega^2$ never vanishes: the operator has become elliptic.

Dictionary: Minkowski versus Euclidean

Minkowski (real time t)	Euclidean (imaginary time $\tau = it$)
wave / Klein–Gordon operator: hyperbolic	Laplacian $+ m^2$: elliptic
symbol vanishes on the mass shell	symbol $\geq m^2 > 0$
Green's function needs $i\varepsilon$; singular on light cone	unique Green's function; singular only at $x = 0$
propagation of signals	correlations decaying like $e^{-m\lvert x\rvert}$
e^{iS}, oscillatory path integral	$e^{-S_{\mathrm{E}}}$, damped path integral
Schrödinger evolution e^{-iHt}	heat / diffusion evolution $e^{-H\tau}$

This is why Nash, and the index theory that powers Chapters 8 and 10, work in Euclidean signature: only there are the relevant operators elliptic.

2.1.8 Parabolic operators: Schrödinger and heat

There is a third class. Nash's example is the free Schrödinger equation in one space dimension (with $\hbar = 2m = 1$), written as

$$Lu \;=\; -i\frac{\partial u}{\partial t} - \frac{\partial^2 u}{\partial x^2} \;=\; 0, \tag{2.33}$$

Nash's (2.13). Let (p_1, p_2) be the Fourier variables for (t, x). Then $-i\partial_t \to -i(ip_1) = p_1$ and $-\partial_x^2 \to p_2^2$, so

$$\sigma(L) \;=\; p_1 + p_2^2, \tag{2.34}$$

and the level curves $\sigma = c$ are the parabolas $p_2^2 + p_1 = c$. (Nash's (2.14), $\sigma = -p_1 + p_2^2$, comes from his opposite Fourier sign; the parabola simply opens the other way.) So this is a **parabolic** equation. The heat operator $\partial_t - \partial_x^2$ is the same up to replacing $-i\partial_t$ by ∂_t. Its symbol is $ip_1 + p_2^2$.

Nash then makes a point that matters for everything that follows. Although the symbol (2.34) happens to describe a parabola, the classification is *not* really made from the whole symbol. It is made from the *highest-order* part only, here p_2^2, which comes from ∂_x^2. In the elliptic and hyperbolic examples every term had the same order, 2, so the distinction never arose. For the Schrödinger operator the second-order part p_2^2 is a *degenerate* quadratic form: its matrix $\left(\begin{smallmatrix} 0 & 0 \\ 0 & 1 \end{smallmatrix}\right)$ has a zero eigenvalue in the p_1 (time) direction. That degenerate direction is what makes it parabolic.

2.1.9 The classification of second-order operators

Nash now gives one definition covering all three types. Take the general second-order operator with constant coefficients on $\mathbb{R}^n$,

$$L \;=\; -\sum_{i,j=1}^{n} a_{ij}\frac{\partial^2}{\partial x_i \partial x_j} + \sum_{i=1}^{n} b_i \frac{\partial}{\partial x_i} + c, \qquad a_{ij} = a_{ji}, \tag{2.35}$$

Nash's (2.16). (We may take a_{ij} symmetric because $\partial_i\partial_j = \partial_j\partial_i$; only the symmetric part of a_{ij} contributes.) Fourier transform only the second-order part:

$$-\sum_{i,j} a_{ij}\,\partial_i\partial_j \;\longrightarrow\; -\sum_{i,j} a_{ij}(ip_i)(ip_j) \;=\; \sum_{i,j} a_{ij}\,p_i p_j \;=:\; \sigma_2(L)(p), \tag{2.36}$$

Nash's (2.17). This is a quadratic form, with symmetric matrix $A = (a_{ij})$.

Working definition 2.4 (elliptic / hyperbolic / parabolic, Nash's (2.18))

Diagonalise the symmetric matrix $A = (a_{ij})$ of the second-order part and count the signs of its eigenvalues. Then L is

- **elliptic** if all n eigenvalues have the same sign (signature [number of positive eigenvalues minus number of negative ones] $\pm n$);
- **hyperbolic** if $\det A \neq 0$ and exactly one eigenvalue has the opposite sign to the others (signature $\pm(n-2)$);
- **parabolic** if $\det A = 0$, i.e. at least one eigenvalue is zero.

In two variables, with $L = -(A\,\partial_x^2 + 2B\,\partial_x\partial_y + C\,\partial_y^2) + \dots$, the test is the sign of $\det A = AC - B^2$: positive means elliptic, negative hyperbolic, zero parabolic.

Watch out: The classification is not exhaustive, and "parabolic" needs more

For $n \geq 4$ there are forms with two or more eigenvalues of each sign, such as $p_1^2 + p_2^2 - p_3^2 - p_4^2$. They are called **ultrahyperbolic** and fit none of Nash's three boxes. Also, $\det A = 0$ alone does not make a good parabolic equation. The heat and Schrödinger equations also have a *first-order* derivative in the degenerate direction (∂_t), which is what makes the time evolution well posed. The operator ∂_x^2 on $\mathbb{R}^2$ has $\det A = 0$ but no ∂_y term, and it is really a one-dimensional operator with y as a spectator.

Worked example 2.10: Classifying three operators by diagonalising

Classify, on $\mathbb{R}^2$, the operators $L_k = -(\partial_x^2 + 2\beta_k\,\partial_x\partial_y + \partial_y^2)$ with $\beta_1 = 2$, $\beta_2 = \tfrac{1}{2}$, $\beta_3 = 1$. The matrix of the second-order part is $A = \left(\begin{smallmatrix} 1 & \beta \\ \beta & 1 \end{smallmatrix}\right)$. Its eigenvectors are $(1,1)/\sqrt{2}$ and $(1,-1)/\sqrt{2}$, with eigenvalues

$$A\begin{pmatrix}1\\1\end{pmatrix} \overset{(1)}{=} \begin{pmatrix}1+\beta\\ \beta+1\end{pmatrix} = (1+\beta)\begin{pmatrix}1\\1\end{pmatrix}, \qquad A\begin{pmatrix}1\\-1\end{pmatrix} \overset{(2)}{=} \begin{pmatrix}1-\beta\\ \beta-1\end{pmatrix} = (1-\beta)\begin{pmatrix}1\\-1\end{pmatrix}.$$

(1) Multiply out: first row $1\cdot 1 + \beta\cdot 1$, second row $\beta\cdot 1 + 1\cdot 1$.
(2) First row $1-\beta$, second row $\beta - 1$.

So the eigenvalues are $1 \pm \beta$:

β	eigenvalues	$\det A = 1-\beta^2$	type
2	$3, -1$	-3	hyperbolic
$\frac{1}{2}$	$\frac{3}{2}, \frac{1}{2}$	$\frac{3}{4}$	elliptic
1	$2, 0$	0	parabolic (degenerate)

In the rotated coordinates $s = (x+y)/\sqrt{2}$, $w = (x-y)/\sqrt{2}$ the operator becomes $L = -(1+\beta)\partial_s^2 - (1-\beta)\partial_w^2$. For $\beta = 2$ this is $-3\partial_s^2 + \partial_w^2$, a wave operator in which w plays the role of time and the "speed of light" is $\sqrt{3}$. For $\beta = 1$ it is $-2\partial_s^2$: the operator does not differentiate in the w direction at all.

Worked example 2.11: An equation that changes type: the Tricomi equation

Coefficients need not be constant, and then the type can change from point to point. The Tricomi operator on $\mathbb{R}^2$,

$$L \;=\; -\big(y\,\partial_x^2 + \partial_y^2\big), \qquad \sigma_2(L)(x,y;p) \;=\; y\,p_1^2 + p_2^2,$$

is elliptic in the upper half-plane $y > 0$ (both coefficients positive), hyperbolic in the lower half-plane $y < 0$, and parabolic on the line $y = 0$. It is the model for *transonic flow*: $y > 0$ is the subsonic region (the flow "feels" disturbances in every direction), $y < 0$ the supersonic region (disturbances propagate only inside a Mach cone), and $y = 0$ is the sonic line. This example is the reason Nash moves on, in Section 2.2, to operators with *variable* coefficients, where ellipticity becomes a property checked point by point.

2.1.10 Characteristics: the directions an operator cannot see

The zero set of the principal symbol has a direct meaning in position space, and it explains the word "characteristic" that we have been using.

Working definition 2.5 (characteristic covector and hypersurface)

A nonzero covector [a list of n numbers, like a momentum p or a gradient $\partial_i\varphi$] $\xi = (\xi_1,\dots,\xi_n)$ at a point x is **characteristic** for L if the principal symbol [the second-order part only, $\sigma_2(L)(x,\xi) = \sum_{ij} a_{ij}(x)\xi_i\xi_j$] vanishes on it, $\sigma_2(L)(x,\xi) = 0$. A hypersurface [a surface of dimension $n-1$ in $\mathbb{R}^n$] $S = \{\varphi(x) = 0\}$ is a **characteristic surface** if its normal covector $\mathrm{d}\varphi = (\partial_1\varphi,\dots,\partial_n\varphi)$ is characteristic at every point of S. *Test for ellipticity:* L is elliptic exactly when it has *no real characteristic covectors*, hence no characteristic surfaces.

Why do characteristic surfaces matter? Try to solve $Lu = 0$ near a surface S on which we know u and its normal derivative (Cauchy data). Choose coordinates with $S = \{x_1 = 0\}$, so the normal covector is $\xi = (1,0,\dots,0)$. On S we know u, hence all its tangential derivatives $\partial_j u$, $\partial_j\partial_k u$ for $j,k \geq 2$. We know $\partial_1 u$, hence its tangential derivatives $\partial_1\partial_j u$. The only second derivative we do not know is $\partial_1^2 u$. The equation (2.35) reads

$$0 \;=\; Lu \overset{(1)}{=} -a_{11}\,\partial_1^2 u \;-\; \Big(\text{terms known on } S\Big) \overset{(2)}{=} -\sigma_2(L)(\xi)\,\partial_1^2 u \;-\; \Big(\text{terms known on } S\Big).$$

(1) Separate the one term containing $\partial_1^2 u$; every other term involves at most one normal derivative and is known on S.

(2) For $\xi = (1,0,\dots,0)$ we have $\sigma_2(\xi) = \sum a_{ij}\xi_i\xi_j = a_{11}$.

If $\sigma_2(\xi) \neq 0$ we can solve for $\partial_1^2 u$ on S. Differentiating the equation, we then get all higher normal derivatives: the Cauchy data determines u (formally, as a Taylor series) near S. If $\sigma_2(\xi) = 0$, the equation gives no information about $\partial_1^2 u$. Then two solutions can agree on one side of S and differ on the other, with a jump in the second derivative across S. That is exactly what we saw in Example 2.7 and Example 2.8: the kinks sit on the characteristic lines $x \pm t = \text{const}$, whose normals $(1,\pm 1)$ satisfy $-\xi_1^2 + \xi_2^2 = 0$.

Physical picture: Why elliptic solutions cannot have kinks

A kink or jump in a solution must sit on a surface across which the equation does not see the jump, i.e. on a characteristic surface. An elliptic operator has no characteristic surfaces, so there is nowhere for a singularity to hide. For the wave operator the characteristic surfaces are the null (light-like) surfaces, and singularities ride on them at the speed of

light.

	Laplace $-\nabla^2$	wave $\partial_t^2 - \nabla^2$	heat $\partial_t - \nabla^2$
principal symbol	$\lvert p\rvert^2$	$-p_0^2 + \lvert\vec{p}\rvert^2$	$\lvert\vec{p}\rvert^2$ (degenerate)
type	elliptic	hyperbolic	parabolic
characteristics	none	light cones	$t = \text{const}$
Green's function	$\propto r^{2-n}$, smooth off 0	singular on light cone	smooth off origin
smooth $f \Rightarrow$ smooth u?	yes	no (kinks propagate)	yes (Section 2.2.8)
physics	statics, Euclidean QFT	radiation, Minkowski QFT	diffusion, imaginary time

Table 2.1: The three archetypes of second-order operator compared. The heat equation is not elliptic but still smooths; this is the phenomenon of hypo-ellipticity studied in Section 2.2.

Nash closes §1 by announcing the two generalisations that the connection between the smoothness of f and the smoothness of u calls for: operators of *arbitrary order with variable coefficients*, and the property of *hypo-ellipticity*. These are the subject of the next section.

Reading Nash (§1, pp. 27–32, (2.1)–(2.18))

- p. 27, (2.1): the Hodge result $\dim \operatorname{Ker} \Delta_p = \dim H^p(M;\mathbb{R})$, our (2.1), proved in Section 2.3.12.
- p. 28, (2.2)–(2.6): positive Laplacian, its Fourier symbol $\lvert p\rvert^2$, stretched Laplacian $L = -\sum a_i \partial_i^2$ with symbol $\sum a_i p_i^2$, and the ellipsoid picture; our Sections 2.1.2 and 2.1.3. Beware the Fourier sign in his footnote 1 (page 728).
- pp. 28–29, (2.7)–(2.9): regularity via the Green's function. Nash's "it is easy to check" and "appropriate use of Cauchy's theorem" are our Steps 1 and 2 in Section 2.1.4.
- pp. 29–30, (2.10)–(2.12): the wave operator, its Green's function, the C^2 solution $(x+t)^{5/2}$, the Cauchy problem and Huygens' principle; our Sections 2.1.5 and 2.1.6.
- pp. 30–31: the $z^{5/2}$ puzzle; our Section 2.1.7, where we also add the QFT Wick rotation.
- p. 31, (2.13)–(2.18): Schrödinger as parabolic, the general second-order classification; our Sections 2.1.8 and 2.1.9. Nash's signs in (2.14) differ from ours by the Fourier convention.

Recap: The meaning of ellipticity

- Fourier transformation turns ∂_j into ip_j and a constant-coefficient operator into a polynomial $\sigma(p)$. Solving $Lu = f$ means dividing by σ.
- Elliptic (second order): the top-order quadratic form is definite; level sets are ellipsoids; $\sigma(p) \neq 0$ for $p \neq 0$; no real characteristics.
- Elliptic regularity: the Green's function is smooth away from the source, because $1/\sigma$ gains decay with every p-derivative. Hence smooth f on Ω gives smooth u on Ω.

Weyl: harmonic functions are smooth, being their own averages.

- Hyperbolic: the symbol vanishes on a cone; the Green's function is singular on the light cone; kinks propagate along characteristics; Huygens' principle holds in odd space dimensions ≥ 3.
- Wick rotation $t \to -i\tau$ turns the hyperbolic wave operator into the elliptic Laplacian. Nash's $z^{5/2}$ is not a counterexample, because of its branch cut.
- Parabolic: the top-order form is degenerate (heat, Schrödinger). The classification only looks at the highest-order terms.

2.2 Ellipticity and hypo-ellipticity

So far every operator we met had *constant* coefficients and was of *second* order. That is far too narrow for what follows. The operators of geometry and physics come in all orders and nearly always have coefficients that depend on position:

- The Cauchy–Riemann operator $\bar\partial$ and the Dirac operator $\not{D}$ are of *first* order.
- The biharmonic operator Δ^2 of elasticity (bending of plates) is of *fourth* order.
- The Laplacian on a curved space, written in coordinates, is $-g^{ij}(x)\partial_i\partial_j + \dots$, with coefficients given by the inverse metric. They depend on x unless the space is flat and the coordinates Cartesian. Even the flat Laplacian in polar coordinates has variable coefficients.
- The Tricomi operator of Example 2.11 changes type from point to point.

This section answers two questions. *How do we define ellipticity for an operator of any order with variable coefficients?* And, since the heat equation smooths just as well as Laplace's equation without being elliptic, *what is the right name for "smooth source gives smooth solution", and which operators have it?* The answers are the *leading symbol* and *hypo-ellipticity*.

2.2.1 Multi-index notation

A general operator of order m on $\mathbb{R}^n$ is a sum of terms, each a coefficient times some mixed partial derivative of total order at most m. Writing this out with explicit indices is painful, so everybody uses multi-indices.

Working definition 2.6 (multi-index notation)

A **multi-index** is an n-tuple of non-negative integers $\alpha = (\alpha_1, \dots, \alpha_n)$. Some of the α_i may be zero. With it we write

$$
\begin{aligned}
|\alpha| &= \alpha_1 + \cdots + \alpha_n && \text{(the \textbf{length}, or order),}\\
p^\alpha &= p_1^{\alpha_1} p_2^{\alpha_2} \cdots p_n^{\alpha_n} && \text{(a monomial of degree } |\alpha|\text{),}\\
\partial^\alpha &= \frac{\partial^{\alpha_1}}{\partial x_1^{\alpha_1}} \cdots \frac{\partial^{\alpha_n}}{\partial x_n^{\alpha_n}} && \text{(a mixed partial derivative of order } |\alpha|\text{),}\\
D^\alpha &= (-i)^{|\alpha|}\,\partial^\alpha = D_1^{\alpha_1}\cdots D_n^{\alpha_n}, \quad D_j = -i\frac{\partial}{\partial x_j} && \text{(the same, times a convenient phase).}
\end{aligned}
$$

Operationally: α_j counts how many times we differentiate with respect to x_j, and $|\alpha|$ is the total number of derivatives.

With this notation the general linear differential operator of order m is

$$L \;=\; \sum_{|\alpha|\le m} a_\alpha(x)\, D^\alpha, \tag{2.37}$$

Nash's (2.19). Written out in full, this is

$$L \;=\; \sum_{|\alpha|\le m} a_{(\alpha_1,\dots,\alpha_n)}(x)\,(-i)^{|\alpha|}\,\frac{\partial^{\alpha_1}}{\partial x_1^{\alpha_1}}\cdots\frac{\partial^{\alpha_n}}{\partial x_n^{\alpha_n}}, \tag{2.38}$$

Nash's (2.20). The sum runs over all multi-indices of length $0, 1, \dots, m$. For example, in $n = 2$ variables and order $m = 2$ there are six of them:

$$(0,0);\quad (1,0),\ (0,1);\quad (2,0),\ (1,1),\ (0,2),$$

corresponding to 1; D_1, D_2; D_1^2, D_1D_2, D_2^2. In general the number of multi-indices of length exactly k in n variables is $\binom{n+k-1}{k}$ (the number of ways of distributing k derivatives among n variables).

Why the factor $(-i)^{|\alpha|}$? Because $D_j = -i\partial_j$ becomes multiplication by p_j under our Fourier transform (2.5), so D^α becomes multiplication by p^α with no stray factors of i. Nash says the factor "removes it from expressions obtained later by Fourier transformation." The price is that the coefficients a_α of a real operator may be imaginary, as the next example shows.

Worked example 2.12: Translating an operator into multi-index form

Consider on $\mathbb{R}^2$, with coordinates (x, y),

$$L \;=\; \frac{\partial^3}{\partial x^2\,\partial y} \;-\; 3x\,\frac{\partial}{\partial x} \;+\; 5.$$

Each partial derivative is $\partial_j = iD_j$, so $\partial^\alpha = i^{|\alpha|}D^\alpha$. Hence

$$\frac{\partial^3}{\partial x^2 \partial y} \overset{(1)}{=} \partial^{(2,1)} \overset{(2)}{=} i^3\, D^{(2,1)} \overset{(3)}{=} -i\, D^{(2,1)},$$
$$-3x\,\frac{\partial}{\partial x} \overset{(4)}{=} -3x \cdot i\, D^{(1,0)} \;=\; -3ix\, D^{(1,0)}.$$

(1) Two derivatives in x and one in y: $\alpha = (2,1)$, $|\alpha| = 3$.
(2) $\partial^\alpha = i^{|\alpha|}D^\alpha$, the inverse of $D^\alpha = (-i)^{|\alpha|}\partial^\alpha$.
(3) $i^3 = -i$.
(4) One derivative in x: $\alpha = (1,0)$, and $\partial_x = iD_x$.

So the non-zero coefficients are $a_{(2,1)} = -i$, $a_{(1,0)}(x,y) = -3ix$ and $a_{(0,0)} = 5$, and $m = 3$. The coefficients are imaginary even though L is a real operator. That is the bookkeeping cost of using D instead of ∂.

2.2.2 The symbol: what L does to a plane wave

We now Fourier transform the general operator (2.37), as Nash does in (2.21). Write u as a superposition of plane waves (2.3) and apply L term by term:

$$\begin{aligned} Lu(x) &\overset{(1)}{=} \sum_{|\alpha|\le m} a_\alpha(x)\, D^\alpha \frac{1}{(2\pi)^{n/2}} \int_{\mathbb{R}^n} e^{ip\cdot x}\, \hat{u}(p)\, \mathrm{d}^n p \\ &\overset{(2)}{=} \sum_{|\alpha|\le m} a_\alpha(x) \frac{1}{(2\pi)^{n/2}} \int_{\mathbb{R}^n} p^\alpha\, e^{ip\cdot x}\, \hat{u}(p)\, \mathrm{d}^n p \\ &\overset{(3)}{=} \frac{1}{(2\pi)^{n/2}} \int_{\mathbb{R}^n} \sigma(x,p)\, \hat{u}(p)\, e^{ip\cdot x}\, \mathrm{d}^n p, \end{aligned} \tag{2.39}$$

(1) Definition (2.37) and the inverse Fourier transform (2.3).
(2) Differentiate under the integral. Each D_j acting on $e^{ip\cdot x}$ brings down p_j, so $D^\alpha e^{ip\cdot x} = p^\alpha e^{ip\cdot x}$. The coefficient $a_\alpha(x)$ multiplies *after* differentiation, so it is not differentiated.
(3) Pull the finite sum inside the integral and collect it into one function.

The function

$$\sigma(x,p) \;=\; \sum_{|\alpha|\le m} a_\alpha(x)\, p^\alpha \tag{2.40}$$

is the **symbol** of L, Nash's (2.22). It is a polynomial of degree m in p whose coefficients depend on x. Formula (2.39) says: *to apply L, multiply the Fourier amplitudes by $\sigma(x,p)$ and transform back.* For constant coefficients this is exactly the "derivatives become multiplication" of Section 2.1.2. For variable coefficients it is still true, but σ now depends on the point x where we evaluate Lu.

The most useful way to remember (2.40) is as a test you apply to one plane wave.

Working definition 2.7 (symbol, by the plane-wave test)

To find the symbol of a differential operator [a finite sum $L = \sum_{|\alpha|\le m} a_\alpha(x) D^\alpha$] L, apply L to the plane wave $e^{ip\cdot x}$ and divide by the plane wave:

$$\sigma(x,p) \;=\; e^{-ip\cdot x}\, L\big(e^{ip\cdot x}\big). \tag{2.41}$$

How to compute: replace every ∂_j by ip_j (equivalently every D_j by p_j), keeping each coefficient where it is.

Formula (2.41) follows from $D^\alpha e^{ip\cdot x} = p^\alpha e^{ip\cdot x}$, which is the step (2) of (2.39). It is the version we will generalise to manifolds and vector bundles.

Watch out: Variable coefficients: the symbol is not a multiplier

For constant coefficients, $\widehat{Lu}(p) = \sigma(p)\hat{u}(p)$. For variable coefficients this is *false*: $\sigma(x,p)$ depends on both x and p, so (2.39) is not the inverse Fourier transform of anything simple. It is a mixed position-momentum representation, like a classical phase-space function $H(x,p)$ in quantum mechanics. The plane-wave test (2.41) is exact, but the product of two operators does *not* simply have the product of the symbols as its symbol, because D also differentiates the coefficients of the operator to its right. We come back to this in Section 2.3.8, and in part 2b it becomes the calculus of pseudo-differential operators.

2.2.3 The leading symbol

In Section 2.1.8 we saw that the classification of second-order operators used only the second-order terms. Nash now makes this the general rule.

Working definition 2.8 (leading symbol)

The **leading symbol** of $L = \sum_{|\alpha|\le m} a_\alpha(x) D^\alpha$ is the top-degree part of its symbol [$\sigma(x,p) = \sum_{|\alpha|\le m} a_\alpha(x) p^\alpha$, the factor by which L multiplies the plane wave $e^{ip\cdot x}$]:

$$\sigma_m(x,p) \;=\; \sum_{|\alpha|=m} a_\alpha(x)\, p^\alpha, \tag{2.42}$$

Nash's (2.23). It is also called the **principal symbol** or **highest-order symbol**. *How to compute*: keep only the terms with the maximal number m of derivatives, and replace each ∂_j by ip_j. It is a homogeneous polynomial of degree m in p:

$$\sigma_m(x,\lambda p) \;=\; \lambda^m\, \sigma_m(x,p) \qquad (\lambda \in \mathbb{R}). \tag{2.43}$$

Nash stresses the obvious but important point that different operators of order m with the same top-order terms, differing only in lower orders, have the *same* leading symbol and *different* full symbols.

Worked example 2.13: Same leading symbol, different full symbols

Here are four second-order operators on $\mathbb{R}^3$ from physics, with their full symbols obtained by the plane-wave test (replace ∂_j by ip_j):

operator	full symbol $\sigma(x,p)$	physics
$-\nabla^2$	$\lvert p\rvert^2$	electrostatics
$-\nabla^2 + m^2$	$\lvert p\rvert^2 + m^2$	static Yukawa field
$-\nabla^2 + \vec{b}\cdot\nabla$	$\lvert p\rvert^2 + i\,\vec{b}\cdot\vec{p}$	steady advection–diffusion
$-\nabla^2 + V(x)$	$\lvert p\rvert^2 + V(x)$	time-independent Schrödinger

For the third, $\vec{b}\cdot\nabla e^{ip\cdot x} = i\,\vec{b}\cdot\vec{p}\, e^{ip\cdot x}$. All four have the same leading symbol $\sigma_2 = |p|^2$, so (as we will define in a moment) all four are elliptic, and all four have smooth solutions for smooth sources and potentials. Their full symbols differ, and so do their Green's functions: $1/(4\pi r)$ for the first, the Yukawa potential $e^{-mr}/(4\pi r)$ for the second. But *near the source* all the Green's functions have the same leading singularity $1/(4\pi r)$, as the next paragraph explains.

Why only the top order matters: high frequencies

Why should the lower-order terms be irrelevant for questions of smoothness? Because smoothness is about *high frequencies* ("smoothness is decay in p", Section 2.1.2), and at high frequencies the top-order terms win. Fix a direction $\hat{p}$ with $|\hat{p}| = 1$ and follow the symbol out along the ray $p = \lambda\hat{p}$:

$$\sigma(x,\lambda\hat{p}) \overset{(1)}{=} \sum_{k=0}^{m} \sum_{|\alpha|=k} a_\alpha(x)\, \lambda^k\, \hat{p}^{\,\alpha}$$

$$\overset{(2)}{=} \lambda^m \left[\sigma_m(x,\hat{p}) + \frac{1}{\lambda}\,\sigma_{m-1}(x,\hat{p}) + \cdots + \frac{1}{\lambda^m}\,\sigma_0(x) \right]. \tag{2.44}$$

(1) Group the terms of (2.40) by their degree $k = |\alpha|$, and use $(\lambda\hat{p})^\alpha = \lambda^{|\alpha|}\hat{p}^{\,\alpha}$.
(2) Factor out λ^m; here $\sigma_k = \sum_{|\alpha|=k} a_\alpha p^\alpha$ is the degree-k part of the symbol.

As $\lambda \to \infty$ the bracket tends to $\sigma_m(x,\hat{p})$. So for a wave of very short wavelength in the direction $\hat{p}$, the operator acts like multiplication by $\lambda^m \sigma_m(x,\hat{p})$, whatever the lower-order terms are. *The leading symbol is the operator as seen by short waves.* There is one exception: if $\sigma_m(x,\hat{p}) = 0$ for some direction, the top order does not dominate in that direction, and the lower-order terms decide what happens. That is exactly the parabolic case, where the first-order term ∂_t took over in the direction where p_2^2 vanished (Figure 2.10).

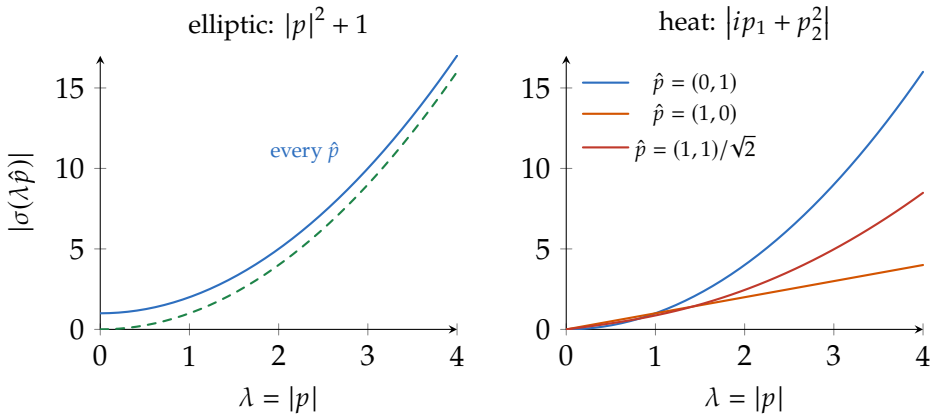

Figure 2.10: How the symbol grows along rays $p = \lambda\hat{p}$. Left: for the elliptic operator $-\nabla^2 + 1$ the symbol grows like λ^2 in every direction; the lower order term (+1, the gap between the blue curve and the dashed green λ^2) is irrelevant at large λ. Right: for the heat operator $\partial_t - \partial_x^2$ the growth is quadratic in most directions but only *linear* in the direction $\hat{p} = (1,0)$ (orange), where the leading symbol p_2^2 vanishes and the lower-order term ip_1 takes over.

The same scaling explains why the Green's functions in Example 2.13 all have the same singularity. The singularity of G at $x = 0$ comes from the large-$|p|$ part of $\int e^{ip\cdot x}/\sigma(p)\,\mathrm{d}^n p$, and there $1/\sigma \approx 1/\sigma_m$. For instance, for the Yukawa operator,

$$\frac{1}{|p|^2 + m^2} \overset{(1)}{=} \frac{1}{|p|^2} \cdot \frac{1}{1 + m^2/|p|^2} \overset{(2)}{=} \frac{1}{|p|^2} - \frac{m^2}{|p|^4} + \frac{m^4}{|p|^6} - \cdots \qquad (|p| > m),$$

(1) Factor out the leading symbol.
(2) Geometric series in $m^2/|p|^2 < 1$.

The first term gives the Coulomb singularity $1/(4\pi r)$. The second decays faster by two powers of p, so it produces a milder singularity (in $\mathbb{R}^3$, the inverse Fourier transform of $1/|p|^4$ is $-r/(8\pi)$, which is continuous). Indeed $e^{-mr}/(4\pi r) = 1/(4\pi r) - m/(4\pi) + m^2 r/(8\pi) - \cdots$: the Coulomb term, then a constant, then the r term. Up to the smooth constant term, this matches the series. Each lower-order correction is smoother than the one before. This "expansion in powers of $1/|p|$" is the germ of the symbol calculus of part 2b.

2.2.4 Ellipticity for general operators

We are ready for Nash's definition.

Working definition 2.9 (elliptic operator (Nash, p. 33))

The operator $L = \sum_{|\alpha|\le m} a_\alpha(x) D^\alpha$ of order m is **elliptic** if its leading symbol [$\sigma_m(x,p) = \sum_{|\alpha|=m} a_\alpha(x) p^\alpha$, from the terms with exactly m derivatives] never vanishes for non-zero p:

$$\sigma_m(x,p) \neq 0 \qquad \text{for every } x \text{ and every real } p \neq 0. \tag{2.45}$$

It is **elliptic at the point** x_0 if this holds at $x = x_0$, and elliptic on an open set Ω if it holds at every point of Ω. *How to test*: compute σ_m by replacing $\partial_j \to i p_j$ in the top-order terms only. Check that the resulting homogeneous polynomial has no real zeros other than $p = 0$. By homogeneity (2.43) it is enough to check the unit sphere $|p| = 1$.

For second-order operators with real coefficients this reproduces Section 2.1.9: $\sigma_2(x,p) = \sum a_{ij}(x) p_i p_j$ vanishes only at $p = 0$ exactly when the matrix $(a_{ij}(x))$ is definite. The new definition applies to every order, and to complex coefficients, and it is checked point by point.

Key idea: Ellipticity means "the symbol is large in every direction"

Because σ_m is continuous and non-zero on the unit sphere $|p| = 1$, which is compact, it has a positive minimum there, $|\sigma_m(x,\hat{p})| \ge c(x) > 0$. By homogeneity, $|\sigma_m(x,p)| \ge c(x)\,|p|^m$ for all p. So an elliptic operator of order m "costs" m powers of $|p|$ in *every* direction of momentum space. Inverting it gains back m powers in every direction. That is the source of elliptic regularity: *if Lu has k derivatives, then u has $k+m$.*

The lower-order terms cannot spoil this at high frequencies. At a fixed point x, bound the lower-order part of the symbol by $|\sigma(x,p) - \sigma_m(x,p)| \le C(1+|p|)^{m-1}$. Then

$$|\sigma(x,p)| \overset{(1)}{\ge} |\sigma_m(x,p)| - |\sigma(x,p) - \sigma_m(x,p)| \overset{(2)}{\ge} c\,|p|^m - C(1+|p|)^{m-1} \overset{(3)}{\ge} \tfrac{c}{2}\,|p|^m \qquad (|p| \ge R), \tag{2.46}$$

(1) The triangle inequality $|a| \ge |b| - |a-b|$.
(2) Ellipticity (the key idea above) for the first term; the lower-order bound for the second.
(3) $C(1+|p|)^{m-1}/|p|^m \to 0$ as $|p| \to \infty$, so it is below $c/2$ once $|p|$ exceeds some radius R.

So the *full* symbol of an elliptic operator can vanish only inside a bounded ball $|p| < R$. That does not matter for smoothness, which is about large $|p|$. The Yukawa example shows the full symbol need not vanish at all. For $-\nabla^2 - k^2$ (the Helmholtz operator), the full symbol $|p|^2 - k^2$ vanishes on the sphere $|p| = k$, which is bounded, so Helmholtz is elliptic. It gives the wave-number-k solutions of scattering theory, all smooth.

Ellipticity as invertibility

Nash remarks that one can think of ellipticity "as being characterised by the invertibility of the leading symbol of L, or the invertibility of L itself modulo lower order terms." For scalar operators "invertible" just means "non-zero". The point of the phrase becomes clear for matrix-valued symbols in Section 2.3. But the second half deserves an explanation now, because it is the idea behind the *parametrix* of part 2b.

Take L with constant coefficients for simplicity, and let Q be the operator that, in Fourier space, multiplies by

$$q(p) \;=\; \frac{1 - \chi(p)}{\sigma_m(p)},$$

where χ is a smooth bump equal to 1 near $p = 0$, inserted only to avoid dividing by zero at the

origin. Then LQ multiplies by

$$\sigma(p)\,q(p) \overset{(1)}{=} \frac{\sigma_m(p) + \big(\sigma(p) - \sigma_m(p)\big)}{\sigma_m(p)}\,\big(1 - \chi(p)\big) \overset{(2)}{=} 1 \;-\; \chi(p) \;+\; \frac{\sigma(p) - \sigma_m(p)}{\sigma_m(p)}\big(1 - \chi(p)\big).$$

(1) Split the full symbol into its top-order and lower-order parts.
(2) Multiply out.

The term $\chi(p)$ has compact support in p, so it corresponds to an operator that turns any function into a smooth one (a "smoothing" operator). The last term is of size $|p|^{m-1}/|p|^m = |p|^{-1}$ at large $|p|$: it is "of order -1", one order better than the identity. So $LQ = 1 + (\text{order} \le -1)$, and Q inverts L *up to lower-order terms*. This is possible precisely because σ_m can be divided by, which is ellipticity. Iterating the construction improves the error to order $-2, -3, \ldots$. The result, a **parametrix**, is an approximate inverse whose error is smoothing, and it is the rigorous replacement for the Green's function when the coefficients vary.

2.2.5 The leading symbol lives on the cotangent space

For the definition (2.45) to make sense on a manifold, ellipticity must not depend on the coordinates we choose. The full symbol does depend on the coordinates. The leading symbol does not, *provided we transform p as a covector*. This is the key to the bundle picture of Section 2.3, and Nash alludes to it in his footnote 4, so we work it out.

The oscillatory test. Replace the plane wave in (2.41) by a wave with a general phase, $e^{i\lambda\psi(x)}$, where ψ is a smooth real function and λ is a large parameter. Locally this is a plane wave with wave-vector $\lambda\,\nabla\psi(x)$. Differentiate once: $\partial_j e^{i\lambda\psi} = i\lambda(\partial_j\psi)e^{i\lambda\psi}$. Differentiate again:

$$\partial_j\partial_k e^{i\lambda\psi} \overset{(1)}{=} \partial_j\big(i\lambda\,\partial_k\psi\,e^{i\lambda\psi}\big) \overset{(2)}{=} \big[(i\lambda)^2\,\partial_j\psi\,\partial_k\psi + i\lambda\,\partial_j\partial_k\psi\big]e^{i\lambda\psi}.$$

(1) The first derivative, computed above.
(2) Product rule: the derivative hits either the exponential (giving another $i\lambda\,\partial_j\psi$) or the factor $\partial_k\psi$ (giving no new λ).

The pattern is general: each ∂_j gives $i\lambda\,\partial_j\psi$ plus terms with fewer powers of λ. For an operator of order m,

$$e^{-i\lambda\psi}\,L\big(e^{i\lambda\psi}\big) \;=\; \lambda^m\,\sigma_m\big(x, \mathrm{d}\psi(x)\big) + O(\lambda^{m-1}), \qquad \text{so} \qquad \sigma_m(x, \mathrm{d}\psi(x)) \;=\; \lim_{\lambda\to\infty} \lambda^{-m} e^{-i\lambda\psi} L\, e^{i\lambda\psi}, \tag{2.47}$$

where $\mathrm{d}\psi(x) = (\partial_1\psi, \ldots, \partial_n\psi)$ is the gradient covector. The right-hand side mentions no coordinates at all: just a function ψ, the operator, and a limit. So σ_m *is a well-defined function of the point x and of the covector $\xi = \mathrm{d}\psi(x) \in T^*_xM$.* Every covector at x is $\mathrm{d}\psi(x)$ for some ψ (take ψ linear in local coordinates), so this defines σ_m on the whole cotangent space.

The transformation law. In practice: if we change coordinates $x \mapsto y(x)$, the momentum variable must change like the components of a gradient. By the chain rule, $\partial\psi/\partial x_i = \sum_k (\partial y_k/\partial x_i)\,\partial\psi/\partial y_k$, so

$$p_i^{(x)} \;=\; \sum_{k=1}^{n} \frac{\partial y_k}{\partial x_i}\, p_k^{(y)}, \tag{2.48}$$

and $\sigma_m^{(x)}(x, p^{(x)}) = \sigma_m^{(y)}(y(x), p^{(y)})$. The "$p$" of the symbol is a momentum, and momenta are covectors, just as in Hamiltonian mechanics, where (x, p) are coordinates on phase space T^*M.

Worked example 2.14: The Laplacian in polar coordinates

In the plane the positive Laplacian in polar coordinates (r, θ) is

$$\Delta \;=\; -\frac{\partial^2}{\partial r^2} - \frac{1}{r}\frac{\partial}{\partial r} - \frac{1}{r^2}\frac{\partial^2}{\partial \theta^2}.$$

Its coefficients depend on r. Let (p_r, p_θ) be the momenta conjugate to (r, θ). The plane-wave test (replace $\partial_r \to i p_r$, $\partial_\theta \to i p_\theta$) gives the full and leading symbols

$$\sigma(r, \theta; p) \;=\; p_r^2 - \frac{i}{r}\, p_r + \frac{p_\theta^2}{r^2}, \qquad \sigma_2(r, \theta; p) \;=\; p_r^2 + \frac{p_\theta^2}{r^2}. \tag{2.49}$$

Now check that σ_2 is the Cartesian symbol $p_x^2 + p_y^2$, transformed as a covector. With $x = r\cos\theta$, $y = r\sin\theta$, the law (2.48) (with the roles of old and new coordinates chosen so that (r, θ) are the "x") gives

$$\begin{aligned} p_r &\overset{(1)}{=} \frac{\partial x}{\partial r} p_x + \frac{\partial y}{\partial r} p_y \;=\; \cos\theta\, p_x + \sin\theta\, p_y, \\ p_\theta &\overset{(2)}{=} \frac{\partial x}{\partial \theta} p_x + \frac{\partial y}{\partial \theta} p_y \;=\; -r\sin\theta\, p_x + r\cos\theta\, p_y. \end{aligned}$$

(1) (2.48) with $i = r$; $\partial_r(r\cos\theta) = \cos\theta$, $\partial_r(r\sin\theta) = \sin\theta$.
(2) (2.48) with $i = \theta$; $\partial_\theta(r\cos\theta) = -r\sin\theta$, $\partial_\theta(r\sin\theta) = r\cos\theta$.

Therefore

$$\begin{aligned} p_r^2 + \frac{p_\theta^2}{r^2} &\overset{(1)}{=} (\cos\theta\, p_x + \sin\theta\, p_y)^2 + (-\sin\theta\, p_x + \cos\theta\, p_y)^2 \\ &\overset{(2)}{=} (\cos^2\theta + \sin^2\theta)\, p_x^2 + (\sin^2\theta + \cos^2\theta)\, p_y^2 \\ &\qquad + 2(\cos\theta\sin\theta - \sin\theta\cos\theta)\, p_x p_y \;=\; p_x^2 + p_y^2. \end{aligned}$$

(1) Substitute the two formulas above; the factor r in p_θ cancels the $1/r^2$.
(2) Expand both squares; the cross terms cancel.

So the leading symbol is coordinate independent, as promised. The full symbol is not. In Cartesian coordinates it has no first-order part. In polar coordinates it has the first-order part $-ip_r/r$, produced by the change of coordinates. Notice also that σ_2 in (2.49) is positive for $(p_r, p_\theta) \neq 0$ only when $r > 0$. At $r = 0$ it degenerates to p_r^2. This is not a failure of ellipticity: polar coordinates are singular at the origin, and the "operator in coordinates" there is not the Laplacian in any honest chart.

Worked example 2.15: The Laplace–Beltrami operator of a curved metric

On a Riemannian manifold with metric $g_{ij}(x)$, inverse metric g^{ij} and $\sqrt{g} = \sqrt{\det g_{ij}}$, the positive Laplacian on functions is

$$\Delta_g u \;=\; -\frac{1}{\sqrt{g}}\,\partial_i\big(\sqrt{g}\, g^{ij}\, \partial_j u\big) \;=\; -g^{ij}\,\partial_i\partial_j u \;-\; \frac{1}{\sqrt{g}}\,\partial_i\big(\sqrt{g}\, g^{ij}\big)\,\partial_j u, \tag{2.50}$$

with summation over repeated indices (the second form is the product rule). Only the first term has two derivatives, so

$$\sigma_2(\Delta_g)(x, p) \;=\; g^{ij}(x)\, p_i p_j \;=\; |p|_g^2, \tag{2.51}$$

the squared length of the covector p in the metric. A Riemannian metric is positive definite, so $g^{ij}p_ip_j > 0$ for $p \neq 0$: *the Laplacian of any Riemannian metric is elliptic.* For the round unit sphere, $g = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2$, so $g^{\theta\theta} = 1$, $g^{\phi\phi} = 1/\sin^2\theta$ and $\sigma_2 = p_\theta^2 + p_\phi^2/\sin^2\theta$. For a Lorentzian metric the same formula gives $g^{\mu\nu}p_\mu p_\nu$, which vanishes on the null cone: the wave operator of general relativity is hyperbolic, as it must be.

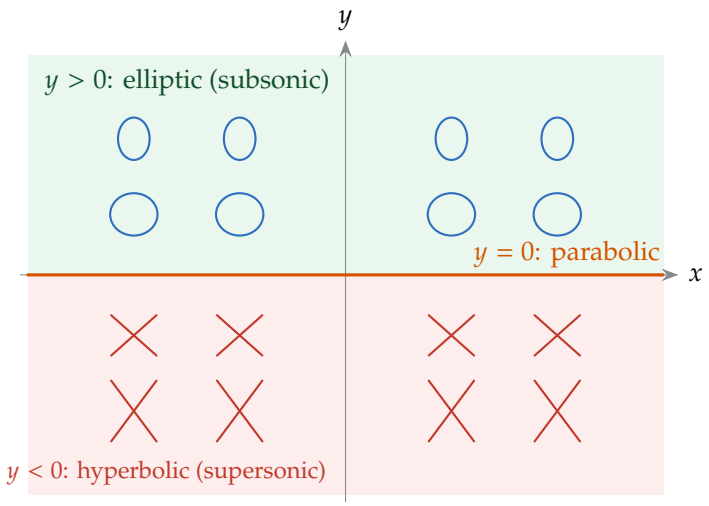

Figure 2.11: Ellipticity is checked point by point. For the Tricomi operator $-(y\partial_x^2 + \partial_y^2)$ we draw, at sample points, the level set $\sigma_2(x, y; p) = yp_1^2 + p_2^2 = c$ in the momentum plane attached to that point (a small copy of p-space at each point). In the upper half-plane these are ellipses, which get wider as $y \to 0$. In the lower half-plane the leading symbol vanishes on a pair of null directions (red crosses). They open up as y becomes more negative, and they are the directions normal to the Mach lines. On the sonic line $y = 0$ the form is degenerate.

2.2.6 More examples of the definition at work

Worked example 2.16: The biharmonic operator: elliptic of order four

The deflection $u(x, y)$ of a thin elastic plate under a load f obeys $\Delta^2 u = f$, with

$$\Delta^2 = \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right)^2 = \frac{\partial^4}{\partial x^4} + 2\frac{\partial^4}{\partial x^2 \partial y^2} + \frac{\partial^4}{\partial y^4}.$$

In multi-index form, $\partial^\alpha = i^{|\alpha|}D^\alpha$ with $|\alpha| = 4$ gives $i^4 = 1$, so $\Delta^2 = D^{(4,0)} + 2D^{(2,2)} + D^{(0,4)}$ and

$$\sigma_4(p) \overset{(1)}{=} p_1^4 + 2p_1^2p_2^2 + p_2^4 \overset{(2)}{=} (p_1^2 + p_2^2)^2 = |p|^4.$$

(1) Replace each D^α by p^α.
(2) Recognise a perfect square.

This vanishes only at $p = 0$, so Δ^2 is elliptic. It is also the square of an elliptic operator, and indeed the leading symbol of a composition is the product of leading symbols (we derive this in Section 2.3.8). By contrast, the fourth-order operator $\partial_x^4 - \partial_y^4$ has $\sigma_4 = p_1^4 - p_2^4 = (p_1^2 - p_2^2)(p_1^2 + p_2^2)$, which vanishes on $p_1 = \pm p_2$. It is the product of an elliptic and a hyperbolic operator, and it is not elliptic.

Worked example 2.17: Why a scalar first-order operator is almost never elliptic

Take a first-order scalar operator $L = \sum_j a_j(x)\partial_j + b(x)$ on $\mathbb{R}^n$ with complex coefficients. Its leading symbol is

$$\sigma_1(x,p) \;=\; i\sum_{j=1}^{n} a_j(x)\,p_j \;=\; i\,(\vec{u}\cdot p + i\,\vec{v}\cdot p),$$

where we split the complex vector $a = \vec{u} + i\vec{v}$ into real and imaginary parts $\vec{u}, \vec{v} \in \mathbb{R}^n$. For real p, $\vec{u}\cdot p$ and $\vec{v}\cdot p$ are real, so $\sigma_1 = 0$ exactly when $\vec{u}\cdot p = 0$ *and* $\vec{v}\cdot p = 0$. That is, p is orthogonal to both $\vec{u}$ and $\vec{v}$. Now count:

- $n = 1$: $\sigma_1 = ia\,p$ is non-zero for $p \neq 0$ iff $a \neq 0$. Every non-degenerate first-order ODE operator is elliptic.
- $n = 2$: two vectors $\vec{u}, \vec{v}$ in the plane have no common non-zero orthogonal vector iff they are linearly independent. For example $a = (1, i)$, i.e. $\vec{u} = (1, 0)$, $\vec{v} = (0, 1)$, which is $L = \partial_x + i\partial_y = 2\bar{\partial}$. So *the Cauchy–Riemann operator is elliptic*, and up to a change of coordinates it is the only type of elliptic scalar first-order operator in the plane.
- $n \geq 3$: the vectors orthogonal to both $\vec{u}$ and $\vec{v}$ form a subspace of dimension at least $n - 2 \geq 1$. There is always a non-zero characteristic p. *No scalar first-order operator in three or more dimensions is elliptic.*

A real first-order operator (such as the transport operator $\partial_t + c\,\partial_x$) is never elliptic for $n \geq 2$: its symbol $i(p_t + cp_x)$ vanishes on a whole line. Transport is "pure propagation". This counting is the reason the Dirac operator is a *matrix* operator: to take a first-order "square root" of the Laplacian in $n \geq 3$ dimensions we are forced to use matrices (gamma matrices). The next section builds the framework, vector bundles, in which such operators live.

Try it: Ellipticity of a few operators

Decide whether each operator on $\mathbb{R}^2$ is elliptic, and where. (a) $-\partial_x^2 - 4\partial_x\partial_y - 5\partial_y^2 + 7\partial_x$. (b) $-\partial_x^2 - (1 + x^2)\partial_y^2$. (c) $\partial_x^2\partial_y^2$. (d) $\partial_x + ix\,\partial_y$.

Answers. (a) $\sigma_2 = p_1^2 + 4p_1p_2 + 5p_2^2 = (p_1 + 2p_2)^2 + p_2^2 > 0$ for $p \neq 0$: elliptic (the $7\partial_x$ is irrelevant). (b) $\sigma_2 = p_1^2 + (1 + x^2)p_2^2 > 0$: elliptic everywhere. (c) $\sigma_4 = p_1^2p_2^2$ vanishes on both axes: not elliptic. (d) $\sigma_1 = i(p_1 + ixp_2)$, which vanishes for $p = (0, 1)$ exactly when $x = 0$: elliptic for $x \neq 0$, not elliptic on the line $x = 0$. (This is the Mizohata operator, a famous source of counterexamples in PDE theory.)

2.2.7 Hypo-ellipticity: smoothing without ellipticity

In Section 2.1 we saw that the benefit of ellipticity is elliptic regularity: $Lu = f$ with f smooth forces u to be smooth. Is ellipticity *necessary* for this? No. Some parabolic operators, the heat operator above all, smooth just as well. So Nash gives the regularity property its own name.

Working definition 2.10 (hypo-elliptic operator (Nash, p. 33))

A differential operator L is **hypo-elliptic** if, for every open set Ω and every (generalised) function [possibly as rough as a point source δ] u,

$$Lu \text{ is } C^\infty \text{ on } \Omega \quad\Longrightarrow\quad u \text{ is } C^\infty \text{ on } \Omega. \tag{2.52}$$

Operationally: solutions are never rougher than the source, locally. In the language of (2.19), $\operatorname{sing\,supp} u = \operatorname{sing\,supp} Lu$ [the singular support is the closed set of points near which the function is not smooth]. *How to test* (constant coefficients): find the Green's function G and check whether it is C^∞ away from the origin. If it is, the localisation argument of Section 2.1.4 (Step 2) goes through word for word, and L is hypo-elliptic.

The inclusion one way is what Section 2.1.4 showed.

Key idea: Elliptic ⇒ hypo-elliptic, not conversely

Every elliptic operator is hypo-elliptic: this is elliptic regularity. For variable coefficients the proof replaces the Green's function by the parametrix of Section 2.2.4, an approximate inverse whose error is smoothing. But there are hypo-elliptic operators that are not elliptic. Nash's example is the heat operator.

2.2.8 The heat operator: hypo-elliptic but not elliptic

The heat (diffusion) operator on $\mathbb{R}^{n+1}$, with coordinates $(x,t) = (x_1,\dots,x_n,t)$, is

$$L \;=\; \frac{\partial}{\partial t} - \frac{\partial^2}{\partial x_1^2} - \cdots - \frac{\partial^2}{\partial x_n^2} \;=\; \frac{\partial}{\partial t} + \Delta_x, \tag{2.53}$$

Nash's (2.24). Its leading symbol, in the variables (p,p_0) dual to (x,t), is $\sigma_2 = |p|^2$. It does not involve p_0 at all, so it vanishes at $(p,p_0) = (0,1) \neq 0$. The heat operator is *not* elliptic, which is what we called parabolic in Section 2.1.9. Yet it smooths. We see this by computing its Green's function.

Worked example 2.18: The heat kernel, Nash's (2.25)

We want G with $LG = \delta(x)\delta(t)$ and $G = 0$ for $t < 0$ (the heat released by a unit burst at the origin at time 0). Fourier transform in x only: $G(x,t) = (2\pi)^{-n}\int e^{ip\cdot x} g(p,t)\,\mathrm{d}^n p$. Then $-\partial_{x_j}^2 \to p_j^2$ and $\delta(x) \to 1$ in these units, so for each p

$$\frac{\partial g}{\partial t} + |p|^2\, g \;=\; \delta(t), \qquad g = 0 \text{ for } t<0, \qquad \text{hence} \qquad g(p,t) = \theta(t)\, e^{-|p|^2 t}.$$

(Check: for $t>0$ this solves $g' = -|p|^2 g$, and the jump of g from 0 to 1 at $t=0$ produces the $\delta(t)$.) Each Fourier mode simply decays, the short wavelengths fastest. Transforming back, the integral factorises into n one-dimensional Gaussian integrals. For $t>0$ and one coordinate,

$$\int_{-\infty}^{\infty} e^{ipx - p^2 t}\,\mathrm{d}p \overset{(1)}{=} \int_{-\infty}^{\infty} e^{-t\,(p - \frac{ix}{2t})^2 - \frac{x^2}{4t}}\,\mathrm{d}p \overset{(2)}{=} e^{-x^2/4t}\int_{-\infty}^{\infty} e^{-tq^2}\,\mathrm{d}q \overset{(3)}{=} \sqrt{\frac{\pi}{t}}\; e^{-x^2/4t}.$$

(1) Complete the square: $-t\big(p - \frac{ix}{2t}\big)^2 = -tp^2 + ipx + \frac{x^2}{4t}$, so $ipx - tp^2 = -t\big(p - \frac{ix}{2t}\big)^2 - \frac{x^2}{4t}$.
(2) Shift the contour, $q = p - ix/2t$. This is allowed by Cauchy's theorem because the Gaussian decays at both ends of the strip between $\operatorname{Im} q = 0$ and $\operatorname{Im} q = -x/2t$.
(3) The Gaussian integral $\int e^{-tq^2}\mathrm{d}q = \sqrt{\pi/t}$.

Multiplying n of these and the prefactor $(2\pi)^{-n}$,

$$G(x,t) \;=\; \theta(t)\,\frac{1}{(2\pi)^n}\Big(\frac{\pi}{t}\Big)^{n/2} e^{-|x|^2/4t} \;=\; \frac{\theta(t)}{(4\pi t)^{n/2}}\,\exp\Big[-\frac{\sum_i x_i^2}{4t}\Big], \tag{2.54}$$

which is Nash's (2.25), since $(4\pi t)^{n/2} = (2\sqrt{\pi t})^n$. It is a Gaussian of width $\sqrt{2t}$ and total heat $\int G\,\mathrm{d}^n x = 1$ for every $t > 0$.
As a direct check that $LG = 0$ for $t > 0$, write $r^2 = |x|^2$:

$$\frac{\partial G}{\partial t} \overset{(1)}{=} \Big(-\frac{n}{2t} + \frac{r^2}{4t^2}\Big)G, \qquad \frac{\partial^2 G}{\partial x_j^2} \overset{(2)}{=} \Big(-\frac{1}{2t} + \frac{x_j^2}{4t^2}\Big)G,$$

(1) Differentiate $(4\pi t)^{-n/2}$ (giving $-n/2t$ times itself) and the exponent $-r^2/4t$ (giving $+r^2/4t^2$).
(2) $\partial_j G = -\frac{x_j}{2t}G$; differentiate again with the product rule.

Summing the second formula over j gives $\nabla^2 G = (-\frac{n}{2t} + \frac{r^2}{4t^2})G = \partial_t G$, so $(\partial_t - \nabla^2)G = 0$ for $t > 0$.

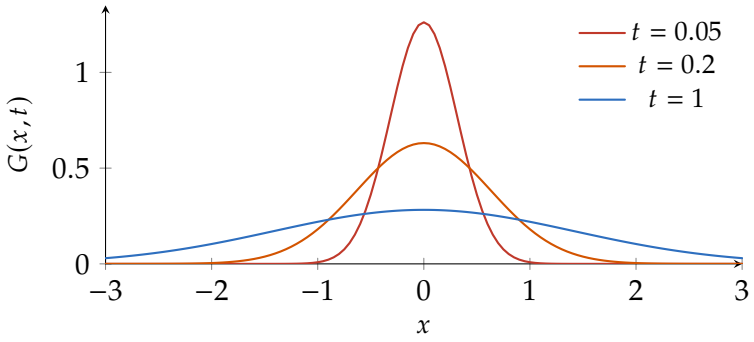

Figure 2.12: The one-dimensional heat kernel (2.54) at three times. A unit burst of heat at the origin spreads into Gaussians of width $\sqrt{2t}$ and constant area 1. For every $t > 0$ the profile is C^∞ (indeed analytic) in x. As $t \to 0^+$ it concentrates into $\delta(x)$.

Why the heat kernel is smooth away from the origin

Nash's key claim is that G in (2.54) is singular *only* at the origin $x = t = 0$ of $\mathbb{R}^{n+1}$. For $t > 0$ it is obviously smooth. For $t < 0$ it is identically zero. The only question is the hyperplane $t = 0$ with $x \neq 0$, where the two formulas meet. Every partial derivative of G for $t > 0$ has the form

$$\partial_x^\beta \partial_t^k G(x,t) \;=\; P\big(x, t^{-1}\big)\, t^{-n/2}\, e^{-|x|^2/4t}, \tag{2.55}$$

where P is a polynomial. (Each derivative either hits the prefactor, producing a power of $1/t$, or hits the exponential, producing a factor like x_j/t or $|x|^2/t^2$.) Fix $x \neq 0$ and let $t \to 0^+$. With $s = 1/t \to \infty$ and $a = |x|^2/4 > 0$, every term is a power of s times e^{-as}, and

$$\lim_{t\to 0^+} t^{-N} e^{-a/t} \overset{(1)}{=} \lim_{s\to\infty} s^N e^{-as} \overset{(2)}{=} \lim_{s\to\infty} \frac{s^N}{1 + as + \cdots + \frac{(as)^{N+1}}{(N+1)!} + \cdots} \;=\; 0.$$

(1) Substitute $s = 1/t$.
(2) e^{as} is its Taylor series, every term of which is positive; keeping only the term of degree $N+1$ in the denominator shows the ratio is at most $(N+1)!/(a^{N+1}s) \to 0$.

So every derivative of G tends to 0 as $t \to 0^+$ at fixed $x \neq 0$, matching the derivatives of the zero function on the other side. Hence G is C^∞ at every point with $x \neq 0$ (Nash: "all other partial derivatives of $G(x,t)$ converge (strongly) for $x \neq 0$ and $t > 0$, and vanish (because of the

$\theta(t)$) for $x \neq 0$ and $t < 0$"). At $x = 0$, however, $G(0,t) = (4\pi t)^{-n/2} \to \infty$: the origin is the only singular point. The same proof as in Section 2.1.4 then shows the heat operator is hypo-elliptic.

Physical picture: Diffusion kills high frequencies

In Fourier space the heat evolution is $\hat{u}(p,t) = e^{-|p|^2 t}\hat{u}(p,0)$. For any $t > 0$ the factor $e^{-|p|^2 t}$ decays faster than every power of $|p|$. By the principle "smoothness is decay in p", *any* initial temperature profile, however rough, is C^∞ in x an instant later. A step function becomes the error function $\frac{1}{2}[1 + \operatorname{erf}(x/2\sqrt{t})]$. A kink rounds off at once. This is exactly the opposite of Example 2.8, where the wave equation kept kinks forever. The price is irreversibility: running the heat equation backwards multiplies by $e^{+|p|^2 t}$, which blows up the high frequencies, and the backward problem is ill-posed.

Worked example 2.19: A function that is smooth but not analytic: $e^{-1/t}$

The one-variable function behind the heat kernel is

$$h(t) \;=\; \begin{cases} e^{-1/t}, & t > 0, \\ 0, & t \le 0. \end{cases}$$

The argument above (with $a = 1$) shows that every derivative $h^{(k)}(t)$ tends to 0 as $t \to 0^+$. So h is C^∞ on all of $\mathbb{R}$, with $h^{(k)}(0) = 0$ for every k. Its Taylor series at 0 is therefore

$$\sum_{k=0}^{\infty} \frac{h^{(k)}(0)}{k!}\, t^k \;=\; 0 + 0 + 0 + \cdots \;=\; 0,$$

which converges (to zero) but does not equal $h(t) = e^{-1/t} > 0$ for any $t > 0$. A function is **real analytic** at a point if it equals its convergent Taylor series in a neighbourhood of that point. So h is smooth but *not* analytic at $t = 0$. For each fixed $x \neq 0$ the heat kernel, as a function of t, is a copy of this function: $G(x,t) = (4\pi t)^{-n/2} h(4t/|x|^2)$. This is the content of Nash's footnote 3: G is C^∞ but not analytic on the hyperplane $t = 0$, and analytic off it.

2.2.9 The Schrödinger operator: not hypo-elliptic

The free Schrödinger operator (with $\hbar = 2m = 1$) in n space dimensions,

$$L \;=\; -i\frac{\partial}{\partial t} - \nabla^2, \tag{2.56}$$

looks like the heat operator with t replaced by it. Both are parabolic with the same leading symbol $|p|^2$. Nash shows that, despite this similarity, the Schrödinger operator is *not* hypo-elliptic. Again the Green's function tells the story.

Worked example 2.20: The Schrödinger Green's function, Nash's (2.26)

Fourier transform in x as before. The mode equation is $-i\,\partial_t g + |p|^2 g = \delta(t)$ with $g = 0$ for $t < 0$. Its solution is $g(p,t) = i\,\theta(t)\,e^{-i|p|^2 t}$. To check it,

$$\begin{aligned} -i\frac{\partial g}{\partial t} + |p|^2 g &\overset{(1)}{=} -i \cdot i\Big[\delta(t)\,e^{-i|p|^2 t} - i\,|p|^2\;\theta(t)\,e^{-i|p|^2 t}\Big] + i\,|p|^2\;\theta(t)\,e^{-i|p|^2 t} \\ &\overset{(2)}{=} \delta(t) - i\,|p|^2\;\theta(t)\,e^{-i|p|^2 t} + i\,|p|^2\;\theta(t)\,e^{-i|p|^2 t} \;=\; \delta(t). \end{aligned}$$

(1) Product rule on $\theta(t)e^{-i|p|^2 t}$, using $\theta' = \delta$.

(2) $-i \cdot i = 1$, and $\delta(t)e^{-i|p|^2 t} = \delta(t)$ because the exponential equals 1 at $t = 0$.

Transforming back uses the same Gaussian integral as Example 2.18 with t replaced by it (justified by analytic continuation, or by inserting a damping factor $e^{-\varepsilon|p|^2}$ and letting $\varepsilon \to 0$):

$$G(x,t) \;=\; i\,\frac{\theta(t)}{(4\pi i t)^{n/2}}\,\exp\!\Big[-\frac{\sum_j x_j^2}{4it}\Big] \;=\; i\,\frac{\theta(t)}{(4\pi i t)^{n/2}}\,e^{\,i|x|^2/4t}, \tag{2.57}$$

Nash's (2.26). This is the free-particle propagator of quantum mechanics.

Now compare the two kernels on the hyperplane $t = 0$, $x \neq 0$. For the heat kernel the exponential factor is $e^{-|x|^2/4t}$. It is real and tends to zero faster than any power of t, which is what made everything smooth. For the Schrödinger kernel the exponential factor is $e^{i|x|^2/4t}$, a pure phase of modulus one. Then

$$|G(x,t)| \;=\; \frac{1}{(4\pi t)^{n/2}} \quad (t > 0),$$

which blows up as $t \to 0^+$ at *every* x, while the phase $|x|^2/4t$ spins round infinitely often. Nash says it "behaves monstrously" on $t = 0$. G is not even continuous there, let alone C^∞ (Figure 2.13).

The failure of hypo-ellipticity follows at once. Take any point $(x_0, 0)$ with $x_0 \neq 0$ and a small ball Ω around it not containing the origin. On Ω, $LG = \delta(x)\delta(t) = 0$, which is certainly smooth. But G is not smooth on Ω. So (2.52) fails: *the Schrödinger operator is not hypo-elliptic.*

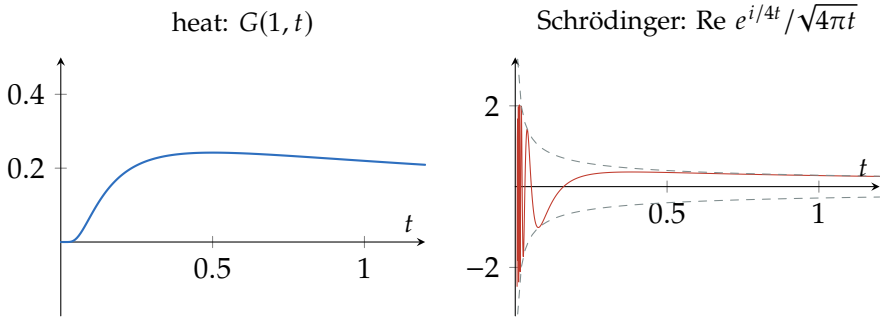

Figure 2.13: The two Green's functions at the fixed position $x = 1$ (one space dimension), as functions of time. Left: the heat kernel $e^{-1/4t}/\sqrt{4\pi t}$ leaves $t = 0$ so flatly that every derivative vanishes there: it is C^∞ (though not analytic). Right: (the real part of) the Schrödinger kernel oscillates infinitely fast inside an envelope $\pm 1/\sqrt{4\pi t}$ (dashed) that blows up as $t \to 0^+$: it is not even continuous at $t = 0$. This is why the heat operator is hypo-elliptic and the Schrödinger operator is not.

Physical picture: Dispersion moves high frequencies, it does not kill them

In Fourier space, Schrödinger evolution is $\hat{u}(p,t) = e^{-i|p|^2 t}\hat{u}(p,0)$. The multiplier has modulus one, so $|\hat{u}(p,t)| = |\hat{u}(p,0)|$: the high-frequency content is never damped. The phase makes a wave-packet of momentum p move with group velocity $2p$. So short waves are not destroyed, only sent away very fast. Time reversal is a symmetry ($t \to -t$ with complex conjugation), so short waves can equally well arrive from far away and focus to a singularity at a chosen point and time. The Green's function is exactly such a focused wave. The heat equation has no such symmetry: it damps short waves, and nothing can

reassemble them.

Watch out: Non-hypo-elliptic does not mean "never smooths"

Free Schrödinger evolution of nice, rapidly decaying initial data is in fact smooth for $t \neq 0$: the roughness disperses off to infinity. (Physicists call this dispersive smoothing.) This uses information about the solution *at infinity*. Hypo-ellipticity is a *local* property: it must hold on every small open set, whatever the solution does elsewhere. The Green's function shows that locally, near $(x_0, 0)$, a solution of $Lu = 0$ can be as singular as we like. By contrast, for the heat equation every local solution is smooth.

Hörmander's test for constant coefficients

There is a neat criterion, due to Hörmander, that explains all these examples at once in terms of the *full* symbol. We state it because it makes the difference between heat and Schrödinger visible in one line. A constant-coefficient operator L with symbol $\sigma(p)$ is hypo-elliptic if and only if

$$\frac{\left|\partial_p^\gamma \sigma(p)\right|}{|\sigma(p)|} \longrightarrow 0 \qquad \text{as } |p| \to \infty,\ p \text{ real, for every } \gamma \neq 0. \tag{2.58}$$

In words: at high frequency, the symbol is much larger than all its derivatives. This is the property (2.18) that made the Green's function smooth: each p-derivative of $1/\sigma$ gains decay. In particular σ must be non-zero for large $|p|$.

- **Laplace**, $\sigma = |p|^2$: $\partial_j \sigma / \sigma = 2p_j/|p|^2 = O(1/|p|) \to 0$. Hypo-elliptic.
- **Heat**, $\sigma = ip_0 + |p|^2$ (with p_0 dual to t), so $|\sigma| = \sqrt{p_0^2 + |p|^4}$. Then $\left|\partial_{p_0}\sigma\right|/|\sigma| = 1/\sqrt{p_0^2 + |p|^4} \to 0$. Also $\left|\partial_{p_j}\sigma\right|/|\sigma| = 2\left|p_j\right|/\sqrt{p_0^2 + |p|^4}$. If $|p|^2 \geq |p_0|$ this is at most $2/|p|$, and if $|p|^2 < |p_0|$ it is at most $2\,|p_0|^{1/2}/|p_0|$; either way it tends to 0. Hypo-elliptic, even though the leading symbol vanishes at $(p, p_0) = (0, 1)$.
- **Schrödinger**, $\sigma = p_0 + |p|^2$: it vanishes on the whole paraboloid $p_0 = -|p|^2$, which goes off to infinity. The ratio is infinite there. Not hypo-elliptic.
- **Wave**, $\sigma = -p_0^2 + |p|^2$: vanishes on the light cone. Not hypo-elliptic.

The factor i in front of p_0 is the whole difference between heat and Schrödinger. It moves the zero set of the full symbol off the real p-space.

2.2.10 The Cauchy–Riemann operator

Nash's last example of the section is the most important one for later chapters: the operator whose solutions are the holomorphic functions. On $\mathbb{C} = \mathbb{R}^2$ with $z = x + iy$ set

$$L = \bar\partial = \frac{\partial}{\partial \bar z} = \frac{1}{2}\Big(\frac{\partial}{\partial x} + i\frac{\partial}{\partial y}\Big), \qquad \partial = \frac{\partial}{\partial z} = \frac{1}{2}\Big(\frac{\partial}{\partial x} - i\frac{\partial}{\partial y}\Big), \tag{2.59}$$

Nash's (2.27). These are defined so that $\partial z = 1$, $\bar\partial z = 0$, $\partial \bar z = 0$, $\bar\partial \bar z = 1$. Check one: $\bar\partial z = \frac{1}{2}(\partial_x + i\partial_y)(x + iy) = \frac{1}{2}(1 + i \cdot i) = 0$.

Holomorphic means $\bar\partial f = 0$. Write $f = u + iv$ with u, v real. Then

$$2\bar\partial f \overset{(1)}{=} (\partial_x + i\partial_y)(u + iv) \overset{(2)}{=} (\partial_x u - \partial_y v) + i\,(\partial_y u + \partial_x v).$$

(1) Definition (2.59).
(2) Multiply out and collect real and imaginary parts, using $i \cdot i = -1$.

So $\bar\partial f = 0$ is the pair of Cauchy–Riemann equations $\partial_x u = \partial_y v$, $\partial_y u = -\partial_x v$: f is holomorphic.

$\bar\partial$ is a square root of the Laplacian. Compose the two operators:

$$4\,\partial\bar\partial \overset{(1)}{=} (\partial_x - i\partial_y)(\partial_x + i\partial_y) \overset{(2)}{=} \partial_x^2 + i\partial_x\partial_y - i\partial_y\partial_x + \partial_y^2 \overset{(3)}{=} \partial_x^2 + \partial_y^2 \;=\; -\Delta. \tag{2.60}$$

(1) Definitions (2.59); the factors $\frac12 \cdot \frac12 \cdot 4 = 1$.
(2) Multiply out; $(-i)(i) = 1$.
(3) Mixed partials commute, so the middle terms cancel.

This is the two-dimensional version of what the Dirac operator does in any dimension: a first-order operator whose "square" is the Laplacian.

Worked example 2.21: The Green's function of $\bar\partial$ is $1/\pi z$, Nash's (2.28)–(2.29)

Nash states that

$$\bar\partial\, G \;=\; \delta(x,y) \qquad \text{is solved by} \qquad G(x,y) \;=\; \frac{1}{\pi(x+iy)} \;=\; \frac{1}{\pi z}. \tag{2.61}$$

We give two derivations.
From the Laplacian. The Green's function of Δ in the plane is $G_2 = -\frac{1}{2\pi}\ln|z|$ (2.16). By (2.60), $\Delta G_2 = \delta$ means $\bar\partial(-4\,\partial G_2) = \delta$. So $G = -4\partial G_2$ works, and

$$-4\,\partial G_2 \overset{(1)}{=} \frac{4}{2\pi}\,\partial\Big(\tfrac12 \ln(z\bar z)\Big) \overset{(2)}{=} \frac{1}{\pi}\cdot\frac{\bar z}{z\bar z} \;=\; \frac{1}{\pi z}.$$

(1) $\ln|z| = \frac12 \ln|z|^2 = \frac12 \ln(z\bar z)$.
(2) ∂ treats $\bar z$ as a constant, so $\partial \ln(z\bar z) = \bar z/(z\bar z)$. With the prefactors: $\frac{4}{2\pi}\cdot\frac12 = \frac{1}{\pi}$.

From Stokes' theorem. Test against a smooth compactly supported function φ. By definition of the derivative of a distribution, $\langle \bar\partial G, \varphi\rangle = -\int G\,\bar\partial\varphi\,\mathrm{d}x\,\mathrm{d}y$. Remove a small disc D_ε around the singularity. On the rest, $1/z$ is holomorphic, so $\frac{1}{z}\bar\partial\varphi = \bar\partial(\varphi/z)$. We also need $\mathrm{d}z \wedge \mathrm{d}\bar z$. Since $\mathrm{d}\bar z \wedge \mathrm{d}z = (\mathrm{d}x - i\mathrm{d}y)\wedge(\mathrm{d}x + i\mathrm{d}y) = 2i\,\mathrm{d}x\wedge\mathrm{d}y$, we have $\mathrm{d}(\psi\,\mathrm{d}z) = \bar\partial\psi\,\mathrm{d}\bar z\wedge\mathrm{d}z = 2i\,\bar\partial\psi\,\mathrm{d}x\wedge\mathrm{d}y$ for any function ψ. Hence

$$\begin{aligned} -\int_{|z|>\varepsilon} \frac{1}{\pi z}\,\bar\partial\varphi\,\mathrm{d}x\,\mathrm{d}y &\overset{(1)}{=} -\frac{1}{\pi}\int_{|z|>\varepsilon} \bar\partial\Big(\frac{\varphi}{z}\Big)\mathrm{d}x\,\mathrm{d}y \overset{(2)}{=} -\frac{1}{2\pi i}\int_{|z|>\varepsilon} \mathrm{d}\Big(\frac{\varphi}{z}\,\mathrm{d}z\Big) \\ &\overset{(3)}{=} +\frac{1}{2\pi i}\oint_{|z|=\varepsilon} \frac{\varphi\,\mathrm{d}z}{z} \;\xrightarrow{\varepsilon\to 0}\; \frac{1}{2\pi i}\,\varphi(0)\cdot 2\pi i \;=\; \varphi(0). \end{aligned}$$

(1) $1/z$ is holomorphic away from 0, so $\bar\partial$ passes through it.
(2) The identity $\mathrm{d}(\psi\,\mathrm{d}z) = 2i\,\bar\partial\psi\,\mathrm{d}x\wedge\mathrm{d}y$ with $\psi = \varphi/z$.
(3) Stokes' theorem. The region $|z| > \varepsilon$ has as its boundary the small circle traversed *clockwise*, which gives the sign flip. (φ vanishes far away.) Then $\oint \mathrm{d}z/z = 2\pi i$ counter-clockwise and $\varphi \to \varphi(0)$ on the shrinking circle.

So $\langle\bar\partial G, \varphi\rangle = \varphi(0)$, i.e. $\bar\partial G = \delta$.

The leading symbol. Using $\partial_x \to ip_1$, $\partial_y \to ip_2$,

$$\sigma_1(\bar\partial)(z,p) \;=\; \frac{1}{2}\big(ip_1 + i\cdot ip_2\big) \;=\; \frac{i}{2}\,(p_1+ip_2). \tag{2.62}$$

Its modulus is $\frac{1}{2}\,|p|$, which vanishes only at $p=0$. So $\bar\partial$ is elliptic, as Example 2.17 predicted. (Nash's (2.30) reads $\frac{1}{2}(p_1+ip_2)$, without the factor i. The factor is a matter of convention and does not affect ellipticity.) Consistently with (2.60), $4\,\sigma_1(\partial)\sigma_1(\bar\partial) = 4\cdot\frac{i}{2}(p_1-ip_2)\cdot\frac{i}{2}(p_1+ip_2) = -\,|p|^2$, which is the symbol of $-\Delta$.

Elliptic regularity for $\bar\partial$ is Cauchy's integral formula. The Green's function $1/\pi z$ is smooth, indeed real analytic, away from $z=0$. So by the argument of Section 2.1.4, $\bar\partial u = f$ with f smooth forces u to be smooth. For $f=0$ this is the classical fact that holomorphic functions are infinitely differentiable, and the localisation argument of Step 2 becomes Cauchy's integral formula. If $\bar\partial u = 0$ on a neighbourhood of the closed disc $|w|\le R$, then for $|z|<R$,

$$u(z) \overset{(1)}{=} \frac{1}{2\pi i}\oint_{|w|=R}\frac{u(w)}{w-z}\,\mathrm{d}w \overset{(2)}{=} \frac{1}{2\pi i}\oint_{|w|=R}\frac{u(w)}{w}\sum_{k=0}^{\infty}\Big(\frac{z}{w}\Big)^k\mathrm{d}w \overset{(3)}{=} \sum_{k=0}^{\infty} c_k\,z^k. \tag{2.63}$$

(1) Cauchy's integral formula. It is the Stokes computation of Example 2.21, run with the Green's function $1/\pi(w-z)$ centred at z and with the boundary term on $|w|=R$ kept.

(2) $\frac{1}{w-z} = \frac{1}{w}\,\frac{1}{1-z/w}$, a geometric series that converges uniformly on the circle because $|z/w| = |z|\,/R < 1$.

(3) Integrate term by term, with $c_k = \frac{1}{2\pi i}\oint u(w)\,w^{-k-1}\,\mathrm{d}w$.

The right-hand side is a convergent power series. So u is not merely smooth but real analytic. The values of u on a circle (the "shell" of Figure 2.3, shrunk to a curve) determine u inside through the smooth kernel $1/(w-z)$, $w\neq z$.

Analytic hypo-ellipticity

This suggests a stronger property than hypo-ellipticity.

Working definition 2.11 (analytic-hypo-elliptic operator)

L is **analytic-hypo-elliptic** if, whenever Lu is real analytic [equal to its convergent Taylor series near every point] on an open set Ω, u is real analytic on Ω. *How to test* (constant coefficients): check whether the Green's function is real analytic away from the origin.

- $\bar\partial$ is analytic-hypo-elliptic: $G = 1/\pi z$ is real analytic for $z\neq 0$, and (2.63) shows solutions of $\bar\partial u = 0$ are analytic.
- The Laplacian is analytic-hypo-elliptic (Nash: "not difficult to check"). Its Green's functions (2.16) are real analytic off the origin. In the plane, a harmonic function is locally the real part of a holomorphic function (Example 2.5), so it is analytic.
- The heat operator is hypo-elliptic but *not* analytic-hypo-elliptic (Nash's footnote 3). Near a point $(x_0,0)$ with $x_0\neq 0$ the heat kernel solves $LG=0$ (analytic source), but as a function of t it is a copy of $e^{-1/t}$, smooth and not analytic (Example 2.19). Physically: a solution of the heat equation can be exactly zero up to time 0 and non-zero afterwards, which an analytic function of t could never do.

For constant coefficients the picture is completely clean (a theorem of Petrowsky): *analytic-hypo-elliptic is the same as elliptic*. So we have the nested classes of Figure 2.14.

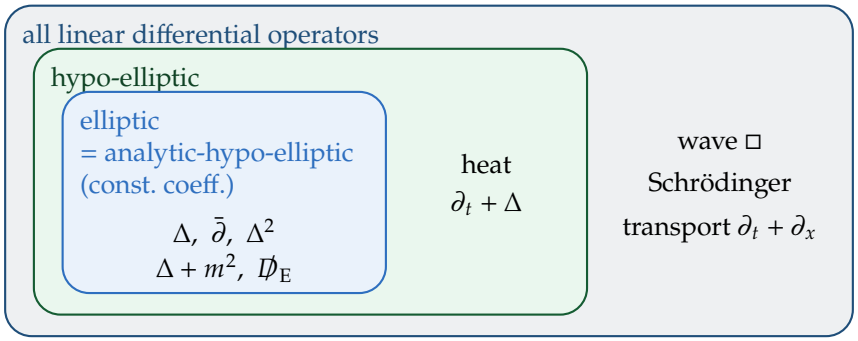

Figure 2.14: Nested classes of operators. Elliptic operators (blue) are hypo-elliptic (green); for constant coefficients they are exactly the analytic-hypo-elliptic ones. The heat operator smooths but is not elliptic. The wave, Schrödinger and transport operators propagate singularities and are not hypo-elliptic. ($\not{D}_{\mathrm{E}}$ is the Euclidean Dirac operator of Section 2.3.)

2.2.11 Ordinary differential equations

Nash ends the section with ODEs, where everything can be seen by hand. The general linear ODE of order n with smooth coefficients is

$$a_n(x)\frac{\mathrm{d}^n u}{\mathrm{d}x^n} + \cdots + a_1(x)\frac{\mathrm{d}u}{\mathrm{d}x} + a_0(x)\,u \;=\; f(x), \tag{2.64}$$

Nash's (2.31). Only the first term has n derivatives, so by the plane-wave test

$$\sigma_n(x,p) \;=\; a_n(x)\,(ip)^n, \tag{2.65}$$

Nash's (2.32), up to the harmless factor i^n which Nash absorbs into the coefficient. In one dimension $p \neq 0$ means $p^n \neq 0$, so:

Key idea: Ellipticity of an ODE

The ODE operator (2.64) is elliptic exactly where the top coefficient $a_n(x)$ is non-zero. Points where $a_n(x_0) = 0$ are the **singular points** of the ODE. Constant-coefficient ODEs with $a_n \neq 0$ are elliptic everywhere, and their solutions (combinations of $x^k e^{rx}$) are indeed smooth.

Regularity for ODEs, by induction (Nash's (2.37)). If a_n never vanishes we may divide by it:

$$\frac{\mathrm{d}^n u}{\mathrm{d}x^n} \;=\; \frac{f(x)}{a_n(x)} - \frac{a_{n-1}(x)}{a_n(x)}\frac{\mathrm{d}^{n-1}u}{\mathrm{d}x^{n-1}} - \cdots - \frac{a_0(x)}{a_n(x)}\,u. \tag{2.66}$$

Suppose u is a solution, so u has at least n continuous derivatives: $u \in C^n$. Suppose we know $u \in C^{n+j}$ for some $j \geq 0$ (true for $j = 0$). Then

$$\frac{\mathrm{d}^n u}{\mathrm{d}x^n} \overset{(1)}{\in} C^{j+1} \quad\Longrightarrow\quad u \overset{(2)}{\in} C^{n+j+1}.$$

(1) Look at the right side of (2.66). The functions f/a_n and a_k/a_n are C^∞, because $a_n \neq 0$ and everything is smooth. The derivatives $u^{(k)}$ with $k \leq n-1$ are in $C^{n+j-k} \subseteq C^{j+1}$. So the whole right side is in C^{j+1}.

(2) If the n-th derivative of u has $j+1$ continuous derivatives, then u has $n+j+1$.

By induction on j, $u \in C^\infty$. Every step used $a_n \neq 0$: *dividing by the leading symbol is what gains derivatives.* This is elliptic regularity in its most elementary form: the order-n operator gains back n derivatives.

Where a_n vanishes, this breaks down, and solutions can indeed be singular. Nash's two examples are the classic equations of mathematical physics with regular singular points.

Worked example 2.22: Bessel's equation, Nash's (2.33)–(2.34)

Bessel's equation of order λ,

$$x^2\frac{\mathrm{d}^2u}{\mathrm{d}x^2} + x\frac{\mathrm{d}u}{\mathrm{d}x} + (x^2-\lambda^2)\,u \;=\; 0, \tag{2.67}$$

arises from separating the Laplacian in cylindrical coordinates. Its leading symbol is $\sigma_2 = x^2(ip)^2 = -x^2p^2$ (Nash writes x^2p^2), which vanishes at $x=0$. So the operator is elliptic on $x>0$ and on $x<0$, but not at the origin. How do solutions behave there? Try a power $u = x^r(1+O(x))$ (the method of Frobenius). The terms of lowest order in x are

$$x^2\,r(r-1)x^{r-2} + x\,r\,x^{r-1} - \lambda^2x^r \overset{(1)}{=} \left[r(r-1)+r-\lambda^2\right]x^r \overset{(2)}{=} (r^2-\lambda^2)\,x^r.$$

(1) $(x^r)' = rx^{r-1}$, $(x^r)'' = r(r-1)x^{r-2}$; the x^2u term is of higher order, x^{r+2}, and is dropped.
(2) $r^2 - r + r = r^2$.

The lowest-order terms cancel only if $r^2=\lambda^2$ (the **indicial equation**), so $r=\pm\lambda$. The two solutions behave like x^λ and $x^{-\lambda}$ near 0 (with a logarithm, $x^\lambda\ln x$, when the two roots differ by an integer). Unless λ is a non-negative integer and we pick the right solution, u is not C^∞ at $x=0$.

Worked example 2.23: Bessel of order $\frac12$: explicit non-smooth solutions

For $\lambda=\frac12$ the solutions are elementary. We check that $u = x^{-1/2}\cos x$ solves (2.67). First,

$$u' \overset{(1)}{=} -\tfrac12 x^{-3/2}\cos x - x^{-1/2}\sin x,$$
$$u'' \overset{(2)}{=} \tfrac34 x^{-5/2}\cos x + x^{-3/2}\sin x - x^{-1/2}\cos x.$$

(1) Product rule.
(2) Differentiate each term of u' with the product rule; the two $\sin x$ terms, $\frac12x^{-3/2}\sin x$ each, add up.

Now assemble the three terms of (2.67), sorted by the type of term:

$$x^2u'' + xu' + \left(x^2-\tfrac14\right)u \overset{(1)}{=} \left(\tfrac34-\tfrac12-\tfrac14\right)x^{-1/2}\cos x + (1-1)\,x^{1/2}\sin x$$
$$+ (-1+1)\,x^{3/2}\cos x \;=\; 0.$$

(1) $x^2u'' = \frac34x^{-1/2}\cos x + x^{1/2}\sin x - x^{3/2}\cos x$; $xu' = -\frac12x^{-1/2}\cos x - x^{1/2}\sin x$; $(x^2-\frac14)u = x^{3/2}\cos x - \frac14x^{-1/2}\cos x$. Collect coefficients.

The same calculation works for $x^{-1/2}\sin x$. Both solutions are C^∞ on $x>0$, where the operator is elliptic. Neither is smooth at 0. The first blows up like $x^{-1/2}$. The second behaves like $x^{1/2}(1-x^2/6+\cdots)$, which is continuous but has infinite slope at 0 (Figure 2.15). The source is zero, hence smooth. The singularity of the solutions sits exactly at the zero of the leading symbol.

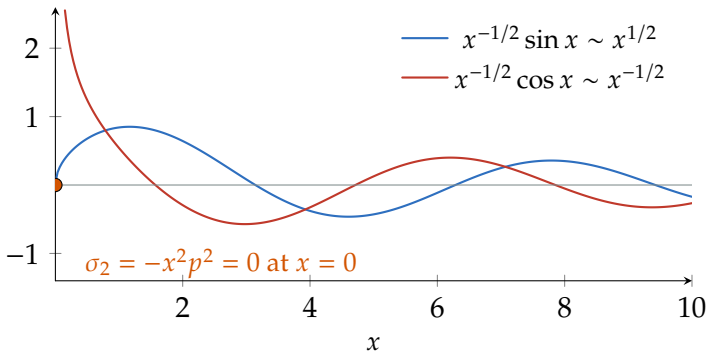

Figure 2.15: The two solutions of Bessel's equation of order $\frac{1}{2}$. On $x > 0$ the operator is elliptic and both are smooth (oscillating like sin and cos with a slowly decaying amplitude). At $x = 0$, where the leading symbol vanishes (orange), the red solution blows up and the blue one has a vertical tangent.

Worked example 2.24: Gauss's hypergeometric equation, Nash's (2.35)–(2.36)

The hypergeometric equation

$$x(1-x)\frac{\mathrm{d}^2u}{\mathrm{d}x^2} + \{\gamma - (\alpha+\beta+1)x\}\frac{\mathrm{d}u}{\mathrm{d}x} - \alpha\beta\, u \;=\; 0 \tag{2.68}$$

has leading symbol $\sigma_2 = -x(1-x)p^2$ (Nash: $x(1-x)p^2$), vanishing at $x = 0$ and $x = 1$. So it is non-elliptic at two points. One solution is the hypergeometric series

$$F(\alpha,\beta;\gamma;x) \;=\; \sum_{k=0}^{\infty} c_k x^k, \qquad \frac{c_{k+1}}{c_k} \;=\; \frac{(k+\alpha)(k+\beta)}{(k+\gamma)(k+1)}, \quad c_0 = 1,$$

whose ratio of coefficients tends to 1, so its radius of convergence is exactly 1: the distance to the next singular point. Take $\alpha = \beta = 1$, $\gamma = 2$. Then

$$\frac{c_{k+1}}{c_k} \overset{(1)}{=} \frac{(k+1)^2}{(k+2)(k+1)} \;=\; \frac{k+1}{k+2} \quad\Longrightarrow\quad c_k \;=\; \frac{1}{k+1},$$

$$F(1,1;2;x) \overset{(2)}{=} \sum_{k=0}^{\infty} \frac{x^k}{k+1} \overset{(3)}{=} \frac{1}{x}\sum_{k=1}^{\infty} \frac{x^k}{k} \overset{(4)}{=} -\frac{\ln(1-x)}{x}.$$

(1) The ratio formula with $\alpha = \beta = 1$, $\gamma = 2$; then $c_k = \frac{1}{2}\cdot\frac{2}{3}\cdots\frac{k}{k+1} = \frac{1}{k+1}$ (telescoping product).
(2) Insert the coefficients.
(3) Shift the index $k \to k-1$ and pull out $1/x$.
(4) The Mercator series $-\ln(1-x) = \sum_{k\geq 1} x^k/k$ for $|x| < 1$.

So this solution has a logarithmic branch point at $x = 1$, the zero of the leading symbol, exactly as Nash says. It is smooth everywhere else on $x < 1$, including at $x = 0$ ($-\ln(1-x)/x \to 1$). A second, independent solution near 0 behaves like $x^{1-\gamma}$ (with logarithms when γ is an integer) and is singular at $x = 0$ instead.

Watch out: Singular points of ODEs are not "bad" operators

The Bessel and hypergeometric equations are among the most useful equations in physics, and their singular points carry the physics: $x = 0$ is the axis of a cylinder, or the position

of a Coulomb centre. Non-ellipticity at a point just warns us that solutions need not be smooth there, so boundary conditions ("regular at the origin") must be imposed by hand. That is exactly how quantisation conditions arise in the hydrogen atom.

Reading Nash (§2, pp. 32–36, (2.19)–(2.37))

- p. 32, (2.19)–(2.23): multi-indices, $D^\alpha = (-i)^{|\alpha|}\partial^\alpha$, the symbol $\sigma(x,p) = \sum a_\alpha p^\alpha$ and the leading symbol σ_m; our Sections 2.2.1 to 2.2.3. His (2.21) has the opposite Fourier sign to ours (Page 728).
- p. 33: the definition of ellipticity ($\sigma_m(x,p) \neq 0$ for $p \neq 0$), the remark on invertibility modulo lower order, and the definition of hypo-ellipticity; our Sections 2.2.4 and 2.2.7. We added the covector transformation law (Section 2.2.5), which Nash only mentions in his footnote 4 on p. 37.
- pp. 33–34, (2.24)–(2.26): heat kernel and Schrödinger kernel; our Sections 2.2.8 and 2.2.9, with Hörmander's criterion added.
- pp. 34–35, (2.27)–(2.30) and footnote 3: Cauchy–Riemann operator, $G = 1/\pi z$, analytic hypo-ellipticity; our Section 2.2.10. Nash's symbol (2.30) lacks our factor i.
- pp. 35–36, (2.31)–(2.37): ODEs, Bessel, hypergeometric, and regularity by induction; our Section 2.2.11.

Recap: Ellipticity and hypo-ellipticity

- A general operator is $L = \sum_{|\alpha|\le m} a_\alpha(x) D^\alpha$. Its symbol $\sigma(x,p) = e^{-ip\cdot x} L e^{ip\cdot x} = \sum a_\alpha(x) p^\alpha$; its leading symbol σ_m keeps only $|\alpha| = m$.
- The leading symbol is what L looks like to short waves. It is homogeneous of degree m and transforms as a function of a *covector* $p \in T^*_x M$, so it is coordinate independent. The full symbol is not.
- Elliptic: $\sigma_m(x,p) \neq 0$ for $p \neq 0$. Then $|\sigma| \ge \frac{c}{2}|p|^m$ at large $|p|$, L is invertible modulo lower order (parametrix), and L gains m derivatives.
- Hypo-elliptic: Lu smooth on $\Omega \Rightarrow u$ smooth on Ω. Elliptic $\Rightarrow$ hypo-elliptic. The heat operator is hypo-elliptic but not elliptic (its kernel is smooth off the origin, like $e^{-1/t}$). The Schrödinger operator is not hypo-elliptic (its kernel oscillates wildly on $t = 0$).
- $\bar\partial$ is elliptic with Green's function $1/\pi z$. Its regularity is Cauchy's integral formula, which gives analyticity: $\bar\partial$ and Δ are analytic-hypo-elliptic, the heat operator is not.
- ODEs: elliptic where $a_n(x) \neq 0$. Singular points (Bessel at 0, hypergeometric at $0, 1$) are zeros of the leading symbol, and there solutions can be singular.

2.3 Ellipticity and vector bundles

Almost no field in physics is a single real function. The electric field has three components. A gauge potential A_μ has four, and each is a matrix in the Lie algebra. A Dirac spinor has four complex components, and on a curved space-time those components are not even functions: they are sections of a spinor bundle, and they mix when we change frames. The operators that

act on such fields, like $\nabla\times$, $\gamma^\mu\partial_\mu$ or d acting on p-forms, are *matrices of differential operators*.

So here is the question this section answers: *what does it mean for a matrix of differential operators, acting on sections of a vector bundle, to be elliptic?* The answer is a direct upgrade of what we have: the leading symbol becomes a *matrix*, and "non-zero" becomes "invertible". Once we have it, we will compute the symbol of the most important operator in the book, the Laplacian on p-forms, and arrive at Hodge's theorem.

2.3.1 Vector bundles and their sections: a working reminder

Nash uses vector bundles freely. We recall what we need; bundles are treated at length in Chapter 1 and Chapter T3.

Working definition 2.12 (vector bundle, in practice)

A (real or complex) **vector bundle** U of **rank** q over a manifold [a space covered by patches, each with coordinates $x_1,\dots,x_n$] M is a family of q-dimensional vector spaces U_x, the **fibres**, one for each point $x\in M$, glued together smoothly. *Operationally*: cover M by open sets Ω_a. Over each Ω_a choose a **local frame**, that is, q smoothly varying bases $e_1(x),\dots,e_q(x)$ of the fibres. Then a point of the bundle over Ω_a is labelled by (x,u) with $x\in\Omega_a$ and $u\in\mathbb{R}^q$ (or $\mathbb{C}^q$), the components in the frame: this is a **local trivialisation** $U|_{\Omega_a}\cong\Omega_a\times\mathbb{R}^q$. On an overlap $\Omega_a\cap\Omega_b$ the two sets of components are related by an invertible matrix,

$$u_{(a)} \;=\; h_{ab}(x)\,u_{(b)}, \qquad h_{ab}(x)\in \mathrm{GL}(q)\,[\text{ the invertible } q\times q \text{ matrices }], \tag{2.69}$$

the **transition functions**. The bundle is *trivial* if one frame works on all of M.

Working definition 2.13 (section)

A **section** s of U picks one vector $s(x)\in U_x$ for each x, smoothly. *Operationally*: over each Ω_a it is a column vector of q smooth functions $u_{(a)}(x)$, and on overlaps these obey (2.69). The space of smooth sections is written $\Gamma(M,U)$, or $\Gamma(U)$ for short. It is an infinite-dimensional vector space: the space of field configurations.

The examples we need are all built from the tangent and cotangent bundles.

- The **trivial bundle** $M\times\mathbb{R}^q$. Its sections are just $\mathbb{R}^q$-valued functions. On $\mathbb{R}^n$ every bundle is trivial, so on $\mathbb{R}^n$ "operators between bundles" are simply matrices of operators acting on vector-valued functions.
- The **tangent bundle** TM, of rank n. Its fibre T_xM is the space of velocity vectors at x, with local frame $\partial/\partial x^i$. A section is a vector field.
- The **cotangent bundle** T^*M, of rank n. Its fibre T^*_xM is the dual space of covectors (gradients) at x, with local frame $\mathrm{d}x^i$. A section is a 1-form. Under a change of coordinates the components of a covector transform as in (2.48): h_{ab} is the Jacobian matrix, transposed.
- The **bundle of p-forms** Λ^pT^*M, with local frame $\mathrm{d}x^{i_1}\wedge\cdots\wedge\mathrm{d}x^{i_p}$ $(i_1<\cdots<i_p)$, of rank $\binom{n}{p}$. A section is a p-form, and $\Gamma(\Lambda^pT^*M)=\Omega^p(M)$.
- Twisted bundles such as $\Lambda^pT^*M\otimes E$, where E carries the gauge indices: Lie-algebra-valued forms, like a Yang–Mills potential.

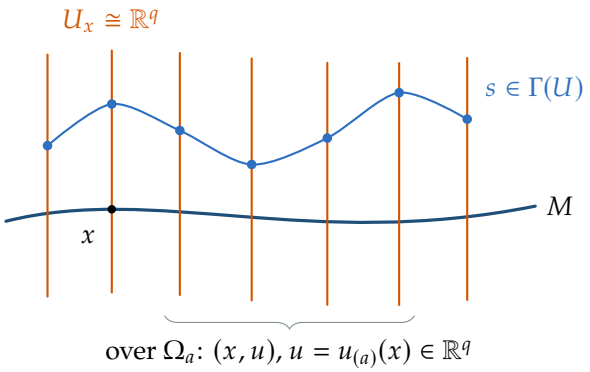

Figure 2.16: A vector bundle drawn as fibres (orange) standing over the base M (blue-black curve). Each fibre U_x is a copy of $\mathbb{R}^q$, drawn as a line. A section (blue) chooses one point in each fibre, smoothly: it is a "vector-valued function whose values live in different spaces at different points". Over a patch Ω_a a frame identifies every fibre with $\mathbb{R}^q$, and then the section is an honest column of q functions.

Worked example 2.25: The tangent bundle of S^2 is not trivial, but has transition functions

Cover S^2 by the two stereographic charts, from the north and south poles, with complex coordinates z and $w = 1/z$ on the overlap $\mathbb{C} \setminus \{0\}$. A tangent vector with component $v_{(z)}$ in the frame ∂_z has component $v_{(w)}$ in the frame ∂_w given by the chain rule:

$$v_{(w)} \overset{(1)}{=} \frac{\mathrm{d}w}{\mathrm{d}z}\, v_{(z)} \overset{(2)}{=} -\frac{1}{z^2}\, v_{(z)},$$

(1) A vector's components transform with the Jacobian (here a 1×1 complex matrix, since we treat TS^2 as a complex line bundle).

(2) $w = 1/z$, so $\mathrm{d}w/\mathrm{d}z = -1/z^2$.

So $h(z) = -z^{-2}$. On the equator $z = e^{i\phi}$ this is $-e^{-2i\phi}$, which winds -2 times around the origin as ϕ goes once around. The winding number is (up to sign conventions) the Euler number $\chi(S^2) = 2$, and it is the reason the bundle cannot be trivial: "you cannot comb a hairy ball". We mention this because the same kind of winding reappears below inside the *symbol* of an elliptic operator.

2.3.2 Why smooth sections?

Nash insists (p. 36) that the operator

$$L : \Gamma(M, U) \longrightarrow \Gamma(M, V) \tag{2.70}$$

act between spaces of *smooth* sections. This is his (2.38). His reason is elliptic regularity. We are doing differential topology, so smooth objects are the natural ones. For an elliptic L the smooth world is closed under "solving": if $Lu = f$ with f smooth, then u is automatically smooth. So restricting to smooth sections loses no solutions of elliptic equations. For a non-elliptic operator this is false, and the equation $Lu = f$ with smooth f may have non-smooth solutions that the smooth setting cannot see (the kinks of the wave equation, Example 2.8).

Later (in part 2b) we shall enlarge $\Gamma(M, U)$ to Sobolev spaces, where the analysis is easier, and then use elliptic regularity to come back.

2.3.3 Operators between bundles are matrices of operators

Take a patch $\Omega \subset M$ over which both bundles are trivial and on which we have coordinates $x = (x_1, \dots, x_n)$. Write U with frame components $u = (u_1, \dots, u_q)$, and V with components $(v_1, \dots, v_p)$. Then a linear differential operator of order m from sections of U to sections of V takes the form

$$(Lu)_i(x) \;=\; \sum_{j=1}^{q} \sum_{|\alpha| \le m} a_\alpha^{ij}(x)\, D^\alpha u_j(x), \qquad i = 1, \dots, p, \tag{2.71}$$

Nash's (2.39). Read it as follows: the i-th component of the output is a sum, over all input components j, of a scalar differential operator L_{ij} acting on u_j. In matrix form, $Lu = \sum_\alpha a_\alpha(x) D^\alpha u$, where each coefficient $a_\alpha(x)$ is now a $p \times q$ matrix: p rows because the output has p components, q columns because the input has q.

The symbol is found by the same plane-wave test as before (Definition 2.7), now applied to a plane wave with a constant *vector* amplitude.

Working definition 2.14 (matrix symbol and leading symbol)

For L as in (2.71), the **symbol** is the $p \times q$ matrix

$$\sigma(x, k) \;=\; \sum_{|\alpha| \le m} a_\alpha(x)\, k^\alpha, \tag{2.72}$$

Nash's (2.40), and the **leading symbol** is its top-degree part,

$$\sigma_m(x, k) \;=\; \sum_{|\alpha| = m} a_\alpha(x)\, k^\alpha, \tag{2.73}$$

Nash's (2.41). *How to compute*: for each fixed vector $v \in \mathbb{R}^q$,

$$\sigma(x, k)\, v \;=\; e^{-ik\cdot x}\, L\big(e^{ik\cdot x}\, v\big), \tag{2.74}$$

that is, in each entry L_{ij} replace $\partial_l \to i k_l$. Keep only the terms with m derivatives for σ_m. At each point x and for each covector [the momentum $k = (k_1, \dots, k_n)$ of the plane wave $e^{ik\cdot x}$] k, $\sigma_m(x, k)$ is a linear map

$$\sigma_m(x, k) : U_x \longrightarrow V_x.$$

Nash now writes k instead of p for the Fourier variable, and we follow him in this section. It is the same momentum variable, and (Section 2.2.5) it is a covector: $k = k_i\, \mathrm{d}x^i \in T_x^* M$.

Worked example 2.26: Gradient, curl and divergence as bundle operators on $\mathbb{R}^3$

On $\mathbb{R}^3$ take U and V trivial, of the appropriate ranks. We compute the three symbols with (2.74).

Gradient, $\nabla : \Gamma(\mathbb{R}^3 \times \mathbb{R}) \to \Gamma(\mathbb{R}^3 \times \mathbb{R}^3)$, a 3×1 matrix of operators. Apply it to $e^{ik\cdot x} v$ with $v \in \mathbb{R}$:

$$\nabla\big(e^{ik\cdot x} v\big) \overset{(1)}{=} \begin{pmatrix} \partial_1 \\ \partial_2 \\ \partial_3 \end{pmatrix} e^{ik\cdot x} v \overset{(2)}{=} e^{ik\cdot x}\, i \begin{pmatrix} k_1 \\ k_2 \\ k_3 \end{pmatrix} v, \qquad \text{so} \qquad \sigma_1(\nabla)(k) = i\,\vec{k}.$$

(1) The gradient as a column of three derivatives.
(2) Each ∂_l brings down $i k_l$.

Divergence, $\nabla\cdot : \Gamma(\mathbb{R}^3\times\mathbb{R}^3)\to\Gamma(\mathbb{R}^3\times\mathbb{R})$, the 1×3 row $(\partial_1,\partial_2,\partial_3)$. The same computation gives $\sigma_1(\nabla\cdot)(k)\,\vec v = i\,\vec k\cdot\vec v$: the row matrix $i\vec k^{\,T}$.
Curl, a 3×3 matrix of operators,

$$\nabla\times \;=\; \begin{pmatrix} 0 & -\partial_3 & \partial_2 \\ \partial_3 & 0 & -\partial_1 \\ -\partial_2 & \partial_1 & 0 \end{pmatrix}, \qquad \sigma_1(\nabla\times)(k) \;=\; i\begin{pmatrix} 0 & -k_3 & k_2 \\ k_3 & 0 & -k_1 \\ -k_2 & k_1 & 0 \end{pmatrix} =:\; i\,[\vec k]_\times,$$

because $\nabla\times(e^{ik\cdot x}\vec v) = e^{ik\cdot x}\,i\,\vec k\times\vec v$. The matrix $[\vec k]_\times$ is "cross product with $\vec k$".
All three are first order and have constant coefficients, so the symbol equals the leading symbol. Now look at the shapes: 3×1, 1×3 and 3×3. Only the last one can possibly be invertible. We shall see in a moment that it is not.

Worked example 2.27: The Cauchy–Riemann equations as a 2×2 real system

Write a complex function as $f = u + iv$. The Cauchy–Riemann equations $u_x = v_y$, $u_y = -v_x$ say that the real operator

$$L\begin{pmatrix} u \\ v \end{pmatrix} \;=\; \begin{pmatrix} \partial_x & -\partial_y \\ \partial_y & \partial_x \end{pmatrix}\begin{pmatrix} u \\ v \end{pmatrix} \;=\; \begin{pmatrix} u_x - v_y \\ u_y + v_x \end{pmatrix}$$

vanishes. (It is $2\bar\partial f = (\partial_x + i\partial_y)(u+iv)$, split into real and imaginary parts.) Its leading symbol and determinant are

$$\sigma_1(L)(k) \overset{(1)}{=} i\begin{pmatrix} k_1 & -k_2 \\ k_2 & k_1 \end{pmatrix}, \qquad \det\sigma_1(L)(k) \overset{(2)}{=} i^2\big(k_1^2+k_2^2\big) \;=\; -\,|k|^2\,.$$

(1) Replace $\partial_x\to ik_1$, $\partial_y\to ik_2$ in each entry.
(2) The determinant of a 2×2 matrix, with the factor i pulled out of both rows.

So $\sigma_1(L)(k)$ is invertible for every $k\neq 0$: L is elliptic in the matrix sense. Geometrically, $\begin{pmatrix} k_1 & -k_2 \\ k_2 & k_1 \end{pmatrix}$ is $|k|$ times a rotation, the real form of multiplication by the complex number $k_1 + ik_2$. This matches the scalar symbol $\sigma_1(2\bar\partial) = i(k_1+ik_2)$ of Section 2.2.10. The same operator is elliptic whether we view it as one complex equation or two real ones.

2.3.4 How the matrix symbol transforms

Nash's footnote 4 warns that the coefficients $a_\alpha^{ij}(x)$ "will change by a Jacobian-type transformation" when we change local coordinates, and he suppresses this from the notation. Let us see exactly what changes, because the result is the reason the leading symbol is a *geometric* object while the rest of the symbol is not.

There are two kinds of change: of coordinates on M, and of frame in the fibres. The first we have already done: k transforms as a covector (2.48). The second is new. Change frames in U and V by invertible matrix functions $h_U(x)$ and $h_V(x)$, so the new components are $u' = h_U u$ and $v' = h_V v$. The operator in the new frames is $L' = h_V\,L\,h_U^{-1}$. For a first-order operator $L = \sum_j A^j(x)\partial_j + B(x)$ this is

$$L'u' \overset{(1)}{=} h_V\Big(\sum_j A^j\partial_j + B\Big)\big(h_U^{-1}u'\big)$$

$$\overset{(2)}{=} \sum_j h_V A^j h_U^{-1}\, \partial_j u' \;+\; \Big(\sum_j h_V A^j\, \partial_j\big(h_U^{-1}\big) + h_V B h_U^{-1}\Big) u'. \tag{2.75}$$

(1) Express $u = h_U^{-1} u'$, apply L, and convert the output to the new frame with h_V.
(2) Product rule: ∂_j hits either u' or the matrix h_U^{-1}.

So the top-order coefficients transform *tensorially*, $A'^j = h_V A^j h_U^{-1}$, and therefore

$$\sigma_1(L')(x,k) \;=\; h_V(x)\, \sigma_1(L)(x,k)\, h_U(x)^{-1}. \tag{2.76}$$

This is exactly how a linear map $U_x \to V_x$ must transform when we change bases in both spaces. The zeroth-order coefficient, by contrast, picks up the extra term $h_V A^j \partial_j h_U^{-1}$, which depends on *derivatives* of the frame change. The same happens in every order: the top-order part transforms as a linear map between fibres, and the lower-order parts mix with derivatives of the transition functions.

Dictionary: Frame changes are gauge transformations

Physicists have met (2.75) before. Take $U = V$, $h_U = h_V = g(x)^{-1}$ and $L = \gamma^\mu(\partial_\mu + A_\mu)$, a Dirac operator coupled to a gauge field. Then the zeroth-order part $\gamma^\mu A_\mu$ transforms into $\gamma^\mu(g^{-1}A_\mu g + g^{-1}\partial_\mu g)$: the inhomogeneous term is the $g^{-1}\mathrm{d}g$ of a gauge transformation (the convention of Chapter T3). The leading symbol $i\gamma^\mu k_\mu$ does not see A_μ at all. *Gauge fields are lower order.* So coupling any elliptic operator to a gauge field, or to gravity through a spin connection, never changes whether it is elliptic.

2.3.5 The leading symbol as a bundle map over T^*M

At a point x, for each covector $k \in T_x^*M$, we have a linear map $\sigma_m(x,k) : U_x \to V_x$. Nash now packages this family globally, and the packaging is worth understanding because it is exactly the input of the index theorem in Chapter 4.

Step 1: the base becomes phase space. The pair (x,k) is a point of the cotangent bundle T^*M, the classical phase space of a particle on M. Let

$$\pi : T^*M \to M, \qquad \pi(x,k) = x,$$

be the projection that forgets the momentum. T^*M is a manifold of dimension $2n$.

Step 2: pull the bundles back. We want σ_m to be a map between bundles *over* T^*M. So we build a bundle over T^*M whose fibre over (x,k) is U_x.

Working definition 2.15 (pullback bundle)

Given a map $\pi : T^*M \to M$ and a bundle U over M, the **pullback bundle** π^*U is the bundle over T^*M whose fibre at the point (x,k) is

$$(\pi^*U)_{(x,k)} \;=\; U_{\pi(x,k)} \;=\; U_x.$$

Operationally: same fibres, but each fibre U_x is now repeated once for every momentum k at x. Its transition functions [the matrices h_{ab} relating components in two overlapping frames] are those of U, composed with π: they depend on x only, not on k.

Step 3: the symbol is a bundle homomorphism. A **bundle homomorphism** $\phi : E \to F$ between two bundles over the same base assigns to each base point b a linear map $\phi_b : E_b \to F_b$, depending smoothly on b. Over the base point $b = (x, k) \in T^*M$, the fibres of π^*U and π^*V are U_x and V_x, and $\sigma_m(x, k)$ is a linear map between them. So

$$\sigma_m : \pi^*U \longrightarrow \pi^*V \tag{2.77}$$

is a bundle homomorphism over T^*M. This is Nash's "elucidation" on p. 38. The transformation law (2.76), together with the covector law for k, is precisely the statement that the local matrices glue into a global bundle map.

Step 4: delete the zero section. Ellipticity is a condition for $k \neq 0$ only. At $k = 0$ the leading symbol, being homogeneous of degree $m \geq 1$, always vanishes: $\sigma_m(x, 0) = 0$. So we remove the set $\{(x, 0)\} \subset T^*M$ of zero covectors. This set is the image of the **zero section** $x \mapsto (x, 0)$, a copy of M sitting inside T^*M. What remains, $T^*M \setminus \{\text{zero section}\}$, is the bundle of non-zero covectors.

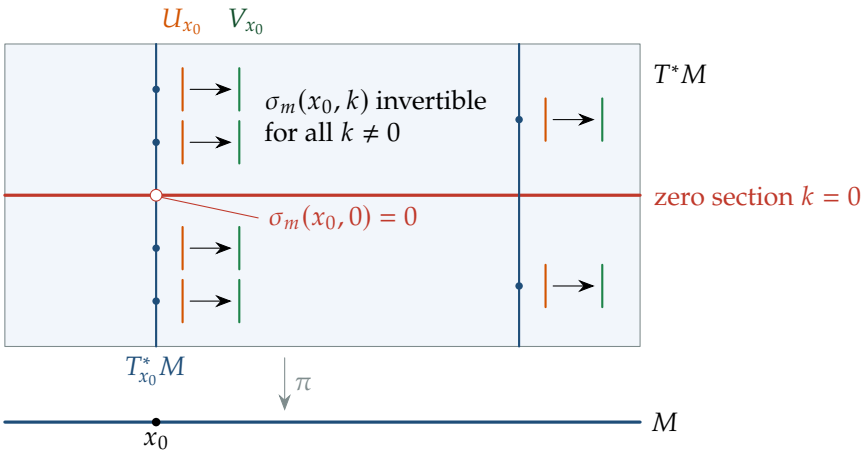

Figure 2.17: The global picture of the leading symbol. The cotangent bundle T^*M (shaded) sits over M: above each point x_0 stands the whole momentum space $T^*_{x_0}M$ (vertical blue line). At every point (x_0, k) of T^*M the pulled-back bundles supply a copy of U_{x_0} (orange) and of V_{x_0} (green), and the symbol is a linear map between them. Ellipticity asks that every one of these maps be invertible, except on the zero section (red line), where the symbol always vanishes.

2.3.6 The definition of ellipticity for bundles

With all this in place Nash gives two versions of the definition. They say the same thing.

Working definition 2.16 (elliptic operator between vector bundles (Nash, p. 38))

The m-th order linear differential operator $L : \Gamma(M, U) \to \Gamma(M, V)$ is **elliptic** if, in every local chart and trivialisation [a choice of local frame, so that sections become columns of functions], its leading symbol $\sigma_m(x, k)$ is an *invertible matrix* for every x and every $k \neq 0$. *Equivalently* (Nash's "more abstract definition"), the bundle homomorphism [one linear map $U_x \to V_x$ at each point (x, k) of T^*M, varying smoothly] $\sigma_m : \pi^*U \to \pi^*V$ is a **bundle isomorphism off the zero section** [the points $(x, 0)$ with $k = 0$] of T^*M. *How to test*: compute the $p \times q$ matrix $\sigma_m(x, k)$; check that it is square; check that $\det \sigma_m(x, k) \neq 0$ for $k \neq 0$. By homogeneity it suffices to check $|k| = 1$.

Three remarks make this concrete.

(a) It is the old definition when $p = q = 1$. A 1×1 matrix is invertible exactly when it is non-zero, so we recover Definition 2.9. This is Nash's remark that the new definition is "the natural linear algebraic generalisation".

(b) An elliptic operator connects bundles of the same rank. An invertible matrix is square. So if L is elliptic, $p = q$: the bundles U and V have equal rank. The gradient ($p = 3$, $q = 1$) and the divergence ($p = 1$, $q = 3$) fail at once. Nash notes that "in the coordinate free method of dealing with symbols" this is the abstract definition: an isomorphism between π^*U and π^*V forces equal rank.

(c) It is coordinate- and frame-independent. By (2.76), changing frames replaces σ_m by $h_V \sigma_m h_U^{-1}$, which is invertible exactly when σ_m is. Changing coordinates replaces k by the transformed covector, which is non-zero exactly when k is. So it makes sense to say "L is elliptic" on a manifold.

Key idea: Ellipticity for systems

An operator between bundles is elliptic when, for every non-zero momentum k, the matrix "what L does to a short wave of momentum k" can be inverted. Physically: no polarisation of a short wave is invisible to the operator (injectivity), and every polarisation of the output can be produced (surjectivity).

Worked example 2.28: The curl is not elliptic: the longitudinal mode

The curl on $\mathbb{R}^3$ is a square (3×3) operator, so the rank test passes. But $\sigma_1(\nabla\times)(k) = i[\vec{k}]_\times$ and

$$
\begin{aligned}
[\vec{k}]_\times \vec{k} &\overset{(1)}{=} \vec{k} \times \vec{k} \overset{(2)}{=} 0, \\
\det[\vec{k}]_\times &\overset{(3)}{=} 0 \cdot \big(0 \cdot 0 + k_1^2\big) - (-k_3)\big(k_3 \cdot 0 - k_1 k_2\big) + k_2\big(k_3 k_1 - 0 \cdot k_2\big) \\
&= -k_1 k_2 k_3 + k_1 k_2 k_3 \;=\; 0.
\end{aligned}
$$

(1) The matrix $[\vec{k}]_\times$ is, by construction, cross product with $\vec{k}$.

(2) Any vector crossed with itself is zero. So $\vec{k} \neq 0$ lies in the kernel.

(3) Expand the determinant along the first row $(0, -k_3, k_2)$. (Faster: an antisymmetric 3×3 matrix A has $\det A = \det A^T = \det(-A) = -\det A$, so $\det A = 0$.)

The kernel of the symbol is the *longitudinal* polarisation $\vec{v} \parallel \vec{k}$. The transverse polarisations $\vec{v} \perp \vec{k}$ are rotated by 90° about $\vec{k}$ and stretched by $|k|$; the longitudinal one is annihilated (Figure 2.18).

The failure of ellipticity has a concrete price: there is no regularity. Take any function f that is continuous but nowhere differentiable in some region, and let $\vec{B} = \nabla f$ (in the sense of distributions). Then $\nabla \times \vec{B} = 0$, which is as smooth as can be, but $\vec{B}$ is very rough. The rough part lives entirely in the longitudinal modes $\hat{\vec{B}}(k) \parallel \vec{k}$, which the curl cannot see. This is also the physicist's statement that $\nabla \times \vec{B} = \mu_0 \vec{J}$ determines $\vec{B}$ only up to a gradient: we need $\nabla \cdot \vec{B} = 0$ as well.

Worked example 2.29: Repairing the curl: the div–grad–curl operator is elliptic

The cure is to add the missing information. Act on a pair (scalar f, vector field $\vec{A}$) and

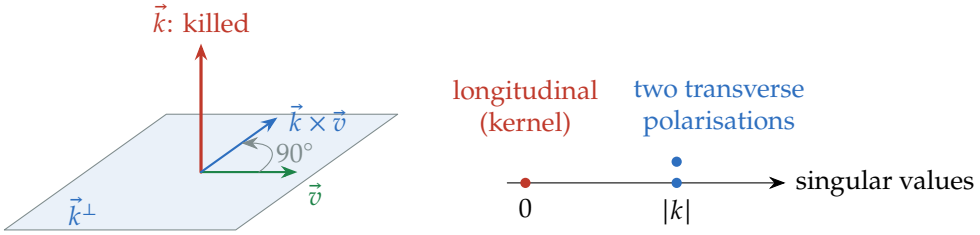

Figure 2.18: Why the curl fails to be elliptic. Left: its symbol $i\,\vec{k}\times(\cdot)$ rotates each transverse vector $\vec{v}\perp\vec{k}$ by 90° within the plane $\vec{k}^{\perp}$ and scales it by $|k|$, but it annihilates the longitudinal direction $\vec{k}$ (red). Right: the singular values of $[\vec{k}]_\times$ are $|k|, |k|, 0$. One zero singular value, at every $k\neq 0$, is enough to destroy ellipticity.

output a pair (scalar, vector):

$$L\begin{pmatrix} f \\ \vec{A}\end{pmatrix} = \begin{pmatrix} \nabla\cdot\vec{A} \\ \nabla f + \nabla\times\vec{A}\end{pmatrix}, \qquad L:\Gamma(\mathbb{R}^3\times\mathbb{R}^4)\to\Gamma(\mathbb{R}^3\times\mathbb{R}^4).$$

Using Example 2.26, its leading symbol is the 4×4 matrix

$$\sigma_1(L)(k) = i\,M(k), \qquad M(k) = \begin{pmatrix} 0 & \vec{k}^{\,T} \\ \vec{k} & [\vec{k}]_\times\end{pmatrix} = \begin{pmatrix} 0 & k_1 & k_2 & k_3 \\ k_1 & 0 & -k_3 & k_2 \\ k_2 & k_3 & 0 & -k_1 \\ k_3 & -k_2 & k_1 & 0\end{pmatrix}.$$

Is it invertible? Compute M^TM block by block, using $[\vec{k}]_\times^T = -[\vec{k}]_\times$:

$$\begin{aligned} M^TM &\overset{(1)}{=} \begin{pmatrix} 0 & \vec{k}^{\,T} \\ \vec{k} & -[\vec{k}]_\times\end{pmatrix}\begin{pmatrix} 0 & \vec{k}^{\,T} \\ \vec{k} & [\vec{k}]_\times\end{pmatrix} \\ &\overset{(2)}{=} \begin{pmatrix} \vec{k}^{\,T}\vec{k} & \vec{k}^{\,T}[\vec{k}]_\times \\ -[\vec{k}]_\times\vec{k} & \vec{k}\vec{k}^{\,T} - [\vec{k}]_\times^2\end{pmatrix} \\ &\overset{(3)}{=} \begin{pmatrix} |k|^2 & 0 \\ 0 & \vec{k}\vec{k}^{\,T} - \left(\vec{k}\vec{k}^{\,T} - |k|^2\,I_3\right)\end{pmatrix} = |k|^2\,I_4. \end{aligned}$$

(1) The transpose of a block matrix transposes the blocks and swaps the off-diagonal ones; $(\vec{k})^T = \vec{k}^{\,T}$ and $[\vec{k}]_\times^T = -[\vec{k}]_\times$.

(2) Multiply the blocks.

(3) $[\vec{k}]_\times\vec{k} = \vec{k}\times\vec{k} = 0$, and its transpose $\vec{k}^{\,T}[\vec{k}]_\times = -([\vec{k}]_\times\vec{k})^T = 0$. For the corner use $\vec{k}\times(\vec{k}\times\vec{v}) = \vec{k}(\vec{k}\cdot\vec{v}) - |k|^2\,\vec{v}$ ("BAC–CAB"), i.e. $[\vec{k}]_\times^2 = \vec{k}\vec{k}^{\,T} - |k|^2\,I_3$.

So $M(k)/|k|$ is an orthogonal matrix, $\det M(k) = \pm|k|^4 \neq 0$, and L is elliptic. The longitudinal mode killed by the curl is now caught by the gradient term, and the divergence adds the equation that the curl lacked. Moreover $\sigma_1(L)^\dagger\sigma_1(L) = |k|^2\,I_4$ is the symbol of the Laplacian: L is a *square root of the Laplacian* on four-component fields. In Section 2.3.11 we will recognise L as $\mathrm{d}+\mathrm{d}^*$ acting on (0-forms $\oplus$ 2-forms) in $\mathbb{R}^3$, and it is also the Dirac operator of $\mathbb{R}^3$ written in quaternionic form.

Worked example 2.30: The Dirac operator is elliptic in Euclidean signature

The Euclidean Dirac operator on $\mathbb{R}^n$ is $\not{\partial} = \gamma^\mu \partial_\mu$, where the γ^μ are Hermitian matrices with

$$\gamma^\mu \gamma^\nu + \gamma^\nu \gamma^\mu \;=\; 2\,\delta^{\mu\nu}\, I \tag{2.78}$$

(Chapter T4). The leading symbol and its square are

$$\begin{aligned} \sigma_1(\not{\partial})(k) &\overset{(1)}{=} i\,\gamma^\mu k_\mu, \\ \big(\sigma_1(\not{\partial})(k)\big)^2 &\overset{(2)}{=} -\gamma^\mu\gamma^\nu k_\mu k_\nu \overset{(3)}{=} -\tfrac{1}{2}\big(\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu\big)k_\mu k_\nu \overset{(4)}{=} -\,|k|^2\; I. \end{aligned} \tag{2.79}$$

(1) Plane-wave test: $\partial_\mu \to i k_\mu$; the γ's are constant matrices.
(2) $i^2 = -1$.
(3) $k_\mu k_\nu$ is symmetric in $\mu\nu$, so only the symmetric part of $\gamma^\mu\gamma^\nu$ contributes.
(4) The Clifford relation (2.78).

So $\sigma_1(\not{\partial})(k)$ is invertible for $k \neq 0$, with inverse $\sigma_1(\not{\partial})(k)^{-1} = -i\gamma^\mu k_\mu/|k|^2$. This is the Euclidean fermion propagator, $1/(i\not{k})$. The Dirac operator is elliptic.

Explicitly in two dimensions. Take $\gamma^1 = \sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ and $\gamma^2 = \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}$. Then

$$\not{\partial} \;=\; \begin{pmatrix} 0 & \partial_1 - i\partial_2 \\ \partial_1 + i\partial_2 & 0 \end{pmatrix} \;=\; \begin{pmatrix} 0 & 2\partial \\ 2\bar\partial & 0 \end{pmatrix}, \qquad \sigma_1(\not{\partial})(k) \;=\; i\begin{pmatrix} 0 & k_1 - ik_2 \\ k_1 + ik_2 & 0 \end{pmatrix},$$

with $\partial = \tfrac{1}{2}(\partial_1 - i\partial_2)$ and $\bar\partial = \tfrac{1}{2}(\partial_1 + i\partial_2)$. The determinant is $-i^2(k_1 - ik_2)(k_1 + ik_2) = |k|^2$. The two-dimensional Dirac operator is the Cauchy–Riemann operator and its conjugate, stacked. The chiral half $2\bar\partial : \Gamma(S^+) \to \Gamma(S^-)$ is itself elliptic, between rank-one bundles.

Explicitly in four dimensions. In the chiral representation

$$\gamma^j = \begin{pmatrix} 0 & -i\sigma_j \\ i\sigma_j & 0 \end{pmatrix}\ (j = 1,2,3), \qquad \gamma^4 = \begin{pmatrix} 0 & I_2 \\ I_2 & 0 \end{pmatrix},$$

(check: $\gamma^j\gamma^l = \mathrm{diag}(\sigma_j\sigma_l, \sigma_j\sigma_l)$, whose symmetric part is $\delta_{jl}I$, and $\gamma^4\gamma^j = -\gamma^j\gamma^4 = \mathrm{diag}(i\sigma_j, -i\sigma_j)$), the symbol is

$$\sigma_1(\not{\partial})(k) \;=\; i\begin{pmatrix} 0 & q(k)^\dagger \\ q(k) & 0 \end{pmatrix}, \qquad q(k) \;=\; k_4\, I_2 + i\,\vec{k}\cdot\vec{\sigma}.$$

The block $q(k)$ is the symbol (up to the factor i) of the chiral Dirac operator $\Gamma(S^+) \to \Gamma(S^-)$, and

$$q(k)^\dagger q(k) \overset{(1)}{=} (k_4 - i\vec{k}\cdot\vec{\sigma})(k_4 + i\vec{k}\cdot\vec{\sigma}) \overset{(2)}{=} k_4^2 + (\vec{k}\cdot\vec{\sigma})^2 \overset{(3)}{=} k_4^2 + \left|\vec{k}\right|^2 \;=\; |k|^2\,,$$

(1) The Pauli matrices are Hermitian, so $(i\vec{k}\cdot\vec{\sigma})^\dagger = -i\vec{k}\cdot\vec{\sigma}$.
(2) Multiply out; the cross terms $\pm ik_4\,\vec{k}\cdot\vec{\sigma}$ cancel.
(3) $(\vec{k}\cdot\vec{\sigma})^2 = \left|\vec{k}\right|^2 I$, from $\sigma_j\sigma_l + \sigma_l\sigma_j = 2\delta_{jl}$.

So $q(k)/|k| \in \mathrm{SU}(2)$ for $k \neq 0$: it is a unit quaternion.

In Minkowski signature the same computation, with $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$, gives $(i\gamma^\mu k_\mu)^2 = -\eta^{\mu\nu}k_\mu k_\nu = -(k_0^2 - \left|\vec{k}\right|^2)$, which vanishes on the light cone. The Minkowski Dirac operator is not elliptic: it is hyperbolic, like the wave operator whose square root it is. Wick rotation $k_0 \to ik_4$ turns $k_0^2 - \left|\vec{k}\right|^2$ into $-\,|k|^2$ and restores ellipticity, exactly as in Section 2.1.7.

A topological shadow: the symbol on the unit sphere

Because σ_m is homogeneous, $\sigma_m(x,\lambda k)=\lambda^m\sigma_m(x,k)$, all its information is in its values on unit covectors $|k|=1$. At each x these form a sphere S^{n-1}, and together they form the **unit cosphere bundle** $S(T^*M)$. An elliptic symbol therefore gives, at each x, a map

$$S^{n-1}\ni\hat{k}\;\longmapsto\;\sigma_m(x,\hat{k})\in \mathrm{GL}(q)\quad\text{(invertible matrices)}.$$

Maps from a sphere into a group of invertible matrices can wind around, like the transition function of Example 2.25. The winding cannot be undone without making the symbol singular somewhere, that is, without destroying ellipticity. So it is a *topological* invariant of the elliptic operator, and it survives any continuous deformation through elliptic operators.

Two examples. For $2\bar\partial$ on $\mathbb{R}^2$, on the unit circle $\hat{k}=(\cos\phi,\sin\phi)$ the symbol is $i(\cos\phi+i\sin\phi)=ie^{i\phi}$. As ϕ goes once around, this goes once around the origin of $\mathbb{C}\setminus\{0\}=\mathrm{GL}(1,\mathbb{C})$: winding number 1 (Figure 2.19). For the chiral Dirac operator on $\mathbb{R}^4$, $\hat{k}\mapsto q(\hat{k})$ maps S^3 to the unit quaternions $\mathrm{SU}(2)\cong S^3$, and it is the identity map, of degree 1. The Atiyah–Singer index theorem of Chapter 4 says that this kind of winding of the symbol, combined with the twisting of the bundles, determines the number of zero modes. We only note here that the topological data of an elliptic operator *is* its leading symbol, and it lives on T^*M minus the zero section, which is why Nash took such care to put it there.

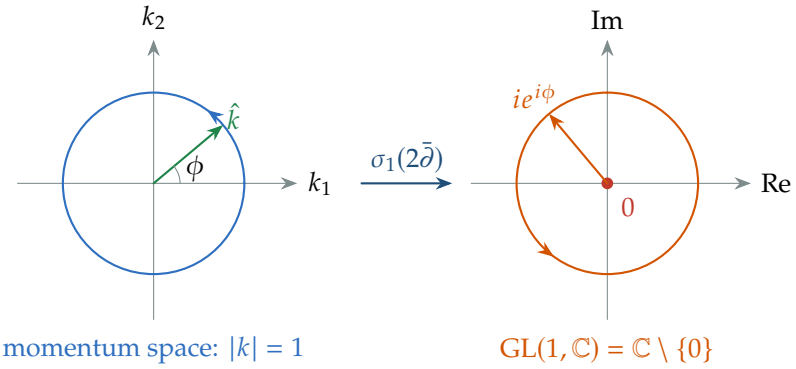

Figure 2.19: The leading symbol of the Cauchy–Riemann operator, restricted to unit momenta, is a map from the circle $|k|=1$ (left) to the non-zero complex numbers (right): $\phi\mapsto ie^{i\phi}$. It winds once around the forbidden point 0 (red), where the symbol would fail to be invertible. No deformation through elliptic symbols can unwind it. This winding number is the simplest example of the topological information carried by an elliptic symbol, which the index theorem converts into a count of zero modes.

Watch out: Operators of mixed order

Nash's definition assumes one order m for the whole matrix. Some important systems mix orders: the Stokes system of slow viscous flow, $-\nu\nabla^2\vec{u}+\nabla P=\vec{f}$, $\nabla\cdot\vec{u}=0$, has second derivatives of $\vec{u}$ but first derivatives of P. If we kept only the second-order terms we would drop ∇P and $\nabla\cdot\vec{u}$ completely and wrongly conclude that the system is not elliptic. The fix (due to Douglis and Nirenberg) assigns separate weights to rows and columns. We never need it in this book: all our operators ($\mathrm{d}+\mathrm{d}^*$, Δ_p, $\not{D}$, $\bar\partial$) have a single order.

Try it: Which systems are elliptic?

On $\mathbb{R}^2$ decide whether each operator is elliptic. (a) $L(u,v)=(u_x+v_y,\ u_y-v_x)$. (b) $L(u,v)=(u_x,\ v_y)$. (c) The Laplacian acting on $\mathbb{R}^q$-valued functions, $u\mapsto-\nabla^2u$ (each

component separately). (d) $L(u,v) = (u_x - v_y,\ u_x + v_y)$.

Answers. (a) $\sigma_1 = i\begin{pmatrix} k_1 & k_2 \\ k_2 & -k_1 \end{pmatrix}$, $\det = i^2(-k_1^2 - k_2^2) = |k|^2 \neq 0$: elliptic (it is the Cauchy–Riemann system for $u - iv$). (b) $\sigma_1 = i\,\mathrm{diag}(k_1, k_2)$, $\det = -k_1 k_2$, which vanishes on both axes: not elliptic (two uncoupled transport operators). (c) $\sigma_2 = |k|^2\, I_q$, invertible: elliptic. (d) $\sigma_1 = i\begin{pmatrix} k_1 & -k_2 \\ k_1 & k_2 \end{pmatrix}$, $\det = i^2(2k_1k_2) = -2k_1k_2$: not elliptic, although it looks similar to Cauchy–Riemann. The determinant, not the appearance, decides.

2.3.7 The Laplacian on p-forms

Nash illustrates the bundle definition with the most important example in the subject. Let M be a compact Riemannian manifold of dimension n with metric g_{ij}. On p-forms we want a Laplacian Δ_p, a second-order operator

$$\Delta_p : \Gamma(M, \Lambda^p T^*M) \longrightarrow \Gamma(M, \Lambda^p T^*M), \tag{2.80}$$

Nash's (2.44). The bundle is $U = V = \Lambda^p T^*M$, of rank $\binom{n}{p}$, and Δ_p maps p-forms to p-forms. Nash defines it by

$$\Delta_p \;=\; \big(\mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}\big)_p, \tag{2.81}$$

his (2.42), where the subscript means "restricted to p-forms" and d^* is the *adjoint* of the exterior derivative. To make sense of d^* we need an inner product on forms, and that is where the metric and the Hodge star come in. We recall them now, with all the formulas of Nash's (2.43). For more on forms and $\star$ see Chapter T1.

Components and the Hodge star

Convention for components. We write a p-form as

$$\omega \;=\; \frac{1}{p!}\,\omega_{i_1\ldots i_p}\,\mathrm{d}x^{i_1}\wedge\cdots\wedge\mathrm{d}x^{i_p} \;=\; \sum_{i_1<\cdots<i_p} \omega_{i_1\ldots i_p}\,\mathrm{d}x^{i_1}\wedge\cdots\wedge\mathrm{d}x^{i_p},$$

with $\omega_{i_1\ldots i_p}$ totally antisymmetric. The first form sums over all index values (with the $1/p!$ correcting the overcounting); the second sums over increasing indices only. Nash writes $\omega = \omega_{i_1\ldots i_p}\mathrm{d}x^{i_1}\wedge\cdots\wedge\mathrm{d}x^{i_p}$ and means the second.

Working definition 2.17 (Hodge star)

The **Hodge star** $\star : \Lambda^p T^*_x M \to \Lambda^{n-p} T^*_x M$ is the linear map defined, in an *oriented orthonormal* coframe [n one-forms at x with $\langle e^i, e^j\rangle = \delta^{ij}$ in the metric, listed in right-handed order] $e^1, \ldots, e^n$ at x, by

$$\star\big(e^{i_1}\wedge\cdots\wedge e^{i_p}\big) \;=\; \pm\, e^{j_1}\wedge\cdots\wedge e^{j_{n-p}}, \tag{2.82}$$

where $\{j_1,\ldots,j_{n-p}\}$ is the complement of $\{i_1,\ldots,i_p\}$ and the sign is chosen so that $e^{i_1}\wedge\cdots\wedge e^{i_p}\wedge\star(e^{i_1}\wedge\cdots\wedge e^{i_p}) = e^1\wedge\cdots\wedge e^n$, the volume form. *In general coordinates* this becomes Nash's formula

$$\star\omega \;=\; \frac{\sqrt{g}}{(n-p)!}\,\epsilon^{i_1\ldots i_p}{}_{i_{p+1}\ldots i_n}\,\omega_{i_1\ldots i_p}\,\mathrm{d}x^{i_{p+1}}\wedge\cdots\wedge\mathrm{d}x^{i_n} \qquad (\text{sum over } i_1<\cdots<i_p), \tag{2.83}$$

where $\sqrt{g} = \sqrt{\det g_{ij}}$, ϵ is the Levi-Civita symbol ($\epsilon_{12\ldots n} = +1$), and its first p indices are raised with g^{ij}.

Geometrically, $\star$ turns a p-dimensional "plane element" into the complementary $(n-p)$-dimensional plane element orthogonal to it, with the same size (Figure 2.20). Two facts from (2.43) are all we will need:

$$\star\star \;=\; (-1)^{p(n-p)} \quad \text{on } p\text{-forms}, \qquad \langle \omega, \nu \rangle \;=\; \int_M \omega \wedge \star\nu \quad (\omega, \nu \in \Omega^p(M)). \tag{2.84}$$

The first follows from (2.82): applying $\star$ twice returns the original basis form, and the sign is the sign of moving p one-forms past $n-p$ others. The second defines the L^2 **inner product** of forms. In an orthonormal coframe $\omega \wedge \star\nu = \left(\sum_I \omega_I \nu_I\right)\mathrm{vol}$, where I runs over increasing multi-indices. So $\langle \omega, \omega \rangle = \int_M \sum_I \omega_I^2 \,\mathrm{vol} \geq 0$, with equality only for $\omega = 0$. This positivity uses the *Riemannian* signature. Nash remarks that some signs would change for a Lorentzian metric; worse, positivity fails.

Worked example 2.31: The Hodge star in $\mathbb{R}^2$ and $\mathbb{R}^3$

In $\mathbb{R}^3$ with the Euclidean metric, $e^i = \mathrm{d}x^i$ and the rule (2.82) gives

$$\star 1 = \mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z, \qquad \star \mathrm{d}x = \mathrm{d}y \wedge \mathrm{d}z, \quad \star \mathrm{d}y = \mathrm{d}z \wedge \mathrm{d}x, \quad \star \mathrm{d}z = \mathrm{d}x \wedge \mathrm{d}y,$$

and $\star(\mathrm{d}y \wedge \mathrm{d}z) = \mathrm{d}x$ and cyclically, $\star(\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z) = 1$. Check one sign: $\mathrm{d}x \wedge \star \mathrm{d}x = \mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z$, the volume form, as required. Here $p(3-p)$ is always even, so $\star\star = +1$. This is the dictionary of vector calculus: a vector $\vec{A}$ can be stored as the 1-form $A_i \mathrm{d}x^i$ or as the 2-form $\star(A_i \mathrm{d}x^i) = A_1 \mathrm{d}y \wedge \mathrm{d}z + A_2 \mathrm{d}z \wedge \mathrm{d}x + A_3 \mathrm{d}x \wedge \mathrm{d}y$ (its "flux form").
In $\mathbb{R}^2$: $\star 1 = \mathrm{d}x \wedge \mathrm{d}y$, $\star \mathrm{d}x = \mathrm{d}y$, $\star \mathrm{d}y = -\mathrm{d}x$, $\star(\mathrm{d}x \wedge \mathrm{d}y) = 1$. On 1-forms $\star\star = -1$, in agreement with $(-1)^{1\cdot 1}$: $\star$ is rotation by 90°, and doing it twice is rotation by 180°.

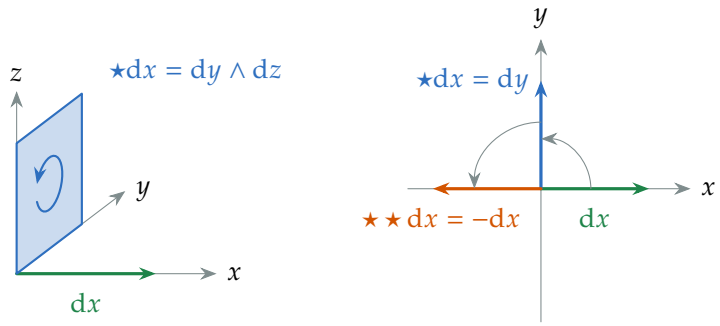

Figure 2.20: The Hodge star turns a p-plane element into the orthogonal complementary one. Left, in $\mathbb{R}^3$: the 1-form $\mathrm{d}x$ (green arrow, pointing along the normal) becomes the 2-form $\mathrm{d}y \wedge \mathrm{d}z$ (blue square in the yz-plane, oriented so that x followed by y, z is right-handed). Right, in $\mathbb{R}^2$: $\star$ on 1-forms is rotation by 90°, so $\star\star = -1$ there, in agreement with $\star\star = (-1)^{p(n-p)}$.

The adjoint d^*

Working definition 2.18 (co-differential)

The **co-differential** (or adjoint of d) $\mathrm{d}^* : \Omega^p(M) \to \Omega^{p-1}(M)$ is the operator with

$$\langle \mathrm{d}\mu, \omega \rangle \;=\; \langle \mu, \mathrm{d}^*\omega \rangle \qquad \text{for all } \mu \in \Omega^{p-1}(M),\ \omega \in \Omega^p(M), \tag{2.85}$$

with $\langle\ ,\ \rangle$ the L^2 inner product [$\langle \omega, \nu \rangle = \int_M \omega \wedge \star\nu$, from (2.84)], on a compact M without boundary. *How to compute*:

$$\mathrm{d}^* \;=\; (-1)^{np+n+1} \star \mathrm{d} \star \qquad \text{on } p\text{-forms}. \tag{2.86}$$

Both lines are in Nash's (2.43), stated without proof (the order of the arguments in the inner product does not matter, since it is symmetric). The formula is a two-line consequence of Stokes' theorem, and we derive it because the sign is the kind of thing one forgets. Take $\mu \in \Omega^{p-1}$ and $\omega \in \Omega^p$. Then $\mu \wedge \star\omega$ is an $(n-1)$-form and

$$\begin{aligned} 0 &\overset{(1)}{=} \int_M \mathrm{d}\big(\mu \wedge \star\omega\big) \overset{(2)}{=} \int_M \mathrm{d}\mu \wedge \star\omega + (-1)^{p-1} \int_M \mu \wedge \mathrm{d} \star \omega \\ &\overset{(3)}{=} \langle \mathrm{d}\mu, \omega \rangle + (-1)^{p-1}(-1)^{(p-1)(n-p+1)} \int_M \mu \wedge \star\star\, \mathrm{d} \star \omega \\ &\overset{(4)}{=} \langle \mathrm{d}\mu, \omega \rangle - (-1)^{np+n+1} \big\langle \mu, \star \mathrm{d} \star \omega \big\rangle. \end{aligned} \tag{2.87}$$

(1) Stokes' theorem on a manifold without boundary: $\int_M \mathrm{d}(\cdot) = \int_{\partial M}(\cdot) = 0$.

(2) The Leibniz rule $\mathrm{d}(\mu \wedge \beta) = \mathrm{d}\mu \wedge \beta + (-1)^{\deg \mu} \mu \wedge \mathrm{d}\beta$, with $\deg \mu = p - 1$.

(3) The first term is the inner product by (2.84). In the second, the form $\mathrm{d} \star \omega$ has degree $n - p + 1$; insert $1 = (-1)^{r(n-r)} \star\star$ with $r = n - p + 1$, valid on r-forms.

(4) Collect signs: the exponent is $(p-1) + (p-1)(n-p+1) = (p-1)(n-p+2)$. Modulo 2 this is $(p-1)(n-p) = pn - p^2 - n + p \equiv pn + n$, because $p^2 \equiv p$. So the total sign is $(-1)^{pn+n} = -(-1)^{np+n+1}$. The remaining integral is $\int \mu \wedge \star(\star \mathrm{d} \star \omega) = \langle \mu, \star \mathrm{d} \star \omega \rangle$.

Setting the last line to zero and comparing with (2.85) gives (2.86). Note that d^* lowers the degree by one, and $(\mathrm{d}^*)^2 = \pm \star\, \mathrm{dd} \star = 0$.

Worked example 2.32: d^* is minus the divergence; Δ_p is minus ∇^2

Work on $\mathbb{R}^3$ (or on a flat torus T^3, so that "compact without boundary" holds and all the integrations by parts are honest). Let $A = A_1 \mathrm{d}x + A_2 \mathrm{d}y + A_3 \mathrm{d}z$. With $n = 3$, $p = 1$ the sign in (2.86) is $(-1)^{3+3+1} = -1$, so

$$\begin{aligned} \mathrm{d}^* A &\overset{(1)}{=} - \star\, \mathrm{d}\left(A_1 \mathrm{d}y \wedge \mathrm{d}z + A_2 \mathrm{d}z \wedge \mathrm{d}x + A_3 \mathrm{d}x \wedge \mathrm{d}y\right) \\ &\overset{(2)}{=} - \star \left((\partial_1 A_1 + \partial_2 A_2 + \partial_3 A_3)\, \mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z\right) \overset{(3)}{=} -\nabla \cdot \vec{A}. \end{aligned}$$

(1) (2.86) and the table of Example 2.31 for $\star A$.

(2) $\mathrm{d}(A_1 \mathrm{d}y \wedge \mathrm{d}z) = \partial_1 A_1\, \mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z$ (the ∂_2, ∂_3 terms die because $\mathrm{d}y \wedge \mathrm{d}y = 0$ etc.), and cyclically.

(3) $\star$ of the volume form is 1.

The minus sign is exactly what integration by parts demands: $\langle \mathrm{d}f, A \rangle = \int \nabla f \cdot \vec{A} = -\int f\, \nabla \cdot \vec{A} = \langle f, \mathrm{d}^* A \rangle$.

Now the Laplacians. On functions, $\Delta_0 f = \mathrm{d}^* \mathrm{d} f$ (there is no dd^* term since $\mathrm{d}^* f = 0$), and

$$\Delta_0 f \;=\; \mathrm{d}^*(\nabla f) \;=\; -\nabla \cdot \nabla f \;=\; -\nabla^2 f,$$

the positive Laplacian (2.7). On 1-forms, the term $\mathrm{dd}^* A = -\nabla(\nabla \cdot \vec{A})$. For the other, $\mathrm{d}A$ is the 2-form $\star(\nabla \times \vec{A})$ (the flux form of the curl), and on 2-forms in $\mathbb{R}^3$ the sign in (2.86) is $(-1)^{6+3+1} = +1$, so $\mathrm{d}^* \mathrm{d} A = \star \mathrm{d} \star \star (\nabla \times \vec{A}) = \star \mathrm{d}(\nabla \times \vec{A}) = \nabla \times (\nabla \times \vec{A})$, read as a 1-form. Hence

$$\Delta_1 \vec{A} \overset{(1)}{=} \nabla \times (\nabla \times \vec{A}) - \nabla(\nabla \cdot \vec{A}) \overset{(2)}{=} -\nabla^2 \vec{A}. \tag{2.88}$$

(1) The two pieces just computed.

(2) The vector identity $\nabla \times (\nabla \times \vec{A}) = \nabla(\nabla \cdot \vec{A}) - \nabla^2 \vec{A}$.

So in flat space the form Laplacian is minus the ordinary Laplacian applied to each component. This is why Nash's notation Δ_p generalises Δ. On a curved manifold the same is true up to terms with fewer derivatives: the **Weitzenböck formula** reads $\Delta_1 = \nabla^*\nabla + \mathrm{Ric}$, where $\nabla^*\nabla$ is $-g^{ij}\nabla_i\nabla_j$ and the Ricci curvature is a zeroth-order term. That lower-order term is invisible to the symbol.

2.3.8 The symbol calculus

We could compute $\sigma_2(\Delta_p)$ by brute force: write out $\mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$ in coordinates and replace $\partial \to ik$. For $p = 1$ in $\mathbb{R}^3$ we just did, in effect. Nash recommends a cleverer way: two rules that let us compute symbols of composite operators from symbols of their pieces.

Rule 1: the symbol of a composition is the product of the symbols

Key idea: Composition (Nash's (2.45))

Let $Q : \Gamma(U) \to \Gamma(V)$ have order j and $P : \Gamma(V) \to \Gamma(W)$ have order i. Then $P \circ Q : \Gamma(U) \to \Gamma(W)$ has order (at most) $i + j$, and its leading symbol is the product of the leading symbols, composed as linear maps:

$$\sigma^{P\circ Q}_{i+j}(x,k) \;=\; \sigma^P_i(x,k)\,\sigma^Q_j(x,k) \qquad \big(U_x \xrightarrow{\sigma^Q_j} V_x \xrightarrow{\sigma^P_i} W_x\big). \tag{2.89}$$

Nash says "the reader can easily verify" this. Here is the verification, using the oscillatory test (2.47). Fix a phase ψ with $\mathrm{d}\psi(x) = k$ and a vector v. Apply Q first:

$$\begin{aligned} Q\big(e^{i\lambda\psi}v\big) &\overset{(1)}{=} e^{i\lambda\psi}\big(\lambda^j\,\sigma^Q_j(x,\mathrm{d}\psi)\,v + O(\lambda^{j-1})\big) \;=:\; e^{i\lambda\psi}\,w_\lambda(x), \\ P\big(e^{i\lambda\psi}w_\lambda\big) &\overset{(2)}{=} e^{i\lambda\psi}\big(\lambda^i\,\sigma^P_i(x,\mathrm{d}\psi)\,w_\lambda(x) + \lambda^{i-1}(\dots)\big) \\ &\overset{(3)}{=} e^{i\lambda\psi}\big(\lambda^{i+j}\,\sigma^P_i(x,\mathrm{d}\psi)\,\sigma^Q_j(x,\mathrm{d}\psi)\,v + O(\lambda^{i+j-1})\big). \end{aligned}$$

(1) The oscillatory test for Q; the correction terms have fewer powers of λ. Call the bracket $w_\lambda(x)$: it is a smooth vector function, of size λ^j.

(2) The oscillatory test for P, now applied to $e^{i\lambda\psi}$ times a non-constant vector. Every derivative that lands on w_λ instead of on the exponential costs one power of λ, so those terms are in the "$\lambda^{i-1}(\dots)$". The derivatives of w_λ are still of size λ^j (differentiating does not bring down λ because w_λ has no oscillating phase).

(3) Insert w_λ and keep the top power λ^{i+j}; everything else is at most λ^{i+j-1}.

Reading off the coefficient of λ^{i+j} gives (2.89). The mechanism: *to leading order, derivatives only hit the fast phase, and on the fast phase each operator is just multiplication by its symbol.* The order of the product is the order of the maps: σ^P after σ^Q, as matrices. (If $\sigma^P_i\,\sigma^Q_j = 0$, the order of PQ is less than $i + j$; we shall see this happen for $\mathrm{d} \circ \mathrm{d}$.)

Worked example 2.33: The lower-order symbol does *not* multiply

On $\mathbb{R}$ take $P = \partial_x$ and $Q = x\,\partial_x$. Then, by the product rule,

$$PQ\,u \;=\; \partial_x(xu') \;=\; xu'' + u', \qquad \text{so} \qquad PQ \;=\; x\partial_x^2 + \partial_x.$$

The symbols (replace $\partial_x \to ik$) are

$$\sigma^P = ik, \qquad \sigma^Q = ixk, \qquad \sigma^{PQ} \overset{(1)}{=} x(ik)^2 + ik = -xk^2 + ik,$$
$$\sigma^P \sigma^Q \overset{(2)}{=} (ik)(ixk) = -xk^2.$$

(1) The plane-wave test applied to $x\partial_x^2 + \partial_x$.
(2) Multiply the two symbols.

The leading symbols agree ($-xk^2$), as (2.89) promises. The full symbols do not: σ^{PQ} has the extra first-order piece ik, produced by ∂_x differentiating the coefficient x. For the record, the exact rule is $\sigma^{PQ} = \sum_\alpha \frac{1}{\alpha!}(\partial_k^\alpha \sigma^P)(D_x^\alpha \sigma^Q)$. Here the $\alpha = 1$ term is $(\partial_k\, ik)\big(-i\partial_x(ixk)\big) = (i)(k) = ik$, which is exactly the discrepancy. Part 2b develops this rule for pseudo-differential operators.

Dictionary: Commutators and Poisson brackets

If P and Q are scalar operators, PQ and QP have the same leading symbol, so the commutator $[P, Q]$ has order at most $i + j - 1$. Its symbol of that order is

$$\sigma_{i+j-1}\big([P, Q]\big) = -i\,\{\sigma_i^P, \sigma_j^Q\}, \qquad \{f, h\} = \sum_l \Big(\frac{\partial f}{\partial k_l}\frac{\partial h}{\partial x_l} - \frac{\partial f}{\partial x_l}\frac{\partial h}{\partial k_l}\Big), \tag{2.90}$$

the Poisson bracket on phase space T^*M. Check with Example 2.33: $[\partial_x, x\partial_x] = \partial_x$ has symbol ik, and $-i\{ik, ixk\} = -i\,(i)(ik) = ik$. This is Dirac's rule "commutator $\leftrightarrow$ $i\hbar\times$ Poisson bracket" with $\hbar = 1$ and $D = -i\partial$ playing the momentum. The symbol calculus *is* the classical limit of quantum mechanics: the leading symbol is the classical observable, the operator is its quantisation.

Rule 2: the symbol of the adjoint is the adjoint of the symbol

If U and V carry fibre inner products and M carries a volume form, every operator $L : \Gamma(U) \to \Gamma(V)$ has a **formal adjoint** $L^* : \Gamma(V) \to \Gamma(U)$, defined by $\langle Lu, v\rangle = \langle u, L^*v\rangle$ for all sections, where $\langle\cdot,\cdot\rangle$ integrates the fibre inner product over M. Nash's (2.47) states that

$$\sigma_m^{L^*}(x, k) = \big(\sigma_m^L(x, k)\big)^*, \tag{2.91}$$

the adjoint (conjugate transpose, in orthonormal frames) of the matrix $\sigma_m^L(x, k)$.

Why. Compute L^* for a scalar first-order operator $L = a(x)\partial_x$ on $\mathbb{R}$, using the inner product $\langle u, v\rangle = \int u\,\bar v\,\mathrm{d}x$ (linear in the first slot, antilinear in the second). For compactly supported u, v:

$$\langle Lu, v\rangle \overset{(1)}{=} \int a\,u'\,\bar v\,\mathrm{d}x \overset{(2)}{=} -\int u\,(a\bar v)'\,\mathrm{d}x \overset{(3)}{=} \int u\,\overline{\big(-\bar a\,v' - \bar a'\,v\big)}\,\mathrm{d}x,$$

(1) Definition, with $\langle f, h\rangle = \int f\bar h$.
(2) Integrate by parts; the boundary terms vanish.
(3) Take the complex conjugate outside.

So $L^*v = -\bar a\,v' - \bar a'\,v$, and its leading symbol is $-\bar a\,(ik) = \overline{a\,(ik)}$ (as k is real). That is $\overline{\sigma_1^L}$. The mechanism in general: each integration by parts moves one derivative across, costing a minus sign, and $-ik = \overline{ik}$; the coefficients get conjugated (and, for matrices, transposed) because they move to the other side of the inner product; derivatives that land on the coefficients

give lower-order terms. This is the symbol-level version of $(\hat{p})^\dagger = \hat{p}$: the momentum operator $D = -i\partial$ is self-adjoint, and its symbol k is real.

Assembling the Laplacian

Put $P = \mathrm{d}$, $Q = \mathrm{d}^*$ (and the other way round) into (2.89). Both are first order, and Δ_p is the sum of two compositions, so

$$\sigma_2^{\Delta_p}(x,k) \;=\; \sigma_1^{\mathrm{d}}(x,k)\,\sigma_1^{\mathrm{d}^*}(x,k) + \sigma_1^{\mathrm{d}^*}(x,k)\,\sigma_1^{\mathrm{d}}(x,k), \tag{2.92}$$

Nash's (2.46). (The first product is $\Lambda^p \to \Lambda^{p-1} \to \Lambda^p$, the second $\Lambda^p \to \Lambda^{p+1} \to \Lambda^p$.) We need the two first-order symbols.

2.3.9 The symbols of d, d^* and Δ_p

The symbol of d. Because we are working with forms, Nash writes the Fourier variable as a 1-form, $k = k_i\,\mathrm{d}x^i$. Apply d to a plane wave times a form v with constant components:

$$\mathrm{d}\big(e^{ik\cdot x}v\big) \overset{(1)}{=} \mathrm{d}\big(e^{ik\cdot x}\big)\wedge v + e^{ik\cdot x}\,\mathrm{d}v \overset{(2)}{=} \big(ik_i\,e^{ik\cdot x}\,\mathrm{d}x^i\big)\wedge v \;=\; e^{ik\cdot x}\,\big(i\,k\wedge v\big). \tag{2.93}$$

(1) Leibniz rule for d (a function times a form).
(2) $\mathrm{d}v = 0$ since v has constant components; $\mathrm{d}(e^{ik\cdot x}) = \partial_i e^{ik\cdot x}\,\mathrm{d}x^i$.

Hence

$$\sigma_1^{\mathrm{d}}(x,k) : \Lambda^p T_x^*M \longrightarrow \Lambda^{p+1}T_x^*M, \qquad v \longmapsto i\,k\wedge v, \tag{2.94}$$

which is Nash's (2.48) up to the factor i (see the pitfall below). The symbol of d is *wedging with the momentum*. It needs no metric at all, and it is a map between different bundles, $\Lambda^p \to \Lambda^{p+1}$, of generally different ranks $\binom{n}{p}$ and $\binom{n}{p+1}$. So it is a non-square matrix, and d alone is never elliptic (except in trivial cases).

The symbol of d^*. By Rule 2, $\sigma_1^{\mathrm{d}^*}(x,k) = (ik\wedge)^* = -i\,(k\wedge)^*$. The adjoint of "wedge with k" with respect to the pointwise inner product of forms is "contract with k":

$$(k\wedge)^* \;=\; \iota_k, \qquad \sigma_1^{\mathrm{d}^*}(x,k) : \Lambda^p T_x^*M \to \Lambda^{p-1}T_x^*M, \quad v \longmapsto -i\,\iota_k v. \tag{2.95}$$

Here ι_k is the **interior product** (contraction) with the vector $k^\sharp = g^{ij}k_j\,\partial_i$ obtained by raising the index of k with the metric. (Nash writes $v \mapsto k \lrcorner v$.) In an orthonormal coframe it acts on basis forms by

$$\iota_{e_1}\big(e^1\wedge e^J\big) = e^J, \qquad \iota_{e_1}\big(e^J\big) = 0 \quad (1\notin J),$$

and it is an anti-derivation: $\iota_k(\alpha\wedge\beta) = (\iota_k\alpha)\wedge\beta + (-1)^{\deg\alpha}\alpha\wedge\iota_k\beta$. To see that it is the adjoint of $k\wedge$, rotate the coframe so that $k = |k|\,e^1$. Then $k\wedge$ sends $e^J \mapsto |k|\,e^1\wedge e^J$ for $1\notin J$ and kills $e^1\wedge e^J$. Its matrix in the orthonormal basis of forms has entries 0 and $|k|$; the transpose sends $e^1\wedge e^J \mapsto |k|\,e^J$ and kills the e^J with $1\notin J$: that is $|k|\,\iota_{e_1} = \iota_k$. Unlike σ^{d}, this symbol uses the metric (through $k^\sharp$), as d^* itself does.

A quick check against Example 2.32: on 1-forms in $\mathbb{R}^3$, $\mathrm{d}^* = -\nabla\cdot$ has symbol $\vec{A} \mapsto -i\,\vec{k}\cdot\vec{A}$, and indeed $\iota_k(A_j\mathrm{d}x^j) = k_jA_j$.

The key identity. For any covector k and any form v,

$$k \wedge \iota_k v + \iota_k(k \wedge v) \;=\; |k|^2\, v, \qquad |k|^2 = g^{ij}k_i k_j. \tag{2.96}$$

Derivation:

$$\iota_k(k \wedge v) \overset{(1)}{=} (\iota_k k)\, v - k \wedge \iota_k v \overset{(2)}{=} |k|^2\, v - k \wedge \iota_k v.$$

(1) The anti-derivation rule with $\alpha = k$, a 1-form ($\deg \alpha = 1$).
(2) $\iota_k k = k(k^\sharp) = g^{ij}k_i k_j = |k|^2$.

Moving the last term to the left gives (2.96).

The symbol of the Laplacian. Now assemble:

$$\begin{aligned} \sigma_2^{\Delta_p}(x,k)\, v &\overset{(1)}{=} (ik\wedge)(-i\iota_k)v + (-i\iota_k)(ik\wedge)v \\ &\overset{(2)}{=} k \wedge \iota_k v + \iota_k(k \wedge v) \overset{(3)}{=} |k|^2\, v. \end{aligned} \tag{2.97}$$

(1) (2.92) with the symbols (2.94) and (2.95).
(2) $(i)(-i) = 1$ in both terms.
(3) The key identity (2.96).

So

$$\boxed{\sigma_2^{\Delta_p}(x,k) \;=\; |k|^2\, I} \tag{2.98}$$

where I is the identity on the $\binom{n}{p}$-dimensional fibre $\Lambda^p T_x^* M$. This is Nash's (2.49), written there as $k^2 I$. It is invertible for every $k \neq 0$, with inverse $|k|^{-2}\, I$. *The Hodge Laplacian is elliptic*, on every Riemannian manifold, for every p. Nash's remark: although σ^{Δ_p} is a matrix, it is a multiple of the identity, whereas σ^{d} is not even square. The two non-invertible pieces $k \wedge \iota_k$ and $\iota_k k\wedge$ are complementary projections (times $|k|^2$): one keeps the part of v containing k, the other the part not containing it. Adding them gives everything.

Worked example 2.34: All the symbols of the de Rham complex of $\mathbb{R}^3$, as explicit matrices

Take the bases $\{1\}$, $\{\mathrm{d}x^1, \mathrm{d}x^2, \mathrm{d}x^3\}$, $\{\mathrm{d}x^2 \wedge \mathrm{d}x^3, \mathrm{d}x^3 \wedge \mathrm{d}x^1, \mathrm{d}x^1 \wedge \mathrm{d}x^2\}$, $\{\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3\}$ of $\Lambda^0, \ldots, \Lambda^3$. These are the bases that make $\star$ look like the identity. Then $k\wedge$ becomes:

$$\begin{aligned} &\Lambda^0 \to \Lambda^1: && f \mapsto k\, f = (k_1 f, k_2 f, k_3 f) && \text{matrix } \vec{k}\ (3\times 1), \\ &\Lambda^1 \to \Lambda^2: && k \wedge (A_j \mathrm{d}x^j) \overset{(1)}{=} (k_2 A_3 - k_3 A_2)\, \mathrm{d}x^2 \wedge \mathrm{d}x^3 + \ldots && \text{matrix } [\vec{k}]_\times\ (3\times 3), \\ &\Lambda^2 \to \Lambda^3: && k \wedge \big(B_1 \mathrm{d}x^2 \wedge \mathrm{d}x^3 + \ldots\big) \overset{(2)}{=} (\vec{k}\cdot\vec{B})\, \mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3 && \text{matrix } \vec{k}^T\ (1\times 3). \end{aligned}$$

(1) Expand $k_i \mathrm{d}x^i \wedge A_j \mathrm{d}x^j$ and collect the coefficient of each basis 2-form: the three coefficients are the components of $\vec{k} \times \vec{A}$.
(2) $\mathrm{d}x^1 \wedge (\mathrm{d}x^2 \wedge \mathrm{d}x^3)$ is the volume form, as are its cyclic versions; all other products vanish.

So $\sigma(\mathrm{d})$ on $\Lambda^0, \Lambda^1, \Lambda^2$ is i times $\vec{k}$, $[\vec{k}]_\times$, $\vec{k}^T$: the symbols of *grad, curl, div* from Example 2.26. The de Rham complex of $\mathbb{R}^3$ is the grad–curl–div sequence of vector calculus. The symbols of d^* are the conjugate transposes: $-i\vec{k}^T$, $-i[\vec{k}]_\times^T = i[\vec{k}]_\times$, $-i\vec{k}$.
Now verify (2.98) degree by degree, using $[\vec{k}]_\times^2 = \vec{k}\vec{k}^T - |k|^2\, I_3$ from Example 2.29:

$$\Lambda^0: \quad (-i\vec{k}^T)(i\vec{k}) \;=\; \vec{k}^T\vec{k} \;=\; |k|^2,$$

$$\Lambda^1: \quad (i\vec{k})(-i\vec{k}^T) + (i[\vec{k}]_\times)(i[\vec{k}]_\times) \overset{(1)}{=} \vec{k}\vec{k}^T - \left(\vec{k}\vec{k}^T - |k|^2 I_3\right) \;=\; |k|^2 I_3,$$
$$\Lambda^2: \quad (i[\vec{k}]_\times)(i[\vec{k}]_\times) + (-i\vec{k})(i\vec{k}^T) \overset{(2)}{=} -\left(\vec{k}\vec{k}^T - |k|^2 I_3\right) + \vec{k}\vec{k}^T \;=\; |k|^2 I_3,$$
$$\Lambda^3: \quad (i\vec{k}^T)(-i\vec{k}) \;=\; |k|^2 .$$

(1) On 1-forms the first term is $\sigma(\mathrm{d})\sigma(\mathrm{d}^*)$ through Λ^0 (the $\nabla\nabla\cdot$ term), the second is $\sigma(\mathrm{d}^*)\sigma(\mathrm{d})$ through Λ^2 (the curl curl term); then $i \cdot i = -1$ and BAC–CAB.
(2) On 2-forms, the same two terms in the other order.

On 1-forms this is the symbol of the identity $\nabla \times \nabla \times - \nabla\nabla\cdot = -\nabla^2$ from (2.88): $\vec{k} \times (\vec{k} \times \vec{A})$ removes the transverse part of $\vec{A}$, $\vec{k}(\vec{k} \cdot \vec{A})$ supplies the longitudinal part, and together they give $|k|^2 \vec{A}$.

Watch out: Nash's $\sigma(\mathrm{d}) = k\wedge$ versus our $ik\wedge$

Nash drops the factor i in (2.48), as he did for the Cauchy–Riemann operator in (2.30). With our Fourier convention $\partial_j \to ik_j$ (Section 2.1.2), the symbol of any first-order operator carries an i. Nothing depends on it: invertibility is unchanged by a factor i, and in products like (2.97) the factors combine to $(i)(-i) = 1$, so Nash's (2.49) is correct as it stands. The i does matter for signs of second-order symbols built from a single first-order operator squared, like $\sigma(\not{\partial})^2 = -|k|^2$ in (2.79).

2.3.10 Generalisations: twisting, gauge fields and gauge fixing

Nash mentions that "various generalisations of the Laplacian can be formed by tensoring the bundle $\Lambda^p T^*M$ with another vector bundle E, and by studying the equations of motion for Yang–Mills theories". Let us make both concrete.

Twisting by a bundle with a connection. Let E be a vector bundle with a connection A (a gauge field, anti-Hermitian matrix-valued 1-form, in the conventions of Chapter T3). Forms with values in E are sections of $\Lambda^p T^*M \otimes E$, and the covariant exterior derivative is

$$\mathrm{d}_A \omega \;=\; \mathrm{d}\omega + A \wedge \omega.$$

The extra term $A \wedge \omega$ has no derivatives, so it is zeroth order and invisible to the leading symbol:

$$\sigma_1^{\mathrm{d}_A}(x,k) \;=\; i\,k\wedge \otimes I_E, \qquad \sigma_2^{\Delta_A}(x,k) \;=\; |k|^2\, I, \tag{2.99}$$

where $\Delta_A = \mathrm{d}_A\mathrm{d}_A^* + \mathrm{d}_A^*\mathrm{d}_A$ is the gauge-covariant Laplacian. It is elliptic, whatever the gauge field. (This is the bundle version of the "gauge fields are lower order" remark in Section 2.3.4.)

Worked example 2.35: Maxwell's operator is not elliptic; gauge fixing makes it so

The Euclidean Maxwell action is $\frac{1}{2}\|\mathrm{d}A\|^2 = \frac{1}{2}\langle A, \mathrm{d}^*\mathrm{d}A\rangle$, so the field equation in vacuum is $\mathrm{d}^*\mathrm{d}A = 0$. Is $\mathrm{d}^*\mathrm{d}$ (on 1-forms) elliptic? Its symbol, by Rule 1, is

$$\sigma_2^{\mathrm{d}^*\mathrm{d}}(k)\,A \overset{(1)}{=} (-i\iota_k)(ik\wedge A) \overset{(2)}{=} |k|^2 A - k\,(\iota_k A) \;=\; |k|^2 A - k\,(k\cdot A).$$

(1) The composition rule with the symbols of d and d^*.
(2) The key identity (2.96), with $\iota_k A = k \cdot A$ a function.

As a matrix this is $|k|^2 I - kk^T$, which is $|k|^2$ times the projection onto the plane transverse

to k. It kills the longitudinal polarisation $A \propto k$, so *Maxwell's operator is not elliptic*. The reason is gauge invariance: $A \mapsto A + \mathrm{d}\chi$ does not change $\mathrm{d}A$, and at the symbol level $\mathrm{d}\chi$ has symbol $ik\chi$, exactly the longitudinal direction. Every gauge theory has this problem, and it is why the photon propagator $(|k|^2\,\delta_{\mu\nu} - k_\mu k_\nu)^{-1}$ does not exist until we fix a gauge. Fixing the gauge repairs it. Add the gauge-fixing term $\frac{1}{2}\,\|\mathrm{d}^*A\|^2$ (the Lorenz/Feynman gauge). The operator becomes $\mathrm{d}^*\mathrm{d} + \mathrm{d}\mathrm{d}^* = \Delta_1$, with symbol

$$|k|^2\, I - kk^T + kk^T \;=\; |k|^2\, I,$$

elliptic, and the propagator is the familiar Feynman-gauge $\delta_{\mu\nu}/|k|^2$. More general R_ξ gauges give $|k|^2\, I - (1-\xi^{-1})kk^T$, which is elliptic for any finite $\xi > 0$. For Yang–Mills theory the same happens with d_A in place of d: the linearised field equation $\mathrm{d}_A^*\mathrm{d}_A$ is not elliptic, and adding the background-field gauge-fixing term $\left\|\mathrm{d}_A^*\,\delta A\right\|^2$ produces the elliptic operator Δ_A. This is the step that makes the one-loop determinant $\det \Delta_A$ and the instanton moduli counting of Chapter 8 meaningful.

2.3.11 The de Rham complex and its symbol sequence

We end the section on operators with an idea that Nash postpones to Chapter 4 but that is already visible here, and that explains *why* the symbol of Δ_p came out invertible. The operators d form a chain

$$0 \longrightarrow \Omega^0(M) \xrightarrow{\mathrm{d}} \Omega^1(M) \xrightarrow{\mathrm{d}} \Omega^2(M) \xrightarrow{\mathrm{d}} \cdots \xrightarrow{\mathrm{d}} \Omega^n(M) \longrightarrow 0, \tag{2.100}$$

the **de Rham complex**, with $\mathrm{d}\circ\mathrm{d} = 0$. Take its leading symbols at a point (x,k) with $k \neq 0$. We get a chain of finite-dimensional vector spaces and linear maps,

$$0 \longrightarrow \Lambda^0 T_x^* \xrightarrow{ik\wedge} \Lambda^1 T_x^* \xrightarrow{ik\wedge} \Lambda^2 T_x^* \xrightarrow{ik\wedge} \cdots \xrightarrow{ik\wedge} \Lambda^n T_x^* \longrightarrow 0, \tag{2.101}$$

the **symbol sequence**. It is again a complex, $(ik\wedge)(ik\wedge) = -k\wedge k\wedge = 0$, because $k\wedge k = 0$. (This is also Rule 1 applied to $\mathrm{d}\circ\mathrm{d} = 0$.)

Working definition 2.19 (exact sequence)

A sequence of linear maps $\cdots \to A_{p-1} \xrightarrow{f_{p-1}} A_p \xrightarrow{f_p} A_{p+1} \to \cdots$ with $f_p \circ f_{p-1} = 0$ is **exact at** A_p if $\operatorname{Ker} f_p = \operatorname{Im} f_{p-1}$: everything killed by the next map comes from the previous one. It is *exact* if it is exact at every place. *How to test*: check $\dim \operatorname{Ker} f_p = \dim \operatorname{Im} f_{p-1}$ at each place, i.e. $\dim A_p = \operatorname{rank} f_{p-1} + \operatorname{rank} f_p$ [$\operatorname{rank} f = \dim \operatorname{Im} f$, the number of independent output vectors].

Key idea: The symbol sequence of the de Rham complex is exact

For every $k \neq 0$ the sequence (2.101) is exact: a form v with $k \wedge v = 0$ is of the form $v = k \wedge w$.

Why. The key identity (2.96) does all the work. Suppose $k \wedge v = 0$. Then

$$v \overset{(1)}{=} \frac{1}{|k|^2}\Big(k \wedge \iota_k v + \iota_k(k \wedge v)\Big) \overset{(2)}{=} \frac{1}{|k|^2}\, k \wedge \iota_k v \;=\; k \wedge w, \qquad w = \frac{\iota_k v}{|k|^2}.$$

(1) The key identity, divided by $|k|^2 \neq 0$. This is where $k \neq 0$ is used.

(2) The second term vanishes because $k \wedge v = 0$.

So $\mathrm{Ker}(k\wedge) \subset \mathrm{Im}(k\wedge)$, and $\mathrm{Im} \subset \mathrm{Ker}$ because $k \wedge k = 0$. The operator $h = \iota_k/|k|^2$ is a **contracting homotopy**: $h\,(k\wedge) + (k\wedge)\,h = 1$. At the ends: at Λ^0, $k \wedge f = 0$ forces $f = 0$ (injective), and at Λ^n every n-form is $k \wedge$ (something) (surjective). At $k = 0$, on the other hand, all maps are zero and the sequence is as far from exact as possible.

Worked example 2.36: Exactness for grad–curl–div, by hand

In $\mathbb{R}^3$ the symbol sequence is (dropping the i's, which do not change kernels and images)

$$0 \to \mathbb{R} \xrightarrow{\vec{k}} \mathbb{R}^3 \xrightarrow{\vec{k}\times} \mathbb{R}^3 \xrightarrow{\vec{k}\cdot} \mathbb{R} \to 0.$$

Check each place with $\vec{k} \neq 0$:

- at the first $\mathbb{R}$: $f\vec{k} = 0 \Rightarrow f = 0$. Kernel 0, image of the incoming map 0. Exact.
- at the first $\mathbb{R}^3$: $\vec{k}\times\vec{v} = 0 \iff \vec{v} \parallel \vec{k} \iff \vec{v} = f\vec{k}$. Kernel = image = the line through $\vec{k}$. (Physics: a curl-free plane wave is a gradient.)
- at the second $\mathbb{R}^3$: $\vec{k}\cdot\vec{w} = 0 \iff \vec{w} \perp \vec{k}$, and the image of $\vec{k}\times$ is exactly the plane $\vec{k}^\perp$ (Figure 2.18). Kernel = image. (Physics: a divergence-free plane wave is a curl.)
- at the last $\mathbb{R}$: $\vec{k}\cdot$ is onto, since $\vec{k}\cdot(c\,\vec{k}/|k|^2) = c$. Exact.

Count dimensions: $1 = 0+1, 3 = 1+2, 3 = 2+1, 1 = 1+0$ (rank in plus rank out). Figure 2.21 shows this bookkeeping. A necessary consequence of exactness is that the alternating sum of the dimensions vanishes: $1 - 3 + 3 - 1 = 0$. In general $\sum_p (-1)^p \binom{n}{p} = (1-1)^n = 0$.

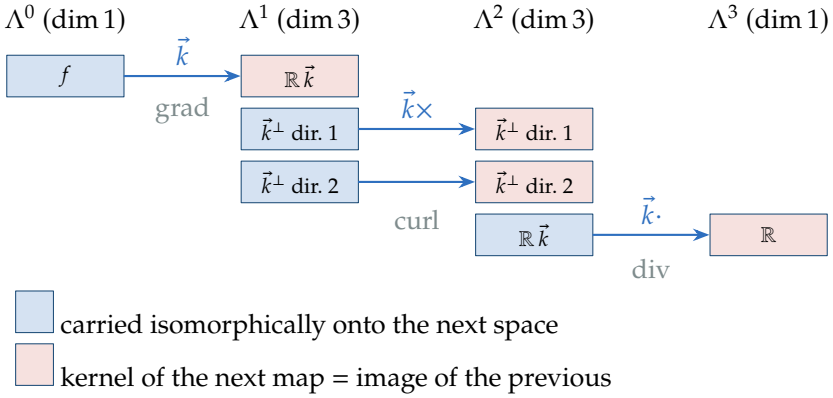

Figure 2.21: Exactness of the symbol sequence of the de Rham complex of $\mathbb{R}^3$, for a fixed $\vec{k} \neq 0$. Each fibre Λ^p splits into a part hit by the incoming map (red) and a part carried isomorphically onto the next space (blue). Nothing is left over anywhere: that is exactness. The dimensions obey $\binom{3}{p}$ = (red) + (blue), which is why $1 - 3 + 3 - 1 = 0$.

Elliptic complexes

The exactness we just found is precisely the reason that Δ_p is elliptic, and it is the pattern for a whole class of objects.

Working definition 2.20 (elliptic complex)

A sequence of differential operators $0 \to \Gamma(E_0) \xrightarrow{D_0} \Gamma(E_1) \xrightarrow{D_1} \cdots \xrightarrow{D_{N-1}} \Gamma(E_N) \to 0$ [$\Gamma(E_p)$ is the space of smooth sections of the bundle E_p, like $\Omega^p(M)$ for d], all of the same order, with $D_{p+1} \circ D_p = 0$, is an **elliptic complex** if its symbol sequence [the leading symbols at one point x, linear maps between the fibres, like $ik\wedge$ for d]

$$0 \to E_{0,x} \xrightarrow{\sigma(D_0)(x,k)} E_{1,x} \to \cdots \to E_{N,x} \to 0$$

is exact for every x and every $k \neq 0$. *How to test*: compute the symbol matrices, and at each place check $\dim E_p = \operatorname{rank}\sigma(D_{p-1}) + \operatorname{rank}\sigma(D_p)$.

A single elliptic operator $L : \Gamma(U) \to \Gamma(V)$ is the special case $N = 1$: $0 \to U_x \xrightarrow{\sigma(L)} V_x \to 0$ is exact exactly when $\sigma(L)$ is injective and surjective, i.e. invertible. So elliptic complexes generalise elliptic operators. Conversely, every elliptic complex produces elliptic operators, its Laplacians.

Key idea: Exact symbol sequence $\Longleftrightarrow$ elliptic Laplacians

For a complex with symbols $s_p = \sigma(D_p)(x,k)$, the symbol of the Laplacian $\Delta_p = D_{p-1}D_{p-1}^* + D_p^*D_p$ is $s_{p-1}s_{p-1}^* + s_p^*s_p$, and this is invertible for all $k \neq 0$ if and only if the symbol sequence is exact at E_p.

Why (the direction we need). Suppose the sequence is exact and $(s_{p-1}s_{p-1}^* + s_p^*s_p)v = 0$. Then

$$0 \overset{(1)}{=} \left(v, (s_{p-1}s_{p-1}^* + s_p^*s_p)v\right) \overset{(2)}{=} \left|s_{p-1}^*v\right|^2 + \left|s_pv\right|^2,$$

(1) Take the inner product of the equation with v.
(2) Move each s across the inner product: $(v, ss^*v) = (s^*v, s^*v)$ and $(v, s^*sv) = (sv, sv)$.

So $s_pv = 0$ and $s_{p-1}^*v = 0$. By exactness, $s_pv = 0$ means $v = s_{p-1}w$ for some w. Then $0 = (w, s_{p-1}^*v) = (s_{p-1}w, v) = |v|^2$, so $v = 0$. The symbol of Δ_p is injective, hence (being a square matrix) invertible. This is the *same* argument as Nash's (2.50) for harmonic forms, which we meet in the next subsection, but performed on the finite-dimensional fibres at one momentum.

Worked example 2.37: Rolling up the complex: $\mathrm{d} + \mathrm{d}^*$ and the Euler characteristic operator

Collect the even and odd forms, $\Omega^{\mathrm{ev}} = \bigoplus_p \Omega^{2p}$ and $\Omega^{\mathrm{odd}} = \bigoplus_p \Omega^{2p+1}$, and consider

$$\mathrm{d} + \mathrm{d}^* : \Omega^{\mathrm{ev}}(M) \longrightarrow \Omega^{\mathrm{odd}}(M).$$

Its symbol is $s = i(k \wedge -\iota_k)$, and, using $k \wedge k\wedge = 0 = \iota_k\iota_k$,

$$s^*s \overset{(1)}{=} (-i)(k \wedge -\iota_k)^*\, i(k \wedge -\iota_k) \overset{(2)}{=} (\iota_k - k\wedge)(k \wedge -\iota_k) \overset{(3)}{=} \iota_k k \wedge + k \wedge \iota_k \overset{(4)}{=} |k|^2.$$

(1) $s^* = \bar{i}\,(k \wedge -\iota_k)^* = -i(k \wedge -\iota_k)^*$.
(2) $(k\wedge)^* = \iota_k$ and $\iota_k^* = k\wedge$; and $(-i)(i) = 1$.
(3) Expand; the terms $\iota_k\iota_k$ and $k \wedge k\wedge$ vanish.
(4) The key identity.

So $\mathrm{d} + \mathrm{d}^*$ is an elliptic operator between the bundles of even and odd forms. (They have equal rank, $\sum_p \binom{n}{2p} = \sum_p \binom{n}{2p+1} = 2^{n-1}$, as they must.) It is a first-order square root of the Laplacian, like the Dirac operator; indeed the div–grad–curl operator of Example 2.29

is exactly $\mathrm{d}+\mathrm{d}^*$ on $\Omega^0\oplus\Omega^2\to\Omega^1\oplus\Omega^3$ in $\mathbb{R}^3$, with 2-forms stored as vectors via $\star$. In Chapter 4 we shall see that the number of its zero modes minus the number of zero modes of its adjoint is the Euler characteristic, $\mathrm{index}(\mathrm{d}+\mathrm{d}^*)=\sum_p(-1)^p b_p=\chi(M)$.

Worked example 2.38: The instanton deformation complex is elliptic

Here is an elliptic complex that appears in Chapter 8. On a 4-manifold, 2-forms split into self-dual and anti-self-dual parts, $\Lambda^2=\Lambda^2_+\oplus\Lambda^2_-$, with $\star=\pm1$ on $\Lambda^2_\pm$ (each of rank 3). Consider

$$0\to\Omega^0\xrightarrow{\mathrm{d}}\Omega^1\xrightarrow{\mathrm{d}^+}\Omega^2_+\to 0,\qquad \mathrm{d}^+\omega=\tfrac12(\mathrm{d}\omega+\star\mathrm{d}\omega).$$

(With a gauge field, d becomes d_A; the first map is an infinitesimal gauge transformation and the second is the linearised self-duality equation $F_A^+=0$.) The symbols are $f\mapsto ikf$ and $a\mapsto i(k\wedge a)^+$. Take $k=e^1$ (rotate and rescale). A basis of Λ^2_+ is $\{e^{12}+e^{34},\ e^{13}+e^{42},\ e^{14}+e^{23}\}$ (with $e^{ij}=e^i\wedge e^j$). Then

$$(e^1\wedge e^2)^+=\tfrac12(e^{12}+e^{34}),\quad (e^1\wedge e^3)^+=\tfrac12(e^{13}+e^{42}),\quad (e^1\wedge e^4)^+=\tfrac12(e^{14}+e^{23}),\quad (e^1\wedge e^1)^+=0.$$

So $a\mapsto(k\wedge a)^+$ maps Λ^1 (rank 4) *onto* Λ^2_+ (rank 3), with kernel spanned by $e^1=k$, which is exactly the image of Λ^0. The first map is injective. Exact everywhere:

$$\text{ranks } 1,\ 4,\ 3:\qquad 1=0+1,\quad 4=1+3,\quad 3=3+0.$$

The index of this complex (computed in Chapter 8) gives the dimension $8k-3$ of the moduli space of SU(2) instantons of charge k on S^4. Its exactness at Λ^1 is, once more, gauge invariance: the only polarisations the linearised self-duality equation cannot see are pure gauge.

Physical picture: Complexes: ellipticity "modulo gauge"

The Maxwell operator $\mathrm{d}^*\mathrm{d}$ failed to be elliptic only because of gauge directions. The complex $\Omega^0\xrightarrow{\mathrm{d}}\Omega^1\xrightarrow{\mathrm{d}}\Omega^2$ says: "the only directions the field strength cannot see are the gauge directions, and nothing else." That is exactly the statement that the symbol sequence is exact at Λ^1. An elliptic complex is the right notion of ellipticity for a gauge theory, and the first map is the ghost of BRST quantisation.

2.3.12 Harmonic forms and Hodge's theorem

We have shown that Δ_p is elliptic. Now we cash in. Nash ends §3 with the result that opened this chapter, (2.1): the zero modes of Δ_p count the p-dimensional holes of M. The question is: *why should solutions of a PDE know about topology?* The answer has two halves. The first is a short computation with inner products (Nash's (2.50)). It shows that a zero mode of Δ_p is a closed form, and so it defines a cohomology class. The second is Hodge's theorem proper: every cohomology class contains exactly one zero mode. Ellipticity is what makes the second half work.

Throughout, M is *compact*, *without boundary*, *oriented* and *Riemannian*. Each of the four words will be used, and we will point out where.

Working definition 2.21 (harmonic form)

A p-form ω on M is **harmonic** if $\Delta_p\omega = 0$ [$\Delta_p = \mathrm{dd}^* + \mathrm{d}^*\mathrm{d}$, the Laplacian on p-forms], i.e. if it lies in $\operatorname{Ker}\Delta_p$. We write

$$\mathcal{H}^p(M) \;:=\; \operatorname{Ker}\Delta_p \;=\; \{\omega \in \Omega^p(M) :\; \Delta_p\omega = 0\}.$$

How to test: check the two first-order equations $\mathrm{d}\omega = 0$ and $\mathrm{d}^*\omega = 0$ [d^* is the adjoint of d, lowering the degree by one] (this is equivalent on a compact manifold, as we show next). Physically: ω is a *static, source-free field configuration*, a zero mode of the Laplacian.

For functions ($p = 0$) this is the harmonic-function notion of Section 2.1.4, with $\Delta_0 = -\nabla^2$ in flat space. For $p = 1$ in $\mathbb{R}^3$, (2.88) says $\Delta_1\vec{A} = -\nabla^2\vec{A}$, so a harmonic 1-form is a vector field whose components are harmonic functions.

Zero modes are closed and co-closed: Nash's (2.50)

Suppose $\Delta_p\omega = 0$. Pair the equation with ω itself:

$$\begin{aligned} 0 &\overset{(1)}{=} \langle\omega, \Delta_p\omega\rangle \overset{(2)}{=} \langle\omega, \mathrm{dd}^*\omega\rangle + \langle\omega, \mathrm{d}^*\mathrm{d}\omega\rangle \\ &\overset{(3)}{=} \langle\mathrm{d}^*\omega, \mathrm{d}^*\omega\rangle + \langle\mathrm{d}\omega, \mathrm{d}\omega\rangle \overset{(4)}{=} \|\mathrm{d}^*\omega\|^2 + \|\mathrm{d}\omega\|^2 . \end{aligned} \tag{2.102}$$

(1) $\Delta_p\omega = 0$, and the inner product with 0 is 0.
(2) The definition (2.81) of Δ_p, and linearity of the inner product.
(3) The defining property (2.85) of d^*, used twice: once to move d off the second slot as d^* onto the first, once to move d^* off as d (the inner product is symmetric). This is an integration by parts; there are no boundary terms because $\partial M = \varnothing$.
(4) The definition $\|\eta\|^2 = \langle\eta, \eta\rangle = \int_M \eta \wedge \star\eta$.

Both terms in the last line are *non-negative*, because the metric is Riemannian (Section 2.3.7: in an orthonormal coframe $\eta \wedge \star\eta = \sum_I \eta_I^2\,\mathrm{vol}$). A sum of two non-negative numbers is zero only if both are zero. So $\mathrm{d}\omega = 0$ and $\mathrm{d}^*\omega = 0$. The converse is immediate: if $\mathrm{d}\omega = \mathrm{d}^*\omega = 0$ then $\Delta_p\omega = \mathrm{d}(\mathrm{d}^*\omega) + \mathrm{d}^*(\mathrm{d}\omega) = 0$. Hence Nash's (2.51):

$$\omega \in \operatorname{Ker}\Delta_p \quad\Longleftrightarrow\quad \mathrm{d}\omega = 0 \;\text{ and }\; \mathrm{d}^*\omega = 0. \tag{2.103}$$

One second-order equation has become two first-order equations. In vector-calculus language in $\mathbb{R}^3$ (Example 2.32): a harmonic 1-form is a field with $\nabla\times\vec{A} = 0$ and $\nabla\cdot\vec{A} = 0$; a field with neither curl nor divergence, i.e. with no sources of either kind.

Physical picture: The energy argument

Line (2.102) is the familiar statement that the energy of a static field is a sum of squares. For $p = 1$ read ω as a vector potential A: $\|\mathrm{d}A\|^2$ is the magnetic energy $\int \left|\vec{B}\right|^2$, and $\|\mathrm{d}^*A\|^2 = \int(\nabla\cdot\vec{A})^2$ is the gauge-fixing term of Example 2.35. The quadratic form $\langle\omega, \Delta_p\omega\rangle$ is *positive semi-definite*, and its null vectors are the configurations with zero energy. Positivity is also why Δ_p has no negative eigenvalues: if $\Delta_p\omega = \lambda\omega$ then $\lambda\,\|\omega\|^2 = \|\mathrm{d}\omega\|^2 + \|\mathrm{d}^*\omega\|^2 \geq 0$.

Watch out: Each hypothesis is needed

- *Compactness / no boundary.* On $\mathbb{R}$ the function $u(x) = x$ has $\Delta_0 u = -u'' = 0$ but $\mathrm{d}u = \mathrm{d}x \neq 0$. The integration by parts in step (3) fails: $\int_{\mathbb{R}} u\,u''$ and $\int_{\mathbb{R}} (u')^2$ are both undefined, and x is not normalisable. On a compact M harmonic functions are constant, as we are about to see.
- *Riemannian signature.* On the Lorentzian torus T^2 with coordinates (t, x), both of period 2π, the analogue of Δ_0 is the wave operator $\Box = \partial_t^2 - \partial_x^2$. The "energy" becomes $\int \big((\partial_t u)^2 - (\partial_x u)^2\big)$, which is not positive. The plane waves $e^{i(mt+nx)}$ have $\Box e^{i(mt+nx)} = (n^2 - m^2)e^{i(mt+nx)}$, so every pair with $|m| = |n|$ is a zero mode: $\operatorname{Ker}\Box$ is *infinite-dimensional* (all $f(t-x) + g(t+x)$ with f, g periodic). There is no hope of counting holes with it. This is the global face of the local fact (Section 2.1) that the wave operator is hyperbolic, not elliptic.

A harmonic form defines a cohomology class: Nash's (2.52)

Recall from Chapter T2 that the p-th de Rham cohomology group is

$$H^p_{\mathrm{dR}}(M) \;=\; \frac{\operatorname{Ker}\big(\mathrm{d} : \Omega^p \to \Omega^{p+1}\big)}{\operatorname{Im}\big(\mathrm{d} : \Omega^{p-1} \to \Omega^p\big)} \;=\; \frac{\text{closed } p\text{-forms}}{\text{exact } p\text{-forms}},$$

whose elements are classes $[\alpha] = \{\alpha + \mathrm{d}\beta\}$ of closed forms, two closed forms being equivalent if they differ by an exact form. Its dimension is the **Betti number** b_p. (Nash writes $H^p(M;\mathbb{R})$, or $H^p_{\text{de Rham}}(M)$, and quotes his (1.43) of Chapter 1 for the definition.) Since a harmonic form is closed by (2.103), it has a class, and we get a linear map

$$\mathcal{H}^p(M) \longrightarrow H^p_{\mathrm{dR}}(M), \qquad \omega \longmapsto [\omega], \tag{2.104}$$

Nash's (2.52). The content of Hodge's theorem is that this map is an isomorphism.

Key idea: Hodge's theorem (Nash p. 41)

On a compact, closed, oriented Riemannian manifold there is *precisely one* harmonic p-form in each de Rham cohomology class. Equivalently, (2.104) is an isomorphism, and

$$\dim \operatorname{Ker} \Delta_p \;=\; \dim H^p_{\mathrm{dR}}(M) \;=\; b_p, \tag{2.105}$$

Nash's (2.53). The left side needs a metric; the right side does not. So the *number* of harmonic forms is independent of the metric, even though the harmonic forms themselves move when the metric changes.

Nash refers to Wells for the proof. We give it in two steps: "at most one" (injectivity) is three lines, and "at least one" (surjectivity) is where ellipticity enters.

At most one harmonic form per class. Suppose ω and ω' are harmonic and $[\omega] = [\omega']$. Then $\eta = \omega - \omega'$ is harmonic (the kernel is a vector space) and exact, $\eta = \mathrm{d}\beta$. Now

$$\|\eta\|^2 \overset{(1)}{=} \langle \eta, \mathrm{d}\beta \rangle \overset{(2)}{=} \langle \mathrm{d}^*\eta, \beta \rangle \overset{(3)}{=} 0.$$

(1) $\eta = \mathrm{d}\beta$ in the second slot.
(2) Move d across as d^*, by (2.85).

(3) $\mathrm{d}^*\eta = 0$, since η is harmonic, by (2.103).

So $\eta = 0$ and $\omega = \omega'$. In words: *a harmonic form is orthogonal to every exact form*, so the only exact harmonic form is zero. The map (2.104) is injective.

At least one: the variational (Dirichlet) picture. Fix a closed form α. Among all forms in its class, $\alpha + \mathrm{d}\beta$, look for the one of *least energy* $E(\beta) = \|\alpha + \mathrm{d}\beta\|^2$. At a minimum, the first variation in every direction $\mathrm{d}\eta$ vanishes:

$$0 \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}\epsilon}\Big|_{\epsilon=0} \|\alpha + \mathrm{d}\beta + \epsilon\,\mathrm{d}\eta\|^2 \overset{(2)}{=} 2\,\langle \alpha + \mathrm{d}\beta, \mathrm{d}\eta\rangle \overset{(3)}{=} 2\,\langle \mathrm{d}^*(\alpha + \mathrm{d}\beta), \eta\rangle \qquad \text{for all } \eta \in \Omega^{p-1}.$$

(1) The condition for β to be a critical point of E.
(2) Expand $\|a + \epsilon b\|^2 = \|a\|^2 + 2\epsilon\langle a, b\rangle + \epsilon^2\,\|b\|^2$ (real forms).
(3) Move d across as d^*.

Since η is arbitrary, the Euler–Lagrange equation is $\mathrm{d}^*(\alpha + \mathrm{d}\beta) = 0$. The minimiser $h = \alpha + \mathrm{d}\beta$ is closed (it is in the class of α) and co-closed, so it is harmonic. This is the physicist's derivation: *the harmonic representative is the minimum-energy field with the prescribed topological fluxes* (the periods $\int_c \alpha$ over closed cycles c, which are the same for every form in the class, by Stokes). A magnetic field on a torus with given fluxes through the two holes settles into the harmonic one.

What the variational argument does *not* show is that a minimiser exists, and that it is smooth. The infimum of E could be approached by a sequence of forms that gets rougher and rougher and converges to nothing smooth. That is exactly the gap that ellipticity closes, by the mechanism we now describe.

Where ellipticity enters: discrete spectrum and the Green's operator

Ellipticity gives three facts about Δ_p on a compact manifold. We have seen their local versions in Sections 2.1.4 and 2.2; the global versions are proved with the Sobolev spaces of part 2b.

1. *Regularity.* If $\Delta_p\omega$ is smooth then ω is smooth (even if ω was only known to be a weak, square-integrable solution). This is Weyl's lemma (Section 2.1.4) for systems. In particular every eigenform is smooth.

2. *Discrete spectrum.* Δ_p has an orthonormal basis of eigenforms ω_j with eigenvalues $0 \le \lambda_0 \le \lambda_1 \le \cdots \to \infty$, each of *finite multiplicity*. The mechanism is the symbol: $\sigma_2 = |k|^2\, I$ grows in *every* direction of momentum space, so there are only finitely many modes below any energy (Weyl's law: roughly $\binom{n}{p}\,\mathrm{vol}(M)\,\lambda^{n/2}/(4\pi)^{n/2}\Gamma(\frac{n}{2}+1)$ of them below λ). Compare the Lorentzian torus of the pitfall above, where the symbol $n^2 - m^2$ vanishes along the light cone and infinitely many modes sit at zero.

3. *A spectral gap.* In particular $\operatorname{Ker}\Delta_p = \mathcal{H}^p$ is finite-dimensional, and the smallest *non-zero* eigenvalue λ_* is strictly positive.

With these facts, let $P_{\mathcal{H}}$ be the orthogonal projection onto $\mathcal{H}^p$ and define the **Green's operator** G by inverting Δ_p on the orthogonal complement of its kernel:

$$G\,\omega_j \;=\; \begin{cases} \lambda_j^{-1}\,\omega_j, & \lambda_j > 0, \\ 0, & \lambda_j = 0. \end{cases} \qquad \text{so} \qquad \Delta_p G \;=\; G\Delta_p \;=\; 1 - P_{\mathcal{H}}. \tag{2.106}$$

The gap makes G bounded ($\|G\| \le 1/\lambda_*$), and regularity makes it map smooth forms to smooth forms. (In physics language: G is the propagator with the zero modes removed, just as one

removes zero modes before inverting the fluctuation operator in an instanton calculation.) Now every form splits in one line. For any $\omega \in \Omega^p(M)$,

$$\omega \overset{(1)}{=} P_{\mathcal{H}}\omega + \Delta_p G\omega \overset{(2)}{=} P_{\mathcal{H}}\omega + \mathrm{d}\big(\mathrm{d}^* G\omega\big) + \mathrm{d}^*\big(\mathrm{d}G\omega\big). \tag{2.107}$$

(1) (2.106): $1 = P_{\mathcal{H}} + \Delta_p G$.
(2) The definition $\Delta_p = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$.

The three pieces are harmonic, exact and *co-exact* (in the image of d^*).

Key idea: The Hodge decomposition

On a compact closed Riemannian manifold, every p-form splits uniquely and orthogonally as

$$\Omega^p(M) \;=\; \mathcal{H}^p(M) \;\oplus\; \mathrm{d}\Omega^{p-1}(M) \;\oplus\; \mathrm{d}^*\Omega^{p+1}(M), \qquad \omega \;=\; h + \mathrm{d}\beta + \mathrm{d}^*\gamma, \tag{2.108}$$

with $h = P_{\mathcal{H}}\omega$, $\beta = \mathrm{d}^* G\omega$, $\gamma = \mathrm{d}G\omega$. The closed forms are exactly $\mathcal{H}^p \oplus \mathrm{d}\Omega^{p-1}$.

Why the pieces are orthogonal. For any $h \in \mathcal{H}^p$, $\beta \in \Omega^{p-1}$, $\gamma \in \Omega^{p+1}$:

$$\langle \mathrm{d}\beta, \mathrm{d}^*\gamma\rangle \overset{(1)}{=} \langle \mathrm{d}\mathrm{d}\beta, \gamma\rangle = 0, \qquad \langle h, \mathrm{d}\beta\rangle \overset{(2)}{=} \langle \mathrm{d}^* h, \beta\rangle = 0, \qquad \langle h, \mathrm{d}^*\gamma\rangle \overset{(3)}{=} \langle \mathrm{d}h, \gamma\rangle = 0.$$

(1) Move d^* across as d; then $\mathrm{d}\circ\mathrm{d} = 0$.
(2) Move d across; $\mathrm{d}^* h = 0$ because h is harmonic.
(3) Move d^* across; $\mathrm{d}h = 0$ because h is harmonic.

Orthogonal subspaces meet only in 0, which gives uniqueness of the splitting.

Why closed forms have no co-exact part. Let α be closed with decomposition $\alpha = h + \mathrm{d}\beta + \mathrm{d}^*\gamma$. Apply d: $0 = \mathrm{d}\alpha = \mathrm{d}\mathrm{d}^*\gamma$ (as $\mathrm{d}h = 0$ and $\mathrm{d}\mathrm{d}\beta = 0$). Then

$$\|\mathrm{d}^*\gamma\|^2 \overset{(1)}{=} \langle \mathrm{d}^*\gamma, \mathrm{d}^*\gamma\rangle \overset{(2)}{=} \langle \gamma, \mathrm{d}\mathrm{d}^*\gamma\rangle \overset{(3)}{=} 0,$$

(1) Definition of the norm.
(2) Move the first d^* across as d.
(3) $\mathrm{d}\mathrm{d}^*\gamma = \mathrm{d}\alpha = 0$.

so $\mathrm{d}^*\gamma = 0$ and $\alpha = h + \mathrm{d}\beta$. That is surjectivity of (2.104): $[\alpha] = [h]$ with h harmonic. Together with injectivity, this proves Hodge's theorem, modulo the three analytic facts supplied by ellipticity.

The picture also explains the minimisation: since $h \perp \mathrm{d}\beta$, $\|h + \mathrm{d}\beta\|^2 = \|h\|^2 + \|\mathrm{d}\beta\|^2 \geq \|h\|^2$, with equality only at $\mathrm{d}\beta = 0$. The harmonic representative is the *foot of the perpendicular* from the origin to the class.

Dictionary: Hodge decomposition in physics

- In $\mathbb{R}^3$ ($p = 1$, suitably decaying fields): the **Helmholtz decomposition** $\vec{A} = \nabla\phi + \nabla\times\vec{C}$ is $\mathrm{d}\beta + \mathrm{d}^*\gamma$ (longitudinal + transverse). On a compact space a third, harmonic, piece appears.
- On a torus T^3 (a box with periodic boundary conditions, as in lattice gauge theory), $\vec{A} = \vec{a} + \nabla\phi + \nabla\times\vec{C}$, where $\vec{a}$ is a *constant* vector: the zero-momentum mode, which is neither a gradient nor a curl of a periodic field.

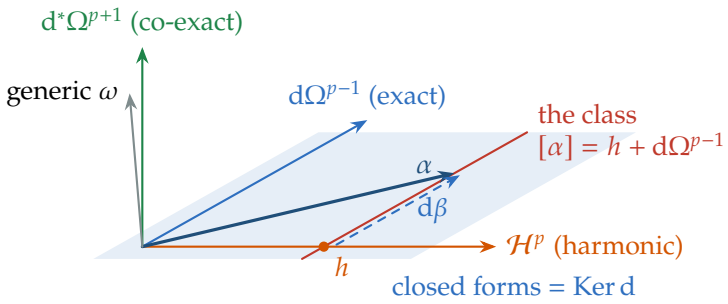

Figure 2.22: The Hodge decomposition (2.108), drawn as three orthogonal axes (each really an infinite-dimensional space, except $\mathcal{H}^p$, which is finite-dimensional). The closed forms fill the shaded plane spanned by the harmonic and exact directions; a generic form (grey) sticks out of it into the co-exact direction. A cohomology class is a line (red) parallel to the exact axis. It meets the harmonic axis in exactly one point h, the harmonic representative, which is also the point of the line closest to the origin: the minimum-energy member of the class.

- In Maxwell theory the three pieces are: the pure-gauge part $\mathrm{d}\beta$, removed by gauge fixing; the transverse photons $\mathrm{d}^*\gamma$; and the harmonic part, the topological "zero modes" (constant potentials whose Wilson loops around the cycles of M are gauge invariant).

2.3.13 A finite-dimensional model: Hodge theory on a triangle

Everything above is linear algebra, except the analysis that guarantees the infinite-dimensional spaces behave. So we can watch Hodge's theorem work *exactly* in a finite-dimensional model, where the analysis is trivial. Replace the circle by a triangle: three vertices v_1, v_2, v_3 and three oriented edges $e_1 = v_1 \to v_2$, $e_2 = v_2 \to v_3$, $e_3 = v_3 \to v_1$ (Figure 2.23).

- A "0-form" is a function on vertices, $f = (f_1, f_2, f_3) \in \mathbb{R}^3$.
- A "1-form" (a **cochain**) assigns a number to each edge, $a = (a_1, a_2, a_3) \in \mathbb{R}^3$: think of a_j as $\int_{e_j} a$.
- The "exterior derivative" is the discrete Stokes theorem: $(\mathrm{d}f)(e) = f(\text{head}) - f(\text{tail})$.

So $\mathrm{d}f = (f_2 - f_1,\ f_3 - f_2,\ f_1 - f_3)$, and with the standard inner products on $\mathbb{R}^3$,

$$\mathrm{d} = \begin{pmatrix} -1 & 1 & 0 \\ 0 & -1 & 1 \\ 1 & 0 & -1 \end{pmatrix}, \qquad \mathrm{d}^* = \mathrm{d}^T = \begin{pmatrix} -1 & 0 & 1 \\ 1 & -1 & 0 \\ 0 & 1 & -1 \end{pmatrix}. \tag{2.109}$$

There are no 2-cells, so d on 1-forms is zero and every 1-cochain is "closed".

Worked example 2.39: The discrete Laplacians and their zero modes

The two Laplacians are $\Delta_0 = \mathrm{d}^*\mathrm{d} = \mathrm{d}^T\mathrm{d}$ (on vertices) and $\Delta_1 = \mathrm{d}\mathrm{d}^* = \mathrm{d}\,\mathrm{d}^T$ (on edges; the other term $\mathrm{d}^*\mathrm{d}$ vanishes since $\mathrm{d} = 0$ on 1-forms). Multiply out:

$$\Delta_0 \overset{(1)}{=} \begin{pmatrix} -1 & 0 & 1 \\ 1 & -1 & 0 \\ 0 & 1 & -1 \end{pmatrix}\begin{pmatrix} -1 & 1 & 0 \\ 0 & -1 & 1 \\ 1 & 0 & -1 \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{pmatrix},$$

$$\Delta_1 \overset{(3)}{=} \begin{pmatrix} -1 & 1 & 0 \\ 0 & -1 & 1 \\ 1 & 0 & -1 \end{pmatrix} \begin{pmatrix} -1 & 0 & 1 \\ 1 & -1 & 0 \\ 0 & 1 & -1 \end{pmatrix} \overset{(4)}{=} \begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{pmatrix}.$$

(1) $\Delta_0 = \mathrm{d}^T \mathrm{d}$ with the matrices (2.109).

(2) Row times column: e.g. the $(1,1)$ entry is $(-1)(-1) + 0 + (1)(1) = 2$ and the $(1,2)$ entry is $(-1)(1) + 0 + (1)(0) = -1$. This is the **graph Laplacian**: degree on the diagonal, -1 for each neighbour. It is the finite-difference version of $-\partial_\theta^2$, $-(f_{j+1} - 2f_j + f_{j-1})$.

(3) $\Delta_1 = \mathrm{d}\,\mathrm{d}^T$.

(4) Row times column again; e.g. the $(1,2)$ entry pairs edge e_1 with edge e_2, which share the vertex v_2 with opposite orientations, giving -1.

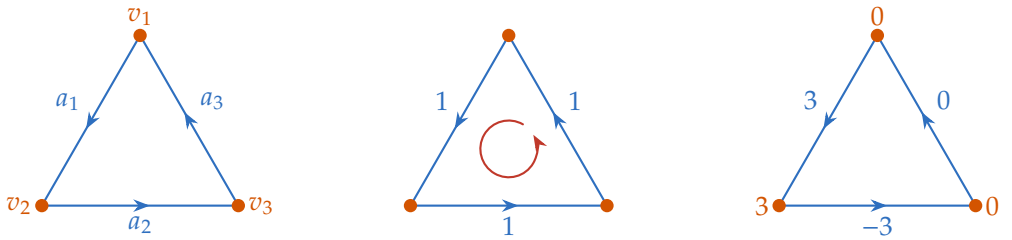
Both matrices are $3I - J$, where J is the all-ones matrix. J has eigenvalues 3 (on $(1,1,1)$) and 0 (twice, on vectors with zero sum), so both Laplacians have spectrum $\{0,3,3\}$. The zero modes:

- $\operatorname{Ker}\Delta_0 = \mathbb{R}(1,1,1)$: the *constant* functions. So $b_0 = 1$: the triangle is connected.
- $\operatorname{Ker}\Delta_1 = \mathbb{R}(1,1,1)$: the cochain assigning 1 to every edge. This is the discrete $\mathrm{d}\theta$, a uniform circulation around the loop. So $b_1 = 1$: the triangle has one hole.

Now check Hodge's theorem directly. The exact cochains are $\operatorname{Im}\mathrm{d} = \{a : a_1 + a_2 + a_3 = 0\}$, a plane (the sum telescopes: $(f_2 - f_1) + (f_3 - f_2) + (f_1 - f_3) = 0$). All cochains are closed, so $H^1 = \mathbb{R}^3/\operatorname{Im}\mathrm{d} \cong \mathbb{R}$, the isomorphism being the total circulation $a \mapsto a_1 + a_2 + a_3$ (the discrete $\oint a$). The harmonic line $\mathbb{R}(1,1,1)$ is *orthogonal* to the exact plane, and meets each class (each plane $a_1 + a_2 + a_3 = c$) in exactly one point, $\frac{c}{3}(1,1,1)$. That is Figure 2.22 with actual numbers. For instance

$$a = (5,-1,2) \;=\; \underbrace{(2,2,2)}_{\text{harmonic}} + \underbrace{(3,-3,0)}_{\text{exact}}, \qquad (3,-3,0) = \mathrm{d}f \;\text{ with }\; f = (0,3,0),$$

and the harmonic part has the same circulation, 6, as a.



cochain $a = (a_1, a_2, a_3)$ on the edges

harmonic: $(1,1,1)$, circulation 3

exact: $\mathrm{d}f$, $f = (0,3,0)$, circulation 0

Figure 2.23: Hodge theory on a triangle, the discrete circle of Example 2.39. Left: the data (numbers on oriented edges). Middle: the unique harmonic cochain up to scale, a uniform circulation around the hole (red arrow); it is the discrete $\mathrm{d}\theta$. Right: an exact cochain, the differences of a vertex function (orange), with zero circulation. Every cochain is uniquely a multiple of the middle one plus one of the right kind.

Try it: A square instead of a triangle

Do the same for a square with four vertices and four edges in a cycle. *Answer*: Δ_0 and Δ_1 are both the 4×4 cycle Laplacian with 2 on the diagonal and -1 for the two neighbours. Its eigenvalues are $2-2\cos(2\pi j/4) = 0,2,4,2$ ($j=0,1,2,3$), with the zero mode $(1,1,1,1)$ in both degrees. Again $b_0 = b_1 = 1$. With N vertices the eigenvalues are $2-2\cos(2\pi j/N) \approx (2\pi j/N)^2$ for small j: after rescaling by $N^2/(2\pi)^2$ they converge to j^2, the spectrum of $-\partial_\theta^2$ on the circle. The discrete model becomes the smooth one.

2.3.14 Examples of Hodge's theorem

Worked example 2.40: The circle: zero modes, spectrum and pairing

Take $M = S^1$ with coordinate $\theta \in [0,2\pi)$ and the round metric $\mathrm{d}\theta^2$. Then $\star 1 = \mathrm{d}\theta$ and $\star \mathrm{d}\theta = 1$. On functions and on 1-forms $f\,\mathrm{d}\theta$,

$$\Delta_0 u \overset{(1)}{=} \mathrm{d}^*\mathrm{d}u \overset{(2)}{=} -u'', \qquad \Delta_1(f\,\mathrm{d}\theta) \overset{(3)}{=} \mathrm{d}\mathrm{d}^*(f\,\mathrm{d}\theta) \overset{(4)}{=} -f''\,\mathrm{d}\theta.$$

(1) On 0-forms $\mathrm{d}^* = 0$, so only $\mathrm{d}^*\mathrm{d}$ survives.
(2) $\mathrm{d}u = u'\mathrm{d}\theta$, and on 1-forms in dimension $n=1$ the sign in (2.86) is $(-1)^{1+1+1} = -1$, so $\mathrm{d}^*(u'\mathrm{d}\theta) = -\star\,\mathrm{d}\star(u'\mathrm{d}\theta) = -\star\,\mathrm{d}u' = -\star(u''\mathrm{d}\theta) = -u''$.
(3) On 1-forms (top degree) $\mathrm{d} = 0$, so only $\mathrm{d}\mathrm{d}^*$ survives.
(4) $\mathrm{d}^*(f\mathrm{d}\theta) = -f'$ by the same computation, and $\mathrm{d}(-f') = -f''\mathrm{d}\theta$.

The eigenforms are Fourier modes: $\Delta_0 e^{in\theta} = n^2 e^{in\theta}$ and $\Delta_1(e^{in\theta}\mathrm{d}\theta) = n^2 e^{in\theta}\mathrm{d}\theta$. The kernels are the $n=0$ modes,

$$\operatorname{Ker}\Delta_0 = \{\text{constants}\}, \qquad \operatorname{Ker}\Delta_1 = \{c\,\mathrm{d}\theta\},$$

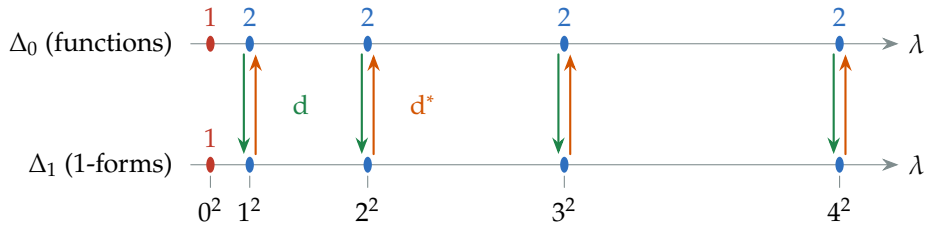
so $b_0 = b_1 = 1$, in agreement with the cohomology of the circle (Chapter T2): $\mathrm{d}\theta$ is closed but not exact, since $\oint \mathrm{d}\theta = 2\pi \neq 0$.
The Hodge decomposition of a 1-form $f(\theta)\,\mathrm{d}\theta$ is its Fourier split into the zero mode and the rest. Let $\bar f = \frac{1}{2\pi}\oint f\,\mathrm{d}\theta$ be the average. Then

$$f\,\mathrm{d}\theta \;=\; \underbrace{\bar f\,\mathrm{d}\theta}_{\text{harmonic}} \;+\; \underbrace{\mathrm{d}g}_{\text{exact}}, \qquad g(\theta) = \int_0^\theta \big(f(s)-\bar f\big)\,\mathrm{d}s,$$

and g is periodic precisely because we subtracted the average. (There is no co-exact part: there are no 2-forms on a circle.) The harmonic part carries all the "flux": $\oint f\mathrm{d}\theta = 2\pi\bar f$.
Finally, notice the *pairing* of the non-zero modes (Figure 2.24). The map d sends the eigenfunction $e^{in\theta}$ of Δ_0 to $in\,e^{in\theta}\mathrm{d}\theta$, an eigenform of Δ_1 with the same eigenvalue n^2; and d^* goes back. For $n\neq 0$ this is a bijection between eigenspaces. Only the zero modes are unpaired: d kills the constants, and d^* kills $\mathrm{d}\theta$. Hence

$$\dim\operatorname{Ker}\Delta_0 - \dim\operatorname{Ker}\Delta_1 \;=\; 1-1 \;=\; 0 \;=\; \chi(S^1),$$

the Euler characteristic. This is the first glimpse of the index theorem of Chapter 4: the non-zero spectrum cancels in pairs, and only topology survives.



non-zero modes paired by d, d*; zero modes (red) unpaired: $\dim\operatorname{Ker}\Delta_0 - \dim\operatorname{Ker}\Delta_1 = \chi(S^1) = 0$

Figure 2.24: The spectra of Δ_0 and Δ_1 on the round circle. Each dot is an eigenvalue n^2; the number above it is its multiplicity ($e^{\pm in\theta}$, or $\cos n\theta$ and $\sin n\theta$). The exterior derivative (green) and its adjoint (orange) map the λ-eigenspace of one Laplacian isomorphically onto that of the other whenever $\lambda \neq 0$. Only the zero modes are left over, and they count the cohomology: $b_0 = b_1 = 1$. Ellipticity is visible as the discreteness of the spectrum and the gap between 0 and the first non-zero eigenvalue.

Worked example 2.41: A lumpy circle: the harmonic form moves, its count does not

Now give S^1 a non-uniform metric $g = h(\theta)^2\,\mathrm{d}\theta^2$ with $h > 0$ smooth and periodic, for example $h = 1 + \frac{1}{2}\cos\theta$. The total length is $\ell = \oint h\,\mathrm{d}\theta$. The oriented orthonormal coframe is $e = h\,\mathrm{d}\theta$ (the arc-length element $\mathrm{d}s$), so

$$\star 1 = e = h\,\mathrm{d}\theta, \qquad \star e = 1 \;\Rightarrow\; \star\mathrm{d}\theta = \frac{1}{h}.$$

Harmonic 1-forms. Every 1-form $\omega = f\,\mathrm{d}\theta$ is closed (top degree). Co-closed means

$$0 \;=\; \mathrm{d}^*\omega \overset{(1)}{=} -\star\,\mathrm{d}\,\star\,(f\,\mathrm{d}\theta) \overset{(2)}{=} -\star\,\mathrm{d}\Big(\frac{f}{h}\Big) \overset{(3)}{=} -\frac{1}{h}\Big(\frac{f}{h}\Big)',$$

(1) (2.86) with $n = p = 1$: sign -1.
(2) $\star(f\,\mathrm{d}\theta) = f\,\star\mathrm{d}\theta = f/h$.
(3) $\mathrm{d}(f/h) = (f/h)'\mathrm{d}\theta$ and $\star\mathrm{d}\theta = 1/h$.

So f/h is constant: the harmonic 1-forms are $\omega = c\,h\,\mathrm{d}\theta = c\,\mathrm{d}s$. The harmonic form *has changed*: it is no longer $\mathrm{d}\theta$, it is the arc-length form, largest where the circle is most stretched. But the space of harmonic 1-forms is still one-dimensional, $b_1 = 1$.
Harmonic functions. $\Delta_0 u = \mathrm{d}^*\mathrm{d}u = -\frac{1}{h}\big(\frac{u'}{h}\big)'$ by the same steps. Its zero modes satisfy $u'/h = a$, i.e. $u(\theta) = a\,s(\theta) + b$ with $s(\theta) = \int_0^\theta h$. Periodicity, $u(2\pi) = u(0)$, forces $a\ell = 0$, so $a = 0$: only constants, $b_0 = 1$. (Here compactness entered: on the line the non-constant solution $a\,s$ would be allowed.)
The harmonic representative of a class. Given any 1-form $f\,\mathrm{d}\theta$ with period $P = \oint f\mathrm{d}\theta$, its harmonic representative is $\frac{P}{\ell}\,h\,\mathrm{d}\theta$: it is the unique harmonic form with the same period. The difference $\big(f - \frac{P}{\ell}h\big)\mathrm{d}\theta$ has zero period, hence is $\mathrm{d}g$ for a periodic g. Figure 2.25 plots this.

Worked example 2.42: The flat torus T^n: harmonic forms are constant forms

Let $T^n = \mathbb{R}^n/(2\pi\mathbb{Z})^n$ with the flat metric. In the flat coordinates the basis forms $\mathrm{d}x^I = \mathrm{d}x^{i_1}\wedge\cdots\wedge\mathrm{d}x^{i_p}$ are parallel, and the computation of Example 2.32 generalises verbatim:

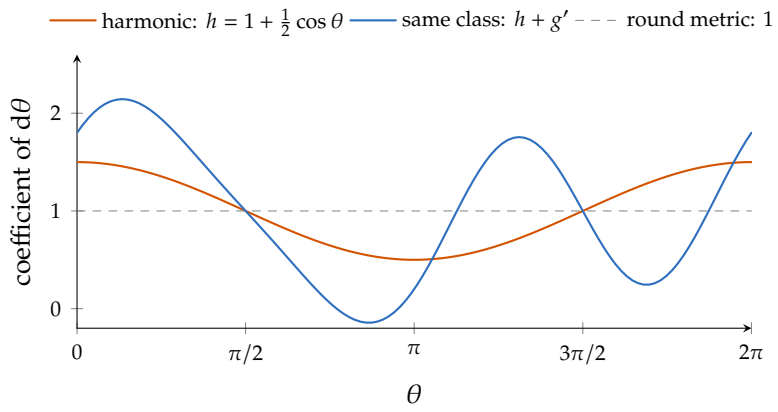


Figure 2.25: The lumpy circle of Example 2.41, with metric $h(\theta)^2 d\theta^2$ and $h = 1 + \frac{1}{2}\cos\theta$. The orange curve is the coefficient of its harmonic 1-form $h\,d\theta$ (the arc-length form); for the round metric it would be the flat dashed line. The blue curve is another closed form in the same class, $h\,d\theta + dg$ with $g = -0.4\cos 2\theta + 0.1\sin 3\theta$: it has the same area under it (the same period 2π), but is not co-closed. Changing the metric moves the harmonic representative, but there is always exactly one per class.

Δ_p acts on each component as $-\nabla^2$,

$$\Delta_p\Big(\sum_I \omega_I\,dx^I\Big) = \sum_I \big(-\nabla^2\omega_I\big)\,dx^I.$$

Expand each component in Fourier modes, $\omega_I = \sum_{m\in\mathbb{Z}^n} c_{I,m} e^{im\cdot x}$. Then

$$\Delta_p\omega = 0 \overset{(1)}{\iff} \sum_{I,m} |m|^2\, c_{I,m}\, e^{im\cdot x} dx^I = 0 \overset{(2)}{\iff} c_{I,m} = 0 \text{ for all } m \neq 0.$$

(1) $-\nabla^2 e^{im\cdot x} = |m|^2 e^{im\cdot x}$: here the symbol $|k|^2$ is literally the eigenvalue, with $k = m$ restricted to the lattice.

(2) The functions $e^{im\cdot x}dx^I$ are linearly independent; $|m|^2 \neq 0$ unless $m = 0$.

So the harmonic p-forms are exactly the forms with *constant* coefficients, and there are $\binom{n}{p}$ independent ones:

$$b_p(T^n) = \binom{n}{p}, \qquad \sum_p b_p\, t^p = (1+t)^n.$$

For T^2: $b = (1, 2, 1)$, with harmonic forms $1;\ dx, dy;\ dx\wedge dy$. The two harmonic 1-forms are dual to the two independent loops. (Compare the discrete model: the constant cochain is the harmonic one.) For a *non-rectangular* flat torus, or a curved metric on T^2, the harmonic forms change, but by (2.105) there are still $1, 2, 1$ of them.

Dictionary: Flat connections and Wilson lines on a torus

A harmonic 1-form on T^2, $A = a\,dx + b\,dy$ with constant a, b, is a U(1) gauge potential with $F = dA = 0$ and $d^*A = 0$: a *flat connection in Lorenz gauge*. It is not pure gauge: its Wilson loops around the two cycles, $W_x = \exp\big(ie\oint_x A\big) = e^{2\pi iea}$ and $W_y = e^{2\pi ieb}$ (physicists' Hermitian convention, charge e), are gauge-invariant and non-trivial. Gauge transformations $e^{ie\chi}$ with $\chi = nx/e$, single-valued as e^{inx}, shift $a \mapsto a + n/e$. So the

space of flat connections modulo gauge transformations is the torus $(a, b) \in (\mathbb{R}/\frac{1}{e}\mathbb{Z})^2$, of dimension $b_1(T^2) = 2$. In general the harmonic 1-forms are the tangent space to the moduli space of flat U(1) connections, which has dimension $b_1(M)$. These are the Aharonov–Bohm phases of the manifold. (Conventions for anti-Hermitian gauge fields are in Chapter T3: $A_{\text{math}} = -ieA_{\text{phys}}$.)

Worked example 2.43: The 2-sphere, and the Dirac monopole as a harmonic form

Take S^2 with the round metric $\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2$ and area form $\mathrm{vol} = \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi = \star 1$.

- $p = 0$. If $\Delta_0 u = 0$ then $\|\mathrm{d}u\|^2 = 0$ by (2.102), so u is constant. $b_0 = 1$. (In terms of spherical harmonics: $\Delta_0 Y_{lm} = l(l+1)Y_{lm}$, and only $l = 0$ is a zero mode.)
- $p = 2$. By the duality below, $\star$ maps $\mathcal{H}^0$ to $\mathcal{H}^2$, so the harmonic 2-forms are $c\,\mathrm{vol}$. Check directly: $\mathrm{d}(c\,\mathrm{vol}) = 0$ (a 3-form on a surface) and $\mathrm{d}^*(c\,\mathrm{vol}) = \pm\star\,\mathrm{d}\star(c\,\mathrm{vol}) = \pm\star\,\mathrm{d}c = 0$. $b_2 = 1$.
- $p = 1$. A harmonic 1-form ω is closed. On S^2 every closed 1-form is exact (every loop can be shrunk, so the integral of ω from a base point is path-independent; see Chapter T2). So $\omega = \mathrm{d}u$ is harmonic and exact, and the "at most one" argument gives $\omega = 0$. $b_1 = 0$.

So $(b_0, b_1, b_2) = (1, 0, 1)$ and $\chi(S^2) = 1 - 0 + 1 = 2$.
Now the physics. The field of a magnetic monopole of strength g at the origin of $\mathbb{R}^3$ is $\vec{B} = \frac{g}{4\pi}\frac{\hat{r}}{r^2}$; restricted to the unit sphere its flux 2-form is

$$F \;=\; \frac{g}{4\pi}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi \;=\; \frac{g}{4\pi}\,\mathrm{vol}, \qquad \int_{S^2} F = g.$$

This is *the* harmonic 2-form with flux g. The source-free Maxwell equations on a closed surface, $\mathrm{d}F = 0$ and $\mathrm{d}^*F = 0$, are exactly harmonicity (2.103). So Hodge's theorem says: *on a compact space, source-free static field strengths are classified by their fluxes, one field for each value of the flux*. For the monopole, Dirac quantisation $eg \in 2\pi\mathbb{Z}$ makes the class $[\frac{e}{2\pi}F]$ integral: it is the first Chern class of the monopole bundle, with harmonic representative $\frac{eg}{8\pi^2}\mathrm{vol}$.

Two consequences: Poincaré duality and the Euler characteristic

The Hodge star preserves harmonicity. Let ω be a harmonic p-form. Using $\mathrm{d}^* = \pm\star\,\mathrm{d}\star$ and $\star\star = \pm 1$ (the signs do not matter for vanishing):

$$\mathrm{d}^*(\star\omega) \overset{(1)}{=} \pm\star\,\mathrm{d}\star\star\omega \overset{(2)}{=} \pm\star\,\mathrm{d}\omega \overset{(3)}{=} 0,$$
$$\mathrm{d}(\star\omega) \overset{(4)}{=} \pm\star\star\mathrm{d}\star\,\omega \overset{(5)}{=} \pm\star\;\mathrm{d}^*\omega \overset{(6)}{=} 0.$$

(1) (2.86) applied to the $(n-p)$-form $\star\omega$.
(2) $\star\star\,\omega = \pm\omega$ by (2.84).
(3) ω is closed.
(4) Insert $1 = \pm\star\star$ in front of the $(n-p+1)$-form $\mathrm{d}\star\omega$.
(5) $\star\mathrm{d}\star\,\omega = \pm\mathrm{d}^*\omega$ by (2.86).
(6) ω is co-closed.

So $\star : \mathcal{H}^p \to \mathcal{H}^{n-p}$, and it is invertible ($\star\star = \pm 1$). With (2.105):

$$b_p \;=\; b_{n-p} \qquad (\textbf{Poincaré duality}). \tag{2.110}$$

A purely topological statement, proved with a metric. The metric is a tool, and the answer does not depend on the tool. We saw it in every example: $(1,1)$ for S^1, $(1,2,1)$ for T^2, $(1,0,1)$ for S^2, and $\binom{n}{p} = \binom{n}{n-p}$ for T^n. It requires M to be *oriented* (so that $\star$ exists globally).

The Euler characteristic. The alternating sum of the Betti numbers is the Euler characteristic, and by (2.105)

$$\chi(M) \;=\; \sum_{p=0}^{n} (-1)^p b_p \;=\; \sum_{p=0}^{n} (-1)^p \dim \operatorname{Ker} \Delta_p \;=\; \dim \operatorname{Ker} \Delta_{\text{ev}} - \dim \operatorname{Ker} \Delta_{\text{odd}}. \tag{2.111}$$

The last expression is the index of the elliptic operator $\mathrm{d} + \mathrm{d}^* : \Omega^{\text{ev}} \to \Omega^{\text{odd}}$ of Example 2.37: its kernel is $\bigoplus_p \mathcal{H}^{2p}$, because $\|(\mathrm{d}+\mathrm{d}^*)\omega\|^2 = \|\mathrm{d}\omega\|^2 + \|\mathrm{d}^*\omega\|^2 + 2\langle \mathrm{d}\omega, \mathrm{d}^*\omega\rangle$ and the cross term is $2\langle \mathrm{dd}\omega, \omega\rangle = 0$, so $(\mathrm{d}+\mathrm{d}^*)\omega = 0$ forces $\mathrm{d}\omega = \mathrm{d}^*\omega = 0$, and the kernel of its adjoint is $\bigoplus_p \mathcal{H}^{2p+1}$. In odd dimensions Poincaré duality pairs b_p with b_{n-p} of opposite parity, so $\chi = 0$; for S^1 we found this by pairing eigenvalues in Figure 2.24.

Generalisations

Nash closes the section by noting that Hodge's theorem "generalises to include cases where the exterior derivative d is replaced by other differential operators". The recipe is the one of Definition 2.20: take an *elliptic complex* $\Gamma(E_0) \xrightarrow{D_0} \Gamma(E_1) \xrightarrow{D_1} \cdots$. Its cohomology $H^p = \operatorname{Ker} D_p / \operatorname{Im} D_{p-1}$ is isomorphic to the kernel of the Laplacian $\Delta_p = D_{p-1}D_{p-1}^* + D_p^* D_p$, by exactly the arguments above:

- the energy identity $\langle \omega, \Delta_p \omega\rangle = \left\| D_{p-1}^* \omega \right\|^2 + \left\| D_p \omega \right\|^2$ gives $\operatorname{Ker} \Delta_p = \operatorname{Ker} D_p \cap \operatorname{Ker} D_{p-1}^*$;
- ellipticity of Δ_p (equivalent to exactness of the symbol sequence, by the key idea of Section 2.3.11) gives a discrete spectrum, a finite-dimensional kernel and a Green's operator, hence a Hodge decomposition.

In particular the cohomology of an elliptic complex on a compact manifold is *finite-dimensional*. Examples we shall meet:

- the **Dolbeault complex** $\bar\partial : \Omega^{p,q} \to \Omega^{p,q+1}$ on a complex manifold, whose symbol is built from the Cauchy–Riemann symbol of Section 2.2.10; its harmonic forms compute the sheaf cohomology of Chapters 3 and 5;
- the **spin complex**, the Dirac operator $\not{D} : \Gamma(S^+) \to \Gamma(S^-)$ of Example 2.30, whose zero modes are the fermion zero modes of anomalies (Chapter 10);
- the **instanton deformation complex** of Example 2.38, whose first cohomology is the tangent space to the instanton moduli space (Chapter 8).

In all of them the index, the alternating sum of the dimensions of the cohomology groups, is topological. That is the subject of Chapter 4.

Reading Nash (§3, pp. 36–41, (2.38)–(2.53))

- pp. 36–37, (2.38)–(2.41) and footnote 4: operators $L : \Gamma(M, U) \to \Gamma(M, V)$ between bundles of ranks q, p; locally a $p \times q$ matrix of operators, with a matrix symbol and leading symbol $\sigma_m(x, k) : U_x \to V_x$ depending on a covector k. Our Section 2.3. Nash's footnote says the local expression depends on the chart; we worked out how it transforms (frame changes act by conjugation, like gauge transformations).
- pp. 37–38: the global picture with $\pi : T^*M \to M$, the pull-back bundles π^*U, π^*V, and ellipticity as "σ_m is an isomorphism $\pi^*U \to \pi^*V$ off the zero section" (which forces $p = q$). We added the examples of curl, div–grad–curl, Cauchy–Riemann as a real system and the Dirac operator, with the winding of the symbol.
- p. 39, (2.42)–(2.44): the Hodge Laplacian $\Delta_p = (\mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d})_p$ and the summary (2.43) of inner product, adjoint and Hodge star. Our Section 2.3.7, where we derived the sign of $\mathrm{d}^* = (-1)^{np+n+1} \star \mathrm{d} \star$ from Stokes' theorem. Nash's formula for $\star\omega$ contains a factor $\sqrt{g}/(n-p)!$ and uses the sum-over-all-indices convention on the right; see (2.83) for our reading.
- pp. 39–40, (2.45)–(2.49): composition and adjoint rules for symbols, which Nash calls "easily verifiable"; our Section 2.3.8, with the oscillatory-test proof of (2.45), the integration-by-parts proof of (2.47) and the Poisson-bracket remark. His $\sigma_1(\mathrm{d}) = k\wedge$ lacks our factor i (pitfall in Section 2.3.9); his conclusion $\sigma_2(\Delta_p) = k^2 I$ (2.49) is unaffected. His "elementary calculation" is our identity (2.96).
- p. 40: "generalisations of the Laplacian ... by tensoring with another vector bundle E, and by studying ... Yang–Mills theories"; our Section 2.3.10, with gauge fixing of Maxwell theory. Nash does not discuss elliptic complexes here (they come in his Chapter IV); we previewed them in Section 2.3.11 because they explain why Δ_p is elliptic.
- pp. 40–41, (2.50)–(2.53): harmonic forms, Hodge's theorem, $\dim \operatorname{Ker} \Delta_p = b_p$, metric independence, and the remark that the theorem extends to other operators. Our Section 2.3.12. Nash cites Wells for the proof; we gave the injectivity argument in full, the variational argument for existence, and the Green's-operator proof of the Hodge decomposition, isolating the three analytic inputs that ellipticity provides.

Recap: Ellipticity and vector bundles

- An operator between bundles $U \to V$ is locally a matrix of differential operators. Its leading symbol $\sigma_m(x, k)$ is a matrix $U_x \to V_x$, depending on a covector $k \in T^*_x M$, polynomial of degree m in k. Globally it is a bundle map $\pi^*U \to \pi^*V$ over T^*M.
- *Elliptic*: $\sigma_m(x, k)$ is invertible for every $k \neq 0$. So U and V have equal rank. The curl and the Maxwell operator fail (longitudinal/gauge modes); the div–grad–curl operator, the Dirac operator and Δ_p pass.
- Symbol calculus: $\sigma(PQ) = \sigma(P)\sigma(Q)$ and $\sigma(L^*) = \sigma(L)^*$ at leading order. Then $\sigma(\mathrm{d}) = ik\wedge$, $\sigma(\mathrm{d}^*) = -i\iota_k$, and $\sigma(\Delta_p) = k \wedge \iota_k + \iota_k k\wedge = |k|^2 I$.
- The symbol sequence of the de Rham complex is exact for $k \neq 0$; this is the same fact as ellipticity of all the Δ_p, and makes de Rham an *elliptic complex*. Gauge theories are elliptic "modulo gauge" in exactly this sense.

- Harmonic forms: $\Delta_p\omega = 0 \iff \mathrm{d}\omega = 0 = \mathrm{d}^*\omega$ (energy argument, needs compactness and Riemannian signature). Hodge: each class of $H^p_{\mathrm{dR}}(M)$ contains exactly one harmonic form, the minimum-energy representative; $\dim \operatorname{Ker} \Delta_p = b_p$ for every metric.
- Behind the scenes, ellipticity gives regularity, a discrete spectrum and a spectral gap, hence a Green's operator and the Hodge decomposition $\Omega^p = \mathcal{H}^p \oplus \mathrm{d}\Omega^{p-1} \oplus \mathrm{d}^*\Omega^{p+1}$.
- Examples: S^1 $(1,1)$, lumpy S^1 (harmonic form = arc-length form), T^n $(\binom{n}{p})$, constant forms), S^2 $(1,0,1$; the monopole field is the harmonic 2-form), and the triangle, where it is all 3×3 matrices. Consequences: Poincaré duality $b_p = b_{n-p}$ and $\chi(M) = \operatorname{index}(\mathrm{d}+\mathrm{d}^*)$, the first index theorem.

2.4 Pseudo-differential operators

Here is the question this section answers. Differential operators are the operators of classical physics: ∇^2, $\partial_t - \nabla^2$, $\gamma^\mu\partial_\mu$. But the moment we try to *solve* an equation $Lu = f$, or build a Hamiltonian like $\sqrt{p^2+m^2}$, or regularise a determinant with ζ-functions, we meet operators that are *not* differential operators:

- the Green's operator $(-\nabla^2 + m^2)^{-1}$, which is an integral against the Yukawa potential $e^{-mr}/4\pi r$;
- the relativistic kinetic energy $\sqrt{-\nabla^2+m^2}$;
- the heat operator $e^{t\nabla^2}$, which smears a function out with a Gaussian;
- complex powers $(-\nabla^2+m^2)^{-s}$, whose traces are ζ-functions.

All four have one thing in common. In Fourier space each of them is simply *multiplication by a function of momentum*: $1/(p^2+m^2)$, $\sqrt{p^2+m^2}$, e^{-tp^2}, $(p^2+m^2)^{-s}$. A differential operator is multiplication by a *polynomial* in momentum. A **pseudo-differential operator** is what you get when you allow the polynomial to be replaced by any function that grows or decays like a power of momentum. That single move gives a class of operators that contains every differential operator, is closed under taking inverses (up to harmless errors), square roots and complex powers, and in which ellipticity has exactly the same meaning as before. This is the class in which the index theorem of Chapter 4 is naturally stated and proved.

Before we make the leap, we tie off the last result of the previous section, because it is the reason we care about kernels of elliptic operators at all.

2.4.1 Where we stand: Hodge's theorem and the question of kernels

Recall the setting at the end of the previous section. M is a compact Riemannian manifold without boundary, of dimension n. On p-forms we have the exterior derivative d, its adjoint d^* with respect to the L^2 inner product

$$\langle \omega, \nu\rangle = \int_M \omega \wedge \star\nu,$$

and the Hodge Laplacian

$$\Delta_p = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d} : \ \Omega^p(M) \to \Omega^p(M). \tag{2.112}$$

(See Chapter T1 for $\star$ and $\mathrm{d}^* = (-1)^{n(p+1)+1}\star\mathrm{d}\star$ in Riemannian signature.) A form with $\Delta_p\omega = 0$ is called **harmonic**.

Harmonic means closed and co-closed. Take the inner product of $\Delta_p\omega$ with ω itself:

$$\begin{aligned}\langle\omega, \Delta_p\omega\rangle &\overset{(1)}{=} \langle\omega, \mathrm{d}\mathrm{d}^*\omega\rangle + \langle\omega, \mathrm{d}^*\mathrm{d}\omega\rangle \\ &\overset{(2)}{=} \langle\mathrm{d}^*\omega, \mathrm{d}^*\omega\rangle + \langle\mathrm{d}\omega, \mathrm{d}\omega\rangle \\ &\overset{(3)}{=} \|\mathrm{d}^*\omega\|^2 + \|\mathrm{d}\omega\|^2 .\end{aligned} \tag{2.113}$$

(1) Definition (2.112) and linearity of the inner product.
(2) Move one d (resp. d^*) across the inner product; this is the defining property $\langle\alpha, \mathrm{d}\beta\rangle = \langle\mathrm{d}^*\alpha, \beta\rangle$ of the adjoint. No boundary terms appear because $\partial M = \varnothing$ (Stokes).
(3) Each term is the squared L^2 norm, which is ≥ 0 because the metric is positive definite.

If $\Delta_p\omega = 0$ the left side vanishes, so a sum of two non-negative numbers is zero and each vanishes:

$$\omega \in \operatorname{Ker}\Delta_p \iff \mathrm{d}\omega = 0 \ \text{ and } \ \mathrm{d}^*\omega = 0. \tag{2.114}$$

(The arrow $\Leftarrow$ is obvious from (2.112).) In particular a harmonic form is closed, so it defines a de Rham class $[\omega] \in H^p_{\mathrm{dR}}(M) = \operatorname{Ker}\mathrm{d}/\operatorname{Im}\mathrm{d}$.

Key idea: Hodge's theorem

On a compact Riemannian manifold without boundary, each de Rham class contains *exactly one* harmonic form. Hence

$$\dim\operatorname{Ker}\Delta_p = \dim H^p_{\mathrm{dR}}(M) = b_p, \tag{2.115}$$

the p-th Betti number. The left side needs a metric; the right side does not. So the *number* of zero modes of the Laplacian is a topological invariant, although the zero modes themselves change when we change the metric.

Why at most one? If ω and ω' are harmonic and in the same class, then $\omega - \omega' = \mathrm{d}\beta$ is exact and harmonic, hence co-closed: $\mathrm{d}^*\mathrm{d}\beta = 0$. Then $\|\mathrm{d}\beta\|^2 = \langle\beta, \mathrm{d}^*\mathrm{d}\beta\rangle = 0$, so $\omega = \omega'$. *Why at least one?* Given a closed α, we want to subtract the exact piece $\mathrm{d}\beta$ that minimises $\|\alpha - \mathrm{d}\beta\|^2$; the minimiser is orthogonal to all exact forms, i.e. co-closed. That the minimum is actually *attained* is an analytic statement: it needs the machinery of this part (Sobolev spaces, compactness, the Fredholm property). This is one reason Nash now turns to analysis.

Worked example 2.44: Harmonic forms on the circle and on the flat torus

Circle. Let $M = S^1$ with coordinate $\theta \in [0, 2\pi)$ and metric $\mathrm{d}\theta^2$. On functions $\Delta_0 f = -f''$, and on 1-forms $\Delta_1(f\,\mathrm{d}\theta) = -f''\,\mathrm{d}\theta$. Expanding $f = \sum_{n\in\mathbb{Z}} c_n e^{in\theta}$ gives $\Delta_0 f = \sum_n n^2 c_n e^{in\theta}$, which vanishes iff only $c_0 \neq 0$. So $\operatorname{Ker}\Delta_0 = \{\text{constants}\}$ and $\operatorname{Ker}\Delta_1 = \{c\,\mathrm{d}\theta\}$: $b_0 = b_1 = 1$.
Torus. Let $M = T^2 = \mathbb{R}^2/2\pi\mathbb{Z}^2$ with the flat metric $\mathrm{d}x^2 + \mathrm{d}y^2$. In flat coordinates $\star$ has constant coefficients, so Δ_p acts on each component of a form as $-(\partial_x^2 + \partial_y^2)$. A general 1-form is $\omega = f\,\mathrm{d}x + g\,\mathrm{d}y$ and

$$\begin{aligned}\Delta_1\omega &\overset{(1)}{=} -(\partial_x^2 + \partial_y^2)f\,\mathrm{d}x - (\partial_x^2 + \partial_y^2)g\,\mathrm{d}y \\ &\overset{(2)}{=} \sum_{k\in\mathbb{Z}^2} |k|^2 \left(f_k\,\mathrm{d}x + g_k\,\mathrm{d}y\right)e^{ik\cdot x},\end{aligned}$$

(1) Flat metric: $\mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d} = -\nabla^2$ componentwise (the Weitzenböck curvature term vanishes).
(2) Expand $f = \sum_k f_k e^{ik\cdot x}$, $g = \sum_k g_k e^{ik\cdot x}$ with $k = (k_1, k_2) \in \mathbb{Z}^2$ and use $-\nabla^2 e^{ik\cdot x} = |k|^2 e^{ik\cdot x}$.

The kernel is the $k = 0$ part: $\omega = a\,\mathrm{d}x + b\,\mathrm{d}y$ with constants a, b. Doing the same on 0- and 2-forms,

$$\operatorname{Ker}\Delta_0 = \{c\}, \qquad \operatorname{Ker}\Delta_1 = \{a\,\mathrm{d}x + b\,\mathrm{d}y\}, \qquad \operatorname{Ker}\Delta_2 = \{c\,\mathrm{d}x\wedge\mathrm{d}y\},$$

so $(b_0, b_1, b_2) = (1, 2, 1)$. The two harmonic 1-forms are dual to the two independent loops of Figure 2.26: $\oint_a \mathrm{d}x = 2\pi$, $\oint_a \mathrm{d}y = 0$, and so on. If we change the metric to a sheared lattice, the harmonic forms change (they are the constant forms in the new flat coordinates) but there are still exactly two of them.

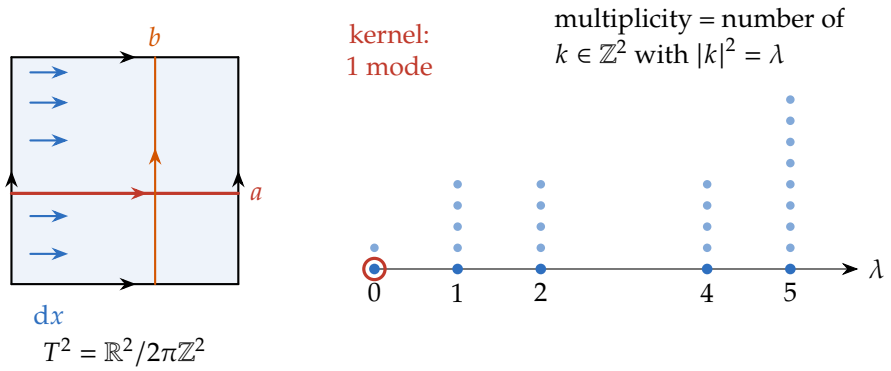

Figure 2.26: Left: the flat torus as a square with opposite sides glued. The constant form $\mathrm{d}x$ (blue arrows) integrates to 2π around the loop a and to 0 around b, so it detects a; $\mathrm{d}y$ detects b. These are the $b_1 = 2$ harmonic 1-forms. Right: the spectrum of Δ_0 on T^2. Eigenvalues are $|k|^2$, $k \in \mathbb{Z}^2$; the dots above each eigenvalue count its multiplicity $(1, 4, 4, 4, 8, \dots)$. The kernel (red circle) is one-dimensional: $b_0 = 1$. The spectrum is discrete and runs off to infinity; both features are consequences of ellipticity that we explain in Section 2.6.

Reading Nash (p. 41, (2.51)–(2.53))

Nash states Hodge's theorem without proof (referring to Wells) and remarks that "the whole question of kernels of elliptic operators is resumed in chapter 4". The finiteness of $\dim\operatorname{Ker}\Delta_p$ is not an accident of the Laplacian: every elliptic operator on a compact manifold has a finite-dimensional kernel. The purpose of §§4–5 is to set up the analysis (pseudo-differential operators, Sobolev spaces) that makes this statement precise. We come back to it in Section 2.6.

2.4.2 Differential operators are Fourier multipliers

We first fix conventions, because factors of 2π and signs in the exponent are the main source of confusion in this subject.

Dictionary: our Fourier conventions (used throughout this part)

On $\mathbb{R}^n$, with $x \cdot \xi = \sum_j x^j \xi_j$:

$$\hat{u}(\xi) = \int_{\mathbb{R}^n} e^{-ix\cdot\xi}\, u(x)\, \mathrm{d}^n x, \qquad u(x) = \int_{\mathbb{R}^n} e^{ix\cdot\xi}\, \hat{u}(\xi)\, \frac{\mathrm{d}^n \xi}{(2\pi)^n},$$
$$D_j = -i\,\frac{\partial}{\partial x^j}, \qquad D^\alpha = D_1^{\alpha_1}\cdots D_n^{\alpha_n},$$
$$\xi^\alpha = \xi_1^{\alpha_1}\cdots\xi_n^{\alpha_n}, \qquad \langle \xi \rangle = (1+|\xi|^2)^{1/2}.$$

Here $\alpha = (\alpha_1, \dots, \alpha_n)$ is a multi-index of non-negative integers with length $|\alpha| = \sum \alpha_j$. Physically, ξ is momentum in units $\hbar = 1$ and $D_j = -i\partial_j$ is the momentum operator $\hat{p}_j$. The **Laplacian** Δ always means the *positive* (geometer's) Laplacian:

$$\Delta = -\sum_j \frac{\partial^2}{\partial (x^j)^2} = -\nabla^2 = \sum_j D_j^2,$$

so that its eigenvalues are ≥ 0. A physicist's $-\nabla^2 + m^2$ is our $\Delta + m^2$.

The whole point of the Fourier transform is that a plane wave is an eigenfunction of every derivative:

$$D_j\, e^{ix\cdot\xi} = -i \cdot i\xi_j\, e^{ix\cdot\xi} = \xi_j\, e^{ix\cdot\xi}, \qquad D^\alpha e^{ix\cdot\xi} = \xi^\alpha e^{ix\cdot\xi}. \tag{2.116}$$

Now let $L = \sum_{|\alpha|\leq m} a_\alpha(x) D^\alpha$ be a differential operator of order m with smooth coefficients. Apply it to u written as a superposition of plane waves:

$$\begin{aligned} Lu(x) &\overset{(1)}{=} \sum_{|\alpha|\leq m} a_\alpha(x)\, D^\alpha \int e^{ix\cdot\xi} \hat{u}(\xi)\, \frac{\mathrm{d}^n\xi}{(2\pi)^n} \\ &\overset{(2)}{=} \sum_{|\alpha|\leq m} a_\alpha(x) \int \xi^\alpha e^{ix\cdot\xi} \hat{u}(\xi)\, \frac{\mathrm{d}^n\xi}{(2\pi)^n} \\ &\overset{(3)}{=} \int e^{ix\cdot\xi}\, \sigma(x,\xi)\, \hat{u}(\xi)\, \frac{\mathrm{d}^n\xi}{(2\pi)^n}, \qquad \sigma(x,\xi) \coloneqq \sum_{|\alpha|\leq m} a_\alpha(x)\xi^\alpha. \end{aligned} \tag{2.117}$$

(1) Fourier inversion for u.
(2) Differentiate under the integral (fine for u in the Schwartz space, defined in Section 2.5.5) and use (2.116).
(3) Pull the finite sum inside the integral.

The polynomial $\sigma(x,\xi)$ is the **symbol** of L and its top-degree part $\sigma_m(x,\xi) = \sum_{|\alpha|=m} a_\alpha(x)\xi^\alpha$ is the **principal (leading) symbol**. Operationally: *replace every D_j by ξ_j, keeping the coefficients to the left.*

Worked example 2.45: Symbols of three familiar operators

(a) The Laplacian with mass. $\Delta + m^2 = \sum_j D_j^2 + m^2$, so $\sigma(\xi) = |\xi|^2 + m^2$ and $\sigma_2(\xi) = |\xi|^2$. This is the Euclidean propagator denominator $p^2 + m^2$.

(b) A variable-coefficient ODE. On $\mathbb{R}$ let $L = a(x)\dfrac{\mathrm{d}^2}{\mathrm{d}x^2} + b(x)\dfrac{\mathrm{d}}{\mathrm{d}x} + c(x)$. Write it in terms of $D = -i\,\mathrm{d}/\mathrm{d}x$:

$$L \overset{(1)}{=} a(x)(iD)^2 + b(x)(iD) + c(x)$$

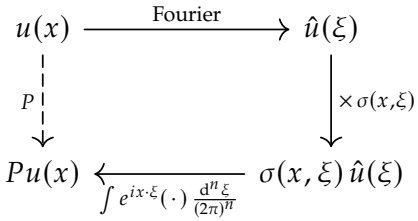

Figure 2.27: The Fourier-multiplier picture of an operator. Go to momentum space, multiply by the symbol, come back. For a differential operator the symbol is a polynomial in ξ; a pseudo-differential operator is anything that fits this diagram with a symbol that behaves like a power of $|\xi|$ at large momentum. When σ depends on x the right-hand arrow is not a "multiplication in momentum space" in the strict sense, but the formula still makes sense: at each x we weight each plane wave by $\sigma(x,\xi)$.

$$\overset{(2)}{=} -a(x)D^2 + i\,b(x)D + c(x),$$

(1) $\mathrm{d}/\mathrm{d}x = iD$ because $D = -i\,\mathrm{d}/\mathrm{d}x$.
(2) $i^2 = -1$.

so $\sigma(x,\xi) = -a(x)\xi^2 + ib(x)\xi + c(x)$ and $\sigma_2(x,\xi) = -a(x)\xi^2$. The operator is elliptic exactly where $a(x) \neq 0$. Bessel's operator $x^2\partial_x^2 + x\partial_x + (x^2 - \lambda^2)$ has $\sigma_2 = -x^2\xi^2$, which dies at $x = 0$: non-elliptic there, as found in the previous section.

(c) A matrix symbol: the 2d Dirac operator. On $\mathbb{R}^2$ take the Pauli matrices $\sigma^1 = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, $\sigma^2 = \left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right)$ as Euclidean gamma matrices and let $\not{D} = \sigma^1 D_1 + \sigma^2 D_2$ act on $u = (u_1, u_2)^T$. Then

$$\sigma_{\not{D}}(\xi) = \sigma^1\xi_1 + \sigma^2\xi_2 = \begin{pmatrix} 0 & \xi_1 - i\xi_2 \\ \xi_1 + i\xi_2 & 0 \end{pmatrix}, \qquad \sigma_{\not{D}}(\xi)^2 = |\xi|^2\,\mathbb{1}.$$

The square identity is the Clifford relation $\sigma^j\sigma^k + \sigma^k\sigma^j = 2\delta^{jk}$ (Chapter T4); it shows $\sigma_{\not{D}}(\xi)$ is invertible for $\xi \neq 0$, with inverse $\sigma_{\not{D}}(\xi)/|\xi|^2$. So $\not{D}$ is elliptic, and $\not{D}^2 = \Delta\,\mathbb{1}$.

Watch out: Nash's sign and 2π conventions

Nash writes $u(x) = \int \hat{u}(p)\,e^{-ipx}\,\mathrm{d}p$ (so his $\hat{u}$ absorbs the $(2\pi)^{-n}$) and $D^\alpha = (-i)^{|\alpha|}\partial^\alpha$. With these two choices $D^\alpha e^{-ipx} = (-p)^\alpha e^{-ipx}$, so his claim that the symbol is $\sum a_\alpha p^\alpha$ is off by a sign for odd $|\alpha|$. Nothing important depends on it: his p is our $-\xi$, and every symbol Nash actually uses in §4 is even in p. We use the conventions in the box above and never rely on Nash's signs. Similarly, overall constants in Nash's kernels (factors of 2π or $\sqrt{2\pi}$) do not affect orders or ellipticity; we point out the discrepancies as we meet them.

2.4.3 The leap: allow any symbol

Formula (2.117) makes sense for *any* reasonable function $\sigma(x,\xi)$, not just polynomials in ξ. That is the definition Nash starts from.

Working definition 2.22 (operator with symbol σ)

Given a function $\sigma(x,\xi)$ on $\mathbb{R}^n \times \mathbb{R}^n$, the operator $P = \mathrm{Op}(\sigma)$ **with symbol** σ acts by

$$Pu(x) = \int_{\mathbb{R}^n} e^{ix\cdot\xi}\,\sigma(x,\xi)\,\hat{u}(\xi)\,\frac{\mathrm{d}^n\xi}{(2\pi)^n}. \tag{2.118}$$

To compute Pu: Fourier transform u, multiply by $\sigma(x,\xi)$, transform back (Figure 2.27). *To find the symbol of a given P:* apply P to a plane wave; by (2.118) with $\hat{u}(\eta) = (2\pi)^n \delta(\eta - \xi)$,

$$\sigma(x,\xi) = e^{-ix\cdot\xi}\, P\big(e^{ix\cdot\xi}\big). \tag{2.119}$$

P is a **pseudo-differential operator** (ΨDO) of order m when σ lies in the symbol class S^m [symbols that grow at most like $|\xi|^m$, each ξ-derivative lowering the growth by one power] defined in Section 2.4.4.

If σ does not depend on x, then (2.118) says $\widehat{Pu}(\xi) = \sigma(\xi)\hat{u}(\xi)$: P is a **Fourier multiplier**, and we write $P = \sigma(D)$. For example $\sigma(\xi) = |\xi|^2 + m^2$ gives $P = \Delta + m^2$, and $\sigma(\xi) = \sqrt{|\xi|^2 + m^2}$ *defines* $\sqrt{\Delta + m^2}$. Functions of the momentum operator are Fourier multipliers, exactly as in quantum mechanics.

Kernels. Every such P is also an integral operator. Substitute $\hat{u}(\xi) = \int e^{-iy\cdot\xi} u(y)\, \mathrm{d}^n y$ into (2.118):

$$\begin{aligned} Pu(x) &\overset{(1)}{=} \int \frac{\mathrm{d}^n\xi}{(2\pi)^n}\, e^{ix\cdot\xi}\sigma(x,\xi) \int \mathrm{d}^n y\, e^{-iy\cdot\xi} u(y) \\ &\overset{(2)}{=} \int \mathrm{d}^n y \left[\int \frac{\mathrm{d}^n\xi}{(2\pi)^n}\, e^{i(x-y)\cdot\xi}\sigma(x,\xi)\right] u(y) \\ &\overset{(3)}{=} \int K(x,y)\, u(y)\, \mathrm{d}^n y, \qquad K(x,y) = \int e^{i(x-y)\cdot\xi}\, \sigma(x,\xi)\, \frac{\mathrm{d}^n\xi}{(2\pi)^n}. \end{aligned} \tag{2.120}$$

(1) Definition of $\hat{u}$.
(2) Exchange the order of integration. For a polynomial or growing σ this exchange is formal, and the ξ-integral is a distribution rather than a function; for decaying σ it is literal.
(3) Name the bracket: the **Schwartz kernel** of P.

Inverting the Fourier transform in $z = x - y$ recovers the symbol from the kernel:

$$\sigma(x,\xi) = \int K(x, x-z)\, e^{-iz\cdot\xi}\, \mathrm{d}^n z. \tag{2.121}$$

For a Fourier multiplier $K(x,y) = k(x-y)$ is a convolution kernel and $\sigma = \hat{k}$. This is Nash's pair (2.57)–(2.58): solving an integral equation $\int K(x,y)u(y)\,\mathrm{d}y = f(x)$ is the same as inverting the pseudo-differential operator with symbol (2.121).

Dictionary: symbol and kernel

Operator side	Kernel side
symbol polynomial in ξ (differential op.)	K = derivatives of $\delta(x-y)$, supported on $x = y$
symbol decays like $\lvert\xi\rvert^m$, $m < 0$	K singular only at $x = y$, like $\lvert x-y\rvert^{-n-m}$
symbol decays faster than any power	K smooth everywhere (smoothing operator)
symbol smooth in ξ	K smooth (even decaying) away from $x = y$

The last line is the heart of *pseudo-locality* (Section 2.4.15): smoothness in momentum is decay in position.

The next three examples are the operators from the opening of the section. Each has an explicit kernel, and each kernel tells a physical story.

Worked example 2.46: The Yukawa potential is the kernel of $(\Delta + m^2)^{-1}$ in $\mathbb{R}^3$

The symbol is $\sigma(\xi) = 1/(|\xi|^2 + m^2)$, a Fourier multiplier. By (2.120) its kernel is $k(x-y)$ with, writing $r = |x|$,

$$k(x) \overset{(1)}{=} \int_0^\infty \int_0^\pi \int_0^{2\pi} \frac{e^{i\rho r\cos\vartheta}}{\rho^2+m^2}\,\frac{\rho^2\sin\vartheta\,\mathrm{d}\varphi\,\mathrm{d}\vartheta\,\mathrm{d}\rho}{(2\pi)^3}$$
$$\overset{(2)}{=} \frac{1}{4\pi^2}\int_0^\infty \frac{\rho^2}{\rho^2+m^2}\left[\frac{e^{i\rho r t}}{i\rho r}\right]_{t=-1}^{t=1}\mathrm{d}\rho = \frac{1}{2\pi^2 r}\int_0^\infty \frac{\rho\sin\rho r}{\rho^2+m^2}\,\mathrm{d}\rho$$
$$\overset{(3)}{=} \frac{1}{2\pi^2 r}\cdot\frac{\pi}{2}e^{-mr} = \frac{e^{-mr}}{4\pi r}.$$

(1) Spherical coordinates in ξ-space with the polar axis along x, so $x\cdot\xi = \rho r\cos\vartheta$ where $\rho = |\xi|$.

(2) Do the φ integral (2π) and substitute $t = \cos\vartheta$, $\mathrm{d}t = -\sin\vartheta\,\mathrm{d}\vartheta$; then $(e^{i\rho r} - e^{-i\rho r})/(i\rho r) = 2\sin(\rho r)/(\rho r)$.

(3) The standard integral $\int_0^\infty \rho\sin(\rho r)/(\rho^2+m^2)\,\mathrm{d}\rho = \frac{\pi}{2}e^{-mr}$ for $r>0$ (close the contour of $\int_{-\infty}^{\infty}\rho e^{i\rho r}/(\rho^2+m^2)$ in the upper half plane; the residue at $\rho = im$ is $e^{-mr}/2$).

So $(\Delta+m^2)^{-1}u(x) = \int \frac{e^{-m|x-y|}}{4\pi|x-y|}u(y)\,\mathrm{d}^3y$: the Yukawa potential of a source u. At $m=0$ it is the Coulomb potential. The kernel is singular only at $x=y$, where it behaves like $|x-y|^{-1} = |x-y|^{-n-m}$ with $n=3$ and order $m=-2$, as the dictionary predicts. And the operator is *not local*: a source confined to a small ball produces a potential everywhere, decaying on the length scale $1/m$ (the Compton wavelength of the exchanged particle).

Worked example 2.47: The one-dimensional resolvent, checked directly

In one dimension the same computation gives

$$(D^2+m^2)^{-1}: \qquad k(x) = \int_{-\infty}^{\infty}\frac{e^{ix\xi}}{\xi^2+m^2}\frac{\mathrm{d}\xi}{2\pi} = \frac{e^{-m|x|}}{2m}.$$

Let us *check* that this kernel inverts $D^2+m^2 = -\mathrm{d}^2/\mathrm{d}x^2 + m^2$, i.e. $(-\partial_x^2+m^2)k = \delta$. Away from 0, $k'' = m^2k$, so the left side vanishes. At 0, k' jumps from $+\frac12$ to $-\frac12$:

$$\int_{-\varepsilon}^{\varepsilon}(-k''+m^2k)\mathrm{d}x \overset{(1)}{=} -\big[k'(\varepsilon)-k'(-\varepsilon)\big] + O(\varepsilon)$$
$$\overset{(2)}{=} -\Big[-\tfrac12 e^{-m\varepsilon} - \tfrac12 e^{-m\varepsilon}\Big] + O(\varepsilon) \xrightarrow{\varepsilon\to0} 1.$$

(1) Fundamental theorem of calculus for k''; k is bounded, so $\int m^2k = O(\varepsilon)$.

(2) $k'(x) = -\frac12\operatorname{sgn}(x)e^{-m|x|}$.

A unit-weight spike at 0 and zero elsewhere: that is $\delta(x)$.

Worked example 2.48: The kernel of the relativistic kinetic energy $\sqrt{D^2+m^2}$

In one dimension, $H = \sqrt{D^2+m^2}$ is the Hamiltonian of a free spinless relativistic particle in the "square-root Klein–Gordon" formulation. Its symbol $\sqrt{\xi^2+m^2}$ is not a polynomial, so H is not a differential operator. What does it do in position space? Start from the inverse,

$\sigma = (\xi^2 + m^2)^{-1/2}$, whose kernel is a classical integral:

$$k_{-1/2}(x) \overset{(1)}{=} \int_{-\infty}^{\infty} \frac{e^{ix\xi}}{\sqrt{\xi^2+m^2}} \frac{\mathrm{d}\xi}{2\pi} = \frac{1}{\pi}\int_0^{\infty} \frac{\cos(x\xi)}{\sqrt{\xi^2+m^2}}\,\mathrm{d}\xi$$
$$\overset{(2)}{=} \frac{1}{\pi} K_0(m\,|x|),$$

(1) The integrand's odd part (sin) integrates to zero.
(2) Substitute $\xi = mt$ and use the integral representation $K_0(z) = \int_0^{\infty} \cos(zt)(1+t^2)^{-1/2}\mathrm{d}t$ of the modified Bessel function K_0.

Now $H = (D^2 + m^2) \circ (D^2 + m^2)^{-1/2}$, because Fourier multipliers compose by multiplying symbols. So away from $x = 0$, writing $z = m\,|x|$,

$$k_{1/2}(x) \overset{(1)}{=} \Big(-\frac{\mathrm{d}^2}{\mathrm{d}x^2} + m^2\Big)\frac{K_0(m\,|x|)}{\pi} = \frac{m^2}{\pi}\big(-K_0''(z) + K_0(z)\big)$$
$$\overset{(2)}{=} \frac{m^2}{\pi}\frac{K_0'(z)}{z} \overset{(3)}{=} -\frac{m}{\pi}\frac{K_1(m\,|x|)}{|x|} \qquad (x \neq 0).$$

(1) Apply $D^2 + m^2$ to the kernel of $(D^2 + m^2)^{-1/2}$; chain rule with $\mathrm{d}z/\mathrm{d}x = \pm m$.
(2) Modified Bessel equation $K_0'' + K_0'/z - K_0 = 0$.
(3) $K_0' = -K_1$.

Two lessons. First, H is *non-local*: $Hu(x)$ depends on u at all points, with a weight $\sim e^{-m|x-y|}$ at distances beyond the Compton wavelength $1/m$ (since $K_1(z) \sim \sqrt{\pi/2z}\,e^{-z}$). This is the classic obstacle to a local one-particle relativistic quantum mechanics. Second, as $m \to 0$, $K_1(z) \approx 1/z$ gives $k_{1/2} \to -1/(\pi x^2)$: the kernel of $|D|$, singular like $|x-y|^{-n-m}$ with $n = 1$, order $m = 1$ (interpreted as a finite-part distribution at $x = y$).

Worked example 2.49: The heat operator: a smoothing operator

For $t > 0$ let $\sigma_t(\xi) = e^{-t|\xi|^2}$, so $P_t = e^{-t\Delta}$, the operator that evolves an initial temperature by the heat equation $\partial_t u = -\Delta u = \nabla^2 u$. Its kernel is a Gaussian:

$$k_t(x) \overset{(1)}{=} \prod_{j=1}^{n} \int_{-\infty}^{\infty} e^{ix_j\xi_j - t\xi_j^2}\frac{\mathrm{d}\xi_j}{2\pi}$$
$$\overset{(2)}{=} \prod_{j=1}^{n} \frac{1}{2\pi}\sqrt{\frac{\pi}{t}}\,e^{-x_j^2/4t} = (4\pi t)^{-n/2} e^{-|x|^2/4t}.$$

(1) The integrand factorises over coordinates.
(2) Complete the square, $-t\xi^2 + ix\xi = -t(\xi - \frac{ix}{2t})^2 - \frac{x^2}{4t}$, and use $\int e^{-t\eta^2}\mathrm{d}\eta = \sqrt{\pi/t}$.

In one dimension with $t = \frac{1}{2}$ this is Nash's example (2.64): kernel $(2\pi)^{-1/2}e^{-(x-y)^2/2}$, symbol $e^{-\xi^2/2}$. The symbol decays faster than any power of ξ, and correspondingly $P_t u$ is C^∞ for any integrable u (differentiate under the integral: every derivative lands on the smooth Gaussian). Even $u = \delta$ becomes the smooth function k_t. As $t \to 0$ the kernel sharpens into δ and $P_t \to \mathrm{id}$ (Figure 2.28).

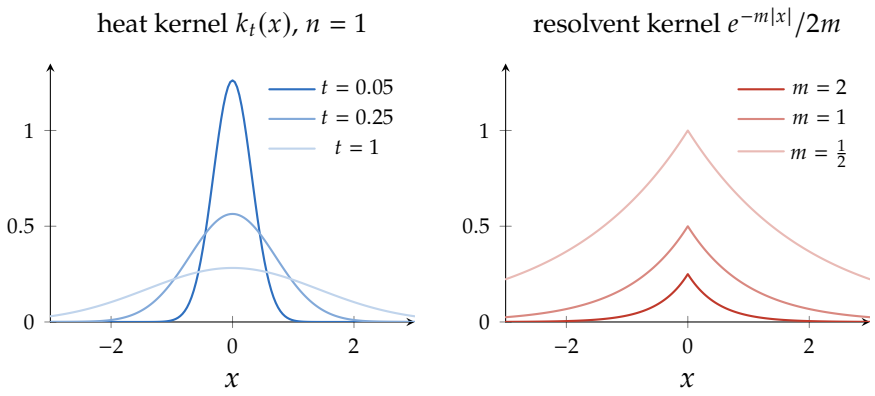

Figure 2.28: Kernels of two pseudo-differential operators on $\mathbb{R}$. Left: the heat kernel is smooth everywhere; its symbol $e^{-t\xi^2}$ decays faster than any power, so $e^{-t\Delta}$ has order $-\infty$ (smoothing). As $t \to 0$ it concentrates into $\delta(x)$. Right: the kernel of $(D^2 + m^2)^{-1}$ (order -2) is smooth except for a kink at $x = 0$ (the jump in k' that produces the δ). Neither kernel is supported at $x = 0$ alone, so neither operator is local; both are smooth off the diagonal, which is pseudo-locality.

Reading Nash (pp. 41, 44, (2.54), (2.57)–(2.58))

Nash's (2.54) is our (2.118) in his conventions (e^{-ipx} and $(2\pi)^{-n}$ absorbed into $\hat{u}$). His (2.58) gives the symbol in terms of the kernel with a prefactor $(2\pi)^{-n}$; in the conventions of his own (2.54) the correct formula has no such prefactor, as in our (2.121). You can see the slip in his Gaussian example: the kernel $e^{-(x-y)^2/2}$ has symbol $\sqrt{2\pi}\, e^{-p^2/2}$, not $e^{-p^2/2}/\sqrt{2\pi}$. The constant is irrelevant for everything he does with it (the order is $-\infty$ either way), but it is worth knowing if you check his formulas.

2.4.4 Symbol classes: what "behaves like a polynomial of degree m" means

We cannot allow *any* function $\sigma(x, \xi)$; the operator would have no useful properties. The trick is to ask what is special about a polynomial of degree m in ξ, and to keep exactly that. Look at $\sigma(\xi) = \xi^3$ in one variable:

$$\sigma = \xi^3, \qquad \partial_\xi \sigma = 3\xi^2, \qquad \partial_\xi^2 \sigma = 6\xi, \qquad \partial_\xi^3 \sigma = 6, \qquad \partial_\xi^4 \sigma = 0.$$

Each ξ-derivative lowers the growth rate at large $|\xi|$ by one power. Derivatives in x act only on the coefficients $a_\alpha(x)$ and do not change the growth rate at all. That is the whole definition.

Working definition 2.23 (symbol class S^m)

Let $m \in \mathbb{R}$ and $\Omega \subset \mathbb{R}^n$ open. A smooth function $\sigma(x, \xi)$ on $\Omega \times \mathbb{R}^n$ belongs to $S^m(\Omega)$ if for every compact [closed and bounded, staying away from the edge of Ω] $K \subset \Omega$ and all multi-indices [α_j counts the derivatives in ξ_j, and β_j those in x_j] α, β there is a constant $C_{\alpha\beta}(K)$ with

$$\left|\partial_x^\beta \partial_\xi^\alpha \sigma(x, \xi)\right| \le C_{\alpha\beta}(K)\, \langle \xi \rangle^{m-|\alpha|} \qquad (x \in K,\ \xi \in \mathbb{R}^n), \tag{2.122}$$

where $\langle \xi \rangle = (1 + |\xi|^2)^{1/2}$ [like $|\xi|$ at large ξ, but never zero]. *Test:* (i) bound $|\sigma|$ by a constant times $\langle \xi \rangle^m$; (ii) check that every ξ-derivative buys one extra power of decay; (iii) check that x-derivatives cost nothing. The number m is an **order** of σ and of $P = \mathrm{Op}(\sigma)$.

Nash writes $(1 + |p|)^{m-|\beta|}$ instead of $\langle \xi \rangle^{m-|\alpha|}$ (and his α, β are swapped relative to ours). The

two weights are interchangeable, because for every ξ

$$\langle\xi\rangle \;\le\; 1+|\xi| \;\le\; \sqrt{2}\,\langle\xi\rangle : \tag{2.123}$$

square both sides; the left inequality is $1+|\xi|^2 \le 1+2|\xi|+|\xi|^2$, and the right one is $1+2|\xi|+|\xi|^2 \le 2+2|\xi|^2$, i.e. $(1-|\xi|)^2 \ge 0$. We prefer $\langle\xi\rangle$ because it is smooth.

Three features of the definition deserve comment.

- *Any real m is allowed:* fractional, negative, and (by intersection) $-\infty$. Operators like $\sqrt{\Delta}$ (order 1) or $\Delta^{-1/3}$ (order $-2/3$) are now on the same footing as ∇^2.
- *The classes are nested:* if $m \le m'$ then $\langle\xi\rangle^{m-|\alpha|} \le \langle\xi\rangle^{m'-|\alpha|}$, so $S^m \subset S^{m'}$. An operator of order m is also of every higher order. We write
$$S^{-\infty} = \bigcap_{m\in\mathbb{R}} S^m, \qquad S^{\infty} = \bigcup_{m\in\mathbb{R}} S^m.$$
- *"The" order is not defined as the smallest m.* One could try $\inf\{m : \sigma \in S^m\}$, but the infimum need not be attained: there are symbols in $S^{m+\varepsilon}$ for every $\varepsilon > 0$ but not in S^m (Example 2.63). So one always says "of order m", meaning "in S^m".

Worked example 2.50: Polynomials, Japanese brackets, and a resolvent

(a) A polynomial of degree m is in S^m. Take $\sigma = a(x)\xi^2$ in one variable, with a smooth. On a compact K, $\left|\partial_x^\beta a\right| \le A_\beta$. Then

$$\left|\partial_x^\beta \sigma\right| = \left|\partial_x^\beta a\right| \xi^2 \overset{(1)}{\le} A_\beta\langle\xi\rangle^2, \qquad \left|\partial_x^\beta \partial_\xi \sigma\right| = 2\left|\partial_x^\beta a\right| |\xi| \overset{(2)}{\le} 2A_\beta\langle\xi\rangle^1,$$
$$\left|\partial_x^\beta \partial_\xi^2 \sigma\right| = 2\left|\partial_x^\beta a\right| \le 2A_\beta\langle\xi\rangle^0, \qquad \partial_\xi^k \sigma = 0 \;\; (k \ge 3).$$

(1) $\xi^2 \le 1+\xi^2 = \langle\xi\rangle^2$.
(2) $|\xi| \le \langle\xi\rangle$.

For $k \ge 3$ the bound $0 \le C\langle\xi\rangle^{2-k}$ is trivially true.
(b) $\langle\xi\rangle^s \in S^s$ for every real s. In one variable,

$$\partial_\xi\langle\xi\rangle^s \overset{(1)}{=} \tfrac{s}{2}(1+\xi^2)^{\frac{s}{2}-1}\cdot 2\xi = s\,\xi\,\langle\xi\rangle^{s-2},$$
$$\partial_\xi^2\langle\xi\rangle^s \overset{(2)}{=} s\langle\xi\rangle^{s-2} + s(s-2)\,\xi^2\langle\xi\rangle^{s-4},$$

(1) Chain rule on $(1+\xi^2)^{s/2}$.
(2) Product rule on $\xi\cdot\langle\xi\rangle^{s-2}$, using the first line with $s \to s-2$.

Using $|\xi| \le \langle\xi\rangle$: $|\partial_\xi\langle\xi\rangle^s| \le |s|\,\langle\xi\rangle^{s-1}$ and $\left|\partial_\xi^2\langle\xi\rangle^s\right| \le (|s|+|s(s-2)|)\langle\xi\rangle^{s-2}$. Inductively, $\partial_\xi^k\langle\xi\rangle^s$ is a finite sum of terms $\xi^j\langle\xi\rangle^{s-k-j}$, each bounded by $\langle\xi\rangle^{s-k}$. So $\langle\xi\rangle^s \in S^s$. The operator $\langle D\rangle^s = (1+\Delta)^{s/2}$, the **Bessel potential** of order s, will define the Sobolev spaces in Section 2.5.
(c) The resolvent symbol is in S^{-2}. $\sigma = (|\xi|^2+m^2)^{-1}$ with $m > 0$. The same computation as (b) works, because $|\xi|^2+m^2$ is comparable to $\langle\xi\rangle^2$: $\min(1,m^2)\langle\xi\rangle^2 \le |\xi|^2+m^2 \le \max(1,m^2)\langle\xi\rangle^2$. For instance

$$\left|\partial_{\xi_j}\sigma\right| = \frac{2\left|\xi_j\right|}{(|\xi|^2+m^2)^2} \le \frac{2\langle\xi\rangle}{\min(1,m^2)^2\langle\xi\rangle^4} = C\langle\xi\rangle^{-3}.$$

Worked example 2.51: Why the derivative condition matters: translation is not a ΨDO

Let $\sigma(\xi) = e^{ia\xi}$ in one variable ($a \neq 0$ real). It is smooth and bounded, $|\sigma| = 1 \leq \langle\xi\rangle^0$, so it passes test (i) for $m = 0$. But $\partial_\xi \sigma = ia\, e^{ia\xi}$ has modulus $|a|$, which is *not* $\leq C\langle\xi\rangle^{-1}$ for large ξ. So $\sigma \notin S^0$. In fact $\sigma \notin S^m$ for any finite m: the k-th derivative has constant modulus $|a|^k$, and $|a|^k \leq C\langle\xi\rangle^{m-k}$ for all large ξ would force $m \geq k$ for every k. What operator is it?

$$\sigma(D)u(x) \overset{(1)}{=} \int e^{ix\xi} e^{ia\xi} \hat{u}(\xi) \frac{\mathrm{d}\xi}{2\pi} \overset{(2)}{=} u(x+a).$$

(1) Definition (2.118).

(2) Fourier inversion at the point $x + a$.

It is the translation $u \mapsto u(\cdot + a)$, i.e. $e^{iaD} = e^{a\,\mathrm{d}/\mathrm{d}x}$, the familiar $e^{ia\hat{p}}$ of quantum mechanics. Translation *moves* singularities (a kink at 0 goes to $-a$), whereas we will see that genuine ΨDOs never create singularities in new places. The condition "each ξ-derivative gains decay" is exactly what forbids this.

Watch out: Symbols that are singular at $\xi = 0$

$|\xi|$, $|\xi|^{2\lambda}$ and $\xi/|\xi|$ are not smooth at $\xi = 0$, so strictly they are not in any S^m. This is Nash's reason for excluding $a = 0$ in his example (2.59). The standard cure: only large $|\xi|$ matters. Pick a smooth cutoff $\chi(\xi)$ with $\chi = 0$ for $|\xi| \leq \frac{1}{2}$ and $\chi = 1$ for $|\xi| \geq 1$, and use $\chi(\xi)\,|\xi|$ instead of $|\xi|$. The difference $(1 - \chi)\,|\xi|$ is bounded with compact support in ξ, which is in $S^{-\infty}$ (all derivatives are bounded and vanish for $|\xi| \geq 1$). Operators with symbols in $S^{-\infty}$ are *smoothing* and are "negligible" in the theory. So we can say: $|D|$ is a ΨDO of order 1 *modulo smoothing operators*.

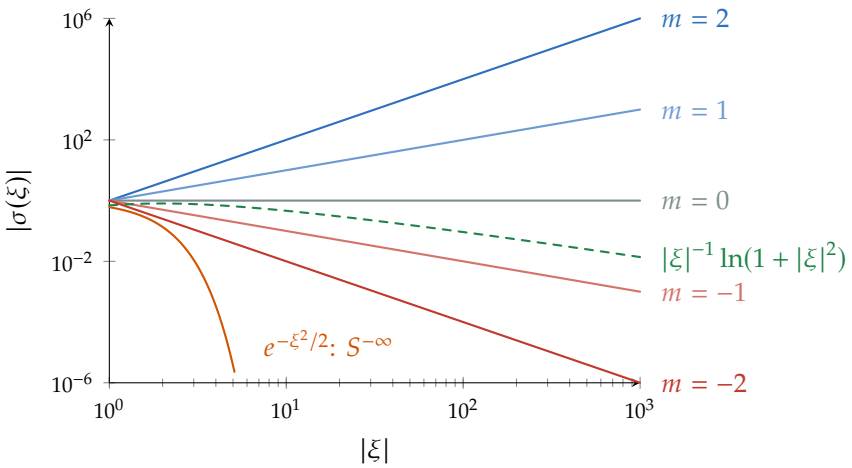

Figure 2.29: Growth of symbols at large momentum on a log–log plot. A symbol of order m is bounded by a line of slope m. The Gaussian (orange) falls below every line: it is in $S^{-\infty}$, and the operator is smoothing. The dashed green symbol $|\xi|^{-1}\ln(1 + |\xi|^2)$ lies above the slope -1 line (the log grows) but below the line of slope $-1 + \varepsilon$ for any $\varepsilon > 0$ eventually: it is in $S^{-1+\varepsilon}$ for all $\varepsilon > 0$ but not in S^{-1}.

A larger family of symbol classes. Nash mentions in a footnote the classes $S^m_{\rho,\delta}$, defined by

$$\left|\partial_x^\beta \partial_\xi^\alpha \sigma\right| \leq C_{\alpha\beta}(K)\langle\xi\rangle^{m-\rho|\alpha|+\delta|\beta|}, \qquad 0 \leq \delta < \rho \leq 1.$$

Here ρ is how much decay each ξ-derivative buys and δ is how much growth each x-derivative costs. Our S^m is $S^m_{1,0}$. For example $\sigma(\xi) = e^{i\langle\xi\rangle^{1/2}}$ has $\partial_\xi\sigma = \frac{i}{2}\xi\langle\xi\rangle^{-3/2}\sigma$, of size $\langle\xi\rangle^{-1/2}$: each derivative gains only half a power, so $\sigma \in S^0_{1/2,0}$ but $\sigma \notin S^0$. Such classes appear for parametrices of hypo-elliptic but non-elliptic operators (for example the heat operator, where time counts as two powers of space). We will not need them.

2.4.5 Pseudo-differential operators on manifolds and between bundles

On a compact manifold we cannot Fourier transform globally, but a ΨDO is defined chart by chart, exactly as a differential operator is.

Working definition 2.24 (ΨDO between vector bundles (Nash's definition))

Let M be a compact n-manifold and $U, V \to M$ vector bundles of ranks s and r. A linear map $P : \Gamma(M,U) \to \Gamma(M,V)$ is a **pseudo-differential operator of order** m if in every chart $\Omega \subset M$ with coordinates x, dual momenta ξ, and local trivialisations [local frames, in which sections become columns of functions] of U and V, P acts on vector-valued functions by (2.118) with an $r \times s$ *matrix* symbol $\sigma(x,\xi)$ each of whose entries lies in $S^m(\Omega)$, up to a smoothing operator. *Operationally:* cover M by charts Ω_i, choose a partition of unity [smooth $\phi_i \geq 0$, each zero outside its chart Ω_i] $\sum_i \phi_i = 1$ and functions ψ_i with $\psi_i = 1$ on $\operatorname{supp}\phi_i$; then $P = \sum_i \phi_i \operatorname{Op}(\sigma_i)\,\psi_i + R$ with R smoothing (a smooth kernel on $M \times M$).

The phrase "up to a smoothing operator" handles the fact that a ΨDO is not local: Pu on a chart Ω depends on u outside Ω too, but only through a smooth kernel (pseudo-locality again).

How the symbol changes under a change of coordinates. The full symbol $\sigma(x,\xi)$ changes in a messy way under changes of coordinates (lower-order terms mix in). The principal symbol does not: it transforms as a function on the cotangent bundle T^*M, with ξ transforming as a covector $\xi_j\,\mathrm{d}x^j$. Here is the simplest check.

Worked example 2.52: The principal symbol lives on T^*M

On an interval let $L = \mathrm{d}^2/\mathrm{d}x^2$, with $\sigma_2 = (i\xi)^2 = -\xi^2$ (from $\mathrm{d}/\mathrm{d}x = iD_x$). Change coordinates $x = g(t)$ with $g' > 0$. Then

$$\frac{\mathrm{d}}{\mathrm{d}x} \overset{(1)}{=} \frac{1}{g'(t)}\frac{\mathrm{d}}{\mathrm{d}t}, \qquad \frac{\mathrm{d}^2}{\mathrm{d}x^2} \overset{(2)}{=} \frac{1}{g'(t)^2}\frac{\mathrm{d}^2}{\mathrm{d}t^2} - \frac{g''(t)}{g'(t)^3}\frac{\mathrm{d}}{\mathrm{d}t},$$

(1) Chain rule, $\mathrm{d}t/\mathrm{d}x = 1/g'$.

(2) Apply the first formula twice; the derivative of $1/g'$ produces the first-order term.

In the t-chart the principal symbol is $-\tau^2/g'(t)^2$, where τ is the momentum dual to t, and the first-order term has changed. Now compare: since $\mathrm{d}x = g'\,\mathrm{d}t$, the covector $\xi\,\mathrm{d}x$ equals $\tau\,\mathrm{d}t$ exactly when $\tau = g'\xi$. Substituting, $-\tau^2/g'^2 = -\xi^2$: the principal symbol is the *same function* on T^*M, written in two coordinate systems. The lower-order part of the symbol is not.

So the principal symbol of $P : \Gamma(U) \to \Gamma(V)$ is a globally defined object: for each point $x \in M$ and each covector $\xi \in T^*_xM$, a linear map $\sigma_m(P)(x,\xi) : U_x \to V_x$. Pulling U and V back along the projection $\pi : T^*M \to M$ (so the fibre of π^*U over (x,ξ) is U_x) we can say it in one breath:

$$\sigma_m(P) :\ \pi^*U \longrightarrow \pi^*V \qquad \text{is a bundle map over } T^*M.$$

2.4.6 The principal symbol of a pseudo-differential operator

For a differential operator the principal symbol is the top-degree part of a polynomial. For a general $\sigma \in S^m$ there is no "top degree", so Nash defines it by zooming out to large momentum.

Working definition 2.25 (m-th order (principal) symbol, Nash (2.56))

If P has symbol $\sigma \in S^m$ [growing at most like $|\xi|^m$ at large momentum], its **m-th order symbol** is

$$\sigma_m(x,\xi) = \lim_{\mu\to+\infty} \frac{\sigma(x,\mu\xi)}{\mu^m}, \qquad \xi \neq 0, \tag{2.124}$$

when the limit exists. *To compute:* expand σ at large $|\xi|$ and keep the leading term. It is **positively homogeneous** of degree m: $\sigma_m(x,\mu\xi) = \mu^m \sigma_m(x,\xi)$ for $\mu > 0$ (replace ξ by $\mu\xi$ in the limit and rescale).

Worked example 2.53: Principal symbols by zooming out

(a) Polynomials. $\sigma = -a(x)\xi^2 + ib(x)\xi + c(x)$ gives $\sigma(x,\mu\xi)/\mu^2 = -a\xi^2 + ib\xi/\mu + c/\mu^2 \to -a(x)\xi^2$: the top-degree part, as before.

(b) The relativistic kinetic energy. For $\sigma = \sqrt{|\xi|^2 + m^2} \in S^1$,

$$\frac{\sigma(\mu\xi)}{\mu} \overset{(1)}{=} \sqrt{|\xi|^2 + m^2/\mu^2} \xrightarrow{\mu\to\infty} |\xi|\,.$$

(1) Pull μ^2 out of the square root ($\mu > 0$).

So $\sigma_1 = |\xi|$: at high momentum every particle is massless. Keep going and we get the full large-momentum (**classical** or **polyhomogeneous**) expansion, a sum of terms of decreasing homogeneity:

$$\sqrt{|\xi|^2 + m^2} \overset{(1)}{=} |\xi| \left(1 + \frac{m^2}{|\xi|^2}\right)^{1/2} \overset{(2)}{=} |\xi| + \frac{m^2}{2\,|\xi|} - \frac{m^4}{8\,|\xi|^3} + \frac{m^6}{16\,|\xi|^5} - \cdots$$

(1) Factor out $|\xi|$ (valid for $\xi \neq 0$).

(2) Binomial series $(1+u)^{1/2} = 1 + \frac{u}{2} - \frac{u^2}{8} + \frac{u^3}{16} - \cdots$ with $u = m^2/|\xi|^2 < 1$ for $|\xi| > m$.

Each term is positively homogeneous: of degree $1, -1, -3, -5, \ldots$ This is the non-relativistic expansion read backwards: $E = |p| + m^2/2\,|p| + \ldots$ is the ultra-relativistic expansion.

(c) A symbol of order 0 that is only positively homogeneous. Take $\sigma(\xi) = \xi/\langle\xi\rangle$ on $\mathbb{R}$. Then $\sigma(\mu\xi) = \mu\xi/\sqrt{1+\mu^2\xi^2} \to \operatorname{sgn}(\xi)$, so $\sigma_0(\xi) = \operatorname{sgn}\xi$. Now $\sigma_0(\mu\xi) = \operatorname{sgn}(\mu)\operatorname{sgn}(\xi)$, which equals $\mu^0\sigma_0(\xi)$ for $\mu > 0$ but not for $\mu < 0$. Similarly $|\xi|$ is positively homogeneous of degree 1 but $|-\xi| \neq -|\xi|$. Symbols of differential operators are polynomials, so they are homogeneous for all real μ; for ΨDOs only $\mu > 0$ is guaranteed. The operator $\operatorname{sgn}(D)$ is i times the Hilbert transform; on the circle it multiplies $e^{in\theta}$ by $\operatorname{sgn} n$.

Every differential operator is a ΨDO. If $\sigma = \sum_{|\alpha|\le m} a_\alpha(x)\xi^\alpha$, then each monomial ξ^α with $|\alpha| \le m$ obeys (2.122) (as in Example 2.50(a)), so $\sigma \in S^m$, and (2.124) returns the top-degree part. So the new definitions extend the old ones without changing them.

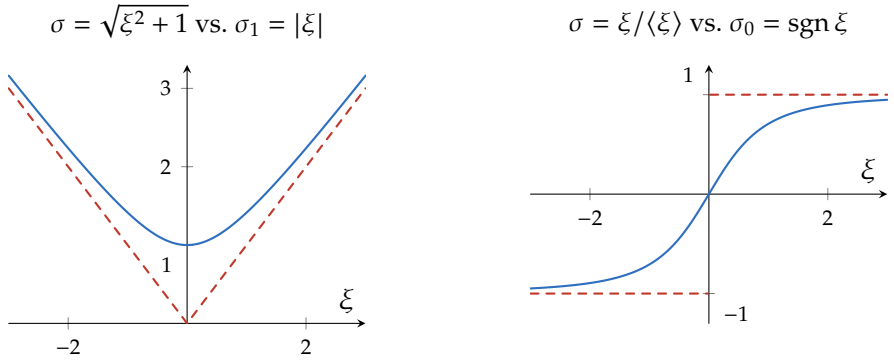

Figure 2.30: The principal symbol is what the full symbol looks like at large momentum. Left: $\sqrt{\xi^2+1}$ (blue) approaches $|\xi|$ (red dashed); the difference $\sim 1/2\,|\xi|$ is of order -1. Right: $\xi/\langle\xi\rangle$ approaches $\operatorname{sgn}\xi$. Both principal symbols have a corner or jump at $\xi = 0$, which is harmless: ellipticity and the whole theory only use $\xi \neq 0$ ("off the zero section"), and only large $|\xi|$ matters.

2.4.7 Ellipticity for pseudo-differential operators

Nothing new is needed: ellipticity is still invertibility of the principal symbol away from $\xi = 0$.

Working definition 2.26 (elliptic ΨDO)

Let U, V have the same rank r. $P : \Gamma(U) \to \Gamma(V)$ with symbol in S^m is **elliptic of order** m if its m-th order symbol [the large-momentum limit $\lim_{\mu\to\infty} \sigma(x,\mu\xi)/\mu^m$] $\sigma_m(x,\xi)$ exists and is an invertible $r \times r$ matrix for every x and every $\xi \neq 0$. Equivalently (Nash's "alternative definition"):

$$\sigma_m(P) : \pi^*U \to \pi^*V \text{ is a bundle isomorphism off the zero section of } T^*M.$$

Test: compute σ_m and its determinant; check $\det \sigma_m(x,\xi) \neq 0$ for $\xi \neq 0$. Quantitatively (by homogeneity and compactness of the unit sphere in ξ), ellipticity means $\left|\sigma_m(x,\xi)^{-1}\right| \leq C\,|\xi|^{-m}$: *the symbol is bounded below by its order.*

Watch out: Elliptic of order m is not elliptic of order $m+1$

An operator of order m is also of order $m+1$, since $S^m \subset S^{m+1}$. But its $(m+1)$-th order symbol is $\lim \sigma(x,\mu\xi)/\mu^{m+1} = \lim\big(\sigma(x,\mu\xi)/\mu^m\big)/\mu = \sigma_m/\mu \to 0$, which is not invertible. So ellipticity pins down the order. For example, Δ is elliptic of order 2 and not of order 3.

Worked example 2.54: Which of our operators are elliptic?

Operator	symbol	σ_m	elliptic?
$\Delta + m^2$	$\lvert\xi\rvert^2 + m^2$	$\lvert\xi\rvert^2$, $m = 2$	yes
$\sqrt{\Delta + m^2}$	$\sqrt{\lvert\xi\rvert^2 + m^2}$	$\lvert\xi\rvert$, $m = 1$	yes
$(\Delta + m^2)^{-1}$	$(\lvert\xi\rvert^2 + m^2)^{-1}$	$\lvert\xi\rvert^{-2}$, $m = -2$	yes
$\operatorname{sgn}(D)$ on $\mathbb{R}$	$\xi/\langle\xi\rangle$	$\operatorname{sgn}\xi$, $m = 0$	yes
$\not{D}$ on $\mathbb{R}^2$	$\sigma^1\xi_1 + \sigma^2\xi_2$	same, $m = 1$	yes ($\det = -\lvert\xi\rvert^2$)
∂_1 on $\mathbb{R}^2$	$i\xi_1$	$i\xi_1$, $m = 1$	no: vanishes on $\xi = (0, \xi_2)$
$e^{-t\Delta}$	$e^{-t\lvert\xi\rvert^2}$	0 for every m	no (order $-\infty$)

Inverses of elliptic operators are elliptic (of the negative order), and their principal symbols are the inverse matrices. Smoothing operators are never elliptic: an elliptic operator must "see" arbitrarily high momenta with full strength.

2.4.8 The symbol calculus: composing, adjoining, commuting

The single most useful fact about ΨDOs is that their symbols compose *almost* like numbers. This is where the theory earns its keep, and it is also where the physicist's intuition about quantisation (x and p almost commute, up to $\hbar$) is made precise.

Constant coefficients: exact multiplication. If $P = p(D)$ and $Q = q(D)$ are Fourier multipliers, then

$$\widehat{PQu}(\xi) \overset{(1)}{=} p(\xi)\,\widehat{Qu}(\xi) \overset{(2)}{=} p(\xi)q(\xi)\,\hat{u}(\xi),$$

(1) P multiplies the Fourier transform of whatever it acts on by $p(\xi)$.
(2) Likewise for Q.

so $\sigma_{PQ} = pq$ exactly, and $PQ = QP$. For instance $\sqrt{\Delta + m^2} \circ \sqrt{\Delta + m^2} = \Delta + m^2$ and $(\Delta + m^2)^z(\Delta + m^2)^w = (\Delta + m^2)^{z+w}$.

Variable coefficients: the composition formula. When coefficients depend on x, derivatives in P also hit the x-dependence of Q's symbol. Let us derive the formula when P is a differential operator, where everything is a finite sum. Write $P = \sum_\alpha a_\alpha(x)D^\alpha$ with symbol $p(x,\xi) = \sum_\alpha a_\alpha(x)\xi^\alpha$, and Q with symbol $q(x,\xi)$. Then

$$\begin{aligned} PQu(x) &\overset{(1)}{=} \sum_\alpha a_\alpha(x) D_x^\alpha \int e^{ix\cdot\xi} q(x,\xi)\hat{u}(\xi)\,\frac{\mathrm{d}^n\xi}{(2\pi)^n} \\ &\overset{(2)}{=} \int e^{ix\cdot\xi} \sum_\alpha a_\alpha(x)(\xi + D_x)^\alpha q(x,\xi)\,\hat{u}(\xi)\,\frac{\mathrm{d}^n\xi}{(2\pi)^n} \\ &\overset{(3)}{=} \int e^{ix\cdot\xi} \sum_\alpha a_\alpha(x) \sum_{\gamma\le\alpha} \binom{\alpha}{\gamma} \xi^{\alpha-\gamma} D_x^\gamma q(x,\xi)\,\hat{u}(\xi)\,\frac{\mathrm{d}^n\xi}{(2\pi)^n} \\ &\overset{(4)}{=} \int e^{ix\cdot\xi} \sum_\gamma \frac{1}{\gamma!}\,\partial_\xi^\gamma p(x,\xi)\,D_x^\gamma q(x,\xi)\,\hat{u}(\xi)\,\frac{\mathrm{d}^n\xi}{(2\pi)^n}. \end{aligned} \tag{2.125}$$

(1) Definition of Q, then apply P.

(2) Leibniz: $D_j(e^{ix\cdot\xi}f) = e^{ix\cdot\xi}(\xi_j + D_j)f$, since $D_j e^{ix\cdot\xi} = \xi_j e^{ix\cdot\xi}$.
(3) Binomial expansion in each variable (ξ_j and D_j commute when acting on functions of x): $(\xi + D)^\alpha = \sum_{\gamma\le\alpha}\binom{\alpha}{\gamma}\xi^{\alpha-\gamma}D^\gamma$, with $\binom{\alpha}{\gamma} = \prod_j \binom{\alpha_j}{\gamma_j}$.
(4) $\frac{1}{\gamma!}\partial_\xi^\gamma \xi^\alpha = \binom{\alpha}{\gamma}\xi^{\alpha-\gamma}$; then sum over α to rebuild $\partial_\xi^\gamma p$. Here $\gamma! = \prod_j \gamma_j!$.

Key idea: Composition of symbols

The symbol of PQ is

$$\sigma_{PQ}(x,\xi) \sim \sum_\gamma \frac{1}{\gamma!}\,\partial_\xi^\gamma \sigma_P(x,\xi)\, D_x^\gamma \sigma_Q(x,\xi), \qquad D_x = -i\partial_x. \tag{2.126}$$

For differential P the sum is finite and exact. For general $P \in S^m$, $Q \in S^{m'}$ it is an asymptotic series: the γ-th term is in $S^{m+m'-|\gamma|}$ (each ∂_ξ lowers the order by one and D_x does not raise it), and truncating after $|\gamma| < N$ leaves an error in $S^{m+m'-N}$. In particular PQ has order $m + m'$ and

$$\sigma_{m+m'}(PQ) = \sigma_m(P)\,\sigma_{m'}(Q). \tag{2.127}$$

Equation (2.127) is the ΨDO version of Nash's (2.45) for differential operators, which he used to compute the symbol of the Hodge Laplacian from those of d and d*.

Worked example 2.55: The canonical commutation relation from the symbol calculus

On $\mathbb{R}$ take $P = D$ (symbol ξ) and $Q = x$ (multiplication, symbol x). By (2.126),

$$\sigma_{DQ} \overset{(1)}{=} \xi\cdot x + \partial_\xi(\xi)\,D_x(x) = x\xi - i, \qquad \sigma_{xD} \overset{(2)}{=} x\cdot\xi = x\xi,$$

(1) Terms $\gamma = 0$ and $\gamma = 1$; $D_x(x) = -i$; higher terms vanish since $\partial_\xi^2\xi = 0$.
(2) Here $P = x$ has no ξ-dependence, so only $\gamma = 0$ survives.

Hence $[D, x]$ has symbol $-i$: $[D, x] = -i$, i.e. $[x, \hat{p}] = i$ with $\hat{p} = D$. Directly: $D(xu) - xDu = -iu$. The product of symbols $x\xi$ is the same for both orders; the commutator lives entirely in the first correction.

Commutators and Poisson brackets. Apply (2.126) to PQ and QP and subtract. The $\gamma = 0$ terms cancel (symbols commute as scalars), and the $|\gamma| = 1$ terms give

$$\begin{aligned}\sigma_{[P,Q]} &\overset{(1)}{=} \sum_j \Big(\partial_{\xi_j} p\, D_{x^j} q - \partial_{\xi_j} q\, D_{x^j} p\Big) + \dots \\ &\overset{(2)}{=} i\sum_j \Big(\partial_{x^j} p\,\partial_{\xi_j} q - \partial_{\xi_j} p\,\partial_{x^j} q\Big) + \cdots = i\,\{p,q\} + \dots\end{aligned} \tag{2.128}$$

(1) First-order terms of (2.126) for PQ minus those for QP (scalar symbols).
(2) $D_x = -i\partial_x$; reorder. The bracket is the classical Poisson bracket $\{p,q\} = \sum_j(\partial_{x^j}p\,\partial_{\xi_j}q - \partial_{\xi_j}p\,\partial_{x^j}q)$, with the physicists' sign ($\{x,\xi\} = 1$).

The dots are of order $m + m' - 2$. So $[P, Q]$ has order $m + m' - 1$, one less than naive counting, and its principal symbol is $i\{\sigma_m(P), \sigma_{m'}(Q)\}$.

Dictionary: symbol calculus ↔ quantum mechanics

ΨDO theory	Quantum mechanics ($\hbar = 1$)
symbol $\sigma(x,\xi)$	classical observable $f(x,p)$ on phase space
$\mathrm{Op}(\sigma)$	its quantisation ("x to the left, p to the right")
T^*M	phase space
$\sigma_{PQ} = \sigma_P\sigma_Q +$ lower order	$\widehat{fg} = \hat f\hat g + O(\hbar)$
$\sigma_{[P,Q]} = i\{\sigma_P,\sigma_Q\} + \dots$	Dirac's rule $[\hat f,\hat g] = i\hbar\widehat{\{f,g\}} + O(\hbar^2)$
"lower order" (one fewer power of ξ)	one more power of $\hbar$ (semiclassical expansion)

Large momentum is the classical limit: at $|\xi| \to \infty$ the quantum corrections (lower-order terms) are negligible relative to the leading term. That is why ellipticity, a statement about the principal symbol, is a "classical" condition with "quantum" consequences.

Worked example 2.56: A commutator with the Laplacian

Let $f(x)$ be a smooth function on $\mathbb{R}^n$, viewed as a multiplication operator of order 0. By (2.128), $[\Delta, f]$ has order $2+0-1=1$ and principal symbol

$$i\{|\xi|^2, f\} \overset{(1)}{=} i\Big(\sum_j \partial_{x^j}|\xi|^2\,\partial_{\xi_j} f - \partial_{\xi_j}|\xi|^2\,\partial_{x^j} f\Big) \overset{(2)}{=} -2i\,\xi\cdot\nabla f.$$

(1) Definition of the bracket.
(2) $|\xi|^2$ does not depend on x, f does not depend on ξ, and $\partial_{\xi_j}|\xi|^2 = 2\xi_j$.

Check directly: $[\Delta,f]u = -\nabla^2(fu) + f\nabla^2 u = -(\nabla^2 f)u - 2\nabla f\cdot\nabla u$. The first-order part is $-2\nabla f\cdot\nabla u = -2i\,\nabla f\cdot Du$, whose symbol is $-2i\,\xi\cdot\nabla f$. It agrees.

Adjoints. With respect to the L^2 inner product $\langle u,v\rangle = \int \bar u\, v$ (or $\int u^\dagger v$ for vector-valued functions), the formal adjoint P^* has symbol

$$\sigma_{P^*}(x,\xi) \sim \sum_\gamma \frac{1}{\gamma!}\partial_\xi^\gamma D_x^\gamma\,\sigma_P(x,\xi)^\dagger, \qquad \text{so} \qquad \sigma_m(P^*) = \sigma_m(P)^\dagger, \tag{2.129}$$

which is Nash's (2.47). The principal symbol of the adjoint is the conjugate-transpose matrix, so *P is elliptic iff P^* is elliptic*. This small fact will give us finite cokernels.

Worked example 2.57: Adjoint of a first-order operator

On $\mathbb{R}$ let $P = a(x)D$ with a complex-valued. For test functions u, v,

$$\langle Pu, v\rangle \overset{(1)}{=} \int \overline{a\,(-i)u'}\,v\,\mathrm{d}x = \int i\,\bar a\,\bar u'\,v\,\mathrm{d}x \overset{(2)}{=} -i\int \bar u\,(\bar a v)'\,\mathrm{d}x \overset{(3)}{=} \langle u, D(\bar a v)\rangle,$$

(1) $D = -i\,\mathrm{d}/\mathrm{d}x$ and complex conjugation.
(2) Integrate by parts (test functions vanish at infinity).
(3) $-i(\bar a v)' = D(\bar a v)$.

So $P^*v = D(\bar a v) = \bar a\,Dv + (D\bar a)v$, with symbol $\bar a\xi + D_x\bar a$. The formula (2.129) gives $\gamma=0$: $\bar a\xi$; $\gamma=1$: $\partial_\xi D_x(\bar a\xi) = D_x\bar a$. It agrees, and the principal symbol $\bar a\xi$ is the complex conjugate of $a\xi$.

2.4.9 Inverting an elliptic operator: the parametrix

Now the payoff. An elliptic operator cannot always be inverted exactly (it may have a kernel). But it can always be inverted *up to a smoothing operator*, and the inverse is again a ΨDO. The construction is a bootstrap that uses nothing but (2.126).

Working definition 2.27 (parametrix)

A **parametrix** for P is an operator Q with

$$PQ = I - R_1, \qquad QP = I - R_2, \qquad R_1, R_2 \text{ smoothing (order } -\infty).$$

Here smoothing means [given by a smooth kernel $R(x,y)$, so Ru is smooth for every input u]. *To build one for an elliptic P of order m:*

(i) First guess: $q_0(x,\xi) = \chi(\xi)\,\sigma_m(P)(x,\xi)^{-1} \in S^{-m}$, with χ a cutoff vanishing near $\xi = 0$ (where σ_m may fail to be invertible or smooth).

(ii) Compute $PQ_0 = I - R$ by (2.126). The leading term is $\sigma_m(P)q_0 = 1$ for large ξ, so R has order -1.

(iii) Correct: $Q = Q_0(I + R + R^2 + R^3 + \cdots)$, summed asymptotically [one operator whose difference from the first N terms has order $-m-N$, for every N] (the k-th term has order $-m-k$). Then $PQ = (I-R)(I+R+R^2+\cdots) = I$ up to order $-\infty$.

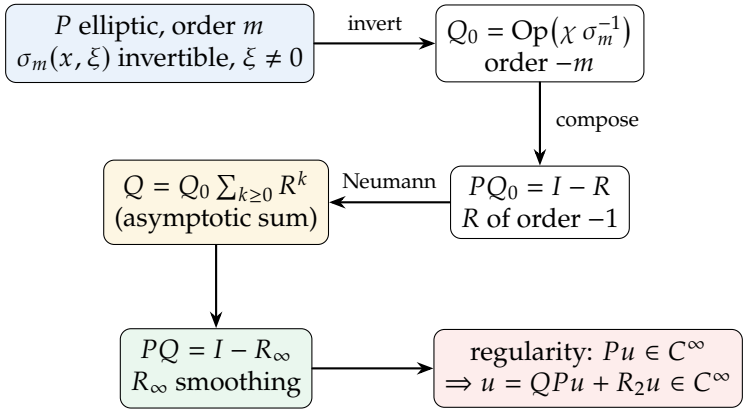

Figure 2.31: The logic of the parametrix construction. Only the principal symbol has to be inverted by hand (a matrix inversion at each (x,ξ)); the symbol calculus does the rest, one order at a time. The end product, invertibility modulo smoothing operators, gives elliptic regularity at once (bottom right) and, on Sobolev spaces, the Fredholm property (Section 2.6).

Worked example 2.58: Parametrix of a variable-coefficient second-order operator

On $\mathbb{R}$ let $P = a(x)D^2 + b(x)D + c(x)$ with $a(x) > 0$ smooth, so $p = a\xi^2 + b\xi + c$ and $\sigma_2(P) = a\xi^2$ is invertible for $\xi \neq 0$. *Step 1.* $q_0 = \chi(\xi)/(a(x)\xi^2)$. For $|\xi| \geq 1$ (where $\chi = 1$):

$$\begin{aligned}\sigma_{PQ_0} &\overset{(1)}{=} p\,q_0 + \partial_\xi p\, D_x q_0 + \tfrac{1}{2}\partial_\xi^2 p\, D_x^2 q_0 \\ &\overset{(2)}{=} \left(1 + \frac{b}{a\xi} + \frac{c}{a\xi^2}\right) + (2a\xi + b)\,\frac{i\,a'}{a^2\xi^2} + a\,D_x^2\!\left(\frac{1}{a}\right)\frac{1}{\xi^2} \\ &\overset{(3)}{=} 1 + \frac{b + 2i\,a'}{a\,\xi} + O(\xi^{-2}).\end{aligned}$$

(1) Composition formula (2.126); it stops at $\gamma = 2$ because p is quadratic in ξ.

(2) $p\,q_0$ multiplied out; $D_x q_0 = -i\,\partial_x(a^{-1})\xi^{-2} = i\,a'a^{-2}\xi^{-2}$; $\frac{1}{2}\partial_\xi^2 p = a$.

(3) Collect the terms of order ξ^{-1}: $b/(a\xi)$ and $2i\,a'/(a\xi)$. Everything else is $O(\xi^{-2})$.

So $R = I - PQ_0$ has order -1 with principal symbol $-(b + 2ia')/(a\xi)$. *Step 2.* Add q_1 of order -3 chosen so that $\sigma_2(P)\,q_1$ cancels it:

$$a\xi^2\, q_1 = -\frac{b + 2i\,a'}{a\,\xi} \quad\Longrightarrow\quad q_1 = -\frac{b + 2i\,a'}{a^2\,\xi^3}.$$

Then $P(Q_0 + Q_1) = I + (\text{order } -2)$, and we could continue. *Sanity check with constant coefficients* ($a = 1, a' = 0$): the exact inverse symbol is $1/(\xi^2 + b\xi + c) = \xi^{-2}(1 + b/\xi + c/\xi^2)^{-1} = \xi^{-2} - b\xi^{-3} + O(\xi^{-4})$, and indeed $q_0 + q_1 = \xi^{-2} - b\xi^{-3}$. The term $2ia'$ is the new, purely "quantum" correction from the x-dependence of a.

Worked example 2.59: On the circle the parametrix is an inverse up to rank one

On S^1 let $P = D^2 = -\mathrm{d}^2/\mathrm{d}\theta^2$, which multiplies $e^{in\theta}$ by n^2. Define Q by $Qe^{in\theta} = n^{-2}e^{in\theta}$ for $n \neq 0$ and $Qe^0 = 0$. Its symbol is n^{-2} for $n \neq 0$: order -2. Let $\Pi_0 u = \frac{1}{2\pi}\int_0^{2\pi} u\,\mathrm{d}\theta$ (projection onto constants). Then for $u = \sum c_n e^{in\theta}$,

$$PQu \overset{(1)}{=} \sum_{n\neq 0} n^2 \cdot n^{-2} c_n e^{in\theta} = u - c_0 \overset{(2)}{=} (I - \Pi_0)u,$$

(1) Apply Q then P mode by mode.

(2) $c_0 = \frac{1}{2\pi}\int u\,\mathrm{d}\theta = \Pi_0 u$.

and likewise $QP = I - \Pi_0$. The error Π_0 has the smooth kernel $K(\theta, \theta') = 1/2\pi$, so it is smoothing; it is also of rank one. It is exactly the projection onto $\operatorname{Ker} P$. This is the whole Fredholm story in miniature: invertible except on a finite-dimensional space.

Key idea: Elliptic ⇔ invertible modulo smoothing; elliptic regularity

A ΨDO is elliptic if and only if it has a parametrix. Consequence: if P is elliptic and $Pu = f$ with f smooth on an open set, then u is smooth there. Reason: $u = QPu + R_2 u = Qf + R_2 u$. Q, being a ΨDO, maps smooth functions to smooth functions (pseudo-locality, next subsection), and R_2 maps *anything* to a smooth function. So elliptic ΨDOs are hypo-elliptic, which generalises the result of the previous section from differential operators to ΨDOs.

2.4.10 Nash's gallery I: solving an integral equation with a Bessel potential

Nash motivates ΨDOs with a practical problem. Suppose we are handed an **integral equation of the first kind**,

$$Pu(x) = \int_{\mathbb{R}^n} K(x, y)\, u(y)\, \mathrm{d}^n y = f(x), \tag{2.130}$$

with the kernel K and the right-hand side f known, and u unknown. By (2.120)–(2.121), P is the operator with symbol $\sigma(x, \xi) = \int K(x, x - z)e^{-iz\cdot\xi}\,\mathrm{d}^n z$. If this symbol lies in some S^m and is elliptic, the machinery of Section 2.4.9 inverts P, at least modulo smoothing operators. When K depends only on $x - y$ and the symbol has no zeros, we can do better: the inverse is *exactly* the Fourier multiplier $1/\sigma(\xi)$, and

$$u(x) = \int e^{ix\cdot\xi}\,\frac{\hat f(\xi)}{\sigma(\xi)}\,\frac{\mathrm{d}^n\xi}{(2\pi)^n}. \tag{2.131}$$

Nash's example is the one-dimensional family of symbols

$$\sigma_\lambda(\xi) = (a^2 + \xi^2)^\lambda, \qquad a > 0, \quad -\tfrac{1}{2} < \lambda < 0. \tag{2.132}$$

By Example 2.50(b),(c) (the same computation with a^2 in place of 1), $\sigma_\lambda \in S^{2\lambda}$. Its principal symbol is $|\xi|^{2\lambda}$, which never vanishes for $\xi \neq 0$: P_λ is elliptic of order $2\lambda \in (-1, 0)$. It is a smoothing-by-a-fraction-of-a-derivative operator, a **Bessel potential**.

Its kernel. We need one classical integral, Basset's representation of the modified Bessel function K_ν: for $x > 0$ and $\nu > -\frac{1}{2}$,

$$\int_0^\infty \frac{\cos(xt)}{(t^2 + a^2)^{\nu+1/2}}\,\mathrm{d}t = \frac{\sqrt{\pi}}{\Gamma(\nu + \frac{1}{2})}\Big(\frac{x}{2a}\Big)^\nu K_\nu(ax). \tag{2.133}$$

(Recall that K_ν is the decaying solution of $z^2w'' + zw' - (z^2 + \nu^2)w = 0$, that $K_{-\nu} = K_\nu$, that $K_\nu(z) \approx \sqrt{\pi/2z}\,e^{-z}$ for large z, and that $K_\nu(z) \approx \frac{1}{2}\Gamma(\nu)(2/z)^\nu$ for small z and $\nu > 0$. The special case $K_{1/2}(z) = \sqrt{\pi/2z}\,e^{-z}$ is elementary.)

Worked example 2.60: The kernel of the Bessel potential $(a^2 + D^2)^\lambda$

By (2.120) the kernel is $k_\lambda(x - y)$ with

$$\begin{aligned} k_\lambda(x) &\overset{(1)}{=} \int_{-\infty}^{\infty} e^{ix\xi}(a^2 + \xi^2)^\lambda \frac{\mathrm{d}\xi}{2\pi} = \frac{1}{\pi}\int_0^\infty \cos(|x|\,\xi)\,(a^2 + \xi^2)^\lambda\,\mathrm{d}\xi \\ &\overset{(2)}{=} \frac{1}{\pi}\cdot\frac{\sqrt{\pi}}{\Gamma(-\lambda)}\Big(\frac{|x|}{2a}\Big)^{-\lambda-\frac{1}{2}} K_{-\lambda-\frac{1}{2}}(a\,|x|) \\ &\overset{(3)}{=} \frac{(2a)^{\lambda+\frac{1}{2}}}{\sqrt{\pi}\,\Gamma(-\lambda)}\,\frac{K_{\lambda+\frac{1}{2}}(a\,|x|)}{|x|^{\lambda+\frac{1}{2}}}. \end{aligned} \tag{2.134}$$

(1) The symbol is even in ξ, so only the cosine part of $e^{ix\xi}$ survives, and the integral over $\mathbb{R}$ is twice that over $(0, \infty)$. The integral converges (conditionally) because $\lambda < 0$.
(2) Basset's formula (2.133) with $\nu + \frac{1}{2} = -\lambda$, i.e. $\nu = -\lambda - \frac{1}{2}$, which is $> -\frac{1}{2}$ exactly because $\lambda < 0$.
(3) Collect the constants and use $K_{-\nu} = K_\nu$.

This is Nash's first formula in (2.60): his prefactor $2^{1+\lambda}a^{\frac{1}{2}+\lambda}/(\sqrt{2\pi}\,\Gamma(-\lambda))$ equals ours, since $2^{1+\lambda}/\sqrt{2\pi} = 2^{\lambda+\frac{1}{2}}/\sqrt{\pi}$.
Check at $\lambda = -1$ (outside Nash's range, but the formula is valid for all $\lambda < 0$). Then $\nu = \frac{1}{2}$ and $K_{1/2}(z) = \sqrt{\pi/2z}\,e^{-z}$, so

$$k_{-1}(x) \overset{(1)}{=} \frac{(2a)^{-1/2}}{\sqrt{\pi}\cdot 1}\,|x|^{1/2}\sqrt{\frac{\pi}{2a\,|x|}}\,e^{-a|x|} \overset{(2)}{=} \frac{e^{-a|x|}}{2a},$$

(1) Put $\lambda = -1$ into (2.134); $\Gamma(1) = 1$.
(2) The powers of $|x|$ cancel and $(2a)^{-1/2}(2a)^{-1/2} = 1/2a$.

which is the resolvent kernel of Example 2.47. Good.
Short-distance behaviour. For $|x| \to 0$, with $\nu = \lambda + \frac{1}{2} \in (0, \frac{1}{2})$,

$$k_\lambda(x) \overset{(1)}{=} \frac{(2a)^\nu}{\sqrt{\pi}\,\Gamma(-\lambda)}\,|x|^{-\nu}\cdot\frac{\Gamma(\nu)}{2}\Big(\frac{2}{a\,|x|}\Big)^\nu\big(1 + o(1)\big) \overset{(2)}{=} \frac{2^{2\lambda}\,\Gamma(\lambda + \frac{1}{2})}{\sqrt{\pi}\,\Gamma(-\lambda)}\,\frac{1 + o(1)}{|x|^{1+2\lambda}}.$$

(1) Small-argument form of K_ν.

(2) $(2a)^{\nu}2^{\nu}a^{-\nu}/2 = 2^{2\nu-1} = 2^{2\lambda}$ and $|x|^{-2\nu} = |x|^{-1-2\lambda}$.

So the kernel is singular only at $x = y$, like $|x-y|^{-n-m}$ with $n = 1$ and order $m = 2\lambda$, exactly as the symbol–kernel dictionary predicts. Because $-1 < -1-2\lambda < 0$ the singularity is integrable, and $P_\lambda u$ is a genuine integral. At large distance k_λ decays like $|x|^{-\lambda-1}\, e^{-a|x|}$: the mass a sets a screening length $1/a$.

The solution. The inverse of P_λ is $P_{-\lambda}$, whose symbol $(a^2+\xi^2)^{-\lambda}$ has positive order $-2\lambda \in (0,1)$. Formally its kernel is (2.134) with $\lambda \to -\lambda$, and that is Nash's second formula in (2.60):

$$u(x) = \frac{(2a)^{\frac{1}{2}-\lambda}}{\sqrt{\pi}\,\Gamma(\lambda)} \int_{\mathbb{R}} \frac{K_{\frac{1}{2}-\lambda}(a\,|x-y|)}{|x-y|^{\frac{1}{2}-\lambda}}\, f(y)\,\mathrm{d}y. \tag{2.135}$$

But look at it closely. $\Gamma(\lambda) < 0$ for $\lambda \in (-\frac{1}{2}, 0)$, and the kernel behaves like $|x-y|^{-1+2\lambda}$ near the diagonal, with $-1+2\lambda < -1$: *not integrable*. This is no accident. An operator of positive order differentiates, and differentiation cannot be written as an honest integral against a locally integrable kernel. The integral in (2.135) has to be read as a distribution (Hadamard's *finite part*: subtract $f(x)$ from $f(y)$ inside the integral, which makes it converge). Nash alludes to this with "we take an appropriate definition of the fractional powers". In momentum space there is no subtlety at all: (2.131) with $1/\sigma_\lambda = (a^2+\xi^2)^{-\lambda}$.

Watch out: Positive order means a non-integrable kernel

Kernels of negative-order operators are locally integrable (in n dimensions, order $m < 0$ gives $|x-y|^{-n-m}$ with $-n-m > -n$). Kernels of operators of order $m \geq 0$ are not functions near the diagonal: they are δ and its derivatives (differential operators) or finite-part distributions like f.p. $|x-y|^{-n-m}$. This is why symbols, not kernels, are the convenient way to handle ΨDOs.

2.4.11 Nash's gallery II: fractional integration and differentiation

Now set $a = 0$ in (2.132). The symbol becomes

$$\sigma_\lambda(\xi) = |\xi|^{2\lambda}, \tag{2.136}$$

and $P_\lambda = |D|^{2\lambda} = \Delta^\lambda$ is a fractional power of the Laplacian. For $\lambda = 1$ it is $\Delta = -\mathrm{d}^2/\mathrm{d}x^2$ itself; for $\lambda = \frac{1}{2}$ it is $|D|$; for $\lambda < 0$ it is **fractional integration** of order -2λ; its inverse $\Delta^{-\lambda}$ is **fractional differentiation** of order -2λ. Strictly $|\xi|^{2\lambda}$ is not in $S^{2\lambda}$ because it is not smooth at $\xi = 0$ (the pitfall in Section 2.4.4); but only large $|\xi|$ matters for the order, and the operator is perfectly well defined.

Worked example 2.61: The Riesz kernel and its constant

For $-\frac{1}{2} < \lambda < 0$,

$$\begin{aligned} k^0_\lambda(x) &\overset{(1)}{=} \frac{1}{\pi}\int_0^\infty \xi^{2\lambda}\cos(|x|\,\xi)\,\mathrm{d}\xi \overset{(2)}{=} \frac{1}{\pi\,|x|^{1+2\lambda}}\int_0^\infty t^{2\lambda}\cos t\,\mathrm{d}t \\ &\overset{(3)}{=} \frac{\Gamma(1+2\lambda)\cos\!\left(\frac{\pi}{2}(1+2\lambda)\right)}{\pi\;|x|^{1+2\lambda}} \overset{(4)}{=} \frac{1}{2\cos(\pi\lambda)\,\Gamma(-2\lambda)}\cdot\frac{1}{|x|^{1+2\lambda}}. \end{aligned} \tag{2.137}$$

(1) As in Example 2.60: even symbol, cosine part only.

(2) Substitute $t = |x|\,\xi$; this is where the homogeneity of the symbol turns into a pure power of $|x|$.
(3) The Euler integral $\int_0^\infty t^{s-1}\cos t\,\mathrm{d}t = \Gamma(s)\cos(\pi s/2)$, valid for $0 < s < 1$; here $s = 1 + 2\lambda \in (0,1)$.
(4) $\cos(\frac{\pi}{2} + \pi\lambda) = -\sin\pi\lambda$, then the reflection formula $\Gamma(1+2\lambda)\Gamma(-2\lambda) = \pi/\sin(-2\pi\lambda)$ and $\sin 2\pi\lambda = 2\sin\pi\lambda\cos\pi\lambda$.

Nash's (2.61) has $\sqrt{2}\cos(\lambda\pi)\Gamma(-2\lambda)$ in the denominator instead of our $2\cos(\lambda\pi)\Gamma(-2\lambda)$: an overall factor of $\sqrt{2}$ from his normalisation of the Fourier transform. The $|x|$-dependence, which is what matters, agrees. It is also the $a \to 0$ limit of the short-distance form of Example 2.60: one can check with the duplication formula that $2^{2\lambda}\Gamma(\lambda+\frac{1}{2})/(\sqrt{\pi}\,\Gamma(-\lambda)) = 1/(2\cos\pi\lambda\,\Gamma(-2\lambda))$. (At $\lambda = -\frac{1}{4}$ both are $1/\sqrt{2\pi} \approx 0.399$.)

So fractional integration of order $-2\lambda =: \alpha \in (0,1)$ is

$$\Delta^{-\alpha/2}u(x) = \frac{1}{2\cos(\pi\alpha/2)\,\Gamma(\alpha)}\int_{\mathbb{R}} \frac{u(y)}{|x-y|^{1-\alpha}}\,\mathrm{d}y,$$

the symmetric (Riesz) cousin of the Riemann–Liouville fractional integral

$$I^{\alpha}u(x) = \frac{1}{\Gamma(\alpha)}\int_{-\infty}^{x}(x-y)^{\alpha-1}u(y)\,\mathrm{d}y.$$

As $\alpha \to 1$ the kernel flattens to a constant and the prefactor blows up: fractional integration of order one is not quite "$\int$" on the whole line, because $1/|\xi|$ is not locally integrable at $\xi = 0$ (an infrared problem, not an ultraviolet one).

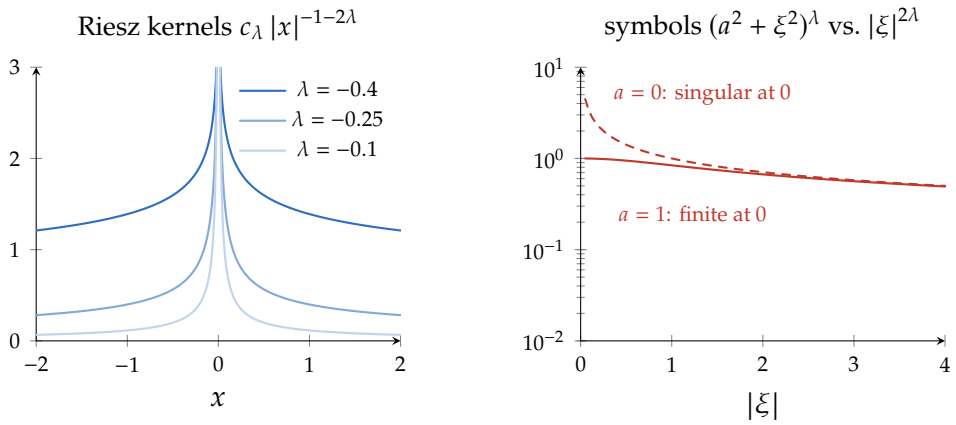

Figure 2.32: Left: kernels of fractional integration Δ^λ on $\mathbb{R}$ for three values of λ. The closer the order 2λ is to 0, the more sharply the kernel concentrates at $x = 0$ (as $\lambda \to 0$ it becomes δ, the kernel of the identity). All three are integrable at 0. Right: the Bessel symbol with $a = 1$ (solid) and the Riesz symbol $a = 0$ (dashed), $\lambda = -\frac{1}{4}$. They agree at large $|\xi|$ (same order, same principal symbol) and differ only near $\xi = 0$, which affects the long-distance tail of the kernel, not its singularity.

The group law $P_\lambda P_\mu = P_{\lambda+\mu}$. Nash notes that "$P$ does possess one of the essential properties of a derivative": the powers compose additively. In momentum space it is one line,

$$\widehat{P_\lambda P_\mu u}(\xi) \overset{(1)}{=} \sigma_\lambda(\xi)\sigma_\mu(\xi)\hat{u}(\xi) \overset{(2)}{=} (a^2+\xi^2)^{\lambda+\mu}\hat{u}(\xi) = \widehat{P_{\lambda+\mu}u}(\xi),$$

(1) Fourier multipliers compose by multiplying symbols (Section 2.4.8).

(2) $x^\lambda x^\mu = x^{\lambda+\mu}$ for $x > 0$.

for any $a \geq 0$. In position space it is a non-trivial statement about convolutions of kernels, and the structure is visible by power counting.

Worked example 2.62: The group law for Riesz kernels, by scaling

With $a = 0$, $P_\lambda P_\mu$ has kernel $k^0_\lambda * k^0_\mu$. Write $\alpha = 1+2\lambda$, $\beta = 1+2\mu$ (both in $(0,1)$) and assume $\alpha+\beta > 1$ so the integral converges at infinity. For $x \neq 0$,

$$\int_{\mathbb{R}} \frac{\mathrm{d}y}{|x-y|^\alpha\,|y|^\beta} \overset{(1)}{=} \int_{\mathbb{R}} \frac{|x|\,\mathrm{d}t}{|x|^\alpha\,|\hat{x}-t|^\alpha\;|x|^\beta\,|t|^\beta} \overset{(2)}{=} \frac{C_{\alpha\beta}}{|x|^{\alpha+\beta-1}}, \qquad C_{\alpha\beta} = \int_{\mathbb{R}} \frac{\mathrm{d}t}{|1-t|^\alpha\,|t|^\beta},$$

(1) Substitute $y = |x|\,t$, and write $x = |x|\,\hat{x}$ with $\hat{x} = \pm 1$.
(2) The remaining integral does not depend on x (by $t \to -t$ it is the same for $\hat{x} = \pm 1$), and converges: near $t = 0$ and $t = 1$ because $\alpha, \beta < 1$, at infinity because $\alpha+\beta > 1$.

Now $\alpha+\beta-1 = 1+2(\lambda+\mu)$: the convolution is proportional to $|x|^{-1-2(\lambda+\mu)}$, the Riesz kernel of $P_{\lambda+\mu}$. Scaling fixes the power; the constant $C_{\alpha\beta}$ (a combination of Beta functions) is guaranteed by the momentum-space argument to come out right. This is the position-space shadow of $|\xi|^{2\lambda}\,|\xi|^{2\mu} = |\xi|^{2(\lambda+\mu)}$.

When the integrals diverge (for instance $\lambda+\mu \geq 0$, where the result has non-negative order), the composition still makes sense as a statement about distributions; Nash refers to Gel'fand–Shilov for this. Our viewpoint: *define* P_λ by its symbol for every $\lambda \in \mathbb{C}$, and the group law holds identically. The kernel is a secondary object.

2.4.12 Nash's gallery III: a logarithm, and an order that is not attained

Worked example 2.63: The symbol $(a^2+\xi^2)^\lambda \ln(a^2+\xi^2)$

Nash's (2.62) is the operator

$$Pu(x) = \int e^{ix\xi}(a^2+\xi^2)^\lambda \ln(a^2+\xi^2)\,\hat{u}(\xi)\,\frac{\mathrm{d}\xi}{2\pi}, \qquad \sigma(\xi) = (a^2+\xi^2)^\lambda \ln(a^2+\xi^2).$$

It is in $S^{2\lambda+\varepsilon}$ for every $\varepsilon > 0$. The logarithm grows more slowly than any power: $\ln(a^2+\xi^2) \leq C_\varepsilon\langle\xi\rangle^\varepsilon$ for all ξ, because $\ln(a^2+\xi^2)/\langle\xi\rangle^\varepsilon \to 0$ as $|\xi| \to \infty$ (l'Hôpital) and it is continuous. So

$$|\sigma(\xi)| \overset{(1)}{\leq} C\langle\xi\rangle^{2\lambda}\cdot C_\varepsilon\langle\xi\rangle^\varepsilon = C'\langle\xi\rangle^{2\lambda+\varepsilon},$$
$$|\partial_\xi\sigma| \overset{(2)}{=} \left|2\lambda\xi(a^2+\xi^2)^{\lambda-1}\ln(a^2+\xi^2) + 2\xi(a^2+\xi^2)^{\lambda-1}\right| \overset{(3)}{\leq} C''\langle\xi\rangle^{2\lambda+\varepsilon-1}.$$

(1) $(a^2+\xi^2)^\lambda$ is comparable to $\langle\xi\rangle^{2\lambda}$ (Example 2.50(c)).
(2) Product rule: the derivative of $\ln(a^2+\xi^2)$ is $2\xi/(a^2+\xi^2)$.
(3) Each term is $|\xi|\,\langle\xi\rangle^{2\lambda-2}$ times a logarithm or a constant; bound the logarithm by $C_\varepsilon\langle\xi\rangle^\varepsilon$.

Higher derivatives work the same way: each ∂_ξ either hits the power (costing one order) or the logarithm (turning it into a rational function of order -1).
It is not in $S^{2\lambda}$. That would need $|\sigma(\xi)| \leq C\langle\xi\rangle^{2\lambda}$, i.e. $\ln(a^2+\xi^2) \leq C'$ for all ξ, which is false. So the set of admissible orders is the open half-line $(2\lambda, \infty)$ and its infimum 2λ is not attained. This is the example promised in Section 2.4.4.

It has no principal symbol in Nash's sense. With $m = 2\lambda$, $\sigma(\mu\xi)/\mu^{2\lambda} \approx |\xi|^{2\lambda}\,(\ln\mu^2 + \ln\xi^2) \to \infty$; with $m = 2\lambda + \varepsilon$ the limit is 0. Neither is an invertible homogeneous function, so P is *not* elliptic of any order, even though its symbol never vanishes for large ξ. Operators like this are not "classical" (their symbols have no expansion in homogeneous terms).

The kernel by differentiating in λ. Nash's trick: $\partial_\lambda (a^2+\xi^2)^\lambda = (a^2+\xi^2)^\lambda \ln(a^2+\xi^2)$. So the kernel G of P is ∂_λ of the Bessel kernel (2.134). Write $z = |x|$, $\nu = \lambda + \frac{1}{2}$, and $k_\lambda(z) = A(\lambda)\,(z/2a)^{-\nu} K_\nu(az)$ with $A = 1/(\sqrt{\pi}\,\Gamma(-\lambda))$. Then

$$G(z) = \partial_\lambda k_\lambda(z) \overset{(1)}{=} A'(\lambda)\Big(\frac{z}{2a}\Big)^{-\nu} K_\nu + A\,\partial_\lambda\Big(\frac{z}{2a}\Big)^{-\nu} K_\nu + A\Big(\frac{z}{2a}\Big)^{-\nu}\partial_\nu K_\nu$$
$$\overset{(2)}{=} \Big[\psi(-\lambda) + \ln(2a) - \ln z\Big] k_\lambda(z) + A\Big(\frac{z}{2a}\Big)^{-\nu}\frac{\partial K_\nu}{\partial \nu}(az), \tag{2.138}$$

(1) Product rule; $\mathrm{d}\nu/\mathrm{d}\lambda = 1$.

(2) $A'(\lambda) = \psi(-\lambda)A(\lambda)$ where $\psi = \Gamma'/\Gamma$ is the digamma function (differentiate $1/\Gamma(-\lambda)$), and $\partial_\lambda (z/2a)^{-\nu} = -\ln(z/2a)\,(z/2a)^{-\nu}$.

Since $\psi(-\lambda) = -\frac{\mathrm{d}}{\mathrm{d}\lambda}\ln\Gamma(-\lambda)$ this is Nash's "formidable looking" (2.63), term by term: the braces $\{\ln(2a) - \frac{\mathrm{d}}{\mathrm{d}\lambda}\ln\Gamma(-\lambda)\}$ and $\{\frac{\mathrm{d}}{\mathrm{d}\lambda}K_{\frac{1}{2}+\lambda} - K_{\frac{1}{2}+\lambda}\ln z\}$. The $-\ln z$ factor is the kernel-side fingerprint of the logarithm in the symbol: it makes the singularity at $z = 0$ slightly worse than $z^{-1-2\lambda}$, but better than $z^{-1-2\lambda-\varepsilon}$ for any $\varepsilon > 0$, in perfect parallel with the order.

2.4.13 Nash's gallery IV: smoothing operators

Nash's next example (2.64) is the Gaussian integral operator

$$Pu(x) = \int_{\mathbb{R}} e^{-(x-y)^2/2}\,u(y)\,\mathrm{d}y.$$

In Example 2.49 we computed that its symbol is (in our conventions) $\sigma(\xi) = \sqrt{2\pi}\,e^{-\xi^2/2}$. Nash's key observation (2.65) is that this symbol is dominated by *every* power of $\langle\xi\rangle$.

Worked example 2.64: The Gaussian symbol is in S^m for every m

We need, for each real m and each $k \ge 0$, a constant with $\left|\partial_\xi^k e^{-\xi^2/2}\right| \le C_{m,k}\langle\xi\rangle^{m-k}$. First $k = 0$, $m = -M < 0$: we want $\sup_\xi e^{-\xi^2/2}(1+\xi^2)^{M/2} < \infty$. Put $s = \xi^2 \ge 0$ and $g(s) = e^{-s/2}(1+s)^{M/2}$. Then

$$g'(s) \overset{(1)}{=} e^{-s/2}(1+s)^{M/2-1}\Big(-\tfrac{1}{2}(1+s) + \tfrac{M}{2}\Big) \overset{(2)}{=} 0 \iff s = M-1,$$

(1) Product rule, then factor out $e^{-s/2}(1+s)^{M/2-1}$.

(2) The bracket vanishes at $1 + s = M$.

so for $M \ge 1$ the maximum is $g(M-1) = e^{-(M-1)/2}M^{M/2}$, a finite number (for $M < 1$ the maximum is $g(0) = 1$). For example with $M = 2$ we get $C = 2e^{-1/2} \approx 1.21$; with $M = 10$, $C = 10^5 e^{-4.5} \approx 1.1 \times 10^3$. The constants grow with M, but each is finite, and that is all the definition asks. For $k \ge 1$: $\partial_\xi^k e^{-\xi^2/2} = (-1)^k \mathrm{He}_k(\xi) e^{-\xi^2/2}$, where He_k is the (probabilists') Hermite polynomial of degree k (for instance $\mathrm{He}_1 = \xi$, $\mathrm{He}_2 = \xi^2 - 1$). A polynomial times a Gaussian is again dominated by every power, by the same argument. Hence $\sigma \in S^m$ for all m: $\sigma \in S^{-\infty}$.

Working definition 2.28 (smoothing operator)

An operator is **smoothing** (of order $-\infty$) if it maps every distribution [a generalised function such as δ or its derivatives], however rough, to a C^∞ function. *Tests:* (a) its symbol lies in $S^{-\infty}$ [it decays faster than every power $\langle\xi\rangle^{-N}$, like the Gaussian]; equivalently (b) its Schwartz kernel [the function K with $Pu(x) = \int K(x,y)\,u(y)\,dy$] $K(x,y)$ is a C^∞ function of both variables. Then $D_x^\beta P u(x) = \int D_x^\beta K(x,y)\,u(y)\,dy$: every derivative lands on the smooth kernel, never on u.

Nash's sufficient condition for the kernel-side test is: $K(x,y)$ smooth in x and compactly supported in y. As he notes, it is not necessary (the Gaussian is not compactly supported), and on a compact manifold every smooth kernel satisfies it automatically. The name is literal: P does to u what infinitely many integrations would do.

Worked example 2.65: Smoothing operators on the circle

On S^1 every operator that is diagonal in Fourier modes, $Pe^{in\theta} = p_n e^{in\theta}$, has kernel

$$K(\theta,\theta') \overset{(1)}{=} \frac{1}{2\pi}\sum_{n\in\mathbb{Z}} p_n\, e^{in(\theta-\theta')},$$

(1) Write $u = \sum_n c_n e^{in\theta}$ with $c_n = \frac{1}{2\pi}\int u(\theta')e^{-in\theta'}d\theta'$, apply P, and exchange sum and integral.

The *symbol* is the sequence p_n. If p_n decays faster than every power of n, the series for K can be differentiated term by term any number of times ($\sum |n|^k\,|p_n| < \infty$ for all k), so K is C^∞: P is smoothing. Three instances:

- $p_n = e^{-tn^2}$: the heat operator $e^{-t\Delta}$ on the circle; K is the periodic Gaussian (a theta function).
- $p_n = 1$ for $n = 0$, else 0: the projection Π_0 onto constants, $K = 1/2\pi$ (Example 2.59). Every finite-rank operator with smooth range and smooth "co-range" is smoothing.
- $p_n = r^{|n|}$, $0 < r < 1$: the Poisson kernel $K = \frac{1}{2\pi}\frac{1-r^2}{1-2r\cos(\theta-\theta')+r^2}$, which maps boundary data on the circle to the value of the harmonic function at radius r.

By contrast $p_n = |n|$ ($|D|$, order 1), $p_n = (1+n^2)^{-1}$ (order -2) and $p_n = \operatorname{sgn} n$ (order 0) decay at most like a power, and their kernels are singular on the diagonal $\theta = \theta'$.

Smoothing operators are the "zero" of the theory: ΨDOs are usually considered modulo them. On a compact manifold, they are also *compact* operators on every Sobolev space (Section 2.5.8), and that is what turns "invertible modulo smoothing" into "Fredholm".

2.4.14 Nash's gallery V: complex powers of an elliptic operator

The last example is the most important for later chapters. Let $a > 0$ and $z \in \mathbb{C}$, and define

$$P = (a^2+\Delta)^z, \qquad \sigma(\xi) = (a^2+|\xi|^2)^z := e^{z\ln(a^2+|\xi|^2)}, \tag{2.139}$$

which is unambiguous because $a^2 + |\xi|^2 > 0$ (we use the real logarithm).

Worked example 2.66: Order and ellipticity of $(a^2+\Delta)^z$

Write $z = u + iv$. The size of the symbol is

$$|\sigma(\xi)| \overset{(1)}{=} \left|e^{(u+iv)\ln(a^2+|\xi|^2)}\right| \overset{(2)}{=} e^{u\ln(a^2+|\xi|^2)} = (a^2+|\xi|^2)^u \overset{(3)}{\le} C\langle\xi\rangle^{2u}.$$

(1) Definition (2.139).
(2) $|e^w| = e^{\operatorname{Re} w}$; the imaginary part $v\ln(a^2+|\xi|^2)$ is a pure phase.
(3) Comparability of $a^2+|\xi|^2$ with $\langle\xi\rangle^2$.

This is Nash's (2.68): $\left|(a^2+p^2)^{iv}\right| = 1$. For the derivatives,

$$\left|\partial_{\xi_j}\sigma\right| \overset{(1)}{=} |z|\;2\left|\xi_j\right|\;(a^2+|\xi|^2)^{u-1} \overset{(2)}{\le} C\,|z|\,\langle\xi\rangle^{2u-1},$$

(1) Chain rule: $\partial_{\xi_j} e^{zL} = z\,(\partial_{\xi_j}L)\,e^{zL}$ with $L = \ln(a^2+|\xi|^2)$ and $\partial_{\xi_j}L = 2\xi_j/(a^2+|\xi|^2)$; take absolute values as in the first chain.
(2) $\left|\xi_j\right| \le \langle\xi\rangle$ and comparability.

and so on for higher derivatives. So $\sigma \in S^{2\operatorname{Re} z}$: *the order is* $2\operatorname{Re} z$; the imaginary part of the exponent does not affect growth. The principal symbol is $|\xi|^{2z}$, homogeneous of the complex degree $2z$, and $\left||\xi|^{2z}\right| = |\xi|^{2u} \neq 0$ for $\xi \neq 0$. So P is elliptic of order $2\operatorname{Re} z$.

The imaginary powers $(a^2+\Delta)^{iv}$ are unitary on L^2 (the symbol has modulus one), of order 0, and elliptic. They are not smoothing and not the identity: they oscillate faster and faster at high momentum, with a phase $v\ln(a^2+|\xi|^2)$. The family $z \mapsto (a^2+\Delta)^z$ is a one-parameter group, $(a^2+\Delta)^z(a^2+\Delta)^w = (a^2+\Delta)^{z+w}$, analytic in z.

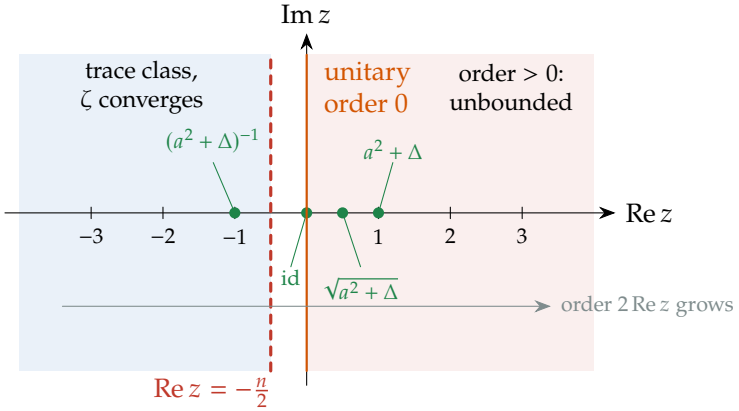

Figure 2.33: The complex powers $(a^2+\Delta)^z$ as a map from the z-plane to elliptic ΨDOs. Only $\operatorname{Re} z$ controls the order (and hence how much the operator smooths or roughens). Integer points are the familiar operators; the imaginary axis (orange) consists of unitary operators of order 0, and to its right (shaded red) the order is positive and the operator is unbounded on L^2. To the left of $\operatorname{Re} z = -n/2$ (shaded blue, drawn for $n = 1$) the operator is trace class on a compact n-manifold, and its trace defines the ζ-function, which is then continued analytically to the whole plane.

Worked example 2.67: Complex powers on the circle, the ζ-function, and a determinant

On S^1 the operator $D_\theta^2 = -\mathrm{d}^2/\mathrm{d}\theta^2$ has eigenvalues n^2 ($n \in \mathbb{Z}$) with eigenfunctions $e^{in\theta}$. Removing the zero mode, its complex power acts by $(D_\theta^2)^{-s}e^{in\theta} = n^{-2s}e^{in\theta}$ ($n \neq 0$). The

trace (sum of the diagonal entries) is

$$\zeta_{D^2}(s) := \operatorname{Tr}'(D_\theta^2)^{-s} \overset{(1)}{=} \sum_{n\neq 0} \frac{1}{|n|^{2s}} \overset{(2)}{=} 2\sum_{n=1}^{\infty} \frac{1}{n^{2s}} = 2\,\zeta_R(2s),$$

(1) The operator is diagonal in the basis $e^{in\theta}$; the prime means the zero mode is omitted.
(2) n and $-n$ contribute equally.

The series converges for $\operatorname{Re} s > \frac{1}{2}$, i.e. when the order $-2\operatorname{Re} s$ is below $-1 = -\dim S^1$: a ΨDO is trace class when its order is less than minus the dimension. Riemann's ζ_R continues analytically to all $s \neq 1$, with $\zeta_R(0) = -\frac{1}{2}$ and $\zeta_R'(0) = -\frac{1}{2}\ln 2\pi$. The **ζ-regularised determinant** is defined by $\ln\det' A = -\zeta_A'(0)$ (for a finite matrix, $-\frac{\mathrm{d}}{\mathrm{d}s}\sum \lambda_j^{-s}\big|_{s=0} = \sum \ln\lambda_j$), so

$$\ln\det' D_\theta^2 \overset{(1)}{=} -\frac{\mathrm{d}}{\mathrm{d}s}\,2\zeta_R(2s)\Big|_{s=0} = -4\zeta_R'(0) \overset{(2)}{=} 2\ln(2\pi), \qquad \det' D_\theta^2 = (2\pi)^2.$$

(1) Chain rule: $\frac{\mathrm{d}}{\mathrm{d}s}\zeta_R(2s) = 2\zeta_R'(2s)$.
(2) $\zeta_R'(0) = -\frac{1}{2}\ln(2\pi)$.

The formally infinite product $\prod_{n\neq 0} n^2$ has been given the finite value $4\pi^2$. This is how one-loop determinants $\det(-\nabla^2 + V)$ in the Euclidean path integral are defined, and it is why Nash cares about complex powers of elliptic operators. Note also $\zeta_{D^2}(0) = 2\zeta_R(0) = -1 = -\dim\operatorname{Ker} D_\theta^2$: a first hint that the value of ζ at 0 knows about zero modes (Chapter 4).

2.4.15 Locality and pseudo-locality

Differential operators are *local*. Pseudo-differential operators, as every example above shows, are not. What survives is a weaker and very useful property: they never create singularities where there were none.

Working definition 2.29 (support and singular support)

The **support** $\operatorname{supp} u$ of a function (or distribution) u is the closure [the set together with its limit points, so a support is always closed] of the set where $u \neq 0$; equivalently the complement of the largest open set on which u vanishes. The **singular support** $\operatorname{sing\,supp} u$ is the complement of the largest open set on which u is C^∞ (Nash's footnote 7). *Test:* $x_0 \notin \operatorname{sing\,supp} u$ iff u agrees with a smooth function on some neighbourhood of x_0.

For example: $u(x) = |x|$ on $\mathbb{R}$ has $\operatorname{supp} u = \mathbb{R}$, $\operatorname{sing\,supp} u = \{0\}$; δ has $\operatorname{supp}\delta = \operatorname{sing\,supp}\delta = \{0\}$; the box function $\mathbf{1}_{[-1,1]}$ has support $[-1,1]$ and singular support $\{-1,1\}$; any smooth u has empty singular support.

Working definition 2.30 (local operator)

P is **local** if $\operatorname{supp} Pu \subset \operatorname{supp} u$ for all u: if u vanishes on an open set, so does Pu. *Test:* feed P a bump function [a smooth function that is nonzero only on a small ball] and see whether the output is supported in the same place.

A differential operator is local: if $u = 0$ on an open set W, all its derivatives vanish on W, so $\sum a_\alpha D^\alpha u = 0$ on W. Nash's footnote 6 points out that the converse holds too, which is **Peetre's theorem**: a linear operator on smooth functions that is local (and continuous) is, locally, a differential operator of finite order. So "local" can be taken as the *definition* of "differential".

A genuinely pseudo-differential operator is never local: in kernel terms, a local operator has $K(x,y)$ supported on the diagonal $x=y$, which forces K to be a finite sum of derivatives of $\delta(x-y)$, and then the symbol is a polynomial.

Working definition 2.31 (pseudo-local operator)

P is **pseudo-local** if

$$\operatorname{sing\,supp} Pu \subset \operatorname{sing\,supp} u \qquad \text{for all } u, \tag{2.140}$$

where sing supp is the singular support [the points near which the function is not smooth]. *Picture:* P may smear u out over all of space, but it cannot create a kink, a jump or a spike where u was smooth.

Key idea: ΨDOs are pseudo-local

Every pseudo-differential operator satisfies (2.140) (Nash's (2.69)). The mechanism: *the kernel of a ΨDO is smooth off the diagonal*, because smoothness of the symbol in ξ becomes decay of the kernel in $x-y$.

Here is the calculation behind the mechanism. For $\sigma \in S^m$ and any multi-index α, with K from (2.120),

$$\begin{aligned}(x-y)^\alpha K(x,y) &\overset{(1)}{=} \int \left(D_\xi^\alpha e^{i(x-y)\cdot\xi}\right)\sigma(x,\xi)\,\frac{\mathrm{d}^n\xi}{(2\pi)^n}\\ &\overset{(2)}{=} \int e^{i(x-y)\cdot\xi}\left((-D_\xi)^\alpha\sigma\right)(x,\xi)\,\frac{\mathrm{d}^n\xi}{(2\pi)^n}.\end{aligned} \tag{2.141}$$

(1) $D_{\xi_j} e^{i(x-y)\cdot\xi} = -i\cdot i(x-y)^j e^{i(x-y)\cdot\xi} = (x-y)^j e^{i(x-y)\cdot\xi}$, applied α_j times in each variable.
(2) Integrate by parts in ξ, $|\alpha|$ times (each moves one D_{ξ_j} onto σ with a minus sign; boundary terms are dropped, rigorously in the sense of distributions).

Now $(-D_\xi)^\alpha\sigma \in S^{m-|\alpha|}$. Once $m-|\alpha|<-n$ the last integrand is bounded by $C\langle\xi\rangle^{m-|\alpha|}$, which is integrable over $\mathbb{R}^n$, so $(x-y)^\alpha K$ is a continuous function. Taking $|\alpha|$ larger still, we may differentiate under the integral sign j times as long as $m-|\alpha|+j<-n$. Hence $(x-y)^\alpha K$ is C^j for $|\alpha|$ large, and away from $x=y$ we can divide by $(x-y)^\alpha$ (choosing α along a coordinate where $x^i\neq y^i$). So K is C^∞ off the diagonal. The more smoothly σ depends on ξ, the faster K decays: that is the content of the last line of the symbol–kernel dictionary.

From smooth kernels to pseudo-locality. Let u be smooth on an open set W and $x_0\in W$. Pick a cutoff ϕ with $\phi=1$ near x_0 and $\operatorname{supp}\phi\subset W$, and split $u=\phi u+(1-\phi)u$.

- ϕu is smooth with compact support, so $\widehat{\phi u}$ decays faster than any power, and $P(\phi u)=\int e^{ix\cdot\xi}\sigma\,\widehat{\phi u}\,\frac{\mathrm{d}^n\xi}{(2\pi)^n}$ can be differentiated under the integral any number of times: it is smooth everywhere.
- $(1-\phi)u$ vanishes near x_0, say for $|y-x_0|<2\delta$. For x with $|x-x_0|<\delta$, $P((1-\phi)u)(x)=\int K(x,y)(1-\phi(y))u(y)\,\mathrm{d}y$ only uses K at $|x-y|>\delta$, where it is smooth: so this piece is smooth near x_0.

So Pu is smooth near x_0: $x_0\notin\operatorname{sing\,supp} Pu$.

Worked example 2.68: $|D|$ applied to a box: not local, but pseudo-local

Let $u=\mathbf{1}_{[-1,1]}$ on $\mathbb{R}$. We use $|D|=H\circ\frac{\mathrm{d}}{\mathrm{d}x}$, where H is the **Hilbert transform** $Hf(x)=$

$\frac{1}{\pi}\,\mathrm{p.v.}\int \frac{f(y)}{x-y}\,\mathrm{d}y$, whose symbol is $-i\,\mathrm{sgn}\,\xi$. (Check: $(-i\,\mathrm{sgn}\,\xi)(i\xi) = |\xi|$.) Then

$$|D|\,u \overset{(1)}{=} H\big(\delta(\cdot+1)-\delta(\cdot-1)\big) \overset{(2)}{=} \frac{1}{\pi}\Big(\frac{1}{x+1}-\frac{1}{x-1}\Big) \overset{(3)}{=} \frac{2}{\pi(1-x^2)}.$$

(1) The box jumps up by 1 at $x=-1$ and down by 1 at $x=+1$, so $u' = \delta(x+1)-\delta(x-1)$.
(2) $H\delta(\cdot - c) = \frac{1}{\pi(x-c)}$, straight from the kernel.
(3) Common denominator: $(x-1)-(x+1) = -2$ over $(x+1)(x-1) = x^2-1$.

(The result is valid for $x \neq \pm 1$.) Read off the two properties: $\mathrm{supp}\,|D|\,u = \mathbb{R}$, much bigger than $\mathrm{supp}\,u = [-1,1]$, so $|D|$ is not local; but $|D|\,u$ is smooth (indeed real-analytic) except at $x=\pm1$, so $\mathrm{sing\,supp}\,|D|\,u = \{-1,1\} = \mathrm{sing\,supp}\,u$. The singularities stayed put. For comparison, $Hu = \frac{1}{\pi}\ln\left|\frac{x+1}{x-1}\right|$: again smooth off $\{\pm1\}$, with a logarithmic singularity (order 0 keeps the jump's strength roughly the same) instead of the pole of the order-1 operator.

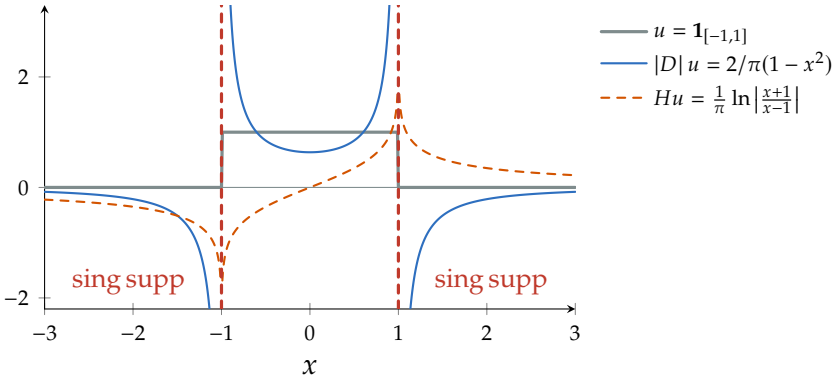

Figure 2.34: Pseudo-locality in action. The box u (grey) is supported in $[-1,1]$ and singular only at ±1 (red dashed lines). After applying the order-1 operator $|D|$ (blue) or the order-0 Hilbert transform H (orange), the result is nonzero on the whole line (the operators are not local), but it is still smooth everywhere except at ±1. Higher order makes the singularity stronger (a pole instead of a logarithm); it never moves it.

When singular supports coincide: hypo-ellipticity again. Pseudo-locality is only an inclusion. It allows P to *remove* singularities. A smoothing operator removes all of them. Nash's (2.70) considers operators that can remove none:

$$\mathrm{sing\,supp}\,Pu = \mathrm{sing\,supp}\,u \qquad \text{for all } u. \tag{2.142}$$

Then "Pu smooth" means $\mathrm{sing\,supp}\,Pu = \varnothing$, hence $\mathrm{sing\,supp}\,u = \varnothing$, hence u smooth: P is hypo-elliptic, in the sense of the previous sections. Conversely, if P is hypo-elliptic on every open set, then u smooth where Pu is smooth gives $\mathrm{sing\,supp}\,u \subset \mathrm{sing\,supp}\,Pu$, and pseudo-locality gives the other inclusion. So (2.142) is a characterisation of hypo-ellipticity (for pseudo-local operators), and elliptic ΨDOs satisfy it by the parametrix argument of Section 2.4.9: $u = Q(Pu) + R_2u$, with Q pseudo-local and R_2 smoothing, so $\mathrm{sing\,supp}\,u \subset \mathrm{sing\,supp}\,Pu$.

Reading Nash (pp. 41–47, (2.54)–(2.70))

Nash's §4 is short and example-driven. The dictionary to these notes: (2.54) is (2.118); (2.55) is (2.122); (2.56) is (2.124); the two definitions of ellipticity are in Section 2.4.7; (2.57)–(2.58) are (2.130) and (2.121); (2.59)–(2.60) are Example 2.60; (2.61) is Example 2.61; (2.62)–(2.63) are Example 2.63 and (2.138); (2.64)–(2.65) are Examples 2.49 and 2.64; (2.66)–

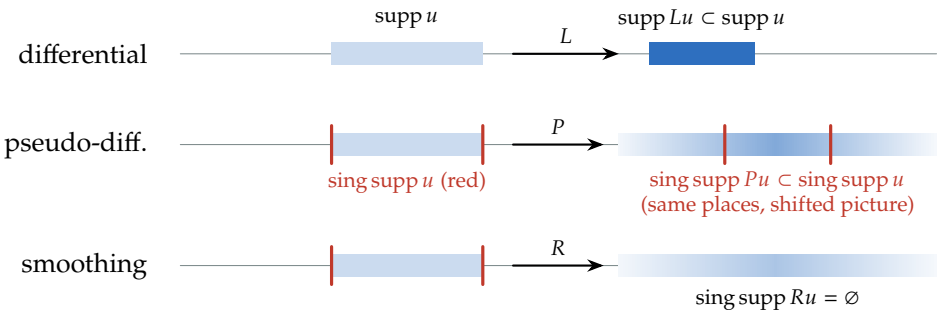

Figure 2.35: Three levels of "respecting" a function. A differential operator keeps supports (local). A ΨDO spreads the support over everything, but keeps singularities where they were (pseudo-local): in the middle row the red marks of the output sit over the same points $x = \pm 1$ as those of the input, drawn to the right only for legibility. A smoothing operator spreads everything and erases all singularities. Elliptic operators are the ones that erase *no* singularity: sing supp $Pu =$ sing supp u.

(2.68) are Example 2.66; (2.69)–(2.70) are (2.140) and (2.142). Nash's constants in (2.58), (2.61) and (2.64) differ from ours by factors of $\sqrt{2\pi}$ or $\sqrt{2}$, coming from his mixed Fourier normalisations; orders, principal symbols and ellipticity are unaffected. What Nash does *not* do, and we added, is the symbol calculus (composition, adjoints, commutators) and the parametrix; these are the tools that make the Fredholm theory of §5 work, and they are what his remark "elliptic operators are invertible modulo smoothing operators" (p. 55) rests on.

Recap: Pseudo-differential operators

- A ΨDO is "Fourier transform, multiply by $\sigma(x,\xi)$, transform back". Differential operators are the case of polynomial symbols.
- $\sigma \in S^m$: each ξ-derivative gains one power of decay; x-derivatives cost nothing. Orders can be any real number, or $-\infty$ (smoothing).
- Principal symbol $\sigma_m = \lim \sigma(x,\mu\xi)/\mu^m$: positively homogeneous, lives on T^*M. Elliptic: $\sigma_m(x,\xi)$ invertible for $\xi \neq 0$.
- Symbols multiply to leading order; commutators give Poisson brackets; elliptic operators have parametrices (inverses modulo smoothing).
- Examples: resolvents and Yukawa kernels, $\sqrt{\Delta + m^2}$, Bessel and Riesz potentials (fractional integration), a logarithmic symbol whose order is not attained, the Gaussian (smoothing), complex powers (order $2\operatorname{Re} z$, the route to ζ-functions and determinants).
- ΨDOs are not local but are pseudo-local: sing supp $Pu \subset$ sing supp u. Elliptic ones are exactly those that also keep every singularity: hypo-ellipticity.

2.5 Pseudo-differential operators and Sobolev spaces

We now have a large class of operators. The next question is: *on which spaces do they act, and how do we measure what they do?* Nash's answer is the Sobolev spaces, and the reasons are worth stating up front.

- A ΨDO of order m "costs m derivatives". We want spaces labelled by a number s that counts derivatives, so that P maps the space with label s to the one with label $s-m$, continuously. C^k spaces almost do this but fail in small, annoying ways; Sobolev spaces do it exactly, for every real s.
- We want Hilbert spaces, so that adjoints, orthogonal complements and spectral theory are available. C^k spaces are not Hilbert spaces; H^s spaces are.
- We want *compactness*: a bounded set of functions with one extra derivative under control should have convergent subsequences. That is what will make elliptic operators Fredholm, with finite-dimensional kernels, and give a finite index.

Physicists meet Sobolev norms constantly without the name. The energy of a static scalar field, $\frac{1}{2}\int(|\nabla\phi|^2 + m^2\phi^2)\,\mathrm{d}^n x$, is (for $m=1$) half the square of the H^1 norm. "Finite-energy configurations" means "$\phi \in H^1$". The δ-function source of a point charge lives in a Sobolev space of negative order. And the paths that dominate a Feynman path integral are continuous but not differentiable: they live in H^s for every $s < \frac{1}{2}$ and no better.

2.5.1 Counting derivatives in L^2 and L^p

The idea is the simplest one possible: a function is "k times differentiable in the L^2 sense" if it and all its derivatives up to order k are square integrable. For $f:\mathbb{R}^n \to \mathbb{C}$ this means (Nash's (2.71))

$$\sum_{|\alpha|\le k} \int_{\mathbb{R}^n} \left|\partial^\alpha f\right|^2 \mathrm{d}^n x < \infty, \tag{2.143}$$

and replacing the square by a p-th power gives the L^p version (2.72).

Working definition 2.32 (Sobolev space L^p_k, integer k; Nash (2.73)–(2.74))

Let $\Omega \subset \mathbb{R}^n$ be open, $k \in \{0,1,2,\dots\}$ and $1 \le p < \infty$. The **Sobolev space** $L^p_k(\Omega)$ consists of the functions f on Ω for which

$$\|f\|_{k,p} = \sum_{|\alpha|\le k} \left\{ \int_\Omega |\partial^\alpha f|^p \; \mathrm{d}^n x \right\}^{1/p} < \infty, \tag{2.144}$$

where the derivatives are taken in the *weak* (distributional) sense [moved onto smooth test functions by integrating by parts, so a kink like $|x|$ still has a first derivative] defined below. For $p=2$ it is a Hilbert space [its norm can be taken to come from an inner product, and every Cauchy sequence converges] and is written $H^k(\Omega) = L^2_k(\Omega)$. *Test:* compute all weak derivatives of order $\le k$ and check that each has finite L^p norm.

Two remarks on the norm. First, Nash adds the L^p norms of the derivatives. For $p=2$ it is more convenient to add their squares, $\|f\|^2_{H^k} = \sum_{|\alpha|\le k}\|\partial^\alpha f\|^2_{L^2}$, because then the norm comes from an inner product. The two choices are **equivalent norms**: for N non-negative numbers a_i, $\sum a_i^2 \le (\sum a_i)^2 \le N\sum a_i^2$ (the right inequality is Cauchy–Schwarz). Equivalent norms define the same space and the same notion of convergence, so we switch freely. Second, for $k=0$ there are no derivatives: $L^p_0 = L^p$ and $H^0 = L^2$.

Weak derivatives. Nash stresses that "the derivatives must be understood in the distributional sense". Here is what that means and why it matters. If f is C^1 and ϕ is a smooth function van-

ishing outside a bounded set (a *test function*), integration by parts gives $\int f'\phi\,\mathrm{d}x = -\int f\phi'\,\mathrm{d}x$, with no boundary terms. The right side makes sense even when f is not differentiable. So:

Working definition 2.33 (weak derivative)

g is the **weak derivative** $\partial^\alpha f$ if

$$\int g\,\phi\,\mathrm{d}^n x = (-1)^{|\alpha|}\int f\,\partial^\alpha\phi\,\mathrm{d}^n x \qquad \text{for every test function } \phi.$$

To compute: differentiate classically on the pieces where f is smooth, then check whether the jumps of f produce extra δ-functions (they do whenever f itself jumps).

Worked example 2.69: Weak derivatives of $|x|$ and of a step

(a) $f(x) = |x|$ on $\mathbb{R}$. For a test function ϕ,

$$\begin{aligned} -\int_{-\infty}^{\infty} |x|\;\phi'(x)\,\mathrm{d}x &\overset{(1)}{=} \int_{-\infty}^{0} x\,\phi'\,\mathrm{d}x - \int_{0}^{\infty} x\,\phi'\,\mathrm{d}x \\ &\overset{(2)}{=} \Big([x\phi]_{-\infty}^{0} - \int_{-\infty}^{0}\phi\,\mathrm{d}x\Big) - \Big([x\phi]_{0}^{\infty} - \int_{0}^{\infty}\phi\,\mathrm{d}x\Big) \\ &\overset{(3)}{=} \int_{-\infty}^{\infty} \operatorname{sgn}(x)\,\phi(x)\,\mathrm{d}x. \end{aligned}$$

(1) $|x| = -x$ for $x < 0$ and x for $x > 0$.
(2) Integrate by parts on each half-line.
(3) The boundary terms vanish: $x\phi = 0$ at $x = 0$, and $\phi = 0$ far away.

So the weak derivative of $|x|$ is $\operatorname{sgn} x$, a bounded function, as the classical derivative away from 0 suggests. *(b)* Now differentiate $\operatorname{sgn} x$:

$$-\int \operatorname{sgn}(x)\,\phi'(x)\,\mathrm{d}x \overset{(1)}{=} \int_{-\infty}^{0}\phi'\,\mathrm{d}x - \int_{0}^{\infty}\phi'\,\mathrm{d}x \overset{(2)}{=} \phi(0) + \phi(0) = 2\phi(0).$$

(1) Split at 0 as before.
(2) Fundamental theorem of calculus, ϕ vanishing at $\pm\infty$.

No function g satisfies $\int g\phi = 2\phi(0)$ for all ϕ; the weak derivative is the distribution 2δ. So, near the origin, $|x|$ has one weak derivative in L^2 but not two: multiplied by a cutoff it is in H^1 and not in H^2.

On manifolds and bundles. Sobolev spaces are defined on a compact manifold M by the partition-of-unity trick Nash mentions: cover M by charts Ω_i, pick $\phi_i \geq 0$ with $\sum\phi_i = 1$ and $\operatorname{supp}\phi_i \subset \Omega_i$, and set $\|f\|_{L^p_k(M)} = \sum_i \|\phi_i f\|_{L^p_k(\Omega_i)}$, computing each term in the coordinates of Ω_i. Different choices give equivalent norms (the chain rule converts derivatives in one chart into combinations of derivatives in another, with smooth, hence bounded, coefficients on the compact supports). For a vector bundle $E \to M$ we do the same with the components of a section in local trivialisations, giving $L^p_k(M,E)$ and $H^k(M,E)$: "vector-valued functions on M". When nothing is lost, we abbreviate to L^p_k and H^k.

2.5.2 Sobolev spaces of any real order via the Fourier transform

Derivatives count as powers of momentum. So instead of adding the norms of derivatives, we can weight the Fourier transform by a power of momentum, and then nothing forces the power to be an integer.

Working definition 2.34 (H^s for real s; Nash (2.75))

For $s \in \mathbb{R}$, $H^s(\mathbb{R}^n)$ is the space of (tempered) distributions [generalised functions, such as δ, that grow at most polynomially, so they have a Fourier transform] f whose Fourier transform is a function with

$$\|f\|_s^2 = \int_{\mathbb{R}^n} \langle\xi\rangle^{2s} \left|\hat f(\xi)\right|^2 \frac{\mathrm{d}^n\xi}{(2\pi)^n} < \infty, \qquad \langle\xi\rangle^{2s} = (1+|\xi|^2)^s. \tag{2.145}$$

Equivalently $f \in H^s$ iff $(1+\Delta)^{s/2} f \in L^2$, and $\|f\|_s = \left\|(1+\Delta)^{s/2} f\right\|_{L^2}$: *apply the Bessel potential of order s (Example 2.50(b)) and ask for square integrability*. For $1 \le p < \infty$, L^p_s is defined by asking that $(1+\Delta)^{s/2} f \in L^p$.

The "equivalently" is one line: $(1+\Delta)^{s/2}$ is the Fourier multiplier $\langle\xi\rangle^s$, and Plancherel's theorem $\int |g|^2 \,\mathrm{d}^n x = \int |\hat g|^2 \frac{\mathrm{d}^n\xi}{(2\pi)^n}$ (in our conventions) turns $\left\|(1+\Delta)^{s/2} f\right\|_{L^2}^2$ into (2.145). At $s = 0$ it is just Plancherel: $H^0 = L^2$.

Agreement with the old definition for integer k. This is Nash's (2.76)–(2.77). Expand the weight with the multinomial theorem:

$$(1+\xi_1^2+\cdots+\xi_n^2)^k = \sum_{|\beta|\le k} \binom{k}{\beta} \xi^{2\beta}, \qquad \binom{k}{\beta} = \frac{k!}{(k-|\beta|)!\,\beta_1!\cdots\beta_n!}, \tag{2.146}$$

a finite sum with positive integer coefficients (Nash's a_α). Then

$$\begin{aligned} \|f\|_k^2 &\overset{(1)}{=} \sum_{|\beta|\le k} \binom{k}{\beta} \int \xi^{2\beta} \left|\hat f(\xi)\right|^2 \frac{\mathrm{d}^n\xi}{(2\pi)^n} \overset{(2)}{=} \sum_{|\beta|\le k} \binom{k}{\beta} \int \left|\widehat{D^\beta f}(\xi)\right|^2 \frac{\mathrm{d}^n\xi}{(2\pi)^n} \\ &\overset{(3)}{=} \sum_{|\beta|\le k} \binom{k}{\beta} \int \left|D^\beta f(x)\right|^2 \mathrm{d}^n x \overset{(4)}{=} \sum_{|\beta|\le k} \binom{k}{\beta} \left\|\partial^\beta f\right\|_{L^2}^2 . \end{aligned} \tag{2.147}$$

(1) Insert (2.146) into (2.145) and integrate term by term.

(2) $\widehat{D^\beta f} = \xi^\beta \hat f$ (derivatives become multiplication), and $\xi^{2\beta}\left|\hat f\right|^2 = \left|\xi^\beta \hat f\right|^2$ since ξ is real.

(3) Plancherel for each $D^\beta f$.

(4) $\left|D^\beta f\right| = \left|(-i)^{|\beta|}\partial^\beta f\right| = \left|\partial^\beta f\right|$.

All coefficients lie between 1 and $k!$, so this norm is equivalent to $\sum \left\|\partial^\beta f\right\|^2$, hence to Nash's (2.144) with $p = 2$. For instance in one dimension

$$\|f\|_1^2 = \|f\|^2 + \|f'\|^2, \qquad \|f\|_2^2 = \|f\|^2 + 2\|f'\|^2 + \|f''\|^2,$$

from $1+\xi^2$ and $(1+\xi^2)^2 = 1 + 2\xi^2 + \xi^4$.

Worked example 2.70: The tent function: both definitions, and its exact smoothness

Let $f(x) = (1-|x|)_+$ (equal to $1-|x|$ on $[-1,1]$, zero outside). Its weak derivative is $f' = +1$ on $(-1,0)$, -1 on $(0,1)$, zero outside (as in Example 2.69, the corners produce no δ). *Position space:*

$$\|f\|^2 = 2\int_0^1 (1-x)^2 dx = \tfrac{2}{3}, \qquad \|f'\|^2 = \int_{-1}^1 1\,dx = 2, \qquad \|f\|_1^2 = \tfrac{8}{3}.$$

Momentum space:

$$\hat f(\xi) \overset{(1)}{=} 2\int_0^1 (1-x)\cos(x\xi)\,dx \overset{(2)}{=} \frac{2(1-\cos\xi)}{\xi^2} = \frac{4\sin^2(\xi/2)}{\xi^2}.$$

(1) f is even, so $e^{-ix\xi}$ may be replaced by $\cos x\xi$ and the integral doubled.

(2) Integrate by parts once: $2\big[(1-x)\frac{\sin x\xi}{\xi}\big]_0^1 + \frac{2}{\xi}\int_0^1 \sin(x\xi)\,dx = \frac{2(1-\cos\xi)}{\xi^2}$.

Then, with the classical integrals $\int_{\mathbb{R}} (\sin x/x)^4 dx = 2\pi/3$ and $\int_{\mathbb{R}} \sin^4 x/x^2\,dx = \pi/2$ (substituting $x = \xi/2$),

$$\int |\hat f|^2 \frac{d\xi}{2\pi} \overset{(1)}{=} \frac{16}{2\pi}\int \frac{\sin^4(\xi/2)}{\xi^4}\,d\xi \overset{(2)}{=} \frac{16}{2\pi}\cdot\frac{2}{16}\cdot\frac{2\pi}{3} = \frac{2}{3},$$
$$\int \xi^2 |\hat f|^2 \frac{d\xi}{2\pi} \overset{(3)}{=} \frac{16}{2\pi}\int \frac{\sin^4(\xi/2)}{\xi^2}\,d\xi \overset{(4)}{=} \frac{16}{2\pi}\cdot\frac{2}{4}\cdot\frac{\pi}{2} = 2.$$

(1) Square $\hat f$.

(2) $\xi = 2x$: $\sin^4(\xi/2)/\xi^4 = \sin^4 x/(16x^4)$ and $d\xi = 2dx$.

(3) Same, with one factor ξ^2 cancelled.

(4) $\xi = 2x$: $\sin^4 x/(4x^2)$, $d\xi = 2dx$.

The two definitions agree: $\frac{2}{3} + 2 = \frac{8}{3}$. But the Fourier side tells us more. Since $|\hat f| \sim 4\sin^2(\xi/2)/\xi^2$ decays like $|\xi|^{-2}$ (on average), $\int \langle\xi\rangle^{2s} |\hat f|^2$ behaves like $\int^\infty \xi^{2s-4} d\xi$, finite iff $2s - 4 < -1$:

$$f \in H^s(\mathbb{R}) \iff s < \tfrac{3}{2}.$$

The tent is in H^1, and even in $H^{1.4}$, but not in $H^{3/2}$. Integer derivatives alone could only have told us "H^1 but not H^2".

Watch out: Normalisation conventions

Nash's (2.75) omits the $(2\pi)^{-n}$ and uses $\langle\xi\rangle^k$ inside a p-th power. Different books use $(1+4\pi^2|\xi|^2)^s$, or $(1+|\xi|)^{2s}$, or $|\xi|^{2s}$ plus the L^2 norm. All of these give the same spaces with equivalent norms (by (2.123) and its relatives); only numerical constants change. The *homogeneous* weight $|\xi|^{2s}$ alone, without the 1, does *not* give an equivalent norm: it ignores low momenta and defines a different space.

2.5.3 Sobolev spaces on the circle, explicitly

On a compact manifold without boundary the cleanest picture is the circle, where the Fourier transform is a Fourier series and every statement becomes a statement about how fast coefficients

decay. Write

$$u(\theta)=\sum_{n\in\mathbb{Z}} c_n\, e^{in\theta}, \qquad c_n=\frac{1}{2\pi}\int_0^{2\pi} u(\theta)e^{-in\theta}\,\mathrm{d}\theta, \qquad \|u\|_{L^2}^2=2\pi\sum_n |c_n|^2,$$

the last being Parseval's identity. The derivative $D_\theta=-i\,\mathrm{d}/\mathrm{d}\theta$ acts by $c_n\mapsto nc_n$, and $\Delta=D_\theta^2$ by $c_n\mapsto n^2c_n$.

Working definition 2.35 ($H^s(S^1)$ and $H^s(T^n)$)

$$H^s(S^1)=\Big\{u=\sum c_n e^{in\theta}:\ \|u\|_s^2=2\pi\sum_{n\in\mathbb{Z}}(1+n^2)^s\,|c_n|^2<\infty\Big\}.$$

On the torus $T^n=\mathbb{R}^n/2\pi\mathbb{Z}^n$ [the cube $[0,2\pi]^n$ with opposite faces identified], replace $n\in\mathbb{Z}$ by $k\in\mathbb{Z}^n$ and $1+n^2$ by $1+|k|^2$. *Test:* find the power law of $|c_n|$ at large $|n|$. If $|c_n|\sim|n|^{-a}$, then $u\in H^s$ iff $2s-2a<-1$, i.e. $s<a-\frac12$.

The test is the p-series: $\sum_{n\ge1} n^{2s}n^{-2a}$ converges iff $2s-2a<-1$.

Worked example 2.71: Triangle, square wave, delta: three rungs of the ladder

Work on $\theta\in(-\pi,\pi]$, extended periodically.
Square wave $q(\theta)=\operatorname{sgn}\theta$. Its coefficients:

$$c_n(q)\overset{(1)}{=}\frac{1}{2\pi}\Big(\int_0^{\pi}e^{-in\theta}\mathrm{d}\theta-\int_{-\pi}^{0}e^{-in\theta}\mathrm{d}\theta\Big)\overset{(2)}{=}\frac{-i}{\pi}\int_0^{\pi}\sin n\theta\,\mathrm{d}\theta\overset{(3)}{=}\frac{-i\,(1-(-1)^n)}{\pi n},$$

(1) Definition, splitting at 0.
(2) Substitute $\theta\to-\theta$ in the second integral; $e^{-in\theta}-e^{in\theta}=-2i\sin n\theta$.
(3) $\int_0^{\pi}\sin n\theta\,\mathrm{d}\theta=(1-\cos n\pi)/n$ and $\cos n\pi=(-1)^n$.

So $c_n=-2i/(\pi n)$ for odd n and 0 for even n: $|c_n|\sim|n|^{-1}$, $a=1$, and $q\in H^s$ iff $s<\frac12$.
Triangle wave $t(\theta)=|\theta|$. Here $c_0=\pi/2$ and for $n\neq0$

$$c_n(t)\overset{(1)}{=}\frac{1}{\pi}\int_0^{\pi}\theta\cos n\theta\,\mathrm{d}\theta\overset{(2)}{=}\frac{(-1)^n-1}{\pi n^2},$$

(1) t is even, so only the cosine part survives.
(2) Integrate by parts: $\big[\theta\frac{\sin n\theta}{n}\big]_0^{\pi}+\big[\frac{\cos n\theta}{n^2}\big]_0^{\pi}$.

so $c_n=-2/(\pi n^2)$ for odd n: $a=2$, and $t\in H^s$ iff $s<\frac32$ (the tent again).
Delta at $\theta=0$: $c_n=\frac{1}{2\pi}$ for every n, so $a=0$ and $\delta\in H^s$ iff $s<-\frac12$.
The ladder. Now differentiate. Term by term, $\frac{\mathrm{d}}{\mathrm{d}\theta}$ multiplies c_n by in:

$$in\,c_n(t)=in\cdot\frac{-2}{\pi n^2}=\frac{-2i}{\pi n}=c_n(q)\quad(n\text{ odd}),$$
$$in\,c_n(q)=in\cdot\frac{-2i}{\pi n}=\frac{2}{\pi}=c_n(2\delta_0-2\delta_\pi)\quad(n\text{ odd}),$$

where δ_π is the delta at $\theta=\pi$, with $c_n(\delta_\pi)=(-1)^n/2\pi$, so $c_n(2\delta_0-2\delta_\pi)=(1-(-1)^n)/\pi$. So $t'=q$ and $q'=2\delta_0-2\delta_\pi$: the square wave jumps up by 2 at 0 and down by 2 at π. Each derivative moves one rung down the Sobolev ladder: thresholds $\frac32\to\frac12\to-\frac12$ (Figure 2.36).

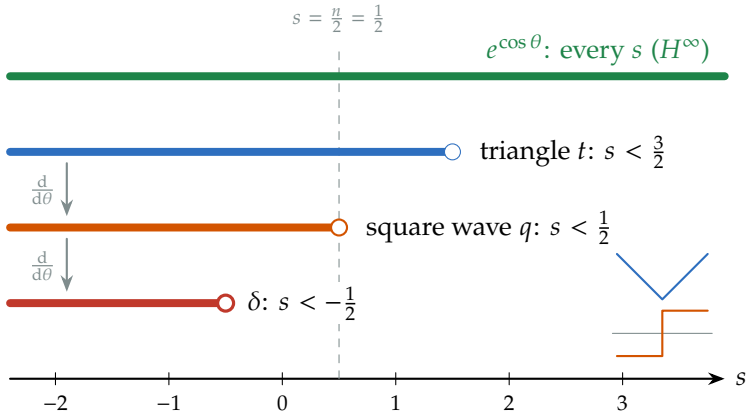

Figure 2.36: The Sobolev ladder on the circle. Each bar shows the values of s for which the function lies in $H^s(S^1)$; the open circle marks the threshold, which is never attained. Differentiating moves a function down one rung (threshold decreases by exactly 1). A jump discontinuity sits just below $s = \frac{1}{2} = \frac{n}{2}$, the dimension-dependent line above which functions are guaranteed to be continuous (Sobolev embedding, Section 2.5.7). Small inset: the triangle (blue) and its derivative, the square wave (orange).

Worked example 2.72: A smooth function is in every H^s

For $u = e^{\cos\theta}$ the coefficients are the modified Bessel numbers $c_n = I_n(1) = \sum_{j\geq 0} \frac{(1/2)^{2j+|n|}}{j!\,(j+|n|)!}$, and $I_n(1) \leq \frac{(1/2)^{|n|}}{|n|!} e^{1/4}$. This decays faster than any power of n, so $\sum (1+n^2)^s\,|c_n|^2 < \infty$ for every s. In general, integrating by parts k times shows $|c_n| \leq \left\|u^{(k)}\right\|_{L^1} / (2\pi\,|n|^k)$ for any C^k function: *smooth functions have rapidly decreasing Fourier coefficients*, and conversely. So $C^\infty(S^1) = \bigcap_s H^s(S^1)$, a first glimpse of $H^\infty = C^\infty$ on compact manifolds.

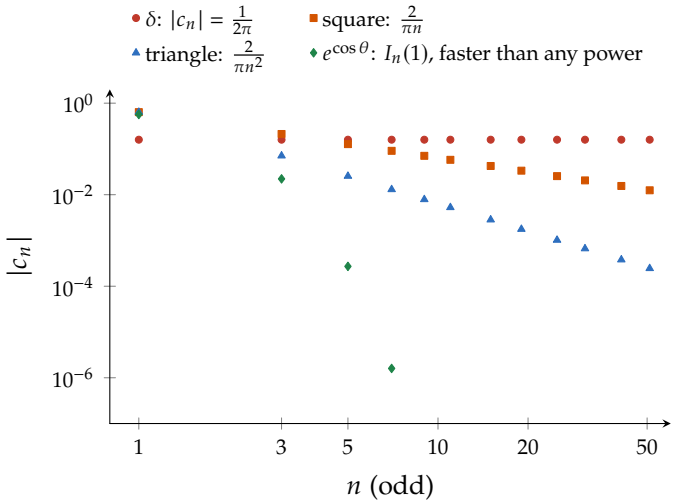

Figure 2.37: Decay of Fourier coefficients on a log–log plot. A power law $|c_n| \sim n^{-a}$ is a straight line of slope $-a$, and the Sobolev threshold is $s = a - \frac{1}{2}$. Slopes $0, -1, -2$ give thresholds $-\frac{1}{2}, \frac{1}{2}, \frac{3}{2}$. The smooth function's coefficients (green) bend down off every straight line: it is in every H^s.

Physical picture: Brownian paths and the path integral

A Brownian path on $[0, 2\pi]$ (with the endpoints pinned) has a random Fourier sine series with independent Gaussian coefficients of size $|c_n| \sim n^{-1}$: this is the free-particle path integral of quantum mechanics in Euclidean time. By the test above, a typical path is in H^s exactly for $s < \frac{1}{2}$: continuous (just), but with no square-integrable derivative. So the kinetic term $\int \dot{x}^2 \, \mathrm{d}t$ of the action is infinite on almost every path that contributes. This is the simplest example of the general fact that the field configurations in a Euclidean path integral are distributions in some H^s with s below the threshold where the action is finite.

2.5.4 Negative orders are dual spaces

What is H^{-1}? The Fourier definition (2.145) works for negative s without change: the weight $\langle \xi \rangle^{2s}$ now *damps* high momenta, so $\hat{f}$ is allowed to grow, and f can be a distribution such as δ. Nash's point is that these spaces are exactly the dual spaces of the positive ones:

$$H^{-s} = (H^s)^*, \tag{2.148}$$

where V^* is the space of continuous linear functionals on V. In words: *an element of H^{-s} is something you can integrate against a function with s derivatives in L^2.*

Take $f \in H^s$ and $g \in H^{-s}$ and pair them by $\langle f, g \rangle = \int f \, \bar{g} \, \mathrm{d}^n x$ (Nash's $g(f)$). Then

$$\begin{aligned} |\langle f, g \rangle| &\overset{(1)}{=} \left| \int \hat{f}(\xi) \overline{\hat{g}(\xi)} \, \frac{\mathrm{d}^n \xi}{(2\pi)^n} \right| \overset{(2)}{=} \left| \int \langle \xi \rangle^s \hat{f}(\xi) \, \langle \xi \rangle^{-s} \overline{\hat{g}(\xi)} \, \frac{\mathrm{d}^n \xi}{(2\pi)^n} \right| \\ &\overset{(3)}{\le} \left(\int \langle \xi \rangle^{2s} \left| \hat{f} \right|^2 \frac{\mathrm{d}^n \xi}{(2\pi)^n} \right)^{1/2} \left(\int \langle \xi \rangle^{-2s} \, |\hat{g}|^2 \, \frac{\mathrm{d}^n \xi}{(2\pi)^n} \right)^{1/2} \overset{(4)}{=} \|f\|_s \, \|g\|_{-s} \, . \end{aligned} \tag{2.149}$$

(1) Parseval (the polarised form of Plancherel).
(2) Multiply and divide by $\langle \xi \rangle^s$: this is Nash's $h^k = (1 + \xi^2)^{k/2}$ trick in (2.78).
(3) Cauchy–Schwarz in $L^2(\frac{\mathrm{d}^n \xi}{(2\pi)^n})$. This is Nash's (2.79).
(4) Definition (2.145) with s and $-s$.

So every $g \in H^{-s}$ defines a bounded functional on H^s, with norm at most $\|g\|_{-s}$. Conversely, every bounded functional ℓ on the Hilbert space H^s is $\ell(f) = (f, h)_s$ for some $h \in H^s$ (Riesz representation), and $(f, h)_s = \int \hat{f} \, \langle \xi \rangle^{2s} \bar{\hat{h}} \, \frac{\mathrm{d}^n \xi}{(2\pi)^n} = \langle f, g \rangle$ with $\hat{g} = \langle \xi \rangle^{2s} \hat{h}$, which has $\|g\|_{-s} = \|h\|_s < \infty$. So the correspondence is onto and (2.148) holds isometrically. (Nash's own argument shows one direction, "$g(f) < \infty$ for all f iff $g \in H^{-k}$"; the Riesz step supplies the other.)

Worked example 2.73: The delta function as an element of H^{-s}

On the circle. Pairing with δ_0 is evaluation, $u \mapsto u(0) = \sum_n c_n$. Is it bounded on $H^s(S^1)$?

$$\begin{aligned} |u(0)| &\overset{(1)}{\le} \sum_n (1 + n^2)^{s/2} \, |c_n| \, (1 + n^2)^{-s/2} \overset{(2)}{\le} \left(\sum_n (1 + n^2)^s \, |c_n|^2 \right)^{1/2} \left(\sum_n (1 + n^2)^{-s} \right)^{1/2} \\ &= \frac{1}{\sqrt{2\pi}} \, \|u\|_s \, \left(\sum_n (1 + n^2)^{-s} \right)^{1/2} . \end{aligned}$$

(1) Triangle inequality, and multiply and divide by $(1 + n^2)^{s/2}$.
(2) Cauchy–Schwarz for sequences.

The last sum is finite iff $2s > 1$. So evaluation at a point is continuous on $H^s(S^1)$ precisely

for $s > \frac{1}{2}$, which matches $\delta \in H^{-s}$ iff $-s < -\frac{1}{2}$ (Example 2.71). *In* $\mathbb{R}^n$. $\hat{\delta} = 1$, so $\|\delta\|_s^2 = \int (1+|\xi|^2)^s \frac{d^n\xi}{(2\pi)^n} = \frac{\mathrm{vol}(S^{n-1})}{(2\pi)^n} \int_0^\infty (1+\rho^2)^s \rho^{n-1} d\rho$, finite iff $2s + n - 1 < -1$:

$$\delta \in H^s(\mathbb{R}^n) \iff s < -\tfrac{n}{2}.$$

A point charge in three dimensions is in $H^{-3/2-\varepsilon}$; its Coulomb potential, $(\Delta)^{-1}$ of it, gains two derivatives and is (locally) in $H^{1/2-\varepsilon}$: indeed $1/r$ is locally square integrable in $\mathbb{R}^3$ but its gradient $\sim 1/r^2$ is not.

The L^p version. For $1 < p < \infty$ Nash quotes (from Treves)

$$(L^p_k)^* = L^{p'}_{-k}, \qquad p' = \frac{p}{p-1}, \qquad \text{i.e. } \frac{1}{p} + \frac{1}{p'} = 1. \tag{2.150}$$

At $k = 0$ this is the familiar statement $(L^p)^* = L^{p'}$, which rests on Hölder's inequality $\left|\int f\bar{g}\right| \le \|f\|_{L^p}\,\|g\|_{L^{p'}}$ (the L^p replacement for Cauchy–Schwarz). For $p = 2$, $p' = 2$ and we are back to (2.148). The conjugate exponent is forced by scaling: the pairing $\int f\bar{g}$ is invariant under $f \to \lambda^{n/p} f(\lambda x)$, $g \to \lambda^{n/p'} g(\lambda x)$ exactly when $1/p + 1/p' = 1$.

2.5.5 Test functions, distributions, and rigged Hilbert space

Since negative Sobolev spaces contain distributions, Nash pauses to recall the standard function and distribution spaces. We give each one with examples, because the whole point is to know what lives where.

Working definition 2.36 (the three test-function spaces; Nash (2.81))

- $\mathcal{D}(\mathbb{R}^n)$: C^∞ functions with compact support [each one is zero outside some bounded set] (**test functions**).
- $\mathcal{S}(\mathbb{R}^n)$: C^∞ functions such that $x^\alpha D^\beta f \to 0$ as $|x| \to \infty$ for all α, β (**Schwartz space**: smooth and rapidly decreasing, with all derivatives).
- $\mathcal{E}(\mathbb{R}^n) = C^\infty(\mathbb{R}^n)$: all smooth functions.

Clearly $\mathcal{D} \subset \mathcal{S} \subset \mathcal{E}$.

Worked example 2.74: Who lives where

A bump function in $\mathcal{D}$. $\psi(x) = e^{-1/(1-x^2)}$ for $|x| < 1$ and 0 otherwise. It is smooth even at $x = \pm 1$: near $x = 1$ it is $e^{-1/t}$ times a smooth function, with $t = 1 - x^2 \to 0^+$, and every derivative of $e^{-1/t}$ is (polynomial in $1/t$) $e^{-1/t} \to 0$ as $t \to 0^+$, because the exponential beats every power. So all derivatives match the zero function from outside. *In $\mathcal{S}$ but not $\mathcal{D}$:* the Gaussian e^{-x^2} (every $x^\alpha D^\beta e^{-x^2}$ is a polynomial times e^{-x^2}), and $1/\cosh x$. *In $\mathcal{E}$ but not $\mathcal{S}$:* $1/(1+x^2)$ (smooth, but $x^2 \cdot \frac{1}{1+x^2} \to 1 \neq 0$), $\sin x$, x^3, e^x.

Distributions are the continuous linear functionals on these spaces:

$$\mathcal{D} \subset \mathcal{S} \subset \mathcal{E} \qquad \Longrightarrow \qquad \mathcal{E}' \subset \mathcal{S}' \subset \mathcal{D}'. \tag{2.151}$$

The inclusions reverse (Nash's (2.82)): the more test functions a functional must accept, the fewer functionals qualify. A functional on $\mathcal{E}$ must cope with e^{x^2}; a functional on $\mathcal{D}$ only with compactly supported functions.

Working definition 2.37 (distribution, operationally)

A **distribution** $T \in \mathcal{D}'$ is a linear rule $\phi \mapsto T(\phi)$ on test functions that is continuous in the sense: for each bounded region K there are C, N with $|T(\phi)| \le C \sum_{|\alpha|\le N} \sup |\partial^\alpha \phi|$ for all ϕ supported in K. *Every locally integrable function f [$\int_K |f| < \infty$ over every bounded region K, e.g. $1/|x|$ in $\mathbb{R}^3$] is one*, via $T_f(\phi) = \int f\phi$. Derivatives are defined by moving them onto ϕ: $(\partial^\alpha T)(\phi) = (-1)^{|\alpha|} T(\partial^\alpha \phi)$, which is the weak derivative again. **Tempered distributions** $\mathcal{S}'$ are those that also accept Schwartz functions; $\mathcal{E}'$ consists of the distributions with compact support [there is a bounded set K with $T(\phi) = 0$ whenever ϕ vanishes near K].

Worked example 2.75: Examples of distributions and where they sit

T	$\mathcal{E}'$ (compact support)	$\mathcal{S}'$ (tempered)	$\mathcal{D}'$
δ, δ', $\mathbf{1}_{[0,1]}$	yes	yes	yes
1, x^3, e^{ipx}, $\lvert x\rvert^{-1/2}$, p.v.$\frac{1}{x}$	no	yes	yes
e^x, e^{x^2}	no	no	yes

Why $e^x \notin \mathcal{S}'$: pair it with the Schwartz function $\phi(x) = e^{-\sqrt{1+x^2}}$ (smooth, and it decays exponentially together with its derivatives). For $x \to +\infty$, $e^x\phi(x) = e^{x-\sqrt{1+x^2}} \to e^0 = 1$, so $\int e^x\phi$ diverges. *Why* p.v.$\frac{1}{x}$ *is a distribution:* $\lim_{\varepsilon\to 0}\int_{|x|>\varepsilon} \frac{\phi(x)}{x}\mathrm{d}x = \int_0^\infty \frac{\phi(x)-\phi(-x)}{x}\mathrm{d}x$, and the integrand is bounded by $2\sup|\phi'|$ near 0. This is the kernel of the Hilbert transform in Example 2.68.

The Fourier transform maps $\mathcal{S}$ onto $\mathcal{S}$ (derivatives and multiplication by x swap roles, and both are harmless there), and hence, by duality, $\mathcal{S}'$ onto $\mathcal{S}'$. That is why tempered distributions are the natural home of Fourier analysis: $\hat{1} = (2\pi)^n\delta$, $\hat{\delta} = 1$, $\widehat{e^{ipx}} = (2\pi)^n\delta(\xi - p)$. It is also why our $H^s(\mathbb{R}^n)$ were defined as subspaces of $\mathcal{S}'$.

The rigged Hilbert space (Nash's (2.83)). $\mathcal{S} \subset L^2$, and L^2 is its own dual (Riesz again: $g \in L^2$ is the functional $f \mapsto \langle g, f\rangle$). Dualising $\mathcal{S} \subset L^2$ gives $(L^2)' \subset \mathcal{S}'$, hence the **Gelfand triple**

$$\mathcal{S} \subset L^2 \subset \mathcal{S}'. \tag{2.152}$$

This is the identification "a function is a distribution" made precise.

Dictionary: Dirac's bras and kets live in a Gelfand triple

Quantum mechanics	Functional analysis
normalisable state $\lvert\psi\rangle$	$\psi \in L^2$
"nice" states (finite $\langle x^a p^b\rangle$ for all a, b)	$\psi \in \mathcal{S}$
momentum eigenstate $\lvert p\rangle$, $\langle x\rvert p\rangle = e^{ipx}$	$e^{ipx} \in \mathcal{S}' \setminus L^2$
position eigenstate $\lvert x_0\rangle$, $\langle x\rvert x_0\rangle = \delta(x - x_0)$	$\delta_{x_0} \in \mathcal{S}' \setminus L^2$
$\langle p\rvert\psi\rangle$ for $\psi \in \mathcal{S}$	a finite number: $\hat{\psi}(p)$
$\langle p\rvert p'\rangle = 2\pi\delta(p - p')$	pairing of two elements of $\mathcal{S}'$: only a distribution

Dirac's formalism works because the generalised eigenvectors sit in $\mathcal{S}'$ and are only ever paired with states in $\mathcal{S}$. In Sobolev terms $\delta \in H^{-1/2-\varepsilon}(\mathbb{R})$: one needs slightly more than half a derivative of smoothness in the state to evaluate it at a point.

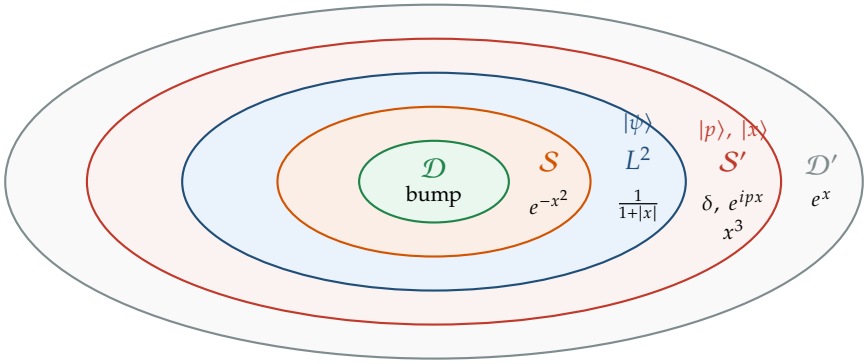

Figure 2.38: The nested spaces of (2.151)–(2.152) on $\mathbb{R}$, with one inhabitant of each shell. Test functions (green) sit inside Schwartz functions, inside L^2 (normalisable states), inside tempered distributions (where plane waves and δ live), inside all distributions (where even e^x lives). The Sobolev spaces H^s interpolate between $\mathcal{S}$ and $\mathcal{S}'$: H^s shrinks towards $\mathcal{S}$-like smoothness as $s \to +\infty$ and grows towards $\mathcal{S}'$ as $s \to -\infty$.

2.5.6 The Sobolev scale

Since $\langle\xi\rangle \geq 1$, a larger exponent gives a larger weight:

$$s > s' \implies \langle\xi\rangle^{2s'} \leq \langle\xi\rangle^{2s} \implies \|f\|_{s'} \leq \|f\|_s \implies H^s \subset H^{s'}.$$

So the spaces *shrink* as s increases (Nash's (2.84)):

$$\cdots \subset H^2 \subset H^1 \subset H^0 = L^2 \subset H^{-1} \subset H^{-2} \subset \cdots, \tag{2.153}$$

with the inclusion maps having norm ≤ 1. The extremes are (Nash's (2.85))

$$H^\infty = \bigcap_{s\in\mathbb{R}} H^s, \qquad H^{-\infty} = \bigcup_{s\in\mathbb{R}} H^s = (H^\infty)^*, \tag{2.154}$$

and the whole hierarchy (Nash's (2.86)) is

$$\mathcal{D} \subset \mathcal{S} \subset H^\infty \subset \cdots \subset H^k \subset \cdots \subset H^0 \subset \cdots \subset H^{-k} \subset \cdots \subset H^{-\infty} \subset \mathcal{S}' \subset \mathcal{D}'. \tag{2.155}$$

Each step of the chain is a real loss or gain: the tent function is in H^1 but not H^2; the square wave in H^0 but not H^1; δ in H^{-1} but not H^0 (in one dimension).

Watch out: $H^\infty(\mathbb{R}^n)$ is not $\mathcal{S}$

$H^\infty(\mathbb{R}^n)$ contains $1/(1+x^2)$: all its derivatives are square integrable, but it does not decay rapidly, so it is not in $\mathcal{S}$. Sobolev norms measure smoothness and L^2-size, not decay. On a *compact* manifold there is no "infinity" to decay at, and the chain simplifies (Nash): drop $\mathcal{S}$ and $\mathcal{S}'$, and

$$C^\infty(M,E) = H^\infty(M,E) \subset \cdots \subset H^k(M,E) \subset \cdots \subset H^{-\infty}(M,E) = \mathcal{D}'(M,E).$$

The first equality is the Sobolev embedding theorem of the next subsection (and Example 2.72 on the circle).

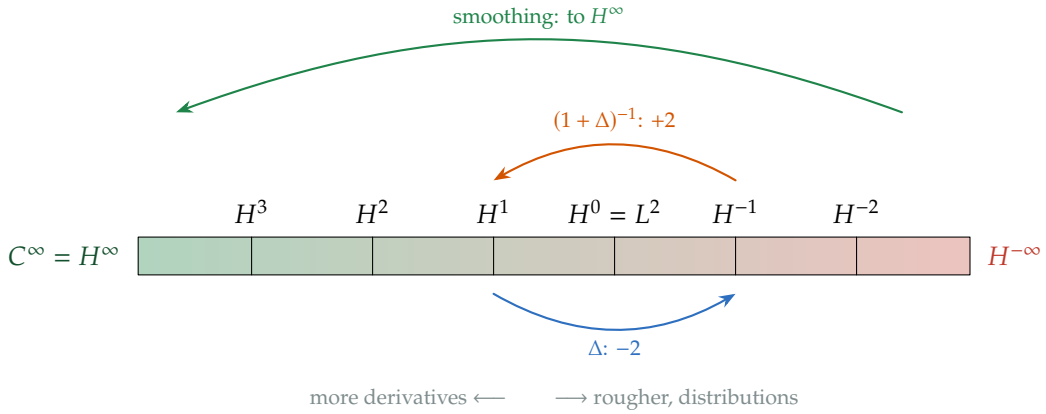

Figure 2.39: The Sobolev scale as a ruler. Smooth functions sit at the left end, distributions at the right. A ΨDO of order m moves everything m steps to the right (for $m > 0$) or $|m|$ steps to the left (for $m < 0$): the Laplacian moves H^1 to H^{-1}, its inverse moves H^{-1} to H^1. A smoothing operator sends everything to the far left end.

2.5.7 How many derivatives buy continuity: the Sobolev embedding theorem

An element of H^k is defined through integrals. Integrals do not see what happens on a set of measure zero, so a priori an element of H^k is not a function with definite values at points; it is a class of functions that agree almost everywhere. The question Nash now answers is: *when is an element of H^k (or L^p_k) an honest continuous function, or an honest C^l function?* Physically: when does "the value of the field at the point x" mean anything?

We have already seen the answer on the circle in one special case. In Example 2.73, evaluation at a point, $u \mapsto u(0)$, was a bounded functional on $H^s(S^1)$ exactly when $s > \frac{1}{2}$. A bounded evaluation functional is what continuity at a point needs. So on the circle *half a derivative in L^2 plus a little bit* is what it takes to be continuous. The general rule replaces $\frac{1}{2}$ by $\frac{n}{p}$.

The rule from dimensional analysis. Before any theorem, here is the physicist's derivation. Suppose an inequality of the form

$$\sup_x |\partial^\alpha f(x)| \le C \, \|f\|_{k,p} \qquad (|\alpha| = l) \tag{2.156}$$

were true for all f, with C independent of f. Test it on a function that is squeezed into a small region: pick any bump f and set $f_\lambda(x) = f(\lambda x)$ with $\lambda \gg 1$ (Figure 2.40). For a multi-index β,

$$\begin{aligned} \left\|\partial^\beta f_\lambda\right\|_{L^p}^p &\overset{(1)}{=} \int \left|\lambda^{|\beta|}(\partial^\beta f)(\lambda x)\right|^p \, \mathrm{d}^n x \overset{(2)}{=} \lambda^{p|\beta|} \int \left|(\partial^\beta f)(y)\right|^p \, \lambda^{-n} \mathrm{d}^n y \\ &\overset{(3)}{=} \lambda^{p|\beta|-n} \left\|\partial^\beta f\right\|_{L^p}^p, \qquad \text{so} \qquad \left\|\partial^\beta f_\lambda\right\|_{L^p} = \lambda^{|\beta|-\frac{n}{p}} \left\|\partial^\beta f\right\|_{L^p}. \end{aligned} \tag{2.157}$$

(1) Chain rule: each derivative of $f(\lambda x)$ brings out a factor λ.
(2) Substitute $y = \lambda x$, $\mathrm{d}^n x = \lambda^{-n} \mathrm{d}^n y$.
(3) Collect powers of λ and take the p-th root.

For large λ the terms with $|\beta| = k$ dominate the norm (2.144), so $\|f_\lambda\|_{k,p} \approx \lambda^{k-n/p} \times$(const). The left side of (2.156) scales as $\sup|\partial^\alpha f_\lambda| = \lambda^l \sup|\partial^\alpha f|$, with no $\lambda^{-n/p}$ because a supremum is not an integral. So (2.156) can only survive $\lambda \to \infty$ if

$$\lambda^l \lesssim \lambda^{k-n/p} \quad \text{for all large } \lambda \qquad \Longleftrightarrow \qquad l \le k - \frac{n}{p}.$$

The number $k - n/p$ is the **Sobolev number** (or "differential dimension") of L^p_k: it counts derivatives, but each L^p integral over n dimensions costs n/p of them. A C^l space has Sobolev number l (the supremum norm is $p = \infty$). The theorem says that the naive bookkeeping is right, provided the inequality is strict.

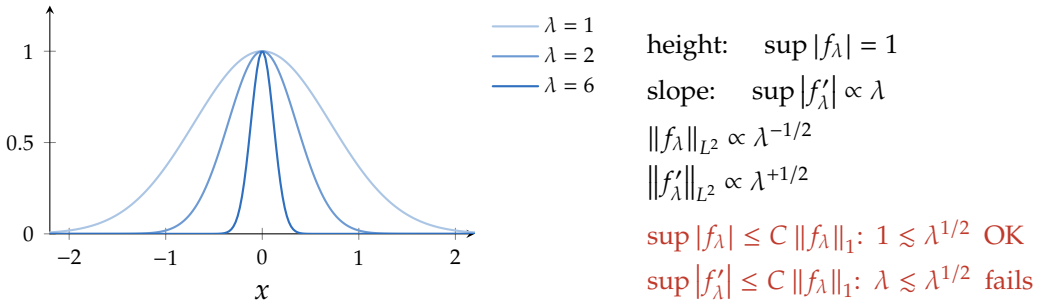

Figure 2.40: The scaling test behind the Sobolev embedding, in $n = 1$, $p = 2$. Squeezing a bump by a factor λ keeps its height, multiplies its slope by λ, and changes its L^2-type norms by $\lambda^{|\beta|-1/2}$. An H^1 bound can control the height (Sobolev number $1 - \frac{1}{2} = \frac{1}{2} > 0$) but not the slope ($\frac{1}{2} < 1$). This is dimensional analysis, with λ playing the role of an inverse length.

Key idea: Nash calls it Sobolev (i), (2.87)

Let $M = \mathbb{R}^n$ or M a compact n-manifold. If

$$k - \frac{n}{p} > l \qquad \text{then} \qquad L^p_k(M) \subset C^l(M), \tag{2.158}$$

where C^l is the space of l times differentiable functions with continuous derivatives. More precisely: every $f \in L^p_k$ agrees almost everywhere with a C^l function, and $\sup_{|\alpha|\le l} \sup_x |\partial^\alpha f| \le C \|f\|_{k,p}$. On a compact M the inclusion map $L^p_k \to C^l$ is moreover a *compact operator* (Section 2.5.8).

Why it is true, for $p = 2$. This is Nash's (2.89)–(2.90), with every step filled in. Let $f \in H^k(\mathbb{R}^n)$ and $|\alpha| = l$. Fourier inversion writes the derivative as

$$\partial^\alpha f(x) = \int e^{ix\cdot\xi} (i\xi)^\alpha \hat f(\xi) \frac{\mathrm{d}^n\xi}{(2\pi)^n}, \tag{2.159}$$

provided the integral converges absolutely. If it does, the right side is automatically a continuous function of x: the integrand is continuous in x and bounded by the fixed integrable function $\left|\xi^\alpha \hat f(\xi)\right|$, so we may pass limits $x \to x_0$ inside the integral (dominated convergence). So everything reduces to one estimate:

$$\begin{aligned}
\int \left|\xi^\alpha \hat f(\xi)\right| \frac{\mathrm{d}^n\xi}{(2\pi)^n} &\overset{(1)}{=} \int \langle\xi\rangle^k \left|\hat f(\xi)\right| \cdot \frac{|\xi^\alpha|}{\langle\xi\rangle^k} \frac{\mathrm{d}^n\xi}{(2\pi)^n} \\
&\overset{(2)}{\le} \left(\int \langle\xi\rangle^{2k} \left|\hat f(\xi)\right|^2 \frac{\mathrm{d}^n\xi}{(2\pi)^n}\right)^{1/2} \left(\int \frac{|\xi^\alpha|^2}{(1+|\xi|^2)^k} \frac{\mathrm{d}^n\xi}{(2\pi)^n}\right)^{1/2} \\
&\overset{(3)}{=} \|f\|_k \left(\int \frac{|\xi^\alpha|^2}{(1+|\xi|^2)^k} \frac{\mathrm{d}^n\xi}{(2\pi)^n}\right)^{1/2} \overset{(4)}{\le} \|f\|_k \left(\int \frac{|\xi|^{2l}}{(1+|\xi|^2)^k} \frac{\mathrm{d}^n\xi}{(2\pi)^n}\right)^{1/2}.
\end{aligned} \tag{2.160}$$

(1) Multiply and divide by $\langle\xi\rangle^k = (1+|\xi|^2)^{k/2}$: the same trick as in the duality argument (2.149).

(2) Cauchy–Schwarz in $L^2(\frac{\mathrm{d}^n\xi}{(2\pi)^n})$.
(3) The first factor is the H^k norm (2.145).
(4) $|\xi^\alpha| = |\xi_1|^{\alpha_1}\cdots|\xi_n|^{\alpha_n} \le |\xi|^{|\alpha|} = |\xi|^l$.

It remains to decide when the last integral is finite. Only large $|\xi|$ can cause trouble (the integrand is bounded near $\xi = 0$). Go to polar coordinates, $\mathrm{d}^n\xi = \rho^{n-1}\mathrm{d}\rho\,\mathrm{d}\Omega_{n-1}$ with $\rho = |\xi|$:

$$\int_{|\xi|>1} \frac{|\xi|^{2l}}{(1+|\xi|^2)^k}\,\mathrm{d}^n\xi \overset{(1)}{=} \mathrm{vol}(S^{n-1}) \int_1^\infty \frac{\rho^{2l+n-1}}{(1+\rho^2)^k}\,\mathrm{d}\rho \overset{(2)}{\le} \mathrm{vol}(S^{n-1}) \int_1^\infty \rho^{2l-2k+n-1}\,\mathrm{d}\rho$$
$$\overset{(3)}{=} \mathrm{vol}(S^{n-1})\,\frac{1}{2k-2l-n} < \infty \qquad \text{iff} \qquad 2l-2k+n<0. \tag{2.161}$$

(1) The integrand depends only on ρ; the angular integral gives the area of the unit sphere.
(2) $(1+\rho^2)^k \ge \rho^{2k}$. For the "only if" direction use $(1+\rho^2)^k \le (2\rho^2)^k$ for $\rho \ge 1$ instead.
(3) $\int_1^\infty \rho^{-1-a}\mathrm{d}\rho = 1/a$ for $a>0$ and $=\infty$ for $a \le 0$; here $a = 2k-2l-n$.

The condition $2l-2k+n<0$ is $k - \frac{n}{2} > l$: exactly (2.158) for $p=2$. This is what Nash calls "power counting". It is the *same* power counting that decides whether a Feynman integral $\int \mathrm{d}^n\xi\,\xi^{2l}/(\xi^2+m^2)^k$ is ultraviolet convergent; here the "loop momentum" is the Fourier variable of f.

For a compact M, cut f into pieces $\phi_i f$ with a partition of unity, each supported in a chart; each piece is a compactly supported function on $\mathbb{R}^n$ to which the estimate applies, and a finite sum of C^l functions is C^l. On the circle or torus we can even skip the charts:

Worked example 2.76: The sharp constant for $H^1(\mathbb{R}) \subset C^0$, and its extremal

Take $n=1$, $k=1$, $l=0$. Then (2.160) with $\alpha=0$ gives

$$\sup_x |f(x)| \overset{(1)}{\le} \int \left|\hat f(\xi)\right| \frac{\mathrm{d}\xi}{2\pi} \overset{(2)}{\le} \|f\|_1 \left(\int_{-\infty}^\infty \frac{1}{1+\xi^2}\frac{\mathrm{d}\xi}{2\pi}\right)^{1/2} \overset{(3)}{=} \frac{1}{\sqrt{2}}\,\|f\|_1 .$$

(1) $\left|\int e^{ix\xi}\hat f\,\mathrm{d}\xi\right| \le \int\left|\hat f\right|\mathrm{d}\xi$.
(2) (2.160).
(3) $\int_{-\infty}^\infty \mathrm{d}\xi/(1+\xi^2) = \pi$, so the bracket is $\frac12$.

Is the constant $1/\sqrt{2}$ best possible? Equality in Cauchy–Schwarz needs $\langle\xi\rangle\hat f \propto \langle\xi\rangle^{-1}$, i.e. $\hat f \propto 1/(1+\xi^2)$. By Example 2.47 (with $m=1$) this is $f(x) = e^{-|x|}$. Check directly:

$$\|f\|_{L^2}^2 = \int e^{-2|x|}\mathrm{d}x = 1, \qquad \|f'\|_{L^2}^2 = \int e^{-2|x|}\mathrm{d}x = 1,$$
$$\|f\|_1 = \sqrt{2}, \qquad \tfrac{1}{\sqrt2}\|f\|_1 = 1 = f(0).$$

Equality holds. So the extremal function of the Sobolev inequality is the Green's function of $1+D^2$: the function with the least "energy" $\|f\|^2+\|f'\|^2$ for a given peak height. Physically, it is the shape of an elastic string on a spring foundation pulled up at one point. The kink at $x=0$ shows the function is continuous but no better: $e^{-|x|} \in H^s$ iff $s < \frac32$, just like the tent.

Worked example 2.77: Continuity on the circle and on the torus

On S^1, for $u = \sum c_n e^{in\theta} \in H^1(S^1)$,

$$\sup_\theta |u(\theta)| \overset{(1)}{\le} \sum_n |c_n| \overset{(2)}{\le} \Big(\sum_n (1+n^2)\,|c_n|^2\Big)^{1/2} \Big(\sum_n \frac{1}{1+n^2}\Big)^{1/2} \overset{(3)}{=} \Big(\frac{\pi\coth\pi}{2\pi}\Big)^{1/2} \|u\|_1 .$$

(1) Triangle inequality on the Fourier series; $\left|e^{in\theta}\right| = 1$.
(2) Cauchy–Schwarz for sequences, as in Example 2.73.
(3) $\sum_{n\in\mathbb{Z}} \frac{1}{1+n^2} = \pi\coth\pi \approx 3.153$ (the Mittag-Leffler expansion of coth), and $\|u\|_1^2 = 2\pi\sum(1+n^2)\,|c_n|^2$.

Since the Fourier series converges absolutely and uniformly, its sum is continuous. On the torus T^n the same argument needs $\sum_{k\in\mathbb{Z}^n}(1+|k|^2)^{-s} < \infty$, which (comparing the lattice sum with the integral (2.161)) holds iff $2s > n$. On T^2, H^1 is *not* enough for continuity: $\sum_{k\in\mathbb{Z}^2}(1+|k|^2)^{-1}$ diverges logarithmically, like $\int \rho\,\mathrm{d}\rho/\rho^2$. The next example shows the divergence is real.

The condition cannot be dropped. Nash says it is "easy enough" to give evidence that $k - n/p > l$ is necessary. Here is the standard evidence. Let χ be a smooth cutoff equal to 1 near 0 and vanishing for $|x| \ge \frac12$, and let $f(x) = \chi(x)\,|x|^\lambda$ on $\mathbb{R}^n$ with λ not an even integer. Near 0, each derivative lowers the power by one: $\left|\partial^\beta f\right| \sim |x|^{\lambda-|\beta|}$. So

$$\int_{|x|<\frac12} \left|\partial^\beta f\right|^p \,\mathrm{d}^n x \overset{(1)}{=} c\int_0^{1/2} r^{p(\lambda-|\beta|)}\, r^{n-1}\mathrm{d}r < \infty$$
$$\iff \quad p(\lambda-|\beta|)+n > 0 \quad \iff \quad \lambda > |\beta| - \frac{n}{p}.$$

(1) Polar coordinates, as in (2.161); convergence at $r = 0$ of $\int r^{a-1}\mathrm{d}r$ needs $a > 0$.

Hence $f \in L^p_k$ iff $\lambda > k - \frac{n}{p}$, while $f \in C^l$ iff $\lambda > l$ (the l-th derivative $\sim |x|^{\lambda-l}$ must stay bounded and continuous at 0). If $k - \frac{n}{p} < l$, pick λ strictly between them: $f \in L^p_k$ but $f \notin C^l$.

Worked example 2.78: The borderline case: an unbounded function of finite energy in two dimensions

When $k - \frac{n}{p} = l$ exactly, the power $|x|^\lambda$ is not subtle enough, but a double logarithm is. Take $n = 2$, $k = 1$, $p = 2$, $l = 0$ (so $k - \frac{n}{p} = 0 = l$), and

$$f(x) = \log\log\frac{1}{|x|} \quad \text{for } 0 < |x| < e^{-1}, \qquad f = 0 \text{ otherwise.}$$

f vanishes on the circle $|x| = e^{-1}$ (since $\log\log e = 0$), so it is continuous there, and it blows up (very slowly) at the origin: f is not bounded. Yet with $r = |x|$:

$$\|\nabla f\|_{L^2}^2 \overset{(1)}{=} \int_0^{1/e} \Big(\frac{1}{r\log(1/r)}\Big)^2 2\pi r\,\mathrm{d}r \overset{(2)}{=} 2\pi\int_1^\infty \frac{\mathrm{d}t}{t^2} \overset{(3)}{=} 2\pi.$$

(1) f is radial with $\partial_r f = \frac{1}{\log(1/r)}\cdot\left(-\frac1r\right)$; area element $2\pi r\,\mathrm{d}r$.
(2) Substitute $t = \log(1/r)$, $\mathrm{d}t = -\mathrm{d}r/r$; $r = 1/e \mapsto t = 1$, $r \to 0 \mapsto t \to \infty$.
(3) Elementary.

And $\int f^2 < \infty$ because $\log\log(1/r)$ grows more slowly than any power. So $f \in H^1(\mathbb{R}^2)$ but $f \notin C^0$. In physics language: in two dimensions a massless scalar with finite Dirichlet energy $\int |\nabla\phi|^2$ need not have a finite value at a point. This is the analytic root of the logarithmic infrared and ultraviolet behaviour of two-dimensional scalar fields (the propagator $-\frac{1}{2\pi}\log|x|$, the absence of spontaneous breaking of continuous symmetries, the need to exponentiate $e^{i\beta\phi}$ with normal ordering).

Watch out: Nash's example for the necessity of $k - n/p > l$

Nash suggests the function $(1 + x_1^2 + \cdots + x_n^2)^{1/2}$ as a test. As printed this cannot be right: that function is C^∞ (so it is in every C^l) and it grows at infinity (so it is in no L^p). The intended example is a function with a power singularity at a point, such as the $\chi(x)\,|x|^\lambda$ above; the missing exponent and cutoff were probably lost in typesetting.

The smoothness deficit. Nash's way of remembering the result (his (2.91)): for $\varepsilon > 0$ and $k \geq n/2$,

$$H^{k+\varepsilon} \subset C^{\,k-n/2}, \qquad \text{and more generally} \qquad L^p_{k+\varepsilon} \subset C^{\,k-n/p}. \tag{2.162}$$

(Check: the Sobolev number of $H^{k+\varepsilon}$ is $k + \varepsilon - \frac{n}{2} > k - \frac{n}{2}$.) Read it as: *an element of H^k is not C^k; it has lost $n/2$ derivatives*, the price of measuring derivatives by integrals instead of suprema. When $k - n/2$ is not an integer, read $C^{k-n/2}$ as $C^{\lfloor k-n/2\rfloor}$ (or as a Hölder space $C^{j,\gamma}$, whose functions have j derivatives that are Hölder continuous of exponent γ, with $j + \gamma = k - n/2$). Examples in one dimension: the tent function and $e^{-|x|}$ are in $H^{3/2-\varepsilon}$, and $\frac{3}{2} - \frac{1}{2} = 1$: they are "almost" C^1, and indeed they are Lipschitz ($C^{0,1}$) but not C^1.

Physical picture: Can a quantum field be evaluated at a point?

A free scalar field of mass m in d Euclidean dimensions is a random distribution ϕ with $\langle|\hat\phi(\xi)|^2\rangle \propto 1/(|\xi|^2 + m^2)$ (per unit volume). Its expected H^s norm density is therefore $\int \langle\xi\rangle^{2s}(|\xi|^2 + m^2)^{-1}\mathrm{d}^d\xi$, finite iff $2s - 2 + d < 0$: typical configurations lie in H^s_{loc} exactly for $s < 1 - \frac{d}{2}$. For $d = 1$ (quantum mechanics, $s < \frac{1}{2}$) the paths are continuous: $H^{1/2-\varepsilon} \subset C^0$ just fails to apply, but Hölder continuity of exponent $< \frac{1}{2}$ does hold, as for Brownian motion. For $d \geq 2$ the threshold $1 - \frac{d}{2} \leq 0$ lies below every Sobolev number that guarantees continuity: the field is a genuine distribution, $\phi(x)$ is meaningless, and only smeared fields $\phi(g) = \int \phi(x)g(x)\,\mathrm{d}^d x$ with test functions g make sense. This is why the Wightman axioms use operator-valued distributions, and why products $\phi(x)^2$ need renormalisation.

Sobolev (ii): embedding one Sobolev space in another. The same scaling bookkeeping predicts when $L^p_k \subset L^q_l$: by (2.157), the norm $\|\partial^\alpha f_\lambda\|_{L^q}$ with $|\alpha| = l$ scales as $\lambda^{l-n/q}$, which must not beat $\lambda^{k-n/p}$.

Key idea: Nash calls it Sobolev (ii), (2.88)

Let $M = \mathbb{R}^n$ or M compact. If

$$k \geq l \qquad \text{and} \qquad k - \frac{n}{p} \;\geq\; l - \frac{n}{q}, \tag{2.163}$$

then $L^p_k \subset L^q_l$, with $\|f\|_{l,q} \leq C\,\|f\|_{k,p}$: *you may trade derivatives for integrability at the exchange rate fixed by the Sobolev number.* On compact M, if both inequalities are strict, the inclusion

is a compact operator (the Rellich–Kondrachov theorem).

Watch out: On $\mathbb{R}^n$ one also needs $q \geq p$

Take $k = l = 0$. Then (2.163) reads $-\frac{n}{p} \geq -\frac{n}{q}$, i.e. $q \leq p$, and asserts $L^p \subset L^q$. On a compact M (finite volume) this is true, by Hölder's inequality: $\int |f|^q \leq (\int |f|^p)^{q/p} \mathrm{vol}(M)^{1-q/p}$. On $\mathbb{R}^n$ it is false: $(1+|x|)^{-n/q}$ is in L^p for $p > q$ but not in L^q. Large distances behave oppositely to small distances. On $\mathbb{R}^n$ the correct statement adds $p \leq q$ (and excludes some endpoint cases such as $q = \infty$ with equality); Nash's (2.88) is stated for both cases at once and silently means the compact case for $q < p$.

Worked example 2.79: Critical exponents and renormalisable interactions

Take $k = 1$, $p = 2$, $l = 0$ on $\mathbb{R}^d$. Then (2.163) gives $H^1 \subset L^q$ for

$$1 - \frac{d}{2} \geq -\frac{d}{q} \qquad \Longleftrightarrow \qquad q \leq q_* = \frac{2d}{d-2} \quad (d \geq 3),$$

(together with $q \geq 2$). This is the **Sobolev inequality** $\|\phi\|_{L^{q_*}} \leq C \|\nabla\phi\|_{L^2}$ (at the endpoint only the gradient term is needed, by scaling). Its physical content: *the kinetic energy* $\int |\nabla\phi|^2$ *controls the interaction* $\int |\phi|^q$ *for all* $q \leq q_*$.

d	$q_* = \frac{2d}{d-2}$	critical interaction	where it appears
3	6	ϕ^6	tricritical point; $H^1(\mathbb{R}^3) \subset L^6$ in stability of matter
4	4	ϕ^4	Higgs self-coupling; scale invariance of 4d instantons (Chapter 8)
6	3	ϕ^3	cubic scalar theory in six dimensions

These are exactly the polynomial interactions that are renormalisable by power counting: with $[\phi] = \frac{d-2}{2}$ in mass units, the coupling of ϕ^q has dimension $d - q\frac{d-2}{2} \geq 0$ iff $q \leq \frac{2d}{d-2}$. Both statements are the same dimensional analysis, (2.157). At the critical exponent the inequality is scale invariant and the embedding is *not* compact (squeezed bumps $\lambda^{(d-2)/2} f(\lambda x)$ keep their norms), which is the analytic face of the "bubbling" of instantons in four dimensions.

2.5.8 Compact operators and Rellich's theorem

Nash's footnote 9 introduces *compact operators* in two lines. They are the single most important idea in the rest of this section, so we give them room. The motivating fact is from linear algebra: in finite dimensions every bounded sequence has a convergent subsequence (Bolzano–Weierstrass). In infinite dimensions this fails. In ℓ^2 (or in $L^2(S^1)$ with the basis $e_n = e^{in\theta}/\sqrt{2\pi}$) the orthonormal vectors $e_1, e_2, e_3, \ldots$ all have norm 1, yet

$$\|e_n - e_m\|^2 = \|e_n\|^2 + \|e_m\|^2 = 2 \qquad (n \neq m),$$

so no subsequence is Cauchy. The unit ball of an infinite-dimensional Hilbert space is not compact. Compact operators are the operators that repair this.

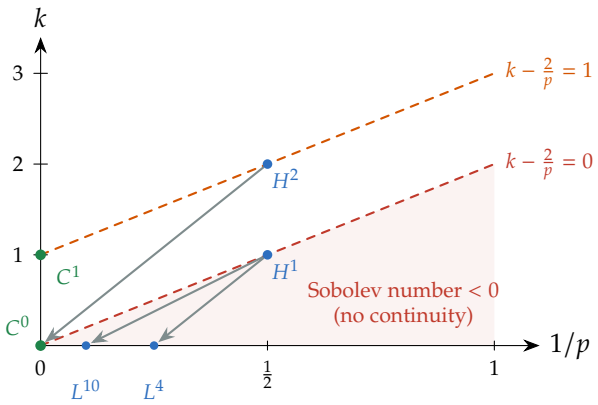

Figure 2.41: The Sobolev diagram in $n = 2$ dimensions. Each space L^p_k is a point $(1/p, k)$; C^l spaces sit on the vertical axis ($p = \infty$). The Sobolev number $k - n/p$ is constant along lines of slope $n = 2$ (dashed). Grey arrows: $H^2 \subset C^0$ (Sobolev number $1 > 0$) and $H^1 \subset L^4, L^{10}$. An embedding $L^p_k \subset L^q_l$ goes *down and to the left* without crossing to a higher Sobolev number; strictly below the dashed line through the start it is compact (on compact M). H^1 lies exactly on the Sobolev-number-0 line, which is why it embeds in every L^q, $q < \infty$, but not in C^0 (Example 2.78).

Working definition 2.38 (compact operator)

A bounded operator [$\|Tu\| \le C \|u\|$ for one constant C and all u] $T : H_1 \to H_2$ between Hilbert spaces is **compact** if it maps bounded sequences to sequences with a convergent subsequence (equivalently, the image of the unit ball has compact closure). *Tests, in order of usefulness:*

(i) T has **finite rank** (finite-dimensional image) $\Rightarrow$ compact.

(ii) T is a norm limit of finite-rank operators, $\|T - T_N\| \to 0$ [$\|T - T_N\|$ is the smallest C with $\|(T - T_N)u\| \le C \|u\|$] $\Leftrightarrow$ compact (for Hilbert spaces).

(iii) T is diagonal, $Te_n = \lambda_n f_n$ in orthonormal bases: compact $\Leftrightarrow \lambda_n \to 0$.

Test (iii) follows from (ii). Let T_N keep only the first N modes, $T_N e_n = \lambda_n f_n$ for $n \le N$ and 0 otherwise. For $u = \sum u_n e_n$,

$$\|(T - T_N)u\|^2 \overset{(1)}{=} \Big\| \sum_{n>N} \lambda_n u_n f_n \Big\|^2 \overset{(2)}{=} \sum_{n>N} |\lambda_n|^2 |u_n|^2 \overset{(3)}{\le} \Big(\sup_{n>N} |\lambda_n|\Big)^2 \sum_{n>N} |u_n|^2 \overset{(4)}{\le} \Big(\sup_{n>N} |\lambda_n|\Big)^2 \|u\|^2 . \tag{2.164}$$

(1) Only the modes beyond N survive in $T - T_N$.

(2) Pythagoras: the f_n are orthonormal.

(3) Bound each $|\lambda_n|$ by the largest one in the tail.

(4) The tail of $\sum |u_n|^2$ is at most the whole sum.

So $\|T - T_N\| \le \sup_{n>N} |\lambda_n|$ (with equality, testing on $u = e_n$), which tends to 0 iff $\lambda_n \to 0$. Conversely if $\lambda_n \not\to 0$, the images of e_n along a subsequence with $|\lambda_n| \ge c > 0$ stay $\ge c\sqrt{2}$ apart, as for the identity.

Physical picture: Compact means "effectively finite-dimensional"

A compact operator squeezes the unit ball into an "ellipsoid" whose semi-axes $|\lambda_n|$ shrink to zero (Figure 2.42). Up to any error ε, only finitely many directions survive. This is Nash's remark that a compact operator "can always be approximated by a sequence of operators with a finite dimensional range". For a physicist: a compact operator is one

that can be truncated to a finite matrix with controllable error, like keeping only the modes below a cutoff. Integral operators with square-integrable kernels ($\iint |K(x,y)|^2 < \infty$, **Hilbert–Schmidt** operators) are the typical examples; every smoothing operator on a compact manifold is one.

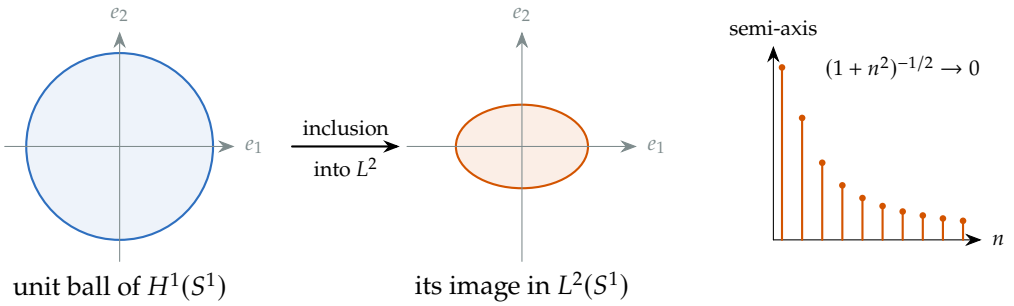

Figure 2.42: Rellich's theorem on the circle, seen as geometry. The inclusion $H^1(S^1) \hookrightarrow L^2(S^1)$ maps the unit ball of H^1 to an ellipsoid in L^2 whose semi-axis along the mode $e^{in\theta}$ is $(1+n^2)^{-1/2}$ (right). The semi-axes shrink to zero, so the image is "thin" in all but finitely many directions, up to any tolerance: the inclusion is compact. Two of the infinitely many directions are drawn.

Key idea: Rellich's theorem

On a compact manifold M and for a vector bundle $E \to M$, the inclusion

$$H^s(M,E) \hookrightarrow H^t(M,E) \qquad (s > t)$$

is a compact operator. In words: *a bounded family of functions with a little extra smoothness has a convergent subsequence in the rougher norm.* Together with Sobolev (i), $H^s \hookrightarrow C^l$ is compact for $s - \frac{n}{2} > l$.

Why, on the circle. Use the orthonormal bases $e_n^{(s)} = e^{in\theta}/\left(\sqrt{2\pi}(1+n^2)^{s/2}\right)$ of $H^s(S^1)$ and $e_n^{(t)}$ of $H^t(S^1)$ (orthonormal by the definition of $\|\cdot\|_s$ in Section 2.5.3). The inclusion ι sends

$$\iota\left(e_n^{(s)}\right) \overset{(1)}{=} \frac{e^{in\theta}}{\sqrt{2\pi}(1+n^2)^{s/2}} \overset{(2)}{=} (1+n^2)^{\frac{t-s}{2}}\, e_n^{(t)},$$

(1) Definition of $e_n^{(s)}$; the inclusion does nothing to the function.

(2) Rewrite in terms of $e_n^{(t)}$.

a diagonal operator with $\lambda_n = (1+n^2)^{(t-s)/2} \to 0$ because $t - s < 0$. By test (iii) it is compact, and by (2.164) the error of truncating at $|n| \le N$ is exactly $(1+(N+1)^2)^{(t-s)/2}$. On the torus T^n the same computation holds with $k \in \mathbb{Z}^n$. On a general compact M, a partition of unity cuts f into finitely many pieces supported in coordinate balls; each ball can be placed inside a large torus, and the torus result applies piece by piece.

Watch out: Rellich fails on $\mathbb{R}^n$ and for $s = t$

Both hypotheses are needed. *Equal orders:* the identity $H^s \to H^s$ is not compact (its λ_n are all 1). *Non-compact space:* on $\mathbb{R}^n$ take one bump f and translate it, $f_j(x) = f(x - 3j\,e_1)$. All f_j have the same H^1 norm, but they have disjoint supports if f is supported in a unit ball, so $\|f_i - f_j\|_{L^2}^2 = 2\,\|f\|_{L^2}^2$ and no subsequence converges. Mass can escape to infinity. This is the mathematical reason why a free particle on $\mathbb{R}^n$ has continuous spectrum while a

particle in a box, or on a compact manifold, has discrete spectrum (next paragraph).

Compact self-adjoint operators have discrete spectra. We need one more standard fact, the spectral theorem for compact self-adjoint operators: *if $T = T^*$ is compact on a Hilbert space, then H has an orthonormal basis of eigenvectors of T; the eigenvalues are real, accumulate only at 0, and every non-zero eigenvalue has finite multiplicity.* It is the infinite-dimensional version of diagonalising a Hermitian matrix; compactness is what guarantees the largest $|\lambda|$ is attained (maximise $|\langle u, Tu\rangle|$ over the unit ball: a maximising sequence has a convergent subsequence), after which we restrict to the orthogonal complement and repeat.

Worked example 2.80: Why the Laplacian on a compact manifold has discrete spectrum

Let M be compact and Δ the (positive) Laplacian on functions. We will see in Section 2.6.5 that $\Delta + 1 : H^2(M) \to L^2(M)$ is invertible (on the circle this is obvious: it multiplies c_n by $1 + n^2 \geq 1$). Consider

$$T = (\Delta + 1)^{-1} : \; L^2 \xrightarrow{\text{bounded}} H^2 \xrightarrow{\text{compact (Rellich)}} L^2.$$

A bounded operator followed by a compact one is compact, and T is self-adjoint and positive. So T has eigenvalues $\mu_1 \geq \mu_2 \geq \cdots > 0$ with $\mu_j \to 0$, each of finite multiplicity, and an orthonormal eigenbasis. Since $\Delta u = \lambda u \iff Tu = (1+\lambda)^{-1}u$, the Laplacian has eigenvalues $\lambda_j = \mu_j^{-1} - 1 \to +\infty$, each of finite multiplicity, with a complete set of eigenfunctions. This is the spectrum of dots on a line in Figure 2.26: discreteness is Rellich, and "running off to infinity" is compactness of the inverse. In quantum mechanics this is the statement that a particle confined to a compact region has quantised energy levels. The rate at which the λ_j grow is **Weyl's law**: on $T^2 = \mathbb{R}^2/2\pi\mathbb{Z}^2$ the number of eigenvalues $|k|^2 \leq \Lambda$ is the number of lattice points in a disc of radius $\sqrt{\Lambda}$, about $\pi\Lambda = \frac{\text{Area}(T^2)}{4\pi}\Lambda$ (the area is $4\pi^2$).

2.5.9 Pseudo-differential operators act on the Sobolev scale

Now we can say precisely what "a ΨDO of order m costs m derivatives" means.

Key idea: ΨDOs are bounded on the Sobolev scale; Nash's (2.92)

If P is a pseudo-differential operator of order m (on $\mathbb{R}^n$ with symbol in S^m satisfying the estimates uniformly in x, or on a compact manifold between bundles U and V), then for every $s \in \mathbb{R}$

$$P : \; H^s \longrightarrow H^{s-m} \quad \text{is bounded:} \qquad \|Pu\|_{s-m} \leq C_s \, \|u\|_s \, . \tag{2.165}$$

Since orders can be fractional or negative (Section 2.4), this is one reason we needed H^s for all real s: $\sqrt{\Delta+1}$ maps H^s to H^{s-1}, $|D|^{1/3}$ maps H^s to $H^{s-1/3}$, and the resolvent $(\Delta+1)^{-1}$ maps H^s *up* to H^{s+2}.

Why, for a Fourier multiplier. If $P = \sigma(D)$ with $|\sigma(\xi)| \leq C\langle\xi\rangle^m$, then

$$\|Pu\|_{s-m}^2 \overset{(1)}{=} \int \langle\xi\rangle^{2(s-m)} \, |\sigma(\xi)\hat{u}(\xi)|^2 \, \frac{\mathrm{d}^n\xi}{(2\pi)^n} \overset{(2)}{\leq} C^2 \int \langle\xi\rangle^{2(s-m)}\langle\xi\rangle^{2m} \, |\hat{u}(\xi)|^2 \, \frac{\mathrm{d}^n\xi}{(2\pi)^n} \overset{(3)}{=} C^2 \, \|u\|_s^2 \, . \tag{2.166}$$

(1) Definition (2.145), with $\widehat{Pu} = \sigma\hat{u}$.

(2) The symbol estimate (2.122) with $\alpha = \beta = 0$.
(3) The powers of $\langle\xi\rangle$ combine to $\langle\xi\rangle^{2s}$.

The best constant is $C = \sup_\xi |\sigma(\xi)|\,\langle\xi\rangle^{-m}$. Only the size of the symbol entered, not its derivatives: those are needed for composition and for pseudo-locality, not for boundedness of multipliers.

Why, with x-dependence. The new ingredient is multiplication by a smooth function $a(x)$, which is an operator of order 0 (its symbol is $a(x)$). The Fourier transform turns a product into a convolution, $\widehat{au}(\xi) = \int \hat a(\xi-\eta)\hat u(\eta)\,\frac{\mathrm{d}^n\eta}{(2\pi)^n}$, and the weights are moved through the convolution by **Peetre's inequality**

$$\langle\xi\rangle^s \le 2^{|s|/2}\,\langle\xi-\eta\rangle^{|s|}\,\langle\eta\rangle^s \qquad (s\in\mathbb{R}), \tag{2.167}$$

whose proof is two lines:

$$\langle\xi\rangle^2 = 1+|(\xi-\eta)+\eta|^2 \overset{(1)}{\le} 1+2\,|\xi-\eta|^2+2\,|\eta|^2 \overset{(2)}{\le} 2\,(1+|\xi-\eta|^2)(1+|\eta|^2) = 2\langle\xi-\eta\rangle^2\langle\eta\rangle^2.$$

(1) $|a+b|^2 \le 2\,|a|^2+2\,|b|^2$ (parallelogram law).
(2) Expand the right side: $2+2\,|\xi-\eta|^2+2\,|\eta|^2+2\,|\xi-\eta|^2\,|\eta|^2$ is larger.

Raising to the power $s/2 \ge 0$ gives (2.167) for $s \ge 0$; for $s<0$ swap the roles of ξ and η (write $\langle\eta\rangle^2 \le 2\langle\eta-\xi\rangle^2\langle\xi\rangle^2$ and raise to the power $|s|/2$). With it,

$$\langle\xi\rangle^s\,\big|\widehat{au}(\xi)\big| \overset{(1)}{\le} \int \langle\xi\rangle^s\,|\hat a(\xi-\eta)|\;|\hat u(\eta)|\,\frac{\mathrm{d}^n\eta}{(2\pi)^n} \overset{(2)}{\le} 2^{|s|/2}\int \langle\xi-\eta\rangle^{|s|}\,|\hat a(\xi-\eta)|\;\langle\eta\rangle^s\,|\hat u(\eta)|\,\frac{\mathrm{d}^n\eta}{(2\pi)^n},$$

(1) Triangle inequality for the convolution integral.
(2) Peetre (2.167).

a convolution of the L^1 function $A(\zeta) = \langle\zeta\rangle^{|s|}\,|\hat a(\zeta)|$ (integrable because $\hat a$ decays rapidly for smooth compactly supported a) with the L^2 function $\langle\eta\rangle^s\,|\hat u(\eta)|$. Young's inequality $\|A*B\|_{L^2} \le \|A\|_{L^1}\,\|B\|_{L^2}$ gives $\|au\|_s \le 2^{|s|/2}\,\|A\|_{L^1}\,\|u\|_s$ (with the $(2\pi)^{-n}$ absorbed in the normalisation of $\|A\|_{L^1}$). A general ΨDO is handled by the same idea applied to the x-Fourier transform of its symbol; the derivative estimates in x provide the decay of that transform.

Worked example 2.81: Operators on the circle and their Sobolev norms

On S^1 an operator diagonal in Fourier modes, $e^{in\theta} \mapsto p_n e^{in\theta}$, satisfies, by the same computation as (2.166),

$$\|P\|_{H^s\to H^{s-m}} = \sup_n\;|p_n|\;(1+n^2)^{-m/2}.$$

- *Hilbert transform* $p_n = -i\,\operatorname{sgn} n$ ($p_0=0$), order 0: norm 1 on every H^s.
- $|D|$, $p_n = |n|$, order 1: norm $\sup_n |n|/\sqrt{1+n^2} = 1$ as a map $H^s \to H^{s-1}$.
- $\sqrt{\Delta+\mu^2}$, $p_n = \sqrt{n^2+\mu^2}$: norm $\max(1,\mu)$ from H^s to H^{s-1}.
- The heat operator $e^{-t\Delta}$, $p_n = e^{-tn^2}$: bounded from H^s to H^{s+N} for every N, with norm $\sup_n e^{-tn^2}(1+n^2)^{N/2}$, which blows up like $(N/2et)^{N/2}$ as $t\to 0$ (maximise over n^2): the smoothing gets weaker as the Gaussian sharpens.

Smoothing operators, again (Nash's (2.93)). A smoothing operator has order $-\infty$, i.e. order $-N$ for every N. By (2.165) it maps $H^s \to H^{s+N}$ for all N, hence

$$P:\; H^s \longrightarrow H^\infty \subset C^\infty, \tag{2.168}$$

the last inclusion being Sobolev (i) applied for every l. This is the Sobolev-space proof of the claim in Section 2.4.13 that a smoothing operator "maps any function onto a smooth function", and even any distribution in $H^{-\infty}$: the heat operator turns δ into a Gaussian.

Unbounded on L^2, bounded on the scale. Nash raises an apparent paradox. The Laplacian has eigenvalues $0, 1, 4, 9, \dots$ on the circle. The norm of an operator $L : H \to H$ is

$$\|L\| = \sup_{v \neq 0} \frac{\|Lv\|}{\|v\|}, \tag{2.169}$$

and testing on eigenvectors gives $\|L\| \geq |\lambda_n|$ for every n. So as a map $L^2 \to L^2$ the Laplacian has infinite norm: it is **unbounded** (and not even defined on all of L^2). How can it then be a "bounded operator between Sobolev spaces"? Because the target is measured with two fewer derivatives.

Worked example 2.82: Nash's example: $P = -\mathrm{d}^2/\mathrm{d}\theta^2$ on the circle has norm 1 from H^k to H^{k-2}

Let $P = D_\theta^2$, so $Pe_n = n^2 e_n$ with $e_n = e^{in\theta}$. *With the Fourier norm* $\|u\|_s^2 = 2\pi \sum (1+n^2)^s |c_n|^2$ and any real k:

$$\|Pu\|_{k-2}^2 \overset{(1)}{=} 2\pi \sum_n (1+n^2)^{k-2} n^4 |c_n|^2 \overset{(2)}{=} 2\pi \sum_n \left(\frac{n^2}{1+n^2}\right)^2 (1+n^2)^k |c_n|^2$$
$$\overset{(3)}{\leq} \sup_n \left(\frac{n^2}{1+n^2}\right)^2 \cdot \|u\|_k^2 = \|u\|_k^2 .$$

(1) Pu has coefficients $n^2 c_n$.
(2) $(1+n^2)^{k-2} n^4 = \left(\frac{n^2}{1+n^2}\right)^2 (1+n^2)^k$.
(3) Bound the factor by its supremum, which is 1 (approached as $|n| \to \infty$, never attained).

And on eigenvectors $\|Pe_n\|_{k-2} / \|e_n\|_k = n^2/(1+n^2) \to 1$. So $\|P\|_{H^k \to H^{k-2}} = 1$ exactly. *With Nash's norm* $\|u\|_{k,2} = \sum_{j=0}^k \left\|D_\theta^j u\right\|$ (integer $k \geq 2$), the bound is even simpler:

$$\|Pu\|_{k-2,2} \overset{(1)}{=} \sum_{j=0}^{k-2} \left\|D_\theta^{j+2} u\right\| \overset{(2)}{=} \sum_{j=2}^{k} \left\|D_\theta^j u\right\| \overset{(3)}{\leq} \sum_{j=0}^{k} \left\|D_\theta^j u\right\| = \|u\|_{k,2} ,$$

(1) Definition of the norm applied to $Pu = D_\theta^2 u$.
(2) Shift the summation index $j \to j-2$.
(3) Add the two missing non-negative terms $j = 0, 1$.

and on e_n, where $\left\|D_\theta^j e_n\right\| = \sqrt{2\pi}\, |n|^j$, the ratio is $\sum_{j=2}^k n^j \,/\, \sum_{j=0}^k n^j \to 1$. Either way the norm is 1: finite, as befits an operator that will turn out to be Fredholm.

Watch out: A slip in Nash's (2.96), and a caution about eigenvectors

(a) In the middle expression of (2.96) Nash re-indexes $\sum_{j=0}^{k-2} \left\|D^j (D^2 e_n)\right\|$ as $\sum_{j=0}^k \left\|D^j e_n\right\|$; the correct range is $j = 2, \dots, k$, as in step (2) above. With his version the ratio would be identically 1; with the correct one it is < 1 for each n and tends to 1. The supremum is 1 either way. (b) "Take the supremum over the eigenvectors" is legitimate here only because *P and the norms* are diagonal in the same orthogonal basis $\{e_n\}$. For a general operator the norm is not the supremum over eigenvectors: the matrix $\left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$ has only the eigenvalue 0 but norm 1.

Dictionary: unbounded Hamiltonians and Sobolev spaces

Quantum mechanics	Sobolev language
domain of $H = -\nabla^2 + V$ (smooth bounded V)	H^2: $H : H^2 \to L^2$ bounded
finite-energy states, $\langle \psi, H\psi \rangle < \infty$	form domain H^1: $H : H^1 \to H^{-1}$ bounded
"H is unbounded"	$H : L^2 \to L^2$ has infinite norm (2.169)
resolvent $(H + c)^{-1}$	bounded $L^2 \to H^2$; compact on L^2 if space compact
point spectrum only (box, compact M)	compact resolvent (Rellich)

The elliptic estimate. Boundedness says $\|Pu\|_{s-m} \le C \|u\|_s$: P costs at most m derivatives. Ellipticity gives the reverse: P costs *exactly* m derivatives, up to a harmless lower-order error. Let Q be a parametrix (Section 2.4.9), so $QP = I - R$ with R smoothing. For any u in some H^t, $t < s$:

$$\|u\|_s \overset{(1)}{=} \|QPu + Ru\|_s \overset{(2)}{\le} \|Q(Pu)\|_s + \|Ru\|_s \overset{(3)}{\le} C_1 \|Pu\|_{s-m} + C_2 \|u\|_t . \tag{2.170}$$

(1) $u = QPu + Ru$ from $QP = I - R$.
(2) Triangle inequality.
(3) Q has order $-m$, so it is bounded $H^{s-m} \to H^s$ by (2.165); R is smoothing, so it is bounded $H^t \to H^s$ for any t.

This is the **elliptic estimate** (in the Laplacian case, Gårding's inequality). Two immediate consequences:

- *Elliptic regularity in Sobolev form:* if $u \in H^t$ and $Pu \in H^{s-m}$, then $u \in H^s$. (The right side of (2.170) is finite.) Taking $s \to \infty$: $Pu \in C^\infty \Rightarrow u \in C^\infty$, which is hypo-ellipticity once more.
- *Zero modes are smooth:* if $Pu = 0$ with $u \in H^t$ for some t, then $u \in H^s$ for every s, i.e. $u \in C^\infty$. In particular $\operatorname{Ker} P$ does not depend on which Sobolev space we let P act on.

Worked example 2.83: The elliptic estimate for $D^2 + 1$ on the circle, with constant 1

For $P = D_\theta^2 + 1$ the Fourier norms make (2.170) an identity:

$$\left\|(D_\theta^2 + 1)u\right\|_{s-2}^2 = 2\pi \sum_n (1 + n^2)^{s-2}(1 + n^2)^2 |c_n|^2 = \|u\|_s^2 .$$

P is an isometry $H^s \to H^{s-2}$, invertible, with no error term needed. For $P = D_\theta^2$ (no mass) the estimate needs the error term: the constants are in the kernel and $\left\|D_\theta^2 \cdot 1\right\|_{s-2} = 0$ while $\|1\|_s \neq 0$. Split off the $n = 0$ mode:

$$\|u\|_s^2 \overset{(1)}{=} 2\pi |c_0|^2 + 2\pi \sum_{n \neq 0} (1 + n^2)^s |c_n|^2 \overset{(2)}{\le} 2\pi |c_0|^2 + 4 \cdot 2\pi \sum_{n \neq 0} (1 + n^2)^{s-2} n^4 |c_n|^2$$
$$\overset{(3)}{\le} \|u\|_t^2 + 4 \left\|D_\theta^2 u\right\|_{s-2}^2 .$$

(1) Definition of the norm; the $n = 0$ weight is 1.
(2) For $n \neq 0$, $n^4/(1 + n^2)^2 \ge \frac{1}{4}$ (the worst case is $n = \pm 1$), so $(1 + n^2)^s \le 4(1 + n^2)^{s-2} n^4$.
(3) $2\pi |c_0|^2 \le \|u\|_t^2$ for any t, and the sum is $\left\|D_\theta^2 u\right\|_{s-2}^2$ (the $n = 0$ term vanishes anyway).

So $\|u\|_s \le 2\left\|D_\theta^2 u\right\|_{s-2} + \|u\|_t$: the estimate holds, but a single low mode must be controlled by the weak norm, and that mode is exactly the kernel. This is the Fredholm theory of the next section in miniature.

Reading Nash (pp. 47–54, (2.71)–(2.96))

Nash's §5 up to (2.96) maps onto these notes as follows: (2.71)–(2.74) are Section 2.5.1; (2.75)–(2.77) are (2.145) and (2.147); (2.78)–(2.80) are (2.149) and (2.150); (2.81)–(2.86) are Sections 2.5.5 and 2.5.6; (2.87)–(2.91) are (2.158)–(2.162); (2.92)–(2.93) are (2.165) and (2.168); (2.94)–(2.96) are Example 2.82. Nash's H_k in the proof of Sobolev (i) is his H^k. His remark that $L^p_{k+\varepsilon} \subset C^{k-n/p}$ is (2.162). Rellich's theorem is implicit in his footnote 9 and his claim that the inclusions are compact; we have made it explicit because it is what the Fredholm property rests on.

Recap: Pseudo-differential operators and Sobolev spaces

- H^s measures "s derivatives in L^2" by the Fourier weight: $\|u\|_s^2 = \int \langle\xi\rangle^{2s} |\hat{u}|^2 \frac{d^n\xi}{(2\pi)^n}$; on S^1 it is $2\pi \sum (1+n^2)^s |c_n|^2$, a statement about how fast Fourier coefficients decay. For integer k it agrees with "all derivatives up to order k in L^2".
- Negative orders are duals, $H^{-s} = (H^s)^*$; $\delta \in H^{-s}$ iff $s > \frac{n}{2}$. The chain $\mathcal{S} \subset \cdots \subset H^s \subset \cdots \subset L^2 \subset \cdots \subset H^{-s} \subset \cdots \subset \mathcal{S}'$ is the Sobolev scale; L^2 in the middle is the physicist's Hilbert space of kets.
- Sobolev (i): $H^s \subset C^l$ if $s - \frac{n}{2} > l$ (power counting of $\int \langle\xi\rangle^{2l-2s}$); functions in H^s have a smoothness deficit $n/2$. Sobolev (ii) compares two L^p_k spaces by the Sobolev number $k - n/p$.
- Rellich: on a compact manifold $H^s \hookrightarrow H^t$ $(s > t)$ is compact, because the ratio of weights $(1+n^2)^{(t-s)/2}$ tends to 0. This is why elliptic operators on compact spaces have discrete spectra.
- A ΨDO of order m is bounded $H^s \to H^{s-m}$ for every s; smoothing operators map everything into $H^\infty \subset C^\infty$. The Laplacian is unbounded on L^2 but has norm 1 as a map $H^k \to H^{k-2}$ on the circle.
- Elliptic estimate: $\|u\|_s \le C\,\|Pu\|_{s-m} + C\,\|u\|_t$. Elliptic regularity and smoothness of zero modes follow at once.

2.6 Elliptic operators are Fredholm

Here are the two questions every physicist asks about a linear equation $Pu = f$.

(1) *How many solutions does the homogeneous equation $Pu = 0$ have?* These are the zero modes: the harmonic forms of Hodge theory, the fermion zero modes in an instanton background, the flat directions of a moduli space.

(2) *For which sources f can we solve $Pu = f$ at all?* On a compact space there are often constraints. The simplest is Gauss's law: on a closed universe the total charge must vanish.

In finite dimensions, linear algebra answers both at once: for a matrix, (number of zero modes) − (number of constraints) is fixed by the sizes of the matrix, whatever its entries. Nash's last

page of the chapter says that elliptic operators on compact manifolds behave in the same way: they have finitely many zero modes and finitely many constraints, and the difference, the **index**, is robust. He says it in one paragraph and two equations, (2.96)–(2.97). In this section we unpack that paragraph. Every tool of the previous two sections gets used: the parametrix, the smoothing operators, Rellich's compactness theorem and the boundedness of ΨDOs on the Sobolev scale.

2.6.1 Warm-up: the index of a matrix

Let $A : \mathbb{C}^n \to \mathbb{C}^m$ be an $m \times n$ matrix. Two subspaces measure how far it is from being invertible.

- The **kernel** $\operatorname{Ker} A = \{u : Au = 0\} \subset \mathbb{C}^n$: the solutions of the homogeneous equation.
- The **cokernel** $\operatorname{Coker} A = \mathbb{C}^m / \operatorname{Im} A$: the directions in the target that A cannot reach. Its dimension is the number of independent linear conditions that f must satisfy for $Au = f$ to be solvable.

The **rank–nullity theorem** says $\dim \operatorname{Ker} A + \dim \operatorname{Im} A = n$: the domain splits into the part A kills and a part that A maps isomorphically onto its image. Hence

$$\begin{aligned} \dim \operatorname{Ker} A - \dim \operatorname{Coker} A &\overset{(1)}{=} \dim \operatorname{Ker} A - \big(m - \dim \operatorname{Im} A\big) \\ &\overset{(2)}{=} \big(\dim \operatorname{Ker} A + \dim \operatorname{Im} A\big) - m \\ &\overset{(3)}{=} n - m. \end{aligned} \tag{2.171}$$

(1) The dimension of a quotient is the dimension of the big space minus that of the subspace.
(2) Regroup.
(3) Rank–nullity.

The left side depends on the entries of A; the right side does not. That is the whole phenomenon of this section in its simplest form.

The cokernel is the kernel of the adjoint. With the standard inner products, a vector $f \in \mathbb{C}^m$ is orthogonal to the image of A if and only if $A^\dagger f = 0$:

$$f \perp \operatorname{Im} A \iff \langle f, Au\rangle = 0 \ \forall u \overset{(1)}{\iff} \langle A^\dagger f, u\rangle = 0 \ \forall u \iff A^\dagger f = 0. \tag{2.172}$$

(1) Definition of the adjoint, $\langle f, Au\rangle = \langle A^\dagger f, u\rangle$.

(The last step: take $u = A^\dagger f$.) So $\operatorname{Coker} A \cong (\operatorname{Im} A)^\perp = \operatorname{Ker} A^\dagger$, and

$$\operatorname{index} A = \dim \operatorname{Ker} A - \dim \operatorname{Ker} A^\dagger.$$

This version is the one that generalises: it counts zero modes of A minus zero modes of $A^\dagger$, and $Au = f$ is solvable exactly when f is orthogonal to every zero mode of $A^\dagger$ (the **Fredholm alternative** in finite dimensions).

Worked example 2.84: The kernel jumps, the index does not

Take the 2×3 family

$$A_\varepsilon = \begin{pmatrix} 1 & 2 & 3 \\ 2 & 4 & 6+\varepsilon \end{pmatrix} : \mathbb{C}^3 \to \mathbb{C}^2.$$

At $\varepsilon = 0$ the second row is twice the first, so the rank is 1. The kernel is the plane $u_1 + 2u_2 + 3u_3 = 0$, of dimension 2. The image is the line spanned by $(1,2)^T$, so the cokernel has dimension $2-1=1$; concretely $\operatorname{Ker} A_0^\dagger$ is spanned by $(2,-1)^T$, and $A_0 u = f$ is solvable iff $2f_1 - f_2 = 0$. Index: $2-1=1$.
At $\varepsilon \neq 0$ the rows are independent, the rank is 2, the kernel is the line through the vector

$$v = (1,2,3)\times(2,4,6+\varepsilon) \overset{(1)}{=} (2\varepsilon,\ -\varepsilon,\ 0) \ \propto\ (2,-1,0),$$

(1) The cross product of the rows is orthogonal to both rows, hence in the kernel: $\big(2(6+\varepsilon)-3\cdot 4,\ 3\cdot 2 - 1\cdot(6+\varepsilon),\ 1\cdot 4 - 2\cdot 2\big)$.

and the cokernel is 0. Index: $1-0=1$. As $\varepsilon \to 0$ one kernel vector and one cokernel vector appear *together*; their difference never changes, and equals $n-m=3-2$ as (2.171) demands.

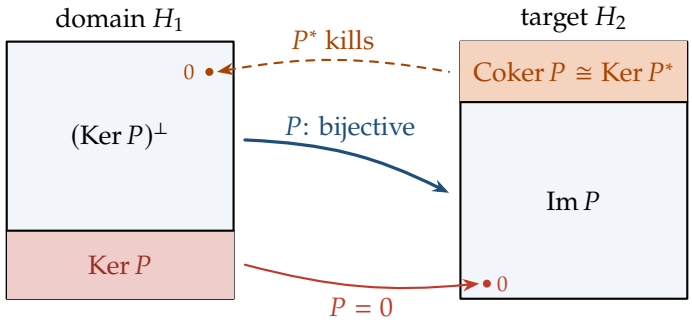

Figure 2.43: What a Fredholm operator looks like. The domain splits into the zero modes Ker P (red, finite-dimensional) and their orthogonal complement, which P maps bijectively onto its image. The image is closed, and its orthogonal complement (orange) is finite-dimensional: it is the cokernel, and it consists of the zero modes of the adjoint. The index is (red dimension) − (orange dimension). For a matrix this is $n-m$; for an operator on infinite-dimensional spaces it is a number that the sizes alone do not determine.

Watch out: A square matrix always has index 0; an operator need not

For $A : \mathbb{C}^n \to \mathbb{C}^n$, (2.171) gives index 0: a square matrix has as many zero modes as constraints. In infinite dimensions "$n-m$" reads $\infty - \infty$, and an operator from a Hilbert space to itself can have any integer index (Section 2.6.3). This is not a pathology; it is exactly why the index of an elliptic operator carries information.

2.6.2 Kernel, cokernel and the adjoint in Hilbert space

Now let $T : H_1 \to H_2$ be a bounded operator between Hilbert spaces (for us: $P : H^s(M,U) \to H^{s-m}(M,V)$). Its kernel Ker T is a closed subspace, because T is continuous. Its **cokernel** is again the quotient Coker $T = H_2/\operatorname{Im} T$. The computation (2.172) goes through word for word and gives

$$(\operatorname{Im} T)^\perp = \operatorname{Ker} T^*, \tag{2.173}$$

where $T^* : H_2 \to H_1$ is the Hilbert-space adjoint. But there is a new subtlety. $(\operatorname{Im} T)^\perp$ only sees the *closure* of the image, because $(\operatorname{Im} T)^\perp = (\overline{\operatorname{Im} T})^\perp$. So

$$\operatorname{Coker} T \cong \operatorname{Ker} T^* \qquad \text{only when } \operatorname{Im} T \text{ is closed.}$$

Worked example 2.85: An operator whose range is not closed

On ℓ^2 (sequences $u = (u_1, u_2, \dots)$ with $\sum |u_n|^2 < \infty$, or equivalently $L^2(S^1)$ through Fourier coefficients) let T be diagonal with $Te_n = \frac{1}{n} e_n$.

- $\operatorname{Ker} T = 0$: if $u_n/n = 0$ for all n then $u = 0$.
- $T = T^*$, so $\operatorname{Ker} T^* = 0$ too, and $(\operatorname{Im} T)^\perp = 0$: the image is dense.
- But T is not onto. For $f = (1, \frac{1}{2}, \frac{1}{3}, \dots) \in \ell^2$ the only candidate solution is $u_n = n f_n = 1$ for all n, which is not in ℓ^2.

In fact $f^{(a)} = (n^{-a})_n$ for $\frac{1}{2} < a \le 1$ gives infinitely many independent elements of ℓ^2 outside the image (no finite combination of them lies in $\operatorname{Im} T$), so $H_2/\operatorname{Im} T$ is infinite-dimensional even though $\operatorname{Ker} T^* = 0$. Such a T is compact (its eigenvalues $1/n \to 0$, test (iii) of Section 2.5.8), and this is typical: *a compact operator on an infinite-dimensional space never has closed range of finite codimension*. Compact operators are the opposite of Fredholm ones.

Working definition 2.39 (Fredholm operator, index)

A bounded operator $T : H_1 \to H_2$ is **Fredholm** if

$$\dim \operatorname{Ker} T < \infty \qquad \text{and} \qquad \dim \operatorname{Coker} T < \infty.$$

Then $\operatorname{Im} T$ is automatically closed, $\operatorname{Coker} T \cong \operatorname{Ker} T^*$ [T^* is the adjoint, $\langle Tu, v\rangle = \langle u, T^*v\rangle$. Each independent v with $T^*v = 0$ is one obstruction to solving $Tu = f$], and the **index** is the integer

$$\operatorname{index} T = \dim \operatorname{Ker} T - \dim \operatorname{Coker} T = \dim \operatorname{Ker} T - \dim \operatorname{Ker} T^*. \tag{2.174}$$

Operational test: count the zero modes [independent nonzero solutions of $Tu = 0$, respectively $T^*v = 0$] of T and of T^*; check that both counts are finite and that T is bounded below on the complement of its kernel, $\|Tu\| \ge c\,\|u\|$ for $u \perp \operatorname{Ker} T$ (this is closed range).

Why the image is automatically closed. Pick a finite-dimensional subspace $C \subset H_2$ complementary to $\operatorname{Im} T$ (possible because the quotient is finite-dimensional). The map $(u, c) \mapsto Tu + c$ from $(\operatorname{Ker} T)^\perp \oplus C$ to H_2 is bounded, injective and onto. By the open mapping theorem (a bounded bijection between Hilbert spaces has a bounded inverse) it is an isomorphism, so it maps the closed subspace $(\operatorname{Ker} T)^\perp \oplus 0$ onto a closed subspace, which is $\operatorname{Im} T$. Nash lists only the two dimension conditions; this remark is why that is enough.

Why "bounded below" is the same as closed range. If $\|Tu\| \ge c\,\|u\|$ on $(\operatorname{Ker} T)^\perp$ and $Tu_j \to f$ with $u_j \perp \operatorname{Ker} T$, then

$$\|u_i - u_j\| \overset{(1)}{\le} \frac{1}{c}\,\|T(u_i - u_j)\| = \frac{1}{c}\,\|Tu_i - Tu_j\| \longrightarrow 0, \tag{2.175}$$

(1) The lower bound, applied to $u_i - u_j \perp \operatorname{Ker} T$.

so (u_j) is Cauchy, converges to some u, and $Tu = f$ by continuity: $f \in \operatorname{Im} T$. The diagonal T of Example 2.85 fails exactly here: $\|Te_n\| = \frac{1}{n}\,\|e_n\|$, so no $c > 0$ works.

2.6.3 A gallery on ℓ^2: shifts and the Hilbert hotel

The simplest operators with non-zero index are shifts. Work in ℓ^2 with orthonormal basis $e_0, e_1, e_2, \dots$ (think of $e_n = e^{in\theta}$, $n \geq 0$, on the circle: this is the **Hardy space** of boundary values of holomorphic functions on the disc). Define the **unilateral shift**

$$Se_n = e_{n+1}, \qquad S\Big(\sum_{n\geq 0} u_n e_n\Big) = \sum_{n\geq 0} u_n e_{n+1}.$$

On the circle, S is multiplication by $e^{i\theta}$. Its adjoint moves the other way:

$$\langle e_m, S^* e_n\rangle \overset{(1)}{=} \langle Se_m, e_n\rangle \overset{(2)}{=} \langle e_{m+1}, e_n\rangle = \delta_{m+1,n} \quad\Longrightarrow\quad S^* e_n = e_{n-1}\ (n \geq 1),\ \ S^* e_0 = 0. \tag{2.176}$$

(1) Definition of the adjoint (with $\langle\cdot,\cdot\rangle$ conjugate-linear in the first slot, and real matrix elements here, so the order is harmless).
(2) Definition of S.

Now count.

- $\operatorname{Ker} S = 0$: S preserves norms, $\|Su\| = \|u\|$.
- $\operatorname{Im} S = \{u : u_0 = 0\} = e_0^{\perp}$, closed, with cokernel $\operatorname{span}(e_0) = \operatorname{Ker} S^*$.
- So $\operatorname{index} S = 0 - 1 = -1$, and $\operatorname{index} S^* = 1 - 0 = +1$.
- S^k shifts by k: $\operatorname{Ker} S^k = 0$, $\operatorname{Coker} S^k = \operatorname{span}(e_0, \dots, e_{k-1})$, $\operatorname{index} S^k = -k$.

Also $S^*S = I$ while $SS^* = I - \Pi_0$ with Π_0 the projection onto e_0: S is invertible *modulo a rank-one operator*, which is the Fredholm property in its purest form.

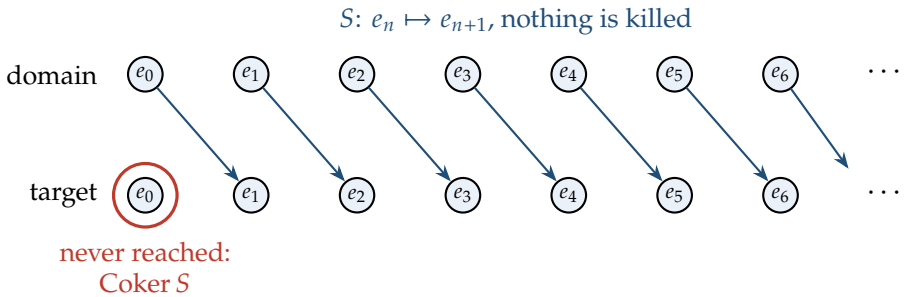

Figure 2.44: The unilateral shift, drawn as a map from the basis of the domain (top) to the basis of the target (bottom). Every basis vector is sent to a distinct basis vector, so the kernel is zero; but e_0 in the target is never hit, so the cokernel is one-dimensional and $\operatorname{index} S = -1$. This is Hilbert's hotel: every guest moves up one room, and room 0 becomes free. A matrix cannot do this, because a finite hotel has a last room.

Worked example 2.86: A table of operators on ℓ^2: Fredholm or not?

operator	dim Ker	dim Coker	index	comment
I	0	0	0	invertible
S	0	1	-1	isometry, not onto
S^*	1	0	$+1$	onto, kills e_0
S^k, $(S^*)^k$	$0, k$	$k, 0$	$\mp k$	every integer occurs
$I - \Pi_0$	1	1	0	projection of finite corank
Π_{even}	∞	∞	–	kills all odd modes: not Fredholm
$e_n \mapsto \frac{1}{n} e_n$	0	∞	–	compact; range dense, not closed
$e_n \mapsto (1 + \frac{1}{n}) e_n$	0	0	0	I plus a compact operator

For the last line: the inverse is $e_n \mapsto \frac{n}{n+1} e_n$, bounded by 1. It is the identity plus the compact diagonal operator $e_n \mapsto \frac{1}{n} e_n$, an example of the general rule "Fredholm plus compact is Fredholm, with the same index" (Section 2.6.6).

Physical picture: The shift is the Dirac sea moving by one level

In second quantisation the one-particle states are labelled by energy levels, and the vacuum fills every negative level. If an external field makes the levels flow so that each one moves up by one step, the new vacuum differs from the old one by one particle: one state has crossed zero. The operator that relabels the levels is a shift, and its index (± 1) is the charge created. This "spectral flow equals index" mechanism is how anomalies appear in Chapter 10; we see a concrete instance on the circle in Figure 2.47.

2.6.4 Fredholm means invertible modulo compact operators

Nash states: "A further well known property of Fredholm operators is that they are invertible modulo a compact operator." This is **Atkinson's theorem**, and it is the bridge between the parametrix of Section 2.4.9 and the Fredholm property.

Key idea: Atkinson's theorem; Nash's (2.97)

A bounded operator $T : H_1 \to H_2$ is Fredholm if and only if there is a bounded $Q : H_2 \to H_1$ (a **parametrix**) and compact operators K_1 on H_2 and K_2 on H_1 with

$$TQ = I_{H_2} - K_1, \qquad QT = I_{H_1} - K_2. \tag{2.177}$$

Moreover Q is then itself Fredholm, with $\operatorname{index} Q = -\operatorname{index} T$.

From Fredholm to a parametrix (with finite-rank errors). Suppose T is Fredholm. By Figure 2.43, T restricts to a bounded bijection $T_0 : (\operatorname{Ker} T)^\perp \to \operatorname{Im} T$ between closed subspaces, whose inverse is bounded (open mapping theorem again). Let Π_{Ker} be the orthogonal projection onto $\operatorname{Ker} T$ and Π_{Coker} the projection onto $(\operatorname{Im} T)^\perp$. Define $Q = T_0^{-1}(I - \Pi_{\text{Coker}})$: project onto the image, then invert. Then for $u \in H_1$,

$$QTu \overset{(1)}{=} T_0^{-1} T u \overset{(2)}{=} T_0^{-1} T_0 (I - \Pi_{\text{Ker}}) u = (I - \Pi_{\text{Ker}}) u, \tag{2.178}$$

(1) Tu already lies in $\operatorname{Im} T$, so the projection $I - \Pi_{\text{Coker}}$ does nothing to it.

(2) Split $u = \Pi_{\mathrm{Ker}} u + (I - \Pi_{\mathrm{Ker}})u$; T kills the first piece and acts as T_0 on the second.

and similarly $TQ = I - \Pi_{\mathrm{Coker}}$. So (2.177) holds with $K_2 = \Pi_{\mathrm{Ker}}$ and $K_1 = \Pi_{\mathrm{Coker}}$, which are *finite rank*, hence compact. We met this for $P = D_\theta^2$ on the circle in Example 2.59, where both errors were the projection Π_0 onto the constants.

From a parametrix to Fredholm. Now suppose (2.177) holds with K_1, K_2 compact. Three things must be checked.

(a) The kernel is finite-dimensional. If $Tu = 0$ then $0 = QTu = u - K_2 u$, so K_2 acts as the identity on $\operatorname{Ker} T$. Let B be the closed unit ball of $\operatorname{Ker} T$. Then

$$B \overset{(1)}{=} K_2(B) \overset{(2)}{\subset} K_2(\text{unit ball of } H_1),$$

(1) $K_2 u = u$ for every $u \in \operatorname{Ker} T$.
(2) B is part of the unit ball of H_1.

and the right side has compact closure because K_2 is compact. So B is a closed subset of a compact set, hence compact. But the unit ball of an infinite-dimensional Hilbert space is never compact: an orthonormal sequence has $\|e_i - e_j\| = \sqrt{2}$ for all $i \neq j$ (Section 2.5.8). Therefore $\dim \operatorname{Ker} T < \infty$.

(b) T is bounded below on $(\operatorname{Ker} T)^\perp$, so its image is closed. Suppose not. Then there are $u_j \perp \operatorname{Ker} T$ with $\|u_j\| = 1$ and $Tu_j \to 0$. By compactness of K_2, a subsequence has $K_2 u_j \to v$. Along it,

$$u_j \overset{(1)}{=} QTu_j + K_2 u_j \longrightarrow Q(0) + v = v,$$

(1) $u = QTu + K_2 u$ is (2.177) rearranged; Q is bounded, so $QTu_j \to 0$.

so $u_j \to v$ in norm. Then $\|v\| = 1$, $v \perp \operatorname{Ker} T$ (a closed condition), and $Tv = \lim Tu_j = 0$, so $v \in \operatorname{Ker} T$. A unit vector cannot be both in $\operatorname{Ker} T$ and orthogonal to it: contradiction. By (2.175) the image is closed.

(c) The cokernel is finite-dimensional. Take adjoints in $TQ = I - K_1$: $Q^*T^* = I - K_1^*$, and K_1^* is compact (adjoints of compact operators are compact). Step (a) applied to T^* with parametrix Q^* gives $\dim \operatorname{Ker} T^* < \infty$. Since the image is closed, $\operatorname{Coker} T \cong \operatorname{Ker} T^*$ by (2.173). Done.

Physical picture: Why "modulo compact" is the right notion of "almost invertible"

A compact operator is, up to any ε, a finite matrix (Section 2.5.8). "Invertible modulo compact" therefore means "invertible except on an effectively finite-dimensional piece". Whatever goes wrong goes wrong in finitely many dimensions, and in finitely many dimensions rank–nullity (2.171) controls the count. The Fredholm index is the infinite-dimensional shadow of $n - m$.

Worked example 2.87: Fredholm's integral equation on the circle

Fredholm introduced these ideas in 1903 for integral equations of the second kind, $u - \lambda K u = f$. On S^1 take the smooth kernel $K(\theta, \theta') = \frac{1}{\pi}\cos(\theta - \theta')$:

$$(Ku)(\theta) = \frac{1}{\pi}\int_0^{2\pi} \cos(\theta - \theta')\, u(\theta')\, \mathrm{d}\theta'.$$

Act on a Fourier mode:

$$Ke^{in\theta} \overset{(1)}{=} \frac{1}{2\pi}\int_0^{2\pi} \left(e^{i(\theta-\theta')} + e^{-i(\theta-\theta')}\right) e^{in\theta'}\, \mathrm{d}\theta' \overset{(2)}{=} \frac{1}{2\pi}\left(e^{i\theta}\cdot 2\pi\,\delta_{n,1} + e^{-i\theta}\cdot 2\pi\,\delta_{n,-1}\right)$$

$$= \begin{cases} e^{in\theta}, & n = \pm 1, \\ 0, & \text{otherwise.} \end{cases}$$

(1) $\cos x = \frac{1}{2}(e^{ix} + e^{-ix})$.

(2) $\int_0^{2\pi} e^{i(n-1)\theta'} \mathrm{d}\theta' = 2\pi\delta_{n,1}$, and similarly for the other term.

So K is the orthogonal projection onto $\operatorname{span}(e^{i\theta}, e^{-i\theta})$: finite rank, smoothing, compact. The operator $I - \lambda K$ multiplies $e^{\pm i\theta}$ by $1 - \lambda$ and every other mode by 1.

- $\lambda \neq 1$: $I - \lambda K$ is invertible, with $(I - \lambda K)^{-1} = I + \frac{\lambda}{1-\lambda} K$ (check: $K^2 = K$). Index 0.
- $\lambda = 1$: $\operatorname{Ker}(I - K) = \operatorname{span}(\cos\theta, \sin\theta)$, and since $I - K$ is self-adjoint, the cokernel is the same space. The equation $u - Ku = f$ is solvable iff $\int f \cos\theta = \int f \sin\theta = 0$, and then the solution is unique up to adding $a\cos\theta + b\sin\theta$. Index $2 - 2 = 0$.

This is the classical **Fredholm alternative**: *either* $u - \lambda K u = f$ has a unique solution for every f, *or* the homogeneous equation has finitely many solutions and f must satisfy the same finite number of orthogonality conditions. In both cases the index of $I - \lambda K$ is 0; we will see in Section 2.6.6 that this is true for every compact K.

Watch out: Nash's (2.97) has its identities swapped

Nash writes, for $P : H^k \to H^{k-m}$ with parametrix $Q : H^{k-m} \to H^k$, "$P \circ Q_1 - K_1 = I_{H^k}$ and $Q \circ P - K_2 = I_{H^{k-m}}$". Follow the arrows: $Q \circ P$ starts and ends in H^k, while $P \circ Q$ starts and ends in H^{k-m}. The correct statement is

$$P \circ Q = I_{H^{k-m}} + K_1, \qquad Q \circ P = I_{H^k} + K_2,$$

with K_1 compact on H^{k-m} and K_2 compact on H^k (the "Q_1" is a misprint for Q). The sign in front of K_i is immaterial, since $-K$ is compact when K is. In (2.177) we write $I - K$ to match Section 2.4.9.

2.6.5 Elliptic operators on compact manifolds are Fredholm

We can now assemble Nash's claim. Throughout, M is a compact manifold without boundary, $U, V \to M$ are vector bundles of the same rank, and P is an elliptic ΨDO of order m from sections of U to sections of V (a differential operator is the special case of polynomial symbol).

Key idea: Elliptic ⇒ Fredholm (Nash, p. 54)

For every real s:

(i) $P : H^s(M, U) \to H^{s-m}(M, V)$ is a Fredholm operator.

(ii) Its kernel consists of smooth sections and does not depend on s.

(iii) Its cokernel is isomorphic to $\operatorname{Ker} P^*$, where P^* is the formal adjoint (again elliptic); these are smooth sections too. Concretely, for $f \in H^{s-m}$:

$$Pu = f \text{ has a solution} \iff \int_M \langle v, f \rangle \,\mathrm{dvol} = 0 \ \text{ for every } v \in \operatorname{Ker} P^*. \tag{2.179}$$

(iv) Hence the index $\operatorname{index} P = \dim \operatorname{Ker} P - \dim \operatorname{Ker} P^*$ is a finite integer, the same for all s.

The mechanism: parametrix plus Rellich. By Section 2.4.9, P has a parametrix Q of order $-m$ with

$$QP = I - R_2, \qquad PQ = I - R_1, \qquad R_1, R_2 \text{ smoothing.}$$

By (2.165), Q is bounded $H^{s-m} \to H^s$. The errors are compact on the relevant Sobolev spaces, because

$$R_2 : H^s \xrightarrow[\text{bounded}]{\text{(2.165), order } -1} H^{s+1} \xrightarrow[\text{compact}]{\text{Rellich}} H^s, \tag{2.180}$$

and a bounded operator followed by a compact one is compact: a bounded sequence u_j in H^s goes to a bounded sequence $R_2 u_j$ in H^{s+1}, which has a subsequence converging in H^s. (We used only that a smoothing operator has order ≤ -1; any negative order would do.) The same holds for R_1 on H^{s-m}. Atkinson's theorem (2.177) now gives (i). This is exactly Nash's sentence "this is nothing other than the Sobolev space version of the property that elliptic operators possess of being invertible modulo a smoothing operator": *smoothing becomes compact* once we measure in Sobolev norms on a compact space.

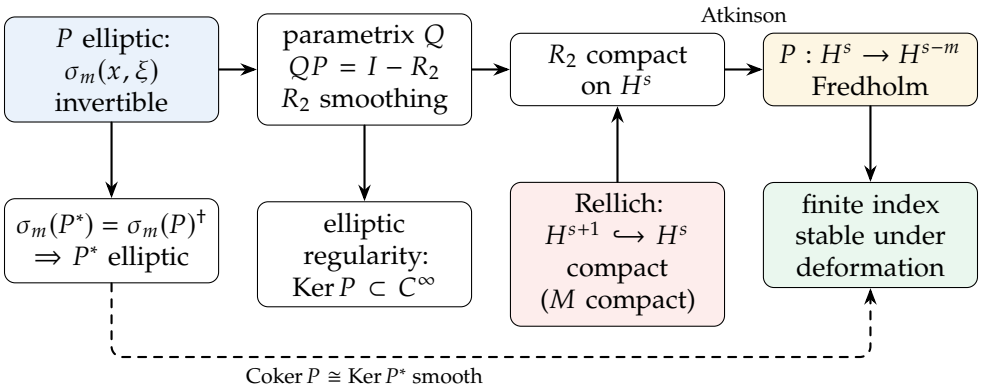

Figure 2.45: The logic of "elliptic implies Fredholm". The top row is the proof: invert the principal symbol, build a parametrix, observe that the smoothing error is compact because of Rellich's theorem (which needs M compact), and apply Atkinson's theorem. The bottom row gives the extra information: zero modes are smooth, the cokernel is the kernel of the (elliptic) adjoint, and the index is a finite integer that survives deformations.

The adjoint is elliptic. Nash's reason: "the leading symbol of P^* is the adjoint of that of P". In formulas, $\sigma_m(P^*)(x,\xi) = \sigma_m(P)(x,\xi)^\dagger$ (the first term of (2.129)). If $\sigma = \sigma_m(P)(x,\xi)$ is an invertible matrix, then

$$\sigma^\dagger (\sigma^{-1})^\dagger \overset{(1)}{=} (\sigma^{-1}\sigma)^\dagger = I^\dagger = I,$$

(1) $(AB)^\dagger = B^\dagger A^\dagger$.

and similarly in the other order, so $\sigma^\dagger$ is invertible with inverse $(\sigma^{-1})^\dagger$. Hence P^* is elliptic of order m, from V to U, and everything we say about P applies to it.

Why the cokernel is $\operatorname{Ker} P^*$, on every Sobolev space. There is a subtlety: the Hilbert-space adjoint of $P : H^s \to H^{s-m}$ is taken with respect to the H^s and H^{s-m} inner products, not the L^2 one, so it is not literally the differential (or pseudo-differential) operator P^*. The clean way round is duality. The L^2 pairing identifies the dual of H^{s-m} with H^{m-s} (Section 2.5.4). A closed subspace is the set of vectors on which every continuous functional vanishing on the subspace

also vanishes (Hahn–Banach, or just orthogonal projection in a Hilbert space). So, for $f \in H^{s-m}$,

$$\begin{aligned} f \in \operatorname{Im} P &\overset{(1)}{=}\Longleftrightarrow \ \langle v, f\rangle_{L^2} = 0 \ \text{ for all } v \in H^{m-s} \text{ with } \langle v, Pu\rangle_{L^2} = 0 \ \forall u \in H^s \\ &\overset{(2)}{=}\Longleftrightarrow \ \langle v, f\rangle_{L^2} = 0 \ \text{ for all } v \in H^{m-s} \text{ with } P^*v = 0 \\ &\overset{(3)}{=}\Longleftrightarrow \ \langle v, f\rangle_{L^2} = 0 \ \text{ for all } v \in \operatorname{Ker} P^* \subset C^\infty. \end{aligned} \tag{2.181}$$

(1) $\operatorname{Im} P$ is closed by (i); describe it by the functionals $v \in H^{m-s} = (H^{s-m})^*$ that annihilate it.
(2) $\langle v, Pu\rangle = \langle P^*v, u\rangle$ for all smooth u is the definition of P^*v as a distribution; vanishing for all u means $P^*v = 0$.
(3) P^* is elliptic, so its distributional zero modes are smooth (the elliptic estimate (2.170)), and $\operatorname{Ker} P^*$ is the same finite-dimensional space of smooth sections whichever Sobolev space we start from.

This is (2.179): the constraints on the source are "orthogonality to the zero modes of the adjoint", measured in the ordinary L^2 inner product. The number of independent constraints is $\dim \operatorname{Ker} P^*$, the same for every s. With (ii), the index is independent of s.

Worked example 2.88: $\Delta + 1$ is invertible on any compact manifold

We promised this in Example 2.80. Let $\Delta = \mathrm{d}^*\mathrm{d}$ be the positive Laplacian on functions on a compact Riemannian M, and $P = \Delta + 1 : H^{s+2} \to H^s$. It is elliptic ($\sigma_2 = |\xi|^2$), so Fredholm. Its kernel is zero: if $Pu = 0$ then u is smooth and

$$0 = \langle u, (\Delta + 1)u\rangle \overset{(1)}{=} \langle u, \mathrm{d}^*\mathrm{d}u\rangle + \langle u, u\rangle \overset{(2)}{=} \|\mathrm{d}u\|^2 + \|u\|^2 ,$$

(1) Definition of Δ on functions (d^* of a function vanishes).
(2) Move d^* across; no boundary terms since $\partial M = \varnothing$.

so $\|u\| = 0$. The operator is formally self-adjoint, $P^* = P$, so $\operatorname{Ker} P^* = 0$ as well, and by (2.179) there are no constraints. A bounded bijection between Hilbert spaces has a bounded inverse, so $(\Delta + 1)^{-1} : H^s \to H^{s+2}$ exists and is bounded for every s. Composed with the Rellich inclusion it is compact on L^2, which is what gave the discrete spectrum in Example 2.80. The same argument works for $\Delta + \mu^2$ with any $\mu \neq 0$: a mass term makes the Laplacian invertible.

Worked example 2.89: Gauss's law on a closed universe

Now drop the mass. For $P = \Delta$ on functions on a connected compact M:

- $\operatorname{Ker} \Delta$: as above $\|\mathrm{d}u\|^2 = 0$, so $\mathrm{d}u = 0$ and u is constant (M connected). One zero mode.
- $\Delta^* = \Delta$, so $\operatorname{Ker} \Delta^* = \{\text{constants}\}$: one constraint.
- By (2.179), $\Delta u = f$ is solvable iff $\int_M f \,\mathrm{dvol} = 0$, and the solution is unique up to an additive constant. Index $1 - 1 = 0$.

The necessity of the constraint is Stokes' theorem: $\int_M \Delta u = \int_M \mathrm{d}^*\mathrm{d}u = -\int_M \mathrm{d}\star\mathrm{d}u \cdot (\pm 1) = 0$, since $\partial M = \varnothing$. The sufficiency is the Fredholm theory.
Physics. Electrostatics with our positive Laplacian reads $\Delta\phi = \rho/\varepsilon_0$. On a three-torus (a periodic box, as in lattice QED or a cosmological model with compact space) this has a solution iff the total charge $\int \rho$ vanishes. You cannot put a single point charge in a closed universe: its field lines have nowhere to go. This is why numerical simulations of charged

systems in periodic boxes add a uniform "neutralising background" $-Q/\mathrm{Vol}$, and why the Green's function on a compact manifold solves $\Delta G = \delta - 1/\mathrm{Vol}$ rather than $\Delta G = \delta$.
On the circle, explicitly. Solve $-u'' = \cos\theta + b$. In modes, $n^2 c_n(u) = c_n(f)$. For $n = \pm 1$: $c_{\pm 1}(u) = \frac{1}{2}$; for $n = 0$: $0 = b$. So a solution exists iff $b = 0$, and then $u = \cos\theta + c$ with c arbitrary.

Watch out: On $\mathbb{R}^n$ elliptic operators need not be Fredholm

Compactness of M entered through Rellich, and it cannot be dropped. Take $P = \mathrm{d}/\mathrm{d}x : H^1(\mathbb{R}) \to L^2(\mathbb{R})$. Its kernel is 0 (constants are not in L^2) and so is the kernel of its adjoint $-\mathrm{d}/\mathrm{d}x$. If P were Fredholm it would be invertible. It is not bounded below: with $u_\lambda(x) = \lambda^{1/2}\phi(\lambda x)$ for a fixed bump ϕ,

$$\|u_\lambda\|_{L^2} = \|\phi\|_{L^2}, \qquad \|u_\lambda'\|_{L^2} = \lambda\,\|\phi'\|_{L^2} \xrightarrow{\lambda\to 0} 0.$$

Wider and wider bumps have smaller and smaller derivatives, so the range is dense but not closed. In physics language: a massless field in infinite volume has modes of arbitrarily low momentum, a continuum reaching down to zero, and no finite count of "zero modes" makes sense. A mass gap ($\Delta + \mu^2$ on $\mathbb{R}^n$ is invertible) or a confining potential (Example 2.96) restores the Fredholm property.

2.6.6 The index and its stability

Working definition 2.40 (analytical index of an elliptic operator)

For an elliptic P [its principal symbol $\sigma_m(P)(x,\xi)$ is an invertible matrix for every $\xi \neq 0$] on a compact manifold,

$$\operatorname{index} P = \dim \operatorname{Ker} P - \dim \operatorname{Ker} P^*,$$

where P^* is the adjoint [$\langle Pu, v\rangle = \langle u, P^*v\rangle$ in the L^2 inner product], computed on smooth sections (by Section 2.6.5 it is the same on every H^s). *To compute it:* solve $Pu = 0$ and $P^*v = 0$, count, subtract. *To avoid computing it:* deform P to something simpler without leaving the elliptic operators; the index cannot change.

The second half of that box is the reason the index is interesting. It rests on the following properties.

Key idea: Stability of the index

(i) *Local constancy.* If T is Fredholm and $\|S - T\|$ is small enough, then S is Fredholm, $\operatorname{index} S = \operatorname{index} T$, and $\dim \operatorname{Ker} S \le \dim \operatorname{Ker} T$.
(ii) *Compact perturbations.* If T is Fredholm and K compact, $\operatorname{index}(T + K) = \operatorname{index} T$. In particular $\operatorname{index}(I - K) = 0$.
(iii) *Elliptic operators.* $\operatorname{index} P$ depends only on the principal symbol $\sigma_m(P)$, and only on its homotopy class through elliptic (invertible off $\xi = 0$) symbols.
(iv) *Products and adjoints.* $\operatorname{index}(T_1T_2) = \operatorname{index} T_1 + \operatorname{index} T_2$ and $\operatorname{index} T^* = -\operatorname{index} T$. A self-adjoint Fredholm operator has index 0.

Why (i): reduction to a finite matrix. Let $N = \operatorname{Ker} T$ and $C = (\operatorname{Im} T)^{\perp} \cong \operatorname{Coker} T$, both finite-dimensional. Split the domain and target:

$$H_1 = N^{\perp} \oplus N, \qquad H_2 = \operatorname{Im} T \oplus C.$$

Any bounded $S : H_1 \to H_2$ becomes a 2×2 block operator matrix, and T itself is block diagonal with an invertible top-left block T_0:

$$S = \begin{pmatrix} A & B \\ \Gamma & E_0 \end{pmatrix}, \qquad T = \begin{pmatrix} T_0 & 0 \\ 0 & 0 \end{pmatrix}, \qquad \begin{array}{ll} A : N^{\perp} \to \operatorname{Im} T, & B : N \to \operatorname{Im} T, \\ \Gamma : N^{\perp} \to C, & E_0 : N \to C. \end{array}$$

If $\|S - T\| < \left\|T_0^{-1}\right\|^{-1}$, then A is invertible, because $A = T_0\big(I + T_0^{-1}(A - T_0)\big)$ and $\left\|T_0^{-1}(A - T_0)\right\| < 1$, so the Neumann series $\sum_k \big(-T_0^{-1}(A - T_0)\big)^k$ inverts the bracket. Now clear the off-diagonal blocks by "row and column operations":

$$\begin{aligned} \begin{pmatrix} I & 0 \\ -\Gamma A^{-1} & I \end{pmatrix} \begin{pmatrix} A & B \\ \Gamma & E_0 \end{pmatrix} \begin{pmatrix} I & -A^{-1}B \\ 0 & I \end{pmatrix} &\overset{(1)}{=} \begin{pmatrix} I & 0 \\ -\Gamma A^{-1} & I \end{pmatrix} \begin{pmatrix} A & 0 \\ \Gamma & E_0 - \Gamma A^{-1} B \end{pmatrix} \\ &\overset{(2)}{=} \begin{pmatrix} A & 0 \\ 0 & E \end{pmatrix}, \qquad E \coloneqq E_0 - \Gamma A^{-1} B : \; N \to C. \end{aligned} \tag{2.182}$$

(1) Right multiplication: the second column becomes $-AA^{-1}B + B = 0$ and $-\Gamma A^{-1}B + E_0$.
(2) Left multiplication: the bottom-left block becomes $-\Gamma A^{-1}A + \Gamma = 0$; the rest is unchanged.

The outer factors are invertible (their inverses just flip the sign of the off-diagonal block), so S has the same kernel and cokernel dimensions as $\operatorname{diag}(A, E)$. Since A is invertible, all of the kernel and cokernel sit in the finite matrix E, of size $\dim C \times \dim N$. Therefore

$$\operatorname{index} S \overset{(1)}{=} \dim \operatorname{Ker} E - \dim \operatorname{Coker} E \overset{(2)}{=} \dim N - \dim C \overset{(3)}{=} \operatorname{index} T, \tag{2.183}$$

(1) $\operatorname{diag}(A, E)$ with A invertible: only E contributes.
(2) Rank–nullity (2.171) for the matrix $E : N \to C$.
(3) $N = \operatorname{Ker} T$, $C \cong \operatorname{Coker} T$.

and $\dim \operatorname{Ker} S = \dim \operatorname{Ker} E \le \dim N$. When we perturb, the infinite-dimensional part stays invertible; all the action happens in a finite matrix, and a finite matrix cannot change its index.

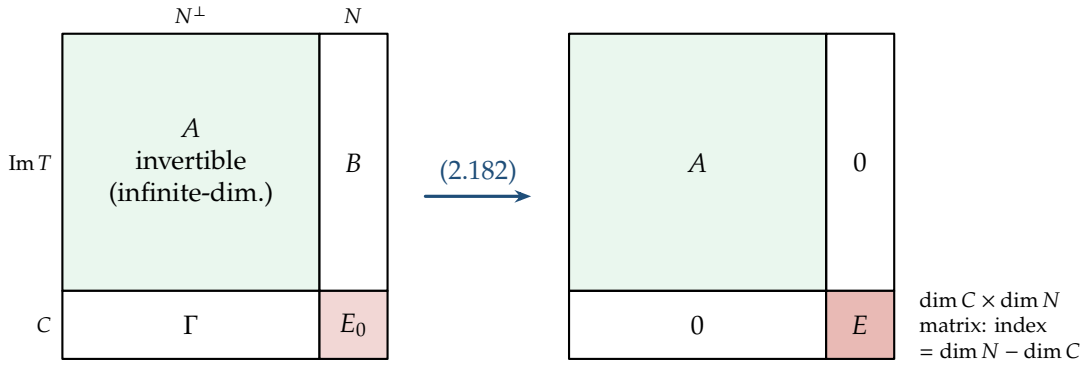

Figure 2.46: Why the index is stable. Split domain and target so that T is invertible on the big block. A small perturbation S keeps the big block A invertible. Row and column operations then push everything that can go wrong into the small red corner E, a finite matrix from the old kernel N to the old cokernel C. The kernel of S may shrink (if E has rank), but the index of E is $\dim N - \dim C$ by rank–nullity, whatever its entries.

Why (ii). For $t \in [0,1]$ consider $T_t = T + tK$. Each T_t is Fredholm, because a parametrix Q of T still works: $QT_t = I - K_2 + tQK$ and QK is compact (bounded after compact), and similarly on the other side; Atkinson applies. The function $t \mapsto \operatorname{index} T_t$ is locally constant by (i), since $\|T_t - T_{t'}\| = |t - t'|\,\|K\|$. A locally constant integer-valued function on the connected interval $[0,1]$ is constant:

$$\operatorname{index}(T+K) = \operatorname{index} T_1 \overset{(1)}{=} \operatorname{index} T_0 = \operatorname{index} T.$$

(1) Local constancy along the connected path $t \mapsto T_t$.

With $T = I$ this proves the claim made after Example 2.87: $I - K$ always has index 0, for every compact K. That is the full *Fredholm alternative*: for $u - Ku = f$, the number of independent solutions of the homogeneous equation equals the number of constraints on f.

Why (iii). If P_0 and P_1 have the same principal symbol, their difference has order $m-1$, so as a map $H^s \to H^{s-m}$ it factors as

$$P_1 - P_0 :\ H^s \xrightarrow{\text{bounded}} H^{s-m+1} \xrightarrow{\text{compact (Rellich)}} H^{s-m},$$

which is compact, and (ii) gives $\operatorname{index} P_1 = \operatorname{index} P_0$. *Lower-order terms never change the index.* If instead the principal symbols are joined by a continuous path σ_t of elliptic symbols, we can choose operators P_t with these symbols depending continuously on t in the norm of bounded maps $H^s \to H^{s-m}$; by (i) the index is constant along the path. So the index is a function of the *homotopy class* of the principal symbol: a topological quantity attached to an analytical object. Classifying these homotopy classes is what K-theory does, and computing the function is the Atiyah–Singer index theorem (Chapters 3 and 4).

Why (iv). For adjoints, $\operatorname{index} T^* = \dim\operatorname{Ker} T^* - \dim\operatorname{Ker} T = -\operatorname{index} T$, and if $T = T^*$ this forces $\operatorname{index} T = 0$. For products, one checks that the sequence

$$0 \to \operatorname{Ker} T_2 \to \operatorname{Ker} T_1T_2 \xrightarrow{T_2} \operatorname{Ker} T_1 \to \operatorname{Coker} T_2 \xrightarrow{T_1} \operatorname{Coker} T_1T_2 \to \operatorname{Coker} T_1 \to 0$$

(inclusion; apply T_2; take the class of v modulo $\operatorname{Im} T_2$; apply T_1; project) is exact, and the alternating sum of dimensions in a finite exact sequence is zero. Rearranged, that is $\operatorname{index} T_1T_2 = \operatorname{index} T_1 + \operatorname{index} T_2$. Check on shifts: $S^k(S^*)^k = I - \Pi_{<k}$ has index $0 = -k + k$.

Watch out: The number of zero modes is not stable; only the difference is

$\dim\operatorname{Ker} P$ by itself can jump under an arbitrarily small deformation (Example 2.84, and Example 2.90 below). What is protected is $\dim\operatorname{Ker} P - \dim\operatorname{Ker} P^*$. Zero modes can only be lifted *in pairs*, one of P together with one of P^*, exactly as the red corner E in Figure 2.46 can only gain rank by using up a direction of N and a direction of C at once. In a theory of chiral fermions, the index of the chiral Dirac operator is therefore a number of zero modes that no small perturbation (masses aside, which couple the two chiralities) can remove.

2.6.7 Worked operators on the circle

On S^1 we write $e_n = e^{in\theta}$, $D = -i\,\mathrm{d}/\mathrm{d}\theta$ (so $De_n = ne_n$) and $|D|\,e_n = |n|\,e_n$, as in Section 2.5.3. All operators below are Fredholm by Section 2.6.5; the point is to see their kernels, cokernels and indices with our own eyes.

Worked example 2.90: The twisted derivative: the kernel jumps, the index stays 0

Let $a \in \mathbb{R}$ and $D_a = D + a = -i\,\mathrm{d}/\mathrm{d}\theta + a : H^1(S^1) \to L^2(S^1)$. Physically this is the momentum of a charged particle on a ring threaded by a magnetic flux (Aharonov–Bohm), with a the flux in units of the flux quantum; mathematically it is the covariant derivative $-i(\mathrm{d}/\mathrm{d}\theta + ia)$ of a flat U(1) connection with holonomy $e^{-2\pi i a}$ around the circle.

- Spectrum: $D_a e_n = (n + a)e_n$. The eigenvalues are $n + a$, $n \in \mathbb{Z}$.
- Kernel: $n + a = 0$ has a solution iff $a \in \mathbb{Z}$. So $\dim \operatorname{Ker} D_a = 1$ for integer a, and 0 otherwise.
- Adjoint: $D_a^* = D_a$ (D is formally self-adjoint and a is real), so $\dim \operatorname{Coker} D_a = \dim \operatorname{Ker} D_a$.
- Index: 0 for every a, as (iv) demands.

The reduction (2.182) made explicit. At $a = 0$, $N = C = \{\text{constants}\}$. For small a, D_a maps the constants to the constants ($D_a 1 = a \cdot 1$) and non-constant modes to non-constant modes, so $B = \Gamma = 0$, $A = D_a$ on the non-constant modes (invertible, eigenvalues $n + a$ with $n \neq 0$), and the red corner is the 1×1 matrix $E = (a)$. Its kernel is everything when $a = 0$ and nothing otherwise, and its index is $1 - 1 = 0$ always.

A non-constant potential is a gauge transformation away. For a smooth real $a(\theta)$ let $\bar{a} = \frac{1}{2\pi}\int_0^{2\pi} a\,\mathrm{d}\theta$ and $\chi(\theta) = \int_0^\theta \big(a(\theta') - \bar{a}\big)\mathrm{d}\theta'$, which is periodic because $\chi(2\pi) = 2\pi\bar{a} - 2\pi\bar{a} = 0$. For any v,

$$\begin{aligned}\big(D + a\big)\big(e^{-i\chi}v\big) &\overset{(1)}{=} -i\big(-i\chi' e^{-i\chi}v + e^{-i\chi}v'\big) + a\,e^{-i\chi}v \\ &\overset{(2)}{=} e^{-i\chi}\big(-iv' + (a - \chi')v\big) \overset{(3)}{=} e^{-i\chi}\,(D + \bar{a})v.\end{aligned}$$

(1) Product rule for $-i\,\mathrm{d}/\mathrm{d}\theta$.
(2) Collect terms: $-i \cdot (-i) = -1$.
(3) $\chi' = a - \bar{a}$.

So $D + a(\theta) = e^{-i\chi}(D + \bar{a})e^{i\chi}$: conjugate to the constant case. The spectrum is $n + \bar{a}$, and a zero mode exists iff the holonomy $e^{-2\pi i\bar{a}}$ is 1. Only the gauge-invariant flux $\bar{a}$ matters, as it must.

Worked example 2.91: Every scalar elliptic differential operator on S^1 has index 0

Let $P = \sum_{j=0}^m a_j(\theta)D^j$ with $a_m(\theta) \neq 0$ everywhere (elliptic, since $\sigma_m = a_m(\theta)\xi^m$). Write

$$P = a_m\,(D^m + i) \;+\; \underbrace{\Big(\sum_{j<m} a_j D^j - i\,a_m\Big)}_{\text{order } \leq m-1}.$$

Then

$$\operatorname{index} P \overset{(1)}{=} \operatorname{index}\big(a_m(D^m + i)\big) \overset{(2)}{=} \operatorname{index}(a_m) + \operatorname{index}(D^m + i) \overset{(3)}{=} 0 + 0.$$

(1) Stability (iii): the underbraced lower-order part is compact $H^s \to H^{s-m}$.
(2) Product rule (iv), with a_m the multiplication operator $H^{s-m} \to H^{s-m}$.

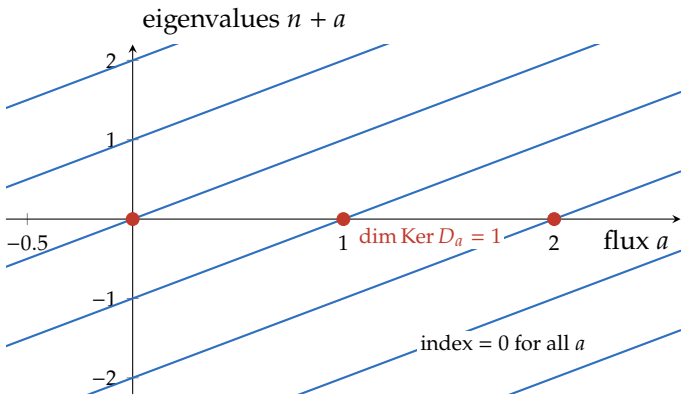

Figure 2.47: Spectral flow of the twisted derivative $D_a = -i\,\mathrm{d}/\mathrm{d}\theta + a$ on the circle. Each Fourier mode $e^{in\theta}$ gives a line $n + a$. As the flux a increases by one unit, every eigenvalue moves up by one: the spectrum returns to itself, but one eigenvalue has crossed zero from below (red dots mark the crossings, where a zero mode exists). The kernel jumps at each integer a; the index, $\dim\mathrm{Ker} - \dim\mathrm{Ker}^*$, is 0 throughout because D_a is self-adjoint. The net number of crossings per unit flux (here +1) is the *spectral flow*; in the second-quantised theory it is the charge pumped out of the Dirac sea (the intuition box after Figure 2.44).

(3) Multiplication by the nowhere-zero smooth function a_m is invertible (its inverse is multiplication by $1/a_m$), so its index is 0; and $D^m + i$ multiplies e_n by $n^m + i \neq 0$, so it is invertible too.

A concrete check. $P = D + e^{i\theta}$. Solve $Pu = 0$: $-iu' + e^{i\theta}u = 0$, i.e. $u' = -ie^{i\theta}u$, whose solution $u = \exp(-e^{i\theta})$ is periodic (note $\frac{\mathrm{d}}{\mathrm{d}\theta}(-e^{i\theta}) = -ie^{i\theta}$). So $\dim\mathrm{Ker}\,P = 1$. The formal adjoint is $P^* = D + e^{-i\theta}$, and $P^*v = 0$ gives $v = \exp(e^{-i\theta})$: $\dim\mathrm{Ker}\,P^* = 1$. Index $1 - 1 = 0$. (Both zero modes exist because $\int_0^{2\pi} e^{\pm i\theta}\mathrm{d}\theta = 0$: the complex "flux" $\bar{a}$ of the previous example is zero.) Nash proves the vanishing of the index of elliptic differential operators on *every* odd-dimensional manifold in Chapter 4, using the antipodal map $\xi \mapsto -\xi$. On the circle we have just seen the elementary version.

Worked example 2.92: A pseudo-differential operator with non-zero index

ΨDOs escape the last example. Let $\Pi_\pm$ be the projections onto the non-negative and the negative modes:

$$\Pi_+ e_n = \begin{cases} e_n, & n \geq 0 \\ 0, & n < 0 \end{cases}, \qquad \Pi_- = I - \Pi_+.$$

Π_+ is a Fourier multiplier whose symbol is 1 for large positive ξ and 0 for large negative ξ (smooth it arbitrarily near $\xi = 0$): a ΨDO of order 0 with principal symbol $\sigma_0(\Pi_+) = 1$ on $\xi > 0$ and 0 on $\xi < 0$. (It is the Szegő projection onto boundary values of holomorphic functions, and $\Pi_+ - \Pi_-$ is i times the Hilbert transform of Example 2.81, up to the $n = 0$ mode.) For $k \in \mathbb{Z}$ define the order-0 operator

$$T_k = e^{ik\theta}\,\Pi_+ + \Pi_-, \qquad \sigma_0(T_k)(\theta, \xi) = \begin{cases} e^{ik\theta}, & \xi > 0, \\ 1, & \xi < 0. \end{cases}$$

The principal symbol never vanishes, so T_k is elliptic. Its action on the basis is

$$T_k e_n = \begin{cases} e_{n+k}, & n \geq 0, \\ e_n, & n < 0. \end{cases}$$

For $k > 0$: distinct basis vectors go to distinct basis vectors, so $\operatorname{Ker} T_k = 0$. The image contains e_m for $m < 0$ and for $m \geq k$, and misses $e_0, \dots, e_{k-1}$. So $\dim \operatorname{Coker} T_k = k$ and $\operatorname{index} T_k = -k$. (On the non-negative modes T_k is the shift S^k of Section 2.6.3.)
For $k = -j < 0$: $T_{-j} e_n = e_{n-j}$ for $n \geq 0$, so the j vectors $e_0, \dots, e_{j-1}$ land on $e_{-j}, \dots, e_{-1}$, which are also the images of themselves under Π_-. Hence the j vectors $e_n - e_{n-j}$ $(0 \leq n < j)$ are killed, every basis vector is hit, and $\operatorname{index} T_{-j} = j - 0 = j$.
In both cases

$$\operatorname{index} T_k = -k = -\big(\text{winding number of } \sigma_0(T_k) \text{ on } \xi > 0\big) + \big(\text{winding number on } \xi < 0\big).$$

This is the **Toeplitz index theorem** in its simplest form, and a first glimpse of the Atiyah–Singer philosophy: the index is the topology (here, a winding number) of the principal symbol. For a *differential* operator the symbols on $\xi > 0$ and $\xi < 0$ are $a_m(\theta)\xi^m$ and $a_m(\theta)(-|\xi|)^m$: the same function up to a constant sign, with equal winding numbers, which cancel. That is the circle version of Nash's antipodal argument.
Nash's example (4.35). In Chapter 4 Nash exhibits the order-1 operator with symbol $e^{-i\theta}(\xi + |\xi|) + (\xi - |\xi|)$. In our notation it is

$$P_N = e^{-i\theta}(D + |D|) + (D - |D|) = T_{-1} \circ 2D,$$

because $D + |D| = 2D\Pi_+$ and $D - |D| = 2D\Pi_-$ (check on e_n: $n + |n|$ is $2n$ for $n \geq 0$ and 0 for $n < 0$). Directly: $P_N e_n = 2n e_{n-1}$ for $n \geq 0$ and $P_N e_n = 2n e_n$ for $n < 0$. So $\operatorname{Ker} P_N = \operatorname{span}(e_0)$, every e_m is hit, and $\operatorname{index} P_N = 1$, in agreement with $\operatorname{index} T_{-1} + \operatorname{index}(2D) = 1 + 0$.

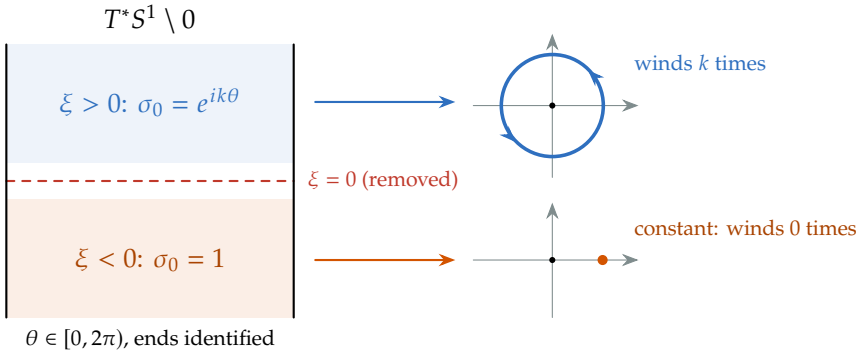

Figure 2.48: The principal symbol of $T_k = e^{ik\theta}\Pi_+ + \Pi_-$ lives on T^*S^1 with the zero section removed, which has two components, $\xi > 0$ and $\xi < 0$. On each component the symbol is a map from a circle to $\mathbb{C} \setminus \{0\}$, with a winding number: k on top, 0 below. The index is $-k$. A differential operator cannot do this: its symbols on the two halves are tied together by $\xi \mapsto -\xi$ and have equal winding numbers, so its index is 0.

2.6.8 Worked operators on the torus

Now $M = T^2 = \mathbb{R}^2/2\pi\mathbb{Z}^2$ with coordinates (x, y), flat metric, and Fourier modes $e_k = e^{i(k_1 x + k_2 y)}$, $k = (k_1, k_2) \in \mathbb{Z}^2$. Write $z = x + iy$ and

$$\partial = \tfrac{1}{2}(\partial_x - i\partial_y), \qquad \bar\partial = \tfrac{1}{2}(\partial_x + i\partial_y), \qquad \bar\partial e_k = \tfrac{i}{2}(k_1 + ik_2)\, e_k, \qquad \partial e_k = \tfrac{i}{2}(k_1 - ik_2)\, e_k.$$

Worked example 2.93: The Cauchy–Riemann operator on the torus

$\bar\partial : H^1(T^2) \to L^2(T^2)$ is elliptic (its symbol $\frac{i}{2}(\xi_1 + i\xi_2)$ vanishes only at $\xi = 0$; see the Cauchy–Riemann operator in the section *Ellipticity and hypo-ellipticity*).

- Kernel: $\frac{i}{2}(k_1 + ik_2) = 0$ iff $k = 0$. So $\operatorname{Ker}\bar\partial = \{\text{constants}\}$: a holomorphic function on a compact Riemann surface is constant (Liouville).
- Adjoint: $\partial_x^* = -\partial_x$ and $(i\partial_y)^* = (-i)(-\partial_y) = i\partial_y$, so $\bar\partial^* = \frac{1}{2}(-\partial_x + i\partial_y) = -\partial$. Its kernel is again the constants.
- Index: $1 - 1 = 0$.

This matches the Riemann–Roch formula index $\bar\partial = 1 - g$ for the trivial bundle on a surface of genus g (here $g = 1$), which we meet in Chapter 5.
Twisting. For a constant $c \in \mathbb{C}$ (a flat connection on the trivial line bundle), $\bar\partial + c$ multiplies e_k by $\frac{i}{2}(k_1 + ik_2) + c$, so it has a zero mode iff $c = -\frac{i}{2}(k_1 + ik_2) = \frac{1}{2}(k_2 - ik_1)$ for some $k \in \mathbb{Z}^2$, i.e. iff c lies on the lattice $\frac{1}{2}(\mathbb{Z} + i\mathbb{Z})$. Off the lattice there are no zero modes of either $\bar\partial + c$ or its adjoint; on it, one of each. The index is 0 throughout, as it must be since c is a compact (order $0 < 1$) perturbation.

Worked example 2.94: The Dirac operator on the torus, in explicit matrices

Use the Pauli matrices $\sigma_1 = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, $\sigma_2 = \left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right)$, which satisfy $\sigma_a\sigma_b + \sigma_b\sigma_a = 2\delta_{ab}$ (the Clifford relations of Chapter T4), and set $\not{D} = -i(\sigma_1\partial_x + \sigma_2\partial_y)$. Multiplying out,

$$\not{D} \overset{(1)}{=} -i\begin{pmatrix} 0 & \partial_x - i\partial_y \\ \partial_x + i\partial_y & 0 \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} 0 & -2i\,\partial \\ -2i\,\bar\partial & 0 \end{pmatrix}.$$

(1) $\sigma_1\partial_x + \sigma_2\partial_y$ has off-diagonal entries $\partial_x - i\partial_y$ (top right) and $\partial_x + i\partial_y$ (bottom left).
(2) The definitions of ∂ and $\bar\partial$.

So $\not{D}$ is off-diagonal in the chiral splitting $\psi = (\psi_+, \psi_-)$, with chiral part $\not{D}_+ = -2i\bar\partial : \psi_+ \mapsto$ lower component, and $\not{D}_- = -2i\partial = (\not{D}_+)^*$. Its square is

$$\not{D}^2 \overset{(1)}{=} -\sum_{a,b} \sigma_a\sigma_b\,\partial_a\partial_b \overset{(2)}{=} -\tfrac{1}{2}\sum_{a,b}(\sigma_a\sigma_b + \sigma_b\sigma_a)\partial_a\partial_b \overset{(3)}{=} -(\partial_x^2 + \partial_y^2)\,I,$$

(1) Expand $\left(-i\sum_a \sigma_a\partial_a\right)^2$; partial derivatives commute with constant matrices.
(2) $\partial_a\partial_b$ is symmetric, so only the symmetric part of $\sigma_a\sigma_b$ survives.
(3) Clifford relation.

so $\not{D}$ is elliptic (a square root of the Laplacian). With periodic boundary conditions for both spinor components (one of the four spin structures on T^2), the zero modes are the constant spinors: $\operatorname{Ker}\not{D}_+ = \mathbb{C}$, $\operatorname{Ker}\not{D}_- = \mathbb{C}$, and index $\not{D}_+ = 1 - 1 = 0$. With an antiperiodic direction the momenta are shifted to $\mathbb{Z} + \frac{1}{2}$, the symbol $\frac{i}{2}(k_1 + ik_2)$ never vanishes on the allowed k, and there are no zero modes at all. The index is 0 either way; the number of zero modes depends on the spin structure. A non-zero index on a surface needs curvature or a background gauge field with non-zero flux: that is the content of the index theorem, and of the anomaly in Chapter 10.

Worked example 2.95: The operator $\mathrm{d}+\mathrm{d}^*$ and the Euler characteristic

On a compact oriented M consider $\mathrm{d}+\mathrm{d}^*$ from even forms to odd forms,

$$\mathrm{d}+\mathrm{d}^*:\ \Omega^{\text{even}}(M)=\bigoplus\nolimits_p \Omega^{2p}\longrightarrow \Omega^{\text{odd}}(M)=\bigoplus\nolimits_p \Omega^{2p+1}.$$

Its square (on all forms) is $\mathrm{d}\mathrm{d}^*+\mathrm{d}^*\mathrm{d}=\Delta$, because $\mathrm{d}^2=0=(\mathrm{d}^*)^2$; so its principal symbol squares to $|\xi|^2\,I$ and it is elliptic.
Its zero modes are the harmonic forms. For a form ω (of mixed degree),

$$\begin{aligned}\|(\mathrm{d}+\mathrm{d}^*)\omega\|^2 &\overset{(1)}{=} \|\mathrm{d}\omega\|^2+\|\mathrm{d}^*\omega\|^2+2\,\mathrm{Re}\langle \mathrm{d}\omega,\mathrm{d}^*\omega\rangle \overset{(2)}{=} \|\mathrm{d}\omega\|^2+\|\mathrm{d}^*\omega\|^2+2\,\mathrm{Re}\langle \mathrm{d}\mathrm{d}\omega,\omega\rangle\\ &\overset{(3)}{=} \|\mathrm{d}\omega\|^2+\|\mathrm{d}^*\omega\|^2,\end{aligned}$$

(1) Expand the square of a sum.
(2) Move d^* back across the inner product as d.
(3) $\mathrm{d}^2=0$.

so $(\mathrm{d}+\mathrm{d}^*)\omega=0$ iff $\mathrm{d}\omega=\mathrm{d}^*\omega=0$ iff ω is harmonic, by (2.114). The adjoint is $\mathrm{d}+\mathrm{d}^*$ from odd to even forms, whose kernel is the odd harmonic forms. By Hodge's theorem (2.115):

$$\operatorname{index}\big(\mathrm{d}+\mathrm{d}^*\big)_{\text{even}\to\text{odd}} \overset{(1)}{=} \sum_p \dim\operatorname{Ker}\Delta_{2p}-\sum_p \dim\operatorname{Ker}\Delta_{2p+1} \overset{(2)}{=} \sum_q (-1)^q\, b_q \overset{(3)}{=} \chi(M). \tag{2.184}$$

(1) Kernel = even harmonic forms; cokernel = kernel of the adjoint = odd harmonic forms.
(2) Hodge: $\dim\operatorname{Ker}\Delta_q=b_q$.
(3) The alternating sum of Betti numbers is the Euler characteristic.

On T^2, explicitly. An even form is $(f,h)\leftrightarrow f+h\,\mathrm{d}x\wedge\mathrm{d}y$ and an odd form is $(a,b)\leftrightarrow a\,\mathrm{d}x+b\,\mathrm{d}y$. Using $\mathrm{d}^*=-\star\,\mathrm{d}\star$ on 2-forms in two dimensions, $\star(\mathrm{d}x\wedge\mathrm{d}y)=1$, $\star\mathrm{d}x=\mathrm{d}y$, $\star\mathrm{d}y=-\mathrm{d}x$:

$$\mathrm{d}^*(h\,\mathrm{d}x\wedge\mathrm{d}y)\overset{(1)}{=}-\star\,\mathrm{d}h\overset{(2)}{=}-\star\,(h_x\,\mathrm{d}x+h_y\,\mathrm{d}y)\overset{(3)}{=}h_y\,\mathrm{d}x-h_x\,\mathrm{d}y,$$

(1) $\star(h\,\mathrm{d}x\wedge\mathrm{d}y)=h$.
(2) Exterior derivative of a function.
(3) $\star\mathrm{d}x=\mathrm{d}y$ and $\star\mathrm{d}y=-\mathrm{d}x$.

so, as a matrix of operators acting on the column $(f,h)^T$,

$$\mathrm{d}+\mathrm{d}^*=\begin{pmatrix}\partial_x & \partial_y\\ \partial_y & -\partial_x\end{pmatrix},\qquad \sigma_1(\mathrm{d}+\mathrm{d}^*)(\xi)=i\begin{pmatrix}\xi_1 & \xi_2\\ \xi_2 & -\xi_1\end{pmatrix},\qquad \det\begin{pmatrix}\xi_1 & \xi_2\\ \xi_2 & -\xi_1\end{pmatrix}=-|\xi|^2.$$

On the mode e_k the operator is i times the same matrix with $\xi=k$, invertible for $k\neq 0$. So the kernel is $k=0$: the constants (f,h), dimension $2=b_0+b_2$. The cokernel is the constant 1-forms $a\,\mathrm{d}x+b\,\mathrm{d}y$, dimension $2=b_1$. Index $0=\chi(T^2)$. On the sphere S^2 the same operator has index $b_0-b_1+b_2=2$; on a surface of genus g, $2-2g$. By Gauss–Bonnet (Chapter T2) this equals $\frac{1}{2\pi}\int_M K\,\mathrm{d}A$: an analytical count of zero modes equals an integral of curvature. That sentence, for every elliptic operator, is the index theorem of Chapter 4.

Try it: Index of a matrix-valued operator on the circle

On S^1 let $P = \left(\begin{smallmatrix} D & 0 \\ 0 & D+\frac{1}{2} \end{smallmatrix}\right)$ acting on pairs of functions. What are $\dim\operatorname{Ker} P$, $\dim\operatorname{Ker} P^*$ and index P? What happens if you add the off-diagonal term $\left(\begin{smallmatrix} 0 & \varepsilon \\ \varepsilon & 0 \end{smallmatrix}\right)$?
Answer. D has the constants as kernel; $D+\frac{1}{2}$ has none (eigenvalues $n+\frac{1}{2}$). P is self-adjoint, so $\dim\operatorname{Ker} P = \dim\operatorname{Ker} P^* = 1$ and index $P = 0$. The perturbation is order 0, so the index stays 0. On the constants the 2×2 block becomes $\left(\begin{smallmatrix} 0 & \varepsilon \\ \varepsilon & \frac{1}{2} \end{smallmatrix}\right)$, with determinant $-\varepsilon^2 \neq 0$ for $\varepsilon \neq 0$, and on the mode e_n it is $\left(\begin{smallmatrix} n & \varepsilon \\ \varepsilon & n+\frac{1}{2} \end{smallmatrix}\right)$, with determinant $n^2 + \frac{n}{2} - \varepsilon^2$, which for small $\varepsilon \neq 0$ vanishes for no integer n. So the zero mode is lifted, together with the zero mode of P^* (it is the same one): a pair, as the pitfall in Section 2.6.6 says.

2.6.9 Counting zero modes with the heat kernel

The index can be computed without solving $Pu = 0$. The idea is that the non-zero modes of P^*P and PP^* come in pairs, and cancel in a suitable difference of traces.

Pairing. Suppose $P^*Pu = \lambda u$ with $\lambda \neq 0$. Then

$$PP^*(Pu) = P(P^*Pu) \overset{(1)}{=} \lambda\, Pu, \qquad \|Pu\|^2 \overset{(2)}{=} \langle u, P^*Pu\rangle = \lambda\,\|u\|^2 \neq 0. \tag{2.185}$$

(1) u is an eigenvector of P^*P.
(2) Definition of the adjoint.

So Pu is a non-zero eigenvector of PP^* with the same eigenvalue, and $P/\sqrt{\lambda}$ maps the λ-eigenspace of P^*P isometrically onto the λ-eigenspace of PP^* (the inverse is $P^*/\sqrt{\lambda}$). At $\lambda = 0$ the pairing fails: $\operatorname{Ker} P^*P = \operatorname{Ker} P$ (since $\langle u, P^*Pu\rangle = \|Pu\|^2$) and $\operatorname{Ker} PP^* = \operatorname{Ker} P^*$, and these have different dimensions in general.

Key idea: McKean–Singer formula

For an elliptic P on a compact manifold and every $t > 0$,

$$\operatorname{index} P = \operatorname{Tr} e^{-tP^*P} - \operatorname{Tr} e^{-tPP^*}. \tag{2.186}$$

Why. P^*P and PP^* are elliptic, self-adjoint and non-negative, so (by the argument of Example 2.80) they have discrete spectra $\lambda_j \to \infty$ with finite multiplicities; e^{-tP^*P} is a smoothing operator, and its trace $\sum_j e^{-t\lambda_j}$ converges (Weyl's law makes λ_j grow like a power of j). Then

$$\begin{aligned}\operatorname{Tr} e^{-tP^*P} - \operatorname{Tr} e^{-tPP^*} &\overset{(1)}{=} \sum_{\lambda} \big(m_{P^*P}(\lambda) - m_{PP^*}(\lambda)\big) e^{-t\lambda} \overset{(2)}{=} m_{P^*P}(0) - m_{PP^*}(0) \\ &\overset{(3)}{=} \dim\operatorname{Ker} P - \dim\operatorname{Ker} P^*,\end{aligned}$$

(1) Sum over distinct eigenvalues with multiplicities $m(\lambda)$.
(2) The pairing (2.185): multiplicities agree for $\lambda \neq 0$.
(3) $\operatorname{Ker} P^*P = \operatorname{Ker} P$ and $\operatorname{Ker} PP^* = \operatorname{Ker} P^*$.

The left side of (2.186) looks t-dependent, but is not. As $t \to \infty$ it reduces to the zero modes (the definition of the index). As $t \to 0$ the heat kernels become local, and their diagonal values have an expansion in the curvature at each point: the index becomes an integral of a local density. That is the heat-kernel proof of the index theorem (Chapter 4), and the Fujikawa computation

of anomalies (Chapter 10). The smoothing property of the heat operator, which in this chapter we met as Nash's Gaussian example, is what makes it work.

Worked example 2.96: Supersymmetric harmonic oscillator: index 1

Take $P = \frac{\mathrm{d}}{\mathrm{d}x} + x$ on $L^2(\mathbb{R})$. (This is on $\mathbb{R}$, but the potential x^2 confines, the resolvent is compact, and all the above goes through.) Its adjoint is $P^* = -\frac{\mathrm{d}}{\mathrm{d}x} + x$, and

$$P^*Pu \overset{(1)}{=} \Big(-\frac{\mathrm{d}}{\mathrm{d}x} + x\Big)(u' + xu) \overset{(2)}{=} -u'' - u - xu' + xu' + x^2u = \Big(-\frac{\mathrm{d}^2}{\mathrm{d}x^2} + x^2 - 1\Big)u,$$
$$PP^*u \overset{(3)}{=} \Big(\frac{\mathrm{d}}{\mathrm{d}x} + x\Big)(-u' + xu) \overset{(4)}{=} -u'' + u + xu' - xu' + x^2u = \Big(-\frac{\mathrm{d}^2}{\mathrm{d}x^2} + x^2 + 1\Big)u.$$

(1) Apply P, then P^*.
(2) Product rule: $(xu)' = u + xu'$.
(3) Apply P^*, then P.
(4) Product rule again, now with the opposite sign.

With $H = -\frac{\mathrm{d}^2}{\mathrm{d}x^2} + x^2$ (eigenvalues $2n+1$, $n \geq 0$), $P^*P = H - 1$ has eigenvalues $0, 2, 4, \ldots$ and $PP^* = H + 1$ has eigenvalues $2, 4, 6, \ldots$. The zero modes: $Pu = 0$ gives $u' = -xu$, $u = e^{-x^2/2} \in L^2$; $P^*v = 0$ gives $v = e^{x^2/2} \notin L^2$. So index $P = 1 - 0 = 1$, and

$$\operatorname{Tr} e^{-tP^*P} - \operatorname{Tr} e^{-tPP^*} \overset{(1)}{=} \sum_{n\geq 0} e^{-2nt} - \sum_{n\geq 0} e^{-2(n+1)t} \overset{(2)}{=} 1,$$

(1) The two spectra.
(2) The second sum is the first sum minus its $n = 0$ term; both are geometric series.

independent of t, as promised. In the language of supersymmetric quantum mechanics (Chapter 7): P^*P and PP^* are the bosonic and fermionic Hamiltonians, P is the supercharge that pairs their excited states, and the index is the **Witten index** $\operatorname{Tr}(-1)^F e^{-tH}$, which counts supersymmetric ground states.

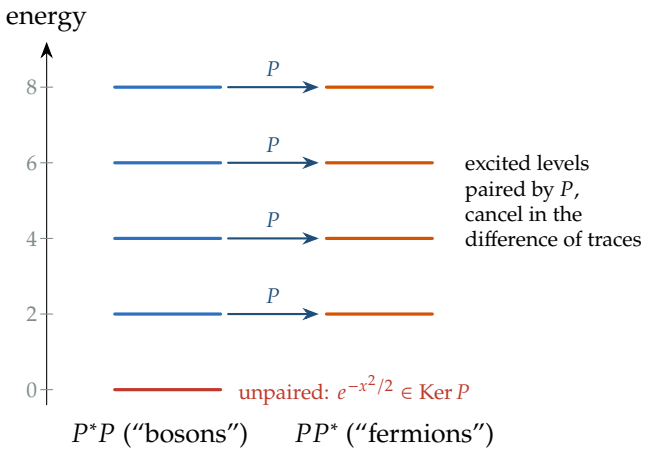

Figure 2.49: The McKean–Singer mechanism for the supersymmetric oscillator $P = \mathrm{d}/\mathrm{d}x + x$. Every excited level of P^*P is carried by P onto a level of PP^* with the same energy, so these cancel in $\operatorname{Tr} e^{-tP^*P} - \operatorname{Tr} e^{-tPP^*}$ for every t. Only the zero mode of P (red) is left unpaired; PP^* has none. The difference of traces is the index, 1.

2.6.10 Looking ahead: the space of Fredholm operators

Let $\mathcal{F}(H)$ be the set of all Fredholm operators on a Hilbert space H. Stability (i) says that the index is constant on each connected component of $\mathcal{F}(H)$; the shifts S^k and $(S^*)^k$ show that every integer occurs. In fact two Fredholm operators can be joined by a path in $\mathcal{F}(H)$ exactly when they have the same index, so

$$\text{index} : \ \pi_0\big(\mathcal{F}(H)\big) \xrightarrow{\cong} \mathbb{Z}.$$

Nash takes this one step further at the end of Chapter 3: for a family of Fredholm operators parametrised by a compact space X, the "index" is no longer an integer but an element of the K-theory group $K(X)$, and $[X, \mathcal{F}] \cong K(X)$. For X a point this is the statement above. Families of Dirac operators parametrised by gauge fields are exactly such families, and their K-theoretic index is how global anomalies are detected (Chapter 10).

Dictionary: Fredholm theory and physics

Mathematics	Physics
$\operatorname{Ker} P$, finite-dimensional	normalisable zero modes (harmonic forms, fermion zero modes)
$\operatorname{Ker} P^*$ and (2.179)	constraints on sources: Gauss's law on a closed space
$\operatorname{index} P = \dim \operatorname{Ker} P - \dim \operatorname{Ker} P^*$	net number of chiral zero modes; Witten index
stability of the index	zero modes are lifted only in pairs; "protected" zero modes
compact perturbation	adding lower-order terms, masses in P^*P, smooth potentials
parametrix	propagator up to smooth (non-singular) corrections
spectral flow of a self-adjoint family	charge pumped from the Dirac sea
McKean–Singer (2.186)	$\operatorname{Tr}(-1)^F e^{-tH}$; Fujikawa's regularised Jacobian
$\pi_0(\mathcal{F}) = \mathbb{Z}$, $[X, \mathcal{F}] = K(X)$	topological classes of families; global anomalies

Reading Nash (pp. 54–55, (2.94)–(2.97))

Nash's final page and a half is dense. Here is the map. "If P is an elliptic mth order differential operator on a compact manifold then P has a finite dimensional kernel": our Section 2.6.5, via the parametrix, Rellich (Section 2.5.8) and part (a) of Atkinson's theorem in Section 2.6.4; it holds for ΨDOs as well. "P elliptic implies P^* elliptic": the adjoint-symbol computation in Section 2.6.5. "Bounded linear operators between Hilbert spaces with this property are called Fredholm operators": our working definition in Section 2.6.2, with the remark that the cokernel is $\operatorname{Ker} P^*$ only once the range is known to be closed. The boundedness discussion (2.94)–(2.96) is Example 2.82. "Fredholm operators ... are invertible modulo a compact operator" is Atkinson's theorem (2.177), and "the Sobolev space version of ... invertible modulo a smoothing operator" is (2.180). The parametrix (2.97) is (2.177), with the identities corrected (pitfall in Section 2.6.4). Nash never writes down the index in this chapter; he postpones it to his Chapter 4 (our Chapter 4) and, for Fredholm families, to the end of his Chapter 3. We have introduced it here, with its stability, because it is the reason for the whole chapter.

Recap: Elliptic operators are Fredholm

- For a matrix, $\dim\mathrm{Ker} - \dim\mathrm{Coker} = n - m$ regardless of the entries. A Fredholm operator is one where both are finite; its index $\dim\mathrm{Ker}\,T - \dim\mathrm{Ker}\,T^*$ is the infinite-dimensional replacement for $n - m$, and can be any integer (shifts).
- Atkinson: Fredholm $\iff$ invertible modulo compact operators. Compact kernels act as the identity only on finite-dimensional spaces; that is where finiteness comes from.
- On a compact manifold, an elliptic ΨDO of order m is Fredholm $H^s \to H^{s-m}$: parametrix errors are smoothing, smoothing is compact by Rellich. Kernel and cokernel $\mathrm{Ker}\,P^*$ are smooth and independent of s; $Pu = f$ is solvable iff $f \perp \mathrm{Ker}\,P^*$ (Gauss's law).
- The index is locally constant, unchanged by compact (in particular lower-order) perturbations, and depends only on the homotopy class of the principal symbol. The proof reduces everything to a finite matrix. Self-adjoint operators have index 0.
- Examples: $D + a$ on S^1 (kernel jumps, index 0; spectral flow), scalar differential operators on S^1 (index 0), Toeplitz operators (index = − winding number), $\bar\partial$ and $\not{D}$ on T^2 (index 0), $\mathrm{d} + \mathrm{d}^*$ (index $\chi(M)$), the SUSY oscillator (index 1).
- McKean–Singer: $\mathrm{index}\,P = \mathrm{Tr}\,e^{-tP^*P} - \mathrm{Tr}\,e^{-tPP^*}$ for all t, because non-zero modes pair up. This is the bridge to the heat-kernel proof of the index theorem and to anomalies.

Chapter summary

This chapter asked one question: *which differential operators behave like the Laplacian?* "Behave like the Laplacian" turned out to mean three things. Smooth sources give smooth solutions (regularity). On a compact space there are only finitely many zero modes, and only finitely many obstructions to solving $Pu = f$ (finiteness). And the difference of those two numbers does not change when we deform the operator (stability). The answer was a single algebraic test on a single matrix of polynomials: the operator is *elliptic* when its principal symbol $\sigma_m(x,\xi)$ is invertible for every $\xi \neq 0$.

The story, in eight sentences:

1. The Fourier transform turns $-i\partial_j$ into multiplication by the momentum ξ_j, so a differential operator becomes a polynomial $\sigma(x,\xi)$, its *symbol*.
2. Its top-degree part $\sigma_m(x,\xi)$ controls the high-momentum (short-distance) behaviour. When it never vanishes for $\xi \neq 0$ (elliptic), the operator can be inverted at high momentum; when it vanishes on a cone (hyperbolic), singularities travel along that cone.
3. Nothing changes for systems of equations, i.e. operators between vector bundles: σ_m becomes a matrix, and ellipticity means that the matrix is invertible.
4. The Hodge Laplacian has $\sigma_2 = |\xi|^2\, I$, so it is elliptic. Hodge's theorem follows: its zero modes on p-forms count the p-dimensional holes, $\dim\mathrm{Ker}\,\Delta_p = b_p$.
5. To invert an elliptic operator we have to allow symbols that are not polynomials, such as $1/|\xi|^2$ and $\sqrt{|\xi|^2 + m^2}$: these give the pseudo-differential operators, with a calculus in which principal symbols multiply.

6. The inverse of the principal symbol quantises to a *parametrix* Q, an inverse up to smoothing errors: $PQ = I - R_1$, $QP = I - R_2$.
7. Sobolev spaces H^s count derivatives in L^2 with the weight $(1 + |\xi|^2)^s$. On them ΨDOs of order m are bounded maps $H^s \to H^{s-m}$, and on a compact manifold smoothing operators are compact (Rellich).
8. Invertible modulo compact operators means Fredholm (Atkinson). So an elliptic operator on a compact manifold has a finite index $\dim \operatorname{Ker} P - \dim \operatorname{Ker} P^*$, which depends only on the homotopy class of its principal symbol. Computing that integer from the symbol and the topology is the index theorem of Chapter 4.

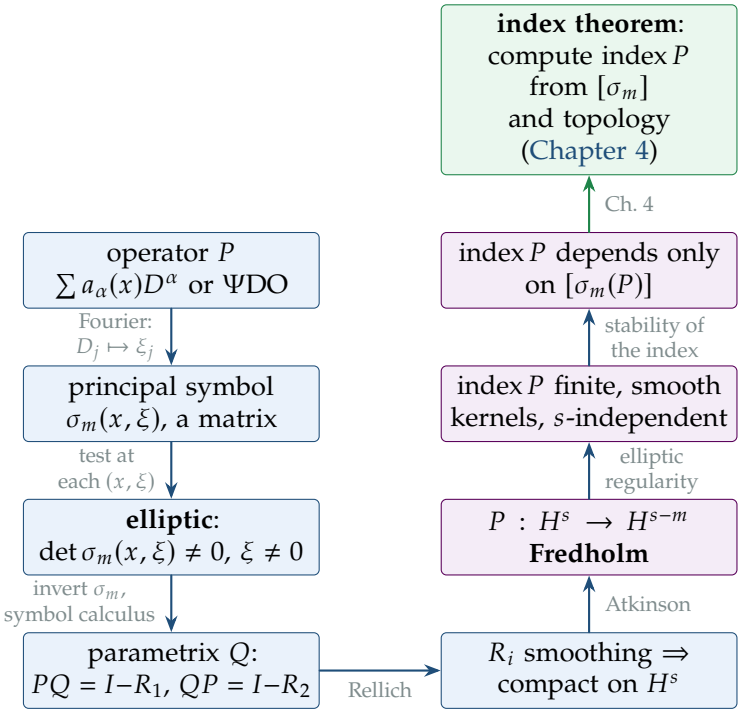

Figure 2.50: The logical spine of the chapter: from a polynomial to an integer. Down the left column we stay in *symbol space*: plane waves, polynomials in ξ, and inverting a matrix at each point of T^*M. At the bottom we cross into *function space*: the smoothing error of the parametrix is compact on Sobolev spaces (Rellich), and Atkinson's theorem turns "invertible modulo compact" into "Fredholm". Up the right column come the consequences. Each arrow is one tool of the chapter, named in grey.

One operator through every lens: the Laplacian on the circle

Almost every idea of the chapter can be seen, with every number explicit, on the simplest elliptic operator of all: $\Delta = -\mathrm{d}^2/\mathrm{d}\theta^2 = D_\theta^2$ on $S^1 = \mathbb{R}/2\pi\mathbb{Z}$, acting on $u = \sum_n c_n e^{in\theta}$ by $c_n \mapsto n^2 c_n$. Table 2.2 collects the facts. Three of the entries are worth deriving once more, because together they show the whole mechanism at work.

The Green's function, by solving an ODE. We want G with $\Delta_\theta G(\theta - \varphi) = \delta(\theta - \varphi) - \frac{1}{2\pi}$. The constant $\frac{1}{2\pi}$ has to be subtracted: by the solvability condition, $\Delta u = f$ needs $\int f = 0$, and

Concept	For $\Delta = D_\theta^2$ on S^1
symbol, principal symbol	$\sigma(\theta,\xi) = \xi^2 = \sigma_2(\theta,\xi)$: no lower-order terms
ellipticity	$\xi^2 \neq 0$ for $\xi \neq 0$; characteristic set empty
harmonic functions, Hodge	$\operatorname{Ker}\Delta = \{\text{constants}\}$, $\dim = 1 = b_0(S^1)$; on 1-forms, $\operatorname{Ker}\Delta_1 = \{c\,\mathrm{d}\theta\}$, $b_1 = 1$
Green's operator, kernel	$G(x) = \frac{\pi}{6} - \frac{x}{2} + \frac{x^2}{4\pi}$ on $[0,2\pi]$, $x = \theta - \varphi$: smooth off the diagonal, a kink on it (pseudo-locality)
parametrix	$Q = \sum_{n\neq 0} n^{-2}\,\Pi_n$; $Q\Delta = \Delta Q = I - \Pi_0$ with $\Pi_0 u = \frac{1}{2\pi}\int u$: smoothing, rank 1
Sobolev norm	$\|u\|_s^2 = 2\pi\sum_n (1+n^2)^s\,\lvert c_n\rvert^2$; $G \in H^s$ iff $s < \frac{3}{2}$
boundedness (Nash (2.95)–(2.96))	$\Delta : H^s \to H^{s-2}$ has norm exactly 1
Sobolev embedding	$H^s(S^1) \subset C^0$ for $s > \frac{1}{2}$; so G is continuous but G' jumps
Rellich	$H^s \hookrightarrow H^t$ $(s > t)$ is diagonal with entries $(1+n^2)^{(t-s)/2} \to 0$: compact
Fredholm, index	$\operatorname{Ker}\Delta = \operatorname{Ker}\Delta^* = \text{constants}$; $\operatorname{index}\Delta = 1 - 1 = 0$
solvability (Gauss's law)	$\Delta u = f$ solvable iff $\int_0^{2\pi} f\,\mathrm{d}\theta = 0$
spectrum, Weyl law	eigenvalues n^2 (multiplicity 2 for $n \neq 0$); $N(\lambda) = \#\{n^2 \leq \lambda\} \approx 2\sqrt{\lambda}$
heat trace	$\operatorname{Tr} e^{-t\Delta} = \sum_n e^{-tn^2} = \sqrt{\pi/t}\,\sum_k e^{-\pi^2k^2/t} \approx \sqrt{\pi/t}$ as $t \to 0$
complex powers, ζ, det	$\zeta_\Delta(s) = 2\zeta_R(2s)$, $\zeta_\Delta(0) = -1$, $\det'\Delta = (2\pi)^2$ (Section 2.4.14)

Table 2.2: The Laplacian on the circle as a one-page model of Chapter 2. Read down the right column: every row is a concept of the chapter reduced to a statement about the numbers n^2.

$\int \delta = 1$. Put $x = \theta - \varphi \in (0, 2\pi)$. Away from $x = 0$ the equation is $-G'' = -\frac{1}{2\pi}$, so

$$G(x) \overset{(1)}{=} \frac{x^2}{4\pi} + bx + c, \qquad G(2\pi) - G(0) \overset{(2)}{=} \pi + 2\pi b = 0 \;\Rightarrow\; b = -\tfrac{1}{2},$$

$$G'(0^+) - G'(2\pi^-) \overset{(3)}{=} b - (1 + b) = -1, \qquad \int_0^{2\pi} G \,\mathrm{d}x \overset{(4)}{=} \frac{2\pi^2}{3} - \pi^2 + 2\pi c = 0 \;\Rightarrow\; c = \frac{\pi}{6}.$$

(1) Integrate $G'' = \frac{1}{2\pi}$ twice; b, c are constants of integration.
(2) G must be continuous around the circle (periodic).
(3) The derivative jumps by -1 across $x = 0$, so $-G''$ contains $+\delta(x)$: this is automatic once b is fixed.
(4) We choose G orthogonal to the zero mode (the constants), which fixes c: $\int_0^{2\pi} \frac{x^2}{4\pi} = \frac{2\pi^2}{3}$ and $\int_0^{2\pi} bx = 2\pi^2 b = -\pi^2$.

So $G(x) = \frac{\pi}{6} - \frac{x}{2} + \frac{x^2}{4\pi}$. Its Fourier coefficients are $\frac{1}{2\pi n^2}$ for $n \neq 0$ and 0 for $n = 0$, the symbol $1/\xi^2$ sampled at the integers. The operator Q with this kernel is an integral operator of order -2. Its kernel is a polynomial away from the diagonal and has a kink on the diagonal, which is pseudo-locality (Section 2.4.15) in its simplest form.

The parametrix identity. For $u = \sum c_n e^{in\theta}$,

$$Q\Delta u \overset{(1)}{=} Q \sum_n n^2 c_n e^{in\theta} \overset{(2)}{=} \sum_{n\neq 0} \frac{n^2}{n^2}\, c_n e^{in\theta} \overset{(3)}{=} u - c_0 \overset{(4)}{=} \Big(I - \Pi_0\Big)u, \qquad \Pi_0 u = \frac{1}{2\pi}\int_0^{2\pi} u \,\mathrm{d}\theta.$$

(1) Δ multiplies the n-th coefficient by n^2.
(2) Q divides the n-th coefficient by n^2 for $n \neq 0$, and kills $n = 0$.
(3) Add and subtract the $n = 0$ term.
(4) c_0 is the mean of u.

The error Π_0 has the smooth kernel $\frac{1}{2\pi}$ and rank one. It is compact, so Δ is Fredholm by Atkinson's theorem (2.177). Its range is the image of $I - \Pi_0$, the functions of mean zero, which is the Gauss-law condition in Table 2.2.

The norm, Nash's (2.95)–(2.96).

$$\|\Delta u\|_{s-2}^2 \overset{(1)}{=} 2\pi \sum_n (1 + n^2)^{s-2}\, n^4\, |c_n|^2 \overset{(2)}{\leq} 2\pi \sum_n (1 + n^2)^s\, |c_n|^2 = \|u\|_s^2 ,$$

(1) Definition of the H^{s-2} norm, applied to the coefficients $n^2 c_n$ of Δu.
(2) $n^4 \leq (1 + n^2)^2$.

The ratio $n^4/(1 + n^2)^2$ tends to 1 as $n \to \infty$, so no constant smaller than 1 works: the norm is exactly 1 (Section 2.5.9). The operator loses exactly two derivatives, no more and no less, at every rung of the Sobolev ladder.

Every concept of the chapter

The tables below list every concept introduced in Chapter 2, one table per section of Nash. The middle column is the *operational* meaning: how to compute it or test for it. The last column says where the concept is used later in the book.

Nash §1, The meaning of ellipticity (Nash pp. 27–32)

Concept	Operational meaning	Used later
Fourier transform	$\partial_j \mapsto i\xi_j$: derivatives become multiplication by momentum; $\hat{u}(\xi) = \int e^{-ix\cdot\xi} u \, \mathrm{d}^n x$	everywhere: symbols, Sobolev norms, heat kernels
symbol	act on a plane wave $e^{ix\cdot\xi}$ and divide by it: $\sigma(x,\xi) = e^{-ix\cdot\xi} L e^{ix\cdot\xi}$	index theorem (Chapter 4)
elliptic (2nd order)	the quadratic form $a^{ij}\xi_i\xi_j$ is definite; its level sets are ellipsoids	Laplacians, $\not{D}^2$, Yang–Mills (Chapter 8)
hyperbolic, parabolic	form of Lorentzian signature / degenerate form plus a first-order term	wave and heat equations; heat kernel (Chapter 4)
elliptic regularity	Lu smooth $\Rightarrow u$ smooth; test: $\sigma_m \neq 0$ off $\xi = 0$	zero modes and harmonic forms are smooth
Green's function	$LG = \delta$; Δ on $\mathbb{R}^3$: $G = 1/(4\pi r)$; the propagator	parametrices; propagators in QFT
characteristic covector	$\sigma_m(x,\xi) = 0$ with $\xi \neq 0$: a direction singularities can travel along	light cones; elliptic = no characteristics
propagation of singularities	kinks move along light rays (Huygens) for hyperbolic L	contrast with pseudo-locality
Wick rotation	$t \mapsto -i\tau$ turns $\partial_t^2 - \nabla^2$ into $-\partial_\tau^2 - \nabla^2 = \Delta$	Euclidean QFT, instantons (Chapter 8), anomalies (Chapter 10)

Nash §2, Ellipticity and hypo-ellipticity (Nash pp. 32–36)

Concept	Operational meaning	Used later
multi-index	$\alpha = (\alpha_1, \dots, \alpha_n)$, $\lvert\alpha\rvert = \sum \alpha_j$, $\xi^\alpha = \prod \xi_j^{\alpha_j}$, $D^\alpha = \prod D_j^{\alpha_j}$	all symbol formulas
leading symbol σ_m	keep the terms of top degree m in ξ; homogeneous: $\sigma_m(x, \lambda\xi) = \lambda^m \sigma_m(x, \xi)$	symbol class in K-theory (Chapter 3, Chapter 4)
ellipticity (general)	$\sigma_m(x, \xi) \neq 0$ for all x and all $\xi \neq 0$	every index computation
σ_m on T^*M	ξ transforms as a covector under changes of coordinates, so σ_m is a function on T^*M	the index as a function of $[\sigma_m]$
hypo-ellipticity	$\operatorname{sing\,supp} Lu = \operatorname{sing\,supp} u$: L creates no smoothness and destroys none	heat-kernel methods
heat operator	$\partial_t - \nabla^2$: hypo-elliptic but not elliptic; the heat kernel is smooth for $t > 0$	McKean–Singer, heat-kernel proof (Chapter 4)
Schrödinger operator	$i\partial_t + \nabla^2$: not hypo-elliptic; singularities persist	real-time vs Euclidean QFT
Cauchy–Riemann $\bar\partial$	$\bar\partial = \frac{1}{2}(\partial_x + i\partial_y)$, $\sigma = \frac{i}{2}(\xi_1 + i\xi_2) \neq 0$: elliptic	Riemann surfaces (Chapter 5), CFT (Chapter 11)
analytic hypo-ellipticity	analytic data give analytic solutions (holomorphic functions)	holomorphic sections
elliptic ODE	order-m ODE with nowhere-zero leading coefficient	supersymmetric QM (Chapter 7)

Nash §3, Ellipticity and vector bundles (Nash pp. 36–41)

Concept	Operational meaning	Used later
vector bundle, section	a field with internal indices, glued by transition matrices $g_{\alpha\beta}(x)$	gauge fields (Chapter T3), every chapter
operator between bundles	a matrix of differential operators in each trivialisation	Dirac, $\mathrm{d}+\mathrm{d}^*$, $\bar\partial$, twisted operators
matrix symbol	replace D_j by ξ_j entrywise; the leading part is an $r\times s$ matrix	index theorem (Chapter 4)
pullback bundle π^*U	over each point (x,ξ) of T^*M, put the fibre U_x	the symbol class in $K(TM)$ (Chapter 3)
elliptic (bundles)	$\sigma_m(x,\xi): U_x \to V_x$ invertible for $\xi\neq 0$; needs $\operatorname{rank} U = \operatorname{rank} V$	every index problem
Hodge star, d^*	$\star$ from the metric; $\mathrm{d}^* = \pm\star\,\mathrm{d}\star$, the L^2 adjoint of d	Maxwell, Yang–Mills, gauge fixing
Hodge Laplacian	$\Delta_p = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$; $\sigma_2(\Delta_p) = \lvert\xi\rvert^2 I$	Hodge theorem; heat kernel
symbols of d, d^*	$\sigma(\mathrm{d}) = i\xi\wedge$, $\sigma(\mathrm{d}^*) = -i\,\iota_\xi$; composition multiplies leading symbols	de Rham, Dolbeault, signature complexes (Chapter 4)
elliptic complex	$\cdots\to\Gamma(E_i)\xrightarrow{P_i}\Gamma(E_{i+1})\to\ldots$, $P_{i+1}P_i=0$, symbol sequence exact off $\xi=0$	Dolbeault (Chapter 3), instanton deformations (Chapter 8)
harmonic form	$\Delta\omega=0 \iff \mathrm{d}\omega=0=\mathrm{d}^*\omega$ (on compact M)	zero modes; Chern–Simons, TQFT (Chapter 12)
Hodge theorem	one harmonic form per de Rham class: $\dim\operatorname{Ker}\Delta_p = b_p$	Euler characteristic and signature as indices
Hodge decomposition	$\Omega^p = \mathcal{H}^p \oplus \operatorname{Im}\mathrm{d}\oplus\operatorname{Im}\mathrm{d}^*$	gauge fixing, BRST
twisting	replace d by d_A with a connection; leading symbol unchanged	Yang–Mills, instanton moduli (Chapter 8)

Nash §4, Pseudo-differential operators (Nash pp. 41–47)

Concept	Operational meaning	Used later
operator with symbol	$Pu(x) = \int e^{ix\cdot\xi}\sigma(x,\xi)\hat{u}(\xi)\,\frac{\mathrm{d}^n\xi}{(2\pi)^n}$ (Section 2.4.3); Nash's (2.54)	inverses, square roots, propagators
Schwartz kernel	$K(x,y) = \int e^{i(x-y)\cdot\xi}\sigma(x,\xi)\frac{\mathrm{d}^n\xi}{(2\pi)^n}$: the inverse Fourier transform in ξ	propagators, heat kernels
symbol class S^m	$\left\lvert\partial_x^\beta\partial_\xi^\alpha\sigma\right\rvert \le C\langle\xi\rangle^{m-\lvert\alpha\rvert}$: each ξ-derivative gains one power of decay	the calculus
ΨDO on a manifold	locally a symbol in S^m in each chart, matrices for bundles (Section 2.4.5)	index theory of ΨDOs
principal symbol	$\sigma_m = \lim_{\mu\to\infty}\mu^{-m}\sigma(x,\mu\xi)$; positively homogeneous	symbol classes in K-theory
elliptic ΨDO	$\sigma_m(x,\xi)$ invertible for $\xi\neq 0$; order m elliptic is not order $m+1$ elliptic	Fredholm theory
composition	$\sigma_{PQ}\sim\sum_\gamma\frac{1}{\gamma!}\partial_\xi^\gamma\sigma_P\,D_x^\gamma\sigma_Q$; principal symbols multiply	parametrices
commutator	$\sigma_{[P,Q]} = i\{\sigma_P,\sigma_Q\}+\ldots$: quantum commutator ↔ Poisson bracket	semiclassics; anomalies
adjoint	$\sigma_m(P^*) = \sigma_m(P)^\dagger$; P elliptic $\iff$ P^* elliptic	finite cokernels
parametrix	Q with symbol $\sigma_m^{-1}+\ldots$; $PQ = I-R_1$, $QP = I-R_2$, R_i smoothing	Fredholm property, regularity
Bessel potential	$(a^2+\Delta)^\lambda$, kernel $\propto r^{-\nu}K_\nu(ar)$, $\nu=\frac{n}{2}+\lambda$; Yukawa e^{-ar}/r for $n=3$, $\lambda=-1$	massive propagators
Riesz potential	Δ^λ, kernel $\propto\lvert x\rvert^{-n-2\lambda}$: fractional derivatives and integrals	fractional powers, conformal dimensions
logarithmic symbol	$(a^2+\lvert\xi\rvert^2)^\lambda\ln(a^2+\lvert\xi\rvert^2)$: in $S^{2\lambda+\varepsilon}$ for all $\varepsilon>0$, not in $S^{2\lambda}$	ζ', determinants
smoothing operator	symbol in $S^{-\infty}$, i.e. smooth kernel; e.g. the Gaussian $e^{-t\Delta}$	heat kernel, McKean–Singer
complex powers	$(a^2+\Delta)^z$ has order $2\operatorname{Re}z$, elliptic; trace gives $\zeta(s)$	det′ (Chapter 9, Chapter 12, Chapter 10)
locality	$\operatorname{supp}Pu\subset\operatorname{supp}u$: true exactly for differential operators (Peetre)	
pseudo-locality	$\operatorname{sing\,supp}Pu\subset\operatorname{sing\,supp}u$: kernel smooth off the diagonal	regularity, heat-kernel localisation

Nash §5, Pseudo-differential operators and Sobolev spaces (Nash pp. 47–55)

Concept	Operational meaning	Used later
weak derivative	$\int(\partial^\alpha u)\phi = (-1)^{\lvert\alpha\rvert}\int u\,\partial^\alpha\phi$ for all test functions ϕ	distributions
L^p_k, H^k	derivatives up to order k in L^p (in L^2 for H^k), Nash's (2.73)–(2.74)	function spaces for gauge fields (Chapter 6, Chapter 8)
H^s, real s	$\lVert u\rVert_s^2 = \int(1+\lvert\xi\rvert^2)^s\,\lvert\hat u\rvert^2\,\frac{\mathrm{d}^n\xi}{(2\pi)^n}$; on S^1: $2\pi\sum(1+n^2)^s\,\lvert c_n\rvert^2$	domain of Fredholm operators
negative orders	$H^{-s} = (H^s)^*$ via the L^2 pairing; $\delta\in H^{-s}(\mathbb{R}^n)$ iff $s>\frac{n}{2}$	sources, distributional fields
$\mathcal{D},\mathcal{S},\mathcal{E}$ and duals	test functions (compact support, rapid decay, all smooth) and the distributions dual to them	Green's functions, QFT fields
Gelfand triple	$\mathcal{S}\subset L^2\subset\mathcal{S}'$: kets, the Hilbert space, bras (plane waves, δ)	Dirac notation made honest
Sobolev scale	$H^\infty\subset\cdots\subset H^1\subset H^0 = L^2\subset H^{-1}\subset\cdots\subset H^{-\infty}$	bookkeeping for orders
Sobolev (i)	$k-\frac{n}{p}>l\Rightarrow L^p_k\subset C^l$; power counting $\int\langle\xi\rangle^{2l-2k}\mathrm{d}^n\xi<\infty$	regularity of zero modes; UV divergences
Sobolev (ii)	$k\ge l$, $k-\frac{n}{p}\ge l-\frac{n}{q}\Rightarrow L^p_k\subset L^q_l$	critical dimensions of Yang–Mills
compact operator	maps bounded sets to precompact sets; a norm limit of finite-rank operators	Fredholm theory
Rellich	$H^s\hookrightarrow H^t$ compact for $s>t$ on compact M; so smoothing operators are compact	discrete spectrum, finite index
ΨDO boundedness	order $m\Rightarrow P: H^s\to H^{s-m}$ bounded for every s, Nash's (2.92)	Fredholm property
elliptic estimate	$\lVert u\rVert_s\le C(\lVert Pu\rVert_{s-m}+\lVert u\rVert_t)$; regularity: $Pu\in H^{s-m}\Rightarrow u\in H^s$	smoothness of kernels
operator norm	$\Delta: H^k\to H^{k-2}$ on S^1 has norm 1 (Nash (2.94)–(2.96))	

Fredholm operators and the index (Nash pp. 54–55, expanded in Section 2.6)

Concept	Operational meaning	Used later
index of a matrix	$m \times n$ matrix: $\dim\mathrm{Ker} - \dim\mathrm{Coker} = n - m$ whatever the entries	the model for everything
cokernel	$H_2/\mathrm{Im}\,T \cong \mathrm{Ker}\,T^*$ when $\mathrm{Im}\,T$ is closed: the obstructions to solving $Tu = f$	solvability conditions
Fredholm operator	bounded, $\dim\mathrm{Ker}$ and $\dim\mathrm{Coker}$ finite (so closed range)	Chapter 4, Chapter 3
index	$\mathrm{index}\,T = \dim\mathrm{Ker}\,T - \dim\mathrm{Ker}\,T^*$	the analytical side of the index theorem
shift operators	$Se_n = e_{n+1}$ on ℓ^2: $\mathrm{index}\,S = -1$, $\mathrm{index}\,S^* = +1$; every integer occurs	Toeplitz operators, spectral flow
Atkinson's theorem	Fredholm $\iff$ invertible modulo compact operators; Nash's (2.97)	elliptic $\Rightarrow$ Fredholm
elliptic $\Rightarrow$ Fredholm	$P : H^s \to H^{s-m}$ Fredholm; kernel and $\mathrm{Ker}\,P^*$ smooth, independent of s	every index
solvability	$Pu = f$ solvable $\iff$ $f \perp \mathrm{Ker}\,P^*$; Gauss's law on a closed space	constraints, Gauss law
stability	index locally constant, unchanged by compact (lower-order) terms, depends only on $[\sigma_m]$	topological invariance of the index
spectral flow	for $D_\theta + a$ on S^1, eigenvalues $n + a$ cross zero as a varies; the index stays 0	anomalies (Chapter 10)
Toeplitz operator	$e^{ik\theta}\Pi_+ + \Pi_-$: index $= -k$, minus the winding number of the symbol	a first index theorem
$\mathrm{d} + \mathrm{d}^*$	even $\to$ odd forms: index $= \sum(-1)^q b_q = \chi(M)$	Gauss–Bonnet as an index theorem
McKean–Singer	$\mathrm{index}\,P = \mathrm{Tr}\,e^{-tP^*P} - \mathrm{Tr}\,e^{-tPP^*}$ for every $t > 0$	heat-kernel proof, Fujikawa
SUSY oscillator	$P = \frac{\mathrm{d}}{\mathrm{d}x} + x$: index 1, the Witten index	Morse theory (Chapter 7)
space of Fredholm ops	$\pi_0(\mathcal{F}) \cong \mathbb{Z}$ via the index; families give $K(X)$	families index, global anomalies

Formulas to keep at your fingertips

F1. *Plane-wave test.* $D^\alpha e^{ix\cdot\xi} = \xi^\alpha e^{ix\cdot\xi}$, so $L = \sum a_\alpha D^\alpha$ has $\sigma_L(x,\xi) = \sum a_\alpha(x)\xi^\alpha$ and $\sigma_m(x,\xi) = \sum_{|\alpha|=m} a_\alpha(x)\xi^\alpha$.

F2. *Ellipticity.* $\det\sigma_m(x,\xi) \neq 0$ for $\xi \neq 0$; equivalently $\left|\sigma_m(x,\xi)^{-1}\right| \leq C\,|\xi|^{-m}$.

F3. *Hodge.* $\sigma_2(\Delta_p)(\xi) = (i\xi\wedge)(-i\iota_\xi) + (-i\iota_\xi)(i\xi\wedge) = |\xi|^2\, I$, and $\dim\mathrm{Ker}\,\Delta_p = b_p(M)$.

F4. *Composition.* $\sigma_{PQ} \sim \sum_\gamma \frac{1}{\gamma!}\,\partial_\xi^\gamma \sigma_P\, D_x^\gamma \sigma_Q$; $\sigma_{m+m'}(PQ) = \sigma_m(P)\sigma_{m'}(Q)$; $\sigma_{[P,Q]} = i\{\sigma_P, \sigma_Q\} + \ldots$; $\sigma_m(P^*) = \sigma_m(P)^\dagger$.

F5. *Parametrix.* $q \sim \sigma_m^{-1} + \ldots$, $PQ = I - R_1$, $QP = I - R_2$, with R_1, R_2 smoothing.

F6. *Sobolev norm.* $\|u\|_s^2 = \int (1 + |\xi|^2)^s\, |\hat{u}(\xi)|^2\, \frac{\mathrm{d}^n\xi}{(2\pi)^n}$; on T^n: $(2\pi)^n \sum_k (1 + |k|^2)^s\, |c_k|^2$.

F7. *Sobolev embedding.* $H^s \subset C^l$ if $s > l + \frac{n}{2}$; the smoothness deficit is $\frac{n}{p}$ ($\frac{n}{2}$ in L^2).

F8. *Mapping property.* Order $m \Rightarrow H^s \to H^{s-m}$ bounded; smoothing $\Rightarrow H^s \to H^\infty = C^\infty$ (compact M).

F9. *Fredholm.* $\operatorname{index} P = \dim \operatorname{Ker} P - \dim \operatorname{Ker} P^*$, finite, s-independent, unchanged by lower-order terms.

F10. *McKean–Singer.* $\operatorname{index} P = \operatorname{Tr} e^{-tP^*P} - \operatorname{Tr} e^{-tPP^*}$ for all $t > 0$.

Where the chapter is used later

The tools of this chapter are used in almost every later chapter. Figure 2.51 shows the main routes.

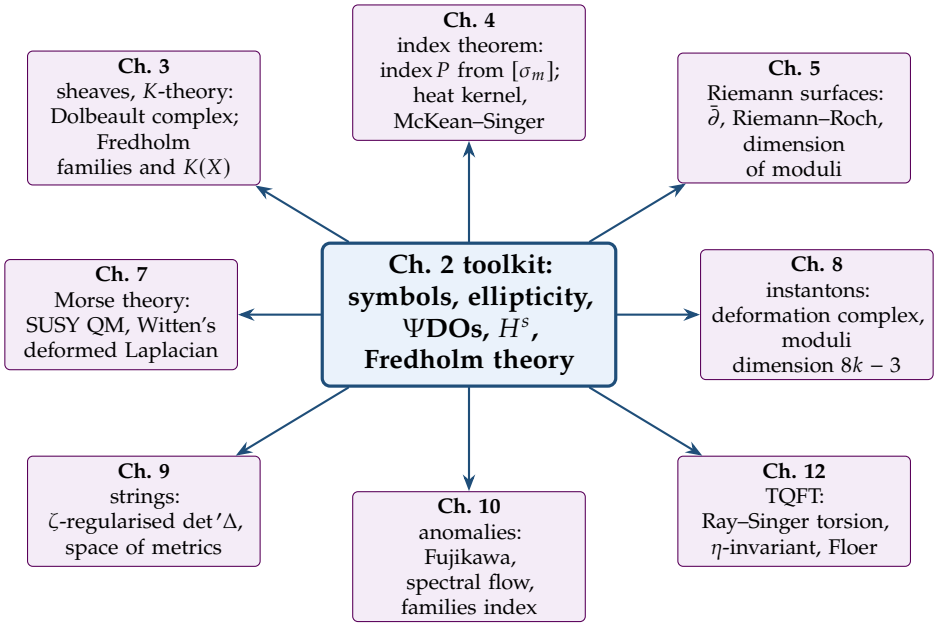

Figure 2.51: Where Chapter 2 is used. Each purple box names a later chapter and the tool it takes from this one. The index theorem (top) uses the whole spine of Figure 2.50. The other chapters mostly use one piece of it: complex powers and ζ-determinants (strings, TQFT), heat kernels and spectral flow (anomalies), the index of an elliptic complex (instantons, Riemann surfaces), or Fredholm families (K-theory).

- **Counting moduli.** The dimension of a moduli space (of instantons in Chapter 8, of complex structures on a Riemann surface in Chapter 5) is the index of the elliptic complex that linearises the defining equations. The index is stable, so the dimension can be computed from topology alone.
- **Counting zero modes.** Fermion zero modes in an instanton background are $\operatorname{Ker} \not{D}_A$; their net chirality is an index (Chapter 4), and it drives the anomalies of Chapter 10.
- **Regularising determinants.** One-loop amplitudes are det′ of elliptic operators, defined through ζ-functions of complex powers (Chapter 9, Chapter 12).
- **Function spaces.** Spaces of connections $\mathcal{A}$ and gauge groups $\mathcal{G}$ are completed in Sobolev norms, so that they become Hilbert manifolds and Lie groups (Chapter 6, Chapter 8).

Watch out: The five confusions of this chapter

1. *Elliptic is about the top order only.* $\Delta + V(x)$ is elliptic for every potential V, and $\Delta - m^2$ is elliptic although it has zero modes for special m. Ellipticity does not mean invertible. It means *invertible modulo smoothing*.
2. *Elliptic is not positive.* $\bar\partial$ and $\not{D}$ are elliptic with complex or indefinite symbols. What matters is that $\det \sigma_m \neq 0$, not that $\sigma_m > 0$.
3. *Signs and 2π's.* Nash's Fourier conventions differ from ours by the sign in the exponent (see the Fourier dictionary in Section 2.4.2). Symbols of odd-order operators change sign accordingly. Ellipticity and the index do not.
4. *Cokernel is not kernel of the adjoint in general.* The identification $\operatorname{Coker} P \cong \operatorname{Ker} P^*$ needs a closed range. For elliptic operators on compact manifolds the range is closed, and the identification holds.
5. *Compactness is essential.* On $\mathbb{R}^n$, Δ is elliptic but not Fredholm on L^2: its spectrum $[0, \infty)$ reaches 0 continuously. Finiteness of the index needs a compact manifold, or a confining potential as in the SUSY oscillator.

Try it: Self-test on the whole chapter

(a) Is $\partial_x^2 - \partial_y^2 + \partial_x$ elliptic? Is $\partial_x^4 + \partial_y^4$?
(b) What is the principal symbol of $\sqrt{\Delta + m^2}$, and its order?
(c) For which s is the square wave in $H^s(S^1)$? Is it continuous?
(d) On T^2, what is index $\bar\partial$? Why does adding a smooth potential $V(z)$ not change it?
(e) Why is $\operatorname{index}(\Delta + 1) = 0$ on a compact M without computing anything?

Answers. (a) The first has $\sigma_2 = -\xi_1^2 + \xi_2^2$, which vanishes on the lines $\xi_1 = \pm\xi_2$, so it is not elliptic (it is hyperbolic). The second has $\sigma_4 = \xi_1^4 + \xi_2^4 > 0$ for $\xi \neq 0$, so it is elliptic. (b) $\sigma_1 = |\xi|$, order 1; it is elliptic, and non-local but pseudo-local. (c) Its coefficients fall like $1/|n|$, so it is in H^s exactly for $s < \frac{1}{2}$. Consistently with Sobolev embedding (which needs $s > \frac{1}{2}$), it is not continuous. (d) Zero: the kernel and cokernel are the constants. V is of order 0, a compact perturbation, so the index is unchanged. (e) $\Delta + 1$ is self-adjoint, so its index is 0. In fact it is invertible, since $\langle u, (\Delta + 1)u\rangle = \|\mathrm{d}u\|^2 + \|u\|^2 > 0$ for $u \neq 0$.

Reading Nash (Chapter II, pp. 27–55: section map)

Nash section	Nash pages, equations	In these notes
§1 The meaning of ellipticity	pp. 27–32, (2.1)–(2.18)	part 2a, first section
§2 Ellipticity and hypo-ellipticity	pp. 32–36, (2.19)–(2.37)	part 2a, second section
§3 Ellipticity and vector bundles	pp. 36–41, (2.38)–(2.53)	part 2a, third section; Section 2.4.1
§4 Pseudo-differential operators	pp. 41–47, (2.54)–(2.70)	Section 2.4
§5 ΨDOs and Sobolev spaces	pp. 47–54, (2.71)–(2.93)	Section 2.5
§5, last page	pp. 54–55, (2.94)–(2.97)	Section 2.6

Nash's chapter ends abruptly, with the parametrix identity (2.97) and the remark that elliptic operators are Fredholm. He takes up the index itself in his Chapter 4 (Chapter 4) and the space of Fredholm operators at the end of his Chapter 3 (Chapter 3). Our Section 2.6 bridges that gap, so that when the index theorem arrives, every word in its statement already has an operational meaning.

Chapter 3

Cohomology of Sheaves and Bundles

Where this chapter is going

Physics is full of objects that are easy to write down *locally* and hard to write down *globally*. A vector potential A for a magnetic monopole exists on the northern hemisphere and on the southern hemisphere, but not on the whole sphere. A wavefunction of a charged particle in the monopole field is an honest function on each hemisphere, but only a "twisted" function on the sphere. A solution of a differential equation exists near every point, but may fail to exist everywhere at once. In each case the local pieces are fine, and the interesting physics lives in the *mismatch* between them.

This chapter builds the machinery that measures such mismatches. It has two halves. The first half (this part, Nash §1–§2) introduces *sheaves*, which are the bookkeeping device for "data defined on open sets that can be restricted and glued", and *sheaf cohomology*, which is the group that counts the obstructions to gluing. The payoff is a pair of theorems that say that two very different-looking computations give the same answer: the de Rham theorem (combinatorial cohomology with real coefficients equals closed forms modulo exact forms) and the Dolbeault theorem (sheaf cohomology of holomorphic forms equals $\bar\partial$-closed forms modulo $\bar\partial$-exact forms). Along the way we will see that complex line bundles, and hence $U(1)$ gauge fields such as the Dirac monopole, are classified by a sheaf cohomology group, and that Dirac's quantisation condition is literally the cocycle condition of that cohomology.

The second half of the chapter (Nash §3–§6, later parts) turns to *vector bundles as algebraic objects*: K-theory, Bott periodicity, characteristic classes (Chern classes, the Chern character, the Todd class, the $\hat A$-genus), and the relation between Fredholm operators and $K(X)$. All of that is the raw material of the Atiyah–Singer index theorem in Chapter 4. Figure 3.1 shows how the pieces feed into each other.

Physical picture: One sentence for the whole chapter

A sheaf remembers what you are allowed to do *locally*; its cohomology measures what goes wrong when you try to do it *globally*. For a physicist: H^0 counts the global solutions, H^1 counts the ways local solutions can be patched together with a twist (gauge transformations on overlaps), and H^2 counts the twists of twists (the quantised magnetic charges).

3.1 Sheaves

Nash opens the chapter with a question that every physicist has met without naming it: *when does something that is true locally become true globally?*

Some properties pass from local to global for free. If every small open set of a connected

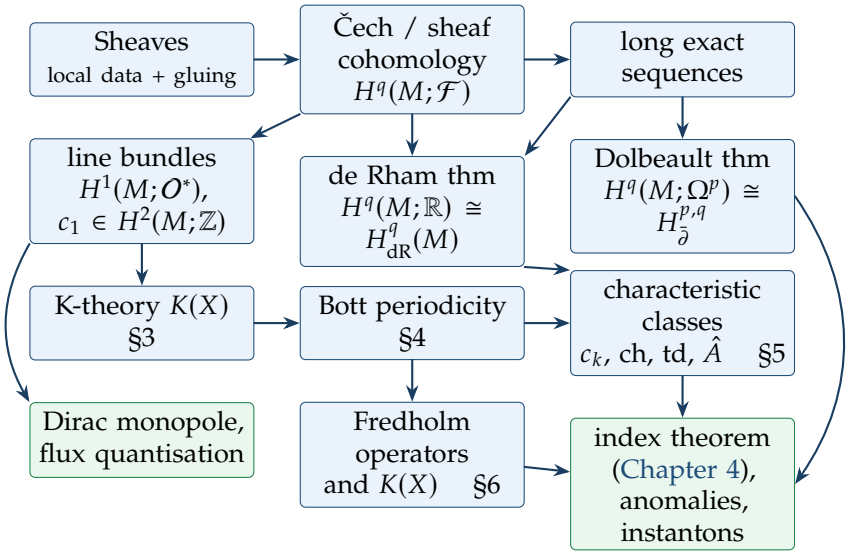

Figure 3.1: The logic of Chapter 3. Blue boxes are mathematics, green boxes are where the physics comes out. This part covers the top two rows (sheaves, their cohomology, the de Rham and Dolbeault theorems, line bundles and c_1). The later parts of the chapter build K-theory and characteristic classes, which feed, together with the Dolbeault complex, into the index theorem.

manifold looks like a piece of $\mathbb{R}^n$, the manifold has dimension n: there is nothing more to check. Other properties do not pass at all. Nash's example is scalar curvature. On a flat torus the scalar curvature is zero everywhere, so it is "locally constant"; but on a surface built from a flat cylinder capped by two round hemispheres, the curvature is locally constant near every point (zero on the cylinder, positive on the caps) and yet not constant globally. "Locally constant" and "constant" differ, and the difference is detected by the global shape of the space.

The physicist's version of the same question is sharper.

- Maxwell: $\mathrm{d}F = 0$ means that near every point there is a potential with $F = \mathrm{d}A$ (Poincaré lemma). Is there a single A on the whole of space? Not if there is a monopole.
- Quantum mechanics: the Schrödinger equation can be solved near every point. Is there a single-valued global wavefunction? Not always: Aharonov–Bohm phases and monopoles force the wavefunction to be a section of a nontrivial line bundle.
- Complex analysis: every nonvanishing holomorphic function has a logarithm near every point. Is there a global logarithm? Not for z on $\mathbb{C} \setminus \{0\}$.

A **sheaf** is the device that packages "the things we are allowed to write down on each open set" together with the two operations that every one of these examples uses: *restricting* data from a big set to a small set, and *gluing* data on small sets into data on a big set. Sheaf *cohomology* (Section 3.3) then measures the failure of gluing. Nash warns the reader not to be put off by the abstract appearance of the definition. We follow his advice and his order: definition, then lots of examples.

3.1.1 Local data on open sets: presheaves

Fix a topological space M; for us it will almost always be a smooth manifold. The basic example to keep in mind is:

$$\mathcal{E}(U) \;=\; \{\text{smooth real functions } f : U \to \mathbb{R}\}, \qquad U \subset M \text{ open}.$$

Three facts about this assignment are so obvious that we normally never say them.

(a) Each $\mathcal{E}(U)$ is an abelian group under pointwise addition (in fact a vector space, even a ring).

(b) If $U \subset V$, a smooth function on the big set V can be *restricted* to the small set U. Restriction respects addition: $(f+g)|_U = f|_U + g|_U$.

(c) Restricting in two steps is the same as restricting in one step, and "restricting" U to itself does nothing.

Anything with these three properties is a presheaf.

Working definition 3.1 (presheaf)

A **presheaf** $\mathcal{F}$ of abelian groups on M assigns

- to every open set $U \subset M$ an abelian group $\mathcal{F}(U)$ [the allowed local objects on U, which can be added, like the smooth functions on U], whose elements are called **sections of $\mathcal{F}$ over U**;
- to every pair of open sets $U \subset V$ a group homomorphism [a map that respects addition, $r(s+t) = r(s) + r(t)$] $r^V_U : \mathcal{F}(V) \to \mathcal{F}(U)$, called **restriction**,

such that

$$r^U_U = \mathrm{id}, \qquad r^W_U = r^V_U \circ r^W_V \quad \text{whenever } U \subset V \subset W. \tag{3.1}$$

We usually write $s|_U$ for $r^V_U(s)$. *Operational test:* decide what the "allowed local objects" on U are, check they can be added (or multiplied, for a multiplicative sheaf), and check that restricting an allowed object gives an allowed object.

Figure 3.2 shows the picture. Restriction goes from big sets to small sets. Nash's gloss is worth repeating: the first rule says restricting from U to U leaves s unchanged; the second says restricting from W to U may be done via an intermediate set V.

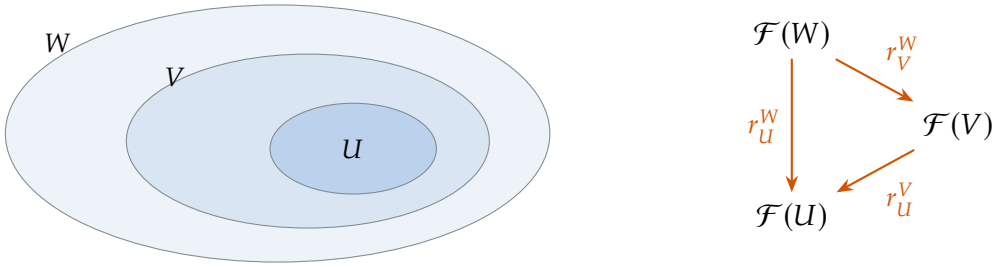

Figure 3.2: Nested open sets $U \subset V \subset W$ (left) and the restriction maps between their groups of sections (right). Restriction always goes from a bigger set to a smaller one, and the triangle commutes: $r^W_U = r^V_U \circ r^W_V$.

Watch out: Arrows go the "wrong" way

The open sets are included $U \hookrightarrow V$, but the sections go $\mathcal{F}(V) \to \mathcal{F}(U)$. Bigger sets carry *fewer* sections (there are more conditions to satisfy), smaller sets carry *more*. Keeping this reversal straight saves a lot of confusion later.

We also set $\mathcal{F}(\varnothing) = 0$ (the trivial group). This is the only sensible choice: there is exactly one function on the empty set.

3.1.2 The two gluing axioms: sheaves

A presheaf only knows how to go from big to small. The interesting direction is from small to big: given data on the pieces of a cover, can we assemble global data? For smooth functions the answer is "yes, if the pieces agree on overlaps, and then uniquely". This is what makes a presheaf a sheaf.

Working definition 3.2 (sheaf)

A presheaf $\mathcal{F}$ is a **sheaf** if for every open set U and every open cover $U = \bigcup_i U_i$ the following hold.

(S1) **Locality** [a section is determined by its pieces]. If $s_1, s_2 \in \mathcal{F}(U)$ and $s_1|_{U_i} = s_2|_{U_i}$ for every i, then $s_1 = s_2$.

(S2) **Gluing** [pieces that agree on overlaps assemble into one section]. If $s_i \in \mathcal{F}(U_i)$ is given for every i and $s_i|_{U_i \cap U_j} = s_j|_{U_i \cap U_j}$ for all i, j, then there is a section $s \in \mathcal{F}(U)$ with $s|_{U_i} = s_i$ for every i.

(By (S1) the glued section in (S2) is unique.) This is Nash's condition (3.1). *Operational test:* the defining condition for the allowed objects must be checkable point by point, or at least in an arbitrarily small neighbourhood of each point. Conditions of that kind are called **local**, and local conditions always give sheaves.

The two axioms pull in opposite directions, as Nash points out. (S1) says a section over U is *determined* by its restrictions: global $\to$ local loses no information. (S2) says compatible local data can be *assembled*: local $\to$ global is possible whenever the pieces are compatible. What sheaf cohomology will measure is the more interesting situation where local pieces exist but are *not* compatible, and we ask whether they can be *made* compatible.

For groups there is a neat way to package (S1) and (S2) at once. Write $U_{ij} = U_i \cap U_j$. Consider

$$0 \longrightarrow \mathcal{F}(U) \xrightarrow{\;r\;} \prod_i \mathcal{F}(U_i) \xrightarrow{\;\delta\;} \prod_{i<j} \mathcal{F}(U_{ij}), \qquad r(s) = (s|_{U_i})_i, \quad \delta(s_i)_{ij} = s_j|_{U_{ij}} - s_i|_{U_{ij}}. \tag{3.2}$$

Then (S1) says r is injective, and (S2) says every element killed by δ is in the image of r. In other words: $\mathcal{F}$ *is a sheaf exactly when* (3.2) *is exact*. We will meet the map δ again: it is the first Čech coboundary.

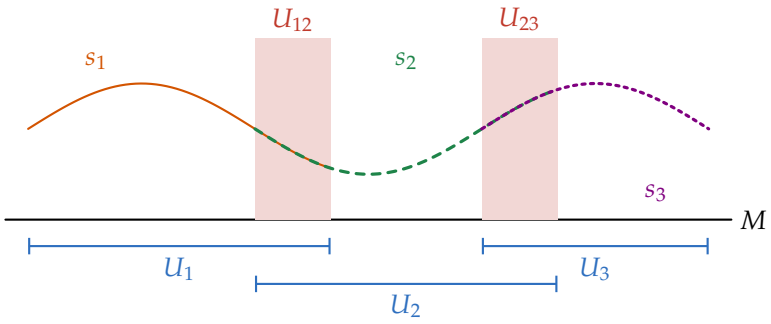

Figure 3.3: The gluing axiom for smooth functions on an interval covered by three open sets. The local sections s_1, s_2, s_3 (solid, dashed, dotted) agree on the overlaps U_{12} and U_{23} (shaded), so they are pieces of one global smooth function, and that function is unique.

Worked example 3.1: Smooth functions form a sheaf

Nash leaves as an exercise the check that $\mathcal{E}(U) = C^\infty(U, \mathbb{R})$ with ordinary restriction is a sheaf. Let us do it.
Presheaf. $C^\infty(U)$ is a group under addition. The restriction of a smooth function to a smaller open set is smooth (smoothness at a point only involves a neighbourhood of the point). The rules (3.1) hold because restriction of functions is literally "forget the values outside U".
Locality (S1). If $s_1|_{U_i} = s_2|_{U_i}$ for every i, then for any $x \in U$ pick i with $x \in U_i$; then $s_1(x) = s_2(x)$. So $s_1 = s_2$ as functions.
Gluing (S2). Given compatible s_i, define $s : U \to \mathbb{R}$ by

$$s(x) \overset{(1)}{=} s_i(x) \quad \text{for any } i \text{ with } x \in U_i.$$

(1) This is well defined: if also $x \in U_j$, then $x \in U_{ij}$ and $s_i(x) = s_j(x)$ by compatibility.

Near each x the function s coincides with the smooth function s_i on the open set U_i, so all derivatives of s exist at x. Hence $s \in C^\infty(U)$ and $s|_{U_i} = s_i$. The key point is that smoothness is a *local* condition: it can be checked in an arbitrarily small neighbourhood of each point.

Exactly the same argument works for many other local conditions, which gives Nash's first list of sheaves.

- C^0: continuous functions.
- $\mathcal{E}$: smooth (C^∞) functions. Nash's notation, after Wells; the letter $\mathcal{E}$ is traditional (it goes back to Schwartz's $\mathcal{E}$ for smooth test functions).
- $\mathcal{A}$: real-analytic functions (those equal to their convergent Taylor series near each point).
- $\mathcal{O}$: holomorphic functions on a complex manifold of complex dimension n (in local coordinates $z^1, \dots, z^n$, functions that are complex-differentiable in each variable, equivalently $\partial f / \partial \bar{z}^i = 0$; see Section 3.7.3).

Each is a sheaf because continuity, smoothness, analyticity and holomorphicity are all checked point by point.

Worked example 3.2: Constant functions: a presheaf that is not a sheaf

Let $M = \mathbb{R}$ and let $\mathcal{P}(U) = \{\text{constant functions } U \to \mathbb{R}\} \cong \mathbb{R}$ for $U \neq \varnothing$, with the obvious restrictions. This is a presheaf. Take $U = (0,1) \cup (2,3)$, covered by $U_1 = (0,1)$ and $U_2 = (2,3)$, and let $s_1 = 0$, $s_2 = 1$. The overlap is empty, so the compatibility condition $s_1|_{U_{12}} = s_2|_{U_{12}}$ is vacuous (both sides live in $\mathcal{P}(\varnothing) = 0$). Gluing would need a *constant* function on U equal to 0 on one interval and 1 on the other. None exists, so (S2) fails.
The repair is to ask for **locally constant** functions: functions that are constant near each point. Then the glued function "0 on $(0,1)$, 1 on $(2,3)$" is allowed, and we get a sheaf. We denote it by $\underline{\mathbb{R}}$, or just $\mathbb{R}$, and call it the **constant sheaf**. Its sections are

$$\underline{\mathbb{R}}(U) \;=\; \mathbb{R}^{\#\{\text{connected components of } U\}}. \tag{3.3}$$

The same construction with values in $\mathbb{Z}$, $\mathbb{C}$ or any group G gives the constant sheaves $\underline{\mathbb{Z}}$, $\underline{\mathbb{C}}$, $\underline{G}$.

Watch out: "The sheaf of constant functions"

Nash (p. 59–60) says that $\mathbb{R}$ can be thought of as "the sheaf of constant functions". He means *locally* constant functions, as in Example 3.2. Being constant is not a local property (it compares values at far-away points); being locally constant is. On a connected M the two agree for global sections, which is why the sloppy name survives.

Worked example 3.3: Bounded holomorphic functions are not a sheaf

This is Nash's non-example (taken from Wells). Let $M = \mathbb{C}$ and

$$\mathcal{F}(U) = \{f : U \to \mathbb{C} \text{ holomorphic and bounded}\}.$$

Sums and restrictions of bounded holomorphic functions are bounded and holomorphic, so this is a presheaf. Now cover $\mathbb{C}$ by the discs $D_R = \{|z| < R\}$, $R = 1, 2, 3, \ldots$, and on each disc take

$$s_R(z) = z \in \mathcal{F}(D_R), \qquad \text{bounded because } |s_R(z)| < R \text{ on } D_R.$$

On any overlap $D_R \cap D_{R'} = D_{\min(R,R')}$ the functions agree. If (S2) held they would glue to a bounded holomorphic s on $\mathbb{C}$ with $s(z) = z$ everywhere. But

$$\sup_{z\in\mathbb{C}} |s(z)| \overset{(1)}{=} \sup_{z\in\mathbb{C}} |z| \overset{(2)}{=} \infty,$$

(1) s restricts to $s_R(z) = z$ on every disc and the discs cover $\mathbb{C}$.
(2) $|z|$ is unbounded on $\mathbb{C}$.

So the gluing axiom fails. Nash's version of the argument uses Liouville's theorem: a bounded holomorphic function on all of $\mathbb{C}$ is constant, so the only global sections are constants, while there are many non-constant local sections that agree on overlaps. *Why it fails:* "bounded" is not a local condition. Near any single point every continuous function is bounded; boundedness is about behaviour far away.

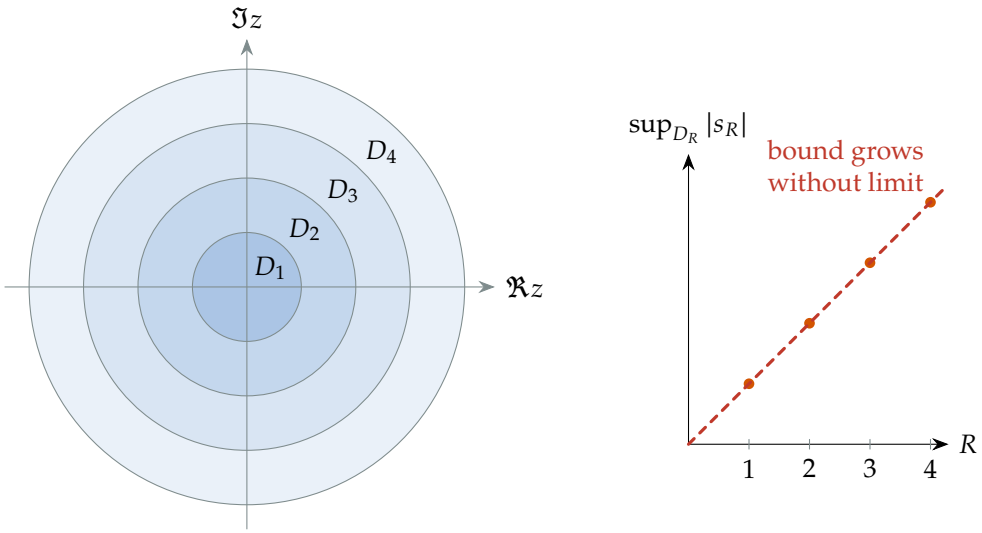

Figure 3.4: Left: the discs D_R exhaust $\mathbb{C}$. On each one, $s_R(z) = z$ is a bounded holomorphic function, and neighbouring s_R agree on overlaps. Right: the bound on D_R is R, which grows without limit, so the glued function is not bounded. "Bounded" is not a local condition, and the gluing axiom fails.

Physical picture: Local conditions are the ones physics writes down

Differential equations, regularity conditions and gauge conditions are checked at points; they give sheaves. Conditions such as "bounded", "normalisable", "finite total energy" or "constant" are global; they do not. This is why the local-field-theory language of a physicist sits so naturally in sheaf language: a local Lagrangian produces equations of motion whose solutions form a sheaf (the sheaf of local solutions), and all the global subtleties are then pushed into cohomology.

3.1.3 Germs and stalks

As U gets bigger, $\mathcal{F}(U)$ gets smaller, because there are more conditions to satisfy. Conversely, as U shrinks down around a point x, $\mathcal{F}(U)$ gets bigger. Nash asks what we get "in the limit" when U shrinks to the point x. The answer is not "the value at x"; it is something richer, called the **germ** at x.

Here is the idea for smooth functions. Two functions f and g defined near x have the *same germ at x* if they agree on *some* neighbourhood of x, however small. So the germ remembers the value $f(x)$, all derivatives of f at x, and more, but it forgets what f does at any fixed distance from x.

Working definition 3.3 (germ and stalk)

Let $x \in M$. Consider pairs (U, s) with U an open neighbourhood of x and $s \in \mathcal{F}(U)$. Declare

$$(U,s) \sim (V,t) \quad \Longleftrightarrow \quad s|_W = t|_W \text{ for some open } W \ni x,\ W \subset U \cap V.$$

The equivalence class of (U, s) is the **germ** s_x of s at x. The set of germs is the **stalk**

$$\mathcal{F}_x \;=\; \varinjlim_{U \ni x} \mathcal{F}(U). \tag{3.4}$$

This is Nash's (3.2); the symbol $\varinjlim$ is the **direct limit** [here it just produces the set of germs defined above, as U shrinks towards x] over neighbourhoods of x ordered by reverse inclusion. *Operational test:* to decide whether two local sections have the same germ at x, ask whether they agree on some small ball around x.

The stalk is a group: add germs by adding representatives on a common neighbourhood, $s_x + t_x = (s|_W + t|_W)_x$. This does not depend on the representatives chosen, because shrinking W further does not change the germ.

Worked example 3.4: Three stalks, three sizes

(a) Locally constant sheaf. For $\underline{\mathbb{R}}$ and any x, a small connected neighbourhood carries exactly one real number's worth of sections, so

$$\underline{\mathbb{R}}_x \cong \mathbb{R}.$$

(b) Holomorphic functions. A holomorphic function near $x = 0 \in \mathbb{C}$ is determined on a small disc by its Taylor series (identity theorem), and any power series with positive radius of convergence defines one. Hence

$$\mathcal{O}_0 \;\cong\; \mathbb{C}\{z\} \;=\; \Big\{ \sum_{n \geq 0} a_n z^n \;:\; \text{radius of convergence} > 0 \Big\}.$$

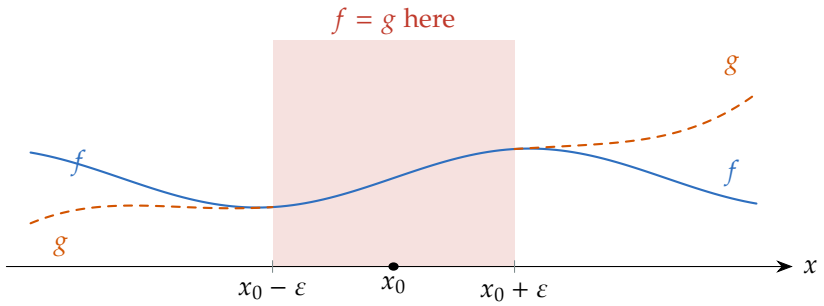

Figure 3.5: Two functions with the same germ at x_0. They agree on the shaded neighbourhood $(x_0 - \varepsilon, x_0 + \varepsilon)$ and differ outside it. The stalk $\mathcal{E}_{x_0}$ cannot tell them apart: a germ remembers everything about f infinitely close to x_0 and nothing at a finite distance.

The germ at a point knows the function on its whole disc of convergence, and (by analytic continuation) essentially on the whole connected domain. *(c) Smooth functions.* The map "germ $\mapsto$ Taylor series" $\mathcal{E}_0 \to \mathbb{R}[[x]]$ is *not* injective. The function

$$\phi(x) = \begin{cases} e^{-1/x^2} & x \neq 0 \\ 0 & x = 0 \end{cases} \qquad \text{has} \qquad \phi^{(k)}(0) \overset{(1)}{=} \lim_{x \to 0} P_k(1/x)\, e^{-1/x^2} \overset{(2)}{=} 0$$

(1) By induction, the k-th derivative away from 0 is a polynomial P_k in $1/x$ times e^{-1/x^2} (differentiate once more and use the product rule).

(2) e^{-1/x^2} goes to zero faster than any power of $1/x$ blows up (substitute $u = 1/x^2$ and compare $u^m e^{-u} \to 0$).

So ϕ has zero Taylor series at 0 but a nonzero germ there (it is positive at every $x \neq 0$, arbitrarily close to 0). Smooth germs carry information invisible to all derivatives.

This contrast (b) versus (c) is the root of one of the most important differences in the chapter: smooth functions are "floppy" and can be cut off, holomorphic functions are "rigid" and cannot. The floppy sheaves will turn out to have no higher cohomology (Section 3.2.5); all the interesting cohomology comes from rigid sheaves such as $\underline{\mathbb{Z}}$, $\underline{\mathbb{R}}$, $\mathcal{O}$ and $\mathcal{O}^*$.

The sheaf as a space of germs

Nash's footnote on p. 58 says that a sheaf is sometimes called a "sheaf of germs". This refers to an equivalent, more geometric picture. Collect all the stalks into one set,

$$\mathrm{Et}(\mathcal{F}) = \bigsqcup_{x \in M} \mathcal{F}_x, \qquad \pi : \mathrm{Et}(\mathcal{F}) \to M, \quad \pi(s_x) = x.$$

This is the **étalé space** ("spread-out space"). Each section $s \in \mathcal{F}(U)$ gives a map $x \mapsto s_x$ from U into $\mathrm{Et}(\mathcal{F})$, which is a section of π in the ordinary sense of bundles: a choice of one point in each "fibre" $\mathcal{F}_x$ (Figure 3.6). One topologises $\mathrm{Et}(\mathcal{F})$ so that these maps are continuous, and then *the continuous sections of π over U are exactly $\mathcal{F}(U)$*. So a sheaf is "a bundle-like object whose sections are the things we care about", except that the fibres $\mathcal{F}_x$ can be huge and the space is usually very non-Hausdorff. For calculations we never need the étalé space, but it explains the name: a sheaf (French *faisceau*, a bundle of stalks of wheat) is literally a bundle of stalks.

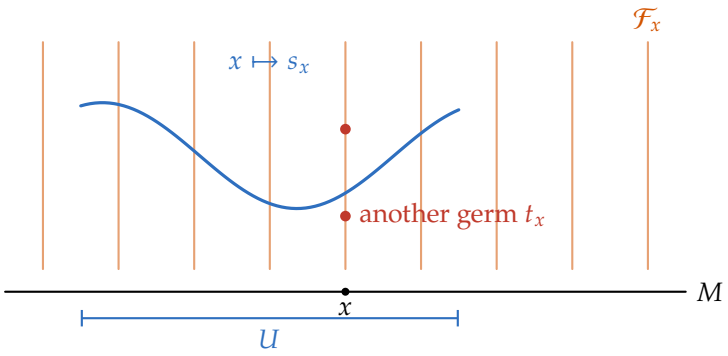

Figure 3.6: The étalé space of a sheaf: above each point x sits the stalk $\mathcal{F}_x$ (orange). A section s over U becomes a continuous choice of one germ in each stalk (blue curve). Two sections that agree near x pass through the same point of $\mathcal{F}_x$; a section with a different germ at x passes through a different point (red).

Reading Nash (p. 57, (3.2))

Nash introduces the stalk with the single line $\mathcal{F}_x = \varinjlim_{x \in U} \mathcal{F}(U)$ and the remark that stalks are used when we discuss sheaf cohomology. We will use them in exactly one place, but it is a crucial one: *a sequence of sheaves is called exact if it is exact on every stalk* (Section 3.2.3). Exactness on stalks is exactness "infinitely close to each point", which is the right notion of "locally exact".

3.1.4 Sheaves of sections of vector bundles

Nash's second rich source of sheaves is vector bundles. Recall (Chapter 1, Chapter T2) that a rank-k vector bundle $E \to M$ is described by an open cover $\{U_i\}$, local trivialisations $E|_{U_i} \cong U_i \times \mathbb{R}^k$ (or $\mathbb{C}^k$), and **transition functions** $g_{ij} : U_{ij} \to \mathrm{GL}(k)$ telling us how to translate between trivialisations. With the convention we will use throughout this part,

$$s_i = g_{ij}\, s_j \quad \text{on } U_{ij}, \tag{3.5}$$

where $s_i : U_i \to \mathbb{R}^k$ is the local component vector of a section s in the i-th trivialisation. Consistency on triple overlaps ($s_i = g_{ij}s_j = g_{ij}g_{jk}s_k$ must equal $g_{ik}s_k$) forces the **cocycle condition**

$$g_{ij}\, g_{jk} = g_{ik} \quad \text{on } U_{ijk} = U_i \cap U_j \cap U_k, \qquad g_{ii} = 1, \quad g_{ji} = g_{ij}^{-1}. \tag{3.6}$$

Remember this equation: it will reappear as "$\delta g = 1$" in Čech cohomology.

Working definition 3.4 (sheaf of sections)

For a vector bundle $E \to M$ let $\mathcal{F}(U) = \Gamma(U, E)$ be the smooth (or continuous, or, if M and E are complex, holomorphic) sections of E over U [maps that pick one vector $s(x)$ in the fibre E_x over each point $x \in U$], with restriction the ordinary restriction of sections. In terms of a trivialising cover, a section over U is a collection of vector-valued functions s_i on $U \cap U_i$ obeying (3.5).

Being a smooth section is a local condition, so this is a sheaf by the same argument as Example 3.1. Nash's point is that almost every sheaf we need is of this kind, for a bundle E "reflecting the geometry of M".

- $E = M \times \mathbb{R}$ (trivial line bundle): sections are functions, and we get back $\mathcal{E}$.

- $E = T^*M$: sections are smooth 1-forms. For $E = \Lambda^p T^*M$ the sections are smooth p-forms; Nash writes $\mathcal{E}^p$ for this sheaf, so $\mathcal{E}^p(U) = \Omega^p(U)$ and $\mathcal{E}^0 = \mathcal{E}$.

- M complex, E the holomorphic cotangent bundle (spanned by $\mathrm{d}z^1, \dots, \mathrm{d}z^n$) and its exterior powers: the sheaf Ω^p of *holomorphic* p-forms, $\omega = \frac{1}{p!}\omega_{i_1 \dots i_p}(z)\,\mathrm{d}z^{i_1} \wedge \cdots \wedge \mathrm{d}z^{i_p}$ with holomorphic coefficients. In particular $\Omega^0 = \mathcal{O}$.

- $\mathcal{O}^*$: nowhere-vanishing holomorphic functions. Sums of nonvanishing functions can vanish ($1 + (-1) = 0$), so $\mathcal{O}^*$ is not a group under addition. It is a group under *multiplication*, and Nash stresses that $\mathcal{O}^*$ is to be viewed as a **multiplicative sheaf**: its "zero" is the constant function 1, and "$f - g$" means f/g. Similarly $\mathcal{E}^*$ denotes nowhere-vanishing smooth complex functions.

Worked example 3.5: The Möbius bundle as a sheaf

Cover S^1 (angle θ) by two arcs $U_1 = \{-\varepsilon < \theta < \pi + \varepsilon\}$ and $U_2 = \{\pi - \varepsilon < \theta < 2\pi + \varepsilon\}$. The overlap has two components, A near $\theta = 0$ and B near $\theta = \pi$. The trivial line bundle has $g_{12} = +1$ on both components; the **Möbius bundle** has

$$g_{12} = +1 \text{ on } B, \qquad g_{12} = -1 \text{ on } A.$$

There are no triple overlaps, so the cocycle condition is empty. A section is a pair of functions s_1 on U_1 and s_2 on U_2 with $s_1 = s_2$ on B and $s_1 = -s_2$ on A. Near any point the sheaf of sections looks exactly like $\mathcal{E}$ (on a small arc the section is just a function). Globally, a continuous section must vanish somewhere:

$$\begin{aligned} s_1(\text{near } 0) &\overset{(1)}{=} -s_2(\text{near } 2\pi) \\ &\overset{(2)}{=} -\big(\text{value obtained by continuing } s \text{ once round}\big), \end{aligned}$$

(1) The transition rule on A, where the angle 0 in U_1 is the angle 2π in U_2.
(2) Going from $\theta = 0$ in U_1 to $\theta = \pi$, across B with no sign change, then on through U_2 up to 2π, we follow the section continuously round the circle.

So a continuous section returns with its sign flipped, and by the intermediate value theorem it has a zero. The sheaves "smooth functions" and "smooth sections of the Möbius bundle" agree on every small open set (all their stalks are the same), but their global sections differ. Telling such sheaves apart is exactly what H^1 will do (Example 3.15).

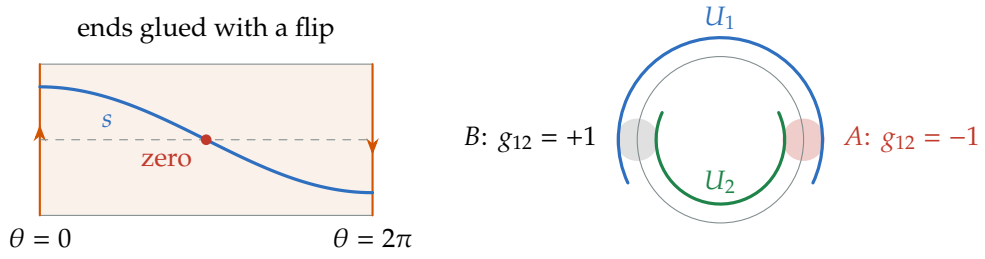

Figure 3.7: Left: the Möbius bundle over S^1, cut open along $\theta = 0$. The two ends of the strip are glued with a flip (the arrows point opposite ways), so a section must return to minus its starting value. The blue section $s(\theta) = 0.7\cos(\theta/2)$ therefore crosses zero (red dot). Right: the same bundle as gluing data. Two arcs overlap in two pieces; on A the transition function is -1, on B it is $+1$.

Worked example 3.6: The line bundles $O(n)$ over $\mathbb{CP}^1$ and their sections

Cover the Riemann sphere $\mathbb{CP}^1 = \mathbb{C} \cup \{\infty\}$ by $U_0 = \mathbb{C}$ with coordinate z and $U_1 = \mathbb{CP}^1 \setminus \{0\}$ with coordinate $w = 1/z$. The overlap is $U_{01} = \mathbb{C}^*$. For each integer n define a holomorphic line bundle $\mathcal{O}(n)$ by the single transition function

$$g_{01}(z) = z^{\,n} \in \mathcal{O}^*(U_{01}), \qquad \text{i.e.} \quad s_0(z) = z^n\, s_1(1/z) \text{ on } \mathbb{C}^*. \tag{3.7}$$

(Again no triple overlaps, so no cocycle condition.) Which global holomorphic sections are there? Write $s_0(z) = \sum_{k\ge 0} a_k z^k$, an entire function. Then

$$\begin{aligned} s_1(w) &\overset{(1)}{=} w^{\,n}\, s_0(1/w) \\ &\overset{(2)}{=} \sum_{k\ge 0} a_k\, w^{\,n-k}, \end{aligned}$$

(1) Invert (3.7): $s_1(1/z) = z^{-n} s_0(z)$, and put $z = 1/w$.
(2) Substitute the Taylor series of s_0.

For s_1 to be holomorphic at $w = 0$ we need $a_k = 0$ whenever $n - k < 0$. So

$$\Gamma(\mathbb{CP}^1, \mathcal{O}(n)) = \{\, a_0 + a_1 z + \cdots + a_n z^n \,\}, \qquad \dim \Gamma(\mathbb{CP}^1, \mathcal{O}(n)) = \begin{cases} n+1, & n \ge 0, \\ 0, & n < 0. \end{cases}$$

All the bundles $\mathcal{O}(n)$ look alike locally (every stalk is $\mathcal{O}_x$), but the dimensions of their global sections differ. For $n = 0$ we recover Liouville's theorem on the Riemann sphere: the only global holomorphic functions are the constants. We will compute the "higher" version of this count, $H^1(\mathbb{CP}^1; \mathcal{O}(n))$, in Example 3.18; the difference $\dim H^0 - \dim H^1 = n + 1$ is the simplest instance of the Riemann–Roch theorem, which Chapter 4 and Chapter 5 develop.

Coefficients in a bundle

Nash next combines the geometric sheaves with an *additional* bundle E. The sheaf $\mathcal{E}^p(E)$ of **p-forms with values in E** has sections

$$\mathcal{E}^p(E)(U) = \Gamma\big(U, \Lambda^p T^*M \otimes E\big). \tag{3.8}$$

This is Nash's (3.3). Concretely: over an open set U on which E is trivial, with a frame $e_1, \dots, e_k$, such a section is

$$\omega = \sum_{a=1}^{k} \omega^a \otimes e_a, \qquad \omega^a \in \Omega^p(U),$$

that is, a column vector of ordinary p-forms. On overlaps the column vectors are related by the transition matrices of E. This is familiar from gauge theory: the curvature of a connection on E is a section of $\mathcal{E}^2(\operatorname{End} E)$, a matrix of 2-forms that transforms by conjugation (Chapter T3). The holomorphic analogue is $\Omega^p(E)$. Using direct sums and tensor products of bundles we manufacture further sheaves such as $\mathcal{E}(E \otimes F)$ and $\mathcal{O}(E \oplus E \oplus \cdots)$.

Dictionary: Sheaves a physicist already uses

Sheaf	Physics meaning
$\mathcal{E}$, $\mathcal{E}^p$	smooth scalar fields, smooth p-form fields
$\underline{\mathbb{R}}$, $\underline{\mathbb{Z}}$	locally constant quantities: coupling constants, quantised charges
$\mathcal{E}^1(\mathfrak{g})$	local gauge potentials A on each patch
$\mathcal{E}^*$, $\mathcal{O}^*$	local $U(1)$ gauge transformations $e^{i\lambda}$ (smooth, or holomorphic)
$\Gamma(\,\cdot\,, L)$ for a line bundle L	wavefunctions of a charged particle in a background field
$\mathcal{O}$, Ω^p	holomorphic fields, e.g. chiral fields on a worldsheet

3.1.5 Why analysts like sheaves

Nash (p. 58) explains why sheaves are valuable in analysis. Two situations make differential forms awkward.

- *Non-compact manifolds.* Global integrals may diverge, and compactness arguments fail; but local statements ("near every point there is a solution") remain true.
- *Singular spaces.* Complex analytic spaces such as the cone $\{z_1^2 + z_2^2 + z_3^2 = 0\} \subset \mathbb{C}^3$ have singular points where there are no good local coordinates, so "differential form" is not even well defined there. But "holomorphic function on an open set" still makes sense (restrict holomorphic functions of z_1, z_2, z_3), so the sheaf $\mathcal{O}$ still exists.

The methods of partial differential equations are essentially local: they produce solutions near points. Sheaves are exactly the tool that takes local solvability and asks what survives globally. Combining the two gives a theory that works on this wider class of spaces. For us the main beneficiaries will be the Dolbeault theorem (Section 3.7) and, in Chapter 5, algebraic geometry, where sheaves are the basic language.

Reading Nash (pp. 56–59, (3.1)–(3.3))

Nash's §1 is a definition, three examples ($\mathcal{E}$, $\mathcal{A}$, $\mathcal{O}$), one non-example (bounded holomorphic functions, via Liouville), and a list of sheaves of sections: $\mathcal{E}^p$, Ω^p, $\Omega^0 = \mathcal{O}$, the multiplicative sheaf $\mathcal{O}^*$, and forms with values in a bundle, $\mathcal{E}^p(E)$ with sections $\Gamma(M, \Lambda^p T^*M \otimes E)$, his (3.3). His condition (ii), equation (3.1), is our pair of axioms (S1) locality and (S2) gluing, written for a cover $U = \bigcup U_i$. His "stalk" (3.2) is our Eq. (3.4); his footnote identifies stalks with germs. Everything in the section is local bookkeeping; the global content arrives in §2.

Recap

- A *presheaf* assigns a group $\mathcal{F}(U)$ to each open set, with restriction maps from big sets to small sets.
- A *sheaf* also satisfies locality (a section is determined by its restrictions) and gluing (compatible local sections glue). Local conditions (continuity, smoothness, holomorphicity, being a section of a bundle, satisfying a differential equation) give sheaves; global conditions (boundedness, constancy) do not.

- Main examples: $\mathcal{C}^0, \mathcal{E}, \mathcal{A}, \mathcal{O}$; $\mathcal{E}^p$, Ω^p; $\mathcal{O}^*$ and $\mathcal{E}^*$ (multiplicative); locally constant $\underline{\mathbb{R}}, \underline{\mathbb{Z}}$; sections of any bundle, e.g. Möbius or $\mathcal{O}(n)$; $\mathcal{E}^p(E)$.
- The *stalk* $\mathcal{F}_x$ is the group of germs at x: sections near x modulo agreement on a smaller neighbourhood.
- Different sheaves can have identical stalks everywhere but different global sections (trivial vs Möbius, $\mathcal{O}$ vs $\mathcal{O}(n)$). Measuring this is the job of cohomology.

3.2 Morphisms and exact sequences of sheaves

Nash's §2 begins by recalling ordinary cohomology $H^i(M; G)$ with coefficients in an abelian group G such as $\mathbb{Z}$, $\mathbb{R}$ or $\mathbb{Q}$ (Chapter 1). Sheaf cohomology replaces the fixed group G by a sheaf such as $\mathcal{E}$ or $\mathcal{O}$. The two theories overlap: the locally constant sheaf $\underline{\mathbb{R}}$ gives back $H^i(M; \mathbb{R})$.

Before defining anything, Nash makes a remark that organises the whole section: *cohomology is a measure of how far some sequence is from being exact*. So we first need sequences of sheaves, and a notion of exactness for them. This section supplies both, and then shows the basic phenomenon: a sequence of sheaves can be exact (locally) while its global sections are not. That failure is what sheaf cohomology measures.

3.2.1 Reminder: exact sequences of groups

A sequence of abelian groups and homomorphisms

$$A \xrightarrow{\alpha} B \xrightarrow{\beta} C$$

is **exact at** B if $\operatorname{Im}\alpha = \operatorname{Ker}\beta$. Read it as two statements: $\beta \circ \alpha = 0$ ("everything coming from A dies in C") and, conversely, everything that dies in C came from A. A **short exact sequence**

$$0 \longrightarrow A \xrightarrow{\alpha} B \xrightarrow{\beta} C \longrightarrow 0 \tag{3.9}$$

is exact at A, B and C. Exactness at A means α is injective (its kernel is the image of 0). Exactness at C means β is surjective (its image is the kernel of $C \to 0$, which is all of C). So A is a subgroup of B and $C \cong B/A$.

Worked example 3.7: Three short exact sequences to keep in mind

(a) $0 \to \mathbb{Z} \xrightarrow{\times 2} \mathbb{Z} \to \mathbb{Z}_2 \to 0$: the even integers inside the integers, with quotient "parity".

(b) $0 \to \mathbb{Z} \xrightarrow{i} \mathbb{R} \xrightarrow{e} U(1) \to 0$ with $e(x) = e^{2\pi i x}$. Check exactness in the middle:

$$e(x) = 1 \overset{(1)}{=} \iff e^{2\pi i x} = 1 \overset{(2)}{=} \iff x \in \mathbb{Z} = \operatorname{Im} i.$$

(1) Definition of e.

(2) $e^{2\pi i x} = \cos 2\pi x + i \sin 2\pi x$ equals 1 exactly when x is an integer.

And e is surjective because every unit complex number is $e^{i\phi}$ for some real ϕ; take $x = \phi/2\pi$. This sequence is the "one-point" version of the exponential sequence below: a phase is a real number modulo integers.

(c) $0 \to \mathbb{R} \to C^\infty(\mathbb{R}) \xrightarrow{\mathrm{d}/\mathrm{d}x} C^\infty(\mathbb{R}) \to 0$: the kernel of differentiation is the constants, and every smooth function is a derivative (integrate it). On the circle, the last map is *not* surjective, which is the first sign of topology; see Example 3.11.

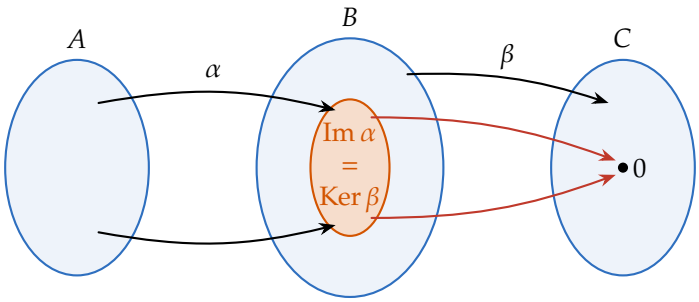

Figure 3.8: Exactness at B: the image of α (orange) is precisely the set of elements that β sends to 0 (red arrows). Elements of B outside the orange region have nonzero image in C.

3.2.2 Sheaf morphisms

A map between sheaves must act on sections over every open set, and it must not care whether we restrict before or after applying it.

Working definition 3.5 (sheaf morphism)

A **sheaf morphism** $m : \mathcal{A} \to \mathcal{B}$ is a collection of group homomorphisms [maps respecting addition, $m_U(s+t) = m_U(s) + m_U(t)$] $m_U : \mathcal{A}(U) \to \mathcal{B}(U)$, one for each open U, that commute with restriction: for $U \subset V$,

$$\begin{array}{ccc} \mathcal{A}(V) & \xrightarrow{m_V} & \mathcal{B}(V) \\ {\scriptstyle r_U^V}\downarrow & & \downarrow{\scriptstyle r_U^V} \\ \mathcal{A}(U) & \xrightarrow[m_U]{} & \mathcal{B}(U) \end{array} \qquad \text{i.e.} \qquad m_V(s)\big|_U = m_U\big(s|_U\big). \tag{3.10}$$

This is Nash's diagram (3.5). *Operational test:* the operation must be *local*: the value of $m(s)$ near a point depends only on s near that point. Pointwise operations and differential operators pass; integral operators (which smear over distances) usually fail.

Worked example 3.8: Morphisms we will use

- The exterior derivative $\mathrm{d} : \mathcal{E}^p \to \mathcal{E}^{p+1}$. Commuting with restriction is the statement that $\mathrm{d}(\omega|_U) = (\mathrm{d}\omega)|_U$: derivatives at a point only see a neighbourhood of the point.
- The inclusion $i : \underline{\mathbb{Z}} \to \mathcal{O}$ (a locally constant integer-valued function is a holomorphic function) and the inclusion $\underline{\mathbb{R}} \to \mathcal{E}$.
- The exponential $\exp : \mathcal{O} \to \mathcal{O}^*$, $f \mapsto e^{2\pi i f}$. It turns addition into multiplication: $e^{2\pi i(f+g)} = e^{2\pi i f} e^{2\pi i g}$, so it is a homomorphism from the additive group $\mathcal{O}(U)$ to the multiplicative group $\mathcal{O}^*(U)$.
- The operator $\bar\partial : \mathcal{E}^{p,q} \to \mathcal{E}^{p,q+1}$ on a complex manifold (Section 3.7).

A *non-example*: $\mathcal{E}(\mathbb{R}) \ni f \mapsto F(x) = \int_0^x f$ is not defined open set by open set in a way that commutes with restriction: on $U = (5, 6)$ the integral from 0 needs values of f outside U.

A morphism m induces maps on stalks, $m_x : \mathcal{A}_x \to \mathcal{B}_x$, $m_x(s_x) = (m_U s)_x$. This is well defined precisely because m commutes with restriction: if s and s' agree near x, so do $m(s)$ and $m(s')$.

3.2.3 Exact sequences of sheaves: exact on stalks

What should it mean for a sequence of sheaves

$$\mathcal{E} \xrightarrow{e} \mathcal{F} \xrightarrow{f} \mathcal{G} \tag{3.11}$$

to be exact? (This is Nash's (3.4)/(3.6); his $\mathcal{E}$ here is a generic sheaf, not the sheaf of smooth functions.) The naive answer, "exact on U for every open U", is too strong: it would already fail for the most basic example (the Poincaré lemma sequence below on the circle). The right answer is "exact near every point", and the precise version uses stalks.

Working definition 3.6 (exact sequence of sheaves)

The sequence (3.11) of sheaf morphisms is **exact** if for every $x \in M$ the induced sequence of stalks [germs at x, i.e. sections remembered only on arbitrarily small neighbourhoods of x]

$$\mathcal{E}_x \xrightarrow{e_x} \mathcal{F}_x \xrightarrow{f_x} \mathcal{G}_x \tag{3.12}$$

is an exact sequence of groups [the image of e_x is exactly the set of germs that f_x sends to 0] (Nash's (3.7)). *Operational test:* (i) $f \circ e = 0$; (ii) if $f(t) = 0$ for a section t near x, then *on some smaller neighbourhood of* x, $t = e(s)$ for some s.

The phrase "on some smaller neighbourhood" is the whole point. It is the sheaf-theoretic version of the physicist's "locally". Surjectivity of a sheaf map $f : \mathcal{F} \to \mathcal{G}$ means: every section of $\mathcal{G}$ can be lifted *near each point*, not necessarily globally.

Worked example 3.9: The exponential sequence

On any complex manifold M (for instance an open set in $\mathbb{C}$), the sequence

$$0 \longrightarrow \underline{\mathbb{Z}} \xrightarrow{i} \mathcal{O} \xrightarrow{\exp} \mathcal{O}^* \longrightarrow 0, \qquad \exp(f) = e^{2\pi i f}, \tag{3.13}$$

is exact. This is Nash's (3.8). Recall that $\mathcal{O}^*$ is multiplicative, so its "zero" is the constant function 1. We check the three exactness conditions at a point x.

Exact at $\underline{\mathbb{Z}}$ *(*i *injective).* A locally constant integer function that is zero as a holomorphic function is zero. Nothing to do.

Exact at $\mathcal{O}$ ($\operatorname{Ker}\exp = \operatorname{Im} i$). Let f be holomorphic near x with $\exp f = 1$. Then on a connected neighbourhood W of x

$$\begin{aligned} e^{2\pi i f(z)} = 1 \ \ \forall z \in W &\overset{(1)}{\Longrightarrow} \ f(z) \in \mathbb{Z} \ \ \forall z \in W \\ &\overset{(2)}{\Longrightarrow} \ f \text{ constant on } W \\ &\overset{(3)}{\Longrightarrow} \ f_x \in \operatorname{Im} i_x. \end{aligned}$$

(1) $e^{2\pi i w} = 1$ exactly when $w \in \mathbb{Z}$ (Example 3.7(b), now for complex w: $\left|e^{2\pi i w}\right| = e^{-2\pi \Im w} = 1$ forces $\Im w = 0$).

(2) A continuous function from a connected set to the discrete set $\mathbb{Z}$ is constant. (Nash's phrase "the exactness follows trivially from $(\exp \circ i)(n) = e^{2\pi i n} = 1$" covers the other inclusion, $\operatorname{Im} i \subset \operatorname{Ker}\exp$.)

(3) A constant integer function is in the image of i.

Exact at $\mathcal{O}^*$ (exp *surjective on stalks).* Let g be holomorphic and nonzero near x. Choose a small disc (or polydisc) W around x on which g is nonzero. On a disc, g'/g is holomorphic

and has a primitive, and

$$f(z) := \frac{1}{2\pi i}\Big(\log g(x) + \int_x^z \frac{g'(w)}{g(w)}\,\mathrm{d}w\Big) \quad \text{satisfies}$$
$$\frac{\mathrm{d}}{\mathrm{d}z}\Big(g\,e^{-2\pi i f}\Big) \overset{(1)}{=} (g' - 2\pi i f' g)e^{-2\pi i f} \overset{(2)}{=} 0,$$

(1) Product and chain rules.
(2) By construction $2\pi i f' = g'/g$.

so $g\,e^{-2\pi i f}$ is constant on W, and it equals 1 at $z = x$ by the choice of the constant $\log g(x)$ (any branch). Hence $g = e^{2\pi i f}$ on W. The integral is path-independent because a disc is simply connected (Cauchy's theorem).

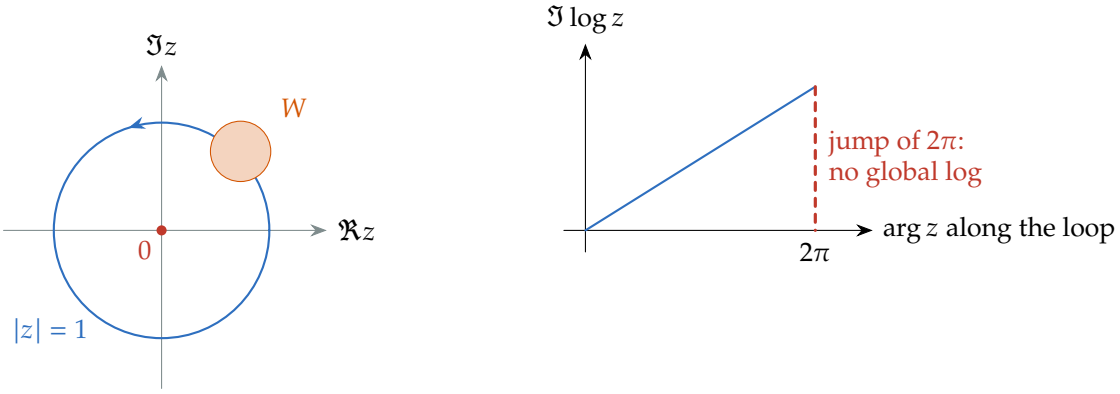

Figure 3.9: The function $g(z) = z$ on $M = \mathbb{C}^*$. Near any point, e.g. on the small disc W (orange), z has a logarithm, so $z = e^{2\pi i f}$ locally and exp is surjective on stalks. Following the logarithm once round the loop $|z| = 1$ (left) adds $2\pi i$ (right), so there is no global f with $z = e^{2\pi i f}$: exp is not surjective on global sections.

Worked example 3.10: Poincaré-lemma sequences

Let $\mathcal{Z}^p \subset \mathcal{E}^p$ be the sheaf of *closed* p-forms ($\mathrm{d}\omega = 0$). Then for $p \geq 0$

$$0 \to \underline{\mathbb{R}} \to \mathcal{E}^0 \xrightarrow{\mathrm{d}} \mathcal{Z}^1 \to 0, \qquad 0 \to \mathcal{Z}^p \hookrightarrow \mathcal{E}^p \xrightarrow{\mathrm{d}} \mathcal{Z}^{p+1} \to 0 \tag{3.14}$$

are exact sequences of sheaves. Exactness at the left and middle is easy: d lands in closed forms because $\mathrm{d}^2 = 0$; the kernel of d on functions is the locally constant functions (so $\mathcal{Z}^0 = \underline{\mathbb{R}}$, as Nash notes); and the kernel of $\mathrm{d} : \mathcal{E}^p \to \mathcal{Z}^{p+1}$ is $\mathcal{Z}^p$ by definition. Surjectivity on stalks is the **Poincaré lemma**: *on a ball, every closed form is exact.*
Here is the explicit primitive for a closed 1-form $\alpha = \alpha_\mu\,\mathrm{d}x^\mu$ on a ball centred at 0:

$$f(x) = \int_0^1 x^\mu\,\alpha_\mu(tx)\,\mathrm{d}t. \tag{3.15}$$

Check:

$$\partial_\nu f(x) \overset{(1)}{=} \int_0^1 \Big(\alpha_\nu(tx) + t\,x^\mu(\partial_\nu\alpha_\mu)(tx)\Big)\mathrm{d}t$$
$$\overset{(2)}{=} \int_0^1 \Big(\alpha_\nu(tx) + t\,x^\mu(\partial_\mu\alpha_\nu)(tx)\Big)\mathrm{d}t$$

$$\overset{(3)}{=} \int_0^1 \frac{\mathrm{d}}{\mathrm{d}t}\Big(t\,\alpha_\nu(tx)\Big)\mathrm{d}t \;=\; \alpha_\nu(x).$$

(1) Differentiate under the integral; ∂_ν hits the explicit x^μ (giving δ^μ_ν) and the argument tx (giving a factor t by the chain rule).
(2) Closedness, $\mathrm{d}\alpha = 0$, means $\partial_\nu\alpha_\mu = \partial_\mu\alpha_\nu$.
(3) $\frac{\mathrm{d}}{\mathrm{d}t}\alpha_\nu(tx) = x^\mu(\partial_\mu\alpha_\nu)(tx)$, so the integrand is a total t-derivative; evaluate between 0 and 1.

The same trick for a divergence-free magnetic field $\vec{B}$ in $\mathbb{R}^3$ gives the familiar formula $\vec{A}(\vec{x}) = \int_0^1 t\,\vec{B}(t\vec{x})\times\vec{x}\,\mathrm{d}t$ with $\nabla\times\vec{A} = \vec{B}$: the Poincaré lemma for 2-forms. The formula needs every segment from 0 to x to stay in the domain (a ball, or any star-shaped set). On a domain with a hole it can fail, and that is where topology enters.

There is also a smooth version of the exponential sequence. Let $\mathcal{E}_{\mathbb{C}}$ be smooth complex functions and $\mathcal{E}^*$ smooth nowhere-zero complex functions. Then

$$0 \longrightarrow \underline{\mathbb{Z}} \longrightarrow \mathcal{E}_{\mathbb{C}} \xrightarrow{\exp} \mathcal{E}^* \longrightarrow 0, \qquad \exp(f) = e^{2\pi i f}, \tag{3.16}$$

is exact on any manifold, by the same argument (a smooth nonvanishing function on a ball has a smooth logarithm, obtained by integrating $\mathrm{d}g/g$ along radial segments as in (3.15)).

3.2.4 Global sections: exact on the left, not on the right

Now take a short exact sequence of sheaves

$$0 \longrightarrow \mathcal{E} \xrightarrow{e} \mathcal{F} \xrightarrow{f} \mathcal{G} \longrightarrow 0 \tag{3.17}$$

(Nash's (3.9)) and look at global sections, i.e. at the groups of sections over all of M:

$$0 \longrightarrow \mathcal{E}(M) \xrightarrow{e_M} \mathcal{F}(M) \xrightarrow{f_M} \mathcal{G}(M) \longrightarrow 0. \tag{3.18}$$

This is Nash's (3.10). He says "it is easy to check" that it can only fail to be exact at the right-hand end. Here is the check.

e_M is injective. If $e_M(s) = 0$, then every germ $e_x(s_x) = 0$, so $s_x = 0$ for every x (stalks are exact at $\mathcal{E}_x$). A section all of whose germs vanish is zero, by the locality axiom (S1).

Exact at $\mathcal{F}(M)$. Clearly $f_M \circ e_M = 0$ (it is zero on every stalk, hence zero by (S1)). Conversely let $t \in \mathcal{F}(M)$ with $f_M(t) = 0$. By stalk exactness, each x has a neighbourhood U_x and a section $s^{(x)} \in \mathcal{E}(U_x)$ with $e(s^{(x)}) = t|_{U_x}$. On an overlap $U_x \cap U_y$,

$$e\big(s^{(x)} - s^{(y)}\big) \overset{(1)}{=} t|_{U_x\cap U_y} - t|_{U_x\cap U_y} = 0 \quad \overset{(2)}{\Longrightarrow} \quad s^{(x)} = s^{(y)} \text{ on } U_x \cap U_y,$$

(1) Both local lifts map to the same global t.
(2) e is injective (on stalks, hence on sections over any open set, by the argument just given).

So the local lifts are compatible and glue, by (S2), to $s \in \mathcal{E}(M)$ with $e_M(s) = t$.

f_M need not be surjective. Every $g \in \mathcal{G}(M)$ can be lifted locally, $g|_{U_i} = f(t_i)$. The local lifts t_i are ambiguous up to adding something from $\mathcal{E}$, and they may not agree on overlaps. If we cannot choose them to agree, there is no global lift. Two examples show that this really happens.

Worked example 3.11: Global surjectivity fails: two classic cases

(a) The exponential sequence on $M = \mathbb{C}^*$. The function $g(z) = z$ is a global section of $\mathcal{O}^*(\mathbb{C}^*)$. Suppose $z = e^{2\pi i f(z)}$ for a holomorphic f on $\mathbb{C}^*$. Differentiating, $1 = 2\pi i f'(z)\, z$, so $f'(z) = 1/(2\pi i z)$. Integrate round the unit circle:

$$0 \overset{(1)}{=} \oint_{|z|=1} f'(z)\,\mathrm{d}z \overset{(2)}{=} \frac{1}{2\pi i}\oint_{|z|=1}\frac{\mathrm{d}z}{z} \overset{(3)}{=} \frac{1}{2\pi i}\int_0^{2\pi}\frac{i e^{i\phi}\,\mathrm{d}\phi}{e^{i\phi}} = 1,$$

(1) The integral of the derivative of a single-valued function round a closed loop is zero (fundamental theorem of calculus).
(2) Substitute $f' = 1/(2\pi i z)$.
(3) Parametrise $z = e^{i\phi}$, $\mathrm{d}z = i e^{i\phi}\mathrm{d}\phi$.

Contradiction: $0 = 1$. So $\exp_M : \mathcal{O}(\mathbb{C}^*) \to \mathcal{O}^*(\mathbb{C}^*)$ is not surjective. The obstruction is the winding number of g round the origin (Figure 3.9).
(b) The Poincaré sequence on $M = S^1$. The 1-form $\mathrm{d}\theta$ is a global section of $\mathcal{Z}^1(S^1)$ (it is well defined although θ is not: $\mathrm{d}\theta = (x\,\mathrm{d}y - y\,\mathrm{d}x)/(x^2+y^2)$). If $\mathrm{d}\theta = \mathrm{d}F$ for a smooth function F on S^1, then $2\pi = \oint \mathrm{d}\theta = \oint \mathrm{d}F = 0$, again a contradiction. So $\mathrm{d} : \mathcal{E}^0(S^1) \to \mathcal{Z}^1(S^1)$ is not surjective, although it is surjective on every stalk (Poincaré lemma on small arcs).

Both obstructions are integers, or real numbers, attached to loops. Sheaf cohomology will package them: in (a) the obstruction lives in $H^1(\mathbb{C}^*;\underline{\mathbb{Z}}) \cong \mathbb{Z}$, in (b) in $H^1(S^1;\underline{\mathbb{R}}) \cong \mathbb{R}$.

Physical picture: Gauge theory reading

In (b), think of $\mathrm{d}\theta$ as a flat $U(1)$ gauge field a on a circle (an Aharonov–Bohm flux line piercing the plane). Locally it is pure gauge, $a = \mathrm{d}\lambda$, because every closed form is locally exact. Globally it is not, and the obstruction $\oint a$ is the Aharonov–Bohm phase. Sheaf cohomology is the systematic way of computing all such "locally pure gauge but globally not" configurations.

3.2.5 Soft sheaves, fine sheaves and partitions of unity

When is (3.18) exact after all? Nash gives a sufficient condition: the left-hand sheaf $\mathcal{E}$ should be able to extend sections from small sets to all of M. Sheaves of smooth objects can do this, because smooth functions can be cut off with bump functions. Holomorphic functions and locally constant functions cannot.

Bump functions

The basic tool is a smooth function that is 1 on one set and 0 outside a slightly larger one. Start from

$$\phi(t) = \begin{cases} e^{-1/t}, & t > 0, \\ 0, & t \le 0, \end{cases} \tag{3.19}$$

which is smooth by the argument of Example 3.4(c). The smooth step

$$h(t) = \frac{\phi(t)}{\phi(t) + \phi(1-t)} \tag{3.20}$$

is 0 for $t \le 0$, 1 for $t \ge 1$, smooth everywhere (the denominator never vanishes, since at least one of $t, 1-t$ is positive). Products such as $h\big(\frac{x-a}{\varepsilon}\big)\,h\big(\frac{b-x}{\varepsilon}\big)$ give bumps equal to 1 on $[a+\varepsilon, b-\varepsilon]$

and 0 outside (a,b). In $\mathbb{R}^n$ the function $h\big(2-|x|\big)$ is 1 on the ball of radius 1 and 0 outside the ball of radius 2.

Working definition 3.7 (partition of unity)

A **partition of unity** subordinate to an open cover $\{U_i\}$ of M is a family of smooth functions $\rho_i : M \to [0,1]$ with

(i) $\operatorname{supp}\rho_i \subset U_i$ [the closure of the set where $\rho_i \neq 0$ lies inside U_i];

(ii) locally finite: each point has a neighbourhood meeting only finitely many $\operatorname{supp}\rho_i$;

(iii) $\sum_i \rho_i = 1$ everywhere.

Construction: pick bumps $\psi_i \geq 0$ supported in U_i whose positivity sets still cover M, and set $\rho_i = \psi_i / \sum_j \psi_j$. Every paracompact [every open cover can be refined to a locally finite one. Every manifold we meet is paracompact] manifold (Section 3.3.5) admits partitions of unity subordinate to any open cover.

Worked example 3.12: A partition of unity on the circle

Use the two-arc cover of Example 3.5: $U_1 = (-\varepsilon, \pi+\varepsilon)$, $U_2 = (\pi-\varepsilon, 2\pi+\varepsilon)$, overlaps A near 0 and B near π. Define

$$\rho_1(\theta) = h\!\left(\frac{\theta+\varepsilon}{2\varepsilon}\right) h\!\left(\frac{\pi+\varepsilon-\theta}{2\varepsilon}\right) \quad \left(-\tfrac{\pi}{2} \leq \theta \leq \tfrac{3\pi}{2}\right), \qquad \rho_2 = 1-\rho_1.$$

Then ρ_1 rises from 0 to 1 across A, equals 1 on the middle of U_1, and falls back to 0 across B; so $\operatorname{supp}\rho_1 \subset U_1$. Its complement ρ_2 is 1 on the middle of U_2 and vanishes on the middle of U_1; so $\operatorname{supp}\rho_2 \subset U_2$ (Figure 3.10). They add to 1 by construction.

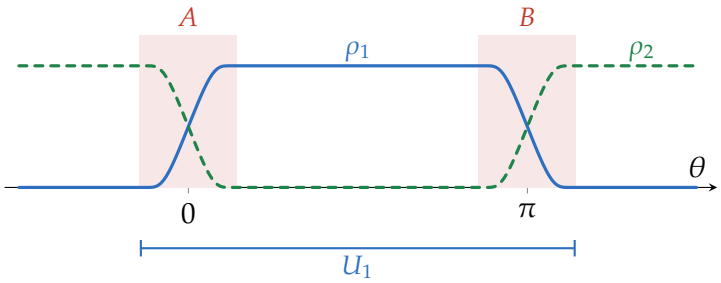

Figure 3.10: A smooth partition of unity on S^1 (the angle runs from $-\pi/2$ to $3\pi/2$, one full turn). ρ_1 (solid) lives inside U_1, $\rho_2 = 1-\rho_1$ (dashed) lives inside U_2, and all the switching happens inside the overlaps A and B (shaded). No holomorphic or locally constant function can do this.

Soft sheaves

Working definition 3.8 (soft sheaf)

A sheaf $\mathcal{F}$ is **soft** if every section defined on (a neighbourhood of) a *closed* set $K \subset M$ agrees on K with some global section [a section over all of M]. Nash's (3.11) expresses this as surjectivity of restriction $r_U^M : \mathcal{F}(M) \to \mathcal{F}(U)$. *Operational test:* can you multiply a local section by a cut-off function and extend by zero?

Watch out: Open versus closed sets in (3.11)

Taken literally for *open* U, Nash's condition (3.11) fails even for smooth functions: $1/x$ on $U = (0, \infty)$ is smooth but is not the restriction of any smooth function on $\mathbb{R}$. The correct notion of softness uses closed sets (or, equivalently for manifolds, "given s on an open U and a closed $K \subset U$, there is a global section equal to s near K"). This is Wells' definition, and it is what the bump-function argument proves: multiply s by a bump ψ equal to 1 near K and supported in U, and extend ψs by zero.

With this definition $\mathcal{E}$ and every $\mathcal{E}^p$ are soft (by the bump-function argument), and so is $\mathcal{E}^p(E)$ for any bundle E. The sheaves $\mathcal{O}$, $\underline{\mathbb{Z}}$, $\underline{\mathbb{R}}$ are not soft: a holomorphic function on a small disc in $\mathbb{CP}^1$ is not the restriction of a global holomorphic function unless it is constant; a locally constant function equal to 0 on one small disc and 1 on another cannot be extended to a connected M.

Fine sheaves

In practice we use a slightly stronger and more checkable property.

Working definition 3.9 (fine sheaf)

A sheaf $\mathcal{F}$ is **fine** if it admits partitions of unity: for every locally finite open cover $\{U_i\}$ there are sheaf morphisms [maps acting on sections over every open set, compatible with restriction] $\eta_i : \mathcal{F} \to \mathcal{F}$ with $\eta_i(s) = 0$ outside a closed subset of U_i and $\sum_i \eta_i = \mathrm{id}$. *Operational test:* if $\mathcal{F}$ is a sheaf of modules over smooth functions (you can multiply its sections by smooth functions), it is fine: take $\eta_i(s) = \rho_i s$ for a partition of unity $\{\rho_i\}$.

Fine (hence soft)	Not fine	Why not
$\mathcal{E}$, $\mathcal{E}_{\mathbb{C}}$, $\mathcal{E}^p$	$\underline{\mathbb{Z}}$, $\underline{\mathbb{R}}$	ρf is not locally constant
$\mathcal{E}^p(E)$, $\mathcal{E}^{p,q}$	$\mathcal{O}$, Ω^p	ρf is not holomorphic
$\Gamma(\cdot, E)$ smooth sections	$\mathcal{O}^*$, $\mathcal{E}^*$	multiplicative; ρg may vanish

Nash states, without proof (he refers to Wells), that fine sheaves are soft and that *soft sheaves have no higher cohomology*: $H^q(M; \mathcal{F}) = 0$ for $q > 0$. The proof for fine sheaves is short and important enough that we give it now in the simplest case, and in general in Section 3.3.7.

Key idea: Fine on the left makes global sections exact

If in $0 \to \mathcal{E} \to \mathcal{F} \to \mathcal{G} \to 0$ the sheaf $\mathcal{E}$ is fine, then $\mathcal{F}(M) \to \mathcal{G}(M)$ is surjective, so (3.18) is exact.

Why. Take $g \in \mathcal{G}(M)$. Stalk surjectivity gives a cover $\{U_i\}$ (which we may take locally finite) and local lifts $t_i \in \mathcal{F}(U_i)$ with $f(t_i) = g|_{U_i}$. On overlaps the lifts differ by something that f kills, hence by the image of a section of $\mathcal{E}$:

$$t_j - t_i = e(c_{ij}), \qquad c_{ij} \in \mathcal{E}(U_{ij}). \tag{3.21}$$

On a triple overlap, $(t_k - t_j) - (t_k - t_i) + (t_j - t_i) = 0$, and e is injective, so

$$c_{jk} - c_{ik} + c_{ij} = 0 \quad \text{on } U_{ijk}. \tag{3.22}$$

We want to correct each t_i by $e(h_i)$ so that the corrected lifts agree. Use the partition of unity $\{\rho_k\}$ and set

$$h_i = \sum_k \rho_k \, c_{ki} \ \in \mathcal{E}(U_i) \tag{3.23}$$

(each term is defined on $U_k \cap U_i$ and vanishes near the edge of U_k, so it extends by zero to all of U_i). Then on U_{ij}

$$h_j - h_i \overset{(1)}{=} \sum_k \rho_k (c_{kj} - c_{ki}) \overset{(2)}{=} \sum_k \rho_k \, c_{ij} \overset{(3)}{=} c_{ij}.$$

(1) Definition (3.23), subtracted.
(2) The cocycle identity (3.22) for the triple (k, i, j) reads $c_{ij} - c_{kj} + c_{ki} = 0$, i.e. $c_{kj} - c_{ki} = c_{ij}$.
(3) $\sum_k \rho_k = 1$.

Now put $t_i' = t_i - e(h_i)$. Then $t_j' - t_i' = e(c_{ij}) - e(h_j - h_i) = 0$, so the t_i' glue to a global $t \in \mathcal{F}(M)$, and $f(t) = g$ because $f \circ e = 0$. The whole argument is: *local lifts disagree by a cocycle; a partition of unity writes the cocycle as a difference; correct the lifts.* The next section turns "cocycle" and "difference" into the definition of Čech cohomology.

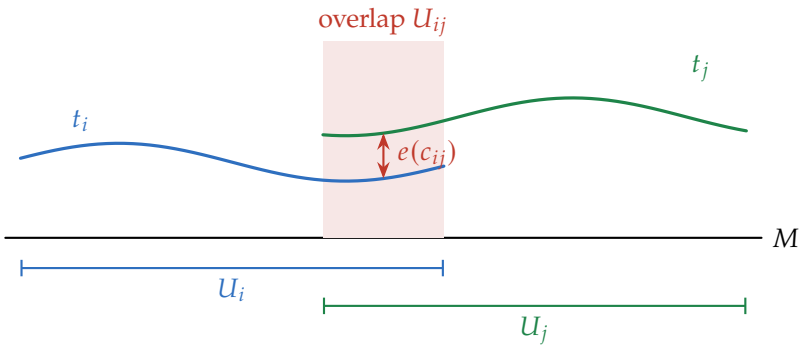

Figure 3.11: Local lifts t_i and t_j of the same global section g disagree on the overlap by $e(c_{ij})$, a section of the kernel sheaf. If the c_{ij} can be written as differences $h_j - h_i$ (which a partition of unity achieves when $\mathcal{E}$ is fine), shifting each lift by $e(h_i)$ removes the disagreement and the lifts glue.

Reading Nash (pp. 59–61, (3.4)–(3.11))

Nash's sequence $\mathcal{E} \xrightarrow{e} \mathcal{F} \xrightarrow{f} \mathcal{G}$ in (3.4) uses $\mathcal{E}$ as a generic sheaf, not the sheaf of smooth functions; beware the clash of notation. His (3.5) is our commuting square (3.10); (3.6)–(3.7) define exactness by stalks; (3.8) is the exponential sequence, with $\exp f = e^{2\pi i f}$ so that the kernel is exactly $\mathbb{Z}$. His claim that (3.10) "can only fail to be exact at its right-hand end" is Section 3.2.4; the extension property (3.11) should be read with closed sets (see the pitfall). He also asserts that $H^q(M; \mathcal{F}) = 0$ for $q > 0$ when $\mathcal{F}$ is soft, that $\mathcal{E}$ and $\mathcal{E}^p$ are soft, and that fine sheaves (those admitting a locally finite partition of unity) are a subclass of soft sheaves. We have explained the mechanism above; Section 3.3.7 gives it in general.

Recap

- A sheaf morphism is a family of homomorphisms commuting with restriction, i.e. a *local* operation (d, $\bar{\partial}$, exp, inclusions).
- A sequence of sheaves is exact if it is exact on every stalk: "locally exact". Key examples: the exponential sequence $0 \to \mathbb{Z} \to \mathcal{O} \to \mathcal{O}^* \to 0$ and the Poincaré-lemma sequences $0 \to \mathcal{Z}^p \to \mathcal{E}^p \to \mathcal{Z}^{p+1} \to 0$.
- On global sections, a short exact sequence of sheaves gives a sequence that is exact except possibly at the right end. Failures: z on $\mathbb{C}^*$ has no global logarithm; $\mathrm{d}\theta$ on S^1 has no global primitive.

- Smooth objects can be cut off with bump functions: the sheaves $\mathcal{E}$, $\mathcal{E}^p$, $\mathcal{E}^p(E)$ are fine (and soft). If the left sheaf is fine, global sections are exact. The mechanism is a partition-of-unity correction of a cocycle.

3.3 Čech cohomology

At the end of the last section we met a very specific piece of bookkeeping. Local lifts t_i of a global section disagreed on overlaps by amounts c_{ij}; these amounts satisfied $c_{jk} - c_{ik} + c_{ij} = 0$ on triple overlaps; and if we could write $c_{ij} = h_j - h_i$, the disagreement could be removed. Exactly the same pattern appears for vector bundles: transition functions g_{ij} obey $g_{ij}g_{jk} = g_{ik}$, and changing trivialisations replaces g_{ij} by $h_i g_{ij} h_j^{-1}$.

So there is a recurring question:

> *Given data c_{ij} on the overlaps of a cover that is consistent on triple overlaps, is it just the "difference" of data h_i on the open sets themselves?*

Čech cohomology is the systematic answer, in every degree at once. It is the construction Nash uses to define sheaf cohomology (pp. 61–62, equations (3.12)–(3.17)). Its great virtue for us is that it is *computable*: for a sensible cover, everything reduces to finite matrices.

3.3.1 Covers, overlaps and the nerve

Fix an open cover $\mathcal{U} = \{U_i\}_{i \in I}$ of M (Nash writes $O = \{O_\alpha\}$). We label the index set by integers and use the shorthand

$$U_{ij} = U_i \cap U_j, \qquad U_{ijk} = U_i \cap U_j \cap U_k, \qquad U_{i_0 i_1 \cdots i_q} = U_{i_0} \cap U_{i_1} \cap \cdots \cap U_{i_q}.$$

A list $(i_0, \dots, i_q)$ with $U_{i_0 \cdots i_q} \neq \varnothing$ is what Nash calls a Δ: "a collection $(O_1, \dots, O_{q+1})$ of $q+1$ of the O_α with non-empty intersection".

A useful picture is the **nerve** of the cover. Draw one vertex for each open set, an edge between i and j whenever $U_{ij} \neq \varnothing$, a filled triangle on i, j, k whenever $U_{ijk} \neq \varnothing$, a solid tetrahedron for each non-empty fourfold overlap, and so on. The result is a combinatorial skeleton of M (Figure 3.12). For a good cover (defined in Section 3.3.5) the nerve has the same shape as M, up to deformation, and Čech cohomology with constant coefficients is just the cohomology of this skeleton.

3.3.2 Cochains and the coboundary

Working definition 3.10 (Čech cochains)

A **Čech q-cochain** of the cover $\mathcal{U}$ with coefficients in the sheaf $\mathcal{F}$ is a choice of one section [one allowed local object, for $\underline{\mathbb{R}}$ one real number per connected component]

$$c_{i_0 i_1 \cdots i_q} \in \mathcal{F}\left(U_{i_0 i_1 \cdots i_q}\right)$$

for every $(q+1)$-fold overlap [the intersection $U_{i_0} \cap \cdots \cap U_{i_q}$ of $q+1$ sets of the cover]. We require the choice to be **alternating**: swapping two indices flips the sign ($c_{ji} = -c_{ij}$,

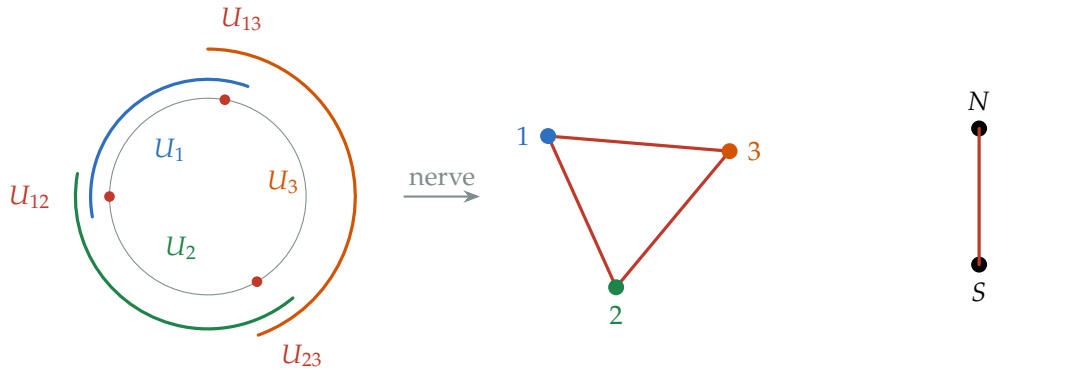

Figure 3.12: The nerve of a cover. Left: three arcs on a circle overlap in pairs (red dots) but never all three at once, so the nerve (middle) is a hollow triangle, which is a circle again. Right: two caps covering S^2 overlap in an annulus; the nerve is a single edge, which has lost the "hole" of the sphere. The first cover is good; the second is not, and it will give the wrong H^2.

$c_{jik} = -c_{ijk}, \dots$), and a cochain with a repeated index is zero. The q-cochains form a group

$$C^q(\mathcal{U};\mathcal{F}) = \prod_{i_0<i_1<\cdots<i_q} \mathcal{F}\left(U_{i_0\cdots i_q}\right). \tag{3.24}$$

This is Nash's (3.12), $C^q(O,\mathcal{F}) = \mathcal{F}(\Delta)$. *Operational recipe:* list the non-empty overlaps with increasing indices; a q-cochain is a column vector with one entry (a section) per $(q+1)$-fold overlap.

In low degrees:

- a 0-cochain is a section f_i on each open set U_i (no compatibility required);
- a 1-cochain is a section c_{ij} on each double overlap U_{ij};
- a 2-cochain is a section n_{ijk} on each triple overlap U_{ijk}.

If an overlap $U_{i_0\cdots i_q}$ has several connected components and $\mathcal{F} = \underline{\mathbb{R}}$, the "section" is one real number per component. This will matter in almost every example.

Working definition 3.11 (Čech coboundary)

The **coboundary** $\delta : C^q(\mathcal{U};\mathcal{F}) \to C^{q+1}(\mathcal{U};\mathcal{F})$ is

$$(\delta c)_{i_0 i_1 \cdots i_{q+1}} = \sum_{k=0}^{q+1} (-1)^k \, c_{i_0\cdots \widehat{i_k} \cdots i_{q+1}}\Big|_{U_{i_0\cdots i_{q+1}}}, \tag{3.25}$$

where the hat means "omit this index". This is Nash's (3.13), with his restriction map $r^{\Delta}_{\Delta_i}$ written as "|" [cutting a section down to the smaller overlap]. *Operational recipe:* to evaluate δc on an overlap of $q+2$ sets, drop each index in turn, restrict the corresponding entry of c to the smaller set, and add with alternating signs.

Written out in the three degrees we will use constantly (Nash calls δ simply d; we reserve d

for the exterior derivative):

$$(\delta f)_{ij} = f_j - f_i, \tag{3.26}$$
$$(\delta c)_{ijk} = c_{jk} - c_{ik} + c_{ij}, \tag{3.27}$$
$$(\delta n)_{ijkl} = n_{jkl} - n_{ikl} + n_{ijl} - n_{ijk}. \tag{3.28}$$

(Each right-hand side is restricted to the overlap named on the left.) These are exactly the combinations we met in (3.21) and (3.22).

Key idea: $\delta^2 = 0$

Applying the coboundary twice gives zero: $\delta \circ \delta = 0$.

Check it in the lowest degree, for a 0-cochain f:

$$\begin{aligned}(\delta\delta f)_{ijk} &\overset{(1)}{=} (\delta f)_{jk} - (\delta f)_{ik} + (\delta f)_{ij} \\ &\overset{(2)}{=} (f_k - f_j) - (f_k - f_i) + (f_j - f_i) \\ &= 0.\end{aligned}$$

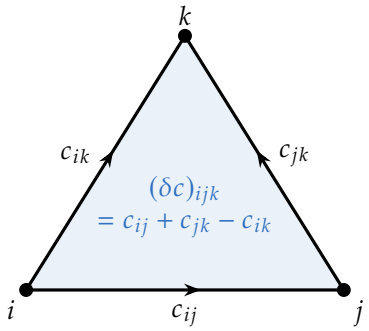
(1) Formula (3.27) applied to the 1-cochain $c = \delta f$.
(2) Formula (3.26) for each of the three entries.

And one degree up, for a 1-cochain c:

$$\begin{aligned}(\delta\delta c)_{ijkl} &\overset{(1)}{=} (\delta c)_{jkl} - (\delta c)_{ikl} + (\delta c)_{ijl} - (\delta c)_{ijk} \\ &\overset{(2)}{=} (c_{kl} - c_{jl} + c_{jk}) - (c_{kl} - c_{il} + c_{ik}) + (c_{jl} - c_{il} + c_{ij}) - (c_{jk} - c_{ik} + c_{ij}) \\ &= 0.\end{aligned}$$

(1) Formula (3.28) applied to $n = \delta c$.
(2) Formula (3.27) for each entry; now every c appears exactly twice with opposite signs.

The general reason is the same bookkeeping: in $\delta\delta c$ each term has two indices removed, say i_a and i_b with $a < b$. It arises once by removing i_b first and then i_a (sign $(-1)^b(-1)^a$), and once by removing i_a first, after which i_b has moved to position $b-1$ (sign $(-1)^a(-1)^{b-1}$). The two cancel. This is the same sign trick that makes $\partial^2 = 0$ for the boundary of a simplex, and δ is its dual; Nash simply says "it is straightforward to verify that $d^2 = 0$".



Walk $i \to j \to k$ and then back from k to i, adding the value on each edge, with a minus sign when an edge is traversed against its orientation. A *cocycle* ($\delta c = 0$) is data whose total round every triangle is zero, like a curl-free field. A *coboundary* ($c = \delta f$) is a difference of vertex values, like a gradient.

Figure 3.13: The coboundary of a 1-cochain, read on the nerve. 1-cochains live on edges, δc lives on triangles and is the signed sum round the triangle. This is a discrete "curl"; δ on 0-cochains is a discrete "gradient", and $\delta^2 = 0$ is "curl grad = 0".

Physical picture: Discrete vector calculus

On the nerve, δ on 0-cochains is a discrete gradient (difference of values at the ends of an edge), on 1-cochains a discrete curl (circulation round a triangle), on 2-cochains a discrete divergence (flux out of a tetrahedron). The Čech complex is lattice vector calculus on the skeleton of the cover, with the values replaced by sections of a sheaf.

3.3.3 The cohomology of a cover

Because $\delta^2 = 0$ we have a **cochain complex** (Nash's (3.14))

$$0 \longrightarrow C^0(\mathcal{U};\mathcal{F}) \xrightarrow{\delta} C^1(\mathcal{U};\mathcal{F}) \xrightarrow{\delta} C^2(\mathcal{U};\mathcal{F}) \xrightarrow{\delta} \cdots \tag{3.29}$$

in which the image of each map lies inside the kernel of the next.

Working definition 3.12 (Čech cohomology of a cover)

A q-cochain c is a **cocycle** if $\delta c = 0$ [for $q = 1$: $c_{jk} - c_{ik} + c_{ij} = 0$ on every triple overlap] and a **coboundary** if $c = \delta b$ for some $(q-1)$-cochain b [for $q = 1$: $c_{ij} = b_j - b_i$ on every double overlap]. Every coboundary is a cocycle. The **Čech cohomology of the cover** is

$$H^q(\mathcal{U};\mathcal{F}) = \frac{\operatorname{Ker}\left(\delta : C^q \to C^{q+1}\right)}{\operatorname{Im}\left(\delta : C^{q-1} \to C^q\right)} = \frac{\{q\text{-cocycles}\}}{\{q\text{-coboundaries}\}}, \tag{3.30}$$

Nash's (3.15). *Operational recipe:* write the matrices of δ, compute kernels and images, take the quotient. For finite covers and $\mathcal{F} = \underline{\mathbb{R}}$ this is linear algebra: $\dim H^q = \dim C^q - \operatorname{rank}\delta_q - \operatorname{rank}\delta_{q-1}$.

Key idea: Nash (3.17): H^0 is global sections

For any sheaf $\mathcal{F}$ and any cover, $H^0(\mathcal{U};\mathcal{F}) = \mathcal{F}(M) = \Gamma(M,\mathcal{F})$.

There are no (-1)-cochains, so H^0 is just the 0-cocycles:

$$\begin{aligned} H^0(\mathcal{U};\mathcal{F}) &\overset{(1)}{=} \{(f_i) \;:\; (\delta f)_{ij} = 0 \;\forall i,j\} \\ &\overset{(2)}{=} \{(f_i) \;:\; f_i|_{U_{ij}} = f_j|_{U_{ij}} \;\forall i,j\} \\ &\overset{(3)}{=} \mathcal{F}(M). \end{aligned}$$

(1) Definition (3.30) with $\operatorname{Im}\delta_{-1} = 0$.
(2) Formula (3.26).
(3) The sheaf axioms: compatible local sections glue to a unique global section (S2, S1), and every global section restricts to a compatible family.

So H^0 is the familiar thing (global solutions, global wavefunctions), and the gluing axiom is literally the statement "0-cocycles are global sections". The higher H^q are new.

Physical picture: What H^1 means

A 1-cocycle is a set of "transition data" c_{ij} on overlaps that is consistent on triple overlaps. It is a coboundary if it can be undone by a change of local data, $c_{ij} = f_j - f_i$. So H^1 counts *twisted gluings modulo re-gaugings*. For the multiplicative sheaf of $U(1)$-valued functions

the c_{ij} are gauge transformations between patches, and H^1 is the set of $U(1)$ bundles (Section 3.5). In the fine-sheaf argument of Section 3.2.5, H^1 of the kernel sheaf is precisely the obstruction to lifting a global section.

Watch out: Multiplicative sheaves

For $\mathcal{O}^*$, $\mathcal{E}^*$ or $U(1)$-valued functions the group operation is multiplication. Then "$-$" becomes "$\div$", and the formulas read $(\delta h)_{ij} = h_j h_i^{-1}$ and $(\delta g)_{ijk} = g_{jk} g_{ik}^{-1} g_{ij}$. The alternating condition becomes $g_{ji} = g_{ij}^{-1}$. A 1-cocycle is therefore $g_{ij} g_{jk} = g_{ik}$: the cocycle condition (3.6) for transition functions of a line bundle.

3.3.4 First computations: the circle

Worked example 3.13: S^1 with three arcs, coefficients $\underline{\mathbb{R}}$

Take the cover of Figure 3.12: three open arcs U_1, U_2, U_3 with connected pairwise overlaps and $U_{123} = \varnothing$. Every overlap is connected, so each section of $\underline{\mathbb{R}}$ is one real number:

$$C^0 = \mathbb{R}^3 \ni (a_1, a_2, a_3), \qquad C^1 = \mathbb{R}^3 \ni (c_{12}, c_{13}, c_{23}), \qquad C^2 = 0.$$

By (3.26), $\delta(a) = (a_2 - a_1,\ a_3 - a_1,\ a_3 - a_2)$, i.e.

$$\delta_0 = \begin{pmatrix} -1 & 1 & 0 \\ -1 & 0 & 1 \\ 0 & -1 & 1 \end{pmatrix} \quad (\text{rows } 12, 13, 23;\ \text{columns } a_1, a_2, a_3). \tag{3.31}$$

The kernel of δ_0 is the constants (a, a, a), so

$$H^0(\mathcal{U}; \underline{\mathbb{R}}) \overset{(1)}{=} \operatorname{Ker} \delta_0 \cong \mathbb{R},$$
$$H^1(\mathcal{U}; \underline{\mathbb{R}}) \overset{(2)}{=} C^1 / \operatorname{Im} \delta_0 \overset{(3)}{=} \mathbb{R}^3 / \mathbb{R}^2 \cong \mathbb{R},$$

(1) H^0 is the kernel of δ_0: a locally constant function on a connected circle is constant.
(2) Every 1-cochain is a cocycle because $C^2 = 0$.
(3) $\operatorname{rank} \delta_0 = 3 - \dim \operatorname{Ker} \delta_0 = 2$.

An explicit isomorphism $H^1 \to \mathbb{R}$: the image of δ_0 is the plane $c_{12} - c_{13} + c_{23} = 0$ (check: $(a_2 - a_1) - (a_3 - a_1) + (a_3 - a_2) = 0$). So

$$[c] \longmapsto c_{12} + c_{23} - c_{13} \tag{3.32}$$

is well defined on classes and is an isomorphism. It is the signed sum round the triangle $1 \to 2 \to 3 \to 1$: a discrete line integral round the circle. The class of $c = (0, 0, -1)$, for instance, is the generator "one unit of circulation".
With $\underline{\mathbb{Z}}$ coefficients the same matrix gives $H^0 = \mathbb{Z}$ and $H^1 = \mathbb{Z}^3 / \operatorname{Im} \delta_0 \cong \mathbb{Z}$, again via (3.32), which is now onto $\mathbb{Z}$. This matches the topologist's $H^1(S^1; \mathbb{Z}) = \mathbb{Z}$ (Chapter 1).

Worked example 3.14: S^1 with two arcs: disconnected overlaps

Now use the two-arc cover U_1, U_2 of Example 3.5. The overlap $U_{12} = A \sqcup B$ has two

components, so a section of $\underline{\mathbb{R}}$ over U_{12} is a pair of numbers:

$$C^0 = \mathbb{R}^2 \ni (a_1, a_2), \qquad C^1 = \underline{\mathbb{R}}(A \sqcup B) = \mathbb{R}^2 \ni (c_A, c_B), \qquad C^2 = 0.$$

The coboundary restricts $a_2 - a_1$ to each component:

$$\delta(a_1, a_2) \overset{(1)}{=} \big((a_2 - a_1)|_A,\ (a_2 - a_1)|_B\big) = (a_2 - a_1,\ a_2 - a_1), \qquad \delta_0 = \begin{pmatrix} -1 & 1 \\ -1 & 1 \end{pmatrix}.$$

(1) Formula (3.26); a constant restricted to each component is the same constant.

So $\operatorname{Ker}\delta_0 = \{(a, a)\} \cong \mathbb{R}$ and $\operatorname{Im}\delta_0 = \{(c, c)\}$, giving

$$H^0 = \mathbb{R}, \qquad H^1 = \mathbb{R}^2/\{(c, c)\} \cong \mathbb{R}, \quad [c] \mapsto c_A - c_B.$$

The same answer as with three arcs, although the nerve is now a single edge. The information about the hole is hiding in the fact that the edge carries *two* numbers: the overlap is disconnected. A disconnected overlap is harmless here, because each component is still contractible.

Worked example 3.15: The Möbius bundle in Čech language

The Möbius bundle of Example 3.5 has transition function $g_{12} = (-1 \text{ on } A,\ +1 \text{ on } B)$. Two related Čech computations tell it apart from the trivial bundle.

(a) The transition function as a class in $H^1(S^1; \underline{\mathbb{Z}_2})$. Take the multiplicative sheaf $\underline{\mathbb{Z}_2}$ of locally constant functions with values in $\{\pm 1\}$. With the two-arc cover a 1-cochain is a pair (g_A, g_B) of signs, and every cochain is a cocycle ($C^2 = 0$). The coboundaries are

$$(\delta\epsilon)_{12} \overset{(1)}{=} \epsilon_2\epsilon_1^{-1}\big|_{A\sqcup B} = (\epsilon_2\epsilon_1,\ \epsilon_2\epsilon_1),$$

(1) Multiplicative form of (3.26), with constants $\epsilon_1, \epsilon_2 \in \{\pm 1\}$ on the connected arcs; $\epsilon^{-1} = \epsilon$.

So a coboundary has *equal* signs on A and B. The trivial bundle $(+1, +1)$ is a coboundary; the Möbius bundle $(-1, +1)$ is not. Hence $H^1(\mathcal{U}; \underline{\mathbb{Z}_2}) = \{\pm 1\}^2/\{(\epsilon, \epsilon)\} \cong \mathbb{Z}_2$, the class is $g_A g_B$, and the Möbius bundle is the nontrivial element. No change of trivialisation ($s_i \mapsto \epsilon_i s_i$) can untwist it. Real line bundles over M are classified by $H^1(M; \underline{\mathbb{Z}_2})$ in general: this class is the first **Stiefel–Whitney class**.

(b) Cohomology of the twisted constant sheaf. Let $\underline{\mathbb{R}}^{\mathrm{tw}}$ be the sheaf of locally constant sections of the Möbius bundle. Over each arc a section is a constant a_i in the i-th trivialisation. To compare on the overlap we express everything in trivialisation 1, using $s_1 = g_{12}s_2$:

$$(\delta a)|_A \overset{(1)}{=} a_1 - g_{12}|_A\, a_2 = a_1 + a_2, \qquad (\delta a)|_B = a_1 - a_2, \qquad \delta_0 = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}.$$

(1) The difference of the two local sections on A, written in the first trivialisation. (The overall sign convention for δ does not affect kernels and images.)

$\det\delta_0 = -2 \neq 0$, so δ_0 is invertible: $H^0(S^1; \underline{\mathbb{R}}^{\mathrm{tw}}) = 0$ (no global flat section: it would have to change sign) and $H^1(S^1; \underline{\mathbb{R}}^{\mathrm{tw}}) = 0$. Compare the untwisted answer $H^0 = H^1 = \mathbb{R}$. Two sheaves with isomorphic stalks everywhere, and completely different cohomology.

Physical picture: Aharonov–Bohm in a line

Replace $\{\pm 1\}$ by $U(1)$ in Example 3.15(a): a flat $U(1)$ bundle on a circle is a pair of phases (g_A, g_B) modulo $(e^{i\alpha}, e^{i\alpha})$, i.e. one phase $g_A g_B^{-1}$. This is the Aharonov–Bohm phase $e^{ie\oint A}$ of a charged particle encircling a flux tube. A wavefunction in this background is a section of the flat bundle, and the twisted-coefficient computation (b) says a flat section exists only if the phase is 1.

3.3.5 Refinements, the limit over covers, and good covers

Nash writes $H^q(O;\mathcal{F})$, with the cover in the notation, "to draw attention to the fact that our construction could depend on the covering used". It really can.

Worked example 3.16: S^2 with two caps: the wrong answer

Cover S^2 by a northern cap U_N and a southern cap U_S, each a little bigger than a hemisphere; U_{NS} is an open annulus round the equator (connected). With $\underline{\mathbb{R}}$ coefficients

$$C^0 = \mathbb{R}^2, \qquad C^1 = \mathbb{R}, \qquad C^2 = 0, \qquad \delta(a_N, a_S) = a_S - a_N.$$

The map $\delta_0 = (-1 \;\; 1)$ is onto, so $H^0 = \mathbb{R}$, $H^1 = 0$ and $H^2 = 0$ (because $C^2 = 0$). But the true answer (Chapter 1, Chapter T2) is $H^2(S^2;\mathbb{R}) = \mathbb{R}$: the sphere encloses a volume, and the area form is closed but not exact. The cover is too coarse to see this: a cover with only two sets has no triple overlaps and can never see H^2.

The culprit is that the overlap annulus is not contractible: it has its own H^1, which the cover does not resolve. Nash's remedy is to use finer and finer covers.

Working definition 3.13 (refinement)

A cover $\mathcal{V} = \{V_\beta\}_{\beta\in J}$ is a **refinement** of $\mathcal{U} = \{U_\alpha\}_{\alpha\in I}$ if every V_β lies in some U_α (Nash's footnote 2). Choose such an $\alpha = \tau(\beta)$ for each β [the choice is not unique, but the induced map on cohomology does not depend on it]. Then cochains can be pulled back,

$$(\tau^* c)_{\beta_0\cdots\beta_q} = c_{\tau(\beta_0)\cdots\tau(\beta_q)}\big|_{V_{\beta_0\cdots\beta_q}},$$

which makes sense because $V_{\beta_0\cdots\beta_q} \subset U_{\tau(\beta_0)\cdots\tau(\beta_q)}$. *Operational recipe:* a cochain on the coarse cover gives one on the fine cover by restricting each entry to the smaller overlaps.

The map τ^* commutes with δ (both are built from restrictions), so it maps cocycles to cocycles and coboundaries to coboundaries, and induces $\tau^* : H^q(\mathcal{U};\mathcal{F}) \to H^q(\mathcal{V};\mathcal{F})$. One checks that a different choice of τ changes $\tau^* c$ by a coboundary, so the map on cohomology depends only on the two covers. Nash then defines

$$H^q(M;\mathcal{F}) = \varinjlim_{\mathcal{U}} H^q(\mathcal{U};\mathcal{F}), \tag{3.33}$$

his (3.16). In words: a class in $H^q(M;\mathcal{F})$ is represented by a cocycle on *some* cover, and two such are identified if they become cohomologous on a common refinement. This is the **sheaf cohomology** of M with coefficients in $\mathcal{F}$.

Taking a limit over all covers sounds hopeless for computation. In practice one never does it, because of the following fact.

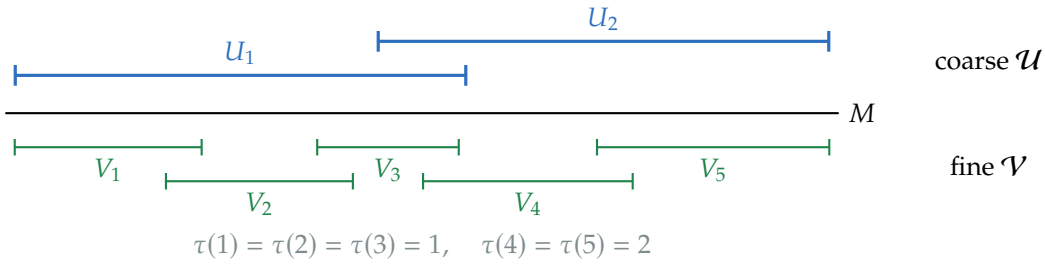


Figure 3.14: A refinement: every green set V_β sits inside some blue set $U_{\tau(\beta)}$. Cochains of the coarse cover restrict to cochains of the fine cover. Sheaf cohomology is what remains when we pass to ever finer covers; for a good cover nothing changes any more.

Key idea: Leray's theorem: good covers compute sheaf cohomology

If the sheaf $\mathcal{F}$ has no higher cohomology on every finite overlap, $H^p(U_{i_0 \cdots i_q}; \mathcal{F}) = 0$ for all $p > 0$, then $H^q(\mathcal{U}; \mathcal{F}) = H^q(M; \mathcal{F})$. Such a cover is called a **Leray cover** for $\mathcal{F}$. For $\underline{\mathbb{R}}$, $\underline{\mathbb{Z}}$ or any locally constant sheaf, a **good cover**, one in which every non-empty finite overlap is contractible (or a disjoint union of contractible pieces), is a Leray cover.

Why it is plausible. Refining a cover changes the cochains only if the finer cover detects something new inside the old overlaps. If every overlap is already "cohomologically trivial" for $\mathcal{F}$, there is nothing new to detect. Every manifold has good covers: take small geodesically convex balls for some Riemannian metric; intersections of convex sets are convex. This is why the three-arc cover of S^1 gave the right answer, and the two-cap cover of S^2 did not (its overlap, an annulus, has $H^1 = \mathbb{R} \neq 0$). For $\mathcal{O}$ on a complex manifold, open sets such as discs, polydiscs, $\mathbb{C}$ and $\mathbb{C}^*$ have no higher cohomology (this follows from the Dolbeault lemma of Section 3.7.3), so covers by such sets are Leray covers for $\mathcal{O}$.

Watch out: The cover must be fine enough for the sheaf and the degree

A cover by m open sets has no q-cochains for $q \geq m$ (with alternating cochains), so it cannot see H^q for $q \geq m$. More generally, a cover whose overlaps have hidden topology gives answers that are simply wrong, as Example 3.16 shows. Always check the Leray condition before trusting a finite computation.

Paracompactness and the other definition

Nash mentions that there is a second, more abstract definition of sheaf cohomology using *resolutions* of the sheaf (Wells). One replaces $\mathcal{F}$ by an exact sequence $0 \to \mathcal{F} \to \mathcal{L}^0 \to \mathcal{L}^1 \to \cdots$ of fine (or soft, or injective) sheaves and takes the cohomology of the complex of global sections $\mathcal{L}^0(M) \to \mathcal{L}^1(M) \to \cdots$. We will see exactly this happen in the de Rham theorem, where the resolution is $0 \to \underline{\mathbb{R}} \to \mathcal{E}^0 \to \mathcal{E}^1 \to \cdots$ (Section 3.6). The two definitions agree when M is **paracompact**: every open cover has a **locally finite** refinement, meaning that each point has a neighbourhood meeting only finitely many sets of the refinement. Every manifold is paracompact (Spivak), and paracompactness is also exactly what guarantees partitions of unity subordinate to any cover. For us: *on manifolds, all definitions of $H^q(M; \mathcal{F})$ agree, and a good cover computes it.*

3.3.6 The sphere, done right

Worked example 3.17: S^2 with a tetrahedral cover

Inflate a tetrahedron into a sphere. Its four faces become four closed spherical triangles; let U_0, U_1, U_2, U_3 be slightly enlarged open versions of them, with U_i the face *opposite* vertex i (Figure 3.15). Then:

- each pair of faces shares an edge, so U_{ij} is a thin strip along that edge: contractible, 6 of them;
- each triple of faces shares a vertex, so U_{ijk} is a small disc round that vertex: contractible, 4 of them;
- no point lies in all four faces, so $U_{0123} = \varnothing$.

This is a good cover, and its nerve is the (hollow) boundary of a tetrahedron, which is a sphere. With $\underline{\mathbb{R}}$ coefficients:

$$C^0 = \mathbb{R}^4, \qquad C^1 = \mathbb{R}^6, \qquad C^2 = \mathbb{R}^4, \qquad C^3 = 0.$$

Order the pairs $01, 02, 03, 12, 13, 23$ and the triples $012, 013, 023, 123$. The formulas (3.26)–(3.27) give

$$\delta_0 = \begin{pmatrix} -1 & 1 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ -1 & 0 & 0 & 1 \\ 0 & -1 & 1 & 0 \\ 0 & -1 & 0 & 1 \\ 0 & 0 & -1 & 1 \end{pmatrix}, \qquad \delta_1 = \begin{pmatrix} 1 & -1 & 0 & 1 & 0 & 0 \\ 1 & 0 & -1 & 0 & 1 & 0 \\ 0 & 1 & -1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & -1 & 1 \end{pmatrix}. \tag{3.34}$$

(Row 012 of δ_1 reads $c_{12} - c_{02} + c_{01}$, and so on.)
Check $\delta_1\delta_0 = 0$ on the first row. Row 012 of δ_1 combines rows 01, 02, 12 of δ_0 with signs $+, -, +$:

$$\begin{aligned}(\delta_1\delta_0)_{012,\bullet} &\overset{(1)}{=} (-1,1,0,0) - (-1,0,1,0) + (0,-1,1,0) \\ &= (0,0,0,0).\end{aligned}$$

(1) Row 012 of δ_1 has entries $+1, -1, +1$ in the columns 01, 02, 12.

The other rows work the same way.
Ranks. $\operatorname{Ker}\delta_0$ is the constants, so $\operatorname{rank}\delta_0 = 3$. For δ_1: its rows $r_{012}, r_{013}, r_{023}$ are independent (each is the only one with an entry in column 12, 13, 23 respectively), and

$$r_{012} - r_{013} + r_{023} \overset{(1)}{=} (0,0,0,1,-1,1) = r_{123},$$

(1) Add the rows entry by entry: columns 01, 02, 03 cancel.

so $\operatorname{rank}\delta_1 = 3$. Therefore

$$\begin{aligned}\dim H^0 &= 4 - 3 = 1, \\ \dim H^1 &\overset{(1)}{=} (6 - \operatorname{rank}\delta_1) - \operatorname{rank}\delta_0 = 3 - 3 = 0, \\ \dim H^2 &\overset{(2)}{=} 4 - \operatorname{rank}\delta_1 = 1.\end{aligned}$$

(1) $\dim\operatorname{Ker}\delta_1 - \dim\operatorname{Im}\delta_0$.

(2) Every 2-cochain is a cocycle ($C^3 = 0$).

So $H^0(S^2;\mathbb{R}) = \mathbb{R}$, $H^1(S^2;\mathbb{R}) = 0$, $H^2(S^2;\mathbb{R}) = \mathbb{R}$: the correct answer. The alternating sum $4 - 6 + 4 = 2$ is the Euler characteristic of the sphere, and it equals $1 - 0 + 1$, as it must (the alternating sum of dimensions is the same for a complex and for its cohomology).

An explicit generator. The row relation above says that for every 1-cochain c, $(\delta c)_{123} - (\delta c)_{023} + (\delta c)_{013} - (\delta c)_{012} = 0$. So

$$\ell(n) = n_{123} - n_{023} + n_{013} - n_{012} \tag{3.35}$$

vanishes on coboundaries and defines a map $H^2 \to \mathbb{R}$. It is an isomorphism. It even works over $\mathbb{Z}$: if $\ell(n) = 0$, set $c_{12} = n_{012}$, $c_{13} = n_{013}$, $c_{23} = n_{023}$, all other $c = 0$; then δc agrees with n on 012, 013, 023 by construction, and on 123

$$(\delta c)_{123} \overset{(1)}{=} c_{23} - c_{13} + c_{12} = n_{023} - n_{013} + n_{012} \overset{(2)}{=} n_{123},$$

(1) Formula (3.27).

(2) The assumption $\ell(n) = 0$.

so $n = \delta c$. Hence $H^2(S^2;\mathbb{Z}) \cong \mathbb{Z}$ via ℓ. The integer $\ell(n)$ is the discrete analogue of $\int_{S^2}$; in Section 3.5 it will be the magnetic charge of a monopole.

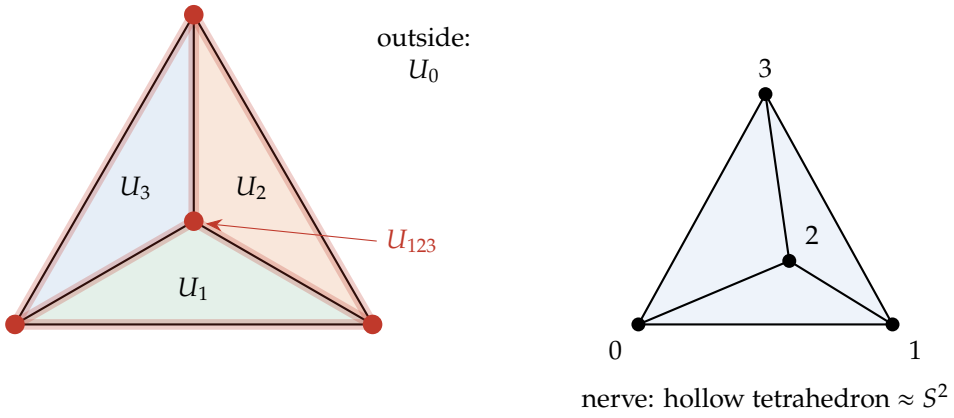

Figure 3.15: Left: the sphere, stereographically flattened so that face U_0 is everything outside the big triangle. Each pair of faces meets along an edge (red strips: the double overlaps U_{ij}) and each triple meets at a vertex (red dots: the triple overlaps U_{ijk}). Right: the nerve, with one vertex per face, is the surface of a tetrahedron. Four vertices, six edges, four triangles: $4 - 6 + 4 = 2$.

3.3.7 Fine sheaves have no higher cohomology

Nash asserts that for a soft sheaf $H^q(M;\mathcal{F}) = 0$ for $q > 0$ and that $\mathcal{E}$, $\mathcal{E}^p$ are soft (indeed fine). For fine sheaves the proof is one formula, the general version of the correction we used in Section 3.2.5.

Let $\mathcal{F}$ be fine, $\mathcal{U}$ a locally finite cover and $\{\rho_k\}$ a partition of unity subordinate to it. Define the **homotopy operator** $K : C^q(\mathcal{U};\mathcal{F}) \to C^{q-1}(\mathcal{U};\mathcal{F})$ by

$$(Kc)_{i_0\cdots i_{q-1}} = \sum_k \rho_k \, c_{k\, i_0\cdots i_{q-1}}. \tag{3.36}$$

Each term $\rho_k c_{k i_0\cdots i_{q-1}}$ is a section on $U_k \cap U_{i_0\cdots i_{q-1}}$ that vanishes near the edge of U_k, so it extends by zero to a section on all of $U_{i_0\cdots i_{q-1}}$; local finiteness makes the sum finite near each point.

Key idea: The homotopy formula

For $q \geq 1$ and every $c \in C^q(\mathcal{U};\mathcal{F})$: $\delta Kc + K\delta c = c$. Hence every cocycle is a coboundary, $c = \delta(Kc)$, and $H^q(\mathcal{U};\mathcal{F}) = 0$ for $q \geq 1$. Taking the limit, $H^q(M;\mathcal{F}) = 0$ for $q \geq 1$.

The check, for $q = 1$ (the general case is identical, with more indices):

$$\begin{aligned}(\delta Kc)_{ij} + (K\delta c)_{ij} &\overset{(1)}{=} \big((Kc)_j - (Kc)_i\big) + \sum_k \rho_k (\delta c)_{kij} \\ &\overset{(2)}{=} \sum_k \rho_k \big(c_{kj} - c_{ki}\big) + \sum_k \rho_k \big(c_{ij} - c_{kj} + c_{ki}\big) \\ &= \sum_k \rho_k\, c_{ij} \overset{(3)}{=} c_{ij}.\end{aligned}$$

(1) Formula (3.26) for δ of the 0-cochain Kc, and definition (3.36) for K of the 2-cochain δc.
(2) Definition of K again, and formula (3.27) for $(\delta c)_{kij}$.
(3) $\sum_k \rho_k = 1$.

For general q the same thing happens: the terms of $(K\delta c)$ in which the index k has been removed give $c_{i_0\cdots i_q} \sum \rho_k = c$, and the remaining terms cancel exactly against δKc.

Physical picture: Why floppy sheaves are cohomologically trivial

The formula says: *a partition of unity lets you spread any mismatch on overlaps back onto the open sets.* This is only possible if you are allowed to multiply sections by bump functions. That is why $\mathcal{E}$, $\mathcal{E}^p$, $\mathcal{E}^{p,q}$ and $\Gamma(\,\cdot\,, E)$ have $H^q = 0$ for $q > 0$, while the rigid sheaves $\underline{\mathbb{Z}}$, $\underline{\mathbb{R}}$, $\mathcal{O}$, $\mathcal{O}^*$ carry all the topology. The whole strategy of the next sections is to connect a rigid sheaf to floppy ones by exact sequences, and let the floppy ones do the work.

3.3.8 Holomorphic example: the Riemann sphere

Our last example uses the rigid sheaf $\mathcal{O}$ and shows H^1 doing genuinely analytic work: it counts the obstructions to solving a Mittag-Leffler type problem.

Worked example 3.18: $H^q(\mathbb{CP}^1;\mathcal{O}(n))$ by Laurent series

Use the cover $U_0 = \mathbb{C} \ni z$, $U_1 = \mathbb{CP}^1 \setminus \{0\} \ni w = 1/z$ of Example 3.6, with $U_{01} = \mathbb{C}^*$. Both $U_i \cong \mathbb{C}$ and $U_{01} = \mathbb{C}^*$ have no higher $\mathcal{O}$-cohomology (we justify this with the $\bar\partial$ equation in Section 3.7.3), so this two-set cover is a Leray cover and computes $H^q(\mathbb{CP}^1;\mathcal{O}(n))$. With two sets, $C^q = 0$ for $q \geq 2$, so $H^q = 0$ for $q \geq 2$.
A 0-cochain is a pair (s_0, s_1) of entire functions of z and of w. A 1-cochain is one holomorphic function $c(z)$ on $\mathbb{C}^*$, i.e. a convergent Laurent series $c(z) = \sum_{k\in\mathbb{Z}} c_k z^k$. The coboundary, written in the trivialisation over U_0 and using $s_0 = z^n s_1$ (3.7), is

$$\begin{aligned}(\delta s)_{01}(z) &\overset{(1)}{=} s_0(z) - z^n\, s_1(1/z) \\ &\overset{(2)}{=} \sum_{k\geq 0} a_k z^k - \sum_{m\geq 0} b_m\, z^{\,n-m},\end{aligned}$$

(1) Compare the two local sections in the same trivialisation (the sign convention is irrelevant for kernels and images).
(2) Taylor series $s_0 = \sum a_k z^k$, $s_1(w) = \sum b_m w^m$, and $w = 1/z$.

So the image of δ consists of all Laurent series whose nonzero coefficients have exponent $k \geq 0$ (from s_0) or $k \leq n$ (from s_1). (Convergent series split this way: the part with $k \geq 0$ converges on $\mathbb{C}$, the part with $k < 0$ converges on $\mathbb{CP}^1 \setminus \{0\}$.)
Case $n \geq -1$. Every integer k satisfies $k \geq 0$ or $k \leq n$, since $n \geq -1$. So every Laurent series is a coboundary and $H^1(\mathbb{CP}^1; \mathcal{O}(n)) = 0$.
Case $n \leq -2$. The exponents $k = n+1, n+2, \dots, -1$ are missed: they are negative, and larger than n. So

$$H^1(\mathbb{CP}^1; \mathcal{O}(n)) \cong \operatorname{span}\{z^{n+1}, \dots, z^{-1}\}, \qquad \dim H^1 = -n-1.$$

Together with $\dim H^0 = n+1$ for $n \geq 0$ and 0 for $n < 0$ (Example 3.6):

n	-4	-3	-2	-1	0	1	2
$\dim H^0(\mathbb{CP}^1; \mathcal{O}(n))$	0	0	0	0	1	2	3
$\dim H^1(\mathbb{CP}^1; \mathcal{O}(n))$	3	2	1	0	0	0	0
$\dim H^0 - \dim H^1$	-3	-2	-1	0	1	2	3

The last row is always $n+1$. This is the Riemann–Roch theorem for the sphere, $\dim H^0 - \dim H^1 = \deg + 1 - g$ with genus $g = 0$ and degree n, and it is the first example of an *index*: the individual dimensions jump around, but their difference is topological. The case $n = -2$ is the bundle of holomorphic 1-forms ($dz = -w^{-2}dw$ transforms with z^{-2} in our convention), and $H^1(\mathbb{CP}^1; \Omega^1) \cong \mathbb{C}$ is spanned by the class of z^{-1}: the residue. In particular (case $n = 0$) $H^1(\mathbb{CP}^1; \mathcal{O}) = 0$.

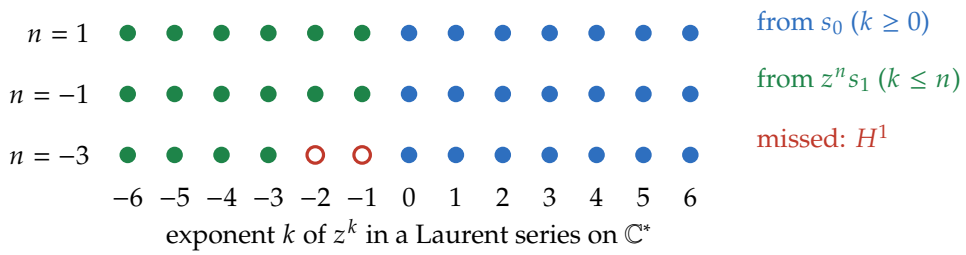

Figure 3.16: Which Laurent monomials on the overlap $\mathbb{C}^*$ are coboundaries for $\mathcal{O}(n)$ on $\mathbb{CP}^1$. Filled dots are hit by entire functions of z (blue) or by $z^n \times$ entire functions of $1/z$ (green). Open red circles are missed, and span $H^1(\mathbb{CP}^1; \mathcal{O}(n))$. For $n \geq -1$ nothing is missed; for $n = -3$ the two monomials z^{-2}, z^{-1} are missed.

Reading Nash (pp. 61–62, (3.12)–(3.17))

Nash's $\Delta = (O_1, \dots, O_{q+1})$ is our overlap $U_{i_0 \cdots i_q}$, and his (3.12) $C^q(O, \mathcal{F}) = \mathcal{F}(\Delta)$ means "one section for each such overlap", our (3.24). In (3.13) the sum runs over the $q+2$ sets of a $(q+1)$-cochain's overlap (his indexing is slightly loose), and $r^{\Delta}_{\Delta_i}$ is the restriction from the overlap with the i-th set omitted; this is our (3.25), and his d is our δ. His (3.14)–(3.15) are (3.29)–(3.30). The limit (3.16) over ever finer covers is (3.33), with refinement as in his footnote 2; we have added Leray's theorem, which is how one actually computes. His (3.17), $H^0 = \Gamma(M, \mathcal{F})$, is our first key idea. His remarks on paracompactness and the alternative definition via resolutions are expanded in Section 3.3.5; the vanishing of higher cohomology of soft and fine sheaves, which he states without proof, is Section 3.3.7.

Recap

- A Čech q-cochain is a section on every $(q+1)$-fold overlap of a cover. The coboundary δ is the alternating sum of restrictions; $\delta^2 = 0$. On the nerve, δ is discrete grad, curl, div.
- $H^q(\mathcal{U};\mathcal{F})$ = cocycles/coboundaries. $H^0 = \Gamma(M,\mathcal{F})$ always. H^1 = twisted gluing data modulo re-gauging.
- Sheaf cohomology $H^q(M;\mathcal{F})$ is the limit over refinements; in practice a Leray (good) cover computes it. Too coarse a cover gives wrong answers (two caps on S^2).
- Worked answers: $H^*(S^1;\mathbb{R}) = (\mathbb{R},\mathbb{R})$ from two or three arcs; Möbius = nontrivial class in $H^1(S^1;\mathbb{Z}_2)$; $H^*(S^2;\mathbb{R}) = (\mathbb{R},0,\mathbb{R})$ from the tetrahedral cover, with $H^2(S^2;\mathbb{Z}) \cong \mathbb{Z}$ via $\ell(n)$; $H^1(\mathbb{CP}^1;\mathcal{O}(n))$ of dimension $\max(0,-n-1)$ by Laurent series.
- Fine sheaves have $H^q = 0$ for $q > 0$, by the homotopy formula $\delta K + K\delta = 1$ built from a partition of unity.

3.4 The long exact sequence

We now have two facts that pull in opposite directions. A short exact sequence of sheaves $0 \to \mathcal{E} \to \mathcal{F} \to \mathcal{G} \to 0$ is exact near every point, but its global sections need not be exact at the right-hand end (Section 3.2.4). And we have a cohomology theory $H^q(M;\,\cdot\,)$ whose degree-zero part is global sections. Nash's (3.18)–(3.19) connects them: the failure of exactness at the right end of the global-section sequence is measured by H^1 of the left-hand sheaf, the failure one step further along by H^2, and so on. The result is the single most useful computational tool in the subject.

Key idea: The long exact cohomology sequence

A short exact sequence of sheaves $0 \to \mathcal{E} \xrightarrow{e} \mathcal{F} \xrightarrow{f} \mathcal{G} \to 0$ (Nash's (3.18)) produces a long exact sequence (Nash's (3.19))

$$\begin{aligned} 0 \to\ & H^0(M;\mathcal{E}) \xrightarrow{e_*} H^0(M;\mathcal{F}) \xrightarrow{f_*} H^0(M;\mathcal{G}) \\ & \xrightarrow{\delta^*} H^1(M;\mathcal{E}) \xrightarrow{e_*} H^1(M;\mathcal{F}) \xrightarrow{f_*} H^1(M;\mathcal{G}) \\ & \xrightarrow{\delta^*} H^2(M;\mathcal{E}) \xrightarrow{e_*} H^2(M;\mathcal{F}) \xrightarrow{f_*} \cdots \end{aligned} \tag{3.37}$$

The maps e_*, f_* apply e, f to cochains. The new ingredient is the **connecting homomorphism** $\delta^* : H^q(M;\mathcal{G}) \to H^{q+1}(M;\mathcal{E})$, which raises the degree by one.

The first row is exactly the global-section sequence (3.18). So the long exact sequence says, in its first two rows:

$$\operatorname{Coker}\big(\mathcal{F}(M) \to \mathcal{G}(M)\big) \ \hookrightarrow\ H^1(M;\mathcal{E}). \tag{3.38}$$

If $H^1(M;\mathcal{E}) = 0$, then $\mathcal{F}(M) \to \mathcal{G}(M)$ is onto. That is the key idea of Section 3.2.5 again: a fine $\mathcal{E}$ has $H^1 = 0$ (Section 3.3.7).

3.4.1 Building the connecting homomorphism

The recipe is a "zig-zag" through the diagram of cochain groups. Fix a cover $\mathcal{U}$. Applying e and f entry by entry gives, in each degree, a sequence of cochain groups, and e, f commute with δ (both are built from restrictions, and sheaf morphisms commute with restriction):

$$\begin{array}{ccccccc} 0 & \longrightarrow & C^{q+1}(\mathcal{U};\mathcal{E}) & \xrightarrow{e} & C^{q+1}(\mathcal{U};\mathcal{F}) & \xrightarrow{f} & C^{q+1}(\mathcal{U};\mathcal{G}) \\ & & \uparrow{\scriptstyle\delta} & & \uparrow{\scriptstyle\delta} & & \uparrow{\scriptstyle\delta} \\ 0 & \longrightarrow & C^{q}(\mathcal{U};\mathcal{E}) & \xrightarrow{e} & C^{q}(\mathcal{U};\mathcal{F}) & \xrightarrow{f} & C^{q}(\mathcal{U};\mathcal{G}) \end{array} \tag{3.39}$$

Working definition 3.14 (connecting homomorphism, by zig-zag)

Start with a cocycle $\gamma \in C^q(\mathcal{U};\mathcal{G})$, $\delta\gamma = 0$.

(1) *Lift* (go left): find $\beta \in C^q(\mathcal{U};\mathcal{F})$ with $f(\beta) = \gamma$. This may require refining the cover [replacing it by smaller open sets, each inside one of the old ones], because f is only surjective *locally*.

(2) *Go up:* form $\delta\beta \in C^{q+1}(\mathcal{U};\mathcal{F})$.

(3) *Observe:* $f(\delta\beta) = \delta f(\beta) = \delta\gamma = 0$. By exactness in the middle [what f sends to 0 is exactly what e produces, and e is injective], $\delta\beta = e(\alpha)$ for a unique $\alpha \in C^{q+1}(\mathcal{U};\mathcal{E})$ (go left again).

(4) *Declare* $\delta^*[\gamma] = [\alpha] \in H^{q+1}(\mathcal{U};\mathcal{E})$ [the class of α, i.e. α up to adding a coboundary. Other choices of β change α only by such a term].

Operational summary: lift, take the Čech coboundary, and read off the answer, which automatically lies in the smaller sheaf.

Three things need checking, and each is one line.

- α *is a cocycle:* $e(\delta\alpha) = \delta e(\alpha) = \delta\delta\beta = 0$, and e is injective, so $\delta\alpha = 0$.
- *Independent of the lift:* another lift is $\beta' = \beta + e(\eta)$ (two lifts differ by something f kills), and then $\alpha' = \alpha + \delta\eta$, which is cohomologous to α.
- *Independent of the representative:* replacing γ by $\gamma + \delta\kappa$ we may lift κ to $\tilde{\kappa}$ and take $\beta + \delta\tilde{\kappa}$ as the new lift; its coboundary is unchanged.

Why the sequence is exact (one spot, carefully)

Let us check exactness at $H^1(M;\mathcal{E})$, i.e. $\operatorname{Im}\delta^* = \operatorname{Ker} e_*$. The other spots are similar diagram chases.

$e_* \circ \delta^* = 0$: by construction $e(\alpha) = \delta\beta$ is a coboundary in $C^1(\mathcal{U};\mathcal{F})$, so $e_*[\alpha] = 0$.

$\operatorname{Ker} e_* \subset \operatorname{Im}\delta^*$: suppose α is a 1-cocycle of $\mathcal{E}$ and $e(\alpha) = \delta\beta$ for some 0-cochain β of $\mathcal{F}$. Put $\gamma = f(\beta)$. Then

$$\delta\gamma \overset{(1)}{=} f(\delta\beta) \overset{(2)}{=} f(e(\alpha)) \overset{(3)}{=} 0,$$

(1) f commutes with δ.

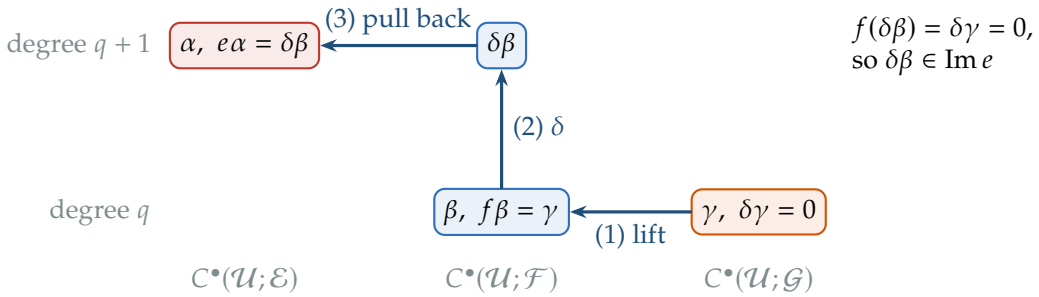

Figure 3.17: The zig-zag that defines δ^*. Start at the right with a cocycle γ of $\mathcal{G}$ (orange), lift it to $\mathcal{F}$, go up one degree with δ, and come back into $\mathcal{E}$ (red). The answer lands one degree higher than where we started. Every connecting homomorphism in this chapter, including the Chern class and the de Rham isomorphism, is this picture.

(2) The assumption $e(\alpha) = \delta\beta$.
(3) $f \circ e = 0$.

so γ is a 0-cocycle, i.e. a global section of $\mathcal{G}$, and running the zig-zag on γ with the lift β returns exactly α. So $[\alpha] = \delta^*[\gamma]$.

In words: *a class in $H^1(M;\mathcal{E})$ dies in $H^1(M;\mathcal{F})$ exactly when it is the obstruction to lifting some global section of $\mathcal{G}$.* This is the precise version of Nash's remark that sheaf cohomology "can measure any obstruction to exactness".

3.4.2 The exponential sequence on the punctured plane

Worked example 3.19: δ^* is the winding number

Take the exponential sequence $0 \to \underline{\mathbb{Z}} \to \mathcal{O} \to \mathcal{O}^* \to 0$ on $M = \mathbb{C}^*$ and the global section $g(z) = z$ of $\mathcal{O}^*$. We showed in Example 3.11 that g has no global logarithm. Now we compute the obstruction $\delta^*[g] \in H^1(\mathbb{C}^*;\underline{\mathbb{Z}})$.
Cover $\mathbb{C}^*$ by two slit planes (Figure 3.18):

$$U_1 = \mathbb{C} \setminus (-\infty, 0], \ \arg z \in (-\pi, \pi); \qquad U_2 = \mathbb{C} \setminus [0, \infty), \ \arg z \in (0, 2\pi).$$

Each is simply connected, and $U_{12} = H_+ \sqcup H_-$ is the union of the open upper and lower half-planes. This is a good cover.
(1) Lift. On each U_i, z has a logarithm. Take $f_i(z) = \frac{1}{2\pi i}(\ln|z| + i \arg_i z)$, with $\arg_i$ the branch in the stated range, so that $e^{2\pi i f_i} = z$ on U_i.
(2) Coboundary. On the two components of the overlap:

$$(\delta f)_{12}\big|_{H_+} \overset{(1)}{=} \frac{1}{2\pi i}\, i\,(\arg_2 z - \arg_1 z)\Big|_{H_+} \overset{(2)}{=} \frac{1}{2\pi}(\phi - \phi) = 0,$$
$$(\delta f)_{12}\big|_{H_-} \overset{(1)}{=} \frac{1}{2\pi}(\arg_2 z - \arg_1 z)\Big|_{H_-} \overset{(3)}{=} \frac{1}{2\pi}((\phi + 2\pi) - \phi) = 1.$$

(1) $(\delta f)_{12} = f_2 - f_1$; the $\ln|z|$ terms cancel.
(2) In H_+ both branches give the same angle $\phi \in (0, \pi)$.
(3) In H_-, $\arg_1 z = \phi \in (-\pi, 0)$ while $\arg_2 z = \phi + 2\pi$.

(3) Read off. The result $(0, 1)$ is integer-valued, as it must be: it lies in $\underline{\mathbb{Z}}$. By Example 3.14 (the same combinatorics: two sets, overlap with two contractible pieces), $H^1(\mathcal{U};\underline{\mathbb{Z}}) = \mathbb{Z}^2/\{(m, m)\} \cong \mathbb{Z}$ via $(c_+, c_-) \mapsto c_- - c_+$. So

$$\delta^*[z] = 1 \in H^1(\mathbb{C}^*;\underline{\mathbb{Z}}) \cong \mathbb{Z}.$$

Repeating with $g(z) = z^m$ multiplies every argument by m and gives $\delta^*[z^m] = m$. For a general nonvanishing g, the jump of $\frac{1}{2\pi}\arg g$ between the two half-planes is the winding number $\frac{1}{2\pi i}\oint g'/g\,\mathrm{d}z$. So the connecting homomorphism is the winding number, and it vanishes exactly when g has a global logarithm.

Push the example one step further along the long exact sequence:

$$\mathcal{O}(\mathbb{C}^*) \xrightarrow{\exp} \mathcal{O}^*(\mathbb{C}^*) \xrightarrow{\delta^*} H^1(\mathbb{C}^*;\underline{\mathbb{Z}}) \longrightarrow H^1(\mathbb{C}^*;\mathcal{O}).$$

It turns out that $H^1(\mathbb{C}^*;\mathcal{O}) = 0$ (the $\bar\partial$ equation can be solved on any open subset of $\mathbb{C}$; see Section 3.7.3). Exactness then says δ^* is onto $\mathbb{Z}$ and that its kernel is $\exp\mathcal{O}(\mathbb{C}^*)$. In plain terms: *every nonvanishing holomorphic function on $\mathbb{C}^*$ is $z^m e^{2\pi i h(z)}$ for a unique integer m (its winding number) and some holomorphic h.* A structure theorem, obtained without touching a single integral.

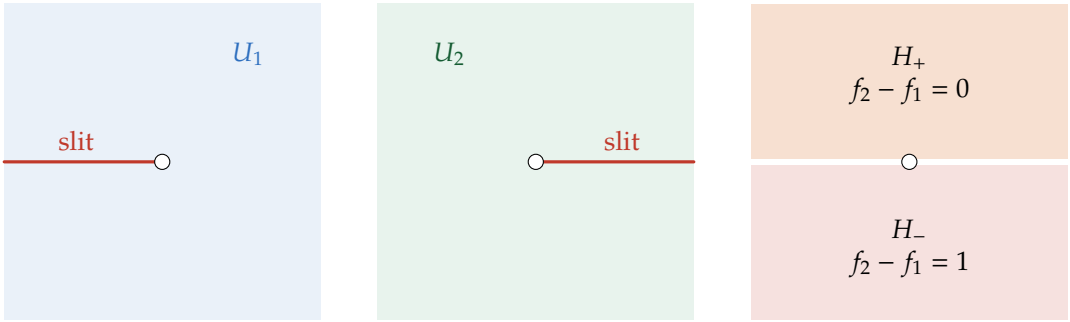

Figure 3.18: Computing $\delta^*[z]$ on $\mathbb{C}^*$. Each slit plane carries a branch of $\frac{1}{2\pi i}\log z$. On the overlap (right) the two branches agree in the upper half-plane and differ by exactly 1 in the lower half-plane. That integer mismatch is the Čech 1-cocycle representing the winding number.

3.5 Line bundles, $H^1(M;\mathcal{O}^*)$ and the first Chern class

This section is not in Nash's §2, but the brief for these notes asks for it, and it is the reason a physicist should care about H^1 and H^2. It also prepares for the characteristic classes of §5 of Nash's chapter. The statement is:

> *Complex line bundles (equivalently $U(1)$ gauge fields' "topological sectors") are classified by H^1 of a multiplicative sheaf; the exponential sequence turns this into an integer class $c_1 \in H^2(M;\mathbb{Z})$; and for the Dirac monopole c_1 is the quantised magnetic charge.*

3.5.1 Line bundles are 1-cocycles

A complex line bundle $L \to M$ is given by a cover $\{U_i\}$ and transition functions $g_{ij} : U_{ij} \to \mathbb{C}^*$ with $s_i = g_{ij}s_j$ (3.5) and $g_{ij}g_{jk} = g_{ik}$ (3.6). In the language of the previous section:

- the collection (g_{ij}) is a 1-cochain with coefficients in the multiplicative sheaf $\mathcal{E}^*$ (smooth L) or $\mathcal{O}^*$ (holomorphic L);
- the cocycle condition $g_{ij}g_{jk}g_{ik}^{-1} = 1$ says exactly that $\delta g = 1$ (the multiplicative form of (3.27)).

Now change the trivialisations: $s'_i = h_i s_i$ with $h_i : U_i \to \mathbb{C}^*$. Then

$$s'_i \overset{(1)}{=} h_i\, g_{ij}\, s_j \overset{(2)}{=} h_i\, g_{ij}\, h_j^{-1}\, s'_j, \qquad \text{so} \qquad g'_{ij} = g_{ij}\, h_i h_j^{-1} = g_{ij}\,(\delta h)_{ij}^{-1},$$

(1) Definition of s'_i and the transition rule $s_i = g_{ij} s_j$.
(2) Invert $s'_j = h_j s_j$.

using the multiplicative coboundary $(\delta h)_{ij} = h_j h_i^{-1}$. So isomorphic bundles have transition cocycles that differ by a coboundary.

Key idea: Line bundles = H^1 of the multiplicative sheaf

Isomorphism classes of smooth complex line bundles on M are in one-to-one correspondence with $H^1(M;\mathcal{E}^*)$; holomorphic line bundles on a complex manifold with $H^1(M;\mathcal{O}^*)$. Tensor product of bundles is multiplication of cocycles, $(L \otimes L')_{ij} = g_{ij} g'_{ij}$, and the dual bundle has cocycle g_{ij}^{-1}. So line bundles form an abelian group, the **Picard group** $\mathrm{Pic}(M) = H^1(M;\mathcal{O}^*)$.

For $U(1)$ gauge theory one may use $U(1)$-valued transition functions instead of $\mathbb{C}^*$-valued ones. Nothing changes: any $g : U \to \mathbb{C}^*$ can be written $g = |g| \cdot (g/|g|)$, and the positive factor $|g| = e^{\ln|g|}$ is the exponential of a smooth real function, which a partition of unity can always absorb into the h_i. So smooth complex line bundles = $U(1)$ bundles, and the transition functions are the gauge transformations between patches.

Worked example 3.20: The bundles $\mathcal{O}(n)$ as classes

On $\mathbb{CP}^1$ with the two-set cover, $\mathcal{O}(n)$ has the single transition function $g_{01} = z^n$ (3.7). Tensor products: $\mathcal{O}(m) \otimes \mathcal{O}(n)$ has $z^m z^n = z^{m+n}$, so $\mathcal{O}(m) \otimes \mathcal{O}(n) \cong \mathcal{O}(m+n)$, and $\mathcal{O}(n)^* \cong \mathcal{O}(-n)$. Are the $\mathcal{O}(n)$ different from each other? A coboundary on this cover is $h_1 h_0^{-1}$ with h_0 nonvanishing entire in z and h_1 nonvanishing entire in $w = 1/z$. A nonvanishing entire function has winding number 0 round any circle (its logarithm is entire), so every coboundary has winding number 0 round $|z| = 1$, while z^n has winding number n. Hence the classes $[z^n]$ are all distinct. We will now see that the winding number is the first Chern class.

3.5.2 The first Chern class from the exponential sequence

Apply the long exact sequence to the *smooth* exponential sequence (3.16), $0 \to \underline{\mathbb{Z}} \to \mathcal{E}_{\mathbb{C}} \to \mathcal{E}^* \to 0$. The middle sheaf is fine, so $H^q(M;\mathcal{E}_{\mathbb{C}}) = 0$ for $q \geq 1$, and the relevant stretch of (3.37) is

$$0 = H^1(M;\mathcal{E}_{\mathbb{C}}) \longrightarrow H^1(M;\mathcal{E}^*) \xrightarrow{\delta^*} H^2(M;\underline{\mathbb{Z}}) \longrightarrow H^2(M;\mathcal{E}_{\mathbb{C}}) = 0. \tag{3.40}$$

So δ^* is an *isomorphism*: smooth complex line bundles are classified by an integer cohomology class, their **first Chern class**.

Working definition 3.15 (Čech formula for c_1)

Given transition functions g_{ij} on a good cover [every set and every nonempty overlap is contractible], choose on each (connected, contractible) overlap a branch [one value of the multivalued log, so λ_{ij} is fixed up to adding an integer] of

$$\lambda_{ij} = \frac{i}{2\pi} \log g_{ij}, \qquad \text{so that} \qquad g_{ij} = e^{-2\pi i \lambda_{ij}}, \tag{3.41}$$

with $\lambda_{ji} = -\lambda_{ij}$. Then

$$n_{ijk} = \lambda_{jk} - \lambda_{ik} + \lambda_{ij} = (\delta\lambda)_{ijk} \tag{3.42}$$

is a locally constant *integer* on each triple overlap, $\delta n = 0$, and $c_1(L) = [n] \in H^2(M;\mathbb{Z})$. *Operational recipe:* take logs of the transition functions, add them round each triangle of the nerve [each triple i, j, k with U_{ijk} nonempty], the integers you get are the Chern cocycle.

Why the n_{ijk} are integers. Exponentiate:

$$e^{-2\pi i\, n_{ijk}} \overset{(1)}{=} e^{-2\pi i\lambda_{jk}}\, e^{+2\pi i\lambda_{ik}}\, e^{-2\pi i\lambda_{ij}} \overset{(2)}{=} g_{jk}\, g_{ik}^{-1}\, g_{ij} \overset{(3)}{=} 1,$$

(1) Definition (3.42); exponentials turn sums into products.
(2) Definition (3.41).
(3) The cocycle condition $g_{ij}g_{jk} = g_{ik}$ (the g's are numbers, so they commute).

A continuous function n_{ijk} with $e^{-2\pi i n_{ijk}} = 1$ takes integer values, and is constant on each connected component. It is a Čech cocycle because it is a coboundary ($\delta n = \delta\delta\lambda = 0$) of real-valued cochains; it is *not* in general the coboundary of an integer-valued cochain, and that is the whole point. This is exactly the zig-zag of Figure 3.17: $\gamma = g$, lift $\beta = \lambda$, $\alpha = n = \delta\lambda$.

Why the class is well defined. Two kinds of choice were made.

- *Branches of the logarithm:* $\lambda_{ij} \mapsto \lambda_{ij} + m_{ij}$ with $m_{ij} \in \mathbb{Z}$ changes n by δm, an integer coboundary.
- *Trivialisations:* $g_{ij} \mapsto g_{ij} h_i h_j^{-1}$ changes λ_{ij} by $\mu_i - \mu_j$ with $\mu_i = \frac{i}{2\pi}\log h_i$ (a logarithm exists on the contractible U_i), i.e. by $-(\delta\mu)_{ij}$, and then n changes by $-\delta\delta\mu = 0$.

Watch out: The sign of c_1 is a convention

Nash's exponential map is $f \mapsto e^{2\pi i f}$, so his connecting homomorphism uses $f_{ij} = \frac{1}{2\pi i}\log g_{ij} = -\lambda_{ij}$ and produces $-[n]$. Different books also differ on whether g_{ij} acts on components ($s_i = g_{ij}s_j$, as here) or on frames, which inverts g. The only convention-independent statement is the normalisation: *c_1 is fixed so that $c_1(\mathcal{O}(1)) = +1$ on $\mathbb{CP}^1$ with its complex orientation, and so that c_1 agrees with the curvature integral $\frac{i}{2\pi}\int F$* (Section 3.6.4). Our $\lambda_{ij} = \frac{i}{2\pi}\log g_{ij}$ is chosen to make both hold, and it parallels the real curvature form $\frac{i}{2\pi}F$ of Section 3.6.4.

The holomorphic version

For holomorphic bundles the middle sheaf $\mathcal{O}$ is *not* fine, and the long exact sequence of $0 \to \mathbb{Z} \to \mathcal{O} \to \mathcal{O}^* \to 0$ reads

$$H^1(M;\mathbb{Z}) \to H^1(M;\mathcal{O}) \to H^1(M;\mathcal{O}^*) \xrightarrow{c_1} H^2(M;\mathbb{Z}) \to H^2(M;\mathcal{O}). \tag{3.43}$$

So a holomorphic line bundle still has an integer Chern class, but now

- bundles with $c_1 = 0$ need not be holomorphically trivial: they form the group obtained from $H^1(M;\mathcal{O})$ by dividing out the image of $H^1(M;\mathbb{Z})$. This is a complex torus when M is compact Kähler, called the **Picard variety** or **Jacobian**;
- not every integer class need come from a holomorphic bundle: the obstruction lies in $H^2(M;\mathcal{O})$.

Worked example 3.21: Holomorphic line bundles on $\mathbb{CP}^1$ and on a torus

$\mathbb{CP}^1$. $H^1(\mathbb{CP}^1;\mathcal{O}) = 0$ (Example 3.18, $n = 0$) and $H^2(\mathbb{CP}^1;\mathcal{O}) = 0$ (a two-set Leray cover has no 2-cochains). By (3.43), $c_1 : \mathrm{Pic}(\mathbb{CP}^1) \to H^2(\mathbb{CP}^1;\mathbb{Z}) = \mathbb{Z}$ is an isomorphism. Every holomorphic line bundle on the Riemann sphere is $\mathcal{O}(n)$ for exactly one n, and $n = c_1$.
Torus $T = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$. Here $H^1(T;\mathbb{Z}) = \mathbb{Z}^2$ and $H^1(T;\mathcal{O}) \cong \mathbb{C}$ (Example 3.33). The bundles with $c_1 = 0$ form $\mathbb{C}/\mathbb{Z}^2$, a torus again: a flat $U(1)$ bundle on T is specified by the two holonomies ("Wilson lines") $e^{i\theta_1}, e^{i\theta_2}$ round the two cycles, and each such flat bundle carries a unique holomorphic structure. The moduli space of flat line bundles is the dual torus.

3.5.3 The Dirac monopole as a Čech cocycle

Now the physics. A magnetic monopole of strength g_m at the origin of $\mathbb{R}^3$ has field $\vec{B} = g_m\,\hat{r}/r^2$, i.e. the closed 2-form

$$F^{\mathrm{phys}} = g_m \sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi \qquad \text{on } S^2 \text{ (any sphere round the origin)}, \qquad \int_{S^2} F^{\mathrm{phys}} = 4\pi g_m. \tag{3.44}$$

(We write g_m for the magnetic charge, to avoid a clash with the transition functions g_{ij}; units $\hbar = c = 1$.) Because $\int_{S^2} F \neq 0$, Stokes' theorem forbids a global potential: if $F = \mathrm{d}A$ on all of S^2 then $\int_{S^2} F = \int_{\partial S^2} A = 0$. Wu and Yang's resolution is to use two patches.

Worked example 3.22: Two patches, and quantisation as a well-defined transition function

Let $U_N = \{\theta < \frac{\pi}{2} + \varepsilon\}$ and $U_S = \{\theta > \frac{\pi}{2} - \varepsilon\}$, and put

$$A_N^{\mathrm{phys}} = g_m(1-\cos\theta)\,\mathrm{d}\phi, \qquad A_S^{\mathrm{phys}} = -g_m(1+\cos\theta)\,\mathrm{d}\phi. \tag{3.45}$$

Each is smooth on its patch: $\mathrm{d}\phi$ is singular at the poles, but its coefficient vanishes at $\theta = 0$ for A_N and at $\theta = \pi$ for A_S (the would-be Dirac strings are pushed into the other patch). Both give the monopole field:

$$\mathrm{d}A_N^{\mathrm{phys}} \overset{(1)}{=} g_m\,\mathrm{d}(1-\cos\theta)\wedge\mathrm{d}\phi \overset{(2)}{=} g_m\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi = F^{\mathrm{phys}},$$

(1) $\mathrm{d}(f\,\mathrm{d}\phi) = \mathrm{d}f\wedge\mathrm{d}\phi$ since $\mathrm{d}\mathrm{d}\phi = 0$ away from the poles.
(2) $\mathrm{d}(-\cos\theta) = \sin\theta\,\mathrm{d}\theta$.

and similarly for A_S. On the overlap they differ by a gauge transformation:

$$A_N^{\mathrm{phys}} - A_S^{\mathrm{phys}} \overset{(1)}{=} g_m\big[(1-\cos\theta)+(1+\cos\theta)\big]\mathrm{d}\phi = 2g_m\,\mathrm{d}\phi = \mathrm{d}\Lambda, \qquad \Lambda = 2g_m\phi.$$

(1) Subtract (3.45).

A particle of charge e couples through $D = \mathrm{d} - ieA^{\mathrm{phys}}$, and the wavefunctions in the two gauges are related by $\psi_N = e^{ie\Lambda}\psi_S = e^{2ieg_m\phi}\psi_S$. The transition function of the line bundle in which ψ lives is therefore

$$g_{NS} = e^{2ieg_m\phi} \quad \text{on the equatorial annulus } U_{NS}.$$

This must be a single-valued function on the annulus, i.e. a section of $\mathcal{E}^*(U_{NS})$. Going once round, $\phi \to \phi + 2\pi$:

$$e^{2ieg_m(\phi+2\pi)} = e^{2ieg_m\phi} \iff e^{4\pi ieg_m} = 1 \iff 2eg_m = n \in \mathbb{Z}. \tag{3.46}$$

This is **Dirac's quantisation condition**. The bundle is then the one with $g_{NS} = e^{in\phi}$, which on $\mathbb{CP}^1 = S^2$ is $\mathcal{O}(n)$ restricted to the equator (with $z = \tan(\theta/2)e^{i\phi}$, $U_N = U_0$, and $z^n = e^{in\phi}$ on $|z| = 1$).

The two-patch cover has no triple overlaps, so it cannot display c_1 as a Čech 2-cocycle: in this cover the integer is hidden in the requirement that g_{NS} be single-valued on a non-contractible overlap, just as the two-cap cover of S^2 hid H^2 (Example 3.16). To see the cocycle we refine.

Worked example 3.23: A three-set cover of S^2 and the monopole cocycle

Keep $V_1 = U_N$ and split the southern region into two overlapping halves that share a neighbourhood of the south pole (Figure 3.19):

$$V_2 = U_S \cap \big(\{\phi \in (-\varepsilon, \pi + \varepsilon)\} \cup D\big), \qquad V_3 = U_S \cap \big(\{\phi \in (\pi - \varepsilon, 2\pi + \varepsilon)\} \cup D\big),$$

where D is a small disc round the south pole. The overlaps are:

- V_{12}, V_{13}: the two halves of the equatorial annulus (contractible);
- V_{23}: a band through the south pole along the meridians $\phi = 0$ and $\phi = \pi$, together with D (contractible);
- V_{123}: *two* small squares on the equator, one near $\phi = 0$ and one near $\phi = \pi$.

All pieces are contractible, so this is a Leray cover for $\underline{\mathbb{Z}}$.
Cohomology of S^2 from this cover. $C^0 = \mathbb{Z}^3$, $C^1 = \mathbb{Z}^3$, $C^2 = \underline{\mathbb{Z}}(V_{123}) = \mathbb{Z}^2 \ni (m_0, m_\pi)$ (one integer per square). A 1-cochain (c_{12}, c_{13}, c_{23}) consists of constants on connected sets, so

$$(\delta c)_{123} = c_{23} - c_{13} + c_{12} \text{ takes the same value on both squares:} \qquad \operatorname{Im} \delta_1 = \{(m, m)\}.$$

Hence $H^2 = \mathbb{Z}^2/\{(m,m)\} \cong \mathbb{Z}$ via $\ell(m) = m_0 - m_\pi$. (One also checks $H^0 = \mathbb{Z}$, $H^1 = 0$ as for the tetrahedron.) The choice of sign in ℓ is the one compatible with integration, as the Čech–de Rham check in Example 3.27 confirms.
The monopole cocycle. The transition functions from V_1 (north gauge) to V_2, V_3 (south gauge) are $e^{in\phi}$, and V_2, V_3 use the same gauge:

$$g_{12} = e^{in\phi} \text{ on } V_{12}, \qquad g_{13} = e^{in\phi} \text{ on } V_{13}, \qquad g_{23} = 1.$$

Take logarithms with ϕ in the range natural to each set, $\phi \in (-\varepsilon, \pi + \varepsilon)$ on V_{12} and $\phi \in (\pi - \varepsilon, 2\pi + \varepsilon)$ on V_{13}:

$$\lambda_{12} \overset{(1)}{=} \frac{i}{2\pi}(in\phi) = -\frac{n\phi}{2\pi}, \qquad \lambda_{13} = -\frac{n\phi}{2\pi}, \qquad \lambda_{23} = 0.$$

(1) Definition (3.41); $\log e^{in\phi} = in\phi$ is a smooth branch on each (contractible) half-annulus.

Now evaluate (3.42) on the two squares:

$$n_{123}\big|_{\phi\approx\pi} \overset{(1)}{=} 0 - \left(-\frac{n\pi}{2\pi}\right) + \left(-\frac{n\pi}{2\pi}\right) = 0,$$
$$n_{123}\big|_{\phi\approx 0} \overset{(2)}{=} 0 - \left(-\frac{n\cdot 2\pi}{2\pi}\right) + \left(-\frac{n\cdot 0}{2\pi}\right) = n.$$

(1) Near $\phi = \pi$ both half-annuli use the same value of the angle.
(2) Near $\phi = 0$ the square is at $\phi \approx 0$ as seen from V_{12} but at $\phi \approx 2\pi$ as seen from V_{13}.

So $n = (n_0, n_\pi) = (n, 0)$ and $c_1 = \ell(n) = n$: the Chern class is the quantised magnetic charge $2eg_m$.
Dirac's condition as the cocycle condition. Suppose we did not know (3.46) and wrote $g_{12} = e^{2ieg_m\phi}$ on V_{12}, $g_{13} = e^{2ieg_m\phi}$ on V_{13}, $g_{23} = 1$. On this cover each of these is a perfectly good function, because each overlap is contractible and we never go round a loop. The only condition left is the cocycle condition $g_{12}g_{23} = g_{13}$ on V_{123}. Near $\phi = \pi$ it holds trivially. Near $\phi = 0$:

$$g_{12}\,g_{23} = g_{13} \overset{(1)}{\iff} e^{2ieg_m\phi} = e^{2ieg_m(\phi+2\pi)} \iff e^{4\pi ieg_m} = 1 \iff 2eg_m \in \mathbb{Z}.$$

(1) On the square near $\phi = 0$ the angle is ϕ in V_{12} and $\phi + 2\pi$ in V_{13}.

Dirac quantisation is literally the Čech cocycle condition on the triple overlap, and the resulting integer is the class of the cocycle in $H^2(S^2;\mathbb{Z})$.

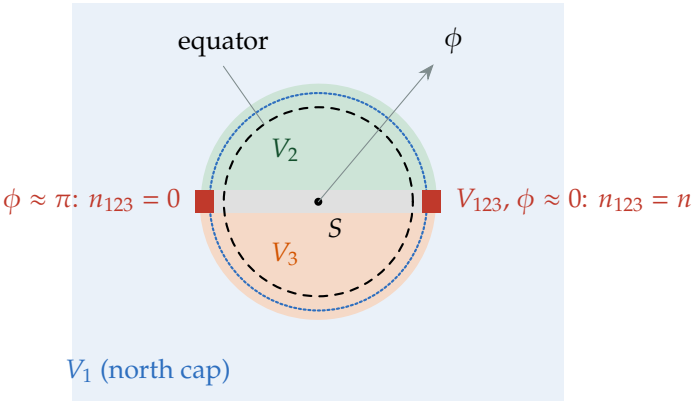

Figure 3.19: The three-set cover of S^2 used for the monopole, drawn by stereographic projection from the north pole (south pole at the centre, equator dashed, north cap V_1 everything outside the blue dotted circle). The southern halves V_2 (green, $0 < \phi < \pi$) and V_3 (orange, $\pi < \phi < 2\pi$) overlap along the grey band through S. The triple overlap is the two red squares on the equator. The angle ϕ is continuous on each half but jumps by 2π between V_{12} and V_{13} at $\phi \approx 0$: that is where the Chern integer n sits.

Dictionary: Monopole physics ↔ Čech data

Physics	Sheaf cohomology
local gauge potential A_i on patch U_i	0-cochain of $\mathcal{E}^1$
gauge transformation $e^{ie\Lambda_{ij}}$ between patches	1-cochain g_{ij} of $\mathcal{E}^*$
consistency on triple overlaps	$\delta g = 1$
global gauge change $\psi_i \mapsto e^{ie\chi_i}\psi_i$	$g \mapsto g \cdot (\delta h)^{-1}$
topological sector (bundle)	class in $H^1(M;\mathcal{E}^*)$
Dirac quantisation $2e g_m = n$	$\delta g = 1$ on a refined cover; $n = [\delta\lambda]$
magnetic charge n	$c_1 \in H^2(S^2;\mathbb{Z}) \cong \mathbb{Z}$
flux $\frac{e}{2\pi}\int F^{\text{phys}} = n$	de Rham image of c_1

Physical picture: Why magnetic charge is an integer

On each patch you may shift the phase of the wavefunction as you like. What you cannot change is the *mismatch round a triangle of patches*: the product of three gauge transformations round a triple overlap must be 1, so the sum of their logarithms is 2π times an integer. Summed over the sphere, those integers give the total flux in units of $2\pi/e$. Quantisation of magnetic charge is the statement that c_1 lives in $H^2(M;\mathbb{Z})$ rather than $H^2(M;\mathbb{R})$.

Reading Nash (pp. 62–63, (3.18)–(3.19))

Nash states the long exact sequence (3.19) for $0 \to \mathcal{E} \to \mathcal{F} \to \mathcal{G} \to 0$ (3.18) without constructing the connecting maps; he calls it "one of the most fundamental calculational tools". Our Section 3.4.1 builds δ^* by the zig-zag and checks exactness at one spot. Nash's

only application in §2 is the de Rham and Dolbeault theorems, which follow. Line bundles, c_1 via the exponential sequence (his (3.8)), and the monopole are our additions; Nash returns to Chern classes in §5 of this chapter (via curvature) and to monopoles and instantons in Chapter 8.

Recap

- A short exact sequence of sheaves gives a long exact sequence in cohomology. The connecting map δ^* is the zig-zag: lift, apply δ, pull back.
- δ^* for the exponential sequence on $\mathbb{C}^*$ is the winding number; with $H^1(\mathbb{C}^*;\mathcal{O}) = 0$ this gives every nonvanishing holomorphic function as $z^m e^{2\pi i h}$.
- Line bundles are 1-cocycles of $\mathcal{E}^*$ or $\mathcal{O}^*$; isomorphism classes form $H^1(M;\mathcal{E}^*)$ or $\mathrm{Pic}(M) = H^1(M;\mathcal{O}^*)$.
- The exponential sequence gives $c_1 : H^1(M;\mathcal{E}^*) \xrightarrow{\cong} H^2(M;\mathbb{Z})$, computed by $n_{ijk} = \delta\lambda$, $\lambda_{ij} = \frac{i}{2\pi}\log g_{ij}$. On $\mathbb{CP}^1$, $\mathrm{Pic} = \mathbb{Z}$ via $c_1(\mathcal{O}(n)) = n$.
- Dirac monopole: two patches, $g_{NS} = e^{2ieg_m\phi}$; on a refined cover Dirac's condition $2eg_m \in \mathbb{Z}$ is the cocycle condition, and $c_1 = 2eg_m$.

3.6 The de Rham theorem

We now have two completely different ways of computing "the cohomology of a circle".

- *Combinatorially.* Cover S^1 by arcs, write one real number on each overlap, and compute the kernel and image of a small integer matrix (Example 3.13, Example 3.14). Answer: $H^1(S^1;\mathbb{R}) \cong \mathbb{R}$.
- *Analytically.* Take closed 1-forms on S^1 modulo exact ones. Every 1-form is closed; $f(\theta)\,d\theta$ is exact precisely when $\oint f\,d\theta = 0$. Answer: $H^1_{\mathrm{dR}}(S^1) \cong \mathbb{R}$, via $\oint$.

The answers agree. Is that a coincidence? The **de Rham theorem** says it is not: for every manifold and every degree,

$$H^q(M;\mathbb{R}) \;\cong\; H^q_{\mathrm{dR}}(M) = \frac{\{\text{closed } q\text{-forms}\}}{\{\text{exact } q\text{-forms}\}}.$$

The left side knows only about open sets and locally constant numbers. The right side knows about derivatives and integrals. Nash proves the theorem in half a page, using the long exact sequence and the fact that the sheaves of forms are soft. In this section we unpack his argument step by step, then make the isomorphism completely explicit with the Čech–de Rham double complex, and finally run it on the monopole, where it turns "field strength" into "potentials on patches" into "gauge transformations on overlaps" into "an integer on triple overlaps".

Physical picture: Why a physicist should care

De Rham cohomology is where *fluxes* live: $\int_\Sigma F$ over closed surfaces, $\oint A$ round closed loops. Čech cohomology is where *patching data* live: gauge transformations between coordinate patches. The de Rham theorem says these are the same information. It is the reason that a flux through a closed surface can be read off from how the gauge potentials

are glued, and conversely.

3.6.1 The de Rham resolution

Recall the sheaves involved (Example 3.10):

- $\mathcal{E}^p$: smooth p-forms. Its sections over U are the p-forms on U. It is fine (multiply by a partition of unity).
- $\mathcal{Z}^p \subset \mathcal{E}^p$: *closed* p-forms, $\mathrm{d}\omega = 0$. It is not fine: $\rho\,\omega$ is usually not closed.
- $\mathcal{Z}^0 = \underline{\mathbb{R}}$: a closed 0-form is a function with $\mathrm{d}f = 0$, i.e. a locally constant function.

The exterior derivative is a sheaf morphism $\mathrm{d} : \mathcal{E}^p \to \mathcal{E}^{p+1}$ (it is local: $\mathrm{d}(\omega|_U) = (\mathrm{d}\omega)|_U$). Stringing these together we get a long sequence of sheaves

$$0 \longrightarrow \underline{\mathbb{R}} \xrightarrow{\iota} \mathcal{E}^0 \xrightarrow{\mathrm{d}} \mathcal{E}^1 \xrightarrow{\mathrm{d}} \mathcal{E}^2 \xrightarrow{\mathrm{d}} \cdots \xrightarrow{\mathrm{d}} \mathcal{E}^n \longrightarrow 0, \tag{3.47}$$

where ι regards a locally constant function as a smooth one.

Working definition 3.16 (fine resolution)

A **resolution** of a sheaf $\mathcal{F}$ is an exact sequence of sheaves [what one map kills, the previous map produces, on some small neighbourhood of each point] $0 \to \mathcal{F} \to \mathcal{L}^0 \to \mathcal{L}^1 \to \cdots$. It is a **fine resolution** if every $\mathcal{L}^p$ is fine [its sections can be cut up by a partition of unity, like smooth forms]. *Operational test for exactness:* on a small ball round any point, every section of $\mathcal{L}^p$ killed by the next map comes from a section of $\mathcal{L}^{p-1}$. For (3.47) that is the Poincaré lemma: *on a ball every closed form is exact.*

So (3.47) is a fine resolution of $\underline{\mathbb{R}}$. The content is entirely the Poincaré lemma, which we checked for 1-forms in (3.15). For higher forms the same radial trick works. On a star-shaped domain centred at 0 define, for a p-form ω,

$$(h\omega)(x) = \int_0^1 t^{\,p-1}\, \iota_x\, \omega(tx)\, \mathrm{d}t, \tag{3.48}$$

where ι_x inserts the radial vector $x^\mu \partial_\mu$ into the first slot. One checks $\mathrm{d}h\omega + h\,\mathrm{d}\omega = \omega$ for $p \geq 1$, so a closed ω is $\mathrm{d}(h\omega)$. Rather than prove the general identity, we check it where every physicist has used it.

Worked example 3.24: The Poincaré lemma for 2-forms: a vector potential for any divergence-free $\vec{B}$

In $\mathbb{R}^3$ a 2-form is a vector field $\vec{B}$ (via $B_x\,\mathrm{d}y \wedge \mathrm{d}z + \cdots$), and it is closed exactly when $\nabla \cdot \vec{B} = 0$. The formula (3.48) with $p = 2$ becomes

$$\vec{A}(\vec{x}) = \int_0^1 t\, \vec{B}(t\vec{x}) \times \vec{x}\, \mathrm{d}t. \tag{3.49}$$

We check $\nabla \times \vec{A} = \vec{B}$ when $\nabla \cdot \vec{B} = 0$. Write $\vec{b} = \vec{B}(t\vec{x})$ for the field evaluated at the scaled point, and use the identity $\nabla \times (\vec{u} \times \vec{v}) = \vec{u}(\nabla \cdot \vec{v}) - \vec{v}(\nabla \cdot \vec{u}) + (\vec{v} \cdot \nabla)\vec{u} - (\vec{u} \cdot \nabla)\vec{v}$ with $\vec{u} = \vec{b}$, $\vec{v} = \vec{x}$:

$$\nabla \times (\vec{b} \times \vec{x}) \overset{(1)}{=} \vec{b}\,(\nabla \cdot \vec{x}) - \vec{x}\,(\nabla \cdot \vec{b}) + (\vec{x} \cdot \nabla)\vec{b} - (\vec{b} \cdot \nabla)\vec{x}$$

$$\overset{(2)}{=} 3\,\vec{b} - \vec{x}\; t\,(\nabla\cdot\vec{B})(t\vec{x}) + t\,\frac{\mathrm{d}}{\mathrm{d}t}\vec{B}(t\vec{x}) - \vec{b}$$
$$\overset{(3)}{=} 2\,\vec{B}(t\vec{x}) + t\,\frac{\mathrm{d}}{\mathrm{d}t}\vec{B}(t\vec{x}).$$

(1) The vector identity for the curl of a cross product.

(2) $\nabla\cdot\vec{x} = 3$; the chain rule gives $\partial_j[B_k(t\vec{x})] = t(\partial_j B_k)(t\vec{x})$, so $\nabla\cdot\vec{b} = t(\nabla\cdot\vec{B})(t\vec{x})$ and $(\vec{x}\cdot\nabla)\vec{b} = t\,x^j(\partial_j\vec{B})(t\vec{x}) = t\frac{\mathrm{d}}{\mathrm{d}t}\vec{B}(t\vec{x})$; finally $(\vec{b}\cdot\nabla)\vec{x} = \vec{b}$.

(3) $\nabla\cdot\vec{B} = 0$ kills the second term; $3\vec{b} - \vec{b} = 2\vec{b}$.

Now multiply by t and integrate:

$$\nabla\times\vec{A} \overset{(1)}{=} \int_0^1 \Big(2t\,\vec{B}(t\vec{x}) + t^2\frac{\mathrm{d}}{\mathrm{d}t}\vec{B}(t\vec{x})\Big)\mathrm{d}t \overset{(2)}{=} \int_0^1 \frac{\mathrm{d}}{\mathrm{d}t}\Big(t^2\,\vec{B}(t\vec{x})\Big)\mathrm{d}t \overset{(3)}{=} \vec{B}(\vec{x}).$$

(1) Differentiate (3.49) under the integral and use the previous chain.

(2) Product rule: $\frac{\mathrm{d}}{\mathrm{d}t}(t^2\vec{B}) = 2t\vec{B} + t^2\frac{\mathrm{d}\vec{B}}{\mathrm{d}t}$.

(3) Fundamental theorem of calculus; the $t = 0$ end vanishes because of the factor t^2.

For a uniform field $\vec{B} = B\hat{z}$ this gives $\vec{A} = \frac{1}{2}B\,\hat{z}\times\vec{x} = \frac{1}{2}B(-y, x, 0)$, the symmetric gauge of Landau-level problems. For the monopole field $\vec{B} = g_m\hat{r}/r^2$ the formula fails: the domain $\mathbb{R}^3\setminus\{0\}$ is not star-shaped, the segment from 0 to $\vec{x}$ passes through the monopole, and, as we know, no global $\vec{A}$ exists. Exactness of (3.47) is a *local* statement, true on balls; what fails globally is the business of cohomology.

Nash does not use the long resolution (3.47) directly. He chops it into short exact pieces, one for each degree:

$$\begin{gathered} 0\to\underline{\mathbb{R}}\to\mathcal{E}^0\xrightarrow{\mathrm{d}}\mathcal{Z}^1\to 0, \qquad 0\to\mathcal{Z}^1\to\mathcal{E}^1\xrightarrow{\mathrm{d}}\mathcal{Z}^2\to 0, \qquad \dots, \\ 0\to\mathcal{Z}^p\to\mathcal{E}^p\xrightarrow{\mathrm{d}}\mathcal{Z}^{p+1}\to 0, \qquad \dots \end{gathered} \tag{3.50}$$

This is his (3.20). Each piece is exact by the Poincaré lemma, and each has a fine sheaf in the middle. Figure 3.20 shows how the pieces fit back together: every $\mathcal{Z}^{p+1}$ is at the same time the image of $\mathcal{E}^p$ and the kernel in $\mathcal{E}^{p+1}$.

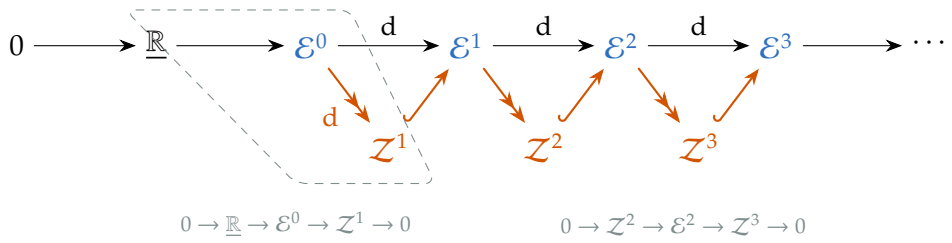

Figure 3.20: Splicing. The long exact de Rham resolution (top row) is built from the short exact sequences (3.50) (the "V" shapes, one of which is outlined): $\mathcal{E}^p$ maps *onto* the closed forms $\mathcal{Z}^{p+1}$ (Poincaré lemma), which then sit *inside* $\mathcal{E}^{p+1}$. Blue sheaves are fine and cohomologically invisible; orange sheaves carry the topology.

3.6.2 Nash's dimension-shifting argument

Feed one short sequence $0 \to \mathcal{Z}^p \to \mathcal{E}^p \to \mathcal{Z}^{p+1} \to 0$ into the long exact sequence (3.37). A typical stretch is

$$\cdots \to H^k(M;\mathcal{E}^p) \to H^k(M;\mathcal{Z}^{p+1}) \xrightarrow{\delta^*} H^{k+1}(M;\mathcal{Z}^p) \to H^{k+1}(M;\mathcal{E}^p) \to \cdots \tag{3.51}$$

Because $\mathcal{E}^p$ is fine, $H^k(M;\mathcal{E}^p) = 0$ for every $k \geq 1$ (Section 3.3.7). Two cases follow.

Case $k \geq 1$. Both outer groups in (3.51) vanish:

$$0 \to H^k(M;\mathcal{Z}^{p+1}) \xrightarrow{\delta^*} H^{k+1}(M;\mathcal{Z}^p) \to 0,$$

and a map sandwiched between zeros in an exact sequence is an isomorphism (injective because the kernel is the image of 0; surjective because the image is the kernel of the map to 0, which is everything). So

$$H^{k+1}(M;\mathcal{Z}^p) \cong H^k(M;\mathcal{Z}^{p+1}) \qquad (k \geq 1). \tag{3.52}$$

Moving one step up in the sheaf lowers the degree by one.

Case $k = 0$. Now the left end is $H^0(M;\mathcal{E}^p) = \mathcal{E}^p(M)$, the global p-forms, which is certainly not zero. The sequence is

$$\mathcal{E}^p(M) \xrightarrow{\mathrm{d}} \mathcal{Z}^{p+1}(M) \xrightarrow{\delta^*} H^1(M;\mathcal{Z}^p) \longrightarrow H^1(M;\mathcal{E}^p) = 0,$$

so δ^* is onto, with kernel the image of d:

$$H^1(M;\mathcal{Z}^p) \cong \frac{\mathcal{Z}^{p+1}(M)}{\mathrm{d}\,\mathcal{E}^p(M)} = \frac{\text{closed } (p+1)\text{-forms on } M}{\text{exact } (p+1)\text{-forms on } M} = H^{p+1}_{\mathrm{dR}}(M). \tag{3.53}$$

This is Nash's (3.22), with $H^0(M;\mathcal{Z}^{p+1}) = \mathcal{Z}^{p+1}(M)$ and $H^0(M;\mathcal{E}^p) = \mathcal{E}^p(M)$ by (3.17).

Now chain the isomorphisms. For $q \geq 1$,

$$\begin{aligned} H^q(M;\underline{\mathbb{R}}) &\overset{(1)}{=} H^q(M;\mathcal{Z}^0) \\ &\overset{(2)}{=} H^{q-1}(M;\mathcal{Z}^1) \overset{(2)}{=} H^{q-2}(M;\mathcal{Z}^2) \overset{(2)}{=} \cdots \overset{(2)}{=} H^1(M;\mathcal{Z}^{q-1}) \\ &\overset{(3)}{=} \frac{\mathcal{Z}^q(M)}{\mathrm{d}\,\mathcal{E}^{q-1}(M)} \overset{(4)}{=} H^q_{\mathrm{dR}}(M). \end{aligned} \tag{3.54}$$

(1) $\underline{\mathbb{R}} = \mathcal{Z}^0$: locally constant functions are the closed 0-forms.
(2) Each step is (3.52) with $(k+1, p) = (q-j, j)$, which needs $k = q-j-1 \geq 1$; we can go on until the degree has dropped to 1. (Here "=" means "is canonically isomorphic to". For $q = 1$ this line is empty.)
(3) The last step (3.53) with $p = q-1$.
(4) Definition of de Rham cohomology.

For $q = 0$ both sides are the locally constant functions: $H^0(M;\underline{\mathbb{R}}) = \underline{\mathbb{R}}(M)$, and $H^0_{\mathrm{dR}}(M) = \{f : \mathrm{d}f = 0\}$.

Key idea: The de Rham theorem (Nash's (3.23))

For every smooth manifold M and every $q \geq 0$,

$$H^q(M;\mathbb{R}) \;\cong\; H^q_{\mathrm{dR}}(M).$$

The mechanism: $\underline{\mathbb{R}}$ has a resolution by fine sheaves (the Poincaré lemma), fine sheaves have

no higher cohomology (partitions of unity), and the long exact sequence shifts degrees until everything is expressed through global sections, which are forms.

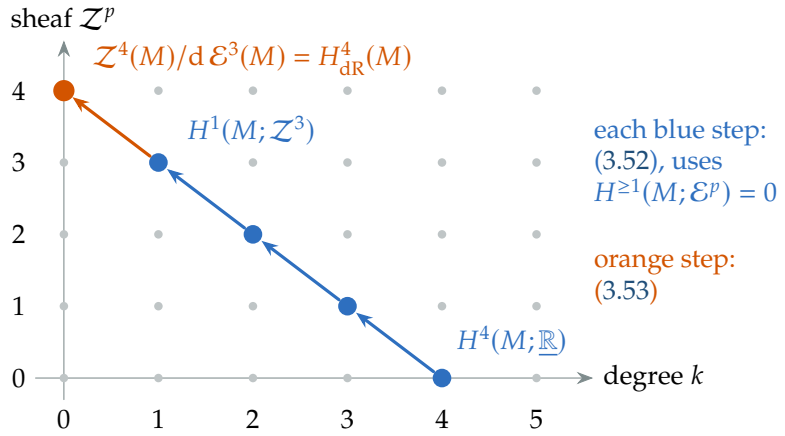

Figure 3.21: Nash's induction (3.54) for $q = 4$. Dots are the groups $H^k(M;\mathcal{Z}^p)$. Each blue arrow is an isomorphism that trades one unit of cohomological degree for one unit of form degree, staying on the antidiagonal $k + p = q$. The orange step, at $k = 1$, lands in global forms, where cohomology becomes "closed modulo exact".

Three remarks make the statement sharper.

- *Vanishing above the dimension.* For $q > n = \dim M$, the chain reaches $H^1(M;\mathcal{Z}^{q-1})$ with $q - 1 \geq n$. But $\mathcal{Z}^n = \mathcal{E}^n$ (every top form is closed), which is fine, and $\mathcal{Z}^p = 0$ for $p > n$. So $H^q(M;\mathbb{R}) = 0$ for $q > n$, as it must be.

- *Integers.* The argument uses real numbers essentially: there is no fine resolution of $\underline{\mathbb{Z}}$ by forms, since $\int$ of a form is a real number. The de Rham theorem computes $H^q(M;\mathbb{Z}) \otimes \mathbb{R}$ and loses torsion (for instance the $\mathbb{Z}_2$ in $H^2(\mathbb{RP}^3;\mathbb{Z})$). The integer-valued Čech cocycles of Section 3.5 are finer information than forms can hold.

- *Other resolutions.* The same argument works for any fine resolution of any sheaf. That is Nash's remark about the "alternative definition" via resolutions: whichever fine resolution you choose, the cohomology of its complex of global sections is $H^q(M;\mathcal{F})$. We use this again, with $\bar{\partial}$ in place of d, in Section 3.7.

Watch out: A garbled line in Nash

Just before (3.22) Nash writes "since $H^0(M;\mathcal{E}^p) \neq 0$, we cannot conclude that $H^1(M;\mathcal{Z}^{q-1}) \neq H^0(M;\mathcal{Z}^p)$". The intended statement is: *we cannot conclude that* $H^1(M;\mathcal{Z}^{q-1}) \cong H^0(M;\mathcal{Z}^q)$, because at $k = 0$ the left-hand term of (3.51) is the nonzero group of global forms. Instead one gets the quotient (3.53). Also, in (3.22) the p should be q: $H^1(M;\mathcal{Z}^{q-1}) \cong H^0(M;\mathcal{Z}^q)/\mathrm{d}H^0(M;\mathcal{E}^{q-1})$.

3.6.3 The isomorphism, made explicit on the circle

Abstract isomorphisms are hard to trust. Every map in (3.54) is a connecting homomorphism, i.e. a zig-zag (Figure 3.17), so we can run it by hand.

Worked example 3.25: From $\mathrm{d}\theta$ to a Čech cocycle, and back

Take $M = S^1$ with the two-arc cover $U_1 = (-\varepsilon, \pi + \varepsilon)$, $U_2 = (\pi - \varepsilon, 2\pi + \varepsilon)$, overlaps A near $\theta = 0$ and B near $\theta = \pi$ (Example 3.14). For $q = 1$, (3.54) is the single connecting map of $0 \to \underline{\mathbb{R}} \to \mathcal{E}^0 \to \mathcal{Z}^1 \to 0$:

$$\delta^* : \; H^1_{\mathrm{dR}}(S^1) = \frac{\mathcal{Z}^1(S^1)}{\mathrm{d}\,\mathcal{E}^0(S^1)} \xrightarrow{\;\cong\;} H^1(S^1; \underline{\mathbb{R}}).$$

Forward: from a form to numbers. Start with $\omega = \mathrm{d}\theta$.

(1) *Lift* to $\mathcal{E}^0$ on each arc: $f_1 = \theta_1$, the angle with values in $(-\varepsilon, \pi + \varepsilon)$, and $f_2 = \theta_2$, with values in $(\pi - \varepsilon, 2\pi + \varepsilon)$. Then $\mathrm{d}f_i = \omega$ on U_i.

(2) *Coboundary:* $(\delta f)_{12} = f_2 - f_1$ on $U_{12} = A \sqcup B$.

(3) *Read off:* the difference is locally constant, as it must be ($\mathrm{d}(f_2 - f_1) = \omega - \omega = 0$):

$$c_A \overset{(1)}{=} (\theta_2 - \theta_1)\big|_A = 2\pi, \qquad c_B \overset{(2)}{=} (\theta_2 - \theta_1)\big|_B = 0.$$

(1) Near $\theta = 0$, a point with $\theta_1 = \theta \in (-\varepsilon, \varepsilon)$ has $\theta_2 = \theta + 2\pi$.
(2) Near $\theta = \pi$ both arcs use the same value of the angle.

Under the isomorphism $[c] \mapsto c_A - c_B$ of Example 3.14, the class of $\mathrm{d}\theta$ goes to $2\pi = \oint \mathrm{d}\theta$. More generally, for any closed $\omega = g(\theta)\mathrm{d}\theta$, the jump $c_A - c_B$ of its local primitives is $\oint \omega$: *the Čech class of a closed* 1*-form is its period.*

Backward: from numbers to a form. Start with a cocycle (c_A, c_B) and the partition of unity $\rho_1, \rho_2 = 1 - \rho_1$ of Example 3.12. The homotopy operator (3.36) gives a 0-cochain of functions with $\delta f = c$:

$$f_1 \overset{(1)}{=} \rho_2\, c_{21} = -\rho_2\, c_{12}, \qquad f_2 \overset{(1)}{=} \rho_1\, c_{12},$$
$$f_2 - f_1 \overset{(2)}{=} (\rho_1 + \rho_2)\, c_{12} \overset{(3)}{=} c_{12} \quad \text{on } U_{12}.$$

(1) $(Kc)_i = \sum_k \rho_k c_{ki}$; the term $k = i$ vanishes because $c_{ii} = 0$; each product is extended by zero outside U_{12}.
(2) Subtract.
(3) $\rho_1 + \rho_2 = 1$.

The form $\omega = \mathrm{d}f_i$ is then globally defined, since $\mathrm{d}f_2 - \mathrm{d}f_1 = \mathrm{d}c_{12} = 0$. Explicitly, on U_2,

$$\omega = \mathrm{d}(\rho_1 c_{12}) = c_A\, \rho_1'(\theta)\, \mathrm{d}\theta\big|_A + c_B\, \rho_1'(\theta)\, \mathrm{d}\theta\big|_B, \tag{3.55}$$

a form supported in the overlaps. Integrating,

$$\oint \omega \overset{(1)}{=} c_A \int_A \rho_1'\, \mathrm{d}\theta + c_B \int_B \rho_1'\, \mathrm{d}\theta \overset{(2)}{=} c_A(1 - 0) + c_B(0 - 1) = c_A - c_B.$$

(1) (3.55); $\omega = 0$ outside $A \cup B$.
(2) ρ_1 rises from 0 to 1 across A and falls from 1 to 0 across B (Figure 3.10).

So the backward map sends (c_A, c_B) to a form with period $c_A - c_B$: it is the inverse of the forward map. For $(c_A, c_B) = (2\pi, 0)$ we get $\omega = 2\pi\rho_1'\, \mathrm{d}\theta$, a bump concentrated near $\theta = 0$ (Figure 3.22). It is *not* equal to $\mathrm{d}\theta$, but it is cohomologous to it: the difference has zero period, hence is d of a periodic function.

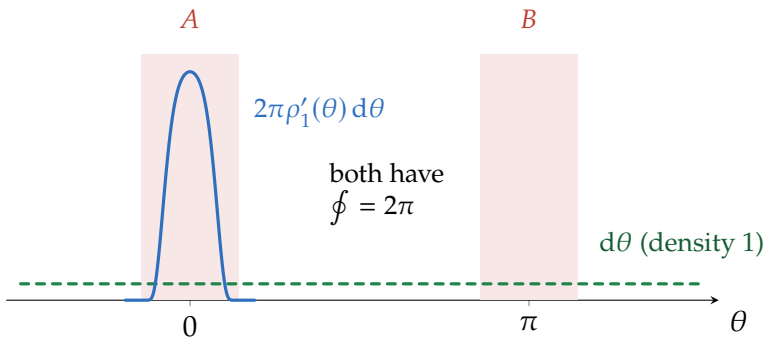

Figure 3.22: Two representatives of the same de Rham class on S^1. The uniform form $d\theta$ (dashed) and the bump form $2\pi\rho_1' d\theta$ (solid) that the partition of unity manufactures from the Čech cocycle $(c_A, c_B) = (2\pi, 0)$. All of the second form's "circulation" is squeezed into the overlap A, where the two local primitives disagree.

Worked example 3.26: The area form of S^2 by dimension shifting

For $q = 2$ on $M = S^2$ the chain (3.54) has two steps:

$$H^2(S^2;\underline{\mathbb{R}}) \xleftarrow{\delta^*} H^1(S^2;\mathcal{Z}^1) \xleftarrow{\delta^*} \frac{\mathcal{Z}^2(S^2)}{d\,\mathcal{E}^1(S^2)}.$$

Let us run the second (rightmost) map on $\omega = \sin\theta\, d\theta \wedge d\phi$, using the two caps U_N, U_S with the equatorial annulus U_{NS}.

Why two caps are enough here. We saw (Example 3.16) that two caps cannot compute $H^2(S^2;\underline{\mathbb{R}})$. But they *can* compute $H^1(S^2;\mathcal{Z}^1)$: by (3.52), $H^k(U;\mathcal{Z}^1) \cong H^{k+1}(U;\underline{\mathbb{R}})$ for $k \geq 1$, which vanishes on a cap and on an annulus (both have no cohomology above degree 1). So the caps form a Leray cover for $\mathcal{Z}^1$. Shifting the sheaf changes which covers are good.

The zig-zag.

(1) *Lift:* on each cap ω is exact (the caps are contractible). The monopole potentials of Example 3.22 with $g_m = 1$ do it: $\alpha_N = (1 - \cos\theta)\,d\phi$, $\alpha_S = -(1 + \cos\theta)\,d\phi$, $d\alpha_N = d\alpha_S = \omega$.

(2) *Coboundary:* $(\delta\alpha)_{NS} = \alpha_S - \alpha_N = -2\,d\phi$ on the annulus.

(3) *Read off:* $-2\,d\phi$ is a closed 1-form on U_{NS}, i.e. a 1-cochain of $\mathcal{Z}^1$, automatically a cocycle (no triple overlaps).

Which classes are there? On this cover $H^1(\mathcal{U};\mathcal{Z}^1) = \mathcal{Z}^1(U_{NS})/\{\beta_S - \beta_N\}$ with β_N, β_S closed on the caps. A closed form on a cap is exact, $\beta = dh$, and every function on the annulus is a difference $h_S - h_N$ (use a partition of unity, as in Example 3.25). So the coboundaries are exactly the exact 1-forms on the annulus, and

$$H^1(S^2;\mathcal{Z}^1) \cong \frac{\mathcal{Z}^1(U_{NS})}{d\,\mathcal{E}^0(U_{NS})} = H^1_{\mathrm{dR}}(\text{annulus}) \cong \mathbb{R}, \qquad [\beta] \mapsto -\oint_{\mathrm{eq}} \beta,$$

with the equator traversed in the direction of increasing ϕ. The class of ω goes to $-\oint(-2\,d\phi) = 4\pi$. Why the minus sign? Stokes on the two hemispheres:

$$\int_{S^2} \omega \overset{(1)}{=} \int_{\theta\leq\pi/2} d\alpha_N + \int_{\theta\geq\pi/2} d\alpha_S \overset{(2)}{=} \oint_{\mathrm{eq}} \alpha_N - \oint_{\mathrm{eq}} \alpha_S \overset{(3)}{=} -\oint_{\mathrm{eq}} (\delta\alpha)_{NS} = 4\pi.$$

(1) Split the sphere along the equator; on each half use the local primitive.

(2) Stokes. With the orientation $d\theta \wedge d\phi$, the boundary of the northern hemisphere is the equator traversed with ϕ increasing, and the boundary of the southern one is the same circle traversed backwards.
(3) $(\delta\alpha)_{NS} = \alpha_S - \alpha_N$; and $-\oint(-2\,d\phi) = 4\pi$.

In physics language: *the flux through the sphere equals the circulation of the difference of the two gauge potentials round the equator.* That is exactly the step "field strength → gauge transformation on the overlap". The first map of the chain, from $H^1(S^2;\mathcal{Z}^1)$ to $H^2(S^2;\underline{\mathbb{R}})$, requires a cover with triple overlaps, and we carry it out in Example 3.27.

3.6.4 The Čech–de Rham double complex

Nash's induction proves that the groups are isomorphic, but it hides the map in a sequence of connecting homomorphisms. There is a way to see all the steps at once, due to Weil and popularised by Bott and Tu: put Čech cochains and differential forms into one grid.

Working definition 3.17 (Čech–de Rham double complex)

Fix a good cover $\mathcal{U}$ of M [every set and every nonempty overlap is contractible]. Let

$$K^{p,q} = C^p(\mathcal{U};\mathcal{E}^q) = \left\{\text{a } q\text{-form } \omega_{i_0\cdots i_p} \text{ on each } (p+1)\text{-fold overlap } U_{i_0\cdots i_p}\right\},$$

with two commuting differentials [maps that each give 0 when applied twice]: the Čech coboundary $\delta : K^{p,q} \to K^{p+1,q}$ (alternating sum of restrictions, applied to forms) and the exterior derivative $d : K^{p,q} \to K^{p,q+1}$ (applied on each overlap separately). They commute, $\delta d = d\delta$, because d commutes with restriction. *Operational picture:* a grid whose horizontal direction is "number of patches" and whose vertical direction is "form degree" (Figure 3.23).

Two facts make the grid useful. Both are things we have already proved.

- *The rows are exact* (except at the left edge). Fix a form degree q. The row

$$0 \to \mathcal{E}^q(M) \xrightarrow{r} C^0(\mathcal{U};\mathcal{E}^q) \xrightarrow{\delta} C^1(\mathcal{U};\mathcal{E}^q) \xrightarrow{\delta} C^2(\mathcal{U};\mathcal{E}^q) \to \cdots \tag{3.56}$$

  (with r restricting a global form to each patch) is exact. Exactness at C^0 is the gluing axiom; exactness further right is the homotopy formula $\delta K + K\delta = 1$ of Section 3.3.7, since $\mathcal{E}^q$ is fine. *In words: any Čech cocycle of forms is a Čech coboundary of forms.*

- *The columns are exact* (except at the bottom). Fix p. The column

$$0 \to C^p(\mathcal{U};\underline{\mathbb{R}}) \xrightarrow{\iota} C^p(\mathcal{U};\mathcal{E}^0) \xrightarrow{d} C^p(\mathcal{U};\mathcal{E}^1) \xrightarrow{d} C^p(\mathcal{U};\mathcal{E}^2) \to \cdots \tag{3.57}$$

  is exact, because every overlap of a good cover is contractible and the Poincaré lemma holds there. *In words: on each overlap, a closed form is exact, and a closed function is a constant.*

So the grid has two "edges": the left edge holds global forms $\mathcal{E}^q(M)$ (the de Rham complex), the bottom edge holds Čech cochains with constant coefficients $C^p(\mathcal{U};\underline{\mathbb{R}})$ (the Čech complex). The zig-zag through the interior connects them.

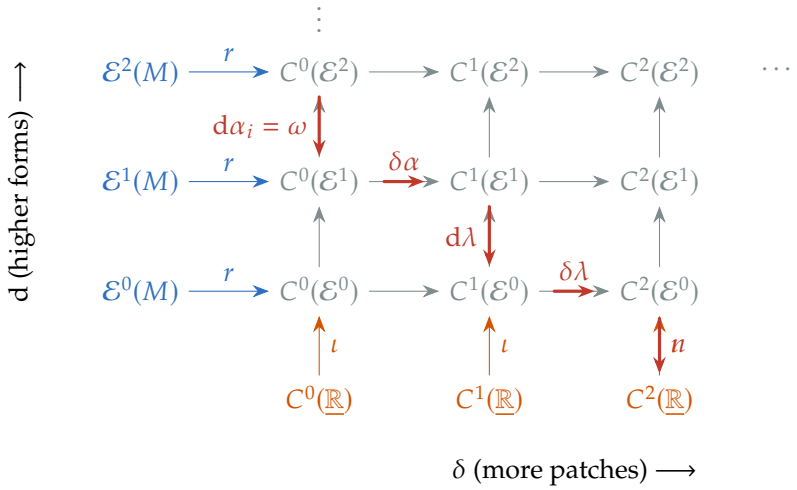

Figure 3.23: The Čech–de Rham double complex $K^{p,q} = C^p(\mathcal{U}; \mathcal{E}^q)$. The left edge (blue) is the de Rham complex of global forms; the bottom edge (orange) is the Čech complex with constant coefficients. The red staircase is the zig-zag (3.58) for a closed 2-form ω: primitives α_i on patches, their mismatch $\delta\alpha = \mathrm{d}\lambda$ on double overlaps, and the mismatch $\delta\lambda = n$ of those, which is a constant on triple overlaps. Every step moves one square down or one square right.

Working definition 3.18 (the zig-zag from a closed form to a Čech cocycle)

Let ω be a closed 2-form on M and $\mathcal{U}$ a good cover.

(1) On each U_i: $\omega = \mathrm{d}\alpha_i$ (Poincaré lemma [on a contractible set every closed form is exact]).

(2) On each U_{ij}: $\mathrm{d}(\alpha_j - \alpha_i) = \omega - \omega = 0$, so $\alpha_j - \alpha_i = \mathrm{d}\lambda_{ij}$ for a function λ_{ij} (Poincaré lemma again), chosen with $\lambda_{ji} = -\lambda_{ij}$.

(3) On each U_{ijk}: $n_{ijk} = (\delta\lambda)_{ijk} = \lambda_{jk} - \lambda_{ik} + \lambda_{ij}$ has $\mathrm{d}n_{ijk} = 0$, so it is a constant.

In one line:

$$\omega = \mathrm{d}\alpha, \qquad \delta\alpha = \mathrm{d}\lambda, \qquad \delta\lambda = n \in C^2(\mathcal{U}; \underline{\mathbb{R}}). \tag{3.58}$$

The class $[n] \in H^2(\mathcal{U}; \underline{\mathbb{R}})$ is the Čech image [the Čech class matched with $[\omega]$ by the de Rham isomorphism] of $[\omega] \in H^2_{\mathrm{dR}}(M)$. For a closed 1-form the recipe stops one step earlier ($\omega = \mathrm{d}f$, $n = \delta f$), which is Example 3.25; for a closed q-form it takes q steps.

Check that step (3) is really a constant:

$$\mathrm{d}n \overset{(1)}{=} \mathrm{d}\,\delta\lambda \overset{(2)}{=} \delta\,\mathrm{d}\lambda \overset{(3)}{=} \delta\delta\alpha \overset{(4)}{=} 0.$$

(1) Definition of n.
(2) d and δ commute.
(3) Step (2): $\mathrm{d}\lambda = \delta\alpha$.
(4) $\delta^2 = 0$ (Section 3.3.2).

And n is a Čech cocycle because $\delta n = \delta\delta\lambda = 0$.

Why the class does not depend on the choices. Each choice is made "up to something one step further along":

- $\alpha_i \mapsto \alpha_i + \mathrm{d}\mu_i$ changes $\delta\alpha$ by $\mathrm{d}\delta\mu$, which we absorb by $\lambda \mapsto \lambda + \delta\mu$; then $n \mapsto n + \delta\delta\mu = n$.

- $\lambda_{ij} \mapsto \lambda_{ij} + m_{ij}$ with constants m_{ij} (the only freedom once $\mathrm{d}\lambda$ is fixed) changes n by δm, a Čech coboundary.
- $\omega \mapsto \omega + \mathrm{d}\beta$ with global β: take $\alpha_i + \beta$; then $\delta\alpha$ is unchanged.

The inverse map, by partitions of unity. Start instead with a Čech 2-cocycle n of constants and a partition of unity $\{\rho_k\}$. Walk the staircase the other way, each time using row exactness in the form "a Čech cocycle of forms is δ of K of itself":

$$\lambda \overset{(1)}{=} Kn, \quad \text{i.e.} \quad \lambda_{ij} = \sum_k \rho_k\, n_{kij}, \qquad \text{so } \delta\lambda = n;$$

$$\alpha \overset{(2)}{=} K(\mathrm{d}\lambda), \quad \text{i.e.} \quad \alpha_i = \sum_k \rho_k\, \mathrm{d}\lambda_{ki} = \sum_{k,l} n_{lki}\, \rho_k\, \mathrm{d}\rho_l, \qquad \text{so } \delta\alpha = \mathrm{d}\lambda;$$

$$\omega \overset{(3)}{=} \mathrm{d}\alpha_i = \sum_{k,l} n_{lki}\, \mathrm{d}\rho_k \wedge \mathrm{d}\rho_l \qquad \text{on } U_i.$$

(1) Homotopy formula: $\delta Kn = n - K\delta n = n$ because $\delta n = 0$.
(2) $\mathrm{d}\lambda$ is a Čech 1-cocycle of 1-forms ($\delta\mathrm{d}\lambda = \mathrm{d}\delta\lambda = \mathrm{d}n = 0$, n constant), so again $\delta K(\mathrm{d}\lambda) = \mathrm{d}\lambda$. Then substitute $\lambda_{ki} = \sum_l \rho_l n_{lki}$ and use $\mathrm{d}n = 0$.
(3) $\delta(\mathrm{d}\alpha) = \mathrm{d}\delta\alpha = \mathrm{d}\mathrm{d}\lambda = 0$, so the $\mathrm{d}\alpha_i$ agree on overlaps and glue to a global closed 2-form.

Running the forward recipe on this ω with these very α and λ returns n, so the two maps are inverse to each other. The formula $\omega = \sum n_{lki}\, \mathrm{d}\rho_k \wedge \mathrm{d}\rho_l$ is worth a look: it is a closed 2-form supported where three partition functions change at once, i.e. near the triple overlaps, with "strength" given by the integers n_{lki}. It is the 2-dimensional version of the bump form of Figure 3.22.

Key idea: De Rham theorem, Čech–de Rham version

On a good cover $\mathcal{U}$, the zig-zag (3.58) gives an isomorphism $H^q_{\mathrm{dR}}(M) \cong H^q(\mathcal{U}; \underline{\mathbb{R}})$, whose inverse is built from a partition of unity. Rows exact = fine sheaves; columns exact = Poincaré lemma. This is the same theorem as Nash's (3.23), with every map written out.

3.6.5 The monopole through the double complex

We now close the loop with Section 3.5. There we defined c_1 of a line bundle by taking logarithms of transition functions. Here we start from the field strength and walk down the staircase. The two must agree, and checking that they do fixes all the signs.

Conventions for $U(1)$ connections

A connection on a line bundle with transition functions g_{ij} (so that local components obey $s_i = g_{ij} s_j$) is a collection of 1-forms A_i, one per patch, with covariant derivative $Ds_i = \mathrm{d}s_i + A_i s_i$. Following Nash and the house convention, A_i is *anti-Hermitian*: for $U(1)$, an imaginary-valued 1-form. The covariant derivative of a section must transform like the section, $Ds_i = g_{ij} Ds_j$. Then

$$\mathrm{d}s_i + A_i s_i \overset{(1)}{=} \mathrm{d}(g_{ij} s_j) + A_i\, g_{ij} s_j \overset{(2)}{=} g_{ij}\big(\mathrm{d}s_j + (g_{ij}^{-1}\mathrm{d}g_{ij} + A_i)\, s_j\big),$$

(1) Substitute $s_i = g_{ij} s_j$.
(2) Leibniz rule $\mathrm{d}(gs) = g\,\mathrm{d}s + \mathrm{d}g\, s$; factor out g_{ij}.

and comparing with $g_{ij}(\mathrm{d}s_j + A_j s_j)$ gives

$$A_j = A_i + g_{ij}^{-1}\mathrm{d}g_{ij} = A_i + \mathrm{d}\log g_{ij} \qquad \text{on } U_{ij}. \tag{3.59}$$

The curvature $F = \mathrm{d}A_i$ is the same on every patch (abelian case: $\mathrm{d}\,\mathrm{d}\log g = 0$), so it is a global closed 2-form. Its real normalisation is the **first Chern form**

$$\omega = \frac{i}{2\pi}F, \qquad a_i = \frac{i}{2\pi}A_i \text{ (real 1-forms)}, \qquad \omega = \mathrm{d}a_i. \tag{3.60}$$

Dictionary: Mathematicians' versus physicists' $U(1)$ potential

For a particle of charge e the physicist writes $D = \mathrm{d} - ieA^{\mathrm{phys}}$ with real A^{phys}, so $A = -ieA^{\mathrm{phys}}$ and $F = -ieF^{\mathrm{phys}}$. Then

$$a_i = \frac{e}{2\pi}A_i^{\mathrm{phys}}, \qquad \omega = \frac{i}{2\pi}F = \frac{e}{2\pi}F^{\mathrm{phys}}.$$

So $\int \omega$ is the magnetic flux measured in units of the flux quantum $2\pi/e$ (with $\hbar = 1$).

Now multiply (3.59) by $\frac{i}{2\pi}$:

$$a_j - a_i \overset{(1)}{=} \frac{i}{2\pi}\,\mathrm{d}\log g_{ij} \overset{(2)}{=} \mathrm{d}\lambda_{ij}, \qquad \lambda_{ij} = \frac{i}{2\pi}\log g_{ij}.$$

(1) (3.59) times $\frac{i}{2\pi}$, with (3.60).
(2) Definition (3.41) of λ_{ij} in Section 3.5.2.

So *the zig-zag* (3.58) *of the Chern form, with the gauge potentials as the first lift, produces exactly the λ_{ij} of Section 3.5.2, and hence exactly the Chern cocycle $n = \delta\lambda$.* This proves the promised normalisation: the image of $c_1(L) \in H^2(M;\mathbb{Z})$ in $H^2(M;\mathbb{R}) \cong H^2_{\mathrm{dR}}(M)$ is the class of $\frac{i}{2\pi}F$. In particular, for any closed surface $\Sigma \subset M$,

$$\int_\Sigma \frac{i}{2\pi}F \in \mathbb{Z}, \tag{3.61}$$

whatever connection we choose. This is *flux quantisation* in its general form.

Worked example 3.27: The monopole's Chern form, walked down the staircase

Take the monopole bundle with $n = 2e g_m$ and the three-set cover V_1, V_2, V_3 of Example 3.23 (Figure 3.19). By the dictionary,

$$\omega \overset{(1)}{=} \frac{e}{2\pi}\,g_m \sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi = \frac{n}{4\pi}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi,$$
$$a_N \overset{(2)}{=} \frac{n}{4\pi}(1-\cos\theta)\,\mathrm{d}\phi, \qquad a_S = -\frac{n}{4\pi}(1+\cos\theta)\,\mathrm{d}\phi.$$

(1) $\omega = \frac{e}{2\pi}F^{\mathrm{phys}}$ with (3.44); $e g_m = n/2$.
(2) $a = \frac{e}{2\pi}A^{\mathrm{phys}}$ with (3.45).

Step (1), potentials on patches: $a_1 = a_N$ on V_1 and $a_2 = a_3 = a_S$ on V_2, V_3 (both southern sets use the south gauge).
Step (2), gauge functions on double overlaps.

$$a_2 - a_1 \overset{(1)}{=} -\frac{n}{4\pi}\big[(1+\cos\theta) + (1-\cos\theta)\big]\mathrm{d}\phi = -\frac{n}{2\pi}\,\mathrm{d}\phi \overset{(2)}{=} \mathrm{d}\lambda_{12}, \qquad \lambda_{12} = -\frac{n\phi}{2\pi},$$

(1) Subtract a_N from a_S.
(2) On the half-annulus V_{12}, ϕ is a smooth function with values in $(-\varepsilon, \pi+\varepsilon)$.

and in the same way $\lambda_{13} = -n\phi/2\pi$ on V_{13} with $\phi \in (\pi-\varepsilon, 2\pi+\varepsilon)$, while $a_3 - a_2 = 0$ gives $\lambda_{23} = 0$. These are the logarithms of $g_{12} = g_{13} = e^{in\phi}$, $g_{23} = 1$ found in Example 3.23.

Step (3), integers on the triple overlaps. As computed there, $n_{123} = n$ on the square near $\phi = 0$ and $n_{123} = 0$ on the square near $\phi = \pi$. Write P_0, P_π for points in these two squares.

The check against integration. We now show that for *any* zig-zag data $(\omega, a_i, \lambda_{ij}, n_{123})$ on this cover, $\int_{S^2}\omega = n_{123}(P_0) - n_{123}(P_\pi) = \ell(n)$, which confirms the sign of ℓ chosen in Example 3.23. Cut the sphere into three closed regions (Figure 3.24): D_1 the northern hemisphere, D_2 the southern quarter-sphere with $0 \le \phi \le \pi$, D_3 the one with $\pi \le \phi \le 2\pi$, so $D_i \subset V_i$. Their common edges are the equatorial arcs E_2 ($D_1|D_2$, from P_0 to P_π) and E_3 ($D_1|D_3$, from P_π round to P_0), both traversed with ϕ increasing, and the meridian arcs M_0 and M_π ($D_2|D_3$, at $\phi = 0$ and $\phi = \pi$), both traversed from the equator down to the south pole S. With the orientation $\mathrm{d}\theta \wedge \mathrm{d}\phi$, i.e. counter-clockwise in the (θ, ϕ) rectangle, one reads off

$$\partial D_1 = E_2 + E_3, \qquad \partial D_2 = M_0 - M_\pi - E_2, \qquad \partial D_3 = M_\pi - M_0 - E_3.$$

Then

$$\begin{aligned}
\int_{S^2}\omega &\overset{(1)}{=} \sum_{i=1}^{3}\int_{D_i}\mathrm{d}a_i \overset{(2)}{=} \sum_{i=1}^{3}\oint_{\partial D_i} a_i \\
&\overset{(3)}{=} \int_{E_2}(a_1 - a_2) + \int_{E_3}(a_1 - a_3) + \int_{M_0}(a_2 - a_3) + \int_{M_\pi}(a_3 - a_2) \\
&\overset{(4)}{=} -\int_{E_2}\mathrm{d}\lambda_{12} - \int_{E_3}\mathrm{d}\lambda_{13} - \int_{M_0}\mathrm{d}\lambda_{23} + \int_{M_\pi}\mathrm{d}\lambda_{23} \\
&\overset{(5)}{=} -\big[\lambda_{12}(P_\pi) - \lambda_{12}(P_0)\big] - \big[\lambda_{13}(P_0) - \lambda_{13}(P_\pi)\big] \\
&\qquad - \big[\lambda_{23}(S) - \lambda_{23}(P_0)\big] + \big[\lambda_{23}(S) - \lambda_{23}(P_\pi)\big] \\
&\overset{(6)}{=} \big(\lambda_{23} - \lambda_{13} + \lambda_{12}\big)(P_0) - \big(\lambda_{23} - \lambda_{13} + \lambda_{12}\big)(P_\pi) \\
&\overset{(7)}{=} n_{123}(P_0) - n_{123}(P_\pi).
\end{aligned}$$

(1) Split the integral over the three regions and use $\omega = \mathrm{d}a_i$ on $D_i \subset V_i$.
(2) Stokes' theorem on each region.
(3) Insert the boundaries listed above and collect the terms on each common edge.
(4) $a_j - a_i = \mathrm{d}\lambda_{ij}$, so $a_1 - a_2 = -\mathrm{d}\lambda_{12}$ etc.
(5) Fundamental theorem of calculus along each oriented arc: end minus start. E_3 runs from P_π to P_0 inside V_{13}, where λ_{13} is a single smooth function.
(6) The two $\lambda_{23}(S)$ terms cancel; regroup the rest point by point.
(7) Definition $n = \delta\lambda$.

For the monopole this gives $n - 0 = n$, and directly $\int\omega = \frac{n}{4\pi}\cdot 4\pi = n$. The two computations agree, and the Chern number of the monopole bundle is the flux in units of $2\pi/e$:

$$c_1 = \int_{S^2}\frac{e}{2\pi}F^{\mathrm{phys}} = \frac{e}{2\pi}\cdot 4\pi g_m = 2e g_m = n.$$

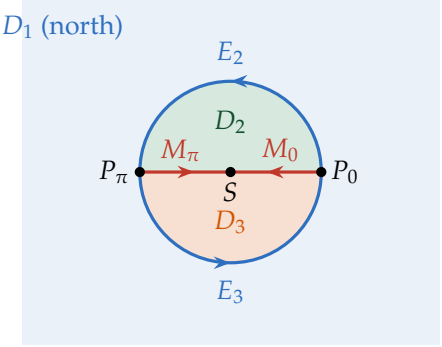

Figure 3.24: The three regions used to integrate the Chern form, drawn as in Figure 3.19 (south pole at the centre, equator the circle). Stokes' theorem turns $\int \omega$ into line integrals of the mismatches $a_j - a_i = \mathrm{d}\lambda_{ij}$ along the edges; the fundamental theorem of calculus then turns those into values of λ at the vertices P_0, P_π, S. The contributions at S cancel, and what survives at P_0 and P_π is exactly the Čech cocycle n_{123}.

Physical picture: Stokes, three times

The integration check is Stokes' theorem applied in every dimension of the staircase: a 2-dimensional integral of $\mathrm{d}a$ becomes 1-dimensional integrals of $a_j - a_i = \mathrm{d}\lambda$, which become 0-dimensional evaluations of $\delta\lambda = n$. The double complex is a bookkeeping device for doing Stokes' theorem "patch by patch". The same computation on any surface with any good cover gives

$$\int_\Sigma \omega = \sum_{\text{vertices } v} \pm\, n_{ijk}(v),$$

a signed count of the integers at the triple points of a triangulation dual to the cover. The integer c_1 is literally a sum of integers.

Reading Nash (pp. 63, (3.20)–(3.23))

Nash's (3.20) is our (3.50): the short exact sequences $0 \to \mathcal{Z}^p \to \mathcal{E}^p \xrightarrow{\mathrm{d}} \mathcal{Z}^{p+1} \to 0$, with $\mathcal{Z}^0 = \mathbb{R}$, each followed by the isomorphism $H^{q-1}(M;\mathcal{Z}^{p+1}) \cong H^q(M;\mathcal{Z}^p)$ it produces (our (3.52)). His (3.21) is the chain (3.54); his (3.22) is (3.53) (read the p there as q, see the pitfall); his (3.23) is the de Rham theorem. He uses exactly two facts: the long exact sequence (3.19) and the softness of $\mathcal{E}^p$. We have added the explicit form of the maps (Example 3.25, Example 3.26), the Čech–de Rham double complex, and the monopole check that ties Section 3.5 to the curvature: $c_1 \mapsto [\frac{i}{2\pi}F]$.

Recap

- $0 \to \underline{\mathbb{R}} \to \mathcal{E}^0 \xrightarrow{\mathrm{d}} \mathcal{E}^1 \xrightarrow{\mathrm{d}} \cdots$ is a fine resolution of $\underline{\mathbb{R}}$. Exactness is the Poincaré lemma (explicit radial homotopy, e.g. $\vec{A} = \int_0^1 t\, \vec{B}(t\vec{x}) \times \vec{x}\, \mathrm{d}t$).
- Chop it into $0 \to \mathcal{Z}^p \to \mathcal{E}^p \to \mathcal{Z}^{p+1} \to 0$; fine middle terms give $H^{k+1}(\mathcal{Z}^p) \cong H^k(\mathcal{Z}^{p+1})$ for $k \geq 1$ and $H^1(\mathcal{Z}^p) \cong H^{p+1}_{\mathrm{dR}}$; chaining gives $H^q(M;\mathbb{R}) \cong H^q_{\mathrm{dR}}(M)$.
- The isomorphism is a zig-zag: $\omega = \mathrm{d}\alpha$, $\delta\alpha = \mathrm{d}\lambda$, $\delta\lambda = n$. On S^1 the Čech class of ω is its period; the inverse uses a partition of unity and produces bump forms.
- For a $U(1)$ bundle, the zig-zag of $\frac{i}{2\pi}F$ through the gauge potentials reproduces $n = \delta\lambda$,

$\lambda = \frac{i}{2\pi}\log g$: the de Rham image of c_1 is $[\frac{i}{2\pi}F]$, and $\int_\Sigma \frac{i}{2\pi}F \in \mathbb{Z}$.

- Monopole: Stokes three times gives $\int \omega = n_{123}(P_0) - n_{123}(P_\pi) = n = 2eg_m$.

3.7 Complex manifolds and the Dolbeault theorem

The de Rham theorem answered a question about the sheaf $\underline{\mathbb{R}}$ of locally constant functions: its Čech cohomology can be computed by solving the differential equation $\mathrm{d}\alpha = \omega$. On a complex manifold there is a second sheaf that we care about just as much, the sheaf $\mathcal{O}$ of holomorphic functions (and its cousins Ω^p, the holomorphic p-forms). We have already met its cohomology several times:

- $H^1(M;\mathcal{O})$ sat in the exponential sequence next to $H^1(M;\mathcal{O}^*)$, the group of holomorphic line bundles (Section 3.5).
- $H^1(\mathbb{CP}^1;\mathcal{O}(n))$ was computed with Laurent series and produced the first index, $\dim H^0 - \dim H^1 = n+1$ (Example 3.18).
- Several times we *assumed* that discs, $\mathbb{C}$ and $\mathbb{C}^*$ have no higher $\mathcal{O}$-cohomology, so that covers by such sets are Leray covers.

The question of this section is: *is there a differential equation whose solvability computes $H^q(M;\mathcal{O})$, the way $\mathrm{d}\alpha = \omega$ computes $H^q(M;\mathbb{R})$?* The answer is yes. The equation is the Cauchy–Riemann equation in its inhomogeneous form,

$$\frac{\partial f}{\partial \bar z} = g,$$

and the resulting statement is the **Dolbeault theorem**. Nash obtains it by rerunning the de Rham argument word for word with $\bar\partial$ in place of d. To make sense of that we first need the objects $\bar\partial$ acts on, the forms of type (p,q).

Physical picture: Why a physicist should care

In two dimensions, written in the complex coordinate $z = x + iy$, the Euclidean Dirac operator splits into ∂_z and $\partial_{\bar z}$ (we show this explicitly below). Zero modes of $\partial_{\bar z}$ are holomorphic functions; the obstruction to solving $\partial_{\bar z} f = g$ is a count of zero modes of the adjoint. So Dolbeault cohomology counts *chiral zero modes*: of fermions on a Riemann surface, of b,c ghosts on a string worldsheet (Chapter 9), of the operators whose index the Riemann–Roch and Atiyah–Singer theorems compute (Chapter 4). It also counts *moduli*: $H^1(M;\mathcal{O})$ is the space of deformations of a holomorphic line bundle, which on a torus are the Wilson lines of a flat $U(1)$ field.

3.7.1 Complex coordinates and Wirtinger derivatives

Start in one complex dimension, on an open set of $\mathbb{C}$ with coordinate $z = x + iy$. Instead of the real basis $\mathrm{d}x, \mathrm{d}y$ of 1-forms we use the complex basis

$$\mathrm{d}z = \mathrm{d}x + i\,\mathrm{d}y, \qquad \mathrm{d}\bar z = \mathrm{d}x - i\,\mathrm{d}y, \qquad \text{so} \qquad \mathrm{d}x = \tfrac{1}{2}(\mathrm{d}z + \mathrm{d}\bar z), \quad \mathrm{d}y = \tfrac{1}{2i}(\mathrm{d}z - \mathrm{d}\bar z). \tag{3.62}$$

This is only a change of basis of the complexified cotangent space $T^*_x \otimes \mathbb{C} \cong \mathbb{C}^2$; nothing has been lost. The dual basis of (complexified) vectors is given by the **Wirtinger derivatives**

$$\frac{\partial}{\partial z} = \frac{1}{2}\Big(\frac{\partial}{\partial x} - i\frac{\partial}{\partial y}\Big), \qquad \frac{\partial}{\partial \bar z} = \frac{1}{2}\Big(\frac{\partial}{\partial x} + i\frac{\partial}{\partial y}\Big). \tag{3.63}$$

They are defined so that $\mathrm{d}z(\partial_z) = 1$, $\mathrm{d}z(\partial_{\bar z}) = 0$, and so on. For example $\mathrm{d}z(\partial_{\bar z}) = \tfrac12(\mathrm{d}x + i\,\mathrm{d}y)(\partial_x + i\partial_y) = \tfrac12(1 + i\cdot i) = 0$. With them the total differential of any smooth complex function $f(x,y)$ reads

$$\begin{aligned} \mathrm{d}f &\overset{(1)}{=} \frac{\partial f}{\partial x}\,\mathrm{d}x + \frac{\partial f}{\partial y}\,\mathrm{d}y \\ &\overset{(2)}{=} \frac{\partial f}{\partial x}\,\tfrac12(\mathrm{d}z + \mathrm{d}\bar z) + \frac{\partial f}{\partial y}\,\tfrac{1}{2i}(\mathrm{d}z - \mathrm{d}\bar z) \\ &\overset{(3)}{=} \tfrac12\Big(\frac{\partial f}{\partial x} - i\frac{\partial f}{\partial y}\Big)\mathrm{d}z + \tfrac12\Big(\frac{\partial f}{\partial x} + i\frac{\partial f}{\partial y}\Big)\mathrm{d}\bar z \\ &\overset{(4)}{=} \frac{\partial f}{\partial z}\,\mathrm{d}z + \frac{\partial f}{\partial \bar z}\,\mathrm{d}\bar z. \end{aligned} \tag{3.64}$$

(1) The usual total differential in real coordinates.
(2) Substitute (3.62) for $\mathrm{d}x, \mathrm{d}y$.
(3) Collect the $\mathrm{d}z$ and $\mathrm{d}\bar z$ terms; $1/(2i) = -i/2$.
(4) The definitions (3.63).

So we may treat z and $\bar z$ "as if they were independent variables". This is a bookkeeping rule, not a claim that they are independent: it works because $\partial_z z = 1$, $\partial_z \bar z = 0$, $\partial_{\bar z} z = 0$, $\partial_{\bar z}\bar z = 1$, which you can check from (3.63).

Working definition 3.19 (holomorphic function)

A smooth function f on an open set of $\mathbb{C}$ is **holomorphic** when

$$\frac{\partial f}{\partial \bar z} = 0,$$

[$\partial_{\bar z} f = \tfrac12(\partial_x f + i\partial_y f)$, the Wirtinger derivative defined just above] i.e. when $\mathrm{d}f$ has no $\mathrm{d}\bar z$ component. *Operational test:* write f as a function of z and $\bar z$ and check that $\bar z$ does not appear. In n complex variables f is holomorphic when $\partial f/\partial \bar z^i = 0$ for $i = 1,\dots,n$.

The condition $\partial_{\bar z} f = 0$ is the Cauchy–Riemann equations in disguise. Write $f = u + iv$ with u, v real:

$$\begin{aligned} 2\,\frac{\partial f}{\partial \bar z} &\overset{(1)}{=} \Big(\frac{\partial}{\partial x} + i\frac{\partial}{\partial y}\Big)(u + iv) \\ &\overset{(2)}{=} \Big(\frac{\partial u}{\partial x} - \frac{\partial v}{\partial y}\Big) + i\Big(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y}\Big). \end{aligned}$$

(1) Definition (3.63).
(2) Multiply out; $i\cdot i\,\partial_y v = -\partial_y v$.

The real and imaginary parts vanish exactly when $u_x = v_y$ and $u_y = -v_x$, the Cauchy–Riemann equations. This is Nash's remark after (3.25): "the familiar Cauchy–Riemann equations for a holomorphic function f are simply the statement $\bar\partial f = 0$".

Worked example 3.28: Which functions are holomorphic?

Treat $z, \bar z$ as independent and differentiate.

- $f = z^2$: $\partial_{\bar z} f = 0$. Holomorphic. Indeed $u = x^2 - y^2$, $v = 2xy$ satisfy $u_x = 2x = v_y$ and $u_y = -2y = -v_x$.

- $f = |z|^2 = z\bar{z}$: $\partial_{\bar{z}} f = z$, which is zero only at the origin. Not holomorphic.
- $f = \bar{z}$: $\partial_{\bar{z}} f = 1$. Not holomorphic; it is *antiholomorphic* ($\partial_z f = 0$).
- $f = \log|z|^2 = \log z + \log \bar{z}$ on $\mathbb{C}^*$: $\partial_z f = 1/z$, $\partial_{\bar{z}} f = 1/\bar{z}$. Neither.

Also the Laplacian factorises:

$$4\,\frac{\partial}{\partial z}\frac{\partial}{\partial \bar{z}} \overset{(1)}{=} \Big(\frac{\partial}{\partial x} - i\frac{\partial}{\partial y}\Big)\Big(\frac{\partial}{\partial x} + i\frac{\partial}{\partial y}\Big) \overset{(2)}{=} \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} = \nabla^2.$$

(1) Definition (3.63), twice.
(2) The cross terms $i\partial_x\partial_y - i\partial_y\partial_x$ cancel, and $-i \cdot i = 1$.

So $\partial_z\partial_{\bar{z}} \log|z|^2 = \partial_z(1/\bar{z}) = 0$ away from 0: $\log|z|^2$ is harmonic, the 2d Coulomb potential. We shall see in Section 3.7.4 that the charge at the origin is also visible in this language.

3.7.2 Complex manifolds and forms of type (p, q)

A **complex manifold** of complex dimension n is a manifold covered by charts with coordinates $z^1, \dots, z^n$ in open sets of $\mathbb{C}^n$, such that on every overlap the new coordinates z'^j are *holomorphic* functions of the old ones. As a real manifold it has dimension $2n$. Examples: any open subset of $\mathbb{C}^n$; the Riemann sphere $\mathbb{CP}^1$ with charts z and $w = 1/z$ (and w is holomorphic in z on $\mathbb{C}^*$); a torus $\mathbb{C}/\Lambda$ for a lattice Λ, with transition maps $z \mapsto z + \lambda$; $\mathbb{CP}^n$ with its standard charts; every smooth complex algebraic curve.

On such a manifold the complexified 1-forms have the local basis $\mathrm{d}z^1, \dots, \mathrm{d}z^n, \mathrm{d}\bar{z}^1, \dots, \mathrm{d}\bar{z}^n$. Nash's (3.24) is the general monomial built from them:

$$\omega = \frac{1}{p!\,q!}\,\omega_{i_1\cdots i_p \bar{j}_1\cdots\bar{j}_q}\,\mathrm{d}z^{i_1} \wedge \cdots \wedge \mathrm{d}z^{i_p} \wedge \mathrm{d}\bar{z}^{j_1} \wedge \cdots \wedge \mathrm{d}\bar{z}^{j_q}, \tag{3.65}$$

summed over indices, with coefficients antisymmetric in the i's and in the j's separately (the factor $1/(p!\,q!)$ is our usual normalisation of forms; Nash omits it). Such an ω is a $(p+q)$-form; we say it has **type** (p, q): p holomorphic differentials and q antiholomorphic ones.

Working definition 3.20 (type of a form)

To find the type decomposition of a complex k-form [a k-form with complex coefficients], rewrite it in the basis $\mathrm{d}z^i, \mathrm{d}\bar{z}^j$ (3.62) and sort the terms by how many $\mathrm{d}\bar{z}$'s they contain. The piece with q of them is the $(k-q, q)$ component. Formally,

$$\Lambda^k T^*M \otimes \mathbb{C} = \bigoplus_{p+q=k} \Lambda^{p,q} T^*M, \tag{3.66}$$

[$\Lambda^{p,q}T^*M$ is spanned by the monomials with exactly p factors $\mathrm{d}z^i$ and q factors $\mathrm{d}\bar{z}^j$] and $\mathcal{E}^{p,q}$ denotes the sheaf of smooth forms of type (p, q) [its sections over U are the smooth (p, q)-forms on U]. This is Nash's (3.27).

Why is "type" meaningful, i.e. independent of the chart? Because the transition functions are holomorphic. Under $z \mapsto z'(z)$,

$$\mathrm{d}z'^j \overset{(1)}{=} \sum_i \frac{\partial z'^j}{\partial z^i}\,\mathrm{d}z^i + \sum_i \frac{\partial z'^j}{\partial \bar{z}^i}\,\mathrm{d}\bar{z}^i \overset{(2)}{=} \sum_i \frac{\partial z'^j}{\partial z^i}\,\mathrm{d}z^i,$$

(1) The chain rule (3.64), in n variables.
(2) z'^j is a holomorphic function of the z^i.

So dz''s are combinations of dz's only, and (conjugating) $d\bar{z}'$'s of $d\bar{z}$'s only. A (p,q)-form in one chart is a (p,q)-form in every chart. On $\mathbb{CP}^1$ with $w = 1/z$: $dw = -z^{-2}dz$ and $d\bar{w} = -\bar{z}^{-2}d\bar{z}$, and the type is preserved.

Watch out: Type needs a complex structure

On a real $2n$-manifold there is no preferred way to split k-forms into types. The splitting depends on which functions we declare holomorphic. If we used the chart $z' = \bar{z}$ on part of $\mathbb{C}$, then $dz' = d\bar{z}$ and types $(1,0)$ and $(0,1)$ would swap. Complex manifolds forbid this: their transition functions are holomorphic, never antiholomorphic.

Counting. At each point $\Lambda^{p,q}$ has a basis of monomials with $i_1 < \cdots < i_p$ and $j_1 < \cdots < j_q$, so

$$\dim_{\mathbb{C}} \Lambda^{p,q} = \binom{n}{p}\binom{n}{q}, \qquad \sum_{p+q=k} \binom{n}{p}\binom{n}{q} = \binom{2n}{k} = \dim_{\mathbb{C}} \Lambda^k(\mathbb{R}^{2n}) \otimes \mathbb{C},$$

the last identity being Vandermonde's (choose k objects out of n "z"s and n "$\bar{z}$"s). For $n = 2$:

degree k	(p,q) pieces	dimensions	total	basis
0	$(0,0)$	1	1	1
1	$(1,0),(0,1)$	$2+2$	4	$dz^1, dz^2 \mid d\bar{z}^1, d\bar{z}^2$
2	$(2,0),(1,1),(0,2)$	$1+4+1$	6	$dz^1dz^2 \mid dz^i d\bar{z}^j \mid d\bar{z}^1 d\bar{z}^2$
3	$(2,1),(1,2)$	$2+2$	4	$dz^1dz^2d\bar{z}^j \mid dz^i d\bar{z}^1 d\bar{z}^2$
4	$(2,2)$	1	1	$dz^1dz^2d\bar{z}^1d\bar{z}^2$

(wedges suppressed in the last column).

Worked example 3.29: Type decomposition of real forms

(a) The area form on $\mathbb{C}$. Using (3.62),

$$dz \wedge d\bar{z} \overset{(1)}{=} (dx + i\,dy) \wedge (dx - i\,dy) \overset{(2)}{=} -i\,dx \wedge dy + i\,dy \wedge dx \overset{(3)}{=} -2i\,dx \wedge dy.$$

(1) Definition of $dz, d\bar{z}$.
(2) Expand; $dx \wedge dx = dy \wedge dy = 0$.
(3) $dy \wedge dx = -dx \wedge dy$.

So $dx \wedge dy = \frac{i}{2}\,dz \wedge d\bar{z}$: the real area form is pure type $(1,1)$. We use this constantly.
(b) A real 1-form. $\alpha = a\,dx + b\,dy$ with a, b real. Substituting (3.62), $\alpha = \frac{1}{2}(a - ib)\,dz + \frac{1}{2}(a + ib)\,d\bar{z}$. The $(1,0)$ and $(0,1)$ parts are complex conjugates of each other; a real form always has $\overline{\omega^{p,q}} = \omega^{q,p}$. The electromagnetic potential $A = A_x dx + A_y dy$ on a surface splits as $A = A_z dz + A_{\bar{z}} d\bar{z}$ with $A_z = \frac{1}{2}(A_x - iA_y)$ and $A_{\bar{z}} = \overline{A_z}$.
(c) A 2-form on $\mathbb{C}^2$. The symplectic form of phase space, $\omega = dx^1 \wedge dy^1 + dx^2 \wedge dy^2$ (identifying $z^k = x^k + iy^k$ with $q^k + ip^k$), is by (a) $\omega = \frac{i}{2}(dz^1 \wedge d\bar{z}^1 + dz^2 \wedge d\bar{z}^2)$, type $(1,1)$. The form $dx^1 \wedge dx^2$ on the other hand is

$$dx^1 \wedge dx^2 \overset{(1)}{=} \tfrac{1}{4}(dz^1 + d\bar{z}^1) \wedge (dz^2 + d\bar{z}^2)$$

$$\overset{(2)}{=} \underbrace{\tfrac{1}{4}\mathrm{d}z^1 \wedge \mathrm{d}z^2}_{(2,0)} + \underbrace{\tfrac{1}{4}(\mathrm{d}z^1 \wedge \mathrm{d}\bar{z}^2 + \mathrm{d}\bar{z}^1 \wedge \mathrm{d}z^2)}_{(1,1)} + \underbrace{\tfrac{1}{4}\mathrm{d}\bar{z}^1 \wedge \mathrm{d}\bar{z}^2}_{(0,2)},$$

(1) $\mathrm{d}x^k = \frac{1}{2}(\mathrm{d}z^k + \mathrm{d}\bar{z}^k)$ from (3.62).
(2) Expand and sort by the number of $\mathrm{d}\bar{z}$'s.

which has all three types.

3.7.3 The operators ∂ and $\bar{\partial}$

Equation (3.64) split $\mathrm{d}f$ into a $(1,0)$ part and a $(0,1)$ part. Nash's (3.25) gives these parts names:

$$\partial = \sum_{i=1}^{n} \mathrm{d}z^i \wedge \frac{\partial}{\partial z^i}, \qquad \bar{\partial} = \sum_{i=1}^{n} \mathrm{d}\bar{z}^i \wedge \frac{\partial}{\partial \bar{z}^i}, \tag{3.67}$$

acting on a form (3.65) by differentiating its coefficients and wedging the differential on from the left:

$$\bar{\partial}\omega = \frac{1}{p!\,q!} \sum_{k} \frac{\partial \omega_{i_1 \cdots i_p \bar{j}_1 \cdots \bar{j}_q}}{\partial \bar{z}^k}\, \mathrm{d}\bar{z}^k \wedge \mathrm{d}z^{i_1} \wedge \cdots \wedge \mathrm{d}\bar{z}^{j_q},$$

and similarly for ∂. So ∂ raises the type from (p,q) to $(p+1,q)$ and $\bar{\partial}$ raises it to $(p,q+1)$.

Key idea: $\mathrm{d} = \partial + \bar{\partial}$ and its square (Nash's (3.26))

On a complex manifold,

$$\mathrm{d} = \partial + \bar{\partial}, \qquad \partial^2 = 0, \qquad \partial\bar{\partial} + \bar{\partial}\partial = 0, \qquad \bar{\partial}^2 = 0.$$

The first identity is the chain rule; the other three are $\mathrm{d}^2 = 0$ sorted by type.

Why $\mathrm{d} = \partial + \bar{\partial}$. For a (p,q)-form $\omega = f\,\mathrm{d}z^I \wedge \mathrm{d}\bar{z}^J$ (multi-index notation, one monomial suffices by linearity),

$$\begin{aligned} \mathrm{d}\omega &\overset{(1)}{=} \mathrm{d}f \wedge \mathrm{d}z^I \wedge \mathrm{d}\bar{z}^J \\ &\overset{(2)}{=} \Big(\sum_k \frac{\partial f}{\partial z^k}\mathrm{d}z^k + \sum_k \frac{\partial f}{\partial \bar{z}^k}\mathrm{d}\bar{z}^k\Big) \wedge \mathrm{d}z^I \wedge \mathrm{d}\bar{z}^J \\ &\overset{(3)}{=} \partial\omega + \bar{\partial}\omega. \end{aligned}$$

(1) The coordinate differentials are closed: $\mathrm{d}(\mathrm{d}z^i) = \mathrm{d}\mathrm{d}x^i + i\,\mathrm{d}\mathrm{d}y^i = 0$, so d only hits the coefficient.
(2) Equation (3.64) in n variables.
(3) Definition (3.67); the first sum is $(p+1,q)$, the second $(p,q+1)$.

(If the transition functions were not holomorphic, $\mathrm{d}(\mathrm{d}z^i)$ would still vanish, but a (p,q)-form in one chart could acquire other types in the next and $\partial, \bar{\partial}$ would not be chart-independent. Holomorphy is what makes the splitting (3.67) global.)

Why the three identities. Apply d twice to a (p,q)-form:

$$\begin{aligned} 0 &\overset{(1)}{=} \mathrm{d}^2\omega \\ &\overset{(2)}{=} (\partial+\bar\partial)(\partial+\bar\partial)\omega \\ &\overset{(3)}{=} \underbrace{\partial^2\omega}_{(p+2,q)} + \underbrace{(\partial\bar\partial+\bar\partial\partial)\omega}_{(p+1,q+1)} + \underbrace{\bar\partial^2\omega}_{(p,q+2)}. \end{aligned}$$

(1) $\mathrm{d}^2=0$ (Chapter T1).
(2) $\mathrm{d}=\partial+\bar\partial$.
(3) Expand and record the type of each piece.

The decomposition (3.66) is a direct sum, so a form is zero only if each of its type components is zero. All three brackets vanish separately.

Worked example 3.30: Checking $\partial\bar\partial=-\bar\partial\partial$ on a function

Let $f(z,\bar z)$ be a smooth function on $\mathbb{C}$. Then

$$\begin{aligned} \partial\bar\partial f &\overset{(1)}{=} \partial\big(\partial_{\bar z} f\,\mathrm{d}\bar z\big) \overset{(2)}{=} \partial_z\partial_{\bar z} f\;\mathrm{d}z\wedge\mathrm{d}\bar z, \\ \bar\partial\partial f &\overset{(3)}{=} \bar\partial\big(\partial_z f\,\mathrm{d}z\big) \overset{(4)}{=} \partial_{\bar z}\partial_z f\;\mathrm{d}\bar z\wedge\mathrm{d}z \overset{(5)}{=} -\partial_z\partial_{\bar z} f\;\mathrm{d}z\wedge\mathrm{d}\bar z. \end{aligned}$$

(1) $\bar\partial f$ is the $\mathrm{d}\bar z$ part of $\mathrm{d}f$.
(2) Differentiate the coefficient in z and wedge $\mathrm{d}z$ on the left.
(3) ∂f is the $\mathrm{d}z$ part of $\mathrm{d}f$.
(4) Differentiate in $\bar z$ and wedge $\mathrm{d}\bar z$ on the left.
(5) Mixed partials commute; $\mathrm{d}\bar z\wedge\mathrm{d}z=-\mathrm{d}z\wedge\mathrm{d}\bar z$.

The sum is zero, as promised. With Example 3.29(a) and $4\partial_z\partial_{\bar z}=\nabla^2$,

$$2i\,\partial\bar\partial f = 2i\cdot\tfrac14\nabla^2 f\cdot(-2i)\,\mathrm{d}x\wedge\mathrm{d}y = \nabla^2 f\;\mathrm{d}x\wedge\mathrm{d}y.$$

So $2i\,\partial\bar\partial$ is "the Laplacian times the area form". In Kähler geometry and in the theory of instantons this operator appears everywhere; for instance, $\frac{i}{2\pi}\partial\bar\partial\log(1+|z|^2)$ is the Fubini–Study area form of $\mathbb{CP}^1$, which we meet in Example 3.34.

Holomorphic p-forms. A $(p,0)$-form $\omega=\frac{1}{p!}\omega_{i_1\cdots i_p}\mathrm{d}z^{i_1}\wedge\cdots\wedge\mathrm{d}z^{i_p}$ is called **holomorphic** if its coefficients are holomorphic functions. Since $\bar\partial\omega$ collects exactly the $\bar z$-derivatives of the coefficients, this is the same as $\bar\partial\omega=0$:

$$\Omega^p = \mathcal{Z}^{p,0} := \operatorname{Ker}\big(\bar\partial:\mathcal{E}^{p,0}\to\mathcal{E}^{p,1}\big), \qquad \Omega^0=\mathcal{O}. \tag{3.68}$$

For example $f(z)\,\mathrm{d}z$ on $\mathbb{C}$ is holomorphic iff $\bar\partial(f\,\mathrm{d}z)=\partial_{\bar z}f\,\mathrm{d}\bar z\wedge\mathrm{d}z=0$ iff f is holomorphic. Note that a holomorphic 1-form is automatically d-closed in one variable: $\mathrm{d}(f\,\mathrm{d}z)=\partial_{\bar z}f\,\mathrm{d}\bar z\wedge\mathrm{d}z=0$. That is why contour integrals of holomorphic functions depend only on the homology class of the contour: Cauchy's theorem is Stokes' theorem for the closed form $f\,\mathrm{d}z$.

Watch out: Nash's "type $(0,p)$"

On p. 64 Nash writes that holomorphic p-forms are "necessarily of type $(0,p)$". This is a slip: they are of type $(p,0)$ (all $\mathrm{d}z$'s, no $\mathrm{d}\bar z$'s), as his own next sentence $\Omega^p=\mathcal{Z}^{p,0}$ says.

Also, in the first line of his (3.28) the arrow $\Omega^p \to \mathcal{E}^{p,0}$ is the inclusion, not $\bar\partial$; the $\bar\partial$ label belongs only on the second arrow.

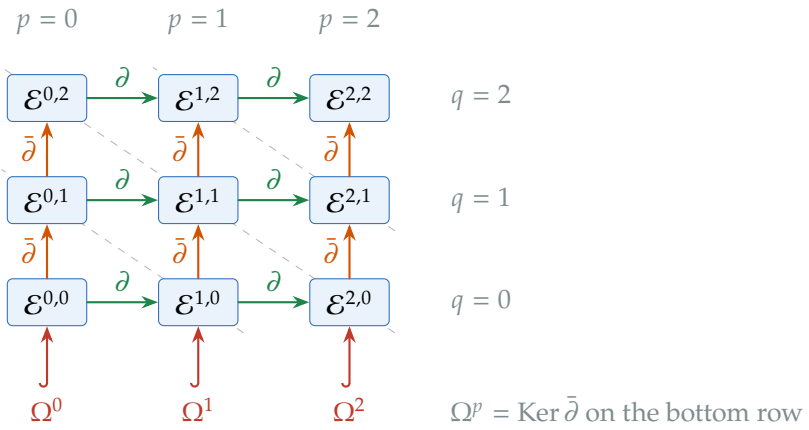

Figure 3.25: The Dolbeault double complex of a complex surface ($n = 2$). The sheaf $\mathcal{E}^{p,q}$ sits at position (p, q); ∂ (green) moves right, $\bar\partial$ (orange) moves up, and $\mathrm{d} = \partial + \bar\partial$ moves from one dashed antidiagonal (fixed total degree $k = p + q$) to the next. Each column, read upwards, is the resolution of the holomorphic p-forms Ω^p (red) that computes $H^q(M; \Omega^p)$.

Dictionary: $\bar\partial$ is half of the 2d Dirac operator

Take the Euclidean gamma matrices $\gamma^1 = \sigma_1$, $\gamma^2 = \sigma_2$ on $\mathbb{R}^2$ (Pauli matrices). Then

$$\not{D} \overset{(1)}{=} \sigma_1\partial_x + \sigma_2\partial_y \overset{(2)}{=} \begin{pmatrix} 0 & \partial_x - i\partial_y \\ \partial_x + i\partial_y & 0 \end{pmatrix} \overset{(3)}{=} \begin{pmatrix} 0 & 2\partial_z \\ 2\partial_{\bar z} & 0 \end{pmatrix}.$$

(1) $\not{D} = \gamma^\mu\partial_\mu$ (Chapter T4).

(2) $\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, $\sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}$.

(3) The Wirtinger derivatives (3.63).

So on a spinor $\psi = (\psi_+, \psi_-)^T$ the Dirac equation $\not{D}\psi = 0$ says $\partial_{\bar z}\psi_+ = 0$ and $\partial_z\psi_- = 0$: the positive-chirality component is holomorphic, the negative one antiholomorphic. "Chiral fermion in 2d" = "$\bar\partial$". Counting chiral zero modes on a compact Riemann surface is exactly counting $\dim \mathrm{Ker}\,\bar\partial - \dim \mathrm{Coker}\,\bar\partial$, which by the Dolbeault theorem is $\dim H^0 - \dim H^1$ of a sheaf: the Riemann–Roch index we met in Example 3.18.

3.7.4 The $\bar\partial$-Poincaré lemma: solving $\partial_{\bar z} f = g$

In the de Rham story, the local input was the Poincaré lemma: on a ball every closed form is exact. Here we need its analogue, the **Dolbeault lemma** (also called the Dolbeault–Grothendieck or $\bar\partial$-Poincaré lemma). Nash uses it silently when he calls the sequences (3.28) exact. We now supply it, starting with the one-variable case, where it amounts to inverting $\partial_{\bar z}$.

Step 1: the Green's function of $\partial_{\bar z}$. We claim

$$\frac{\partial}{\partial \bar z}\,\frac{1}{\pi z} = \delta^2(z), \tag{3.69}$$

where $\delta^2(z) = \delta(x)\delta(y)$ and we integrate against the real area element $\mathrm{d}^2z := \mathrm{d}x\,\mathrm{d}y$. Away from $z = 0$ the left side vanishes, since $1/z$ is holomorphic there. To find the strength of the

singularity, integrate over a disc $D_R = \{|z| < R\}$ using Stokes' theorem in complex form. For any smooth h on a region D,

$$\oint_{\partial D} h\,\mathrm{d}z \overset{(1)}{=} \int_D \mathrm{d}(h\,\mathrm{d}z) \overset{(2)}{=} \int_D \partial_{\bar z} h\;\mathrm{d}\bar z \wedge \mathrm{d}z \overset{(3)}{=} 2i \int_D \partial_{\bar z} h\;\mathrm{d}^2 z. \tag{3.70}$$

(1) Stokes' theorem (Chapter T2).
(2) $\mathrm{d}(h\,\mathrm{d}z) = \mathrm{d}h \wedge \mathrm{d}z$ and only the $\mathrm{d}\bar z$ part of $\mathrm{d}h$ survives the wedge with $\mathrm{d}z$.
(3) $\mathrm{d}\bar z \wedge \mathrm{d}z = +2i\,\mathrm{d}x \wedge \mathrm{d}y$ by Example 3.29(a).

Apply this to $h = 1/z$ on the annulus $\varepsilon < |z| < R$, where h is smooth and $\partial_{\bar z} h = 0$: the outer and inner circle integrals agree, and both equal $\oint \mathrm{d}z/z = 2\pi i$. The "missing" $2\pi i$ must therefore be produced by a point source at the origin. Treating the disc as a whole in the sense of distributions,

$$2i \int_{D_R} \frac{\partial}{\partial \bar z}\frac{1}{z}\,\mathrm{d}^2 z = \oint_{|z|=R} \frac{\mathrm{d}z}{z} = 2\pi i \quad\Longrightarrow\quad \int_{D_R} \frac{\partial}{\partial \bar z}\frac{1}{z}\,\mathrm{d}^2 z = \pi,$$

for every R. A distribution supported at 0 with total integral π is $\pi\delta^2$, which is (3.69). (The same computation with $\partial_z \partial_{\bar z} \log|z|^2 = \partial_{\bar z}(1/z) = \pi\delta^2$ recovers the 2d Coulomb law $\nabla^2 \log|z| = 2\pi\delta^2$, completing Example 3.28.)

Step 2: the Cauchy integral. Given a smooth g with compact support in $\mathbb{C}$, set

$$f(z) := \frac{1}{\pi}\int_{\mathbb{C}} \frac{g(w)}{z-w}\,\mathrm{d}^2 w. \tag{3.71}$$

The integrand has an integrable $1/|z-w|$ singularity, so f is well defined. Then

$$\frac{\partial f}{\partial \bar z}(z) \overset{(1)}{=} \int_{\mathbb{C}} g(w)\,\frac{\partial}{\partial \bar z}\Big(\frac{1}{\pi(z-w)}\Big)\mathrm{d}^2 w \overset{(2)}{=} \int_{\mathbb{C}} g(w)\,\delta^2(z-w)\,\mathrm{d}^2 w \overset{(3)}{=} g(z).$$

(1) Differentiate under the integral sign (in the sense of distributions; the honest version substitutes $u = z - w$ first, differentiates $g(z-u)$, and then undoes the derivative with (3.70) on $\varepsilon < |u| < R$, letting $\varepsilon \to 0$).
(2) The Green's function (3.69), translated to w.
(3) The defining property of δ^2.

So (3.71) solves $\partial_{\bar z} f = g$. Every smooth $(0,1)$-form $g\,\mathrm{d}\bar z$ with compact support is $\bar\partial$-exact on $\mathbb{C}$.

Worked example 3.31: Solving $\partial_{\bar z} f = 1$ on a disc with the Cauchy kernel

Of course $f = \bar z$ solves $\partial_{\bar z} f = 1$. Let us check that the Cauchy integral finds it. Take $g = 1$ on the disc D_R and 0 outside, and evaluate f from (3.71) at a point $|z| < R$. In polar coordinates $w = re^{i\theta}$, first do the angular integral:

$$\int_0^{2\pi} \frac{\mathrm{d}\theta}{z - re^{i\theta}} = \begin{cases} 2\pi/z, & r < |z|\,, \\ 0, & r > |z|\,. \end{cases}$$

For $r < |z|$ expand $\frac{1}{z-w} = \frac{1}{z}\sum_{k\ge 0}(w/z)^k$; only $k = 0$ survives the θ-integral. For $r > |z|$ expand $\frac{1}{z-w} = -\frac{1}{w}\sum_{k\ge 0}(z/w)^k$; every term carries $e^{-i(k+1)\theta}$ and integrates to zero. Then

$$f(z) \overset{(1)}{=} \frac{1}{\pi}\int_0^R r\,\mathrm{d}r \int_0^{2\pi} \frac{\mathrm{d}\theta}{z - re^{i\theta}} \overset{(2)}{=} \frac{1}{\pi}\int_0^{|z|} \frac{2\pi}{z}\,r\,\mathrm{d}r \overset{(3)}{=} \frac{|z|^2}{z} \overset{(4)}{=} \bar z.$$

(1) Definition (3.71) with $\mathrm{d}^2 w = r\,\mathrm{d}r\,\mathrm{d}\theta$.

(2) The angular integral just computed: only the circles inside $|z|$ contribute.
(3) $\int_0^{|z|} r\,\mathrm{d}r = |z|^2/2$.
(4) $|z|^2 = z\bar{z}$.

Inside the disc the Cauchy integral returns exactly $\bar{z}$. (Outside, for $|z| > R$, every circle contributes and $f = R^2/z$, which is holomorphic there, as it must be since $g = 0$ outside the disc.) Electrostatically, this is Gauss's law for a uniformly charged disc, written in complex form: the "field" f grows linearly inside and falls off like $1/z$ outside.

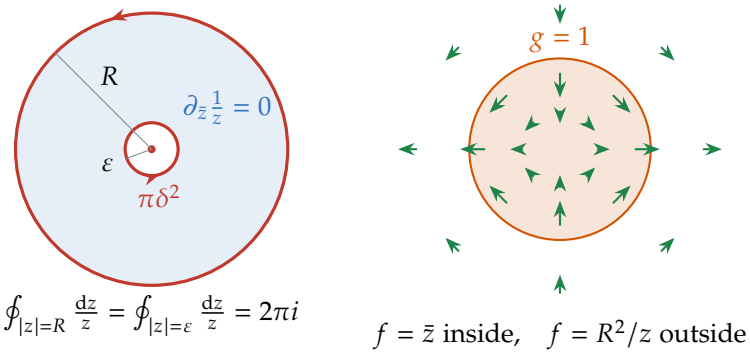

Figure 3.26: Inverting $\partial_{\bar{z}}$. Left: $1/z$ is holomorphic on the shaded annulus, so its contour integrals over the two red circles agree; the whole $2\pi i$ is carried by a point source $\pi\delta^2$ at the origin, which makes $1/(\pi z)$ the Green's function of $\partial_{\bar{z}}$. Right: the Cauchy integral of a uniform source $g = 1$ on a disc (Example 3.31). Green arrows show the complex number $f(z)$ as a vector: $\bar{z}$ inside (growing, reflected in the real axis), and the holomorphic R^2/z outside (decaying).

Step 3: from compact support to any disc. Nash's sheaves are local, so we need to solve $\partial_{\bar{z}} f = g$ near a point for g that need not have compact support. That is easy: to solve on a smaller disc D_r, multiply g by a bump function χ equal to 1 on D_r and supported in D_R, and apply (3.71) to χg. The solution f satisfies $\partial_{\bar{z}} f = \chi g = g$ on D_r. This proves the one-variable Dolbeault lemma: *every point has a neighbourhood on which every* $(0,1)$*-form is* $\bar{\partial}$*-exact.* With a little more work (solve on an exhausting sequence of discs and correct the discrepancies with holomorphic functions, which can be approximated by polynomials by Runge's theorem) one solves $\partial_{\bar{z}} f = g$ on the whole of any open set $U \subset \mathbb{C}$. We use this stronger form below; we do not prove it.

Step 4: several variables. On a polydisc $P = D_1 \times \cdots \times D_n \subset \mathbb{C}^n$ take a $\bar{\partial}$-closed $(0,q)$-form. The standard argument solves the equation one variable at a time, using the Cauchy integral in one variable with the others as parameters. The case $n = 2$, $q = 1$ shows every idea. Let $\omega = g_1\,\mathrm{d}\bar{z}^1 + g_2\,\mathrm{d}\bar{z}^2$ with compact support and $\bar{\partial}\omega = 0$, i.e. (the coefficient of $\mathrm{d}\bar{z}^1 \wedge \mathrm{d}\bar{z}^2$)

$$\frac{\partial g_2}{\partial \bar{z}^1} = \frac{\partial g_1}{\partial \bar{z}^2}. \tag{3.72}$$

Solve the first component with the Cauchy integral in z^1 only: $f(z^1, z^2) = \frac{1}{\pi}\int \frac{g_1(w, z^2)}{z^1 - w}\,\mathrm{d}^2 w$. Then $\partial f/\partial \bar{z}^1 = g_1$ by Step 2, and

$$\frac{\partial f}{\partial \bar{z}^2} \overset{(1)}{=} \frac{1}{\pi}\int \frac{\partial_{\bar{z}^2} g_1(w, z^2)}{z^1 - w}\,\mathrm{d}^2 w \overset{(2)}{=} \frac{1}{\pi}\int \frac{\partial_{\bar{w}} g_2(w, z^2)}{z^1 - w}\,\mathrm{d}^2 w \overset{(3)}{=} g_2(z^1, z^2).$$

(1) The kernel $1/(z^1 - w)$ does not depend on z^2; differentiate the numerator.
(2) The closedness condition (3.72).
(3) The Cauchy–Pompeiu formula: for compactly supported h, $\frac{1}{\pi}\int \frac{\partial_{\bar{w}} h(w)}{z - w}\mathrm{d}^2 w = h(z)$. (Proof: write $h = \frac{1}{\pi}\int \frac{\partial_{\bar{w}} h}{z-w} +$ (holomorphic) by Step 2; the holomorphic remainder is entire and vanishes at infinity, hence is zero by Liouville.)

So $\bar\partial f = g_1 \mathrm{d}\bar z^1 + g_2 \mathrm{d}\bar z^2 = \omega$. For higher q and n one inducts on the number of $\mathrm{d}\bar z^k$'s that appear, and for (p,q)-forms one simply carries the $\mathrm{d}z^{i_1}\wedge\cdots\wedge\mathrm{d}z^{i_p}$ along as spectators ($\bar\partial$ does not touch them).

Key idea: The Dolbeault lemma

On a polydisc (in particular, in a small neighbourhood of any point of a complex manifold), every $\bar\partial$-closed (p,q)-form with $q \geq 1$ is $\bar\partial$-exact. In one variable the inverse of $\partial_{\bar z}$ is convolution with the Green's function $1/(\pi z)$. Consequently, for each p the sequence of sheaves

$$0 \longrightarrow \Omega^p \hookrightarrow \mathcal{E}^{p,0} \xrightarrow{\bar\partial} \mathcal{E}^{p,1} \xrightarrow{\bar\partial} \mathcal{E}^{p,2} \xrightarrow{\bar\partial} \cdots \xrightarrow{\bar\partial} \mathcal{E}^{p,n} \longrightarrow 0 \tag{3.73}$$

is exact: it is a resolution of Ω^p, the **Dolbeault resolution**.

Two structural facts complete the input to Nash's argument.

- *$\mathcal{E}^{p,q}$ is fine.* If $\{\rho_\alpha\}$ is a smooth (real) partition of unity and ω has type (p,q), then $\rho_\alpha\omega$ still has type (p,q): multiplying by a function does not change which differentials appear. So the partition-of-unity argument of Section 3.2.5 applies verbatim, and $H^k(M;\mathcal{E}^{p,q}) = 0$ for $k \geq 1$ (Section 3.3.7).
- *$\mathcal{Z}^{p,q}$ and Ω^p are not fine.* Multiplying a holomorphic function by a bump function destroys holomorphy (by the identity theorem, a holomorphic function vanishing on an open set of a connected domain vanishes everywhere, so holomorphic bump functions do not exist). This rigidity is why $\mathcal{O}$ has interesting cohomology.

3.7.5 Nash's argument: the Dolbeault theorem

We now have everything Nash needs, and his proof is the de Rham proof (Section 3.6.2) with three substitutions:

$$\mathrm{d} \rightsquigarrow \bar\partial, \qquad \mathcal{E}^q \rightsquigarrow \mathcal{E}^{p,q}, \qquad \mathcal{Z}^q \rightsquigarrow \mathcal{Z}^{p,q} := \operatorname{Ker}\bigl(\bar\partial : \mathcal{E}^{p,q} \to \mathcal{E}^{p,q+1}\bigr),$$

with the holomorphic degree p fixed throughout, a passive spectator. Chop the Dolbeault resolution (3.73) into short exact sequences, Nash's (3.28):

$$\begin{gathered} 0 \to \Omega^p \to \mathcal{E}^{p,0} \xrightarrow{\bar\partial} \mathcal{Z}^{p,1} \to 0, \qquad 0 \to \mathcal{Z}^{p,1} \to \mathcal{E}^{p,1} \xrightarrow{\bar\partial} \mathcal{Z}^{p,2} \to 0, \qquad \dots, \\ 0 \to \mathcal{Z}^{p,q} \to \mathcal{E}^{p,q} \xrightarrow{\bar\partial} \mathcal{Z}^{p,q+1} \to 0, \qquad \dots \end{gathered} \tag{3.74}$$

Why is each one exact? On stalks (which is what exactness of sheaves means, Section 3.2.3):

- *at the left*: $\mathcal{Z}^{p,q} \to \mathcal{E}^{p,q}$ is an inclusion, hence injective;
- *in the middle*: the kernel of $\bar\partial$ on $\mathcal{E}^{p,q}$ is $\mathcal{Z}^{p,q}$ by definition;
- *at the right*: $\bar\partial$ maps $\mathcal{E}^{p,q}$ into $\mathcal{Z}^{p,q+1}$ because $\bar\partial^2 = 0$, and *onto* it near every point by the Dolbeault lemma (Section 3.7.4).

Only the last point has content, exactly as in the de Rham case.

Feed one of these into the long exact sequence (3.37):

$$\cdots \to H^k(M;\mathcal{E}^{p,q}) \to H^k(M;\mathcal{Z}^{p,q+1}) \xrightarrow{\delta^*} H^{k+1}(M;\mathcal{Z}^{p,q}) \to H^{k+1}(M;\mathcal{E}^{p,q}) \to \cdots$$

Because $\mathcal{E}^{p,q}$ is fine, the outer terms vanish for $k \geq 1$, and

$$H^{k+1}(M;\mathcal{Z}^{p,q}) \cong H^k(M;\mathcal{Z}^{p,q+1}) \qquad (k \geq 1). \tag{3.75}$$

For $k = 0$ the left-hand term is the space of global (p,q)-forms, and exactness of $\mathcal{E}^{p,q}(M) \xrightarrow{\bar\partial} \mathcal{Z}^{p,q+1}(M) \xrightarrow{\delta^*} H^1(M;\mathcal{Z}^{p,q}) \to 0$ gives

$$H^1(M;\mathcal{Z}^{p,q-1}) \cong \frac{H^0(M;\mathcal{Z}^{p,q})}{\bar\partial\, H^0(M;\mathcal{E}^{p,q-1})} = \frac{\operatorname{Ker}\big(\bar\partial : \mathcal{E}^{p,q}(M) \to \mathcal{E}^{p,q+1}(M)\big)}{\operatorname{Im}\big(\bar\partial : \mathcal{E}^{p,q-1}(M) \to \mathcal{E}^{p,q}(M)\big)}. \tag{3.76}$$

The left equality is Nash's (3.29); the right one, which is (3.30), uses $H^0 = \Gamma$ (3.17) in numerator and denominator.

Working definition 3.21 (Dolbeault cohomology)

The **Dolbeault cohomology** of a complex manifold [charts in $\mathbb{C}^n$ glued by holomorphic coordinate changes] is

$$H^{p,q}_{\bar\partial}(M) := \frac{\{\text{global } (p,q)\text{-forms } \omega \text{ with } \bar\partial\omega = 0\}}{\{\bar\partial\beta : \ \beta \text{ a global } (p,q-1)\text{-form}\}}.$$

[here $\bar\partial\omega$ is the $(p,q+1)$ part of $\mathrm{d}\omega$, obtained by differentiating the coefficients in the $\bar z^j$ only] *To compute it:* find all global solutions of $\bar\partial\omega = 0$ in type (p,q), and decide which of them are $\bar\partial$ of something global. For $q = 0$ there is nothing to divide by: $H^{p,0}_{\bar\partial}(M)$ is the space of global holomorphic p-forms [$(p,0)$-forms whose coefficients are holomorphic functions].

Now chain the isomorphisms, exactly as in (3.54). For $q \geq 1$,

$$\begin{aligned} H^q(M;\Omega^p) &\overset{(1)}{=} H^q(M;\mathcal{Z}^{p,0}) \\ &\overset{(2)}{=} H^{q-1}(M;\mathcal{Z}^{p,1}) \overset{(2)}{=} H^{q-2}(M;\mathcal{Z}^{p,2}) \overset{(2)}{=} \cdots \overset{(2)}{=} H^1(M;\mathcal{Z}^{p,q-1}) \\ &\overset{(3)}{=} \frac{\mathcal{Z}^{p,q}(M)}{\bar\partial\,\mathcal{E}^{p,q-1}(M)} \overset{(4)}{=} H^{p,q}_{\bar\partial}(M). \end{aligned} \tag{3.77}$$

(1) Holomorphic p-forms are the $\bar\partial$-closed $(p,0)$-forms (3.68).
(2) The degree shift (3.75), used $q-1$ times, each time with $k \geq 1$ ("=" means canonically isomorphic).
(3) The last step (3.76).
(4) Definition of Dolbeault cohomology.

For $q = 0$ both sides are the global holomorphic p-forms.

Key idea: The Dolbeault theorem (Nash's (3.31))

For every complex manifold M and all $p, q \geq 0$,

$$H^q(M;\Omega^p) \ \cong \ H^{p,q}_{\bar\partial}(M), \qquad \text{in particular} \qquad H^q(M;\mathcal{O}) \cong H^{0,q}_{\bar\partial}(M).$$

The Čech cohomology of the rigid sheaf of holomorphic forms is computed by solving the inhomogeneous Cauchy–Riemann equation $\bar\partial\beta = \omega$ globally. Mechanism: the same three ingredients as de Rham, namely a local solvability lemma (Dolbeault), fineness of the smooth forms (partitions of unity), and the long exact sequence.

	de Rham	**Dolbeault**
sheaf being resolved	$\underline{\mathbb{R}}$ (locally constant)	Ω^p (holomorphic p-forms)
fine sheaves	$\mathcal{E}^q$ (q-forms)	$\mathcal{E}^{p,q}$ ((p,q)-forms)
differential	d	$\bar\partial$
local lemma	Poincaré: $\mathrm{d}\omega = 0 \Rightarrow \omega = \mathrm{d}\alpha$	Dolbeault: $\bar\partial\omega = 0 \Rightarrow \omega = \bar\partial\beta$
local inverse	radial homotopy (3.48)	Cauchy kernel $1/(\pi z)$ (3.71)
theorem	$H^q(M;\mathbb{R}) \cong H^q_{\mathrm{dR}}(M)$	$H^q(M;\Omega^p) \cong H^{p,q}_{\bar\partial}(M)$
vanishes for	$q > \dim_{\mathbb{R}} M = 2n$	$q > \dim_{\mathbb{C}} M = n$
Nash	(3.20)–(3.23)	(3.28)–(3.31)

Three remarks.

- *Vanishing above the complex dimension.* There are no (p,q)-forms with $q > n$ (a wedge of more than n of the $\mathrm{d}\bar z^j$ is zero). So $H^q(M;\Omega^p) = 0$ for $q > n$, although the real dimension is $2n$. On a Riemann surface ($n = 1$) only H^0 and H^1 of $\mathcal{O}$ can be nonzero, which matches what the two-set cover of $\mathbb{CP}^1$ gave us (Example 3.18).

- *Bundle coefficients.* If $E \to M$ is a holomorphic vector bundle (holomorphic transition functions $g_{\alpha\beta}$), then $\bar\partial$ acts on E-valued forms, the sheaves $\mathcal{E}^{p,q}(E)$ of (3.8). The reason is one line of Leibniz: if $s_\alpha = g_{\alpha\beta}s_\beta$ on an overlap, then

$$\bar\partial s_\alpha \overset{(1)}{=} \bar\partial(g_{\alpha\beta}s_\beta) \overset{(2)}{=} (\bar\partial g_{\alpha\beta})\,s_\beta + g_{\alpha\beta}\,\bar\partial s_\beta \overset{(3)}{=} g_{\alpha\beta}\,\bar\partial s_\beta,$$

  (1) The local components of the section are related by the transition function.
  (2) Leibniz rule for the first-order operator $\bar\partial$.
  (3) $g_{\alpha\beta}$ is holomorphic.

  so the local $\bar\partial s_\alpha$ glue into a global E-valued $(0,1)$-form. (For d this fails: $\mathrm{d}g_{\alpha\beta} \neq 0$, and one needs a connection.) The whole argument goes through and gives $H^q(M;\Omega^p(E)) \cong H^{p,q}_{\bar\partial}(M;E)$. For $E = \mathcal{O}(n)$ on $\mathbb{CP}^1$ this turns the Laurent-series counting of Example 3.18 into a statement about the operator $\bar\partial_{\mathcal{O}(n)}$: its kernel has dimension $\dim H^0$, its cokernel dimension $\dim H^1$, and its index is $n+1$. This is the prototype of the index theorems of Chapter 4.

- *Dolbeault versus de Rham.* On a compact Kähler manifold (for instance any compact Riemann surface, or $\mathbb{CP}^n$) Hodge theory gives $H^k_{\mathrm{dR}}(M)\otimes\mathbb{C} \cong \bigoplus_{p+q=k} H^{p,q}_{\bar\partial}(M)$, so the Betti numbers split as $b_k = \sum_{p+q=k} h^{p,q}$ with $h^{p,q} = \dim H^{p,q}_{\bar\partial}$. We shall check this in the examples below; it is not part of Nash's argument, which works for any complex manifold, compact or not.

3.7.6 Examples

Worked example 3.32: Open subsets of $\mathbb{C}$: no higher $\mathcal{O}$-cohomology

Let $U \subset \mathbb{C}$ be open (a disc, $\mathbb{C}$ itself, $\mathbb{C}^*$, an annulus, ...). Since $n = 1$, the only possibly nonzero higher group is

$$H^1(U;\mathcal{O}) \overset{(1)}{=} H^{0,1}_{\bar\partial}(U) \overset{(2)}{=} \frac{\{g\,\mathrm{d}\bar z :\ g \in C^\infty(U)\}}{\{\partial_{\bar z} f\,\mathrm{d}\bar z :\ f \in C^\infty(U)\}} \overset{(3)}{=} 0.$$

(1) The Dolbeault theorem with $p = 0$, $q = 1$.

(2) In one complex dimension every $(0,1)$-form is $\bar\partial$-closed (its $\bar\partial$ would be a $(0,2)$-form, and there are none), and $\bar\partial f = \partial_{\bar z} f \, d\bar z$.
(3) $\partial_{\bar z} f = g$ is solvable on all of U (Step 3 of Section 3.7.4).

The same argument with $f\,dz$ in place of f gives $H^1(U;\Omega^1) = 0$. This is the fact we borrowed earlier: discs, $\mathbb{C}$ and $\mathbb{C}^*$ are acyclic for $\mathcal{O}$, so the covers of $\mathbb{CP}^1$ and of $\mathbb{C}^*$ used in Example 3.18 and Example 3.19 are Leray covers.
Combine it with the exponential sequence (3.43):

$$0 = H^1(U;\mathcal{O}) \to H^1(U;\mathcal{O}^*) \xrightarrow{c_1} H^2(U;\mathbb{Z}) = 0,$$

where $H^2(U;\mathbb{Z}) = 0$ because an open subset of the plane has no closed surfaces in it to carry flux. Hence $H^1(U;\mathcal{O}^*) = 0$: *every holomorphic line bundle over an open subset of $\mathbb{C}$ is trivial.* In gauge language: on a planar domain every holomorphic transition function g_{01} can be written as h_0/h_1 with h_i holomorphic and nowhere zero on the patches.

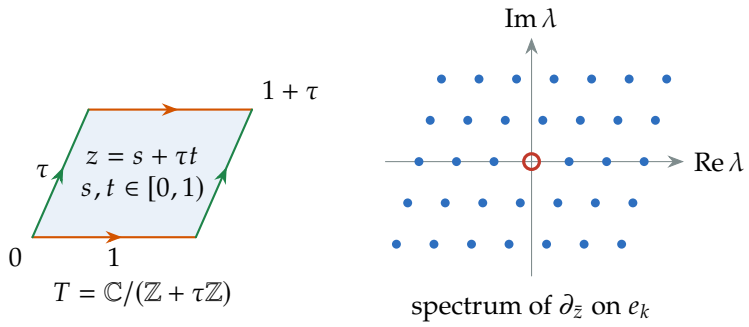

Figure 3.27: Left: a complex torus is the parallelogram with opposite sides identified (orange with orange, green with green); s,t are periodic real coordinates. Right: $\partial_{\bar z}$ is diagonal on the Fourier modes e_k, with eigenvalues $\lambda_k = \pi(k_1\tau - k_2)/\operatorname{Im}\tau$ forming a lattice in $\mathbb{C}$ (drawn for $\tau = 0.3 + 1.1i$). Only $k = 0$ gives zero (red): one zero mode (constants, $H^{0,0}$), and one obstruction to solving $\partial_{\bar z} f = g$ (the average of g, $H^{0,1}$).

Worked example 3.33: The torus: $H^{0,1}_{\bar\partial}(T) \cong \mathbb{C}$ by Fourier analysis

Let $T = \mathbb{C}/\Lambda$ with lattice $\Lambda = \mathbb{Z} + \tau\mathbb{Z}$, $\tau = \tau_1 + i\tau_2$, $\tau_2 > 0$. Every $z \in \mathbb{C}$ is uniquely $z = s + \tau t$ with s,t real, and translating by the lattice shifts s or t by an integer. So a smooth function on T is a smooth function of (s,t) periodic with period 1 in each, and it has a Fourier series

$$f = \sum_{k\in\mathbb{Z}^2} f_k\, e_k, \qquad e_k := e^{2\pi i(k_1 s + k_2 t)},$$

with rapidly decreasing coefficients f_k.
Step 1: express s,t through $z,\bar z$. From $z = s + \tau t$ and $\bar z = s + \bar\tau t$ (s,t are real):

$$t \overset{(1)}{=} \frac{z - \bar z}{\tau - \bar\tau}, \qquad s \overset{(2)}{=} z - \tau t = \frac{\tau\bar z - \bar\tau z}{\tau - \bar\tau},$$

(1) Subtract the two equations.
(2) Substitute back; over the common denominator, $z(\tau - \bar\tau) - \tau(z - \bar z) = \tau\bar z - \bar\tau z$.

hence $\partial_{\bar z} s = \tau/(\tau - \bar\tau)$ and $\partial_{\bar z} t = -1/(\tau - \bar\tau)$, with $\tau - \bar\tau = 2i\tau_2$.
Step 2: $\partial_{\bar z}$ is diagonal on Fourier modes.

$$\partial_{\bar z} e_k \overset{(1)}{=} 2\pi i\,(k_1\partial_{\bar z}s + k_2\partial_{\bar z}t)\, e_k \overset{(2)}{=} 2\pi i\,\frac{k_1\tau - k_2}{2i\tau_2}\, e_k \overset{(3)}{=} \lambda_k\, e_k, \qquad \lambda_k := \frac{\pi\,(k_1\tau - k_2)}{\tau_2}. \tag{3.78}$$

(1) Chain rule on the exponential.
(2) Step 1.
(3) Cancel $2i$ and name the eigenvalue.

When is $\lambda_k = 0$? Its imaginary part is πk_1, so we need $k_1 = 0$, and then $\lambda_k = -\pi k_2/\tau_2$ forces $k_2 = 0$. So $\lambda_k = 0$ only for $k = 0$, and in fact $|\lambda_k| \geq c\ |k|$ for some $c > 0$ (the λ_k form a lattice, Figure 3.27).

Step 3: the cohomology. The form $\mathrm{d}\bar{z}$ is invariant under translations, so it is a global $(0,1)$-form on T, and every $(0,1)$-form is $g\,\mathrm{d}\bar{z}$ with g a smooth function on T. We want to solve $\bar{\partial} f = g\,\mathrm{d}\bar{z}$, i.e. $\partial_{\bar{z}} f = g$. In Fourier components, by (3.78),

$$\lambda_k f_k = g_k \qquad \text{for all } k \in \mathbb{Z}^2.$$

- For $k \neq 0$: $f_k = g_k/\lambda_k$. Since $|\lambda_k| \geq c\,|k|$, these still decrease rapidly, and f is smooth.
- For $k = 0$: $0 \cdot f_0 = g_0$. Solvable only if $g_0 = 0$, and then f_0 is arbitrary.

So

$$H^{0,0}_{\bar{\partial}}(T) = \operatorname{Ker} \partial_{\bar{z}} = \{f :\ f_k = 0\ \forall k \neq 0\} = \mathbb{C} \quad \text{(constants)},$$
$$H^{0,1}_{\bar{\partial}}(T) = \frac{\{g\,\mathrm{d}\bar{z}\}}{\{\partial_{\bar{z}} f\,\mathrm{d}\bar{z}\}} \xrightarrow[\cong]{g\,\mathrm{d}\bar{z} \mapsto g_0} \mathbb{C}, \qquad g_0 = \int_0^1\!\!\int_0^1 g\,\mathrm{d}s\,\mathrm{d}t.$$

The class is represented by $\mathrm{d}\bar{z}$ itself. By the Dolbeault theorem, $H^1(T;\mathcal{O}) \cong \mathbb{C}$, as claimed in Example 3.21. The first line is Liouville's theorem for a compact Riemann surface (holomorphic functions on T are constant), obtained here by Fourier analysis. The same computation with $\mathrm{d}z$ carried along gives $H^{1,0}_{\bar{\partial}}(T) = \mathbb{C}\,\mathrm{d}z$ and $H^{1,1}_{\bar{\partial}}(T) = \mathbb{C}\,[\mathrm{d}z \wedge \mathrm{d}\bar{z}]$. All four Hodge numbers are 1, and $b_1(T) = 2 = h^{1,0} + h^{0,1}$: the two real classes $[\mathrm{d}s]$, $[\mathrm{d}t]$ are recombined into $[\mathrm{d}z]$ and $[\mathrm{d}\bar{z}]$.

Physical picture: $H^{0,1}(T)$ is the space of Wilson lines

Take a flat $U(1)$ connection on T with constant potential (in our anti-Hermitian convention A is i times a real 1-form, $A = -iA_{\text{phys}}$): $A = 2\pi i(\theta_1\,\mathrm{d}s + \theta_2\,\mathrm{d}t)$, whose holonomies round the two cycles are $e^{\pm 2\pi i\theta_1}$ and $e^{\pm 2\pi i\theta_2}$ (the sign depends on the direction of transport). Using Step 1, $\mathrm{d}s = (\tau\mathrm{d}\bar{z} - \bar{\tau}\mathrm{d}z)/(\tau - \bar{\tau})$ and $\mathrm{d}t = (\mathrm{d}z - \mathrm{d}\bar{z})/(\tau - \bar{\tau})$, so its $(0,1)$ part is

$$A^{0,1} = 2\pi i\,\frac{\theta_1\tau - \theta_2}{\tau - \bar{\tau}}\,\mathrm{d}\bar{z} = \lambda_\theta\,\mathrm{d}\bar{z}, \qquad \lambda_\theta = \frac{\pi(\theta_1\tau - \theta_2)}{\tau_2},$$

the *same* formula as (3.78) with θ in place of k. The operator $\bar{\partial}_A = \bar{\partial} + A^{0,1}$ defines a holomorphic structure, and $A^{0,1}$ is a class in $H^{0,1}(T) \cong \mathbb{C}$. A large gauge transformation $g = e_k$ shifts A by $g^{-1}\mathrm{d}g = 2\pi i(k_1\mathrm{d}s + k_2\mathrm{d}t)$, i.e. $\theta \mapsto \theta + k$, and shifts $A^{0,1}$ by $\lambda_k\mathrm{d}\bar{z}$. So the gauge-inequivalent flat connections form $\mathbb{C}/\{\lambda_k\}$, a torus dual to T: the *Jacobian* of T, or in physics language the moduli space of Wilson lines.

Try it: Solve $\partial_{\bar{z}} f = \cos 2\pi s$ on the square torus

Take $\tau = i$. Find a smooth f on T with $\partial_{\bar{z}} f = \cos 2\pi s$. Why is there no solution for $\partial_{\bar{z}} f = 1 + \cos 2\pi s$?

Answer. $\cos 2\pi s = \frac{1}{2}(e_{(1,0)} + e_{(-1,0)})$ and $\lambda_{(\pm 1,0)} = \pm\pi i$, so $f = \frac{1}{2\pi i}(e_{(1,0)} - e_{(-1,0)}) = \frac{\sin 2\pi s}{\pi}$.

Check: $\partial_{\bar z} s = \tau/(\tau-\bar\tau) = \frac12$, so $\partial_{\bar z} f = 2\cos(2\pi s)\cdot\frac12$. The source $1+\cos 2\pi s$ has average $g_0 = 1 \neq 0$, the nonzero class in $H^{0,1}(T)$.

Worked example 3.34: $\mathbb{CP}^1$: the Fubini–Study form and the residue

On the Riemann sphere, with charts z on $U_0 = \mathbb{C}$ and $w = 1/z$ on U_1, we know from Čech cohomology (Example 3.18, cases $n = 0$ and $n = -2$): $H^1(\mathbb{CP}^1; \mathcal{O}) = 0$ and $H^1(\mathbb{CP}^1; \Omega^1) \cong \mathbb{C}$. By the Dolbeault theorem, therefore,

$$H^{0,1}_{\bar\partial}(\mathbb{CP}^1) = 0, \qquad H^{1,1}_{\bar\partial}(\mathbb{CP}^1) \cong \mathbb{C}.$$

The first says: every $(0,1)$-form on the sphere is $\bar\partial$ of a global function. Let us see the second concretely, and watch the Dolbeault class turn into the Čech class.

A nonzero class. The **Fubini–Study form**

$$\omega = \frac{i}{2\pi}\,\frac{\mathrm{d}z\wedge\mathrm{d}\bar z}{(1+|z|^2)^2} = \frac{i}{2\pi}\,\partial\bar\partial\log(1+|z|^2) \tag{3.79}$$

is a $(1,1)$-form on U_0 (the second expression: $\partial_{\bar z}\log(1+z\bar z) = z/(1+z\bar z)$ and ∂_z of that is $1/(1+z\bar z)^2$). It is automatically $\bar\partial$-closed, since there are no $(1,2)$-forms. It extends smoothly over $z=\infty$: with $z = 1/w$, $\mathrm{d}z\wedge\mathrm{d}\bar z = \mathrm{d}w\wedge\mathrm{d}\bar w/|w|^4$ and $(1+|z|^2)^2 = (1+|w|^2)^2/|w|^4$, so ω has the same form in w. Its integral is

$$\int_{\mathbb{CP}^1}\omega \overset{(1)}{=} \frac{i}{2\pi}\int_{\mathbb{C}}\frac{-2i\,\mathrm{d}x\,\mathrm{d}y}{(1+r^2)^2} \overset{(2)}{=} \frac{1}{\pi}\int_0^{2\pi}\!\!\int_0^{\infty}\frac{r\,\mathrm{d}r\,\mathrm{d}\phi}{(1+r^2)^2} \overset{(3)}{=} \frac{1}{\pi}\cdot 2\pi\cdot\frac12 = 1.$$

(1) The point ∞ has measure zero, and $\mathrm{d}z\wedge\mathrm{d}\bar z = -2i\,\mathrm{d}x\wedge\mathrm{d}y$ (Example 3.29(a)).
(2) $\frac{i}{2\pi}(-2i) = \frac{1}{\pi}$; polar coordinates.
(3) $\int_0^\infty \frac{r\,\mathrm{d}r}{(1+r^2)^2} = \left[-\frac{1}{2(1+r^2)}\right]_0^\infty = \frac12$.

If ω were $\bar\partial\beta$ for a global $(1,0)$-form β, then $\omega = \mathrm{d}\beta$ (because $\partial\beta$ would be of type $(2,0)$, which is zero in one dimension), and Stokes would give $\int\omega = 0$. So $[\omega] \neq 0$ in $H^{1,1}_{\bar\partial}(\mathbb{CP}^1)$. Up to normalisation, ω is the round area form $\frac{1}{4\pi}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi$ pulled back by stereographic projection, and the curvature form $\frac{i}{2\pi}F$ of the unit monopole.

The zig-zag to Čech. Now run the connecting map of the Dolbeault resolution, as in Section 3.6.4. First solve $\bar\partial\alpha_i = \omega$ on each patch. Try $\alpha_0 = h\,\mathrm{d}z$; since $\bar\partial(h\,\mathrm{d}z) = -\partial_{\bar z}h\,\mathrm{d}z\wedge\mathrm{d}\bar z$, we need $\partial_{\bar z}h = -\frac{i}{2\pi}(1+z\bar z)^{-2}$, and $h = -\frac{i}{2\pi}\,\bar z/(1+z\bar z)$ works (quotient rule: $\partial_{\bar z}\frac{\bar z}{1+z\bar z} = \frac{(1+z\bar z)-\bar z z}{(1+z\bar z)^2}$). By the $z\leftrightarrow w$ symmetry,

$$\alpha_0 = -\frac{i}{2\pi}\,\frac{\bar z\,\mathrm{d}z}{1+|z|^2}\ \text{on } U_0, \qquad \alpha_1 = -\frac{i}{2\pi}\,\frac{\bar w\,\mathrm{d}w}{1+|w|^2}\ \text{on } U_1.$$

On the overlap $\mathbb{C}^*$ the difference is $\bar\partial$-closed (both have $\bar\partial = \omega$), hence a holomorphic 1-form. Compute it in the z chart:

$$\alpha_1 \overset{(1)}{=} -\frac{i}{2\pi}\,\frac{\bar z^{-1}(-z^{-2}\mathrm{d}z)}{1+|z|^{-2}} \overset{(2)}{=} \frac{i}{2\pi}\,\frac{\mathrm{d}z}{z\,(1+|z|^2)},$$
$$\alpha_0 - \alpha_1 \overset{(3)}{=} -\frac{i}{2\pi}\,\frac{\mathrm{d}z}{1+|z|^2}\left(\bar z + \frac1z\right) \overset{(4)}{=} -\frac{i}{2\pi}\,\frac{\mathrm{d}z}{z}.$$

(1) $w = 1/z$, $\bar w = 1/\bar z$, $\mathrm{d}w = -z^{-2}\mathrm{d}z$.

(2) Multiply numerator and denominator by $|z|^2 = z\bar{z}$.
(3) Subtract, taking out the common factor.
(4) $\bar{z} + 1/z = (1 + z\bar{z})/z$.

The Čech 1-cocycle representing $[\omega]$ in $H^1(\mathbb{CP}^1;\Omega^1)$ is $c_{01} = -\frac{i}{2\pi}\frac{dz}{z}$: a multiple of $z^{-1}dz$, the "residue" monomial that Example 3.18 (case $n = -2$) found to span $H^1(\mathbb{CP}^1;\Omega^1)$. And the numbers match. With $D_0 = \{|z| \le 1\}$, $D_1 = \{|z| \ge 1\}$ and $d\alpha_i = \bar{\partial}\alpha_i = \omega$,

$$1 = \int_{\mathbb{CP}^1} \omega \overset{(1)}{=} \int_{D_0} d\alpha_0 + \int_{D_1} d\alpha_1 \overset{(2)}{=} \oint_{|z|=1} \alpha_0 - \oint_{|z|=1} \alpha_1 \overset{(3)}{=} \oint_{|z|=1} c_{01} \overset{(4)}{=} -\frac{i}{2\pi}\cdot 2\pi i = 1.$$

(1) Split the sphere along the unit circle; on each half $\omega = d\alpha_i$.
(2) Stokes; the unit circle is the boundary of D_0 counterclockwise and of D_1 clockwise.
(3) $c_{01} = \alpha_0 - \alpha_1$.
(4) $\oint dz/z = 2\pi i$.

The Dolbeault class is detected by $\int \omega$, the Čech class by the residue of c_{01}, and Stokes' theorem says they are the same number. This is the monopole flux computation of Example 3.27 in holomorphic dress.

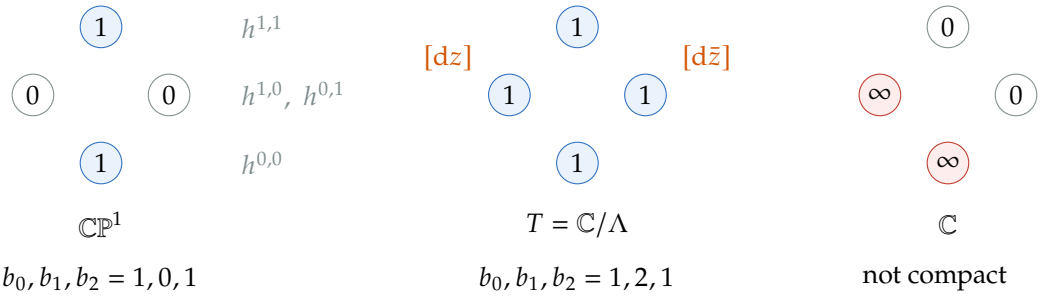

Figure 3.28: Hodge diamonds: the numbers $h^{p,q} = \dim H^{p,q}_{\bar{\partial}}$ arranged with $h^{0,0}$ at the bottom, $h^{1,1}$ at the top, and $h^{1,0}$ (left), $h^{0,1}$ (right) in the middle row. For the compact surfaces each horizontal row adds up to a Betti number: $b_1(T) = h^{1,0} + h^{0,1} = 2$ from $[dz]$ and $[d\bar{z}]$. For the non-compact $\mathbb{C}$ the holomorphic functions and holomorphic 1-forms are infinite-dimensional ($h^{0,0} = h^{1,0} = \infty$, red), while the Cauchy kernel kills $H^{0,1}$ and $H^{1,1}$.

Watch out: Dolbeault cohomology is not topological

Unlike de Rham cohomology, $H^{p,q}_{\bar{\partial}}$ depends on the complex structure, not only on the underlying manifold. On a non-compact manifold it can be infinite-dimensional: on $\mathbb{C}$, $H^{0,0}_{\bar{\partial}}(\mathbb{C})$ is the space of all entire functions. On compact manifolds it is finite-dimensional (a consequence of ellipticity, Chapter 2), and only certain combinations, such as $\sum_q (-1)^q h^{p,q}$, are topological invariants. That alternating sum is exactly the kind of number the index theorem computes.

Reading Nash (pp. 63–65, (3.24)–(3.31))

After the de Rham theorem (3.23) Nash introduces complex forms. His (3.24) is our (3.65) (without the $1/(p!\,q!)$), his (3.25) the operators (3.67), and his (3.26) is our key idea on $d = \partial + \bar{\partial}$; we added the one-line proof "sort $d^2 = 0$ by type". His (3.27) is the type decomposition (3.66); he states that $\mathcal{E}^{p,q}$ is fine, which we justified (real partitions of unity preserve type). His (3.28) is (3.74); its exactness rests on the Dolbeault lemma, which

he does not state and we proved with the Cauchy kernel (Section 3.7.4). His "exactly similar inductive argument" is (3.77), his (3.29)–(3.30) are (3.76), and his theorem (3.31) is the Dolbeault theorem. Two slips (see the pitfall in Section 3.7.3): holomorphic p-forms are of type $(p,0)$, not $(0,p)$; and the first arrow in (3.28) is the inclusion. The examples ($\mathbb{C}$, the torus, $\mathbb{CP}^1$ and the Fubini–Study form), the Dirac operator dictionary and the bundle-valued version are ours. Nash says that "Dolbeault's theorem will be of use later"; it is, in Chapter 4 and Chapter 5, where the index of $\bar\partial$ becomes Riemann–Roch.

Recap

- Complex coordinates: $\mathrm{d}z = \mathrm{d}x + i\mathrm{d}y$, $\partial_{\bar z} = \frac{1}{2}(\partial_x + i\partial_y)$; $\mathrm{d}f = \partial_z f\,\mathrm{d}z + \partial_{\bar z} f\,\mathrm{d}\bar z$; holomorphic $\iff \partial_{\bar z} f = 0 \iff$ Cauchy–Riemann; $4\partial_z\partial_{\bar z} = \nabla^2$.
- On a complex manifold forms split by type, $\Lambda^k \otimes \mathbb{C} = \bigoplus_{p+q=k} \Lambda^{p,q}$, because transition functions are holomorphic; $\mathrm{d} = \partial + \bar\partial$ and $\partial^2 = \bar\partial^2 = \partial\bar\partial + \bar\partial\partial = 0$. Holomorphic p-forms: $\Omega^p = \operatorname{Ker}\bar\partial$ on $(p,0)$-forms.
- Dolbeault lemma: locally, $\bar\partial\omega = 0 \Rightarrow \omega = \bar\partial\beta$. In one variable $\partial_{\bar z}^{-1}$ is convolution with $1/(\pi z)$, because $\partial_{\bar z}(1/\pi z) = \delta^2$ (Stokes).
- Dolbeault theorem: $H^q(M;\Omega^p) \cong H^{p,q}_{\bar\partial}(M)$, by Nash's de Rham argument with $\bar\partial$ for d. Also with coefficients in a holomorphic bundle.
- Examples: open $U \subset \mathbb{C}$ have $H^1(U;\mathcal{O}) = 0$ (so they are Leray and carry only trivial holomorphic line bundles); the torus has $h^{p,q} = 1$ for all $p, q \le 1$, with $H^{0,1}(T) = \mathbb{C}[\mathrm{d}\bar z]$ the space of Wilson lines; $\mathbb{CP}^1$ has $H^{1,1} = \mathbb{C}[\omega_{FS}]$, and the zig-zag turns ω_{FS} into the residue cocycle $-\frac{i}{2\pi}\frac{\mathrm{d}z}{z}$.
- Physics: $\not{D}_{2d} = \begin{pmatrix} 0 & 2\partial_z \\ 2\partial_{\bar z} & 0 \end{pmatrix}$, so Dolbeault cohomology counts chiral zero modes, and $\dim H^0 - \dim H^1$ is an index.

3.8 K-theory: why count bundles, and what we count with

In the previous sections we measured the shape of a manifold M by counting *forms*: closed forms modulo exact ones gave the de Rham groups, and sheaf cohomology generalised that. Now we switch the object being counted. We want to count *vector bundles* over M.

Why would a physicist care? Because a gauge field is a connection on a vector bundle, and a matter field is a section of one. Two field configurations that live on non-isomorphic bundles can never be deformed into each other: they sit in different *topological sectors*. The Dirac monopole of charge 1 and the monopole of charge 2 live on different line bundles over the sphere at infinity. The BPST instanton and the trivial vacuum live on different SU(2) bundles over S^4. So the question "how many different bundles are there over M?" is the question "how many topological sectors does a gauge theory on M have?".

That question is hard in general. K-theory answers an easier, coarser version of it, and the coarse version turns out to be both computable and exactly what the index theorem (Chapter 4) needs. Nash puts it in one line:

Key idea: K-theory in one sentence

K-theory is the linear algebra of *very large matrices*: it keeps the information about a vector bundle that survives when we are allowed to add as many trivial directions as we like. In return for that coarsening, bundles acquire an addition, a subtraction and a multiplication, just like numbers.

Before we can do any of that we need the raw material: vector bundles, written down concretely by transition functions, and the ways of combining them. This section supplies that background, which Nash assumes. Readers who know it well can skim to Section 3.9.

Standing conventions for this part.

- M (or X) is a *compact* manifold, or more generally a compact Hausdorff space. Nash says "Hausdorff" in a footnote; we really need compactness (see Section 3.9).
- Unless stated otherwise, M is *connected*, so every bundle has a single rank.
- $\mathbb{F}$ stands for $\mathbb{R}$, $\mathbb{C}$ or $\mathbb{H}$ (real numbers, complex numbers, quaternions). A bundle with fibre $\mathbb{F}^k$ is a real, complex or quaternionic bundle of **rank** k.
- I^j denotes the **trivial bundle** of rank j: $I^j = M \times \mathbb{R}^j$ (real case) or $I^j = M \times \mathbb{C}^j$ (complex case). We write $I = I^1$ and $I^0 = M \times \{0\}$.
- $\mathrm{Vect}_k(M)$ is the set of isomorphism classes of rank-k bundles over M, and $\mathrm{Vect}(M)$ is the set of isomorphism classes of all bundles. When the field matters we write $\mathrm{Vect}_k(M, \mathbb{F})$.

3.8.1 Vector bundles by transition functions

A vector bundle over M is a family of vector spaces E_x, one for each point $x \in M$, glued together smoothly. Locally it always looks like a product $U \times \mathbb{F}^k$. All the interesting information is in *how the local products are glued*. The gluing data are matrices.

Working definition 3.22 (vector bundle via transition functions)

To specify a rank-k bundle E over M:

1. Cover M by open sets U_a ("patches").
2. Over each patch, use a fibre coordinate $v_a \in \mathbb{F}^k$: a point of E over $x \in U_a$ is a pair (x, v_a).
3. On each overlap $U_a \cap U_b$ give a matrix-valued function $g_{ab} : U_a \cap U_b \to \mathrm{GL}(k, \mathbb{F})$ [invertible $k \times k$ matrices with entries in $\mathbb{F}$], the **transition function**, saying how to convert fibre coordinates: $v_a = g_{ab}(x)\, v_b$.
4. Consistency on triple overlaps (the **cocycle condition**): $g_{ab}\, g_{bc} = g_{ac}$ on $U_a \cap U_b \cap U_c$, and $g_{aa} = 1$.

Two sets of transition functions $\{g_{ab}\}$ and $\{g'_{ab}\}$ describe **isomorphic** bundles, $E \cong E'$, if there are functions $h_a : U_a \to \mathrm{GL}(k, \mathbb{F})$ (a change of fibre coordinates on each patch, a "gauge transformation") with

$$g'_{ab} = h_a\, g_{ab}\, h_b^{-1}.$$

Formally: a vector bundle is a space E with a projection $\pi : E \to M$ whose fibres [the sets $E_x = \pi^{-1}(x)$ sitting over single points x] are vector spaces and which is locally isomorphic to $U \times \mathbb{F}^k$; the g_{ab} are the comparison maps between local isomorphisms.

The cocycle condition simply says that converting from c to b and then from b to a is the same as converting directly from c to a. The isomorphism rule says that we may re-choose fibre coordinates patch by patch: $v'_a = h_a v_a$. Let us check that this really produces the stated rule for g':

$$\begin{aligned} v'_a &\overset{(1)}{=} h_a\, v_a \\ &\overset{(2)}{=} h_a\, g_{ab}\, v_b \\ &\overset{(3)}{=} h_a\, g_{ab}\, h_b^{-1}\, v'_b. \end{aligned}$$

(1) Definition of the new fibre coordinate on U_a.
(2) Old transition rule $v_a = g_{ab} v_b$.
(3) Invert the new coordinate on U_b: $v_b = h_b^{-1} v'_b$.

So the new transition function is $g'_{ab} = h_a g_{ab} h_b^{-1}$, as claimed.

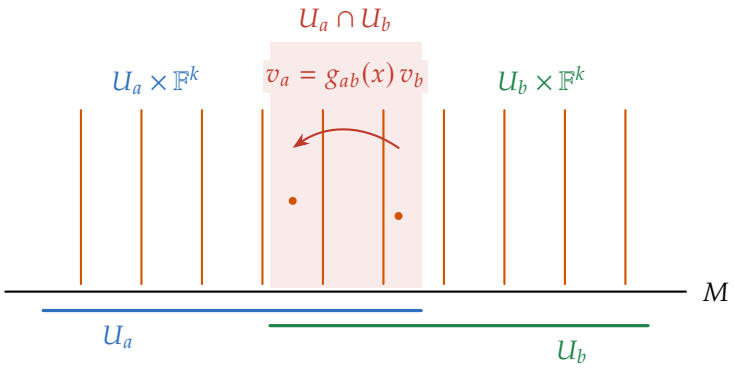

Figure 3.29: A vector bundle drawn as fibres (orange) standing over the base M. Over each patch the bundle is a product. On the overlap (shaded) the same point of the bundle has two fibre coordinates, related by the matrix $g_{ab}(x)$. All of the topology of E lives in these matrices.

Two quick consequences are worth recording.

- **Trivial bundle.** I^k is described by a single patch $U = M$, or by any cover with all $g_{ab} = 1$. A bundle is **trivial** if it is isomorphic to I^k, i.e. if we can find h_a with $h_a g_{ab} h_b^{-1} = 1$, i.e. $g_{ab} = h_a^{-1} h_b$.
- **Sections.** A **section** s of E is a choice of vector $s(x) \in E_x$ for every x, depending smoothly on x. In coordinates it is a collection of functions $s_a : U_a \to \mathbb{F}^k$ with $s_a = g_{ab} s_b$ on overlaps. Physically: a matter field in a background gauge field is a section.

Key idea: A nonvanishing section trivialises a line bundle

If a line bundle L (rank 1) has a section s with $s(x) \neq 0$ for every x, then $L \cong I$.

Why: in each patch $s_a(x)$ is a nonzero number. Use it as the change of fibre coordinate, $h_a = s_a^{-1}$, so that the new fibre coordinate of s is 1 on every patch. Then

$$\begin{aligned} g'_{ab} &\overset{(1)}{=} h_a\, g_{ab}\, h_b^{-1} \\ &\overset{(2)}{=} s_a^{-1}\, g_{ab}\, s_b \\ &\overset{(3)}{=} s_a^{-1}\, s_a = 1. \end{aligned}$$

(1) The isomorphism rule from the working definition.
(2) Our choice $h_a = s_a^{-1}$ (a nonzero number, so invertible).
(3) s is a section, so $g_{ab}s_b = s_a$ (for rank 1 everything commutes).

All transition functions become 1: the bundle is trivial. The same argument with k pointwise linearly independent sections (a **frame**) shows that a rank-k bundle with a global frame is trivial; the h_a is then the inverse of the matrix whose columns are the k sections.

Three bundles we will use over and over

Worked example 3.35: The Möbius bundle over S^1

Cover the circle $S^1 = \{e^{i\theta}\}$ by two arcs U_1 and U_2 which overlap in two small intervals, one near $\theta = 0$ and one near $\theta = \pi$. Define a real line bundle $\mathcal{M}$ by

$$g_{12} = +1 \text{ near } \theta = 0, \qquad g_{12} = -1 \text{ near } \theta = \pi.$$

There are no triple overlaps, so the cocycle condition is automatic. Is $\mathcal{M}$ trivial? We would need nonzero functions h_1, h_2 with $g_{12} = h_1^{-1}h_2$. Follow h_2/h_1 around the circle:

$$\operatorname{sgn}(h_2/h_1)\big|_{\theta\approx 0} \overset{(1)}{=} \operatorname{sgn}(g_{12})\big|_{\theta\approx 0} = +1,$$
$$\operatorname{sgn}(h_2/h_1)\big|_{\theta\approx \pi} \overset{(1)}{=} \operatorname{sgn}(g_{12})\big|_{\theta\approx \pi} = -1.$$

(1) Triviality would require $g_{12} = h_1^{-1}h_2$ on each overlap interval.

But h_1 is a nonzero real function on the connected arc U_1, so it has a fixed sign on all of U_1; the same holds for h_2 on U_2. Then $\operatorname{sgn}(h_2/h_1) = \operatorname{sgn}(h_2)\operatorname{sgn}(h_1)$ is the same number on both overlap intervals. Contradiction. So $\mathcal{M}$ is *not* trivial. The total space is the Möbius band (Figure 3.30). Equivalently: every section of $\mathcal{M}$ must change sign somewhere, so it has a zero.

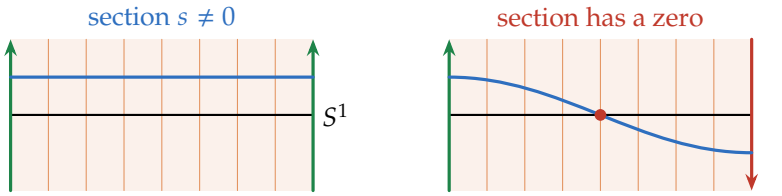

Figure 3.30: Two real line bundles over the circle. On the left every fibre is glued to its neighbour with +1. On the right one of the two gluings is −1 (red arrow reversed), so the fibre comes back upside down after one trip around the base. A section (blue curve crossing every fibre once) that starts above the zero section must end below it, so it vanishes somewhere (red dot).

Worked example 3.36: The tautological (Hopf) line bundle H over $\mathbb{CP}^1 = S^2$

The complex projective line $\mathbb{CP}^1$ is the set of complex lines through the origin in $\mathbb{C}^2$. A line is named by any nonzero vector on it, $[z_0 : z_1]$, with $[z_0 : z_1] = [\lambda z_0 : \lambda z_1]$ for $\lambda \in \mathbb{C}^\times$. Two patches cover it:

$$U_0 = \{z_0 \neq 0\} \text{ with coordinate } z = z_1/z_0, \qquad U_1 = \{z_1 \neq 0\} \text{ with coordinate } w = z_0/z_1.$$

On the overlap, $w = 1/z$. Topologically $\mathbb{CP}^1$ is the Riemann sphere $\mathbb{C} \cup \{\infty\} = S^2$, with z the stereographic coordinate.
The **tautological line bundle** H has as its fibre over the point $[z_0 : z_1]$ *the line itself*, $\{\lambda(z_0, z_1)\} \subset \mathbb{C}^2$. Nash calls it η, "the canonical line bundle over $\mathbb{CP}^1$". We find its transition function by choosing a nonvanishing local section on each patch:

$$s_0(z) = (1, z) \text{ on } U_0, \qquad s_1(w) = (w, 1) \text{ on } U_1.$$

Each is a nonzero vector lying on the line in question. On the overlap,

$$\begin{aligned} s_0 &\overset{(1)}{=} (1, z) \\ &\overset{(2)}{=} z\,(1/z,\, 1) \\ &\overset{(3)}{=} z\, s_1. \end{aligned}$$

(1) Definition of s_0.
(2) Pull out the factor z, which is allowed because $z \neq 0$ on the overlap.
(3) $1/z = w$, so $(1/z, 1) = (w, 1) = s_1$.

A point of H over the overlap can be written $\lambda_0 s_0 = \lambda_1 s_1$; using $s_0 = z s_1$ gives $\lambda_1 = z\lambda_0$. So the fibre coordinates are related by

$$\boxed{\lambda_1 = g_{10}(z)\,\lambda_0, \qquad g_{10}(z) = z} \qquad (z \in U_0 \cap U_1 = \mathbb{C}^\times).$$

On the equator $|z| = 1$, $z = e^{i\phi}$: the transition function winds *once* around U(1) as we go once around the equator. That winding number is the topological charge of H.

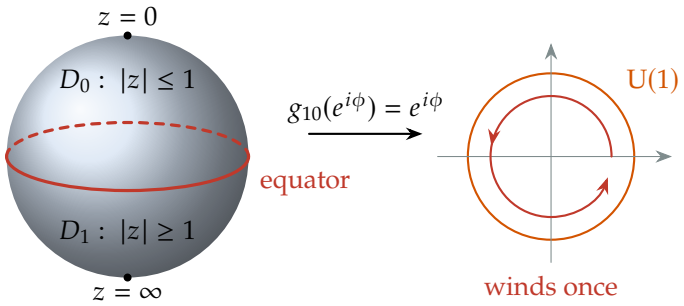

Figure 3.31: The Riemann sphere split into two discs along the equator. Over each disc the Hopf bundle H is trivial. The gluing along the equator is the map $e^{i\phi} \mapsto e^{i\phi}$ into U(1), which winds once. The winding number of the gluing map is the topological invariant of the bundle. Later (Section 3.12) this is called a clutching function.

Worked example 3.37: The tangent bundle of S^2 as a complex line bundle

A tangent vector to the Riemann sphere at a point of U_0 can be written $v = v^z\,\partial_z$, and at a point of U_1 as $v = v^w\,\partial_w$. (Because S^2 is a complex curve, TS^2 is a complex line bundle: a real rank-2 bundle on which rotation by 90° acts as multiplication by i.) The chain rule relates the two:

$$v^z\,\partial_z \overset{(1)}{=} v^z\,\frac{\mathrm{d}w}{\mathrm{d}z}\,\partial_w$$

$$\overset{(2)}{=} v^z \left(-z^{-2}\right) \partial_w ,$$

(1) Chain rule: $\partial_z = (\mathrm{d}w/\mathrm{d}z)\,\partial_w$.
(2) $w = 1/z$, so $\mathrm{d}w/\mathrm{d}z = -1/z^2$.

so $v^w = -z^{-2}\, v^z$ and the transition function is $g_{10}(z) = -z^{-2}$. On the equator it is $-e^{-2i\phi}$, which winds *twice*, in the opposite sense to H. The constant -1 can be removed by a homotopy (rotate it to 1 inside U(1)), so up to isomorphism TS^2 has transition function z^{-2}. Comparing with H (transition z) this says $TS^2 \cong (H^*)^{\otimes 2}$, once we have defined $\otimes$ and duals below. The "2" is the Euler characteristic $\chi(S^2) = 2$.

Watch out: Signs and names for the Hopf bundle

Different books call H the tautological bundle, the Hopf bundle, the canonical bundle, or the monopole bundle, and some use its dual H^* (transition z^{-1}) under the same name. With the complex orientation of S^2, the tautological bundle has first Chern class $c_1(H) = -1$ and H^* (the "hyperplane bundle") has $c_1 = +1$. For everything in this part the distinction is harmless: H and H^* both generate the K-theory of S^2. We keep the name H for the tautological bundle and write Nash's η for the same thing when quoting him.

Physical picture: The Dirac monopole is a bundle

Put a magnetic monopole of charge n at the origin and look at the sphere around it. Use the anti-Hermitian convention of these notes: a U(1) gauge field is $A = -i\,eA_\mu^{\text{phys}}\,\mathrm{d}x^\mu$, and a gauge transformation $g = e^{i\chi}$ acts as $A \mapsto A + g^{-1}\mathrm{d}g$. The potentials

$$A_N = -\tfrac{in}{2}(1-\cos\theta)\,\mathrm{d}\phi, \qquad A_S = +\tfrac{in}{2}(1+\cos\theta)\,\mathrm{d}\phi$$

are regular on the northern and southern hemispheres respectively (the coefficient of $\mathrm{d}\phi$ vanishes at the pole where $\mathrm{d}\phi$ is singular). On the overlap

$$A_S - A_N = \tfrac{in}{2}\big[(1+\cos\theta)+(1-\cos\theta)\big]\mathrm{d}\phi = in\,\mathrm{d}\phi = g^{-1}\mathrm{d}g, \qquad g = e^{in\phi}.$$

So the two patches are glued by the gauge transformation $e^{in\phi}$. It is single-valued on the equator only if $n \in \mathbb{Z}$: that is Dirac's quantisation condition. With the rule $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$, a charged field transforms as $\psi \mapsto g^{-1}\psi$, so $\psi_S = e^{-in\phi}\psi_N$: the fibre-coordinate transition function is $e^{-in\phi}$, which winds n times (clockwise). With these conventions $\frac{i}{2\pi}\int_{S^2} F = n$, and comparing with H (whose fibre coordinates obey $\lambda_1 = e^{+i\phi}\lambda_0$) the charge-$n$ monopole bundle is $(H^*)^{\otimes n}$.

3.8.2 Operations on bundles: sum, product, dual, pullback

Everything one can do to vector spaces one can do to bundles, fibre by fibre. At the level of transition functions each operation is an operation on matrices. Suppose E has rank k and transition functions g_{ab}, and F has rank l and transition functions f_{ab} (take a common cover for both; one can always refine the covers until they agree).

Working definition 3.23 (operations on bundles)

- **Direct (Whitney) sum** $E \oplus F$: fibre $E_x \oplus F_x$, rank $k + l$, transition functions the

block-diagonal matrices

$$(g \oplus f)_{ab} = \begin{pmatrix} g_{ab} & 0 \\ 0 & f_{ab} \end{pmatrix}.$$

- **Tensor product** $E \otimes F$: fibre $E_x \otimes F_x$, rank kl, transition functions the Kronecker products [the $kl \times kl$ matrices sending $v \otimes w$ to $g_{ab}v \otimes f_{ab}w$] $(g \otimes f)_{ab} = g_{ab} \otimes f_{ab}$. For line bundles this is just the product of the two numbers.
- **Dual** E^*: fibre E_x^* (linear functionals), rank k, transition functions $\left(g_{ab}^T\right)^{-1}$. For a U(1) line bundle this is complex conjugation: $e^{i\chi} \mapsto e^{-i\chi}$.
- **Pullback** f^*E along a map $f : N \to M$: the fibre over $y \in N$ is $E_{f(y)}$. Transition functions $g_{ab} \circ f$ on the cover $f^{-1}(U_a)$ [the points of N that f sends into U_a] of N.

Let us check that the block-diagonal and Kronecker matrices really satisfy the cocycle condition, so these are genuine bundles:

$$(g \oplus f)_{ab}(g \oplus f)_{bc} \overset{(1)}{=} \begin{pmatrix} g_{ab}g_{bc} & 0 \\ 0 & f_{ab}f_{bc} \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} g_{ac} & 0 \\ 0 & f_{ac} \end{pmatrix} = (g \oplus f)_{ac},$$

$$(g \otimes f)_{ab}(g \otimes f)_{bc} \overset{(3)}{=} (g_{ab}g_{bc}) \otimes (f_{ab}f_{bc}) \overset{(2)}{=} g_{ac} \otimes f_{ac} = (g \otimes f)_{ac}.$$

(1) Block-diagonal matrices multiply block by block.
(2) The cocycle conditions for E and F separately.
(3) The mixed-product rule for Kronecker products, $(A \otimes B)(C \otimes D) = AC \otimes BD$.

For the dual, $\left((g_{ab}g_{bc})^T\right)^{-1} = (g_{ab}^T)^{-1}(g_{bc}^T)^{-1}$ because transposing reverses the order and inverting reverses it again.

Worked example 3.38: Powers of the Hopf bundle

Using $g_{10} = z$ for H:

$$\begin{aligned} H \otimes H: &\quad g_{10} = z \cdot z = z^2, \\ H^*: &\quad g_{10} = (z)^{-1} = z^{-1}, \\ H \otimes H^*: &\quad g_{10} \overset{(1)}{=} z \cdot z^{-1} = 1 \implies H \otimes H^* \cong I, \\ H \oplus H: &\quad g_{10} = \begin{pmatrix} z & 0 \\ 0 & z \end{pmatrix}. \end{aligned}$$

(1) Tensor product of line bundles multiplies transition functions; the result is identically 1, which is the trivial bundle.

In general $H^{\otimes n}$ has transition function z^n for any $n \in \mathbb{Z}$ (negative powers meaning powers of H^*). So the line bundles over S^2 form a group under $\otimes$, isomorphic to $\mathbb{Z}$ via the winding number; we justify "every line bundle is one of these" in Section 3.12. By Example 3.37, $TS^2 \cong H^{\otimes(-2)}$.

Worked example 3.39: Möbius ⊗ Möbius is trivial

For $\mathcal{M}$ the transition function is ± 1, so for $\mathcal{M} \otimes \mathcal{M}$ it is $(\pm 1)^2 = +1$ on both overlap intervals. Hence $\mathcal{M} \otimes \mathcal{M} \cong I$. Geometrically: flipping twice is not flipping.

The operations obey the rules one expects from arithmetic, because they hold fibre by fibre

for vector spaces:

$$E \oplus F \cong F \oplus E, \qquad (E \oplus F) \oplus G \cong E \oplus (F \oplus G), \qquad E \oplus I^0 \cong E,$$
$$E \otimes F \cong F \otimes E, \qquad E \otimes (F \oplus G) \cong (E \otimes F) \oplus (E \otimes G), \qquad E \otimes I \cong E,$$

and ranks behave like numbers: $\operatorname{rk}(E \oplus F) = \operatorname{rk} E + \operatorname{rk} F$, $\operatorname{rk}(E \otimes F) = \operatorname{rk} E \cdot \operatorname{rk} F$. Pullback respects everything: $f^*(E \oplus F) \cong f^*E \oplus f^*F$ and $f^*(E \otimes F) \cong f^*E \otimes f^*F$, because composing with f commutes with forming block-diagonal or Kronecker matrices.

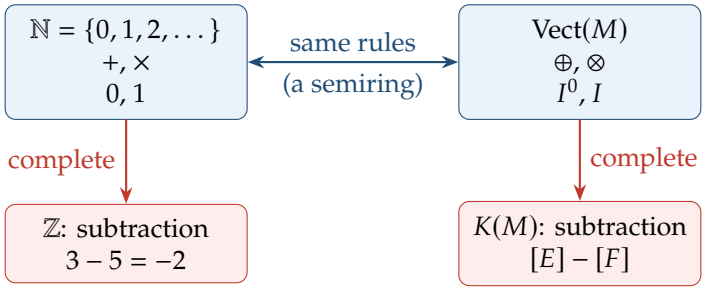

Figure 3.32: The analogy that drives K-theory. Bundles under $\oplus$ and $\otimes$ behave like natural numbers under $+$ and $\times$, with the zero bundle and the trivial line bundle playing 0 and 1. What is missing is subtraction. Completing $\mathbb{N}$ to $\mathbb{Z}$ supplies it for numbers; the same construction applied to bundles gives $K(M)$ (Section 3.10).

Worked example 3.40: Pullback of H along a degree-n map

Let $f_n : S^2 \to S^2$ be $f_n(z) = z^n$ ($n \geq 1$). It maps $U_0 = \{z \neq \infty\}$ into U_0 and U_1 into U_1. The pulled-back transition function is

$$(f_n^* g)_{10}(z) \overset{(1)}{=} g_{10}\big(f_n(z)\big) \overset{(2)}{=} z^n,$$

(1) Definition of pullback: compose the transition function with f.
(2) $g_{10}(u) = u$ for H, evaluated at $u = z^n$.

so $f_n^* H \cong H^{\otimes n}$: pulling back along a map of degree n multiplies the charge by n.

3.8.3 What "generalised cohomology theory" means

Nash calls K-theory "probably the most important example of a *generalised* cohomology theory" and says the adjective refers to the failure of one of the Eilenberg–Steenrod axioms. Here is what that means, at the level we need.

A cohomology theory assigns abelian groups $h^n(X)$ to spaces X, for each integer n, and to each map $f : X \to Y$ a *pullback* $f^* : h^n(Y) \to h^n(X)$ (note the reversed direction: this is the **contravariance** we already know from pulling back forms). Eilenberg and Steenrod listed the properties that the ordinary theories (de Rham, singular, Čech) share:

1. **Homotopy.** If $f \simeq g$ then $f^* = g^*$. (For de Rham: homotopic maps pull back closed forms to forms differing by an exact form.)
2. **Exactness.** A pair $A \subset X$ gives a long exact sequence $\cdots \to h^n(X, A) \to h^n(X) \to h^n(A) \to h^{n+1}(X, A) \to \cdots$.
3. **Excision.** Cutting out a small piece deep inside A does not change $h^n(X, A)$. (This is the formal version of "locality": cohomology can be computed patch by patch, as in Mayer–Vietoris.)

4. **Additivity.** h^n of a disjoint union is the product of the h^n's.

5. **Dimension.** For a single point, $h^0(\mathrm{pt}) = \mathbb{Z}$ (or $\mathbb{R}$) and $h^n(\mathrm{pt}) = 0$ for $n \neq 0$.

The dimension axiom says: "a point has no cohomology except the constants in degree zero". The de Rham theory satisfies it: on a point, the only forms are 0-forms (numbers), so $H^0_{\mathrm{dR}}(\mathrm{pt}) = \mathbb{R}$ and nothing else.

Key idea: Why K-theory is "generalised"

K-theory satisfies axioms 1–4 but *not* the dimension axiom. When we have built the groups K^{-n} in Section 3.13, we will find

$$K^{-n}(\mathrm{pt}) = \begin{cases} \mathbb{Z}, & n \text{ even}, \\ 0, & n \text{ odd}. \end{cases}$$

A point carries K-theory in infinitely many degrees. Everything else about K-theory behaves like cohomology: it pulls back, it is homotopy invariant, it has exact sequences and a product.

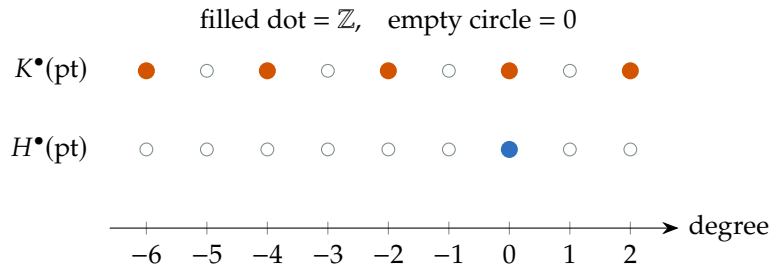

Figure 3.33: The dimension axiom in a picture. Ordinary cohomology of a point is a single $\mathbb{Z}$ in degree 0 (blue). K-theory of a point is a $\mathbb{Z}$ in every even degree (orange). The repetition with period 2 is Bott periodicity (Section 3.13); the extra groups are why K-theory is called a *generalised* cohomology theory.

Dictionary: K-theory words

Mathematics	Physics
vector bundle E over M	arena for a gauge field and its matter fields
transition function g_{ab}	gauge transformation relating two local gauges
isomorphism $E \cong E'$	the same physics in different gauges
isomorphism class	topological sector
trivial bundle I^k	no topological charge; global gauge exists
$E \oplus F$	two decoupled multiplets side by side
$E \otimes F$	a field carrying both charges (e.g. quark colour ⊗ flavour)
element of $K(M)$	a charge that survives adding neutral junk (e.g. D-brane charge)

Reading Nash (p. 65, opening of §3)

Nash introduces K-theory in one paragraph: a "cohomology theory for vector bundles", a "kind of linear algebra for large matrices", the most important generalised cohomology theory, failing the Eilenberg–Steenrod dimension axiom. He then fixes the notation $I^j \cong M \times \mathbb{R}^j$ or $M \times \mathbb{C}^j$ and announces that bundles will be sorted into "two sorts of equivalence classes". The two sorts are *stable equivalence classes* (Section 3.9) and *formal differences* (Section 3.10). Nash takes all the bundle background above for granted.

Recap

- A bundle is encoded by transition functions g_{ab} obeying $g_{ab}g_{bc} = g_{ac}$; isomorphism means $g' = hgh^{-1}$ patchwise.
- Key examples: Möbius ($g = \pm 1$ on S^1), Hopf H ($g = z$ on S^2), TS^2 ($g = -z^{-2} \simeq z^{-2}$), monopole of charge n ($g = e^{in\phi}$).
- $\oplus$ = block-diagonal, $\otimes$ = Kronecker product, dual = inverse transpose, pullback = composition.
- Bundles form a semiring like $\mathbb{N}$; K-theory will add subtraction.
- K-theory is a cohomology theory except that a point has $K^{-n}(\mathrm{pt}) = \mathbb{Z}$ for all even n.

3.9 Stable equivalence: ignoring trivial junk

Here is the problem that K-theory is built to solve. For numbers, $a + c = b + c$ implies $a = b$: we can cancel. For vector bundles we cannot. There are bundles E, F, G with $E \oplus G \cong F \oplus G$ but $E \not\cong F$. So "adding the same thing to both sides" loses information, and bundle arithmetic is not like number arithmetic.

K-theory's response is pragmatic: if adding trivial bundles can make two bundles isomorphic, we agree to *call them equivalent*. This section makes that precise, shows the classic example (the tangent bundle of a sphere), and proves Nash's stable equivalence theorem, which says that cancellation *does* work once we allow ourselves to add trivial bundles.

3.9.1 The definition

Working definition 3.24 (stable equivalence)

Two bundles E and F over M (possibly of *different* ranks) are **stably equivalent**, written $E \overset{s}{\sim} F$, if

$$E \oplus I^j \cong F \oplus I^k \qquad \text{for some } j, k \geq 0. \tag{3.80}$$

[I^j is the trivial bundle $M \times \mathbb{R}^j$ or $M \times \mathbb{C}^j$, and $\cong$ means isomorphic as bundles] *Test:* add trivial lines to both until the ranks agree and some large enough number of extra trivial lines have been added; then check for an isomorphism. A bundle stably equivalent to a trivial bundle is called **stably trivial**.

Note that if E has rank m and F rank n, then (3.80) forces $m + j = n + k$, so $j - k = n - m$ is fixed by the ranks. Only the "overall amount of padding" is free.

Nash says "it is easy to verify" that this is an equivalence relation. Let us verify it.

- *Reflexive:* $E \oplus I^0 \cong E \oplus I^0$ (take $j = k = 0$).
- *Symmetric:* the definition is symmetric in E and F (swap j and k).
- *Transitive:* suppose $E \oplus I^j \cong F \oplus I^k$ and $F \oplus I^l \cong G \oplus I^m$. Then

$$\begin{aligned} E \oplus I^{j+l} &\overset{(1)}{=} (E \oplus I^j) \oplus I^l \\ &\overset{(2)}{\cong} (F \oplus I^k) \oplus I^l \\ &\overset{(3)}{=} (F \oplus I^l) \oplus I^k \\ &\overset{(4)}{\cong} (G \oplus I^m) \oplus I^k = G \oplus I^{m+k}. \end{aligned}$$

  (1) $I^{j+l} = I^j \oplus I^l$ (block-diagonal identity transition functions), and $\oplus$ is associative.
  (2) First hypothesis, then add I^l to both sides (adding the same bundle preserves isomorphism: use the block-diagonal isomorphism $\mathrm{diag}(h, 1)$).
  (3) Commutativity and associativity of $\oplus$.
  (4) Second hypothesis, then add I^k to both sides.

  So $E \overset{s}{\sim} G$.

The equivalence classes are **stable equivalence classes**.

Worked example 3.41: All trivial bundles are one stable class

I^3 and I^7 have different ranks, so they are not isomorphic. But $I^3 \oplus I^4 \cong I^7 \oplus I^0$, so $I^3 \overset{s}{\sim} I^7$. In fact every I^j is stably equivalent to I^0, the zero bundle. Stable equivalence forgets rank completely; rank will be restored separately in Section 3.10.

3.9.2 Cancellation fails: the tangent bundle of a sphere

Nash states

$$E \oplus G \cong F \oplus G \not\Longrightarrow E \cong F \tag{3.81}$$

and gives the standard counterexample. Let $S^n \subset \mathbb{R}^{n+1}$ be the unit sphere. At a point $x \in S^n$ (a unit vector) every vector $u \in \mathbb{R}^{n+1}$ splits uniquely into a part tangent to the sphere and a part along the normal:

$$u = \underbrace{\big(u - (u \cdot x)\, x\big)}_{\in T_x S^n} + \underbrace{(u \cdot x)\, x}_{\in N_x}.$$

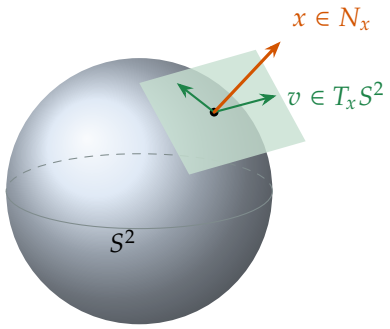
The tangent part is perpendicular to x: $(u - (u \cdot x)x) \cdot x = u \cdot x - (u \cdot x)(x \cdot x) = 0$ because $x \cdot x = 1$. Doing this at every point gives the bundle statement

$$T\mathbb{R}^{n+1}\big|_{S^n} \cong TS^n \oplus N(S^n), \tag{3.82}$$

where $N(S^n)$ is the **normal bundle**, the line bundle whose fibre at x is the line $\mathbb{R}x$.

Now we assemble the counterexample in labelled steps.

$$\begin{aligned} TS^n \oplus I &\overset{(1)}{\cong} TS^n \oplus N(S^n) \\ &\overset{(2)}{\cong} T\mathbb{R}^{n+1}\big|_{S^n} \\ &\overset{(3)}{\cong} I^{n+1} \\ &\overset{(4)}{=} I^n \oplus I. \end{aligned}$$



$T_xS^2 \oplus N_x = \mathbb{R}^3$
$TS^2 \oplus N \cong I^3$
$N \cong I$ (section $x \mapsto x$)
so $TS^2 \oplus I \cong I^2 \oplus I$
but $TS^2 \not\cong I^2$

Figure 3.34: At each point x of the sphere, $\mathbb{R}^3$ splits into the tangent plane (green) and the normal line (orange). The normal line bundle has the nowhere-zero section $x \mapsto x$, so it is trivial. Adding it to TS^2 gives the trivial bundle I^3, yet TS^2 itself is not trivial: we cannot cancel the I.

(1) $N(S^n)$ has the global nowhere-vanishing section $x \mapsto x$ (the outward normal); by the key idea of Section 3.8.1, a line bundle with a nonvanishing section is trivial.
(2) The pointwise splitting (3.82).
(3) $T\mathbb{R}^{n+1} = \mathbb{R}^{n+1} \times \mathbb{R}^{n+1}$ is trivial (use the constant frame $\partial_1, \dots, \partial_{n+1}$), and so is its restriction.
(4) Splitting off one trivial direction.

So $TS^n \oplus I \cong I^n \oplus I$ (Nash's (3.36)). With $E = TS^n$, $F = I^n$, $G = I$ this is $E \oplus G \cong F \oplus G$. If cancellation held, TS^n would be trivial. It is not, for most n:

Key idea: Which tangent bundles of spheres are trivial

TS^n is trivial ("S^n is **parallelisable**") only for $n = 1, 3, 7$ (and trivially $n = 0$). This is a deep theorem of Adams (1960), closely tied to the existence of the real division algebras $\mathbb{C}$, $\mathbb{H}$ and the octonions $\mathbb{O}$.

We will not prove Adams' theorem, but we can do the two things a physicist wants: show the trivial cases explicitly, and prove non-triviality in the most important case $n = 2$.

Worked example 3.42: Explicit frames on S^1 and S^3

S^1: at $x = (x_1, x_2)$ the vector $e(x) = (-x_2, x_1)$ is tangent ($e \cdot x = -x_2x_1 + x_1x_2 = 0$) and never zero. One nonvanishing section trivialises the line bundle TS^1.
S^3: write $x \in S^3 \subset \mathbb{R}^4$ as a unit quaternion $q = a + b\,i + c\,j + d\,k$, with $i^2 = j^2 = k^2 = ijk = -1$. Right-multiply by i, j, k:

$$q\,i \overset{(1)}{=} ai + bi^2 + c\,ji + d\,ki \overset{(2)}{=} -b + ai + dj - ck,$$
$$q\,j \overset{(1)}{=} aj + b\,ij + cj^2 + d\,kj \overset{(2)}{=} -c - di + aj + bk,$$
$$q\,k \overset{(1)}{=} ak + b\,ik + c\,jk + dk^2 \overset{(2)}{=} -d + ci - bj + ak.$$

(1) Distribute the product over the four components of q.
(2) Quaternion multiplication table: $ij = k = -ji$, $jk = i = -kj$, $ki = j = -ik$.

As vectors in $\mathbb{R}^4$ (components along $1, i, j, k$):

$$e_1 = (-b, a, d, -c), \qquad e_2 = (-c, -d, a, b), \qquad e_3 = (-d, c, -b, a).$$

Each is perpendicular to $x = (a, b, c, d)$; for instance $e_1 \cdot x = -ab + ab + dc - cd = 0$. They are mutually perpendicular; for instance $e_1 \cdot e_2 = bc - ad + ad - bc = 0$. Each has length

1. So (e_1, e_2, e_3) is a global orthonormal frame of TS^3, and $TS^3 \cong I^3$. (The same trick with octonions frames S^7.) Physically: $S^3 = \mathrm{SU}(2)$, and e_1, e_2, e_3 are the left-invariant vector fields generated by the three Pauli directions.

Worked example 3.43: The hairy-ball theorem from transition functions

We show TS^2 is not trivial. First we need a fact about complex line bundles over $S^2 = D_0 \cup D_1$ glued along the equator $|z| = 1$ with transition function $g(e^{i\phi}) \in \mathrm{U}(1)$: *the winding number $w(g)$ of g around the equator is an isomorphism invariant.* Suppose $g' = h_1\, g\, h_0^{-1}$ with h_0 defined (and nonzero) on all of D_0 and h_1 on all of D_1. Then

$$\begin{aligned} w(g') &\overset{(1)}{=} w(h_1) + w(g) - w(h_0) \\ &\overset{(2)}{=} 0 + w(g) - 0 = w(g). \end{aligned}$$

(1) The winding number of a product of loops in $\mathbb{C}^\times$ is the sum of their winding numbers (phases add), and an inverse has minus the winding.

(2) h_0 restricted to the equator is the boundary of the map h_0 on the disc D_0. A loop in $\mathbb{C}^\times$ that extends over a disc can be shrunk to a point through the disc, so its winding number is zero. The same holds for h_1 on D_1.

In Example 3.37 we found that TS^2 has transition function $-z^{-2}$, winding number $-2 \neq 0$, while I has transition function 1, winding number 0. So $TS^2 \not\cong I$ as complex line bundles. As a real rank-2 bundle it is also non-trivial: a real trivialisation would give a nowhere-zero tangent vector field s, and then s and is (the 90° rotation of s) would be a complex frame, trivialising it as a complex line bundle too.

Conclusion: *every tangent vector field on S^2 has a zero* (you cannot comb a hairy ball flat). The number 2 we found is the Euler characteristic $\chi(S^2)$, which by Poincaré–Hopf is also the sum of the indices of the zeros of any vector field.

So TS^2 is *stably trivial but not trivial*: the simplest example of information that stable equivalence throws away.

Watch out: Stably trivial is not trivial, and not every bundle is stably trivial

Stable equivalence throws some information away (the winding number of TS^2 disappears), but not all. The Möbius bundle $\mathcal{M}$ and the Hopf bundle H are *not* stably trivial. The tool is the **determinant line bundle** $\det E = \Lambda^{\mathrm{top}} E$, whose transition functions are $\det g_{ab}$. Since

$$\begin{aligned} \det(g_{ab} \oplus 1_j) &\overset{(1)}{=} \det g_{ab} \cdot \det 1_j \\ &= \det g_{ab}, \end{aligned}$$

(1) The determinant of a block-diagonal matrix is the product of the determinants of the blocks.

we have $\det(E \oplus I^j) \cong \det E$: the determinant line bundle is a *stable invariant*. Now $\det \mathcal{M} = \mathcal{M}$ is non-trivial, while $\det I^k = I$ is trivial; so $\mathcal{M} \oplus I^j$ is never trivial. Likewise $\det H = H$ has winding number 1, so H is not stably trivial. (And for TS^2 viewed as a real bundle, det is the orientation bundle, which is trivial because S^2 is orientable: consistent.)

3.9.3 Complements and the stable equivalence theorem

The failure of cancellation is annoying. The saving fact is that every bundle has a "complement" that makes it trivial.

Key idea: Every bundle is a summand of a trivial bundle

If M is compact, then for every bundle G there is a bundle G' and an integer n with

$$G \oplus G' \cong I^n. \tag{3.83}$$

Why this is true. The idea is to embed G inside a big trivial bundle and take the orthogonal complement.

1. Because M is compact, finitely many patches $U_1, \dots, U_N$ trivialise G, with local fibre-coordinate maps $\varphi_a : G|_{U_a} \to U_a \times \mathbb{F}^k$.
2. Take a partition of unity ρ_a subordinate to the cover (smooth functions ≥ 0, ρ_a vanishing outside U_a, $\sum_a \rho_a = 1$).
3. Map a vector $v \in G_x$ to the big vector $\Phi(v) = \big(\rho_1(x)\varphi_1(v), \dots, \rho_N(x)\varphi_N(v)\big) \in \mathbb{F}^{kN}$. This is linear on each fibre, and injective: if $\Phi(v) = 0$, pick a with $\rho_a(x) > 0$; then $\varphi_a(v) = 0$, so $v = 0$.
4. So G sits inside $I^{kN} = M \times \mathbb{F}^{kN}$ as a subbundle. Let G' be its orthogonal complement with respect to the standard inner product on $\mathbb{F}^{kN}$. Pointwise $\mathbb{F}^{kN} = G_x \oplus G'_x$, so $G \oplus G' \cong I^{kN}$.

Compactness was used in step 1: with infinitely many patches, Φ would need infinitely many components. Nash's footnote says "we assume M to be Hausdorff", but compactness (or finite-dimensionality of the base with finitely many patches) is what matters. For a physicist: work on a compact spacetime (a sphere or a torus, after imposing boundary conditions at infinity).

Worked example 3.44: The complement of the Hopf bundle is its dual

The Hopf bundle H is *defined* as a subbundle of $I^2 = \mathbb{CP}^1 \times \mathbb{C}^2$: its fibre over $[z_0 : z_1]$ is the line through (z_0, z_1). Its orthogonal complement $H^\perp$ (using the Hermitian inner product $\langle u, v\rangle = \bar{u}_0 v_0 + \bar{u}_1 v_1$) has fibre spanned by $(-\bar{z}_1, \bar{z}_0)$, because $\langle (z_0, z_1), (-\bar{z}_1, \bar{z}_0)\rangle = -\bar{z}_0\bar{z}_1 + \bar{z}_1\bar{z}_0 = 0$. Choose local sections as for H:

$$t_0 = (-\bar{z},\, 1) \text{ on } U_0, \qquad t_1 = (-1,\, \bar{w}) \text{ on } U_1.$$

(Put $(z_0, z_1) = (1, z)$ and $(w, 1)$ respectively into $(-\bar{z}_1, \bar{z}_0)$.) On the overlap,

$$\begin{aligned} t_0 &\overset{(1)}{=} (-\bar{z},\, 1) \\ &\overset{(2)}{=} \bar{z}\,\big(-1,\, 1/\bar{z}\big) \\ &\overset{(3)}{=} \bar{z}\, t_1, \end{aligned}$$

(1) Definition of t_0.
(2) Pull out the nonzero factor $\bar{z}$.
(3) $1/\bar{z} = \overline{1/z} = \bar{w}$.

So fibre coordinates obey $\lambda_1 = \bar{z}\,\lambda_0$. On the equator $\bar{z} = e^{-i\phi} = z^{-1}$: winding number -1, the same as the dual H^*. Hence

$$H \oplus H^* \cong H \oplus H^\perp \cong I^2.$$

A complement of H is H^*, with $n = 2$. This single identity will give us $[H^*] = 2 - [H]$ in K-theory.

Worked example 3.45: Möbius ⊕ Möbius is trivial

Realise $\mathcal{M}$ inside $S^1 \times \mathbb{R}^2$: over the angle θ take the line spanned by $u(\theta) = (\cos\frac{\theta}{2}, \sin\frac{\theta}{2})$. Going once around, $\theta \to \theta + 2\pi$, the spanning vector goes to $-u$: the same line, but the direction has flipped. That is exactly the Möbius twist. The orthogonal complement is spanned by $u^\perp(\theta) = (-\sin\frac{\theta}{2}, \cos\frac{\theta}{2})$, which also flips sign after one trip, so it is again a Möbius bundle. Hence

$$\mathcal{M} \oplus \mathcal{M} \cong I^2.$$

Check with transition functions: $\mathcal{M} \oplus \mathcal{M}$ is glued by $\mathrm{diag}(1,1)$ near $\theta = 0$ and $\mathrm{diag}(-1,-1)$ near $\theta = \pi$. But $\mathrm{diag}(-1,-1)$ is the rotation by π, which can be continuously rotated back to $\mathrm{diag}(1,1)$ inside $\mathrm{SO}(2)$. The gluing is homotopic to the identity, so the bundle is trivial.

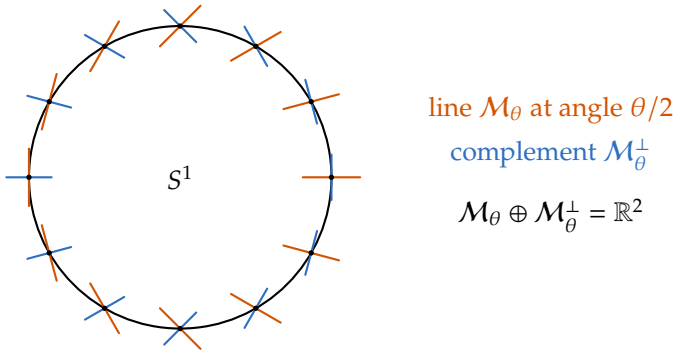


Figure 3.35: The Möbius bundle realised inside the trivial bundle $S^1 \times \mathbb{R}^2$. At angle θ the orange line points at angle $\theta/2$, so after one trip it has turned by only π: the same line with its direction reversed. The blue perpendicular lines form a second Möbius bundle, and together they fill $\mathbb{R}^2$ at every point: $\mathcal{M} \oplus \mathcal{M} \cong I^2$.

Now the theorem.

Key idea: Nash's stable equivalence theorem

If $E \oplus G \cong F \oplus G$, then $E \overset{s}{\sim} F$. Cancellation fails for isomorphism, but it holds for stable equivalence.

The proof is a two-line calculation once we have complements. Choose G' with $G \oplus G' \cong I^n$. Then

$$\begin{aligned} E \oplus I^n &\overset{(1)}{\cong} E \oplus (G \oplus G') \\ &\overset{(2)}{=} (E \oplus G) \oplus G' \\ &\overset{(3)}{\cong} (F \oplus G) \oplus G' \\ &\overset{(2)}{=} F \oplus (G \oplus G') \\ &\overset{(1)}{\cong} F \oplus I^n. \end{aligned}$$

(1) The complement relation (3.83).
(2) Associativity of $\oplus$.

(3) The hypothesis $E \oplus G \cong F \oplus G$, with G' added to both sides.

So $E \oplus I^n \cong F \oplus I^n$, which is stable equivalence with $j = k = n$. The whole trick is: *adding G' converts the arbitrary common summand G into a trivial one*, and trivial summands are exactly what stable equivalence allows us to ignore.

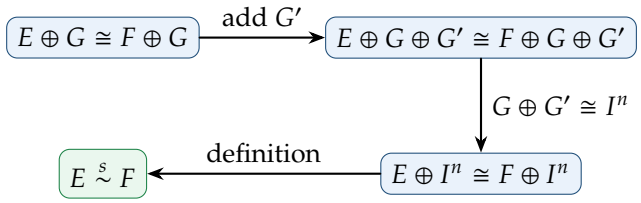

Figure 3.36: The logic of the stable equivalence theorem. The only input beyond bookkeeping is the existence of a complement G', which needs a compact base.

Worked example 3.46: Applying the theorem to TS^2

We found $TS^2 \oplus I \cong I^2 \oplus I$. The theorem (with $G = I$, $G' = I^0$, $n = 1$) gives $TS^2 \overset{s}{\sim} I^2$, which is the definition of stably trivial. Similarly, $H \oplus H^* \cong I^2 = I \oplus I$ does *not* say $H \overset{s}{\sim} I$ (the common summand would have to be the same on both sides, and $H^* \neq I$). Indeed H is not stably trivial.

Try it: Stable classes of line bundles on S^1

Show that every real line bundle on S^1 is isomorphic to I or $\mathcal{M}$, and that these are in different stable classes. *Answer:* glue two arcs by nonzero real numbers on the two overlap intervals; rescaling on one arc lets us make both gluings ± 1, and only the product of the two signs is invariant. So there are two bundles, I (product $+1$) and $\mathcal{M}$ (product -1). They are stably distinct because their determinant bundles, I and $\mathcal{M}$, differ.

Reading Nash (pp. 66–67, (3.32)–(3.39))

Nash defines stable equivalence (3.32)–(3.33), states that cancellation fails (3.34) and gives the example $T\mathbb{R}^{n+1} \cong TS^n \oplus N(S^n)$, (3.35)–(3.36), citing parallelisability only for $n = 1, 3, 7$. His theorem (3.37) is proved in (3.38)–(3.39) using a complement G' with $G \oplus G' \cong I^n$, whose existence he relegates to a footnote ("we assume M to be Hausdorff"). We have supplied: the verification that stable equivalence is an equivalence relation; the construction of G' (which needs *compactness*); explicit frames for S^1, S^3; a self-contained proof that TS^2 is non-trivial; explicit complements for H and $\mathcal{M}$; and the determinant bundle as a stable invariant.

Recap

- $E \overset{s}{\sim} F$ means $E \oplus I^j \cong F \oplus I^k$; ranks may differ.
- Cancellation fails: $TS^2 \oplus I \cong I^3$ but $TS^2 \not\cong I^2$ (winding number 2; hairy-ball theorem).
- Over a compact base every G has a complement: $G \oplus G' \cong I^n$ (embed and take $\perp$). Examples: $H \oplus H^* \cong I^2$, $\mathcal{M} \oplus \mathcal{M} \cong I^2$.
- Stable equivalence theorem: $E \oplus G \cong F \oplus G \Rightarrow E \overset{s}{\sim} F$.
- Stable invariants survive: e.g. $\det E$, so $\mathcal{M}$ and H are not stably trivial.

3.10 The group $K(M)$: subtracting bundles

We can add bundles with $\oplus$, but we cannot subtract them. Given E and F, there is usually no bundle X with $F \oplus X \cong E$ (think of $E = I$ and $F = H$ over S^2: no bundle of rank 0 does it, obviously). In algebraic language, $\mathrm{Vect}(M)$ with $\oplus$ is an abelian **semigroup** (really a monoid: it has the zero bundle I^0 as identity), not a group. And by (3.81) it does not even have cancellation.

This is exactly the situation of the natural numbers $\mathbb{N} = \{0, 1, 2, \ldots\}$: you can add, you cannot subtract, and the fix is to invent negative numbers as *formal differences*. Nash's second kind of equivalence class is precisely this: formal differences of bundles. The resulting group is $K(M)$.

3.10.1 Completing a semigroup: the Grothendieck construction

Let S be any abelian semigroup with operation $+$ and identity 0. We want a group $G(S)$ in which every pair (s, t) stands for "$s - t$".

Working definition 3.25 (Grothendieck group)

Elements of $G(S)$ are pairs $(s, t) \in S \times S$, thought of as $s - t$, modulo the relation

$$(s_1, t_1) \sim (s_2, t_2) \iff s_1 + t_2 + u = s_2 + t_1 + u \quad \text{for some } u \in S. \tag{3.84}$$

[the extra u matters only when S lacks cancellation, as $\mathrm{Vect}(M)$ does] Add componentwise: $(s, t) + (s', t') = (s + s',\ t + t')$. The zero is $(0, 0)$ (equivalently any (s, s)) and the negative of (s, t) is (t, s). *Test for equality:* two formal differences $s_1 - t_1$ and $s_2 - t_2$ are equal when "cross-adding" gives equal answers *after adding some common* u.

Without the u, the relation $s_1 + t_2 = s_2 + t_1$ is what you would write for numbers ($5 - 3 = 7 - 5$ because $5 + 5 = 7 + 3$). The extra u is needed because S may lack cancellation; it is what makes $\sim$ transitive. Let us check transitivity, since it shows exactly where u earns its keep. Suppose $(s_1, t_1) \sim (s_2, t_2)$ via u and $(s_2, t_2) \sim (s_3, t_3)$ via v. Then

$$\begin{aligned}(s_1 + t_3) + (t_2 + u + v + s_2) &\overset{(1)}{=} (s_1 + t_2 + u) + (s_2 + t_3 + v)\\ &\overset{(2)}{=} (s_2 + t_1 + u) + (s_3 + t_2 + v)\\ &\overset{(1)}{=} (s_3 + t_1) + (t_2 + u + v + s_2).\end{aligned}$$

(1) Rearranging a sum in the abelian semigroup S.
(2) The two hypotheses, $s_1 + t_2 + u = s_2 + t_1 + u$ and $s_2 + t_3 + v = s_3 + t_2 + v$.

So $(s_1, t_1) \sim (s_3, t_3)$ via $w = t_2 + u + v + s_2$. We could not have cancelled $t_2 + s_2$ from both sides; we did not need to, because w is allowed.

That (t, s) really is the negative of (s, t):

$$\begin{aligned}(s, t) + (t, s) &\overset{(1)}{=} (s + t,\ t + s)\\ &\overset{(2)}{\sim} (0, 0),\end{aligned}$$

(1) Componentwise addition.
(2) Test (3.84) with $u = 0$: $(s + t) + 0 = 0 + (t + s)$ by commutativity.

so every element has an inverse and $G(S)$ is an abelian group.

Worked example 3.47: From $\mathbb{N}$ to $\mathbb{Z}$

Take $S = \mathbb{N}$. The pairs $(5,3)$, $(7,5)$, $(2,0)$ are all equivalent: $5+5 = 7+3$, $5+0 = 2+3$. Each equivalence class is a diagonal line of lattice points in $\mathbb{N}\times\mathbb{N}$ (Figure 3.37), and the classes are labelled by $s-t \in \mathbb{Z}$. So $G(\mathbb{N}) = \mathbb{Z}$. Here $\mathbb{N}$ has cancellation, so u is never needed.

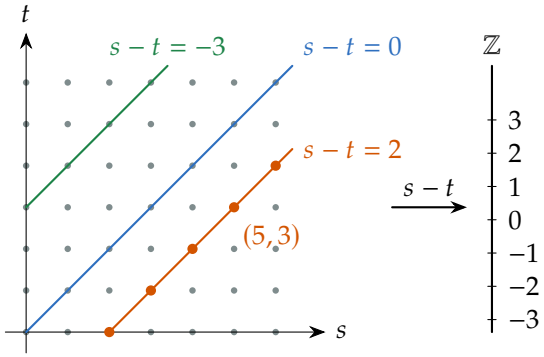

Figure 3.37: The Grothendieck construction for $\mathbb{N}$. A pair (s,t) is a lattice point; pairs on the same diagonal are declared equal. The diagonals are labelled by $s-t$, which runs over all of $\mathbb{Z}$. For bundles the lattice is $\mathrm{Vect}(M)\times\mathrm{Vect}(M)$ and the "diagonals" are the classes $[E]-[F]$.

Worked example 3.48: What the u does when cancellation fails

Take $S = \mathbb{N}\cup\{\infty\}$ with $n+\infty = \infty$. For *any* two pairs choose $u = \infty$: then both sides of (3.84) equal ∞. So every pair is equivalent to $(0,0)$ and $G(S) = 0$. The lesson: in $G(S)$, s and s' become equal as soon as $s+u = s'+u$ for *some* u. The Grothendieck group identifies things that cannot be told apart after adding something. For bundles, this is precisely stable equivalence, as we now see.

3.10.2 Definition of $K(M)$

Apply the construction to $S = \mathrm{Vect}(M)$ with $+ = \oplus$. The relation (3.84) becomes

$$(E,F)\sim(G,H) \iff E\oplus H\oplus J \cong G\oplus F\oplus J \text{ for some bundle } J. \tag{3.85}$$

Working definition 3.26 (the K-group $K(M)$)

$$K(M) = \big(\mathrm{Vect}(M)\times\mathrm{Vect}(M)\big)\,/\sim .$$

[$\mathrm{Vect}(M)$ is the set of isomorphism classes of bundles over M] The class of (E,F) is written $[E]-[F]$, and the class of (E,I^0) is written $[E]$. Elements are called **virtual bundles** [formal differences $[E]-[F]$, in general not the class of an actual bundle]. Addition is $([E]-[F])+([G]-[H]) = [E\oplus G]-[F\oplus H]$. We write n for $[I^n]$. *Test for equality:* $[E]-[F] = [G]-[H]$ iff $E\oplus H\oplus I^N \cong G\oplus F\oplus I^N$ for some N.

The last line of the box (with a *trivial* J) is not the definition but follows from it using complements. If $E\oplus H\oplus J \cong G\oplus F\oplus J$, choose J' with $J\oplus J' \cong I^N$ and add J' to both sides:

$$\begin{aligned} E\oplus H\oplus I^N &\overset{(1)}{\cong} E\oplus H\oplus J\oplus J' \\ &\overset{(2)}{\cong} G\oplus F\oplus J\oplus J' \\ &\overset{(1)}{\cong} G\oplus F\oplus I^N. \end{aligned}$$

(1) Complement (3.83) of J.
(2) Hypothesis, with J' added to both sides.

In particular $[E] = [F]$ in $K(M)$ iff $E \oplus I^N \cong F \oplus I^N$ for some N: stably equivalent *with the same rank*.

Worked example 3.49: The K-group of a point

A vector bundle over a single point is just a vector space, determined up to isomorphism by its dimension. So $\mathrm{Vect}(\mathrm{pt}) \cong \mathbb{N}$ (with $\oplus$ corresponding to $+$), and by Example 3.47

$$K(\mathrm{pt}) = G(\mathbb{N}) = \mathbb{Z}.$$

A virtual vector space $[\mathbb{C}^a] - [\mathbb{C}^b]$ is remembered only through the integer $a - b$: its *super-dimension*, if we think of $\mathbb{C}^a$ as bosonic and $\mathbb{C}^b$ as fermionic states.

3.10.3 Every virtual bundle is "bundle minus trivial"

A formal difference $[E] - [F]$ has a bundle on both sides. Nash shows that we can always make the subtracted bundle trivial. Choose F' with $F \oplus F' \cong I^n$. Then

$$\begin{aligned} [E] - [F] &\overset{(1)}{=} \big([E] + [F']\big) - \big([F] + [F']\big) \\ &\overset{(2)}{=} [E \oplus F'] - [F \oplus F'] \\ &\overset{(3)}{=} [E \oplus F'] - [I^n] \\ &\overset{(4)}{=} [H] - [I^n], \qquad H \coloneqq E \oplus F'. \end{aligned} \tag{3.86}$$

(1) Add and subtract $[F']$ (legitimate in a group).
(2) Addition in $K(M)$ is induced by $\oplus$.
(3) $F \oplus F' \cong I^n$, and isomorphic bundles have the same class.
(4) Name the bundle $E \oplus F'$.

Worked example 3.50: Negatives in $K(S^2)$

From $H \oplus H^* \cong I^2$ (Example 3.44),

$$[H] + [H^*] \overset{(1)}{=} [H \oplus H^*] \overset{(2)}{=} [I^2] = 2,$$

(1) Addition in K is $\oplus$.
(2) The complement relation.

so $[H^*] = 2 - [H]$ and $-[H] = [H^*] - 2$. The "negative of the Hopf bundle" is represented by H^* minus two trivial lines. Similarly,

$$\begin{aligned} 1 - [H] &\overset{(1)}{=} \big(1 + [H^*]\big) - \big([H] + [H^*]\big) \\ &\overset{(2)}{=} [I \oplus H^*] - [I^2], \end{aligned}$$

(1) Add and subtract $[H^*]$.
(2) $1 + [H^*] = [I \oplus H^*]$, and $[H] + [H^*] = 2$ from the chain above.

which is of the form (3.86) with $H \to I \oplus H^*$ and $n = 2$.

3.10.4 Virtual dimension

Working definition 3.27 (virtual dimension)

The **virtual dimension** (or virtual rank) of $[E]-[F]$ is $\operatorname{rk}E-\operatorname{rk}F\in\mathbb{Z}$ [rk is the dimension of the fibres]. It can be positive, negative or zero. By (3.86) [every class can be written $[H]-n$ for one bundle H] it equals $\operatorname{rk}H-n$.

It is worth checking that this is well defined: two representatives of the same class must give the same integer. If $(E,F)\sim(G,H)$ then $E\oplus H\oplus J\cong G\oplus F\oplus J$, and taking ranks,

$$\operatorname{rk}E+\operatorname{rk}H+\operatorname{rk}J\overset{(1)}{=}\operatorname{rk}G+\operatorname{rk}F+\operatorname{rk}J$$
$$\Longrightarrow\ \operatorname{rk}E-\operatorname{rk}F\overset{(2)}{=}\operatorname{rk}G-\operatorname{rk}H.$$

(1) Isomorphic bundles have equal rank, and rank is additive under $\oplus$.
(2) Subtract $\operatorname{rk}J+\operatorname{rk}F+\operatorname{rk}H$ from both sides (these are integers, so cancellation is fine).

Physical picture: Virtual bundles in physics

A virtual bundle $E\ominus F$ is a $\mathbb{Z}_2$-graded object: think of E as bosonic and F as fermionic, with a rule that equal pieces on the two sides cancel. The virtual dimension is then "number of bosons minus number of fermions", like a Witten index. The most important virtual bundle in this book is the *index bundle* of a family of Dirac operators D_y parametrised by $y\in Y$: roughly $[\operatorname{Ker}D_y]-[\operatorname{Coker}D_y]$. The kernel and cokernel can jump in dimension as y varies (zero modes appear in pairs), but the difference is stable, and its virtual dimension is the index (Chapter 4, Chapter 10).

3.10.5 Stable classes are the virtual bundles of dimension zero

Nash now links his two kinds of equivalence classes. Assign to a bundle E_m of rank m the virtual bundle

$$E_m\longmapsto[E_m]-[I^m],$$

which has virtual dimension $m-m=0$. *Claim:* this map gives a one-to-one correspondence between stable equivalence classes of bundles and virtual bundles of dimension zero. There are three things to check.

(a) Same image $\Rightarrow$ stably equivalent. Suppose E_m (rank m) and F_n (rank n) have the same image. Then

$$[E_m]-[I^m]=[F_n]-[I^n]$$
$$\Longrightarrow\ E_m\oplus I^n\oplus K\overset{(1)}{\cong}F_n\oplus I^m\oplus K\quad\text{for some } K$$
$$\Longrightarrow\ E_m\oplus I^n\overset{(2)}{\overset{s}{\sim}}F_n\oplus I^m$$
$$\Longrightarrow\ E_m\overset{(3)}{\overset{s}{\sim}}F_n.$$

(1) The equality test (3.85) with $(E,F)=(E_m,I^m)$, $(G,H)=(F_n,I^n)$.
(2) Nash's stable equivalence theorem, cancelling the common summand K.
(3) $E\overset{s}{\sim}E\oplus I^j$ for any j (definition), and $\overset{s}{\sim}$ is transitive.

(b) Stably equivalent ⇒ same image (so the map is well defined on stable classes). Suppose $E_m \oplus I^j \cong F_n \oplus I^k$; ranks give $m + j = n + k$. Then

$$\begin{aligned}[E_m] - [I^m] &\overset{(1)}{=} [E_m \oplus I^j] - [I^{m+j}] \\ &\overset{(2)}{=} [F_n \oplus I^k] - [I^{n+k}] \\ &\overset{(1)}{=} [F_n] - [I^n].\end{aligned}$$

(1) Add and subtract $[I^j]$ (respectively $[I^k]$).
(2) The hypothesis $E_m \oplus I^j \cong F_n \oplus I^k$, and $m + j = n + k$.

(c) Every virtual bundle of dimension zero is hit. By (3.86) it is $[H] - [I^n]$ with $\operatorname{rk} H = n$, which is the image of H. (Nash leaves this step implicit.)

Key idea: Reduced K-theory

The **reduced K-group** $\widetilde{K}(M)$ is the set of stable equivalence classes of bundles over M. By (a)–(c) it is the same thing as the subgroup of $K(M)$ of virtual bundles of virtual dimension zero:

$$\widetilde{K}(M) = \{\, [E] - [I^{\operatorname{rk} E}] \,\} = \ker\big(\mathrm{Rk} : K(M) \to \mathbb{Z}\big),$$

where $\mathrm{Rk}([E] - [F]) = \operatorname{rk} E - \operatorname{rk} F$. In this form it is automatically a group.

Watch out: The group law on stable classes

Defined as "stable classes", it is not obvious that $\widetilde{K}(M)$ is a group: $\oplus$ adds, but what is the inverse of the stable class of E? It is the stable class of a complement E', since $E \oplus E' \cong I^n \overset{s}{\sim} I^0$. The identification with $\ker \mathrm{Rk}$ makes this automatic.

3.10.6 $K(M) = \widetilde{K}(M) \oplus \mathbb{Z}$: pulling back to a point

Rk is a group homomorphism onto $\mathbb{Z}$ (onto because $\mathrm{Rk}[I^n] = n$), and $\widetilde{K}(M)$ is its kernel. Nash repackages this using pullbacks, which is the form that generalises.

Pullback on K-theory. A map $\alpha : N \to M$ pulls bundles back, $E \mapsto \alpha^* E$ (Section 3.8.2), and respects $\oplus$ and isomorphism. So it induces a group homomorphism

$$\alpha^* : K(M) \to K(N), \qquad \alpha^*\big([E] - [F]\big) = [\alpha^* E] - [\alpha^* F]. \tag{3.87}$$

It is well defined: if $E \oplus H \oplus J \cong G \oplus F \oplus J$ then pulling back gives $\alpha^* E \oplus \alpha^* H \oplus \alpha^* J \cong \alpha^* G \oplus \alpha^* F \oplus \alpha^* J$, which is the same relation on N. It is functorial, $(\alpha \circ \beta)^* = \beta^* \circ \alpha^*$, because composing transition functions with α and then with β is composing with $\alpha \circ \beta$. And it is homotopy invariant: *homotopic maps pull back isomorphic bundles* over a compact base. The reason: along a homotopy α_t the transition functions $g_{ab} \circ \alpha_t$ vary continuously in t, and two sets of transition functions that are close enough are related by h_a's close to 1, hence define isomorphic bundles; by compactness of $[0, 1]$ finitely many small steps connect $t = 0$ to $t = 1$.

The point and its two maps. Let $m_0 \in M$ be a base point. There are two natural maps

$$i : \{m_0\} \hookrightarrow M \ \text{(inclusion)}, \qquad c : M \to \{m_0\} \ \text{(collapse everything to } m_0),$$

with $c \circ i = \mathrm{id}_{\{m_0\}}$. On K-theory:

- $i^* : K(M) \to K(\{m_0\}) = \mathbb{Z}$ restricts a virtual bundle to the single fibre over m_0: $i^*([E]-[F]) = \dim E_{m_0} - \dim F_{m_0}$. For connected M this is Rk. (Nash's footnote 4: on a disconnected M ranks can differ from component to component, and i^* only sees the component of m_0.)
- $c^* : \mathbb{Z} \to K(M)$ pulls back $\mathbb{C}^n$ (or $\mathbb{R}^n$) over the point to the constant family: $c^*(n) = [I^n]$.
- $i^* \circ c^* = (c \circ i)^* = \mathrm{id}$: restricting a trivial bundle of rank n to a point gives $\mathbb{C}^n$.

This is summarised by the **split exact sequence**

$$0 \longrightarrow \widetilde{K}(M) \xrightarrow{I} K(M) \underset{c^*}{\overset{i^*}{\rightleftarrows}} K(\{m_0\}) \longrightarrow 0, \tag{3.88}$$

where I is the inclusion. "Exact" means: at each spot, the image of the incoming arrow equals the kernel of the outgoing one. Here: I is injective, $\operatorname{Im} I = \widetilde{K}(M) = \ker i^*$, and i^* is onto. "Split" means that c^* is a right inverse of i^*.

$$0 \longrightarrow \widetilde{K}(M) \xrightarrow{I} K(M) \underset{c^*}{\overset{i^*}{\rightleftarrows}} K(\mathrm{pt}) = \mathbb{Z} \longrightarrow 0$$

$$[E] - [I^{\mathrm{rk}\,E}] \longmapsto [E] \longmapsto \mathrm{rk}\,E$$

Figure 3.38: The split exact sequence for $K(M)$. Going right, i^* remembers only the rank (the fibre over one point). Going back, c^* turns an integer n into the trivial bundle I^n. What i^* forgets is exactly $\widetilde{K}(M)$, the stable class. The bottom row follows one bundle through the maps.

A split exact sequence of abelian groups always gives a direct sum. Every $x \in K(M)$ decomposes as

$$x \overset{(1)}{=} \big(x - c^*i^*x\big) + c^*i^*x,$$

(1) Add and subtract c^*i^*x.

and the first piece lies in $\ker i^*$ because $i^*(x - c^*i^*x) = i^*x - (i^*c^*)(i^*x) = i^*x - i^*x = 0$. The decomposition is unique: if $y \in \ker i^*$ and $y = c^*n$, then $n = i^*c^*n = i^*y = 0$. Hence

$$K(M) = \ker i^* \oplus c^*K(\{m_0\}) = \widetilde{K}(M) \oplus \mathbb{Z}. \tag{3.89}$$

Concretely, $[E]-[F]$ splits as $\big([E]-[F]-(\mathrm{rk}\,E-\mathrm{rk}\,F)\big)+(\mathrm{rk}\,E-\mathrm{rk}\,F)$: "stable class" plus "virtual rank".

Worked example 3.51: K of the circle, complex case

Every complex bundle over S^1 is trivial. Glue two arcs with transition matrices $g \in \mathrm{GL}(k,\mathbb{C})$ on the two overlap intervals. Rechoosing the fibre coordinate on one arc lets us make one gluing the identity, leaving one matrix g. Since $\mathrm{GL}(k,\mathbb{C})$ is *connected* (any invertible complex matrix can be joined to 1: diagonalise or triangularise it and move each eigenvalue to 1 along a path in $\mathbb{C}^\times$ avoiding 0), g can be deformed to 1, and a homotopy of transition functions gives an isomorphic bundle. So $\mathrm{Vect}_k(S^1,\mathbb{C}) = \{I^k\}$ and

$$KU(S^1) = \mathbb{Z}, \qquad \widetilde{KU}(S^1) = 0.$$

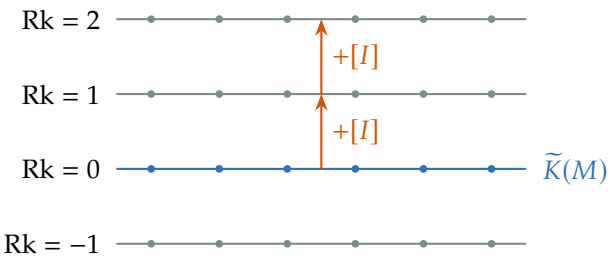

Figure 3.39: A picture of $K(M) = \widetilde{K}(M) \oplus \mathbb{Z}$. Virtual bundles sit in rows according to their virtual rank. Adding a trivial line moves straight up to the next row without changing the stable class. The reduced group $\widetilde{K}(M)$ is the row of rank zero (blue).

Worked example 3.52: K of the circle, real case

For real bundles the gluing matrix lies in $\mathrm{GL}(k,\mathbb{R})$, which has *two* components, $\det > 0$ and $\det < 0$. So there are exactly two bundles of each rank $k \geq 1$: I^k and $\mathcal{M} \oplus I^{k-1}$ (the latter glued by $\mathrm{diag}(-1,1,\dots,1)$). Hence $\widetilde{KO}(S^1)$ has two elements, 0 and $x := [\mathcal{M}] - 1$, and

$$2x \overset{(1)}{=} [\mathcal{M} \oplus \mathcal{M}] - 2 \overset{(2)}{=} [I^2] - 2 = 0,$$

(1) $2x = 2[\mathcal{M}] - 2$ and addition is $\oplus$.
(2) $\mathcal{M} \oplus \mathcal{M} \cong I^2$ (Example 3.45).

So $\widetilde{KO}(S^1) = \mathbb{Z}_2$ and $KO(S^1) = \mathbb{Z} \oplus \mathbb{Z}_2$. The $\mathbb{Z}_2$ is the orientability of the bundle (its determinant line), invisible to complex K-theory.

Worked example 3.53: A disconnected space

Let $M = \{p, q\}$ be two points. A bundle is a pair of vector spaces of dimensions (a, b), so $\mathrm{Vect}(M) = \mathbb{N} \times \mathbb{N}$ and $K(M) = \mathbb{Z} \oplus \mathbb{Z}$. With base point p, $i^*(a,b) = a$, so $\widetilde{K}(M) = \mathbb{Z}$ (generated by the bundle that is 0 over p and $\mathbb{C}$ over q). Here "Rk" is not a single number, which is why Nash assumes M connected.

3.10.7 The ring structure

K-theory has a multiplication, induced by $\otimes$. For formal differences we multiply out as for numbers:

$$\big([E] - [F]\big) \cdot \big([G] - [H]\big) := [E \otimes G \oplus F \otimes H] - [E \otimes H \oplus F \otimes G]. \tag{3.90}$$

This is what $(e - f)(g - h) = (eg + fh) - (eh + fg)$ says. It is well defined because $\otimes$ distributes over $\oplus$ and respects isomorphism (so if we change (E, F) to an equivalent pair, the product changes to an equivalent pair). The unit is $1 = [I]$, since $E \otimes I \cong E$.

Key idea: K-theory is a ring

$K(M)$ is a commutative ring with unit $[I]$, and α^* is a ring homomorphism. Rank is multiplicative, $\mathrm{Rk}(xy) = \mathrm{Rk}(x)\,\mathrm{Rk}(y)$, so the product of anything with an element of rank zero has rank zero: $\widetilde{K}(M)$ is an *ideal*. Having a product is, as Nash says, another sign that we are dealing with a cohomology theory (compare the wedge product on de Rham cohomology).

Worked example 3.54: The ring $KO(S^1)$

With $x = [\mathcal{M}] - 1$:

$$\begin{aligned} x^2 &\overset{(1)}{=} [\mathcal{M}]^2 - 2[\mathcal{M}] + 1 \\ &\overset{(2)}{=} [\mathcal{M} \otimes \mathcal{M}] - 2[\mathcal{M}] + 1 \\ &\overset{(3)}{=} 1 - 2[\mathcal{M}] + 1 \\ &= -2\big([\mathcal{M}] - 1\big) = -2x \overset{(4)}{=} 0. \end{aligned}$$

(1) Expand using the ring axioms.
(2) Multiplication in K is induced by $\otimes$.
(3) $\mathcal{M} \otimes \mathcal{M} \cong I$ (Example 3.39).
(4) $2x = 0$ (Example 3.52).

So $KO(S^1) = \mathbb{Z}[x]/(2x,\ x^2)$: additively $\mathbb{Z} \oplus \mathbb{Z}_2$, and the reduced part squares to zero.

Worked example 3.55: A preview: the ring $K(S^2)$

In Section 3.12 we will show $\widetilde{KU}(S^2) = \mathbb{Z}$, generated by $b = [H] - 1$, and that $H \oplus H \cong H^{\otimes 2} \oplus I$. Granting that,

$$\begin{aligned} b^2 &\overset{(1)}{=} [H \otimes H] - 2[H] + 1 \\ &\overset{(2)}{=} \big(2[H] - 1\big) - 2[H] + 1 = 0. \end{aligned}$$

(1) Expand $([H] - 1)^2$ and use $[H]^2 = [H \otimes H]$.
(2) $[H \otimes H] + [I] = [H \oplus H] = 2[H]$.

So $K(S^2) = \mathbb{Z}[b]/(b^2)$, i.e. $(H - 1)^2 = 0$. This innocent relation is the seed of Bott periodicity.

Reading Nash (pp. 67–70, (3.40)–(3.55))

Nash observes that $\mathrm{Vect}(M)$ is only a semigroup (3.40), defines the Grothendieck group by (3.41), specialises to bundles (3.42) and defines $K(M)$ (3.43). He proves $[E] - [F] = [H] - [I^n]$ (3.44), defines virtual dimension (3.45), and proves that stable classes correspond to elements of virtual dimension zero (3.46)–(3.47). Reduced K-theory is (3.48), Rk is (3.49), and $K(M) = \widetilde{K}(M) \oplus \mathbb{Z}$ is (3.50), proved via pullbacks (3.51)–(3.55). Two corrections: on p. 70 Nash writes "$\ker i^* = \widetilde{K}(\{m_0\})$", which should read $\ker i^* = \widetilde{K}(M)$ (the reduced K-group of a point is zero); and the surjectivity in (c) above is left implicit. The ring structure is mentioned in one sentence; we supplied the formula (3.90) and the examples.

Recap

- Grothendieck group: pairs (s, t) with $(s_1, t_1) \sim (s_2, t_2)$ iff $s_1 + t_2 + u = s_2 + t_1 + u$; the u absorbs the failure of cancellation.
- $K(M)$: formal differences $[E] - [F]$; $[E] = [F]$ iff $E \oplus I^N \cong F \oplus I^N$. Every element is $[H] - [I^n]$.
- Virtual dimension $\operatorname{rk} E - \operatorname{rk} F$; $\widetilde{K}(M)$ = stable classes = virtual dimension zero.

- $K(M) = \widetilde{K}(M) \oplus \mathbb{Z}$ via i^* (restrict to a point) and c^* (trivial bundles).
- $\otimes$ makes $K(M)$ a ring. $KU(S^1) = \mathbb{Z}$; $KO(S^1) = \mathbb{Z}[x]/(2x, x^2)$; $KU(S^2) = \mathbb{Z}[b]/(b^2)$ with $b = [H] - 1$.

3.11 Classifying spaces and the stable range

So far we have described bundles one at a time, by transition functions. There is a completely different way to describe *all* rank-k bundles at once. Build one special space B with one special bundle Q over it, so that every bundle over every M is obtained by pulling Q back along some map $f : M \to B$. Then

$$\text{bundles over } M \quad \longleftrightarrow \quad \text{maps } M \to B \text{ up to homotopy.}$$

A question about bundles becomes a question about maps, which is a question in homotopy theory. For spheres $M = S^n$ it becomes a question about homotopy groups, and those are known. This is how Nash computes $\widetilde{K}(S^n)$, and it is the gateway to Bott periodicity.

We met this idea in Chapter 1 as the classifying space BG of a group G. Here we make it completely concrete: B will be a *Grassmannian*, a space of planes, and Q will be the bundle whose fibre over a plane is that plane.

A physicist has met this construction without the name. Take a Hamiltonian $\hat{H}(x)$ depending on parameters $x \in M$, with a band of k states separated by a gap from the rest. At each x the band spans a k-dimensional subspace of the Hilbert space. The map $x \mapsto$ (that subspace) is a map from M into a Grassmannian, and the bundle of band states, whose Berry connection gives Berry phases, is the pullback of Q. We will see this explicitly for a spin-$\frac{1}{2}$ in a magnetic field.

3.11.1 Reducing the structure group: $\mathrm{GL}(k)$ to $\mathrm{O}(k)$

Nash's first remark is that a real rank-k bundle has structure group $\mathrm{GL}(k, \mathbb{R})$, "reducible to $\mathrm{O}(k)$ on choosing a metric". Here is what that means.

A **fibre metric** on E is an inner product $\langle\,,\rangle_x$ on each fibre E_x, varying smoothly with x. One always exists: on each patch use the standard dot product of the fibre coordinates, and average these with a partition of unity $\{\rho_a\}$ ($\rho_a \geq 0$, supported in U_a, $\sum_a \rho_a = 1$):

$$\langle v, w\rangle_x = \sum_a \rho_a(x)\, v_a^T w_a.$$

A positive combination of inner products is an inner product, so this is positive definite.

Given a metric, apply Gram–Schmidt to any local frame. The result is an **orthonormal frame** on each patch. Use orthonormal fibre coordinates, so that on every patch $\langle v, w\rangle = v_a^T w_a$. Then the transition functions are forced to be orthogonal:

$$\begin{aligned} v_b^T w_b &\overset{(1)}{=} \langle v, w\rangle \\ &\overset{(2)}{=} v_a^T w_a \\ &\overset{(3)}{=} (g_{ab} v_b)^T (g_{ab} w_b) \\ &\overset{(4)}{=} v_b^T \left(g_{ab}^T g_{ab}\right) w_b. \end{aligned}$$

(1) The coordinates on U_b are orthonormal.

(2) So are the coordinates on U_a.
(3) The transition rule $v_a = g_{ab} v_b$.
(4) Transpose of a product reverses the order.

Since this holds for all v_b, w_b, we get $g_{ab}^T g_{ab} = 1$: every g_{ab} lies in $\mathrm{O}(k)$. The same argument with a Hermitian metric gives $g_{ab}^\dagger g_{ab} = 1$ for complex bundles, i.e. structure group $\mathrm{U}(k)$, and with a quaternionic metric gives $\mathrm{Sp}(k)$.

Key idea: Only the compact group matters

Every real, complex or quaternionic bundle can be described by transition functions in $\mathrm{O}(k)$, $\mathrm{U}(k)$ or $\mathrm{Sp}(k)$ respectively. Topologically nothing is lost, because $\mathrm{GL}(k,\mathbb{R})$ deformation-retracts onto $\mathrm{O}(k)$ (and $\mathrm{GL}(k,\mathbb{C})$ onto $\mathrm{U}(k)$).

The retraction is the **polar decomposition**. Every invertible matrix factors uniquely as $g = O\,P$ with O orthogonal and P symmetric positive definite, namely $P = (g^T g)^{1/2}$ and $O = g P^{-1}$. The path

$$g_t = O\,P^{1-t} = O\exp\big((1-t)\log P\big), \qquad t \in [0,1],$$

runs inside $\mathrm{GL}(k,\mathbb{R})$ from $g_0 = g$ to $g_1 = O \in \mathrm{O}(k)$, and fixes the points already in $\mathrm{O}(k)$ (where $P = 1$).

Worked example 3.56: Polar decomposition of a 2×2 matrix

Take $g = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ (a shear). Then

$$g^T g = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix}.$$

This has eigenvalues $\lambda_\pm = \frac{3\pm\sqrt{5}}{2}$, both positive, so $P = (g^T g)^{1/2}$ exists. Using $\sqrt{\lambda_\pm} = \frac{\sqrt{5}\pm 1}{2}$ (check: $\big(\frac{\sqrt{5}\pm1}{2}\big)^2 = \frac{6\pm 2\sqrt{5}}{4} = \lambda_\pm$) one finds

$$P = \frac{1}{\sqrt{5}}\begin{pmatrix} 2 & 1 \\ 1 & 3 \end{pmatrix}, \qquad O = g P^{-1} \overset{(1)}{=} \frac{1}{\sqrt{5}}\begin{pmatrix} 2 & 1 \\ -1 & 2 \end{pmatrix}.$$

(1) $\det P = (6-1)/5 = 1$, so $P^{-1} = \frac{1}{\sqrt{5}}\begin{pmatrix} 3 & -1 \\ -1 & 2 \end{pmatrix}$, and $gP^{-1} = \frac{1}{\sqrt{5}}\begin{pmatrix} 3-1 & -1+2 \\ -1 & 2 \end{pmatrix}$.

Check: $P^2 = \frac{1}{5}\begin{pmatrix} 5 & 5 \\ 5 & 10 \end{pmatrix} = g^T g$, and O is a rotation by $\arctan(-\frac{1}{2})$, since its columns are orthonormal and $\det O = (4+1)/5 = 1$. The shear has been deformed to a rotation without ever becoming singular.

Watch out: The metric is extra structure, but it costs nothing

Different metrics give different orthonormal frames, but the resulting $\mathrm{O}(k)$-bundles are isomorphic: two metrics are joined by the straight line $(1-t)\langle,\rangle_0 + t\langle,\rangle_1$, which is a metric for every t. So "real bundle" and "$\mathrm{O}(k)$-bundle" are interchangeable for counting purposes, and from now on we use whichever is convenient.

3.11.2 Grassmannians, concretely

Working definition 3.28 (real Grassmannian)

$\mathrm{Gr}(k,m,\mathbb{R})$ is the set of k-dimensional linear subspaces ("k-planes through the origin") of $\mathbb{R}^m$. Three equivalent ways to hold a point of it in your hand:

1. a k-plane $P \subset \mathbb{R}^m$;
2. an $m \times k$ matrix A of rank k whose columns span P, modulo $A \sim AG$ for $G \in \mathrm{GL}(k,\mathbb{R})$ [an invertible $k \times k$ real matrix] (change of basis of P);
3. the orthogonal projector Π onto P [the matrix sending each vector of $\mathbb{R}^m$ to its nearest point in P]: an $m \times m$ matrix with $\Pi^T = \Pi$, $\Pi^2 = \Pi$, $\mathrm{tr}\,\Pi = k$.

The third description is the most useful in practice: it has no redundancy, and $\Pi = A(A^TA)^{-1}A^T$ converts from the second.

The simplest case is $k = 1$: a line through the origin in $\mathbb{R}^m$. That is real projective space, $\mathrm{Gr}(1,m,\mathbb{R}) = \mathbb{RP}^{m-1}$. For $m = 2$ it is a circle, as we now check with projectors.

Worked example 3.57: $\mathrm{Gr}(1,2,\mathbb{R}) = \mathbb{RP}^1$ is a circle

The line at angle θ is spanned by $u = (\cos\theta, \sin\theta)^T$. Its projector is

$$\Pi(\theta) \overset{(1)}{=} u\,u^T = \begin{pmatrix} \cos^2\theta & \cos\theta\sin\theta \\ \cos\theta\sin\theta & \sin^2\theta \end{pmatrix} \overset{(2)}{=} \frac{1}{2}\begin{pmatrix} 1+\cos 2\theta & \sin 2\theta \\ \sin 2\theta & 1-\cos 2\theta \end{pmatrix} \overset{(3)}{=} \frac{1}{2}\left(1 + \cos 2\theta\,\sigma_3 + \sin 2\theta\,\sigma_1\right).$$

(1) For a unit vector u, uu^T is the orthogonal projector onto its span ($uu^Tu = u$, and $uu^Tw = 0$ for $w \perp u$).
(2) Double-angle formulas.
(3) In terms of the Pauli matrices $\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, $\sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$.

The projector depends only on 2θ. As θ runs from 0 to π (and the line turns through half a revolution, returning to itself), the point $(\cos 2\theta, \sin 2\theta)$ runs once round a circle. So $\mathbb{RP}^1$ is a circle, parametrised by 2θ.

As a homogeneous space. The orthogonal group $\mathrm{O}(m)$ moves k-planes around: $P \mapsto RP$ for $R \in \mathrm{O}(m)$. It moves any k-plane to any other (rotate an orthonormal basis of one onto an orthonormal basis of the other and extend). The rotations that fix the reference plane $\mathbb{R}^k \subset \mathbb{R}^m$ as a set are the block-diagonal ones, $\begin{pmatrix} A & 0 \\ 0 & B \end{pmatrix}$ with $A \in \mathrm{O}(k)$ acting inside the plane and $B \in \mathrm{O}(m-k)$ acting on its orthogonal complement. Hence

$$\mathrm{Gr}(k,m,\mathbb{R}) = \frac{\mathrm{O}(m)}{\mathrm{O}(m-k) \times \mathrm{O}(k)}. \tag{3.91}$$

This is Nash's (3.56). Counting dimensions, with $\dim \mathrm{O}(p) = p(p-1)/2$:

$$\dim \mathrm{Gr}(k,m,\mathbb{R}) \overset{(1)}{=} \tfrac{m(m-1)}{2} - \tfrac{k(k-1)}{2} - \tfrac{(m-k)(m-k-1)}{2}$$

$$\overset{(2)}{=} \tfrac{1}{2}\left[m^2 - m - k^2 + k - (m-k)^2 + (m-k)\right]$$
$$\overset{(3)}{=} \tfrac{1}{2}\left[2mk - 2k^2\right] = k(m-k).$$

(1) Dimension of a quotient group/subgroup is the difference of dimensions.
(2) Expand.
(3) $(m-k)^2 = m^2 - 2mk + k^2$; the linear terms $-m + k + (m-k)$ cancel.

There is a direct way to see $k(m-k)$: a k-plane near $\mathbb{R}^k$ is the graph of a linear map $\mathbb{R}^k \to \mathbb{R}^{m-k}$, i.e. an $(m-k)\times k$ matrix of free parameters. For $k=1$, $m=2$ we get 1, the circle.

Worked example 3.58: $\mathrm{Gr}(2,3,\mathbb{R}) \cong \mathbb{RP}^2$

A plane through the origin of $\mathbb{R}^3$ is determined by its normal line, so $\mathrm{Gr}(2,3,\mathbb{R}) \cong \mathrm{Gr}(1,3,\mathbb{R}) = \mathbb{RP}^2$, and indeed $\dim = 2\cdot 1 = 1\cdot 2$. In projector language, $\Pi_{\text{plane}} = 1 - \Pi_{\text{normal}} = 1 - nn^T$ for a unit normal n; the sign of n drops out, which is why we get $\mathbb{RP}^2 = S^2/\pm$ rather than S^2. In general $\mathrm{Gr}(k,m) \cong \mathrm{Gr}(m-k,m)$ via $P \mapsto P^\perp$, $\Pi \mapsto 1-\Pi$.

The universal bundle. Over $\mathrm{Gr}(k,m,\mathbb{R})$ there is a tautological rank-k bundle, Nash's $Q(k,m,\mathbb{R})$:

$$Q(k,m,\mathbb{R}) = \{\,(P,v) \;:\; P \in \mathrm{Gr}(k,m,\mathbb{R}),\; v \in P\,\}.$$

The fibre over the plane P *is* the plane P. It sits inside the trivial bundle $\mathrm{Gr}\times\mathbb{R}^m$, and its fibre at Π is the image of the projector Π.

Worked example 3.59: The universal line bundle over $\mathbb{RP}^1$ is the Möbius bundle

Over $\mathrm{Gr}(1,2,\mathbb{R})$, the fibre over the line at angle θ is that line, with the local nonvanishing section $s(\theta) = u(\theta) = (\cos\theta, \sin\theta)$. Follow s once around the base, i.e. from θ to $\theta+\pi$ (by Example 3.57, that is one full loop in $\mathbb{RP}^1$):

$$s(\theta+\pi) \overset{(1)}{=} (\cos(\theta+\pi), \sin(\theta+\pi))$$
$$\overset{(2)}{=} -(\cos\theta, \sin\theta) = -s(\theta).$$

(1) Definition of s.
(2) cos and sin change sign under a shift by π.

The frame comes back reversed: the gluing is -1. So $Q(1,2,\mathbb{R})$ is the Möbius bundle $\mathcal{M}$ of Example 3.35. Similarly, over $\mathrm{Gr}(1,2,\mathbb{C}) = \mathbb{CP}^1$ the universal bundle is, by definition, the tautological bundle H of Example 3.36.

3.11.3 Every bundle is a pullback of Q

Here is the construction that makes Q universal. It uses only the complement of Section 3.9.3.

Working definition 3.29 (classifying map)

Let E be a rank-k bundle over M. Choose a complement [a second bundle E' with $E\oplus E'$ trivial, which exists because M is compact], $E \oplus E' \cong I^m = M\times\mathbb{R}^m$. Then each fibre E_x is a k-plane in the *fixed* vector space $\mathbb{R}^m$. Define

$$f : M \to \mathrm{Gr}(k,m,\mathbb{R}), \qquad f(x) = E_x \subset \mathbb{R}^m.$$

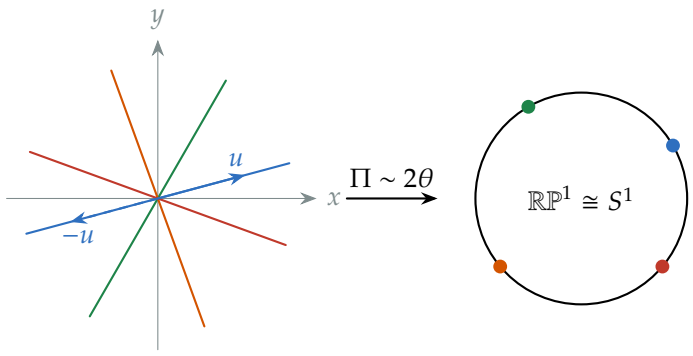

Figure 3.40: The Grassmannian of lines in the plane. Each coloured line through the origin is one point of $\mathrm{Gr}(1,2,\mathbb{R})$. The line at angle θ and the line at $\theta+\pi$ are the same line, so the natural coordinate is 2θ, and the space of lines is a circle (right). The unit vector u spanning a line comes back as $-u$ after one loop: the tautological bundle over this circle is the Möbius bundle.

In projector form, $f(x)=\Pi(x)$ is the orthogonal projector onto E_x. The map f is the **classifying map** of E.

The pullback of Q along f is E again, tautologically:

$$\begin{aligned}(f^*Q)_x &\overset{(1)}{=} Q_{f(x)}\\ &\overset{(2)}{=} \text{the plane } f(x)\\ &\overset{(3)}{=} E_x.\end{aligned}$$

(1) Definition of pullback: the fibre over x is the fibre of Q over $f(x)$.
(2) Definition of Q: its fibre over a plane is that plane.
(3) Definition of f.

Both are subbundles of $M\times\mathbb{R}^m$ with the same fibre at every point, so $f^*Q\cong E$. This is Nash's (3.57).

Worked example 3.60: The Gauss map of the sphere

For $TS^2\subset S^2\times\mathbb{R}^3$ (complement: the normal bundle, $m=3$), the classifying map sends x to its tangent plane:

$$f: S^2\to \mathrm{Gr}(2,3,\mathbb{R}),\qquad f(x)=x^{\perp},\qquad \Pi(x)=1-xx^T.$$

Composing with $\mathrm{Gr}(2,3)\cong\mathbb{RP}^2$ (plane $\mapsto$ normal line), f is the map $S^2\to\mathbb{RP}^2$, $x\mapsto\{\pm x\}$. This is the classical **Gauss map** of a surface, which records the direction of the normal at each point. Its degree (suitably defined) is what the Gauss–Bonnet theorem integrates.

Worked example 3.61: Spin-$\frac{1}{2}$ in a magnetic field: the Hopf bundle as a pullback

Take $\hat H(\vec n)=-\vec n\cdot\vec\sigma$ for a unit vector $\vec n\in S^2$. The ground state is the $+1$ eigenvector of $\vec n\cdot\vec\sigma$, and the projector onto it is

$$\Pi(\vec n)\overset{(1)}{=}\tfrac{1}{2}\big(1+\vec n\cdot\vec\sigma\big)$$

$$\overset{(2)}{=} \frac{1}{2}\begin{pmatrix} 1+n_3 & n_1 - in_2 \\ n_1 + in_2 & 1-n_3 \end{pmatrix}.$$

(1) $(\vec{n}\cdot\vec{\sigma})^2 = |\vec{n}|^2 = 1$, so the eigenvalues are ± 1, and $\frac{1}{2}(1 \pm \vec{n}\cdot\vec{\sigma})$ are the projectors onto the two eigenspaces (they are idempotent: $\frac{1}{4}(1 + 2\vec{n}\cdot\vec{\sigma} + 1) = \frac{1}{2}(1 + \vec{n}\cdot\vec{\sigma})$; their trace is 1).
(2) Write out the Pauli matrices.

So $\vec{n} \mapsto \Pi(\vec{n})$ is a map $S^2 \to \mathrm{Gr}(1,2,\mathbb{C}) = \mathbb{CP}^1$. It is a bijection (the Bloch sphere: every pure state of a qubit is $\Pi(\vec{n})$ for exactly one $\vec{n}$). The ground-state bundle is the pullback of $Q(1,2,\mathbb{C}) = H$ along a bijection, i.e. it is H itself. The Berry phase of the ground state around a loop on S^2 is half the solid angle, and its integrated Berry curvature over S^2 is 2π times the Chern number ∓ 1 (the sign depends on orientation conventions): a monopole of unit charge in parameter space.

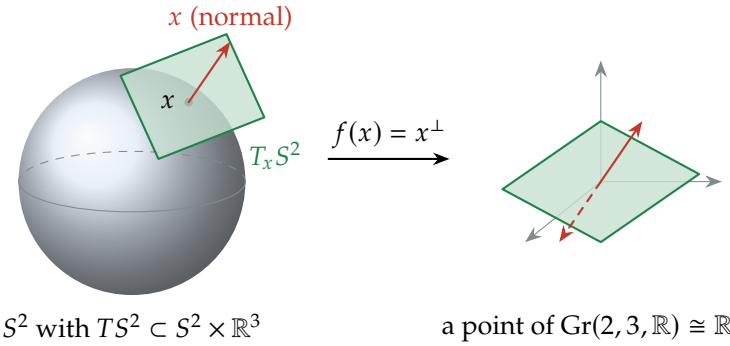

Figure 3.41: The classifying map of the tangent bundle of S^2. At each point x the tangent plane is a 2-plane in $\mathbb{R}^3$; translate it to the origin and you have a point of the Grassmannian of planes in $\mathbb{R}^3$. The plane is determined by its normal line (red), and $\pm x$ give the same line, so the target is $\mathbb{RP}^2$. Pulling back the tautological plane bundle along this map returns TS^2.

How big must m be? A dimension count

Nash states the universal property for $m \geq n + k + 1$, where $n = \dim M$. Where does that number come from? Two facts are needed.

(i) Every rank-k bundle embeds in I^m once $m \geq n + k$. An embedding is the same as m global sections $s_1, \ldots, s_m$ which span E_x at every x (then E' is the kernel of the resulting map, and $E_x = \mathrm{span}\{s_i(x)\}$ sits in $\mathbb{R}^m$ via the dual map). Written in a local frame, the sections form a $k \times m$ matrix $S(x)$, and they fail to span exactly where $S(x)$ has rank $< k$. Count the codimension of the bad matrices:

$$\begin{aligned} \mathrm{codim}\{S : \mathrm{rank}\, S \leq k-1\} &\overset{(1)}{=} km - (k-1)\big(k + m - (k-1)\big) \\ &\overset{(2)}{=} km - (k-1)(m+1) \\ &= m - k + 1. \end{aligned}$$

(1) The $k \times m$ matrices of rank r form a space of dimension $r(k+m-r)$ (choose the r-dimensional row space, $r(m-r)$ parameters, then k rows in it, kr parameters); take $r = k-1$.
(2) Simplify.

A generic n-parameter family of matrices $S(x)$ misses a set of codimension $m - k + 1$ as soon as $m - k + 1 > n$, i.e. $m \geq n + k$. So generic sections span everywhere.

(ii) Any two classifying maps are homotopic once $m \geq n + k + 1$. Two embeddings are joined by a family of embeddings over $M \times [0, 1]$, which has dimension $n + 1$. Repeating the count with $n \to n + 1$ gives the condition $m \geq n + k + 1$. A homotopy between embeddings is a homotopy between the classifying maps.

Conversely, homotopic maps pull back isomorphic bundles (the homotopy invariance of Section 3.10.6). Putting (i), (ii) and this together:

$$\mathrm{Vect}_k(M) \;\cong\; [M, \mathrm{Gr}(k, m, \mathbb{R})] \qquad (m \geq n + k + 1), \tag{3.92}$$

where $[A, B]$ denotes homotopy classes of maps $A \to B$. Only the homotopy class of f matters.

3.11.4 The infinite Grassmannian and $BO(k)$

The bound on m depends on $\dim M$. To get one space that works for all M at once, let $m \to \infty$. The inclusion $\mathbb{R}^m \subset \mathbb{R}^{m+1}$ (as the first m coordinates) makes every k-plane in $\mathbb{R}^m$ a k-plane in $\mathbb{R}^{m+1}$:

$$\mathrm{Gr}(k, m, \mathbb{R}) \subset \mathrm{Gr}(k, m + 1, \mathbb{R}) \subset \mathrm{Gr}(k, m + 2, \mathbb{R}) \subset \cdots \tag{3.93}$$

The union is the **infinite Grassmannian**

$$\mathrm{Gr}(k, \infty, \mathbb{R}) = \bigcup_m \mathrm{Gr}(k, m, \mathbb{R}), \tag{3.94}$$

the space of k-planes in $\mathbb{R}^\infty = \bigcup_m \mathbb{R}^m$ (sequences with finitely many nonzero entries). A map from a compact M lands in some finite $\mathrm{Gr}(k, m, \mathbb{R})$, so (3.92) gives, for every compact M,

$$\mathrm{Vect}_k(M) \cong [M, \mathrm{Gr}(k, \infty, \mathbb{R})] = [M, BO(k)]. \tag{3.95}$$

These are Nash's (3.60)–(3.61). The notation $BO(k)$ is the classifying space of the group $\mathrm{O}(k)$ from Chapter 1.

Physical picture: Why this is the classifying space BG

In Chapter 1, BG was the base of a principal G-bundle $EG \to BG$ with *contractible* total space. Here EG is the space of orthonormal k-frames in $\mathbb{R}^\infty$ (the Stiefel manifold $V(k, \infty)$). $\mathrm{O}(k)$ acts on frames by rotating them within their plane, freely, and the quotient ("forget the frame, keep the plane") is $\mathrm{Gr}(k, \infty)$. The frame space is contractible because there is infinite room: any frame can be slid, one coordinate at a time, into the unused far-away coordinates and then rotated to a standard frame. For $k = 1$ this says: the unit sphere $S^\infty \subset \mathbb{R}^\infty$ is contractible, which is false for every finite S^{m-1}.

Worked example 3.62: Real line bundles and $\mathbb{RP}^\infty$

For $k = 1$: $BO(1) = \mathbb{RP}^\infty$, and real line bundles over M correspond to $[M, \mathbb{RP}^\infty]$. For $M = S^1$, a based loop in $\mathbb{RP}^\infty$ lifts to a path in S^∞ which either closes up or ends at the antipode; these two cases are the two elements of $\pi_1(\mathbb{RP}^\infty) = \mathbb{Z}_2$. So there are exactly two real line bundles over S^1, I and $\mathcal{M}$, matching Example 3.35 and Example 3.59. (In general $[M, \mathbb{RP}^\infty] = H^1(M; \mathbb{Z}_2)$, and the class of a line bundle there is its first Stiefel–Whitney class w_1, the obstruction to orienting it.)

Worked example 3.63: Complex line bundles and $\mathbb{CP}^\infty$: monopoles

For complex line bundles, $BU(1) = \mathrm{Gr}(1,\infty,\mathbb{C}) = \mathbb{CP}^\infty$. Line bundles over S^2 are classified by $[S^2, \mathbb{CP}^\infty] = \pi_2(\mathbb{CP}^\infty)$. The fibration $S^1 \to S^\infty \to \mathbb{CP}^\infty$ with contractible S^∞ gives $\pi_2(\mathbb{CP}^\infty) \cong \pi_1(S^1) = \mathbb{Z}$: one line bundle $H^{\otimes n}$ for each integer n, the monopole charges. (In general $[M, \mathbb{CP}^\infty] = H^2(M;\mathbb{Z})$, and the class is the first Chern class c_1.)

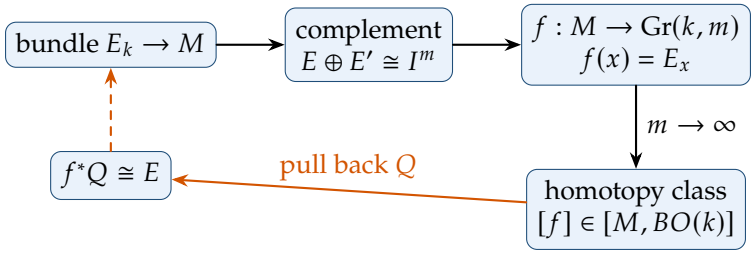

Figure 3.42: The logic of classifying spaces. A bundle has a complement inside a big trivial bundle; that makes each fibre a plane in a fixed $\mathbb{R}^m$, i.e. a point of the Grassmannian. The resulting map, up to homotopy, is a complete invariant: pulling back the tautological bundle Q recovers the bundle up to isomorphism.

3.11.5 The stable range theorem

Now raise the rank. What happens to $\mathrm{Vect}_k(M)$ as k grows? Nash's answer: it stops changing once $k > \dim M$, and it then *is* the reduced K-group.

Key idea: Stable range theorem, real case (Nash, p. 72)

Let $n = \dim M$. If E_k is a real bundle of rank $k > n$, then

$$E_k \cong F_n \oplus I^{k-n}$$

for some bundle F_n of rank n. Moreover, for $k > n$, two rank-k bundles that are stably equivalent are isomorphic. Such E_k are said to be in the **stable range**.

Why: a section of a high-rank bundle need not vanish. Pick a generic section s of E_k. In a local frame s is k real functions of n variables. Its zeros are where all k functions vanish at once:

$$\dim\{x : s(x) = 0\} \overset{(1)}{=} n - k.$$

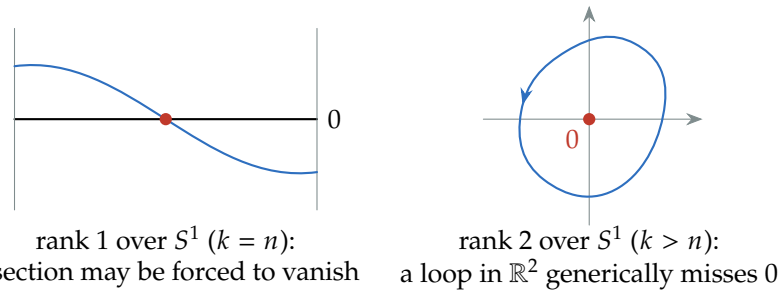
(1) k independent equations in n unknowns cut out a set of dimension $n - k$ (generic transversality); a negative dimension means the set is empty.

So if $k > n$ a generic section never vanishes. A nonvanishing section spans a trivial line subbundle $I \subset E_k$ (Section 3.8.1), and with a fibre metric $E_k = I \oplus s^\perp$. Now $s^\perp$ has rank $k-1$. If still $k - 1 > n$, repeat. We stop at rank n:

$$E_k \cong E_{k-1} \oplus I \cong E_{k-2} \oplus I^2 \cong \cdots \cong F_n \oplus I^{k-n}.$$

Why stable equivalence implies isomorphism for $k > n$. Suppose $E \oplus I \cong F \oplus I$ with $\mathrm{rk}\, E = \mathrm{rk}\, F = k > n$. The bundle $G := E \oplus I$ has two nonvanishing sections: $s_0 =$ the I in $E \oplus I$, and $s_1 =$ the I in $F \oplus I$ transported by the isomorphism, with $E \cong s_0^\perp$ and $F \cong s_1^\perp$. Join them by a family s_t, $t \in [0,1]$, of sections. This is a section of a rank-$(k+1)$ bundle over the

$(n+1)$-dimensional space $M \times [0,1]$; generically it has no zeros if $k+1 > n+1$, i.e. $k > n$. Then $s_t^{\perp}$ is a bundle over $M \times [0,1]$ restricting to E at $t=0$ and F at $t=1$, and homotopy invariance gives $E \cong F$. Induction handles $E \oplus I^j \cong F \oplus I^j$.



rank 1 over S^1 ($k = n$): a section may be forced to vanish

rank 2 over S^1 ($k > n$): a loop in $\mathbb{R}^2$ generically misses 0

Figure 3.43: The dimension count behind the stable range. Left: a section of a real line bundle over a circle is one function of one variable; for the Möbius bundle it must change sign and so it vanishes (red dot). Right: a section of a rank-2 bundle over a circle traces a loop in the fibre $\mathbb{R}^2$; a small push moves it off the origin, so the section is nowhere zero and splits off a trivial line.

The K-theory meaning. Combine the theorem with Section 3.10.5. The map

$$\mathrm{Vect}_k(M) \longrightarrow \widetilde{K}(M), \qquad E_k \longmapsto [E_k] - [I^k],$$

is *onto* for $k \geq n$ (every stable class is $[H] - [I^N]$; if $\mathrm{rk}\, H < k$ add trivial lines, if $\mathrm{rk}\, H > k$ split them off with the theorem) and *one-to-one* for $k > n$ (equal images mean stably equivalent, hence isomorphic). So

$$\widetilde{K}(M) \;\cong\; \mathrm{Vect}_k(M) \;\cong\; [M, \mathrm{Gr}(k,\infty,\mathbb{R})] \qquad (k > \dim M). \tag{3.96}$$

This is Nash's (3.62). Nash sums it up: "there is nothing to be gained by considering bundles of very high rank". In the stable range, bundles and their K-theory classes are the same thing.

Worked example 3.64: Inside and outside the stable range over S^1

Over S^1 ($n=1$) every real bundle of rank $k \geq 2$ is in the stable range. By Example 3.52 there are exactly two of each rank, I^k and $\mathcal{M} \oplus I^{k-1}$, and $\widetilde{KO}(S^1) = \mathbb{Z}_2$ also has two elements. The theorem says $\mathcal{M} \oplus \mathcal{M}$ (rank $2 > 1$) must be one of these two; its determinant is $\det(\mathrm{diag}(-1,-1)) = +1$, so it is I^2, as we found by hand in Example 3.45.

Worked example 3.65: Outside the stable range bundles are finer than K-theory

Take oriented real rank-2 bundles over S^2 ($k = n = 2$, not in the stable range). Such a bundle is the same as a complex line bundle (rotation by 90° is multiplication by i), so by Example 3.63 there is one for each integer: $H^{\otimes d}$, with TS^2 at $d=-2$. There are infinitely many. But we saw in Section 3.9 that $TS^2 \oplus I \cong I^3$, so TS^2 and I^2 become equal in $\widetilde{KO}(S^2)$. Adding one trivial line kills the even charges. We will find in Section 3.12 that $\widetilde{KO}(S^2) = \mathbb{Z}_2$: only d mod 2 survives stabilisation. Outside the stable range, the set of bundles is bigger than the K-group.

Watch out: Stable versus unstable information

K-theory deliberately throws away information that is only visible at low rank, such as the Euler class of TS^2 (which is $\chi(S^2) = 2$ and detects that TS^2 is non-trivial). Invariants that

survive adding I (Chern classes, Pontryagin classes, Stiefel–Whitney classes, the Chern character) are *stable*; the Euler class is not. The index theorem involves only stable invariants, which is one reason K-theory is the right language for it.

Try it: How many trivial lines can a bundle over S^3 shed?

A real rank-5 bundle over S^3: by the theorem it is $F_3 \oplus I^2$. Can one always go further, to $F_2 \oplus I^3$?
Answer: Not by the dimension count, which only guarantees a nonvanishing section when rk > dim. (In fact every bundle over S^3 is trivial, because $\pi_2(\mathrm{O}(k)) = 0$; see Section 3.12. But that is special to S^3.)

Reading Nash (pp. 70–72, (3.56)–(3.62))

Nash reduces $\mathrm{GL}(k,\mathbb{R})$ to $\mathrm{O}(k)$ with a metric, introduces the Grassmannian (3.56) and the universal bundle $Q(k,m,\mathbb{R})$, states the classifying property (3.57) for $m \geq n+k+1$, passes to $\mathrm{Gr}(k,\infty,\mathbb{R}) = BO(k)$ via the inclusions (3.58)–(3.61), and states the stable range theorem, referring to Husemoller for the proof by induction on k. Its K-theory translation is (3.62). He writes that E_k is stably equivalent to "F_n of lower rank n where $n = \dim M + 1$"; the rank of F_n is $n = \dim M$, as in the statement of the theorem. We have added the polar decomposition, three concrete descriptions of the Grassmannian with the dimension count $k(m-k)$, the explicit classifying maps for TS^2 and the Hopf bundle, the dimension counts behind $m \geq n+k+1$ and $k > n$, and the $k = 1$ cases $\mathbb{RP}^\infty$, $\mathbb{CP}^\infty$.

Recap

- A fibre metric reduces $\mathrm{GL}(k,\mathbb{R})$ to $\mathrm{O}(k)$ ($\mathrm{U}(k)$, $\mathrm{Sp}(k)$ for $\mathbb{C}$, $\mathbb{H}$); polar decomposition shows nothing topological is lost.
- $\mathrm{Gr}(k,m,\mathbb{R}) = \mathrm{O}(m)/(\mathrm{O}(m-k)\times\mathrm{O}(k))$, dimension $k(m-k)$; points are projectors $\Pi = \Pi^T = \Pi^2$, $\operatorname{tr}\Pi = k$.
- Tautological bundle Q: fibre over a plane is the plane. Over $\mathbb{RP}^1$ it is Möbius; over $\mathbb{CP}^1$ it is H.
- Classifying map $f(x) = E_x \subset \mathbb{R}^m$; $f^*Q \cong E$; $\mathrm{Vect}_k(M) = [M, BO(k)]$, $BO(k) = \mathrm{Gr}(k,\infty,\mathbb{R})$.
- Stable range $k > \dim M$: $E_k \cong F_n \oplus I^{k-n}$, and $\mathrm{Vect}_k(M) \cong \widetilde{K}(M) = [M, \mathrm{Gr}(k,\infty)]$.

3.12 Bundles over spheres: clutching functions and $\widetilde{K}(S^n)$

We now have a formula, (3.96), that turns K-theory into homotopy theory. Nash applies it to the simplest spaces with interesting topology, the spheres S^n. This section computes $\widetilde{K}(S^n)$ for $n \leq 4$ in the real, complex and quaternionic cases, and shows where the answers come from. Two ideas do all the work:

1. a bundle over a sphere is determined by *one* transition function on the equator, the **clutching function**;
2. the homotopy groups of $\mathrm{O}(k)$, $\mathrm{U}(k)$, $\mathrm{Sp}(k)$ stop depending on k when k is large.

For a physicist this is the familiar statement that the topological sectors of a gauge theory on a sphere are classified by the winding of the gauge transformation that relates the "north" and "south" gauges. The monopole (S^2, winding in U(1)) and the instanton (S^4, winding in SU(2)) are the two famous cases.

3.12.1 $\widetilde{K}(S^n)$ as a homotopy group

Put $M = S^n$ in (3.96). For $k > n$,

$$\widetilde{K}(S^n) = [S^n, \mathrm{Gr}(k, \infty, \mathbb{R})] \cong \pi_n\big(\mathrm{Gr}(k, \infty, \mathbb{R})\big). \tag{3.97}$$

This is Nash's (3.63). Recall that the **homotopy group** $\pi_n(X)$ is the set of maps $S^n \to X$ sending a chosen base point of S^n to a chosen base point x_0 of X, up to homotopies that keep the base point fixed. The group law glues two spheres at their base points.

Watch out: Free versus based homotopy

$[S^n, X]$ (free homotopy classes) and $\pi_n(X)$ (based classes) are not quite the same. A based class can be dragged around a loop in X while the base point travels with it; this is an action of $\pi_1(X)$ on $\pi_n(X)$, and the free classes are the orbits. If X is simply connected (as $BU(k) = \mathrm{Gr}(k, \infty, \mathbb{C})$ is) nothing changes. For $BO(k)$, $\pi_1 = \mathbb{Z}_2$ (orientation), and the identification in (3.97) really counts bundles *with a chosen trivialisation of the fibre over the base point*. Nash calls this "the minor technical point". For the groups we compute below the distinction never changes the answer.

3.12.2 The clutching construction

Split S^n into two closed hemispheres ("caps") D_+ and D_-, each a disc D^n, meeting along the equator S^{n-1}. Thicken them slightly to open sets $U \supset D_+$ and $V \supset D_-$; the overlap $U \cap V$ is a band around the equator, which deformation-retracts onto S^{n-1}.

Step 1: every bundle over a disc is trivial. A disc is contractible: the map $r_t(x) = (1-t)x$ shrinks it to its centre. Pulling a bundle E back along the homotopy r_t from $r_0 = \mathrm{id}$ to $r_1 =$(constant map) gives, by homotopy invariance,

$$E \overset{(1)}{=} r_0^* E \overset{(2)}{\cong} r_1^* E \overset{(3)}{=} D \times E_0 = I^k.$$

(1) r_0 is the identity.
(2) Homotopic maps pull back isomorphic bundles.
(3) The pullback along a constant map with value 0 is the constant family of vector spaces E_0: a product.

Step 2: glue. So $E|_U \cong U \times \mathbb{R}^k$ and $E|_V \cong V \times \mathbb{R}^k$, and E is determined by a single transition function

$$g : U \cap V \to \mathrm{O}(k) \qquad \rightsquigarrow \qquad g : S^{n-1} \to \mathrm{O}(k)$$

(restrict to the equator; the band retracts onto it). This g is the **clutching function**.

Working definition 3.30 (clutching)

Given a map $g : S^{n-1} \to G$, where $G = \mathrm{O}(k)$, $\mathrm{U}(k)$ or $\mathrm{Sp}(k)$ [the matrices preserving lengths in $\mathbb{F}^k$ for $\mathbb{F} = \mathbb{R}, \mathbb{C}, \mathbb{H}$ respectively], the bundle E_g over S^n is obtained by taking $D_+ \times \mathbb{F}^k$ and $D_- \times \mathbb{F}^k$ and identifying $(x, v) \in \partial D_- \times \mathbb{F}^k$ with $(x, g(x)v) \in \partial D_+ \times \mathbb{F}^k$ for each x on the equator. *To test whether* $E_g \cong E_{g'}$: check whether g and g' are homotopic [one can be deformed continuously into the other] as maps $S^{n-1} \to G$ (after normalising both to send a base point to 1).

Why only the homotopy class of g matters, and why constants can be normalised away: a change of trivialisation on the two caps is a pair of maps $h_\pm : D_\pm \to G$, and changes g to $g'(x) = h_+(x)\, g(x)\, h_-(x)^{-1}$. Since each disc is contractible, h_+ restricted to the equator is homotopic to the constant $h_+(0)$ (restrict h_+ to the circles of radius $1 - t$), and likewise for h_-. So

$$g' \;\simeq\; h_+(0)\, g\, h_-(0)^{-1},$$

a constant times g times a constant. If G is connected, the constants can be moved to 1 and drop out. For $G = \mathrm{O}(k)$ we fix them by demanding that g send a base point to 1; this is the "chosen trivialisation at the base point" of the pitfall above. Conversely, a homotopy g_t gives a bundle E_{g_t} over $S^n \times [0,1]$, so $E_{g_0} \cong E_{g_1}$. Hence

$$\mathrm{Vect}_k(S^n) \;\cong\; \pi_{n-1}\big(\mathrm{O}(k)\big) \quad \text{(based, i.e. with a framing at the base point).} \tag{3.98}$$

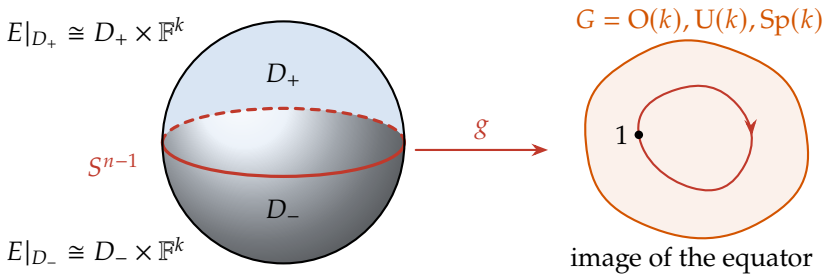


Figure 3.44: The clutching construction. Over each cap the bundle is a product. All the information is in how the two products are glued along the equator S^{n-1}: a map g from the equator into the structure group. Deforming the loop (red) inside G does not change the bundle, so the bundle is labelled by the homotopy class of g, an element of $\pi_{n-1}(G)$.

Worked example 3.66: Clutching over S^1 and S^2

$n = 1$. The "equator" of S^1 is S^0, two points. Normalising $g = 1$ at one point, a real bundle is fixed by g(other point) $\in \mathrm{O}(k)$, up to homotopy, i.e. by the component $\det g = \pm 1$. So $\mathrm{Vect}_k(S^1, \mathbb{R}) \cong \pi_0(\mathrm{O}(k)) = \mathbb{Z}_2$: I^k or $\mathcal{M} \oplus I^{k-1}$, exactly Example 3.52.
$n = 2$, *complex line bundles.* $g : S^1 \to \mathrm{U}(1)$ is a loop $e^{i\phi} \mapsto g(e^{i\phi})$ on the unit circle, classified by its winding number

$$d = \frac{1}{2\pi i} \oint_{S^1} g^{-1} \mathrm{d}g \in \mathbb{Z} = \pi_1(\mathrm{U}(1)).$$

From Section 3.8: H has $g = e^{i\phi}$, $d = 1$; $H^{\otimes d}$ has $g = e^{id\phi}$; TS^2 has $g = -e^{-2i\phi} \simeq e^{-2i\phi}$, $d = -2$. Every line bundle over S^2 is some $H^{\otimes d}$, as promised in Example 3.38.

Let us verify the winding-number integral for $g = e^{id\phi}$, since it is the prototype of every

topological charge in this book:

$$\frac{1}{2\pi i}\oint g^{-1}\mathrm{d}g \overset{(1)}{=} \frac{1}{2\pi i}\int_0^{2\pi} e^{-id\phi}\,(id)\,e^{id\phi}\,\mathrm{d}\phi$$
$$\overset{(2)}{=} \frac{id}{2\pi i}\cdot 2\pi = d.$$

(1) $\mathrm{d}(e^{id\phi}) = id\,e^{id\phi}\mathrm{d}\phi$.
(2) The integrand is the constant id.

The integral is unchanged by any deformation of g (it is an integer depending continuously on g), which is the homotopy invariance in action.

3.12.3 $[S^n, BG] = [S^{n-1}, G]$: loop spaces

We now have two descriptions of $\mathrm{Vect}_k(S^n)$: maps $S^n \to BG$ (classifying maps) and maps $S^{n-1} \to G$ (clutching functions). Nash digresses to explain why they agree, for any group G.

Working definition 3.31 (loop space and suspension)

The **loop space** ΩX of a based space (X, x_0) [a space with one chosen point x_0] is the space of loops $\gamma : [0,1] \to X$ with $\gamma(0) = \gamma(1) = x_0$. The **reduced suspension** SX is $X \times [0,1]$ with the top $X \times \{1\}$, the bottom $X \times \{0\}$ and the segment $\{x_0\} \times [0,1]$ all collapsed to a single point. For spheres, $SS^{n-1} \cong S^n$.

The basic relation (Nash's (1.22) in Chapter 1) is the **adjunction**

$$[SX, Y] \cong [X, \Omega Y]. \tag{3.99}$$

Why: a point of SX is a pair (x,t). A map $F : SX \to Y$ can be read as: for each x, the path $t \mapsto F(x,t)$, which starts and ends at the base point (because the top and bottom are collapsed). That is a map $X \to \Omega Y$, $x \mapsto F(x,\cdot)$, and conversely. With $X = S^{n-1}$ this gives $\pi_n(Y) = [S^n, Y]_0 = [S^{n-1}, \Omega Y]_0 = \pi_{n-1}(\Omega Y)$.

Now the chain Nash writes, for a group G:

$$[S^{n-1}, G] \overset{(1)}{=} [S^n, BG]$$
$$\overset{(2)}{=} [SS^{n-1}, BG]$$
$$\overset{(3)}{=} [S^{n-1}, \Omega BG]. \tag{3.100}$$

(1) Both sides classify G-bundles over S^n: clutching functions on the left, classifying maps on the right.
(2) $S^n \cong SS^{n-1}$.
(3) The adjunction (3.99).

This holds for every n, which suggests (and it is true) that

$$\Omega BG \;\simeq\; G.$$

Nash: "think of the loop space operand Ω as being a kind of homotopic inverse to the classifying space operand B".

Physical picture: A loop in BG is a group element: holonomy

Recall $EG \to BG$ is a principal G-bundle with contractible total space. Start at a point e in the fibre over the base point and lift a loop γ in BG to a path in EG. It ends in the same fibre, at some point $e \cdot g$. The group element g is the *holonomy* of the loop, just as a Wilson loop in gauge theory records the group element picked up by parallel transport around a closed path (Chapter T3). Contractibility of EG makes this a homotopy equivalence $\Omega BG \to G$. For a bundle over $S^n = SS^{n-1}$, each point x of the equator gives a loop in BG (up over D_+ and back down over D_- through x), and its holonomy is the clutching value $g(x)$.

Combining (3.97) and (3.100) with $G = \mathrm{O}(k)$:

$$\boxed{\widetilde{K}(S^n) \cong \pi_{n-1}\big(\mathrm{O}(k)\big), \qquad k > n.} \tag{3.101}$$

This is Nash's (3.64). All the K-theory of spheres is in the homotopy groups of the classical groups.

3.12.4 Stability of the homotopy groups of $\mathrm{O}(k)$

Nash quotes from Husemoller that $\pi_{n-1}(\mathrm{O}(k)) = \pi_{n-1}(\mathrm{O}(k+1))$ for $k > n$. This is the group-theoretic face of the stable range theorem, and it has a short explanation.

The group $\mathrm{O}(k+1)$ acts on the unit sphere $S^k \subset \mathbb{R}^{k+1}$, transitively, and the rotations fixing the north pole e_{k+1} form $\mathrm{O}(k)$. So the map

$$\mathrm{O}(k+1) \longrightarrow S^k, \qquad R \longmapsto R\, e_{k+1}$$

("where does the north pole go?") has fibre $\mathrm{O}(k)$: it is a **fibration** $\mathrm{O}(k) \to \mathrm{O}(k+1) \to S^k$. A fibration $F \to E \to B$ has a long exact sequence of homotopy groups,

$$\cdots \to \pi_{j+1}(B) \to \pi_j(F) \to \pi_j(E) \to \pi_j(B) \to \pi_{j-1}(F) \to \cdots .$$

(A physicist's reading: a sphere in E projects to a sphere in B; if B has no spheres of that dimension to wrap, the sphere can be pushed into a single fibre.) For $B = S^k$, $\pi_j(S^k) = 0$ whenever $j < k$ (a lower- dimensional sphere in S^k can always be moved off a point and then shrunk through the resulting $\mathbb{R}^k$). The segment of the sequence

$$\underbrace{\pi_{j+1}(S^k)}_{0 \text{ if } j+1<k} \to \pi_j(\mathrm{O}(k)) \to \pi_j(\mathrm{O}(k+1)) \to \underbrace{\pi_j(S^k)}_{0 \text{ if } j<k}$$

then says that the middle map is an isomorphism whenever $j \le k-2$. For $j = n-1$ this is $k \ge n+1$, i.e. $k > n$: precisely the stable range. The common value is written $\pi_j(\mathrm{O})$, the homotopy of the **infinite orthogonal group** $\mathrm{O} = \mathrm{O}(\infty) = \bigcup_k \mathrm{O}(k)$.

The same argument with $\mathrm{U}(k) \to \mathrm{U}(k+1) \to S^{2k+1}$ (acting on the unit sphere of $\mathbb{C}^{k+1}$) and $\mathrm{Sp}(k) \to \mathrm{Sp}(k+1) \to S^{4k+3}$ (unit sphere of $\mathbb{H}^{k+1}$) gives

$$\pi_j(\mathrm{U}(k)) \cong \pi_j(\mathrm{U}(k+1)) \ \ (j \le 2k-1), \qquad \pi_j(\mathrm{Sp}(k)) \cong \pi_j(\mathrm{Sp}(k+1)) \ \ (j \le 4k+1). \tag{3.102}$$

The spheres are bigger, so the groups stabilise sooner.

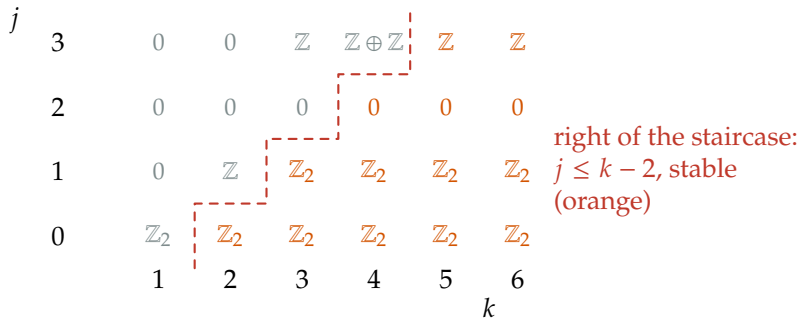

Figure 3.45: The homotopy groups $\pi_j(\mathrm{O}(k))$ for small j and k. Reading along a row, the entries settle down once $k \geq j+2$ (orange, to the right of the red staircase). The unstable entries (grey) are accidents of small groups: $\pi_1(\mathrm{O}(2)) = \mathbb{Z}$ because SO(2) is a circle, and $\pi_3(\mathrm{O}(4)) = \mathbb{Z} \oplus \mathbb{Z}$ because SO(4) is locally $\mathrm{SU}(2) \times \mathrm{SU}(2)$. K-theory sees only the stable values.

3.12.5 The real table: $\widetilde{KO}(S^n)$ for $n \leq 4$

Nash lists the result (his (3.65)):

$$\begin{aligned} & & \widetilde{KO}(S^0) &= \mathbb{Z} \\ \pi_0(\mathrm{O}(k)) = \mathbb{Z}_2,\ k \geq 1 &\Rightarrow & \widetilde{KO}(S^1) &= \mathbb{Z}_2 \\ \pi_1(\mathrm{O}(k)) = \mathbb{Z}_2,\ k \geq 3 &\Rightarrow & \widetilde{KO}(S^2) &= \mathbb{Z}_2 \\ \pi_2(\mathrm{O}(k)) = 0,\ k \geq 4 &\Rightarrow & \widetilde{KO}(S^3) &= 0 \\ \pi_3(\mathrm{O}(k)) = \mathbb{Z},\ k \geq 5 &\Rightarrow & \widetilde{KO}(S^4) &= \mathbb{Z} \end{aligned} \tag{3.103}$$

Each line deserves an explanation.

$n = 0$. S^0 is two points $\{p, q\}$. A bundle is a pair of vector spaces of dimensions (a, b), $K(S^0) = \mathbb{Z} \oplus \mathbb{Z}$, and with base point p the reduced group is $\{(0, b)\} \cong \mathbb{Z}$ (the disconnected example in Section 3.10.6). Here the "rank" is not constant, which is why $\widetilde{K}(S^0)$ is not zero.

$n = 1$: $\pi_0(\mathrm{O}(k)) = \mathbb{Z}_2$. $\mathrm{O}(k)$ has two components, det $= +1$ ($\mathrm{SO}(k)$) and det $= -1$. The generator of $\widetilde{KO}(S^1)$ is $[\mathcal{M}] - 1$.

$n = 2$: $\pi_1(\mathrm{O}(k)) = \pi_1(\mathrm{SO}(k)) = \mathbb{Z}_2$ for $k \geq 3$. This is the famous fact that a 2π rotation is not deformable to the identity but a 4π rotation is: the reason spinors exist (Chapter T4). We show it in Example 3.67 below. The generator of $\widetilde{KO}(S^2)$ is the underlying real rank-2 bundle of H (clutching $e^{i\phi} \in \mathrm{U}(1) = \mathrm{SO}(2) \subset \mathrm{SO}(k)$, a single 2π turn), minus 2.

$n = 3$: $\pi_2(\mathrm{O}(k)) = 0$. In fact $\pi_2(G) = 0$ for every compact Lie group G (a theorem of É. Cartan). So every real bundle over S^3 is trivial (with a framing at the base point).

$n = 4$: $\pi_3(\mathrm{O}(k)) = \mathbb{Z}$ for $k \geq 5$. Start with SO(3). Its double cover is $\mathrm{SU}(2) = S^3$, and a covering map does not change π_j for $j \geq 2$ (a sphere S^j with $j \geq 2$ is simply connected, so it lifts), so $\pi_3(\mathrm{SO}(3)) = \pi_3(S^3) = \mathbb{Z}$, the degree of a map $S^3 \to S^3$. This $\mathbb{Z}$ survives into SO(5) and beyond. The generator of $\widetilde{KO}(S^4)$ can be taken to be the underlying real rank-4 bundle of the quaternionic Hopf bundle (the BPST instanton bundle; see Example 3.70), minus 4.

Worked example 3.67: $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$, explicitly

The 2π loop is not contractible. Let $R(t)$ be rotation about the z-axis by angle $2\pi t$, $t \in [0,1]$, a closed loop at 1 in SO(3). The map $\mathrm{SU}(2) \to \mathrm{SO}(3)$, $U \mapsto R_U$ with $R_U(\vec{x}\cdot\vec{\sigma}) = U(\vec{x}\cdot\vec{\sigma})U^\dagger$, is two-to-one ($\pm U \mapsto$ the same rotation). Lift $R(t)$ to SU(2):

$$U(t) \overset{(1)}{=} \exp\left(-i\pi t\,\sigma_3\right) = \begin{pmatrix} e^{-i\pi t} & 0 \\ 0 & e^{i\pi t} \end{pmatrix}, \qquad U(1) \overset{(2)}{=} -1.$$

(1) $e^{-i\theta\sigma_3/2}$ rotates by angle θ about z; here $\theta = 2\pi t$.
(2) $e^{\mp i\pi} = -1$.

The lift starts at 1 and ends at -1: it is not a closed loop in SU(2). If $R(t)$ could be shrunk to the constant loop, the lift would deform along with it (lifts vary continuously) while keeping its endpoints in the discrete set $\{\pm 1\}$, so the endpoint would stay -1; but the constant loop lifts to the constant path, ending at $+1$. Contradiction.
The 4π loop is contractible. Let $R_{\vec{a}}(\theta)$ denote rotation by θ about the unit axis $\vec{a}$. Consider the family of loops, for $s \in [0,1]$,

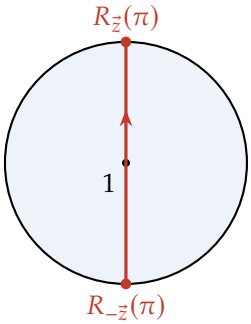
$$\gamma_s: \quad \text{first } R_{\vec{z}}(2\pi t),\ t\in[0,1]; \quad \text{then } R_{\vec{a}(s)}(2\pi t),\ t\in[0,1],$$

where $\vec{a}(s)$ tilts from $\vec{a}(0) = \vec{z}$ to $\vec{a}(1) = -\vec{z}$ through the xz-plane. Each half is a closed loop, so each γ_s is a closed loop. At $s = 0$ it is the 4π rotation about z. At $s = 1$,

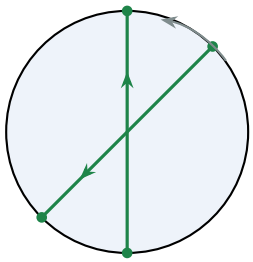
$$\begin{aligned} \gamma_1 &\overset{(1)}{=} R_{\vec{z}}(2\pi t) \text{ followed by } R_{-\vec{z}}(2\pi t) \\ &\overset{(2)}{=} R_{\vec{z}}(2\pi t) \text{ followed by } R_{\vec{z}}(-2\pi t), \end{aligned}$$

(1) Definition of γ_s at $s = 1$.
(2) Rotating by θ about $-\vec{z}$ is rotating by $-\theta$ about $\vec{z}$.

which is a loop followed by its own reverse: it retracts to the constant loop. So $2\cdot[2\pi \text{ loop}] = 0$, and $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$. In SU(2): the lift of the 4π loop ends at $(-1)^2 = +1$.



2π loop: a diameter with antipodal ends identified



4π loop: two diameters; rotate one onto the other

Figure 3.46: SO(3) as a solid ball of radius π: the point at vector $\theta\vec{a}$ is rotation by θ about $\vec{a}$, and antipodal points of the boundary sphere are identified (rotation by π about $\vec{a}$ equals rotation by π about $-\vec{a}$). Left: the 2π loop runs along a diameter and jumps from one end to the other; it cannot be shrunk, since its two ends must stay antipodal. Right: the 4π loop crosses twice; moving the second diameter until the crossing points meet lets the loop unhook and shrink.

Worked example 3.68: Stably, TS^2 is trivial and $H_{\mathbb{R}}$ is not

The clutching function of the real rank-2 bundle underlying $H^{\otimes d}$ is the loop $e^{id\phi} \in \mathrm{SO}(2)$, a rotation by $d\phi$ in a fixed plane. Put it into SO(3) by adding a trivial line: that is d times the 2π loop, so its class in $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$ is d mod 2. Hence

$$[TS^2] - 2 \overset{(1)}{=} (-2 \bmod 2) \cdot x = 0, \qquad [H_{\mathbb{R}}] - 2 \overset{(2)}{=} (1 \bmod 2) \cdot x = x \neq 0,$$

(1) TS^2 has $d = -2$ (Example 3.66); x is the generator of $\widetilde{KO}(S^2) = \mathbb{Z}_2$.
(2) H has $d = 1$.

This recovers $TS^2 \oplus I \cong I^3$ (Section 3.9) from a completely different direction.

3.12.6 Complex and quaternionic bundles

Everything so far works with $\mathbb{R}$ replaced by $\mathbb{C}$ or by the quaternions $\mathbb{H}$. Nash notes that only the Grassmannian and the stable range change.

Quaternions in one paragraph. $\mathbb{H}$ is the real algebra with basis $1, \mathbf{i}, \mathbf{j}, \mathbf{k}$ and $\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = \mathbf{ijk} = -1$ (so $\mathbf{ij} = \mathbf{k} = -\mathbf{ji}$, etc.). It is a Clifford algebra, $\mathbb{H} = \mathrm{Cl}_{0,2}$ (Chapter T4). A faithful representation by 2×2 complex matrices is

$$1 \mapsto \mathbb{1}, \quad \mathbf{i} \mapsto -i\sigma_1, \quad \mathbf{j} \mapsto -i\sigma_2, \quad \mathbf{k} \mapsto -i\sigma_3,$$

so a quaternion $q = a + b\,\mathbf{i} + c\,\mathbf{j} + d\,\mathbf{k}$ becomes $a\mathbb{1} - i(b\sigma_1 + c\sigma_2 + d\sigma_3)$. Check one relation:

$$\mathbf{ij} \overset{(1)}{=} (-i\sigma_1)(-i\sigma_2) = -\sigma_1\sigma_2 \overset{(2)}{=} -i\sigma_3 \overset{(3)}{=} \mathbf{k}.$$

(1) $(-i)^2 = -1$.
(2) $\sigma_1\sigma_2 = i\sigma_3$.
(3) The assignment $\mathbf{k} \mapsto -i\sigma_3$.

The norm is $|q|^2 = a^2 + b^2 + c^2 + d^2 = \det(\text{matrix})$, and the unit quaternions $|q| = 1$ are exactly the matrices in SU(2). Topologically they form the sphere $S^3 \subset \mathbb{R}^4$. The **compact symplectic group** $\mathrm{Sp}(k)$ is the group of $k \times k$ quaternionic matrices A with $A^\dagger A = 1$ (quaternionic conjugate transpose); $\mathrm{Sp}(1) = \mathrm{SU}(2) = S^3$.

The Grassmannians. By the same argument as (3.91),

$$\mathrm{Gr}(k, m, \mathbb{C}) = \frac{\mathrm{U}(m)}{\mathrm{U}(m-k) \times \mathrm{U}(k)}, \qquad \mathrm{Gr}(k, m, \mathbb{H}) = \frac{\mathrm{Sp}(m)}{\mathrm{Sp}(m-k) \times \mathrm{Sp}(k)}, \tag{3.104}$$

Nash's (3.66), of real dimensions $2k(m-k)$ and $4k(m-k)$. The classifying statements become

$$\begin{aligned} \mathrm{Vect}_k(M, \mathbb{C}) &\cong [M, \mathrm{Gr}(k, \infty, \mathbb{C})] = [M, BU(k)], \\ \mathrm{Vect}_k(M, \mathbb{H}) &\cong [M, \mathrm{Gr}(k, \infty, \mathbb{H})] = [M, BSp(k)], \end{aligned} \tag{3.105}$$

Nash's (3.67).

Worked example 3.69: Projective lines are spheres: $\mathbb{CP}^1 = S^2$ and $\mathbb{H}P^1 = S^4$

$\mathrm{Gr}(1,2,\mathbb{C}) = \mathbb{CP}^1$ has real dimension $2\cdot 1\cdot 1 = 2$; it is the Riemann sphere, $\mathbb{C}\cup\{\infty\}$, via $[z_0 : z_1] \mapsto z_1/z_0$. In exactly the same way $\mathrm{Gr}(1,2,\mathbb{H}) = \mathbb{H}P^1$, of real dimension 4, is $\mathbb{H}\cup\{\infty\} = S^4$, via $[q_0 : q_1] \mapsto q_1 q_0^{-1}$ (with quaternionic scalars acting on the right). The tautological quaternionic line bundle over $\mathbb{H}P^1$ has, by the computation of Example 3.36 word for word, clutching function

$$g(q) = q, \qquad q \in S^3 = \{|q| = 1\} = \mathrm{Sp}(1) = \mathrm{SU}(2),$$

the identity map $S^3 \to \mathrm{SU}(2)$, of degree 1. This is a generator of $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$.

Worked example 3.70: The instanton bundle

On $\mathbb{R}^4$ (compactified to S^4), an SU(2) gauge field of finite action approaches pure gauge at infinity, $A \to g^{-1}\mathrm{d}g$ on the large sphere S^3_∞, with $g : S^3_\infty \to \mathrm{SU}(2)$. Viewed on S^4 this g is the clutching function between the gauge near the origin and the gauge near infinity. The bundle, hence the topological sector, is fixed by $k = \deg g \in \pi_3(\mathrm{SU}(2)) = \mathbb{Z}$, the instanton number $k = \frac{1}{8\pi^2}\int \mathrm{tr}\, F\wedge F$ (up to the orientation sign; see Chapter 8). The BPST instanton lives on the bundle with $g(q) = q$ of Example 3.69. So $\widetilde{KU}(S^4) = \mathbb{Z}$ and $\widetilde{KSp}(S^4) = \mathbb{Z}$ below are the instanton number.

The stable range, complex and quaternionic. The dimension count of Section 3.11.5 changes only in that a section of a complex rank-k bundle is $2k$ real functions, and of a quaternionic one $4k$ real functions. A generic section is nowhere zero if $2k > n$ (respectively $4k > n$). Nash's theorem, with $[m]$ the integer part of m:

Key idea: Stable range, complex and quaternionic cases (Nash, p. 74)

Let $\dim M = n$, $k(c) = [(n+1)/2]$, $k(h) = [(n+1)/4]$. A complex bundle of rank $k > k(c)$ is isomorphic to $F_{k(c)} \oplus I^{k-k(c)}$; a quaternionic bundle of rank $k > k(h)$ is isomorphic to $F_{k(h)} \oplus I^{k-k(h)}$. In particular it is enough that $k > n/2$ (complex) or $k > n/4$ (quaternionic). Then

$$\mathrm{Vect}_k(M,\mathbb{C}) \cong \widetilde{KU}(M) \ \ (k > \tfrac{n}{2}), \qquad \mathrm{Vect}_k(M,\mathbb{H}) \cong \widetilde{KSp}(M) \ \ (k > \tfrac{n}{4}). \tag{3.106}$$

We write $\widetilde{KO}$, $\widetilde{KU}$, $\widetilde{KSp}$ for the real, complex and quaternionic theories. (When no letter is given, "K" usually means KU.) Clutching gives, exactly as in (3.101),

$$\widetilde{KU}(S^n) \cong \pi_{n-1}(\mathrm{U}(k)) \ \ (k > \tfrac{n}{2}), \qquad \widetilde{KSp}(S^n) \cong \pi_{n-1}(\mathrm{Sp}(k)) \ \ (k > \tfrac{n}{4}), \tag{3.107}$$

Nash's (3.69), and the stability ranges (3.102) confirm that these k are large enough.

Watch out: Nash's bound is sufficient, not sharp

The condition $k > k(c)$ is sometimes stronger than needed. For example, on S^2 the complex line bundles ($k = 1$, not $> n/2 = 1$) already map bijectively to $\widetilde{KU}(S^2)$: $H^{\otimes d} \mapsto [H^{\otimes d}] - 1 = d\,([H]-1)$ (see (3.110) below). For isomorphism one needs a nonvanishing section over $M\times[0,1]$ for the next rank, $2(k+1) > n+1$, and for the splitting only $2(k+1) > n$; for $n = 2$, $k = 1$ both hold ($4 > 3$). Nash's rounded bounds are always safe.

The complex and quaternionic tables

Inserting the homotopy groups (Nash's (3.70)):

$\pi_{n-1}(\mathrm{U}(k)),\ \pi_{n-1}(\mathrm{Sp}(k))$	$\widetilde{KU}(S^n)$	$\widetilde{KSp}(S^n)$
$n=0$	$\mathbb{Z}$	$\mathbb{Z}$
$n=1:\ \pi_0(\mathrm{U})=0,\ \pi_0(\mathrm{Sp})=0$	0	0
$n=2:\ \pi_1(\mathrm{U})=\mathbb{Z},\ \pi_1(\mathrm{Sp})=0$	$\mathbb{Z}$	0
$n=3:\ \pi_2(\mathrm{U})=0,\ \pi_2(\mathrm{Sp})=0$	0	0
$n=4:\ \pi_3(\mathrm{U})=\mathbb{Z},\ \pi_3(\mathrm{Sp})=\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}$

(3.108)

Why each entry:

- π_0: $\mathrm{U}(k)$ and $\mathrm{Sp}(k)$ are *connected* (every unitary matrix is e^{iX} with X Hermitian; shrink X to 0). So there is no Möbius-type bundle over S^1 in the complex world (Example 3.51).
- $\pi_1(\mathrm{U}(k))=\mathbb{Z}$: the determinant $\det:\mathrm{U}(k)\to\mathrm{U}(1)$ has simply connected fibre $\mathrm{SU}(k)$, so loops in $\mathrm{U}(k)$ are classified by the winding of their determinant. $\pi_1(\mathrm{Sp}(k))=0$ because $\mathrm{Sp}(1)=S^3$ is simply connected and the group is stable already.
- $\pi_2=0$: Cartan's theorem again.
- $\pi_3=\mathbb{Z}$: for both, generated by $\mathrm{SU}(2)=\mathrm{Sp}(1)=S^3\subset\mathrm{U}(k)$ or $\mathrm{Sp}(k)$, and measured by the instanton number (second Chern class).

Nash points out: *the* $\widetilde{KU}(S^n)$ *have period* 2 *in* n, $\mathbb{Z},0,\mathbb{Z},0,\mathbb{Z},\ldots$, and this persists for all n. That is Bott periodicity, the subject of the next section.

	S^0	S^1	S^2	S^3	S^4	S^5	S^6	S^7	S^8
$\widetilde{KO}$	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	0	$\mathbb{Z}$	0	0	0	$\mathbb{Z}$
$\widetilde{KU}$	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$

Nash (3.65), (3.70) — beyond Nash's table (Bott periodicity)

Figure 3.47: The reduced K-groups of spheres. The columns left of the dashed line are Nash's tables, computed from homotopy groups of $\mathrm{O}(k)$, $\mathrm{U}(k)$ and $\mathrm{Sp}(k)$. To the right, the values that Bott periodicity predicts: $\widetilde{KU}$ repeats with period 2 (blue), $\widetilde{KO}$ with period 8 (orange), and $\widetilde{KSp}$ is $\widetilde{KO}$ shifted by 4 (green).

3.12.7 The ring $K(S^2)$ from clutching: $(H-1)^2=0$

We can now prove the relation $H\oplus H\cong H^{\otimes 2}\oplus I$ promised in Example 3.55, and with it the full ring structure of $K(S^2)$. This is the one computation on which complex Bott periodicity rests.

Rank-k complex bundles over S^2. By (3.98) with $\mathrm{U}(k)$, they correspond to $\pi_1(\mathrm{U}(k))=\mathbb{Z}$, detected by the winding number of $\det g$. So two clutching functions $g,g':S^1\to\mathrm{U}(k)$ give isomorphic bundles if and only if $\det g$ and $\det g'$ have the same winding number. In particular, every rank-k bundle is $H^{\otimes d}\oplus I^{k-1}$ for a unique $d\in\mathbb{Z}$ (clutching $\mathrm{diag}(z^d,1,\ldots,1)$, determinant z^d).

The key isomorphism. Compare

$$H \oplus H:\ g = \begin{pmatrix} z & 0 \\ 0 & z \end{pmatrix}, \qquad H^{\otimes 2} \oplus I:\ g' = \begin{pmatrix} z^2 & 0 \\ 0 & 1 \end{pmatrix} \qquad (z = e^{i\phi}).$$

Both determinants are z^2, so the bundles are isomorphic. It is instructive to see the homotopy explicitly. Let $R(t) = \begin{pmatrix} \cos\frac{\pi t}{2} & -\sin\frac{\pi t}{2} \\ \sin\frac{\pi t}{2} & \cos\frac{\pi t}{2} \end{pmatrix}$ and

$$g_t(z) = \begin{pmatrix} z & 0 \\ 0 & 1 \end{pmatrix} R(t) \begin{pmatrix} z & 0 \\ 0 & 1 \end{pmatrix} R(t)^{-1}, \qquad t \in [0,1].$$

Each $g_t(z)$ is a product of unitary matrices, hence unitary, and depends continuously on (t, z). At the two ends:

$$\begin{aligned} g_0(z) &\overset{(1)}{=} \begin{pmatrix} z & 0 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} z & 0 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} z^2 & 0 \\ 0 & 1 \end{pmatrix} = g'(z), \\ g_1(z) &\overset{(2)}{=} \begin{pmatrix} z & 0 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} z & 0 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \\ &\overset{(3)}{=} \begin{pmatrix} z & 0 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 0 & z \end{pmatrix} = \begin{pmatrix} z & 0 \\ 0 & z \end{pmatrix} = g(z). \end{aligned}$$

(1) $R(0) = 1$.
(2) $R(1)$ is the rotation by $90°$; its inverse is its transpose.
(3) Conjugating a diagonal matrix by the $90°$ rotation swaps its diagonal entries:

$$\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} z & 0 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & -1 \\ z & 0 \end{pmatrix}\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & z \end{pmatrix}.$$

So $g \simeq g'$ and

$$H \oplus H \ \cong\ H^{\otimes 2} \oplus I. \tag{3.109}$$

Key idea: The ring $K(S^2)$

In $K(S^2)$ write H for $[H]$. Then (3.109) says $2H = H^2 + 1$, i.e.

$$(H-1)^2 = 0, \qquad K(S^2) = \mathbb{Z}[H]/(H-1)^2, \qquad \widetilde{KU}(S^2) = \mathbb{Z}\cdot b,\ \ b = H-1,\ \ b^2 = 0.$$

Let us derive H^n for every integer n from this. With $H = 1 + b$ and $b^2 = 0$, for $n \geq 0$:

$$\begin{aligned} H^n &\overset{(1)}{=} (1+b)^n \\ &\overset{(2)}{=} 1 + nb + \tbinom{n}{2} b^2 + \cdots \\ &\overset{(3)}{=} 1 + n\,b = 1 + n(H-1). \end{aligned} \tag{3.110}$$

(1) $H = 1 + b$ by definition of b.
(2) Binomial theorem (the ring is commutative).
(3) $b^2 = 0$ kills every term beyond the linear one.

For negative powers, $(1+b)(1-b) = 1 - b^2 = 1$, so $H^{-1} = [H^*] = 1 - b = 2 - H$, agreeing with $[H] + [H^*] = 2$ from Example 3.50. Then $H^{-n} = (1-b)^n = 1 - nb$, so (3.110) holds for all $n \in \mathbb{Z}$. Consequences:

- The line bundle $H^{\otimes d}$ (monopole charge d, up to the sign convention) has K-class $1+d\,b$: *the reduced K-class of a line bundle over S^2 is its monopole charge times the generator*. In particular $\widetilde{KU}(S^2)=\mathbb{Z}$ is detected by c_1.
- $[TS^2]=H^{-2}=1-2b$ in $KU(S^2)$ (complex structure), so TS^2 is *not* stably trivial as a complex bundle, while its underlying real bundle is (Example 3.68).
- Tensor products are computed by multiplying out. For example $[H^{\otimes 2}\oplus I]\cdot[H^*]=(H^2+1)H^{-1}=H+H^{-1}=(1+b)+(1-b)=2$, and indeed $(H^{\otimes 2}\oplus I)\otimes H^*\cong H\oplus H^*\cong I^2$ (the last step by Example 3.44).

Physical picture: Why $b^2=0$ is "obvious" in cohomology

The Chern character (the subject of Nash's next section, §5) sends $H\mapsto e^{c_1(H)}=1+c_1(H)+\frac{1}{2}c_1(H)^2+\cdots$. On S^2 there are no 4-forms, so $c_1^2=0$ and $\mathrm{ch}(H)=1+c_1(H)$, $\mathrm{ch}(b)=c_1(H)$, $\mathrm{ch}(b)^2=0$. The K-theory relation $b^2=0$ is the shadow of "no forms of degree higher than $\dim S^2$". What is remarkable is that it holds in K-theory itself, with integer coefficients, where it is proved by the explicit homotopy above.

Worked example 3.71: A stably trivial but non-trivial complex bundle

Stability can fail below the stable range even for complex bundles. Take S^5 and rank 2 (note $2<5/2$). Rank-2 bundles correspond to $\pi_4(\mathrm{U}(2))$. Topologically $\mathrm{U}(2)\cong\mathrm{U}(1)\times\mathrm{SU}(2)=S^1\times S^3$, so $\pi_4(\mathrm{U}(2))=\pi_4(S^3)=\mathbb{Z}_2$: there is exactly one non-trivial rank-2 complex bundle E over S^5. But $\pi_4(\mathrm{U}(k))$ for $k\geq 3$ is the stable group $\pi_4(\mathrm{U})=\widetilde{KU}(S^5)=0$ (from Bott periodicity: $\widetilde{KU}$ of an odd sphere vanishes). So $E\oplus I\cong I^3$: E is invisible to K-theory.

Reading Nash (pp. 72–75, (3.63)–(3.70))

Nash sets $M=S^n$ in (3.62) to get (3.63), mentions the free/based subtlety, and then describes clutching in one paragraph: cover S^n by two hemispheres, the bundle is trivial on each, and the transition function on the overlap gives an element of $\pi_{n-1}(\mathrm{O}(k))$. He digresses on $[S^n,BG]=[S^{n-1},G]$ and $\Omega BG\simeq G$, arrives at (3.64), quotes the stability of $\pi_{n-1}(\mathrm{O}(k))$ and the table (3.65) from Husemoller, then repeats everything for $\mathbb{C}$ and $\mathbb{H}$: Grassmannians (3.66), classification (3.67), stable range theorem with $k(c)$, $k(h)$, (3.68), (3.69) and the table (3.70), remarking on the period 2 of $\widetilde{KU}(S^n)$. We have supplied: why bundles over discs are trivial, why only the homotopy class of the clutching function matters, the winding integral, the adjunction and the holonomy picture of $\Omega BG\simeq G$, the fibration argument for stability, a line-by-line justification of both tables, the explicit $\pi_1(\mathrm{SO}(3))=\mathbb{Z}_2$ computation, quaternions and $\mathbb{H}P^1=S^4$, the instanton interpretation, and the explicit proof of $(H-1)^2=0$.

Recap

- A bundle over S^n is trivial on each hemisphere and is fixed by the clutching function $g:S^{n-1}\to G$ up to homotopy: $\mathrm{Vect}_k(S^n)=\pi_{n-1}(G)$.
- $[S^n,BG]=[S^{n-1},G]$ because $\Omega BG\simeq G$ (holonomy).
- $\widetilde{K}(S^n)=\pi_{n-1}(\mathrm{O}(k))$, $\pi_{n-1}(\mathrm{U}(k))$, $\pi_{n-1}(\mathrm{Sp}(k))$ in the stable range; the groups stabilise by the fibrations $G(k)\to G(k+1)\to S^\bullet$.
- Tables: $\widetilde{KO}(S^n)=\mathbb{Z},\mathbb{Z}_2,\mathbb{Z}_2,0,\mathbb{Z}$; $\widetilde{KU}(S^n)=\mathbb{Z},0,\mathbb{Z},0,\mathbb{Z}$; $\widetilde{KSp}(S^n)=\mathbb{Z},0,0,0,\mathbb{Z}$ for

$n = 0, \dots, 4$.

- $H \oplus H \cong H^2 \oplus I$ by an explicit homotopy of clutching functions, so $K(S^2) = \mathbb{Z}[H]/(H-1)^2$ and $H^n = 1 + n(H-1)$.

3.13 Bott periodicity

The tables of the previous section showed a pattern: $\widetilde{KU}(S^n) = \mathbb{Z}, 0, \mathbb{Z}, 0, \mathbb{Z}$ for $n = 0, \dots, 4$. Bott's theorem says the pattern never stops. It is one of the deepest facts in topology, and it is the reason K-theory is so computable: once you know K^0 and K^{-1} you know everything.

Nash first states it as a fact about homotopy groups of the unitary group (the original form, due to Bott, 1959), and then reformulates it as a statement internal to K-theory: multiplication by the Hopf class $b = [H] - 1$ is an isomorphism $\widetilde{KU}^{-n}(X) \to \widetilde{KU}^{-n-2}(X)$. We follow the same route, filling in the definitions of suspension, wedge and smash product on the way, and adding a physicist's sketch of *why* it is true. As in Nash, we treat the complex case first and leave the real and quaternionic cases to Section 3.14.

3.13.1 Periodicity of the homotopy of $\mathrm{U}(\infty)$

Embed each unitary group in the next as the upper-left block,

$$\mathrm{U}(k) \hookrightarrow \mathrm{U}(k+1), \qquad A \longmapsto \begin{pmatrix} A & 0 \\ 0 & 1 \end{pmatrix},$$

and let $\mathrm{U} = \mathrm{U}(\infty) = \bigcup_k \mathrm{U}(k)$, the **infinite unitary group**: unitary matrices of any size that differ from the identity in finitely many entries. By the stability (3.102), $\pi_j(\mathrm{U}(k))$ does not change once $k > j/2$, and that common value is $\pi_j(\mathrm{U})$. Letting $k \to \infty$ in (3.107):

$$\widetilde{KU}(S^n) = \pi_{n-1}(\mathrm{U}(\infty)). \tag{3.111}$$

This is Nash's (3.71).

Key idea: Bott periodicity, homotopy form (Nash (3.72))

$$\pi_n(\mathrm{U}(\infty)) = \pi_{n+2}(\mathrm{U}(\infty)) \qquad \text{for all } n \geq 0, \qquad \text{i.e.} \qquad \pi_n(\mathrm{U}) = \begin{cases} 0, & n \text{ even}, \\ \mathbb{Z}, & n \text{ odd}. \end{cases}$$

Combined with (3.111) this gives Nash's (3.73) immediately:

$$\begin{aligned} \widetilde{KU}(S^n) &\overset{(1)}{=} \pi_{n-1}(\mathrm{U}) \\ &\overset{(2)}{=} \pi_{n+1}(\mathrm{U}) \\ &\overset{(1)}{=} \widetilde{KU}(S^{n+2}). \end{aligned} \tag{3.112}$$

(1) Clutching and stability, (3.111) (with n and $n+2$).
(2) Bott periodicity with $n \to n-1$.

The periodicity is a *stable* phenomenon. For small k the groups $\pi_j(\mathrm{U}(k))$ are wild: $\pi_4(\mathrm{U}(2)) = \mathbb{Z}_2$ (Example 3.71), $\pi_5(\mathrm{U}(2)) = \pi_5(S^3) = \mathbb{Z}_2$, $\pi_6(\mathrm{U}(2)) = \pi_6(S^3) = \mathbb{Z}_{12}$, and so on, reflecting the notoriously complicated homotopy groups of spheres. Only after enough stabilisation does the simple pattern emerge (Figure 3.48).

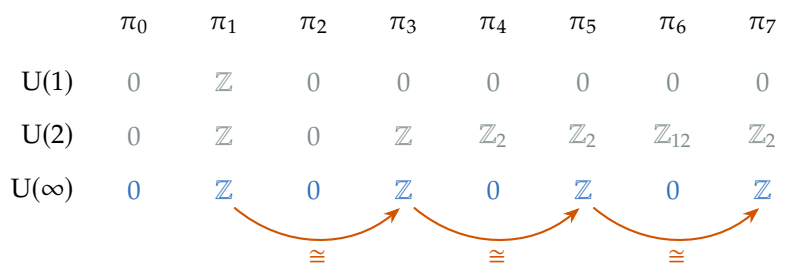

Figure 3.48: Homotopy groups of unitary groups. The small groups U(1) and U(2) (grey) have irregular homotopy, inherited from spheres ($\mathrm{U}(1) = S^1$; $\mathrm{U}(2) \cong S^1 \times S^3$). The infinite unitary group (blue) has the simple pattern $0, \mathbb{Z}, 0, \mathbb{Z}, \ldots$ with period two (orange arrows). This regularity is Bott periodicity.

Worked example 3.72: The odd homotopy of U as winding numbers

The $\mathbb{Z}$'s in odd degree are detected by integrals of the Maurer–Cartan form $g^{-1}\mathrm{d}g$, the same object as a pure-gauge field. For $g : S^1 \to \mathrm{U}(k)$,

$$w_1(g) = \frac{1}{2\pi i} \oint_{S^1} \operatorname{tr}\left(g^{-1}\mathrm{d}g\right) \in \mathbb{Z},$$

which equals the winding of $\det g$ (since $\operatorname{tr}(g^{-1}\mathrm{d}g) = \mathrm{d}\log\det g$). For $g : S^3 \to \mathrm{U}(k)$,

$$w_3(g) = \frac{1}{24\pi^2} \int_{S^3} \operatorname{tr}\left(g^{-1}\mathrm{d}g\right)^3 \in \mathbb{Z}$$

(up to an orientation sign). Let us check the normalisation on the generator $g(q) = q$ of Example 3.69, $S^3 = \mathrm{SU}(2)$. The integrand is left-invariant ($g \mapsto hg$ leaves $g^{-1}\mathrm{d}g$ unchanged), so it is a constant multiple of the volume form, and we evaluate it at $g = 1$. There, with $q = x^0 - i\,x^a\sigma_a$ near $x = (1,0,0,0)$, we have $g^{-1}\mathrm{d}g = -i\sigma_a\,\mathrm{d}x^a$, and

$$\begin{aligned}\operatorname{tr}\left(g^{-1}\mathrm{d}g\right)^3 &\overset{(1)}{=} (-i)^3\,\operatorname{tr}(\sigma_a\sigma_b\sigma_c)\,\mathrm{d}x^a\wedge\mathrm{d}x^b\wedge\mathrm{d}x^c\\ &\overset{(2)}{=} i\cdot 2i\,\varepsilon_{abc}\,\mathrm{d}x^a\wedge\mathrm{d}x^b\wedge\mathrm{d}x^c\\ &\overset{(3)}{=} -2\cdot 3!\,\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3 = -12\,\mathrm{vol}.\end{aligned}$$

(1) Multiply out; the $\mathrm{d}x$'s anticommute, the σ's do not.
(2) $(-i)^3 = i$, and only the totally antisymmetric part of $\operatorname{tr}(\sigma_a\sigma_b\sigma_c) = 2i\varepsilon_{abc} +$ (symmetric in two indices) survives against the wedge product.
(3) $\varepsilon_{abc}\,\mathrm{d}x^a\wedge\mathrm{d}x^b\wedge\mathrm{d}x^c = 3!\,\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3$, which at $x = (1,0,0,0)$ is the volume form of the unit S^3.

Since $\mathrm{Vol}(S^3) = 2\pi^2$, $w_3 = \frac{-12\cdot 2\pi^2}{24\pi^2} = -1$: a unit winding, with a sign fixed by orientation. This is exactly the instanton number of the BPST instanton (Example 3.70), computed from its behaviour at infinity. The next one, w_5 for $\pi_5(\mathrm{U}) = \mathbb{Z}$, governs the non-abelian anomaly in four dimensions (Chapter 10).

3.13.2 Loop spaces: $\Omega^2\mathrm{U} \simeq \mathrm{U}$

Why should π_n and π_{n+2} agree? Nash recalls, from Chapter 1 and the adjunction (3.99),

$$\pi_n(X) = \pi_{n-1}(\Omega X) \qquad\Longrightarrow\qquad \pi_n(X) = \pi_{n-2}(\Omega^2 X). \tag{3.113}$$

With $X = \mathrm{U}$ this gives $\pi_{n+2}(\mathrm{U}) = \pi_n(\Omega^2\mathrm{U})$. So periodicity would follow if the double loop space of U looked like U itself. That is what Bott proved:

$$\Omega^2\mathrm{U} \;\simeq\; \mathrm{U},$$

more precisely in two steps,

$$\Omega\mathrm{U} \;\simeq\; \mathbb{Z}\times BU, \qquad \Omega(\mathbb{Z}\times BU) = \Omega BU \;\simeq\; \mathrm{U}. \tag{3.114}$$

The second step is $\Omega BG \simeq G$ from Section 3.12.3 (loops based at a point only see one component, so the $\mathbb{Z}$ drops out). The first step is the real content. Here is Bott's idea, which uses Morse theory (Chapter 7) on the loop space.

Physical picture: Bott's proof: minimal geodesics from 1 to -1

Think of $\Omega\mathrm{SU}(2m)$ as the space of paths from 1 to -1 in $\mathrm{SU}(2m)$ (a path space is homotopy equivalent to a loop space). Give each path its energy $\int |\dot\gamma|^2\,\mathrm{d}t$. Critical points are geodesics $\gamma(t) = \exp(i\pi t A)$ with A Hermitian and $\exp(i\pi A) = -1$, so the eigenvalues of A are odd integers, summing to zero (for $\det = 1$). The energy is proportional to $\mathrm{tr}\,A^2$, so the *minimal* geodesics have all eigenvalues ±1, m of each:

$$A = 2\Pi - 1, \qquad \Pi \text{ a projector of rank } m \text{ on } \mathbb{C}^{2m}.$$

So the space of minimal geodesics is exactly the Grassmannian $\mathrm{Gr}(m, 2m, \mathbb{C})$. Morse theory says the loop space is built from the minimum by attaching cells of dimension equal to the Morse indices of the other geodesics, and Bott computed that these indices grow like $2m$. As $m \to \infty$ the non-minimal geodesics are pushed to infinite dimension and become invisible to homotopy groups of any fixed degree:

$$\Omega\mathrm{SU} \;\simeq\; \mathrm{Gr}(\infty, \infty, \mathbb{C}) = BU.$$

For U instead of SU the paths also have a winding number of the determinant, giving the extra $\mathbb{Z}$ in $\Omega\mathrm{U} \simeq \mathbb{Z}\times BU$.

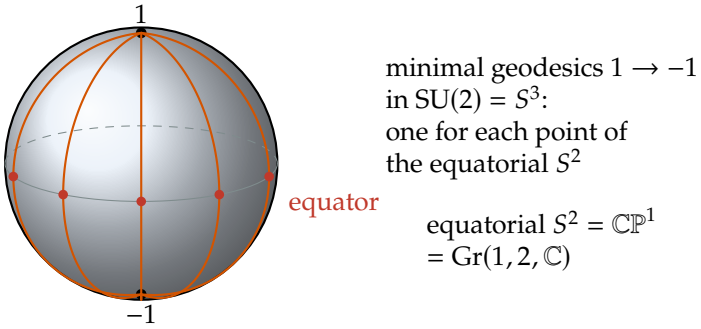

Figure 3.49: A cartoon of Bott's proof in the smallest case, drawn one dimension down. In $\mathrm{SU}(2) = S^3$ the shortest paths from 1 (north pole) to -1 (south pole) are the great semicircles (orange). Each crosses the equatorial 2-sphere at one point (red), so the space of minimal geodesics is $S^2 = \mathbb{CP}^1 = \mathrm{Gr}(1,2,\mathbb{C})$. In $\mathrm{SU}(2m)$ the same count gives $\mathrm{Gr}(m,2m,\mathbb{C})$, and as $m \to \infty$ this approximates the whole loop space: $\Omega\mathrm{SU} \simeq BU$.

Worked example 3.73: Checking $\Omega\mathrm{U} \simeq \mathbb{Z} \times BU$ on low homotopy groups

Take π_j of both sides, using $\pi_j(\Omega\mathrm{U}) = \pi_{j+1}(\mathrm{U})$ and $\pi_j(BU) = \pi_{j-1}(\mathrm{U})$ (the latter from $\Omega BU \simeq \mathrm{U}$):

$$\begin{aligned} \pi_0(\Omega\mathrm{U}) &\overset{(1)}{=} \pi_1(\mathrm{U}) = \mathbb{Z} && \text{vs} \quad \pi_0(\mathbb{Z} \times BU) = \mathbb{Z}, \\ \pi_1(\Omega\mathrm{U}) &\overset{(1)}{=} \pi_2(\mathrm{U}) = 0 && \text{vs} \quad \pi_1(BU) \overset{(2)}{=} \pi_0(\mathrm{U}) = 0, \\ \pi_2(\Omega\mathrm{U}) &\overset{(1)}{=} \pi_3(\mathrm{U}) = \mathbb{Z} && \text{vs} \quad \pi_2(BU) \overset{(2)}{=} \pi_1(\mathrm{U}) = \mathbb{Z}. \end{aligned}$$

(1) (3.113).
(2) $\Omega BU \simeq \mathrm{U}$.

The two sides agree, as they must. Note that $\pi_2(BU) = \mathbb{Z}$ is the monopole charge of Example 3.63 and $\pi_2(\Omega\mathrm{U}) = \pi_3(\mathrm{U}) = \mathbb{Z}$ is the instanton winding: Bott periodicity identifies them.

3.13.3 Suspension and the groups K^{-n}

To state periodicity for any space X, not just spheres, Nash defines the negative-degree K-groups using suspension.

Recall the **reduced suspension** SX (Section 3.12.3): $X \times [0,1]$ with $X \times \{0\}$, $X \times \{1\}$ and $\{x_0\} \times [0,1]$ collapsed to one point. Picture it as a double cone on X, pinched along a line (Figure 3.50). Iterate: $S^n X = S(S^{n-1}X)$. The key example is $SS^m \cong S^{m+1}$: the double cone on a circle is a sphere.

Working definition 3.32 (negative K-groups)

$$\widetilde{KU}^{-n}(X) := \widetilde{KU}(S^n X), \qquad n = 0, 1, 2, \dots \tag{3.115}$$

[$\widetilde{KU}$ is reduced K-theory, the virtual bundles of virtual dimension 0, and $S^n X$ is the n-fold suspension] (Nash's (3.75)). For the unreduced groups use $X_+ = X \sqcup \{\mathrm{pt}\}$ (add a disjoint base point) and set $KU^{-n}(X) = \widetilde{KU}^{-n}(X_+)$; for $n = 0$ this gives back $KU(X)$, since $\widetilde{K}(X_+) = K(X \sqcup \mathrm{pt})/K(\mathrm{pt}) = K(X)$ [$K(X \sqcup \mathrm{pt}) = K(X) \oplus \mathbb{Z}$, the $\mathbb{Z}$ recording the rank on the extra point].

For spheres, repeatedly using $SS^m = S^{m+1}$:

$$\widetilde{KU}^{-n}(S^m) \overset{(1)}{=} \widetilde{KU}(S^n S^m) \overset{(2)}{=} \widetilde{KU}(S^{m+n}), \tag{3.116}$$

Nash's (3.76), where (1) is the definition (3.115) and (2) is $SS^m \cong S^{m+1}$ applied n times.

The K-theory of a point in every degree. Take $X = \mathrm{pt}$, so $X_+ = S^0$ and $S^n S^0 = S^n$:

$$KU^{-n}(\mathrm{pt}) \overset{(1)}{=} \widetilde{KU}(S^n S^0) \overset{(2)}{=} \widetilde{KU}(S^n) \overset{(3)}{=} \begin{cases} \mathbb{Z}, & n \text{ even}, \\ 0, & n \text{ odd}. \end{cases}$$

(1) Definition, with $\mathrm{pt}_+ = S^0$.
(2) $S^n S^0 \cong S^n$.
(3) Bott periodicity and the table (3.108).

This is the failure of the dimension axiom announced in Section 3.8.3 and drawn in Figure 3.33.

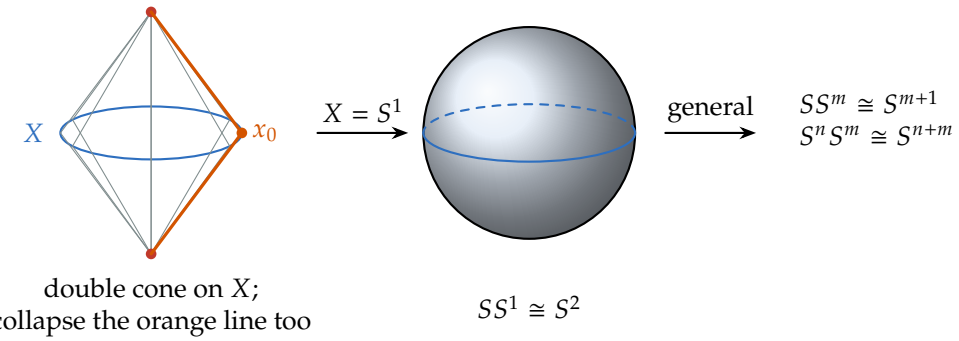

Figure 3.50: The reduced suspension. Stack copies of X over the interval $[0,1]$, shrink the top and bottom copies to points (red), and also collapse the segment over the base point x_0 (orange). For X a circle the result is a sphere: each copy of the circle becomes a line of latitude. Collapsing the orange segment in addition changes nothing up to homotopy for nice spaces, but makes the construction compatible with base points.

K^{-1} is maps into U. For a based space X the classifying space picture gives a neat description:

$$\begin{aligned}\widetilde{KU}^{-1}(X) &\overset{(1)}{=} \widetilde{KU}(SX)\\ &\overset{(2)}{=} [SX, BU]\\ &\overset{(3)}{=} [X, \Omega BU]\\ &\overset{(4)}{=} [X, \mathrm{U}].\end{aligned} \tag{3.117}$$

(1) Definition (3.115).
(2) Stable classes are classified by maps to $BU = \mathrm{Gr}(\infty, \infty, \mathbb{C})$ (the stable range statement (3.106) with $k \to \infty$; SX is connected).
(3) Adjunction (3.99).
(4) $\Omega BU \simeq \mathrm{U}$.

Similarly $KU(X) = [X, \mathbb{Z} \times BU]$, the $\mathbb{Z}$ recording the virtual rank. So the two basic K-groups are homotopy classes of maps into the two spaces $\mathbb{Z} \times BU$ and U, and by (3.114) each is the loop space of the other. An element of $K^{-1}(X)$ is concretely a family of unitary matrices $g(x)$, i.e. a clutching function; for $X = S^1$ it is a loop of unitaries, and $\widetilde{KU}^{-1}(S^1) = \widetilde{KU}(S^2) = \mathbb{Z}$ counts its winding.

Dictionary: K^0 and K^{-1} in physics

$KU^0(X) = [X, \mathbb{Z} \times BU]$	families of subspaces/projectors: filled bands of a gapped Hamiltonian, Chern insulators; D-brane charges in type IIB
$KU^{-1}(X) = [X, \mathrm{U}]$	families of unitaries: gauge transformations, Floquet operators, chiral-symmetric Hamiltonians; D-brane charges in type IIA
Bott map $K^{-n} \to K^{-n-2}$	dimensional shift of topological phases by 2 (class A: Chern number in $d = 2$, second Chern number in $d = 4$)

3.13.4 Products: internal and external

The K-theoretic form of Bott periodicity uses a product. Nash distinguishes two.

Internal product. The ring structure of Section 3.10.7, induced by $\otimes$:

$$\beta : KU(X) \otimes KU(X) \to KU(X), \qquad a \otimes b \mapsto a \bullet b.$$

Nash's footnote 5 explains the notation: one usually writes a product on a set S as a map $S \times S \to S$, but because $KU(X)$ is an abelian group and the product is bilinear, it is a linear map on the tensor product of groups $KU(X) \otimes_{\mathbb{Z}} KU(X)$. (Here $\otimes$ of abelian groups: $\mathbb{Z} \otimes A = A$, $\mathbb{Z}^a \otimes \mathbb{Z}^b = \mathbb{Z}^{ab}$, $\mathbb{Z}_2 \otimes \mathbb{Z} = \mathbb{Z}_2$.)

External product. This involves two spaces. Let $\pi_X : X \times Y \to X$ and $\pi_Y : X \times Y \to Y$ be the projections, which induce pullbacks

$$\pi_X^* : KU(X) \to KU(X \times Y), \qquad \pi_Y^* : KU(Y) \to KU(X \times Y) \tag{3.118}$$

(Nash's (3.78)). Then (Nash's (3.77), (3.79))

$$\alpha : KU(X) \otimes KU(Y) \to KU(X \times Y), \qquad c \otimes d \longmapsto \pi_X^*(c) \bullet \pi_Y^*(d). \tag{3.119}$$

Working definition 3.33 (external tensor product of bundles)

For bundles $E \to X$ and $F \to Y$, the **external tensor product** $E \boxtimes F := \pi_X^* E \otimes \pi_Y^* F$ [$\pi_X^* E$ has fibre E_x at (x, y), whatever y is] is the bundle over $X \times Y$ with fibre $E_x \otimes F_y$ at (x, y). Its transition functions are the Kronecker products $g^E_{ab}(x) \otimes g^F_{cd}(y)$ on the product patches $U_a \times V_c$. On K-classes, $\alpha([E] \otimes [F]) = [E \boxtimes F]$.

Worked example 3.74: $K(S^2 \times S^2)$ and the Bott class

Take $X = Y = S^2$, and let $b_1 = \pi_1^* b$, $b_2 = \pi_2^* b$ be the Hopf class pulled back from each factor. Then $b_1^2 = \pi_1^*(b^2) = 0$, $b_2^2 = 0$, and the periodicity theorem below says α is an isomorphism, so

$$K(S^2 \times S^2) \cong K(S^2) \otimes K(S^2) = \mathbb{Z}[b_1, b_2]/(b_1^2, b_2^2),$$

free abelian of rank 4 with basis $1, b_1, b_2, b_1 b_2$. (Compare $H^\bullet(S^2 \times S^2)$: also rank 4, in degrees $0, 2, 2, 4$.) The line bundle $H^{\otimes p} \boxtimes H^{\otimes q}$ has class

$$\begin{aligned} [H^{\otimes p} \boxtimes H^{\otimes q}] &\overset{(1)}{=} \pi_1^*[H^{\otimes p}] \bullet \pi_2^*[H^{\otimes q}] \\ &\overset{(2)}{=} (1 + p\, b_1)(1 + q\, b_2) \\ &= 1 + p\, b_1 + q\, b_2 + pq\, b_1 b_2. \end{aligned}$$

(1) Definition of $\boxtimes$ and (3.119).
(2) $[H^{\otimes n}] = 1 + nb$, (3.110), pulled back.

The top class $b_1 b_2 = b \boxtimes b$ restricts to zero on $S^2 \vee S^2$ and will turn out to be the generator of $\widetilde{KU}(S^4)$: the **Bott class**. Under the Chern character it maps to $c_1 \boxtimes c_1$, which integrates to ± 1 over $S^2 \times S^2$: it is an "instanton number one" class.

3.13.5 Wedges, smashes, and the reduced external product

Nash states the key fact first: *for $Y = S^2$, α is an isomorphism* (his (3.80)),

$$KU(X) \otimes KU(S^2) \cong KU(X \times S^2). \tag{3.120}$$

To connect this with periodicity of $\widetilde{KU}(S^n)$ he rewrites both sides in reduced K-theory. That needs two constructions.

Working definition 3.34 (wedge and smash)

For based spaces [spaces with one chosen point] (X, x_0) and (Y, y_0):

- the **wedge** $X \vee Y$ is the disjoint union with the two base points identified; inside $X \times Y$ it is $X \times \{y_0\} \cup \{x_0\} \times Y$ (the "axes");
- the **smash** $X \wedge Y = (X \times Y)/(X \vee Y)$ collapses the axes to a single point.

Worked example 3.75: $S^1 \wedge S^1 = S^2$

$S^1 \times S^1$ is the torus, a square with opposite sides identified. $S^1 \vee S^1$ is the figure-eight formed by the two circles $\theta_1 = 0$ and $\theta_2 = 0$, which in the square are the boundary edges. Collapsing the whole boundary of a square to one point gives a sphere (Figure 3.51). In general $S^n \wedge S^m \cong S^{n+m}$: S^n is $\mathbb{R}^n$ plus a point at infinity, $S^n \times S^m$ minus the axes is $\mathbb{R}^n \times \mathbb{R}^m = \mathbb{R}^{n+m}$, and collapsing the axes adds back one point at infinity. Also $SX \cong S^1 \wedge X$, so $S^n X \cong S^n \wedge X$.

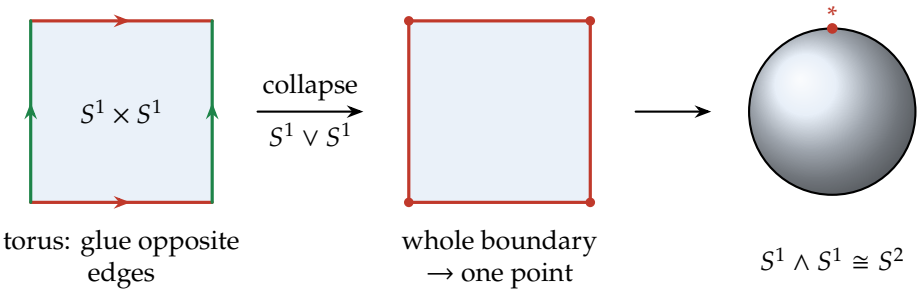

Figure 3.51: The smash product of two circles. The torus is a square with opposite edges glued (red to red, green to green). The two glued edge circles form the wedge $S^1 \vee S^1$. Collapsing them means collapsing the entire boundary of the square to one point, which turns the open square ($\cong \mathbb{R}^2$) into a sphere with the collapsed boundary as its north pole.

Reducing the left side of α. Write $KU(X) = \widetilde{KU}(X) \oplus \mathbb{Z}$ ((3.89), with the $\mathbb{Z}$ coming from the base point x_0) and similarly for Y. Tensor products distribute over direct sums, and $\mathbb{Z} \otimes A = A$:

$$\begin{aligned} KU(X) \otimes KU(Y) &\overset{(1)}{=} \left(\widetilde{KU}(X) \oplus \mathbb{Z}\right) \otimes \left(\widetilde{KU}(Y) \oplus \mathbb{Z}\right) \\ &\overset{(2)}{=} \left(\widetilde{KU}(X) \otimes \widetilde{KU}(Y)\right) \oplus \left(\widetilde{KU}(X) \otimes \mathbb{Z}\right) \oplus \left(\mathbb{Z} \otimes \widetilde{KU}(Y)\right) \oplus (\mathbb{Z} \otimes \mathbb{Z}) \\ &\overset{(3)}{=} \left(\widetilde{KU}(X) \otimes \widetilde{KU}(Y)\right) \oplus \widetilde{KU}(X) \oplus \widetilde{KU}(Y) \oplus \mathbb{Z}. \end{aligned} \tag{3.121}$$

(1) The splitting (3.89) for X and for Y.
(2) $\otimes$ distributes over $\oplus$.
(3) $A \otimes \mathbb{Z} \cong A$.

This is Nash's (3.81).

Reducing the right side. The inclusion and the collapse

$$X \vee Y \xrightarrow{i} X \times Y \longrightarrow \frac{X \times Y}{X \vee Y} = X \wedge Y \tag{3.122}$$

(Nash's (3.82)) induce maps on K-theory in the reverse direction, forming a short exact sequence

$$0 \to \widetilde{KU}(X \wedge Y) \to \widetilde{KU}(X \times Y) \to \widetilde{KU}(X \vee Y) \to 0 \tag{3.123}$$

(Nash's (3.83)). What the three maps mean:

- $\widetilde{KU}(X \times Y) \to \widetilde{KU}(X \vee Y)$ is restriction to the axes. It is onto, and even split: a class on $X \vee Y$ is a pair (class on X, class on Y), and $\pi_X^* a + \pi_Y^* b$ restricts to it. This also shows $\widetilde{KU}(X \vee Y) \cong \widetilde{KU}(X) \oplus \widetilde{KU}(Y)$: a bundle over a wedge is a bundle over each piece, glued along the single fibre at the common point.
- $\widetilde{KU}(X \wedge Y) \to \widetilde{KU}(X \times Y)$ pulls back along the collapse. A bundle pulled back from $X \wedge Y$ is trivial on the axes (they map to a single point).
- Exactness in the middle is the converse: a (stable) bundle on $X \times Y$ that is trivial on $X \vee Y$ can be trivialised there and then *descends* to the quotient $X \wedge Y$, where the collapsed axes carry the chosen trivialisation.

A split short exact sequence gives a direct sum (as in Section 3.10.6):

$$\begin{aligned} \widetilde{KU}(X \times Y) &\overset{(1)}{=} \widetilde{KU}(X \wedge Y) \oplus \widetilde{KU}(X \vee Y) \\ &\overset{(2)}{=} \widetilde{KU}(X \wedge Y) \oplus \widetilde{KU}(X) \oplus \widetilde{KU}(Y), \end{aligned} \tag{3.124}$$

(1) The split exact sequence (3.123).
(2) $\widetilde{KU}(X \vee Y) \cong \widetilde{KU}(X) \oplus \widetilde{KU}(Y)$.

which is Nash's (3.84). Adding the $\mathbb{Z}$ from the base point, $KU(X \times Y) = \widetilde{KU}(X \wedge Y) \oplus \widetilde{KU}(X) \oplus \widetilde{KU}(Y) \oplus \mathbb{Z}$.

The reduced product. Comparing (3.121) and (3.124), α has the form

$$\alpha : \big(\widetilde{KU}(X) \otimes \widetilde{KU}(Y)\big) \oplus R \longrightarrow \widetilde{KU}(X \wedge Y) \oplus R, \qquad R = \widetilde{KU}(X) \oplus \widetilde{KU}(Y) \oplus \mathbb{Z} \tag{3.125}$$

(Nash's (3.85)), and it is the identity on R (e.g. $a \otimes 1 \mapsto \pi_X^* a$). Discarding R leaves the **reduced external product**

$$\tilde{\alpha} : \widetilde{KU}(X) \otimes \widetilde{KU}(Y) \to \widetilde{KU}(X \wedge Y), \qquad a \otimes b \mapsto \pi_X^* a \bullet \pi_Y^* b \tag{3.126}$$

(Nash's (3.86)). Why does $\pi_X^* a \bullet \pi_Y^* b$ come from $X \wedge Y$? Restricted to $X \times \{y_0\}$ it is $a \bullet (\text{rank of } b) = a \cdot 0 = 0$, since b has virtual rank zero; similarly on $\{x_0\} \times Y$. So it vanishes on the axes, and by exactness of (3.123) it comes from $X \wedge Y$.

Worked example 3.76: $\tilde{\alpha}$ for $X = Y = S^2$

$\widetilde{KU}(S^2) \otimes \widetilde{KU}(S^2) = \mathbb{Z}b \otimes \mathbb{Z}b = \mathbb{Z}(b \otimes b)$, and $\tilde{\alpha}(b \otimes b) = b_1 b_2$, the class of Example 3.74. Since $S^2 \wedge S^2 = S^4$, the periodicity theorem says $b_1 b_2$ generates $\widetilde{KU}(S^4) = \mathbb{Z}$. So the reduced

K-theory of S^4 is generated by the "square" of the Hopf class, and by induction

$$\widetilde{KU}(S^{2j}) = \mathbb{Z} \cdot b^{\boxtimes j}, \qquad b^{\boxtimes j} = \underbrace{b \boxtimes \cdots \boxtimes b}_{j} \text{ on } S^2 \wedge \cdots \wedge S^2 = S^{2j}.$$

3.13.6 The Bott map and the periodicity theorem

Now put $Y = S^2$ in $\tilde{\alpha}$ and replace X by $S^n X$. Bott periodicity says the result is an isomorphism:

$$\begin{aligned} \widetilde{KU}(S^n X) \otimes \widetilde{KU}(S^2) &\overset{(1)}{\cong} \widetilde{KU}(S^n X \wedge S^2) \\ &\overset{(2)}{=} \widetilde{KU}(S^{n+2} \wedge X) \\ &\overset{(3)}{=} \widetilde{KU}^{-(n+2)}(X). \end{aligned} \tag{3.127}$$

(1) $\tilde{\alpha}$ with $Y = S^2$ is an isomorphism (the reduced form of (3.120)).
(2) $S^n X \wedge S^2 = S^n \wedge X \wedge S^2 \cong S^n \wedge S^2 \wedge X \cong S^{n+2} \wedge X$ (the smash product is commutative and associative up to homeomorphism, and $S^n \wedge S^2 = S^{n+2}$).
(3) $S^{n+2} \wedge X = S^{n+2}X$ and the definition (3.115).

The left side is $\widetilde{KU}^{-n}(X) \otimes \widetilde{KU}(S^2)$ (Nash's (3.87)).

The generator b. By Section 3.12.7, $\widetilde{KU}(S^2) = \mathbb{Z}$, generated by $b = [\eta] - [I]$ where $\eta = H$ is the canonical line bundle over $\mathbb{CP}^1$. Nash names it after the Hopf fibration: the unit vectors in the fibres of H,

$$\{(z_0, z_1) \in \mathbb{C}^2 : |z_0|^2 + |z_1|^2 = 1\} = S^3 \longrightarrow \mathbb{CP}^1 = S^2, \qquad (z_0, z_1) \mapsto [z_0 : z_1],$$

form the Hopf fibration, with circle fibres (the phases $e^{i\chi}$ of a unit vector on a given line). It is also the bundle of the Dirac monopole (Section 3.8). Since $\widetilde{KU}(S^2)$ is free on one generator, $A \otimes \widetilde{KU}(S^2) \cong A$ via $a \otimes b \mapsto a$, and we may drop the tensor factor.

Key idea: Bott periodicity, K-theory form (Nash (3.88)–(3.89))

The **Bott map**

$$\gamma : \widetilde{KU}^{-n}(X) \longrightarrow \widetilde{KU}^{-(n+2)}(X), \qquad a \longmapsto \tilde{\alpha}(a \otimes b),$$

"multiply externally by the Hopf class $b = [H] - 1$", is an isomorphism:

$$\widetilde{KU}^{-n}(X) \cong \widetilde{KU}^{-(n+2)}(X) \qquad \text{for every } X,\ n \geq 0.$$

Recovering the sphere statement. Take $X = S^0$. Then $S^n S^0 = S^n$ and

$$\widetilde{KU}(S^n) \overset{(1)}{=} \widetilde{KU}^{-n}(S^0) \overset{(2)}{\cong} \widetilde{KU}^{-(n+2)}(S^0) \overset{(1)}{=} \widetilde{KU}(S^{n+2}),$$

(1) Definition (3.115) and $S^n S^0 = S^n$.
(2) The Bott map γ.

which is (3.112), Nash's (3.73). Explicitly, the generator of $\widetilde{KU}(S^{n+2})$ is b times the generator of $\widetilde{KU}(S^n)$.

$$\widetilde{KU}(S^0)=\mathbb{Z} \xrightarrow{\cdot b} \widetilde{KU}(S^2)=\mathbb{Z} \xrightarrow{\cdot b} \widetilde{KU}(S^4)=\mathbb{Z} \xrightarrow{\cdot b} \widetilde{KU}(S^6)=\mathbb{Z} \xrightarrow{\cdot b} \cdots$$

$$1 \longmapsto b \longmapsto b\boxtimes b \longmapsto b^{\boxtimes 3} \longmapsto \cdots$$

$$\widetilde{KU}(S^1)=0 \xrightarrow{\cdot b} \widetilde{KU}(S^3)=0 \xrightarrow{\cdot b} \widetilde{KU}(S^5)=0 \xrightarrow{\cdot b} \widetilde{KU}(S^7)=0 \xrightarrow{\cdot b} \cdots$$

Figure 3.52: The Bott map at work on spheres. External multiplication by the Hopf class $b=[H]-1$ raises the dimension of the sphere by two and is an isomorphism at every step. Starting from $\widetilde{KU}(S^0)=\mathbb{Z}$ (generator 1) and $\widetilde{KU}(S^1)=0$ it produces the whole pattern. The generator of $\widetilde{KU}(S^{2j})$ is the j-fold external power of b.

Consequences.

- Since $K^{-n}=K^{-n-2}$, we can *define* K^n for positive n as well, by periodicity. Complex K-theory then has only two distinct groups, $K^0(X)$ and $K^1(X):=K^{-1}(X)$: it is a $\mathbb{Z}_2$-graded theory, like the even/odd split of fermion number.
- The long exact sequences of the Eilenberg–Steenrod exactness axiom close up into a hexagon (the *six-term exact sequence*) linking K^0 and K^1 of a pair.
- K of any space built from spheres can be computed: e.g. $\widetilde{KU}(S^{2j})=\mathbb{Z}$, $\widetilde{KU}(S^{2j+1})=0$, $K(S^2\times S^2)=\mathbb{Z}^4$, and for the torus T^2, $K^0(T^2)=\mathbb{Z}^2$, $K^1(T^2)=\mathbb{Z}^2$ (build T^2 from the wedge $S^1\vee S^1$ by attaching one 2-cell, the square of Figure 3.51, and use the exact sequences).

Why it is true: clutching functions become polynomials

Here is the idea of the Atiyah–Bott proof of (3.120), at the physicist's level. A bundle on $X\times S^2$ is obtained, as in Section 3.12.2, by gluing two trivial pieces over $X\times D_+$ and $X\times D_-$ with a clutching function

$$g(x,z):\ X\times S^1\to \mathrm{GL}(N,\mathbb{C}),\qquad z=e^{i\phi}.$$

1. *Fourier.* Expand g in Fourier modes in ϕ and truncate: up to homotopy, g is a Laurent polynomial $\sum_{j=-L}^{L} a_j(x)z^j$. Multiplying by z^L (tensoring with a power of H) makes it a polynomial.
2. *Linearise.* A polynomial clutching function of degree L in z can be traded, by enlarging the matrix size (a "companion matrix" trick, as when a high-order ODE is written as a first-order system), for a *linear* one, $a(x)z+c(x)$.
3. *Projectors.* A linear clutching function can be deformed to the form $g(x,z)=z\,\Pi(x)+(1-\Pi(x))$ with $\Pi(x)$ a family of projectors. It multiplies the image of Π by z and leaves the kernel alone, so the bundle is $(\mathrm{Im}\,\Pi)\boxtimes H\ \oplus\ (\mathrm{Ker}\,\Pi)\boxtimes I$.

So every bundle on $X\times S^2$ is, stably, of the form $E\boxtimes H\oplus F\boxtimes I$ with E,F bundles on X, i.e. it lies in the image of α, and a similar argument for homotopies shows there are no extra relations. For $X=\mathrm{pt}$, step 3 says: every bundle on S^2 is $H^{\oplus r}\oplus I^s$ stably, exactly what Section 3.12.7 found.

Worked example 3.77: The linear clutching function on S^2

For $X = \mathrm{pt}$ and $\Pi = \mathrm{diag}(1,0)$,

$$g(z) = z\,\Pi + (1-\Pi) = \begin{pmatrix} z & 0 \\ 0 & 1 \end{pmatrix},$$

which is the clutching function of $H \oplus I$. For the rank-one projector $\Pi(\vec{n}) = \tfrac{1}{2}(1 + \vec{n}\cdot\vec{\sigma})$ of Example 3.61 the same formula gives $g(z) = z\Pi(\vec{n}) + (1-\Pi(\vec{n}))$, which is conjugate to $\mathrm{diag}(z,1)$ for each fixed $\vec{n}$; as $\vec{n}$ varies over a parameter space X we get exactly the external product of the ground-state bundle with H, plus the excited-state bundle times I: $(\mathrm{Im}\,\Pi)\boxtimes H \oplus (\ker\Pi)\boxtimes I$. This is the Bott map made concrete.

Reading Nash (pp. 75–78, (3.71)–(3.89))

Nash's §4 begins with $\widetilde{KU}(S^n) = \pi_{n-1}(\mathrm{U}(\infty))$ (3.71) and Bott's theorem $\pi_n(\mathrm{U}(\infty)) = \pi_{n+2}(\mathrm{U}(\infty))$ (3.72), giving (3.73). He explains it via $\pi_n(X) = \pi_{n-2}(\Omega^2 X)$ (3.74) and $\Omega^2\mathrm{U} \simeq \mathrm{U}$. He defines $\widetilde{KU}^{-n}(X) = \widetilde{KU}(S^n X)$ (3.75)–(3.76), the internal product β (footnote 5) and the external product α (3.77)–(3.79), and states that α is an isomorphism for $Y = S^2$ (3.80), citing Husemoller. He reduces α to $\tilde{\alpha}$ using (3.81)–(3.86), and obtains the Bott map γ (3.88) and periodicity (3.89) by setting $Y = S^2$ and $X \to S^n X$ (3.87). In (3.84) the last term "$K(Y)$" should read $\widetilde{K}(Y)$. We have added the table of unstable groups, the winding-number integrals, the Morse-theory sketch of $\Omega\mathrm{U} \simeq \mathbb{Z}\times BU$, the computation of $K^{-n}(\mathrm{pt})$ and $K^{-1}(X) = [X,\mathrm{U}]$, pictures of suspension and smash product, the example $K(S^2\times S^2)$ with the Bott class, and the Atiyah–Bott idea of polynomial clutching functions.

Recap

- $\widetilde{KU}(S^n) = \pi_{n-1}(\mathrm{U})$ and $\pi_n(\mathrm{U}) = \pi_{n+2}(\mathrm{U})$: $0,\mathbb{Z},0,\mathbb{Z},\ldots$; the $\mathbb{Z}$'s are winding numbers $\propto \int \mathrm{tr}(g^{-1}\mathrm{d}g)^{2j-1}$.
- Mechanism: $\Omega\mathrm{U} \simeq \mathbb{Z}\times BU$ and $\Omega BU \simeq \mathrm{U}$, so $\Omega^2\mathrm{U} \simeq \mathrm{U}$ (Bott: minimal geodesics form Grassmannians).
- $\widetilde{KU}^{-n}(X) = \widetilde{KU}(S^n X)$; $K^{-n}(\mathrm{pt}) = \mathbb{Z},0,\mathbb{Z},0,\ldots$; $K^0 = [X,\mathbb{Z}\times BU]$, $K^{-1} = [X,\mathrm{U}]$.
- External product $\alpha(c\otimes d) = \pi_X^* c \bullet \pi_Y^* d$; $\widetilde{K}(X\times Y) = \widetilde{K}(X\wedge Y)\oplus\widetilde{K}(X)\oplus\widetilde{K}(Y)$; reduced product $\tilde{\alpha}$ lands in $\widetilde{K}(X\wedge Y)$.
- Bott map $\gamma(a) = \tilde{\alpha}(a\otimes b)$, $b = [H]-1$, is an isomorphism $\widetilde{KU}^{-n}(X) \to \widetilde{KU}^{-n-2}(X)$.

3.14 Real and quaternionic periodicity: the period eight

Nash ends his section on Bott periodicity in four lines. He "simply quotes" the real and quaternionic versions and remarks that we can now compute $\widetilde{KO}(S^n)$, $\widetilde{KU}(S^n)$ and $\widetilde{KSp}(S^n)$ for every n. Those four lines hide one of the most striking patterns in mathematics. The real theory has period *eight*, the same eight that controls Clifford algebras, Majorana spinors, and the dimensions where indices are only defined mod 2.

This section unpacks the four lines. We state the theorem and tabulate it. We then see where the eight comes from in three ways: from Bott's chain of loop spaces, from Clifford

modules (the Atiyah–Bott–Shapiro construction, which also *writes down* the generators), and from the comparison between real and complex K-theory. We finish with applications: vector fields on spheres and a dictionary of places where the period eight appears in physics.

Throughout, $\mathrm{Cl}_{0,k}$ is the real Clifford algebra with k generators squaring to -1, as in Chapter T4:

$$e_i e_j + e_j e_i = -2\delta_{ij}, \qquad i, j = 1, \dots, k.$$

3.14.1 Nash's statement and the full tables

Write $\mathrm{O} = \mathrm{O}(\infty)$ and $\mathrm{Sp} = \mathrm{Sp}(\infty)$ for the infinite orthogonal and symplectic groups, defined like $\mathrm{U}(\infty)$ by upper-left block inclusions $\mathrm{O}(k) \hookrightarrow \mathrm{O}(k+1)$, $\mathrm{Sp}(k) \hookrightarrow \mathrm{Sp}(k+1)$. By the stability results of Section 3.12.4, $\pi_j(\mathrm{O}) = \pi_j(\mathrm{O}(k))$ once $k > j+1$, and $\pi_j(\mathrm{Sp}) = \pi_j(\mathrm{Sp}(k))$ once $j \le 4k+1$ ((3.102)).

Key idea: Real and quaternionic Bott periodicity (Nash (3.90))

$$\pi_n(\mathrm{O}) = \pi_{n+8}(\mathrm{O}), \qquad \widetilde{KO}^{-n}(X) \cong \widetilde{KO}^{-n-8}(X),$$
$$\pi_n(\mathrm{Sp}) = \pi_{n+4}(\mathrm{O}), \qquad \widetilde{KSp}^{-n}(X) \cong \widetilde{KO}^{-n-4}(X).$$

Here $\widetilde{KO}^{-n}(X) := \widetilde{KO}(S^n X)$ and $\widetilde{KSp}^{-n}(X) := \widetilde{KSp}(S^n X)$, exactly as in (3.115). By symmetry also $\pi_n(\mathrm{O}) = \pi_{n+4}(\mathrm{Sp})$ and $\widetilde{KO}^{-n}(X) \cong \widetilde{KSp}^{-n-4}(X)$.

So the quaternionic theory is the real theory shifted by half a period. Going round twice, $\mathrm{Sp} \to \mathrm{O} \to \mathrm{Sp}$, is a shift by 8, consistent with the first line.

The homotopy groups. One period of each stable group:

n mod 8	0	1	2	3	4	5	6	7
$\pi_n(\mathrm{O})$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	0	$\mathbb{Z}$	0	0	0	$\mathbb{Z}$
$\pi_n(\mathrm{U})$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$
$\pi_n(\mathrm{Sp})$	0	0	0	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	0	$\mathbb{Z}$

(3.128)

The U row has period 2 (Section 3.13). The Sp row is the O row read four places further along. Let us check the second line of Nash's (3.90) entry by entry:

$$\pi_0(\mathrm{Sp}) \overset{(1)}{=} 0 = \pi_4(\mathrm{O}), \qquad \pi_1(\mathrm{Sp}) \overset{(1)}{=} 0 = \pi_5(\mathrm{O}),$$
$$\pi_2(\mathrm{Sp}) \overset{(2)}{=} 0 = \pi_6(\mathrm{O}), \qquad \pi_3(\mathrm{Sp}) \overset{(3)}{=} \mathbb{Z} = \pi_7(\mathrm{O}),$$
$$\pi_4(\mathrm{Sp}) \overset{(4)}{=} \mathbb{Z}_2 = \pi_8(\mathrm{O}) \overset{(5)}{=} \pi_0(\mathrm{O}), \qquad \pi_5(\mathrm{Sp}) \overset{(4)}{=} \mathbb{Z}_2 = \pi_9(\mathrm{O}) \overset{(5)}{=} \pi_1(\mathrm{O}).$$

(1) $\mathrm{Sp}(1) = S^3$ is connected and simply connected, and these groups are already stable (table (3.108)).
(2) Cartan: π_2 of any compact Lie group vanishes.
(3) $\pi_3(\mathrm{Sp}(1)) = \pi_3(S^3) = \mathbb{Z}$, the instanton number.
(4) $\pi_4(\mathrm{Sp}) = \pi_4(\mathrm{Sp}(1)) = \pi_4(S^3) = \mathbb{Z}_2$, and similarly $\pi_5(\mathrm{Sp}) = \pi_5(S^3) = \mathbb{Z}_2$; for these j the group $\mathrm{Sp}(1)$ is already in the stable range, since $j \le 4 \cdot 1 + 1$.
(5) The first line of (3.90).

The first four entries are the tables of Section 3.12.5; the $\mathbb{Z}_2$'s in degrees 4, 5 are the classical homotopy groups $\pi_4(S^3) = \pi_5(S^3) = \mathbb{Z}_2$ of the three-sphere, which we quote.

The K-groups of every sphere. Clutching gives $\widetilde{KO}(S^n) = \pi_{n-1}(\mathrm{O})$, $\widetilde{KU}(S^n) = \pi_{n-1}(\mathrm{U})$, $\widetilde{KSp}(S^n) = \pi_{n-1}(\mathrm{Sp})$ for $n \geq 1$ ((3.101), (3.107) with $k \to \infty$). Shifting the index by one:

n mod 8	0	1	2	3	4	5	6	7
$\widetilde{KO}(S^n) = KO^{-n}(\mathrm{pt})$	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	0	$\mathbb{Z}$	0	0	0
$\widetilde{KU}(S^n) = KU^{-n}(\mathrm{pt})$	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0
$\widetilde{KSp}(S^n) = KSp^{-n}(\mathrm{pt})$	$\mathbb{Z}$	0	0	0	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	0

(3.129)

The identification with the groups of a point is the one of Section 3.13.3: $KO^{-n}(\mathrm{pt}) = \widetilde{KO}(S^n S^0) = \widetilde{KO}(S^n)$. The $n = 0$ column is $\widetilde{K}(S^0) = \mathbb{Z}$ (a bundle over two points modulo its rank at the base point), and is consistent with periodicity: $\widetilde{KO}(S^8) = \pi_7(\mathrm{O}) = \mathbb{Z}$. This is Nash's closing remark: there is now enough information to calculate any of these groups.

Worked example 3.78: Reading off K-groups of large spheres

$$\widetilde{KO}(S^{27}) \overset{(1)}{=} \pi_{26}(\mathrm{O}) \overset{(2)}{=} \pi_2(\mathrm{O}) \overset{(3)}{=} 0,$$
$$\widetilde{KSp}(S^{13}) \overset{(4)}{=} \widetilde{KO}(S^{17}) \overset{(1)}{=} \pi_{16}(\mathrm{O}) \overset{(2)}{=} \pi_0(\mathrm{O}) \overset{(3)}{=} \mathbb{Z}_2,$$
$$\widetilde{KO}(S^{12}) \overset{(1)}{=} \pi_{11}(\mathrm{O}) \overset{(2)}{=} \pi_3(\mathrm{O}) \overset{(3)}{=} \mathbb{Z}, \qquad \widetilde{KU}(S^{11}) \overset{(5)}{=} \pi_{10}(\mathrm{U}) \overset{(6)}{=} \pi_0(\mathrm{U}) = 0.$$

(1) Clutching: $\widetilde{KO}(S^n) = \pi_{n-1}(\mathrm{O})$.
(2) Real Bott periodicity, $26 = 3 \cdot 8 + 2$, $16 = 2 \cdot 8$, $11 = 8 + 3$.
(3) The table (3.128).
(4) The second line of (3.90) with $X = S^0$: $\widetilde{KSp}(S^n) = \widetilde{KO}(S^{n+4})$.
(5) Clutching for U.
(6) Complex Bott periodicity, five times.

As a cross-check of the second line, directly: $\widetilde{KSp}(S^{13}) = \pi_{12}(\mathrm{Sp}) = \pi_4(\mathrm{Sp}) = \mathbb{Z}_2$ from (3.128) (using that the Sp row has period 8 too). Concretely: there is exactly one stably non-trivial quaternionic bundle over S^{13}, and there are infinitely many stably distinct real bundles over S^{12}, labelled by an integer.

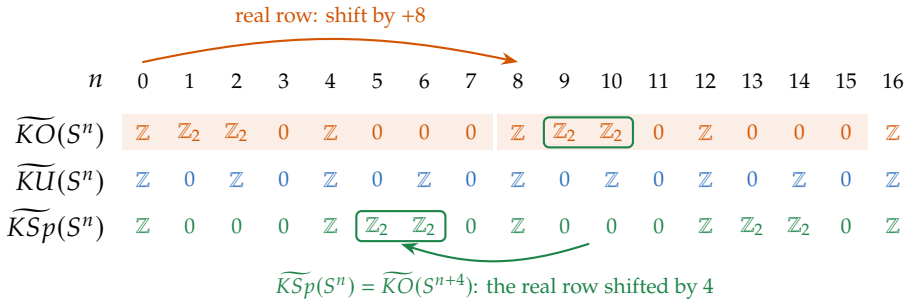

Figure 3.53: The reduced K-groups of spheres up to S^{16}. The real row (orange) repeats every 8 (the shaded blocks are identical). The complex row (blue) repeats every 2. The quaternionic row (green) is the real row shifted by 4: for example the $\mathbb{Z}_2$'s of $\widetilde{KSp}$ at $n = 5, 6$ (green box) are the $\mathbb{Z}_2$'s of $\widetilde{KO}$ at $n = 9, 10$ (green box).

3.14.2 From unstable to stable: π_3 and π_4 of $\mathrm{SO}(k)$

Periodicity is a statement about $k = \infty$. For a physicist it is worth seeing how the small groups settle down. The tool is the list of *exceptional isomorphisms* of spin groups from Chapter T4:

$$\mathrm{Spin}(3) = \mathrm{SU}(2), \quad \mathrm{Spin}(4) = \mathrm{SU}(2) \times \mathrm{SU}(2), \quad \mathrm{Spin}(5) = \mathrm{Sp}(2), \quad \mathrm{Spin}(6) = \mathrm{SU}(4).$$

$\mathrm{Spin}(k) \to \mathrm{SO}(k)$ is a double cover, and a covering map does not change π_j for $j \geq 2$ (a map from a simply connected sphere lifts uniquely once a base point is chosen). So $\pi_j(\mathrm{SO}(k)) = \pi_j(\mathrm{Spin}(k))$ for $j \geq 2$.

Worked example 3.79: $\pi_3(\mathrm{SO}(k))$ and $\pi_4(\mathrm{SO}(k))$ for $k = 3, \ldots, 7$

Using $\pi_3(S^3) = \mathbb{Z}$, $\pi_4(S^3) = \mathbb{Z}_2$, and the stability ranges:

k	$\mathrm{Spin}(k)$	$\pi_3(\mathrm{SO}(k))$	$\pi_4(\mathrm{SO}(k))$
3	$\mathrm{SU}(2) = S^3$	$\mathbb{Z}$	$\mathbb{Z}_2$
4	$S^3 \times S^3$	$\mathbb{Z} \oplus \mathbb{Z}$	$\mathbb{Z}_2 \oplus \mathbb{Z}_2$
5	$\mathrm{Sp}(2)$	$\mathbb{Z}$	$\mathbb{Z}_2$
6	$\mathrm{SU}(4)$	$\mathbb{Z}$	0
7	(stable)	$\mathbb{Z}$	0

The entries for $k = 5$ and $k = 6$ come from chains like

$$\pi_4(\mathrm{SO}(5)) \overset{(1)}{=} \pi_4(\mathrm{Sp}(2)) \overset{(2)}{=} \pi_4(\mathrm{Sp}(1)) \overset{(3)}{=} \pi_4(S^3) = \mathbb{Z}_2,$$
$$\pi_4(\mathrm{SO}(6)) \overset{(1)}{=} \pi_4(\mathrm{SU}(4)) \overset{(4)}{=} \pi_4(\mathrm{U}) \overset{(5)}{=} 0.$$

(1) Double cover and the exceptional isomorphism.
(2) The inclusion $\mathrm{Sp}(1) \to \mathrm{Sp}(2)$ has quotient $\mathrm{Sp}(2)/\mathrm{Sp}(1) = S^7$, which has no homotopy below degree 7, so it is an isomorphism on π_j for $j < 6$.
(3) $\mathrm{Sp}(1) = S^3$.
(4) $\mathrm{SU}(4) \to \mathrm{U}(4)$ does not change π_j for $j \geq 2$ (the quotient is $\mathrm{U}(1)$), and $\mathrm{U}(4)$ is in the stable range for π_4 ((3.102): $j \leq 2k - 1$, here $4 \leq 7$).
(5) Bott: $\pi_{\mathrm{even}}(\mathrm{U}) = 0$.

Reading the columns: π_3 passes through $\mathbb{Z} \oplus \mathbb{Z}$ at $k = 4$ and settles at $\mathbb{Z} = \pi_3(\mathrm{O})$; π_4 settles at $0 = \pi_4(\mathrm{O})$ from $k = 6$ on, exactly when the stability bound $k > j + 1 = 5$ is met.

Physical picture: The $\mathbb{Z} \oplus \mathbb{Z}$ at $k = 4$

$\mathrm{SO}(4)$ bundles over S^4 are the frame bundles of four-dimensional Euclidean gauge theory with gauge group $\mathrm{SO}(4) = (\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R)/\mathbb{Z}_2$. The two integers are the instanton numbers of the two $\mathrm{SU}(2)$ factors (self-dual and anti-self-dual parts). Adding a trivial line, $\mathrm{SO}(4) \subset \mathrm{SO}(5)$, identifies them into a single integer: stably only one combination survives. This is the topological shadow of the fact that $\Lambda^2\mathbb{R}^4$ splits into self-dual and anti-self-dual pieces only in dimension four (Chapter T1).

3.14.3 Where the eight comes from, I: Bott's chain of loop spaces

In the complex case the mechanism was $\Omega\mathrm{U} \simeq \mathbb{Z} \times BU$ and $\Omega(\mathbb{Z} \times BU) \simeq \mathrm{U}$: two steps, period two (Section 3.13.2). In the real case Bott's Morse-theory argument produces eight steps before

returning to the start:

$$\begin{aligned} &\Omega(\mathbb{Z}\times BO)\simeq \mathrm{O}, \quad \Omega\mathrm{O}\simeq \mathrm{O/U}, \quad \Omega(\mathrm{O/U})\simeq \mathrm{U/Sp}, \quad \Omega(\mathrm{U/Sp})\simeq \mathbb{Z}\times BSp,\\ &\Omega(\mathbb{Z}\times BSp)\simeq \mathrm{Sp}, \quad \Omega\mathrm{Sp}\simeq \mathrm{Sp/U}, \quad \Omega(\mathrm{Sp/U})\simeq \mathrm{U/O}, \quad \Omega(\mathrm{U/O})\simeq \mathbb{Z}\times BO. \end{aligned} \tag{3.130}$$

Here O/U means $\mathrm{O}(2m)/\mathrm{U}(m)$ with $m\to\infty$ (orthogonal complex structures on $\mathbb{R}^{2m}$), U/Sp means $\mathrm{U}(2m)/\mathrm{Sp}(m)$ (quaternionic structures on $\mathbb{C}^{2m}$), Sp/U means $\mathrm{Sp}(m)/\mathrm{U}(m)$, and U/O means $\mathrm{U}(m)/\mathrm{O}(m)$ (real forms of $\mathbb{C}^m$, i.e. Lagrangian planes). Composing eight loopings, $\Omega^8\mathrm{O}\simeq\mathrm{O}$, and $\Omega^4\mathrm{O}\simeq\mathbb{Z}\times BSp$, $\Omega^4\mathrm{Sp}\simeq\mathbb{Z}\times BO$, which is (3.90).

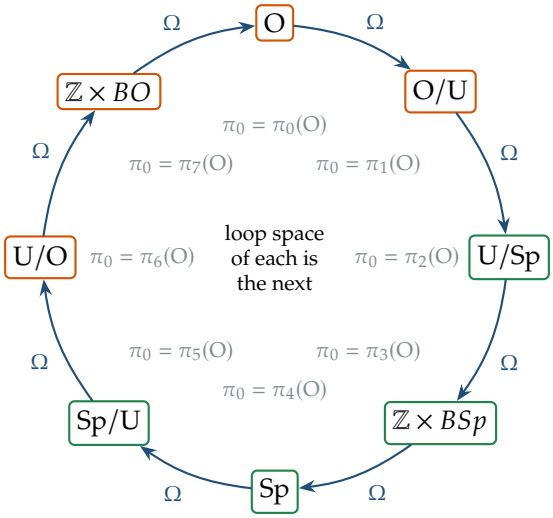

Figure 3.54: Bott's eight-step clock. Following an arrow means "take the loop space"; after eight steps we are back at O, so $\Omega^8\mathrm{O}\simeq\mathrm{O}$. The inner labels say what each space contributes: its set of components π_0 is $\pi_k(\mathrm{O})$, because $\pi_k(\mathrm{O})=\pi_0(\Omega^k\mathrm{O})$. Real-flavoured spaces are orange, quaternionic-flavoured ones green; the clock is half real, half quaternionic, and the quaternionic half is the real half shifted by four steps.

Let us check this chain against the table (3.128), using $\pi_k(\mathrm{O})=\pi_{k-1}(\Omega\mathrm{O})=\cdots=\pi_0(\Omega^k\mathrm{O})$ ((3.113) repeatedly):

$$\begin{aligned} &\pi_0(\mathrm{O})\overset{(1)}{=}\mathbb{Z}_2, && \pi_1(\mathrm{O})\overset{(2)}{=}\pi_0(\mathrm{O/U})\overset{(3)}{=}\mathbb{Z}_2,\\ &\pi_2(\mathrm{O})\overset{(2)}{=}\pi_0(\mathrm{U/Sp})\overset{(4)}{=}0, && \pi_3(\mathrm{O})\overset{(2)}{=}\pi_0(\mathbb{Z}\times BSp)\overset{(5)}{=}\mathbb{Z},\\ &\pi_4(\mathrm{O})\overset{(2)}{=}\pi_0(\mathrm{Sp})\overset{(6)}{=}0, && \pi_5(\mathrm{O})\overset{(2)}{=}\pi_0(\mathrm{Sp/U})\overset{(6)}{=}0,\\ &\pi_6(\mathrm{O})\overset{(2)}{=}\pi_0(\mathrm{U/O})\overset{(6)}{=}0, && \pi_7(\mathrm{O})\overset{(2)}{=}\pi_0(\mathbb{Z}\times BO)\overset{(5)}{=}\mathbb{Z}. \end{aligned}$$

(1) Two components, det $=\pm1$.
(2) $\pi_k(\mathrm{O})=\pi_0(\Omega^k\mathrm{O})$ and the chain (3.130).
(3) A complex structure J on $\mathbb{R}^{2m}$ ($J^2=-1$, J orthogonal) is either orientation-compatible with the standard one or not: $\mathrm{O}(2m)/\mathrm{U}(m)$ has two components. (For $m=1$: $J=\pm\left(\begin{smallmatrix}0&-1\\1&0\end{smallmatrix}\right)$, a rotation by $\pm90°$.)
(4) $\mathrm{U}(2m)$ is connected, so its quotient is.
(5) The components of $\mathbb{Z}\times BG$ are labelled by the virtual rank.
(6) $\mathrm{Sp}(m)$ and $\mathrm{U}(m)$ are connected, so they and their quotients are.

All eight entries agree with the table. The eight spaces are exactly the compact symmetric spaces that appear in Cartan's classification, and they return in physics as the eight real classes of random matrices and of topological insulators (Section 3.14.7).

Physical picture: Complex structures that anticommute: Clifford algebras appear

Milnor's version of Bott's proof describes the k-th space in the chain as the set of orthogonal matrices J on $\mathbb{R}^N$ (N large) with

$$J^2 = -1, \qquad JJ_i = -J_iJ \quad (i = 1, \dots, k-1),$$

for fixed $J_1, \dots, J_{k-1}$ satisfying the same relations. In words: $J_1, \dots, J_{k-1}, J$ make $\mathbb{R}^N$ into a module over $\mathrm{Cl}_{0,k}$. The minimal geodesics from J_k to $-J_k$ in the k-th space are parametrised by the $(k+1)$-st space (compare Figure 3.49). So each loop step adds one anticommuting generator, and *the period eight of Bott is the period eight of Clifford algebras*, $\mathrm{Cl}_{0,k+8} \cong \mathrm{Cl}_{0,k} \otimes \mathbb{R}(16)$ (Chapter T4).

Worked example 3.80: $\pi_1(\mathrm{U}/\mathrm{O}) = \mathbb{Z}$ is the Maslov index

The chain says $\pi_1(\mathrm{U}/\mathrm{O}) = \pi_7(\mathrm{O}) = \mathbb{Z}$. We can see this $\mathbb{Z}$ directly. $\mathrm{U}(m)/\mathrm{O}(m)$ is the space of Lagrangian planes in $\mathbb{C}^m = \mathbb{R}^{2m}$: the image $g\mathbb{R}^m$ of the real subspace under a unitary g, where g and gh ($h \in \mathrm{O}(m)$) give the same plane. The function

$$\mu : \mathrm{U}(m)/\mathrm{O}(m) \to \mathrm{U}(1), \qquad [g] \mapsto \det(g)^2$$

is well defined, because

$$\det(gh)^2 \overset{(1)}{=} \det(g)^2 \det(h)^2 \overset{(2)}{=} \det(g)^2.$$

(1) det is multiplicative.
(2) h is real orthogonal, so $\det h = \pm 1$ and $\det(h)^2 = 1$.

The winding number of $\det^2$ around a loop of Lagrangian planes is the **Maslov index**. For $m = 1$ the Lagrangian "planes" are the lines $e^{i\theta}\mathbb{R} \subset \mathbb{C}$, $\theta \in [0, \pi)$, and $\mu = e^{2i\theta}$ winds once as the line turns through 180° back to itself. Physically: in semiclassical (WKB) quantisation a periodic orbit carries a loop of Lagrangian planes (the tangent planes of the invariant torus), and its Maslov index μ corrects the Bohr–Sommerfeld rule to $\oint p\,\mathrm{d}q = 2\pi\hbar(n + \mu/4)$. For the harmonic oscillator $\mu = 2$ (two turning points), which gives $E = \hbar\omega(n + \frac{1}{2})$: the zero-point energy is a $\pi_7(\mathrm{O})$ in disguise.

3.14.4 Where the eight comes from, II: real versus complex

A second way to see the pattern, and to see that the $\mathbb{Z}$'s in $\widetilde{KO}(S^4)$ and $\widetilde{KO}(S^8)$ are *not* the same kind of $\mathbb{Z}$, is to compare real and complex bundles.

Working definition 3.35 (complexification, realification, conjugation)

- **Complexification** $c : KO(X) \to KU(X)$ [K-groups built from real, respectively complex, bundles], $[E] \mapsto [E \otimes_{\mathbb{R}} \mathbb{C}]$. Transition functions: the same real matrices, now regarded as complex.
- **Realification** $r : KU(X) \to KO(X)$, $[F] \mapsto [F_{\mathbb{R}}]$: forget the complex structure [the rule for multiplying fibre vectors by i]. A complex rank-k bundle becomes a real rank-$2k$ bundle; a transition function $A + iB$ becomes the real $2k \times 2k$ matrix $\left(\begin{smallmatrix} A & -B \\ B & A \end{smallmatrix}\right)$.
- **Conjugation** $\psi : KU(X) \to KU(X)$, $[F] \mapsto [\bar{F}]$: complex conjugate the transition functions. For a line bundle, $\bar{L} \cong L^* = L^{-1}$ (with a Hermitian metric [a complex inner

product on each fibre, which lets one take g unitary], $\bar{g} = g^{-1}$ for $g \in \mathrm{U}(1)$).

They satisfy

$$r \circ c = 2, \qquad c \circ r = 1 + \psi. \tag{3.131}$$

["2" is multiplication by 2: $E \otimes_{\mathbb{R}} \mathbb{C}$, viewed as a real bundle, is $E \oplus E$]

Why (3.131): for a real E, $(E \otimes_{\mathbb{R}} \mathbb{C})_{\mathbb{R}} = E \oplus iE \cong E \oplus E$. For a complex F, $F_{\mathbb{R}} \otimes_{\mathbb{R}} \mathbb{C} \cong F \oplus \bar{F}$: the complex structure J of F extends $\mathbb{C}$-linearly to $F_{\mathbb{R}} \otimes \mathbb{C}$, where $J^2 = -1$ splits it into the $+i$ eigenspace ($\cong F$) and the $-i$ eigenspace ($\cong \bar{F}$). This is the same splitting as $T_{\mathbb{C}}\mathbb{R}^2 = T^{1,0} \oplus T^{0,1}$, spanned by ∂_z and $\partial_{\bar{z}}$.

Worked example 3.81: c kills $\widetilde{KO}(S^2)$

The generator of $\widetilde{KO}(S^2) = \mathbb{Z}_2$ is $r(b) = [H_{\mathbb{R}}] - 2$, the Hopf bundle regarded as a real plane bundle (Section 3.12.5). Its complexification is

$$c\big(r(b)\big) \overset{(1)}{=} b + \psi(b) \overset{(2)}{=} ([H] - 1) + ([H^{-1}] - 1)$$
$$\overset{(3)}{=} (1 + b - 1) + (1 - b - 1) = 0.$$

(1) (3.131).
(2) $\psi(b) = [\bar{H}] - 1 = [H^{-1}] - 1$ for the line bundle H.
(3) $[H^n] = 1 + nb$ for all $n \in \mathbb{Z}$, (3.110).

So $c = 0$ on $\widetilde{KO}(S^2)$. This had to be: c is a group homomorphism $\mathbb{Z}_2 \to \mathbb{Z}$, and the only one is zero. Physically, the monopole of charge +1 and the monopole of charge −1 are the same *real* bundle (complex conjugation is a real isomorphism $H_{\mathbb{R}} \cong \bar{H}_{\mathbb{R}}$), and together they form a trivial complex bundle. Also $r(c(r(b))) = 2r(b) = 0$, consistent with $r(b)$ having order 2.

Worked example 3.82: c doubles on $\widetilde{KO}(S^4)$

Let E be the quaternionic Hopf line bundle over $S^4 = \mathbb{H}P^1$ (Example 3.69), viewed as a complex rank-2 bundle with clutching $g(q) = q \in \mathrm{SU}(2)$. By Example 3.70, $y = [E] - 2$ generates $\widetilde{KU}(S^4) = \mathbb{Z}$, and $\alpha_4 = r(y) = [E_{\mathbb{R}}] - 4$ generates $\widetilde{KO}(S^4) = \mathbb{Z}$. Quaternionic multiplication by $\mathbf{j}$ on the right is a complex-antilinear isomorphism $E \to E$, so $\bar{E} \cong E$ and $\psi(y) = y$. Then

$$c(\alpha_4) \overset{(1)}{=} c\big(r(y)\big) \overset{(2)}{=} y + \psi(y) \overset{(3)}{=} 2y.$$

(1) Definition of α_4.
(2) (3.131).
(3) $\bar{E} \cong E$.

So $c : \widetilde{KO}(S^4) = \mathbb{Z} \to \widetilde{KU}(S^4) = \mathbb{Z}$ is multiplication by 2. In terms of characteristic classes: the real generator has first Pontryagin number ±2, twice the instanton number of the complex generator, because $p_1(E_{\mathbb{R}}) = -c_2(E \oplus \bar{E}) = -2c_2(E)$.

In degree 8, by contrast, $c : \widetilde{KO}(S^8) \to \widetilde{KU}(S^8)$ is an isomorphism: the real generator (built from octonions in Section 3.14.5) complexifies to the generator $b^{\boxtimes 4}$. The full comparison over

one period is:

n	0	1	2	3	4	5	6	7
$\widetilde{KO}(S^n)$	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	0	$\mathbb{Z}$	0	0	0
c	$\cong$	0	0	0	$\times 2$	0	0	0
$\widetilde{KU}(S^n)$	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0

(3.132)

The ring $KO^{-*}(\mathrm{pt})$. Products (external, as in Section 3.13.4) make $\bigoplus_n KO^{-n}(\mathrm{pt})$ a ring. Its generators are

$$\eta \in KO^{-1}\ (\text{Möbius} - 1), \qquad \alpha_4 \in KO^{-4}, \qquad \beta_8 \in KO^{-8}\ (\text{the real Bott class}),$$

with $\eta^2 = r(b)$ generating $KO^{-2} = \mathbb{Z}_2$, and relations

$$2\eta = 0, \qquad \eta^3 = 0, \qquad \eta\,\alpha_4 = 0, \qquad \alpha_4^2 = 4\beta_8.$$

The first three hold because the groups they land in are $\mathbb{Z}_2$ (with $2x = 0$), $KO^{-3} = 0$ and $KO^{-5} = 0$. The last one is a genuine calculation, done by complexifying. Since c is a ring homomorphism and is injective on $KO^{-8} = \mathbb{Z}$,

$$c(\alpha_4^2) \overset{(1)}{=} c(\alpha_4)^2 \overset{(2)}{=} (2b^{\boxtimes 2})^2 = 4\,b^{\boxtimes 4} \overset{(3)}{=} 4\,c(\beta_8) \overset{(4)}{=} c(4\beta_8),$$

(1) c preserves products.
(2) Example 3.82, with the generator of $\widetilde{KU}(S^4)$ written as $b^{\boxtimes 2}$ (up to a sign, which squares away).
(3) c is an isomorphism in degree 8, $c(\beta_8) = b^{\boxtimes 4}$.
(4) c is additive.

and injectivity gives $\alpha_4^2 = 4\beta_8$. Multiplication by β_8 is the real Bott map $\widetilde{KO}^{-n}(X) \to \widetilde{KO}^{-n-8}(X)$ of (3.90), the analogue of γ in (3.127). The quaternionic isomorphism of (3.90) is similarly multiplication by the class of the quaternionic Hopf bundle in $\widetilde{KSp}(S^4)$ (a real bundle tensored with a quaternionic one is quaternionic).

Watch out: Period eight does not mean "the same $\mathbb{Z}$"

The groups $\widetilde{KO}(S^4)$ and $\widetilde{KO}(S^8)$ are both $\mathbb{Z}$, but they sit differently relative to complex K-theory: one complexifies with a factor 2, the other isomorphically. The honest period is 8, not 4: $\widetilde{KO}(S^5) = 0$ but $\widetilde{KO}(S^9) = \mathbb{Z}_2$. Nash's statement $\widetilde{KSp}^{-n} \cong \widetilde{KO}^{-n-4}$ is a relation between two *different* theories, not a period 4 of either.

3.14.5 Where the eight comes from, III: Clifford modules build the generators

The brief of this chapter promised a link with Clifford algebras. Here it is, in the form found by Atiyah, Bott and Shapiro (1964). It does something the homotopy tables cannot: it *writes down* a clutching function for the generator of every $\widetilde{KO}(S^k)$, and it explains the whole table by linear algebra.

Clutching by Clifford multiplication

Recall the clutching construction (Section 3.12.2): a bundle over S^k is two trivial pieces over the hemispheres $D^k_\pm$, glued along the equator S^{k-1} by a map $g : S^{k-1} \to \mathrm{GL}(N)$. Clifford algebras supply such maps for free.

Working definition 3.36 (the ABS clutching function)

Let $M = M^0 \oplus M^1$ be a **graded module** of $\mathrm{Cl}_{0,k}$: real matrices $e_1, \dots, e_k$ on M with $e_i e_j + e_j e_i = -2\delta_{ij}$, each mapping $M^0 \to M^1$ and $M^1 \to M^0$ ("odd"). For a unit vector $x = (x_1, \dots, x_k) \in S^{k-1}$ put

$$g(x) := x\cdot = \sum_{i=1}^{k} x_i e_i\Big|_{M^0} : M^0 \longrightarrow M^1.$$

It is invertible, because

$$(x\cdot)^2 \overset{(1)}{=} \sum_{i,j} x_i x_j\, e_i e_j \overset{(2)}{=} \tfrac{1}{2}\sum_{i,j} x_i x_j\,(e_i e_j + e_j e_i) \overset{(3)}{=} -\sum_i x_i^2 \overset{(4)}{=} -1,$$

(1) Expand; the x_i are numbers.
(2) $x_i x_j$ is symmetric in i, j.
(3) The Clifford relation.
(4) x is a unit vector.

so $g(x)^{-1} = -x\cdot$ (restricted to M^1). Gluing $D^k_+ \times M^0$ to $D^k_- \times M^1$ with g gives a real bundle over S^k; its class minus the trivial bundle is the **ABS class** $[M] \in \widetilde{KO}(S^k)$ [real virtual bundles over S^k of virtual dimension 0].

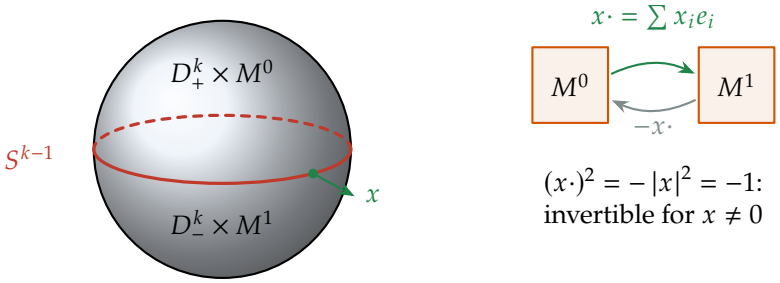

Figure 3.55: The Atiyah–Bott–Shapiro construction. Over the northern hemisphere the fibre is M^0, over the southern it is M^1. At a point x of the equator (red) they are glued by Clifford multiplication by x (green), which is invertible because a unit vector squares to -1. The Clifford algebra hands us a clutching function without any choices.

This is the same construction as the symbol of a Dirac operator: on $\mathbb{R}^k$, $\not{D} = \sum e_i \partial_i$ has symbol $i\sum \xi_i e_i$, invertible for $\xi \neq 0$. The ABS class of the spinor module is the class of the Dirac symbol, which is how the index theorem (Chapter 4) enters K-theory.

Worked example 3.83: The generators in degrees $1, 2, 4, 8$

$k = 1$. $\mathrm{Cl}_{0,1} = \mathbb{C}$ with $e_1 = i$; grade it as $M^0 = \mathbb{R}$, $M^1 = i\mathbb{R}$. The equator of S^1 is $S^0 = \{\pm 1\}$, and $g(\pm 1) = \pm i$. Identifying M^1 with M^0 via e_1, the clutching function is $+1$ at one point and -1 at the other: a flip. This is the Möbius bundle (Example 3.35), the generator η of $\widetilde{KO}(S^1) = \mathbb{Z}_2$.

$k = 2$. $\mathrm{Cl}_{0,2} = \mathbb{H}$ with $e_1 = \mathbf{i}$, $e_2 = \mathbf{j}$ and $J := e_1 e_2 = \mathbf{k}$. Grade it by $M^0 = \mathrm{span}(1, J) \cong \mathbb{C}$ and $M^1 = \mathrm{span}(e_1, e_2) = e_1 M^0$. For $x = (\cos\phi, \sin\phi)$,

$$\cos\phi\, e_1 + \sin\phi\, e_2 \overset{(1)}{=} e_1\big(\cos\phi - \sin\phi\, e_1 e_2\big) \overset{(2)}{=} e_1\, e^{-\phi J}.$$

(1) $e_1(-e_1 e_2) = -e_1^2 e_2 = e_2$.

(2) $J^2 = e_1e_2e_1e_2 = -e_1^2e_2^2 = -1$, so J behaves like i and $\cos\phi - \sin\phi\, J = e^{-\phi J}$.

After identifying $M^1 = e_1M^0$ with $M^0 \cong \mathbb{C}$, the clutching function is multiplication by the phase $e^{-i\phi}$: winding number ±1 (the sign is orientation). This is the Hopf bundle regarded as a real plane bundle, the generator $\eta^2 = r(b)$ of $\widetilde{KO}(S^2)$.

$k = 4$. Let $u_1, \dots, u_4 = 1, \mathbf{i}, \mathbf{j}, \mathbf{k}$ and let $\mathrm{Cl}_{0,4}$ act on $M = \mathbb{H} \oplus \mathbb{H}$ (real dimension 8) by

$$e_\mu = \begin{pmatrix} 0 & -\bar{u}_\mu \\ u_\mu & 0 \end{pmatrix} \quad \text{(left multiplication by quaternions).}$$

The relations hold:

$$e_\mu e_\nu + e_\nu e_\mu \overset{(1)}{=} \begin{pmatrix} -(\bar{u}_\mu u_\nu + \bar{u}_\nu u_\mu) & 0 \\ 0 & -(u_\mu \bar{u}_\nu + u_\nu \bar{u}_\mu) \end{pmatrix} \overset{(2)}{=} -2\,\mathrm{Re}(\bar{u}_\mu u_\nu) \overset{(3)}{=} -2\delta_{\mu\nu}.$$

(1) Block multiplication.

(2) For quaternions, $\bar{p}q + \bar{q}p = 2\,\mathrm{Re}(\bar{p}q) = p\bar{q} + q\bar{p}$ (the real part of $\bar{p}q$ is the Euclidean dot product in $\mathbb{R}^4$).

(3) $1, \mathbf{i}, \mathbf{j}, \mathbf{k}$ are orthonormal.

For $x \in S^3$ the clutching function $M^0 \to M^1$ is left multiplication by the unit quaternion $q = \sum x_\mu u_\mu$: $g(q) = q$, the clutching function of the quaternionic Hopf bundle (Example 3.69). It gives the generator α_4 of $\widetilde{KO}(S^4)$, the BPST instanton bundle. The matrices e_μ are the Euclidean gamma matrices in a chiral basis, $\gamma_\mu = \left(\begin{smallmatrix} 0 & \bar{\sigma}_\mu \\ \sigma_\mu & 0 \end{smallmatrix}\right)$ (Chapter T4), up to factors of i.

$k = 8$. Replace quaternions by octonions $\mathbb{O}$ (real dimension 8), with unit basis $u_1, \dots, u_8$. The same block formula on $M = \mathbb{O} \oplus \mathbb{O}$ gives sixteen-dimensional real gamma matrices for $\mathrm{Cl}_{0,8} = \mathbb{R}(16)$. The octonions are not associative, but they are *alternative*: $\bar{u}(ux) = |u|^2 x$ for all u, x, and polarising this in u gives $\bar{u}_\mu(u_\nu x) + \bar{u}_\nu(u_\mu x) = 2\delta_{\mu\nu}x$, which is all the computation above needs. The clutching function is left octonion multiplication, $S^7 \to \mathrm{GL}(8,\mathbb{R})$, $x \mapsto L_x$, and its class is the real Bott class β_8 generating $\widetilde{KO}(S^8) = \mathbb{Z}$.

The complex story is the same with $\mathrm{Cl}_{0,k} \otimes \mathbb{C}$. For $k = 2$ use $e_1 = i\sigma_1$, $e_2 = i\sigma_2$, graded by the eigenvalues of σ_3. Then

$$x\cdot = i \begin{pmatrix} 0 & x_1 - ix_2 \\ x_1 + ix_2 & 0 \end{pmatrix},$$

and the block $M^0 \to M^1$ is $i(x_1 + ix_2) = ie^{i\phi}$: the Hopf bundle H, generator b of $\widetilde{KU}(S^2)$. For $k = 2m$ the chiral block of $x \cdot \gamma$ on Weyl spinors $S^+ \to S^-$ gives the generator $b^{\boxtimes m}$ of $\widetilde{KU}(S^{2m})$. Bott periodicity is "tensoring with one more pair of gamma matrices".

Which modules give trivial bundles

Not every module gives a new class. Here is the one mechanism that kills classes.

Key idea: Extendable modules give trivial bundles

If the graded $\mathrm{Cl}_{0,k}$-module M extends to a graded $\mathrm{Cl}_{0,k+1}$-module (an extra odd e_{k+1} with $e_{k+1}^2 = -1$ anticommuting with $e_1, \dots, e_k$), then its ABS bundle over S^k is trivial.

The reason is a rotation into the new direction. For $t \in [0, \pi/2]$ put

$$g_t(x) := \cos t\,(x\cdot) + \sin t\, e_{k+1} : \; M^0 \to M^1.$$

Each $g_t(x)$ is Clifford multiplication by the vector $(\cos t\, x, \sin t) \in \mathbb{R}^{k+1}$, which has length one, so by the same computation as before $g_t(x)^2 = -1$ and $g_t(x)$ is invertible. At $t = 0$ it is g; at $t = \pi/2$ it is the constant e_{k+1}, which clutches a trivial bundle. A homotopy of clutching functions does not change the bundle (Section 3.12.2), so the ABS bundle is trivial.

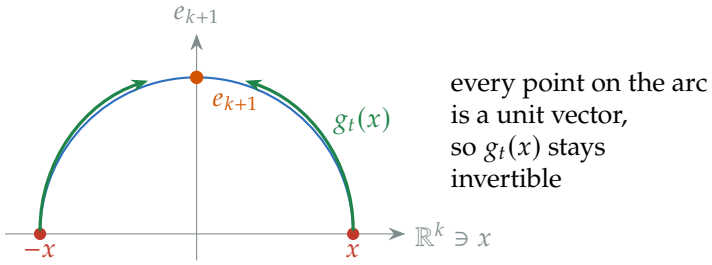

Figure 3.56: Why an extra Clifford generator trivialises the bundle. For each equator point x we rotate the unit vector x towards the new direction e_{k+1} (green). Every point of the quarter circle is a unit vector, so Clifford multiplication by it stays invertible. At the end all equator points have been moved to the same vector e_{k+1}, and the clutching function is constant.

So the ABS classes form a quotient

$$A_k := \frac{\{\text{graded } \mathrm{Cl}_{0,k}\text{-modules}\}}{\{\text{those that extend to } \mathrm{Cl}_{0,k+1}\}} \longrightarrow \widetilde{KO}(S^k),$$

where "modules" means the Grothendieck group of modules under $\oplus$, exactly as in Section 3.10.

Key idea: Atiyah–Bott–Shapiro

The map $A_k \to \widetilde{KO}(S^k)$ is an isomorphism for every k. The complex version, with $\mathrm{Cl}_{0,k} \otimes \mathbb{C}$, gives $A_k^{\mathbb{C}} \cong \widetilde{KU}(S^k)$.

Counting modules: the table from linear algebra

We now compute A_k by hand. Two facts make this pure bookkeeping.

(a) Graded $\mathrm{Cl}_{0,k}$-modules are ungraded $\mathrm{Cl}_{0,k-1}$-modules. Given a graded M, the even elements $f_i := e_i e_k$ $(i < k)$ map M^0 to itself, and

$$f_i^2 \overset{(1)}{=} e_i e_k e_i e_k \overset{(2)}{=} -e_i e_i e_k e_k \overset{(3)}{=} -(-1)(-1) = -1,$$
$$f_i f_j \overset{(2)}{=} e_i e_k e_j e_k = -e_i e_j e_k e_k \overset{(3)}{=} e_i e_j \qquad (i \neq j),$$

(1) Definition of f_i.
(2) Move one e_k past one e_i or e_j $(i, j \neq k)$: one sign.
(3) $e_i^2 = e_k^2 = -1$.

so $f_i f_j = e_i e_j = -e_j e_i = -f_j f_i$ for $i \neq j$. Thus $f_1, \dots, f_{k-1}$ make M^0 a $\mathrm{Cl}_{0,k-1}$-module. Conversely, from a $\mathrm{Cl}_{0,k-1}$-module W one rebuilds $M = W \oplus W$. So graded $\mathrm{Cl}_{0,k}$-modules correspond to ungraded $\mathrm{Cl}_{0,k-1}$-modules, and extending the graded module to $\mathrm{Cl}_{0,k+1}$ corresponds to extending W to $\mathrm{Cl}_{0,k}$. Hence

$$A_k \cong \frac{N_{k-1}}{\text{image of } N_k \text{ under restriction}}, \qquad N_j := \{\text{ungraded } \mathrm{Cl}_{0,j}\text{-modules}\}. \tag{3.133}$$

(b) The modules of $\mathrm{Cl}_{0,j}$ are read off from its matrix type (Chapter T4, table of Clifford algebras). A matrix algebra $\mathbb{F}(m)$ ($\mathbb{F} = \mathbb{R}, \mathbb{C}, \mathbb{H}$) has exactly one irreducible module, $\mathbb{F}^m$; a sum $\mathbb{F}(m) \oplus \mathbb{F}(m)$

has two. So $N_j = \mathbb{Z}$ or $\mathbb{Z}^2$, and we record the real dimension d_j of the irreducible modules:

j	0	1	2	3	4	5	6	7	8
$\mathrm{Cl}_{0,j}$	$\mathbb{R}$	$\mathbb{C}$	$\mathbb{H}$	$\mathbb{H}\oplus\mathbb{H}$	$\mathbb{H}(2)$	$\mathbb{C}(4)$	$\mathbb{R}(8)$	$\mathbb{R}(8)\oplus\mathbb{R}(8)$	$\mathbb{R}(16)$
N_j	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}^2$	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}$	$\mathbb{Z}^2$	$\mathbb{Z}$
d_j	1	2	4	4	8	8	8	8	16

(3.134)

When there are two irreducible modules ($j = 3, 7$), they are distinguished by the action of the volume element $\omega = e_1 e_2 \cdots e_j$, which is central with $\omega^2 = +1$, acting as $+1$ on one and -1 on the other. (In general $\omega^2 = (-1)^{j(j-1)/2}(-1)^j$ for $\mathrm{Cl}_{0,j}$, which is $+1$ for $j = 3, 7$ and -1 for $j = 1, 5$.)

Now restrict. An irreducible $\mathrm{Cl}_{0,k}$-module of dimension d_k, viewed as a $\mathrm{Cl}_{0,k-1}$-module, decomposes into irreducibles of dimension d_{k-1}. When $N_{k-1} = \mathbb{Z}$ it contains d_k/d_{k-1} copies. When $N_{k-1} = \mathbb{Z}^2$ ($k - 1 = 3, 7$), the extra generator e_k anticommutes with the volume element $\omega = e_1 \cdots e_{k-1}$ (moving e_k past $k-1$ odd generators gives $(-1)^{k-1} = -1$ for $k = 4, 8$), so e_k swaps the $\omega = \pm 1$ eigenspaces: they have equal size, and the restriction contains one of each.

Worked example 3.84: The ABS count for $k = 1, \ldots, 8$

Combining (3.133) and (3.134):

$$A_1 \overset{(1)}{=} \mathbb{Z}/(d_1/d_0)\mathbb{Z} = \mathbb{Z}/2\mathbb{Z} = \mathbb{Z}_2, \qquad A_2 \overset{(1)}{=} \mathbb{Z}/(d_2/d_1)\mathbb{Z} = \mathbb{Z}/2\mathbb{Z} = \mathbb{Z}_2,$$
$$A_3 \overset{(2)}{=} \mathbb{Z}/\langle 1, 1\rangle = 0, \qquad A_4 \overset{(3)}{=} \mathbb{Z}^2/\langle (1,1)\rangle = \mathbb{Z},$$
$$A_5 \overset{(1)}{=} \mathbb{Z}/(d_5/d_4)\mathbb{Z} = \mathbb{Z}/\mathbb{Z} = 0, \qquad A_6 \overset{(1)}{=} \mathbb{Z}/(d_6/d_5)\mathbb{Z} = 0,$$
$$A_7 \overset{(2)}{=} \mathbb{Z}/\langle 1, 1\rangle = 0, \qquad A_8 \overset{(3)}{=} \mathbb{Z}^2/\langle (1,1)\rangle = \mathbb{Z}.$$

(1) $N_{k-1} = N_k = \mathbb{Z}$, and the irreducible $\mathrm{Cl}_{0,k}$-module restricts to d_k/d_{k-1} copies of the irreducible $\mathrm{Cl}_{0,k-1}$-module; for example the $\mathbb{H}$-module $\mathbb{H} = \mathbb{C}^2$ restricts to two copies of $\mathbb{C}$.

(2) $N_{k-1} = \mathbb{Z}$, $N_k = \mathbb{Z}^2$: each of the two irreducible $\mathrm{Cl}_{0,k}$-modules has dimension $d_k = d_{k-1}$ and restricts to the irreducible $\mathrm{Cl}_{0,k-1}$-module; the image is generated by 1 and 1, which is all of $\mathbb{Z}$.

(3) $N_{k-1} = \mathbb{Z}^2$, $N_k = \mathbb{Z}$: the irreducible module restricts to one copy of each $\omega = \pm 1$ module, so the image is the diagonal $\mathbb{Z}(1,1)$, and $\mathbb{Z}^2/\mathbb{Z}(1,1) \cong \mathbb{Z}$ via $(a, b) \mapsto a - b$.

The result $\mathbb{Z}_2, \mathbb{Z}_2, 0, \mathbb{Z}, 0, 0, 0, \mathbb{Z}$ is exactly the $\widetilde{KO}(S^k)$ row of (3.129). The $\mathbb{Z}_2$'s come from the *doubling* of irreducible dimension ($1 \to 2 \to 4$), the $\mathbb{Z}$'s from the *splitting* into two modules by the volume element, and the zeros from everything else. Since $\mathrm{Cl}_{0,k+8} = \mathrm{Cl}_{0,k} \otimes \mathbb{R}(16)$ changes each d_j by the same factor 16 and nothing else, the count repeats with period 8: this is real Bott periodicity, derived from linear algebra.

Try it

Do the complex count. $\mathrm{Cl}_{0,j} \otimes \mathbb{C}$ is $\mathbb{C}(2^{j/2})$ for j even (one module, complex dimension $2^{j/2}$) and $\mathbb{C}(2^{(j-1)/2}) \oplus \mathbb{C}(2^{(j-1)/2})$ for j odd (two modules). Show that $A_k^{\mathbb{C}} = \mathbb{Z}$ for k even and 0 for k odd.

Answer. k even: $N_{k-1}^{\mathbb{C}} = \mathbb{Z}^2$, $N_k^{\mathbb{C}} = \mathbb{Z}$ restricts to $(1,1)$, so $A_k^{\mathbb{C}} = \mathbb{Z}^2/\mathbb{Z}(1,1) = \mathbb{Z}$. k odd: $N_{k-1}^{\mathbb{C}} = \mathbb{Z}$, and each of the two modules of $N_k^{\mathbb{C}}$ restricts to the single irreducible, so the image is all of $\mathbb{Z}$ and $A_k^{\mathbb{C}} = 0$. This is $\widetilde{KU}(S^k) = \mathbb{Z}, 0, \mathbb{Z}, 0, \ldots$: complex Bott periodicity with period 2.

3.14.6 Clifford modules at work: vector fields on spheres

In Example 3.42 we framed S^1 and S^3 by explicit vector fields, and noted that S^n is parallelisable only for $n = 1, 3, 7$. Clifford modules answer the more refined question: *how many* everywhere linearly independent vector fields does S^{n-1} carry?

Working definition 3.37 (vector fields from a Clifford module)

Suppose $\mathbb{R}^n$ is a module over $\mathrm{Cl}_{0,k}$ [there are real $n \times n$ matrices $e_1, \dots, e_k$ with $e_i e_j + e_j e_i = -2\delta_{ij}$], with the e_i orthogonal matrices (always possible: average an inner product over the finite group generated by the e_i). Then for $x \in S^{n-1}$ the k vectors

$$v_1(x) = e_1 x, \ \dots, \ v_k(x) = e_k x$$

are orthonormal and tangent to S^{n-1} at x [perpendicular to x, because an orthogonal e_i with $e_i^2 = -1$ is antisymmetric, so $\langle x, e_i x\rangle = 0$].

Check: e_i orthogonal with $e_i^2 = -1$ means $e_i^T = e_i^{-1} = -e_i$ (antisymmetric). Then

$$\langle e_i x, x\rangle \overset{(1)}{=} \langle x, e_i^T x\rangle \overset{(2)}{=} -\langle x, e_i x\rangle \overset{(3)}{=} -\langle e_i x, x\rangle \quad \Longrightarrow \quad \langle e_i x, x\rangle = 0,$$
$$\langle e_i x, e_j x\rangle \overset{(1)}{=} \langle x, e_i^T e_j x\rangle \overset{(2)}{=} -\langle x, e_i e_j x\rangle \overset{(4)}{=} \tfrac{1}{2}\langle x, -(e_i e_j + e_j e_i)x\rangle \overset{(5)}{=} \delta_{ij}\,|x|^2 .$$

(1) Definition of the transpose.
(2) $e_i^T = -e_i$.
(3) Symmetry of the inner product.
(4) $\langle x, Ax\rangle$ only sees the symmetric part of A.
(5) The Clifford relation.

The first line says $v_i(x) \perp x$ (tangent), the second that the v_i are orthonormal.

Worked example 3.85: S^1, S^3, S^7, S^{15}

$n = 2$: $\mathbb{R}^2 = \mathbb{C}$ is a $\mathrm{Cl}_{0,1}$-module ($e_1 = i$), giving $v_1(x) = ix$: the rotation field $(-x_2, x_1)$ on S^1 of Example 3.42.
$n = 4$: $\mathbb{R}^4 = \mathbb{H}$ is a $\mathrm{Cl}_{0,3}$-module via right multiplication by $\mathbf{i}, \mathbf{j}, \mathbf{k}$ (right multiplications reverse the order of products but preserve anticommutation), giving the three fields $q\mathbf{i}$, $q\mathbf{j}$, $q\mathbf{k}$ of Example 3.42: a full frame of TS^3.
$n = 8$: $\mathbb{R}^8 = \mathbb{O}$ is a $\mathrm{Cl}_{0,7}$-module (an irreducible module of $\mathbb{R}(8) \oplus \mathbb{R}(8)$) via the seven imaginary octonion units: seven fields, a frame of TS^7.
$n = 16$: from (3.134), the largest k with d_k dividing 16 is $k = 8$ ($d_8 = 16$, $d_9 = 32$). So S^{15} carries 8 independent vector fields, not 15: it is not parallelisable.

The general count is the **Hurwitz–Radon number**: write $n = 2^{4a+b} \cdot (\text{odd})$ with $0 \le b \le 3$; then $\rho(n) = 2^b + 8a$, and the construction gives $\rho(n) - 1$ fields on S^{n-1}. For $n = 2, 4, 8, 16, 32$ this is $1, 3, 7, 8, 9$ fields. For odd n it is 0: the hairy ball theorem on even-dimensional spheres (Example 3.43). That no sphere carries *more* fields than this was proved by Adams (1962), using $\widetilde{KO}$ of real projective spaces and operations on K-theory. So the question "which spheres are parallelisable?", raised in Section 3.9, is answered by the same period-eight structure: $\rho(n) = n$ only for $n = 1, 2, 4, 8$.

3.14.7 The period eight in physics

The eight real K-groups of a point, $KO^{-n}(\mathrm{pt}) = \mathbb{Z}, \mathbb{Z}_2, \mathbb{Z}_2, 0, \mathbb{Z}, 0, 0, 0$, keep reappearing. A few places where they do:

Dictionary: $KO^{-n}(\mathrm{pt})$ in physics

Majorana spinors	Real spinors exist when the Clifford algebra is a real matrix algebra, which depends on the dimension and signature mod 8 (Chapter T4). This is the same period eight, seen in the algebra before the topology.
Mod-2 indices	A real skew-adjoint Dirac-type operator has an index defined only mod 2 (the number of zero modes mod 2). It lives in $KO^{-1}(\mathrm{pt}) = \mathbb{Z}_2$ or $KO^{-2}(\mathrm{pt}) = \mathbb{Z}_2$, so it occurs in dimensions $8m+1$ and $8m+2$.
Global anomalies	Witten's SU(2) anomaly uses $\pi_4(\mathrm{SU}(2)) = \pi_4(\mathrm{Sp}(1)) = \mathbb{Z}_2$; stably this is $\widetilde{KSp}(S^5) = \widetilde{KO}(S^9) = \mathbb{Z}_2$, a mod-2 index (Chapter 10).
Topological insulators and superconductors	The "ten-fold way" (Kitaev, 2009): gapped free-fermion phases in d dimensions in real symmetry class s ($s = 0, \dots, 7$ for AI, BDI, D, DIII, AII, CII, C, CI) are classified by $KO^{-(s-d)}(\mathrm{pt})$. For example: Kitaev's Majorana chain (D, $d=1$) is $\mathbb{Z}_2$; the $p+ip$ superconductor (D, $d=2$) is $\mathbb{Z}$; the quantum spin Hall insulator (AII, $d=2$) is $\mathbb{Z}_2$. The two complex classes follow KU, with period 2.
Type I D-branes	Charges of Dp-branes in type I string theory lie in $\widetilde{KO}(S^{9-p})$ (Witten, 1998): $\mathbb{Z}$ for $p = 9, 5, 1$, and $\mathbb{Z}_2$ for $p = 8, 7, 0, -1$, the stable non-BPS branes. There is no D3-brane charge: $\widetilde{KO}(S^6) = 0$.

Worked example 3.86: Checking two entries of the ten-fold way

Class D has $s = 2$. For the Kitaev chain ($d = 1$) and the $p + ip$ superconductor ($d = 2$):

$$KO^{-(2-1)}(\mathrm{pt}) \overset{(1)}{=} \widetilde{KO}(S^1) \overset{(2)}{=} \mathbb{Z}_2, \qquad KO^{-(2-2)}(\mathrm{pt}) \overset{(1)}{=} \widetilde{KO}(S^0) \overset{(2)}{=} \mathbb{Z}.$$

(1) $KO^{-n}(\mathrm{pt}) = \widetilde{KO}(S^n)$.
(2) The table (3.129).

The $\mathbb{Z}_2$ of the Kitaev chain is the presence or absence of unpaired Majorana zero modes at its ends, exactly like the Möbius bundle's "twist or no twist", the generator η of $\widetilde{KO}(S^1)$. The $\mathbb{Z}$ of the $p + ip$ superconductor is a Chern number. For class AII ($s = 4$) in $d = 3$ one gets $KO^{-1} = \mathbb{Z}_2$: the strong invariant of a three-dimensional topological insulator.

Reading Nash (p. 78, (3.90))

Nash says: "We simply quote the corresponding facts for the real and the quaternionic cases. Both theories possess periodicities and these can be traced back to the stable homotopy of the infinite orthogonal and symplectic groups respectively." He gives (3.90): $\pi_n(\mathrm{O}(\infty)) = \pi_{n+8}(\mathrm{O}(\infty))$ with $\widetilde{KO}^{-n}(X) = \widetilde{KO}^{-n-8}(X)$, and $\pi_n(\mathrm{Sp}(\infty)) = \pi_{n+4}(\mathrm{O}(\infty))$ with $\widetilde{KSp}^{-n}(X) = \widetilde{KO}^{-n-4}(X)$, and concludes that there is now enough information to calculate $\widetilde{KO}(S^n)$, $\widetilde{KU}(S^n)$ and $\widetilde{KSp}(S^n)$ for all n. We have added: the full tables (3.128) and (3.129) with checks; the unstable groups of $\mathrm{SO}(k)$ via spin groups; Bott's eight-step chain of loop

spaces and the Maslov index; complexification and realification, including $c = 0$ on $\widetilde{KO}(S^2)$, $c = \times 2$ on $\widetilde{KO}(S^4)$, and the ring relation $\alpha_4^2 = 4\beta_8$; the Atiyah–Bott–Shapiro clutching functions and the Clifford module count that reproduces the real table; vector fields on spheres; and the physics dictionary.

Recap

- Real K-theory has period 8, quaternionic K-theory is real K-theory shifted by 4, complex K-theory has period 2: $\widetilde{KO}(S^n) = \mathbb{Z}, \mathbb{Z}_2, \mathbb{Z}_2, 0, \mathbb{Z}, 0, 0, 0$ (n mod 8), $\widetilde{KSp}(S^n) = \widetilde{KO}(S^{n+4})$.
- Mechanism 1: Bott's chain of eight loop spaces $\mathrm{O} \to \mathrm{O/U} \to \mathrm{U/Sp} \to \mathbb{Z} \times BSp \to \mathrm{Sp} \to \mathrm{Sp/U} \to \mathrm{U/O} \to \mathbb{Z} \times BO \to \mathrm{O}$; each step adds an anticommuting complex structure.
- Mechanism 2: $rc = 2$, $cr = 1 + \psi$. c kills $\widetilde{KO}(S^2)$, doubles on $\widetilde{KO}(S^4)$, is an isomorphism on $\widetilde{KO}(S^8)$; $\alpha_4^2 = 4\beta_8$.
- Mechanism 3 (ABS): Clifford multiplication $x \mapsto x\cdot$ is a clutching function; $\widetilde{KO}(S^k) =$ graded $\mathrm{Cl}_{0,k}$-modules modulo those extending to $\mathrm{Cl}_{0,k+1}$. The generators are the Möbius, Hopf, quaternionic Hopf (instanton) and octonionic bundles in degrees $1, 2, 4, 8$.
- Clifford modules also give $\rho(n) - 1$ vector fields on S^{n-1}; the period eight appears in physics as Majorana conditions, mod-2 indices, the ten-fold way, and type I D-brane charges.

3.15 Characteristic classes: what they measure and where they live

The last two sections built a machine, K-theory, that sorts vector bundles into classes and adds and multiplies those classes. Bott periodicity then told us what the K-groups of spheres are. But a physicist holding a particular bundle in their hands (the bundle of a monopole, of an instanton, the tangent bundle of a curved space) still has a practical problem: *how do we tell whether this bundle is twisted, and by how much?*

We already know the kind of answer we want. For the Dirac monopole the answer is a single integer, the magnetic charge n, which we get by integrating the field strength over a sphere that surrounds the monopole. For an SU(2) instanton on $\mathbb{R}^4$ it is again an integer, the instanton number $k = \frac{1}{8\pi^2}\int \operatorname{tr} F \wedge F$. In both cases we integrate a polynomial in the curvature over a closed manifold and get an integer that does not change when we deform the field.

This section and the next five explain the general machine behind such integers. The objects it produces are called **characteristic classes**. They are cohomology classes on the base space, built from the bundle, with three properties:

- isomorphic bundles give the same classes;
- they are compatible with pulling bundles back along maps;
- they vanish (apart from a trivial constant) on a trivial bundle.

So a nonzero characteristic class *proves* that a bundle is twisted, exactly as a nonzero magnetic flux through a sphere proves that no global vector potential exists.

There are two complementary ways in. Nash starts with the *topological* definition, pulling classes back from a classifying space, and only at the end of the section (his p. 87) turns to the *curvature* formulas. We follow the same order for the definition, then move the curvature formulas forward to Section 3.16, because curvature is where a physicist actually computes.

Reading Nash (p. 78, (3.87)–(3.90), the end of §4)

Nash's page 78 opens with the last step of Bott periodicity, which the previous part treated: $\widetilde{KU}^{-n}(X) \cong \widetilde{KU}^{-(n+2)}(X)$, proved by multiplying by the generator $b = [\eta] - [I]$ of $\widetilde{KU}(S^2) \cong \mathbb{Z}$. Here η is the Hopf line bundle over $\mathbb{CP}^1 = S^2$, which is also the bundle of the Dirac monopole, and I is the trivial line bundle. Two facts from there matter to us now. First, K-theory of spheres is made of integers. Second, those integers were found by homotopy theory, not by a formula. Characteristic classes are the formula: in Section 3.18 we will see that the Chern character turns b into the integer ± 1 by integrating a curvature over S^2.

3.15.1 The universal bundle and the classifying map

Here is the organising idea. There is one "mother" bundle of rank k from which every other rank-k complex bundle is obtained by pulling back. Any invariant we define on the mother bundle is then automatically defined on every bundle.

The mother bundle. Take a very large complex vector space $\mathbb{C}^N$. The **Grassmannian** $\mathrm{Gr}(k, N, \mathbb{C})$ is the set of all k-dimensional complex subspaces ("k-planes") of $\mathbb{C}^N$. It is a compact manifold. For $k = 1$ it is the space of lines through the origin, $\mathrm{Gr}(1, N, \mathbb{C}) = \mathbb{CP}^{N-1}$. Over the Grassmannian there is a bundle with a completely tautological description:

$$Q(k, N, \mathbb{C}) = \big\{(P, v) \;:\; P \in \mathrm{Gr}(k, N, \mathbb{C}),\; v \in P\big\}.$$

The fibre over the point P is the plane P itself. Letting $N \to \infty$ gives the **classifying space** $BU(k) = \mathrm{Gr}(k, \infty, \mathbb{C}) = \bigcup_N \mathrm{Gr}(k, N, \mathbb{C})$ and the **universal bundle** $E_{U(k)} = Q(k, \infty, \mathbb{C})$ over it. For $k = 1$ we get $BU(1) = \mathbb{CP}^\infty$ with its tautological line bundle.

The classifying map. Now let $E \to X$ be any rank-k complex bundle over a compact space X. It is always possible to put E inside a trivial bundle $X \times \mathbb{C}^N$ for some large N (choose N global sections that span every fibre, or choose a complement E' with $E \oplus E'$ trivial, as in the stable-equivalence argument of the previous part). Then each fibre E_x *is* a k-plane in $\mathbb{C}^N$, and we can define

$$f : X \longrightarrow \mathrm{Gr}(k, N, \mathbb{C}) \subset BU(k), \qquad f(x) = E_x. \tag{3.135}$$

By construction the fibre of the universal bundle over $f(x)$ is E_x again. In other words

$$E \;\cong\; f^* E_{U(k)}. \tag{3.136}$$

Physical picture: The Gauss map

The real version of this construction is an old friend. A surface $\Sigma \subset \mathbb{R}^3$ has at each point a tangent plane $T_x\Sigma$, which is a 2-plane in $\mathbb{R}^3$. The map $x \mapsto T_x\Sigma$ into the real Grassmannian $\mathrm{Gr}(2, 3, \mathbb{R})$ of planes in $\mathbb{R}^3$ is (essentially) Gauss's map $x \mapsto$ unit normal. The tangent bundle $T\Sigma$ is the pullback of the tautological plane bundle along this map. Gauss discovered that the total curvature $\int_\Sigma K \, \mathrm{d}A$ equals the signed area that the unit normal sweeps out on the unit sphere. Dividing by 2π gives the Euler characteristic of Σ. That is our first

characteristic class (the Euler class of Section 3.20), computed through the classifying map.

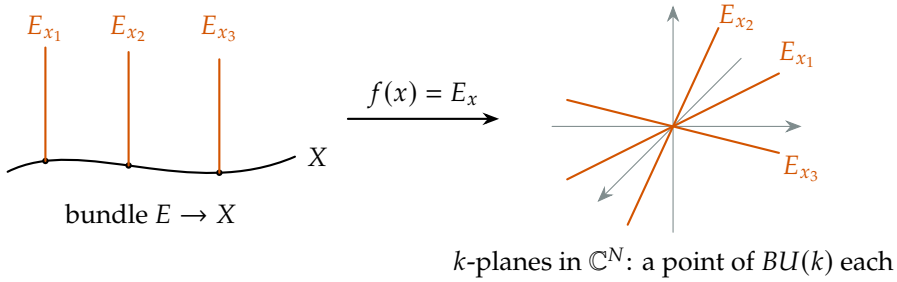

Figure 3.57: The classifying map. Once E sits inside a trivial bundle $X \times \mathbb{C}^N$, every fibre E_x is a k-plane in $\mathbb{C}^N$, that is, a point of the Grassmannian. The map f sends x to that point. The universal bundle has the plane itself as its fibre, so pulling it back along f gives E back.

Two facts make this useful. We state them and explain why they are plausible.

Key idea: Classification of bundles

1. Every rank-k complex bundle over X is $f^*E_{U(k)}$ for some map $f : X \to BU(k)$.
2. $f^*E_{U(k)} \cong g^*E_{U(k)}$ if and only if f and g are homotopic.

So isomorphism classes of rank-k bundles are the same thing as homotopy classes of maps: $\mathrm{Vect}_k(X, \mathbb{C}) \cong [X, BU(k)]$.

Part 1 is the construction above. For part 2, a homotopy f_t is a family of classifying maps, that is, a bundle over $X \times [0,1]$; bundles over a cylinder are "constant in the t direction" (one can parallel transport along t with any connection), so the two ends are isomorphic. The infinite size of $BU(k)$ is what makes the choices of N and of embedding irrelevant: any two embeddings can be rotated into each other inside a big enough $\mathbb{C}^N$.

$$\begin{array}{ccc} E = f^*E_{U(k)} & \longrightarrow & E_{U(k)} \\ \downarrow & & \downarrow \\ X & \xrightarrow{\ f\ } & BU(k) \end{array} \qquad \begin{array}{ccc} H^{2i}(X;\mathbb{Z}) & \xleftarrow{\ f^*\ } & H^{2i}(BU(k);\mathbb{Z}) \\ \Psi & & \Psi \\ c_i(E) = f^*c_i & \longleftarrow\!\shortmid & c_i \end{array}$$

Figure 3.58: Left: every bundle is a pullback of the universal bundle. Right: cohomology goes the other way. The universal Chern classes c_i living on $BU(k)$ are pulled back by f^* to classes on X. Homotopic maps induce the same f^*, so the result depends only on the isomorphism class of E.

3.15.2 Chern classes defined by pulling back

The cohomology of the universal space is known exactly. We state the result and then make it believable for $k = 1$.

Key idea: Cohomology of $BU(k)$

$H^*(BU(k);\mathbb{Z}) = \mathbb{Z}[c_1, \dots, c_k]$, a polynomial ring on k generators with $c_i \in H^{2i}(BU(k);\mathbb{Z})$. There is nothing in odd degrees, and no relations between the generators.

For $k = 1$, $BU(1) = \mathbb{CP}^\infty$. Build $\mathbb{CP}^n$ by induction: the points $[z_0 : \cdots : z_n]$ with $z_n \neq 0$ can be written $[z_0/z_n : \cdots : 1]$, a copy of $\mathbb{C}^n = \mathbb{R}^{2n}$, an open $2n$-dimensional cell; the points with $z_n = 0$ form $\mathbb{CP}^{n-1}$. So

$$\mathbb{CP}^n = \mathrm{pt} \cup \mathbb{R}^2 \cup \mathbb{R}^4 \cup \cdots \cup \mathbb{R}^{2n},$$

one cell in each even dimension. With no odd cells, there is nothing for a coboundary map to do, and $H^{2j}(\mathbb{CP}^n; \mathbb{Z}) = \mathbb{Z}$ for $0 \le j \le n$. The generator of H^2 is called x (it will be $-c_1$ of the tautological bundle), and Poincaré duality on $\mathbb{CP}^n$ shows that x^j generates H^{2j}. Letting $n \to \infty$ gives $H^*(\mathbb{CP}^\infty; \mathbb{Z}) = \mathbb{Z}[x]$.

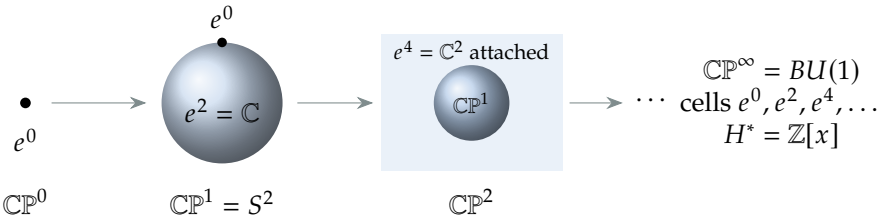

Figure 3.59: The cell structure of complex projective space: one cell in each even dimension and none in odd dimensions. This is why $BU(1) = \mathbb{CP}^\infty$ has cohomology $\mathbb{Z}$ in every even degree, generated by powers of a single degree-2 class. That class, pulled back, is the first Chern class.

Working definition 3.38 (Chern classes, topological version)

Let $E \to X$ be a complex vector bundle of rank k and $f : X \to BU(k)$ its classifying map [the map with $E \cong f^* E_{U(k)}$, unique up to homotopy]. The ***i*-th Chern class** of E is

$$c_i(E) = f^*\big(c_i(E_{U(k)})\big) \in H^{2i}(X; \mathbb{Z}), \qquad i = 1, \ldots, k. \tag{3.137}$$

[$c_i(E_{U(k)})$ is the degree-$2i$ generator of $H^*(BU(k); \mathbb{Z}) = \mathbb{Z}[c_1, \ldots, c_k]$] We set $c_0(E) = 1$ and $c_i(E) = 0$ for $i > k$. *Operationally:* you never compute f. You use the properties below (naturality, the Whitney formula, normalisation), or the curvature formula of Section 3.16, which produces a closed differential form representing $c_i(E)$ in de Rham cohomology.

Three properties follow almost immediately, and together they pin the classes down completely.

1. **Naturality.** If $g : Y \to X$ is a map, then $c_i(g^* E) = g^* c_i(E)$. Reason: the classifying map of $g^* E$ is $f \circ g$, and $(f \circ g)^* = g^* f^*$.

2. **Whitney sum formula.** $c(E \oplus F) = c(E)\, c(F)$ for the total class defined next. (We will see it with curvature in Section 3.16: the curvature of a direct sum is block diagonal, and a determinant of a block-diagonal matrix factorises.)

3. **Normalisation.** For the tautological line bundle γ over $\mathbb{CP}^1$, $\int_{\mathbb{CP}^1} c_1(\gamma) = -1$, where $\mathbb{CP}^1$ carries its complex orientation. (Some books normalise the sign the other way; ours agrees with the curvature formula $c_1 = \frac{i}{2\pi} \operatorname{tr} F$ and with Milnor and Stasheff. We check the sign by a calculation in Example 3.92.)

Working definition 3.39 (Total Chern class)

The **total Chern class** of a rank-k bundle is the inhomogeneous [a sum of pieces of different degrees $0, 2, \ldots, 2k$] cohomology class

$$c(E) = 1 + c_1(E) + c_2(E) + \cdots + c_k(E) \ \in \ H^{\text{even}}(X; \mathbb{Z}). \tag{3.138}$$

It is a bookkeeping device: the Whitney formula $c(E \oplus F) = c(E)c(F)$ unpacks, degree by degree, into

$$c_n(E \oplus F) = \sum_{i+j=n} c_i(E)\, c_j(F).$$

Worked example 3.87: The trivial bundle has $c = 1$

Let $E = X \times \mathbb{C}^k = I^k$. Its classifying map can be chosen constant: every fibre is the same plane $\mathbb{C}^k \subset \mathbb{C}^N$. A constant map factors through a point, $X \to \{\mathrm{pt}\} \to BU(k)$. Then for $i \geq 1$

$$\begin{aligned} c_i(I^k) &\overset{(1)}{=} f^* c_i \\ &\overset{(2)}{=} (\mathrm{const})^* \left(c_i\big|_{\mathrm{pt}}\right) \\ &\overset{(3)}{=} 0. \end{aligned}$$

(1) Definition (3.137).
(2) The constant map factors through a point, and pullback is functorial.
(3) $H^{2i}(\mathrm{pt};\mathbb{Z}) = 0$ for $i \geq 1$: a point has no cohomology above degree zero.

So $c(I^k) = 1$. Combined with Whitney: $c(E \oplus I^j) = c(E) \cdot 1 = c(E)$. *Chern classes cannot see trivial summands*, which is exactly the behaviour of K-theory's stable equivalence. Stably equivalent bundles have the same Chern classes.

3.15.3 Line bundles over the sphere: c_1 is the clutching degree

Let us see what the definition says in the first nontrivial case, complex line bundles over S^2. The previous part classified bundles over spheres by **clutching**: cover S^2 by a northern disc U_N and a southern disc U_S, trivialise the bundle over each (discs are contractible, so every bundle is trivial over them), and record how the two trivialisations are glued on the overlap, a band around the equator. For a line bundle, the gluing is a function

$$g : \text{ equator} \cong S^1 \longrightarrow U(1), \qquad \phi \mapsto g(\phi),$$

and only its winding number $n \in \pi_1(U(1)) = \mathbb{Z}$ matters. Write L_n for the bundle glued with a map of winding $-n$, for instance $g(\phi) = e^{-in\phi}$. (The sign is chosen so that L_n will have $c_1 = n$ below; with this choice L_{-1} is the tautological bundle, which we will check.)

Worked example 3.88: Chern classes of $L_m \oplus L_n$ over S^2

Let $u \in H^2(S^2;\mathbb{Z})$ be the generator with $\int_{S^2} u = 1$. Anticipating the calculation of Example 3.91, $c(L_n) = 1 + nu$. Then

$$\begin{aligned} c(L_m \oplus L_n) &\overset{(1)}{=} (1 + mu)(1 + nu) \\ &= 1 + (m+n)u + mn\, u^2 \\ &\overset{(2)}{=} 1 + (m+n)u. \end{aligned}$$

(1) The Whitney sum formula.
(2) $u^2 \in H^4(S^2;\mathbb{Z}) = 0$: a 2-dimensional space has no cohomology in degree 4.

So $c_1(L_m \oplus L_n) = (m+n)u$ and $c_2 = 0$. This matches the clutching picture: a rank-2 bundle over S^2 is glued by a loop in $U(2)$, and $\pi_1(U(2)) = \mathbb{Z}$ is detected by the determinant,

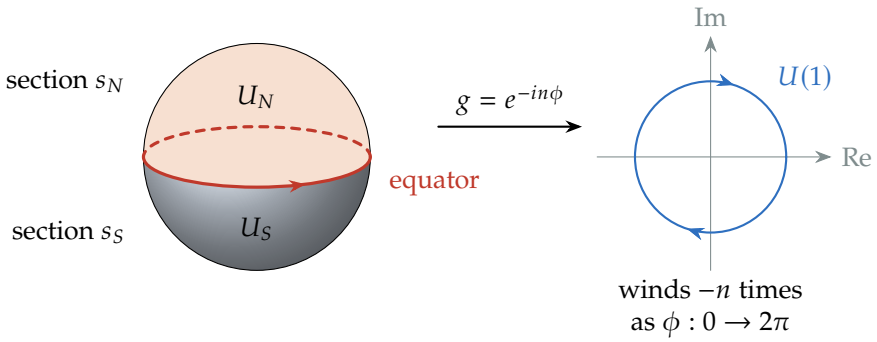

Figure 3.60: Clutching a line bundle over S^2. The bundle is trivial over each hemisphere. All the twisting is recorded by the gluing function on the equator, a loop in $U(1)$. Its winding number is the only invariant, and it is the first Chern class (up to the sign convention stated in the text).

$\det\big(\mathrm{diag}(e^{-im\phi}, e^{-in\phi})\big) = e^{-i(m+n)\phi}$, of winding $-(m+n)$. In particular $L_m \oplus L_n \cong L_{m+n} \oplus I$, the same total winding. On S^2 the first Chern class is a *complete* invariant of complex bundles, rank by rank.

Worked example 3.89: c_2 lives on four-dimensional spaces

Why do we need higher Chern classes at all? Because $c_i \in H^{2i}(X)$, and on a space of real dimension d only c_i with $2i \le d$ can be nonzero. On S^2 only c_1 survives (Example 3.88). On S^4, $H^2(S^4) = 0$, so $c_1 = 0$ for every bundle, and the only possible invariant is $c_2 \in H^4(S^4;\mathbb{Z}) = \mathbb{Z}$. Clutching agrees: bundles over S^4 are glued along the equatorial S^3 by maps $S^3 \to \mathrm{SU}(2)$, classified by $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$. We will show in Example 3.93 that c_2 equals this winding number. It is the instanton number.

Dictionary: Characteristic classes and charges

Mathematics	Physics
c_1 of a $U(1)$ bundle over S^2	magnetic charge of a Dirac monopole
c_2 of an SU(2) bundle over S^4	instanton number (topological charge)
clutching function on the equator	large gauge transformation between patches
classifying map $X \to BU(k)$	"which vacuum/gauge sector we are in"
$c(E \oplus I) = c(E)$	adding a free, untwisted field changes no charge

Watch out: Characteristic classes do not classify

Equal Chern classes do not imply isomorphic bundles. Two examples. (i) Over S^5, rank-2 complex bundles are clutched along the equatorial S^4 by maps $S^4 \to U(2)$, and $\pi_4(U(2)) = \pi_4(S^3) = \mathbb{Z}_2$, so there is a nontrivial rank-2 bundle over S^5 (the previous part met it as a stably trivial but nontrivial bundle). Yet all its Chern classes vanish, simply because $H^2(S^5) = H^4(S^5) = 0$. (ii) The real tangent bundle TS^2 is not trivial (hairy-ball theorem), but all its Pontryagin classes vanish (Example 3.114); only the Euler class of Section 3.20 sees it. The classes are *obstructions*: nonzero means twisted; zero means "no information from this test". For *line* bundles c_1 is always complete (line bundles over X correspond one-to-one to $H^2(X;\mathbb{Z})$, because $\mathbb{CP}^\infty$ has only one nonzero homotopy group, $\pi_2 = \mathbb{Z}$), and over S^2 it is complete in every rank. Beyond that, completeness is luck of low dimension.

Watch out: Integer classes versus differential forms

The topological definition gives classes in $H^{2i}(X;\mathbb{Z})$. Differential forms only see $H^{2i}(X;\mathbb{R})$, which forgets *torsion*: elements t with $mt = 0$ for some integer m. On all the manifolds we compute with (spheres, tori, $\mathbb{CP}^n$, K3) the integer cohomology has no torsion, and nothing is lost. When Nash writes "modulo elements of order 2" (Section 3.19.6), he is warning about precisely this.

Reading Nash (pp. 78–79, (3.91)–(3.92))

Nash states the definition in one display (3.91): for a rank-k bundle E with classifying map $f : X \to BU(k)$ and $E = f^*E_{U(k)}$, $H^*(BU(k);\mathbb{Z})$ has even generators $c_i(E_{U(k)}) \in H^{2i}(BU(k);\mathbb{Z})$, and $c_i(E) = f^*(c_i(E_{U(k)})) \in H^{2i}(X;\mathbb{Z})$. Then (3.92) introduces the total class $c(E) = 1 + c_1(E) + \cdots + c_k(E)$ and states $c(E \oplus F) = c(E)c(F)$. His $\mathrm{Vect}(X,\mathbb{C})$ is the set of complex vector bundles over X. The classifying spaces themselves were introduced in his Chapter 1, §5 and in (3.66)–(3.67) as infinite Grassmannians $BU(k) = \mathrm{Gr}(k,\infty,\mathbb{C})$.

Recap

- Every rank-k bundle is the pullback $f^*E_{U(k)}$ of the universal bundle over $BU(k) = \mathrm{Gr}(k,\infty,\mathbb{C})$; homotopic f give isomorphic bundles.
- $H^*(BU(k);\mathbb{Z}) = \mathbb{Z}[c_1,\dots,c_k]$; pulling back defines $c_i(E) \in H^{2i}(X;\mathbb{Z})$.
- Properties: naturality, Whitney $c(E \oplus F) = c(E)c(F)$, normalisation $\int_{\mathbb{CP}^1} c_1(\gamma) = -1$, and $c(\text{trivial}) = 1$.
- Over S^2: c_1 = winding of the clutching function; over S^4: c_2 = winding of a map $S^3 \to \mathrm{SU}(2)$.
- Characteristic classes detect twisting; they do not always classify.

3.16 Chern–Weil theory: characteristic classes from curvature

The definition of the last section is clean but useless for computation: nobody writes down classifying maps. Nash closes his section (p. 87) by recalling that characteristic classes "are often calculated using curvature methods", and in this book those are the methods we will actually use, for anomalies, instantons and index densities. So we develop them now, in full.

The puzzle to keep in mind is this. Curvature is *local*: it is a field strength, it depends on the connection, and it changes from point to point. A characteristic class is *global and rigid*: it is an integer that does not change under deformations. How can the one produce the other? The answer has two halves.

1. Suitable polynomials in the curvature are *closed* forms, so they define de Rham cohomology classes.

2. Changing the connection changes those forms by an *exact* form, so the cohomology class, and hence every integral over a closed cycle, does not change.

The exact form in half 2 has a name that every physicist knows: for $\operatorname{tr} F^2$ it is the *Chern–Simons form*.

3.16.1 Reminder: connections and curvature on a vector bundle

A full treatment is in Chapter T2 and Chapter T3; here is what we need, with the conventions fixed.

Let $E \to X$ be a complex vector bundle of rank k. Over an open set U choose a **local frame**: k sections $s = (s_1, \dots, s_k)$ that form a basis of each fibre. A **connection** ∇ differentiates sections. On the frame it is recorded by a $k \times k$ matrix $A = (A_{ij})$ of 1-forms:

$$\nabla s_j = \sum_i s_i \, A_{ij}, \qquad \text{or in matrix shorthand} \quad \nabla s = s\, A. \tag{3.139}$$

A general section $\psi = s\, u$ (with u a column of functions) then has $\nabla\psi = s\,(\mathrm{d}u + Au)$. This is the covariant derivative $D = \mathrm{d} + A$ of gauge theory. The **curvature** is the matrix of 2-forms

$$F = \mathrm{d}A + A \wedge A. \tag{3.140}$$

Conventions. If E carries a Hermitian metric and we use orthonormal frames and a metric-compatible connection, then A and F take values in $\mathfrak{u}(k)$, the *anti-Hermitian* matrices. This is Nash's convention and ours. Physicists usually write $D_\mu = \partial_\mu - i g\, A^a_\mu T^a$ with Hermitian generators T^a.

Dictionary: Anti-Hermitian (maths) versus Hermitian (physics) gauge fields

Maths / Nash	Physics
$A = A_\mu \,\mathrm{d}x^\mu$, $A_\mu^\dagger = -A_\mu$	$A_\mu = -ig\, A^a_\mu T^a$, T^a Hermitian, $\operatorname{tr} T^a T^b = \tfrac{1}{2}\delta^{ab}$
$F = \mathrm{d}A + A \wedge A$	$F = -ig\, F^a T^a$, $F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g f^{abc} A^b_\mu A^c_\nu$
$\operatorname{tr} F \wedge F$	$-\frac{g^2}{2} F^a \wedge F^a = -\frac{g^2}{4} F^a_{\mu\nu} \tilde{F}^{a\,\mu\nu}\, \mathrm{d}^4x$
iF Hermitian	field strength as an observable
$U(1)$: $A = -ieA^{\mathrm{phys}}$	$F = -ie\, F^{\mathrm{phys}}$, $F^{\mathrm{phys}} = \mathrm{d}A^{\mathrm{phys}}$

Here $\tilde{F}^{a\,\mu\nu} = \frac{1}{2}\varepsilon^{\mu\nu\rho\sigma} F^a_{\rho\sigma}$ and we used $F^a \wedge F^a = \frac{1}{2} F^a_{\mu\nu} \tilde{F}^{a\,\mu\nu} \mathrm{d}^4x$.

Changing the frame (a gauge transformation). On an overlap of two patches, or simply by choice, we may replace the frame s by $s' = s\, g$ with $g : U \to \mathrm{GL}(k, \mathbb{C})$ (or $U(k)$ for orthonormal frames). Then

$$\begin{aligned} \nabla s' &\overset{(1)}{=} \nabla(s)\, g + s\, \mathrm{d}g \\ &\overset{(2)}{=} s\, A\, g + s\, \mathrm{d}g \\ &\overset{(3)}{=} s' \left(g^{-1} A g + g^{-1} \mathrm{d}g \right), \end{aligned} \tag{3.141}$$

(1) The Leibniz rule for ∇; the entries of g are functions.
(2) The definition (3.139) of A.
(3) Substitute $s = s' g^{-1}$.

so $A' = g^{-1}Ag + g^{-1}\mathrm{d}g$, the familiar gauge transformation. The curvature transforms *homogeneously*:

$$\begin{aligned} F' &\overset{(1)}{=} \mathrm{d}\big(g^{-1}Ag + g^{-1}\mathrm{d}g\big) + \big(g^{-1}Ag + g^{-1}\mathrm{d}g\big) \wedge \big(g^{-1}Ag + g^{-1}\mathrm{d}g\big) \\ &\overset{(2)}{=} \big(-g^{-1}\mathrm{d}g\, g^{-1}Ag + g^{-1}\mathrm{d}A\, g - g^{-1}A\,\mathrm{d}g - g^{-1}\mathrm{d}g\, g^{-1}\mathrm{d}g\big) \\ &\qquad + \big(g^{-1}A^2 g + g^{-1}A\,\mathrm{d}g + g^{-1}\mathrm{d}g\, g^{-1}Ag + g^{-1}\mathrm{d}g\, g^{-1}\mathrm{d}g\big) \\ &\overset{(3)}{=} g^{-1}(\mathrm{d}A + A \wedge A)\, g = g^{-1}Fg. \end{aligned} \tag{3.142}$$

(1) Definition (3.140) applied to A'.
(2) $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\, g^{-1}$ (differentiate $g^{-1}g = 1$); moving d past the 1-form A costs a sign; expand the product.
(3) The three pairs of terms containing $\mathrm{d}g$ cancel in pairs.

This one line is the reason Chern–Weil theory works: F changes by *conjugation*, and there are functions of matrices that do not care about conjugation.

The Bianchi identity. Differentiating (3.140),

$$\begin{aligned} \mathrm{d}F &\overset{(1)}{=} \mathrm{d}A \wedge A - A \wedge \mathrm{d}A \\ &\overset{(2)}{=} (F - A^2) \wedge A - A \wedge (F - A^2) \\ &= F \wedge A - A \wedge F, \end{aligned} \tag{3.143}$$

(1) $\mathrm{d}^2 A = 0$, and $\mathrm{d}(A \wedge A) = \mathrm{d}A \wedge A - A \wedge \mathrm{d}A$ because A is a 1-form.
(2) Substitute $\mathrm{d}A = F - A^2$; the A^3 terms cancel.

In the language of covariant derivatives, $DF := \mathrm{d}F + A \wedge F - F \wedge A = 0$.

Graded cyclicity of the trace. We will move matrix-valued forms around inside traces all the time. If α is a matrix of p-forms and β a matrix of q-forms, then

$$\operatorname{tr}(\alpha \wedge \beta) = (-1)^{pq} \operatorname{tr}(\beta \wedge \alpha). \tag{3.144}$$

The ordinary cyclicity of the trace moves the matrices; moving a p-form past a q-form costs $(-1)^{pq}$. In particular 2-forms such as F can be moved freely, and $\operatorname{tr}(A \wedge A) = -\operatorname{tr}(A \wedge A) = 0$ for a 1-form A. A consequence we use repeatedly: for any matrix-valued p-form ω that transforms by conjugation, with $D\omega = \mathrm{d}\omega + A \wedge \omega - (-1)^p \omega \wedge A$,

$$\mathrm{d} \operatorname{tr} \omega = \operatorname{tr} D\omega, \tag{3.145}$$

because $\operatorname{tr}(A \wedge \omega) = (-1)^p \operatorname{tr}(\omega \wedge A)$ makes the extra terms cancel.

3.16.2 Invariant polynomials

Working definition 3.40 (Invariant polynomial)

A polynomial function P of the entries of a $k \times k$ matrix X is **invariant** if $P(g^{-1}Xg) = P(X)$ for every invertible g. *Test:* it is enough to check $P(XY) = P(YX)$ for all X, Y. The basic examples are the traces of powers, $\operatorname{tr} X^m$, and the coefficients $\sigma_j(X)$ [$\sigma_1 = \operatorname{tr} X$ and

$\sigma_k = \det X$] of the characteristic polynomial,

$$\det(t\,\mathbb{1} + X) = \sum_{j=0}^{k} t^{\,k-j}\,\sigma_j(X). \tag{3.146}$$

Every invariant polynomial is a polynomial in the σ_j (equivalently, in the $\operatorname{tr} X^m$, $m \le k$).

Why the σ_j are enough: an invariant polynomial is unchanged by diagonalising X (when X is diagonalisable), so it is a function of the eigenvalues $\lambda_1, \dots, \lambda_k$. It is also unchanged by permuting the eigenvalues (a permutation matrix is a conjugation). A symmetric polynomial in the λ's is a polynomial in the elementary symmetric ones, and $\sigma_j(X) = \sigma_j(\lambda_1, \dots, \lambda_k)$. Diagonalisable matrices are dense, so the conclusion holds for all X. We return to this argument in Section 3.17; it is exactly Nash's justification of the splitting principle on p. 88.

Worked example 3.90: The 2×2 case by hand

Let $X = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$. Then

$$\begin{aligned} \det(t\mathbb{1} + X) &= (t + a)(t + d) - bc \\ &= t^2 + (a + d)\,t + (ad - bc), \end{aligned}$$

so $\sigma_1 = \operatorname{tr} X$ and $\sigma_2 = \det X$. Also

$$\begin{aligned} \tfrac{1}{2}\big[(\operatorname{tr} X)^2 - \operatorname{tr} X^2\big] &\overset{(1)}{=} \tfrac{1}{2}\big[(a + d)^2 - (a^2 + 2bc + d^2)\big] \\ &= ad - bc = \sigma_2. \end{aligned}$$

(1) X^2 has diagonal entries $a^2 + bc$ and $bc + d^2$.

This is the first Newton identity, $\sigma_2 = \frac{1}{2}(\sigma_1^2 - \operatorname{tr} X^2)$, which we will meet again in Section 3.17.3.

Plugging in curvature. Now put $X = \frac{i}{2\pi}F$. The entries of F are 2-forms, and 2-forms commute with each other under $\wedge$. So all the algebra of ordinary polynomials (in particular det, and its expansion) works verbatim with the entries of F, with products read as wedge products. Because $F' = g^{-1}Fg$, an invariant polynomial gives the *same* form in every frame:

$$P(F') = P(g^{-1}Fg) = P(F).$$

So $P(F)$ is a globally defined differential form on X, even though F itself is only defined patch by patch.

3.16.3 Half 1: invariant polynomials of F are closed

It suffices to treat $P = \operatorname{tr} F^m$, since the others are polynomials in these, and a product of closed forms is closed.

$$\begin{aligned} \mathrm{d}\operatorname{tr} F^m &\overset{(1)}{=} \sum_{r=0}^{m-1} \operatorname{tr}\big(F^r \wedge \mathrm{d}F \wedge F^{m-1-r}\big) \\ &\overset{(2)}{=} m\ \operatorname{tr}\big(F^{m-1} \wedge \mathrm{d}F\big) \\ &\overset{(3)}{=} m\ \operatorname{tr}\big(F^{m-1} \wedge (F \wedge A - A \wedge F)\big) \end{aligned}$$

$$
\begin{aligned}
&= m\ \mathrm{tr}\big(F^m \wedge A\big) - m\ \mathrm{tr}\big(F^{m-1} \wedge A \wedge F\big) \\
&\overset{(4)}{=} 0.
\end{aligned}
\tag{3.147}
$$

(1) Leibniz rule; each F is a 2-form, so no signs appear.
(2) Graded cyclicity (3.144): the 2-forms F^r can be cycled to the back without sign.
(3) The Bianchi identity (3.143).
(4) Cycle the final 2-form F in the second term to the front (no sign), giving $\mathrm{tr}(F^m \wedge A)$, which cancels the first term.

So $\mathrm{tr}\, F^m$ is closed, and it defines a class in $H^{2m}_{\mathrm{dR}}(X)$.

3.16.4 Half 2: the class does not depend on the connection

Take two connections ∇_0, ∇_1 on the same bundle, with matrices A_0, A_1 in a frame. Their difference $\eta = A_1 - A_0$ transforms homogeneously, $\eta' = g^{-1}\eta g$ (the inhomogeneous $g^{-1}\mathrm{d}g$ cancels in the difference), so η is a globally defined $\mathrm{End}(E)$-valued 1-form. Connections form an *affine space*: the straight line

$$
A_t = A_0 + t\,\eta, \qquad 0 \le t \le 1,
\tag{3.148}
$$

consists of connections, with curvatures $F_t = \mathrm{d}A_t + A_t^2$. (Physicists know this as the statement that the space $\mathcal{A}$ of gauge fields is contractible.) Differentiating in t,

$$
\frac{\mathrm{d}F_t}{\mathrm{d}t} = \mathrm{d}\eta + A_t \wedge \eta + \eta \wedge A_t = D_t\eta,
\tag{3.149}
$$

the covariant derivative of η with respect to A_t. Now watch $\mathrm{tr}\, F_t^m$ change:

$$
\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}t}\,\mathrm{tr}\, F_t^m &\overset{(1)}{=} m\ \mathrm{tr}\Big(F_t^{m-1} \wedge \frac{\mathrm{d}F_t}{\mathrm{d}t}\Big) \\
&\overset{(2)}{=} m\ \mathrm{tr}\big(F_t^{m-1} \wedge D_t\eta\big) \\
&\overset{(3)}{=} m\ \mathrm{tr}\big(D_t(F_t^{m-1} \wedge \eta)\big) \\
&\overset{(4)}{=} \mathrm{d}\Big[m\ \mathrm{tr}\big(F_t^{m-1} \wedge \eta\big)\Big].
\end{aligned}
\tag{3.150}
$$

(1) Leibniz in t and cyclicity, exactly as in step (1)–(2) of (3.147).
(2) Equation (3.149).
(3) Leibniz for D_t: $D_t(F_t^{m-1} \wedge \eta) = D_t(F_t^{m-1}) \wedge \eta + F_t^{m-1} \wedge D_t\eta$, and $D_t F_t = 0$ by Bianchi, so the first term vanishes.
(4) Identity (3.145): the trace of a covariant derivative is an ordinary derivative of the trace.

Integrating from $t = 0$ to $t = 1$ gives the **transgression formula**

$$
\boxed{\mathrm{tr}\, F_1^m - \mathrm{tr}\, F_0^m = \mathrm{d}\, Q_m(A_1, A_0), \qquad Q_m(A_1, A_0) = m \int_0^1 \mathrm{tr}\big(F_t^{m-1} \wedge (A_1 - A_0)\big)\, \mathrm{d}t.}
\tag{3.151}
$$

Q_m is a globally defined $(2m-1)$-form (it is built from η and F_t, both of which transform by conjugation). So $\mathrm{tr}\, F_1^m$ and $\mathrm{tr}\, F_0^m$ differ by an exact form, and they define the same de Rham class.

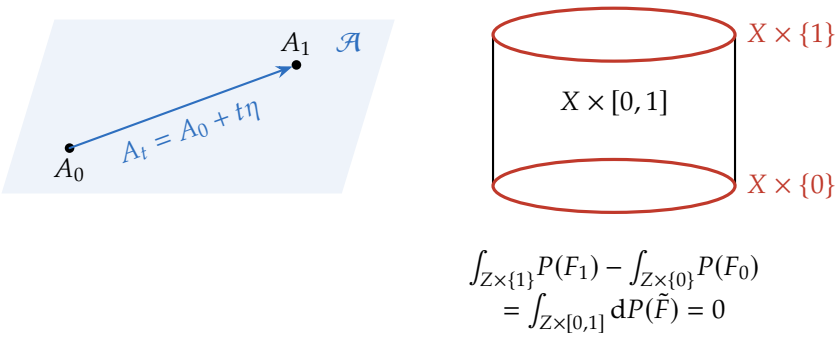

Figure 3.61: Two pictures of the same argument. Left: connections form an affine space, so any two can be joined by a straight line A_t, along which the Chern–Weil form changes by an exact form, $\mathrm{d}Q$. Right: equivalently, put the connection A_t on the bundle pulled back to the cylinder $X \times [0,1]$. For any closed cycle Z in X, Stokes' theorem on $Z \times [0,1]$ (whose boundary is the two ends) and closedness of $P(\tilde{F})$ show that the two ends give the same integral.

Key idea: The Chern–Weil theorem

For an invariant polynomial P and any connection on E:

1. $P(F)$ is a closed, globally defined form;
2. its de Rham class $[P(F)]$ is independent of the connection;
3. for $P(X) = \det\!\left(\mathbb{1} + \frac{i}{2\pi}X\right)$ the class is the image in real cohomology of the topological total Chern class $c(E)$ of Section 3.15. In particular all its periods (integrals over closed cycles) are integers.

Items 1 and 2 we have proved. Item 3 is plausible from two facts. The Chern–Weil classes are natural under pullback (the pullback connection has the pulled-back curvature), and they satisfy the Whitney formula (below). So they obey the same axioms as the topological classes, and axioms plus the normalisation on $\mathbb{CP}^1$ (checked in Example 3.92) determine characteristic classes uniquely, via the splitting principle of Section 3.17. The integrality we will see directly in every example: transgression pushes the integral onto an equator, where it becomes a winding number.

3.16.5 The Chern forms

Working definition 3.41 (Chern forms and Chern classes from curvature)

For a connection [a matrix A of 1-forms on each patch, the gauge potential] with curvature F [the matrix of 2-forms $F = \mathrm{d}A + A \wedge A$] on a rank-k complex bundle, define the **Chern forms** by expanding a determinant:

$$c(F) = \det\!\left(\mathbb{1} + \frac{i}{2\pi}F\right) = 1 + c_1(F) + c_2(F) + \cdots + c_k(F), \tag{3.152}$$

with $c_j(F)$ a closed $2j$-form. Their classes are the Chern classes, $c_j(E) = [c_j(F)] \in H^{2j}_{\mathrm{dR}}(X)$ [closed $2j$-forms modulo exact ones]. *Operationally:* pick any connection (the simplest you can find), compute F, expand the determinant, integrate.

Nash writes the same thing with a bookkeeping variable t (his (3.125)–(3.126)):

$$P(t) = \det\Big(t\,\mathbb{1} + \frac{iF}{2\pi}\Big) = \sum_{j=0}^{k} t^{\,j}\, c_{k-j}(F), \tag{3.153}$$

which is (3.146) with $X = iF/2\pi$; setting $t = 1$ recovers (3.152).

Let us extract the first two explicitly. Write $X = \frac{i}{2\pi}F$ and expand $\det(\mathbb{1} + X)$ to second order:

$$\begin{aligned} \det(\mathbb{1} + X) &\overset{(1)}{=} \exp \operatorname{tr} \log(\mathbb{1} + X) \\ &\overset{(2)}{=} \exp\big(\operatorname{tr} X - \tfrac{1}{2}\operatorname{tr} X^2 + \dots\big) \\ &\overset{(3)}{=} 1 + \operatorname{tr} X + \tfrac{1}{2}\big[(\operatorname{tr} X)^2 - \operatorname{tr} X^2\big] + \dots \end{aligned} \tag{3.154}$$

(1) $\det e^{Y} = e^{\operatorname{tr} Y}$ (true for diagonal Y, hence for all Y by conjugation-invariance and density); take $Y = \log(\mathbb{1} + X)$.
(2) Power series $\log(1+X) = X - \frac{1}{2}X^2 + \dots$; the entries of X are commuting 2-forms, so formal manipulations are legitimate and the series terminate.
(3) $e^{u} = 1 + u + \frac{1}{2}u^2 + \dots$ with $u = \operatorname{tr} X - \frac{1}{2}\operatorname{tr} X^2$, keeping terms of degree ≤ 4.

Hence

$$c_1(F) = \frac{i}{2\pi}\operatorname{tr} F, \tag{3.155}$$

$$c_2(F) = \frac{1}{2}\Big(\frac{i}{2\pi}\Big)^2\big[(\operatorname{tr} F)^2 - \operatorname{tr} F^2\big] = \frac{1}{8\pi^2}\big[\operatorname{tr}(F\wedge F) - \operatorname{tr} F \wedge \operatorname{tr} F\big]. \tag{3.156}$$

For an $\mathrm{SU}(k)$ bundle, $\operatorname{tr} F = 0$ ($\mathfrak{su}(k)$ is traceless), so $c_1(F) = 0$ and

$$c_2(F) = \frac{1}{8\pi^2}\operatorname{tr}(F\wedge F) \qquad (\mathrm{SU}(k)\text{ bundles}). \tag{3.157}$$

This is the instanton-number density.

Reality. For a unitary connection $F^\dagger = -F$, so iF is a Hermitian matrix of 2-forms and $\overline{\det(\mathbb{1} + \frac{i}{2\pi}F)} = \det(\mathbb{1} + \frac{i}{2\pi}F)^T = \det(\mathbb{1} + \frac{i}{2\pi}F)$. The Chern forms are *real* forms, as they must be to represent classes that are ultimately integers.

Whitney formula from curvature. For $E\oplus E'$ with the direct sum connection, $F_{E\oplus E'} = \begin{pmatrix} F_E & 0 \\ 0 & F_{E'} \end{pmatrix}$ and

$$\begin{aligned} c(F_{E\oplus E'}) &\overset{(1)}{=} \det\begin{pmatrix} \mathbb{1} + \frac{i}{2\pi}F_E & 0 \\ 0 & \mathbb{1} + \frac{i}{2\pi}F_{E'} \end{pmatrix} \\ &\overset{(2)}{=} \det\Big(\mathbb{1} + \frac{i}{2\pi}F_E\Big)\det\Big(\mathbb{1} + \frac{i}{2\pi}F_{E'}\Big) = c(F_E)\,c(F_{E'}). \end{aligned}$$

(1) The direct sum connection does not mix the two summands.
(2) The determinant of a block-diagonal matrix is the product of the blocks' determinants (the entries commute, so ordinary algebra applies).

The Chern–Simons form. Take $m = 2$ in the transgression formula, with $A_0 = 0$ (the trivial flat connection in a local trivialisation, so the formula holds on that patch) and $A_1 = A$. Then $\eta = A$ and $F_t = t\,\mathrm{d}A + t^2A^2$:

$$\begin{aligned} Q_2(A,0) &\overset{(1)}{=} 2\int_0^1 \operatorname{tr}\big((t\,\mathrm{d}A + t^2A^2)\wedge A\big)\,\mathrm{d}t \\ &\overset{(2)}{=} 2\Big(\tfrac{1}{2}\operatorname{tr}(\mathrm{d}A\wedge A) + \tfrac{1}{3}\operatorname{tr}(A^3)\Big) \\ &\overset{(3)}{=} \operatorname{tr}\Big(A\wedge \mathrm{d}A + \tfrac{2}{3}A\wedge A\wedge A\Big) \;:=\; \mathrm{CS}(A). \end{aligned} \tag{3.158}$$

(1) (3.151) with $m = 2$.
(2) $\int_0^1 t\,\mathrm{d}t = \frac{1}{2}$ and $\int_0^1 t^2\mathrm{d}t = \frac{1}{3}$.
(3) Graded cyclicity: $\operatorname{tr}(\mathrm{d}A\wedge A) = (-1)^{2\cdot 1}\operatorname{tr}(A\wedge \mathrm{d}A)$.

It is reassuring to check $\mathrm{d}\,\mathrm{CS} = \operatorname{tr}F^2$ directly:

$$\begin{aligned} \mathrm{d}\,\mathrm{CS}(A) &\overset{(1)}{=} \operatorname{tr}(\mathrm{d}A\wedge \mathrm{d}A) + \tfrac{2}{3}\cdot 3\,\operatorname{tr}(\mathrm{d}A\wedge A^2) \\ &\overset{(2)}{=} \operatorname{tr}\big(\mathrm{d}A\wedge \mathrm{d}A + \mathrm{d}A\wedge A^2 + A^2\wedge \mathrm{d}A + A^4\big) \\ &= \operatorname{tr}\big((\mathrm{d}A + A^2)\wedge(\mathrm{d}A + A^2)\big) = \operatorname{tr}F^2. \end{aligned} \tag{3.159}$$

(1) $\mathrm{d}\operatorname{tr}(A\,\mathrm{d}A) = \operatorname{tr}(\mathrm{d}A\,\mathrm{d}A)$; and $\mathrm{d}\operatorname{tr}A^3 = \operatorname{tr}(\mathrm{d}A\,A^2) - \operatorname{tr}(A\,\mathrm{d}A\,A) + \operatorname{tr}(A^2\mathrm{d}A) = 3\operatorname{tr}(\mathrm{d}A\,A^2)$, each term cycled by (3.144).
(2) Split $2\operatorname{tr}(\mathrm{d}A\,A^2) = \operatorname{tr}(\mathrm{d}A\,A^2) + \operatorname{tr}(A^2\,\mathrm{d}A)$, and add $\operatorname{tr}A^4 = 0$ (graded cyclicity gives $\operatorname{tr}(A\cdot A^3) = -\operatorname{tr}(A^3\cdot A)$).

Two limits are worth remembering. For $U(1)$ (or the trace part), $\operatorname{tr}F = \mathrm{d}\operatorname{tr}A$: the transgression form of c_1 is just the gauge field. For a *pure gauge* $A = g^{-1}\mathrm{d}g$ we have $F = 0$, so $\mathrm{d}A = -A^2$, and

$$\mathrm{CS}(g^{-1}\mathrm{d}g) = \operatorname{tr}\big(-A^3 + \tfrac{2}{3}A^3\big) = -\tfrac{1}{3}\operatorname{tr}\big(g^{-1}\mathrm{d}g\big)^3. \tag{3.160}$$

3.16.6 Worked examples

Worked example 3.91: The monopole bundles: $c_1 = n$

Cover S^2 by $U_N = \{\theta < \pi\}$ and $U_S = \{\theta > 0\}$. On each patch take a unitary frame and the $U(1)$ gauge fields

$$A_N = -\frac{in}{2}(1-\cos\theta)\,\mathrm{d}\phi, \qquad A_S = +\frac{in}{2}(1+\cos\theta)\,\mathrm{d}\phi.$$

Each is smooth on its own patch: $(1-\cos\theta)\,\mathrm{d}\phi$ vanishes like $\theta^2\mathrm{d}\phi$ at the north pole, where $\mathrm{d}\phi$ is singular, and similarly for A_S at the south pole. On the overlap

$$A_N - A_S = -in\,\mathrm{d}\phi = g^{-1}\mathrm{d}g \qquad \text{with} \qquad g = e^{-in\phi},$$

so by (3.141) the frames are related by $s_N = s_S\,e^{-in\phi}$: this is the bundle L_n of Section 3.15.3. The curvature is the same on both patches, $F = \mathrm{d}A_N = \mathrm{d}A_S = -\frac{in}{2}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi$. Then

$$\begin{aligned} \int_{S^2} c_1(F) &\overset{(1)}{=} \frac{i}{2\pi}\int_{S^2} F \\ &\overset{(2)}{=} \frac{i}{2\pi}\cdot\Big(-\frac{in}{2}\Big)\int_0^{2\pi}\!\!\int_0^{\pi} \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \end{aligned}$$

$$\overset{(3)}{=} \frac{n}{4\pi}\cdot 4\pi = n.$$

(1) (3.155) for a line bundle (tr of a 1×1 matrix).
(2) Substitute F; (θ,ϕ) cover the sphere once with the outward orientation $\mathrm{d}\theta\wedge\mathrm{d}\phi$.
(3) $i\cdot(-i)=1$ and the area of the unit sphere is 4π.

Now the same answer by transgression, which shows *why* it is an integer. Split the sphere along the equator C and use $F=\mathrm{d}A_N$ on the north, $F=\mathrm{d}A_S$ on the south:

$$\begin{aligned}\frac{i}{2\pi}\int_{S^2}F &\overset{(1)}{=} \frac{i}{2\pi}\Big(\int_{\text{north}}\mathrm{d}A_N+\int_{\text{south}}\mathrm{d}A_S\Big)\\ &\overset{(2)}{=} \frac{i}{2\pi}\Big(\oint_C A_N-\oint_C A_S\Big)\\ &\overset{(3)}{=} \frac{i}{2\pi}\oint_C g^{-1}\mathrm{d}g \overset{(4)}{=} \frac{i}{2\pi}(-in)(2\pi)=n.\end{aligned}$$

(1) On each hemisphere F is exact, with its own potential.
(2) Stokes. C with increasing ϕ is the boundary of the north hemisphere and, with the opposite orientation, of the south one.
(3) $A_N-A_S=g^{-1}\mathrm{d}g$ on the overlap.
(4) $g^{-1}\mathrm{d}g=-in\,\mathrm{d}\phi$ and $\oint\mathrm{d}\phi=2\pi$.

The magnetic charge is the winding number of the gauge transformation between patches: $\frac{i}{2\pi}\oint g^{-1}\mathrm{d}g=-\frac{1}{2\pi i}\oint\frac{\mathrm{d}g}{g}=-\mathrm{wind}(g)$. It is an integer because g is single valued. In physical units ($A=-ieA^{\mathrm{phys}}$) this is Dirac's quantisation: the flux $\int F^{\mathrm{phys}}=2\pi n/e$.

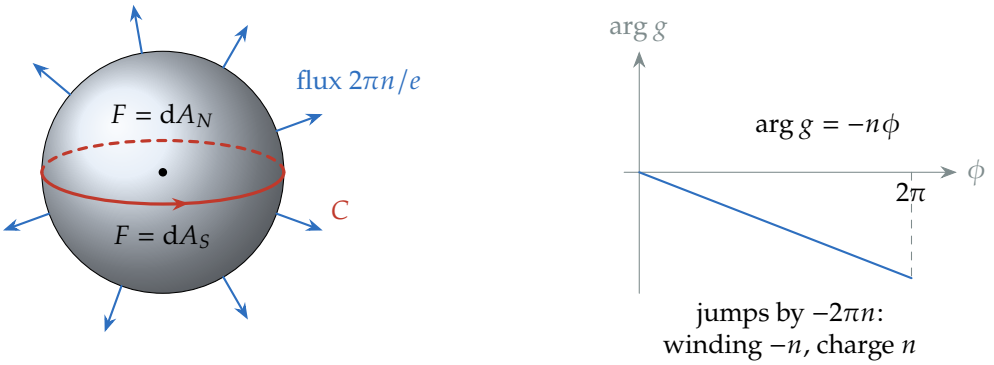

Figure 3.62: The monopole as a bundle. Left: the field strength is exact on each hemisphere separately, with different potentials; all the flux is "paid for" on the equator C. Right: the gauge transformation $g=e^{-in\phi}$ relating the two potentials on C. Its phase must return to itself modulo 2π, so the winding, and hence the flux, is quantised.

Worked example 3.92: The tautological (Hopf) line bundle over $\mathbb{CP}^1$ has $c_1=-1$

The tautological bundle $\gamma\to\mathbb{CP}^1$ has as fibre over the line $\ell=[z_0:z_1]$ the line $\ell\subset\mathbb{C}^2$ itself. On the patch $z_0\neq 0$ use the affine coordinate $z=z_1/z_0$, and the nowhere-zero section

$$s(z)=(1,z)\in\ell.$$

It inherits the length $h(z)=\|s\|^2=1+|z|^2$ from $\mathbb{C}^2$. The natural connection is orthogonal projection of the ordinary derivative back onto the line: $\nabla s=\frac{\langle s,\mathrm{d}s\rangle}{\langle s,s\rangle}s$, with $\langle u,v\rangle=$

$\bar{u}_0 v_0 + \bar{u}_1 v_1$. Since $\mathrm{d}s = (0, \mathrm{d}z)$,

$$A = \frac{\bar{z}\,\mathrm{d}z}{1+|z|^2} \qquad \text{(in the frame } s\text{)}.$$

This frame is not unitary. Normalise: $\hat{s} = s/\sqrt{h}$. By (3.141) with $g = h^{-1/2}$,

$$\begin{aligned}\hat{A} &\overset{(1)}{=} A + h^{1/2}\,\mathrm{d}\big(h^{-1/2}\big) = A - \tfrac{1}{2}\mathrm{d}\log h \\ &\overset{(2)}{=} \frac{\bar{z}\,\mathrm{d}z}{1+|z|^2} - \frac{\bar{z}\,\mathrm{d}z + z\,\mathrm{d}\bar{z}}{2(1+|z|^2)} = \frac{\bar{z}\,\mathrm{d}z - z\,\mathrm{d}\bar{z}}{2(1+|z|^2)} \\ &\overset{(3)}{=} \frac{i\,r^2\,\mathrm{d}\phi}{1+r^2}.\end{aligned}$$

(1) Abelian gauge transformation; $h^{1/2}\mathrm{d}h^{-1/2} = -\frac{1}{2}\mathrm{d}\log h$.
(2) $\mathrm{d}h = \bar{z}\,\mathrm{d}z + z\,\mathrm{d}\bar{z}$.
(3) Polar coordinates $z = re^{i\phi}$: $\bar{z}\,\mathrm{d}z - z\,\mathrm{d}\bar{z} = 2ir^2\mathrm{d}\phi$.

$\hat{A}$ is imaginary, i.e. anti-Hermitian, as it should be for a unitary frame. Its curvature is $F = \mathrm{d}\hat{A} = \frac{2ir}{(1+r^2)^2}\,\mathrm{d}r \wedge \mathrm{d}\phi$, and

$$\begin{aligned}\int_{\mathbb{CP}^1} c_1(F) &\overset{(1)}{=} \frac{i}{2\pi}\int_0^{2\pi}\int_0^{\infty} \frac{2ir}{(1+r^2)^2}\,\mathrm{d}r\,\mathrm{d}\phi \\ &\overset{(2)}{=} -\frac{1}{2\pi}\cdot 2\pi\cdot\left[-\frac{1}{1+r^2}\right]_0^{\infty} \\ &= -1.\end{aligned}$$

(1) The patch $z_0 \neq 0$ is all of $\mathbb{CP}^1$ except one point, which has zero area; $\mathrm{d}r \wedge \mathrm{d}\phi$ is the complex orientation ($\mathrm{d}x \wedge \mathrm{d}y = r\,\mathrm{d}r \wedge \mathrm{d}\phi$).
(2) $i \cdot 2i = -2$; $\int_0^{\infty} \frac{2r\,\mathrm{d}r}{(1+r^2)^2} = 1$.

In spherical coordinates, via stereographic projection $r = \tan(\theta/2)$, $\frac{r^2}{1+r^2} = \sin^2\frac{\theta}{2} = \frac{1}{2}(1-\cos\theta)$, so $\hat{A} = \frac{i}{2}(1-\cos\theta)\,\mathrm{d}\phi$. This is A_N of Example 3.91 with $n = -1$. *The tautological bundle is the monopole bundle L_{-1}*, confirming the normalisation we announced in Section 3.15.2. Its dual, the hyperplane bundle $\gamma^* = L_1$, has $c_1 = +1$ (Section 3.19.1).

Physical picture: Where the Hopf fibration comes in

The unit vectors in the fibres of γ form the unit sphere $S^3 = \{|z_0|^2 + |z_1|^2 = 1\} \subset \mathbb{C}^2$, and forgetting the phase gives the Hopf map $S^3 \to \mathbb{CP}^1 = S^2$. The connection of Example 3.92 comes from the single 1-form $a = \bar{z}_0\mathrm{d}z_0 + \bar{z}_1\mathrm{d}z_1$ on S^3. (It is imaginary on S^3 because $\mathrm{d}(|z_0|^2 + |z_1|^2) = a + \bar{a} = 0$ there.) Pulling a back by the local section $z \mapsto (1, z)/\sqrt{1+|z|^2}$ gives exactly $\hat{A}$. So the monopole of charge -1 *is* the Hopf fibration with its round connection: the fibre circles are the Dirac-string-free description of the monopole's $U(1)$ phase.

Worked example 3.93: An SU(2) bundle over S^4: c_2 is the winding number

Identify $S^4 = \mathbb{R}^4 \cup \{\infty\}$. A connection on an SU(2) bundle over S^4 can be described in a single gauge on $\mathbb{R}^4$, provided that as $|x| \to \infty$ it approaches a pure gauge, $A \to g^{-1}\mathrm{d}g$, for a map $g : S^3_\infty \to \mathrm{SU}(2)$. (That map is the clutching function to the patch around ∞.) The

standard choice, used by Belavin, Polyakov, Schwartz and Tyupkin, is

$$g(x) = \frac{x_4 \mathbb{1} + i\, x_k \sigma_k}{|x|}, \qquad A = f(r)\, g^{-1} \mathrm{d} g, \qquad f(r) = \frac{r^2}{r^2 + \lambda^2},$$

with σ_k the Pauli matrices, $r = |x|$ and $\lambda > 0$ the instanton size. The matrix g is in SU(2): its determinant is $x_4^2 + x_1^2 + x_2^2 + x_3^2 = r^2$ divided by r^2, and it is unitary because it is a unit quaternion. We orient $\mathbb{R}^4$ by $\mathrm{d}x_1 \wedge \mathrm{d}x_2 \wedge \mathrm{d}x_3 \wedge \mathrm{d}x_4$ and the sphere S^3_R of radius R as the boundary of the ball B_R (outward normal first).

Step 1: reduce to the sphere at infinity. By (3.157), the transgression (3.159) and Stokes,

$$\int_{B_R} c_2(F) \overset{(1)}{=} \frac{1}{8\pi^2} \int_{B_R} \operatorname{tr} F^2 \overset{(2)}{=} \frac{1}{8\pi^2} \int_{S^3_R} \mathrm{CS}(A).$$

(1) SU(2) bundle, so $c_1(F) = 0$ and (3.157) applies.

(2) A is a single smooth 1-form on all of $\mathbb{R}^4$ (at $r \to 0$, $f \sim r^2/\lambda^2$ cancels the $1/r$ of $g^{-1}\mathrm{d}g$), so $\operatorname{tr} F^2 = \mathrm{d}\,\mathrm{CS}(A)$ globally on B_R.

Step 2: the Chern–Simons form of $A = f\theta$, where $\theta = g^{-1}\mathrm{d}g$ satisfies $\mathrm{d}\theta = -\theta^2$ and f depends only on r, so on S^3_R it is a constant:

$$\begin{aligned} \mathrm{CS}(f\theta)\big|_{S^3_R} &\overset{(1)}{=} \operatorname{tr}\!\left(f\theta \wedge f\,\mathrm{d}\theta + \tfrac{2}{3} f^3 \theta^3\right) \\ &\overset{(2)}{=} \left(-f^2 + \tfrac{2}{3} f^3\right) \operatorname{tr} \theta^3. \end{aligned}$$

(1) Definition (3.158); $\mathrm{d}f = 0$ along the sphere.

(2) $\mathrm{d}\theta = -\theta^2$ (differentiate $g^{-1}g = \mathbb{1}$).

Step 3: compute $\operatorname{tr}\theta^3$. At the "north pole" $p = (0,0,0,R)$ we have $g(p) = \mathbb{1}$ and, along the sphere, $\mathrm{d}x_4 = 0$ and $\mathrm{d}r = 0$ to first order, so $\theta = \frac{i}{R}\sigma_k \mathrm{d}x_k$. Then

$$\begin{aligned} \operatorname{tr}\theta^3\big|_p &\overset{(1)}{=} \frac{i^3}{R^3} \operatorname{tr}(\sigma_a\sigma_b\sigma_c)\, \mathrm{d}x_a \wedge \mathrm{d}x_b \wedge \mathrm{d}x_c \\ &\overset{(2)}{=} \frac{-i}{R^3}\, \varepsilon_{abc} \operatorname{tr}(\sigma_a\sigma_b\sigma_c)\, \mathrm{d}x_1 \wedge \mathrm{d}x_2 \wedge \mathrm{d}x_3 \\ &\overset{(3)}{=} \frac{-i}{R^3}\,(12i)\, \mathrm{d}x_1 \wedge \mathrm{d}x_2 \wedge \mathrm{d}x_3 = \frac{12}{R^3}\, \mathrm{d}x_1 \wedge \mathrm{d}x_2 \wedge \mathrm{d}x_3. \end{aligned}$$

(1) Substitute θ and pull the constants out.

(2) $\mathrm{d}x_a \wedge \mathrm{d}x_b \wedge \mathrm{d}x_c = \varepsilon_{abc}\, \mathrm{d}x_1 \wedge \mathrm{d}x_2 \wedge \mathrm{d}x_3$.

(3) $\operatorname{tr}(\sigma_a\sigma_b\sigma_c) = 2i\varepsilon_{abc}$ and $\varepsilon_{abc}\varepsilon_{abc} = 6$.

Now two observations finish the job. (i) θ is unchanged under $g \mapsto hg$ for a constant $h \in \mathrm{SU}(2)$, and these left multiplications move p to any point of S^3_R while preserving the round volume form; so $\operatorname{tr}\theta^3$ is a *constant* multiple of the volume form of S^3_R. (ii) At p the outward normal is e_4, and (e_4, e_1, e_2, e_3) is an odd permutation of (e_1, e_2, e_3, e_4); so the boundary orientation at p is $-\mathrm{d}x_1 \wedge \mathrm{d}x_2 \wedge \mathrm{d}x_3$, and $\mathrm{d}x_1 \wedge \mathrm{d}x_2 \wedge \mathrm{d}x_3 = -R^3\, \mathrm{vol}_{S^3}$ in terms of the unit-sphere volume element. Therefore

$$\int_{S^3_R} \operatorname{tr}\theta^3 \overset{(1)}{=} -12\,\mathrm{Vol}(S^3) \overset{(2)}{=} -12 \cdot 2\pi^2 = -24\pi^2.$$

(1) Observations (i) and (ii); the factors of R cancel.

(2) The unit 3-sphere has volume $2\pi^2$.

Step 4: assemble. Combining steps 1–3,

$$\int_{B_R} c_2(F) = \frac{1}{8\pi^2}\left(-f^2 + \tfrac{2}{3}f^3\right)(-24\pi^2) = 3f(R)^2 - 2f(R)^3,$$

and as $R \to \infty$, $f \to 1$:

$$\boxed{\int_{S^4} c_2 = \frac{1}{8\pi^2}\int_{\mathbb{R}^4} \operatorname{tr} F \wedge F = 1.}$$

The profile f only affects *where* the charge sits (Figure 3.63); the total is fixed by g alone, as Chern–Weil theory promises. With $A \to g^{-1}\mathrm{d}g$ at infinity for a general g, the same steps give

$$\int_{S^4} c_2 = -\frac{1}{24\pi^2}\int_{S^3} \operatorname{tr}\left(g^{-1}\mathrm{d}g\right)^3 := w(g) \in \mathbb{Z},$$

the **winding number** (degree) of $g : S^3 \to \mathrm{SU}(2) \cong S^3$. For our g (the identity map of the unit quaternions) $w = 1$; for g^m one finds $w = m$.

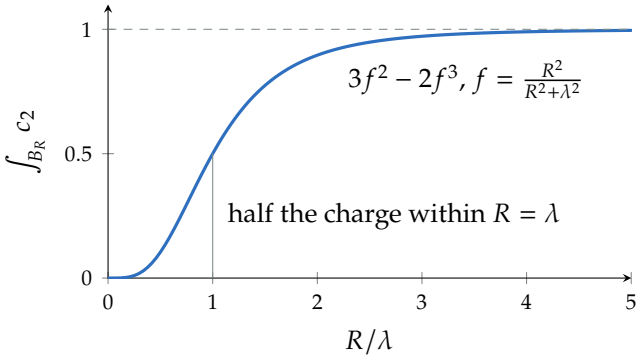

Figure 3.63: How much instanton number lies inside the ball of radius R for the BPST connection. It rises from 0 to exactly 1; the size λ sets the scale (at $R = \lambda$, $f = \frac{1}{2}$ and the enclosed charge is $\frac{1}{2}$). Changing f changes the curve but never its limit: the total is the winding number of g on the sphere at infinity.

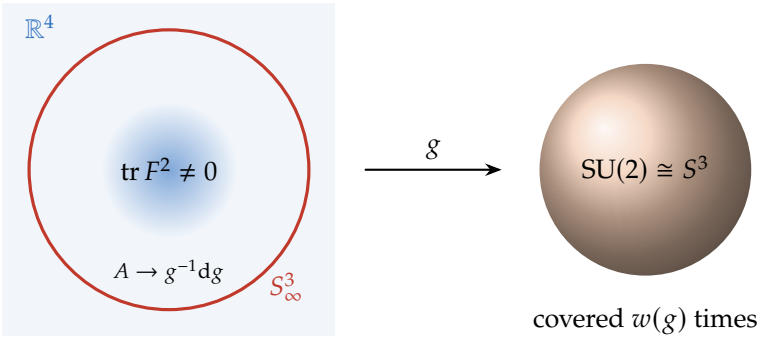

Figure 3.64: The instanton number as a winding number. The curvature is concentrated in a region of size λ; far away the field is pure gauge, $A \approx g^{-1}\mathrm{d}g$, and $\operatorname{tr} F^2 = \mathrm{d}\,\mathrm{CS}$ turns the 4-volume integral into a surface integral over the sphere at infinity. There $\mathrm{CS} = -\frac{1}{3}\operatorname{tr}(g^{-1}\mathrm{d}g)^3$ counts how many times g wraps S^3_∞ around the group manifold $\mathrm{SU}(2) \cong S^3$.

Watch out: Signs of c_2 and of "the" instanton number

With our conventions (anti-Hermitian F, $c_2 = \frac{1}{8\pi^2}\operatorname{tr} F\wedge F$, standard orientation of $\mathbb{R}^4$), write $F = F^a T^a$ with $T^a = -\frac{i}{2}\sigma_a$, so $\operatorname{tr} F\wedge F = -\frac{1}{2}F^a\wedge F^a$. A self-dual field ($\star F = F$) has $F^a\wedge F^a = |F^a|^2\,\mathrm{vol} \geq 0$, hence $c_2 \leq 0$; the BPST field above, with $c_2 = +1$, is therefore *anti*-self-dual in this orientation. This is the convention of Donaldson theory (anti-self-dual connections on bundles with $c_2 = k > 0$). Physics texts usually define the topological charge $Q = \frac{g^2}{32\pi^2}\int F^a_{\mu\nu}\tilde F^{a\,\mu\nu}\mathrm{d}^4x$; by the dictionary above, $Q = -c_2[S^4]$. Nothing physical depends on the choice, but always check which one a formula uses.

Worked example 3.94: The Chern–Simons form under a gauge transformation

$\mathrm{CS}(A)$ is *not* gauge invariant, and how it fails is physics. Let $A' = g^{-1}(A+\rho)g$ with $\rho = \mathrm{d}g\,g^{-1}$ (this is the same as $g^{-1}Ag + g^{-1}\mathrm{d}g$). Write $\mathrm{CS}(A) = \operatorname{tr}(A\wedge F - \frac{1}{3}A^3)$, which equals (3.158) because $F = \mathrm{d}A + A^2$. Then

$$\begin{aligned}
\mathrm{CS}(A') &\overset{(1)}{=} \operatorname{tr}\big((A+\rho)F\big) - \tfrac{1}{3}\operatorname{tr}(A+\rho)^3\\
&\overset{(2)}{=} \mathrm{CS}(A) + \operatorname{tr}(\rho F) - \operatorname{tr}(A^2\rho) - \operatorname{tr}(A\rho^2) - \tfrac{1}{3}\operatorname{tr}\rho^3\\
&\overset{(3)}{=} \mathrm{CS}(A) + \operatorname{tr}(\rho\,\mathrm{d}A) - \operatorname{tr}(A\,\mathrm{d}\rho) - \tfrac{1}{3}\operatorname{tr}\rho^3\\
&\overset{(4)}{=} \mathrm{CS}(A) - \mathrm{d}\operatorname{tr}(\rho\wedge A) - \tfrac{1}{3}\operatorname{tr}\big(g^{-1}\mathrm{d}g\big)^3.
\end{aligned}$$

(1) $F' = g^{-1}Fg$, $A'^3 = g^{-1}(A+\rho)^3 g$, and the trace kills the conjugation.
(2) Expand the cube; by graded cyclicity the three orderings of A, A, ρ have equal traces, as do those of A, ρ, ρ.
(3) $\operatorname{tr}(\rho A^2)$ cancels $\operatorname{tr}(A^2\rho)$; and $\mathrm{d}\rho = \rho^2$ (from $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\,g^{-1}$), so $\operatorname{tr}(A\rho^2) = \operatorname{tr}(A\,\mathrm{d}\rho)$.
(4) $\mathrm{d}\operatorname{tr}(\rho A) = \operatorname{tr}(\mathrm{d}\rho\,A) - \operatorname{tr}(\rho\,\mathrm{d}A)$ and $\operatorname{tr}(\mathrm{d}\rho\,A) = \operatorname{tr}(A\,\mathrm{d}\rho)$; also $\operatorname{tr}\rho^3 = \operatorname{tr}(g\theta g^{-1})^3 = \operatorname{tr}\theta^3$.

On a closed 3-manifold M the exact term integrates to zero, and

$$\int_M \mathrm{CS}(A') - \int_M \mathrm{CS}(A) = -\frac{1}{3}\int_M \operatorname{tr}(g^{-1}\mathrm{d}g)^3 = 8\pi^2\, w(g).$$

So the Chern–Simons action $S = \frac{\kappa}{8\pi^2}\cdot 2\pi\int_M \mathrm{CS}(A) = \frac{\kappa}{4\pi}\int_M \mathrm{CS}(A)$ shifts by $2\pi\kappa\, w(g)$, and e^{iS} is gauge invariant only if the level κ is an integer. This is the level quantisation of Chern–Simons theory, which we meet again in Chapter 12; the "secondary" nature of CS is the subject of Nash's Chapter 8, Chapter 8.

Try it: Abelian Chern–Simons and linking

For $U(1)$, $\mathrm{CS}(A) = A\wedge\mathrm{d}A$. Show that under $A\to A+\mathrm{d}\chi$ it changes by the exact form $\mathrm{d}(\chi\,\mathrm{d}A)$, so on a closed 3-manifold it is gauge invariant for single-valued χ.
Answer: $(A+\mathrm{d}\chi)\wedge\mathrm{d}A = A\wedge\mathrm{d}A + \mathrm{d}\chi\wedge\mathrm{d}A = A\wedge\mathrm{d}A + \mathrm{d}(\chi\,\mathrm{d}A)$.

Reading Nash (pp. 87–88, (3.125)–(3.127))

Nash introduces curvature methods only at the end of his §5: F is a curvature 2-form of a rank-k bundle with group $U(k)$, $O(k)$ or $\mathrm{SO}(k)$, and $P(t) = \det(t + iF/2\pi)$ (3.125) is a polynomial in t whose coefficients are closed forms, representing the characteristic

classes; for complex bundles $\det(t + iF/2\pi) = \sum_j t^j c_{k-j}(F)$ (3.126). He does not prove closedness or independence of the connection, and refers to Nash and Sen. We have supplied both (Sections 3.16.3 and 3.16.4), with the explicit Chern–Simons form. His (3.127), $\mathrm{ch}(F) = \operatorname{tr}\exp(iF/2\pi)$, is in Section 3.18.

Recap

- Under a gauge transformation $F \mapsto g^{-1}Fg$, so conjugation-invariant polynomials of F are global forms.
- Bianchi $\Rightarrow \mathrm{d}\operatorname{tr} F^m = 0$. Transgression $\Rightarrow \operatorname{tr} F_1^m - \operatorname{tr} F_0^m = \mathrm{d}Q_m$: the class does not depend on the connection.
- $c(F) = \det(1 + \frac{i}{2\pi}F)$; $c_1 = \frac{i}{2\pi}\operatorname{tr} F$; $c_2 = \frac{1}{8\pi^2}(\operatorname{tr} F^2 - \operatorname{tr} F \wedge \operatorname{tr} F)$.
- $\operatorname{tr} F^2 = \mathrm{d}\,\mathrm{CS}$, $\mathrm{CS} = \operatorname{tr}(A\mathrm{d}A + \frac{2}{3}A^3)$; for pure gauge $\mathrm{CS} = -\frac{1}{3}\operatorname{tr}(g^{-1}\mathrm{d}g)^3$.
- Monopole: c_1 = minus the winding of the patching function; tautological bundle has $c_1 = -1$. SU(2) on S^4: c_2 = winding of $g : S^3 \to \mathrm{SU}(2)$; BPST has $c_2 = 1$.

3.17 The splitting principle: pretend every bundle is a sum of lines

The Whitney formula tells us the Chern classes of a *direct sum*. But physics hands us other combinations all the time. A quark field in the fundamental representation coupled to a $U(1)$ charge lives in $E \otimes L$. Gluons live in the adjoint bundle $\mathrm{End}_0 E$. Antiparticles live in the conjugate bundle. Fermion bilinears live in $\Lambda^2 E$. We want the Chern classes of all of these in terms of those of E and L. Is there a single trick that handles every such question?

There is, and it is the linear algebra trick every physicist uses without thinking: *diagonalise*. If E were a sum of line bundles, $E = L_1 \oplus \cdots \oplus L_k$, then everything would be easy, because line bundles are described by one number each (their c_1), tensor products of lines add those numbers, and Whitney handles the sum. The splitting principle says we may always compute *as if* E split this way.

3.17.1 Chern roots

Suppose first that E really is a sum of line bundles. Write $x_i = c_1(L_i) \in H^2(X;\mathbb{Z})$. For a line bundle $c(L_i) = 1 + x_i$, since a rank-1 bundle has only c_0 and c_1. Then

$$\begin{aligned} c(E) &\overset{(1)}{=} c(L_1)\,c(L_2)\cdots c(L_k) \\ &\overset{(2)}{=} \prod_{i=1}^{k}(1 + x_i) \\ &\overset{(3)}{=} 1 + \sum_i x_i + \sum_{i<j} x_i x_j + \cdots + x_1 x_2 \cdots x_k. \end{aligned} \tag{3.161}$$

(1) The Whitney sum formula, applied $k - 1$ times.
(2) $c(L_i) = 1 + c_1(L_i)$ for a line bundle.
(3) Multiply out. Cohomology classes of even degree commute, so the product behaves like an ordinary polynomial.

Comparing degrees with $c(E) = 1 + c_1(E) + \cdots + c_k(E)$ gives

$$\begin{aligned} c_1(E) &= \sum_i x_i, \qquad c_2(E) = \sum_{i<j} x_i x_j, \qquad \dots \\ c_j(E) &= \sum_{i_1<\cdots<i_j} x_{i_1}\cdots x_{i_j}, \qquad \dots, \qquad c_k(E) = x_1 \cdots x_k. \end{aligned} \tag{3.162}$$

These are the **elementary symmetric functions** $\sigma_j(x_1, \dots, x_k)$ of the x_i. Nash's (3.93) and (3.94) are exactly (3.161) and (3.162).

Working definition 3.42 (Chern roots)

For any complex bundle E of rank k, the **Chern roots** $x_1, \dots, x_k$ are formal degree-2 classes [symbols that need not be classes on X itself. Only their symmetric polynomials are] defined by the single rule

$$c(E) = \prod_{i=1}^{k} (1 + x_i),$$

that is, $c_j(E) = \sigma_j(x_1, \dots, x_k)$. *Operationally:* to compute any characteristic class of anything built from E, (1) pretend $E = \bigoplus L_i$ with $c_1(L_i) = x_i$; (2) work out the answer as a polynomial in the x_i; (3) check it is symmetric in the x_i [unchanged by every permutation of $x_1, \dots, x_k$]; (4) rewrite it in terms of the $\sigma_j = c_j(E)$. The result is correct for every E, split or not.

This is exactly like the characteristic polynomial of a matrix. The coefficients of $\det(t + X)$ are honest functions of the matrix entries; the eigenvalues are convenient fictions (they may not even be real or distinct), but any *symmetric* function of the eigenvalues is a polynomial in the coefficients and therefore honest too. The Chern classes are the coefficients; the Chern roots are the eigenvalues. In Section 3.17.5 this analogy becomes literal: the Chern roots are the eigenvalues of $\frac{i}{2\pi}F$.

Worked example 3.95: Rank 2 and rank 3 written out

For rank 2,

$$(1 + x_1)(1 + x_2) = 1 + (x_1 + x_2) + x_1 x_2,$$

so $c_1 = x_1 + x_2$ and $c_2 = x_1 x_2$. For rank 3,

$$\begin{aligned} (1 + x_1)(1 + x_2)(1 + x_3) &\overset{(1)}{=} \big(1 + (x_1 + x_2) + x_1 x_2\big)(1 + x_3) \\ &= 1 + (x_1 + x_2 + x_3) + (x_1 x_2 + x_1 x_3 + x_2 x_3) + x_1 x_2 x_3, \end{aligned}$$

(1) The rank-2 result, then multiply by $1 + x_3$ and collect by degree.

so $c_1 = \sigma_1$, $c_2 = \sigma_2$, $c_3 = \sigma_3$, each a sum over subsets of $\{1, 2, 3\}$ of the corresponding size.

3.17.2 Why the principle is true: the flag bundle

Of course most bundles do *not* split. The tangent bundle of S^2 is not a sum of two real line bundles, and the instanton bundle over S^4 is not a sum of two complex line bundles (if it were, $c_2 = x_1 x_2$ with $x_i \in H^2(S^4) = 0$ would vanish). The trick is to *move to a bigger base space* on which the pulled-back bundle does split, and to lose no information in the process.

Step 1: split off one line. Given $E \to X$ of rank k, form the **projectivisation** $\mathbb{P}(E)$: a point of $\mathbb{P}(E)$ is a pair (x, ℓ) with $x \in X$ and ℓ a complex line in the fibre E_x. The map $\pi : \mathbb{P}(E) \to X$, $(x, \ell) \mapsto x$, has fibre $\mathbb{CP}^{k-1}$ (the lines in $E_x \cong \mathbb{C}^k$). Pull E back to $\mathbb{P}(E)$: the fibre of π^*E over (x, ℓ) is E_x, and it contains a *preferred* line, namely ℓ itself. These preferred lines form a line bundle $\gamma_E \subset \pi^*E$, the tautological bundle again. With a Hermitian metric,

$$\pi^*E = \gamma_E \oplus \gamma_E^{\perp},$$

where $\gamma_E^{\perp}$ has rank $k-1$.

Step 2: repeat. Apply step 1 to $\gamma_E^{\perp}$ over $\mathbb{P}(E)$, and so on. After $k-1$ steps we reach a space $\mathrm{Fl}(E)$, the **flag bundle**, whose points are $x \in X$ together with an ordered splitting of E_x into k orthogonal lines. Over it the pullback splits completely:

$$\pi^*E = L_1 \oplus L_2 \oplus \cdots \oplus L_k. \tag{3.163}$$

Step 3: nothing is lost. The key topological fact is that $\pi^* : H^*(X) \to H^*(\mathrm{Fl}(E))$ is *injective*. For one step, the reason is the **Leray–Hirsch theorem**: the class $y = c_1(\gamma_E^*)$ restricts on each fibre $\mathbb{CP}^{k-1}$ to the generator of $H^2(\mathbb{CP}^{k-1})$, whose powers $1, y, \dots, y^{k-1}$ give all the cohomology of the fibre (Figure 3.59). So $H^*(\mathbb{P}(E))$ is a free module over $H^*(X)$ with basis $1, y, \dots, y^{k-1}$, exactly as the cohomology of a product $X \times \mathbb{CP}^{k-1}$ would be. In particular a class $a \in H^*(X)$ with $\pi^*a = 0$ must vanish, because $\pi^*a = a \cdot 1$ is a coefficient in that basis.

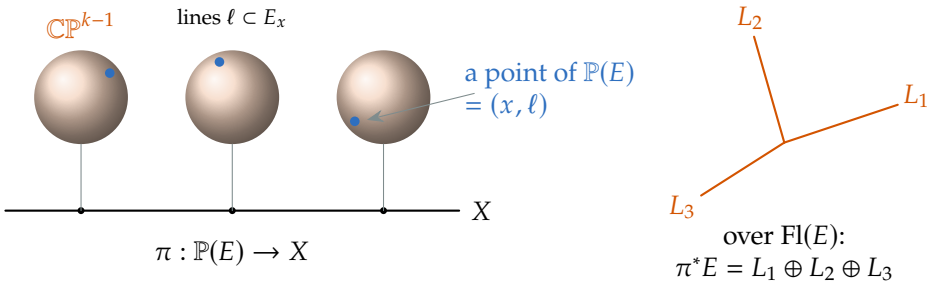

Figure 3.65: The splitting construction. Left: over each point x of the base, the projectivisation $\mathbb{P}(E)$ has a whole $\mathbb{CP}^{k-1}$ of points, one for each line ℓ in the fibre E_x. Pulled back to $\mathbb{P}(E)$, the bundle contains the chosen line as a sub-line-bundle. Right: repeating the construction (the flag bundle) chooses a complete orthogonal frame of lines, so the pulled-back bundle splits. The cohomology of X injects into that of the bigger space, so an identity checked upstairs holds downstairs.

Key idea: The splitting principle

For every complex vector bundle $E \to X$ there is a space Y and a map $\pi : Y \to X$ such that

1. π^*E is a direct sum of line bundles, and
2. $\pi^* : H^*(X; \mathbb{Z}) \to H^*(Y; \mathbb{Z})$ is injective.

Consequently, a polynomial identity among characteristic classes which is natural under pullback and holds for all sums of line bundles holds for all bundles.

The last sentence is a two-line argument. Let $P(E)$ and $Q(E)$ be two natural expressions in

characteristic classes that agree for split bundles. Then

$$\pi^*\big(P(E)-Q(E)\big) \overset{(1)}{=} P(\pi^*E)-Q(\pi^*E) \overset{(2)}{=} 0,$$

(1) Naturality: characteristic classes commute with pullback.
(2) π^*E splits, and $P = Q$ on split bundles.

and injectivity of π^* gives $P(E) = Q(E)$.

Watch out: The splitting is a device, not a fact about E

Upstairs on $\mathrm{Fl}(E)$ the classes $x_i = c_1(L_i)$ really exist. Downstairs on X they do *not*: only their symmetric combinations descend. So never write "x_1" as a class on X unless the bundle genuinely splits. An expression like $x_1 - x_2$ is meaningless downstairs; $(x_1-x_2)^2 = c_1^2 - 4c_2$ is fine.

3.17.3 Power sums and the Newton identities

The elementary symmetric functions are one natural basis of the symmetric polynomials. Another is the **power sums**

$$s_m(x_1,\dots,x_k) = x_1^m + x_2^m + \cdots + x_k^m.$$

They matter because the Chern character (Section 3.18) is built from them, and because in curvature language they are the simplest invariants, $s_m \leftrightarrow \mathrm{tr}\big(\frac{i}{2\pi}F\big)^m$. The dictionary between the two bases is the set of Newton identities. Here is a clean way to derive them all at once. Take the generating function $\prod_i(1+x_it)$ and its logarithm:

$$\log\sum_{j\ge 0}\sigma_j\,t^j \overset{(1)}{=} \log\prod_{i=1}^{k}(1+x_it) \overset{(2)}{=} \sum_{i=1}^{k}\log(1+x_it)$$
$$\overset{(3)}{=} \sum_{i=1}^{k}\sum_{m\ge 1}\frac{(-1)^{m-1}}{m}x_i^m t^m \overset{(4)}{=} \sum_{m\ge 1}\frac{(-1)^{m-1}}{m}s_m\,t^m. \tag{3.164}$$

(1) The product expands to $\sum_j \sigma_j t^j$, as in (3.161).
(2) The log of a product is the sum of logs.
(3) Taylor series $\log(1+u) = u - \frac{u^2}{2} + \frac{u^3}{3} - \dots$.
(4) Exchange the sums and collect $\sum_i x_i^m = s_m$.

Now expand the left side in powers of t, using $\log(1+u) = u - \frac{1}{2}u^2 + \frac{1}{3}u^3 - \dots$ with $u = \sigma_1 t + \sigma_2 t^2 + \sigma_3 t^3 + \dots$, and compare coefficients:

$$\begin{aligned} t^1:&\quad s_1 = \sigma_1,\\ t^2:&\quad -\tfrac{1}{2}s_2 = \sigma_2 - \tfrac{1}{2}\sigma_1^2 \;\Rightarrow\; s_2 = \sigma_1^2 - 2\sigma_2,\\ t^3:&\quad \tfrac{1}{3}s_3 = \sigma_3 - \sigma_1\sigma_2 + \tfrac{1}{3}\sigma_1^3 \;\Rightarrow\; s_3 = \sigma_1^3 - 3\sigma_1\sigma_2 + 3\sigma_3. \end{aligned}$$

The t^3 coefficient of $u - \frac{1}{2}u^2 + \frac{1}{3}u^3$ collects σ_3 from u, $-\frac{1}{2}\cdot 2\sigma_1\sigma_2$ from u^2 and $\frac{1}{3}\sigma_1^3$ from u^3. Going one order further (or differentiating (3.164) in t to get the recursion $s_m = \sigma_1 s_{m-1} - \sigma_2 s_{m-2} + \cdots + (-1)^{m-1} m\,\sigma_m$),

$$s_4 = \sigma_1^4 - 4\sigma_1^2\sigma_2 + 2\sigma_2^2 + 4\sigma_1\sigma_3 - 4\sigma_4. \tag{3.165}$$

Worked example 3.96: Checking s_2 and s_3 on numbers

Take $k = 3$ and $(x_1, x_2, x_3) = (1, 2, 3)$. Then $\sigma_1 = 6$, $\sigma_2 = 2 + 3 + 6 = 11$, $\sigma_3 = 6$. Directly $s_2 = 1 + 4 + 9 = 14$ and $s_3 = 1 + 8 + 27 = 36$. From the identities,

$$\sigma_1^2 - 2\sigma_2 = 36 - 22 = 14,$$
$$\sigma_1^3 - 3\sigma_1\sigma_2 + 3\sigma_3 = 216 - 198 + 18 = 36.$$

Both agree. (For a matrix with eigenvalues $1, 2, 3$, these say $\operatorname{tr} X^2 = (\operatorname{tr} X)^2 - 2\sigma_2(X)$ and similarly for $\operatorname{tr} X^3$.)

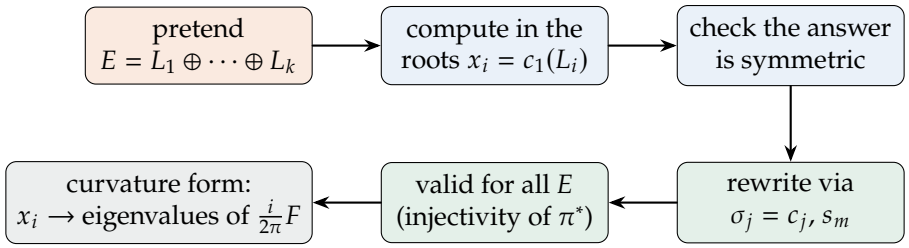

Figure 3.66: The splitting-principle recipe as a flowchart. Every computation in the rest of this chapter follows these arrows: work with the fictitious roots, confirm that only symmetric combinations appear, translate back to Chern classes, and (if a differential form is wanted) replace the roots by the eigenvalues of the curvature.

3.17.4 Recipes: duals, tensor products, exterior powers, $\mathbb{CP}^n$

To use Chern roots for tensor constructions we need one fact about line bundles: c_1 *turns tensor products into sums*, $c_1(L \otimes M) = c_1(L) + c_1(M)$. With connections this is one line. Give L and M connections with curvatures F_L, F_M (imaginary 2-forms). The tensor product connection $\nabla(s \otimes t) = \nabla s \otimes t + s \otimes \nabla t$ has $A_{L\otimes M} = A_L + A_M$, hence $F_{L\otimes M} = F_L + F_M$ (abelian, so no $A \wedge A$ terms), and c_1 is linear in F. In the clutching picture, transition functions multiply, $g_{L\otimes M} = g_L g_M$, and winding numbers add. In particular $L \otimes L^*$ is trivial, so $c_1(L^*) = -c_1(L)$.

Now the recipes. In each, E has roots x_i; if $E = \bigoplus L_i$, then the construction is again a sum of lines, whose first Chern classes we read off.

Worked example 3.97: The dual bundle

If $E = \bigoplus L_i$ then $E^* = \bigoplus L_i^*$, with roots $-x_i$. So

$$c(E^*) \overset{(1)}{=} \prod_i (1 - x_i)$$
$$\overset{(2)}{=} 1 - \sigma_1 + \sigma_2 - \cdots + (-1)^k \sigma_k,$$

(1) $c_1(L_i^*) = -c_1(L_i)$ and Whitney.

(2) Replacing $x_i \to -x_i$ multiplies a degree-j symmetric function by $(-1)^j$.

that is, $c_j(E^*) = (-1)^j c_j(E)$. Complex conjugation gives the same answer, since $\bar{E} \cong E^*$ for a unitary bundle (Section 3.19.1). *Physics:* antiparticles carry the opposite charges.

Worked example 3.98: Twisting by a line bundle

Let L have $c_1(L) = y$. If $E = \bigoplus L_i$ then $E \otimes L = \bigoplus (L_i \otimes L)$, with roots $x_i + y$. For rank 2,

$$\begin{aligned} c(E \otimes L) &\overset{(1)}{=} (1 + x_1 + y)(1 + x_2 + y) \\ &= 1 + (x_1 + x_2 + 2y) + \big(x_1 x_2 + (x_1 + x_2)y + y^2\big) \\ &\overset{(2)}{=} 1 + \big(c_1 + 2y\big) + \big(c_2 + c_1 y + y^2\big). \end{aligned}$$

(1) Roots of $E \otimes L$ are $x_i + y$.
(2) $x_1 + x_2 = c_1(E)$ and $x_1 x_2 = c_2(E)$.

In general $c_1(E \otimes L) = c_1(E) + k\,y$. A charged multiplet of k fields each carrying charge y has total "charge" ky added to its own.

Worked example 3.99: The adjoint bundle $\mathrm{End}\,E$ and the $\mathrm{SO}(3)$ instanton number

$\mathrm{End}\,E = E \otimes E^*$ has roots $x_i - x_j$ for all pairs (i, j), including the k zero roots $i = j$. For rank 2 the roots are $0, 0, x_1 - x_2, x_2 - x_1$, so

$$\begin{aligned} c(\mathrm{End}\,E) &\overset{(1)}{=} (1 + 0)^2\,(1 + x_1 - x_2)(1 - x_1 + x_2) \\ &= 1 - (x_1 - x_2)^2 \\ &\overset{(2)}{=} 1 - \big((x_1 + x_2)^2 - 4x_1 x_2\big) = 1 + \big(4c_2 - c_1^2\big). \end{aligned}$$

(1) Whitney over the four roots.
(2) $(x_1 - x_2)^2 = (x_1 + x_2)^2 - 4x_1 x_2$, which is symmetric, as it must be.

So $c_1(\mathrm{End}\,E) = 0$ and $c_2(\mathrm{End}\,E) = 4c_2(E) - c_1(E)^2$. For an SU(2) bundle, $c_1 = 0$ and $c_2(\mathrm{End}\,E) = 4c_2(E)$. The gluons of an SU(2) gauge theory live in the traceless part $\mathrm{End}_0\,E = \mathfrak{su}(2) \otimes \mathbb{C}$, and the trivial trace part does not change c. So in the adjoint representation the instanton number looks four times bigger: the familiar factor relating $\mathrm{tr}_{\mathrm{adj}}$ and $\mathrm{tr}_{\mathrm{fund}}$, $\mathrm{tr}_{\mathrm{adj}}\,F^2 = 4\,\mathrm{tr}_{\mathrm{fund}}\,F^2$ for SU(2) (that is, $2N$ with $N = 2$).

Worked example 3.100: Exterior powers and the determinant line

$\Lambda^p E$ has roots $x_{i_1} + \cdots + x_{i_p}$, one for each subset $i_1 < \cdots < i_p$. Summing all roots, each x_i appears in $\binom{k-1}{p-1}$ subsets, so

$$c_1(\Lambda^p E) = \binom{k-1}{p-1} c_1(E).$$

Two special cases: the **determinant line bundle** $\det E = \Lambda^k E$ has the single root $x_1 + \cdots + x_k$, hence $c_1(\det E) = c_1(E)$; and for rank 3, $\Lambda^2 E$ has roots $x_1 + x_2$, $x_1 + x_3$, $x_2 + x_3$, with $c_1(\Lambda^2 E) = 2c_1(E)$ and

$$\begin{aligned} c_2(\Lambda^2 E) &\overset{(1)}{=} (x_1 + x_2)(x_1 + x_3) + (x_1 + x_2)(x_2 + x_3) + (x_1 + x_3)(x_2 + x_3) \\ &\overset{(2)}{=} \sigma_1^2 + \sigma_2 = c_1^2 + c_2. \end{aligned}$$

(1) σ_2 of the three roots.
(2) Expanding gives $x_1^2 + x_2^2 + x_3^2 + 3(x_1 x_2 + x_1 x_3 + x_2 x_3) = s_2 + 3\sigma_2 = \sigma_1^2 - 2\sigma_2 + 3\sigma_2$.

Why $c_1(\det E) = c_1(E)$ matters: the determinant line of a family of Dirac operators is where the global anomaly lives (Chapter 10), and its first Chern class is computed from the index bundle by exactly this rule.

Worked example 3.101: The tangent bundle of $\mathbb{CP}^n$

Let $\gamma \to \mathbb{CP}^n$ be the tautological line bundle and $h = c_1(\gamma^*)$, the generator of $H^2(\mathbb{CP}^n;\mathbb{Z})$ with $\int_{\mathbb{CP}^1} h = 1$ on a line $\mathbb{CP}^1 \subset \mathbb{CP}^n$ (Example 3.92). A tangent vector at the point $\ell \in \mathbb{CP}^n$ is an infinitesimal tilt of the line ℓ inside $\mathbb{C}^{n+1}$, that is, a linear map $\ell \to \ell^\perp$:

$$T_\ell \mathbb{CP}^n \cong \mathrm{Hom}(\ell, \ell^\perp).$$

Add the trivial line bundle $\mathrm{Hom}(\gamma,\gamma) = \gamma^* \otimes \gamma \cong I$ (it has the nowhere-zero section id):

$$\begin{aligned} T\mathbb{CP}^n \oplus I &\overset{(1)}{=} \mathrm{Hom}(\gamma, \gamma^\perp) \oplus \mathrm{Hom}(\gamma,\gamma) \\ &\overset{(2)}{=} \mathrm{Hom}(\gamma, \mathbb{C}^{n+1}) \\ &\overset{(3)}{=} \gamma^* \oplus \cdots \oplus \gamma^* \qquad (n+1 \text{ copies}). \end{aligned}$$

(1) The identification above, plus the trivial line.
(2) $\gamma^\perp \oplus \gamma = \mathbb{C}^{n+1}$ fibrewise.
(3) A linear map from ℓ to $\mathbb{C}^{n+1}$ is $n+1$ linear functionals on ℓ, one per coordinate.

This is the **Euler sequence**. By Whitney and $c(I) = 1$,

$$c(T\mathbb{CP}^n) = (1+h)^{n+1} = \sum_{j=0}^{n} \binom{n+1}{j} h^j. \tag{3.166}$$

Checks: for $n = 1$, $c_1(T\mathbb{CP}^1) = 2h$, and $\int_{\mathbb{CP}^1} c_1 = 2 = \chi(S^2)$ (so TS^2, viewed as a complex line bundle, is the monopole bundle L_2). For $n = 2$, $c_1 = 3h$, $c_2 = 3h^2$ and $\int_{\mathbb{CP}^2} c_2 = 3 = \chi(\mathbb{CP}^2)$, the number of cells in Figure 3.59. That the top Chern class of the tangent bundle integrates to the Euler characteristic is the Gauss–Bonnet–Chern theorem of Section 3.20.

Try it: Symmetric square

Show that for rank 2, $\mathrm{Sym}^2 E$ (roots $2x_1$, x_1+x_2, $2x_2$) has $c_1 = 3c_1(E)$ and $c_2 = 2c_1^2 + 4c_2$.
Answer: $c_1 = 3(x_1+x_2)$. $c_2 = 2x_1(x_1+x_2) + 4x_1x_2 + 2x_2(x_1+x_2) = 2(x_1+x_2)^2 + 4x_1x_2$.

3.17.5 The curvature version: roots are eigenvalues of $\frac{i}{2\pi}F$

Nash ends his §5 with the observation that every splitting-principle formula has a curvature counterpart, obtained by a rule of substitution. Here is why.

For a unitary connection, $\frac{i}{2\pi}F$ is at each point a Hermitian matrix whose entries are commuting 2-forms. Pretend for a moment that it is diagonal,

$$\frac{i}{2\pi}F = \begin{pmatrix} \frac{i}{2\pi}F_1 & & \\ & \ddots & \\ & & \frac{i}{2\pi}F_k \end{pmatrix}. \tag{3.167}$$

This is exactly the curvature of a direct sum of line bundles with curvatures F_i, each contributing the Chern form $\frac{i}{2\pi}F_i$. So in this case

$$\det\Big(\mathbb{1} + \frac{i}{2\pi}F\Big) \overset{(1)}{=} \prod_{i=1}^{k}\Big(1 + \frac{i}{2\pi}F_i\Big), \qquad \mathrm{tr}\Big(\frac{i}{2\pi}F\Big)^m \overset{(2)}{=} \sum_{i=1}^{k}\Big(\frac{i}{2\pi}F_i\Big)^m,$$

(1) The determinant of a diagonal matrix is the product of its entries.
(2) Powers and traces of a diagonal matrix act entry by entry.

which are (3.161) and the power sums with $x_i \to \frac{i}{2\pi}F_i$. The general rule is:

Key idea: From roots to curvature

Let $f(x_1, \dots, x_k)$ be a symmetric (formal power series) expression in the Chern roots. Its curvature representative is obtained by replacing the x_i by the eigenvalues of $\frac{i}{2\pi}F$; equivalently, write f as a function of the matrix X that is conjugation invariant, and set $X = \frac{i}{2\pi}F$. Examples: $\prod(1 + x_i) \to \det(\mathbb{1} + \frac{i}{2\pi}F)$, $\sum x_i^m \to \operatorname{tr}(\frac{i}{2\pi}F)^m$, $\sum e^{x_i} \to \operatorname{tr}\exp(\frac{i}{2\pi}F)$.

Why may we pretend F is diagonal? Nash's argument (p. 88, following Eguchi, Gilkey and Hanson) is purely algebraic. An invariant polynomial is a *continuous* function on the space of matrices. The diagonalisable matrices are *dense*: a matrix with distinct eigenvalues is diagonalisable, and any matrix can be perturbed slightly to make its eigenvalues distinct. Two continuous functions that agree on a dense set agree everywhere. So an identity between invariant polynomials that holds for diagonal matrices holds for all matrices. This is "a kind of linear algebraic analogue of the validity of the splitting principle".

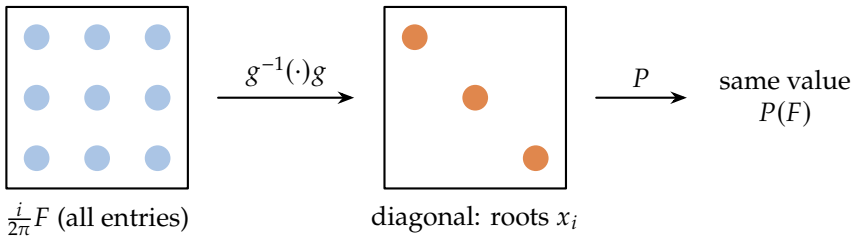

Figure 3.67: Why roots are eigenvalues. An invariant polynomial P does not change under conjugation, so (where possible) we may diagonalise $\frac{i}{2\pi}F$ first; the diagonal entries play the role of the Chern roots. Where the matrix cannot be diagonalised, continuity and density of the diagonalisable matrices finish the job. No global splitting of the bundle is ever needed.

Worked example 3.102: The curvature form of c_2 from the roots

From $c_2 = \sigma_2 = \frac{1}{2}(\sigma_1^2 - s_2)$ (Newton) and the substitution rule,

$$c_2(F) \overset{(1)}{=} \tfrac{1}{2}\left[\left(\operatorname{tr}\tfrac{i}{2\pi}F\right)^2 - \operatorname{tr}\left(\tfrac{i}{2\pi}F\right)^2\right]$$
$$\overset{(2)}{=} \frac{1}{8\pi^2}\left[\operatorname{tr}F\wedge F - \operatorname{tr}F\wedge\operatorname{tr}F\right],$$

(1) $\sigma_1 \to \operatorname{tr}\frac{i}{2\pi}F$ and $s_2 \to \operatorname{tr}(\frac{i}{2\pi}F)^2$.
(2) $(i/2\pi)^2 = -1/4\pi^2$, and the overall $\frac{1}{2}$.

which reproduces (3.156) of the previous section without expanding any determinant.

Reading Nash (pp. 79–80, (3.93)–(3.94), and p. 88)

Nash introduces the splitting principle in words (p. 79): to prove an identity it suffices to prove it for $E = L_1 \oplus \cdots \oplus L_k$, because any bundle F over X "can always be regarded as the pullback of another rank k bundle E over Y which is a sum of line bundles" (Bott and Tu). He does not mention the injectivity of $H^*(X) \to H^*(Y)$, which is the essential point; we have supplied it with the flag bundle. His (3.93) is $c(E) = \prod(1 + x_i)$ with $x_i = c_1(L_i)$ and

(3.94) lists the c_j as elementary symmetric functions. On p. 88 he gives the curvature rule $x_i \to iF_i/2\pi$ and justifies it by density of diagonalisable matrices.

Recap

- Chern roots: $c(E) = \prod(1 + x_i)$, $c_j = \sigma_j(x)$; they are the "eigenvalues" of the bundle.
- Splitting principle: pull back to the flag bundle, where E splits and $H^*(X)$ injects; identities true for sums of lines are true.
- Newton: $s_1 = c_1$, $s_2 = c_1^2 - 2c_2$, $s_3 = c_1^3 - 3c_1c_2 + 3c_3$.
- Recipes: E^* has roots $-x_i$; $E \otimes L$ has $x_i + y$; $\operatorname{End} E$ has $x_i - x_j$; $\Lambda^p E$ has sums of p distinct roots; $c(T\mathbb{CP}^n) = (1 + h)^{n+1}$.
- Curvature: replace the roots by the eigenvalues of $\frac{i}{2\pi}F$.

3.18 The Chern character and the Todd class

K-theory has two operations, $\oplus$ and $\otimes$. Cohomology also has two, $+$ and the cup (wedge) product. The previous two parts built K-theory; this chapter is about linking it to cohomology, where we can integrate and get numbers. So the question is: *is there a characteristic class that turns $\oplus$ into $+$ and $\otimes$ into the product?*

The total Chern class does not do it: it turns $\oplus$ into a *product*, $c(E \oplus F) = c(E)c(F)$, and it behaves messily under $\otimes$ (Example 3.98). We need a function that converts sums of roots into products and is additive over the roots. With Chern roots the answer is forced on us. The roots of $E \oplus F$ are the x_i together with the y_j; the roots of $E \otimes F$ are all the sums $x_i + y_j$. A function $\phi(E) = \sum_i f(x_i)$ is automatically additive under $\oplus$. It is multiplicative under $\otimes$ exactly when $\sum_{i,j} f(x_i + y_j) = \sum_i f(x_i) \sum_j f(y_j)$, that is, when $f(x + y) = f(x)f(y)$. The solution is the exponential. This is the Chern character.

The Todd class comes along for a different reason, which Nash flags in advance: together with the Chern character it makes up the index formula of Chapter 4.

3.18.1 Definition and first terms

Working definition 3.43 (Chern character)

For a complex bundle E of rank k with Chern roots $x_1, \dots, x_k$ [formal classes with $c(E) = \prod_i(1 + x_i)$, as if E were a sum of line bundles with $c_1 = x_i$],

$$\operatorname{ch}(E) = \sum_{i=1}^{k} e^{x_i} = \sum_{m \geq 0} \frac{1}{m!}\, s_m(x), \tag{3.168}$$

where $s_m = \sum_i x_i^m$ are the power sums. The degree-$2m$ part is $\operatorname{ch}_m(E) = s_m/m!$. The series stops at $m = \lfloor \dim X/2 \rfloor$ because higher cohomology vanishes. *Operationally:* use the Newton identities [$s_1 = c_1$, $s_2 = c_1^2 - 2c_2$, and so on] to write s_m in Chern classes; or, with a connection, use the curvature formula $\operatorname{ch}(F) = \operatorname{tr} \exp\left(\frac{i}{2\pi}F\right)$ of Section 3.18.5.

Nash calls (3.168) "a kind of generating function": the m-th power sum is generated with

weight $1/m!$. Using the Newton identities of Section 3.17.3,

$$\begin{aligned}\operatorname{ch}(E) &\overset{(1)}{=} k + s_1 + \tfrac{1}{2}s_2 + \tfrac{1}{6}s_3 + \dots \\ &\overset{(2)}{=} k + c_1 + \tfrac{1}{2}\big(c_1^2 - 2c_2\big) + \tfrac{1}{6}\big(c_1^3 - 3c_1c_2 + 3c_3\big) + \dots\end{aligned} \tag{3.169}$$

(1) $e^x = 1 + x + \frac{x^2}{2} + \frac{x^3}{6} + \dots$ for each root; summing over k roots gives k from the constant terms and $s_m/m!$ from the rest.

(2) $s_1 = \sigma_1$, $s_2 = \sigma_1^2 - 2\sigma_2$, $s_3 = \sigma_1^3 - 3\sigma_1\sigma_2 + 3\sigma_3$, and $\sigma_j = c_j$.

The first three terms are Nash's (3.97). Note what the degree-0 part is: the *rank*. The Chern character remembers the dimension of the fibre, which the total Chern class forgets.

Worked example 3.103: Line bundles and monopoles

For a line bundle L with $c_1(L) = x$, $\operatorname{ch}(L) = e^x = 1 + x + \frac{x^2}{2} + \dots$. Over S^2, $x^2 = 0$, so for the monopole bundles

$$\operatorname{ch}(L_n) = 1 + n\,u, \qquad \int_{S^2} \operatorname{ch}(L_n) = n.$$

Nash's Bott generator $b = [\eta] - [I] \in \widetilde{K}(S^2)$ then has $\operatorname{ch}(b) = \operatorname{ch}(\eta) - 1 = c_1(\eta)$, and $\int_{S^2} \operatorname{ch}(b) = \pm 1$: $+1$ if η is the hyperplane bundle L_1, -1 if η is the tautological bundle L_{-1} (the two conventions for "the Hopf bundle" both occur in the literature). Either way the Chern character identifies $\widetilde{K}(S^2) \cong \mathbb{Z}$ with $H^2(S^2;\mathbb{Z}) \cong \mathbb{Z}$: the K-theory class is literally the monopole charge.

Worked example 3.104: The instanton bundle over S^4

Let $E \to S^4$ be an SU(2) bundle with $\int c_2(E) = k$. Then $c_1 = 0$ and there is no degree-6 or higher cohomology, so

$$\begin{aligned}\operatorname{ch}(E) &\overset{(1)}{=} 2 + c_1 + \tfrac{1}{2}\big(c_1^2 - 2c_2\big) \\ &\overset{(2)}{=} 2 - c_2, \qquad \int_{S^4} \operatorname{ch}(E) = -k.\end{aligned}$$

(1) (3.169) with rank 2, truncated at degree 4.

(2) $c_1 = 0$ for SU(2).

The class $[E] - [I^2] \in \widetilde{K}(S^4)$ has $\operatorname{ch} = -c_2$. For the BPST bundle of Example 3.93, $\int \operatorname{ch}_2 = -1$: the generator of $\widetilde{K}(S^4) \cong \mathbb{Z}$ (which 3b built as the external product $b \boxtimes b$ on $S^2 \times S^2$ collapsed to S^4) is, up to sign, the instanton.

Worked example 3.105: The tangent bundle of $\mathbb{CP}^2$, two ways

From the Euler sequence $T\mathbb{CP}^n \oplus I = (n+1)\gamma^*$ (Example 3.101) and additivity (proved below),

$$\operatorname{ch}(T\mathbb{CP}^n) + 1 \overset{(1)}{=} (n+1)\,e^h \quad \Rightarrow \quad \operatorname{ch}(T\mathbb{CP}^2) = 3e^h - 1 = 2 + 3h + \tfrac{3}{2}h^2.$$

(1) ch of I is 1 and $\operatorname{ch}(\gamma^*) = e^{c_1(\gamma^*)} = e^h$.

Check against (3.169) with $k = 2$, $c_1 = 3h$, $c_2 = 3h^2$:

$$2 + 3h + \tfrac{1}{2}(9h^2 - 6h^2) = 2 + 3h + \tfrac{3}{2}h^2. \quad \checkmark$$

The coefficient $\frac{3}{2}$ is not an integer. Integrated over $\mathbb{CP}^2$ (where $\int h^2 = 1$), $\int_{\mathbb{CP}^2} \mathrm{ch}_2(T\mathbb{CP}^2) = \frac{3}{2}$.

3.18.2 Rational, not integral

The factorials make $\mathrm{ch}(E)$ a class with *rational* coefficients, Nash's (3.96):

$$\mathrm{ch}(E) \in H^*(X;\mathbb{Q}).$$

Two consequences follow, and Nash mentions both.

The values on cycles need not be integers. Example 3.105 already showed this. An even simpler case: for the hyperplane bundle $\gamma^* = L_1$ over $\mathbb{CP}^2$, $\mathrm{ch}(\gamma^*) = 1 + h + \frac{1}{2}h^2$ and $\int_{\mathbb{CP}^2} \mathrm{ch}_2(\gamma^*) = \frac{1}{2}$. On spheres, by contrast, the top component ch_n on S^{2n} *is* integral (a theorem of Bott: ch maps $\widetilde{K}(S^{2n})$ onto $H^{2n}(S^{2n};\mathbb{Z})$), which is what Examples 3.103 and 3.104 found.

Torsion is invisible. A class $t \in H^*(X;\mathbb{Z})$ with $mt = 0$ for some integer m becomes 0 in rational cohomology, since $t = \frac{1}{m}(mt) = 0$ once we may divide. So the Chern character cannot distinguish bundles that differ only in torsion.

Worked example 3.106: A bundle the Chern character cannot see

On the real projective plane $\mathbb{RP}^2$ (a disc with antipodal boundary points identified) take the real Möbius line bundle μ and complexify it, $L = \mu \otimes_{\mathbb{R}} \mathbb{C}$. Its transition functions are the constants ± 1, so L carries a *flat* connection (constant transition functions are compatible with $A = 0$ in every patch). Then

$$\mathrm{ch}(L) \overset{(1)}{=} \mathrm{tr}\exp\Big(\frac{i}{2\pi}F\Big) \overset{(2)}{=} \mathrm{tr}\exp(0) = 1 = \mathrm{ch}(I).$$

(1) The curvature formula (3.173) below, with any connection (the class does not depend on it).
(2) The flat connection has $F = 0$.

Yet L is not trivial: $L \otimes L$ has transition functions $(\pm 1)^2 = 1$, so $2c_1(L) = c_1(L \otimes L) = 0$, and in fact $c_1(L)$ is the nonzero element of $H^2(\mathbb{RP}^2;\mathbb{Z}) = \mathbb{Z}_2$. The Chern class sees L; the Chern character, like any curvature integral, cannot. Physically: a flat gauge field with holonomy -1 around a non-contractible loop has no field strength anywhere, so no local density can detect it, but it is a different sector (an Aharonov–Bohm phase).

Watch out: Rational does not mean "approximate"

$\mathrm{ch}(E)$ is an exact cohomology class; only its coefficients live in $\mathbb{Q}$. Integrality comes back in index theory: $\int_X \mathrm{ch}(E)\ \mathrm{td}(X)$ and $\int_X \mathrm{ch}(E)\hat{A}(X)$ are always integers (they are indices), even though neither factor alone need be.

3.18.3 Sums and products

Nash says it is "straightforward to check" (3.98). Here is the check, by the splitting principle. Let E and F have roots x_i ($i \le k$) and y_j ($j \le l$). Then

$$\operatorname{ch}(E \oplus F) \overset{(1)}{=} \sum_{i=1}^{k} e^{x_i} + \sum_{j=1}^{l} e^{y_j} = \operatorname{ch} E + \operatorname{ch} F, \tag{3.170}$$

$$\operatorname{ch}(E \otimes F) \overset{(2)}{=} \sum_{i,j} e^{x_i + y_j} \overset{(3)}{=} \sum_{i,j} e^{x_i} e^{y_j} = \Big(\sum_i e^{x_i}\Big)\Big(\sum_j e^{y_j}\Big) = \operatorname{ch} E \, \operatorname{ch} F. \tag{3.171}$$

(1) The roots of $E \oplus F$ are the x_i together with the y_j (Whitney).
(2) If $E = \bigoplus L_i$ and $F = \bigoplus M_j$ then $E \otimes F = \bigoplus_{i,j} L_i \otimes M_j$, and $c_1(L_i \otimes M_j) = x_i + y_j$.
(3) The exponential of a sum of commuting classes is the product of exponentials (the classes have even degree, so they commute).

Worked example 3.107: Checking multiplicativity in low degree

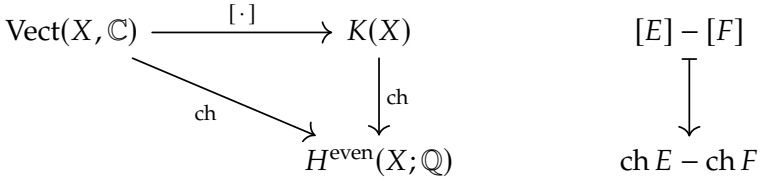
Take E of rank 2 and L a line bundle with $c_1(L) = y$. By (3.171),

$$\operatorname{ch}(E \otimes L) = \big(2 + c_1 + \tfrac{1}{2}(c_1^2 - 2c_2)\big)\big(1 + y + \tfrac{1}{2}y^2\big) = 2 + (c_1 + 2y) + \big(\tfrac{1}{2}c_1^2 - c_2 + c_1 y + y^2\big) + \dots$$

From Example 3.98 instead, $c_1(E \otimes L) = c_1 + 2y$ and $c_2(E \otimes L) = c_2 + c_1 y + y^2$, so

$$\begin{aligned} \tfrac{1}{2}\big(c_1(E \otimes L)^2 - 2c_2(E \otimes L)\big) &= \tfrac{1}{2}\big(c_1^2 + 4c_1 y + 4y^2\big) - c_2 - c_1 y - y^2 \\ &= \tfrac{1}{2}c_1^2 - c_2 + c_1 y + y^2. \end{aligned}$$

The two computations agree.



in $K(X)$	$\xrightarrow{\text{ch}}$	in $H^{\text{even}}(X;\mathbb{Q})$
$\oplus$ (sum)		$+$
$\otimes$ (product)		$\wedge$ (cup product)
rank k		degree-0 part k
$[L_n] - [I]$ on S^2		$n\,u$
torsion elements		0

Figure 3.68: The Chern character as a ring homomorphism from K-theory to even rational cohomology. Top: it is defined on actual bundles and extended to formal differences. Bottom: what it does to each piece of structure. The last row is the price of rational coefficients.

3.18.4 The Chern character on $K(X)$

Since ch is additive, it extends from bundles to the K-group. Recall from the previous part that every element of $K(X)$ is a formal difference $[E] - [F]$. Define (Nash's (3.99))

$$\operatorname{ch} : K(X) \longrightarrow H^*(X;\mathbb{Q}), \qquad [E] - [F] \longmapsto \operatorname{ch} E - \operatorname{ch} F. \tag{3.172}$$

Well defined? The same element has many representatives, and we must check that they all give the same answer, Nash's (3.100). Recall the rule (3.42) of the previous part: $[E]-[F]=[G]-[H]$ exactly when $E\oplus H\oplus J\cong G\oplus F\oplus J$ for some bundle J. Then

$$\begin{aligned}[E]-[F]=[G]-[H] &\overset{(1)}{=} E\oplus H\oplus J\cong G\oplus F\oplus J\\ &\overset{(2)}{=} \operatorname{ch}(E\oplus H\oplus J)=\operatorname{ch}(G\oplus F\oplus J)\\ &\overset{(3)}{=} \operatorname{ch}E+\operatorname{ch}H+\operatorname{ch}J=\operatorname{ch}G+\operatorname{ch}F+\operatorname{ch}J\\ &\overset{(4)}{=} \operatorname{ch}E-\operatorname{ch}F=\operatorname{ch}G-\operatorname{ch}H.\end{aligned}$$

(1) The definition of equality in the Grothendieck group (Nash's (3.42)). Here "=" in the chain means "implies".
(2) Isomorphic bundles have the same characteristic classes.
(3) Additivity (3.170).
(4) Cancel $\operatorname{ch}J$ (cohomology is a group, so cancellation is allowed there, unlike for bundles).

This is Nash's (3.101). The same additivity and multiplicativity give

$$\begin{aligned}\operatorname{ch}\big(([E]-[F])([G]-[H])\big) &\overset{(1)}{=} \operatorname{ch}\big([E\otimes G]-[E\otimes H]-[F\otimes G]+[F\otimes H]\big)\\ &\overset{(2)}{=} \operatorname{ch}E\operatorname{ch}G-\operatorname{ch}E\operatorname{ch}H-\operatorname{ch}F\operatorname{ch}G+\operatorname{ch}F\operatorname{ch}H\\ &=(\operatorname{ch}E-\operatorname{ch}F)(\operatorname{ch}G-\operatorname{ch}H),\end{aligned}$$

(1) The product in $K(X)$ is induced by $\otimes$, expanded bilinearly.
(2) Additivity on each term, then multiplicativity.

so ch is a **ring homomorphism** (Nash's (3.102)). Since all Chern roots have degree 2, ch lands in even degrees (Nash's (3.103)):

$$\operatorname{ch}: K(X)\longrightarrow \bigoplus_{i\geq 0} H^{2i}(X;\mathbb{Q}).$$

A theorem beyond Nash's text makes the link precise: for a finite cell complex, ch becomes an *isomorphism* after tensoring with $\mathbb{Q}$, $K(X)\otimes\mathbb{Q}\cong H^{\text{even}}(X;\mathbb{Q})$. K-theory and even cohomology carry the same rational information; K-theory additionally knows about torsion and integrality.

3.18.5 The curvature formula

By the substitution rule of Section 3.17.5, $\sum_i e^{x_i}$ becomes the trace of the exponential of the matrix $\frac{i}{2\pi}F$, Nash's (3.127):

$$\operatorname{ch}(F)=\operatorname{tr}\exp\Big(\frac{i}{2\pi}F\Big)=\sum_{m\geq 0}\frac{1}{m!}\Big(\frac{i}{2\pi}\Big)^m\operatorname{tr}F^m. \tag{3.173}$$

The exponential series terminates because F^m is a $2m$-form. The first terms are

$$\operatorname{ch}(F)=k+\frac{i}{2\pi}\operatorname{tr}F-\frac{1}{8\pi^2}\operatorname{tr}F\wedge F-\frac{i}{48\pi^3}\operatorname{tr}F\wedge F\wedge F+\dots \tag{3.174}$$

Each $\operatorname{tr}F^m$ is closed and its class is independent of the connection (Sections 3.16.3 and 3.16.4), so no further proof is needed that (3.173) represents a characteristic class.

Physical picture: Why physicists meet $\operatorname{tr} e^{iF/2\pi}$

The Chern character is the trace of the exponential of the field strength: the same structure as a partition function $\operatorname{tr} e^{-\beta H}$. This is not a coincidence. In the heat-kernel proof of the index theorem (Chapter 4) the operator $e^{-t\not{D}^2}$ contains, through the Lichnerowicz formula, the factor $e^{-t\,\sigma^{\mu\nu}F_{\mu\nu}/2}$, and its supertrace as $t \to 0$ produces exactly $\operatorname{ch}(F)$. In the anomaly computation (Chapter 10) the four-dimensional chiral anomaly density is $\operatorname{ch}_2(F) \propto \operatorname{tr} F \wedge F$.

Worked example 3.108: The instanton again, from curvature

For an SU(2) connection, $\operatorname{tr} F = 0$, so by (3.174) and (3.157)

$$\operatorname{ch}_2(F) \overset{(1)}{=} -\frac{1}{8\pi^2}\operatorname{tr} F \wedge F \overset{(2)}{=} -c_2(F),$$

(1) The $m = 2$ term: $\frac{1}{2}(\frac{i}{2\pi})^2 = -\frac{1}{8\pi^2}$.

(2) $c_2(F) = \frac{1}{8\pi^2}\operatorname{tr} F \wedge F$ for traceless F.

in agreement with Example 3.104. For the BPST connection, $\int_{\mathbb{R}^4} \operatorname{ch}_2(F) = -1$.

3.18.6 The Todd class

The second class of the section is also defined by a generating function in the roots. Its motivation will only be fully visible in Chapter 4: the Riemann–Roch–Hirzebruch theorem says that the index of the Dolbeault operator on a complex manifold X, twisted by a bundle E, is $\int_X \operatorname{ch}(E)\,\operatorname{td}(TX)$. We preview this below on $\mathbb{CP}^1$.

Working definition 3.44 (Todd class)

For a complex bundle E with Chern roots x_i, the **total Todd class** is (Nash's (3.104))

$$\operatorname{td}(E) = \prod_{i=1}^{k} \frac{x_i}{1 - e^{-x_i}}. \tag{3.175}$$

Each factor is a power series starting with 1 $[\,1 + \frac{x_i}{2} + \frac{x_i^2}{12} + \cdots\,]$, so $\operatorname{td}(E) = 1 + (\text{higher degree})$, and it is invertible [it has an inverse power series, because its degree-0 part is 1]. *Operationally:* expand each factor to the degree you need, multiply, and rewrite in Chern classes; or replace x by the matrix $\frac{i}{2\pi}F$ and take a determinant, $\operatorname{td}(F) = \det\!\left(\frac{iF/2\pi}{1-e^{-iF/2\pi}}\right)$.

The one-variable series. First expand $x/(1-e^{-x})$. Write $\frac{1-e^{-x}}{x} = 1 - \frac{x}{2} + \frac{x^2}{6} - \frac{x^3}{24} + \frac{x^4}{120} - \dots$ and look for the inverse series $1 + a_1 x + a_2 x^2 + a_3 x^3 + a_4 x^4 + \dots$. Their product must be 1, so each coefficient of x^n, $n \geq 1$, must vanish:

$$\begin{aligned}
x^1: &\quad a_1 - \tfrac{1}{2} = 0 && \Rightarrow\ a_1 = \tfrac{1}{2},\\
x^2: &\quad a_2 - \tfrac{1}{2}a_1 + \tfrac{1}{6} = 0 && \Rightarrow\ a_2 = \tfrac{1}{4} - \tfrac{1}{6} = \tfrac{1}{12},\\
x^3: &\quad a_3 - \tfrac{1}{2}a_2 + \tfrac{1}{6}a_1 - \tfrac{1}{24} = 0 && \Rightarrow\ a_3 = \tfrac{1}{24} - \tfrac{1}{12} + \tfrac{1}{24} = 0,\\
x^4: &\quad a_4 - \tfrac{1}{2}a_3 + \tfrac{1}{6}a_2 - \tfrac{1}{24}a_1 + \tfrac{1}{120} = 0 && \Rightarrow\ a_4 = -\tfrac{1}{72} + \tfrac{1}{48} - \tfrac{1}{120} = -\tfrac{1}{720}.
\end{aligned}$$

So

$$\frac{x}{1-e^{-x}} = 1 + \frac{x}{2} + \frac{x^2}{12} - \frac{x^4}{720} + \dots \tag{3.176}$$

The vanishing of all odd terms beyond the first has a neat reason:

$$\frac{x}{1-e^{-x}} - \frac{x}{2} = \frac{x}{2}\cdot\frac{1+e^{-x}}{1-e^{-x}} = \frac{x}{2}\coth\frac{x}{2},$$

an even function. Equivalently $\frac{x}{1-e^{-x}} = e^{x/2}\,\frac{x/2}{\sinh(x/2)}$, a factorisation that becomes the relation $\mathrm{td} = e^{c_1/2}\hat{A}$ in Section 3.20.8.

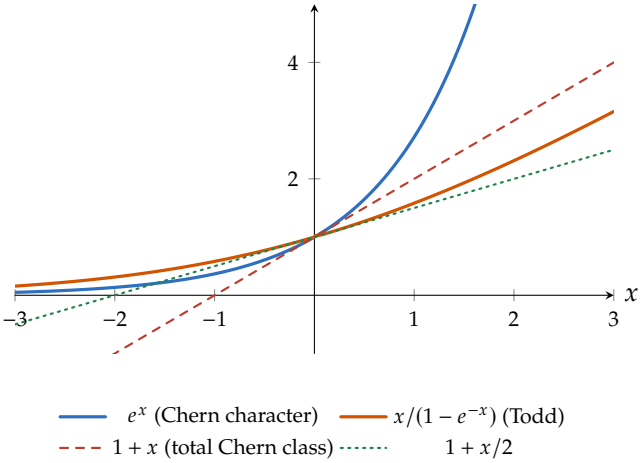


Figure 3.69: The one-variable generating functions of this section. A multiplicative class is fixed by a series $Q(x)$ through $\prod_i Q(x_i)$: $1+x$ gives the total Chern class, $x/(1-e^{-x})$ the Todd class. The Chern character is additive instead, $\sum_i e^{x_i}$. Near $x=0$ the Todd series hugs its tangent line $1+x/2$ (its degree-1 coefficient is $\frac{1}{2}$) and bends up with curvature $\frac{1}{12}$; it is smooth at $x=0$ despite the $0/0$ in its formula.

In Chern classes. Multiply the series for all roots and collect by degree. The degree-1 part is $\frac{1}{2}\sum x_i = \frac{1}{2}c_1$. The degree-2 part has $x_i^2/12$ from one factor and $\frac{x_i}{2}\frac{x_j}{2}$ from two:

$$\mathrm{td}_2 \overset{(1)}{=} \frac{1}{12}\sum_i x_i^2 + \frac{1}{4}\sum_{i<j} x_i x_j$$
$$\overset{(2)}{=} \frac{1}{12}\left(c_1^2 - 2c_2\right) + \frac{1}{4}c_2 = \frac{1}{12}\left(c_1^2 + c_2\right).$$

(1) Pick the x^2 term from one factor, or the x term from two different factors.
(2) $s_2 = c_1^2 - 2c_2$ and $\sigma_2 = c_2$.

The degree-3 part has no x_i^3 terms ($a_3 = 0$), terms $x_i^2 x_j$ ($i \neq j$) with coefficient $\frac{1}{12}\cdot\frac{1}{2}$, and terms $x_i x_j x_l$ ($i<j<l$) with coefficient $\frac{1}{8}$:

$$\mathrm{td}_3 \overset{(1)}{=} \frac{1}{24}\sum_{i\neq j} x_i^2 x_j + \frac{1}{8}\sum_{i<j<l} x_i x_j x_l$$
$$\overset{(2)}{=} \frac{1}{24}\left(c_1c_2 - 3c_3\right) + \frac{1}{8}c_3 = \frac{1}{24}c_1c_2.$$

(1) Choose which factors contribute which powers.
(2) $\sigma_1\sigma_2 = \sum_{i\neq j} x_i^2 x_j + 3\sigma_3$, since each triple product $x_i x_j x_l$ arises three times in $\sigma_1\sigma_2$.

Altogether, Nash's (3.106):

$$\mathrm{td}(E) = 1 + \frac{1}{2}c_1 + \frac{1}{12}\left(c_1^2 + c_2\right) + \frac{1}{24}c_1c_2 + \dots \tag{3.177}$$

Being a product over roots, td is multiplicative, $\mathrm{td}(E \oplus F) = \mathrm{td}(E)\,\mathrm{td}(F)$ (Nash's (3.105)), and like ch it is a rational class.

Worked example 3.109: The Todd genus of $\mathbb{CP}^n$ is 1

By the Euler sequence and multiplicativity ($\mathrm{td}(I) = 1$), $\mathrm{td}(T\mathbb{CP}^n) = \left(\frac{h}{1-e^{-h}}\right)^{n+1}$. The **Todd genus** is $\int_{\mathbb{CP}^n} \mathrm{td}(T\mathbb{CP}^n)$, the coefficient of h^n. For $n = 1$: $\mathrm{td} = 1 + \frac{1}{2}c_1 = 1 + h$, and $\int = 1$. For $n = 2$: $c_1 = 3h$, $c_2 = 3h^2$, and $\mathrm{td}_2 = \frac{1}{12}(9+3)h^2 = h^2$, so again $\int = 1$. For general n, a residue does it:

$$\int_{\mathbb{CP}^n} \mathrm{td} \overset{(1)}{=} \frac{1}{2\pi i}\oint \left(\frac{h}{1-e^{-h}}\right)^{n+1}\frac{\mathrm{d}h}{h^{n+1}} = \frac{1}{2\pi i}\oint \frac{\mathrm{d}h}{(1-e^{-h})^{n+1}}$$
$$\overset{(2)}{=} \frac{1}{2\pi i}\oint \frac{\mathrm{d}w}{w^{n+1}(1-w)} \overset{(3)}{=} 1.$$

(1) The coefficient of h^n in a power series $f(h)$ is $\frac{1}{2\pi i}\oint f(h)\,h^{-n-1}\mathrm{d}h$ around a small circle.
(2) Substitute $w = 1 - e^{-h}$, so $\mathrm{d}w = e^{-h}\mathrm{d}h = (1-w)\mathrm{d}h$; a small circle around $h = 0$ becomes a small circle around $w = 0$.
(3) The coefficient of w^n in $\frac{1}{1-w} = \sum w^j$ is 1.

In Chapter 4 this "1" will be the statement that the only holomorphic functions on $\mathbb{CP}^n$ are constants: the Dolbeault index is $\dim H^{0,0} = 1$.

Worked example 3.110: Riemann–Roch on $\mathbb{CP}^1$: a preview

Take $X = \mathbb{CP}^1$ and the line bundle $L_n = \mathcal{O}(n)$ (the monopole bundle, $c_1 = nh$). Then

$$\int_{\mathbb{CP}^1} \mathrm{ch}(L_n)\,\mathrm{td}(T\mathbb{CP}^1) \overset{(1)}{=} \int_{\mathbb{CP}^1} (1+nh)(1+h)$$
$$\overset{(2)}{=} \int_{\mathbb{CP}^1} \big(1 + (n+1)h\big) = n+1.$$

(1) $\mathrm{ch}(L_n) = e^{nh} = 1 + nh$ and $\mathrm{td}(T\mathbb{CP}^1) = 1 + \frac{1}{2}c_1(T\mathbb{CP}^1) = 1 + h$, since $h^2 = 0$ on $\mathbb{CP}^1$.
(2) Only the degree-2 part integrates.

For $n \geq 0$ this is exactly the number of holomorphic sections of $\mathcal{O}(n)$: the homogeneous polynomials of degree n in (z_0, z_1), spanned by $z_0^n, z_0^{n-1}z_1, \dots, z_1^n$, which is $n+1$ of them (computed with Čech cohomology in part 3a). For $n = -2$ the formula gives -1: no sections, and one-dimensional H^1. The Chern character counts the twisting, the Todd class corrects for the curvature of the base, and the product integrates to an integer that counts zero modes. This is the index theorem in miniature.

Reading Nash (pp. 78–82, (3.95)–(3.106))

Nash introduces the Chern character as "an extremely valuable tool in K-theory" linking $K(X)$ and $H^*(X)$, defines it by (3.95), $\mathrm{ch}(E) = \sum e^{x_i}$, stresses rational coefficients and blindness to torsion (3.96), gives the first terms (3.97), states additivity and multiplicativity (3.98) as "straightforward", and defines ch on $K(X)$ (3.99), checking well-definedness (3.100)–(3.101) with the Grothendieck-group relation (3.42) and concluding it is a ring

homomorphism into even rational cohomology (3.102)–(3.103). His closing remark, that $\mathrm{ch}(E)$ evaluated on a cycle "need only be rational rather than integral", is Example 3.105. The Todd class (3.104) comes with multiplicativity (3.105) and the expansion (3.106), which we derived term by term. His curvature formula (3.127), $\mathrm{ch}(F) = \operatorname{tr}\exp(iF/2\pi)$, is (3.173).

Recap

- $\mathrm{ch}(E) = \sum e^{x_i} = k + c_1 + \frac{1}{2}(c_1^2 - 2c_2) + \frac{1}{6}(c_1^3 - 3c_1c_2 + 3c_3) + \dots$; with curvature $\mathrm{ch}(F) = \operatorname{tr} e^{iF/2\pi}$.
- $\mathrm{ch}(E \oplus F) = \mathrm{ch}\,E + \mathrm{ch}\,F$, $\mathrm{ch}(E \otimes F) = \mathrm{ch}\,E\ \mathrm{ch}\,F$; so $\mathrm{ch} : K(X) \to H^{\mathrm{even}}(X;\mathbb{Q})$ is a well-defined ring homomorphism.
- Rational coefficients: values on cycles can be fractions ($\frac{1}{2}$ on $\mathbb{CP}^2$); torsion (the flat bundle on $\mathbb{RP}^2$) is invisible.
- Monopole: $\mathrm{ch}(L_n) = 1 + nu$. Instanton: $\mathrm{ch} = 2 - c_2$, $\int \mathrm{ch}_2 = -k$.
- $\mathrm{td}(E) = \prod \frac{x_i}{1-e^{-x_i}} = 1 + \frac{1}{2}c_1 + \frac{1}{12}(c_1^2 + c_2) + \frac{1}{24}c_1c_2 + \dots$; Todd genus of $\mathbb{CP}^n$ is 1; $\int_{\mathbb{CP}^1} \mathrm{ch}(\mathcal{O}(n))\,\mathrm{td} = n + 1$.

3.19 Real bundles, complexification and Pontryagin classes

The tangent bundle of spacetime, or of any real manifold, is a *real* vector bundle. Chern classes are defined only for complex bundles. So how do we measure the twisting of a real bundle, the kind of twisting that gravitational anomalies and the $\hat{A}$-genus of the Dirac index see? Nash's answer is the obvious one: turn the real bundle into a complex one by allowing complex coefficients in each fibre, then take Chern classes. The result is the Pontryagin classes. Before we get there we need a small toolkit of operations on bundles, each of which is one line in terms of transition functions: dual, conjugate, complexification and realification.

Throughout, a bundle is described by transition functions $g_{\alpha\beta}$ on overlaps, relating the local frames: $s_\beta = s_\alpha\, g_{\alpha\beta}$ on $U_\alpha \cap U_\beta$. A section with components u_β in the frame s_β has components $u_\alpha = g_{\alpha\beta}u_\beta$ in the frame s_α.

3.19.1 The dual and the conjugate bundle

Dual. The fibre of E^* at x is the space of linear functionals on E_x. If $s = (s_1, \dots, s_k)$ is a frame of E, the **dual frame** $s^* = (s^1, \dots, s^k)$ is defined by $s^i(s_j) = \delta^i_j$. How does it change when $s' = s\,g$? Writing the dual frame as a column, we need $s'^* = h\,s^*$ for some matrix h with

$$\delta^i_j = s'^{\,i}(s'_j) \overset{(1)}{=} \sum_{l,m} h_{il}\, s^l\big(s_m\, g_{mj}\big) \overset{(2)}{=} \sum_l h_{il}\, g_{lj} = (hg)_{ij},$$

(1) Substitute $s'^{\,i} = \sum_l h_{il}s^l$ and $s'_j = \sum_m s_m g_{mj}$.

(2) Linearity and $s^l(s_m) = \delta^l_m$.

so $h = g^{-1}$. The *components* of a covector then transform by $(g^{-1})^T$, and the transition functions of E^* are

$$g^{E^*}_{\alpha\beta} = \left(g^{-1}_{\alpha\beta}\right)^T.$$

This is the "inverse transpose" that every physicist knows from upper and lower indices: $v^\mu \mapsto \Lambda^\mu{}_\nu v^\nu$ but $w_\mu \mapsto w_\nu (\Lambda^{-1})^\nu{}_\mu$.

Conjugate. The **conjugate bundle** $\bar{E}$ has the same underlying real bundle as E but with scalar multiplication by λ redefined as multiplication by $\bar{\lambda}$. In coordinates this just means complex-conjugating everything:

$$g^{\bar{E}}_{\alpha\beta} = \bar{g}_{\alpha\beta}.$$

Unitary bundles: $E^* \cong \bar{E}$. Choose a Hermitian inner product on the fibres (always possible, by a partition of unity) and use only orthonormal frames. Then the transition functions are unitary, $g^{-1} = g^\dagger = \bar{g}^T$, and therefore

$$\left(g^{-1}\right)^T = \bar{g} \qquad \Longrightarrow \qquad E^* \cong \bar{E}.$$

Concretely, the isomorphism is $v \mapsto \langle v, \cdot \rangle$: the inner product turns a vector into a covector, antilinearly in v, which is exactly a complex-*linear* map from $\bar{E}$ to E^*. (This is the bra–ket correspondence $|v\rangle \mapsto \langle v|$.)

Nash's footnote 6 is about the step "use only orthonormal frames". Given any frame, Gram–Schmidt makes it orthonormal by a smooth upper-triangular change of frame, so every bundle has a cover with unitary transition functions: the **structure group** reduces from $\mathrm{GL}(k,\mathbb{C})$ to $U(k)$. Nothing topological is lost, because $\mathrm{GL}(k,\mathbb{C})$ deformation retracts onto $U(k)$ (polar decomposition $g = u\,p$ with p positive, and p^t, $0 \le t \le 1$, shrinks p to $\mathbb{1}$).

Worked example 3.111: Duals and conjugates of monopole bundles

The monopole bundle L_n is glued by $g = e^{-in\phi}$ on the equator. Its dual has transition function $(g^{-1})^T = e^{+in\phi}$, and so does its conjugate, $\bar{g} = e^{+in\phi}$. Both are L_{-n}:

$$L_n^* \cong \bar{L}_n \cong L_{-n}, \qquad c_1(L_n^*) = -c_1(L_n).$$

In particular the dual of the tautological bundle $\gamma = L_{-1}$ is the **hyperplane bundle** $\gamma^* = L_1$. Its fibre over the line ℓ is ℓ^*, so each linear function on $\mathbb{C}^2$ restricts to a section: the coordinate z_0 gives a section of γ^* that vanishes only on the line $\{z_0 = 0\}$, a single point of $\mathbb{CP}^1$, with multiplicity one. One zero, and $c_1(\gamma^*) = +1$: for holomorphic line bundles c_1 counts the zeros of a section, a first glimpse of the Euler class of Section 3.20.

3.19.2 Line bundles form a group

For line bundles the transition functions are 1×1, so they commute and multiply: $L \otimes M$ has transition functions $g^L g^M$. The trivial bundle (transition functions 1) is a unit, and L^* (transition functions $1/g^L$) is an inverse, since $L \otimes L^*$ has transition functions 1. So isomorphism classes of line bundles form an **abelian group** under $\otimes$. This justifies Nash's notation L^{-1} for L^* and L^n for $\otimes^n L$.

Key idea: c_1 is a group isomorphism for line bundles

$c_1(L \otimes M) = c_1(L) + c_1(M)$ and $c_1(L^{-1}) = -c_1(L)$. For smooth complex line bundles, $L \mapsto c_1(L)$ is an isomorphism from the group of line bundles to $H^2(X;\mathbb{Z})$.

The homomorphism property was shown in Section 3.17.4. That it is an isomorphism is the statement $[X, \mathbb{CP}^\infty] = H^2(X;\mathbb{Z})$; part 3a obtained it from the exponential sequence of sheaves, $0 \to \mathbb{Z} \to \mathcal{E} \to \mathcal{E}^* \to 0$. On S^2 the group is $\mathbb{Z}$, generated by L_1, and $L_1^n = L_n$: this is the statement that a monopole of charge n is the n-th tensor power of the unit monopole. (In K-theory, by contrast, $[L_1]^n = [L_n]$ but also $[L_n] = n[L_1] - (n-1)$, because $([L_1]-1)^2 = 0$ in $K(S^2)$: the ring structure of K and the group structure of line bundles are different things.)

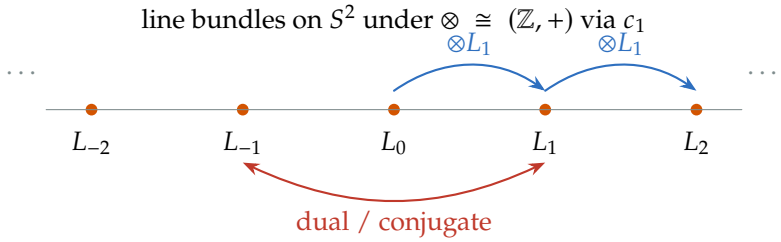

Figure 3.70: Line bundles over S^2 form the group $\mathbb{Z}$. Tensoring with the unit monopole L_1 steps one place to the right; the dual (equivalently, for unitary bundles, the conjugate) reflects $L_n \mapsto L_{-n}$. The trivial bundle L_0 is the identity element.

3.19.3 Real bundles

Now let V be a *real* vector bundle of rank k. A Riemannian (fibre) metric reduces the structure group from $\mathrm{GL}(k,\mathbb{R})$ to $\mathrm{O}(k)$, by the same Gram–Schmidt argument. For orthogonal g, $(g^{-1})^T = g$, so

$$V^* \cong V,$$

and conjugation does nothing on real fibres, $\bar{V} = V$. So for real bundles the dual and conjugate bring nothing new *topologically*. Nash adds a sensible caution: for $V = TX$ we still keep TX and T^*X apart in analysis. The isomorphism $TX \cong T^*X$ depends on the choice of metric (it is the index-lowering map $v^\mu \mapsto g_{\mu\nu}v^\nu$), while the distinction between a velocity and a gradient does not.

3.19.4 Complexification

Working definition 3.45 (Complexification)

The **complexification** $V \otimes_{\mathbb{R}} \mathbb{C}$ (also written $V_{\mathbb{C}}$) of a real bundle V of rank k is the complex bundle of rank k whose fibre is $V_x \otimes_{\mathbb{R}} \mathbb{C} = V_x \oplus iV_x$, the vectors $v_1 + iv_2$ with $v_1, v_2 \in V_x$. Its transition functions [the matrices g_{ab} converting fibre coordinates between patches] are the *same real matrices* g as for V, now acting on $\mathbb{C}^k$ (Nash writes $g \otimes 1$). *Operationally:* keep the transition functions, allow complex coefficients.

Nash's (3.107) writes this as $V \otimes_{\mathbb{R}} \mathbb{C} = V \otimes (\mathbb{R} \oplus i\mathbb{R})$, and the conjugate bundle as $V \otimes (\mathbb{R} \oplus -i\mathbb{R})$. The key point is that *nothing is new*:

Key idea: Nash's (3.108)

For a real bundle V,

$$V \otimes_{\mathbb{R}} \mathbb{C} \;\cong\; \overline{V \otimes_{\mathbb{R}} \mathbb{C}} \;\cong\; \left(V \otimes_{\mathbb{R}} \mathbb{C}\right)^*.$$

Why: the transition functions g of $V_{\mathbb{C}}$ are real, so $\bar{g} = g$, which gives the first isomorphism; and with an orthogonal choice $(g^{-1})^T = g$, which gives the second. Concretely, the fibrewise

map $v_1 + iv_2 \mapsto v_1 - iv_2$ is a complex-linear isomorphism $\overline{V_{\mathbb{C}}} \to V_{\mathbb{C}}$ (antilinear on $V_{\mathbb{C}}$, hence linear on the conjugate).

Consequence: odd Chern classes of $V_{\mathbb{C}}$ are 2-torsion. Combine (3.108) with the dual rule $c_j(E^*) = (-1)^j c_j(E)$ of Example 3.97:

$$c_j(V_{\mathbb{C}}) \overset{(1)}{=} c_j\big((V_{\mathbb{C}})^*\big) \overset{(2)}{=} (-1)^j\, c_j(V_{\mathbb{C}}),$$

(1) Isomorphic bundles have equal Chern classes, and $V_{\mathbb{C}} \cong (V_{\mathbb{C}})^*$.
(2) The roots of a dual bundle are minus the roots.

so for odd j, $2c_j(V_{\mathbb{C}}) = 0$. In real (de Rham) cohomology the odd classes simply vanish. Only the even ones, $c_2, c_4, \ldots$, carry information. That is why the Pontryagin classes below are built from c_{2i} alone.

Worked example 3.112: The complexified tangent bundle of S^2

TS^2 is a real rank-2 bundle. The complex structure of $S^2 = \mathbb{CP}^1$ makes it a complex line bundle, $T\mathbb{CP}^1 = L_2$ (Example 3.101). By the result of the next subsection, $TS^2 \otimes_{\mathbb{R}} \mathbb{C} \cong L_2 \oplus \bar{L}_2 = L_2 \oplus L_{-2}$, so

$$c(TS^2 \otimes \mathbb{C}) \overset{(1)}{=} (1 + 2u)(1 - 2u) \overset{(2)}{=} 1 - 4u^2 \overset{(3)}{=} 1.$$

(1) Whitney, with $c_1(L_{\pm 2}) = \pm 2u$.
(2) Multiply out.
(3) $u^2 \in H^4(S^2) = 0$.

$c_1(TS^2 \otimes \mathbb{C}) = 0$, as the torsion argument demands ($H^2(S^2;\mathbb{Z}) = \mathbb{Z}$ has no torsion, so the 2-torsion class c_1 must be zero). In the local complex coordinate z, the splitting is the familiar one: $T_{\mathbb{C}}S^2 = \operatorname{span}\{\partial_z\} \oplus \operatorname{span}\{\partial_{\bar{z}}\}$.

3.19.5 Realify, then complexify: $E_r \otimes \mathbb{C} = E \oplus \bar{E}$

Going the other way, a complex bundle E of rank k can be viewed as a real bundle E_r of rank $2k$ by forgetting that we can multiply by i. What is left of i is a real bundle map $J : E_r \to E_r$, $J(v) = iv$, with $J^2 = -1$. Complexifying E_r gives a complex bundle of rank $2k$, and Nash's (3.109) identifies it:

$$E_r \otimes_{\mathbb{R}} \mathbb{C} \;\cong\; E \oplus \bar{E}. \tag{3.178}$$

Nash derives this by writing $\mathbb{C} = \mathbb{R} \oplus i\mathbb{R}$. The cleanest way to see it is through the eigenvalues of J. Extend J complex-linearly to $E_r \otimes \mathbb{C}$. Since $J^2 = -1$, its eigenvalues are $\pm i$, and the fibre splits into the two eigenspaces

$$E^{1,0} = \{w : Jw = +iw\}, \qquad E^{0,1} = \{w : Jw = -iw\}.$$

Each vector $v \in E_r$ produces one vector in each:

$$J\big(v - iJv\big) \overset{(1)}{=} Jv - iJ^2v = Jv + iv \overset{(2)}{=} i\big(v - iJv\big),$$
$$J\big(v + iJv\big) \overset{(3)}{=} Jv + iJ^2v = Jv - iv = -i\big(v + iJv\big).$$

(1) J is complex-linear on $E_r \otimes \mathbb{C}$, so it passes the scalar i.
(2) $J^2 = -1$; factor out i.

(3) Same computation with the opposite sign.

The map $\phi_+(v) = \frac{1}{2}(v - iJv)$ from E to $E^{1,0}$ is complex-linear: multiplying v by i in E means applying J, and $\phi_+(Jv) = \frac{1}{2}(Jv + iv) = i\phi_+(v)$. The map $\phi_-(v) = \frac{1}{2}(v + iJv)$ has $\phi_-(Jv) = \frac{1}{2}(Jv - iv) = -i\phi_-(v)$: it is antilinear, that is, a linear isomorphism from $\bar{E}$ onto $E^{0,1}$. Hence $E_r \otimes \mathbb{C} = E^{1,0} \oplus E^{0,1} \cong E \oplus \bar{E}$.

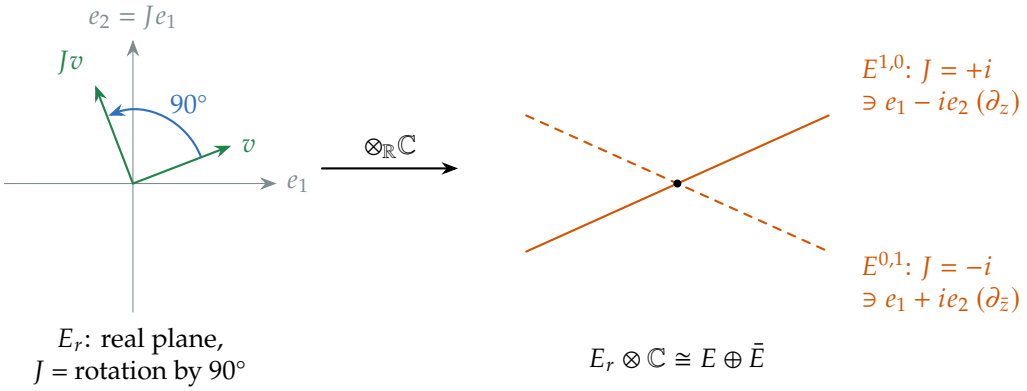

Figure 3.71: Realify, then complexify. Left: a complex line, seen as a real plane, remembers i only as the rotation J. Right: after allowing complex coefficients, J can be diagonalised; its $+i$ and $-i$ eigenlines are copies of E and of $\bar{E}$. For the tangent plane of a Riemann surface these are spanned by $\partial_z = \frac{1}{2}(\partial_x - i\partial_y)$ and $\partial_{\bar{z}}$, the splitting behind the (p,q)-forms of part 3a.

Worked example 3.113: J and its eigenvectors for $\mathbb{C}$ itself

Take $E = \mathbb{C}$, a trivial line. As a real plane with basis $e_1 = 1$, $e_2 = i$, multiplication by i is $J = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$. Then

$$J\begin{pmatrix} 1 \\ -i \end{pmatrix} \overset{(1)}{=} \begin{pmatrix} i \\ 1 \end{pmatrix} = i\begin{pmatrix} 1 \\ -i \end{pmatrix}, \qquad J\begin{pmatrix} 1 \\ i \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} -i \\ 1 \end{pmatrix} = -i\begin{pmatrix} 1 \\ i \end{pmatrix}.$$

(1) First row: $0 \cdot 1 + (-1)(-i) = i$; second row: $1 \cdot 1 + 0 = 1$.
(2) First row: $-i$; second row: 1.

So $e_1 - ie_2$ spans $E^{1,0}$ and $e_1 + ie_2$ spans $E^{0,1}$. With $e_1 = \partial_x$, $e_2 = \partial_y$ these are $2\partial_z$ and $2\partial_{\bar{z}}$.

3.19.6 Pontryagin classes

Working definition 3.46 (Pontryagin classes)

For a real vector bundle V of rank k, the ***i*-th Pontryagin class** is (Nash's (3.111))

$$p_i(V) = (-1)^i\, c_{2i}(V \otimes_{\mathbb{R}} \mathbb{C}) \;\in\; H^{4i}(X;\mathbb{Z}), \tag{3.179}$$

[only even Chern classes are used, because the odd ones of $V \otimes_{\mathbb{R}} \mathbb{C}$ satisfy $2c_{2i+1} = 0$ and vanish in real cohomology] and the total Pontryagin class is (Nash's (3.112))

$$p(V) = 1 + p_1(V) + \cdots + p_{[k/2]}(V). \tag{3.180}$$

Operationally: complexify, compute the even Chern classes, insert the signs. With an $\mathrm{O}(k)$ connection [its matrix A of 1-forms is real antisymmetric, so parallel transport preserves

the metric] whose curvature is the real antisymmetric matrix of 2-forms Ω,

$$p(\Omega) = \det\Big(\mathbb{1} + \frac{\Omega}{2\pi}\Big), \qquad p_1(\Omega) = -\frac{1}{8\pi^2}\operatorname{tr}(\Omega \wedge \Omega). \tag{3.181}$$

The top class is $p_{[k/2]}$, where $[k/2]$ is the integer part of $k/2$: the complexification has rank k, so $c_{2i}(V_{\mathbb{C}}) = 0$ once $2i > k$. As always, some classes can vanish just because X is too small: $p_i \in H^{4i}(X)$ is zero whenever $4i > \dim X$. On a 4-manifold only p_1 can be nonzero.

The curvature formula. An $\mathrm{O}(k)$ connection on V is also a connection on $V_{\mathbb{C}}$, with the same real antisymmetric curvature matrix Ω (anti-Hermitian, since real and antisymmetric). So $c(V_{\mathbb{C}}) = \det(\mathbb{1} + \frac{i}{2\pi}\Omega)$. The degree-$2j$ part carries $i^{2j} = (-1)^j$ times the corresponding coefficient of $\det(\mathbb{1} + \frac{\Omega}{2\pi})$, which cancels the sign in (3.179); this gives the first formula in (3.181). The odd terms vanish identically, as forms:

$$\det\Big(\mathbb{1} + \frac{\Omega}{2\pi}\Big) \overset{(1)}{=} \det\Big(\mathbb{1} + \frac{\Omega}{2\pi}\Big)^{T} \overset{(2)}{=} \det\Big(\mathbb{1} - \frac{\Omega}{2\pi}\Big),$$

(1) A determinant equals that of the transpose (the entries commute).
(2) $\Omega^T = -\Omega$.

and $\Omega \to -\Omega$ flips the sign of every odd-degree coefficient. For p_1, by (3.156) with $\operatorname{tr}\Omega = 0$,

$$p_1(\Omega) \overset{(1)}{=} -c_2(\Omega) \overset{(2)}{=} -\frac{1}{8\pi^2}\operatorname{tr}(\Omega \wedge \Omega) \overset{(3)}{=} \frac{1}{8\pi^2}\sum_{a,b} \Omega_{ab} \wedge \Omega_{ab},$$

(1) Definition (3.179) with $i = 1$.
(2) (3.156), and $\operatorname{tr}\Omega = 0$ for an antisymmetric matrix.
(3) $\operatorname{tr}(\Omega \wedge \Omega) = \sum_{a,b} \Omega_{ab} \wedge \Omega_{ba} = -\sum_{a,b} \Omega_{ab} \wedge \Omega_{ab}$.

For the Levi-Civita connection this is the gravitational Pontryagin density $\frac{1}{8\pi^2} R_{ab} \wedge R_{ab}$, which appears in the gravitational anomaly and in the signature theorem.

Whitney sums, modulo 2-torsion. Pontryagin classes are "not quite as well behaved" as Chern classes, Nash warns (3.113). Let us see exactly what goes wrong at the first step. Since $(V \oplus W)_{\mathbb{C}} = V_{\mathbb{C}} \oplus W_{\mathbb{C}}$,

$$\begin{aligned} p_1(V \oplus W) &\overset{(1)}{=} -c_2(V_{\mathbb{C}} \oplus W_{\mathbb{C}}) \\ &\overset{(2)}{=} -\big(c_2(V_{\mathbb{C}}) + c_1(V_{\mathbb{C}})c_1(W_{\mathbb{C}}) + c_2(W_{\mathbb{C}})\big) \\ &\overset{(3)}{=} p_1(V) + p_1(W) - c_1(V_{\mathbb{C}})\, c_1(W_{\mathbb{C}}). \end{aligned}$$

(1) Definition.
(2) Whitney for Chern classes, degree 4.
(3) Definition again for V and W.

The leftover $r = -c_1(V_{\mathbb{C}})c_1(W_{\mathbb{C}})$ satisfies $2r = 0$, because $2c_1(V_{\mathbb{C}}) = 0$. So

$$p(V \oplus W) = p(V)\, p(W) \quad \text{modulo elements of order 2 in } H^*(X;\mathbb{Z}), \tag{3.182}$$

which is Nash's (3.114). If $H^*(X;\mathbb{Z})$ has no torsion, or if we only use de Rham cohomology, the correction is invisible and p is honestly multiplicative. With connections it is automatic: the direct-sum curvature is block diagonal and $\det(\mathbb{1} + \Omega/2\pi)$ factorises.

Worked example 3.114: Pontryagin classes of spheres

Nash's example (3.115). The sphere $S^n \subset \mathbb{R}^{n+1}$ has at each point a tangent space and a normal line, together filling $\mathbb{R}^{n+1}$:

$$TS^n \oplus N(S^n) \cong I^{n+1}.$$

The normal bundle $N(S^n)$ is trivial: the outward unit normal $x \mapsto x$ is a nowhere-zero section, and a line bundle with a nowhere-zero section is trivial. The cohomology of S^n has no torsion, so Whitney holds exactly:

$$p(TS^n) \overset{(1)}{=} p(TS^n)\,p(I) \overset{(2)}{=} p\big(TS^n \oplus N(S^n)\big) \overset{(3)}{=} p(I^{n+1}) \overset{(4)}{=} 1.$$

(1) $p(I) = 1$: a trivial bundle has trivial complexification, whose Chern classes vanish (Example 3.87).
(2) Whitney (3.182), exact here, and $N(S^n) \cong I$.
(3) The isomorphism above.
(4) Trivial bundle again.

So $p_i(S^n) := p_i(TS^n) = 0$ for all $i > 0$. The cause is stable triviality: TS^n becomes trivial after adding one trivial line, and Pontryagin classes, like all classes built from Chern classes, cannot see trivial summands. Yet TS^2 is not trivial. The Pontryagin classes are blind to it; we need a class that is *not* stable, the Euler class.

A curvature check on the round S^4: in an orthonormal frame the Levi-Civita curvature of the unit sphere is $\Omega_{ab} = e^a \wedge e^b$ (constant curvature 1). Then

$$\sum_{a,b} \Omega_{ab} \wedge \Omega_{ab} = \sum_{a,b} e^a \wedge e^b \wedge e^a \wedge e^b = 0,$$

since each term repeats a 1-form. The Pontryagin *form* of the round metric vanishes pointwise, not just in cohomology.

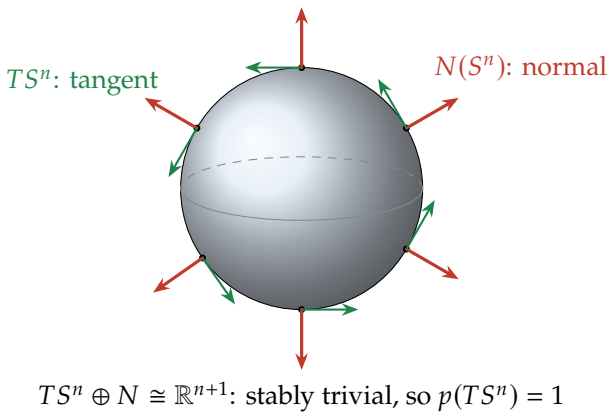

Figure 3.72: Why the Pontryagin classes of a sphere vanish. At each point the tangent space (green) and the normal line (red) together span $\mathbb{R}^{n+1}$, and the normal line is trivialised by the outward normal. Adding a trivial summand to TS^n makes it trivial, and Pontryagin classes cannot see trivial summands. (They are therefore also blind to the hairy-ball twisting of TS^2.)

Pontryagin classes of complex bundles. Nash extends the definition to a complex bundle E of rank k by applying it to the underlying real bundle: $p(E) \coloneqq p(E_r)$. Then

$$p_i(E) \overset{(1)}{=} (-1)^i\, c_{2i}(E_r \otimes \mathbb{C}) \overset{(2)}{=} (-1)^i\, c_{2i}(E \oplus \bar{E}), \tag{3.183}$$

(1) Definition (3.179) applied to E_r.
(2) (3.178).

which is Nash's (3.116). Now expand with Whitney and $c_j(\bar{E}) = (-1)^j c_j(E)$, Nash's (3.117):

$$c(E \oplus \bar{E}) = \big(1 + c_1 + c_2 + \cdots + c_k\big)\big(1 - c_1 + c_2 - \cdots + (-1)^k c_k\big). \tag{3.184}$$

The degree-$2i$ part is

$$c_{2i}(E \oplus \bar{E}) \overset{(1)}{=} \sum_{j=0}^{2i} c_j\,(-1)^{2i-j} c_{2i-j} \overset{(2)}{=} \sum_{j=0}^{2i} (-1)^j c_j\, c_{2i-j},$$

(1) Pick c_j from the first factor and $(-1)^{2i-j}c_{2i-j}$ from the second.
(2) $(-1)^{2i-j} = (-1)^j$.

and multiplying by $(-1)^i$ gives Nash's (3.118):

$$p_i(E) = \sum_{j=0}^{2i} (-1)^{i+j} c_j(E)\, c_{2i-j}(E) = c_i^2 - 2c_{i-1}c_{i+1} + 2c_{i-2}c_{i+2} - \cdots + (-1)^i\, 2c_{2i}. \tag{3.185}$$

(The terms j and $2i-j$ are equal, which produces the factors of 2; the middle term $j = i$ is c_i^2 with sign $(-1)^{2i} = +1$.) The first two cases are

$$p_1(E) = c_1^2 - 2c_2, \qquad p_2(E) = c_2^2 - 2c_1c_3 + 2c_4.$$

The splitting version. With Chern roots x_i of E, $\bar{E}$ has roots $-x_i$, so (Nash's (3.119))

$$\begin{aligned} c(E_r \otimes \mathbb{C}) &\overset{(1)}{=} \prod_{i=1}^{k} (1 + x_i)(1 - x_i) = \prod_{i=1}^{k} \big(1 - x_i^2\big), \\ p_j(E) &\overset{(2)}{=} \sigma_j\big(x_1^2, \ldots, x_k^2\big) : \qquad p_1 = \sum_i x_i^2, \quad p_2 = \sum_{i<j} x_i^2 x_j^2, \quad \ldots, \quad p_k = x_1^2 \cdots x_k^2. \end{aligned} \tag{3.186}$$

(1) (3.178) and the dual/conjugate rule for roots.
(2) The degree-$4j$ part of $\prod(1 - x_i^2)$ is $(-1)^j \sigma_j(x^2)$, and the sign cancels against $(-1)^j$ in the definition.

So the Pontryagin roots are the *squares* of the Chern roots. For a real bundle V of rank $2m$ or $2m+1$ the same holds with $\pm x_1, \ldots, \pm x_m$ (and a zero root if the rank is odd) as the roots of $V_{\mathbb{C}}$: an antisymmetric real matrix has eigenvalues in pairs $\pm i\lambda$.

Watch out: A typo in Nash's (3.119)

Nash writes $p_2(E) = \sum_{i,j} x_i^2 x_j^2$. The sum must run over $i < j$ (each unordered pair once, no $i = j$ terms), as the elementary symmetric function $\sigma_2(x^2)$ requires. With $\sum_{i,j}$ unrestricted one would get p_1^2 instead.

Worked example 3.115: Pontryagin classes of $\mathbb{CP}^n$ and of $\mathbb{CP}^2$

By the Euler sequence, $T\mathbb{CP}^n \oplus I = (n+1)\gamma^*$, so $T\mathbb{CP}^n$ has, "up to a zero root", the $n+1$ roots all equal to h. The Pontryagin roots are their squares, and

$$p(T\mathbb{CP}^n) = (1+h^2)^{n+1}. \tag{3.187}$$

For $\mathbb{CP}^2$: $p_1 = 3h^2$ and $\int_{\mathbb{CP}^2} p_1 = 3$. Check with (3.185): $p_1 = c_1^2 - 2c_2 = 9h^2 - 6h^2 = 3h^2$. ✓ This 3 will become the signature $\sigma(\mathbb{CP}^2) = 1$ after dividing by 3 (Section 3.20.9). For $\mathbb{CP}^4$: $p_1 = 5h^2$, $p_2 = 10h^4$.

Worked example 3.116: Instanton bundles as real bundles; the $\mathrm{SO}(3)$ bundle

Let $E \to S^4$ be an SU(2) bundle with $\int c_2 = k$. As a real rank-4 bundle,

$$p_1(E_r) \overset{(1)}{=} c_1^2 - 2c_2 \overset{(2)}{=} -2c_2, \qquad \int_{S^4} p_1(E_r) = -2k.$$

(1) (3.185) with $i = 1$.
(2) $c_1 = 0$ for SU(2).

The adjoint bundle $\mathrm{ad}E$ is the real rank-3 bundle of $\mathfrak{su}(2)$ values, whose complexification is $\mathrm{End}_0 E$. From Example 3.99, $c_2(\mathrm{End}_0 E) = 4c_2(E)$, so

$$p_1(\mathrm{ad}E) = -c_2(\mathrm{ad}E \otimes \mathbb{C}) = -4c_2(E), \qquad \int_{S^4} p_1(\mathrm{ad}E) = -4k.$$

This is how instanton numbers are phrased for SO(3) gauge theory, where p_1 of the adjoint bundle replaces c_2 (and can be any integer $\equiv w_2^2$ mod 4 on a general 4-manifold).

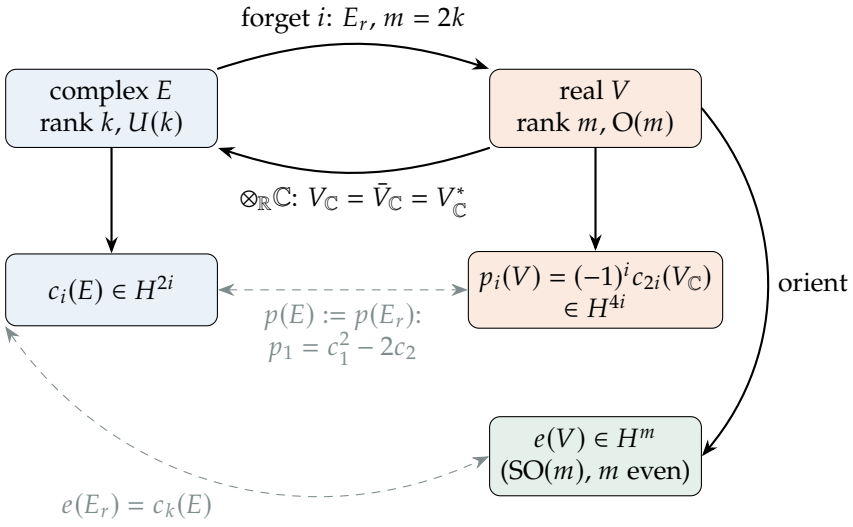

Figure 3.73: How the classes are related. A complex bundle has Chern classes; forgetting i makes it real, and a real bundle has Pontryagin classes, obtained by complexifying and taking the even Chern classes. Orientation (structure group $\mathrm{SO}(m)$, m even) adds the Euler class, the subject of the next section. The dashed arrows are the conversion formulae.

Reading Nash (pp. 82–86, (3.107)–(3.119))

Nash's "brief summary of a few useful properties" (p. 82) covers: the dual E^* with transition functions $(g^{-1})^T$ and the conjugate $\bar{E}$ with $\bar{g}$, equal for unitary g (footnote 6 on reduction to $U(k)$); line bundles as an abelian group with $L^{-1} = L^*$; real bundles with $V \cong V^*$, $\bar{V} = V$; complexification $V \otimes_{\mathbb{R}} \mathbb{C}$ with (3.107)–(3.108); realification and $E_r \otimes \mathbb{C} = E \oplus \bar{E}$ (3.109)–(3.110); Pontryagin classes (3.111)–(3.112); the Whitney formula up to 2-torsion (3.113)–(3.114); the sphere example (3.115), which rests on his (3.36), $TS^n \oplus N(S^n) \cong I^{n+1}$; Pontryagin classes of complex bundles (3.116)–(3.118); and the splitting form (3.119). We added the J-eigenspace derivation, the explanation of why odd $c_j(V_{\mathbb{C}})$ are 2-torsion, the curvature formula, and the examples $\mathbb{CP}^n$, ad$E$ and round S^4.

Recap

- E^*: transition $(g^{-1})^T$; $\bar{E}$: $\bar{g}$; for unitary g they agree. $c_j(E^*) = (-1)^j c_j(E)$.
- Line bundles form a group under $\otimes$; c_1 identifies it with $H^2(X;\mathbb{Z})$.
- Real V: $V \cong V^*$; $V_{\mathbb{C}} \cong \bar{V}_{\mathbb{C}}$, so odd $c_j(V_{\mathbb{C}})$ are 2-torsion.
- $E_r \otimes \mathbb{C} \cong E \oplus \bar{E}$: the $\pm i$ eigenspaces of J.
- $p_i(V) = (-1)^i c_{2i}(V_{\mathbb{C}}) \in H^{4i}$; $p(\Omega) = \det(1 + \Omega/2\pi)$; Whitney up to 2-torsion; $p(TS^n) = 1$; $p(T\mathbb{CP}^n) = (1 + h^2)^{n+1}$.
- For complex E: $p_1 = c_1^2 - 2c_2$, $p_2 = c_2^2 - 2c_1c_3 + 2c_4$; roots x_i^2.

3.20 The Euler class, Gauss–Bonnet–Chern, and the genera $\hat{A}$ and L

The last section ended with a puzzle. The tangent bundle of S^2 is twisted: the hairy-ball theorem says every vector field on S^2 has a zero, so TS^2 has no nowhere-zero section and cannot be trivial. Yet all its Pontryagin classes vanish (Example 3.114). The Pontryagin classes are *stable*: they cannot tell TS^2 from $TS^2 \oplus I$, which is trivial. We want a class that sees the hairy-ball twisting.

The missing ingredient is *orientation*. Nash puts it in one sentence (p. 86): on an orientable space, an oriented real bundle of even rank has one extra characteristic class, the Euler class. This section builds it from a single piece of linear algebra, the Pfaffian, computes it by curvature, and integrates it to get the Euler characteristic: the Gauss–Bonnet–Chern theorem. We then complete the toolbox of the index theorem with the two remaining generating-function classes, the $\hat{A}$-genus (Dirac operator) and the L-genus (signature).

3.20.1 Why orientation gives a new invariant polynomial

Chern–Weil theory (Section 3.16) turns every *invariant polynomial* of the structure group into a characteristic class. For $\mathrm{O}(k)$ the invariant polynomials of an antisymmetric matrix Ω are generated by the coefficients of $\det(\mathbb{1} + \Omega/2\pi)$: these are the Pontryagin forms. Why not the other coefficients, the odd ones? They vanish identically for antisymmetric matrices (Section 3.19.6).

Now shrink the group from $\mathrm{O}(k)$ to $\mathrm{SO}(k)$. That is what an **orientation** does: it lets us use only frames that are positively oriented, so the transition functions have $\det g = +1$. With fewer allowed transformations there can be more invariants. Is there a polynomial P with $P(g^{-1}\Omega g) = P(\Omega)$ for every $g \in \mathrm{SO}(k)$, but not for reflections? For even $k = 2m$ there is, and it

is essentially unique: the *square root of the determinant*.

Physical picture: The simplest case, $k = 2$

An antisymmetric 2×2 matrix is $\Omega = \begin{pmatrix} 0 & \omega \\ -\omega & 0 \end{pmatrix}$, an infinitesimal rotation of the plane with angular speed ω. Its determinant is ω^2. A rotation of the plane does not change the angular speed of another rotation, since SO(2) is abelian: ω itself is invariant. A reflection reverses the sense of rotation, $\omega \to -\omega$; only ω^2 survives. So SO(2) has the linear invariant ω, O(2) only the quadratic one ω^2. The Euler class of a rank-2 bundle is built from ω.

3.20.2 The Pfaffian

Working definition 3.47 (Pfaffian)

For an antisymmetric $2m \times 2m$ matrix A with commuting entries [numbers, or even-degree forms such as curvature 2-forms], the **Pfaffian** is

$$\begin{aligned} \mathrm{Pf}(A) &= \frac{1}{2^m\, m!} \sum_{\sigma \in S_{2m}} \operatorname{sgn}(\sigma)\, A_{\sigma(1)\sigma(2)} A_{\sigma(3)\sigma(4)} \cdots A_{\sigma(2m-1)\sigma(2m)} \\ &= \frac{1}{2^m\, m!}\, \varepsilon_{a_1 a_2 \ldots a_{2m}} A_{a_1 a_2} \cdots A_{a_{2m-1} a_{2m}}. \end{aligned} \tag{3.188}$$

[$\operatorname{sgn}(\sigma) = \pm 1$ for even or odd σ. For $m = 1$ this gives $\mathrm{Pf}(A) = A_{12}$, and always $\mathrm{Pf}(A)^2 = \det A$] *Operationally:* sum over all ways of splitting $\{1, \ldots, 2m\}$ into unordered pairs, each pairing contributing the product of the corresponding entries A_{ij} $(i < j)$ times the sign of the permutation that lists the pairs in order. There are $(2m-1)!! = 1 \cdot 3 \cdot 5 \cdots (2m-1)$ pairings.

The factor $2^m m!$ removes overcounting: swapping the two members of a pair (2 ways per pair, 2^m in all) and reordering the pairs ($m!$ ways) give the same term, because A is antisymmetric and the entries commute.

The first two cases, written out.

$$m = 1: \quad \mathrm{Pf}\begin{pmatrix} 0 & a \\ -a & 0 \end{pmatrix} = a, \tag{3.189}$$

$$m = 2: \quad \mathrm{Pf}(A) = A_{12}A_{34} - A_{13}A_{24} + A_{14}A_{23}. \tag{3.190}$$

For $m = 2$ the three pairings of $\{1,2,3,4\}$ are $\{12,34\}$, $\{13,24\}$ and $\{14,23\}$, and the permutations 1234, 1324, 1423 have signs $+, -, +$.

Worked example 3.117: $\mathrm{Pf}^2 = \det$ for a 4×4 matrix

Take the general antisymmetric matrix with entries $a = A_{12}$, $b = A_{13}$, $c = A_{14}$, $d = A_{23}$, $e = A_{24}$, $f = A_{34}$:

$$A = \begin{pmatrix} 0 & a & b & c \\ -a & 0 & d & e \\ -b & -d & 0 & f \\ -c & -e & -f & 0 \end{pmatrix}, \qquad \mathrm{Pf}(A) = af - be + cd.$$

Expand the determinant along the first row. Each 3×3 minor is quickly computed, and

one finds

$$\begin{aligned}\det A &\overset{(1)}{=} a^2f^2 + b^2e^2 + c^2d^2 - 2abef + 2acdf - 2bcde \\ &\overset{(2)}{=} (af - be + cd)^2 = \mathrm{Pf}(A)^2.\end{aligned}$$

(1) Cofactor expansion along the first row and collection of terms (tedious but mechanical; a computer algebra system confirms it).
(2) Multiply out $(af - be + cd)^2 = a^2f^2 + b^2e^2 + c^2d^2 - 2abef + 2acdf - 2bcde$.

A quick numerical check: $a = f = 1$, all others 0 is two independent rotations in the (12) and (34) planes; $\det A = 1$, $\mathrm{Pf}(A) = 1$.

A physicist's representation: Grassmann integrals. The cleanest way to prove everything about Pfaffians is the fermionic Gaussian integral. Let $\theta_1, \dots, \theta_{2m}$ be anticommuting (Grassmann) variables, with the Berezin rule $\int \mathrm{d}\theta_a\, \theta_a = 1$, $\int \mathrm{d}\theta_a\, 1 = 0$. Then

$$\int \mathrm{d}\theta_{2m} \cdots \mathrm{d}\theta_1 \; \exp\!\Big(\tfrac{1}{2}\,\theta^T A\,\theta\Big) = \mathrm{Pf}(A), \tag{3.191}$$

because only the term with every θ_a exactly once survives, and that term is the m-th term of the exponential series. Check for $m = 1$:

$$\begin{aligned}\tfrac{1}{2}\theta^T A\theta &\overset{(1)}{=} \tfrac{1}{2}\big(a\,\theta_1\theta_2 - a\,\theta_2\theta_1\big) \overset{(2)}{=} a\,\theta_1\theta_2, \\ \int \mathrm{d}\theta_2\mathrm{d}\theta_1\, e^{a\theta_1\theta_2} &\overset{(3)}{=} \int \mathrm{d}\theta_2\mathrm{d}\theta_1\,(1 + a\,\theta_1\theta_2) \overset{(4)}{=} a.\end{aligned}$$

(1) $A_{12} = a$, $A_{21} = -a$.
(2) $\theta_2\theta_1 = -\theta_1\theta_2$.
(3) $(\theta_1\theta_2)^2 = 0$, so the series stops.
(4) Do the inner integral first: $\int \mathrm{d}\theta_1\, \theta_1\theta_2 = \theta_2$, then $\int \mathrm{d}\theta_2\, \theta_2 = 1$.

The Dirac-fermion version, $\int \mathrm{d}\bar\psi\, \mathrm{d}\psi\, e^{\bar\psi M\psi} = \det M$, is familiar from the QFT path integral; (3.191) is its *Majorana* version. A Majorana (real) fermion gives Pf, a Dirac (complex) fermion, which is two Majoranas, gives det = Pf^2.

How the Pfaffian transforms. Change variables $\theta = B\eta$ with B an invertible real matrix. The Berezin measure transforms with the *inverse* Jacobian, $\mathrm{d}\theta_{2m} \cdots \mathrm{d}\theta_1 = (\det B)^{-1}\mathrm{d}\eta_{2m} \cdots \mathrm{d}\eta_1$. So

$$\begin{aligned}\mathrm{Pf}(A) &\overset{(1)}{=} \int \mathrm{d}^{2m}\theta\, e^{\frac{1}{2}\theta^T A\theta} \overset{(2)}{=} (\det B)^{-1} \int \mathrm{d}^{2m}\eta\, e^{\frac{1}{2}\eta^T (B^T AB)\eta} \overset{(3)}{=} (\det B)^{-1}\,\mathrm{Pf}(B^T AB), \\ &\Longrightarrow \quad \mathrm{Pf}(B^T AB) = \det(B)\,\mathrm{Pf}(A).\end{aligned} \tag{3.192}$$

(1) (3.191).
(2) Substitute $\theta = B\eta$: the exponent becomes $\frac{1}{2}\eta^T B^T AB\eta$, and the measure picks up $(\det B)^{-1}$ (Berezin integration is "differentiation", so Jacobians appear inverted).
(3) (3.191) again, for the matrix $B^T AB$.

This one formula contains the whole story:

- For $g \in \mathrm{SO}(2m)$, $g^{-1} = g^T$ and $\det g = 1$, so $\mathrm{Pf}(g^{-1}Ag) = \mathrm{Pf}(A)$: the Pfaffian is an $\mathrm{SO}(2m)$-invariant polynomial.

- For a reflection, $\det g = -1$ and Pf changes sign: it is *not* $\mathrm{O}(2m)$-invariant. Orientation is essential.
- Scaling: $\mathrm{Pf}(tA) = t^m \mathrm{Pf}(A)$, a homogeneous polynomial of degree m, half the degree of $\det A$.

Normal form. Every real antisymmetric matrix can be brought by some $g \in \mathrm{SO}(2m)$ to block-diagonal form,

$$g^T A g = \begin{pmatrix} 0 & \lambda_1 & & & \\ -\lambda_1 & 0 & & & \\ & & \ddots & & \\ & & & 0 & \lambda_m \\ & & & -\lambda_m & 0 \end{pmatrix}, \qquad \mathrm{Pf}(A) = \lambda_1 \lambda_2 \cdots \lambda_m, \qquad \det A = \lambda_1^2 \cdots \lambda_m^2. \tag{3.193}$$

Geometrically: an infinitesimal rotation of $\mathbb{R}^{2m}$ is a set of independent rotations in m orthogonal planes, with angular speeds λ_j. The determinant forgets the senses of rotation; the Pfaffian remembers their product (one sign can be flipped by flipping the orientation of one plane, which is why the overall orientation matters).

$\mathrm{Pf}^2 = \det$ in general. Bring A to normal form with $g \in \mathrm{SO}(2m)$. Then

$$\mathrm{Pf}(A)^2 \overset{(1)}{=} \mathrm{Pf}(g^T A g)^2 \overset{(2)}{=} (\lambda_1 \cdots \lambda_m)^2 \overset{(3)}{=} \det(g^T A g) \overset{(4)}{=} \det A,$$

(1) (3.192) with $\det g = 1$.
(2) (3.193): the Pfaffian of a block-diagonal matrix is the product of the 2×2 Pfaffians (3.189), since a pairing that joins two different blocks picks up a zero entry.
(3) The determinant of the block-diagonal matrix is $\prod_j \lambda_j^2$.
(4) $\det g^T = \det g = 1$.

Example 3.117 is the brute-force check of this for $m = 2$. The identity holds as a polynomial identity in the entries, so it also holds when the entries are commuting 2-forms, which is how we will use it.

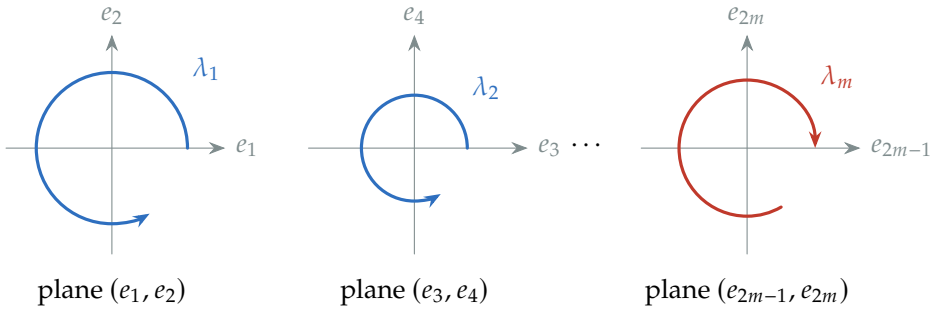

Figure 3.74: What the Pfaffian measures. An antisymmetric matrix is an infinitesimal rotation, and after an $\mathrm{SO}(2m)$ change of basis it rotates m orthogonal planes independently. The determinant is the product of the squared angular speeds. The Pfaffian is the signed product; reversing one plane (red, drawn clockwise) flips its sign, which is why it is only defined once an orientation is fixed.

3.20.3 The Euler class: definition and properties

Working definition 3.48 (Euler class)

Let $V \to X$ be an oriented real bundle [frames chosen so that every transition function has $\det g = +1$] of even rank $k = 2m$, with a metric and an $\mathrm{SO}(k)$ connection [a real antisymmetric matrix of 1-forms in each oriented orthonormal frame] whose curvature, in an oriented orthonormal frame, is the antisymmetric matrix of 2-forms $\Omega = (\Omega_{ab})$. The **Euler class** $e(V) \in H^k(X)$ is represented by

$$e(\Omega) = \mathrm{Pf}\Big(\frac{\Omega}{2\pi}\Big) = \frac{1}{(4\pi)^m\, m!}\, \varepsilon_{a_1 \dots a_{2m}}\, \Omega_{a_1 a_2} \wedge \cdots \wedge \Omega_{a_{2m-1} a_{2m}}. \tag{3.194}$$

Operationally: write the curvature in an oriented orthonormal frame and take its Pfaffian, treating the 2-forms as commuting numbers. For odd rank there is no Pfaffian and we set $e(V) = 0$ in real cohomology.

The second form of (3.194) comes from (3.188): $\frac{1}{2^m m!} \cdot \frac{1}{(2\pi)^m} = \frac{1}{(4\pi)^m m!}$. The two most used cases are

$$k = 2: \quad e = \frac{1}{2\pi}\, \Omega_{12}, \tag{3.195}$$

$$k = 4: \quad e = \frac{1}{32\pi^2}\, \varepsilon_{abcd}\, \Omega_{ab} \wedge \Omega_{cd} = \frac{1}{4\pi^2}\big(\Omega_{12} \wedge \Omega_{34} - \Omega_{13} \wedge \Omega_{24} + \Omega_{14} \wedge \Omega_{23}\big). \tag{3.196}$$

Why it is a characteristic class. Everything from Section 3.16 applies, because the argument there used only invariance under conjugation. Under a change of oriented orthonormal frame, $\Omega \mapsto g^{-1}\Omega g$ with $g \in \mathrm{SO}(k)$, and Pf does not change by (3.192); so $e(\Omega)$ is a globally defined k-form. The Bianchi identity makes it closed, and the transgression formula makes its class independent of the connection. Nash does not use curvature here; he defines $e(V)$ "up to a sign" by its square. The Pfaffian fixes the sign: it is the orientation.

The properties Nash lists. Each is now a one-line consequence.

1. *Square root of the top Pontryagin class* (Nash's (3.120)):

$$e(V)^2 \overset{(1)}{=} \mathrm{Pf}\Big(\frac{\Omega}{2\pi}\Big)^2 \overset{(2)}{=} \det\Big(\frac{\Omega}{2\pi}\Big) \overset{(3)}{=} p_m(V).$$

   (1) Definition (3.194); forms of even degree commute.
   (2) $\mathrm{Pf}^2 = \det$ for antisymmetric matrices.
   (3) The top-degree part of $p(\Omega) = \det(\mathbb{1} + \Omega/2\pi)$ (3.181) is $\det(\Omega/2\pi)$, of degree $2k = 4m$.

2. *Degree* (Nash's (3.121)): $e(V) \in H^k(X; \mathbb{Z})$ for rank k. With integer coefficients this needs the topological definition (the Thom class, Chapter 4); with forms we see $H^k(X; \mathbb{R})$.

3. *Whitney* (Nash's (3.122)): $e(V \oplus W) = e(V)\, e(W)$. With the direct sum connection the curvature is block diagonal, and the Pfaffian of a block-diagonal matrix is the product of the Pfaffians (the pairings never mix the blocks, since the off-block entries are zero).

4. *Complex bundles* (Nash's (3.123)): $e(E) := e(E_r)$, with E_r oriented by the complex structure, frames $(s_1, Js_1, \dots, s_k, Js_k)$.

5. *Top Chern class* (Nash's (3.124)): $e(E_r) = c_k(E)$. This is computed in Section 3.20.4 below.

6. *Orientation reversal* flips the sign: $e(\bar{V}) = -e(V)$, where $\bar{V}$ is V with the opposite orientation. This is (3.192) with a reflection.

7. *A nowhere-zero section kills it.* If V has a nowhere-zero section s, then $V = V' \oplus I$ with I spanned by $s/|s|$. Choose a connection that preserves this splitting (the direct sum of a connection on V' and the trivial one on I). In a frame whose last vector is $s/|s|$, the last row and column of Ω vanish; every pairing in the Pfaffian uses the last index, so $e(\Omega) = 0$ identically. In particular $e(W \oplus I) = 0$ for every W. This is the property the Pontryagin classes lacked: *e is not stable*.

Watch out: Odd rank

For odd k the reflection $v \mapsto -v$ has $\det = -1$ and reverses the orientation of V, yet it is an automorphism of V. So $e(V) = -e(V)$ and $2e(V) = 0$: the integral Euler class of an odd-rank bundle is at most 2-torsion, and it is zero in de Rham cohomology. Similarly $\chi(M) = 0$ for every closed odd-dimensional manifold.

3.20.4 The Euler class of a complex bundle is its top Chern class

Nash's argument (3.124) is: $e^2 = p_k$ and, for a complex bundle of rank k, $p_k(E) = x_1^2 \cdots x_k^2 = (x_1 \cdots x_k)^2 = c_k(E)^2$; so $e = \pm c_k$, and the sign "can be justified". With curvature we can see the sign directly.

Rank one. Let L be a Hermitian line bundle with unitary frame s and connection $\nabla s = s\,A$, $A = i\alpha$ with α a real 1-form (anti-Hermitian 1×1 matrix). The curvature is $F = i\beta$ with $\beta = \mathrm{d}\alpha$. As a real bundle L_r has the oriented orthonormal frame $(e_1, e_2) = (s, is)$. Then

$$\nabla e_1 \overset{(1)}{=} s\, i\alpha = e_2\, \alpha,$$
$$\nabla e_2 \overset{(2)}{=} i\, s\, i\alpha = -e_1\, \alpha,$$

(1) $\nabla s = s\, i\alpha$, and $is = e_2$.
(2) ∇ is complex-linear, so $\nabla(is) = i\nabla s$, and $i \cdot i = -1$.

In the convention $\nabla e_b = \sum_a e_a\, A^{\mathbb{R}}_{ab}$ this says $A^{\mathbb{R}}_{21} = \alpha$, $A^{\mathbb{R}}_{12} = -\alpha$:

$$A^{\mathbb{R}} = \begin{pmatrix} 0 & -\alpha \\ \alpha & 0 \end{pmatrix} = \alpha\, J, \qquad \Omega = \mathrm{d}A^{\mathbb{R}} = \begin{pmatrix} 0 & -\beta \\ \beta & 0 \end{pmatrix},$$

with J the rotation by $+90°$ of Example 3.113. So

$$e(L_r) \overset{(1)}{=} \frac{1}{2\pi}\,\Omega_{12} \overset{(2)}{=} -\frac{\beta}{2\pi} \overset{(3)}{=} \frac{i}{2\pi}\,(i\beta) \overset{(4)}{=} c_1(L).$$

(1) (3.195).
(2) Read off $\Omega_{12} = -\beta$.
(3) $i \cdot i = -1$.
(4) $c_1 = \frac{i}{2\pi} F$ with $F = i\beta$ (3.155).

The signs agree: with the complex orientation, $e = c_1$ exactly, as forms.

Any rank. By the splitting principle (or by diagonalising the curvature, Section 3.17.5) we may assume $F = \operatorname{diag}(i\beta_1, \dots, i\beta_k)$, a sum of line bundles with roots $x_j = \frac{i}{2\pi}(i\beta_j) = -\beta_j/2\pi$. The realified curvature is block diagonal with blocks $\begin{pmatrix} 0 & -\beta_j \\ \beta_j & 0 \end{pmatrix}$, so by the normal form (3.193),

$$e(E_r) \overset{(1)}{=} \prod_{j=1}^{k} \frac{-\beta_j}{2\pi} \overset{(2)}{=} x_1 x_2 \cdots x_k \overset{(3)}{=} c_k(E), \tag{3.197}$$

(1) The Pfaffian of a block-diagonal matrix is the product of the block Pfaffians, each being its $(1,2)$ entry $-\beta_j/2\pi$.
(2) $x_j = -\beta_j/2\pi$.
(3) $c_k = \sigma_k(x)$, the product of all roots (3.162).

and $e(E_r)^2 = \prod x_j^2 = p_k(E)$ reproduces Nash's (3.124). The same block computation also recovers the Pontryagin roots: each block contributes $\det \begin{pmatrix} 1 & -\beta_j/2\pi \\ \beta_j/2\pi & 1 \end{pmatrix} = 1 + x_j^2$ to $p = \det(\mathbb{1} + \Omega/2\pi)$.

Key idea: Three faces of one class

For a complex bundle E of rank k with Chern roots x_j:

$$e(E_r) = c_k(E) = x_1 \cdots x_k, \qquad p_k(E_r) = e(E_r)^2 = x_1^2 \cdots x_k^2.$$

For the tangent bundle of a complex n-manifold, $e(TX) = c_n(TX)$.

Worked example 3.118: Monopole bundles as real plane bundles

The monopole bundle $L_n \to S^2$ viewed as an oriented real plane bundle has $\int_{S^2} e(L_n) = \int c_1(L_n) = n$. What does n count? A *section*. For $n \geq 0$ the homogeneous polynomial z_1^n (a holomorphic section of $L_n = \mathcal{O}(n)$, Example 3.110) vanishes only at $[1:0]$, where in the local coordinate $w = z_1/z_0$ it looks like w^n: a zero of order n. A generic smooth perturbation, such as $\prod_{j=1}^{n}(z_1 - a_j z_0)$, splits it into n simple zeros, each where the section winds once around the origin of the fibre. The Euler number counts zeros of a section, with signs. For $n < 0$ the zeros must wind the other way, and there are $|n|$ of them.

3.20.5 Zeros of sections: the geometric meaning

Example 3.118 is the general rule. Let s be a section of an oriented rank-k bundle V over a closed oriented k-manifold M, with isolated zeros. Near a zero p, in a local trivialisation, s is a map $\mathbb{R}^k \to \mathbb{R}^k$ with $s(p) = 0$; restricted to a small sphere around p it gives a map $s/|s| : S^{k-1} \to S^{k-1}$, whose degree is the **index** of the zero, $\operatorname{index}_p(s)$. (For $k = 2$: the winding number of the arrow s as we walk once around p.) Then

$$\int_M e(V) = \sum_{s(p)=0} \operatorname{index}_p(s). \tag{3.198}$$

For $V = TM$ this is the **Poincaré–Hopf theorem**: the sum of the indices of the zeros of any vector field is a topological invariant, and it equals the Euler characteristic $\chi(M) = \sum_i (-1)^i b_i(M)$.

Why (3.198) holds (Chern's argument, in words). Away from the zeros, s picks out a unit vector $\hat{s} = s/|s|$, i.e. a nowhere-zero section, and a nowhere-zero section makes e *exact* there:

on the complement of the zeros one can write $e(\Omega) = d\Pi$ for a $(k-1)$-form Π built from $\hat{s}$ (for $k = 2$, Π is the connection 1-form in a frame whose first vector is $\hat{s}$, divided by 2π). Cut out small balls B_p around the zeros and use Stokes:

$$\int_M e \overset{(1)}{=} \lim_{\varepsilon\to 0} \int_{M\setminus \cup_p B_p} d\Pi \overset{(2)}{=} -\lim_{\varepsilon\to 0} \sum_p \int_{\partial B_p} \Pi \overset{(3)}{=} \sum_p \operatorname{index}_p(s).$$

(1) The balls have vanishing volume as $\varepsilon \to 0$, and $e = d\Pi$ outside them.
(2) Stokes; the boundary of $M \setminus \cup B_p$ is $\cup \partial B_p$ with the inward orientation, hence the minus sign.
(3) On a tiny sphere around p, $-\Pi$ integrates to the degree of $\hat{s}$ measured against a frame that extends across p. For $k = 2$: if ψ is the angle of $\hat{s}$ in such a frame, then in the frame $(\hat{s}, J\hat{s})$ one has $\Pi = -d\psi/2\pi$ up to terms that vanish as $\varepsilon \to 0$, and $\oint d\psi = 2\pi \operatorname{index}_p(s)$.

This is the Stokes-theorem mechanism of the whole subject: a closed form that is exact away from a few points integrates to a sum of local contributions at those points.

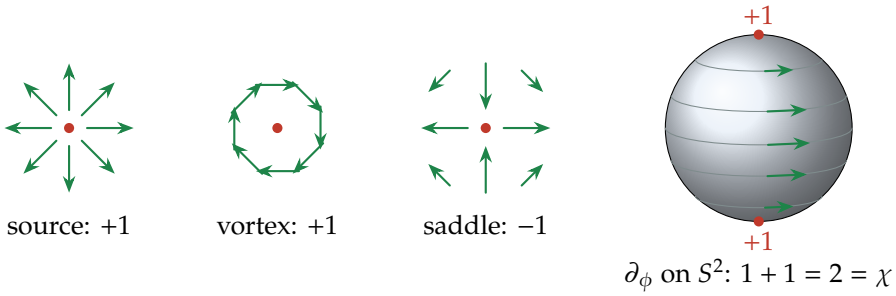

Figure 3.75: Indices of zeros of a vector field in the plane: a source and a vortex both wind once (+1), a saddle winds backwards (−1). Right: the rotation field ∂_ϕ on the sphere vanishes only at the two poles, each a vortex of index +1; the total 2 is $\chi(S^2) = \int_{S^2} e(TS^2)$. No vector field on S^2 avoids zeros, because the total must be 2, not 0.

3.20.6 The Gauss–Bonnet–Chern theorem

Put (3.194) and (3.198) together for $V = TM$, with the Levi-Civita connection:

Key idea: Gauss–Bonnet–Chern

For a closed oriented Riemannian manifold M of even dimension $2m$, with Levi-Civita curvature Ω_{ab} in an oriented orthonormal frame,

$$\chi(M) = \int_M e(TM) = \int_M \operatorname{Pf}\Big(\frac{\Omega}{2\pi}\Big) = \frac{1}{(4\pi)^m m!} \int_M \varepsilon_{a_1\dots a_{2m}} \Omega_{a_1a_2} \wedge \cdots \wedge \Omega_{a_{2m-1}a_{2m}}. \quad (3.199)$$

The left side is a count $(\sum(-1)^i b_i$, or vertices minus edges plus faces); the right side is an integral of curvature. Neither side depends on the metric.

Reminder: Cartan's structure equations. (See Chapter T2 and [Dray Ch. 18].) Choose an orthonormal coframe e^a, so the metric is $\sum_a (e^a)^2$. The Levi-Civita connection 1-forms $\omega^a{}_b = -\omega^b{}_a$ are fixed by the torsion-free condition, and the curvature 2-forms follow:

$$de^a = -\omega^a{}_b \wedge e^b, \qquad \Omega^a{}_b = d\omega^a{}_b + \omega^a{}_c \wedge \omega^c{}_b. \quad (3.200)$$

Indices are raised and lowered with δ_{ab}, so $\Omega_{ab} = \Omega^a{}_b$. On a surface, $\Omega_{12} = K\, e^1 \wedge e^2$ with K the Gaussian curvature.

Worked example 3.119: Gauss–Bonnet for the round S^2

On the sphere of radius R take $e^1 = R\,\mathrm{d}\theta$, $e^2 = R\sin\theta\,\mathrm{d}\phi$ (orientation $\mathrm{d}\theta \wedge \mathrm{d}\phi$, outward normal). Then

$$\mathrm{d}e^2 \overset{(1)}{=} R\cos\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi \overset{(2)}{=} -\big(\cos\theta\,\mathrm{d}\phi\big) \wedge \big(R\,\mathrm{d}\theta\big), \qquad \text{so} \quad \omega^2{}_1 = \cos\theta\,\mathrm{d}\phi,$$

$$\Omega^1{}_2 \overset{(3)}{=} \mathrm{d}\big(-\cos\theta\,\mathrm{d}\phi\big) \overset{(4)}{=} \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi \overset{(5)}{=} \frac{1}{R^2}\, e^1 \wedge e^2.$$

(1) Differentiate $R\sin\theta\,\mathrm{d}\phi$.
(2) Reorder the wedge; compare with $\mathrm{d}e^2 = -\omega^2{}_1 \wedge e^1$. The other equation, $\mathrm{d}e^1 = 0 = -\omega^1{}_2 \wedge e^2$, holds because $\omega^1{}_2 \propto \mathrm{d}\phi$ and $e^2 \propto \mathrm{d}\phi$.
(3) $\omega^1{}_2 = -\omega^2{}_1$; the quadratic term $\omega \wedge \omega$ vanishes for a 2×2 antisymmetric matrix of 1-forms.
(4) $\mathrm{d}(-\cos\theta) = \sin\theta\,\mathrm{d}\theta$.
(5) $e^1 \wedge e^2 = R^2 \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$.

So $K = 1/R^2$, and

$$\int_{S^2} e(TS^2) \overset{(1)}{=} \frac{1}{2\pi}\int_{S^2} \Omega_{12} \overset{(2)}{=} \frac{1}{2\pi}\cdot\frac{1}{R^2}\cdot 4\pi R^2 \overset{(3)}{=} 2 = \chi(S^2).$$

(1) (3.195).
(2) $\Omega_{12} = K\,\mathrm{d}A$ and the area is $4\pi R^2$.
(3) $\chi(S^2) = V - E + F = 2$ (e.g. the tetrahedron: $4 - 6 + 4$).

The radius cancels, as it must: squash the sphere into an egg and the curvature moves around, but its total stays 4π. And since $TS^2 = T\mathbb{CP}^1 = L_2$ as a complex line bundle, $e = c_1(L_2)$ and $\int = 2$ again.

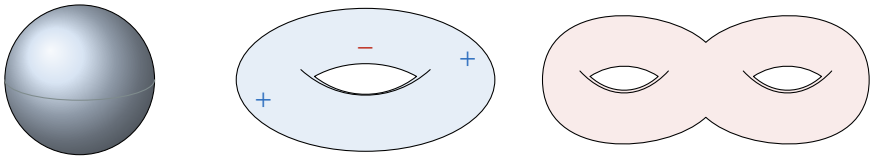
Worked example 3.120: Surfaces of every genus

Torus. The flat torus $\mathbb{R}^2/\mathbb{Z}^2$ has $e^1 = \mathrm{d}x$, $e^2 = \mathrm{d}y$, $\omega = 0, \Omega = 0$; so $\chi(T^2) = 0$. The embedded doughnut has $K > 0$ on the outside and $K < 0$ on the inside, and the two cancel exactly.
Genus $g \geq 2$. Such a surface carries a hyperbolic metric, $K = -1$. Then

$$2 - 2g \overset{(1)}{=} \chi(\Sigma_g) \overset{(2)}{=} \frac{1}{2\pi}\int_{\Sigma_g} K\,\mathrm{d}A \overset{(3)}{=} -\frac{\mathrm{Area}(\Sigma_g)}{2\pi} \quad\Longrightarrow\quad \mathrm{Area}(\Sigma_g) = 4\pi(g-1).$$

(1) Each handle lowers χ by 2 ([Dray §18.10]).
(2) Gauss–Bonnet, (3.199) with $m = 1$.
(3) $K = -1$.

Topology fixes the area of every hyperbolic surface. This is the fact behind the dimension counts of moduli spaces of Riemann surfaces in string theory (Chapter 9).



S^2: $K > 0$ $\chi = 2$ | T^2: + and − cancel $\chi = 0$ | Σ_2: mostly $K < 0$ $\chi = -2$

Figure 3.76: Gauss–Bonnet: $\frac{1}{2\pi}\int K\,\mathrm{d}A = \chi = 2 - 2g$. The sphere is positively curved everywhere. On the torus the outer (positive) and inner (negative) curvature cancel exactly. A surface with two handles must be negatively curved on balance, with total curvature -4π. However the surface is deformed, the totals do not change.

Worked example 3.121: Gauss–Bonnet–Chern on the round S^4

On the unit sphere S^n (constant curvature 1) the Levi-Civita curvature in any orthonormal frame is $\Omega_{ab} = e^a \wedge e^b$; on S^2 this is Example 3.119 with $R = 1$. For S^4:

$$\varepsilon_{abcd}\,\Omega_{ab}\wedge\Omega_{cd} \overset{(1)}{=} \varepsilon_{abcd}\,e^a\wedge e^b\wedge e^c\wedge e^d \overset{(2)}{=} 4!\;e^1\wedge e^2\wedge e^3\wedge e^4 = 24\,\mathrm{vol},$$

$$\int_{S^4} e(TS^4) \overset{(3)}{=} \frac{24}{32\pi^2}\,\mathrm{Vol}(S^4) \overset{(4)}{=} \frac{3}{4\pi^2}\cdot\frac{8\pi^2}{3} = 2.$$

(1) Constant curvature 1.
(2) Each of the 4! orderings (a,b,c,d) of $(1,2,3,4)$ gives $\varepsilon_{abcd}\,e^a\wedge e^b\wedge e^c\wedge e^d = \varepsilon^2_{abcd}\,e^1\wedge e^2\wedge e^3\wedge e^4$.
(3) (3.196).
(4) $\mathrm{Vol}(S^4) = \frac{8\pi^2}{3}$.

And indeed $\chi(S^4) = 2$ ($b_0 = b_4 = 1$, all others zero). Compare Example 3.114: on the same sphere the Pontryagin form vanishes identically, while the Euler form is a positive multiple of the volume form. The two classes see completely different things.

Try it: All even spheres

Show that $\int_{S^{2m}} e = 2$ for the unit sphere, using $\mathrm{Vol}(S^{2m}) = \frac{2^{2m+1}\pi^m\,m!}{(2m)!}$.
Answer: as in Example 3.121, $e = \frac{(2m)!}{(4\pi)^m m!}\mathrm{vol}$, so $\int e = \frac{(2m)!}{4^m\pi^m m!}\cdot\frac{2^{2m+1}\pi^m m!}{(2m)!} = \frac{2^{2m+1}}{2^{2m}} = 2$.

Worked example 3.122: Complex manifolds: $\chi = \int c_n$

For a complex n-manifold, $e(TX) = c_n(TX)$. For $\mathbb{CP}^n$, by (3.166),

$$\chi(\mathbb{CP}^n) = \int_{\mathbb{CP}^n} c_n(T\mathbb{CP}^n) = \binom{n+1}{n} = n+1,$$

which matches the cell decomposition $\mathbb{CP}^n = \mathbb{C}^0\cup\mathbb{C}^1\cup\cdots\cup\mathbb{C}^n$ (Figure 3.59): one even cell in each dimension $0,2,\ldots,2n$, so $b_0 = b_2 = \cdots = b_{2n} = 1$. For $S^2\times S^2$, Whitney for e gives $e(T(S^2\times S^2)) = e(TS^2)\times e(TS^2)$, so $\chi = 2\cdot 2 = 4$, again right ($b_0 = b_4 = 1$, $b_2 = 2$). For the K3 surface, $c_2 = 24$ and $\chi = 24$.

Physical picture: Why physicists meet the Euler class

(i) In two-dimensional gravity and string theory, the Einstein–Hilbert action $\frac{1}{4\pi}\int \sqrt{g}\,R$ is *topological*: since $R = 2K$ it equals $\chi(\Sigma)$, and $e^{-\lambda\chi}$ weights the genus expansion by g_s^{2g-2}. (ii) In four dimensions the Gauss–Bonnet–Chern density $\varepsilon\, R \wedge R$ is a total derivative locally, which is why the Gauss–Bonnet term does not change the classical equations of motion. (iii) The index of $\mathrm{d}+\mathrm{d}^*$ from even to odd forms is $\chi(M)$; in supersymmetric quantum mechanics it is the Witten index $\mathrm{Tr}(-1)^F e^{-\beta H}$, and the Grassmann-integral formula (3.191) is exactly how the Pfaffian of the curvature emerges from the fermion zero modes (Chapter 4).

Reading Nash (pp. 86–87, (3.120)–(3.124))

Nash introduces the Euler class for real bundles V of *even* rank over an *orientable* space: orientation reduces $\mathrm{O}(k)$ to $\mathrm{SO}(k)$, and for even k the determinant of an antisymmetric matrix has an $\mathrm{SO}(k)$-invariant square root, the Pfaffian (he cites Nash and Sen). He then defines $e(V)$ only up to sign by $e^2(V) = p_{k/2}(V)$ (3.120), so $e(V) \in H^k(X;\mathbb{Z})$ (3.121); states the Whitney rule $e(V\oplus W) = e(V)e(W)$ (3.122); defines $e(E) = e(E_r)$ for complex E (3.123); and shows $e(E) = c_k(E)$ from $p_k = x_1^2\cdots x_k^2$ (3.124), leaving the sign to Bott–Tu and Milnor–Stasheff. We have supplied the Pfaffian explicitly, fixed the sign with the curvature formula $e = \mathrm{Pf}(\Omega/2\pi)$, and added Poincaré–Hopf and Gauss–Bonnet–Chern with examples.

3.20.7 Genera from generating functions

We have now met several classes defined by a one-variable function of the roots. It is worth seeing them as one construction, because the index theorem uses two more of them, $\hat{A}$ and L.

Working definition 3.49 (Multiplicative class from a power series)

Let $Q(z) = 1 + a_1 z + a_2 z^2 + \dots$ be a formal power series [convergence is never needed, since forms above the dimension of X vanish].

- For a complex bundle E with Chern roots [formal classes with $c(E) = \prod_i (1 + x_i)$] x_i, the **multiplicative class** of Q is $Q(E) = \prod_i Q(x_i)$. It is symmetric in the roots, hence a polynomial in the c_j in each degree.
- If Q is *even*, $Q(z) = \tilde{Q}(z^2)$, then $\prod_i \tilde{Q}(x_i^2)$ is symmetric in the squares x_i^2, hence a polynomial in the Pontryagin classes. It therefore makes sense for any *real* bundle V, using the Pontryagin roots x_j^2 of (3.186).
- The **genus** of a closed manifold [compact, without boundary] M is $\int_M Q(TM)$.

Operationally: expand Q to the degree needed, multiply over roots, convert with the symmetric-function rules of Section 3.17; or with curvature, $Q(E) = \det Q\big(\frac{i}{2\pi}F\big)$.

The multiplicative property is automatic: $Q(E\oplus F) = Q(E)Q(F)$, because the roots of a sum are the union of the roots. Here is the catalogue.

class	$Q(z)$	first terms	index theorem it appears in
c	$1+z$	$1+c_1+c_2+\dots$	(top term) Euler characteristic
td	$\dfrac{z}{1-e^{-z}}$	$1+\frac{1}{2}c_1+\frac{1}{12}(c_1^2+c_2)$	Dolbeault (Riemann–Roch)
$\hat{A}$	$\dfrac{z/2}{\sinh(z/2)}$	$1-\frac{1}{24}p_1+\frac{1}{5760}(7p_1^2-4p_2)$	Dirac
L	$\dfrac{z}{\tanh z}$	$1+\frac{1}{3}p_1+\frac{1}{45}(7p_2-p_1^2)$	signature
ch (additive)	$\sum e^z$	$k+c_1+\frac{1}{2}(c_1^2-2c_2)$	twisting by a bundle

3.20.8 The $\hat{A}$ class

Working definition 3.50 ($\hat{A}$-class)

For a real bundle V with Pontryagin roots x_j^2 [formal classes with $p(V)=\prod_j(1+x_j^2)$] (for TM of a $2m$-manifold, $j=1,\dots,m$),

$$\hat{A}(V)=\prod_j \frac{x_j/2}{\sinh(x_j/2)}. \tag{3.201}$$

With curvature, $\hat{A}(\Omega)=\det{}^{1/2}\!\left(\dfrac{i\Omega/4\pi}{\sinh(i\Omega/4\pi)}\right)$. The $\hat{A}$-**genus** of a closed $4k$-manifold is $\hat{A}(M)=\int_M \hat{A}(TM)$.

Where does the curvature form come from? In normal form the curvature is made of blocks $\begin{pmatrix}0 & -\beta\\ \beta & 0\end{pmatrix}$, and the Hermitian matrix $\frac{i}{2\pi}\Omega$ has, on each block, the eigenvalues $\pm x$ with $x=-\beta/2\pi$ (the same x as in (3.197)). The function $\frac{z/2}{\sinh(z/2)}$ is even, so the pair $\pm x$ contributes the same factor twice to the determinant; the square root keeps one copy. The same reasoning gives $L(\Omega)=\det{}^{1/2}\!\left(\frac{i\Omega/2\pi}{\tanh(i\Omega/2\pi)}\right)$ for the L-class below.

The series. Put $y=x/2$. First, $\frac{\sinh y}{y}=1+\frac{y^2}{6}+\frac{y^4}{120}+\dots$. Its inverse $1+b_1y^2+b_2y^4$ satisfies

$$\begin{aligned} y^2:&\quad b_1+\tfrac{1}{6}=0 && \Rightarrow\ b_1=-\tfrac{1}{6},\\ y^4:&\quad b_2+\tfrac{1}{6}b_1+\tfrac{1}{120}=0 && \Rightarrow\ b_2=\tfrac{1}{36}-\tfrac{1}{120}=\tfrac{7}{360}. \end{aligned}$$

So $\frac{y}{\sinh y}=1-\frac{y^2}{6}+\frac{7y^4}{360}-\dots$, and with $y=x/2$,

$$\frac{x/2}{\sinh(x/2)}=1-\frac{x^2}{24}+\frac{7x^4}{5760}-\dots \tag{3.202}$$

(using $\frac{1}{6\cdot 4}=\frac{1}{24}$ and $\frac{7}{360\cdot 16}=\frac{7}{5760}$).

In Pontryagin classes. Multiply over the roots and collect by degree. With $p_1=\sum_j x_j^2$, $p_2=\sum_{i<j}x_i^2x_j^2$:

$$\hat{A}_1 \overset{(1)}{=} -\frac{1}{24}\sum_j x_j^2=-\frac{p_1}{24},$$

$$\hat{A}_2 \overset{(2)}{=} \frac{7}{5760}\sum_j x_j^4 + \frac{1}{576}\sum_{i<j} x_i^2 x_j^2$$
$$\overset{(3)}{=} \frac{7}{5760}(p_1^2 - 2p_2) + \frac{10}{5760}p_2 = \frac{7p_1^2 - 4p_2}{5760}.$$

(1) Degree 4: the x^2 term from one factor.
(2) Degree 8: the x^4 term from one factor, or the x^2 term from two different factors, with coefficient $(\frac{1}{24})^2 = \frac{1}{576}$.
(3) $\sum x_j^4 = p_1^2 - 2p_2$ (Newton, for the variables x_j^2), and $\frac{1}{576} = \frac{10}{5760}$.

This agrees with [Bär Ex. 4.3.6]. So on a 4-manifold, $\hat{A}(M) = -\frac{1}{24}\int_M p_1$, and on an 8-manifold $\hat{A}(M) = \frac{1}{5760}\int_M (7p_1^2 - 4p_2)$.

Relation to Todd. Nash's Todd series factorises (Section 3.18.6):

$$\frac{x}{1-e^{-x}} = e^{x/2}\cdot\frac{x/2}{\sinh(x/2)}.$$

For a complex manifold X, the Pontryagin roots of TX are the squares of the Chern roots, so taking the product over the Chern roots of TX,

$$\mathrm{td}(TX) = e^{c_1(TX)/2}\,\hat{A}(TX). \tag{3.203}$$

When c_1 is even, $e^{c_1/2}$ is the Chern character of a square root $K^{-1/2}$ of the anticanonical bundle. Physically: on a Kähler manifold, the Dirac operator is the Dolbeault operator twisted by $K^{1/2}$, and (3.203) is the statement that the two index formulae agree (Chapter 4).

Worked example 3.123: $\hat{A}$ of K3 and of $\mathbb{CP}^2$: integrality as a test

K3. A K3 surface is a compact complex surface with $c_1 = 0$ and $c_2 = 24$. Then

$$\hat{A}(\mathrm{K3}) \overset{(1)}{=} -\frac{1}{24}\int p_1 \overset{(2)}{=} -\frac{1}{24}\int (c_1^2 - 2c_2) \overset{(3)}{=} -\frac{1}{24}(0 - 48) = 2.$$

(1) $\hat{A}_1 = -p_1/24$.
(2) $p_1 = c_1^2 - 2c_2$ for a complex bundle (3.185).
(3) $c_1 = 0$, $\int c_2 = 24$.

An integer, as it must be: K3 is a spin manifold and $\hat{A}$ is the index of its Dirac operator. (By (3.203) it is also the Todd genus, since $c_1 = 0$: $\frac{1}{12}\int(c_1^2 + c_2) = 2$.)
$\mathbb{CP}^2$. Here $p_1 = 3h^2$ (Example 3.115), so $\hat{A}(\mathbb{CP}^2) = -\frac{3}{24} = -\frac{1}{8}$. Not an integer! So $\mathbb{CP}^2$ cannot carry a spin structure: if it did, $-\frac{1}{8}$ would be the index of a Dirac operator. This is the index theorem used as a no-go theorem.

Worked example 3.124: Zero modes in an instanton background: a preview

The twisted Dirac index is $\int_M \hat{A}(TM)\,\mathrm{ch}(E)$ (Chapter 4). On S^4 with the round metric, $p_1(TS^4) = 0$, so $\hat{A} = 1$. For the SU(2) bundle E with $\int c_2 = k$,

$$\int_{S^4} \hat{A}(TS^4)\,\mathrm{ch}(E) \overset{(1)}{=} \int_{S^4} 1\cdot(2 - c_2(E)) \overset{(2)}{=} -k.$$

(1) $\hat{A} = 1$, and Example 3.104.

(2) Only the 4-form part integrates.

So a Dirac fermion in the fundamental representation, in a charge-k instanton background, has $|k|$ more zero modes of one chirality than of the other (the chirality is fixed by orientation conventions, which Chapter 4 makes precise). These are the 't Hooft zero modes responsible for instanton-induced fermion interactions and, through the anomaly, for baryon-number violation.

Physical picture: Where sinh comes from: Landau levels

Put a unit-charge particle of unit mass in the plane, in a uniform magnetic field B, with $H = \frac{1}{2}(p - A)^2$. Its levels are the Landau levels $E_n = B(n + \frac{1}{2})$, each with $B/2\pi$ states per unit area. The heat trace per unit area is therefore

$$\frac{B}{2\pi}\sum_{n\geq 0} e^{-tB(n+\frac{1}{2})} = \frac{B}{2\pi}\cdot\frac{1}{2\sinh(tB/2)},$$

while for $B = 0$ it is $\frac{1}{2\pi t}$. The ratio is $\frac{tB/2}{\sinh(tB/2)}$: exactly the $\hat{A}$ factor, with tB in place of x. In the heat-kernel proof of the index theorem (Chapter 4) the curvature of each tangent 2-plane acts on spinors like a magnetic field, and this Landau-level (Mehler) factor is where $\hat{A}$ comes from. In anomaly language, the term $\hat{A}_1 = -p_1/24 = \frac{1}{192\pi^2}\operatorname{tr}(\Omega\wedge\Omega)$ is the gravitational contribution to the index density, and hence to the chiral anomaly (Chapter 10).

3.20.9 The L class and the signature

The signature. On a closed oriented $4k$-manifold M the middle cohomology carries the **intersection form**

$$Q(\alpha,\beta) = \int_M \alpha\wedge\beta, \qquad \alpha,\beta\in H^{2k}(M;\mathbb{R}).$$

It is symmetric (2-forms of even degree $2k$ commute) and non-degenerate (Poincaré duality). Its **signature** $\sigma(M) = b^+ - b^-$ is the number of positive minus negative eigenvalues. Examples, with matrices in a basis of H^2:

M	H^2 basis	matrix of Q	σ
$\mathbb{CP}^2$	h	(1)	1
$\overline{\mathbb{CP}^2}$ (reversed orientation)	h	(-1)	-1
$S^2\times S^2$	u_1, u_2	$\begin{pmatrix}0&1\\1&0\end{pmatrix}$	0
S^4	none	–	0
K3	22 classes	$3\begin{pmatrix}0&1\\1&0\end{pmatrix}\oplus 2(-E_8)$	-16

For $S^2\times S^2$: $u_1^2 = u_2^2 = 0$ (each is pulled back from a 2-sphere) and $\int u_1u_2 = 1$; the eigenvalues of the matrix are ± 1.

Working definition 3.51 (L-class)

The **Hirzebruch L-class** of a real bundle with Pontryagin roots x_j^2 is

$$L(V) = \prod_j \frac{x_j}{\tanh x_j}, \tag{3.204}$$

[each factor is even in x_j, so $L(V)$ is a polynomial in the Pontryagin classes] and the **L-genus** of a closed $4k$-manifold is $\int_M L(TM)$ [Hirzebruch's theorem says this number equals the signature $\sigma(M)$].

The series. $\frac{\tanh y}{y} = 1 - \frac{y^2}{3} + \frac{2y^4}{15} - \dots$, and its inverse $1 + b_1 y^2 + b_2 y^4$ has

$$\begin{aligned} y^2: &\quad b_1 - \tfrac{1}{3} = 0 &&\Rightarrow\ b_1 = \tfrac{1}{3},\\ y^4: &\quad b_2 - \tfrac{1}{3}b_1 + \tfrac{2}{15} = 0 &&\Rightarrow\ b_2 = \tfrac{1}{9} - \tfrac{2}{15} = -\tfrac{1}{45}. \end{aligned}$$

So

$$\frac{x}{\tanh x} = 1 + \frac{x^2}{3} - \frac{x^4}{45} + \dots \tag{3.205}$$

Multiplying over roots, exactly as for $\hat{A}$:

$$L_1 = \frac{1}{3}\sum_j x_j^2 = \frac{p_1}{3},$$

$$L_2 \overset{(1)}{=} -\frac{1}{45}\sum_j x_j^4 + \frac{1}{9}\sum_{i<j} x_i^2 x_j^2 \overset{(2)}{=} -\frac{1}{45}(p_1^2 - 2p_2) + \frac{5}{45}p_2 = \frac{7p_2 - p_1^2}{45}.$$

(1) The x^4 term from one factor, or x^2 from two factors, $(\frac{1}{3})^2 = \frac{1}{9}$.
(2) $\sum x_j^4 = p_1^2 - 2p_2$ and $\frac{1}{9} = \frac{5}{45}$.

Key idea: Hirzebruch signature theorem

For a closed oriented $4k$-manifold, $\sigma(M) = \int_M L(TM)$. In four dimensions, $\sigma(M) = \frac{1}{3}\int_M p_1(TM)$.

Nash does not state this here; it is the index theorem for the signature operator $d + d^*$ acting from self-dual to anti-self-dual forms ([Bär Thm. 4.3.9], and Chapter 4). Let us test it.

Worked example 3.125: Checking the signature theorem

$\mathbb{CP}^2$. $p_1 = 3h^2$, so $\frac{1}{3}\int p_1 = 1 = \sigma(\mathbb{CP}^2)$. ✓ (This is the "3 becomes 1" promised in Example 3.115.)
$S^2\times S^2$ *and* S^4. Both have $p_1 = 0$: $p(S^4) = 1$ by Example 3.114, and $p(S^2\times S^2) = p(S^2)\,p(S^2) = 1$ by Whitney (the tangent bundle of a product is the sum of the pulled-back tangent bundles). Both have $\sigma = 0$. ✓
$\mathbb{CP}^4$. $p(T\mathbb{CP}^4) = (1+h^2)^5$, so $p_1 = 5h^2$, $p_2 = 10h^4$, and

$$\int_{\mathbb{CP}^4} L_2 \overset{(1)}{=} \frac{7\cdot 10 - 5^2}{45} \overset{(2)}{=} \frac{45}{45} = 1.$$

(1) $L_2 = \frac{7p_2 - p_1^2}{45}$ and $\int h^4 = 1$.

(2) Arithmetic: $70 - 25 = 45$.

And $\sigma(\mathbb{CP}^4) = 1$: H^4 is spanned by h^2, with $\int h^2 \cdot h^2 = 1$. ✓

K3. $p_1 = -48$ (Example 3.123), so $\frac{1}{3}\int p_1 = -16 = \sigma(\mathrm{K3})$. ✓

Worked example 3.126: Why the L series is forced: all $\mathbb{CP}^{2k}$ at once

Hirzebruch found L by demanding $\int_{\mathbb{CP}^{2k}} L = \sigma(\mathbb{CP}^{2k}) = 1$ for every k. Let us verify it for all k with a residue, exactly as for the Todd genus in Example 3.109. By the Euler sequence, $L(T\mathbb{CP}^{2k}) = \left(\frac{h}{\tanh h}\right)^{2k+1}$, and we need its h^{2k} coefficient:

$$\int_{\mathbb{CP}^{2k}} L \overset{(1)}{=} \frac{1}{2\pi i}\oint \left(\frac{h}{\tanh h}\right)^{2k+1}\frac{\mathrm{d}h}{h^{2k+1}} = \frac{1}{2\pi i}\oint \frac{\mathrm{d}h}{(\tanh h)^{2k+1}}$$
$$\overset{(2)}{=} \frac{1}{2\pi i}\oint \frac{\mathrm{d}w}{w^{2k+1}(1-w^2)} \overset{(3)}{=} 1.$$

(1) Coefficient extraction by a contour integral around $h = 0$.

(2) Substitute $w = \tanh h$, $\mathrm{d}w = (1 - \tanh^2 h)\,\mathrm{d}h = (1 - w^2)\,\mathrm{d}h$.

(3) The coefficient of w^{2k} in $\frac{1}{1-w^2} = \sum_j w^{2j}$ is 1.

The Pontryagin classes of $\mathbb{CP}^{2k}$ determine the coefficients of Q one at a time, so this computation, together with multiplicativity of σ under products and its invariance under cobordism, pins down $x/\tanh x$ uniquely.

Worked example 3.127: Rokhlin-type constraint from $\hat{A}$ and L

On a 4-manifold, $\hat{A} = -\frac{1}{24}\int p_1$ and $\sigma = \frac{1}{3}\int p_1$, so

$$\hat{A}(M) = -\frac{\sigma(M)}{8}.$$

If M is spin, $\hat{A}(M)$ is an index, hence an integer, so $\sigma(M)$ is a multiple of 8. (A finer argument, using the quaternionic structure of spinors in four dimensions, gives Rokhlin's theorem: $\sigma \equiv 0 \bmod 16$.) K3: $\sigma = -16$, $\hat{A} = 2$. $\mathbb{CP}^2$: $\sigma = 1$, not divisible by 8, so not spin, as found in Example 3.123.

Recap

- Orientation reduces $\mathrm{O}(2m)$ to $\mathrm{SO}(2m)$ and allows a new invariant, the Pfaffian: $\mathrm{Pf}(B^T AB) = \det B\,\mathrm{Pf}(A)$, $\mathrm{Pf}^2 = \det$; $\mathrm{Pf}(A) = \int \mathrm{d}\theta\, e^{\theta^T A\theta/2}$.
- $e(V) = \mathrm{Pf}(\Omega/2\pi) \in H^{2m}$; $e^2 = p_m$; $e(V \oplus W) = e(V)e(W)$; $e(E_r) = c_k(E)$; e vanishes if there is a nowhere-zero section.
- $\int_M e(V)$ counts zeros of a section with indices; for TM: Poincaré–Hopf and Gauss–Bonnet–Chern, $\chi(M) = \int \mathrm{Pf}(\Omega/2\pi)$. Checks: S^2, T^2, Σ_g, S^4, $\mathbb{CP}^n$.
- Genera: $\mathrm{td} = \prod \frac{x}{1-e^{-x}}$, $\hat{A} = \prod \frac{x/2}{\sinh(x/2)} = 1 - \frac{p_1}{24} + \frac{7p_1^2 - 4p_2}{5760}$, $L = \prod \frac{x}{\tanh x} = 1 + \frac{p_1}{3} + \frac{7p_2 - p_1^2}{45}$; $\mathrm{td} = e^{c_1/2}\hat{A}$.
- $\sigma = \int L$; $\hat{A}(\mathrm{K3}) = 2$, $\hat{A}(\mathbb{CP}^2) = -\frac{1}{8}$ (not spin); on 4-manifolds $\hat{A} = -\sigma/8$.

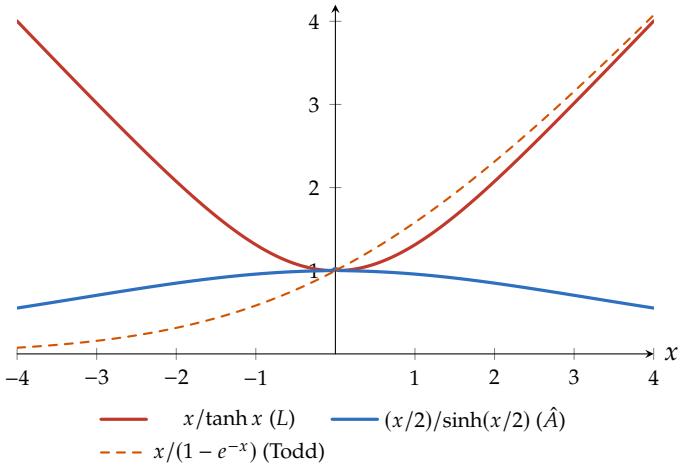


Figure 3.77: The generating functions of the three genera of the index theorem. The L and $\hat{A}$ series are even, so they are functions of x^2 and make sense for real bundles (through Pontryagin classes). The Todd series is not even: it is $e^{x/2}$ times the $\hat{A}$ series, which tilts the blue curve into the orange one; this is td $= e^{c_1/2}\hat{A}$. Near $x = 0$: $L \approx 1 + x^2/3$ bends up, $\hat{A} \approx 1 - x^2/24$ bends down gently.

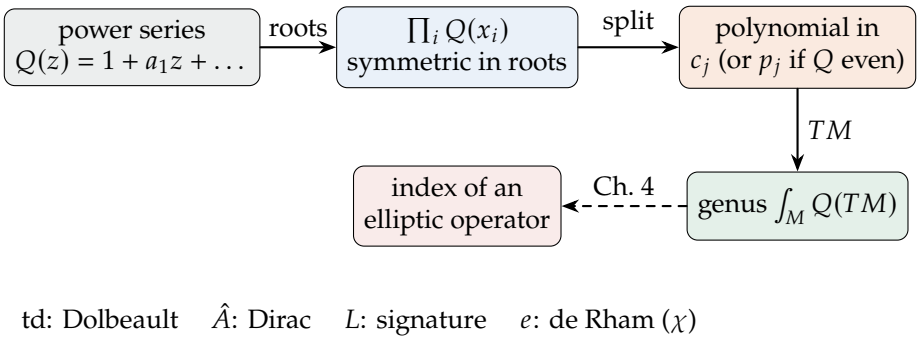

Figure 3.78: The genus machine. A power series fixes a multiplicative class through the roots; the splitting principle rewrites it in Chern or Pontryagin classes; integrating over M gives a number which, for the right series, is the index of a natural elliptic operator.

3.21 Fredholm operators and $K(X)$

Here is a question every field theorist meets sooner or later. A Dirac operator in an instanton background has some zero modes. How many? If we deform the gauge field a little, the zero modes may move away from zero, or new ones may appear. So the *number* of zero modes is not a robust quantity. But something is robust: in an instanton background of charge k the number of left-handed zero modes *minus* the number of right-handed zero modes is fixed by k, whatever we do. That difference controls the 't Hooft vertex, the axial anomaly and the fermion-number violation in the electroweak theory.

The mathematical name for "zero modes of D minus zero modes of $D^\dagger$" is the **index** of D, and the operators for which it makes sense are the **Fredholm operators**. Nash closes his chapter with a one-paragraph section, §6, that says something remarkable about them: *the space of all Fredholm operators is itself a machine for producing K-theory.* A family of Fredholm operators parametrised by a space X has an index that is not a number but an element of $K(X)$, and every element of $K(X)$ arises this way. This is the bridge from the K-theory of the previous sections to the index theory of Chapter 4.

Nash's paragraph uses words (Hilbert space, Fredholm, cokernel, homotopy classes of maps into an operator space) that he does not define. We supply them all. The plan is:

(a) the index of a matrix (finite dimensions: the index exists but is boring);

(b) Hilbert spaces, bounded and compact operators (the background);

(c) Fredholm operators and a gallery of examples: shifts, the harmonic oscillator, Toeplitz operators;

(d) why the index is stable (the heart of the matter);

(e) families of Fredholm operators and the index bundle;

(f) the Atiyah–Jänich theorem $[X, \mathcal{F}] \cong K(X)$ and Kuiper's theorem;

(g) elliptic operators as the source of Fredholm families, and a look ahead to the index theorem.

3.21.1 Warm-up: the index of a matrix

Take an $m \times n$ complex matrix A, viewed as a linear map $A : \mathbb{C}^n \to \mathbb{C}^m$. Two subspaces measure how far A is from being invertible:

- the **kernel** $\operatorname{Ker} A = \{v \in \mathbb{C}^n : Av = 0\}$, the solutions of the homogeneous equation (the "zero modes");
- the **cokernel** $\operatorname{Coker} A = \mathbb{C}^m / \operatorname{Im} A$, which measures how many right-hand sides b the equation $Av = b$ *cannot* reach.

The **index** is the difference of their dimensions. By rank–nullity,

$$\begin{aligned} \operatorname{index} A &\overset{(1)}{=} \dim \operatorname{Ker} A - \dim \operatorname{Coker} A \\ &\overset{(2)}{=} (n - \operatorname{rank} A) - (m - \operatorname{rank} A) \\ &= n - m. \end{aligned} \tag{3.206}$$

(1) The definition of the index.

(2) Rank–nullity: $\dim \operatorname{Ker} A = n - \dim \operatorname{Im} A$; and $\dim \operatorname{Coker} A = m - \dim \operatorname{Im} A$, since a quotient has dimension "big space minus subspace". Both use $\dim \operatorname{Im} A = \operatorname{rank} A$.

The rank cancels. The index does not depend on A at all, only on the dimensions of the two spaces. It is the difference "number of unknowns minus number of equations".

Worked example 3.128: A matrix whose kernel jumps, but whose index does not

Consider the family of 2×3 matrices

$$A_\varepsilon = \begin{pmatrix} 1 & 2 & 3 \\ 2 & 4 & 6+\varepsilon \end{pmatrix} : \mathbb{C}^3 \to \mathbb{C}^2.$$

At $\varepsilon = 0$. The second row is twice the first, so the rank is 1. The kernel is the plane $v_1 + 2v_2 + 3v_3 = 0$, of dimension 2. The image is the line spanned by $(1,2)^T$, so the cokernel $\mathbb{C}^2/\operatorname{Im} A_0$ has dimension 1. Index $2 - 1 = 1$.
At $\varepsilon \neq 0$. The columns $(1,2)^T$ and $(3, 6+\varepsilon)^T$ are independent, so the rank is 2, the image is all of $\mathbb{C}^2$, the cokernel is 0, and the kernel is a line (spanned by $(-2,1,0)^T$). Index $1 - 0 = 1$.
As $\varepsilon \to 0$ one extra zero mode appears, and at the same moment one extra cokernel direction appears. They come and go *in pairs*, so the index $3 - 2 = 1$ never moves. See Figure 3.79.

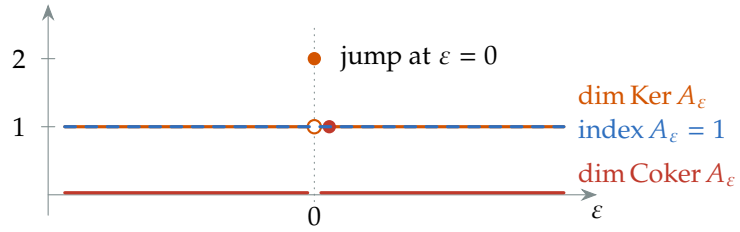

Figure 3.79: The family of Example 3.128. The dimension of the kernel (orange) jumps from 1 to 2 at $\varepsilon = 0$; at the same point the cokernel (red) jumps from 0 to 1. Their difference (blue, dashed) is constant. This pairing of jumps is the whole mechanism behind the stability of the index.

There is a second way to count the cokernel that generalises better. Use the standard inner product $\langle u, v \rangle = \sum_i \bar{u}_i v_i$ (antilinear in the first slot, the physicists' convention, used throughout this section). The cokernel is represented by the vectors orthogonal to the image, and those are the zero modes of the adjoint:

$$\begin{aligned} w \perp \operatorname{Im} A &\overset{(1)}{=} \langle w, Av \rangle = 0 \text{ for all } v \\ &\overset{(2)}{=} \langle A^\dagger w, v \rangle = 0 \text{ for all } v \\ &\overset{(3)}{=} A^\dagger w = 0. \end{aligned}$$

(1) Definition of "orthogonal to every vector of the image". (Each "=" in this chain means "is equivalent to".)
(2) Definition of the adjoint $A^\dagger = \bar{A}^T$.
(3) A vector orthogonal to every v is zero (take $v = A^\dagger w$).

So $\operatorname{Coker} A \cong \operatorname{Ker} A^\dagger$ and

$$\operatorname{index} A = \dim \operatorname{Ker} A - \dim \operatorname{Ker} A^\dagger. \tag{3.207}$$

This is the physicist's form: *zero modes of A minus zero modes of $A^\dagger$*.

Key idea: What finite dimensions teach us

Even for matrices, dim Ker and dim Coker jump under perturbation, but only together, so the index is constant. In finite dimensions the constant is the uninteresting number $n - m$. In infinite dimensions "$n - m$" is "$\infty - \infty$", and the index becomes a genuine invariant of the operator.

3.21.2 Background: Hilbert spaces and bounded operators

Nash takes for granted the functional analysis of operators on Hilbert space. Here is the minimum we need, stated operationally.

Working definition 3.52 (Hilbert space)

A **Hilbert space** H is a complex vector space with an inner product $\langle \cdot, \cdot \rangle$ in which every Cauchy sequence [a sequence whose terms get arbitrarily close to each other] converges (it is *complete*). We only need *separable* ones, which have a countable orthonormal basis $e_0, e_1, e_2, \dots$ [every vector is a convergent infinite sum of the e_n, not only a finite combination] Then every vector is a square-summable sequence of components:

$$v = \sum_{n \geq 0} v_n e_n, \qquad \|v\|^2 = \sum_{n \geq 0} |v_n|^2 < \infty.$$

So every separable infinite-dimensional Hilbert space "is" the sequence space $\ell^2 = \ell^2(\mathbb{N})$ in a chosen basis. Three incarnations will appear repeatedly:

- ℓ^2 itself, with basis vectors $e_n = (0, \dots, 0, 1, 0, \dots)$;
- $L^2(S^1)$, with the Fourier basis $e^{in\theta}/\sqrt{2\pi}$, $n \in \mathbb{Z}$ (a basis indexed by $\mathbb{Z}$ rather than $\mathbb{N}$; relabelling $0, 1, -1, 2, -2, \dots$ turns it into ℓ^2);
- the Fock space of a harmonic oscillator, with basis $|n\rangle$, $n = 0, 1, 2, \dots$

Working definition 3.53 (bounded operator)

A linear map $T : H \to H'$ is **bounded** if $\|T\| = \sup_{v \neq 0} \|Tv\| / \|v\| < \infty$. Bounded is the same as continuous [$v_t \to v$ implies $Tv_t \to Tv$]. The bounded operators form a vector space $B(H, H')$ with the **norm topology**: $T_t \to T$ means $\|T_t - T\| \to 0$. Every bounded T has an adjoint $T^* : H' \to H$ (written $T^\dagger$ by physicists), defined by $\langle T^* w, v \rangle = \langle w, Tv \rangle$.

Watch out: Differential operators are not bounded on L^2, but that is fine

$-i\,\mathrm{d}/\mathrm{d}\theta$ sends $e^{in\theta}$ to $n\,e^{in\theta}$, and n is unbounded, so it is not a bounded operator $L^2 \to L^2$. The cure is to change the domain: as a map from the Sobolev space $H^1(S^1)$ (norm $\|u\|_1^2 = \sum (1 + n^2)\,|u_n|^2$) to $L^2(S^1)$ it is bounded, with norm ≤ 1. Nash's phrase "elliptic operators are Fredholm operators when viewed as operators in Hilbert space" always means "between suitable Sobolev spaces"; see Chapter 2. With this understanding everything below applies to differential operators.

Two things go wrong in infinite dimensions that cannot go wrong for matrices.

- *Injective does not imply surjective.* The shift below is injective and misses a direction.

- *The image need not be closed.* Then $H'/\operatorname{Im} T$ is a wild, infinite-dimensional space with no good topology. Fredholm operators are exactly the ones for which neither pathology is serious.

Working definition 3.54 (compact operator)

An operator K is **compact** if it is a norm limit [$\|K - K_N\| \to 0$ for a sequence K_N] of *finite-rank* operators (operators whose image is finite-dimensional). *Operational test:* in a suitable basis, K acts nontrivially only on a finite number of modes, up to an error that can be made as small as we like. The model is a diagonal operator $Ke_n = \lambda_n e_n$ with $\lambda_n \to 0$.

Why is $Ke_n = \lambda_n e_n$ with $\lambda_n \to 0$ compact? Truncate it: $K_N e_n = \lambda_n e_n$ for $n < N$ and $K_N e_n = 0$ for $n \geq N$. Then K_N has rank $\leq N$ and

$$\|K - K_N\| \overset{(1)}{=} \sup_{v \neq 0} \frac{\left(\sum_{n \geq N} |\lambda_n|^2 \, |v_n|^2\right)^{1/2}}{\left(\sum_n |v_n|^2\right)^{1/2}} \overset{(2)}{=} \sup_{n \geq N} |\lambda_n| \xrightarrow{N \to \infty} 0.$$

(1) $K - K_N$ keeps only the modes $n \geq N$, each multiplied by λ_n.
(2) The ratio is largest when v is concentrated on the mode with the largest $|\lambda_n|$, $n \geq N$; that supremum tends to 0 because $\lambda_n \to 0$.

The identity on an infinite-dimensional space is *not* compact: every truncation misses a mode of eigenvalue 1, so $\|1 - K_N\| \geq 1$.

Physical picture: Compact means "negligible at high mode number"

Think of H as the space of modes of a field. A compact operator affects only finitely many low modes appreciably; at high mode number it is as small as we like. Adding a mass term to a Dirac operator, or any lower-order term to an elliptic operator, is (after composing with a parametrix) a compact perturbation. Things that depend only on the "ultraviolet" behaviour of an operator are therefore blind to compact perturbations. The index will be one of them.

The one fact about compact operators we shall use is the **Fredholm alternative** (Riesz): *if K is compact, then $1 + K$ has a finite-dimensional kernel, a closed image and a cokernel of the same dimension as its kernel.* For diagonal K this is plain to see: $1 + K$ multiplies e_n by $1 + \lambda_n$, which vanishes for at most finitely many n (since $\lambda_n \to 0$), and those same finitely many e_n span both the kernel and the cokernel.

3.21.3 Fredholm operators and the index

Working definition 3.55 (Fredholm operator and its index)

A bounded operator $T : H \to H'$ is **Fredholm** if

$$\dim \operatorname{Ker} T < \infty \qquad \text{and} \qquad \dim \operatorname{Coker} T = \dim\left(H'/\operatorname{Im} T\right) < \infty.$$

[finitely many independent zero modes $Tv = 0$, and only finitely many independent directions of H' missed by T] (The image is then automatically closed.) Its **index** is Nash's (3.128):

$$\operatorname{index} T = \dim \operatorname{Ker} T - \dim \operatorname{Coker} T = \dim \operatorname{Ker} T - \dim \operatorname{Ker} T^*. \tag{3.208}$$

Operational test: solve $Tv = 0$ and $T^*w = 0$. If both solution spaces are finite-dimensional (and the image is closed, which is automatic once the cokernel is finite-dimensional), T is Fredholm, and the index is the difference of the two dimensions. We write $\mathcal{F} = \mathcal{F}(H, H')$ for the set of Fredholm operators, with the norm topology.

The second form of (3.208) holds for the same reason as in finite dimensions: the orthogonal complement of the (closed) image is $\operatorname{Ker} T^*$, by the chain before (3.207).

Worked example 3.129: Easy cases

- Every invertible bounded operator is Fredholm with index 0: kernel and cokernel are both zero. In particular the identity.
- Every linear map between finite-dimensional spaces is Fredholm, with index $n - m$ by (3.206).
- $1 + K$ with K compact is Fredholm of index 0, by the Fredholm alternative.
- The zero operator on an infinite-dimensional H is *not* Fredholm: its kernel is all of H.
- The orthogonal projection onto the even modes, $Pe_{2n} = e_{2n}$, $Pe_{2n+1} = 0$, is not Fredholm: its kernel (all odd modes) is infinite-dimensional.

Worked example 3.130: A compact operator is never Fredholm: the image fails to close

Let $Ke_n = \frac{1}{n+1} e_n$ on ℓ^2. The kernel is 0. The image contains every finite combination of basis vectors, so it is dense. Is it everything? Try to solve $Kv = w$ with $w_n = \frac{1}{n+1}$, which is in ℓ^2 because $\sum \frac{1}{(n+1)^2} = \frac{\pi^2}{6}$:

$$\begin{aligned} Kv = w &\overset{(1)}{=} \frac{v_n}{n+1} = \frac{1}{n+1} \text{ for all } n \\ &\overset{(2)}{=} v_n = 1 \text{ for all } n, \end{aligned}$$

(1) Compare components; K is diagonal.
(2) Multiply by $n + 1$.

but $\sum_n |1|^2 = \infty$, so $v \notin \ell^2$. Thus $w \notin \operatorname{Im} K$ although it is a limit of vectors in the image: the image is not closed, and $\ell^2/\operatorname{Im} K$ is infinite-dimensional (the same argument works for $w_n = (n+1)^{-s}$ for any $\frac{1}{2} < s \leq \frac{3}{2}$). So K is not Fredholm. Every compact operator on an infinite-dimensional space fails in this way: it squashes the high modes, so it cannot be "almost invertible".

The shift: the Hilbert hotel has index -1

The fundamental example is the **unilateral shift** on ℓ^2,

$$Se_n = e_{n+1}, \qquad S(v_0, v_1, v_2, \dots) = (0, v_0, v_1, v_2, \dots).$$

It is the Hilbert hotel: every guest moves one room up, and room 0 is left empty.

Worked example 3.131: Index of the shift and its adjoint

Kernel of S. $Sv = (0, v_0, v_1, \dots) = 0$ forces every $v_n = 0$. So $\operatorname{Ker} S = 0$.
Adjoint. Compute matrix elements:

$$\langle S^* e_m, e_n \rangle \overset{(1)}{=} \langle e_m, S e_n \rangle \overset{(2)}{=} \langle e_m, e_{n+1} \rangle = \delta_{m,n+1}.$$

(1) Definition of the adjoint.
(2) Definition of S.

So $S^* e_m = e_{m-1}$ for $m \geq 1$ and $S^* e_0 = 0$: the adjoint shifts down and kills the bottom vector. As a matrix,

$$S = \begin{pmatrix} 0 & 0 & 0 & \cdots \\ 1 & 0 & 0 & \cdots \\ 0 & 1 & 0 & \cdots \\ 0 & 0 & 1 & \cdots \\ \vdots & & & \ddots \end{pmatrix}, \qquad S^* = \begin{pmatrix} 0 & 1 & 0 & 0 & \cdots \\ 0 & 0 & 1 & 0 & \cdots \\ 0 & 0 & 0 & 1 & \cdots \\ \vdots & & & & \ddots \end{pmatrix}.$$

Kernel of S^*. $S^* v = (v_1, v_2, \dots) = 0$ forces $v_n = 0$ for $n \geq 1$, so $\operatorname{Ker} S^* = \mathbb{C} e_0$.
Index.

$$\operatorname{index} S \overset{(1)}{=} \dim \operatorname{Ker} S - \dim \operatorname{Ker} S^* = 0 - 1 = -1,$$

$$\operatorname{index} S^* \overset{(2)}{=} \dim \operatorname{Ker} S^* - \dim \operatorname{Ker} S^{**} = 1 - 0 = +1.$$

(1) (3.208) with the two kernels just found.
(2) The same, using $S^{**} = S$.

Products. $S^* S = 1$ (up then down: nothing lost), while $S S^* = 1 - |e_0\rangle\langle e_0|$ (down then up: the bottom component is lost). And S^k has kernel 0 and cokernel spanned by $e_0, \dots, e_{k-1}$, so $\operatorname{index} S^k = -k$, $\operatorname{index} (S^*)^k = +k$. *Every integer is the index of some Fredholm operator.*

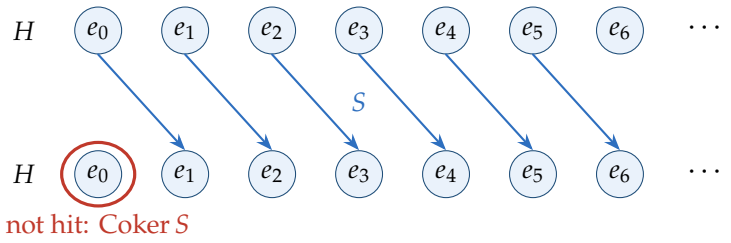

Figure 3.80: The shift S as the Hilbert hotel. Every basis vector moves one step up; nothing is sent to zero, so $\operatorname{Ker} S = 0$; the bottom vector e_0 is never reached, so $\operatorname{Coker} S = \mathbb{C} e_0$. Index $0 - 1 = -1$. For a matrix this is impossible (an injective square matrix is surjective); in infinite dimensions there is always "room at the top".

The harmonic oscillator, and why there is no phase operator

Worked example 3.132: The annihilation operator has index $+1$

On Fock space, $a|n\rangle = \sqrt{n}\,|n-1\rangle$ and $a^\dagger|n\rangle = \sqrt{n+1}\,|n+1\rangle$. These are unbounded (the factors $\sqrt{n}$ grow), so, as for differential operators, we regard a as a bounded map from the domain $D = \{\psi : \sum n\,|\psi_n|^2 < \infty\}$ (with norm $\|\psi\|_D^2 = \sum (1+n)\,|\psi_n|^2$) to H.

- $\operatorname{Ker} a = \mathbb{C}|0\rangle$: the vacuum is the unique state killed by a.
- a is onto: given $\phi = \sum c_n|n\rangle \in H$, the state $\psi = \sum_n \frac{c_n}{\sqrt{n+1}}|n+1\rangle$ satisfies $a\psi = \phi$ and lies in D, since $\sum_n (n+2)\frac{|c_n|^2}{n+1} \le 2\sum_n |c_n|^2 < \infty$.

So $\operatorname{index} a = 1 - 0 = 1$, and likewise $\operatorname{index} a^\dagger = -1$. In fact a is the shift S^* dressed with the factors $\sqrt{n}$. Write $N = a^\dagger a$ for the number operator, $N|n\rangle = n|n\rangle$. Then

$$a|n\rangle \overset{(1)}{=} \sqrt{n}\,|n-1\rangle \overset{(2)}{=} S^*\big(\sqrt{n}|n\rangle\big) \overset{(3)}{=} S^*\sqrt{N}|n\rangle,$$

(1) Definition of a.
(2) S^* lowers $|n\rangle$ to $|n-1\rangle$ (and kills $|0\rangle$, consistent with $\sqrt{0} = 0$), with $e_n = |n\rangle$.
(3) $\sqrt{N}|n\rangle = \sqrt{n}|n\rangle$.

so $a = S^*\sqrt{N}$. This is the *polar decomposition* of a, and S^* is the Susskind–Glogower "exponential of the phase" $\widehat{e^{i\varphi}}$.

Worked example 3.133: No unitary phase operator: an index argument

Dirac hoped to write $a = U\sqrt{N}$ with $U = e^{i\hat{\varphi}}$ *unitary*, which would make $\hat{\varphi}$ a Hermitian phase operator conjugate to N. Suppose it were possible. On every $|n\rangle$ with $n \ge 1$ we must have $U|n\rangle = \frac{1}{\sqrt{n}}a|n\rangle = |n-1\rangle = S^*|n\rangle$; so U and S^* differ only on the single vector $|0\rangle$, i.e. $U - S^*$ has rank at most 1. Then

$$0 \overset{(1)}{=} \operatorname{index} U \overset{(2)}{=} \operatorname{index}\big(S^* + (U - S^*)\big) \overset{(3)}{=} \operatorname{index} S^* \overset{(4)}{=} 1,$$

(1) A unitary operator is invertible.
(2) Trivial rewriting.
(3) The index does not change under a finite-rank (compact) perturbation; we prove this in Section 3.21.4.
(4) Example 3.131.

a contradiction. *The nonexistence of a Hermitian phase operator for the oscillator is the statement* $\operatorname{index} a = 1 \neq 0$. Physically: the spectrum of N is bounded below, so the "lowering" operator must annihilate something, and no unitary can do that.

Toeplitz operators: the first index theorem

Now a family of examples where the index is computed by a *topological* number, exactly as in the Atiyah–Singer theorem, but where everything can be checked by hand.

Inside $L^2(S^1)$ take the **Hardy space** H^2: the closed span of the nonnegative Fourier modes $z^n = e^{in\theta}$, $n \ge 0$. These are the boundary values of functions holomorphic inside the unit disc, $h(z) = \sum_{n\ge 0} h_n z^n$. With $e_n = z^n$, H^2 is just ℓ^2. Let P be the orthogonal projection of $L^2(S^1)$ onto H^2 (throw away the negative modes).

Working definition 3.56 (Toeplitz operator)

For a continuous function $f : S^1 \to \mathbb{C}$ (the **symbol**), the **Toeplitz operator** is

$$T_f : H^2 \to H^2, \qquad T_f h = P(fh) :$$

[H^2 is spanned by the modes z^n with $n \ge 0$, and P discards the negative modes] multiply

by f, then project back to the nonnegative modes. Its matrix in the basis z^n is $(T_f)_{mn} = \hat{f}_{m-n}$, where $\hat{f}_k$ are the Fourier coefficients of f [$f = \sum_{k\in\mathbb{Z}} \hat{f}_k z^k$]: constant along diagonals (a "Toeplitz matrix").

Worked example 3.134: Symbols z^k give the shifts

For $f = z$: $T_z z^n = P(z^{n+1}) = z^{n+1}$, so $T_z = S$. For $f = z^{-1} = \bar{z}$: $T_{\bar{z}} z^n = P(z^{n-1})$, which is z^{n-1} for $n \geq 1$ and 0 for $n = 0$ (since z^{-1} is a negative mode). So $T_{\bar{z}} = S^*$. In general $T_{z^k} = S^k$ and $T_{z^{-k}} = (S^*)^k$ for $k \geq 0$, hence

$$\operatorname{index} T_{z^k} = -k.$$

The function z^k winds k times around the origin. The index is minus the winding number of the symbol.

Worked example 3.135: The symbol $z - a$: a zero inside the disc makes a cokernel

Take $f(z) = z - a$ with $a \in \mathbb{C}$, $|a| \neq 1$, so that f never vanishes on the circle. Then $T_f = S - a$.
Case $|a| > 1$. The symbol winds 0 times around the origin (the zero $z = a$ is outside the circle). Since $\|S\| = 1 < |a|$,

$$S - a = -a\big(1 - a^{-1}S\big), \qquad \big(1 - a^{-1}S\big)^{-1} = \sum_{j\geq 0} a^{-j} S^j,$$

the geometric (Neumann) series converging in norm. So $S - a$ is invertible: index 0.
Case $|a| < 1$. The symbol winds once. Kernel: $(S - a)h = 0$ reads, in components, $-a h_0 = 0$ and $h_{n-1} - a h_n = 0$ for $n \geq 1$. If $a \neq 0$ the first gives $h_0 = 0$ and then the second gives $h_n = h_{n-1}/a = 0$ for all n; if $a = 0$, S is injective anyway. So $\operatorname{Ker}(S - a) = 0$. Cokernel: look for zero modes of the adjoint $S^* - \bar{a}$. Try the vector

$$k_a = \sum_{n\geq 0} \bar{a}^{\,n} e_n, \qquad \|k_a\|^2 = \sum_n |a|^{2n} = \frac{1}{1 - |a|^2} < \infty.$$

Then

$$S^* k_a \overset{(1)}{=} \sum_{n\geq 1} \bar{a}^{\,n} e_{n-1} \overset{(2)}{=} \bar{a} \sum_{m\geq 0} \bar{a}^{\,m} e_m = \bar{a}\, k_a,$$

(1) S^* lowers each e_n and kills e_0.
(2) Put $m = n - 1$ and pull out one factor $\bar{a}$.

so $(S - a)^* k_a = (S^* - \bar{a})k_a = 0$. Conversely any solution of $S^* v = \bar{a} v$ has $v_{n+1} = \bar{a} v_n$, so $v = v_0 k_a$: $\operatorname{Ker}(S - a)^* = \mathbb{C} k_a$. Hence $\operatorname{index}(S - a) = 0 - 1 = -1$.
What the cokernel is. Since $\langle k_a, h\rangle = \sum_n a^n h_n = h(a)$, the vector k_a is "evaluation at a". The image of $S - a$ consists of the functions $(z - a)h(z)$, which all vanish at $z = a$: the cokernel is the single condition $h(a) = 0$ that the image obeys. It exists exactly when a is inside the disc, where holomorphic functions can be evaluated.
Check by stability. Write $P_0 = |e_0\rangle\langle e_0|$. For $|a| < 1$,

$$S(1 - aS^*) \overset{(1)}{=} S - a\, SS^* \overset{(2)}{=} S - a(1 - P_0) = (S - a) + aP_0,$$

(1) Distribute.
(2) $SS^* = 1 - P_0$, Example 3.131.

so $S - a = S(1 - aS^*) - aP_0$: the index -1 operator S, times an invertible operator ($\|aS^*\| < 1$), plus a rank-one operator. Index $-1 + 0 = -1$, agreeing with the direct computation.

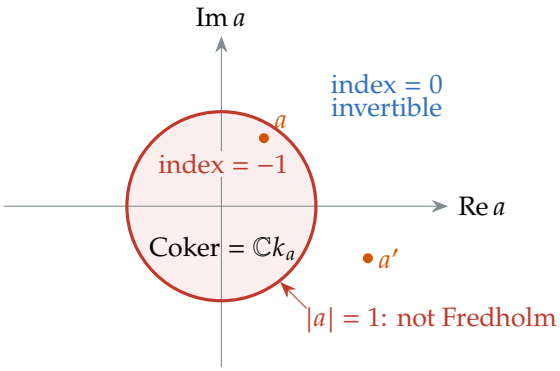

Figure 3.81: The index of the Toeplitz operator $T_{z-a} = S - a$ as a function of a. Inside the unit circle the symbol $z - a$ winds once around 0 and the index is -1; outside it winds 0 times and the operator is invertible. The index can only change by crossing the red wall $|a| = 1$, where the symbol vanishes somewhere on the circle and $S - a$ stops being Fredholm (its image is no longer closed). The index is locally constant on the space of Fredholm operators, and the walls between its values are made of non-Fredholm operators.

Key idea: The Toeplitz index theorem (Noether, Gohberg–Krein)

If $f : S^1 \to \mathbb{C}$ is continuous and never zero, T_f is Fredholm and

$$\operatorname{index} T_f = -\operatorname{wind}(f) = -\frac{1}{2\pi i}\oint_{S^1}\frac{\mathrm{d}f}{f}. \tag{3.209}$$

Left side: an analytic count of solutions. Right side: a topological invariant of the symbol, the class of f in $\pi_1(\mathbb{C}^*) = \mathbb{Z}$.

Why it is true. Any nowhere-zero f can be deformed through nowhere-zero functions into z^k with $k = \operatorname{wind}(f)$ (this is what it means for the winding number to classify loops in $\mathbb{C}^*$). Along the deformation T_f moves continuously in norm (since $\|T_f - T_g\| \le \sup|f - g|$) and stays Fredholm, so its index cannot change (Section 3.21.4), and at the end it is index $S^k = -k$. The step we skip is that T_f is Fredholm when f has no zeros: the parametrix is $T_{1/f}$, because $T_f T_{1/f} - 1$ is compact (it is a product of two "Hankel" operators, which are compact for continuous symbols).

This is the prototype of every index theorem in this book: *an operator whose "symbol" is invertible has an index, and the index is a topological invariant of the symbol.* For elliptic operators the symbol is the principal symbol $\sigma(x, p)$, invertible for $p \neq 0$, and its topology lives in K-theory.

3.21.4 Why the index is stable

We have used several times that the index does not change under small or compact perturbations. This is *the* property that makes the index useful, so we now explain it twice: once with a physicist's spectral argument, once with a two-line block-matrix computation that is actually a proof.

The spectral argument: nonzero modes come in pairs

Two facts about T^*T and TT^*. First, they have the same zero modes as T and T^*:

$$T^*Tv = 0 \overset{(1)}{=} \langle v, T^*Tv\rangle = 0 \overset{(2)}{=} \|Tv\|^2 = 0 \overset{(3)}{=} Tv = 0.$$

(1) Take the inner product with v. (Conversely $Tv = 0$ clearly gives $T^*Tv = 0$, so each "=" here is an equivalence.)
(2) $\langle v, T^*Tv\rangle = \langle Tv, Tv\rangle$ by the definition of the adjoint.
(3) Only the zero vector has norm zero.

So $\operatorname{Ker} T = \operatorname{Ker} T^*T$, and likewise $\operatorname{Ker} T^* = \operatorname{Ker} TT^*$. Second, their *nonzero* eigenvalues coincide, with multiplicity. If $T^*Tv = \lambda v$ with $\lambda \neq 0$, then

$$TT^*(Tv) \overset{(1)}{=} T(T^*Tv) \overset{(2)}{=} \lambda\, Tv, \qquad \|Tv\|^2 \overset{(3)}{=} \lambda\, \|v\|^2 \neq 0.$$

(1) Associativity of composition.
(2) v is a λ-eigenvector of T^*T.
(3) $\|Tv\|^2 = \langle v, T^*Tv\rangle = \lambda\langle v, v\rangle$.

So T maps the λ-eigenspace of T^*T injectively into the λ-eigenspace of TT^*, and T^* maps back the same way; the two eigenspaces have equal dimension. Therefore

$$\operatorname{index} T = \dim \operatorname{Ker} T^*T - \dim \operatorname{Ker} TT^*, \tag{3.210}$$

and the right-hand side counts only the *unpaired* levels. When we deform T, the eigenvalues of T^*T and TT^* move, but the nonzero ones move in locked pairs. A zero mode of T^*T can rise off zero only if a partner rises off zero with it in TT^*, and vice versa. The difference of the numbers of zero modes cannot change.

Worked example 3.136: Supersymmetric quantum mechanics and the Witten index

Package T into a "supercharge" on $H \oplus H'$ (bosons $\oplus$ fermions):

$$Q = \begin{pmatrix} 0 & T^* \\ T & 0 \end{pmatrix}, \qquad \mathcal{H} = Q^2 = \begin{pmatrix} T^*T & 0 \\ 0 & TT^* \end{pmatrix}, \qquad (-1)^F = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

The pairing above is the statement that Q maps bosonic states of energy $\lambda \neq 0$ to fermionic states of the same energy. The **Witten index** is

$$\begin{aligned} \operatorname{Tr}(-1)^F e^{-\beta\mathcal{H}} &\overset{(1)}{=} \operatorname{Tr}_H e^{-\beta T^*T} - \operatorname{Tr}_{H'} e^{-\beta TT^*} \\ &\overset{(2)}{=} \dim \operatorname{Ker} T^*T - \dim \operatorname{Ker} TT^* + \sum_{\lambda\neq 0} (m_\lambda - m_\lambda) e^{-\beta\lambda} \\ &\overset{(3)}{=} \operatorname{index} T, \end{aligned}$$

(1) The supertrace of a block-diagonal operator.
(2) Split each trace into zero modes (contributing $e^0 = 1$ each) and nonzero levels, where m_λ is the common multiplicity of λ in T^*T and in TT^*.
(3) The nonzero levels cancel pairwise, and (3.210).

independent of β (whenever the traces converge). For the oscillator, $T = a$ gives $T^*T = a^\dagger a = N$ with spectrum $\{0, 1, 2, \dots\}$ and $TT^* = aa^\dagger = N + 1$ with spectrum $\{1, 2, 3, \dots\}$:

$$\operatorname{Tr}(-1)^F e^{-\beta\mathcal{H}} \overset{(1)}{=} \sum_{n\geq 0} e^{-\beta n} - \sum_{n\geq 0} e^{-\beta(n+1)} \overset{(2)}{=} \frac{1 - e^{-\beta}}{1 - e^{-\beta}} = 1 = \operatorname{index} a.$$

(1) The two spectra.
(2) Sum both geometric series: $\frac{1}{1-e^{-\beta}} - \frac{e^{-\beta}}{1-e^{-\beta}}$.

This β-independence is the germ of the heat-kernel proof of the index theorem (the McKean–Singer formula, Chapter 4): at large β only zero modes survive, at small β the traces are computed by local curvature integrals, and the answer is the same.

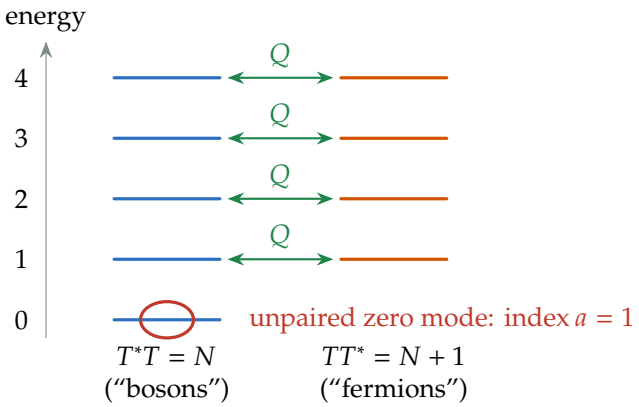

Figure 3.82: The spectra of $a^\dagger a$ and $aa^\dagger$ for the harmonic oscillator. Every nonzero level on the left has a partner on the right (green arrows: the supercharge Q maps one to the other). Only the vacuum on the left is unpaired. Deforming a can move the levels, but only in pairs, so the one unpaired level, the index, survives any deformation.

The block-matrix argument: reduction to a finite matrix

Now the real mechanism, which works for any Fredholm $T : H \to H'$. Split the two spaces into "zero-mode" and "non-zero-mode" parts:

$$H = \underbrace{\operatorname{Ker} T}_{H_0} \oplus \underbrace{(\operatorname{Ker} T)^\perp}_{H_1}, \qquad H' = \underbrace{(\operatorname{Im} T)^\perp}_{H_0' \cong \operatorname{Coker} T} \oplus \underbrace{\operatorname{Im} T}_{H_1'}.$$

H_0 and H_0' are finite-dimensional, of dimensions $\dim \operatorname{Ker} T$ and $\dim \operatorname{Coker} T$. In these blocks

$$T = \begin{pmatrix} 0 & 0 \\ 0 & T_{11} \end{pmatrix},$$

where $T_{11} : H_1 \to H_1'$ is a bijection, hence has a bounded inverse (by the open mapping theorem of functional analysis). Now perturb, $T \to T + R$, and write the perturbed operator in the same blocks:

$$T + R = \begin{pmatrix} A & B \\ C & D \end{pmatrix}, \qquad A = R_{00} : H_0 \to H_0', \quad D = T_{11} + R_{11} : H_1 \to H_1'.$$

If $\|R\| < 1/\left\|T_{11}^{-1}\right\|$, then $D = T_{11}(1 + T_{11}^{-1}R_{11})$ is invertible (Neumann series again). Now do Gaussian elimination with operator entries:

$$\begin{pmatrix} 1 & -BD^{-1} \\ 0 & 1 \end{pmatrix} \begin{pmatrix} A & B \\ C & D \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -D^{-1}C & 1 \end{pmatrix} \overset{(1)}{=} \begin{pmatrix} 1 & -BD^{-1} \\ 0 & 1 \end{pmatrix} \begin{pmatrix} A - BD^{-1}C & B \\ 0 & D \end{pmatrix}$$
$$\overset{(2)}{=} \begin{pmatrix} A - BD^{-1}C & 0 \\ 0 & D \end{pmatrix}. \tag{3.211}$$

(1) Multiply the right two factors: the first column becomes $(A - BD^{-1}C,\ C - DD^{-1}C) = (A - BD^{-1}C,\ 0)$, the second is unchanged.

(2) Multiply by the left factor: the top-right entry becomes $B - BD^{-1}D = 0$; the top-left gets $-BD^{-1} \cdot 0 = 0$ added.

The two outer factors are invertible (triangular with 1 on the diagonal), so they change neither the dimension of the kernel nor that of the cokernel. The block D is invertible. So all the kernel and cokernel of $T + R$ sit in the *finite matrix*

$$M = A - BD^{-1}C : H_0 \longrightarrow H_0',$$

the **Schur complement**, and

$$\operatorname{index}(T+R) \overset{(1)}{=} \operatorname{index} M \overset{(2)}{=} \dim H_0 - \dim H_0' \overset{(3)}{=} \dim \operatorname{Ker} T - \dim \operatorname{Coker} T = \operatorname{index} T. \quad (3.212)$$

(1) (3.211): $\operatorname{Ker}(T+R) \cong \operatorname{Ker} M$ and $\operatorname{Coker}(T+R) \cong \operatorname{Coker} M$, because the invertible block D contributes nothing.
(2) M is a matrix from a space of dimension $\dim H_0$ to one of dimension $\dim H_0'$; its index is the difference, by (3.206).
(3) The definitions of H_0 and H_0'.

Key idea: Finite-dimensional reduction

Near any Fredholm operator T, every nearby operator is, up to invertible changes of basis, "an invertible operator on the non-zero modes" $\oplus$ "a finite matrix M from $\operatorname{Ker} T$ to $\operatorname{Coker} T$". All jumping of kernels happens inside M, where rank–nullity forces the kernel and cokernel to jump together. So:

- the Fredholm operators form an *open* set in $B(H, H')$;
- $\dim \operatorname{Ker}$ can only drop nearby ($\dim \operatorname{Ker} M \leq \dim H_0$): it is *upper semicontinuous*;
- the index is *locally constant*, hence constant along any continuous path of Fredholm operators: it is a *homotopy invariant*.

This is exactly the picture of Figure 3.79, now in infinite dimensions, and it is how one computes an index in practice: identify a finite-dimensional "low-mode" problem and discard the rest.

Composition, adjoints and parametrices

Adjoints. Since $\operatorname{Ker} T^* = (\operatorname{Im} T)^\perp$ and $\operatorname{Coker} T^* \cong \operatorname{Ker} T$, the roles swap:

$$\operatorname{index} T^* = -\operatorname{index} T.$$

Composition. For Fredholm $T : H_1 \to H_2$ and $S : H_2 \to H_3$, the kernels and cokernels fit into a sequence of finite-dimensional spaces

$$0 \to \operatorname{Ker} T \xrightarrow{\iota} \operatorname{Ker} ST \xrightarrow{T} \operatorname{Ker} S \xrightarrow{\pi} \operatorname{Coker} T \xrightarrow{S} \operatorname{Coker} ST \xrightarrow{\pi'} \operatorname{Coker} S \to 0,$$

where ι is inclusion ($Tv = 0 \Rightarrow STv = 0$), the second map applies T (if $STv = 0$ then $Tv \in \operatorname{Ker} S$), π sends $w \in \operatorname{Ker} S \subset H_2$ to its class in $H_2/\operatorname{Im} T$, the next map is induced by S, and π' is the projection $H_3/\operatorname{Im} ST \to H_3/\operatorname{Im} S$ (valid since $\operatorname{Im} ST \subset \operatorname{Im} S$). One checks directly that this sequence is *exact*: the image of each map is the kernel of the next. For instance, at $\operatorname{Ker} S$: an element $w \in \operatorname{Ker} S$ maps to 0 in $\operatorname{Coker} T$ iff $w = Tv$ for some v, and then $STv = Sw = 0$, so $v \in \operatorname{Ker} ST$ and w is in the image of the previous map. The alternating sum of dimensions in a finite exact sequence vanishes (apply rank–nullity at each spot), so

$$\begin{aligned} 0 &\overset{(1)}{=} \dim \operatorname{Ker} T - \dim \operatorname{Ker} ST + \dim \operatorname{Ker} S \\ &\qquad - \dim \operatorname{Coker} T + \dim \operatorname{Coker} ST - \dim \operatorname{Coker} S \\ &\overset{(2)}{=} \operatorname{index} T - \operatorname{index} ST + \operatorname{index} S, \\ \text{i.e.} \quad \operatorname{index}(ST) &= \operatorname{index} S + \operatorname{index} T. \end{aligned} \quad (3.213)$$

(1) Alternating sum over the six-term exact sequence.
(2) Regroup into the three indices.

Checks: $S^*S = 1$ gives $\operatorname{index} S^* + \operatorname{index} S = 1 - 1 = 0 = \operatorname{index} 1$. $SS^* = 1 - P_0$ has kernel and cokernel both $\mathbb{C}e_0$, index $0 = -1 + 1$. And $\operatorname{index}\big(S^j(S^*)^k\big) = k - j$.

Working definition 3.57 (parametrix; Atkinson's theorem)

A **parametrix** for $T : H \to H'$ is a bounded $Q : H' \to H$ such that $QT - 1$ and $TQ - 1$ are compact [norm limits of finite-rank operators, negligible at high mode number]. *Atkinson's theorem:* T is Fredholm [finite-dimensional kernel and cokernel] if and only if it has a parametrix. In words, *Fredholm = invertible modulo compact operators*.

Both directions are short.

- *Fredholm $\Rightarrow$ parametrix.* In the blocks above, let Q be T_{11}^{-1} on $H_1' = \operatorname{Im} T$ and 0 on H_0'. Then $QT = 1 - P_{\operatorname{Ker} T}$ and $TQ = 1 - P_{(\operatorname{Im} T)^\perp}$, where P denotes orthogonal projection. These differ from 1 by finite-rank projections. Physically, Q is the propagator with the zero modes removed.
- *Parametrix $\Rightarrow$ Fredholm.* If $QT = 1 + K$ with K compact, then $\operatorname{Ker} T \subset \operatorname{Ker}(1 + K)$, which is finite-dimensional by the Fredholm alternative. If $TQ = 1 + K'$, then $\operatorname{Im} T \supset \operatorname{Im}(1 + K')$, which has finite codimension. So kernel and cokernel are finite.

Two consequences.

- *Compact perturbations do not change the index.* A parametrix Q of T is also one of $T + tK$ for every t (the extra terms tQK, tKQ are compact), so $T + tK$ is Fredholm for all $t \in [0, 1]$, and by homotopy invariance $\operatorname{index}(T + K) = \operatorname{index} T$. This justifies step (3) of Example 3.133 and the stability check in Example 3.135.
- *Elliptic operators are Fredholm.* In Chapter 2 a parametrix for an elliptic operator is built by inverting its principal symbol $\sigma(x, p)$ for large $|p|$; the error is a smoothing operator, which is compact on a compact manifold. Atkinson's theorem then gives Nash's remark on p. 88.

Key idea: The components of $\mathcal{F}$ are labelled by the index

The index is a continuous map $\operatorname{index} : \mathcal{F} \to \mathbb{Z}$, and it is a bijection on path components:

$$\pi_0(\mathcal{F}) \xrightarrow{\cong} \mathbb{Z}.$$

It is onto because $\operatorname{index} S^k = -k$ and $\operatorname{index}(S^*)^k = k$. It is one-to-one because two Fredholm operators of the same index can be joined by a path in $\mathcal{F}$ (reduce each to "invertible $\oplus$ finite matrix" by (3.211), join the finite matrices through matrices of the same size, and join the invertible parts using the connectedness of $\mathrm{GL}(H)$, discussed in Section 3.21.6). This is Nash's (3.128) read as $[\text{point}, \mathcal{F}] \cong \mathbb{Z} = K(\text{point})$.

3.21.5 Families of Fredholm operators and the index bundle

Now let the operator depend on parameters. Let X be a compact space (think of a sphere of gauge fields, a torus of Wilson lines, a moduli space of instantons) and H a fixed separable infinite-dimensional Hilbert space.

Working definition 3.58 (families and $[X,\mathcal{F}]$)

A **family of Fredholm operators** over X is a continuous map $T : X \to \mathcal{F}$, $x \mapsto T_x$, continuous in the norm topology [$\|T_{x'} - T_x\| \to 0$ as $x' \to x$]. Two families are **homotopic** if they are joined by a family over $X \times [0,1]$. The set of homotopy classes is Nash's $[X,\mathcal{F}]$. Pointwise composition, $(ST)_x = S_x T_x$, is a product on it: the product of Fredholm operators is Fredholm (by (3.213)), and it respects homotopy. So $[X,\mathcal{F}]$ is a semigroup [it has an associative product, but inverses need not exist], with the constant family 1 as unit.

For each x we get an integer index T_x, but on a connected X it is constant, so it carries little information. The natural guess is to use the kernels themselves: the vector spaces $\operatorname{Ker} T_x$, $x \in X$, look like the fibres of a vector bundle, and so do the cokernels. The guess fails, because kernels jump.

Worked example 3.137: A family whose kernels do not form a bundle

On $H = \ell^2 \oplus \mathbb{C}$ take $X = [-1,1]$ and

$$T_t = \begin{pmatrix} S^* & 0 \\ 0 & t \end{pmatrix} : \ (h,z) \mapsto (S^*h,\ tz).$$

For $t \neq 0$: $\operatorname{Ker} T_t = \mathbb{C}(e_0, 0)$ and T_t is onto, so $\dim \operatorname{Ker} = 1$, $\dim \operatorname{Coker} = 0$. At $t = 0$: $\operatorname{Ker} T_0 = \mathbb{C}(e_0,0) \oplus \mathbb{C}(0,1)$ and $\operatorname{Coker} T_0 = \mathbb{C}(0,1)$, so $\dim \operatorname{Ker} = 2$, $\dim \operatorname{Coker} = 1$. The index is 1 throughout, but the kernels have rank 1 except at one point, so $\{\operatorname{Ker} T_t\}$ is not a vector bundle.

The cure is to add enough extra directions to the target that the cokernel disappears everywhere. Then the kernel has constant dimension, by the index.

Working definition 3.59 (the index bundle)

Let $T : X \to \mathcal{F}(H, H')$ with X compact.

1. Choose finitely many vectors $w_1, \dots, w_N \in H'$ such that $\operatorname{Im} T_x + \operatorname{span}(w_1, \dots, w_N) = H'$ for every $x \in X$.
2. Define the *stabilised* family
$$\hat{T}_x : H \oplus \mathbb{C}^N \to H', \qquad \hat{T}_x(h,c) = T_x h + \textstyle\sum_j c_j w_j.$$
It is surjective for every x, so its kernels $K_x = \operatorname{Ker} \hat{T}_x$ all have the same dimension and form a vector bundle $K \to X$.
3. The **index bundle** of the family is the K-theory class
$$\operatorname{index} T = [K] - [\mathbb{C}^N] \ \in K(X). \tag{3.214}$$
[$[\mathbb{C}^N]$ is the trivial bundle $X \times \mathbb{C}^N$, and $K(X)$ holds formal differences of bundles over X]

Special case: if $\dim \operatorname{Ker} T_x$ is constant, then $\operatorname{Ker} T$ and $\operatorname{Coker} T$ are honest bundles and $\operatorname{index} T = [\operatorname{Ker} T] - [\operatorname{Coker} T]$.

Let us check each step.

Step 1 is possible. At a single point x_0, take the w_j to be a basis of $(\operatorname{Im} T_{x_0})^\perp$; then $\hat{T}_{x_0}$ is onto. A

surjective Fredholm operator stays surjective under small perturbations: in (3.211) its cokernel block H_0' is zero, so the Schur complement M maps into the zero space and has no cokernel. So $\hat{T}_x$ is onto for x in a neighbourhood U_{x_0}. Finitely many such neighbourhoods cover the compact space X; take all their w's together.

The rank of K. For each x,

$$\dim K_x \overset{(1)}{=} \operatorname{index} \hat{T}_x \overset{(2)}{=} \operatorname{index}\big(T_x \circ \mathrm{pr}_H\big) \overset{(3)}{=} \operatorname{index} T_x + \operatorname{index} \mathrm{pr}_H \overset{(4)}{=} \operatorname{index} T_x + N.$$

(1) $\hat{T}_x$ is onto, so its cokernel is 0 and its index is the dimension of its kernel.
(2) $\hat{T}_x = T_x \circ \mathrm{pr}_H +$ (the finite-rank map $(h, c) \mapsto \sum c_j w_j$), where $\mathrm{pr}_H : H \oplus \mathbb{C}^N \to H$ is the projection; a finite-rank perturbation does not change the index.
(3) Additivity (3.213).
(4) pr_H is onto with kernel $\mathbb{C}^N$.

Constant, as promised. (That the K_x fit together into a locally trivial bundle follows from the same block picture: near x_0, orthogonal projection onto K_{x_0} restricts to an isomorphism $K_x \to K_{x_0}$.)

The answer does not depend on the choice of w's. Adding M more vectors $w_1', \dots, w_M'$ gives $\hat{T}'$ with kernel K', and there is a short exact sequence of bundles

$$0 \to K \to K' \to \mathbb{C}^M \to 0, \qquad (h, c) \mapsto (h, c, 0), \quad (h, c, c') \mapsto c',$$

exact on the right because for every c' the vector $-\sum c_j' w_j'$ lies in $H' = \operatorname{Im} \hat{T}_x$. Short exact sequences of bundles split (choose a metric), so $K' \cong K \oplus \mathbb{C}^M$ and

$$[K'] - [\mathbb{C}^{N+M}] = [K] + [\mathbb{C}^M] - [\mathbb{C}^N] - [\mathbb{C}^M] = [K] - [\mathbb{C}^N].$$

Any two choices are dominated by their union, so all choices agree.

Homotopy invariance. A homotopy is a family over $X \times [0, 1]$, whose index bundle restricts to the index bundles at the two ends; bundles over $X \times [0, 1]$ have isomorphic restrictions to $X \times \{0\}$ and $X \times \{1\}$ (homotopic maps pull back isomorphic bundles, as in the discussion of classifying maps in the previous part). So index is a well-defined map

$$\operatorname{index} : [X, \mathcal{F}] \longrightarrow K(X).$$

At a point (Nash's (3.128)). If X is a point, $K(\mathrm{pt}) \cong \mathbb{Z}$ by the dimension, and

$$\operatorname{index} T = [K] - [\mathbb{C}^N] \;\longmapsto\; \dim K - N \overset{(1)}{=} \operatorname{index} T + N - N = \dim \operatorname{Ker} T - \dim \operatorname{Coker} T.$$

(1) The rank computation above.

So the index bundle is the promised generalisation of the integer index.

The special case. If $\dim \operatorname{Ker} T_x$ is constant, there is an exact sequence of bundles

$$0 \to \operatorname{Ker} T \to K \to \mathbb{C}^N \to \operatorname{Coker} T \to 0,$$

with maps $h \mapsto (h, 0)$, $(h, c) \mapsto c$, and $c \mapsto [\sum c_j w_j]$. (Exactness at $\mathbb{C}^N$: c comes from K iff $\sum c_j w_j = -T_x h$ for some h, iff its class in the cokernel is zero.) The alternating sum of the classes of an exact sequence of bundles is zero in $K(X)$, so

$$\operatorname{index} T \overset{(1)}{=} [K] - [\mathbb{C}^N] \overset{(2)}{=} [\operatorname{Ker} T] - [\operatorname{Coker} T].$$

(1) Definition (3.214).
(2) $[\operatorname{Ker} T] - [K] + [\mathbb{C}^N] - [\operatorname{Coker} T] = 0$ from the exact sequence.

Worked example 3.138: Stabilising the jumping family

In Section 3.21.5 the only cokernel direction ever needed is $w = (0, 1)$. With $N = 1$,

$$\hat{T}_t(h, z, c) = \big(S^*h,\ tz + c\big), \qquad K_t = \operatorname{Ker} \hat{T}_t = \mathbb{C}(e_0, 0, 0) \oplus \mathbb{C}(0, 1, -t).$$

Now $\dim K_t = 2$ for every t, including $t = 0$: the jump has been absorbed by the extra coordinate c. K is a trivial rank-2 bundle over the interval, and index $T = [\mathbb{C}^2] - [\mathbb{C}^1]$, the class of virtual dimension 1. Nothing twisted here (an interval is contractible); the point is only that the construction removes the jumps.

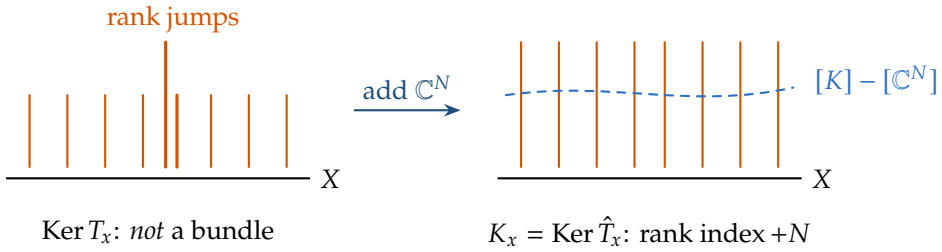

Figure 3.83: Left: the kernels of a Fredholm family have jumping dimension, so they do not form a vector bundle. Right: after adding N auxiliary directions that kill every cokernel, the kernels have constant rank index $T_x + N$ and form a bundle K. The index bundle is the virtual bundle $[K] - [\mathbb{C}^N]$; the N auxiliary directions are subtracted off again.

Watch out: Finite-dimensional families only give trivial classes

If every T_x acts between fixed spaces $\mathbb{C}^n \to \mathbb{C}^m$ (with constant rank, say), the exact sequence $0 \to \operatorname{Ker} T \to \mathbb{C}^n \to \mathbb{C}^m \to \operatorname{Coker} T \to 0$ gives index $T = [\operatorname{Ker} T] - [\operatorname{Coker} T] = [\mathbb{C}^n] - [\mathbb{C}^m]$, which is trivial. The twisting of an index bundle can only come from infinite dimensions: from the "room at the top" of the Hilbert hotel. This is why K-theory needs Hilbert space, and why the index of a matrix was boring.

Every K-class is an index bundle

Here is a family that produces any given bundle $E \to X$. By the stable equivalence theorem of the previous part, E sits inside a trivial bundle $X \times \mathbb{C}^N$ (it has a complement E' with $E \oplus E' \cong \mathbb{C}^N$). Let P_x be the orthogonal projection of $\mathbb{C}^N$ onto the fibre E_x; it depends continuously on x. On $H = \mathbb{C}^N \otimes \ell^2$ define

$$T^E_x = P_x \otimes S^* + (1 - P_x) \otimes 1. \tag{3.215}$$

In words: on $E_x \otimes \ell^2$ it acts as the down-shift, on $E_x^\perp \otimes \ell^2$ as the identity. Its kernel is $E_x \otimes \operatorname{Ker} S^* = E_x \otimes e_0$ and it is onto. The kernels have constant dimension $\operatorname{rank} E$, so

$$\operatorname{index} T^E = [\operatorname{Ker} T^E] - [\operatorname{Coker} T^E] = [E \otimes e_0] - 0 = [E].$$

The adjoint family $(T^E)^* = P_x \otimes S + (1 - P_x) \otimes 1$ has no kernel and cokernel $E \otimes e_0$, so $\operatorname{index}(T^E)^* = -[E]$. Finally, for two bundles E, F,

$$\operatorname{index}\big(T^E \oplus (T^F)^*\big) = [E] - [F].$$

Every element of $K(X)$ has the form $[E] - [F]$, so *every element of $K(X)$ is the index bundle of some Fredholm family*: the map index : $[X, \mathcal{F}] \to K(X)$ is onto.

Worked example 3.139: The Bott class as an operator family on $\mathbb{CP}^1$

Let $L \to \mathbb{CP}^1$ be the tautological line bundle, whose fibre over $[1:z]$ is the line through $u = (1,z)^T$. The projection onto it is

$$P_z = \frac{uu^\dagger}{u^\dagger u} = \frac{1}{1+|z|^2}\begin{pmatrix} 1 & \bar z \\ z & |z|^2 \end{pmatrix},$$

which tends to $\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$ as $z \to \infty$, so it is continuous on the whole sphere. On $H = \ell^2 \oplus \ell^2$ the family (3.215) is the 2×2 matrix of operators

$$\begin{aligned} T_z &\overset{(1)}{=} P_z \otimes S^* + (1-P_z)\otimes 1 \\ &\overset{(2)}{=} \frac{1}{1+|z|^2}\begin{pmatrix} S^* + |z|^2 & \bar z\,(S^*-1) \\ z\,(S^*-1) & |z|^2\,S^* + 1 \end{pmatrix}. \end{aligned}$$

(1) Definition (3.215) with $N = 2$.

(2) $1 - P_z = \frac{1}{1+|z|^2}\begin{pmatrix} |z|^2 & -\bar z \\ -z & 1 \end{pmatrix}$; add the two matrices entry by entry.

Check that (e_0, ze_0) is in the kernel, using $S^* e_0 = 0$:

$$(1+|z|^2)\,T_z\begin{pmatrix} e_0 \\ ze_0 \end{pmatrix} \overset{(1)}{=} \begin{pmatrix} |z|^2 e_0 + \bar z z(-e_0) \\ z(-e_0) + z\,e_0 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}.$$

(1) Apply each entry: $(S^* + |z|^2)e_0 = |z|^2\,e_0$, $(S^*-1)ze_0 = -ze_0$, and $(|z|^2\,S^* + 1)ze_0 = ze_0$. So $\operatorname{Ker} T_z = \mathbb{C}\,u\otimes e_0 \cong L_z$, each T_z has index 1, and the index bundle is $[L]$. By Example 3.92, $c_1(L) = -1$, so

$$\operatorname{ch}(\operatorname{index} T) = 1 - h, \qquad \int_{\mathbb{CP}^1} \operatorname{ch}(\operatorname{index} T) = -1.$$

The reduced class $\operatorname{index} T - 1 = [L] - [\mathbb{C}]$ is the Bott generator of $\widetilde K(S^2) \cong \mathbb{Z}$ (in the tautological convention of Example 3.103). We have written the generator of Bott periodicity as an explicit family of operators on Hilbert space. Its topology is invisible in any single T_z (each is just "a shift in some direction"), and visible only in how the zero mode $u \otimes e_0$ rotates as z goes around the sphere: it winds like the monopole wavefunction.

3.21.6 The Atiyah–Jänich theorem and Kuiper's theorem

Key idea: Atiyah–Jänich (Nash: "it can be shown that $[X,\mathcal{F}]$ is isomorphic to $K(X)$")

For compact X, the index bundle is an isomorphism

$$\operatorname{index} : [X,\mathcal{F}] \xrightarrow{\cong} K(X), \qquad \operatorname{index}(ST) = \operatorname{index} S + \operatorname{index} T.$$

Composition of families corresponds to addition in K. In particular $[X,\mathcal{F}]$ is not just a semigroup but a group, with the inverse of $[T]$ given by $[T^*]$.

We have shown that index is well defined and onto. Additivity comes from the families version of the six-term sequence (3.213). Here is why it is one-to-one, as a narrative.

Suppose $\operatorname{index} T = 0$ in $K(X)$, i.e. $[K] = [\mathbb{C}^N]$. Adding more trivial directions to the

stabilisation, we may assume $K \cong \mathbb{C}^N$ is actually trivial. Pick a bundle isomorphism $\phi_x : K_x \to \mathbb{C}^N$ and change the family on the finite-rank piece so that the new operator sends K_x isomorphically onto the auxiliary directions. The result is a family of *invertible* operators, homotopic to the original one through Fredholm families. So the question becomes: *is every family of invertible operators homotopic to the constant family* 1*?* In finite dimensions the answer would be no ($\mathrm{GL}(1,\mathbb{C}) = \mathbb{C}^*$ has a loop $e^{i\theta}$ that does not contract, detected by the winding of the determinant). In infinite dimensions the answer is yes:

Key idea: Kuiper's theorem

The group $\mathrm{GL}(H)$ of invertible bounded operators on an infinite-dimensional separable Hilbert space, and its unitary subgroup $\mathrm{U}(H)$, are *contractible* in the norm topology. So every map $X \to \mathrm{GL}(H)$ is homotopic to the constant map 1, and $[X, \mathrm{GL}(H)]$ has just one element.

The core of the proof is the **Eilenberg swindle**, and it is worth seeing because it is the Hilbert hotel once more.

Step 1: $u \oplus u^{-1}$ is connected to 1. For any unitary u on a space V, work on $V \oplus V$ with the rotation $R_t = \begin{pmatrix} \cos t & -\sin t \\ \sin t & \cos t \end{pmatrix}$ (entries are multiples of 1_V). Define the path $h_t = \begin{pmatrix} u & 0 \\ 0 & 1 \end{pmatrix} R_t \begin{pmatrix} u^{-1} & 0 \\ 0 & 1 \end{pmatrix} R_t^{-1}$, $0 \le t \le \frac{\pi}{2}$. Then $h_0 = 1$ and

$$h_{\pi/2} \overset{(1)}{=} \begin{pmatrix} u & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & u^{-1} \end{pmatrix} = \begin{pmatrix} u & 0 \\ 0 & u^{-1} \end{pmatrix}.$$

(1) Conjugating a diagonal matrix by the quarter turn $R_{\pi/2} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ swaps its entries: $R_{\pi/2}\,\mathrm{diag}(a,b)R_{\pi/2}^{-1} = \mathrm{diag}(b,a)$.

Every h_t is unitary, and h_t depends continuously on t (and on x, if $u = u_x$ is a family).

Step 2: the swindle. Identify H with an infinite direct sum $V \oplus V \oplus V \oplus \cdots$ (possible since $\ell^2 \otimes V \cong H$ for $V = H$). Consider $U = \mathrm{diag}(u, 1, 1, 1, \dots)$. Apply Step 1 simultaneously to the slots $(2,3), (4,5), \dots$, running $1 \oplus 1 \to u^{-1} \oplus u$ in each pair (Step 1 with u^{-1} in place of u):

$$\mathrm{diag}(u, \underbrace{1,1}, \underbrace{1,1}, \dots) \simeq \mathrm{diag}(u, \underbrace{u^{-1}, u}, \underbrace{u^{-1}, u}, \dots) = \mathrm{diag}(\underbrace{u, u^{-1}}, \underbrace{u, u^{-1}}, \dots) \simeq 1.$$

In the middle we only re-bracketed; in the last step we apply Step 1 to the pairs $(1,2), (3,4), \dots$ The same path is used in every block, so the homotopy is uniformly continuous in norm. The hard part of Kuiper's proof, which we skip, is to show that every u can first be deformed into the form $\mathrm{diag}(u', 1, 1, \dots)$.

Watch out: $\mathrm{U}(H)$ is contractible, but $\mathrm{U}(\infty)$ is not

In the previous part, $\mathrm{U}(\infty) = \bigcup_n \mathrm{U}(n)$ had $\pi_1 = \mathbb{Z}$ and the whole of Bott periodicity. There is no contradiction with Kuiper: $\mathrm{U}(\infty)$ consists of unitaries that differ from 1 in only finitely many entries, and the swindle needs infinitely many nontrivial blocks. The larger group $\mathrm{U}(H)$ (all unitaries, norm topology) contains the swindle and is contractible.

Physical picture: $\mathcal{F}$ is a classifying space for K-theory

Combine the pieces. $\mathrm{GL}(H)$ acts on $\mathcal{F}$ by composition and is contractible, and what survives in $\mathcal{F}$ is exactly the finite-dimensional kernel–cokernel data. The Atiyah–Jänich

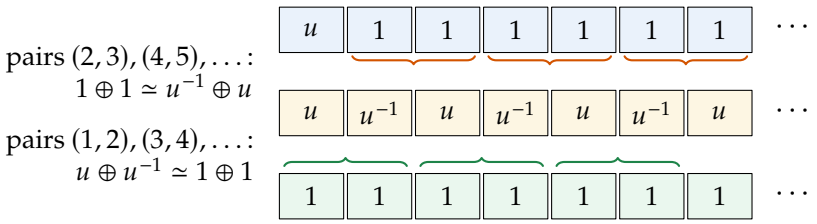

Figure 3.84: The Eilenberg swindle. Top row: u in the first slot, 1 everywhere else. Rotating each orange pair turns the row into the alternating pattern in the middle. Re-bracketing into the green pairs and rotating again gives 1 everywhere. The winding carried by u has been pushed off to infinity, one room at a time. With finitely many slots the last u would be left over, which is why $\mathrm{U}(n)$ is not contractible.

theorem says that $\mathcal{F}$ is a classifying space for K:

$$K(X) = [X, \mathcal{F}], \qquad \mathcal{F} \;\simeq\; \mathbb{Z} \times BU,$$

where the $\mathbb{Z}$ labels the components by the index (the virtual dimension) and each component looks like the infinite Grassmannian BU that classified bundles in the previous part ($\widetilde{K}(X) = [X, BU]$ for connected X). The Grassmannian is the "geometric" model of K-theory; $\mathcal{F}$ is the "analytic" model. The index bundle translates between them.

3.21.7 Where Fredholm families come from: elliptic operators

Nash ends with: "Since elliptic operators are Fredholm operators when viewed as operators in Hilbert space, one might expect $K(X)$ to turn up in a discussion of the index of elliptic operators." Let us see this concretely.

Worked example 3.140: The Dirac operator on the circle is Fredholm

Let $D = -i\,\mathrm{d}/\mathrm{d}\theta : H^1(S^1) \to L^2(S^1)$. In the Fourier basis $De^{in\theta} = n\,e^{in\theta}$, a diagonal operator with entries $n \in \mathbb{Z}$.

- $\operatorname{Ker} D$: the mode $n = 0$, the constants. Dimension 1.
- $\operatorname{Im} D$: every mode except $n = 0$, so $\operatorname{Coker} D$ is again the constants (D is self-adjoint, so $\operatorname{Ker} D^* = \operatorname{Ker} D$). Dimension 1.
- Index $1 - 1 = 0$.

The parametrix is "divide by the symbol": $Qe^{in\theta} = \frac{1}{n}e^{in\theta}$ for $n \neq 0$, $Q1 = 0$. Then

$$QDe^{in\theta} \overset{(1)}{=} Q\,n\,e^{in\theta} \overset{(2)}{=} \begin{cases} e^{in\theta}, & n \neq 0, \\ 0, & n = 0, \end{cases}$$

(1) The action of D on a Fourier mode.
(2) For $n \neq 0$ the factors n and $\frac{1}{n}$ cancel; for $n = 0$ the mode was already killed by D.

so $QD = 1 - P_0$ and similarly $DQ = 1 - P_0$, with P_0 the rank-one projection onto the constants. Atkinson's theorem: D is Fredholm. The mechanism is general: the symbol n (in general $\sigma(x, p)$) is invertible for large $|n|$, and only finitely many low modes can fail.

Worked example 3.141: A non-elliptic operator is not Fredholm

On the torus T^2 let $D = \partial/\partial\theta_1$. On the modes $e^{i(n_1\theta_1+n_2\theta_2)}$ it multiplies by in_1. Every mode with $n_1 = 0$ is in the kernel: the functions of θ_2 alone. The kernel is infinite-dimensional, so D is not Fredholm. The symbol ip_1 vanishes on the nonzero covectors $p = (0, p_2)$: the operator is not elliptic, and nothing controls the modes in that direction.

Worked example 3.142: Operators with nonzero index: $\bar\partial$ on $\mathbb{CP}^1$ and on T^2

Take the Cauchy–Riemann operator $\bar\partial$ acting on sections of the monopole bundle $L_n = \mathcal{O}(n)$ over $\mathbb{CP}^1$ (between the appropriate Sobolev spaces). Its kernel is the space of holomorphic sections, the polynomials of degree $\le n$ in the affine coordinate, of dimension $n+1$ for $n \ge 0$; its cokernel is the Dolbeault group $H^{0,1}(\mathbb{CP}^1; \mathcal{O}(n))$, which vanishes for $n \ge -1$ (both computed with Čech cohomology in part 3a). So

$$\operatorname{index} \bar\partial_{\mathcal{O}(n)} = n + 1 = \int_{\mathbb{CP}^1} \operatorname{ch}(L_n)\, \operatorname{td}(T\mathbb{CP}^1),$$

the last equality being Example 3.110. On the torus $T^2 = \mathbb{C}/(\mathbb{Z} + i\mathbb{Z})$, $\bar\partial$ on functions has kernel the constants and cokernel spanned by $d\bar z$ (the Dolbeault group $H^{0,1}(T^2)$ is one-dimensional), so its index is $0 = \int_{T^2} \operatorname{td}(TT^2)$, because the tangent bundle of the torus is trivial and $c_1 = 0$. In each case the left side is Fredholm theory and the right side is the characteristic-class calculus of this chapter.

Key idea: The index theorem, as a preview of Chapter 4

For an elliptic operator D on a compact manifold M, the *analytical index* $\dim\operatorname{Ker} D - \dim\operatorname{Coker} D$ (this section) equals a *topological index* built from characteristic classes (Sections 3.18 and 3.20). The two most important cases:

$$\operatorname{index} \bar\partial_E = \int_M \operatorname{ch}(E)\, \operatorname{td}(TM), \qquad \operatorname{index} \not{D}_E = \int_M \operatorname{ch}(E)\, \hat A(TM).$$

The Toeplitz theorem (3.209) is the one-dimensional ancestor. For a *family* of elliptic operators D_x, $x \in X$ (a Dirac operator coupled to a family of gauge fields, say), the index is an element of $K(X)$ by this section, and the families index theorem computes its Chern character. Its degree-2 part is the first Chern class of the determinant line bundle, which is the gauge anomaly (Chapter 10).

Aside: self-adjoint families and spectral flow

A self-adjoint Fredholm operator has index 0 ($\operatorname{Ker} D^* = \operatorname{Ker} D$), so a single one carries no integer. But a *loop* of them does. Take the Dirac operator on a circle coupled to a constant U(1) gauge field A (a Wilson line),

$$D_A = -i\frac{\mathrm{d}}{\mathrm{d}\theta} + A, \qquad D_A e^{in\theta} = (n + A)\, e^{in\theta}, \qquad 0 \le A \le 1.$$

The endpoints are gauge equivalent. With $g = e^{i\theta}$,

$$g^{-1} D_0 (gu) \overset{(1)}{=} e^{-i\theta}\left(-i\frac{\mathrm{d}}{\mathrm{d}\theta}\right)\left(e^{i\theta}u\right) \overset{(2)}{=} e^{-i\theta}\left(e^{i\theta}u - ie^{i\theta}u'\right) = D_1 u,$$

(1) Conjugate D_0 by multiplication by g.

(2) Product rule: $-i(e^{i\theta}u)' = e^{i\theta}u - ie^{i\theta}u'$.

so $D_1 = g^{-1}D_0 g$ has the same spectrum as D_0, and $A \in [0,1]$ is really a loop. Yet along the loop the eigenvalue $-1 + A$ rises from -1 to 0 and the eigenvalue A rises from 0 to 1: the spectrum as a whole returns to itself, but it has shifted up by one unit. Exactly one eigenvalue crosses zero from below. This net number of crossings is the **spectral flow**, here +1. It is a homotopy invariant of loops of self-adjoint Fredholm operators, just as the index is for single operators, and such loops (more generally, maps $X \to \mathcal{F}^{\mathrm{sa}}$) classify the K-group $K^{-1}(X)$ in the same way that $\mathcal{F}$ classifies $K(X)$ (Atiyah–Singer).

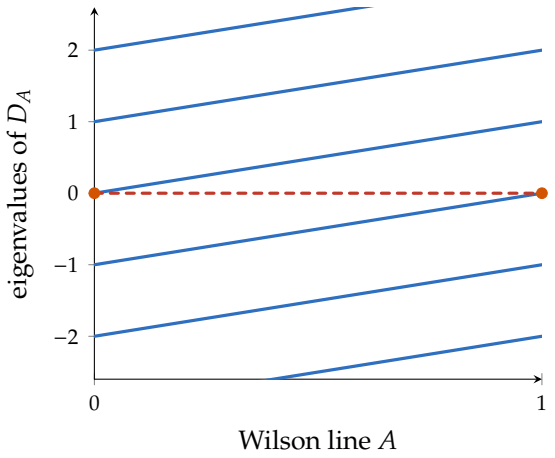

Figure 3.85: Spectral flow. The eigenvalues $n + A$ of the circle Dirac operator D_A as the Wilson line A goes from 0 to 1. The spectrum at $A = 1$ is the same set as at $A = 0$ (the two operators are gauge equivalent), but every level has moved up by one place: one eigenvalue has crossed the red line 0 from below. In a second-quantised theory this is one unit of fermion number created by an adiabatic change of flux: the mechanism behind level-crossing pictures of the chiral anomaly (Chapter 10).

Dictionary: Fredholm theory

Mathematics	Physics
$\operatorname{Ker} D$, $\operatorname{Ker} D^*$	zero modes of D and of $D^\dagger$ (e.g. left- and right-handed fermion zero modes)
$\operatorname{index} D$	net number of zero modes; Witten index $\operatorname{Tr}(-1)^F e^{-\beta\mathcal{H}}$
Fredholm	well-posed up to finitely many zero modes and constraints
compact perturbation	lower-order terms, masses, smooth potentials: UV-irrelevant
parametrix	propagator with zero modes removed
family over X; index bundle in $K(X)$	zero modes varying over a parameter space (moduli, Wilson lines, background fields)
spectral flow	level crossing; fermion number created by an adiabatic process
Kuiper's theorem	in infinite dimensions no winding survives in the invertible operators; only zero modes carry topology

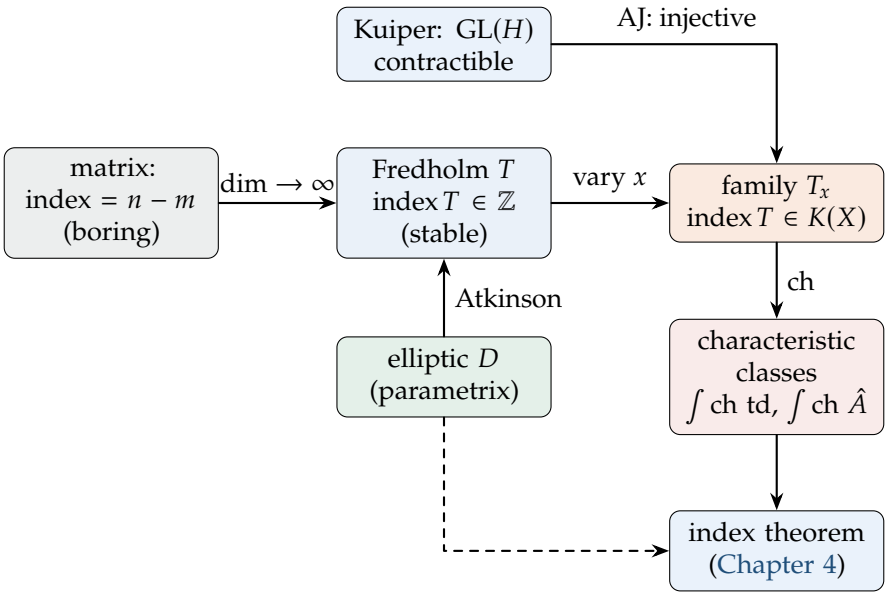

Figure 3.86: The logic of this section. Infinite dimensions make the index a real invariant; parameters promote it to a K-theory class (Atiyah–Jänich, with Kuiper's theorem ensuring nothing else survives); elliptic operators supply the Fredholm operators; the Chern character turns the K-class into cohomology, where the characteristic classes of §5 compute it. The index theorem is the dashed arrow.

Reading Nash (p. 88, §6, (3.128))

Nash's whole section is one paragraph. He introduces $\mathcal{F}$, "the space of all Fredholm operators", without defining Fredholm; we did so in Section 3.21.3 (finite-dimensional kernel and cokernel), with the norm topology understood. His "product of two Fredholm operators is also Fredholm" is our (3.213), which also shows that the index turns products into sums. He calls $[X, \mathcal{F}]$ a semigroup; by the Atiyah–Jänich theorem it is in fact a group, isomorphic to $K(X)$. "Actually it can be shown" hides two ingredients: the index bundle construction (Section 3.21.5) and Kuiper's theorem (Section 3.21.6). His (3.128), $\dim\ker F - \dim\operatorname{coker} F$, is the case $X =$ point. His closing sentence, that elliptic operators are Fredholm "when viewed as operators in Hilbert space", means between Sobolev spaces (see the pitfall in Section 3.21.2), and it is Atkinson's theorem applied to the parametrix of Chapter 2. The standard references for this material are Atiyah's *K-theory* (appendix) and Lawson–Michelsohn, *Spin Geometry*, §III.7.

Recap

- $\operatorname{index} T = \dim\operatorname{Ker} T - \dim\operatorname{Coker} T = \dim\operatorname{Ker} T - \dim\operatorname{Ker} T^*$. For matrices it is $n - m$; in infinite dimensions it is a real invariant.
- Fredholm: finite kernel and cokernel $\Leftrightarrow$ invertible modulo compacts (Atkinson). Examples: shift S (index -1), a (index $+1$, hence no unitary phase operator), Toeplitz T_f (index $-$ wind f).
- Stability: nonzero modes of T^*T and TT^* pair up; near T every operator is "invertible $\oplus$ finite matrix $\operatorname{Ker} T \to \operatorname{Coker} T$" (Schur complement). The index is locally constant, homotopy invariant, blind to compact perturbations, and additive: $\operatorname{index} ST = \operatorname{index} S + \operatorname{index} T$.

- $\pi_0(\mathcal{F}) \cong \mathbb{Z}$ (Nash (3.128)). A family $T : X \to \mathcal{F}$ has an index bundle $[K]-[\mathbb{C}^N] \in K(X)$ (stabilise to kill cokernels).
- Atiyah–Jänich: $[X, \mathcal{F}] \cong K(X)$. Onto via $T^E = P \otimes S^* + (1 - P) \otimes 1$; one-to-one via Kuiper ($\mathrm{GL}(H)$ contractible, Eilenberg swindle). The Bott class is the family of Example 3.139.
- Elliptic operators are Fredholm (parametrix from the symbol); their indices are computed by characteristic classes: the index theorem. Self-adjoint loops carry spectral flow.

Chapter summary

This chapter had one theme, played three times. Physics hands us objects that are easy to write down on small patches and hard to write down globally: a vector potential, a wavefunction in a monopole field, a solution of a differential equation, a family of zero modes. The chapter built three machines that measure the global twisting of such objects.

1. *Sheaf cohomology* (Nash §1–§2) measures the failure of local solutions to glue. Its outputs are groups such as $H^1(M;\mathcal{O}^*)$ (line bundles) and $H^2(M;\mathbb{Z})$ (their magnetic charges), and two theorems, de Rham and Dolbeault, that let us compute them with differential forms.

2. *K-theory* (Nash §3–§4) counts vector bundles up to adding trivial ones, and turns the counting into a ring. Over spheres it is a homotopy group of a Lie group (clutching), and Bott periodicity says these groups repeat with period 2 (complex) or 8 (real).

3. *Characteristic classes* (Nash §5) turn a bundle into cohomology classes that can be computed from any gauge field by integrating invariant polynomials of the curvature. *Fredholm operators* (Nash §6) turn families of operators into K-theory classes. Together they set up the index theorem: an analytic count of zero modes on one side, an integral of characteristic classes on the other.

Figure 3.87 draws the logic, and the tables below list every concept of the chapter with its operational meaning and where it is used again.

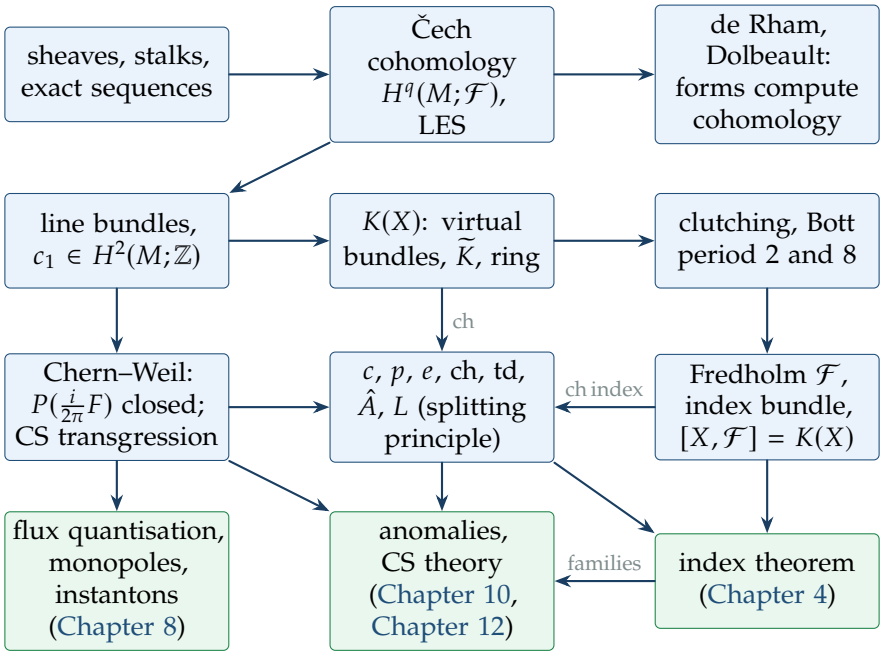

Figure 3.87: Chapter 3 in one picture. Top row: local data and its cohomology (Nash §1–§2). Middle row: bundles and K-theory (§3–§4). Third row: characteristic classes and Fredholm operators (§5–§6). The green boxes are where the later chapters use the machinery. (The de Rham theorem is what lets the curvature forms of the third row represent the integral classes of the second.) Every arrow into the index theorem passes through the third row: the Chern character takes the K-theory class of an operator family into cohomology, where the classes td and $\hat{A}$ evaluate it.

Concept table I: sheaves and their cohomology (Nash §1–§2)

Concept	Operational meaning: how to compute or test it	Used later
presheaf, sheaf $\mathcal{F}$	A group $\mathcal{F}(U)$ for each open U with restrictions. Sheaf: sections are determined by, and glue from, compatible local pieces. Test: is the defining condition *local*? (smooth, holomorphic, solves a PDE: yes; bounded, constant: no).	sheaf cohomology of $\mathcal{O}(D)$ in Chapter 5; strings Chapter 9
stalk, germ $\mathcal{F}_x$	Sections near x, two identified if they agree on a smaller neighbourhood. For $\mathcal{O}$: convergent power series at x.	exactness tests, Chapter 5
sheaf morphism; exact sequence	A local operation commuting with restriction (d, $\bar\partial$, $\exp 2\pi i$). Exact means exact on every stalk, i.e. locally solvable.	resolutions in Chapter 4, Chapter 5
exponential sequence	$0 \to \mathbb{Z} \to \mathcal{O} \xrightarrow{e^{2\pi i\,\cdot}} \mathcal{O}^* \to 0$; it is exact because logarithms exist locally but not globally.	c_1 of line bundles, divisors (Chapter 5)
fine / soft sheaf	Sections can be cut off with bump functions ($\mathcal{E}^p$, sections of a smooth bundle). Then $H^q = 0$ for $q > 0$.	every de Rham-type argument
Čech cochains, δ, $H^q(\mathcal{U};\mathcal{F})$	One section per $(q+1)$-fold overlap; δ = alternating restriction; cocycles modulo coboundaries. H^0 = global sections; H^1 = twisted gluing data modulo re-gauging. Use a good (Leray) cover.	line bundles, instanton patching (Chapter 8)
long exact sequence, δ^*	Zig-zag: lift locally, apply δ, pull back. For the exponential sequence on $\mathbb{C}^*$, δ^* is the winding number.	c_1; Riemann–Roch arguments in Chapter 5
de Rham theorem	$H^q(M;\mathbb{R}) \cong H^q_{\mathrm{dR}}(M)$ via the fine resolution $\underline{\mathbb{R}} \to \mathcal{E}^0 \to \mathcal{E}^1 \to \cdots$. The Čech class of a closed form is read off by the zig-zag $\omega = \mathrm{d}\alpha$, $\delta\alpha = \mathrm{d}\lambda$, $\delta\lambda = n$.	Betti numbers in Morse theory (Chapter 7); index of $\mathrm{d}+\mathrm{d}^*$ (Chapter 4)
complex manifold, (p,q)-forms, $\bar\partial$	Holomorphic transition functions split forms by type; $\partial_{\bar z} = \frac{1}{2}(\partial_x + i\partial_y)$; holomorphic $\iff \bar\partial f = 0$.	Dolbeault complex (Chapter 4), Riemann surfaces (Chapter 5, Chapter 9)
Dolbeault theorem	$H^q(M;\Omega^p) \cong H^{p,q}_{\bar\partial}(M)$, also with coefficients in a holomorphic bundle. Example: $H^{0,1}(T^2) = \mathbb{C}[\mathrm{d}\bar z]$, $\dim H^1(\mathbb{CP}^1;\mathcal{O}(n)) = \max(0,-n-1)$.	Riemann–Roch as an index (Chapter 4, Chapter 5); moduli of Riemann surfaces
line bundles $= H^1(M;\mathcal{E}^*)$; c_1	Transition functions g_{ij} form a 1-cocycle; $c_1 = [\delta\lambda]$, $\lambda_{ij} = \frac{i}{2\pi}\log g_{ij}$; de Rham image $[\frac{i}{2\pi}F]$.	monopoles (Chapter 8), determinant line bundle (Chapter 10)
Dirac quantisation	$2eg_m \in \mathbb{Z}$ is the cocycle condition on triple overlaps; $c_1 = 2eg_m$.	monopoles (Chapter 8)

Concept table II: K-theory and Bott periodicity (Nash §3–§4)

Concept	Operational meaning: how to compute or test it	Used later
vector bundle by transition functions	Matrices g_{ab} on overlaps with $g_{ab}g_{bc} = g_{ac}$; isomorphic if $g' = h_a g h_b^{-1}$. Examples: Möbius (± 1), Hopf (z), TS^2 (z^{-2}), monopole ($e^{in\phi}$).	everywhere: gauge fields are connections on bundles
$\oplus$, $\otimes$, dual, pullback	Block-diagonal, Kronecker product, inverse transpose, composition of the transition functions.	twisted operators (Chapter 4)
stable equivalence	$E \oplus I^j \cong F \oplus I^k$. Cancellation can fail: $TS^2 \oplus I \cong I^3$ but $TS^2 \not\cong I^2$. Every bundle over a compact base has a complement.	$\widetilde{K}$, stable classes
$K(X)$, $\widetilde{K}(X)$	Formal differences $[E] - [F]$ (Grothendieck group); every class is $[E] - [I^n]$; virtual dimension; $K = \widetilde{K} \oplus \mathbb{Z}$; ring under $\otimes$. $K(S^2) = \mathbb{Z}[H]/(H-1)^2$.	symbol class of an elliptic operator (Chapter 4); families (Chapter 10)
reduction of structure group	A fibre metric reduces $\mathrm{GL}(k)$ to $\mathrm{O}(k)$, $\mathrm{U}(k)$ or $\mathrm{Sp}(k)$ (polar decomposition), losing no topology.	unitary gauge groups; orthonormal frames
Grassmannian, classifying map	$x \mapsto E_x \subset \mathbb{C}^m$ (a projector Π_x); $E = f^*Q$; $\mathrm{Vect}_k(X) = [X, BU(k)]$, $BU(k) = \mathrm{Gr}(k, \infty)$.	definition of characteristic classes (Section 3.15)
stable range	If $k > \dim X$ (real), a generic section never vanishes, so $E_k \cong F \oplus I^{k-n}$ and $\mathrm{Vect}_k = \widetilde{K}$.	dimension counts in Chapter 8
clutching	A bundle over S^n = a map $g : S^{n-1} \to G$ up to homotopy: $\mathrm{Vect}_k(S^n) = \pi_{n-1}(G)$. c_1 = winding of $g : S^1 \to \mathrm{U}(1)$; c_2 = degree of $g : S^3 \to \mathrm{SU}(2)$.	instanton number (Chapter 8); global anomalies (Chapter 10)
tables $\widetilde{K}(S^n)$	$\widetilde{KU}$: $\mathbb{Z}, 0, \mathbb{Z}, 0, \ldots$ $\widetilde{KO}$: $\mathbb{Z}, \mathbb{Z}_2, \mathbb{Z}_2, 0, \mathbb{Z}, 0, 0, 0$ (n mod 8) $\widetilde{KSp}(S^n) = \widetilde{KO}(S^{n+4})$.	mod-2 indices, Witten's SU(2) anomaly ($\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$)
Bott periodicity	$\Omega^2 \mathrm{U} \simeq \mathrm{U}$, so $\widetilde{KU}^{-n}(X) \cong \widetilde{KU}^{-n-2}(X)$, implemented by multiplication with $b = [H] - 1$. Real: eight loop spaces, or Clifford modules.	Thom isomorphism and proof of the index theorem (Chapter 4); loop groups (Chapter 6)
K^{-n}, external product	$\widetilde{K}^{-n}(X) = \widetilde{K}(S^n X)$; $K^{-1}(X) = [X, \mathrm{U}]$; $\pi_X^* a \cdot \pi_Y^* b$ builds classes on products.	families index, spectral flow (K^{-1})

Concept table III: characteristic classes (Nash §5)

Concept	Operational meaning: how to compute or test it	Used later
Chern classes $c_i(E) \in H^{2i}(X;\mathbb{Z})$	Pull back the generators of $H^*(BU(k)) = \mathbb{Z}[c_1,\dots,c_k]$ by the classifying map (Section 3.15). Naturality, Whitney $c(E\oplus F) = c(E)c(F)$, $\int_{\mathbb{CP}^1} c_1(\text{taut.}) = -1$.	every index formula (Chapter 4)
Chern–Weil forms	$c(F) = \det\big(1 + \frac{i}{2\pi}F\big)$; $c_1 = \frac{i}{2\pi}\operatorname{tr} F$, $c_2 = \frac{1}{8\pi^2}(\operatorname{tr}F^2 - \operatorname{tr}F\wedge\operatorname{tr}F)$. Closed by Bianchi; class independent of A by transgression (Section 3.16).	instanton number $k = \int c_2$ (Chapter 8)
Chern–Simons form	$\operatorname{tr}F^2 = \mathrm{d}\,\operatorname{tr}(A\,\mathrm{d}A + \frac{2}{3}A^3)$. Under a large gauge transformation it shifts by $-\frac{1}{3}\operatorname{tr}(g^{-1}\mathrm{d}g)^3$, a winding number.	secondary classes (Chapter 8); descent and anomalies (Chapter 10); CS theory (Chapter 12)
splitting principle, Chern roots	Pretend $E = L_1\oplus\cdots\oplus L_k$: $c(E) = \prod(1+x_i)$, $c_j = \sigma_j(x)$. With curvature, the x_i are the eigenvalues of $\frac{i}{2\pi}F$ (Section 3.17). Newton: $s_2 = c_1^2 - 2c_2$.	every multiplicative class below
Chern character ch	$\operatorname{ch}E = \sum e^{x_i} = \operatorname{tr}e^{iF/2\pi} = k + c_1 + \frac{1}{2}(c_1^2 - 2c_2) + \dots$; additive and multiplicative, so a ring map $K(X)\to H^{\text{even}}(X;\mathbb{Q})$; blind to torsion (Section 3.18).	the "bundle" factor in every index formula; anomaly polynomial
Todd class td	$\prod \frac{x_i}{1-e^{-x_i}} = 1 + \frac{c_1}{2} + \frac{c_1^2+c_2}{12} + \frac{c_1c_2}{24} + \dots$; Todd genus of $\mathbb{CP}^n$ is 1.	Riemann–Roch–Hirzebruch (Chapter 4, Chapter 5)
dual, conjugate, line bundle group	E^*: $(g^{-1})^T$; $\bar{E}$: $\bar{g}$; equal for unitary g; $c_j(E^*) = (-1)^j c_j(E)$. Line bundles under $\otimes$: c_1 identifies them with $H^2(X;\mathbb{Z})$ (Section 3.19).	antiparticles, charge conjugation; Chapter 5
complexification, realification	$V_{\mathbb{C}} = V\otimes_{\mathbb{R}}\mathbb{C} \cong \bar{V}_{\mathbb{C}}$; $E_r\otimes\mathbb{C}\cong E\oplus\bar{E}$ (the $\pm i$ eigenspaces of J).	real families, mod-2 indices
Pontryagin classes $p_i \in H^{4i}$	$p_i(V) = (-1)^i c_{2i}(V_{\mathbb{C}})$; $p(\Omega) = \det(1+\Omega/2\pi)$; roots $\pm x_i$, $p_j = \sigma_j(x^2)$; $p(TS^n) = 1$, $p(T\mathbb{CP}^n) = (1+h^2)^{n+1}$; for complex E: $p_1 = c_1^2 - 2c_2$.	gravitational anomalies (Chapter 10); framing in Chapter 12
Euler class e	$e(V) = \operatorname{Pf}(\Omega/2\pi)$ for oriented even rank; $e^2 = p_{top}$; $e(E_r) = c_{top}(E)$; $\int e$ counts zeros of a section with signs (Section 3.20).	Poincaré–Hopf in Morse theory (Chapter 7); Gauss–Bonnet as an index (Chapter 4)
Gauss–Bonnet–Chern	$\chi(M) = \int_M \operatorname{Pf}(\Omega/2\pi)$; $\chi(S^2) = 2$, $\chi(\Sigma_g) = 2-2g$, $\chi(S^4) = 2$, $\chi(\mathbb{CP}^n) = n+1$.	string genus expansion (Chapter 9); Chapter 4
$\hat{A}$ and L	$\hat{A} = \prod \frac{x_i/2}{\sinh(x_i/2)} = 1 - \frac{p_1}{24} + \frac{7p_1^2-4p_2}{5760}$; $L = \prod \frac{x_i}{\tanh x_i} = 1 + \frac{p_1}{3} + \frac{7p_2-p_1^2}{45}$; $\operatorname{td} = e^{c_1/2}\hat{A}$; $\sigma(M) = \int L$.	Dirac index, Hirzebruch signature (Chapter 4); Donaldson (Chapter 12)

Concept table IV: Fredholm operators and $K(X)$ (Nash §6)

Concept	Operational meaning: how to compute or test it	Used later
Fredholm operator, index	Bounded T with finite-dimensional kernel and cokernel; index $T = \dim \operatorname{Ker} T - \dim \operatorname{Ker} T^*$. Count zero modes of T and of $T^\dagger$ (Section 3.21).	Chapter 4 throughout
shift, ladder, Toeplitz	index $S = -1$; index $a = +1$ (so no unitary phase operator); index $T_f = -\operatorname{wind}(f)$: the first index theorem.	loop groups and Fock space (Chapter 6)
stability	Nonzero modes of T^*T and TT^* pair up; near T everything reduces to a finite matrix $\operatorname{Ker} T \to \operatorname{Coker} T$ (Schur complement). Index is locally constant, homotopy invariant, blind to compact perturbations; index ST = index S + index T.	heat-kernel proof, Witten index (Chapter 4, Chapter 7)
Atkinson, parametrix	Fredholm $\iff$ invertible modulo compacts. Elliptic operators have a parametrix built from the inverse symbol, so they are Fredholm.	Chapter 2 → Chapter 4
index bundle	Add $\mathbb{C}^N$ to kill all cokernels; kernels then form a bundle K; index $T = [K] - [\mathbb{C}^N] \in K(X)$.	families index theorem; determinant line (Chapter 10)
Atiyah–Jänich, Kuiper	$[X, \mathcal{F}] \cong K(X)$; $\mathrm{GL}(H)$ is contractible (Eilenberg swindle), so only zero-mode data carries topology; $\mathcal{F} \simeq \mathbb{Z} \times BU$.	anomalies from a Hamiltonian view (Chapter 10)
spectral flow	Net number of eigenvalues crossing 0 along a loop of self-adjoint Fredholm operators; e.g. $D_A = -i\partial_\theta + A$, $A : 0 \to 1$, flow +1.	level crossing and anomalies (Chapter 10); Floer theory (Chapter 12)

The formula sheet: every class from one generating function

Most of §5 is one idea: choose a power series $Q(x)$, and define a class by $\prod_i Q(x_i)$ over the Chern roots (or over the roots $\pm x_i$ of a real bundle). The following table collects them, together with the first terms we derived and the curvature formula that computes them from a gauge field.

Class	Roots	First terms	From curvature
c	$\prod(1 + x_i)$	$1 + c_1 + c_2 + \dots$	$\det\big(1 + \frac{i}{2\pi}F\big)$
ch	$\sum e^{x_i}$	$k + c_1 + \frac{1}{2}(c_1^2 - 2c_2) + \frac{1}{6}(c_1^3 - 3c_1c_2 + 3c_3)$	$\operatorname{tr} \exp \frac{iF}{2\pi}$
td	$\prod \frac{x_i}{1-e^{-x_i}}$	$1 + \frac{1}{2}c_1 + \frac{1}{12}(c_1^2 + c_2) + \frac{1}{24}c_1c_2$	$\det \frac{iF/2\pi}{1-e^{-iF/2\pi}}$
p	$\prod(1 + x_i^2)$	$1 + p_1 + p_2 + \dots$	$\det\big(1 + \frac{\Omega}{2\pi}\big)$
e	$\prod x_i$ (half the roots)	top degree only	$\operatorname{Pf}\big(\frac{\Omega}{2\pi}\big)$
$\hat{A}$	$\prod \frac{x_i/2}{\sinh(x_i/2)}$	$1 - \frac{p_1}{24} + \frac{7p_1^2 - 4p_2}{5760}$	$\det{}^{1/2} \frac{i\Omega/4\pi}{\sinh(i\Omega/4\pi)}$
L	$\prod \frac{x_i}{\tanh x_i}$	$1 + \frac{p_1}{3} + \frac{7p_2 - p_1^2}{45}$	$\det{}^{1/2} \frac{i\Omega/2\pi}{\tanh(i\Omega/2\pi)}$

In the last three rows the matrix functions are defined by their power series, and the square root of a determinant of an even power series in Ω is unambiguous term by term. For a real bundle, Ω is the $\mathfrak{so}(k)$-valued curvature in an orthonormal frame. Viewed as a complex matrix it is anti-Hermitian, so $\frac{i}{2\pi}\Omega$ has real eigenvalues $\pm x_j$: these are the roots, exactly as $\frac{i}{2\pi}F$ supplies the Chern roots of a complex bundle. (This is why an i appears inside $\hat{A}$ and L; without it

sinh would turn into sin and the sign of p_1 would flip.) The sign conventions are fixed in Sections 3.19 and 3.20.

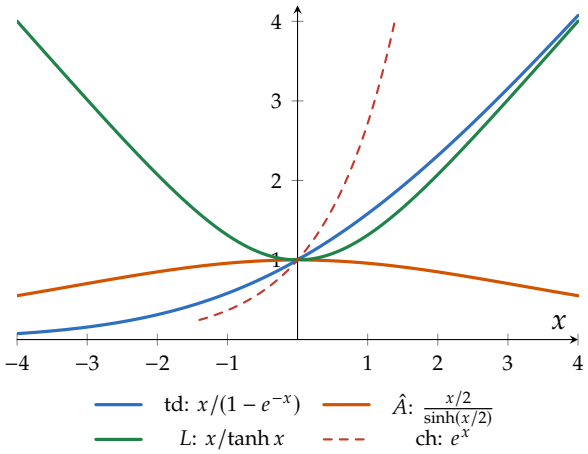

Figure 3.88: The four generating functions of §5, drawn as functions of one Chern root. All equal 1 at $x = 0$, which is why each class starts with 1 (or with the rank, for ch). $\hat{A}$ and L are *even* (orange and green are symmetric), so they involve only x^2: they are Pontryagin classes of a real bundle. The Todd function is not even; its odd part $x/2$ is exactly the factor $e^{c_1/2}$ in $\mathrm{td} = e^{c_1/2}\hat{A}$, and indeed $\frac{x}{1-e^{-x}} = e^{x/2}\frac{x/2}{\sinh(x/2)}$.

We verify the identity quoted in the caption, since it is the bridge between the two index formulas of Chapter 4:

$$e^{x/2}\,\frac{x/2}{\sinh(x/2)} \overset{(1)}{=} e^{x/2}\,\frac{x/2}{\frac{1}{2}\left(e^{x/2}-e^{-x/2}\right)} \overset{(2)}{=} \frac{x\,e^{x/2}}{e^{x/2}\left(1-e^{-x}\right)} = \frac{x}{1-e^{-x}}.$$

(1) The definition $\sinh u = \frac{1}{2}(e^u - e^{-u})$ with $u = x/2$.

(2) Cancel the factors $\frac{1}{2}$, and factor $e^{x/2}$ out of the bracket: $e^{x/2} - e^{-x/2} = e^{x/2}(1 - e^{-x})$.

Taking the product over the roots gives $\mathrm{td}(E) = e^{c_1(E)/2}\,\hat{A}(E)$, because $\prod_i e^{x_i/2} = e^{\sum_i x_i/2} = e^{c_1/2}$. (Here $\hat{A}(E)$ means the same product over the complex roots x_i, which for $E = TM$ of a complex manifold is the $\hat{A}$ of the underlying real bundle.)

The test cases: numbers to check any formula against

The same handful of spaces appeared in every section. Here are their invariants, all computed in this chapter; h is the hyperplane class, with $\int_{\mathbb{CP}^n} h^n = 1$. Any new formula should be checked against this table before it is trusted.

Space	**Classes of** TM	χ	σ	$\int \mathrm{td}$	$\int \hat{A}$
$S^2 = \mathbb{CP}^1$	$c = 1 + 2h, \quad e = c_1$	2	–	1	0
T^2	$c = 1$ (trivial tangent bundle)	0	–	0	0
Σ_g	$\int c_1 = 2 - 2g$	$2-2g$	–	$1-g$	0
S^4	$p = 1$ (stably trivial), $\int e = 2$	2	0	–	0
$\mathbb{CP}^2$	$c = (1+h)^3$, $p = (1+h^2)^3$, $p_1 = 3h^2$	3	1	1	$-\frac{1}{8}$
K3	$c_1 = 0$, $\int c_2 = 24$, $\int p_1 = -48$	24	−16	2	2

Three checks the table passes. (i) On a complex surface $\chi = \int c_2$ (the Euler class is the top Chern class): 3 for $\mathbb{CP}^2$, 24 for K3. (ii) $\sigma = \int L_1 = \frac{1}{3}\int p_1$: $\frac{3}{3} = 1$ and $-\frac{48}{3} = -16$. (iii) On a

4-manifold $\int \hat{A} = -\frac{1}{24}\int p_1 = -\frac{\sigma}{8}$: $-\frac{1}{8}$ for $\mathbb{CP}^2$ (not an integer, because $\mathbb{CP}^2$ is not spin, so this number is not the index of any Dirac operator) and 2 for K3. The Todd genus of a Riemann surface, $\int \frac{c_1}{2} = 1 - g$, is Riemann–Roch for the trivial bundle: $\dim H^0(\mathcal{O}) - \dim H^1(\mathcal{O}) = 1 - g$.

And two bundles that are not tangent bundles:

- the *monopole* bundle L_n over S^2: $c_1(L_n) = nu$ with $\int_{S^2} u = 1$, $\mathrm{ch}(L_n) = 1 + nu$, and index $\bar{\partial}_{L_n} = \int \mathrm{ch}(L_n)\,\mathrm{td}(TS^2) = n + 1$; the tautological (Hopf) bundle has $\int c_1 = -1$;
- the *instanton* bundle over S^4 clutched by $g(x) = (x_4 + i\vec{x}\cdot\vec{\sigma})/|x|$: $c_1 = 0$, $\int c_2 = 1$ in the orientation of Section 3.16, $\mathrm{ch} = 2 - c_2$, and the Dirac index formula $\int \mathrm{ch}\,\hat{A}(TS^4) = -\int c_2$ (as $\hat{A}(TS^4) = 1$), whose absolute value $|k|$ counts the chiral zero modes of the fundamental fermion in the instanton background (Chapter 8).

What the later chapters take from this one

- **Chapter 4 (index theory)** uses almost everything: the symbol of an elliptic operator defines a class in K-theory (§3), Bott periodicity gives the Thom isomorphism that turns it into a number (§4), the Chern character and the Todd and $\hat{A}$ classes write the answer as an integral (§5), and Fredholm theory (§6) makes the analytical index well defined and homotopy invariant. The de Rham, Dolbeault, signature and spin complexes give Gauss–Bonnet–Chern, Riemann–Roch–Hirzebruch, the signature theorem and the $\hat{A}$ theorem, each already met here as a characteristic-class identity.
- **Chapter 5 (algebraic geometry)** uses sheaves of holomorphic sections, $H^1(M;\mathcal{O}^*)$ as the Picard group, divisors via the exponential sequence, and Dolbeault cohomology for Serre duality and Riemann–Roch on Riemann surfaces.
- **Chapter 6 (infinite-dimensional groups)** uses Bott's $\Omega\mathrm{U} \simeq \mathbb{Z}\times BU$, Fredholm and Toeplitz operators on the Hardy space, and c_1 of line bundles for central extensions.
- **Chapter 7 (Morse theory)** uses de Rham cohomology (Betti numbers), Poincaré–Hopf (zeros of sections count χ), and the pairing of nonzero modes behind the Witten index.
- **Chapter 8 (instantons and monopoles)** uses clutching ($\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$), c_2 as the instanton number, c_1 as the monopole charge, and the Chern–Simons form as a secondary characteristic class.
- **Chapter 9 (the elliptic geometry of strings)** uses Riemann surfaces, holomorphic line bundles, Gauss–Bonnet and the Riemann–Roch count of moduli.
- **Chapter 10 (anomalies)** uses the Chern character and $\hat{A}$ in the anomaly polynomial, the Chern–Simons transgression for the descent equations, the index bundle and determinant line of a family of Dirac operators, $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$ for the global anomaly, and spectral flow for the Hamiltonian picture.
- **Chapter 12 (topological field theories)** uses the Chern–Simons functional and its behaviour under large gauge transformations, p_1 and framings, and spectral flow in Floer theory.

Recap: The chapter in five sentences

- Local data glue into global objects with a twist; sheaf cohomology counts the twists, and de Rham and Dolbeault compute it with forms.

- Bundles modulo trivial ones form the ring $K(X)$; over spheres it is a homotopy group of a Lie group, and it repeats with period 2 (or 8).
- Invariant polynomials of the curvature give closed forms whose classes do not depend on the gauge field: c, ch, td, p, e, $\hat{A}$, L, all from generating functions of the Chern roots.
- A family of Fredholm operators has an index in $K(X)$, and every K-class arises this way.
- The index theorem (next chapter) says that the number of zero modes is an integral of characteristic classes.

Chapter 4

Index Theory for Elliptic Operators

Where this chapter is going

A physicist meets the index long before meeting the word. Count the zero modes of a Dirac operator in an instanton background: so many of left-handed chirality, so many of right-handed. Each number separately depends on the details of the gauge field and jumps when we deform it. The *difference* does not. It is an integer that stays put under every smooth deformation, so it must be computable from topology alone. That integer is the **index**, and this chapter is about the theorem of Atiyah and Singer which says exactly how to compute it.

The chapter has a simple logical spine. First we define the index analytically: solve the equation $D\psi = 0$, count solutions, subtract the count for the adjoint equation. Then we notice that this integer depends only on the *leading symbol* of D, a matrix-valued function on phase space T^*X, and only on it up to deformation. Deformation classes of such symbols form a K-theory group $K(T^*X)$. Next we build a second, purely topological integer out of the same symbol class, using embeddings and the Thom isomorphism. The Atiyah–Singer theorem says the two integers agree. The rest of the chapter (§2 onward in Nash) turns the topological side into a formula with characteristic classes, works out the classical examples (Gauss–Bonnet, signature, Riemann–Roch, the Dirac operator), and extends the theorem to families of operators, group actions and fixed points, and manifolds with boundary. Those extensions are exactly what the later physics chapters use: anomalies, the dimension of instanton moduli spaces, moduli of Riemann surfaces and supersymmetric quantum mechanics.

This first part covers Nash's §1. Because Nash is extremely terse here (nine pages which quote rather than explain), we also build the ground floor: finite-dimensional linear algebra, Fredholm operators, explicit operators on the circle, and the heat-kernel formula which is how most physicists actually meet the index theorem.

4.1 Counting solutions: the index of a linear map

Here is the question that starts the whole subject. We have a linear equation $Au = f$. How many solutions does it have, and for which f can it be solved at all? The first question is answered by the kernel of A, the second by its cokernel. Both answers depend delicately on A. We will find a combination of the two that does not, and see that it survives the passage to infinite dimensions, where the differential operators live.

4.1.1 Kernel, image, cokernel

Let $A\colon V \to W$ be a linear map between vector spaces.

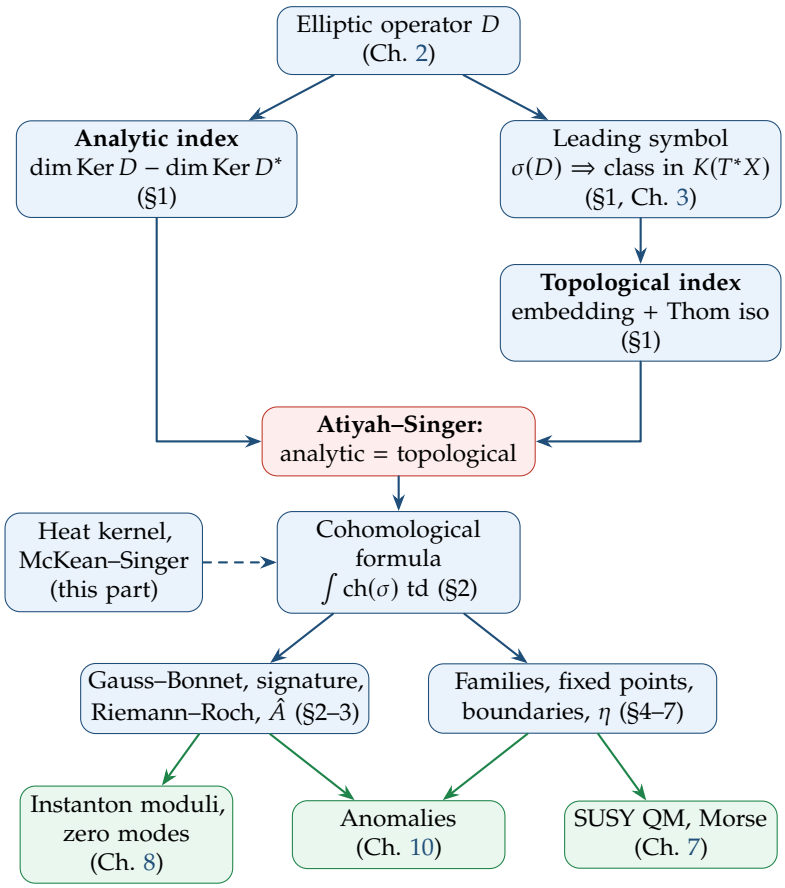

Figure 4.1: The logic of Chapter 4. Two roads leave the elliptic operator D: counting solutions (left) and looking only at the symbol (right). The Atiyah–Singer theorem is the statement that they arrive at the same integer. Everything below the red box is about computing that integer and using it in physics (green).

Working definition 4.1 (kernel, image, cokernel)

- The **kernel** $\operatorname{Ker} A = \{v \in V : Av = 0\}$ is the space of solutions of the homogeneous equation [$Au = f$ with $f = 0$]. Its dimension counts independent solutions ("zero modes").
- The **image** $\operatorname{Im} A = \{Av : v \in V\} \subset W$ is the set of right-hand sides f for which $Au = f$ can be solved.
- The **cokernel** $\operatorname{Coker} A = W/\operatorname{Im} A$ [two vectors of W count as the same if they differ by some Av] measures what is missing from the image. Its dimension counts independent *obstructions* to solving $Au = f$.

Operational test. Write A as a matrix. Then $\dim \operatorname{Ker} A$ is the number of columns minus the rank [the number of linearly independent columns], and $\dim \operatorname{Coker} A$ is the number of rows minus the rank.

The cokernel is a quotient, which is awkward to picture. When W has an inner product there is a concrete stand-in. A vector w is orthogonal to the whole image exactly when

$$0 = \langle w, Av\rangle \ \ \forall v \overset{(1)}{=} \langle A^* w, v\rangle \ \ \forall v \\ \iff A^* w = 0.$$

(1) Definition of the adjoint A^* (the conjugate transpose, for matrices).

So $(\operatorname{Im} A)^\perp = \operatorname{Ker} A^*$, and since $W = \operatorname{Im} A \oplus (\operatorname{Im} A)^\perp$,

$$\operatorname{Coker} A \ \cong\ (\operatorname{Im} A)^\perp \ =\ \operatorname{Ker} A^*. \tag{4.1}$$

The obstructions to solving $Au = f$ are the zero modes of the adjoint equation. This is the "Fredholm alternative" familiar from Green's function problems: $Au = f$ is solvable if and only if f is orthogonal to every solution of $A^* w = 0$.

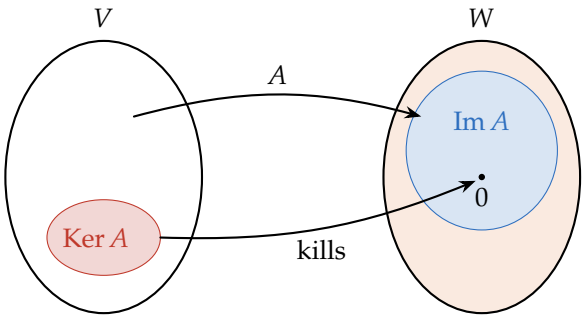

Figure 4.2: A linear map $A\colon V \to W$. The red blob $\operatorname{Ker} A$ is crushed to 0. The image (blue) is where A lands; the part of W outside it (orange) is the cokernel, the directions in which $Au = f$ has no solution.

4.1.2 The index in finite dimensions

Suppose V and W are finite-dimensional. The rank–nullity theorem says $\dim V = \dim \operatorname{Ker} A + \dim \operatorname{Im} A$ (every direction in V is either killed or survives into the image). Then

$$\dim \operatorname{Ker} A - \dim \operatorname{Coker} A \overset{(1)}{=} \dim \operatorname{Ker} A - \big(\dim W - \dim \operatorname{Im} A\big)$$

$$\overset{(2)}{=} \big(\dim \operatorname{Ker} A + \dim \operatorname{Im} A\big) - \dim W$$
$$\overset{(3)}{=} \dim V - \dim W. \tag{4.2}$$

(1) $\operatorname{Coker} A = W/\operatorname{Im} A$, and the dimension of a quotient is the difference of dimensions.
(2) Rearrange.
(3) Rank–nullity.

Working definition 4.2 (index of a linear map)

The **index** of $A\colon V \to W$ is

$$\operatorname{index} A \coloneqq \dim \operatorname{Ker} A - \dim \operatorname{Coker} A \;=\; \dim \operatorname{Ker} A - \dim \operatorname{Ker} A^{*}.$$

[A^{*} is the conjugate-transpose matrix. $A^{*}w = 0$ exactly when w is orthogonal to every Av].
In finite dimensions it equals $\dim V - \dim W$, *whatever* A *is*.

This is the whole philosophy of the chapter in miniature. The two numbers $\dim \operatorname{Ker} A$ and $\dim \operatorname{Coker} A$ depend on the fine details of A. Their difference depends only on the "shape" of the problem: the number of unknowns minus the number of equations. A physicist would call it a counting of degrees of freedom: unknowns minus constraints.

Worked example 4.1: A family of 2×3 matrices

Let $A_\varepsilon\colon \mathbb{C}^3 \to \mathbb{C}^2$ be

$$A_\varepsilon = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \varepsilon & 0 \end{pmatrix}.$$

For $\varepsilon \neq 0$ the two rows are independent, so the rank is 2. For $\varepsilon = 0$ the second row vanishes and the rank is 1. Hence

$$\varepsilon \neq 0: \quad \operatorname{index} A_\varepsilon \overset{(1)}{=} (3-2) - (2-2) = 1 - 0 = 1,$$
$$\varepsilon = 0: \quad \operatorname{index} A_0 \overset{(1)}{=} (3-1) - (2-1) = 2 - 1 = 1.$$

(1) $\dim \operatorname{Ker} = \#\text{columns} - \operatorname{rank}$ and $\dim \operatorname{Coker} = \#\text{rows} - \operatorname{rank}$.

Explicitly, for $\varepsilon \neq 0$ the kernel is spanned by $(0, 0, 1)$ and the map is onto. At $\varepsilon = 0$ the kernel gains $(0, 1, 0)$ and the image loses the direction $(0, 1)$. A zero mode and an obstruction appear *together*, so the index stays $1 = 3 - 2$. See Figure 4.3.

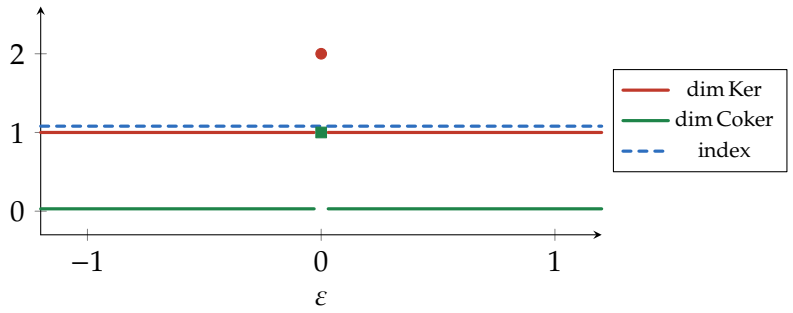

Figure 4.3: The 2×3 family A_ε of the worked example above: as ε passes through 0, $\dim \operatorname{Ker} A_\varepsilon$ (red) jumps from 1 to 2 and $\dim \operatorname{Coker} A_\varepsilon$ (green) from 0 to 1 at the same moment. The index (blue, dashed, drawn slightly offset for visibility) never moves.

Try it: Square matrices

Show that every square matrix has index 0, and find a 2×2 family B_ε whose kernel is 0 for $\varepsilon \neq 0$ and one-dimensional at $\varepsilon = 0$.
Answer. $\dim V = \dim W$, so the index is 0 by (4.2). Take $B_\varepsilon = \operatorname{diag}(\varepsilon, 1)$: at $\varepsilon = 0$ the kernel is spanned by $(1, 0)$ and the cokernel by $(1, 0)$.

4.1.3 Why the index cannot jump: reduction to a finite matrix

In finite dimensions the stability of the index is trivial, because it equals $\dim V - \dim W$. In infinite dimensions that formula is $\infty - \infty$ and means nothing. We need an argument for stability that does not use it. The argument below is worth understanding, because it is the real reason the index of a differential operator is stable. It shows that under a small perturbation, everything interesting happens inside a *finite* matrix.

Let $T\colon H_1 \to H_2$ be a linear map with finite-dimensional kernel $K_1 = \operatorname{Ker} T$ and finite-dimensional cokernel, and suppose the image $R = \operatorname{Im} T$ is closed. Let $C = R^\perp \cong \operatorname{Coker} T$. Split both spaces:

$$H_1 = K_1^\perp \oplus K_1, \qquad H_2 = R \oplus C.$$

In these splittings T is block diagonal,

$$T = \begin{pmatrix} T_0 & 0 \\ 0 & 0 \end{pmatrix}, \qquad T_0\colon K_1^\perp \to R \text{ invertible},$$

because T kills K_1, lands in R, and is one-to-one and onto from the complement of its kernel to its image. Now perturb: $P = T + \varepsilon B$ with B bounded. In blocks,

$$P = \begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} T_0 + \varepsilon B_{11} & \varepsilon B_{12} \\ \varepsilon B_{21} & \varepsilon B_{22} \end{pmatrix}.$$

For small ε the corner $a = T_0 + \varepsilon B_{11}$ is still invertible (a small perturbation of an invertible operator is invertible: the geometric series $(T_0 + \varepsilon B_{11})^{-1} = T_0^{-1} \sum_n (-\varepsilon B_{11} T_0^{-1})^n$ converges). Then Gaussian elimination in blocks gives

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} \overset{(1)}{=} \begin{pmatrix} 1 & 0 \\ c\,a^{-1} & 1 \end{pmatrix} \begin{pmatrix} a & 0 \\ 0 & d - c\,a^{-1} b \end{pmatrix} \begin{pmatrix} 1 & a^{-1} b \\ 0 & 1 \end{pmatrix}. \tag{4.3}$$

(1) Multiply out the right-hand side: the middle and right factors give $\begin{pmatrix} a & b \\ 0 & d - c a^{-1} b \end{pmatrix}$, and the left factor adds $c a^{-1}$ times the first row to the second, producing $\begin{pmatrix} a & b \\ c & d \end{pmatrix}$.

The outer factors are invertible (triangular with 1's on the diagonal), and invertible factors do not change the dimension of kernel or cokernel. The middle factor is block diagonal with an invertible block a and the **Schur complement**

$$S := d - c\,a^{-1} b\colon K_1 \to C,$$

a map between *finite-dimensional* spaces. Therefore

$$\begin{aligned} \operatorname{index}(T + \varepsilon B) &\overset{(1)}{=} \operatorname{index} a + \operatorname{index} S \\ &\overset{(2)}{=} 0 + \big(\dim K_1 - \dim C\big) \\ &\overset{(3)}{=} \dim \operatorname{Ker} T - \dim \operatorname{Coker} T = \operatorname{index} T. \end{aligned} \tag{4.4}$$

(1) Use (4.3); kernels and cokernels of a block diagonal map are direct sums of those of the blocks.
(2) a is invertible, so its index is 0; S is a map between finite-dimensional spaces, so (4.2) applies.
(3) Definitions $K_1 = \operatorname{Ker} T$ and $C \cong \operatorname{Coker} T$.

Key idea: Stability of the index

Under a small perturbation, the zero modes of T and of T^* can only interact with each other through the finite matrix $S\colon \operatorname{Ker} T \to \operatorname{Coker} T$. The kernel of S may be anything from 0 to $\dim \operatorname{Ker} T$, so $\dim \operatorname{Ker}$ can drop. But whenever a zero mode is lost, an obstruction is lost with it: the index of S is fixed at $\dim \operatorname{Ker} T - \dim \operatorname{Coker} T$.

Worked example 4.2: Watching a pair of zero modes lift

Take $H_1 = H_2 = \mathbb{C}^3$ and $T = \operatorname{diag}(1, 0, 0)$, so $\operatorname{Ker} T$ is spanned by e_2, e_3 and $\operatorname{Coker} T$ by e_2, e_3 as well. Perturb with

$$P_\varepsilon = \begin{pmatrix} 1 & \varepsilon & 0 \\ \varepsilon & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Here $a = 1$, $b = (\varepsilon, 0)$, $c = (\varepsilon, 0)^T$, $d = 0$, so

$$S = d - c\,a^{-1}b \overset{(1)}{=} -\begin{pmatrix} \varepsilon \\ 0 \end{pmatrix}\begin{pmatrix} \varepsilon & 0 \end{pmatrix} = \begin{pmatrix} -\varepsilon^2 & 0 \\ 0 & 0 \end{pmatrix}.$$

(1) $a^{-1} = 1$ and $d = 0$; the product of a column and a row is a 2×2 matrix.

For $\varepsilon \neq 0$, S has a one-dimensional kernel and a one-dimensional cokernel: one zero mode of T and one obstruction of T have "paired up" and left zero together. The index is 0 before and after. Directly: $\det P_\varepsilon$ restricted to the first two coordinates is $-\varepsilon^2 \neq 0$, so $\operatorname{Ker} P_\varepsilon$ is spanned by e_3 alone, and so is its cokernel.

4.1.4 Infinite dimensions: Fredholm operators and the shift

In finite dimensions every index is $\dim V - \dim W$, which is boring. Infinite dimensions are where the index becomes interesting, because now a map from a space to *itself* can have nonzero index.

Working definition 4.3 (Fredholm operator)

A bounded operator [$\|Tv\| \le C\|v\|$ for one constant C] $T\colon H_1 \to H_2$ between Hilbert spaces is **Fredholm** if $\operatorname{Ker} T$ and $\operatorname{Coker} T$ are finite-dimensional (finite dimensionality of the cokernel forces $\operatorname{Im} T$ to be closed [a limit of vectors Tv_n is again of the form Tv]). Its index is $\operatorname{index} T = \dim \operatorname{Ker} T - \dim \operatorname{Coker} T = \dim \operatorname{Ker} T - \dim \operatorname{Ker} T^*$. *Operational test:* T is Fredholm if it is invertible "up to finite-rank errors": there is Q with $QT - 1$ and $TQ - 1$ of finite rank [with finite-dimensional image] (or, more generally, compact [norm limits of finite-rank operators, see below]).

Worked example 4.3: The shift operator: Hilbert's hotel

Let $H = \ell^2$, the square-summable sequences $(x_0, x_1, x_2, \dots)$, with orthonormal basis $e_0, e_1, e_2, \dots$. The **shift** is

$$Se_n = e_{n+1}, \qquad S(x_0, x_1, x_2, \dots) = (0, x_0, x_1, \dots).$$

Its adjoint shifts back: $\langle e_m, Se_n \rangle = \delta_{m,n+1}$, so $S^* e_n = e_{n-1}$ for $n \geq 1$ and $S^* e_0 = 0$. Now

$$\operatorname{index} S \overset{(1)}{=} \dim \operatorname{Ker} S - \dim \operatorname{Ker} S^* \overset{(2)}{=} 0 - 1 = -1.$$

(1) Definition, with $\operatorname{Coker} S \cong \operatorname{Ker} S^*$ by (4.1).

(2) $Sx = 0$ forces every $x_n = 0$; $S^* x = 0$ forces $x_1 = x_2 = \cdots = 0$ and leaves x_0 free, so $\operatorname{Ker} S^* = \mathbb{C} e_0$.

In the same way $\operatorname{index} S^* = +1$ and $\operatorname{index} S^k = -k$. The operator S is a map from ℓ^2 to itself, yet its index is not zero: "unknowns minus equations" is $\infty - \infty$, and the shift makes that difference -1.

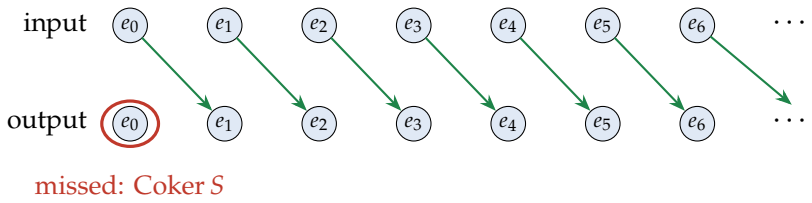

Figure 4.4: The shift S moves every basis vector one step to the right, like guests in Hilbert's hotel each moving to the next room. Nothing is killed ($\operatorname{Ker} S = 0$), but room e_0 is left empty ($\operatorname{Coker} S = \mathbb{C} e_0$), so $\operatorname{index} S = -1$.

4.1.5 Compact perturbations do not change the index

Nash says (p. 89) that the index is "stable under perturbations of the operator by a compact operator". Let us say what that means and why it is true.

Working definition 4.4 (compact operator)

An operator K is **compact** if it is a norm limit [$\|K - K_n\| \to 0$, i.e. the largest stretching $\max_{\|v\|=1} \|(K - K_n)v\|$ goes to 0] of finite-rank operators. *Operational test:* in a suitable orthonormal basis, K is (close to) a matrix whose entries die off, such as $\operatorname{diag}(1, \frac{1}{2}, \frac{1}{3}, \dots)$. Compact operators squash all but finitely many directions to almost nothing.

Two facts, both plausible from the finite-rank case, do the job:

1. If T is Fredholm and K is compact, $T + K$ is Fredholm. (A compact perturbation spoils invertibility-up-to-compacts by only a compact amount.)
2. The index is locally constant on Fredholm operators. This is exactly (4.4).

Now join T to $T + K$ by the straight path $T + sK$, $s \in [0, 1]$. Every operator on the path is Fredholm by fact 1. The index is an integer that is locally constant along the path by fact 2, so it is constant:

$$\operatorname{index}(T + K) = \operatorname{index} T \qquad (K \text{ compact}). \tag{4.5}$$

The same argument shows that the index is constant along *any* continuous path of Fredholm operators. That is the precise sense in which the index is a topological invariant: it labels the connected components of the space of Fredholm operators.

Worked example 4.4: A rank-one perturbation of the shift

Let K be the rank-one operator $Ke_0 = -e_1$, $Ke_n = 0$ for $n \geq 1$. Then $(S+K)e_0 = e_1 - e_1 = 0$ and $(S+K)e_n = e_{n+1}$ for $n \geq 1$. So

$$\begin{aligned} \operatorname{index}(S+K) &\overset{(1)}{=} \dim \operatorname{span}\{e_0\} - \dim \operatorname{span}\{e_0, e_1\} \\ &= 1 - 2 = -1 = \operatorname{index} S. \end{aligned}$$

(1) e_0 is now killed, and the image is spanned by $e_2, e_3, \ldots$, which misses both e_0 and e_1.

Both the kernel and the cokernel grew by one; the index did not move.

Physical picture: Zero modes come and go in pairs

Think of $\operatorname{Ker} T$ as the zero modes of a "left-handed" sector and $\operatorname{Ker} T^*$ as those of a "right-handed" sector. A perturbation can give a mass to a left-handed zero mode only by pairing it with a right-handed one, just as a Dirac mass term $m\bar{\psi}_L\psi_R$ needs both chiralities. The unpaired zero modes are protected. The index counts them. We will see in Section 4.8 that this is literally the supersymmetric pairing of nonzero modes.

Reading Nash (p. 89, (4.1))

Nash opens the chapter with $\operatorname{index} O = \dim \operatorname{Ker} O - \dim \operatorname{Coker} O$ and the remark that the index "is also stable under perturbations of the operator O by a compact operator". The Fredholm-operator picture sits at the end of his Chapter 3 (§6, p. 88), where he notes that homotopy classes of maps into the space of Fredholm operators give $K(X)$, and that for X a point this is just the index $\dim \operatorname{Ker} F - \dim \operatorname{Coker} F$. Everything in this section is the background those two remarks assume.

Recap

- $\operatorname{index} A = \dim \operatorname{Ker} A - \dim \operatorname{Coker} A$, and $\operatorname{Coker} A \cong \operatorname{Ker} A^*$.
- Finite dimensions: $\operatorname{index} A = \dim V - \dim W$ for every A.
- Under perturbation, zero modes and obstructions interact only through a finite Schur-complement matrix, so they appear and disappear in pairs and the index is locally constant.
- Infinite dimensions allow index $\neq 0$ for maps of a space to itself (shift: -1). The index is unchanged by compact perturbations and along continuous paths of Fredholm operators.

4.2 Elliptic operators have an index

A differential operator acts on functions, and function spaces are infinite-dimensional. So why should $D\psi = 0$ have only finitely many independent solutions? For most operators it does not: the wave equation on a torus has infinitely many. The operators with finite-dimensional kernel

and cokernel are the *elliptic* ones, and for them Nash's definition (4.1),

$$\operatorname{index} D = \dim \operatorname{Ker} D - \dim \operatorname{Coker} D,$$

makes sense. In this section we recall what ellipticity is, see with Fourier modes why it forces finiteness, and compute the index of the first honest examples: $\mathrm{d}/\mathrm{d}x + a$ on a circle, $\bar\partial$ on a torus, and the Toeplitz operator, which is our first operator with nonzero index.

4.2.1 Reminder: the leading symbol

Let E and F be vector bundles of ranks q and p over a manifold X of dimension n, and let $\Gamma(X,E)$ denote the smooth sections of E ("vector-valued fields"). A linear differential operator of order m, $D\colon \Gamma(X,E) \to \Gamma(X,F)$, looks in local coordinates x^μ and local trivialisations like

$$(Du)(x) = \sum_{|\alpha| \le m} a_\alpha(x)\, \partial^\alpha u(x), \qquad \partial^\alpha = \partial_1^{\alpha_1} \cdots \partial_n^{\alpha_n}, \tag{4.6}$$

where each coefficient $a_\alpha(x)$ is a $p \times q$ matrix (Nash (2.39)).

Working definition 4.5 (leading symbol)

To get the **leading symbol** of D, keep only the top-order terms $|\alpha| = m$ and replace each derivative ∂_μ by $\mathrm{i}k_\mu$:

$$\sigma_m(D)(x,k) = \sum_{|\alpha|=m} a_\alpha(x)\, (\mathrm{i}k)^\alpha.$$

For each point x and covector $k = k_\mu \mathrm{d}x^\mu \in T^*_x X$ [a momentum at x, with components k_μ] this is a $p \times q$ matrix, i.e. a linear map $E_x \to F_x$ [from the field components at x to the output components at x]. So $\sigma_m(D)$ is a matrix-valued function on phase space T^*X [the pairs (x,k) of a point and a momentum at that point], homogeneous of degree m [$\sigma_m(D)(x,\lambda k) = \lambda^m \sigma_m(D)(x,k)$] in the momentum k.

The rule $\partial_\mu \to \mathrm{i}k_\mu$ is just what a plane wave does: $\partial_\mu e^{\mathrm{i}k\cdot x} = \mathrm{i}k_\mu e^{\mathrm{i}k\cdot x}$. The leading symbol records how D acts on very rapidly oscillating waves, where the highest derivatives dominate. It is a matrix, not a number, because D mixes the components of the field.

Working definition 4.6 (elliptic operator)

D is **elliptic** if $\sigma_m(D)(x,k)\colon E_x \to F_x$ is an invertible matrix for every x and every $k \neq 0$ [every nonzero momentum. So at leading order D sends no rapidly oscillating wave $e^{\mathrm{i}k\cdot x}v$, $v \neq 0$, to zero]. (So in particular $p = q$.) *Operational test:* compute $\det \sigma_m(D)(x,k)$ and check that it vanishes only at $k = 0$.

Globally, Nash (p. 38) packages this as follows. Let $\pi\colon T^*X \to X$ be the projection. Pull E and F back to bundles π^*E, π^*F over T^*X (same fibres, now attached to each point (x,k)). Then $\sigma_m(D)$ is a bundle map $\pi^*E \to \pi^*F$, and ellipticity says it is an isomorphism *off the zero section* $\{k = 0\}$. This geometric phrasing is what makes K-theory enter later.

Worked example 4.5: A table of symbols

operator	on	$\sigma_m(x,k)$	elliptic?
$\mathrm{d}/\mathrm{d}x$	S^1	$\mathrm{i}k$	yes
$-\partial_x^2-\partial_y^2$	$\mathbb{R}^2$	$k_x^2+k_y^2$	yes
$\bar\partial=\frac12(\partial_x+\mathrm{i}\partial_y)$	$\mathbb{C}$	$\frac{\mathrm{i}}{2}(k_x+\mathrm{i}k_y)$	yes
$\sigma_1\partial_x+\sigma_2\partial_y$	$\mathbb{R}^2$, 2-spinors	$\mathrm{i}(\sigma_1k_x+\sigma_2k_y)$	yes
$\partial_t^2-\partial_x^2$	$\mathbb{R}^2$	$-k_t^2+k_x^2$	no (light cone)
$\partial_t-\partial_x^2$	$\mathbb{R}^2$	k_x^2 (order 2)	no ($k_x=0$)

For the two-dimensional Dirac-type operator we use the Pauli matrices $\sigma_1=\left(\begin{smallmatrix}0&1\\1&0\end{smallmatrix}\right)$, $\sigma_2=\left(\begin{smallmatrix}0&-\mathrm{i}\\\mathrm{i}&0\end{smallmatrix}\right)$. Its symbol is invertible for $k\neq0$ because

$$\begin{aligned}\big(\mathrm{i}(\sigma_1k_x+\sigma_2k_y)\big)^2 &\overset{(1)}{=} -\big(\sigma_1^2k_x^2+\sigma_2^2k_y^2+(\sigma_1\sigma_2+\sigma_2\sigma_1)k_xk_y\big)\\ &\overset{(2)}{=} -(k_x^2+k_y^2)\,\mathbb{1}.\end{aligned}$$

(1) Expand the square, keeping the order of the matrices.
(2) Pauli algebra: $\sigma_1^2=\sigma_2^2=\mathbb{1}$ and $\sigma_1\sigma_2+\sigma_2\sigma_1=0$.

A matrix whose square is $-|k|^2\mathbb{1}$ has inverse $-\sigma/|k|^2$. This "square root of the Laplacian" property is exactly Dirac's trick, and it is why Dirac operators are elliptic. The wave operator fails on the light cone $k_t=\pm k_x$, the heat operator fails on the line $k_x=0$ (its leading, second-order part does not see k_t).

Watch out: Nash drops the i

Nash writes the symbol as $\sum a_\alpha(x)k^\alpha$, without the factors of i (his (2.40)–(2.41)). For deciding ellipticity this makes no difference: it multiplies σ_m by the nonzero number i^m. We keep the i because it makes symbols of adjoints and products come out with the right signs, e.g. $\sigma(\mathrm{d}/\mathrm{d}x)=\mathrm{i}k$ and $\sigma(-\mathrm{d}^2/\mathrm{d}x^2)=k^2>0$.

Physical picture: Ellipticity is a dispersion relation with no massless directions

A physicist reads $\sigma_m(D)(x,k)$ as a dispersion relation: it is the matrix that a plane wave of momentum k sees. Ellipticity says this matrix is invertible for every direction of $k\neq0$, i.e. there is no direction in momentum space where the leading term vanishes and a mode can propagate for free at arbitrarily high momentum. That is exactly why the wave operator ($\sigma=k_t^2-k_x^2$, vanishing on the light cone) and the heat operator ($\sigma=k_x^2$, blind to k_t) are *not* elliptic: each has a whole ray of high-momentum directions with no restoring term, which is why they support propagating waves or an unconstrained time direction. An elliptic operator, by contrast, behaves like a field with a mass gap in every direction of T^*X: only finitely many low-momentum modes can be soft, which is the Fourier-mode argument of the next subsection.

4.2.2 Why ellipticity makes the kernel finite

The cleanest way to see finiteness is on a torus with constant coefficients, where Fourier modes diagonalise everything. Let $X=T^n=\mathbb{R}^n/(2\pi\mathbb{Z})^n$ and let $D=\sum_{|\alpha|\le m}a_\alpha\partial^\alpha$ have constant matrix

coefficients. On a plane wave with integer wave-vector $N \in \mathbb{Z}^n$,

$$D\big(v\, e^{\mathrm{i}N\cdot x}\big) \overset{(1)}{=} \sum_{|\alpha|\le m} a_\alpha (\mathrm{i}N)^\alpha v\, e^{\mathrm{i}N\cdot x} \overset{(2)}{=} \sigma_{\mathrm{full}}(N)\, v\, e^{\mathrm{i}N\cdot x}, \tag{4.7}$$

(1) Each ∂_μ brings down $\mathrm{i}N_\mu$; v is a constant vector in the fibre.
(2) Define the **full symbol** $\sigma_{\mathrm{full}}(N) = \sum_{|\alpha|\le m} a_\alpha (\mathrm{i}N)^\alpha$, whose top-degree part is $\sigma_m(N)$.

So D acts on the N-th Fourier mode as the finite matrix $\sigma_{\mathrm{full}}(N)$. Hence

$$\operatorname{Ker} D = \bigoplus_N \operatorname{Ker} \sigma_{\mathrm{full}}(N)\, e^{\mathrm{i}N\cdot x}, \qquad \operatorname{Coker} D \cong \bigoplus_N \operatorname{Coker} \sigma_{\mathrm{full}}(N)\, e^{\mathrm{i}N\cdot x}.$$

Now use ellipticity. By homogeneity and invertibility on the unit sphere, $\|\sigma_m(N)v\| \ge c\,|N|^m\,\|v\|$ for some $c > 0$. The lower-order terms grow at most like $|N|^{m-1}$. So for $|N|$ large enough, the top term wins and $\sigma_{\mathrm{full}}(N)$ is invertible. Only the finitely many lattice points in some ball $|N| \le R$ can contribute to kernel or cokernel. Each contributes a finite-dimensional space. Therefore $\operatorname{Ker} D$ and $\operatorname{Coker} D$ are finite-dimensional.

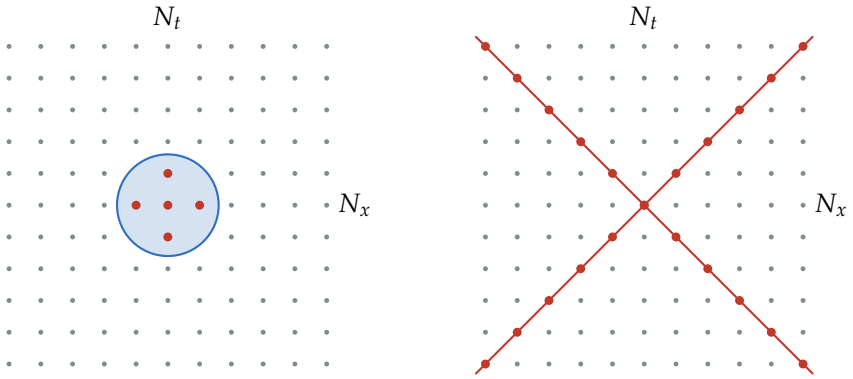
Worked example 4.6: The wave operator has an infinite kernel

On T^2 with coordinates (t, x), take $\Box = \partial_t^2 - \partial_x^2$. By (4.7), on $e^{\mathrm{i}(N_t t + N_x x)}$,

$$\Box\, e^{\mathrm{i}(N_t t+N_x x)} \overset{(1)}{=} \big((\mathrm{i}N_t)^2 - (\mathrm{i}N_x)^2\big) e^{\mathrm{i}(N_t t+N_x x)} = (N_x^2 - N_t^2)\, e^{\mathrm{i}(N_t t+N_x x)}.$$

(1) Each derivative brings down i times the wave number.

Every mode with $N_t = \pm N_x$ is killed: $\operatorname{Ker}\Box$ contains $e^{\mathrm{i}N(t\pm x)}$ for every $N \in \mathbb{Z}$, an infinite-dimensional space (left- and right-moving waves). The symbol's zeros on the light cone are exactly the zero modes that escape to infinity. See Figure 4.5.



elliptic: zero modes only near $N = 0$ wave operator: whole light cone

Figure 4.5: Fourier lattice $\mathbb{Z}^2$ of a two-torus. Red dots are modes that may lie in the kernel. Left: for an elliptic operator the symbol grows in every direction, so only finitely many modes inside a disc (blue) can be zero modes. Right: the wave operator's symbol vanishes along the light cone $N_t = \pm N_x$, and infinitely many modes are killed.

For variable coefficients on a general compact manifold, the Fourier argument is replaced by a **parametrix**: an approximate inverse Q built by inverting the symbol, with $QD = 1 + K_1$,

$DQ = 1 + K_2$ and K_1, K_2 compact (they are "smoothing", of order -1 or lower). By the working definition in Section 4.1.4, D is then Fredholm between the appropriate Sobolev spaces (Nash Chapter 2, §5). The moral is the same as on the torus: the symbol is invertible at high momentum, so all the trouble lives in a finite-dimensional low-momentum corner.

4.2.3 The index, and why the adjoint appears

Working definition 4.7 (index of an elliptic operator)

For an elliptic $D\colon \Gamma(X,E) \to \Gamma(X,F)$ on a compact manifold X without boundary,

$$\operatorname{index} D = \dim \operatorname{Ker} D - \dim \operatorname{Coker} D = \dim \operatorname{Ker} D - \dim \operatorname{Ker} D^*.$$

[D^* is the formal adjoint, $\int \langle D^*\chi, \psi\rangle = \int \langle \chi, D\psi\rangle$. Each independent solution of $D^*\chi = 0$ is one independent obstruction to solving $D\psi = f$] *Operational recipe:* solve $D\psi = 0$ and count independent smooth solutions; solve $D^*\chi = 0$ and count; subtract.

Here D^* is the **formal adjoint**, defined by integration by parts. Choose inner products on the fibres of E, F and a volume form on X, so that $\langle u, v\rangle = \int_X (u, v)\,\mathrm{vol}$. Then D^* is the operator with $\langle \chi, D\psi\rangle = \langle D^*\chi, \psi\rangle$ for all smooth ψ, χ. For example,

$$\begin{aligned} \left\langle \chi, \frac{\mathrm{d}\psi}{\mathrm{d}x} \right\rangle &\overset{(1)}{=} \int_0^{2\pi} \bar{\chi}\,\psi'\,\mathrm{d}x \\ &\overset{(2)}{=} \big[\bar{\chi}\psi\big]_0^{2\pi} - \int_0^{2\pi} \bar{\chi}'\,\psi\,\mathrm{d}x \\ &\overset{(3)}{=} \left\langle -\frac{\mathrm{d}\chi}{\mathrm{d}x}, \psi \right\rangle. \end{aligned} \tag{4.8}$$

(1) The L^2 inner product on the circle, antilinear in the first slot.
(2) Integration by parts.
(3) The circle has no boundary: χ and ψ are periodic, so the boundary term cancels.

So $(\mathrm{d}/\mathrm{d}x)^* = -\mathrm{d}/\mathrm{d}x$. Step (3) is where "$X$ has no boundary" (Nash p. 89) is used. On an interval, the boundary term survives, and one must impose boundary conditions; that is the business of Nash §7 (the Atiyah–Patodi–Singer theorem).

Why is $\operatorname{Coker} D \cong \operatorname{Ker} D^*$? In finite dimensions this was (4.1). Here the same computation shows that the L^2-orthogonal complement of $\operatorname{Im} D$ consists of (weak) solutions of $D^*\chi = 0$. D^* is elliptic too (its symbol is the adjoint matrix $\sigma_m(D)^\dagger$, Nash (2.47)), and solutions of elliptic equations are smooth (Nash Chapter 2, elliptic regularity). So those weak solutions are honest smooth zero modes of D^*.

4.2.4 First example: $\mathrm{d}/\mathrm{d}x + a$ on the circle

Worked example 4.7: $D_a = \mathrm{d}/\mathrm{d}x + a$ with constant $a \in \mathbb{C}$

Take $X = S^1 = \mathbb{R}/2\pi\mathbb{Z}$ and $D_a = \mathrm{d}/\mathrm{d}x + a\colon C^\infty(S^1) \to C^\infty(S^1)$. Its leading symbol is $\mathrm{i}k$, invertible for $k \neq 0$: elliptic. On Fourier modes $e_N = e^{\mathrm{i}Nx}$,

$$D_a e_N \overset{(1)}{=} (\mathrm{i}N + a)\,e_N, \qquad D_a^* e_N \overset{(2)}{=} (-\mathrm{i}N + \bar{a})\,e_N.$$

(1) $\frac{\mathrm{d}}{\mathrm{d}x} e^{\mathrm{i}Nx} = \mathrm{i}N e^{\mathrm{i}Nx}$.
(2) $D_a^* = -\mathrm{d}/\mathrm{d}x + \bar{a}$ by (4.8), since multiplication by a has adjoint multiplication by $\bar{a}$.

So D_a is the infinite diagonal matrix $\operatorname{diag}(\dots, a-2\mathrm{i}, a-\mathrm{i}, a, a+\mathrm{i}, a+2\mathrm{i}, \dots)$. A mode e_N is in the kernel iff $a = -\mathrm{i}N$, and in the kernel of D_a^* iff $\bar{a} = \mathrm{i}N$, which is the same condition. Hence

$$\dim\operatorname{Ker} D_a = \dim\operatorname{Ker} D_a^* = \begin{cases} 1 & a \in \mathrm{i}\mathbb{Z}, \\ 0 & \text{otherwise}, \end{cases} \qquad \text{and} \qquad \operatorname{index} D_a = 0 \text{ for every } a.$$

In position space: $u' + au = 0$ gives $u = Ce^{-ax}$, which is 2π-periodic iff $e^{-2\pi a} = 1$, i.e. $a \in \mathrm{i}\mathbb{Z}$. (Physically: a charged particle on a ring; $a = \mathrm{i}\theta$ is a constant gauge field, and a zero mode exists exactly when the flux θ is an integer.)

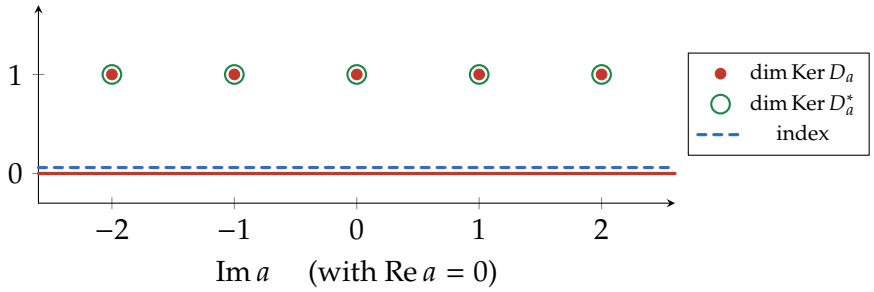


Figure 4.6: $D_a = \mathrm{d}/\mathrm{d}x + a$ on the circle. The kernel (red dots) and the cokernel (green rings) are both 0 except at the integer points $a \in \mathrm{i}\mathbb{Z}$, where both jump to 1 at the same time. The index (blue dashed line) is identically 0.

Worked example 4.8: $D = \mathrm{d}/\mathrm{d}x + a(x)$ with a variable coefficient

Now let $a(x)$ be any smooth periodic complex function, and let $\bar{a}_0 = \frac{1}{2\pi}\int_0^{2\pi} a\,\mathrm{d}x$ be its average. Solve $u' + au = 0$:

$$u(x) \overset{(1)}{=} C\exp\Big(-\int_0^x a(s)\,\mathrm{d}s\Big),$$
$$u(2\pi) \overset{(2)}{=} u(0)\,e^{-2\pi\bar{a}_0}.$$

(1) Separation of variables: $u'/u = -a$.
(2) Put $x = 2\pi$ and use the definition of the average.

So a periodic solution exists iff $e^{-2\pi\bar{a}_0} = 1$, i.e. $\bar{a}_0 \in \mathrm{i}\mathbb{Z}$. The adjoint $D^* = -\mathrm{d}/\mathrm{d}x + \bar{a}(x)$ has solutions $\chi = C\exp(\int_0^x \bar{a})$, periodic iff $e^{2\pi\overline{\bar{a}_0}} = 1$: the same condition. Again $\dim\operatorname{Ker} D = \dim\operatorname{Ker} D^*$ and $\operatorname{index} D = 0$. Notice that only the *average* of a (the holonomy of the gauge field around the ring) decides whether zero modes exist, but no choice of a changes the index.

4.2.5 Lower-order terms never change the index

The last two examples illustrate a general principle that Nash states on p. 93: "two elliptic D with the same leading symbol have the same index". Here is why. If D_0 and D_1 are elliptic of order m with the same leading symbol, then $D_1 - D_0$ has order at most $m-1$. As a map from the Sobolev space H^m (fields with m square-integrable derivatives) to L^2, an operator of order $m-1$ is compact: it only uses $m-1$ derivatives, and the "spare" derivative makes high-momentum modes negligible (this is Rellich's lemma; on the torus it is visible in the

Fourier picture, where the ratio $|N|^{m-1}/|N|^m \to 0$ plays the role of the decaying diagonal entries $1, \frac{1}{2}, \frac{1}{3}, \dots$). Therefore

$$\begin{aligned} \operatorname{index} D_1 &\overset{(1)}{=} \operatorname{index}\big(D_0 + (D_1 - D_0)\big) \\ &\overset{(2)}{=} \operatorname{index} D_0. \end{aligned} \tag{4.9}$$

(1) Trivially rewrite D_1.
(2) $D_1 - D_0 \colon H^m \to L^2$ is compact, and compact perturbations do not change the index, (4.5).

More generally, if the leading symbol is deformed continuously *through elliptic symbols*, the operators form a continuous path of Fredholm operators and the index is constant. So:

Key idea: The index lives in the symbol

The index of an elliptic operator depends only on the leading symbol $\sigma_m(D)$, and only on its deformation class among symbols that stay invertible off the zero section. This is the fact that lets topology in: deformation classes of invertible matrix-valued functions are exactly what K-theory counts.

In Example 4.8 this is visible directly: every $\mathrm{d}/\mathrm{d}x + a(x)$ has symbol $\mathrm{i}k$, the same as $\mathrm{d}/\mathrm{d}x$, whose kernel and cokernel are the constants. So every such operator has index $1 - 1 = 0$.

Worked example 4.9: $\bar\partial$ on a torus

Let $X = T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$ with complex coordinate $z = x + \mathrm{i}y$, and $\bar\partial = \frac{1}{2}(\partial_x + \mathrm{i}\partial_y)$ acting on functions. On $e_{MN} = e^{\mathrm{i}(Mx+Ny)}$,

$$\begin{aligned} \bar\partial e_{MN} &\overset{(1)}{=} \tfrac{1}{2}\big(\mathrm{i}M + \mathrm{i}\cdot\mathrm{i}N\big)e_{MN} = \tfrac{\mathrm{i}}{2}(M + \mathrm{i}N)\, e_{MN}, \\ \bar\partial^* e_{MN} &\overset{(2)}{=} -\tfrac{1}{2}(\partial_x - \mathrm{i}\partial_y)e_{MN} = -\tfrac{\mathrm{i}}{2}(M - \mathrm{i}N)\, e_{MN}. \end{aligned}$$

(1) Differentiate the plane wave.
(2) Integrate by parts as in (4.8): each ∂_μ changes sign and i is conjugated.

$M + \mathrm{i}N = 0$ only for $M = N = 0$. So $\operatorname{Ker}\bar\partial$ = constants (the holomorphic functions on a compact surface are constant) and $\operatorname{Ker}\bar\partial^*$ = constants. Index $= 1 - 1 = 0$. We will see in the next part that the index of $\bar\partial$ on a surface of genus g is $1 - g$, and the torus has $g = 1$.

4.2.6 An operator with nonzero index: the Toeplitz operator

Every example so far has index 0. That is not an accident: we will see that on odd-dimensional manifolds, and for self-adjoint operators, the index of a differential operator always vanishes (for $D = D^*$ it is obvious: $\dim\operatorname{Ker} D - \dim\operatorname{Ker} D^* = 0$). To see a nonzero index on the circle we must leave differential operators and allow **pseudo-differential** ones, whose symbols need not be polynomials in k. This is why Nash insists throughout on "differential or pseudo-differential" operators.

Split $L^2(S^1)$ into positive and negative frequencies. Let P be the projection onto the **Hardy space** $H^2 = \overline{\operatorname{span}}\{e_N : N \geq 0\}$:

$$P\Big(\sum_N c_N e_N\Big) = \sum_{N\geq 0} c_N e_N.$$

P acts on $e^{\mathrm{i}Nx}$ as the step function $\theta(N)$ (with $\theta(0) = 1$). It is a pseudo-differential operator of order 0 with symbol $\theta(k)$: not a polynomial, so not a differential operator.

Working definition 4.8 (Toeplitz operator)

For a continuous function $f\colon S^1 \to \mathbb{C}\setminus\{0\}$ [f never vanishes, so it has a winding number around 0], the **Toeplitz operator** is $T_f = PM_fP\colon H^2 \to H^2$, where M_f is multiplication by f. In the basis $e_0, e_1, \dots$ its matrix is $(T_f)_{MN} = \hat{f}_{M-N}$, constant along diagonals, where $\hat{f}_j$ are the Fourier coefficients of f [$f(x) = \sum_j \hat{f}_j e^{ijx}$].

Worked example 4.10: T_{z^k} is the k-fold shift

Let $z = e^{ix}$ and $f = z^k$ with $k \geq 0$. Then $M_f e_N = e_{N+k}$, which stays in H^2 when $N \geq 0$, so $T_{z^k} e_N = e_{N+k}$: this is S^k, the shift of Example 4.3 applied k times. Hence

$$\operatorname{index} T_{z^k} = -k.$$

For $k < 0$, $T_{z^k} e_N = e_{N+k}$ if $N + k \geq 0$ and 0 otherwise: this is $(S^*)^{|k|}$, with index $+|k| = -k$. In all cases, index $T_{z^k} = -k = -$(winding number of z^k around 0).

Now take any nonvanishing f with winding number w around 0. The loop $f(S^1)$ can be deformed to z^w through nonvanishing loops (that is what equal winding number means). Along the deformation f_s, T_{f_s} is Fredholm, because

$$T_f T_{1/f} - 1 \;=\; PM_f PM_{1/f}P - P \;=\; -PM_f(1-P)M_{1/f}P \tag{4.10}$$

is compact (the commutator of P with multiplication by a smooth function only mixes finitely many modes near $N = 0$, up to rapidly decaying tails), so $T_{1/f}$ is an inverse up to compacts. By the stability of the index along Fredholm paths,

$$\begin{aligned} \operatorname{index} T_f &\overset{(1)}{=} \operatorname{index} T_{z^w} \\ &\overset{(2)}{=} -w = -\frac{1}{2\pi i}\oint_{S^1} \frac{df}{f}. \end{aligned} \tag{4.11}$$

(1) f is homotopic to z^w through nonvanishing functions, and the index is constant along the corresponding path of Fredholm operators.

(2) Example 4.10's computation, and the standard argument-principle formula for the winding number.

Key idea: The first index theorem

The **Noether–Gohberg–Krein** index theorem, $\operatorname{index} T_f = -\operatorname{wind}(f)$, is the Atiyah–Singer theorem on the circle. The left side is analytic (count solutions). The right side is topological (a winding number, an integral of a closed form). Every feature of the general theorem is already here: the index depends only on the symbol f, only through its homotopy class, and the answer is an integral of a characteristic class ($\frac{1}{2\pi i} d\log f$ is the simplest Chern character).

To regard T_f as an operator on all of $L^2(S^1)$ (so that its symbol lives on T^*S^1), extend it by the identity on negative frequencies: $A_f = PM_fP + (1-P)$. It has the same kernel and cokernel as T_f. Its principal symbol is

$$\sigma(A_f)(x,k) = \begin{cases} f(x) & k > 0, \\ 1 & k < 0. \end{cases} \tag{4.12}$$

T^*S^1 minus its zero section is two half-cylinders, $k > 0$ and $k < 0$. The symbol is a nonvanishing function on each. Its winding number on the $k > 0$ half is w, on the $k < 0$ half it is 0. Compare

a differential operator $\mathrm{d}/\mathrm{d}x + a$: its symbol ik winds 0 times on both halves. The index in both cases is minus the difference (winding on $k > 0$) − (winding on $k < 0$): $-w$ for Toeplitz, 0 for $\mathrm{d}/\mathrm{d}x + a$. This is the circle version of the topological index we will construct in Section 4.6.

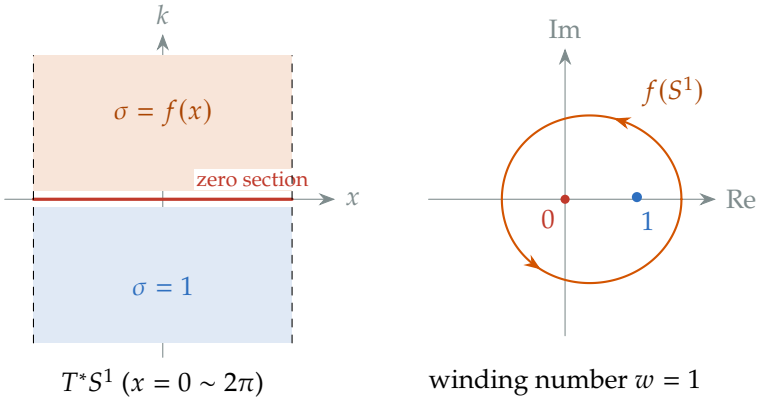

Figure 4.7: Left: the symbol of the Toeplitz-type operator A_f on the two halves of T^*S^1 minus the zero section. Right: the loop traced by f on the upper half winds once around 0, while the constant 1 on the lower half does not wind. The mismatch is what gives index $A_f = -1$.

Reading Nash (p. 89, (4.1))

Nash: "We have already discussed elliptic operators in chapter 2 where we saw that such operators have finite dimensional kernels and cokernels. This being so one can define the index ... index O = dim Ker O − dim Coker O ... Let this operator O act on a topological space X ... For the moment we require X to have no boundary." He also notes that the index theorem applies to "differential or pseudo-differential" operators. The Toeplitz example shows why the pseudo-differential ones are needed: on the circle they are the only source of nonzero index. And his remark on p. 93 that operators with the same leading symbol have the same index is (4.9).

Recap

- Leading symbol: keep top derivatives, $\partial_\mu \to ik_\mu$; a matrix-valued function on T^*X. Elliptic = invertible for $k \neq 0$.
- Ellipticity ⇒ only low-momentum modes can be zero modes ⇒ finite kernel and cokernel; the wave operator fails on its light cone.
- index D = dim Ker D − dim Ker D^* (X closed, so no boundary terms in the adjoint).
- $\mathrm{d}/\mathrm{d}x + a(x)$ on S^1, $\bar\partial$ on T^2: kernels jump, index 0. Lower-order terms never change the index.
- Toeplitz: index $T_f = -\mathrm{wind}(f)$, the first index theorem.

4.3 K-theory from complexes of bundles

We have just seen that the index of an elliptic operator depends only on its leading symbol $\sigma_m(D)$, and only on the deformation class of that symbol. The symbol is a bundle map $\pi^*E \to \pi^*F$ over phase space T^*X which is invertible everywhere except on the zero section. So the question is: *what group classifies such things?* Ordinary K-theory, as we met it in Chapter 3, classifies bundles,

not maps between bundles. Nash (p. 90) therefore switches to a second description of K-theory, due to Segal, in which the basic objects are *complexes* of bundles. This section explains that description from scratch, because it is the language of everything that follows.

4.3.1 Reminder: $K(X)$ as formal differences of bundles

Recall the construction of Chapter 3. Isomorphism classes of complex vector bundles over X form a set $\mathrm{Vect}(X)$, and direct sum makes it an abelian **semigroup**: we can add, but not subtract. We complete it to a group exactly as we build the integers from the natural numbers.

Working definition 4.9 (the group $K(X)$)

An element of $K(X)$ is a formal difference $[E]-[F]$ [a pair of bundles (E,F), read as "E minus F"] of two bundles, with the rule

$$[E]-[F]=[E']-[F'] \iff E\oplus F'\oplus G \cong E'\oplus F\oplus G \text{ for some bundle } G.$$

[G is needed because $E\oplus G\cong E'\oplus G$ need not imply $E\cong E'$] *Operational meaning:* think of $[E]-[F]$ as a "virtual bundle" of rank $\operatorname{rank}E-\operatorname{rank}F$, which may be negative.

Worked example 4.11: From $\mathbb{N}$ to $\mathbb{Z}$, and $K(\text{point})=\mathbb{Z}$

A vector bundle over a single point is just a vector space, and a complex vector space is determined up to isomorphism by its dimension. So $\mathrm{Vect}(\mathrm{pt})=\{0,1,2,\dots\}=\mathbb{N}$ with addition. Pairs (a,b) stand for $a-b$, and

$$(a,b)\sim(a',b') \overset{(1)}{\Leftrightarrow} a+b'+c=a'+b+c \text{ for some } c$$
$$\overset{(2)}{\Leftrightarrow} a-b=a'-b'.$$

(1) The equivalence relation of the working definition, with dimensions in place of bundles.

(2) Cancel c; this is allowed in $\mathbb{N}$.

So $K(\mathrm{pt})\cong\mathbb{Z}$, the isomorphism being "virtual dimension": $[\mathbb{C}^a]-[\mathbb{C}^b]\mapsto a-b$. Keep this in mind: it is the first hint that K-theory and the index are made for each other, since the index of a linear map $\mathbb{C}^a\to\mathbb{C}^b$ is also $a-b$.

Nash notes (p. 89–90) that there are real and quaternionic versions (KO, KSp) and that "$K(X)$" in this chapter always means the complex one, $KU(X)$.

4.3.2 Complexes of bundles

Working definition 4.10 (complex of bundles, Nash (4.2))

A **complex** E over X is a finite sequence of vector bundles and bundle maps ("homomorphisms", i.e. fibrewise linear maps depending continuously on the base point)

$$0\longrightarrow E^0\xrightarrow{\alpha_0}E^1\xrightarrow{\alpha_1}\cdots\xrightarrow{\alpha_n}E^{n+1}\longrightarrow 0, \qquad \alpha_i\circ\alpha_{i-1}=0. \tag{4.13}$$

Concretely: over each point x we have a string of matrices $\alpha_i(x)$, and the product of any two consecutive ones is the zero matrix: "the image of one map lies inside the kernel of the next".

The condition $\alpha_i\alpha_{i-1} = 0$ is the same as $\mathrm{d}\circ\mathrm{d} = 0$ for the exterior derivative. At each point x it lets us form the *cohomology* of the fibre sequence, $\operatorname{Ker}\alpha_i(x)/\operatorname{Im}\alpha_{i-1}(x)$. When all of these vanish the sequence is called **exact** at x.

Working definition 4.11 (support, Nash (4.3))

The **support** of a complex E is the set of points $x \in X$ at which the sequence of vector spaces

$$0 \to E^0_x \xrightarrow{\alpha_0(x)} E^1_x \xrightarrow{\alpha_1(x)} \cdots \xrightarrow{\alpha_n(x)} E^{n+1}_x \to 0$$

fails to be exact. *Operational test* for a two-term complex $0 \to E^0 \xrightarrow{\alpha} E^1 \to 0$: exactness means $\alpha(x)$ is an isomorphism, so the support is where $\det\alpha(x) = 0$ (or where the ranks differ [$\operatorname{rank}E^0 \neq \operatorname{rank}E^1$, so no $\alpha(x)$ can be invertible], in which case the support is everything).

Exactness is an open condition (an invertible matrix stays invertible under small changes), so the support is always a closed set.

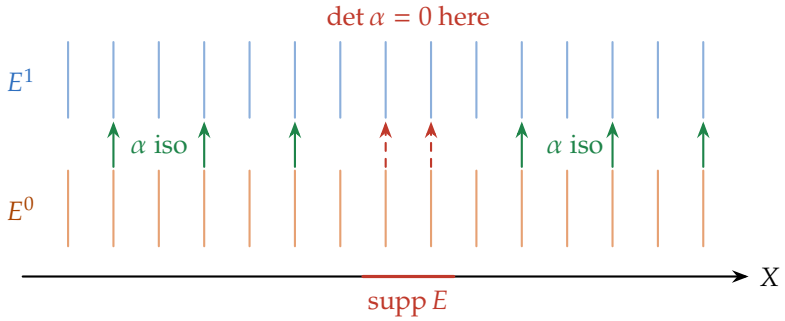

Figure 4.8: A two-term complex $0 \to E^0 \xrightarrow{\alpha} E^1 \to 0$ drawn as two families of fibres over X with a map between them. Where α is an isomorphism (green) the complex is exact and "carries no information"; the red segment where α fails to be invertible is the support. A complex is a virtual bundle $E^0 - E^1$ that has been told it may only live on its support.

Working definition 4.12 (homotopy of complexes)

Two complexes E, F over X are **homotopic** if there is a complex G over $X \times [0,1]$ with $G|_{X\times\{0\}} \cong E$ [G restricted to the bottom slice $X \times \{0\}$ is isomorphic to E, i.e. equal after a pointwise invertible change of basis] and $G|_{X\times\{1\}} \cong F$. *Concretely:* we may continuously deform the maps $\alpha_i(x)$ (and the bundles), keeping $\alpha_i\alpha_{i-1} = 0$ all the way.

Let $C(X)$ denote the set of homotopy classes of complexes over X. Direct sum of complexes (take $E^i \oplus F^i$ and $\alpha_i \oplus \beta_i$, block-diagonal matrices) makes $C(X)$ an abelian semigroup. Inside it sits the sub-semigroup $C_\phi(X)$ of complexes with *empty* support: those that are exact at every point.

Key idea: Segal's description of K-theory, Nash (4.4)

$$K(X) \;\cong\; \frac{C(X)}{C_\phi(X)}. \tag{4.14}$$

In words: a K-theory class is a complex of bundles, up to homotopy, where everywhere-exact complexes count as zero. The class of E is written $[E]$.

Why is this the same group as before? The dictionary is:

- A single bundle V is the complex $0 \to V \to 0$ with V in degree 0.
- The "trivially exact" complex $0 \to V \xrightarrow{\mathrm{id}} V \to 0$ has empty support, so it is zero in the quotient. That is the same as saying that V placed in degree 1 is the negative of V placed in degree 0. So degree 1 plays the role of the minus sign.

The next subsection makes this precise and derives Nash's formula (4.5).

Physical picture: Complexes as brane–antibrane pairs

There is a vivid physical picture for "bundle in even degree minus bundle in odd degree, up to exact sequences". In string theory a stack of D-branes wrapping E^0 and a stack of anti-D-branes wrapping E^1 carry a **tachyon field** $\alpha_0 \colon E^0 \to E^1$ (a bifundamental scalar, since the branes have opposite charge). Where α_0 is invertible the branes and antibranes can pair up and annihilate completely, leaving nothing: that is exactly an everywhere-exact two-term complex, and it is zero in $C_\phi(X)$. Where α_0 degenerates (its support), some brane charge survives. Sen's conjecture (brane-antibrane annihilation via tachyon condensation) is precisely the statement that the surviving, stable D-brane charge is classified by K-theory built from such complexes, which is why physicists call this "K-theory charges of D-branes". The Bott class of Example 4.13 below is, in this language, one unit of brane charge localised where the tachyon vanishes.

4.3.3 The alternating-sum formula (compact X)

Suppose X is compact. Given a complex E with maps α_i, consider the family of complexes E_s with the same bundles and maps $s\,\alpha_i$, $s \in [0,1]$. Since $(s\alpha_i)(s\alpha_{i-1}) = s^2\alpha_i\alpha_{i-1} = 0$, each E_s is a complex, so $E = E_1$ is homotopic to E_0, the complex with all maps zero. A complex with zero maps is a direct sum of one-bundle complexes $V[i]$, meaning "V sitting alone in degree i". Finally,

$$\begin{aligned} [V[i]] + [V[i+1]] &\overset{(1)}{=} \big[\, 0 \to V \xrightarrow{0} V \to 0 \,\big] \\ &\overset{(2)}{=} \big[\, 0 \to V \xrightarrow{\mathrm{id}} V \to 0 \,\big] \\ &\overset{(3)}{=} 0. \end{aligned} \tag{4.15}$$

(1) Direct sum of the two one-bundle complexes, with V in degrees i and $i+1$ and the zero map between them.
(2) The maps $s \cdot \mathrm{id}$, $s \in [0,1]$, give a homotopy (any linear map between consecutive terms of a two-term complex is allowed, since there is no condition $\alpha_i\alpha_{i-1} = 0$ to check).
(3) The identity is invertible at every point, so this complex has empty support and lies in $C_\phi(X)$.

So $[V[i+1]] = -[V[i]]$, and by induction $[V[i]] = (-1)^i[V]$. Putting the pieces together gives Nash's (4.5):

$$[E] \overset{(1)}{=} [E_0] \overset{(2)}{=} \Big[\bigoplus_i E^i[i] \Big] \overset{(3)}{=} \sum_i \big[E^i[i]\big] \overset{(4)}{=} \sum_i (-1)^i [E^i]. \tag{4.16}$$

(1) The homotopy $s\alpha_i$ from E to the zero-map complex E_0.
(2) A complex with zero maps is the direct sum of its terms, each in its own degree.
(3) Addition in $C(X)$ is direct sum.
(4) $[V[i]] = (-1)^i[V]$ from (4.15).

Watch out: Where compactness was used

On a non-compact space the homotopy $s\alpha_i$ is not allowed. As we will see next, for non-compact spaces we only consider complexes whose support is compact, and homotopies whose support is compact. At $s = 0$ the support of E_0 is all of X (zero maps are never exact unless the bundles vanish), which is not compact. So on a non-compact space *the maps carry the information*, and (4.16) would destroy it. This is Nash's footnote on p. 90, and it is the whole point of the complex description: on phase space T^*X, the interesting information is in the symbol map, not in the bundles.

Worked example 4.12: Complexes over a point: the Euler characteristic

Over $X = \mathrm{pt}$ a complex is a string of matrices. Take

$$0 \to \mathbb{C} \xrightarrow{\alpha_0} \mathbb{C}^2 \xrightarrow{\alpha_1} \mathbb{C} \to 0, \qquad \alpha_0 = \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \quad \alpha_1 = \begin{pmatrix} 1 & -1 \end{pmatrix}.$$

It is a complex, since $\alpha_1\alpha_0 = 1 - 1 = 0$. It is exact: α_0 is injective, $\operatorname{Ker}\alpha_1 = \operatorname{span}\{(1,1)\} = \operatorname{Im}\alpha_0$, and α_1 is onto. So its support is empty, $[E] = 0$, and indeed

$$\sum_i (-1)^i \dim E^i = 1 - 2 + 1 = 0.$$

Now take the two-term complex $0 \to \mathbb{C}^2 \xrightarrow{A} \mathbb{C}^3 \to 0$ for *any* 3×2 matrix A. By (4.16) and Example 4.11,

$$[E] \overset{(1)}{=} [\mathbb{C}^2] - [\mathbb{C}^3] \overset{(2)}{=} 2 - 3 = -1 \overset{(3)}{=} \operatorname{index} A.$$

(1) Alternating sum formula (a point is compact).
(2) $K(\mathrm{pt}) \cong \mathbb{Z}$ by dimension.
(3) Finite-dimensional index (4.2).

Over a point, *the K-class of a two-term complex is the index of the map*. The whole analytic index of Section 4.5 is a vast generalisation of this remark.

4.3.4 Non-compact spaces and compact supports

The space we care about, T^*X, is never compact: its fibres are vector spaces. Nash's footnotes on pp. 90–91 prescribe what to do.

Working definition 4.13 (K-theory with compact supports)

For non-compact Y, $K(Y)$ (more precisely $K_c(Y)$) is defined by (4.14) [complexes of bundles up to homotopy, with everywhere-exact complexes counted as zero] using only complexes *whose support is compact* [the complex fails to be exact only inside some bounded region], and homotopies over $Y \times [0,1]$ whose support is compact. Equivalently,

$$K_c(Y) \;\cong\; \widetilde{K}(Y^+),$$

the reduced K-theory of the one-point compactification $Y^+ = Y \cup \{\infty\}$ [one extra point ∞ that every sequence running off to infinity approaches, e.g. $(\mathbb{R}^n)^+ = S^n$]. ("Reduced" means: virtual bundles of virtual dimension 0, i.e. those that are trivial near the added point.)

Why the two descriptions agree: a complex with compact support is exact outside some large compact set, so near ∞ it is "nothing", and it defines a virtual bundle on Y^+ which is trivial at ∞. We will see exactly how in the next example. For compact X nothing changes: $X^+ = X \sqcup \{\infty\}$ and $\widetilde{K}(X \sqcup \mathrm{pt}) = K(X)$.

Worked example 4.13: The Bott class: $K_c(\mathbb{C}) = \widetilde{K}(S^2)$

Let $Y = \mathbb{C}$ with coordinate z, and consider the two-term complex of trivial line bundles

$$\beta: \qquad 0 \to \mathbb{C}\times\mathbb{C} \xrightarrow{\cdot z} \mathbb{C}\times\mathbb{C} \to 0, \qquad (z,v) \mapsto (z, zv). \tag{4.17}$$

The map at the point z is the 1×1 matrix (z). It is invertible unless $z = 0$, so $\operatorname{supp}\beta = \{0\}$, which is compact. Hence β defines a class in $K_c(\mathbb{C})$, the **Bott class**.

Can we deform it away? Try the homotopy $z \mapsto z - c(s)$. It moves the zero to $z = c(s)$ but never removes it. More convincingly, on a large circle $|z| = R$ the map is the loop $z/|z|$ in $\mathrm{U}(1)$, and its winding number 1 cannot change under any compactly supported homotopy (which leaves the map invertible on a large enough circle for all s). A complex with empty support would give winding number 0 there (an invertible function on the whole disc $|z| \le R$ winds 0 times). So $[\beta] \neq 0$. More generally, the map z^n gives a class $[\beta_n]$ whose large-circle winding number is n.

The bundle on the sphere. Compactify $\mathbb{C}^+ = S^2$. Cover it by the disc $D_0 = \{|z| \le 1\}$ and the cap $D_\infty = \{|z| \ge 1\} \cup \{\infty\}$. On D_∞ the map z is invertible, so we may use it to identify the fibre of E^1 with the fibre of E^0. Doing so, E^0 is the trivial bundle on all of S^2, while E^1 becomes the line bundle L obtained by gluing the trivial bundle on D_0 to the trivial bundle on D_∞ with transition function $g(z) = z$ on the equator $|z| = 1$. So

$$[\beta] \;=\; [\mathbf{1}] - [L] \;\in\; \widetilde{K}(S^2), \tag{4.18}$$

where $\mathbf{1}$ is the trivial line bundle. A transition function $z = e^{i\phi}$ with winding number one produces a line bundle of degree ± 1: the monopole bundle of charge one (the tautological bundle over $\mathbb{CP}^1$ or its dual, depending on orientation conventions). Its first Chern class integrates to ± 1. It is a basic fact (Bott periodicity in its simplest form) that $\widetilde{K}(S^2) \cong \mathbb{Z}$, generated by exactly this class.

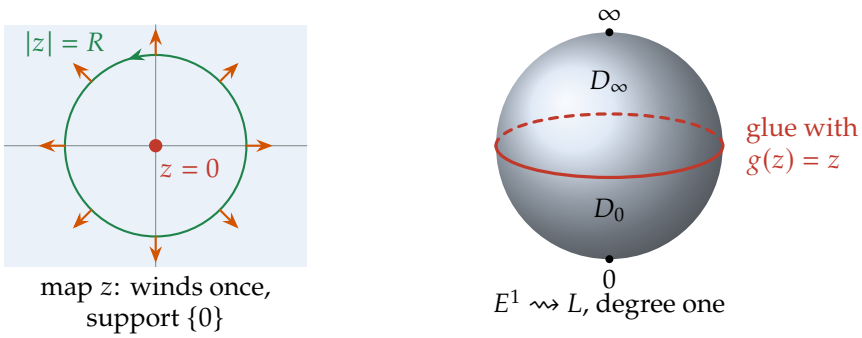

Figure 4.9: Left: the Bott complex on $\mathbb{C}$. Its map z vanishes only at the origin (red), and on a large circle it is the phase $z/|z|$ (orange arrows), which winds once. Right: after one-point compactification to S^2, the invertibility of z near ∞ is used to glue the two halves of E^1 with transition function z along the equator, producing the charge-one monopole line bundle L.

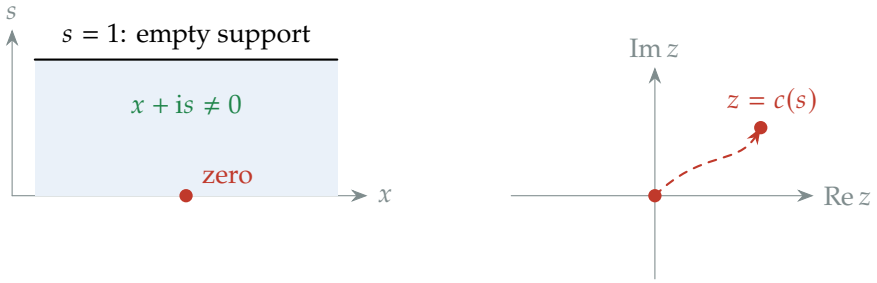
Worked example 4.14: One real dimension is not enough: $K_c(\mathbb{R}) = 0$

On $Y = \mathbb{R}$ take $0 \to \mathbb{C} \xrightarrow{\cdot x} \mathbb{C} \to 0$, multiplication by the real coordinate x. Its support is $\{0\}$. Now use the homotopy

$$\alpha_s(x) = x + \mathrm{i}s, \qquad s \in [0,1].$$

This vanishes only at $(x,s) = (0,0)$, so the support of the homotopy in $\mathbb{R} \times [0,1]$ is a single point: compact, as required. At $s = 1$ the map $x + \mathrm{i}$ never vanishes, so the complex has empty support and is zero. Therefore $[\cdot x] = 0$. The zero was able to escape into the imaginary direction. On $\mathbb{C}$ there is no extra direction to escape into: the zero of z is trapped by its winding number. In the language of one-point compactifications, $\mathbb{R}^+ = S^1$ and $\widetilde{K}(S^1) = 0$, whereas $\mathbb{C}^+ = S^2$ and $\widetilde{K}(S^2) = \mathbb{Z}$. More generally Bott periodicity says

$$K_c(\mathbb{R}^{2n}) = \widetilde{K}(S^{2n}) \cong \mathbb{Z}, \qquad K_c(\mathbb{R}^{2n+1}) = \widetilde{K}(S^{2n+1}) = 0.$$



on $\mathbb{R}$: the zero disappears on $\mathbb{C}$: the zero only moves

Figure 4.10: Left: on the real line the zero of x can be removed by the compactly supported homotopy $x + \mathrm{i}s$, so the class is 0. Right: on the complex plane any homotopy of z merely drags the zero around; it can never be removed, because the winding number on a large circle is fixed.

4.3.5 Products of complexes

$K(X)$ is a ring: $[V] \cdot [W] = [V \otimes W]$. On complexes, the product is the tensor product of complexes, which we need for the Thom homomorphism in Section 4.6. For two-term complexes $A = (A^0 \xrightarrow{a} A^1)$ and $B = (B^0 \xrightarrow{b} B^1)$,

$$A \otimes B: \quad 0 \to A^0 \otimes B^0 \xrightarrow{\begin{pmatrix} a\otimes 1 \\ 1\otimes b \end{pmatrix}} (A^1 \otimes B^0) \oplus (A^0 \otimes B^1) \xrightarrow{(-1\otimes b \;\; a\otimes 1)} A^1 \otimes B^1 \to 0. \tag{4.19}$$

The composite of the two maps is $-(a \otimes b) + (a \otimes b) = 0$, so this is a complex (the minus sign is the same sign as in the Leibniz rule $\mathrm{d}(\alpha \wedge \beta) = \mathrm{d}\alpha \wedge \beta + (-1)^p \alpha \wedge \mathrm{d}\beta$). Two facts make it useful:

1. Its class is the product of classes: by (4.16), $[A \otimes B] = A^0B^0 - (A^1B^0 + A^0B^1) + A^1B^1 = (A^0 - A^1)(B^0 - B^1)$ (writing V for $[V]$).
2. $\operatorname{supp}(A \otimes B) = \operatorname{supp} A \cap \operatorname{supp} B$. At a point where, say, a is invertible, one checks directly that the sequence is exact (the cohomology of a tensor product of complexes of vector spaces is the tensor product of their cohomologies, and one factor has none).

The second fact explains why products of compactly supported classes are compactly supported, and gives a quick proof of a relation we will use.

Worked example 4.15: $(1-L)^2=0$ in $K(S^2)$

The class $\mathbf{1}-L$ of (4.18) is represented by the complex $0\to\mathbf{1}\xrightarrow{s}L\to 0$, where s is a section of $\mathrm{Hom}(\mathbf{1},L)=L$. A degree-one line bundle has a section with a single simple zero, and we may put that zero anywhere, say at p or at $q\neq p$. Choose one representative with support $\{p\}$ and one with support $\{q\}$. Then

$$(\mathbf{1}-L)^2 \overset{(1)}{=} \left[(\mathbf{1}\xrightarrow{s_p}L)\otimes(\mathbf{1}\xrightarrow{s_q}L)\right] \overset{(2)}{=} [\text{complex with support } \{p\}\cap\{q\}=\varnothing] \overset{(3)}{=} 0.$$

(1) Product of classes is the class of the tensor product.
(2) Support of a tensor product is the intersection of the supports.
(3) Empty support means zero in $C(X)/C_\phi(X)$.

Consequently $L^n=\big(\mathbf{1}-(\mathbf{1}-L)\big)^n=\mathbf{1}-n(\mathbf{1}-L)$ by the binomial theorem, i.e. $[\beta_n]=\mathbf{1}-L^n=n(\mathbf{1}-L)=n[\beta]$: the class of the map z^n is n times the Bott class. The K-class sees exactly the winding number.

4.3.6 Why this is the right language for symbols

Now return to an elliptic operator $D\colon\Gamma(X,E)\to\Gamma(X,F)$ on a compact manifold. Its leading symbol gives a two-term complex over T^*X,

$$0\to\pi^*E\xrightarrow{\sigma_m(D)}\pi^*F\to 0. \tag{4.20}$$

Ellipticity says exactly that the support is contained in the zero section $\{k=0\}\cong X$, which is compact. So (4.20) defines a class in $K_c(T^*X)$, which Nash simply writes $K(T^*X)$ (footnote 2, p. 91). Homotopies of elliptic symbols are compactly supported homotopies of complexes. So:

$$\textit{deformation classes of elliptic symbols}\longrightarrow K(T^*X).$$

This is the map through which the index will factor.

Worked example 4.16: Two symbols as complexes

(a) For $D=\mathrm{d}/\mathrm{d}x$ on S^1, $T^*S^1=S^1\times\mathbb{R}$ with coordinates (x,k), and the symbol complex is $0\to\mathbb{C}\xrightarrow{\mathrm{i}k}\mathbb{C}\to 0$, with support $S^1\times\{0\}$: a circle, compact.
(b) For $\bar\partial=\frac12(\partial_x+\mathrm{i}\partial_y)$ on $\mathbb{R}^2$, the symbol at a fixed base point is

$$\sigma(\bar\partial)(k)=\tfrac{\mathrm{i}}{2}(k_x+\mathrm{i}k_y)=\tfrac{\mathrm{i}}{2}\,\kappa,\qquad \kappa:=k_x+\mathrm{i}k_y.$$

As a function of the momentum plane this is (up to the harmless nonzero factor $\mathrm{i}/2$) exactly the Bott complex (4.17) in the variable κ. The Cauchy–Riemann operator *is* the Bott class, one fibre of $T^*\mathbb{R}^2$ at a time. This is why $\bar\partial$ and its relatives (Dolbeault, Dirac) generate everything in index theory.

Reading Nash (pp. 89–91, (4.2)–(4.5) and footnotes 1–2)

Nash recalls $K(X)$ as the group completion of $\mathrm{Vect}(X)$, then introduces Segal's complexes (4.2), their homotopies, the semigroup $C(X)$, the support (4.3), the sub-semigroup $C_\phi(X)$ of complexes with empty support, and the isomorphism $K(X)=C(X)/C_\phi(X)$ (4.4). For

compact X he quotes $[E]=\sum_i(-1)^i[E^i]$ (4.5), which we derived in (4.16) from the homotopy $s\alpha_i$. His footnotes say that for non-compact X one uses complexes with compact support, and that $K(T^*X)$ means compactly supported K-theory, equivalently the reduced K-theory of the one-point compactification. Nash writes ϕ for the empty set in C_ϕ; we have kept his notation.

Recap

- A complex of bundles is a string of bundle maps with $\alpha_i\alpha_{i-1}=0$; its support is where it fails to be exact.
- $K(X)=C(X)/C_\phi(X)$: complexes up to homotopy, exact ones counting as zero. Degree i carries the sign $(-1)^i$.
- Compact X: $[E]=\sum(-1)^i[E^i]$. Non-compact Y: use compact supports; $K_c(Y)=\widetilde{K}(Y^+)$, and the maps carry the information.
- Bott class: $0\to\mathbb{C}\xrightarrow{z}\mathbb{C}\to 0$ on $\mathbb{C}$, the generator of $K_c(\mathbb{C})=\widetilde{K}(S^2)=\mathbb{Z}$; the map z^n gives n times it. $K_c(\mathbb{R})=0$.
- Tensor products of complexes multiply classes and intersect supports.
- An elliptic symbol is a two-term complex over T^*X supported on the zero section, hence a class in $K(T^*X)$.

4.4 Elliptic complexes and the rolled-up operator

The most important operators in geometry do not come alone. The exterior derivative d maps 0-forms to 1-forms, 1-forms to 2-forms, and so on, with $\mathrm{d}\circ\mathrm{d}=0$. In three dimensions this is the familiar chain

$$\text{functions}\xrightarrow{\nabla}\text{vector fields}\xrightarrow{\nabla\times}\text{vector fields}\xrightarrow{\nabla\cdot}\text{functions},\qquad \nabla\times\nabla=0,\quad \nabla\cdot\nabla\times=0.$$

None of these operators is elliptic on its own: the gradient maps a 1-component field to a 3-component field, so its symbol cannot be an invertible square matrix. Yet the chain as a whole is "elliptic" in a sense we now make precise, and it has an index, the Euler characteristic. Nash's (4.6)–(4.16) set this up. The key trick is to roll the whole chain up into a *single* elliptic operator D, so that everything we know about indices of single operators applies.

4.4.1 Complexes of operators and their symbol complexes

Working definition 4.14 (complex of operators, Nash (4.6))

Let $E^0,\dots,E^{n+1}$ be vector bundles over a compact manifold X. A **complex of operators** is a sequence of differential (or pseudo-differential [acting on waves through a symbol that need not be a polynomial in k]) operators, all of the same order m [at most m derivatives, or a symbol growing like $|k|^m$],

$$0\to\Gamma(X,E^0)\xrightarrow{d_0}\Gamma(X,E^1)\xrightarrow{d_1}\cdots\xrightarrow{d_n}\Gamma(X,E^{n+1})\to 0,\qquad d_i\circ d_{i-1}=0. \tag{4.21}$$

[$\Gamma(X,E^i)$ is the space of smooth sections, the fields $x\mapsto e(x)\in E^i_x$]

(Atiyah and Bott allow operators of different orders; Nash, and we, do not need that generality.) Each d_i has a leading symbol $\sigma_m(d_i)(x,k)\colon E^i_x \to E^{i+1}_x$. The first thing to check is that the symbols form a complex too. The cleanest way is to feed the operators a rapidly oscillating wave. For a real function φ with $\mathrm{d}\varphi = k$ at x and a large parameter λ, an operator P of order m satisfies

$$P\big(e^{\mathrm{i}\lambda\varphi}u\big) = \lambda^m\, e^{\mathrm{i}\lambda\varphi}\big(\sigma_m(P)(x,\mathrm{d}\varphi)u + O(\lambda^{-1})\big), \tag{4.22}$$

because every derivative that hits the exponential brings down $\mathrm{i}\lambda\,\partial_\mu\varphi$, and the terms with the most such factors are exactly the top-order terms with $\partial_\mu \to \mathrm{i}k_\mu$. Applying this twice,

$$\begin{aligned} 0 = d_i d_{i-1}\big(e^{\mathrm{i}\lambda\varphi}u\big) &\overset{(1)}{=} d_i\Big(\lambda^m e^{\mathrm{i}\lambda\varphi}\big(\sigma_m(d_{i-1})u + O(\lambda^{-1})\big)\Big) \\ &\overset{(2)}{=} \lambda^{2m} e^{\mathrm{i}\lambda\varphi}\big(\sigma_m(d_i)\sigma_m(d_{i-1})u + O(\lambda^{-1})\big). \end{aligned} \tag{4.23}$$

(1) (4.22) for $P = d_{i-1}$.
(2) (4.22) for $P = d_i$, applied to the leading term.

Dividing by λ^{2m} and letting $\lambda \to \infty$ gives $\sigma_m(d_i)\sigma_m(d_{i-1}) = 0$. So we get Nash's **symbol complex** (4.7), a complex of bundles over T^*X in the sense of Section 4.3:

$$\sigma(E)\colon \quad 0 \to \pi^*E^0 \xrightarrow{\sigma_m(d_0)} \pi^*E^1 \xrightarrow{\sigma_m(d_1)} \cdots \xrightarrow{\sigma_m(d_n)} \pi^*E^{n+1} \to 0. \tag{4.24}$$

Working definition 4.15 (elliptic complex)

The complex (4.21) is **elliptic** if its symbol complex (4.24) is exact [the kernel of each map equals the image of the previous one] off the zero section [the points $(x, k = 0)$] of T^*X: for every x and every $k \neq 0$, the sequence of matrices $\sigma_m(d_i)(x,k)$ is exact. Equivalently, the support of $\sigma(E)$ [the points (x,k) where the symbol sequence fails to be exact] lies in the zero section.
Operational test: at a fixed $k \neq 0$ compute the ranks r_i of the symbol matrices; exactness means $r_i + r_{i-1} = \operatorname{rank} E^i$ for every i (kernel of the i-th map = image of the $(i-1)$-th, given that the composite is zero).

Note that the complex of operators itself has no reason to be exact (its cohomology will turn out to be the interesting part). Only the symbol complex must be exact. If there are only two nonzero terms, $0 \to \Gamma(E^0) \xrightarrow{d_0} \Gamma(E^1) \to 0$, exactness of the symbol complex says that $\sigma_m(d_0)$ is an isomorphism for $k \neq 0$: that is ordinary ellipticity of d_0.

Worked example 4.17: The de Rham complex is elliptic

Take $E^p = \Lambda^p T^*X \otimes \mathbb{C}$ (complex-valued p-forms) and $d_p = \mathrm{d}$. Using (4.22) with $P = \mathrm{d}$,

$$\begin{aligned} \mathrm{d}\big(e^{\mathrm{i}\lambda\varphi}\omega\big) &\overset{(1)}{=} \mathrm{i}\lambda\,\mathrm{d}\varphi \wedge e^{\mathrm{i}\lambda\varphi}\omega + e^{\mathrm{i}\lambda\varphi}\mathrm{d}\omega \\ &\overset{(2)}{=} \lambda\, e^{\mathrm{i}\lambda\varphi}\big(\mathrm{i}k \wedge \omega + O(\lambda^{-1})\big), \end{aligned}$$

(1) Leibniz rule for d acting on a function times a form.
(2) $\mathrm{d}\varphi = k$ at the point; the second term has no factor of λ.

so $\sigma_1(\mathrm{d})(x,k)\omega = \mathrm{i}\,k \wedge \omega$. Exactness for $k \neq 0$: choose an orthonormal basis $e^1, \dots, e^n$ of T^*_xX with $e^1 = k/|k|$. Every form splits uniquely as $\omega = e^1 \wedge \alpha + \beta$ with α, β built from $e^2, \dots, e^n$ only. Then

$$k \wedge \omega \overset{(1)}{=} |k|\, e^1 \wedge e^1 \wedge \alpha + |k|\, e^1 \wedge \beta \overset{(2)}{=} |k|\, e^1 \wedge \beta,$$

(1) Substitute $k = |k|e^1$ and the splitting of ω.
(2) $e^1 \wedge e^1 = 0$.

which vanishes iff $\beta = 0$, i.e. iff $\omega = e^1 \wedge \alpha = k \wedge (\alpha/|k|)$. So $\mathrm{Ker}(k\wedge) = \mathrm{Im}(k\wedge)$: exact. This is Nash's "$k \wedge v = 0 \Rightarrow v = k \wedge w$" (p. 94).

Worked example 4.18: grad, curl, div in momentum space

On $\mathbb{R}^3$ the de Rham complex, with 1- and 2-forms identified with vector fields, is ∇, $\nabla\times$, $\nabla\cdot$. Its symbol complex at momentum $k = (k_1, k_2, k_3)$ is

$$0 \to \mathbb{C} \xrightarrow{\mathrm{i}k} \mathbb{C}^3 \xrightarrow{\mathrm{i}k\times} \mathbb{C}^3 \xrightarrow{\mathrm{i}k\cdot} \mathbb{C} \to 0,$$

with matrices

$$\sigma_0 = \mathrm{i}\begin{pmatrix} k_1 \\ k_2 \\ k_3 \end{pmatrix}, \quad \sigma_1 = \mathrm{i}\begin{pmatrix} 0 & -k_3 & k_2 \\ k_3 & 0 & -k_1 \\ -k_2 & k_1 & 0 \end{pmatrix}, \quad \sigma_2 = \mathrm{i}\begin{pmatrix} k_1 & k_2 & k_3 \end{pmatrix}.$$

The composites vanish: $\sigma_1\sigma_0 = -k \times k = 0$ and $\sigma_2\sigma_1 v = -k \cdot (k \times v) = 0$. For $k \neq 0$ the ranks are $r_0 = 1$ (a nonzero column), $r_1 = 2$ (the kernel of $v \mapsto k \times v$ is the line through k), $r_2 = 1$ (a nonzero row). The exactness test:

$$r_0 = 1 = \mathrm{rank}\, E^0, \qquad r_0 + r_1 = 3 = \mathrm{rank}\, E^1,$$
$$r_1 + r_2 = 3 = \mathrm{rank}\, E^2, \qquad r_2 = 1 = \mathrm{rank}\, E^3.$$

All satisfied, so the complex is elliptic. At $k = 0$ all maps vanish and exactness fails: the support is the zero section. Physically: a plane wave field is longitudinal ($\propto k$) exactly when it is curl-free, and transverse ($\perp k$) exactly when it is divergence-free and then it is a curl.

The Dolbeault complex $\bar\partial\colon \Omega^{0,q} \to \Omega^{0,q+1}$ on a complex manifold is elliptic by the same argument, with $k\wedge$ replaced by $k^{0,1}\wedge$; the next part treats it in detail.

4.4.2 Rolling the complex up into one operator

Choose Hermitian metrics on the bundles E^i and a volume form on X, so that every d_i has a formal adjoint $d_i^*\colon \Gamma(E^{i+1}) \to \Gamma(E^i)$ (Section 4.2.3). Taking adjoints of $d_i d_{i-1} = 0$ gives

$$d_{i-1}^* d_i^* = (d_i d_{i-1})^* = 0. \tag{4.25}$$

Group the bundles into even and odd (Nash (4.8)):

$$E^+ = E^0 \oplus E^2 \oplus E^4 \oplus \cdots, \qquad E^- = E^1 \oplus E^3 \oplus E^5 \oplus \cdots. \tag{4.26}$$

Working definition 4.16 (rolled-up operator, Nash (4.9))

$$D = \sum_i \left(d_{2i} + d_{2i+1}^*\right)\colon \Gamma(X, E^+) \to \Gamma(X, E^-),$$
$$D(e_0, e_2, e_4, \dots) = (d_0 e_0 + d_1^* e_2,\ d_2 e_2 + d_3^* e_4,\ \dots). \tag{4.27}$$

As a matrix of operators, with rows labelled by $E^1, E^3, \dots$ and columns by $E^0, E^2, \dots$ [each d_i runs from E^i up to E^{i+1}, and its formal adjoint d_i^* runs back down from E^{i+1} to E^i],

$$D = \begin{pmatrix} d_0 & d_1^* & 0 & \cdots \\ 0 & d_2 & d_3^* & \cdots \\ 0 & 0 & d_4 & \cdots \\ \vdots & & & \ddots \end{pmatrix}, \qquad D^* = \begin{pmatrix} d_0^* & 0 & 0 & \cdots \\ d_1 & d_2^* & 0 & \cdots \\ 0 & d_3 & d_4^* & \cdots \\ \vdots & & & \ddots \end{pmatrix}.$$

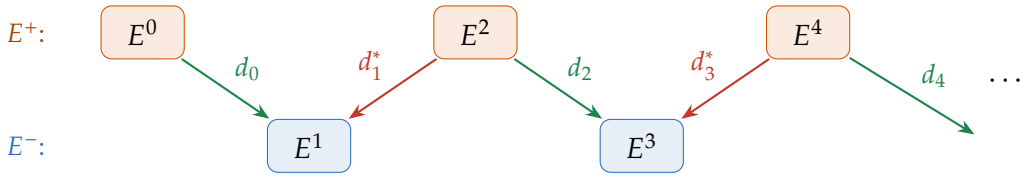


Figure 4.11: The rolled-up operator. The even bundles (top row, orange) make E^+, the odd ones (bottom row, blue) make E^-. D is the sum of all downward arrows: each d_{2i} steps forward (green) and each adjoint d_{2i+1}^* steps back (red). A single elliptic operator $E^+ \to E^-$ remembers the whole complex.

Worked example 4.19: The de Rham complex of a surface

For a surface, $E^+ = \Lambda^0 \oplus \Lambda^2$ and $E^- = \Lambda^1$, and $D(f, \beta) = \mathrm{d}f + \mathrm{d}^*\beta$. On the flat torus $T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$ write $\beta = g\,\mathrm{d}x \wedge \mathrm{d}y$. With the Hodge star $\star \mathrm{d}x = \mathrm{d}y$, $\star \mathrm{d}y = -\mathrm{d}x$, $\star(\mathrm{d}x \wedge \mathrm{d}y) = 1$ and $\mathrm{d}^* = -\star\,\mathrm{d}\star$ on 2-forms in two dimensions,

$$\mathrm{d}^*(g\,\mathrm{d}x \wedge \mathrm{d}y) \overset{(1)}{=} -\star\,\mathrm{d}g \overset{(2)}{=} -\star\,(g_x \mathrm{d}x + g_y \mathrm{d}y) \overset{(3)}{=} g_y\,\mathrm{d}x - g_x\,\mathrm{d}y.$$

(1) $\star(g\,\mathrm{d}x \wedge \mathrm{d}y) = g$.
(2) Exterior derivative of a function.
(3) $\star \mathrm{d}x = \mathrm{d}y$ and $\star \mathrm{d}y = -\mathrm{d}x$.

So, writing a 1-form as the column of its $\mathrm{d}x$ and $\mathrm{d}y$ components,

$$D\begin{pmatrix} f \\ g \end{pmatrix} = \begin{pmatrix} \partial_x & \partial_y \\ \partial_y & -\partial_x \end{pmatrix}\begin{pmatrix} f \\ g \end{pmatrix}, \qquad \sigma_1(D)(k) = \mathrm{i}\begin{pmatrix} k_x & k_y \\ k_y & -k_x \end{pmatrix}.$$

The symbol squares to $-(k_x^2 + k_y^2)\mathbb{1}$ (multiply it out), so it is invertible for $k \neq 0$: D is elliptic, as promised, although the individual d's are not square. The equations $D(f, g) = 0$ read $f_x + g_y = 0$, $f_y - g_x = 0$: these are the Cauchy–Riemann equations for $f - \mathrm{i}g$. On a Fourier mode $e^{\mathrm{i}(Mx+Ny)}$ the matrix of D is $\sigma_1(D)(M, N)$, invertible unless $M = N = 0$. Hence $\operatorname{Ker} D$ = constant pairs (f, g), dimension 2; similarly $\operatorname{Ker} D^*$ = constant 1-forms $a\,\mathrm{d}x + b\,\mathrm{d}y$, dimension 2; and index $D = 2 - 2 = 0$. We will see in a moment that this is $\chi(T^2) = 1 - 2 + 1$.

4.4.3 Why the rolled-up operator is elliptic

Nash (p. 92) says that ellipticity of D "follows" from exactness of $\sigma(E)$. Here is the linear algebra behind it. Fix (x, k) with $k \neq 0$ and write σ_i for the matrix $\sigma_m(d_i)(x, k)$. With our convention (keeping the i's) the symbol of an adjoint is the adjoint matrix, $\sigma_m(d_i^*) = \sigma_i^\dagger$. So the symbol of D is $\sigma(D) = \sum_i (\sigma_{2i} + \sigma_{2i+1}^\dagger)$, and the same block computation we are about to do for D^*D in (4.30)

gives

$$\sigma(D)^\dagger\sigma(D) = \bigoplus_{i \text{ even}} \left(\sigma_i^\dagger\sigma_i + \sigma_{i-1}\sigma_{i-1}^\dagger\right).$$

Now suppose $v \in E_x^i$ is killed by the i-th block. Then

$$0 = \left\langle v, (\sigma_i^\dagger\sigma_i + \sigma_{i-1}\sigma_{i-1}^\dagger)v\right\rangle \overset{(1)}{=} \|\sigma_i v\|^2 + \left\|\sigma_{i-1}^\dagger v\right\|^2, \tag{4.28}$$

(1) Move one factor of each product to the other side of the inner product.

so $\sigma_i v = 0$ and $\sigma_{i-1}^\dagger v = 0$. The first says $v \in \operatorname{Ker}\sigma_i = \operatorname{Im}\sigma_{i-1}$ (exactness). The second says $v \perp \operatorname{Im}\sigma_{i-1}$ (by the same argument that gave (4.1)). A vector in a subspace and orthogonal to it is zero. So $\sigma(D)^\dagger\sigma(D)$ is injective, hence invertible, hence $\sigma(D)$ is injective. The same argument for $\sigma(D)\sigma(D)^\dagger$ shows $\sigma(D)$ is onto. So $\sigma(D)$ is an isomorphism $E_x^+ \to E_x^-$ for $k \neq 0$, i.e. D is elliptic. In particular $\operatorname{rank} E^+ = \operatorname{rank} E^-$, i.e. $\sum_i (-1)^i \operatorname{rank} E^i = 0$, which is the familiar fact that the alternating sum of dimensions of an exact sequence vanishes.

In the language of Section 4.3, the two-term complex $0 \to \pi^*E^+ \xrightarrow{\sigma(D)} \pi^*E^- \to 0$ (Nash (4.10)) is exact off the zero section. It is a "rolled-up" version of $\sigma(E)$, and one can show it represents the same class in $K(T^*X)$.

4.4.4 Laplacians and harmonic sections

Working definition 4.17 (Laplacians of a complex)

The **Laplacians** of the complex are

$$\Delta_i = d_i^*d_i + d_{i-1}d_{i-1}^* \colon \Gamma(X, E^i) \to \Gamma(X, E^i).$$

For the de Rham complex these are the Hodge Laplacians $\Delta = \mathrm{d}^*\mathrm{d} + \mathrm{d}\mathrm{d}^*$ [d^* is the adjoint of d, lowering the form degree by one] on p-forms; on functions on $\mathbb{R}^n$, $\Delta_0 = \mathrm{d}^*\mathrm{d} = -\sum_\mu \partial_\mu^2$.

A section e with $\Delta_i e = 0$ is called **harmonic**. On a compact manifold harmonic is the same as "closed and co-closed":

$$\begin{aligned}\Delta_i e = 0 \implies 0 = \langle e, \Delta_i e\rangle &\overset{(1)}{=} \langle e, d_i^*d_i e\rangle + \langle e, d_{i-1}d_{i-1}^* e\rangle \\ &\overset{(2)}{=} \|d_i e\|^2 + \left\|d_{i-1}^* e\right\|^2\end{aligned} \tag{4.29}$$

(1) Definition of Δ_i.
(2) Definition of the adjoint, $\langle e, d^*de\rangle = \langle de, de\rangle$; no boundary terms because X is closed.

so $d_i e = 0$ and $d_{i-1}^* e = 0$; the converse is obvious. Nash writes this as $\Delta_i e_i = 0 \iff d_i e_i = d_{i-1}^* e_i = 0$.

Now compute D^*D on E^+. Its E^0 component and its E^2 component are

$$\begin{aligned}\left(D^*D(e_0, e_2, \dots)\right)_0 &\overset{(1)}{=} d_0^*\left(d_0e_0 + d_1^*e_2\right) \\ &\overset{(2)}{=} d_0^*d_0e_0 + (d_1d_0)^*e_2 \overset{(3)}{=} \Delta_0 e_0, \\ \left(D^*D(e_0, e_2, \dots)\right)_2 &\overset{(4)}{=} d_1\left(d_0e_0 + d_1^*e_2\right) + d_2^*\left(d_2e_2 + d_3^*e_4\right) \\ &\overset{(5)}{=} d_1d_0e_0 + \left(d_1d_1^* + d_2^*d_2\right)e_2 + (d_3d_2)^*e_4 \overset{(6)}{=} \Delta_2 e_2.\end{aligned} \tag{4.30}$$

(1) Row 0 of D^* is $(d_0^*, 0, 0, \dots)$, applied to the first component of De.

(2) Expand; $d_0^* d_1^* = (d_1 d_0)^*$.
(3) $d_1 d_0 = 0$; and $\Delta_0 = d_0^* d_0$ since there is no d_{-1}.
(4) Row 2 of D^* is $(d_1, d_2^*, 0, \dots)$.
(5) Expand.
(6) $d_1 d_0 = 0$ and $d_3 d_2 = 0$ kill the cross terms; what is left is the definition of Δ_2.

The same pattern continues. So all the cross terms cancel because $d \circ d = 0$, and (Nash (4.11))

$$\Delta^+ := D^* D = \Delta_0 \oplus \Delta_2 \oplus \Delta_4 \oplus \cdots, \qquad \Delta^- := D D^* = \Delta_1 \oplus \Delta_3 \oplus \cdots. \tag{4.31}$$

Since these are block diagonal, their kernels are direct sums (Nash (4.12)): $\operatorname{Ker} \Delta^+ = \bigoplus_i \operatorname{Ker} \Delta_{2i}$ and $\operatorname{Ker} \Delta^- = \bigoplus_i \operatorname{Ker} \Delta_{2i+1}$. And $\operatorname{Ker} D = \operatorname{Ker} \Delta^+$ by the same positivity trick (Nash (4.13)):

$$D^* D e = 0 \implies 0 = \langle e, D^* D e \rangle \overset{(1)}{=} \langle De, De \rangle \implies De = 0, \tag{4.32}$$

(1) Definition of the adjoint.

and conversely $De = 0 \Rightarrow D^* De = 0$. Likewise $\operatorname{Ker} D^* = \operatorname{Ker} \Delta^-$. Therefore (Nash (4.14))

$$\begin{aligned} \operatorname{index} D &\overset{(1)}{=} \dim \operatorname{Ker} D - \dim \operatorname{Ker} D^* \\ &\overset{(2)}{=} \dim \operatorname{Ker} \Delta^+ - \dim \operatorname{Ker} \Delta^- \\ &\overset{(3)}{=} \sum_i \dim \operatorname{Ker} \Delta_{2i} - \sum_i \dim \operatorname{Ker} \Delta_{2i+1} \\ &= \sum_i (-1)^i \dim \operatorname{Ker} \Delta_i. \end{aligned} \tag{4.33}$$

(1) Definition of the index, with $\operatorname{Coker} D \cong \operatorname{Ker} D^*$.
(2) $\operatorname{Ker} D = \operatorname{Ker} \Delta^+$ and $\operatorname{Ker} D^* = \operatorname{Ker} \Delta^-$.
(3) Block-diagonal form (4.31).

The index of D counts harmonic sections, with a sign for parity.

4.4.5 The Hodge theorem: harmonic sections are cohomology

The complex (4.21) has cohomology

$$H^i(E) := \frac{\operatorname{Ker} d_i}{\operatorname{Im} d_{i-1}}.$$

For the de Rham complex this is de Rham cohomology $H^i_{\mathrm{dR}}(X; \mathbb{C})$, whose dimensions are the Betti numbers b_i. Nash quotes (from Wells):

Key idea: Hodge theorem for elliptic complexes, Nash (4.15)

For an elliptic complex over a compact closed manifold,

$$H^i(E) \;\cong\; \operatorname{Ker} \Delta_i :$$

every cohomology class has exactly one harmonic representative.

The mechanism is pure linear algebra, and it is worth seeing in finite dimensions first. Let $0 \to V^0 \xrightarrow{d_0} V^1 \to \cdots$ be a complex of finite-dimensional inner-product spaces. Then each V^i splits orthogonally into three pieces,

$$V^i = \operatorname{Im} d_{i-1} \;\oplus\; \operatorname{Ker} \Delta_i \;\oplus\; \operatorname{Im} d_i^*. \tag{4.34}$$

Why: $\operatorname{Im} d_{i-1} \perp \operatorname{Im} d_i^*$ because $\langle d_{i-1}a, d_i^* b\rangle = \langle d_i d_{i-1} a, b\rangle = 0$. A vector orthogonal to both satisfies $d_{i-1}^* v = 0$ (orthogonal to $\operatorname{Im} d_{i-1}$) and $d_i v = 0$ (orthogonal to $\operatorname{Im} d_i^*$), i.e. it is harmonic by (4.29). Moreover $\operatorname{Ker} d_i = (\operatorname{Im} d_i^*)^\perp = \operatorname{Im} d_{i-1} \oplus \operatorname{Ker} \Delta_i$. Hence

$$H^i \overset{(1)}{=} \frac{\operatorname{Ker} d_i}{\operatorname{Im} d_{i-1}} \overset{(2)}{=} \frac{\operatorname{Im} d_{i-1} \oplus \operatorname{Ker} \Delta_i}{\operatorname{Im} d_{i-1}} \overset{(3)}{=} \operatorname{Ker} \Delta_i. \tag{4.35}$$

(1) Definition of cohomology.
(2) The splitting of $\operatorname{Ker} d_i$ just derived.
(3) Quotienting a direct sum by one summand leaves the other.

In infinite dimensions the same argument works once one knows that the images are closed and the pieces fit together, and *that* is where ellipticity (via the Fredholm property of D and elliptic regularity) is needed.

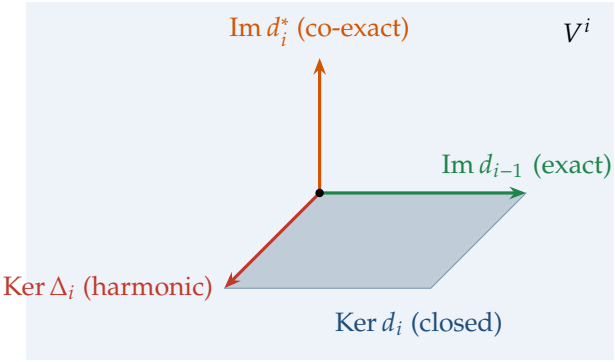

Figure 4.12: The Hodge decomposition (4.34), drawn like three perpendicular coordinate axes. Closed vectors fill the shaded plane spanned by the exact and harmonic axes; modding out by exact ones leaves exactly the harmonic direction. So each cohomology class has one harmonic representative, the one of smallest norm in its class.

Combining (4.33) with the Hodge theorem gives Nash's (4.16):

$$\operatorname{index} D = \sum_i (-1)^i \dim H^i(E) =: \chi(E), \tag{4.36}$$

the **Euler characteristic** of the elliptic complex. For the de Rham complex it is the ordinary Euler characteristic $\chi(X) = \sum_i (-1)^i b_i$.

Worked example 4.20: A finite complex: the triangulated circle

Triangulate the circle as a triangle with vertices v_1, v_2, v_3 and oriented edges $e_1 = [v_1 v_2]$, $e_2 = [v_2 v_3]$, $e_3 = [v_3 v_1]$. A 0-cochain assigns a number to each vertex, a 1-cochain a number to each edge, and the coboundary is "value at the head minus value at the tail":

$$0 \to \mathbb{C}^3 \xrightarrow{\ \delta\ } \mathbb{C}^3 \to 0, \qquad \delta = \begin{pmatrix} -1 & 1 & 0 \\ 0 & -1 & 1 \\ 1 & 0 & -1 \end{pmatrix}.$$

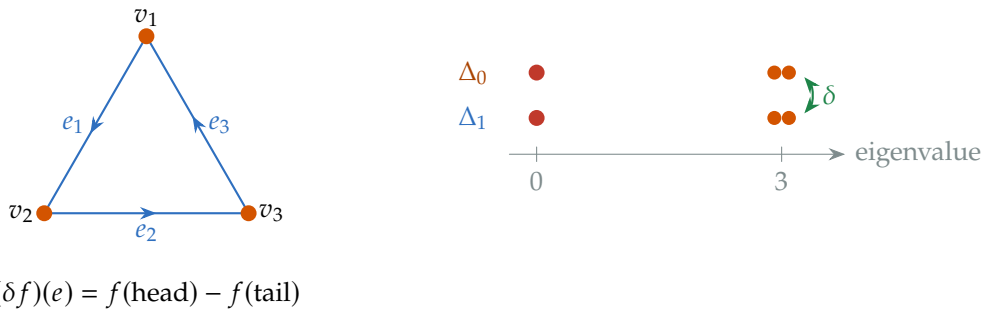
The rows sum to zero and any two are independent, so $\operatorname{rank} \delta = 2$. Then

$$\dim H^0 = \dim \operatorname{Ker} \delta = 3 - 2 = 1, \qquad \dim H^1 = \dim \operatorname{Coker} \delta = 3 - 2 = 1,$$

and $\chi = 1 - 1 = 0 = 3 - 3$. The Laplacians are

$$\Delta_0 = \delta^T\delta = \begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{pmatrix}, \qquad \Delta_1 = \delta\delta^T = \begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{pmatrix}.$$

Δ_0 is the graph Laplacian; its kernel is the constant cochain $(1,1,1)$, the harmonic representative of H^0. $\operatorname{Ker}\Delta_1$ is spanned by $(1,1,1)$ too: the "uniform circulation" 1-cochain, the harmonic representative of the generator of H^1 (the discrete version of $\mathrm{d}\theta$). The other eigenvalues of both Laplacians are $3, 3$; they occur in pairs, one for Δ_0 and one for Δ_1, matched by δ. Keep this pairing in mind: it is the heart of Section 4.8.



$(\delta f)(e) = f(\text{head}) - f(\text{tail})$

Figure 4.13: Left: the triangulated circle and its coboundary. Right: the spectra of Δ_0 and Δ_1. The nonzero eigenvalues (orange, 3 twice each) are matched by δ; only the zero modes (red), one on each side, are unmatched. Their difference $1 - 1 = 0$ is the Euler characteristic of the circle.

For finite complexes the Euler characteristic can be computed without finding the cohomology at all. Write $r_i = \operatorname{rank} d_i$. Then

$$\begin{aligned} \sum_i (-1)^i \dim H^i &\overset{(1)}{=} \sum_i (-1)^i \big(\dim \operatorname{Ker} d_i - r_{i-1}\big) \\ &\overset{(2)}{=} \sum_i (-1)^i \big(\dim V^i - r_i - r_{i-1}\big) \\ &\overset{(3)}{=} \sum_i (-1)^i \dim V^i. \end{aligned} \tag{4.37}$$

(1) $H^i = \operatorname{Ker} d_i / \operatorname{Im} d_{i-1}$ and $\dim \operatorname{Im} d_{i-1} = r_{i-1}$.
(2) Rank–nullity for d_i.
(3) The sum $\sum_i (-1)^i (r_i + r_{i-1})$ telescopes to zero (each r_j appears once with sign $(-1)^j$ and once with $(-1)^{j+1}$).

This is the finite-dimensional statement "the index depends only on the shape" again, (4.2), now for complexes. For the de Rham complex of a manifold each $V^i = \Omega^i$ is infinite-dimensional, the right-hand side is meaningless, and computing the left-hand side topologically is exactly what the index theorem achieves.

Worked example 4.21: $D = \mathrm{d} + \mathrm{d}^*$ on the circle and on the two-sphere

Circle. $E^+ = \Lambda^0$, $E^- = \Lambda^1$, $D = \mathrm{d}$. $\operatorname{Ker}\mathrm{d}$ = constant functions; $\operatorname{Ker}\mathrm{d}^*$ on 1-forms $h\,\mathrm{d}x$ is $\{h' = 0\}$, the constant multiples of $\mathrm{d}x$. So $\operatorname{index} D = 1 - 1 = 0 = \chi(S^1)$, in agreement with the triangulated circle.
Two-sphere. $E^+ = \Lambda^0 \oplus \Lambda^2$, $D(f,\beta) = \mathrm{d}f + \mathrm{d}^*\beta$. Suppose $D(f,\beta) = 0$. The two terms are

orthogonal:

$$\langle \mathrm{d}f, \mathrm{d}^*\beta\rangle \overset{(1)}{=} \langle \mathrm{d}\mathrm{d}f, \beta\rangle \overset{(2)}{=} 0,$$

(1) Move d^* across as d.
(2) $\mathrm{d}\circ\mathrm{d} = 0$.

so $0 = \|\mathrm{d}f + \mathrm{d}^*\beta\|^2 = \|\mathrm{d}f\|^2 + \|\mathrm{d}^*\beta\|^2$ forces $\mathrm{d}f = 0$ and $\mathrm{d}^*\beta = 0$: f is constant and β is a constant multiple of the area form. $\dim\operatorname{Ker} D = 2$. $\operatorname{Ker} D^* =$ harmonic 1-forms $\cong H^1_{\mathrm{dR}}(S^2) = 0$ (every closed loop on the sphere can be shrunk, so every closed 1-form is exact). So $\operatorname{index} D = 2 - 0 = 2 = \chi(S^2) = 1 - 0 + 1$. Compare the torus of Example 4.19: $\operatorname{index} D = 0 = 1 - 2 + 1$.

Physical picture: Why physicists like the rolled-up operator

Put $Q = \left(\begin{smallmatrix} 0 & D^* \\ D & 0 \end{smallmatrix}\right)$ acting on $E^+ \oplus E^-$. Then Q is self-adjoint and $Q^2 = \left(\begin{smallmatrix} D^*D & 0 \\ 0 & DD^* \end{smallmatrix}\right) = \Delta^+ \oplus \Delta^-$. This is a supercharge whose square is a Hamiltonian, with E^+ "bosonic" and E^- "fermionic". For the de Rham complex, $Q = \mathrm{d} + \mathrm{d}^*$ and the grading is the parity of the form degree: this is Witten's supersymmetric quantum mechanics on X, and (4.36) is the statement that its Witten index is $\chi(X)$. We return to this in Section 4.8 and in Chapter 7.

Reading Nash (pp. 91–93, (4.6)–(4.16))

Nash defines complexes of operators d_i of the same order m (4.6), their symbol complex $\sigma(E)$ over T^*X built from the leading symbols of p. 38 (4.7), and calls the complex elliptic when $\sigma(E)$ is exact off the zero section. He forms $E^{\pm}$ (4.8), the operator $D = \sum(d_{2i} + d^*_{2i+1})$ (4.9), notes the two-term complexes (4.10), and asserts that exactness of $\sigma(E)$ gives ellipticity of D; we supplied the positivity argument (4.28). The Laplacians, the decomposition $D^*D = \Delta_0 \oplus \Delta_2 \oplus \cdots$ (4.11)–(4.12), the kernel argument (4.13), the index as an alternating count of harmonic sections (4.14), the Hodge theorem (4.15) and $\operatorname{index} D = \chi(E)$ (4.16) are all there; we filled in the cross-term cancellation (4.30) and the linear algebra of the Hodge decomposition.

Recap

- A complex of operators d_i with $d_i d_{i-1} = 0$ is elliptic if its symbol complex is exact for $k \neq 0$ (de Rham: $\mathrm{i}k\wedge$; in $\mathbb{R}^3$: $\mathrm{i}k$, $\mathrm{i}k\times$, $\mathrm{i}k\cdot$).
- Rolled-up operator $D = \sum(d_{2i} + d^*_{2i+1})$: $E^+ \to E^-$ is elliptic by a positivity argument.
- $D^*D = \bigoplus \Delta_{2i}$, $DD^* = \bigoplus \Delta_{2i+1}$ because $d \circ d = 0$ kills cross terms.
- $\operatorname{index} D = \sum(-1)^i \dim\operatorname{Ker}\Delta_i = \sum(-1)^i \dim H^i(E) = \chi(E)$ by the Hodge theorem.
- Examples: $\chi(S^1) = 0$, $\chi(S^2) = 2$, $\chi(T^2) = 0$ from explicit kernels; nonzero eigenvalues of the Laplacians pair up.

4.5 The analytical index

We now have all the pieces for the first of Nash's two definitions. The question of this section is: *in what sense is the index a function on K-theory?* The answer is a map

$$\mathrm{ind}_a \colon K(T^*X) \longrightarrow \mathbb{Z},$$

the **analytical index**. Its input is a K-theory class of symbols; its output is the number of solutions of $D\psi = 0$ minus the number for $D^*\chi = 0$, for any operator D with that symbol class.

4.5.1 From an operator to a K-class

Start with an elliptic complex E, or just a single elliptic operator. Roll it up to $D \colon \Gamma(X, E^+) \to \Gamma(X, E^-)$ as in Section 4.4.2. The leading symbol of D is a two-term complex of bundles over T^*X (Nash (4.17)),

$$0 \longrightarrow \pi^*E^+ \xrightarrow{\sigma_m(D)} \pi^*E^- \longrightarrow 0, \tag{4.38}$$

which is exact off the zero section. By Section 4.3.6 it has compact support and defines a class

$$[\sigma_m(D)] \in K(T^*X) \qquad \text{(compactly supported K-theory)}.$$

For a single elliptic operator $D \colon \Gamma(E) \to \Gamma(F)$ it is just $0 \to \pi^*E \xrightarrow{\sigma_m(D)} \pi^*F \to 0$.

4.5.2 Why the index only depends on the class

For the rule $[\sigma_m(D)] \mapsto \operatorname{index} D$ to be a function on $K(T^*X)$, three things must hold. Each is a consequence of something we already know.

1. *Homotopic symbols give equal indices.* A compactly supported homotopy of two-term symbol complexes is a continuous family of elliptic symbols. Choosing operators with these symbols gives a continuous path of Fredholm operators, along which the index is constant (Sections 4.1.5 and 4.2.5). Operators with literally the same leading symbol differ by lower order terms and have the same index by (4.9).

2. *Direct sums add.* The symbol $\sigma_1 \oplus \sigma_2$ is the symbol of $D_1 \oplus D_2$, which acts block-diagonally; its kernel and cokernel are direct sums, so

$$\begin{aligned} \operatorname{index}(D_1 \oplus D_2) &\overset{(1)}{=} \dim(\operatorname{Ker} D_1 \oplus \operatorname{Ker} D_2) - \dim(\operatorname{Ker} D_1^* \oplus \operatorname{Ker} D_2^*) \\ &\overset{(2)}{=} \operatorname{index} D_1 + \operatorname{index} D_2. \end{aligned} \tag{4.39}$$

   (1) The adjoint of a block-diagonal operator is block-diagonal.
   (2) Dimensions add under direct sum; regroup.

3. *Symbols with empty support give index zero.* If the symbol is invertible even on the zero section, it can be deformed (by $\sigma(x,k) \to \sigma(x,sk)$, $s \to 0$, which does not create zeros) to the k-independent symbol $\sigma(x,0)$, which is the symbol of the order-zero operator "multiply by the invertible bundle map $\sigma(x,0)$". An invertible operator has no kernel and no cokernel, so its index is 0. (Such symbols only exist for order-zero, i.e. pseudo-differential, operators: a homogeneous symbol of degree $m > 0$ vanishes at $k = 0$.)

Items 1 and 2 make "index" a homomorphism on the semigroup $C(T^*X)$ of homotopy classes of symbol complexes; item 3 says it vanishes on $C_\phi(T^*X)$. By Segal's description (4.14), it therefore descends to the quotient $K(T^*X)$.

Working definition 4.18 (analytical index, Nash (4.18))

$$\operatorname{ind}_a : K(T^*X) \to \mathbb{Z}, \qquad [\sigma_m(D)] \longmapsto \operatorname{index} D = \dim \operatorname{Ker} D - \dim \operatorname{Ker} D^*. \tag{4.40}$$

Operational recipe: given a class, find any elliptic (pseudo-)differential operator whose symbol represents it [the class of its leading symbol $\sigma_m(D)$ in $K(T^*X)$ is the given class], and count its zero modes [independent solutions of $D\psi = 0$] minus the zero modes of its adjoint.

Watch out: Two hidden facts

The definition quietly assumes two things. First, that *every* element of $K(T^*X)$ is the class of some elliptic symbol; otherwise ind_a would only be defined on part of the group. This is true, but only if we allow pseudo-differential operators (Atiyah–Singer [2]); differential operators alone do not reach every class (on the circle they only reach 0, as we are about to see). Second, that the index depends only on the class, which is items 1–3 above; item 1 is where the Fredholm theory of Section 4.1 is really used.

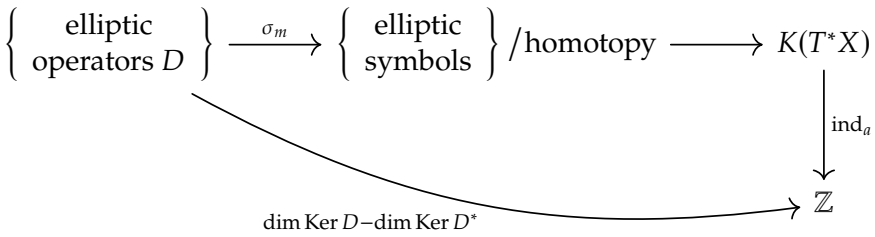


Figure 4.14: The analytical index as a factorisation. Counting zero modes (the curved arrow) is defined on operators, but it factors through the symbol, its homotopy class and finally its K-theory class. The vertical arrow is ind_a. The Atiyah–Singer theorem will give a second, topological description of the same vertical arrow.

Physical picture: The analytical index is renormalisation-group-blind

Physicists compute effective actions and anomalies by integrating out high-momentum modes; the answer can depend on how that is done (the choice of regulator). The factorisation in Figure 4.14 says the *index* cannot: two operators with homotopic leading symbols – however different their low-momentum, "infrared" details – have exactly the same index. Only the ultraviolet data, the leading symbol at large momentum, matters, and even that only through its topological class. This is the same phenomenon as the RG-invariance of an 't Hooft anomaly coefficient: it is fixed by the short-distance theory and cannot change under any smooth deformation of the low-energy physics.

4.5.3 Examples

Worked example 4.22: X a point: ind_a is the identity of $\mathbb{Z}$

If $X = \mathrm{pt}$ then $T^*X = \mathrm{pt}$, bundles are vector spaces, and an "elliptic operator" is simply a linear map $A : \mathbb{C}^a \to \mathbb{C}^b$ (every map is elliptic, since there are no $k \neq 0$ to check). Its symbol class is the complex $0 \to \mathbb{C}^a \xrightarrow{A} \mathbb{C}^b \to 0$, whose class in $K(\mathrm{pt}) = \mathbb{Z}$ is $a - b$ by Example 4.12.

Then

$$\operatorname{ind}_a(a-b) \overset{(1)}{=} \operatorname{index} A \overset{(2)}{=} a-b.$$

(1) Definition (4.40).
(2) Finite-dimensional index (4.2).

So $\operatorname{ind}_a : K(\mathrm{pt}) \to \mathbb{Z}$ is the identity. This "normalisation" is one of the axioms that pins down the index uniquely (Section 4.7).

Worked example 4.23: The circle: $K(T^*S^1) \cong \mathbb{Z}$ and winding numbers

Let $X = S^1$, so $T^*S^1 = S^1 \times \mathbb{R}$ is an infinite cylinder with coordinates (x, k). A symbol of order 0 on the trivial line bundle is a function $\sigma(x, k)$, homogeneous of degree 0 in k, hence determined by its values on the two circles $k = +1$ and $k = -1$. Ellipticity says both loops

$$x \mapsto \sigma(x, +1), \qquad x \mapsto \sigma(x, -1)$$

avoid 0, so each has a winding number, w_+ and w_- (for matrix symbols, the winding numbers of $\det \sigma$). Two observations:

- Multiplying σ by a k-independent invertible function $g(x)$ (the symbol of the invertible operator "multiply by g", which has index 0) shifts w_+ and w_- by the same amount. So only the difference $w_+ - w_-$ can matter.
- The Toeplitz-type operator A_f of (4.12) has $w_+ = \operatorname{wind}(f)$, $w_- = 0$ and index $-\operatorname{wind}(f)$.

Hence, for every elliptic symbol on the circle,

$$\operatorname{ind}_a[\sigma] = -(w_+ - w_-). \tag{4.41}$$

Topologically: the one-point compactification of the cylinder $S^1 \times \mathbb{R}$ is a sphere with its north and south poles glued together, which has the same K-theory as S^2 with a circle attached, so $K(T^*S^1) = \widetilde{K}(S^2) \oplus \widetilde{K}(S^1) = \mathbb{Z} \oplus 0 = \mathbb{Z}$, and $w_+ - w_-$ is the isomorphism. Now look at a differential operator of order m such as $\mathrm{d}/\mathrm{d}x + a$. Its leading symbol is a polynomial homogeneous of degree m, so $\sigma(x, -k) = (-1)^m \sigma(x, k)$: the loop at $k = -1$ is the loop at $k = +1$ times the constant $(-1)^m$, and $w_- = w_+$. So *every differential operator on the circle has index zero*, and only pseudo-differential operators reach the nonzero classes. This is the simplest case of the vanishing theorem in odd dimensions proved in the next part.

Worked example 4.24: Additivity, and the class of the adjoint

On the circle take $D_1 = A_{z^2}$ (index -2) and $D_2 = A_{z^{-3}}$ (index 3). Then $D_1 \oplus D_2$ acts on $\mathbb{C}^2$-valued functions with diagonal symbol $\operatorname{diag}(\sigma_1, \sigma_2)$; the winding number of its determinant on $k = +1$ is $2 + (-3) = -1$, on $k = -1$ it is 0. So by (4.41) its index is $+1$, and by (4.39) it is $-2 + 3 = +1$. Consistent.
The adjoint D^* has symbol $\sigma^\dagger$, whose determinant is the complex conjugate of $\det \sigma$ and so winds the opposite way: $w_\pm \to -w_\pm$ and ind_a changes sign. That matches $\operatorname{index} D^* = \dim \operatorname{Ker} D^* - \dim \operatorname{Ker} D = -\operatorname{index} D$.

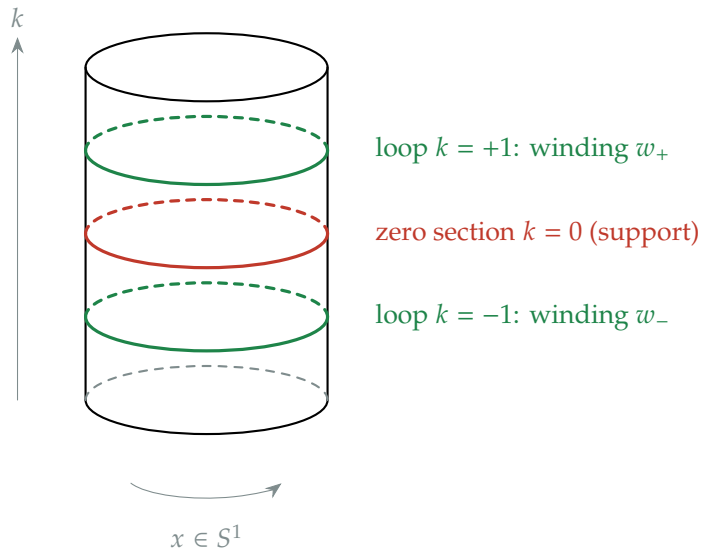

Figure 4.15: The phase space T^*S^1, drawn as a cylinder: the circle direction x runs around the cylinder and k runs up its axis. An elliptic symbol may vanish only on the red zero section. Its class is recorded by the winding numbers of the two loops $k = \pm 1$ (green); the index is $-(w_+ - w_-)$. For a differential operator the two loops differ by the sign $(-1)^m$, so $w_+ = w_-$ and the index vanishes.

Worked example 4.25: The de Rham class

For the de Rham complex on a closed X, the rolled-up symbol $\sigma(\mathrm{d} + \mathrm{d}^*)(x, k) = \mathrm{i}(k \wedge - \iota_k)$ (wedge with k plus its adjoint, contraction with the vector dual to k) gives a class $[\sigma_{\mathrm{dR}}] \in K(T^*X)$, and (4.36) says $\mathrm{ind}_a[\sigma_{\mathrm{dR}}] = \chi(X)$. For $X = S^2$ this is 2, for T^2 it is 0, for a surface of genus g it is $2 - 2g$. On the circle, $\sigma(\mathrm{d}) = \mathrm{i}k$ winds zero times on both $k = \pm 1$ (the loops are the constants $\pm\mathrm{i}$), so $w_+ = w_- = 0$ and the index is $0 = \chi(S^1)$, in agreement with (4.41).

Reading Nash (pp. 93–94, (4.17)–(4.18))

Nash: the symbol complex $0 \to \pi^*E^+ \to \pi^*E^- \to 0$ (4.17) gives an element $[\sigma_m(D)] \in K(T^*X)$; "two elliptic D with the same leading symbol have the same index"; so computing the index is a map from $K(T^*X)$ to $\mathbb{Z}$, the analytical index (4.18). He remarks that it is "tacit" that every element of $K(T^*X)$ arises as $[\sigma_m(D)]$, which Atiyah–Singer [2] guarantee once pseudo-differential operators are allowed. We added the three-step argument for well-definedness and the complete answer on a point and on a circle.

Recap

- Elliptic $D \Rightarrow$ symbol complex $0 \to \pi^*E^+ \to \pi^*E^- \to 0$ with compact support $\Rightarrow$ $[\sigma_m(D)] \in K(T^*X)$.
- Index is homotopy invariant, additive, and zero on everywhere-exact symbols, so it descends to $\mathrm{ind}_a : K(T^*X) \to \mathbb{Z}$.
- Point: $\mathrm{ind}_a = \mathrm{id}_{\mathbb{Z}}$. Circle: $K(T^*S^1) = \mathbb{Z}$, $\mathrm{ind}_a = -(w_+ - w_-)$; differential operators have $w_+ = w_-$ and index 0.
- Every class is realised by a pseudo-differential operator.

4.6 The topological index

The analytical index needs analysis: we must solve a PDE and count solutions. The question of this section is whether the same integer can be extracted from the class $[\sigma] \in K(T^*X)$ by *topology alone*, with no operator in sight. The idea is simple to state:

> Embed X in a big Euclidean space $\mathbb{R}^n$. Push the class $[\sigma]$ from T^*X into $T^*\mathbb{R}^n = \mathbb{R}^{2n}$. There the K-group is just $\mathbb{Z}$, so the pushed class *is* an integer. That integer is the topological index.

To push classes forward we need two tools, both of which Nash introduces in a few lines on pp. 94–95: the *Thom homomorphism*, which moves a class from a space into the total space of a vector bundle over it, and *extension by zero*, which moves a compactly supported class from an open subset into the whole space. And to connect the two we need *tubular neighbourhoods*. We explain all three, then assemble them.

4.6.1 Tubular neighbourhoods

Nash's picture: a curved piece of string S in $\mathbb{R}^3$. Thicken it into a tube U. The tube is a union of small discs, one through each point of the string and perpendicular to it. Each disc is a copy of a neighbourhood of 0 in the plane perpendicular to the string, i.e. in the **normal space** $N_s = (T_sS)^\perp$. So the tube looks like the **normal bundle** $N(S)$, the vector bundle over S whose fibre at s is N_s.

Working definition 4.19 (normal bundle and tubular neighbourhood)

For a submanifold $S \subset M$ of a Riemannian manifold, the **normal bundle** $N(S)$ has fibre $N_s = (T_sS)^\perp \subset T_sM$. A **tubular neighbourhood** is an open set $U \supset S$ with a diffeomorphism [a smooth bijection with smooth inverse] $N(S) \cong U$ (or from a disc bundle [the normal vectors $v \in N_s$ with $|v| < \epsilon$] in $N(S)$) sending the zero section [the vectors $v = 0$, one at each $s \in S$] to S. *Operational recipe* in $\mathbb{R}^n$: send (s, v), with $v \in N_s$ small, to the point $s + v$. For v small enough this is one-to-one (the normal discs do not collide).

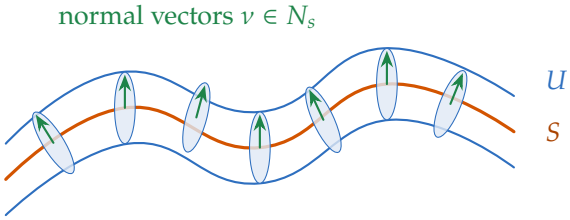

Figure 4.16: A string S (orange) in $\mathbb{R}^3$ and its tubular neighbourhood U (blue). Every point of the tube lies on exactly one small normal disc, centred at a point s of the string, so the tube is a copy of (a disc bundle in) the normal bundle $N(S)$. The green arrows are normal vectors.

Worked example 4.26: Three tubular neighbourhoods

(a) *The unit circle in* $\mathbb{R}^2$. At $s = (\cos\theta, \sin\theta)$ the normal line is spanned by $\hat{n} = (\cos\theta, \sin\theta)$ itself. The map $(\theta, r) \mapsto (1 + r)\hat{n}$, $|r| < 1$, identifies the trivial line bundle $S^1 \times (-1, 1)$ with the open annulus $0 < |x| < 2$. The normal bundle is trivial.

(b) *A point in $\mathbb{R}^n$.* $T_p\{p\} = 0$, so $N_p = \mathbb{R}^n$ and the tubular neighbourhood of a point is all of $\mathbb{R}^n$ (or a ball around it).
(c) *The central circle of a Möbius band.* Going once round the circle, the normal direction comes back reversed. The tubular neighbourhood is the Möbius band itself, and the normal bundle is the non-trivial real line bundle over S^1. So normal bundles carry topology, and that is why the construction below needs the full Thom homomorphism rather than a simple product.

4.6.2 The exterior complex and the Thom class

Let $F \to X$ be a complex vector bundle of rank r, with projection $p\colon F \to X$. Points of the total space are pairs (x, v) with $v \in F_x$. Over the total space F we have the pulled-back bundles $p^*\Lambda^i F$, whose fibre at (x, v) is the exterior power $\Lambda^i F_x$. At (x, v), wedge with v itself:

$$\Lambda(F)\colon \quad 0 \to \Lambda^0 F \xrightarrow{v\wedge} \Lambda^1 F \xrightarrow{v\wedge} \cdots \xrightarrow{v\wedge} \Lambda^r F \to 0, \qquad \omega \mapsto v \wedge \omega. \tag{4.42}$$

This is Nash's **exterior complex** (4.20). It is a complex because $v \wedge v \wedge \omega = 0$. It is exact whenever $v \neq 0$, by exactly the argument of Example 4.17 (choose a basis of F_x with first vector v). At $v = 0$ every map is zero and exactness fails. So

$$\operatorname{supp} \Lambda(F) = \text{zero section} \cong X,$$

which is compact when X is. Its class $\lambda_F := [\Lambda(F)] \in K(F)$ is the **Thom class** of F.

Worked example 4.27: The exterior complex in ranks one and two

Rank one, $F = X \times \mathbb{C}$. $\Lambda^0 = \mathbb{C}$, $\Lambda^1 = \mathbb{C}$, and $v\wedge$ is multiplication by the number v:

$$0 \to \mathbb{C} \xrightarrow{v} \mathbb{C} \to 0.$$

Over a point this is precisely the Bott complex (4.17). So *the Thom class of $\mathbb{C}$ over a point is the Bott class.*
Rank two, $F = X \times \mathbb{C}^2$. Use the basis 1; e_1, e_2; $e_1 \wedge e_2$, and write $v = v_1 e_1 + v_2 e_2$. Then $v \wedge 1 = v_1 e_1 + v_2 e_2$ and

$$v \wedge (a e_1 + b e_2) \overset{(1)}{=} v_1 b\, e_1 \wedge e_2 + v_2 a\, e_2 \wedge e_1 \overset{(2)}{=} (-v_2 a + v_1 b)\, e_1 \wedge e_2,$$

(1) $e_1 \wedge e_1 = e_2 \wedge e_2 = 0$.
(2) $e_2 \wedge e_1 = -e_1 \wedge e_2$.
so the complex is

$$0 \to \mathbb{C} \xrightarrow{\binom{v_1}{v_2}} \mathbb{C}^2 \xrightarrow{(-v_2\ v_1)} \mathbb{C} \to 0.$$

The composite is $-v_2 v_1 + v_1 v_2 = 0$. For $v \neq 0$ both maps have rank 1, and $1+1 = 2 = \dim \mathbb{C}^2$, so it is exact. Now compare with the tensor product formula (4.19) for two Bott complexes, with $a = v_1$ and $b = v_2$: the maps are $\binom{a}{b}$ and $(-b\ a)$. Identical. So

$$\lambda_{\mathbb{C}^2} = \beta \boxtimes \beta, \qquad \text{and in general} \qquad \lambda_{\mathbb{C}^r} = \beta \boxtimes \cdots \boxtimes \beta \ (r \text{ factors}),$$

where $\boxtimes$ is the product of classes pulled back from the separate factors. The Thom class of a trivial bundle is a product of Bott classes, one for each complex direction.

Watch out: Nash's $k = k_i\,\mathrm{d}k^i$

On p. 94 Nash writes the exactness argument as "if v is an i-form and $k = k_i\,\mathrm{d}k^i \neq 0$, then $k \wedge v = 0 \Rightarrow v = k \wedge w$". He is recycling the de Rham notation. In the exterior complex the thing we wedge with is the point $v \in F_x$ of the fibre, not a covector on X, and the forms are elements of $\Lambda^\bullet F_x$, not differential forms. The linear algebra is the same.

4.6.3 The Thom homomorphism

Working definition 4.20 (Thom homomorphism, Nash (4.19), (4.21))

For a complex vector bundle $p\colon F \to X$,

$$\phi\colon K(X) \to K(F), \qquad \phi(a) = p^*a \cdot \lambda_F. \tag{4.43}$$

In words: pull the class a back to the total space [F itself, the set of all vectors in all fibres F_x] (constant along the fibres), then multiply by the Thom class [the class of the exterior complex, exact wherever the fibre vector $v \neq 0$], which cuts it down to a neighbourhood of the zero section.

The product has compact support even though p^*a does not, because the support of a product of complexes is the intersection of the supports (Section 4.3.5), and λ_F is supported on the compact zero section. For non-compact X (such as X replaced by T^*X, which is how we will use it) the same formula works with compactly supported classes a (Atiyah–Singer [2]).

Key idea: Thom isomorphism and Bott periodicity

$\phi\colon K(X) \to K(F)$ is an *isomorphism*. For X a point and $F = \mathbb{C}^r$ this says

$$\mathbb{Z} \overset{(1)}{=} K(\mathrm{pt}) \xrightarrow{\phi} K(\mathbb{C}^r) \overset{(2)}{=} K(\mathbb{R}^{2r}) \overset{(3)}{=} \widetilde{K}(S^{2r}), \tag{4.44}$$

(1) Example 4.11.
(2) $\mathbb{C}^r = \mathbb{R}^{2r}$ as a space.
(3) Compact supports = reduced K-theory of the one-point compactification, and $(\mathbb{R}^{2r})^+ = S^{2r}$ (stereographic projection).

i.e. $\widetilde{K}(S^{2r}) \cong \mathbb{Z}$, generated by $\phi(1) = \lambda_{\mathbb{C}^r} = \beta^{\boxtimes r}$. This is Bott periodicity.

Physical picture: The Thom class is a K-theoretic delta function

In de Rham cohomology the analogue of λ_F is the **Thom form**: a closed form on F, concentrated near the zero section (a Gaussian bump in the fibre directions, times the fibre volume form), whose integral over each fibre is 1. Multiplying by it is "multiplying by $\delta(v)$ in the normal directions". The Thom homomorphism takes a field on X and turns it into a field on the bigger space F localised on X, like a field living on a brane. The K-theory Thom class does the same job, with the Bott complex playing the role of the normalised bump: in each complex fibre direction it contributes one unit of winding.

4.6.4 Extension by zero

Let $i\colon S \hookrightarrow M$ be the inclusion of an *open* subset. Nash (p. 95) first explains the idea with differential forms: a p-form ω on S "can be extended to the whole of M by letting it be zero

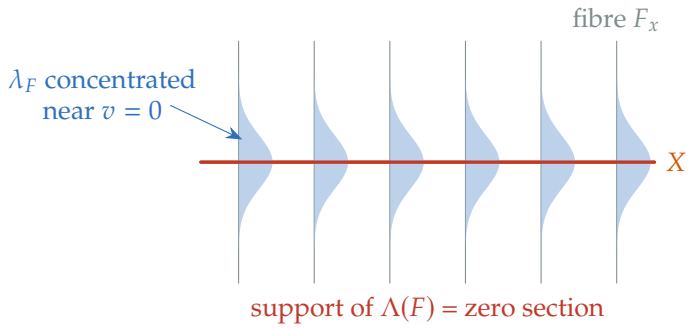

Figure 4.17: The Thom class of a vector bundle $F \to X$, drawn as its de Rham cousin: a bump (blue) in each fibre, centred on the zero section. The exterior complex $\Lambda(F)$ is exact wherever $v \neq 0$, so as a K-class it lives only on the zero section (red). Multiplying by it transplants a class on X into a compactly supported class on F.

outside S".

Worked example 4.28: A bump form on an arc of the circle

Let $S = (a, b) \subset S^1 = M$ be an open arc, and let $\omega = h(x)\,\mathrm{d}x$ with $h \geq 0$ a smooth bump supported inside $[a + \varepsilon, b - \varepsilon]$ and $\int_a^b h\,\mathrm{d}x = 1$. Extended by zero, ω is a smooth 1-form on the whole circle with

$$\int_{S^1} i_*\omega \overset{(1)}{=} \int_a^b h(x)\,\mathrm{d}x \overset{(2)}{=} 1,$$

(1) $i_*\omega$ vanishes outside (a, b).
(2) Normalisation of the bump.

So $i_*\omega$ represents the generator of $H^1_{\mathrm{dR}}(S^1)$, although on the arc itself $\omega = \mathrm{d}\big(\int_a^x h\big)$ is exact. The extension is smooth only because ω vanishes near the ends of the arc.

Watch out: Extension by zero needs compact supports

Nash writes the induced map as $H^p_{\text{de Rham}}(S) \to H^p_{\text{de Rham}}(M)$. As the example shows, it is only defined for forms that vanish near the edge of S, i.e. for compactly supported cohomology: $i_*\colon H^p_c(S) \to H^p(M)$ (or $\to H^p_c(M)$). A general form on S (say $\mathrm{d}x/(x - a)$) does not extend. The same caveat applies in K-theory, and it is harmless there because all our classes have compact support.

Working definition 4.21 (extension by zero in K-theory, Nash (4.22))

For an open inclusion $i\colon S \hookrightarrow M$ [S is an open subset of M and i is the identity on it],

$$i_*\colon K(S) \to K(M)$$

(compactly supported K-theory [classes of complexes that are exact outside some compact set] on both sides) sends the class of a complex E on S with compact support $C \subset S$ to the class of a complex on M that agrees with E near C and is exact everywhere else. *How:* outside C the complex is exact, so its bundles can be identified with each other through the maps (as in the clutching of Example 4.13); this identification lets us continue the complex across the edge of S as a trivially exact complex.

Worked example 4.29: The Bott class on the plane, the sphere and the torus

Identify $\mathbb{C}$ with S^2 minus the north pole by stereographic projection. The Bott complex on $\mathbb{C}$ extends by zero to the class $\mathbf{1} - [L] \in \widetilde{K}(S^2)$ found in (4.18): this is i_* for $\mathbb{C} \hookrightarrow S^2$. Equally, a small open disc in the torus T^2 is a copy of $\mathbb{C}$, and extending the Bott class from it gives $\mathbf{1} - [L_{T^2}]$, where L_{T^2} is a line bundle of degree one on the torus. In both cases the result is "one unit of winding, localised at a point". The first Chern number of the resulting bundle counts the units: this is the K-theory version of the bump form above.

4.6.5 Assembling the topological index

Now we put the pieces together. Let X be compact of dimension d, and choose an embedding $X \subset \mathbb{R}^n$ (Whitney's theorem guarantees one for n large enough). Let $N = N(X)$ be its normal bundle, of real rank $n - d$.

Step 1: the phase space of X sits inside the phase space of $\mathbb{R}^n$. Using the Euclidean metric to identify covectors with vectors, $T^*X \subset T^*\mathbb{R}^n = \mathbb{R}^n \times \mathbb{R}^n$: a point (x, k) of T^*X is a position on X and a momentum tangent to X.

Step 2: its tubular neighbourhood. At (x, k) we may move off T^*X in two independent kinds of normal direction: shift the position along N_x, or add to the momentum a vector in N_x. So the normal bundle of T^*X in $T^*\mathbb{R}^n$ is $\pi^*(N \oplus N)$, the pull-back to T^*X of two copies of N. Nash's trick is to regard the pair $(a, b) \in N_x \oplus N_x$ as the single complex vector $a + \mathrm{i}b$:

$$N(T^*X) \;\cong\; \pi^*(N \oplus N) \;\cong\; \pi^*(N \oplus \mathrm{i}N) \;=\; \pi^*(N \otimes_{\mathbb{R}} \mathbb{C}) \;=:\; F. \tag{4.45}$$

So the tubular neighbourhood of T^*X is a *complex* vector bundle F of complex rank $n - d$. That is what makes a K-theory Thom homomorphism available. (This is the physicist's familiar $z = q + \mathrm{i}p$: a normal position and its conjugate normal momentum combine into one complex coordinate.) Dimension check:

$$\dim_{\mathbb{R}} F \overset{(1)}{=} \dim_{\mathbb{R}} T^*X + 2\,\mathrm{rank}_{\mathbb{C}}\, F \overset{(2)}{=} 2d + 2(n-d) = 2n = \dim_{\mathbb{R}} T^*\mathbb{R}^n. \tag{4.46}$$

(1) Base plus fibre; a complex fibre of rank r has real dimension $2r$.
(2) $\dim T^*X = 2d$, and $\mathrm{rank}_{\mathbb{C}}\, F = \mathrm{rank}_{\mathbb{R}}\, N = n - d$.

As it should be: F is (identified with) an open subset of $T^*\mathbb{R}^n$.

Step 3: the maps. Thom homomorphism for $F \to T^*X$ (Nash (4.23)), then extension by zero for the open inclusion $F \subset T^*\mathbb{R}^n$ (Nash (4.24)), composed (Nash (4.25)):

$$i_!\colon K(T^*X) \xrightarrow{\phi} K(F) \xrightarrow{i_*} K(T^*\mathbb{R}^n), \qquad i_! = i_* \circ \phi. \tag{4.47}$$

Step 4: compare with a point. Let $P = \{x_0\}$ be the origin of $\mathbb{R}^n$ and $j\colon P \to \mathbb{R}^n$ its inclusion (Nash (4.26)). Running the same construction for P: $T^*P = P$, the normal bundle of P is $\mathbb{R}^n$, and $N \otimes \mathbb{C} = \mathbb{C}^n$, whose total space is all of $T^*\mathbb{R}^n = \mathbb{R}^{2n}$. So $j_! = \phi_{\mathbb{C}^n}\colon K(\mathrm{pt}) \to K(\mathbb{C}^n)$ is the Thom isomorphism of a point, i.e. Bott periodicity (4.44).

Step 5: the K-groups at the ends. (Nash (4.29).)

$$K(T^*P) \overset{(1)}{=} K(P) \overset{(2)}{=} \mathbb{Z}, \qquad K(T^*\mathbb{R}^n) \overset{(3)}{=} K(\mathbb{R}^n \times \mathbb{R}^n) = K(\mathbb{R}^{2n}) \overset{(4)}{=} \widetilde{K}(S^{2n}) \overset{(5)}{=} \mathbb{Z}. \tag{4.48}$$

(1) The cotangent space of a point is the point.
(2) Example 4.11.
(3) $T^*\mathbb{R}^n$ is a bundle over a contractible base, hence trivial.

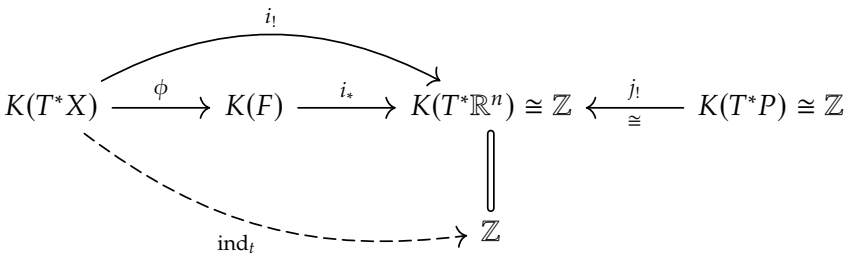

Figure 4.18: Nash's diagram (4.27), with the Thom homomorphism and the extension by zero written out. A symbol class on T^*X is transplanted into a tubular neighbourhood F of T^*X in $T^*\mathbb{R}^n$ by ϕ, then extended by zero to all of $T^*\mathbb{R}^n$. There it is compared, via the Bott isomorphism $j_!$, with the K-theory of a point. The result is the integer $\mathrm{ind}_t[\sigma]$.

(4) Compact supports and one-point compactification.
(5) Bott periodicity.

Working definition 4.22 (topological index, Nash (4.28), (4.30))

$$\mathrm{ind}_t = (j_!)^{-1} \circ i_! \colon K(T^*X) \to K(T^*P) = \mathbb{Z}, \qquad [\sigma_m(D)] \longmapsto (j_!)^{-1}\big(i_!([\sigma_m(D)])\big). \tag{4.49}$$

[$i_!$ is the Thom homomorphism followed by extension by zero, from T^*X into $T^*\mathbb{R}^n$. $j_!$ does the same for a point $P \in \mathbb{R}^n$, and is an isomorphism] *In words:* transplant the symbol class into Euclidean phase space, where every class is an integer multiple of the Bott class [$j_!(1)$, the Thom class of $T^*\mathbb{R}^n = \mathbb{C}^n$ over the point P], and read off the multiple.

Two remarks from Nash (p. 97). First, the construction used an embedding and a tubular neighbourhood, so one must check that the answer does not depend on these choices (it does not; Atiyah–Singer [2]). Any two embeddings become isotopic after enlarging n, and isotopic choices give homotopic complexes. Second, $j_!$ is an isomorphism $\mathbb{Z} \to \mathbb{Z}$ sending generator to generator, so it is "the identity", and we could omit it. It is kept because in the equivariant theory of §6, where a group G acts and $K(\mathrm{pt})$ is replaced by the representation ring $R(G)$, it is no longer trivial.

Worked example 4.30: The topological index of a point

Take $X = P$ itself. Then $i = j$, so $i_! = j_!$ and

$$\mathrm{ind}_t \overset{(1)}{=} (j_!)^{-1} \circ j_! = \mathrm{id}_{\mathbb{Z}} \overset{(2)}{=} \mathrm{ind}_a.$$

(1) Definition (4.49) with $i = j$.
(2) Example 4.22.

The two indices agree on a point. This is the "normalisation axiom" of Section 4.7.

Worked example 4.31: The circle in the plane: the construction in coordinates

Let $X = S^1 \subset \mathbb{R}^2$ ($d = 1$, $n = 2$), with unit tangent $\hat{t} = (-\sin\theta, \cos\theta)$ and unit normal $\hat{n} = (\cos\theta, \sin\theta)$. Then:

- $T^*S^1 \subset T^*\mathbb{R}^2 = \mathbb{R}^4$ consists of the points $(\hat{n},\ k\,\hat{t})$: position on the unit circle, momentum tangent to it. Coordinates (θ, k).

- N is the trivial real line bundle spanned by $\hat{n}$, so $F = \pi^*(N \otimes \mathbb{C})$ is the trivial complex line bundle over the cylinder, with fibre coordinate $w = r + ip$.
- The tubular neighbourhood map is

$$(\theta, k, w) \longmapsto \Big(\underbrace{(1+r)\,\hat{n}}_{\text{position}},\ \underbrace{k\,\hat{t} + p\,\hat{n}}_{\text{momentum}} \Big) \in \mathbb{R}^4, \qquad |r| < 1.$$

  It is one-to-one: from the position we read off θ and r, and from the momentum, decomposed along $\hat{t}$ and $\hat{n}$, we read off k and p. Its image is (annulus)$\times\mathbb{R}^2$, open in $\mathbb{R}^4$.
- The Thom class of F is the rank-one exterior complex $0 \to \mathbb{C} \xrightarrow{w} \mathbb{C} \to 0$. For a symbol class $[\sigma]$, $\phi[\sigma] = [\sigma] \cdot [w]$, the tensor product of the symbol complex with the complex "multiply by w". Its support is $\{k = 0\} \cap \{w = 0\}$, the circle $\{(\hat{n}, 0)\}$ inside $\mathbb{R}^4$: compact, so i_* can extend it to $K(\mathbb{R}^4) = \widetilde{K}(S^4) = \mathbb{Z}$.

The resulting integer is $\mathrm{ind}_t[\sigma]$. The Atiyah–Singer theorem (next section) says it equals $-(w_+ - w_-)$ from (4.41). Doing that last identification by hand is possible but not illuminating; its content is that the class in $\widetilde{K}(S^4)$ measures how many times the combined map (σ, w) "wraps" around its zero set, and that wrapping is the relative winding of the symbol on the two halves of T^*S^1.

Reading Nash (pp. 94–97, (4.19)–(4.30))

Nash introduces the tubular neighbourhood with the string-in-$\mathbb{R}^3$ picture, defines the Thom homomorphism $\phi\colon K(X) \to K(F)$ (4.19) using the exterior complex (4.20) and its class λ_F, as multiplication by λ_F (4.21), and notes that it is an isomorphism which for a point is Bott periodicity $\widetilde{K}(S^{2n}) = \mathbb{Z}$. Then comes extension by zero $i_*\colon K(S) \to K(M)$ for open $S \subset M$ (4.22), motivated by differential forms. The embedding $X \subset \mathbb{R}^n$ gives the complex bundle $F = \pi^*(N(X) \otimes_{\mathbb{R}} \mathbb{C})$ (4.23), the maps i_* (4.24), $i_! = i_* \circ \phi$ (4.25), $j\colon P \to \mathbb{R}^n$ and $j_!$ (4.26), the diagram (4.27), and $\mathrm{ind}_t = (j_!)^{-1} \circ i_!$ (4.28), (4.30), with $K(T^*P) = K(T^*\mathbb{R}^n) = \mathbb{Z}$ (4.29). We added the explicit exterior complexes, their identification with products of Bott classes, the bump-form example, the dimension check (4.46) and the circle in coordinates.

Recap

- Tubular neighbourhood of $S \subset M \cong$ normal bundle $N(S)$.
- Exterior complex $v\wedge\colon \Lambda^i F \to \Lambda^{i+1} F$, exact for $v \neq 0$; its class λ_F is the Thom class; for $F = \mathbb{C}^r$ it is the product of r Bott classes.
- Thom homomorphism $\phi(a) = p^*a \cdot \lambda_F$ is an isomorphism; for a point it is Bott periodicity.
- Extension by zero i_* for open inclusions (compact supports).
- $T^*X \subset T^*\mathbb{R}^n$ has tubular neighbourhood $F = \pi^*(N \otimes \mathbb{C})$ ($q + ip$ in the normal directions); $\mathrm{ind}_t = (j_!)^{-1} \circ i_* \circ \phi\colon K(T^*X) \to \mathbb{Z}$.

4.7 The Atiyah–Singer index theorem

We now have two maps from the same group to the integers:

$$\mathrm{ind}_a,\ \mathrm{ind}_t \colon K(T^*X) \longrightarrow \mathbb{Z}.$$

The first counts zero modes. To evaluate it we must solve a partial differential equation on the whole of X, which is a global and usually hopeless problem. The second pushes the symbol class into Euclidean phase space and reads off a multiple of the Bott class. To evaluate it we need only the symbol, and only up to deformation. The question of this section is the obvious one: *are they the same map?* The answer, yes, is the Atiyah–Singer index theorem. We state it, test it on every example where both sides can be computed by hand, and then explain the two strategies by which it is proved.

4.7.1 The statement

Key idea: The Atiyah–Singer index theorem (Nash p. 97)

For every compact manifold X without boundary,

$$\mathrm{ind}_t = \mathrm{ind}_a \colon K(T^*X) \to \mathbb{Z}. \tag{4.50}$$

Concretely: for every elliptic (pseudo-)differential operator, or elliptic complex, D on X,

$$\underbrace{\dim \operatorname{Ker} D - \dim \operatorname{Ker} D^*}_{\text{analysis: count solutions}} = \underbrace{(j_!)^{-1}\, i_! \,[\sigma_m(D)]}_{\text{topology: symbol class only}} .$$

It is worth saying slowly why this is surprising. The left side depends, a priori, on everything: the coefficients of D at every point, the metric used to define D^*, the global shape of X. The right side depends only on

- the leading symbol, i.e. how D acts on very short wavelengths,
- and only on its homotopy class through elliptic symbols,
- together with the topology of X (through the embedding and the normal bundle).

We already knew from Sections 4.2 and 4.5 that the index is *insensitive* to lower-order terms and to deformations. The theorem goes much further: it says the index can be *computed* from the symbol alone. Short-wavelength data determines a count of zero modes, which are the longest-wavelength states there are.

Physical picture: A conserved charge computed from its flux

Think of Gauss's law. The total charge inside a closed surface is a global quantity, yet it can be read off from the flux of $\vec{E}$ through any surface enclosing it, and it does not change as we deform the surface. The index behaves the same way. The symbol class lives near "infinity in momentum space" (on the sphere bundle $|k| = 1$, where it is invertible), and it measures how many zero modes are trapped inside, just as the flux at infinity measures the charge. In the Toeplitz example this is literal: the index is a winding number $\frac{1}{2\pi \mathrm{i}} \oint \mathrm{d}f/f$, a flux integral of the symbol around the circle at large $|k|$.

In §2 of Nash (the next part of these notes) the right-hand side is turned, via the Chern character, into an integral of characteristic classes:

$$\operatorname{index} D = (-1)^n \big\{ \operatorname{ch}[\sigma_m(D)] \operatorname{td}(TX \otimes \mathbb{C}) \big\}[TX].$$

That is the form in which physicists use the theorem. The K-theory version (4.50) is the sharper one: it is an equality of integers with no denominators, and it survives in situations (families, real operators, group actions) where the cohomological formula loses information.

4.7.2 Checking the theorem where both sides are computable

Before looking at proofs, let us convince ourselves the theorem is true. We run through examples where the analytic side has been computed in earlier sections and the topological side can be found independently. For the topological side we will sometimes use the cohomological form of the theorem (proved in the next part) as a stand-in for $(j_!)^{-1} i_!$; this is honest, since the cohomological form is derived from ind_t alone, without any analysis.

Worked example 4.32: The point, once more

For $X = \mathrm{pt}$ we found $\operatorname{ind}_a = \mathrm{id}_{\mathbb{Z}}$ (Example 4.22) and $\operatorname{ind}_t = (j_!)^{-1} j_! = \mathrm{id}_{\mathbb{Z}}$ (Example 4.30). The theorem on a point is rank–nullity, (4.2): $\dim \operatorname{Ker} A - \dim \operatorname{Coker} A = \dim V - \dim W$. The left side needs the matrix; the right side needs only the "symbol class" $[V]-[W] \in K(\mathrm{pt})$, i.e. the sizes of the two spaces. This is the whole theorem in miniature.

Worked example 4.33: The de Rham operator on a closed surface: Gauss–Bonnet

Let $X = \Sigma_g$ be a closed orientable surface of genus g and $D = \mathrm{d} + \mathrm{d}^* \colon \Omega^0 \oplus \Omega^2 \to \Omega^1$.
Analytic side. By (4.36) and the Hodge theorem, $\operatorname{index} D = b_0 - b_1 + b_2 = 1 - 2g + 1 = 2 - 2g$. (For S^2 and T^2 we found the kernels by hand in Examples 4.19 and 4.21.)
Topological side. For the de Rham symbol class the cohomological index formula (next part, Nash (4.53)–(4.54)) reduces to the integral of the Euler class, which in two dimensions is the Gaussian curvature K times the area form divided by 2π:

$$\operatorname{ind}_t[\sigma_{\mathrm{dR}}] \overset{(1)}{=} \int_{\Sigma_g} e(TX) \overset{(2)}{=} \frac{1}{2\pi} \int_{\Sigma_g} K \, \mathrm{d}A.$$

(1) Cohomological form of ind_t for the de Rham complex.
(2) The Euler form of a surface; see Chapter T2 for Gauss–Bonnet.

For the round sphere of radius R, $K = 1/R^2$ and the area is $4\pi R^2$, so

$$\frac{1}{2\pi} \int_{S^2} K \, \mathrm{d}A \overset{(1)}{=} \frac{1}{2\pi} \cdot \frac{1}{R^2} \cdot 4\pi R^2 = 2 = \chi(S^2).$$

(1) K is constant, so the integral is K times the area.

For the flat torus $K = 0$ and the integral is $0 = \chi(T^2)$. For genus $g \geq 2$ with a hyperbolic metric ($K = -1$) the area must be $4\pi(g-1)$ for the two sides to agree, and it is (a hyperbolic surface of genus g is glued from a $4g$-gon with interior angles summing to 2π, whose area by the hyperbolic Gauss–Bonnet formula is $(4g-2)\pi - 2\pi$). Gauss–Bonnet *is* the Atiyah–Singer theorem for $\mathrm{d} + \mathrm{d}^*$ in two dimensions.

Worked example 4.34: Riemann–Roch on the Riemann sphere

Let $X = \mathbb{CP}^1 = \mathbb{C} \cup \{\infty\}$ and let L_n be the line bundle $\mathcal{O}(n)$: a section is a function $f(z)$ on the z-chart and a function $\tilde f(w)$ on the $w = 1/z$ chart, related on the overlap by $\tilde f(w) = w^n f(1/w)$. Let $D = \bar\partial_{L_n}$, the Cauchy–Riemann operator on sections of L_n, whose kernel is the holomorphic sections.

Analytic side, $n \geq 0$. A holomorphic section is an entire function $f(z)$ such that $w^n f(1/w)$ is holomorphic at $w = 0$, i.e. $f(z) = O(|z|^n)$ as $z \to \infty$. By Liouville's theorem f is a polynomial of degree at most n, so

$$\operatorname{Ker} \bar\partial_{L_n} = \operatorname{span}\{1, z, z^2, \dots, z^n\}, \qquad \dim \operatorname{Ker} \bar\partial_{L_n} = n + 1.$$

The cokernel is $H^{0,1}(L_n)$, which vanishes for $n \geq -1$ (by Serre duality it is dual to the holomorphic sections of L_{-n-2}, and a negative-degree bundle has none). So index $\bar\partial_{L_n} = n+1$.

Analytic side, $n \leq -2$. Now f must be entire and decay like $|z|^n$, so $f = 0$: no kernel. The cokernel is dual to the sections of L_{-n-2}, of dimension $-n-1$. So index $\bar\partial_{L_n} = 0 - (-n-1) = n+1$ again.

Topological side. The cohomological formula for twisted Dolbeault operators is the Riemann–Roch theorem (next part, and Chapter 5):

$$\begin{aligned}\operatorname{ind}_t[\sigma(\bar\partial_{L_n})] &\overset{(1)}{=} \int_{\mathbb{CP}^1} \operatorname{ch}(L_n)\,\operatorname{td}(\mathbb{CP}^1) \overset{(2)}{=} \int_{\mathbb{CP}^1} \big(1 + c_1(L_n)\big)\big(1 + \tfrac12 c_1(T\mathbb{CP}^1)\big) \\ &\overset{(3)}{=} \int_{\mathbb{CP}^1} c_1(L_n) + \tfrac12 \int_{\mathbb{CP}^1} c_1(T\mathbb{CP}^1) \overset{(4)}{=} n + \tfrac12 \cdot 2 = n + 1.\end{aligned}$$

(1) Riemann–Roch form of the index formula.
(2) Expand ch $= 1 + c_1 + \dots$ and td $= 1 + \frac12 c_1 + \dots$; on a surface only two-forms survive integration.
(3) Keep the degree-two part.
(4) $\int c_1(L_n) = n$ (degree of $\mathcal{O}(n)$; its transition function $w^n = z^{-n}$ winds n times), and $\int c_1(T\mathbb{CP}^1) = \chi(\mathbb{CP}^1) = 2$.

Analytic and topological sides agree for every n. Note how the analytic side changed character at $n = -1$ (kernel for $n \geq 0$, cokernel for $n \leq -2$), while the topological side is one linear formula: this is the index doing its job of ignoring which of the two spaces the zero modes live in.

Worked example 4.35: The Toeplitz operator on the circle

Here both sides were found in the previous sections: the analytic index is index $A_f = -\operatorname{wind}(f)$ ((4.11)), and the K-group $K(T^*S^1) \cong \mathbb{Z}$ is detected by $-(w_+ - w_-)$ ((4.41)). The Atiyah–Singer theorem on S^1 is the statement that the topological construction of Example 4.31 produces this same integer. Historically this case came first: it is the Noether–Gohberg–Krein theorem (1950s), and Gel'fand's question of 1960, "can the index of every elliptic operator be expressed through its symbol by a topological formula?", is exactly the question the Atiyah–Singer theorem answered.

4.7.3 The axiomatic proof: why the topological index is forced

Nash describes the proof in one paragraph (p. 97): the topological index is characterised as the *unique* map satisfying certain axioms; the analytical index is then shown, "after considerable amount of work", to satisfy the same axioms. We now make this concrete. The uniqueness half

Operator on X	analytic side	topological side	value
linear map $\mathbb{C}^a \to \mathbb{C}^b$ on a point	$\dim\ker - \dim\operatorname{coker}$	$[\mathbb{C}^a] - [\mathbb{C}^b]$	$a - b$
Toeplitz A_f on S^1	kernel of T_f in H^2	$-(w_+ - w_-)$	$-\operatorname{wind} f$
$\mathrm{d} + \mathrm{d}^*$ on Σ_g	$b_0 - b_1 + b_2$	$\frac{1}{2\pi}\int K\,\mathrm{d}A$	$2 - 2g$
$\bar\partial_{\mathcal{O}(n)}$ on $\mathbb{CP}^1$	polynomials of degree $\le n$	$\int \operatorname{ch}\operatorname{td}$	$n + 1$
$\mathrm{d} + \mathrm{d}^*$ on X^{2m}	$\sum(-1)^i b_i$	$\int e(TX)$	$\chi(X)$
$\bar\partial$ on complex X	$\sum(-1)^q h^{0,q}$	$\int \operatorname{td}(X)$	arithmetic genus

Table 4.1: The Atiyah–Singer theorem in the classical cases. Each row equates a count of solutions (second column) with a symbol-and-topology computation (third column). The last three rows use the cohomological form of the topological index derived in §2 of Nash; the classical theorems they reproduce are Gauss–Bonnet, Riemann–Roch, Chern–Gauss–Bonnet and Hirzebruch–Riemann–Roch.

is short and beautiful, and we give it in full. The existence half is where the analysis lives, and we explain what has to be checked and why each check is plausible.

Index functions and the axioms

Suppose that for every compact manifold X we are given a homomorphism

$$\operatorname{ind}^X \colon K(T^*X) \to \mathbb{Z}.$$

Call this family an **index function** if it satisfies:

(A0) *Naturality.* A diffeomorphism $f \colon X \to X'$ induces $f^* \colon K(T^*X') \to K(T^*X)$, and $\operatorname{ind}^X \circ f^* = \operatorname{ind}^{X'}$. (Relabelling the points of X changes nothing.)

(A1) *Normalisation.* For $X = \mathrm{pt}$, $\operatorname{ind}^{\mathrm{pt}} \colon K(\mathrm{pt}) = \mathbb{Z} \to \mathbb{Z}$ is the identity.

(A2) *Embedding axiom.* For every embedding $i \colon X \hookrightarrow Y$ of compact manifolds, with $i_! = i_* \circ \phi \colon K(T^*X) \to K(T^*Y)$ built from a tubular neighbourhood as in Section 4.6.5,

$$\operatorname{ind}^Y \circ i_! = \operatorname{ind}^X. \tag{4.51}$$

Axiom (A2) says that transplanting a symbol class from X to a neighbourhood of X inside a bigger manifold, using the Thom class in the normal directions, does not change its index. We already met the simplest instance: for $X = \mathrm{pt}$ inside $Y = \mathbb{R}^n$ (or its compactification), (A2) says the Bott class of $\mathbb{R}^{2n} = T^*\mathbb{R}^n$ has index one.

Uniqueness

Key idea: Uniqueness of the index function

Any index function satisfying (A1) and (A2) equals ind_t.

Here is the argument. Embed X in $\mathbb{R}^n$ and compactify $\mathbb{R}^n$ to the sphere $S^n = \mathbb{R}^n \cup \{\infty\}$, with open inclusion $k \colon \mathbb{R}^n \hookrightarrow S^n$. Then $k \circ i \colon X \hookrightarrow S^n$ is an embedding of compact manifolds, and its shriek map is $(k \circ i)_! = k_* \circ i_!$ (extend the class from $T^*\mathbb{R}^n$ to T^*S^n by zero). Similarly, for the origin P, $(k \circ j)_! = k_* \circ j_!$. Let $u \in K(T^*X)$ and let $m = \operatorname{ind}_t(u) \in \mathbb{Z}$. By definition (4.49) of m,

$$i_!(u) = m \cdot j_!(1) \qquad \text{in } K(T^*\mathbb{R}^n) \cong \mathbb{Z}, \tag{4.52}$$

since $j_!(1)$ (the Bott class) generates $K(T^*\mathbb{R}^n)$. Now

$$\begin{aligned}\operatorname{ind}^X(u) &\overset{(1)}{=} \operatorname{ind}^{S^n}\big(k_*\, i_!(u)\big)\\ &\overset{(2)}{=} \operatorname{ind}^{S^n}\big(k_*\big(m\, j_!(1)\big)\big)\\ &\overset{(3)}{=} m\cdot \operatorname{ind}^{S^n}\big(k_*\, j_!(1)\big)\\ &\overset{(4)}{=} m\cdot \operatorname{ind}^{\mathrm{pt}}(1)\\ &\overset{(5)}{=} m \overset{(6)}{=} \operatorname{ind}_t(u).\end{aligned} \tag{4.53}$$

(1) Axiom (A2) for the embedding $k\circ i\colon X\hookrightarrow S^n$.
(2) (4.52).
(3) k_* and ind^{S^n} are homomorphisms of groups.
(4) Axiom (A2) for the embedding $k\circ j\colon \mathrm{pt}\hookrightarrow S^n$.
(5) Axiom (A1).
(6) Definition of m.

That is the whole proof of uniqueness. Look at what it uses: we route the class u through the sphere, where it becomes m copies of the class coming from a point, and the point is where the normalisation fixes everything. The embedding axiom is a statement that the index can be "transported" from X to the sphere and from the sphere to a point.

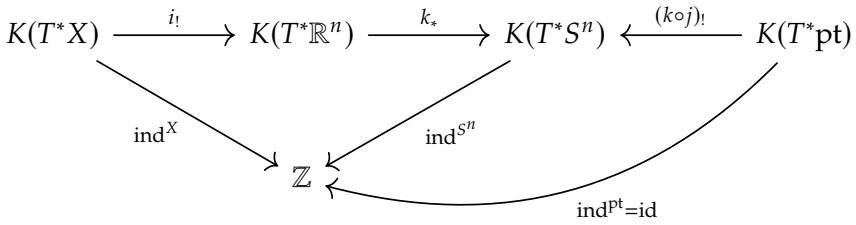

Figure 4.19: The uniqueness argument (4.53). By the embedding axiom both triangles commute. A class u on T^*X is carried to the sphere, where it equals m times the image of the generator from the point; the normalisation on the point then forces $\operatorname{ind}^X(u) = m = \operatorname{ind}_t(u)$.

The topological index satisfies the axioms

(A0) and (A1) are immediate from the definition (for a point, see Example 4.30). For (A2) one needs that shriek maps compose, $(i'\circ i)_! = i'_!\circ i_!$: embedding X in Y and then Y in $\mathbb{R}^n$ is the same as embedding X in $\mathbb{R}^n$, and the Thom classes multiply (the normal bundle of X in $\mathbb{R}^n$ is the normal bundle of X in Y plus the normal bundle of Y, restricted to X; the Thom class of a direct sum is the product of Thom classes, as we saw for $\lambda_{\mathbb{C}^2} = \beta\boxtimes\beta$ in Example 4.27). Then $\operatorname{ind}_t^Y(i_!u) = (j_!)^{-1}i'_!i_!u = (j_!)^{-1}(i'\circ i)_!u = \operatorname{ind}_t^X(u)$ (with $i'\colon Y\hookrightarrow\mathbb{R}^n$). The only real work is the independence of the choices (embedding, tubular neighbourhood), mentioned at the end of Section 4.6.5.

The analytical index satisfies the axioms

This is the "considerable amount of work". (A0) is clear (a diffeomorphism carries operators to operators and zero modes to zero modes) and (A1) is Example 4.22. For (A2), Atiyah and Singer split the embedding axiom into two simpler properties of the analytical index, each of which has a transparent meaning.

Working definition 4.23 (Excision)

Let $U \subset X$ be open, and let $u \in K(T^*U)$ have compact support [u is represented by a symbol complex that is exact outside a compact set of T^*U]. Then $\mathrm{ind}_a^X(i_* u)$, where i_* is extension by zero, depends only on u, not on the compact manifold X into which U is placed. *Analytic meaning:* an elliptic operator which, outside a compact set $C \subset U$, is simply an isomorphism ("multiplication by an invertible bundle map") has its index determined by what happens near C.

The physical content of excision: zero modes and obstructions can only live where the symbol fails to be "trivially invertible". Away from C the operator is an isomorphism and cannot support any unpaired modes, so we may cut X away from U and glue in any other manifold without changing the index. It is the same logic as the statement that the charge enclosed by a surface does not depend on what lies outside it.

Working definition 4.24 (Multiplicativity)

For compact X, Y and classes $u \in K(T^*X)$, $v \in K(T^*Y)$,

$$\mathrm{ind}_a^{X\times Y}(u \boxtimes v) = \mathrm{ind}_a^X(u) \cdot \mathrm{ind}_a^Y(v), \tag{4.54}$$

where $u \boxtimes v$ is the product of the pulled-back classes on $T^*(X \times Y) = T^*X \times T^*Y$ (the tensor product of symbol complexes (4.19)). *Analytic meaning:* there is an explicit "product operator" [built from $D_X \otimes 1$ and $1 \otimes D_Y$ together with their adjoints] on $X \times Y$, and its zero modes are products of zero modes [$\psi_X \otimes \psi_Y$, each factor a zero mode of D_X or D_X^*, and of D_Y or D_Y^*].

Both properties can be checked by hand in the key cases, and we do so now. Once they are known, (A2) follows: by excision the index of $i_! u$ only depends on a tubular neighbourhood of X in Y, which looks locally like $X \times \mathbb{R}^k$, and by multiplicativity the index of $u \boxtimes$ (Bott class on $\mathbb{R}^{2k}$) is $\mathrm{ind}(u) \cdot \mathrm{ind}(\mathrm{Bott}) = \mathrm{ind}(u) \cdot 1$. (When the normal bundle is not trivial, one needs a "twisted" version of multiplicativity, in which the second factor varies over X; this is the step in which Atiyah and Singer genuinely need their pseudo-differential machinery.)

Worked example 4.36: The product operator and multiplicativity

Let $D_1 \colon \Gamma(E_1) \to \Gamma(F_1)$ on X and $D_2 \colon \Gamma(E_2) \to \Gamma(F_2)$ on Y be elliptic, both of order one. On $X \times Y$ let D act from $(E_1 \boxtimes E_2) \oplus (F_1 \boxtimes F_2)$ to $(F_1 \boxtimes E_2) \oplus (E_1 \boxtimes F_2)$ by

$$D = \begin{pmatrix} D_1 \otimes 1 & -1 \otimes D_2^* \\ 1 \otimes D_2 & D_1^* \otimes 1 \end{pmatrix}, \qquad D^* = \begin{pmatrix} D_1^* \otimes 1 & 1 \otimes D_2^* \\ -1 \otimes D_2 & D_1 \otimes 1 \end{pmatrix}.$$

(Here $D_1 \otimes 1$ differentiates in the X variables only, and $1 \otimes D_2$ in the Y variables only; the two commute.) Then

$$(D^*D)_{11} \overset{(1)}{=} (D_1^* \otimes 1)(D_1 \otimes 1) + (1 \otimes D_2^*)(1 \otimes D_2) = D_1^*D_1 \otimes 1 + 1 \otimes D_2^*D_2,$$
$$(D^*D)_{12} \overset{(2)}{=} -(D_1^* \otimes 1)(1 \otimes D_2^*) + (1 \otimes D_2^*)(D_1^* \otimes 1) \overset{(3)}{=} -D_1^* \otimes D_2^* + D_1^* \otimes D_2^* = 0,$$
$$(D^*D)_{22} \overset{(4)}{=} (1 \otimes D_2)(1 \otimes D_2^*) + (D_1 \otimes 1)(D_1^* \otimes 1) = D_1D_1^* \otimes 1 + 1 \otimes D_2D_2^*.$$

(1) Row one of D^* times column one of D.
(2) Row one of D^* times column two of D.
(3) Operators acting on different variables commute: $(A\otimes 1)(1\otimes B) = (1\otimes B)(A\otimes 1) = A\otimes B$.

(4) Row two of D^* times column two of D; the two minus signs cancel.

(The minus sign in D is there exactly to kill the cross term, the same sign as in the tensor product of complexes (4.19).) So D^*D is block diagonal, and each block is a sum of two non-negative operators. A sum $A\otimes 1+1\otimes B$ with $A, B \geq 0$ has kernel $\operatorname{Ker} A\otimes\operatorname{Ker} B$ (expand in eigenvectors: the eigenvalue $\alpha+\beta$ vanishes only if $\alpha=\beta=0$). With $k_i = \dim\operatorname{Ker} D_i$ and $c_i = \dim\operatorname{Ker} D_i^*$,

$$\dim\operatorname{Ker} D \overset{(1)}{=} \dim\operatorname{Ker} D^*D \overset{(2)}{=} k_1k_2 + c_1c_2,$$

(1) $\operatorname{Ker} D = \operatorname{Ker} D^*D$ by the positivity argument (4.32).

(2) First block: $\operatorname{Ker} D_1^*D_1 \otimes \operatorname{Ker} D_2^*D_2 = \operatorname{Ker} D_1 \otimes \operatorname{Ker} D_2$; second block: $\operatorname{Ker} D_1^* \otimes \operatorname{Ker} D_2^*$.

and the same computation for DD^* (whose blocks are $D_1D_1^*\otimes 1 + 1\otimes D_2^*D_2$ and $D_1^*D_1\otimes 1 + 1\otimes D_2D_2^*$) gives $\dim\operatorname{Ker} D^* = c_1k_2 + k_1c_2$. Therefore

$$\operatorname{index} D = k_1k_2 + c_1c_2 - c_1k_2 - k_1c_2 \overset{(1)}{=} (k_1-c_1)(k_2-c_2) = \operatorname{index} D_1 \cdot \operatorname{index} D_2.$$

(1) Factorise.

Its leading symbol is the same block matrix with $D_i \to \sigma(D_i)$; since $\sigma^*\sigma = \sigma_1^*\sigma_1\otimes 1+1\otimes\sigma_2^*\sigma_2$ is positive unless both momenta vanish, D is elliptic, and its symbol class is $[\sigma_1]\boxtimes[\sigma_2]$. This is multiplicativity (4.54), checked with explicit zero modes.

Instance. The kernel computation above used nothing about the orders of the operators, so it applies verbatim to order-zero operators (making the product symbol elliptic then needs a small modification, which Atiyah–Singer supply). Take $D_1 = D_2 = A_{\bar z}$, the Toeplitz-type operator of the conjugate loop $\bar z = e^{-\mathrm{i}x}$, index +1, on each factor of the torus $T^2 = S^1\times S^1$. The product has index $1\cdot 1 = 1$; its single zero mode is the product of the two single zero modes. With $D_1 = A_z$ (index −1) and $D_2 = A_{\bar z}$ we get index −1. And Example 4.19 is also an instance: the de Rham operator of T^2 is the product of two copies of $\mathrm{d}/\mathrm{d}x$ on S^1, and its index is $0\cdot 0 = 0 = \chi(T^2)$.

The analytic Bott class: the harmonic oscillator

The embedding axiom for a point in $\mathbb{R}^n$ asks that the Bott class of $T^*\mathbb{R}^n = \mathbb{R}^{2n}$ have analytical index 1. What operator has the Bott class as its symbol? The Bott complex on $\mathbb{C}$ is "multiply by z" ((4.17)). On $T^*\mathbb{R} = \mathbb{R}^2$ with coordinates (x,ξ) we set $z = x + \mathrm{i}\xi$. We need an operator on functions of x whose symbol is $x+\mathrm{i}\xi$. The rule $\partial_x \to \mathrm{i}\xi$ from Section 4.2.1 gives it immediately:

$$a \coloneqq x + \frac{\mathrm{d}}{\mathrm{d}x}, \qquad \sigma(a)(x,\xi) = x + \mathrm{i}\xi. \tag{4.55}$$

This is the **annihilation operator** of the harmonic oscillator (in units $\hbar = m = \omega = 1$, up to the conventional factor $1/\sqrt{2}$). Its full symbol $x+\mathrm{i}\xi$ vanishes only at the origin of phase space, so it is invertible outside a compact set, which is exactly what a compactly supported class on $T^*\mathbb{R}$ requires. (Strictly, a is not elliptic in the sense of Section 4.2.1, because its symbol is not homogeneous; it is elliptic in the sense appropriate to $\mathbb{R}^n$, where position and momentum are treated alike. That is enough for its index to be well defined and deformation invariant.)

Worked example 4.37: The index of the annihilation operator is one

Kernel of a. Solve $au = 0$:

$$u' + xu = 0 \overset{(1)}{\Longrightarrow} \frac{u'}{u} = -x \overset{(2)}{\Longrightarrow} u(x) = C\,e^{-x^2/2}.$$

(1) Divide by u (separation of variables).
(2) Integrate: $\ln u = -x^2/2 + \text{const}$.

This is square integrable: it is the oscillator ground state. So $\dim \operatorname{Ker} a = 1$.
Kernel of a^*. The adjoint on $L^2(\mathbb{R})$ is $a^* = x - \mathrm{d}/\mathrm{d}x$ (integrate by parts; x is real). Solving $a^*v = 0$ gives $v' = xv$, i.e. $v = Ce^{+x^2/2}$, which is not square integrable unless $C = 0$. So $\dim \operatorname{Ker} a^* = 0$.
Hence

$$\operatorname{index} a = 1 - 0 = 1 = \operatorname{ind}_a(\text{Bott class of } T^*\mathbb{R}),$$

as the embedding axiom requires. In n dimensions take the product operator of Example 4.36 built from $a_1 = x_1 + \partial_1, \dots, a_n = x_n + \partial_n$; its index is $1^n = 1$ and its single zero mode is the Gaussian $e^{-|x|^2/2}$. Its symbol class is $\beta \boxtimes \cdots \boxtimes \beta = \lambda_{\mathbb{C}^n} = j_!(1)$, by Example 4.27. So $\operatorname{ind}_a(j_!1) = 1$: the analytic Bott periodicity.

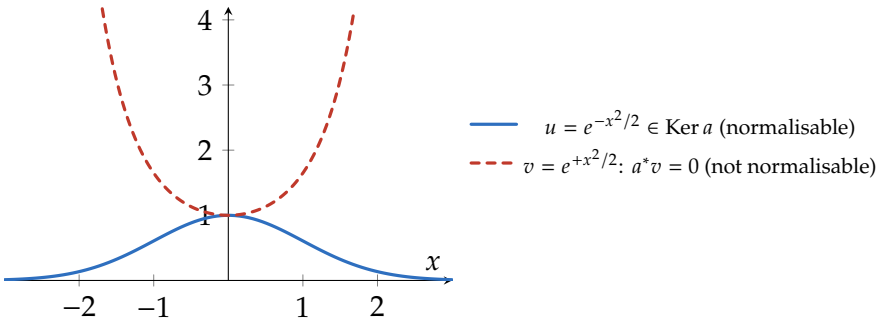

Figure 4.20: Zero modes of the annihilation operator $a = x + \mathrm{d}/\mathrm{d}x$ and its adjoint $a^* = x - \mathrm{d}/\mathrm{d}x$. The equation $au = 0$ has the Gaussian ground state (blue); $a^*v = 0$ has only a growing exponential (red), which is thrown out. One zero mode, no obstruction: $\operatorname{index} a = 1$, the analytic incarnation of the Bott class $z = x + \mathrm{i}\xi$ on phase space.

Watch out: Normalisability is a boundary condition at infinity

On a compact manifold every smooth solution of $Du = 0$ counts. On $\mathbb{R}$, the growing exponential $e^{x^2/2}$ is a perfectly smooth solution of $a^*v = 0$, and we discard it because it is not in L^2. The index of an operator on a non-compact space depends on such conditions at infinity. That is why Atiyah–Singer work with compact manifolds and why the Bott class is placed on the sphere S^n in the uniqueness argument. (The same issue reappears for manifolds with boundary in the last part of this chapter, where the boundary condition changes the index.)

4.7.4 The older proof: cobordism and spheres

Nash also sketches the first proof (Atiyah–Singer [1], 1963, published in detail by Palais' seminar). It follows the model of Hirzebruch's proof of his signature theorem. The problem looks formidable because "both the operator and the manifold are unrestricted". The proof reduces both.

1. *Reduce the manifold.* Embed $X \hookrightarrow \mathbb{R}^n$ and compactify to S^n, exactly as in the construction of ind_t. By excision, the index of D can be computed from an operator on the sphere.

2. *Reduce the operator.* Show that every symbol class is, at least rationally, a combination of symbol classes of the **twisted signature operators** $\mathrm{d} + \mathrm{d}^*$ acting on forms with values in

an auxiliary bundle F (Nash §3). These are "the generalised signature operators".

3. *Cobordism invariance.* Both indices are invariant under cobordism: if $X = \partial W$ is the boundary of a compact manifold W (and the operator extends over W suitably), then its index is 0. So each side is a homomorphism out of a cobordism group, which is known (Thom) and has explicit generators.

4. *Compute on generators.* Check the theorem for the twisted signature operators on spheres and on the complex projective spaces by explicit calculation.

Working definition 4.25 (cobordism)

Two closed n-manifolds [compact and without boundary] X_0, X_1 are **cobordant** if there is a compact $(n+1)$-manifold W with $\partial W = X_0 \sqcup \overline{X_1}$ [the boundary of W is the two manifolds side by side, not touching] (the bar reverses orientation). *Operational test for the simplest case:* X is cobordant to nothing ("null-cobordant") if it bounds [$X = \partial W$ for some compact W].

Worked example 4.38: Why the signature of a boundary is zero

Let $X^{4k} = \partial W$. The signature of X is the signature of the intersection form $(\alpha, \beta) \mapsto \int_X \alpha \wedge \beta$ on $H^{2k}(X)$. Classes that extend over W (restrictions $\alpha = \iota^* A$ of closed forms A on W) are isotropic:

$$\int_X \iota^* A \wedge \iota^* B \overset{(1)}{=} \int_{\partial W} A \wedge B \overset{(2)}{=} \int_W \mathrm{d}(A \wedge B) \overset{(3)}{=} 0.$$

(1) Pullback commutes with wedge, and $\iota : X \to W$ is the inclusion of the boundary.
(2) Stokes' theorem (Chapter T2).
(3) A and B are closed, so $\mathrm{d}(A \wedge B) = \mathrm{d}A \wedge B \pm A \wedge \mathrm{d}B = 0$.

A standard duality argument shows these classes fill exactly half of $H^{2k}(X)$, a Lagrangian subspace, and a quadratic form with a half-dimensional isotropic subspace has signature 0. Since the signature is the index of the signature operator (Nash §2), this is cobordism invariance of the index in its oldest form: *the index of the signature operator of a boundary vanishes.* Example: $S^4 = \partial B^5$ has $H^2 = 0$ and signature 0; $\mathbb{CP}^2$ has signature 1, so it bounds no compact oriented 5-manifold.

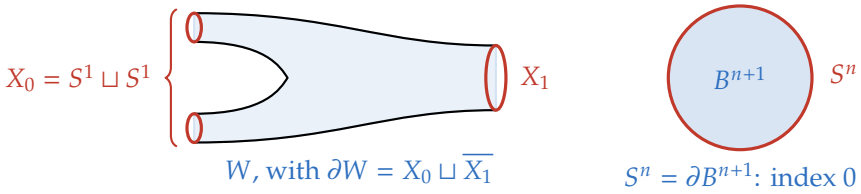

Figure 4.21: Cobordism. Left: a pair of pants W is a cobordism from X_0, a disjoint union of two circles, to one circle X_1. Right: a sphere (red circle) is the boundary of a ball (blue disc), so it is null-cobordant. The index of the (twisted) signature operator vanishes on boundaries, so it only depends on the cobordism class of (X, F), and the old proof reduces the theorem to a check on a few generators.

Physical picture: Why the index should vanish on a boundary

Suppose $X = \partial W$. A zero mode on X ought to be the boundary value of a solution on W (think of harmonic functions on a ball, determined by their boundary values). A careful

analysis shows that the boundary values of solutions of the extended operator on W form a Lagrangian subspace of the zero-mode space of X, which pairs positive-chirality modes with negative ones. Paired modes cancel in the index. The signature example above is the cohomological shadow of this.

4.7.5 A third proof: the heat equation

There is a third route, not described by Nash on these pages but used throughout physics, which proves the cohomological form of the theorem directly: the **heat equation method** of Atiyah–Bott–Patodi, McKean–Singer and Gilkey, streamlined by Getzler and by the supersymmetric path integral of Alvarez-Gaumé and Friedan–Windey. Its starting point is the formula

$$\operatorname{index} D = \operatorname{tr} e^{-tD^*D} - \operatorname{tr} e^{-tDD^*} \qquad \text{for every } t > 0,$$

whose right side, as $t \to 0$, becomes the integral over X of a *local* expression in the curvature. It explains, better than either of the K-theory proofs, why the index is the integral of a characteristic form. It is the subject of the next section.

Reading Nash (p. 97)

Nash: ind_t is independent of the embedding and tubular neighbourhood (Atiyah–Singer [2]); $j_!$ is a ring isomorphism $\mathbb{Z} \to \mathbb{Z}$, hence the identity, but is kept in the definition for the equivariant theory of §6. *Theorem (Atiyah–Singer): the topological and the analytical index are equal.* The proof is axiomatic: the topological index is the *unique* map satisfying certain index axioms, and the analytical index is shown "after considerable amount of work" to satisfy them. The earlier proof (Atiyah–Singer [1]) reduces X to a sphere via $i\colon X \to \mathbb{R}^n$ and D to a generalised signature operator, and checks spheres by calculation. We have written out the axioms (A0)–(A2), the uniqueness argument (4.53), excision and multiplicativity with the explicit product operator, the harmonic oscillator as the analytic Bott class, the cobordism step, and the checks of Table 4.1.

Recap

- Atiyah–Singer: $\operatorname{ind}_a = \operatorname{ind}_t$ on $K(T^*X)$; the number of zero modes minus obstructions is computed by the symbol class and the topology of X.
- Checks: point (rank–nullity), S^1 (Toeplitz, winding number), surfaces (Gauss–Bonnet), $\mathbb{CP}^1$ (Riemann–Roch, $n+1$).
- Uniqueness: normalisation on a point plus the embedding axiom $\operatorname{ind}^Y \circ i_! = \operatorname{ind}^X$ force the index to be $(j_!)^{-1} i_!$; the proof routes a class through the sphere.
- The analytical index satisfies the axioms by excision (zero modes live where the symbol is non-trivial) and multiplicativity (the product operator has index index $D_1 \cdot$ index D_2); the oscillator $a = x + \mathrm{d}/\mathrm{d}x$ has index 1 and realises the Bott class.
- Older proof: reduce to spheres and twisted signature operators; the index vanishes on boundaries (cobordism invariance).

4.8 The heat-kernel view: McKean–Singer

The index is a difference of two dimensions, $\dim\operatorname{Ker} D - \dim\operatorname{Ker} D^*$. Each dimension separately is hard to compute: we must find all solutions of a PDE, and the answer jumps under deformation. The question of this section is: *can we write the index as a sum over all modes of the operator, in such a way that the sum is easy to evaluate?* The answer is yes. Weight every eigenmode of D^*D and of DD^* by a Boltzmann factor $e^{-t\lambda}$ and subtract. The nonzero modes cancel in pairs, for every t, leaving the index. Then let $t \to 0$: the heat operator only feels the geometry within a distance $\sqrt{t}$ of each point, so the index becomes the integral of a *local* density built from the curvature. This is the heat-equation proof of the index theorem, and it is how the theorem enters physics, through the Witten index and Fujikawa's computation of anomalies.

Nash does not develop this on his pp. 89–97; we follow Bär, Chapter 3 [Bär §3.1–3.4], and use the rolled-up operators of Section 4.4 as examples.

4.8.1 Nonzero modes come in pairs

Let $D\colon \Gamma(E^+) \to \Gamma(E^-)$ be elliptic on a compact manifold X (for instance a rolled-up complex), and put

$$\Delta^+ = D^*D \ \text{ on } E^+, \qquad \Delta^- = DD^* \ \text{ on } E^-.$$

Both are self-adjoint, non-negative, elliptic operators, so each has a discrete spectrum of eigenvalues $0 \le \lambda_1 \le \lambda_2 \le \cdots \to \infty$ with finite-dimensional eigenspaces $E_\lambda(\Delta^\pm)$ (Nash Chapter 2). We know from (4.32) that $\operatorname{Ker}\Delta^+ = \operatorname{Ker} D$ and $\operatorname{Ker}\Delta^- = \operatorname{Ker} D^*$, so

$$\operatorname{index} D = \dim E_0(\Delta^+) - \dim E_0(\Delta^-). \tag{4.56}$$

Now let $\lambda > 0$ and $\Delta^+\varphi = \lambda\varphi$. Then

$$\Delta^-(D\varphi) \overset{(1)}{=} DD^*D\varphi \overset{(2)}{=} D(\Delta^+\varphi) \overset{(3)}{=} \lambda\, D\varphi, \tag{4.57}$$

(1) Definition $\Delta^- = DD^*$.
(2) Regroup: $D(D^*D) = (DD^*)D$.
(3) φ is an eigenvector of Δ^+ with eigenvalue λ.

so D carries $E_\lambda(\Delta^+)$ into $E_\lambda(\Delta^-)$. It does not kill anything there, since

$$\|D\varphi\|^2 \overset{(1)}{=} \langle \varphi, D^*D\varphi\rangle \overset{(2)}{=} \lambda\,\|\varphi\|^2 > 0.$$

(1) Definition of the adjoint.
(2) Eigenvalue equation, and $\lambda > 0$.

In the same way D^* carries $E_\lambda(\Delta^-)$ into $E_\lambda(\Delta^+)$, and on $E_\lambda(\Delta^+)$

$$\tfrac{1}{\lambda}D^*(D\varphi) \overset{(1)}{=} \tfrac{1}{\lambda}\Delta^+\varphi \overset{(2)}{=} \varphi,$$

(1) $D^*D = \Delta^+$.
(2) Eigenvalue equation.

so $\frac{1}{\lambda}D^*$ is the inverse of D between the two eigenspaces [Bär p. 149].

Key idea: Supersymmetric pairing

For every $\lambda > 0$, $D\colon E_\lambda(\Delta^+) \to E_\lambda(\Delta^-)$ is an isomorphism. Hence

$$\dim E_\lambda(\Delta^+) = \dim E_\lambda(\Delta^-) \qquad (\lambda > 0)\,: \tag{4.58}$$

Δ^+ and Δ^- have the same nonzero spectrum, with the same multiplicities. Only the zero modes can be unpaired, and their mismatch is the index.

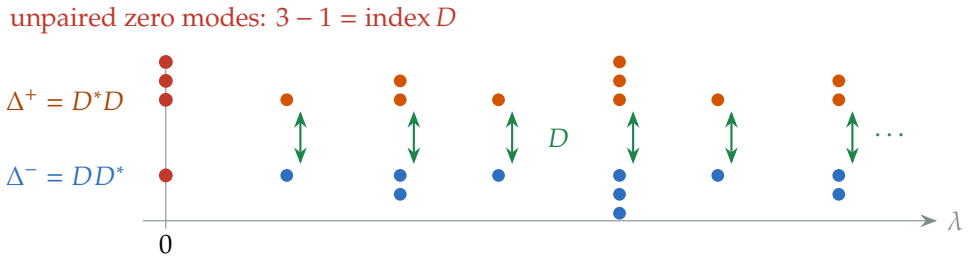

Figure 4.22: The spectra of Δ^+ (top) and Δ^- (bottom). At every nonzero eigenvalue the two eigenspaces have the same dimension (the stacks of dots), because D maps one isomorphically onto the other (green). Only the zero modes (red) can fail to match; here there are three on top and one below, so index $D = 2$.

Dictionary: Index theory ↔ supersymmetric quantum mechanics

Mathematics	Physics
$\mathcal{H} = \Gamma(E^+) \oplus \Gamma(E^-)$	Hilbert space: bosonic ⊕ fermionic states
grading $\Gamma = \mathrm{diag}(1,-1)$	$(-1)^F$, fermion parity
$Q = \left(\begin{smallmatrix} 0 & D^* \\ D & 0 \end{smallmatrix}\right)$	supercharge, $Q = Q^\dagger$, $Q\Gamma = -\Gamma Q$
$Q^2 = \Delta^+ \oplus \Delta^-$	Hamiltonian $H = Q^2 \geq 0$
pairing (4.58)	boson–fermion degeneracy of excited states
$\operatorname{Ker} Q = \operatorname{Ker} D \oplus \operatorname{Ker} D^*$	supersymmetric ground states ($E = 0$)
index D	Witten index $\mathrm{Tr}(-1)^F$

Worked example 4.39: The harmonic oscillator, mode by mode

Take $D = a = x + \mathrm{d}/\mathrm{d}x$ on $L^2(\mathbb{R})$, index 1 (Example 4.37). First compute the two Laplacians:

$$a^*a\,u \overset{(1)}{=} \Big(x - \frac{\mathrm{d}}{\mathrm{d}x}\Big)(xu + u') \overset{(2)}{=} x^2u + xu' - u - xu' - u'' = \big(-\tfrac{\mathrm{d}^2}{\mathrm{d}x^2} + x^2 - 1\big)u,$$

(1) $a^* = x - \mathrm{d}/\mathrm{d}x$ applied to $au = xu + u'$.
(2) Product rule: $\frac{\mathrm{d}}{\mathrm{d}x}(xu) = u + xu'$.

and in the same way $aa^* = -\frac{\mathrm{d}^2}{\mathrm{d}x^2} + x^2 + 1$. The oscillator Hamiltonian $-\frac{\mathrm{d}^2}{\mathrm{d}x^2} + x^2$ has eigenvalues $2n + 1$ with Hermite functions ψ_n, $n = 0, 1, 2, \ldots$. Hence

$$\operatorname{spec}\Delta^+ = \{0, 2, 4, 6, \ldots\}, \qquad \operatorname{spec}\Delta^- = \{2, 4, 6, \ldots\},$$

each eigenvalue with multiplicity one. The pairing is the ladder: $a\psi_n = \sqrt{2n}\,\psi_{n-1}$ takes the level-$2n$ state of Δ^+ (which is ψ_n) to the level-$2n$ state of Δ^- (which is ψ_{n-1}, since $aa^*\psi_{n-1} = (2(n-1) + 1 + 1)\psi_{n-1} = 2n\,\psi_{n-1}$). The ground state ψ_0 at $\lambda = 0$ has no partner. One unpaired mode: index 1.

4.8.2 The heat operator and the heat kernel

To turn (4.58) into a formula we need a way of summing over all eigenvalues that converges. The Boltzmann weight $e^{-t\lambda}$ is the natural choice.

Working definition 4.26 (heat operator, heat kernel, heat trace)

Let Δ be a non-negative [$\langle u, \Delta u\rangle \geq 0$, so every $\lambda_j \geq 0$] self-adjoint elliptic operator of order two (a Laplacian) on sections of $E \to X$, with orthonormal eigensections $\Delta\varphi_j = \lambda_j\varphi_j$.

- The **heat operator** $e^{-t\Delta}$, $t > 0$, multiplies each eigensection by $e^{-t\lambda_j}$. Applied to initial data u_0 it solves the heat equation $(\partial_t + \Delta)u = 0$, $u|_{t=0} = u_0$.
- It is an integral operator, $(e^{-t\Delta}u)(x) = \int_X K_t(x,y)\,u(y)\,\mathrm{dvol}(y)$, with the **heat kernel**

$$K_t(x,y) = \sum_j e^{-t\lambda_j}\,\varphi_j(x)\otimes\varphi_j(y)^\dagger, \tag{4.59}$$

  a matrix $E_y \to E_x$ [$\varphi_j(y)^\dagger$ is the conjugate-transpose row vector, so each term is a column times a row] for each pair of points [Bär Def. 3.1.3].
- The **heat trace** is $\operatorname{Tr} e^{-t\Delta} = \sum_j e^{-t\lambda_j} = \int_X \operatorname{tr} K_t(x,x)\,\mathrm{dvol}(x)$ [tr is the matrix trace over the fibre E_x, Tr the trace over all sections].

Physically: $K_t(x,y)$ is the temperature at x at time t when a unit of heat is released at y; equivalently, the Euclidean propagator $\langle x|e^{-tH}|y\rangle$ of a particle with Hamiltonian $H = \Delta$.

Why the trace formula holds:

$$\int_X \operatorname{tr} K_t(x,x)\,\mathrm{dvol} \overset{(1)}{=} \sum_j e^{-t\lambda_j}\int_X \varphi_j(x)^\dagger\varphi_j(x)\,\mathrm{dvol} \overset{(2)}{=} \sum_j e^{-t\lambda_j}.$$

(1) Insert (4.59) at $y = x$; the trace of the matrix $v\otimes v^\dagger$ is $v^\dagger v = |v|^2$.
(2) The φ_j are normalised.

The sum converges for every $t > 0$ because the eigenvalues grow: by Weyl's law, on an n-manifold λ_j grows like $j^{2/n}$, and $\sum_j e^{-tj^{2/n}} < \infty$. It diverges as $t \to 0$, where it counts every mode; how it diverges is the subject of Section 4.8.4.

Worked example 4.40: The heat kernel of the line

On $X = \mathbb{R}$ with $\Delta = -\mathrm{d}^2/\mathrm{d}x^2$, the heat kernel is the Gaussian

$$K_t(x,y) = (4\pi t)^{-1/2}\,e^{-(x-y)^2/4t}.$$

Check the heat equation. Write $K = K_t(x,y)$ and $s = x - y$:

$$\partial_t K \overset{(1)}{=} \Big(-\frac{1}{2t} + \frac{s^2}{4t^2}\Big)K,$$
$$\partial_x^2 K \overset{(2)}{=} \partial_x\Big(-\frac{s}{2t}K\Big) \overset{(3)}{=} \Big(-\frac{1}{2t} + \frac{s^2}{4t^2}\Big)K,$$

(1) Differentiate $t^{-1/2}$ (giving $-\frac{1}{2t}$) and the exponent $-s^2/4t$ (giving $+s^2/4t^2$).
(2) $\partial_x e^{-s^2/4t} = -\frac{s}{2t}e^{-s^2/4t}$.
(3) Product rule: $\partial_x(-\frac{s}{2t}) = -\frac{1}{2t}$, plus $-\frac{s}{2t}\cdot(-\frac{s}{2t})K$.

so $\partial_t K = \partial_x^2 K$, i.e. $(\partial_t + \Delta)K = 0$. Also $\int K\,\mathrm{d}x = 1$ (a normalised Gaussian of variance $2t$), and as $t \to 0$ it tends to $\delta(x-y)$. In n dimensions the kernel is the product $(4\pi t)^{-n/2} e^{-|x-y|^2/4t}$. Its value on the diagonal, $(4\pi t)^{-n/2}$, is the leading behaviour of every heat kernel on every n-manifold [Bär Def. 3.2.3].

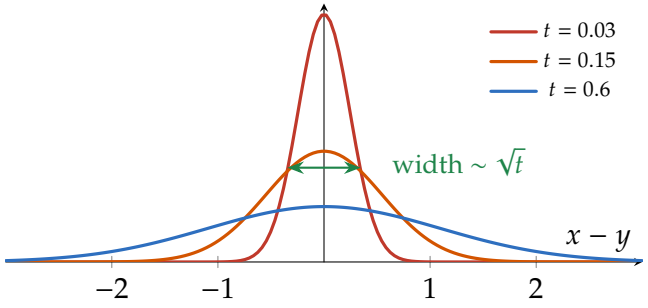

Figure 4.23: The heat kernel $K_t(x,y) = (4\pi t)^{-1/2} e^{-(x-y)^2/4t}$ at three times (the red curve is cut off at the top of the plot). Heat released at y spreads a distance of order $\sqrt{t}$. For small t the kernel is sharply peaked, so $K_t(x,x)$ can only depend on the geometry within a distance $\sim \sqrt{t}$ of x: this is why the small-t behaviour of the heat trace is local.

Worked example 4.41: The circle: local and global pieces of the heat trace

On $S^1 = \mathbb{R}/2\pi\mathbb{Z}$ with $\Delta = -\mathrm{d}^2/\mathrm{d}x^2$ the eigenfunctions are $e^{\mathrm{i}Nx}/\sqrt{2\pi}$, $N \in \mathbb{Z}$, with eigenvalues N^2. So

$$K_t(x,y) = \frac{1}{2\pi} \sum_{N\in\mathbb{Z}} e^{-tN^2} e^{\mathrm{i}N(x-y)}, \qquad \operatorname{Tr} e^{-t\Delta} = \sum_{N\in\mathbb{Z}} e^{-tN^2}.$$

This sum is a theta function; it is easy for large t (only $N = 0, \pm 1$ matter) but not for small t. Use Poisson summation, $\sum_N f(N) = \sum_m \hat{f}(2\pi m)$ with $\hat{f}(\omega) = \int f(s) e^{-\mathrm{i}\omega s}\mathrm{d}s$:

$$\begin{aligned} \sum_{N\in\mathbb{Z}} e^{-tN^2} &\overset{(1)}{=} \sum_{m\in\mathbb{Z}} \int_{-\infty}^{\infty} e^{-ts^2} e^{-2\pi \mathrm{i} m s}\,\mathrm{d}s \\ &\overset{(2)}{=} \sqrt{\frac{\pi}{t}} \sum_{m\in\mathbb{Z}} e^{-\pi^2 m^2/t} \\ &\overset{(3)}{=} (4\pi t)^{-1/2} \cdot 2\pi \cdot \left(1 + 2e^{-\pi^2/t} + 2e^{-4\pi^2/t} + \cdots\right). \end{aligned} \tag{4.60}$$

(1) Poisson summation with $f(s) = e^{-ts^2}$.

(2) Gaussian integral: $\int e^{-ts^2 - \mathrm{i}\omega s}\mathrm{d}s = \sqrt{\pi/t}\, e^{-\omega^2/4t}$, at $\omega = 2\pi m$.

(3) $\sqrt{\pi/t} = 2\pi/\sqrt{4\pi t}$; group $\pm m$.

Read the answer. The leading factor $(4\pi t)^{-1/2} \cdot 2\pi$ is "flat-space diagonal value times length of the circle": local. The corrections $e^{-\pi^2 m^2/t} = e^{-(2\pi m)^2/4t}$ are the flat heat kernel evaluated at distance $2\pi m$, i.e. heat that has gone m times round the circle and come back (the method of images). They are global, and they are exponentially small as $t \to 0$. So the power-series part of the small-t expansion is purely local, with no powers of t beyond the leading one here because the circle is flat.

4.8.3 The McKean–Singer formula

Now combine the heat trace with the pairing.

Key idea: McKean–Singer formula

For every $t > 0$,

$$\operatorname{index} D = \operatorname{Tr} e^{-tD^*D} - \operatorname{Tr} e^{-tDD^*} = \operatorname{Str} e^{-tQ^2}, \tag{4.61}$$

where $\operatorname{Str} A = \operatorname{Tr}(\Gamma A)$ is the **supertrace** (trace over E^+ minus trace over E^-).

Derivation by pairing [Bär (3.17)]:

$$\begin{aligned} \operatorname{Tr} e^{-t\Delta^+} - \operatorname{Tr} e^{-t\Delta^-} &\overset{(1)}{=} \sum_{\lambda \geq 0} e^{-t\lambda} \big(\dim E_\lambda(\Delta^+) - \dim E_\lambda(\Delta^-)\big) \\ &\overset{(2)}{=} e^{-t\cdot 0} \big(\dim E_0(\Delta^+) - \dim E_0(\Delta^-)\big) \\ &\overset{(3)}{=} \operatorname{index} D. \end{aligned} \tag{4.62}$$

(1) Group each trace by distinct eigenvalues, each counted with its multiplicity.
(2) Pairing (4.58): every term with $\lambda > 0$ vanishes.
(3) (4.56).

Derivation by supersymmetry. It is instructive to see the t-independence directly, without diagonalising anything, because this is the argument that generalises to path integrals. Two facts about the supertrace: Γ anticommutes with Q (Q is "odd": it maps E^+ to E^- and back), and the trace is cyclic, $\operatorname{Tr}(AB) = \operatorname{Tr}(BA)$, for the smoothing operators we meet here. For any odd operator B (also anticommuting with Γ),

$$\operatorname{Str}(QB) \overset{(1)}{=} \operatorname{Tr}(\Gamma QB) \overset{(2)}{=} -\operatorname{Tr}(Q\Gamma B) \overset{(3)}{=} -\operatorname{Tr}(\Gamma BQ) \overset{(4)}{=} -\operatorname{Str}(BQ), \tag{4.63}$$

(1) Definition of the supertrace.
(2) $\Gamma Q = -Q\Gamma$.
(3) Cyclicity: move Q from the front to the back.
(4) Definition of the supertrace again.

so $\operatorname{Str}(QB+BQ) = 0$: *the supertrace of an anticommutator of odd operators vanishes*. Now differentiate:

$$\frac{\mathrm{d}}{\mathrm{d}t} \operatorname{Str} e^{-tQ^2} \overset{(1)}{=} -\operatorname{Str}\big(Q^2 e^{-tQ^2}\big) \overset{(2)}{=} -\tfrac{1}{2} \operatorname{Str}\big(Q\,(Qe^{-tQ^2}) + (Qe^{-tQ^2})\,Q\big) \overset{(3)}{=} 0. \tag{4.64}$$

(1) Differentiate the exponential.
(2) Q commutes with e^{-tQ^2}, so $Q^2 e^{-tQ^2} = Q(Qe^{-tQ^2}) = (Qe^{-tQ^2})Q$; write it as half the sum.
(3) (4.63) with the odd operator $B = Qe^{-tQ^2}$ (e^{-tQ^2} is even, commuting with Γ, so B is odd).

So $\operatorname{Str} e^{-tQ^2}$ is independent of t. As $t \to \infty$ every mode with $\lambda > 0$ is exponentially suppressed and the heat operator becomes the projection onto $\operatorname{Ker} Q^2 = \operatorname{Ker} D \oplus \operatorname{Ker} D^*$; the supertrace of that projection is $\dim \operatorname{Ker} D - \dim \operatorname{Ker} D^*$. Since the supertrace does not depend on t, it equals $\operatorname{index} D$ for every t.

Watch out: The ordinary trace is not constant

$\operatorname{Tr} e^{-t\Delta^+}$ and $\operatorname{Tr} e^{-t\Delta^-}$ each depend strongly on t and blow up as $t \to 0$. Only their difference is constant. Likewise, the cancellation in (4.63) needs the operators to be trace

class: Str(Q) or Str(1) make no sense on an infinite-dimensional space (the formal "index $=\dim E^+ - \dim E^-$" is $\infty - \infty$). The factor e^{-tQ^2} is exactly what makes everything trace class; it is a regulator that the answer does not depend on.

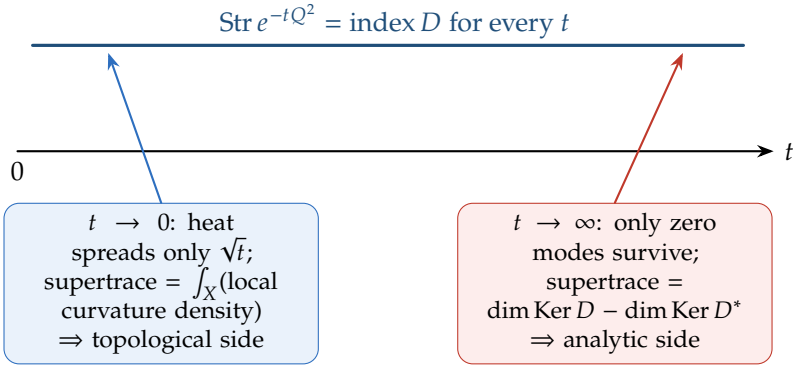

Figure 4.24: The logic of the heat-equation proof. The supertrace of the heat operator is constant in t. At large t it visibly counts zero modes (the analytical index). At small t it becomes an integral of a local expression in the curvature, which turns out to be the characteristic-class integrand of the topological index.

Worked example 4.42: The oscillator: McKean–Singer summed exactly

With the spectra of Example 4.39,

$$\operatorname{Tr} e^{-ta^*a} - \operatorname{Tr} e^{-taa^*} \overset{(1)}{=} \sum_{n=0}^{\infty} e^{-2nt} - \sum_{n=1}^{\infty} e^{-2nt} \overset{(2)}{=} \frac{1}{1-e^{-2t}} - \frac{e^{-2t}}{1-e^{-2t}} \overset{(3)}{=} 1.$$

(1) $\operatorname{spec} a^*a = \{0, 2, 4, \dots\}$, $\operatorname{spec} aa^* = \{2, 4, \dots\}$.
(2) Geometric series.
(3) $1 - e^{-2t}$ over itself.

Each trace separately is $\approx \frac{1}{2t}$ for small t (the classical phase-space volume $\int \frac{dx\,d\xi}{2\pi} e^{-t(x^2+\xi^2)} = \frac{1}{2t}$); the difference is exactly 1 for every t.

Worked example 4.43: The de Rham operator on the circle

On S^1, $E^+ = \Lambda^0$, $E^- = \Lambda^1$, $D = d$. The Laplacian on functions has eigenvalues N^2 ($N \in \mathbb{Z}$); on 1-forms $h\,dx$ it acts on h in the same way, with the same eigenvalues. So $\operatorname{Tr} e^{-t\Delta_0} = \operatorname{Tr} e^{-t\Delta_1} = \sum_N e^{-tN^2}$ and $\operatorname{Str} e^{-tQ^2} = 0 = \chi(S^1)$, mode by mode, for every t, including the zero modes 1 and dx, which pair with each other.

Worked example 4.44: The de Rham operator on the two-sphere, all t

Take the unit sphere, $D = d + d^*$ from $\Omega^0 \oplus \Omega^2$ to Ω^1, so $\Delta^+ = \Delta_0 \oplus \Delta_2$ and $\Delta^- = \Delta_1$.

- Δ_0: spherical harmonics Y_{lm}, eigenvalue $l(l+1)$, multiplicity $2l+1$, $l \geq 0$.
- Δ_2: the Hodge star $\star\colon \Omega^0 \to \Omega^2$ commutes with the Laplacian, so Δ_2 has the same spectrum as Δ_0 (eigenforms $Y_{lm}\,dA$).
- Δ_1: there are no harmonic 1-forms ($b_1 = 0$), and by the Hodge decomposition every 1-form is $df + \star dg$. The forms dY_{lm} and $\star dY_{lm}$, $l \geq 1$, are eigenforms with eigenvalue

$l(l+1)$ (because Δ commutes with d and $\star$), giving multiplicity $2(2l+1)$.

Write $\vartheta(t) = \sum_{l\geq 0}(2l+1)e^{-tl(l+1)}$. Then

$$\begin{aligned}\operatorname{Str} e^{-tQ^2} &\overset{(1)}{=} \operatorname{Tr} e^{-t\Delta_0} + \operatorname{Tr} e^{-t\Delta_2} - \operatorname{Tr} e^{-t\Delta_1} \\ &\overset{(2)}{=} 2\vartheta(t) - 2\big(\vartheta(t) - 1\big) \\ &= 2 = \chi(S^2).\end{aligned}$$

(1) $\Delta^+ = \Delta_0 \oplus \Delta_2$, $\Delta^- = \Delta_1$.
(2) The spectra above; the Δ_1 sum is 2ϑ minus its $l = 0$ term, which is $2 \cdot 1$.

The pairing is visible: d maps Y_{lm} to $\mathrm{d}Y_{lm}$, and d^* maps $Y_{lm}\mathrm{d}A$ to $\pm \star\, \mathrm{d}Y_{lm}$. The two unpaired zero modes are the constant function and the area form. See Figure 4.25.

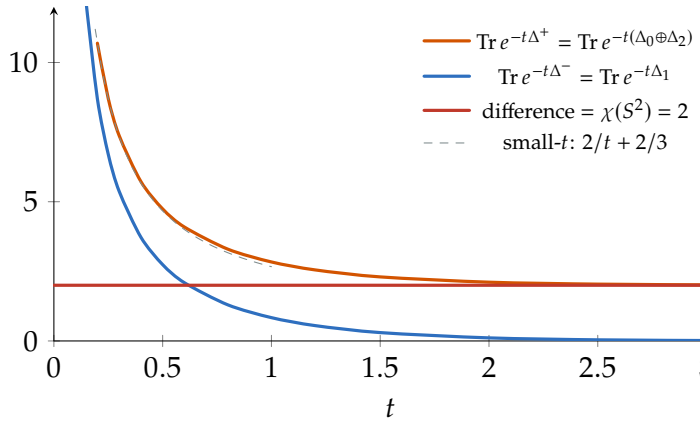

Figure 4.25: Heat traces on the unit two-sphere, computed from the exact spectra. Each trace blows up like $2/t$ as $t \to 0$ (Weyl's law: it counts all modes) and decays to its number of zero modes as $t \to \infty$ (2 for Δ^+, 0 for Δ^-). Their difference is exactly 2 at every t. The dashed curve is the small-t expansion of the upper trace derived in Example 4.45.

4.8.4 Small t: the index is a local integral

We now use the freedom to take t small. For small t, heat has spread only a distance $\sim \sqrt{t}$ (Figure 4.23), so the heat kernel on the diagonal can only know about the geometry near x. Making this precise gives the central analytic fact of the method.

Key idea: Short-time expansion of the heat kernel [Bär Cor. 3.2.10–3.2.11]

Let $\Delta = \nabla^*\nabla + \mathcal{K}$ be a Laplace-type operator on a bundle E of rank r over a compact Riemannian n-manifold ($\nabla^*\nabla$ is the connection Laplacian and $\mathcal{K}$ a symmetric endomorphism field). Then as $t \to 0$,

$$K_t(x,x) \sim (4\pi t)^{-n/2} \sum_{j=0}^{\infty} t^j\, \Phi_j(x), \qquad \Phi_0 = \mathrm{id}_E, \quad \Phi_1 = \tfrac{1}{6}\operatorname{scal}\mathrm{id}_E - \mathcal{K}, \tag{4.65}$$

where scal is the scalar curvature and each $\Phi_j(x)$ is a universal polynomial in the curvature of X, the curvature of ∇, $\mathcal{K}$, and their covariant derivatives at x. Integrating,

$$\operatorname{Tr} e^{-t\Delta} \sim (4\pi t)^{-n/2}\Big(r\operatorname{vol}(X) + t\int_X \big(\tfrac{r}{6}\operatorname{scal} - \operatorname{tr}\mathcal{K}\big)\mathrm{dvol} + O(t^2)\Big). \tag{4.66}$$

A dimensional check: t has dimensions of length^2 (because $\partial_t \sim \partial_x^2$), so Φ_j has dimensions of length^{-2j}, i.e. it contains $2j$ derivatives of the metric. Φ_1 is linear in curvature (two derivatives), Φ_2 quadratic in curvature, and so on. The leading term of (4.66) is Weyl's law: the number of eigenvalues below Λ grows like $r\,\mathrm{vol}(X)\Lambda^{n/2}$ times a universal constant. ("One can hear the volume of a drum.")

Now feed (4.65) into McKean–Singer. Write $a_j(x) = \operatorname{tr}\Phi_j^{\Delta^+}(x) - \operatorname{tr}\Phi_j^{\Delta^-}(x)$. Then [Bär (3.18)–(3.19)]

$$\begin{aligned}\operatorname{index} D &\overset{(1)}{=} \int_X \big(\operatorname{tr} K_t^+(x,x) - \operatorname{tr} K_t^-(x,x)\big)\,\mathrm{dvol}\\ &\overset{(2)}{=} (4\pi t)^{-n/2}\sum_{j\ge 0} t^j \int_X a_j\,\mathrm{dvol} + (\text{terms vanishing faster than any power of } t)\\ &\overset{(3)}{=} (4\pi)^{-n/2}\int_X a_{n/2}\,\mathrm{dvol}\quad (n \text{ even}),\qquad 0\quad (n \text{ odd}).\end{aligned}\tag{4.67}$$

(1) McKean–Singer (4.61) written with heat kernels.
(2) Short-time expansion (4.65) for $\Delta^\pm$.
(3) The left side does not depend on t. So on the right the coefficient of every negative power $t^{j-n/2}$, $j < n/2$, must vanish, and the t^0 coefficient is the index. For n even that is $j = n/2$. For n odd there is no t^0 term at all ($j - n/2$ is a half-integer), and letting $t \to 0$ gives 0.

Key idea: What the heat equation proves

1. $\operatorname{index} D = (4\pi)^{-n/2}\int_X a_{n/2}(x)\,\mathrm{dvol}$: the index is the integral of a *local* density built from the curvature and the coefficients of D [Bär Thm. 3.4.4].
2. On odd-dimensional manifolds the index of every such (Dirac-type) operator vanishes. (Compare the circle: differential operators on S^1 have index 0, Example 4.23.)
3. The index is constant under smooth deformations of the metric and of D, because it is an integer that depends smoothly on the parameters [Bär Cor. 3.4.7].

Identifying $a_{n/2}$ with the characteristic-class integrand of the topological index (ch · td, or the Euler form, or $\hat{A}$) is the remaining, and hardest, step. For $n = 2$ we can do it by hand.

Worked example 4.45: The sphere: the small-t expansion from the exact spectrum

Let us check (4.66) on the unit S^2 for Δ_0, where $r = 1$, $\mathcal{K} = 0$, vol $= 4\pi$, and scal $= 2$ (twice the Gaussian curvature $K = 1$). The prediction is

$$\vartheta(t) \overset{(1)}{=} (4\pi t)^{-1}\Big(4\pi + t\cdot\tfrac{1}{6}\cdot 2\cdot 4\pi + O(t^2)\Big) = \frac{1}{t} + \frac{1}{3} + O(t).$$

(1) (4.66) with $n = 2$.

Now compute from the spectrum. Put $f(l) = (2l+1)e^{-tl(l+1)}$, so $\vartheta = \sum_{l\ge 0} f(l)$. The Euler–Maclaurin formula $\sum_{l=0}^{\infty} f(l) = \int_0^\infty f\,\mathrm{d}l + \frac{1}{2}f(0) - \frac{1}{12}f'(0) + \frac{1}{720}f'''(0) - \cdots$ gives

$$\begin{aligned}\vartheta(t) &\overset{(1)}{=} \Big[-\tfrac{1}{t}e^{-tl(l+1)}\Big]_0^\infty + \tfrac{1}{2} - \tfrac{1}{12}(2-t) + O(t)\\ &\overset{(2)}{=} \frac{1}{t} + \frac{1}{2} - \frac{1}{6} + O(t) = \frac{1}{t} + \frac{1}{3} + O(t).\end{aligned}$$

(1) $f = -\frac{1}{t}\frac{\mathrm{d}}{\mathrm{d}l}e^{-tl(l+1)}$ is an exact derivative; $f(0) = 1$; $f'(l) = \big(2 - t(2l+1)^2\big)e^{-tl(l+1)}$, so $f'(0) = 2 - t$; the t^0 part of f is the linear polynomial $2l + 1$, so $f'''(0) = O(t)$.

(2) Evaluate the integral: $0 - (-\frac{1}{t}) = \frac{1}{t}$.

The two agree. (Numerically, $\vartheta(0.1) = 10.3401$ against $\frac{1}{0.1} + \frac{1}{3} + \frac{0.1}{15} = 10.3400$; the next coefficient is $\frac{1}{15}$.)

For Δ_1 we need the Weitzenböck formula: on 1-forms, $\Delta_1 = \nabla^*\nabla + \mathrm{Ric}$, so $r = 2$ and $\operatorname{tr}\mathcal{K} = \mathrm{scal} = 2$. Then

$$\operatorname{Tr} e^{-t\Delta_1} \overset{(1)}{=} (4\pi t)^{-1}\Big(2\cdot 4\pi + t\big(\tfrac{2}{6}\cdot 2 - 2\big)4\pi + O(t^2)\Big) = \frac{2}{t} - \frac{4}{3} + O(t),$$

(1) (4.66) with $r = 2$, $\mathcal{K} = \mathrm{Ric}$; all curvatures are constant on the round sphere.

which agrees with the exact $2(\vartheta - 1) = \frac{2}{t} + \frac{2}{3} - 2$. The supertrace at small t:

$$\Big(\frac{1}{t} + \frac{1}{3}\Big) + \Big(\frac{1}{t} + \frac{1}{3}\Big) - \Big(\frac{2}{t} - \frac{4}{3}\Big) + O(t) = 0\cdot\frac{1}{t} + 2 + O(t).$$

The $1/t$ terms cancel (ranks $1 + 1 - 2 = 0$), exactly as the argument of (4.67) demands, and the constant is $\chi(S^2) = 2$.

Worked example 4.46: Gauss–Bonnet for every surface, from the heat kernel

Now let X be any closed oriented surface with any metric. For the de Rham operator [Bär Ex. 3.4.6]:

$$\begin{aligned} a_1 &\overset{(1)}{=} \operatorname{tr}\Phi_1^{\Delta_0} + \operatorname{tr}\Phi_1^{\Delta_2} - \operatorname{tr}\Phi_1^{\Delta_1} \\ &\overset{(2)}{=} \tfrac{1}{6}\mathrm{scal} + \tfrac{1}{6}\mathrm{scal} - \big(\tfrac{2}{6}\mathrm{scal} - \mathrm{scal}\big) \\ &= \mathrm{scal}. \end{aligned} \tag{4.68}$$

(1) $\Delta^+ = \Delta_0 \oplus \Delta_2$, $\Delta^- = \Delta_1$.

(2) $\Phi_1 = \frac{1}{6}\mathrm{scal}\,\mathrm{id} - \mathcal{K}$: on functions and on 2-forms (isomorphic to functions via $\star$) $\mathcal{K} = 0$, $r = 1$; on 1-forms $r = 2$ and $\operatorname{tr}\mathcal{K} = \operatorname{tr}\mathrm{Ric} = \mathrm{scal}$.

With $n = 2$, (4.67) and $\mathrm{scal} = 2K$ give

$$\chi(X) \overset{(1)}{=} \operatorname{index}(\mathrm{d} + \mathrm{d}^*) \overset{(2)}{=} \frac{1}{4\pi}\int_X \mathrm{scal}\,\mathrm{d}A \overset{(3)}{=} \frac{1}{2\pi}\int_X K\,\mathrm{d}A.$$

(1) (4.36).

(2) (4.67) with $n/2 = 1$ and $a_1 = \mathrm{scal}$.

(3) For a surface the scalar curvature is twice the Gaussian curvature.

This is the Gauss–Bonnet theorem, derived with no triangulation and no Euler class: only the pairing of eigenmodes and the first heat coefficient. Notice what happened: the *pointwise* density $a_1(x) = \mathrm{scal}(x)$ depends on the metric, but its integral cannot, because it equals an integer that does not move when the metric is deformed.

Worked example 4.47: Coverings multiply the index

If $\tilde{X} \to X$ is a k-sheeted covering and $\tilde{D}$ is the pull-back of D, then the local density $a_{n/2}$ of $\tilde{D}$ is the pull-back of that of D, and $\tilde{X}$ has k times the volume [Bär Cor. 3.4.8]:

$$\operatorname{index}\tilde{D} \overset{(1)}{=} (4\pi)^{-n/2}\int_{\tilde{X}} \tilde{a}_{n/2}\,\mathrm{dvol} \overset{(2)}{=} k\,(4\pi)^{-n/2}\int_X a_{n/2}\,\mathrm{dvol} = k\operatorname{index} D.$$

(1) (4.67) on $\tilde{X}$.
(2) Locally $\tilde{X}$ looks exactly like X, and each small patch of X is covered by k identical patches.

Example: $S^2 \to \mathbb{RP}^2$ is a double cover, so $2 = \chi(S^2) = 2\chi(\mathbb{RP}^2)$ and $\chi(\mathbb{RP}^2) = 1$ ($b_0 = 1$, $b_1 = b_2 = 0$ for the non-orientable $\mathbb{RP}^2$ with real coefficients, as it must be). Local formulas make such statements immediate; counting zero modes directly would not.

Physical picture: The miraculous cancellation

In (4.67) the coefficients $\int a_j$, $j < n/2$, vanish because the left side does not depend on t. For Dirac operators much more is true: the densities $a_j(x)$ themselves vanish *pointwise* for $j < n/2$, and $a_{n/2}(x)$ is exactly the degree-n part of the characteristic form $\hat{A}(X)\,\mathrm{ch}(F)$. This is the **local index theorem** (Patodi, Gilkey, Getzler). Getzler's proof rescales $t \to \varepsilon^2 t$ and Clifford generators $\gamma^\mu \to \varepsilon^{-1}\gamma^\mu$; in the limit $\varepsilon \to 0$ the Dirac Laplacian becomes a harmonic oscillator on the Clifford algebra, whose heat kernel (Mehler's formula) produces the $\hat{A}$ genus $\prod \frac{x_i/2}{\sinh(x_i/2)}$. Chapter T4 has the Clifford algebra background.

4.8.5 Physics: the Witten index, path integrals and anomalies

Physical picture: The Witten index as a path integral

In supersymmetric quantum mechanics with supercharge Q and Hamiltonian $H = Q^2$, the **Witten index** is $\mathrm{Tr}(-1)^F e^{-\beta H}$. By McKean–Singer it is independent of β and equals the index of D. Written as a Euclidean path integral, the trace becomes an integral over loops of period β, and the insertion of $(-1)^F$ makes the fermions *periodic* rather than antiperiodic around the loop:

$$\mathrm{Tr}(-1)^F e^{-\beta H} = \int_{\text{periodic}} [\mathrm{d}x][\mathrm{d}\psi]\, e^{-S_E[x,\psi]}.$$

As $\beta \to 0$ the loops shrink (their size is $\sim \sqrt{\beta}$, the same $\sqrt{t}$ as in Figure 4.23), and the path integral localises onto constant loops. What remains is an ordinary integral over X of the one-loop determinant around each constant loop: a characteristic form. For the de Rham complex (fermions $\psi^\mu \leftrightarrow \mathrm{d}x^\mu$, $Q = \mathrm{d} + \mathrm{d}^*$) this gives $\chi(X)$ as the integral of the Euler form; for the $N = 1$ theory whose supercharge is the Dirac operator it gives $\int \hat{A}$ (Alvarez-Gaumé, Friedan–Windey). This is the physicist's proof of the index theorem, and Example 4.46 is its rigorous two-dimensional shadow. Chapter 7 develops Witten's version for Morse theory.

Physical picture: Fujikawa and anomalies

In a Euclidean gauge theory with massless fermions, a chiral rotation $\psi \to e^{\mathrm{i}\alpha\gamma_5}\psi$ changes the fermion measure by a Jacobian $\exp\bigl(-2\mathrm{i}\alpha \sum_n \varphi_n^\dagger \gamma_5 \varphi_n\bigr)$, summed over eigenmodes of $\not{D}$. The sum is ill-defined and Fujikawa regularises it with exactly our factor: $\sum_n \varphi_n^\dagger \gamma_5 e^{-t\not{D}^2}\varphi_n = \mathrm{Str}\, e^{-t\not{D}^2}$, with grading γ_5. By McKean–Singer this is $n_+ - n_- = \mathrm{index}\,\not{D}$, independent of the regulator, and its small-t limit is the local density $\frac{1}{8\pi^2}\,\mathrm{tr}\, F \wedge F$ in four dimensions (up to the sign fixed by orientation). So the chiral anomaly *is* the index density. Chapter 10 and [QFT notes Ch. 22] have the details.

Try it: McKean–Singer for a finite complex

For the triangulated circle of Example 4.20, compute $\operatorname{Tr} e^{-t\Delta_0} - \operatorname{Tr} e^{-t\Delta_1}$ from the spectra and show it is 0 for all t.
Answer. Both Laplacians have spectrum $\{0, 3, 3\}$, so both traces equal $1 + 2e^{-3t}$ and the difference is $0 = \chi(S^1)$. In finite dimensions McKean–Singer at $t = 0$ is just (4.37): $\operatorname{Str}(1) = \dim V^0 - \dim V^1$.

Reading Nash (context)

Nash's §1 (pp. 89–97) states the theorem and the two definitions of the index but not the heat-equation method; he mentions the heat-equation proof of Atiyah–Bott–Patodi only in passing later in the chapter, in connection with zeta functions and the η-invariant (§7). We included it because it is the version physicists use, because it makes the "pairing" mechanism behind stability explicit, and because it is needed for the fixed-point formulas (heat-kernel localisation) and for anomalies in later parts. Sources: Bär §3.1–3.4, in particular (3.17)–(3.19), Theorem 3.4.4, Example 3.4.6 and Corollaries 3.4.7–3.4.8.

Recap

- D maps the λ-eigenspace of D^*D isomorphically onto that of DD^* for $\lambda > 0$: nonzero modes pair up (supersymmetry).
- Heat kernel $K_t(x, y) = \sum e^{-t\lambda_j} \varphi_j(x) \varphi_j(y)^\dagger$; heat trace $= \int \operatorname{tr} K_t(x, x)$; on $\mathbb{R}^n$ it is $(4\pi t)^{-n/2} e^{-|x-y|^2/4t}$.
- McKean–Singer: $\operatorname{index} D = \operatorname{Tr} e^{-tD^*D} - \operatorname{Tr} e^{-tDD^*} = \operatorname{Str} e^{-tQ^2}$ for all t; t-independence because the supertrace of an anticommutator of odd operators is zero.
- Small t: $K_t(x, x) \sim (4\pi t)^{-n/2} \sum t^j \Phi_j$ with local Φ_j; so $\operatorname{index} D = (4\pi)^{-n/2} \int a_{n/2}$, and 0 in odd dimensions.
- Checks: oscillator (1 for all t), S^1 (0), S^2 (2, including the $1/t + 1/3$ expansion); $a_1 = \operatorname{scal}$ gives Gauss–Bonnet; coverings multiply the index.
- Physics: Witten index $\operatorname{Tr}(-1)^F e^{-\beta H}$ and Fujikawa's regulated Jacobian are this supertrace.

4.9 From K-theory to numbers: the index formula in characteristic classes

The Atiyah–Singer theorem, as stated at the end of the previous section, says that two integers attached to an elliptic operator D agree: the *analytical index* $\dim \operatorname{Ker} D - \dim \operatorname{Coker} D$, which counts solutions, and the *topological index*, which is built out of the K-theory class $[\sigma_m(D)] \in K(T^*X)$ of the principal symbol by a chain of Thom isomorphisms and push-forwards. That is a beautiful statement, but as it stands it is not a formula anyone can evaluate. Nobody computes Thom homomorphisms in K-theory on a Tuesday afternoon.

What a physicist wants is something of the form

$$\operatorname{index} D \;=\; \int_X \big(\text{some polynomial in curvatures}\big),$$

because integrals of curvature polynomials are things we know how to do: we have done them

for the Gauss–Bonnet theorem, for the monopole charge and for the instanton number. This section explains how to get there. The tool is the **Chern character**, which turns K-theory classes into de Rham cohomology classes, i.e. into closed differential forms. Before we can state the formula we have to set up the characteristic classes it uses. Nash assumes all of this from his Chapter 3 (Chapter 3); we rebuild what we need, concretely, so that every later example in this part can be computed by hand.

4.9.1 Characteristic classes as curvature polynomials

Let $E \to X$ be a complex vector bundle of rank k with a connection. In a local trivialisation the connection is a matrix of 1-forms A and the curvature is the matrix of 2-forms

$$F = \mathrm{d}A + A \wedge A. \tag{4.69}$$

We use the mathematicians' convention, which is also Nash's: for a unitary connection A and F are *anti-Hermitian* matrices. The dictionary to the physicists' Hermitian gauge field is $A_{\text{math}} = -i\,g\,A^a_{\text{phys}}T^a$ with Hermitian generators T^a (see Chapter T3). Under a change of trivialisation $F \mapsto g^{-1}Fg$, so any *conjugation-invariant* polynomial in F is a globally defined form. The two basic ones are the determinant and the trace of the exponential.

Working definition 4.27 (Chern classes and Chern character)

Given the curvature F of a connection on E, form the matrix of 2-forms $\frac{i}{2\pi}F$ (it is Hermitian, so its "eigenvalues" are real). Then

$$c(E) = \det\!\Big(1 + \tfrac{i}{2\pi}F\Big) = 1 + c_1(E) + c_2(E) + \cdots, \qquad c_j(E) \in \Omega^{2j}(X),$$
$$\mathrm{ch}(E) = \operatorname{tr}\exp\!\Big(\tfrac{i}{2\pi}F\Big) = \mathrm{ch}_0(E) + \mathrm{ch}_1(E) + \mathrm{ch}_2(E) + \cdots, \qquad \mathrm{ch}_j(E) \in \Omega^{2j}(X).$$

Expand, keep the part of each degree, and you have explicit closed forms. Their de Rham classes [two closed forms count as the same if they differ by d of a form] do not depend on the connection chosen. *Formally:* c_j and ch_j are the Chern–Weil images of the invariant polynomials "j-th elementary symmetric function" [the sum of all products of j distinct eigenvalues] and "$\frac{1}{j!}\operatorname{tr}(\cdot)^j$".

Why are these closed, and why is their class independent of A? The mechanism is the Bianchi identity $\mathrm{d}F = F\wedge A - A\wedge F$. For example

$$\begin{aligned}\mathrm{d}\,\operatorname{tr}(F\wedge F) &\overset{(1)}{=} \operatorname{tr}(\mathrm{d}F\wedge F) + \operatorname{tr}(F\wedge \mathrm{d}F)\\ &\overset{(2)}{=} \operatorname{tr}\big((FA-AF)F\big) + \operatorname{tr}\big(F(FA-AF)\big)\\ &\overset{(3)}{=} \operatorname{tr}(FAF) - \operatorname{tr}(AFF) + \operatorname{tr}(FFA) - \operatorname{tr}(FAF) = 0.\end{aligned}$$

(1) The Leibniz rule; F is a 2-form, so no sign appears when d passes it.
(2) The Bianchi identity, obtained by applying d to (4.69).
(3) Expand; then use cyclicity of the trace, which holds for matrices of forms up to the sign $(-1)^{\deg\cdot\deg}$; moving a 1-form past a 4-form costs no sign, so $\operatorname{tr}(FFA) = \operatorname{tr}(AFF)$ and everything cancels.

The independence of the connection is the same computation done for a one-parameter family A_t: the t-derivative of $\operatorname{tr}F_t^j$ turns out to be d of something (the Chern–Simons form), so the

class does not move. We will use this repeatedly: *we may compute characteristic numbers with any connection we like*, usually the most symmetric one.

Expanding the definitions to low order gives the formulas we will use again and again. With $\Phi := \frac{i}{2\pi}F$,

$$\begin{aligned}\det(1+\Phi) &\overset{(1)}{=} \exp \operatorname{tr}\log(1+\Phi)\\ &\overset{(2)}{=} \exp\Big(\operatorname{tr}\Phi - \tfrac{1}{2}\operatorname{tr}\Phi^2 + \cdots\Big)\\ &\overset{(3)}{=} 1 + \operatorname{tr}\Phi + \tfrac{1}{2}\big[(\operatorname{tr}\Phi)^2 - \operatorname{tr}\Phi^2\big] + \cdots .\end{aligned} \tag{4.70}$$

(1) The identity $\det M = \exp\operatorname{tr}\log M$, valid for matrices near the identity; 2-forms commute, so the matrix entries behave like ordinary commuting numbers here.
(2) The Taylor series $\log(1+\Phi) = \Phi - \Phi^2/2 + \cdots$.
(3) Expand the exponential and collect terms of form degree 2 and 4.

Reading off,

$$c_1 = \frac{i}{2\pi}\operatorname{tr}F, \qquad c_2 = \frac{1}{2}\Big(\frac{i}{2\pi}\Big)^2\big[\operatorname{tr}F\wedge\operatorname{tr}F - \operatorname{tr}(F\wedge F)\big] \;=\; \frac{1}{8\pi^2}\big[\operatorname{tr}(F\wedge F) - \operatorname{tr}F\wedge\operatorname{tr}F\big], \tag{4.71}$$

and, from $\operatorname{tr}e^{\Phi} = k + \operatorname{tr}\Phi + \frac{1}{2}\operatorname{tr}\Phi^2 + \cdots$,

$$\mathrm{ch}_0 = k, \qquad \mathrm{ch}_1 = c_1, \qquad \mathrm{ch}_2 = \tfrac{1}{2}\operatorname{tr}\Phi^2 = -\frac{1}{8\pi^2}\operatorname{tr}(F\wedge F) = \tfrac{1}{2}c_1^2 - c_2. \tag{4.72}$$

For an SU(2) gauge field $\operatorname{tr}F = 0$, so $c_2 = \frac{1}{8\pi^2}\int \operatorname{tr}F\wedge F$ is the instanton number k of Chapter 8 (with our orientation), and $\int \mathrm{ch}_2 = -k$.

4.9.2 Chern roots and the splitting principle

Every formula above is a symmetric function of the eigenvalues of the Hermitian matrix $\Phi = \frac{i}{2\pi}F$. At each point we can (formally) diagonalise it:

$$\Phi \sim \begin{pmatrix} x_1 & & \\ & \ddots & \\ & & x_k \end{pmatrix},$$

where the x_j are commuting 2-forms, the **Chern roots** of E. They need not exist as honest global forms, but every *symmetric* expression in them does, because a symmetric polynomial in eigenvalues is a polynomial in the traces $\operatorname{tr}\Phi^j$.

Working definition 4.28 (Chern roots; splitting principle)

To compute any characteristic class of E, pretend that $E = L_1 \oplus \cdots \oplus L_k$ is a sum of line bundles [rank-one bundles, one complex dimension in each fibre] with $c_1(L_j) = x_j$. Then

$$c(E) = \prod_{j=1}^{k}(1 + x_j), \qquad \mathrm{ch}(E) = \sum_{j=1}^{k} e^{x_j},$$

compute whatever you need as a symmetric function [unchanged by any permutation of the x_j] of the x_j, and at the end rewrite it in terms of the elementary symmetric functions $c_1 = \sum x_j$, $c_2 = \sum_{i<j} x_i x_j$, ... Any identity proved this way holds for all bundles (this is

the **splitting principle**).

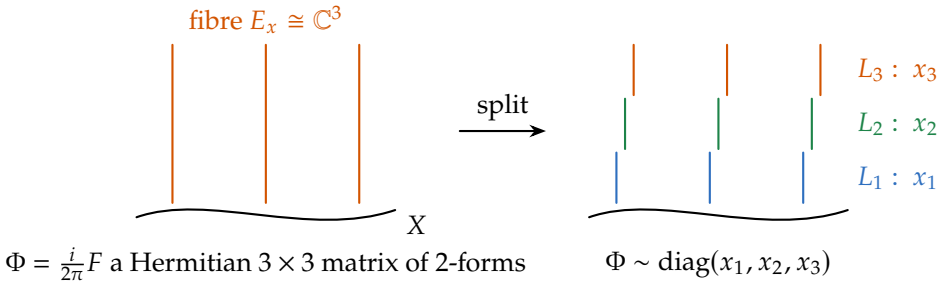

Figure 4.26: The splitting principle. Left: a rank-3 bundle, whose curvature is a Hermitian matrix of 2-forms. Right: for the purpose of computing characteristic classes we may pretend the bundle is a sum of three line bundles whose first Chern classes x_1, x_2, x_3 are the eigenvalues of Φ. Every symmetric function of the x_j is a genuine global form.

Worked example 4.48: The splitting principle reproduces (4.72)

For a rank-2 bundle with Chern roots x_1, x_2,

$$\begin{aligned} \mathrm{ch}_2(E) &\overset{(1)}{=} \tfrac{1}{2}\left(x_1^2 + x_2^2\right) \\ &\overset{(2)}{=} \tfrac{1}{2}\left[(x_1+x_2)^2 - 2x_1x_2\right] \\ &\overset{(3)}{=} \tfrac{1}{2}c_1^2 - c_2. \end{aligned}$$

(1) $\mathrm{ch}(E) = e^{x_1} + e^{x_2}$; the degree-4 part of e^x is $x^2/2$.
(2) The algebraic identity $a^2 + b^2 = (a+b)^2 - 2ab$.
(3) $c_1 = x_1 + x_2$ and $c_2 = x_1x_2$ are the elementary symmetric functions.

The answer agrees with the curvature computation (4.72), as it must: both are $\frac{1}{2}\operatorname{tr}\Phi^2$.

Two properties of ch make it the right bridge from K-theory, and the splitting principle makes them obvious:

$$\begin{aligned} \mathrm{ch}(E \oplus E') &\overset{(1)}{=} \sum_j e^{x_j} + \sum_l e^{x'_l} = \mathrm{ch}\,E + \mathrm{ch}\,E', \\ \mathrm{ch}(E \otimes E') &\overset{(2)}{=} \sum_{j,l} e^{x_j + x'_l} = \Big(\sum_j e^{x_j}\Big)\Big(\sum_l e^{x'_l}\Big) = \mathrm{ch}\,E\ \mathrm{ch}\,E'. \end{aligned} \tag{4.73}$$

(1) The Chern roots of a direct sum are the union of the two lists (the curvature is block diagonal).
(2) The Chern roots of a tensor product are all sums $x_j + x'_l$, because $L \otimes L'$ has $c_1(L\otimes L') = c_1(L) + c_1(L')$ (the connections add: $A_{L\otimes L'} = A_L + A_{L'}$).

So ch turns $\oplus$ into $+$ and $\otimes$ into $\times$. A K-theory class is a formal difference $[E]-[E']$ of bundles, so $\mathrm{ch}([E]-[E']) = \mathrm{ch}\,E - \mathrm{ch}\,E'$ is well defined, and ch is a ring homomorphism $K(X) \to H^{\mathrm{even}}(X;\mathbb{Q})$. This is precisely the mechanism Nash asks for on [Nash p. 97–98]: a way of passing from K-theory to cohomology.

Two more rules we will need. For the dual bundle E^* the connection is $-A^T$, so its Chern roots are $-x_j$:

$$c_j(E^*) = (-1)^j c_j(E), \qquad \mathrm{ch}(E^*) = \sum_j e^{-x_j}. \tag{4.74}$$

The complex conjugate bundle $\bar{E}$ has connection $\bar{A} = -A^T$ (for a unitary connection), so $\bar{E} \cong E^*$ as far as characteristic classes are concerned. And for exterior powers,

$$E = L_1 \oplus \cdots \oplus L_k \implies \Lambda^p E = \bigoplus_{i_1 < \cdots < i_p} L_{i_1} \otimes \cdots \otimes L_{i_p}, \tag{4.75}$$

which is just the statement that $e_{i_1} \wedge \cdots \wedge e_{i_p}$, $i_1 < \cdots < i_p$, is a basis of $\Lambda^p \mathbb{C}^k$ when $e_1, \dots, e_k$ is a basis of $\mathbb{C}^k$. We use (4.75) heavily in Section 4.12.

4.9.3 Multiplicative classes: Todd, $\hat{A}$ and L

The Chern character is *additive*: a sum over Chern roots. The other classes in the index theorem are *multiplicative*: a product over Chern roots of one fixed power series.

Working definition 4.29 (multiplicative class of a power series)

Pick a power series $Q(x) = 1 + q_1 x + q_2 x^2 + \cdots$. For a bundle with Chern roots $x_1, \dots, x_k$ define

$$Q(E) := \prod_{j=1}^{k} Q(x_j),$$

expand, and rewrite each degree in terms of $c_1, c_2, \dots$. Then $Q(E \oplus E') = Q(E)\,Q(E')$ [the Chern roots of $E \oplus E'$ are those of E together with those of E'].

The **Todd class** is the multiplicative class of

$$\frac{x}{1 - e^{-x}} = 1 + \frac{x}{2} + \frac{x^2}{12} - \frac{x^4}{720} + \cdots. \tag{4.76}$$

(The x^3 coefficient vanishes because $\frac{x}{1-e^{-x}} - \frac{x}{2} = \frac{x}{2} \coth \frac{x}{2}$ is even.) Multiplying out and collecting,

$$\begin{aligned} \operatorname{td}(E) &\overset{(1)}{=} \prod_j \left(1 + \tfrac{1}{2}x_j + \tfrac{1}{12}x_j^2 + 0 \cdot x_j^3 + \cdots\right) \\ &\overset{(2)}{=} 1 + \tfrac{1}{2}\sum_j x_j + \left[\tfrac{1}{12}\sum_j x_j^2 + \tfrac{1}{4}\sum_{i<j} x_i x_j\right] + \left[\tfrac{1}{24}\sum_{i \neq j} x_i^2 x_j + \tfrac{1}{8}\sum_{i<j<l} x_i x_j x_l\right] + \cdots \\ &\overset{(3)}{=} 1 + \tfrac{1}{2}c_1 + \tfrac{1}{12}\left(c_1^2 + c_2\right) + \tfrac{1}{24}c_1 c_2 + \cdots. \end{aligned} \tag{4.77}$$

(1) Definition of the multiplicative class with the series (4.76).

(2) Collect terms of polynomial degree 1, 2, 3 in the x_j (form degrees 2, 4, 6): either one factor contributes its x^2 or x^3 term, or several factors contribute their linear term.

(3) Use $\sum x_j^2 = c_1^2 - 2c_2$, so $\frac{1}{12}(c_1^2 - 2c_2) + \frac{1}{4}c_2 = \frac{1}{12}(c_1^2 + c_2)$; and $\sum_{i \neq j} x_i^2 x_j = c_1 c_2 - 3c_3$, so $\frac{1}{24}(c_1 c_2 - 3c_3) + \frac{1}{8}c_3 = \frac{1}{24}c_1 c_2$.

For the dual bundle, (4.74) gives

$$\operatorname{td}(E^*) = \prod_{j=1}^{k} \frac{-x_j}{1 - e^{x_j}}. \tag{4.78}$$

Real bundles, Pontryagin classes and the Euler class

The index formula involves the *complexified* tangent bundle $TX_{\mathbb{C}} = TX \otimes_{\mathbb{R}} \mathbb{C}$ of a real manifold. A complexified real bundle is isomorphic to its own conjugate (complex conjugation of the $\mathbb{C}$

factor), hence to its own dual. By (4.74) this forces $c_j(TX_{\mathbb{C}}) = (-1)^j c_j(TX_{\mathbb{C}})$, so all odd Chern classes vanish (as de Rham classes). In terms of Chern roots: they come in pairs $\pm x_j$.

We can see this directly from curvature. Take a Riemannian metric on X (dimension $n = 2m$) and its Levi-Civita connection in an orthonormal frame. The curvature $R = (R^a{}_b)$ is a *real antisymmetric* $n \times n$ matrix of 2-forms. A real antisymmetric matrix can be brought to block-diagonal form by a rotation:

$$\frac{R}{2\pi} \sim \begin{pmatrix} 0 & x_1 & & & & \\ -x_1 & 0 & & & & \\ & & \ddots & & & \\ & & & 0 & x_m \\ & & & -x_m & 0 \end{pmatrix}. \tag{4.79}$$

Each block $\left(\begin{smallmatrix} 0 & x \\ -x & 0 \end{smallmatrix}\right)$ has eigenvalues $\pm ix$, so $\Phi = \frac{i}{2\pi}R$ has eigenvalues $\mp x$: the Chern roots of $TX_{\mathbb{C}}$ are $\pm x_1, \dots, \pm x_m$. Physically, each x_j is the "rotation angle" (really a 2-form) of the curvature in the j-th 2-plane.

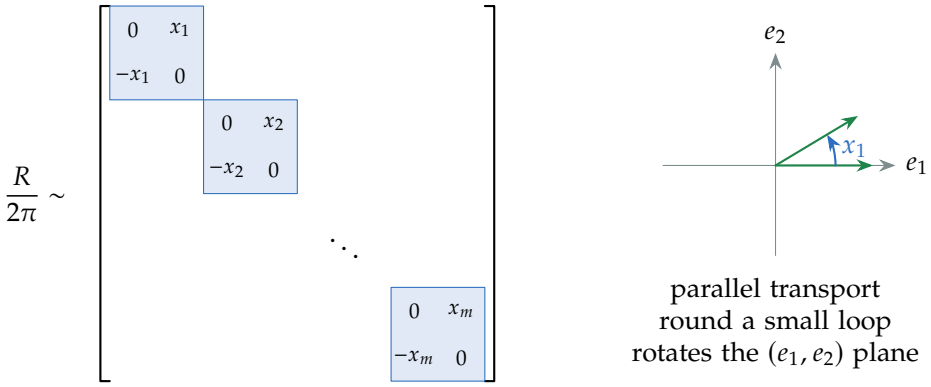

Figure 4.27: Left: the curvature of a Riemannian manifold, divided by 2π, is a real antisymmetric matrix of 2-forms; it can be brought to 2×2 blocks. Right: the j-th block describes an infinitesimal rotation of the j-th 2-plane, by an "angle" x_j that is a 2-form. The x_j play the role of Chern roots for real bundles.

Working definition 4.30 (Pontryagin and Euler classes)

For a real oriented bundle V [with a chosen orientation of every fibre, which fixes the sign of $e(V)$] of rank $2m$ with curvature in the block form (4.79) [$R/2\pi$ rotated into 2×2 blocks with entries $\pm x_j$]:

$$p(V) = \prod_{j=1}^{m}(1 + x_j^2), \qquad p_i(V) = (-1)^i c_{2i}(V_{\mathbb{C}}), \quad \text{e.g. } p_1(V) = \sum_j x_j^2 = -\frac{1}{8\pi^2}\operatorname{tr}(R \wedge R),$$

$$e(V) = x_1 x_2 \cdots x_m = \operatorname{Pf}\left(\frac{R}{2\pi}\right), \qquad \text{so } e(V)^2 = p_m(V).$$

Here $V_{\mathbb{C}} = V \otimes \mathbb{C}$ [the same fibres and transition matrices, now acting on complex vectors]. The Pfaffian of an antisymmetric $2m \times 2m$ matrix is $\operatorname{Pf}(M) = \frac{1}{2^m m!}\epsilon_{a_1 \cdots a_{2m}} M^{a_1 a_2} \cdots M^{a_{2m-1} a_{2m}}$; on the block form it is the product of the upper-right entries.

Let us check the formula for p_1 in terms of R, because we will use it for the signature and

the $\hat{A}$-genus:

$$\begin{aligned} p_1(V) &\overset{(1)}{=} -c_2(V_{\mathbb{C}}) \\ &\overset{(2)}{=} -\frac{1}{8\pi^2}\left[\operatorname{tr}(R\wedge R) - \operatorname{tr} R \wedge \operatorname{tr} R\right] \\ &\overset{(3)}{=} -\frac{1}{8\pi^2}\operatorname{tr}(R\wedge R). \end{aligned}$$

(1) Definition of p_1 with $i = 1$.
(2) Formula (4.71) with F replaced by the real curvature R (which is also anti-Hermitian, being real antisymmetric).
(3) R is antisymmetric, so $\operatorname{tr} R = 0$.

And in terms of the roots: $\operatorname{tr}(R\wedge R)/(2\pi)^2$ on the block form is $\sum_j 2\cdot x_j\cdot(-x_j) = -2\sum_j x_j^2$, so $p_1 = -\frac{1}{8\pi^2}\cdot(-8\pi^2)\sum_j x_j^2 = \sum_j x_j^2$. The two descriptions agree.

Finally, the relation between the Euler class and the top Chern class of the complexification (Nash's (3.124)), which the de Rham calculation will need:

$$\begin{aligned} c_{2m}(V_{\mathbb{C}}) &\overset{(1)}{=} \prod_{j=1}^{m} x_j(-x_j) \\ &\overset{(2)}{=} (-1)^m\Big(\prod_j x_j\Big)^2 = (-1)^m e(V)^2. \end{aligned} \tag{4.80}$$

(1) The top Chern class is the product of all Chern roots, and the roots of $V_{\mathbb{C}}$ are $\pm x_j$.
(2) Pull out one sign per pair; the remaining product is $e(V)$ squared.

The genera that appear in the index theorem

Here is the key simplification that Nash states as (4.32). The Todd class of a complexified tangent bundle is a perfect square:

$$\begin{aligned} \operatorname{td}(TX_{\mathbb{C}}) &\overset{(1)}{=} \prod_{j=1}^{m} \frac{x_j}{1-e^{-x_j}}\cdot\frac{-x_j}{1-e^{x_j}} \\ &\overset{(2)}{=} \prod_{j=1}^{m} \frac{x_j^2}{(e^{x_j/2}-e^{-x_j/2})^2} \\ &\overset{(3)}{=} \prod_{j=1}^{m}\Big(\frac{x_j/2}{\sinh(x_j/2)}\Big)^2 \;=\; \hat{A}(X)^2. \end{aligned} \tag{4.81}$$

(1) The Chern roots of $TX_{\mathbb{C}}$ are $\pm x_j$; insert them into the Todd series (4.76).
(2) $(1-e^{-x})(1-e^{x}) = 2 - e^{x} - e^{-x} = -(e^{x/2}-e^{-x/2})^2$, and the numerator is $-x^2$, so the two minus signs cancel.
(3) $e^{x/2}-e^{-x/2} = 2\sinh(x/2)$; the product of $(x/2)/\sinh(x/2)$ is by definition the $\hat{A}$-class, which we meet properly in Section 4.15.

Now expand. With $t = x/2$, $t/\sinh t = 1 - \frac{t^2}{6} + \frac{7t^4}{360} - \cdots$, so

$$\frac{x/2}{\sinh(x/2)} = 1 - \frac{x^2}{24} + \frac{7x^4}{5760} - \cdots, \tag{4.82}$$

and therefore

$$\hat{A}(X) \overset{(1)}{=} 1 - \frac{1}{24}\sum_j x_j^2 + \Big[\frac{7}{5760}\sum_j x_j^4 + \frac{1}{576}\sum_{i<j} x_i^2 x_j^2\Big] + \cdots$$
$$\overset{(2)}{=} 1 - \frac{p_1}{24} + \frac{7(p_1^2 - 2p_2) + 10p_2}{5760} + \cdots = 1 - \frac{p_1}{24} + \frac{7p_1^2 - 4p_2}{5760} + \cdots . \tag{4.83}$$

(1) Multiply the series (4.82) over j and collect degrees.
(2) In the variables x_j^2, $p_1 = \sum x_j^2$ and $p_2 = \sum_{i<j} x_i^2 x_j^2$, so $\sum x_j^4 = p_1^2 - 2p_2$; and $\frac{1}{576} = \frac{10}{5760}$.

Squaring,

$$\mathrm{td}(TX_{\mathbb{C}}) \overset{(1)}{=} 1 - 2\cdot\frac{p_1}{24} + \Big[2\cdot\frac{7p_1^2 - 4p_2}{5760} + \frac{p_1^2}{576}\Big] + \cdots$$
$$\overset{(2)}{=} 1 - \frac{p_1}{12} + \frac{24p_1^2 - 8p_2}{5760} + \cdots = 1 - \frac{1}{12}p_1 + \frac{1}{720}(3p_1^2 - p_2) + \cdots , \tag{4.84}$$

(1) $(1 + a + b)^2 = 1 + 2a + (2b + a^2) + \cdots$ with $a = -p_1/24$ and b the degree-8 term.
(2) $14 + 10 = 24$ and $24/5760 = 3/720$, $8/5760 = 1/720$.

which is exactly Nash's (4.32). Only Pontryagin classes appear, as they must for a real bundle.

class	series (per root)	low-order expansion	where it appears
$\mathrm{ch}(E)$ (additive)	$\sum e^{x_j}$	$k + c_1 + \frac{1}{2}(c_1^2 - 2c_2)$	every twisted index
$\mathrm{td}(E)$	$\dfrac{x}{1 - e^{-x}}$	$1 + \frac{1}{2}c_1 + \frac{1}{12}(c_1^2 + c_2) + \frac{1}{24}c_1c_2$	Dolbeault, (4.31)
$\hat{A}(V)$	$\dfrac{x/2}{\sinh(x/2)}$	$1 - \frac{1}{24}p_1 + \frac{1}{5760}(7p_1^2 - 4p_2)$	Dirac
$\mathcal{L}(V)$ (Nash)	$\dfrac{x/2}{\tanh(x/2)}$	$1 + \frac{1}{12}p_1 + \frac{1}{720}(7p_2 - p_1^2)$	signature
$e(V)$	x (product of m roots)	$x_1 \cdots x_m = \mathrm{Pf}(R/2\pi)$	Gauss–Bonnet

Table 4.2: The characteristic classes of the four classical index theorems, each given by one power series in the Chern roots. For real bundles, the roots are the block "angles" x_j of (4.79). The $\mathcal{L}$ row uses Nash's normalisation; we derive it in Section 4.14.

4.9.4 The index formula

We can now read Nash's cohomological formula. Recall from the previous section that an elliptic operator D of order m on an n-manifold X determines a class $[\sigma_m(D)] \in K(T^*X)$ (K-theory with compact support on the cotangent bundle). Apply the Chern character to get a compactly supported cohomology class $\mathrm{ch}[\sigma_m(D)]$ on T^*X. Pull back the Todd class of $TX_{\mathbb{C}}$ to T^*X (or TX; for our purposes the metric identifies them). Multiply, and integrate over the $2n$-dimensional total space.

Key idea: The cohomological index formula, Nash (4.31)

For an elliptic operator D of order m on a compact n-manifold X,

$$\mathrm{index}\, D = (-1)^n \big\{\mathrm{ch}\big([\sigma_m(D)]\big)\cdot \mathrm{td}(TX_{\mathbb{C}})\big\}[TX], \tag{4.85}$$

where $[TX]$ is the fundamental class of the total space of the tangent bundle and $\{\cdots\}[TX]$ means "evaluate on it", i.e. integrate the top-degree ($2n$-form) part of the integrand over TX. The integrand has compact support in the fibre directions because the symbol complex is exact away from the zero section.

It is worth pausing on what this formula claims. The right-hand side is built from ch and td, whose power series have denominators $2, 12, 24, 720, \ldots$. It is a number in rational cohomology. Nothing in its definition makes it an integer. Yet it equals $\dim \operatorname{Ker} D - \dim \operatorname{Coker} D$, which is an integer. Nash calls this "far from obvious". Indeed, whole theorems will fall out of this integrality alone: Rokhlin's theorem in Section 4.15.9 is one. Historically, the same combination $\mathrm{ch} \cdot \mathrm{td}$ had already appeared in Hirzebruch's Riemann–Roch theorem for complex manifolds (1954), which is the special case we derive in Section 4.13.

Physical picture: Why characteristic classes at all

The index is stable: it does not change when D is deformed continuously through elliptic operators. So it can only depend on topological data, and the only topological data around are the bundles E^p the operator acts on and the tangent bundle of X. Characteristic classes are exactly the topological invariants of bundles that can be written as local integrals. The index theorem says: the global count of zero modes is a local integral. This is the same philosophy as Gauss–Bonnet, and, in physics, as the anomaly: a global quantity (a count of states, a phase) fixed by a local density.

In practice we will never integrate over TX directly. The next two sections show how to push the computation down to X itself, where it becomes $\int_X$(curvature polynomial). Before that, three computations that we will reuse.

Worked example 4.49: Characteristic classes of $S^2 = \mathbb{CP}^1$

Think of S^2 as the Riemann sphere. Its holomorphic tangent bundle $T = T^{1,0}S^2$ is a complex line bundle, with one Chern root $y = c_1(T)$. For the round metric of radius 1, the Levi-Civita connection on T has curvature $F = -i\,K\,\mathrm{d}A$ with Gaussian curvature $K = 1$ (this is just the rotation of the tangent plane under parallel transport), so

$$\int_{S^2} c_1(T) \overset{(1)}{=} \int_{S^2} \frac{i}{2\pi}\left(-iK\,\mathrm{d}A\right) \overset{(2)}{=} \frac{1}{2\pi}\int_{S^2} \mathrm{d}A = \frac{4\pi}{2\pi} = 2.$$

(1) Definition of c_1 for a line bundle (tr of a 1×1 matrix).
(2) $K = 1$ for the unit sphere; the area is 4π.

So $T \cong \mathcal{O}(2)$, the line bundle of degree 2. The underlying real bundle TS^2 has one block angle $x_1 = y$, so $e(TS^2) = y$ with $\int e = 2$, and $p_1(TS^2) = y^2 = 0$ since there are no 4-forms on a surface. The Todd class $\mathrm{td}(T) = 1 + \frac{1}{2}y$ integrates to 1.

Worked example 4.50: Pontryagin class of $\mathbb{CP}^2$

Let h be the positive generator of $H^2(\mathbb{CP}^2;\mathbb{Z})$, the Poincaré dual of a line $\mathbb{CP}^1 \subset \mathbb{CP}^2$, so $\int_{\mathbb{CP}^2} h^2 = 1$ (two lines meet in one point). A standard fact (the Euler sequence; Bär's Example

4.3.4) is that the holomorphic tangent bundle T has total Chern class $c(T) = (1+h)^3$. Then

$$\begin{aligned} p_1(\mathbb{CP}^2) &\overset{(1)}{=} \sum_j y_j^2 \\ &\overset{(2)}{=} c_1(T)^2 - 2c_2(T) \\ &\overset{(3)}{=} (3h)^2 - 2\cdot 3h^2 = 3h^2, \qquad \text{so} \quad \int_{\mathbb{CP}^2} p_1 = 3. \end{aligned}$$

(1) For a complex manifold, $TX_{\mathbb{C}} = T \oplus \bar{T}$ has Chern roots y_j (of T) and $-y_j$ (of $\bar{T} \cong T^*$), so the "block angles" are the y_j and $p_1 = \sum y_j^2$.

(2) $\sum y_j^2 = (\sum y_j)^2 - 2\sum_{i<j} y_i y_j$.

(3) Expand $(1+h)^3 = 1 + 3h + 3h^2$: $c_1 = 3h$, $c_2 = 3h^2$.

Also $\int e(\mathbb{CP}^2) = \int c_2(T) = 3$, which is $\chi(\mathbb{CP}^2) = 1+1+1$ (cells in dimensions 0, 2, 4). Both numbers will be used below.

Worked example 4.51: The round S^4: $p_1 = 0$, $\int e = 2$

For the unit sphere S^n the curvature 2-forms in an orthonormal coframe e^a are $R^{ab} = e^a \wedge e^b$ (constant sectional curvature 1). Then

$$\operatorname{tr}(R \wedge R) = \sum_{a,b} R^{ab} \wedge R^{ba} = \sum_{a,b} e^a \wedge e^b \wedge e^b \wedge e^a = 0,$$

because $e^b \wedge e^b = 0$. So $p_1(S^4) = 0$. (More generally $TS^n \oplus \mathbb{R} = \mathbb{R}^{n+1}$ is trivial, so $p(TS^n) = 1$.) The Euler form is not zero:

$$\begin{aligned} \int_{S^4} e &\overset{(1)}{=} \int_{S^4} \frac{1}{2^2\, 2!\, (2\pi)^2} \epsilon_{abcd} R^{ab} \wedge R^{cd} \\ &\overset{(2)}{=} \frac{1}{32\pi^2} \int_{S^4} \epsilon_{abcd}\, e^a \wedge e^b \wedge e^c \wedge e^d \\ &\overset{(3)}{=} \frac{24}{32\pi^2} \operatorname{vol}(S^4) = \frac{24}{32\pi^2} \cdot \frac{8\pi^2}{3} = 2. \end{aligned}$$

(1) The Pfaffian formula with $m = 2$ applied to $R/2\pi$.

(2) $R^{ab} = e^a \wedge e^b$ for the unit sphere.

(3) Each of the $4! = 24$ orderings of $(1,2,3,4)$ contributes $+e^1 \wedge e^2 \wedge e^3 \wedge e^4$, the volume form; the volume of the unit 4-sphere is $8\pi^2/3$.

And $\chi(S^4) = 2$. We have just checked the four-dimensional Gauss–Bonnet theorem on one example; Section 4.12 derives it from the index theorem.

Watch out: Nash's $[TX]$ and $[X]$

Nash writes $\{\cdots\}[TX]$ in (4.31) and later $\{\cdots\}[X]$. Both mean "take the top-degree component and integrate". The difference is which space you integrate over: the $2n$-dimensional total space TX (whose orientation is canonical; this is why no orientation of X is needed in (4.31)), or X itself (which requires X oriented). The sign factors $(-1)^n$, $(-1)^{n(n+1)/2}$, $(-1)^{n/2}$ that Nash carries around are bookkeeping of these orientation conventions. We will always fix them at the end by checking a known case.

Reading Nash (pp. 97–98, (4.31)–(4.32))

Nash's §2 opens by saying that the K-theoretic index can be translated into cohomology with the Chern character, and quotes the result (4.31) from Atiyah–Singer III, calling the translation "slightly lengthy but routine". He then notes that $TX_{\mathbb{C}}$ is self-conjugate, so odd Chern classes vanish, and quotes the Todd expansion (4.32) in Pontryagin classes, referring to his (3.106) and (3.108). We have derived (4.32) from $\mathrm{td}(TX_{\mathbb{C}}) = \hat{A}(X)^2$, eq. (4.84).

Recap

- Characteristic classes are closed curvature polynomials: $c(E) = \det(1 + \frac{i}{2\pi}F)$, $\mathrm{ch}(E) = \operatorname{tr} e^{iF/2\pi}$.
- Splitting principle: compute with Chern roots x_j as if E were a sum of line bundles; ch is additive and multiplicative, so it maps K-theory to cohomology.
- Real bundles: roots $\pm x_j$ (block angles of $R/2\pi$); $p = \prod(1 + x_j^2)$, $e = \prod x_j = \mathrm{Pf}(R/2\pi)$, $c_{2m}(V_{\mathbb{C}}) = (-1)^m e^2$.
- $\mathrm{td}(TX_{\mathbb{C}}) = \hat{A}(X)^2 = 1 - \frac{1}{12}p_1 + \frac{1}{720}(3p_1^2 - p_2) + \cdots$.
- Index formula: $\operatorname{index} D = (-1)^n\{\mathrm{ch}[\sigma(D)]\ \mathrm{td}(TX_{\mathbb{C}})\}[TX]$, an integer although it is built from rational classes.

4.10 Two vanishing results: odd dimensions and operators on functions

Before computing indices we should know when not to bother. Nash's first two examples are *vanishing theorems*: situations where the index formula forces $\operatorname{index} D = 0$ without any calculation, purely by a symmetry or a dimension count. They are also good practice in reading the formula (4.85): what depends on what, and in which degree.

The two statements are:

1. On an *odd*-dimensional manifold every elliptic *differential* operator has index zero.

2. An elliptic differential operator acting on (scalar) *functions*, i.e. between trivial line bundles, always has index zero; and even a *pseudo-differential* one has index zero once $\dim X > 1$.

Both have an exception for pseudo-differential operators in dimension one, and we shall compute that exception explicitly.

4.10.1 Symbols are homogeneous polynomials in the momentum

Recall (Chapter 2) how the principal symbol is read off. Write the operator in local coordinates, $D = \sum_{|\alpha|\le m} a_\alpha(x)\,\partial^\alpha$ with multi-index notation $\partial^\alpha = \partial_1^{\alpha_1}\cdots\partial_n^{\alpha_n}$, replace each ∂_μ by ip_μ (the Fourier rule: $\partial_\mu e^{ip\cdot x} = ip_\mu e^{ip\cdot x}$), and keep only the top-order terms:

$$\sigma_m^D(x,p) = \sum_{|\alpha|=m} a_\alpha(x)\,(ip)^\alpha. \tag{4.86}$$

(Nash absorbs the powers of i into a_α and writes $\sum_{|\alpha|=m} a_\alpha(x)p^\alpha$.) Each term is a monomial of degree exactly m in p. Hence the **homogeneity** property

$$\sigma_m^D(x,\lambda p) = \lambda^m\,\sigma_m^D(x,p) \qquad \text{for all real } \lambda. \tag{4.87}$$

The important case for us is $\lambda = -1$:

$$\sigma_m^D(x,-p) = (-1)^m\,\sigma_m^D(x,p). \tag{Nash 4.33}$$

For example, the Laplacian $-\sum_\mu \partial_\mu^2$ has symbol $|p|^2$ (even, $m=2$); the operator $\mathrm{d}/\mathrm{d}\theta$ on the circle has symbol ip (odd, $m=1$); the Dirac operator has symbol $i\gamma^\mu p_\mu$ (odd, $m=1$). All obey (Nash 4.33). What fails for pseudo-differential operators is precisely this: their symbols are only required to be homogeneous for $\lambda > 0$, so $|p|$ is allowed, and $|-p| = |p|$ is not $(-1)^1\,|p|$.

4.10.2 Why the index vanishes in odd dimensions

The idea is to apply the **antipodal map**

$$R : T^*X \to T^*X, \qquad (x,p) \mapsto (x,-p)$$

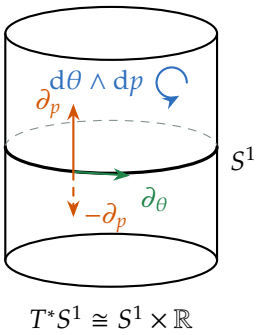
to the index formula. It changes the integrand in a controlled way (by (Nash 4.33)), and it may reverse the orientation of the space we integrate over. Let us see when.

In local coordinates $(x^1,\dots,x^n,p_1,\dots,p_n)$ on T^*X, the canonical orientation is given by the volume form $\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^n\wedge\mathrm{d}p_1\wedge\cdots\wedge\mathrm{d}p_n$ (any other ordering convention changes it by a fixed sign, which does not matter here). Pull it back by R:

$$\begin{aligned} R^*\big(\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^n\wedge\mathrm{d}p_1\wedge\cdots\wedge\mathrm{d}p_n\big) &\overset{(1)}{=} \mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^n\wedge\mathrm{d}(-p_1)\wedge\cdots\wedge\mathrm{d}(-p_n) \\ &\overset{(2)}{=} (-1)^n\,\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^n\wedge\mathrm{d}p_1\wedge\cdots\wedge\mathrm{d}p_n. \end{aligned}$$

(1) R leaves the x^μ alone and sends $p_\mu \mapsto -p_\mu$; pull-back commutes with d.
(2) Pull out one minus sign from each of the n factors $\mathrm{d}p_\mu$.

So R preserves orientation when n is even and *reverses* it when n is odd. On fundamental classes: $R_*[T^*X] = (-1)^n[T^*X]$.



$R : (x,p) \mapsto (x,-p)$
$n=1$: $\mathrm{d}\theta\wedge\mathrm{d}p \mapsto -\mathrm{d}\theta\wedge\mathrm{d}p$
(flips the cylinder's orientation)
$n=2$: $\mathrm{d}^2x\,\mathrm{d}^2p \mapsto (-1)^2\,\mathrm{d}^2x\,\mathrm{d}^2p$
general: factor $(-1)^n$

Figure 4.28: The antipodal map on the cotangent bundle of the circle. The cotangent bundle is a cylinder with coordinates (θ,p); reversing p reverses the orientation $\mathrm{d}\theta\wedge\mathrm{d}p$. In n dimensions the sign is $(-1)^n$, so the antipodal map is orientation-reversing exactly when $\dim X$ is odd.

Next, what does R do to the K-theory class of the symbol? By (Nash 4.33), $R^*\sigma_m(D) = (-1)^m\sigma_m(D)$. If m is even there is nothing to say. If m is odd, the symbol has been multiplied by the constant -1. But the constant matrix -1 can be joined to $+1$ through invertible matrices, for example by the path $t \mapsto e^{i\pi t}\cdot 1$, $t\in[0,1]$. Multiplying the symbol by $e^{i\pi t}$ keeps it invertible

off the zero section at every t, so it is a homotopy of elliptic symbols, and homotopic symbols define the same K-class:

$$\big[(-1)^m \sigma_m(D)\big] = \big[\sigma_m(D)\big] \in K(T^*X). \tag{4.88}$$

Now we can run the argument. Suppose n is odd and D is a differential operator. Integrals are invariant under diffeomorphisms up to the orientation sign, $\int_M R^*\omega = \pm \int_M \omega$ with + for orientation-preserving R. So

$$\begin{aligned}
\operatorname{index} D &\overset{(1)}{=} (-1)^n \big\{\operatorname{ch}[\sigma_m(D)] \cdot \operatorname{td}(TX_{\mathbb{C}})\big\}[TX] \\
&\overset{(2)}{=} (-1)^n \big\{\operatorname{ch}[R^*\sigma_m(D)] \cdot \operatorname{td}(TX_{\mathbb{C}})\big\}\big(-[TX]\big) \\
&\overset{(3)}{=} (-1)^n \big\{\operatorname{ch}[(-1)^m\sigma_m(D)] \cdot \operatorname{td}(TX_{\mathbb{C}})\big\}\big(-[TX]\big) \\
&\overset{(4)}{=} -(-1)^n \big\{\operatorname{ch}[\sigma_m(D)] \cdot \operatorname{td}(TX_{\mathbb{C}})\big\}[TX] \\
&\overset{(5)}{=} -\operatorname{index} D.
\end{aligned} \tag{4.89}$$

(1) The cohomological index formula (4.85).
(2) Change variables by the diffeomorphism R. The integrand is pulled back (the Todd class is pulled back from X, and R covers the identity on X, so only the symbol part changes); because n is odd, R reverses orientation, which is the sign on $[TX]$.
(3) Homogeneity of the symbol of a differential operator, (Nash 4.33).
(4) Equation (4.88): the sign $(-1)^m$ does not change the K-class, hence not its Chern character; pull out the orientation sign.
(5) The index formula again.

An integer equal to its own negative is zero.

Key idea: Odd dimensions (Nash (4.34))

If $\dim X$ is odd and D is an elliptic *differential* operator, then $\operatorname{index} D = 0$. The mechanism: the antipodal map $p \mapsto -p$ reverses the orientation of T^*X but leaves the K-class of a polynomial symbol unchanged.

Worked example 4.52: Every differential operator on the circle has index zero

Take $X = S^1$ with coordinate θ and the first-order operator $D_c = \dfrac{\mathrm{d}}{\mathrm{d}\theta} - ic$ on complex functions, with $c \in \mathbb{R}$ a constant. Its symbol ip is invertible for $p \neq 0$, so it is elliptic. Expand $f = \sum_{k\in\mathbb{Z}} a_k e^{ik\theta}$. Then

$$D_c f = \sum_k i(k-c)\, a_k e^{ik\theta}.$$

Kernel. $D_c f = 0$ iff $(k-c)a_k = 0$ for all k. If $c \notin \mathbb{Z}$ this forces every $a_k = 0$; if $c = k_0 \in \mathbb{Z}$ the mode $e^{ik_0\theta}$ survives. So $\dim \operatorname{Ker} D_c = 1$ if $c \in \mathbb{Z}$ and 0 otherwise.
Cokernel. The equation $D_c f = g$ with $g = \sum b_k e^{ik\theta}$ is solved by $a_k = b_k/(i(k-c))$, which works for every k unless $k = c$. So $\dim \operatorname{Coker} D_c = 1$ if $c \in \mathbb{Z}$ and 0 otherwise.
Hence

$$\begin{aligned}
\operatorname{index} D_c &\overset{(1)}{=} \dim \operatorname{Ker} D_c - \dim \operatorname{Coker} D_c \\
&\overset{(2)}{=} \begin{cases} 1-1 & c \in \mathbb{Z} \\ 0-0 & c \notin \mathbb{Z} \end{cases} = 0.
\end{aligned}$$

(1) Definition of the analytical index.

(2) The two mode counts above.

This is the stability of the index in action. As c moves, the kernel jumps from 0 to 1 at integer c, but the cokernel jumps with it: zero modes can only appear in pairs that the index does not see. The odd-dimensional vanishing theorem says this is not a special feature of D_c: *any* elliptic differential operator on S^1, of any order and acting on any bundle, has kernel and cokernel of equal dimension.

4.10.3 The pseudo-differential exception on the circle

A **pseudo-differential operator** on S^1 is, for our purposes, an operator that acts diagonally (or nearly so) on Fourier modes with a multiplier that grows like a power of $|k|$, not necessarily polynomially. The basic example is

$$|D_\theta| := \sqrt{-\partial_\theta^2}: \qquad |D_\theta|\, e^{ik\theta} = |k|\, e^{ik\theta},$$

the "absolute value of the momentum". Its symbol is $|p|$, homogeneous of degree 1 for $\lambda > 0$ but even under $p \to -p$. We also write $D_\theta := -i\partial_\theta$, so that $D_\theta e^{ik\theta} = k e^{ik\theta}$ and its symbol is p.

Nash's example (4.35) is built from the two combinations $D_\theta \pm |D_\theta|$, which are (twice) the projections onto positive and negative frequencies:

$$(D_\theta + |D_\theta|)e^{ik\theta} = \begin{cases} 2k\, e^{ik\theta} & k > 0 \\ 0 & k \le 0 \end{cases}, \qquad (D_\theta - |D_\theta|)e^{ik\theta} = \begin{cases} 0 & k \ge 0 \\ 2k\, e^{ik\theta} & k < 0 \end{cases}.$$

Define

$$D := e^{-i\theta}\big(D_\theta + |D_\theta|\big) + \big(D_\theta - |D_\theta|\big), \qquad \sigma_1^D(\theta, p) = e^{-i\theta}(p + |p|) + (p - |p|). \tag{4.90}$$

The symbol equals $2p\, e^{-i\theta}$ for $p > 0$ and $2p$ for $p < 0$: never zero for $p \neq 0$, so D is elliptic. And $\sigma(\theta, -p)$ bears no simple relation to $\sigma(\theta, p)$, so the argument (4.89) does not apply.

Watch out: A sign typo in Nash (4.35)

Nash prints the operator as $e^{-i\theta}(-i\partial_\theta + \sqrt{-\partial_\theta^2}) - (\partial_\theta + \sqrt{-\partial_\theta^2})$ but its symbol as $e^{-i\theta}(p + |p|) + (p - |p|)$. These do not match (the second bracket would have symbol $-(ip + |p|)$). The symbol is the intended object; the operator (4.90) is the one with that symbol, and it is the one we analyse.

Worked example 4.53: Nash's pseudo-differential operator has index one

Apply D to a single mode, using the two projection formulas:

$$D\, e^{ik\theta} = \begin{cases} 2k\, e^{i(k-1)\theta} & k > 0, \\ 0 & k = 0, \\ 2k\, e^{ik\theta} & k < 0. \end{cases}$$

So positive modes are *shifted down by one* and rescaled, negative modes are rescaled in place, and the constant mode is killed.

Kernel. For $f = \sum a_k e^{ik\theta}$, $Df = \sum_{k>0} 2k a_k e^{i(k-1)\theta} + \sum_{k<0} 2k a_k e^{ik\theta}$. The first sum only contains modes $k - 1 \ge 0$, the second only modes $k < 0$, so the two cannot cancel each other. Thus $Df = 0$ iff $a_k = 0$ for all $k \neq 0$: $\operatorname{Ker} D = \operatorname{span}\{1\}$.

Cokernel. Every target mode is hit: a mode $e^{ij\theta}$ with $j \geq 0$ is D of $e^{i(j+1)\theta}/(2(j+1))$, and a mode with $j < 0$ is D of $e^{ij\theta}/(2j)$. So D is onto and $\operatorname{Coker} D = 0$.
Hence

$$\operatorname{index} D \overset{(1)}{=} \dim \operatorname{Ker} D - \dim \operatorname{Coker} D \overset{(2)}{=} 1 - 0 = 1.$$

(1) Definition of the analytical index.
(2) The kernel is the constants; the operator is surjective.

A nonzero index on an odd-dimensional manifold: pseudo-differential operators really do escape the theorem.

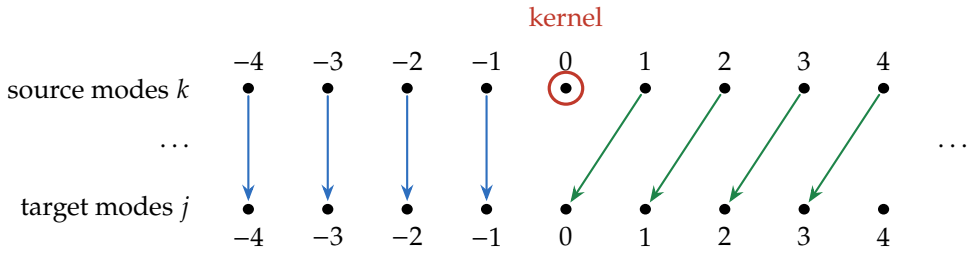


Figure 4.29: How Nash's pseudo-differential operator acts on Fourier modes. Negative modes go straight down (blue); positive modes are shifted one step to the left (green). Every target mode is hit exactly once, so the cokernel is zero, while the source mode $k = 0$ has nowhere to go: it is the kernel. Index $= 1 - 0 = 1$. A differential operator could never do this: it cannot treat $k > 0$ and $k < 0$ differently.

Physical picture: A winding number in disguise

Restrict the symbol to the unit cosphere bundle $|p| = 1$, which over S^1 is two circles, $p = +1$ and $p = -1$. On them $\sigma = 2e^{-i\theta}$ (winding number -1 around the origin of $\mathbb{C}$) and $\sigma = -2$ (winding number 0). The index is the difference $0 - (-1) = 1$. This is the classical Noether–Toeplitz index formula: for operators of this "positive frequencies times a, negative frequencies times b" type, the index is $w(b) - w(a)$, the difference of the winding numbers of the two symbol branches. A differential operator has $\sigma(\theta, -1) = \pm\sigma(\theta, +1)$, so the two windings agree and the index vanishes, which is (4.89) again, seen from the circle.

Try it: More winding

Replace $e^{-i\theta}$ by $e^{-iN\theta}$, $N \geq 1$, in (4.90). Show that the index is N.
Answer. Now $e^{ik\theta} \mapsto 2k\, e^{i(k-N)\theta}$ for $k > 0$ and $e^{ik\theta} \mapsto 2ke^{ik\theta}$ for $k < 0$. Every target mode is hit (modes $j \geq 1 - N$ from $k = j + N > 0$, and all $j < 0$), so the cokernel is zero. The target modes $j = 1 - N, \ldots, -1$ are hit twice, once from $k = j + N$ and once from $k = j$; the combination $a_{j+N}(j + N) + a_j j = 0$ gives one kernel direction for each such j, i.e. $N - 1$ directions, plus the constant. So index $= N - 0 = N = w(-2) - w(2e^{-iN\theta}) = 0 - (-N)$.

4.10.4 Operators acting on functions

Now suppose $D : \Gamma(X, E) \to \Gamma(X, F)$ with E and F both *trivial* of rank k (the ranks agree because D is elliptic, so its symbol is an isomorphism $E_x \to F_x$). Then D acts on k-component functions, and its leading symbol at (x, p) is literally a $k \times k$ matrix $\sigma_m(D)(x, p)$, invertible for $p \neq 0$.

By homogeneity, the symbol is determined by its values on unit covectors $|p| = 1$. The

set of unit covectors is the **unit sphere bundle** (cosphere bundle) $S(X) \subset T^*X$, a bundle of $(n-1)$-spheres over X, of total dimension $2n-1$. So the symbol is a map

$$\sigma_m(D) : S(X) \longrightarrow \mathrm{GL}(k, \mathbb{C}). \tag{Nash 4.36}$$

All the topology of the symbol is in how this map wraps $S(X)$ around $\mathrm{GL}(k,\mathbb{C})$, which is recorded by the pull-back on cohomology,

$$\sigma_m(D)^* : H^*(\mathrm{GL}(k,\mathbb{C});\mathbb{Z}) \longrightarrow H^*(S(X);\mathbb{Z}). \tag{Nash 4.37}$$

Two simplifications. First, $\mathrm{GL}(k,\mathbb{C})$ deformation-retracts onto $\mathrm{U}(k)$ (polar decomposition $M = U\,(M^\dagger M)^{1/2}$, and the positive factor can be shrunk to 1 through positive matrices), so we may replace $\mathrm{GL}(k,\mathbb{C})$ by $\mathrm{U}(k)$ in (Nash 4.37). Second, specialise to a single function, $k = 1$. Then $\mathrm{U}(1) = S^1$, whose cohomology is $\mathbb{Z}$ in degrees 0 and 1, with degree-1 generator h: the "angle form" $\frac{1}{2\pi}\mathrm{d}\arg z$. The pull-back $\sigma^*h = \frac{1}{2\pi}\mathrm{d}\arg\sigma$ is a closed 1-form on $S(X)$ whose integral over any loop is the winding number of the symbol around that loop.

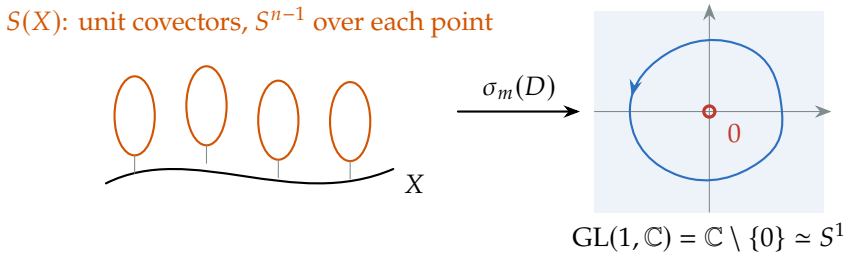

Figure 4.30: The symbol of an elliptic operator on functions ($k = 1$) is a map from the unit cosphere bundle $S(X)$ to the punctured plane. Its only topological content is how many times loops in $S(X)$ wind around the origin: a class in $H^1(S(X);\mathbb{Z})$. That single degree-1 class is what the dimension count in the text works with.

Now Nash argues that the index formula can be evaluated on $S(X)$ rather than on TX (the compactly supported cohomology of T^*X is reached from $S(X)$ by a suspension, the "clutching" construction of Chapter 4's first part):

$$\mathrm{index}\, D = (-1)^n \left\{ \mathrm{ch}[\sigma_m(D)] \cdot \mathrm{td}(TX_{\mathbb{C}}) \right\} [S(X)]. \tag{Nash 4.38}$$

Now count degrees.

- The symbol part: the only cohomology σ can carry is the pulled back 1-dimensional class, so $\mathrm{ch}[\sigma_m(D)]$ is proportional to $\sigma^*h \in H^1(S(X);\mathbb{Z})$: it has degree 1.
- The Todd part: by (4.84), $\mathrm{td}(TX_{\mathbb{C}})$ is a polynomial in Pontryagin classes, which live in degrees $0, 4, 8, \ldots$: pick its degree-$4i$ piece.
- The evaluation on $[S(X)]$ only sees forms of degree $\dim S(X) = 2n-1$.

So a nonzero contribution requires

$$4i + 1 = 2n - 1 \quad \Longrightarrow \quad n = 2i + 1. \tag{Nash 4.39}$$

In words: the index can be nonzero only if n is odd. But in odd dimensions a differential operator has index zero by (4.89). Both alternatives give zero.

For a pseudo-differential operator we lose the odd-dimensional theorem, but we gain a second constraint. The Todd class is pulled back from X, and a form on X of degree bigger than n vanishes. So $4i \le n$ as well:

$$0 \le 4i \le n, \qquad n = 2i + 1 \quad \Longrightarrow \quad 4i \le 2i + 1 \Longrightarrow\ i = 0,\ n = 1. \tag{Nash 4.40}$$

The only escape is $\dim X = 1$, and the circle example (4.90) shows the escape is real.

Key idea: Operators on functions

The index of an elliptic *differential* operator acting on a single function (trivial line bundles $E = F = X \times \mathbb{C}$) is always zero. For a *pseudo-differential* operator on functions the index is zero whenever $\dim X > 1$; in dimension 1 it is a winding number and can be anything.

Worked example 4.54: Why the hypothesis "functions" matters: $\bar\partial$ on a Riemann surface

The Cauchy–Riemann operator $\bar\partial : f \mapsto \partial_{\bar z} f \, d\bar z$ on a compact Riemann surface Σ_g of genus g takes functions to $(0,1)$-forms. Its kernel is the holomorphic functions, which on a compact surface are constants (maximum principle), so $\dim \operatorname{Ker} \bar\partial = 1$; its cokernel has dimension g (the number of independent holomorphic 1-forms, as we shall see in Section 4.13). So

$$\operatorname{index} \bar\partial = 1 - g.$$

This is nonzero for $g \neq 1$, but there is no contradiction: the target bundle $\Lambda^{0,1}$ is a nontrivial line bundle of degree $2g-2$ (it is $\bar K$), except on the torus $g = 1$, where $\Lambda^{0,1}$ *is* trivial (spanned by $d\bar z$) and indeed $\operatorname{index} \bar\partial = 1 - 1 = 0$, as the theorem demands.

Watch out: Systems of functions

For $k > 1$ the theorem changes. The symbol is now a map $S(X) \to \mathrm{U}(k)$, and $\mathrm{U}(k)$ has cohomology in degrees $1, 3, 5, \dots, 2k-1$, so the degree count (Nash 4.39) admits more solutions. Atiyah and Singer (paper III) show that vanishing statements survive for a certain range of k and n, but not in general. The Dirac operator on $\mathbb{R}^4$ is a 2×2 system and can have nonzero index once it is coupled to a nontrivial gauge field, which makes the bundle nontrivial (Section 4.16).

Reading Nash (pp. 98–101, (4.33)–(4.40))

Nash's "index when dim X is odd" is our Section 4.10.2; his (4.33) is (Nash 4.33), (4.34) is (4.89). The counterexample (4.35) is from Eguchi–Gilkey–Hanson; we have computed its index (one) mode by mode and corrected a sign in the printed operator. His "index when D acts on functions" is Section 4.10.4, with (4.36)–(4.40) reproduced as displayed. He says "we can now argue informally" before (4.38): the evaluation on $S(X)$ is indeed a sketch, and so is ours. From p. 101 on, Nash restricts to orientable X and differential operators; we follow him in the next section.

Recap

- Symbols of differential operators are homogeneous polynomials in p: $\sigma(x,-p) = (-1)^m \sigma(x,p)$, and the sign does not change the K-class.
- The antipodal map on T^*X has orientation sign $(-1)^n$; in odd dimensions it forces $\operatorname{index} D = -\operatorname{index} D = 0$.
- Pseudo-differential operators, like $e^{-i\theta}(D_\theta + |D_\theta|) + (D_\theta - |D_\theta|)$ on S^1, can have nonzero index (here 1) because $|p|$ is even.
- On functions ($k = 1$) the symbol only carries a degree-1 winding class; degree counting then kills the index except for pseudo-differential operators in dimension 1.

4.11 Orientable manifolds: the index formula on X itself

The formula (4.85) integrates over the $2n$-dimensional total space of the tangent bundle. That is awkward: we know how to integrate curvature forms over X, not over TX. In this section we push the integral down to X. The price is two mild restrictions, which Nash imposes from here on:

- X is *orientable*, so that it has a fundamental class $[X]$ and "$\int_X$" makes sense;
- D is a *differential* operator, and in fact part of an *elliptic complex* $0 \to \Gamma(E^0) \to \Gamma(E^1) \to \cdots$. (By Section 4.10 the interesting case is then n even.)

The tool for passing between TX and X is the **Thom isomorphism**. It is nothing more exotic than *integration over the fibres*, and the object that makes it work, the **Thom class**, is a closed form concentrated near the zero section whose integral over each fibre is 1: a normalised "bump" or "Gaussian" in the fibre directions. Its value on the zero section turns out to be the Euler class, and this is why $e(X)$ appears in Nash's second index formula (4.48).

4.11.1 Orientation and the fundamental class

An **orientation** of an n-manifold is a consistent choice of "positive" ordering of bases of every tangent space, equivalently a nowhere-vanishing n-form up to positive multiples, equivalently an atlas whose transition functions have positive Jacobian determinant. The circle, the spheres, the tori and every complex manifold are orientable; the Möbius strip, $\mathbb{RP}^2$ and the Klein bottle are not.

Working definition 4.31 (fundamental class; evaluation)

On a compact oriented n-manifold X, the **fundamental class** $[X] \in H_n(X;\mathbb{Z})$ [integer combinations of closed n-dimensional pieces of X, up to boundaries] is "X itself, counted once with its orientation". For a cohomology class a represented by a closed form α [$\mathrm{d}\alpha = 0$, a sum of pieces of several degrees] we write

$$a[X] \;:=\; \int_X \alpha^{(n)},$$

where $\alpha^{(n)}$ is the degree-n component. Components of other degrees are simply ignored. *Operationally*: "evaluate on $[X]$" means "integrate the top-degree part".

Stokes' theorem guarantees this is well defined on classes: if $\alpha^{(n)}$ changes by $\mathrm{d}\beta$, the integral changes by $\int_X \mathrm{d}\beta = \int_{\partial X} \beta = 0$. The same notation $b[TX]$ was used in (4.85) for a compactly supported class b on the non-compact manifold TX; compact support is exactly what makes Stokes' theorem (and so well-definedness) work there.

4.11.2 The Thom class: a unit bump in the fibres

Start with a single fibre $\mathbb{R}^n$, coordinates $v^1, \dots, v^n$. Among all n-forms on $\mathbb{R}^n$ with compact support (or rapid decay) consider

$$u_{\mathbb{R}^n} \;=\; \pi^{-n/2}\, e^{-|v|^2}\, \mathrm{d}v^1 \wedge \cdots \wedge \mathrm{d}v^n. \tag{4.91}$$

It is closed (it is a top form) and its integral is

$$\int_{\mathbb{R}^n} u_{\mathbb{R}^n} \overset{(1)}{=} \pi^{-n/2} \prod_{j=1}^{n} \int_{-\infty}^{\infty} e^{-(v^j)^2}\, \mathrm{d}v^j$$
$$\overset{(2)}{=} \pi^{-n/2} \big(\sqrt{\pi}\big)^n = 1.$$

(1) The Gaussian factorises, $e^{-|v|^2} = \prod_j e^{-(v^j)^2}$, and the orientation $\mathrm{d}v^1 \wedge \cdots \wedge \mathrm{d}v^n$ is the standard one, so the form integral is an ordinary iterated integral.

(2) The one-dimensional Gaussian integral $\int e^{-t^2}\mathrm{d}t = \sqrt{\pi}$.

Any other rapidly decaying n-form with total integral 1 differs from $u_{\mathbb{R}^n}$ by d of a rapidly decaying $(n-1)$-form (this is the statement that the compactly supported cohomology $H^n_c(\mathbb{R}^n)$ is one-dimensional, detected by the total integral). So the *class* of $u_{\mathbb{R}^n}$ is canonical: the generator of $H^n_c(\mathbb{R}^n) \cong \mathbb{R}$.

Now let $V \to X$ be an oriented real vector bundle of rank n (for us, $V = TX$). We want a closed n-form u on the total space of V which, on every fibre, looks like (4.91).

Working definition 4.32 (Thom class)

A **Thom form** of an oriented rank-n bundle $\pi : V \to X$ is a closed n-form u on the total space [V itself, the set of all vectors in all fibres], with compact support (or Gaussian decay) in the fibre directions, whose integral over every fibre V_x is 1:

$$\mathrm{d}u = 0, \qquad \int_{V_x} u = 1 \quad \text{for all } x \in X.$$

Its class $u \in H^n_c(V)$ is the **Thom class**. *Formally:* u is the unique class in compactly supported cohomology [closed forms vanishing outside a compact set, up to d of such forms] restricting to the orientation generator [the class whose integral over V_x, with its orientation, is +1] of each $H^n_c(V_x)$.

On a product $X \times \mathbb{R}^n$ we can take $u = \pi_2^* u_{\mathbb{R}^n}$. On a twisted bundle the naive Gaussian is not closed, because the fibre coordinates rotate from patch to patch. One must add correction terms involving the connection; the result (the Mathai–Quillen form) is closed, and its correction terms carry the curvature. We work this out completely in rank 2 below; it is exactly these correction terms that produce the Euler class.

4.11.3 The Thom isomorphism is integration over the fibre

Nash's map (4.41) sends a class a on X to a compactly supported class on TX:

$$\psi : H^*(X) \xrightarrow{\pi^*} H^*(TX) \xrightarrow{\cdot u} H^{*+n}_c(TX), \qquad \psi(a) = \pi^*(a) \cdot u. \tag{Nash 4.41}$$

Pull a back to the total space (a form constant along each fibre), then multiply by the unit bump to make it compactly supported. The inverse goes the other way, by integrating over the fibres. The **fibre integral** π_* of a form on TX is the form on X obtained by integrating out the fibre coordinates. For a product form,

$$\pi_*\big(\psi(a)\big) \overset{(1)}{=} \pi_*\big(\pi^* a \wedge u\big)$$
$$\overset{(2)}{=} a \cdot \int_{V_x} u$$
$$\overset{(3)}{=} a. \tag{4.92}$$

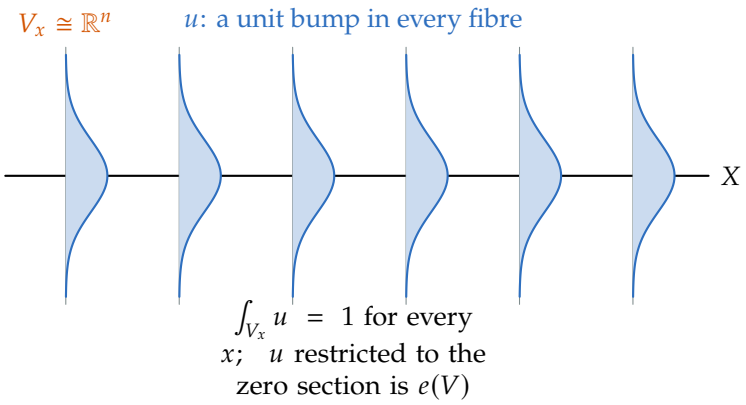

Figure 4.31: The Thom form of a vector bundle $V \to X$, drawn as a bump function of the fibre coordinate over each point of the base (the fibres are the vertical lines, the zero section is the horizontal line X). The area under each bump is 1. Integrating a form of the type $\pi^* a \wedge u$ over the total space therefore gives $\int_X a$: the Thom class "converts" integrals over V into integrals over X.

(1) Definition (Nash 4.41).
(2) $\pi^* a$ does not depend on the fibre coordinates, so it comes out of the fibre integral (the **projection formula**); only the degree-n fibre part of u survives the integration.
(3) Normalisation of the Thom form.

So $\psi^{-1} = \pi_*$ on the image of ψ. The content of the *Thom isomorphism theorem* is that ψ is onto: *every* compactly supported class on TX is of the form $\pi^* a \cdot u$. In words, the only topology a compactly supported class on a vector bundle can have is "topology of the base, times a bump".

And evaluation on fundamental classes is compatible:

$$\begin{aligned} \psi(a)[TX] &\overset{(1)}{=} \int_{TX} \pi^* a \wedge u \\ &\overset{(2)}{=} \int_X a \cdot \left(\int_{T_x X} u \right) = a[X]. \end{aligned} \tag{4.93}$$

(1) Definition of evaluation for a compactly supported class.
(2) Fubini: integrate first over the fibre, then over the base. This holds with the "base first, then fibre" orientation of TX; with another orientation convention a sign appears (see below).

4.11.4 The Thom class restricted to the zero section is the Euler class

Let $s_0 : X \to TX$ be the zero section, $x \mapsto (x, 0)$. Restricting u to it gives an n-form on X. For a trivial bundle this is zero (the Gaussian form $u_{\mathbb{R}^n}$ contains $\mathrm{d}v^1 \wedge \cdots \wedge \mathrm{d}v^n$, which vanishes when pulled back to $v = 0$). For a twisted bundle, the connection terms survive:

Key idea: Thom class on the zero section

For an oriented rank-n bundle V,

$$s_0^* u = e(V), \tag{4.94}$$

the Euler class. In particular the Euler class of an odd-rank bundle vanishes: the fibrewise map $v \mapsto -v$ reverses the orientation of odd-dimensional fibres, so it sends $u \mapsto -u$, while it fixes the zero section; hence $e(V) = -e(V) = 0$.

Let us see (4.94) with our own eyes in rank 2, where everything can be written down.

Worked example 4.55: Thom form of an oriented plane bundle

Let V have rank 2 with a metric and a compatible (SO(2)) connection. Over a patch, choose an orthonormal frame and polar fibre coordinates (r, φ). The connection is a single real 1-form ω (the SO(2) matrix is $\left(\begin{smallmatrix} 0 & -\omega \\ \omega & 0 \end{smallmatrix}\right)$ up to sign conventions), and under a change of frame by a rotation through angle $\lambda(x)$,

$$\varphi \mapsto \varphi - \lambda, \qquad \omega \mapsto \omega - \mathrm{d}\lambda.$$

Hence the combination $\Psi := \mathrm{d}\varphi - \omega$ is a globally defined 1-form on V minus its zero section (the **global angular form**), and

$$\mathrm{d}\Psi = -\mathrm{d}\omega = -\pi^*\big(2\pi\, e\big), \qquad e := \frac{\mathrm{d}\omega}{2\pi}. \tag{4.95}$$

Here $\mathrm{d}\omega$ is the curvature 2-form, and $e = \mathrm{d}\omega/2\pi$ is the Pfaffian of $R/2\pi$ for rank 2: the Euler form. Pick a function $\rho(r)$ with $\rho(0) = -1$ and $\rho(r) = 0$ for large r (for example $\rho = -e^{-r^2}$), and set

$$u := \mathrm{d}\Big(\rho(r)\,\frac{\Psi}{2\pi}\Big) = \frac{\rho'(r)}{2\pi}\,\mathrm{d}r \wedge \Psi + \frac{\rho(r)}{2\pi}\,\mathrm{d}\Psi. \tag{4.96}$$

It is exact on V minus the zero section, but it is *closed* on all of V (it is smooth across $r = 0$ because ρ is constant to first order there, and $\mathrm{d} \circ \mathrm{d} = 0$). Its support is near the zero section. Now check the two properties.

Fibre integral. On a fibre ω and $\mathrm{d}\omega$ restrict to zero (they are pulled back from the base), so

$$\begin{aligned} \int_{V_x} u &\overset{(1)}{=} \int_0^\infty \int_0^{2\pi} \frac{\rho'(r)}{2\pi}\,\mathrm{d}r\,\mathrm{d}\varphi \\ &\overset{(2)}{=} \rho(\infty) - \rho(0) = 0 - (-1) = 1. \end{aligned}$$

(1) On a single fibre $\Psi = \mathrm{d}\varphi$, and $\mathrm{d}\Psi = 0$; the orientation $\mathrm{d}r \wedge \mathrm{d}\varphi$ is the standard one of the plane.

(2) The φ integral gives 2π; the r integral is a total derivative.

Restriction to the zero section. At $r = 0$ we have $\mathrm{d}r = 0$ along the zero section and $\rho(0) = -1$, so

$$\begin{aligned} s_0^* u &\overset{(1)}{=} \frac{\rho(0)}{2\pi}\, s_0^* \mathrm{d}\Psi \\ &\overset{(2)}{=} \frac{-1}{2\pi}\big(-2\pi e\big) = e. \end{aligned}$$

(1) The first term of (4.96) contains $\mathrm{d}r$, which restricts to zero on $r = 0$.

(2) Equation (4.95).

For $V = TS^2$ with the round metric: in the orthonormal coframe $e^1 = \mathrm{d}\theta$, $e^2 = \sin\theta\,\mathrm{d}\varphi$ the Levi-Civita connection is $\omega = -\cos\theta\,\mathrm{d}\varphi$ (up to orientation of the frame rotation), so $\mathrm{d}\omega = \sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\varphi$ and $\int_{S^2} e = 4\pi/2\pi = 2$. The Thom form of TS^2 carries the Euler number 2 on its zero section.

Worked example 4.56: Euler number from zeros of a vector field

The Euler class has a second, very physical, meaning. A vector field s is a section of TX. Pull the Thom form back by s instead of the zero section. Since s is homotopic to s_0 (through ts, $t \in [0,1]$) and u is closed, $\int_X s^* u = \int_X s_0^* u = \int_X e$. But if we scale $s \to \lambda s$ with

$\lambda \to \infty$, the bump u becomes a delta function, and s^*u localises at the *zeros* of s:

$$\int_X e \overset{(1)}{=} \int_X (\lambda s)^* u \overset{(2)}{=} \sum_{s(x_k)=0} \int_{B_k} (\lambda s)^* u \overset{(3)}{=} \sum_{s(x_k)=0} \operatorname{ind}_{x_k}(s).$$

(1) Homotopy invariance: λs is homotopic to the zero section, and integrals of pull-backs of a closed form are homotopy invariant.

(2) For large λ the integrand vanishes except in small balls B_k around the zeros, because u decays away from the zero section.

(3) Near an isolated zero, λs maps a small ball onto a large region of the fibre; the integral of the unit bump over it counts how many times (with sign) s covers the fibre: the local **index** (degree) of the zero, ± 1 for a non-degenerate zero.

On S^2 take the "rotation" field $s = \partial_\varphi$, which vanishes at the two poles. Near each pole it looks like $(x, y) \mapsto (-y, x)$, a rotation, of index +1. So $\int e = 1 + 1 = 2$. This is the **Poincaré–Hopf theorem**, $\sum \text{ind} = \chi(X)$ once we know $\int e = \chi$ (which the de Rham example below proves from the index theorem). On a torus the constant field ∂_x has no zeros: $\int_{T^2} e = 0 = \chi(T^2)$.

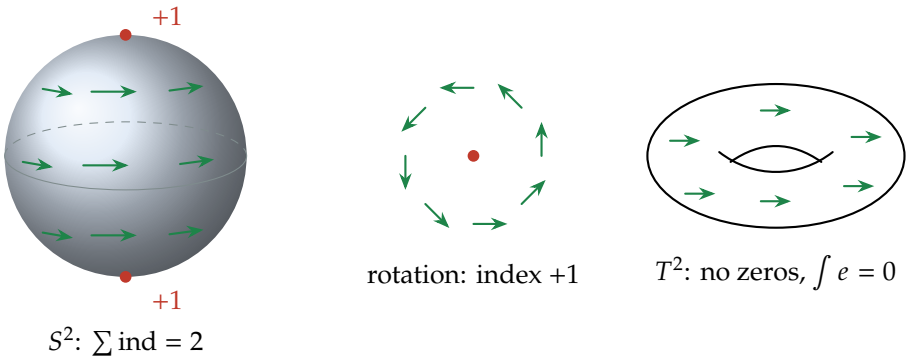

Figure 4.32: The Euler class counts zeros of vector fields. Left: the rotation field on S^2 vanishes only at the poles (red dots), each a zero of index +1 (middle: the local picture). Right: the torus carries a nowhere-vanishing field. Pulling the Thom form back by a large multiple of the vector field concentrates it at the zeros, which is why $\int_X e$ equals the sum of the indices.

4.11.5 The K-class of an elliptic complex

Now the operator side. An **elliptic complex** is a sequence

$$0 \longrightarrow \Gamma(X, E^0) \xrightarrow{d_0} \Gamma(X, E^1) \xrightarrow{d_1} \cdots \xrightarrow{d_{N-1}} \Gamma(X, E^N) \longrightarrow 0, \qquad d_{i+1} \circ d_i = 0, \tag{4.97}$$

of differential operators whose *symbol sequence*

$$0 \longrightarrow \pi^* E^0 \xrightarrow{\sigma(d_0)} \pi^* E^1 \xrightarrow{\sigma(d_1)} \cdots \longrightarrow \pi^* E^N \longrightarrow 0 \tag{Nash 4.44}$$

is *exact* at every (x,p) with $p \neq 0$. (Here π^*E^i is the bundle over T^*X whose fibre at (x,p) is E^i_x.) A single elliptic operator is the case $N=1$: exactness of $0 \to E^0_x \to E^1_x \to 0$ just says the symbol is an isomorphism. The index of the complex is the alternating sum of the dimensions of its cohomology groups, index $= \sum_i (-1)^i \dim H^i$; rolling up the complex into the single operator $d + d^* : \Gamma(\oplus E^{\text{even}}) \to \Gamma(\oplus E^{\text{odd}})$ gives an elliptic operator with the same index (Chapter 2).

For a complex of *vector bundles* $0 \to E^0 \to E^1 \to \cdots$ over a space, the K-theory class is the alternating sum

$$[E] = \sum_i (-1)^i [E^i]. \tag{Nash 4.43}$$

The logic: if the complex is exact, it splits, $E^i \cong B^i \oplus B^{i+1}$ with B^i the image of the previous map, and the alternating sum telescopes to zero. So (Nash 4.43) measures the failure of exactness, and a complex which is exact outside a compact set defines a compactly supported class. The symbol complex (Nash 4.44) is exact off the zero section, so it defines

$$[\sigma_m(D)] = \sum_p (-1)^p [\pi^* E^p] \in K(T^*X),$$

$$\operatorname{ch}[\sigma_m(D)] \overset{(1)}{=} \operatorname{ch}\Big(\sum_p (-1)^p [\pi^* E^p]\Big) \overset{(2)}{=} \pi^* \operatorname{ch}\Big(\sum_p (-1)^p [E^p]\Big). \tag{Nash 4.45}$$

(1) ch is additive, so it can be applied term by term.

(2) ch commutes with pull-back (the curvature of π^*E is the pull-back of the curvature of E).

We must be careful about what (Nash 4.45) means. The right-hand side, π^* of a class on X, is not compactly supported. The left-hand side is: it is the compactly supported class of the whole complex including its maps $\sigma(d_i)$, which is what cuts it off at large $|p|$. The honest statement is that the two agree *on the zero section*:

$$s_0^* \operatorname{ch}[\sigma_m(D)] = \operatorname{ch}\Big(\sum_p (-1)^p [E^p]\Big) \in H^{\text{even}}(X). \tag{4.98}$$

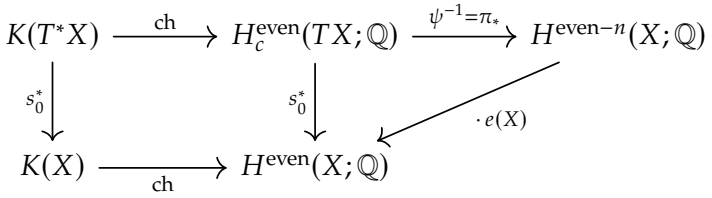

Figure 4.33: The bookkeeping behind Nash's (4.47). A compactly supported class on TX (top middle) can be pushed down in two ways: integrate over the fibres (ψ^{-1}), or restrict to the zero section (s_0^*). Because $\psi(b) = \pi^*b \cdot u$ and u restricts to $e(X)$, the two routes differ by multiplication by the Euler class: $s_0^*\psi(b) = b \cdot e(X)$.

4.11.6 Nash's second index formula

We now have all the pieces. Write the compactly supported class $\operatorname{ch}[\sigma_m(D)]$ as $\psi(b) = \pi^*b \cdot u$ for a class b on X (possible by the Thom isomorphism). Restrict to the zero section:

$$\operatorname{ch}\Big(\sum_p (-1)^p [E^p]\Big) \overset{(1)}{=} s_0^* \operatorname{ch}[\sigma_m(D)]$$

$$\overset{(2)}{=} s_0^*\big(\pi^*b \cdot u\big)$$

$$\overset{(3)}{=} b \cdot s_0^* u$$
$$\overset{(4)}{=} b \cdot e(X). \tag{4.99}$$

(1) Equation (4.98).
(2) The Thom isomorphism: $\mathrm{ch}[\sigma_m(D)] = \psi(b)$.
(3) $\pi \circ s_0 = \mathrm{id}_X$, so $s_0^* \pi^* b = b$; pull-back is multiplicative.
(4) The Thom class restricts to the Euler class, (4.94).

Dividing, $b = \psi^{-1}\,\mathrm{ch}[\sigma_m(D)] = \mathrm{ch}(\sum(-1)^p[E^p])/e(X)$, which is Nash's (4.47).

Watch out: Dividing by the Euler class

Cohomology classes cannot in general be divided: $e(X)$ lives in top degree n, so $b \cdot e(X)$ only remembers the degree-0 part of b! The quotient in (4.47)–(4.48) must be read as a *formal identity in the Chern roots*. In every example the numerator $\mathrm{ch}(\sum_p (-1)^p E^p)$ turns out to be a polynomial in the roots that is divisible by $x_1 \cdots x_m$ (e.g. it is $\prod_j (1 - e^{x_j})(1 - e^{-x_j})$ for the de Rham complex); one cancels the factor $x_1 \cdots x_m$ *before* evaluating. The result is the correct formula for b because the splitting-principle computation is really done on the universal bundle, where there are no zero divisors.

Now the index. Start from (4.85). Two orientation conventions for TX are in play: the canonical one used by Atiyah and Singer in (4.31), and the "base, then fibre" one used in (4.93). They differ by a sign we can compute. In local coordinates, the canonical (symplectic) orientation of T^*X is $\frac{1}{n!}\big(\sum_\mu \mathrm{d}x^\mu \wedge \mathrm{d}p_\mu\big)^n = \mathrm{d}x^1 \wedge \mathrm{d}p_1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}p_2 \wedge \cdots$, and

$$\mathrm{d}x^1 \wedge \mathrm{d}p_1 \wedge \cdots \wedge \mathrm{d}x^n \wedge \mathrm{d}p_n \overset{(1)}{=} (-1)^{0+1+\cdots+(n-1)}\,\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^n \wedge \mathrm{d}p_1 \wedge \cdots \wedge \mathrm{d}p_n$$
$$\overset{(2)}{=} (-1)^{n(n-1)/2}\,\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^n \wedge \mathrm{d}p_1 \wedge \cdots \wedge \mathrm{d}p_n.$$

(1) Move $\mathrm{d}x^2$ to the left past one $\mathrm{d}p$, then $\mathrm{d}x^3$ past two, and so on; each transposition of 1-forms costs a sign.
(2) $0 + 1 + \cdots + (n-1) = n(n-1)/2$.

So $[TX] = (-1)^{n(n-1)/2}[TX]_{\text{base-fibre}}$. Together with the explicit $(-1)^n$ in (4.31) the total sign is $(-1)^n(-1)^{n(n-1)/2} = (-1)^{n(n+1)/2}$, which is the factor in Nash's (4.42). (Different books orient TX differently; what matters is that the final formula is right, and we will confirm the sign against the de Rham complex, whose index we know independently.) Hence

$$\begin{aligned}
\mathrm{index}\, D &\overset{(1)}{=} (-1)^n \big\{\mathrm{ch}[\sigma_m(D)] \cdot \mathrm{td}(TX_{\mathbb{C}})\big\}[TX] \\
&\overset{(2)}{=} (-1)^{n(n+1)/2} \big\{\psi(b) \cdot \pi^*\,\mathrm{td}(TX_{\mathbb{C}})\big\}[TX]_{\text{base-fibre}} \\
&\overset{(3)}{=} (-1)^{n(n+1)/2} \big\{b \cdot \mathrm{td}(TX_{\mathbb{C}})\big\}[X] \\
&\overset{(4)}{=} (-1)^{n/2} \left\{\frac{\mathrm{ch}\big(\sum_p (-1)^p [E^p]\big)}{e(X)} \cdot \mathrm{td}(TX_{\mathbb{C}})\right\}[X].
\end{aligned} \tag{4.100}$$

(1) The cohomological index formula (4.85).
(2) Change the orientation convention (sign computed above); the Todd class on TX is pulled back from X.
(3) $\psi(b) \cdot \pi^*\,\mathrm{td} = \pi^*(b \cdot \mathrm{td}) \cdot u = \psi(b \cdot \mathrm{td})$, and (4.93).
(4) Insert b from (4.99). Now n is even (in odd dimensions the index of a differential operator vanishes, and $e(X) = 0$ anyway), $n = 2l$, and $n(n+1)/2 = l(2l+1) \equiv l \pmod 2$, so the sign is $(-1)^{n/2}$.

Key idea: Index formula for elliptic complexes, Nash (4.48)

For an elliptic complex $(E^\bullet, d)$ of differential operators on a compact oriented manifold X of even dimension n,

$$\operatorname{index} D = (-1)^{n/2} \int_X \frac{\operatorname{ch}\big(\sum_p (-1)^p E^p\big)}{e(X)} \operatorname{td}(TX_{\mathbb{C}}). \tag{4.101}$$

Recipe: (i) write $\operatorname{ch}(\sum_p (-1)^p E^p)$ in Chern roots; (ii) cancel the product $x_1 \cdots x_m$ against $e(X)$; (iii) multiply by $\operatorname{td}(TX_{\mathbb{C}}) = \prod_j \frac{x_j}{1-e^{-x_j}} \frac{-x_j}{1-e^{x_j}}$; (iv) pick out the degree-n part and integrate.

Physical picture: What the division by $e(X)$ is doing

The symbol class is concentrated near the zero section of TX, like the Thom form. It is "some cohomology on X times a unit bump". The formula asks for the "some cohomology" part. Restricting to the zero section gives it multiplied by the value of the bump at its centre, $e(X)$; the division removes that factor. In the four examples that follow, the numerator will always factorise as $e(X)$ times something nice, which is the index density.

Worked example 4.57: A first run of the recipe: $\bar\partial$ on a Riemann surface

Let $X = \Sigma_g$ be a compact Riemann surface ($n = 2$) and take the two-term complex $\bar\partial : \Gamma(E^0) \to \Gamma(E^1)$ with $E^0 = X \times \mathbb{C}$ (functions) and $E^1 = \Lambda^{0,1}$ (forms $f\, d\bar z$). The real tangent bundle has one block angle x, which is also the first Chern class of the holomorphic tangent line bundle $T^{1,0}$, and $e(X) = x$. The bundle $\Lambda^{0,1}$ is the complex conjugate of $\Lambda^{1,0} = (T^{1,0})^*$, so it has Chern root $-(-x) = x$. Therefore $\operatorname{ch}(E^0 - E^1) = 1 - e^x$. In dimension 2, $\operatorname{td}(TX_{\mathbb{C}}) = 1 - \frac{p_1}{12} + \cdots = 1$ (there are no 4-forms). Then

$$\begin{aligned}
\operatorname{index} \bar\partial &\overset{(1)}{=} (-1)^1 \int_X \frac{1 - e^x}{x} \cdot 1 \\
&\overset{(2)}{=} -\int_X \frac{-x - \frac{1}{2}x^2 - \cdots}{x} \\
&\overset{(3)}{=} \int_X \Big(1 + \tfrac{1}{2}x + \cdots\Big) \\
&\overset{(4)}{=} \tfrac{1}{2} \int_X e(X) = \tfrac{1}{2}(2 - 2g) = 1 - g.
\end{aligned}$$

(1) The recipe (4.101) with $n/2 = 1$.
(2) Expand $e^x = 1 + x + \frac{1}{2}x^2 + \cdots$. The degree-0 part of the numerator cancels, which is the ellipticity of the complex showing up.
(3) Cancel the common factor x as a formal polynomial division.
(4) Only the degree-2 piece $\frac{1}{2}x$ is integrated; $x = e(X)$ and $\int_{\Sigma_g} e = 2 - 2g$ (Gauss–Bonnet, which the de Rham example below derives from the same formula).

This agrees with the direct count $\operatorname{index} \bar\partial = \dim\{\text{holomorphic functions}\} - \dim\{\text{holomorphic 1-forms}\} = 1 - g$ of Section 4.10. The sign $(-1)^{n/2}$ was essential: without it we would have obtained $g - 1$.

Watch out: The formula needs to know how E^p is built from TX

If E^0 and E^1 were arbitrary line bundles with Chern classes a and b, the recipe would ask for "$(a-b)/x$", a degree-0 quantity not determined by cohomology. The index depends on the *symbol*, not only on the bundles. In each classical complex, E^p is a natural bundle (exterior powers, spinors) whose Chern roots are functions of the x_j, and the division by $x_1 \cdots x_m$ is an honest polynomial division. This is why the rest of the section treats the four classical complexes one at a time.

Reading Nash (pp. 101–103, (4.41)–(4.48))

Nash now assumes X orientable and D differential, introduces the Thom isomorphism $\psi(a) = \pi^*(a)\cdot u$ (4.41) ("for homology", with the symbol ϕ reserved for its K-theory cousin), applies ψ^{-1} to the index formula (4.42), recalls the K-class of a complex (4.43), writes the symbol complex (4.44) and its Chern character (4.45)–(4.46), and quotes $\psi^{-1}\{\pi^*\,\mathrm{ch}(\cdots)\} = \mathrm{ch}(\cdots)/e(X)$ from Atiyah–Singer (4.47), arriving at (4.48). We have supplied: an explicit Thom form, the proof that it restricts to the Euler class (in rank 2), the Poincaré–Hopf interpretation, the derivation of (4.47) via the zero section, and the origin of the sign $(-1)^{n(n+1)/2} \to (-1)^{n/2}$. Nash's "$\psi^{-1}\{\pi^*u\} = u/e(X)$" uses u for a generic class on X, not the Thom class.

Recap

- The Thom class u of an oriented bundle is a closed unit bump in the fibres; $\psi(a) = \pi^*a\cdot u$ and ψ^{-1} is integration over the fibre.
- u restricted to the zero section is the Euler class e; pulled back by a vector field it counts zeros (Poincaré–Hopf).
- An elliptic complex has symbol class $\sum(-1)^p[\pi^*E^p]$; on the zero section its Chern character is $\mathrm{ch}(\sum(-1)^pE^p) = b\cdot e(X)$.
- Nash (4.48): $\operatorname{index} D = (-1)^{n/2}\int_X \mathrm{ch}(\sum(-1)^pE^p)\ \mathrm{td}(TX_{\mathbb{C}})/e(X)$, the division done formally in Chern roots.

4.12 The de Rham complex and the Gauss–Bonnet theorem

The remaining examples are the four classical elliptic complexes, where geometry and topology meet. The simplest is the de Rham complex. Its index is a number every physicist has met: the Euler characteristic $\chi(X) = V - E + F$ of a triangulated surface, or more generally the alternating sum of Betti numbers. The index theorem will express it as the integral of a curvature density, the Euler form. In two dimensions this is the Gauss–Bonnet theorem, $\int_X K\,\mathrm{d}A = 2\pi\chi(X)$. In four dimensions it is the Chern–Gauss–Bonnet theorem, whose integrand is the "Gauss–Bonnet term" $R_{abcd}R^{abcd} - 4R_{ab}R^{ab} + R^2$ familiar from higher-curvature gravity.

4.12.1 The complex and its symbol

We use *complex-valued* forms, because the index theorem is phrased with the Chern character, which needs complex vector bundles. Nothing changes except that coefficients are allowed to

be complex:

$$\cdots \xrightarrow{\mathrm{d}_{p-1}} \Omega^p(X) \xrightarrow{\mathrm{d}_p} \Omega^{p+1}(X) \xrightarrow{\mathrm{d}_{p+1}} \cdots, \qquad \Omega^p(X) = \Gamma\big(X, \Lambda^p T^*X_{\mathbb{C}}\big), \tag{Nash 4.49}$$

where $T^*X_{\mathbb{C}} = T^*X \otimes_{\mathbb{R}} \mathbb{C}$ is the complexified cotangent bundle. A p-form is

$$\omega = \tfrac{1}{p!}\, \omega_{\mu_1 \cdots \mu_p}(x)\, \mathrm{d}x^{\mu_1} \wedge \cdots \wedge \mathrm{d}x^{\mu_p}$$

with complex component functions, and $\mathrm{d} \circ \mathrm{d} = 0$ makes this a complex.

The symbol of d**.** To read off a symbol, feed the operator a rapidly oscillating form $e^{it\phi(x)}\omega$ and keep the leading power of t:

$$\begin{aligned} \mathrm{d}\big(e^{it\phi}\omega\big) &\overset{(1)}{=} it\, e^{it\phi}\, \mathrm{d}\phi \wedge \omega + e^{it\phi}\, \mathrm{d}\omega \\ &\overset{(2)}{=} e^{it\phi}\big(it\, \mathrm{d}\phi \wedge \omega + O(t^0)\big). \end{aligned}$$

(1) The Leibniz rule for d acting on a function times a form.
(2) Collect powers of t.

With $p = t\, \mathrm{d}\phi$ the covector, the principal symbol is

$$\sigma_1(\mathrm{d})(x, p)\, \omega = i\, p \wedge \omega. \tag{4.102}$$

So the symbol sequence is "wedge with ip":

$$\cdots \xrightarrow{ip\wedge} \pi^*\big(\Lambda^p T^*X_{\mathbb{C}}\big) \xrightarrow{ip\wedge} \pi^*\big(\Lambda^{p+1} T^*X_{\mathbb{C}}\big) \xrightarrow{ip\wedge} \cdots. \tag{Nash 4.50}$$

Exactness of the symbol sequence. Let ι_p denote the interior product with the vector $p^\sharp$ dual to p (using a metric). It is an antiderivation, $\iota_p(\alpha \wedge \beta) = (\iota_p\alpha) \wedge \beta + (-1)^{\deg \alpha} \alpha \wedge \iota_p\beta$, and $\iota_p p = |p|^2$. Then for any form ω,

$$\begin{aligned} \big(p \wedge \iota_p + \iota_p\, p\wedge\big)\omega &\overset{(1)}{=} p \wedge \iota_p\omega + (\iota_p p)\, \omega - p \wedge \iota_p\omega \\ &\overset{(2)}{=} |p|^2\, \omega. \end{aligned} \tag{4.103}$$

(1) The antiderivation rule applied to $\iota_p(p \wedge \omega)$, with $\deg p = 1$ giving the minus sign.
(2) The two $p \wedge \iota_p\omega$ terms cancel; $\iota_p p = |p|^2$.

Now suppose $p \neq 0$ and $p \wedge \omega = 0$. Then (4.103) gives $\omega = p \wedge \big(\iota_p\omega/|p|^2\big)$: ω is in the image of $p\wedge$. So kernel = image at every step: the symbol sequence is exact away from $p = 0$, and the de Rham complex is elliptic. (This is the "same argument as for (4.20)" that Nash refers to.)

Worked example 4.58: The symbol complex of d in two dimensions, as matrices

On a surface use the bases $\{1\}$, $\{\mathrm{d}x^1, \mathrm{d}x^2\}$, $\{\mathrm{d}x^1 \wedge \mathrm{d}x^2\}$ for $\Lambda^0, \Lambda^1, \Lambda^2$. Then $ip \wedge 1 = i(p_1\mathrm{d}x^1 + p_2\mathrm{d}x^2)$ and $ip \wedge (a\, \mathrm{d}x^1 + b\, \mathrm{d}x^2) = i(p_1 b - p_2 a)\, \mathrm{d}x^1 \wedge \mathrm{d}x^2$. So the symbol complex is

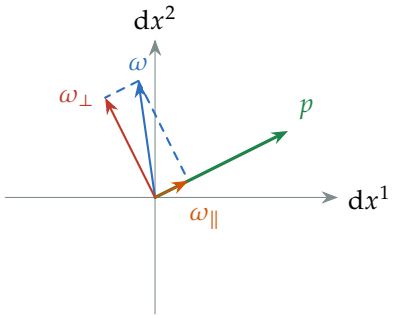
$$0 \longrightarrow \mathbb{C} \xrightarrow{i\,(p_1,\ p_2)^T} \mathbb{C}^2 \xrightarrow{i\,(-p_2\ \ p_1)} \mathbb{C} \longrightarrow 0.$$

Check that it is a complex and that it is exact:

$$\sigma(\mathrm{d}_1)\,\sigma(\mathrm{d}_0) \overset{(1)}{=} i^2 \begin{pmatrix} -p_2 & p_1 \end{pmatrix} \begin{pmatrix} p_1 \\ p_2 \end{pmatrix} \overset{(2)}{=} -(-p_2 p_1 + p_1 p_2) = 0.$$

(1) Compose the two matrices.
(2) Multiply out.

For $p \neq 0$: the first map is injective (a nonzero column), the last is surjective (a nonzero row), and the kernel of the row $(-p_2, p_1)$ is the line spanned by $(p_1, p_2)^T$, which is the image of the first map. The alternating sum of the ranks is $1 - 2 + 1 = 0$, as it must be for an exact sequence.



$p \wedge \omega = p \wedge \omega_\perp$: only the part of ω *not* along p survives.

$p \wedge \omega = 0 \iff \omega = \omega_\parallel = p \wedge (\iota_p \omega / |p|^2)$.

Kernel of $p\wedge$ = image of $p\wedge$: the symbol complex is exact for every $p \neq 0$, and fails to be exact only at $p = 0$.

Figure 4.34: Why the symbol complex of d is exact. Wedging with a nonzero covector p kills exactly the components along p (orange) and is injective on the rest (red). So anything killed by $p\wedge$ is itself a multiple of p. The identity $p \wedge \iota_p + \iota_p\, p\wedge = |p|^2$ is the algebraic form of this picture.

4.12.2 The index of the de Rham complex is the Euler characteristic

The underlying elliptic operator is obtained by rolling up the complex:

$$\mathrm{d} + \mathrm{d}^* : \left(\Omega^0 \oplus \Omega^2 \oplus \cdots\right) \longrightarrow \left(\Omega^1 \oplus \Omega^3 \oplus \cdots\right). \tag{Nash 4.51}$$

Here d^* is the adjoint of d with respect to the L^2 inner product $\langle \omega, \nu \rangle = \int_X \omega \wedge \star\bar{\nu}$; it lowers degree by one. Its symbol is the adjoint of $ip\wedge$, namely $-i\,\iota_p$. So

$$\begin{aligned} \sigma(\mathrm{d} + \mathrm{d}^*)^2 &\overset{(1)}{=} \left(i\, p \wedge -i\, \iota_p\right)^2 \\ &\overset{(2)}{=} -\left(p \wedge p \wedge - p \wedge \iota_p - \iota_p\, p \wedge + \iota_p \iota_p\right) \\ &\overset{(3)}{=} p \wedge \iota_p + \iota_p\, p\wedge = |p|^2 . \end{aligned}$$

(1) The symbols of d and d^*.
(2) Expand the square, with $i^2 = -1$.
(3) $p \wedge p = 0$ and $\iota_p \iota_p = 0$ (both are antisymmetric in a repeated slot); then (4.103).

The square of the symbol is $|p|^2$ times the identity: $\mathrm{d} + \mathrm{d}^*$ is a "square root of the Laplacian" $\Delta = (\mathrm{d} + \mathrm{d}^*)^2 = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$, which is the statement that $p \wedge -\iota_p$ generates a Clifford algebra (Chapter T4). In particular $\sigma(\mathrm{d} + \mathrm{d}^*)$ is invertible for $p \neq 0$: the operator is elliptic.

Hodge theory. On a compact manifold, each de Rham class has a unique **harmonic** representative, $\Delta\omega = 0$, equivalently $\mathrm{d}\omega = 0$ and $\mathrm{d}^*\omega = 0$. (Reason: $\langle \Delta\omega, \omega\rangle = \|\mathrm{d}\omega\|^2 + \|\mathrm{d}^*\omega\|^2$, so harmonic means closed and co-closed; and the harmonic representative minimises $\|\omega\|^2$ within its class.) Hence

$$\operatorname{Ker}(\mathrm{d}+\mathrm{d}^*)\big|_{\Omega^p} \;=\; \mathcal{H}^p \;\cong\; H^p_{\mathrm{dR}}(X;\mathbb{C}),$$

the cohomology $H^p(E)$ of the complex is de Rham cohomology, and its dimension is the p-th **Betti number** b_p. (With complex coefficients, $b_p = \dim_{\mathbb{C}} H^p(X;\mathbb{C})$, but this equals the usual $\dim_{\mathbb{R}} H^p(X;\mathbb{R})$: complexifying a real vector space does not change its dimension. This is Nash's footnote 3.) The index of the complex is therefore

$$\begin{aligned}
\operatorname{index}\mathrm{d} &\overset{(1)}{=} \dim\operatorname{Ker}(\mathrm{d}+\mathrm{d}^*)_{\text{even}} - \dim\operatorname{Ker}(\mathrm{d}+\mathrm{d}^*)_{\text{odd}} \\
&\overset{(2)}{=} \sum_i (-1)^i \dim_{\mathbb{C}} H^i_{\mathrm{dR}}(X;\mathbb{C}) \\
&\overset{(3)}{=} \sum_i (-1)^i b_i = \chi(X). \qquad \text{(Nash 4.52)}
\end{aligned}$$

(1) The index of the rolled-up operator (Nash 4.51): its cokernel on odd forms is the kernel of its adjoint, which is $\mathrm{d}+\mathrm{d}^*$ on odd forms.
(2) Hodge theory: harmonic forms of degree i are the de Rham classes.
(3) Definition of Betti numbers and of the Euler–Poincaré characteristic.

Worked example 4.59: Harmonic forms on S^2 and T^2

Torus $T^2 = \mathbb{R}^2/\mathbb{Z}^2$ with the flat metric. The harmonic forms are those with constant coefficients: $1;\ \mathrm{d}x, \mathrm{d}y;\ \mathrm{d}x\wedge\mathrm{d}y$. So $b_0 = 1$, $b_1 = 2$, $b_2 = 1$ and

$$\operatorname{index}\mathrm{d} = \underbrace{(1+1)}_{\text{even: } 1,\ \mathrm{d}x\wedge\mathrm{d}y} - \underbrace{2}_{\text{odd: } \mathrm{d}x,\mathrm{d}y} = 0 = \chi(T^2).$$

Sphere S^2 with the round metric. Harmonic 0-forms are constants. Harmonic 2-forms are constant multiples of the area form $\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\varphi$. There are no harmonic 1-forms: a closed 1-form on S^2 is exact, $\omega = \mathrm{d}f$ (every loop bounds), and then $\mathrm{d}^*\mathrm{d}f = 0$ forces f constant, so $\omega = 0$. Hence

$$\operatorname{index}\mathrm{d} = (1+1) - 0 = 2 = \chi(S^2).$$

In both cases the count agrees with $V - E + F$ for a triangulation: a tetrahedron has $4 - 6 + 4 = 2$; the standard square torus with one vertex, two edges and one face has $1 - 2 + 1 = 0$.

Physical picture: Supersymmetric quantum mechanics and the Witten index

Think of differential forms on X as the states of a quantum particle moving on X with fermionic partners: a p-form has fermion number p (one fermion for each $\mathrm{d}x^\mu$). The supercharge is $Q = \mathrm{d}+\mathrm{d}^*$, the Hamiltonian $H = Q^2 = \Delta$, and $(-1)^F$ is $(-1)^p$. States with $H > 0$ come in boson–fermion pairs (Q maps one to the other, preserving the energy), so they cancel in the **Witten index**

$$\operatorname{Tr}(-1)^F e^{-\beta H} = \sum_p (-1)^p \dim\mathcal{H}^p = \chi(X),$$

for every β. Taking $\beta \to 0$ (high temperature, short paths) turns the trace into a local integral over X; its density is the Euler form. This is the path-integral proof of Gauss–Bonnet due to

Alvarez-Gaumé and Witten, and the heat-kernel proof of the index theorem is its rigorous version.

4.12.3 The characteristic-class side

Now evaluate the right-hand side of (4.101). The bundles are $E^p = \Lambda^p T^*X_{\mathbb{C}}$, so we need

$$\mathrm{ch}\big([\sigma_1(\mathrm{d})]\big) \;\to\; \mathrm{ch}\Big(\sum_p (-1)^p [E^p]\Big) = \sum_p (-1)^p \,\mathrm{ch}\big(\Lambda^p T^*X_{\mathbb{C}}\big). \tag{Nash 4.55}$$

Exterior powers by the splitting principle. Let F be any complex bundle of rank N with Chern roots $y_1, \dots, y_N$, i.e. formally $F = L_1 \oplus \cdots \oplus L_N$, $c_1(L_i) = y_i$. By (4.75),

$$\Lambda^p F = \bigoplus_{1 \le i_1 < \cdots < i_p \le N} L_{i_1} \otimes \cdots \otimes L_{i_p}. \tag{Nash 4.56}$$

Apply ch, using additivity and multiplicativity (4.73):

$$\begin{aligned} \mathrm{ch}(\Lambda^p F) &\overset{(1)}{=} \sum_{i_1<\cdots<i_p} \mathrm{ch}(L_{i_1}) \cdots \mathrm{ch}(L_{i_p}) \\ &\overset{(2)}{=} \sum_{i_1<\cdots<i_p} e^{y_{i_1}} \cdots e^{y_{i_p}} \;=\; \sum_{i_1<\cdots<i_p} e^{y_{i_1}+\cdots+y_{i_p}}. \end{aligned} \tag{Nash 4.57–4.58}$$

(1) ch of a direct sum is the sum; ch of a tensor product is the product.
(2) $\mathrm{ch}(L) = e^{c_1(L)}$ for a line bundle.

Now the alternating sum. The key observation is that $\sum_p (-1)^p \sum_{i_1<\cdots<i_p} t_{i_1} \cdots t_{i_p} = \prod_i (1 - t_i)$: expanding the product, each subset $\{i_1, \dots, i_p\}$ of factors from which we take $-t_i$ contributes $(-1)^p t_{i_1} \cdots t_{i_p}$. With $t_i = e^{y_i}$:

$$\sum_{p=0}^{N} (-1)^p \,\mathrm{ch}(\Lambda^p F) = \prod_{i=1}^{N} \big(1 - e^{y_i}\big). \tag{Nash 4.59}$$

Worked example 4.60: Checking (Nash 4.59) in rank 1 and rank 2

Rank 1: $\Lambda^0 F = \mathbb{C}$, $\Lambda^1 F = F$, so the left side is $1 - e^{y}$. ✓
Rank 2: $\Lambda^0 F = \mathbb{C}$, $\Lambda^1 F = L_1 \oplus L_2$, $\Lambda^2 F = L_1 \otimes L_2$ (the determinant line bundle), so

$$\begin{aligned} \sum_p (-1)^p \,\mathrm{ch}(\Lambda^p F) &\overset{(1)}{=} 1 - \big(e^{y_1} + e^{y_2}\big) + e^{y_1+y_2} \\ &\overset{(2)}{=} \big(1 - e^{y_1}\big)\big(1 - e^{y_2}\big). \end{aligned}$$

(1) (Nash 4.57–4.58) for $p = 0, 1, 2$.
(2) Factorise: $(1-a)(1-b) = 1 - a - b + ab$.

The lowest-order term is $(-y_1)(-y_2) = y_1 y_2 = c_2(F)$: the alternating sum starts in degree $2N$, the top Chern class. That is the "divisibility by the Euler class" promised in Section 4.11.

Recognising the Todd class. Pull out the lowest-order factor of each term:

$$\begin{aligned}\prod_{i=1}^{N}\bigl(1-e^{y_i}\bigr) &\overset{(1)}{=} \prod_{i=1}^{N}(-y_i)\cdot\prod_{i=1}^{N}\frac{1-e^{y_i}}{-y_i}\\ &\overset{(2)}{=} (-1)^N y_1\cdots y_N\cdot\Bigl(\prod_{i=1}^{N}\frac{-y_i}{1-e^{y_i}}\Bigr)^{-1}\\ &\overset{(3)}{=} \frac{c_N(F^*)}{\mathrm{td}(F^*)}.\end{aligned}\tag{Nash 4.60}$$

(1) Multiply and divide each factor by $-y_i$.
(2) Rearrange the signs and invert the second product.
(3) The dual bundle has roots $-y_i$: $c_N(F^*)=\prod(-y_i)=(-1)^N y_1\cdots y_N$, and $\mathrm{td}(F^*)=\prod\frac{-y_i}{1-e^{y_i}}$ by (4.78).

Putting it together. Take $F=T^*X_{\mathbb{C}}$, which has complex rank $N=n$. It is the complexification of a real bundle, so $F\cong F^*$ (Section 4.9), and $T^*X_{\mathbb{C}}\cong TX_{\mathbb{C}}$ via the metric. Its Chern roots are $\pm x_1,\dots,\pm x_m$, $n=2m$. Then

$$\begin{aligned}\operatorname{index}\mathrm{d} &\overset{(1)}{=} (-1)^{n/2}\int_X \frac{c_n(TX_{\mathbb{C}})}{e(X)\ \mathrm{td}(TX_{\mathbb{C}})}\ \mathrm{td}(TX_{\mathbb{C}})\\ &\overset{(2)}{=} (-1)^{n/2}\int_X \frac{c_n(TX_{\mathbb{C}})}{e(X)}\\ &\overset{(3)}{=} (-1)^{n/2}\int_X \frac{(-1)^{n/2}\,e(X)^2}{e(X)}\\ &\overset{(4)}{=} \int_X e(X).\end{aligned}\tag{Nash 4.61–4.62}$$

(1) Nash's formula (4.101) with the numerator (Nash 4.60), $F^*=F=TX_{\mathbb{C}}$.
(2) The Todd classes cancel.
(3) The top Chern class of a complexified real bundle, (4.80): $c_{2m}(V_{\mathbb{C}})=(-1)^m e(V)^2$.
(4) $(-1)^{n/2}(-1)^{n/2}=1$; cancel one factor $e(X)$ (formally, in the roots).

It is instructive to redo this directly in the roots, without the intermediate c_N/td step, to see the division by $e(X)$ happen honestly:

$$\begin{aligned}\prod_{j=1}^{m}\bigl(1-e^{x_j}\bigr)\bigl(1-e^{-x_j}\bigr) &\overset{(1)}{=} \prod_{j=1}^{m}\Bigl(-\bigl(e^{x_j/2}-e^{-x_j/2}\bigr)^2\Bigr)\\ &\overset{(2)}{=} (-1)^m\prod_j x_j^2\cdot\prod_j\Bigl(\frac{\sinh(x_j/2)}{x_j/2}\Bigr)^2 \;=\; (-1)^m\,\frac{e(X)^2}{\mathrm{td}(TX_{\mathbb{C}})}.\end{aligned}$$

(1) $(1-e^{x})(1-e^{-x})=2-e^{x}-e^{-x}=-(e^{x/2}-e^{-x/2})^2$.
(2) $e^{x/2}-e^{-x/2}=2\sinh(x/2)=x\cdot\frac{\sinh(x/2)}{x/2}$; then $\prod x_j=e(X)$ and (4.81).

Dividing by $e(X)$ leaves $(-1)^m e(X)/\mathrm{td}(TX_{\mathbb{C}})$, a genuine polynomial in the roots; multiplying by $(-1)^m\,\mathrm{td}(TX_{\mathbb{C}})$ leaves exactly $e(X)$.

Key idea: The Gauss–Bonnet theorem from the index theorem (Nash (4.53)–(4.54))

For a compact oriented even-dimensional manifold,

$$\chi(X) = \sum_i (-1)^i b_i = \int_X e(X), \qquad e(X) = \mathrm{Pf}\Big(\frac{R}{2\pi}\Big). \tag{4.104}$$

A topological count (the alternating number of harmonic forms) equals the integral of a local curvature density.

4.12.4 Explicit Euler densities

Dimension 2. The curvature of an oriented surface in an orthonormal coframe (e^1, e^2) is the single 2-form $R^1{}_2 = K\, e^1 \wedge e^2 = K\, \mathrm{d}A$, with K the Gaussian curvature. The Pfaffian of a 2×2 antisymmetric matrix is its upper-right entry, so

$$e = \frac{1}{2\pi} K\, \mathrm{d}A, \qquad \int_X K\, \mathrm{d}A = 2\pi\chi(X) = 2\pi(2-2g). \tag{4.105}$$

Dimension 4. With $R^{ab} = \tfrac{1}{2} R^{ab}{}_{cd}\, e^c \wedge e^d$ and the Pfaffian formula of Section 4.9,

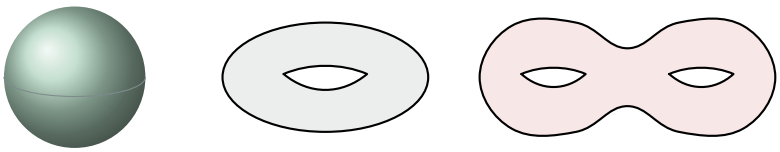
$$\begin{aligned} e &\overset{(1)}{=} \frac{1}{2^2\, 2!}\, \epsilon_{abcd}\, \frac{R^{ab}}{2\pi} \wedge \frac{R^{cd}}{2\pi} = \frac{1}{32\pi^2}\, \epsilon_{abcd}\, R^{ab} \wedge R^{cd} \\ &\overset{(2)}{=} \frac{1}{128\pi^2}\, \epsilon_{abcd}\, \epsilon^{efgh}\, R^{ab}{}_{ef}\, R^{cd}{}_{gh}\ \mathrm{vol} \\ &\overset{(3)}{=} \frac{1}{32\pi^2}\Big(R_{abcd}R^{abcd} - 4R_{ab}R^{ab} + R^2\Big)\mathrm{vol}. \end{aligned} \tag{4.106}$$

(1) The Pfaffian with $m = 2$: $\mathrm{Pf}(M) = \frac{1}{2^m m!}\epsilon_{a_1\cdots a_4} M^{a_1a_2} M^{a_3a_4}$.

(2) Insert $R^{ab} = \frac{1}{2} R^{ab}{}_{ef} e^e \wedge e^f$ (two factors of $\frac{1}{2}$) and $e^e \wedge e^f \wedge e^g \wedge e^h = \epsilon^{efgh}\mathrm{vol}$.

(3) The contraction identity $\epsilon_{abcd}\epsilon^{efgh} R^{ab}{}_{ef} R^{cd}{}_{gh} = 4\big(R_{abcd}R^{abcd} - 4R_{ab}R^{ab} + R^2\big)$, obtained by writing $\epsilon\epsilon$ as a determinant of Kronecker deltas and using $R^a{}_{bad} = R_{bd}$, $R^a{}_a = R$.

Check on the unit S^4: $R_{abcd} = \delta_{ac}\delta_{bd} - \delta_{ad}\delta_{bc}$ gives $R_{abcd}R^{abcd} = 2\cdot 4\cdot 3 = 24$, $R_{ab} = 3\delta_{ab}$ so $R_{ab}R^{ab} = 36$, and $R = 12$. The bracket is $24 - 144 + 144 = 24$, and $\int e = \frac{24}{32\pi^2}\cdot\frac{8\pi^2}{3} = 2 = \chi(S^4)$, agreeing with Example 4.51.



$g = 0$, $\chi = 2$
$K > 0$: $\int K\mathrm{d}A = 4\pi$

$g = 1$, $\chi = 0$
flat: $K = 0$

$g = 2$, $\chi = -2$
$K = -1$: area $4\pi(g-1)$

Figure 4.35: Gauss–Bonnet for surfaces: $\int_X K\, \mathrm{d}A = 2\pi\chi = 2\pi(2-2g)$. The sphere is positively curved (green), the torus can be made flat, and a surface of genus $g \geq 2$ can be given constant curvature -1 (red), whose area must then be $4\pi(g-1)$. However we deform the metric, the total curvature cannot change.

Worked example 4.61: Gauss–Bonnet on the three model geometries

Round sphere of radius a. $K = 1/a^2$ and area $4\pi a^2$: $\int K\,\mathrm{d}A = 4\pi = 2\pi\cdot 2$. The radius drops out, as it must for a topological invariant.
Flat torus. $K = 0$ everywhere: $\int K\,\mathrm{d}A = 0 = 2\pi\cdot 0$.
Genus g hyperbolic surface. Uniformisation provides a metric with $K = -1$. Then

$$\mathrm{Area}(\Sigma_g) \overset{(1)}{=} -\int_{\Sigma_g} K\,\mathrm{d}A \overset{(2)}{=} -2\pi\chi(\Sigma_g) = -2\pi(2-2g) = 4\pi(g-1).$$

(1) $K = -1$, so $\mathrm{d}A = -K\,\mathrm{d}A$.
(2) Gauss–Bonnet (4.105).

Geometry (the area) is fixed by topology (the genus).

Worked example 4.62: Four-dimensional Euler numbers

$S^2\times S^2$. The curvature is block diagonal (one block per factor), so the Pfaffian factorises: $e(S^2\times S^2) = e(S^2)\wedge e(S^2)$, and $\int e = 2\cdot 2 = 4$. Directly: $b_0 = 1, b_2 = 2, b_4 = 1$, $\chi = 4$.
$\mathbb{CP}^2$. By Example 4.50, $e(\mathbb{CP}^2) = c_2(T) = 3h^2$, so $\int e = 3 = 1+1+1$.
T^4 *and* $S^1\times S^3$. Both admit nowhere-vanishing vector fields (the circle direction), and both have $\chi = 0$; T^4 is flat, so the Euler density vanishes pointwise.
K3 surface. Its Betti numbers are $1, 0, 22, 0, 1$, so $\chi = 24$, and this is the integral of (4.106) for its Ricci-flat (Calabi–Yau) metric, where only the $R_{abcd}R^{abcd}$ term survives: $\frac{1}{32\pi^2}\int_{K3} R_{abcd}R^{abcd}\,\mathrm{vol} = 24$.

Physical picture: Why string perturbation theory is a genus expansion

On a two-dimensional worldsheet Σ, the Einstein–Hilbert action $\frac{1}{4\pi}\int_\Sigma \sqrt{g}\,R\,\mathrm{d}^2\sigma$ is (with $R = 2K$) exactly $\chi(\Sigma)$ by (4.105): it has no dynamics, only topology. Adding $\lambda\chi(\Sigma)$ to the string action weights a worldsheet of genus g by $e^{-\lambda(2-2g)} = g_s^{2g-2}$ with $g_s = e^{\lambda}$. This is why the string coupling counts handles (Chapter 9). In four dimensions the Gauss–Bonnet density (4.106) plays the same role: adding it to the gravitational action changes nothing in the equations of motion, only the weight $e^{-\lambda\chi}$ of each topology in the path integral.

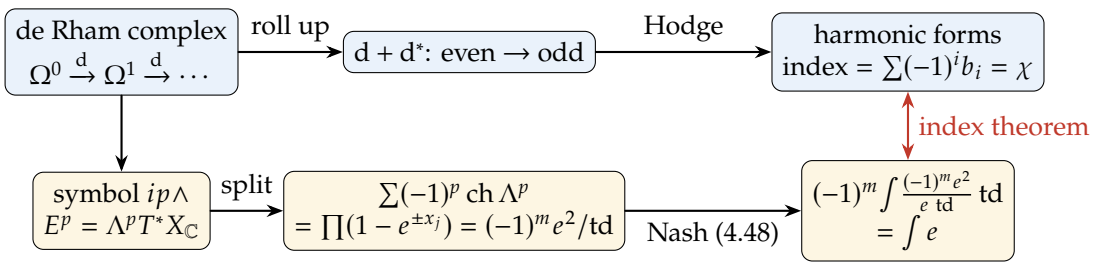


Figure 4.36: The logic of the de Rham example. Top row: the analytic side (count harmonic forms). Bottom row: the topological side (characteristic classes of the symbol). The index theorem equates the right-hand ends: this is the Gauss–Bonnet theorem $\chi(X) = \int_X e(X)$.

Watch out: Odd dimensions

In odd dimensions both sides vanish separately: $e(X) = 0$ for an odd-rank bundle (Section 4.11), and $\chi(X) = 0$ by Poincaré duality ($b_i = b_{n-i}$ and $n - i$ has the opposite parity from i, so the terms cancel in pairs). The index theorem is consistent with the odd-dimensional vanishing of Section 4.10, but tells us nothing new there.

Reading Nash (pp. 103–106, (4.49)–(4.62))

Nash takes complex-valued forms (4.49), states that the symbol complex (4.50) is exact "by the same argument as for (4.20)" (we gave it: $p \wedge \iota_p + \iota_p p \wedge = |p|^2$), rolls up to $\mathrm{d} + \mathrm{d}^*$ (4.51), and gets $\operatorname{index} \mathrm{d} = \chi(X)$ (4.52) from Hodge theory. On the topological side he computes (4.55)–(4.60) by the splitting principle exactly as we did, then uses $F = F^*$ and his relation (3.124) $c_n(TX_{\mathbb{C}}) = (-1)^{n/2} e^2(X)$ (our (4.80)) to obtain $\int_X e(X) = \chi(X)$ (4.53)–(4.54), (4.61)–(4.62). In (4.61) his c_n is the top Chern class of the rank-n complex bundle $TX_{\mathbb{C}}$; he writes e^2 for $e \wedge e$.

Recap

- de Rham complex: symbol $ip\wedge$, exact for $p \neq 0$ because $p \wedge \iota_p + \iota_p p \wedge = |p|^2$; rolled-up operator $\mathrm{d} + \mathrm{d}^*$.
- Analytic index $= \sum (-1)^i b_i = \chi(X)$ by Hodge theory (the Witten index of SUSY quantum mechanics on X).
- Topological side: $\sum (-1)^p \operatorname{ch} \Lambda^p F = \prod (1 - e^{y_i}) = c_N(F^*)/\operatorname{td}(F^*)$, and with $c_n(TX_{\mathbb{C}}) = (-1)^{n/2} e^2$ the formula gives $\int_X e$.
- Gauss–Bonnet: $\int K \mathrm{d}A = 2\pi\chi$ in 2D; $\chi = \frac{1}{32\pi^2} \int (R^2_{abcd} - 4R^2_{ab} + R^2)$ in 4D.

4.13 The Dolbeault complex and the Riemann–Roch theorem

The de Rham complex counts *closed forms modulo exact ones*. On a complex manifold there is a finer question: how many *holomorphic* objects are there? How many holomorphic functions, holomorphic 1-forms, holomorphic sections of a line bundle? On a compact complex manifold these spaces are finite dimensional, and the numbers are among the most important invariants in algebraic geometry. They are also physics numbers: the number of holomorphic sections of a line bundle over a surface is the degeneracy of the lowest Landau level of a charged particle on that surface, and zero modes of two-dimensional chiral fermions are holomorphic sections.

Counting holomorphic sections one by one is hard. The individual numbers can jump when the complex structure is deformed. The index theorem computes an alternating sum of them, which cannot jump, as the integral of a curvature polynomial: the Todd class. This is the Riemann–Roch–Hirzebruch theorem. Historically it came first (Hirzebruch, 1954), and it was the model that led Atiyah and Singer to their general theorem.

4.13.1 Complex coordinates and (p, q)-forms

We first set up what Nash takes for granted from his Chapter 3 (Chapter 3).

A **complex manifold** of complex dimension m is a manifold of real dimension $n = 2m$ covered by charts with complex coordinates $z^j = x^j + iy^j$, $j = 1, \ldots, m$, whose transition

functions are holomorphic. (Nash writes $n/2$ for the complex dimension; we write $m = n/2$.) In each chart we have the complex 1-forms and the dual vector fields

$$\mathrm{d}z^j = \mathrm{d}x^j + i\,\mathrm{d}y^j, \quad \mathrm{d}\bar z^j = \mathrm{d}x^j - i\,\mathrm{d}y^j, \qquad \frac{\partial}{\partial z^j} = \tfrac12\Big(\frac{\partial}{\partial x^j} - i\frac{\partial}{\partial y^j}\Big), \quad \frac{\partial}{\partial \bar z^j} = \tfrac12\Big(\frac{\partial}{\partial x^j} + i\frac{\partial}{\partial y^j}\Big). \tag{4.107}$$

One checks $\mathrm{d}z^j(\partial/\partial z^k) = \delta^j_k$, $\mathrm{d}z^j(\partial/\partial \bar z^k) = 0$, and so on. A function is holomorphic exactly when $\partial f/\partial \bar z^j = 0$ for all j: this is the Cauchy–Riemann system, written compactly.

Working definition 4.33 ((p,q)-forms and the operators ∂, $\bar\partial$)

A (p,q)**-form** is a complex form that in every holomorphic chart [complex coordinates z^j whose changes $z \mapsto z'(z)$ are holomorphic] contains exactly p factors $\mathrm{d}z$ and q factors $\mathrm{d}\bar z$:

$$\omega = \frac{1}{p!\,q!}\,\omega_{j_1\cdots j_p \bar k_1\cdots \bar k_q}\,\mathrm{d}z^{j_1}\wedge\cdots\wedge\mathrm{d}z^{j_p}\wedge\mathrm{d}\bar z^{k_1}\wedge\cdots\wedge\mathrm{d}\bar z^{k_q}.$$

Holomorphic coordinate changes preserve this type, so (p,q) is a global notion. The bundle of (p,q)-forms is $\Lambda^{p,q}T^*X$, of complex rank $\binom{m}{p}\binom{m}{q}$ [choose p of the m differentials $\mathrm{d}z^j$ and q of the m differentials $\mathrm{d}\bar z^k$], and $\Lambda^k T^*X_{\mathbb C} = \bigoplus_{p+q=k}\Lambda^{p,q}$. The exterior derivative splits as $\mathrm{d} = \partial + \bar\partial$ with

$$\partial\omega = \frac{\partial \omega_{\dots}}{\partial z^j}\,\mathrm{d}z^j\wedge(\cdots), \qquad \bar\partial\omega = \frac{\partial\omega_{\dots}}{\partial\bar z^j}\,\mathrm{d}\bar z^j\wedge(\cdots),$$

so ∂ raises p by one and $\bar\partial$ raises q by one.

Why do ∂ and $\bar\partial$ separately square to zero? Expand $0 = \mathrm{d}^2 = (\partial+\bar\partial)^2$ and sort by type:

$$0 = \mathrm{d}^2\omega \overset{(1)}{=} \partial^2\omega + (\partial\bar\partial + \bar\partial\partial)\omega + \bar\partial^2\omega \overset{(2)}{=} \underbrace{\partial^2\omega}_{(p+2,q)} + \underbrace{(\partial\bar\partial+\bar\partial\partial)\omega}_{(p+1,q+1)} + \underbrace{\bar\partial^2\omega}_{(p,q+2)}.$$

(1) Expand the square of $\mathrm{d} = \partial + \bar\partial$.
(2) Each term has a definite type, and forms of different types are linearly independent.

So each piece vanishes separately: $\partial^2 = 0$, $\bar\partial^2 = 0$ and $\partial\bar\partial = -\bar\partial\partial$. (The splitting $\mathrm{d} = \partial + \bar\partial$ with no extra pieces is where the holomorphy of the transition functions, i.e. the integrability of the complex structure, is used.)

Worked example 4.63: One complex dimension: $\bar\partial$ is the Cauchy–Riemann operator

On $\mathbb C$ with $z = x + iy$, a function $f = u + iv$ has

$$\bar\partial f \overset{(1)}{=} \frac{\partial f}{\partial \bar z}\,\mathrm{d}\bar z \overset{(2)}{=} \tfrac12\big(u_x + iv_x + iu_y - v_y\big)\mathrm{d}\bar z \overset{(3)}{=} \tfrac12\big[(u_x - v_y) + i(v_x + u_y)\big]\mathrm{d}\bar z.$$

(1) Definition of $\bar\partial$ on a $(0,0)$-form.
(2) Insert $\partial/\partial\bar z = \frac12(\partial_x + i\partial_y)$ from (4.107) and $f = u + iv$.
(3) Collect real and imaginary parts.

So $\bar\partial f = 0$ is exactly $u_x = v_y$, $u_y = -v_x$: the Cauchy–Riemann equations. The complex $0 \to \Omega^{0,0} \xrightarrow{\bar\partial} \Omega^{0,1} \to 0$ has kernel "holomorphic functions" and cokernel "$(0,1)$-forms that are not $\partial_{\bar z}$ of anything".

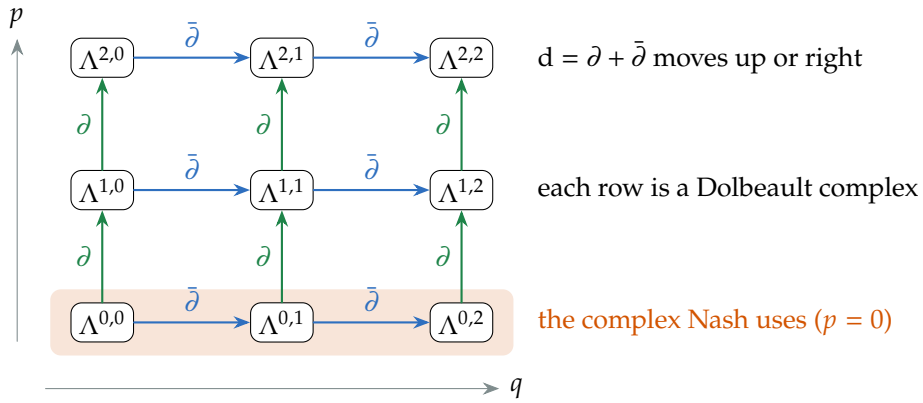

Figure 4.37: Forms on a complex surface ($m = 2$) sorted by type. The operator $\bar\partial$ moves one step right, ∂ one step up, and d is their sum, which changes the total degree $p + q$ by one. Each row $\Lambda^{p,0} \to \Lambda^{p,1} \to \Lambda^{p,2}$ is an elliptic complex; its cohomology groups are the $H^{p,q}_{\bar\partial}$. Nash sets $p = 0$ (orange).

4.13.2 The Dolbeault complex, its cohomology and its symbol

For each fixed p we get a complex, and its cohomology

$$\cdots \xrightarrow{\bar\partial_{p,q-1}} \Omega^{p,q}(X) \xrightarrow{\bar\partial_{p,q}} \Omega^{p,q+1}(X) \longrightarrow \cdots, \qquad H^{p,q}_{\bar\partial}(X) = \frac{\operatorname{Ker}\left(\bar\partial : \Omega^{p,q} \to \Omega^{p,q+1}\right)}{\operatorname{Im}\left(\bar\partial : \Omega^{p,q-1} \to \Omega^{p,q}\right)} \tag{Nash 4.63}$$

is **Dolbeault cohomology**. Its dimensions $h^{p,q} = \dim_{\mathbb{C}} H^{p,q}_{\bar\partial}(X)$ are the **Hodge numbers**. (Nash writes $h_{p,q}$.) Two of them are easy to interpret:

- $H^{0,0}_{\bar\partial} = \{f : \bar\partial f = 0\}$ is the space of global holomorphic functions. On a compact connected X these are constant (the maximum principle), so $h^{0,0} = 1$.
- $H^{p,0}_{\bar\partial} = \{\omega \in \Omega^{p,0} : \bar\partial\omega = 0\}$ (there is nothing to divide by) is the space of holomorphic p-forms.

The symbol. Feed $\bar\partial$ a rapidly oscillating form, exactly as for d in Section 4.12:

$$\begin{aligned}\bar\partial\left(e^{it\phi}\omega\right) &\overset{(1)}{=} it\, e^{it\phi}\,\bar\partial\phi \wedge \omega + e^{it\phi}\,\bar\partial\omega \\ &\overset{(2)}{=} e^{it\phi}\left(i\,p^{0,1} \wedge \omega + O(t^0)\right), \qquad p^{0,1} := t\,\bar\partial\phi.\end{aligned}$$

(1) Leibniz rule; $\bar\partial$ of a function ϕ is the $(0,1)$ part of $\mathrm{d}\phi$.
(2) Set the covector $p = t\,\mathrm{d}\phi$; then $t\,\bar\partial\phi$ is its $(0,1)$-part $p^{0,1}$.

So $\sigma_1(\bar\partial)(x,p) = i\,p^{0,1}\wedge$. The crucial point: for a *real* nonzero covector p, the $(0,1)$-part is never zero. Indeed $p = p^{1,0} + p^{0,1}$ with $p^{1,0} = \overline{p^{0,1}}$ (because p is real), so $p^{0,1} = 0$ would force $p = 0$. In

one complex dimension, $p = p_x\mathrm{d}x + p_y\mathrm{d}y$ gives

$$\begin{aligned} p &\overset{(1)}{=} p_x\,\tfrac{1}{2}(\mathrm{d}z + \mathrm{d}\bar z) + p_y\,\tfrac{1}{2i}(\mathrm{d}z - \mathrm{d}\bar z) \\ &\overset{(2)}{=} \tfrac{1}{2}(p_x - ip_y)\,\mathrm{d}z + \tfrac{1}{2}(p_x + ip_y)\,\mathrm{d}\bar z, \end{aligned}$$

(1) Invert (4.107): $\mathrm{d}x = \frac{1}{2}(\mathrm{d}z + \mathrm{d}\bar z)$, $\mathrm{d}y = \frac{1}{2i}(\mathrm{d}z - \mathrm{d}\bar z)$.
(2) Collect the coefficients of $\mathrm{d}z$ and $\mathrm{d}\bar z$.

and $p^{0,1} = \frac{1}{2}(p_x + ip_y)\mathrm{d}\bar z$ vanishes only at $p = 0$. The symbol of $\partial_{\bar z}$ is the complex number $\frac{i}{2}(p_x + ip_y)$, whose modulus is $\frac{1}{2}\,|p|$: the Cauchy–Riemann operator is a "square root" of the Laplacian, $4\partial_z\partial_{\bar z} = \partial_x^2 + \partial_y^2$. With $p^{0,1} \neq 0$ the Koszul argument (4.103) (with ι_p replaced by contraction with the vector dual to $p^{0,1}$) shows that the symbol sequence

$$\cdots \xrightarrow{\sigma_1(\bar\partial_{0,q-1})} \pi^*\big(\Lambda^{0,q}T^*X\big) \xrightarrow{\sigma_1(\bar\partial_{0,q})} \pi^*\big(\Lambda^{0,q+1}T^*X\big) \xrightarrow{\sigma_1(\bar\partial_{0,q+1})} \cdots \tag{Nash 4.66}$$

is exact for $p \neq 0$. The Dolbeault complex is elliptic.

The index. Following Nash we set $p = 0$ and call the resulting complex $\Omega^{0,0} \to \Omega^{0,1} \to \cdots \to \Omega^{0,m}$, and its index, simply index $\bar\partial$. Rolling it up as for de Rham gives the elliptic operator $\bar\partial + \bar\partial^* : \Omega^{0,\mathrm{even}} \to \Omega^{0,\mathrm{odd}}$, and the Hodge theorem for the Laplacian $\Box = \bar\partial\bar\partial^* + \bar\partial^*\bar\partial$ identifies $H^{0,q}_{\bar\partial}$ with harmonic $(0,q)$-forms. Therefore

$$\operatorname{index}\bar\partial = \sum_{q=0}^{m}(-1)^q \dim H^{0,q}_{\bar\partial}(X) = \sum_{q=0}^{m}(-1)^q h^{0,q} \;=:\; \chi(\mathcal{O}_X). \tag{Nash 4.64–4.65}$$

Nash writes $\chi(\mathcal{E})$, with $\mathcal{E}$ standing for the Dolbeault complex; in algebraic geometry it is written $\chi(X, \mathcal{O}_X)$, the Euler characteristic of the sheaf of holomorphic functions (Chapter 3), and it is called the **arithmetic genus** of X.

Worked example 4.64: The arithmetic genus of a torus and of a Riemann surface

Complex torus $X = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$, $\operatorname{Im}\tau > 0$. The flat metric makes the harmonic forms those with constant coefficients: 1 in degree $(0,0)$ and $\mathrm{d}\bar z$ in degree $(0,1)$. So $h^{0,0} = h^{0,1} = 1$ and $\chi(\mathcal{O}) = 1 - 1 = 0$. In complex dimension m, $X = \mathbb{C}^m/\Lambda$, the harmonic $(0,q)$-forms are spanned by the $\binom{m}{q}$ constant forms $\mathrm{d}\bar z^{k_1} \wedge \cdots \wedge \mathrm{d}\bar z^{k_q}$, so

$$\chi(\mathcal{O}_{T^{2m}}) = \sum_q (-1)^q \binom{m}{q} = (1-1)^m = 0.$$

Riemann surface of genus g. Here $h^{0,0} = 1$ and $h^{0,1} = g$. The second number is the classical statement that a genus-g surface carries g independent holomorphic 1-forms: $h^{1,0} = g$, and complex conjugation maps harmonic $(1,0)$-forms to harmonic $(0,1)$-forms, so $h^{0,1} = h^{1,0} = g$. (For $g = 1$: $\mathrm{d}z$ and $\mathrm{d}\bar z$.) So $\chi(\mathcal{O}_{\Sigma_g}) = 1 - g$, which is what we found in Example 4.57.

4.13.3 The characteristic-class side: the Todd class appears

Now we evaluate Nash's formula (4.101) with $E^q = \Lambda^{0,q}T^*X$. Two small facts about complex bundles are needed.

Fact 1: $\Lambda^{0,1} \cong T^{1,0}$. Let us write T for the *holomorphic tangent bundle* $T^{1,0}X$, spanned by the $\partial/\partial z^j$. (Nash calls it TX in this example; see the pitfall below.) Its dual $T^* = \Lambda^{1,0}$ is spanned by the dz^j, and its conjugate $\Lambda^{0,1} = \overline{T^*}$ by the $d\bar z^j$. Given a Hermitian metric, the conjugate of a bundle is isomorphic to its dual ((4.74) and the remark after it), so $\Lambda^{0,1} = \overline{T^*} \cong (T^*)^* = T$. Therefore

$$\Lambda^{0,q}T^*X = \Lambda^q\big(\overline{T^*}\big) \cong \Lambda^q T.$$

Concretely, the metric turns $d\bar z^j$ into $g^{\bar j k}\,\partial/\partial z^k$.

Fact 2: $TX_{\mathbb C} = T \oplus \bar T$. A complexified real tangent vector $v = v^j\partial_{x^j} + w^j\partial_{y^j}$ with complex v^j, w^j can be rewritten in the basis $\partial/\partial z^j, \partial/\partial \bar z^j$: the complexified tangent bundle splits into the ∂_z-part T and the $\partial_{\bar z}$-part $\bar T \cong T^*$. If $x_1, \dots, x_m$ are the Chern roots of T, then $TX_{\mathbb C}$ has roots $x_1, \dots, x_m, -x_1, \dots, -x_m$. Comparing with the real picture of Section 4.9, the block angles of the underlying real bundle are exactly the x_j, and so

$$e(X) = x_1 \cdots x_m = c_m(T), \qquad \operatorname{td}(TX_{\mathbb C}) = \operatorname{td}(T)\,\operatorname{td}(\bar T) = \operatorname{td}(T)\,\operatorname{td}(T^*). \tag{Nash 4.69}$$

(On $\mathbb{CP}^2$ this is Example 4.50: $\int e = \int c_2(T) = 3$.)

The computation. Put $F = T$. By Fact 1 and the de Rham computation (Nash 4.59)–(Nash 4.60),

$$\operatorname{ch}\big(\sigma_1(\bar\partial)\big) \to \sum_{q=0}^{m}(-1)^q \operatorname{ch}\big(\Lambda^{0,q}\big) = \sum_{q=0}^{m}(-1)^q \operatorname{ch}\big(\Lambda^q F\big) = \prod_{j=1}^{m}\big(1 - e^{x_j}\big) = \frac{c_m(F^*)}{\operatorname{td}(F^*)}. \tag{Nash 4.67}$$

Now insert into the index formula:

$$\begin{aligned}
\operatorname{index}\bar\partial &\overset{(1)}{=} (-1)^m \int_X \frac{c_m(F^*)}{e(X)\,\operatorname{td}(F^*)}\,\operatorname{td}(TX_{\mathbb C}) \\
&\overset{(2)}{=} (-1)^m \int_X \frac{(-1)^m e(X)}{e(X)\,\operatorname{td}(F^*)}\,\operatorname{td}(F)\,\operatorname{td}(F^*) \\
&\overset{(3)}{=} \int_X \operatorname{td}(F) \;=\; \int_X \operatorname{td}(X).
\end{aligned} \tag{Nash 4.68, 4.70–4.71}$$

(1) Nash's formula (4.101) with $n/2 = m$ and the numerator (Nash 4.67).
(2) $c_m(F^*) = (-1)^m c_m(F)$ by (4.74), and $c_m(F) = e(X)$ by (Nash 4.69); also $\operatorname{td}(TX_{\mathbb C}) = \operatorname{td}(F)\operatorname{td}(F^*)$.
(3) $(-1)^m(-1)^m = 1$; the Euler classes cancel, and so does $\operatorname{td}(F^*)$. We abbreviate $\operatorname{td}(X) := \operatorname{td}(T^{1,0}X)$, as Nash does.

Let us also do it directly in the roots, to see the cancellation happen:

$$\begin{aligned}
(-1)^m \prod_{j=1}^{m} \frac{1 - e^{x_j}}{x_j} \cdot \frac{x_j}{1 - e^{-x_j}} \cdot \frac{-x_j}{1 - e^{x_j}} &\overset{(1)}{=} (-1)^m \prod_{j=1}^{m} \frac{-x_j}{1 - e^{-x_j}} \\
&\overset{(2)}{=} \prod_{j=1}^{m} \frac{x_j}{1 - e^{-x_j}} = \operatorname{td}(T).
\end{aligned}$$

(1) Cancel $1 - e^{x_j}$ and one x_j in each factor.
(2) Pull out one -1 per factor; $(-1)^m(-1)^m = 1$.

Key idea: The Riemann–Roch–Hirzebruch theorem (Nash (4.72))

For a compact complex manifold X of complex dimension m,

$$\chi(\mathcal{O}_X) = \sum_{q=0}^{m} (-1)^q h^{0,q} = \int_X \mathrm{td}(X), \qquad \mathrm{td}(X) = \prod_{j=1}^{m} \frac{x_j}{1 - e^{-x_j}}. \tag{4.108}$$

More generally, for a holomorphic vector bundle $V \to X$ (twist every $\Lambda^{0,q}$ by V; the Chern character just multiplies, as the next section explains in general):

$$\chi(X, V) = \sum_{q} (-1)^q \dim H^{0,q}_{\bar\partial}(X; V) = \int_X \mathrm{ch}(V)\ \mathrm{td}(X). \tag{4.109}$$

A count of holomorphic objects equals the integral of a curvature polynomial.

4.13.4 The Todd integrand in low dimensions

By (4.77), the top-degree part of $\mathrm{td}(X)$ in complex dimension $m = 1, 2, 3$ is

$$\chi(\mathcal{O}_X) = \begin{cases} \dfrac{1}{2}\displaystyle\int_X c_1, & m = 1, \\ \dfrac{1}{12}\displaystyle\int_X (c_1^2 + c_2), & m = 2 \quad \text{(Noether's formula)}, \\ \dfrac{1}{24}\displaystyle\int_X c_1 c_2, & m = 3, \end{cases} \tag{4.110}$$

where $c_j = c_j(T^{1,0}X)$. In curvature language: for a Kähler manifold the curvature of T is the Hermitian matrix of $(1,1)$-forms $\Phi = \frac{i}{2\pi} F$, and $c_1 = \mathrm{tr}\,\Phi$ is $\frac{1}{2\pi}$ times the Ricci form. For $m = 1$, $c_1(T) = \frac{1}{2\pi} K\,\mathrm{d}A$ (Example 4.49), so

$$\begin{aligned} \chi(\mathcal{O}_{\Sigma_g}) &\overset{(1)}{=} \frac{1}{2}\int_{\Sigma_g} c_1(T) \\ &\overset{(2)}{=} \frac{1}{4\pi}\int_{\Sigma_g} K\,\mathrm{d}A \\ &\overset{(3)}{=} \frac{1}{4\pi}\cdot 2\pi(2 - 2g) = 1 - g. \end{aligned}$$

(1) (4.110) with $m = 1$.
(2) The curvature of the tangent line bundle is the Gaussian curvature.
(3) Gauss–Bonnet (4.105).

This reproduces $h^{0,0} - h^{0,1} = 1 - g$ of Example 4.64. On a curve, Riemann–Roch for $\mathcal{O}$ *is* half of Gauss–Bonnet.

Worked example 4.65: Noether's formula on three complex surfaces

$\mathbb{CP}^2$. From Example 4.50, $c(T) = (1 + h)^3$, so $c_1 = 3h$, $c_2 = 3h^2$, $\int h^2 = 1$:

$$\chi(\mathcal{O}_{\mathbb{CP}^2}) = \tfrac{1}{12}(9 + 3) = 1.$$

Directly: $h^{0,0} = 1$, and $h^{0,1} = h^{0,2} = 0$ ($\mathbb{CP}^2$ has no holomorphic 1- or 2-forms; its only cohomology is in the classes $1, h, h^2$, all of type (p,p)).

$\mathbb{CP}^1 \times \mathbb{CP}^1$. Let a, b be the area classes of the two factors, $\int a = \int b = 1$ on the respective factor, so $a^2 = b^2 = 0$ and $\int ab = 1$. The tangent bundle is $T = \mathcal{O}(2) \boxplus \mathcal{O}(2)$, one line for each factor, with Chern roots $2a$ and $2b$. Then

$$\begin{aligned}\chi(\mathcal{O}) &\overset{(1)}{=} \tfrac{1}{12}\int \big(c_1^2 + c_2\big)\\ &\overset{(2)}{=} \tfrac{1}{12}\int \big((2a+2b)^2 + (2a)(2b)\big)\\ &\overset{(3)}{=} \tfrac{1}{12}\int \big(8ab + 4ab\big) = 1.\end{aligned}$$

(1) Noether's formula (4.110).
(2) $c_1 = x_1 + x_2$ and $c_2 = x_1 x_2$ with roots $x_1 = 2a$, $x_2 = 2b$.
(3) $a^2 = b^2 = 0$; $\int ab = 1$.

Also $\int c_2 = 4 = \chi(S^2 \times S^2)$, as it must be.
The K3 surface. This is a compact complex surface with $c_1 = 0$ (a nowhere-vanishing holomorphic 2-form $\Omega = \mathrm{d}z^1 \wedge \mathrm{d}z^2$ trivialises $\Lambda^{2,0}$) and $\chi = \int c_2 = 24$. So

$$\chi(\mathcal{O}_{K3}) = \tfrac{1}{12}(0 + 24) = 2,$$

and directly: $h^{0,0} = 1$, $h^{0,1} = 0$ (K3 is simply connected), $h^{0,2} = h^{2,0} = 1$ (spanned by $\bar{\Omega}$): $1 - 0 + 1 = 2$. ✓

Worked example 4.66: Integrality forbids a complex structure on S^4

Noether's formula says that $c_1^2 + c_2$ is divisible by 12 on every compact complex surface. Suppose S^4 were a complex surface. Then $c_2 = e$ integrates to $\chi(S^4) = 2$, and $c_1 \in H^2(S^4) = 0$, so $c_1^2 = 0$. The formula would give

$$\chi(\mathcal{O}_{S^4}) = \tfrac{1}{12}(0 + 2) = \tfrac{1}{6} \notin \mathbb{Z},$$

a contradiction. So S^4 carries no complex structure. (The same argument, run through the spin^c Dirac operator, shows that S^4 does not even carry an *almost* complex structure.) This is the "far from obvious" integrality of the index formula doing real work.

Worked example 4.67: Complex dimension 3: $\mathbb{CP}^3$ and Calabi–Yau threefolds

$\mathbb{CP}^3$: $c(T) = (1 + h)^4$, so $c_1 = 4h$, $c_2 = 6h^2$, $\int h^3 = 1$, and $\chi(\mathcal{O}) = \frac{1}{24} \cdot 4 \cdot 6 = 1$, matching $h^{0,0} = 1$, $h^{0,1} = h^{0,2} = h^{0,3} = 0$.
A Calabi–Yau threefold (the internal space of many string compactifications) has $c_1 = 0$, so $\chi(\mathcal{O}) = \frac{1}{24}\int c_1 c_2 = 0$. Directly: $h^{0,0} = 1$, $h^{0,1} = h^{0,2} = 0$, $h^{0,3} = 1$ (the holomorphic 3-form), and $1 - 0 + 0 - 1 = 0$. ✓

4.13.5 Riemann–Roch for curves, checked by hand

The original Riemann–Roch theorem (Riemann 1857, Roch 1865) is about line bundles on a Riemann surface. It is the case $m = 1$ of (4.109), and it is worth checking completely.

Let $L \to \Sigma_g$ be a holomorphic line bundle, with $\deg L := \int_{\Sigma_g} c_1(L)$ (an integer, the "number of zeros minus poles" of any meromorphic section). Its Chern character is $1 + c_1(L)$ and

$\mathrm{td}(\Sigma_g) = 1 + \frac{1}{2}c_1(T)$. Then

$$\begin{aligned} h^0(L) - h^1(L) &\overset{(1)}{=} \int_{\Sigma_g} \big(1 + c_1(L)\big)\big(1 + \tfrac{1}{2}c_1(T)\big) \\ &\overset{(2)}{=} \int_{\Sigma_g} \Big(c_1(L) + \tfrac{1}{2}c_1(T)\Big) \\ &\overset{(3)}{=} \deg L + 1 - g. \end{aligned} \tag{4.111}$$

(1) Riemann–Roch (4.109) for $V = L$; here $h^q(L) = \dim H^{0,q}(\Sigma_g; L)$.
(2) Keep only the 2-form part: the product $c_1(L)c_1(T)$ is a 4-form and vanishes on a surface.
(3) $\int c_1(T) = \chi(\Sigma_g) = 2 - 2g$.

The second number has a classical meaning: by **Serre duality**, $h^1(L) = h^0(K \otimes L^{-1})$, where $K = \Lambda^{1,0} = T^*$ is the canonical bundle (holomorphic 1-forms), of degree $2g - 2$. (The pairing $H^{0,1}(L) \times H^0(K \otimes L^{-1}) \to \mathbb{C}$, $(\alpha, \beta) \mapsto \int \alpha \wedge \beta$, is perfect.)

Worked example 4.68: Line bundles on $\mathbb{CP}^1$: homogeneous polynomials

On $\mathbb{CP}^1$ ($g = 0$) the line bundle $\mathcal{O}(d)$ has holomorphic sections the homogeneous polynomials of degree d in (z_0, z_1). In the chart $z = z_1/z_0$ a section is a polynomial $s(z) = a_0 + a_1 z + \cdots + a_d z^d$; in the other chart $w = 1/z$ it is $w^d s(1/w) = a_0 w^d + \cdots + a_d$, which is holomorphic at $w = 0$ precisely because $\deg s \le d$. So

$$h^0(\mathcal{O}(d)) = d + 1 \quad (d \ge 0), \qquad h^0(\mathcal{O}(d)) = 0 \quad (d < 0).$$

For the h^1: $K = \mathcal{O}(-2)$ on $\mathbb{CP}^1$ (Example 4.49: $T = \mathcal{O}(2)$), so $h^1(\mathcal{O}(d)) = h^0(\mathcal{O}(-2-d))$, which is $-d - 1$ for $d \le -2$ and 0 otherwise. Now the check:

d	-4	-3	-2	-1	0	1	2
h^0	0	0	0	0	1	2	3
h^1	3	2	1	0	0	0	0
$h^0 - h^1$	-3	-2	-1	0	1	2	3
$d + 1 - g$	-3	-2	-1	0	1	2	3

The individual numbers have a kink at $d = -1$; the difference is the straight line $d + 1$ (Figure 4.38).

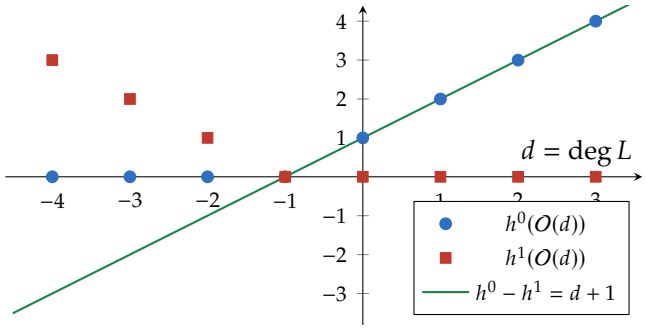

Figure 4.38: Riemann–Roch on $\mathbb{CP}^1$. The number of holomorphic sections h^0 (blue) and the obstruction count h^1 (red) each have a corner, but their difference is exactly the linear function $d + 1 - g$ (green) predicted by the index theorem. Only the difference is a topological invariant.

Worked example 4.69: The canonical bundle and the elliptic curve

$L = K$ *on* Σ_g. $h^0(K) = g$ (holomorphic 1-forms) and, by Serre duality, $h^1(K) = h^0(\mathcal{O}) = 1$. Riemann–Roch predicts $h^0 - h^1 = \deg K + 1 - g = (2g-2) + 1 - g = g - 1$, and indeed $g - 1 = g - 1$. Turned around, this *proves* $\deg K = 2g - 2$, i.e. Gauss–Bonnet again.
Elliptic curve ($g = 1$, K trivial). For $\deg L = d > 0$ we have $h^1(L) = h^0(L^{-1}) = 0$ (a bundle of negative degree has no sections: a section would have $d < 0$ zeros). So $h^0(L) = d$. For $d = 1$ the unique section (up to scale) is a Jacobi theta function; the d sections for $\deg L = d$ are the theta functions of level d.

Physical picture: Landau levels on a sphere and on a torus

A charged particle on a surface Σ in a uniform magnetic field with N_ϕ flux quanta, $\frac{1}{2\pi}\int B = N_\phi$, is a section of a line bundle L of degree N_ϕ. The lowest-Landau-level wavefunctions are the solutions of $\bar\partial_A \psi = 0$, i.e. holomorphic sections of L (up to a spin/curvature shift, which on the sphere replaces L by $L \otimes K^{1/2}$ or not, depending on the Hamiltonian). For strong enough field $h^1 = 0$ and Riemann–Roch gives the degeneracy

$$\dim(\mathrm{LLL}) = N_\phi + 1 - g.$$

On the torus this is N_ϕ, the familiar "one state per flux quantum". On Haldane's sphere, with our $\mathcal{O}(N_\phi)$, it is $N_\phi + 1$; the shift by $1 - g$ is a topological property of the surface, which is the origin of the "shift" in quantum Hall physics.

4.13.6 Hodge numbers refine Betti numbers

Forgetting the complex structure, X has a de Rham complex and an Euler characteristic. Since $\mathrm{d} = \partial + \bar\partial$, one expects the Betti numbers to decompose into Hodge numbers. Nash states (4.73)

$$\chi(X) = \sum_k (-1)^k b_k = \sum_{p,q} (-1)^{p+q} h^{p,q}. \tag{Nash 4.73}$$

Why is this true? Both sides are indices. The left side is the index of the de Rham complex. The right side is $\sum_p (-1)^p$ times the index of the Dolbeault complex in row p of Figure 4.37, i.e. the index of $\bar\partial + \bar\partial^*$ on all forms, graded by total degree. The symbols of $\mathrm{d} + \mathrm{d}^*$ and of $\sqrt{2}(\bar\partial + \bar\partial^*)$ can be deformed into each other through elliptic symbols (on a Kähler manifold the operators themselves agree: $\Delta_d = 2\Box_{\bar\partial}$), and the index cannot change under such a deformation. On a Kähler manifold we have more: each harmonic k-form splits into harmonic (p,q)-pieces, so

$$b_k = \sum_{p+q=k} h^{p,q} \qquad \text{(Kähler)},$$

and (Nash 4.73) follows by summing. The Hodge numbers also obey $h^{p,q} = h^{q,p}$ (conjugation) and $h^{p,q} = h^{m-p,m-q}$ (Serre duality), which gives the **Hodge diamond** its symmetry.

Worked example 4.70: Checking (Nash 4.73) on K3

From the diamond in Figure 4.39:

$$\sum_{p,q}(-1)^{p+q}h^{p,q} \overset{(1)}{=} h^{0,0} - (h^{1,0}+h^{0,1}) + (h^{2,0}+h^{1,1}+h^{0,2}) - (h^{2,1}+h^{1,2}) + h^{2,2}$$

$$\overset{(2)}{=} 1 - 0 + (1 + 20 + 1) - 0 + 1 = 24,$$

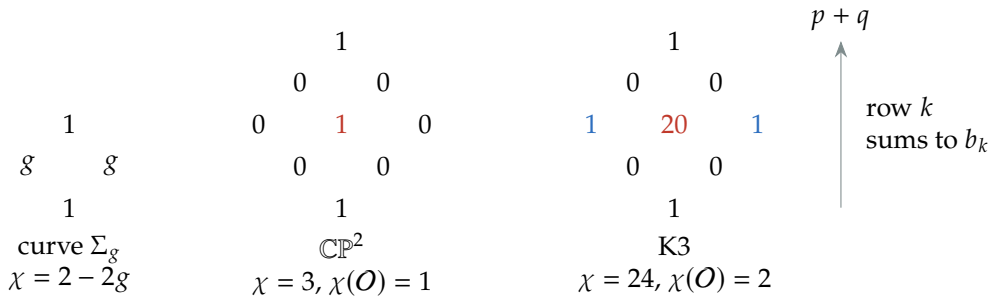

Figure 4.39: Hodge diamonds: $h^{p,q}$ is placed at height $p+q$, with $h^{m,0}$ at the far left and $h^{0,m}$ at the far right of the middle row. Summing row k gives the Betti number b_k (e.g. for K3, $b_2 = 1+20+1 = 22$); the alternating sum over all entries is $\chi(X)$; the alternating sum along the right-hand edge $(h^{0,0}, h^{0,1}, \dots, h^{0,m})$ is the arithmetic genus $\chi(\mathcal{O})$ computed by the Todd class.

(1) Group the Hodge numbers by total degree $p+q$.
(2) Read off the diamond.

which is $\chi(K3) = \int c_2 = 24$, the value we used in Example 4.62.

Watch out: Two meanings of TX

In this example Nash writes TX for the *holomorphic* tangent bundle $T^{1,0}X$, a complex bundle of rank $m = n/2$, and $\overline{TX}$ for its conjugate. Elsewhere TX is the real tangent bundle of rank n. The two are related by $TX_{\mathbb{C}} = T^{1,0}X \oplus \overline{T^{1,0}X}$, which is exactly Nash's (4.69). Also, Nash writes $\mathrm{td}(X)$ for $\mathrm{td}(T^{1,0}X)$; it is *not* $\mathrm{td}(TX_{\mathbb{C}})$, which is $\hat{A}(X)^2$ and involves only Pontryagin classes.

Watch out: The sign in Nash (4.67)

The Chern roots of $\Lambda^{0,1}$ are $+x_j$ (not $-x_j$): $\mathrm{d}\bar{z}$ transforms like $\partial/\partial z$, not like $\mathrm{d}z$. With the wrong sign one obtains $\int \mathrm{td}(T^*) = (-1)^m \int \mathrm{td}(T)$, i.e. $g-1$ instead of $1-g$ on a curve. The check $\chi(\mathcal{O}_{\mathbb{CP}^m}) = 1$ is a quick way to catch this.

Reading Nash (pp. 106–108, (4.63)–(4.73))

Nash introduces the Dolbeault complex and its cohomology (4.63), notes that there is one complex for each p and sets $p = 0$, and identifies the index with the arithmetic genus $\chi(\mathcal{E}) = \sum (-1)^q h_{0,q}$ (4.64)–(4.65). The symbol complex is (4.66). Using $\overline{T^*X} \cong TX$ (holomorphic tangent bundle) he reuses the de Rham manipulation to get (4.67)–(4.68), then (4.69) $c_{n/2}(F^*) = (-1)^{n/2} e(X)$ and $\mathrm{td}(TX_{\mathbb{C}}) = \mathrm{td}(F)\,\mathrm{td}(F^*)$, and arrives at index $\bar{\partial} = \mathrm{td}(X)[X]$ (4.70)–(4.71), the Riemann–Roch theorem (4.72). Finally (4.73) relates the Euler characteristic to the Hodge numbers. We added: explicit (p,q)-calculus, the symbol and its ellipticity, low dimensional Todd integrands, and checks on curves, $\mathbb{CP}^1$ line bundles, $\mathbb{CP}^2$, $\mathbb{CP}^1 \times \mathbb{CP}^1$, K3, $\mathbb{CP}^3$ and Calabi–Yau threefolds.

Recap

- On a complex manifold $\mathrm{d} = \partial + \bar{\partial}$; each row of the (p,q)-grid is an elliptic complex with symbol $ip^{0,1}\wedge$.
- index $\bar{\partial} = \sum_q (-1)^q h^{0,q} = \chi(\mathcal{O}_X)$, the arithmetic genus.

- $\Lambda^{0,q} \cong \Lambda^q T^{1,0}$ gives ch $= \prod(1 - e^{x_j}) = c_m(T^*)/\mathrm{td}(T^*)$, and the index formula collapses to $\int_X \mathrm{td}(X)$: Riemann–Roch–Hirzebruch.
- Low dimensions: $\frac{1}{2}c_1$; $\frac{1}{12}(c_1^2 + c_2)$; $\frac{1}{24}c_1c_2$. On curves with a line bundle: $h^0 - h^1 = \deg L + 1 - g$.
- Integrality has teeth: S^4 is not a complex surface.
- $\chi(X) = \sum(-1)^{p+q} h^{p,q}$: Hodge numbers refine Betti numbers.

4.14 The signature complex and the Hirzebruch signature theorem

The Euler characteristic uses all the Betti numbers but forgets how the cohomology classes multiply. The *signature* is an invariant that uses the multiplication. On a $4k$-manifold two middle-dimensional classes can be multiplied to a top-degree class and integrated, giving a number: geometrically, the number of points (with signs) in which two $2k$-dimensional submanifolds intersect. This **intersection form** is a symmetric matrix of integers, and its signature (number of positive minus number of negative eigenvalues) is a topological invariant.

Physicists meet it in several places: the classification of four-manifolds (Donaldson and Seiberg–Witten theory, Chapter 12), the gravitational contribution to the axial anomaly, and chiral 2-form fields, whose zero modes are the self-dual harmonic forms. The index theorem will express the signature as the integral of a curvature polynomial, the L-polynomial. In four dimensions,

$$\mathrm{Sign}(X) = -\frac{1}{24\pi^2}\int_X \mathrm{tr}\big(R \wedge R\big).$$

An integer (a count of eigenvalue signs) equals an integral of curvature.

4.14.1 The intersection form

Let X be compact and oriented, $\dim X = n = 2l$. Cohomology classes of degree l can be multiplied (cup product; for de Rham classes, the wedge product of representatives) to degree $2l = n$ and then integrated:

$$q(u, v) = (u \cup v)[X] = \int_X u \wedge v, \qquad u, v \in H^l(X). \tag{Nash 4.74}$$

With integer coefficients, q is an integer-valued bilinear form on the lattice $H^l(X;\mathbb{Z})$ (modulo torsion). By Poincaré duality it is *unimodular*: in an integral basis its matrix has determinant ± 1, in particular it is non-degenerate.

Working definition 4.34 (Signature)

Choose a basis of $H^l(X;\mathbb{R})$ and write q as a real matrix Q. Diagonalise it. Let b^+ and b^- be the numbers of positive and negative eigenvalues ($b^+ + b^- = b_l$ [the Betti number $\dim H^l(X;\mathbb{R})$] since q is non-degenerate). The **signature** is

$$\mathrm{Sign}(X) = b^+ - b^-. \tag{Nash 4.75}$$

By Sylvester's law of inertia [under a change of basis $Q \mapsto P^T Q P$ the numbers of positive and of negative eigenvalues stay the same], $b^\pm$ do not depend on the basis.

Why only $n = 4k$. The symmetry of q is that of the wedge product:

$$q(u,v) \overset{(1)}{=} \int_X u \wedge v \overset{(2)}{=} (-1)^{l\cdot l} \int_X v \wedge u \overset{(3)}{=} (-1)^l\, q(v,u). \tag{Nash 4.76}$$

(1) Definition (Nash 4.74).
(2) Commuting an l-form past an l-form costs $(-1)^{l\cdot l}$.
(3) $l^2 \equiv l \pmod 2$.

If l is odd, q is antisymmetric. A real antisymmetric matrix has purely imaginary eigenvalues $\pm i\lambda$ (it is i times a Hermitian matrix), so there are no positive or negative ones, and the signature is zero by fiat. The interesting case is l even, i.e. $n = 4k$. Reversing the orientation of X flips the sign of $\int_X$, hence $q \mapsto -q$ and $\mathrm{Sign}(\bar{X}) = -\mathrm{Sign}(X)$: the signature is an invariant of *oriented* manifolds.

Physical picture: Counting intersection points

If u and v are Poincaré dual to closed oriented submanifolds A and B of dimension l (i.e. $\int_A u' = \int_X u' \wedge u$ for all closed u'), then $q(u,v)$ is the number of intersection points of A and B, each counted $+1$ or -1 according to whether the orientations of A and B at the point add up to that of X. The self-intersection $q(u,u)$ is computed by pushing A off itself to a nearby copy A' and counting $A \cap A'$.

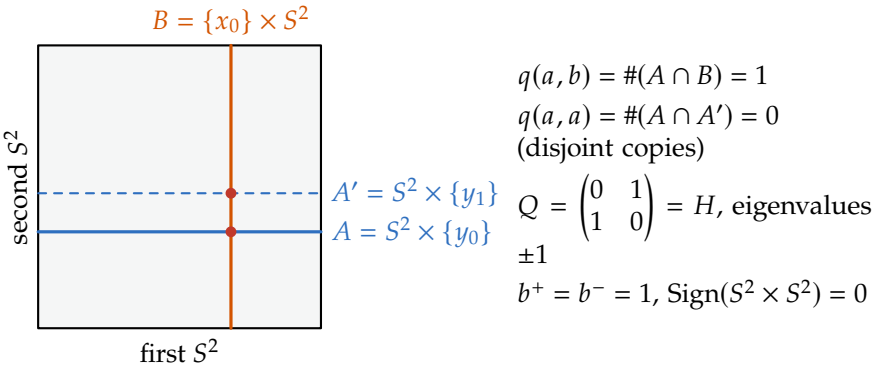

Figure 4.40: The intersection form of $S^2 \times S^2$, drawn as a square (each side stands for one sphere factor). A horizontal sphere A and a vertical sphere B meet in one point (red), so $q(a,b) = 1$; A can be pushed off itself to a disjoint parallel copy A', so $q(a,a) = 0$. The matrix is the hyperbolic form H, with one positive and one negative eigenvalue.

Worked example 4.71: Intersection forms of the basic four-manifolds

$\mathbb{CP}^2$. $H^2 = \mathbb{Z}h$ with $\int h^2 = 1$ (two lines meet in a point). $Q = (1)$, Sign $= 1$. For $\overline{\mathbb{CP}^2}$ (reversed orientation) $Q = (-1)$, Sign $= -1$.
$S^2 \times S^2$. $Q = H$ as in Figure 4.40, Sign $= 0$.
$T^4 = \mathbb{R}^4/\mathbb{Z}^4$. H^2 is spanned by the six forms $\mathrm{d}x^{ij} := \mathrm{d}x^i \wedge \mathrm{d}x^j$, $i < j$. The only nonzero pairings are between complementary pairs:

$$\int \mathrm{d}x^{12} \wedge \mathrm{d}x^{34} = +1,$$
$$\int \mathrm{d}x^{13} \wedge \mathrm{d}x^{24} \overset{(1)}{=} -\int \mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4 = -1,$$
$$\int \mathrm{d}x^{14} \wedge \mathrm{d}x^{23} \overset{(2)}{=} +\int \mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4 = +1.$$

(1) Swap dx^3 and dx^2: one transposition.
(2) Move dx^4 to the end, past dx^2 and dx^3: two transpositions.

So $Q = H \oplus (-H) \oplus H$. Since $-H$ becomes H after changing the sign of one basis vector, $Q \cong 3H$; either way each block has eigenvalues ± 1, $b^+ = b^- = 3$ and $\mathrm{Sign}(T^4) = 0$.
K3. $b_2 = 22$ and (by a theorem of Freedman type, or by explicit construction as a Kummer surface) $Q = 3H \oplus 2(-E_8)$, where E_8 is the Cartan matrix of the Lie algebra E_8:

$$E_8 = \begin{pmatrix} 2 & -1 & & & & & & \\ -1 & 2 & -1 & & & & & \\ & -1 & 2 & -1 & & & & \\ & & -1 & 2 & -1 & & & \\ & & & -1 & 2 & -1 & & -1 \\ & & & & -1 & 2 & -1 & \\ & & & & & -1 & 2 & \\ & & & & -1 & & & 2 \end{pmatrix}.$$

It is positive definite, has $\det E_8 = 1$ (unimodular) and even diagonal. So $b^+ = 3$, $b^- = 3 + 16 = 19$, and $\mathrm{Sign}(K3) = 3 - 19 = -16$.

4.14.2 The involution τ

To realise $\mathrm{Sign}(X)$ as an index we need a way to tell "positive" from "negative" middle-dimensional forms using an operator. In four dimensions the answer is familiar from Yang–Mills theory: for a real 2-form ω,

$$q(\omega,\omega) = \int_X \omega \wedge \omega = \begin{cases} +\int_X \omega \wedge \star\omega = +\|\omega\|^2 & \text{if } \star\,\omega = \omega \text{ (self-dual)}, \\ -\int_X \omega \wedge \star\omega = -\|\omega\|^2 & \text{if } \star\,\omega = -\omega \text{ (anti-self-dual)}. \end{cases}$$

So the Hodge star on 2-forms sorts classes into positive and negative ones. Nash extends this to an involution on *all* forms.

The Hodge star on complex forms. Complex forms carry the Hermitian inner product

$$\langle \omega, \nu \rangle = \int_X \omega \wedge \star\bar{\nu}, \qquad \omega, \nu \in \Omega^p(X),$$

with $\star$ extended complex-linearly. On an n-manifold with Riemannian metric $\star\star = (-1)^{p(n-p)}$ on p-forms. For n even, $p(n-p) \equiv p^2 \equiv p \pmod 2$, so

$$\star^2 = (-1)^p \qquad \text{on } \Omega^p,\ n \text{ even}.$$

Working definition 4.35 (The involution τ (Nash (4.77)))

On an even-dimensional oriented Riemannian manifold define

$$\tau : \Omega^p(X) \to \Omega^{n-p}(X), \qquad \tau\omega = i^{\lambda(p)} \star \omega, \qquad \lambda(p) = p(p-1) + \tfrac{n}{2}. \qquad \text{(Nash 4.77)}$$

[the forms here are complex-valued, since τ contains powers of i] It is the Hodge star dressed with the phase needed to make it square to one.

Check that $\tau^2 = 1$ on $\omega \in \Omega^p$:

$$\tau^2\omega \overset{(1)}{=} i^{\lambda(p)}\,\tau(\star\omega) \overset{(2)}{=} i^{\lambda(p)+\lambda(n-p)}\,\star^2\,\omega$$
$$\overset{(3)}{=} i^{2p}\ \star^2\,\omega \overset{(4)}{=} (-1)^p(-1)^p\omega = \omega. \tag{Nash 4.78}$$

(1) Definition of τ on Ω^p; τ is complex linear.
(2) $\star\omega$ has degree $n-p$, so the second τ brings $i^{\lambda(n-p)}$.
(3) $\lambda(p)+\lambda(n-p) = p^2 - p + (n-p)^2 - (n-p) + n = 2p^2 - 2np + n^2$. With n even, $n^2 \equiv 0$ and $2np \equiv 0 \pmod 4$, and $2p^2 \equiv 2p \pmod 4$ (since $2p(p-1)$ is divisible by 4). So $i^{\lambda(p)+\lambda(n-p)} = i^{2p}$.
(4) $i^{2p} = (-1)^p$ and $\star^2 = (-1)^p$.

Since $\tau^2 = 1$, its eigenvalues are ± 1, and every form splits uniquely as $\omega = \frac{1}{2}(\omega+\tau\omega)+\frac{1}{2}(\omega-\tau\omega)$:

$$\Omega^*(X) = \bigoplus_p \Omega^p(X) = \Omega^+ \oplus \Omega^-, \qquad \Omega^\pm = \{\omega : \tau\omega = \pm\omega\}. \tag{Nash 4.79}$$

The corresponding bundles are $\Lambda^\pm T^*X_{\mathbb{C}}$, each of rank $\frac{1}{2}\cdot 2^n = 2^{n-1}$ (the pairing $\omega \mapsto \omega \pm \tau\omega$ is a bijection between Λ^p and each $\Lambda^\pm \cap (\Lambda^p \oplus \Lambda^{n-p})$ for $p < n/2$, and the middle degree splits in half).

Worked example 4.72: τ in two and four dimensions, explicitly

$n = 2$ (so $n/2 = 1$), orthonormal coframe e^1, e^2, $\mathrm{vol} = e^1 \wedge e^2$, $\star 1 = \mathrm{vol}$, $\star e^1 = e^2$, $\star e^2 = -e^1$, $\star\mathrm{vol} = 1$. The phases are $i^{\lambda(0)} = i$, $i^{\lambda(1)} = i$, $i^{\lambda(2)} = i^3 = -i$. So

$$\tau 1 = i\,\mathrm{vol}, \quad \tau\,\mathrm{vol} = -i, \quad \tau e^1 = ie^2, \quad \tau e^2 = -ie^1.$$

The eigenvectors: $\tau(1 + i\,\mathrm{vol}) = i\,\mathrm{vol} + 1$ and $\tau(e^1 + ie^2) = ie^2 + e^1$ have eigenvalue $+1$; $1 - i\,\mathrm{vol}$ and $e^1 - ie^2$ have eigenvalue -1. With $z = x^1 + ix^2$ along the plane,

$$\Lambda^+ = \mathrm{span}\{1 + i\,\mathrm{vol},\ \mathrm{d}z\}, \qquad \Lambda^- = \mathrm{span}\{1 - i\,\mathrm{vol},\ \mathrm{d}\bar{z}\}.$$

$n = 4$ ($n/2 = 2$). The phases are $i^{\lambda(p)} = i^{p(p-1)+2}$: -1 for $p = 0, 1$; $+1$ for $p = 2, 3$; -1 for $p = 4$. So $\tau = -\star$ on 0-, 1- and 4-forms and $\tau = +\star$ on 2- and 3-forms. In particular

$$\Lambda^+ = \underbrace{\mathrm{span}\{1 - \mathrm{vol}\}}_{1} \oplus \underbrace{\{\alpha - \star\alpha : \alpha \in \Lambda^1\}}_{4} \oplus \underbrace{\Lambda^2_+}_{3},$$

where Λ^2_+ are the self-dual 2-forms, e.g. $e^{12} + e^{34}$, $e^{13} - e^{24}$, $e^{14} + e^{23}$. (Check one piece: $\tau(\alpha - \star\alpha) = -\star\alpha + \star\star\alpha = -\star\alpha + \alpha$, using $\star^2 = -1$ on 1-forms.) The rank is $1+4+3 = 8 = 2^{4-1}$.

4.14.3 The signature operator

The key property is that τ *anticommutes* with $\mathrm{d} + \mathrm{d}^*$. First recall that on an even-dimensional manifold $\mathrm{d}^* = -\star\,\mathrm{d}\star$. Then for $\omega \in \Omega^p$:

$$\tau\,\mathrm{d}\,\tau\,\omega \overset{(1)}{=} i^{\lambda(p)}\,\tau\big(\mathrm{d}\star\omega\big)$$
$$\overset{(2)}{=} i^{\lambda(p)+\lambda(n-p+1)}\ \star\,\mathrm{d}\star\,\omega$$
$$\overset{(3)}{=} -\,i^{\lambda(p)+\lambda(n-p+1)}\,\mathrm{d}^*\omega \overset{(4)}{=} -\mathrm{d}^*\omega. \tag{4.112}$$

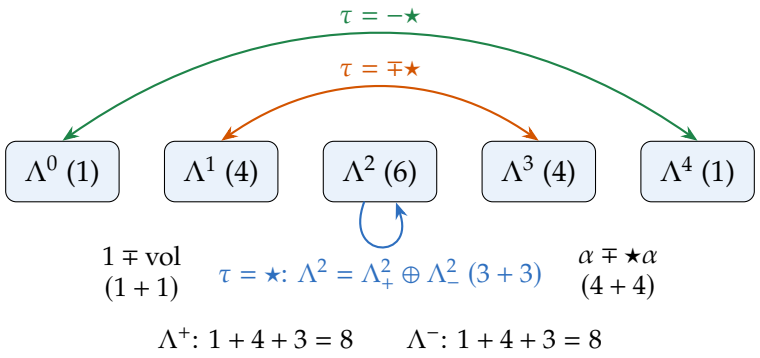

Figure 4.41: How τ acts on forms in four dimensions (ranks in brackets). It exchanges Λ^p with Λ^{4-p}, so each pair $\Lambda^p \oplus \Lambda^{4-p}$ splits evenly into ± 1 eigenspaces; on the middle degree it is the Hodge star itself, and its eigenspaces are the self-dual and anti-self-dual 2-forms. Only the middle degree can contribute an imbalance between + and −.

(1) $\tau\omega = i^{\lambda(p)} \star \omega$ and d is linear.
(2) $\mathrm{d} \star \omega$ has degree $n - p + 1$.
(3) $\mathrm{d}^* = - \star \mathrm{d} \star$.
(4) $\lambda(p) + \lambda(n-p+1) = p^2 - p + (n-p+1)(n-p) + n = n^2 - 2np + 2p^2 + 2n - 2p$. For n even, n^2, $2np$ and $2n$ are divisible by 4, and so is $2p^2 - 2p = 2p(p-1)$. So the phase is $i^0 = 1$.

Multiplying (4.112) on the right by τ (using $\tau^2 = 1$) gives $\tau\mathrm{d} = -\mathrm{d}^*\tau$, and taking adjoints ($\tau$ is unitary and squares to one, hence self-adjoint) gives $\tau\mathrm{d}^* = -\mathrm{d}\tau$. Adding:

$$\tau(\mathrm{d} + \mathrm{d}^*) = -(\mathrm{d} + \mathrm{d}^*)\tau. \tag{4.113}$$

So if $\tau\omega = \omega$ then $\tau(\mathrm{d} + \mathrm{d}^*)\omega = -(\mathrm{d} + \mathrm{d}^*)\omega$: $\mathrm{d} + \mathrm{d}^*$ maps Ω^+ into Ω^- and vice versa.

Working definition 4.36 (Signature operator and signature complex)

The **signature operator** is the restriction

$$\mathrm{d}_+ = (\mathrm{d} + \mathrm{d}^*)\big|_{\Omega^+} : \Omega^+(X) \longrightarrow \Omega^-(X), \tag{Nash 4.80}$$

[d^* is the adjoint of d, lowering the form degree by one] and the **signature complex** is the two-term complex

$$0 \longrightarrow \Gamma\big(X, \Lambda^+ T^*X \otimes_{\mathbb{R}} \mathbb{C}\big) \xrightarrow{\mathrm{d}_+} \Gamma\big(X, \Lambda^- T^*X \otimes_{\mathbb{R}} \mathbb{C}\big) \longrightarrow 0, \tag{Nash 4.81}$$

with symbol complex [the leading symbol, here $\sigma_1(\mathrm{d} + \mathrm{d}^*)(x,k) = i(k \wedge - \iota_k)$, acting on the same fibre at every $(x,k) \in T^*X$]

$$0 \longrightarrow \pi^*\Lambda^+ T^*X \otimes_{\mathbb{R}} \mathbb{C} \xrightarrow{\sigma_1(\mathrm{d}_+)} \pi^*\Lambda^- T^*X \otimes_{\mathbb{R}} \mathbb{C} \longrightarrow 0. \tag{Nash 4.82}$$

Its adjoint is $\mathrm{d}_- = (\mathrm{d} + \mathrm{d}^*)|_{\Omega^-}$.

Ellipticity is inherited from $\mathrm{d} + \mathrm{d}^*$: its symbol $\sigma_1 = i(p \wedge - \iota_p)$ squares to $|p|^2$ (Section 4.12), so its restriction $\Lambda^+ \to \Lambda^-$ is invertible for $p \neq 0$. The only difference from the de Rham operator is *how the forms are split* into two halves: by τ instead of by the parity of the degree.

4.14.4 The index is the signature

Since d_+ is elliptic, Hodge theory identifies kernel and cokernel with harmonic forms. The Laplacian $\Delta = (\mathrm{d}+\mathrm{d}^*)^2$ commutes with τ (two anticommutations), so τ preserves the harmonic forms $\mathcal{H}^* \cong H^*(X;\mathbb{C})$, and

$$H^{\pm}(X;\mathbb{C}) = \{\omega \in \mathcal{H}^* : \tau\omega = \pm\omega\}, \qquad h_\pm = \dim H^\pm, \qquad H^*(X;\mathbb{C}) = H^+ \oplus H^-. \quad \text{(Nash 4.83)}$$

The kernel of d_+ is H^+ and the kernel of its adjoint d_- is H^-, so

$$\operatorname{index} \mathrm{d}_+ = h_+ - h_-. \quad \text{(Nash 4.84)}$$

Now we sort the harmonic forms by degree, as in Figure 4.41. For $0 \le p < n/2$ put

$$I^p = H^p(X;\mathbb{C}) \oplus H^{n-p}(X;\mathbb{C}). \quad \text{(Nash 4.85)}$$

The involution τ maps I^p to itself, exchanging the two summands (it is an isomorphism $H^p \to H^{n-p}$: this is Poincaré duality realised by the Hodge star). For any $\alpha \in H^p$, the forms $\alpha \pm \tau\alpha$ are ±1 eigenvectors, and every eigenvector in I^p has this form. Hence

$$I^p = I^p_+ \oplus I^p_-, \qquad \dim I^p_+ = \dim I^p_- = b_p. \quad \text{(Nash 4.86)}$$

What is left is the middle degree $p = n/2 = l$, where τ maps H^l to itself:

$$H^l(X;\mathbb{C}) = H^l_+(X;\mathbb{C}) \oplus H^l_-(X;\mathbb{C}), \qquad h^l_\pm = \dim H^l_\pm. \quad \text{(Nash 4.87)}$$

On middle forms the phase is $i^{\lambda(l)} = i^{l(l-1)+l} = i^{l^2} = 1$ because l is even. So $\tau = \star$ on H^l, a *real* operator, and its eigenspaces are spanned by real forms. For a real harmonic ω with $\star\omega = \pm\omega$,

$$q(\omega,\omega) \overset{(1)}{=} \int_X \omega \wedge \omega \overset{(2)}{=} \pm \int_X \omega \wedge \star\omega \overset{(3)}{=} \pm \|\omega\|^2,$$

(1) The intersection form on de Rham representatives.
(2) $\omega = \pm \star \omega$.
(3) For real forms, $\int \omega \wedge \star\omega$ is the L^2 norm squared.

and for $\omega_+ \in H^l_+$, $\omega_- \in H^l_-$, $q(\omega_+,\omega_-) = -\int \omega_+ \wedge \star\omega_- = -\langle \omega_+, \omega_-\rangle = 0$ (eigenvectors of the self-adjoint $\star$ with different eigenvalues are orthogonal). So q is positive definite on H^l_+, negative definite on H^l_-, and these are q-orthogonal: by Sylvester, $h^l_\pm = b^\pm$.

Now collect everything:

$$\begin{aligned} H^*(X;\mathbb{C}) &\overset{(1)}{=} I^0 \oplus \cdots \oplus I^{l-1} \oplus H^l(X;\mathbb{C}) \\ &\overset{(2)}{=} \left(I^0_+ \oplus \cdots \oplus I^{l-1}_+ \oplus H^l_+\right) \oplus \left(I^0_- \oplus \cdots \oplus I^{l-1}_- \oplus H^l_-\right) = H^+ \oplus H^-, \\ \implies h_\pm &\overset{(3)}{=} h^l_\pm + \sum_{p=0}^{l-1} \dim I^p_\pm, \end{aligned} \quad \text{(Nash 4.88)}$$

(1) Group the degrees in pairs $(p, n-p)$ plus the middle degree.
(2) Split each piece into τ-eigenspaces, by (Nash 4.86) and (Nash 4.87).
(3) Take dimensions.

and therefore

$$\operatorname{index} \mathrm{d}_+ = h_+ - h_- \overset{(1)}{=} h^l_+ - h^l_- \overset{(2)}{=} b^+ - b^- = \operatorname{Sign}(X). \quad \text{(Nash 4.89)}$$

(1) (Nash 4.88): the $I^p_\pm$ have equal dimensions and cancel.
(2) The identification $h^l_\pm = b^\pm$ just made.

Worked example 4.73: Two harmonic checks

Surfaces ($n = 2$, $l = 1$ odd). By Example 4.72, $\Lambda^+ = \{1 + i\,\mathrm{vol}\} \oplus \Lambda^{1,0}$. Harmonic forms in Ω^+: the constant $1 + i$ vol and the g holomorphic 1-forms; in Ω^-: $1 - i$ vol and the g antiholomorphic 1-forms. So $\operatorname{index} \mathrm{d}_+ = (1 + g) - (1 + g) = 0$, as it must be for l odd.
$S^2 \times S^2$ with the product of unit round metrics. The harmonic 2-forms are spanned by the two area forms ω_1, ω_2. The Hodge star of the product metric swaps them: $\star\omega_1 = \omega_2$ (the orthogonal complement of the first factor's tangent plane is the second's). So $\omega_1 + \omega_2$ is self-dual and $\omega_1 - \omega_2$ anti-self-dual: $b^+ = b^- = 1$, Sign $= 0$, matching $Q = H$. Note $q(\omega_1 + \omega_2, \omega_1 + \omega_2) = 2\int \omega_1 \wedge \omega_2 > 0$. ✓

4.14.5 The characteristic-class side: the L-polynomial

We now need

$$\mathrm{ch}\big(\sigma_1(\mathrm{d}_+)\big) \longrightarrow \mathrm{ch}\big(\Lambda^+ T^*X \otimes \mathbb{C}\big) - \mathrm{ch}\big(\Lambda^- T^*X \otimes \mathbb{C}\big). \tag{Nash 4.90}$$

Nash quotes the answer from Atiyah–Singer ("the splitting principle and a little group theory"). Here is the argument.

Step 1: τ is a product over 2-planes. Use the orthonormal frame in which the curvature has the block form (4.79), so that $\mathbb{R}^n = P_1 \oplus \cdots \oplus P_m$ is a sum of oriented 2-planes, $n = 2m$. Let $c(v) = v \wedge - \,\iota_v$ act on forms; it satisfies $c(v)^2 = -|v|^2$, the Clifford relation (Chapter T4). One checks (as we do in a moment in two dimensions, and as in Lawson–Michelsohn or Bär) that

$$\tau = i^m\, c(e_1)c(e_2)\cdots c(e_n) = \prod_{j=1}^{m} \underbrace{\big(i\, c(e_{2j-1})c(e_{2j})\big)}_{\tau_j}. \tag{4.114}$$

In two dimensions: $i\,c(e_1)c(e_2)1 = i\,c(e_1)e^2 = i\,e^1 \wedge e^2 = \tau 1$, and $i\,c(e_1)c(e_2)e^1 = i\,c(e_1)(e^2 \wedge e^1) = -i\,c(e_1)\mathrm{vol} = -i(-e^2) = ie^2 = \tau e^1$. Each τ_j involves only the plane P_j, the τ_j commute (they are products of an even number of c's from disjoint planes), and each squares to one. Under $\Lambda^*\mathbb{R}^n = \Lambda^* P_1 \otimes \cdots \otimes \Lambda^* P_m$, τ_j acts on the j-th factor only. The $+1$ eigenspace of the product consists of tensor products with an even number of -1 factors. So, as virtual bundles,

$$\Lambda^+ - \Lambda^- = \bigotimes_{j=1}^{m} \big(\Lambda^+_{P_j} - \Lambda^-_{P_j}\big). \tag{4.115}$$

Step 2: one plane. By Example 4.72, $\Lambda^\pm_{P_j} = \mathbb{C}\cdot(1 \pm i\,\mathrm{vol}_j) \oplus \mathbb{C}\cdot(e^{2j-1} \pm ie^{2j})$. The first summand is rotation invariant: a trivial line. The second is a line on which a rotation of P_j by angle θ acts by $e^{\mp i\theta}$. In the curvature language of Section 4.9, $\mathrm{d}z_j = e^{2j-1} + ie^{2j}$ spans a line with Chern root $-x_j$ (it is dual to $\partial/\partial z_j$, which has root $+x_j$), and $\mathrm{d}\bar z_j$ a line with root $+x_j$. So

$$\mathrm{ch}\,\Lambda^+_{P_j} - \mathrm{ch}\,\Lambda^-_{P_j} = (1 + e^{-x_j}) - (1 + e^{x_j}) = e^{-x_j} - e^{x_j}.$$

Step 3: multiply. Since ch is multiplicative,

$$\mathrm{ch}\big(\Lambda^+ T^*X \otimes \mathbb{C}\big) - \mathrm{ch}\big(\Lambda^- T^*X \otimes \mathbb{C}\big) = \prod_{j=1}^{m} \big(e^{-x_j} - e^{x_j}\big). \tag{Nash 4.91}$$

Its lowest-order term is $\prod(-2x_j) = (-2)^m e(X)$: again divisible by the Euler class, as the recipe requires.

Step 4: the index formula. Insert (Nash 4.91) into (4.101), with $e = \prod x_j$ and $\mathrm{td}(TX_{\mathbb{C}}) = \prod_j \frac{x_j}{1-e^{-x_j}} \frac{-x_j}{1-e^{x_j}}$:

$$\begin{aligned}
\operatorname{index} \mathrm{d}_+ &\overset{(1)}{=} (-1)^m \int_X \prod_{j=1}^m \frac{e^{-x_j} - e^{x_j}}{x_j} \cdot \frac{x_j}{1-e^{-x_j}} \cdot \frac{-x_j}{1-e^{x_j}} \\
&\overset{(2)}{=} (-1)^m \int_X \prod_{j=1}^m \left(-x_j \frac{e^{x_j/2} + e^{-x_j/2}}{e^{x_j/2} - e^{-x_j/2}}\right) \\
&\overset{(3)}{=} \int_X \prod_{j=1}^m \frac{x_j\left(e^{x_j}+1\right)}{e^{x_j}-1} \;=\; \int_X \prod_{j=1}^m \frac{x_j \cosh(x_j/2)}{\sinh(x_j/2)} \\
&\overset{(4)}{=} 2^m \int_X \prod_{j=1}^m \frac{x_j/2}{\tanh(x_j/2)}.
\end{aligned} \tag{Nash 4.92}$$

(1) The index formula for complexes, $n/2 = m$.
(2) Write $a = e^{x/2} - e^{-x/2}$, $b = e^{x/2} + e^{-x/2}$. Then $e^{-x} - e^{x} = -ab$ and $(1-e^{-x})(1-e^{x}) = -a^2$, so each factor is $\frac{-ab}{x} \cdot \frac{-x^2}{-a^2} = -x\, b/a$.
(3) Pull out $(-1)^m$; multiply numerator and denominator by $e^{x/2}$; $b/a = \coth(x/2)$.
(4) $x \coth(x/2) = 2 \cdot \frac{x/2}{\tanh(x/2)}$, one factor 2 per root.

Key idea: The Hirzebruch signature theorem (Nash (4.93)–(4.95))

For a compact oriented manifold of dimension $n = 4k$,

$$\operatorname{Sign}(X) = \operatorname{index} \mathrm{d}_+ = 2^{n/2} \int_X \mathcal{L}(X) = \int_X L(X), \tag{4.116}$$

where

$$\mathcal{L} = \prod_j \frac{x_j/2}{\tanh(x_j/2)}, \qquad L = \prod_j \frac{x_j}{\tanh x_j}.$$

The number $L(X) := 2^{n/2}\mathcal{L}(X)[X]$ is the **L-genus**.

Two normalisations. Nash's $\mathcal{L}$ uses $x/2$; Hirzebruch's L uses x. They agree on the top-degree term after the factor $2^{n/2}$:

$$\begin{aligned}
2^m \Big[\prod_j \frac{x_j/2}{\tanh(x_j/2)}\Big]_{\deg 2m} &\overset{(1)}{=} 2^m \Big[\prod_j \frac{y_j}{\tanh y_j}\Big]_{\deg 2m}\Big|_{y=x/2} \\
&\overset{(2)}{=} 2^m\, 2^{-m} \Big[\prod_j \frac{x_j}{\tanh x_j}\Big]_{\deg 2m} = \big[L(X)\big]_{\deg 2m}.
\end{aligned}$$

(1) Substitute $y_j = x_j/2$.
(2) The top-degree part is a homogeneous polynomial of degree m in the roots (form degree $2m = n$), so rescaling every root by $\frac{1}{2}$ multiplies it by 2^{-m}.

The lower-degree terms differ. They do not matter here, but they do when $\mathcal{L}$ is multiplied by another class, as in the twisted signature operator of the next section; then one must use Nash's $2^{n/2}\mathcal{L}$.

4.14.6 The L-polynomials explicitly

Expand $x/\tanh x = 1 + \frac{x^2}{3} - \frac{x^4}{45} + \frac{2x^6}{945} - \cdots$ (this follows from $\coth x = \frac{1}{x} + \frac{x}{3} - \frac{x^3}{45} + \cdots$). Then, with $p_1 = \sum x_j^2$ and $p_2 = \sum_{i<j} x_i^2 x_j^2$,

$$\begin{aligned} L(X) &\overset{(1)}{=} \prod_j \left(1 + \tfrac{1}{3}x_j^2 - \tfrac{1}{45}x_j^4 + \cdots\right) \\ &\overset{(2)}{=} 1 + \tfrac{1}{3}\sum_j x_j^2 + \left[-\tfrac{1}{45}\sum_j x_j^4 + \tfrac{1}{9}\sum_{i<j} x_i^2 x_j^2\right] + \cdots \\ &\overset{(3)}{=} 1 + \tfrac{1}{3}p_1 + \tfrac{1}{45}(7p_2 - p_1^2) + \cdots . \end{aligned} \tag{4.117}$$

(1) Definition of L with the series of $x/\tanh x$.
(2) Collect form degrees 4 and 8.
(3) $\sum x_j^4 = p_1^2 - 2p_2$, so $-\frac{1}{45}(p_1^2 - 2p_2) + \frac{5}{45}p_2 = \frac{1}{45}(7p_2 - p_1^2)$.

The next term is $L_3 = \frac{1}{945}(62p_3 - 13p_2p_1 + 2p_1^3)$. In dimension 4 the signature theorem reads, using $p_1 = -\frac{1}{8\pi^2}\operatorname{tr}(R \wedge R)$ from Section 4.9,

$$\begin{aligned} \operatorname{Sign}(X) &\overset{(1)}{=} \frac{1}{3}\int_X p_1 \overset{(2)}{=} -\frac{1}{24\pi^2}\int_X \operatorname{tr}\big(R \wedge R\big) \\ &\overset{(3)}{=} \frac{1}{96\pi^2}\int_X \epsilon^{cdef}\, R_{abcd}\, R^{ab}{}_{ef}\ \mathrm{vol}. \end{aligned} \tag{4.118}$$

(1) The degree-4 part of L is $\frac{1}{3}p_1$.
(2) $p_1 = -\frac{1}{8\pi^2}\operatorname{tr}(R \wedge R)$.
(3) Insert $R^a{}_b = \frac{1}{2}R^a{}_{bcd}\, e^c \wedge e^d$, so $\operatorname{tr}(R \wedge R) = R^a{}_b \wedge R^b{}_a = \frac{1}{4}R^a{}_{bcd}R^b{}_{aef}\,\epsilon^{cdef}\mathrm{vol}$; in an orthonormal frame $R^b{}_{aef} = -R_{abef}$, which turns $-\frac{1}{24\pi^2}\cdot\frac{1}{4}$ into $+\frac{1}{96\pi^2}$.

The last form is the "Pontryagin density" $R\tilde{R}$ of gravity, the gravitational analogue of $F\tilde{F}$ in the axial anomaly.

Worked example 4.74: Checking $\operatorname{Sign} = p_1/3$ in four dimensions

$\mathbb{CP}^2$: $\int p_1 = 3$ (Example 4.50), so Sign $= 1$, matching $Q = (1)$.
S^4, $S^2 \times S^2$, T^4: $p_1 = 0$ (for S^4 see Example 4.51; $S^2 \times S^2$ has $p = p(S^2)p(S^2) = 1$; T^4 is flat). All have Sign $= 0$, matching $Q = 0, H, 3H$.
K3: $c_1 = 0$ and $c_2 = 24$, so $p_1 = c_1^2 - 2c_2 = -48$ (the formula of Example 4.50) and Sign $= -48/3 = -16$, matching $Q = 3H \oplus 2(-E_8)$.
A consequence: for every closed oriented 4-manifold, $\int p_1$ is divisible by 3. Nothing in the definition $p_1 = -\frac{1}{8\pi^2}\operatorname{tr} R \wedge R$ suggests this.

Worked example 4.75: Eight dimensions: $\mathbb{CP}^4$ and $\mathbb{H}P^2$

$\mathbb{CP}^4$. With h the hyperplane class, $\int h^4 = 1$, the total Pontryagin class is $p = (1 + h^2)^5$ (Bär, Example 4.3.4): $p_1 = 5h^2$, $p_2 = 10h^4$. Then

$$\operatorname{Sign}(\mathbb{CP}^4) = \tfrac{1}{45}(7 \cdot 10 - 25) = \tfrac{45}{45} = 1,$$

matching $H^4(\mathbb{CP}^4) = \mathbb{Z}h^2$ with $\int h^2 \cdot h^2 = 1$.
Quaternionic projective plane $\mathbb{H}P^2$. Its cohomology is $\mathbb{Z}[u]/(u^3)$ with $\deg u = 4$, $\int u^2 = 1$,

and $p(\mathbb{H}P^2) = 1 + 2u + 7u^2$. So

$$\mathrm{Sign}(\mathbb{H}P^2) = \tfrac{1}{45}(7 \cdot 7 - 2^2) = \tfrac{45}{45} = 1.$$

Two quite different manifolds, and in both cases the 45 in the denominator is exactly cancelled. Hirzebruch's formula is how Milnor (1956) proved that certain 7-dimensional manifolds homeomorphic to S^7 are not diffeomorphic to it: a hypothetical smooth 8-manifold bounding them would have to have a non-integral $\int p_1^2$.

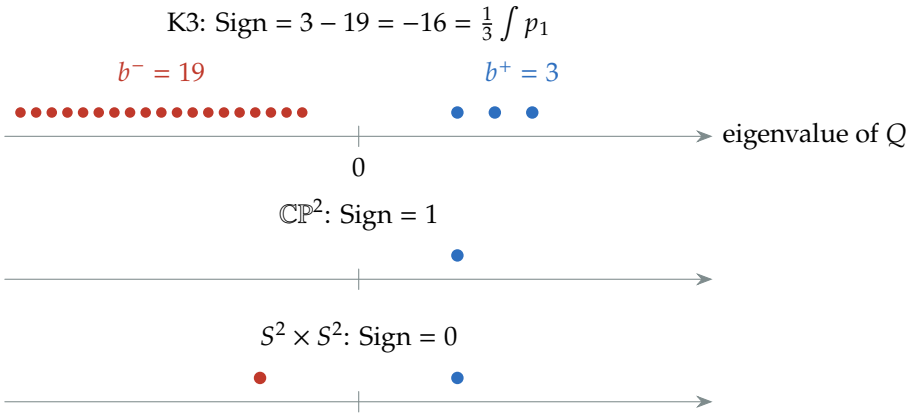

Figure 4.42: The signature as an eigenvalue count. Each dot is an eigenvalue of the intersection form on $H^2(X;\mathbb{R})$ (positions schematic; only the sign is invariant). The index theorem turns "blue dots minus red dots" into the curvature integral $\frac{1}{3}\int p_1 = -\frac{1}{24\pi^2}\int \mathrm{tr}\, R \wedge R$.

Physical picture: Self-dual forms and chiral fields

The self-dual harmonic 2-forms on a four-manifold are the zero modes of a chiral (self-dual) 2-form field; in six dimensions the analogous self-dual 3-forms appear in the M5-brane and in type IIB supergravity's 5-form in ten dimensions. The signature operator is the "Dirac operator" of such fields, and the L-polynomial is its anomaly polynomial. We will see in Section 4.16 that d_+ is literally the Dirac operator twisted by the spinor bundle, which is why $\mathcal{L}$ and $\hat{A}$ look so alike.

Watch out: Manifolds with boundary

The formula $\mathrm{Sign} = \int L$ is for *closed* manifolds. For a manifold with boundary the curvature integral is not an integer in general, and Atiyah–Patodi–Singer showed that the correction is a spectral invariant of the boundary, the η-invariant: $\mathrm{Sign}(X) = \int_X L - \eta(\partial X)$. This is the mathematics behind parity anomalies and the boundary states of topological insulators (Chapter 10).

Reading Nash (pp. 108–112, (4.74)–(4.95))

Nash defines the intersection form q (4.74), its signature (4.75), shows q is antisymmetric for l odd (4.76), and introduces $\tau = i^{p(p-1)+n/2}\star$ (4.77) with $\tau^2 = 1$ (4.78). (In (4.78) he writes the key step as $i^{\lambda(p)+\lambda(n-p)} = i^{2p}$; this is true mod 4, as we showed.) He defines $\Omega^{\pm}$ (4.79), notes $\tau \mathrm{d}_+ = -\mathrm{d}_+ \tau$ (we proved (4.113)), and writes the signature complex and symbol (4.80)–(4.82). The index is $h_+ - h_-$ (4.83)–(4.84); the bookkeeping (4.85)–(4.88) with I^p gives $\mathrm{index}\, \mathrm{d}_+ = \mathrm{Sign}(X)$ (4.89). Then (4.90)–(4.92) evaluate the index formula, (4.93) defines

the L-genus, and he remarks on the two normalisations. The theorem is (4.94)–(4.95). Note that in (4.79) Nash says "eigenvalues ∓ 1" while labelling the spaces $\Omega^{\pm}$; the labelling $\Omega^{\pm} = \{\tau = \pm 1\}$ is the one used throughout.

Recap

- Intersection form $q(u,v) = \int u \wedge v$ on $H^{n/2}$; symmetric for $n = 4k$; Sign $= b^+ - b^-$. Examples: $\mathbb{CP}^2$: (1); $S^2 \times S^2$: H; T^4: $3H$; K3: $3H \oplus 2(-E_8)$.
- $\tau = i^{p(p-1)+n/2}\star$ squares to 1 and anticommutes with $\mathrm{d} + \mathrm{d}^*$; $\mathrm{d}_+ : \Omega^+ \to \Omega^-$ is the signature operator.
- Paired degrees I^p cancel; the middle degree gives $\operatorname{index} \mathrm{d}_+ = b^+ - b^-$, with $\tau = \star$ there (self-dual vs anti-self-dual).
- $\operatorname{ch}\Lambda^+ - \operatorname{ch}\Lambda^- = \prod(e^{-x_j} - e^{x_j})$ (one 2-plane at a time), leading to Sign $= \int \prod \frac{x_j}{\tanh x_j}$.
- $L_1 = \frac{1}{3}p_1$, $L_2 = \frac{1}{45}(7p_2 - p_1^2)$; in 4D Sign $= -\frac{1}{24\pi^2}\int \operatorname{tr} R \wedge R$.

4.15 The spin complex, the Dirac operator and the $\hat{A}$-genus

The three complexes we have met so far act on differential forms. Forms are built out of the tangent bundle, so they exist on every manifold, and the operators d, d^*, $\bar{\partial}$ come for free. Nash's last example is different, and for a physicist it is the most important one. It is the operator that governs the electron: the **Dirac operator**. The question we want to answer is

How many zero modes does a massless fermion have on a compact curved space, and how many of each chirality?

The index theorem answers with a curvature integral, the $\hat{A}$-genus. On the way we have to face a problem that forms never posed: spinors are not built from the tangent bundle. A spinor changes sign under a rotation by 2π, and a manifold must carry extra structure, a *spin structure*, before spinor fields make sense on it. So the section has three parts: what a spin structure is and when it exists; the Dirac operator and its chiral halves; and the characteristic-class computation, which ends in some of the most striking consequences of the whole theory, such as the fact that $\mathbb{CP}^2$ admits no spinors and Rokhlin's theorem that the signature of a smooth spin 4-manifold is divisible by 16.

Throughout this section X is compact, oriented, Riemannian, of dimension n, and from Section 4.15.3 on $n = 2m$ is even.

4.15.1 Why spinors need more than a metric

A vector at a point transforms under a rotation $R \in \mathrm{SO}(n)$. A spinor transforms under an element g of the group $\mathrm{Spin}(n)$, which maps onto $\mathrm{SO}(n)$ two-to-one: g and $-g$ give the same rotation. The simplest case shows everything.

The two-dimensional case, explicitly. Take two anticommuting matrices with Nash's normalisation $\gamma_a^2 = -1$ (we write them down in Section 4.15.3; all we need now is $\gamma_1\gamma_2 = -\gamma_2\gamma_1$

and $\gamma_1^2 = \gamma_2^2 = -1$). Then $(\gamma_1\gamma_2)^2 = -\gamma_1^2\gamma_2^2 = -1$, so $\gamma_1\gamma_2$ behaves like the imaginary unit and

$$g_\theta := \exp\Big(\tfrac{\theta}{2}\gamma_1\gamma_2\Big) = \cos\tfrac{\theta}{2} + \sin\tfrac{\theta}{2}\,\gamma_1\gamma_2.$$

Let us see which rotation g_θ produces when it acts on "vectors" $v = v^1\gamma_1 + v^2\gamma_2$ by conjugation, $v \mapsto g_\theta v g_\theta^{-1}$:

$$\begin{aligned} g_\theta\,\gamma_1\,g_\theta^{-1} &\overset{(1)}{=} \gamma_1\,g_\theta^{-1}g_\theta^{-1} = \gamma_1\,g_{-2\theta} \\ &\overset{(2)}{=} \gamma_1\big(\cos\theta - \sin\theta\,\gamma_1\gamma_2\big) \\ &\overset{(3)}{=} \cos\theta\,\gamma_1 + \sin\theta\,\gamma_2. \end{aligned} \tag{4.119}$$

(1) $\gamma_1\gamma_2$ anticommutes with γ_1 ($\gamma_1\gamma_1\gamma_2 = -\gamma_1\gamma_2\gamma_1$), so moving γ_1 to the left through g_θ flips the sign of the sin term: $g_\theta\gamma_1 = \gamma_1 g_{-\theta} = \gamma_1 g_\theta^{-1}$.
(2) $g_{-\theta}g_{-\theta} = g_{-2\theta}$, and the half-angle formula with $\theta/2 \to -\theta$.
(3) $\gamma_1\gamma_1\gamma_2 = -\gamma_2$, so $-\sin\theta\,\gamma_1\gamma_1\gamma_2 = +\sin\theta\,\gamma_2$.

The same computation gives $g_\theta\gamma_2 g_\theta^{-1} = \cos\theta\,\gamma_2 - \sin\theta\,\gamma_1$. So g_θ rotates the plane by the angle θ, while it itself depends on $\theta/2$. Going once round, $\theta = 2\pi$, the rotation is the identity but

$$g_{2\pi} = \cos\pi + \sin\pi\,\gamma_1\gamma_2 = -1.$$

Only $\theta = 4\pi$ brings g back to $+1$. The group $\mathrm{Spin}(2) = \{g_\theta\}$ is a circle that wraps twice around the circle $\mathrm{SO}(2) = \{R_\theta\}$ (Figure 4.43).

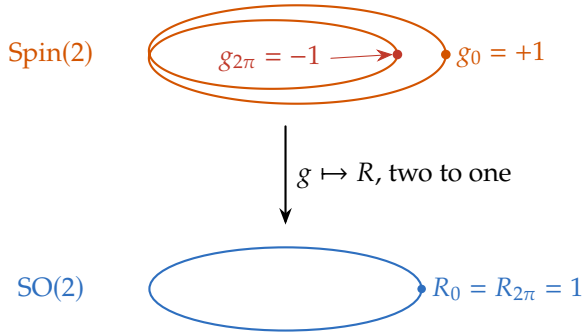

Figure 4.43: $\mathrm{Spin}(2) \to \mathrm{SO}(2)$ is the connected double cover of a circle. Follow the orange curve once round ($\theta : 0 \to 2\pi$): the rotation below comes back to the identity, but the spin element arrives at -1, on the other sheet. A second turn is needed to return to $+1$.

In three dimensions the same thing is the familiar statement $\mathrm{Spin}(3) = \mathrm{SU}(2)$: a 2×2 unitary matrix U rotates the vector $\vec{v}$ by $U(\vec{v}\cdot\vec{\sigma})U^\dagger = (R\vec{v})\cdot\vec{\sigma}$, and $\pm U$ give the same R. In four Euclidean dimensions $\mathrm{Spin}(4) = \mathrm{SU}(2)\times\mathrm{SU}(2)$, which we will see explicitly below. All of this is developed in Chapter T4; here we only need the two-to-one map and the sign $g_{2\pi} = -1$.

Physical picture: What the sign means physically

A spinor field is a quantity whose sign is flipped by a 2π rotation of the frame. On a manifold we describe fields in local orthonormal frames, and neighbouring frames are related by rotations. To define a spinor field globally we must lift *every* such frame rotation from $\mathrm{SO}(n)$ to $\mathrm{Spin}(n)$, consistently. Each lift is ambiguous by a sign, and the question is whether the signs can be chosen consistently round every loop and over every triple overlap. Sometimes they cannot.

4.15.2 Spin structures and the Stiefel–Whitney classes

Cover X by charts U_i, each with an orthonormal frame of TX. On an overlap $U_i \cap U_j$ the two frames differ by a rotation-or-reflection $g_{ij}(x) \in \mathrm{O}(n)$; these are the **transition functions** of the tangent bundle, and they satisfy $g_{ij}g_{jk}g_{ki} = 1$ on triple overlaps.

Working definition 4.37 (Orientation, spin structure, w_1, w_2)

Orientation. The signs $\det g_{ij} = \pm 1$ form a $\mathbb{Z}_2$-valued Čech 1-cocycle [a sign on each overlap, with product $+1$ around every triple overlap]. Its class [two such sign assignments count as the same if they differ by flipping the frames on some charts] is the **first Stiefel–Whitney class** $w_1(X) \in H^1(X;\mathbb{Z}_2)$. X is orientable iff we can flip frames so that all $\det g_{ij} = +1$, iff $w_1(X) = 0$. Then $g_{ij} \in \mathrm{SO}(n)$.
Spin structure. Choose, for every overlap, one of the two lifts [$\mathrm{Spin}(n) \to \mathrm{SO}(n)$ is two-to-one, so each g_{ij} has exactly two preimages $\pm\tilde g_{ij}$] $\tilde g_{ij} \in \mathrm{Spin}(n)$ of $g_{ij} \in \mathrm{SO}(n)$, with $\tilde g_{ji} = \tilde g_{ij}^{-1}$. On a triple overlap $\tilde g_{ij}\tilde g_{jk}\tilde g_{ki}$ lies over $g_{ij}g_{jk}g_{ki} = 1$, so it is a sign:

$$\tilde g_{ij}\tilde g_{jk}\tilde g_{ki} = \varepsilon_{ijk} \in \{\pm 1\}.$$

The signs ε_{ijk} form a Čech 2-cocycle whose class is the **second Stiefel–Whitney class** $w_2(X) \in H^2(X;\mathbb{Z}_2)$. If $w_2(X) = 0$ we can re-choose the lifts so that all $\varepsilon_{ijk} = +1$. Such a consistent choice of lifts (up to the obvious equivalence [changing $\tilde g_{ij}$ to $\eta_i\tilde g_{ij}\eta_j$, with one sign $\eta_i = \pm 1$ per chart]) is a **spin structure**, and X with a spin structure is a **spin manifold**.
Test in practice: for a complex manifold, $w_2 = c_1 \bmod 2$; for a simply connected 4-manifold, $w_2 = 0$ iff the intersection form is even [$q(a,a)$ is even for every integral class a] (see Section 4.15.9).

This is Nash's (4.96):

$$w_1(X) = 0 \iff X \text{ orientable}, \qquad w_2(X) = 0 \iff \text{spinors are globally defined on } X. \tag{Nash 4.96}$$

How many spin structures? Suppose one spin structure $\{\tilde g_{ij}\}$ has been found. Any other one is $\{\eta_{ij}\tilde g_{ij}\}$ with signs $\eta_{ij} = \pm 1$, and the cocycle condition for the new lifts says $\eta_{ij}\eta_{jk}\eta_{ki} = 1$: η is a $\mathbb{Z}_2$ 1-cocycle. Changing the lift in one chart by a sign (which is a mere relabelling) changes η by a coboundary. So the spin structures are in one-to-one correspondence with $H^1(X;\mathbb{Z}_2)$, once a reference one is chosen. A simply connected manifold (such as S^n or $\mathbb{CP}^n$) has $H^1(X;\mathbb{Z}_2) = 0$, hence at most one spin structure.

Watch out: A torsor, not a group

Nash says that each spin structure "determines an element of $H^1(X;\mathbb{Z}_2)$". More precisely the *difference* of two spin structures is an element of $H^1(X;\mathbb{Z}_2)$. There is no preferred "zero" spin structure in general, so the set of spin structures is a copy of $H^1(X;\mathbb{Z}_2)$ with the origin forgotten (a torsor). On the circle, for example, the two spin structures are genuinely different (one bounds a disc, one does not; see below), and neither is "the trivial one" in any invariant sense.

Worked example 4.76: Line bundles on S^2, and why TS^2 is spin

Cover S^2 by a northern and a southern disc overlapping in a band around the equator, with angular coordinate ϕ. An oriented real 2-plane bundle (equivalently a complex line

bundle L) is specified by one transition function on the band, a rotation

$$g_{NS}(\phi) = R_{d\phi}, \qquad d \in \mathbb{Z},$$

and the integer d is the degree, $d = \int c_1(L)$. For the tangent bundle $d = 2$ (Example 4.49): the frame "∂_x, ∂_y" of the northern chart turns twice relative to that of the southern chart as we go once round the equator.
A lift to Spin(2) must be a continuous function $\tilde{g}_{NS}(\phi)$ on the band with $\tilde{g}_{NS} \mapsto R_{d\phi}$. By (4.119), the lift of R_α is $\pm g_\alpha = \pm\exp(\frac{\alpha}{2}\gamma_1\gamma_2)$, so the only candidates are $\pm g_{d\phi}$. Following ϕ once round the band:

$$\begin{aligned} g_{d(\phi+2\pi)} &\overset{(1)}{=} \exp\left(\tfrac{d\phi}{2}\gamma_1\gamma_2\right)\exp\left(d\pi\gamma_1\gamma_2\right) \\ &\overset{(2)}{=} (-1)^d\, g_{d\phi}. \end{aligned}$$

(1) $\gamma_1\gamma_2$ commutes with itself, so the exponential of a sum is the product of exponentials.
(2) $\exp(d\pi\gamma_1\gamma_2) = \cos(d\pi) + \sin(d\pi)\gamma_1\gamma_2 = (-1)^d$.

So the lift is single-valued on the band iff d is even. With only two charts there are no triple overlaps, and this single-valuedness is the whole obstruction: $w_2(L) = d \bmod 2 = c_1(L) \bmod 2$. In particular TS^2 ($d = 2$) is spin, with the lift g_ϕ that turns *once* while the frames turn twice (Figure 4.44).

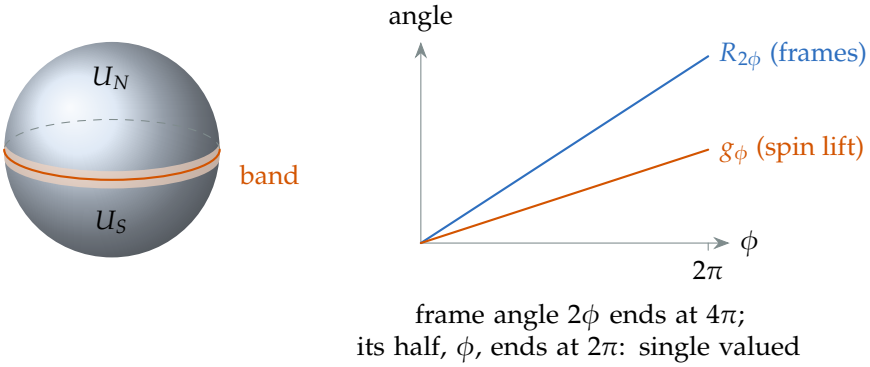

Figure 4.44: Lifting the transition function of TS^2. Across the equatorial band the northern frame is rotated by 2ϕ relative to the southern one (degree $d = 2$). The spin lift needs half that angle, ϕ, and returns to itself after $\phi \to \phi + 2\pi$. For a bundle of odd degree the half angle would end at an odd multiple of π, i.e. at -1: no spin lift.

Complex projective spaces. The computation above is the prototype of a general rule: for a complex manifold, $w_2(TX)$ is the reduction mod 2 of $c_1(TX)$. (Split TX into line bundles; each contributes its degree mod 2.) For $\mathbb{CP}^n$ the tangent bundle has $c(T\mathbb{CP}^n) = (1+h)^{n+1}$, with h the hyperplane class (the Euler sequence; the case $n = 2$ was used in Example 4.50), so

$$\begin{aligned} w_2(\mathbb{CP}^n) &\overset{(1)}{=} c_1(T\mathbb{CP}^n) \bmod 2 \\ &\overset{(2)}{=} (n+1)\,h \bmod 2, \end{aligned}$$

(1) The rule $w_2 = c_1 \bmod 2$ for complex manifolds.
(2) The degree-2 part of $(1+h)^{n+1}$ is $(n+1)h$.

and h mod 2 generates $H^2(\mathbb{CP}^n;\mathbb{Z}_2)$. So $\mathbb{CP}^n$ is spin iff n is odd, as Nash says: $\mathbb{CP}^1 = S^2$ and $\mathbb{CP}^3$ are spin, $\mathbb{CP}^2$ and $\mathbb{CP}^4$ are not. Being simply connected, the spin ones have exactly one spin structure. We shall see in Example 4.85 that the index theorem itself "knows" that $\mathbb{CP}^2$ is not spin.

Worked example 4.77: The two spin structures on a circle

For $X = S^1$ the frame is just the unit tangent vector, and there are no rotations to lift: $\mathrm{SO}(1) = \{1\}$ and $\mathrm{Spin}(1) = \{\pm 1\}$. A spin structure is then a double cover of the circle, and there are $\left|H^1(S^1;\mathbb{Z}_2)\right| = 2$ of them (Figure 4.45):

- the trivial cover (two disjoint circles): spinor fields are **periodic**, $\psi(\theta + 2\pi) = \psi(\theta)$. String theorists call this the **Ramond** sector;
- the connected cover (one circle of length 4π): spinor fields are **antiperiodic**, $\psi(\theta + 2\pi) = -\psi(\theta)$, the **Neveu–Schwarz** sector. Fermions at finite temperature live here: the Euclidean time circle carries antiperiodic fermions.

Which one extends over the disc D^2 whose boundary is the circle? Take a constant spinor ψ_0 on the flat disc, in the constant frame (∂_x, ∂_y). On the boundary circle the natural frame is the tangent frame $(\partial_r, \partial_\theta/r)$, rotated by the angle θ relative to (∂_x, ∂_y). Re-expressed in the rotating frame the same spinor has components $g_{-\theta}\psi_0$, and $g_{-(\theta+2\pi)} = -g_{-\theta}$. So the spin structure that bounds the disc is the *antiperiodic* one; the periodic one does not bound. On a torus $T^2 = S^1 \times S^1$ there are $2 \times 2 = 4$ spin structures, labelled by periodic (P) or antiperiodic (A) in each direction; on a surface of genus g there are 2^{2g}.

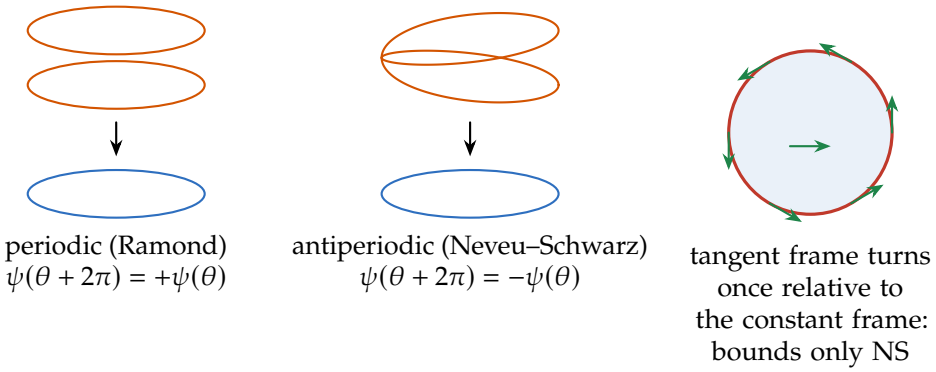

Figure 4.45: The two spin structures on S^1 are the two double covers of the circle (blue). Spinor fields are functions on the cover that change sign under the deck transformation. Right: along the boundary of a disc the tangent frame (green) makes one full turn relative to a constant frame, so the spin structure inherited from the disc is the antiperiodic one.

4.15.3 Spinors: the representation and the gamma matrices

From now on $n = 2m$ is even. Nash (4.97)–(4.99) collects the facts about the spin representation. We state them and then exhibit them.

Working definition 4.38 (Gamma matrices, chirality, Weyl spinors)

The **gamma matrices** are $N \times N$ complex matrices $\gamma_1, \dots, \gamma_n$, $N = 2^{n/2}$, with (Nash's convention, Euclidean)

$$\gamma_a\gamma_b + \gamma_b\gamma_a = \{\gamma_a, \gamma_b\} = -2\delta_{ab}\, I, \qquad \gamma_5 := i^{n(n+1)/2}\gamma_1\gamma_2\cdots\gamma_n. \tag{Nash 4.99}$$

They can be chosen anti-Hermitian, $\gamma_a^\dagger = -\gamma_a$. The **chirality operator** γ_5 satisfies $\gamma_5^2 = 1$ and $\{\gamma_5, \gamma_a\} = 0$. The space of spinors $S = \mathbb{C}^N$ splits into the ± 1 eigenspaces of γ_5, the **Weyl** or **chiral spinors**:

$$S = S^+ \oplus S^-, \qquad \dim S = 2^{n/2}, \qquad \dim S^\pm = 2^{n/2-1}. \tag{Nash 4.97}$$

For odd n one has $N = 2^{(n-1)/2}$ and no chirality splitting. *Formally:* S is the unique irreducible module [no proper nonzero subspace is mapped into itself by all γ_a] of the complex Clifford algebra [polynomials in the γ_a, with only the anticommutation rule imposed] $\mathrm{Cl}_n \otimes \mathbb{C}$; restricted to $\mathrm{Spin}(n) \subset \mathrm{Cl}_n$ it splits into the two inequivalent half-spin representations $S^\pm$ [$\mathrm{Spin}(n)$ is generated by the products $\gamma_a\gamma_b$, which commute with γ_5, so it maps S^+ and S^- to themselves].

Physicists usually take $\{\gamma_a, \gamma_b\} = +2\delta_{ab}$. The two conventions differ by $\gamma_a^{\text{phys}} = i\gamma_a^{\text{Nash}}$; nothing below depends on which is used, except that signs in intermediate formulas change.

Let us verify $\gamma_5^2 = 1$, because the odd-looking phase is chosen exactly for it:

$$\begin{aligned}
\gamma_5^2 &\overset{(1)}{=} i^{n(n+1)}\,(\gamma_1\cdots\gamma_n)(\gamma_1\cdots\gamma_n) \\
&\overset{(2)}{=} i^{n(n+1)}\,(-1)^{n(n-1)/2}\,\gamma_1^2\gamma_2^2\cdots\gamma_n^2 \\
&\overset{(3)}{=} (-1)^{n(n+1)/2}(-1)^{n(n-1)/2}(-1)^n \\
&\overset{(4)}{=} (-1)^{n^2+n} = 1.
\end{aligned}$$

(1) Definition of γ_5.
(2) Reverse the order of the second product to bring equal matrices next to each other. Reversing n anticommuting objects takes $n(n-1)/2$ transpositions, each costing a sign.
(3) $i^{n(n+1)} = (i^2)^{n(n+1)/2}$, and each $\gamma_a^2 = -1$.
(4) Add the exponents: $\frac{n(n+1)+n(n-1)}{2} + n = n^2 + n$, which is even.

And $\gamma_a\gamma_5 = -\gamma_5\gamma_a$ for n even: moving γ_a through the product $\gamma_1\cdots\gamma_n$ passes $n-1$ matrices that anticommute with it and one (itself) that commutes, a total sign $(-1)^{n-1} = -1$.

The chirality operator is a product over 2-planes. Group the product in pairs:

$$\begin{aligned}
\gamma_5 &\overset{(1)}{=} i^{m(2m+1)}\,(\gamma_1\gamma_2)(\gamma_3\gamma_4)\cdots(\gamma_{n-1}\gamma_n) \\
&\overset{(2)}{=} \prod_{j=1}^{m}\big(-i\,\gamma_{2j-1}\gamma_{2j}\big).
\end{aligned} \tag{4.120}$$

(1) $n(n+1)/2 = m(2m+1)$ for $n = 2m$.
(2) $i^{m(2m+1)} = (i^2)^{m^2} i^m = (-1)^m i^m = (-i)^m$, using $m^2 \equiv m \pmod 2$; distribute one factor $-i$ to each pair.

Each factor $-i\gamma_{2j-1}\gamma_{2j}$ squares to 1 (since $(\gamma_{2j-1}\gamma_{2j})^2 = -1$), and factors for different planes commute. So chirality is the product of m independent two-dimensional chiralities. This observation is all we will need for the characteristic classes.

Worked example 4.78: Gamma matrices in two dimensions

Take

$$\gamma_1 = i\sigma_2 = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \qquad \gamma_2 = i\sigma_1 = \begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix}.$$

Then $\gamma_1^2 = -\sigma_2^2 = -1$, $\gamma_2^2 = -\sigma_1^2 = -1$, and $\{\gamma_1, \gamma_2\} = -\{\sigma_2, \sigma_1\} = 0$. For the chirality:

$$\begin{aligned} \gamma_5 &\overset{(1)}{=} i^3 \gamma_1\gamma_2 = -i\,(i\sigma_2)(i\sigma_1) \\ &\overset{(2)}{=} i\,\sigma_2\sigma_1 = i(-i\sigma_3) = \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \end{aligned}$$

(1) Nash's definition with $n = 2$: $i^{n(n+1)/2} = i^3 = -i$.
(2) $\sigma_2\sigma_1 = -i\sigma_3$.

So S^+ is the upper component and S^- the lower. The rotation generator is $\gamma_1\gamma_2 = i\gamma_5 = i\sigma_3$, hence

$$g_\theta = \exp\!\left(\tfrac{\theta}{2}\gamma_1\gamma_2\right) = \begin{pmatrix} e^{i\theta/2} & 0 \\ 0 & e^{-i\theta/2} \end{pmatrix}.$$

A rotation of the plane by θ multiplies a positive-chirality spinor by $e^{i\theta/2}$ and a negative-chirality one by $e^{-i\theta/2}$. The tangent plane viewed as a complex line ($e_1 \leftrightarrow 1$, $e_2 \leftrightarrow i$) is multiplied by $e^{i\theta}$. So S^+ is a "square root" of the tangent line, $S^+ \otimes S^+ \cong T$, and S^- is a square root of its dual. In the Chern-root language of Section 4.9: if x is the root of T, then $S^\pm$ have roots $\pm x/2$.

Worked example 4.79: Gamma matrices in four dimensions and $\mathrm{Spin}(4) = \mathrm{SU}(2) \times \mathrm{SU}(2)$

Let s_a, $a = 1, \dots, 4$, be the 2×2 matrices

$$s_1 = i\sigma_1, \quad s_2 = i\sigma_2, \quad s_3 = i\sigma_3, \quad s_4 = I,$$

which represent the quaternions $\mathbf{i}, \mathbf{j}, \mathbf{k}, 1$. Their Hermitian conjugates are $\bar{s}_a := s_a^\dagger$ (so $\bar{s}_k = -s_k$ for $k \le 3$ and $\bar{s}_4 = I$). The key identity is

$$s_a\bar{s}_b + s_b\bar{s}_a = 2\delta_{ab} I = \bar{s}_a s_b + \bar{s}_b s_a, \tag{4.121}$$

which is the quaternion statement $p\bar{q} + q\bar{p} = 2\langle p, q\rangle$; for example $s_1\bar{s}_2 + s_2\bar{s}_1 = -(i\sigma_1)(i\sigma_2) - (i\sigma_2)(i\sigma_1) = \{\sigma_1, \sigma_2\} = 0$ and $s_1\bar{s}_1 = \sigma_1^2 = I$. Define the 4×4 matrices

$$\gamma_a = \begin{pmatrix} 0 & s_a \\ -\bar{s}_a & 0 \end{pmatrix}.$$

Then

$$\begin{aligned} \{\gamma_a, \gamma_b\} &\overset{(1)}{=} \begin{pmatrix} -s_a\bar{s}_b - s_b\bar{s}_a & 0 \\ 0 & -\bar{s}_a s_b - \bar{s}_b s_a \end{pmatrix} \\ &\overset{(2)}{=} -2\delta_{ab}\, I_4. \end{aligned}$$

(1) Multiply the block matrices: the product of two off-diagonal blocks is block diagonal.

(2) The identity (4.121).

For the chirality ($n = 4$, $i^{10} = -1$):

$$\gamma_5 \overset{(1)}{=} -\gamma_1\gamma_2\gamma_3\gamma_4 = -\begin{pmatrix} s_1\bar{s}_2s_3\bar{s}_4 & 0 \\ 0 & \bar{s}_1s_2\bar{s}_3s_4 \end{pmatrix}$$
$$\overset{(2)}{=} -\begin{pmatrix} (i\sigma_1)(-i\sigma_2)(i\sigma_3) & 0 \\ 0 & (-i\sigma_1)(i\sigma_2)(-i\sigma_3) \end{pmatrix}$$
$$\overset{(3)}{=} -\begin{pmatrix} i\cdot i & 0 \\ 0 & -i\cdot i \end{pmatrix} = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}.$$

(1) $\gamma_1\gamma_2 = \mathrm{diag}(-s_1\bar{s}_2, -\bar{s}_1s_2)$ and similarly for $\gamma_3\gamma_4$; the two minus signs cancel.
(2) Insert the matrices; $s_4 = \bar{s}_4 = I$.
(3) $\sigma_1\sigma_2\sigma_3 = iI$; the prefactors are $i(-i)i = i$ and $(-i)i(-i) = -i$.

This is Nash's block form (4.101). The generators of rotations, $\gamma_a\gamma_b$ with $a \neq b$, are block diagonal: $\gamma_a\gamma_b = \mathrm{diag}(-s_a\bar{s}_b, -\bar{s}_as_b)$, and each block is a traceless anti-Hermitian 2×2 matrix, i.e. an element of $\mathfrak{su}(2)$. So Spin(4) acts on $S^+ = \mathbb{C}^2$ and $S^- = \mathbb{C}^2$ by two separate SU(2) matrices: $\mathrm{Spin}(4) = \mathrm{SU}(2)_+ \times \mathrm{SU}(2)_-$.

Which rotations act on which half? Take the self-dual combination $\gamma_1\gamma_2 + \gamma_3\gamma_4$ (it corresponds to the 2-form $e^1\wedge e^2 + e^3\wedge e^4 = \star(e^1\wedge e^2 + e^3\wedge e^4)$). On S^- it is $-\bar{s}_1s_2 - \bar{s}_3s_4 = -\sigma_1\sigma_2 + i\sigma_3 = -i\sigma_3 + i\sigma_3 = 0$. On S^+ it is $-s_1\bar{s}_2 - s_3\bar{s}_4 = -\sigma_1\sigma_2 - i\sigma_3 = -2i\sigma_3 \neq 0$. *Self-dual 2-forms act only on S^+, anti-self-dual ones only on S^-* (check $\gamma_1\gamma_2 - \gamma_3\gamma_4$ yourself). This is the spinor form of the splitting $\mathfrak{so}(4) = \mathfrak{su}(2)_+ \oplus \mathfrak{su}(2)_- \cong \Lambda^+ \oplus \Lambda^-$, and it will decide the chirality of instanton zero modes in Section 4.16.

Weights in general. Put the rotation by angles θ_j in the planes (e_{2j-1}, e_{2j}) together. Its spin lift is $\prod_j \exp(\frac{\theta_j}{2}\gamma_{2j-1}\gamma_{2j})$. By (4.120) we may diagonalise all the commuting operators $-i\gamma_{2j-1}\gamma_{2j}$ at once; their eigenvalues are signs $\varepsilon_j = \pm 1$, and on the joint eigenvector the lift acts by

$$\prod_j \exp\Big(\tfrac{\theta_j}{2}\, i\varepsilon_j\Big) = \exp\Big(\tfrac{i}{2}\sum_j \varepsilon_j\theta_j\Big), \qquad \gamma_5 = \prod_j \varepsilon_j.$$

There are $2^m = \dim S$ choices of signs, one per basis spinor, so

$$S \text{ has weights } \tfrac{1}{2}(\pm\theta_1 \pm \cdots \pm \theta_m); \qquad S^+ : \text{ an even number of } - \text{ signs}, \quad S^- : \text{ odd}. \tag{4.122}$$

(In two dimensions: S^+ has weight $+\theta/2$, S^- has $-\theta/2$, as in Example 4.78.)

The spinor bundles. On a spin manifold the frame bundle P of TX (a principal $\mathrm{SO}(n)$ bundle) has a double cover $\tilde{P}$ with group $\mathrm{Spin}(n)$; concretely $\tilde{P}$ is glued from the lifts $\tilde{g}_{ij}$. Nash defines

$$E^\pm = \tilde{P} \times_{\mathrm{Spin}(n)} S^\pm, \qquad E = E^+ \oplus E^-. \tag{Nash 4.98}$$

In words: a spinor field is, in each chart U_i, a column vector $\psi_i(x) \in \mathbb{C}^{2^m}$, and on overlaps $\psi_i = \tilde{g}_{ij}\psi_j$. The cocycle condition $\tilde{g}_{ij}\tilde{g}_{jk}\tilde{g}_{ki} = 1$ is exactly what makes this consistent. Since γ_5 commutes with every $\tilde{g}_{ij}$ (spin elements are even products of gammas), the splitting into $E^\pm$ is global.

4.15.4 The Dirac operator and the spin complex

To differentiate a spinor field we need a connection on E, and the metric provides one. Let $e_a = e_a^\mu\partial_\mu$ be a local orthonormal frame (the **vielbein** or **tetrad**), with dual coframe $e^a = e^a_\mu \mathrm{d}x^\mu$,

so that

$$e^a_\mu e^b_\nu \delta_{ab} = g_{\mu\nu}.$$

The Levi-Civita connection in this frame is a matrix of 1-forms $\omega^a{}_b = -\omega^b{}_a$, defined by $\nabla e_b = e_a\,\omega^a{}_b$, and determined by Cartan's first structure equation $de^a = -\omega^a{}_b \wedge e^b$ (Chapter T2). At each point $\omega_\mu = (\omega_\mu{}^a{}_b)$ is an infinitesimal rotation, an element of $\mathfrak{so}(n)$. To make it act on spinors we lift it to the Lie algebra of $\mathrm{Spin}(n)$.

Lifting an infinitesimal rotation. Let $A = (A^a{}_b)$ be an antisymmetric matrix, $Ae_b = e_a A^a{}_b$. We claim its lift is

$$\rho(A) = -\tfrac{1}{4} A^a{}_b\, \gamma_a \gamma_b \qquad \text{(sum over } a, b\text{)}. \tag{4.123}$$

Test it on the rotation of the (e_1, e_2) plane by the angle θ: $A^2{}_1 = \theta$, $A^1{}_2 = -\theta$. Then

$$\begin{aligned}\rho(A) &\overset{(1)}{=} -\tfrac{1}{4}\big(A^1{}_2\gamma_1\gamma_2 + A^2{}_1\gamma_2\gamma_1\big)\\ &\overset{(2)}{=} -\tfrac{1}{4}\big(-\theta\gamma_1\gamma_2 - \theta\gamma_1\gamma_2\big) = \tfrac{\theta}{2}\gamma_1\gamma_2,\end{aligned}$$

(1) Only the entries $A^1{}_2$ and $A^2{}_1$ are nonzero.
(2) $\gamma_2\gamma_1 = -\gamma_1\gamma_2$.

which is the generator of g_θ from Section 4.15.1, as required. (Equivalently: $[\rho(A), \gamma_c] = \gamma_a A^a{}_c$, the infinitesimal version of (4.119).)

Working definition 4.39 (Dirac operator)

The **spin connection** is $\nabla_\mu \psi = (\partial_\mu + \omega_\mu)\psi$ with $\omega_\mu = -\tfrac{1}{4}\omega_\mu{}^a{}_b \gamma_a \gamma_b$ [$\omega_\mu{}^a{}_b$ is the Levi-Civita connection written in the orthonormal frame e_a]. The **Dirac operator** is Clifford multiplication [contracting the free frame index with γ^a] composed with it:

$$\not{D} : \Gamma(X, E) \to \Gamma(X, E), \qquad \not{D} = \gamma^a e^\mu_a(x)\big(\partial_\mu + \omega_\mu\big), \tag{Nash 4.100}$$

where Latin indices are frame indices (raised and lowered with δ_{ab}, so $\gamma^a = \gamma_a$) and Greek indices are coordinate indices [E is the spinor bundle, with fibre $S = \mathbb{C}^N$, and $e_a = e^\mu_a \partial_\mu$ are the orthonormal frame vectors]. *To compute:* find e^a [the dual coframe, $e^a(e_b) = \delta^a_b$], solve $de^a = -\omega^a{}_b \wedge e^b$ for ω, insert.

In flat space with the constant frame, $\omega = 0$ and $\not{D} = \gamma^a \partial_a$. Squaring it recovers the Laplacian, which is the reason Dirac introduced it:

$$\begin{aligned}\not{D}^2 &\overset{(1)}{=} \gamma^a\gamma^b\partial_a\partial_b = \tfrac{1}{2}\{\gamma^a, \gamma^b\}\partial_a\partial_b\\ &\overset{(2)}{=} -\delta^{ab}\partial_a\partial_b = -\sum_a \partial_a^2.\end{aligned} \tag{4.124}$$

(1) $\partial_a\partial_b$ is symmetric in a, b, so only the symmetric part of $\gamma^a\gamma^b$ survives.
(2) Nash's Clifford relation (Nash 4.99).

With Nash's sign convention $\not{D}^2$ is the *positive* Laplacian, and $\not{D}$ is formally self-adjoint: γ^a and ∂_a are both anti-Hermitian, so their product is Hermitian.

The chiral Dirac operator. Since γ_5 anticommutes with every γ^a and commutes with ω_μ (an even product of gammas),

$$\not{D}\gamma_5 = -\gamma_5 \not{D}.$$

In the block form $\gamma_5 = \mathrm{diag}(I, -I)$ of Nash's (4.101) this means $\not{D}$ is block off-diagonal:

$$\not{D} = \begin{pmatrix} 0 & \not{D}^- \\ \not{D}^+ & 0 \end{pmatrix}, \qquad \not{D}^+ = \not{D}\,\tfrac{1+\gamma_5}{2} : \Gamma(E^+) \to \Gamma(E^-), \tag{4.125}$$

and $\not{D}^- : \Gamma(E^-) \to \Gamma(E^+)$. Nash writes $\not{\partial}$ for the chiral operator $\not{D}^+$ and calls the two-term complex

$$0 \longrightarrow \Gamma(X, E^+) \xrightarrow{\not{D}^+} \Gamma(X, E^-) \longrightarrow 0, \qquad 0 \longrightarrow \pi^* E^+ \xrightarrow{\sigma_1(\not{D}^+)} \pi^* E^- \longrightarrow 0 \tag{Nash 4.102}$$

the **spin complex** and its symbol complex.

Ellipticity, and why it needs Euclidean signature. The symbol is obtained by $\partial_\mu \to i p_\mu$ in the highest-order part (the connection term ω_μ is lower order and drops out):

$$\sigma_1(\not{D})(x, p) = i\gamma^a e_a^\mu p_\mu =: i\,\not{p}.$$

Its square is

$$\begin{aligned} (i\not{p})^2 &\overset{(1)}{=} -\gamma^a\gamma^b\, p_a p_b \\ &\overset{(2)}{=} \delta^{ab} p_a p_b = |p|^2 , \end{aligned}$$

(1) $i^2 = -1$; $p_a = e_a^\mu p_\mu$ are the frame components.
(2) Symmetrise and use (Nash 4.99), as in (4.124).

so $\sigma_1(\not{D})(x,p)^{-1} = i\not{p}/|p|^2$ exists for every $p \neq 0$: $\not{D}$, and hence each block $\not{D}^\pm$, is elliptic. In Lorentzian signature the same computation gives $p_0^2 - |\vec{p}|^2$, which vanishes on the light cone; there the symbol is not invertible and the operator is hyperbolic, not elliptic (Figure 4.46). The Dirac index is a Euclidean notion, which is why physicists meet it after a Wick rotation, in instanton and anomaly calculations.

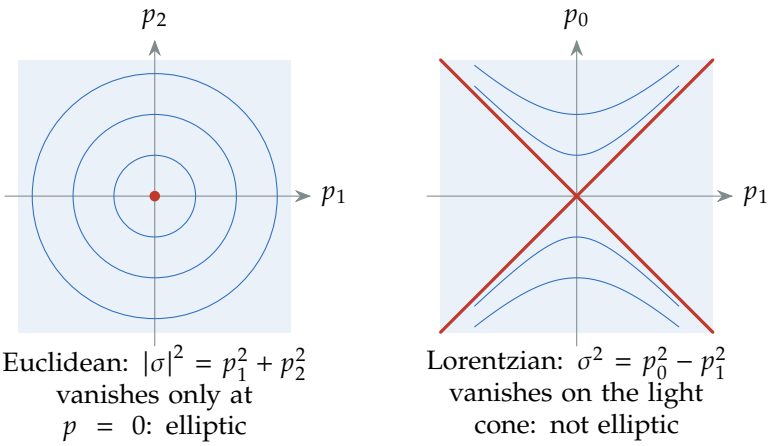

Figure 4.46: Where the Dirac symbol fails to be invertible (red). With Euclidean signature the level sets of σ^2 are circles and only the origin is bad, which is what ellipticity requires. With Lorentzian signature the whole light cone is bad; the Dirac equation then propagates waves along it instead of having a finite-dimensional space of zero modes.

The adjoint. Give E the Hermitian inner product $\langle \psi, \chi \rangle = \int_X \psi^\dagger \chi \,\mathrm{vol}$. The Dirac operator is formally self-adjoint (the spin connection is metric, and the flat-space argument above goes through with ∇ in place of ∂; see Bär §2.5). Taking the adjoint of the block matrix (4.125) then gives $(\not{D}^+)^* = \not{D}^-$. Nash writes $\not{\partial}^*$ for $\not{D}^-$ and notes that it is also the operator one gets by interchanging the roles of E^+ and E^-.

Worked example 4.80: The flat Dirac operator in two dimensions

With the matrices of Example 4.78 and $z = x^1 + ix^2$, $\partial_z = \tfrac{1}{2}(\partial_1 - i\partial_2)$, $\partial_{\bar z} = \tfrac{1}{2}(\partial_1 + i\partial_2)$:

$$\not{D} \overset{(1)}{=} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \partial_1 + \begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix} \partial_2 = \begin{pmatrix} 0 & \partial_1 + i\partial_2 \\ -\partial_1 + i\partial_2 & 0 \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} 0 & 2\partial_{\bar z} \\ -2\partial_z & 0 \end{pmatrix}.$$

(1) Insert γ_1, γ_2; $\omega = 0$ in the constant frame.
(2) $\partial_1 + i\partial_2 = 2\partial_{\bar z}$ and $-\partial_1 + i\partial_2 = -2\partial_z$.

So $\not{D}^+ = -2\partial_z$ and $\not{D}^- = 2\partial_{\bar z}$. The Dirac equation in two dimensions is the Cauchy–Riemann equation: negative-chirality zero modes are holomorphic functions, positive-chirality ones antiholomorphic. On the plane there are infinitely many of each (e.g. z^k); on a compact surface only finitely many survive, and counting them is the index problem. This is why the two-dimensional Dirac index and the Riemann–Roch theorem of Section 4.13 are the same subject.

Worked example 4.81: The Dirac operator on the round two-sphere

Use the metric $\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2$ and the coframe $e^1 = \mathrm{d}\theta$, $e^2 = \sin\theta\,\mathrm{d}\phi$. *Spin connection:*

$$\mathrm{d}e^2 \overset{(1)}{=} \cos\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi \overset{(2)}{=} -\omega^2{}_1 \wedge e^1 \quad \text{with} \quad \omega^2{}_1 = \cos\theta\,\mathrm{d}\phi,$$

(1) Differentiate $e^2 = \sin\theta\,\mathrm{d}\phi$.
(2) Cartan's equation $\mathrm{d}e^2 = -\omega^2{}_1 \wedge e^1$: $-\cos\theta\,\mathrm{d}\phi \wedge \mathrm{d}\theta = \cos\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$. The other equation, $\mathrm{d}e^1 = 0 = -\omega^1{}_2 \wedge e^2$, holds because $\omega^1{}_2 = -\cos\theta\,\mathrm{d}\phi$ is proportional to e^2.

Then by (4.123), only ω_ϕ is nonzero:

$$\omega_\phi \overset{(1)}{=} -\tfrac{1}{4}\big(\omega_\phi{}^1{}_2 \gamma_1\gamma_2 + \omega_\phi{}^2{}_1 \gamma_2\gamma_1\big) \overset{(2)}{=} -\tfrac{1}{4}\big(-\cos\theta\,\gamma_1\gamma_2 - \cos\theta\,\gamma_1\gamma_2\big) = \tfrac{1}{2}\cos\theta\,\gamma_1\gamma_2.$$

(1) The lift formula; only the $(1,2)$ and $(2,1)$ entries are nonzero.
(2) $\omega^1{}_2 = -\cos\theta\,\mathrm{d}\phi$, $\omega^2{}_1 = +\cos\theta\,\mathrm{d}\phi$, and $\gamma_2\gamma_1 = -\gamma_1\gamma_2$.

Dirac operator: with $e_1 = \partial_\theta$, $e_2 = \frac{1}{\sin\theta}\partial_\phi$,

$$\not{D} \overset{(1)}{=} \gamma_1\partial_\theta + \gamma_2 \frac{1}{\sin\theta}\Big(\partial_\phi + \tfrac{1}{2}\cos\theta\,\gamma_1\gamma_2\Big) \overset{(2)}{=} \gamma_1\Big(\partial_\theta + \tfrac{1}{2}\cot\theta\Big) + \gamma_2 \frac{1}{\sin\theta}\partial_\phi. \tag{4.126}$$

(1) Definition (Nash 4.100) with the frame above.
(2) $\gamma_2\gamma_1\gamma_2 = -\gamma_1\gamma_2\gamma_2 = \gamma_1$.

The spin connection has turned into the term $\frac{1}{2}\cot\theta$: the "spinor version" of the $\frac{1}{r}$ in the flat divergence $\partial_r + \frac{1}{r}$. In components (with Example 4.78)

$$\not{D}^+ = -\left(\partial_\theta + \tfrac{1}{2}\cot\theta\right) + \frac{i}{\sin\theta}\partial_\phi, \qquad \not{D}^- = \left(\partial_\theta + \tfrac{1}{2}\cot\theta\right) + \frac{i}{\sin\theta}\partial_\phi.$$

One subtlety: the frame (e_1, e_2) is singular at the poles, where it rotates once as we circle the pole. By the argument of Example 4.77, the spinor components in this frame are then *antiperiodic* in ϕ: $\psi \propto e^{ik\phi}$ with $k \in \mathbb{Z} + \frac{1}{2}$.

4.15.5 Harmonic spinors and the index

Working definition 4.40 (Harmonic spinors and the Dirac index)

A spinor with $\not{D}\psi = 0$ is a **harmonic spinor**, i.e. a zero mode of the massless Dirac operator. Write Ψ for the space of harmonic spinors. Since $\not{D}$ anticommutes with γ_5, γ_5 maps Ψ to itself, and Ψ splits by chirality:

$$\Psi = \Psi^+ \oplus \Psi^-, \qquad n^\pm := \dim \Psi^\pm. \tag{Nash 4.104}$$

Then

$$\operatorname{index} \not{D}^+ = \dim \operatorname{Ker} \not{D}^+ - \dim \operatorname{Ker}(\not{D}^+)^* = \dim \Psi^+ - \dim \Psi^- = n^+ - n^-.$$

(Nash 4.103–4.106)

[$\not{D}^+$ is $\not{D}$ acting on positive-chirality spinors. Its adjoint is $\not{D}^-$, since $\not{D}$ is self-adjoint, so $\operatorname{Ker}(\not{D}^+)^* = \Psi^-$] *Operationally:* count the zero modes of each chirality and subtract.

The middle step is Nash's (4.105): $\operatorname{Ker}\not{D}^+ = \Psi^+$ is clear, and $\operatorname{Ker}(\not{D}^+)^* = \operatorname{Ker}\not{D}^- = \Psi^-$ because $\not{D}\psi = 0$ for $\psi = \psi^+ + \psi^-$ means $\not{D}^+\psi^+ = 0$ and $\not{D}^-\psi^- = 0$ separately (they land in different chiralities). "Hodge theory" here is the observation that $\operatorname{Ker}\not{D} = \operatorname{Ker}\not{D}^2$ for the self-adjoint operator $\not{D}$: if $\not{D}^2\psi = 0$ then $\|\not{D}\psi\|^2 = \langle\psi, \not{D}^2\psi\rangle = 0$.

Physical picture: Why only the difference is topological

Nonzero modes of $\not{D}$ come in pairs: if $\not{D}\psi = \lambda\psi$ then $\not{D}(\gamma_5\psi) = -\lambda\gamma_5\psi$. Under a deformation of the metric, a pair $\pm\lambda$ can descend to zero and become one zero mode of each chirality, or a zero-mode pair can leave. Either way n^+ and n^- change by the same amount. So n^+ and n^- separately depend on the metric, while $n^+ - n^-$ does not. This is the McKean–Singer mechanism of the previous section, specialised to the Dirac operator.

The Lichnerowicz formula. There is one more piece of general information about harmonic spinors, and it is extremely useful. In curved space the square of the Dirac operator is not quite the Laplacian: a curvature term appears. The result (Lichnerowicz, 1963; Bär Theorem 2.5.11) is

$$\not{D}^2 = \nabla^*\nabla + \frac{R}{4}, \tag{4.127}$$

where R is the scalar curvature (normalised so that the unit S^n has $R = n(n-1)$) and $\nabla^*\nabla = -\sum_a \nabla_a\nabla_a$ + (connection terms) is the non-negative "rough Laplacian". Here is why. Write $\not{D}^2 = \gamma^a\gamma^b\nabla_a\nabla_b$ at a point where the frame is parallel, and split $\gamma^a\gamma^b$ into its symmetric

and antisymmetric parts:

$$\begin{aligned} \not{D}^2 &\overset{(1)}{=} \tfrac{1}{2}\{\gamma^a,\gamma^b\}\nabla_a\nabla_b + \tfrac{1}{2}\gamma^a\gamma^b[\nabla_a,\nabla_b] \\ &\overset{(2)}{=} -\nabla_a\nabla_a + \tfrac{1}{2}\gamma^a\gamma^b\,\rho\big(R(e_a,e_b)\big) \\ &\overset{(3)}{=} \nabla^*\nabla - \tfrac{1}{8}R_{ab}{}^{c}{}_{d}\,\gamma^a\gamma^b\gamma_c\gamma^d \overset{(4)}{=} \nabla^*\nabla + \tfrac{1}{4}R. \end{aligned}$$

(1) $\gamma^a\gamma^b = \frac{1}{2}\{\gamma^a,\gamma^b\} + \frac{1}{2}[\gamma^a,\gamma^b]$, and the antisymmetric part only sees the antisymmetric part $\frac{1}{2}[\nabla_a,\nabla_b]$ of $\nabla_a\nabla_b$.

(2) The Clifford relation for the first term. The commutator of covariant derivatives is the curvature, acting on spinors through the lift ρ of (4.123).

(3) At the chosen point $-\nabla_a\nabla_a = \nabla^*\nabla$; and $\rho(R(e_a,e_b)) = -\frac{1}{4}R_{ab}{}^{c}{}_{d}\gamma_c\gamma^d$.

(4) The product of four gammas contracted with the Riemann tensor collapses, using the first Bianchi identity $R_{a[bcd]} = 0$ to kill the totally antisymmetric part and the Clifford relation to contract the rest, to $-2R$. (This index gymnastics is done in full in Bär §2.5; we check the overall sign on S^2 just below.)

Key idea: Positive scalar curvature kills harmonic spinors

If $R > 0$ everywhere then, for any spinor ψ,

$$\big\|\not{D}\psi\big\|^2 = \|\nabla\psi\|^2 + \int_X \frac{R}{4}\,|\psi|^2\ \mathrm{vol} > 0 \quad (\psi \neq 0),$$

so $\operatorname{Ker}\not{D} = 0$: $n^+ = n^- = 0$ and $\operatorname{index}\not{D}^+ = 0$. Combined with the index theorem below: *a compact spin manifold with $\hat{A}(X) \neq 0$ admits no metric of positive scalar curvature.*

Worked example 4.82: No zero modes on S^2, by hand

Look for $\psi^+ = e^{ik\phi}f(\theta)$, $k \in \mathbb{Z} + \frac{1}{2}$, with $\not{D}^+\psi^+ = 0$. From Example 4.81:

$$\begin{aligned} 0 &\overset{(1)}{=} -\Big(f' + \tfrac{1}{2}\cot\theta\, f\Big) + \frac{i\cdot ik}{\sin\theta}f \\ &\overset{(2)}{=} -\Big(f' + \tfrac{1}{2}\cot\theta\, f + \frac{k}{\sin\theta}f\Big), \end{aligned}$$

(1) Insert ψ^+ into $\not{D}^+$; $\partial_\phi \to ik$.

(2) $i\cdot i = -1$; collect.

so $(\ln f)' = -\frac{1}{2}\cot\theta - \frac{k}{\sin\theta}$. Since $\int \cot\theta\,\mathrm{d}\theta = \ln\sin\theta$ and $\int \frac{\mathrm{d}\theta}{\sin\theta} = \ln\tan\frac{\theta}{2}$,

$$f(\theta) = (\sin\theta)^{-1/2}\big(\tan\tfrac{\theta}{2}\big)^{-k}.$$

Near the north pole $f \sim \theta^{-1/2-k}$, which is bounded only if $k \le -\frac{1}{2}$. Near the south pole, with $u = \pi - \theta$, $\sin\theta \approx u$ and $\tan\frac{\theta}{2} \approx \frac{2}{u}$, so $f \sim u^{-1/2+k}$, bounded only if $k \ge \frac{1}{2}$. No k does both: $\Psi^+ = 0$. The same computation for $\not{D}^-$ gives $f = (\sin\theta)^{-1/2}(\tan\frac{\theta}{2})^k$ and again no solution. So $n^+ = n^- = 0$.

This agrees with Lichnerowicz ($R = 2 > 0$ on the unit sphere). In fact the whole spectrum is known: the eigenvalues of $\not{D}$ on the unit S^2 are $\pm(\ell+1)$, $\ell = 0,1,2,\dots$, each with multiplicity $2(\ell+1)$ (Bär §2.5). The smallest eigenvalue of $\not{D}^2$ is 1, and the bound from (4.127) is $\not{D}^2 \ge R/4 = \frac{1}{2}$: consistent, and a check that the sign of the curvature term is right.

Worked example 4.83: The four spin structures on a flat torus

Let $T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$ with the flat metric and constant frame, so $\not{D}$ is the flat operator of Example 4.80 and $\not{D}^2 = -(\partial_1^2 + \partial_2^2)$. A spin structure is a choice of periodic or antiperiodic boundary condition in each direction. Plane waves $\psi = u\, e^{i(k_1 x^1 + k_2 x^2)}$ ($u \in \mathbb{C}^2$ constant) satisfy these conditions when

$$k_j \in \mathbb{Z}\ (\mathrm{P}) \qquad \text{or} \qquad k_j \in \mathbb{Z} + \tfrac{1}{2}\ (\mathrm{A}),$$

and they have $\not{D}^2\psi = (k_1^2 + k_2^2)\psi$. A zero mode needs $k = 0$, which is allowed only for the (P,P) structure. There the zero modes are the constant spinors: $u = (1,0)^T$ of positive chirality and $u = (0,1)^T$ of negative chirality. Hence

$$(\mathrm{P},\mathrm{P}):\ n^+ = n^- = 1; \qquad (\mathrm{P},\mathrm{A}),\ (\mathrm{A},\mathrm{P}),\ (\mathrm{A},\mathrm{A}):\ n^+ = n^- = 0.$$

In all four cases $\operatorname{index} \not{D}^+ = 0$, as it must be ($T^2$ is flat, and we will see that the two-dimensional index always vanishes). But the numbers $n^\pm$ themselves depend on the spin structure: they are not topological for the index theorem, only their difference is. (Their parity *is* a deformation invariant, the mod 2 index of the next part of this chapter: (P,P) is the "odd" spin structure.)

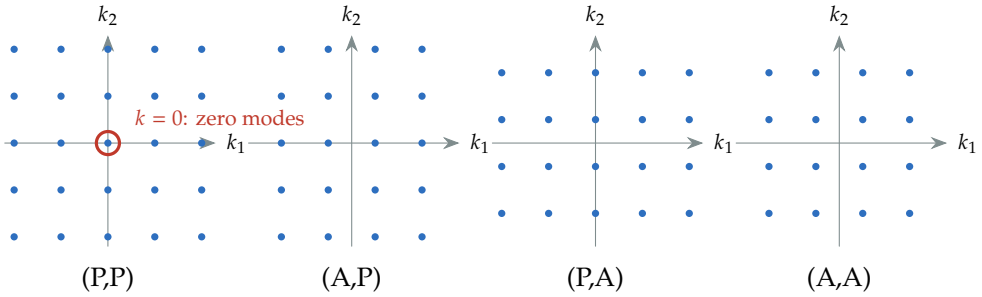

Figure 4.47: Allowed momenta for spinors on the square torus, for the four spin structures. $\not{D}^2$ has eigenvalue $|k|^2$, so zero modes sit at $k = 0$. Only the periodic–periodic structure contains the origin (red circle), and there the two constant spinors (one of each chirality) are the zero modes. The index $n^+ - n^-$ is zero in every case.

4.15.6 The Chern character of the spinor bundles

We now run the recipe (4.101) on the spin complex. The complex has two terms, $E^0 = E^+$ and $E^1 = E^-$, so the numerator we need is

$$\operatorname{ch}\big(\textstyle\sum_p (-1)^p E^p\big) = \operatorname{ch}(E^+) - \operatorname{ch}(E^-).$$

Nash quotes the answer (4.107) from Atiyah–Singer, saying it needs "some properties of the characters of the maximal torus of Spin(n)". Those properties are exactly the weights (4.122) that we have already found by hand. What remains is to turn weights into Chern roots.

Step 1: the curvature of the spinor bundle. The spinor bundle carries the connection $\nabla = \mathrm{d} + \omega$ with $\omega = \rho(\omega^a{}_b)$, the lift (4.123) of the Levi-Civita connection. Its curvature is the lift of the Riemann curvature, $\rho(R) = -\frac{1}{4} R^a{}_b \gamma_a \gamma_b$, because ρ is a Lie algebra homomorphism (it maps commutators of rotation generators to commutators of the $\gamma_a\gamma_b$). Now put R into the block

form (4.79): in the j-th plane $R^{2j-1}{}_{2j} = 2\pi x_j$ and $R^{2j}{}_{2j-1} = -2\pi x_j$, all other entries zero. Then

$$\begin{aligned}\rho(R) &\overset{(1)}{=} -\tfrac{1}{4}\sum_{j=1}^{m}\Big(R^{2j-1}{}_{2j}\,\gamma_{2j-1}\gamma_{2j} + R^{2j}{}_{2j-1}\,\gamma_{2j}\gamma_{2j-1}\Big)\\ &\overset{(2)}{=} -\tfrac{1}{4}\sum_{j=1}^{m}\big(2\pi x_j + 2\pi x_j\big)\gamma_{2j-1}\gamma_{2j} = -\pi\sum_{j=1}^{m} x_j\,\gamma_{2j-1}\gamma_{2j}\\ &\overset{(3)}{=} -i\pi\sum_{j=1}^{m} x_j\,\big(-i\gamma_{2j-1}\gamma_{2j}\big) = -i\pi\sum_{j=1}^{m}\varepsilon_j x_j \quad \text{on the joint eigenvector.}\end{aligned} \tag{4.128}$$

(1) The lift formula, keeping only the nonzero entries of the block matrix.
(2) $\gamma_{2j}\gamma_{2j-1} = -\gamma_{2j-1}\gamma_{2j}$ and $R^{2j}{}_{2j-1} = -2\pi x_j$, so both terms contribute $2\pi x_j\,\gamma_{2j-1}\gamma_{2j}$.
(3) Write $\gamma_{2j-1}\gamma_{2j} = i\,(-i\gamma_{2j-1}\gamma_{2j})$ and replace the commuting operators $-i\gamma_{2j-1}\gamma_{2j}$ by their eigenvalues $\varepsilon_j = \pm 1$, as in (4.122).

The Chern roots of a bundle are the eigenvalues of $\frac{i}{2\pi}\times$(curvature) (Section 4.9). So the Chern root belonging to the sign choice $\varepsilon = (\varepsilon_1, \dots, \varepsilon_m)$ is

$$\frac{i}{2\pi}\big(-i\pi\textstyle\sum_j \varepsilon_j x_j\big) = \tfrac{1}{2}\big(\varepsilon_1 x_1 + \varepsilon_2 x_2 + \cdots + \varepsilon_m x_m\big). \tag{4.129}$$

The same normalisation applied to $TX_{\mathbb{C}}$ gives roots $\pm x_j$ (Section 4.9). So: *the spinor bundle has the "half" roots* $\frac{1}{2}(\pm x_1 \pm \cdots \pm x_m)$, the positive-chirality part E^+ taking the choices with $\prod_j \varepsilon_j = +1$.

Step 2: sum over the roots. Since ch of a bundle is the sum of e^{root} over its roots, and $\gamma_5 = \prod_j \varepsilon_j$ is $+1$ on E^+ and -1 on E^-,

$$\begin{aligned}\operatorname{ch}(E^+) - \operatorname{ch}(E^-) &\overset{(1)}{=} \sum_{\varepsilon\in\{\pm1\}^m}\Big(\prod_{j=1}^{m}\varepsilon_j\Big)\exp\Big(\tfrac{1}{2}\sum_{j=1}^{m}\varepsilon_j x_j\Big)\\ &\overset{(2)}{=} \sum_{\varepsilon_1=\pm1}\cdots\sum_{\varepsilon_m=\pm1}\prod_{j=1}^{m}\big(\varepsilon_j\, e^{\varepsilon_j x_j/2}\big)\\ &\overset{(3)}{=} \prod_{j=1}^{m}\Big(\sum_{\varepsilon_j=\pm1}\varepsilon_j\, e^{\varepsilon_j x_j/2}\Big) \;=\; \prod_{j=1}^{m}\big(e^{x_j/2} - e^{-x_j/2}\big).\end{aligned} \tag{Nash 4.107}$$

(1) Each root (4.129) contributes e^{root} to $\operatorname{ch}(E^+)$ if $\prod \varepsilon_j = +1$ and to $\operatorname{ch}(E^-)$ if $\prod \varepsilon_j = -1$; the factor $\prod \varepsilon_j$ supplies the relative minus sign.
(2) The exponential of a sum is a product of exponentials, and the sign $\prod \varepsilon_j$ is a product too, so the summand factorises over j.
(3) The signs ε_j are summed independently, so the sum of products is the product of sums (like $(a+b)(c+d) = ac + ad + bc + bd$ read backwards).

The lowest-order term of each factor is x_j, so the lowest-order term of the product is $x_1 \cdots x_m = e(X)$. The numerator is divisible by the Euler class, as the recipe needs (Section 4.11). This divisibility is ellipticity again: on the zero section of TX the symbol complex is not exact, and the non-exactness is measured by exactly one power of $e(X)$.

Worked example 4.84: Checking (4.107) in two and four dimensions

Two dimensions ($m = 1$). From Example 4.78, E^+ is a line bundle with root $+x/2$ and E^- has root $-x/2$. Directly, $\operatorname{ch} E^+ - \operatorname{ch} E^- = e^{x/2} - e^{-x/2} = x + \frac{x^3}{24} + \cdots$, and on a surface only the x survives: $\int_X (\operatorname{ch} E^+ - \operatorname{ch} E^-) = \int_X e(X) = \chi(X)$. For the round S^2, $E^\pm$ are line bundles of degree ± 1 ("square roots" of $T = \mathcal{O}(2)$ and of its dual), i.e. $E^+ \cong \mathcal{O}(1)$, $E^- \cong \mathcal{O}(-1)$, and $1 - (-1) = 2 = \chi(S^2)$.

Four dimensions ($m = 2$). The four sign choices give

$$E^+ : \ \pm\tfrac{1}{2}(x_1 + x_2), \qquad E^- : \ \pm\tfrac{1}{2}(x_1 - x_2).$$

This matches Example 4.79: E^+ is the spin-$\frac{1}{2}$ representation of $\mathrm{SU}(2)_+$, whose Cartan generator is the self-dual rotation $\gamma_1\gamma_2 + \gamma_3\gamma_4$ (angles $\theta_1 = \theta_2$), and E^- that of $\mathrm{SU}(2)_-$ ($\theta_1 = -\theta_2$). Then

$$\begin{aligned} \operatorname{ch} E^+ - \operatorname{ch} E^- &\overset{(1)}{=} 2\cosh\tfrac{x_1+x_2}{2} - 2\cosh\tfrac{x_1-x_2}{2} \\ &\overset{(2)}{=} 4\sinh\tfrac{x_1}{2}\sinh\tfrac{x_2}{2} = \left(e^{x_1/2} - e^{-x_1/2}\right)\left(e^{x_2/2} - e^{-x_2/2}\right). \end{aligned}$$

(1) $e^a + e^{-a} = 2\cosh a$ for each pair of opposite roots.

(2) The identity $\cosh(u+v) - \cosh(u-v) = 2\sinh u \sinh v$ with $u = x_1/2$, $v = x_2/2$; and $2\sinh u = e^u - e^{-u}$.

Expanding, $4\sinh\frac{x_1}{2}\sinh\frac{x_2}{2} = x_1x_2 + \frac{1}{24}x_1x_2(x_1^2 + x_2^2) + \cdots = e(X)\left(1 + \frac{p_1}{24} + \cdots\right)$. The bracket is $1/\hat{A}$ to this order; we will see in a moment that this is no accident.

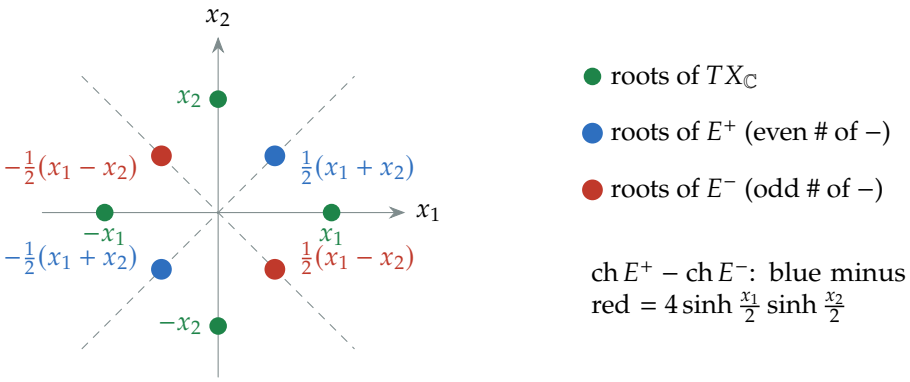

Figure 4.48: Chern roots in four dimensions, drawn as points in the (x_1, x_2) plane. The tangent bundle has the roots $\pm x_1, \pm x_2$ (green). The spinor roots sit at the half-way points $\frac{1}{2}(\pm x_1 \pm x_2)$: the positive-chirality ones on the diagonal (the self-dual direction), the negative ones on the anti-diagonal. Every spinor root is "half" a tangent root: this is the square root that forced us to introduce spin structures.

4.15.7 The index of the Dirac operator

Insert (Nash 4.107) into the index formula for complexes (4.101), with $e(X) = \prod_j x_j$ and $\operatorname{td}(TX_{\mathbb{C}}) = \prod_j \frac{x_j}{1-e^{-x_j}}\frac{-x_j}{1-e^{x_j}}$:

$$\operatorname{index} \not{D}^+ \overset{(1)}{=} (-1)^m \int_X \prod_{j=1}^{m} \frac{e^{x_j/2} - e^{-x_j/2}}{x_j} \cdot \frac{x_j}{1-e^{-x_j}} \cdot \frac{-x_j}{1-e^{x_j}}$$

$$\overset{(2)}{=} (-1)^m \int_X \prod_{j=1}^{m} \frac{e^{x_j/2} - e^{-x_j/2}}{x_j} \cdot \frac{x_j^2}{\left(e^{x_j/2} - e^{-x_j/2}\right)^2}$$

$$\overset{(3)}{=} (-1)^m \int_X \prod_{j=1}^{m} \frac{x_j}{e^{x_j/2} - e^{-x_j/2}}$$

$$\overset{(4)}{=} (-1)^m \int_X \prod_{j=1}^{m} \frac{x_j/2}{\sinh(x_j/2)}. \qquad \text{(Nash 4.108)}$$

(1) The recipe (4.101) with $n/2 = m$: numerator (Nash 4.107), one factor x_j of $e(X)$ per plane, and the Todd class of $TX_{\mathbb{C}}$ with roots $\pm x_j$.

(2) $(1 - e^{-x})(1 - e^{x}) = 2 - e^{x} - e^{-x} = -(e^{x/2} - e^{-x/2})^2$; with the numerator $-x^2$ the two minus signs cancel. (This is the step of (4.81).)

(3) Cancel one factor $e^{x_j/2} - e^{-x_j/2}$ and one factor x_j in each plane.

(4) $e^{x/2} - e^{-x/2} = 2\sinh(x/2)$; move the 2 under x_j.

Nash writes the two Todd factors in the other order; the product is the same.

There is a slicker way to see the same thing. Compare (Nash 4.107) with the definition of $\hat{A}$: per plane, $\frac{e^{x/2}-e^{-x/2}}{x} = \frac{\sinh(x/2)}{x/2}$, so

$$\operatorname{index} \not{D}^+ \overset{(1)}{=} (-1)^m \int_X \frac{\operatorname{ch} E^+ - \operatorname{ch} E^-}{e(X)} \operatorname{td}(TX_{\mathbb{C}})$$

$$\overset{(2)}{=} (-1)^m \int_X \frac{1}{\hat{A}(X)} \cdot \hat{A}(X)^2 = (-1)^m \int_X \hat{A}(X).$$

(1) The recipe.

(2) $\frac{\operatorname{ch} E^+ - \operatorname{ch} E^-}{e(X)} = \prod_j \frac{\sinh(x_j/2)}{x_j/2} = \hat{A}(X)^{-1}$, and $\operatorname{td}(TX_{\mathbb{C}}) = \hat{A}(X)^2$ by (4.81).

Physical picture: The Dirac operator is the square root of everything

The spinor roots are halves of the tangent roots, and correspondingly the spin complex is a "square root" of the de Rham complex: we will see in Section 4.16 that $\Lambda^* \otimes \mathbb{C} \cong E \otimes E$. At the level of characteristic classes, $\hat{A} = \sqrt{\operatorname{td}(TX_{\mathbb{C}})}$. The Dirac index density is the most basic of all the index densities; the others are obtained from it by twisting.

4.15.8 The $\hat{A}$-genus

Working definition 4.41 ($\hat{A}$-class and $\hat{A}$-genus (Nash (4.109)–(4.111)))

The **$\hat{A}$-class** ("A-roof" or "A-hat") of a Riemannian manifold is the multiplicative class [the product of $Q(x_j)$ over the x_j of the block form of $R/2\pi$] of the even power series [only even powers of x occur, so the result depends only on the x_j^2, i.e. on the p_i] $\frac{x/2}{\sinh(x/2)}$:

$$\hat{A}(X) = \prod_{j=1}^{n/2} \frac{x_j/2}{\sinh(x_j/2)} = \det{}^{1/2}\left(\frac{R/4\pi}{\sin(R/4\pi)}\right). \qquad \text{(Nash 4.109)}$$

The **$\hat{A}$-genus** is the number $\hat{A}(X) := \int_X \hat{A}(X)$ (Nash writes $\hat{A}[X]$). *To compute:* expand

$$\hat{A}(X) = 1 - \frac{1}{24}p_1 + \frac{1}{5760}(7p_1^2 - 4p_2) + \cdots \qquad \text{(Nash 4.110, corrected)}$$

and integrate the degree-n term.

Let us justify the curvature form of (Nash 4.109), which is what one actually integrates. The real antisymmetric matrix $R/4\pi$ has, in the block form, eigenvalues $\pm\frac{i}{2}x_j$ (each block $\left(\begin{smallmatrix}0 & x/2\\ -x/2 & 0\end{smallmatrix}\right)$ has eigenvalues $\pm ix/2$). Hence

$$\det{}^{1/2}\!\left(\frac{R/4\pi}{\sin(R/4\pi)}\right) \overset{(1)}{=} \Big[\prod_{j=1}^{m}\frac{ix_j/2}{\sin(ix_j/2)}\cdot\frac{-ix_j/2}{\sin(-ix_j/2)}\Big]^{1/2}$$
$$\overset{(2)}{=} \Big[\prod_{j=1}^{m}\Big(\frac{ix_j/2}{i\sinh(x_j/2)}\Big)^2\Big]^{1/2} = \prod_{j=1}^{m}\frac{x_j/2}{\sinh(x_j/2)}.$$

(1) The determinant of a function of a diagonalisable matrix is the product of the function over the eigenvalues; there are $2m$ eigenvalues $\pm ix_j/2$.
(2) $y/\sin y$ is even, so both members of a pair give the same factor; and $\sin(iu) = i\sinh u$.

The square root is needed because each plane contributes two eigenvalues but only one factor. Since $y/\sin y = 1 + \frac{y^2}{6} + \cdots$ is a power series in y^2, the determinant is a polynomial in $\operatorname{tr}(R^2), \operatorname{tr}(R^4), \ldots$, which is the Chern–Weil representative. Only even powers of R appear.

The expansion, by logarithms. The quickest route to (Nash 4.110, corrected) (the one Bär uses, [Bär §4.3]) goes through the logarithm, because the logarithm of a product over roots is a sum over roots, i.e. a symmetric power sum. First, with $t = x/2$,

$$\ln\frac{t}{\sinh t} \overset{(1)}{=} -\ln\Big(1+\frac{t^2}{6}+\frac{t^4}{120}+\cdots\Big)$$
$$\overset{(2)}{=} -\frac{t^2}{6}-\frac{t^4}{120}+\frac{1}{2}\Big(\frac{t^2}{6}\Big)^2+\cdots = -\frac{t^2}{6}+\frac{t^4}{180}-\cdots$$
$$\overset{(3)}{=} -\frac{x^2}{24}+\frac{x^4}{2880}-\cdots.$$

(1) $\sinh t/t = 1 + t^2/3! + t^4/5! + \cdots$.
(2) $\ln(1+u) = u - \frac{u^2}{2} + \cdots$ with $u = \frac{t^2}{6} + \frac{t^4}{120}$; and $-\frac{1}{120} + \frac{1}{72} = \frac{-3+5}{360} = \frac{1}{180}$.
(3) $t^2 = x^2/4$ and $t^4 = x^4/16$; $6\cdot 4 = 24$, $180\cdot 16 = 2880$.

Now sum over roots and exponentiate, using $\sum_j x_j^2 = p_1$ and $\sum_j x_j^4 = p_1^2 - 2p_2$:

$$\hat{A}(X) \overset{(1)}{=} \exp\Big(-\frac{1}{24}\sum_j x_j^2 + \frac{1}{2880}\sum_j x_j^4 - \cdots\Big)$$
$$\overset{(2)}{=} \exp\Big(-\frac{p_1}{24}+\frac{p_1^2-2p_2}{2880}-\cdots\Big)$$
$$\overset{(3)}{=} 1-\frac{p_1}{24}+\frac{p_1^2-2p_2}{2880}+\frac{1}{2}\Big(\frac{p_1}{24}\Big)^2+\cdots$$
$$\overset{(4)}{=} 1-\frac{p_1}{24}+\frac{2p_1^2-4p_2+5p_1^2}{5760}+\cdots = 1-\frac{p_1}{24}+\frac{7p_1^2-4p_2}{5760}+\cdots. \tag{4.130}$$

(1) $\hat{A} = \prod_j \frac{x_j/2}{\sinh(x_j/2)} = \exp\sum_j \ln\frac{x_j/2}{\sinh(x_j/2)}$.
(2) Newton's identity for the power sums in the variables x_j^2, whose elementary symmetric functions are $p_1, p_2, \ldots$.

(3) $e^u = 1 + u + \frac{1}{2}u^2 + \cdots$, keeping terms up to degree 8.
(4) Common denominator $5760 = 2 \cdot 2880 = 10 \cdot 576$: $\frac{1}{2880} = \frac{2}{5760}$ and $\frac{1}{2 \cdot 576} = \frac{5}{5760}$.

This agrees with the direct multiplication (4.83) of Section 4.9. The next term, for completeness, is $\hat{A}_3 = \frac{1}{967680}\left(-31p_1^3 + 44p_1p_2 - 16p_3\right)$.

Watch out: A misprint in Nash's (4.110)

Nash prints the degree-8 term as $\frac{1}{5760}(7p_1^2 - p_2)$. The correct coefficient of p_2 is -4, as the two independent derivations above show. The misprint matters: the quaternionic projective plane $\mathbb{H}P^2$ (a spin manifold, see Example 4.87) has $\int p_1^2 = 4$ and $\int p_2 = 7$, which gives $\frac{28-28}{5760} = 0$ with the correct formula, but the non-integer $\frac{28-7}{5760}$ with the misprinted one.

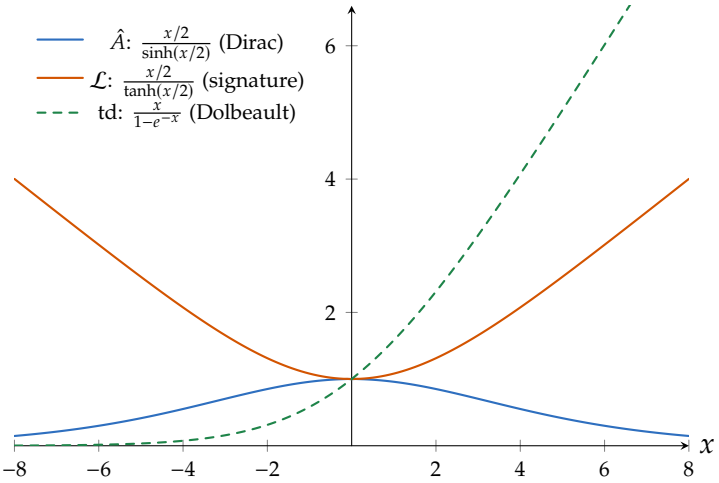

Figure 4.49: The generating functions of three genera, as ordinary functions of one variable. $\hat{A}$ and $\mathcal{L}$ are even (mirror-symmetric), so their classes involve only x_j^2, i.e. Pontryagin classes, and live in degrees $0, 4, 8, \ldots$: this is why the Dirac and signature indices can be nonzero only when $4 \mid n$. The Todd function is not even; its odd part $x/2$ is what lets c_1 enter the Riemann–Roch formula. All three equal 1 at $x = 0$, so each class starts with 1.

Why the index vanishes unless $4 \mid n$. The series $\frac{x/2}{\sinh(x/2)}$ is even, so $\hat{A}(X)$ is a polynomial in the x_j^2, i.e. in the Pontryagin classes, whose form degrees are multiples of 4 (Figure 4.49). If $n \equiv 2 \pmod 4$ the integrand has no component of degree n and the integral is zero. If $n \equiv 0 \pmod 4$ then $m = n/2$ is even and the sign $(-1)^m$ in (Nash 4.108) is $+1$. This gives Nash's final formula.

Key idea: The index theorem for the Dirac operator (Nash (4.111))

On a compact spin manifold X of even dimension n,

$$n^+ - n^- = \operatorname{index} \not{D}^+ = \begin{cases} \hat{A}(X) = \displaystyle\int_X \hat{A}(X), & n \equiv 0 \pmod 4, \\ 0, & n \equiv 2 \pmod 4. \end{cases} \qquad \text{(Nash 4.111)}$$

In particular the $\hat{A}$-genus of a spin manifold is an *integer*, although its definition has denominators $24, 5760, 967680, \ldots$

Dictionary: Low-dimensional forms of the Dirac index

n	index $\not{D}^+$	in terms of curvature / other invariants
2	0	(no 4-forms; $n^+ = n^-$ always)
4	$-\frac{1}{24}\int_X p_1$	$= \frac{1}{192\pi^2}\int_X \operatorname{tr}(R\wedge R) = -\frac{\operatorname{Sign}(X)}{8}$
6	0	
8	$\frac{1}{5760}\int_X (7p_1^2 - 4p_2)$	$= \frac{1}{896}\Big(\int_X p_1^2 - 4\operatorname{Sign}(X)\Big)$

The four-dimensional entry follows from $p_1 = -\frac{1}{8\pi^2}\operatorname{tr}(R\wedge R)$ (Section 4.9) and $\operatorname{Sign} = \frac{1}{3}\int p_1$ (Section 4.14):

$$\operatorname{index}\not{D}^+ \overset{(1)}{=} -\frac{1}{24}\int_X p_1 = -\frac{1}{24}\cdot\Big(-\frac{1}{8\pi^2}\Big)\int_X \operatorname{tr}(R\wedge R) = \frac{1}{192\pi^2}\int_X \operatorname{tr}(R\wedge R)$$
$$\overset{(2)}{=} -\frac{1}{24}\cdot 3\operatorname{Sign}(X) = -\frac{\operatorname{Sign}(X)}{8}.$$

(1) The degree-4 term of $\hat{A}$, and the Chern–Weil form of p_1.
(2) The signature theorem in dimension 4, $\int p_1 = 3\operatorname{Sign}(X)$.

For the eight-dimensional entry, eliminate p_2 with the signature theorem $\operatorname{Sign} = \frac{1}{45}\int(7p_2 - p_1^2)$, i.e. $7\int p_2 = 45\operatorname{Sign} + \int p_1^2$:

$$5760\,\hat{A}(X) \overset{(1)}{=} 7\int p_1^2 - \frac{4}{7}\Big(45\operatorname{Sign} + \int p_1^2\Big)$$
$$\overset{(2)}{=} \frac{45}{7}\int p_1^2 - \frac{180}{7}\operatorname{Sign} = \frac{45}{7}\Big(\int p_1^2 - 4\operatorname{Sign}\Big),$$

(1) Substitute $\int p_2 = \frac{1}{7}(45\operatorname{Sign} + \int p_1^2)$.
(2) $7 - \frac{4}{7} = \frac{45}{7}$.

and $5760\cdot\frac{7}{45} = 896$. So on an 8-dimensional spin manifold $\int p_1^2 \equiv 4\operatorname{Sign} \pmod{896}$: again a strong integrality constraint invisible from the definitions.

Worked example 4.85: $\mathbb{CP}^2$ is not spin, and the index theorem knows it

By Example 4.50, $\int_{\mathbb{CP}^2} p_1 = 3$. So the would-be index is

$$\int_{\mathbb{CP}^2}\hat{A} = -\frac{3}{24} = -\frac{1}{8} \notin \mathbb{Z}.$$

If $\mathbb{CP}^2$ had a spin structure, this number would be $n^+ - n^-$, an integer. So $\mathbb{CP}^2$ has no spin structure, in agreement with the direct computation $w_2(\mathbb{CP}^2) = 3h \bmod 2 \neq 0$ of Section 4.15.2. The $\hat{A}$-integrand is still a perfectly good closed 4-form on $\mathbb{CP}^2$; it is only its interpretation as an index that fails, because there is no Dirac operator to take the index of. (For the physicist: $\mathbb{CP}^2$ does admit a Dirac operator *coupled to a* U(1) *gauge field of half-integral flux*, a so-called spin^c structure. The half-integral flux cancels the half-integral gravitational contribution and the index becomes an integer; this is the Dolbeault operator in disguise, see Section 4.16.)

Worked example 4.86: Four-dimensional spin manifolds: S^4, T^4, $S^2 \times S^2$, K3

S^4. $p_1 = 0$ (Example 4.51), so index $\not{D}^+ = 0$. Stronger: the round metric has $R = 12 > 0$, so by Lichnerowicz there are no harmonic spinors at all, $n^+ = n^- = 0$.
T^4. Flat, so the integrand vanishes identically and the index is 0. With the flat metric and the periodic spin structure in all four directions the harmonic spinors are the constant ones, exactly as in Example 4.83: $n^+ = n^- = 2$ (a basis of $\mathbb{C}^2 \oplus \mathbb{C}^2$).
$S^2 \times S^2$. Spin (each factor is), $p_1 = 0$, index 0; with the product of round metrics $R = 2+2 > 0$, so again no harmonic spinors.
K3. This is the interesting one. It is spin: it is a complex surface with $c_1 = 0$, so $w_2 = c_1 \bmod 2 = 0$. From Example 4.74, $\int p_1 = -48$ and Sign $= -16$, hence

$$\begin{aligned} \operatorname{index} \not{D}^+ &\overset{(1)}{=} -\frac{1}{24}\int_{\mathrm{K3}} p_1 = -\frac{-48}{24} = 2 \\ &\overset{(2)}{=} -\frac{\operatorname{Sign}(\mathrm{K3})}{8} = -\frac{-16}{8} = 2. \end{aligned}$$

(1) The four-dimensional $\hat{A}$-genus.
(2) Cross-check through the signature.

So every metric on K3 has at least two positive-chirality harmonic spinors. For the Ricci-flat (Calabi–Yau) metric we can see them: the holonomy of this metric is SU(2), sitting inside $\mathrm{Spin}(4) = \mathrm{SU}(2)_+ \times \mathrm{SU}(2)_-$ as one of the two factors, and it acts trivially on the other half-spin bundle. That half is then flat, and a basis of it at one point extends to two covariantly constant spinors: these are the two zero modes. (Lichnerowicz with $R = 0$ says every harmonic spinor is parallel, so there are no others.) This is why K3 compactifications preserve half of the supersymmetry: covariantly constant spinors are unbroken supersymmetry parameters.
A consequence: since $\hat{A}(\mathrm{K3}) \neq 0$, K3 admits *no* metric of positive scalar curvature (Section 4.15.5). The index theorem has turned a topological number into a statement about all possible geometries.

Worked example 4.87: Eight dimensions: $\mathbb{H}P^2$ and $\mathrm{K3} \times \mathrm{K3}$

$\mathbb{H}P^2$. It is simply connected with $H^2 = 0$, so $w_2 = 0$ and it is spin. With the data of Example 4.75 ($p_1 = 2u$, $p_2 = 7u^2$, $\int u^2 = 1$):

$$\hat{A}(\mathbb{H}P^2) = \frac{7 \cdot 4 - 4 \cdot 7}{5760} = 0.$$

Consistent with Lichnerowicz: the standard metric of $\mathbb{H}P^2$ has positive scalar curvature. The alternative formula gives $\frac{1}{896}(4 - 4 \cdot 1) = 0$ too.
$\mathrm{K3} \times \mathrm{K3}$. Let a and b be the pull-backs of $p_1(\mathrm{K3})$ from the two factors, $\int_{\mathrm{K3}} p_1 = -48$. The Pontryagin class is multiplicative (up to 2-torsion, invisible here): $p = (1 + a)(1 + b)$, so $p_1 = a + b$ and $p_2 = ab$, with $a^2 = b^2 = 0$ (8-forms on a 4-manifold vanish) and $\int ab = (-48)^2 = 2304$. Then

$$\begin{aligned} \hat{A}(\mathrm{K3} \times \mathrm{K3}) &\overset{(1)}{=} \frac{1}{5760}\int \big(7(a+b)^2 - 4ab\big) = \frac{1}{5760}\int \big(14ab - 4ab\big) \\ &\overset{(2)}{=} \frac{10 \cdot 2304}{5760} = 4 = \hat{A}(\mathrm{K3})^2. \end{aligned}$$

(1) The degree-8 term of $\hat{A}$; $(a+b)^2 = 2ab$.

(2) $\int ab = 2304$, and $23040/5760 = 4$.

The answer $2 \cdot 2$ is what multiplicativity of $\hat{A}$ predicts ($\hat{A}(X \times Y) = \hat{A}(X)\hat{A}(Y)$, since the Chern roots of $T(X \times Y)$ are the union of those of X and of Y). Both checks fail with Nash's misprinted coefficient.

Try it: $\hat{A}$ of products and a divisibility

(a) Show that $\hat{A}(X \times Y) = \hat{A}(X)\hat{A}(Y)$, and deduce that $\hat{A}(\mathrm{K3} \times T^4) = 0$. (b) Using Rokhlin's theorem (next subsection), show that $\int_X p_1$ is divisible by 48 on every closed smooth spin 4-manifold.

Answer. (a) Roots of a product are the union of the roots, and $\hat{A}$ is multiplicative; $\hat{A}(T^4) = 0$. (b) $\int p_1 = 3\,\mathrm{Sign}$ and $16 \mid \mathrm{Sign}$.

4.15.9 Rokhlin's theorem

Here is a striking consequence of the integrality in (Nash 4.111). The question is:

Which integers occur as the signature of a closed smooth spin 4-manifold?

The answer, due to Rokhlin (1952), long before the index theorem, is: only multiples of 16. We give the index-theory proof, which has three steps. The first is algebra, the second is the index theorem, the third is a symmetry of four-dimensional spinors.

Step 0: spin means even intersection form. Let X be a closed simply connected 4-manifold with intersection form q on $H^2(X;\mathbb{Z})$ (Section 4.14). The **Wu formula** says that for every $x \in H^2(X;\mathbb{Z})$

$$q(x,x) \equiv \int_X w_2(X) \cup x \pmod 2. \tag{4.131}$$

So $w_2 = 0$ exactly when $q(x,x)$ is even for every x, i.e. when the intersection form is **even**. We can check this on the examples of Section 4.14: $S^2 \times S^2$ has $q = H = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, even, and is spin; $\mathbb{CP}^2$ has $q = (1)$, odd, and is not spin; K3 has $q = 3H \oplus 2(-E_8)$, even, and is spin. (Why the Wu formula holds, in one sentence for complex surfaces: $w_2 = c_1 \bmod 2$, and the adjunction formula for a curve C representing x says $x \cdot x - c_1 \cdot x = 2g(C) - 2$, which is even, so $x \cdot x \equiv c_1 \cdot x \pmod 2$.)

Step 1: the index theorem gives $8 \mid \mathrm{Sign}$. For a spin 4-manifold index $\not{D}^+ = -\mathrm{Sign}(X)/8$ is an integer, so $\mathrm{Sign}(X) \equiv 0 \pmod 8$. Honesty requires a remark: this step alone is not news. A purely algebraic theorem (Serre) says that every even unimodular symmetric form has signature divisible by 8; the form E_8 has signature exactly 8. The index theorem re-proves this for forms that come from spin manifolds. The new information is in the next step.

Step 2: four-dimensional spinors are quaternionic. We show that $n^+ = \dim \mathrm{Ker}\, \not{D}^+$ is *even*. The reason is an antilinear symmetry. Take the gamma matrices of Example 4.79, built from the real quaternion matrices s_a, $\bar{s}_a$. Let K denote complex conjugation of components and $\varepsilon = i\sigma_2 = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$.

Working definition 4.42 (Quaternionic structure on four-dimensional spinors)

Define the antilinear map [$J(c\psi) = \bar{c}\, J\psi$ for every complex number c]

$$J = \begin{pmatrix} \varepsilon K & 0 \\ 0 & \varepsilon K \end{pmatrix} : \mathbb{C}^2 \oplus \mathbb{C}^2 \to \mathbb{C}^2 \oplus \mathbb{C}^2, \qquad J \begin{pmatrix} z_1 \\ z_2 \\ w_1 \\ w_2 \end{pmatrix} = \begin{pmatrix} \bar{z}_2 \\ -\bar{z}_1 \\ \bar{w}_2 \\ -\bar{w}_1 \end{pmatrix}.$$

It preserves chirality, satisfies $J^2 = -1$ [so $J\psi$ is never a multiple of ψ when $\psi \neq 0$, and zero modes come in independent pairs $\psi, J\psi$], and commutes with every γ_a, with every $\gamma_a\gamma_b$, and hence with $\not{D}$.

Let us verify these claims. First, a real quaternion matrix $q = q^0 I + q^1(i\sigma_1) + q^2(i\sigma_2) + q^3(i\sigma_3)$ ($q^\alpha \in \mathbb{R}$) commutes with εK. On a vector v:

$$\varepsilon K(qv) \overset{(1)}{=} \varepsilon\, \bar{q}\, \bar{v} = \left(\varepsilon \bar{q} \varepsilon^{-1}\right) \varepsilon \bar{v} \overset{(2)}{=} q\, \varepsilon \bar{v} = q\,(\varepsilon K v).$$

(1) Complex conjugation of a product is the product of the conjugates ($\bar{q}$ is the entrywise conjugate); insert $\varepsilon^{-1}\varepsilon = 1$.

(2) $\varepsilon \bar{q} \varepsilon^{-1} = q$. Check on each basis element: $\bar{I} = I$; $\overline{i\sigma_1} = -i\sigma_1$ and $\sigma_2\sigma_1\sigma_2 = -\sigma_1$, so $\varepsilon(-i\sigma_1)\varepsilon^{-1} = -i\sigma_2\sigma_1\sigma_2 = i\sigma_1$ (using $\varepsilon = i\sigma_2$, $\varepsilon^{-1} = -i\sigma_2$); likewise for $i\sigma_3$; and $\overline{i\sigma_2} = i\sigma_2$ commutes with ε.

The blocks of every γ_a are $\pm s_a$, $\pm \bar{s}_a$, real quaternion matrices, and J acts by the same εK on both chiral halves, so $J\gamma_a = \gamma_a J$; products of gammas then commute with J as well. Second,

$$J^2 v \overset{(1)}{=} \varepsilon\, \overline{\varepsilon \bar{v}} = \varepsilon\, \bar{\varepsilon}\, v \overset{(2)}{=} \varepsilon^2 v = -v.$$

(1) Apply εK twice; $\bar{\bar{v}} = v$.

(2) ε is real, and $\varepsilon^2 = (i\sigma_2)^2 = -I$.

Finally $\not{D} = \gamma^a e_a^\mu(\partial_\mu + \omega_\mu)$: the vielbein e_a^μ is real, ∂_μ commutes with complex conjugation, and ω_μ is a real combination of the $\gamma_a\gamma_b$. So $J\not{D} = \not{D}J$ and J maps $\operatorname{Ker} \not{D}^+$ into itself.

Why J forces even dimension. Let $V = \operatorname{Ker} \not{D}^+$ (finite dimensional). If $0 \neq \psi \in V$, then $J\psi \in V$ and $J\psi$ is not a complex multiple of ψ: if $J\psi = \lambda\psi$ then

$$-\psi \overset{(1)}{=} J^2\psi = J(\lambda\psi) \overset{(2)}{=} \bar{\lambda} J\psi = \bar{\lambda}\lambda\psi = |\lambda|^2\, \psi,$$

(1) $J^2 = -1$, and the assumption.

(2) J is antilinear, so it conjugates scalars.

which is impossible since $|\lambda|^2 \geq 0$. So $\{\psi, J\psi\}$ spans a 2-dimensional subspace, invariant under J (as $J(J\psi) = -\psi$). J also preserves the L^2 inner product up to conjugation, so the orthogonal complement of this subspace in V is again J-invariant, and we repeat. The dimension of V is $2 + 2 + \cdots$: even. In the language of algebra, V is a vector space over the quaternions $\mathbb{H}$, with J

as right multiplication by the quaternion $\mathbf{j}$. The same holds for $\operatorname{Ker} \not{D}^-$. Hence n^+ and n^- are both even, and

$$\hat{A}(X) = n^+ - n^- \in 2\mathbb{Z} \qquad (\dim X = 4). \tag{4.132}$$

Key idea: Rokhlin's theorem

If X is a closed smooth spin 4-manifold then

$$\operatorname{Sign}(X) = -8\,\hat{A}(X) \equiv 0 \pmod{16}. \tag{4.133}$$

Mechanism: the index theorem ($\operatorname{Sign} = -8\hat{A}$) plus the quaternionic structure of four-dimensional spinors ($\hat{A}$ even).

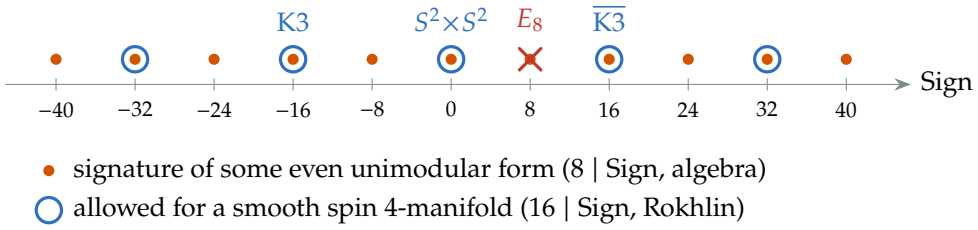

Figure 4.50: Signatures of spin 4-manifolds. Algebra alone allows every multiple of 8 (orange dots) for an even form. Smoothness and the index theorem cut this down to multiples of 16 (blue circles). The form E_8, of signature 8, is even but is not the intersection form of any smooth spin 4-manifold (red cross); K3 and K3 with reversed orientation realise ∓ 16.

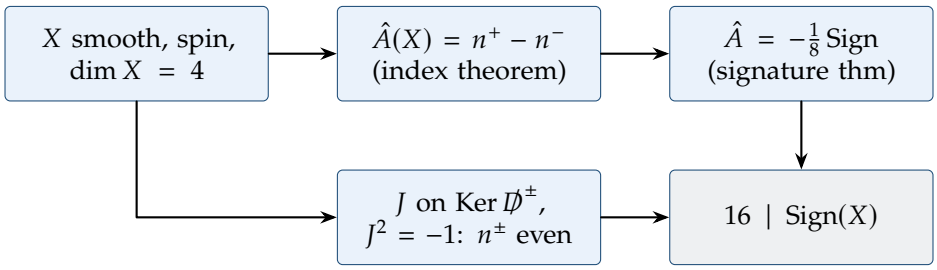

Figure 4.51: The logic of Rokhlin's theorem. Two independent inputs meet: the index theorem expresses the signature through the number of spinor zero modes, and the quaternionic structure of four-dimensional spinors says that zero modes come in pairs.

Worked example 4.88: What Rokhlin rules out

The E_8 form. E_8 is the 8×8 Cartan matrix of the Lie algebra $\mathfrak{e}_8$; it is even, unimodular and positive definite, so its signature is 8. A simply connected smooth 4-manifold with intersection form E_8 would be spin (even form, Step 0) with signature 8, contradicting (4.133). Such a manifold does not exist. (Freedman showed that a *topological* 4-manifold with form E_8 does exist; so it admits no smooth structure at all. This was an early sign of how strange smooth 4-manifold topology is, later made systematic by Donaldson's instanton methods of Chapter 8.)

K3 is optimal. $\operatorname{Sign}(\text{K3}) = -16$ and $\hat{A}(\text{K3}) = 2$: the smallest nonzero values allowed. Its form $3H \oplus 2(-E_8)$ contains two copies of $-E_8$; neither can be "split off" into a smooth spin manifold of its own.

Non-spin examples are unconstrained. $\mathbb{CP}^2$ has signature 1. Rokhlin does not apply: the form (1) is odd.

Watch out: Where the factor 2 comes from, and in which dimensions

The quaternionic structure exists because the spin representations in dimension 4 are pseudo-real: SU(2) matrices commute with εK. In dimension $8k+4$ the half-spin representations are again quaternionic and $\hat{A}$ is even; in dimension $8k$ they are real and no such doubling occurs (the Bott manifold in dimension 8 has $\hat{A}=1$). The mod-2 phenomena in dimensions $8k+1$, $8k+2$ are the mod-2 index of the next part of this chapter. Physicists meet the same pseudo-reality in Witten's SU(2) anomaly: a single Weyl doublet of SU(2) has its zero modes in pairs, and an odd number of doublets makes the theory inconsistent.

Physical picture: Rokhlin as a statement about fermions

Think of X as a Euclidean spacetime, a "gravitational instanton". The index n^+-n^- is the net number of fermion zero modes in this background, and it controls the violation of fermion number (chiral charge) by $\Delta Q_5 = 2\,\mathrm{index}\,\not{D}^+$ for one Dirac fermion (Chapter 10). Rokhlin's theorem says: in a smooth spin spacetime the gravitational chiral anomaly always comes in units of 2 zero modes per Weyl fermion, and the signature of spacetime is -8 times it.

Reading Nash (pp. 113–116, (4.96)–(4.111))

Nash introduces Spin(n), spin structures and w_1, w_2 (4.96); states that spin structures are parametrised by $H^1(X;\mathbb{Z}_2)$ (more precisely, as we noted, a torsor over it) and that $\mathbb{CP}^n$ is spin iff n is odd; describes the spin representation and its chiral halves (4.97) and the spinor bundles (4.98); gives the Clifford relations and γ_5 (4.99) (with the mathematicians' sign $\{\gamma_a,\gamma_b\}=-2\delta_{ab}$), the Dirac operator (4.100), the block form of γ_5 (4.101) and the spin complex (4.102). He then notes that the symbol $i\gamma^a e_a^\mu p_\mu$ is invertible only in Euclidean signature, defines harmonic spinors and $n^\pm$ (4.103)–(4.106), quotes the Chern character (4.107) and derives (4.108), defines $\hat{A}$ (4.109)–(4.110) and states the theorem (4.111). We have supplied: explicit Spin(2) and gamma matrices, the construction of spin structures from transition functions, the lift of the connection and explicit Dirac operators on $\mathbb{R}^2$, S^2 and T^2, Lichnerowicz, the derivation of (4.107) from the weights, two derivations of (4.110) (which has a misprint: read $-4p_2$ for $-p_2$), and the applications to $\mathbb{CP}^2$, K3, $\mathbb{H}P^2$ and Rokhlin's theorem, which Nash does not discuss in this section.

Recap

- Spinors need a spin structure: consistent lifts of the frame transition functions to Spin(n); obstruction $w_2(X)$; choices form a torsor over $H^1(X;\mathbb{Z}_2)$. $\mathbb{CP}^n$ is spin iff n is odd.
- Nash's gammas: $\{\gamma_a,\gamma_b\}=-2\delta_{ab}$, $\gamma_5 = i^{n(n+1)/2}\gamma_1\cdots\gamma_n = \prod_j(-i\gamma_{2j-1}\gamma_{2j})$; $S = S^+\oplus S^-$ of dimensions $2^{n/2-1}$ each.
- $\not{D} = \gamma^a e_a^\mu(\partial_\mu+\omega_\mu)$, with $\omega = -\frac{1}{4}\omega^a{}_b\gamma_a\gamma_b$; $\not{D}^2 = \nabla^*\nabla + R/4$; elliptic only in Euclidean signature.
- $\mathrm{index}\,\not{D}^+ = n^+-n^-$ (harmonic spinors of each chirality).
- Spinor Chern roots $\frac{1}{2}(\pm x_1\pm\cdots\pm x_m)$ give $\mathrm{ch}\,E^+-\mathrm{ch}\,E^- = \prod(e^{x_j/2}-e^{-x_j/2})$, and $\mathrm{index}\,\not{D}^+ = \int\hat{A}$ for $4\mid n$, zero otherwise.
- $\hat{A} = 1-\frac{p_1}{24}+\frac{7p_1^2-4p_2}{5760}$; in 4D $\mathrm{index}\,\not{D}^+ = \frac{1}{192\pi^2}\int \mathrm{tr}\,R\wedge R = -\,\mathrm{Sign}/8$.

- Examples: $\mathbb{CP}^2$: $-\frac{1}{8}$ (not spin); K3: 2 (no psc metric); $\mathbb{H}P^2$: 0. Rokhlin: smooth spin 4-manifolds have 16 | Sign.

4.16 Coupling to gauge fields: counting fermion zero modes

So far the Dirac operator has felt only gravity, through the spin connection. In physics a fermion also carries charge: it is a section of $E \otimes F$, where F is a vector bundle carrying a gauge field. An electron in a magnetic field, a quark in an instanton background. The question of this section is the physicist's version of the index problem:

Given a gauge field configuration, how many zero modes does a massless charged fermion have, and of which chirality?

The answer controls some of the most important non-perturbative effects in field theory: the degeneracy of the lowest Landau level, the 't Hooft vertex and the breaking of chiral symmetry by instantons, and the dimension of the instanton moduli space. Nash treats the general theory of "twisted" complexes in his next section (§3, which is the subject of the next part of this chapter). Here we derive the one formula we need, count zero modes by hand in two and four dimensions, and then use the same formula to show that the four classical complexes of this section are all Dirac operators in disguise.

4.16.1 The Dirac operator with a gauge field

Conventions. A gauge field is a connection on a Hermitian vector bundle $F \to X$ of rank r, with structure group $\mathrm{U}(r)$ or a subgroup such as $\mathrm{SU}(2)$. In a local trivialisation it is a matrix of 1-forms $A = A_\mu \mathrm{d}x^\mu$ with *anti-Hermitian* values, and its curvature is $F_A = \mathrm{d}A + A \wedge A$ (we write F_A for the curvature to keep F for the bundle). Under a gauge transformation $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$. The Chern character is $\mathrm{ch}(F) = \operatorname{tr} \exp(\frac{i}{2\pi}F_A)$, so that

$$\mathrm{ch}(F) = r + c_1(F) + \tfrac{1}{2}\big(c_1^2 - 2c_2\big)(F) + \cdots, \qquad c_1 = \frac{i}{2\pi}\operatorname{tr} F_A, \quad \mathrm{ch}_2(F) = -\frac{1}{8\pi^2}\operatorname{tr}(F_A \wedge F_A). \tag{4.134}$$

The last expression is $\frac{1}{2}\big(\frac{i}{2\pi}\big)^2 \operatorname{tr}(F_A \wedge F_A)$. For an $\mathrm{SU}(r)$ bundle $c_1 = 0$ and $\mathrm{ch}_2 = -c_2$; we define the **instanton number** as $k := c_2(F)[X] = \frac{1}{8\pi^2}\int_X \operatorname{tr}(F_A \wedge F_A)$.

Dictionary: Gauge fields, mathematicians vs physicists

here (Nash)	physics textbooks
A_μ anti-Hermitian	$A_\mu = -ig\, A_\mu^a T^a$, T^a Hermitian, $\operatorname{tr} T^a T^b = \frac{1}{2}\delta^{ab}$
$\nabla_\mu = \partial_\mu + A_\mu$	$D_\mu = \partial_\mu - igA_\mu^a T^a$
$U(1)$: $A = -i\,a$, $F_A = -i\,\mathrm{d}a$	a_μ real (charge absorbed), $\mathrm{d}a = B\,\mathrm{d}x \wedge \mathrm{d}y$ in 2D
$k = c_2 = \frac{1}{8\pi^2}\int \operatorname{tr} F_A \wedge F_A$	$k_{\text{phys}} = \frac{g^2}{32\pi^2}\int F^a_{\mu\nu}\tilde{F}^{a\mu\nu}\,\mathrm{d}^4x = -k$
anti-self-dual ($\star F_A = -F_A$): $k > 0$	"anti-instanton" in many physics texts

(The last two rows use $\operatorname{tr}(F_A \wedge F_A) = -\frac{g^2}{2}F^a \wedge F^a$ and $F^a \wedge F^a = \frac{1}{2}F^a_{\mu\nu}\tilde{F}^{a\mu\nu}\mathrm{d}^4x$. Signs of k are orientation conventions; the invariant statements below are phrased so that they do not depend on them.)

Working definition 4.43 (Twisted Dirac operator)

On a spin manifold with a gauge field A on F [a connection on the colour bundle F, a matrix of 1-forms A_μ acting on the colour index], the **twisted** (or **coupled**) Dirac operator acts on sections of $E \otimes F$ (spinor index $\otimes$ colour index):

$$\not{D}_A = \gamma^a e_a^\mu \big(\partial_\mu + \omega_\mu \otimes 1 + 1 \otimes A_\mu\big), \qquad \not{D}_A^+ : \Gamma(E^+ \otimes F) \to \Gamma(E^- \otimes F). \tag{4.135}$$

Everything said about $\not{D}$ goes through: γ_5 still anticommutes, the symbol is still $i\not{p} \otimes 1$ [$\partial_\mu \to i p_\mu$ gives $i\gamma^a p_a$] (the gauge field is lower order [A_μ comes with no derivative, so it drops out of the leading symbol]), and index $\not{D}_A^+ = n^+ - n^-$ counts charged zero modes by chirality.

The index density. The symbol is unchanged, but the bundles are: E^p is replaced by $E^p \otimes F$. The curvature of $E^\pm \otimes F$ is $\rho(R) \otimes 1 + 1 \otimes F_A$; the two terms commute, so its Chern roots are the sums (spinor root) + (root y_k of F). Therefore

$$\begin{aligned} \operatorname{ch}(E^+ \otimes F) - \operatorname{ch}(E^- \otimes F) &\overset{(1)}{=} \sum_{\varepsilon} \Big(\prod_j \varepsilon_j\Big) \sum_{k=1}^{r} \exp\Big(\tfrac{1}{2}\sum_j \varepsilon_j x_j + y_k\Big) \\ &\overset{(2)}{=} \Big[\sum_{\varepsilon} \Big(\prod_j \varepsilon_j\Big) e^{\frac{1}{2}\sum_j \varepsilon_j x_j}\Big]\Big[\sum_k e^{y_k}\Big] = \big(\operatorname{ch} E^+ - \operatorname{ch} E^-\big)\operatorname{ch}(F), \end{aligned} \tag{4.136}$$

(1) Chern roots of a tensor product are the pairwise sums of roots.
(2) $e^{a+b} = e^a e^b$, and the double sum factorises.

and running the recipe exactly as in (Nash 4.108), the extra factor $\operatorname{ch}(F)$ rides along:

Key idea: Index of the twisted Dirac operator (Nash (4.122), next part)

$$\operatorname{index} \not{D}_A^+ = (-1)^{n/2} \int_X \hat{A}(X)\, \operatorname{ch}(F). \tag{4.137}$$

Unlike the untwisted case, this is generally nonzero in every even dimension, because $\operatorname{ch}(F)$ has components in all even degrees.

Explicitly, in the two cases that matter most:

$$n = 2: \qquad \operatorname{index} \not{D}_A^+ = -\int_X c_1(F) = -\frac{i}{2\pi}\int_X \operatorname{tr} F_A, \tag{4.138}$$

$$n = 4: \qquad \operatorname{index} \not{D}_A^+ = -\frac{r}{24}\int_X p_1 + \int_X \operatorname{ch}_2(F) = \frac{r}{192\pi^2}\int_X \operatorname{tr}(R \wedge R) - \frac{1}{8\pi^2}\int_X \operatorname{tr}(F_A \wedge F_A). \tag{4.139}$$

For (4.138): $\hat{A} = 1$ on a surface and the 2-form part of $\operatorname{ch} F$ is c_1; the sign is $(-1)^1$. For (4.139): the 4-form part of $\big(1 - \frac{p_1}{24}\big)\big(r + c_1 + \operatorname{ch}_2\big)$ is $-\frac{r}{24}p_1 + \operatorname{ch}_2$, and the sign is $(-1)^2 = +1$. The gravitational term is r times the untwisted index; the gauge term is the "instanton contribution". The pure gauge term $-\frac{1}{8\pi^2}\int \operatorname{tr} F_A \wedge F_A$ is, up to normalisation, the integrated chiral anomaly $\int \partial_\mu J_5^\mu$ (Chapter 10).

Watch out: Index zero untwisted, nonzero twisted

On S^2 the untwisted index vanishes (as it does on every surface), but with a magnetic monopole it is $-d$ for monopole charge d (below). Nash stresses this in §3: a manifold on

which index $\not{D} = 0$ can still have index $\not{D}_A \neq 0$. The index of the twisted operator measures the topology of the gauge field, not only of the manifold.

4.16.2 Two dimensions: monopoles and Landau levels

Take a U(1) gauge field, $A = -i\,a$ with a a real 1-form. Then $F_A = -i\,\mathrm{d}a$, $c_1 = \frac{1}{2\pi}\mathrm{d}a$, and on a surface $\int c_1 = \Phi/2\pi$ with Φ the total magnetic flux. The index theorem (4.138) says $n^+ - n^- = -\Phi/2\pi$ on a compact surface, where $\Phi/2\pi = d \in \mathbb{Z}$ is the monopole charge (the degree of the line bundle). We now find the zero modes explicitly, first on the plane, then on the sphere.

The Dirac operator with a magnetic field. With the gamma matrices of Example 4.78 and $\partial_\mu \to \partial_\mu - i a_\mu$, the blocks of Example 4.80 become

$$\not{D}_A^+ = -2\big(\partial_z - i a_z\big), \qquad \not{D}_A^- = 2\big(\partial_{\bar z} - i a_{\bar z}\big), \qquad a_z = \tfrac{1}{2}(a_1 - i a_2), \quad a_{\bar z} = \tfrac{1}{2}(a_1 + i a_2).$$

Choose the Coulomb gauge $a_1 = -\partial_2\phi$, $a_2 = \partial_1\phi$, so that $B = \partial_1 a_2 - \partial_2 a_1 = \nabla^2\phi$. Then

$$\begin{aligned} a_{\bar z} &\overset{(1)}{=} \tfrac{1}{2}\big(-\partial_2\phi + i\partial_1\phi\big) = \tfrac{i}{2}\big(\partial_1\phi + i\partial_2\phi\big) \\ &\overset{(2)}{=} i\,\partial_{\bar z}\phi, \qquad \text{and similarly} \qquad a_z = -i\,\partial_z\phi. \end{aligned}$$

(1) Insert the gauge choice; factor out i (note $i\cdot i\partial_2\phi = -\partial_2\phi$).
(2) $\partial_{\bar z} = \tfrac{1}{2}(\partial_1 + i\partial_2)$.

Hence $\partial_{\bar z} - i a_{\bar z} = \partial_{\bar z} + \partial_{\bar z}\phi = e^{-\phi}\partial_{\bar z} e^{\phi}$, and $\partial_z - i a_z = \partial_z - \partial_z\phi = e^{\phi}\partial_z e^{-\phi}$. The zero-mode equations are solved by "gauging away" the field:

$$\not{D}_A^- \psi^- = 0 \iff \psi^- = e^{-\phi} f(z), \qquad \not{D}_A^+ \psi^+ = 0 \iff \psi^+ = e^{\phi} g(\bar z), \tag{4.140}$$

with f holomorphic and g antiholomorphic. Which of these are acceptable depends on the behaviour of ϕ at infinity.

Worked example 4.89: Aharonov–Casher: zero modes on the plane

Let B be localised with total flux $\Phi > 0$. The solution of $\nabla^2\phi = B$ is $\phi(x) = \frac{1}{2\pi}\int \ln|x - x'|\, B(x')\,\mathrm{d}^2x'$, so $\phi \approx \frac{\Phi}{2\pi}\ln r$ for large r. Then $\psi^+ = e^{\phi} g$ grows like $r^{\Phi/2\pi}\,|g|$ and is never normalisable: $n^+ = 0$. For $\psi^- = e^{-\phi} z^k$ (f must be a polynomial, or the growth of an entire function beats any power):

$$\begin{aligned} \int |\psi^-|^2\,\mathrm{d}^2x &\overset{(1)}{=} \int^{\infty} r^{2k}\, r^{-\Phi/\pi}\, r\,\mathrm{d}r \cdot (\text{finite}) \\ &\overset{(2)}{=} \text{finite} \iff 2k - \frac{\Phi}{\pi} + 1 < -1 \iff k < \frac{\Phi}{2\pi} - 1. \end{aligned}$$

(1) $\big|z^k\big|^2 = r^{2k}$, $e^{-2\phi} \approx r^{-\Phi/\pi}$, and $\mathrm{d}^2x = r\,\mathrm{d}r\,\mathrm{d}\theta$; the region of finite r gives a finite contribution.
(2) Convergence of $\int^{\infty} r^s \mathrm{d}r$ requires $s < -1$.

So the zero modes are $e^{-\phi} z^k$ with $0 \le k < \frac{\Phi}{2\pi} - 1$:

$$n^- = \left\lceil \frac{\Phi}{2\pi} \right\rceil - 1, \qquad n^+ = 0 \qquad (\Phi > 0),$$

all of one chirality (for $\Phi < 0$ the roles of $\psi^{\pm}$ swap). This is the Aharonov–Casher theorem (1979). Notice: *not* $\Phi/2\pi$. For $\Phi = 2\pi d$ exactly, the would-be d-th mode $z^{d-1}e^{-\phi} \sim r^{-1}$ is only logarithmically divergent. The plane is not compact, so the index theorem does not apply as it stands; the deficit is a boundary effect at infinity, of the Atiyah–Patodi–Singer type treated in the next part.

The sphere, by a conformal map. The round sphere is conformally flat: in the stereographic coordinate z the metric is $g = \rho^2 |\mathrm{d}z|^2$ with $\rho = \frac{2}{1+|z|^2}$. The Dirac operator transforms simply under $g = \rho^2\delta$. Take the coframe $e^a = \rho\,\mathrm{d}x^a$ and write $\sigma = \ln\rho$. Cartan's equations give $\omega^1{}_2 = \partial_2\sigma\,\mathrm{d}x - \partial_1\sigma\,\mathrm{d}y$, hence $\omega_\mu = -\frac{1}{2}\omega_\mu{}^1{}_2\,\gamma_1\gamma_2$, and

$$\begin{aligned} \not{D}_g &\overset{(1)}{=} \rho^{-1}\gamma^a\big(\partial_a + \omega_a + A_a\big) \\ &\overset{(2)}{=} \rho^{-1}\Big(\gamma^a(\partial_a + A_a) - \tfrac{1}{2}\partial_2\sigma\,\gamma_1\gamma_1\gamma_2 + \tfrac{1}{2}\partial_1\sigma\,\gamma_2\gamma_1\gamma_2\Big) \\ &\overset{(3)}{=} \rho^{-1}\Big(\gamma^a(\partial_a + A_a) + \tfrac{1}{2}\gamma^a\partial_a\sigma\Big) \\ &\overset{(4)}{=} \rho^{-3/2}\,\not{D}_{\text{flat}}\,\rho^{1/2}. \end{aligned} \tag{4.141}$$

(1) The definition (4.135) with $e_a = \rho^{-1}\partial_a$.
(2) $\omega_1 = -\frac{1}{2}\partial_2\sigma\,\gamma_1\gamma_2$ and $\omega_2 = +\frac{1}{2}\partial_1\sigma\,\gamma_1\gamma_2$. (Cartan: $\mathrm{d}e^1 = \partial_2\rho\,\mathrm{d}y\wedge\mathrm{d}x$ must equal $-\omega^1{}_2\wedge\rho\,\mathrm{d}y$, and similarly for e^2.)
(3) $\gamma_1\gamma_1\gamma_2 = -\gamma_2$ and $\gamma_2\gamma_1\gamma_2 = \gamma_1$.
(4) $\gamma^a\partial_a(\rho^{1/2}\psi) = \rho^{1/2}\big(\gamma^a\partial_a\psi + \frac{1}{2}\gamma^a\partial_a\sigma\,\psi\big)$, so the bracket is $\rho^{-1/2}\not{D}_{\text{flat}}\rho^{1/2}$.

So $\not{D}_g\psi = 0$ iff $\not{D}_{\text{flat}}(\rho^{1/2}\psi) = 0$: *zero modes on the sphere are $\rho^{-1/2}$ times zero modes on the plane*, with the same gauge field. (For $A = 0$ this reproduces Example 4.82: $\rho^{-1/2}f(z)$ grows like r^{1+k}, while the area element is $\rho^2\mathrm{d}^2x \sim r^{-4}\mathrm{d}^2x$, so $\int |\psi|^2\,\rho^2\mathrm{d}^2x$ converges only for $k < 0$: no zero modes.)

Worked example 4.90: Zero modes of a charge-d monopole on S^2

The rotationally symmetric monopole of charge $d > 0$ has $\phi = \frac{d}{2}\ln(1+|z|^2)$. Check the flux:

$$\begin{aligned} \int_{\mathbb{R}^2} \nabla^2\phi\,\mathrm{d}^2x &\overset{(1)}{=} \int_{\mathbb{R}^2} \frac{2d}{(1+r^2)^2}\,\mathrm{d}^2x \\ &\overset{(2)}{=} 2d\cdot 2\pi\int_0^\infty \frac{r\,\mathrm{d}r}{(1+r^2)^2} = 2d\cdot 2\pi\cdot\tfrac{1}{2} = 2\pi d. \end{aligned}$$

(1) $\nabla^2\ln(1+r^2) = \frac{1}{r}\big(r\cdot\frac{2r}{1+r^2}\big)' = \frac{4}{(1+r^2)^2}$, times $\frac{d}{2}$.
(2) Polar coordinates; $\int_0^\infty \frac{r\,\mathrm{d}r}{(1+r^2)^2} = \frac{1}{2}$.

So $\int c_1 = d$. The field is uniform on the sphere: $B\,\mathrm{d}^2x = \frac{d}{2}\rho^2\mathrm{d}^2x$ is $\frac{d}{2}$ times the round area form. By (4.140) and (4.141), the negative-chirality candidates are

$$\psi_k^- = \rho^{-1/2}e^{-\phi}z^k \propto (1+|z|^2)^{\frac{1-d}{2}}\,z^k, \qquad k = 0,1,2,\dots$$

Normalisability on the sphere:

$$\begin{aligned} \int_{S^2} \big|\psi_k^-\big|^2\,\mathrm{d}A &\overset{(1)}{=} \int_{\mathbb{R}^2} (1+r^2)^{1-d}\,r^{2k}\,\frac{4\,\mathrm{d}^2x}{(1+r^2)^2} \\ &\overset{(2)}{=} \text{finite} \iff 2k + 2(1-d) - 4 + 1 < -1 \iff k < d. \end{aligned}$$

(1) The area element of the unit sphere is $\rho^2 \mathrm{d}^2x$.
(2) Large-r power counting, as in Example 4.89.

(Equivalently, in the southern chart $w = 1/z$ the mode is smooth at $w = 0$ exactly when $k \le d-1$.) The positive-chirality candidates $\rho^{-1/2} e^{\phi} g(\bar{z})$ grow even faster and none survive. So

$$n^- = d, \qquad n^+ = 0, \qquad \operatorname{index} \not{D}_A^+ = -d = -\int_{S^2} c_1,$$

exactly as (4.138) predicts. On the plane the same flux gave $d-1$ modes; compactness supplies the missing one.

Physical picture: Zero modes are the lowest Landau level

Squaring the Dirac operator gives the Pauli Hamiltonian. On flat $\mathbb{R}^2$ the twisted Lichnerowicz formula (4.143) below reads $\not{D}_A^2 = -\nabla_A^2 + \gamma_5 B$: the curvature term is $\gamma_1\gamma_2 F_{A,12} = (i\gamma_5)(-iB)$. For $B > 0$ the operator $-\nabla_A^2$ has lowest eigenvalue B (the zero-point energy of the cyclotron motion), and on negative chirality the Zeeman term $-B$ cancels it exactly. So the Dirac zero modes are the lowest Landau level of a spin-$\frac{1}{2}$ particle with gyromagnetic ratio $g = 2$. On a sphere pierced by d flux quanta (Haldane's sphere of the quantum Hall effect) this level has degeneracy d, one state per flux quantum. (A *spinless* particle on the same sphere has $d+1$ states in its lowest level, as the Riemann–Roch count of Section 4.13 with $\mathcal{O}(d)$ showed; the difference is the $K^{1/2}$ carried by the spinor.) The index theorem is the statement that this degeneracy is topological and survives any deformation of B and of the metric. In graphene, whose electrons obey a two-dimensional Dirac equation, this is the famous zero-energy Landau level.

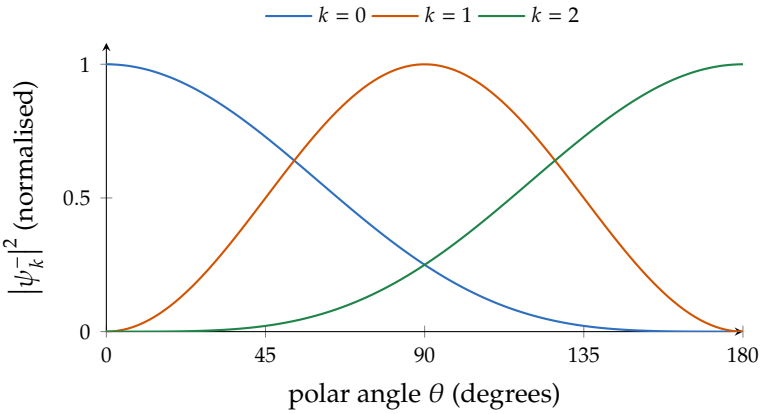

Figure 4.52: The $d = 3$ zero modes of a monopole on the unit sphere, as functions of the polar angle ($|z| = \tan\frac{\theta}{2}$, so $|\psi_k^-|^2 \propto \sin^{2k}\frac{\theta}{2}\cos^{2(d-1-k)}\frac{\theta}{2}$; each curve scaled to maximum 1). They are rings of charge centred at latitudes that move from the north pole ($k = 0$) to the south pole ($k = d-1$): the lowest Landau level on the sphere, one state per flux quantum.

Riemann–Roch cross-check. By Example 4.80 negative-chirality zero modes solve a $\bar{\partial}$-equation, and with the field they are holomorphic sections of $E^- \otimes L$, where $E^- \cong K^{1/2}$ (a square root of the canonical bundle, degree $g-1$) and L is the monopole line bundle, of degree d. On $\mathbb{CP}^1$, $\deg(K^{1/2} \otimes L) = d-1$, and the Riemann–Roch count of Section 4.13.5 gives $h^0 = (d-1)+1-0 = d$ holomorphic sections when $d \ge 1$ (they are the polynomials of degree $\le d-1$, i.e. our z^k). The Dirac index and Riemann–Roch are the same computation.

4.16.3 Four dimensions: instanton zero modes

Now let X be S^4 (or $\mathbb{R}^4$ with fields decaying at infinity, which by conformal invariance is the same problem) and F an SU(2) bundle with instanton number k. Then $p_1(S^4) = 0$ and $c_1(F) = 0$, and (4.139) becomes

$$\operatorname{index} \not{D}_A^+ = \int_{S^4} \operatorname{ch}_2(F) = -c_2(F)[S^4] = -k \qquad \text{(fundamental representation)}. \tag{4.142}$$

Which chirality? A vanishing theorem. The index gives $n^+ - n^-$. To get $n^\pm$ separately we need the twisted Lichnerowicz formula ([Bär Thm. 5.1.1])

$$\not{D}_A^2 = \nabla^*\nabla + \frac{R}{4} + \frac{1}{2}\gamma^a\gamma^b \otimes F_{A,ab}. \tag{4.143}$$

The derivation is the one of (4.127): the commutator $[\nabla_a, \nabla_b]$ now also contains the gauge curvature $F_{A,ab}$. The new term involves $\gamma^a\gamma^b F_{A,ab}$, i.e. the 2-form F_A acting by Clifford multiplication, and by Example 4.79 self-dual 2-forms act only on E^+ and anti-self-dual ones only on E^-. So for an *anti-self-dual* field ($\star F_A = -F_A$) the curvature term vanishes on $E^+ \otimes F$, and there

$$\not{D}_A^- \not{D}_A^+ = \nabla^*\nabla + \frac{R}{4}.$$

On S^4 ($R = 12$) this is strictly positive, so $n^+ = 0$; on $\mathbb{R}^4$ ($R = 0$) a normalisable ψ^+ with $\not{D}_A^+\psi^+ = 0$ would have $\nabla\psi^+ = 0$ and hence constant norm, so again $n^+ = 0$. Combined with the index:

Key idea: Counting instanton zero modes

In an anti-self-dual SU(2) instanton of charge $k > 0$, a massless Weyl fermion in the fundamental representation has exactly $n^- = k$ zero modes, all of negative chirality, and none of positive chirality. For a self-dual instanton ($k < 0$) the roles are exchanged: $|k|$ zero modes of positive chirality.

For $k = 1$ and the BPST instanton of size λ centred at the origin, the zero mode was found by 't Hooft (1976). In the regular gauge it has the form

$$\psi^-_{\alpha i}(x) \propto \frac{\lambda}{(|x|^2 + \lambda^2)^{3/2}}\, \varepsilon_{\alpha i},$$

where α is the spinor index of $E^- = \mathbb{C}^2$ and i the colour index of $F = \mathbb{C}^2$: the zero mode *locks* spin to colour, being the singlet $\varepsilon_{\alpha i}$ of the diagonal SU(2). We do not verify this here (it is a pleasant calculation with the BPST connection of Chapter 8), but the power law is easy to understand: far from the instanton the field is pure gauge, so the zero mode must look like a flat-space solution, and $\not{D}(\not{x}/|x|^4) = 0$ away from the origin in four dimensions. Its decay $|x|^{-3}$ is exactly that of $\lambda(|x|^2 + \lambda^2)^{-3/2}$, and $\int |x|^{-6}\, \mathrm{d}^4x$ converges at infinity: the mode is normalisable.

Worked example 4.91: Other representations: the Dynkin index

If the fermion transforms in a representation $\mathbf{R}$ of SU(2), the bundle is $F_{\mathbf{R}}$ and $\operatorname{ch}_2(F_{\mathbf{R}}) = -\frac{1}{8\pi^2}\operatorname{tr}_{\mathbf{R}}(F_A \wedge F_A)$. Write $F_A = F^a T_a$ with anti-Hermitian generators; then $\operatorname{tr}_{\mathbf{R}}(T_a T_b) = -T(\mathbf{R})\,\delta_{ab}$ with $T(\mathbf{R})$ the **Dynkin index**. For isospin j, $T(j) = \frac{1}{3}j(j+1)(2j+1)$ (so $T(\frac{1}{2}) = \frac{1}{2}$,

$T(1) = 2$). Hence

$$\operatorname{index} \not{D}^+_{A,\mathbf{R}} \overset{(1)}{=} -\frac{1}{8\pi^2}\int \operatorname{tr}_{\mathbf{R}}(F_A \wedge F_A) = \frac{T(\mathbf{R})}{8\pi^2}\int F^a \wedge F^a$$
$$\overset{(2)}{=} \frac{T(\mathbf{R})}{T(\frac12)}\cdot\Big(-\frac{1}{8\pi^2}\int \operatorname{tr}_{\frac12}(F_A\wedge F_A)\Big) = -\frac{T(\mathbf{R})}{T(\frac12)}\,k = -\tfrac{2}{3}j(j+1)(2j+1)\,k.$$

(1) Definition of ch_2 and of the Dynkin index.
(2) Compare with the fundamental, for which the bracket is $-k$ by (4.142).

Check: $j=\frac12$ gives $\frac23\cdot\frac12\cdot\frac32\cdot 2 = 1$. For the adjoint ($j=1$): $\frac23\cdot1\cdot2\cdot3 = 4$, so a gluino has $4k$ zero modes in a charge-k instanton. For $k=1$ in $\mathcal{N}=1$ super Yang–Mills, two of the four are generated by the broken supersymmetries and two by the broken superconformal symmetries: the index knows about symmetries the operator never mentions. For $\mathrm{SU}(N)$ one finds $1\cdot k$ modes in the fundamental and $2N\cdot k$ in the adjoint.

Worked example 4.92: The dimension of the instanton moduli space

The infinitesimal deformations $a\in\Omega^1(X;\operatorname{ad}F)$ of an anti-self-dual connection satisfy the linearised equations $\mathrm{d}^+_A a = 0$ (stay anti-self-dual) and $\mathrm{d}^*_A a = 0$ (not a gauge transformation). So the moduli space has dimension $\operatorname{index}\big(\mathrm{d}^*_A+\mathrm{d}^+_A : \Omega^1\to\Omega^0\oplus\Omega^+\big)$ when the cokernel vanishes (it does on S^4, by a vanishing theorem like the one above). This operator is a twisted Dirac operator. In four dimensions the representation theory of $\mathrm{Spin}(4)=\mathrm{SU}(2)_+\times\mathrm{SU}(2)_-$ gives

$$\Lambda^1\otimes\mathbb{C} = E^+\otimes E^-, \qquad (\Lambda^0\oplus\Lambda^+)\otimes\mathbb{C} = E^+\otimes E^+$$

(a vector is $(\frac12,\frac12)$; $(\frac12,0)\otimes(\frac12,0)=(0,0)\oplus(1,0)$, the scalar and the self-dual 2-forms). So $(\Lambda^0\oplus\Lambda^+)\to\Lambda^1$ is $\not{D}^+$ twisted by $W = E^+\otimes\operatorname{ad}F$, and the operator we want is its adjoint. On S^4 with $\operatorname{ad}F$ of rank 3:

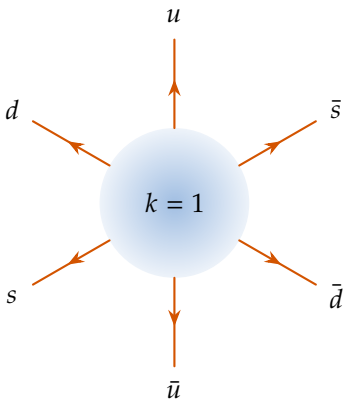
$$\operatorname{index}\big(\mathrm{d}^*_A+\mathrm{d}^+_A\big) \overset{(1)}{=} -\operatorname{index}\not{D}^+_W = -\int_{S^4}\hat{A}\,\mathrm{ch}(E^+)\,\mathrm{ch}(\operatorname{ad}F)$$
$$\overset{(2)}{=} -\int_{S^4}\Big(2\,\mathrm{ch}_2(\operatorname{ad}F) + 3\,\mathrm{ch}_2(E^+)\Big)$$
$$\overset{(3)}{=} -\big(2\cdot(-4k)+3\cdot1\big) = 8k-3.$$

(1) The index of an adjoint is minus the index; (4.137) with $n/2=2$ and $\mathrm{ch}(W) = \mathrm{ch}(E^+)\,\mathrm{ch}(\operatorname{ad}F)$.
(2) $\hat{A}=1$ on S^4 ($p_1=0$); E^+ has rank 2, $\operatorname{ad}F$ rank 3, and both have $c_1=0$, so the 4-form part of the product is $2\,\mathrm{ch}_2(\operatorname{ad}F)+3\,\mathrm{ch}_2(E^+)$.
(3) $\int\mathrm{ch}_2(\operatorname{ad}F) = -4k$ by Example 4.91. For E^+, whose roots are $\pm\frac12(x_1+x_2)$ (Example 4.84), $\mathrm{ch}_2(E^+) = \frac14(x_1+x_2)^2 = \frac14 p_1+\frac12 e$, which integrates on S^4 to $0+\frac12\cdot2=1$.

This is the celebrated $8k-3$ of Atiyah–Hitchin–Singer: for $k=1$, five parameters, the centre (4) and the size (1) of the BPST instanton. (On $\mathbb{R}^4$ one adds the 3 global gauge orientations and gets $8k$.) The moduli spaces are the subject of Chapter 8.

Physical picture: Why physicists care: anomalies from zero modes

In the Euclidean path integral, a fermion zero mode is a Grassmann variable that does not appear in the action, and $\int \mathrm{d}\theta\,1 = 0$. So in an instanton background the partition



each of the N_f Dirac flavours contributes one zero mode of each Weyl component, ψ_L and $\bar{\psi}_R$

Grassmann integration over the $2N_f k$ zero modes gives an effective $2N_f$-fermion vertex: $\Delta Q_5 = 2N_f k$

Figure 4.53: The 't Hooft vertex. In a one-instanton background the fermion path integral vanishes unless every zero mode is soaked up by an external fermion line. With three light flavours (QCD) the instanton induces a six-quark interaction that violates the axial U(1) charge by $2N_f = 6$. The number of legs is fixed by the index theorem.

function vanishes, and only correlation functions with enough fermion insertions to absorb every zero mode survive. Each flavour gives $n^- - n^+ = k$ zero modes of one chirality, so the surviving correlators carry net chiral charge $2N_f k$ (a Dirac fermion has two Weyl components). This is the integrated form of the Adler–Bell–Jackiw anomaly: the index theorem is the statement that $\int \partial_\mu J_5^\mu = 2N_f \ \mathrm{index}\, \not{D}_A^+$ up to sign, and the anomaly density is the index density. It solves the $\mathrm{U}(1)_A$ problem of QCD and is the subject of Chapter 10.

4.16.4 The four classical complexes as twisted Dirac operators

We end this section by closing a circle. The de Rham, signature and Dolbeault complexes were introduced independently, and their index densities (the Euler class, the L-class, the Todd class) were computed separately. But all three are Dirac operators twisted by a suitable bundle, and their densities are $\hat{A} \cdot \mathrm{ch}(\mathrm{twist})$.

Forms are spinors times spinors. On a spin manifold of dimension $n = 2m$ the bundle of complex forms is

$$\Lambda^* T^* X \otimes \mathbb{C} \ \cong \ E \otimes E^*, \tag{4.144}$$

with ranks $2^n = 2^m \cdot 2^m$. This is the linear-algebra fact that $\mathrm{End}(S)$, the $2^m \times 2^m$ matrices, has the products $\gamma_{a_1} \cdots \gamma_{a_p}$ $(a_1 < \cdots < a_p)$ as a basis, one for each basic p-form $e^{a_1} \wedge \cdots \wedge e^{a_p}$. For $n = 2$: $1, \gamma_1, \gamma_2, \gamma_1\gamma_2$ span all 2×2 matrices, matching $1, e^1, e^2, e^1 \wedge e^2$. Under this identification, Clifford multiplication by e^a from the left is $e^a \wedge - \iota_{e_a}$ on forms (up to a sign convention), and so $\mathrm{d} + \mathrm{d}^*$ is the Dirac operator on E twisted by E^*. The different complexes differ only in how the 2^n-dimensional space is split into "even" and "odd":

- grading by $\gamma_5 \otimes 1$ (chirality of the left factor): this is τ, and gives the *signature* complex;
- grading by $\gamma_5 \otimes \gamma_5$ (both factors): this is the parity of the form degree, and gives the *de Rham* complex.

Signature. With the twist $E^* \cong E$ (for even n the spin representation is self-dual up to isomorphism, so $\mathrm{ch}\, E^* = \mathrm{ch}\, E$), whose Chern character is $\mathrm{ch}\, E = \prod_j (e^{x_j/2} + e^{-x_j/2}) = \prod_j 2\cosh \frac{x_j}{2}$

(the sum over all sign choices, now without the factor $\prod \varepsilon_j$):

$$(-1)^m \int_X \hat{A}\,\mathrm{ch}(E) \overset{(1)}{=} (-1)^m \int_X \prod_{j=1}^{m} \frac{x_j/2}{\sinh(x_j/2)} \cdot 2\cosh\frac{x_j}{2}$$
$$\overset{(2)}{=} (-1)^m\, 2^m \int_X \prod_{j=1}^{m} \frac{x_j/2}{\tanh(x_j/2)} = (-1)^m\, 2^m \int_X \mathcal{L}(X). \tag{4.145}$$

(1) The twisted index formula (4.137) with $F = E$.
(2) $\cosh/\sinh = 1/\tanh$; one factor 2 per plane.

For $n = 4k$ the sign is $+1$ and this is exactly Nash's $\mathrm{Sign}(X) = 2^{n/2}\mathcal{L}(X)[X]$ of Section 4.14, now with the normalisation $\mathcal{L} = \prod \frac{x/2}{\tanh(x/2)}$ explained: the $\frac{x}{2}$ comes from the spinor roots. (This is Bär's proof of the signature theorem, [Bär §5.2].)

de Rham. Now the twist is graded as well, and the numerator is $(\mathrm{ch}\,E^+ - \mathrm{ch}\,E^-)(\mathrm{ch}\,E^{+*} - \mathrm{ch}\,E^{-*})$. The dual bundles have the negated roots, so

$$(\mathrm{ch}\,E^+ - \mathrm{ch}\,E^-)\big(\mathrm{ch}\,E^{+*} - \mathrm{ch}\,E^{-*}\big) \overset{(1)}{=} \prod_j \big(e^{x_j/2} - e^{-x_j/2}\big)\big(e^{-x_j/2} - e^{x_j/2}\big)$$
$$\overset{(2)}{=} \prod_j \big(1 - e^{x_j}\big)\big(1 - e^{-x_j}\big), \tag{4.146}$$

(1) (Nash 4.107) for $E^{\pm}$, and the same with $x_j \to -x_j$ for the duals.
(2) Multiply out: $(a - a^{-1})(a^{-1} - a) = 2 - a^2 - a^{-2} = (1 - a^2)(1 - a^{-2})$ with $a = e^{x/2}$.

which is Nash's (4.59) for $\sum_p (-1)^p\,\mathrm{ch}\,\Lambda^p$, the alternating sum that led to Gauss–Bonnet in Section 4.12. The corresponding index density is

$$(-1)^m\,\hat{A} \cdot \big(\mathrm{ch}\,E^{+*} - \mathrm{ch}\,E^{-*}\big) \overset{(1)}{=} (-1)^m \prod_j \frac{x_j/2}{\sinh(x_j/2)} \cdot \big(-2\sinh\tfrac{x_j}{2}\big)$$
$$\overset{(2)}{=} (-1)^m (-1)^m \prod_j x_j = e(X),$$

(1) The graded twist has $\mathrm{ch} = \prod_j (e^{-x_j/2} - e^{x_j/2}) = \prod_j (-2\sinh\frac{x_j}{2})$.
(2) The sinh cancels, leaving $-x_j$ per plane.

the Euler class, and $\mathrm{index}(\mathrm{d} + \mathrm{d}^*)_{\mathrm{even}\to\mathrm{odd}} = \chi(X)$.

Dolbeault. On a complex manifold with holomorphic Chern roots $y_1, \dots, y_m$ (so that the real block angles are $x_j = y_j$ and $c_1 = \sum y_j$), compare the Todd and $\hat{A}$ series root by root:

$$\mathrm{td}(X) \overset{(1)}{=} \prod_{j=1}^{m} \frac{y_j}{1 - e^{-y_j}} = \prod_{j=1}^{m} \frac{y_j\, e^{y_j/2}}{e^{y_j/2} - e^{-y_j/2}}$$
$$\overset{(2)}{=} \prod_{j=1}^{m} e^{y_j/2}\,\frac{y_j/2}{\sinh(y_j/2)} = e^{c_1(X)/2}\,\hat{A}(X). \tag{4.147}$$

(1) Definition of the Todd class; multiply numerator and denominator by $e^{y/2}$.
(2) $e^{y/2} - e^{-y/2} = 2\sinh(y/2)$; the product of $e^{y_j/2}$ is $e^{\sum y_j/2} = e^{c_1/2}$.

And $e^{c_1/2} = \mathrm{ch}(K^{-1/2})$, the Chern character of a line bundle with first Chern class $\frac{1}{2}c_1(X)$: a square root of the anticanonical bundle $K^{-1} = \Lambda^m T^{1,0}X$. So *the Dolbeault operator is the Dirac operator twisted by* $K^{-1/2}$, and Riemann–Roch–Hirzebruch $\chi(X,\mathcal{O}) = \int \mathrm{td}(X)$ is the Dirac index theorem $\int \hat{A}\ \mathrm{ch}(K^{-1/2})$ (up to the chirality convention; in complex dimension 1 we checked all signs in the Riemann–Roch cross-check above).

Worked example 4.93: Two wrongs make a right: $\mathbb{CP}^2$

On $\mathbb{CP}^2$ neither E nor $K^{-1/2}$ exists ($c_1 = 3h$ is odd, so no square root). But their product $E \otimes K^{-1/2} \cong \Lambda^{0,*}$ does exist: the transition-function signs that obstruct each factor cancel in the product. Such a structure is a **spin^c structure**. The index density still makes sense, and

$$\int_{\mathbb{CP}^2} \hat{A}\, e^{c_1/2} \overset{(1)}{=} \int_{\mathbb{CP}^2} \Big(1 - \frac{p_1}{24}\Big)\Big(1 + \frac{c_1}{2} + \frac{c_1^2}{8}\Big) = \int_{\mathbb{CP}^2} \Big(-\frac{p_1}{24} + \frac{c_1^2}{8}\Big)$$
$$\overset{(2)}{=} -\frac{3}{24} + \frac{9}{8} = -\frac{1}{8} + \frac{9}{8} = 1.$$

(1) Expand both factors and keep the 4-form part.
(2) $\int p_1 = 3$ and $\int c_1^2 = \int 9h^2 = 9$ (Example 4.50).

The non-integral gravitational part $-\frac{1}{8}$ (Example 4.85) is compensated by the half-integral "flux" of $K^{-1/2}$, and the total is the integer $\chi(\mathbb{CP}^2,\mathcal{O}) = h^{0,0} - h^{0,1} + h^{0,2} = 1 - 0 + 0 = 1$. Physically: on a non-spin spacetime a fermion can still be defined if it carries half-integral charge under a U(1) gauge field. This is the mechanism behind spin^c structures in Seiberg–Witten theory.

complex	as twisted Dirac	index density	index	§
de Rham	$E \otimes E^*$, graded by $\gamma_5 \otimes \gamma_5$	$e(X)$	$\chi(X) = \sum(-1)^p b_p$	4.12
signature	$E \otimes E^*$, graded by $\gamma_5 \otimes 1$	$2^{n/2}\mathcal{L}(X)$	$\mathrm{Sign}(X) = b^+ - b^-$	4.14
Dolbeault	$E \otimes K^{-1/2}$	$\mathrm{td}(X) = e^{c_1/2}\hat{A}$	$\chi(X,\mathcal{O}) = \sum(-1)^q h^{0,q}$	4.13
spin	E	$\hat{A}(X)$	$n^+ - n^-$	4.15
gauge-coupled spin	$E \otimes F$	$\hat{A}(X)\,\mathrm{ch}(F)$	charged zero modes	4.16

Table 4.3: The classical complexes of Nash's §2, seen as one operator. Each is the Dirac operator on spinors tensored with a "coefficient" bundle, and each index density is $\hat{A}$ times the Chern character of the coefficients (with the appropriate grading). The de Rham and signature complexes exist even on non-spin manifolds, because $E \otimes E^*$ always exists although E may not; the local computation is the same.

Watch out: Non-spin manifolds

The identification (4.144) needs spinors, which may not exist. The de Rham and signature operators do exist on every oriented manifold, and their index theorems hold there too. The reason the spin computation still gives the right answer is that index densities are *local*: every point has a neighbourhood that is spin, and on it the local integrand is $\hat{A}\,\mathrm{ch}(E)$, a polynomial in the curvature. The global identity then follows for all manifolds ([Bär §5.2] uses exactly this argument).

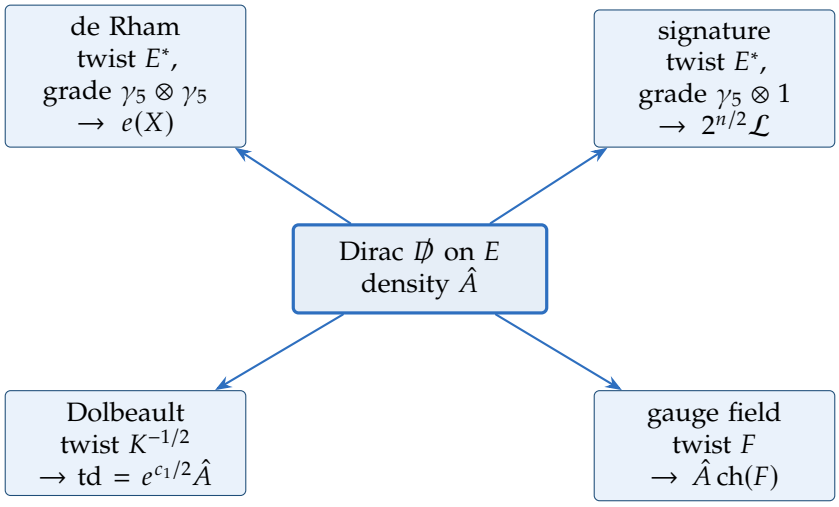


Figure 4.54: All roads lead from the Dirac operator. Twisting the spinor bundle by a coefficient bundle multiplies the index density $\hat{A}$ by the Chern character of the coefficients; choosing how to grade the result selects the complex. The Euler class, L-class and Todd class are all of the form $\hat{A} \cdot \mathrm{ch}(\cdots)$.

Reading Nash (beyond §2; compare Nash pp. 116–119, (4.112)–(4.122))

Nash's §2 ends with (4.111) and does not couple the Dirac operator to gauge fields. His §3 ("Twisted complexes", treated in full in the next part of these notes) replaces each E^p by $F \otimes E^p$ and finds, among others, the twisted Dirac index $(-1)^{n/2}\int \mathrm{ch}(F)\hat{A}(X)$, his (4.122), and the remark that this is nonzero also in dimensions not divisible by 4. This section has used that formula to count zero modes explicitly (monopoles on $\mathbb{R}^2$ and S^2, instantons on S^4), and has shown how the de Rham, signature and Dolbeault complexes of §2 are themselves twisted Dirac operators, which explains why all the index densities are built from the same few power series.

Recap

- Charged fermions: $\not{D}_A = \gamma^a e_a^\mu(\partial_\mu + \omega_\mu + A_\mu)$ on $E \otimes F$; index $\not{D}_A^+ = (-1)^{n/2}\int \hat{A}\ \mathrm{ch}(F)$.
- 2D: index $\not{D}_A^+ = -\int c_1(F)$. On S^2 with d flux quanta there are d zero modes, $(1+|z|^2)^{(1-d)/2}z^k$, $0 \le k < d$: the lowest Landau level. On $\mathbb{R}^2$ only $\lceil \Phi/2\pi \rceil - 1$ (Aharonov–Casher).
- 4D: index $\not{D}_A^+ = \frac{r}{192\pi^2}\int \mathrm{tr}\, R \wedge R - \frac{1}{8\pi^2}\int \mathrm{tr}\, F_A \wedge F_A$. ASD SU(2) instanton of charge k: k zero modes (fundamental), $4k$ (adjoint), all of one chirality by the twisted Lichnerowicz formula.
- The moduli space of SU(2) instantons on S^4 has dimension $8k-3$, a twisted Dirac index.
- $\Lambda^* \otimes \mathbb{C} = E \otimes E^*$: de Rham and signature are Dirac twisted by spinors, Dolbeault is Dirac twisted by $K^{-1/2}$; e, $2^{n/2}\mathcal{L}$, td are all $\hat{A} \cdot \mathrm{ch}(\cdots)$.

4.17 Twisted complexes

In physics, almost nothing is "bare". An electron field is not just a spinor: it is a spinor that also carries an electric charge, so it lives in a spinor bundle *tensored* with a U(1) line bundle. A quark is a spinor tensored with a colour triplet. A gluino is a spinor tensored with the adjoint of SU(3). The operator that acts on such a field is not the bare Dirac operator $\not{D}$ but the gauge-covariant one, $\gamma^\mu(\partial_\mu + \omega_\mu + A_\mu)$.

So the question of this section is:

> *If we couple a classical elliptic operator to a gauge field, how does its index change?*

The answer turns out to be pleasingly simple. The index formula of the untwisted operator gets multiplied, under the integral sign, by the Chern character $\mathrm{ch}(F)$ of the gauge bundle F. Whether this changes anything depends on the operator. For the de Rham complex it changes almost nothing (only the rank of F survives). For the Dolbeault, signature and Dirac operators the gauge field changes the index completely. This is the mathematical origin of the fact that fermion zero modes in an instanton or monopole background are counted by the topological charge.

Nash calls the construction **twisting**, and the new complexes **twisted complexes**.

4.17.1 The tools: index of a complex and the Chern character

We first collect, in one place, the two tools the whole section relies on. Both were introduced earlier in the chapter; we restate them so that this part can be read on its own.

Elliptic complexes and the index formula

An **elliptic complex** is a sequence of vector bundles $E^0, E^1, \dots, E^N$ over a closed n-manifold X and differential operators between their sections,

$$0 \longrightarrow \Gamma(X, E^0) \xrightarrow{d_0} \Gamma(X, E^1) \xrightarrow{d_1} \cdots \xrightarrow{d_{N-1}} \Gamma(X, E^N) \longrightarrow 0, \qquad d_p \circ d_{p-1} = 0, \tag{4.148}$$

such that the corresponding sequence of *symbols* (replace each derivative ∂_μ by ip_μ and keep only the highest-order terms) is exact whenever $p \neq 0$. The cohomology $H^p(E) = \operatorname{Ker} d_p / \operatorname{Im} d_{p-1}$ is finite dimensional, and the **index of the complex** is

$$\operatorname{index} E \;=\; \sum_p (-1)^p \dim H^p(E). \tag{4.149}$$

One can always "roll up" a complex into a single operator: choose inner products, and let

$$D = d + d^* : \bigoplus_{p \text{ even}} \Gamma(E^p) \longrightarrow \bigoplus_{p \text{ odd}} \Gamma(E^p). \tag{4.150}$$

By Hodge theory $\operatorname{Ker} D$ is the sum of the even cohomologies and $\operatorname{Ker} D^*$ the sum of the odd ones, so $\operatorname{index} D = \operatorname{index} E$.

The index formula for complexes that we will use repeatedly (Nash's (4.48), derived in the earlier part of this chapter) reads, for X even dimensional and oriented:

$$\operatorname{index} E \;=\; (-1)^{n/2} \left\{ \frac{\mathrm{ch}\big(\sum_p (-1)^p E^p\big)}{e(X)} \; \mathrm{td}(TX_{\mathbb{C}}) \right\} [X]. \tag{4.151}$$

Here $TX_{\mathbb{C}} = TX \otimes_{\mathbb{R}} \mathbb{C}$, $e(X)$ is the Euler class of TX, td is the Todd class, and "$\{\cdots\}[X]$" means: take the part of the inhomogeneous differential form of degree exactly n and integrate it over X. The ratio makes sense because the numerator always turns out to be divisible by $e(X)$ in the examples.

Key idea: How to read the index formula

The integrand is a polynomial in curvatures. We expand it, keep only the piece of total form degree $n = \dim X$, and integrate. Everything of lower or higher degree is thrown away. Most of this section consists of doing this bookkeeping carefully.

The Chern character

Let $F \to X$ be a complex vector bundle of rank m with a connection A (an anti-Hermitian $m \times m$ matrix of 1-forms in a local trivialisation) and curvature $F_A = \mathrm{d}A + A \wedge A$.

Working definition 4.44 (Chern character)

The **Chern character** of F is the closed, inhomogeneous [a sum of pieces of degrees $0, 2, 4, \ldots$] differential form

$$\mathrm{ch}(F) = \operatorname{tr} \exp\!\left(\frac{iF_A}{2\pi}\right) = m + \frac{i}{2\pi}\operatorname{tr} F_A + \frac{1}{2}\left(\frac{i}{2\pi}\right)^2 \operatorname{tr}(F_A \wedge F_A) + \cdots .$$

To compute it: write down the curvature matrix, take traces of its wedge powers, and sort by degree: $\mathrm{ch}_0 = m$ (the rank), $\mathrm{ch}_1 = c_1$, $\mathrm{ch}_2 = \frac{1}{2}(c_1^2 - 2c_2)$, and so on. *Splitting-principle form:* if we pretend $F = L_1 \oplus \cdots \oplus L_m$ is a sum of line bundles [rank-one bundles] with first Chern classes $x_1, \ldots, x_m$ (the **Chern roots**), then $\mathrm{ch}(F) = \sum_i e^{x_i}$.

Dictionary: anti-Hermitian versus Hermitian gauge fields

We use the mathematicians' convention (as Nash does): A is anti-Hermitian, $F_A = \mathrm{d}A + A \wedge A$, and gauge transformations act as $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$. The physicists' Hermitian field $A^a_\mu T^a$ with coupling g is related by $A_{\text{math}} = -i\, g\, A^a_{\text{phys}} T^a$. For U(1) with a real potential $a = a_\mu \mathrm{d}x^\mu$ (charge absorbed), $A = -ia$, $F_A = -i\,\mathrm{d}a$ and $c_1 = \frac{i}{2\pi}F_A = \frac{1}{2\pi}\mathrm{d}a$: the first Chern class is the magnetic field divided by 2π.

The two properties that make ch useful are that it turns $\oplus$ into $+$ and $\otimes$ into $\times$. The second one is the only thing Nash uses in [Nash p. 117, (4.115)], so let us see why it holds. Take a connection A on F and B on G. The natural connection on $F \otimes G$ is $A \otimes 1 + 1 \otimes B$, and its curvature is $F_{A\otimes G} = F_A \otimes 1 + 1 \otimes F_B$. The two terms commute (they act on different tensor factors, and they are even forms). Hence

$$\begin{aligned}
\mathrm{ch}(F \otimes G) &\overset{(1)}{=} \operatorname{tr}_{F\otimes G} \exp\!\left(\tfrac{i}{2\pi}(F_A \otimes 1 + 1 \otimes F_B)\right) \\
&\overset{(2)}{=} \operatorname{tr}_{F\otimes G}\left[\exp\!\left(\tfrac{i}{2\pi}F_A\right) \otimes \exp\!\left(\tfrac{i}{2\pi}F_B\right)\right] \\
&\overset{(3)}{=} \operatorname{tr}_F \exp\!\left(\tfrac{i}{2\pi}F_A\right)\ \operatorname{tr}_G \exp\!\left(\tfrac{i}{2\pi}F_B\right) \\
&= \mathrm{ch}(F)\ \mathrm{ch}(G).
\end{aligned} \tag{4.152}$$

(1) Definition of ch applied to the tensor product connection.
(2) $e^{X+Y} = e^X e^Y$ when X and Y commute; $X \otimes 1$ and $1 \otimes Y$ always commute, and $e^{X\otimes 1} = e^X \otimes 1$.

(3) The trace of a tensor product of matrices is the product of the traces: $\operatorname{tr}(M \otimes N) = \sum_{i,a} M_{ii} N_{aa} = (\operatorname{tr} M)(\operatorname{tr} N)$.

In terms of Chern roots this is the statement that the roots of $F \otimes G$ are all the sums $x_i + y_a$, and $\sum_{i,a} e^{x_i + y_a} = \left(\sum_i e^{x_i}\right)\left(\sum_a e^{y_a}\right)$. Similarly $\operatorname{ch}(F \oplus G) = \operatorname{ch} F + \operatorname{ch} G$ because the curvature of a direct sum is block diagonal and the trace of a block-diagonal matrix is the sum of the traces.

Worked example 4.94: The Chern character of the monopole bundle

On S^2 with polar angles (θ, ϕ), the charge-k monopole bundle L_k has the two local connection forms

$$A_N = -\tfrac{ik}{2}(1 - \cos\theta)\,\mathrm{d}\phi \quad (\theta < \pi), \qquad A_S = +\tfrac{ik}{2}(1 + \cos\theta)\,\mathrm{d}\phi \quad (\theta > 0).$$

Each is non-singular in its patch ($1 - \cos\theta$ vanishes at the north pole, where $\mathrm{d}\phi$ is ill-defined, and similarly in the south). On the overlap $A_N - A_S = -ik\,\mathrm{d}\phi = g^{-1}\mathrm{d}g$ with $g = e^{-ik\phi}$, which is single-valued precisely because $k \in \mathbb{Z}$. The curvature is the same in both patches:

$$\begin{aligned} F_A &\overset{(1)}{=} \mathrm{d}A_N = -\tfrac{ik}{2}\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi, \\ \int_{S^2} \operatorname{ch}_1(L_k) &\overset{(2)}{=} \frac{i}{2\pi}\int_{S^2}\left(-\frac{ik}{2}\right)\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi \\ &\overset{(3)}{=} \frac{k}{4\pi}\cdot 4\pi = k. \end{aligned}$$

(1) For a U(1) bundle $A \wedge A = 0$, so $F_A = \mathrm{d}A$; and $\mathrm{d}(1 - \cos\theta) = \sin\theta\,\mathrm{d}\theta$.
(2) $\operatorname{ch}_1 = c_1 = \frac{i}{2\pi}F_A$ for a line bundle.
(3) $i \cdot (-i) = 1$ and the area of the unit sphere is 4π.

So $\operatorname{ch}(L_k) = 1 + c_1(L_k)$ with $\int_{S^2} c_1(L_k) = k$. There is no degree-4 term because S^2 has no 4-forms.

For reference, here are the characteristic classes that appear in the four classical complexes, written in terms of the Chern roots x_i of TX (for a real 2ℓ-manifold, $TX_{\mathbb{C}}$ has roots $\pm x_1, \dots, \pm x_\ell$).

class	as a product over roots	first terms
Euler $e(X)$	$\prod_{i=1}^{\ell} x_i$	top degree only
Todd $\operatorname{td}(X)$ (complex X)	$\prod_i \dfrac{x_i}{1 - e^{-x_i}}$	$1 + \frac{1}{2}c_1 + \frac{1}{12}(c_1^2 + c_2) + \cdots$
$\hat{A}(X)$	$\prod_i \dfrac{x_i/2}{\sinh(x_i/2)}$	$1 - \frac{1}{24}p_1 + \frac{1}{5760}(7p_1^2 - 4p_2) + \cdots$
Hirzebruch $L(X)$	$\prod_i \dfrac{x_i}{\tanh x_i}$	$1 + \frac{1}{3}p_1 + \frac{1}{45}(7p_2 - p_1^2) + \cdots$

Here $p_1 = \sum_i x_i^2$ and $p_2 = \sum_{i<j} x_i^2 x_j^2$ are the Pontrjagin classes.

4.17.2 Matrix-valued forms and the twisted de Rham complex

What a matrix-valued form is

The ordinary de Rham complex [Nash p. 116, (4.112)] is

$$\cdots \xrightarrow{d_{p-1}} \Omega^p(X) \xrightarrow{d_p} \Omega^{p+1}(X) \xrightarrow{d_{p+1}} \cdots, \qquad \Omega^p(X) = \Gamma(X, \Lambda^p T^* X_{\mathbb{C}}).$$

In gauge theory we constantly meet forms that carry an extra index: the gauge potential $A^a{}_b$, the field strength $F^a{}_b$, a charged scalar ϕ^a, a covariant derivative $D\phi^a$. These are **vector-valued** (or matrix-valued) forms.

Working definition 4.45 (forms with values in a bundle)

Let $F \to X$ be a complex vector bundle of rank m. An **F-valued p-form** is, in each local trivialisation U_α of F, a column of m ordinary p-forms $\psi_\alpha = (\psi_\alpha^1, \dots, \psi_\alpha^m)^T$, such that on overlaps $\psi_\alpha = g_{\alpha\beta}\,\psi_\beta$, where $g_{\alpha\beta}$ are the transition functions [the $m \times m$ matrices $g_{\alpha\beta}(x)$ relating the two trivialisations on $U_\alpha \cap U_\beta$] of F. The space of them is

$$\Omega^p(X;F) = \Gamma(X, F \otimes \Lambda^p T^*X_{\mathbb{C}}).$$

[smooth sections, with one F-index and p antisymmetric form indices at each point] *Test:* if you can write it as "(an index in the gauge representation) × (a differential form)", and it transforms under gauge transformations only through the gauge index, it is an F-valued form.

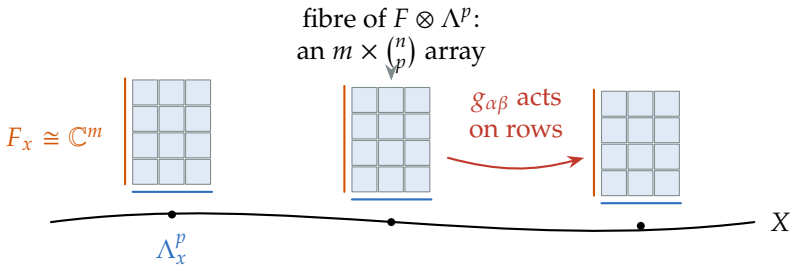

Figure 4.55: An F-valued p-form assigns to each point an array: one column index for the p-form components ($\binom{n}{p}$ of them) and one row index for the gauge components (m of them). Gauge transformations $g_{\alpha\beta}$ mix only the rows. The ordinary de Rham complex is the case of a single row.

The twisted exterior derivative

To differentiate an F-valued form in a gauge-covariant way we need a connection A on F. The **covariant exterior derivative** is

$$d_A\psi = \mathrm{d}\psi + A \wedge \psi, \tag{4.153}$$

where $A \wedge \psi$ means matrix multiplication in the gauge index and wedge product in the form index. Nash writes d_F for it. Let us check it is covariant. Under a gauge transformation $\psi' = g^{-1}\psi$ and $A' = g^{-1}Ag + g^{-1}\mathrm{d}g$:

$$\begin{aligned} d_{A'}\psi' &\overset{(1)}{=} \mathrm{d}(g^{-1}\psi) + (g^{-1}Ag + g^{-1}\mathrm{d}g)\,g^{-1}\psi \\ &\overset{(2)}{=} -g^{-1}(\mathrm{d}g)\,g^{-1}\psi + g^{-1}\mathrm{d}\psi + g^{-1}A\psi + g^{-1}(\mathrm{d}g)\,g^{-1}\psi \\ &\overset{(3)}{=} g^{-1}(\mathrm{d}\psi + A\psi) = g^{-1}\,d_A\psi. \end{aligned}$$

(1) Definition (4.153) in the new gauge.
(2) Leibniz rule and $\mathrm{d}(g^{-1}) = -g^{-1}(\mathrm{d}g)\,g^{-1}$ (differentiate $g^{-1}g = 1$).
(3) The two $\mathrm{d}g$ terms cancel.

So $d_A\psi$ transforms exactly like ψ: it is again an F-valued form. Replacing d by d_A in the de Rham complex gives Nash's **twisted de Rham complex** [Nash p. 116, (4.113)]:

$$\cdots \xrightarrow{d_A} \Omega^{p-1}(X;F) \xrightarrow{d_A} \Omega^p(X;F) \xrightarrow{d_A} \Omega^{p+1}(X;F) \xrightarrow{d_A} \cdots . \tag{4.154}$$

Watch out: The twisted de Rham sequence is a complex only for flat F

Unlike $\mathrm{d}^2 = 0$, the square of d_A is not zero:

$$\begin{aligned} d_A(d_A\psi) &\overset{(1)}{=} \mathrm{d}(\mathrm{d}\psi + A\wedge\psi) + A\wedge(\mathrm{d}\psi + A\wedge\psi) \\ &\overset{(2)}{=} (\mathrm{d}A)\wedge\psi - A\wedge\mathrm{d}\psi + A\wedge\mathrm{d}\psi + A\wedge A\wedge\psi \\ &\overset{(3)}{=} (\mathrm{d}A + A\wedge A)\wedge\psi = F_A\wedge\psi. \end{aligned}$$

(1) Apply (4.153) twice.
(2) $\mathrm{d}^2 = 0$, and the graded Leibniz rule $\mathrm{d}(A\wedge\psi) = \mathrm{d}A\wedge\psi - A\wedge\mathrm{d}\psi$ (the minus sign because A is a 1-form).
(3) The $A\wedge\mathrm{d}\psi$ terms cancel; what remains is the curvature.

So (4.154) is literally a complex only when $F_A = 0$, i.e. for a flat bundle. Nash passes over this. It does not matter for the *index*: the operator whose index we compute is the rolled-up $D_A = d_A + d_A^*$ from even to odd F-valued forms, and this is elliptic for *every* connection. Its leading symbol is $\sigma(D_A)(x,p) = i(p\wedge - \iota_p)\otimes 1_F$, independent of A: the connection only enters at order zero. Since the index depends only on the symbol class, the formula below holds for any F and any A.

The index of the twisted de Rham operator

Recall how the untwisted index came out [Nash p. 117, (4.114)]: with $E^p = \Lambda^p T^*X_{\mathbb{C}}$,

$$\operatorname{index} d = (-1)^{n/2}\,\frac{\operatorname{ch}\big(\sum_p (-1)^p[E^p]\big)}{e(X)}\,\operatorname{td}(TX_{\mathbb{C}})[X] = \int_X e(X) = \chi(X). \tag{4.155}$$

Passing to d_A changes only one thing: E^p becomes $F\otimes E^p$. Then

$$\begin{aligned} \operatorname{index} d_A &\overset{(1)}{=} (-1)^{n/2}\,\frac{\operatorname{ch}\big(\sum_p (-1)^p[F\otimes E^p]\big)}{e(X)}\,\operatorname{td}(TX_{\mathbb{C}})[X] \\ &\overset{(2)}{=} (-1)^{n/2}\operatorname{ch}(F)\,\frac{\operatorname{ch}\big(\sum_p (-1)^p[E^p]\big)}{e(X)}\,\operatorname{td}(TX_{\mathbb{C}})[X] \\ &\overset{(3)}{=} \operatorname{ch}(F)\,e(X)\,[X] = \int_X \operatorname{ch}(F)\wedge e(X) \qquad (4.156) \\ &\overset{(4)}{=} \int_X \big(m + c_1(F) + \operatorname{ch}_2(F) + \cdots\big)\wedge e(X) \\ &\overset{(5)}{=} m\int_X e(X) = m\,\chi(X). \qquad (4.157) \end{aligned}$$

(1) The general formula (4.151) for the complex with bundles $F\otimes E^p$.
(2) ch is additive, so $\operatorname{ch}(\sum(-1)^p F\otimes E^p) = \sum(-1)^p \operatorname{ch}(F)\operatorname{ch}(E^p) = \operatorname{ch}(F)\operatorname{ch}(\sum(-1)^p E^p)$ by (4.152).
(3) The remaining factor is exactly the untwisted integrand, which (4.155) simplifies to $e(X)$. This is Nash's (4.116).
(4) Expand $\operatorname{ch}(F)$ by degree; $m = \operatorname{rk} F$.
(5) $e(X)$ is already a form of top degree n; wedging it with anything of positive degree gives a form of degree $> n$, which vanishes on an n-manifold. Only the degree-0 part m of $\operatorname{ch}(F)$ survives. This is Nash's (4.117).

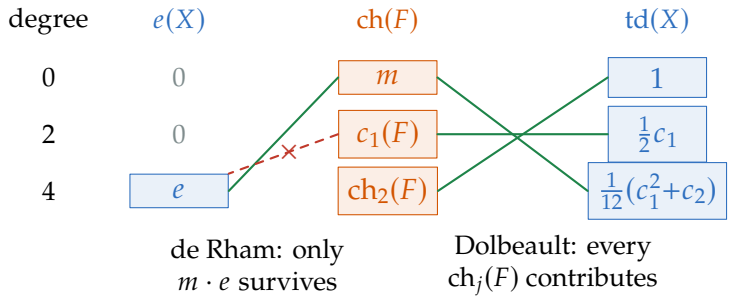

Figure 4.56: Degree bookkeeping on a real 4-manifold. We need products of total degree 4. On the left, the Euler class sits entirely in degree 4, so it can only be paired with the degree-0 part m of $\mathrm{ch}(F)$ (green line; the dashed red pairing would have degree 6 and vanishes). On the right, the Todd class has pieces in every degree, so every component of $\mathrm{ch}(F)$ finds a partner. This is why twisting changes nothing essential for de Rham but a lot for Dolbeault.

Physical picture: Why a gauge field cannot change the Euler characteristic

The de Rham index counts (with signs) the harmonic forms. Twisting by a rank-m bundle is, as far as topology is concerned, like taking m copies of the forms. The individual cohomology groups of the twisted complex can be wildly different from m copies of the untwisted ones (see the examples), but the alternating sum is rigid.

Worked example 4.95: A flat line bundle on the circle

Let $X = S^1$ with coordinate $\theta \in [0, 1)$ and let F be the trivial line bundle with the flat connection $A = 2\pi i a \, \mathrm{d}\theta$, $a \in \mathbb{R}$. Its holonomy around the circle is $\exp(-\oint A) = e^{-2\pi i a}$. The twisted complex is $\Omega^0 \xrightarrow{d_A} \Omega^1$ with $d_A f = (f' + 2\pi i a f)\,\mathrm{d}\theta$. Expand $f = \sum_n f_n e^{2\pi i n\theta}$ and $g\,\mathrm{d}\theta = \sum_n g_n e^{2\pi i n\theta}\mathrm{d}\theta$. Then

$$d_A f \overset{(1)}{=} \sum_n 2\pi i\,(n + a)\, f_n\, e^{2\pi i n\theta}\,\mathrm{d}\theta.$$

(1) $\frac{\mathrm{d}}{\mathrm{d}\theta} e^{2\pi i n\theta} = 2\pi i n\, e^{2\pi i n\theta}$, plus the term $2\pi i a f$.

So d_A is diagonal in the Fourier basis with eigenvalue $2\pi i(n + a)$.

- If $a \notin \mathbb{Z}$, every eigenvalue is non-zero: $\ker d_A = 0$, and every g is hit ($f_n = g_n/2\pi i(n + a)$), so $H^1 = 0$. Both cohomologies vanish.
- If $a \in \mathbb{Z}$, the mode $n = -a$ is killed: $H^0 = \mathbb{C}$ and the corresponding g_{-a} cannot be reached, so $H^1 = \mathbb{C}$.

In both cases $\dim H^0 - \dim H^1 = 0 = 1 \cdot \chi(S^1)$. The groups jump as the holonomy passes through 1; their alternating sum does not.

Worked example 4.96: Flat line bundles on the torus

On $T^2 = \mathbb{R}^2/\mathbb{Z}^2$ with coordinates (x, y) take $A = 2\pi i(a\,\mathrm{d}x + b\,\mathrm{d}y)$. Exactly as on the circle, d_A acts on the Fourier mode $e^{2\pi i(mx+ny)}$ by multiplying the $\mathrm{d}x$ and $\mathrm{d}y$ components by $2\pi i(m + a)$ and $2\pi i(n + b)$. The twisted Laplacian $\Delta_A = d_A d_A^* + d_A^* d_A$ therefore acts on every mode, in every form degree, by the number

$$4\pi^2\big[(m + a)^2 + (n + b)^2\big].$$

For $(a,b) \notin \mathbb{Z}^2$ this never vanishes, so there are no harmonic forms at all: $h^0 = h^1 = h^2 = 0$. For $(a,b) \in \mathbb{Z}^2$ one mode is harmonic in each form component: $h^0 = 1$, $h^1 = 2$ (the $\mathrm{d}x$ and $\mathrm{d}y$ components), $h^2 = 1$. In both cases

$$h^0 - h^1 + h^2 = 0 = 1 \cdot \chi(T^2),$$

as (4.157) predicts. This example is worth remembering: the parameter (a,b) lives on a torus of its own, and the kernel jumps at one point of it. We will meet this "parameter torus" again when we discuss families in Section 4.18.

Worked example 4.97: The monopole bundle on S^2: kernel grows, index does not

Now take $X = S^2$ and $F = L_k$, the charge-k monopole bundle of Example 4.94. It is not flat, so we work with the operator $D_A = d_A + d_A^* : \Omega^0(L_k) \oplus \Omega^2(L_k) \to \Omega^1(L_k)$. The prediction (4.157) is $\operatorname{index} D_A = 1 \cdot \chi(S^2) = 2$ for every k.

On a surface there is a neat way to see this. Use $\star$ to write a 2-form as $g\,\mathrm{vol}$, with g a function (section of L_k). Use a local complex coordinate $z = x + iy$ and split $d_A = \partial_A + \bar\partial_A$ into its $\mathrm{d}z$ and $\mathrm{d}\bar z$ parts. With orientation $\mathrm{d}x \wedge \mathrm{d}y$ we have $\star \mathrm{d}z = -i\,\mathrm{d}z$ and $\star \mathrm{d}\bar z = i\,\mathrm{d}\bar z$, and on 2-forms in two dimensions $d_A^* = - \star d_A \star$. Then

$$\begin{aligned} D_A(f, g\,\mathrm{vol}) &\overset{(1)}{=} d_A f - \star d_A g \\ &\overset{(2)}{=} \partial_A f + \bar\partial_A f - \left(-i\,\partial_A g + i\,\bar\partial_A g\right) \\ &\overset{(3)}{=} \partial_A (f + ig) + \bar\partial_A (f - ig). \end{aligned}$$

(1) $d_A^*(g\,\mathrm{vol}) = - \star d_A \star (g\,\mathrm{vol}) = - \star d_A g$.
(2) Split $d_A g = \partial_A g + \bar\partial_A g$ and apply the Hodge star to each piece.
(3) Collect the $\mathrm{d}z$ and $\mathrm{d}\bar z$ components.

So D_A is two decoupled operators: $\bar\partial_A$ acting on $u = f - ig$ and ∂_A acting on $v = f + ig$. The first is the Cauchy–Riemann operator of the holomorphic line bundle $\mathcal{O}(k)$; the second, after complex conjugation, is the Cauchy–Riemann operator of $\overline{L_k} = L_{-k}$, i.e. of $\mathcal{O}(-k)$. Anticipating the count of holomorphic sections in Example 4.98 below (index $\bar\partial_{\mathcal{O}(j)} = j + 1$):

$$\operatorname{index} D_A = \underbrace{(k+1)}_{\mathcal{O}(k)} + \underbrace{(-k+1)}_{\mathcal{O}(-k)} = 2.$$

For $k > 0$ the kernel of D_A has dimension $k + 1$ and the cokernel $k - 1$: both grow with the magnetic charge, but their difference is always 2.

4.17.3 The twisted Dolbeault complex and Riemann–Roch

Now let X be a complex manifold of complex dimension ℓ ($n = 2\ell$ real dimensions) with local holomorphic coordinates $z^1, \dots, z^\ell$. The Dolbeault complex uses forms of type $(0,p)$, i.e. built from $\mathrm{d}\bar z^{j_1} \wedge \cdots \wedge \mathrm{d}\bar z^{j_p}$, with the operator $\bar\partial = \mathrm{d}\bar z^j\, \partial/\partial \bar z^j$. Its cohomology $H^{0,p}(X)$ has dimensions $h^{0,p}$ and its index is the arithmetic genus $\sum_p (-1)^p h^{0,p} = \int_X \mathrm{td}(X)$ (Nash's (4.72)).

Twisting by a *holomorphic* vector bundle F (one whose transition functions are holomorphic) gives $(0,p)$-forms with values in F, which Nash writes $\Omega^p(F)$ (Chapter 3 called them the sheaf of p-forms with coefficients in F). The operator $\bar\partial_F$ acts componentwise in any holomorphic trivialisation; this is consistent because holomorphic transition functions are annihilated by

$\bar\partial$. Now $\bar\partial_F^2 = 0$ honestly, so this is a genuine complex, with cohomology groups $H^{0,p}(X;F) = H^p(X;\mathcal{O}(F))$, the sheaf cohomology of the sheaf of holomorphic sections of F.

The calculation is identical in shape to (4.156):

$$\begin{aligned}\operatorname{index}\bar\partial_F &\overset{(1)}{=} (-1)^\ell \frac{\operatorname{ch}\big(\sum_p (-1)^p [F\otimes\Lambda^{0,p}]\big)}{e(X)}\ \operatorname{td}(TX_{\mathbb{C}})[X]\\ &\overset{(2)}{=} \operatorname{ch}(F)\,(-1)^\ell \frac{\operatorname{ch}\big(\sum_p (-1)^p [\Lambda^{0,p}]\big)}{e(X)}\ \operatorname{td}(TX_{\mathbb{C}})[X]\\ &\overset{(3)}{=} \int_X \operatorname{ch}(F)\wedge\operatorname{td}(X) = \chi(X,F).\end{aligned} \tag{4.158}$$

(1) General formula (4.151) for the bundles $E^p = F\otimes\Lambda^{0,p}$.
(2) Additivity and multiplicativity of ch.
(3) The untwisted combination reduces to $\operatorname{td}(X)$, the Todd class of the holomorphic tangent bundle (Nash's (4.70)–(4.71)); and the alternating sum of dimensions of sheaf cohomology is by definition the **holomorphic Euler characteristic** $\chi(X,F) = \sum_p (-1)^p \dim H^p(X;\mathcal{O}(F))$.

Equation (4.158) is Nash's (4.118): the **Hirzebruch–Riemann–Roch theorem**. Unlike the de Rham case, $\operatorname{td}(X)$ has components in every even degree (Figure 4.56), so every Chern class of F contributes.

Complex dimension one: the classical Riemann–Roch theorem

Let X be a compact Riemann surface of genus g and F a holomorphic bundle of rank r and degree $\deg F = \int_X c_1(F)$. Then

$$\begin{aligned}\operatorname{index}\bar\partial_F &\overset{(1)}{=} \int_X \big(r + c_1(F)\big)\wedge\big(1+\tfrac12 c_1(X)\big)\\ &\overset{(2)}{=} \int_X c_1(F) + \frac{r}{2}\int_X c_1(X)\\ &\overset{(3)}{=} \deg F + \frac{r}{2}(2-2g) = \deg F + r(1-g).\end{aligned} \tag{4.159}$$

(1) $\operatorname{ch}(F) = r + c_1(F)$ and $\operatorname{td}(X) = 1 + \frac12 c_1(X)$, truncated at real degree 2 because X has no forms of higher degree.
(2) Keep only the 2-form part: $r\cdot\frac12 c_1(X) + c_1(F)\cdot 1$.
(3) For a curve $c_1(X) = c_1(TX) = e(X)$, and Gauss–Bonnet gives $\int_X e(X) = \chi(X) = 2-2g$.

In words: $\dim H^0(X;F) - \dim H^1(X;F) = \deg F + r(1-g)$. This is the classical Riemann–Roch theorem, now seen as an index theorem.

Worked example 4.98: Holomorphic sections of $\mathcal{O}(k)$ on $\mathbb{CP}^1$

On $\mathbb{CP}^1 = S^2$ use the two coordinates z (near 0) and $w = 1/z$ (near ∞). The line bundle $\mathcal{O}(k)$ is defined by the transition function z^k: a section is a pair of holomorphic functions $s_0(z)$ and $s_\infty(w)$ with $s_\infty(w) = w^k s_0(1/w)$. It is the holomorphic version of the monopole bundle L_k, with $\deg\mathcal{O}(k) = k$.

Direct count. Let $s_0(z) = \sum_{j\ge 0} a_j z^j$ be entire. Then $s_\infty(w) = \sum_j a_j w^{k-j}$ must be holomorphic at $w=0$, which forces $a_j = 0$ for $j > k$. Hence the global holomorphic sections are exactly the polynomials of degree $\le k$:

$$H^0(\mathbb{CP}^1;\mathcal{O}(k)) = \operatorname{span}\{1, z, z^2, \dots, z^k\}, \qquad h^0 = k+1 \quad (k\ge 0).$$

One can show $h^1 = 0$ for $k \geq -1$ (and by Serre duality $h^1(\mathcal{O}(k)) = h^0(\mathcal{O}(-2-k))$ in general). *Index theorem.* With $g = 0$, $r = 1$, (4.159) gives index $\bar\partial_{\mathcal{O}(k)} = k + 1$, matching the count. For $k \leq -2$ there are no sections, and the index $k + 1 < 0$ is carried entirely by $h^1 = -k - 1$.

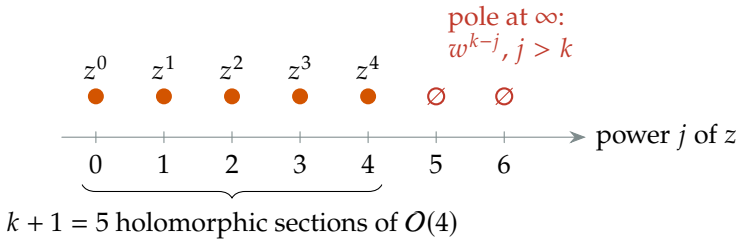

Figure 4.57: Global holomorphic sections of $\mathcal{O}(k)$ on $\mathbb{CP}^1$, here $k = 4$. In the z-chart a section is a power series $\sum a_j z^j$; in the $w = 1/z$ chart it becomes $\sum a_j w^{k-j}$, which is regular at $w = 0$ only if $j \leq k$ (orange dots). The index $k + 1$ is literally the number of allowed monomials.

Physical picture: Lowest Landau level = index

A charged particle on a torus T^2 in a uniform magnetic field with N flux quanta has a lowest Landau level of degeneracy exactly N. The lowest-Landau-level wave functions are the zero modes of $\bar\partial_A$, i.e. holomorphic sections of a degree-N line bundle (they are theta functions). Riemann–Roch with $g = 1$ gives index $= N + 1 \cdot (1 - 1) = N$, and one checks $h^1 = 0$ for $N > 0$. The celebrated "degeneracy = number of flux quanta" is a twisted index theorem.

Complex dimension two

Nash works out the next case [Nash p. 118, (4.119)–(4.120)]. On a complex surface ($\ell = 2$, real dimension 4) we need everything up to real degree 4:

$$\operatorname{ch}(F) = \operatorname{rk} F + c_1(F) + \tfrac{1}{2}\big(c_1^2(F) - 2c_2(F)\big) + \cdots,$$
$$\operatorname{td}(X) = 1 + \tfrac{1}{2}c_1(X) + \tfrac{1}{12}\big(c_1^2(X) + c_2(X)\big) + \cdots.$$

Multiplying and keeping the degree-4 part:

$$\begin{aligned}\operatorname{index}\bar\partial_F &\overset{(1)}{=} \int_X \Big[\operatorname{rk} F \cdot \tfrac{1}{12}(c_1^2 + c_2)(X) + c_1(F)\cdot\tfrac{1}{2}c_1(X) + \tfrac{1}{2}\big(c_1^2(F) - 2c_2(F)\big)\cdot 1\Big] \\ &\overset{(2)}{=} \frac{\operatorname{rk} F}{12}\int_X \big(c_1^2(X) + c_2(X)\big) + \frac{1}{2}\int_X \big(c_1^2(F) - 2c_2(F) + c_1(F)c_1(X)\big).\end{aligned} \tag{4.160}$$

(1) The three ways to make degree 4: (degree 0 of ch)×(degree 4 of td), (degree 2)×(degree 2), (degree 4)×(degree 0).
(2) Regroup; this is Nash's (4.120).

For F trivial of rank 1 this gives Noether's formula $\chi(X, \mathcal{O}) = \frac{1}{12}\int (c_1^2 + c_2)$.

Worked example 4.99: $\mathbb{CP}^2$ and homogeneous polynomials

Let h be the hyperplane class of $\mathbb{CP}^2$, normalised by $\int_{\mathbb{CP}^2} h^2 = 1$. The total Chern class of $T\mathbb{CP}^2$ is $(1 + h)^3$, so $c_1(X) = 3h$ and $c_2(X) = 3h^2$. The bundle $\mathcal{O}(k)$ has $c_1 = kh$, $c_2 = 0$, rank

1. Then

$$\operatorname{index}\bar\partial_{\mathcal{O}(k)} \overset{(1)}{=} \frac{1}{12}(9+3)+\frac{1}{2}\big(k^2+3k\big) \overset{(2)}{=} 1+\frac{k^2+3k}{2}=\frac{(k+1)(k+2)}{2}.$$

(1) Insert into (4.160): $c_1^2(X)+c_2(X)=9h^2+3h^2$, and $c_1^2(F)+c_1(F)c_1(X)=k^2h^2+3kh^2$; integrate using $\int h^2=1$.

(2) Arithmetic: $2+k^2+3k=(k+1)(k+2)$.

The holomorphic sections of $\mathcal{O}(k)$ on $\mathbb{CP}^2$ are the homogeneous polynomials of degree k in (z_0,z_1,z_2), and there are $\binom{k+2}{2}=\frac{(k+1)(k+2)}{2}$ monomials $z_0^a z_1^b z_2^c$ with $a+b+c=k$. For $k\geq 0$ the higher cohomology vanishes, and the index theorem reproduces the count exactly. For $k=0$ we get 1: the only holomorphic functions are constants.

Try it: A K3 surface

A K3 surface has $c_1=0$ and $\int c_2=\chi=24$. Compute $\chi(X,\mathcal{O})=h^{0,0}-h^{0,1}+h^{0,2}$.
Answer: Noether gives $\frac{1}{12}(0+24)=2$; indeed $h^{0,0}=1$, $h^{0,1}=0$, $h^{0,2}=1$ (the holomorphic 2-form).

4.17.4 The twisted signature complex

Recall the signature operator. On an oriented Riemannian n-manifold (n even) there is an involution τ on complex forms, $\tau=i^{p(p-1)+n/2}\star$ on p-forms, with $\tau^2=1$. Its ±1 eigenspaces $\Omega^{\pm}$ are exchanged by $d+d^*$, and the **signature operator** is $d_+=d+d^*:\Omega^+\to\Omega^-$. When $n\equiv 0 \bmod 4$, $\operatorname{index} d_+=\operatorname{Sign}(X)$, the signature of the intersection form on $H^{n/2}$. Twisting by F with a connection gives $d_+^F=d_A+d_A^*:\Omega^+(F)\to\Omega^-(F)$.

The index calculation needs $\operatorname{ch}\big(\Lambda^+-\Lambda^-\big)$. Nash showed [Nash p. 106, (4.91)] that $\operatorname{ch}(\Lambda^+-\Lambda^-)=\prod_i(e^{-x_i}-e^{x_i})$ up to sign, and inserting it into (4.151) with the extra factor $\operatorname{ch}(F)$ one finds

$$\operatorname{index} d_+^F=\int_X \operatorname{ch}(F)\wedge\prod_{i=1}^{n/2}\frac{x_i}{\tanh(x_i/2)}. \tag{4.161}$$

Nash writes this as $2^{n/2}\int_X \operatorname{ch}(F)\wedge\mathcal{L}(X)$ [Nash p. 118, (4.121)].

Watch out: Which "L" is Nash's $\mathcal{L}$?

Pull a factor of 2 out of each root: $\frac{x}{\tanh(x/2)}=2\cdot\frac{x/2}{\tanh(x/2)}$. So (4.161) equals $2^{n/2}\int\operatorname{ch}(F)\,\mathcal{L}$ exactly when $\mathcal{L}=\prod_i\frac{x_i/2}{\tanh(x_i/2)}$. This is the normalisation Nash uses (it is what makes his (4.93)–(4.95) consistent). The Hirzebruch polynomial $L=\prod_i\frac{x_i}{\tanh x_i}$ is different. The two agree in top degree after the factor $2^{n/2}$, because the degree-$4j$ part of $\mathcal{L}$ is $2^{-2j}L_j$ and for $4j=n$ this is $2^{-n/2}L_{n/4}$. But the *lower*-degree parts, which pair with $\operatorname{ch}(F)$, differ by powers of 2. The safe form is (4.161), or equivalently

$$\operatorname{index} d_+^F=\sum_{j\geq 0}2^{\,n/2-2j}\int_X \operatorname{ch}_{n/2-2j}(F)\wedge L_j(X).$$

Let us expand (4.161) in low dimensions. We need the power series

$$\frac{x}{\tanh(x/2)} \overset{(1)}{=} 2 \cdot \frac{y}{\tanh y}\Big|_{y=x/2} \overset{(2)}{=} 2\Big(1 + \frac{y^2}{3} - \frac{y^4}{45} + \cdots\Big)_{y=x/2}$$
$$= 2 + \frac{x^2}{6} - \frac{x^4}{360} + \cdots . \tag{4.162}$$

(1) Write $x = 2y$.

(2) $\tanh y = y - \frac{y^3}{3} + \frac{2y^5}{15} - \cdots$, so $\frac{y}{\tanh y} = \big(1 - \frac{y^2}{3} + \frac{2y^4}{15}\big)^{-1} = 1 + \frac{y^2}{3} - \frac{y^4}{45} + \cdots$.

Dimension 2 ($n = 2$, one root x). The degree-2 part of $\mathrm{ch}(F)\,(2 + \frac{x^2}{6} + \cdots)$ is $2c_1(F)$ (note x^2 has degree 4, too high). So

$$\operatorname{index} d_+^F = 2\int_X c_1(F) \qquad (n = 2). \tag{4.163}$$

Dimension 4 ($n = 4$, roots x_1, x_2). Here $\prod_{i=1}^2 (2 + \frac{x_i^2}{6}) = 4 + \frac{1}{3}(x_1^2 + x_2^2) + \cdots = 4 + \frac{1}{3}p_1 + \cdots$, so

$$\operatorname{index} d_+^F = 4\int_X \mathrm{ch}_2(F) + \operatorname{rk} F \cdot \frac{1}{3}\int_X p_1 = 4\int_X \mathrm{ch}_2(F) + \operatorname{rk} F \cdot \operatorname{Sign}(X). \tag{4.164}$$

For trivial F of rank 1 we recover Hirzebruch's $\operatorname{Sign}(X) = \frac{1}{3}\int p_1$.

Worked example 4.100: Twisted signature operator on S^2 and S^4

S^2 with the monopole bundle L_k. The untwisted signature operator in dimension 2 has index 0 (there is no signature in dimension 2). By (4.163) and Example 4.94:

$$\operatorname{index} d_+^{L_k} = 2\int_{S^2} c_1(L_k) = 2k \neq 0.$$

S^4 with an SU(2) *instanton.* Let F be the rank-2 bundle of a charge-k instanton; $c_1(F) = 0$ and $\int c_2(F) = k$ (this fixes our orientation convention). Then $\mathrm{ch}_2(F) = \frac{1}{2}(c_1^2 - 2c_2) = -c_2$ and $\operatorname{Sign}(S^4) = 0$, so (4.164) gives

$$\operatorname{index} d_+^F = 4 \cdot (-k) + 2 \cdot 0 = -4k.$$

Nash's remark [Nash p. 118] that $\operatorname{index} d_+^F$ can be non-zero in any even dimension, unlike $\operatorname{index} d_+$, is illustrated by the first case.

4.17.5 The twisted spin complex: Dirac operators in gauge fields

This is the case physicists care about most. Let X be a spin manifold of even dimension n with spinor bundle $E = E^+ \oplus E^-$ (split by the chirality operator γ_5). A Dirac fermion coupled to a Yang–Mills field in the representation carried by F is a section of $E \otimes F$, and the covariant Dirac operator is, in local coordinates [Nash p. 118],

$$\not{D}_F = \gamma^a e_a{}^\mu(x)\big(\partial_\mu + \omega_\mu + A_\mu\big), \qquad \not{D}_F^+ = \not{D}_F\,\tfrac{1}{2}(1 + \gamma_5) : \Gamma(E^+ \otimes F) \to \Gamma(E^- \otimes F). \tag{4.165}$$

Here $e_a{}^\mu$ is the vielbein, ω_μ the spin connection and A_μ the Yang–Mills connection (an anti-Hermitian matrix in the representation of F).

An explicit representation in two dimensions

Let us be concrete. In two Euclidean dimensions take

$$\gamma^1 = \sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad \gamma^2 = \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \qquad \gamma_5 = -i\gamma^1\gamma^2 = \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{4.166}$$

One checks $(\gamma^1)^2 = (\gamma^2)^2 = 1$, $\gamma^1\gamma^2 = i\sigma_3 = -\gamma^2\gamma^1$, and γ_5 anticommutes with both. (Nash normalises $\{\gamma_a, \gamma_b\} = -2\delta_{ab}$, which amounts to multiplying our γ's by i; this and the choice of orientation are the source of his sign $(-1)^{n/2}$ below.) On flat $\mathbb{R}^2$ with complex coordinate $z = x + iy$, $\partial_z = \tfrac{1}{2}(\partial_x - i\partial_y)$, $\partial_{\bar z} = \tfrac{1}{2}(\partial_x + i\partial_y)$:

$$\not{D} \overset{(1)}{=} \sigma_1\partial_x + \sigma_2\partial_y \overset{(2)}{=} \begin{pmatrix} 0 & \partial_x - i\partial_y \\ \partial_x + i\partial_y & 0 \end{pmatrix} \overset{(3)}{=} \begin{pmatrix} 0 & 2\partial_z \\ 2\partial_{\bar z} & 0 \end{pmatrix}. \tag{4.167}$$

(1) Flat space: ${e_a}^\mu = \delta_a^\mu$, $\omega = 0$.
(2) Insert the Pauli matrices (4.166).
(3) Definitions of ∂_z and $\partial_{\bar z}$.

So on $\psi = (\psi_+, \psi_-)^T$, $\not{D}^+\psi_+ = 2\partial_{\bar z}\psi_+$: a positive-chirality zero mode is a holomorphic function, and $\not{D}^-\psi_- = 2\partial_z\psi_-$: a negative-chirality zero mode is antiholomorphic. With a gauge field, $\partial_{\bar z} \to \partial_{\bar z} + A_{\bar z}$.

The index formula

For the twisted spin complex the same manipulation as before gives [Nash p. 118, (4.122)]

$$\operatorname{index} \not{D}_F^+ = \pm \int_X \operatorname{ch}(F) \wedge \hat{A}(X), \tag{4.168}$$

where Nash's sign is $(-1)^{n/2}$. With the representation (4.166), the orientation $\mathrm{d}x \wedge \mathrm{d}y$ and the gauge convention of the Dictionary above, the sign is $+$, as the explicit computation below confirms; we use $+$ from now on.

Key idea: What twisting does to the Dirac index

$\hat{A}(X) = 1 - \frac{1}{24}p_1 + \cdots$ has a non-zero degree-0 term. So every component $\operatorname{ch}_j(F)$ of the gauge bundle contributes. In particular in dimension n the pure gauge term is $\int_X \operatorname{ch}_{n/2}(F)$: *in flat space, the index of the Dirac operator in a gauge field is the $(n/2)$-th Chern character number of the gauge field.* In $n = 2$ this is the magnetic flux over 2π; in $n = 4$ it is minus the instanton number.

Worked example 4.101: Aharonov–Casher zero modes in the plane

Let a U(1) magnetic field $B(x, y) \geq 0$ with total flux $\Phi = \int B\,\mathrm{d}x\,\mathrm{d}y$ be localised near the origin of $\mathbb{R}^2$. Choose a potential ϕ with $\nabla^2\phi = B$, and the gauge $a = (-\partial_y\phi, \partial_x\phi)$, so $\partial_x a_y - \partial_y a_x = \nabla^2\phi = B$. In our convention $A = -ia$. Then

$$A_{\bar z} \overset{(1)}{=} \tfrac{1}{2}(A_x + iA_y) \overset{(2)}{=} -\tfrac{i}{2}\big(-\partial_y\phi + i\partial_x\phi\big) \overset{(3)}{=} \tfrac{1}{2}(\partial_x + i\partial_y)\phi = \partial_{\bar z}\phi,$$

$$\not{D}_A^+\psi_+ \overset{(4)}{=} 2(\partial_{\bar z} + \partial_{\bar z}\phi)\psi_+ \overset{(5)}{=} 2e^{-\phi}\,\partial_{\bar z}\big(e^{\phi}\psi_+\big).$$

(1) $A_{\bar z}\,\mathrm{d}\bar z + A_z\,\mathrm{d}z = A_x\mathrm{d}x + A_y\mathrm{d}y$ with $\mathrm{d}\bar z = \mathrm{d}x - i\mathrm{d}y$ gives $A_{\bar z} = \tfrac{1}{2}(A_x + iA_y)$.
(2) $A = -ia$ with $a_x = -\partial_y\phi$, $a_y = \partial_x\phi$.

(3) Multiply out: $-\frac{i}{2}\cdot i\,\partial_x\phi = \frac{1}{2}\partial_x\phi$ and $-\frac{i}{2}(-\partial_y\phi) = \frac{i}{2}\partial_y\phi$.
(4) The positive-chirality block of (4.167) with $\partial_{\bar z} \to \partial_{\bar z} + A_{\bar z}$.
(5) Product rule: $\partial_{\bar z}(e^{\phi}\psi) = e^{\phi}(\partial_{\bar z}\psi + \psi\,\partial_{\bar z}\phi)$.

So the zero modes are $\psi_+ = e^{-\phi}f(z)$ with f entire. Far away, $\phi \approx \frac{\Phi}{2\pi}\ln r$ (the 2D Green's function: $\nabla^2 \ln r = 2\pi\delta^2$), so $e^{-\phi} \approx r^{-\Phi/2\pi}$. Taking $f = z^j$, the mode is square-integrable iff $\int^{\infty} r^{2j-\Phi/\pi}\, r\,\mathrm{d}r < \infty$, i.e. $j < \frac{\Phi}{2\pi} - 1$. The analogous computation for $\psi_- = e^{\phi}\overline{g(z)}$ gives nothing normalisable. Therefore

$$n_+ = \#\Big\{j \in \mathbb{Z}_{\geq 0} :\ j < \tfrac{\Phi}{2\pi} - 1\Big\} \approx \frac{\Phi}{2\pi}, \qquad n_- = 0.$$

All zero modes have the same chirality, and their number is the flux in units of 2π, i.e. $\int c_1$, up to a boundary effect of at most one that comes from the plane not being compact.

Worked example 4.102: Dirac operator on S^2 in a monopole field

On the closed sphere the boundary ambiguity disappears. With $\hat{A}(S^2) = 1$ (there are no degree-4 forms), (4.168) and Example 4.94 give

$$\operatorname{index} \not{D}^{+}_{L_k} \overset{(1)}{=} \int_{S^2} \big(1 + c_1(L_k)\big) \wedge 1 \overset{(2)}{=} \int_{S^2} c_1(L_k) = k.$$

(1) $\operatorname{ch}(L_k) = 1 + c_1(L_k)$, $\hat{A}(S^2) = 1$.
(2) Only the 2-form part integrates; $\int c_1 = k$.

We can confirm this by counting. On a Riemann surface the positive spinors are $E^+ = K^{1/2}$, a square root of the canonical bundle ($K = \mathcal{O}(-2)$ on $\mathbb{CP}^1$, so $K^{1/2} = \mathcal{O}(-1)$), and $\not{D}^{+}_{L_k} = \sqrt{2}\,\bar\partial$ acting on sections of $K^{1/2} \otimes L_k = \mathcal{O}(k-1)$. By Example 4.98 for $k \geq 1$ there are exactly k holomorphic sections (polynomials of degree $\leq k-1$) and no cokernel. So there are k zero modes, all of positive chirality. Note the pleasant cross-check between two index theorems: Dirac on L_k equals Dolbeault on $\mathcal{O}(k-1)$, and $k = (k-1) + 1$.

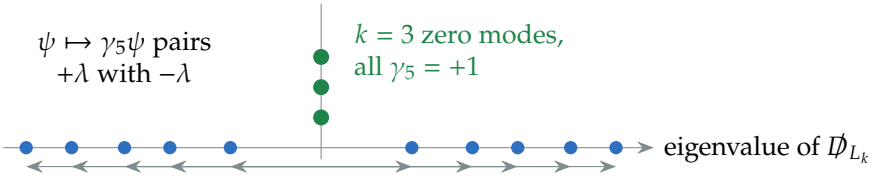

Figure 4.58: Spectrum of the Dirac operator on S^2 coupled to a charge-3 monopole. Because γ_5 anticommutes with $\not{D}$, non-zero eigenvalues come in pairs $\pm\lambda$ (blue), each pair mixing both chiralities. The zero modes (green) are unpaired, and they all have positive chirality: $\operatorname{index} \not{D}^{+} = n_+ - n_- = 3$.

Worked example 4.103: Instantons and fermion zero modes in four dimensions

On S^4 (or $\mathbb{R}^4$ with finite action) $p_1 = 0$, so $\hat{A}(S^4) = 1$ and the untwisted Dirac operator has index 0. Couple it to a charge-k SU(2) instanton in the fundamental representation ($\int c_2 = k$, $c_1 = 0$):

$$\operatorname{index} \not{D}^{+}_{F} \overset{(1)}{=} \int_{S^4} \operatorname{ch}_2(F) \overset{(2)}{=} \int_{S^4} \tfrac{1}{2}\big(c_1^2 - 2c_2\big)(F) \overset{(3)}{=} -k.$$

(1) $\hat{A} = 1$ on S^4; the degree-4 part of $\operatorname{ch}(F)\cdot 1$.

(2) $\mathrm{ch}_2 = \frac{1}{2}(c_1^2 - 2c_2)$.
(3) $c_1 = 0$ and $\int c_2 = k$.

One can show the kernel of $\not{D}_F^+$ vanishes for a self-dual connection, so there are exactly k zero modes, all of negative chirality. These are 't Hooft's zero modes, responsible for the instanton-induced violation of axial charge. For the adjoint representation of SU(2) one finds $\int \mathrm{ch}_2(\mathrm{ad}) = -4k$: $4k$ gluino zero modes.

Worked example 4.104: When twisting creates an index where there was none

Nash notes [Nash pp. 118–119] two ways in which $\not{D}_F$ differs from $\not{D}$:

- In dimensions $n \not\equiv 0 \bmod 4$, $\int \hat{A} = 0$ automatically (it is a polynomial in the p_i, of degree divisible by 4), so index $\not{D} = 0$. But index $\not{D}_F \neq 0$ is possible: S^2 with a monopole, index k.
- Even when $4 \mid n$, one may have index $\not{D} = 0$ but index $\not{D}_F \neq 0$: S^4 with an instanton, index $-k$.

For contrast, an untwisted index that is non-zero: for a K3 surface $p_1 = -48$, so index $\not{D} = \int \hat{A} = -\frac{1}{24}(-48) = 2$.

complex	untwisted index	twisted index	does F matter?
de Rham	$\int e(X) = \chi(X)$	$\int \mathrm{ch}(F)\, e(X) = m\,\chi(X)$	only its rank
Dolbeault	$\int \mathrm{td}(X)$	$\int \mathrm{ch}(F)\ \mathrm{td}(X) = \chi(X, F)$	yes, all $c_j(F)$
signature	$\int L(X) = \mathrm{Sign}\, X$	$\int \mathrm{ch}(F) \prod \frac{x_i}{\tanh(x_i/2)}$	yes, all $c_j(F)$
spin (Dirac)	$\int \hat{A}(X)$	$\int \mathrm{ch}(F)\, \hat{A}(X)$	yes, all $c_j(F)$

Figure 4.59: The four classical complexes and their twisted versions. In every case twisting multiplies the integrand by $\mathrm{ch}(F)$. Only for de Rham is the untwisted integrand concentrated in top degree, which is why only there the twist is invisible (apart from the factor $m = \mathrm{rk}\, F$).

Reading Nash (pp. 116–119, (4.112)–(4.122))

Nash introduces matrix-valued forms $\Omega^p(X; F) = \Gamma(X, F \otimes \Lambda^p T^* X_{\mathbb{C}})$ and the twisted de Rham complex (4.113). He then observes that in the index formula (4.114) the only change is $E^p \to F \otimes E^p$ and uses $\mathrm{ch}(A \otimes B) = \mathrm{ch}\, A\ \mathrm{ch}\, B$ to get (4.115)–(4.117): index $d_F = m\,\chi(X)$. He repeats the argument for Dolbeault (4.118), expands in complex dimension 2 (4.119)–(4.120), states the twisted signature (4.121) and Dirac (4.122) formulas, and remarks that these twisted indices can be non-zero in dimensions where the untwisted ones vanish. What we added: the covariance of d_A, the fact that $d_A^2 = F_A$ (so (4.113) is a complex only for flat F), the explicit Fourier-mode examples, the exact normalisation of $\mathcal{L}$ in (4.121), and the explicit zero-mode counts.

Recap

- Twisting = tensoring every bundle in a complex with a gauge bundle F and replacing d by the covariant d_A.

- Because ch is multiplicative, the index integrand is multiplied by $\mathrm{ch}(F)$.
- de Rham: $\operatorname{index} d_A = \operatorname{rk} F \cdot \chi(X)$; the gauge field is invisible since $e(X)$ is top degree.
- Dolbeault: Hirzebruch–Riemann–Roch $\chi(X,F) = \int \mathrm{ch}(F)\,\mathrm{td}(X)$; on curves $\deg F + r(1-g)$; on $\mathbb{CP}^1$, $k+1$ sections of $\mathcal{O}(k)$.
- Dirac: $\operatorname{index} \not{D}_F^+ = \int \mathrm{ch}(F)\hat{A}(X)$; the number of fermion zero modes is the magnetic flux (2D) or instanton number (4D).

4.18 The index theorem for families of operators

So far we have always had *one* elliptic operator and computed *one* integer. Physics rarely hands us a single operator. The Dirac operator of a fermion depends on the background gauge field A; as A varies over the space $\mathcal{A}$ of all gauge fields we get a whole *family* $\{\not{D}_A\}_{A\in\mathcal{A}}$. The Laplacian on a torus depends on the shape of the torus; as the shape varies over the moduli space we again get a family. The Hamiltonian of an electron in a crystal depends on the Bloch momentum k in the Brillouin zone. In each case there is a **parameter space** Y, and for each $y \in Y$ an operator D_y.

The question of this section is:

> *For a family of elliptic operators, is there a topological invariant that is richer than the (constant) integer* $\operatorname{index} D_y$*? And can we compute it?*

The answer is yes. The kernels and cokernels of the D_y fit together into (virtual) vector bundles over Y, and their difference is an element $\operatorname{index} D$ of the K-theory $K(Y)$. The integer index is only the rank of this class. The rest of it, for example its Chern classes, carries information that no single operator can see. The **families index theorem** of Atiyah and Singer computes it by a formula that is the single-operator formula with the final integral over X replaced by an integration along the fibres. In physics this is the machinery behind the geometry of the fermion determinant, the Berry phase of the lowest Landau level, and the topological analysis of gauge anomalies in Chapter 10.

4.18.1 A family of operators and what varies with it

Working definition 4.46 (family of elliptic operators)

A **family of elliptic operators** parametrised by a (compact) space Y is a map $y \mapsto D_y$ that assigns to each point $y \in Y$ an elliptic operator [leading symbol invertible at every nonzero momentum] $D_y : \Gamma(X,E) \to \Gamma(X,F)$ on a fixed closed manifold [compact and without boundary] X, such that the coefficients of D_y (in local coordinates) depend continuously on y. *In practice:* write down the operator with some parameters in it; the set of allowed parameter values is Y.

Because the index is a deformation invariant, $\operatorname{index} D_y$ is the same integer for all y in a connected Y. But the kernel and cokernel themselves vary. Their *dimensions* may jump, and even when the dimensions stay fixed, the *subspaces* $\ker D_y$ rotate inside the space of sections as y moves. It is this rotation that the families index captures.

Worked example 4.105: The simplest jumping kernel

Take X to be a point, so that sections are just vectors, and let $Y = \mathbb{C}$ with the family of 1×1 matrices

$$D_y : \mathbb{C} \to \mathbb{C}, \qquad D_y(v) = y\, v.$$

For $y \neq 0$ this is invertible: $\operatorname{Ker} D_y = 0$, $\operatorname{Coker} D_y = 0$. At $y = 0$ it is the zero map: $\operatorname{Ker} D_0 = \mathbb{C}$, $\operatorname{Coker} D_0 = \mathbb{C}$. So

$$\dim \operatorname{Ker} D_y = \begin{cases} 1, & y = 0, \\ 0, & y \neq 0, \end{cases} \qquad \operatorname{index} D_y = \dim \operatorname{Ker} D_y - \dim \operatorname{Coker} D_y = 0 \text{ for all } y.$$

The kernel jumps, but it jumps *together* with the cokernel, so the index does not move. This is the general mechanism: a zero mode can only appear or disappear in company with a zero mode of the adjoint.

Worked example 4.106: A family on the circle: the Aharonov–Bohm phase

Take $X = S^1$ ($\theta \in [0, 1)$) and the family of Example 4.95,

$$D_a = \frac{\mathrm{d}}{\mathrm{d}\theta} + 2\pi i a : \ \Omega^0(S^1) \to \Omega^0(S^1), \qquad a \in \mathbb{R}.$$

Physically, a is the magnetic flux (in units of the flux quantum) threading a ring on which a charged particle moves. On the Fourier mode $e^{2\pi i n\theta}$ the operator acts by multiplication by $\lambda_n(a) = 2\pi i(n + a)$. The parameter is really periodic: the gauge transformation $g = e^{-2\pi i\theta}$ maps D_a to

$$g^{-1} D_a\, g \overset{(1)}{=} e^{2\pi i\theta}\Big(\frac{\mathrm{d}}{\mathrm{d}\theta} + 2\pi i a\Big)e^{-2\pi i\theta} \overset{(2)}{=} \frac{\mathrm{d}}{\mathrm{d}\theta} - 2\pi i + 2\pi i a = D_{a-1}.$$

(1) Conjugate by the gauge transformation (a unitary operator on $L^2(S^1)$, so kernels and cokernels are carried into each other).
(2) Product rule: $\frac{\mathrm{d}}{\mathrm{d}\theta}(e^{-2\pi i\theta} f) = e^{-2\pi i\theta}(f' - 2\pi i f)$.

So D_a and D_{a-1} are unitarily equivalent, and the genuine parameter space is the circle $Y = \mathbb{R}/\mathbb{Z}$ of Aharonov–Bohm phases $e^{2\pi i a}$. On this circle the kernel is zero except at the single point $a = 0$, where it is spanned by the constants. Again $\operatorname{index} D_a = 0$ for all a.

4.18.2 Reminder: the K-theory of a parameter space

Earlier in the chapter we met K-theory as the natural home of symbols. Here we need it for the parameter space Y, so we recall the essentials.

Working definition 4.47 (virtual bundles and $K(Y)$)

An element of $K(Y)$ is a formal difference $[E] - [F]$ of complex vector bundles over Y (a **virtual bundle**). Two differences are equal, $[E]-[F] = [E']-[F']$, when $E \oplus F' \oplus G \cong E' \oplus F \oplus G$ for some bundle G [G is needed because $E \oplus G \cong E' \oplus G$ need not imply $E \cong E'$]. Addition is $\oplus$, multiplication is $\otimes$. *To detect an element:* compute its rank $\operatorname{rk} E - \operatorname{rk} F$ and its Chern character $\operatorname{ch} E - \operatorname{ch} F \in H^{\text{even}}(Y; \mathbb{Q})$ [cohomology classes of degrees $0, 2, 4, \ldots$, with rational

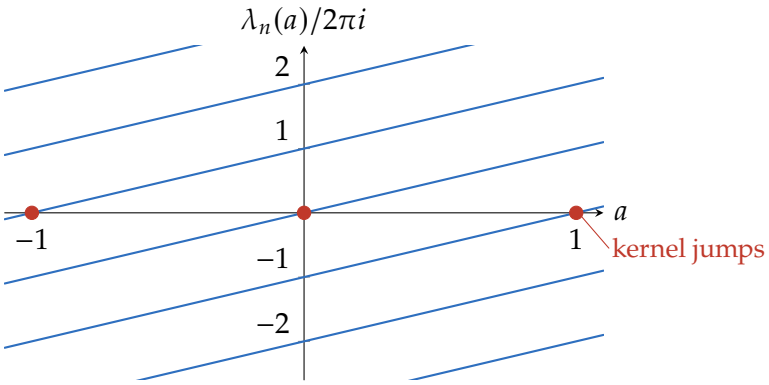

Figure 4.60: The eigenvalues $\lambda_n(a)/2\pi i = n + a$ of the family $D_a = \mathrm{d}/\mathrm{d}\theta + 2\pi i a$ on the circle, one straight line for each Fourier mode n. A zero mode exists exactly when a line crosses the axis (red dots, at $a \in \mathbb{Z}$). The picture is periodic under $a \to a + 1$ (the lines are relabelled $n \to n - 1$), which is why the parameter space is a circle. Although no line stays at zero, one line passes through zero per period: this "one eigenvalue crosses per loop" will reappear as spectral flow in Section 4.21.10.

coefficients].

Two examples fix ideas.

- $K(\mathrm{pt}) = \mathbb{Z}$: a vector bundle over a point is a vector space, classified by its dimension, so $[V] - [W] \mapsto \dim V - \dim W$. *The ordinary index lives in* $K(\mathrm{pt})$.
- $K(S^2) = \mathbb{Z} \oplus \mathbb{Z}$, generated by the trivial line 1 and $[H] - 1$, where H is the monopole (Hopf) line bundle with $\int c_1(H) = \pm 1$. The rank detects the first $\mathbb{Z}$, and $\int_{S^2} c_1$ detects the second. Since $c_1(H)^2 = 0$ on S^2, $([H] - 1)^2 = 0$ in $K(S^2)$.

The Chern character is additive and multiplicative (Eq. (4.152)), so it extends to a ring homomorphism

$$\mathrm{ch} : K(Y) \longrightarrow H^{\mathrm{even}}(Y; \mathbb{Q}), \qquad \mathrm{ch}\big([E] - [F]\big) = \mathrm{ch}\, E - \mathrm{ch}\, F.$$

It loses exactly the torsion part of $K(Y)$ (see Section 4.18.9 below); after tensoring with $\mathbb{Q}$ it is an isomorphism.

4.18.3 The index bundle when the kernel does not jump

Suppose first that $\dim \operatorname{Ker} D_y$ and $\dim \operatorname{Coker} D_y$ are constant in y. Then the kernels form a vector bundle over Y,

$$\operatorname{Ker} D = \bigcup_{y \in Y} \operatorname{Ker} D_y \longrightarrow Y,$$

whose fibre over y is the finite-dimensional vector space $\operatorname{Ker} D_y$. (Constancy of the dimension is what makes the kernels vary smoothly: the orthogonal projector onto $\operatorname{Ker} D_y$ can be written as a contour integral of the resolvent of $D_y^* D_y$ around 0, and this is continuous in y as long as no other eigenvalue enters the contour.) The same holds for $\operatorname{Coker} D = \bigcup_y \operatorname{Coker} D_y$. Nash then defines [Nash p. 119, (4.123)]

$$\operatorname{index} D = [\operatorname{Ker} D] - [\operatorname{Coker} D] \ \in K(Y). \tag{4.169}$$

Key idea: The index of a family is a virtual bundle

For one operator, the index is a number: $\dim\operatorname{Ker} - \dim\operatorname{Coker}$. For a family, it is a K-theory class: [bundle of kernels] − [bundle of cokernels]. Its rank is the old integer index. Its Chern classes are new invariants, which measure how the zero modes twist as we go around loops and surfaces in the parameter space.

Physical picture: Berry phases

A physicist already knows one instance. If $H(y)$ is a family of Hamiltonians with an isolated, non-degenerate ground state $|0(y)\rangle$, the ground states form a line bundle over Y. Its Berry connection is $\mathcal{A} = \langle 0(y)|\mathrm{d}\,0(y)\rangle$ and its Berry curvature integrated over a closed surface in Y, divided by $2\pi i$, is an integer: the first Chern number of the ground-state bundle. The families index is the same idea applied to the bundle of zero modes of an elliptic operator. When the cokernel is zero, $\operatorname{index} D$ *is* the bundle of zero modes and its c_1 is literally a Berry-curvature integral.

Watch out: Finite-dimensional families between fixed spaces are boring

Let $D_y : \mathbb{C}^N \to \mathbb{C}^M$ be a family of matrices with constant rank. The exact sequence $0 \to \operatorname{Ker} D_y \to \mathbb{C}^N \to \mathbb{C}^M \to \operatorname{Coker} D_y \to 0$ holds fibrewise, and for vector bundles an exact sequence splits, so $\operatorname{Ker} D \oplus \underline{\mathbb{C}}^M \cong \underline{\mathbb{C}}^N \oplus \operatorname{Coker} D$. Hence

$$\operatorname{index} D = [\operatorname{Ker} D] - [\operatorname{Coker} D] = [\underline{\mathbb{C}}^N] - [\underline{\mathbb{C}}^M] = N - M,$$

a trivial class: no Chern classes survive. Kernels of matrices can twist, but the cokernels twist in exactly the compensating way. A non-trivial index bundle needs *infinite*-dimensional spaces of sections. This is one reason the families index is a genuinely analytic object.

4.18.4 Jumping kernels and the stabilisation trick

Nash points out [Nash p. 119] that in practice $\dim\operatorname{Ker} D_y$ does jump (as in Examples 4.105 and 4.106), and then $\bigcup_y \operatorname{Ker} D_y$ is not a vector bundle. He refers to Atiyah and Singer for the fix. The fix is a piece of linear algebra worth seeing, because it is also how one proves that $\operatorname{index} D$ is well defined.

The idea: add a finite number of extra directions

Fix $y_0 \in Y$. Since $\operatorname{Coker} D_{y_0}$ is finite dimensional, we can choose a finite-dimensional subspace $W \subset \Gamma(X, F)$ that, together with the image, spans everything:

$$\operatorname{Im} D_{y_0} + W = \Gamma(X, F).$$

(Take for W the cokernel itself, realised as $\operatorname{Ker} D_{y_0}^*$.) Being surjective is an *open* condition, so for y in a neighbourhood U of y_0 we still have $\operatorname{Im} D_y + W = \Gamma(X, F)$. Now enlarge the operator:

$$\widetilde{D}_y : \Gamma(X, E) \oplus W \longrightarrow \Gamma(X, F), \qquad \widetilde{D}_y(u, w) = D_y u + w. \tag{4.170}$$

This is surjective for $y \in U$. Its kernel is

$$\operatorname{Ker} \widetilde{D}_y = \{(u, -D_y u) : D_y u \in W\} \cong D_y^{-1}(W),$$

the set of sections that D_y maps into the finite-dimensional space W. Its dimension is

$$\dim\operatorname{Ker} \widetilde{D}_y \overset{(1)}{=} \operatorname{index} \widetilde{D}_y \overset{(2)}{=} \operatorname{index} D_y + \dim W. \tag{4.171}$$

(1) $\widetilde{D}_y$ is surjective, so its cokernel is zero and its index equals the dimension of its kernel.
(2) Adding the finite-dimensional space W to the domain (and mapping it in by the inclusion) raises the index by $\dim W$: the extra piece is a finite-rank perturbation of $D_y \oplus 0_W$, and $\operatorname{index}(D_y \oplus 0_W) = \operatorname{index} D_y + \dim W - 0$.

The right side of (4.171) does not depend on y. So the spaces $D_y^{-1}(W)$ have *constant* dimension and form an honest vector bundle over U, even though $\operatorname{Ker} D_y$ jumps. We then define

$$\operatorname{index} D\big|_U = [D^{-1}(W)] - [\underline{W}] \ \in K(U), \tag{4.172}$$

where $\underline{W} = U \times W$ is a trivial bundle. By compactness of Y one can use a single W for all of Y (take the span of finitely many local choices).

Working definition 4.48 (index bundle of a family)

To compute $\operatorname{index} D \in K(Y)$: find a finite-dimensional space W of sections of F such that $\operatorname{Im} D_y + W$ is everything [every f can be written as $D_y u + w$ with $w \in W$] for all y. The index is [$\{u : D_y u \in W\}$] $-$ [W] [the first term is the vector bundle over Y whose fibre at y is this finite-dimensional space of u]. If the kernel dimension is constant, one may take $W = \operatorname{Coker} D_y$ [realised as the zero modes of D_y^*, a finite-dimensional space of sections of F] (varying with y) and recover $[\operatorname{Ker} D] - [\operatorname{Coker} D]$.

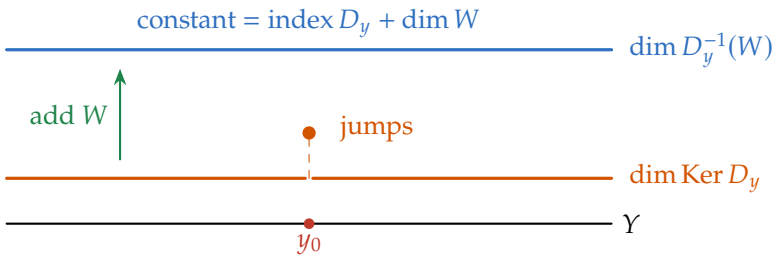

Figure 4.61: The stabilisation trick. The kernel dimension (orange) jumps at y_0, so the kernels do not form a vector bundle. After enlarging the domain by a fixed finite-dimensional space W that fills in the cokernel, the kernels $D_y^{-1}(W)$ of the enlarged operator have constant dimension (blue) and do form a bundle. Subtracting the trivial bundle W gives the index class.

Worked example 4.107: Stabilising the two jumping families

The 1×1 family $D_y = y$. Take $W = \mathbb{C}$, the whole target. Then $D_y^{-1}(W) = \mathbb{C}$ for every y, and $\operatorname{index} D = [\underline{\mathbb{C}}] - [\underline{\mathbb{C}}] = 0$. The jump at $y = 0$ has been absorbed.
The circle family D_a near $a = 0$. Take $W = \operatorname{span}\{1\}$, the constant functions in the target. For a near 0 the modes $n \neq 0$ are mapped isomorphically onto themselves (their eigenvalues $2\pi i(n + a)$ stay away from zero), and the mode $n = 0$ is mapped into W. Thus

$$D_a^{-1}(W) \overset{(1)}{=} \left\{ f = \textstyle\sum_n f_n e^{2\pi i n\theta} : \ 2\pi i(n+a) f_n = 0 \text{ for } n \neq 0 \right\}$$
$$\overset{(2)}{=} \operatorname{span}\{1\},$$

(1) $D_a f$ lies in W iff all its non-constant Fourier coefficients vanish.
(2) For $n \neq 0$ and $|a| < 1$, $n + a \neq 0$, so $f_n = 0$; f_0 is free.

a trivial line. Hence $\operatorname{index} D = [\underline{\mathbb{C}}] - [\underline{\mathbb{C}}] = 0$ near $a = 0$, consistent with $\operatorname{index} D_a = 0$ elsewhere.

4.18.5 Operators on a varying manifold: fibre bundles of manifolds

Nash's second generalisation [Nash pp. 119–120, (4.124)] is that the manifold itself may vary with y. The Laplacian on a torus depends on the torus's shape; in string theory one integrates over all shapes of a Riemann surface, and the operators on each surface form a family whose manifold changes from point to point.

Working definition 4.49 (family on a fibration)

Let $\pi : Z \to Y$ be a fibre bundle whose fibres $X_y = \pi^{-1}(y)$ are closed n-manifolds, all diffeomorphic [identified by a smooth bijection with smooth inverse] to a model X. Over Z let there be vector bundles E, F, with restrictions E_y, F_y to X_y. A family is a collection of elliptic operators

$$D_y : \Gamma(X_y, E_y) \longrightarrow \Gamma(X_y, F_y), \qquad y \in Y, \tag{4.173}$$

varying continuously with y. *Locally* (over a small $U \subset Y$) $Z \cong U \times X$ and this is just a family on the fixed manifold X; globally, going around a loop in Y may bring X back to itself by a non-trivial diffeomorphism [e.g. on a torus, $(\theta_1, \theta_2) \mapsto (\theta_1 + \theta_2, \theta_2)$, which cannot be deformed to the identity].

The structure group of $Z \to Y$ is $\mathrm{Diff}(X)$, the diffeomorphism group of the fibre. Nash's point is that this is exactly what is required for the local analysis to be meaningful: whatever we compute on X_y in local coordinates must be invariant under diffeomorphisms of X, so that it does not matter which identification $X_y \cong X$ we used. Kernels and cokernels are invariantly defined, so (4.169) and the stabilisation trick carry over unchanged.

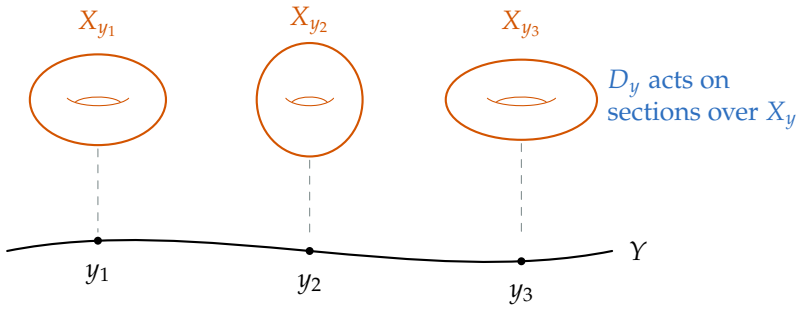

Figure 4.62: A family on a fibration. Over each point y of the parameter space sits a manifold X_y (here a torus whose shape changes with y), and an operator D_y acting on fields on X_y. Locally in Y this is the same as a family on a fixed torus; globally, transporting a torus around a loop in Y may return it to itself by a diffeomorphism (for example a Dehn twist).

Worked example 4.108: The family of flat tori

For τ in the upper half plane let $X_\tau = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$, with the flat metric $|\mathrm{d}z|^2$. Every flat torus (up to scale) is of this form, and $X_\tau \cong X_{\tau'}$ isometrically iff $\tau' = \frac{a\tau+b}{c\tau+d}$ with $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in \mathrm{SL}(2,\mathbb{Z})$. Identify each X_τ with the fixed square torus $X = \mathbb{R}^2/\mathbb{Z}^2$ through $z = x + \tau y$. Then $\mathrm{d}z = \mathrm{d}x + \tau\,\mathrm{d}y$ and

$$\frac{\partial}{\partial \bar z} \overset{(1)}{=} \frac{1}{\tau - \bar\tau}\left(\tau\frac{\partial}{\partial x} - \frac{\partial}{\partial y}\right) \overset{(2)}{=} \frac{1}{2i\,\mathrm{Im}\,\tau}\left(\tau\,\partial_x - \partial_y\right).$$

(1) Invert $x = \frac{\tau\bar z - \bar\tau z}{\tau - \bar\tau}$, $y = \frac{z - \bar z}{\tau - \bar\tau}$ and use the chain rule: $\partial x/\partial\bar z = \tau/(\tau - \bar\tau)$, $\partial y/\partial\bar z = -1/(\tau - \bar\tau)$.
(2) $\tau - \bar\tau = 2i\,\mathrm{Im}\,\tau$.

So on the fixed torus X we get the family of operators $D_\tau = (\tau\partial_x - \partial_y)/2i\,\mathrm{Im}\,\tau$, parametrised by τ. The honest parameter space is the moduli space $Y = \{\mathrm{Im}\,\tau > 0\}/\mathrm{SL}(2,\mathbb{Z})$, and going around a loop in Y (for example $\tau \to \tau + 1$) brings X back to itself by the diffeomorphism $(x, y) \mapsto (x + y, y)$, a Dehn twist. This is exactly the situation of (4.173) with structure group $\mathrm{Diff}(X)$. On each fibre $\mathrm{Ker}\, D_\tau = \mathbb{C}$ (the constants), and the families index is the statement that these kernels, and the corresponding cokernels (spanned by the class of $\mathrm{d}\bar z = \mathrm{d}x + \bar\tau\,\mathrm{d}y$, which does change with τ), form line bundles over moduli space. Their determinant is the object behind the "measure on moduli space" in string theory (Chapter 9).

4.18.6 Analytic and topological index for families

The proof of the families index theorem follows the same pattern as for one operator: we define an analytic index and a topological index and show they agree. What changes is where the symbol lives.

The symbol class

Each D_y has a leading symbol $\sigma_m(D_y)(x, p)$, defined for $x \in X_y$ and $p \in T^*_x X_y$. For a single operator the symbol defines a class in $K(T^*X)$ (compactly supported K-theory, because the symbol is an isomorphism off the zero section). For a family we collect all the cotangent spaces *along the fibres*:

$$T_F Z = \bigcup_{y \in Y} T^* X_y,$$

the **cotangent bundle along the fibres** of Z (Nash's $T_F Z$). A point of $T_F Z$ is a triple (y, x, p) with $x \in X_y$ and p a covector tangent to the fibre. Its dimension is $\dim Y + 2n$. The symbols of all the D_y together give an element

$$[\sigma_m(D)] \in K(T_F Z).$$

The analytic index is then the map [Nash p. 120, (4.125)]

$$\mathrm{index}_a : K(T_F Z) \longrightarrow K(Y), \qquad [\sigma_m(D)] \longmapsto \mathrm{index}\, D. \tag{4.174}$$

It is well defined for the same reason as before: two families with the same symbol class can be deformed into each other, and the index bundle is invariant under deformations (a homotopy of families over Y is a family over $Y \times [0,1]$, and vector bundles over $Y \times [0,1]$ are pulled back from Y).

The topological index

For one operator the topological index was built by embedding X in some $\mathbb{R}^N$, pushing the symbol class forward by the Thom isomorphism $K(T^*X) \to K(T^*\mathbb{R}^N)$, and then using Bott periodicity $K(T^*\mathbb{R}^N) = K(\mathbb{R}^{2N}) \cong K(\mathrm{pt}) = \mathbb{Z}$. For a family, we embed the whole fibration fibrewise,

$$Z \hookrightarrow Y \times \mathbb{R}^N, \qquad X_y \hookrightarrow \{y\} \times \mathbb{R}^N,$$

push $[\sigma_m(D)]$ forward to $K(Y \times \mathbb{R}^{2N})$ and use Bott periodicity *with parameters*: $K(Y \times \mathbb{R}^{2N}) \cong K(Y)$. The result is a homomorphism $\mathrm{index}_t : K(T_F Z) \to K(Y)$.

Key idea: The families index theorem (Atiyah–Singer IV)

For every elliptic family,

$$\operatorname{index}_a = \operatorname{index}_t : \ K(T_F Z) \longrightarrow K(Y).$$

The bundle of zero modes, modulo the bundle of zero modes of the adjoint, is computed by a purely topological construction from the symbols. *Why it is true:* the proof for a single operator used only properties (functoriality under embeddings, excision, normalisation on a point) that hold "with parameters"; everything goes through fibre by fibre, and the constructions are continuous in y. Setting $Y = \mathrm{pt}$ recovers the ordinary index theorem.

4.18.7 The cohomological formula and integration along the fibre

Applying the Chern character to the K-theory statement gives a formula in cohomology [Nash p. 120, (4.126)]:

$$\operatorname{ch}(\operatorname{index} D) = (-1)^n \, \pi_* \Big\{ \operatorname{ch}\big([\sigma_m(D)]\big) \ \operatorname{td}(T_F Z_{\mathbb{C}}) \Big\} \ \in H^{\mathrm{even}}(Y; \mathbb{Q}), \tag{4.175}$$

where $T_F Z_{\mathbb{C}}$ is the complexified tangent bundle along the fibres and π_* is **integration along the fibre**. This is the single-operator formula with one change: the final "evaluate on $[X]$" becomes "integrate over the fibres, leaving a form on Y". The output is not a number but a cohomology class on Y: its degree-0 part is the integer index, its degree-2 part is $c_1(\operatorname{index} D)$, and so on.

What integration along the fibre is

Working definition 4.50 (integration along the fibre)

Let $\pi : Z \to Y$ have oriented [with a consistent handedness of fibre coordinates, which fixes the sign of $\int_X$] k-dimensional fibres. Locally $Z = U \times X$ with fibre coordinates $x^1, \dots, x^k$ and base coordinates y^α. Write a form on Z as a sum of terms

$$\omega = f(x,y)\, \mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^k \wedge \mathrm{d}y^{\alpha_1} \wedge \cdots \wedge \mathrm{d}y^{\alpha_q} + (\text{terms with fewer than } k \text{ fibre differentials}).$$

Then

$$\pi_* \omega = \Big(\int_X f(x,y)\, \mathrm{d}^k x \Big) \mathrm{d}y^{\alpha_1} \wedge \cdots \wedge \mathrm{d}y^{\alpha_q},$$

and the terms with fewer than k fibre differentials are thrown away. *Rule of thumb:* "integrate out the fibre directions, keep the base directions". The degree drops by k: $\pi_* : \Omega^p(Z) \to \Omega^{p-k}(Y)$.

Nash writes this as [Nash p. 121, (4.127)]: $\pi_*[\omega] = [\nu]$ with $\nu = \int_X \omega \in \Omega^{p-n}(Y)$. Two facts make it work in cohomology.

- *It commutes with* d: $\mathrm{d}(\pi_* \omega) = \pi_*(\mathrm{d}\omega)$ when the fibres are closed. (The x-derivative part of $\mathrm{d}\omega$ integrates to zero over the closed fibre by Stokes; the y-derivative part can be pulled out of the integral.) So closed forms go to closed forms and exact to exact.
- *Projection formula*: $\pi_*(\pi^* \beta \wedge \omega) = \beta \wedge \pi_* \omega$ for any form β on Y, up to the sign fixed by where we put the fibre differentials. (Base forms are constant along the fibre, so they come out of the integral.)

For $Y = \mathrm{pt}$ it is ordinary integration over X.

Worked example 4.109: Integration along the fibre in coordinates

Let $Z = S^1_\theta \times \mathbb{R}^2_{(u,v)} \to Y = \mathbb{R}^2_{(u,v)}$, and

$$\omega = \cos^2\theta\,\mathrm{d}\theta \wedge \mathrm{d}u + u\,\mathrm{d}\theta \wedge \mathrm{d}u \wedge \mathrm{d}v + \sin\theta\,\mathrm{d}u \wedge \mathrm{d}v.$$

Then (with $\theta \in [0, 2\pi)$)

$$\pi_*\omega \overset{(1)}{=} \Big(\int_0^{2\pi} \cos^2\theta\,\mathrm{d}\theta\Big)\mathrm{d}u + \Big(\int_0^{2\pi} u\,\mathrm{d}\theta\Big)\mathrm{d}u \wedge \mathrm{d}v + 0$$
$$\overset{(2)}{=} \pi\,\mathrm{d}u + 2\pi u\,\mathrm{d}u \wedge \mathrm{d}v.$$

(1) The first two terms contain the single fibre differential $\mathrm{d}\theta$ (in front); the last term has no $\mathrm{d}\theta$ and is discarded.
(2) $\int_0^{2\pi} \cos^2\theta\,\mathrm{d}\theta = \pi$; u is constant on the fibre.

The degrees drop by one: the 2-form part became a 1-form and the 3-form part a 2-form. Notice the discarded term: a form that has no leg along the fibre carries no information about the integral over the fibre.

Watch out: Which fibre is integrated in (4.126)?

The class $\mathrm{ch}([\sigma_m(D)])\ \mathrm{td}(T_F Z_{\mathbb{C}})$ lives on $T_F Z$, whose fibre over $y \in Y$ is T^*X_y, of dimension $2n$. So π_* in (4.175) really integrates over $2n$ dimensions, and lowers degree by $2n$. Nash's (4.127) describes integration over the n-dimensional X. The two are reconciled by doing the integral in two stages: first integrate over each cotangent fibre $T^*_x X_y \cong \mathbb{R}^n$ (this is the Thom isomorphism, which is how the single-operator formula turned into $\{\mathrm{ch}(\cdot)\ \mathrm{td}/e\}[X]$), then over X_y. In the examples below we always use the second, "integrate over X" form.

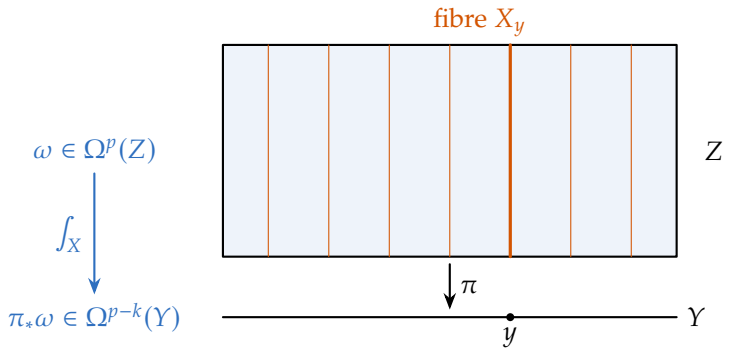

Figure 4.63: Integration along the fibre. A form on the total space Z is integrated over each fibre X_y (orange), with the base point y held fixed. What is left is a form on Y whose degree is lower by the fibre dimension k. For Y a point this is ordinary integration over X.

The families Riemann–Roch formula

For the twisted operators of Section 4.17 the formula simplifies exactly as it did for one operator. Suppose $Z = X \times Y$ and the family is $\bar\partial$ on a complex curve or surface X, twisted by a family of holomorphic bundles, i.e. by one bundle $P \to X \times Y$ whose restriction to $X \times \{y\}$ is the twisting

bundle P_y. Then the chain that led to (4.158) goes through verbatim, with $[X]$ replaced by π_*:

$$\operatorname{ch}(\operatorname{index}\bar\partial_P) = \pi_*\big(\operatorname{ch}(P)\,\operatorname{td}(X)\big) = \int_X \operatorname{ch}(P)\wedge\operatorname{td}(X). \tag{4.176}$$

The same holds for twisted Dirac families, $\operatorname{ch}(\operatorname{index}\not{D}_P) = \int_X \operatorname{ch}(P)\wedge\hat A(X)$. This is the **families index theorem** in the form physicists use. The only new feature is that $\operatorname{ch}(P)$ now has mixed components (some legs along X, some along Y), and the Y-legs survive the integral.

4.18.8 Worked example: flat line bundles on a torus

We now compute a non-trivial index bundle from beginning to end. It continues Example 4.96.

The family

Let $X = \mathbb{R}^2/\mathbb{Z}^2$ with coordinates (x,y) and $z = x+iy$ (the square torus, flat metric). For $(a,b)\in\mathbb{R}^2$ consider the flat connection $A_{a,b} = 2\pi i(a\,\mathrm{d}x + b\,\mathrm{d}y)$ on the trivial line bundle and the twisted Cauchy–Riemann operator

$$\bar\partial_{a,b} f = \big(\partial_{\bar z} + (A_{a,b})_{\bar z}\big) f\,\mathrm{d}\bar z.$$

Exactly as for the circle (Example 4.106), shifting a or b by an integer is a gauge transformation ($g = e^{-2\pi i x}$ or $e^{-2\pi i y}$), so the parameter space is a second torus, the **dual torus** $\hat X = \{(a,b)\}/\mathbb{Z}^2$.

The spectrum and the jumping kernel

We have $(A_{a,b})_{\bar z} = \tfrac12(A_x + iA_y) = \pi i(a+ib)$ and $\partial_{\bar z} = \tfrac12(\partial_x + i\partial_y)$. On a Fourier mode $e_{m,n} = e^{2\pi i(mx+ny)}$:

$$\begin{aligned}\bar\partial_{a,b}\, e_{m,n} &\overset{(1)}{=} \Big[\tfrac12\big(2\pi i m + i\cdot 2\pi i n\big) + \pi i(a+ib)\Big] e_{m,n}\,\mathrm{d}\bar z \\ &\overset{(2)}{=} \pi i\big[(m+a) + i(n+b)\big] e_{m,n}\,\mathrm{d}\bar z.\end{aligned} \tag{4.177}$$

(1) $\partial_x e_{m,n} = 2\pi i m\, e_{m,n}$, $\partial_y e_{m,n} = 2\pi i n\, e_{m,n}$.
(2) Collect: $\tfrac12(2\pi i m - 2\pi n) = \pi i(m+in)$.

So the operator is diagonal, with eigenvalue $\pi i\,(w+m+in)$ where $w = a+ib$. The kernel is zero unless $w\in\mathbb{Z}+i\mathbb{Z}$, i.e. unless (a,b) is the origin of $\hat X$; there, one mode is annihilated and one mode of the target is missed. So $\operatorname{index}\bar\partial_{a,b} = 0$ for all (a,b), and the kernel jumps at a single point of $\hat X$. Riemann–Roch agrees: degree 0, genus 1, index $= 0 + 1\cdot(1-1) = 0$.

The index bundle from the families formula

To use (4.176) we need the line bundle $P\to X\times\hat X$ (the **Poincaré bundle**) whose restriction to $X\times\{(a,b)\}$ is the flat bundle with connection $A_{a,b}$. The natural connection on P is the same expression, now read as a 1-form on the 4-manifold $X\times\hat X$ with a,b as coordinates:

$$\mathbb{A} = 2\pi i(a\,\mathrm{d}x + b\,\mathrm{d}y).$$

Its curvature has mixed components only:

$$c_1(P) \overset{(1)}{=} \frac{i}{2\pi}\,\mathrm{d}\mathbb{A} \overset{(2)}{=} \frac{i}{2\pi}\cdot 2\pi i\,(\mathrm{d}a\wedge\mathrm{d}x + \mathrm{d}b\wedge\mathrm{d}y) = -(\mathrm{d}a\wedge\mathrm{d}x + \mathrm{d}b\wedge\mathrm{d}y). \tag{4.178}$$

(1) $c_1 = \frac{i}{2\pi} F$ and $F = \mathrm{d}\mathbb{A}$ for a line bundle.
(2) $\mathrm{d}(a\,\mathrm{d}x) = \mathrm{d}a \wedge \mathrm{d}x$; now a varies, which is the whole point.

(On $X \times \{(a,b)\}$ with a, b fixed the curvature vanishes: each P_y is flat, as it should be.) The torus is flat, so $\mathrm{td}(X) = 1$. Now

$$\begin{aligned}\mathrm{ch}(\operatorname{index}\bar\partial) &\overset{(1)}{=} \int_X \Big(1 + c_1(P) + \tfrac{1}{2}c_1(P)^2\Big) \\ &\overset{(2)}{=} \int_X \tfrac{1}{2}\big(\mathrm{d}a \wedge \mathrm{d}x + \mathrm{d}b \wedge \mathrm{d}y\big)^2 \\ &\overset{(3)}{=} \int_X \mathrm{d}a \wedge \mathrm{d}x \wedge \mathrm{d}b \wedge \mathrm{d}y \\ &\overset{(4)}{=} \int_X (-\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}a \wedge \mathrm{d}b) \overset{(5)}{=} -\mathrm{d}a \wedge \mathrm{d}b. \end{aligned} \tag{4.179}$$

(1) Families Riemann–Roch (4.176) with $\mathrm{td}(X) = 1$; higher powers of $c_1(P)$ are 6-forms and vanish on a 4-manifold.
(2) The 1 has no X-legs and $c_1(P)$ has only one X-leg in each term; integrating over the 2-dimensional X needs two, so both drop out.
(3) $(\alpha+\beta)^2 = \alpha^2 + 2\alpha\wedge\beta + \beta^2$ for 2-forms, and $\alpha^2 = \beta^2 = 0$ here because each contains a repeated differential.
(4) Reorder: moving $\mathrm{d}x$ past $\mathrm{d}a$ costs a sign; moving $\mathrm{d}y$ past $\mathrm{d}b$ and $\mathrm{d}a$ costs two signs.
(5) Integration along the fibre with $\int_X \mathrm{d}x \wedge \mathrm{d}y = 1$.

Reading off by degree: the rank of $\operatorname{index}\bar\partial$ is 0 (as it must be), and

$$c_1(\operatorname{index}\bar\partial) = -\mathrm{d}a \wedge \mathrm{d}b, \qquad \int_{\hat X} c_1(\operatorname{index}\bar\partial) = -1.$$

So *the index bundle of this family is a non-trivial element of* $K(\hat X)$, even though every single operator has index zero. (The sign depends on the orientation of $\hat X$; the fact that the Chern number is ± 1, not 0, does not.)

A check via a twisted family with no jumping

Now twist in addition by a fixed holomorphic line bundle L of degree 1 on X, with $c_1(L) = h$, $\int_X h = 1$. The family is $\bar\partial_{L\otimes P_{a,b}}$, of index $1 + 1\cdot(1-1) = 1$ at every point. For a degree-1 bundle on a torus $h^1 = 0$, so the cokernel vanishes and the kernel is a genuine line bundle over $\hat X$: at each (a,b) it is spanned by one theta function, the unique lowest-Landau-level state of a particle on the torus with one flux quantum and Aharonov–Bohm fluxes a, b through the two cycles. The families formula gives

$$\mathrm{ch}(\mathrm{index}) \overset{(1)}{=} \int_X e^{h}\, e^{c_1(P)} \overset{(2)}{=} \int_X \Big(h + h c_1(P) + \tfrac{1}{2}c_1(P)^2\Big) \overset{(3)}{=} 1 - \mathrm{d}a \wedge \mathrm{d}b.$$

(1) $\mathrm{ch}(L\otimes P) = \mathrm{ch}\,L\ \mathrm{ch}\,P = e^h e^{c_1(P)}$ and $\mathrm{td}(X) = 1$.
(2) Keep terms with exactly two X-legs. Terms with h^2 vanish (h is already a top form on X).
(3) $\int_X h = 1$; $h \wedge c_1(P) = 0$ because every term of $c_1(P)$ contains $\mathrm{d}x$ or $\mathrm{d}y$ and $h \propto \mathrm{d}x\wedge\mathrm{d}y$; the last term is (4.179).
