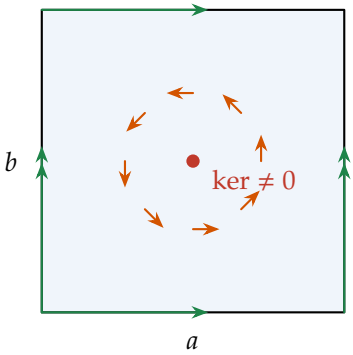
So the bundle of lowest-Landau-level states over the flux torus is a line bundle of Chern number -1. This is precisely the Niu–Thouless–Wu computation of the quantised Hall conductance: threading one flux quantum through each cycle of the torus sweeps the ground state around a Berry-phase monopole of unit charge, and $\sigma_{xy} = \frac{e^2}{h}\,|c_1| = \frac{e^2}{h}$.



dual torus $\hat{X}$ of flat connections
(origin moved to the centre)

index $\bar{\partial}_{a,b} = 0$ at every point,
but $\int_{\hat{X}} c_1(\text{index}\,\bar{\partial}) = -1$:
the phase of the small eigenvalue
$\pi i(a + ib)$ winds once (orange).

Figure 4.64: The Poincaré family on the dual torus. Only at one point (red) does $\bar{\partial}_{a,b}$ have a kernel. Near it, the only small eigenvalue is $\pi i(a + ib)$, whose phase winds once around the red point (orange arrows). This winding cannot be undone globally on $\hat{X}$, and it is what the families index theorem detects as a unit first Chern class.

4.18.9 What the Chern character cannot see: torsion

Nash remarks [Nash p. 121] that (4.175) computes $\text{ch}(\text{index}\,D) \in H^*(Y;\mathbb{Q})$, not $\text{index}\,D \in K(Y)$ itself, "thus we lose any torsion that may be present". What does that mean concretely?

A **torsion** element $\xi \in K(Y)$ is one with $N\xi = 0$ for some integer $N \geq 1$. Since ch is additive, $N\,\text{ch}(\xi) = \text{ch}(N\xi) = 0$, and in rational cohomology this forces $\text{ch}(\xi) = 0$. So the cohomological formula is blind to torsion.

Worked example 4.110: A torsion class on $\mathbb{RP}^2$

On $Y = \mathbb{RP}^2$ (the sphere with antipodal points identified) take the real line bundle ℓ whose sections are odd functions on S^2, and its complexification $\ell_{\mathbb{C}}$. Then $\ell_{\mathbb{C}} \otimes \ell_{\mathbb{C}}$ is trivial (the product of two odd functions is even), and one shows that $\xi = [\ell_{\mathbb{C}}] - 1$ satisfies $\xi^2 = -2\xi$ and $2\xi = 0$ in $K(\mathbb{RP}^2)$: $K(\mathbb{RP}^2) = \mathbb{Z} \oplus \mathbb{Z}_2$. The Chern class $c_1(\ell_{\mathbb{C}})$ is a torsion class in $H^2(\mathbb{RP}^2;\mathbb{Z}) = \mathbb{Z}_2$, so in real (de Rham) cohomology $c_1(\ell_{\mathbb{C}}) = 0$ and $\text{ch}(\xi) = 0$. Concretely: $\ell_{\mathbb{C}}$ admits a flat connection (holonomy -1 around the non-contractible loop), so its curvature form is identically zero. Any Chern–Weil formula gives zero for it, yet it is not trivial. A family whose index bundle were ξ would have $\text{ch}(\text{index}\,D) = 0$ with $\text{index}\,D \neq 0$.

This is not an academic worry. Torsion index classes are precisely what the next section (real families) is about, and in physics they correspond to *global* anomalies, such as Witten's SU(2) anomaly, which no Feynman diagram (no curvature integral) can detect.

4.18.10 The determinant line bundle and anomalies

Nash defers examples of families to Chapter 10. We give here the one construction that makes the link to physics, because it is the main reason a physicist should care about families.

The fermion determinant is not a function

In a Euclidean path integral, integrating out a fermion in a background gauge field gives

$$Z[A] = \int \mathcal{D}\bar{\psi}\,\mathcal{D}\psi\; e^{-\int \bar{\psi} D_A \psi} = \det D_A .$$

For a chiral (Weyl) fermion, $D_A = \not{D}_A^+ : \Gamma(E^+ \otimes F) \to \Gamma(E^- \otimes F)$ maps one space to a *different* space. The determinant of a map between different vector spaces is not a number: it depends on choices of bases in both. What it naturally is, is an element of a line.

Working definition 4.51 (determinant line)

For a linear map $T : V \to W$ between finite-dimensional spaces of equal dimension d, the determinant is an element

$$\det T \in \Lambda^d V^* \otimes \Lambda^d W,$$

[a one-dimensional space, since $\Lambda^d V$ is spanned by $v_1 \wedge \cdots \wedge v_d$ for any basis] namely the map $v_1 \wedge \cdots \wedge v_d \mapsto Tv_1 \wedge \cdots \wedge Tv_d$. Choosing bases identifies this line with $\mathbb{C}$ and $\det T$ with the usual number. For a Fredholm operator [finite-dimensional kernel and cokernel] D one sets

$$\mathrm{DET}(D) = \left(\Lambda^{\max} \operatorname{Ker} D\right)^* \otimes \Lambda^{\max} \operatorname{Coker} D.$$

[$\Lambda^{\max}$ is the top exterior power, Λ^k with k the dimension, again a line] *Recipe:* if D is invertible, $\mathrm{DET}(D)$ is canonically $\mathbb{C}$ and $\det D$ is (a regularised version of) the product of eigenvalues; if not, $\det D = 0$ and the line is "spanned by the zero modes".

For a family $\{D_y\}$ these lines fit together into a line bundle $\mathrm{DET} \to Y$, the **determinant line bundle** (Quillen), even where the kernels jump. The reason is the finite-dimensional identity: for $T : V \to W$ there is an exact sequence $0 \to \operatorname{Ker} T \to V \xrightarrow{T} W \to \operatorname{Coker} T \to 0$, and exactness gives a canonical isomorphism

$$(\Lambda^{\max} \operatorname{Ker} T)^* \otimes \Lambda^{\max} \operatorname{Coker} T \cong \Lambda^{\max} V^* \otimes \Lambda^{\max} W.$$

Applied to the stabilised operators of Section 4.18.4 (with $V = D_y^{-1}(W)$, which varies nicely), the right side varies smoothly with y, so the left side does too. Comparing with $\operatorname{index} D = [\mathrm{Ker}] - [\mathrm{Coker}]$,

$$c_1(\mathrm{DET}) \overset{(1)}{=} -c_1(\operatorname{Ker} D) + c_1(\operatorname{Coker} D) \overset{(2)}{=} -c_1(\operatorname{index} D). \tag{4.180}$$

(1) $c_1(\Lambda^{\max} E) = c_1(E)$ (the top exterior power has Chern root $\sum x_i$), $c_1(L^*) = -c_1(L)$, and c_1 adds under $\otimes$ of line bundles.

(2) c_1 is additive on K-theory: $c_1([E] - [F]) = c_1(E) - c_1(F)$.

So *the families index theorem computes the topology of the determinant line bundle*: $c_1(\mathrm{DET}) = -[\mathrm{ch}(\operatorname{index} D)]_{(2)}$, the degree-2 part of the families formula.

Worked example 4.111: The determinant on the dual torus

For the Poincaré family, (4.179) and (4.180) give $\int_{\hat{X}} c_1(\mathrm{DET}) = +1$. Directly: $\det \bar{\partial}_{a,b}$ is the (zeta-regularised) product of the eigenvalues (4.177),

$$\det \bar{\partial}_{a,b} \text{ “} = \text{”} \prod_{m,n \in \mathbb{Z}} \pi i \,(w + m + in), \qquad w = a + ib.$$

As a function of w this is (up to a non-vanishing factor) a theta-function-like object: it vanishes exactly when w is a lattice point, with a simple zero, and it is holomorphic in w, so near each zero it behaves like w itself and its phase winds by $+1$. It is not periodic under $w \to w + 1$, $w \to w + i$ (the regularisation spoils periodicity by a non-vanishing factor), which is exactly what one expects of a section of a non-trivial line bundle. A section of a line bundle over a closed surface with a single simple positively oriented zero has Chern number $+1$. The analytic count and the families formula agree.

Anomalies as the topology of the determinant bundle

Now take $Y = \mathcal{A}/\mathcal{G}$, the space of gauge fields modulo gauge transformations, and the family of chiral Dirac operators $\not{D}_A^+$ in n dimensions. The partition function $\det \not{D}_A^+$ is a section of $\mathrm{DET} \to \mathcal{A}/\mathcal{G}$.

- If DET is a *trivial* line bundle (with its natural connection flat), we can pick a nowhere-vanishing reference section and turn $\det \not{D}_A^+$ into a genuine gauge-invariant function of A. The theory is consistent.
- If DET is *non-trivial*, no such choice exists: the effective action cannot be made gauge invariant. This is a **gauge anomaly**.

The families index theorem computes $c_1(\mathrm{DET})$. To evaluate it on a 2-sphere $S^2 \subset \mathcal{A}/\mathcal{G}$, form the $(n+2)$-manifold $X \times S^2$ with the gauge bundle P whose restriction to $X \times \{s\}$ carries the gauge field A_s. Then

$$\int_{S^2} c_1(\mathrm{DET}) \overset{(1)}{=} -\int_{S^2}\int_X \mathrm{ch}(P)\,\hat{A}(X) \overset{(2)}{=} -\int_{X\times S^2} \mathrm{ch}(P)\,\hat{A}(X\times S^2). \tag{4.181}$$

(1) (4.180) and the families formula for twisted Dirac operators.
(2) Integration along the fibre followed by integration over the base is integration over the total space; $\hat{A}(S^2) = 1$.

This is the celebrated statement that *the gauge anomaly in n dimensions is governed by the index density in $n+2$ dimensions*: the anomaly of a 4D chiral fermion is controlled by $\int \mathrm{ch}_3(F) \propto \int \mathrm{tr}\, F^3$ in six dimensions, which is where the famous $d^{abc} = \mathrm{tr}\, T^a\{T^b, T^c\}$ anomaly coefficient comes from. The perturbative (triangle-diagram) form of this, and the torsion (global) anomalies invisible to ch, are the subject of Chapter 10.

Dictionary: families index ↔ physics

parameter space Y	space of background fields, moduli, Bloch momenta
bundle of kernels $\mathrm{Ker}\, D$	bundle of zero modes / ground states
$c_1(\mathrm{Ker}\, D)$ when $\mathrm{Coker}\, D = 0$	integrated Berry curvature
$\mathrm{DET} \to Y$	where the fermion determinant $Z[A]$ lives
$c_1(\mathrm{DET}) \neq 0$	perturbative gauge anomaly
torsion part of index D	global anomaly (invisible to diagrams)
integration along the fibre	descent from $n+2$ to n dimensions

Reading Nash (pp. 119–121, (4.123)–(4.127))

Nash defines the index of a family as $[\mathrm{Ker}\, D] - [\mathrm{Coker}\, D] \in K(Y)$ (4.123), notes that this needs modification when $\dim \mathrm{Ker}\, D_y$ jumps (we supplied the stabilisation trick of Atiyah–Singer), generalises to operators on the fibres X_y of a bundle $Z \to Y$ with structure group $\mathrm{Diff}(X)$ (4.124), introduces the symbol class in $K(T_F Z)$ and the analytic index (4.125), sketches the topological index via an embedding $Z \hookrightarrow Y \times \mathbb{R}^n$, and states the cohomological formula (4.126) with integration along the fibre (4.127). He closes by noting that the formula only computes $\mathrm{ch}(\mathrm{index}\, D) \in H^*(Y;\mathbb{Q})$, losing torsion. He defers examples to Chapter 10 (Chapter 10). We added: the explicit jumping examples, the Poincaré family on the torus with its Chern number, the Hall-conductance interpretation, the determinant line bundle and its link to anomalies. Beware the dimension count in (4.127) (see the pitfall on which

fibre is integrated).

Recap

- A family $\{D_y\}_{y\in Y}$ has index $\operatorname{index} D = [\operatorname{Ker} D] - [\operatorname{Coker} D] \in K(Y)$; its rank is the ordinary index, its Chern classes are new.
- When the kernel jumps, stabilise: $\operatorname{index} D = [D^{-1}(W)] - [W]$ for a finite-dimensional W filling the cokernels.
- The manifold may vary: families live on fibrations $Z \to Y$ with structure group $\mathrm{Diff}(X)$; symbols give a class in $K(T_F Z)$.
- Families index theorem: $\operatorname{index}_a = \operatorname{index}_t : K(T_F Z) \to K(Y)$; cohomologically $\operatorname{ch}(\operatorname{index} D) = \int_{\text{fibre}}(\cdots)$, e.g. $\int_X \operatorname{ch}(P)\operatorname{td}(X)$.
- Example: flat bundles on T^2 give an index bundle over the dual torus with $c_1 = \mp 1$ (Hall conductance).
- $c_1(\mathrm{DET}) = -c_1(\operatorname{index} D)$: the families index controls whether the fermion determinant is a function (no anomaly) or only a section.
- ch loses torsion.

4.19 The index for real families

Many operators in physics are *real*. The Laplacian has real coefficients. The Dirac operator of a Majorana fermion, written in a Majorana basis of gamma matrices, is a real matrix of real derivatives. The Bogoliubov–de Gennes Hamiltonian of a superconductor, in a Majorana basis, is i times a real antisymmetric matrix. For such operators there is a natural question that the complex theory cannot even ask:

> *A real skew-adjoint operator always has index zero. Is there nevertheless a robust integer, or at least a robust parity, attached to it?*

The answer is the **mod 2 index**: the number of zero modes, counted modulo 2, is a deformation invariant. Physically it counts unpaired Majorana zero modes; its parity cannot change under any continuous deformation because zero modes of a real skew operator can only be created or destroyed in pairs. Nash explains [Nash pp. 121–123] that this invariant is an index of a *real family*, living in a real K-theory group that is pure torsion, and so is invisible to any curvature formula.

4.19.1 Real elliptic operators

The reality condition on the symbol

Recall that the symbol of a differential operator is obtained by replacing ∂_μ with ip_μ. If the operator has real coefficients, complex conjugation of the symbol flips the sign of every i, which is the same as flipping $p \to -p$. Nash takes this as the definition [Nash p. 121].

Working definition 4.52 (real elliptic operator)

An elliptic operator D is **real** if its symbol satisfies

$$\overline{\sigma^D(x,p)} = \sigma^D(x,-p) \tag{4.182}$$

[the bar conjugates every matrix entry] in every local coordinate system. For a differential operator this just means *it has real coefficients*: it maps real-valued fields to real-valued fields. A family $\{D_y\}$ is **real** if every D_y is real; otherwise it is called complex.

The condition (4.182) is the symbol-level shadow of a familiar fact from Fourier analysis: a function $f(x)$ is real if and only if its Fourier transform satisfies $\overline{\hat{f}(p)} = \hat{f}(-p)$.

Worked example 4.112: Which operators are real?

- $D = \mathrm{d}/\mathrm{d}x$ on functions: $\sigma(p) = ip$, so $\overline{\sigma(p)} = -ip = \sigma(-p)$. Real.
- The Laplacian $\Delta = -\sum_\mu \partial_\mu^2$: $\sigma(p) = |p|^2$, real and even. Real.
- $D = \mathrm{d}/\mathrm{d}x + ia$ with $a \in \mathbb{R}$, $a \neq 0$: the leading symbol ip satisfies (4.182), but the operator does not map real functions to real functions. The symbol condition only sees the leading part; to have a real *operator* we need all coefficients real.
- The 2D Dirac operator with the gamma matrices $\gamma^1 = \sigma_1$, $\gamma^2 = \sigma_3$ (both real):

$$\not{D} = \sigma_1\partial_x + \sigma_3\partial_y = \begin{pmatrix} \partial_y & \partial_x \\ \partial_x & -\partial_y \end{pmatrix},$$

  a matrix of real operators. This is the *Majorana representation*: it acts on real two-component spinors. In the representation $\gamma^2 = \sigma_2$ of (4.166), by contrast, $\not{D}$ contains i and is not real.

A single real operator: nothing new

For a single real operator D, complexify: let it act on complex fields. Then $\mathrm{Ker}_{\mathbb{C}} D = \mathrm{Ker}_{\mathbb{R}} D \otimes \mathbb{C}$ (take real and imaginary parts of a complex zero mode separately; both are real zero modes since D is real), so $\dim_{\mathbb{C}} \mathrm{Ker}_{\mathbb{C}} D = \dim_{\mathbb{R}} \mathrm{Ker}_{\mathbb{R}} D$, and similarly for the cokernel. The index is unchanged, and the index theorem for the complexified operator computes it. Nash's first point [Nash p. 121] is that this is no longer true for families.

4.19.2 Real families and real K-theory

Complexification loses information for families

For a real family, the kernels are *real* vector spaces, so the index bundle is a class of *real* vector bundles over Y: an element of real K-theory $KO(Y)$. Complexifying gives a map

$$c : KO(Y) \longrightarrow K(Y), \qquad [E] \longmapsto [E \otimes_{\mathbb{R}} \mathbb{C}].$$

Nash's observation is that this map is *not injective*. The simplest example shows what gets lost.

Worked example 4.113: The Möbius bundle dies under complexification

Let $Y = S^1$ with angle $t \in [0, 2\pi]$. The **Möbius bundle** μ is the real line bundle obtained from $[0, 2\pi] \times \mathbb{R}$ by gluing $(2\pi, v) \sim (0, -v)$. A section is a function $s(t)$ with $s(2\pi) = -s(0)$; it must vanish somewhere (intermediate value theorem), so μ has no nowhere-zero section and is not trivial.

Its complexification $\mu_{\mathbb{C}}$ is glued by the same rule with $v \in \mathbb{C}$. Now $s(t) = e^{it/2}$ satisfies $s(2\pi) = e^{i\pi} = -1 = -s(0)$ and never vanishes. So $\mu_{\mathbb{C}}$ has a nowhere-zero section: $\mu_{\mathbb{C}}$ is trivial. The real class $[\mu] - 1 \neq 0$ in $KO(S^1)$ maps to $[\mu_{\mathbb{C}}] - 1 = 0$ in $K(S^1)$.

Moreover $\mu \oplus \mu$ *is* trivial as a real bundle: it is glued by $-1_2 = \left(\begin{smallmatrix} \cos\pi & -\sin\pi \\ \sin\pi & \cos\pi \end{smallmatrix}\right)$, and the rotation matrices $R(t/2)$, $t \in [0, 2\pi]$, give two sections

$$e_1(t) = \left(\cos\tfrac{t}{2}, \sin\tfrac{t}{2}\right), \qquad e_2(t) = \left(-\sin\tfrac{t}{2}, \cos\tfrac{t}{2}\right),$$

which satisfy $e_j(2\pi) = -e_j(0)$ and are everywhere linearly independent. Hence $2([\mu]-1) = 0$ in $KO(S^1)$. With some more work one shows

$$\widetilde{KO}(S^1) = \mathbb{Z}_2, \text{ generated by } \eta := [\mu] - 1, \qquad \widetilde{K}(S^1) = 0.$$

(Here $\widetilde{K}$ denotes the **reduced** group: classes of virtual rank zero.) A real family over S^1 can therefore carry a $\mathbb{Z}_2$ index that its complexification cannot see.

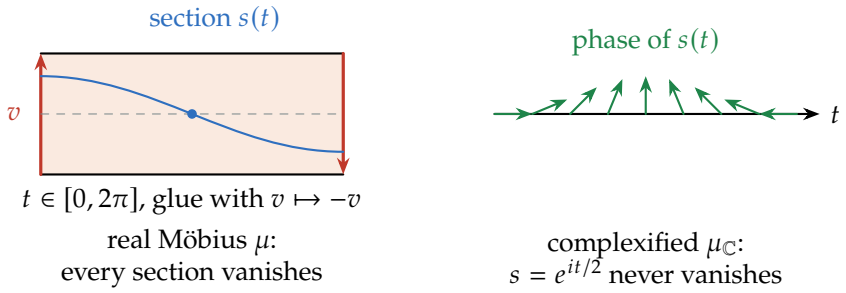


Figure 4.65: Left: the real Möbius bundle; a section starting at $+v$ must end at $-v$, so it crosses zero (blue dot). Right: after complexification the fibre is $\mathbb{C}$, and the section can rotate its phase from 1 to -1 (green arrows) without ever vanishing, so $\mu_{\mathbb{C}}$ is trivial. This is the simplest instance of information lost by complexifying a real family.

Why KR and not KO

One might expect the symbol class of a real family to live in real K-theory $KO(T_F Z)$. Nash notes [Nash pp. 121–122] that the correct group is $KR(T_F Z)$, Atiyah's K-theory of spaces with involution. The reason is visible in (4.182): the symbol is not a real matrix; complex conjugation relates the symbol at p to the symbol at $-p$.

Working definition 4.53 (Real spaces and KR)

A **Real space** is a space T with an involution $\tau : T \to T$, $\tau^2 = \mathrm{id}$. A **Real vector bundle** over it is a complex vector bundle $E \to T$ together with an *antilinear* [$\kappa(cv) = \bar{c}\,\kappa v$ for every complex number c] map $\kappa : E_t \to E_{\tau(t)}$ with $\kappa^2 = 1$ (a "complex conjugation that moves the base point"). $KR(T)$ is the K-theory built from Real vector bundles.

- If $\tau = \mathrm{id}$, then κ is an honest complex conjugation on each fibre, its fixed vectors form a real bundle $E_{\mathbb{R}}$ with $E = E_{\mathbb{R}} \otimes \mathbb{C}$, and $KR(T) = KO(T)$ [the K-theory built from real

vector bundles].

- For $T = T_F Z$ [the momenta along the fibres, points (y, x, p) with $x \in X_y$] with $\tau(y, x, p) = (y, x, -p)$, a real symbol is exactly a Real bundle map: (4.182) says that $\kappa\, \sigma(x, p) = \sigma(x, -p)\, \kappa$ with κ fibrewise complex conjugation.

So a real family has a symbol class $[\sigma(D)] \in KR(T_F Z)$, and the topological index is a map

$$\text{index}_t : KR(T_F Z) \longrightarrow KR(Y) = KO(Y),$$

where Y carries the trivial involution (each D_y is itself real). The real families index theorem says again $\text{index}_a = \text{index}_t$.

4.19.3 Skew-adjoint real operators and the mod 2 index

Their ordinary index is zero

Nash now focuses on real operators of *odd* order, such as first-order Dirac-type operators, which we take to be **skew-adjoint**: $D^* = -D$. For them the ordinary index is trivially zero:

$$\text{index}\, D \overset{(1)}{=} \dim \text{Ker}\, D - \dim \text{Ker}\, D^* \overset{(2)}{=} \dim \text{Ker}\, D - \dim \text{Ker}(-D) \overset{(3)}{=} 0. \tag{4.183}$$

(1) The cokernel of D is identified with the kernel of its adjoint.
(2) Skew-adjointness.
(3) $-D$ and D have the same kernel.

Watch out: "Automatically skew-adjoint"

Nash says that real operators of odd order are "automatically skew-adjoint". The accurate statement is about the leading symbol. For a real operator of odd order m, (4.182) and homogeneity give $\overline{\sigma(x,p)} = \sigma(x,-p) = (-1)^m \sigma(x,p) = -\sigma(x,p)$, so the symbol is purely imaginary. If in addition it is a symmetric matrix (as for scalar operators, or for Dirac operators with real symmetric gamma matrices), then $\sigma^\dagger = \bar{\sigma}^T = -\sigma$: the symbol is skew-Hermitian. The operator itself then differs from its skew-adjoint part $\frac{1}{2}(D - D^*)$ only by lower-order terms, which can be deformed away. For example $\frac{\mathrm{d}}{\mathrm{d}\theta} + V(\theta)$ with real V is real and first order but not skew-adjoint; its skew-adjoint part is $\frac{\mathrm{d}}{\mathrm{d}\theta}$.

Eigenvalues come in pairs

The key linear algebra: a real antisymmetric matrix K ($K^T = -K$) has purely imaginary eigenvalues, and they come in conjugate pairs $\pm i\lambda$. Indeed, if $Kv = i\lambda v$ with $\lambda \in \mathbb{R}$, then taking complex conjugates, $K\bar{v} = -i\lambda \bar{v}$ because K is real. By a real orthogonal change of basis, every real antisymmetric matrix takes the block form

$$K \sim \begin{pmatrix} 0 & \lambda_1 \\ -\lambda_1 & 0 \end{pmatrix} \oplus \begin{pmatrix} 0 & \lambda_2 \\ -\lambda_2 & 0 \end{pmatrix} \oplus \cdots \oplus \underbrace{0 \oplus \cdots \oplus 0}_{\dim \text{Ker}\, K}, \qquad \lambda_j > 0. \tag{4.184}$$

The non-zero eigenvalues occupy an even number of dimensions. So for an $N \times N$ real antisymmetric matrix,

$$\dim \text{Ker}\, K \equiv N \pmod 2.$$

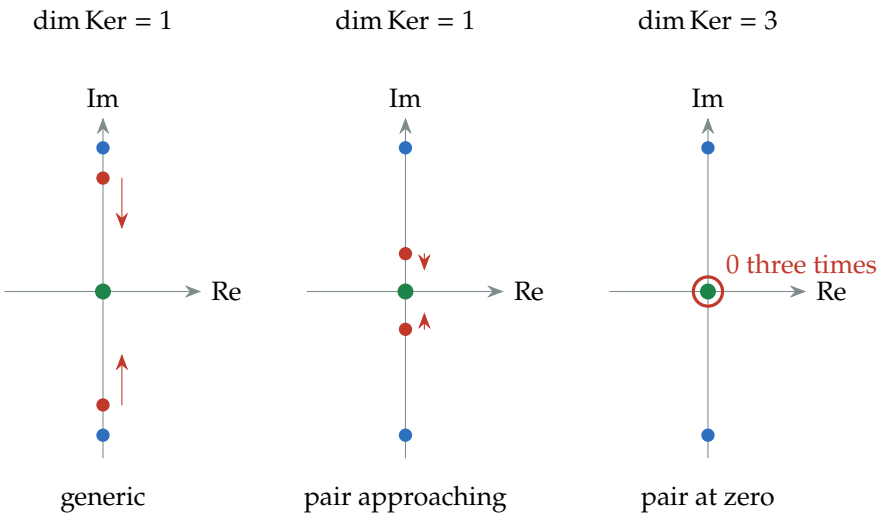

Figure 4.66: Spectrum of a real skew-adjoint operator: eigenvalues lie on the imaginary axis in pairs $\pm i\lambda$ (blue, red). The kernel (green) here is one-dimensional. When a pair (red) is deformed down to zero, the kernel jumps by two, from 1 to 3. Its parity, the mod 2 index, never changes.

As K is deformed, a pair $\pm i\lambda$ can shrink to zero, adding *two* dimensions to the kernel, or a two-dimensional piece of the kernel can split off into a pair. The kernel can never change by one.

Working definition 4.54 (mod 2 index)

For a real skew-adjoint [$D^* = -D$, so its eigenvalues are purely imaginary] elliptic operator D,

$$\operatorname{index}_1 D := \dim \operatorname{Ker} D \pmod 2 \in \mathbb{Z}_2.$$

To compute it: count the real zero modes [independent real solutions of $D\psi = 0$. Since D is real, their number equals $\dim_{\mathbb{C}} \operatorname{Ker} D$] and take the parity. *Why it is invariant:* non-zero eigenvalues of D come in pairs $\pm i\lambda$ (the finite-dimensional argument above applies to the eigenspaces), so under a continuous deformation through real skew-adjoint operators, zero modes appear and disappear two at a time.

Worked example 4.114: A family of skew matrices

Consider the 3×3 family

$$K(s) = \begin{pmatrix} 0 & s & 0 \\ -s & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad s \in \mathbb{R}.$$

Its characteristic polynomial is

$$\det(K(s) - \mu) \overset{(1)}{=} -\mu \cdot \det \begin{pmatrix} -\mu & s \\ -s & -\mu \end{pmatrix} \overset{(2)}{=} -\mu(\mu^2 + s^2),$$

(1) Expand along the third row, which has only the entry $-\mu$.
(2) $(-\mu)(-\mu) - s(-s) = \mu^2 + s^2$.

so the eigenvalues are $0, \pm is$. For $s \neq 0$, $\dim \operatorname{Ker} K(s) = 1$; at $s = 0$, $\dim \operatorname{Ker} K(0) = 3$. Both are odd, as they must be for $N = 3$.

Examples on the circle

Worked example 4.115: Majorana fermions on a circle: two spin structures

Let $D = \frac{\mathrm{d}}{\mathrm{d}\theta}$ act on real functions on the circle $\theta \in [0,1)$. It is real, first order and skew-adjoint:

$$\langle f, Dg\rangle \overset{(1)}{=} \int_0^1 f\, g'\,\mathrm{d}\theta \overset{(2)}{=} \big[f g\big]_0^1 - \int_0^1 f'\, g\,\mathrm{d}\theta \overset{(3)}{=} -\langle Df, g\rangle.$$

(1) The real L^2 inner product.
(2) Integration by parts.
(3) The boundary term vanishes for periodic functions (and also for antiperiodic ones, since then $f(1)g(1) = (-f(0))(-g(0))$).

Its kernel depends on the boundary condition, which in 1D is the choice of *spin structure*:

- *Periodic* (Ramond): $f(\theta+1) = f(\theta)$. The kernel is the constants: $\operatorname{index}_1 D = 1$.
- *Antiperiodic* (Neveu–Schwarz): $f(\theta+1) = -f(\theta)$, i.e. f is a section of the Möbius bundle. A constant antiperiodic function is zero, so $\operatorname{index}_1 D = 0$.

The mod 2 index distinguishes the two spin structures. Physically: a single real (Majorana) fermion on a periodic circle has one zero mode ψ_0 with $\psi_0^2 = \frac{1}{2}$, which cannot be paired into a complex fermion; the ground state then carries an ambiguous fermion parity. This is the one-dimensional ancestor of Majorana zero modes at the ends of a Kitaev chain.

Worked example 4.116: Deforming without changing the parity

(a) Changing the metric. If the circle has metric $a(\theta)^{-2}\mathrm{d}\theta^2$ with $a > 0$ periodic, the skew-adjoint operator is $D_a = a\frac{\mathrm{d}}{\mathrm{d}\theta} + \frac{1}{2}a'$ (the $\frac{1}{2}a'$ restores skew-adjointness with respect to $\int f g\,\mathrm{d}\theta$, since $(a\,\mathrm{d}/\mathrm{d}\theta)^* = -a\,\mathrm{d}/\mathrm{d}\theta - a'$). Its kernel:

$$a u' + \tfrac{1}{2}a' u = 0 \overset{(1)}{=} \frac{u'}{u} = -\frac{a'}{2a} \overset{(2)}{=} u = C\, a^{-1/2},$$

(1) Divide by au (where $u \neq 0$).
(2) Integrate: $\ln u = -\frac{1}{2}\ln a + \text{const}$.

which is periodic. So $\dim\operatorname{Ker} D_a = 1$ for every metric: $\operatorname{index}_1 = 1$.

(b) A rotating frame. Let $D_t = \frac{\mathrm{d}}{\mathrm{d}\theta} + tL$ act on $\mathbb{R}^3$-valued periodic functions, where $L = \left(\begin{smallmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{smallmatrix}\right)$ generates rotations about the third axis. D_t is real and skew-adjoint ($L^T = -L$). The third component obeys $u_3' = 0$: always one constant zero mode. For the first two, set $w = u_1 + iu_2$; since $L(u_1, u_2) = (-u_2, u_1)$ corresponds to $w \mapsto iw$,

$$D_t w = w' + itw = 0 \quad\Longrightarrow\quad w = Ce^{-it\theta},$$

which is periodic iff $t \in 2\pi\mathbb{Z}$, giving two more real zero modes. Hence

$$\dim\operatorname{Ker} D_t = \begin{cases} 3, & t \in 2\pi\mathbb{Z}, \\ 1, & \text{otherwise}, \end{cases} \qquad \operatorname{index}_1 D_t = 1 \text{ for all } t.$$

The kernel jumps by two, exactly as in Figure 4.66.

4.19.4 The mod 2 index as the index of a real family over the circle

Nash now explains [Nash p. 122, (4.128)–(4.129)] how the mod 2 index, which is an invariant of a *single* operator, fits into the families framework. Atiyah and Singer attach to D a real family $\widetilde{D}$ parametrised by the circle S^1, so that

$$\operatorname{index} \widetilde{D} \in KR(S^1) = KO(S^1) = \mathbb{Z} \oplus \widetilde{KO}(S^1) = \mathbb{Z} \oplus \mathbb{Z}_2.$$

The associated family

A natural candidate is the path of real operators

$$\widetilde{D}_t = \cos t \cdot 1 + \sin t \cdot D, \qquad t \in [0, \pi], \tag{4.185}$$

which starts at the identity and ends at minus the identity. It is Fredholm of index zero throughout. To see where it fails to be invertible, use the normal form (4.184): on a 2-plane where $D = \lambda \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$,

$$\det\big(\widetilde{D}_t\big|_{\text{plane}}\big) \overset{(1)}{=} \det \begin{pmatrix} \cos t & \lambda \sin t \\ -\lambda \sin t & \cos t \end{pmatrix} \overset{(2)}{=} \cos^2 t + \lambda^2 \sin^2 t > 0,$$

(1) Insert the 2×2 block of D.
(2) $\cos t$ and $\sin t$ never vanish together, and $\lambda > 0$.

while on $\operatorname{Ker} D$ the operator is $\cos t \cdot 1_m$, which vanishes at $t = \pi/2$. So $\widetilde{D}_t$ is invertible except at $t = \pi/2$, where its kernel is exactly $\operatorname{Ker} D$. In finite dimensions (D an $N \times N$ matrix, $m = \dim \operatorname{Ker} D$) the determinant along the path is

$$\det \widetilde{D}_t = (\cos t)^m \prod_j \big(\cos^2 t + \lambda_j^2 \sin^2 t\big),$$

which *changes sign* at $t = \pi/2$ if and only if m is odd.

To close the path into a loop we must return from -1 to $+1$ through invertible real operators. In infinite dimensions this is always possible (the group of invertible operators on a real Hilbert space is connected, by Kuiper's theorem). The result is a loop of real Fredholm operators: the family $\widetilde{D}$ over S^1. Its index bundle is computed by stabilisation (Section 4.18.4) near $t = \pi/2$: the kernel $\operatorname{Ker} D$ appears and disappears, and whether the real line $\Lambda^{\max}$ of the index bundle comes back to itself with or without a sign flip is decided by the sign change of the determinant: once per kernel dimension. Each zero mode of D contributes one copy of the Möbius twist.

Key idea: The mod 2 index as a family index (Nash's (4.128)–(4.129))

The index of the associated real family is

$$\operatorname{index} \widetilde{D} = m\,[\eta] \in \widetilde{KO}(S^1) = \mathbb{Z}_2, \qquad m = \dim \operatorname{Ker} D,$$

where $[\eta] = [\mu] - 1$ is the Möbius generator. Since $2[\eta] = 0$, only the parity of m survives:

$$\operatorname{index} \widetilde{D} = \dim \operatorname{Ker} D \bmod 2 = \operatorname{index}_1 D.$$

The mod 2 index of a single skew-adjoint operator is the index of a real family over a circle.

Physical picture: Counting sign flips

Think of the determinant of $\widetilde{D}_t$ as an orientation of the space of fields. Going once around the loop, each zero mode of D flips the orientation once (the factor $\cos t$ passes through zero). An even number of flips is no flip. The $\mathbb{Z}_2$ index says whether, after transporting around the circle, the "orientation of the fermion measure" comes back reversed. This is the mechanism of global anomalies: Witten's SU(2) anomaly is precisely a mod 2 index of a five-dimensional real operator, detecting that the fermion determinant changes sign along a loop of gauge transformations (Chapter 10).

4.19.5 No cohomological formula

The ordinary and families index theorems both have cohomological versions obtained by applying ch. Nash's final remark [Nash p. 123] is that this fails here. The index of a real family lies in $KR(Y)$, not in $H^*(Y)$, and in the present case it is a *torsion* element ($2[\eta] = 0$). As we saw in Section 4.18.9, the Chern character kills torsion:

$$\mathrm{ch}\big(c(\eta)\big) \overset{(1)}{=} \mathrm{ch}(\mu_{\mathbb{C}}) - \mathrm{ch}(1) \overset{(2)}{=} 1 - 1 = 0.$$

(1) Complexify and use additivity.

(2) $\mu_{\mathbb{C}}$ is trivial (Example 4.113); even without that, it has a flat connection, so its Chern form vanishes.

So no formula of the form "integral of a curvature polynomial" can compute $\mathrm{index}_1 D$. One might hope for a formula in mod 2 cohomology (Stiefel–Whitney classes: $w_1(\mu) \neq 0$ does detect the Möbius bundle), and in special cases such formulas exist, but there is no general local-integrand formula. This is a real limitation: *mod 2 indices are global, not local, invariants*.

$$\begin{array}{ccccc} KR(T_F Z) & \xrightarrow{\mathrm{index}_t = \mathrm{index}_a} & KO(Y) & \xrightarrow{\text{rank, } w_1, \ldots} & \mathbb{Z},\ \mathbb{Z}_2, \ldots \\ \downarrow{\scriptstyle c} & & \downarrow{\scriptstyle c} & & \\ K(T_F Z) & \xrightarrow{\mathrm{index}_t = \mathrm{index}_a} & K(Y) & \xrightarrow{\mathrm{ch}} & H^{\mathrm{even}}(Y;\mathbb{Q}) \end{array}$$

Figure 4.67: Where information is lost. A real family has an index in $KO(Y)$ (top row). Complexifying (c, down arrows) forgets torsion such as the Möbius class $\eta \in \widetilde{KO}(S^1)$, and the Chern character forgets any remaining torsion. The mod 2 index lives only in the top row, which is why it has no curvature formula.

Reading Nash (pp. 121–123, (4.128)–(4.129))

Nash defines real operators by $\overline{\sigma(x,p)} = \sigma(x,-p)$, notes that complexifying a single real operator loses nothing but that for families the map from real to complex index is not injective (our Example 4.113), and that the index of a real family lives in $KR(Y)$ (Atiyah's K-theory with involution, reducing to $KO(Y)$ for trivial involutions), with the involution $p \mapsto -p$ on $T_F Z$. He then introduces the mod 2 index $\mathrm{index}_1 D = \dim \mathrm{Ker}\, D \bmod 2$ of a real skew-adjoint operator, states that it equals the index of an associated real family $\widetilde{D}$ over S^1, (4.128)–(4.129), with $\widetilde{KR}(S^1) = \mathbb{Z}_2$ generated by $[\eta]$, and observes that torsion kills any cohomological formula. We supplied the eigenvalue-pairing argument, explicit examples on the circle (including the spin-structure dependence), the Möbius computations, and a concrete version of the family $\widetilde{D}$.

Recap

- Real operator: $\overline{\sigma(x,p)} = \sigma(x,-p)$, i.e. real coefficients.
- For families, complexification loses information: the Möbius class in $\widetilde{KO}(S^1) = \mathbb{Z}_2$ becomes trivial in $\widetilde{K}(S^1) = 0$.
- Symbols of real families live in $KR(T_F Z)$ (involution $p \to -p$); indices in $KR(Y) = KO(Y)$.
- Real skew-adjoint operators have index 0 but a mod 2 index $\dim\operatorname{Ker} D$ mod 2, invariant because eigenvalues pair as $\pm i\lambda$.
- $d/d\theta$ on the circle: $\operatorname{index}_1 = 1$ (periodic), 0 (antiperiodic).
- $\operatorname{index}_1 D = \operatorname{index}\widetilde{D} = m[\eta]$ for a family over S^1; torsion, hence no curvature formula.

4.20 Index theory and fixed points

Symmetry is the physicist's favourite tool. If a symmetry g acts on a system, we do not just count states; we count them *weighted by the eigenvalue of* g. The partition function becomes a character $\operatorname{Tr}(g\, e^{-\beta H})$, the Witten index becomes the twisted index $\operatorname{Tr}\big((-1)^F g\, e^{-\beta H}\big)$, and a degeneracy becomes a representation. The question of this section is:

> *If a symmetry g acts on a manifold and on an elliptic complex, can we compute the "g-weighted index" $\sum_p (-1)^p \operatorname{tr}(g|_{H^p})$ topologically? And what does the answer look like?*

The answer, due to Atiyah, Bott and Segal, is one of the most beautiful results in the subject. The weighted index is computed entirely by the *fixed points* of g: everything away from the fixed points cancels. For the de Rham complex this is the classical Lefschetz fixed point theorem; for the Dolbeault complex on $\mathbb{CP}^1$ it is the Weyl character formula for SU(2). In physics this is the prototype of **localisation**: the Duistermaat–Heckman formula, equivariant localisation of supersymmetric path integrals, and the evaluation of twisted indices by fixed points all follow the same pattern.

4.20.1 Maps act on cohomology: the Lefschetz number

Pullback on cohomology

A smooth map $g : X \to X$ pulls forms back: $(g^*\omega)(x) = \omega(g(x))$ with all differentials transformed by the chain rule. Pullback commutes with d (Chapter T1), so it maps closed forms to closed forms and exact forms to exact forms, and therefore acts on cohomology:

$$g_p^* : H^p(X) \longrightarrow H^p(X).$$

Choosing a basis of H^p, g_p^* is a matrix. For integer cohomology $H^p(X;\mathbb{Z})$ its entries are integers; in de Rham language, the basis is dual to a set of p-cycles and the entries are integrals of pulled-back forms over them.

Working definition 4.55 (Lefschetz number)

The **Lefschetz number** of $g : X \to X$ is [Nash p. 123, (4.130)]

$$L(g) = \sum_{p=0}^{n} (-1)^p \operatorname{tr}\big(g_p^*\big|_{H^p(X)}\big). \tag{4.186}$$

To compute it: find a basis of each cohomology group (for example a set of closed forms, one per independent cycle [a closed p-dimensional submanifold, or combination of them, with no boundary]), pull each back by g, express the result in the basis, and take traces.

Three properties follow at once.

- *Identity.* If $g = \mathrm{id}$, each g_p^* is the identity matrix, of trace $b_p = \dim H^p$, so [Nash p. 123, (4.131)]
$$L(\mathrm{id}) = \sum_p (-1)^p b_p = \chi(X). \tag{4.187}$$
- *Homotopy invariance.* Homotopic maps induce the same map on cohomology, so $L(g)$ depends only on the homotopy class of g. In particular $L(g) = \chi(X)$ for every g homotopic to the identity.
- *The fixed point theorem.* If $L(g) \neq 0$ then g has at least one fixed point (a point with $g(x) = x$). We explain why in Section 4.20.2.

Combining the last two: if $\chi(X) \neq 0$, every map homotopic to the identity has a fixed point. A rotation of S^2 ($\chi = 2$) must fix something; a rotation of the torus ($\chi = 0$) need not, and indeed a translation of T^2 fixes nothing.

Worked example 4.117: Maps of the circle

On S^1 with angle θ, $H^0 = \mathbb{R}$ (constants) and $H^1 = \mathbb{R}$, spanned by the class of $\mathrm{d}\theta$ (with $\oint \mathrm{d}\theta = 2\pi \neq 0$). Constants pull back to constants, so $\operatorname{tr} g_0^* = 1$ for every g. Hence $L(g) = 1 - \operatorname{tr} g_1^*$, and we need only the action on $\mathrm{d}\theta$.

- *Rotation* $g(\theta) = \theta + \alpha$: $g^*\mathrm{d}\theta = \mathrm{d}(\theta + \alpha) = \mathrm{d}\theta$, so $L = 1 - 1 = 0$. For $\alpha \notin 2\pi\mathbb{Z}$ there are indeed no fixed points.
- *Reflection* $g(\theta) = -\theta$: $g^*\mathrm{d}\theta = -\mathrm{d}\theta$, so $L = 1 - (-1) = 2$. Fixed points: $\theta = 0$ and $\theta = \pi$. Two of them.
- *Degree-k map* $g(e^{i\theta}) = e^{ik\theta}$: $g^*\mathrm{d}\theta = k\,\mathrm{d}\theta$, so $L = 1 - k$. Fixed points solve $e^{ik\theta} = e^{i\theta}$, i.e. $e^{i(k-1)\theta} = 1$: there are $|k - 1|$ of them. For $k = -1$ this is the reflection again.

In the last case $|L|$ equals the number of fixed points, but the sign of L is negative for $k \geq 2$. Fixed points come with signs; we now find out which.

Worked example 4.118: Maps of the sphere

On S^2, $H^0 = \mathbb{R}$ and $H^2 = \mathbb{R}$ spanned by the area form ω (with $\int \omega = 4\pi$), and $H^1 = 0$. For any g, $\int_{S^2} g^*\omega = \deg(g) \int \omega$, so $g_2^* = \deg g$ and

$$L(g) = 1 + \deg g.$$

- *Rotation* by angle α about the z-axis: deg = 1, so $L = 2$. Fixed points: the two poles.

- *Antipodal map* $x \mapsto -x$: it reverses orientation on S^2 ($\deg = -1$), so $L = 0$. Indeed it has no fixed points.
- *Any map homotopic to the identity* has $L = 2 = \chi(S^2)$ and so a fixed point. This is the "hairy ball theorem": flowing a little way along a tangent vector field gives a map homotopic to the identity, and its fixed points are the zeros of the vector field.

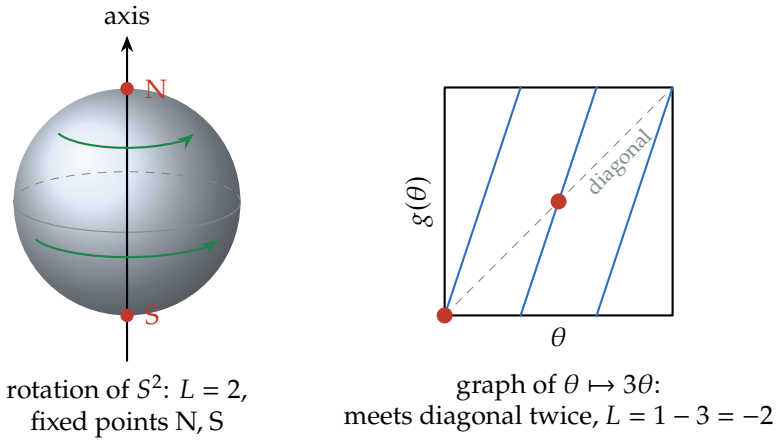

Figure 4.68: Left: a rotation of the sphere fixes exactly the two poles, and $L(g) = 2 = \chi(S^2)$. Right: the graph of the degree-3 map of the circle (blue) crosses the diagonal (fixed points, red) at $|k-1| = 2$ points, counting $\theta = 0 \equiv 2\pi$ once. Each crossing is from below to above, steeper than the diagonal, and contributes -1, giving $L = -2$.

4.20.2 Why fixed points: the Lefschetz–Hopf formula

Nash states that $L(g) \neq 0$ implies a fixed point and, for isolated fixed points, that $\chi(X)$ equals the number of fixed points. The precise statement assigns a sign to each fixed point.

Key idea: Lefschetz–Hopf fixed point formula

If $g : X \to X$ has only isolated fixed points P, each *non-degenerate* ($\det(1 - \mathrm{d}g_P) \neq 0$, i.e. 1 is not an eigenvalue of the Jacobian at P), then

$$L(g) = \sum_{P:\, g(P)=P} \operatorname{sgn} \det\bigl(1 - \mathrm{d}g_P\bigr). \tag{4.188}$$

In particular if there are no fixed points, $L(g) = 0$; contrapositively, $L(g) \neq 0$ forces a fixed point.

Why it is true (the physicist's picture). Consider the graph $\Gamma_g = \{(x, g(x))\}$ and the diagonal $\Delta = \{(x, x)\}$ in $X \times X$. Fixed points are the intersection points $\Gamma_g \cap \Delta$. The Lefschetz number is the *signed intersection number* $\Gamma_g \cdot \Delta$: it can be computed in cohomology (giving (4.186): the Poincaré dual of Δ is $\sum_i e_i \otimes e^i$ in terms of dual bases, and pairing it with the graph produces the traces), or geometrically by counting intersections with orientation signs (giving (4.188)). The sign at P compares the orientation of $T\Gamma_g \oplus T\Delta$ with that of $T(X \times X)$; in coordinates $T\Gamma_g$ is spanned by $(v, \mathrm{d}g\, v)$ and $T\Delta$ by (w, w), and the determinant of the matrix $\left(\begin{smallmatrix} 1 & 1 \\ \mathrm{d}g & 1 \end{smallmatrix}\right)$ is $\det(1 - \mathrm{d}g)$.

Worked example 4.119: Checking the signs

Degree-k map of the circle. At each fixed point $\mathrm{d}g = k$, so each contributes $\operatorname{sgn}(1-k)$. With $|k-1|$ fixed points,

$$\sum_P \operatorname{sgn}\det(1-\mathrm{d}g_P) \overset{(1)}{=} |k-1|\,\operatorname{sgn}(1-k) \overset{(2)}{=} 1-k,$$

(1) All fixed points have the same Jacobian k.
(2) $|x|\operatorname{sgn}(x) = x$ with $x = 1-k$.

matching $L = 1-k$ from Example 4.117.
Rotation of S^2 by $\alpha \notin 2\pi\mathbb{Z}$. At the north pole, in a tangent plane with the outward orientation, $\mathrm{d}g$ is the rotation matrix $R(\alpha)$. At the south pole it is $R(-\alpha)$ in the outward orientation. Either way

$$\det\bigl(1-R(\pm\alpha)\bigr) \overset{(1)}{=} \det\begin{pmatrix} 1-\cos\alpha & \pm\sin\alpha \\ \mp\sin\alpha & 1-\cos\alpha \end{pmatrix} \overset{(2)}{=} (1-\cos\alpha)^2+\sin^2\alpha \overset{(3)}{=} 2-2\cos\alpha > 0.$$

(1) $R(\alpha) = \left(\begin{smallmatrix} \cos\alpha & -\sin\alpha \\ \sin\alpha & \cos\alpha \end{smallmatrix}\right)$.
(2) 2×2 determinant.
(3) $\cos^2+\sin^2 = 1$.

Each pole contributes $+1$: total $2 = L(g)$. *Identity perturbed by a vector field.* If g is the time-ε flow of a vector field V with non-degenerate zeros, then $\mathrm{d}g_P \approx 1+\varepsilon\,\partial V(P)$ and $\operatorname{sgn}\det(1-\mathrm{d}g_P) = \operatorname{sgn}\det(-\partial V(P)) = (-1)^n \operatorname{sgn}\det\partial V(P)$. Up to the overall sign $(-1)^n$ (which is $+1$ in even dimensions) this is the index of the zero of V, and (4.188) with (4.187) becomes the Poincaré–Hopf theorem: the sum of the indices of the zeros of a vector field is $\chi(X)$.

Watch out: "The number of fixed points equals χ"

Nash says that for isolated fixed points of a map homotopic to the identity, $\chi(X)$ is the number of fixed points. This is true when every fixed point has sign $+1$ (for instance, rotations of S^2, or generic isometries). In general each fixed point counts with the sign (4.188): the flow of $V = x\partial_x - y\partial_y$ near a saddle contributes -1.

4.20.3 Lefschetz numbers for elliptic complexes

The Euler characteristic is the index of the de Rham complex, and $L(\mathrm{id}) = \chi$. This suggests generalising from de Rham to any elliptic complex [Nash p. 124, (4.132)]

$$0 \to \Gamma(X,E^0) \xrightarrow{d_0} \Gamma(X,E^1) \xrightarrow{d_1} \cdots \xrightarrow{d_{N-1}} \Gamma(X,E^N) \to 0, \qquad d_i \circ d_{i-1} = 0.$$

Working definition 4.56 (invariant complex and generalised Lefschetz number)

Let $g : X \to X$ be a map and suppose we are given linear maps $T_i : \Gamma(X,E^i) \to \Gamma(X,E^i)$ that commute with the operators [Nash p. 124, (4.133)]:

$$d_i T_i = T_{i+1} d_i.$$

Then the complex is **invariant** under g. Because T commutes with d, it maps kernels to kernels and images to images, and so acts on each cohomology group $H^i(E)$ [$\operatorname{Ker} d_i/\operatorname{Im} d_{i-1}$, solutions of $d_i s = 0$ modulo those of the form $d_{i-1}t$]; call this action $g_i^*(E)$. The **generalised**

Lefschetz number is [Nash p. 124, (4.134)]

$$L(g,E)=\sum_i (-1)^i \operatorname{tr}\big(g_i^*(E)\big). \tag{4.189}$$

Typical source of the T_i: g lifts to the bundles ($\phi_i : E^i_{g(x)} \to E^i_x$, linear), and $T_i s(x) = \phi_i\, s(g(x))$. For the de Rham complex, $\phi_i = \Lambda^i(\mathrm{d}g)^T$ [the transposed Jacobian of g acting on each covector factor of an i-form] and $T_i = g^*$, giving back (4.186).

For $g = \mathrm{id}$ and $T_i = \mathrm{id}$, $L(\mathrm{id},E) = \operatorname{index} E$: *the generalised Lefschetz number is a g-weighted index.*

Group actions and characters

To have many g's at once, let a compact Lie group G act on X, i.e. a continuous map $G\times X\to X$, $(g,x)\mapsto g\cdot x$, with $(gh)\cdot x = g\cdot(h\cdot x)$. If the complex is invariant under every $g\in G$, each $H^i(E)$ becomes a finite-dimensional *representation* of G, and

$$g \longmapsto L(g,E)=\sum_i (-1)^i \chi_{H^i(E)}(g)$$

is an alternating sum of *characters*. Nash's remark that $L(g,E)$ "is a little reminiscent of the character of a group representation" [Nash p. 124] is exactly right: it *is* a (virtual) character. Nash's footnote observes that the maps are then all invertible (g^{-1} is in G too), which is more special than general fixed point theory but is precisely the situation in which index theory is powerful.

Working definition 4.57 (representation ring)

The **representation ring** $R(G)$ consists of formal differences $[V]-[W]$ of finite-dimensional complex representations, with $\oplus$ and $\otimes$. An element is determined by its *character* $g\mapsto \operatorname{tr}_V(g)-\operatorname{tr}_W(g)$, a class function [unchanged under $g\mapsto hgh^{-1}$, since $\operatorname{tr}(hgh^{-1})=\operatorname{tr} g$] on G.

Worked example 4.120: Representation rings

- $G=\mathrm{U}(1)$, $g=\lambda=e^{i\alpha}$. The irreducible representations are one-dimensional, $\lambda\mapsto\lambda^j$, $j\in\mathbb{Z}$. So $R(\mathrm{U}(1))=\mathbb{Z}[\lambda,\lambda^{-1}]$: characters are Laurent polynomials. The virtual representation $2-\lambda^3$ is "two copies of the trivial representation minus one of charge 3".
- $G=\mathbb{Z}_2=\{1,g\}$: two irreducibles (trivial, sign), characters $(1,1)$ and $(1,-1)$. $R(\mathbb{Z}_2)=\mathbb{Z}[\varepsilon]/(\varepsilon^2-1)$.
- $G=\mathrm{SU}(2)$: irreducibles V_s of spin $s=0,\tfrac12,1,\dots$, with character on $\operatorname{diag}(e^{i\alpha/2},e^{-i\alpha/2})$

$$\chi_s(\alpha)=\sum_{m=-s}^{s} e^{im\alpha}=\frac{\sin\big((s+\tfrac12)\alpha\big)}{\sin(\alpha/2)}.$$

Equivariant K-theory

To formulate an index theorem one needs K-theory that remembers the group action [Nash p. 125].

Working definition 4.58 (G-vector bundle and $K_G(X)$)

Let X be a G-space [each $g \in G$ moves points by a map $x \mapsto g \cdot x$, compatibly with the group law]. A **G-vector bundle** is a vector bundle $\pi : F \to X$ on which G also acts, such that

- the action covers the action on X: $\pi(g \cdot f) = g \cdot \pi(f)$;
- g maps fibres *linearly*: $F_x \to F_{g\cdot x}$ is linear [Nash (4.135)].

$K_G(X)$ is the K-theory of G-vector bundles (formal differences, as for $K(X)$).

Two special cases identify it with familiar objects.

- $G = \{e\}$ trivial: every bundle is a G-bundle, so $K_{\{e\}}(X) = K(X)$.
- $X = \{x_0\}$ a point: a G-bundle over a point is a vector space with a linear G-action, i.e. a representation. So $K_G(\mathrm{pt}) = R(G)$.

Worked example 4.121: The monopole bundles as $\mathrm{U}(1)$-bundles

Let U(1) act on $\mathbb{CP}^1$ by $\lambda \cdot z = \lambda z$ (rotation about the z-axis). The bundle $\mathcal{O}(k)$ (sections: pairs $s_0(z)$, $s_\infty(w) = w^k s_0(1/w)$) becomes a U(1)-bundle by

$$(\lambda \cdot s)_0(z) = s_0(\lambda z).$$

In the other chart this reads, for $s_0 = z^j$, $(\lambda \cdot s)_\infty(w) = \lambda^j w^{k-j} = \lambda^k\, s_\infty(\lambda^{-1} w)$: the action pulls back along $w \mapsto \lambda^{-1} w$ and multiplies the fibre by λ^k. At the two fixed points the group acts on the fibre by

$$\text{at } z = 0 :\ 1, \qquad \text{at } z = \infty :\ \lambda^k.$$

These two numbers are all the fixed point formula below will need. (The lift is not unique: multiplying by an overall character λ^c gives another lift. Choosing $c = -k/2$, when allowed, makes the picture symmetric under $z \to 1/z$ and turns the action into an SU(2) one.)

4.20.4 The G-index theorem

Analytic index

Let D be a G-invariant elliptic operator (it commutes with the G action on sections). Its symbol, being built from G-invariant data, defines a class $[\sigma_m(D)] \in K_G(T^*X)$. The kernel and cokernel are finite-dimensional representations, and Nash defines [Nash p. 126, (4.136)–(4.137)]

$$\mathrm{index}_G D = [\mathrm{Ker}\, D] - [\mathrm{Coker}\, D] \in R(G), \qquad \mathrm{index}_a : K_G(T^*X) \to R(G),\ [\sigma_m(D)] \mapsto \mathrm{index}_G D. \tag{4.190}$$

Evaluating the character at $g = e$ gives back the ordinary index, $\dim \mathrm{Ker}\, D - \dim \mathrm{Coker}\, D$.

Topological index

The topological index is built as before, with one change: X must be embedded G-equivariantly, and $\mathbb{R}^N$ is replaced by a real *representation space* V of G (by a theorem of Mostow and Palais this is always possible). With $i : X \hookrightarrow V$ and $j : P \hookrightarrow V$ the inclusion of the origin (a point,

necessarily fixed by G), the diagram is [Nash p. 126, (4.138)]

$$K_G(T^*X) \xrightarrow{i_!} K_G(T^*V) \xleftarrow[\cong]{j_!} K_G(T^*P)\ , \qquad \operatorname{index}_t = (j_!)^{-1} \circ i_!. \tag{4.191}$$

Since P is a point, $T^*P = P$ and $K_G(P) = R(G)$ rather than $\mathbb{Z}$ [Nash (4.139)]. So the topological index is automatically character-valued: $\operatorname{index}_t : K_G(T^*X) \to R(G)$. The map $j_!$ is the equivariant Bott (Thom) isomorphism, which is where the representation theory enters.

Worked example 4.122: An equivariant embedding

$S^2 \subset \mathbb{R}^3$ as the unit sphere is SO(3)-equivariant: SO(3) acts on $V = \mathbb{R}^3$ by its defining representation, and rotations of the sphere are restrictions of this linear action. The origin $P = 0$ is fixed. For the circle action of Example 4.121, $V = \mathbb{R}^3 = \mathbb{C} \oplus \mathbb{R}$ with λ acting by multiplication on $\mathbb{C}$ and trivially on $\mathbb{R}$.

Key idea: The G-index theorem and the Atiyah–Segal formula

For a G-invariant elliptic operator (or complex),

$$\operatorname{index}_a = \operatorname{index}_t : K_G(T^*X) \longrightarrow R(G).$$

Taking the character at $g \in G$, the generalised Lefschetz number is [Nash p. 126, (4.140)]

$$L(g, E) = \chi(g), \qquad \chi = \operatorname{index}_t(u), \quad u = [\sigma(E)] \in K_G(T^*X). \tag{4.192}$$

The right side can be evaluated by a cohomological formula which involves only the *fixed point set* $X^g = \{x : g \cdot x = x\}$: it is an integral over X^g of characteristic classes of X^g, of its normal bundle, and of the restrictions of the E^i, with g acting on the normal bundle and on the fibres.

For $g = e$, $X^e = X$ and the formula is the ordinary cohomological index formula. For g with isolated fixed points, X^g is a finite set, the "integral over X^g" is a finite sum, and the formula becomes remarkably simple. We now derive it.

4.20.5 Why only fixed points contribute: heat-kernel localisation

Recall the heat-kernel form of the index (McKean–Singer): for an elliptic complex with Laplacians $\Delta_i = d_i^* d_i + d_{i-1} d_{i-1}^*$, $\operatorname{index} E = \sum_i (-1)^i \operatorname{Tr} e^{-t\Delta_i}$ for every $t > 0$. The non-zero eigenvalues cancel in the alternating sum, because d maps a Δ_i-eigenform to a Δ_{i+1}-eigenform with the same eigenvalue. If T commutes with d (and with d^*, e.g. if g is an isometry), the same cancellation holds with T inserted:

$$L(g, E) = \sum_i (-1)^i \operatorname{Tr}\big(T_i\, e^{-t\Delta_i}\big) \qquad \text{for every } t > 0. \tag{4.193}$$

Now write the trace with the heat kernel $K_t^i(x, y)$: $\operatorname{Tr}(T_i e^{-t\Delta_i}) = \int_X \operatorname{tr}\big(\phi_i\, K_t^i(g(x), x)\big)\, \mathrm{d}x$. For small t the heat kernel is sharply peaked on the diagonal:

$$K_t(y, x) \approx \frac{1}{(4\pi t)^{n/2}}\, e^{-|y-x|^2/4t} \cdot \big(1 + O(t)\big).$$

The integrand involves $K_t(g(x), x)$, which is exponentially small unless $g(x)$ is close to x. As $t \to 0$ *only neighbourhoods of the fixed points contribute*. Near a non-degenerate fixed point P, in

coordinates centred at P, $g(x) \approx Ax$ with $A = \mathrm{d}g_P$. Then

$$\begin{aligned}\int_{\mathbb{R}^n} \frac{e^{-|Ax-x|^2/4t}}{(4\pi t)^{n/2}}\,\mathrm{d}^n x &\overset{(1)}{=} \int_{\mathbb{R}^n} \frac{e^{-|y|^2/4t}}{(4\pi t)^{n/2}}\,\frac{\mathrm{d}^n y}{|\det(1-A)|} \\ &\overset{(2)}{=} \frac{1}{|\det(1-A)|}\prod_{k=1}^{n}\int_{\mathbb{R}} \frac{e^{-y_k^2/4t}}{(4\pi t)^{1/2}}\,\mathrm{d}y_k \\ &\overset{(3)}{=} \frac{1}{|\det(1-A)|}.\end{aligned} \tag{4.194}$$

(1) Change variables $y = (A-1)x$; non-degeneracy means $1-A$ is invertible, and $\mathrm{d}^n y = |\det(1-A)|\,\mathrm{d}^n x$.

(2) The Gaussian factorises over the components of y.

(3) $\int_{\mathbb{R}} e^{-y^2/4t}\,\mathrm{d}y = \sqrt{4\pi t}$.

The answer does not depend on t, as it must not. Including the fibre maps $\phi_{i,P}$ at the fixed point, we arrive at:

Key idea: Atiyah–Bott fixed point formula

If g has isolated non-degenerate fixed points, then

$$L(g,E) = \sum_{P:\,g(P)=P} \frac{\sum_i (-1)^i \operatorname{tr}(\phi_{i,P})}{\left|\det(1-\mathrm{d}g_P)\right|}, \tag{4.195}$$

where $\phi_{i,P} : E^i_P \to E^i_P$ is the lifted action on the fibre over the fixed point. Everything away from the fixed points cancels; each fixed point contributes a rational function of the eigenvalues of g there.

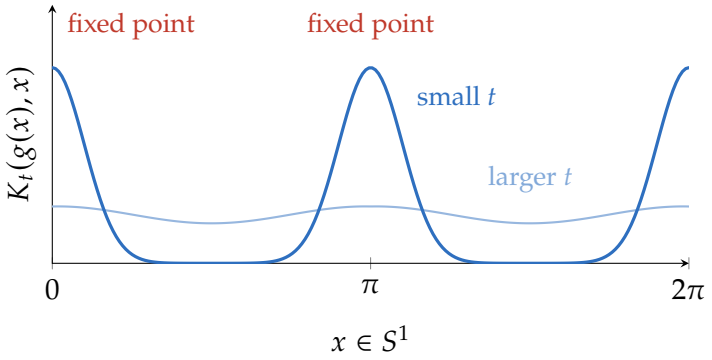

Figure 4.69: Localisation. For the reflection $g(x) = -x$ of the circle, the integrand $K_t(g(x),x)$ of the g-twisted heat trace is peaked where $g(x) = x$, i.e. at the fixed points 0 and π. As $t \to 0$ the peaks narrow (dark curve), but their areas, $1/|\det(1-\mathrm{d}g)| = \frac{1}{2}$ each, stay fixed. The whole Lefschetz number is carried by the fixed points.

Recovering the classical formula

For the de Rham complex, $E^i = \Lambda^i T^*X$ and $\phi_{i,P} = \Lambda^i A^T$, with $A = \mathrm{d}g_P$. The numerator is the alternating sum of traces of the exterior powers of A^T, which is a characteristic polynomial:

$$\sum_i (-1)^i \operatorname{tr}\Lambda^i A^T \overset{(1)}{=} \prod_{k=1}^{n}(1-a_k) \overset{(2)}{=} \det(1-A). \tag{4.196}$$

(1) If A has eigenvalues $a_1, \dots, a_n$, then $\Lambda^i A^T$ has eigenvalues $a_{k_1} \cdots a_{k_i}$ ($k_1 < \cdots < k_i$), so $\operatorname{tr} \Lambda^i A^T = e_i(a)$, the i-th elementary symmetric polynomial, and $\sum_i (-1)^i e_i(a) = \prod_k (1 - a_k)$.
(2) The determinant is the product of the eigenvalues.

So the Atiyah–Bott contribution is $\det(1-A)/|\det(1-A)| = \operatorname{sgn}\det(1-A)$, which is precisely the Lefschetz–Hopf formula (4.188).

Worked example 4.123: The reflection of the circle, by heat kernels

Let $g(\theta) = -\theta$ on S^1 and check (4.193) directly. On functions use the basis $1, \cos n\theta, \sin n\theta$ ($n \geq 1$), eigenfunctions of $\Delta = -\mathrm{d}^2/\mathrm{d}\theta^2$ with eigenvalue n^2. Then $g^* \cos n\theta = \cos n\theta$ and $g^* \sin n\theta = -\sin n\theta$, so

$$\operatorname{Tr}\big(g^* e^{-t\Delta_0}\big) \overset{(1)}{=} 1 + \sum_{n \geq 1} \big(e^{-tn^2} - e^{-tn^2}\big) = 1.$$

(1) Diagonal entries: $+1$ on $\cos n\theta$, -1 on $\sin n\theta$, each weighted by e^{-tn^2}; the constant contributes 1.

On 1-forms, $g^*(f(\theta)\mathrm{d}\theta) = -f(-\theta)\,\mathrm{d}\theta$, so $\mathrm{d}\theta \mapsto -\mathrm{d}\theta$, $\cos n\theta\,\mathrm{d}\theta \mapsto -\cos n\theta\,\mathrm{d}\theta$, $\sin n\theta\,\mathrm{d}\theta \mapsto +\sin n\theta\,\mathrm{d}\theta$, and $\operatorname{Tr}(g^* e^{-t\Delta_1}) = -1$. Hence

$$L(g) = 1 - (-1) = 2 \quad \text{for every } t.$$

By Atiyah–Bott: at each fixed point $A = -1$, $|\det(1-A)| = 2$, and the numerator is $\operatorname{tr}\phi_0 - \operatorname{tr}\phi_1 = 1 - (-1) = 2$. Each fixed point contributes $2/2 = 1$; two fixed points give 2. Figure 4.69 shows how the heat-kernel integrand localises.

The holomorphic Lefschetz formula

For the Dolbeault complex of a complex manifold of complex dimension ℓ, with a holomorphic g, $E^i = \Lambda^{0,i}$ and the numerator involves the *antiholomorphic* part $\bar{A}$ of $\mathrm{d}g_P$, while the real Jacobian has $|\det_{\mathbb{R}}(1 - \mathrm{d}g_P)| = |\det_{\mathbb{C}}(1-A)|^2$. Therefore, for the bundle F twisted in, with fibre action ϕ_P on F_P:

$$\nu(P) \overset{(1)}{=} \frac{\operatorname{tr}\phi_P \ \sum_i (-1)^i \operatorname{tr}\Lambda^i \bar{A}}{|\det_{\mathbb{C}}(1-A)|^2} \overset{(2)}{=} \frac{\operatorname{tr}\phi_P \ \det(1-\bar{A})}{\det(1-A)\,\det(1-\bar{A})} \overset{(3)}{=} \frac{\operatorname{tr}\phi_P}{\det_{\mathbb{C}}(1-A)}. \tag{4.197}$$

(1) Atiyah–Bott (4.195) for $E^i = F \otimes \Lambda^{0,i}$ (traces multiply on tensor products).
(2) (4.196) applied to $\bar{A}$; and $|z|^2 = z\bar{z}$ with $z = \det(1-A)$.
(3) Cancel $\det(1-\bar{A})$ (non-zero by non-degeneracy).

This is the **holomorphic Lefschetz formula**. (Here A is the holomorphic derivative of g at P, i.e. its action on $T^{1,0}_P$.)

Worked example 4.124: Rotating $\mathbb{CP}^1$: the Weyl character formula

Take $g(z) = \lambda z$, $\lambda = e^{i\alpha} \neq 1$, on $\mathbb{CP}^1$ acting on $\mathcal{O}(k)$ as in Example 4.121. *Direct computation.* For $k \geq 0$, $H^0(\mathbb{CP}^1; \mathcal{O}(k)) = \operatorname{span}\{1, z, \dots, z^k\}$ and $H^1 = 0$. The action $(\lambda \cdot s)(z) = s(\lambda z)$ sends $z^j \mapsto \lambda^j z^j$. So

$$L(g, \bar{\partial}_{\mathcal{O}(k)}) = \sum_{j=0}^{k} \lambda^j.$$

Fixed points. g fixes $z = 0$ and $z = \infty$.

- At $z = 0$: $A = \mathrm{d}g = \lambda$, and the fibre action is 1.
- At $z = \infty$, in the coordinate $w = 1/z$: $g(w) = \lambda^{-1}w$, so $A = \lambda^{-1}$, and the fibre action is λ^{k}.

The holomorphic Lefschetz formula (4.197) gives

$$L(g, \bar\partial_{O(k)}) \overset{(1)}{=} \frac{1}{1-\lambda} + \frac{\lambda^{k}}{1-\lambda^{-1}} \overset{(2)}{=} \frac{1}{1-\lambda} - \frac{\lambda^{k+1}}{1-\lambda} \overset{(3)}{=} \frac{1-\lambda^{k+1}}{1-\lambda} \overset{(4)}{=} \sum_{j=0}^{k} \lambda^{j}.$$

(1) One term per fixed point: numerator the fibre action, denominator $1 - A$.
(2) Multiply numerator and denominator of the second term by $-\lambda$: $\frac{\lambda^{k}}{1-\lambda^{-1}} = \frac{-\lambda^{k+1}}{1-\lambda}$.
(3) Common denominator.
(4) Geometric series.

The two fixed points reproduce the full character. Expanding the first term as $1+\lambda+\lambda^{2}+\cdots$ and the second as $-\lambda^{k+1} - \lambda^{k+2} - \cdots$, the "tail" of the north pole's geometric series is cancelled by the south pole's, leaving exactly the $k+1$ weights (Figure 4.70).
With the symmetric lift (multiply by $\lambda^{-k/2}$, $\lambda = e^{i\alpha}$, $s = k/2$) this reads

$$\frac{\lambda^{-s} - \lambda^{s+1}}{1-\lambda} = \frac{\sin\!\big((s+\tfrac{1}{2})\alpha\big)}{\sin(\alpha/2)} = \chi_{s}(\alpha),$$

the Weyl character formula for spin s. Setting $\lambda \to 1$ gives $k+1$, the Riemann–Roch index of Example 4.98.

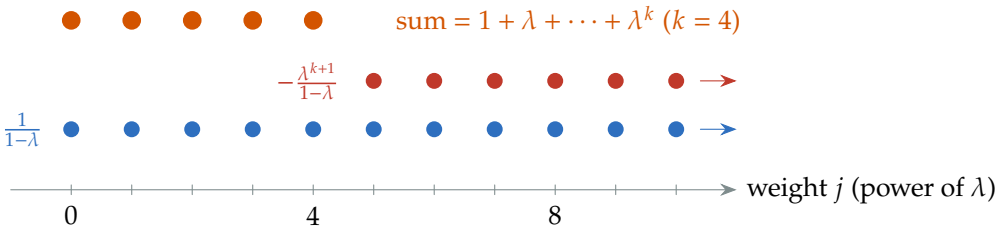

Figure 4.70: The holomorphic Lefschetz formula on $\mathbb{CP}^{1}$ for $\mathcal{O}(4)$. The north pole contributes the infinite geometric series of all weights $j \geq 0$ (blue); the south pole contributes minus all weights $j \geq k+1$ (red). The infinite tails cancel and exactly the $k+1 = 5$ weights of H^{0} survive (orange). This is the Weyl character formula as a fixed point formula.

Worked example 4.125: Spinors on a rotating sphere

The (untwisted) Dirac operator on the round S^{2} has no zero modes (Lichnerowicz: $\not{D}^{2} = \nabla^{*}\nabla + \frac{R}{4}$ with $R > 0$), so its Lefschetz number vanishes for every rotation. Check with Atiyah–Bott. The spin complex has $E^{0} = S^{+}$, $E^{1} = S^{-}$. A rotation by α of a tangent plane lifts to spinors as $e^{\pm i\alpha/2}$ on $S^{\pm}$ (the lift of $R(\alpha)$ to Spin(2), chosen continuously from the identity). At a fixed point where $\mathrm{d}g = R(\alpha)$ in the oriented tangent plane:

$$\nu \overset{(1)}{=} \frac{e^{i\alpha/2} - e^{-i\alpha/2}}{2 - 2\cos\alpha} \overset{(2)}{=} \frac{2i\sin(\alpha/2)}{4\sin^{2}(\alpha/2)} \overset{(3)}{=} \frac{i}{2\sin(\alpha/2)}.$$

(1) Atiyah–Bott with numerator $\operatorname{tr}\phi_{0} - \operatorname{tr}\phi_{1}$ and denominator from Example 4.119.
(2) $e^{ix} - e^{-ix} = 2i\sin x$ and $1 - \cos\alpha = 2\sin^{2}(\alpha/2)$.

(3) Cancel.

At the north pole the rotation is $R(\alpha)$ in the outward orientation; at the south pole it is $R(-\alpha)$. So the total is $\frac{i}{2\sin(\alpha/2)} + \frac{i}{2\sin(-\alpha/2)} = 0$, as it must be. Coupled to the monopole bundle L_k, the two contributions acquire different fibre factors and no longer cancel; the result is the character of the k zero modes of Example 4.102, which form the spin-$\frac{k-1}{2}$ representation of SU(2).

Physical picture: Twisted indices and localisation in physics

In a supersymmetric quantum mechanics with a symmetry g commuting with the supercharge, the twisted Witten index $\mathrm{Tr}\big((-1)^F g\, e^{-\beta H}\big)$ is independent of β (non-zero-energy states cancel in boson–fermion pairs, exactly as in (4.193)). Computed as a path integral over loops $x(\tau)$ with twisted boundary condition $x(\beta) = g\,x(0)$, the $\beta \to 0$ limit forces $x(0)$ to be a fixed point of g, and the Gaussian fluctuation integral around it is (4.194). This is the Atiyah–Bott formula as a path integral, and it is the simplest example of equivariant localisation, the technique behind Duistermaat–Heckman, Nekrasov's instanton partition functions and supersymmetric localisation.

Reading Nash (pp. 123–127, (4.130)–(4.140))

Nash recalls the classical Lefschetz number (4.130) and $L(\mathrm{id}) = \chi(X)$ (4.131); generalises to invariant elliptic complexes (4.132)–(4.134); introduces compact group actions, G-vector bundles (4.135), equivariant K-theory with $K_{\{e\}}(X) = K(X)$ and $K_G(\mathrm{pt}) = R(G)$; the character-valued analytic index (4.136)–(4.137); the topological index via an equivariant embedding into a representation space, diagram (4.138), (4.139); and the Atiyah–Segal theorem $L(g, E) = \chi(g)$ (4.140). He does not write the fixed point formula, saying only that it is an evaluation on X^g that simplifies when X^g is finite. We supplied: the explicit circle and sphere computations, the Lefschetz–Hopf signs, the heat-kernel derivation of the Atiyah–Bott formula, its de Rham, holomorphic and spin versions, and the Weyl character formula on $\mathbb{CP}^1$.

Recap

- $L(g) = \sum (-1)^p \,\mathrm{tr}\, g^*|_{H^p}$; $L(\mathrm{id}) = \chi(X)$; $L(g) \neq 0 \Rightarrow$ fixed point; $L = \sum_P \mathrm{sgn}\det(1 - \mathrm{d}g_P)$.
- Circle: rotation $L = 0$, reflection $L = 2$, degree k: $L = 1 - k$. Sphere: $L = 1 + \deg g$.
- For G-invariant complexes, $L(g, E)$ is a virtual character; $\mathrm{index}_G D \in R(G) = K_G(\mathrm{pt})$; G-index theorem $\mathrm{index}_a = \mathrm{index}_t$.
- Atiyah–Bott: $L(g, E) = \sum_P \frac{\sum (-1)^i \,\mathrm{tr}\, \phi_{i,P}}{|\det(1 - \mathrm{d}g_P)|}$, derived by heat-kernel localisation.
- Holomorphic version on $\mathbb{CP}^1$ gives the Weyl character formula.

4.21 Index theory for manifolds with boundary

Everything so far has lived on a *closed* manifold: compact, with no edge. Physics is full of edges. A bag model confines quarks to a ball. A Hall bar has an edge where chiral modes run. A lattice simulation lives on a box; a domain wall is an edge between two phases; a spacetime region between two time slices has the initial and final slices as its boundary. So the question of

this section is:

> *What becomes of the index theorem when X has a boundary ∂X? What boundary conditions make the index finite, and what extra term does the boundary contribute to the index formula?*

The answer, due to Atiyah, Patodi and Singer (APS), is one of the most beautiful results in the subject. It has three ingredients.

1. For the operators physicists care about (Dirac, signature, $\bar\partial$) there is *no* local boundary condition that works. We must use a *global* one: a spectral projection onto half of the spectrum of an operator L that lives on the boundary.
2. With this condition the index is the usual bulk integral *plus a correction* that depends only on the spectrum of L.
3. The correction is $-\frac{1}{2}(h + \eta(0))$, where $h = \dim\operatorname{Ker} L$ and $\eta(0)$ measures the *asymmetry* between the positive and negative eigenvalues of L: the **eta invariant**.

The eta invariant then turns out to be a physical quantity in its own right: it is the fractional fermion number of a Dirac sea, the phase of a three-dimensional fermion determinant (the parity anomaly), and, through its jumps, it counts the *spectral flow* that underlies anomalous charge non-conservation. We build up to all of this slowly.

4.21.1 Why a boundary forces us to choose boundary conditions

On a closed manifold an elliptic operator has a finite-dimensional kernel. With a boundary, this fails badly.

Worked example 4.126: $\bar\partial$ on a disc has an infinite kernel

Let $X = \{|z| \le 1\}$ and $D = \bar\partial = \frac{1}{2}(\partial_x + i\partial_y)$ acting on functions. Its kernel is the space of holomorphic functions on the disc. This contains $1, z, z^2, z^3, \dots$, which are linearly independent. So $\dim\operatorname{Ker}\bar\partial = \infty$. The same operator on the closed sphere $\mathbb{CP}^1$ has kernel the constants only (Liouville: a holomorphic function on a compact Riemann surface is constant).

What went wrong? On a closed manifold, a zero mode must be globally consistent; this is a strong constraint. On a disc, we can start with *any* boundary data compatible with the equation and extend it inwards. The kernel is as big as a space of functions on the boundary. To get back a finite index, we must *throw away* a suitable half of this boundary data: that is what a boundary condition does.

Local boundary conditions: Dirichlet and Neumann

The classical elliptic boundary problems are *local*: the condition at a boundary point x involves only the values (and finitely many derivatives) of u at x. Nash's two examples [Nash p. 127, (4.141)–(4.142)], for the Laplacian Δ on a region $\Omega \subset \mathbb{R}^n$ with inward or outward normal n:

$$\Delta u = 0, \qquad u = g \text{ on } \partial\Omega \qquad \text{(Dirichlet)}, \tag{4.198}$$

$$\Delta u = 0, \qquad \frac{\partial u}{\partial n} = g \text{ on } \partial\Omega \qquad \text{(Neumann)}. \tag{4.199}$$

In electrostatics: Dirichlet prescribes the potential on a conductor; Neumann prescribes the normal electric field (the surface charge).

An elliptic boundary problem is a *pair* of operators, one in the interior and one on the boundary. For the index we regard it as a single map

$$\mathcal{P} = (\Delta, B):\ C^\infty(\Omega) \longrightarrow C^\infty(\Omega) \oplus C^\infty(\partial\Omega), \qquad u \longmapsto \big(\Delta u,\ Bu|_{\partial\Omega}\big), \tag{4.200}$$

with $B = 1$ (Dirichlet) or $B = \partial/\partial n$ (Neumann). Its kernel is the set of solutions of the *homogeneous* problem; its cokernel is the set of constraints the data (f, g) must satisfy for a solution to exist.

Worked example 4.127: Dirichlet and Neumann on the unit disc, by Fourier series

Take Ω the unit disc, polar coordinates (r, θ), and expand the boundary data $g(\theta) = \sum_{m\in\mathbb{Z}} g_m e^{im\theta}$. The Laplacian in polar coordinates is $\Delta = \partial_r^2 + \frac{1}{r}\partial_r + \frac{1}{r^2}\partial_\theta^2$. Try $u = r^\alpha e^{im\theta}$:

$$\Delta\big(r^\alpha e^{im\theta}\big) \overset{(1)}{=} \big(\alpha(\alpha-1) + \alpha - m^2\big) r^{\alpha-2} e^{im\theta} \overset{(2)}{=} (\alpha^2 - m^2)\, r^{\alpha-2} e^{im\theta}.$$

(1) Each ∂_r lowers the power of r by one; ∂_θ^2 brings down $-m^2$.
(2) Simplify.

So $\alpha = \pm|m|$. Only $\alpha = +|m|$ is regular at the centre (and for $m = 0$ the second solution is $\log r$, also singular). Hence every harmonic function on the disc is $u = \sum_m c_m r^{|m|} e^{im\theta}$.
Dirichlet. $u|_{r=1} = g$ forces $c_m = g_m$ for all m: a unique solution for every g. Kernel 0, cokernel 0, index 0.
Neumann (outward normal ∂_r). $\partial_r u|_{r=1} = \sum_m |m| c_m e^{im\theta} = g$. For $m \neq 0$, $c_m = g_m/|m|$. For $m = 0$ the left side has no term, so we need $g_0 = 0$, i.e. $\int_0^{2\pi} g\, \mathrm{d}\theta = 0$; and c_0 is free. Kernel: the constants (dimension 1). Cokernel: the single constraint $\int g = 0$ (dimension 1). Index $1 - 1 = 0$.
The Neumann constraint is Gauss's law: $\oint \partial_n u\, \mathrm{d}s = \int_\Omega \Delta u = 0$, so with no charge inside the total flux through the boundary must vanish.

Both problems have finite kernel and cokernel, and both are *local*. Nash's point is that this is special. For the operators of index theory it is impossible.

A test for good boundary conditions: count the decaying modes

How do we know whether a boundary condition gives a finite index? There is a very physical test. Zoom in on a boundary point until the boundary looks flat and the coefficients look constant. Take the half-space $y > 0$ with boundary coordinate x, and Fourier transform along the boundary, $u = e^{i\xi x} v(y)$. The equation $Du = 0$ becomes an ODE in the normal variable y. Some of its solutions decay into the interior ($y \to +\infty$); some grow. The decaying ones are the modes that are "localised at the boundary", and those are what the boundary condition must control.

Working definition 4.59 (good (elliptic) boundary condition — decaying-mode test)

For each boundary momentum $\xi \neq 0$ let $M^+(\xi)$ be the space of solutions $v(y)$ of the frozen, flattened equation [coefficients fixed at one boundary point, boundary taken flat, $y \geq 0$ the normal coordinate] that *decay* as $y \to +\infty$. A boundary condition B imposing k conditions is good if, for every $\xi \neq 0$, B maps $M^+(\xi)$ *isomorphically* onto $\mathbb{C}^k$: it kills no decaying mode (uniqueness) and misses no data (existence). *Formally*: this is the Lopatinskii–Shapiro condition.

Worked example 4.128: The test on the Laplacian and on $\bar\partial$

Laplacian. $\Delta = \partial_x^2 + \partial_y^2$ and $u = e^{i\xi x}v(y)$ give $v'' = \xi^2 v$, so $v = e^{-|\xi|y}$ (decays) or $e^{+|\xi|y}$ (grows). Thus $\dim M^+(\xi) = 1$ for every $\xi \neq 0$, and we need exactly $k = 1$ condition. Dirichlet: $B = 1$ sends $e^{-|\xi|y} \mapsto v(0) = 1 \neq 0$. Good. Neumann: $B = \partial_y$ sends it to $-|\xi| \neq 0$. Good.

Cauchy–Riemann. $\bar\partial = \frac{1}{2}(\partial_x + i\partial_y)$ and $u = e^{i\xi x}v(y)$ give

$$0 = \bar\partial u \overset{(1)}{=} \tfrac{1}{2}\big(i\xi v + iv'\big)e^{i\xi x} \quad\Longrightarrow\quad v' \overset{(2)}{=} -\xi v \quad\Longrightarrow\quad v \overset{(3)}{=} e^{-\xi y}.$$

(1) ∂_x acts on $e^{i\xi x}$ as $i\xi$; ∂_y acts on v.
(2) Divide by $\frac{i}{2}e^{i\xi x}$.
(3) Solve the first-order ODE.

So $e^{-\xi y}$ decays for $\xi > 0$ and grows for $\xi < 0$:

$$\dim M^+(\xi) = \begin{cases} 1, & \xi > 0, \\ 0, & \xi < 0. \end{cases}$$

A local condition imposes the same number k of conditions at every ξ (it is a fixed matrix, or a polynomial in ξ, acting on boundary values). We would need $k = 1$ for $\xi > 0$ and $k = 0$ for $\xi < 0$. *No local boundary condition exists for $\bar\partial$.*

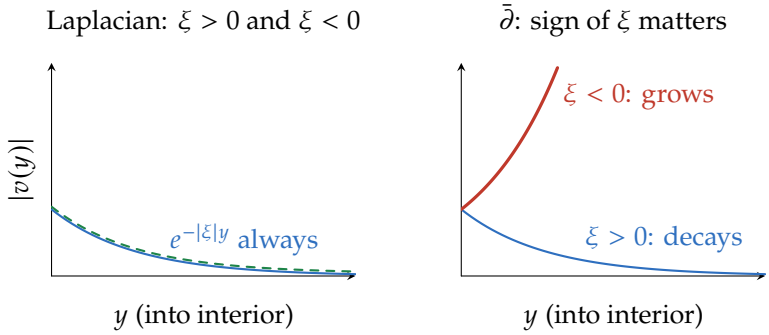

Figure 4.71: The decaying-mode test. Left: for the Laplacian, every boundary frequency ξ has exactly one mode decaying into the interior, so one local condition (Dirichlet or Neumann) is right for all ξ. Right: for $\bar\partial$ only the positive frequencies have a decaying mode. The number of conditions needed jumps from 1 to 0 as ξ changes sign, and no local condition can do that. A condition that depends on the *sign of the boundary frequency* can: this is the APS projection.

This is the simplest instance of what Nash calls the *topological obstruction* to local boundary conditions [Nash p. 127], found by Atiyah and Bott. In general the decaying modes $M^+(x,\xi)$ form a vector bundle over the set of unit boundary covectors (x,ξ) (the cosphere bundle of ∂X), and a local boundary condition exists only if this bundle is, stably, pulled back from ∂X itself, i.e. does not twist as ξ turns around. For $\bar\partial$ on a surface the cosphere bundle of a boundary circle is two circles, $\xi = +1$ and $\xi = -1$, and the bundle has rank 1 on one and rank 0 on the other: the crudest possible failure. For the signature operator d_+ and the chiral Dirac operator in any even dimension the failure is subtler (the ranks agree, but the bundle twists), and the conclusion is the same.

Watch out: The full Dirac operator does have local conditions

Bag-model physicists impose the local MIT condition $i\gamma^n\psi = \psi$ on the full Dirac operator $\not{D}$ on $S^+ \oplus S^-$. That is fine: the full $\not{D}$ is self-adjoint and has index zero. The obstruction concerns the *chiral* half $\not{D}^+ : S^+ \to S^-$, the operator whose index counts chiral zero modes. The MIT condition mixes S^+ with S^- and so does not define a boundary problem for $\not{D}^+$ alone.

Where the symbol lives: relative K-theory

On a closed manifold the symbol of an elliptic operator defines a class in $K(T^*X)$ (Chapter 4, first part). Nash notes [Nash p. 127] that with a boundary the natural home is a **relative K-group** $K(X, \partial X)$. Operationally: an element of $K(X, \partial X)$ is a pair of bundles on X *together with an isomorphism between them over* ∂X. Collapsing ∂X to a point, such a pair becomes a pair of bundles on the quotient $X/\partial X$, so $K(X, \partial X) \cong \tilde{K}(X/\partial X)$. For example $D^2/S^1 = S^2$, so $K(D^2, S^1) \cong \tilde{K}(S^2) \cong \mathbb{Z}$, generated by the monopole bundle. In the boundary problem the interior symbol gives the pair of bundles, and the boundary condition supplies the isomorphism over the boundary. For $\bar{\partial}$ there is no *local* way to supply it (the rank of M^+ jumps), which is the K-theoretic form of Example 4.128.

4.21.2 The signature operator near the boundary

Nash now takes the signature operator $d_+ : \Gamma(\Lambda^+ T^*X \otimes \mathbb{C}) \to \Gamma(\Lambda^- T^*X \otimes \mathbb{C})$ on a manifold with boundary and asks for boundary conditions under which its index is the signature [Nash p. 128]. We follow him, but first set up the geometry that every such problem shares.

A collar and the normal form $D = A(\partial_n + L)$

Near the boundary choose coordinates (n, y) with y coordinates on ∂X and $n \geq 0$ the distance from the boundary measured *inwards*. The region $0 \leq n < \varepsilon$ is a **collar** $\partial X \times [0, \varepsilon)$. Assume the metric is a **product** there:

$$\mathrm{d}s^2 = \mathrm{d}n^2 + h_{ij}(y)\,\mathrm{d}y^i \mathrm{d}y^j, \tag{4.201}$$

with h independent of n. (We relax this at the end, in Section 4.21.11.) Any first-order operator splits into a normal part and a tangential part, Nash's (4.143):

$$D = A\frac{\partial}{\partial n} + B \cdot D^T, \tag{4.202}$$

where A, B are matrices and D^T differentiates only along ∂X. Ellipticity says the symbol $\sigma(n, p) = i(Ap_n + \dots)$ is invertible for $p = (p_n, 0) \neq 0$, so A is invertible. Factor it out [Nash (4.144)]:

$$D \overset{(1)}{=} A\Big(\frac{\partial}{\partial n} + A^{-1}B \cdot D^T\Big) \overset{(2)}{=} A\Big(\frac{\partial}{\partial n} + L\Big), \qquad L := A^{-1}B \cdot D^T. \tag{4.203}$$

(1) A is invertible, so $A\,A^{-1} = 1$ can be inserted.
(2) Definition of the **boundary operator** L.

For Dirac-type operators (Dirac, signature, $\bar{\partial}$) with a product metric, A is Clifford multiplication by the unit normal, L is independent of n, and L is a *self-adjoint elliptic operator on the closed manifold* ∂X. It is essentially "the same kind of operator, one dimension down".

Worked example 4.129: The boundary operator of the 2D chiral Dirac operator

On the flat half-cylinder $\{(n,\theta) : n \geq 0,\ \theta \in S^1\}$, with complex coordinate $w = n + i\theta$, the Cauchy–Riemann operator is

$$\bar\partial_w = \tfrac{1}{2}(\partial_n + i\partial_\theta) = \tfrac{1}{2}\big(\partial_n + L\big), \qquad L = i\partial_\theta.$$

So $A = \frac{1}{2}$ and $L = i\,\mathrm{d}/\mathrm{d}\theta$. Check self-adjointness on $L^2(S^1)$: integrating by parts, $\int \bar f\,(ig')\,\mathrm{d}\theta = -i\int \bar f' g\,\mathrm{d}\theta = \int \overline{(if')}\,g\,\mathrm{d}\theta$, using that there is no boundary term on the closed circle. Its eigenfunctions are $e^{-ik\theta}$ with eigenvalues $k \in \mathbb{Z}$: $i\partial_\theta e^{-ik\theta} = k\,e^{-ik\theta}$. Up to the relabelling $k \to -k$ this is the Dirac operator $-i\,\mathrm{d}/\mathrm{d}\theta$ of the circle. The chiral Dirac operator in the Weyl basis (4.167) of the first section of this part is a multiple of $\bar\partial$ on one chirality, so it has the same boundary operator.

For the signature operator, Nash's d_+^T is the tangential part of $d + d^*$. On a $4k$-manifold, restricting a form in Ω^+ to the collar and keeping its components without $\mathrm{d}n$ identifies $\Omega^+|_{\text{collar}}$ with all forms on ∂X, and L becomes the operator $\phi \mapsto \pm(\star\mathrm{d} - \mathrm{d}\star)\phi$ on $\Omega^*(\partial X)$ (with degree-dependent signs; Atiyah–Patodi–Singer, Part I, §4). For a 3-manifold boundary its most important piece is the *curl operator* $\star\mathrm{d}$ on 1-forms: in $\mathbb{R}^3$, $\star\mathrm{d}A = \nabla \times \vec{A}$.

Separation of variables in the collar

The normal form makes the local analysis explicit. Let $L\phi_\lambda = \lambda\phi_\lambda$ be the eigen-decomposition of L on ∂X (discrete real spectrum, because L is self-adjoint elliptic on a closed manifold). Expand a solution of $Du = 0$ in the collar:

$$u = \sum_\lambda f_\lambda(n)\,\phi_\lambda(y), \qquad 0 = Du \overset{(1)}{=} A\sum_\lambda \big(f_\lambda' + \lambda f_\lambda\big)\phi_\lambda \quad\Longrightarrow\quad f_\lambda(n) \overset{(2)}{=} f_\lambda(0)\,e^{-\lambda n}.$$

(1) ∂_n acts on the coefficients; L acts on the eigenfunctions by λ.
(2) A is invertible and the ϕ_λ are independent, so each coefficient solves $f' = -\lambda f$.

A mode with $\lambda > 0$ decays into the interior; one with $\lambda < 0$ grows into the interior. This is the decaying-mode test again, now globally on ∂X: the boundary frequencies of Example 4.128 have become the eigenvalues of L.

The APS boundary condition

Split the boundary data by the sign of λ. Nash [Nash p. 128] writes

$$H_+ = \overline{\operatorname{span}}\{\phi_\lambda : \lambda \geq 0\}, \qquad H_- = \overline{\operatorname{span}}\{\phi_\lambda : \lambda < 0\}, \qquad L^2(\partial X) = H_+ \oplus H_-.$$

Working definition 4.60 (APS (spectral) boundary condition)

Let Π be the orthogonal projection [keeps the H_+ components and sets the H_- components to zero] of $L^2(\partial X)$ onto H_+, the span of the eigenvectors of L [the boundary operator in $D = A(\partial_n + L)$ near ∂X] with $\lambda \geq 0$. The **Atiyah–Patodi–Singer boundary condition** on u is

$$\Pi\big(u|_{\partial X}\big) = 0, \qquad \text{equivalently} \qquad u|_{\partial X} \in H_-, \tag{4.204}$$

Nash's (4.145)–(4.146). *To impose it*: expand the boundary value of u in eigenfunctions of L and demand that every coefficient with $\lambda \geq 0$ vanish. The condition on the adjoint problem [the equation $D^*v = 0$] is the complementary one, $(1 - \Pi)(v|_{\partial X}) = 0$.

Physical picture: Gluing on an infinite cylinder

Here is why this is the natural condition. Glue a half-infinite cylinder $(-\infty, 0] \times \partial X$ onto X along the boundary, and extend the product metric and the operator $A(\partial_n + L)$ to it (Figure 4.72). A solution in the collar continues onto the cylinder by the same formula $f_\lambda(0)e^{-\lambda n}$, now with $n \to -\infty$. It is square-integrable there if and only if every λ that appears is *negative*. So

u satisfies the APS condition $\iff$ *u extends to an L^2 solution on the elongated manifold $\hat{X} = X \cup$ cylinder,*

except for $\lambda = 0$ modes, which extend as bounded but non-L^2 constants along the cylinder ("extended L^2 solutions"; they are the origin of the h in the index formula). The APS index is thus the honest L^2 index of an operator on a complete manifold with a cylindrical end: a very physical set-up (an infinitely long tube, with no reflection at a wall).

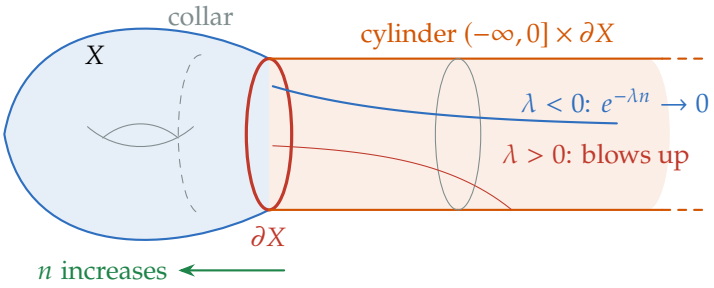

Figure 4.72: The elongated manifold $\hat{X}$. The collar of X (blue) is continued by a half-infinite cylinder (orange) on which the operator is $A(\partial_n + L)$ with $n \to -\infty$ along the tube. Boundary data in an eigenmode of L with $\lambda < 0$ continue as decaying tails; those with $\lambda > 0$ blow up. The APS condition $\Pi(u|_{\partial X}) = 0$ keeps exactly the modes that live happily on the infinite tube.

Worked example 4.130: APS on the half-cylinder: kernel and cokernel

Take the half-infinite cylinder $X = [0, \infty) \times S^1$ itself (now n runs *into* X as $n \to +\infty$) with $D = \partial_n + L$, $L = -i\partial_\theta$, eigenvalues $k \in \mathbb{Z}$ on $e^{ik\theta}$. Solutions of $Du = 0$ are $\sum_k c_k e^{-kn} e^{ik\theta}$. Square-integrability as $n \to +\infty$ needs $c_k = 0$ for $k < 0$ (these blow up) and for $k = 0$ (constant, not L^2 on an infinite tube). The APS condition independently removes $k \geq 0$. So $\operatorname{Ker} D = 0$. The adjoint $D^* = -\partial_n + L$ has solutions $\sum_k d_k e^{kn} e^{ik\theta}$; L^2 needs $k < 0$, and the complementary condition $(1 - \Pi)v| = 0$ removes $k < 0$. So $\operatorname{Coker} D = 0$ and the index is 0. The bulk contributes nothing here (flat metric, trivial bundle), so all the interest of the index formula must come from the spectrum of L, and here $\{k\}$ is symmetric about 0. We will see in Section 4.21.6 that a flat twist makes it asymmetric.

The projection Π is a pseudo-differential operator

Nash shows that Π is not exotic: it is a *zeroth-order pseudo-differential operator* [Nash p. 128–129, (4.147)]. The recipe:

1. Make L invertible: $M := L + N$ where N is the orthogonal projection onto $\operatorname{Ker} L$. On ϕ_λ with $\lambda \neq 0$, M acts as λ; on $\operatorname{Ker} L$ it acts as 1.
2. Take the positive square root $|M| = \sqrt{M^2}$ (Seeley's complex powers of an elliptic operator, Chapter 2).

3. Set
$$\Pi = \tfrac{1}{2}M^{-1}\big(M + |M|\big). \tag{4.205}$$

Check it on the eigenvectors:
$$\Pi\phi_\lambda \overset{(1)}{=} \frac{\lambda + |\lambda|}{2\lambda}\phi_\lambda \overset{(2)}{=} \begin{cases}\phi_\lambda, & \lambda > 0,\\ 0, & \lambda < 0,\end{cases} \qquad \Pi\phi_0 \overset{(3)}{=} \frac{1+1}{2}\phi_0 = \phi_0.$$

(1) For $\lambda \neq 0$, M, $|M|$ and M^{-1} act on ϕ_λ as λ, $|\lambda|$ and $1/\lambda$.
(2) $\lambda + |\lambda|$ is 2λ or 0.
(3) On $\operatorname{Ker} L$, $M = |M| = 1$.

So Π is exactly the projection onto H_+ (including $\operatorname{Ker} L$). The operators M and $|M|$ are first order, M^{-1} is of order -1, so Π has order 0. Its leading symbol is
$$\sigma_0(\Pi)(y,\xi) = \tfrac{1}{2}\Big(1 + \frac{\sigma(L)(y,\xi)}{|\sigma(L)(y,\xi)|}\Big),$$
the projection onto the positive eigenspace of the *symbol* of L at (y,ξ). This is homogeneous of degree zero in ξ but not polynomial: it is not the symbol of any differential operator.

Worked example 4.131: Π on the circle is the Hardy projection, and is non-local

Take $L = -i\,\mathrm{d}/\mathrm{d}\theta$ on S^1, $Le^{ik\theta} = ke^{ik\theta}$. Then Π keeps $k \geq 0$: $\Pi f = \sum_{k\geq 0}\hat f_k e^{ik\theta}$ with $\hat f_k = \frac{1}{2\pi}\int f(\phi)e^{-ik\phi}\mathrm{d}\phi$. Write it as an integral kernel:
$$\begin{aligned}(\Pi f)(\theta) &\overset{(1)}{=} \frac{1}{2\pi}\int_0^{2\pi}\Big(\sum_{k\geq 0} e^{ik(\theta-\phi)}\Big)f(\phi)\,\mathrm{d}\phi\\ &\overset{(2)}{=} \frac{1}{2\pi}\int_0^{2\pi}\Big(\pi\delta(\theta-\phi) + \tfrac{1}{2} + \tfrac{i}{2}\cot\tfrac{\theta-\phi}{2}\Big)f(\phi)\,\mathrm{d}\phi\\ &\overset{(3)}{=} \tfrac{1}{2}f(\theta) + \tfrac{1}{2}\hat f_0 + \frac{i}{4\pi}\,\mathrm{p.v.}\int_0^{2\pi}\cot\tfrac{\theta-\phi}{2}\,f(\phi)\,\mathrm{d}\phi.\end{aligned}$$

(1) Insert the Fourier coefficients and exchange sum and integral.
(2) Split $\sum_{k\geq 0} = \frac{1}{2}\big(\sum_{k\in\mathbb{Z}}+1\big) + \frac{1}{2}\sum_{k\neq 0}\operatorname{sgn}(k)e^{ikx}$, and use $\sum_{k\in\mathbb{Z}} e^{ikx} = 2\pi\delta(x)$ and $\sum_{k\neq 0}\operatorname{sgn}(k)e^{ikx} = 2i\sum_{k>0}\sin kx = i\cot\frac{x}{2}$ (Abel summation: $\operatorname{Im}\frac{e^{ix}}{1-e^{ix}} = \frac{1}{2}\cot\frac{x}{2}$).
(3) Do the δ and constant integrals; the cot is integrated as a principal value.

The last term is the **Hilbert transform** (the conjugate-function operator of Fourier analysis, the Kramers–Kronig transform of optics). Its kernel $\cot\frac{\theta-\phi}{2} \approx \frac{2}{\theta-\phi}$ has a long tail: $(\Pi f)(\theta)$ depends on f at *every* point of the circle. The APS condition $\Pi(u|_{S^1}) = 0$ is therefore genuinely non-local; it says "the boundary value of u has only negative frequencies", a statement about the whole function, not about its values point by point. Its symbol is $\sigma_0(\Pi)(\theta,\xi) = \frac{1}{2}(1+\operatorname{sgn}\xi)$: 1 for $\xi > 0$, 0 for $\xi < 0$. Compare Figure 4.71: that is exactly the rank-jumping behaviour a local condition could not provide.

Watch out: Why a non-local condition does not spoil the index

One might worry that a non-local condition breaks the analysis. It does not: Π is a pseudo-differential operator of order zero, and the Fredholm theory of elliptic boundary problems works just as well with pseudo-differential boundary conditions. What matters

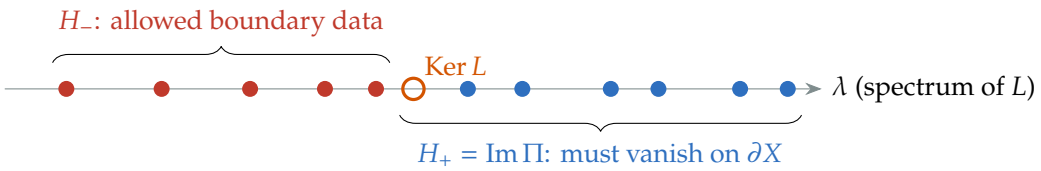

Figure 4.73: The APS condition splits the spectrum of the boundary operator L at zero. The zero modes are put with H_+ (Nash's convention and APS's). Boundary data may contain only the red (negative) modes. The index correction will measure how *unevenly* the dots are spread on the two sides: the eta invariant.

for the index is only the *homotopy class* of the symbol data. If we could deform $\sigma_0(\Pi)(y,\xi)$ through projections into one independent of ξ (the symbol of a multiplication operator, which is local), we would get an equivalent local problem. For d_+ no such homotopy exists, precisely because of the Atiyah–Bott obstruction [Nash p. 129].

4.21.3 A warm-up where the boundary term is local: Gauss–Bonnet

Before computing any index with a boundary, Nash looks at a case where the answer is already known [Nash p. 129, (4.148)]: the Euler characteristic of a surface with boundary. For a compact oriented surface X with Gaussian curvature K (Nash writes R) and boundary geodesic curvature k_g (Nash's R_g),

$$\frac{1}{2\pi}\int_X K\,\mathrm{d}A + \frac{1}{2\pi}\oint_{\partial X} k_g\,\mathrm{d}s = \chi(X). \tag{4.206}$$

The geodesic curvature k_g of a boundary curve is how much it bends *within* the surface (its acceleration projected onto the surface, positive when it bends towards the interior). A geodesic has $k_g = 0$.

Worked example 4.132: Checking (4.206) on discs and caps

Flat disc of radius a. $K = 0$; the boundary circle bends towards the centre with curvature $1/a$, and has length $2\pi a$:

$$0 + \frac{1}{2\pi}\cdot\frac{1}{a}\cdot 2\pi a = 1 = \chi(D^2).$$

Spherical cap. On a sphere of radius a take the cap $0 \le \vartheta \le \vartheta_0$ (polar angle). Then $K = 1/a^2$ and $\mathrm{d}A = a^2\sin\vartheta\,\mathrm{d}\vartheta\,\mathrm{d}\varphi$. The boundary is the latitude circle, of radius $a\sin\vartheta_0$ in space; its curvature vector $1/(a\sin\vartheta_0)$ points to the axis, and its component tangent to the sphere is $\cos\vartheta_0/(a\sin\vartheta_0)$. So:

$$\frac{1}{2\pi}\int_X K\,\mathrm{d}A + \frac{1}{2\pi}\oint k_g\,\mathrm{d}s \overset{(1)}{=} \frac{1}{2\pi}\int_0^{2\pi}\int_0^{\vartheta_0}\sin\vartheta\,\mathrm{d}\vartheta\,\mathrm{d}\varphi + \frac{1}{2\pi}\cdot\frac{\cot\vartheta_0}{a}\cdot 2\pi a\sin\vartheta_0$$
$$\overset{(2)}{=} (1-\cos\vartheta_0) + \cos\vartheta_0 \overset{(3)}{=} 1.$$

(1) $K\,\mathrm{d}A = \sin\vartheta\,\mathrm{d}\vartheta\,\mathrm{d}\varphi$; $k_g = \cot\vartheta_0/a$; the latitude has length $2\pi a\sin\vartheta_0$.
(2) Do the integrals.
(3) The two pieces trade off as ϑ_0 varies; only the sum is topological.

As $\vartheta_0 \to 0$ we recover the flat disc (everything in the boundary term); at $\vartheta_0 = \pi/2$ (hemisphere) the boundary is a geodesic and everything is in the bulk.

Flat annulus $r_1 \le r \le r_2$. $K = 0$. The outer circle bends towards the interior ($k_g = +1/r_2$); the inner circle bends away from it ($k_g = -1/r_1$). Total $\frac{1}{2\pi}(2\pi r_2/r_2 - 2\pi r_1/r_1) = 0 = \chi(\text{annulus})$.

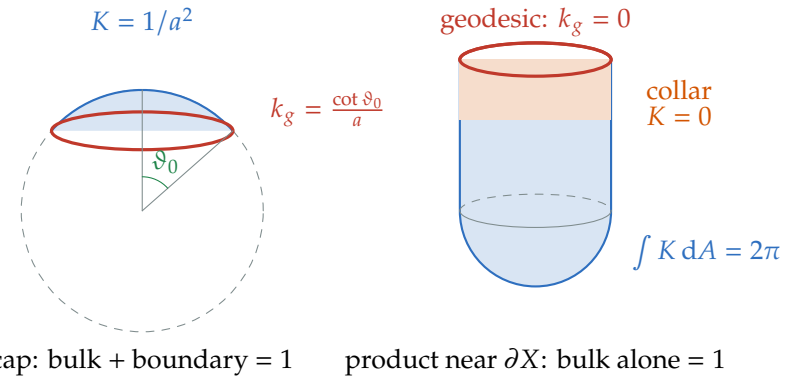

Figure 4.74: Gauss–Bonnet with boundary. Left: on a spherical cap the Euler number 1 is shared between the bulk curvature and the bending of the rim. Right: a "test tube" has a cylindrical collar, i.e. a product metric near the boundary; the rim is a geodesic, and the bulk integral alone gives $\chi = 1$. This is Nash's (4.149): for Euler characteristic, a product metric makes the boundary term disappear.

Why is the boundary term there, and why does it vanish for a product? In two dimensions $K\,\mathrm{d}A = \mathrm{d}\omega$ locally, where ω is the Levi-Civita connection 1-form of an orthonormal frame (Chapter T2). Stokes turns the bulk integral into $\oint \omega$ on the boundary, and $\oint \omega$ measures how the frame rotates relative to parallel transport along the rim, i.e. $2\pi\chi$ minus the turning of the rim's own tangent, which is $\oint k_g\,\mathrm{d}s$. For a product collar $\mathrm{d}n^2 + h$ the rim $n = 0$ is a geodesic ($k_g = 0$), so [Nash (4.149)]

$$\frac{1}{2\pi}\int_X K\,\mathrm{d}A = \chi(X) \qquad \text{if } X \text{ is a product near } \partial X. \tag{4.207}$$

In index language: the Euler characteristic is the index of the de Rham complex; with a product metric the bulk formula holds unchanged, with *no* boundary correction. We will see why in Section 4.21.8.

4.21.4 The signature with boundary: where the eta invariant comes from

The signature of a manifold with boundary

For a closed oriented 4-manifold the signature is that of the intersection form $Q(a,b) = \int_X a \wedge b$ on $H^2(X)$: diagonalise it and count (#positive) − (#negative) (Chapter 4, the signature theorem). With a boundary, use closed 2-forms that vanish near ∂X (compactly supported, relative classes $H^2(X, \partial X)$). The form Q may now be degenerate; $\mathrm{Sign}(X)$ is the signature of its non-degenerate part.

Worked example 4.133: Signatures of some manifolds with boundary

- The ball B^4: $H^2(B^4, S^3) = 0$, so Sign = 0.
- $\mathbb{CP}^2$ minus a small ball: take a projective line $\mathbb{CP}^1 \subset \mathbb{CP}^2$ missing the ball. Its Poincaré dual is a closed 2-form supported in a tube around the line, so it vanishes near the boundary. Two lines meet in one point, positively, so $Q = (+1)$ and Sign = 1, as for $\mathbb{CP}^2$ itself.
- The disc bundle of the line bundle of degree e over S^2: the zero section has self-intersection e, so $Q = (e)$ and $\mathrm{Sign} = \mathrm{sgn}\, e$. Its boundary is S^3 for $e = \pm 1$ (the Hopf fibration), $S^2 \times S^1$ for $e = 0$, and the lens space $L(|e|, 1)$ otherwise.

The bulk formula fails, by a boundary number

For a closed 4-manifold $\tilde{X}$, Hirzebruch's theorem is [Nash p. 129, (4.150)]

$$\operatorname{Sign}(\tilde{X}) = \frac{1}{3}\int_{\tilde{X}} p_1(\tilde{X}), \qquad p_1 = -\frac{1}{8\pi^2}\operatorname{tr}(R\wedge R). \tag{4.208}$$

Nash states that if X has a boundary, even with a product metric near it, (4.208) fails, and the failure defines a real number attached to the boundary [Nash p. 130, (4.151)]:

$$\operatorname{Sign}(X) - \frac{1}{3}\int_X p_1(X) = -\frac{1}{2}\,\eta(\partial X). \tag{4.209}$$

The factor $-\frac{1}{2}$ is a normalisation chosen for later convenience.

The defect depends only on the boundary

Nash's key observation [Nash (4.152)] is that the left side of (4.209) depends only on ∂X (with its metric), not on how X fills it in. The argument is a gluing, and it is worth doing carefully.

Let X and Y be two oriented 4-manifolds with the same boundary $\partial X = \partial Y = W$, with the same metric on W and product metrics on both collars. Reverse the orientation of Y (write $-Y$) and glue it to X along W to form a closed manifold $Z = X \cup_W (-Y)$ (Figure 4.75). The product collars fit together smoothly into a collar $W \times (-\varepsilon, \varepsilon)$, so Z has a smooth metric that agrees with the old ones on each piece. Then

$$\begin{aligned} 0 &\overset{(1)}{=} \operatorname{Sign}(Z) - \frac{1}{3}\int_Z p_1 \\ &\overset{(2)}{=} \Big(\operatorname{Sign}(X) + \operatorname{Sign}(-Y)\Big) - \frac{1}{3}\Big(\int_X p_1 + \int_{-Y} p_1\Big) \\ &\overset{(3)}{=} \Big(\operatorname{Sign}(X) - \frac{1}{3}\int_X p_1\Big) - \Big(\operatorname{Sign}(Y) - \frac{1}{3}\int_Y p_1\Big). \end{aligned}$$

(1) Hirzebruch's theorem (4.208) on the closed manifold Z.
(2) The signature is additive under gluing along a common boundary (Novikov additivity), and an integral over Z is the sum of the integrals over the pieces.
(3) Reversing orientation flips the sign of the intersection form, so $\operatorname{Sign}(-Y) = -\operatorname{Sign}(Y)$, and flips the sign of every integral of a top form.

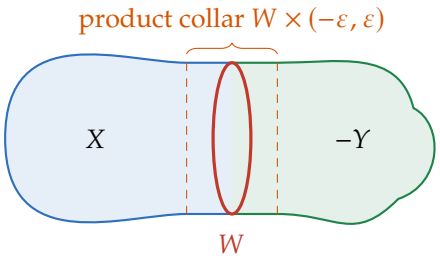
Hence

$$\operatorname{Sign}(X) - \frac{1}{3}\int_X p_1 = \operatorname{Sign}(Y) - \frac{1}{3}\int_Y p_1 \qquad \text{whenever } \partial X = \partial Y, \tag{4.210}$$

which is Nash's (4.152). The defect is a function of W alone: $\eta(W)$ is well defined.

Two consequences follow at once.

- *Orientation reversal.* Replacing X by $-X$ flips both Sign and $\int p_1$, so $\eta(-W) = -\eta(W)$.
- *Symmetric boundaries.* If W has an orientation-reversing isometry (for example the round S^3, via a reflection), then $(W, h) \cong (-W, h)$ and $\eta(W) = -\eta(W) = 0$.



$Z = X \cup_W (-Y)$ closed: $\operatorname{Sign} Z = \frac{1}{3}\int_Z p_1$

Figure 4.75: Why the signature defect depends only on the boundary. Glue X to the orientation reversal of any other filling Y of the same W. Product collars make the glued metric smooth. On the closed Z the defect is zero, and the defects of X and Y enter with opposite signs, so they are equal. The defect is therefore a property of (W, h): the eta invariant.

Worked example 4.134: A consistency check with $\mathbb{CP}^2$

Write $\mathbb{CP}^2 = X \cup_{S^3} B$ with $X = \mathbb{CP}^2 \setminus B$ and B a small ball. Choose a metric that is a product near a round S^3 (deform the Fubini–Study metric in a thin shell). The round S^3 has $\eta = 0$ (it has an orientation-reversing isometry). Then (4.209) applied to each piece, with $\operatorname{Sign}(X) = 1$ and $\operatorname{Sign}(B) = 0$ from Example 4.133, gives $\frac{1}{3}\int_X p_1 = 1$ and $\frac{1}{3}\int_B p_1 = 0$. They add to $\frac{1}{3}\int_{\mathbb{CP}^2} p_1 = 1 = \operatorname{Sign}\mathbb{CP}^2$, as they must. All of the Pontryagin number sits in the piece that carries the topology.

What the number is: the spectral asymmetry of L

Nash stresses [Nash p. 130] that $\eta(\partial X)$ is *not* a local geometric quantity: no integral of curvature over ∂X produces it. Instead it is built out of the spectrum of the boundary operator L of (4.203). Let $\{\lambda_n\}$ be the eigenvalues of L and define, for $\operatorname{Re} s$ large, [Nash (4.153)]

$$\eta_L(s) = \sum_{\lambda_n \neq 0} \frac{\operatorname{sgn}(\lambda_n)}{|\lambda_n|^s}. \tag{4.211}$$

Working definition 4.61 (eta invariant)

For a self-adjoint elliptic operator L on a closed manifold [compact and without boundary, here ∂X], the **eta function** $\eta_L(s)$ is (4.211). It converges for $\operatorname{Re} s > \dim(\partial X)$, continues to a meromorphic function [analytic except at isolated poles] of s, and is finite at $s = 0$. The **eta invariant** is $\eta_L(0)$. *To compute it*: list the eigenvalues, sum their signs with a regulator $|\lambda|^{-s}$, continue to $s = 0$. Informally,

$$\eta_L(0) = \text{“}\#\{\lambda > 0\} - \#\{\lambda < 0\}\text{”},$$

the regularised excess of positive over negative eigenvalues: the **spectral asymmetry**.

If the spectrum is symmetric (λ and $-\lambda$ with equal multiplicities), every term cancels and $\eta(s) \equiv 0$. So η is a direct measure of the failure of $\lambda \to -\lambda$ symmetry.

The connection with (4.209) is [Nash (4.154)–(4.155)]

$$\eta(\partial X) = \eta_L(0), \qquad \operatorname{Sign}(X) = \frac{1}{3}\int_X p_1(X) - \frac{1}{2}\,\eta_L(0). \tag{4.212}$$

Why the spectrum of L should appear. Near the boundary, everything about d_+ is encoded in L (Section 4.21.2). Under $\lambda \to -\lambda$ the roles of H_+ and H_- in the boundary condition swap, which is what reversing the orientation does. A boundary quantity that is odd under orientation reversal, additive over disjoint boundaries, and built from the spectrum of L has to be an odd function of the spectrum; η is the simplest. The actual proof (heat kernels on the elongated manifold) we sketch in Section 4.21.9.

Watch out: Normalisations of η, and the harmonic forms h

Nash's L is the boundary operator of d_+ acting on *all* forms of ∂X. APS work instead with its restriction B^{ev} to even forms; the spectrum of L is two copies of that of B^{ev}, so $\eta_L = 2\eta_{B^{\mathrm{ev}}}$, and (4.212) reads, in APS's form, $\mathrm{Sign}(X) = \int_X L(p) - \eta_{B^{\mathrm{ev}}}(0)$. Also, Nash's remark [Nash p. 131] that "Sign(X) is the index of d_+ subject to the global boundary conditions" needs a correction: L always has a kernel (the harmonic forms on ∂X, including the constants), and APS find $\mathrm{index}_{\mathrm{APS}}\, d_+ = \mathrm{Sign}(X) - h$, with h the dimension of the space of harmonic forms of even degree on ∂X. The index formula of Section 4.21.7 accounts for h explicitly.

Reading Nash (pp. 127–131, (4.141)–(4.155))

Nash introduces boundary problems through the local Dirichlet and Neumann problems (4.141)–(4.142), mentions the Atiyah–Bott obstruction and $K(X, \partial X)$, writes the signature operator near the boundary as $A(\partial/\partial n + L)$ (4.143)–(4.144), imposes $u|_{\partial X} \in H_-$ (4.145)–(4.146), and exhibits $\Pi = \frac{1}{2}M^{-1}(M + |M|)$ (4.147). He then recalls Gauss–Bonnet with boundary (4.148)–(4.149), and uses the failure of Hirzebruch's formula (4.150) on a manifold with boundary to define $\eta(\partial X)$ (4.151), shows it depends only on ∂X (4.152), and identifies it with $\eta_L(0)$ (4.153)–(4.155). We added the Fourier solution of the Dirichlet and Neumann problems, the decaying-mode test explaining *why* $\bar\partial$ has no local condition, the elongated manifold picture, the Hardy-projection form of Π on the circle, the cap and annulus checks of Gauss–Bonnet, the gluing computation behind (4.152), and the normalisation caveats.

Recap

- With a boundary, an elliptic operator has an infinite kernel until we impose boundary conditions. Dirichlet and Neumann are local and fine for Δ.
- Decaying-mode test: for $\bar\partial$ (and chiral Dirac, and d_+) the number of boundary-localised modes depends on the sign of the boundary frequency, so no local condition works.
- Near a product boundary $D = A(\partial_n + L)$ with L self-adjoint elliptic on ∂X. APS condition: boundary data in H_- (negative spectrum of L); equivalently, L^2 extension to an attached infinite cylinder.
- $\Pi = \frac{1}{2}M^{-1}(M+|M|)$ is a zeroth-order pseudo-differential, non-local projection (Hardy projection on S^1).
- Gauss–Bonnet with boundary needs $\oint k_g$; for a product collar it vanishes. The signature needs a genuinely spectral correction: $\mathrm{Sign}\, X = \frac{1}{3}\int p_1 - \frac{1}{2}\eta_L(0)$, and the defect depends only on ∂X (gluing).

4.21.5 Giving a divergent sum a value: zeta functions

The eta function $\eta_L(s) = \sum \operatorname{sgn}(\lambda_n)|\lambda_n|^{-s}$ of (4.211) is a convergent series only when $\operatorname{Re} s$ is large. The number we want is its value at $s = 0$, where the series is the meaningless "$\sum \pm 1$". So we must say precisely how a function defined by a series far to the right in the complex s-plane is continued to $s = 0$. Nash does this by reducing η to zeta functions [Nash p. 131, (4.156)–(4.158)]. The zeta function trick is also the standard way physicists regularise determinants and Casimir energies, so it is worth learning properly.

The zeta function of a positive operator

Working definition 4.62 (zeta function of an operator, Nash (4.156))

Let P be a positive [all eigenvalues ≥ 0] self-adjoint elliptic operator of order $m > 0$ [m derivatives, so that μ_k grows like $k^{m/n}$] on a closed manifold of dimension n, with eigenvalues $0 < \mu_1 \leq \mu_2 \leq \cdots$ (zero eigenvalues, if any, are left out). Its **zeta function** is

$$\zeta_P(s) = \sum_k \frac{1}{\mu_k^s} = \operatorname{Tr} P^{-s}, \tag{4.213}$$

which converges for $\operatorname{Re} s > n/m$. *To compute it*: list the eigenvalues, raise each to the power $-s$, sum where the sum converges, and then continue analytically. Seeley's theorem: ζ_P continues to a meromorphic function [analytic except at isolated poles] on all of $\mathbb{C}$ with only simple poles [near each pole s_0 it behaves like $c/(s - s_0)$], and it is *regular at* $s = 0$.

The convergence bound comes from Weyl's law: the number of eigenvalues below Λ grows like $\Lambda^{n/m}$, so $\mu_k \sim k^{m/n}$ and $\sum \mu_k^{-s} \sim \sum k^{-sm/n}$ converges exactly when $sm/n > 1$.

Worked example 4.135: The Laplacian on the circle gives the Riemann zeta function

Take $P = -\mathrm{d}^2/\mathrm{d}\theta^2$ on S^1. Its eigenfunctions are $e^{ik\theta}$, $k \in \mathbb{Z}$, with eigenvalue k^2. Leaving out $k = 0$,

$$\zeta_P(s) \overset{(1)}{=} \sum_{k \neq 0} \frac{1}{(k^2)^s} \overset{(2)}{=} 2 \sum_{k=1}^{\infty} \frac{1}{k^{2s}} \overset{(3)}{=} 2\,\zeta_R(2s).$$

(1) Definition (4.213) with $\mu = k^2$.
(2) k and $-k$ give the same eigenvalue.
(3) $\zeta_R(s) = \sum_{k \geq 1} k^{-s}$ is the Riemann zeta function.

Here $n = 1$, $m = 2$, so convergence needs $\operatorname{Re} s > \frac{1}{2}$, as it should for $\sum k^{-2s}$. The continued value is $\zeta_P(0) = 2\zeta_R(0) = 2 \cdot (-\frac{1}{2}) = -1$. We will derive $\zeta_R(0) = -\frac{1}{2}$ below from the heat kernel, without quoting it.

How the continuation works: the Mellin transform and the heat trace

The engine behind every zeta-function continuation is one line of calculus, the **Mellin transform** of an exponential. For $\mu > 0$ and $\operatorname{Re} s > 0$,

$$\int_0^\infty t^{s-1} e^{-t\mu}\,\mathrm{d}t \overset{(1)}{=} \int_0^\infty \left(\frac{x}{\mu}\right)^{s-1} e^{-x}\,\frac{\mathrm{d}x}{\mu} \overset{(2)}{=} \mu^{-s}\,\Gamma(s). \tag{4.214}$$

(1) Substitute $x = t\mu$, so $t = x/\mu$ and $\mathrm{d}t = \mathrm{d}x/\mu$.

(2) Pull out μ^{-s}; what is left is Euler's integral $\Gamma(s)=\int_0^\infty x^{s-1}e^{-x}\mathrm{d}x$.

Sum (4.214) over the eigenvalues of P:

$$\zeta_P(s)=\frac{1}{\Gamma(s)}\int_0^\infty t^{s-1}\,\operatorname{Tr}'\!\left(e^{-tP}\right)\mathrm{d}t, \qquad \operatorname{Tr}' e^{-tP}:=\sum_{\mu_k>0} e^{-t\mu_k}=\operatorname{Tr}e^{-tP}-\dim\operatorname{Ker}P. \tag{4.215}$$

The heat trace $\operatorname{Tr}e^{-tP}$ is the object we met in the heat-kernel proof of the index theorem (Chapter 4, McKean–Singer). Its two limits are what we need:

- *Large t*: $\operatorname{Tr}' e^{-tP}\le Ce^{-t\mu_1}$ decays exponentially, so $\int_1^\infty$ is an entire function of s.
- *Small t*: there is an asymptotic expansion in powers of t whose coefficients are integrals of local curvature invariants,

$$\operatorname{Tr}e^{-tP}\sim\sum_{j\ge 0}a_j\,t^{(j-n)/m}\qquad(t\to 0). \tag{4.216}$$

Now split $\int_0^\infty=\int_0^1+\int_1^\infty$ and put the expansion into the first piece:

$$\begin{aligned}\Gamma(s)\zeta_P(s)&\overset{(1)}{=}\int_0^1 t^{s-1}\Big(\sum_{j\le J}a_j t^{(j-n)/m}-\dim\operatorname{Ker}P\Big)\mathrm{d}t+\big(\text{holomorphic for }\operatorname{Re}s>\tfrac{n-J-1}{m}\big)\\&\overset{(2)}{=}\sum_{j\le J}\frac{a_j}{s+(j-n)/m}-\frac{\dim\operatorname{Ker}P}{s}+\big(\text{holomorphic}\big).\end{aligned}$$

(1) Insert (4.216) truncated at order J; the remainder is $O(t^{(J+1-n)/m})$ and its integral converges further to the left, as does $\int_1^\infty$.

(2) $\int_0^1 t^{s-1+c}\mathrm{d}t=1/(s+c)$.

So $\Gamma(s)\zeta_P(s)$ is meromorphic with simple poles at $s=(n-j)/m$. Near $s=0$ we have $\Gamma(s)=\frac{1}{s}-\gamma+O(s)$, so $1/\Gamma(s)=s+O(s^2)$ has a *zero* at $s=0$ that cancels the pole there. Therefore

$$\zeta_P(0)=a_n-\dim\operatorname{Ker}P, \tag{4.217}$$

where a_n is the coefficient of t^0 in the heat expansion. This is the reason $\zeta_P(0)$ is always finite, as Nash asserts: the would-be pole is killed by $1/\Gamma$. Informally, $\zeta_P(0)$ is "the regularised number of nonzero eigenvalues".

Worked example 4.136: $\zeta_R(0)=-\frac{1}{2}$ from the heat kernel on the circle

For $P=-\mathrm{d}^2/\mathrm{d}\theta^2$ on S^1 the heat trace is the Jacobi theta function, and Poisson summation (Section 4.21.12 does this in detail) gives

$$\operatorname{Tr}e^{-tP}=\sum_{k\in\mathbb{Z}}e^{-tk^2}=\sqrt{\frac{\pi}{t}}\sum_{m\in\mathbb{Z}}e^{-\pi^2m^2/t}=\sqrt{\frac{\pi}{t}}+O\big(t^{-1/2}e^{-\pi^2/t}\big).$$

So in (4.216) (with $n=1$, $m=2$) only $a_0=\sqrt{\pi}$ is nonzero; in particular the t^0 coefficient is $a_1=0$. The kernel is the constants, $\dim\operatorname{Ker}P=1$. Hence (4.217) gives $\zeta_P(0)=0-1=-1$, and comparing with Example 4.135, $2\zeta_R(0)=-1$, i.e. $\zeta_R(0)=-\frac{1}{2}$. The "regularised number of all eigenvalues" is $a_1=0$, and removing the one zero mode leaves -1.

Dictionary: zeta regularisation in physics

$\zeta_P(0)$	regularised number of modes (a heat coefficient)
$-\zeta_P'(0) = \ln\det P$	one-loop effective action of a Gaussian field, $\int \mathcal{D}\phi\, e^{-\frac{1}{2}\langle\phi, P\phi\rangle} \propto (\det P)^{-1/2}$
$\frac{1}{2}\zeta_H(-1)$ for H with spectrum ω_k	Casimir (zero-point) energy $\frac{1}{2}\sum\omega_k$; e.g. $\sum_{k\geq 1} k = \zeta_R(-1) = -\frac{1}{12}$ gives the $-\frac{1}{24}$ of string theory (Chapter 9)

Eta from two zeta functions: Nash's trick

The zeta function needs a *positive* operator; L has eigenvalues of both signs. Nash (following APS) builds two positive operators out of L [Nash (4.157)]. Assume for now that L is invertible, and let $|L| = \sqrt{L^2}$:

$$L_+ = \tfrac{3}{2}|L| + \tfrac{1}{2}L, \qquad L_- = \tfrac{3}{2}|L| - \tfrac{1}{2}L. \tag{4.218}$$

Write the positive eigenvalues of L as $\lambda_k^+ > 0$ and the negative ones as $\lambda_k^- < 0$. On an eigenvector with eigenvalue λ, $L_\pm$ acts by $\frac{3}{2}|\lambda| \pm \frac{1}{2}\lambda$:

	$\lambda = \lambda^+ > 0$	$\lambda = \lambda^- < 0$
L_+	$\frac{3}{2}\lambda^+ + \frac{1}{2}\lambda^+ = 2\lambda^+$	$-\frac{3}{2}\lambda^- + \frac{1}{2}\lambda^- = -\lambda^-$
L_-	$\frac{3}{2}\lambda^+ - \frac{1}{2}\lambda^+ = \lambda^+$	$-\frac{3}{2}\lambda^- - \frac{1}{2}\lambda^- = -2\lambda^-$

All four entries are positive, so $\zeta_{L_\pm}$ exist. Now subtract [Nash (4.158)]:

$$\begin{aligned}
\zeta_{L_+}(s) - \zeta_{L_-}(s) &\overset{(1)}{=} \Big\{\sum_{\lambda^+}\frac{1}{(2\lambda^+)^s} + \sum_{\lambda^-}\frac{1}{(-\lambda^-)^s}\Big\} - \Big\{\sum_{\lambda^+}\frac{1}{(\lambda^+)^s} + \sum_{\lambda^-}\frac{1}{(-2\lambda^-)^s}\Big\} \\
&\overset{(2)}{=} (2^{-s}-1)\sum_{\lambda^+}\frac{1}{(\lambda^+)^s} - (2^{-s}-1)\sum_{\lambda^-}\frac{1}{|\lambda^-|^s} \\
&\overset{(3)}{=} (2^{-s}-1)\,\eta_L(s), \\
\Longrightarrow \quad \eta_L(s) &= \frac{\zeta_{L_+}(s) - \zeta_{L_-}(s)}{2^{-s}-1}.
\end{aligned} \tag{4.219}$$

(1) Read the eigenvalues of $L_\pm$ off the table.
(2) Collect the λ^+ sums, $(2\lambda^+)^{-s} - (\lambda^+)^{-s} = (2^{-s}-1)(\lambda^+)^{-s}$, and the λ^- sums, $|\lambda^-|^{-s} - (2|\lambda^-|)^{-s} = -(2^{-s}-1)|\lambda^-|^{-s}$.
(3) The bracket is $\sum \operatorname{sgn}(\lambda)|\lambda|^{-s}$, the definition (4.211).

The right side of (4.219) is a ratio of meromorphic functions, so η_L is meromorphic on $\mathbb{C}$. That is all Nash uses the formula for.

Watch out: The formula does not by itself show that $\eta(0)$ is finite

The denominator $2^{-s} - 1 = -s\ln 2 + O(s^2)$ *vanishes* at $s = 0$ (and at $s = 2\pi i k/\ln 2$). So (4.219) is finite at $s = 0$ only if $\zeta_{L_+}(0) = \zeta_{L_-}(0)$, and then $\eta_L(0) = -\frac{1}{\ln 2}\frac{\mathrm{d}}{\mathrm{d}s}\big(\zeta_{L_+} - \zeta_{L_-}\big)\big|_{s=0}$. The regularity of η at 0 is a separate, deep fact (Section 4.21.12). The zeros of $2^{-s} - 1$ on the imaginary axis away from 0 produce no poles: the heat-kernel form (4.221) below shows that all poles of η lie on the real axis, so the numerator must vanish there too.

Eta as a trace, and its heat-kernel form

Nash remarks [Nash p. 132] that $\eta(s)$ is also a trace. On an eigenvector, $\lambda\,|\lambda|^{-s-1} = \operatorname{sgn}(\lambda)|\lambda| \cdot |\lambda|^{-s-1} = \operatorname{sgn}(\lambda)|\lambda|^{-s}$, so

$$\eta_L(s) = \operatorname{Tr}\big(L\,|L|^{-s-1}\big). \tag{4.220}$$

Applying the Mellin transform (4.214) with $\mu = \lambda^2$ and exponent $\frac{s+1}{2}$ turns this into a heat-kernel integral:

$$\begin{aligned}\eta_L(s) &\overset{(1)}{=} \sum_\lambda \lambda\,(\lambda^2)^{-\frac{s+1}{2}} \overset{(2)}{=} \sum_\lambda \frac{\lambda}{\Gamma(\frac{s+1}{2})}\int_0^\infty t^{\frac{s+1}{2}-1} e^{-t\lambda^2}\,\mathrm{d}t \\ &\overset{(3)}{=} \frac{1}{\Gamma(\frac{s+1}{2})}\int_0^\infty t^{\frac{s-1}{2}}\,\operatorname{Tr}\big(L\,e^{-tL^2}\big)\,\mathrm{d}t.\end{aligned} \tag{4.221}$$

(1) (4.220) with $|\lambda|^{-s-1} = (\lambda^2)^{-(s+1)/2}$.

(2) (4.214) with $\mu = \lambda^2$ and $s \to \frac{s+1}{2}$.

(3) Exchange sum and integral; $\sum \lambda e^{-t\lambda^2} = \operatorname{Tr}(Le^{-tL^2})$. (Zero modes contribute $0 \cdot e^0 = 0$, so they drop out automatically.)

At $s = 0$ the prefactor is $1/\Gamma(\frac{1}{2}) = 1/\sqrt{\pi}$:

$$\eta_L(0) = \frac{1}{\sqrt{\pi}}\int_0^\infty t^{-1/2}\,\operatorname{Tr}\big(L\,e^{-tL^2}\big)\,\mathrm{d}t, \tag{4.222}$$

provided the integral converges at $t \to 0$. Unlike $\operatorname{Tr} e^{-tL^2}$, the "odd" heat trace $\operatorname{Tr}(Le^{-tL^2})$ weighs each eigenvalue with its sign, so the big positive and negative contributions cancel. Whether they cancel well enough as $t \to 0$ is exactly the finiteness question.

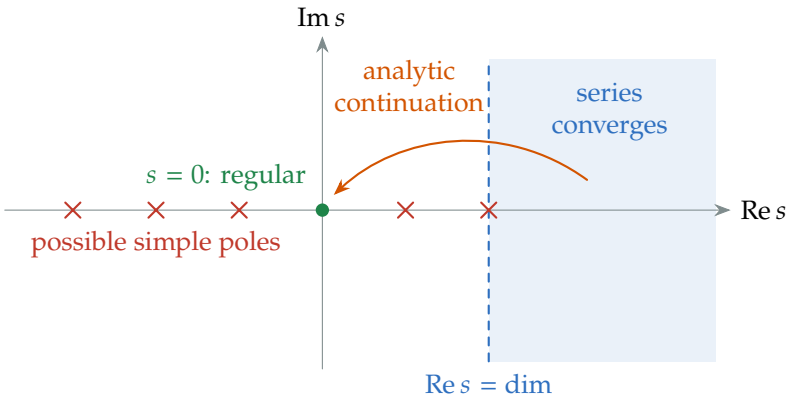


Figure 4.76: The life of a zeta or eta function in the complex s-plane. The defining series converges only in the shaded half-plane. The heat-kernel formulas (4.215) and (4.221) continue it to the left; small-t powers of the heat trace produce simple poles on the real axis (crosses). At $s = 0$ the function is regular: for ζ because $1/\Gamma(s)$ vanishes there, for η because of a deeper cancellation (Section 4.21.12).

Key idea: Zeta functions compute indices: Nash's footnote 5

Let D be elliptic on a closed manifold. The nonzero eigenvalues of D^*D and DD^* coincide (if $D^*D\phi = \mu\phi$ with $\mu \neq 0$, then $DD^*(D\phi) = \mu D\phi$ and $D\phi \neq 0$). So their zeta functions are *identical*, and (4.217) at $s = 0$ gives

$$0 \overset{(1)}{=} \zeta_{D^*D}(0) - \zeta_{DD^*}(0) \overset{(2)}{=} \big(a_n(D^*D) - \dim\operatorname{Ker} D^*D\big) - \big(a_n(DD^*) - \dim\operatorname{Ker} DD^*\big),$$

$$\operatorname{index} D \overset{(3)}{=} \dim\operatorname{Ker} D - \dim\operatorname{Ker} D^* \overset{(4)}{=} a_n(D^*D) - a_n(DD^*).$$

(1) Equal nonzero spectra give equal zeta functions.
(2) (4.217) for each operator.
(3) Definition of the index; $\operatorname{Ker} D^*D = \operatorname{Ker} D$ and $\operatorname{Ker} DD^* = \operatorname{Ker} D^*$ (if $D^*D\phi = 0$ then $\|D\phi\|^2 = \langle\phi, D^*D\phi\rangle = 0$).
(4) Rearrange the first line.

The index is a difference of *local* heat coefficients. This is the heat-equation derivation of the index theorem (Atiyah–Bott–Patodi) that Nash's footnote mentions; it is the same statement as McKean–Singer in Chapter 4. With a boundary the same idea works, and the boundary produces η: see Section 4.21.9.

4.21.6 Explicit computation: η for the Dirac operator on the circle

Nash computes one eta invariant explicitly [Nash p. 132, (4.159)–(4.161)], and it is the one every physicist should know: a Dirac fermion on a circle threaded by a magnetic flux. We do the computation three ways.

The operator and its spectrum

Nash's operator is

$$L_t = i\frac{\mathrm{d}}{\mathrm{d}\theta} + t \qquad \text{on functions on } S^1, \quad 0 < t < 1. \tag{4.223}$$

It is the Dirac operator of the circle in the presence of a constant gauge potential. With the U(1) connection $A = -it\,\mathrm{d}\theta$ (anti-Hermitian, our convention), the covariant derivative is $\nabla_\theta = \partial_\theta - it$, and $i\nabla_\theta = i\partial_\theta + t = L_t$. Physically, t is the magnetic flux through the ring in units of the flux quantum 2π (an Aharonov–Bohm flux), since the holonomy is $\exp(-\oint A) = e^{2\pi i t}$. Equivalently, by the gauge transformation $\psi \to e^{-it\theta}\psi$ one can remove t from the operator and put it into a twisted boundary condition $\psi(\theta + 2\pi) = e^{2\pi i t}\psi(\theta)$.

The eigenfunctions are Fourier modes:

$$L_t\, e^{-in\theta} \overset{(1)}{=} \big(i\cdot(-in) + t\big)e^{-in\theta} \overset{(2)}{=} (n+t)\, e^{-in\theta}, \qquad n \in \mathbb{Z}.$$

(1) $\frac{\mathrm{d}}{\mathrm{d}\theta}e^{-in\theta} = -in\, e^{-in\theta}$.
(2) $i\cdot(-i) = 1$.

So the spectrum is $\lambda_n = n + t$, $n \in \mathbb{Z}$, Nash's (4.159). It is the integer lattice shifted by t (Figure 4.77). For $t = 0$ it is symmetric about 0 and contains 0; for $t = \frac{1}{2}$ it is $\{\pm\frac{1}{2}, \pm\frac{3}{2}, \dots\}$, again symmetric; for any other t the dots sit unevenly around 0.

First way: Hurwitz zeta functions (Nash's route)

Split the spectrum by sign. With $0 < t < 1$, $n + t > 0$ exactly when $n \geq 0$, and $n + t < 0$ exactly when $n \leq -1$. Then

$$\begin{aligned}\eta_{L_t}(s) &\overset{(1)}{=} \sum_{n\geq 0}\frac{1}{(n+t)^s} - \sum_{n\leq -1}\frac{1}{|n+t|^s} \overset{(2)}{=} \sum_{n\geq 0}\frac{1}{(n+t)^s} - \sum_{m\geq 1}\frac{1}{(m-t)^s}\\ &\overset{(3)}{=} \sum_{n\geq 0}\frac{1}{(n+t)^s} - \sum_{m'\geq 0}\frac{1}{(m'+1-t)^s} \overset{(4)}{=} \zeta(s,t) - \zeta(s,1-t).\end{aligned} \tag{4.224}$$

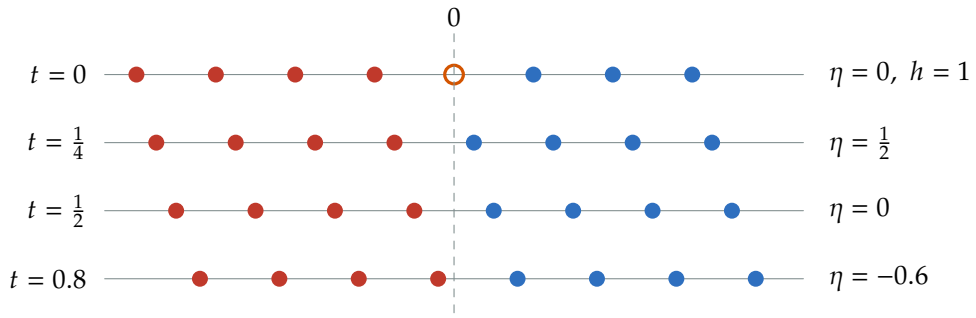

Figure 4.77: The spectrum $\{n+t\}$ of $L_t = i\,\mathrm{d}/\mathrm{d}\theta + t$ for four values of the flux t: negative eigenvalues red, positive blue, a zero mode as an orange ring. Shifting the lattice by t moves every dot the same distance to the right. Near 0 the nearest positive eigenvalue is t and the nearest negative one is $t-1$; that imbalance is what $\eta(0) = 1 - 2t$ measures. The far-away dots are balanced and cancel in the regularised count.

(1) Definition (4.211): positive eigenvalues with $+$, negative with $-$.
(2) Put $m = -n \geq 1$; then $|n+t| = m - t$.
(3) Put $m' = m - 1 \geq 0$, so $m - t = m' + (1-t)$.
(4) The **Hurwitz zeta function** $\zeta(s,t) = \sum_{n\geq 0}(n+t)^{-s}$, Nash's (4.160); it is Riemann's ζ_R when $t = 1$.

Nash quotes (from Whittaker and Watson) the value $\zeta(0,t) = \frac{1}{2} - t$. Let us derive it, since it is the heart of the matter. Apply the Mellin transform (4.214) to each term and sum the geometric series:

$$\Gamma(s)\,\zeta(s,t) \overset{(1)}{=} \int_0^\infty \varepsilon^{s-1} \sum_{n\geq 0} e^{-\varepsilon(n+t)}\,\mathrm{d}\varepsilon \overset{(2)}{=} \int_0^\infty \varepsilon^{s-1}\,\frac{e^{-\varepsilon t}}{1-e^{-\varepsilon}}\,\mathrm{d}\varepsilon.$$

(1) (4.214) with $\mu = n + t$, summed over n.
(2) $\sum_{n\geq 0} e^{-\varepsilon n} = 1/(1-e^{-\varepsilon})$.

The small-ε behaviour of the integrand controls everything. Expand:

$$\frac{e^{-\varepsilon t}}{1-e^{-\varepsilon}} \overset{(1)}{=} \Big(1 - \varepsilon t + \tfrac{1}{2}\varepsilon^2 t^2 - \cdots\Big)\Big(\frac{1}{\varepsilon} + \frac{1}{2} + \frac{\varepsilon}{12} + \cdots\Big) \overset{(2)}{=} \frac{1}{\varepsilon} + \Big(\frac{1}{2} - t\Big) + O(\varepsilon).$$

(1) Taylor series of $e^{-\varepsilon t}$; and $\frac{1}{1-e^{-\varepsilon}} = \frac{1}{\varepsilon - \varepsilon^2/2 + \varepsilon^3/6 - \cdots} = \frac{1}{\varepsilon}\big(1 + \frac{\varepsilon}{2} + \frac{\varepsilon^2}{12} + \cdots\big)$.
(2) Multiply out and collect the ε^{-1} and ε^0 terms.

Now split the integral at $\varepsilon = 1$ as in Section 4.21.5. The piece $\int_1^\infty$ is entire. In $\int_0^1$ the first two terms give $\int_0^1 \varepsilon^{s-2}\mathrm{d}\varepsilon = \frac{1}{s-1}$ and $(\frac{1}{2} - t)\int_0^1 \varepsilon^{s-1}\mathrm{d}\varepsilon = \frac{1/2 - t}{s}$, and the $O(\varepsilon)$ remainder is holomorphic for $\operatorname{Re} s > -1$. So near $s = 0$,

$$\zeta(s,t) \overset{(1)}{=} \frac{1}{\Gamma(s)}\Big(\frac{\frac{1}{2}-t}{s} + \text{regular}\Big) \overset{(2)}{=} \big(s + O(s^2)\big)\Big(\frac{\frac{1}{2}-t}{s} + \text{regular}\Big) \xrightarrow{s\to 0} \frac{1}{2} - t. \tag{4.225}$$

(1) Divide by $\Gamma(s)$; the $\frac{1}{s-1}$ term is regular at $s = 0$.
(2) $1/\Gamma(s) = s + O(s^2)$.

(The same bookkeeping at higher order gives the classical $\zeta(-k,t) = -B_{k+1}(t)/(k+1)$ with Bernoulli polynomials; here $B_1(t) = t - \frac{1}{2}$.) Putting (4.225) into (4.224):

$$\eta_{L_t}(0) \overset{(1)}{=} \Big(\frac{1}{2} - t\Big) - \Big(\frac{1}{2} - (1-t)\Big) \overset{(2)}{=} 1 - 2t, \qquad 0 < t < 1. \tag{4.226}$$

(1) $\zeta(0,t) = \frac{1}{2} - t$ and $\zeta(0,1-t) = \frac{1}{2} - (1-t)$.
(2) Arithmetic.

This is Nash's (4.161). At $t = \frac{1}{2}$ the answer is 0, as the symmetric spectrum demands. As $t \to 0^+$ the answer tends to 1: the eigenvalue t is about to become a zero mode, and it is the one unpaired positive eigenvalue.

Second way: a smooth cutoff

The ε-integrand above suggests a quicker route. Regularise the divergent "$\sum \operatorname{sgn}\lambda$" with a cutoff $e^{-\varepsilon|\lambda|}$ and let $\varepsilon \to 0$:

$$\sum_n \operatorname{sgn}(\lambda_n) e^{-\varepsilon|\lambda_n|} \overset{(1)}{=} \sum_{n\geq 0} e^{-\varepsilon(n+t)} - \sum_{m\geq 1} e^{-\varepsilon(m-t)} \overset{(2)}{=} \frac{e^{-\varepsilon t} - e^{-\varepsilon(1-t)}}{1-e^{-\varepsilon}}$$
$$\overset{(3)}{=} \frac{\varepsilon(1-2t) + O(\varepsilon^2)}{\varepsilon + O(\varepsilon^2)} \xrightarrow{\varepsilon\to 0} 1 - 2t.$$

(1) Split by sign as in (4.224).
(2) Two geometric series with ratio $e^{-\varepsilon}$; the second starts at $e^{-\varepsilon(1-t)}$.
(3) Expand numerator and denominator to first order in ε: $e^{-\varepsilon t} - e^{-\varepsilon(1-t)} = \varepsilon(1-t) - \varepsilon t + O(\varepsilon^2)$.

The two infinite sums each diverge like $1/\varepsilon$; the divergences cancel exactly, and the finite remainder is the eta invariant. This is the sense in which $\eta(0)$ is "$\#(\lambda > 0) - \#(\lambda < 0)$". (For this operator any reasonable cutoff gives the same answer; in general the zeta/heat version is the one guaranteed to be well defined.)

Third way: the heat kernel and Poisson summation

This is the method that generalises, and it shows directly why nothing diverges. We use (4.222), so we need the odd heat trace $\operatorname{Tr}(L_t e^{-\tau L_t^2}) = \sum_n (n+t) e^{-\tau(n+t)^2}$ (we write τ for the heat time to keep t for the flux). The **Poisson summation formula** says that for a rapidly decreasing f,

$$\sum_{n\in\mathbb{Z}} f(n+t) = \sum_{m\in\mathbb{Z}} \hat{f}(2\pi m)\, e^{2\pi i m t}, \qquad \hat{f}(k) = \int_{-\infty}^{\infty} f(x) e^{-ikx}\, \mathrm{d}x. \tag{4.227}$$

(The left side is a periodic function of t with period 1; the right side is its Fourier series.)

Worked example 4.137: $\eta(0) = 1 - 2t$ from the heat kernel

Take $f(x) = x\, e^{-\tau x^2}$. Its Fourier transform is

$$\hat{f}(k) \overset{(1)}{=} i\frac{\mathrm{d}}{\mathrm{d}k} \int e^{-\tau x^2} e^{-ikx}\, \mathrm{d}x \overset{(2)}{=} i\frac{\mathrm{d}}{\mathrm{d}k}\left(\sqrt{\frac{\pi}{\tau}} e^{-k^2/4\tau}\right) \overset{(3)}{=} -\frac{ik}{2\tau}\sqrt{\frac{\pi}{\tau}}\, e^{-k^2/4\tau}.$$

(1) $i\frac{\mathrm{d}}{\mathrm{d}k} e^{-ikx} = x\, e^{-ikx}$.
(2) The Gaussian integral.
(3) Differentiate.

Note $\hat{f}(0) = 0$ because f is odd. Hence by (4.227)

$$\operatorname{Tr}\big(L_t e^{-\tau L_t^2}\big) = -i\pi^{3/2}\tau^{-3/2} \sum_{m\neq 0} m\, e^{-\pi^2 m^2/\tau} e^{2\pi i m t}. \tag{4.228}$$

Every term is *exponentially small* as $\tau \to 0$: the odd heat trace of the circle has no small-τ expansion at all. So the integral (4.222) converges at $\tau = 0$ and

$$\eta_{L_t}(0) \overset{(1)}{=} \frac{1}{\sqrt{\pi}}\left(-i\pi^{3/2}\right) \sum_{m\neq 0} m\, e^{2\pi i m t} \int_0^\infty \tau^{-2} e^{-\pi^2 m^2/\tau}\, \mathrm{d}\tau \overset{(2)}{=} -i\pi \sum_{m\neq 0} \frac{m\, e^{2\pi i m t}}{\pi^2 m^2}$$
$$\overset{(3)}{=} -\frac{i}{\pi} \sum_{m\geq 1} \frac{e^{2\pi i m t} - e^{-2\pi i m t}}{m} \overset{(4)}{=} \frac{2}{\pi} \sum_{m\geq 1} \frac{\sin 2\pi m t}{m} \overset{(5)}{=} \frac{2}{\pi} \cdot \pi\left(\frac{1}{2} - t\right) = 1 - 2t.$$

(1) Insert (4.228) into (4.222); $\tau^{-1/2}\tau^{-3/2} = \tau^{-2}$.
(2) Substitute $u = 1/\tau$: $\int_0^\infty \tau^{-2} e^{-c/\tau} \mathrm{d}\tau = \int_0^\infty e^{-cu}\mathrm{d}u = 1/c$ with $c = \pi^2 m^2$.
(3) Pair m with $-m$.
(4) $e^{ix} - e^{-ix} = 2i \sin x$ and $-\frac{i}{\pi} \cdot 2i = \frac{2}{\pi}$.
(5) The Fourier series of the sawtooth: $\sum_{m\geq 1} \frac{\sin mx}{m} = \frac{\pi - x}{2}$ for $0 < x < 2\pi$, with $x = 2\pi t$.

The third method also tells us what happens at $t = 0$: the Fourier series converges to 0, the average of the two one-sided limits ± 1.

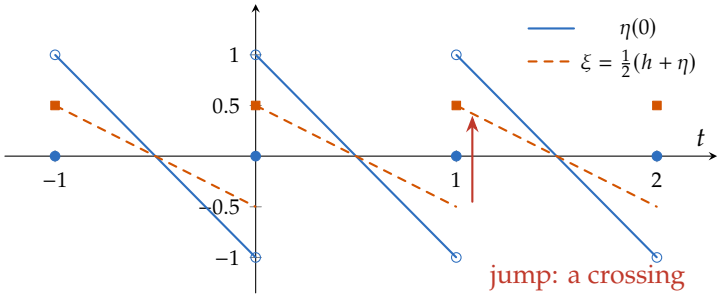

Figure 4.78: The eta invariant of $L_t = i\,\mathrm{d}/\mathrm{d}\theta + t$ as a function of the flux t (solid): the sawtooth $1 - 2t$ on $(0, 1)$, repeated with period 1. Between integers it changes smoothly with slope -2; at each integer it jumps by 2, because one eigenvalue $n + t$ passes through zero; at the integers themselves (filled dots) the spectrum is symmetric and $\eta = 0$. The dashed line is $\xi = \frac{1}{2}(h + \eta)$, with $h = \dim \mathrm{Ker}\, L_t$; it jumps by exactly 1 and takes the right-hand value at the integers (squares). The jumps are the spectral flow of Section 4.21.10.

What the answer teaches

- *η is a measure of asymmetry.* It vanishes exactly at $t = \frac{1}{2}$ (symmetric spectrum) and at $t = 0$ (symmetric, with a zero mode), just as Nash says.

- *η is not local.* A local invariant of the circle with a flat connection could only be an integral of a local density, and a flat connection has no local field strength at all. Yet η depends on t: it sees the holonomy $e^{2\pi i t}$, a global Aharonov–Bohm quantity.

- *η is gauge invariant but discontinuous.* Under a large gauge transformation $t \to t + 1$ the spectrum is relabelled and η is unchanged: η is a function of the holonomy. But it jumps by 2 whenever an eigenvalue crosses zero.

- *$e^{i\pi\eta}$ is smooth.* Because the jumps are by 2, $e^{i\pi\eta(0)} = e^{i\pi(1-2t)} = -e^{-2\pi i t}$ is a smooth function of t, and it is exactly (minus) the inverse holonomy. Phases of this type are the phases of chiral fermion determinants, which is why η enters the theory of anomalies (Chapter 10).

- *η does not care about the size of the circle.* On a circle of length ℓ the operator is $\frac{2\pi}{\ell}L_t$, and $\eta_{cL}(s) = c^{-s}\eta_L(s)$, so $\eta(0)$ is unchanged. In general $\eta(0)$ is invariant under rescaling of the metric.

Worked example 4.138: Spin structures, and a matrix of fluxes

The plain Dirac operator $-i\,\mathrm{d}/\mathrm{d}\theta$ on the circle depends on a choice of **spin structure** (Chapter T4): spinors may be periodic (the "Ramond" or non-bounding structure) or antiperiodic (the "Neveu–Schwarz" structure, the one that extends over a disc). Antiperiodic spinors are $e^{i(n+\frac12)\theta}$: this is $t = \frac12$, so $\eta = 0$, $h = 0$. Periodic spinors are $t = 0$: $\eta = 0$, $h = 1$. So $\xi = \frac12(h+\eta)$ is 0 or $\frac12$; that $\frac12$ is the zero-mode contribution that distinguishes the two spin structures.

Now take an N-component fermion with a constant diagonal potential, $L = i\,\mathrm{d}/\mathrm{d}\theta \otimes \mathbf{1}_N + \mathrm{diag}(t_1,\dots,t_N)$, i.e. a flat $\mathrm{U}(N)$ connection with holonomy $\mathrm{diag}(e^{2\pi i t_j})$. The spectrum is the union of the N shifted lattices, and η is additive over direct sums, so

$$\eta_L(0) = \sum_{j=1}^{N} \bigl(1 - 2\{t_j\}\bigr) \quad (t_j \notin \mathbb{Z}), \qquad \{t\} = t - \lfloor t \rfloor .$$

For example the $\mathrm{SU}(2)$ holonomy $\mathrm{diag}(e^{2\pi i t}, e^{-2\pi i t})$ with $0 < t < 1$ gives $(1-2t) + (1-2(1-t)) = 0$: the $\mathrm{SU}(2)$ case is symmetric, because $\mathrm{diag}(t,-t)$ has a spectrum symmetric under $\lambda \to -\lambda$ combined with $n \to -n$.

Try it: Scaling and orientation

(a) Show that $\eta_{cL}(0) = \eta_L(0)$ for $c > 0$ and $\eta_{-L}(0) = -\eta_L(0)$. (b) Reversing the orientation of the circle replaces θ by $-\theta$. What does it do to L_t and to η? *Answer:* (a) $\eta_{cL}(s) = \sum \mathrm{sgn}(c\lambda)|c\lambda|^{-s} = c^{-s}\eta_L(s)$, and $c^0 = 1$; flipping every sign flips the sum. (b) $i\,\mathrm{d}/\mathrm{d}\theta \to -i\,\mathrm{d}/\mathrm{d}\theta$, so $L_t \to -L_{-t}$, with spectrum $\{-(n-t)\} = \{n+t\}$ again after relabelling. So this particular η is unchanged; the orientation-odd invariant is η of the operator that also keeps track of the chirality, as in Section 4.21.4.

4.21.7 The Atiyah–Patodi–Singer index theorem

Nash now leaves the signature operator and states the general theorem [Nash pp. 132–133, (4.162)–(4.164)]. Everything we have built so far fits into it.

The set-up

Let X be a compact manifold with boundary, $E, F \to X$ vector bundles, and

$$D : \Gamma(X,E) \to \Gamma(X,F) \tag{4.229}$$

a first-order elliptic operator. Assume that near the boundary X is isometric to a product $\partial X \times [0,\varepsilon)$ and D has the form

$$D = A\Bigl(\frac{\partial}{\partial n} + L\Bigr) \quad \text{near } \partial X, \tag{4.230}$$

where n is the inward normal coordinate, A is an invertible bundle map (independent of n), and L is a self-adjoint elliptic operator on ∂X, independent of n. Impose the global boundary condition

$$\Pi\bigl(u|_{\partial X}\bigr) = 0, \qquad u \in \Gamma(X,E), \tag{4.231}$$

where Π is the spectral projection of L onto its eigenvalues $\lambda \geq 0$. This is Nash's (4.162). The zero eigenvalue now needs care. Nash defines [Nash (4.163)]

$$h = \dim \operatorname{Ker} L, \qquad \eta(s) = \sum_{\lambda_n \neq 0} \frac{\operatorname{sgn} \lambda_n}{|\lambda_n|^s}. \tag{4.232}$$

Key idea: The APS index theorem (Nash's "index theory for boundary value problems", (4.164))

The boundary problem (4.230)–(4.231) is Fredholm, and its index is

$$\operatorname{index} D = \int_X P \; - \; \frac{h + \eta(0)}{2}. \tag{4.233}$$

Here $P = P(R, F)$ is the *same* local index density (a combination of characteristic forms built from the curvature) that gives index D on a closed manifold: $\operatorname{ch}(F)\,\operatorname{td}(X)$ for a twisted $\bar{\partial}$, $\operatorname{ch}(F)\hat{A}(X)$ for a twisted Dirac operator, $2^{n/2}L(X)$ for the signature operator (in the normalisations of Chapter 4). The combination $\xi = \frac{1}{2}(h + \eta(0))$ is often called the **xi invariant** of L.

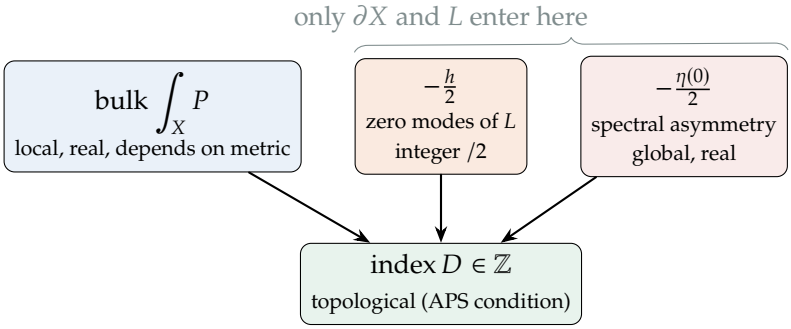

Figure 4.79: The three pieces of the APS formula. The bulk integral is a local density and changes continuously with the metric and gauge field. The integer index D does not. The boundary pieces absorb the difference: η is non-local, and h records zero modes of L. Only their sum with the bulk integral is an integer.

How to read the formula

- *On a closed manifold* there is no boundary, $h = \eta = 0$, and (4.233) is the ordinary index theorem $\operatorname{index} D = \int_X P$.
- *The bulk term is not an integer.* On a manifold with boundary $\int_X P$ is just a real number, which varies continuously with the geometry. The boundary term $-\frac{1}{2}(h + \eta)$ is what makes the total an integer. In particular (4.233) determines $\eta(0)$ modulo 2 from the bulk: $\eta(0) \equiv 2\int_X P - h \pmod 2$.
- *The signature operator.* With $D = d_+$, $\int_X P = \frac{1}{3}\int_X p_1$ in four dimensions, and (4.233) is (4.212) corrected by h (Section 4.21.4).
- *Why the zero modes are counted with* $-\frac{1}{2}$. The APS condition puts $\operatorname{Ker} L$ into H_+, i.e. it forces the zero-mode components of $u|_{\partial X}$ to vanish. That is "half" of the freedom a zero mode has (on the elongated manifold it is a bounded but not square-integrable solution, sitting on the fence between allowed and forbidden). The $-\frac{h}{2}$ is the price.

Worked example 4.139: Consistency check: the adjoint problem

Take $A = 1$ for simplicity, so $D = \partial_n + L$ near the boundary. Its formal adjoint is $D^* = -\partial_n + L = -(\partial_n - L)$, whose boundary operator is $-L$. The *true* adjoint of the APS problem for D carries the complementary condition $(1 - \Pi)v|_{\partial X} = 0$ (boundary data of v in the span of $\lambda \geq 0$), and its index is $-\operatorname{index} D$. The APS problem for D^* in its own right instead demands boundary data in $H_-(-L)$, the span of $\lambda > 0$: a stricter condition, differing by the h-dimensional $\operatorname{Ker} L$. The theorem is consistent with this:

$$\operatorname{index}_{\mathrm{APS}}(D^*) \overset{(1)}{=} \int_X P^* - \frac{h + \eta_{-L}(0)}{2} \overset{(2)}{=} -\int_X P - \frac{h - \eta_L(0)}{2}$$
$$\overset{(3)}{=} -\Big(\int_X P - \frac{h + \eta_L(0)}{2}\Big) - h \overset{(4)}{=} -\operatorname{index}_{\mathrm{APS}}(D) - h.$$

(1) (4.233) for D^*, whose boundary operator is $-L$ with the same kernel.
(2) The local index density of the adjoint is $P^* = -P$ (the roles of D^*D and DD^* swap), and $\eta_{-L} = -\eta_L$.
(3) Rearrange: $-\frac{h-\eta}{2} = \frac{h+\eta}{2} - h$.
(4) (4.233) for D.

So imposing the APS condition on D^* loses exactly h from the index relative to the true adjoint, which is what the h extra constraints should do. We check it by hand in the next example.

The simplest example: a domain wall on an interval

The smallest possible case of the theorem is one-dimensional: $X = [0, 1]$, whose boundary is two points. It is worth doing completely, because it is the Jackiw–Rebbi zero mode of a fermion on a domain wall, and because it shows the theorem working with nothing hidden.

Worked example 4.140: The APS theorem on an interval: Jackiw–Rebbi

Let $D = \dfrac{\mathrm{d}}{\mathrm{d}x} + a(x)$ acting on complex functions on $[0, 1]$, with a a smooth real function (a position-dependent mass). *The boundary operators.* At $x = 0$ the inward normal coordinate is $n = x$, so $D = \partial_n + a(0)$: $A = 1$ and $L_0 = a(0)$, a 1×1 matrix (an operator on the 0-dimensional boundary component). At $x = 1$ the inward coordinate is $n = 1 - x$, so $\partial_x = -\partial_n$ and $D = -(\partial_n - a(1))$: $A = -1$ and $L_1 = -a(1)$. The eta invariant of a 1×1 matrix (λ) is simply $\operatorname{sgn}\lambda$, and $h = 1$ if $\lambda = 0$.
Direct count. Solutions of $Du = 0$ are $u(x) = u(0)\exp\big(-\int_0^x a\big)$, never zero unless identically zero. The APS condition allows $u(0) \neq 0$ only if $L_0 = a(0) < 0$ and $u(1) \neq 0$ only if $L_1 = -a(1) < 0$. So

$$\dim \operatorname{Ker} D = \begin{cases} 1 & a(0) < 0 < a(1), \\ 0 & \text{otherwise.} \end{cases}$$

The adjoint $D^* = -\frac{\mathrm{d}}{\mathrm{d}x} + a$ has solutions $v = v(0)\exp\big(+\int_0^x a\big)$, with the complementary condition: $v(0) \neq 0$ is allowed iff $a(0) \geq 0$ and $v(1) \neq 0$ iff $-a(1) \geq 0$. So $\dim \operatorname{Coker} D = 1$ iff $a(1) \leq 0 \leq a(0)$.

The theorem. In one dimension there is no local index density ($P = 0$: the heat-kernel coefficients of $D^*D = -\partial^2 + a^2 - a'$ and $DD^* = -\partial^2 + a^2 + a'$ agree at order t^0). So

$$\operatorname{index} D \overset{(1)}{=} 0 - \frac{h_0 + \eta(L_0)}{2} - \frac{h_1 + \eta(L_1)}{2} \overset{(2)}{=} \frac{\operatorname{sgn} a(1) - \operatorname{sgn} a(0)}{2} - \frac{h_0 + h_1}{2}.$$

(1) (4.233), one boundary term per boundary point.
(2) $\eta(L_0) = \operatorname{sgn} a(0)$, $\eta(L_1) = \operatorname{sgn}(-a(1)) = -\operatorname{sgn} a(1)$.

Check all cases: $a(0) < 0 < a(1)$ gives $\frac{1+1}{2} = 1$ (one zero mode, no cokernel) ✓; $a(0) > 0 > a(1)$ gives -1 (cokernel only) ✓; equal signs give 0 ✓; and $a \equiv 0$ gives $0 - \frac{1+1}{2} = -1$, matching the direct count (no kernel; the constant v is in the cokernel) ✓. For $a \equiv 0$ one also sees Example 4.139: the APS problem for $D^* = -\mathrm{d}/\mathrm{d}x$ has index $-1 = -(-1) - 2$.

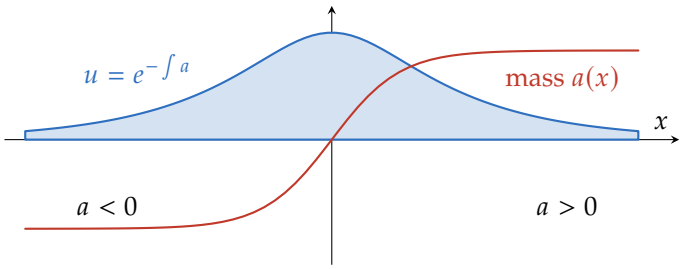

Figure 4.80: The Jackiw–Rebbi zero mode. A mass profile $a(x)$ that changes sign from negative to positive traps exactly one normalisable solution of $(\mathrm{d}/\mathrm{d}x + a)u = 0$, $u = \exp(-\int a)$, localised on the wall. On a finite interval the APS condition reproduces this count through the boundary eta invariants $\operatorname{sgn} a(0)$ and $-\operatorname{sgn} a(1)$; on the whole line (the elongated manifold) it is literally the L^2 kernel. The index is the number of eigenvalues of the "boundary family" $a(x)$ that cross from negative to positive: a first example of spectral flow.

Physical picture: Domain walls and fermion zero modes

In the Jackiw–Rebbi model a Dirac fermion in $1+1$ dimensions couples to a scalar kink $\phi(x)$ through a mass term $g\phi\bar\psi\psi$. With a suitable choice of gamma matrices, the zero-energy Dirac equation for one spinor component reduces to $(\mathrm{d}/\mathrm{d}x + g\phi)u = 0$. A kink, with $\phi(\pm\infty) = \pm v$, therefore carries one fermion zero mode, and the soliton's fermion number is $\pm\frac{1}{2}$ depending on whether the mode is filled. The number of zero modes depends only on the signs of the mass at the two ends, which is exactly the data $\eta(L_0), \eta(L_1)$. The same mechanism puts chiral fermions on domain walls in lattice QCD (domain-wall fermions) and gives the edge modes of topological insulators.

A disc threaded by magnetic flux

Our next example has all three terms of the APS formula nonzero, and it uses the circle computation of Section 4.21.6 as its boundary term.

Worked example 4.141: The $\bar\partial$ operator on a disc with a vortex

Let X be the unit disc $|z| \le 1$, with a metric that equals $|\mathrm{d}z/z|^2 = \mathrm{d}r^2/r^2 + \mathrm{d}\theta^2$ near $|z| = 1$ (so the collar is a flat cylinder) and is smooth inside. Couple $\bar\partial$ on functions to a U(1) gauge field as in Section 4.17: $\bar\partial_A = \partial_{\bar z} + A_{\bar z}$ with $A_{\bar z} = \partial_{\bar z}\phi$ for a real radial function $\phi(r)$, smooth at the origin, and equal to $\alpha \ln r$ near the boundary. The field strength is $F = -i\nabla^2\phi\,\mathrm{d}x \wedge \mathrm{d}y$,

so the flux is confined to the inside and the connection is flat on the collar. The Chern number of the flux is

$$\int_X c_1(F) \overset{(1)}{=} \frac{1}{2\pi}\int_X \nabla^2\phi \,\mathrm{d}x\,\mathrm{d}y \overset{(2)}{=} \frac{1}{2\pi}\oint_{r=1} \partial_r\phi \,\mathrm{d}s \overset{(3)}{=} \frac{1}{2\pi}\cdot\alpha\cdot 2\pi = \alpha.$$

(1) $c_1 = \frac{i}{2\pi}F = \frac{1}{2\pi}\nabla^2\phi\,\mathrm{d}x\wedge\mathrm{d}y$.
(2) The divergence theorem in the plane.
(3) $\partial_r(\alpha\ln r) = \alpha$ at $r=1$, and the circle has length 2π.

So α is the magnetic flux in units of 2π, and it need not be an integer.

The boundary operator. In polar coordinates $\partial_{\bar z} = \frac{e^{i\theta}}{2}\big(\partial_r + \frac{i}{r}\partial_\theta\big)$ (check: it kills $z = re^{i\theta}$ and sends $\bar z$ to 1). On the collar $A_{\bar z} = \frac{e^{i\theta}}{2}\phi'(r) = \frac{e^{i\theta}}{2}\frac{\alpha}{r}$. The inward normal coordinate for the metric $\mathrm{d}r^2/r^2 + \mathrm{d}\theta^2$ is $n = -\ln r$, so $\partial_n = -r\partial_r$. Therefore

$$\bar\partial_A \overset{(1)}{=} \frac{e^{i\theta}}{2r}\big(r\partial_r + i\partial_\theta + \alpha\big) \overset{(2)}{=} -\frac{e^{i\theta}}{2r}\Big(\partial_n - \big(i\partial_\theta + \alpha\big)\Big) \overset{(3)}{=} -\frac{e^{i\theta}}{2r}\big(\partial_n + L\big), \quad L = -i\partial_\theta - \alpha.$$

(1) Add the two pieces and factor out $\frac{e^{i\theta}}{2r}$.
(2) $r\partial_r = -\partial_n$.
(3) Definition of L; the factor $A = -\frac{e^{i\theta}}{2r}$ is invertible.

L acts on $e^{ik\theta}$ by $k-\alpha$, $k\in\mathbb{Z}$.

Direct count of the kernel. Solutions of $\bar\partial_A\psi = 0$ are $\psi = e^{-\phi}f(z)$ with f holomorphic on the disc (Section 4.17), so $\psi = e^{-\phi}\sum_{k\ge0}a_k z^k$. On the boundary ($\phi(1)=0$) this is $\sum_{k\ge0}a_k e^{ik\theta}$. The APS condition kills every coefficient with $k-\alpha\ge 0$. So the kernel is spanned by $e^{-\phi}z^k$ with $0\le k<\alpha$:

$$\dim\operatorname{Ker}\bar\partial_A = \#\{k\in\mathbb{Z}:\ 0\le k<\alpha\} = \lfloor\alpha\rfloor + 1 \qquad (\alpha>0,\ \alpha\notin\mathbb{Z}).$$

The analogous computation for the adjoint (antiholomorphic modes $e^{\phi}\bar z^k$, with the complementary condition) finds nothing when $\alpha>0$, so $\operatorname{index}\bar\partial_A = \lfloor\alpha\rfloor+1$.

The theorem. The local density for $\bar\partial$ twisted by a line bundle is the degree-2 part of $\operatorname{ch}(F)\operatorname{td}(X)$, namely $c_1(F)+\frac12 c_1(X)$, and $c_1(X)$ is the Euler form. The spectrum $\{k-\alpha\}$ is Nash's $\{n+t\}$ with $t = 1-\{\alpha\}\in(0,1)$ (write $-\alpha = -(\lfloor\alpha\rfloor+1)+(1-\{\alpha\})$ and relabel $n = k-\lfloor\alpha\rfloor-1$). Hence $h=0$ and $\eta(0) = 1-2t = 2\{\alpha\}-1$, by (4.226). Then

$$\operatorname{index}\bar\partial_A \overset{(1)}{=} \int_X c_1(F) + \frac12\int_X e(X) - \frac{h+\eta(0)}{2} \overset{(2)}{=} \alpha + \frac12 - \frac{0+2\{\alpha\}-1}{2}$$
$$\overset{(3)}{=} \alpha - \{\alpha\} + 1 \overset{(4)}{=} \lfloor\alpha\rfloor + 1.$$

(1) (4.233) with $P = c_1(F) + \frac12 e(X)$.
(2) The flux integral above; $\int_X e = \chi(\text{disc}) = 1$ by Gauss–Bonnet for a product collar (4.207); the circle eta invariant.
(3) Arithmetic.
(4) $\alpha = \lfloor\alpha\rfloor + \{\alpha\}$.

This agrees with the direct count. If α is an integer, L has the zero mode $e^{i\alpha\theta}$ ($h=1$), the spectrum is symmetric ($\eta=0$), and the formula gives $\alpha+\frac12-\frac12=\alpha$; the direct count ($0\le k<\alpha$) gives α too. With no flux ($\alpha=0$) the index is 0: the constant function is killed by the boundary condition.

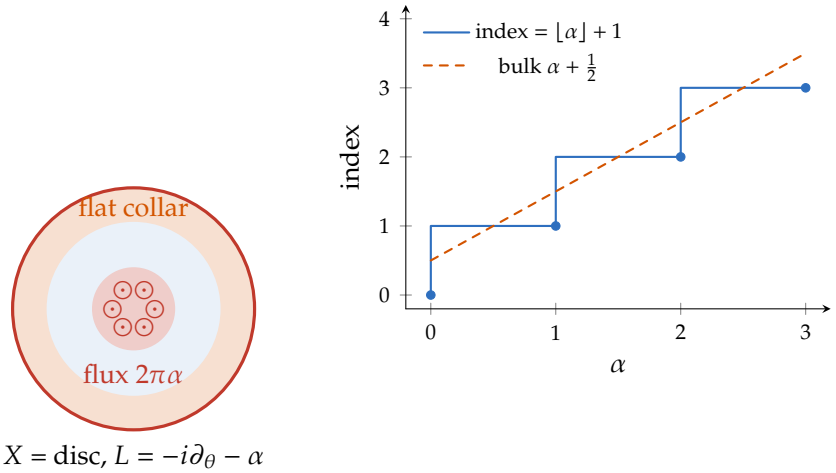

Figure 4.81: Left: a disc threaded by a vortex of flux $2\pi\alpha$, with a flat collar near the rim. Right: the index of $\bar\partial_A$ with APS boundary conditions (solid staircase) and the bulk integral $\alpha + \frac{1}{2}$ (dashed). The vertical gap between them is $\frac{1}{2}(h + \eta(0)) = \{\alpha\} - \frac{1}{2}$ for non-integer α and $\frac{1}{2}$ at the integers: the boundary eta invariant turns a continuous bulk number into an integer.

Nash's example: $\bar\partial$ on a Riemann surface with holes

Now the example Nash works out [Nash pp. 133–135, (4.165)–(4.174)]. Take a closed Riemann surface Σ_g of genus g and remove p disjoint discs $D_1, \dots, D_p$ [Nash (4.165)]:

$$X = \Sigma_g - \bigcup_{i=1}^{p} D_i. \tag{4.234}$$

Then X is a complex manifold whose boundary is p disjoint circles.

Making the metric a product near the boundary. Choose a local complex coordinate z_i on a neighbourhood of each D_i with $z_i = 0$ at its centre, and let $D_i = \{|z_i| < \rho\}$. Near ∂D_i choose the metric [Nash (4.166)]

$$\mathrm{d}s^2 = \left|\frac{\mathrm{d}z_i}{z_i}\right|^2 = \frac{\mathrm{d}r_i^2}{r_i^2} + \mathrm{d}\theta_i^2 = (\mathrm{d}\ln r_i)^2 + \mathrm{d}\theta_i^2, \tag{4.235}$$

using $z_i = r_i e^{i\theta_i}$ and $\mathrm{d}z/z = \mathrm{d}r/r + i\,\mathrm{d}\theta$. In the coordinate $n = \ln(r_i/\rho)$ this is $\mathrm{d}n^2 + \mathrm{d}\theta^2$: a flat cylinder of circumference 2π, i.e. a product. The metric is singular at $z_i = 0$ (the cylinder is infinitely long there), but $z_i = 0$ is not in X, so on X it is perfectly regular. Glue it to any metric on the rest of X (Figure 4.82).

The operator near each boundary circle. As in the flux disc (now with $\alpha = 0$ and X on the *outside* of D_i, so the inward normal is $\partial_n = r\partial_r$):

$$\bar\partial \overset{(1)}{=} \frac{e^{i\theta}}{2}\left(\frac{\partial}{\partial r} + \frac{i}{r}\frac{\partial}{\partial\theta}\right) \overset{(2)}{=} \frac{e^{i\theta}}{2r}\left(\frac{\partial}{\partial n} + i\frac{\partial}{\partial\theta}\right), \tag{4.236}$$

(1) Polar form of $\partial_{\bar z}$, Nash's (4.167).
(2) $r\partial_r = \partial_n$.

So $A = \frac{e^{i\theta}}{2r}$ and $L = i\,\partial_\theta$ on each circle.

Watch out: Nash's $-\frac{i}{r}\partial_\theta$

Nash writes the tangential operator as $(-i/r)\partial/\partial\theta$. The factor $1/r$ disappears once one uses the arc-length normal coordinate $n = \ln r$ of the product metric (4.235), as the normal form (4.230) requires; the overall sign depends on which way the normal points and on how $\Omega^{0,1}$ is identified with functions. None of this matters here: the spectrum is $\mathbb{Z}$ either way.

The boundary invariants. $L = i\partial_\theta$ has eigenfunctions $e^{-ik\theta}$ with eigenvalues $k \in \mathbb{Z}$ (the $t = 0$ case of (4.223)). Its only zero mode is the constant, so $h = 1$ for each circle. The nonzero eigenvalues $\pm1, \pm2, \dots$ pair off, so $\eta(s) \equiv 0$ and $\eta(0) = 0$. Each of the p circles contributes the same $\frac{1}{2}(h + \eta(0)) = \frac{1}{2}$.

The bulk term. For $\bar\partial$ on functions the local index density is the Todd form, $P = \mathrm{td}(X)$ (Chapter 4), whose top component in complex dimension one is [Nash (4.169)]

$$\mathrm{td}(X) = 1 + \frac{c_1(X)}{2}, \qquad c_1(X) = e(X)$$

(the top Chern class of a complex manifold is its Euler class). So [Nash (4.168), (4.170)]

$$\operatorname{index}\bar\partial = \int_X \mathrm{td}(X) - p\,\frac{h + \eta(0)}{2} = \frac{1}{2}\int_X e(X) - \frac{p}{2}. \tag{4.237}$$

The Euler integral by Gauss–Bonnet. Nash computes $\int_X e$ by putting the discs back [Nash (4.171)–(4.173)]. Extend the metric of X over each D_i, so that $\Sigma_g = X \cup \bigcup D_i$ has a smooth metric (cap each cylindrical collar with a hemisphere, as in the test tube of Figure 4.74). Then

$$\begin{aligned}\int_X e(X) &\overset{(1)}{=} \int_{\Sigma_g} e(\Sigma_g) - \sum_{i=1}^{p}\int_{D_i} e(D_i) \overset{(2)}{=} (2-2g) - \sum_{i=1}^{p}\Big(\chi(D_i) - \oint_{\partial D_i}\frac{k_g}{2\pi}\,\mathrm{d}s\Big)\\ &\overset{(3)}{=} (2-2g) - \sum_{i=1}^{p}(1-0) \overset{(4)}{=} 2 - 2g - p.\end{aligned}$$

(1) The integral over Σ_g is the sum of the integrals over the pieces, [Nash (4.171)].
(2) Gauss–Bonnet on the closed Σ_g [Nash (4.172)] and with boundary on each D_i, (4.206) = [Nash (4.173)].
(3) $\chi(D_i) = 1$, and ∂D_i is a geodesic of the product collar, so $k_g = 0$.
(4) Sum.

(This is also $\chi(X)$, directly by (4.207): removing a disc lowers the Euler characteristic by one.) Putting it into (4.237) [Nash (4.174)]:

$$\operatorname{index}\bar\partial \overset{(1)}{=} \frac{1}{2}\big(\chi(\Sigma_g) - p\,\chi(D_i)\big) - \frac{p}{2}\,h \overset{(2)}{=} \frac{1}{2}(2-2g-p) - \frac{p}{2} \overset{(3)}{=} 1 - g - p. \tag{4.238}$$

(1) The Euler integral just computed, and $\eta(0) = 0$.
(2) $\chi(\Sigma_g) = 2 - 2g$, $\chi(D_i) = 1$, $h = 1$.
(3) Arithmetic.

Worked example 4.142: Checking $1 - g - p$ by hand on a cylinder

Take $g = 0$, $p = 2$: the sphere minus two discs is an annulus, and with the metric (4.235) it is exactly the flat cylinder $[0, \ell] \times S^1$ with coordinate $w = u + i\theta$, where $u = \ln r$. The formula predicts $\operatorname{index}\bar\partial = 1 - 0 - 2 = -1$. Directly: on the cylinder $\bar\partial = \partial_{\bar w} = \frac{1}{2}(\partial_u + i\partial_\theta)$. *Kernel*:

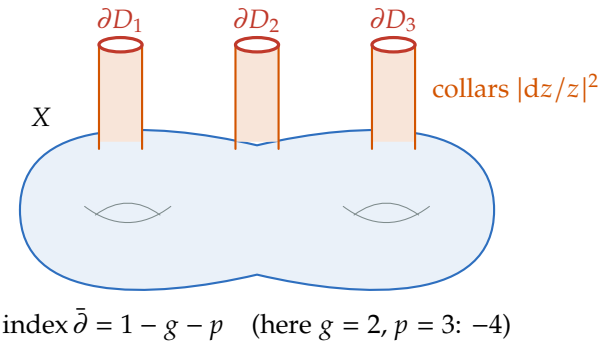

Figure 4.82: Nash's example: a genus-g surface with p discs removed. The metric $|dz_i/z_i|^2$ turns a neighbourhood of each hole into a flat cylinder (orange), so the product-collar hypothesis of the APS theorem holds. Each boundary circle has $L = i\partial_\theta$ with $h = 1$, $\eta = 0$ and contributes $-\frac{1}{2}$; the bulk Todd integral contributes $\frac{1}{2}\chi(X) = \frac{1}{2}(2 - 2g - p)$.

holomorphic functions $\sum_k c_k e^{kw} = \sum_k c_k e^{ku} e^{ik\theta}$. At the end $u = 0$ the inward normal is $+\partial_u$ and $L = i\partial_\theta$, with eigenvalue $-k$ on $e^{ik\theta}$; APS needs $-k < 0$, i.e. $k > 0$. At $u = \ell$ the inward normal is $-\partial_u$, $L = -i\partial_\theta$, eigenvalue k; APS needs $k < 0$. No k satisfies both, so $\operatorname{Ker}\bar\partial = 0$. *Cokernel*: identifying $(0,1)$-forms with functions, the adjoint is $-\partial_w$, with antiholomorphic solutions $\sum_k d_k e^{k\bar w}$. The complementary conditions now keep boundary data with eigenvalue ≥ 0 at each end: $k \leq 0$ at one end and $k \geq 0$ at the other. Only $k = 0$, the constant, survives. So $\dim\operatorname{Coker} = 1$ and the index is -1 ✓. The single cokernel element is the constant: it is "half-killed" at each end by the zero mode of L, which is the $-\frac{h}{2} - \frac{h}{2} = -1$ of the formula (the bulk is flat, $\int \mathrm{td} = 0$).
For $g = 0$, $p = 1$ the formula gives 0, which is the $\alpha = 0$ case of Example 4.141.

Physical picture: What each hole does to Riemann–Roch

On the closed surface Σ_g, Riemann–Roch gives $\operatorname{index}\bar\partial = \dim H^0 - \dim H^1 = 1 - g$ (Chapter 4). Each hole lowers the index by exactly one, and the formula splits that unit into two equal halves: $\frac{1}{2}$ from the bulk (removing a disc lowers χ by one, and the Todd density is $\frac{1}{2}e$) and $\frac{1}{2}$ from the zero mode of the new boundary circle. No eta invariant appears, because the round circle with no flux has a symmetric spectrum. Adding a flux through a hole (Example 4.141) is what switches η on.

4.21.8 Which indices need a boundary correction?

Nash makes a short but important remark [Nash p. 133]. For the signature operator the boundary corrections are genuinely there: the eta invariant of the boundary is in general nonzero. For the Euler characteristic, on the other hand, we saw in (4.207) that a product metric makes the bulk formula exact, with no correction at all. Nash adds that this persists in higher dimensions, and draws the conclusion that "the index of the de Rham complex does not depend on non-local boundary conditions". Why should the two complexes behave so differently? There are two separate reasons, and both are worth seeing concretely.

- *The de Rham complex admits local boundary conditions.* The topological obstruction of Section 4.21.1 vanishes for it, and there are two natural local elliptic conditions, called **absolute** and **relative**. Their indices are the Euler characteristics $\chi(X)$ and $\chi(X, \partial X)$.
- *Even with the APS condition, no eta invariant appears*: the boundary operator of the de Rham

complex has a spectrum that is symmetric under $\lambda \to -\lambda$, so $\eta \equiv 0$ and only the integer h survives.

The signature operator has neither property. We now check both statements by explicit computation.

Absolute and relative conditions on an interval

Working definition 4.63 (absolute and relative boundary conditions)

Near ∂X write a form as $\omega = \omega_{\tan} + \mathrm{d}n \wedge \omega_{\mathrm{nor}}$, where neither piece contains $\mathrm{d}n$ [n is the normal distance from the boundary].

- **Relative** (Dirichlet-type) condition: the tangential part vanishes on the boundary, $\omega_{\tan}|_{\partial X} = 0$ (and the same for $\mathrm{d}^*\omega$). For functions it is $f|_{\partial X} = 0$.
- **Absolute** (Neumann-type) condition: the normal part vanishes, $\omega_{\mathrm{nor}}|_{\partial X} = 0$ (and the same for $\mathrm{d}\omega$). For functions it is $\partial_n f|_{\partial X} = 0$.

Both are *local*: they are pointwise linear conditions on the boundary values. With them, the harmonic forms compute $H^p(X, \partial X)$ [closed forms whose tangential part vanishes on ∂X, modulo d of such forms] (relative) and $H^p(X)$ (absolute), so $\mathrm{index}_{\mathrm{rel}}(\mathrm{d}+\mathrm{d}^*) = \chi(X, \partial X)$ [$\sum_p (-1)^p \dim H^p(X, \partial X)$] and $\mathrm{index}_{\mathrm{abs}}(\mathrm{d}+\mathrm{d}^*) = \chi(X)$.

The relative Euler characteristic is computed from the exact sequence of the pair, which gives $\chi(X, \partial X) = \chi(X) - \chi(\partial X)$. In even dimensions ∂X is a closed odd-dimensional manifold, so $\chi(\partial X) = 0$ and the two answers agree. In odd dimensions they differ.

Worked example 4.143: The Euler operator on an interval, three ways

Let $X = [0, 1]$. Even forms are functions f and odd forms are $g\,\mathrm{d}x$, so the Euler operator is simply

$$D = \mathrm{d} + \mathrm{d}^* : \ \Omega^0 \to \Omega^1, \qquad Df = f'\,\mathrm{d}x, \qquad D^*(g\,\mathrm{d}x) = -g'.$$

Near $x = 0$ the inward normal is $n = x$, so $D = \partial_n + 0$: $A = 1$ and the boundary operator is $L_0 = 0$ on the one-dimensional space of values at the point. Near $x = 1$, $n = 1 - x$ and $D = -(\partial_n - 0)$: again $L_1 = 0$. So each end has $h = 1$ and $\eta = 0$.
Absolute condition ($f'(0) = f'(1) = 0$ for f; the normal part $g\,\mathrm{d}x$ must vanish, $g(0) = g(1) = 0$). Kernel: $f' = 0$, so f is constant; this satisfies $f' = 0$ at the ends, $\dim \mathrm{Ker} = 1$. Cokernel: $g' = 0$ with $g(0) = 0$ forces $g = 0$. Index $= 1 - 0 = 1 = \chi([0, 1])$.
Relative condition ($f(0) = f(1) = 0$; no condition on g). Kernel: constant f with $f(0) = 0$ is zero. Cokernel: $g' = 0$, g constant, allowed. Index $= 0 - 1 = -1 = \chi([0, 1]) - \chi(\{0, 1\}) = 1 - 2$.
APS condition. Π projects onto $\lambda \geq 0$, which includes the zero mode, so $\Pi(f|_{\partial X}) = 0$ means $f(0) = f(1) = 0$: here APS coincides with the relative condition, and the index is -1. The APS theorem (4.233) agrees:

$$\mathrm{index}_{\mathrm{APS}}\, D \overset{(1)}{=} \int_{[0,1]} P - \frac{h_0 + \eta(L_0)}{2} - \frac{h_1 + \eta(L_1)}{2} \overset{(2)}{=} 0 - \frac{1+0}{2} - \frac{1+0}{2} = -1.$$

(1) The APS formula with one boundary term for each end point.
(2) In one dimension there is no local index density ($e(X) = 0$ in odd dimensions); each end has $L = 0$, so $h = 1$ and $\eta = 0$.

All three indices are integers built from h alone. No eta invariant enters, because a 1×1 zero matrix has a symmetric spectrum.

The boundary operator of the Euler operator on a surface

In two dimensions we can write the boundary operator out completely. Take a product collar with coordinates (n, θ), metric $\mathrm{d}n^2 + \mathrm{d}\theta^2$, orientation $\mathrm{d}n \wedge \mathrm{d}\theta$. The Euler operator maps even forms to odd forms:

$$D = \mathrm{d} + \mathrm{d}^* : \Omega^0 \oplus \Omega^2 \to \Omega^1, \qquad (f,\ g\,\mathrm{d}n \wedge \mathrm{d}\theta) \mapsto \mathrm{d}f + \mathrm{d}^*(g\,\mathrm{d}n \wedge \mathrm{d}\theta).$$

In two dimensions $\mathrm{d}^* = - \star \mathrm{d} \star$, and $\star \mathrm{d}n = \mathrm{d}\theta$, $\star \mathrm{d}\theta = -\mathrm{d}n$, $\star(\mathrm{d}n \wedge \mathrm{d}\theta) = 1$. So

$$\mathrm{d}^*(g\,\mathrm{d}n \wedge \mathrm{d}\theta) \overset{(1)}{=} - \star\, \mathrm{d}g \overset{(2)}{=} - \star \left(g_n\,\mathrm{d}n + g_\theta\,\mathrm{d}\theta\right) \overset{(3)}{=} -g_n\,\mathrm{d}\theta + g_\theta\,\mathrm{d}n,$$

(1) $\mathrm{d}^* = - \star \mathrm{d} \star$ on a surface, and $\star(g\,\mathrm{d}n \wedge \mathrm{d}\theta) = g$.
(2) Expand $\mathrm{d}g$; subscripts are partial derivatives.
(3) $\star \mathrm{d}n = \mathrm{d}\theta$ and $\star \mathrm{d}\theta = -\mathrm{d}n$.

and $D(f, g) = (f_n + g_\theta)\,\mathrm{d}n + (f_\theta - g_n)\,\mathrm{d}\theta$. Record a 1-form by its components (a, b) along $(\mathrm{d}n, \mathrm{d}\theta)$. Then

$$D \begin{pmatrix} f \\ g \end{pmatrix} \overset{(1)}{=} \begin{pmatrix} \partial_n & \partial_\theta \\ \partial_\theta & -\partial_n \end{pmatrix} \begin{pmatrix} f \\ g \end{pmatrix} \overset{(2)}{=} \underbrace{\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}}_{A} \left(\partial_n + \underbrace{\begin{pmatrix} 0 & \partial_\theta \\ -\partial_\theta & 0 \end{pmatrix}}_{L} \right) \begin{pmatrix} f \\ g \end{pmatrix}. \tag{4.239}$$

(1) Read off the components of $D(f, g)$.
(2) Factor out $A = \mathrm{diag}(1, -1)$, using $A^{-1} = A$: $A \begin{pmatrix} 0 & \partial_\theta \\ -\partial_\theta & 0 \end{pmatrix} = \begin{pmatrix} 0 & \partial_\theta \\ \partial_\theta & 0 \end{pmatrix}$.

L is self-adjoint on the circle: ∂_θ is anti-self-adjoint, and transposing the matrix while taking adjoints of the entries returns L. On a Fourier mode $e^{ik\theta}$,

$$L = \begin{pmatrix} 0 & ik \\ -ik & 0 \end{pmatrix} = -k\,\sigma_y, \qquad \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix},$$

with eigenvalues $\pm k$. So the spectrum of L is $\{\pm k :\ k \in \mathbb{Z}\}$, perfectly symmetric: $\eta_L(s) = 0$ for all s. The zero modes are the two constant vectors at $k = 0$, so $h = 2$.

Key idea: Why the de Rham boundary operator is symmetric

In (4.239) the matrix $\sigma_z = \mathrm{diag}(1, -1)$ anticommutes with L (it anticommutes with σ_y). So if $L\phi = \lambda\phi$ then $L(\sigma_z\phi) = -\lambda\,\sigma_z\phi$: every eigenvalue comes with its negative, and $\eta_L \equiv 0$. Geometrically σ_z is the *parity of the form degree on the boundary*: f restricts to a 0-form on ∂X and g corresponds to the 1-form $g\,\mathrm{d}\theta$. The same is true in every dimension: the boundary operator of $\mathrm{d} + \mathrm{d}^*$ is built from $\mathrm{d} + \mathrm{d}^*$ of ∂X, which exchanges even and odd forms, so $(-1)^{\text{degree}}$ anticommutes with it. The signature operator is different, because its bundles $\Omega^\pm$ are defined with the Hodge star, and the boundary operator has no such symmetry.

With this, the APS theorem for the Euler operator on a surface with p boundary circles and a product collar reads

$$\mathrm{index}_{\mathrm{APS}}(\mathrm{d} + \mathrm{d}^*) \overset{(1)}{=} \int_X e(X) - p\,\frac{h + \eta(0)}{2} \overset{(2)}{=} \chi(X) - p.$$

(1) (4.233) with the Euler density $P = e(X)$, one boundary term per circle.
(2) Gauss–Bonnet for a product collar (4.207); $h = 2$ and $\eta = 0$ for each circle.

The APS answer differs from the local answers $\chi(X) = \chi(X, \partial X)$ only by the integer p, which records the zero modes. There is no spectral asymmetry to correct for, and nothing depends on the geometry of the boundary. That is the content of Nash's remark.

Worked example 4.144: The signature operator on a 3-manifold boundary is asymmetric

For a 4-manifold with boundary Y, the boundary operator of d_+ is, on the even forms of Y and up to a sign convention,

$$B^{\mathrm{ev}}\phi = (-1)^p\big(\star\mathrm{d} - \mathrm{d}\star\big)\phi, \qquad \phi \in \Omega^{2p}(Y),$$

which is often called the **odd signature operator**. Its interesting part is $\star\mathrm{d}$ acting on co-exact 1-forms of Y (the other pieces pair off symmetrically). The operator $\star\mathrm{d}$ on a 3-manifold is the *curl*: for $Y = \mathbb{R}^3$ and a 1-form $\alpha = \vec{a}\cdot\mathrm{d}\vec{x}$, $\star\mathrm{d}\alpha = (\nabla\times\vec{a})\cdot\mathrm{d}\vec{x}$. Its eigenfields are Beltrami fields, $\nabla\times\vec{a} = \lambda\vec{a}$, and there is no reason for right-handed and left-handed eigenfields to come in equal numbers. For the round S^3 the spectrum *is* symmetric (an orientation-reversing isometry exists), so $\eta = 0$, consistent with $\mathrm{Sign}(B^4) = 0$. For lens spaces $L(p,q) = S^3/\mathbb{Z}_p$ APS computed (in their second paper) a finite trigonometric sum: in one common convention

$$\eta\big(L(p,q)\big) = -\frac{1}{p}\sum_{k=1}^{p-1}\cot\frac{\pi k}{p}\,\cot\frac{\pi k q}{p}.$$

For $p = 2$ ($\mathbb{RP}^3$) every term has $\cot\frac{\pi}{2} = 0$, so $\eta = 0$. For $L(3,1)$, $\cot^2\frac{\pi}{3} = \cot^2\frac{2\pi}{3} = \frac{1}{3}$ gives $\eta = -\frac{1}{3}\cdot\frac{2}{3} = -\frac{2}{9}$: a genuinely nonzero, and non-integer, spectral asymmetry. So for the signature operator the correction $-\frac{1}{2}\eta$ really is there.

Watch out: Two different reasons for "no correction"

Do not confuse the two mechanisms. The Gauss–Bonnet formula (4.207) with no boundary term uses *local* boundary conditions and a product metric: the local boundary contribution (geodesic curvature) vanishes. The APS index of $\mathrm{d}+\mathrm{d}^*$ uses the *global* condition and has the integer correction $-\frac{h}{2}$ per boundary component, but no η. In both cases the answer is independent of the metric on the boundary, which is the point.

4.21.9 Where eta comes from: the heat kernel on the collar

We have stated the APS theorem and checked it on examples. We now show where the $-\frac{1}{2}(h+\eta)$ actually comes from. The argument is the heat-kernel proof of Chapter 4 (McKean–Singer), with one new ingredient: an exactly solvable model for the collar. It is the proof APS gave, stripped to its essentials.

The strategy

Let $D = \partial_u + L$ on the collar, where $u \geq 0$ is the inward normal coordinate (we take $A = 1$; a unitary A changes nothing below). With the APS condition, the nonzero eigenvalues of D^*D and DD^* still pair up (D maps an eigenvector of D^*D in the domain to an eigenvector of DD^* in the adjoint domain). So McKean–Singer still holds:

$$\mathrm{index}\,D = \mathrm{Tr}\,e^{-tD^*D} - \mathrm{Tr}\,e^{-tDD^*} \qquad \text{for every } t > 0. \tag{4.240}$$

Now let $t \to 0$. The heat kernel only sees a neighbourhood of size $\sqrt{t}$ of each point, so the trace splits into two kinds of contribution:

- *interior points*, where the kernel is the same as on a closed manifold, and the $t \to 0$ limit of the local supertrace is the index density P (Chapter 4);

- *points within $\sqrt{t}$ of the boundary*, where the kernel feels the boundary condition. Here the collar is exactly the product $[0,\varepsilon)\times\partial X$ with $D=\partial_u+L$, so the kernel is (up to exponentially small errors) that of the half-infinite cylinder $[0,\infty)\times\partial X$ with the APS condition at $u=0$.

The first gives $\int_X P$. On the cylinder the local density vanishes, because $D^*D=-\partial_u^2+L^2=DD^*$ as differential operators there (L does not depend on u), so everything new comes from the boundary condition. We compute that exactly.

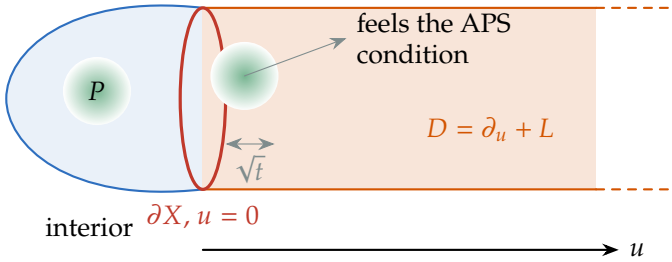

Figure 4.83: The heat-kernel proof of the APS theorem. For small t the heat kernel spreads over a distance $\sqrt{t}$. Deep inside X it cannot tell that there is a boundary, and the local supertrace tends to the index density P. Near ∂X it feels the boundary condition; there the collar is a product, and the problem reduces to one-dimensional problems $\partial_u+\lambda$ on a half-line, one for each eigenvalue λ of L.

One mode on a half-line

Expand in eigenvectors of L: $\phi(u,y)=\sum_\lambda f_\lambda(u)\psi_\lambda(y)$ with $L\psi_\lambda=\lambda\psi_\lambda$. Then D acts on each coefficient as the ordinary differential operator

$$D_\lambda=\frac{\mathrm{d}}{\mathrm{d}u}+\lambda \quad \text{on } [0,\infty), \qquad D_\lambda^*=-\frac{\mathrm{d}}{\mathrm{d}u}+\lambda.$$

The adjoint comes from an integration by parts, which also tells us what boundary condition the adjoint must carry:

$$\langle D_\lambda f,g\rangle \overset{(1)}{=} \int_0^\infty (f'+\lambda f)\bar g\,\mathrm{d}u \overset{(2)}{=} \big[f\bar g\big]_0^\infty+\int_0^\infty f\,\overline{(-g'+\lambda g)}\,\mathrm{d}u \overset{(3)}{=} -f(0)\bar g(0)+\langle f,D_\lambda^* g\rangle.$$

(1) Definition of the L^2 inner product, λ real.
(2) Integrate $f'\bar g$ by parts.
(3) Square-integrable functions vanish at $u=\infty$.

So the boundary term $f(0)\bar g(0)$ must vanish: if the condition on f fixes $f(0)=0$, then $g(0)$ is free, and if $f(0)$ is free, then $g(0)=0$.

The APS condition kills the components with $\lambda\ge 0$. Combining, the domains of $D_\lambda^*D_\lambda$ and $D_\lambda D_\lambda^*$ (both equal to $-\mathrm{d}^2/\mathrm{d}u^2+\lambda^2$ in the interior) are:

	$D_\lambda^*D_\lambda$ (acts on f)	$D_\lambda D_\lambda^*$ (acts on g)
$\lambda>0$	$f(0)=0$ (Dirichlet)	$(-g'+\lambda g)(0)=0$ (Robin, $g'=\lambda g$)
$\lambda=0$	$f(0)=0$ (Dirichlet)	$g'(0)=0$ (Neumann)
$\lambda<0$	$(f'+\lambda f)(0)=0$ (Robin, $f'=\lvert\lambda\rvert f$)	$g(0)=0$ (Dirichlet)

(The second condition in each entry is "$D_\lambda f$ lies in the domain of D_λ^*", respectively "$D_\lambda^* g$ lies in the domain of D_λ".) Define the *boundary defect* of one mode,

$$F_\lambda(t) = \operatorname{Tr} e^{-tD_\lambda^* D_\lambda} - \operatorname{Tr} e^{-tD_\lambda D_\lambda^*},$$

the difference of the two heat traces on the half-line. Neither trace is finite (the half-line is infinite), but their difference is, because far from $u = 0$ both kernels are the same free kernel.

Worked example 4.145: The defect of a zero mode is exactly $-\frac{1}{2}$

For $\lambda = 0$ we need Dirichlet minus Neumann on the half-line. The method of images gives both kernels from the free kernel $G_t(x) = (4\pi t)^{-1/2} e^{-x^2/4t}$: $K_t^{D/N}(u,u') = G_t(u-u') \mp G_t(u+u')$ (an image of opposite or equal sign at $-u'$). So

$$F_0(t) \overset{(1)}{=} \int_0^\infty \big(K_t^D(u,u) - K_t^N(u,u)\big)\,\mathrm{d}u \overset{(2)}{=} -2\int_0^\infty G_t(2u)\,\mathrm{d}u$$
$$\overset{(3)}{=} -\frac{2}{\sqrt{4\pi t}}\int_0^\infty e^{-u^2/t}\,\mathrm{d}u \overset{(4)}{=} -\frac{2}{\sqrt{4\pi t}}\cdot\frac{\sqrt{\pi t}}{2} = -\frac{1}{2}.$$

(1) A trace is the integral of the kernel on the diagonal.
(2) The direct terms $G_t(0)$ cancel; the image terms give $-G_t(2u) - G_t(2u)$.
(3) $G_t(2u) = (4\pi t)^{-1/2} e^{-4u^2/4t}$.
(4) The half Gaussian integral $\int_0^\infty e^{-u^2/t}\mathrm{d}u = \frac{1}{2}\sqrt{\pi t}$.

The answer does not depend on t. It is "half a state": the constant function is a bounded (not normalisable) solution of $D_0 g = 0$ sitting exactly on the fence, and the Neumann problem has half a state more than the Dirichlet problem.

For $\lambda \neq 0$ the Robin condition makes the image method awkward, and a physicist's tool is quicker: count states in a large box and use **phase shifts**. Take $\lambda > 0$. Scattering states of $-\partial_u^2 + \lambda^2$ with energy $k^2 + \lambda^2$ are

$$\text{Dirichlet: } \sin ku = \cos\big(ku - \tfrac{\pi}{2}\big), \qquad \text{Robin: } \cos ku + \frac{\lambda}{k}\sin ku \;\propto\; \cos\big(ku - \delta(k)\big), \quad \tan\delta(k) = \frac{\lambda}{k}.$$

(Check the Robin state: at $u = 0$ its value is 1 and its slope is λ, so $g' = \lambda g$.) Put both problems in a large box $[0, R]$ and impose, for both, that the wave function vanishes at the far end $u = R$. The Dirichlet states need $\sin kR = 0$, i.e. $kR = \pi m$; the Robin states need $\cos(kR - \delta) = 0$, i.e. $kR - \delta(k) = \pi(m - \frac{1}{2})$, with $m = 1, 2, \ldots$ in both cases. So the numbers of states with momentum below k are

$$N_D(k) \approx \frac{kR}{\pi}, \qquad N_R(k) \approx \frac{kR - \delta(k)}{\pi} + \frac{1}{2}, \qquad N_D(k) - N_R(k) \approx \frac{\delta(k)}{\pi} - \frac{1}{2}.$$

The R-dependence cancels in the difference, and differentiating in k gives the difference of the densities of states:

$$\rho_D(k) - \rho_R(k) = \frac{1}{\pi}\frac{\mathrm{d}\delta}{\mathrm{d}k} = \frac{1}{\pi}\frac{\mathrm{d}}{\mathrm{d}k}\arctan\frac{\lambda}{k} = -\frac{1}{\pi}\frac{\lambda}{k^2 + \lambda^2}. \tag{4.241}$$

This is the one-dimensional **Friedel sum rule** (or Levinson's theorem): a boundary condition acts like a scatterer, and it changes the density of states by $\frac{1}{\pi}$ times the derivative of the phase shift. Now

$$F_\lambda(t) \overset{(1)}{=} \int_0^\infty \big(\rho_D(k) - \rho_R(k)\big)e^{-t(k^2+\lambda^2)}\,\mathrm{d}k \overset{(2)}{=} -\frac{\lambda}{\pi}\int_0^\infty \frac{e^{-t(k^2+\lambda^2)}}{k^2 + \lambda^2}\,\mathrm{d}k. \tag{4.242}$$

(1) A heat trace is $\sum e^{-tE}$ over states, i.e. $\int \rho(k) e^{-tE(k)} \mathrm{d}k$. (There are no bound states: $e^{\lambda u}$ is not normalisable.)
(2) (4.241).

Two values are easy. At $t = 0$, $F_\lambda(0) = -\frac{\lambda}{\pi} \cdot \frac{\pi}{2\lambda} = -\frac{1}{2}$, using $\int_0^\infty \frac{\mathrm{d}k}{k^2+\lambda^2} = \frac{\pi}{2\lambda}$. As $t \to \infty$, $F_\lambda \to 0$. In between, differentiate:

$$\frac{\mathrm{d}F_\lambda}{\mathrm{d}t} \overset{(1)}{=} \frac{\lambda}{\pi} \int_0^\infty e^{-t(k^2+\lambda^2)}\, \mathrm{d}k \overset{(2)}{=} \frac{\lambda}{\pi} e^{-t\lambda^2} \frac{1}{2}\sqrt{\frac{\pi}{t}} = \frac{\lambda\, e^{-t\lambda^2}}{2\sqrt{\pi t}}.$$

(1) Differentiating e^{-tE} brings down $-E = -(k^2 + \lambda^2)$, which cancels the denominator.
(2) The half Gaussian integral.

The **complementary error function** $\operatorname{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-y^2} \mathrm{d}y$ has $\frac{\mathrm{d}}{\mathrm{d}t} \operatorname{erfc}(\lambda\sqrt{t}) = -\frac{\lambda e^{-\lambda^2 t}}{\sqrt{\pi t}}$ (chain rule, $\lambda > 0$). Comparing derivatives and the value at $t = \infty$ gives $F_\lambda(t) = -\frac{1}{2}\operatorname{erfc}(\lambda\sqrt{t})$ for $\lambda > 0$.

For $\lambda < 0$ the table shows that the roles are swapped: now $D_\lambda^* D_\lambda$ is the Robin problem with parameter $|\lambda|$ and $D_\lambda D_\lambda^*$ is Dirichlet. So F_λ is minus the previous answer with $\lambda \to |\lambda|$, i.e. $+\frac{1}{2}\operatorname{erfc}(|\lambda|\sqrt{t})$. All three cases are one formula:

$$F_\lambda(t) = \begin{cases} -\frac{1}{2}\operatorname{sgn}(\lambda)\, \operatorname{erfc}\big(|\lambda|\sqrt{t}\big), & \lambda \neq 0, \\ -\frac{1}{2}, & \lambda = 0. \end{cases} \tag{4.243}$$

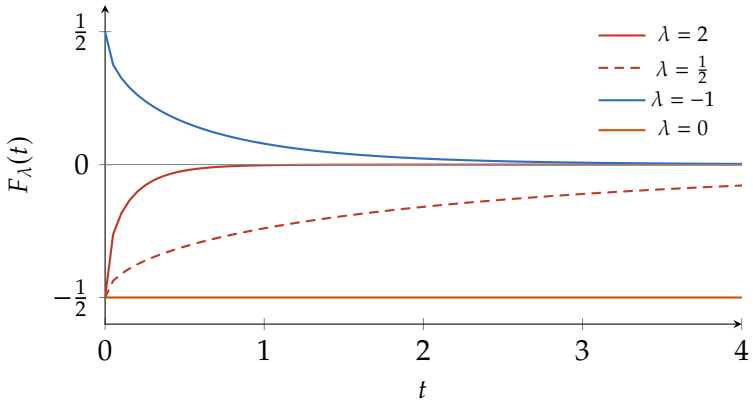

Figure 4.84: The boundary defect $F_\lambda(t)$ of a single mode of L, (4.243). At $t \to 0$ every nonzero mode contributes $-\frac{1}{2}\operatorname{sgn}\lambda$; as t grows the contribution dies off on the time scale $1/\lambda^2$, so large $|\lambda|$ (short wavelength) modes die first. A zero mode (orange) contributes $-\frac{1}{2}$ for all t. The sum over all modes at $t \to 0$ is the regularised $-\frac{1}{2}\sum \operatorname{sgn}\lambda$, i.e. $-\frac{1}{2}\eta(0)$.

Summing the modes: the eta invariant appears

Summing (4.243) over the spectrum of L gives the total boundary contribution to (4.240). For fixed $t > 0$ the sum converges, because $\operatorname{erfc}(|\lambda|\sqrt{t})$ decays like a Gaussian in λ. To take $t \to 0$, rewrite each term as an integral over the heat time:

$$\sum_{\lambda\neq 0} \operatorname{sgn}(\lambda) \operatorname{erfc}\big(|\lambda|\sqrt{t}\big) \overset{(1)}{=} \sum_{\lambda\neq 0} \operatorname{sgn}(\lambda) \int_t^\infty \frac{|\lambda|\, e^{-\lambda^2\tau}}{\sqrt{\pi\tau}}\, \mathrm{d}\tau \overset{(2)}{=} \frac{1}{\sqrt{\pi}} \int_t^\infty \tau^{-1/2} \operatorname{Tr}\big(L\, e^{-\tau L^2}\big)\, \mathrm{d}\tau$$
$$\xrightarrow{t\to 0} \frac{1}{\sqrt{\pi}} \int_0^\infty \tau^{-1/2} \operatorname{Tr}\big(L\, e^{-\tau L^2}\big)\, \mathrm{d}\tau \overset{(3)}{=} \eta_L(0). \tag{4.244}$$

(1) $\operatorname{erfc}(|\lambda|\sqrt{t}) = -\int_t^\infty \frac{\mathrm{d}}{\mathrm{d}\tau}\operatorname{erfc}(|\lambda|\sqrt{\tau})\,\mathrm{d}\tau$ and the derivative computed above; $\operatorname{erfc}(\infty) = 0$.
(2) $\operatorname{sgn}(\lambda)|\lambda| = \lambda$, and $\sum_\lambda \lambda e^{-\lambda^2\tau} = \operatorname{Tr}(Le^{-\tau L^2})$ (zero modes contribute nothing).
(3) The heat-kernel formula (4.222) for $\eta(0)$, valid because the integral converges at $\tau = 0$ (Section 4.21.12).

Putting the pieces into (4.240):

$$\begin{aligned}\operatorname{index} D &\overset{(1)}{=} \lim_{t\to 0}\left(\operatorname{Tr} e^{-tD^*D} - \operatorname{Tr} e^{-tDD^*}\right) \overset{(2)}{=} \int_X P + \lim_{t\to 0}\sum_\lambda F_\lambda(t) \\ &\overset{(3)}{=} \int_X P - \frac{h}{2} - \frac{1}{2}\lim_{t\to 0}\sum_{\lambda\neq 0}\operatorname{sgn}(\lambda)\operatorname{erfc}\left(|\lambda|\sqrt{t}\right) \overset{(4)}{=} \int_X P - \frac{h+\eta_L(0)}{2}.\end{aligned} \tag{4.245}$$

(1) McKean–Singer (4.240): the right side does not depend on t, so we may take any limit.
(2) Interior points give the local index density; the collar gives the half-line defects, one for each eigenvalue of L (errors are $O(e^{-c/t})$).
(3) (4.243): each of the h zero modes gives $-\frac{1}{2}$.
(4) (4.244).

This is the APS theorem (4.233).

Physical picture: What the proof says in words

Each eigenmode of the boundary operator is a little one-dimensional scattering problem. Positive and negative modes are scattered by the APS condition in opposite ways and change the "number of states" of D^*D relative to DD^* by $\mp\frac{1}{2}$. If the spectrum were symmetric, these half-states would cancel. The eta invariant is precisely the net, regularised count of the uncancelled half-states, and the zero modes each leave one half-state behind. The index, being an honest integer count, is the bulk density plus this boundary bookkeeping.

Watch out: What is and is not proved here

The sketch hides two technical points. First, one must show that the APS problem is Fredholm and that (4.240) holds; this is where the spectral projection is essential (a local condition would not make the half-line problems decouple mode by mode). Second, the claim that the interior and collar contributions simply add, with exponentially small error, uses a patching argument (Duhamel's principle). Both are standard and are carried out in APS I; nothing in them changes the answer.

Try it: Why $\mp\frac{1}{2}$ at short times

Explain without any integrals why $F_\lambda(t) \to -\frac{1}{2}\operatorname{sgn}\lambda$ as $t \to 0$. *Answer:* at short times the heat kernel explores only a distance $\sqrt{t}$ from the wall, over which the Robin condition $g' = \lambda g$ is indistinguishable from $g' = 0$ (the term λg is smaller than $g' \sim g/\sqrt{t}$ by a factor $|\lambda|\sqrt{t}$). So for $\lambda > 0$ the defect is Dirichlet minus Neumann, which is $-\frac{1}{2}$ by Example 4.145, and for $\lambda < 0$ it is Neumann minus Dirichlet, $+\frac{1}{2}$. Only the *sign* of λ decides which side of the pair carries the Dirichlet condition.

4.21.10 Spectral flow

The sawtooth of Figure 4.78 showed that η has two kinds of dependence on a parameter: a smooth drift, and jumps by 2 when an eigenvalue crosses zero. The jumps are integers and are

therefore topological. Counting them is so useful that it has its own name. This is not in Nash's Chapter IV, but it is the form in which the APS theorem is most often used in physics (and it is behind the families picture of Section 4.18 for self-adjoint operators).

Working definition 4.64 (spectral flow)

Let L_u, $0 \le u \le 1$, be a continuous family of self-adjoint elliptic operators. Their eigenvalues are continuous functions of u (draw them as curves). The **spectral flow** $\mathrm{SF}(L_u)$ is the net number of eigenvalues that cross zero as u goes from 0 to 1:

$$\mathrm{SF} = \#\{\text{crossings from } \lambda < 0 \text{ to } \lambda \ge 0\} - \#\{\text{crossings from } \lambda \ge 0 \text{ to } \lambda < 0\}.$$

Operationally: draw the spectral curves, and count signed intersections with the horizontal axis. We count an eigenvalue that reaches 0 from below as having crossed (the convention matching ξ [$\xi(L) = \frac{1}{2}\big(h(L) + \eta_L(0)\big)$, with $h(L) = \dim \ker L$] below).

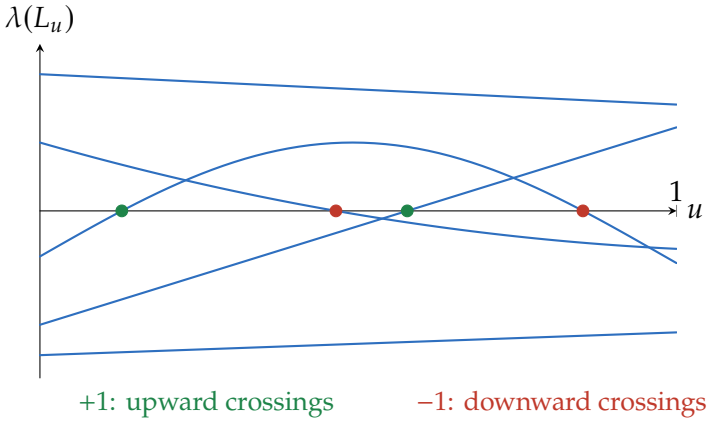

Figure 4.85: Spectral flow is a signed count of zero crossings. Each curve is an eigenvalue of L_u. Green dots: an eigenvalue crosses from negative to positive (+1); red dots: from positive to negative (−1). Here the net flow is $2 - 2 = 0$. Eigenvalues that stay on one side contribute nothing, however much they move; that motion is what the smooth part of η records.

How η changes along a family

Write $\xi(L) = \frac{1}{2}\big(h(L) + \eta_L(0)\big)$ as before. When an eigenvalue moves from negative to 0, η loses a -1 and h gains 1, so ξ jumps by $+\frac{1}{2} + \frac{1}{2} = 1$; as it continues to positive values, h loses 1 and η gains +1, and ξ is unchanged. So ξ jumps by exactly +1 at an upward crossing and -1 at a downward one, and otherwise changes smoothly:

$$\xi(L_1) - \xi(L_0) = \mathrm{SF}(L_u) + \int_0^1 \frac{\mathrm{d}\xi}{\mathrm{d}u}\Big|_{\text{smooth}} \mathrm{d}u. \tag{4.246}$$

The smooth part is *local*. To see this, differentiate the eta function with respect to u at a value of u with no crossing. For an eigenvalue $\lambda(u) \neq 0$, first-order perturbation theory gives $\dot\lambda = \langle \psi_\lambda, \dot L \psi_\lambda \rangle$ (dots are u-derivatives), and

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}u}\eta_{L_u}(s) &\overset{(1)}{=} \sum_\lambda \operatorname{sgn}(\lambda)\,\frac{\mathrm{d}}{\mathrm{d}u}|\lambda|^{-s} \overset{(2)}{=} \sum_\lambda \operatorname{sgn}(\lambda)\,(-s)|\lambda|^{-s-1}\operatorname{sgn}(\lambda)\dot\lambda \\ &\overset{(3)}{=} -s\sum_\lambda \langle \psi_\lambda, \dot L \psi_\lambda\rangle |\lambda|^{-s-1} \overset{(4)}{=} -s\ \operatorname{Tr}\big(\dot L\,|L|^{-s-1}\big). \end{aligned} \tag{4.247}$$

(1) Definition of $\eta(s)$; $\operatorname{sgn}\lambda$ is constant away from crossings.
(2) $\frac{\mathrm{d}}{\mathrm{d}u}|\lambda| = \operatorname{sgn}(\lambda)\dot\lambda$.
(3) $\operatorname{sgn}^2 = 1$, and the Hellmann–Feynman formula for $\dot\lambda$.
(4) The sum of diagonal matrix elements in an eigenbasis is the trace.

At $s = 0$ the explicit factor s kills everything except a *pole* of $\operatorname{Tr}(\dot L|L|^{-s-1})$ at $s = 0$. Poles of such traces come from the small-time expansion of heat traces, which is local. Concretely, $\operatorname{Tr}(\dot L|L|^{-s-1}) = \frac{1}{\Gamma(\frac{s+1}{2})}\int_0^\infty \tau^{\frac{s-1}{2}}\operatorname{Tr}(\dot L e^{-\tau L^2})\mathrm{d}\tau$ (the Mellin transform again), and if $\operatorname{Tr}(\dot L e^{-\tau L^2}) \sim \cdots + b\,\tau^{-1/2} + \dots$ as $\tau \to 0$, the b term gives $\frac{b}{\sqrt\pi}\int_0^1 \tau^{\frac{s}{2}-1}\mathrm{d}\tau = \frac{2b}{\sqrt\pi\, s}$. So

$$\left.\frac{\mathrm{d}\eta_{L_u}(0)}{\mathrm{d}u}\right|_{\text{smooth}} = -\frac{2}{\sqrt\pi}\,b(u), \qquad b(u) = \text{coefficient of } \tau^{-1/2} \text{ in } \operatorname{Tr}\big(\dot L_u e^{-\tau L_u^2}\big), \tag{4.248}$$

and $b(u)$ is the integral over the boundary of a local density built from $\dot L$ and the symbol of L.

Worked example 4.146: Checking (4.248) on the circle

For $L_u = i\,\mathrm{d}/\mathrm{d}\theta + t(u)$ we have $\dot L = \dot t$ (a constant), and the heat trace was computed by Poisson summation in Example 4.136: $\operatorname{Tr} e^{-\tau L^2} = \sum_n e^{-\tau(n+t)^2} = \sqrt{\pi/\tau} + (\text{exponentially small})$. So $\operatorname{Tr}(\dot L e^{-\tau L^2}) = \dot t\sqrt\pi\,\tau^{-1/2} + \dots$, i.e. $b = \dot t\sqrt\pi$, and

$$\left.\frac{\mathrm{d}\eta}{\mathrm{d}u}\right|_{\text{smooth}} = -\frac{2}{\sqrt\pi}\,\dot t\sqrt\pi = -2\dot t.$$

This is the slope -2 of the sawtooth $1-2t$, now obtained with no knowledge of the Hurwitz zeta function. The same slope follows from (4.247) directly: $\operatorname{Tr}|L|^{-s-1} = \zeta(s+1,t) + \zeta(s+1,1-t)$ has a simple pole of residue 2 at $s=0$ (each Hurwitz zeta function has residue 1 at $s+1=1$), so $-s\cdot\dot t\cdot\frac{2}{s} = -2\dot t$.

The index on a cylinder is the spectral flow

Now apply the APS theorem to the cylinder $X = [0,1]\times Y$ with

$$D = \partial_u + L_u,$$

where L_u is constant near $u=0$ and near $u=1$ (so that both ends are product collars). At $u=0$ the inward normal is ∂_u and the boundary operator is L_0. At $u=1$ the inward normal is $-\partial_u$, $D = -(\partial_n - L_1)$, and the boundary operator is $-L_1$. So

$$\begin{aligned}\operatorname{index} D &\overset{(1)}{=} \int_X P - \xi(L_0) - \xi(-L_1) \overset{(2)}{=} \int_X P - \xi(L_0) - \big(h_1 - \xi(L_1)\big)\\ &\overset{(3)}{=} \int_X P + \big(\xi(L_1) - \xi(L_0)\big) - h_1 \overset{(4)}{=} \int_X P + \mathrm{SF} + \int_0^1 \dot\xi_{\text{smooth}}\,\mathrm{d}u - h_1.\end{aligned} \tag{4.249}$$

(1) (4.233) with two boundary components, written with $\xi = \frac12(h+\eta)$.
(2) $\xi(-L) = \frac12(h-\eta_L) = h - \xi(L)$, since $-L$ has the same kernel and the opposite asymmetry.
(3) Rearrange.
(4) (4.246).

Both $\int_X P$ and $\int \dot\xi_{\text{smooth}}$ are integrals of local densities along the family. To compare them, take a family with *no* crossings and L_0, L_1 invertible. Then $\operatorname{index} D = 0$: on each eigenmode the

solution of $Du = 0$ is $f(u) = f(0)\exp(-\int_0^u \lambda)$, and the APS conditions demand $\lambda(0) < 0$ at one end and $-\lambda(1) < 0$ at the other, which is a crossing; similarly for the cokernel. So (4.249) gives $\int_X P = -\int_0^1 \dot{\xi}_{\text{smooth}}\,\mathrm{d}u$ for such families, and since both sides are local this identity holds for all families. Hence

Key idea: Index = spectral flow (APS III)

For $D = \partial_u + L_u$ on $[0,1]\times Y$ with APS conditions,

$$\operatorname{index} D = \operatorname{SF}(L_u) - h(L_1), \tag{4.250}$$

and in particular $\operatorname{index} D = \operatorname{SF}(L_u)$ if L_1 is invertible. The bulk integral and the smooth drift of η cancel identically; what remains is purely the integer count of zero crossings.

Worked example 4.147: A cylinder with a growing magnetic flux

Let $Y = S^1$ and $L_u = i\,\mathrm{d}/\mathrm{d}\theta + Nu$ with N a positive integer (a flux that grows by N quanta along the cylinder). On the Fourier mode with eigenvalue $\lambda_n(u) = n + Nu$ the operator is $\partial_u + \lambda_n(u)$. *Direct count.* The kernel has one solution $f_n = \exp\bigl(-\int_0^u \lambda_n\bigr)$ per n with $\lambda_n(0) < 0 < \lambda_n(1)$, i.e. $n < 0 < n + N$: $n = -N+1, \dots, -1$, giving $N-1$ solutions. The cokernel needs $\lambda_n(1) \le 0 \le \lambda_n(0)$, i.e. $n + N \le 0 \le n$, impossible. So $\operatorname{index} D = N - 1$. *Spectral flow.* The lines $n + Nu$ that go from < 0 to ≥ 0 are $n = -N, \dots, -1$: $\operatorname{SF} = N$. The end $L_1 = i\,\mathrm{d}/\mathrm{d}\theta + N$ has the zero mode $n = -N$, so $h_1 = 1$ and (4.250) gives $N - 1$ ✓. *The full APS formula.* The bulk density is the Chern form of the flux: $\int_X P = \int_0^1 \dot{t}\,\mathrm{d}u = N$, which is minus the smooth drift $\int \dot{\xi}_{\text{smooth}} = \frac{1}{2}\int(-2\dot{t}) = -N$ ✓; both ends have integer flux, so $\eta = 0$ and $h = 1$, and $\operatorname{index} D = N - \frac{1}{2} - \frac{1}{2} = N - 1$ ✓.

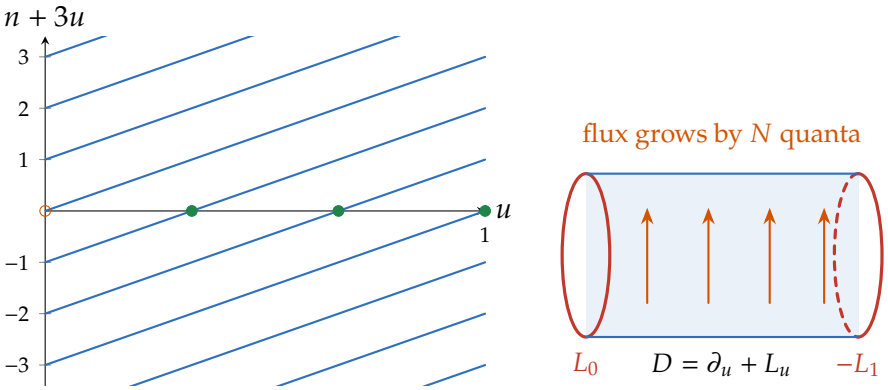

Figure 4.86: Left: the spectrum of $L_u = i\,\mathrm{d}/\mathrm{d}\theta + 3u$ on the circle. Each Fourier mode is a line of slope 3; three lines cross zero upwards (green), so SF = 3 (the one ending exactly on the axis at $u = 1$ counts, and is also the zero mode $h_1 = 1$ of L_1; the orange circle marks the zero mode of L_0, which does not cross). Right: the corresponding cylinder, on which $\operatorname{index}(\partial_u + L_u) = \operatorname{SF} - h_1 = 2$ by Example 4.147.

Physical picture: Closing the cylinder into a torus

If L_1 is gauge equivalent to L_0 (here: integer N, since $t \to t+1$ is a large gauge transformation), the ends of the cylinder can be glued with the gauge transformation, and D becomes $\bar{\partial}$ (up to normalisation) coupled to a line bundle of degree N on the torus T^2. There is no boundary, and the ordinary index theorem (Riemann–Roch with $g = 1$) gives

index $= N + 1 - 1 = N =$ SF around the loop. For a loop of self-adjoint operators the spectral flow is the "index" of the family, and it plays for self-adjoint families the role that the index bundle plays in Section 4.18. It is exactly the "one eigenvalue crosses per period" of Figure 4.60.

Spectral flow in physics: the chiral anomaly by level crossing

Spectral flow is the cleanest way to see an anomaly. The QFT notes do the following argument for two-dimensional QED [QFT notes §22.2.4, pp. 1374–1376]; we rephrase it in our language.

Put a massless Dirac fermion on a spatial circle of length 2π, with a constant, slowly varying gauge potential $a(\tau)$ along the circle (physicists' Hermitian convention; the anti-Hermitian $A = -ia\,\mathrm{d}\theta$). The one-particle Hamiltonians of the two chiralities are

$$H_\pm = \mp i\,\partial_\theta \mp a(\tau) \quad \text{with eigenvalues} \quad E_{\pm,n} = \pm(n - a),\ n \in \mathbb{Z},$$

on the modes $e^{in\theta}$. As a increases by one unit (one flux quantum, $\oint a\,\mathrm{d}\theta$ changes by 2π), every level of H_+ moves down by one and every level of H_- moves up by one: $\mathrm{SF}(H_+) = -1$ and $\mathrm{SF}(H_-) = +1$. The spectrum returns to itself, but one filled level of H_- has risen out of the Dirac sea, and one empty level of H_+ has sunk into it. The charges therefore change by

$$\Delta N_+ = \mathrm{SF}(H_+) = -1, \qquad \Delta N_- = \mathrm{SF}(H_-) = +1, \qquad \Delta(N_+ - N_-) = -2,$$

while the total charge $N_+ + N_-$ is conserved. This is the integrated chiral anomaly, the QFT notes' (22.2.48). The anomaly is literally the spectral flow of the Dirac Hamiltonian, and by (4.250) it is also the index of the Euclidean Dirac operator $\partial_\tau + H$ on the space-time cylinder, which is the Chern number of the gauge field on the time-slab. In the path-integral language of Chapter 10 this index is the number of zero modes that make the fermion measure non-invariant (Fujikawa).

Dictionary: spectral flow

$\mathrm{SF}(L_u)$	net number of levels crossing zero energy
$\mathrm{index}(\partial_u + L_u) = \mathrm{SF}$	number of fermions created from the Dirac sea during an adiabatic process (Euclidean time u)
smooth drift of η	polarisation of the Dirac sea: charge that moves continuously, not in units
closed loop of L_u	periodic adiabatic process; SF is a topological invariant of the loop (a "Thouless pump")

4.21.11 Relaxing the product metric: the second fundamental form

Everything so far assumed that near ∂X the manifold looks exactly like a cylinder $\partial X \times [0, \varepsilon)$ (4.201). That is convenient but unnatural: the flat unit disc, the round hemisphere and a ball in $\mathbb{R}^4$ are not products near their boundaries. Nash ends the section [Nash pp. 135–136, (4.175)–(4.177)] by explaining what changes when we drop the assumption. The answer is simple to state:

> *the index formula acquires one more term, an integral over ∂X of a local expression in the second fundamental form of the boundary.*

We have already met the prototype. In Gauss–Bonnet (4.206) the extra term is $\frac{1}{2\pi}\oint k_g \, \mathrm{d}s$, and the geodesic curvature k_g is the second fundamental form of a curve. Our job is to see where such a term comes from in general, and to compute it in examples.

Coordinates adapted to the boundary

Nash writes the metric near the boundary as [Nash (4.175)]

$$\mathrm{d}s^2 = g_{11}\,\mathrm{d}n^2 + \sum_{i,j\geq 2} h_{ij}\,\mathrm{d}x^i\mathrm{d}x^j, \tag{4.251}$$

where n is a normal coordinate and x^i, $i = 2, \dots, \dim X$, are coordinates on ∂X. We can always make $g_{11} = 1$ by choosing n to be the geodesic distance from the boundary (walk inwards along the geodesic that leaves ∂X at right angles, and let n be the arc length). Then the metric is

$$\mathrm{d}s^2 = \mathrm{d}n^2 + h_{ij}(n, x)\,\mathrm{d}x^i\mathrm{d}x^j,$$

and the only difference from a product is that the metric h_{ij} of the slices $n = \text{const}$ *depends on* n. How fast it changes as we move off the boundary is measured by one tensor.

Working definition 4.65 (second fundamental form)

In the coordinates above, with n the inward normal distance, the **second fundamental form** of ∂X is the symmetric tensor on ∂X

$$K_{ij} = -\frac{1}{2}\frac{\partial h_{ij}}{\partial n}\Big|_{n=0}.$$

Operationally: slide the boundary inwards by a distance δn and see how lengths on it change; $K_{ij}\,\delta n$ is (minus) the change of the metric. The sign is chosen so that $K > 0$ when the boundary is convex, i.e. when it shrinks as we move inwards, as for the rim of a disc. Its trace $H = h^{ij}K_{ij}$ [h^{ij} is the inverse matrix of h_{ij}] is the **mean curvature**. For a curve on a surface, K is a 1×1 matrix, and $h^{\theta\theta}K_{\theta\theta}$ is the geodesic curvature k_g [how fast the curve turns within the surface, e.g. $1/r$ for a circle of radius r in the plane].

Nash describes the same object differently: as the *normal component* of the Levi-Civita connection on the boundary. The two descriptions agree. Use the standard formula $\Gamma^a{}_{bc} = \frac{1}{2}g^{ad}(\partial_b g_{dc} + \partial_c g_{db} - \partial_d g_{bc})$ with $g_{nn} = 1$, $g_{ni} = 0$, $g_{ij} = h_{ij}$:

$$\Gamma^n{}_{ij} \overset{(1)}{=} \frac{1}{2}g^{nn}\big(\partial_i g_{nj} + \partial_j g_{ni} - \partial_n g_{ij}\big) \overset{(2)}{=} -\frac{1}{2}\,\partial_n h_{ij} \overset{(3)}{=} K_{ij} \quad \text{at } n = 0,$$

$$\Gamma^i{}_{nj} \overset{(4)}{=} \frac{1}{2}h^{ik}\big(\partial_n g_{kj} + \partial_j g_{kn} - \partial_k g_{nj}\big) \overset{(5)}{=} \frac{1}{2}h^{ik}\partial_n h_{kj} \overset{(6)}{=} -K^i{}_j \quad \text{at } n = 0.$$

(1) The Christoffel formula; g^{nd} is nonzero only for $d = n$.
(2) $g_{nj} = 0$ identically, so its derivatives vanish.
(3) Definition of K_{ij}.
(4) The Christoffel formula; g^{id} is nonzero only for $d = k$ tangential.
(5) Again $g_{kn} = g_{nj} = 0$.
(6) Raise an index with h^{ik}.

All the other mixed components ($\Gamma^n{}_{nn}$, $\Gamma^n{}_{ni}$, $\Gamma^i{}_{nn}$) vanish because $g_{nn} = 1$ is constant. So the parts of the connection that mix the normal direction with the tangential ones are *exactly* $\pm K$. Nash's statement "the metric is a product near the boundary, so Γ has no normal component" is the statement $K = 0$ (for all n in the collar).

Worked example 4.148: Surfaces of revolution: the geodesic curvature from K_{ij}

Take a disc with the rotationally symmetric metric

$$\mathrm{d}s^2 = \mathrm{d}r^2 + f(r)^2\,\mathrm{d}\theta^2, \qquad 0 \le r \le R,$$

with $f(r) \approx r$ near $r = 0$ (smooth at the centre). The inward normal distance from the rim is $n = R - r$, so $h_{\theta\theta} = f(R-n)^2$ and

$$K_{\theta\theta} \overset{(1)}{=} -\frac{1}{2}\frac{\partial}{\partial n} f(R-n)^2\Big|_{n=0} \overset{(2)}{=} f(R)f'(R), \qquad k_g \overset{(3)}{=} h^{\theta\theta}K_{\theta\theta} \overset{(4)}{=} \frac{f'(R)}{f(R)}.$$

(1) Definition of K.
(2) Chain rule: $\partial_n f(R-n)^2 = -2ff'$.
(3) The geodesic curvature is the trace of K on a curve.
(4) $h^{\theta\theta} = 1/f(R)^2$.

Three cases, all familiar from Example 4.132:

- *Flat disc*, $f = r$: $k_g = 1/R$, the curvature of a circle of radius R.
- *Spherical cap* on the unit sphere, $f = \sin r$, $R = \vartheta_0$: $k_g = \cot\vartheta_0$. It vanishes at the equator $\vartheta_0 = \pi/2$, which is a great circle (a geodesic).
- *Test tube*: f constant for r near R (a hemisphere glued to a straight cylinder). Then $f'(R) = 0$, so $K = 0$: this is a product collar.

Why the extra term is a boundary integral: transgression

Here is the mechanism in one sentence: *characteristic forms of two different connections differ by an exact form*. Nash quotes it as [Nash (4.176)]: if Γ and Γ' are two connections with curvatures R and R', and P is an invariant polynomial, then

$$P(R) - P(R') = \mathrm{d}Q. \tag{4.252}$$

The form Q is called the **transgression form** (or secondary characteristic form). Integrating over X and using Stokes,

$$\int_X P(R) = \int_X P(R') + \int_{\partial X} Q. \tag{4.253}$$

On a closed manifold the last term is absent, which is the familiar statement that characteristic numbers do not depend on the connection (Chapter 4). With a boundary it is the only thing that changes.

Key idea: The transgression formula, derived

Join the two connections by the straight line $A_t = A' + t\,a$, $a = A - A'$, $0 \le t \le 1$, and write $F_t = \mathrm{d}A_t + A_t \wedge A_t$. Take $P(F) = \operatorname{tr} F^k$ (every invariant polynomial is built from these). Then

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\operatorname{tr}F_t^k &\overset{(1)}{=} k\,\operatorname{tr}\big(\dot F_t \wedge F_t^{k-1}\big) \overset{(2)}{=} k\,\operatorname{tr}\big((\mathrm{d}a + a\wedge A_t + A_t\wedge a)\wedge F_t^{k-1}\big)\\ &\overset{(3)}{=} k\,\operatorname{tr}\big(D_t a \wedge F_t^{k-1}\big) \overset{(4)}{=} k\,\mathrm{d}\,\operatorname{tr}\big(a\wedge F_t^{k-1}\big).\end{aligned} \tag{4.254}$$

(1) Product rule; the cyclicity of the trace (with the signs for even forms, which are all +) lets us collect the k terms.

(2) $\dot{A}_t = a$, so $\dot{F}_t = \mathrm{d}a + a \wedge A_t + A_t \wedge a$.
(3) This combination is the covariant derivative $D_t a$ of the adjoint-valued 1-form a (Chapter T3).
(4) For any adjoint-valued form ω, $\mathrm{d}\,\mathrm{tr}\,\omega = \mathrm{tr}\, D_t\omega$; and the Bianchi identity $D_t F_t = 0$ lets D_t act on a alone.

Integrating from $t = 0$ to $t = 1$ gives (4.252) with the explicit

$$Q = k \int_0^1 \mathrm{tr}\big(a \wedge F_t^{k-1}\big)\,\mathrm{d}t, \qquad a = A - A'. \tag{4.255}$$

Q is built out of the difference a of the connections and the curvatures; it is local and gauge covariant.

Worked example 4.149: The Chern–Simons form

Take $k = 2$, $A' = 0$ (on a region where the bundle is trivialised), so $a = A$, $A_t = tA$ and $F_t = t\,\mathrm{d}A + t^2 A \wedge A$. Then

$$Q \overset{(1)}{=} 2\int_0^1 \mathrm{tr}\big(A \wedge (t\,\mathrm{d}A + t^2 A \wedge A)\big)\mathrm{d}t \overset{(2)}{=} 2\Big(\frac{1}{2}\,\mathrm{tr}(A \wedge \mathrm{d}A) + \frac{1}{3}\,\mathrm{tr}(A \wedge A \wedge A)\Big)$$
$$\overset{(3)}{=} \mathrm{tr}\Big(A \wedge \mathrm{d}A + \frac{2}{3} A \wedge A \wedge A\Big).$$

(1) (4.255) with $k = 2$.
(2) $\int_0^1 t\,\mathrm{d}t = \frac{1}{2}$ and $\int_0^1 t^2 \mathrm{d}t = \frac{1}{3}$.
(3) Multiply out.

This is the **Chern–Simons form**, and we can check $\mathrm{d}Q = \mathrm{tr}\, F \wedge F$ directly: $\mathrm{d}\,\mathrm{tr}(A\,\mathrm{d}A) = \mathrm{tr}(\mathrm{d}A\,\mathrm{d}A)$, and $\mathrm{d}\,\mathrm{tr}(A^3) = 3\,\mathrm{tr}(\mathrm{d}A\,A^2)$, while $\mathrm{tr}\,F^2 = \mathrm{tr}(\mathrm{d}A\,\mathrm{d}A) + 2\,\mathrm{tr}(\mathrm{d}A\,A^2) + \mathrm{tr}(A^4)$ with $\mathrm{tr}\,A^4 = 0$ (a cyclic permutation of four 1-forms costs a sign). So $\mathrm{d}Q = \mathrm{tr}(\mathrm{d}A)^2 + \frac{2}{3}\cdot 3\,\mathrm{tr}(\mathrm{d}A\,A^2) = \mathrm{tr}\,F^2$ ✓. For an abelian field $A = -ia$ it is $Q = -a \wedge \mathrm{d}a$. The same form will be the action of Chern–Simons theory in Chapter 12, and the anomaly polynomial's descendant in Chapter 10.

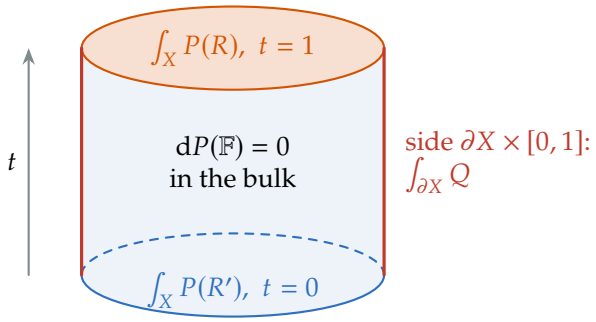

Figure 4.87: Transgression as Stokes' theorem. Put the interpolating connection A_t on the cylinder $X \times [0,1]$; its characteristic form $P(\mathbb{F})$ is closed. Stokes says the integrals over the whole boundary of the cylinder add to zero: top minus bottom equals the side. On a closed X there is no side, and $\int_X P$ is independent of the connection. With $\partial X \neq \varnothing$ the side contributes $\int_{\partial X} Q$, where Q is $P(\mathbb{F})$ integrated along t (integration along the fibre, as in Section 4.18).

The general index formula

Now apply (4.253) to the Levi-Civita connections. Let g be any metric on X, and let g' be a metric that agrees with g away from a thin collar and is a product near ∂X (deform $h_{ij}(n)$ to $h_{ij}(0)$ in the collar). For g' the APS theorem holds as stated. The boundary operator L only sees the metric *on* ∂X, which is the same for both. Hence

$$\operatorname{index} D \overset{(1)}{=} \int_X P(R') - \frac{h+\eta(0)}{2} \overset{(2)}{=} \int_X P(R) - \int_{\partial X} Q - \frac{h+\eta(0)}{2}. \tag{4.256}$$

(1) The APS theorem (4.233) for the product metric g'. The index itself does not change under the deformation: with the APS condition fixed, a continuous deformation of the operator keeps it Fredholm and cannot change the integer.

(2) (4.253) with R the curvature of g and R' that of g'.

In the collar the two connections differ by $a = \Gamma - \Gamma'$, whose only nonzero components at the boundary are the normal–tangential ones we computed, $\pm K_{ij}$ (for g' they are zero). So Q restricted to ∂X is a polynomial in the second fundamental form and the curvature of ∂X: this is Nash's "appropriate Q expressed in terms of the second fundamental form". Writing the boundary term with the opposite sign gives Nash's [Nash (4.177)],

$$\operatorname{index} D = \int_X P(R) + \int_{\partial X} \widetilde{Q} - \frac{h+\eta(0)}{2}, \qquad \widetilde{Q} = -Q\big|_{\partial X}. \tag{4.257}$$

Worked example 4.150: Gauss–Bonnet from the transgression

We re-derive Gauss–Bonnet with boundary from (4.253), for the metric $\mathrm{d}r^2 + f^2\mathrm{d}\theta^2$ of Example 4.148. Use the orthonormal coframe $e^1 = \mathrm{d}r$, $e^2 = f\,\mathrm{d}\theta$ (Chapter T2). The first structure equation $\mathrm{d}e^a = -\omega^a{}_b \wedge e^b$ gives the connection 1-form:

$$\mathrm{d}e^2 \overset{(1)}{=} f'\,\mathrm{d}r \wedge \mathrm{d}\theta \overset{(2)}{=} -\omega^2{}_1 \wedge \mathrm{d}r \quad\Longrightarrow\quad \omega^2{}_1 \overset{(3)}{=} f'\,\mathrm{d}\theta.$$

(1) Differentiate $e^2 = f(r)\,\mathrm{d}\theta$.

(2) The structure equation for $a = 2$ ($\omega^2{}_2 = 0$).

(3) $-f'\mathrm{d}\theta \wedge \mathrm{d}r = f'\mathrm{d}r \wedge \mathrm{d}\theta$ ✓; also $\mathrm{d}e^1 = 0 = -\omega^1{}_2 \wedge e^2$ holds because $\mathrm{d}\theta \wedge \mathrm{d}\theta = 0$.

The curvature is $\Omega^2{}_1 = \mathrm{d}\omega^2{}_1 = f''\,\mathrm{d}r \wedge \mathrm{d}\theta$, and comparing with $\Omega^2{}_1 = -K_{\mathrm{G}}\, e^1 \wedge e^2$ gives the Gaussian curvature $K_{\mathrm{G}} = -f''/f$ (= 1 for $f = \sin r$). The Euler form is

$$e(g) = \frac{1}{2\pi} K_{\mathrm{G}}\,\mathrm{d}A = -\frac{1}{2\pi} f''\,\mathrm{d}r \wedge \mathrm{d}\theta = \mathrm{d}\Big(-\frac{f'}{2\pi}\mathrm{d}\theta\Big).$$

Let g' have the profile $\tilde{f}$, equal to f near $r = 0$ and constant near $r = R$. Then

$$e(g) - e(g') \overset{(1)}{=} \mathrm{d}Q, \qquad Q = -\frac{f' - \tilde{f}'}{2\pi}\,\mathrm{d}\theta,$$
$$\int_X e(g) \overset{(2)}{=} \int_X e(g') + \oint_{r=R} Q \overset{(3)}{=} \chi(X) - f'(R) \overset{(4)}{=} \chi(X) - \frac{1}{2\pi}\oint k_g\,\mathrm{d}s.$$

(1) Subtract the two Euler forms. Q is a smooth 1-form on the whole disc, because $f' - \tilde{f}'$ vanishes near the centre, where $\mathrm{d}\theta$ is singular.

(2) Stokes, (4.253).

(3) Gauss–Bonnet for the product metric (4.207); $\tilde{f}'(R) = 0$ and $\oint \mathrm{d}\theta = 2\pi$.

(4) $k_g = f'(R)/f(R)$ from Example 4.148, and the rim has length $2\pi f(R)$.

This is Gauss–Bonnet with boundary (4.206). The boundary term $\widetilde{Q} = -Q = \frac{1}{2\pi}k_g\,\mathrm{d}s$ is linear in the second fundamental form, as promised.

Worked example 4.151: $\bar\partial$ on a flat disc versus a test tube

Consider $\bar\partial$ on functions on the unit disc with APS conditions. We computed in Example 4.141 (with $\alpha = 0$) that the index is 0 for a metric with a product collar. Now take the *flat* metric $\mathrm{d}x^2 + \mathrm{d}y^2$, which is not a product.

The boundary operator. With $n = 1 - r$, so $\partial_r = -\partial_n$,

$$\partial_{\bar z} = \frac{e^{i\theta}}{2}\Big(\partial_r + \frac{i}{r}\partial_\theta\Big) = -\frac{e^{i\theta}}{2}\Big(\partial_n - \frac{i}{1-n}\partial_\theta\Big).$$

The tangential operator now depends on n. At $n = 0$ it is $L = -i\partial_\theta$, with eigenvalue k on $e^{ik\theta}$: spectrum $\mathbb{Z}$, $h = 1$, $\eta = 0$, as before.

Direct count. A holomorphic $f = \sum_{k\ge 0} a_k z^k$ has boundary values $\sum_{k\ge 0} a_k e^{ik\theta}$. The APS condition removes all modes with $k \ge 0$, so Ker = 0. The index is conformally invariant data here (the kernel does not depend on the conformal factor, and neither does the boundary condition), so it is still 0.

The formula. The index density is the degree-2 part of $\mathrm{td}\, X$, $\frac12 c_1(TX) = \frac12 e$, so Q is half the Gauss–Bonnet transgression:

$$\operatorname{index}\bar\partial \overset{(1)}{=} \frac12\int_X e(g_{\mathrm{flat}}) + \frac12\cdot\frac{1}{2\pi}\oint k_g\,\mathrm{d}s - \frac{h+\eta(0)}{2} \overset{(2)}{=} 0 + \frac12\cdot 1 - \frac{1+0}{2} = 0\ \checkmark$$

(1) (4.257) with $P = \frac12 e$ and $\widetilde Q = \frac12\cdot\frac{1}{2\pi}k_g\,\mathrm{d}s$ (Example 4.150).
(2) The flat disc has $K_{\mathrm G} = 0$; its rim has $k_g = 1$ and length 2π.

For the test tube all of the $\frac12$ sits in the bulk (the curvature of the hemispherical cap) and $\widetilde Q = 0$. For a spherical cap of angle ϑ_0 it is split as $\frac12(1-\cos\vartheta_0) + \frac12\cos\vartheta_0$. In each case the total of the *local* terms is $\frac12$, and the boundary spectral term $-\frac12$ is unchanged.

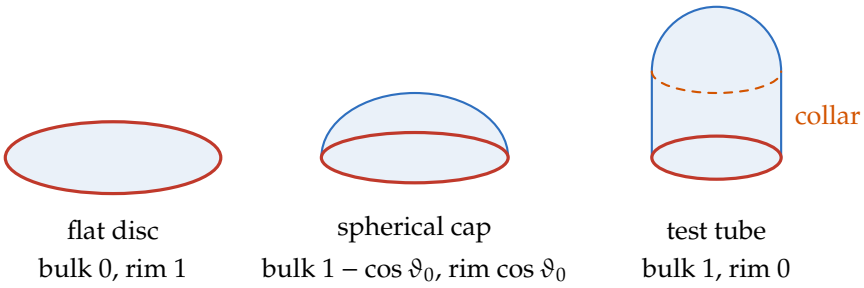

Figure 4.88: Three metrics on the disc, and where the Euler characteristic $\chi = 1$ is stored. For the flat disc all of it is in the geodesic curvature of the rim (a boundary transgression term); for the test tube, whose collar is a product, all of it is in the bulk curvature of the cap. The index of $\bar\partial$ with APS conditions is 0 in every case: $\frac12\chi$ from the local terms, $-\frac12$ from the zero mode of the boundary circle.

Watch out: The sign of Q in Nash's (4.177), and what L means

Whether Q enters with a plus or a minus depends only on which metric is called R and which R' in (4.176); Nash avoids the issue by saying "an appropriate Q". In our conventions (4.256), the correction is $-\int_{\partial X} Q$ with Q the transgression from the product metric to the actual one. A second subtlety: when the metric is not a product, $D = A_n(\partial_n + L_n)$ with A_n and L_n both depending on n, and there is freedom to move zeroth-order terms between them. The APS condition uses the boundary operator $L = L_0$ defined intrinsically by the

geometry of ∂X (for Dirac operators, the Dirac operator of ∂X). Any other choice shifts η by a local amount, which is compensated by a change in $\widetilde{Q}$.

Physical picture: Why a product collar is the natural normalisation

A product collar is precisely the situation in which the bulk index density "does not know" where the boundary is: the geometry near ∂X is translation invariant in n, so nothing local can accumulate there. Every local boundary effect then lives in the transgression term, and every non-local one in η. APS chose this normalisation because it separates the two kinds of correction cleanly; a physicist would call $\widetilde{Q}$ a *surface counterterm*.

4.21.12 Is $\eta(0)$ always finite?

Our treatment of η has quietly assumed that $\eta_L(s)$, continued from the half-plane where its series converges, is finite at $s = 0$. For the zeta function this was automatic: the factor $1/\Gamma(s)$ in (4.215) vanishes at $s = 0$ and kills the only possible pole. For eta the corresponding prefactor is $1/\Gamma(\frac{s+1}{2})$, which is $1/\sqrt{\pi}$ at $s = 0$, finite and nonzero. Nothing kills a pole. Nash raises the question at the very end of the chapter [Nash p. 136]:

> *If we take any self-adjoint elliptic operator B on a closed manifold Y and form $\eta_B(s)$, is $\eta_B(0)$ finite?*

His answer has three parts. For the boundary operators L of the APS theorem, yes: the index theorem itself proves it, because every other term in (4.233) is finite. For general B it is also yes, if $\dim Y$ is odd, or if $\dim Y$ is even and B is a differential operator of odd order; but the proof is delicate. And the delicacy is visible: the *operator* $B|B|^{-s-1}$ can have a pole at $s = 0$ with a nonzero matrix-valued residue whose *trace* is zero. We now make each of these statements concrete.

Where a pole at $s = 0$ would come from

Let L be a first-order self-adjoint elliptic operator on a closed manifold Y of dimension m. As $t \to 0$, the odd heat trace has an asymptotic expansion in powers of $\sqrt{t}$, like the ordinary heat trace (4.216):

$$\operatorname{Tr}\big(L\, e^{-tL^2}\big) \sim \sum_{k\geq 0} c_k\, t^{\frac{k-m-1}{2}}, \qquad c_k = \int_Y \gamma_k(y)\, \mathrm{d}^m y, \tag{4.258}$$

where each $\gamma_k(y)$ is a *local* density: a polynomial in the coefficients of L and their derivatives at y (with k derivatives in total, counting a coefficient of order zero as one derivative). The power is fixed by dimensional analysis: L has dimension $1/\text{length}$, t has dimension length^2, the diagonal of a kernel on Y has dimension length^{-m}, so the leading term is $\text{length}^{-m-1} \sim t^{-\frac{m+1}{2}}$, and each extra derivative contributes another $t^{1/2}$.

Put (4.258) into the heat-kernel formula (4.221). Split the t integral at $t = 1$: the piece $\int_1^\infty$ is an entire function of s (the integrand decays exponentially if we remove the zero modes, which contribute nothing to $\operatorname{Tr}(Le^{-tL^2})$ anyway). The piece $\int_0^1$ gives, term by term,

$$\frac{1}{\Gamma(\frac{s+1}{2})}\int_0^1 t^{\frac{s-1}{2}}\, c_k\, t^{\frac{k-m-1}{2}}\, \mathrm{d}t \overset{(1)}{=} \frac{c_k}{\Gamma(\frac{s+1}{2})}\int_0^1 t^{\frac{s+k-m}{2}-1}\, \mathrm{d}t \overset{(2)}{=} \frac{c_k}{\Gamma(\frac{s+1}{2})}\cdot\frac{2}{s+k-m}. \tag{4.259}$$

(1) Add the exponents: $\frac{s-1}{2} + \frac{k-m-1}{2} = \frac{s+k-m}{2} - 1$.

(2) $\int_0^1 t^{a-1}\mathrm{d}t = 1/a$, continued to all $a \neq 0$.

So $\eta_L(s)$ has (at most) simple poles at $s = m-k$, $k = 0,1,2,\dots$, with residue $2c_k/\Gamma(\frac{m-k+1}{2})$. (When $\frac{m-k+1}{2}$ is a non-positive integer, $1/\Gamma$ vanishes and that pole is absent.) The point $s = 0$ corresponds to $k = m$:

Key idea: The finiteness criterion

$$\eta_L(s) \text{ is regular at } s = 0 \iff c_m = 0, \qquad \operatorname*{Res}_{s=0} \eta_L = \frac{2c_m}{\sqrt{\pi}},$$

where c_m is the coefficient of $t^{-1/2}$ in $\mathrm{Tr}(Le^{-tL^2})$. The residue is the integral over Y of a local density $\gamma_m(y)$. So the question "is $\eta(0)$ finite?" is a question about one local heat coefficient.

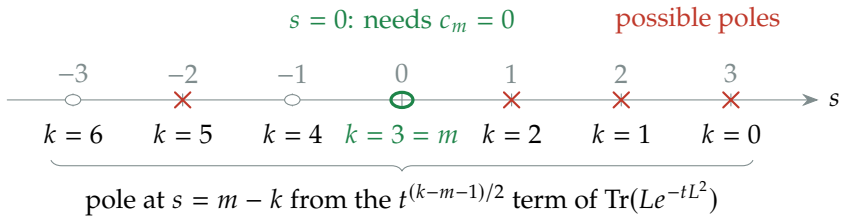

Figure 4.89: The ladder of possible poles of $\eta_L(s)$ for $\dim Y = m$ (drawn for $m = 3$). Each term $c_k t^{(k-m-1)/2}$ in the small-t expansion of the odd heat trace can produce a simple pole at $s = m-k$. The point $s = 0$ is hit by exactly one term, $k = m$, the coefficient of $t^{-1/2}$. (Grey circles: at $s = -1, -3, \dots$ the prefactor $1/\Gamma(\frac{s+1}{2})$ vanishes and cancels the would-be pole.)

Even dimensions and differential operators: a parity argument

The first mechanism that makes c_m vanish is a symmetry of momentum space. Start with the simplest case: constant coefficients on a flat torus T^m, $L = \gamma^j p_j$ with $p_j = -i\partial_j$ and Hermitian matrices γ^j satisfying $\gamma^j\gamma^k + \gamma^k\gamma^j = 2\delta^{jk}$ (Chapter T4). Then $L^2 = p^2$ and, up to exponentially small corrections (Poisson summation, as in Example 4.136), the trace is a momentum integral:

$$\mathrm{Tr}\big(L\,e^{-tL^2}\big) \overset{(1)}{=} \mathrm{Vol}(T^m) \int \frac{\mathrm{d}^m p}{(2\pi)^m}\, \mathrm{tr}\big(\gamma^j p_j\big) e^{-tp^2} \overset{(2)}{=} 0.$$

(1) The trace over plane waves $e^{ip\cdot y}$ becomes a momentum integral; tr is the matrix trace.
(2) The integrand is odd under $p \to -p$ (and also $\mathrm{tr}\,\gamma^j = 0$).

The general statement is a refinement of step (2). For a *differential* operator the full symbol is a polynomial in p, and its homogeneous pieces have definite parity: the order-1 piece is odd in p, the order-0 piece even. When we build the local heat coefficient $\gamma_k(y)$ from the symbol, every term is a momentum integral whose integrand has parity $(-1)^{k+1}$ under $p \to -p$. (Each derivative of a coefficient trades one power of p for one power of ∂_y, flipping the parity; the leading term, $k = 0$, is odd as we just saw.) So

$$\gamma_k(y) = 0 \quad \text{pointwise, for every even } k.$$

If m is even, c_m has $k = m$ even and vanishes identically: $\eta_L(0)$ is finite. The same argument works for any differential operator of odd order. It fails for pseudo-differential operators, whose symbols need not be polynomials, and it fails for m odd, where $k = m$ is odd and the integrand is even.

Worked example 4.152: The first local coefficient, and a cancellation in one dimension

Add a constant Hermitian matrix potential: $L = \gamma^j p_j + V$ on T^m. We compute the term linear in V of the local odd heat trace (this is the $k = 1$ coefficient, since V counts as one derivative). Since p^2 is a scalar matrix it commutes with everything, and $L^2 = p^2 + \{\gamma \cdot p, V\} + V^2$, so to first order $e^{-tL^2} \approx e^{-tp^2}\big(1 - t\{\gamma \cdot p, V\}\big)$. Then, per unit volume,

$$\gamma_1 \overset{(1)}{=} \int \frac{\mathrm{d}^m p}{(2\pi)^m}\, e^{-tp^2}\ \mathrm{tr}\Big[(\gamma \cdot p + V)\big(1 - t\{\gamma \cdot p, V\}\big)\Big]_{\text{linear in } V}$$
$$\overset{(2)}{=} \int \frac{\mathrm{d}^m p}{(2\pi)^m}\, e^{-tp^2}\big(\mathrm{tr}\, V - 2t\, p^2\ \mathrm{tr}\, V\big) \overset{(3)}{=} \mathrm{tr}\, V\,(4\pi t)^{-m/2}\Big(1 - 2t \cdot \frac{m}{2t}\Big) \overset{(4)}{=} (1-m)\,\frac{\mathrm{tr}\, V}{(4\pi t)^{m/2}}.$$

(1) The trace over plane waves, keeping first order in V.
(2) $\mathrm{tr}(\gamma \cdot p\{\gamma \cdot p, V\}) = 2\,\mathrm{tr}\big((\gamma \cdot p)^2 V\big) = 2p^2\,\mathrm{tr}\, V$ by cyclicity and $(\gamma \cdot p)^2 = p^2$.
(3) Gaussian integrals: $\int \frac{\mathrm{d}^m p}{(2\pi)^m} e^{-tp^2} = (4\pi t)^{-m/2}$ and $\int \frac{\mathrm{d}^m p}{(2\pi)^m} p^2 e^{-tp^2} = \frac{m}{2t}(4\pi t)^{-m/2}$.
(4) Arithmetic.

This is $c_1\, t^{(1-m-1)/2} = c_1 t^{-m/2}$, as (4.258) predicts. It produces a pole of η at $s = m - 1$ with residue proportional to $(1 - m)\,\mathrm{tr}\, V$. For $m = 3$ that is a genuine pole at $s = 2$, harmless for $\eta(0)$. For $m = 1$ the pole would sit exactly at $s = 0$; and there the factor $1 - m$ *vanishes*. This is our circle operator $i\,\mathrm{d}/\mathrm{d}\theta + t$ in disguise, whose odd heat trace we found to be exponentially small (Example 4.137). The cancellation is between the explicit V and the V hidden in e^{-tL^2}: a small instance of the kind of cancellation that makes $\eta(0)$ finite in general.

Odd dimensions: the residue is a matrix, its trace is zero

In odd dimensions the parity argument gives nothing, and the local density $\gamma_m(y)$ need not vanish. Nash's last remark describes what actually happens. Think of $\eta_L(s) = \mathrm{Tr}\big(L|L|^{-s-1}\big)$ as the trace of an operator-valued function of s. Its Schwartz kernel on the diagonal, $K_s(y, y)$, is a *matrix* (an endomorphism of the fibre at y), and it continues meromorphically in s. APS found examples where $K_s(y, y)$ has a pole at $s = 0$ with a nonzero matrix-valued residue $\mathcal{R}(y)$. But the residue of η is $\int_Y \mathrm{tr}\,\mathcal{R}(y)\,\mathrm{d}^m y$, and this turned out to be zero:

$$\mathcal{R}(y) \neq 0, \qquad \text{but} \qquad \int_Y \mathrm{tr}\,\mathcal{R}(y)\,\mathrm{d}^m y = 0.$$

The argument for the vanishing is not a local cancellation. It goes as follows:

1. The residue $\mathrm{Res}_{s=0}\,\eta_L$ is the integral of a local density, so it varies smoothly (in fact, polynomially in the derivatives) under deformations of L.
2. Its variation is computed by (4.247): the derivative of $\eta_L(s)$ is $-s\,\mathrm{Tr}(\dot{L}|L|^{-s-1})$, which has at most a simple pole times s at $s = 0$, i.e. it is *finite*. So $\frac{\mathrm{d}}{\mathrm{d}u}\,\mathrm{Res}_{s=0}\,\eta_{L_u} = 0$: the residue is a *homotopy invariant* of L.
3. A homotopy invariant that is additive and local must be a topological invariant of the symbol, in K-theory. One then checks enough examples (for which $\eta(0)$ is known to be finite, e.g. boundary operators, by the APS theorem) to see that it vanishes on a set of generators.

This is the proof, due to APS for odd dimensions and completed by Gilkey in general. It uses the index theorem, which is why Nash says that the finiteness of $\eta(0)$ is implied by its validity.

Try it: Pole or no pole?

For which of these is $\eta(0)$ finite by the parity argument alone? (a) The Dirac operator on T^2. (b) The odd signature operator on a 3-manifold. (c) A first-order differential operator on S^1. (d) The pseudo-differential operator $|D|^{1/2}\operatorname{sgn} D$ on T^2. *Answer:* (a) yes ($m = 2$ even, order 1). (b) no, $m = 3$ is odd; it is finite by the APS theorem, since it is a boundary operator. (c) no, $m = 1$ is odd; but Example 4.152 and the reparametrisation $\mathrm{d}\phi = \mathrm{d}\theta/a(\theta)$, which turns any such operator into $i\,\mathrm{d}/\mathrm{d}\phi + \text{const}$ up to a unitary transformation and a rescaling, show it is finite. (d) no, it is not a differential operator.

4.21.13 The eta invariant in physics

We promised at the start of this section that the eta invariant is not only a correction term in an index formula. Here are the three places a physicist meets it. In each case L is a Dirac-type operator (a one-particle Hamiltonian, or a Euclidean Dirac operator in odd dimension), and η measures the asymmetry between its positive and negative spectrum.

The fermion number of the Dirac sea

Second-quantise a Dirac field whose one-particle Hamiltonian H has discrete spectrum $\{\lambda\}$ with no zero modes. The vacuum fills every negative level. With the charge-conjugation symmetric definition of the charge operator, $Q = \frac{1}{2}\sum_\lambda [\psi_\lambda^\dagger, \psi_\lambda]$, the vacuum value is

$$\langle Q\rangle_{\mathrm{vac}} \overset{(1)}{=} \frac{1}{2}\Big(\sum_{\lambda<0} 1 - \sum_{\lambda>0} 1\Big) \overset{(2)}{=} -\frac{1}{2}\sum_{\lambda} \operatorname{sgn}\lambda \overset{(3)}{=} -\frac{1}{2}\,\eta_H(0). \tag{4.260}$$

(1) $\frac{1}{2}[\psi^\dagger,\psi] = \psi^\dagger\psi - \frac{1}{2}$ has expectation $+\frac{1}{2}$ on a filled level and $-\frac{1}{2}$ on an empty one.
(2) Collect the terms: a filled (negative) level has $\operatorname{sgn}\lambda = -1$.
(3) The divergent sum is regularised by the eta function, the only regularisation that respects the symmetry $\lambda \to -\lambda$ and locality.

(If H has h zero modes, each can be filled or empty, and the charge is $-\frac{1}{2}\eta_H(0) \pm \frac{1}{2}$ per zero mode.) So the vacuum charge is minus half the spectral asymmetry. It is *fractional* whenever η is.

Worked example 4.153: Fractional charge on a ring with flux

A single chiral fermion on a ring threaded by flux t (in units of the flux quantum) has $H = i\,\mathrm{d}/\mathrm{d}\theta + t$, eigenvalues $n + t$. By the circle computation (4.226), $\eta_H(0) = 1 - 2t$ for $0 < t < 1$, so

$$\langle Q\rangle_{\mathrm{vac}} = -\frac{1}{2}(1-2t) = t - \frac{1}{2}.$$

As the flux increases from 0 to 1, the vacuum charge increases continuously from $-\frac{1}{2}$ to $+\frac{1}{2}$. At $t = 1$ a level crosses zero, the old vacuum becomes an excited state with charge $+\frac{1}{2}$, and the new vacuum has charge $-\frac{1}{2}$ again. The charge transported by one flux quantum is the continuous drift $\int_0^1 \frac{\mathrm{d}\langle Q\rangle}{\mathrm{d}t}\mathrm{d}t = 1$, which equals the spectral flow: this is the chiral anomaly of Section 4.21.10 seen from the vacuum's point of view. For the Jackiw–Rebbi soliton of Example 4.140, charge-conjugation symmetry makes the continuum part of η vanish and the single zero mode gives charge $\pm\frac{1}{2}$: the famous half-integer fermion number of a soliton (Jackiw–Rebbi; Goldstone–Wilczek for the general formula $\langle Q\rangle = -\frac{1}{2}\eta$).

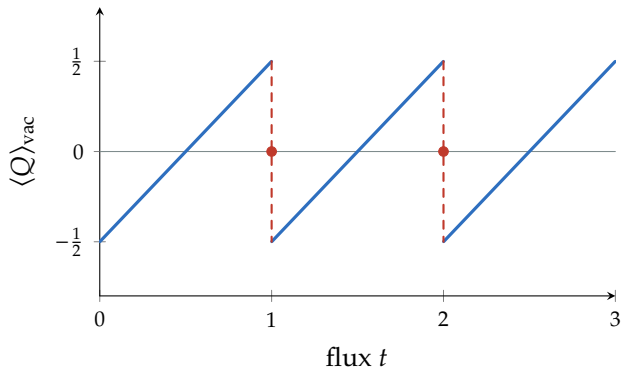

Figure 4.90: The vacuum charge $-\frac{1}{2}\eta$ of a chiral fermion on a ring, as a function of the magnetic flux. It drifts up continuously by one unit per flux quantum, the charge pumped by the anomaly, and drops by one each time a level crosses zero (red dots, where $h = 1$ and the charge is 0 on the symmetric average). The sawtooth is $-\frac{1}{2}$ times the eta sawtooth of Figure 4.78.

The phase of a fermion determinant: the parity anomaly

In odd space-time dimension n, the Euclidean Dirac operator $i\not{D}_A$ is self-adjoint and there is no chirality to split it. The fermion path integral gives $\det(i\not{D}_A)$, a product of real eigenvalues of both signs, and it must be regularised. A gauge-invariant regularisation (for instance Pauli–Villars with a heavy fermion of mass $M \to \infty$) gives

$$\det{}_{\text{reg}}(i\not{D}_A) = \left|\det(i\not{D}_A)\right| \exp\!\left(\mp \frac{i\pi}{2}\, \eta_{i\not{D}_A}(0)\right). \tag{4.261}$$

The reason is simple. The modulus of the determinant is the (regularised) product of the $|\lambda|$. Its sign is $(-1)^{N_-}$, where N_- is the (infinite) number of negative eigenvalues. Write $(-1)^{N_-} = e^{\pm i\pi N_-}$ and split $N_- = \frac{1}{2}(N_+ + N_-) - \frac{1}{2}(N_+ - N_-)$. The first half is a constant that a local counterterm can absorb; the second is $-\frac{1}{2}\sum_\lambda \operatorname{sgn}\lambda$, regularised to $-\frac{1}{2}\eta(0)$. So the phase is $e^{\mp \frac{i\pi}{2}\eta(0)}$ up to a constant, and which sign occurs is fixed by the sign of the regulator mass.

Now compare two gauge fields in $n = 3$. The variation of η is local (Section 4.21.10), and the APS theorem on a 4-manifold X with $\partial X = Y$ identifies it: for a U(1) field with the Hermitian potential a and field strength $f = \mathrm{d}a$ (so $F = -if$), and ignoring the gravitational part,

$$\begin{aligned} \frac{\eta(0)}{2} &\overset{(1)}{=} \int_X \mathrm{ch}_2(F) - \operatorname{index} D_X - \frac{h}{2} \overset{(2)}{=} \frac{1}{8\pi^2}\int_X f \wedge f \quad (\mathrm{mod}\ \mathbb{Z}\ \text{and}\ h) \\ &\overset{(3)}{=} \frac{1}{8\pi^2}\int_Y a \wedge \mathrm{d}a \quad (\mathrm{mod}\ \mathbb{Z}\ \text{and}\ h). \end{aligned}$$

(1) The APS theorem (4.233) for the Dirac operator on X, solved for η (the $\hat{A}$ part omitted).
(2) $\mathrm{ch}_2 = \frac{1}{2}\left(\frac{iF}{2\pi}\right)^2$ with $F = -if$, $f = \mathrm{d}a$; the index is an integer.
(3) $f \wedge f = \mathrm{d}(a \wedge \mathrm{d}a)$ and Stokes; this is Example 4.149 for U(1).

So the phase in (4.261) is $\exp\!\left(\mp\frac{i}{2}\cdot\frac{1}{4\pi}\int_Y a\wedge \mathrm{d}a\right)$ up to integer-level pieces: a single Dirac fermion in three dimensions induces a **Chern–Simons term at level $\frac{1}{2}$**. A level-$\frac{1}{2}$ Chern–Simons term is not gauge invariant under large gauge transformations (only integer levels are), and this clash between gauge invariance and parity is the **parity anomaly** (Redlich; Niemi–Semenoff; Alvarez-Gaumé, Della Pietra and Moore). It is the reason the surface of a topological insulator carries a half-quantised Hall conductance $\sigma_{xy} = \frac{1}{2}\frac{e^2}{h}$.

Global anomalies: eta of a mapping torus

The determinant line bundle of Section 4.18 carries a natural connection (Quillen, Bismut–Freed). Its curvature is the degree-2 part of the families index formula, the local anomaly. Its *holonomy* around a loop in the space of gauge fields is a global quantity, and Witten and Bismut–Freed showed that it is an eta invariant: if the loop of gauge fields A_u on a $2k$-manifold X is glued into a gauge field on the $(2k+1)$-dimensional mapping torus $X \times [0,1]/\sim$, then

$$\text{holonomy of DET} = \lim_{\text{adiabatic}} \exp\bigl(-i\pi\,\eta(0)\bigr),$$

with η that of the odd-dimensional Dirac operator on the mapping torus. A nontrivial holonomy is a **global anomaly**; Witten's SU(2) anomaly (an odd number of Weyl doublets is inconsistent) is the case where the relevant η is 1 modulo 2, and it is equivalent to the mod 2 index of Section 4.19. These are developed in Chapter 10.

Dictionary: the eta invariant

$\eta_H(0)$	$-2\times$ vacuum charge of the Dirac sea
jump of η by 2	a level crossing zero; one unit of spectral flow
smooth drift of η	charge pumped continuously by the anomaly
$\exp(-\frac{i\pi}{2}\eta)$	phase of the odd-dimensional fermion determinant (parity anomaly, Chern–Simons at level $\frac{1}{2}$)
$\exp(-i\pi\eta)$ on a mapping torus	holonomy of the determinant line bundle (global anomaly)
$-\frac{1}{2}(h+\eta)$ in APS	the boundary's share of the index; zero modes count as half-states

Reading Nash (pp. 131–136, (4.156)–(4.177) and footnote 5)

After identifying the signature defect with $\eta(0)$, Nash defines the zeta function of a positive operator (4.156), notes that $\zeta_P(0)$ is finite, and derives η from two zeta functions of $L_\pm = \frac{3}{2}|L| \pm \frac{1}{2}L$ (4.157)–(4.158). He computes $\eta(0) = 1 - 2t$ for $L = i\,\mathrm{d}/\mathrm{d}\theta + t$ on the circle via the Hurwitz zeta function (4.159)–(4.161). He then states the APS theorem for a general first-order $D = A(\partial_n + L)$ with global boundary conditions (4.162)–(4.164), remarks that the Euler characteristic needs no correction, and works out $\bar\partial$ on Σ_g minus p discs, finding $1 - g - p$ (4.165)–(4.174). The last page relaxes the product metric (4.175)–(4.177), with a transgression term Q built from the second fundamental form, and discusses the finiteness of $\eta_B(0)$ for general self-adjoint elliptic B. Footnote 5 mentions the heat-equation proof. We added the Mellin/heat-kernel continuation of ζ and η with explicit pole structure; two further computations of the circle η (smooth cutoff and Poisson summation); the domain wall (Jackiw–Rebbi) and flux-disc examples; the explicit cylinder check of Nash's surface example; the absolute/relative/APS comparison for the Euler operator and the symmetry that forces $\eta = 0$ there; lens-space values of η; the half-line heat-kernel derivation of $-\frac{1}{2}(h+\eta)$; spectral flow and index = spectral flow; the explicit Christoffel symbols, transgression and Chern–Simons forms, and the flat-disc check of (4.177); the pole ladder and parity argument for finiteness; and the physics of η (fractional charge, parity anomaly, global anomalies).

Recap: Section 7

- Zeta functions $\zeta_P(s) = \sum \mu^{-s} = \operatorname{Tr} P^{-s}$ are defined by analytic continuation through the Mellin transform of the heat trace; $\zeta_P(0)$ is always finite. Eta is

$\eta_L(s) = \sum \operatorname{sgn}\lambda |\lambda|^{-s} = \operatorname{Tr}(L|L|^{-s-1})$.

- On the circle, $L = i\,\mathrm{d}/\mathrm{d}\theta + t$ has $\eta(0) = 1 - 2t$ for $0 < t < 1$: a sawtooth with slope -2 (local) and jumps of 2 (level crossings).
- APS: $\operatorname{index} D = \int_X P - \frac{1}{2}(h + \eta(0))$ for $D = A(\partial_n + L)$ with the spectral boundary condition. Examples: domain wall (Jackiw–Rebbi), flux disc ($\lfloor \alpha \rfloor + 1$), $\bar\partial$ on Σ_g minus p discs $(1 - g - p)$.
- Mechanism: each mode of L is a half-line scattering problem contributing $-\frac{1}{2}\operatorname{sgn}\lambda \operatorname{erfc}(|\lambda|\sqrt{t})$ to the supertrace; the zero modes give $-\frac{1}{2}$ each.
- The de Rham complex needs no η (its boundary spectrum is symmetric); the signature operator does.
- Spectral flow: $\operatorname{index}(\partial_u + L_u) = \mathrm{SF}(L_u) - h(L_1)$ on a cylinder; it is the level-crossing picture of the chiral anomaly.
- Non-product metrics add $\int_{\partial X} \widetilde{Q}$, a transgression (Chern–Simons-type) form built from the second fundamental form.
- $\eta(0)$ is finite: by parity in even dimensions, by a global (index-theoretic) argument in odd dimensions, where the local residue is a nonzero matrix of zero trace.
- Physics: vacuum charge $-\frac{1}{2}\eta$, fermion determinant phase $e^{\mp i\pi\eta/2}$ (parity anomaly), global anomalies as $e^{-i\pi\eta}$.

Chapter summary

This chapter answered one question and then asked it again in six new settings. The question: *how many zero modes does an elliptic operator have, net of the zero modes of its adjoint?* The answer (Atiyah–Singer) is that this integer, the index, depends only on the leading symbol up to deformation, and it can be computed by integrating a polynomial in the curvatures over the manifold. The rest of the chapter kept the question and changed the setting.

1. *One operator on a closed manifold* (Nash §1). The index is defined analytically ($\dim\operatorname{Ker} D - \dim\operatorname{Ker} D^*$), repackaged as a map $\operatorname{index}_a : K(T^*X) \to \mathbb{Z}$ on symbol classes, and compared with a topological map index_t built from an embedding and the Thom isomorphism. The theorem is $\operatorname{index}_a = \operatorname{index}_t$. The heat kernel (McKean–Singer) gives a second road to the same integer, and shows why it is a *local* integral.

2. *The classical complexes* (Nash §2). Applying the Chern character turns index_t into $\int_X(\text{characteristic classes})$. For the de Rham, Dolbeault, signature and spin complexes this gives Gauss–Bonnet ($\chi = \int e$), Riemann–Roch ($\chi(X, \mathcal{O}) = \int \mathrm{td}$), Hirzebruch ($\mathrm{Sign} = \int L$) and the $\hat{A}$-genus ($\operatorname{index} \not{D} = \int \hat{A}$).

3. *Coupling to a gauge field* (Nash §3, Section 4.17). Tensor every bundle with a gauge bundle F. The integrand is multiplied by $\mathrm{ch}(F)$. This is the formula that counts fermion zero modes in monopole and instanton backgrounds.

4. *Families* (Nash §4, Section 4.18). Let the operator depend on parameters $y \in Y$. The index becomes a virtual bundle over Y, and its Chern classes (computed by integrating along the fibre) measure how the zero modes twist over Y. The determinant line bundle, where the fermion determinant lives, is its top exterior power; its curvature is the perturbative anomaly.

5. *Real families* (Nash §5, Section 4.19). For real operators the index lives in $KR(Y)$. Torsion appears, and with it invariants such as $\dim\operatorname{Ker} D \bmod 2$ that no curvature integral can see. These are behind global anomalies and Majorana zero modes.

6. *Symmetry* (Nash §6, Section 4.20). If a group G acts, the kernel and cokernel are representations of G and the index is a character. Evaluated at g it is a Lefschetz number, and it is a sum of contributions from the fixed points of g alone (Atiyah–Bott). The Weyl character formula is an example.

7. *Boundaries* (Nash §7, Section 4.21). The boundary condition that keeps the index topological is non-local: keep only the negative spectrum of the boundary operator L. The price is a correction $-\frac{1}{2}(h + \eta)$, where η measures the asymmetry of the spectrum of L. Its jumps are spectral flow; its phase is the parity anomaly.

Figure 4.91 draws the logic. After it come a formula sheet, one example that runs through several of the theorems at once, a picture of the four spectral mechanisms of the chapter, the concept tables, and a guide to which tool answers which physics question.

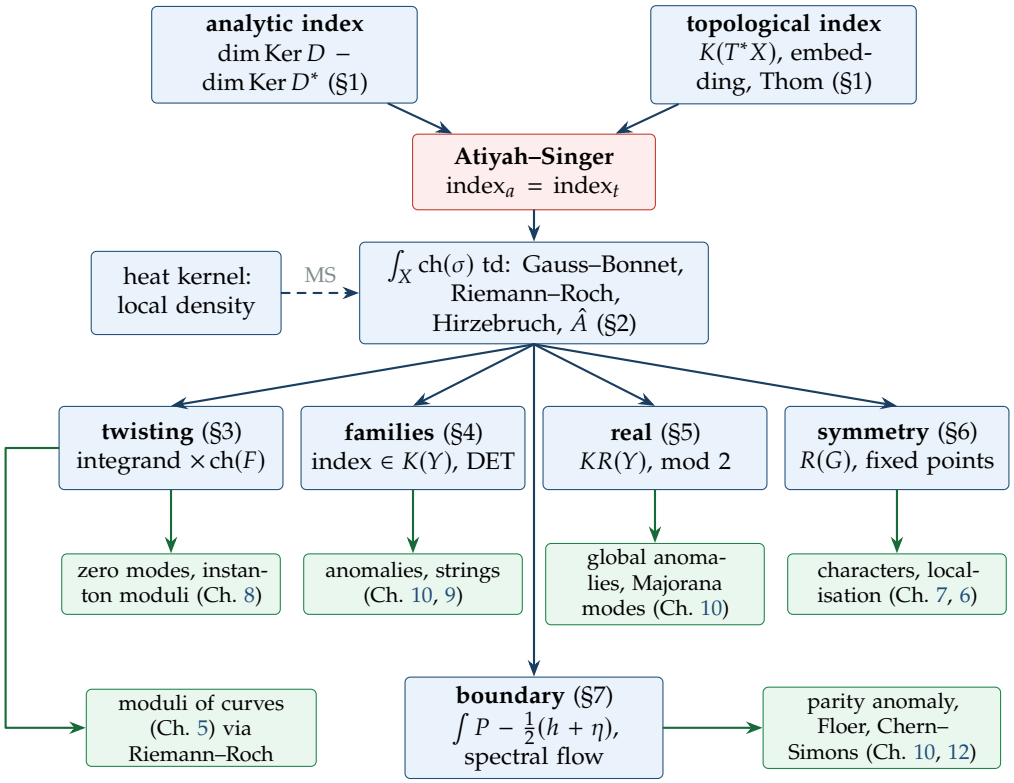

Figure 4.91: Chapter 4 in one picture. The red box is the theorem of §1, reached from the analytic side and the topological side. The cohomological formula (§2) turns it into integrals of curvature; the heat kernel (McKean–Singer, "MS") explains why the integrand is local. The four blue boxes in the middle row are the generalisations of §3–§6; each changes *where the index lives* ($\mathbb{Z}$, $K(Y)$, $KR(Y)$, $R(G)$). The boundary theorem (§7) uses the same local density plus a spectral correction; its proof is the heat kernel on a collar, and its jumps are the spectral flow of a family. Green boxes: where the later chapters use each piece.

The formula sheet

Every index formula of the chapter is the same recipe. *Write the integrand in Chern roots, keep the part of form degree $n = \dim X$, and integrate.* The master formulas of §1 and §2 are

$$\operatorname{index} D = (-1)^n \big\{ \operatorname{ch}[\sigma(D)]\ \operatorname{td}(TX_{\mathbb{C}}) \big\}[TX], \qquad \operatorname{index} D = (-1)^{n/2} \int_X \frac{\operatorname{ch}\big(\sum_p (-1)^p E^p\big)}{e(X)}\ \operatorname{td}(TX_{\mathbb{C}}), \tag{4.262}$$

the first for any elliptic operator (Nash (4.31)), the second for an elliptic complex $E^\bullet$ on an oriented even-dimensional X (Nash (4.48)). The quotient by $e(X)$ is a formal cancellation in the Chern roots. Worked out for the classical complexes, and then twisted by a gauge bundle F of rank r, they give the table below. Here x_i are the Chern roots of TX (roots $\pm x_i$ for the complexification of a real 2ℓ-manifold), $c_1 = c_1(TX)$ for a complex manifold, and $p_1 = \sum x_i^2$.

Complex	Index	Integrand (twisted by F)	Low dimensions
de Rham d_F	$r\,\chi(X)$	$\operatorname{ch}(F)\,e(X) \to r\,e(X)$ (only the rank survives)	$n=2$: $\frac{r}{2\pi}\int K\,\mathrm{d}A$
Dolbeault $\bar\partial_F$	$\chi(X,F) = \sum(-1)^q h^{0,q}(F)$	$\operatorname{ch}(F)\ \operatorname{td}(X)$, $\operatorname{td} = \prod \frac{x_i}{1-e^{-x_i}}$	curve: $\deg F + r(1-g)$; surface: $\int \operatorname{ch}_2(F) + \frac{1}{2}c_1\,c_1(F) + \frac{r}{12}(c_1^2 + c_2)$
signature d_+^F	$\operatorname{Sign}(X)$ if F trivial	$\operatorname{ch}(F)\prod \frac{x_i}{\tanh(x_i/2)}$ (Nash: $2^{n/2}\operatorname{ch}(F)\mathcal{L}$)	$n=2$: $2\int c_1(F)$; $n=4$: $4\int \operatorname{ch}_2(F) + r\operatorname{Sign} X$
spin $\not{D}_F^+$	$n_+ - n_-$ (chiral zero modes)	$\operatorname{ch}(F)\,\hat A(X)$, $\hat A = \prod \frac{x_i/2}{\sinh(x_i/2)}$	$n=2$: $\int c_1(F)$; $n=4$: $\int \operatorname{ch}_2(F) - \frac{r}{24}\int p_1$
family $\{D_y\}$	$[\mathrm{Ker}] - [\mathrm{Coker}] \in K(Y)$	$\operatorname{ch}(\operatorname{index} D) = \pi_*\big(\operatorname{ch}(P)\ \operatorname{td}\big)$ or $\pi_*(\operatorname{ch}(P)\hat A)$	$c_1(\mathrm{DET}) = -[\operatorname{ch}\operatorname{index} D]_{(2)}$
real skew D	$\dim\operatorname{Ker} D \bmod 2$	none (torsion)	Majorana on S^1: R 1, NS 0
G-invariant	$L(g,E) = \sum(-1)^i \operatorname{tr}(g\vert H^i)$	fixed points: $\sum_P \frac{\sum(-1)^i \operatorname{tr}\phi_{i,P}}{\vert\det(1-\mathrm{d}g_P)\vert}$	$\mathbb{CP}^1$, $O(k)$: $\sum_{j=0}^k \lambda^j$
boundary (APS)	index D with $\Pi_{\geq 0}(u\vert_{\partial X}) = 0$	$\int_X P - \frac{1}{2}\big(h + \eta_L(0)\big)$ $(+\int_{\partial X} Q)$	$L = i\frac{\mathrm{d}}{\mathrm{d}\theta} + t$: $\eta(0) = 1 - 2t$
cylinder	$\mathrm{SF}(L_u) - h(L_1)$	bulk and smooth η-drift cancel	flux N pumped: $N - 1$

Two computations show the recipe at work; both are the kind of thing one does on the back of an envelope once the table is memorised.

Worked example 4.154: Chiral zero modes in four dimensions, in one line

Let X be a compact spin 4-manifold and F a gauge bundle of rank r. Then

$$\operatorname{index} \not{D}_F^+ \overset{(1)}{=} \int_X \Big[\operatorname{ch}(F)\,\hat A(X)\Big]_4 \overset{(2)}{=} \int_X \Big[\big(r + c_1(F) + \operatorname{ch}_2(F)\big)\big(1 - \tfrac{1}{24}p_1\big)\Big]_4$$
$$\overset{(3)}{=} \int_X \operatorname{ch}_2(F) - \frac{r}{24}\int_X p_1 \overset{(4)}{=} \int_X \operatorname{ch}_2(F) - \frac{r}{8}\operatorname{Sign}(X).$$

(1) The twisted spin row of the table, degree-4 part.
(2) $\operatorname{ch}(F) = r + c_1(F) + \operatorname{ch}_2(F) + \cdots$ and $\hat A = 1 - \frac{p_1}{24} + \cdots$; higher terms have degree > 4.
(3) Multiply out and keep degree 4: $r\cdot(-\frac{p_1}{24})$ and $\operatorname{ch}_2(F)\cdot 1$; $c_1(F)$ times a degree-4 class is degree 6.
(4) Hirzebruch in four dimensions: $\operatorname{Sign}(X) = \frac{1}{3}\int p_1$.

Two checks. For F trivial ($r = 1$, $\mathrm{ch}_2 = 0$) on K3, with Sign $= -16$, the index is $+2$: the two covariantly constant spinors. For $X = S^4$ (Sign $= 0$) and F the fundamental SU(2) bundle of an instanton, $\mathrm{ch}_2(F) = -c_2(F)$ and the index is $-c_2(F)$: one zero mode per unit of instanton number (the sign is fixed by the orientation convention for k). Rokhlin's theorem hides in the same line: on a spin 4-manifold with F trivial the index is $-\frac{1}{8}$ Sign, so Sign is divisible by 8 (and in fact by 16, because 4D spinors are quaternionic).

Worked example 4.155: Riemann–Roch for a line bundle on a curve

Let $X = \Sigma_g$ be a compact Riemann surface and F a holomorphic line bundle of degree $d = \int c_1(F)$. Then

$$h^0(F) - h^1(F) \overset{(1)}{=} \int_{\Sigma_g} \Big[\mathrm{ch}(F)\,\mathrm{td}(\Sigma_g)\Big]_2 \overset{(2)}{=} \int_{\Sigma_g} \Big[\big(1 + c_1(F)\big)\big(1 + \tfrac{1}{2}c_1(T\Sigma_g)\big)\Big]_2$$
$$\overset{(3)}{=} \int_{\Sigma_g} c_1(F) + \frac{1}{2}\int_{\Sigma_g} c_1(T\Sigma_g) \overset{(4)}{=} d + \frac{1}{2}(2 - 2g) = d + 1 - g.$$

(1) The twisted Dolbeault row: index $= \chi(\Sigma_g, F)$.
(2) $\mathrm{ch}(F) = e^{c_1(F)}$ and $\mathrm{td} = 1 + \frac{1}{2}c_1 + \cdots$ in complex dimension 1.
(3) Keep the 2-form part.
(4) $\int c_1(F) = d$; $c_1(T\Sigma_g)$ is the Euler class, and Gauss–Bonnet gives $\chi(\Sigma_g) = 2 - 2g$.

For $F = \mathcal{O}(k)$ on $\mathbb{CP}^1$ ($g = 0$, $d = k$) this is $k + 1$, the number of polynomials of degree $\le k$. For $F = K^2$, the quadratic differentials ($d = 4g - 4$, $h^0(K^{-1}) = 0$ for $g \ge 2$), it gives $h^0(K^2) = 3g - 3$, the complex dimension of the moduli space of Riemann surfaces used in Chapter 5 and Chapter 9.

One sphere, several theorems

The best way to see that the generalisations of §3–§7 are one theory is to run them on the same object. Take $X = \mathbb{CP}^1 = S^2$ and the operator $\bar\partial$ twisted by $\mathcal{O}(k)$, $k \ge 0$. We already know three things about it.

- *Closed index* (§2–§3): index $= k + 1$, the polynomials $1, z, \ldots, z^k$ (Example 4.155).
- *Character* (§6): under $z \mapsto \lambda z$ the kernel carries the character $\sum_{j=0}^{k} \lambda^j$, and the Atiyah–Bott formula recovers it from the two poles (Example 4.124).
- *Relation to Dirac* (§3): $\not{D}^+$ in a monopole of charge k is $\bar\partial$ on $\mathcal{O}(k-1)$, so it has k zero modes (Example 4.102), forming a spin-$\frac{k-1}{2}$ multiplet by the previous item.

Now we cut the sphere along a circle into two discs and use the boundary theorem (§7) on each half. Gluing the halves back must reproduce $k + 1$. This tests the whole boundary machinery, including the eta invariant and the half-integer bookkeeping of h.

Worked example 4.156: Gluing two APS indices back into Riemann–Roch

Fix $0 < \alpha < k$. Put a metric on $\mathbb{CP}^1$ which is a flat cylinder $\mathrm{d}n^2 + \mathrm{d}\theta^2$ near the equator, and a U(1) connection on $\mathcal{O}(k)$ which is flat there, with flux α through the northern disc X_1 and $k - \alpha$ through the southern disc X_2 (Figure 4.92). Each disc, in its own complex coordinate (z or $w = 1/z$), is exactly the flux disc of Example 4.141, whose boundary

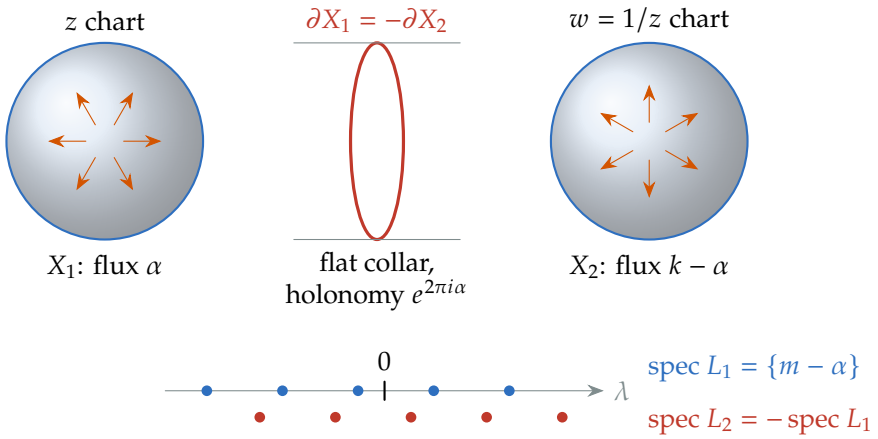

Figure 4.92: Cutting $\mathbb{CP}^1$ into two discs. The flux k of $\mathcal{O}(k)$ is split as α in the northern disc and $k-\alpha$ in the southern one, with a flat collar in between. Seen from the two sides, the collar has boundary operators L_1 and L_2 with *opposite* spectra (blue and red dots, drawn here for $\{\alpha\} \approx 0.35$), because the two discs induce opposite orientations on the circle. So $\eta_{L_2} = -\eta_{L_1}$: the spectral asymmetries cancel on gluing.

operator $L = -i\partial_\theta - \alpha$ has spectrum $\{m - \alpha\}_{m\in\mathbb{Z}}$ and

$$\eta_L(0) = 2\{\alpha\} - 1 \ (\alpha \notin \mathbb{Z}), \qquad \eta_L(0) = 0,\ h = 1 \ (\alpha \in \mathbb{Z}).$$

For X_2 replace α by $\beta = k - \alpha$. Since k is an integer, $\{\beta\} = 1 - \{\alpha\}$ when $\alpha \notin \mathbb{Z}$, so $\eta_{L_2}(0) = 2(1 - \{\alpha\}) - 1 = -\eta_{L_1}(0)$, as the figure says.

Non-integer α ($h = 0$). The APS theorem on each disc gives

$$\begin{aligned}\operatorname{index}_{X_1} + \operatorname{index}_{X_2} &\overset{(1)}{=} \left[\alpha + \tfrac{1}{2} - \tfrac{1}{2}\eta_{L_1}(0)\right] + \left[(k-\alpha) + \tfrac{1}{2} - \tfrac{1}{2}\eta_{L_2}(0)\right] \\ &\overset{(2)}{=} k + 1 - \tfrac{1}{2}\big(\eta_{L_1}(0) + \eta_{L_2}(0)\big) \overset{(3)}{=} k + 1.\end{aligned}$$

(1) (4.233) on each disc, with $\int_{X_i} P = \int c_1(F) + \frac{1}{2}\int e = (\text{flux}) + \frac{1}{2}$ and $h = 0$.

(2) Collect terms; the two half Euler characteristics add up to $\frac{1}{2}\chi(S^2) = 1$.

(3) $\eta_{L_2} = -\eta_{L_1}$.

In terms of the direct counts: $(\lfloor\alpha\rfloor + 1) + (\lfloor k - \alpha\rfloor + 1) = \lfloor\alpha\rfloor + 1 + (k - \lfloor\alpha\rfloor - 1) + 1 = k + 1$. The polynomials z^j with $j < \alpha$ are counted on the north side; those with $j > \alpha$, rewritten as w^{k-j}, on the south side.

Integer α ($h = 1$). Now L_1 has the zero mode $e^{i\alpha\theta}$, the spectra are symmetric, and each disc gives just its flux: $\operatorname{index}_{X_1} = \alpha$, $\operatorname{index}_{X_2} = k - \alpha$. The sum is k, one short. The missing section is z^α itself. On the circle it is the zero mode of L, and both APS conditions project it out (each keeps only strictly negative modes of its own L, and $\lambda = 0$ is not negative for either side). So the gluing law reads

$$\operatorname{index}_X = \operatorname{index}_{X_1} + \operatorname{index}_{X_2} + h, \tag{4.263}$$

and gives $\alpha + (k - \alpha) + 1 = k + 1$. In the non-integer case $h = 0$ and (4.263) is the chain above.

What this shows. The APS pieces are not individually topological: each depends on where we cut (α), through the flux integral and through η. The dependence cancels between the two halves, the local part because the integrals add, and the spectral part because the two sides see L and $-L$. This is the gluing argument of Section 4.21.4 (the defect depends only on the boundary) seen from the index side.

Four spectral pictures

Behind every theorem of the chapter there is a simple statement about how eigenvalues move. Figure 4.93 collects the four mechanisms.

1. *Pairing* (§1). D^*D and DD^* have the same nonzero eigenvalues, because D maps one eigenspace isomorphically onto the other. Only zero modes are unpaired, and their net number cannot change when the nonzero levels move: that is why the index is invariant, and why $\operatorname{Tr} e^{-tD^*D} - \operatorname{Tr} e^{-tDD^*}$ does not depend on t (McKean–Singer).

2. *Jumping* (§4). In a family, a nonzero pair can come down to zero together: dim Ker and dim Coker jump by the same amount and the index does not. The kernels do not form a bundle, but the virtual difference does (stabilisation).

3. *Pairs on the imaginary axis* (§5). A real skew-adjoint operator has eigenvalues $\pm i\lambda$ in pairs. Zero modes can only enter or leave two at a time, so dim Ker mod2 is invariant, even though the complex index is 0.

4. *Asymmetry and flow* (§7). A self-adjoint L (the boundary operator) need not have a symmetric spectrum. The regularised excess of positive over negative eigenvalues is $\eta_L(0)$. When an eigenvalue crosses zero, η jumps by 2; the net number of crossings is the spectral flow, and it equals an index on the cylinder.

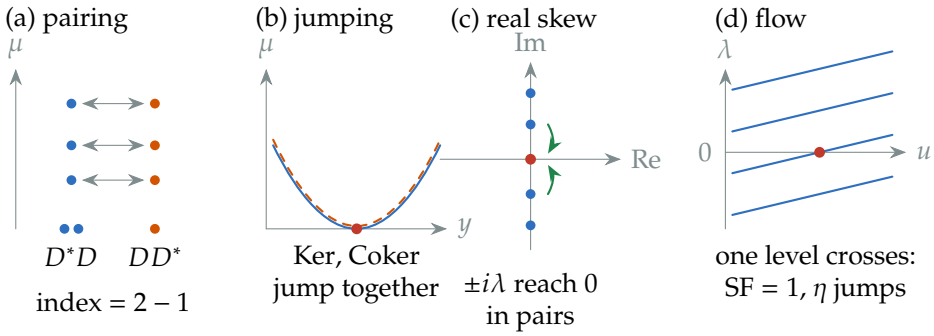

Figure 4.93: The four spectral mechanisms of the chapter. (a) Nonzero levels of D^*D and DD^* are paired; only zero modes (at $\mu = 0$) count, here $2 - 1 = 1$. (b) In a family a paired level can touch zero (red dot): kernel and cokernel jump together, the index does not. (c) For a real skew-adjoint operator eigenvalues come in pairs $\pm i\lambda$ and reach zero two at a time, so dim Ker mod2 is invariant. (d) Eigenvalues of a self-adjoint family L_u drift upward; the level that crosses $\lambda = 0$ is one unit of spectral flow, and it makes $\eta_{L_u}(0)$ jump by 2.

Concept table I: the index and the Atiyah–Singer theorem (Nash §1)

Concept	Operational meaning: how to compute or test it	Used later
kernel, cokernel, index of a linear map	$\operatorname{Coker} T = W/\operatorname{Im} T \cong \operatorname{Ker} T^*$. In finite dimensions $\operatorname{index} T = \dim V - \dim W$ whatever T is (rank–nullity), so the index ignores the details of T.	everywhere
Fredholm operator	Finite-dimensional kernel and cokernel, closed range. Index is locally constant, unchanged by compact perturbations, additive under composition. Test case: the shift on ℓ^2, index -1.	spectral flow (Chapter 10); Fock spaces (Chapter 6)
elliptic operator is Fredholm	Invertible leading symbol $\Rightarrow$ parametrix (inverse up to smoothing, hence compact, errors) $\Rightarrow$ Fredholm. Lower-order terms never change the index ($\mathrm{d}/\mathrm{d}x + a$ on S^1 has index 0 for every a).	all index computations
Toeplitz operator	T_f on the Hardy space of S^1: $\operatorname{index} T_f = -\operatorname{wind}(f)$. The simplest index theorem: analysis (zero modes) equals topology (winding).	loop groups (Chapter 6)
K-theory from complexes	A complex of bundles exact outside a compact set defines a class in K_c; on compact X it is $\sum(-1)^i[E^i]$. Bott class on $\mathbb{C}$: $0 \to \underline{\mathbb{C}} \xrightarrow{z} \underline{\mathbb{C}} \to 0$, i.e. the monopole bundle on S^2.	symbol classes; Thom classes
elliptic complex, rolled-up operator	$\cdots \to \Gamma(E^i) \xrightarrow{d} \Gamma(E^{i+1}) \to \cdots$ with exact symbol sequence. $D = d + d^*$ from even to odd; Laplacians $\Delta_i = d^*d + dd^*$; Hodge: $H^i \cong \operatorname{Ker} \Delta_i$; $\operatorname{index} D = \sum(-1)^i \dim H^i$.	deformation complexes of instantons (Chapter 8), moduli (Chapter 5)
analytic index index_a	$\operatorname{index}_a : K(T^*X) \to \mathbb{Z}$, $[\sigma(D)] \mapsto \operatorname{index} D$: well defined because deformations of the symbol do not change the index.	families, G-index, all of §3–§7
Thom isomorphism, topological index index_t	Embed $X \subset \mathbb{R}^m$; push the symbol class to $T^*\mathbb{R}^m$ with the Thom class of the normal bundle (a Gaussian bump / product of Bott classes); Bott periodicity identifies $K_c(\mathbb{R}^{2m}) = \mathbb{Z}$.	the Thom form in the cohomological formula
Atiyah–Singer theorem	$\operatorname{index}_a = \operatorname{index}_t$. Forced by axioms (excision, multiplicativity, normalisation on a point); checked on Gauss–Bonnet and Riemann–Roch for $\mathbb{CP}^1$.	the whole book
heat kernel, McKean–Singer	$\operatorname{index} D = \operatorname{Tr} e^{-tD^*D} - \operatorname{Tr} e^{-tDD^*}$ for every $t > 0$; as $t \to 0$ this is $\int_X$(local density). Witten index $\operatorname{Tr}(-1)^F e^{-\beta H}$ of SUSY QM.	Morse theory (Chapter 7); Fujikawa anomaly (Chapter 10)

Concept table II: the cohomological formula and the classical complexes (Nash §2)

Concept	Operational meaning: how to compute or test it	Used later
Chern character, Chern roots	$\mathrm{ch}(E) = \mathrm{tr}\, e^{iF/2\pi} = \sum_i e^{x_i}$; additive and multiplicative, so a ring map $K(X) \to H^{\mathrm{even}}(X;\mathbb{Q})$. Splitting principle: compute as if E were a sum of line bundles.	every index formula
td, $\hat{A}$, L	Multiplicative classes from the power series $\frac{x}{1-e^{-x}}$, $\frac{x/2}{\sinh(x/2)}$, $\frac{x}{\tanh x}$. First terms: $1 + \frac{c_1}{2} + \frac{c_1^2+c_2}{12}$; $1 - \frac{p_1}{24}$; $1 + \frac{p_1}{3}$.	Riemann–Roch (Chapter 5); gravitational anomalies (Chapter 10)
cohomological index formula	(4.262). Integrality of $\int \hat{A}$, $\int \mathrm{td}$ is a nontrivial consequence (e.g. Sign $\equiv 0$ mod 16 for spin 4-manifolds).	as above
odd dimensions	Differential operators on odd-dimensional closed manifolds have index 0 (the antipodal map $p \to -p$ reverses the orientation of T^*X). Pseudo-differential operators can evade this (Nash's example on S^1 has index 1).	why η, not the index, is the odd-dimensional invariant (§7)
Thom class, Euler class	The Thom form is a unit-mass Gaussian in the fibres; restricted to the zero section it is $e(X) = \mathrm{Pf}(\Omega/2\pi)$. Poincaré–Hopf: $\int e = \sum$ indices of zeros of a vector field.	Morse theory (Chapter 7)
de Rham complex	$\mathrm{index}(\mathrm{d} + \mathrm{d}^*) = \chi(X) = \int_X e(X)$ (Chern–Gauss–Bonnet); in 2D $\frac{1}{2\pi}\int K\, \mathrm{d}A$.	Morse inequalities (Chapter 7)
Dolbeault complex	$\mathrm{index}(\bar{\partial} + \bar{\partial}^*) = \sum (-1)^q h^{0,q} = \int \mathrm{td}(X)$; Hodge numbers $h^{p,q}$; Noether's formula $\chi(\mathcal{O}) = \frac{1}{12}\int (c_1^2 + c_2)$ on surfaces.	Riemann surfaces, Teichmüller space (Chapter 5, Chapter 9)
signature complex	$\tau = i^{p(p-1)+n/2}\star$ splits forms; $\mathrm{index}\, \mathrm{d}_+ = \mathrm{Sign}(X) = b^+ - b^-$ of the intersection form $= \int L$ (Hirzebruch; $\frac{1}{3}\int p_1$ in 4D).	intersection forms, Donaldson theory (Chapter 8, Chapter 12)
spin structure, Dirac operator	Spin structures exist iff $w_1 = w_2 = 0$; $\not{D} = \gamma^a e_a{}^\mu(\partial_\mu + \omega_\mu)$; $\mathrm{index}\, \not{D}^+ = n_+ - n_- = \int \hat{A}$. Lichnerowicz: positive scalar curvature $\Rightarrow$ no harmonic spinors $\Rightarrow \int \hat{A} = 0$.	gravitational anomalies (Chapter 10), strings (Chapter 9)
twisted Dirac, zero modes	$\mathrm{index}\, \not{D}_F^+ = \int \mathrm{ch}(F)\hat{A}$: $\int c_1(F)$ zero modes in a 2D flux (Aharonov–Casher); $\lvert k\rvert$ fundamental and $4\lvert k\rvert$ adjoint zero modes for an SU(2) instanton; moduli dimension $8k - 3$.	instantons, 't Hooft vertex (Chapter 8, Chapter 10)

Concept table III: twisting, families and real families (Nash §3–§5)

Concept	Operational meaning: how to compute or test it	Used later
matrix-valued forms, d_A	$\Omega^p(X;F)=\Gamma(F\otimes\Lambda^pT^*X_{\mathbb{C}})$; $d_A\omega=\mathrm{d}\omega+A\wedge\omega$ is gauge covariant and $d_A^2=F_A$, so the twisted de Rham sequence is a complex only for flat F (Section 4.17.2).	gauge fields throughout (Chapter 8)
twisting rule	Replace E^p by $F\otimes E^p$; since $\mathrm{ch}(A\otimes B)=\mathrm{ch}\,A\ \mathrm{ch}\,B$ the integrand is multiplied by $\mathrm{ch}(F)$ (Section 4.17.1).	all of the above
twisted de Rham	$\operatorname{index}\mathrm{d}_F=\int\mathrm{ch}(F)e(X)=r\chi(X)$: only the rank survives, because $e(X)$ is already top degree.	flat bundles, local systems
twisted Dolbeault	$\chi(X,F)=\int\mathrm{ch}(F)\,\mathrm{td}(X)$ (Hirzebruch–Riemann–Roch). On $\mathbb{CP}^1$: $\dim H^0(\mathcal{O}(k))=k+1$; on $\mathbb{CP}^2$: $\binom{k+2}{2}$ (Section 4.17.3).	Chapter 5, Chapter 9
twisted signature, twisted Dirac	$\int\mathrm{ch}(F)\prod\frac{x_i}{\tanh(x_i/2)}$ and $\int\mathrm{ch}(F)\hat{A}$ (Sections 4.17.4 and 4.17.5); nonzero even in dimensions where the untwisted index vanishes (e.g. $\not{D}$ on S^2 in a monopole: k).	zero modes (Chapter 8)
family, index bundle	$\{D_y\}_{y\in Y}$: $\operatorname{index}D=[\ker D]-[\operatorname{Coker}D]\in K(Y)$; if the kernel jumps, stabilise by adding $\mathbb{C}^N$ to kill the cokernel (Sections 4.18.3 and 4.18.4).	anomalies (Chapter 10)
fibre bundle of manifolds	$X\to Z\to Y$ with structure group $\mathrm{Diff}(X)$; symbols give a class in $K(T_FZ)$ (tangent along fibres); $\operatorname{index}_a=\operatorname{index}_t:K(T_FZ)\to K(Y)$ (Section 4.18.5).	gravitational anomalies, moduli of metrics (Chapter 10, Chapter 9)
families formula, π_*	$\mathrm{ch}(\operatorname{index}D)=(-1)^n\pi_*\{\mathrm{ch}[\sigma]\,\mathrm{td}(T_FZ_{\mathbb{C}})\}$; π_* integrates the components with $\dim X$ legs along the fibre and lowers degree by $\dim X$ (Section 4.18.7). Flat bundles on T^2: $c_1=\mp1$ over the dual torus (Section 4.18.8).	descent equations (Chapter 10)
torsion	ch is rational and kills torsion in $K(Y)$; a family can be nontrivial with $\mathrm{ch}(\operatorname{index}D)=\text{rank}$ (Section 4.18.9).	global anomalies (Chapter 10)
determinant line bundle	$\mathrm{DET}=(\Lambda^{\max}\ker)^*\otimes\Lambda^{\max}\operatorname{Coker}$, a line bundle even when kernels jump; $c_1(\mathrm{DET})=-c_1(\operatorname{index}D)$. The fermion determinant is a section of it; $c_1\neq0$ is a gauge anomaly (Section 4.18.10).	Quillen metric, anomalies, string measure (Chapter 10, Chapter 9)
real operator, KR	Real symbol: $\overline{\sigma(x,p)}=\sigma(x,-p)$ (real coefficients). Real families have index in $KR(Y)$, K-theory with the involution $p\to-p$; for trivial involution $KR=KO$ (Sections 4.19.1 and 4.19.2).	global anomalies (Chapter 10)
mod 2 index	Real skew-adjoint D: $\operatorname{index}_1D=\dim\ker D \bmod 2$, invariant because eigenvalues $\pm i\lambda$ pair up. It is the index of a real family over S^1, $m[\eta]$ with $[\eta]$ the Möbius generator of $\widetilde{KR}(S^1)=\mathbb{Z}_2$; no cohomological formula (Sections 4.19.3 to 4.19.5).	Witten's SU(2) anomaly (Chapter 10); $(-1)^F$ in SUSY QM (Chapter 7)

Concept table IV: symmetries and fixed points (Nash §6)

Concept	Operational meaning: how to compute or test it	Used later
Lefschetz number $L(g)$	$\sum_p (-1)^p \operatorname{tr}(g^* \mid H^p)$; homotopy invariant, $L(\mathrm{id}) = \chi(X)$; $L(g) \neq 0 \Rightarrow$ fixed point. Circle maps: $L = 1 - \deg g$; sphere maps: $L = 1 + \deg g$ (Section 4.20.1).	Morse theory (Chapter 7)
Lefschetz–Hopf	$L(g) = \sum_{g(P)=P} \operatorname{sgn} \det(1 - \mathrm{d}g_P)$ for non-degenerate fixed points; rotation of S^2: two poles, each +1 (Section 4.20.2).	localisation (Chapter 7)
$L(g, E)$ for an elliptic complex	$\sum_i (-1)^i \operatorname{tr}(g \mid H^i(E))$ for g commuting with the d_i; with G compact it is a character, the *character-valued index* (Section 4.20.3).	symmetric instantons and monopoles (Chapter 8)
equivariant K-theory, $R(G)$	$K_G(X)$ from G-bundles ($F_x \to F_{gx}$); $K_G(\mathrm{pt}) = R(G)$, the representation ring (formal differences of representations, added by $\oplus$, multiplied by $\otimes$); $K_{\{e\}}(X) = K(X)$.	loop group representations (Chapter 6)
G-index theorem, Atiyah–Segal	$\mathrm{index}_a = \mathrm{index}_t : K_G(T^*X) \to R(G)$; $L(g, E) = \chi(g)$ is an integral over the fixed-point set X^g (Section 4.20.4).	equivariant Morse theory (Chapter 7)
Atiyah–Bott formula	Isolated fixed points: $L(g, E) = \sum_P \frac{\sum_i (-1)^i \operatorname{tr} \phi_{i,P}}{\lvert \det(1 - \mathrm{d}g_P) \rvert}$. Holomorphic version on $\mathbb{CP}^1$ gives the Weyl character $\frac{\sin(s+\frac{1}{2})\alpha}{\sin \frac{\alpha}{2}}$ (Example 4.124).	characters, fusion (Chapter 6, Chapter 11)
heat-kernel localisation	$\operatorname{Tr}(g\, e^{-t\Delta})$ has kernel $K_t(gx, x)$, which is exponentially small unless $gx \approx x$; so as $t \to 0$ only fixed points contribute (Section 4.20.5).	SUSY localisation (Chapter 7)

Concept table V: manifolds with boundary (Nash §7)

Concept	Operational meaning: how to compute or test it	Used later
boundary conditions, local vs global	Dirichlet/Neumann are local and fine for Δ; for $\bar\partial$, chiral Dirac and d_+ the number of decaying boundary modes depends on the sign of the boundary frequency, so no local condition gives a Fredholm problem (Section 4.21.1).	domain walls, edge states
boundary operator, APS condition	Near a product boundary $D = A(\partial_n + L)$, L self-adjoint elliptic on ∂X; impose $\Pi_{\geq 0}(u|_{\partial X}) = 0$, i.e. L^2 on the elongated manifold; $\Pi = \frac{1}{2}M^{-1}(M + |M|)$ is non-local (Hardy projection on S^1) (Section 4.21.2).	Chapter 10, Chapter 12
Gauss–Bonnet with boundary	$\chi(X) = \frac{1}{2\pi}(\int K\,\mathrm{d}A + \oint k_g\,\mathrm{d}s)$; the boundary term is local and vanishes for a product collar (Section 4.21.3).	string world-sheets with boundary (Chapter 9)
signature defect	$\mathrm{Sign}(X) - \frac{1}{3}\int p_1 = -\frac{1}{2}\eta_L(0)$ depends only on ∂X (gluing argument) and is not a local integral (Section 4.21.4).	3-manifold invariants (Chapter 12)
zeta function	$\zeta_P(s) = \sum \mu^{-s} = \mathrm{Tr}\,P^{-s} = \frac{1}{\Gamma(s)}\int_0^\infty t^{s-1}\,\mathrm{Tr}'\,e^{-tP}\mathrm{d}t$; finite at $s = 0$; $\zeta_P(0) = a_n - \dim\mathrm{Ker}\,P$, a_n the t^0 heat coefficient (Section 4.21.5).	determinants, conformal anomaly (Chapter 9, Chapter 11)
eta invariant	$\eta_L(s) = \sum \mathrm{sgn}\,\lambda|\lambda|^{-s}$; $\eta_L(0)$ = regularised $\#(\lambda > 0) - \#(\lambda < 0)$. Circle: $L = i\frac{\mathrm{d}}{\mathrm{d}\theta} + t$ gives $\eta(0) = 1 - 2t$ on $0 < t < 1$ (Hurwitz zeta, heat kernel, Poisson) (Section 4.21.6).	parity anomaly, CS framing (Chapter 10, Chapter 12)
APS index theorem	$\mathrm{index}\,D = \int_X P - \frac{1}{2}(h + \eta_L(0))$ with $h = \dim\mathrm{Ker}\,L$. Examples: Jackiw–Rebbi domain wall, flux disc $\lfloor\alpha\rfloor + 1$, $\bar\partial$ on Σ_g minus p discs: $1 - g - p$ (Section 4.21.7).	anomalies (Chapter 10)
which indices need η	The de Rham (Euler) complex needs no correction: its boundary spectrum is symmetric. The signature and Dirac operators do (Section 4.21.8).	
spectral flow	$\mathrm{SF}(L_u)$ = net number of eigenvalues crossing 0 upward; $\mathrm{index}(\partial_u + L_u) = \mathrm{SF} - h(L_1)$ on a cylinder (Section 4.21.10).	Hamiltonian anomalies (Chapter 10); Floer homology (Chapter 12)
non-product metrics	Add $\int_{\partial X} Q$, a transgression (Chern–Simons type) form built from the second fundamental form: $P(R) - P(R') = \mathrm{d}Q$ (Section 4.21.11).	Chern–Simons forms (Chapter 8, Chapter 12)
finiteness of $\eta(0)$	Residue at $s = 0$ is a local integral that vanishes: by parity in even dimensions, by a global argument in odd ones (Section 4.21.12).	
η in physics	Vacuum charge $-\frac{1}{2}\eta_H(0)$; odd-dimensional fermion determinant phase $e^{\mp i\pi\eta/2}$ (parity anomaly); $e^{-i\pi\eta}$ on a mapping torus is a global anomaly (Section 4.21.13).	Chapter 10, Chapter 12

Which tool answers which physics question

The concept tables are organised by mathematics. A physicist usually starts from a question. The table below runs the other way: from the question to the invariant that answers it, the formula that computes it, and the chapter where the answer is used.

Question	Invariant	Formula	Where
How many chiral fermion zero modes in this gauge background?	index $\not{D}_F^+$	$\int \mathrm{ch}(F)\hat{A}$; 2D: flux; 4D: $\int \mathrm{ch}_2(F)$	Chapter 8
How many parameters does the space of instantons / complex structures have?	index of a deformation complex	$8k-3$ for SU(2) on S^4; $3g-3$ for curves	Chapter 8, Chapter 5
Is the fermion determinant a gauge-invariant function?	$c_1(\mathrm{DET})$ over $\mathcal{A}/\mathcal{G}$	families formula in $n+2$ dimensions	Chapter 10
Is there an anomaly no Feynman diagram sees?	torsion of index; mod 2 index; $e^{-i\pi\eta}$	dim Ker mod2 of a 5D operator (Witten SU(2))	Chapter 10
How much charge does a soliton or a flux carry?	$\eta_H(0)$	$\langle Q\rangle = -\frac{1}{2}\eta_H(0)$	Chapter 10
How much charge is pumped when a parameter winds?	spectral flow	$\mathrm{SF} = \mathrm{index}(\partial_u + L_u)$	Chapter 10, Chapter 12
Phase of the fermion path integral in odd dimensions?	$\eta(0)$ of $i\not{D}_A$	$\lvert\det\rvert\, e^{\mp i\pi\eta/2}$	Chapter 10, Chapter 12
How do the zero modes transform under a symmetry?	character-valued index	Atiyah–Bott sum over fixed points	Chapter 7, Chapter 6
Does SUSY break? How many ground states?	Witten index	$\mathrm{Tr}(-1)^F e^{-\beta H} = \mathrm{index}$	Chapter 7
Why is $\sum \lambda^{-s}$ or $\det\Delta$ finite?	ζ function	Mellin transform of the heat trace	Chapter 9, Chapter 11

Reading Nash (Chapter IV at a glance, pp. 89–136 (PDF 99–146))

Nash's chapter, section by section, with where each part of these notes treats it.

- §1 *The index of an elliptic operator*, pp. 89–97, (4.1)–(4.30): Fredholm property, symbol classes, index_a and index_t, the Atiyah–Singer theorem. Nash quotes rather than explains; the first part of this chapter builds it from linear algebra, and adds Toeplitz operators and the heat kernel.
- §2 *Some examples*, pp. 97–116, (4.31)–(4.111): the cohomological formula, odd dimensions, the Thom and Euler classes, and the de Rham, Dolbeault, signature and spin complexes.
- §3 *Twisted complexes*, pp. 116–119, (4.112)–(4.122): Section 4.17.
- §4 *The index theorem for families of operators*, pp. 119–121, (4.123)–(4.127): Section 4.18; the determinant line bundle is our addition, and Nash takes it up in his anomalies chapter.
- §5 *The index for real families*, pp. 121–123, (4.128)–(4.129): Section 4.19.
- §6 *Index theory and fixed points*, pp. 123–127, (4.130)–(4.140): Section 4.20; the Atiyah–Bott formula and its examples are our addition to Nash's statement of the Atiyah–Segal

theorem.

- §7 *Index theory for manifolds with boundary*, pp. 127–136, (4.141)–(4.177): Section 4.21.

Nash ends the chapter without a summary. The formula sheet, the gluing example of Example 4.156 and the tables above are ours.

Recap: What to carry forward from Chapter

- The index is the only part of the zero-mode count that is stable. It depends on the leading symbol up to deformation, so it is topological, and it is a local integral of curvature.
- The integrand is always a product: ch(coefficients) times a genus of X (e, td, L, $\hat{A}$). Keep the top-degree part and integrate.
- With parameters the index becomes a bundle, its top exterior power is the determinant line, and its Chern classes are anomalies. Torsion (mod 2 indices) carries global anomalies, invisible to curvature.
- With a symmetry the index becomes a character, and it localises on fixed points.
- With a boundary the index needs a non-local boundary condition and picks up $-\frac{1}{2}(h+\eta)$; η is the spectral asymmetry, its jumps are spectral flow, and its phase is the parity anomaly.
- The heat kernel is the common engine: it proves McKean–Singer, localisation on fixed points, and the η term of APS.

Chapter 5

Some Algebraic Geometry

Where this chapter is going

Physics keeps producing complex manifolds. The worldsheet of a closed string in Euclidean signature is a two-dimensional surface with a conformal structure, and a surface with a conformal structure is the same thing as a *Riemann surface*. The extra dimensions of superstring theory are Calabi–Yau manifolds, which are Kähler. The self-dual instantons of Chapter 8 are classified by holomorphic data on twistor space. Supersymmetric sigma models with extended supersymmetry need a Kähler target. In all of these places the most efficient way to describe the manifold is not by charts and transition functions but by *polynomial equations*: the torus that a one-loop string amplitude integrates over is the solution set of $y^2 = x(x-1)(x-\lambda)$, and the number λ is the modulus of the torus.

Algebraic geometry is the study of such solution sets. Nash's Chapter V is a compact tour of the pieces of it that a physicist needs later in the book. We go in the following order. First, what an algebraic variety is, and why projective space is the natural place to put it (§5.1). We learn to see projective space in the real projective plane $\mathbb{RP}^2$, where parallel lines meet on the horizon and a parabola closes up into a circle, before passing to $\mathbb{CP}^n$ and the Hopf fibration, and we sort out which pictures of these spaces can be trusted. Then we specialise to complex dimension one, the Riemann surfaces Σ_p of genus p, and learn to describe line bundles on them by recording where their sections vanish or blow up: this bookkeeping device is a *divisor* (§5.2). The integrals of holomorphic 1-forms around the $2p$ independent loops of Σ_p form the *period matrix*, which packages the complex structure into a $p \times p$ symmetric matrix and produces a torus, the *Jacobian*. Next come the global tools (§5.3): Serre duality, the Riemann–Roch theorem that counts holomorphic sections, the classification of line bundles by the exponential sheaf sequence, and finally Kähler manifolds and the Hodge decomposition of their cohomology. The second part of the chapter (Teichmüller space and the moduli space $\mathcal{M}_p$) uses all of this to parametrise the possible complex structures on Σ_p, which is exactly the space a string path integral integrates over in Chapter 9.

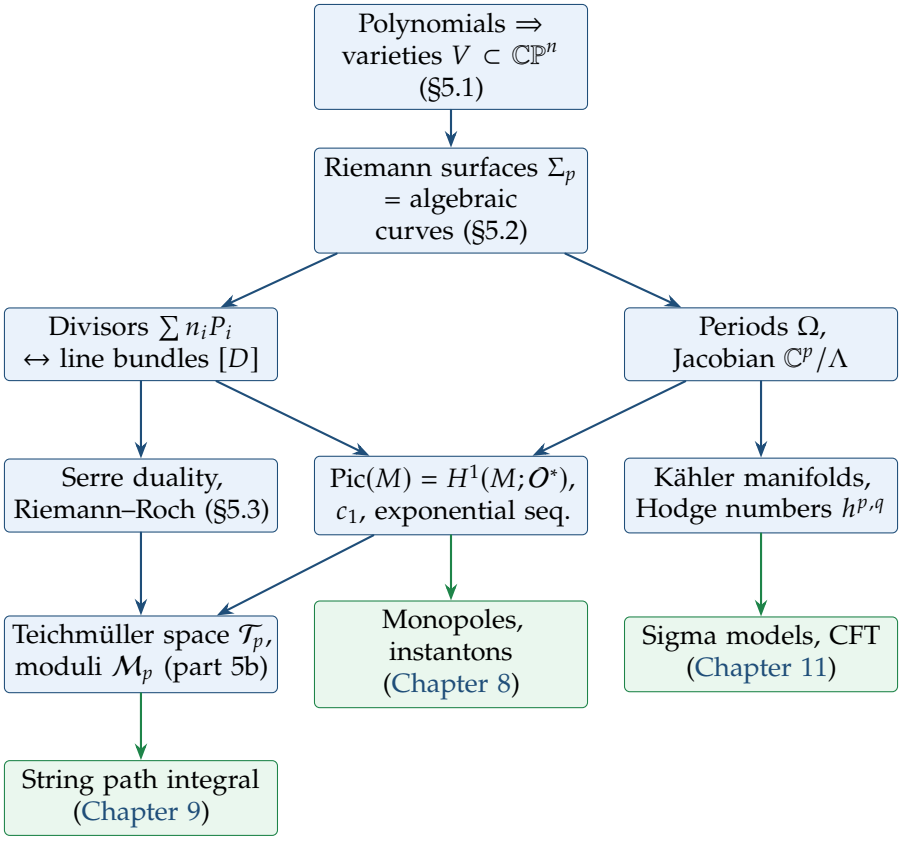

Figure 5.1: The logic of Chapter V. Blue boxes are the mathematics of this part and the next; green boxes are where the physics uses it. The central object is the Riemann surface. Divisors, periods and Kähler geometry are three complementary ways of getting a handle on its complex structure, and Teichmüller theory assembles them into a space of complex structures.

Dictionary: algebraic geometry for physicists

Mathematics	Physics
compact Riemann surface Σ_p	Euclidean closed-string worldsheet with p loops
complex structure modulus (λ, τ, Ω)	shape parameters integrated over in string amplitudes
holomorphic line bundle L	bundle whose sections are charged wavefunctions
degree $\deg L = c_1(L)$	magnetic flux through the surface (Dirac quantisation)
holomorphic section of L	lowest-Landau-level wavefunction
divisor of a section	positions of the zeros (vortices) of that wavefunction
Kähler form ω	symplectic form; phase space of a system; target metric of an $N = 2$ sigma model

5.1 Algebraic varieties

What kind of space do you get if you solve polynomial equations? In real variables the answer can be almost anything: $x^2 + y^2 = 1$ is a circle, $x^2 + y^2 = -1$ is empty, and $y^2 = x^3$ has a sharp corner. Over the complex numbers the answers become much more uniform and much more rigid. A single polynomial equation in two complex variables always has solutions, the solution set is (apart from finitely many bad points) a smooth surface, and once we add the "points at infinity" the surface becomes compact and its topology is fixed by the degree of the polynomial. This section sets up the language: affine varieties; complex functions pictured as maps from a plane to a plane; projective space, first real (where we can draw it: lines through the origin, perspective, conics closing up at infinity) and then complex; projective varieties; singular points; and two theorems (Chow and Kodaira) that say when a complex manifold can be described by polynomials at all.

Throughout, as in Nash, the field of numbers is $\mathbb{C}$.

5.1.1 Zero sets of polynomials

Working definition 5.1 (affine variety)

Pick polynomials $P_1, \dots, P_k$ in m complex variables $x = (x_1, \dots, x_m)$. Their common zero set

$$V(P_1, \dots, P_k) \;=\; \{\, x \in \mathbb{C}^m \;:\; P_1(x) = \cdots = P_k(x) = 0 \,\}$$

is an **affine algebraic variety**. ["affine" means it sits in ordinary $\mathbb{C}^m$, with no points at infinity added] *Operationally*: a point belongs to V if you can substitute it into every P_i and get zero.

A count of equations gives a first guess at the size of V. Each equation cuts one complex dimension, so we expect $\dim_{\mathbb{C}} V = m - k$. When that guess is correct and the equations are "independent" at every point, V is a complex manifold of dimension $m - k$. When it fails, V has *singular points*. We make this precise in Section 5.1.9.

Watch out: complex dimension versus real dimension

A complex curve (complex dimension one) is a real surface (real dimension two). Algebraic geometers say "curve" and draw surfaces. When we draw a picture of a complex curve in $\mathbb{C}^2$ we usually draw only its *real points*, the solutions with $x, y \in \mathbb{R}$. This is a one-dimensional slice of a two-dimensional object. It is useful for spotting singularities, but it can badly misrepresent topology.

Worked example 5.1: The complex circle is a punctured plane

Take $V = \{x^2 + y^2 = 1\} \subset \mathbb{C}^2$. Its real points form the unit circle. Its complex points are a very different space. Introduce $u = x + \mathrm{i}y$ and $v = x - \mathrm{i}y$ (with x, y complex, so u and v are independent complex numbers, not conjugates). Then

$$x^2 + y^2 \overset{(1)}{=} (x + \mathrm{i}y)(x - \mathrm{i}y) \overset{(2)}{=} uv,$$

(1) Expand: $(x + \mathrm{i}y)(x - \mathrm{i}y) = x^2 - \mathrm{i}^2 y^2 = x^2 + y^2$, valid for any complex x, y.
(2) Definition of u and v.

So $V = \{uv = 1\}$. For every $u \neq 0$ there is exactly one $v = 1/u$, so $u \mapsto (u, 1/u)$ identifies V with $\mathbb{C}^* = \mathbb{C} \setminus \{0\}$, a cylinder. The real circle is the loop $|u| = 1$ going once round that cylinder. The complex circle is not compact: it has two ends, $u \to 0$ and $u \to \infty$. Adding one point at each end would close it up into a sphere. That is exactly what projective space will do for us.

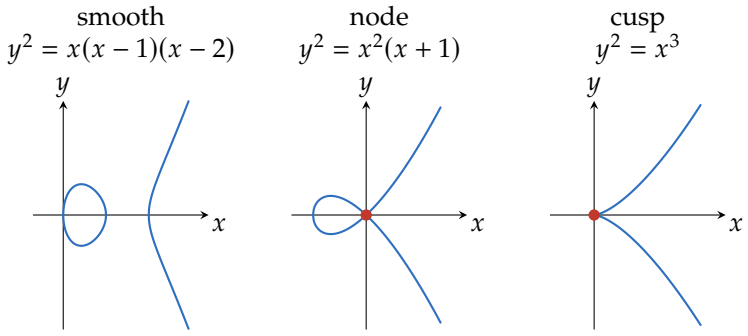

Figure 5.2: Real points of three plane cubic curves. The smooth cubic (left) has two real pieces, an oval and an unbounded branch; its complex points form a torus with one point missing (the point at infinity). The node (middle) has two branches crossing at the red point; the cusp (right) has a single branch with a sharp point. At the red points the Jacobian of the defining polynomial vanishes: those are the singular points.

5.1.2 A complex function is a map from a plane to a plane

From here on the variables are complex, and complex functions appear everywhere: the map $u \mapsto 1/u$ just above, the square root $y = \pm\sqrt{q(x)}$ that solves a cubic, the changes of chart on a Riemann surface. How do we draw a function $y = f(x)$ when x and y are complex?

A complex number $x = a + ib$ is a point (a, b) of a plane, the **complex x-plane**. One complex dimension is two real dimensions. A function $f : \mathbb{C} \to \mathbb{C}$ takes each point of the x-plane to a point of a second plane, the complex y-plane. In real terms it is a pair of real functions of two

real variables,

$$\operatorname{Re} y = U(a,b), \qquad \operatorname{Im} y = W(a,b),$$

that is, a map $\mathbb{R}^2 \to \mathbb{R}^2$, like a change of coordinates or the velocity field of a flow in a plane. Its graph $\{(x, f(x))\}$ lives in $\mathbb{C}^2 = \mathbb{R}^4$, and we cannot draw it. So we draw something else.

Working definition 5.2 (picturing a complex function)

Draw two planes side by side: the x-plane on the left (the inputs) and the y-plane on the right (the outputs). Pick a simple curve in the x-plane, such as a circle around the origin, a ray out of the origin or a straight grid line. Send every point of the curve through f. The image points form a curve in the y-plane; draw it in the same colour. A few such pairs of curves show how f stretches, turns and folds the plane, just as a few grid lines show what a change of coordinates does. *Operationally*: write the curve as $x(t)$, compute $y(t) = f(x(t))$, split it into real and imaginary parts, and eliminate t.

The tool that makes circles and rays easy is the polar form. Write $x = r\,e^{\mathrm{i}\theta}$, where $r = |x|$ is the distance from the origin and $\theta = \arg x$ is the angle from the positive real axis, and $e^{\mathrm{i}\theta} = \cos\theta + \mathrm{i}\sin\theta$ (Euler's formula). Since $e^{\mathrm{i}\alpha}e^{\mathrm{i}\beta} = e^{\mathrm{i}(\alpha+\beta)}$, multiplying two complex numbers multiplies their lengths and adds their angles.

Worked example 5.2: $y = x^2$ doubles angles and squares lengths

Circles and rays. Put $x = r\,e^{\mathrm{i}\theta}$. Then

$$\begin{aligned} y &\overset{(1)}{=} \left(r\,e^{\mathrm{i}\theta}\right)^2 \\ &\overset{(2)}{=} r^2\,e^{2\mathrm{i}\theta}. \end{aligned}$$

(1) Definition of the map.
(2) $(r\,e^{\mathrm{i}\theta})^2 = r^2\,e^{\mathrm{i}\theta}e^{\mathrm{i}\theta}$, and the angles add: $e^{\mathrm{i}\theta}e^{\mathrm{i}\theta} = e^{2\mathrm{i}\theta}$.

So $|y| = r^2$ and $\arg y = 2\theta$. The circle $|x| = r$ goes to the circle $|y| = r^2$. As x runs once around its circle, θ runs from 0 to 2π and 2θ runs from 0 to 4π: the image circle is traced *twice*. The ray $\arg x = \theta$ goes to the ray $\arg y = 2\theta$. The opposite ray, $\arg x = \theta + \pi$, goes to $\arg y = 2\theta + 2\pi$, which is the same ray. In general x and $-x$ have the same image, so every $y \neq 0$ has exactly two preimages: the map is two-to-one.
A grid line. Take the vertical line $\operatorname{Re} x = c$ with $c > 0$, that is, $x = c + \mathrm{i}t$ with $t \in \mathbb{R}$. Then

$$\begin{aligned} y &\overset{(1)}{=} c^2 + 2\mathrm{i}ct + (\mathrm{i}t)^2 \\ &\overset{(2)}{=} c^2 - t^2 + 2\mathrm{i}ct, \end{aligned}$$

(1) Expand $(c + \mathrm{i}t)^2$.
(2) $\mathrm{i}^2 = -1$.

so $\operatorname{Re} y = c^2 - t^2$ and $\operatorname{Im} y = 2ct$. Eliminate t:

$$\begin{aligned} \operatorname{Re} y &\overset{(1)}{=} c^2 - t^2 \\ &\overset{(2)}{=} c^2 - \left(\frac{\operatorname{Im} y}{2c}\right)^2 \\ &= c^2 - \frac{(\operatorname{Im} y)^2}{4c^2}. \end{aligned}$$

(1) The real part found above.

(2) Solve $\operatorname{Im} y = 2ct$ for t, using $c \neq 0$.

This is a parabola that opens to the left. Its tip is at $y = c^2$ (from $t = 0$), and it crosses the imaginary axis at $\operatorname{Im} y = \pm 2c^2$ (from $t = \pm c$). The line $\operatorname{Re} x = -c$ goes to the same parabola, again because $(-x)^2 = x^2$.

Angles. In the x-plane the circles and the rays cross at right angles, and so do their images. This is a general fact: a complex-differentiable map preserves angles wherever $f'(x) \neq 0$. Physicists use it in two-dimensional electrostatics and fluid flow, where such a **conformal map** carries one field pattern to another. Here $f'(x) = 2x$ vanishes at $x = 0$, and exactly there angles are doubled rather than preserved: two rays at angle θ to each other go to rays at angle 2θ.

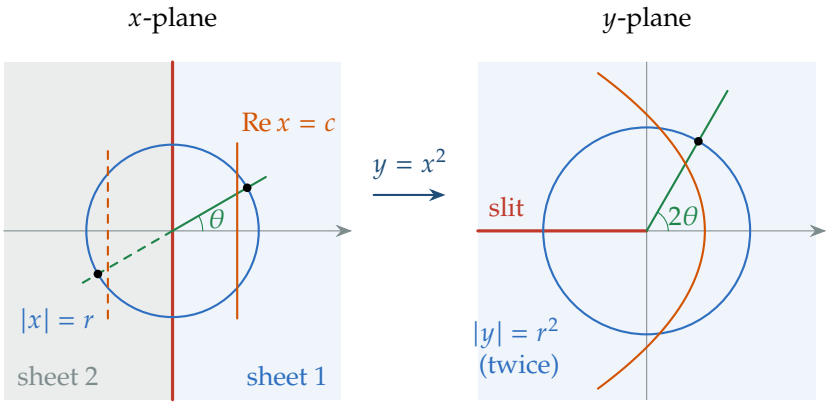

Figure 5.3: The map $y = x^2$, drawn as two planes; curves of the same colour correspond. The circle $|x| = r$ (blue) goes to the circle $|y| = r^2$, traced twice. The ray $\arg x = \theta$ (green, solid) and the opposite ray (green, dashed) both go to the ray $\arg y = 2\theta$. The vertical line $\operatorname{Re} x = c$ (orange, solid) and the line $\operatorname{Re} x = -c$ (orange, dashed) both go to the parabola $\operatorname{Re} y = c^2 - (\operatorname{Im} y)^2/(4c^2)$. The two black dots $\pm x_0$ go to the one black dot x_0^2. Each half of the x-plane, the right half (sheet 1) and the left half (sheet 2), covers the whole y-plane once, except for the negative real axis (red), which is the image of the imaginary axis where the two halves meet. So the square root $x = \sqrt{y}$ has two values, one on each sheet, and crossing the red slit takes it from one sheet to the other.

The square root needs two sheets. Now read the picture from right to left, as the inverse function $x = \sqrt{y}$. Every $y \neq 0$ has two square roots, $\pm x$, one in each half of the x-plane. The right half-plane, $-\frac{\pi}{2} < \theta < \frac{\pi}{2}$, is sent to $-\pi < 2\theta < \pi$: the whole y-plane except the negative real axis. The left half-plane is sent onto the same slit plane. So the two values of $\sqrt{y}$ are organised as two copies of the y-plane, called **sheets**, each cut along the negative real axis (the **slit**). The imaginary axis of the x-plane, where the two halves meet, is sent to the slit: $x = \pm it$ gives $y = -t^2$. Now walk once around the circle $|y| = \rho$, as $y = \rho\, e^{i\varphi}$ with φ running from 0 to 2π, and follow the square root that starts at $\sqrt{\rho}$ on sheet 1:

$$x(\varphi) = \sqrt{\rho}\, e^{i\varphi/2}, \qquad x(2\pi) \overset{(1)}{=} \sqrt{\rho}\, e^{i\pi} \overset{(2)}{=} -\sqrt{\rho} = -x(0).$$

(1) Put $\varphi = 2\pi$; half the angle of y is π.

(2) Euler's formula: $e^{i\pi} = \cos\pi + i\sin\pi = -1$.

One trip around $y = 0$ turns x only halfway around. We come back to the same y but to the other square root: crossing the slit moved us from sheet 1 to sheet 2. A second trip brings us back to sheet 1. So $\sqrt{y}$ is an honest, single-valued, continuous function once we glue the two

sheets *crosswise* along the slit: the upper edge of the slit on each sheet is joined to the lower edge on the other. The point $y = 0$, where the two values coincide and around which they swap, is a **branch point**. So is $y = \infty$: a huge circle also turns x only halfway around. Here the glued sheets are just a copy of the x-plane again.

The same construction, with the letters swapped, is the picture of the cubic curve $y^2 = x(x-1)(x-\lambda)$ in Figure 5.16. There $y = \pm\sqrt{q(x)}$, each of $x = 0, 1, \lambda, \infty$ is a branch point like $y = 0$ here (Example 5.19), and two sheets of the x-sphere are glued crosswise along two slits. With two slits instead of one, the glued sheets form a torus instead of a sphere.

Worked example 5.3: $y = 1/x$ turns the plane inside out

Put $x = r\,e^{i\theta}$ with $r > 0$. Then

$$y \overset{(1)}{=} \frac{1}{r\,e^{i\theta}} \overset{(2)}{=} \frac{1}{r}\,e^{-i\theta}.$$

(1) Definition of the map.
(2) $e^{i\theta}e^{-i\theta} = e^0 = 1$, so $1/e^{i\theta} = e^{-i\theta}$.

So $|y| = 1/r$ and $\arg y = -\theta$. The circle $|x| = r$ goes to the circle $|y| = 1/r$, traced in the opposite direction. The unit circle goes to itself, flipped: $e^{i\theta} \mapsto e^{-i\theta}$ is the reflection in the real axis. The inside of the unit disc goes to the outside, and the outside to the inside. Small circles around $x = 0$ go to huge circles: as $x \to 0$, y runs off to infinity. Unlike x^2, this map is one-to-one on $\mathbb{C} \setminus \{0\}$, and it is its own inverse. It only lacks somewhere to send $x = 0$, and somewhere to receive $x = \infty$. Add one point ∞ to each plane, with $1/0 = \infty$ and $1/\infty = 0$. Then $y = 1/x$ becomes a one-to-one map of the enlarged plane onto itself, which swaps 0 and ∞. The enlarged plane is the Riemann sphere $\mathbb{CP}^1$ of Example 5.9, and $1/x$ is exactly its change of chart near ∞. The complex circle $\{uv = 1\}$ of the example above is the graph of $v = 1/u$.

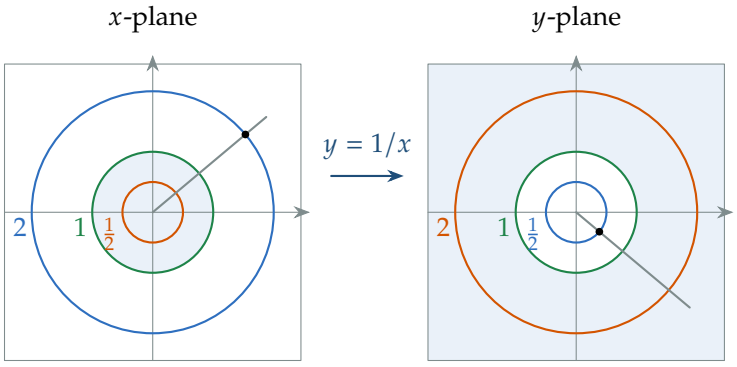

Figure 5.4: The map $y = 1/x$. The circle of radius r goes to the circle of radius $1/r$ (same colour; the radii are written on the negative real axis): the small orange circle goes to the large one, the large blue circle to the small one, and the green unit circle to itself. The shaded unit disc goes to the shaded outside. The gray ray at angle θ goes to the ray at angle $-\theta$, and the black dot $2e^{i\theta}$ goes to $\frac{1}{2}e^{-i\theta}$. The centre $x = 0$ has no image in the plane: it goes to the extra point ∞ of the Riemann sphere.

Try it

Picture $y = x^3$. What happens to circles and rays, and how many sheets does the cube root need?
Answer: $x = r\,e^{i\theta}$ gives $y = r^3 e^{3i\theta}$. Circles $|x| = r$ go to circles $|y| = r^3$, traced three times, and rays $\arg x = \theta$ go to rays $\arg y = 3\theta$. Each of the three sectors $-\frac{\pi}{3} < \theta - \frac{2\pi k}{3} < \frac{\pi}{3}$ ($k = 0, 1, 2$) covers the slit y-plane once, so $\sqrt[3]{y}$ needs three sheets, and one trip around $y = 0$ moves it on to the next sheet.

5.1.3 Real projective space: lines through the origin

Affine varieties are almost never compact: $\mathbb{C}^m$ itself runs off to infinity. Compact spaces are what we want (closed worldsheets, finite-dimensional spaces of sections, integrals that converge), so we enlarge $\mathbb{C}^m$ by adding points at infinity. The systematic way to do this is *projective space*.

Nash works with complex projective space $\mathbb{CP}^n$ from the start. It has real dimension $2n$, so already $\mathbb{CP}^2$ is four-dimensional and cannot be drawn. Its real cousin $\mathbb{RP}^n$ has real dimension n, and $\mathbb{RP}^1$ and $\mathbb{RP}^2$ can be drawn. Every idea we need (homogeneous coordinates, charts, points at infinity, curves that close up) already appears in $\mathbb{RP}^2$. So we build the pictures over $\mathbb{R}$ first, and then replace $\mathbb{R}$ by $\mathbb{C}$ in Section 5.1.6.

The starting question is an old one. A painter stands at a window and paints what she sees onto the glass. Railway tracks never meet, yet on her canvas they meet at a point of the horizon. Straight lines stay straight. A circular pond becomes an ellipse. Where, mathematically, is the point at which the rails meet? Projective geometry grew out of exactly this question (Desargues, in the seventeenth century; cf. the Poppe notes on projective space). The answer is that the rails meet at a point that is not in the plane, but in a slightly larger space. To build that space we change what we mean by "point".

Working definition 5.3 (real projective space)

A point of **real projective space** $\mathbb{RP}^n$ is a line through the origin of $\mathbb{R}^{n+1}$. We name it by any nonzero vector $x = (x_0, \dots, x_n)$ on the line, and remember that proportional vectors name the same point:

$$[x_0 : \cdots : x_n] = [t x_0 : \cdots : t x_n], \qquad t \in \mathbb{R}^* = \mathbb{R} \setminus \{0\}.$$

The x_i are **homogeneous coordinates**. *Operationally*: $[x] = [y]$ exactly when x and y are proportional, that is, when every 2×2 minor $x_i y_j - x_j y_i$ [the determinant of the 2×2 matrix built from entries i and j of x and of y] vanishes.

For $n = 1$ a point is a line through the origin of the plane; for $n = 2$ it is a line through the origin of space. The origin itself is not a line, so $[0 : \cdots : 0]$ is not a point.

Homogeneous coordinates record proportions. The colons are there to remind us that $[x : y : z]$ is a *ratio*, like "flour to sugar to butter = 2 : 1 : 1" in a recipe. Only the proportions $x : y : z$ carry information; the overall size does not. So

$$[x : y : z] = [\lambda x : \lambda y : \lambda z] \qquad \text{for every } \lambda \neq 0,$$

for example $[1 : 2 : 3] = [2 : 4 : 6] = [-\frac{1}{3} : -\frac{2}{3} : -1]$. Geometrically, the vectors $\lambda(x, y, z)$ with $\lambda \neq 0$ fill out the line through the origin in direction (x, y, z) (with the origin removed). So "a proportion class $[x : y : z]$" and "a line through the origin of $\mathbb{R}^3$" are the same thing, said in two ways.

Each line meets the sphere twice. Instead of the whole line we can record where it crosses the unit sphere $S^n = \{|x| = 1\} \subset \mathbb{R}^{n+1}$. The line through $v \neq 0$ is $\{tv : t \in \mathbb{R}\}$, and

$$|tv| = 1 \overset{(1)}{\iff} |t|\,|v| = 1 \overset{(2)}{\iff} t = \pm\frac{1}{|v|}.$$

(1) Euclidean length scales: $|tv| = |t|\,|v|$.
(2) The only real numbers of absolute value $1/|v|$ are $+1/|v|$ and $-1/|v|$.

So every line meets S^n in exactly two points, $\hat{v} = v/|v|$ and $-\hat{v}$. They are **antipodal**: diametrically opposite. The map

$$\pi : S^n \to \mathbb{RP}^n, \qquad x \mapsto [x],$$

is onto, and $\pi(x) = \pi(y)$ exactly when $y = \pm x$. Hence

$$\mathbb{RP}^n = S^n/(x \sim -x). \tag{5.1}$$

Two more facts follow at once. First, π is *locally* one-to-one: a small cap around x (angular radius less than $\pi/2$) never contains a pair of antipodal points, so π maps it bijectively onto its image. A map that is locally a homeomorphism and has exactly k preimages over every point is a **k-fold covering**. So π is 2-to-1, a **double cover**. (Covering spaces are treated in Chapter 1.) Second, $\mathbb{RP}^n$ is compact, because it is a continuous image of the compact sphere.

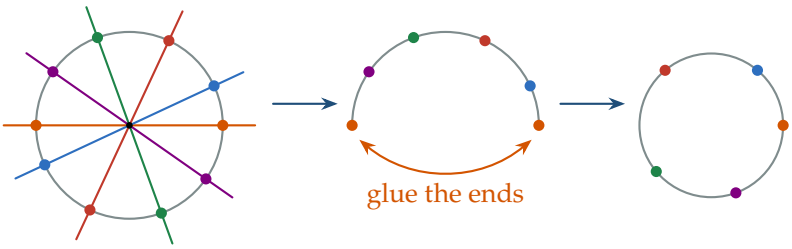

Figure 5.5: $\mathbb{RP}^1$ is a circle. Left: every line through the origin of $\mathbb{R}^2$ meets the unit circle in two antipodal points, drawn in the line's colour. Middle: keep one point per line by keeping the upper half-circle. Only the horizontal (orange) line still has both of its points, the two ends, and they must be glued. Right: an arc with its ends glued is a circle. The map that does this doubles angles (Example 5.4): the line at angle θ lands at 2θ.

Worked example 5.4: $\mathbb{RP}^1$ is a circle: angle doubling

A line through the origin of $\mathbb{R}^2$ has a direction $(\cos\theta, \sin\theta)$. The angles θ and $\theta + \pi$ give the same line, and each line has exactly one angle $\theta \in [0, \pi)$. Identify $\mathbb{R}^2$ with $\mathbb{C}$ and define

$$f : \mathbb{RP}^1 \to S^1 \subset \mathbb{C}, \qquad f([x : y]) = \frac{(x + \mathrm{i}y)^2}{x^2 + y^2}.$$

Well defined. Replacing (x, y) by (tx, ty) multiplies the numerator and the denominator by t^2, so f depends only on the line. *What it does.* Write $x = r\cos\theta$, $y = r\sin\theta$ with $r > 0$. Then

$$f([x : y]) \overset{(1)}{=} \frac{(re^{\mathrm{i}\theta})^2}{r^2} \overset{(2)}{=} e^{2\mathrm{i}\theta}$$

$$\overset{(3)}{=} \cos 2\theta + \mathrm{i}\sin 2\theta.$$

(1) $x + \mathrm{i}y = re^{\mathrm{i}\theta}$ and $x^2 + y^2 = r^2$.
(2) Cancel r^2.
(3) Euler's formula.

So f doubles the angle. As θ runs once over $[0, \pi)$, 2θ runs once over $[0, 2\pi)$. Hence f is a bijection, continuous in both directions, and $\mathbb{RP}^1 \cong S^1$. In real components, $f = \big((x^2 - y^2)/(x^2 + y^2),\ 2xy/(x^2 + y^2)\big)$.
The same map, read in a chart, shows the point at infinity. For lines with $x \neq 0$ use the slope $m = y/x$: it is the height at which the line crosses the vertical line $x = 1$. Then

$$f([1 : m]) \overset{(1)}{=} \frac{(1 + \mathrm{i}m)^2}{1 + m^2} \overset{(2)}{=} \frac{1 - m^2}{1 + m^2} + \mathrm{i}\,\frac{2m}{1 + m^2}.$$

(1) $[x : y] = [1 : m]$; substitute $x = 1$, $y = m$.
(2) Expand $(1 + \mathrm{i}m)^2 = 1 - m^2 + 2\mathrm{i}m$.

As $m \to +\infty$ *and* as $m \to -\infty$ this tends to $-1 = f([0 : 1])$, the image of the vertical line. The chart of slopes is a copy of $\mathbb{R}$ that misses one point, and both ends of $\mathbb{R}$ run into that point: $\mathbb{RP}^1 = \mathbb{R} \cup \{\infty\}$. (With $m = \tan\theta$ these are the half-angle formulas $\cos 2\theta = (1 - \tan^2\theta)/(1 + \tan^2\theta)$ and $\sin 2\theta = 2\tan\theta/(1 + \tan^2\theta)$.) Finally, composing f with π shows that the double cover $S^1 \to \mathbb{RP}^1 \cong S^1$ is $e^{\mathrm{i}\theta} \mapsto e^{2\mathrm{i}\theta}$, that is, $z \mapsto z^2$ on the unit circle.

Watch out: $\mathbb{RP}^1$ is a circle, but $\mathbb{RP}^2$ is not a sphere

The pattern breaks in dimension two. $S^2 \to \mathbb{RP}^2$ is a double cover of a genuinely new surface, one with no inside and no outside. We prove this with an Euler characteristic count in Example 5.5, and we see what it means for drawing in Section 5.1.7.

The disc model of $\mathbb{RP}^2$. Keep only the upper hemisphere $H = \{x \in S^2 : x_3 \geq 0\}$. A line through the origin of $\mathbb{R}^3$ that is not horizontal has exactly one of its two points $\pm\hat{v}$ strictly above the equator, so it meets H once, in the interior. A horizontal line meets H in both of its points $\pm\hat{v}$, and both lie on the equator. Now flatten H onto the unit disc by forgetting x_3.

Working definition 5.4 (disc model of $\mathbb{RP}^2$)

$\mathbb{RP}^2$ is the closed unit disc $D = \{u \in \mathbb{R}^2 : |u| \leq 1\}$ with each boundary point u glued to its antipode $-u$. [the diametrically opposite point of the boundary circle] Interior points of D are the non-horizontal lines; each pair $\pm u$ on the boundary is one horizontal line. *Operationally*: the point $[x_1 : x_2 : x_3]$ with $x_3 \neq 0$ sits at $u = \operatorname{sgn}(x_3)\,(x_1, x_2)/|x|$, [$\operatorname{sgn}(x_3) = \pm 1$ flips the representative so that $x_3 > 0$, the upper hemisphere] and a curve that leaves the disc at u re-enters at $-u$.

This is the construction of Figure 5.5 one dimension up. There the upper half-circle, flattened, is the interval $[-1, 1]$ with its two ends glued, which is a circle.

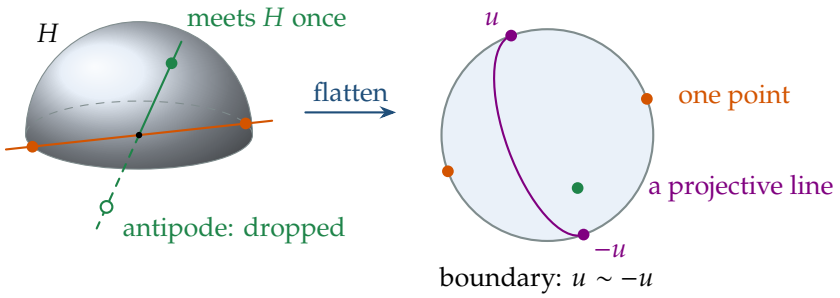

Figure 5.6: The disc model of $\mathbb{RP}^2$. Left: a non-horizontal line through the origin (green) meets the upper hemisphere H once; its other point lies below and is dropped. A horizontal line (orange) meets H twice, at antipodal points of the equator. Right: flattened, H becomes a disc whose boundary points are glued in antipodal pairs, so the two orange dots are a single point of $\mathbb{RP}^2$. A projective line (violet, the image of a great circle) runs from u to $-u$; since those are the same point, it is a closed loop.

Worked example 5.5: The Euler characteristic of $\mathbb{RP}^2$ is 1

From the double cover. The octahedron with vertices $\pm e_1, \pm e_2, \pm e_3$ is a triangulation of S^2 that the antipodal map carries to itself, and no vertex, edge or face is carried to itself. So its 6 vertices, 12 edges and 8 faces pair off into 3 vertices, 6 edges and 4 faces of $\mathbb{RP}^2$:

$$\begin{aligned}\chi(\mathbb{RP}^2) &\overset{(1)}{=} \tfrac{1}{2}V - \tfrac{1}{2}E + \tfrac{1}{2}F \\ &\overset{(2)}{=} \tfrac{1}{2}(6 - 12 + 8) \\ &\overset{(3)}{=} \tfrac{1}{2}\chi(S^2) = 1.\end{aligned}$$

(1) Each cell of $\mathbb{RP}^2$ has exactly two preimages, which $x \mapsto -x$ swaps.
(2) Count the vertices, edges and faces of the octahedron.
(3) $6 - 12 + 8 = 2 = \chi(S^2)$.

From the disc model. The disc model has one 2-cell (the open disc), one 1-cell (the open upper half of the boundary circle, since the lower half is glued onto it) and one 0-cell (the two points $(\pm 1, 0)$, glued into one). So $V - E + F = 1 - 1 + 1 = 1$ again.
We will see in (5.7) that every closed *orientable* surface has $\chi = 2 - 2p$, an even number. Since $\chi(\mathbb{RP}^2) = 1$ is odd, $\mathbb{RP}^2$ is a closed surface that is not orientable. (A double cover without branch points halves χ. With branch points it does not: that is the count of Example 5.19 for the cubic.)

5.1.4 From the plane to $\mathbb{RP}^2$: perspective and the line at infinity

Return to the painter. Put her eye at the origin of $\mathbb{R}^3$, with coordinates (X, Y, Z), and put the canvas in the plane $\{Z = 1\}$. The canvas is a copy of $\mathbb{R}^2$: the point (x, y) of the plane is the point $(x, y, 1)$ of space. She sees it along the ray of light from her eye through $(x, y, 1)$. That ray lies on exactly one line through the origin, so we get a map

$$j : \mathbb{R}^2 \to \mathbb{RP}^2, \qquad (x, y) \mapsto [x : y : 1].$$

Different points of the canvas lie on different lines, so j is one-to-one. A line through the origin crosses the canvas exactly when it is not horizontal, that is, when its Z-component is nonzero, and then it crosses at $[X : Y : Z] = [X/Z : Y/Z : 1]$.

The painter's picture is exactly the construction of $\mathbb{RP}^2$: the eye is the origin, the canvas is the plane $Z = 1$, and the rays of light are the lines through the origin. Here is the construction step by step.

Key idea: building $\mathbb{RP}^2$ from the plane in four steps

1. *Embed.* Put $\mathbb{R}^2$ in $\mathbb{R}^3$ as the plane $Z = 1$: $(x, y) \mapsto (x, y, 1)$.
2. *Replace points by lines.* Identify each point $(x, y, 1)$ with the line through the origin of $\mathbb{R}^3$ that passes through it.
3. *Name the lines by proportions.* Lines through the origin are exactly the proportion classes $[X : Y : Z]$. The point (x, y) becomes $[x : y : 1]$, and any $[X : Y : Z]$ with $Z \neq 0$ comes from exactly one point, $(X/Z, Y/Z)$.
4. *Add what is missing.* The lines through the origin lying in the plane $Z = 0$ never meet the plane $Z = 1$, because every point on them has $Z = 0 \neq 1$. These lines, $[X : Y : 0]$, are the new **points at infinity**. They are the lines through the origin of a plane, so they form a whole $\mathbb{RP}^1$ of directions: the **line at infinity**.

Step 4 is where a point that runs off to infinity ends up. Let the point (t, mt) run off along the line $y = mx$:

$$j(t, mt) \overset{(1)}{=} [t : mt : 1] \overset{(2)}{=} \left[1 : m : \tfrac{1}{t}\right] \overset{(3)}{\longrightarrow} [1 : m : 0] \qquad (t \to \infty).$$

(1) Step 3: the point (t, mt) is the line through $(t, mt, 1)$.
(2) Divide all three entries by $t \neq 0$; the proportions are unchanged.
(3) $1/t \to 0$. The limit $[1 : m : 0]$ is the line in the plane $Z = 0$ with direction $(1, m)$: the point at infinity of every line of slope m.

Working definition 5.5 (affine chart and line at infinity of $\mathbb{RP}^2$)

In homogeneous coordinates $[X : Y : Z]$, [a nonzero triple, with proportional triples naming the same point] the **affine chart** $U_Z = \{Z \neq 0\}$ is identified with $\mathbb{R}^2$ by

$$[X : Y : Z] \mapsto (x, y) = \left(\frac{X}{Z}, \frac{Y}{Z}\right), \qquad \text{with inverse} \qquad (x, y) \mapsto [x : y : 1].$$

The rest of $\mathbb{RP}^2$ is the **line at infinity** $L_\infty = \{Z = 0\} = \{[X : Y : 0]\}$. *Operationally*: to find where a point of $\mathbb{RP}^2$ sits in the plane, divide by Z. If $Z = 0$, the point is not a place in the plane but a direction (X, Y) in it, and (X, Y) and $(-X, -Y)$ count as the same direction.

The chart is well defined: rescaling (X, Y, Z) by t changes neither X/Z nor Y/Z. The line at infinity is itself a projective line. Its points $[X : Y : 0]$ are the lines through the origin of the horizontal plane $\{Z = 0\}$, so $L_\infty \cong \mathbb{RP}^1 \cong S^1$. Altogether

$$\mathbb{RP}^2 = \mathbb{R}^2 \sqcup L_\infty = \mathbb{R}^2 \sqcup \mathbb{RP}^1,$$

just as $\mathbb{RP}^1 = \mathbb{R} \sqcup \{\text{point}\}$. In general $\mathbb{RP}^n = \mathbb{R}^n \sqcup \mathbb{RP}^{n-1}$. The other two charts, $U_X = \{X \neq 0\}$ and $U_Y = \{Y \neq 0\}$, are also copies of $\mathbb{R}^2$, and the three charts together cover $\mathbb{RP}^2$.

Running off to infinity. Walk away from the origin of the canvas in a fixed direction $(a, b) \neq (0, 0)$, that is, along $(x, y) = (ta, tb)$ with $t \to \infty$. Then

$$j(ta, tb) \overset{(1)}{=} [ta : tb : 1]$$

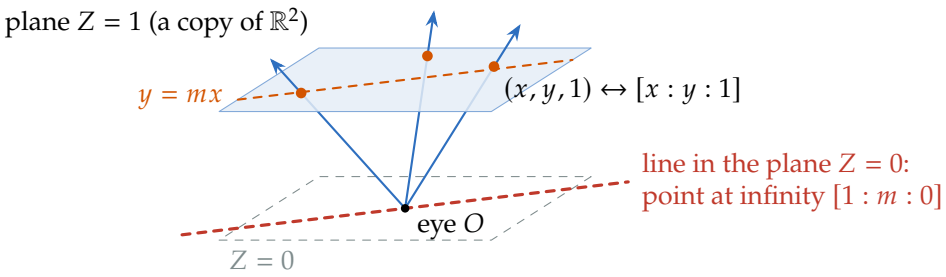

Figure 5.7: Perspective. The eye sits at the origin and the plane $Z = 1$ is a canvas. Each point (x, y) of the canvas (orange) is seen along one ray (blue), so it names one line through the origin, $[x : y : 1]$. As the canvas point runs off to infinity, its ray tilts towards the horizontal. A horizontal ray (red, dashed), lying in the plane $Z = 0$, is still a line through the origin, so it is still a point of $\mathbb{RP}^2$, but it meets no point of the canvas: it is a point at infinity. The red line has the direction $(1, m)$ of the canvas line $y = mx$ (orange, dashed), so it is the point $[1 : m : 0]$ where that line ends up. All the lines through the origin in the plane $Z = 0$ together form the line at infinity L_∞.

$$\overset{(2)}{=} \left[a : b : \tfrac{1}{t}\right]$$
$$\overset{(3)}{\longrightarrow} [a : b : 0] \qquad (t \to \pm\infty).$$

(1) Definition of j.
(2) Divide all three coordinates by $t \neq 0$; this names the same point.
(3) $1/t \to 0$ whether $t \to +\infty$ or $t \to -\infty$, and $[a : b : 0]$ is a genuine point because $(a, b) \neq 0$.

In the picture: as the canvas point runs away, its ray tilts down towards the horizontal, and in the limit it becomes the horizontal line in direction (a, b). Step (3) contains the key point. Walking off in direction (a, b) and walking off in the opposite direction $(-a, -b)$ bring us to the *same* point at infinity, because $[a : b : 0] = [-a : -b : 0]$. Each direction, without its sign, is one point of L_∞.

Lines. Take the line $ax + by + c = 0$ in the plane, with $(a, b) \neq 0$. Substitute $x = X/Z$, $y = Y/Z$ and multiply by Z:

$$aX + bY + cZ = 0.$$

This is a plane through the origin of $\mathbb{R}^3$ with normal vector $n = (a, b, c)$. So a **projective line** is a plane through the origin. As a set of lines through the origin it is an $\mathbb{RP}^1$, a circle. It consists of the old affine line plus one point at infinity: setting $Z = 0$ forces $aX + bY = 0$, so the extra point is $[-b : a : 0]$, the direction of the line. Two distinct planes through the origin always meet in exactly one line through the origin. Therefore:

Key idea: two lines always meet

Any two distinct lines in $\mathbb{RP}^2$ meet in exactly one point. Parallel lines are no exception: they meet on the line at infinity, at the point named by their common direction. *Operationally*: the lines with normals n_1 and n_2 meet at $[n_1 \times n_2]$, because the cross product is orthogonal to both normals and so lies in both planes.

Worked example 5.6: Parallel lines meet at $[1 : m : 0]$

Take $y = mx + c_1$ and $y = mx + c_2$ with $c_1 \neq c_2$. Homogenised, they are

$$Y = mX + c_1 Z, \qquad Y = mX + c_2 Z.$$

A common point $[X : Y : Z]$ satisfies both equations, so

$$\begin{aligned} 0 &\overset{(1)}{=} (mX + c_1 Z) - (mX + c_2 Z) \\ &\overset{(2)}{=} (c_1 - c_2)\, Z, \end{aligned}$$

(1) Subtract the two equations; both left-hand sides equal Y.
(2) Collect terms; the mX cancels.

and $c_1 \neq c_2$ forces $Z = 0$. Then either equation gives $Y = mX$, and

$$\begin{aligned} [X : Y : Z] &\overset{(1)}{=} [X : mX : 0] \\ &\overset{(2)}{=} [1 : m : 0]. \end{aligned}$$

(1) $Y = mX$ and $Z = 0$.
(2) $X \neq 0$, since otherwise all three coordinates would vanish; divide by X.

So the two lines meet in exactly one point, $[1 : m : 0]$. It does not depend on c_1 or c_2: every line of slope m passes through it. Vertical lines $x = c$ homogenise to $X = cZ$, and any two of them meet where $Z = 0$ and $X = 0$, that is, at $[0 : 1 : 0]$, the point of "slope ∞". So the points of L_∞ correspond one-to-one to the slopes $m \in \mathbb{R} \cup \{\infty\}$, which is another way to see that $L_\infty \cong \mathbb{RP}^1$.

As a check, use the cross-product rule. Written as $mx - y + c_i = 0$, the lines have normals $n_i = (m, -1, c_i)$, and

$$\begin{aligned} n_1 \times n_2 &\overset{(1)}{=} \big((-1)c_2 - c_1(-1),\ c_1 m - m c_2,\ m(-1) - (-1)m\big) \\ &\overset{(2)}{=} (c_1 - c_2)\,(1, m, 0). \end{aligned}$$

(1) For $n_i = (a_i, b_i, e_i)$ the cross product is $(b_1 e_2 - e_1 b_2,\ e_1 a_2 - a_1 e_2,\ a_1 b_2 - b_1 a_2)$.
(2) Factor out $c_1 - c_2$.

A tiled floor in perspective. A painter sees the same fact on every tiled floor. Stand on a floor with the eye at height h, looking straight ahead along the y-axis, with x the sideways coordinate. Lay square tiles turned by 45°, so that their edges are two families of parallel lines,

$$y - x = l \quad (\text{slope } 1), \qquad x + y = k \quad (\text{slope } -1), \qquad k, l \in \mathbb{Z}.$$

A tile corner is the crossing point of the edge $x + y = k$ with the edge $y - x = l$. Adding and subtracting the two equations puts it at $x = \frac{k-l}{2}$, $y = \frac{k+l}{2}$; we call it the corner (k, l). The tile with lowest corner (k, l) has the four corners (k, l), $(k+1, l)$, $(k+1, l+1)$, $(k, l+1)$. As in Example 5.11 (with the picture enlarged by a factor S), the ground point (x, y) with $y > 0$ is painted at

$$(u, v) = \Big(S\,\frac{x}{y},\ -\frac{Sh}{y}\Big).$$

A point of the edge $y - x = l$ has the form $(x, y) = (y - l,\ y)$. It is painted at

$$\begin{aligned} (u, v) &\overset{(1)}{=} \Big(S\,\frac{y - l}{y},\ -\frac{Sh}{y}\Big) \\ &\overset{(2)}{=} \Big(S - \frac{l}{h}\,\frac{Sh}{y},\ -\frac{Sh}{y}\Big) \\ &\overset{(3)}{=} \Big(S + \frac{l}{h}\,v,\ v\Big). \end{aligned}$$

(1) The painting map, with $x = y - l$.
(2) Split the fraction, $\frac{y-l}{y} = 1 - \frac{l}{y}$, and write $\frac{l}{y} = \frac{l}{h} \cdot \frac{h}{y}$.
(3) Write $v = -Sh/y$.

So the painted edge is the straight line $u = S + (l/h)\,v$. At eye level, $v = 0$, it passes through $u = S$, whatever l is: every edge of this family runs to the single point $V = (S, 0)$ of the horizon. It gets there only in the limit $y \to \infty$, where $v = -Sh/y \to 0$. The same computation with $x = k - y$ gives $u = -S - (k/h)\,v$, so every edge $x + y = k$ runs to the point $V' = (-S, 0)$.

Now the diagonals. The diagonal of a tile from (k, l) to $(k + 1, l + 1)$ keeps $x = \frac{k-l}{2}$ fixed, so it lies on the ground line $x = \frac{j}{2}$ with $j = k - l$. These lines point straight ahead, and they form a third family of parallels. With $x = \frac{j}{2}$ fixed, the painted point is $(u, v) = \left(\frac{Sj}{2y}, -\frac{Sh}{y}\right) = \left(-\frac{j}{2h}\,v,\ v\right)$, a straight line through $D = (0, 0)$. So the diagonals run to a third vanishing point D, straight ahead. The other diagonal of each tile, from $(k + 1, l)$ to $(k, l + 1)$, keeps y fixed. It is painted as a horizontal line $v = -Sh/y$, parallel to the horizon, and its vanishing point lies at infinity along the horizon. In the language of Example 5.6: each direction on the ground has its own point at infinity, $[1 : m : 0]$ for the lines of slope m and $[0 : 1 : 0]$ for the lines straight ahead, and all of these points lie on one line, the horizon, which is the line at infinity L_∞ of the ground.

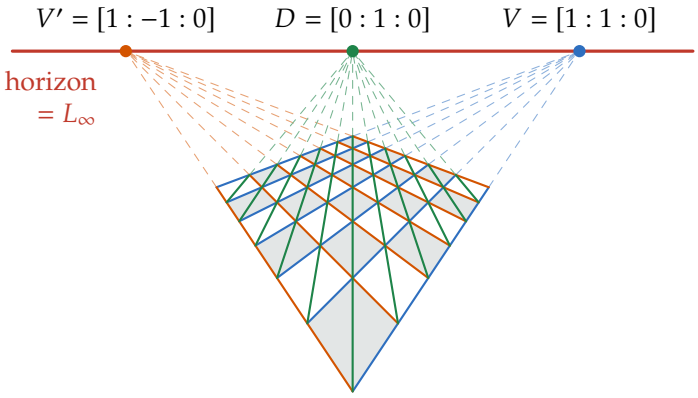

Figure 5.8: Parallel lines meet on the horizon: a tiled floor in two-point perspective. The ground point at distance y ahead and x to the side is painted at $(Sx/y,\ -Sh/y)$, with eye height $h = 3$. The tile edges form two families of parallel lines, $y - x = l$ (blue) and $x + y = k$ (orange). Each family runs, solid on the floor and dashed beyond it, to its own vanishing point: $V = [1 : 1 : 0]$ for the blue edges (slope 1) and $V' = [1 : -1 : 0]$ for the orange ones (slope -1). The green lines are the diagonals of the tiles: each passes through opposite corners of every tile it crosses. They are parallel on the ground (straight ahead, $x = \text{const}$), so they meet at a third vanishing point $D = [0 : 1 : 0]$. The other diagonals, $y = \text{const}$, would be drawn parallel to the horizon; their vanishing point $[1 : 0 : 0]$ is at infinity along the horizon. Each direction on the ground is one point of the horizon, and all of them lie on one line: the horizon is the line at infinity of the ground, made visible (Example 5.11).

Physical picture: the horizon is a genuine line

A painter's horizon is the line at infinity of the ground plane, drawn at a finite place. Every family of parallel lines on the ground runs to its own vanishing point, and all the vanishing points lie on one line. In the projective plane the vanishing points are points like any others. Painters build a whole tiled floor from this one rule. Draw the two families of tile edges to V and V', then draw one diagonal to D. The diagonal crosses the edges exactly at tile corners, which fixes where each new row of tiles begins, and so every tile of the floor follows. We make "drawn at a finite place" precise in Example 5.11.

5.1.5 Conics in the projective plane: closing curves at infinity

Now put a curve in the plane and ask what happens to it at infinity. The recipe is the one we used for lines: substitute $x = X/Z$, $y = Y/Z$, clear the denominators, and then look at $Z = 0$.

Worked example 5.7: The parabola closes up into a circle

Homogenise. On the chart $Z \neq 0$,

$$y = x^2 \overset{(1)}{\iff} \frac{Y}{Z} = \frac{X^2}{Z^2} \overset{(2)}{\iff} YZ = X^2.$$

(1) Substitute $x = X/Z$ and $y = Y/Z$.
(2) Multiply by $Z^2 \neq 0$.

Both sides of $YZ = X^2$ are homogeneous of degree 2 (rescaling by t multiplies each by t^2), so $C = \{YZ = X^2\}$ is a well-defined curve in $\mathbb{RP}^2$.
Points at infinity. Put $Z = 0$. Then $X^2 = 0$, so $X = 0$ and $Y \neq 0$. There is exactly one point, $[0 : 1 : 0]$, the common point of all vertical lines. The equation $X^2 = 0$ has a *double* root there, which means that C touches L_∞ rather than crossing it.
Both arms go there. Along the curve $(x, y) = (t, t^2)$, and

$$[t : t^2 : 1] \overset{(1)}{=} \left[\tfrac{1}{t} : 1 : \tfrac{1}{t^2}\right] \overset{(2)}{\longrightarrow} [0 : 1 : 0] \qquad (t \to \pm\infty).$$

(1) Divide all coordinates by t^2.
(2) $1/t \to 0$ and $1/t^2 \to 0$ for either sign of t.

The right arm ($t \to +\infty$) and the left arm ($t \to -\infty$) both run off in the vertical direction, and "vertically up" and "vertically down" are the same point at infinity. So the two arms are glued at $[0 : 1 : 0]$, and C is the line of parameters t plus one point: a closed loop.
A chart in which the loop is visible. Change coordinates by

$$Y = U + V, \qquad Z = U - V \qquad \left(\text{so } U = \tfrac{Y+Z}{2},\ V = \tfrac{Y-Z}{2}\right).$$

This is an invertible linear map of $\mathbb{R}^3$, so it only relabels the points of $\mathbb{RP}^2$. Then

$$YZ - X^2 \overset{(1)}{=} (U + V)(U - V) - X^2 \overset{(2)}{=} U^2 - V^2 - X^2,$$

(1) Substitute $Y = U + V$ and $Z = U - V$.
(2) Difference of two squares.

so the curve is $U^2 = X^2 + V^2$. In the chart $U \neq 0$, with coordinates $\xi = X/U$ and $\eta = V/U$, divide by U^2:

$$\xi^2 + \eta^2 = 1.$$

The parabola *is* a circle, seen in another chart. To see which point goes where, take the affine point $[x : x^2 : 1]$. Then $U = (x^2 + 1)/2$ and $V = (x^2 - 1)/2$, so

$$\xi = \frac{2x}{x^2 + 1}, \qquad \eta = \frac{x^2 - 1}{x^2 + 1},$$

and indeed

$$\xi^2+\eta^2 \overset{(1)}{=} \frac{4x^2+(x^2-1)^2}{(x^2+1)^2} \overset{(2)}{=} \frac{x^4+2x^2+1}{(x^2+1)^2} \overset{(3)}{=} 1.$$

(1) Put both terms over the common denominator.
(2) Expand $(x^2-1)^2 = x^4-2x^2+1$ and add $4x^2$.
(3) $x^4+2x^2+1 = (x^2+1)^2$.

The vertex $x=0$ goes to $(0,-1)$ and the points $x=\pm1$ go to $(\pm1,0)$. As $x\to\pm\infty$ both arms approach $(0,1)$, which is the point at infinity $[X:Y:Z]=[0:1:0]$: it has $X=0$ and $Z=0$, so $V=U$. The old line at infinity $Z=0$ is $U=V$, the horizontal line $\eta=1$, which touches the circle at its top. The new chart misses only the line $U=0$, that is $Y=-Z$, which in the old chart is the line $y=-1$. The parabola never reaches $y=-1$, and that is why the whole closed curve fits into the new chart. (The map $x\mapsto(\xi,\eta)$ is the inverse of stereographic projection from the top point of the circle. It is the same map that identifies $\mathbb{CP}^1$ with S^2 in Example 5.9, one dimension down.)

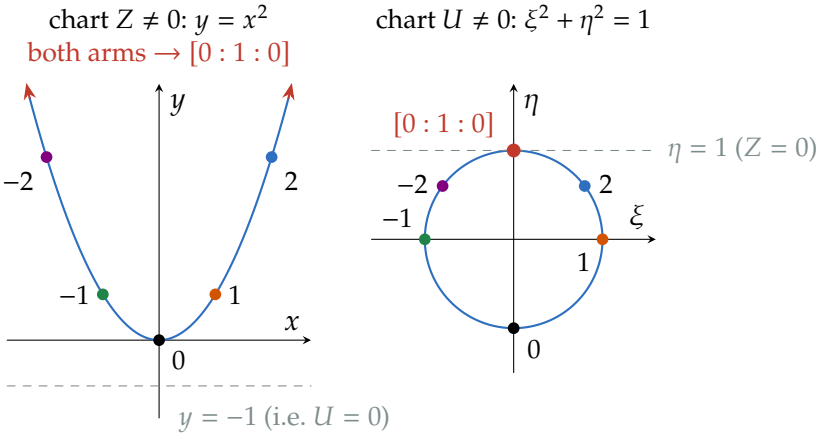

Figure 5.9: One curve, two charts. Left: the parabola $y=x^2$ in the chart $Z\neq0$, with the points $x=-2,\dots,2$ marked. Its point at infinity is not in this chart; both arms run towards it (red arrows). Right: the same curve in the chart $U\neq0$ of Example 5.7, where it is the unit circle. The marked points reappear in the same colours, and the point at infinity $[0:1:0]$ is the red dot at the top. The dashed line on the right is the line at infinity of the left chart, which touches the circle there. The dashed line on the left, $y=-1$, is the line at infinity of the right chart. The parabola never meets it, so the right chart shows the whole curve.

Worked example 5.8: The hyperbola: two branches, one loop

Homogenise $xy=1$:

$$xy=1 \overset{(1)}{\iff} \frac{X}{Z}\cdot\frac{Y}{Z}=1 \overset{(2)}{\iff} XY=Z^2.$$

(1) Substitute $x=X/Z$ and $y=Y/Z$.

(2) Multiply by $Z^2 \neq 0$.

At $Z = 0$ we need $XY = 0$. This gives *two* points at infinity, $[1:0:0]$ and $[0:1:0]$, the directions of the two asymptotes (the x- and y-axes). Parametrise the curve by $(t, 1/t)$ with $t \neq 0$:

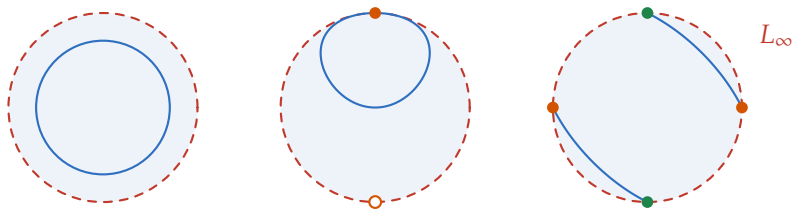
$$\left[t : \tfrac{1}{t} : 1\right] \overset{(1)}{=} \left[1 : \tfrac{1}{t^2} : \tfrac{1}{t}\right] \longrightarrow [1:0:0] \qquad (t \to \pm\infty),$$
$$\left[t : \tfrac{1}{t} : 1\right] \overset{(2)}{=} \left[t^2 : 1 : t\right] \longrightarrow [0:1:0] \qquad (t \to 0^{\pm}).$$

(1) Divide all coordinates by t.

(2) Multiply all coordinates by t.

Now follow the curve. Start on the first-quadrant branch high up near the y-axis ($t \to 0^+$, close to $[0:1:0]$) and move to the right. As $t \to +\infty$ we reach $[1:0:0]$. We pass through that point and come back from the far left on the third-quadrant branch, with t increasing from $-\infty$. As $t \to 0^-$ we run down along the negative y-axis into $[0:1:0]$, where we started. The two branches and the two points at infinity form *one* closed loop.

Two changes of chart make this visible. In the chart $Y \neq 0$, with coordinates $s = X/Y$ and $r = Z/Y$, the equation $XY = Z^2$ becomes $s = r^2$: a parabola, whose only point at infinity is $[1:0:0]$ and whose vertex is $[0:1:0]$. With $X = U + V$ and $Y = U - V$ it becomes $U^2 = V^2 + Z^2$, a circle in the chart $U \neq 0$, exactly as for the parabola.



ellipse $x^2 + y^2 = 1$: misses L_∞ — parabola $y = x^2$: touches L_∞ once — hyperbola $xy = 1$: meets L_∞ twice

Figure 5.10: Three conics in the disc model of $\mathbb{RP}^2$. The chart $Z \neq 0$ is drawn as the open disc, by sending (x, y) to $(x, y)/\sqrt{x^2 + y^2 + 1}$ (the point where the ray through $(x, y, 1)$ meets the upper hemisphere, flattened). The boundary circle (red, dashed) is L_∞, with antipodal points glued. The ellipse stays inside. Both arms of the parabola reach the boundary at the top, and the orange dot at the bottom is the same point. Each branch of the hyperbola runs from an orange boundary point to a green one; since opposite boundary points are glued, the two branches join into one closed loop. In $\mathbb{RP}^2$ all three are the same curve.

Key idea: all non-degenerate conics are the same in $\mathbb{RP}^2$

A conic is the zero set of a quadratic form $Q(X, Y, Z) = w^{\mathsf{T}} M w$, with $w = (X, Y, Z)^{\mathsf{T}}$ and M a real symmetric 3×3 matrix. It is **non-degenerate** if $\det M \neq 0$. By Sylvester's law of inertia, an invertible linear change of coordinates brings M to $\mathrm{diag}(\pm 1, \pm 1, \pm 1)$, and $Q = 0$ and $-Q = 0$ are the same curve. So there are only two cases: $X^2 + Y^2 + Z^2 = 0$, which has no real points, and

$$X^2 + Y^2 = Z^2,$$

the circle. *Every non-degenerate real conic with a real point is the circle, seen in some chart.* Ellipse, parabola and hyperbola differ only in how the circle sits relative to the one line we chose to call L_∞: it misses that line, touches it, or cuts it twice.

For example, $YZ - X^2$ has $M = \begin{pmatrix} -1 & 0 & 0 \\ 0 & 0 & 1/2 \\ 0 & 1/2 & 0 \end{pmatrix}$, with $\det M = \frac{1}{4} \neq 0$ and eigenvalues $-1, \frac{1}{2}, -\frac{1}{2}$: one sign differs from the other two, as for $X^2 + Y^2 - Z^2$. The three affine types compare as follows (cf. the table in the illustrated perspective guide):

affine conic	homogenised	meets L_∞ ($Z = 0$) where	real points at ∞
ellipse $x^2 + y^2 = 1$	$X^2 + Y^2 = Z^2$	$X^2 + Y^2 = 0$: $[1 : \pm i : 0]$	none
parabola $y = x^2$	$YZ = X^2$	$X^2 = 0$: $[0 : 1 : 0]$, double	one (tangent)
hyperbola $xy = 1$	$XY = Z^2$	$XY = 0$: $[1 : 0 : 0]$, $[0 : 1 : 0]$	two

The ellipse has no real points at infinity, but over $\mathbb{C}$ it has two, $[1 : \pm i : 0]$. These are the two points we add to the complex circle in Example 5.13, where they are written $[0 : 1 : \pm i]$ because there the coordinate z_0 (our Z) is listed first. Over $\mathbb{C}$ the distinction disappears completely: every non-degenerate conic in $\mathbb{CP}^2$ is carried to $z_0 z_2 = z_1^2$ by a linear change of coordinates, and so is a copy of $\mathbb{CP}^1$. The degenerate conics, such as $xy = 0$ (two lines) or $x^2 = 0$ (a doubled line), have $\det M = 0$ and really are different.

Physical picture: adding points at infinity closes curves up

Over $\mathbb{R}$: a line gains one point at infinity and becomes a circle. The parabola gains one point and the hyperbola two, and each becomes a single closed loop. Over $\mathbb{C}$ the same thing happens one dimension up, and this is the mechanism behind Nash's torus. The affine cubic $y^2 = x(x-1)(x-\lambda)$ in $\mathbb{C}^2$ is a torus with one point missing. Homogenised, it is $Y^2Z = X(X - Z)(X - \lambda Z)$, and at $Z = 0$ this forces $X^3 = 0$: there is a single point at infinity, $[0 : 1 : 0]$, the vertical direction, just as for the parabola. Every far-away point of the curve runs into it: dividing by y, $[x : y : 1] = [x/y : 1 : 1/y]$, and since $|y| \sim |x|^{3/2}$ both x/y and $1/y$ tend to 0. Adding this one point closes the surface up into a torus (Example 5.19 and Figure 5.16). The real picture shows it too. The unbounded real branch of the smooth cubic in Figure 5.2 is closed up through $[0 : 1 : 0]$, so in $\mathbb{RP}^2$ the real points of that cubic form two loops, the oval and the completed branch.

5.1.6 Complex projective space

Everything in the last three subsections works with $\mathbb{C}$ in place of $\mathbb{R}$. The algebra is unchanged. What changes is the pictures, because each complex dimension counts as two real ones.

Working definition 5.6 (complex projective space)

A point of $\mathbb{CP}^n$ is a complex line through the origin of $\mathbb{C}^{n+1}$. [all complex multiples λv of one nonzero vector v. As a real set it is a plane] We name it by any nonzero vector on that line, $(z_1, \dots, z_{n+1}) \neq 0$, and remember that proportional vectors name the same point:

$$[z_1 : \cdots : z_{n+1}] = [\lambda z_1 : \cdots : \lambda z_{n+1}], \qquad \lambda \in \mathbb{C}^*. \, [\, anynonzerocomplexnumber \,]$$

The z_i are **homogeneous coordinates**. Only their ratios mean anything. *Operationally*: to decide whether two tuples are the same point, check whether they are proportional.

Nash writes the homogeneous coordinates as $(z_1, \dots, z_{n+1})$. Later, for the Fubini–Study metric, he switches to $(z_0, z_1, \dots, z_n)$; we will do the same when we get there.

Charts. Ratios give local coordinates. Let $U_j = \{z_j \neq 0\} \subset \mathbb{CP}^n$. On U_j we can divide by z_j, and the n ratios z_i/z_j ($i \neq j$) determine the point uniquely, because the representative with jth

entry equal to 1 is unique. So

$$\phi_j : U_j \to \mathbb{C}^n, \qquad [z_1 : \cdots : z_{n+1}] \mapsto \left(\tfrac{z_1}{z_j}, \ldots, \widehat{\tfrac{z_j}{z_j}}, \ldots, \tfrac{z_{n+1}}{z_j} \right)$$

(the hat means "omit") is a bijection. Every point has some nonzero coordinate, so the $n+1$ sets U_j cover $\mathbb{CP}^n$. Nash's example is U_{n+1}: if $z_{n+1} \neq 0$ the point is $[z_1/z_{n+1} : \cdots : z_n/z_{n+1} : 1]$.

Transition functions are holomorphic. On the overlap $U_j \cap U_k$ the two sets of coordinates are related by multiplying by z_j/z_k, which is itself one of the k-coordinates. Written out,

$$\begin{aligned} \frac{z_i}{z_k} &\overset{(1)}{=} \frac{z_i}{z_j} \cdot \frac{z_j}{z_k} \\ &\overset{(2)}{=} \frac{z_i/z_j}{z_k/z_j}. \end{aligned}$$

(1) Multiply and divide by z_j, allowed on U_j.
(2) Rewrite $z_j/z_k = 1/(z_k/z_j)$, allowed on U_k.

So each k-coordinate is a ratio of j-coordinates with a denominator z_k/z_j that does not vanish on the overlap: a holomorphic function. This makes $\mathbb{CP}^n$ a **complex manifold** of complex dimension n.

Compactness, and circles instead of pairs. Every complex line through the origin meets the unit sphere $S^{2n+1} = \{\sum |z_i|^2 = 1\} \subset \mathbb{C}^{n+1} = \mathbb{R}^{2n+2}$. In the real case the line met its sphere in a pair of antipodal points. In the complex case it meets it in a whole circle. The complex line through $v \neq 0$ is $\{\lambda v : \lambda \in \mathbb{C}\}$, and

$$\begin{aligned} |\lambda v| = 1 &\overset{(1)}{\iff} |\lambda| = \frac{1}{|v|} \\ &\overset{(2)}{\iff} \lambda = \frac{e^{i\alpha}}{|v|} \text{ for some } \alpha \in [0, 2\pi). \end{aligned}$$

(1) $|\lambda v| = |\lambda|\,|v|$ for the Hermitian length $|v|^2 = \sum_i |v_i|^2$.
(2) A complex number of modulus $1/|v|$ is $1/|v|$ times a phase $e^{i\alpha}$. Over $\mathbb{R}$ the only "phases" are ± 1, which gave the two points of (5.1).

So the line meets the sphere in the circle $\{e^{i\alpha}\hat{v}\}$, and

$$\mathbb{CP}^n = S^{2n+1}/\mathrm{U}(1), \qquad z \sim e^{i\alpha} z. \tag{5.2}$$

In particular $\mathbb{CP}^n$ is a continuous image of a compact sphere, hence compact. The map $S^{2n+1} \to \mathbb{CP}^n$ has circles as its fibres, and counting dimensions,

$$\begin{aligned} \dim_{\mathbb{R}} \mathbb{CP}^n &\overset{(1)}{=} \dim_{\mathbb{R}} S^{2n+1} - \dim_{\mathbb{R}} S^1 \\ &\overset{(2)}{=} (2n+1) - 1 = 2n. \end{aligned}$$

(1) Collapsing each circle fibre to a point removes one real dimension.
(2) S^{2n+1} is the unit sphere in $\mathbb{R}^{2n+2}$.

This agrees with the charts: complex dimension n is real dimension $2n$. Side by side, the two constructions read:

	real	complex
a point is	a line $\mathbb{R}v \subset \mathbb{R}^{n+1}$	a complex line $\mathbb{C}v \subset \mathbb{C}^{n+1}$
unit scalars	$\{\pm 1\} = S^0$	$\{e^{i\alpha}\} = S^1 = \mathrm{U}(1)$
line $\cap$ unit sphere	two antipodal points	a circle
sphere model	$\mathbb{RP}^n = S^n/\{\pm 1\}$	$\mathbb{CP}^n = S^{2n+1}/\mathrm{U}(1)$
real dimension	n	$2n$
$n = 1$	$\mathbb{RP}^1 \cong S^1$, double cover $z \mapsto z^2$	$\mathbb{CP}^1 \cong S^2$, Hopf map $S^3 \to S^2$

Worked example 5.9: $\mathbb{CP}^1$ is the Riemann sphere

Take $n = 1$ and homogeneous coordinates $[z_0 : z_1]$. The two charts are

$$U_0 = \{z_0 \neq 0\},\ z = z_1/z_0; \qquad U_1 = \{z_1 \neq 0\},\ w = z_0/z_1.$$

On the overlap $U_0 \cap U_1$ both are defined and

$$w \overset{(1)}{=} \frac{z_0}{z_1} \overset{(2)}{=} \frac{1}{z_1/z_0} \overset{(3)}{=} \frac{1}{z}.$$

(1) Definition of the chart on U_1.
(2) Divide numerator and denominator by $z_0 \neq 0$.
(3) Definition of the chart on U_0.

The overlap is $\{z \neq 0\} = \mathbb{C}^*$. The only point of $\mathbb{CP}^1$ missing from U_0 is $[0 : 1]$, which has $w = 0$, that is "$z = \infty$". So $\mathbb{CP}^1 = \mathbb{C} \cup \{\infty\}$ with the rule "near ∞ use $w = 1/z$". This is the **Riemann sphere**. Stereographic projection from the north pole of the unit sphere in $\mathbb{R}^3$,

$$(X_1, X_2, X_3) \mapsto z = \frac{X_1 + iX_2}{1 - X_3},$$

identifies it with S^2. The south pole goes to $z = 0$, the north pole to $z = \infty$, and the equator to $|z| = 1$.

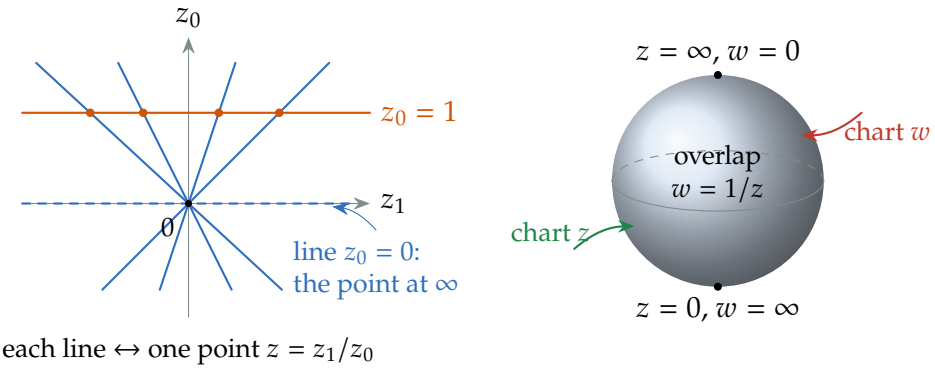


Figure 5.11: Left: a real cartoon of $\mathbb{CP}^1$. Each line through the origin of $\mathbb{C}^2$ (blue) meets the horizontal line $z_0 = 1$ in one point (orange), which we label by $z = z_1/z_0$. The one line that never meets it, $z_0 = 0$ (dashed), is the extra "point at infinity". Right: the result is a sphere covered by two charts, z (everything except the north pole) and w (everything except the south pole), glued by $w = 1/z$ on the overlap.

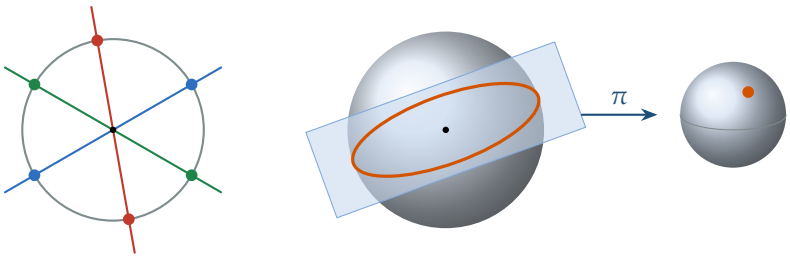
Try it: the charts of $\mathbb{CP}^2$

Write the three charts of $\mathbb{CP}^2$ with homogeneous coordinates $[z_0 : z_1 : z_2]$ and find the transition function from U_0 to U_1.
Answer. On U_0: $(x, y) = (z_1/z_0, z_2/z_0)$. On U_1: $(u, v) = (z_0/z_1, z_2/z_1)$. On the overlap $x \neq 0$, and $(u, v) = (1/x,\ y/x)$, which is holomorphic there.

The Hopf fibration. For $n = 1$, (5.2) is a map $S^3 \to \mathbb{CP}^1 = S^2$ whose fibres are circles. It is the complex counterpart of the angle-doubling double cover $S^1 \to \mathbb{RP}^1$ of Example 5.4. Two points over each point become a circle over each point. This map is the **Hopf fibration**, which Chapter 1 meets as the first map between spheres of different dimensions that cannot be deformed to a constant.



$\mathbb{R}$: line $\cap$ sphere
$= \{\pm\hat{v}\}$, two points

$\mathbb{C}$: line $\cap$ sphere
$= \{e^{i\alpha}\hat{v}\}$, a circle

one point
$[v] \in \mathbb{CP}^1 = S^2$

Figure 5.12: From two points to a circle. Left: the real cartoon. Each line through the origin meets the sphere in two antipodal points, so $S^n \to \mathbb{RP}^n$ is 2-to-1. Middle: over $\mathbb{C}$ the line $\mathbb{C}v$ is a real *plane* (drawn here one dimension down, as a plane cutting a ball), and it meets the unit sphere S^{2n+1} in a great circle, the phases $e^{i\alpha}\hat{v}$. So in the complex case "two antipodal points" becomes "a circle's worth of points". Right: the whole circle is one point of $\mathbb{CP}^n$. For $n = 1$ this is the Hopf fibration $S^3 \to S^2$ with circle fibres.

Worked example 5.10: The Hopf map, explicitly

Let $S^3 = \{(z_0, z_1) \in \mathbb{C}^2 : |z_0|^2 + |z_1|^2 = 1\}$. Send (z_0, z_1) to $[z_0 : z_1] \in \mathbb{CP}^1$, and then to $S^2 \subset \mathbb{R}^3$ by inverting the stereographic projection of Example 5.9. The result is

$$h(z_0, z_1) = (X_1, X_2, X_3), \qquad X_1 + iX_2 = 2\,\bar{z}_0 z_1, \qquad X_3 = |z_1|^2 - |z_0|^2.$$

It lands on the unit sphere:

$$\begin{aligned} X_1^2 + X_2^2 + X_3^2 &\overset{(1)}{=} 4|z_0|^2|z_1|^2 + \left(|z_1|^2 - |z_0|^2\right)^2 \\ &\overset{(2)}{=} \left(|z_0|^2 + |z_1|^2\right)^2 \\ &\overset{(3)}{=} 1. \end{aligned}$$

(1) $X_1^2 + X_2^2 = |X_1 + iX_2|^2 = 4|\bar{z}_0 z_1|^2$.
(2) $4ab + (b - a)^2 = (a + b)^2$ with $a = |z_0|^2$, $b = |z_1|^2$.
(3) (z_0, z_1) lies on S^3.

It really is the point $[z_0 : z_1]$. For $z_0 \neq 0$, apply the stereographic projection $z = (X_1 + iX_2)/(1 - X_3)$:

$$\frac{X_1 + iX_2}{1 - X_3} \overset{(1)}{=} \frac{2\bar{z}_0 z_1}{1 - |z_1|^2 + |z_0|^2}$$

$$\overset{(2)}{=} \frac{2\bar{z}_0 z_1}{2|z_0|^2}$$
$$\overset{(3)}{=} \frac{z_1}{z_0} = z.$$

(1) Substitute the formulas for $X_1 + \mathrm{i}X_2$ and X_3.
(2) $1 = |z_0|^2 + |z_1|^2$, so $1 - |z_1|^2 + |z_0|^2 = 2|z_0|^2$.
(3) $\bar{z}_0/|z_0|^2 = 1/z_0$.

For $z_0 = 0$ we get $X = (0, 0, 1)$, the north pole, which is $z = \infty$, as it should be.
The fibres are the phase circles. Replace (z_0, z_1) by $(e^{\mathrm{i}\alpha} z_0, e^{\mathrm{i}\alpha} z_1)$. The moduli $|z_i|$ do not change, and $\bar{z}_0 z_1 \mapsto e^{-\mathrm{i}\alpha} e^{\mathrm{i}\alpha} \bar{z}_0 z_1 = \bar{z}_0 z_1$. So h is constant on each circle $\{e^{\mathrm{i}\alpha}(z_0, z_1)\}$. By the compactness computation above, these circles are exactly the fibres.
Chapter 1 writes the same map as the Bloch vector $n_a = \psi^\dagger \sigma_a \psi$ of a normalised spinor ψ. With the components of ψ called z_0, z_1, its third component is $|z_0|^2 - |z_1|^2 = -X_3$. The sign only records which pole we call $z = 0$ (here the south pole, as in Example 5.9). There the map is used to show $\pi_3(S^2) = \mathbb{Z}$: any two fibres are linked circles in S^3.

Physical picture: phases, rays and the monopole

In quantum mechanics S^3 is the set of normalised spin-$\frac{1}{2}$ states, $\mathbb{CP}^1$ is the set of physical states (rays in Hilbert space, the Bloch sphere), and the circle fibre is the unobservable global phase. The fibre over $[z]$ is the unit circle inside the line $[z]$ itself. So S^3 is the unit-circle bundle of the tautological line bundle $\mathcal{O}(-1)$ of Example 5.24, and as a U(1) bundle over S^2 it is the Dirac monopole of unit charge. "Projectivising" is exactly the physicist's move of discarding the overall phase and normalisation of a state.

5.1.7 What we can draw, and what we cannot

We plot curves in $\mathbb{R}^2$ all the time, and we trust the plots. A plot of $y = x^2$ is faithful: every point of the curve has its own place on the page, nothing is glued and nothing is doubled. The scale may stretch distances, but no topology is lost. We have now drawn several pictures of projective space, and none of them is a plot of that kind. This subsection explains why no faithful picture exists, what we draw instead, and which conclusions drawn from such pictures can be trusted.

$\mathbb{RP}^2$ does not fit in $\mathbb{R}^3$. A faithful picture of a closed surface would be an embedding in $\mathbb{R}^3$: a smooth one-to-one map with injective derivative. For $\mathbb{RP}^2$ there is none. Two facts combine.

- A closed surface embedded in $\mathbb{R}^3$ separates space into an inside and an outside (the Jordan–Brouwer separation theorem). So it has an outward unit normal n at every point. A continuous nowhere-zero normal defines an orientation: call a tangent basis (e_1, e_2) positive when (e_1, e_2, n) is right-handed. Hence *every closed surface embedded in $\mathbb{R}^3$ is orientable*.
- $\mathbb{RP}^2$ is not orientable. Example 5.5 showed this by parity ($\chi = 1$ is odd). More visibly, $\mathbb{RP}^2$ contains a Möbius band (Figure 5.13).

The best one can do in $\mathbb{R}^3$ is an **immersion**: a map that is locally an embedding but passes through itself. **Boy's surface** is such an immersion of $\mathbb{RP}^2$. It crosses itself along a closed curve that has one triple point. That curve belongs to the picture, not to $\mathbb{RP}^2$: the two sheets that cross are far apart in $\mathbb{RP}^2$. The other textbook model, the cross-cap, is worse still, since it also has two

pinch points where it is not even an immersion. $\mathbb{RP}^2$ does embed in $\mathbb{R}^4$, for instance through the map $(x, y, z) \mapsto (x^2 - y^2,\ xy,\ yz,\ zx)$ on the unit sphere, which takes the same value at x and $-x$ and so descends to $\mathbb{RP}^2$. But $\mathbb{R}^4$ is no easier to draw.

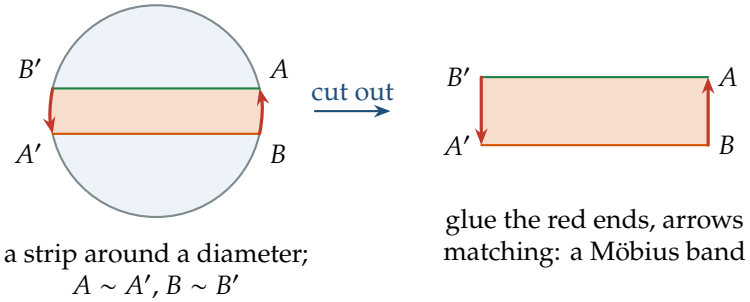


Figure 5.13: $\mathbb{RP}^2$ contains a Möbius band. In the disc model take a strip around a diameter. Its two ends lie on the boundary, and the boundary is glued antipodally: A (top right) is glued to A' (bottom left) and B to B'. So the top (green) edge at one end continues as the bottom (orange) edge at the other end. Cut out and straightened, the strip is a rectangle whose ends are glued with a flip, as the opposite red arrows show. A surface that contains a Möbius band is not orientable, and so it cannot sit in $\mathbb{R}^3$ without crossing itself.

What we draw instead. Three kinds of picture are honest, provided we remember what each one leaves out.

- *One affine chart at a time.* Each of the charts U_X, U_Y, U_Z is an honest copy of $\mathbb{R}^2$, and each shows all of $\mathbb{RP}^2$ except one line. Two charts together show everything. Figure 5.9 shows one curve in two charts.

- *The disc model* (Figures 5.6 and 5.10) is faithful in the interior. On the boundary we must remember the gluing $u \sim -u$.

- *The sphere with antipodal points identified*, (5.1), is faithful up to a factor two. Every figure appears twice, symmetrically under $x \mapsto -x$.

Why chart-by-chart pictures are reliable. Everything we say about curves in projective space is a statement that does not depend on the chart. Such statements can be checked in whichever chart is convenient, and the answer is the same in all of them.

Key idea: intrinsic statements can be checked in any chart

The changes of chart of $\mathbb{RP}^2$ (such as $(x, y) \mapsto (1/x,\ y/x)$ from U_Z to U_X) are smooth with smooth inverses, and so are the projective transformations $[w] \mapsto [Aw]$ with $A \in \mathrm{GL}(3, \mathbb{R})$. A property that is unchanged by all of these is a property of the curve in $\mathbb{RP}^2$, not of the picture. Examples are smoothness, the number of intersection points (counted with multiplicity), tangency, the number of connected components, compactness, and the genus or Euler characteristic.

Here is the check for smoothness. Suppose the curve is $F = 0$ near a point in one chart and $G = 0$ in another, with change of chart ϕ. For a projective curve the two equations are related by $G = h \cdot (F \circ \phi^{-1})$, where h is a nowhere-zero factor (a power of the coordinate we divide by).

At a point p of the curve,

$$\begin{aligned} \mathrm{d}G|_p &\overset{(1)}{=} h(p)\,\mathrm{d}(F\circ\phi^{-1})|_p + (F\circ\phi^{-1})(p)\,\mathrm{d}h|_p \\ &\overset{(2)}{=} h(p)\,\mathrm{d}F|_{\phi^{-1}(p)}\,D\phi^{-1}|_p. \end{aligned}$$

(1) Product rule.
(2) F vanishes at points of the curve, and the chain rule for the first term.

Since $h(p)\neq 0$ and $D\phi^{-1}$ is invertible, $\mathrm{d}G|_p\neq 0$ exactly when $\mathrm{d}F\neq 0$ at the corresponding point. For the parabola, $F=y-x^2$ has $\mathrm{d}F=(-2x,1)\neq 0$ everywhere in the chart $Z\neq 0$, and in the chart $U\neq 0$ the curve is $G=\xi^2+\eta^2-1$ with $\mathrm{d}G=(2\xi,2\eta)\neq 0$ on the circle. So the parabola is smooth everywhere, including at its point at infinity, which only the second chart can see.

Watch out: chart artefacts

Some features of a picture belong to the chart, not to the curve, and must not be taken literally. "The parabola is open, the ellipse is closed" is a statement about the chart $Z\neq 0$: in $\mathbb{RP}^2$ both are the same closed loop (Example 5.7). The same goes for being bounded or unbounded, for the number of branches (the hyperbola has two branches in U_Z and one in U_Y, Example 5.8), for asymptotes, for which points are "at infinity", and for lengths, angles and areas (a circle can be drawn as an ellipse). Even parallelism is chart-dependent: two lines are parallel exactly when they meet on the line we chose to call L_∞.

Intrinsic (trust it in any chart)	**Chart artefact (do not)**
smooth or singular	open or closed; bounded or unbounded
number of intersection points	number of branches; asymptotes
tangency, multiplicity	which points are at infinity
connectedness, compactness	lengths, angles, areas
genus, Euler characteristic	whether two lines are parallel
lines are sent to lines	conic type (ellipse, parabola, hyperbola)

Worked example 5.11: The canvas is another chart

The tiled-floor picture (Figure 5.8) makes the line at infinity of the ground visible as the horizon. Here is why. Put the eye at height h above the ground, looking horizontally along the y-axis, with a vertical canvas at distance 1 in front of the eye. A ground point (x,y) with $y>0$ is seen along the ray from the eye to that point. After moving forward a distance 1 out of y, the ray has covered the fraction $1/y$ of the sideways displacement x and of the drop h. So it crosses the canvas at sideways position u and height v, measured from eye level, given by

$$\begin{aligned} [u:v:1] &\overset{(1)}{=} \left[\frac{x}{y}:-\frac{h}{y}:1\right] \\ &\overset{(2)}{=} [x:-h:y]. \end{aligned}$$

(1) Similar triangles: $u=x/y$ and $v=-h/y$.
(2) Multiply all coordinates by y.

In homogeneous coordinates $[X:Y:Z]$ of the ground (with $[x:y:1]$ for the point (x,y)),

the painting map is therefore

$$[X : Y : Z] \mapsto [X : -hZ : Y], \qquad A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -h \\ 0 & 1 & 0 \end{pmatrix}, \qquad \det A = h \neq 0,$$

a projective transformation of $\mathbb{RP}^2$. The line at infinity of the ground, $Z = 0$, goes to the points $[X : 0 : Y]$, which have $v = 0$: the horizon at eye level. Conversely, the ground line $y = 0$ (the points directly to the left and right of the observer's feet, neither ahead nor behind) goes to $[X : -hZ : 0]$, the line at infinity of the canvas. Rays to those points run parallel to the canvas and are never painted. So the line at infinity is not a special line of $\mathbb{RP}^2$. It is simply the one line that a given chart leaves out, and a change of chart can bring it into view.

The complex case. $\mathbb{CP}^n$ has real dimension $2n$. $\mathbb{CP}^1 = S^2$ can be drawn faithfully, and we do draw it (Figure 5.11). $\mathbb{CP}^2$ is four-dimensional. There is no picture of it on paper, not even of one chart, which is $\mathbb{C}^2 = \mathbb{R}^4$. We picture it in pieces:

- through charts, and real slices of curves in them (with the warning of the pitfall in Section 5.1.1);
- through maps and fibrations: the circle fibration $S^5 \to \mathbb{CP}^2$ of (5.2), or a curve in $\mathbb{CP}^2$ drawn as a branched cover of $\mathbb{CP}^1$, as in Figure 5.16;
- through the moment map below, which draws $\mathbb{CP}^2$ as a triangle with a torus over each interior point.

Worked example 5.12: $\mathbb{CP}^1$ as an interval and $\mathbb{CP}^2$ as a triangle

Define

$$\mu([z_0 : z_1 : z_2]) = \frac{(|z_1|^2,\ |z_2|^2)}{|z_0|^2 + |z_1|^2 + |z_2|^2}.$$

It is well defined, because $z \mapsto \lambda z$ multiplies the numerator and the denominator by $|\lambda|^2$. Its image is the triangle $\Delta = \{(a, b) : a, b \geq 0,\ a + b \leq 1\}$. Take (a, b) in the interior of Δ and choose the representative with $\sum |z_i|^2 = 1$ and z_0 real and positive (this uses up the phase freedom). Then

$$\mu^{-1}(a, b) \overset{(1)}{=} \left\{\left[\sqrt{1 - a - b} : \sqrt{a}\, e^{i\alpha_1} : \sqrt{b}\, e^{i\alpha_2}\right]\right\} \overset{(2)}{=} T^2.$$

(1) The moduli are fixed by $|z_1|^2 = a$, $|z_2|^2 = b$, $|z_0|^2 = 1 - a - b$, with $z_0 > 0$; only the phases of z_1 and z_2 remain free.
(2) Two independent angles α_1, α_2 make a torus.

Over an interior point of an edge, one of the z_i is zero and only one phase remains: the fibre is a circle. Over a vertex only one z_i is nonzero, and the fibre is a single point. Each edge of Δ is one of the lines $z_i = 0$, a copy of $\mathbb{CP}^1$: an interval with a circle over each interior point, where the circles shrink to points at the two ends. That is a sphere. For $\mathbb{CP}^1$ itself the same map is $\mu([z_0 : z_1]) = |z_1|^2/(|z_0|^2 + |z_1|^2)$. On S^3 this is $|z_1|^2$, and in the coordinates of Example 5.10 it equals $(1 + X_3)/2$, the height on the sphere. Its fibres are the circles of latitude.

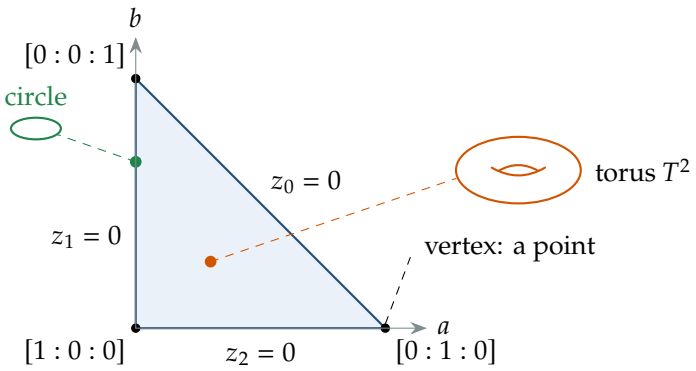

Figure 5.14: A faithful picture of $\mathbb{CP}^2$ by fibres. The moment map $\mu = (|z_1|^2, |z_2|^2)/|z|^2$ sends $\mathbb{CP}^2$ onto a triangle. Over each interior point (orange) sits a torus of phases; over each point of an edge (green) sits a circle; over each vertex sits a single point. Each edge is one of the lines $z_i = 0$, a $\mathbb{CP}^1$ drawn as an interval of circles that shrink to points at the ends. Four real dimensions become a two-dimensional base with the rest of the information stored in the fibres, just as a sphere can be recorded by its height together with a circle of latitude at each height.

Physical picture: no global picture, and nothing lost

We never see all of $\mathbb{RP}^2$ or $\mathbb{CP}^2$ at once, and we do not need to. Every statement we make about a variety in projective space (it is smooth, it meets a line in d points, it has genus p) is intrinsic in the sense of the key idea above. So it can be checked in one chart, or in a fibration picture, and the answer does not depend on the choice. Faithful global pictures are a luxury of low dimension. Charts are the everyday tool, exactly as for any manifold.

Recap: projective space by pictures

- $\mathbb{RP}^n$ is the set of lines through the origin of $\mathbb{R}^{n+1}$. Each line meets S^n in two antipodal points, so $\mathbb{RP}^n = S^n/(x \sim -x)$ and $S^n \to \mathbb{RP}^n$ is a double cover. $\mathbb{RP}^1 \cong S^1$ by angle doubling. $\mathbb{RP}^2$ is a disc with antipodal boundary points glued; $\chi(\mathbb{RP}^2) = 1$, and it is not orientable.
- Perspective puts $\mathbb{R}^2$ inside $\mathbb{RP}^2$ as the chart $Z \neq 0$, $(x, y) \mapsto [x : y : 1]$. What is left over is the line at infinity $Z = 0$, an $\mathbb{RP}^1$ whose points are directions without sign. Any two lines meet in exactly one point; parallels of slope m meet at $[1 : m : 0]$. On a painted floor each direction has its own vanishing point, and all of them lie on the horizon, the line at infinity.
- Homogenising a curve and setting $Z = 0$ finds its points at infinity. The parabola $YZ = X^2$ gains $[0 : 1 : 0]$, and the hyperbola $XY = Z^2$ gains $[1 : 0 : 0]$ and $[0 : 1 : 0]$; each becomes a single loop. Every non-degenerate real conic with real points is the circle $X^2 + Y^2 = Z^2$.
- $\mathbb{CP}^n = S^{2n+1}/\mathrm{U}(1)$: a complex line meets the sphere in a circle. For $n = 1$ this is the Hopf fibration $S^3 \to S^2$.
- No faithful global picture exists for $\mathbb{RP}^2$ (it does not embed in $\mathbb{R}^3$) or for $\mathbb{CP}^2$ (real dimension four). We draw charts, the disc model, the sphere model or fibrations, and we trust only chart-independent statements.

5.1.8 Homogeneous polynomials and projective varieties

A polynomial $P(z_1, \dots, z_{n+1})$ is not a function on $\mathbb{CP}^n$: its value depends on which representative we pick. But its *zero set* can still make sense. This is the key observation of Nash's first page.

Working definition 5.7 (homogeneous polynomial)

P is **homogeneous of degree** d if every monomial in it has total degree d. [the sum of the exponents, e.g. $z_1^2 z_2$ has total degree 3] Equivalently, and this is the operational test,

$$P(\lambda z_1, \dots, \lambda z_{n+1}) \;=\; \lambda^d \, P(z_1, \dots, z_{n+1}) \qquad \text{for all } \lambda \in \mathbb{C}^*. \tag{5.3}$$

This is Nash's (5.1).

Because $\lambda^d \neq 0$, (5.3) says that $P(z) = 0$ if and only if $P(\lambda z) = 0$. So "$P = 0$" is a condition on the line, not on the representative, and

$$V(P) = \{[z] \in \mathbb{CP}^n : P(z) = 0\}$$

is a well-defined subset of $\mathbb{CP}^n$. In the chart U_{n+1} we may choose the representative with $z_{n+1} = 1$, and then

$$\begin{aligned} P(z_1, \dots, z_n, z_{n+1}) = 0 &\overset{(1)}{\iff} z_{n+1}^{-d} \, P(z_1, \dots, z_{n+1}) = 0 \\ &\overset{(2)}{\iff} P\Big(\frac{z_1}{z_{n+1}}, \dots, \frac{z_n}{z_{n+1}}, 1\Big) = 0. \end{aligned} \tag{5.4}$$

(1) Multiply by the nonzero number z_{n+1}^{-d}.
(2) Homogeneity (5.3) with $\lambda = 1/z_{n+1}$.

This is Nash's (5.2) (Nash writes it as a one-way implication; it is in fact an equivalence). In words: *inside a chart, a projective variety is the affine variety of the dehomogenised polynomial*. Conversely, any polynomial $p(x_1, \dots, x_n)$ of degree d can be **homogenised** by setting $x_i = z_i / z_{n+1}$ and multiplying through by z_{n+1}^d:

$$P(z_1, \dots, z_{n+1}) = z_{n+1}^d \, p\big(z_1/z_{n+1}, \dots, z_n/z_{n+1}\big).$$

The zeros of P with $z_{n+1} \neq 0$ are the old affine zeros; the zeros with $z_{n+1} = 0$ are the new **points at infinity**.

Working definition 5.8 (projective variety)

A **projective algebraic variety** is the common zero set in $\mathbb{CP}^n$ of finitely many homogeneous polynomials $P_1, \dots, P_k$ [so whether $P_i = 0$ at a point does not depend on which representative we pick] (their degrees may differ). We write $V \subset \mathbb{CP}^n$. *Operationally*: in each chart U_j [the points with $z_j \neq 0$, a copy of $\mathbb{C}^n$ once we scale to $z_j = 1$] set $z_j = 1$ and solve the resulting ordinary polynomial equations.

Nash phrases this as "V can be thought of as being given by an embedding into $\mathbb{CP}^n$". The point is that we regard V as a space in its own right, and the polynomials describe how it sits inside $\mathbb{CP}^n$.

Worked example 5.13: Completing the complex circle

Homogenise $x^2 + y^2 = 1$ with $x = z_1/z_0$, $y = z_2/z_0$:

$$C = \{\, z_1^2 + z_2^2 - z_0^2 = 0 \,\} \subset \mathbb{CP}^2.$$

The affine part ($z_0 \neq 0$) is the complex circle of the previous example, which we found to be $\mathbb{C}^*$. The points at infinity have $z_0 = 0$, so $z_1^2 + z_2^2 = 0$, that is $z_2 = \pm i z_1$. With $z_1 \neq 0$ (otherwise all coordinates vanish) we get exactly two points,

$$[0 : 1 : \mathrm{i}] \quad \text{and} \quad [0 : 1 : -\mathrm{i}].$$

These are the two missing ends of the cylinder $\mathbb{C}^*$. Adding them gives a sphere. In fact every smooth conic is a copy of $\mathbb{CP}^1$. For the conic $z_0 z_2 = z_1^2$ this is completely explicit:

$$\nu : \mathbb{CP}^1 \to \mathbb{CP}^2, \qquad [s : t] \mapsto [s^2 : st : t^2], \qquad z_0 z_2 \overset{(1)}{=} s^2 t^2 \overset{(2)}{=} (st)^2 = z_1^2.$$

(1) Substitute the components of ν.
(2) Rearrange.

The map ν is well defined, because rescaling $(s, t) \to (\lambda s, \lambda t)$ rescales every component by λ^2. It is injective, because s/t can be read off as z_0/z_1 or z_1/z_2. It is onto, because any point of the conic with $z_0 \neq 0$ is $[1 : a : a^2] = \nu([1 : a])$ and the only point with $z_0 = 0$ is $[0 : 0 : 1] = \nu([0 : 1])$. (Our circle conic is carried to this one by a linear change of coordinates, $z_0 \pm z_1 \to$ new coordinates.)

How many points on a line? A line in $\mathbb{CP}^2$ is the zero set of a linear form, and it is itself a copy of $\mathbb{CP}^1$ (parametrise it by two of its points). Restrict a homogeneous P of degree d to the line: we get a homogeneous polynomial of degree d in the two parameters $[s : t]$, which factors into d linear factors over $\mathbb{C}$. So a degree-d curve meets a line in exactly d points counted with multiplicity (unless it contains the line). This is the simplest case of **Bézout's theorem**: curves of degrees d_1 and d_2 in $\mathbb{CP}^2$ with no common component meet in $d_1 d_2$ points, counted with multiplicity. Over $\mathbb{R}$ none of this is true (a line can miss a circle); over $\mathbb{C}$ and with points at infinity included, counting becomes exact. This is the first sign of the rigidity that makes algebraic geometry so computable.

5.1.9 Singular points and the Jacobian criterion

Nash warns that "an algebraic variety $V \subset \mathbb{CP}^n$ will not in general be a sub-manifold of $\mathbb{CP}^n$": it can have singular points, like the node and the cusp in Figure 5.2. How do we detect them? By the implicit function theorem, which works in the holomorphic setting exactly as in the real one.

Key idea: holomorphic implicit function theorem

Let $P_1, \dots, P_k$ be holomorphic functions of $x \in \mathbb{C}^m$ that vanish at x_0. If the $k \times m$ matrix of first derivatives

$$J(x_0) = \left[\frac{\partial P_i}{\partial x_j}(x_0) \right]_{k \times m}$$

has its maximal rank k, then near x_0 the common zero set is a complex submanifold of dimension $m - k$: we can solve for k of the coordinates as holomorphic functions of the other $m - k$.

Working definition 5.9 (singular point)

Let V be cut out by $P_1, \dots, P_k$ and have the expected dimension $m - k$. [one complex dimension lost per independent equation] A point $x_0 \in V$ is **nonsingular** (or smooth) if the Jacobian matrix $J(x_0) = [\partial P_i / \partial x_j]$ has rank k, [its k rows are linearly independent] and **singular** if the rank drops below k. *Operationally*: compute all $k \times k$ minors of J and solve "all minors vanish" together with $P_1 = \cdots = P_k = 0$. For a single equation ($k = 1$) this means: solve $P = 0$ and $\partial P / \partial x_j = 0$ for all j.

Nash phrases the same thing using the Jacobian of the embedding $e : V \to \mathbb{CP}^n$. Recall that for a smooth map $f : M \to N$ between manifolds, with local coordinates $(x_1, \dots, x_m)$ on M and $(y_1, \dots, y_n)$ on N, the Jacobian $J(f)$ is the $n \times m$ matrix $[\partial y_i / \partial x_j]$. The two versions agree: near a smooth point, the implicit function theorem gives local coordinates on V in which the embedding has a Jacobian of full rank. If the rank drops, no such coordinates exist. When V has no singular points it is a complex submanifold of $\mathbb{CP}^n$, and it is called an **algebraic submanifold** of $\mathbb{CP}^n$.

For a projective hypersurface there is a useful shortcut. If P is homogeneous of degree d, differentiate (5.3) with respect to λ and set $\lambda = 1$:

$$\sum_{i=1}^{n+1} z_i \frac{\partial P}{\partial z_i}(z) \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}\lambda} P(\lambda z)\Big|_{\lambda=1} \overset{(2)}{=} \frac{\mathrm{d}}{\mathrm{d}\lambda} \lambda^d P(z)\Big|_{\lambda=1} = d\, P(z). \tag{5.5}$$

(1) Chain rule: $\frac{\mathrm{d}}{\mathrm{d}\lambda} P(\lambda z) = \sum_i z_i \, (\partial_i P)(\lambda z)$.
(2) Homogeneity (5.3).

This is **Euler's relation**. It implies that if all partial derivatives $\partial P / \partial z_i$ vanish at $z \neq 0$ then $P(z) = 0$ automatically. So: *the singular points of $V(P) \subset \mathbb{CP}^n$ are the points where all $n + 1$ homogeneous partial derivatives vanish.* No chart is needed.

Worked example 5.14: Fermat curves are smooth

Let $F = z_0^d + z_1^d + z_2^d$. Then $\partial F / \partial z_i = d\, z_i^{d-1}$. All three vanish only if $z_0 = z_1 = z_2 = 0$, which is not a point of $\mathbb{CP}^2$. So the Fermat curve of every degree d is a smooth complex curve in $\mathbb{CP}^2$. For $d = 2$ it is a conic (a sphere), for $d = 3$ a torus, and in general its genus is given by the **degree–genus formula**

$$p = \frac{(d-1)(d-2)}{2} \tag{5.6}$$

for any smooth plane curve of degree d. (Plausibility: degenerate the curve into d lines in general position; each line is a sphere, any two meet in one point, so there are $\binom{d}{2}$ junctions; $d - 1$ of them are needed to connect the d spheres into a tree, and each remaining junction adds a handle: $\binom{d}{2} - (d-1) = \frac{(d-1)(d-2)}{2}$. This is the argument in Gathmann's notes, §0.1.)

Worked example 5.15: When is Nash's cubic smooth?

Nash's equation (5.3) is the cubic $F(x, y) = x(x-1)(x-\lambda) - y^2 = 0$. Write $q(x) = x(x-1)(x-\lambda)$. In the affine chart,

$$\frac{\partial F}{\partial y} = -2y, \qquad \frac{\partial F}{\partial x} = q'(x).$$

A singular affine point needs $y = 0$, then $F = 0$ forces $q(x) = 0$, so $x \in \{0, 1, \lambda\}$, and finally $q'(x) = 0$. A root of q is also a root of q' exactly when it is a repeated root, which happens

exactly when $\lambda = 0$ or $\lambda = 1$. Now the point at infinity. Homogenise with $x = X/Z$, $y = Y/Z$:

$$\tilde{F}(X, Y, Z) = X(X - Z)(X - \lambda Z) - Y^2 Z.$$

At $Z = 0$ we need $X^3 = 0$, so the only point at infinity is $[X : Y : Z] = [0 : 1 : 0]$. Use the chart $Y = 1$ with coordinates (X, Z):

$$\frac{\partial \tilde{F}}{\partial Z}(0,1,0) \overset{(1)}{=} \left[\frac{\partial}{\partial Z}\big(X(X - Z)(X - \lambda Z)\big) - 2YZ \cdot 0 - Y^2\right]_{(0,1,0)}$$
$$\overset{(2)}{=} 0 - 1 = -1 \neq 0.$$

(1) Differentiate $\tilde{F}$ term by term; the product rule on $Y^2 Z$ gives Y^2 (with $Y = 1$ in this chart, Y is not a variable).

(2) Every term of the cubic part is at least quadratic in (X, Z), so its derivative vanishes at $X = Z = 0$.

So the point at infinity is always smooth, and *Nash's cubic (5.3) is smooth precisely when* $\lambda \neq 0, 1$. At $\lambda = 0$ the curve becomes $y^2 = x^2(x - 1)$, a node at the origin; at $\lambda = 1$ it becomes $y^2 = x(x - 1)^2$, a node at $(1, 0)$. The parameter space of smooth tori in this family is $\mathbb{C} \setminus \{0, 1\}$. Keep this in mind: it is our first glimpse of a moduli space.

Watch out: a singular cone can have a smooth projectivisation

The affine cone $\{z_1^2 + z_2^2 = z_0^2\} \subset \mathbb{C}^3$ is singular at the origin (all partials vanish there). But the origin is not a point of $\mathbb{CP}^2$, and the projective conic with the same equation is smooth. Singularity is always tested at actual points of the variety.

5.1.10 When is a complex manifold algebraic? Chow and Kodaira

A complex submanifold of $\mathbb{CP}^n$ could, a priori, be cut out by *holomorphic* functions that are not polynomials, such as exp or sin. The first surprise is that compactness rules this out.

Key idea: Chow's theorem

Every closed complex submanifold of $\mathbb{CP}^n$ (more generally, every closed analytic subvariety) is algebraic: it is the zero set of finitely many homogeneous polynomials. Proved in Griffiths–Harris.

Nash puts it as: take a general analytic embedding $e : M \to \mathbb{CP}^n$, not insisting that $e(M)$ be given by polynomials; then $e(M)$ is in fact given by polynomials, and M is a nonsingular algebraic variety. So on compact spaces, "holomorphic" and "algebraic" coincide. The mechanism is visible in the simplest case.

Worked example 5.16: Meromorphic functions on $\mathbb{CP}^1$ are rational

Let f be a meromorphic function on $\mathbb{CP}^1$, that is, holomorphic except for poles, including possibly at $z = \infty$ (tested in the chart $w = 1/z$). Poles are isolated, and $\mathbb{CP}^1$ is compact, so there are finitely many, say at $a_1, \dots, a_r \in \mathbb{C}$, plus perhaps ∞. Near a_j the Laurent series has a finite principal part $\mathrm{pp}_j(z) = \sum_{k=1}^{m_j} c_{jk}(z - a_j)^{-k}$, and near ∞ the principal part is a

polynomial $\mathrm{pp}_\infty(z) = \sum_{k=1}^{m_\infty} c_k z^k$. Consider

$$g(z) = f(z) - \sum_{j=1}^{r} \mathrm{pp}_j(z) - \mathrm{pp}_\infty(z).$$

Then g has no poles in $\mathbb{C}$ and is bounded near ∞. A holomorphic function on all of $\mathbb{C}$ that is bounded is constant (**Liouville's theorem**: the Cauchy estimate $|g'(z_0)| \le \sup|g|/R$ on a circle of radius R gives $g' = 0$ as $R \to \infty$). So

$$f(z) \overset{(1)}{=} \text{const} + \sum_{j=1}^{r}\sum_{k=1}^{m_j} \frac{c_{jk}}{(z-a_j)^k} + \sum_{k=1}^{m_\infty} c_k z^k \overset{(2)}{=} \frac{\text{polynomial}}{\prod_j (z-a_j)^{m_j}}.$$

(1) g is constant by Liouville.
(2) Put everything over a common denominator.

Every meromorphic function on the Riemann sphere is a rational function. The two ingredients are the ones behind Chow's theorem in general: compactness (finitely many poles, controlled growth) and Liouville-type rigidity of holomorphic functions.

Chow's theorem is about subsets of a given $\mathbb{CP}^n$. The second, deeper question is intrinsic: given an abstract compact complex manifold, can it be embedded in some $\mathbb{CP}^n$ at all? To state the answer we need forms of type $(1,1)$, which we treat properly in Section 5.3.1. For now: in local holomorphic coordinates $z^1, \dots, z^n$, a real 2-form of **type** $(1,1)$ is

$$\omega = \frac{\mathrm{i}}{2} \sum_{i,j} h_{i\bar{j}}(z, \bar{z})\, \mathrm{d}z^i \wedge \mathrm{d}\bar{z}^j, \qquad h_{i\bar{j}} = \overline{h_{j\bar{i}}} \text{ (Hermitian)},$$

and it is **positive** if the Hermitian matrix $h_{i\bar{j}}$ is positive definite at every point. (A positive $(1,1)$-form is exactly the Kähler form of a Hermitian metric; see Section 5.3.6.)

Key idea: Kodaira embedding theorem

A compact complex manifold M is an algebraic variety (can be holomorphically embedded in some $\mathbb{CP}^n$) if and only if it carries a closed, positive 2-form ω of type $(1,1)$ whose cohomology class $[\omega]$ lies in $H^2(M;\mathbb{Q})$.

Two remarks from Nash, expanded. First, the class of a closed real 2-form lies automatically in $H^2(M;\mathbb{R})$; the condition is that it is rational. Concretely, $[\omega] \in H^2(M;\mathbb{Q})$ means that $\int_S \omega \in \mathbb{Q}$ for every closed surface S in M. Second, if $[\omega]$ is rational, some integer multiple is integral: $H_2(M;\mathbb{Z})$ is finitely generated, so there are finitely many basis surfaces $S_1, \dots, S_b$; if $\int_{S_a} \omega = r_a/s_a$ then $N = \prod_a s_a$ gives $\int_{S_a} N\omega \in \mathbb{Z}$ for all a. An integral class is exactly the first Chern class of a line bundle (Section 5.3.4), and the embedding in the theorem is built from the holomorphic sections of a high power of that line bundle.

Worked example 5.17: $\mathbb{CP}^1$ and the torus satisfy Kodaira

The sphere. On $\mathbb{CP}^1$ take $\omega = \frac{\mathrm{i}}{2}\frac{\mathrm{d}z\wedge\mathrm{d}\bar{z}}{(1+|z|^2)^2}$ (the Fubini–Study form of Section 5.3.7). With $z = x + \mathrm{i}y$ we have $\mathrm{d}z \wedge \mathrm{d}\bar{z} = -2\mathrm{i}\,\mathrm{d}x \wedge \mathrm{d}y$, so

$$\int_{\mathbb{CP}^1} \omega \overset{(1)}{=} \int_{\mathbb{R}^2} \frac{\mathrm{d}x\,\mathrm{d}y}{(1+x^2+y^2)^2} \overset{(2)}{=} 2\pi \int_0^\infty \frac{r\,\mathrm{d}r}{(1+r^2)^2} \overset{(3)}{=} 2\pi\left[-\frac{1}{2(1+r^2)}\right]_0^\infty = \pi.$$

(1) $\frac{\mathrm{i}}{2}\cdot(-2\mathrm{i})=1$; the chart z misses only one point, which has zero area.
(2) Polar coordinates, $\mathrm{d}x\,\mathrm{d}y = r\,\mathrm{d}r\,\mathrm{d}\theta$.
(3) Antiderivative of $r/(1+r^2)^2$.

Since $H_2(\mathbb{CP}^1;\mathbb{Z})=\mathbb{Z}$ is generated by $\mathbb{CP}^1$ itself, $[\omega/\pi]$ is an integral class. Positivity: $h_{1\bar1}=(1+|z|^2)^{-2}>0$. Closedness: automatic on a surface (see below). So $\mathbb{CP}^1$ is algebraic, as it should be.

The torus. Let $T=\mathbb{C}/\Lambda$ with $\Lambda=\mathbb{Z}+\tau\mathbb{Z}$, $\operatorname{Im}\tau>0$. The flat form $\omega=\frac{\mathrm{i}}{2}\mathrm{d}z\wedge\mathrm{d}\bar z=\mathrm{d}x\wedge\mathrm{d}y$ is positive and closed, and $\int_T\omega$ is the area of the parallelogram spanned by 1 and τ, namely $\operatorname{Im}\tau$. Then $\omega/\operatorname{Im}\tau$ integrates to 1. So *every* complex torus of dimension one is algebraic. We will see it explicitly as the cubic (5.3) in Section 5.2.3. (In complex dimension two and higher this fails: a generic complex torus $\mathbb{C}^2/\Lambda$ has no rational positive $(1,1)$ class, and is not algebraic. The conditions on Λ for it to be algebraic are the Riemann conditions, and they are exactly the symmetry and positivity of the period matrix we meet in Section 5.2.17.)

Physical picture: Kodaira and Dirac quantisation

Think of ω as a magnetic field on M. "$[\omega]$ integral" is Dirac's quantisation condition: the flux through every closed surface is an integer multiple of the flux quantum. It is precisely the condition for a charged particle's wavefunction to be a section of a line bundle L with curvature ω. The holomorphic sections of L^k are the lowest-Landau-level states in the field $k\omega$, and Kodaira's theorem says that for k large there are enough of them to use as homogeneous coordinates: send a point x to $[s_0(x):\cdots:s_N(x)]$. Strong magnetic field embeds the manifold in projective space.

5.1.11 Riemann surfaces are algebraic curves

The most important class of algebraic varieties for us is in complex dimension one. A compact Riemann surface is a compact complex manifold of complex dimension one (we define it carefully in Section 5.2.1). On a real two-dimensional manifold every 2-form is closed, since $\mathrm{d}\omega$ would be a 3-form and there are none. Any Riemann surface carries a Hermitian metric (patch local ones together with a partition of unity), whose $(1,1)$-form is then positive and closed; rescaling it gives total area 1, a rational class. By Kodaira, *every compact Riemann surface is an algebraic curve*. Nash writes Σ_p for the compact Riemann surface of genus p, and so shall we.

Watch out: Nash writes p for the genus

Most books write g for the genus. Nash uses p because he reserves g for a metric on the surface (footnote on p. 138). We follow Nash. Do not confuse this p with the p of a p-form; context always decides, and where both occur we will say so.

Reading Nash (pp. 137–139, (5.1)–(5.2))

Nash defines algebraic varieties as zero loci of homogeneous polynomials in $\mathbb{CP}^n$, explains why the zero locus is well defined (5.1)–(5.2), and detects singular points by the rank of a Jacobian. He then quotes two theorems without proof: Chow's (analytic submanifolds of $\mathbb{CP}^n$ are algebraic) and Kodaira's embedding theorem (algebraic $\iff$ there is a closed positive $(1,1)$-form with rational class). Nash introduces $\mathbb{CP}^n$ directly as the space of lines through the origin of $\mathbb{C}^{n+1}$ and does not discuss $\mathbb{RP}^n$. The real warm-up here (the double cover $S^n\to\mathbb{RP}^n$, the disc model, perspective and the line at infinity, conics in $\mathbb{RP}^2$, which pictures are legitimate) and the Hopf fibration $S^3\to\mathbb{CP}^1$ are background for his

one sentence. Also supplied here: the charts and transition functions of $\mathbb{CP}^n$, the Riemann sphere, the homogenisation dictionary, Euler's relation and the projective Jacobian test, Bézout and the degree–genus formula, the smoothness analysis of Nash's cubic (5.3), the Liouville argument behind Chow's theorem, and the explicit check of Kodaira's hypothesis on $\mathbb{CP}^1$ and on tori.

Recap

- An affine variety is a common zero set in $\mathbb{C}^m$; a projective variety is a common zero set of homogeneous polynomials in $\mathbb{CP}^n$, well defined because $P(\lambda z) = \lambda^d P(z)$.
- A complex function is a map from the x-plane to the y-plane; we draw it by matching curves in the two planes. $y = x^2$ doubles angles and covers each circle twice, so $\sqrt{y}$ lives on two sheets glued crosswise along a slit. $y = 1/x$ swaps inside and outside of the unit circle and wants the extra point ∞ of the Riemann sphere.
- $\mathbb{RP}^n = S^n/(x \sim -x)$; $\mathbb{RP}^2 = \mathbb{R}^2 \sqcup L_\infty$, and adding the line at infinity closes curves up (the parabola and hyperbola become circles). Only chart-independent features of pictures are meaningful.
- $\mathbb{CP}^n = S^{2n+1}/\mathrm{U}(1)$ is covered by $n+1$ charts $z_j \neq 0$ with holomorphic transition functions; it is compact. $\mathbb{CP}^1$ is the Riemann sphere, and $S^3 \to \mathbb{CP}^1$ is the Hopf fibration.
- Singular points are where the Jacobian of the defining polynomials drops rank. For a hypersurface in $\mathbb{CP}^n$: all partials vanish.
- Chow: compact analytic $\Rightarrow$ algebraic. Kodaira: algebraic $\iff$ a closed positive $(1,1)$-form with rational (hence, after scaling, integral) class exists.
- Every compact Riemann surface Σ_p is algebraic. The cubic $y^2 = x(x-1)(x-\lambda)$ is smooth exactly for $\lambda \neq 0, 1$.

5.2 Riemann surfaces and divisors

For the rest of the chapter the main character is a compact Riemann surface Σ_p. Three questions drive this section. What *is* a Riemann surface, concretely, and how do the polynomial descriptions of genus 0, 1 and higher look? How many different complex structures does a surface of genus p admit? And how do we describe holomorphic line bundles on it, which is where all the interesting global information lives? The answer to the last question is the notion of a *divisor*: a finite list of points with integer multiplicities that records where a section vanishes or blows up.

5.2.1 Riemann surfaces: charts and genus

Working definition 5.10 (Riemann surface)

A **Riemann surface** is a connected real 2-manifold [a surface: near each point it looks like a piece of the plane] covered by charts $z_\alpha : U_\alpha \to \mathbb{C}$ [a complex coordinate z_α on each patch U_α] such that on every overlap the change of coordinates $z_\beta = h_{\beta\alpha}(z_\alpha)$ is a *holomorphic* function with [complex differentiable, so near each point a power series in

z_α alone, with no $\bar{z}_\alpha$] nonzero derivative. *Operationally*: to check that some construction makes sense on a Riemann surface, check it in one chart and verify that it is unchanged (or changes in the stated way) under a holomorphic change of variable $z \mapsto w(z)$.

Every holomorphic map with $w'(z) \neq 0$ is conformal: it preserves angles, because locally it is multiplication by the complex number $w'(z)$, a rotation times a dilation. Conversely, on any oriented surface with a metric one can find local **isothermal coordinates** in which $ds^2 = e^{\phi(x,y)}(dx^2 + dy^2) = e^\phi |dz|^2$, and two such coordinate systems differ by a holomorphic map. So

Key idea: complex structure = conformal structure

On an oriented surface, a complex structure is the same thing as a metric up to local rescaling $g \to e^\sigma g$. This is why string theory, whose Polyakov action is invariant under Weyl rescalings of the worldsheet metric, lives on Riemann surfaces.

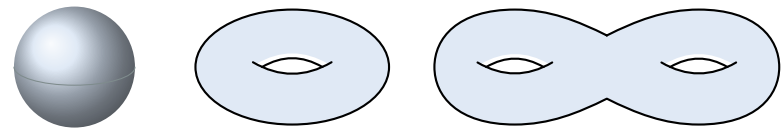
A compact Riemann surface is in particular a compact, orientable, closed surface (orientable because holomorphic changes of coordinates have positive Jacobian determinant $|w'(z)|^2$). Such surfaces are classified topologically by a single integer.

Working definition 5.11 (genus)

The **genus** p of a compact orientable surface is its number of handles: it is homeomorphic to [its points can be matched one-to-one with those of, continuously in both directions,] a sphere with p handles attached. *Operationally*: triangulate it (or divide it into polygons) with V vertices, E edges and F faces; then the **Euler characteristic**

$$\chi(\Sigma_p) = V - E + F = 2 - 2p. \tag{5.7}$$

For example, the surface of a tetrahedron is a sphere with $V - E + F = 4 - 6 + 4 = 2$, so $p = 0$. A square with opposite sides glued is a torus: after gluing there is one vertex, two edges and one face, so $\chi = 1 - 2 + 1 = 0$ and $p = 1$. The $4p$-gon with sides glued in the pattern $a_1 b_1 a_1^{-1} b_1^{-1} \cdots$, which Nash uses in Section 5.2.8, has (after gluing) one vertex, $2p$ edges and one face: $\chi = 1 - 2p + 1 = 2 - 2p$.



$p = 0, \chi = 2$ $p = 1, \chi = 0$ $p = 2, \chi = -2$

Figure 5.15: Compact orientable surfaces are classified by their genus p, the number of handles (holes). The Euler characteristic drops by 2 with every handle. A compact Riemann surface is one of these, with extra structure: a consistent notion of holomorphic function.

5.2.2 Holomorphic and meromorphic functions

A function f on a Riemann surface is **holomorphic** if $f \circ z_\alpha^{-1}$ is holomorphic in every chart. Since changes of chart are holomorphic, it is enough to check one chart around each point.

Working definition 5.12 (meromorphic function; order)

f is **meromorphic** if, near every point P and in a local coordinate z with $z(P) = 0$, it has a Laurent expansion [a power series in z that may also contain negative powers $z^{-1}, z^{-2}, \dots$] with finitely many negative powers:

$$f(z) = \sum_{k \geq n} c_k z^k, \qquad c_n \neq 0.$$

The integer $n = \operatorname{ord}_P f$ is the **order** of f at P. If $n > 0$, f has a zero of order n; if $n < 0$, a pole of order $-n$. Nash's convention is exactly this: *the order of a pole is a negative integer*. *Operationally*: write $f = z^n\, u(z)$ with u holomorphic and $u(0) \neq 0$; then n is the order.

The order does not depend on the coordinate. If $w = w(z)$ is another coordinate centred at P, then $w = z\, v(z)$ with $v(0) = w'(0) \neq 0$, so $z^n = w^n\, v^{-n}$ and $f = w^n \cdot (\text{nonvanishing})$.

Worked example 5.18: Orders of z on the Riemann sphere

Take $f(z) = z$ on $\mathbb{CP}^1$. At $z = 0$ it has a simple zero: $\operatorname{ord}_0 f = 1$. At every other finite point it is holomorphic and nonzero: order 0. At ∞ use the chart $w = 1/z$:

$$f = z = \frac{1}{w} = w^{-1} \cdot 1,$$

so $\operatorname{ord}_\infty f = -1$, a simple pole. The total count is $1 + (-1) = 0$. More generally a rational function $f = a(z)/b(z)$ with $\deg a = m$, $\deg b = k$ has m zeros and k poles in $\mathbb{C}$, and at ∞ it behaves like $z^{m-k} = w^{k-m}$, order $k - m$. Total: $m - k + (k - m) = 0$. We will see in Section 5.2.8 that this is not an accident.

Key idea: holomorphic functions on a compact surface are constant

If Σ is compact and f is holomorphic on all of Σ, then $|f|$ attains a maximum somewhere. A nonconstant holomorphic function is an open map (it maps small discs onto neighbourhoods), so it cannot have a local maximum of $|f|$. Hence f is constant.

So on a compact Riemann surface the interesting functions are *meromorphic*, and the interesting question is: *which pole patterns are allowed?* That is exactly the question divisors and the Riemann–Roch theorem answer.

5.2.3 The three regimes: genus 0, 1 and higher

Nash states that every Σ_p can be embedded in some $\mathbb{CP}^n$ and gives the minimal n in each regime. Let us see each one concretely.

Genus 0. Σ_0 is the Riemann sphere $\mathbb{CP}^1$ of Example 5.9, so "$n = 1$ trivially". (It is a theorem, the uniformisation theorem, that there is only *one* complex structure on the sphere.)

Genus 1. Nash's example (5.3) is the plane cubic

$$x(x-1)(x-\lambda) - y^2 = 0, \qquad \lambda \in \mathbb{C} \setminus \{0, 1\}, \tag{5.8}$$

written in the affine chart of $\mathbb{CP}^2$ and completed by the single point at infinity $[0 : 1 : 0]$ (Example 5.15). Why is this a torus? Two independent arguments follow; the second one is fully explicit.

Worked example 5.19: The cubic as a double cover: counting branch points

Solve (5.8) for y: $y = \pm\sqrt{q(x)}$ with $q(x) = x(x-1)(x-\lambda)$. Over each $x \in \mathbb{CP}^1$ there are two points of the curve, except where the two values of y coincide. That happens at the three roots $x = 0, 1, \lambda$ and also at $x = \infty$: going once around a huge circle $x = Re^{i\theta}$ changes $\sqrt{q} \sim x^{3/2}$ by $e^{3\pi i} = -1$, so the two values are swapped there too. So the curve is a two-sheeted cover of the sphere branched over $b = 4$ points. Now count Euler characteristics with a triangulation of $\mathbb{CP}^1$ that has the four branch points among its vertices. Every face and edge has two preimages; every vertex has two preimages except the branch points, which have one:

$$\begin{aligned}\chi(\text{curve}) &\overset{(1)}{=} 2V - b - 2E + 2F \\ &\overset{(2)}{=} 2\chi(\mathbb{CP}^1) - b \\ &\overset{(3)}{=} 2 \cdot 2 - 4 = 0.\end{aligned}$$

(1) Count preimages of vertices, edges and faces.
(2) $V - E + F = \chi(\mathbb{CP}^1)$.
(3) $\chi(\mathbb{CP}^1) = 2$ and $b = 4$.

By (5.7), $2 - 2p = 0$, so $p = 1$: a torus. The same count for $y^2 = f(x)$ with f of degree $2p+1$ or $2p+2$ and distinct roots gives $b = 2p + 2$ branch points and $\chi = 4 - (2p+2) = 2 - 2p$: genus p. These are the **hyperelliptic curves**.

Figure 5.16 shows how the two sheets fit together. Cut each sheet along the red slits, one from 0 to 1 and one from λ to ∞. Crossing a slit takes you from one value of $\sqrt{q}$ to the other, that is, to the other sheet, so the slits are glued crosswise. Each slit opens into a circle, and two spheres joined along two circles form a torus (bottom of the figure). The red circles on the torus are the former slits. The point $x = \infty$ is one of the four branch points; on the curve in $\mathbb{CP}^2$ it is the single point at infinity $[0:1:0]$, and adding it is what closes the surface up (compare the parabola in Example 5.7).

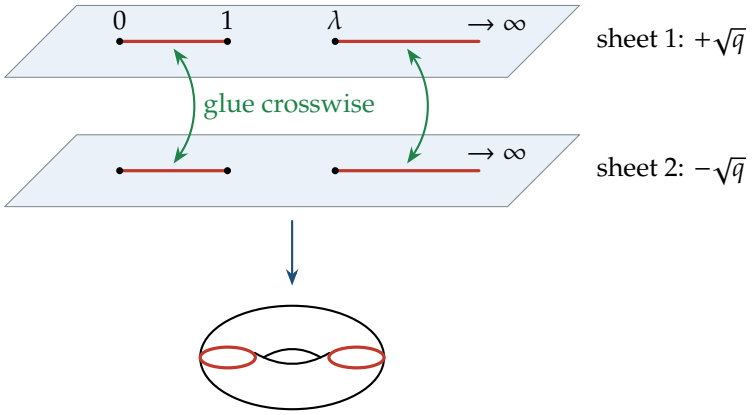


Figure 5.16: The curve $y^2 = x(x-1)(x-\lambda)$ mapped over two copies of the complex x-plane (Riemann spheres), where each sheet represents one of the two possible solutions for y (the two signs of $\sqrt{q}$).

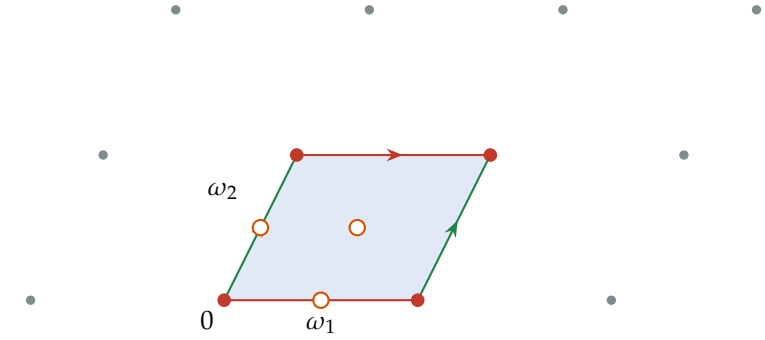
The fully explicit way to see the torus is to start from the torus and write down the cubic. This is the classical theory of the Weierstrass $\wp$-function (Gathmann §6.5).

Working definition 5.13 (complex torus)

Let $\omega_1, \omega_2 \in \mathbb{C}$ be linearly independent over $\mathbb{R}$, [neither is a real multiple of the other, so together they span the plane] and $\Lambda = \mathbb{Z}\omega_1 + \mathbb{Z}\omega_2$ the **lattice** they generate. The quotient $T = \mathbb{C}/\Lambda$, where $z \sim z + m\omega_1 + n\omega_2$, is a **complex torus**. The coordinate z on $\mathbb{C}$ serves as a local coordinate on T, and the changes of chart are translations $z \mapsto z + \omega$, which are holomorphic. Rescaling and rotating ($z \to z/\omega_1$) we may always take $\Lambda = \mathbb{Z} + \tau\mathbb{Z}$ with $\operatorname{Im}\tau > 0$ [here $\tau = \omega_2/\omega_1$, with the two generators swapped if needed so that τ lies in the upper half plane].



• poles of $\wp$ (double) and $\wp'$ (triple): the lattice points
◦ simple zeros of $\wp'$: the half-periods $\frac{\omega_1}{2}$, $\frac{\omega_2}{2}$, $\frac{\omega_1+\omega_2}{2}$

Figure 5.17: The lattice $\Lambda = \mathbb{Z}\omega_1 + \mathbb{Z}\omega_2$ and a fundamental parallelogram. Gluing opposite edges (same colour, same arrow) produces the torus $\mathbb{C}/\Lambda$. The Weierstrass function $\wp$ has a double pole at each lattice point; its derivative $\wp'$ has a triple pole there and three simple zeros at the half-periods (orange circles).

A meromorphic function on T is the same thing as a meromorphic function on $\mathbb{C}$ that is doubly periodic: $f(z+\omega) = f(z)$ for $\omega \in \Lambda$ (an **elliptic function**). There are no nonconstant holomorphic ones (compactness), so we need poles. The simplest choice is a double pole at each lattice point, made convergent by subtracting constants:

$$\wp(z) = \frac{1}{z^2} + \sum_{\omega \in \Lambda \setminus \{0\}} \left(\frac{1}{(z-\omega)^2} - \frac{1}{\omega^2} \right). \tag{5.9}$$

The subtracted $1/\omega^2$ makes each term fall off like $|\omega|^{-3}$, and $\sum |\omega|^{-3}$ converges (there are about $2\pi N$ lattice points at distance $\approx N$, giving $\sum N \cdot N^{-3}$). Its derivative is $\wp'(z) = -2\sum_{\omega\in\Lambda}(z-\omega)^{-3}$, manifestly periodic; $\wp$ itself is even and periodic (Gathmann, Remark 6.5.4).

Worked example 5.20: The torus satisfies a cubic equation

Step 1: Laurent series. Put $G_k = \sum_{\omega \neq 0} \omega^{-k}$ (zero for odd k by $\omega \to -\omega$). Expanding each term of (5.9) in powers of z/ω,

$$\begin{aligned} \wp(z) - \frac{1}{z^2} &\overset{(1)}{=} \sum_{\omega \neq 0} \frac{1}{\omega^2} \left(\sum_{k \geq 0} (k+1) \left(\frac{z}{\omega} \right)^k - 1 \right) \\ &\overset{(2)}{=} \sum_{k \geq 1} (k+1) G_{k+2}\, z^k \\ &\overset{(3)}{=} 3G_4 z^2 + 5G_6 z^4 + O(z^6). \end{aligned}$$

(1) $(z-\omega)^{-2} = \omega^{-2}(1 - z/\omega)^{-2}$ and $(1-u)^{-2} = \sum_{k\geq 0}(k+1)u^k$.

(2) The $k = 0$ term cancels the -1; exchange the sums (absolute convergence).
(3) Odd G's vanish.

Define $g_2 = 60G_4$ and $g_3 = 140G_6$. Then $\wp = z^{-2} + \frac{g_2}{20}z^2 + \frac{g_3}{28}z^4 + \dots$ and $\wp' = -2z^{-3} + \frac{g_2}{10}z + \frac{g_3}{7}z^3 + \dots$.

Step 2: compare poles. Square and cube:

$$\wp'^2 \overset{(1)}{=} 4z^{-6} - \tfrac{2g_2}{5}z^{-2} - \tfrac{4g_3}{7} + O(z^2),$$
$$4\wp^3 \overset{(2)}{=} 4z^{-6} + \tfrac{3g_2}{5}z^{-2} + \tfrac{3g_3}{7} + O(z^2),$$
$$\wp'^2 - 4\wp^3 + g_2\wp + g_3 \overset{(3)}{=} \left(-\tfrac{2}{5} - \tfrac{3}{5} + 1\right)g_2 z^{-2} + \left(-\tfrac{4}{7} - \tfrac{3}{7} + 1\right)g_3 + O(z^2) = O(z^2).$$

(1) $(-2z^{-3})^2 = 4z^{-6}$; cross terms $2(-2z^{-3})(\frac{g_2}{10}z) = -\frac{2g_2}{5}z^{-2}$ and $2(-2z^{-3})(\frac{g_3}{7}z^3) = -\frac{4g_3}{7}$.
(2) $\wp^3 = z^{-6} + 3z^{-4}\left(\frac{g_2}{20}z^2 + \frac{g_3}{28}z^4\right) + O(z^2)$, times 4.
(3) Add, using $g_2\wp = g_2 z^{-2} + O(z^2)$.

Step 3: Liouville. The function $\wp'^2 - 4\wp^3 + g_2\wp + g_3$ is elliptic, has no pole at 0 (hence none anywhere, by periodicity), so it is a holomorphic function on the compact torus, hence constant; and it vanishes at $z = 0$. So

$$\wp'(z)^2 = 4\wp(z)^3 - g_2\wp(z) - g_3. \tag{5.10}$$

The map $z \mapsto [1 : \wp(z) : \wp'(z)]$ (with $0 \mapsto [0 : 0 : 1]$) sends the torus into the cubic $Y^2Z = 4X^3 - g_2XZ^2 - g_3Z^3$ in $\mathbb{CP}^2$, and one checks it is a bijection (Gathmann, Prop. 6.5.7): each value of $\wp$ is taken at two points $\pm z$, and $\wp'$, being odd, separates them.

Worked example 5.21: From Weierstrass to Nash's Legendre form

The half-periods are zeros of $\wp'$: since $\wp'$ is odd and periodic,

$$\wp'\left(\tfrac{\omega_1}{2}\right) \overset{(1)}{=} \wp'\left(\tfrac{\omega_1}{2} - \omega_1\right) = \wp'\left(-\tfrac{\omega_1}{2}\right) \overset{(2)}{=} -\wp'\left(\tfrac{\omega_1}{2}\right) \implies \wp'\left(\tfrac{\omega_1}{2}\right) = 0,$$

(1) Periodicity.
(2) Oddness.

and likewise at $\omega_2/2$ and $\omega_3/2 = (\omega_1 + \omega_2)/2$. So the cubic $4x^3 - g_2x - g_3$ has the three roots $e_i = \wp(\omega_i/2)$, and they are distinct (if $e_1 = e_2$, the function $\wp - e_1$, which has only one double pole per parallelogram, would have two double zeros; but we show in Section 5.2.8 that zeros and poles balance). Substitute $x = e_1 + (e_2 - e_1)X$ and $y = 2(e_2 - e_1)^{3/2}Y$:

$$y^2 \overset{(1)}{=} 4(x - e_1)(x - e_2)(x - e_3)$$
$$\overset{(2)}{=} 4(e_2 - e_1)^3\, X\,(X - 1)\,(X - \lambda), \qquad \lambda = \frac{e_3 - e_1}{e_2 - e_1}.$$

(1) (5.10) with $x = \wp$, $y = \wp'$, and the factorisation by roots.
(2) $x - e_1 = (e_2 - e_1)X$, $x - e_2 = (e_2 - e_1)(X - 1)$, $x - e_3 = (e_2 - e_1)(X - \lambda)$.

Dividing by $4(e_2 - e_1)^3$ gives $Y^2 = X(X - 1)(X - \lambda)$, which is Nash's (5.3). Distinct e_i means $\lambda \neq 0, 1$, matching the smoothness test of Example 5.15. So *the constant λ in (5.3) is a function of the lattice*, that is, of τ.

Watch out: λ is not quite a coordinate on the moduli space

Relabelling the half-periods permutes e_1, e_2, e_3 and replaces λ by one of λ, $1-\lambda$, $1/\lambda$, $1/(1-\lambda)$, $\lambda/(\lambda-1)$, $(\lambda-1)/\lambda$. These six values describe the same torus. The combination that is truly invariant is the j-invariant $j = 256\,(\lambda^2-\lambda+1)^3/\big(\lambda^2(\lambda-1)^2\big)$. Nash calls λ a "local coordinate" on the family, which is the right word: locally, away from the special values, λ determines the torus. The global structure of the family is the subject of part 5b.

Genus 2 and higher. Nash says every Σ_p with $p \geq 2$ can be embedded in $\mathbb{CP}^3$. The reason is general: any smooth curve in $\mathbb{CP}^n$ with $n \geq 4$ can be projected from a point not on it (and not on any of its secant or tangent lines) to $\mathbb{CP}^{n-1}$ injectively; the union of all secant and tangent lines has complex dimension at most 3 (two points on the curve plus one point on the line joining them), so in $\mathbb{CP}^n$ with $n \geq 4$ such a point exists. One cannot in general go down to $\mathbb{CP}^2$: by the degree–genus formula (5.6), only the genera $0, 1, 3, 6, 10, \ldots$ occur for smooth plane curves. A genus-2 surface, for example, is best written as the hyperelliptic curve $y^2 = f(x)$ with f of degree 5 or 6, which is smooth in a weighted projective space rather than $\mathbb{CP}^2$.

5.2.4 How many complex structures? The number $3p-3$

A topological surface of genus p can carry many inequivalent complex structures: we just saw a one-parameter family of tori, labelled by λ (or τ). Nash quotes the answer: for $p = 1$ the family is one dimensional, and for $p > 1$ it has complex dimension $3p-3$. The space of isomorphism classes is the **moduli space** $\mathcal{M}_p$; its covering space is the **Teichmüller space** $\mathcal{T}_p$, studied in part 5b. Riemann's original heuristic for the number $3p-3$ is a nice parameter count.

Worked example 5.22: Riemann's count of moduli

Present Σ_p as a d-sheeted branched cover $f : \Sigma_p \to \mathbb{CP}^1$ (a meromorphic function of degree d), with only simple branch points. The Euler-characteristic count of Example 5.19, done for d sheets and b simple branch points, gives

$$2-2p \overset{(1)}{=} d\,\chi(\mathbb{CP}^1) - b = 2d - b \quad\Longrightarrow\quad b \overset{(2)}{=} 2p-2+2d.$$

(1) Each simple branch point loses one preimage out of d.
(2) Solve for b.

Conversely, a list of b branch points in $\mathbb{CP}^1$ (plus finite combinatorial data about which sheets are joined) determines the pair (Σ_p, f). So pairs (surface, function) form a family of dimension b. How many functions of degree d does a *fixed* surface have? We will derive in Section 5.3.3 that for large d the answer is $2d+1-p$ (choose a degree-d line bundle, p parameters, then two independent sections of it, $2(d+1-p)$ parameters, up to a common scale, -1). So

$$\begin{aligned}\dim \mathcal{M}_p &\overset{(1)}{=} b - (2d+1-p)\\ &\overset{(2)}{=} (2p-2+2d) - (2d+1-p) = 3p-3.\end{aligned}$$

(1) Dimension of the family of pairs minus the dimension of the fibre (functions on a fixed surface).
(2) Substitute b.

The degree d drops out, as it must. For $p = 1$ the formula gives 0, but the torus has a one-dimensional group of automorphisms (translations), each of which can be composed

with f; the correct statement is $\dim \mathcal{M}_p - \dim \mathrm{Aut}(\Sigma_p) = 3p-3$, which gives $1-1=0$ for $p=1$ and $0-3=-3$ for $p=0$ (the sphere has the three-dimensional automorphism group $\mathrm{PSL}(2,\mathbb{C})$). This is exactly the pattern of the string path integral: $3p-3$ complex moduli to integrate over, or conformal Killing vectors to divide by.

5.2.5 Holomorphic line bundles

Nash now says that complex manifolds are "often studied by constructing holomorphic bundles over" them. Let us recall what that means, concretely.

Working definition 5.14 (holomorphic line bundle)

Cover M by open sets U_α. A **holomorphic line bundle** L is specified by **transition functions** $g_{\alpha\beta} : U_\alpha \cap U_\beta \to \mathbb{C}^*$ [$\mathbb{C}^*$ is the nonzero complex numbers. $g_{\alpha\beta}$ converts the patch-β value of a section into the patch-α value], holomorphic and nowhere zero, satisfying the **cocycle condition**

$$g_{\alpha\beta}\, g_{\beta\gamma} = g_{\alpha\gamma} \text{ on } U_\alpha \cap U_\beta \cap U_\gamma, \qquad g_{\alpha\alpha} = 1. \tag{5.11}$$

A **section** s is a collection of local functions $s_\alpha : U_\alpha \to \mathbb{C}$ with $s_\alpha = g_{\alpha\beta}\, s_\beta$ on overlaps. It is holomorphic (meromorphic) if every s_α is. *Operationally*: a line bundle is "a function that picks up a factor $g_{\alpha\beta}$ when you change patch", like a wavefunction that picks up a gauge phase.

Two sets of transition functions describe the same (isomorphic) bundle if $g'_{\alpha\beta} = h_\alpha g_{\alpha\beta} h_\beta^{-1}$ for nowhere-zero holomorphic h_α on U_α: this is a change of local frame, the analogue of a gauge transformation. Line bundles can be multiplied ($L \otimes L'$ has transition functions $g_{\alpha\beta} g'_{\alpha\beta}$) and inverted ($L^{-1} = L^*$ has $g_{\alpha\beta}^{-1}$), so isomorphism classes form an abelian group. The toolkit chapters describe bundles and connections in general (Chapter T2, Chapter T3); sheaves of sections are in Chapter 3.

Worked example 5.23: The line bundles $\mathcal{O}(n)$ on $\mathbb{CP}^1$

Use the two charts of Example 5.9: U_0 with coordinate z, U_1 with $w = 1/z$. For each integer n define $\mathcal{O}(n)$ by the single transition function

$$g_{01}(z) = z^n \qquad \text{on } U_0 \cap U_1 = \mathbb{C}^*.$$

(With only two sets the cocycle condition is empty.) A holomorphic section is a pair $s_0(z)$ holomorphic on $\mathbb{C}$, $s_1(w)$ holomorphic on $\mathbb{C}$, with $s_0 = z^n s_1$. Write $s_0(z) = \sum_{k\ge 0} a_k z^k$. Then

$$s_1(w) \overset{(1)}{=} z^{-n} s_0(z) \overset{(2)}{=} \sum_{k\ge 0} a_k z^{k-n} \overset{(3)}{=} \sum_{k\ge 0} a_k\, w^{n-k}.$$

(1) The transition rule solved for s_1.
(2) Substitute the Taylor series of s_0.
(3) $z = 1/w$.

This is holomorphic at $w=0$ if and only if $a_k = 0$ for $k > n$. So *the holomorphic sections of $\mathcal{O}(n)$ are the polynomials of degree $\le n$ in z*: a vector space of dimension $n+1$ for $n \ge 0$, and $\{0\}$ for $n < 0$. In homogeneous coordinates, $s_0(z) = \sum a_k z^k$ is the dehomogenisation of the degree-n form $\sum a_k z_0^{n-k} z_1^k$ (recall $z = z_1/z_0$): sections of $\mathcal{O}(n)$ are homogeneous polynomials of degree n, which are exactly the objects whose zero sets define varieties.

A section with $s_0 = z^k$ has a zero of order k at $z = 0$ and, since $s_1 = w^{n-k}$, a zero of order $n - k$ at ∞: always n zeros in total.

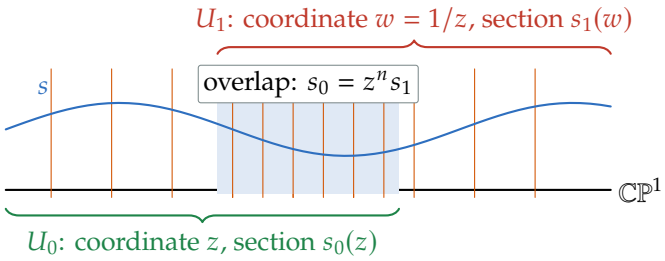


Figure 5.18: A line bundle over $\mathbb{CP}^1$ is two trivial pieces, one over each chart (orange fibres), glued over the overlap by multiplying the fibre coordinate by z^n. A section (blue) is a pair of local functions related by that factor. The integer n is all the information in the gluing: it is the winding number of $g_{01} = z^n$ around the equator $|z| = 1$, and it will turn out to be the degree, or first Chern class, of the bundle.

Worked example 5.24: The tautological bundle is $\mathcal{O}(-1)$

Over each point $[z_0 : z_1]$ of $\mathbb{CP}^1$ put the line it names, $\{\lambda(z_0, z_1)\} \subset \mathbb{C}^2$. This is the **tautological line bundle**. Over U_0 a nonvanishing section is $e_0 = (1, z)$; over U_1 it is $e_1 = (w, 1)$. On the overlap, $e_0 = (1, z) = z\,(1/z, 1) = z\,e_1$. A general point of the fibre is $\xi = s_0 e_0 = s_1 e_1$, so $s_1 e_1 = s_0\, z\, e_1$, that is $s_0 = z^{-1} s_1$. Comparing with Example 5.23, the transition function is z^{-1}: the tautological bundle is $\mathcal{O}(-1)$, and it has no holomorphic sections. Its dual is $\mathcal{O}(1)$, whose sections are linear forms $az_0 + bz_1$: a linear form eats a vector on the line and returns a number.

5.2.6 The canonical bundle

One line bundle is attached to every complex manifold for free. On a complex manifold of dimension n with local coordinates $z^1, \dots, z^n$, the **holomorphic cotangent bundle** T^*M has local frame $\mathrm{d}z^1, \dots, \mathrm{d}z^n$. Under a holomorphic change of coordinates $z \mapsto w(z)$, $\mathrm{d}w^i = \sum_j (\partial w^i / \partial z^j) \mathrm{d}z^j$, so its transition functions are the holomorphic Jacobian matrices. The top exterior power has the single frame $\mathrm{d}z^1 \wedge \cdots \wedge \mathrm{d}z^n$, which transforms by the determinant:

$$\mathrm{d}w^1 \wedge \cdots \wedge \mathrm{d}w^n = \det\left(\frac{\partial w^i}{\partial z^j}\right) \mathrm{d}z^1 \wedge \cdots \wedge \mathrm{d}z^n .$$

Working definition 5.15 (canonical bundle)

The **canonical bundle** is $K_M = \Lambda^n T^*M$, the top exterior power of the holomorphic cotangent bundle. It has rank $\binom{n}{n} = 1$: it is always a line bundle. Its transition functions are the Jacobian determinants $\det(\partial z_\beta / \partial z_\alpha)$. A holomorphic section of K_M is a holomorphic n-form $f(z)\,\mathrm{d}z^1 \wedge \cdots \wedge \mathrm{d}z^n$, that is a form of type $(n, 0)$ [n factors of $\mathrm{d}z$ and none of $\mathrm{d}\bar{z}$]. In sheaf language (Chapter 3), the sheaf of holomorphic sections [the rule that assigns to each open set U the holomorphic sections over U] is $\mathcal{O}(K_M) = \Omega^n$, the sheaf of holomorphic n-forms.

For a Riemann surface $n = 1$, so $T^*\Sigma_p$ is already a line bundle and $K_{\Sigma_p} = T^*\Sigma_p$. Its sections are the expressions $f(z)\,\mathrm{d}z$, and under a change of coordinates $f(z)\,\mathrm{d}z = f(z(w))\,z'(w)\,\mathrm{d}w$.

Worked example 5.25: $K_{\mathbb{CP}^1} = O(-2)$

On the overlap of the two charts of $\mathbb{CP}^1$, $z = 1/w$, so

$$\mathrm{d}z \overset{(1)}{=} -\frac{\mathrm{d}w}{w^2} \overset{(2)}{=} -z^2\,\mathrm{d}w.$$

(1) Differentiate $z = w^{-1}$.
(2) $w^{-2} = z^2$.

A 1-form written $s_0\,\mathrm{d}z$ on U_0 and $s_1\,\mathrm{d}w$ on U_1 satisfies $s_1\,\mathrm{d}w = s_0\,\mathrm{d}z = -z^2 s_0\,\mathrm{d}w$, so $s_0 = -z^{-2}s_1$. The transition function is $-z^{-2}$. The sign is a change of frame on U_1 ($\mathrm{d}w \to -\mathrm{d}w$), so $K_{\mathbb{CP}^1} \cong O(-2)$. By Example 5.23 it has no holomorphic sections: *there is no nonzero holomorphic 1-form on the sphere*. Directly: $\mathrm{d}z$ itself becomes $-\mathrm{d}w/w^2$, a double pole at ∞. The meromorphic form $\mathrm{d}z$ has divisor $-2\cdot\infty$, of degree $-2 = 2\cdot 0 - 2$.

Worked example 5.26: The torus has trivial canonical bundle

On $T = \mathbb{C}/\Lambda$ the changes of chart are translations $z \mapsto z + \omega$, whose derivative is 1. So the transition functions of K_T are all 1, and $\mathrm{d}z$ is a global holomorphic 1-form that never vanishes: K_T is trivial, and its divisor has degree $0 = 2\cdot 1 - 2$. A torus is the one-dimensional example of a Calabi–Yau manifold (trivial canonical bundle, Kähler). For the cubic model, $\mathrm{d}z = \mathrm{d}\wp/\wp' = \mathrm{d}x/y$: the holomorphic 1-form on $y^2 = q(x)$ is $\mathrm{d}x/y$. We will meet its generalisations to higher genus in Section 5.2.16.

The pattern $\deg K = -2, 0, \ldots$ for $p = 0, 1$ continues as $\deg K_{\Sigma_p} = 2p - 2$; we derive this in Section 5.3.3. Nash ends this part of his discussion by noting that one must consider many holomorphic line bundles on Σ_p besides K, and that on algebraic varieties they "can be studied by the closely related notion of divisors". That is next.

5.2.7 Divisors: bookkeeping for zeros and poles

Here is the problem divisors solve. A line bundle L on Σ_p is a collection of transition functions $g_{\alpha\beta}$, and many different collections describe the same bundle. That is a clumsy way to hold on to it. A section is more tangible: in each patch it is a function, and the one thing about a function that does not depend on the patch or the frame is *where it vanishes and where it blows up, and to what order*. That list of points and integers is the divisor. We will see that it remembers the bundle completely.

Take a holomorphic line bundle $L \to \Sigma_p$ and a meromorphic section s (in every patch s_α is meromorphic, and $s_\alpha = g_{\alpha\beta}s_\beta$). Since $g_{\alpha\beta}$ is holomorphic and nowhere zero, s_α and s_β have the same order at every point of the overlap. So the order $\operatorname{ord}_P s := \operatorname{ord}_P s_\alpha$ (computed in any patch containing P) is well defined. On a compact surface a meromorphic section that is not identically zero has only finitely many zeros and poles (they are isolated, and a compact set cannot contain infinitely many isolated points).

Working definition 5.16 (divisor, degree)

A **divisor** on Σ_p is a finite formal sum of points with [a finite list of points, each carrying an integer. The points themselves are never added] integer coefficients,

$$D = \sum_i n_i P_i, \qquad n_i \in \mathbb{Z}.$$

Divisors are added pointwise: $(2P - Q) + (Q + R) = 2P + R$. So they form an abelian group $\mathrm{Div}(\Sigma_p)$, the free abelian group on the points of Σ_p [each element is, in exactly one way, such a finite integer combination of points]. The **degree** is the sum of the coefficients, $\deg D = \sum_i n_i$. A divisor is **effective**, written $D \geq 0$, if all $n_i \geq 0$.
The **divisor of a meromorphic section** $s \not\equiv 0$ is

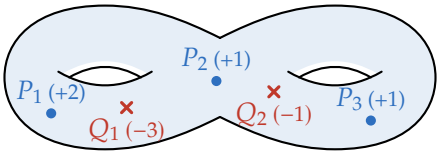
$$\mathrm{div}(s) = \sum_P \mathrm{ord}_P(s)\, P, \tag{5.12}$$

the sum running over the finitely many zeros and poles. Its degree is

$$\deg\big(\mathrm{div}(s)\big) = \sum_P \mathrm{ord}_P(s) = (\text{number of zeros}) - (\text{number of poles}), \tag{5.13}$$

counted with multiplicity. These are Nash's (5.4) and (5.5). *Operationally*: to find $\mathrm{div}(s)$, list the zeros and poles of s in local coordinates and record each with its order (positive for zeros, negative for poles).

A meromorphic function is a meromorphic section of the trivial bundle, so it has a divisor too. A meromorphic 1-form $f(z)\,dz$ is a meromorphic section of K_{Σ_p}, and its divisor records the zeros and poles of the coefficient f (in every chart).



$$D = 2P_1 + P_2 + P_3 - 3Q_1 - Q_2, \qquad \deg D = 4 - 4 = 0$$

Figure 5.19: A divisor is a finite list of points with integer weights: blue dots are zeros (positive weight), red crosses are poles (negative weight). Nothing else about the section is recorded. The divisor shown has degree 0, as the divisor of a meromorphic *function* always must (Section 5.2.8).

Worked example 5.27: Divisors on the Riemann sphere

A rational function. Let $f(z) = \dfrac{z^2(z-1)}{(z+1)^4}$ on $\mathbb{CP}^1$. In $\mathbb{C}$ it has a double zero at 0, a simple zero at 1 and a pole of order 4 at -1. At infinity, in the coordinate $w = 1/z$,

$$f \overset{(1)}{=} \frac{w^{-2}(w^{-1}-1)}{(w^{-1}+1)^4} \overset{(2)}{=} \frac{w^{-3}(1-w)}{w^{-4}(1+w)^4} \overset{(3)}{=} w \cdot \frac{1-w}{(1+w)^4},$$

(1) Substitute $z = 1/w$.
(2) Pull out the powers of w^{-1}: $w^{-1} - 1 = w^{-1}(1-w)$ and $w^{-1} + 1 = w^{-1}(1+w)$.
(3) Collect: $w^{-3}/w^{-4} = w$; the remaining factor is holomorphic and equals 1 at $w = 0$.

so f has a simple zero at ∞. Therefore

$$\mathrm{div}(f) = 2\cdot[0] + [1] - 4\cdot[-1] + [\infty], \qquad \deg = 2 + 1 - 4 + 1 = 0.$$

(We write $[a]$ for the point $z = a$ when a bare number would be ambiguous.)
A section of $\mathcal{O}(n)$. By Example 5.23 a holomorphic section of $\mathcal{O}(n)$ is a polynomial $s_0(z) = c\prod_{k=1}^{m}(z - a_k)$ of degree $m \leq n$ in the chart U_0, and $s_1(w) = w^n s_0(1/w)$ in U_1. Near

$w = 0$, $s_1 = w^n \cdot c\, w^{-m} \prod(1 - a_k w) = c\, w^{n-m} \prod_k (1 - a_k w)$, a zero of order $n - m$. So

$$\operatorname{div}(s) = \sum_{k=1}^{m} [a_k] + (n - m)[\infty], \qquad \deg = n.$$

Every nonzero holomorphic section of $\mathcal{O}(n)$ has exactly n zeros. The degree of the divisor does not depend on the section; it is a property of the bundle.
The 1-form $\mathrm{d}z$. In Example 5.25 we found $\mathrm{d}z = -w^{-2}\mathrm{d}w$: no zeros or poles in $\mathbb{C}$, a double pole at ∞. So $\operatorname{div}(\mathrm{d}z) = -2[\infty]$ and $\deg K_{\mathbb{CP}^1} = -2$.

Worked example 5.28: Divisors on the cubic torus

Let E be Nash's cubic $y^2 = q(x) = x(x-1)(x-\lambda)$ with its point at infinity $O = [0:1:0]$. Write $A_0 = (0,0)$, $A_1 = (1,0)$, $A_\lambda = (\lambda, 0)$.
Local coordinates. At an affine point with $y \neq 0$, $\partial F/\partial y = -2y \neq 0$, so x is a local coordinate (implicit function theorem). At A_0, A_1, A_λ we have $y = 0$ but $\partial F/\partial x = q'(x) \neq 0$, so y is a local coordinate. At O use the chart $Y = 1$ with $X = x/y$, $Z = 1/y$: the curve reads $Z = X(X - Z)(X - \lambda Z)$, so $Z = X^3 + O(X^4)$ and $t = X = x/y$ is a local coordinate at O, with

$$y \overset{(1)}{=} \frac{1}{Z} \overset{(2)}{=} t^{-3}\big(1 + O(t)\big), \qquad x \overset{(3)}{=} \frac{X}{Z} \overset{(4)}{=} t^{-2}\big(1 + O(t)\big).$$

(1) Definition of Z.
(2) $Z = t^3(1 + O(t))$.
(3) $X/Z = (x/y) \cdot y = x$.
(4) $X = t$ and $Z = t^3(1 + O(t))$.

The function y. It vanishes where $q(x) = 0$, i.e. at the three points A_0, A_1, A_λ, and there it is the local coordinate, so each zero is simple. Its only pole is at O, of order 3:

$$\operatorname{div}(y) = A_0 + A_1 + A_\lambda - 3\,O.$$

The function x. It vanishes only at A_0. There the local coordinate is y, and $x = y^2/\big((x-1)(x-\lambda)\big) = y^2/\lambda + O(y^4)$: a double zero. Its only pole is at O, of order 2:

$$\operatorname{div}(x) = 2A_0 - 2\,O.$$

Similarly $\operatorname{div}(x - 1) = 2A_1 - 2O$ and $\operatorname{div}(x - \lambda) = 2A_\lambda - 2O$. All four divisors have degree 0.
The 1-form $\mathrm{d}x/y$. At a point with $y \neq 0$, x is a coordinate and $\mathrm{d}x/y$ has coefficient $1/y$, finite and nonzero. At A_0 (and likewise A_1, A_λ), differentiate $y^2 = q(x)$ to get $2y\,\mathrm{d}y = q'(x)\,\mathrm{d}x$, so $\mathrm{d}x/y = 2\,\mathrm{d}y/q'(x)$, finite and nonzero because $q'(0) = \lambda \neq 0$. At O, $\mathrm{d}x = (-2t^{-3} + \dots)\mathrm{d}t$, so $\mathrm{d}x/y = (-2 + O(t))\mathrm{d}t$, again finite and nonzero. So

$$\operatorname{div}(\mathrm{d}x/y) = 0.$$

This is the nowhere-vanishing holomorphic 1-form of Example 5.26, now seen on the cubic: K_E is trivial, $\deg K_E = 0$.

5.2.8 The divisor of a function has degree zero

In every example so far, the divisor of a meromorphic *function* had degree zero. Nash states this as a general fact and gives a contour-integral argument. We present it in full; it is the model for many arguments on Riemann surfaces (the "residue theorem on a compact surface").

Key idea: zeros and poles balance

If $f \not\equiv 0$ is a meromorphic function on a compact Riemann surface, then

$$\deg \operatorname{div}(f) = 0 :$$

f has as many zeros as poles, counted with multiplicity.

Step 1: the logarithmic derivative counts zeros and poles. Near a point P with $\operatorname{ord}_P f = n$, write $f = z^n u(z)$ with u holomorphic and $u(0) \neq 0$. Then

$$\frac{\mathrm{d}f}{f} \overset{(1)}{=} \frac{nz^{n-1}u\,\mathrm{d}z + z^n u'\,\mathrm{d}z}{z^n u} \overset{(2)}{=} n\,\frac{\mathrm{d}z}{z} + \frac{u'}{u}\,\mathrm{d}z, \tag{5.14}$$

(1) Product rule for $\mathrm{d}(z^n u)$.
(2) Cancel $z^n u$; u'/u is holomorphic near 0 because $u(0) \neq 0$.

So the 1-form $\mathrm{d}f/f$ has a simple pole at every zero and pole of f, with residue equal to the order. Integrating over a small circle $|z| = \varepsilon$ taken anticlockwise,

$$\frac{1}{2\pi\mathrm{i}} \oint_{|z|=\varepsilon} \frac{\mathrm{d}f}{f} \overset{(1)}{=} \frac{n}{2\pi\mathrm{i}} \oint_{|z|=\varepsilon} \frac{\mathrm{d}z}{z} + \frac{1}{2\pi\mathrm{i}} \oint_{|z|=\varepsilon} \frac{u'}{u}\mathrm{d}z \overset{(2)}{=} \frac{n}{2\pi\mathrm{i}} \int_0^{2\pi} \mathrm{i}\,\mathrm{d}\theta + 0 = n.$$

(1) Substitute (5.14).
(2) On the circle $z = \varepsilon e^{\mathrm{i}\theta}$, $\mathrm{d}z/z = \mathrm{i}\,\mathrm{d}\theta$; the second integrand is holomorphic inside the disc, so its integral vanishes (Cauchy, or Stokes: $\oint_{\partial B} \alpha = \int_B \mathrm{d}\alpha$ and $\mathrm{d}(g\,\mathrm{d}z) = \bar\partial g \wedge \mathrm{d}z = 0$ for holomorphic g).

Two further facts make $\mathrm{d}f/f$ useful globally. It is a genuine 1-form on Σ_p minus the zeros and poles, independent of the chart (it is $\mathrm{d}\log f$, and f is a function). And it is *closed* there, because it is locally exact: $\mathrm{d}f/f = \mathrm{d}(\log f)$ for any local branch of the logarithm. So, by Stokes' theorem, its integral over a closed curve depends only on the homology class of the curve in the punctured surface. This is the statement "$\frac{1}{2\pi\mathrm{i}}\int_C \mathrm{d}f/f$ measures $n_0 - n_p$" in Nash: for a curve C bounding a region R that contains some of the zeros and poles, Stokes on R with small discs removed gives

$$\frac{1}{2\pi\mathrm{i}} \oint_C \frac{\mathrm{d}f}{f} = n_0(R) - n_p(R), \tag{5.15}$$

the number of zeros minus the number of poles inside R (the **argument principle**).

Step 2: genus 0. On the sphere Σ_0 let F be the finite set of zeros and poles. Choose a closed curve C that encloses all of F on one side, say in a region R. The complementary region $R' = \Sigma_0 \setminus R$ is a disc containing no point of F (Figure 5.20). Then

$$n_0 - n_p \overset{(1)}{=} \frac{1}{2\pi\mathrm{i}} \oint_C \frac{\mathrm{d}f}{f} \overset{(2)}{=} -\frac{1}{2\pi\mathrm{i}} \oint_{\partial R'} \frac{\mathrm{d}f}{f} \overset{(3)}{=} -\frac{1}{2\pi\mathrm{i}} \int_{R'} \mathrm{d}\Big(\frac{\mathrm{d}f}{f}\Big) \overset{(4)}{=} 0.$$

(1) (5.15) applied to R, which contains all zeros and poles.

(2) C is the boundary of R; as the boundary of R' it carries the opposite orientation.
(3) Stokes' theorem on R', where $\mathrm{d}f/f$ is smooth.
(4) $\mathrm{d}f/f$ is closed.

In Nash's words, C is homologous to a point in $\Sigma_0 - F$: we can slide it over the back of the sphere and shrink it to nothing without crossing F.

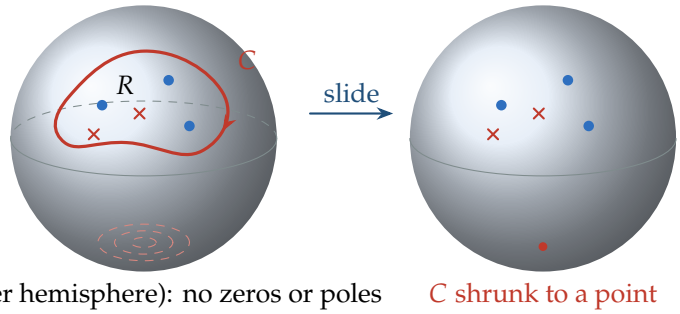


Figure 5.20: The degree-zero argument on the sphere. The red curve C encloses all zeros (blue) and poles (red crosses) in the region R, so $\frac{1}{2\pi\mathrm{i}}\oint_C \mathrm{d}f/f = n_0 - n_p$. But the other side R' is a disc with no zeros or poles, and C can be slid over it and shrunk to a point. The integral of the closed form $\mathrm{d}f/f$ does not change, so it is zero.

Step 3: genus $p > 0$. Now a closed curve need not bound a disc, so the sphere argument fails. Instead Nash uses the standard model of Σ_p as a polygon with $4p$ sides, identified in pairs.

Working definition 5.17 (the $4p$-gon model of Σ_p)

Take a polygon with $4p$ edges, labelled in order around the boundary

$$a_1\, b_1\, a_1^{-1}\, b_1^{-1}\, a_2\, b_2\, a_2^{-1}\, b_2^{-1} \cdots a_p\, b_p\, a_p^{-1}\, b_p^{-1}.$$

Glue the edge a_i to the edge a_i^{-1} and b_i to b_i^{-1}, where the exponent -1 means "the same edge, traversed in the opposite direction" (Figure 5.21). The result is Σ_p. For $p = 1$ this is the square $a\,b\,a^{-1}\,b^{-1}$ with opposite sides identified: the torus. After gluing, all $4p$ vertices become one point, and the $2p$ edges become the $2p$ loops $a_1, b_1, \ldots, a_p, b_p$ that generate the homology [every closed loop on Σ_p counts, up to deformation and cancellation of opposite pieces, as an integer combination of these $2p$ loops] (Section 5.2.15).

Cutting Σ_p along the loops a_i, b_i produces the polygon Π, which is a disc. A meromorphic function f on Σ_p becomes a meromorphic function on Π which takes *equal values at identified boundary points*. Move the loops slightly, if necessary, so that no zero or pole lies on the boundary of Π. Then all zeros and poles lie inside the disc Π, and (5.15) applies to $C = \partial\Pi$:

$$n_0 - n_p \overset{(1)}{=} \frac{1}{2\pi\mathrm{i}} \oint_{\partial\Pi} \frac{\mathrm{d}f}{f} \overset{(2)}{=} \frac{1}{2\pi\mathrm{i}} \sum_{i=1}^{p} \Big(\int_{a_i} + \int_{b_i} + \int_{a_i^{-1}} + \int_{b_i^{-1}} \Big) \frac{\mathrm{d}f}{f} \overset{(3)}{=} 0.$$

(1) (5.15): Π contains all zeros and poles.
(2) The boundary of Π is the union of its $4p$ edges.
(3) On a_i and a_i^{-1} the function f takes the same values at corresponding points, so $\mathrm{d}f/f$ is the same 1-form there; but the two edges are traversed in opposite directions, so $\int_{a_i^{-1}} = -\int_{a_i}$. Likewise for b_i.

Nash phrases this as pushing the contour C out until it coincides with the sides of the polygon, and observing that "the contribution from each side is cancelled by another of opposite orientation". This completes the proof that $\deg \operatorname{div}(f) = 0$ for every genus.

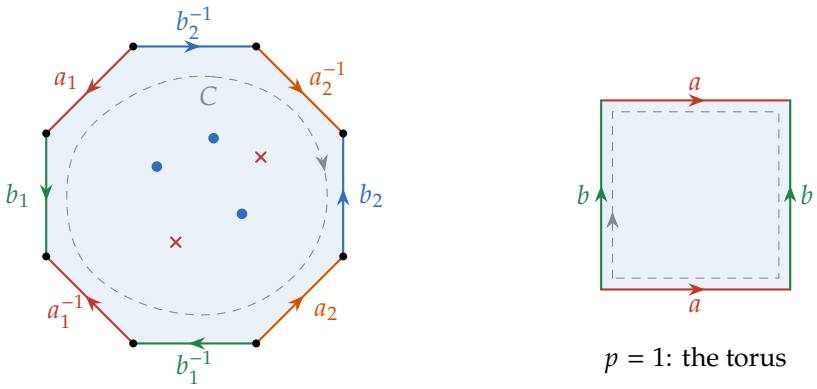

Figure 5.21: Left: the genus-2 surface cut open into an octagon with edges $a_1 b_1 a_1^{-1} b_1^{-1} a_2 b_2 a_2^{-1} b_2^{-1}$; edges of the same colour are glued so that their arrows match. The dashed contour C encloses all zeros and poles; pushing it out to the boundary, the two copies of each edge are traversed in opposite directions and cancel. Right: for $p = 1$ the polygon is the square with opposite sides identified, the torus.

Worked example 5.29: The cancellation on the torus, written out

On $T = \mathbb{C}/\Lambda$, $\Lambda = \mathbb{Z}\omega_1 + \mathbb{Z}\omega_2$, take the fundamental parallelogram Π with corners z_0, $z_0 + \omega_1$, $z_0 + \omega_1 + \omega_2$, $z_0 + \omega_2$, where the base point z_0 is chosen so that no zero or pole of the elliptic function f lies on $\partial\Pi$. Let $g = f'/f$, which is elliptic because f is. The boundary integral splits into two pairs of opposite edges:

$$\begin{aligned}\oint_{\partial\Pi} g(z)\,\mathrm{d}z &\overset{(1)}{=} \int_{z_0}^{z_0+\omega_1} g(z)\,\mathrm{d}z + \int_{z_0+\omega_1}^{z_0+\omega_1+\omega_2} g(z)\,\mathrm{d}z - \int_{z_0+\omega_1+\omega_2}^{z_0+\omega_2} g(z)\,\mathrm{d}z - \int_{z_0}^{z_0+\omega_2} g(z)\,\mathrm{d}z \\ &\overset{(2)}{=} \int_{z_0}^{z_0+\omega_1} \big[g(z) - g(z+\omega_2)\big]\mathrm{d}z + \int_{z_0}^{z_0+\omega_2} \big[g(z+\omega_1) - g(z)\big]\mathrm{d}z \\ &\overset{(3)}{=} 0.\end{aligned}$$

(1) Go round $\partial\Pi$ anticlockwise; the top and left edges are traversed backwards, hence the minus signs.
(2) Substitute $z \to z + \omega_2$ in the third integral and $z \to z + \omega_1$ in the second.
(3) g is periodic, so each bracket vanishes identically.

So every elliptic function has equally many zeros and poles in a period parallelogram. For example $\wp$ has a double pole at 0 and hence exactly two zeros; $\wp - e_1$ has the double pole and a double zero at $\omega_1/2$ (a zero of $\wp - e_1$ that is also a zero of $\wp'$), and no other zeros. This is the fact we used in Example 5.21 to show e_1, e_2, e_3 are distinct.

Try it: residues of a meromorphic 1-form

Repeat the polygon argument for an arbitrary meromorphic 1-form η on Σ_p (not necessarily of the form $\mathrm{d}f/f$). What does it prove?
Answer. η is the same form on identified edges, so $\oint_{\partial\Pi} \eta = 0$; by the residue theorem inside the disc Π this says $\sum_P \operatorname{Res}_P \eta = 0$. *The residues of a meromorphic 1-form on a compact Riemann surface sum to zero.* The degree-zero theorem is the special case $\eta = \mathrm{d}f/f$, whose residues

are the orders.

5.2.9 Changing the section: linear equivalence

The degree-zero theorem has an immediate consequence for line bundles. Let s and s' be two meromorphic sections of the same bundle L, with $s \not\equiv 0$. In each patch the ratio s'_α / s_α is meromorphic, and on overlaps

$$\frac{s'_\alpha}{s_\alpha} \overset{(1)}{=} \frac{g_{\alpha\beta} s'_\beta}{g_{\alpha\beta} s_\beta} = \frac{s'_\beta}{s_\beta},$$

(1) Both sections obey the transition rule with the same $g_{\alpha\beta}$.

so the local ratios patch together into a global meromorphic *function* $f = s'/s$. This is Nash's (5.6):

$$s' = f\, s, \qquad f \text{ a meromorphic function.} \tag{5.16}$$

Orders add under multiplication ($z^m u \cdot z^n v = z^{m+n} uv$), so

$$\operatorname{div}(s') \overset{(1)}{=} \operatorname{div}(fs) \overset{(2)}{=} \operatorname{div}(f) + \operatorname{div}(s), \tag{5.17}$$

$$\deg \operatorname{div}(s') \overset{(3)}{=} \deg \operatorname{div}(f) + \deg \operatorname{div}(s) \overset{(4)}{=} \deg \operatorname{div}(s). \tag{5.18}$$

(1) (5.16).
(2) $\operatorname{ord}_P(fs) = \operatorname{ord}_P f + \operatorname{ord}_P s$ at every point.
(3) deg is additive (it is a sum of coefficients).
(4) The degree-zero theorem of Section 5.2.8.

These are Nash's (5.7) and (5.8). Two conclusions:

- The integer $\deg L := \deg \operatorname{div}(s)$ does not depend on which meromorphic section we use. It is an invariant of the bundle, the **degree** of L.
- The divisor itself does depend on s, but only up to adding the divisor of a function.

Working definition 5.18 (linear equivalence; principal divisor)

A divisor of the form $\operatorname{div}(f)$ for a meromorphic function f is **principal**. [it is the zeros-minus-poles record of one single global function] Two divisors are **linearly equivalent**, $D_1 \sim D_2$, if $D_1 - D_2 = \operatorname{div}(f)$ for some meromorphic f. *Operationally*: to show $D_1 \sim D_2$, exhibit a function with zeros D_1 and poles D_2 (after cancelling common points). Equivalent divisors have equal degree. By (5.17), a line bundle determines a well-defined **divisor class** [the set of all divisors linearly equivalent to one given divisor] $\{\operatorname{div}(s)\}$ modulo $\sim$.

Worked example 5.30: On $\mathbb{CP}^1$ the degree is everything

Let $D = \sum_i n_i [a_i] + n_\infty [\infty]$ be any divisor of degree 0 on $\mathbb{CP}^1$, with $a_i \in \mathbb{C}$. Put $f(z) = \prod_i (z - a_i)^{n_i}$. In $\mathbb{C}$ its divisor is $\sum n_i [a_i]$. At ∞ it behaves like $z^{\sum n_i} = w^{-\sum n_i}$, so

$$\operatorname{div}(f) \overset{(1)}{=} \sum_i n_i [a_i] - \Big(\sum_i n_i\Big)[\infty] \overset{(2)}{=} \sum_i n_i [a_i] + n_\infty [\infty] = D.$$

(1) Orders of f at the finite points and at ∞.
(2) $\deg D = 0$ means $n_\infty = -\sum_i n_i$.

So every degree-zero divisor on the sphere is principal, and two divisors on $\mathbb{CP}^1$ are equivalent if and only if they have the same degree. Combined with the next subsection, this says that *every holomorphic line bundle on $\mathbb{CP}^1$ is $\mathcal{O}(n)$ for exactly one n*, namely its degree.

Worked example 5.31: On the torus the degree is not everything

On $T = \mathbb{C}/\Lambda$ let $P \neq Q$ be two points. Is $P - Q$ principal? It would be the divisor of an elliptic function f with a single simple zero at P and a single simple pole at Q. Consider the meromorphic 1-form $f\,dz$ (dz is a global nowhere-zero holomorphic 1-form on T). Its only pole is at Q, simple, with residue $\operatorname{Res}_Q f \neq 0$. But residues of a meromorphic 1-form sum to zero (the *Try it* above). Contradiction. So

$$P - Q \not\sim 0 \qquad \text{for } P \neq Q,$$

although $\deg(P - Q) = 0$. There are therefore many inequivalent divisor classes of degree 0 on a torus, one for each point P if we fix $Q = O$: we will see in Section 5.2.19 that $P - O \sim P' - O$ only if $P = P'$, and that the degree-zero classes form a copy of the torus itself.

5.2.10 From a divisor to a line bundle

We now go the other way. Given a divisor $D = \sum_i n_i P_i$ (Nash's (5.9)), we build a line bundle $[D]$ and a meromorphic section of it whose divisor is exactly D.

Working definition 5.19 (the line bundle $[D]$)

Cover Σ_p by coordinate discs U_α. [patches shaped like discs, each carrying one complex coordinate z] In each U_α choose a **local defining function**: a meromorphic function f_α on U_α whose divisor is D restricted to U_α. Concretely, with z the coordinate on U_α,

$$f_\alpha(z) = \prod_{P_i \in U_\alpha} \big(z - z(P_i)\big)^{n_i} \qquad (f_\alpha = 1 \text{ if } U_\alpha \text{ contains no } P_i).$$

On an overlap, f_α and f_β have the same divisor, so their ratio has no zeros and no poles. Define

$$g_{\alpha\beta} = \frac{f_\alpha}{f_\beta} \qquad \text{on } U_\alpha \cap U_\beta. \tag{5.19}$$

This is Nash's (5.10). The line bundle with these transition functions [each $g_{\alpha\beta}$ is holomorphic and nowhere zero, and $g_{\alpha\beta}g_{\beta\gamma} = g_{\alpha\gamma}$ holds automatically] is $[D]$, and the collection $s_D = \{f_\alpha\}$ is a meromorphic section of it with $\operatorname{div}(s_D) = D$, the **canonical section** of $[D]$.

Let us check each claim.

- *$g_{\alpha\beta}$ is holomorphic and nowhere zero.* Near any point of $U_\alpha \cap U_\beta$ write $f_\alpha = z^n u$, $f_\beta = z^n v$ with the same n (same divisor) and u, v holomorphic and nonzero; then $g_{\alpha\beta} = u/v$.

- *Cocycle condition.* On triple overlaps $g_{\alpha\beta}g_{\beta\gamma} = \frac{f_\alpha}{f_\beta}\frac{f_\beta}{f_\gamma} = \frac{f_\alpha}{f_\gamma} = g_{\alpha\gamma}$, automatically. This is (5.11).

- *s_D is a section.* We need $f_\alpha = g_{\alpha\beta} f_\beta$, which is (5.19) rearranged.

- *Independence of choices.* Another choice of defining functions is $f'_\alpha = h_\alpha f_\alpha$ with h_α holomorphic and nowhere zero on U_α. Then $g'_{\alpha\beta} = h_\alpha g_{\alpha\beta} h_\beta^{-1}$, which is the same bundle in a different frame (Section 5.2.5).

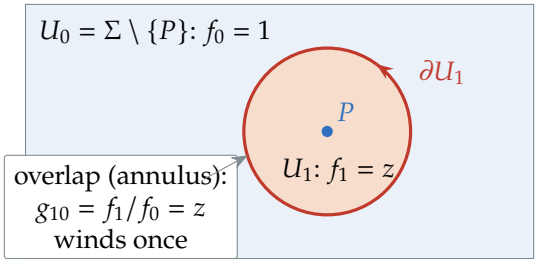

Figure 5.22: The line bundle $[P]$ of a single point. Over the disc U_1 around P the defining function is the coordinate z; everywhere else it is 1. The transition function on the annulus where the two sets overlap is $g_{10} = z$, which winds once around P. That winding number is the degree of $[P]$, and the canonical section (equal to z near P, to 1 elsewhere) has a single simple zero at P.

The dictionary. The following rules follow directly from the construction.

- $[D_1 + D_2] = [D_1] \otimes [D_2]$ and $[-D] = [D]^{-1}$: defining functions multiply, so transition functions multiply.
- $[\operatorname{div} f]$ is trivial: take $f_\alpha = f$ in every patch; then every $g_{\alpha\beta} = 1$.
- Hence $D_1 \sim D_2 \Rightarrow [D_1] \cong [D_2]$.
- Conversely, if L has a meromorphic section $s \not\equiv 0$, then $L \cong [\operatorname{div} s]$: the local functions s_α are themselves local defining functions for $\operatorname{div}(s)$, and $s_\alpha / s_\beta = g_{\alpha\beta}$ are L's own transition functions.

On a compact Riemann surface every holomorphic line bundle has a nonzero meromorphic section (a theorem we will not prove; for $\mathcal{O}(n)$ and K we have seen them). So divisors modulo linear equivalence and holomorphic line bundles up to isomorphism are the same thing:

$$\frac{\operatorname{Div}(\Sigma_p)}{\{\text{principal divisors}\}} \;\cong\; \{\text{holomorphic line bundles on } \Sigma_p\}/\!\cong, \qquad D \mapsto [D]. \tag{5.20}$$

This is what Nash means by saying that "one may work either with (equivalence classes of) divisors or with holomorphic line bundles depending on which is more natural for the problem at hand".

Worked example 5.32: $[n \cdot \infty] = \mathcal{O}(n)$ and $[\operatorname{div} dz] = K$

On $\mathbb{CP}^1$ take $D = n[\infty]$ and the two charts U_0 (z) and U_1 ($w = 1/z$). Local defining functions are $f_0 = 1$ (no point of D in U_0) and $f_1 = w^n$. By (5.19),

$$g_{01} \overset{(1)}{=} \frac{f_0}{f_1} \overset{(2)}{=} w^{-n} \overset{(3)}{=} z^n.$$

(1) Definition (5.19).
(2) $f_0 = 1$, $f_1 = w^n$.
(3) $w = 1/z$.

This is exactly the transition function of $\mathcal{O}(n)$ in Example 5.23. So $[n \cdot \infty] = \mathcal{O}(n)$, and

the canonical section is $s_0 = 1$, $s_1 = w^n$: the constant polynomial 1, vanishing to order n at ∞. Choosing instead $D = n[0]$ gives $f_0 = z^n$, $f_1 = 1$, $g_{01} = z^n$ again, as it must since $n[0] \sim n[\infty]$ (the function z^n has divisor $n[0] - n[\infty]$).
Similarly, since $\operatorname{div}(\mathrm{d}z) = -2[\infty]$, $K_{\mathbb{CP}^1} = [-2 \cdot \infty] = \mathcal{O}(-2)$, confirming Example 5.25. On the cubic torus $\operatorname{div}(\mathrm{d}x/y) = 0$ gives $K_E = [0]$, the trivial bundle. In general $K_{\Sigma_p} = [\operatorname{div}\eta]$ for any meromorphic 1-form η; the class of such divisors is the **canonical divisor class**, usually written K as well.

5.2.11 The degree is the first Chern class

A line bundle has two integer invariants we now know how to compute: the degree of the divisor of any meromorphic section, and the first Chern class $c_1(L) = \frac{\mathrm{i}}{2\pi}F$ integrated over the surface (Chapter T2, Chapter T3). Nash's (5.11) says they agree:

$$c_1([D]) = \deg D, \tag{5.21}$$

where on the left we mean $\int_{\Sigma_p} c_1$. Nash says this "can be proved by starting with D and constructing its transition functions according to (5.10); then one applies the usual curvature formula". Let us do exactly that.

The curvature of a holomorphic line bundle. Give L a Hermitian metric: in each patch a positive function h_α such that the length of a section is $\|s\|^2 = h_\alpha |s_\alpha|^2$. Independence of the patch requires

$$h_\alpha |s_\alpha|^2 = h_\beta |s_\beta|^2 \quad \Longleftrightarrow \quad h_\beta = |g_{\alpha\beta}|^2 h_\alpha. \tag{5.22}$$

There is a unique connection compatible with both the metric and the holomorphic structure (the **Chern connection**); in the holomorphic frame of U_α its connection 1-form is $A_\alpha = \partial \log h_\alpha$, and its curvature is

$$F = \mathrm{d}A_\alpha = \bar\partial\partial \log h_\alpha = -\partial\bar\partial \log h_\alpha, \qquad c_1(L) = \frac{\mathrm{i}}{2\pi}F = -\frac{\mathrm{i}}{2\pi}\,\partial\bar\partial \log h_\alpha. \tag{5.23}$$

Here $\partial = \mathrm{d}z\,\partial_z$ and $\bar\partial = \mathrm{d}\bar z\,\partial_{\bar z}$ are the holomorphic and antiholomorphic parts of $\mathrm{d} = \partial + \bar\partial$ (more on these in Section 5.3.1). Two checks: F is the same in every patch, because by (5.22) $\log h_\beta - \log h_\alpha = \log g_{\alpha\beta} + \log \bar g_{\alpha\beta}$, and $\partial\bar\partial$ kills both a holomorphic and an antiholomorphic function. And F is imaginary (the U(1) curvature is anti-Hermitian, as in our gauge convention), because $\overline{\partial\bar\partial\phi} = \bar\partial\partial\phi = -\partial\bar\partial\phi$ for real ϕ. So c_1 is a real 2-form.

Worked example 5.33: The curvature of $\mathcal{O}(n)$ integrates to n

Give $\mathcal{O}(n)$ the metric $\|s\|^2 = |s_0|^2/(1+|z|^2)^n$, i.e. $h_0 = (1+|z|^2)^{-n}$. (It is consistent: with $s_1 = w^n s_0$ and $|z|^2 = 1/|w|^2$ one finds $h_1 = (1+|w|^2)^{-n}$, the same formula in the other chart.) First the basic derivative:

$$\partial\bar\partial \log(1+z\bar z) \overset{(1)}{=} \partial\Big(\frac{z\,\mathrm{d}\bar z}{1+z\bar z}\Big) \overset{(2)}{=} \frac{(1+z\bar z)-z\bar z}{(1+z\bar z)^2}\,\mathrm{d}z\wedge\mathrm{d}\bar z = \frac{\mathrm{d}z\wedge\mathrm{d}\bar z}{(1+|z|^2)^2}. \tag{5.24}$$

(1) $\partial_{\bar z}\log(1+z\bar z) = z/(1+z\bar z)$.
(2) $\partial_z\big(z/(1+z\bar z)\big) = \big((1+z\bar z)-z\bar z\big)/(1+z\bar z)^2$ by the quotient rule, and the form becomes $\mathrm{d}z\wedge\mathrm{d}\bar z$.

Then

$$\int_{\mathbb{CP}^1} c_1(\mathcal{O}(n)) \overset{(1)}{=} -\frac{\mathrm{i}}{2\pi}\int_{\mathbb{C}} \partial\bar\partial \log(1+|z|^2)^{-n} \overset{(2)}{=} \frac{n\,\mathrm{i}}{2\pi}\int_{\mathbb{C}} \frac{\mathrm{d}z\wedge\mathrm{d}\bar z}{(1+|z|^2)^2}$$
$$\overset{(3)}{=} \frac{n}{\pi}\int_{\mathbb{R}^2}\frac{\mathrm{d}x\,\mathrm{d}y}{(1+x^2+y^2)^2} \overset{(4)}{=} \frac{n}{\pi}\cdot\pi = n.$$

(1) (5.23) in the chart U_0, which misses one point.
(2) $\log h_0 = -n\log(1+|z|^2)$ and (5.24).
(3) $\mathrm{d}z\wedge\mathrm{d}\bar z = -2\mathrm{i}\,\mathrm{d}x\wedge\mathrm{d}y$ and $\mathrm{i}\cdot(-2\mathrm{i}) = 2$.
(4) The integral computed in Example 5.17.

And the divisor of any holomorphic section of $\mathcal{O}(n)$ has degree n (Example 5.27). So $c_1 = \deg$ for all the $\mathcal{O}(n)$. In particular the tautological bundle $\mathcal{O}(-1)$ has $c_1 = -1$: it is the *Dirac monopole* bundle of charge -1 (or $+1$, depending on the sign convention for the charge), and $\frac{\mathrm{i}}{2\pi}F$ is its uniform magnetic field on the sphere.

The general argument. Let s be a meromorphic section of L with zeros and poles at P_i of orders n_i. Away from the P_i, $\|s\|^2$ is a smooth positive function and

$$\log h_\alpha \overset{(1)}{=} \log\|s\|^2 - \log s_\alpha - \log\bar s_\alpha \quad\Longrightarrow\quad \partial\bar\partial\log h_\alpha \overset{(2)}{=} \partial\bar\partial\log\|s\|^2.$$

(1) Take the logarithm of $\|s\|^2 = h_\alpha s_\alpha \bar s_\alpha$ (locally).
(2) $\bar\partial\log s_\alpha = 0$ and $\partial\log\bar s_\alpha = 0$, since s_α is holomorphic and nonzero away from the P_i.

So on $\Sigma^\varepsilon = \Sigma_p \setminus \bigcup_i B_\varepsilon(P_i)$ (small discs removed) the Chern form is the *global* expression $c_1 = -\frac{\mathrm{i}}{2\pi}\partial\bar\partial\log\|s\|^2 = -\frac{\mathrm{i}}{2\pi}\mathrm{d}(\bar\partial\log\|s\|^2)$ (because $\mathrm{d}\bar\partial\phi = \partial\bar\partial\phi + \bar\partial\bar\partial\phi$ and $\bar\partial^2 = 0$). Near P_i, in a coordinate z centred there, $s_\alpha = z^{n_i}u$ and $\log\|s\|^2 = n_i\log|z|^2 + \phi$ with ϕ smooth. Now use Stokes:

$$\int_{\Sigma_p} c_1(L) \overset{(1)}{=} \lim_{\varepsilon\to0}\int_{\Sigma^\varepsilon} -\frac{\mathrm{i}}{2\pi}\,\mathrm{d}\big(\bar\partial\log\|s\|^2\big) \overset{(2)}{=} \lim_{\varepsilon\to0}\frac{\mathrm{i}}{2\pi}\sum_i\oint_{|z|=\varepsilon}\bar\partial\log\|s\|^2$$
$$\overset{(3)}{=} \frac{\mathrm{i}}{2\pi}\sum_i n_i\oint_{|z|=\varepsilon}\frac{\mathrm{d}\bar z}{\bar z} \overset{(4)}{=} \frac{\mathrm{i}}{2\pi}\sum_i n_i\,(-2\pi\mathrm{i}) = \sum_i n_i = \deg\operatorname{div}(s).$$

(1) c_1 is smooth, so removing shrinking discs changes nothing in the limit.
(2) Stokes' theorem; $\partial\Sigma^\varepsilon$ is the union of the small circles traversed *clockwise*, which we rewrite as anticlockwise circles with a minus sign.
(3) $\bar\partial\log|z|^2 = \bar\partial(\log z + \log\bar z) = \mathrm{d}\bar z/\bar z$; the smooth part $\bar\partial\phi$ integrates to $O(\varepsilon)\to0$.
(4) $\oint\mathrm{d}\bar z/\bar z = \overline{\oint\mathrm{d}z/z} = \overline{2\pi\mathrm{i}} = -2\pi\mathrm{i}$.

Applying this to $L = [D]$ and its canonical section s_D gives $c_1([D]) = \deg D$, Nash's (5.11). Applying it to the trivial bundle with $h = 1$ ($F = 0$) and a meromorphic function gives a second proof that $\deg\operatorname{div}(f) = 0$.

Key idea: degree = Chern number = winding number

For a line bundle on a surface,

$$\deg L = \int_\Sigma c_1(L) = \frac{1}{2\pi\mathrm{i}}\oint_{\partial U}\mathrm{d}\log g_{10},$$

where in the last expression Σ is covered by two open sets, a disc $U = U_1$ and the rest U_0,

and g_{10} is the transition function on the annulus between them. For $[P]$ with U_1 a disc around P, $g_{10} = f_1/f_0 = z$ winds once (Figure 5.22). For $\mathcal{O}(n)$ with U_1 the disc around ∞, $g_{10} = z^{-n} = w^n$ winds n times in the coordinate w.

The last equality is the same Stokes argument with the two patches instead of small discs: $\int_{U_1} c_1 + \int_{U_0} c_1 = \frac{i}{2\pi}\oint_{\partial U_1} \bar\partial \log(h_0/h_1)$, and $\log(h_0/h_1) = \log|g_{10}|^2$ by (5.22), whose $\bar\partial$ is $\overline{\mathrm{d}\log g_{10}}$. The physicist will recognise this as the Wu–Yang description of the Dirac monopole: two gauge patches on the sphere, and the monopole charge is the winding number of the U(1) gauge transformation relating them on the equator.

5.2.12 Holomorphic sections and positive degree

Nash next remarks that if $\deg D > 0$ then $[D]$ has a global holomorphic section "and vice versa", and that such a section must vanish somewhere, "otherwise the bundle $[D]$ would be trivial". The second half is simple and important; the first half needs to be stated more carefully. The tool is the following reformulation of sections.

Working definition 5.20 (the space $\mathcal{L}(D)$)

For a divisor D let

$$\mathcal{L}(D) = \{\, f \text{ meromorphic on } \Sigma_p : \ \operatorname{div}(f) + D \geq 0 \,\} \cup \{0\}.$$

If $D = \sum n_i P_i$, this means: f may have a pole of order at most n_i at each P_i with $n_i > 0$, must vanish to order at least $|n_i|$ at each P_i with $n_i < 0$, and is holomorphic everywhere else. It is a complex vector space. [sums and constant multiples of allowed functions are again allowed. That is why 0 is added by hand] *Operationally*: list the allowed poles and the required zeros, and find all functions obeying them.

Key idea: holomorphic sections of $[D]$ = the space $\mathcal{L}(D)$

The map $f \mapsto f\,s_D$ is an isomorphism $\mathcal{L}(D) \cong H^0(\Sigma_p, \mathcal{O}([D]))$, the space of global holomorphic sections of $[D]$. We write $h^0(D) = \dim \mathcal{L}(D)$.

Why: every meromorphic section of $[D]$ is $f\,s_D$ for a meromorphic function f (by (5.16)), and $\operatorname{div}(f\,s_D) = \operatorname{div} f + D$, which is ≥ 0 exactly when $f\,s_D$ is holomorphic. Now the facts:

1. *Negative degree: no sections.* A nonzero holomorphic section has an effective divisor, of degree ≥ 0. So if $\deg L < 0$ then $H^0(L) = 0$. Example: $\mathcal{O}(n)$, $n < 0$; the canonical bundle of the sphere.

2. *Degree zero: sections only if trivial.* If $\deg L = 0$ and $s \neq 0$ is holomorphic, $\operatorname{div}(s)$ is effective of degree 0, hence 0: s vanishes nowhere, and s itself is a nowhere-zero frame, so L is trivial. This is Nash's remark: *a holomorphic section of a nontrivial bundle must vanish somewhere*.

3. *Positive degree.* If D is effective (all $n_i \geq 0$) then the canonical section s_D is holomorphic, so $h^0(D) \geq 1$. More generally $[D]$ has a nonzero holomorphic section if and only if D is linearly equivalent to an effective divisor. Degree ≥ 0 is necessary but, for $p \geq 2$, not sufficient.

Watch out: positive degree does not guarantee a section

Nash's "and vice versa" should be read as: if $[D]$ has a nonzero holomorphic section then $\deg D \geq 0$, with equality only for the trivial bundle; and if $\deg D$ is large enough then there are sections. The precise threshold comes from Riemann–Roch (Section 5.3.3): $\deg D \geq p$ always suffices. Below that it can fail. On a surface of genus 2, the degree-1 bundles form a 2-complex-dimensional family (a copy of the Jacobian, Section 5.3.5), while those with a section are the $[P]$, a 1-dimensional family parametrised by the point P. So a generic degree-1 bundle on Σ_2 has no holomorphic section at all.

Worked example 5.34: $\mathcal{L}(D)$ on the sphere and on the torus

Sphere. $\mathcal{L}(n[\infty])$ consists of the functions holomorphic on $\mathbb{C}$ with at most an nth order pole at ∞. By Example 5.16 these are the polynomials of degree $\leq n$: $h^0 = n + 1$, matching $H^0(\mathcal{O}(n))$ from Example 5.23.
Torus. Let O be the origin of $T = \mathbb{C}/\Lambda$. The space $\mathcal{L}(nO)$ consists of elliptic functions whose only pole is at O, of order at most n. Build it up one n at a time.

- $n = 0$: holomorphic functions on a compact surface are constant: $\mathcal{L}(0) = \mathbb{C} \cdot 1$.
- $n = 1$: a function with a single simple pole would contradict the residue theorem (Example 5.31): $\mathcal{L}(O) = \mathbb{C} \cdot 1$.
- $n = 2, 3, 4, 5, 6$: new functions with poles of exactly that order are $\wp$, $\wp'$, $\wp^2$, $\wp\wp'$, $\wp^3$.

Two functions in $\mathcal{L}(nO)$ with the same leading pole coefficient differ by an element of $\mathcal{L}((n-1)O)$, so each step adds at most one dimension. Hence

$$h^0(nO) = n \qquad (n \geq 1),$$

with basis $1, \wp, \wp', \wp^2, \wp\wp', \wp^3, \ldots$. Now look at $n = 6$. The seven functions $1, \wp, \wp', \wp^2, \wp\wp', \wp^3, \wp'^2$ all lie in the 6-dimensional space $\mathcal{L}(6O)$, so they must satisfy a linear relation. That relation is the Weierstrass equation (5.10), $\wp'^2 = 4\wp^3 - g_2\wp - g_3$. The cubic equation of the torus is *forced* by counting sections. And the three sections $1, \wp, \wp'$ of $[3O]$ give the map $z \mapsto [1 : \wp : \wp']$ into $\mathbb{CP}^2$ of Example 5.20: this is Kodaira's embedding (Section 5.1.10) in its simplest instance.

5.2.13 The sheaf-theoretic viewpoint

Nash rephrases divisors in the language of sheaves (Chapter 3). The point of doing so is that the passage $D \mapsto [D]$ then becomes a standard piece of machinery, the connecting map of a long exact sequence, which generalises to any complex manifold.

Recall two multiplicative sheaves on a complex manifold M:

- $\mathcal{O}^*$: over an open set U, the nowhere-vanishing holomorphic functions on U, with multiplication as the group operation;
- $\mathcal{M}^*$: over U, the meromorphic functions on U that are not identically zero on any component (Nash: "non-trivial"), again under multiplication.

$\mathcal{O}^*$ is a subsheaf of $\mathcal{M}^*$, and we can form the quotient sheaf (Nash's (5.12))

$$\mathcal{D} = \frac{\mathcal{M}^*}{\mathcal{O}^*}. \tag{5.25}$$

Working definition 5.21 (a section of $\mathcal{M}^*/\mathcal{O}^*$)

A global section of $\mathcal{D}$ [a section over all of Σ_p of the quotient sheaf just defined, in which a nonzero meromorphic function counts only up to a holomorphic nowhere-zero factor] is given by an open cover $\{U_\alpha\}$ and nonzero meromorphic functions f_α on U_α such that on each overlap $f_\alpha/f_\beta \in \mathcal{O}^*(U_\alpha \cap U_\beta)$, i.e. is holomorphic and nowhere zero. Two such data define the same section if they differ by multiplying each f_α by an element of $\mathcal{O}^*(U_\alpha)$. *Operationally*: it is exactly a system of local defining functions, and it determines the divisor $\sum_P \operatorname{ord}_P(f_\alpha)\, P$ (which is independent of α since the ratios have order 0).

So a section of $\mathcal{D}$ *is* a divisor (on a Riemann surface, and more generally on a complex manifold: see the next subsection), and Nash's (5.13) is the statement

$$\operatorname{Div}(M) = H^0(M; \mathcal{M}^*/\mathcal{O}^*). \tag{5.26}$$

The exact sequence. The inclusion and the quotient give a short exact sequence of sheaves, and hence (Chapter 3) a long exact sequence in cohomology:

$$0 \to \mathcal{O}^* \to \mathcal{M}^* \to \mathcal{M}^*/\mathcal{O}^* \to 0$$

$$H^0(\mathcal{O}^*) \to H^0(\mathcal{M}^*) \xrightarrow{\text{div}} H^0(\mathcal{M}^*/\mathcal{O}^*) = \operatorname{Div}(M) \xrightarrow{\delta} H^1(\mathcal{O}^*) \to H^1(\mathcal{M}^*)$$

Every map here is something we have already met.

- $H^0(\mathcal{M}^*) \to \operatorname{Div}$ sends a global meromorphic function to its divisor. Its kernel is $H^0(\mathcal{O}^*)$: functions with no zeros or poles, which on a compact M are the nonzero constants.
- The connecting map δ is computed by the standard recipe: lift the section $\{f_\alpha\}$ of the quotient to local sections f_α of $\mathcal{M}^*$, and take the "Čech coboundary" on overlaps, which in multiplicative notation is $f_\alpha f_\beta^{-1}$. The result lies in $\mathcal{O}^*$ and is a cocycle:

  $$\delta\{f_\alpha\} = \{g_{\alpha\beta}\} = \left\{\frac{f_\alpha}{f_\beta}\right\} \in H^1(M; \mathcal{O}^*).$$

  This is precisely (5.19): $\delta(D) = [D]$. A class in $H^1(M; \mathcal{O}^*)$ is a holomorphic line bundle, given by its transition functions modulo changes of frame (Section 5.3.5).
- Exactness at $\operatorname{Div}(M)$ says $\ker\delta = \operatorname{im}(\text{div})$: $[D]$ is trivial if and only if D is principal. This is the injectivity half of (5.20). The surjectivity half is the statement that $H^1(\mathcal{O}^*) \to H^1(\mathcal{M}^*)$ is zero, i.e. every line bundle has a meromorphic section.

Watch out: sections of a quotient sheaf are not quotients of sections

One might guess that $H^0(\mathcal{M}^*/\mathcal{O}^*)$ equals $H^0(\mathcal{M}^*)/H^0(\mathcal{O}^*)$, i.e. global meromorphic functions modulo constants. That is false: the latter gives only the *principal* divisors. A general divisor, like a single point P on a torus, is defined by local functions $(z - z(P))$ near P, 1 elsewhere) that do not come from any global function. The failure of "quotient of sections = sections of quotient" is measured by H^1, and here it is exactly the group of line bundles.

5.2.14 Divisors in higher dimensions

Replace Σ_p by a compact complex manifold M of complex dimension $n > 1$. The zero set of a single holomorphic function is no longer a set of points: one equation cuts one complex dimension, so it is a subvariety of dimension $n - 1$.

Working definition 5.22 (codimension; divisor on M)

The **codimension** of a subvariety $V \subset M$ is $\dim M - \dim V$ (complex dimensions). A **divisor** on M is a finite formal sum

$$D = \sum_i n_i V_i, \qquad n_i \in \mathbb{Z}, \tag{5.27}$$

of irreducible analytic subvarieties V_i [each locally cut out by holomorphic equations, and not the union of two smaller such sets] of codimension one (Nash's (5.14)). The divisor of a meromorphic function f is $\sum_V \operatorname{ord}_V(f)\, V$, where $\operatorname{ord}_V(f)$ is the order of vanishing of f along V (measured in a coordinate transverse to V at a generic smooth point of V) [near such a point $V = \{w = 0\}$ for a coordinate w, and $\operatorname{ord}_V(f)$ is the power of w in f]. For $n = 1$ the codimension-one subvarieties are points, and we recover (5.12).

Locally D is again described by a meromorphic function: a meromorphic function of several complex variables is, near each point, a ratio g/h of holomorphic functions, and its zeros ($g = 0$) and poles ($h = 0$) are each of codimension one. The construction $D \mapsto [D]$ with $g_{\alpha\beta} = f_\alpha / f_\beta$, and the sheaf description $\operatorname{Div}(M) = H^0(M; \mathcal{M}^*/\mathcal{O}^*)$, go through word for word.

Worked example 5.35: Hyperplanes in $\mathbb{CP}^n$ give $\mathcal{O}(1)$

In $\mathbb{CP}^n$ with homogeneous coordinates $[z_0 : \cdots : z_n]$, let $H_j = \{z_j = 0\}$, a copy of $\mathbb{CP}^{n-1}$ of codimension one. The ratio $f = z_1/z_0$ is a meromorphic function on $\mathbb{CP}^n$ (a ratio of two homogeneous polynomials of the same degree is well defined). It vanishes to first order along H_1 and has a first-order pole along H_0:

$$\operatorname{div}(z_1/z_0) = H_1 - H_0,$$

so all hyperplanes are linearly equivalent. Their common line bundle is $\mathcal{O}(1) = [H_0]$: on $U_j = \{z_j \neq 0\}$ a local defining function for H_0 is $f_j = z_0/z_j$, and $g_{jk} = f_j/f_k = z_k/z_j$. A homogeneous polynomial P of degree d defines the hypersurface $V(P)$, and P/z_0^d is a meromorphic function with divisor $V(P) - dH_0$; so $[V(P)] = \mathcal{O}(d) = \mathcal{O}(1)^{\otimes d}$. For $n = 1$ this reduces to Example 5.32.

Worked example 5.36: Zeros and poles can meet

On $\mathbb{C}^2$ take $f = x/y$. Its zero set is the line $\{x = 0\}$ and its pole set the line $\{y = 0\}$, both of codimension one, so $\operatorname{div}(f) = \{x = 0\} - \{y = 0\}$. The two lines meet at the origin, and there f is not even defined as a map to $\mathbb{CP}^1$: along the line $y = kx$ it takes the constant value $1/k$, so every value occurs in every neighbourhood of 0. The origin is a point of **indeterminacy**, of codimension two. In dimension one this never happens (zeros and poles are isolated points, and a point cannot be both).

Nash ends the discussion of divisors with a remark: in high dimensions, working with divisors means dealing with singular sets of codimension one, which are large (for $\dim M = 4$ they are three-dimensional), whereas one might have hoped that the technical difficulties would come from small sets of high codimension. That is the price of the flexibility: codimension one is exactly where the zeros and poles of a single function live.

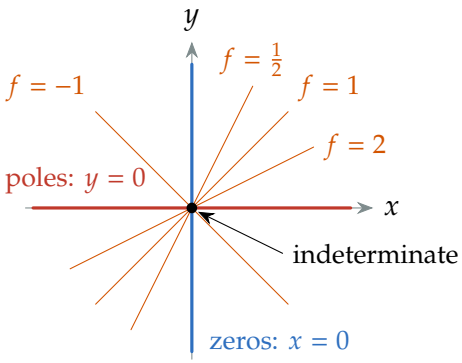

Figure 5.23: The (real picture of the) divisor of $f = x/y$ on $\mathbb{C}^2$: a zero line (blue) and a pole line (red), both of codimension one. The level sets $f = c$ (orange) are the lines $x = cy$, all passing through the origin, where f is indeterminate. Nash's remark that divisors force us to consider "singularities which are not just points" is visible here: the singular set of f is the whole red line.

Reading Nash (pp. 140–142, (5.4)–(5.14))

Nash defines the divisor of a meromorphic section (5.4) and its degree (5.5), and proves that a meromorphic function has a degree-zero divisor with the contour argument: $\frac{1}{2\pi i}\int_C \mathrm{d}f/f = n_0 - n_p$, the contour is contractible in $\Sigma_0 - F$ for genus zero, and for genus $p > 0$ one pushes it to the boundary of the $4p$-gon where opposite sides cancel. Then: $s' = fs$ (5.6), $\mathrm{div}(s') = \mathrm{div}\, f + \mathrm{div}\, s$ (5.7), equal degrees (5.8), linear equivalence, the bundle $[D]$ from $g_{\alpha\beta} = f_\alpha/f_\beta$ (5.9)–(5.10), $c_1([D]) = \deg D$ (5.11), sections of positive-degree bundles, the sheaf $\mathcal{D} = \mathcal{M}^*/\mathcal{O}^*$ (5.12) with $\mathrm{Div}(M) = H^0(M; \mathcal{M}^*/\mathcal{O}^*)$ (5.13), and codimension-one divisors (5.14) in higher dimension. We have added: explicit divisors on the sphere and on the cubic (with local coordinates at infinity), the explicit torus cancellation, the residue theorem for 1-forms, the classification of line bundles on $\mathbb{CP}^1$ by degree, the non-principal divisor $P - Q$ on the torus, a complete curvature computation of $c_1 = \deg$ (including the winding-number form), the spaces $\mathcal{L}(D)$ with the derivation of the Weierstrass cubic by counting sections, the connecting homomorphism, and $\mathcal{O}(1) = [H]$ on $\mathbb{CP}^n$. We have also corrected Nash's "and vice versa" (positive degree does not by itself guarantee a holomorphic section when $p \geq 2$).

5.2.15 Homology of Σ_p and intersection numbers

Divisors and line bundles describe the complex structure of Σ_p from the point of view of functions and sections. Nash now turns to a second, complementary description: integrate the holomorphic 1-forms around the independent loops of the surface. The resulting numbers, the periods, encode the complex structure in a finite matrix. First we need the loops.

Working definition 5.23 (first homology)

$H_1(\Sigma_p; \mathbb{Z})$ is the group of closed oriented curves on Σ_p (and integer combinations of them), where two combinations are regarded as equal if their difference is the boundary of a piece of surface. *Operationally*: a loop is zero in homology if it cuts off a region of the surface; two loops are equal if together (one reversed) they bound a region. The integral of a *closed* 1-form [θ with $\mathrm{d}\theta = 0$] over a loop depends only on its homology class, by Stokes' theorem: if $c_1 - c_2 = \partial S$ then $\int_{c_1}\theta - \int_{c_2}\theta = \int_S \mathrm{d}\theta = 0$.

For the sphere with p handles,

$$H_1(\Sigma_p;\mathbb{Z}) = \underbrace{\mathbb{Z}\oplus\cdots\oplus\mathbb{Z}}_{2p} = \mathbb{Z}^{2p},$$

with a standard basis of $2p$ loops $a_1, b_1, \ldots, a_p, b_p$: a_i goes around the ith handle (around the "tube"), and b_i goes through the ith hole (along the tube and back through the body), as in Figure 5.24. In the $4p$-gon model of Figure 5.21 they are the images of the edges. The count $2p$ also follows from the Euler characteristic: with one vertex, $2p$ edges and one face, the edges are all cycles and the face's boundary $a_1 b_1 a_1^{-1} b_1^{-1}\cdots$ is zero in homology (each edge appears twice with opposite signs), so no relation is imposed and $H_1 = \mathbb{Z}^{2p}$.

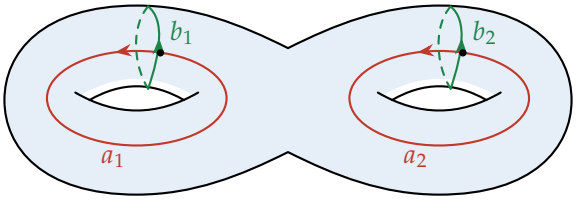

Figure 5.24: The standard homology basis of Σ_2. The red loop a_i goes around the ith hole; the green loop b_i goes over the ith handle, through the hole (dashed part on the back). Each a_i crosses the corresponding b_i exactly once (black dot) and misses all the other loops: $(a_i, b_j) = \delta_{ij}$, $(a_i, a_j) = (b_i, b_j) = 0$.

Working definition 5.24 (intersection number)

For two oriented closed curves a, b meeting transversally, [crossing at a nonzero angle, never touching tangentially] the **intersection number** (a, b) is the number of crossing points, each counted $+1$ if the pair (tangent of a, tangent of b) is a positively oriented basis of the tangent plane there and -1 otherwise. It depends only on the homology classes, and it is bilinear and antisymmetric [$(a + a', b) = (a, b) + (a', b)$, and likewise in b]: $(b, a) = -(a, b)$. *Operationally*: draw both curves, and at each crossing ask whether turning a's direction anticlockwise by less than π brings it to b's direction.

For the standard basis the only crossings are between a_i and b_i, once, which gives Nash's (5.15):

$$(a_i, a_j) = (b_i, b_j) = 0, \qquad (a_i, b_j) = -(b_j, a_i) = \delta_{ij}. \tag{5.28}$$

In matrix form, ordering the basis as $(a_1, \ldots, a_p, b_1, \ldots, b_p)$, the intersection form is

$$J = \begin{pmatrix} 0 & I_p \\ -I_p & 0 \end{pmatrix},$$

the standard symplectic matrix. Changes of homology basis that preserve (5.28) are integer matrices M with $M^T J M = J$: the group $\mathrm{Sp}(2p, \mathbb{Z})$. For $p = 1$ this is $\mathrm{SL}(2, \mathbb{Z})$.

Worked example 5.37: Intersection numbers on the torus

Take $T = \mathbb{R}^2/\mathbb{Z}^2$, a the horizontal loop $t \mapsto (t, 0)$, b the vertical loop $t \mapsto (0, t)$. They cross once at the origin with tangents $(1, 0)$ and $(0, 1)$, a positive basis, so $(a, b) = 1$. A straight loop of slope n/m (winding m times horizontally and n times vertically) is the class $ma + nb$. For two such classes,

$$(ma + nb,\ m'a + n'b) \overset{(1)}{=} mm'(a,a) + mn'(a,b) + nm'(b,a) + nn'(b,b)$$

$$\overset{(2)}{=} mn' - nm' = \det \begin{pmatrix} m & m' \\ n & n' \end{pmatrix}.$$

(1) Bilinearity.
(2) (5.28): $(a,a) = (b,b) = 0$, $(a,b) = 1$, $(b,a) = -1$.

For example the diagonal loop $a + b$ meets a with $(a, a+b) = 1$ and b with $(a+b, b) = 1$: draw it on the square and see one crossing each. The determinant formula also shows that $(ma + nb, m'a + n'b) = \pm 1$ exactly when the two classes form a basis of $\mathbb{Z}^2$.

5.2.16 Holomorphic differentials

Next Nash passes "to the dual": 1-forms, which are integrated over loops. By de Rham's theorem (Chapter T2), $H^1(\Sigma_p; \mathbb{C})$, the closed complex 1-forms modulo exact ones, has complex dimension $2p$, and integration over the $2p$ basis loops identifies it with $\mathbb{C}^{2p}$. On a Riemann surface there is a special class of closed 1-forms.

Working definition 5.25 (holomorphic differential)

A **holomorphic 1-form** (holomorphic differential, **Abelian differential of the first kind**, in Nash's footnote) is a global holomorphic section of K_{Σ_p}: [the canonical bundle, whose local frame is $\mathrm{d}z$] in each chart $\omega = f(z)\,\mathrm{d}z$ with f holomorphic, and $f(z)\,\mathrm{d}z = \tilde{f}(w)\,\mathrm{d}w$ on overlaps. *Operationally*: write it in each chart and check there are no poles, including at the points at infinity [the points added when the affine equation of the curve is completed in projective space].

Every holomorphic 1-form is closed:

$$\mathrm{d}\big(f\,\mathrm{d}z\big) \overset{(1)}{=} \Big(\partial_z f\,\mathrm{d}z + \partial_{\bar{z}} f\,\mathrm{d}\bar{z}\Big) \wedge \mathrm{d}z \overset{(2)}{=} \partial_{\bar{z}} f\,\mathrm{d}\bar{z} \wedge \mathrm{d}z \overset{(3)}{=} 0.$$

(1) $\mathrm{d}f = \partial_z f\,\mathrm{d}z + \partial_{\bar{z}} f\,\mathrm{d}\bar{z}$.
(2) $\mathrm{d}z \wedge \mathrm{d}z = 0$.
(3) f is holomorphic: $\partial_{\bar{z}} f = 0$ (Cauchy–Riemann).

So it defines a class in $H^1(\Sigma_p; \mathbb{C})$ and can be integrated over homology classes. Its complex conjugate $\bar{\omega} = \bar{f}\,\mathrm{d}\bar{z}$ is closed too.

Key idea: there are exactly p holomorphic differentials

The holomorphic 1-forms on Σ_p form a complex vector space of dimension p (the genus). If $\omega_1, \dots, \omega_p$ is a basis, then the $2p$ classes $\omega_1, \dots, \omega_p, \bar{\omega}_1, \dots, \bar{\omega}_p$ form a basis of $H^1(\Sigma_p; \mathbb{C})$.

The dimension count $h^0(K) = p$ is a consequence of Riemann–Roch (Section 5.3.3), or of the Hodge decomposition $H^1 = H^{1,0} \oplus H^{0,1}$ (Section 5.3.9). Here is the part we can see directly: the forms ω and $\bar{\omega}$ can never be cohomologous to zero, and cannot cancel each other. The key is a positivity computation. For $\omega = f\,\mathrm{d}z$, with $z = x + \mathrm{i}y$,

$$\mathrm{i}\,\omega \wedge \bar{\omega} \overset{(1)}{=} \mathrm{i}\,|f|^2\,\mathrm{d}z \wedge \mathrm{d}\bar{z} \overset{(2)}{=} \mathrm{i}\,|f|^2\,(-2\mathrm{i})\,\mathrm{d}x \wedge \mathrm{d}y = 2|f|^2\,\mathrm{d}x \wedge \mathrm{d}y. \tag{5.29}$$

(1) $\omega \wedge \bar{\omega} = f\bar{f}\,\mathrm{d}z \wedge \mathrm{d}\bar{z}$.
(2) $\mathrm{d}z \wedge \mathrm{d}\bar{z} = (\mathrm{d}x + \mathrm{i}\,\mathrm{d}y) \wedge (\mathrm{d}x - \mathrm{i}\,\mathrm{d}y) = -\mathrm{i}\,\mathrm{d}x \wedge \mathrm{d}y + \mathrm{i}\,\mathrm{d}y \wedge \mathrm{d}x = -2\mathrm{i}\,\mathrm{d}x \wedge \mathrm{d}y$.

So $\mathrm{i}\int_\Sigma \omega\wedge\bar\omega>0$ unless $\omega=0$. If ω were exact, $\omega=\mathrm{d}F$, then $\int\omega\wedge\bar\omega=\int\mathrm{d}(F\bar\omega)=0$ by Stokes (and $\mathrm{d}\bar\omega=0$), forcing $\omega=0$. A similar argument (using that $\omega_i\wedge\omega_j=0$, both being of type $(1,0)$) shows that no nonzero combination $\sum c_i\omega_i+\sum d_i\bar\omega_i$ is exact.

Worked example 5.38: Holomorphic differentials on hyperelliptic curves

Let Σ be the curve $y^2=f(x)$ with f a polynomial of degree $2p+1$ with distinct roots; by Example 5.19 it has genus p and one point at infinity, ∞, which is a branch point. Consider

$$\omega_k=\frac{x^k\,\mathrm{d}x}{y},\qquad k=0,1,2,\dots$$

Finite points with $y\neq0$: x is a local coordinate and x^k/y is finite. *Branch points $y=0$:* differentiating $y^2=f(x)$ gives $2y\,\mathrm{d}y=f'(x)\,\mathrm{d}x$, so $\mathrm{d}x/y=2\,\mathrm{d}y/f'(x)$, finite since $f'\neq0$ at a simple root, and y is the local coordinate. *At infinity*: since ∞ is a branch point, a local coordinate is t with $x=t^{-2}$, and then $y^2=f(x)\sim x^{2p+1}=t^{-4p-2}$ gives $y\sim t^{-(2p+1)}$ (up to a nonzero constant and higher-order corrections). So

$$\omega_k\overset{(1)}{=}\frac{t^{-2k}\cdot(-2t^{-3}\,\mathrm{d}t)}{t^{-(2p+1)}\,(1+O(t))}\overset{(2)}{=}-2\,t^{\,2p-2-2k}\,\big(1+O(t)\big)\,\mathrm{d}t.$$

(1) $x^k=t^{-2k}$, $\mathrm{d}x=-2t^{-3}\mathrm{d}t$, and the behaviour of y.
(2) Collect the powers: $-2k-3+2p+1=2p-2-2k$.

This is holomorphic at $t=0$ if and only if $2p-2-2k\geq0$, i.e. $k\leq p-1$. So

$$\frac{\mathrm{d}x}{y},\ \frac{x\,\mathrm{d}x}{y},\ \dots,\ \frac{x^{p-1}\,\mathrm{d}x}{y}$$

are p linearly independent holomorphic differentials, in agreement with the key idea. For $p=1$ this is $\mathrm{d}x/y$ on the cubic (Example 5.28). For genus 2, with $y^2=x^5+\dots$, the basis is $\mathrm{d}x/y$ and $x\,\mathrm{d}x/y$. Bonus: the divisor of $\omega_0=\mathrm{d}x/y$ is $(2p-2)\cdot\infty$ (it has no zeros at finite points and a zero of order $2p-2$ at ∞), so $\deg K_\Sigma=2p-2$, the value Riemann–Roch will predict.

5.2.17 The period matrix

Working definition 5.26 (period matrix)

Choose a basis $\omega_1,\dots,\omega_p$ of holomorphic differentials [there are exactly p independent ones on Σ_p] and the standard homology basis $a_1,\dots,a_p,b_1,\dots,b_p$. [the loops of Figure 5.24, a_i around the ith hole and b_i over the ith handle] The **period matrix** is the $p\times2p$ matrix of all their integrals (Nash's (5.16)):

$$\Omega=\begin{pmatrix}\int_{a_1}\omega_1&\cdots&\int_{a_p}\omega_1&\int_{b_1}\omega_1&\cdots&\int_{b_p}\omega_1\\ \vdots&&\vdots&\vdots&&\vdots\\ \int_{a_1}\omega_p&\cdots&\int_{a_p}\omega_p&\int_{b_1}\omega_p&\cdots&\int_{b_p}\omega_p\end{pmatrix}_{p\times2p}.\tag{5.30}$$

Row j lists the periods of the form ω_j; column k lists the integrals of all the forms over one loop. *Operationally*: parametrise each loop and integrate each form along it.

The $2p$ columns $\Pi_1,\dots,\Pi_{2p}\in\mathbb{C}^p$ are the **periods**. Nash says "it can be verified that the Π_i

are linearly independent over $\mathbb{R}$". Here is the verification. Regard $\mathbb{C}^p$ as $\mathbb{R}^{2p}$; the $2p$ real vectors are independent if and only if the $2p \times 2p$ matrix obtained by stacking Ω on top of its complex conjugate is invertible:

$$\sum_k r_k \Pi_k = 0 \text{ for real } r_k \overset{(1)}{\iff} \sum_k r_k \Pi_k = 0 \text{ and } \sum_k r_k \bar{\Pi}_k = 0 \overset{(2)}{\iff} \begin{pmatrix} \Omega \\ \bar{\Omega} \end{pmatrix} r = 0.$$

(1) For real r_k the second equation is the complex conjugate of the first.
(2) Write the two vector equations as one matrix equation; conversely, any solution $r \in \mathbb{C}^{2p}$ of the stacked system has $\bar{r}$ as a solution too, so the real and imaginary parts of r are real solutions.

The stacked matrix is the matrix of integrals of the $2p$ forms $\omega_1, \dots, \omega_p, \bar{\omega}_1, \dots, \bar{\omega}_p$ over the $2p$ loops. These forms are a basis of $H^1(\Sigma_p; \mathbb{C})$ and the loops a basis of H_1; by de Rham's theorem the pairing between them is nondegenerate, so the matrix is invertible. Hence the periods are $\mathbb{R}$-independent.

Working definition 5.27 (Jacobian variety)

The integer combinations of the periods [$\Pi_k \in \mathbb{C}^p$ is column k of Ω, the integrals of all p forms over one loop] form a lattice of rank $2p$ in $\mathbb{C}^p$, [$2p$ vectors independent over $\mathbb{R}$, together with all their integer combinations]

$$\Lambda = \left\{ \sum_{k=1}^{2p} m_k \Pi_k : m_k \in \mathbb{Z} \right\}, \qquad J(\Sigma_p) = \frac{\mathbb{C}^p}{\Lambda}, \tag{5.31}$$

and the quotient is a compact complex torus of complex dimension p (real dimension $2p$), the **Jacobian variety** of Σ_p. This is Nash's (5.17). $\mathbb{R}$-independence of the $2p$ periods is exactly what makes the quotient compact: the periods span $\mathbb{C}^p = \mathbb{R}^{2p}$ over $\mathbb{R}$, so a fundamental domain [a region that contains one representative of each point of the quotient] is a bounded parallelepiped.

Worked example 5.39: The torus is its own Jacobian

On $T = \mathbb{C}/\Lambda_\tau$, $\Lambda_\tau = \mathbb{Z} + \tau\mathbb{Z}$, the space of holomorphic differentials is spanned by $\omega = \mathrm{d}z$ ($p = 1$). Take a to be the image of the segment from 0 to 1 and b the image of the segment from 0 to τ (each closes up in T). The period matrix is 1×2:

$$\Omega = \left(\int_a \mathrm{d}z \quad \int_b \mathrm{d}z \right) = (1 \;\; \tau).$$

The two periods 1 and τ are $\mathbb{R}$-independent because $\operatorname{Im}\tau \neq 0$. The lattice is $\Lambda = \mathbb{Z} + \tau\mathbb{Z}$ again, so $J(T) = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z}) = T$. For the cubic model $y^2 = x(x-1)(x-\lambda)$, the periods of $\mathrm{d}x/y$ are twice the integrals between branch points (the loop a encircles the slit from 0 to 1, and on the two sheets y has opposite signs):

$$\int_a \frac{\mathrm{d}x}{y} = 2\int_0^1 \frac{\mathrm{d}x}{\sqrt{x(x-1)(x-\lambda)}}, \qquad \int_b \frac{\mathrm{d}x}{y} = 2\int_1^\lambda \frac{\mathrm{d}x}{\sqrt{x(x-1)(x-\lambda)}},$$

elliptic integrals of the first kind. Their ratio $\tau(\lambda)$ is the modulus of the torus: this is how the parameter λ of (5.3) determines the lattice.

Normalising the basis. We may change the basis of holomorphic differentials by any invertible $p \times p$ matrix: $\omega' = C\omega$ multiplies Ω on the left by C. Write $\Omega = (A \;\; B)$ with $A_{jk} = \int_{a_k} \omega_j$ the a-periods and $B_{jk} = \int_{b_k} \omega_j$ the b-periods. We show below that A is invertible. Then $C = A^{-1}$ gives a new basis with

$$\int_{a_k} \omega_j = \delta_{jk}, \tag{5.32}$$

Nash's (5.18), and the period matrix takes the form (5.19)

$$\Omega = \begin{pmatrix} I_{p\times p} & \tilde{\Omega}_{p\times p} \end{pmatrix}, \qquad \tilde{\Omega}_{jk} = \int_{b_k} \omega_j. \tag{5.33}$$

The $p \times p$ matrix $\tilde{\Omega}$ of b-periods of the normalised basis is also called the period matrix (Riemann matrix). For the torus, $\tilde{\Omega} = \tau$.

5.2.18 Riemann's bilinear relations

Nash states that $\tilde{\Omega}$ "is symmetric and possesses a positive imaginary part". These are **Riemann's bilinear relations**, and they come from one identity, which is Stokes' theorem on the cut-open polygon.

Key idea: the reciprocity identity

For any two closed 1-forms θ, η on Σ_p,

$$\int_{\Sigma_p} \theta \wedge \eta = \sum_{i=1}^{p} \Big(\int_{a_i} \theta \int_{b_i} \eta - \int_{b_i} \theta \int_{a_i} \eta \Big). \tag{5.34}$$

Why, for the torus. Take $T = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$ and the fundamental parallelogram Π with corners $0, 1, 1+\tau, \tau$. Pull θ back to $\mathbb{C}$. There it is exact (on a simply connected domain closed forms are exact), $\theta = \mathrm{d}F$, and F is *not* periodic: going along a or b it increases by the period,

$$F(z+1) = F(z) + A(\theta), \qquad F(z+\tau) = F(z) + B(\theta),$$

where $A(\theta) = \int_a \theta$, $B(\theta) = \int_b \theta$. Then

$$\begin{aligned} \int_T \theta \wedge \eta &\overset{(1)}{=} \int_\Pi \mathrm{d}(F\eta) \overset{(2)}{=} \oint_{\partial\Pi} F\eta \\ &\overset{(3)}{=} \int_0^1 \big[F(z) - F(z+\tau)\big]\eta + \int_0^\tau \big[F(z+1) - F(z)\big]\eta \\ &\overset{(4)}{=} -B(\theta)\int_0^1 \eta + A(\theta)\int_0^\tau \eta \overset{(5)}{=} A(\theta)B(\eta) - B(\theta)A(\eta). \end{aligned}$$

(1) $\mathrm{d}(F\eta) = \mathrm{d}F \wedge \eta + F\,\mathrm{d}\eta = \theta \wedge \eta$ since η is closed.
(2) Stokes on the parallelogram.
(3) Pair the bottom edge with the top edge (traversed backwards, shifted by τ) and the right edge with the left edge (backwards, shifted by 1), exactly as in Example 5.29; η is periodic so it takes the same values on paired edges.
(4) The jumps of F are the constant periods, which come out of the integrals.
(5) $\int_0^1 \eta = A(\eta)$ and $\int_0^\tau \eta = B(\eta)$.

Check with $\theta = \mathrm{d}x$, $\eta = \mathrm{d}y$: the left side is the area $\operatorname{Im}\tau$; on the right, $A(\mathrm{d}x) = 1$, $B(\mathrm{d}x) = \operatorname{Re}\tau$, $A(\mathrm{d}y) = 0$, $B(\mathrm{d}y) = \operatorname{Im}\tau$, giving $1 \cdot \operatorname{Im}\tau - \operatorname{Re}\tau \cdot 0 = \operatorname{Im}\tau$. For genus p the same computation is done on the $4p$-gon: each group of four edges $a_i b_i a_i^{-1} b_i^{-1}$ contributes one term of the sum, because across the pair a_i, a_i^{-1} the function F jumps by $\pm\int_{b_i}\theta$ and across b_i, b_i^{-1} by $\pm\int_{a_i}\theta$.

Symmetry. Apply (5.34) to two normalised holomorphic differentials $\theta = \omega_j$, $\eta = \omega_k$:

$$0 \overset{(1)}{=} \int_{\Sigma_p} \omega_j \wedge \omega_k \overset{(2)}{=} \sum_i \bigl(\delta_{ij}\tilde\Omega_{ki} - \tilde\Omega_{ji}\delta_{ik}\bigr) = \tilde\Omega_{kj} - \tilde\Omega_{jk}.$$

(1) Both forms are multiples of $\mathrm{d}z$ locally, and $\mathrm{d}z \wedge \mathrm{d}z = 0$.
(2) (5.34) with the normalisation $\int_{a_i}\omega_j = \delta_{ij}$ and $\int_{b_i}\omega_j = \tilde\Omega_{ji}$.

So $\tilde\Omega^T = \tilde\Omega$.

Positivity. Take $\omega = \sum_j c_j\omega_j$ with $c \in \mathbb{C}^p$ nonzero, and apply (5.34) with $\theta = \omega$, $\eta = \bar\omega$. The periods are $\int_{a_i}\omega = c_i$ and $\int_{b_i}\omega = \sum_j c_j\tilde\Omega_{ji} = (\tilde\Omega c)_i$ (using symmetry), and those of $\bar\omega$ are their conjugates. So

$$0 \overset{(1)}{<} \mathrm{i}\int_{\Sigma_p} \omega\wedge\bar\omega \overset{(2)}{=} \mathrm{i}\sum_i \Bigl(c_i\,\overline{(\tilde\Omega c)_i} - (\tilde\Omega c)_i\,\bar c_i\Bigr) \overset{(3)}{=} \mathrm{i}\bigl(\overline{c^\dagger\tilde\Omega c} - c^\dagger\tilde\Omega c\bigr)$$

$$\overset{(4)}{=} \mathrm{i}\bigl(-2\mathrm{i}\operatorname{Im}(c^\dagger\tilde\Omega c)\bigr) = 2\operatorname{Im}(c^\dagger\tilde\Omega c) \overset{(5)}{=} 2\,c^\dagger(\operatorname{Im}\tilde\Omega)\,c.$$

(1) The positivity (5.29), since $\omega \neq 0$.
(2) (5.34).
(3) $\sum_i \bar c_i(\tilde\Omega c)_i = c^\dagger\tilde\Omega c$, and the other sum is its complex conjugate.
(4) $\bar z - z = -2\mathrm{i}\operatorname{Im} z$.
(5) Write $\tilde\Omega = X + \mathrm{i}Y$ with X, Y real symmetric; then $c^\dagger X c$ and $c^\dagger Y c$ are both real, so $\operatorname{Im}(c^\dagger\tilde\Omega c) = c^\dagger Y c$.

So $\operatorname{Im}\tilde\Omega$ is a positive-definite matrix. For $p = 1$ this is just $\operatorname{Im}\tau > 0$.

The a-periods are invertible. We owe this. Before normalising, suppose $\omega = \sum c_j\omega_j$ has all a-periods zero. Then every term on the right of (5.34) with $\theta = \omega$, $\eta = \bar\omega$ contains a factor $\int_{a_i}\omega$ or its conjugate, so $\mathrm{i}\int\omega\wedge\bar\omega = 0$, and (5.29) forces $\omega = 0$. So $Ac = 0 \Rightarrow c = 0$: A is invertible.

Key idea: Torelli's theorem

Two compact Riemann surfaces whose period matrices $\tilde\Omega$ are equal (for suitable choices of symplectic homology bases) are isomorphic. The complex structure is completely encoded in the $p \times p$ symmetric matrix $\tilde\Omega$ with positive imaginary part.

Watch out: the period matrix depends on the homology basis

Nash's phrase "two Riemann surfaces with the same homology basis are isomorphic if their period matrices are equal" hides a subtlety. A different symplectic basis, related by $\begin{pmatrix} D & C \\ B & A \end{pmatrix} \in \mathrm{Sp}(2p,\mathbb{Z})$ (acting on (b,a)), changes the normalised period matrix by $\tilde\Omega \mapsto (A\tilde\Omega + B)(C\tilde\Omega + D)^{-1}$, a generalised Möbius transformation. For $p = 1$ this is $\tau \mapsto (a\tau+b)/(c\tau+d)$ with $ad - bc = 1$: the action of the modular group that part 5b studies

in detail. So the period matrix determines the surface, but the surface determines the period matrix only up to $\mathrm{Sp}(2p,\mathbb{Z})$. Also, not every symmetric $\tilde{\Omega}$ with positive imaginary part comes from a Riemann surface: such matrices form a space of dimension $p(p+1)/2$, which exceeds $3p-3$ for $p \geq 4$ (e.g. $10 > 9$ at $p = 4$). Characterising the ones that do is the *Schottky problem*.

5.2.19 The Abel–Jacobi map and Abel's theorem

Why build the torus $J(\Sigma_p)$? Because it is where degree-zero divisors live. Fix a base point $P_0 \in \Sigma_p$ and a normalised basis ω_j.

Working definition 5.28 (Abel–Jacobi map)

$$u : \Sigma_p \to J(\Sigma_p), \qquad u(P) = \left(\int_{P_0}^{P} \omega_1, \ \dots, \ \int_{P_0}^{P} \omega_p \right) \bmod \Lambda.$$

[mod Λ: two vectors of $\mathbb{C}^p$ are identified when they differ by a lattice vector] The integral depends on the path from P_0 to P, but two paths differ by a closed loop, which is an integer combination of the a_i, b_i, so the vector of integrals changes by an element of Λ: modulo Λ it is well defined. Extend to divisors by linearity: $u\left(\sum n_i P_i\right) = \sum n_i u(P_i)$. On divisors of degree zero the base point drops out. [changing P_0 shifts every $u(P_i)$ by the same vector, and these shifts cancel when $\sum n_i = 0$]

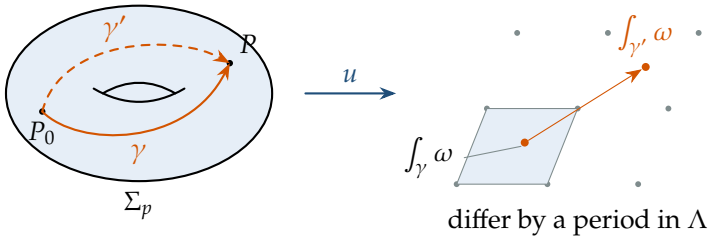

Figure 5.25: The Abel–Jacobi map. Integrating the holomorphic differentials from P_0 to P along two different paths γ, γ' gives vectors in $\mathbb{C}^p$ that differ by the integral over the closed loop $\gamma'\gamma^{-1}$, which is a lattice vector. In the torus $\mathbb{C}^p/\Lambda$ the two answers coincide.

Key idea: Abel's theorem

A divisor D of degree zero is principal, $D = \mathrm{div}(f)$, if and only if $u(D) = 0$ in $J(\Sigma_p)$. Combined with the Jacobi inversion theorem (u is onto on effective divisors of degree p), this identifies the degree-zero divisor classes with the Jacobian:

$$\frac{\{D : \deg D = 0\}}{\{\text{principal}\}} \ \cong \ J(\Sigma_p) = \mathbb{C}^p/\Lambda.$$

We prove the "only if" direction for the torus, where it is a contour integral just like the degree-zero theorem, one power of z higher.

Worked example 5.40: Abel's theorem on the torus

Let f be elliptic on $\mathbb{C}/\Lambda$, $\Lambda = \mathbb{Z}\omega_1 + \mathbb{Z}\omega_2$, with zeros $p_1, \dots, p_n$ and poles $q_1, \dots, q_n$ in a period parallelogram Π (listed with multiplicity; there are equally many by Section 5.2.8).

By the residue theorem applied to $z\,f'(z)/f(z)$, whose residue at a zero or pole c of order m is $m\,c$ (from (5.14)),

$$\frac{1}{2\pi\mathrm{i}}\oint_{\partial\Pi} z\,\frac{f'(z)}{f(z)}\,\mathrm{d}z = \sum_i p_i - \sum_i q_i.$$

Now pair the edges as in Example 5.29. With $g = f'/f$ periodic, the bottom and top edges give

$$\int_{z_0}^{z_0+\omega_1} \big[z\,g(z) - (z+\omega_2)\,g(z+\omega_2)\big]\,\mathrm{d}z \overset{(1)}{=} -\omega_2 \int_{z_0}^{z_0+\omega_1} \frac{f'}{f}\,\mathrm{d}z \overset{(2)}{=} -\omega_2 \cdot 2\pi\mathrm{i}\,k,$$

(1) $g(z+\omega_2) = g(z)$, so the $z\,g$ terms cancel.

(2) $\int f'/f\,\mathrm{d}z$ is the change of $\log f$ along the edge; since $f(z_0+\omega_1) = f(z_0)$ the logarithm returns to its starting value up to $2\pi i k$ for an integer k (the winding number of f along the edge).

and likewise the left and right edges give $+\omega_1 \cdot 2\pi\mathrm{i}\,l$ for an integer l. Dividing by $2\pi\mathrm{i}$:

$$\sum_i p_i - \sum_i q_i = l\,\omega_1 - k\,\omega_2 \in \Lambda.$$

Since $u(P) = z(P) \bmod \Lambda$ on the torus (with $P_0 = 0$ and $\omega = \mathrm{d}z$), this is $u(\operatorname{div} f) = 0$. Consequences:

- $P - O \sim P' - O$ means $P - P'$ is principal, which forces $z(P) - z(P') \in \Lambda$, i.e. $P = P'$. The degree-zero classes on T are in one-to-one correspondence with the points of T, as promised in Example 5.31: $\mathrm{Pic}_0(T) \cong T = J(T)$.
- Check on the cubic: $\operatorname{div}(y) = A_0 + A_1 + A_\lambda - 3O$ with the three branch points at the half-periods $\frac{\omega_1}{2}$, $\frac{\omega_2}{2}$, $\frac{\omega_1+\omega_2}{2}$. Their sum is $\omega_1 + \omega_2 \in \Lambda$. ✓
- A line $\alpha x + \beta y + \gamma = 0$ meets the cubic in three points P, Q, R (Bézout), and the function $\alpha x + \beta y + \gamma$ has divisor $P + Q + R - 3O$. So $z(P) + z(Q) + z(R) \in \Lambda$: *three collinear points on a cubic add up to zero in the group law of the torus*. This is the classical chord construction of addition on an elliptic curve.

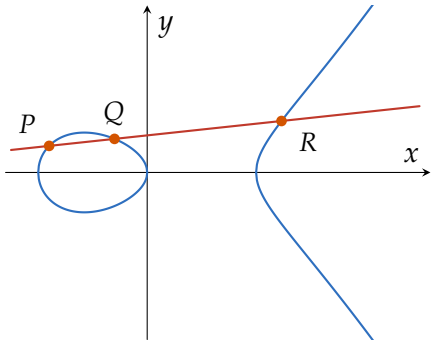

Figure 5.26: Real points of the cubic $y^2 = x(x-1)(x+1)$ (Nash's (5.3) with $\lambda = -1$) and a line meeting it in three points P, Q, R. The line's equation, viewed as a function on the curve, has divisor $P + Q + R - 3O$ (O the point at infinity), so by Abel's theorem $u(P) + u(Q) + u(R) = 0$ in the Jacobian: collinear points sum to zero in the group law of the torus.

Physical picture: periods and Jacobians in physics

Three places where these objects appear later. (1) The Jacobian is the space of *flat* U(1) *connections* on Σ_p (Wilson lines around the $2p$ loops, each a phase): $\mathrm{Hom}(\mathbb{Z}^{2p}, \mathrm{U}(1)) = (S^1)^{2p}$, a real torus of dimension $2p$ which the complex structure turns into $\mathbb{C}^p/\Lambda$ (Section 5.3.5). (2) The one-loop string amplitude integrates over the modulus $\tau = \tilde{\Omega}$ of the worldsheet torus; at p loops the period matrix enters the partition function of a chiral boson through the Riemann theta function $\sum_{n\in\mathbb{Z}^p} \exp(\pi i\, n^T \tilde{\Omega} n + \dots)$, which converges precisely because $\mathrm{Im}\,\tilde{\Omega} > 0$. (3) In Seiberg–Witten theory the matrix of low-energy gauge couplings $\tau_{ij} = \theta_{ij}/2\pi + 4\pi i/g_{ij}^2$ is the period matrix of an auxiliary curve, and positivity of $\mathrm{Im}\,\tilde{\Omega}$ is positivity of the kinetic energy.

Reading Nash (pp. 143–144, (5.15)–(5.19))

Nash recalls $H_1(\Sigma_p;\mathbb{Z}) = \mathbb{Z}^{2p}$ with the basis a_i, b_i and the intersection numbers (5.15); introduces p holomorphic 1-forms (footnote: Abelian differentials, or differentials of the first kind) and their conjugates as a basis of H^1; defines the $p \times 2p$ period matrix (5.16), whose columns are $\mathbb{R}$-independent, the lattice Λ and the Jacobian $J(\Sigma_p) = \mathbb{C}^p/\Lambda$ (5.17); normalises the a-periods (5.18) to get $\Omega = (I, \tilde{\Omega})$ (5.19); and states without proof that $\tilde{\Omega}$ is symmetric with positive imaginary part, and that equal period matrices mean isomorphic surfaces. We have added: the intersection form as a symplectic matrix, the torus computation, the closedness and positivity of holomorphic forms, the explicit basis $x^k \mathrm{d}x/y$ on hyperelliptic curves, the proof of $\mathbb{R}$-independence, the elliptic-integral periods of the cubic, the reciprocity identity with full derivation of symmetry, positivity and invertibility of the a-periods, the $\mathrm{Sp}(2p,\mathbb{Z})$ ambiguity and the Schottky dimension count, and the Abel–Jacobi map with Abel's theorem proved on the torus.

Recap: Section 5.2

- A compact Riemann surface Σ_p is a closed orientable surface of genus p with holomorphic transition functions; complex structure = conformal structure. Genus 0: $\mathbb{CP}^1$. Genus 1: the cubic $y^2 = x(x-1)(x-\lambda) = \mathbb{C}/\Lambda$ (via $\wp$). Genus $p \geq 2$: embeds in $\mathbb{CP}^3$; $3p-3$ complex moduli.
- Line bundles are given by transition functions; $\mathcal{O}(n)$ on $\mathbb{CP}^1$ has sections = polynomials of degree $\leq n$; $K = T^*\Sigma_p$ is the canonical bundle, $K_{\mathbb{CP}^1} = \mathcal{O}(-2)$, K_T trivial.
- The divisor of a meromorphic section lists its zeros and poles with orders. A function's divisor has degree 0 (contour argument). Divisors modulo principal ones = line bundles, via $g_{\alpha\beta} = f_\alpha/f_\beta$, and $c_1([D]) = \deg D$.
- Holomorphic sections of $[D] = \mathcal{L}(D)$; none if $\deg < 0$; for degree 0 only if trivial. $\mathrm{Div} = H^0(\mathcal{M}^*/\mathcal{O}^*)$ and $D \mapsto [D]$ is a connecting homomorphism.
- $H_1 = \mathbb{Z}^{2p}$ with $(a_i, b_j) = \delta_{ij}$; p holomorphic differentials; period matrix $(I, \tilde{\Omega})$ with $\tilde{\Omega}$ symmetric, $\mathrm{Im}\,\tilde{\Omega} > 0$ (bilinear relations); Jacobian $\mathbb{C}^p/\Lambda$ = degree-zero divisor classes (Abel).

5.3 Serre duality, line bundles and Kähler manifolds

In Section 5.2 we collected a list of questions that we kept postponing. How many holomorphic sections does a line bundle of degree d have? Why is $\deg K_{\Sigma_p} = 2p-2$? Why does a surface of genus p have exactly p independent holomorphic 1-forms? Which holomorphic line bundles are trivial, and how big is the set of line bundles with a given Chern class? And, for a general complex manifold: which metrics are compatible with the complex structure, and what does such a metric tell us about the topology?

This section answers all of these with three tools.

1. *Serre duality*, a version of Poincaré duality for holomorphic objects. It pairs holomorphic data of type "(p,q)" with data of type "$(n-p,n-q)$".
2. *The exponential sheaf sequence*, which compares the classification of line bundles up to smooth isomorphism (by an integer, the Chern class) with the classification up to holomorphic isomorphism (by an integer *and* a point of a complex torus).
3. *Kähler metrics*, Hermitian metrics whose 2-form is closed. On a Kähler manifold, harmonic forms split cleanly by type, which forces strong restrictions on Betti numbers.

Along the way we derive the Riemann–Roch theorem for curves, which is the formula that answers the counting questions. Nash does not state it in this section, but it is the engine behind the numbers p, $2p-2$ and $3p-3$ that appear throughout the chapter, and it is the simplest instance of the index theorem of Chapter 4.

From now on, as in Nash, M denotes a closed (compact, no boundary) complex manifold of complex dimension n; for $n=1$ it is a Riemann surface Σ_p.

5.3.1 Forms of type (p,q) and the operators ∂, $\bar\partial$

Serre duality is a statement about the cohomology of holomorphic objects, and the most concrete way to compute that cohomology is with differential forms, exactly as de Rham cohomology computes ordinary cohomology (Chapter T2, Chapter 3). The only new ingredient is that on a complex manifold forms split into "holomorphic" and "antiholomorphic" parts.

One complex variable first. On $\mathbb{C}$ with $z = x + \mathrm{i}y$, the complex 1-forms

$$\mathrm{d}z = \mathrm{d}x + \mathrm{i}\,\mathrm{d}y, \qquad \mathrm{d}\bar z = \mathrm{d}x - \mathrm{i}\,\mathrm{d}y$$

are a basis of the complexified cotangent space, just as $\mathrm{d}x, \mathrm{d}y$ are. The dual basis of vectors is

$$\partial_z = \tfrac12(\partial_x - \mathrm{i}\partial_y), \qquad \partial_{\bar z} = \tfrac12(\partial_x + \mathrm{i}\partial_y),$$

chosen so that $\mathrm{d}z(\partial_z) = 1$, $\mathrm{d}z(\partial_{\bar z}) = 0$ and so on. Every complex 1-form is $a\,\mathrm{d}z + b\,\mathrm{d}\bar z$, and for a function

$$\begin{aligned} \mathrm{d}f &\overset{(1)}{=} f_x\,\mathrm{d}x + f_y\,\mathrm{d}y \overset{(2)}{=} f_x\,\frac{\mathrm{d}z+\mathrm{d}\bar z}{2} + f_y\,\frac{\mathrm{d}z-\mathrm{d}\bar z}{2\mathrm{i}} \\ &\overset{(3)}{=} \tfrac12(f_x - \mathrm{i}f_y)\,\mathrm{d}z + \tfrac12(f_x+\mathrm{i}f_y)\,\mathrm{d}\bar z = \underbrace{\partial_z f\,\mathrm{d}z}_{\partial f} + \underbrace{\partial_{\bar z} f\,\mathrm{d}\bar z}_{\bar\partial f}. \end{aligned} \tag{5.35}$$

(1) The ordinary differential.

(2) Invert: $\mathrm{d}x = \frac{1}{2}(\mathrm{d}z + \mathrm{d}\bar{z})$, $\mathrm{d}y = \frac{1}{2\mathrm{i}}(\mathrm{d}z - \mathrm{d}\bar{z})$.
(3) Collect terms; $1/\mathrm{i} = -\mathrm{i}$.

The condition $\bar{\partial} f = 0$ reads $f_x + \mathrm{i} f_y = 0$. With $f = u + \mathrm{i}v$ its real and imaginary parts are $u_x = v_y$, $u_y = -v_x$: the *Cauchy–Riemann equations*. So

$$\boxed{f \text{ is holomorphic} \iff \bar{\partial} f = 0.}$$

The operator $\bar{\partial}$ is the "obstruction to being holomorphic", and the holomorphic functions are its kernel. This is the sentence to keep in mind for the rest of the section: *holomorphic cohomology is the cohomology of* $\bar{\partial}$.

Working definition 5.29 (forms of type (p,q))

On a complex manifold with local holomorphic coordinates $z^1, \dots, z^n$, [coordinates whose changes of chart are holomorphic functions] a **(p,q)-form** is a form that in every chart can be written

$$\alpha = \frac{1}{p!\,q!}\, \alpha_{i_1 \dots i_p \bar{j}_1 \dots \bar{j}_q}\, \mathrm{d}z^{i_1} \wedge \cdots \wedge \mathrm{d}z^{i_p} \wedge \mathrm{d}\bar{z}^{j_1} \wedge \cdots \wedge \mathrm{d}\bar{z}^{j_q},$$

with p factors $\mathrm{d}z$ and q factors $\mathrm{d}\bar{z}$. The type does not depend on the chart, because a holomorphic change of coordinates sends $\mathrm{d}z$'s to combinations of $\mathrm{d}z$'s ($\mathrm{d}w^i = \frac{\partial w^i}{\partial z^j}\mathrm{d}z^j$, with no $\mathrm{d}\bar{z}$ term). Every complex k-form splits uniquely [sort its terms by how many $\mathrm{d}\bar{z}$ factors each one contains] as a sum of pieces of types (p,q) with $p+q=k$. We write $A^{p,q}(M)$ for the smooth (p,q)-forms. *Operationally*: count the $\mathrm{d}z$'s and the $\mathrm{d}\bar{z}$'s.

The exterior derivative of a (p,q)-form has two pieces. Differentiating a coefficient gives $\sum_k \partial_{z^k}(\cdot)\,\mathrm{d}z^k + \sum_k \partial_{\bar{z}^k}(\cdot)\,\mathrm{d}\bar{z}^k$, so

$$\mathrm{d} = \partial + \bar{\partial}, \qquad \partial : A^{p,q} \to A^{p+1,q}, \qquad \bar{\partial} : A^{p,q} \to A^{p,q+1}.$$

Expanding $0 = \mathrm{d}^2 = \partial^2 + (\partial\bar{\partial} + \bar{\partial}\partial) + \bar{\partial}^2$ and sorting by type (the three pieces have types $(p+2,q)$, $(p+1,q+1)$, $(p,q+2)$, so each must vanish separately) gives

$$\partial^2 = 0, \qquad \bar{\partial}^2 = 0, \qquad \partial\bar{\partial} = -\bar{\partial}\partial. \tag{5.36}$$

Working definition 5.30 (Dolbeault cohomology)

Since $\bar{\partial}^2 = 0$, for each fixed p we have a complex [a chain of maps in which any two applied in a row give zero] $A^{p,0} \xrightarrow{\bar{\partial}} A^{p,1} \xrightarrow{\bar{\partial}} A^{p,2} \to \cdots$, and its cohomology

$$H^{p,q}_{\bar{\partial}}(M) = \frac{\{\alpha \in A^{p,q} : \bar{\partial}\alpha = 0\}}{\{\bar{\partial}\beta : \beta \in A^{p,q-1}\}}$$

is the **Dolbeault cohomology**. *Operationally*: to show a class is zero, solve the equation $\bar{\partial}\beta = \alpha$; the cohomology measures when this $\bar{\partial}$-equation has no global solution. [no β defined on all of M. Locally a solution always exists]

The lowest piece is the one we already know: $H^{p,0}_{\bar{\partial}}(M)$ consists of $(p,0)$-forms α with $\bar{\partial}\alpha = 0$ (there is nothing to divide by), that is, the *holomorphic p-forms*. For $p=0$ these are the holomorphic functions, and $H^{0,0}_{\bar{\partial}} = \mathbb{C}$ on a connected compact M. For $p = n$ they are the holomorphic sections of K_M.

Bundle-valued forms. Let $E \to M$ be a holomorphic vector bundle with transition functions $g_{\alpha\beta}$ (holomorphic matrices). An E-valued (p,q)-form is, in each patch, a column vector α_α of (p,q)-forms, with $\alpha_\alpha = g_{\alpha\beta}\alpha_\beta$. Define $\bar\partial_E \alpha$ patchwise as $\bar\partial \alpha_\alpha$. This is consistent, because

$$\bar\partial \alpha_\alpha \overset{(1)}{=} \bar\partial(g_{\alpha\beta}\alpha_\beta) \overset{(2)}{=} (\bar\partial g_{\alpha\beta}) \wedge \alpha_\beta + g_{\alpha\beta}\,\bar\partial\alpha_\beta \overset{(3)}{=} g_{\alpha\beta}\,\bar\partial\alpha_\beta.$$

(1) The gluing rule.
(2) Leibniz rule for $\bar\partial$ (the matrix g is a 0-form).
(3) $g_{\alpha\beta}$ is holomorphic, so $\bar\partial g_{\alpha\beta} = 0$.

(The same calculation for ∂ or d fails, since $\partial g_{\alpha\beta} \neq 0$: to differentiate sections in the holomorphic directions one needs a connection. The operator $\bar\partial_E$ comes free with the holomorphic structure.) So we get the complex $(A^{p,\bullet}(E), \bar\partial_E)$ and its cohomology $H^{p,q}_{\bar\partial_E}(M)$.

Key idea: the Dolbeault isomorphism

For every holomorphic vector bundle E,

$$H^{p,q}_{\bar\partial_E}(M) \;\cong\; H^q\big(M;\Omega^p(E)\big), \tag{5.37}$$

where $\Omega^p(E)$ is the sheaf of holomorphic E-valued p-forms (sections of $\Lambda^p T^*M \otimes E$ over each open set) and the right side is sheaf cohomology (Chapter 3). This is the form in which Nash quotes it on p. 145. In particular $H^q(M;\mathcal{O}(E)) = H^{0,q}_{\bar\partial_E}(M)$.

Why it is true. It is the same mechanism as the de Rham theorem. There are two ingredients.

- *A local $\bar\partial$-Poincaré lemma* (the Dolbeault–Grothendieck lemma): on a small disc, every $\bar\partial$-closed (p,q)-form with $q \geq 1$ is $\bar\partial$ of something. We verify it below in one variable, where it is the statement that the Green's function of $\partial_{\bar z}$ exists.
- *The sheaves $\mathcal{A}^{p,q}$ of smooth forms are fine*: they admit partitions of unity, so their higher cohomology vanishes (Chapter 3, and Section 5.3.4 below for an explicit computation).

Together they say that $0 \to \Omega^p(E) \to \mathcal{A}^{p,0}(E) \xrightarrow{\bar\partial} \mathcal{A}^{p,1}(E) \xrightarrow{\bar\partial} \cdots$ is a fine resolution of $\Omega^p(E)$, and the cohomology of a sheaf can be computed as the cohomology of global sections of any fine resolution. That is the whole proof, at the level of Chapter 3.

Worked example 5.41: The $\bar\partial$-Poincaré lemma in one variable: the Green's function of $\partial_{\bar z}$

We want to solve $\partial_{\bar z} u = f$ on a disc, for a given smooth f (this is $\bar\partial u = f\,\mathrm{d}\bar z$). The answer is

$$u(z) = \frac{1}{\pi}\int \frac{f(w)}{z-w}\,\mathrm{d}^2 w, \qquad \mathrm{d}^2 w = \mathrm{d}(\mathrm{Re}\,w)\,\mathrm{d}(\mathrm{Im}\,w), \tag{5.38}$$

and the key identity is $\partial_{\bar z}(1/z) = \pi\,\delta^2(z)$. To see it, integrate $\partial_{\bar z}(1/z)$ against the area element over a disc D_ε of radius ε (where $1/z$ is singular, the integral is defined as a limit, i.e. distributionally):

$$\int_{D_\varepsilon} \partial_{\bar z} g\;\mathrm{d}^2 z \overset{(1)}{=} \frac{\mathrm{i}}{2}\int_{D_\varepsilon} \partial_{\bar z} g\;\mathrm{d}z\wedge\mathrm{d}\bar z \overset{(2)}{=} -\frac{\mathrm{i}}{2}\int_{D_\varepsilon} \mathrm{d}(g\,\mathrm{d}z) \overset{(3)}{=} -\frac{\mathrm{i}}{2}\oint_{\partial D_\varepsilon} g\,\mathrm{d}z \overset{(4)}{=} -\frac{\mathrm{i}}{2}\cdot 2\pi\mathrm{i} = \pi.$$

(1) $\mathrm{d}z\wedge\mathrm{d}\bar z = (\mathrm{d}x + \mathrm{i}\,\mathrm{d}y)\wedge(\mathrm{d}x - \mathrm{i}\,\mathrm{d}y) = -2\mathrm{i}\,\mathrm{d}x\wedge\mathrm{d}y$, so $\mathrm{d}^2 z = \frac{\mathrm{i}}{2}\mathrm{d}z\wedge\mathrm{d}\bar z$.
(2) $\mathrm{d}(g\,\mathrm{d}z) = \partial_{\bar z} g\,\mathrm{d}\bar z\wedge\mathrm{d}z = -\partial_{\bar z} g\,\mathrm{d}z\wedge\mathrm{d}\bar z$.

(3) Stokes' theorem.
(4) $g = 1/z$ and $\oint \mathrm{d}z/z = 2\pi\mathrm{i}$.

Away from 0, $\partial_{\bar z}(1/z) = 0$ because $1/z$ is holomorphic there. So $\partial_{\bar z}(1/z)$ is concentrated at the origin with total weight π: $\partial_{\bar z}(1/z) = \pi\delta^2(z)$. Then

$$\partial_{\bar z} u(z) \overset{(1)}{=} \frac{1}{\pi}\int f(w)\,\partial_{\bar z}\frac{1}{z-w}\,\mathrm{d}^2 w \overset{(2)}{=} \frac{1}{\pi}\int f(w)\,\pi\,\delta^2(z-w)\,\mathrm{d}^2 w = f(z).$$

(1) Differentiate under the integral.
(2) The identity just proved, shifted to $z - w$.

A physicist knows this already: since $\partial_z\partial_{\bar z} = \frac{1}{4}\nabla^2$ and $1/z = \partial_z \log|z|^2$, the identity is $\nabla^2 \log|z| = 2\pi\delta^2$, the statement that $\frac{1}{2\pi}\log|z|$ is the Coulomb potential of a point charge in two dimensions. So *locally* the $\bar\partial$-equation can always be solved, and all the obstructions measured by $H^{p,q}_{\bar\partial}$ are global.

Worked example 5.42: Dolbeault cohomology of the torus by Fourier series

Take the square torus $T = \mathbb{C}/(\mathbb{Z} + \mathrm{i}\mathbb{Z})$ with $z = x + \mathrm{i}y$ and $x, y \in \mathbb{R}/\mathbb{Z}$. Which $(0,1)$-forms $f\,\mathrm{d}\bar z$ are $\bar\partial$-exact? (Every $(0,1)$-form is $\bar\partial$-closed, since there are no $(0,2)$-forms in one complex dimension.) Expand in Fourier modes, $f = \sum_{m,n\in\mathbb{Z}} f_{mn}\,e_{mn}$ with $e_{mn} = e^{2\pi\mathrm{i}(mx+ny)}$. The operator $\partial_{\bar z}$ is diagonal on these modes:

$$\partial_{\bar z} e_{mn} \overset{(1)}{=} \tfrac{1}{2}(\partial_x + \mathrm{i}\partial_y)\,e_{mn} \overset{(2)}{=} \tfrac{1}{2}(2\pi\mathrm{i}m + \mathrm{i}\cdot 2\pi\mathrm{i}n)\,e_{mn} = \pi\mathrm{i}\,(m + \mathrm{i}n)\,e_{mn}.$$

(1) Definition of $\partial_{\bar z}$.
(2) $\partial_x e_{mn} = 2\pi\mathrm{i}m\,e_{mn}$, $\partial_y e_{mn} = 2\pi\mathrm{i}n\,e_{mn}$.

The eigenvalue $\pi\mathrm{i}(m + \mathrm{i}n)$ vanishes only for $(m,n) = (0,0)$. So $\partial_{\bar z} u = f$ is solved by $u_{mn} = f_{mn}/\big(\pi\mathrm{i}(m + \mathrm{i}n)\big)$ for every mode except the constant one, and the constant mode can never be hit ($\partial_{\bar z}$ of anything has zero average, by Stokes). Therefore

$$H^{0,1}_{\bar\partial}(T) = \mathbb{C}\cdot[\mathrm{d}\bar z], \qquad H^{0,0}_{\bar\partial}(T) = \ker\partial_{\bar z} = \mathbb{C}\cdot 1.$$

Both are one-dimensional: $h^{0,0} = h^{0,1} = 1$. The same Fourier argument applied to $(1,0)$- and $(1,1)$-forms (multiply everything by $\mathrm{d}z$) gives $h^{1,0} = h^{1,1} = 1$, with representatives $\mathrm{d}z$ and $\mathrm{d}z\wedge\mathrm{d}\bar z$. Notice that $h^{1,0} + h^{0,1} = 2 = b_1(T)$ and $h^{0,0} = h^{1,1} = 1 = b_0 = b_2$: a first glimpse of the Hodge decomposition of Section 5.3.9.

Physical picture: zero modes

Dolbeault cohomology is the language of *zero modes*. The operator $\bar\partial_E$ acting on sections of E is (up to identifying $(0,1)$-forms with spinors of one chirality) the chiral Dirac operator on a surface, coupled to the gauge field of E. Its kernel $H^{0,0}$ is the space of normalisable zero modes of one chirality; its cokernel $H^{0,1}$ is the space of zero modes of the adjoint, of the other chirality. The index $h^0 - h^1$ is what the index theorem computes (Chapter 4); on a surface, that computation is the Riemann–Roch theorem of Section 5.3.3.

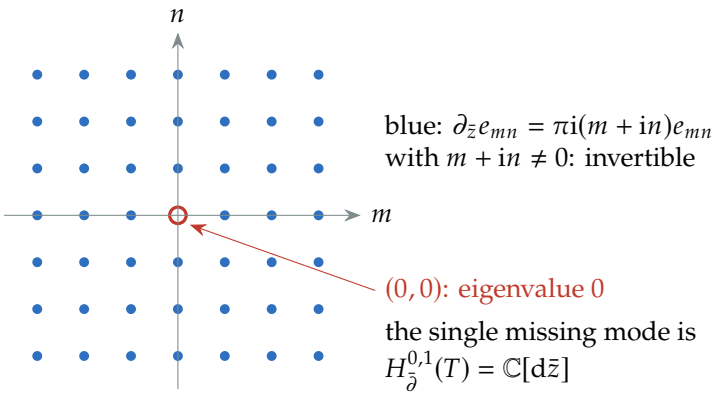

Figure 5.27: The spectrum of $\partial_{\bar z}$ on the square torus. Each Fourier mode e_{mn} is an eigenfunction with eigenvalue $\pi i(m + in)$, the lattice point $m + in$ itself up to a factor. Only the constant mode (open red circle) has eigenvalue zero: it is both the kernel (holomorphic functions, $H^{0,0}$) and the cokernel (the unreachable part of $f\,d\bar z$, $H^{0,1}$). The cohomology of $\bar\partial$ is the zero-mode content of an elliptic operator.

5.3.2 Serre duality

Reminder: Poincaré duality. On a closed oriented real manifold of dimension m, the pairing

$$H^k_{\mathrm{dR}}(M) \times H^{m-k}_{\mathrm{dR}}(M) \to \mathbb{R}, \qquad ([\alpha],[\beta]) \mapsto \int_M \alpha \wedge \beta$$

is well defined (Stokes: $\int d\gamma \wedge \beta = \int d(\gamma \wedge \beta) = 0$ when $d\beta = 0$) and nondegenerate, so $H^k_{\mathrm{dR}} \cong (H^{m-k}_{\mathrm{dR}})^*$ and $b_k = b_{m-k}$. Nondegeneracy has a one-line reason once we have a metric: the harmonic representative α of a nonzero class pairs with $\star\alpha$ (also harmonic) to give $\int \alpha \wedge \star\alpha = \|\alpha\|^2 > 0$.

Serre duality (Nash calls it Kodaira–Serre duality) is the same statement with d replaced by $\bar\partial$. The top-degree forms on a complex n-fold are the (n,n)-forms, so a (p,q)-form must be paired with an $(n-p, n-q)$-form, and a form with values in E must be paired with one with values in the dual bundle E^* so that the values can be contracted to a number.

Key idea: Serre duality

For a holomorphic vector bundle E on a closed complex manifold M of dimension n, the pairing

$$H^{p,q}_{\bar\partial_E}(M) \times H^{n-p,n-q}_{\bar\partial_{E^*}}(M) \to \mathbb{C}, \qquad ([\theta],[\nu]) \mapsto \int_M \langle \theta \wedge \nu \rangle \tag{5.39}$$

is well defined and nondegenerate. Here $\langle \theta \wedge \nu \rangle$ means: wedge the form parts and contract the E values of θ with the E^* values of ν, producing a scalar (n,n)-form. Hence, in sheaf language,

$$H^q\big(M; \Omega^p(E)\big) \;\cong\; \big\{H^{n-q}\big(M; \Omega^{n-p}(E^*)\big)\big\}^*. \tag{5.40}$$

Reading Nash (p. 144, (5.20))

Nash writes (5.20) as $H^p(M, \Omega^q(E)) \simeq \{H^{n-p}(M, \Omega^{n-q}(E^*))\}^*$. His p is the cohomology degree and his q the form degree, the other way round from the Dolbeault labelling $H^{p,q} = H^q(\Omega^p)$ that he uses on the next page and that we use in (5.40). The content is identical: both indices are reflected, (form degree, cohomology degree) $\mapsto (n-\cdot, n-\cdot)$, and E is replaced by E^*. Nash describes the pairing as $\int_M \langle \theta, \nu \rangle$ with "the Hermitian inner

product used to define the ordinary dual $E^{*\prime\prime}$: a Hermitian metric identifies E^* with the complex conjugate of E, which is how one writes $\langle \theta \wedge \nu \rangle$ as an inner product.

The special cases $p = 0$ and $p = n$. A holomorphic E-valued 0-form is just a holomorphic section of E, and a holomorphic E-valued n-form is a holomorphic section of $\Lambda^n T^*M \otimes E = K_M \otimes E$. So (Nash's (5.21))

$$\Omega^0(E) = \mathcal{O}(E), \qquad \Omega^n(E) = \mathcal{O}(K_M \otimes E). \tag{5.41}$$

Putting $p = 0$ in (5.40) gives the most used form of Serre duality, Nash's (5.22):

$$\boxed{H^q\big(M; \mathcal{O}(E)\big) \cong \big\{H^{n-q}\big(M; \mathcal{O}(K_M \otimes E^*)\big)\big\}^*.} \tag{5.42}$$

The canonical bundle appears because it is what turns $(0,q)$-forms into (n,q)-forms. On a Riemann surface ($n = 1$) there are only two groups, and (5.42) says

$$h^1(L) = h^0(K \otimes L^{-1}), \qquad h^0(L) = h^1(K \otimes L^{-1}), \tag{5.43}$$

where $h^q(L) = \dim H^q(\Sigma; \mathcal{O}(L))$ and $L^{-1} = L^*$ for a line bundle. In divisor notation, $h^1(D) = h^0(K - D)$.

Why the pairing is well defined. Take $\theta \in A^{p,q}(E)$ and $\nu \in A^{n-p,n-q}(E^*)$, both $\bar\partial$-closed, and change θ by an exact piece $\bar\partial\alpha$, $\alpha \in A^{p,q-1}(E)$. Then

$$\int_M \langle \bar\partial\alpha \wedge \nu \rangle \overset{(1)}{=} \int_M \bar\partial\langle \alpha \wedge \nu \rangle - (-1)^{p+q-1} \int_M \langle \alpha \wedge \bar\partial\nu \rangle \overset{(2)}{=} \int_M \bar\partial\langle \alpha \wedge \nu \rangle$$
$$\overset{(3)}{=} \int_M \mathrm{d}\langle \alpha \wedge \nu \rangle \overset{(4)}{=} 0.$$

(1) Leibniz rule. It is legitimate to apply $\bar\partial$ to the contracted scalar form: in a local holomorphic frame of E and the dual frame of E^* the contraction is a sum of products of components, and the frames change by holomorphic matrices that $\bar\partial$ does not see.
(2) $\bar\partial_{E^*}\nu = 0$.
(3) $\langle \alpha \wedge \nu \rangle$ has type $(n, n-1)$. Its ∂ would have type $(n+1, n-1)$, which does not exist, so $\mathrm{d} = \partial + \bar\partial$ equals $\bar\partial$ on it.
(4) Stokes' theorem on the closed manifold M.

The same argument works for changing ν. This is word for word the Poincaré duality argument, with the observation in step (3) doing the work of converting $\bar\partial$ into d.

Why it is nondegenerate. Give M a Hermitian metric and E a Hermitian fibre metric. Then there is a conjugate-linear Hodge star $\bar\star_E : A^{p,q}(E) \to A^{n-p,n-q}(E^*)$ with $\langle \theta \wedge \bar\star_E \theta \rangle = |\theta|^2 \,\mathrm{vol}$ (take the Hodge star, complex-conjugate the form part, and use the metric to turn E-values into E^*-values). Hodge theory for the elliptic operator $\Delta_{\bar\partial} = \bar\partial\bar\partial^* + \bar\partial^*\bar\partial$ (the complex version of Chapter 2) says that every Dolbeault class has a unique harmonic representative, and $\bar\star_E$ maps harmonic forms to harmonic forms. So for a nonzero class with harmonic representative θ, $\int \langle \theta \wedge \bar\star_E \theta \rangle = \|\theta\|^2 > 0$: nothing nonzero pairs to zero with everything. In particular $\dim H^{p,q}_{\bar\partial_E} = \dim H^{n-p,n-q}_{\bar\partial_{E^*}}$.

Worked example 5.43: Serre duality on the torus

Take E trivial on $T = \mathbb{C}/\Lambda$, $n = 1$, $p = 0$, $q = 1$. Serre duality pairs $H^{0,1}_{\bar\partial}(T) = H^1(T;\mathcal{O})$ with $H^{1,0}_{\bar\partial}(T) = H^0(T;K)$. From Example 5.42 the first is spanned by $[\mathrm{d}\bar z]$ and from Example 5.26 the second by $\mathrm{d}z$. The pairing is

$$\int_T \mathrm{d}\bar z \wedge \mathrm{d}z \overset{(1)}{=} -\int_T \mathrm{d}z \wedge \mathrm{d}\bar z \overset{(2)}{=} 2\mathrm{i}\int_T \mathrm{d}x \wedge \mathrm{d}y \overset{(3)}{=} 2\mathrm{i}\,\mathrm{Area}(T) \neq 0.$$

(1) Antisymmetry of the wedge product of 1-forms.
(2) $\mathrm{d}z \wedge \mathrm{d}\bar z = -2\mathrm{i}\,\mathrm{d}x \wedge \mathrm{d}y$.
(3) The integral of the area form.

A 1×1 matrix with nonzero entry: the pairing is perfect, and $h^1(\mathcal{O}) = h^0(K) = 1$.

Worked example 5.44: $H^1(\mathbb{CP}^1;\mathcal{O}(n))$ by Laurent series, and Serre duality checked

Here is a computation of H^1 that uses no forms at all, only the Čech description of Chapter 3, and it shows beautifully what H^1 "is". Cover $\mathbb{CP}^1$ by $U_0 = \mathbb{C}$ (coordinate z) and $U_1 = \mathbb{CP}^1 \setminus \{0\}$ (coordinate $w = 1/z$). For a cover by two sets, a Čech 1-cochain of $\mathcal{O}(n)$ is one holomorphic section c_{01} over the overlap $U_0 \cap U_1 = \mathbb{C}^*$ (written in the U_0 frame), there is no cocycle condition, and a coboundary is a difference $c_{01} = s_0 - g_{01}s_1$ of sections over U_0 and U_1. So

$$H^1(\mathbb{CP}^1;\mathcal{O}(n)) = \frac{\mathcal{O}(\mathbb{C}^*)}{\mathcal{O}(U_0) + z^n\,\mathcal{O}(U_1)}.$$

Now write everything as Laurent series in z.

- $c_{01} \in \mathcal{O}(\mathbb{C}^*)$: any convergent Laurent series $\sum_{k\in\mathbb{Z}} c_k z^k$.
- $\mathcal{O}(U_0)$: power series in z, spanned by z^k with $k \geq 0$.
- $z^n\mathcal{O}(U_1)$: z^n times power series in $w = z^{-1}$, spanned by z^{n-j} with $j \geq 0$, i.e. by z^k with $k \leq n$.

The quotient is spanned by the monomials z^k that are in neither list: $k < 0$ and $k > n$. That set is empty if $n \geq -1$, and for $n \leq -2$ it is $k = n+1, \dots, -1$, which has $-n-1$ elements (Figure 5.28). Hence

$$h^1(\mathcal{O}(n)) = \begin{cases} 0, & n \geq -1, \\ -n-1, & n \leq -2, \end{cases} \qquad h^0(\mathcal{O}(n)) = \begin{cases} n+1, & n \geq 0, \\ 0, & n \leq -1. \end{cases} \tag{5.44}$$

(The second formula is Example 5.23: the monomials in *both* lists, $0 \leq k \leq n$, are the global sections.) Now check Serre duality (5.43) with $K = \mathcal{O}(-2)$ (Example 5.25):

$$h^0\big(K \otimes \mathcal{O}(n)^{-1}\big) \overset{(1)}{=} h^0\big(\mathcal{O}(-2-n)\big) \overset{(2)}{=} \begin{cases} -n-1, & -2-n \geq 0, \\ 0, & \text{otherwise}, \end{cases}$$

(1) $\mathcal{O}(a) \otimes \mathcal{O}(b) = \mathcal{O}(a+b)$ (transition functions multiply) and $\mathcal{O}(n)^{-1} = \mathcal{O}(-n)$.
(2) (5.44) with n replaced by $-2-n$: $(-2-n)+1 = -n-1$.

which is exactly $h^1(\mathcal{O}(n))$. One can even see the pairing: the class of z^k ($n < k < 0$) in $H^1(\mathcal{O}(n))$ pairs with the section $z^{-k-1}\,\mathrm{d}z$ of $K \otimes \mathcal{O}(-n)$ by taking the residue of the product at $z = 0$, $\mathrm{Res}_0(z^k \cdot z^{-k-1}\mathrm{d}z) = 1$. (The residue is the Čech form of $\int_M$.) Finally notice

$$h^0(\mathcal{O}(n)) - h^1(\mathcal{O}(n)) = n+1 \qquad \text{for every } n \in \mathbb{Z},$$

a single linear formula valid on both sides of the jump. This is the Riemann–Roch theorem for the sphere.

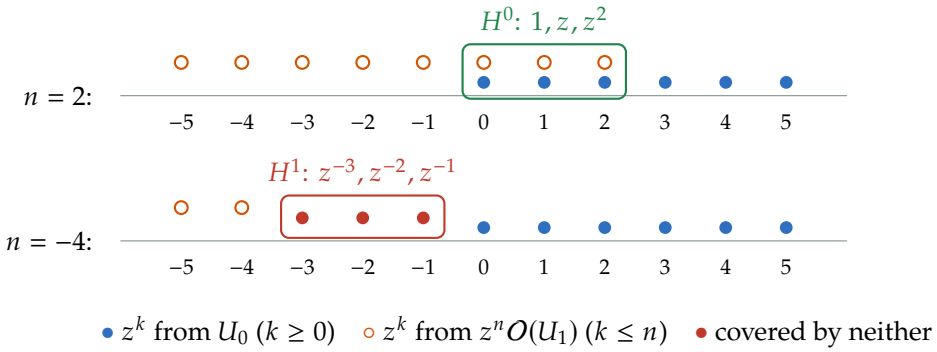

Figure 5.28: Čech cohomology of $\mathcal{O}(n)$ on $\mathbb{CP}^1$ as bookkeeping of Laurent monomials z^k on the overlap $\mathbb{C}^*$. Top ($n = 2$): the two lists overlap in $0 \leq k \leq 2$, giving $h^0 = 3$ global sections, and together they cover everything, so $h^1 = 0$. Bottom ($n = -4$): the lists no longer meet ($h^0 = 0$) and they leave a gap of $-n - 1 = 3$ monomials, which is H^1. Moving n down by one removes one orange dot from the right, and so changes $h^0 - h^1$ by exactly one.

Watch out: Serre duality needs compactness and involves K

On a non-compact manifold (say $\mathbb{C}$) there is no integral over M to pair with, and the statement fails: $H^0(\mathbb{C}; \mathcal{O})$ is infinite-dimensional while $H^1(\mathbb{C}; \mathcal{O}) = 0$. And the dual of $H^q(\mathcal{O}(E))$ is *not* $H^{n-q}(\mathcal{O}(E^*))$: the canonical bundle must be inserted. On $\mathbb{CP}^1$, $h^1(\mathcal{O}(-2)) = 1$ but $h^0(\mathcal{O}(2)) = 3$; the correct partner is $h^0(K \otimes \mathcal{O}(2)) = h^0(\mathcal{O}(0)) = 1$.

5.3.3 The Riemann–Roch theorem for curves

Here is the question that Section 5.2 kept raising. Fix a divisor D on Σ_p: a list of points where we allow poles (positive coefficients) and points where we demand zeros (negative coefficients). How many independent meromorphic functions obey those rules? That number is $h^0(D) = \dim \mathcal{L}(D) = \dim H^0(\Sigma_p; \mathcal{O}([D]))$ (Section 5.2.12). Computing it exactly is hard. Computing it *up to a correction that Serre duality identifies* is easy, and that is the Riemann–Roch theorem.

We write $h^q(D) = \dim H^q(\Sigma_p; \mathcal{O}([D]))$ for $q = 0, 1$ and call

$$\chi(D) = h^0(D) - h^1(D)$$

the **holomorphic Euler characteristic** of $[D]$. On a curve there is no H^2 (by Dolbeault, $H^2(\mathcal{O}(L)) = H^{0,2}_{\bar\partial} = 0$ since there are no $(0,2)$-forms), so χ is the full alternating sum.

Key idea: Riemann–Roch theorem for a compact Riemann surface

For every divisor D on a compact Riemann surface of genus p,

$$h^0(D) - h^1(D) = \deg D + 1 - p. \tag{5.45}$$

By Serre duality (5.43), $h^1(D) = h^0(K - D)$, so equivalently

$$\boxed{h^0(D) - h^0(K - D) = \deg D + 1 - p.} \tag{5.46}$$

The same holds for any holomorphic line bundle L, with $\deg D$ replaced by $\deg L = c_1(L)$.

The left side of (5.46) involves the complex structure (which functions exist); the right side involves only two integers, the degree and the genus. That is the pattern of every index theorem: an analytic count equals a topological number.

Why it is true: three steps. *Step 1: the base case $D = 0$.* Here $h^0(0) = 1$, the constants (Section 5.2.2), and $h^1(0) = h^0(K)$ by Serre duality, the number of independent holomorphic 1-forms. That number is p. We showed in Section 5.2.16 that there are at least "enough" of them to make $\omega, \bar{\omega}$ independent; the exact count comes from the Hodge decomposition $H^1(\Sigma_p;\mathbb{C}) = H^{1,0} \oplus H^{0,1}$ with $H^{0,1} = \overline{H^{1,0}}$ (Section 5.3.9; a Riemann surface is Kähler), which gives $2p = b_1 = 2h^{1,0}$. So

$$\chi(0) = 1 - p. \tag{5.47}$$

Genus p *means*, analytically, $h^0(K) = p$; Riemann–Roch will show it is also the topological genus appearing in $\deg K = 2p - 2$.

Step 2: adding a point raises χ by exactly one. Let P be a point and z a local coordinate centred at P, and suppose D has coefficient m at P. A section of $[D + P]$ is (Section 5.2.12) a meromorphic function f with $\operatorname{div} f + D + P \geq 0$, so near P

$$f = c\, z^{-m-1} + (\text{higher powers of } z).$$

The map "read off the coefficient c" sends $\mathcal{O}([D + P])$ to the **skyscraper sheaf** $\mathbb{C}_P$ (the sheaf whose sections over U are $\mathbb{C}$ if $P \in U$ and 0 otherwise), and its kernel is exactly $\mathcal{O}([D])$ (those f whose pole at P is one order milder). So there is a short exact sequence of sheaves

$$0 \to \mathcal{O}([D]) \to \mathcal{O}([D + P]) \xrightarrow{c} \mathbb{C}_P \to 0,$$

and hence (Chapter 3) a long exact sequence

$$0 \to H^0(D) \to H^0(D + P) \xrightarrow{c} \mathbb{C} \xrightarrow{\delta} H^1(D) \to H^1(D + P) \to H^1(\mathbb{C}_P) = 0. \tag{5.48}$$

($H^1(\mathbb{C}_P) = 0$ because a sheaf concentrated at one point is flabby; concretely, a Čech cocycle of $\mathbb{C}_P$ on a cover where only one set contains P is identically zero.) Now use the elementary fact that in an exact sequence of finite-dimensional vector spaces $0 \to V_1 \to V_2 \to \cdots \to V_k \to 0$ the alternating sum of dimensions is zero. For a short exact sequence $0 \to A \xrightarrow{i} B \xrightarrow{\pi} C \to 0$ this is

$$\dim B \overset{(1)}{=} \dim \ker \pi + \dim \operatorname{im} \pi \overset{(2)}{=} \dim \operatorname{im} i + \dim C \overset{(3)}{=} \dim A + \dim C,$$

(1) Rank–nullity for π.
(2) Exactness: $\ker \pi = \operatorname{im} i$, and π is onto.
(3) i is injective.

and a long sequence is a chain of short ones (each V_j is squeezed between the image coming in and the image going out). Applied to (5.48):

$$\begin{aligned} 0 &\overset{(1)}{=} h^0(D) - h^0(D + P) + 1 - h^1(D) + h^1(D + P) \\ &\overset{(2)}{=} \chi(D) - \chi(D + P) + 1 \quad \Longrightarrow \quad \chi(D + P) = \chi(D) + 1. \end{aligned}$$

(1) Alternating sum of dimensions of the six-term exact sequence; $\dim \mathbb{C} = 1$.
(2) Regroup using $\chi = h^0 - h^1$.

The mechanism is visible: allowing one more pole order at P either produces one new function (the map c is onto) or, if no function with that pole exists, the leftover coefficient is a nonzero obstruction class $\delta(1) \in H^1(D)$ that dies in $H^1(D+P)$. Either way the index goes up by one. We saw exactly this in Figure 5.28, where lowering n by one removed one monomial.

Step 3: induction. Every divisor is reached from 0 by adding and removing points one at a time, and each addition raises both χ and deg by one (each removal lowers both). So $\chi(D) - \deg D$ is the same for all D, and by Step 1 it equals $1 - p$. That is (5.45).

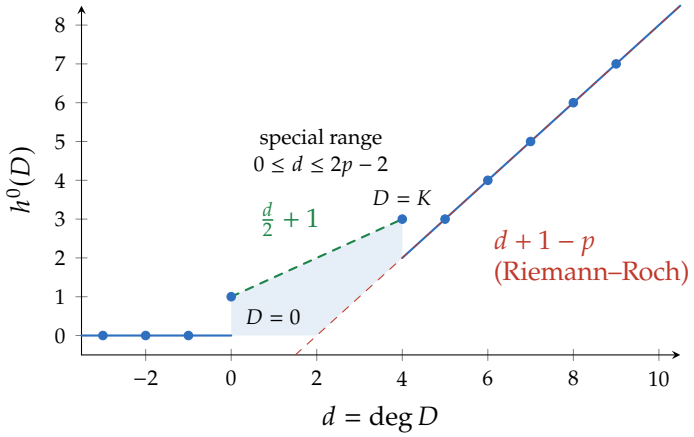

Figure 5.29: What Riemann–Roch says about $h^0(D)$ on a surface of genus $p = 3$. For $d < 0$ there are no sections. For $d > 2p - 2 = 4$ the correction $h^0(K - D)$ vanishes and $h^0 = d + 1 - p$ exactly (solid line). In between (shaded) h^0 depends on the complex structure and on D: it lies between the Riemann–Roch bound $d + 1 - p$ (red dashed) and Clifford's bound $\frac{d}{2} + 1$ (green dashed). The two ends of the special range are pinned: $h^0(0) = 1$ and $h^0(K) = p$.

Consequences. Riemann–Roch is a machine for producing numbers. Here are the ones promised earlier in the chapter.

Worked example 5.45: The degree of the canonical bundle is $2p - 2$

Take $D = K$ in (5.46):

$$h^0(K) - h^0(0) \overset{(1)}{=} \deg K + 1 - p \quad \Longrightarrow \quad p - 1 \overset{(2)}{=} \deg K + 1 - p \quad \Longrightarrow \quad \deg K = 2p - 2.$$

(1) Riemann–Roch with $D = K$, so $K - D = 0$.
(2) $h^0(K) = p$ and $h^0(0) = 1$ (Step 1).

So a holomorphic 1-form on Σ_p has exactly $2p - 2$ zeros, and a meromorphic one has (zeros) − (poles) $= 2p - 2$. Checks: $\mathbb{CP}^1$, dz has a double pole at ∞, degree -2 (Example 5.25); the torus, dz has neither, degree 0 (Example 5.26); genus 2, $y^2 = q(x)$ with $\deg q = 6$, the form dx/y has simple zeros at the two points above $x = \infty$ (Example 5.38), degree 2. Topologically, $K = T^*\Sigma$, so $\deg K = -c_1(T\Sigma) = -\chi(\Sigma) = 2p - 2$: Riemann–Roch has rederived the Gauss–Bonnet theorem (Chapter T2) from function theory.

Worked example 5.46: Large degree: the answer is exact

If $\deg D > 2p - 2$ then $\deg(K - D) < 0$, so $h^0(K - D) = 0$ and

$$h^0(D) = \deg D + 1 - p \qquad (\deg D \ge 2p - 1).$$

In general $h^0(K-D) \geq 0$ gives the **Riemann inequality** $h^0(D) \geq \deg D + 1 - p$, so *every divisor of degree* $\geq p$ *is equivalent to an effective one*: this is the threshold quoted in the pitfall of Section 5.2.12. Two applications.

- *The count* $2d+1-p$ *of Example 5.22.* A meromorphic function of degree d on a fixed Σ_p is a ratio s_0/s_1 of two sections of a line bundle L of degree d (its divisor of poles). The bundles of degree d form a p-dimensional family (Pic_d, a translate of the Jacobian, Section 5.3.5); for $d \geq 2p-1$ each has $h^0 = d+1-p$ sections; the pair (s_0, s_1) matters only up to a common scale. Total: $p + 2(d+1-p) - 1 = 2d+1-p$. ✓
- *Embeddings.* For $\deg D \geq 2p+1$ one checks with (5.46) that for any two points P, Q, $h^0(D-P-Q) = h^0(D)-2$; so sections of $[D]$ separate points (and tangents), and a basis $s_0, \ldots, s_N$ gives an embedding $P \mapsto [s_0(P) : \cdots : s_N(P)]$ into $\mathbb{CP}^N$ with $N = \deg D - p$. This is the curve case of the Kodaira embedding theorem of Section 5.1.10. For the torus with $D = 3O$: $N = 3-1 = 2$, the Weierstrass embedding by $[1 : \wp : \wp']$.

Worked example 5.47: Genus 0 and genus 1 revisited

Genus 0. For $\deg D = 0$ Riemann's inequality gives $h^0(D) \geq 1$, so D is equivalent to an effective divisor of degree 0, i.e. to 0: *every degree-zero divisor on a genus-0 surface is principal*, and holomorphic line bundles are classified by their degree. For $D = P$ a single point, $h^0(P) = 1+1-0 = 2$: there is a nonconstant function f with a single simple pole. It takes every value exactly once (degree 1), so $f : \Sigma_0 \to \mathbb{CP}^1$ is a biholomorphism. *Any Riemann surface of genus* 0 *is* $\mathbb{CP}^1$; there are no moduli, consistent with $3p-3 < 0$.
Genus 1. $h^0(nO) = n+1-1 = n$ for $n \geq 1$ (since $\deg(K-nO) = -n < 0$). This matches the explicit basis $1, \wp, \wp', \wp^2, \ldots$ found by hand in Example 5.34, and explains the gap at $n=1$: $h^0(O) = 1$, only the constants, so there is no elliptic function with a single simple pole.

Worked example 5.48: Quadratic differentials and the number $3p-3$

A **holomorphic quadratic differential** is a holomorphic section of $K^2 = K \otimes K$, locally $\phi(z)\,dz^2$. They are the infinitesimal deformations of the complex structure (their dual space, via Serre duality, is $H^1(T\Sigma)$, the space of first-order changes of the transition functions; this is taken up in part 5b). For $p \geq 2$, $\deg(K-K^2) = \deg K^{-1} = 2-2p < 0$, so

$$h^0(K^2) \overset{(1)}{=} \deg K^2 + 1 - p \overset{(2)}{=} 2(2p-2) + 1 - p = 3p-3.$$

(1) Riemann–Roch with $h^0(K-K^2) = 0$.
(2) $\deg(K \otimes K) = 2\deg K$ (degrees add under $\otimes$).

This is Nash's dimension $3p-3$ of the space of complex structures, now as a theorem. More generally, for $j \geq 2$, $h^0(K^j) = (2j-1)(p-1)$.
Physics: ghost zero modes. In the string path integral the reparametrisation ghosts b and c are sections of K^2 and K^{-1}. The number of b zero modes minus the number of c zero modes is

$$h^0(K^2) - h^0(K^{-1}) \overset{(1)}{=} \deg K^2 + 1 - p \overset{(2)}{=} 3p-3,$$

(1) Riemann–Roch with $D = K^2$, $K-D = K^{-1}$; valid for every p.
(2) As above.

for *every* genus. For $p=0$: $h^0(K^2) = h^0(\mathcal{O}(-4)) = 0$ and $h^0(K^{-1}) = h^0(\mathcal{O}(2)) = 3$, the three conformal Killing vectors $1, z, z^2$ (times ∂_z) generating $\mathrm{PSL}(2,\mathbb{C})$: $0-3 = -3$. For $p=1$:

one modulus and one translation, $1-1=0$. This is the ghost-number anomaly of string theory, and it is Riemann–Roch (Chapter 9).

Worked example 5.49: Theta functions: explicit sections on the torus

We now exhibit the sections that Riemann–Roch counts, for a line bundle of degree N on $T=\mathbb{C}/(\mathbb{Z}+\tau\mathbb{Z})$, $\operatorname{Im}\tau>0$. Describe a line bundle on T by **factors of automorphy**: a section is a holomorphic function ψ on $\mathbb{C}$ with

$$\psi(z+1)=\psi(z), \qquad \psi(z+\tau)=e_\tau(z)\,\psi(z),$$

for a fixed nowhere-zero holomorphic e_τ. (This is the same as transition functions: ψ on $\mathbb{C}$ is the pull-back of the section, and e_τ glues the two sides of the parallelogram.) Take $e_\tau(z)=e^{-\pi\mathrm{i}N\tau-2\pi\mathrm{i}Nz}$. The number of zeros of any section ψ in a parallelogram Π is

$$\begin{aligned}\frac{1}{2\pi\mathrm{i}}\oint_{\partial\Pi}\mathrm{d}\log\psi &\overset{(1)}{=}\frac{1}{2\pi\mathrm{i}}\int_0^1\big[\mathrm{d}\log\psi(x)-\mathrm{d}\log\psi(x+\tau)\big]\\ &\quad+\frac{1}{2\pi\mathrm{i}}\int_0^\tau\big[\mathrm{d}\log\psi(1+t)-\mathrm{d}\log\psi(t)\big]\\ &\overset{(2)}{=}-\frac{1}{2\pi\mathrm{i}}\int_0^1\mathrm{d}\log e_\tau(x)\overset{(3)}{=}-\frac{1}{2\pi\mathrm{i}}\int_0^1(-2\pi\mathrm{i}N)\,\mathrm{d}x=N.\end{aligned}$$

(1) The four edges of Π, anticlockwise: bottom, right, top (backwards), left (backwards), paired as in Example 5.29.
(2) $\psi(1+t)=\psi(t)$ kills the second bracket; $\log\psi(x+\tau)=\log\psi(x)+\log e_\tau(x)$ gives the first.
(3) $\mathrm{d}\log e_\tau=-2\pi\mathrm{i}N\,\mathrm{d}z$.

So this bundle has degree N, a number fixed by the factor of automorphy alone. For $N\geq 1$ Riemann–Roch predicts $h^0=N+1-1=N$ sections. Here they are:

$$\theta_a(z)=\sum_{n\in\mathbb{Z}}\exp\Big(\pi\mathrm{i}N\big(n+\tfrac{a}{N}\big)^2\tau+2\pi\mathrm{i}N\big(n+\tfrac{a}{N}\big)z\Big), \qquad a=0,1,\dots,N-1.$$

The series converges because $|\exp(\pi\mathrm{i}Nk^2\tau)|=e^{-\pi Nk^2\operatorname{Im}\tau}$ is Gaussian in k (positivity of $\operatorname{Im}\tau$ again). Check the factors: $\theta_a(z+1)=\theta_a(z)$ since $e^{2\pi\mathrm{i}(Nn+a)}=1$, and with $k=n+a/N$,

$$\begin{aligned}&\pi\mathrm{i}Nk^2\tau+2\pi\mathrm{i}Nk(z+\tau)\overset{(1)}{=}\pi\mathrm{i}N(k+1)^2\tau-\pi\mathrm{i}N\tau+2\pi\mathrm{i}N(k+1)z-2\pi\mathrm{i}Nz\\ &\quad\Longrightarrow\quad \theta_a(z+\tau)\overset{(2)}{=}e^{-\pi\mathrm{i}N\tau-2\pi\mathrm{i}Nz}\,\theta_a(z).\end{aligned}$$

(1) Complete the square: $k^2+2k=(k+1)^2-1$, and $2kz=2(k+1)z-2z$.
(2) Sum over n; the shift $k\to k+1$ is the relabelling $n\to n+1$ of the summation index, which does not change the sum.

The θ_a are independent (their Fourier modes $e^{2\pi\mathrm{i}(Nn+a)z}$ are disjoint), so they span the N-dimensional space. For $N=1$, θ_0 is the Jacobi theta function $\vartheta(z|\tau)$, whose single zero sits at $z=\frac{1+\tau}{2}$.

Physical picture: Riemann–Roch is the lowest Landau level count

A charged particle on a closed surface Σ_p with N units of magnetic flux lives in a line bundle L with $c_1(L) = N$. With a constant magnetic field, the lowest Landau level wavefunctions are exactly the holomorphic sections of L (the condition $\bar\partial_A \psi = 0$ is the LLL condition $a\psi = 0$ for the lowering operator). So the degeneracy of the lowest Landau level is $h^0(L) = N + 1 - p$ for $N > 2p - 2$. On the sphere (Haldane's geometry) it is $N + 1$; on the torus it is N, and the theta functions of Example 5.49, multiplied by the Gaussian $e^{-\pi N(\operatorname{Im} z)^2/\operatorname{Im}\tau}$ (the Hermitian metric h of Section 5.2.11), are the LLL wavefunctions. The "$1 - p$" is a topological correction to the naive count "one state per flux quantum", the shift that appears in quantum Hall physics.

Riemann–Roch as an index theorem. The number $\chi(L) = h^0(L) - h^1(L)$ is the index of the elliptic operator $\bar\partial_L : A^{0,0}(L) \to A^{0,1}(L)$ (kernel = H^0, cokernel = H^1 by the Dolbeault isomorphism). The Atiyah–Singer index theorem of Chapter 4, in its holomorphic (Hirzebruch–Riemann–Roch) form, says $\chi(L) = \int_M \operatorname{ch}(L)\,\operatorname{td}(TM)$. On a curve only the 2-form parts survive:

$$\chi(L) \overset{(1)}{=} \int_\Sigma \big(1 + c_1(L)\big)\big(1 + \tfrac{1}{2}c_1(T\Sigma)\big) \overset{(2)}{=} \int_\Sigma c_1(L) + \tfrac{1}{2}\int_\Sigma c_1(T\Sigma) \overset{(3)}{=} \deg L + \tfrac{1}{2}(2 - 2p).$$

(1) $\operatorname{ch}(L) = e^{c_1(L)} = 1 + c_1(L) + \dots$ and $\operatorname{td}(T\Sigma) = 1 + \frac{1}{2}c_1(T\Sigma) + \dots$, truncated at 2-forms.
(2) Keep the terms of degree 2.
(3) $c_1(L) = \deg L$ (Section 5.2.11) and $\int c_1(T\Sigma) = \chi(\Sigma) = 2 - 2p$ (Gauss–Bonnet).

That is (5.45). In higher dimensions the same formula, with more terms of ch and td, is the Hirzebruch–Riemann–Roch theorem; for a rank-r bundle E on a curve it reads $h^0(E) - h^1(E) = \deg E + r(1 - p)$.

Try it: Riemann–Roch on $\mathbb{CP}^1$

Check (5.46) on $\mathbb{CP}^1$ for $D = n[\infty]$ using (5.44), for $n = 3$ and for $n = -3$.
Answer. $n = 3$: $h^0 = 4$, $h^0(K - D) = h^0(\mathcal{O}(-5)) = 0$, and $\deg D + 1 - p = 4$. $n = -3$: $h^0 = 0$, $h^0(K - D) = h^0(\mathcal{O}(1)) = 2$, so the left side is $-2 = -3 + 1$. ✓

5.3.4 Line bundles as cohomology classes: the exponential sequence

Nash now turns from counting sections to classifying the bundles themselves. The question is the one a physicist asks about gauge fields on a compact space: *how many inequivalent* U(1) *bundles are there, and what labels them?* For a sphere the answer is Dirac's: an integer, the monopole charge. We now see that this is a general fact about *smooth* line bundles on any manifold, and that it fails, interestingly, for *holomorphic* ones.

Step 0: a line bundle is a Čech 1-cocycle. Recall (Section 5.2.5) that a complex line bundle L on M is given by an open cover $\{U_\alpha\}$ and transition functions $g_{\alpha\beta} : U_\alpha \cap U_\beta \to \mathbb{C}^*$ obeying the cocycle condition $g_{\alpha\beta}g_{\beta\gamma} = g_{\alpha\gamma}$, and that changing the local frames by nowhere-zero functions h_α changes $g_{\alpha\beta}$ to $h_\alpha g_{\alpha\beta} h_\beta^{-1}$. For a merely *smooth* line bundle the $g_{\alpha\beta}$ and h_α are smooth; for a holomorphic one they are holomorphic. Nash writes the cocycle condition in the equivalent form $g_{\alpha\beta}g_{\beta\gamma} = g_{\alpha\gamma} = g_{\gamma\alpha}^{-1}$ (using $g_{\gamma\alpha}g_{\alpha\gamma} = g_{\gamma\gamma} = 1$).

Now read these two sentences in the language of Chapter 3. Let $\mathcal{E}^*$ be the sheaf of smooth nowhere-vanishing complex functions, a sheaf of abelian groups under *multiplication*. Then

- a family $\{g_{\alpha\beta}\}$ with $g_{\alpha\beta} \in \mathcal{E}^*(U_\alpha \cap U_\beta)$ is a Čech 1-cochain, and the cocycle condition says its Čech coboundary $g_{\beta\gamma}\, g_{\alpha\gamma}^{-1}\, g_{\alpha\beta}$ is 1: it is a *1-cocycle* (in multiplicative notation, where "+" is "×" and "0" is "1");
- changing frames multiplies $g_{\alpha\beta}$ by $h_\alpha h_\beta^{-1}$, the Čech coboundary of the 0-cochain $\{h_\alpha\}$.

So isomorphism classes of smooth line bundles are exactly the elements of $H^1(M;\mathcal{E}^*)$, and holomorphic line bundles are the elements of $H^1(M;\mathcal{O}^*)$. The group operation of H^1, multiplying cocycles, is the tensor product of line bundles.

Working definition 5.31 (the class of a line bundle)

To find the element $[g_{\alpha\beta}] \in H^1(M;\mathcal{E}^*)$ [$\mathcal{E}^*$ is the smooth nowhere-zero complex functions] of a line bundle: write down its transition functions on a cover. Two bundles are the same element if and only if you can find frame changes h_α [a nowhere-zero function h_α on each U_α that rescales the local description of sections, $s_\alpha \mapsto h_\alpha s_\alpha$] with $g'_{\alpha\beta} = h_\alpha g_{\alpha\beta} h_\beta^{-1}$. In particular L is *trivial* (the element 1) exactly when it has a nowhere-zero global section: then $h_\alpha = s_\alpha^{-1}$ turns every $g_{\alpha\beta}$ into 1.

This description is concrete but not yet useful: $H^1(M;\mathcal{E}^*)$ is defined through arbitrary covers and arbitrary smooth functions. The trick, which is Nash's (5.23), is to compare the *multiplicative* sheaf $\mathcal{E}^*$ with the *additive* sheaf $\mathcal{E}$ of smooth complex functions by taking logarithms.

Step 1: the exponential sequence. Define

$$0 \longrightarrow \mathbb{Z} \xrightarrow{i} \mathcal{E} \xrightarrow{\exp} \mathcal{E}^* \longrightarrow 0, \qquad i(n) = n, \qquad \exp(f) = e^{2\pi i f}. \tag{5.49}$$

Here $\mathbb{Z}$ is the sheaf of locally constant integer-valued functions. This is a short exact sequence of sheaves. Check each place.

- *Injective at $\mathbb{Z}$:* a constant integer, regarded as a function, is zero only if it is zero.
- *Exact at $\mathcal{E}$:* $e^{2\pi i f} = 1$ on a connected open set means f takes values in $\mathbb{Z}$, and being continuous it is a constant integer. So $\ker \exp = \mathbb{Z}$.
- *Surjective at $\mathcal{E}^*$, as sheaves:* a nowhere-zero function g on a *small* (say contractible) open set has a smooth logarithm $f = \frac{1}{2\pi i} \log g$, so $g = \exp f$ locally. Globally it may not: $g = z$ on the annulus $\{1/2 < |z| < 2\}$ has no single-valued logarithm. This "locally but not globally" is exactly what the long exact sequence measures.

(We follow Nash in putting $2\pi i$ into the exponential; it makes the kernel $\mathbb{Z}$ rather than $2\pi i\mathbb{Z}$.)

Step 2: the long exact sequence. A short exact sequence of sheaves gives a long exact sequence in cohomology (Chapter 3). Here it is Nash's (5.24):

$$\cdots \to H^1(M;\mathcal{E}) \to H^1(M;\mathcal{E}^*) \xrightarrow{\delta} H^2(M;\mathbb{Z}) \to H^2(M;\mathcal{E}) \to \cdots \tag{5.50}$$

The connecting map δ is computed by the standard recipe, and it is worth doing by hand once, because *its output is the first Chern class*. Start from a cocycle $\{g_{\alpha\beta}\}$, on a cover fine enough that all overlaps are contractible.

1. *Lift*: choose logarithms $\lambda_{\alpha\beta} = \frac{1}{2\pi i} \log g_{\alpha\beta} \in \mathcal{E}(U_\alpha \cap U_\beta)$, with $\lambda_{\beta\alpha} = -\lambda_{\alpha\beta}$.

2. *Take the coboundary*: on triple overlaps set $n_{\alpha\beta\gamma} = \lambda_{\beta\gamma} - \lambda_{\alpha\gamma} + \lambda_{\alpha\beta}$.

3. *It lands in $\mathbb{Z}$*:

$$e^{2\pi \mathrm{i}\, n_{\alpha\beta\gamma}} \overset{(1)}{=} e^{2\pi\mathrm{i}\lambda_{\beta\gamma}}\, e^{-2\pi\mathrm{i}\lambda_{\alpha\gamma}}\, e^{2\pi\mathrm{i}\lambda_{\alpha\beta}} \overset{(2)}{=} g_{\beta\gamma}\, g_{\alpha\gamma}^{-1}\, g_{\alpha\beta} \overset{(3)}{=} 1.$$

   (1) The exponential turns sums into products.
   (2) $e^{2\pi\mathrm{i}\lambda} = g$ by the choice of logarithms.
   (3) The cocycle condition $g_{\alpha\beta}g_{\beta\gamma} = g_{\alpha\gamma}$.

   So $n_{\alpha\beta\gamma}$ is a continuous function with values in $\mathbb{Z}$ on the connected set $U_\alpha \cap U_\beta \cap U_\gamma$, hence a constant integer.

4. $\{n_{\alpha\beta\gamma}\}$ is a Čech 2-cocycle with integer coefficients (it is a coboundary of real functions, so its own coboundary vanishes), and changing the choice of logarithms by integers changes it by an integer coboundary. Its class is

$$\delta[g_{\alpha\beta}] = [n_{\alpha\beta\gamma}] = c_1(L) \in H^2(M;\mathbb{Z}).$$

In words: *the first Chern class is the integer ambiguity in the logarithms of the transition functions*. It is zero precisely when the logarithms can be chosen consistently.

Step 3: the de Rham version. To compare with the curvature formula $c_1 = \frac{\mathrm{i}}{2\pi}F$ we translate $[n_{\alpha\beta\gamma}]$ into a 2-form. Take a partition of unity $\{\rho_\gamma\}$ subordinate to the cover ($\sum_\gamma \rho_\gamma = 1$, $\operatorname{supp}\rho_\gamma \subset U_\gamma$) and the closed 1-forms

$$\theta_{\alpha\beta} = \mathrm{d}\lambda_{\alpha\beta} = \frac{1}{2\pi\mathrm{i}}\,\frac{\mathrm{d}g_{\alpha\beta}}{g_{\alpha\beta}} \qquad \text{on } U_\alpha \cap U_\beta.$$

They satisfy $\theta_{\alpha\beta} + \theta_{\beta\gamma} = \theta_{\alpha\gamma}$ (take d log of the cocycle condition) and do not care which branch of the logarithm was chosen. Define on each U_α the 1-form $a_\alpha = \sum_\gamma \rho_\gamma\, \theta_{\alpha\gamma}$. Then on overlaps

$$a_\beta - a_\alpha \overset{(1)}{=} \sum_\gamma \rho_\gamma\big(\theta_{\beta\gamma} - \theta_{\alpha\gamma}\big) \overset{(2)}{=} \sum_\gamma \rho_\gamma\big(-\theta_{\alpha\beta}\big) \overset{(3)}{=} -\theta_{\alpha\beta}. \tag{5.51}$$

(1) Definition of a_α and a_β.
(2) $\theta_{\alpha\beta} + \theta_{\beta\gamma} = \theta_{\alpha\gamma}$ rearranged.
(3) $\sum_\gamma \rho_\gamma = 1$.

Since $\theta_{\alpha\beta}$ is closed, $\mathrm{d}a_\alpha = \mathrm{d}a_\beta$ on overlaps: the local 2-forms $\mathrm{d}a_\alpha$ patch to a global closed 2-form c on M, and its de Rham class is the image of $c_1(L)$ under $H^2(M;\mathbb{Z}) \to H^2(M;\mathbb{R})$. This is exactly the structure of a U(1) gauge field: (5.51) is a gauge transformation between patches and $c = \mathrm{d}a_\alpha$ is the field strength. Indeed, if L is holomorphic with Hermitian metric h_α and Chern connection $A_\alpha = \partial \log h_\alpha$ (Section 5.2.11), then $h_\beta = |g_{\alpha\beta}|^2 h_\alpha$ gives $A_\beta - A_\alpha = \partial \log |g_{\alpha\beta}|^2 = \mathrm{d}\log g_{\alpha\beta} = 2\pi\mathrm{i}\,\theta_{\alpha\beta}$, so $a'_\alpha = \frac{\mathrm{i}}{2\pi}A_\alpha$ obeys the same rule (5.51), and $\mathrm{d}a'_\alpha = \frac{\mathrm{i}}{2\pi}F$. Both recipes give the same class; the curvature formula is just a particular choice of a_α.

Worked example 5.50: The monopole charge as a winding number

Cover $S^2 = \mathbb{CP}^1$ by $U_0 = \{|z| < 2\}$ and $U_1 = \{|z| > \frac{1}{2}\} \cup \{\infty\}$, with overlap the annulus $\{\frac{1}{2} < |z| < 2\}$, and take any smooth line bundle with transition function g_{01} on the annulus. (With two sets there are no triple overlaps, so the Čech recipe needs a finer cover; the

de Rham recipe works directly.) Let ρ_0, ρ_1 be a partition of unity depending only on $r = |z|$, with $\rho_0 = 1$ for $r \le \frac{1}{2}$ and $\rho_0 = 0$ for $r \ge 2$ (Figure 5.30). Then $a_0 = \rho_1\theta_{01}$ and $a_1 = \rho_0\theta_{10} = -\rho_0\theta_{01}$. Let C be the circle $|z| = 1$, anticlockwise:

$$\int_{S^2} c \overset{(1)}{=} \int_{|z|\le 1} \mathrm{d}a_0 + \int_{|z|\ge 1} \mathrm{d}a_1 \overset{(2)}{=} \oint_C a_0 - \oint_C a_1 \overset{(3)}{=} \oint_C (\rho_1 + \rho_0)\,\theta_{01}$$
$$\overset{(4)}{=} \frac{1}{2\pi\mathrm{i}} \oint_C \frac{\mathrm{d}g_{01}}{g_{01}} \overset{(5)}{=} \operatorname{wind}\big(g_{01}|_C\big).$$

(1) Split the sphere along C and use the local expression for c in each half.
(2) Stokes: the disc has boundary C; the outer cap (oriented as part of S^2) has boundary $-C$.
(3) $a_0 - a_1 = \rho_1\theta_{01} + \rho_0\theta_{01}$.
(4) $\rho_0 + \rho_1 = 1$ and the definition of θ_{01}.
(5) The argument principle: $\frac{1}{2\pi\mathrm{i}} \oint \mathrm{d}g/g$ counts how many times $g(C)$ winds around 0.

For $\mathcal{O}(n)$, $g_{01} = z^n$ winds n times, so $\int c = n = \deg \mathcal{O}(n)$, matching Example 5.33. Note that the answer depends only on the homotopy class of the map $g_{01}|_C : S^1 \to \mathbb{C}^*$, that is, on $\pi_1(\mathbb{C}^*) = \mathbb{Z}$. This is the **clutching** description: bundles on S^2 are classified by how the two hemispheres are glued along the equator, and the gluing maps are classified by an integer. For the Dirac monopole, $g_{01} = e^{in\phi}$ is the gauge transformation relating the potentials on the two hemispheres, and single-valuedness forces $n \in \mathbb{Z}$.

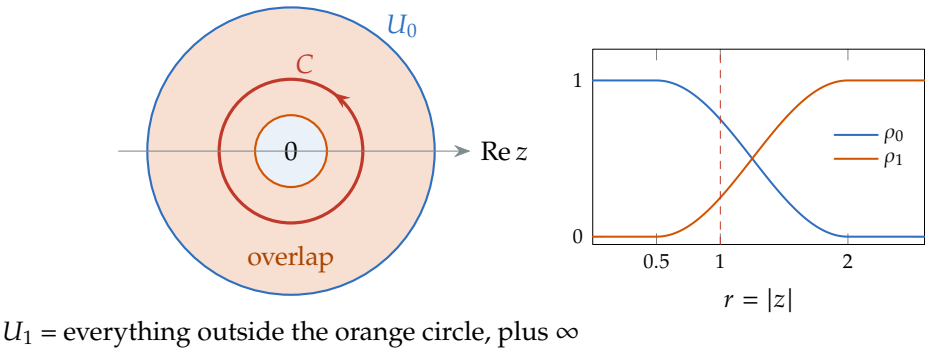

Figure 5.30: Left: the two-set cover of the Riemann sphere used in Example 5.50. U_0 is the blue disc $|z| < 2$, U_1 is the outside of the orange circle $|z| = \frac{1}{2}$ together with ∞, and the overlap is the annulus. All the information in a line bundle is the transition function g_{01} on the annulus; its winding number around the red circle C is the Chern class. Right: a partition of unity depending only on r. The 1-forms $a_0 = \rho_1\theta_{01}$ and $a_1 = -\rho_0\theta_{01}$ are the gauge potentials on the two patches; their curvature lives where ρ changes, in the annulus.

Step 4: $\mathcal{E}$ is fine, so smooth line bundles are classified by c_1. Nash now uses that $\mathcal{E}$ is a *fine* sheaf, so $H^i(M;\mathcal{E}) = 0$ for $i > 0$ (Chapter 3). Let us see why for $i = 1$, since it is a two-line computation and it explains everything that follows. Let $\{f_{\alpha\beta}\}$ be an additive Čech 1-cocycle of smooth functions: $f_{\alpha\beta} + f_{\beta\gamma} = f_{\alpha\gamma}$. Define $k_\alpha = \sum_\gamma \rho_\gamma f_{\alpha\gamma}$ on U_α (each term is extended by zero outside $\operatorname{supp}\rho_\gamma$, which is smooth). Then

$$k_\alpha - k_\beta \overset{(1)}{=} \sum_\gamma \rho_\gamma \big(f_{\alpha\gamma} - f_{\beta\gamma}\big) \overset{(2)}{=} \sum_\gamma \rho_\gamma\, f_{\alpha\beta} \overset{(3)}{=} f_{\alpha\beta}. \tag{5.52}$$

(1) Definition of k_α, k_β.

(2) The cocycle condition: $f_{\alpha\gamma} - f_{\beta\gamma} = f_{\alpha\gamma} + f_{\gamma\beta} = f_{\alpha\beta}$.
(3) $\sum_\gamma \rho_\gamma = 1$.

So every 1-cocycle is a coboundary: $H^1(M;\mathcal{E}) = 0$. (The same trick one degree up gives $H^2(M;\mathcal{E}) = 0$.) The key step is *multiplying by* ρ_γ. A partition of unity is smooth but never holomorphic (a holomorphic function with compact support in a connected open set is zero), so this argument is unavailable for $\mathcal{O}$. Remember that; it is the whole difference between the smooth and the holomorphic stories.

With $H^1(M;\mathcal{E}) = H^2(M;\mathcal{E}) = 0$ the long exact sequence (5.50) becomes

$$0 \longrightarrow H^1(M;\mathcal{E}^*) \xrightarrow{\delta} H^2(M;\mathbb{Z}) \longrightarrow 0.$$

Key idea: smooth line bundles are classified by c_1 (Nash (5.25))

$$H^1(M;\mathcal{E}^*) \;\cong\; H^2(M;\mathbb{Z}), \qquad [L] \longmapsto c_1(L). \tag{5.53}$$

Every class in $H^2(M;\mathbb{Z})$ is the Chern class of some smooth line bundle, and two line bundles are smoothly isomorphic if and only if they have the same c_1. In particular *a line bundle with $c_1(L) = 0$ is (smoothly, and topologically) trivial*.

Why $c_1 = 0$ forces triviality, concretely. If $[n_{\alpha\beta\gamma}] = 0$, adjust the logarithms by integers so that $n_{\alpha\beta\gamma} = 0$ exactly. Then $\{\lambda_{\alpha\beta}\}$ is an additive 1-cocycle of smooth functions, so by (5.52) $\lambda_{\alpha\beta} = k_\alpha - k_\beta$, i.e. $g_{\alpha\beta} = e^{2\pi i k_\alpha}\left(e^{2\pi i k_\beta}\right)^{-1}$. The frame change $h_\alpha = e^{-2\pi i k_\alpha}$ turns all transition functions into 1. On S^2 with the cover of Figure 5.30: if g_{01} has winding number 0 it has a single-valued logarithm λ on the annulus, and $k_0 = \rho_1\lambda$, $k_1 = -\rho_0\lambda$ split it, since $k_0 - k_1 = (\rho_0 + \rho_1)\lambda = \lambda$.

Worked example 5.51: Which smooth line bundles exist?

- $M = S^2$: $H^2 = \mathbb{Z}$. One bundle for each monopole charge n; they are the $\mathcal{O}(n)$ with the holomorphic structure forgotten.
- $M = T^2$ or any closed orientable surface Σ_p: $H^2 = \mathbb{Z}$ again; the bundle is determined by $\int c_1$, the total magnetic flux.
- $M = S^3$, or any M with $H^2(M;\mathbb{Z}) = 0$ (e.g. $\mathbb{R}^n$, S^n for $n \neq 2$): every complex line bundle is trivial, so a U(1) gauge field on S^3 is always a global 1-form. There is no room for a monopole on S^3.
- $M = \mathbb{CP}^n$: $H^2 = \mathbb{Z}$, generated by c_1 of the hyperplane bundle $\mathcal{O}(1)$ (Example 5.35).
- $M = S^2 \times S^2$: $H^2 = \mathbb{Z}^2$; a line bundle is labelled by its two fluxes (n_1, n_2) through the two spheres.
- $M = \mathbb{RP}^3$: $H^2(\mathbb{RP}^3;\mathbb{Z}) = \mathbb{Z}_2$. There is a nontrivial complex line bundle whose c_1 has order two. Its real curvature form is exact, $[c] = 0$ in $H^2(M;\mathbb{R})$, but the bundle is not trivial: $H^2(M;\mathbb{Z}) \to H^2(M;\mathbb{R})$ forgets torsion. Such bundles carry flat connections with nontrivial holonomy.

Watch out: higher rank is different

Nothing like (5.53) holds for vector bundles of rank $k > 1$: it does not follow that a bundle whose Chern classes all vanish is a product. The reason is that the argument

used the *abelian* logarithm; for $\mathrm{GL}(k,\mathbb{C})$-valued transition functions there is no exponential sequence. A concrete example: complex rank-2 bundles on S^5 are classified by clutching maps $S^4 \to \mathrm{U}(2)$ along the equator, that is by $\pi_4(\mathrm{U}(2)) = \pi_4(S^3) = \mathbb{Z}_2$. The nontrivial one has all Chern classes zero, since $H^2(S^5) = H^4(S^5) = 0$. (The same $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$ is behind Witten's global SU(2) anomaly, Chapter 10.) By contrast, rank-2 bundles on S^4 are classified by $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$, detected by c_2: the instanton number of Chapter 8.

5.3.5 Holomorphic line bundles and the Picard group

Now repeat everything with holomorphic functions. Replace $\mathcal{E}$ by the sheaf $\mathcal{O}$ of holomorphic functions and $\mathcal{E}^*$ by $\mathcal{O}^*$ of nowhere-zero holomorphic functions. The exponential is still locally surjective (a nowhere-zero holomorphic function on a disc has a holomorphic logarithm), so we get the **holomorphic exponential sequence** and its long exact sequence, Nash's (5.26):

$$0 \longrightarrow \mathbb{Z} \xrightarrow{i} \mathcal{O} \xrightarrow{\exp} \mathcal{O}^* \longrightarrow 0,$$
$$\cdots \to H^1(M;\mathbb{Z}) \to H^1(M;\mathcal{O}) \to H^1(M;\mathcal{O}^*) \xrightarrow{c_1} H^2(M;\mathbb{Z}) \to H^2(M;\mathcal{O}) \to \cdots \tag{5.54}$$

The connecting map is computed by exactly the same recipe as before, so it is again the first Chern class. What has changed is that $\mathcal{O}$ is *not* fine: the partition-of-unity trick (5.52) is gone, and indeed $H^1(M;\mathcal{O})$ can be nonzero. We already know an example: on a torus $H^1(T;\mathcal{O}) = H^{0,1}_{\bar\partial}(T) = \mathbb{C}$ (Example 5.42), and on Σ_p it is $\mathbb{C}^p$ (Serre duality: $h^1(\mathcal{O}) = h^0(K) = p$).

Working definition 5.32 (Picard group)

The **Picard group** of a complex manifold is the group of holomorphic line bundles up to holomorphic isomorphism, [two bundles count as the same when holomorphic frame changes turn one set of transition functions into the other] with tensor product as the operation (Nash's (5.27)):

$$\mathrm{Pic}(M) = H^1(M;\mathcal{O}^*). \tag{5.55}$$

Its subgroup $\mathrm{Pic}_0(M)$ consists of the holomorphic line bundles with $c_1 = 0$ [the first Chern class. On a curve it is the degree of the bundle], i.e. those that are topologically trivial [trivial as smooth bundles, though not necessarily as holomorphic ones]. *Operationally*: an element of Pic is a set of holomorphic transition functions modulo holomorphic frame changes; on a curve it is a divisor modulo principal divisors (Section 5.2.10).

Now read off the long exact sequence (5.54) piece by piece, for a compact connected M.

The start. $H^0(M;\mathcal{O}) = \mathbb{C}$ (constants) maps onto $H^0(M;\mathcal{O}^*) = \mathbb{C}^*$ by $c \mapsto e^{2\pi i c}$. Onto means the next map $H^1(M;\mathbb{Z}) \to H^1(M;\mathcal{O})$ is injective. So $H^1(M;\mathbb{Z})$ sits inside $H^1(M;\mathcal{O})$.

The middle. Exactness at $H^1(M;\mathcal{O}^*)$ says that the bundles with $c_1 = 0$ are exactly the image of $H^1(M;\mathcal{O})$. Exactness at $H^1(M;\mathcal{O})$ says the kernel of that map is the image of $H^1(M;\mathbb{Z})$. Hence (Nash's (5.28))

$$\mathrm{Pic}_0(M) = \ker c_1 = \frac{H^1(M;\mathcal{O})}{H^1(M;\mathbb{Z})}. \tag{5.56}$$

In words: a topologically trivial holomorphic line bundle is described by transition functions $g_{\alpha\beta} = e^{2\pi i f_{\alpha\beta}}$ with $\{f_{\alpha\beta}\}$ a holomorphic additive cocycle, and two such describe the same bundle if the f's differ by a holomorphic coboundary plus an integer cocycle.

The end. The image of c_1 is the kernel of $H^2(M;\mathbb{Z}) \to H^2(M;\mathcal{O})$, which (via Dolbeault) sends an integral class to the $(0,2)$ part of its de Rham representative. So the Chern classes of

holomorphic line bundles are the integral classes with no $(0,2)$ part; for real classes this means type $(1,1)$ (the *Lefschetz* $(1,1)$ *theorem*). On a curve $H^2(\Sigma;\mathcal{O}) = H^{0,2} = 0$, so every integer is the degree of some holomorphic line bundle, e.g. $[dP]$.

Key idea: smooth versus holomorphic line bundles

	smooth ($\mathcal{E}^*$)	holomorphic ($\mathcal{O}^*$)
classified by	$c_1 \in H^2(M;\mathbb{Z})$	c_1 *and* a point of Pic_0
$c_1 = 0$ means	trivial	a point of the torus $H^1(\mathcal{O})/H^1(\mathbb{Z})$
reason	$\mathcal{E}$ fine, $H^1(\mathcal{E}) = 0$	$H^1(\mathcal{O})$ may be $\neq 0$
on Σ_p	$\mathbb{Z}$	$0 \to J(\Sigma_p) \to \mathrm{Pic}(\Sigma_p) \to \mathbb{Z} \to 0$

A topologically trivial line bundle can carry a whole continuous family of inequivalent holomorphic structures. On a Riemann surface that family is the Jacobian.

$$\begin{array}{ccccccccc}
0 & \longrightarrow & \mathbb{Z} & \xrightarrow{i} & \mathcal{O} & \xrightarrow{\exp} & \mathcal{O}^* & \longrightarrow & 0 \\
 & & \| & & \downarrow & & \downarrow & & \\
0 & \longrightarrow & \mathbb{Z} & \xrightarrow{i} & \mathcal{E} & \xrightarrow{\exp} & \mathcal{E}^* & \longrightarrow & 0
\end{array}$$

$$\begin{array}{ccccccccc}
H^1(M;\mathbb{Z}) & \hookrightarrow & H^1(M;\mathcal{O}) & \longrightarrow & \mathrm{Pic}(M) & \xrightarrow{c_1} & H^2(M;\mathbb{Z}) & \longrightarrow & H^2(M;\mathcal{O}) \\
 & & \downarrow & & \downarrow{\scriptstyle \text{forget}} & & \| & & \\
0 = H^1(M;\mathcal{E}) & \longrightarrow & H^1(M;\mathcal{E}^*) & \xrightarrow[c_1]{\cong} & H^2(M;\mathbb{Z}) & \longrightarrow & 0 = H^2(M;\mathcal{E}) & &
\end{array}$$

Figure 5.31: The holomorphic exponential sequence (top row) maps into the smooth one (bottom row) by regarding a holomorphic function as a smooth one. In cohomology (lower diagram) the smooth row collapses, because $\mathcal{E}$ is fine: smooth line bundles are just their Chern classes. The holomorphic row does not collapse. The "forget" map from $\mathrm{Pic}(M)$ to smooth bundles is *not* injective; its kernel is the image of $H^1(M;\mathcal{O})$, the group $\mathrm{Pic}_0(M)$ of holomorphic structures on the trivial bundle.

Watch out: $\mathrm{Pic}(M)$ is not a subgroup of the smooth line bundles

Nash writes that the holomorphic line bundles "form a subgroup of the group of all smooth line bundles". Read literally this is not right: there is a homomorphism $\mathrm{Pic}(M) \to H^1(M;\mathcal{E}^*)$ (forget the holomorphic structure), but it is not injective, since many holomorphically different bundles are smoothly the same. What is true is that its *image* is a subgroup of $H^1(M;\mathcal{E}^*) = H^2(M;\mathbb{Z})$ (the integral classes of type $(1,1)$), and that its kernel is $\mathrm{Pic}_0(M)$. The very next sentences of Nash, and (5.28), use it in this corrected sense.

Worked example 5.52: $\mathrm{Pic}(\mathbb{CP}^1) = \mathbb{Z}$: every line bundle is some $\mathcal{O}(n)$

On $\mathbb{CP}^1$ we computed $H^1(\mathbb{CP}^1;\mathcal{O}) = 0$ in Example 5.44 (the case $n = 0$: no Laurent monomials fit between 0 and n), and $H^2(\mathbb{CP}^1;\mathcal{O}) = 0$ because there are no $(0,2)$-forms. The long exact sequence becomes

$$0 = H^1(\mathbb{CP}^1;\mathcal{O}) \longrightarrow \mathrm{Pic}(\mathbb{CP}^1) \xrightarrow{c_1} H^2(\mathbb{CP}^1;\mathbb{Z}) = \mathbb{Z} \longrightarrow H^2(\mathbb{CP}^1;\mathcal{O}) = 0,$$

so $c_1 : \mathrm{Pic}(\mathbb{CP}^1) \to \mathbb{Z}$ is an isomorphism. Every holomorphic line bundle on the sphere is

determined by its degree, and since $\mathcal{O}(n)$ has degree n (Example 5.33), every holomorphic line bundle is isomorphic to exactly one $\mathcal{O}(n)$. This is the sheaf-theoretic version of Example 5.30, where we saw that on $\mathbb{CP}^1$ "the degree is everything". The same argument on $\mathbb{CP}^n$ (where $h^{0,1} = h^{0,2} = 0$, Section 5.3.9) gives $\mathrm{Pic}(\mathbb{CP}^n) = \mathbb{Z}$, generated by $\mathcal{O}(1)$.

Worked example 5.53: Holomorphic structures on the trivial bundle over a torus

This is the example Nash has in mind when he says that line bundles with vanishing Chern class "can have rich holomorphic properties". Let $T = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$. Describe line bundles by factors of automorphy as in Example 5.49: for a complex number a, a section of L_a is a function ψ on $\mathbb{C}$ with

$$\psi(z+1) = \psi(z), \qquad \psi(z+\tau) = e^{2\pi i a}\,\psi(z).$$

Degree zero. By the computation of Example 5.49, the number of zeros of a section in a fundamental parallelogram is $-\frac{1}{2\pi i}\int_0^1 \mathrm{d}\log e_\tau$; here $e_\tau = e^{2\pi i a}$ is constant, so $\mathrm{d}\log e_\tau = 0$ and $\deg L_a = 0$.

Smoothly trivial (take a real first). The smooth function $\psi_0(z) = e^{2\pi i a\, y/\mathrm{Im}\,\tau}$, with $y = \mathrm{Im}\, z$, is nowhere zero, and

$$\psi_0(z+1) \overset{(1)}{=} \psi_0(z), \qquad \psi_0(z+\tau) \overset{(2)}{=} e^{2\pi i a\,(y+\mathrm{Im}\,\tau)/\mathrm{Im}\,\tau} = e^{2\pi i a}\,\psi_0(z).$$

(1) Shifting z by 1 does not change y.
(2) Shifting z by τ raises y by $\mathrm{Im}\,\tau$.

So ψ_0 is a nowhere-vanishing *smooth* section, and L_a is smoothly trivial, as (5.53) demands for $c_1 = 0$. (For complex a use $\psi_0 = e^{2\pi i a\, y/\mathrm{Im}\,\tau}$ all the same; it is still nowhere zero.)

Holomorphically nontrivial unless $a \in \mathbb{Z} + \tau\mathbb{Z}$. A holomorphic section ψ is an entire function. First let a be real. Then $|\psi(z+1)| = |\psi(z+\tau)| = |\psi(z)|$, so $|\psi|$ is doubly periodic, hence bounded by its maximum on the compact parallelogram, so ψ is constant by Liouville's theorem, and a nonzero constant satisfies $\psi(z+\tau) = e^{2\pi i a}\psi$ only if $e^{2\pi i a} = 1$. So for $a \notin \mathbb{Z}$ the bundle L_a has *no* holomorphic sections at all, while the trivial bundle has the section 1: L_a is not holomorphically trivial.

For complex a, change the description: replace ψ by $\psi' = e^{2\pi i c z}\psi$ for a constant c. This is a global, holomorphic, nowhere-zero frame change, so it does not change the bundle, and it multiplies the two factors of automorphy by $e^{2\pi i c}$ and $e^{2\pi i c\tau}$. Two consequences.

- With $c = 1$ the factors become $(1,\ e^{2\pi i(a+\tau)})$, so $L_a \cong L_{a+\tau}$. Obviously also $L_a = L_{a+1}$. So L_a depends only on a modulo $\mathbb{Z} + \tau\mathbb{Z}$.
- Write $a = s + t\tau$ with s, t real and take $c = -t$: the factors become $(e^{-2\pi i t},\ e^{2\pi i s})$, both of modulus one. The Liouville argument now applies verbatim: a holomorphic section has doubly periodic modulus, so it is constant, and a nonzero constant needs $e^{-2\pi i t} = e^{2\pi i s} = 1$, i.e. $s, t \in \mathbb{Z}$.

So L_a is holomorphically trivial exactly when $a \in \mathbb{Z} + \tau\mathbb{Z}$, and $L_a \cong L_{a'}$ exactly when $a - a' \in \mathbb{Z} + \tau\mathbb{Z}$ (apply the same argument to $L_a \otimes L_{a'}^{-1} = L_{a-a'}$). Therefore

$$\mathrm{Pic}_0(T) \;\cong\; \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z}) \;=\; T.$$

The torus parametrises its own degree-zero line bundles: this is Abel's theorem (Example 5.40) seen from the other side, with $L_a \cong [P_a - O]$ for the point P_a corresponding to a (up to a sign convention).

Worked example 5.54: (5.56) computed on the torus: the lattice appears

Let us see the quotient $H^1(\mathcal{O})/H^1(\mathbb{Z})$ directly. By Dolbeault, $H^1(T;\mathcal{O}) = H^{0,1}_{\bar\partial}(T) = \mathbb{C}\,[\mathrm{d}\bar z]$; call the coordinate on it c (the class $c\,[\mathrm{d}\bar z]$). The map $H^1(T;\mathbb{Z}) \to H^1(T;\mathcal{O})$ takes a closed real 1-form with integer periods to the $(0,1)$-part of its class. With the cycles a (from 0 to 1) and b (from 0 to τ), the integral basis of $H^1(T;\mathbb{Z})$ is given by the constant forms α_a, α_b with $\int_a \alpha_a = \int_b \alpha_b = 1$ and $\int_b \alpha_a = \int_a \alpha_b = 0$. For a constant form $u\,\mathrm{d}x + v\,\mathrm{d}y$ we have $\int_a = u$ and $\int_b = u\,\mathrm{Re}\,\tau + v\,\mathrm{Im}\,\tau$, so

$$\alpha_a = \mathrm{d}x - \frac{\mathrm{Re}\,\tau}{\mathrm{Im}\,\tau}\,\mathrm{d}y, \qquad \alpha_b = \frac{\mathrm{d}y}{\mathrm{Im}\,\tau}.$$

Their $(0,1)$ parts, using $\mathrm{d}x = \frac12(\mathrm{d}z + \mathrm{d}\bar z)$ and $\mathrm{d}y = \frac{1}{2\mathrm{i}}(\mathrm{d}z - \mathrm{d}\bar z)$, are

$$\alpha_b^{0,1} \overset{(1)}{=} \frac{1}{\mathrm{Im}\,\tau}\cdot\Big(-\frac{1}{2\mathrm{i}}\Big)\mathrm{d}\bar z = \frac{\mathrm{i}}{2\,\mathrm{Im}\,\tau}\,\mathrm{d}\bar z,$$
$$\alpha_a^{0,1} \overset{(2)}{=} \Big(\frac12 - \frac{\mathrm{Re}\,\tau}{\mathrm{Im}\,\tau}\cdot\frac{\mathrm{i}}{2}\Big)\mathrm{d}\bar z \overset{(3)}{=} \frac{\mathrm{Im}\,\tau - \mathrm{i}\,\mathrm{Re}\,\tau}{2\,\mathrm{Im}\,\tau}\,\mathrm{d}\bar z \overset{(4)}{=} \frac{\mathrm{i}}{2\,\mathrm{Im}\,\tau}\,(-\tau)\,\mathrm{d}\bar z.$$

(1) The $\mathrm{d}\bar z$ coefficient of $\mathrm{d}y$ is $-\frac{1}{2\mathrm{i}} = \frac{\mathrm{i}}{2}$.
(2) The $\mathrm{d}\bar z$ coefficient of $\mathrm{d}x$ is $\frac12$, plus the $\mathrm{d}y$ term.
(3) Common denominator.
(4) $\mathrm{i}\cdot(-\tau) = -\mathrm{i}\,\mathrm{Re}\,\tau + \mathrm{Im}\,\tau$.

So the image of $H^1(T;\mathbb{Z})$ is the lattice $\frac{\mathrm{i}}{2\,\mathrm{Im}\,\tau}(\mathbb{Z} + \tau\mathbb{Z})$ in the c-line, and

$$\mathrm{Pic}_0(T) = \frac{H^1(T;\mathcal{O})}{H^1(T;\mathbb{Z})} = \frac{\mathbb{C}}{\frac{\mathrm{i}}{2\,\mathrm{Im}\,\tau}(\mathbb{Z}+\tau\mathbb{Z})} \cong \frac{\mathbb{C}}{\mathbb{Z}+\tau\mathbb{Z}},$$

the last step being multiplication by the nonzero complex number $2\,\mathrm{Im}\,\tau/\mathrm{i}$. The answer agrees with Example 5.53.

General curve. The same computation on Σ_p gives the Jacobian of Section 5.2.17. Identify $H^1(\Sigma_p;\mathcal{O})$ with the dual of $H^0(K)$ by Serre duality, $[\beta] \mapsto \big(\omega \mapsto \int_\Sigma \omega\wedge\beta\big)$. If α is an integral class, Poincaré dual to a cycle γ, then $\int_\Sigma \omega\wedge\alpha^{0,1} = \int_\Sigma \omega\wedge\alpha = \pm\int_\gamma \omega$ (the $(1,0)$ part of α drops out because $\omega\wedge\alpha^{1,0}$ is a $(2,0)$-form, which is zero on a curve). So the image of $H^1(\Sigma_p;\mathbb{Z})$ in $H^0(K)^* \cong \mathbb{C}^p$ is the set of period vectors $\big(\int_\gamma \omega_1, \dots, \int_\gamma \omega_p\big)$, which is the lattice Λ of (5.17). Hence

$$\mathrm{Pic}_0(\Sigma_p) = \mathbb{C}^p/\Lambda = J(\Sigma_p), \qquad \mathrm{Pic}(\Sigma_p) = \bigsqcup_{d\in\mathbb{Z}} \mathrm{Pic}_d(\Sigma_p), \tag{5.57}$$

where Pic_d, the bundles of degree d, is a copy of $J(\Sigma_p)$ (tensor with any fixed bundle of degree d, such as $[dP]$).

Physical picture: flat connections, Wilson lines, and holomorphic structures

Why should a physicist expect Pic_0 to be a torus of real dimension b_1? A degree-zero line bundle carries a *flat* U(1) connection (curvature zero), which is determined by its holonomies (Wilson loops) around the b_1 independent non-contractible loops: b_1 phases, a point of $\mathrm{U}(1)^{b_1} = (\mathbb{R}/\mathbb{Z})^{b_1}$. In Example 5.53 with a real, L_a is exactly the flat bundle with holonomy 1 around a and $e^{2\pi\mathrm{i}a}$ around b: an Aharonov–Bohm flux threading the hole

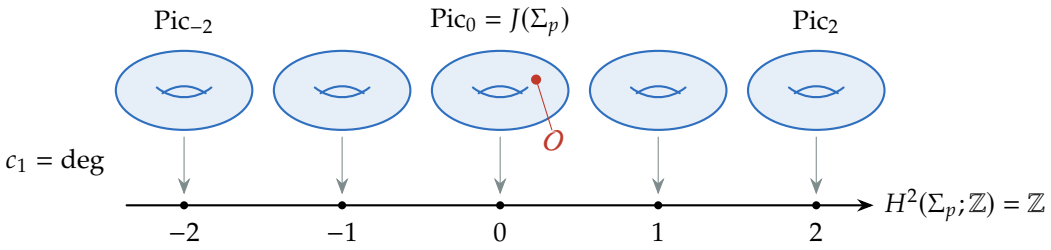

Figure 5.32: The Picard group of a compact Riemann surface. Over each integer d (the Chern class, or degree) sits a whole complex torus Pic_d of holomorphic line bundles, each a translate of the Jacobian $J(\Sigma_p) = \mathbb{C}^p/\Lambda$. Smoothly, everything in one torus is the same bundle; holomorphically, the points are all different. The trivial bundle $\mathcal{O}$ is one point (red) of Pic_0. For $\mathbb{CP}^1$ ($p = 0$) the tori shrink to points and $\mathrm{Pic} = \mathbb{Z}$.

of the torus. Its $\bar\partial$-operator $\bar\partial + A^{0,1}$ is the holomorphic structure. On a compact Kähler manifold every holomorphic line bundle of degree zero arises from exactly one flat unitary connection, so

$$\mathrm{Pic}_0(M) \;=\; \{\text{flat U(1) connections}\}/\text{gauge} \;=\; H^1(M;\mathbb{R})/H^1(M;\mathbb{Z}),$$

a real torus of dimension b_1 whose complex structure comes from $H^1(M;\mathbb{R}) \cong H^{0,1}$. The twisted fermion boundary conditions (spin structures and more general flat twists) in string theory on a torus are points of this torus.

Try it: the Picard group of an abelian surface

Let $M = \mathbb{C}^2/\Lambda$ be a complex 2-torus. Using $h^{0,1} = 2$ and $b_1 = 4$ (constant forms, as in Example 5.42), what is $\mathrm{Pic}_0(M)$ as a real manifold?
Answer. $H^1(M;\mathcal{O}) = \mathbb{C}^2$ modulo the image of $H^1(M;\mathbb{Z}) = \mathbb{Z}^4$, a lattice of rank 4 in $\mathbb{C}^2 = \mathbb{R}^4$: a real 4-torus T^4, carrying a complex structure (the *dual torus*). The discrete part $\mathrm{Pic}/\mathrm{Pic}_0$ is the group of integral $(1,1)$ classes; for generic Λ it is zero, which is one way to see that a generic 2-torus has no positive line bundle and is not algebraic (Example 5.17).

Reading Nash (pp. 144–146, (5.23)–(5.28))

Nash explains that a line bundle is determined by transition functions satisfying the cocycle condition, giving a class in $H^1(M;\mathcal{E}^*)$; writes the exponential sequence (5.23) and its long exact sequence (5.24); uses that $\mathcal{E}$ is fine to get $H^1(M;\mathcal{E}^*) \cong H^2(M;\mathbb{Z})$ (5.25), realised by c_1, so that smooth line bundles are classified by c_1 and $c_1 = 0$ means trivial; warns that this fails in higher rank; repeats the story with $\mathcal{O}$, $\mathcal{O}^*$ (5.26), observing that $\mathcal{O}$ is not fine; defines $\mathrm{Pic}(M) = H^1(M;\mathcal{O}^*)$ (5.27) and $\mathrm{Pic}_0(M) = H^1(M;\mathcal{O})/H^1(M;\mathbb{Z})$ (5.28). Nash's remark that "a global holomorphic section of L is a meromorphic function, and this is not holomorphically trivial" refers to the divisor picture of Section 5.2.12: sections of $[D]$ are meromorphic functions with poles bounded by D, and a bundle of degree 0 other than $\mathcal{O}$ has none. We added: the explicit connecting map (integer ambiguity of logarithms), its de Rham form as a gauge potential, the winding-number computation on S^2, the partition-of-unity proof that $\mathcal{E}$ is fine, a table of $H^2(M;\mathbb{Z})$ with torsion, a rank-2 counterexample on S^5, $\mathrm{Pic}(\mathbb{CP}^n) = \mathbb{Z}$, the explicit family L_a on the torus, the lattice computation, and the identification $\mathrm{Pic}_0(\Sigma_p) = J(\Sigma_p)$.

5.3.6 Hermitian metrics and the Kähler condition

So far we have used almost no metric: divisors, line bundles, Serre duality and the Picard group are all defined by the complex structure alone. But to do analysis (to find harmonic representatives, to define adjoints and Laplacians, to write a sigma-model action) we need a metric, and on a complex manifold we want one that *respects* the complex structure. The question of this subsection is: *which Riemannian metrics are compatible with the complex structure, and what extra condition makes them really useful?* The answer to the second part is Nash's (5.29): the associated 2-form should be closed.

The complex structure as a matrix. A complex manifold has, at every point, an endomorphism J of the real tangent space with $J^2 = -1$: "multiplication by i". In a holomorphic coordinate $z = x + \mathrm{i}y$ on $\mathbb{C}$,

$$J\partial_x = \partial_y, \qquad J\partial_y = -\partial_x, \qquad J = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \text{ in the basis } (\partial_x, \partial_y),$$

a rotation by 90°. On $\mathbb{C}^n$ it is this block in each pair (x^k, y^k). Holomorphic changes of coordinates preserve J (their Jacobian is complex linear, which is exactly the statement that it commutes with J: the Cauchy–Riemann equations again). The complex vectors ∂_{z^k} are the $+\mathrm{i}$ eigenvectors of J and $\partial_{\bar z^k}$ the $-\mathrm{i}$ ones, which is why forms split into types.

Working definition 5.33 (Hermitian metric)

A Riemannian metric g on a complex manifold is **Hermitian** if J is an isometry: [J rotates each tangent vector by 90°, $J\partial_x = \partial_y$, and it must not change lengths or angles] $g(JX, JY) = g(X, Y)$ for all tangent vectors. In local holomorphic coordinates it is written (Nash's notation)

$$\mathrm{d}s^2 = g_{i\bar\jmath}\, \mathrm{d}z^i \otimes \mathrm{d}\bar z^j, \qquad g_{i\bar\jmath} = \overline{g_{j\bar\imath}}, \qquad (g_{i\bar\jmath}) \text{ positive definite},$$

[positive definite: $g_{i\bar\jmath} v^i \bar v^j > 0$ for every nonzero complex vector v] and its **associated 2-form** (Kähler form) is

$$\omega = \frac{\mathrm{i}}{2}\, g_{i\bar\jmath}\, \mathrm{d}z^i \wedge \mathrm{d}\bar z^j, \qquad \omega(X, Y) = g(JX, Y). \tag{5.58}$$

Operationally: a Hermitian metric is a positive Hermitian matrix of functions $g_{i\bar\jmath}(z, \bar z)$ in each chart, transforming like $\mathrm{d}z^i \otimes \mathrm{d}\bar z^j$ under holomorphic changes of coordinates. It has only n^2 real components instead of the $n(2n+1)$ of a general metric in real dimension $2n$.

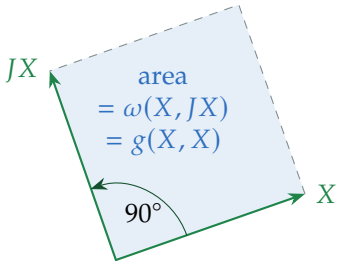
Let us see, in one complex dimension, how the three objects g, J, ω fit together. Take $\mathrm{d}s^2 = \lambda\, \mathrm{d}z \otimes \mathrm{d}\bar z$ with $\lambda > 0$ (a single positive function; every Hermitian metric on a Riemann surface is of this form in a local coordinate). Then

$$\begin{aligned} \lambda\, \mathrm{d}z \otimes \mathrm{d}\bar z &\overset{(1)}{=} \lambda\, (\mathrm{d}x + \mathrm{i}\mathrm{d}y) \otimes (\mathrm{d}x - \mathrm{i}\mathrm{d}y) \\ &\overset{(2)}{=} \lambda\, (\mathrm{d}x \otimes \mathrm{d}x + \mathrm{d}y \otimes \mathrm{d}y) - \mathrm{i}\,\lambda\, (\mathrm{d}x \otimes \mathrm{d}y - \mathrm{d}y \otimes \mathrm{d}x) \\ &\overset{(3)}{=} g - \mathrm{i}\,\omega, \qquad g = \lambda(\mathrm{d}x^2 + \mathrm{d}y^2), \quad \omega = \lambda\, \mathrm{d}x \wedge \mathrm{d}y. \end{aligned} \tag{5.59}$$

(1) $\mathrm{d}z = \mathrm{d}x + \mathrm{i}\mathrm{d}y$, $\mathrm{d}\bar z = \mathrm{d}x - \mathrm{i}\mathrm{d}y$.
(2) Multiply out; the cross terms are $-\mathrm{i}\,\mathrm{d}x \otimes \mathrm{d}y + \mathrm{i}\,\mathrm{d}y \otimes \mathrm{d}x$.

(3) The symmetric part is the Riemannian metric; the antisymmetric part is $dx \wedge dy = dx \otimes dy - dy \otimes dx$.

So *the real part of the Hermitian metric is the Riemannian metric, and minus the imaginary part is the 2-form* ω. Nash's formula for ω agrees: $\frac{i}{2}\lambda\, dz \wedge d\bar{z} = \frac{i}{2}\lambda(-2i)\, dx \wedge dy = \lambda\, dx \wedge dy$. And the formula $\omega(X,Y) = g(JX,Y)$ checks on the basis: $g(J\partial_x, \partial_y) = g(\partial_y, \partial_y) = \lambda = \omega(\partial_x, \partial_y)$. The metric g is conformal to the flat one: a Hermitian metric on a Riemann surface is the same thing as a conformal structure plus a choice of scale (Section 5.2.1).



J: rotate by 90° ("multiply by i")

g: lengths and angles, with $g(JX, JY) = g(X, Y)$

$\omega(X,Y) = g(JX,Y)$: oriented areas

any two of (g, J, ω) determine the third

Figure 5.33: The compatible triple on a single tangent plane. J rotates a vector by a right angle without changing its length. The 2-form ω measures the area of the square spanned by X and JX, which is $|X|^2$; so ω is never degenerate. A Hermitian metric is the Riemannian metric g seen through J; the Kähler condition is the extra requirement that the area form ω, assembled over the whole manifold, is closed.

Working definition 5.34 (Kähler manifold (Nash's (5.29)))

A complex manifold with a Hermitian metric is **Kähler** if the associated 2-form [$\omega(X,Y) = g(JX,Y)$, the area form built from g and J] is closed:

$$ds^2 = g_{i\bar{j}}\, dz^i \otimes d\bar{z}^j, \qquad \omega = \frac{i}{2} g_{i\bar{j}}\, dz^i \wedge d\bar{z}^j, \qquad d\omega = 0. \tag{5.60}$$

The metric is then a **Kähler metric**. *Operational test*: check $\partial_k g_{i\bar{j}} = \partial_i g_{k\bar{j}}$ for all i, j, k (derived next).

The Kähler condition in components. Since ω has type $(1,1)$, $d\omega = \partial\omega + \bar{\partial}\omega$ splits into a $(2,1)$ and a $(1,2)$ part, and each must vanish. Moreover ω is real ($\bar{\omega} = \omega$, because $g_{i\bar{j}}$ is Hermitian), so $\bar{\partial}\omega = \overline{\partial\omega}$ and it is enough to look at $\partial\omega$:

$$\partial\omega \overset{(1)}{=} \frac{i}{2}\, \partial_k g_{i\bar{j}}\, dz^k \wedge dz^i \wedge d\bar{z}^j \overset{(2)}{=} \frac{i}{4}\left(\partial_k g_{i\bar{j}} - \partial_i g_{k\bar{j}}\right) dz^k \wedge dz^i \wedge d\bar{z}^j.$$

(1) ∂ differentiates the coefficient in the holomorphic directions.

(2) $dz^k \wedge dz^i$ is antisymmetric in k, i, so only the antisymmetric part of the coefficient survives; write it out.

The forms $dz^k \wedge dz^i \wedge d\bar{z}^j$ with $k < i$ are independent, so

$$d\omega = 0 \quad \Longleftrightarrow \quad \partial_k g_{i\bar{j}} = \partial_i g_{k\bar{j}} \quad \text{for all } i, j, k. \tag{5.61}$$

This is the integrability condition for $g_{i\bar{j}}$ to be a mixed second derivative:

Key idea: Kähler potential

Locally, a metric is Kähler if and only if there is a real function K, the **Kähler potential**, with

$$g_{i\bar{j}} = \partial_i \partial_{\bar{j}} K, \qquad \omega = \frac{\mathrm{i}}{2}\,\partial\bar{\partial} K.$$

K is determined up to $K \mapsto K + f + \bar{f}$ with f holomorphic (these are killed by $\partial\bar{\partial}$). A Kähler metric in complex dimension n is thus described by *one* real function, instead of n^2.

Why. If $g_{i\bar{j}} = \partial_i \partial_{\bar{j}} K$ then $\partial_k g_{i\bar{j}} = \partial_k \partial_i \partial_{\bar{j}} K$ is symmetric in k, i, so (5.61) holds. Conversely, suppose $\mathrm{d}\omega = 0$ on a ball. By the ordinary Poincaré lemma $\omega = \mathrm{d}\alpha$ with α a real 1-form; split $\alpha = \alpha^{1,0} + \alpha^{0,1}$ with $\alpha^{1,0} = \overline{\alpha^{0,1}}$. Comparing types in $\omega = \partial\alpha^{1,0} + (\bar{\partial}\alpha^{1,0} + \partial\alpha^{0,1}) + \bar{\partial}\alpha^{0,1}$, the $(0,2)$ part gives $\bar{\partial}\alpha^{0,1} = 0$, so by the $\bar{\partial}$-Poincaré lemma (Example 5.41) $\alpha^{0,1} = \bar{\partial} f$ for some complex function f, and then $\alpha^{1,0} = \partial\bar{f}$. The $(1,1)$ part is

$$\omega \overset{(1)}{=} \bar{\partial}\partial\bar{f} + \partial\bar{\partial} f \overset{(2)}{=} \partial\bar{\partial}\big(f - \bar{f}\big) \overset{(3)}{=} \frac{\mathrm{i}}{2}\,\partial\bar{\partial}\big(4\,\mathrm{Im}\, f\big),$$

(1) Substitute $\alpha^{1,0} = \partial\bar{f}$ and $\alpha^{0,1} = \bar{\partial} f$.
(2) $\bar{\partial}\partial = -\partial\bar{\partial}$ (5.36).
(3) $f - \bar{f} = 2\mathrm{i}\,\mathrm{Im}\, f$ and $2\mathrm{i} = \frac{\mathrm{i}}{2}\cdot 4$.

so $K = 4\,\mathrm{Im}\, f$ works. (The $(2,0)$ part $\partial\alpha^{1,0} = \partial\partial\bar{f} = 0$ is automatic.)

Kähler normal coordinates. Nash states that a Hermitian metric is Kähler if and only if around every point there are holomorphic coordinates in which $g_{i\bar{j}} = \delta_{ij} + h_{ij}$ with h_{ij} of order 2: the metric agrees with the flat one *to first order*. In Riemannian geometry this is always possible with *real* coordinates (Riemann normal coordinates); the point is that for a Kähler metric it can be done with *holomorphic* ones. Let us check it. Put the point at $z = 0$ and make a linear change so that $g_{i\bar{j}}(0) = \delta_{ij}$. By Hermiticity the first-order Taylor expansion has the form

$$g_{i\bar{j}}(z) = \delta_{ij} + a_{ijk}\, z^k + \overline{a_{jik}}\,\bar{z}^k + O(|z|^2),$$

and the Kähler condition (5.61) at 0 says $a_{ijk} = a_{kji}$. Try new holomorphic coordinates w with $z^i = w^i + \tfrac{1}{2} c^i_{kl} w^k w^l$, $c^i_{kl} = c^i_{lk}$, so that $\mathrm{d}z^i = \mathrm{d}w^i + c^i_{kl} w^l\,\mathrm{d}w^k$. To first order in w,

$$\begin{aligned} g_{i\bar{j}}\,\mathrm{d}z^i \otimes \mathrm{d}\bar{z}^j &\overset{(1)}{=} \big(\delta_{ij} + a_{ijm} w^m + \overline{a_{jim}}\,\bar{w}^m\big)\big(\mathrm{d}w^i + c^i_{kl} w^l \mathrm{d}w^k\big) \otimes \big(\mathrm{d}\bar{w}^j + \overline{c^j_{kl}}\,\bar{w}^l \mathrm{d}\bar{w}^k\big) \\ &\overset{(2)}{=} \Big[\delta_{ij} + \big(a_{ijm} + c^j_{im}\big) w^m + \big(\overline{a_{jim}} + \overline{c^i_{jm}}\big)\bar{w}^m\Big]\mathrm{d}w^i \otimes \mathrm{d}\bar{w}^j + O(|w|^2). \end{aligned}$$

(1) Substitute the expansion of g and of $\mathrm{d}z^i$; to this order $z^m = w^m$ in the coefficient.
(2) Keep terms of order ≤ 1; in the cross term $\delta_{ij} c^i_{kl} w^l\,\mathrm{d}w^k \otimes \mathrm{d}\bar{w}^j$ rename $k \to i$, $i \to j$, $l \to m$, and similarly for its conjugate.

Choose $c^j_{im} = -a_{ijm}$. This is allowed only if the right side is symmetric in i, m, i.e. $a_{ijm} = a_{mji}$: *exactly the Kähler condition*. With this choice both first-order brackets vanish (the second is the conjugate of the first with $i \leftrightarrow j$), and $g'_{i\bar{j}} = \delta_{ij} + O(|w|^2)$. Conversely, $\mathrm{d}\omega$ involves only first derivatives of g, so if they vanish at a point in some holomorphic coordinates, $\mathrm{d}\omega = 0$ there. So:

Key idea: Kähler $\iff$ flat to first order in holomorphic coordinates

A Hermitian metric is Kähler if and only if at each point there are holomorphic coordinates with $g_{i\bar{j}} = \delta_{ij} + O(|z|^2)$. Consequently, any identity that involves the metric and at most its first derivatives, and that holds on flat $\mathbb{C}^n$, holds on every Kähler manifold.

The second sentence is the working principle behind all of Kähler geometry, and we shall use it for the Laplacians below. Geometrically it says that the Levi-Civita connection preserves J ($\nabla J = 0$), so parallel transport commutes with "multiplication by i" and the holonomy lies in $\mathrm{U}(n) \subset \mathrm{SO}(2n)$.

Kähler manifolds are symplectic. ω is closed, and it is nondegenerate: in coordinates with $g_{i\bar{j}}(x) = \delta_{ij}$ at a point, $\omega = \sum_k \mathrm{d}x^k \wedge \mathrm{d}y^k$ there, and

$$\omega^n \overset{(1)}{=} \Big(\sum_{k=1}^{n} \mathrm{d}x^k \wedge \mathrm{d}y^k\Big)^n \overset{(2)}{=} n!\, \mathrm{d}x^1 \wedge \mathrm{d}y^1 \wedge \cdots \wedge \mathrm{d}x^n \wedge \mathrm{d}y^n \overset{(3)}{=} n!\, \mathrm{vol}_g. \tag{5.62}$$

(1) ω at the point, from (5.59) with $\lambda = 1$ in each complex direction.
(2) The 2-forms $\mathrm{d}x^k \wedge \mathrm{d}y^k$ commute and square to zero, so only products of n distinct ones survive, and there are $n!$ orderings of them.
(3) At that point g is the Euclidean metric in the coordinates (x^k, y^k), whose volume form is the product of all the differentials.

A closed nondegenerate 2-form is a **symplectic form**, so Kähler manifolds are symplectic manifolds, as Nash notes: phase spaces, in physics language. Here is the first topological consequence, straight from Stokes.

Worked example 5.55: The powers of ω are never exact on a compact Kähler manifold

Let M be compact Kähler of complex dimension n, and $1 \le k \le n$. Suppose $\omega^k = \mathrm{d}\beta$. Then

$$n!\,\mathrm{Vol}(M) \overset{(1)}{=} \int_M \omega^n \overset{(2)}{=} \int_M \mathrm{d}\beta \wedge \omega^{n-k} \overset{(3)}{=} \int_M \mathrm{d}\big(\beta \wedge \omega^{n-k}\big) \overset{(4)}{=} \int_{\partial M} \beta \wedge \omega^{n-k} \overset{(5)}{=} 0,$$

(1) Integrate (5.62).
(2) $\omega^n = \omega^k \wedge \omega^{n-k}$ and the assumption.
(3) Leibniz rule: $\mathrm{d}(\beta \wedge \omega^{n-k}) = \mathrm{d}\beta \wedge \omega^{n-k} \pm \beta \wedge \mathrm{d}(\omega^{n-k})$, and $\mathrm{d}\omega = 0$.
(4) Stokes.
(5) M is closed.

a contradiction, since the volume is positive. So $[\omega^k] \neq 0$ in $H^{2k}(M;\mathbb{R})$ and $b_{2k}(M) \ge 1$ for $0 \le k \le n$. In particular $b_2 \ge 1$: *a compact Kähler manifold always has a nonzero second Betti number*. This is item (ii) of Nash's list on p. 148, and it already rules out many complex manifolds (see the Hopf surface in Example 5.64).

Worked example 5.56: Nash's first two examples: flat tori and Riemann surfaces

Complex tori. On $\mathbb{C}^n$ the metric $g_{i\bar{j}} = \delta_{ij}$ has $\omega = \frac{\mathrm{i}}{2}\sum_k \mathrm{d}z^k \wedge \mathrm{d}\bar{z}^k = \sum_k \mathrm{d}x^k \wedge \mathrm{d}y^k$, with constant coefficients, so $\mathrm{d}\omega = 0$. Its Kähler potential is $K = \sum_k |z^k|^2$ (check: $\partial_i \partial_{\bar{j}} \sum_k z^k \bar{z}^k = \delta_{ij}$). The metric is invariant under translations, so it descends to every quotient $T = \mathbb{C}^n/\Lambda$ by a lattice $\Lambda \cong \mathbb{Z}^{2n}$ of translations: every complex torus is Kähler with a flat metric.
Riemann surfaces. On a complex curve ω is a 2-form on a real 2-manifold, so $\mathrm{d}\omega$ is a 3-form on a 2-manifold: zero. *Every* Hermitian metric $\lambda|\mathrm{d}z|^2$ on a Riemann surface is Kähler.

For instance the hyperbolic metric on the upper half plane $\mathbb{H} = \{y > 0\}$ has potential $K = -4\log y$:

$$\partial_z\partial_{\bar z}(-4\log y) \overset{(1)}{=} -4\,\partial_z\partial_{\bar z}\log(z-\bar z) \overset{(2)}{=} -4\,\partial_z\Big(\frac{-1}{z-\bar z}\Big) \overset{(3)}{=} -4\,\frac{1}{(z-\bar z)^2} \overset{(4)}{=} \frac{1}{y^2},$$

(1) $y = (z-\bar z)/2\mathrm{i}$, and the constant $\log(2\mathrm{i})$ is killed by the derivatives.
(2) $\partial_{\bar z}(z-\bar z) = -1$.
(3) $\partial_z(z-\bar z)^{-1} = -(z-\bar z)^{-2}$, and the two minus signs cancel.
(4) $(z-\bar z)^2 = (2\mathrm{i}y)^2 = -4y^2$.

so $\mathrm{d}s^2 = (\mathrm{d}x^2+\mathrm{d}y^2)/y^2$, the Poincaré metric of constant curvature -1. Every surface of genus $p \geq 2$ is a quotient of $\mathbb{H}$ by a group of isometries (uniformisation, part 5b), so it inherits this Kähler metric.

Watch out: Nash's $\mathbb{C}^n/\mathbb{Z}^n$

Nash writes the flat torus as "$\mathbb{C}^n/\mathbb{Z}^n$". For a compact quotient one needs a lattice of *real* rank $2n$, i.e. $\mathbb{C}^n/\Lambda$ with $\Lambda \cong \mathbb{Z}^{2n}$ spanning $\mathbb{C}^n$ over $\mathbb{R}$ (for $n=1$, $\Lambda = \mathbb{Z}+\tau\mathbb{Z}$). The quotient $\mathbb{C}^n/\mathbb{Z}^n$ by the integer points of $\mathbb{R}^n \subset \mathbb{C}^n$ is $(\mathbb{C}^*)^n$, which is not compact. Presumably "$\mathbb{Z}^n$" is shorthand for a lattice.

5.3.7 The Fubini–Study metric on $\mathbb{CP}^n$

The most important example, and the one that makes every projective variety Kähler, is $\mathbb{CP}^n$ with the Fubini–Study metric. Use homogeneous coordinates $[Z_0 : \cdots : Z_n]$ and, on the chart $U_0 = \{Z_0 \neq 0\}$, the affine coordinates $z^i = Z_i/Z_0$, $i = 1,\dots,n$ (Section 5.1.6). Write $|z|^2 = \sum_{k=1}^n z^k\bar z^k$.

Working definition 5.35 (Fubini–Study metric (Nash's (5.30)))

On U_0 the **Fubini–Study metric** is the Kähler metric with potential $K = \log(1+|z|^2)$ [one real function K with $g_{i\bar\jmath} = \partial_i\partial_{\bar\jmath}K$]:

$$g_{i\bar\jmath} = \partial_i\partial_{\bar\jmath}\log\big(1+|z|^2\big) = \frac{\delta_{ij}\big(1+|z|^2\big) - \bar z^i z^j}{\big(1+|z|^2\big)^2}, \qquad \omega = \frac{\mathrm{i}}{2}\,\partial\bar\partial\log\big(1+|z|^2\big). \tag{5.63}$$

In homogeneous coordinates, $\omega = \frac{\mathrm{i}}{2}\partial\bar\partial\log|Z|^2$, with $|Z|^2 = \sum_{a=0}^n |Z_a|^2$ [this is unchanged by $Z \mapsto \lambda Z$, because $\partial\bar\partial$ kills $\log|\lambda|^2$. So ω is defined on all of $\mathbb{CP}^n$].

Computing $g_{i\bar\jmath}$. Two derivatives of the potential:

$$\partial_i\partial_{\bar\jmath}\log\big(1+|z|^2\big) \overset{(1)}{=} \partial_i\Big(\frac{z^j}{1+|z|^2}\Big) \overset{(2)}{=} \frac{\delta_{ij}}{1+|z|^2} - \frac{z^j\,\bar z^i}{\big(1+|z|^2\big)^2} \overset{(3)}{=} \frac{\delta_{ij}\big(1+|z|^2\big) - \bar z^i z^j}{\big(1+|z|^2\big)^2}.$$

(1) $\partial_{\bar\jmath}|z|^2 = \partial_{\bar\jmath}\sum_k z^k\bar z^k = z^j$.
(2) Quotient rule, with $\partial_i z^j = \delta_{ij}$ and $\partial_i|z|^2 = \bar z^i$.
(3) Common denominator.

It is Hermitian: $\overline{g_{j\bar\imath}} = \big(\delta_{ji}(1+|z|^2) - z^j\bar z^i\big)/(1+|z|^2)^2 = g_{i\bar\jmath}$. It is closed, being $\frac{\mathrm{i}}{2}\partial\bar\partial$ of a function ($\mathrm{d}\partial\bar\partial = (\partial+\bar\partial)\partial\bar\partial = 0$ by (5.36)); this is Nash's "it is immediate that the form ω is closed".

It is positive definite. Regard g as the matrix $G = \big[(1+|z|^2)\mathbb{1} - \bar z\, z^T\big]/(1+|z|^2)^2$, where $\bar z\, z^T$ has entries $\bar z^i z^j$. It acts on a vector $v \in \mathbb{C}^n$ by $\bar z\, z^T v = \bar z\,(z^T v)$. Two kinds of eigenvectors:

$$v = \bar z: \quad G\bar z \overset{(1)}{=} \frac{(1+|z|^2)\bar z - \bar z\,|z|^2}{(1+|z|^2)^2} = \frac{1}{(1+|z|^2)^2}\,\bar z,$$
$$z^T v = 0: \quad Gv \overset{(2)}{=} \frac{1}{1+|z|^2}\,v.$$

(1) $z^T\bar z = \sum_k z^k\bar z^k = |z|^2$.
(2) The rank-one term annihilates v.

The eigenvalues $1/(1+|z|^2)^2$ (once, the "radial" direction) and $1/(1+|z|^2)$ ($n-1$ times, the "angular" directions) are positive. They decrease as $|z|\to\infty$, which is how a metric on the noncompact chart $\mathbb{C}^n$ manages to have finite total volume.

It is well defined on all of $\mathbb{CP}^n$. On $U_1 = \{Z_1 \neq 0\}$ use the same formula with Z_1 in place of Z_0. On the overlap the two potentials differ by

$$K_0 - K_1 \overset{(1)}{=} \log\frac{|Z|^2}{|Z_0|^2} - \log\frac{|Z|^2}{|Z_1|^2} \overset{(2)}{=} \log\Big|\frac{Z_1}{Z_0}\Big|^2 \overset{(3)}{=} \log w + \log\bar w, \qquad w = \frac{Z_1}{Z_0},$$

(1) $1+|z|^2 = \sum_a |Z_a|^2/|Z_0|^2$ on U_0, and similarly on U_1.
(2) Subtract the logarithms; $|Z|^2$ cancels.
(3) w is holomorphic and nowhere zero on $U_0\cap U_1$, so it has local logarithms.

which is (locally) a holomorphic plus an antiholomorphic function, killed by $\partial\bar\partial$. So the local forms ω agree on overlaps: ω is a global Kähler form. The potential itself is not global (no nonconstant real function on a compact complex manifold can be a Kähler potential: at its maximum $\partial_i\partial_{\bar j}K$ would be negative semidefinite).

It is homogeneous. The unitary group $\mathrm{U}(n+1)$ acts on $\mathbb{CP}^n$ by $[Z]\mapsto[UZ]$ and preserves $|Z|^2$, hence ω. It acts transitively (any unit vector can be rotated to any other). So the Fubini–Study metric looks the same at every point, and it is enough to understand it at the origin $z=0$ of U_0. There,

$$g_{i\bar j} = \delta_{ij}\big(1-|z|^2\big) - \bar z^i z^j + O(|z|^4), \tag{5.64}$$

from $(1+|z|^2)^{-1} = 1-|z|^2+\dots$ and $(1+|z|^2)^{-2} = 1-2|z|^2+\dots$. There is no first-order term: the affine coordinates are Kähler normal coordinates at the origin, exactly as Nash remarks ("h_{ij} is of order 2 in the coordinates z_i").

Watch out: typos in Nash's (5.30)

Nash's display (5.30) has three slips. (1) The potential is $\log(1+|z_1|^2+\cdots+|z_n|^2)$, not $\log(1+z_1^2+\cdots+z_n^2)$; the latter is not real and not even defined everywhere. (2) The factor $\frac{\mathrm{i}}{2}$ belongs in ω only; in $\mathrm{d}s^2 = g_{i\bar j}\mathrm{d}z^i\otimes\mathrm{d}\bar z^j$ and in $g_{i\bar j}$ itself there is no $\frac{\mathrm{i}}{2}$ (a metric has to be real and positive on the diagonal). (3) With $\mathrm{d}s^2 = g_{i\bar j}\mathrm{d}z^i\otimes\mathrm{d}\bar z^j$, the numerator is $\delta_{ij}(1+|z|^2) - \bar z_i z_j$; Nash's $z_i\bar z_j$ is its transpose (the complex conjugate matrix), which amounts to swapping the roles of $\mathrm{d}z$ and $\mathrm{d}\bar z$. The last line, $\omega = \frac{\mathrm{i}}{2}\partial\bar\partial\log(1+|z|^2)$, is correct as printed, and it is the formula to remember.

Worked example 5.57: The Fubini–Study metric on $\mathbb{CP}^1$ is the round sphere of radius $\frac{1}{2}$

For $n = 1$, (5.63) reads

$$\mathrm{d}s^2 = \frac{\mathrm{d}z\,\mathrm{d}\bar{z}}{(1+|z|^2)^2} = \frac{\mathrm{d}x^2+\mathrm{d}y^2}{(1+x^2+y^2)^2}, \qquad \omega = \frac{\mathrm{i}}{2}\frac{\mathrm{d}z\wedge\mathrm{d}\bar{z}}{(1+|z|^2)^2} = \frac{\mathrm{d}x\wedge\mathrm{d}y}{(1+x^2+y^2)^2},$$

(the 1×1 matrix has $g_{1\bar{1}} = ((1+|z|^2)-|z|^2)/(1+|z|^2)^2$). Which surface is this? Substitute the stereographic coordinate $z = \tan(\theta/2)\,e^{\mathrm{i}\phi}$, with $\theta \in [0,\pi]$ the polar angle from the point $z = 0$:

$$\frac{|\mathrm{d}z|^2}{(1+|z|^2)^2} \overset{(1)}{=} \frac{\frac{1}{4}\sec^4(\theta/2)\,\mathrm{d}\theta^2 + \tan^2(\theta/2)\,\mathrm{d}\phi^2}{\sec^4(\theta/2)}$$
$$\overset{(2)}{=} \tfrac{1}{4}\,\mathrm{d}\theta^2 + \sin^2(\theta/2)\cos^2(\theta/2)\,\mathrm{d}\phi^2 \overset{(3)}{=} \tfrac{1}{4}\big(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2\big).$$

(1) $\mathrm{d}z = e^{\mathrm{i}\phi}\big(\frac{1}{2}\sec^2(\theta/2)\,\mathrm{d}\theta + \mathrm{i}\tan(\theta/2)\,\mathrm{d}\phi\big)$, whose two terms are orthogonal (one real, one imaginary, times the same phase); and $1+\tan^2 = \sec^2$.
(2) Divide; $\tan^2\cos^4 = \sin^2\cos^2$.
(3) $2\sin(\theta/2)\cos(\theta/2) = \sin\theta$.

This is the round metric of a sphere of radius $R = \frac{1}{2}$ ($R^2(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2)$). Three checks.

- *Area.* $4\pi R^2 = \pi$, matching $\int_{\mathbb{CP}^1}\omega = \pi$ computed in Example 5.17.
- *Curvature.* For a conformal metric $\lambda(\mathrm{d}x^2+\mathrm{d}y^2)$ the Gaussian curvature is $K_G = -\frac{1}{2\lambda}\Delta\log\lambda$ with $\Delta = \partial_x^2+\partial_y^2 = 4\partial_z\partial_{\bar{z}}$. Here

$$K_G \overset{(1)}{=} -\frac{(1+|z|^2)^2}{2}\cdot 4\,\partial_z\partial_{\bar{z}}\big(-2\log(1+|z|^2)\big) \overset{(2)}{=} -\frac{(1+|z|^2)^2}{2}\cdot 4\cdot\frac{-2}{(1+|z|^2)^2} = 4 = \frac{1}{R^2}.$$

  (1) $\lambda = (1+|z|^2)^{-2}$, so $1/\lambda = (1+|z|^2)^2$ and $\log\lambda = -2\log(1+|z|^2)$.
  (2) $\partial_z\partial_{\bar{z}}\log(1+|z|^2) = (1+|z|^2)^{-2}$, from (5.24).

- *Gauss–Bonnet.* $\int K_G\,\mathrm{d}A = 4\cdot\pi = 4\pi = 2\pi\chi(S^2)$. ✓

Finally compare with the curvature of $\mathcal{O}(1)$ with its standard metric (Example 5.33): $c_1(\mathcal{O}(1)) = -\frac{\mathrm{i}}{2\pi}\partial\bar{\partial}\log(1+|z|^2)^{-1} = \frac{1}{\pi}\,\omega$. So

$$\frac{\omega_{FS}}{\pi} = c_1\big(\mathcal{O}(1)\big)\,:$$

the Fubini–Study form is (up to π) the field strength of the unit monopole, and its class is integral. That is why $\mathbb{CP}^n$ passes Kodaira's test (Section 5.1.10) with $\omega = \omega_{FS}/\pi$.

Physical picture: Fubini–Study in quantum mechanics

$\mathbb{CP}^n$ is the space of *pure states* of an $(n+1)$-level quantum system: a state is a ray $[\psi]$ in $\mathbb{C}^{n+1}$. The Fubini–Study line element is the natural distance between rays:

$$\mathrm{d}s^2 = \frac{\langle\mathrm{d}\psi|\mathrm{d}\psi\rangle}{\langle\psi|\psi\rangle} - \frac{|\langle\psi|\mathrm{d}\psi\rangle|^2}{\langle\psi|\psi\rangle^2},$$

the part of $\mathrm{d}\psi$ orthogonal to ψ (the component along ψ only changes the phase or normalisation, which is not physical). For $\psi = (1,z)$ this gives $\big(|\mathrm{d}z|^2(1+|z|^2) - |\bar{z}\,\mathrm{d}z|^2\big)/(1+$

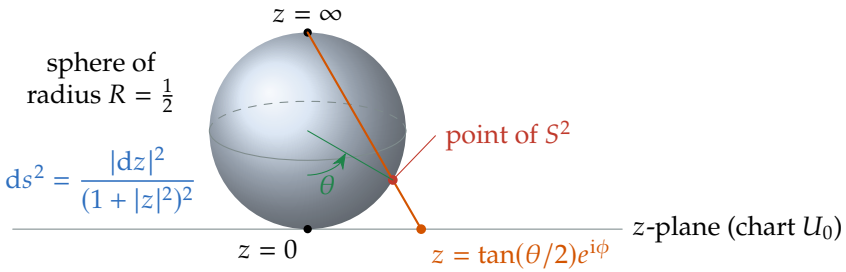


Figure 5.34: The Fubini–Study metric on $\mathbb{CP}^1$ is the round metric on a sphere of radius $\frac{1}{2}$, written in the stereographic coordinate z. Rays from the point $z = \infty$ (top) identify the sphere minus that point with the z-plane; a point at polar angle θ from the bottom lands at $|z| = \tan(\theta/2)$. Far out in the plane the conformal factor $(1 + |z|^2)^{-2}$ is tiny, so the whole infinite plane has finite area π. (The picture is drawn with the sphere enlarged; only the angles matter for the projection.)

$|z|^2)^2 = |dz|^2/(1 + |z|^2)^2$, which is (5.63). For a spin-$\frac{1}{2}$ the ray is a point of the Bloch sphere, and ω is (half) the *Berry curvature*: the Berry phase around a loop on the Bloch sphere is minus half the enclosed solid angle, and 2ω integrates to 2π, the Chern number 1 of the monopole bundle $\mathcal{O}(1)$ (or $\mathcal{O}(-1)$, depending on the convention for the phase). The $\mathbb{CP}^n$ sigma models of Chapter 8 have this metric on their target space.

5.3.8 Complex submanifolds: projective varieties are Kähler

Nash's next observation is short and very powerful. Let $\iota : M \hookrightarrow N$ be a complex submanifold of a Kähler manifold (N, g_N, ω_N): a submanifold whose tangent spaces are J-invariant (locally the zero set of holomorphic functions with independent differentials, Section 5.1.9). Give M the induced metric $g_M = \iota^* g_N$. Then:

- g_M is Hermitian, because J preserves TM and is an isometry of g_N.
- Its 2-form is the restriction of ω_N: for X, Y tangent to M,

$$\omega_M(X,Y) \overset{(1)}{=} g_M(JX,Y) \overset{(2)}{=} g_N(JX,Y) \overset{(3)}{=} \omega_N(X,Y), \qquad \text{so } \omega_M = \iota^*\omega_N.$$

  (1) Definition (5.58) on M.
  (2) JX is again tangent to M, and g_M is g_N on such vectors.
  (3) Definition (5.58) on N.

- It is closed: $d\omega_M = d\iota^*\omega_N = \iota^* d\omega_N = 0$, since pull-back commutes with d (Chapter T1).

(Nash's text has "N is also Kähler" where he means M.) Combining with the Fubini–Study metric:

Key idea: projective ⇒ Kähler

Every complex submanifold of $\mathbb{CP}^n$, in particular every smooth projective variety, is a Kähler manifold, with the restriction of ω_{FS} as Kähler form. Its class $[\omega_{FS}/\pi]$ is integral, being c_1 of the restriction of $\mathcal{O}(1)$.

This is the converse direction of Kodaira's theorem (Section 5.1.10): an algebraic manifold carries a closed positive $(1,1)$-form with rational (indeed integral) class. Kodaira's theorem says that this property also characterises algebraic manifolds.

Worked example 5.58: The area of a complex curve is π times its degree

Take the conic $C = \{Z_0 Z_2 = Z_1^2\} \subset \mathbb{CP}^2$, parametrised by $t \mapsto [1 : t : t^2]$ (together with $[0 : 0 : 1]$ at $t = \infty$). Pull back the Fubini–Study potential: on U_0, $K = \log(1+|Z_1/Z_0|^2+|Z_2/Z_0|^2)$ becomes $K(t) = \log(1 + |t|^2 + |t|^4)$, a function of $r = |t|$ only. For any radial potential,

$$\int_{\mathbb{C}} \frac{\mathrm{i}}{2}\partial\bar\partial K \overset{(1)}{=} \int_{\mathbb{R}^2} \frac{\mathrm{i}}{2}\cdot\frac{\Delta K}{4}\cdot(-2\mathrm{i})\,\mathrm{d}x\,\mathrm{d}y \overset{(2)}{=} \frac{1}{4}\int_0^{2\pi}\int_0^{\infty}\frac{1}{r}\big(rK'\big)'\,r\,\mathrm{d}r\,\mathrm{d}\phi \overset{(3)}{=} \frac{\pi}{2}\Big[rK'(r)\Big]_0^{\infty}.$$

(1) $\partial\bar\partial K = \partial_t\partial_{\bar t}K\,\mathrm{d}t\wedge\mathrm{d}\bar t$ with $\partial_t\partial_{\bar t} = \frac{1}{4}\Delta$ and $\mathrm{d}t\wedge\mathrm{d}\bar t = -2\mathrm{i}\,\mathrm{d}x\wedge\mathrm{d}y$.

(2) The Laplacian of a radial function is $\frac{1}{r}(rK')'$; polar coordinates.

(3) Fundamental theorem of calculus in r, and $\int \mathrm{d}\phi = 2\pi$.

For the conic, $rK' = \dfrac{2r^2+4r^4}{1+r^2+r^4}$, which is 0 at $r = 0$ and tends to 4. So

$$\mathrm{Area}(C) = \frac{\pi}{2}\cdot 4 = 2\pi.$$

For $\mathbb{CP}^1$ itself ($K = \log(1 + r^2)$, $rK' \to 2$) the same formula gives π. In general, for the degree-d curve $t \mapsto [1 : t : \cdots : t^d]$, $rK' \to 2d$ and the area is πd. This is no accident: ω_{FS}/π is $c_1(\mathcal{O}(1))$, and $\int_C c_1(\mathcal{O}(1)|_C)$ is the degree of the divisor cut on C by a hyperplane, i.e. the number of intersection points of C with a line (Section 5.2.11, Section 5.1.8): 2 for a conic.

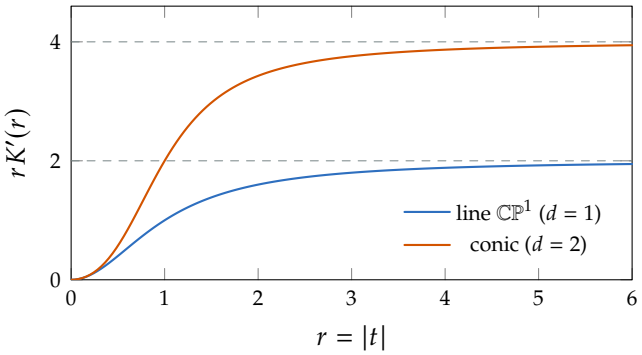

Figure 5.35: The area of a holomorphic curve in $\mathbb{CP}^n$ read off from its Kähler potential. For a radial potential the area is $\frac{\pi}{2}\lim_{r\to\infty} rK'(r)$. For a curve of degree d the potential grows like $2d\log r$, so $rK' \to 2d$ (dashed lines) and the area is πd. In sigma-model language: the action of a holomorphic map (an instanton) is its area, fixed by its topological degree.

Physical picture: holomorphic curves minimise area: BPS bounds

The formula "area = $\pi\times$degree" is a special case of a general fact (Wirtinger's inequality): on a Kähler manifold, $\mathrm{Area}(S) \geq \int_S \omega$ for every surface S, with equality exactly for complex curves. Since $\int_S \omega$ depends only on the homology class of S (ω is closed, Stokes), complex curves are area minimising in their class. In the $\mathbb{CP}^n$ sigma model the action of a map $\Sigma \to \mathbb{CP}^n$ is bounded below by $\int \omega$, a topological charge, and the bound is saturated by holomorphic maps: these are the sigma-model instantons, the two-dimensional analogue of self-dual Yang–Mills fields (Chapter 8).

5.3.9 Hodge theory on Kähler manifolds

We now reach the reason Kähler manifolds are so important: their cohomology splits by type, and the splitting forces strong restrictions on their topology. Recall the question we postponed in Section 5.2.16 and Section 5.3.3: why does a surface of genus p have exactly p independent holomorphic 1-forms? We answer it here.

Three Laplacians. On a compact Hermitian manifold we have an L^2 inner product on forms, $\langle \alpha, \beta \rangle = \int_M \alpha \wedge \star\bar{\beta}$ (the pointwise inner product integrated against the volume form), and hence formal adjoints d^*, ∂^*, $\bar{\partial}^*$, defined by $\langle \mathrm{d}\alpha, \beta \rangle = \langle \alpha, \mathrm{d}^*\beta \rangle$ and so on. They lower the degree: $\bar{\partial}^* : A^{p,q} \to A^{p,q-1}$. From each operator we build a Laplacian, Nash's (5.31):

$$\Delta_d = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}, \qquad \Delta_\partial = \partial\partial^* + \partial^*\partial, \qquad \Delta_{\bar{\partial}} = \bar{\partial}\bar{\partial}^* + \bar{\partial}^*\bar{\partial}. \tag{5.65}$$

$\Delta_{\bar{\partial}}$ preserves the type (p, q), while Δ_d in general mixes types. The Hodge theorem (Chapter 2, Chapter 4) says that each Laplacian is elliptic and each cohomology class has a unique harmonic representative:

$$H^k_{\mathrm{dR}}(M; \mathbb{C}) \cong \{\alpha \in A^k : \Delta_d \alpha = 0\}, \qquad H^{p,q}_{\bar{\partial}}(M) \cong \{\alpha \in A^{p,q} : \Delta_{\bar{\partial}} \alpha = 0\}.$$

Operationally, $\Delta\alpha = 0$ is equivalent to the pair of first-order equations $\mathrm{d}\alpha = 0 = \mathrm{d}^*\alpha$ (resp. $\bar{\partial}\alpha = 0 = \bar{\partial}^*\alpha$), because $\langle \Delta\alpha, \alpha \rangle = \|\mathrm{d}\alpha\|^2 + \|\mathrm{d}^*\alpha\|^2$.

In words: a harmonic form is the "most relaxed" representative of its class. Among all closed forms $h + \mathrm{d}\alpha$ in a class, the harmonic one h has the smallest L^2 norm, because $\|h + \mathrm{d}\alpha\|^2 = \|h\|^2 + \|\mathrm{d}\alpha\|^2$ (the cross term is $\langle h, \mathrm{d}\alpha \rangle = \langle \mathrm{d}^* h, \alpha \rangle = 0$). If the form is a magnetic field, the norm is its energy, and the harmonic field is the least-energy field with the given fluxes.

Hodge decomposition at work: Maxwell and Proca

Before refining the Hodge theorem with the complex structure, we ask what the plain (de Rham) version *does* for a physicist. The test case is the simplest gauge theory: Maxwell's equations in the language of forms (Chapter T1), and their massive cousin, the Proca equation. The splitting of forms into three orthogonal pieces will sort the field into gauge, physical and topological parts. It will also show a striking difference: a massless photon can carry topological flux, and a massive one cannot.

The three operators. We use the conventions of Chapter T1. On an oriented n-manifold whose metric has s minus signs, the exterior derivative d raises the degree by one, and the **codifferential** (the adjoint d^* of the previous paragraph) lowers it:

$$\delta = \mathrm{d}^* = (-1)^{n(k+1)+1+s} \star \mathrm{d} \star \quad \text{on } k\text{-forms}, \qquad \Delta = \mathrm{d}\delta + \delta\mathrm{d}. \tag{5.66}$$

The sign is fixed so that $\langle \mathrm{d}\alpha, \beta \rangle = \langle \alpha, \delta\beta \rangle$. Two special cases are worth remembering. On 1-forms in flat Euclidean space δ is minus the divergence, $\delta(A_j \mathrm{d}x^j) = -\partial_j A_j$, so $\Delta = -\nabla^2$ is a *positive* operator. In Minkowski space with $\eta = \mathrm{diag}(-1, +1, +1, +1)$, $\delta = +\star\mathrm{d}\star$ in every degree, and Δ acts on Cartesian components as $\partial_t^2 - \nabla^2$, the wave operator. We write A^k for the smooth k-forms, as above. (The letter Ω^p is taken in this chapter by the sheaf of holomorphic p-forms.)

Three algebraic facts do all the work below: $\mathrm{d}^2 = 0$, $\delta^2 = 0$, and Δ commutes with d. The second holds because $\delta^2 = \pm \star \mathrm{d} \star \star \mathrm{d} \star = \pm \star \mathrm{d}\mathrm{d} \star = 0$ (the middle $\star\star$ is a sign). The third is a two-line check:

$$\mathrm{d}\Delta \overset{(1)}{=} \mathrm{d}\mathrm{d}\delta + \mathrm{d}\delta\mathrm{d} \overset{(2)}{=} \mathrm{d}\delta\mathrm{d} \overset{(3)}{=} \mathrm{d}\delta\mathrm{d} + \delta\mathrm{d}\mathrm{d} \overset{(4)}{=} \Delta\mathrm{d}.$$

(1) Definition (5.66) of Δ.
(2) $\mathrm{dd} = 0$.
(3) Add $\delta\mathrm{dd} = 0$.
(4) Definition of Δ again, now with d on the right.

In the same way $\delta\Delta = \delta\mathrm{d}\delta = \Delta\delta$. So Δ maps exact forms to exact forms ($\Delta\mathrm{d}\alpha = \mathrm{d}(\Delta\alpha)$) and co-exact forms to co-exact forms.

Working definition 5.36 (the Hodge decomposition, and how to compute it)

Let M be compact, oriented and Riemannian, without boundary. Every k-form splits uniquely as

$$\phi = \underbrace{\mathrm{d}\alpha}_{\text{exact}} + \underbrace{\delta\beta}_{\text{co-exact}} + \underbrace{\omega}_{\text{harmonic}}, \qquad A^k = \mathrm{d}A^{k-1} \oplus \delta A^{k+1} \oplus \mathcal{H}^k, \qquad \mathcal{H}^k = \operatorname{Ker}\Delta \cong H^k_{\mathrm{dR}}(M), \tag{5.67}$$

and the three pieces are mutually orthogonal [in the inner product $\int_M \phi \wedge \star\psi$. Co-exact means $\delta\beta$, with δ the adjoint of d. Harmonic means $\Delta\omega = 0$]. *Recipe:* expand ϕ in eigenforms of Δ. The zero modes make up ω. [the eigenforms with $\lambda = 0$, i.e. nonzero solutions of $\Delta\phi = 0$] An eigenform with $\Delta\phi_\lambda = \lambda\phi_\lambda$, $\lambda \neq 0$, splits as $\phi_\lambda = \lambda^{-1}\mathrm{d}(\delta\phi_\lambda) + \lambda^{-1}\delta(\mathrm{d}\phi_\lambda)$, which is just $\Delta = \mathrm{d}\delta + \delta\mathrm{d}$ divided by λ. *Tests:* ϕ is closed exactly when its co-exact part vanishes, and co-closed exactly when its exact part vanishes.

The orthogonality is one line each: $\langle \mathrm{d}\alpha, \delta\beta\rangle = \langle \mathrm{dd}\alpha, \beta\rangle = 0$, $\langle \mathrm{d}\alpha, \omega\rangle = \langle \alpha, \delta\omega\rangle = 0$ and $\langle \delta\beta, \omega\rangle = \langle \beta, \mathrm{d}\omega\rangle = 0$. The isomorphism with cohomology follows from the tests: closed forms are $\mathrm{d}A^{k-1} \oplus \mathcal{H}^k$, so "closed modulo exact" is $\mathcal{H}^k$. The existence of the splitting is the analytic content of the Hodge theorem (Chapter 2). Figure 5.36 shows the picture we will use.

Where this sits in the section. The three Laplacians of (5.65) each have their own version of (5.67). Below, the Kähler identity $\Delta_d = 2\Delta_{\bar\partial}$ says the harmonic sector $\mathcal{H}^k$ is the same for d and for $\bar\partial$, so it splits further by type into pieces of dimension $h_{p,q}$. And counting harmonic forms is counting zero modes, which is what Riemann–Roch (Section 5.3.3) and the index theorem (Chapter 4) do. Maxwell and Proca show what the three sectors mean physically.

Maxwell: one equation is free, the other is dynamics. Recall from Chapter T1 that the field strength is a 2-form F, the potential a 1-form A with $F = \mathrm{d}A$, and that Maxwell's equations are $\mathrm{d}F = 0$ and $\delta F = J$. The first is not an equation of motion at all:

$$\mathrm{d}F \overset{(1)}{=} \mathrm{dd}A \overset{(2)}{=} 0.$$

(1) $F = \mathrm{d}A$ on each patch where the potential is defined.
(2) $\mathrm{d}^2 = 0$. No field equation was used: this holds for every A.

We call this **kinematic**: it is built into the description of the field. The second equation, in vacuum $\delta F = 0$, is **dynamical**: it comes from varying the action. Put together,

$$\Delta F \overset{(1)}{=} \mathrm{d}(\delta F) + \delta(\mathrm{d}F) \overset{(2)}{=} \mathrm{d}(0) + \delta(0) \overset{(3)}{=} 0.$$

(1) Definition (5.66) of Δ.
(2) The vacuum equation $\delta F = 0$ and the Bianchi identity $\mathrm{d}F = 0$.
(3) d and δ are linear.

A source-free Maxwell field is harmonic. On a compact Riemannian (Euclidean) space the converse also holds, by the positivity argument of the previous paragraph. So the space of source-free

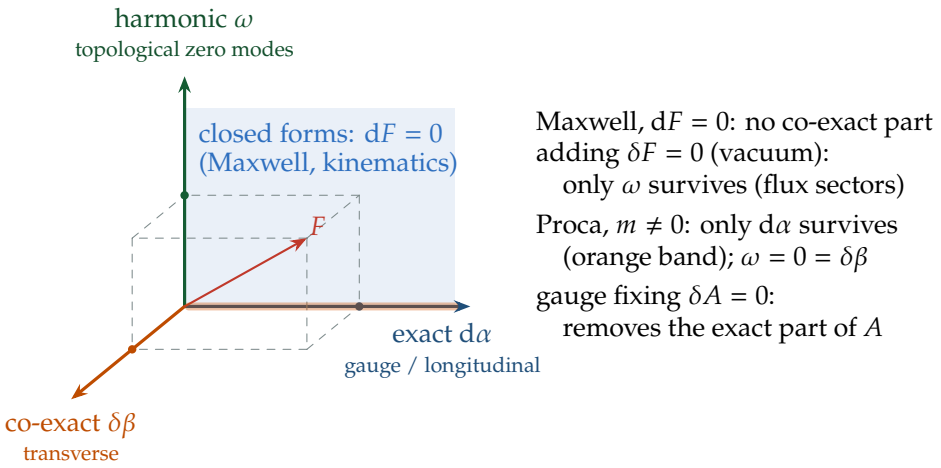

Figure 5.36: The three orthogonal sectors of $A^k(M)$, with the mathematician's names (exact, co-exact, harmonic) and the physicist's (gauge or longitudinal, transverse, topological). A form F (red) is the sum of its three projections (dots). The shaded plane is the space of closed forms: the Bianchi identity $dF = 0$ confines a Maxwell field to it, and the vacuum equation $\delta F = 0$ then leaves only the harmonic axis. The Proca equation instead confines F to the exact axis, so a massive field has no harmonic (topological) part.

fields is exactly $\mathcal{H}^2 \cong H^2_{\mathrm{dR}}(M)$: it is finite-dimensional, and its dimension b_2 is a topological invariant.

There is one subtlety, and it is the whole point. If A were a single global 1-form, $F = dA$ would be exact, its harmonic part would vanish, and the vacuum field would be zero. Harmonic fields exist because $F = dA$ holds only patch by patch: A is a connection on a line bundle that may be nontrivial (Section 5.3.4). Globally, only $dF = 0$ survives.

Flux is topological. For a closed surface Σ (no boundary) and a closed F, write $F = d\alpha + \omega$ (no co-exact part, by the test above). Then

$$\int_\Sigma F \overset{(1)}{=} \int_\Sigma d\alpha + \int_\Sigma \omega \overset{(2)}{=} \int_{\partial\Sigma} \alpha + \int_\Sigma \omega \overset{(3)}{=} \int_\Sigma \omega .$$

(1) The decomposition (5.67), with $\delta\beta = 0$ because F is closed.
(2) Stokes' theorem (Chapter T2); α is a global form, since the exact part is globally exact.
(3) $\partial\Sigma = \varnothing$.

So the flux through any closed surface sees only the harmonic part. It does not change when Σ is deformed (Stokes again, since $d\omega = 0$). With charged matter present it is also quantised, as the next example shows.

Worked example 5.59: Uniform flux on a torus: harmonic, but not exact

Let $T^2 = \mathbb{R}^2/(L_1\mathbb{Z} \times L_2\mathbb{Z})$ with the flat metric $dx^2 + dy^2$ and orientation $dx \wedge dy$. Take a constant magnetic field,

$$F = B\, dx \wedge dy, \qquad B \in \mathbb{R} \text{ constant}.$$

It is harmonic. Closedness is automatic (a 2-form in two dimensions). For co-closedness, (5.66) with $n = 2$, $k = 2$, $s = 0$ gives the sign $(-1)^{2\cdot 3+1} = -1$, and

$$\delta F \overset{(1)}{=} - \star\, d \star (B\, dx \wedge dy) \overset{(2)}{=} - \star\, dB \overset{(3)}{=} 0.$$

(1) The codifferential (5.66) on 2-forms in two Euclidean dimensions.

(2) $\star(\mathrm{d}x \wedge \mathrm{d}y) = 1$, since $\mathrm{d}x \wedge \mathrm{d}y$ is the volume form.
(3) B is constant.

It is not exact. If $F = \mathrm{d}A$ for a global 1-form A on T^2, then

$$BL_1L_2 \overset{(1)}{=} \int_{T^2} F \overset{(2)}{=} \int_{T^2} \mathrm{d}A \overset{(3)}{=} \int_{\partial T^2} A \overset{(4)}{=} 0,$$

(1) $\int_{T^2} \mathrm{d}x \wedge \mathrm{d}y$ is the area L_1L_2.
(2) The assumption $F = \mathrm{d}A$.
(3) Stokes' theorem.
(4) The torus has no boundary.

a contradiction when $B \neq 0$. So there is no global potential. There is a local one, $A = Bx\,\mathrm{d}y$ (indeed $\mathrm{d}A = B\,\mathrm{d}x \wedge \mathrm{d}y$), on the strip $0 \le x < L_1$. It fails to be periodic in x, but only by a gauge transformation:

$$A(x + L_1, y) - A(x, y) \overset{(1)}{=} B(x + L_1)\,\mathrm{d}y - Bx\,\mathrm{d}y \overset{(2)}{=} \mathrm{d}\lambda, \qquad \lambda(y) = BL_1\,y.$$

(1) Substitute into $A = Bx\,\mathrm{d}y$.
(2) $BL_1\,\mathrm{d}y = \mathrm{d}(BL_1y)$.

Flux quantisation. A particle of charge e has wavefunction ψ with $D\psi = (\mathrm{d} - \mathrm{i}eA)\psi$ (units $\hbar = 1$), and a gauge transformation $A \to A + \mathrm{d}\lambda$ acts by $\psi \to e^{\mathrm{i}e\lambda}\psi$. So the gluing across $x \sim x + L_1$ is the transition function $g(y) = e^{\mathrm{i}eBL_1y}$. It must be a well-defined function on the circle $y \sim y + L_2$:

$$1 \overset{(1)}{=} \frac{g(y + L_2)}{g(y)} \overset{(2)}{=} e^{\mathrm{i}eBL_1L_2} \quad \Longrightarrow \quad e\,\Phi = e\,BL_1L_2 \in 2\pi\mathbb{Z}.$$

(1) Single-valuedness of g on the y-circle.
(2) Substitute $g(y) = e^{\mathrm{i}eBL_1y}$.

So $\Phi = 2\pi N/e$: the flux through the torus is an integer number N of flux quanta, and N is the degree (first Chern class) of the line bundle, $N = \frac{e}{2\pi}\int_{T^2} F$ (Section 5.2.11). This is the setting of the lowest Landau level on the torus (Section 5.3.3): the N theta functions of Example 5.49 are the N ground states. Note also that $F = B\,\mathrm{d}x \wedge \mathrm{d}y = \frac{\mathrm{i}}{2}B\,\mathrm{d}z \wedge \mathrm{d}\bar{z}$ is B times the Kähler form of the flat torus, a harmonic form of type $(1,1)$: it is the representative of $h_{1,1} = 1$ in Example 5.62.

The monopole is the same phenomenon. Around a magnetic monopole of charge g, the spatial slice $\mathbb{R}^3 \setminus \{0\}$ has $H^2 = \mathbb{R}$, generated by the sphere. The field $F = \frac{g}{4\pi}\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\phi$ (the flux form of $\vec{B} = g\hat{r}/4\pi r^2$) is closed, co-closed ($\star F = \frac{g}{4\pi r^2}\mathrm{d}r$ is closed), and not exact, since its flux through every sphere is $g \neq 0$. On each sphere it is a constant multiple of the area form, the harmonic generator of $H^2_{\mathrm{dR}}(S^2)$. Dirac's condition $eg \in 2\pi\mathbb{Z}$ is the same gluing argument with two hemispheres instead of a strip (Example 5.50, Chapter T2).

Proca: a massive photon. Now give the photon a mass m. The Proca action adds a mass term to the Maxwell action of Chapter T1,

$$S[A] = \int \left(-\tfrac{1}{2}\,F \wedge \star F - \tfrac{1}{2}\,m^2 A \wedge \star A\right), \qquad F = \mathrm{d}A.$$

Varying $A \to A + a$, the mass term contributes $-m^2\, a \wedge \star A$. This is exactly the form of the coupling $+a \wedge \star J$ that produced $\delta F = J$, with J replaced by $-m^2 A$. So the field equation is

$$\delta F + m^2 A = 0. \tag{5.68}$$

(In components, with $\delta F = J \iff \partial_\mu F^{\nu\mu} = J^\nu$: $\partial_\mu F^{\mu\nu} = m^2 A^\nu$, the standard Proca equation in signature $(-,+,+,+)$.) Texts in which Δ has the opposite sign write this as $\delta F - m^2 A = 0$; the sector analysis below is the same in either convention.

A two-form equation, with no potential assumed. Apply d to (5.68) and use $\mathrm{d}A = F$:

$$\mathrm{d}\delta F + m^2 F = 0. \tag{5.69}$$

Now forget A. Treat (5.69) as an equation for an unknown 2-form F on a compact Riemannian M, and do not assume F has a potential, or even that it is closed. Decompose it by (5.67):

$$F = \mathrm{d}\alpha + \delta\beta + \omega, \qquad \mathrm{d}\omega = 0 = \delta\omega.$$

First we compute the left-hand side sector by sector. The codifferential only sees the exact part:

$$\delta F \overset{(1)}{=} \delta\mathrm{d}\alpha + \delta\delta\beta + \delta\omega \overset{(2)}{=} \delta\mathrm{d}\alpha.$$

(1) Linearity of δ.
(2) $\delta^2 = 0$, and $\delta\omega = 0$ because ω is harmonic.

Applying d gives the Laplacian of the exact part:

$$\mathrm{d}\delta F \overset{(1)}{=} \mathrm{d}\delta(\mathrm{d}\alpha) \overset{(2)}{=} \mathrm{d}\delta(\mathrm{d}\alpha) + \delta\mathrm{d}(\mathrm{d}\alpha) \overset{(3)}{=} \Delta(\mathrm{d}\alpha) \overset{(4)}{=} \mathrm{d}(\Delta\alpha).$$

(1) The previous chain.
(2) Add $\delta\mathrm{d}\mathrm{d}\alpha = 0$, which vanishes by $\mathrm{d}^2 = 0$.
(3) Definition of Δ.
(4) Δ commutes with d. So $\mathrm{d}\delta F$ is exact.

Substituting into (5.69) and grouping by sector:

$$0 \overset{(1)}{=} \Delta(\mathrm{d}\alpha) + m^2\big(\mathrm{d}\alpha + \delta\beta + \omega\big) \overset{(2)}{=} \underbrace{(\Delta + m^2)\mathrm{d}\alpha}_{\text{exact}} + \underbrace{m^2\,\delta\beta}_{\text{co-exact}} + \underbrace{m^2\,\omega}_{\text{harmonic}}.$$

(1) The previous chain for $\mathrm{d}\delta F$, and the decomposition of F.
(2) Regroup. The first term is $\mathrm{d}\big((\Delta + m^2)\alpha\big)$, so it is exact.

Three mutually orthogonal vectors add to zero only if each is zero. To see it explicitly, take the inner product of the equation with $\delta\beta$:

$$0 \overset{(1)}{=} \big\langle \delta\beta, (\Delta + m^2)\mathrm{d}\alpha \big\rangle + m^2\langle \delta\beta, \delta\beta\rangle + m^2\langle \delta\beta, \omega\rangle \overset{(2)}{=} m^2\,\|\delta\beta\|^2.$$

(1) Linearity of the inner product.
(2) Co-exact is orthogonal to exact and to harmonic (the one-line checks after (5.67)).

The same with ω and with $\mathrm{d}\alpha$ gives the other two. So the one equation (5.69) is three:

$$(\Delta + m^2)\,\mathrm{d}\alpha = 0, \qquad m^2\,\delta\beta = 0, \qquad m^2\,\omega = 0. \tag{5.70}$$

For $m \neq 0$, the co-exact and harmonic parts vanish, and $F = \mathrm{d}\alpha$ is exact. A potential exists, and it was not put in by hand: the equation of motion forced it. In fact it can be written down directly, in any signature and without Hodge theory:

$$F \overset{(1)}{=} -\frac{1}{m^2}\,\mathrm{d}\delta F \overset{(2)}{=} \mathrm{d}\Big(-\frac{1}{m^2}\,\delta F\Big).$$

(1) Solve (5.69) for F; this needs $m \neq 0$.
(2) m is a constant, so it passes through d.

The potential $A = -m^{-2}\delta F$ is exactly what (5.68) says it should be.

The Lorenz condition comes for free. Return to (5.68) and apply δ:

$$0 \overset{(1)}{=} \delta\big(\delta F + m^2 A\big) \overset{(2)}{=} \delta\delta F + m^2\,\delta A \overset{(3)}{=} m^2\,\delta A.$$

(1) Apply δ to the field equation (5.68).
(2) Linearity.
(3) $\delta^2 = 0$.

So $\delta A = 0$ for $m \neq 0$. In Maxwell theory this is a gauge *choice* (the Lorenz gauge); here it is a *consequence* of the field equation, and there is no gauge freedom left to choose. Then

$$\Delta A \overset{(1)}{=} \mathrm{d}\delta A + \delta \mathrm{d} A \overset{(2)}{=} \delta \mathrm{d} A \overset{(3)}{=} \delta F \overset{(4)}{=} -m^2 A, \qquad \text{so} \qquad (\Delta + m^2)A = 0, \quad \delta A = 0.$$

(1) Definition of Δ.
(2) $\delta A = 0$, just shown.
(3) $F = \mathrm{d}A$.
(4) The field equation (5.68).

In Minkowski space $\Delta + m^2 = \partial_t^2 - \nabla^2 + m^2$ on each Cartesian component: this is the Klein–Gordon equation, and $\delta A = -\partial_\mu A^\mu = 0$ removes one of the four components, leaving the three polarisations of a massive spin-1 particle.

Key idea: kinematic versus dynamical exactness

In Maxwell theory, F is closed *kinematically*: $\mathrm{d}F = 0$ is the identity $\mathrm{d}^2 = 0$ applied to local potentials, true for every configuration. Closed is weaker than exact, and the gap between them, the harmonic sector $\mathcal{H}^2 \cong H^2_{\mathrm{dR}}(M)$, is where topological flux lives.
In Proca theory, F is exact *dynamically*: the field equation projects onto the three sectors and gives $m^2\omega = 0$ and $m^2\delta\beta = 0$. The mass term kills the harmonic sector. *A massive photon cannot carry topological flux.*

Physical picture: harmonic modes are zero modes, and a mass gaps them

On the harmonic sector every derivative term vanishes: $\mathrm{d}\omega = 0$ and $\delta\omega = 0$. So there the Maxwell operator is 0, and harmonic fields cost no gradient energy. They are *zero modes*. The Proca operator $\mathrm{d}\delta + m^2$ acts on the same sector as multiplication by m^2, which is never zero: the mass lifts every zero mode by the same amount, so the field equation forces every harmonic component to vanish.
A superconductor shows this in the laboratory. Inside it the photon is effectively massive (the Higgs mechanism, with $m = 1/\lambda_L$ for the London penetration depth λ_L), and a static field obeys the London equation $(\Delta + m^2)\vec{B} = 0$: it decays like e^{-x/λ_L} from the surface. This is the Meissner effect. Flux can enter a type-II superconductor only through vortices, where the order parameter vanishes and the mass switches off locally. Each vortex carries one flux quantum $2\pi/e_*$ (with $e_* = 2e$ the Cooper-pair charge), the quantised flux of Example 5.59, squeezed into a tube of radius about λ_L around the core.

Worked example 5.60: Proca mode by mode on the torus T^3

Let $M = T^3 = (\mathbb{R}/2\pi\mathbb{Z})^3$ with the flat metric. A form is a sum of Fourier modes $e^{\mathrm{i}k\cdot x} f$, with $k \in \mathbb{Z}^3$ and f a constant-coefficient form. Write k also for the 1-form $k_j \mathrm{d}x^j$, and ι_k for contraction with the vector $k_j \partial_j$.

Step 1: the operators on a mode. Since $\mathrm{d}(e^{\mathrm{i}k\cdot x}) = \mathrm{i}e^{\mathrm{i}k\cdot x}k$ and, in flat space, $\delta = -\sum_j \iota_{\partial_j}\partial_j$ (the general form of "δ is minus the divergence"),

$$\Delta\big(e^{\mathrm{i}k\cdot x} f\big) \overset{(1)}{=} e^{\mathrm{i}k\cdot x}\big[(\mathrm{i}k\wedge)(-\mathrm{i}\iota_k) + (-\mathrm{i}\iota_k)(\mathrm{i}k\wedge)\big] f \overset{(2)}{=} e^{\mathrm{i}k\cdot x}\big[k\wedge\iota_k f + \iota_k(k\wedge f)\big] \overset{(3)}{=} |k|^2\, e^{\mathrm{i}k\cdot x} f.$$

(1) On a mode, d acts as $\mathrm{i}k\wedge$ and δ as $-\mathrm{i}\iota_k$.
(2) $(\mathrm{i})(-\mathrm{i}) = 1$.
(3) $\iota_k(k\wedge f) = (\iota_k k)f - k\wedge\iota_k f$ and $\iota_k k = |k|^2$.

So the harmonic modes are the $k = 0$ modes, as in Example 5.63. For $k \neq 0$ the recipe of the working definition splits f into $f_\parallel = |k|^{-2} k\wedge\iota_k f$ (exact: it contains the factor k) and $f_\perp = |k|^{-2}\iota_k(k\wedge f)$ (co-exact: $\iota_k f_\perp = 0$).

Step 2: the sectors of a 2-form. Take $k = (1,0,0)$, so $k = \mathrm{d}x$. Then

$$e^{\mathrm{i}x}\,\mathrm{d}x\wedge\mathrm{d}y \overset{(1)}{=} \mathrm{d}\big(-\mathrm{i}e^{\mathrm{i}x}\mathrm{d}y\big), \qquad e^{\mathrm{i}x}\,\mathrm{d}y\wedge\mathrm{d}z \overset{(2)}{=} \delta\big(\mathrm{i}e^{\mathrm{i}x}\,\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z\big).$$

(1) $\mathrm{d}(e^{\mathrm{i}x}) = \mathrm{i}e^{\mathrm{i}x}\mathrm{d}x$ and $(-\mathrm{i})(\mathrm{i}) = 1$.
(2) $\delta = -\mathrm{i}\iota_k$ on the mode, $\iota_{\partial_x}(\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z) = \mathrm{d}y\wedge\mathrm{d}z$, and $(-\mathrm{i})(\mathrm{i}) = 1$. (Directly: $\delta = -\star\mathrm{d}\star$ on 3-forms in three Euclidean dimensions gives the same.)

So for this k the exact 2-forms are spanned by $\mathrm{d}x\wedge\mathrm{d}y$ and $\mathrm{d}x\wedge\mathrm{d}z$ (two of them) and the co-exact ones by $\mathrm{d}y\wedge\mathrm{d}z$ (one). At $k = 0$ there are three harmonic 2-forms, $\mathrm{d}y\wedge\mathrm{d}z$, $\mathrm{d}z\wedge\mathrm{d}x$, $\mathrm{d}x\wedge\mathrm{d}y$: $b_2(T^3) = 3$, three independent fluxes.

Step 3: what survives. On a mode, $\mathrm{d}\delta$ acts as $k\wedge\iota_k$, which is $|k|^2$ on $f_\parallel$ and 0 on $f_\perp$ and on $k = 0$. The two equations become

mode	Maxwell in vacuum: $\mathrm{d}F = 0,\ \delta F = 0$	Proca: $\mathrm{d}\delta F + m^2 F = 0$
$k = 0$, harmonic	$0 = 0$: all 3 survive	$m^2 f = 0$: killed
$k \neq 0$, co-exact $f_\perp$	$k\wedge f_\perp = 0$: killed	$m^2 f_\perp = 0$: killed
$k \neq 0$, exact $f_\parallel$	$\iota_k f_\parallel = 0$: killed	$(\lvert k\rvert^2 + m^2) f_\parallel = 0$: gapped

The last entry is (5.70) mode by mode. In Euclidean signature $|k|^2 + m^2 \geq m^2 > 0$, so this sector is killed too: a static massive field has no source-free configurations on a compact space, and a source produces a field falling off like e^{-mr} (Yukawa). In real time, on $\mathbb{R}_t \times T^3$ with $A = a\, e^{\mathrm{i}(k\cdot x - \omega t)}$, the same factor becomes $-\omega^2 + |k|^2 + m^2$, because $\Delta = \partial_t^2 - \nabla^2$. The exact sector is where the propagating massive photon lives, with $\omega^2 = |k|^2 + m^2$. Its lowest frequency is m, even at $k = 0$: the Maxwell zero modes (constant fluxes, and the constant Wilson lines counted by $b_1(T^3) = 3$) have been lifted by the gap. Figure 5.37 plots both spectra.

Watch out: where the argument is rigorous, and the signs

- *Compactness.* The clean splitting (5.67) holds on a compact Riemannian manifold without boundary. On $\mathbb{R}^n$ one needs fall-off conditions (for example square-integrable forms), and on a manifold with boundary one needs boundary conditions. With such conditions, harmonic forms can disappear: $\mathbb{R}^3$ has no square-integrable harmonic 2-forms, which is why flux sectors need topology.

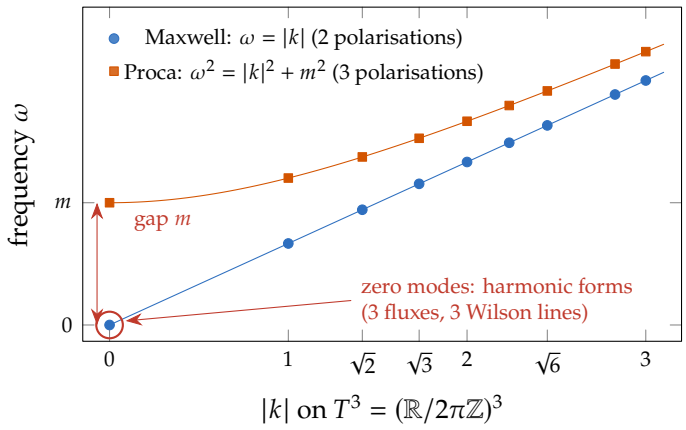

Figure 5.37: The spectrum of photon modes on a spatial torus T^3, one dot per allowed value of $|k|$ (only the values $|k|^2 = 0, 1, 2, 3, 4, 5, 6, 8, 9$ occur). A massless photon has frequency $\omega = |k|$, so the $k = 0$ sector (circled) consists of zero modes: the harmonic forms, which carry the topological fluxes and Wilson lines. A massive photon has $\omega = \sqrt{|k|^2 + m^2}$: every mode, including $k = 0$, is lifted by at least m, and no zero modes remain. This is the spectral meaning of $m^2\omega = 0$ in (5.70).

- *Lorentzian signature.* In Minkowski space the "inner product" $\int F \wedge \star F$ is indefinite (it is $\int (B^2 - E^2)$), so orthogonal pieces need not vanish separately, and $\Delta = \partial_t^2 - \nabla^2$ is not elliptic: its kernel contains every free wave, not a finite-dimensional space. There the sector argument is formal. The conclusions $F = \mathrm{d}(-m^{-2}\delta F)$, $\delta A = 0$ and $(\Delta + m^2)A = 0$ were derived directly, with only $\mathrm{d}^2 = \delta^2 = 0$, so they hold in every signature.

- *Signs.* With δ as in (5.66) and signature $(-,+,+,+)$, $\Delta = -\nabla^2 \geq 0$ in Euclidean signature and $\Delta = \partial_t^2 - \nabla^2$ in Minkowski signature. In both, the Klein–Gordon operator is $\Delta + m^2$, and the Proca equations are $\delta F + m^2 A = 0$ and $\mathrm{d}\delta F + m^2 F = 0$. Books whose Δ is the d'Alembertian $\Box = -\partial_t^2 + \nabla^2$ write $\Delta - m^2$ and $\mathrm{d}\delta F - m^2 F = 0$. The sector equations change only by the sign of m^2, and the conclusions (exactness, $\delta A = 0$, no harmonic part) are the same.

Dictionary: one splitting, two uses

sector	mathematician	physicist
exact $\mathrm{d}\alpha$	zero in cohomology	pure gauge, $A \to A + \mathrm{d}\lambda$; longitudinal modes
co-exact $\delta\beta$	not closed (unless zero); the orthogonal complement of the closed forms	transverse, propagating photons
harmonic ω	$H^k_{\mathrm{dR}}(M)$; Betti numbers b_k; Hodge numbers $h_{p,q}$	zero modes: flux sectors, Wilson lines, moduli, supersymmetric ground states

The mathematician uses (5.67) to *compute* cohomology: solve $\Delta\omega = 0$ and count. The physicist uses the same splitting to *separate* the degrees of freedom. Gauge fixing is a projection. Write $A = \mathrm{d}\lambda + \delta\beta + h$; then $\delta A = \delta\mathrm{d}\lambda = \Delta\lambda$, and on a compact connected Euclidean space $\Delta\lambda = 0$ forces λ to be constant. So the Lorenz condition $\delta A = 0$ is exactly "the exact part of A is zero": it throws away the pure-gauge sector and keeps the transverse and topological ones.

This is also how Nash uses harmonic forms. For him they are the kernels of elliptic operators (Chapter 2), and an index is a difference of numbers of zero modes. The operator $\mathrm{d}+\delta$ from even to odd forms has index $\sum_k (-1)^k b_k = \chi(M)$, because its zero modes are the harmonic forms (Chapter 4). Riemann–Roch counts the zero modes of $\bar\partial_L$ in the same way (Section 5.3.3), and the lowest Landau level of Example 5.59 is such a count. The harmonic sector that a mass removes is precisely the sector an index theorem counts.

Recap: Hodge decomposition in Maxwell and Proca theory

- $A^k = \mathrm{d}A^{k-1} \oplus \delta A^{k+1} \oplus \mathcal{H}^k$ orthogonally, with $\mathcal{H}^k = \operatorname{Ker}\Delta \cong H^k_{\mathrm{dR}}$; closed means no co-exact part, co-closed means no exact part.
- Maxwell: $\mathrm{d}F = 0$ is kinematic ($\mathrm{d}^2 = 0$), $\delta F = 0$ is dynamical, and together $\Delta F = 0$. Source-free fields on a compact space are the harmonic 2-forms: b_2 flux sectors. Flux through a closed surface sees only the harmonic part, and charged matter quantises it. Example: $B\,\mathrm{d}x \wedge \mathrm{d}y$ on T^2, with $eBL_1L_2 \in 2\pi\mathbb{Z}$.
- Proca: $\mathrm{d}\delta F + m^2 F = 0$ splits into $(\Delta + m^2)\mathrm{d}\alpha = 0$, $m^2\delta\beta = 0$, $m^2\omega = 0$. For $m \neq 0$, $F = \mathrm{d}(-m^{-2}\delta F)$ is exact, $\delta A = 0$ is automatic, and $(\Delta + m^2)A = 0$ is Klein–Gordon.
- A mass gaps out the harmonic zero modes: a massive photon carries no topological flux (the Meissner effect).

The Kähler refinement

On a general Hermitian manifold there is no particular relation between these Laplacians. On a Kähler manifold there is (Nash's (5.32)):

Key idea: Kähler identity for Laplacians

$$\Delta_d = 2\Delta_\partial = 2\Delta_{\bar\partial} \qquad \text{on a Kähler manifold.} \tag{5.71}$$

Physically: the zero modes of the full Laplacian Δ_d (the topological sector of Figure 5.36) and the zero modes of $\Delta_{\bar\partial}$ (the holomorphic data, such as lowest-Landau-level states and holomorphic differentials) are the *same* forms. On a Kähler manifold, topology and holomorphy count the same things.

Worked example 5.61: $\Delta_d = 2\Delta_{\bar\partial}$ on functions on $\mathbb{C}$

Take flat $\mathbb{C}$ with $\mathrm{d}s^2 = |\mathrm{d}z|^2$ and compactly supported functions. We need $\bar\partial^*$ on $(0,1)$-forms. The pointwise norm of $\mathrm{d}\bar z = \mathrm{d}x - i\mathrm{d}y$ is $|\mathrm{d}x|^2 + |\mathrm{d}y|^2 = 2$. For a function f and a $(0,1)$-form $\beta = b\,\mathrm{d}\bar z$,

$$\begin{aligned}\langle \bar\partial f, \beta\rangle &\overset{(1)}{=} \int \partial_{\bar z} f\ \bar b\ |\mathrm{d}\bar z|^2\,\mathrm{d}A \overset{(2)}{=} 2\int \partial_{\bar z} f\ \bar b\,\mathrm{d}A \\ &\overset{(3)}{=} -2\int f\ \partial_{\bar z}\bar b\,\mathrm{d}A \overset{(4)}{=} \int f\ \overline{(-2\partial_z b)}\,\mathrm{d}A = \langle f, -2\partial_z b\rangle,\end{aligned}$$

(1) $\bar\partial f = \partial_{\bar z} f\,\mathrm{d}\bar z$, and the inner product of two multiples of $\mathrm{d}\bar z$ is the product of coefficients (one conjugated) times $|\mathrm{d}\bar z|^2$.
(2) $|\mathrm{d}\bar z|^2 = 2$.
(3) Integrate by parts; no boundary term for compact support.

(4) $\partial_{\bar z}\bar b = \overline{\partial_z b}$.

so $\bar\partial^*(b\,\mathrm{d}\bar z) = -2\partial_z b$. Therefore

$$\Delta_{\bar\partial} f \overset{(1)}{=} \bar\partial^*\bar\partial f \overset{(2)}{=} -2\,\partial_z\partial_{\bar z} f \overset{(3)}{=} -\tfrac{1}{2}\big(\partial_x^2+\partial_y^2\big) f \overset{(4)}{=} \tfrac{1}{2}\,\Delta_d f\,,$$

(1) On functions $\bar\partial^* f = 0$ (there are no $(0,-1)$-forms).
(2) The adjoint just computed, with $b = \partial_{\bar z} f$.
(3) $\partial_z\partial_{\bar z} = \frac{1}{4}(\partial_x^2+\partial_y^2)$.
(4) $\Delta_d = \mathrm{d}^*\mathrm{d} = -(\partial_x^2+\partial_y^2)$ on functions (the positive Laplacian).

The same computation with ∂ gives $\Delta_\partial f = -2\partial_{\bar z}\partial_z f$, the same thing. So $\Delta_d = 2\Delta_\partial = 2\Delta_{\bar\partial}$ on flat $\mathbb{C}$. On flat $\mathbb{C}^n$ and on forms of any type the calculation is the same in each coordinate direction.

Why it holds on every Kähler manifold. The standard proof goes through the *Kähler identities*, such as $[\Lambda,\bar\partial] = -\mathrm{i}\,\partial^*$, where Λ is the adjoint of wedging with ω. These are first-order identities: they involve the metric and only its first derivatives. They hold on flat $\mathbb{C}^n$ by a computation like the one above, hence on every Kähler manifold by the principle in the key idea on Kähler normal coordinates. The relation (5.71) then follows from them by algebra (one also uses $\partial\bar\partial^* + \bar\partial^*\partial = 0$, another consequence). Without the Kähler condition the first derivatives of g spoil the identities, and Δ_d, Δ_∂, $\Delta_{\bar\partial}$ differ by first-order terms.

The Hodge decomposition. Now combine. Let α be a Δ_d-harmonic k-form and split it by type, $\alpha = \sum_{p+q=k}\alpha^{p,q}$. Then

$$0 = \Delta_d\alpha = 2\Delta_{\bar\partial}\alpha = 2\sum_{p+q=k}\Delta_{\bar\partial}\alpha^{p,q},$$

and since $\Delta_{\bar\partial}$ preserves type, the terms on the right have different types and must vanish separately. So every component $\alpha^{p,q}$ of a harmonic form is itself harmonic (for all three Laplacians). With the **Hodge numbers** (Nash's (5.33))

$$h_{p,q} = \dim H^{p,q}_{\bar\partial}(M) \tag{5.72}$$

we get the **Hodge decomposition** (Nash's (5.34))

$$H^k(M;\mathbb{C}) = \bigoplus_{p+q=k} H^{p,q}(M;\mathbb{C}), \tag{5.73}$$

where $H^{p,q}(M;\mathbb{C})$ is the space of classes represented by a closed form of type (p,q), and $H^{p,q}(M;\mathbb{C}) \cong H^{p,q}_{\bar\partial}(M)$ because both are the space of harmonic (p,q)-forms. In the language of Section 5.3.9: each topological zero mode carries a definite type (p,q). For example, on the torus the flux sector $B\,\mathrm{d}x\wedge\mathrm{d}y = \frac{\mathrm{i}}{2}B\,\mathrm{d}z\wedge\mathrm{d}\bar z$ of Example 5.59 is pure type $(1,1)$, while the two Wilson-line zero modes $\mathrm{d}x, \mathrm{d}y$ recombine into $\mathrm{d}z$ (type $(1,0)$) and $\mathrm{d}\bar z$ (type $(0,1)$).

Consequences. Nash lists five. Each is now a one-line argument.

(i) $b_k = \sum_{p+q=k} h_{p,q}$: take dimensions in (5.73).

(ii) $b_2 > 0$ (for M compact Kähler): Example 5.55, or (v) with $p = 1$.

(iii) b_{2i+1} is even: by (i) and (iv),

$$b_{2i+1} = \sum_{p+q=2i+1} h_{p,q} = \sum_{p<q} \big(h_{p,q} + h_{q,p}\big) = 2 \sum_{p<q,\ p+q=2i+1} h_{p,q},$$

because $p+q$ odd means $p \neq q$, so the terms pair off.

(iv) $h_{p,q} = h_{q,p}$: Δ_d is a real operator, so the complex conjugate of a harmonic form is harmonic, and conjugation turns dz's into $d\bar{z}$'s, i.e. type (p,q) into (q,p). It is a real-linear bijection between the two spaces of harmonic forms.

(v) $h_{p,p} > 0$ for $0 \le p \le n$: the form ω^p has type (p,p); it is closed; and it is co-closed, because $\star\,\omega^p = \frac{p!}{(n-p)!}\,\omega^{n-p}$ (a pointwise identity, checked in a unitary frame as in (5.62)) and so $d^*\omega^p = \pm \star d \star \omega^p \propto \star d\omega^{n-p} = 0$. So ω^p is a nonzero harmonic (p,p)-form, and $h_{p,p} \ge 1$. For $p = 1$ this says that a compact Kähler manifold always admits a nonzero source-free magnetic field with topological flux: the Kähler form itself, the "uniform" field of the Landau problem.

In addition, Serre duality (5.40) gives $h_{p,q} = h_{n-p,n-q}$. So the Hodge numbers, arranged in a diamond, have a left–right symmetry (conjugation) and an up–down symmetry (Serre duality), and the Betti numbers are the sums along the horizontal rows.

Worked example 5.62: Hodge numbers of a compact Riemann surface, and the genus

For Σ_p ($n = 1$): $h_{0,0} = 1$ (constants), $h_{1,1} = h_{0,0} = 1$ (Serre duality; the class of ω), and $h_{1,0} = \dim H^0(K)$, the number of holomorphic 1-forms. By (iv), $h_{0,1} = h_{1,0}$, and by (i),

$$2p \overset{(1)}{=} b_1(\Sigma_p) \overset{(2)}{=} h_{1,0} + h_{0,1} \overset{(3)}{=} 2h_{1,0} \quad \Longrightarrow \quad h^0(K) = h_{1,0} = p.$$

(1) A closed orientable surface of genus p has $H_1 = \mathbb{Z}^{2p}$ (Section 5.2.15).
(2) Hodge decomposition (5.73) with $k = 1$.
(3) $h_{0,1} = h_{1,0}$ by complex conjugation.

This is the fact used in Step 1 of the proof of Riemann–Roch (Section 5.3.3): *a Riemann surface of topological genus p has exactly p independent holomorphic differentials*, and $h^1(\mathcal{O}) = h_{0,1} = p$. The Hodge diamond is

$$\begin{array}{ccc} & 1 & \\ p & & p \\ & 1 & \end{array} \qquad \big(\text{rows: } h_{1,1};\ h_{1,0},\ h_{0,1};\ h_{0,0}\big).$$

Worked example 5.63: Complex tori and projective spaces

Tori. On a flat torus $T = \mathbb{C}^n/\Lambda$, harmonic forms are exactly the forms with constant coefficients: the Laplacian is $-\sum(\partial^2_{x^k} + \partial^2_{y^k})$ on each coefficient, and on a Fourier mode $e^{2\pi i\langle \kappa, x\rangle}$ it is multiplication by $4\pi^2|\kappa|^2$, which vanishes only for $\kappa = 0$ (as in Example 5.42). A constant (p,q)-form is a combination of $dz^{i_1} \wedge \cdots \wedge dz^{i_p} \wedge d\bar{z}^{j_1} \wedge \cdots \wedge d\bar{z}^{j_q}$ with $i_1 < \cdots < i_p$, $j_1 < \cdots < j_q$, so

$$h_{p,q}(T) = \binom{n}{p}\binom{n}{q}, \qquad \sum_{p+q=k} \binom{n}{p}\binom{n}{q} = \binom{2n}{k} = b_k(T^{2n}),$$

the second being Vandermonde's identity: consistent with (i), since the real torus T^{2n} has $b_k = \binom{2n}{k}$.

Projective space. $\mathbb{CP}^n$ is a union of cells $\mathbb{C}^n \cup \mathbb{C}^{n-1} \cup \cdots \cup \mathbb{C}^0$ (the points with $Z_0 \neq 0$, then those with $Z_0 = 0 \neq Z_1$, and so on), one cell in each even real dimension, so $b_{2k} = 1$ for $0 \le k \le n$ and all odd Betti numbers vanish. Since $h_{k,k} \ge 1$ by (v) and $b_{2k} = \sum_{p+q=2k} h_{p,q} = 1$, we get $h_{k,k} = 1$ and every other Hodge number is zero. In particular $h_{0,1} = h_{0,2} = 0$, which is what Example 5.52 needed to conclude $\mathrm{Pic}(\mathbb{CP}^n) = \mathbb{Z}$.

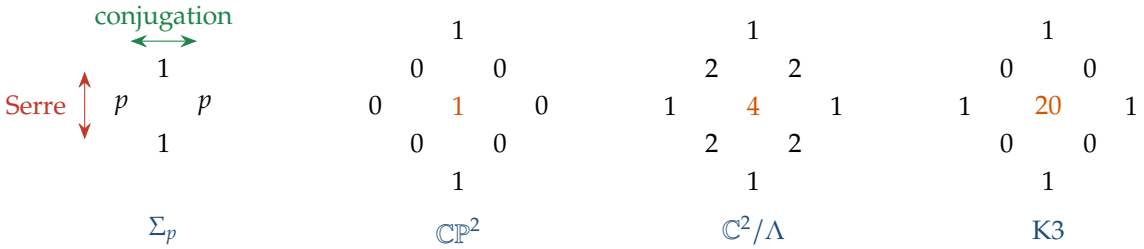

Figure 5.38: Hodge diamonds $h_{p,q}$, with $h_{0,0}$ at the bottom, $h_{n,n}$ at the top, $h_{p,0}$ on the lower-left edge and $h_{0,q}$ on the lower-right edge (for Σ_p the middle row is $h_{1,0}, h_{0,1}$). Row sums are Betti numbers: Σ_p has $b = (1, 2p, 1)$; $\mathbb{CP}^2$ has $(1, 0, 1, 0, 1)$; the complex 2-torus $(1, 4, 6, 4, 1)$; the K3 surface $(1, 0, 22, 0, 1)$. Every diamond is symmetric under left–right reflection (complex conjugation, $h_{p,q} = h_{q,p}$) and under up–down reflection (Serre duality, $h_{p,q} = h_{n-p,n-q}$), and the central column (orange) is never zero (the powers of ω).

Worked example 5.64: A complex manifold that is not Kähler: the Hopf surface

Let $M = (\mathbb{C}^2 \setminus \{0\})/\langle Z \mapsto 2Z \rangle$: identify each nonzero vector Z with $2Z$. The map $Z \mapsto 2Z$ is holomorphic, and the group it generates acts freely and properly, so M is a compact complex surface (complex dimension 2). Topologically, write $Z = e^s u$ with $s \in \mathbb{R}$ and $u \in S^3$; the identification is $s \sim s + \log 2$, so

$$M \cong S^1 \times S^3, \qquad b_0 = b_1 = b_3 = b_4 = 1, \quad b_2 = 0.$$

Both $b_1 = 1$ (odd) and $b_2 = 0$ violate Nash's consequences (iii) and (ii). So *the Hopf surface admits no Kähler metric at all*, and hence (by Section 5.3.8) it cannot be embedded in any $\mathbb{CP}^N$: it is a complex manifold that is not algebraic. For a Hermitian metric on it, such as $\mathrm{d}s^2 = |\mathrm{d}Z|^2/|Z|^2$ (invariant under $Z \mapsto 2Z$), one can check directly that $\mathrm{d}\omega \neq 0$.

Physical picture: Hodge numbers as counts of massless fields

In supersymmetric quantum mechanics on M (Chapter 7), the supercharge is $Q = \mathrm{d} + \mathrm{d}^*$ and the ground states are the harmonic forms, so b_k counts ground states of fermion number k. On a Kähler manifold there are *two* supercharges, $\bar\partial + \bar\partial^*$ and $\partial + \partial^*$, and (5.71) says they generate the same Hamiltonian: the extra supersymmetry refines fermion number into the pair (p, q), and the ground states are counted by $h_{p,q}$. In string compactification on a Calabi–Yau threefold, $h_{1,1}$ and $h_{2,1}$ count massless moduli fields, and the number of quark–lepton generations is $|h_{1,1} - h_{2,1}| = |\chi|/2$. Supersymmetric sigma models with $N = 2$ supersymmetry require a Kähler target, for the same algebraic reason (Zumino's theorem).

Reading Nash (pp. 146–148, (5.29)–(5.34))

Nash defines a Kähler manifold by a Hermitian metric $g_{ij}\mathrm{d}z^i \otimes \mathrm{d}\bar{z}^j$ whose 2-form $\omega = \frac{\mathrm{i}}{2} g_{ij}\mathrm{d}z^i \wedge \mathrm{d}\bar{z}^j$ is closed (5.29); notes $\omega(X,Y) = g(JX,Y)$ and that Kähler manifolds are symplectic; gives the examples of flat tori, Riemann surfaces, and $\mathbb{CP}^n$ with the Fubini–Study metric (5.30) (whose typos we corrected); remarks that Kähler metrics are characterised by $g_{ij} = \delta_{ij} + h_{ij}$ with h of second order; observes that complex submanifolds of Kähler manifolds are Kähler, so projective manifolds are Kähler; introduces the three Laplacians (5.31), states $\Delta_d = 2\Delta_\partial = 2\Delta_{\bar\partial}$ (5.32), the Hodge numbers (5.33) and decomposition (5.34), and lists five consequences (i)–(v) without proof. We added: the matrix J and the compatible triple, the computation $h = g - \mathrm{i}\omega$, the component form of $\mathrm{d}\omega = 0$, the Kähler potential with its derivation, the full construction of Kähler normal coordinates, $\omega^n = n!\,\mathrm{vol}$ and non-exactness of ω^k, the hyperbolic metric, the explicit Fubini–Study matrix with its eigenvalues, overlap consistency and $\mathrm{U}(n+1)$ invariance, the identification of $\mathbb{CP}^1$ with a sphere of radius $\frac{1}{2}$ with curvature and Gauss–Bonnet checks, $\omega_{FS} = \pi c_1(\mathcal{O}(1))$, the area $= \pi\times$degree formula, the Laplacian identity on $\mathbb{C}$ computed, the Hodge decomposition applied to Maxwell and Proca theory (flux sectors, dynamical exactness, the mass gap), proofs of (i)–(v), Hodge diamonds, and the Hopf surface.

Recap: Section 5.3

- Forms split by type, $\mathrm{d} = \partial + \bar\partial$, and holomorphic cohomology is the cohomology of $\bar\partial$: $H^q(M;\Omega^p(E)) \cong H^{p,q}_{\bar\partial_E}(M)$ (Dolbeault).
- Serre duality: $H^q(M;\Omega^p(E)) \cong H^{n-q}(M;\Omega^{n-p}(E^*))^*$, via $\int_M \theta\wedge\nu$; on a curve $h^1(L) = h^0(K\otimes L^{-1})$.
- Riemann–Roch: $h^0(D) - h^0(K-D) = \deg D + 1 - p$. It gives $h^0(K) = p$, $\deg K = 2p-2$, $h^0(K^2) = 3p-3$, and $h^0(D) = \deg D + 1 - p$ for $\deg D > 2p-2$; it is the index theorem for $\bar\partial_L$ and the lowest-Landau-level count.
- Line bundles are classes in $H^1(M;\mathcal{E}^*)$ (smooth) or $H^1(M;\mathcal{O}^*)$ (holomorphic). The exponential sequence gives c_1 as a connecting map; smooth line bundles are classified by $c_1 \in H^2(M;\mathbb{Z})$; holomorphic ones by c_1 and a point of $\mathrm{Pic}_0 = H^1(\mathcal{O})/H^1(\mathbb{Z})$, which for a curve is the Jacobian.
- Kähler: Hermitian metric with $\mathrm{d}\omega = 0$, equivalently $g_{i\bar\jmath} = \partial_i\partial_{\bar\jmath}K$ locally, equivalently flat to first order in holomorphic coordinates. Examples: tori, all Riemann surfaces, $\mathbb{CP}^n$ with Fubini–Study ($\omega = \frac{\mathrm{i}}{2}\partial\bar\partial\log(1+|z|^2)$; on $\mathbb{CP}^1$ the sphere of radius $\frac{1}{2}$), and all projective varieties.
- Hodge decomposition $A^k = \mathrm{d}A^{k-1} \oplus \delta A^{k+1} \oplus \mathcal{H}^k$ in physics: source-free Maxwell fields are harmonic and carry topological flux (quantised, as for $B\,\mathrm{d}x\wedge\mathrm{d}y$ on T^2); the Proca equation forces F to be exact and kills the harmonic sector, so a massive photon has no flux sectors.
- On compact Kähler manifolds $\Delta_d = 2\Delta_{\bar\partial}$, so $H^k = \bigoplus_{p+q=k} H^{p,q}$, $h_{p,q} = h_{q,p} = h_{n-p,n-q}$, b_{odd} even, $h_{p,p} \geq 1$. The Hopf surface $S^1\times S^3$ is complex but not Kähler.

5.4 The Teichmüller space $\mathcal{T}_p$

5.4.1 Why a physicist needs the space of shapes

Here is the question that drives the rest of this chapter. A closed string moving through space-time sweeps out a closed surface Σ, its **worldsheet**. In Polyakov's path integral the worldsheet carries its own metric g_{ab}, and the partition function is, schematically,

$$Z \;=\; \sum_{p=0}^{\infty} \int \mathcal{D}g\, \mathcal{D}\phi \;\exp\!\Big(-\tfrac{1}{2}\int_{\Sigma} \mathrm{d}^2x\, \sqrt{g}\, g^{ab}\, \partial_a \phi^{\mu}\, \partial_b \phi_{\mu}\Big). \tag{5.74}$$

The sum is over the genus p of the surface (the number of handles, i.e. the number of string loops). For each genus we integrate over all metrics g on Σ and over all embeddings $\phi : \Sigma \to \mathbb{R}^d$. Chapter 9 (Chapter 9) does this properly. Here we only ask the preliminary question:

How many genuinely different worldsheets of genus p are there?

The action does not see every detail of g. It is unchanged if we rescale g by a positive function (Weyl invariance, checked in Section 5.4.3 below). It is also unchanged if we move the points of Σ around by a diffeomorphism, because that is just a relabelling of the worldsheet. What survives once we throw away these two redundancies is a *finite-dimensional* space of "shapes". For the torus it is a single complex number τ. For genus $p \geq 2$ it has $3p-3$ complex dimensions. So the enormous integral $\int \mathcal{D}g$ collapses to an ordinary integral over a finite-dimensional space. That space is the **moduli space** $\mathcal{M}_p$, and its simply connected cover is the **Teichmüller space** $\mathcal{T}_p$. This section builds $\mathcal{T}_p$. Section 5.5 builds $\mathcal{M}_p$, Section 5.6 counts its dimension with the index theorem, and Section 5.7 looks at a finer invariant of each individual surface, its Weierstrass points.

Watch out: Notation for the genus

Nash writes the genus as p and a genus-p surface as Σ_p (or just Σ). Most modern books write g for the genus, which clashes with the metric g. We follow Nash: p **is always the genus** in this part, and g is always a metric.

Figure 5.39 is the map of this section and the next. Each arrow is a quotient by a group of redundancies.

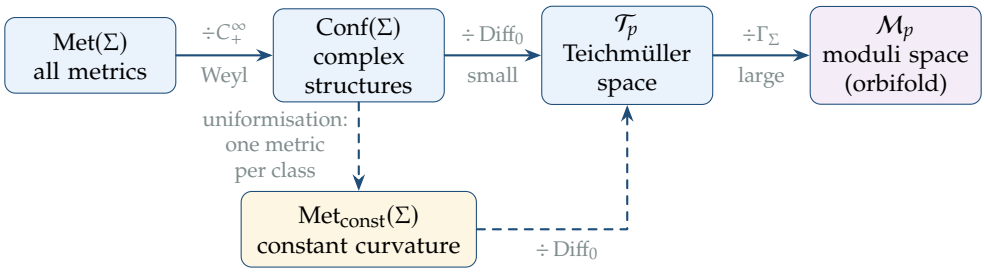

Figure 5.39: The chain of quotients. Reading left to right we throw away Weyl rescalings, then diffeomorphisms that can be deformed to the identity, then the remaining "large" diffeomorphisms. The dashed route is Nash's second definition (5.43): first use uniformisation to pick a canonical metric in each conformal class, then divide by diffeomorphisms.

5.4.2 From a metric to a complex structure

We start with a surface Σ and a Riemannian metric on it. In local coordinates (x, y) the most general metric is

$$\mathrm{d}s^2 \;=\; A\,\mathrm{d}x^2 + 2B\,\mathrm{d}x\,\mathrm{d}y + C\,\mathrm{d}y^2, \qquad A > 0, \quad AC - B^2 > 0. \tag{5.75}$$

The two inequalities say that the matrix $\left(\begin{smallmatrix} A & B \\ B & C \end{smallmatrix}\right)$ is positive definite, so lengths are positive. Nash's first claim [Nash p. 149, (5.35)] is that one can always rewrite this in terms of $z = x + iy$ and $\bar z = x - iy$ as

$$\mathrm{d}s^2 \;=\; \lambda\,(\mathrm{d}z + \mu\,\mathrm{d}\bar z)(\mathrm{d}\bar z + \bar\mu\,\mathrm{d}z) \;=\; \lambda\,|\mathrm{d}z + \mu\,\mathrm{d}\bar z|^2\,, \qquad \lambda > 0,\ |\mu| < 1, \tag{5.76}$$

with λ a positive real function and μ a complex function. Nash says "it is always possible". Let us actually do it, because the explicit formulas are useful.

Expanding the right-hand side

We need three products of differentials. With $\mathrm{d}z = \mathrm{d}x + i\,\mathrm{d}y$:

$$\begin{aligned} \mathrm{d}z\,\mathrm{d}\bar z &= (\mathrm{d}x + i\mathrm{d}y)(\mathrm{d}x - i\mathrm{d}y) = \mathrm{d}x^2 + \mathrm{d}y^2, \\ \mathrm{d}z^2 &= \mathrm{d}x^2 - \mathrm{d}y^2 + 2i\,\mathrm{d}x\,\mathrm{d}y, \\ \mathrm{d}\bar z^2 &= \mathrm{d}x^2 - \mathrm{d}y^2 - 2i\,\mathrm{d}x\,\mathrm{d}y. \end{aligned}$$

(These are *symmetric* products of 1-forms, the kind that make up a metric, not wedge products.) Write $\mu = a + ib$ with a, b real. Then

$$\begin{aligned} |\mathrm{d}z + \mu\,\mathrm{d}\bar z|^2 &\overset{(1)}{=} (1 + |\mu|^2)\,\mathrm{d}z\,\mathrm{d}\bar z + \bar\mu\,\mathrm{d}z^2 + \mu\,\mathrm{d}\bar z^2 \\ &\overset{(2)}{=} (1 + |\mu|^2)(\mathrm{d}x^2 + \mathrm{d}y^2) + 2\,\mathrm{Re}\big[(a - ib)(\mathrm{d}x^2 - \mathrm{d}y^2 + 2i\,\mathrm{d}x\,\mathrm{d}y)\big] \\ &\overset{(3)}{=} (1 + |\mu|^2 + 2a)\,\mathrm{d}x^2 + 4b\,\mathrm{d}x\,\mathrm{d}y + (1 + |\mu|^2 - 2a)\,\mathrm{d}y^2. \end{aligned} \tag{5.77}$$

(1) Multiply out $(\mathrm{d}z + \mu\mathrm{d}\bar z)(\mathrm{d}\bar z + \bar\mu\mathrm{d}z)$; the cross terms are $\bar\mu\,\mathrm{d}z^2$ and $\mu\,\mathrm{d}\bar z^2$, and the diagonal terms give $(1 + \mu\bar\mu)\mathrm{d}z\mathrm{d}\bar z$.

(2) Insert the three products above; the two cross terms are complex conjugates of each other, so together they are twice the real part of one of them.

(3) $\mathrm{Re}[(a - ib)(X + 2iY)] = aX + 2bY$ with $X = \mathrm{d}x^2 - \mathrm{d}y^2$, $Y = \mathrm{d}x\,\mathrm{d}y$; collect the coefficients of $\mathrm{d}x^2$, $\mathrm{d}x\,\mathrm{d}y$ and $\mathrm{d}y^2$.

Solving for λ and μ

Comparing (5.77) (times λ) with (5.75) gives three real equations:

$$A = \lambda(1 + |\mu|^2 + 2a), \qquad B = 2\lambda b, \qquad C = \lambda(1 + |\mu|^2 - 2a).$$

Three real unknowns (λ, a, b), three equations. Form the combinations

$$\begin{aligned} A - C + 2iB &\overset{(1)}{=} 4\lambda a + 4i\lambda b = 4\lambda\mu, \\ A + C &\overset{(2)}{=} 2\lambda(1 + |\mu|^2), \\ AC - B^2 &\overset{(3)}{=} \lambda^2\big[(1 + |\mu|^2)^2 - 4a^2 - 4b^2\big] \overset{(4)}{=} \lambda^2\,(1 - |\mu|^2)^2. \end{aligned} \tag{5.78}$$

(1) Subtract the first and third equations, and add $2i$ times the second.
(2) Add the first and third equations.
(3) $(P+Q)(P-Q) = P^2 - Q^2$ with $P = \lambda(1+|\mu|^2)$ and $Q = 2\lambda a$, then subtract $B^2 = 4\lambda^2 b^2$.
(4) $4a^2 + 4b^2 = 4|\mu|^2$ and $(1+|\mu|^2)^2 - 4|\mu|^2 = (1-|\mu|^2)^2$.

Write $\Delta := AC - B^2 > 0$. Taking the positive square root (we want $|\mu| < 1$) gives $\lambda(1-|\mu|^2) = \sqrt{\Delta}$. Adding this to half of the second line gives $2\lambda = \frac{1}{2}(A+C) + \sqrt{\Delta}$. So

$$\boxed{\lambda = \frac{A + C + 2\sqrt{AC - B^2}}{4}, \qquad \mu = \frac{A - C + 2iB}{A + C + 2\sqrt{AC - B^2}}.} \tag{5.79}$$

Is $|\mu| < 1$ automatic? Yes:

$$\begin{aligned} |A - C + 2iB|^2 &\overset{(1)}{=} (A+C)^2 - 4(AC - B^2) \\ &\overset{(2)}{=} \big(A + C - 2\sqrt{\Delta}\big)\big(A + C + 2\sqrt{\Delta}\big) \overset{(3)}{<} \big(A + C + 2\sqrt{\Delta}\big)^2. \end{aligned}$$

(1) $(A-C)^2 + 4B^2 = (A+C)^2 - 4AC + 4B^2$.
(2) Difference of two squares.
(3) $\sqrt{\Delta} > 0$, so the first factor is smaller than the second.

Dividing by $(A + C + 2\sqrt{\Delta})^2$ gives $|\mu|^2 < 1$. The condition $|\mu| < 1$ is exactly the positivity of the metric.

Working definition 5.37 (Beltrami coefficient of a metric)

Given a metric $A\,\mathrm{d}x^2 + 2B\,\mathrm{d}x\mathrm{d}y + C\,\mathrm{d}y^2$ in local coordinates, its **Beltrami coefficient** is the complex function μ of (5.79) [the metric is $\lambda\,|\mathrm{d}z + \mu\,\mathrm{d}\bar{z}|^2$ with $z = x + \mathrm{i}y$, so μ measures how far it is from round], and its **conformal factor** is λ. *Test:* $\mu \equiv 0$ exactly when $A = C$ and $B = 0$, that is, when the metric is already a multiple of $\mathrm{d}x^2 + \mathrm{d}y^2$. Always $|\mu| < 1$.

Worked example 5.65: A skew constant metric

Take $\mathrm{d}s^2 = \mathrm{d}x^2 + \mathrm{d}x\,\mathrm{d}y + \mathrm{d}y^2$, so $A = C = 1$, $B = \frac{1}{2}$. Then $\Delta = 1 - \frac{1}{4} = \frac{3}{4}$ and $\sqrt{\Delta} = \frac{\sqrt{3}}{2}$, and

$$\lambda \overset{(1)}{=} \frac{2+\sqrt{3}}{4}, \qquad \mu \overset{(2)}{=} \frac{0+i}{2+\sqrt{3}} \overset{(3)}{=} i\,(2-\sqrt{3}) \approx 0.268\,i.$$

(1) Formula (5.79) with $A + C = 2$.
(2) Same formula with $A - C = 0$, $2B = 1$.
(3) Rationalise: $(2+\sqrt{3})(2-\sqrt{3}) = 1$.

Check by expanding back: $1+|\mu|^2 = 1+(2-\sqrt{3})^2 = 8-4\sqrt{3}$ and $\lambda(8-4\sqrt{3}) = (2+\sqrt{3})(2-\sqrt{3}) = 1 = A$, with $a = 0$; and $2\lambda b = \frac{2+\sqrt{3}}{2}(2-\sqrt{3}) = \frac{1}{2} = B$. Good.

What μ looks like: circles become ellipses

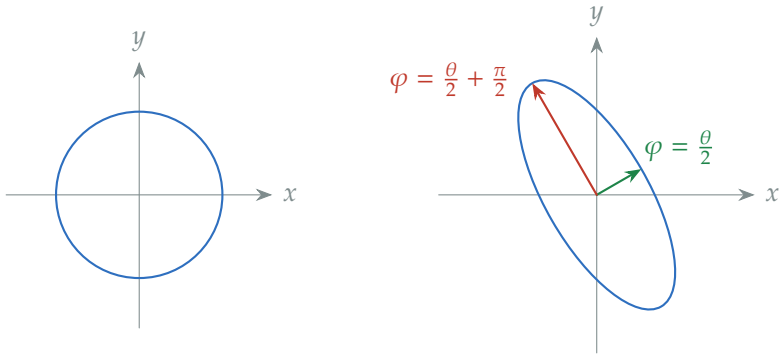
Fix a point and look at the set of tangent vectors of unit length in the metric. If $\mu = 0$, it is a round circle in the (x, y) plane. If $\mu \neq 0$, the condition $\lambda|\mathrm{d}z + \mu\mathrm{d}\bar{z}|^2 = 1$ is an ellipse. Write $\mu = |\mu|e^{i\theta}$ and a tangent direction as $\mathrm{d}z = re^{i\varphi}$. Then

$$|\mathrm{d}z + \mu\,\mathrm{d}\bar{z}| = r\left|e^{i\varphi} + |\mu|e^{i(\theta-\varphi)}\right| = r\left|1 + |\mu|e^{i(\theta-2\varphi)}\right|.$$

This is largest, $r(1+|\mu|)$, when $\varphi = \theta/2$, and smallest, $r(1-|\mu|)$, when $\varphi = \theta/2 + \pi/2$. So a vector of unit length is *short* in the $\theta/2$ direction and *long* in the perpendicular direction. The ellipse has

$$\frac{\text{major axis}}{\text{minor axis}} = \frac{1+|\mu|}{1-|\mu|}, \tag{5.80}$$

a number called the **dilatation**. Figure 5.40 shows this. The coefficient μ is a field of infinitesimal ellipses on Σ: at each point it tells us how the metric's circles are squashed and in which direction. The overall size of the ellipse is λ, and it does not matter for angles.



$\mu = 0$: unit circle is round

$\mu = |\mu|e^{i\theta}$: unit "circle" is an ellipse, axis ratio $(1+|\mu|)/(1-|\mu|)$

Figure 5.40: The Beltrami coefficient as a field of ellipses. Left: a conformally flat metric; the vectors of unit length form a round circle. Right: with $\mu \neq 0$ the unit vectors form an ellipse, short along the direction $\theta/2$ (green) and long perpendicular to it (red). Rescaling the metric by λ changes the size of the ellipse but not its shape; only μ matters for angles.

Why a metric gives a complex structure

A **complex structure** on Σ is an atlas of complex coordinates w_α whose changes of coordinates $w_\beta(w_\alpha)$ are holomorphic. Here is how a metric produces one. Suppose we can find, near each point, a function $w(z,\bar z)$ with

$$\frac{\partial w}{\partial \bar z} = \mu \frac{\partial w}{\partial z}, \qquad \frac{\partial w}{\partial z} \neq 0. \tag{5.81}$$

This is the **Beltrami equation**. Then

$$dw = w_z\,dz + w_{\bar z}\,d\bar z \overset{(1)}{=} w_z\,(dz + \mu\,d\bar z), \qquad \text{so} \qquad ds^2 \overset{(2)}{=} \frac{\lambda}{|w_z|^2}\,|dw|^2.$$

(1) Use (5.81) to replace $w_{\bar z}$ by μw_z.
(2) Take $|\cdot|^2$ and compare with (5.76).

In the new coordinate the metric is a positive function times the flat metric $|dw|^2$. Coordinates with this property are called **isothermal** (or conformal) coordinates. That solutions of (5.81) exist locally, for any smooth μ with $|\mu| < 1$, is a classical theorem of Gauss (for real-analytic metrics), Korn and Lichtenstein, and in full generality Ahlfors and Bers. We take it as given.

Now take two overlapping isothermal coordinates w_1 and w_2. On the overlap $ds^2 = \rho_1|dw_1|^2 = \rho_2|dw_2|^2$ with $\rho_1, \rho_2 > 0$. Then

$$\begin{aligned}\rho_2\,|dw_2|^2 &\overset{(1)}{=} \rho_2\,\left|\partial w_2\,dw_1 + \bar\partial w_2\,d\bar w_1\right|^2 \\ &\overset{(2)}{=} \rho_2\Big[(|\partial w_2|^2 + |\bar\partial w_2|^2)\,|dw_1|^2 + 2\,\mathrm{Re}\big(\overline{\partial w_2}\,\bar\partial w_2\,d\bar w_1^{\,2}\big)\Big].\end{aligned}$$

(1) Chain rule, with $\partial = \partial/\partial w_1$ and $\bar\partial = \partial/\partial \bar w_1$.
(2) Multiply out as in (5.77).

For this to equal $\rho_1 |\mathrm{d}w_1|^2$, the $\mathrm{d}\bar w_1^2$ term must vanish, so $\partial w_2 \cdot \bar\partial w_2 = 0$ everywhere. Hence (on a connected overlap) either $\bar\partial w_2 = 0$, so w_2 is a holomorphic function of w_1, or $\partial w_2 = 0$, so it is antiholomorphic. The antiholomorphic case reverses orientation. If we insist that all coordinates are compatible with a fixed orientation of Σ, the coordinate changes are holomorphic. So:

Key idea: A metric plus an orientation is a complex structure

Isothermal coordinates of a metric, all positively oriented, form a holomorphic atlas. In other words, a metric on an oriented surface determines a complex structure, and so turns Σ into a Riemann surface. The complex structure is encoded locally by the Beltrami coefficient μ.

Worked example 5.66: Flat tori and the Cayley transform

Fix a complex number $\tau = \tau_1 + i\tau_2$ with $\tau_2 > 0$. On the square torus $\mathbb{R}^2/\mathbb{Z}^2$, with coordinates (x, y) taken mod 1, put the metric

$$\mathrm{d}s^2 = |\mathrm{d}x + \tau\,\mathrm{d}y|^2 = \mathrm{d}x^2 + 2\tau_1\,\mathrm{d}x\,\mathrm{d}y + |\tau|^2\,\mathrm{d}y^2. \tag{5.82}$$

Geometrically this is the flat torus $\mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$ pulled back along the linear map $(x, y) \mapsto w = x + \tau y$, which sends the unit square to the parallelogram with sides 1 and τ. Read off $A = 1$, $B = \tau_1$, $C = |\tau|^2$, so $\Delta = |\tau|^2 - \tau_1^2 = \tau_2^2$. Then

$$\lambda \overset{(1)}{=} \frac{1 + |\tau|^2 + 2\tau_2}{4} \overset{(2)}{=} \frac{|\tau + i|^2}{4},$$
$$\mu \overset{(3)}{=} \frac{1 - |\tau|^2 + 2i\tau_1}{|\tau + i|^2} \overset{(4)}{=} \frac{(i - \tau)(\overline{i + \tau})}{|i + \tau|^2} = \frac{i - \tau}{i + \tau}.$$

(1) (5.79) with $\sqrt{\Delta} = \tau_2$.
(2) $|\tau + i|^2 = \tau_1^2 + (\tau_2 + 1)^2 = |\tau|^2 + 2\tau_2 + 1$.
(3) (5.79) again, with $A - C + 2iB = 1 - |\tau|^2 + 2i\tau_1$.
(4) $(i - \tau)(-i + \bar\tau) = 1 + i\bar\tau + i\tau - |\tau|^2 = 1 - |\tau|^2 + 2i\tau_1$.

The map $\tau \mapsto \mu = (i - \tau)/(i + \tau)$ is (minus) the **Cayley transform**. It sends the upper half-plane $\tau_2 > 0$ one-to-one onto the unit disc $|\mu| < 1$: the point τ is closer to i than to $-i$ exactly when $\tau_2 > 0$. The square torus $\tau = i$ has $\mu = 0$. So the constant Beltrami coefficient of a flat torus *is* the modular parameter τ, in disguise. We will meet τ again in Section 5.5.

5.4.3 Conformal classes: Weyl rescalings do not change the shape

Look at (5.79) again. If we multiply the metric by a positive function f, then A, B, C all get multiplied by f. The formula for μ is homogeneous of degree zero in (A, B, C), so μ does not change. Only λ changes, to $f\lambda$. The ellipses of Figure 5.40 change size but not shape. Therefore:

Key idea: Complex structures are conformal classes

Two metrics $g_1 = \lambda_1 |\mathrm{d}z + \mu_1 \mathrm{d}\bar z|^2$ and $g_2 = \lambda_2 |\mathrm{d}z + \mu_2 \mathrm{d}\bar z|^2$ define the same complex structure exactly when $\mu_1 = \mu_2$, that is, exactly when $g_1 = f g_2$ for a positive function $f = \lambda_1/\lambda_2$. Complex structures on an oriented surface are in one-to-one correspondence

with **conformal classes** of metrics [Nash p. 149].

The converse direction (every complex structure comes from some metric) is easy: in each holomorphic chart w_α take the flat metric $|\mathrm{d}w_\alpha|^2$, and glue these together with a partition of unity $\sum_\alpha \chi_\alpha = 1$ into $g = \sum_\alpha \chi_\alpha |\mathrm{d}w_\alpha|^2$. On an overlap $|\mathrm{d}w_\beta|^2 = |w'_\beta(w_\alpha)|^2 |\mathrm{d}w_\alpha|^2$, so g is a positive function times $|\mathrm{d}w_\alpha|^2$ in every chart. It is conformal to the flat metric of every chart, which is what we wanted.

Nash packages this as a group action. Let $\mathrm{Met}(\Sigma)$ be the space of all smooth metrics on Σ, and $C^\infty_+(\Sigma)$ the group (under pointwise multiplication) of smooth positive functions. The group acts by multiplication, and the quotient is the space of conformal classes [Nash p. 149, (5.36)]:

$$A : C^\infty_+(\Sigma) \times \mathrm{Met}(\Sigma) \to \mathrm{Met}(\Sigma), \quad (f, g) \mapsto fg; \qquad \mathrm{Conf}(\Sigma) = \frac{\mathrm{Met}(\Sigma)}{C^\infty_+(\Sigma)}. \tag{5.83}$$

Working definition 5.38 (conformal class, $\mathrm{Conf}(\Sigma)$)

Two metrics are **conformally equivalent** if their ratio is a positive function. *Operational test:* compute μ for each with (5.79) in the same coordinates; they are conformally equivalent if and only if the two μ's agree at every point. $\mathrm{Conf}(\Sigma)$ is the set of equivalence classes; [each class is all the metrics conformally equivalent to one given metric] each point of it is a complex structure on Σ [a choice of which local coordinates z count as holomorphic].

Worked example 5.67: Weyl invariance of the Polyakov action

Why does string theory care about conformal classes? Take the integrand of the worldsheet action (5.74) and replace g by fg. In two dimensions,

$$\sqrt{\det(fg)}\,(fg)^{ab} \overset{(1)}{=} \sqrt{f^2 \det g}\; f^{-1} g^{ab} \overset{(2)}{=} f\sqrt{\det g}\; f^{-1} g^{ab} = \sqrt{\det g}\; g^{ab}.$$

(1) The determinant of a 2×2 matrix scales as f^2; the inverse matrix scales as f^{-1}.

(2) $f > 0$, so $\sqrt{f^2} = f$; the two factors cancel.

So the classical action depends only on the conformal class of g. The cancellation is special to dimension two: in dimension n one would get $f^{n/2} f^{-1}$. Quantum mechanically the Weyl invariance survives only in the critical dimension $d = 26$ (the conformal anomaly, Chapter 10). Granting that, the integral over $\mathrm{Met}(\Sigma)$ reduces to an integral over $\mathrm{Conf}(\Sigma)$.

Watch out: $\mathrm{Conf}(\Sigma)$ is still infinite dimensional

Dividing by $C^\infty_+(\Sigma)$ removes one function's worth of freedom out of the three functions A, B, C. What is left is one complex function μ, still an infinite-dimensional space. The diffeomorphisms remove another complex function's worth (two real vector field components), and that is why the final answer is finite dimensional.

5.4.4 Dividing out by diffeomorphisms

If $\alpha : \Sigma \to \Sigma$ is a diffeomorphism and g is a metric, then the pulled-back metric $\alpha^* g$ makes $(\Sigma, \alpha^* g)$ isometric to (Σ, g): the map α is the isometry. Physically, α is only a relabelling of the points of the worldsheet, and the Polyakov action is invariant under it (the fields ϕ are

pulled back too). So we should not count g and $\alpha^* g$ as different. We need to divide $\mathrm{Conf}(\Sigma)$ by diffeomorphisms as well. Three groups appear.

Working definition 5.39 ($\mathrm{Diff}(\Sigma)$, $\mathrm{Diff}^+(\Sigma)$, $\mathrm{Diff}_0(\Sigma)$)

- $\mathrm{Diff}(\Sigma)$: all diffeomorphisms of Σ. [smooth invertible maps $\Sigma \to \Sigma$ with smooth inverse]
- $\mathrm{Diff}^+(\Sigma)$: the orientation-preserving ones (Jacobian determinant > 0 in oriented charts).
- $\mathrm{Diff}_0(\Sigma)$: those that can be joined to the identity by a continuous path α_t of diffeomorphisms, $\alpha_0 = \mathrm{id}$, $\alpha_1 = \alpha$. It is the connected component of the identity.

Test for Diff_0*:* if α acts non-trivially on the first homology (it moves some closed curve to a curve that is not homologous to it) [the two curves together, one reversed, do not bound a region], then $\alpha \notin \mathrm{Diff}_0$, because a continuous deformation cannot change a homology class.

Why only orientation-preserving maps? Consider the reflection $c(x, y) = (x, -y)$, i.e. $c(z) = \bar{z}$. It pulls back $\mathrm{d}z$ to $\mathrm{d}\bar{z}$. So

$$c^*\left(\lambda\,|\mathrm{d}z + \mu\,\mathrm{d}\bar{z}|^2\right) \overset{(1)}{=} (\lambda \circ c)\,|\mathrm{d}\bar{z} + (\mu \circ c)\,\mathrm{d}z|^2 \overset{(2)}{=} (\lambda \circ c)\left|\mathrm{d}z + \overline{(\mu \circ c)}\,\mathrm{d}\bar{z}\right|^2.$$

(1) Pull back: $c^*\mathrm{d}z = \mathrm{d}\bar{z}$ and $c^*\mathrm{d}\bar{z} = \mathrm{d}z$, and functions get composed with c.
(2) A complex number and its conjugate have the same modulus, so $|\mu\,\mathrm{d}z + \mathrm{d}\bar{z}| = |\bar{\mu}\,\mathrm{d}\bar{z} + \mathrm{d}z|$.

The new Beltrami coefficient is $\bar{\mu}$: the *complex conjugate structure*. For the flat torus of Example 5.66, conjugating $\mu = (i-\tau)/(i+\tau)$ gives $\bar{\mu} = (i+\bar{\tau})/(i-\bar{\tau})$, which is the same formula with τ replaced by $-\bar{\tau}$: the mirror-image parallelogram. Orientation-reversing maps identify a Riemann surface with its mirror image, which is in general a different Riemann surface. We keep the two apart by using only $\mathrm{Diff}^+(\Sigma)$ [Nash p. 150].

$\mathrm{Diff}_0(\Sigma)$ is a **normal subgroup** of $\mathrm{Diff}^+(\Sigma)$: if α_t joins id to α, then $h\alpha_t h^{-1}$ joins id to $h\alpha h^{-1}$ for any h. Normality means the quotient $\mathrm{Diff}^+/\mathrm{Diff}_0$ is again a group, the mapping class group of Section 5.5. In this section we use only Diff_0.

Worked example 5.68: Small and large diffeomorphisms of the torus

On $T^2 = \mathbb{R}^2/\mathbb{Z}^2$:

- The translation $\alpha(x, y) = (x + a,\ y + b)$ lies in Diff_0: the path $\alpha_t(x, y) = (x + ta,\ y + tb)$ joins it to the identity.
- The shear $\beta(x, y) = (x + y,\ y)$ is a well-defined diffeomorphism (it maps $\mathbb{Z}^2$ to itself). It sends the closed curve $b : t \mapsto (0, t)$ to $t \mapsto (t, t)$, which winds once around each direction. In homology $[b] \mapsto [a] + [b]$. So $\beta \notin \mathrm{Diff}_0$. It is orientation preserving (Jacobian determinant 1), so $\beta \in \mathrm{Diff}^+$.
- The rotation $\rho(x, y) = (-y,\ x)$ maps $[a] \mapsto [b]$ and $[b] \mapsto -[a]$. Again $\rho \in \mathrm{Diff}^+$ but $\rho \notin \mathrm{Diff}_0$.

The large diffeomorphisms β and ρ are exactly the ones that will generate the modular group in Section 5.5.

Nash's first definition of Teichmüller space is then [Nash p. 150, (5.37)]

$$\mathcal{T}_p \;=\; \frac{\mathrm{Conf}(\Sigma)}{\mathrm{Diff}_0(\Sigma)}, \qquad p \geq 2. \tag{5.84}$$

Why the restriction $p \geq 2$? To see what goes wrong for the sphere and the torus we need a small detour on group actions.

5.4.5 Free actions, fixed points and conformal Killing vectors

Working definition 5.40 (free action, orbit, stabiliser)

A group G **acts** on a space X if each $h \in G$ gives a map $x \mapsto h \cdot x$ with $e \cdot x = x$ and $(h_1 h_2) \cdot x = h_1 \cdot (h_2 \cdot x)$. The **orbit** of x is $G \cdot x = \{h \cdot x : h \in G\}$; the quotient X/G is the set of orbits. The **stabiliser** of x is $G_x = \{h : h \cdot x = x\}$. The action is **free** if every stabiliser is trivial: $h \cdot x = x$ implies $h = e$. *Dimension count:* if G and X are manifolds, the orbit of x has dimension $\dim G - \dim G_x$. When all stabilisers have the same dimension (for instance, all trivial), the quotient is a manifold of dimension $\dim X - \dim G$. Where a stabiliser jumps, [some point x is fixed by more of G than its neighbours are] the quotient is singular there [Nash p. 150, footnote 4].

Worked example 5.69: Three quotients of the plane

1. $\mathbb{R}$ acting on $\mathbb{R}^2$ by horizontal translation $t \cdot (x, y) = (x + t, y)$. Free. Every orbit is a horizontal line, and $\mathbb{R}^2/\mathbb{R} \cong \mathbb{R}$ (label each line by y). A manifold of dimension $2 - 1 = 1$.

2. SO(2) acting by rotations. The origin has stabiliser all of SO(2), of dimension 1; every other point has trivial stabiliser. The orbits are circles of radius $r > 0$ plus the single point $\{0\}$. The quotient is the half-line $[0, \infty)$, which has an edge at $r = 0$. The generic orbits have dimension 1 and the special one has dimension $0 = 1 - 1$.

3. $\mathbb{Z}_2$ acting by rotation through π, $(x, y) \mapsto (-x, -y)$. Only the origin is fixed. The quotient is a *cone* with cone angle π (Figure 5.41): a smooth surface everywhere except at the tip. This is the prototype of an *orbifold point*, and it is exactly what happens in moduli space.

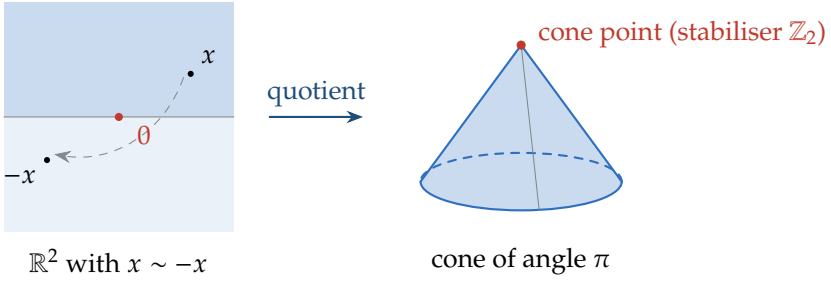


Figure 5.41: Dividing the plane by the rotation through π. The upper half plane (darker) is a fundamental region; the two halves of its edge are glued by $x \sim -x$, rolling it into a cone. Everywhere except the tip the quotient is a smooth surface. At the tip the stabiliser is $\mathbb{Z}_2$ and the space is singular. Moduli spaces of Riemann surfaces have exactly such points.

Now apply this to $\mathrm{Diff}_0(\Sigma)$ acting on $\mathrm{Conf}(\Sigma)$. A point $[g]$ of $\mathrm{Conf}(\Sigma)$ has a nontrivial continuous stabiliser if there is a one-parameter family of diffeomorphisms α_t with $\alpha_t^* g$

conformal to g for all t. Differentiating at $t = 0$, the generating vector field V satisfies

$$\mathcal{L}_V\, g = C\, g \qquad \text{for some function } C. \tag{5.85}$$

Such a V is a **conformal Killing vector** [Nash p. 160, footnote 5]. (If $C = 0$ it is an ordinary Killing vector, an infinitesimal isometry.) So: *the action of* Diff_0 *on* Conf *fails to be free exactly when there are conformal Killing vectors.* Let us find them.

The conformal Killing equation in complex coordinates

We need the Lie derivative of a metric (Chapter T1). In coordinates x^a,

$$(\mathcal{L}_V g)_{ab} = V^c\,\partial_c g_{ab} + g_{cb}\,\partial_a V^c + g_{ac}\,\partial_b V^c. \tag{5.86}$$

The first term is the change of g along the flow, and the other two account for the stretching of the coordinate basis by the flow. We use the complex coordinates $z, \bar z$ as the x^a. A metric in isothermal form $\mathrm{d}s^2 = \lambda\,\mathrm{d}z\,\mathrm{d}\bar z$ has components

$$g_{z\bar z} = g_{\bar z z} = \tfrac{1}{2}\lambda, \qquad g_{zz} = g_{\bar z\bar z} = 0, \tag{5.87}$$

because $\mathrm{d}s^2 = g_{z\bar z}\mathrm{d}z\mathrm{d}\bar z + g_{\bar z z}\mathrm{d}\bar z\mathrm{d}z$. A real vector field is $V = V^z\partial_z + V^{\bar z}\partial_{\bar z}$ with $V^{\bar z} = \overline{V^z}$. Then

$$\begin{aligned}(\mathcal{L}_V g)_{\bar z\bar z} &\overset{(1)}{=} V^c\,\partial_c g_{\bar z\bar z} + g_{c\bar z}\,\partial_{\bar z}V^c + g_{\bar z c}\,\partial_{\bar z}V^c \\ &\overset{(2)}{=} 0 + g_{z\bar z}\,\partial_{\bar z}V^z + g_{\bar z z}\,\partial_{\bar z}V^z \\ &\overset{(3)}{=} \lambda\,\partial_{\bar z}V^z.\end{aligned} \tag{5.88}$$

(1) (5.86) with $a = b = \bar z$.
(2) $g_{\bar z\bar z} \equiv 0$, and the sums over c only keep $c = z$ because $g_{\bar z\bar z} = 0$.
(3) $g_{z\bar z} = g_{\bar z z} = \lambda/2$.

The right side of (5.85), Cg, has zero $\bar z\bar z$ component. The zz component of (5.85) is the complex conjugate of the $\bar z\bar z$ one, and the $z\bar z$ component just determines C. So the conformal Killing equation is simply

$$\boxed{\partial_{\bar z}V^z = 0} \tag{5.89}$$

Conformal Killing vectors are holomorphic vector fields $V = V^z(z)\,\partial_z + \text{c.c.}$

Worked example 5.70: Conformal Killing vectors on the sphere

On $S^2 = \mathbb{C}\cup\{\infty\}$ use z near 0 and $w = 1/z$ near ∞. Since $z = 1/w$, the chain rule gives $\partial_w = (\mathrm{d}z/\mathrm{d}w)\,\partial_z = -w^{-2}\partial_z$, so $\partial_z = -w^2\partial_w$. Try $V = (a + bz + cz^2)\partial_z$:

$$\begin{aligned}V &\overset{(1)}{=} \big(a + bw^{-1} + cw^{-2}\big)(-w^2)\,\partial_w \\ &= -\big(aw^2 + bw + c\big)\,\partial_w.\end{aligned}$$

(1) Substitute $z = 1/w$ and $\partial_z = -w^2\partial_w$.

This is holomorphic at $w = 0$, so V is a global holomorphic vector field. A term $z^3\partial_z = -w^{-1}\partial_w$ would blow up at ∞. In general $V^z(z)$ must be entire, and regularity of $-w^2V^z(1/w)$ at $w = 0$ says $|V^z(z)| \le \text{const}\cdot|z|^2$ for large $|z|$; by the extended Liouville theorem (an entire function bounded by a polynomial of degree k is a polynomial of degree $\le k$), V^z is a quadratic polynomial. So the conformal Killing vectors form a space of complex dimension 3 (real dimension 6). They generate the Möbius maps $z \mapsto (az + b)/(cz + d)$:

∂_z translates, $z\partial_z$ dilates and rotates, $z^2\partial_z$ is a special conformal transformation. In string language they are the $\mathrm{SL}(2,\mathbb{C})$ symmetry that lets one fix three vertex operators on the sphere.

Worked example 5.71: Conformal Killing vectors on the torus

On $T^2 = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$ a holomorphic vector field is $V^z(z)\partial_z$ with V^z holomorphic on $\mathbb{C}$ and doubly periodic. A continuous doubly periodic function is bounded (it is determined by its values on the compact parallelogram), so by Liouville V^z is constant. The conformal Killing vectors are the translations $V = c\,\partial_z + \bar{c}\,\partial_{\bar{z}}$: complex dimension 1 (real dimension 2). They are actually Killing vectors of the flat metric. In a one-loop string amplitude they let one fix the position of one vertex operator.

For genus $p \geq 2$ there are no holomorphic vector fields at all. We prove this in Section 5.6 (it follows from a degree count: a holomorphic vector field is a section of a line bundle of degree $2 - 2p < 0$). Table 5.1 summarises.

Table 5.1: Conformal Killing vectors (holomorphic vector fields) by genus. A non-zero count means Diff_0 does not act freely on $\mathrm{Conf}(\Sigma)$.

genus p	complex dim	real dim	what they are
0 (sphere)	3	6	∂_z, $z\partial_z$, $z^2\partial_z$: Möbius group $\mathrm{PSL}(2,\mathbb{C})$
1 (torus)	1	2	translations ∂_z
≥ 2	0	0	none

Physical picture: Fixed points are symmetric worldsheets

A conformal Killing vector is a continuous symmetry of the worldsheet's shape. A round sphere can be rotated and still look the same; a flat torus can be slid along itself. The orbit of such a symmetric shape under Diff_0 is smaller than a generic orbit, so the naive quotient $\mathrm{Conf}/\mathrm{Diff}_0$ is singular there. For $p \geq 2$ the only symmetries are discrete (Section 5.5), and Diff_0 acts freely.

5.4.6 Uniformisation: one best metric in each conformal class

Nash's fix for $p < 2$ is to choose a canonical representative in each conformal class: a metric of *constant* Gaussian curvature. That such a metric exists is the content of the uniformisation theorem. We need two pieces of background first.

Background: universal covers

A **covering map** $\pi : \tilde{X} \to X$ is a surjective map that looks locally like a stack of copies of X: every point of X has a neighbourhood U with $\pi^{-1}(U)$ a disjoint union of copies of U. The **universal cover** $\tilde{X}$ is the covering space that is simply connected. Standard examples:

- $\mathbb{R} \to S^1$, $t \mapsto e^{2\pi i t}$. The points t and $t + n$ map to the same point. The group $\mathbb{Z}$ acts on $\mathbb{R}$ by $t \mapsto t + n$, and $S^1 = \mathbb{R}/\mathbb{Z}$.
- $\mathbb{C} \to T^2 = \mathbb{C}/\Lambda$ for a lattice $\Lambda = \mathbb{Z}\omega_1 + \mathbb{Z}\omega_2$. Here $\mathbb{Z} \oplus \mathbb{Z}$ acts by translations $z \mapsto z + m\omega_1 + n\omega_2$.

In general the group of **deck transformations** (maps $\tilde X \to \tilde X$ commuting with π) of the universal cover is the fundamental group $\pi_1(X)$, it acts freely, and [Nash p. 151, (5.38)]

$$\Sigma \;=\; \tilde\Sigma/\pi_1(\Sigma). \tag{5.90}$$

If Σ is a Riemann surface, $\tilde\Sigma$ inherits a complex structure (pull back the charts along π), and the deck transformations are holomorphic.

Background: curvature of a conformally flat metric

For $ds^2 = \lambda|dz|^2 = \lambda(dx^2+dy^2)$ the Gaussian curvature is

$$K \;=\; -\frac{1}{2\lambda}\left(\partial_x^2+\partial_y^2\right)\log\lambda \;=\; -\frac{2}{\lambda}\,\partial_z\partial_{\bar z}\log\lambda, \tag{5.91}$$

using $\partial_x^2+\partial_y^2 = 4\partial_z\partial_{\bar z}$. (This is the standard formula for a conformally flat metric; it follows from the curvature 2-form of the orthonormal coframe $\sqrt{\lambda}\,dx$, $\sqrt{\lambda}\,dy$, see Chapter T2.) The area element is $dA = \lambda\,dx\,dy$. We will also need the Gauss–Bonnet theorem

$$\int_\Sigma K\,dA \;=\; 2\pi\chi(\Sigma) \;=\; 2\pi(2-2p). \tag{5.92}$$

Worked example 5.72: The three model geometries

Round sphere. Stereographic projection gives $\lambda = 4/(1+|z|^2)^2$. Then

$$\partial_z\partial_{\bar z}\log\lambda \overset{(1)}{=} -2\,\partial_z\partial_{\bar z}\log(1+z\bar z) \overset{(2)}{=} -2\,\partial_z\left(\frac{z}{1+z\bar z}\right) \overset{(3)}{=} -\frac{2}{(1+z\bar z)^2},$$

$$K \overset{(4)}{=} -\frac{2}{\lambda}\cdot\left(-\frac{2}{(1+|z|^2)^2}\right) = \frac{(1+|z|^2)^2}{2}\cdot\frac{2}{(1+|z|^2)^2} = 1.$$

(1) $\log\lambda = \log 4 - 2\log(1+z\bar z)$; the constant is killed by derivatives.
(2) $\partial_{\bar z}\log(1+z\bar z) = z/(1+z\bar z)$.
(3) Quotient rule: $\partial_z[z(1+z\bar z)^{-1}] = (1+z\bar z)^{-1} - z\bar z(1+z\bar z)^{-2} = (1+z\bar z)^{-2}$.
(4) (5.91) with $2/\lambda = (1+|z|^2)^2/2$.

Flat plane. $\lambda = 1$, $\log\lambda = 0$, $K = 0$.

Upper half-plane $H = \{\operatorname{Im} z > 0\}$ with $\lambda = 1/y^2$, i.e. $ds^2 = (dx^2+dy^2)/y^2$:

$$K \overset{(1)}{=} -\frac{y^2}{2}\,\partial_y^2(-2\log y) \overset{(2)}{=} -\frac{y^2}{2}\cdot\frac{2}{y^2} = -1.$$

(1) (5.91); $\log\lambda = -2\log y$ does not depend on x.
(2) $\partial_y^2(-2\log y) = 2/y^2$.

Watch out: Nash's formula (5.40) for the hyperbolic metric

Nash writes the curvature -1 metric as $ds^2 = dz\,d\bar z/(z-\bar z)^2$. Since $z-\bar z = 2iy$, this is $dz d\bar z/(-4y^2) = -\tfrac14|dz|^2/y^2$: negative, and a quarter of the correct size. The metric that is positive and has $K=-1$ is

$$ds^2 = \frac{|dz|^2}{y^2} = -\frac{4\,dz\,d\bar z}{(z-\bar z)^2}.$$

Treat (5.40) as "proportional to" and use this corrected version.

Key idea: Riemann uniformisation (Nash (5.39))

Up to biholomorphism there are exactly three simply connected Riemann surfaces: the sphere $S^2 = \mathbb{CP}^1$, the plane $\mathbb{C}$, and the upper half-plane H (equivalently the unit disc). They carry the complete metrics of constant curvature $+1$, 0 and -1 of Example 5.72. The universal cover of a compact Riemann surface of genus p is

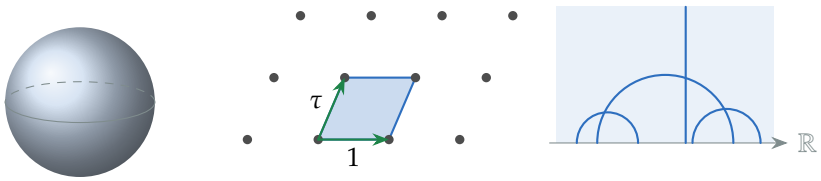
$$\tilde{\Sigma} = S^2 \ (p = 0), \qquad \tilde{\Sigma} = \mathbb{C} \ (p = 1), \qquad \tilde{\Sigma} = H \ (p \geq 2),$$

and the deck group $\pi_1(\Sigma)$ acts by isometries of that metric, so the metric descends to a constant-curvature metric on Σ in the given conformal class.

Which of the three occurs is forced by Gauss–Bonnet. If K is a constant, then (5.92) reads

$$K \cdot \mathrm{Area}(\Sigma) = 2\pi(2 - 2p). \tag{5.93}$$

Area is positive, so $K > 0$ for $p = 0$, $K = 0$ for $p = 1$ and $K < 0$ for $p \geq 2$. With $K = +1$ the sphere has area 4π (the round unit sphere). With $K = -1$ a genus-p surface has area $4\pi(p - 1)$: for example 4π for genus 2. With $K = 0$ the equation says $0 = 0$ and puts no constraint on the area. Figure 5.42 shows the three pictures.



$p = 0$: $\tilde{\Sigma} = \Sigma = S^2$
$K = +1$, $\pi_1 = 1$

$p = 1$: $\tilde{\Sigma} = \mathbb{C}$, $K = 0$
$\pi_1 = \mathbb{Z} \oplus \mathbb{Z}$ (lattice)

$p \geq 2$: $\tilde{\Sigma} = H$, $K = -1$
geodesics: semicircles

Figure 5.42: The three model geometries of uniformisation. Every compact Riemann surface is one of these divided by a group of isometries acting freely: nothing for the sphere, a lattice of translations for the torus (the shaded parallelogram with sides 1 and τ is a copy of the torus), and a discrete group of Möbius maps (a Fuchsian group) for $p \geq 2$. Geodesics of the hyperbolic metric are vertical lines and semicircles centred on the real axis.

5.4.7 The space of constant curvature metrics and Nash's second definition

Uniformisation gives, for each conformal class $c \in \mathrm{Conf}(\Sigma)$, a metric g_c in that class with constant curvature. Nash thinks of $\mathrm{Met}(\Sigma)$ as a bundle over $\mathrm{Conf}(\Sigma)$ (the fibre over c is the set of metrics in the class c, a copy of C^∞_+), and of $c \mapsto g_c$ as a section [Nash p. 151, (5.41)]:

$$s : \mathrm{Conf}(\Sigma) \to \mathrm{Met}(\Sigma), \qquad s(c) = g_c. \tag{5.94}$$

How unique is g_c? Suppose g and $e^{2\sigma} g$ are both flat on a torus. With $g = \lambda |\mathrm{d}z|^2$ and (5.91), flatness of both says $\partial\bar{\partial} \log \lambda = 0$ and $\partial\bar{\partial}(\log \lambda + 2\sigma) = 0$, so $\partial_z \partial_{\bar{z}} \sigma = 0$. Thus σ is a harmonic function on a compact surface. It attains its maximum, and by the maximum principle it is constant. So the flat metric in a conformal class on the torus is unique *up to a constant scale*, and we fix the scale by demanding area 1. For the hyperbolic case the curvature -1 condition fixes the scale as well, and the constant-curvature metric in each conformal class is unique. For the sphere every metric is conformally equivalent to the round one, which is unique up to the conformal automorphisms (the Möbius maps); since we divide by diffeomorphisms anyway this ambiguity is harmless.

So Nash defines [Nash p. 152, (5.42)]

$$\mathrm{Met}_{\mathrm{const}}(\Sigma) = \begin{cases} \{g \in \mathrm{Met}(\Sigma) : R(g) = 1\}, & p = 0, \\ \{g \in \mathrm{Met}(\Sigma) : R(g) = 0,\ \mathrm{vol}(\Sigma) = 1\}, & p = 1, \\ \{g \in \mathrm{Met}(\Sigma) : R(g) = -1\}, & p \geq 2, \end{cases} \tag{5.95}$$

where $R(g)$ is the Gaussian curvature. The second definition of Teichmüller space, which works in every genus, is [Nash p. 152, (5.43)]

$$\boxed{\mathcal{T}_p = \frac{\mathrm{Met}_{\mathrm{const}}(\Sigma)}{\mathrm{Diff}_0(\Sigma)}, \qquad p = 0, 1, 2, \ldots} \tag{5.96}$$

Watch out: A slip in Nash's explanation of the volume condition

Nash says the condition $\mathrm{vol}(\Sigma) = 1$ is imposed "for the $p = 0$ case because in that case Σ is the torus". He means $p = 1$. The logic is (5.93): for $K = 0$ Gauss–Bonnet does not fix the area, so we fix it by hand. For $K = \pm 1$ Gauss–Bonnet fixes it automatically.

Working definition 5.41 (Teichmüller space)

A point of $\mathcal{T}_p$ is a constant-curvature metric [curvature $K = +1, 0, -1$ for $p = 0, 1, \geq 2$, with area fixed to 1 when $K = 0$] on the genus-p surface Σ, where two such metrics count as the same if one is the pull-back of the other by a diffeomorphism isotopic to the identity. [joined to id by a continuous path of diffeomorphisms, i.e. an element of Diff_0] Equivalently it is a complex structure on Σ up to Diff_0. *Operational version:* a complex structure together with a choice of "which curve is which" (a **marking**: a basis a_i, b_i of H_1 up to deformation), since Diff_0 acts trivially on curves up to isotopy, while the larger group Diff^+ can reshuffle them.

Worked example 5.73: Genus zero: $\mathcal{T}_0$ is a point

By uniformisation every metric on S^2 is conformal to one with $K = 1$, and any two metrics with $K = 1$ on S^2 are isometric (both are the round unit sphere). The isometry can be chosen orientation preserving, and $\mathrm{Diff}^+(S^2)$ is connected (every orientation-preserving diffeomorphism of the sphere can be deformed to the identity), so the isometry lies in Diff_0. Hence $\mathrm{Met}_{\mathrm{const}}(S^2)/\mathrm{Diff}_0$ is a single point. The sphere has no shape moduli.

Worked example 5.74: Genus one: $\mathcal{T}_1$ is the upper half-plane

Here is a direct computation of $\mathcal{T}_1$ from (5.96); Section 5.5 redoes it Nash's way with lattices. Work on $T^2 = \mathbb{R}^2/\mathbb{Z}^2$. Take a flat metric of area one. Its universal cover is the flat plane, so in suitable coordinates the metric has *constant* coefficients; after pulling back by an element of Diff_0 we may assume this happens in our coordinates (x, y). (Sketch: a flat torus is $\mathbb{R}^2/\Lambda$ with the Euclidean metric; the linear map sending $\mathbb{Z}^2$ to Λ with the correct marking pulls it back to a constant-coefficient metric on $\mathbb{R}^2/\mathbb{Z}^2$, and the difference between two such identifications is homotopic to the identity.) So we must classify

$$G = \begin{pmatrix} A & B \\ B & C \end{pmatrix}, \qquad A > 0, \quad \det G = AC - B^2 = 1,$$

the determinant being the area of the unit square. Parametrise by $\tau = \tau_1 + i\tau_2$ with $\tau_2 > 0$:

$$G(\tau) = \frac{1}{\tau_2} \begin{pmatrix} 1 & \tau_1 \\ \tau_1 & |\tau|^2 \end{pmatrix}, \qquad \text{i.e.} \qquad \mathrm{d}s^2 = \frac{1}{\tau_2} |\mathrm{d}x + \tau\, \mathrm{d}y|^2. \tag{5.97}$$

Check: $\det G = (|\tau|^2 - \tau_1^2)/\tau_2^2 = \tau_2^2/\tau_2^2 = 1$. The map is invertible: given G with $\det G = 1$, set $\tau_2 = 1/A$ and $\tau_1 = B/A$. Then

$$\frac{|\tau|^2}{\tau_2} \overset{(1)}{=} \left(\frac{B^2}{A^2} + \frac{1}{A^2}\right)A \overset{(2)}{=} \frac{B^2+1}{A} \overset{(3)}{=} \frac{AC}{A} = C,$$

(1) $|\tau|^2 = \tau_1^2 + \tau_2^2$ with the values just chosen, and $1/\tau_2 = A$.
(2) Algebra.
(3) $\det G = 1$ means $B^2 + 1 = AC$.

so $G = G(\tau)$ exactly. Finally, two different τ's are not related by Diff_0: an isometry between two flat tori lifts to an affine map of $\mathbb{R}^2$ preserving $\mathbb{Z}^2$, whose linear part is an integer matrix; being in Diff_0 it acts trivially on H_1, so the linear part is the identity and the map is a translation, which does not change a constant G. Hence

$$\mathcal{T}_1 \;\cong\; \{\tau : \tau_2 > 0\} = H, \tag{5.98}$$

one complex dimension. The space of unit-determinant positive 2×2 matrices is also $\mathrm{SL}(2,\mathbb{R})/\mathrm{SO}(2)$; its natural geometry is the hyperbolic plane, a first hint of the Weil–Petersson metric of chapter 9. Comparing with Example 5.66, the Beltrami coefficient of $G(\tau)$ is $\mu = (i - \tau)/(i + \tau)$ (the overall factor $1/\tau_2$ changes only λ).

Physical picture: What $\mathcal{T}_p$ remembers

Teichmüller space remembers the shape *and* a labelling of the curves on the surface. Two tori with τ and $\tau + 1$ have the same shape (the parallelogram with sides $1, \tau + 1$ tiles the same lattice as the one with sides $1, \tau$), but they are different points of $\mathcal{T}_1$, because the curve we called b has been sent to $a + b$. Forgetting the labelling is the passage to moduli space.

Reading Nash (pp. 148–152, (5.35)–(5.43))

Nash writes the general metric as $\lambda|\mathrm{d}z + \mu\mathrm{d}\bar{z}|^2$ (5.35), observes that μ labels complex structures, and forms $\mathrm{Conf}(\Sigma) = \mathrm{Met}/C^\infty_+$ (5.36). His first definition $\mathcal{T}_p = \mathrm{Conf}/\mathrm{Diff}_0$ (5.37) is valid for $p \geq 2$; footnote 4 explains free actions and orbit dimensions, and the failure for $p < 2$ is blamed on conformal Killing vectors. Uniformisation (5.38)–(5.40) supplies the constant curvature section s (5.41), leading to $\mathrm{Met}_{\mathrm{const}}$ (5.42) and the all-genus definition (5.43). We added: the explicit solution (5.79) for λ, μ; the ellipse picture; the proof that isothermal charts are holomorphic; the conformal Killing equation (5.89) and its solutions on S^2 and T^2; the curvature computations; the corrected hyperbolic metric; and the direct identification $\mathcal{T}_1 = H$.

Recap

- Any metric on a surface is $\lambda|\mathrm{d}z + \mu\mathrm{d}\bar{z}|^2$ with $|\mu| < 1$; μ is a field of infinitesimal ellipses and is unchanged by Weyl rescaling.
- Metric + orientation $\Rightarrow$ complex structure (isothermal charts), and complex structures = conformal classes.
- Teichmüller space $\mathcal{T}_p = \mathrm{Conf}/\mathrm{Diff}_0$ for $p \geq 2$; conformal Killing vectors (holomorphic vector fields, $\partial_{\bar{z}} V^z = 0$) spoil freeness for $p = 0, 1$.
- Uniformisation: each class has a constant-curvature metric ($K = +1, 0, -1$ for $p =$

$0, 1, \geq 2$, forced by Gauss–Bonnet), giving $\mathcal{T}_p = \mathrm{Met}_{\mathrm{const}}/\mathrm{Diff}_0$ in all genera.

- $\mathcal{T}_0$ is a point; $\mathcal{T}_1 = H$, the upper half-plane of τ.

5.5 The moduli space $\mathcal{M}_p$

Teichmüller space still overcounts. In Example 5.74 the tori with parameters τ and $\tau + 1$ were different points of $\mathcal{T}_1$. Yet they are the same flat torus: the lattice $\mathbb{Z} + \tau\mathbb{Z}$ equals the lattice $\mathbb{Z} + (\tau + 1)\mathbb{Z}$, since each basis is an integer combination of the other. They differ only in which closed curve we decided to call "b". A string path integral must count each physically distinct worldsheet exactly once, so it must forget this labelling. The space of Riemann surfaces with the labels forgotten is the moduli space.

5.5.1 Large diffeomorphisms and the mapping class group

The fix is to divide by all orientation-preserving diffeomorphisms, not only those in the identity component [Nash p. 152, (5.44)]:

$$\mathcal{T}_p = \frac{\mathrm{Met}_{\mathrm{const}}(\Sigma)}{\mathrm{Diff}_0(\Sigma)}, \qquad \mathcal{M}_p = \frac{\mathrm{Met}_{\mathrm{const}}(\Sigma)}{\mathrm{Diff}^+(\Sigma)}. \tag{5.99}$$

Because Diff_0 is a normal subgroup of Diff^+, we can take the quotient in two steps. Define the **mapping class group**

$$\Gamma_\Sigma = \frac{\mathrm{Diff}^+(\Sigma)}{\mathrm{Diff}_0(\Sigma)}. \tag{5.100}$$

Then [Nash p. 152, (5.45)]

$$\mathcal{M}_p \overset{(1)}{=} \frac{\mathrm{Met}_{\mathrm{const}}}{\mathrm{Diff}^+} \overset{(2)}{=} \frac{\left(\mathrm{Met}_{\mathrm{const}}/\mathrm{Diff}_0\right)}{\left(\mathrm{Diff}^+/\mathrm{Diff}_0\right)} \overset{(3)}{=} \frac{\mathcal{T}_p}{\Gamma_\Sigma}. \tag{5.101}$$

(1) Definition (5.99).
(2) Two metrics lie in the same Diff^+-orbit iff their Diff_0-orbits are related by some $h \in \mathrm{Diff}^+$; and h and $h\alpha$ with $\alpha \in \mathrm{Diff}_0$ move Diff_0-orbits in the same way (normality: $h\alpha = (h\alpha h^{-1})h$ with $h\alpha h^{-1} \in \mathrm{Diff}_0$), so only the class of h in $\mathrm{Diff}^+/\mathrm{Diff}_0$ matters.
(3) Definitions (5.99) and (5.100).

Working definition 5.42 (mapping class group)

Γ_Σ is the group of orientation-preserving diffeomorphisms of Σ modulo those that can be continuously deformed to the identity. Its elements are the connected components of $\mathrm{Diff}^+(\Sigma)$, so it is a *discrete* group. [no two different elements can be joined by a continuous path] *Operational handle:* let a diffeomorphism act on the first homology $H_1(\Sigma;\mathbb{Z}) \cong \mathbb{Z}^{2p}$. This gives an integer $2p \times 2p$ matrix preserving the intersection form of Nash's (5.15), [(a, b), the signed count of crossings of two loops] i.e. an element of $\mathrm{Sp}(2p, \mathbb{Z})$. [integer matrices M with $M^T J M = J$, where J is the matrix of intersection numbers of the basis loops] For the torus this matrix determines the mapping class completely, and $\Gamma_{T^2} \cong \mathrm{SL}(2, \mathbb{Z})$. For $p \geq 2$ the map $\Gamma_\Sigma \to \mathrm{Sp}(2p, \mathbb{Z})$ is onto, but it has a large kernel (the Torelli group) [mapping classes that send every loop to a homologous loop], so the homology action does not see everything.

The mapping class group acts on $\mathcal{T}_p$ by changing the marking. It does *not* act freely: a Riemann surface with a discrete symmetry is a fixed point. So $\mathcal{M}_p$ is not a manifold. It is an orbifold.

Working definition 5.43 (orbifold)

An **orbifold** is a space that looks locally like $\mathbb{R}^n/G_x$ [points of $\mathbb{R}^n$ related by an element of G_x count as one point] for some finite group G_x acting linearly on $\mathbb{R}^n$. At points with G_x trivial it is an ordinary manifold. At points with $G_x \neq 1$ it has a singularity of the type seen in the cone of Figure 5.41. *Test:* if a space is X/Γ with X a manifold and Γ a discrete group acting with finite stabilisers [each point is fixed by only finitely many elements of Γ], it is an orbifold, and its singular points are the images of points with nontrivial stabiliser [Nash p. 152].

5.5.2 Surfaces as quotients of their universal cover

Nash gets a concrete picture of $\mathcal{M}_p$ from uniformisation (5.90): every Σ is $\tilde{\Sigma}/\pi_1(\Sigma)$ [Nash p. 153, (5.46)]. To build a Riemann surface this way we need an action of $\pi_1(\Sigma)$ on $\tilde{\Sigma}$ that is

- *free*, so that the quotient is a smooth surface (no cone points);
- *holomorphic*, so that the complex structure of $\tilde{\Sigma}$ descends to the quotient.

Classifying genus-p Riemann surfaces then means classifying such group actions up to holomorphic change of coordinates on $\tilde{\Sigma}$.

Genus zero

Here $\tilde{\Sigma} = S^2$ and $\pi_1(S^2) = 1$, so there is nothing to divide by. It is consistent that S^2 has no nontrivial free holomorphic actions at all. The holomorphic automorphisms of $\mathbb{CP}^1$ are the Möbius maps $z \mapsto (az+b)/(cz+d)$ with $ad - bc \neq 0$, and every one has a fixed point:

$$z = \frac{az+b}{cz+d} \iff z(cz+d) = az+b \iff cz^2 + (d-a)z - b = 0.$$

If $c \neq 0$ this quadratic has a root in $\mathbb{C}$ (fundamental theorem of algebra). If $c = 0$ the map is $z \mapsto (az+b)/d$, which fixes $z = \infty$. So every automorphism of the sphere has a fixed point, no nontrivial group acts freely, and *the only Riemann surface of genus zero is* $\mathbb{CP}^1$:

$$\mathcal{M}_0 = \{\text{point}\}.$$

Genus one: $\mathcal{T}_1 = \mathbb{C}^+$

Now $\tilde{\Sigma} = \mathbb{C}$ and $\pi_1(T^2) = \mathbb{Z} \oplus \mathbb{Z}$. The fixed-point-free holomorphic automorphisms of $\mathbb{C}$ are the translations $z \mapsto z + \omega$ (an automorphism $z \mapsto az + b$ with $a \neq 1$ fixes $b/(1-a)$). So $\mathbb{Z} \oplus \mathbb{Z}$ must act by two independent translations,

$$z \mapsto z + m\,\omega_1 + n\,\omega_2, \qquad m, n \in \mathbb{Z},$$

with ω_1, ω_2 linearly independent over $\mathbb{R}$ (otherwise the orbits are not discrete and the quotient is not a surface). Rescaling the coordinate, $z \mapsto z/\omega_1$, is holomorphic and turns the translations into $z \mapsto z + m + n\lambda$ with $\lambda = \omega_2/\omega_1$. If $\operatorname{Im}\lambda < 0$ we replace ω_2 by $-\omega_2$ (this is just choosing the

other generator), so we may take $\lambda \in \mathbb{C}^+ = \{\operatorname{Im}\lambda > 0\}$. Every such λ gives a torus $\mathbb{C}/(\mathbb{Z} + \lambda\mathbb{Z})$, and Nash concludes [Nash p. 153, (5.47)]

$$\mathcal{T}_1 = \mathbb{C}^+, \tag{5.102}$$

in agreement with Example 5.74. Nash calls λ the **modular parameter**; physicists write τ. We will use both.

5.5.3 When are two tori the same? The modular group

Let $T_1^2 = \mathbb{C}/(\mathbb{Z} + \lambda_1\mathbb{Z})$ and $T_2^2 = \mathbb{C}/(\mathbb{Z} + \lambda_2\mathbb{Z})$, and suppose $f : T_1^2 \to T_2^2$ is a biholomorphic (conformal, invertible) map [Nash p. 153, (5.48)]. We want the condition on λ_1, λ_2.

Step 1: the lift is affine

Because $\mathbb{C}$ is simply connected, $f \circ p_1 : \mathbb{C} \to T_2^2$ lifts through the covering $p_2 : \mathbb{C} \to T_2^2$ to a holomorphic map $\tilde f : \mathbb{C} \to \mathbb{C}$ with $f \circ p_1 = p_2 \circ \tilde f$ [Nash p. 154, (5.49)]:

$$\begin{array}{ccc} \mathbb{C} & \xrightarrow{\ \tilde f\ } & \mathbb{C} \\ {\scriptstyle p_1}\downarrow & & \downarrow{\scriptstyle p_2} \\ T_1^2 & \xrightarrow[\ f\ ]{} & T_2^2 \end{array}$$

Nash says "it is immediate that $\tilde f(z) = pz + q$". Here is why. Write $\Lambda_i = \mathbb{Z} + \lambda_i\mathbb{Z}$. For each lattice vector $\omega \in \Lambda_1$, the points z and $z + \omega$ map to the same point of T_1^2, so $\tilde f(z + \omega) - \tilde f(z)$ lies in Λ_2. It depends continuously on z and takes values in a discrete set, so it is a constant $c(\omega)$. Differentiating,

$$\tilde f'(z + \omega) = \tilde f'(z) \qquad \text{for all } \omega \in \Lambda_1.$$

So $\tilde f'$ is an entire function that is doubly periodic, hence bounded, hence constant by Liouville's theorem. Therefore $\tilde f(z) = pz + q$ with $p \neq 0$ (since f is invertible).

Step 2: lattices must correspond

Nash phrases the rest with group actions [Nash p. 154, (5.50)]. Let G_i be the translation group of Λ_i. The lift intertwines them: for each $g_2 \in G_2$ there is $g_1 \in G_1$ with $g_1 \cdot z = \tilde f^{-1}(g_2 \cdot \tilde f(z))$. Take g_2 to be the two generators $w \mapsto w + \lambda_2$ and $w \mapsto w + 1$. With $\tilde f^{-1}(w) = (w - q)/p$:

$$\begin{aligned} \tilde f^{-1}\big(\tilde f(z) + \lambda_2\big) &\overset{(1)}{=} \frac{(pz + q) + \lambda_2 - q}{p} = z + \frac{\lambda_2}{p} \overset{(2)}{=} z + b + a\lambda_1, \\ \tilde f^{-1}\big(\tilde f(z) + 1\big) &\overset{(1)}{=} \frac{(pz + q) + 1 - q}{p} = z + \frac{1}{p} \overset{(2)}{=} z + d + c\lambda_1, \end{aligned} \tag{5.103}$$

with $a, b, c, d \in \mathbb{Z}$ [Nash p. 154, (5.51)].

(1) Insert $\tilde f(z) = pz + q$ and $\tilde f^{-1}(w) = (w - q)/p$.
(2) The result must be a translation by an element of Λ_1, i.e. by $m + n\lambda_1$ for some integers; we name them (b, a) and (d, c).

So $\lambda_2 = p(a\lambda_1 + b)$ and $1 = p(c\lambda_1 + d)$. Divide the first by the second to eliminate p [Nash p. 154, (5.52)]:

$$\lambda_2 = \frac{a\lambda_1 + b}{c\lambda_1 + d}, \qquad a, b, c, d \in \mathbb{Z}. \tag{5.104}$$

Step 3: the determinant is $+1$

The same argument applied to f^{-1} gives integers expressing $(\lambda_1, 1)$ in terms of $(\lambda_2, 1)$. So the integer matrix $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ has an inverse that is also an integer matrix. Its determinant is a nonzero integer (5.53) whose inverse is also an integer, so $ad - bc = \pm 1$. To fix the sign, take imaginary parts in (5.104):

$$\operatorname{Im}\frac{a\lambda + b}{c\lambda + d} \overset{(1)}{=} \operatorname{Im}\frac{(a\lambda + b)(c\bar{\lambda} + d)}{|c\lambda + d|^2} \overset{(2)}{=} \frac{\operatorname{Im}\big(ac|\lambda|^2 + ad\lambda + bc\bar{\lambda} + bd\big)}{|c\lambda + d|^2} \overset{(3)}{=} \frac{(ad - bc)\operatorname{Im}\lambda}{|c\lambda + d|^2}. \tag{5.105}$$

(1) Multiply numerator and denominator by $\overline{c\lambda + d}$; the integers are real.
(2) Expand.
(3) $ac|\lambda|^2$ and bd are real; $\operatorname{Im}(\bar{\lambda}) = -\operatorname{Im}\lambda$.

Both λ_1 and λ_2 are in $\mathbb{C}^+$, so $ad - bc > 0$, hence $ad - bc = +1$. Conversely, if λ_2 is related to λ_1 by such a matrix, then $\tilde{f}(z) = z/(c\lambda_1 + d)$ maps Λ_1 onto Λ_2 and descends to a biholomorphism. We have Nash's criterion [Nash p. 155, (5.54)]:

Key idea: When two tori are the same

$\mathbb{C}/(\mathbb{Z} + \lambda_1\mathbb{Z})$ and $\mathbb{C}/(\mathbb{Z} + \lambda_2\mathbb{Z})$ are biholomorphic if and only if

$$\lambda_2 = \frac{a\lambda_1 + b}{c\lambda_1 + d} \quad \text{with} \quad \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}(2, \mathbb{Z}),$$

i.e. $a, b, c, d \in \mathbb{Z}$ and $ad - bc = 1$.

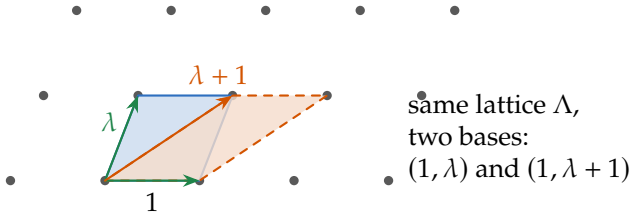


Figure 5.43: One lattice, two bases. The blue parallelogram (sides $1, \lambda$) and the dashed orange one (sides $1, \lambda + 1$) have the same area and tile the plane with the same set of corner points. Both describe the same torus $\mathbb{C}/\Lambda$. Changing basis by an $\mathrm{SL}(2, \mathbb{Z})$ matrix changes λ by the corresponding Möbius map; this is the redundancy that the modular group removes.

The modular group inside the Möbius group

The **Möbius group** is the group of maps [Nash p. 155, (5.55)]

$$z \mapsto \frac{az + b}{cz + d}, \qquad a, b, c, d \in \mathbb{C}, \quad ad - bc = 1.$$

Composition of Möbius maps is matrix multiplication. Indeed, if $M_1 = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ and $M_2 = \left(\begin{smallmatrix} a' & b' \\ c' & d' \end{smallmatrix}\right)$, then

$$M_1 \cdot (M_2 \cdot z) \overset{(1)}{=} \frac{a\,\frac{a'z + b'}{c'z + d'} + b}{c\,\frac{a'z + b'}{c'z + d'} + d} \overset{(2)}{=} \frac{(aa' + bc')z + (ab' + bd')}{(ca' + dc')z + (cb' + dd')} \overset{(3)}{=} (M_1M_2) \cdot z.$$

(1) Apply M_2 first, then M_1.
(2) Multiply numerator and denominator by $c'z + d'$.
(3) The coefficients are exactly the entries of the product matrix $M_1 M_2$.

The matrices M and $-M$ give the same map (numerator and denominator both change sign). So the Möbius group is $\mathrm{SL}(2,\mathbb{C})/\{\pm I\}$. Restricting to integer entries gives the **modular group**

$$\mathrm{PSL}(2,\mathbb{Z}) = \mathrm{SL}(2,\mathbb{Z})/\{\pm I\}, \tag{5.106}$$

which Nash writes $\mathrm{SL}(2,\mathbb{Z})/\{\mp I\}$. It is a discrete subgroup of the Möbius group. Our criterion says precisely that complex structures on the torus are points of $\mathbb{C}^+$ modulo the modular group [Nash p. 155, (5.56)]:

$$\boxed{\mathcal{M}_1 = \frac{\mathcal{T}_1}{\Gamma_{T^2}} = \frac{\mathbb{C}^+}{\mathrm{SL}(2,\mathbb{Z})/\{\pm I\}}.} \tag{5.107}$$

In particular the mapping class group of the torus is $\Gamma_{T^2} \cong \mathrm{SL}(2,\mathbb{Z})/\{\pm I\}$ as far as its action on $\mathcal{T}_1$ goes. (The element $-I$ is the map $z \mapsto -z$, which is a nontrivial mapping class but acts trivially on $\mathbb{C}^+$: every torus has this symmetry.)

Worked example 5.75: The torus automorphisms, explicitly

Write a point of the torus as $x + \lambda y$ with $(x,y) \in \mathbb{R}^2/\mathbb{Z}^2$, so the torus is the unit square with opposite sides glued. Nash's discrete automorphisms [Nash p. 155, (5.57)] are

$$(x,y) \mapsto (ax + by,\ cx + dy), \qquad \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}(2,\mathbb{Z}). \tag{5.108}$$

Integer entries make the map well defined mod $\mathbb{Z}^2$; determinant 1 makes it invertible with integer inverse and orientation preserving. It sends the curve a (the x-axis, $t \mapsto (t,0)$) to $t \mapsto (at, ct)$, which winds a times around the x-direction and c times around the y-direction: $[a] \mapsto a[a] + c[b]$. Likewise $[b] \mapsto b[a] + d[b]$. The action on $H_1 = \mathbb{Z}^2$ is the matrix itself, so for $M \neq I$ the map is not in Diff_0. These maps belong to disconnected components of $\mathrm{Diff}^+(T^2)$, and they are the whole mapping class group.

5.5.4 The generators S and T and the fundamental domain

Two elements do most of the work [Nash p. 156]:

$$S = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} :\ \lambda \mapsto -\frac{1}{\lambda}, \qquad T = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} :\ \lambda \mapsto \lambda + 1. \tag{5.109}$$

Their relations are short matrix multiplications:

$$S^2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix} = -I,$$

$$ST = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix}, \qquad (ST)^2 = \begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix},$$

$$(ST)^3 = \begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix} = -I.$$

So in $\mathrm{PSL}(2,\mathbb{Z})$, $S^2 = 1$ and $(ST)^3 = 1$. In fact these are the only relations, and S, T generate: $\mathrm{PSL}(2,\mathbb{Z}) \cong \mathbb{Z}_2 * \mathbb{Z}_3$. The generation is Euclid's algorithm in disguise: multiplying $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ on the left by T^n replaces a by $a + nc$, and by S swaps the rows up to sign, so one can reduce $|c|$ step by step until $c = 0$, and then the matrix is $\pm T^m$.

Physical picture: S swaps the two radii

Take a rectangular torus with side lengths R_1 (along x) and R_2 (along y), i.e. the lattice $R_1\mathbb{Z} + iR_2\mathbb{Z}$, so $\lambda = iR_2/R_1$. Then $S\lambda = -1/\lambda = iR_1/R_2$: the same torus rotated by 90° and rescaled, i.e. with the roles of the two circles exchanged [Nash p. 156]. In string theory this is the root of T-duality-type statements on a torus target; on the worldsheet it says the two cycles of a torus are on an equal footing. T changes the basis $(1, \lambda)$ to $(1, \lambda + 1)$ (Figure 5.43): a "twist" of the torus by one full turn before regluing.

The fundamental domain

A **fundamental domain** for $\mathrm{PSL}(2,\mathbb{Z})$ acting on $\mathbb{C}^+$ is a region F containing exactly one representative of almost every orbit. The standard choice is

$$F = \left\{\tau \in \mathbb{C}^+ : |\mathrm{Re}\,\tau| \le \tfrac{1}{2},\ |\tau| \ge 1\right\}, \tag{5.110}$$

drawn in Figure 5.44. Its two vertical edges are glued by T, and the two halves of its bottom arc are glued by S (which maps the unit circle to itself, $e^{i\theta} \mapsto -e^{-i\theta}$, reflecting it about i).

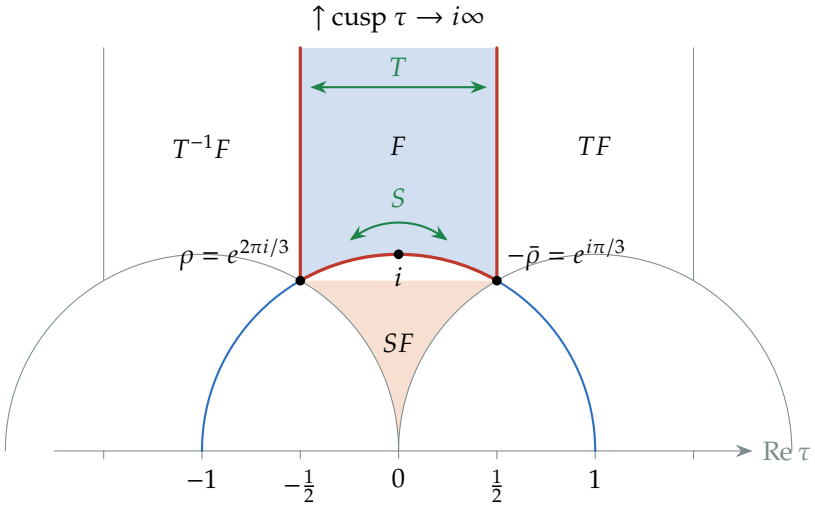

Figure 5.44: The fundamental domain F (blue, red boundary) of the modular group in the upper half-plane. Every torus has a modular parameter in F. The vertical sides are identified by $T : \tau \mapsto \tau + 1$ and the two halves of the bottom arc by $S : \tau \mapsto -1/\tau$. Images SF (orange, below the arc), TF and $T^{-1}F$ tile the half-plane. The special points i and ρ (equivalently $e^{i\pi/3} = T\rho$) are the orbifold points; the cusp at $i\infty$ is the place where the torus degenerates.

Key idea: Every torus has a representative in F

Every $\tau \in \mathbb{C}^+$ can be moved into F by an element of the modular group; two interior points of F are never equivalent; and boundary points are equivalent only via the gluings in Figure 5.44. So, as a set, $\mathcal{M}_1 = F/\!\sim$.

Why can we always get into F? Fix τ and look at the imaginary parts along its orbit. By (5.105), for $\gamma = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in \mathrm{SL}(2,\mathbb{Z})$,

$$\mathrm{Im}(\gamma\tau) = \frac{\mathrm{Im}\,\tau}{|c\tau + d|^2}. \tag{5.111}$$

The numbers $c\tau + d$ with c, d integers form a lattice, so only finitely many of them have $|c\tau + d| < 1$. Hence $\mathrm{Im}(\gamma\tau)$ takes only finitely many values larger than $\mathrm{Im}\,\tau$, and there is a γ

making $\operatorname{Im}(\gamma\tau)$ as large as possible. Call the result τ'. Apply a power T^n to get $|\operatorname{Re}\tau'| \le \frac{1}{2}$; this does not change the imaginary part. Now if $|\tau'| < 1$, then

$$\operatorname{Im}(S\tau') \overset{(1)}{=} \frac{\operatorname{Im}\tau'}{|\tau'|^2} \overset{(2)}{>} \operatorname{Im}\tau',$$

(1) (5.111) with $c = 1$, $d = 0$.
(2) $|\tau'| < 1$.

contradicting maximality. So $|\tau'| \ge 1$ and $\tau' \in F$. The proof is also an algorithm: *translate into the strip, invert if inside the unit circle, repeat.*

Worked example 5.76: Reducing a modular parameter

(a) $\tau = (2+i)/5 = 0.4 + 0.2i$. Then $|\tau|^2 = 0.2 < 1$, so apply S:

$$S\tau \overset{(1)}{=} -\frac{5}{2+i} \overset{(2)}{=} -\frac{5(2-i)}{5} = -2 + i, \qquad T^2 S\tau = i.$$

(1) $S\tau = -1/\tau$.
(2) Multiply top and bottom by $2 - i$; $|2+i|^2 = 5$.

So the skewed torus with $\tau = (2+i)/5$ is the *square* torus. The group element is $T^2S = \left(\begin{smallmatrix} 2 & -1 \\ 1 & 0 \end{smallmatrix}\right)$; check: $(2\tau - 1)/\tau = 2 - 1/\tau = 2 - (2 - i) = i$.

(b) $\tau = (2+3i)/10$. Now $|\tau|^2 = 13/100 < 1$, so

$$S\tau \overset{(1)}{=} -\frac{10}{2+3i} = -\frac{10(2-3i)}{13} = \frac{-20+30i}{13} \approx -1.54 + 2.31i,$$
$$T^2 S\tau \overset{(2)}{=} \frac{6+30i}{13} \approx 0.46 + 2.31i.$$

(1) $|2+3i|^2 = 13$.
(2) Add $2 = 26/13$; now $|\operatorname{Re}| \le \frac{1}{2}$ and $|\tau| > 1$, so we are in F.

A small $\operatorname{Im}\tau$ (a torus that looks very thin in one direction) becomes a large $\operatorname{Im}\tau$ (a long thin torus in the other direction): they are the same torus.

Fixed points: the orbifold points of $\mathcal{M}_1$

Nash notes [Nash p. 156] that $\lambda \mapsto -1/\lambda$ and $\lambda \mapsto 1 - 1/\lambda$ have fixed points. Let us find them.

- S: $\tau = -1/\tau \iff \tau^2 = -1 \iff \tau = i$ (in $\mathbb{C}^+$). The stabiliser of i in $\mathrm{PSL}(2,\mathbb{Z})$ is $\{1, S\} \cong \mathbb{Z}_2$.

- $TS : \tau \mapsto T(-1/\tau) = 1 - 1/\tau$, with matrix $TS = \left(\begin{smallmatrix} 1 & -1 \\ 1 & 0 \end{smallmatrix}\right)$. Fixed points: $\tau^2 - \tau + 1 = 0$, so $\tau = \frac{1+i\sqrt{3}}{2} = e^{i\pi/3}$. Here $(TS)^3 = -I$ (the same computation as for $(ST)^3$), so the stabiliser is $\mathbb{Z}_3$. The point $e^{i\pi/3}$ is $T\rho$ with $\rho = e^{2\pi i/3}$: the two bottom corners of F are the same point of $\mathcal{M}_1$.

These fixed points are the cone points of $\mathcal{M}_1$ (cone angles π and $2\pi/3$). Together with the cusp at $i\infty$ they are the "singularities" of $\mathcal{M}_1$ that Nash refers to.

Worked example 5.77: The square torus is a fixed point in $\mathrm{Met}_{\mathrm{const}}$

Nash also sees the orbifold point upstairs, in the space of metrics [Nash p. 156]. Take the square torus, the unit square with the metric δ_{ij}, so $\lambda = i$. The automorphism corresponding to S has $a = d = 0$, $b = -c = 1$ in (5.108), i.e. $(x, y) \mapsto (y, -x)$: a rotation by $-90°$. It pulls back $\mathrm{d}x^2 + \mathrm{d}y^2$ to $\mathrm{d}y^2 + \mathrm{d}x^2$, the same metric. So this element of $\mathrm{Diff}^+(T^2)$ fixes the point $\delta_{ij} \in \mathrm{Met}_{\mathrm{const}}(T^2)$, the action of Diff^+ is not free there, and $\mathrm{Met}_{\mathrm{const}}(T^2)/\mathrm{Diff}^+(T^2) = \mathcal{M}_1$ is an orbifold. Similarly the hexagonal torus ($\lambda = e^{i\pi/3}$) is invariant under rotation by $60°$.

5.5.5 Integrating over $\mathcal{M}_1$: the one-loop string amplitude

For the torus, the Polyakov integral (5.74) reduces (chapter 9) to an integral of the form

$$Z_1 \;\propto\; \int_F \frac{\mathrm{d}^2\tau}{\tau_2^2}\, \mathcal{Z}(\tau, \bar\tau), \qquad \mathrm{d}^2\tau = \mathrm{d}\tau_1\, \mathrm{d}\tau_2, \tag{5.112}$$

where $\mathcal{Z}$ is a modular-invariant function built from the determinants of chapter 4. Integrating over F rather than over all of $\mathbb{C}^+$ is exactly "count each torus once". For this to make sense the measure must itself be modular invariant.

Worked example 5.78: The invariant measure on the upper half-plane

Let $\tau' = (a\tau + b)/(c\tau + d)$ with $ad - bc = 1$. Then

$$\frac{\mathrm{d}\tau'}{\mathrm{d}\tau} \overset{(1)}{=} \frac{a(c\tau + d) - c(a\tau + b)}{(c\tau + d)^2} \overset{(2)}{=} \frac{1}{(c\tau + d)^2},$$
$$\mathrm{d}^2\tau' \overset{(3)}{=} \left|\frac{\mathrm{d}\tau'}{\mathrm{d}\tau}\right|^2 \mathrm{d}^2\tau = \frac{\mathrm{d}^2\tau}{|c\tau + d|^4},$$
$$\frac{\mathrm{d}^2\tau'}{(\tau_2')^2} \overset{(4)}{=} \frac{\mathrm{d}^2\tau}{|c\tau + d|^4} \cdot \frac{|c\tau + d|^4}{\tau_2^2} = \frac{\mathrm{d}^2\tau}{\tau_2^2}.$$

(1) Quotient rule.
(2) $ad - bc = 1$.
(3) For a holomorphic map the real Jacobian is $|f'|^2$ (Cauchy–Riemann).
(4) (5.105) with $ad - bc = 1$: $\tau_2' = \tau_2/|c\tau + d|^2$.

The same computation shows that the hyperbolic metric $|\mathrm{d}\tau|^2/\tau_2^2$ is invariant under the whole of $\mathrm{SL}(2, \mathbb{R})$: the Möbius maps with real coefficients are isometries of H, and $\mathrm{d}^2\tau/\tau_2^2$ is its area form.

Worked example 5.79: The volume of $\mathcal{M}_1$

$$\int_F \frac{\mathrm{d}\tau_1\, \mathrm{d}\tau_2}{\tau_2^2} \overset{(1)}{=} \int_{-1/2}^{1/2} \mathrm{d}\tau_1 \int_{\sqrt{1-\tau_1^2}}^{\infty} \frac{\mathrm{d}\tau_2}{\tau_2^2} \overset{(2)}{=} \int_{-1/2}^{1/2} \frac{\mathrm{d}\tau_1}{\sqrt{1 - \tau_1^2}}$$
$$\overset{(3)}{=} \arcsin\tfrac{1}{2} - \arcsin\left(-\tfrac{1}{2}\right) = \frac{\pi}{6} + \frac{\pi}{6} = \frac{\pi}{3}.$$

(1) For fixed $\tau_1 \in [-\frac{1}{2}, \frac{1}{2}]$, F runs from the unit circle $\tau_2 = \sqrt{1 - \tau_1^2}$ up to ∞.
(2) $\int_u^\infty \tau_2^{-2} \mathrm{d}\tau_2 = 1/u$.
(3) $\int \mathrm{d}t/\sqrt{1 - t^2} = \arcsin t$.

Although F reaches up to the cusp, its hyperbolic area is finite: $\pi/3$. (Gauss–Bonnet for the hyperbolic triangle with angles $\pi/3, \pi/3, 0$ gives the same: $\pi - \frac{\pi}{3} - \frac{\pi}{3} - 0 = \frac{\pi}{3}$.)

Worked example 5.80: A function on moduli space

A function on $\mathcal{M}_1$ is a function on $\mathbb{C}^+$ invariant under $\mathrm{SL}(2,\mathbb{Z})$. A natural example is the lattice sum (non-holomorphic Eisenstein series), for $\operatorname{Re} s > 1$,

$$E(\tau, s) = \sum_{(m,n)\neq(0,0)} \frac{\tau_2^s}{|m + n\tau|^{2s}}.$$

It is a sum over the nonzero vectors of the lattice $\mathbb{Z} + \tau\mathbb{Z}$ normalised to unit area. Check invariance under $\gamma = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$:

$$|m + n\gamma\tau|^2 \overset{(1)}{=} \frac{|m(c\tau + d) + n(a\tau + b)|^2}{|c\tau + d|^2} \overset{(2)}{=} \frac{|m' + n'\tau|^2}{|c\tau + d|^2}, \quad (m', n') = (md + nb,\ mc + na),$$

$$E(\gamma\tau, s) \overset{(3)}{=} \sum_{(m,n)\neq 0} \frac{\tau_2^s\,|c\tau + d|^{-2s}}{|m' + n'\tau|^{2s}\,|c\tau + d|^{-2s}} \overset{(4)}{=} E(\tau, s).$$

(1) Put everything over the common denominator $c\tau + d$.
(2) Collect the coefficients of 1 and τ.
(3) (5.111) for $\operatorname{Im}(\gamma\tau)^s$, and step 2.
(4) The factors cancel, and $(m, n) \mapsto (m', n')$ is a bijection of $\mathbb{Z}^2 \setminus \{0\}$ (its matrix $\left(\begin{smallmatrix} d & b \\ c & a \end{smallmatrix}\right)$ has determinant 1, so has an integer inverse).

Such lattice sums appear in one-loop amplitudes of strings on tori and in the Casimir energy of a field on a torus.

Physical picture: Modular invariance cuts out the ultraviolet

In field theory a one-loop vacuum amplitude is an integral over the Schwinger proper time t of a particle going round a loop, from $t = 0$ to ∞, and the region $t \to 0$ produces the ultraviolet divergence. For the string, τ_2 plays the role of t, but the integral runs only over F, where $\tau_2 \geq \sqrt{3}/2$. The dangerous region $\tau_2 \to 0$ is not integrated over at all: it is a copy of a region near the cusp, already counted. This is the simplest instance of the statement that string loop amplitudes are ultraviolet finite, and it rests entirely on dividing $\mathcal{T}_1$ by the mapping class group.

5.5.6 Genus $p \geq 2$: Fuchsian groups and orbifold points

For $p \geq 2$ the universal cover is H. Its holomorphic automorphisms are the real Möbius maps [Nash p. 156, (5.58)]

$$z \mapsto \frac{az + b}{cz + d}, \qquad a, b, c, d \in \mathbb{R}, \quad ad - bc = 1,$$

forming $\mathrm{PSL}(2,\mathbb{R}) = \mathrm{SL}(2,\mathbb{R})/\{\pm I\}$. By (5.105) they preserve H, and by Example 5.78 they are isometries of the hyperbolic metric. A genus-p surface is H/G with $G \cong \pi_1(\Sigma)$ a discrete subgroup of $\mathrm{PSL}(2,\mathbb{R})$ acting freely; such discrete groups are called **Fuchsian groups**. The group $\pi_1(\Sigma)$ has $2p$ generators $a_1, b_1, \ldots, a_p, b_p$ and one relation,

$$a_1 b_1 a_1^{-1} b_1^{-1} \cdots a_p b_p a_p^{-1} b_p^{-1} = 1, \tag{5.113}$$

which is read off from the $4p$-gon of Nash's p. 140 (Figure 5.45): walking around its boundary traverses $a_1 b_1 a_1^{-1} b_1^{-1} \cdots$, and the boundary is contractible in the polygon.

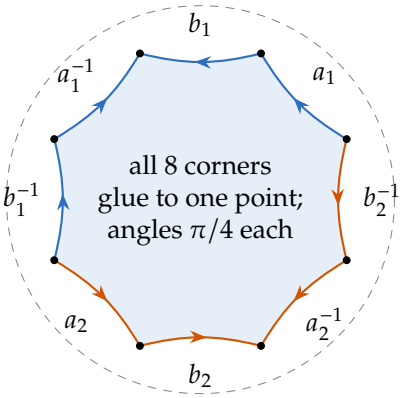

Figure 5.45: A genus-2 surface as a hyperbolic octagon (drawn schematically in the Poincaré disc, whose boundary is the dashed circle) with sides glued in pairs as labelled; the arrows show the gluing directions. Reading the boundary gives the relation $a_1 b_1 a_1^{-1} b_1^{-1} a_2 b_2 a_2^{-1} b_2^{-1} = 1$. In the hyperbolic metric the sides are geodesic arcs and each interior angle is $\pi/4$, so the eight angles add up to 2π around the single glued vertex.

Worked example 5.81: Area of the $4p$-gon and a parameter count

Area. For a hyperbolic polygon with n geodesic sides and interior angles θ_i, Gauss–Bonnet gives area $(n-2)\pi - \sum \theta_i$. For the $4p$-gon all corners glue to one point, so the angles add to 2π:

$$\text{Area} \overset{(1)}{=} (4p-2)\pi - 2\pi \overset{(2)}{=} 4\pi(p-1),$$

(1) $n = 4p$ and $\sum \theta_i = 2\pi$.
(2) Algebra.

which agrees with (5.93) for $K = -1$.
Parameter count. A Fuchsian group for genus p is given by $2p$ matrices in $\mathrm{PSL}(2,\mathbb{R})$, a 3-dimensional group: $6p$ real parameters. The relation (5.113) is an equation in $\mathrm{PSL}(2,\mathbb{R})$: 3 real conditions. Conjugating all generators by the same element of $\mathrm{PSL}(2,\mathbb{R})$ is a change of coordinate on H and gives the same surface: 3 more parameters to remove. So

$$\dim_{\mathbb{R}} \mathcal{T}_p = 6p - 3 - 3 = 6p - 6, \qquad \dim_{\mathbb{C}} \mathcal{T}_p = 3p - 3.$$

This is a heuristic count (one must check that the relation's 3 conditions are independent and that the conjugation acts with finite stabilisers, which uses $p \geq 2$), but it anticipates the index theorem result of Section 5.6.

Symmetric surfaces and the singularities of $\mathcal{M}_p$

A fixed point of Γ_Σ on $\mathcal{T}_p$ is a Riemann surface with a nontrivial holomorphic automorphism that is not isotopic to the identity (at genus $p \geq 2$ none are, apart from the identity). So the orbifold points of $\mathcal{M}_p$ are exactly the surfaces with symmetries, just as for the torus. Nash quotes three facts [Nash p. 156]:

- For $p \geq 2$ the automorphism group of any Σ is finite, of order at most $84(p-1)$ (the **Hurwitz bound**). We will see in Section 5.7 why it is finite: automorphisms must permute the finitely many Weierstrass points.

- For $p \geq 3$ the singular set of $\mathcal{M}_p$ has (complex) codimension at least two (Griffiths and Harris).
- $\mathcal{T}_p$ is contractible and homeomorphic to $\mathbb{C}^{3p-3}$, and it is the universal covering space of $\mathcal{M}_p$ (in the orbifold sense). For $p = 1$ this says $\mathcal{T}_1 = \mathbb{C}^+$ is contractible and $\pi_1(\mathcal{M}_1) = \mathrm{SL}(2,\mathbb{Z})/\{\pm I\}$.

Worked example 5.82: Surfaces with many symmetries

Every genus-2 surface is symmetric. Every genus-2 Riemann surface can be written as $y^2 = (x - e_1)\cdots(x - e_6)$, and $(x, y) \mapsto (x, -y)$ is an automorphism (the hyperelliptic involution) with six fixed points (Section 5.7). So every point of $\mathcal{M}_2$ has at least a $\mathbb{Z}_2$ stabiliser. This $\mathbb{Z}_2$ acts trivially on all of $\mathcal{T}_2$, which is why it does not produce a singularity by itself; the singularities of $\mathcal{M}_2$ come from surfaces with extra symmetry. This is one reason Nash states the codimension result only for $p \geq 3$.
The Hurwitz bound is sharp. The Klein quartic $x^3y + y^3z + z^3x = 0$ in $\mathbb{CP}^2$ is a smooth plane curve of degree 4, so of genus $\frac{(4-1)(4-2)}{2} = 3$, and it has $168 = 84 \cdot (3-1)$ automorphisms, forming the simple group $\mathrm{PSL}(2, \mathbb{F}_7)$.

5.5.7 Dehn twists

How does one get a handle on Γ_Σ for general genus? Nash describes generators [Nash pp. 156–157].

Working definition 5.44 (Dehn twist)

Take a simple closed curve C on Σ [a loop that does not cross itself] and thicken it to an annulus $A \cong S^1 \times [0,1]$. Cut Σ along one boundary circle of A, twist that end through a full 2π rotation, and glue back. In coordinates (θ, t) on A the map is

$$t_C : (\theta, t) \mapsto (\theta + 2\pi\,\chi(t),\ t),$$

where χ increases smoothly from 0 at $t = 0$ to 1 at $t = 1$; outside A it is the identity. The result is a diffeomorphism of Σ, the **Dehn twist** along C. *Test for nontriviality:* a curve that crosses C once is dragged once around C (Figure 5.46); if C is not contractible [it cannot be shrunk to a point on Σ] this changes the homology class of the crossing curve, so $t_C \notin \mathrm{Diff}_0$.

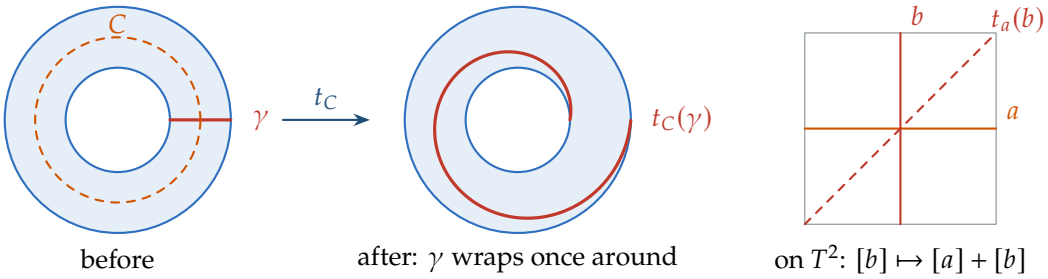

Figure 5.46: A Dehn twist. Left: an annulus around the curve C (dashed orange), crossed by a radial arc γ (red). Middle: after the twist the arc winds once around the annulus; outside the annulus nothing moved. Right: on the torus drawn as a square, the twist along a takes the vertical curve b to the diagonal curve, which is the shear $(x, y) \mapsto (x + y, y)$, i.e. the modular transformation T.

Worked example 5.83: Dehn twists generate the modular group

On $T^2 = \mathbb{R}^2/\mathbb{Z}^2$ let a be the horizontal curve and b the vertical one. The twist along a is (isotopic to) the shear $(x, y) \mapsto (x + y, y)$ and the twist along b is $(x, y) \mapsto (x, y - x)$. By (5.108) their matrices are

$$t_a = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} = T, \qquad t_b = \begin{pmatrix} 1 & 0 \\ -1 & 1 \end{pmatrix}.$$

Then

$$t_a\, t_b\, t_a \overset{(1)}{=} \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ -1 & 1 \end{pmatrix}\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ -1 & 1 \end{pmatrix}\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$$
$$\overset{(2)}{=} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = -S.$$

(1) Multiply the first two matrices.
(2) Multiply by the third; compare with (5.109).

Since $-S$ and S are the same element of $\mathrm{PSL}(2,\mathbb{Z})$, and S and T generate, the two Dehn twists t_a, t_b generate the whole mapping class group of the torus. (The relation $t_a t_b t_a = t_b t_a t_b$, the braid relation, is also easy to verify by multiplying matrices.)

For genus p, the Dehn twists along the curves that go around a handle, through a handle, and between adjacent handles generate Γ_Σ (Dehn, Lickorish: $3p - 1$ twists suffice; Humphries: $2p + 1$ is the minimum). Nash notes that the set of all Dehn twists is far from a minimal generating set, and that the important curves are the non-contractible ones: those around a handle and, for surfaces with punctures, those around a puncture. A twist along a contractible curve is isotopic to the identity.

Physical picture: Dehn twists in string theory

Cut a worldsheet along a closed curve, rotate one side by 2π and reglue: nothing local has changed, so the string amplitude cannot notice. This is the statement that the amplitude must be invariant under Γ_Σ. In the operator language on the torus, the twist T is implemented by $e^{2\pi i(L_0 - \bar{L}_0)}$, and invariance under it is the level-matching condition $L_0 = \bar{L}_0$ of closed strings (Chapter 11).

Nash closes the section by pointing ahead: in chapter 9 Teichmüller space receives a natural Riemannian metric, the **Weil–Petersson metric**, induced from the metric on $\mathrm{Met}(\Sigma)$, and with respect to it $\mathcal{T}_p$ is a Kähler manifold. For $p = 1$ it is the hyperbolic metric $|d\tau|^2/\tau_2^2$ of Example 5.78, whose area form we just integrated over F.

Reading Nash (pp. 152–157, (5.44)–(5.58))

Nash defines $\mathcal{M}_p$ (5.44) and the mapping class group (5.45), notes that $\mathcal{M}_p$ is an orbifold, and uses uniformisation (5.46) to compute $\mathcal{M}_0$ and $\mathcal{M}_1$. For the torus he lifts a conformal map (5.48)–(5.49), derives the $\mathrm{SL}(2,\mathbb{Z})$ criterion (5.50)–(5.54), identifies the modular group inside the Möbius group (5.55), obtains $\mathcal{M}_1 = \mathbb{C}^+/(\mathrm{SL}(2,\mathbb{Z})/\{\mp I\})$ (5.56), writes the torus automorphisms (5.57), and mentions S, T, their fixed points and the fixed point δ_{ij} in $\mathrm{Met}_{\mathrm{const}}$. He then sketches genus ≥ 2 via $\mathrm{SL}(2,\mathbb{R})$ (5.58) and Fuchsian groups, states the orbifold, Hurwitz and contractibility facts, and defines Dehn twists. We filled in: why the lift is affine (Liouville), the imaginary part formula, the matrix relations of S, T, the

fundamental domain and reduction algorithm, the invariant measure and $\mathrm{vol}(F) = \pi/3$, a modular function, the $4p$-gon area and parameter count, explicit symmetric surfaces, and the torus Dehn twists as matrices.

Recap

- $\mathcal{M}_p = \mathrm{Met}_{\mathrm{const}}/\mathrm{Diff}^+ = \mathcal{T}_p/\Gamma_\Sigma$, with $\Gamma_\Sigma = \mathrm{Diff}^+/\mathrm{Diff}_0$ the (discrete) mapping class group. It forgets the labelling of curves.
- $\mathcal{M}_0$ is a point: every Möbius map has a fixed point.
- Tori λ_1, λ_2 are equivalent iff $\lambda_2 = (a\lambda_1 + b)/(c\lambda_1 + d)$ with $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in \mathrm{SL}(2,\mathbb{Z})$, so $\mathcal{M}_1 = \mathbb{C}^+/\mathrm{PSL}(2,\mathbb{Z})$, with fundamental domain F.
- $S : \tau \mapsto -1/\tau$ and $T : \tau \mapsto \tau + 1$ generate; $S^2 = (ST)^3 = -I$. Orbifold points at $\tau = i$ ($\mathbb{Z}_2$) and $\tau = e^{i\pi/3}$ ($\mathbb{Z}_3$); a cusp at $i\infty$.
- $\mathrm{d}^2\tau/\tau_2^2$ is the invariant measure; $\mathrm{vol}(F) = \pi/3$; integrating over F removes the UV region of one-loop amplitudes.
- $p \geq 2$: $\Sigma = H/G$, G Fuchsian; $\dim_{\mathbb{C}} = 3p - 3$ by a parameter count; finitely many automorphisms ($\leq 84(p-1)$); Dehn twists generate Γ_Σ.

5.6 The dimension of the moduli space

In Section 5.5 we found $\mathcal{M}_0$ (a point) and $\mathcal{M}_1$ (the upper half-plane modulo $\mathrm{SL}(2,\mathbb{Z})$, one complex dimension) by hand, and for $p \geq 2$ we only *counted parameters* of Fuchsian groups (Example 5.81) to guess $3p - 3$. This section derives

$$\dim_{\mathbb{C}} \mathcal{M}_p \;=\; 3p - 3 \qquad (p \geq 2)$$

properly. The method is the one we will use again and again in this book (for instantons in Chapter 8, for the string measure in Chapter 9):

(i) write down the *tangent space* to the moduli space as "all infinitesimal deformations modulo infinitesimal gauge transformations";

(ii) recognise that quotient as the cohomology of an elliptic operator;

(iii) compute its dimension with an index theorem plus a vanishing theorem.

Physical picture: Why a string theorist counts moduli

After Weyl and diffeomorphism invariance have been used to fix the worldsheet metric, the Polyakov integral $\int \mathcal{D}g$ of (5.74) becomes an ordinary integral over $\mathcal{M}_p$. The number of integrals left over is $\dim \mathcal{M}_p$. In the Faddeev–Popov language of Chapter 9 the gauge fixing introduces ghosts b and c. The zero modes of c are conformal Killing vectors (leftover gauge symmetry), and the zero modes of b are the *quadratic differentials* we are about to meet (leftover moduli). The difference

$$\#(b \text{ zero modes}) - \#(c \text{ zero modes}) \;=\; 3p - 3$$

is exactly the index we are going to compute. For the torus it is $1 - 1 = 0$; for the sphere $0 - 3 = -3$.

5.6.1 The strategy: count deformations of the metric

Nash starts from the form (5.76) of an arbitrary metric [Nash p. 157, (5.59)],

$$ds^2 = \lambda\, |dz + \mu\, d\bar{z}|^2 ,$$

in which the positive function λ is the Weyl factor and the complex function μ labels the complex structure (Section 5.4.2). A point of $\mathcal{M}_p$ is a metric up to Weyl rescalings and diffeomorphisms. A tangent vector to $\mathcal{M}_p$ at the point $[g]$ is therefore an infinitesimal change δg modulo the changes produced by infinitesimal Weyl rescalings and infinitesimal diffeomorphisms. Since Weyl rescalings only move λ, the tangent vector is carried by $\delta\mu$:

$$T_{[g]}\mathcal{M}_p = \{\textit{perturbations } \delta\mu\} / \{\textit{those produced by diffeomorphisms}\}.$$

If we can compute the dimension of this quotient we have $\dim T_{[g]}\mathcal{M}_p = \dim \mathcal{M}_p$.

Key idea: A heuristic count that already smells of an index

Count real functions. A metric on a surface has 3 components (g_{xx}, g_{xy}, g_{yy}). A Weyl rescaling removes 1. A diffeomorphism is generated by a vector field with 2 real components. So

$$3 - 1 - 2 = 0 \quad \text{functions' worth of moduli.}$$

"Zero functions" does not mean "nothing". It means that what survives is a *finite* number of parameters, and a finite number that arises as "functions minus functions" is precisely what an index measures: the difference between the kernel and the cokernel of an operator that maps 2 real functions (a vector field) to 2 real functions (a $\delta\mu$).

To make this precise we need to know how λ and μ behave when we change coordinates, so that we know what kind of global object $\delta\mu$ is.

5.6.2 How λ and μ transform: Beltrami differentials

Suppose we change to a new holomorphic coordinate $w = f(z)$ (so $f_{\bar{z}} = 0$ and $f_z \neq 0$). The line element ds^2 is a geometric object, so it must look the same in both coordinates:

$$\lambda(z)\, |dz + \mu(z)\, d\bar{z}|^2 \;=\; \tilde{\lambda}(w)\, |dw + \tilde{\mu}(w)\, d\bar{w}|^2 .$$

Here $\tilde{\lambda}$ and $\tilde{\mu}$ are the functions that describe the metric in the w chart. Nash writes them as $\lambda(f(z))$ and $\mu(f(z))$, which is a common abuse of notation. Let us find the relation.

$$\begin{aligned} \tilde{\lambda}\, |dw + \tilde{\mu}\, d\bar{w}|^2 &\overset{(1)}{=} \tilde{\lambda}\, \left| f_z\, dz + \tilde{\mu}\, \overline{f_z}\, d\bar{z} \right|^2 \\ &\overset{(2)}{=} \tilde{\lambda}\, |f_z|^2 \left| dz + \tilde{\mu}\, \frac{\overline{f_z}}{f_z}\, d\bar{z} \right|^2 . \end{aligned} \tag{5.114}$$

(1) Chain rule: $dw = f_z\, dz$ because f is holomorphic, and $d\bar{w} = \overline{f_z}\, d\bar{z}$ by complex conjugation.
(2) Pull the factor f_z out of the absolute value.

Comparing with the left side (the decomposition (5.76) is unique, since (5.79) determines λ and μ from the metric) gives Nash's transformation laws [Nash p. 157, (5.60)]:

$$\tilde{\lambda}(f(z))\, f_z\, \overline{f_z} = \lambda(z), \qquad \tilde{\mu}(f(z))\, \frac{\overline{f_z}}{f_z} = \mu(z). \tag{5.115}$$

The first says that $\lambda\, dz\, d\bar{z}$ is invariant: λ is the component of a $(1,1)$ tensor, a density. The second is more interesting.

Working definition 5.45 (Beltrami differential)

A **Beltrami differential** on a Riemann surface is an object that in each holomorphic chart is written

$$\mu(z,\bar z)\,\frac{\partial}{\partial z}\otimes \mathrm{d}\bar z, \tag{5.116}$$

with the components in two charts related by $\tilde\mu(w)\,\overline{f_z}/f_z = \mu(z)$ [Nash p. 157, (5.61)]. *Operationally:* it is a $(0,1)$-form ($\propto \mathrm{d}\bar z$) whose coefficient is a holomorphic tangent vector ($\propto \partial_z$). To test whether a locally given function μ defines one, check the transformation law on every overlap.

Let us verify that the tensor (5.116) is chart independent exactly when (5.115) holds.

$$\tilde\mu(w)\,\frac{\partial}{\partial w}\otimes \mathrm{d}\bar w \overset{(1)}{=} \tilde\mu(w)\,\frac{1}{f_z}\frac{\partial}{\partial z}\otimes \overline{f_z}\,\mathrm{d}\bar z$$
$$\overset{(2)}{=} \left(\tilde\mu(w)\frac{\overline{f_z}}{f_z}\right)\frac{\partial}{\partial z}\otimes \mathrm{d}\bar z \overset{(3)}{=} \mu(z)\,\frac{\partial}{\partial z}\otimes \mathrm{d}\bar z.$$

(1) $\partial_z = f_z\,\partial_w$ (chain rule, f holomorphic), so $\partial_w = f_z^{-1}\partial_z$; and $\mathrm{d}\bar w = \overline{f_z}\,\mathrm{d}\bar z$.
(2) Collect the scalar factors.
(3) The transformation law (5.115).

Two remarks about (5.115).

- $|\overline{f_z}/f_z| = 1$, so $|\mu|$ is a genuine function on Σ. That fits Figure 5.40: $|\mu|$ fixes the eccentricity of the ellipse field, which cannot depend on the chart. Only the *direction* of the ellipse, encoded in $\arg\mu$, rotates with the chart.
- $\mu = 0$ is preserved by holomorphic coordinate changes. A metric that is conformally flat in one holomorphic chart is conformally flat in all of them.

The Beltrami equation for maps

Nash adds a parenthetical remark [Nash p. 158]: for a general metric with parameters λ,μ, a diffeomorphism $f(z,\bar z)$ is conformal (onto a surface with the standard flat structure $|\mathrm{d}w|^2$) exactly when

$$\frac{f_{\bar z}}{f_z} = \mu. \tag{5.117}$$

This is the Beltrami equation (5.81) of Section 5.4.2, now read as an equation for a map instead of for a coordinate: $\mathrm{d}f = f_z(\mathrm{d}z + \mu\,\mathrm{d}\bar z)$, so $|\mathrm{d}f|^2 = |f_z|^2|\mathrm{d}z+\mu\,\mathrm{d}\bar z|^2$ is a multiple of $\mathrm{d}s^2$.

Worked example 5.84: Solving the Beltrami equation for a constant μ

Take the square torus $\mathbb{C}/(\mathbb{Z}+i\mathbb{Z})$ with coordinate z and a *constant* Beltrami coefficient μ, $|\mu|<1$. Try the affine map $f(z) = z + \mu\bar z$:

$$f_z = 1, \qquad f_{\bar z} = \mu, \qquad \frac{f_{\bar z}}{f_z} = \mu.\checkmark$$

So f is conformal from $(\Sigma, \lambda|\mathrm{d}z+\mu\mathrm{d}\bar z|^2)$ to the flat plane. It sends the lattice generators to

$$f(1) = 1+\mu, \qquad f(i) = i - i\mu = i(1-\mu),$$

so the surface is conformally the flat torus with modular parameter

$$\tau \overset{(1)}{=} \frac{f(i)}{f(1)} = \frac{i(1-\mu)}{1+\mu}.$$

(1) The torus $\mathbb{C}/(\mathbb{Z}\omega_1 + \mathbb{Z}\omega_2)$ is conformal to $\mathbb{C}/(\mathbb{Z} + \mathbb{Z}\,\omega_2/\omega_1)$ by the rescaling $z \mapsto z/\omega_1$ (Section 5.5).

Solving $\tau(1+\mu) = i(1-\mu)$ for μ gives $\mu = (i-\tau)/(i+\tau)$: exactly the Cayley transform found in Example 5.66 from the opposite direction. Two independent calculations agree. Note $|\mu| < 1$ guarantees $\operatorname{Im}\tau > 0$, as it must.

5.6.3 Perturbing the metric

Now we perturb. Choose isothermal coordinates for the unperturbed metric g (Section 5.4.2), so that locally

$$\mathrm{d}s^2 = \lambda\ |\mathrm{d}z|^2 = \lambda\,\mathrm{d}z\,\mathrm{d}\bar{z}.$$

A nearby metric has a slightly different Weyl factor and a small Beltrami coefficient:

$$\mathrm{d}\tilde{s}^2 = (\lambda + \delta\lambda)\ |\mathrm{d}z + \delta\mu\,\mathrm{d}\bar{z}|^2\,.$$

Expand to first order in small quantities:

$$\begin{aligned}\delta(\mathrm{d}s^2) := \mathrm{d}\tilde{s}^2 - \mathrm{d}s^2 &\overset{(1)}{=} (\lambda+\delta\lambda)\big(\mathrm{d}z\,\mathrm{d}\bar{z} + \delta\mu\,\mathrm{d}\bar{z}^2 + \overline{\delta\mu}\,\mathrm{d}z^2 + |\delta\mu|^2\,\mathrm{d}z\,\mathrm{d}\bar{z}\big) - \lambda\,\mathrm{d}z\,\mathrm{d}\bar{z} \\ &\overset{(2)}{=} \delta\lambda\,\mathrm{d}z\,\mathrm{d}\bar{z} + \lambda\,\delta\mu\,\mathrm{d}\bar{z}\,\mathrm{d}\bar{z} + \lambda\,\overline{\delta\mu}\,\mathrm{d}z\,\mathrm{d}z + O(\delta^2). \end{aligned} \tag{5.118}$$

(1) Multiply out $|\mathrm{d}z + \delta\mu\,\mathrm{d}\bar{z}|^2$ as in (5.77).
(2) Drop products of two small quantities ($\delta\lambda\,\delta\mu$, $|\delta\mu|^2$, …); the $\lambda\,\mathrm{d}z\,\mathrm{d}\bar{z}$ terms cancel.

This is Nash's formula [Nash p. 158] for $\delta(\mathrm{d}s^2)$. Now read off the components. In complex coordinates a symmetric tensor is written $\delta(\mathrm{d}s^2) = \delta g_{ab}\,\mathrm{d}x^a\mathrm{d}x^b$ with $a, b \in \{z, \bar{z}\}$:

$$\delta(\mathrm{d}s^2) = \delta g_{zz}\,\mathrm{d}z^2 + 2\,\delta g_{z\bar{z}}\,\mathrm{d}z\,\mathrm{d}\bar{z} + \delta g_{\bar{z}\bar{z}}\,\mathrm{d}\bar{z}^2.$$

Comparing with (5.118):

$$\delta g_{z\bar{z}} = \tfrac{1}{2}\,\delta\lambda, \qquad \delta g_{\bar{z}\bar{z}} = \lambda\,\delta\mu, \qquad \delta g_{zz} = \lambda\,\overline{\delta\mu}. \tag{5.119}$$

Since $g_{z\bar{z}} = \lambda/2$ ((5.87)),

$$\boxed{\delta\mu = \frac{\delta g_{\bar{z}\bar{z}}}{\lambda} = \frac{\delta g_{\bar{z}\bar{z}}}{2\,g_{z\bar{z}}}} \tag{5.120}$$

This is Nash's (5.62) [Nash p. 158]. The Weyl factor sits entirely in $\delta g_{z\bar{z}}$, the trace part, and the complex structure entirely in $\delta g_{\bar{z}\bar{z}}$.

Watch out: A factor of 2 in (5.62) and (5.72)

Nash writes $\delta\mu = \delta g_{\bar{z}\bar{z}}/g_{z\bar{z}}$. This is right if "$g_{z\bar{z}}$" means the coefficient λ of $\mathrm{d}z\,\mathrm{d}\bar{z}$ in $\mathrm{d}s^2$. With the standard tensor convention $\mathrm{d}s^2 = g_{ab}\mathrm{d}x^a\mathrm{d}x^b$ one has $g_{z\bar{z}} = g_{\bar{z}z} = \lambda/2$, and then $\delta\mu = \delta g_{\bar{z}\bar{z}}/(2g_{z\bar{z}})$ as in (5.120). The same factor reappears in his (5.72), $\delta\mu = 2\,\partial_{\bar{z}}V^z$, where we will get $\delta\mu = \partial_{\bar{z}}V^z$. Nash himself notes that "the factor 2 in 5.72 is not of course significant": it only rescales V and cannot change any dimension count.

What $\delta\mu$ means in Cartesian language

It helps to see $\delta g_{\bar z\bar z}$ in terms of the familiar components $\delta g_{xx}, \delta g_{xy}, \delta g_{yy}$. Since $x = (z+\bar z)/2$ and $y = (z-\bar z)/(2i)$, we have $\partial x/\partial \bar z = \frac12$ and $\partial y/\partial \bar z = \frac{i}{2}$. Then

$$\begin{aligned}\delta g_{\bar z\bar z} &\overset{(1)}{=} \frac{\partial x^a}{\partial \bar z}\frac{\partial x^b}{\partial \bar z}\,\delta g_{ab}\\ &\overset{(2)}{=} \tfrac14\,\delta g_{xx} + 2\cdot\tfrac{i}{4}\,\delta g_{xy} + \left(\tfrac{i}{2}\right)^2\delta g_{yy}\\ &= \tfrac14\big(\delta g_{xx} - \delta g_{yy} + 2i\,\delta g_{xy}\big).\end{aligned} \tag{5.121}$$

(1) Tensor transformation law for the components of a symmetric 2-tensor from (x, y) to $(z, \bar z)$.
(2) Sum over $a, b \in \{x, y\}$; the mixed terms xy and yx are equal.

So $\delta\mu$ is (up to $1/4\lambda$) the complex combination of the two *traceless* components of δg: the "stretch in x minus stretch in y" and the "shear". The trace $\delta g_{xx} + \delta g_{yy}$ does not appear. This is the precise meaning of "Weyl rescalings do not change the complex structure" at the infinitesimal level.

Worked example 5.85: Stretching the plane

Take the flat metric $\mathrm{d}x^2 + \mathrm{d}y^2$ ($\lambda = 1$) and stretch it in the x direction: $\mathrm{d}\tilde s^2 = (1+\epsilon)\mathrm{d}x^2 + \mathrm{d}y^2$. Then $\delta g_{xx} = \epsilon$ and the other components vanish, so by (5.121) and (5.120)

$$\delta\mu = \frac{\delta g_{\bar z\bar z}}{\lambda} = \frac{\epsilon}{4}.$$

Cross-check with the exact formula (5.79) of Section 5.4.2, with $A = 1+\epsilon$, $B = 0$, $C = 1$:

$$\mu \overset{(1)}{=} \frac{A - C + 2iB}{A + C + 2\sqrt{AC - B^2}} = \frac{\epsilon}{2 + \epsilon + 2\sqrt{1+\epsilon}} \overset{(2)}{=} \frac{\epsilon}{4} + O(\epsilon^2).$$

(1) (5.79), written as $\mu = (A - C + 2iB)/(4\lambda)$.
(2) $2\sqrt{1+\epsilon} = 2 + \epsilon + O(\epsilon^2)$, so the denominator is $4 + O(\epsilon)$.

Real positive μ squashes the unit circle along the x axis ($\varphi = \theta/2 = 0$ in Figure 5.40): with the metric $(1+\epsilon)\mathrm{d}x^2 + \mathrm{d}y^2$ a unit vector along x is indeed shorter in coordinate terms. A pure shear $\delta g_{xy} = \epsilon/2$ gives instead $\delta\mu = i\epsilon/4$, an ellipse tilted at 45°.

$\delta\mu$ as a global object

Nash then writes $\delta g_{ab} = \epsilon\, h_{ab}$ with ϵ small, so [Nash p. 158, (5.63)]

$$\delta\mu = \epsilon\,\frac{h_{\bar z\bar z}}{g_{z\bar z}}$$

(in his normalisation). The ratio $h_{\bar z\bar z}/g_{z\bar z}$ has the same tensor character as μ itself: $h_{\bar z\bar z}$ carries two lower $\bar z$ indices, like $\mathrm{d}\bar z \otimes \mathrm{d}\bar z$, and dividing by $g_{z\bar z}$ (like $\mathrm{d}z \otimes \mathrm{d}\bar z$) turns one $\mathrm{d}\bar z$ into a $(\mathrm{d}z)^{-1} = \partial_z$. So the perturbation is a Beltrami differential [Nash p. 158, (5.64)]:

$$\nu(z,\bar z)\,\frac{\partial}{\partial z} \otimes \mathrm{d}\bar z. \tag{5.122}$$

To say which space these objects live in we need two line bundles.

Working definition 5.46 (The canonical bundle K_Σ and its dual K_Σ^*)

On a Riemann surface, the **canonical bundle** $K_\Sigma = T^*\Sigma$ (holomorphic cotangent bundle) is the complex line bundle whose local sections are $\phi(z)\,dz$. On an overlap with $w = f(z)$ the local frame changes by $dw = f_z\,dz$, so the transition function is the holomorphic function f_z. Its dual $K_\Sigma^* = T\Sigma$ (holomorphic tangent bundle) has local sections $V^z(z,\bar z)\,\partial_z$ and transition function $1/f_z$. More generally K_Σ^q has sections $\phi(z)\,dz^{\otimes q}$ and transition functions $(f_z)^q$, for any $q \in \mathbb{Z}$ ($K^{-1} = K^*$). *Operationally:* to decide which K^q a local expression belongs to, count powers of dz (with ∂_z counting as -1).

A Beltrami differential is a $(0,1)$-form with values in K_Σ^*. We write the space of smooth ones as $\Omega^{0,1}(K_\Sigma^*)$. Nash's (5.65) [Nash p. 159] is the same statement in local form:

$$\nu\,d\bar z \;\equiv\; \nu(z,\bar z)\,\frac{\partial}{\partial z}\otimes d\bar z. \tag{5.123}$$

Key idea: Every Beltrami differential is $\bar\partial$-closed

On a complex curve there are no $(0,2)$-forms: $d\bar z \wedge d\bar z = 0$. So $\bar\partial$ of any $(0,1)$-form, with or without values in a bundle, is zero. Hence every perturbation $\delta\mu$ lies in the kernel of

$$\bar\partial^{(0,1)}_{K_\Sigma^*} :\ \Omega^{0,1}(K_\Sigma^*) \to \Omega^{0,2}(K_\Sigma^*) = 0.$$

In Nash's words: any element of $\operatorname{Ker}\bar\partial^{(0,1)}_{K_\Sigma^*}$ gives rise to a perturbation in μ, and conversely.

Dictionary: Several names, one object

$\mu\,\partial_z\otimes d\bar z$	Beltrami differential (complex analysis)
$\Omega^{0,1}(K_\Sigma^*)$ or $\Omega^{0,1}(T\Sigma)$	$(0,1)$-forms with values in the tangent bundle
$\delta g_{\bar z\bar z}$, δg_{zz}	traceless part of δg_{ab} (relativity)
$\delta\mu$	infinitesimal change of complex structure
$\int_\Sigma \delta g_{ab}\,T^{ab}$, $\mu\,T_{zz}$	how $\delta\mu$ couples to the stress tensor (CFT)

5.6.4 Removing the diffeomorphisms

Not every $\delta\mu$ changes the point in $\mathcal{M}_p$ (or $\mathcal{T}_p$). If the new metric is just the old one moved around by a diffeomorphism close to the identity, we have gone nowhere. We must find these "fake" perturbations and quotient them out.

The Lie algebra of $\mathrm{Diff}_0(\Sigma)$

An element of $\mathrm{Diff}_0(\Sigma)$ near the identity is generated by a vector field. Nash writes $\mathrm{vect}(\Sigma)$ for the space of smooth vector fields on Σ; it is the Lie algebra of $\mathrm{Diff}_0(\Sigma)$ (and has nothing to do with $\mathrm{Vect}(\Sigma)$, the set of vector bundles over Σ used in K-theory). Given $V \in \mathrm{vect}(\Sigma)$ we "exponentiate" it to a one-parameter family of diffeomorphisms $\alpha_t = \exp(tV)$ [Nash p. 159, (5.66)]:

$$\alpha_t : \Sigma \to \Sigma, \qquad x \mapsto x(t), \tag{5.124}$$

where $x(t)$ is the point reached at time t by moving along the integral curve of V that starts at x. So α_t is the flow of V, the same construction as the time evolution generated by a Hamiltonian vector field in classical mechanics.

The flow acts on metrics [Nash p. 159, (5.67)]:

$$A_t : \mathrm{Diff}_0(\Sigma) \times \mathrm{Met}(\Sigma) \to \mathrm{Met}(\Sigma), \qquad (\alpha_t, g) \mapsto \alpha_t \cdot g, \tag{5.125}$$

with Nash's definition $(\alpha_t \cdot g)(x) = g(\alpha_t(x)) = g(x(t))$: we compare lengths using the metric at the moved point, carried back to x (this is the pull-back $\alpha_t^* g$; Nash calls it a push-forward, and the difference is only $t \to -t$, which does not matter here). As t varies, $g(t) := \alpha_t \cdot g$ is a curve in $\mathrm{Met}(\Sigma)$ through $g(0) = g$ (Figure 5.47). Taylor expanding [Nash p. 159, (5.68)–(5.69)],

$$g(t) = g(0) + t\,\mathcal{L}_V g(0) + \cdots, \qquad g'(0) = \mathcal{L}_V g, \tag{5.126}$$

where $\mathcal{L}_V$ is the Lie derivative (Chapter T1): the rate of change of a tensor as it is dragged along the flow. So $\mathcal{L}_V g$ is the velocity of the curve $g(t)$ at g, a tangent vector to the space of metrics [Nash p. 160, (5.70)]:

$$\mathcal{L}_V\, g \in T_g \mathrm{Met}(\Sigma). \tag{5.127}$$

Nash's finite-dimensional comparison: for a curve $x(t)$ in a manifold generated by a tangent vector $Y = Y^i \partial_i$, the coordinate functions change at the rate $\mathcal{L}_Y x^j = Y(x^j) = Y^i\, \partial x^j/\partial x^i = Y^j$. The Lie derivative of the coordinate functions *is* the velocity. Here the "point" is a whole metric, and its "velocity" is the tensor $\mathcal{L}_V g$.

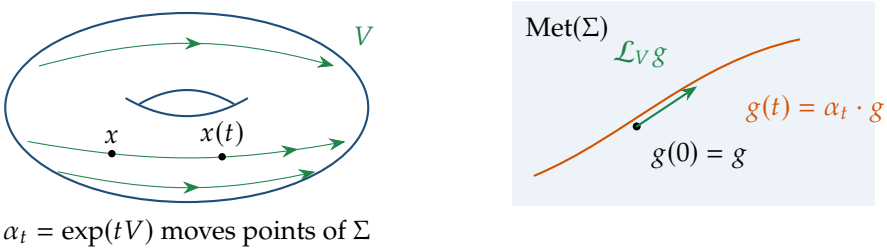

Figure 5.47: Left: a vector field V on Σ generates a flow α_t that slides points along its integral curves. Right: acting on a metric, the flow traces a curve $g(t)$ in the infinite-dimensional space $\mathrm{Met}(\Sigma)$. Its velocity at $t = 0$ is $\mathcal{L}_V g$ (5.68)–(5.70). The curve lies in a single Diff_0-orbit, so every point on it describes the same geometry.

The perturbations produced by a vector field

So we must quotient out every $\delta\mu$ that comes from a $\delta g_{ab} = \mathcal{L}_V g_{ab}$. By (5.120) these are

$$\delta\mu = \frac{(\mathcal{L}_V g)_{z\bar z}}{2 g_{z\bar z}}.$$

The Lie derivative of a symmetric 2-tensor is [Nash p. 160, (5.71)] (this is (5.86))

$$g'_{ab}(0) = \mathcal{L}_V g_{ab} = \frac{\partial g_{ab}}{\partial x^i} V^i + g_{ib} \frac{\partial V^i}{\partial x^a} + g_{ai} \frac{\partial V^i}{\partial x^b}. \tag{5.128}$$

Take $a = b = \bar z$ and sum over $i \in \{z, \bar z\}$, writing $V^z_{,\bar z} = \partial_{\bar z} V^z$ and so on:

$$\begin{aligned}(\mathcal{L}_V g)_{\bar z\bar z} &\overset{(1)}{=} g_{\bar z\bar z, z} V^z + g_{\bar z\bar z, \bar z} V^{\bar z} + g_{z\bar z} V^z_{,\bar z} + g_{\bar z\bar z} V^{\bar z}_{,\bar z} + g_{\bar z z} V^z_{,\bar z} + g_{\bar z\bar z} V^{\bar z}_{,\bar z} \\ &\overset{(2)}{=} 2\, g_{z\bar z}\, \partial_{\bar z} V^z.\end{aligned} \tag{5.129}$$

(1) (5.128): two terms from $V^i \partial_i g_{\bar z\bar z}$, two from $g_{i\bar z}\partial_{\bar z} V^i$, two from $g_{\bar z i}\partial_{\bar z} V^i$. This is the six-term numerator displayed by Nash on p. 160.

(2) In isothermal coordinates the only non-zero components are $g_{z\bar{z}} = g_{\bar{z}z}$, so four of the six terms vanish (including the derivatives of $g_{\bar{z}\bar{z}} \equiv 0$).

Therefore

$$\boxed{\delta\mu = \partial_{\bar{z}} V^z} \qquad \big(\text{Nash's (5.72): } \delta\mu = 2V^z_{,\bar{z}} = 2\partial_{\bar{z}} V^z\big). \tag{5.130}$$

For completeness, the trace part of the same Lie derivative is

$$\begin{aligned}(\mathcal{L}_V g)_{z\bar{z}} &\overset{(1)}{=} V^z \partial_z g_{z\bar{z}} + V^{\bar{z}} \partial_{\bar{z}} g_{z\bar{z}} + g_{z\bar{z}}\, \partial_z V^z + g_{z\bar{z}}\, \partial_{\bar{z}} V^{\bar{z}} \\ &\overset{(2)}{=} \tfrac{1}{2}\big(V^z \partial_z \lambda + V^{\bar{z}} \partial_{\bar{z}} \lambda + \lambda\, \partial_z V^z + \lambda\, \partial_{\bar{z}} V^{\bar{z}}\big),\end{aligned}$$

(1) (5.128) with $a = z$, $b = \bar{z}$, dropping terms with $g_{zz} = g_{\bar{z}\bar{z}} = 0$.
(2) $g_{z\bar{z}} = \lambda/2$.

which is a change of λ only. It is absorbed by a Weyl rescaling, so it does not constrain anything. The whole content of "quotient by diffeomorphisms" is therefore:

Two Beltrami differentials $\delta\mu$ and $\delta\mu'$ describe the same tangent vector to $\mathcal{T}_p$ if $\delta\mu' - \delta\mu = \partial_{\bar{z}} V^z$ for some smooth vector field V.

Worked example 5.86: A diffeomorphism that fakes a change of shape

On the flat plane ($\lambda = 1$) take the real vector field $V = x\,\partial_x - y\,\partial_y$, which generates $\alpha_t(x, y) = (e^t x, e^{-t} y)$: stretch along x, squeeze along y. In complex notation $V^z = V^x + iV^y = x - iy = \bar{z}$. Then (5.130) gives

$$\delta\mu = \partial_{\bar{z}} \bar{z} = 1 \quad \text{(per unit } t\text{)}.$$

Directly: $\alpha_t^*(\mathrm{d}x^2 + \mathrm{d}y^2) = e^{2t}\mathrm{d}x^2 + e^{-2t}\mathrm{d}y^2 \approx (1 + 2t)\mathrm{d}x^2 + (1 - 2t)\mathrm{d}y^2$. So $\delta g_{xx} = 2t$, $\delta g_{yy} = -2t$, $\delta g_{xy} = 0$, and (5.121) gives

$$\delta\mu \overset{(1)}{=} \tfrac{1}{4}\big(2t - (-2t)\big) = t. \checkmark$$

(1) (5.120) with $\lambda = 1$ and (5.121).

So on the plane a constant $\delta\mu$ is *fake*: it is undone by a linear stretch. On a torus the same $V = \bar{z}\,\partial_z$ is *not* allowed, because $\bar{z}$ is not periodic. That single fact is why the torus has a modulus.

Locally, every $\delta\mu$ is fake

On a disc D, every smooth $\delta\mu$ can be written as $\partial_{\bar{z}} V^z$. The reason is the Green's function of $\partial_{\bar{z}}$, familiar from 2d electrostatics:

$$\partial_{\bar{z}} \frac{1}{\pi z} = \delta^2(z) \qquad \text{so} \qquad V^z(z) = \frac{1}{\pi} \int_D \frac{\delta\mu(w)}{z - w}\, \mathrm{d}^2 w \ \text{ solves } \ \partial_{\bar{z}} V^z = \delta\mu. \tag{5.131}$$

(To check the first formula, integrate $\partial_{\bar{z}}(1/\pi z)$ against a test function and use Stokes: $\oint \mathrm{d}z/z = 2\pi i$ around the origin.) So there are no *local* moduli at all: every deformation of complex structure on a disc is a coordinate change. This matches Section 5.4.2, where we used the Beltrami equation to find isothermal coordinates for any metric. Moduli exist because on a *compact* surface the solution V^z has to be a global section of K_Σ^*, and the integral formula does not produce one. The obstruction is global, and global obstructions to solving $\bar{\partial} V = \mu$ are measured by cohomology.

5.6.5 The tangent space as a Dolbeault cohomology group

Background: the operator $\bar\partial_E$

Let E be a holomorphic line bundle on Σ, with local frames related by holomorphic transition functions $g_{\alpha\beta}$. A smooth section is a collection of local functions s_α with $s_\alpha = g_{\alpha\beta}s_\beta$. Because $\partial_{\bar z} g_{\alpha\beta} = 0$,

$$\partial_{\bar z} s_\alpha = g_{\alpha\beta}\,\partial_{\bar z} s_\beta,$$

so the local $(0,1)$-forms $\partial_{\bar z} s_\alpha\,\mathrm{d}\bar z$ glue to a global E-valued $(0,1)$-form. This defines the operator

$$\bar\partial_E = \bar\partial_E^{(0,0)} :\ \Omega^{0,0}(E) \to \Omega^{0,1}(E), \qquad s \mapsto \partial_{\bar z} s\ \mathrm{d}\bar z.$$

It is a first-order elliptic operator (its symbol is multiplication by $\xi_{\bar z}$, which is invertible for $\xi \neq 0$); chapter 4 (Chapter 4) computed its index.

Working definition 5.47 (Dolbeault cohomology of a line bundle on a curve)

For a holomorphic line bundle E on a Riemann surface,

$$H^{0,0}_{\bar\partial_E}(\Sigma) = \operatorname{Ker}\bar\partial_E^{(0,0)} \ \text{(the holomorphic sections)}, \qquad H^{0,1}_{\bar\partial_E}(\Sigma) = \frac{\operatorname{Ker}\bar\partial_E^{(0,1)}}{\operatorname{Im}\bar\partial_E^{(0,0)}} = \frac{\Omega^{0,1}(E)}{\bar\partial_E\,\Omega^{0,0}(E)}.$$

Operationally: $H^{0,0}$ counts solutions of $\bar\partial s = 0$; $H^{0,1}$ counts the right-hand sides β for which $\bar\partial s = \beta$ has *no* solution, modulo those that do. Their dimensions are finite (ellipticity), and $\dim H^{0,0} - \dim H^{0,1} = \operatorname{index}\bar\partial_E$. By Dolbeault's theorem (Chapter 3), $H^{0,q}_{\bar\partial_E}(\Sigma) \cong H^q(\Sigma, \mathcal{O}(E))$, the sheaf cohomology of the sheaf of holomorphic sections of E.

Nash's identification

Take $E = K_\Sigma^*$. A vector field $V = V^z\partial_z + V^{\bar z}\partial_{\bar z}$ has as its $(1,0)$ part $V^z\partial_z$, a smooth section of K_Σ^*. The fake perturbations $\partial_{\bar z}V^z\,\partial_z \otimes \mathrm{d}\bar z$ are exactly the image of $\bar\partial$ acting on sections of K_Σ^* [Nash p. 160, (5.73)]:

$$\{\text{fake } \delta\mu\} = \operatorname{Im}\bar\partial^{(0,0)}_{K_\Sigma^*}, \qquad \text{locally } V^z_{,\bar z}\,\frac{\partial}{\partial z}\otimes\mathrm{d}\bar z. \tag{5.132}$$

The genuine infinitesimal deformations are the quotient [Nash p. 161, (5.74)–(5.76)]:

$$\boxed{T_{[g]}\mathcal{M}_p \;=\; \frac{\operatorname{Ker}\bar\partial^{(0,1)}_{K_\Sigma^*}}{\operatorname{Im}\bar\partial^{(0,0)}_{K_\Sigma^*}} \;=\; H^{0,1}_{\bar\partial_{K_\Sigma^*}}(\Sigma)} \tag{5.133}$$

(Strictly this is the tangent space to $\mathcal{T}_p$, which equals that of $\mathcal{M}_p$ at points where Γ_Σ acts freely; the dimension is the same everywhere.)

Worked example 5.87: The torus in Fourier modes: a complete calculation

Let us compute $H^{0,1}_{\bar\partial_{K^*}}$ for the square torus $\Sigma = \mathbb{C}/(\mathbb{Z}+i\mathbb{Z})$ with $z = x+iy$, x, y mod 1, by brute force. The transition functions of the torus are translations $z \mapsto z+1$, $z \mapsto z+i$, with derivative 1, so ∂_z is a global frame of K^* and a section is just a doubly periodic function $V^z(x,y)$. Likewise $\partial_z \otimes \mathrm{d}\bar z$ is a global frame for Beltrami differentials. Expand in Fourier

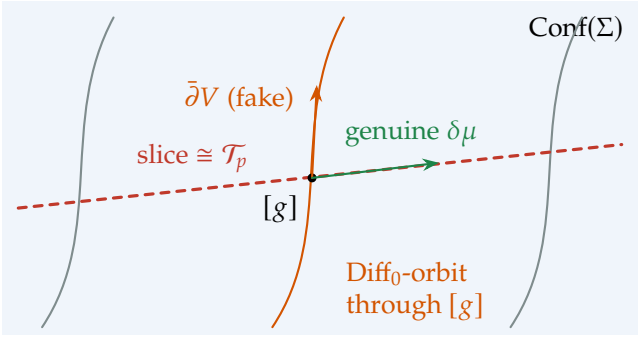

Figure 5.48: The quotient (5.74) as a picture. Each orange curve is one Diff_0-orbit in the space of complex structures: all its points are the same surface. Perturbations tangent to the orbit, $\delta\mu = \bar\partial V$, are fake. The genuine directions are the tangent space modulo the orbit directions, $H^{0,1}(K^*)$; a transverse slice (red dashed) through the orbits is a local model of Teichmüller space.

modes $e_{mn}(x,y) = e^{2\pi i(mx+ny)}$, $(m,n) \in \mathbb{Z}^2$:

$$V^z = \sum_{m,n} v_{mn}\, e_{mn}, \qquad \delta\mu = \sum_{m,n} \mu_{mn}\, e_{mn}.$$

The operator $\bar\partial$ is diagonal in this basis:

$$\partial_{\bar z} e_{mn} \overset{(1)}{=} \tfrac{1}{2}(\partial_x + i\partial_y)\, e^{2\pi i(mx+ny)} \overset{(2)}{=} \tfrac{1}{2}(2\pi i m + i\cdot 2\pi i n)\, e_{mn} \overset{(3)}{=} \pi i\,(m+in)\, e_{mn}.$$

(1) $\partial_{\bar z} = \tfrac{1}{2}(\partial_x + i\partial_y)$, from $x = (z+\bar z)/2$, $y = (z-\bar z)/2i$.
(2) Differentiate the exponential.
(3) $\tfrac{1}{2}(2\pi i m - 2\pi n) = \pi i m - \pi n = \pi i(m+in)$.

So $\bar\partial$ multiplies the (m,n) mode by $\pi i(m+in)$, which is non-zero unless $m = n = 0$ (Figure 5.49). Therefore:

- **Kernel.** $\partial_{\bar z} V^z = 0$ forces $v_{mn} = 0$ for $(m,n) \neq (0,0)$: V^z is constant. $\dim_{\mathbb{C}} \operatorname{Ker} \bar\partial_{K^*} = 1$: the translations, i.e. the conformal Killing vectors of Example 5.71.
- **Image.** Given $\delta\mu$, solve mode by mode: $v_{mn} = \mu_{mn}/(\pi i(m+in))$ for $(m,n) \neq (0,0)$. This is always possible, and the resulting series converges to a smooth V^z because μ_{mn} decays faster than any power. The only obstruction is the zero mode: μ_{00} can never be produced.
- **Cokernel.** $H^{0,1} = \Omega^{0,1}(K^*)/\operatorname{Im}\bar\partial \cong \mathbb{C}$, and the class of $\delta\mu$ is its average, $[\delta\mu] = \mu_{00} = \int_{T^2} \delta\mu\, \mathrm{d}x\, \mathrm{d}y$.

So $\dim_{\mathbb{C}} T\mathcal{T}_1 = 1$, and $\operatorname{index}\bar\partial_{K^*} = 1 - 1 = 0$. Every Beltrami differential on the torus is equivalent to a *constant* one, and the constant is the modulus.

Worked example 5.88: The constant $\delta\mu$ is a change of τ

Take the flat torus $\mathbb{C}/(\mathbb{Z}+\tau\mathbb{Z})$, write points as $z = x + \tau y$ with x, y mod 1, and change $\tau \to \tau + \delta\tau$ while keeping x, y as coordinates. The metric changes from $|\mathrm{d}x + \tau\,\mathrm{d}y|^2 = |\mathrm{d}z|^2$

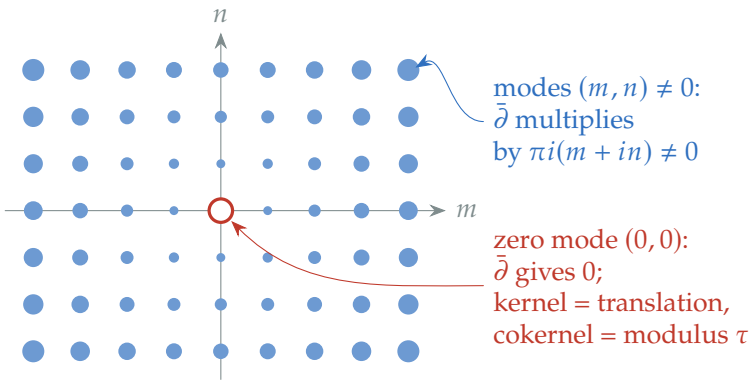

Figure 5.49: The operator $\bar\partial_{K^*}$ on the square torus in the Fourier basis. Each blue dot is a mode $e^{2\pi i(mx+ny)}$; its size shows $|\pi i(m+in)|$, the factor by which $\bar\partial$ rescales it, which never vanishes. Only the zero mode (red circle) is special: a constant V^z is annihilated (a conformal Killing vector) and a constant $\delta\mu$ cannot be reached (a genuine modulus). Kernel and cokernel are both one-dimensional, so the index is 0.

to $|\mathrm{d}x + (\tau+\delta\tau)\mathrm{d}y|^2 = |\mathrm{d}z + \delta\tau\,\mathrm{d}y|^2$. Express $\mathrm{d}y$ in terms of $\mathrm{d}z, \mathrm{d}\bar z$:

$$\mathrm{d}y \overset{(1)}{=} \frac{\mathrm{d}z - \mathrm{d}\bar z}{\tau - \bar\tau} = \frac{\mathrm{d}z - \mathrm{d}\bar z}{2i\tau_2},$$
$$\mathrm{d}z + \delta\tau\,\mathrm{d}y \overset{(2)}{=} \Big(1 + \frac{\delta\tau}{2i\tau_2}\Big)\mathrm{d}z - \frac{\delta\tau}{2i\tau_2}\,\mathrm{d}\bar z,$$
$$\delta\mu \overset{(3)}{=} -\frac{\delta\tau}{2i\tau_2} + O(\delta\tau^2) = \frac{i\,\delta\tau}{2\tau_2}.$$

(1) From $z = x + \tau y$ and $\bar z = x + \bar\tau y$: $z - \bar z = (\tau - \bar\tau)y$.
(2) Substitute.
(3) Divide by the coefficient of $\mathrm{d}z$ to put the metric in the form $\lambda|\mathrm{d}z + \mu\,\mathrm{d}\bar z|^2$, and keep first order.

So $\delta\tau \mapsto [\delta\mu] = i\,\delta\tau/(2\tau_2)$ is a linear isomorphism $T_\tau\mathcal{T}_1 = \mathbb{C} \to H^{0,1}_{\bar\partial_{K^*}}$: Nash's (5.133) for $p = 1$, completely explicitly. (At $\tau = i$ this is $\delta\mu = \frac{i}{2}\delta\tau$, which is also the derivative of the Cayley transform $\mu = (i-\tau)/(i+\tau)$ of Example 5.66 at $\tau = i$: $\mathrm{d}\mu/\mathrm{d}\tau = -2i/(\tau+i)^2 = i/2$.)

5.6.6 Serre duality and quadratic differentials

We now know that $T_{[g]}\mathcal{M}_p = H^{0,1}(K^*)$. This is a quotient space, awkward to compute with. Serre duality replaces it by the dual of a space of honest holomorphic objects, which is much easier to count.

Background: Serre duality

For a holomorphic vector bundle E over a compact complex manifold M of complex dimension n, Serre duality (Chapter 3, and Nash's (5.20), (5.22)) states

$$H^q\big(M, \Omega^p(E)\big) \;\cong\; H^{n-q}\big(M, \Omega^{n-p}(E^*)\big)^*, \tag{5.134}$$

where $\Omega^p(E)$ is the sheaf of holomorphic E-valued p-forms. The pairing that realises it takes a Dolbeault representative θ of type (p,q) and ν of type $(n-p, n-q)$ and integrates their product,

$\int_M \langle \theta, v \rangle$, contracting E with E^*. For a curve ($n = 1$), with $\Omega^0(E) = \mathcal{O}(E)$ and $\Omega^1(E) = \mathcal{O}(K \otimes E)$:

$$H^1\big(\Sigma, \mathcal{O}(E)\big) \;\cong\; H^0\big(\Sigma, \mathcal{O}(K_\Sigma \otimes E^*)\big)^*. \tag{5.135}$$

Applying it to $E = K_\Sigma^*$

Nash's chain [Nash p. 161, (5.77)]:

$$\begin{aligned} H^{0,1}_{\bar\partial_{K_\Sigma^*}}(\Sigma) &\overset{(1)}{=} H^1\big(\Sigma, \mathcal{O}(K_\Sigma^*)\big) \equiv H^1\big(\Sigma, \Omega^0(K_\Sigma^*)\big) \\ &\overset{(2)}{\cong} H^0\big(\Sigma, \Omega^1(K_\Sigma)\big)^* \overset{(3)}{=} H^0\big(\Sigma, \mathcal{O}(K_\Sigma^2)\big)^* \overset{(4)}{=} \big(H^{0,0}_{\bar\partial_{K_\Sigma^2}}(\Sigma)\big)^*. \end{aligned} \tag{5.136}$$

(1) Dolbeault's theorem: $\bar\partial$-cohomology equals sheaf cohomology of holomorphic sections.
(2) Serre duality (5.135) with $E = K^*$, so $E^* = K$.
(3) A holomorphic 1-form with values in K is a holomorphic section of $K \otimes K = K^2$.
(4) H^0 of the sheaf of holomorphic sections is the kernel of $\bar\partial$ on smooth sections.

So [Nash p. 161, (5.78)]:

$$\boxed{T_{[g]}\mathcal{M}_p = H^{0,1}_{\bar\partial_{K_\Sigma^*}}(\Sigma), \qquad T^*_{[g]}\mathcal{M}_p = H^{0,0}_{\bar\partial_{K_\Sigma^2}}(\Sigma)} \tag{5.137}$$

The cotangent space to moduli space is the space of holomorphic sections of K^2.

Working definition 5.48 (Holomorphic quadratic differential)

A **holomorphic quadratic differential** is a holomorphic section of K_Σ^2: in each chart

$$\phi = \phi(z)\,\mathrm{d}z \otimes \mathrm{d}z, \qquad \bar\partial\phi = 0,$$

with $\phi(z) = \tilde\phi(h(z))\,h'(z)^2$ under a holomorphic change of coordinate $w = h(z)$ [Nash p. 162, footnote 6]. *Operationally:* write down a candidate $\phi(z)$ in one chart, transform it to every other chart with the factor $h'(z)^2$, and check it is holomorphic everywhere, including at points added at infinity.

More generally a **holomorphic q-differential** is $\phi = \phi(z)\,\mathrm{d}z^{\otimes q}$, a holomorphic section of K^q, with $\phi(z) = \tilde\phi(h(z))\,h'(z)^q$. Holomorphic 1-differentials are the Abelian differentials of Chapter 5 (there are p of them). The transformation law is the chain rule: $\tilde\phi(w)\,\mathrm{d}w^q = \tilde\phi(h(z))\,(h'(z)\mathrm{d}z)^q$.

Worked example 5.89: Quadratic differentials on the sphere and the torus

Sphere. On $\mathbb{CP}^1 = \mathbb{C} \cup \{\infty\}$ a candidate is $\phi(z)\,\mathrm{d}z^2$ with ϕ entire. Near ∞ use $w = 1/z$, so $z = 1/w$ and $\mathrm{d}z = -w^{-2}\mathrm{d}w$:

$$\phi(z)\,\mathrm{d}z^2 \overset{(1)}{=} \phi(1/w)\,w^{-4}\,\mathrm{d}w^2.$$

(1) $\mathrm{d}z^2 = (-w^{-2}\mathrm{d}w)^2 = w^{-4}\mathrm{d}w^2$.

For this to be holomorphic at $w = 0$ we need $\phi(1/w) = O(w^4)$, i.e. $\phi(z) \to 0$ like z^{-4} as $z \to \infty$. An entire function that tends to 0 at infinity is bounded, hence constant (Liouville), hence zero. So

$$H^0(\mathbb{CP}^1, \mathcal{O}(K^2)) = 0: \quad \text{the sphere has no moduli.}$$

More generally, a holomorphic q-differential with $q \geq 1$ on the sphere vanishes identically,

while for $q \le 0$ ($K^q = (K^*)^{|q|}$) the polynomials of degree $\le 2|q|$ survive: $2|q|+1$ of them. For $q=-1$ these are the three conformal Killing vectors of Example 5.70.
Torus. On $\mathbb{C}/(\mathbb{Z}+\tau\mathbb{Z})$ the translations have $h'=1$, so a quadratic differential is $\phi(z)\,\mathrm{d}z^2$ with ϕ holomorphic and doubly periodic, hence bounded, hence constant:

$$H^0(T^2, \mathcal{O}(K^2)) = \mathbb{C}\cdot \mathrm{d}z^2,$$

one-dimensional, dual to the one-dimensional $H^{0,1}(K^*)$ of Example 5.87. In fact every K^q on the torus is trivial with frame $\mathrm{d}z^q$, and has exactly one holomorphic section.

Nash's example: the duality pairing, explicitly

Nash pauses [Nash p. 162, Example] to show the duality at work. Take a Beltrami differential and a quadratic differential,

$$\mu = \mu(z,\bar z)\,\frac{\partial}{\partial z}\otimes \mathrm{d}\bar z, \qquad \phi = \phi(z)\,\mathrm{d}z\otimes \mathrm{d}z.$$

Contract the ∂_z of μ with one $\mathrm{d}z$ of ϕ ($\langle \partial_z, \mathrm{d}z\rangle = 1$). What is left is $\mu\phi\,\mathrm{d}z\otimes\mathrm{d}\bar z$, a $(1,1)$ object that we integrate as the 2-form $\mu\phi\,\mathrm{d}z\wedge\mathrm{d}\bar z$. We normalise with $\mathrm{d}^2z := \frac{i}{2}\mathrm{d}z\wedge\mathrm{d}\bar z = \mathrm{d}x\wedge\mathrm{d}y$:

$$\langle \mu, \phi\rangle \;:=\; \int_\Sigma \mu(z,\bar z)\,\phi(z)\;\mathrm{d}^2z. \tag{5.138}$$

(Nash writes $\int_\Sigma \mu\phi\,\mathrm{d}z\,\mathrm{d}\bar z$; the constant $i/2$ is immaterial.) First, the integrand is chart independent. Under $w = h(z)$,

$$\begin{aligned}\tilde\mu\,\tilde\phi\;\mathrm{d}w\wedge\mathrm{d}\bar w &\overset{(1)}{=} \Big(\mu\,\frac{h'}{\overline{h'}}\Big)\Big(\phi\,\frac{1}{(h')^2}\Big)\;|h'|^2\;\mathrm{d}z\wedge\mathrm{d}\bar z\\ &\overset{(2)}{=} \mu\,\phi\,\frac{h'\,\overline{h'}}{\overline{h'}\,h'}\;\mathrm{d}z\wedge\mathrm{d}\bar z = \mu\,\phi\;\mathrm{d}z\wedge\mathrm{d}\bar z.\end{aligned}$$

(1) Transformation laws: $\tilde\mu = \mu\,h'/\overline{h'}$ from (5.115); $\tilde\phi = \phi/(h')^2$ from the definition of a quadratic differential; $\mathrm{d}w\wedge\mathrm{d}\bar w = |h'|^2\mathrm{d}z\wedge\mathrm{d}\bar z$.
(2) Collect factors; they cancel exactly.

Second, the pairing vanishes on the fake perturbations, so it is well defined on the quotient $H^{0,1}(K^*)$. If $\mu = \partial_{\bar z}V^z$ then

$$\langle \partial_{\bar z}V^z, \phi\rangle \overset{(1)}{=} \int_\Sigma \partial_{\bar z}\big(V^z\phi\big)\,\mathrm{d}^2z \overset{(2)}{=} -\int_\Sigma V^z\,\partial_{\bar z}\phi\;\mathrm{d}^2z \;+\; 0 \overset{(3)}{=} 0.$$

(1) ϕ is holomorphic, so $\partial_{\bar z}(V^z\phi) = (\partial_{\bar z}V^z)\phi$.
(2) Nash's form of the argument: integrate by parts. The boundary term is zero because Σ is closed. Precisely, $V^z\phi\,\mathrm{d}z$ is a global $(1,0)$-form (a section of $K^*\otimes K^2 = K$), $\mathrm{d}(V^z\phi\,\mathrm{d}z) = \partial_{\bar z}(V^z\phi)\,\mathrm{d}\bar z\wedge\mathrm{d}z$, and Stokes on a surface with $\partial\Sigma=\varnothing$ gives zero.
(3) $\partial_{\bar z}\phi = 0$.

So μ and ϕ "know" about each other in exactly the way Serre duality requires: the pairing ignores the part of μ that is pure gauge.

Why the pairing is perfect: harmonic Beltrami differentials

Nash does not show that the pairing identifies $H^{0,1}(K^*)$ with the *full* dual of $H^0(K^2)$. Here is a concrete way to see it, which also gives the best representative of each class. Choose the metric $\lambda|\mathrm{d}z|^2$ (for instance the constant-curvature one). Given a holomorphic quadratic differential ϕ, set

$$\mu_\phi \;:=\; \frac{\overline{\phi(z)}}{\lambda}\,\frac{\partial}{\partial z}\otimes \mathrm{d}\bar z. \tag{5.139}$$

This is a legitimate Beltrami differential: $\bar\phi\,\mathrm{d}\bar z^2$ divided by $\lambda\,\mathrm{d}z\,\mathrm{d}\bar z$ has exactly the index structure $\mathrm{d}\bar z\otimes(\mathrm{d}z)^{-1}$. Now

$$\langle \mu_\phi,\phi\rangle \overset{(1)}{=} \int_\Sigma \frac{|\phi|^2}{\lambda}\,\mathrm{d}^2z \;>\; 0 \qquad \text{for } \phi\neq 0.$$

(1) (5.138) with (5.139); the integrand is positive wherever $\phi\neq 0$, and a non-zero holomorphic ϕ vanishes only at isolated points.

So no non-zero ϕ pairs to zero with everything: the map $H^{0,1}(K^*)\to H^0(K^2)^*$ is onto. Conversely, the μ_ϕ are exactly the Beltrami differentials orthogonal to all fake ones in the natural inner product $\int \mu_1\bar\mu_2\,\lambda\,\mathrm{d}^2z$, so each class contains exactly one of them (Hodge theory for $\bar\partial_{K^*}$), and the map is also one-to-one. These μ_ϕ are called **harmonic Beltrami differentials**. On the flat torus, $\phi=\mathrm{d}z^2$ gives the constant $\mu=1/\lambda$, in agreement with Example 5.87.

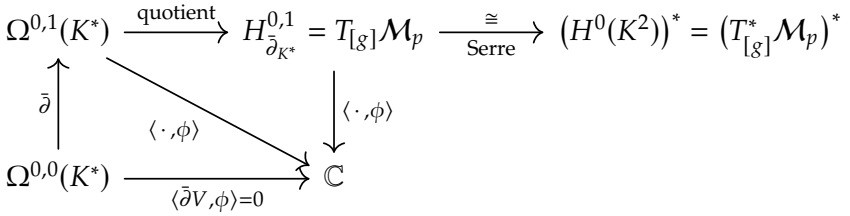

Figure 5.50: The logic of (5.73)–(5.78) as a diagram. Beltrami differentials $\Omega^{0,1}(K^*)$ contain the fake ones, $\bar\partial\Omega^{0,0}(K^*)$. Pairing with a holomorphic quadratic differential ϕ kills the fake ones (bottom row), so it descends to the quotient $H^{0,1}$, and Serre duality says that the resulting map to $H^0(K^2)^*$ is an isomorphism.

Automorphic forms and modular forms

Nash's footnote 6 [Nash p. 162] connects quadratic differentials to a classical subject. Suppose $\Sigma=\tilde\Sigma/\Gamma$ with Γ a discrete group of holomorphic automorphisms of $\tilde\Sigma$ (a Fuchsian group acting on H, as in Section 5.5.6). A holomorphic q-differential on Σ is the same thing as a holomorphic q-differential $\phi(z)\,\mathrm{d}z^q$ on $\tilde\Sigma$ that is invariant under Γ:

$$\phi(z)=\phi(\gamma(z))\,\gamma'(z)^q \qquad \text{for all } \gamma\in\Gamma.$$

Such a ϕ is called an **automorphic form of weight q** for Γ. When Γ is the modular group $\mathrm{SL}(2,\mathbb{Z})/\{\mp I\}$ it is called a **modular form** of weight q.

Worked example 5.90: A modular form as a quadratic differential on H

For $\gamma(\tau)=(a\tau+b)/(c\tau+d)$ with $ad-bc=1$ we found in Example 5.78 that $\gamma'(\tau)=(c\tau+d)^{-2}$. So the invariance condition for $q=2$ reads

$$\phi(\gamma\tau)=(c\tau+d)^4\,\phi(\tau).$$

The holomorphic Eisenstein series $G_4(\tau) = \sum_{(m,n)\neq(0,0)}(m+n\tau)^{-4}$ (the holomorphic cousin of Example 5.80; the sum converges absolutely) satisfies it:

$$G_4(\gamma\tau) \overset{(1)}{=} \sum_{(m,n)\neq 0} \frac{(c\tau+d)^4}{\big(m(c\tau+d)+n(a\tau+b)\big)^4}$$
$$\overset{(2)}{=} (c\tau+d)^4 \sum_{(m',n')\neq 0} \frac{1}{(m'+n'\tau)^4} = (c\tau+d)^4\, G_4(\tau).$$

(1) Put $m + n\gamma\tau$ over the common denominator $c\tau + d$.
(2) Relabel $(m', n') = (md + nb,\ mc + na)$, a bijection of $\mathbb{Z}^2 \setminus 0$ as in Example 5.80.

So $G_4(\tau)\,\mathrm{d}\tau^2$ is invariant under the modular group: it is a quadratic differential on the upper half-plane that descends to the (orbifold) quotient. It is a "modular form of weight 2" in Nash's convention.

Watch out: Two conventions for the weight

Nash's weight q counts powers of $\mathrm{d}z$. Number theorists count powers of $(c\tau + d)$, which is $2q$. So Nash's weight-2 form $G_4\,\mathrm{d}\tau^2$ is the number theorists' "weight 4 modular form G_4". Check which convention a source uses before comparing formulas.

At this point the tangent space problem has become a counting problem:

$$\dim_{\mathbb{C}} \mathcal{M}_p = \textit{number of linearly independent holomorphic quadratic differentials on } \Sigma.$$

The sphere has none and the torus has one (Example 5.89). For higher genus we need a machine, and the machine is the index theorem.

5.6.7 The cotangent space as the kernel of an elliptic operator

We have reduced the problem to counting holomorphic quadratic differentials. Nash now observes [Nash p. 163, (5.79)] that the space of holomorphic sections of K_Σ^2 is, by its definition, the kernel of an operator:

$$H^{0,0}_{\bar\partial_{K_\Sigma^2}}(\Sigma) = \operatorname{Ker}\bar\partial_{K_\Sigma^2}, \qquad \bar\partial_{K_\Sigma^2}:\ \Omega^{0,0}(K_\Sigma^2) \to \Omega^{0,1}(K_\Sigma^2), \quad \phi(z,\bar z)\,\mathrm{d}z^2 \ \mapsto\ \partial_{\bar z}\phi\ \mathrm{d}z^2\otimes\mathrm{d}\bar z. \tag{5.140}$$

Combined with (5.137) this gives Nash's (5.80):

$$\dim \mathcal{M}_p \ =\ \dim T^*_{[g]}\mathcal{M}_p \ =\ \dim \operatorname{Ker}\bar\partial_{K_\Sigma^2}. \tag{5.141}$$

This is the key observation. A question about the geometry of an infinite-dimensional quotient has become a question about the zero modes of a first-order elliptic operator on a compact surface. Zero modes of elliptic operators are what the index theorem of Chapter 4 is built to count.

Physical picture: What we are going to count, in string language

In the Faddeev–Popov treatment of the Polyakov integral (Chapter 9) the ghost c is a vector field, a section of K^*, and the antighost b is a quadratic differential, a section of K^2. Their action is $\int b_{zz}\,\partial_{\bar z}c^z\,\mathrm{d}^2z$, so the equations of motion are $\partial_{\bar z}c^z = 0$ and (after integrating by parts) $\partial_{\bar z}b_{zz} = 0$. Zero modes of c are conformal Killing vectors, zero modes of b are holomorphic quadratic differentials. The path integral over the ghosts vanishes unless we

insert one b for every b zero mode and one c for every c zero mode. Counting them is exactly the calculation below.

The adjoint operator, written out

The index of $\bar\partial_{K^2}$ is $\dim\operatorname{Ker}\bar\partial_{K^2} - \dim\operatorname{Ker}\bar\partial^*_{K^2}$. To see what the second kernel is, we need the adjoint $\bar\partial^*_{K^2}$. Nash never writes it down. Let us do so, because it makes the later Serre-duality step (5.87) completely concrete.

Choose a metric $ds^2 = \lambda\,dz\,d\bar z$. It induces a pointwise length on every tensor. Since $|dx|^2 = |dy|^2 = 1/\lambda$, we have $|dz|^2 = |d\bar z|^2 = 2/\lambda$, and the area element is $\lambda\,d^2z$. Dropping harmless constant factors, the L^2 inner products are

$$\begin{aligned}\langle\phi_1,\phi_2\rangle &= \int_\Sigma \phi_1\bar\phi_2\,\lambda^{-q}\,\lambda\,d^2z && \text{for sections } \phi\,dz^q \text{ of } K^q,\\ \langle\psi_1,\psi_2\rangle &= \int_\Sigma \psi_1\bar\psi_2\,\lambda^{-q-1}\,\lambda\,d^2z && \text{for } \psi\,dz^q\otimes d\bar z\in\Omega^{0,1}(K^q).\end{aligned}\tag{5.142}$$

The adjoint is defined by $\langle\bar\partial\phi,\psi\rangle = \langle\phi,\bar\partial^*\psi\rangle$. Compute the left side:

$$\begin{aligned}\langle\bar\partial\phi,\psi\rangle &\overset{(1)}{=} \int_\Sigma (\partial_{\bar z}\phi)\,\bar\psi\,\lambda^{-q}\,d^2z\\ &\overset{(2)}{=} -\int_\Sigma \phi\,\partial_{\bar z}\big(\lambda^{-q}\bar\psi\big)\,d^2z\\ &\overset{(3)}{=} \int_\Sigma \phi\,\overline{\Big(-\lambda^{q-1}\partial_z\big(\lambda^{-q}\psi\big)\Big)}\,\lambda^{1-q}\,d^2z.\end{aligned}$$

(1) Second line of (5.142); the powers of λ combine to λ^{-q}.

(2) Integrate by parts on the closed surface; the boundary term vanishes by Stokes, exactly as in Nash's Example on p. 162.

(3) Multiply and divide by λ^{1-q} and use $\overline{\partial_z f} = \partial_{\bar z}\bar f$ and λ real.

Comparing with the first line of (5.142):

$$\bar\partial^*_{K^q}\big(\psi\,dz^q\otimes d\bar z\big) = -\lambda^{q-1}\,\partial_z\big(\lambda^{-q}\psi\big)\,dz^q.\tag{5.143}$$

This is the "covariant ∂_z" of the metric. So $\bar\partial^*_{K^q}\psi = 0$ exactly when $\lambda^{-q}\psi$ is *anti*-holomorphic. Now look at the index structure of $\lambda^{-q}\psi$. The coefficient ψ belongs to $dz^q\otimes d\bar z$ and λ belongs to $dz\otimes d\bar z$, so $\lambda^{-q}\psi$ belongs to $d\bar z^{\,1-q}$. Its complex conjugate $v := \overline{\lambda^{-q}\psi}$ belongs to dz^{1-q} and is holomorphic. Hence

$$\operatorname{Ker}\bar\partial^*_{K^q} \xrightarrow{\ \cong\ } \overline{H^0\big(\Sigma,\mathcal{O}(K^{1-q})\big)},\qquad \psi\ \mapsto\ v = \overline{\lambda^{-q}\psi}.\tag{5.144}$$

For $q=2$: *the cokernel of $\bar\partial_{K^2}$ is (the complex conjugate of) the space of holomorphic vector fields*, the conformal Killing vectors of Section 5.4.5. This is Nash's (5.86)–(5.87), which he reaches through Hodge theory and Serre duality; here we reached it by one integration by parts.

Watch out: Holomorphic, anti-holomorphic, dual

The map (5.144) is *conjugate*-linear, because it involves complex conjugation. Serre duality gives a complex-linear isomorphism with the *dual* space instead. For counting dimensions the difference is irrelevant: V, $\bar V$ and V^* all have the same dimension.

5.6.8 The index: Riemann–Roch for quadratic differentials

Background: Chern classes and degrees on a surface

For a complex line bundle E over Σ the **first Chern class** $c_1(E)$ is represented by $\frac{i}{2\pi}F$, where F is the curvature 2-form of any connection on E (Chapter T2). Its integral is an integer, the **degree**:

$$\deg E \;:=\; \int_\Sigma c_1(E) \;=\; \#\{\text{zeros}\} - \#\{\text{poles}\} \text{ of any meromorphic section of } E, \tag{5.145}$$

counted with multiplicity (Chapter 5, $c_1([D]) = \deg D$). Three rules make degrees easy.

- $c_1(E \otimes F) = c_1(E) + c_1(F)$, so $\deg K^q = q \deg K$. (Transition functions multiply, their logarithms add.)
- $c_1(E^*) = -c_1(E)$, so $\deg K^* = -\deg K$.
- $K^* = T\Sigma$, and $c_1(T\Sigma)$ is the Euler class. Gauss–Bonnet (5.92) says $\int_\Sigma c_1(T\Sigma) = \frac{1}{2\pi}\int_\Sigma K\,\mathrm{d}A = 2 - 2p$.

The last rule is Nash's (5.83) [Nash p. 163]:

$$\int_\Sigma c_1(K_\Sigma^*) \;=\; 2-2p \;=\; -\int_\Sigma c_1(K_\Sigma), \qquad \text{i.e.} \quad \deg K_\Sigma = 2p-2. \tag{5.146}$$

Only the 2-form part of any characteristic class can be integrated over a surface, and products of two 2-forms vanish. So on Σ

$$\mathrm{ch}(E) = e^{c_1(E)} = 1 + c_1(E), \qquad \mathrm{td}(E) = \frac{c_1(E)}{1 - e^{-c_1(E)}} = 1 + \tfrac{1}{2}c_1(E).$$

Worked example 5.91: Three ways to see $\deg K = 2p-2$

Sphere, by a meromorphic section. The 1-form $\mathrm{d}z$ on $\mathbb{C}\cup\{\infty\}$ has no zeros or poles on $\mathbb{C}$. Near ∞, with $w = 1/z$,

$$\mathrm{d}z \overset{(1)}{=} -\frac{\mathrm{d}w}{w^2},$$

(1) $z = w^{-1}$, so $\mathrm{d}z = -w^{-2}\mathrm{d}w$.

a double pole. So $\deg K_{S^2} = 0 - 2 = -2 = 2\cdot 0 - 2$. ✓

Sphere, by Poincaré–Hopf. The vector field $\partial_z = -w^2\partial_w$ (Example 5.70) has a double zero at ∞ and no other zeros, so $\deg K^* = 2 = \chi(S^2)$. The degree of the tangent bundle is the sum of the indices of a vector field: that is the Poincaré–Hopf theorem.

Genus p, hyperelliptic. Take $y^2 = f(x)$ with f a polynomial of degree $2p+2$ with distinct roots $e_1, \dots, e_{2p+2}$ (Chapter 5). Consider $\omega = \mathrm{d}x/y$.

- At an ordinary point ($y \neq 0$, x finite), x is a good coordinate and ω is finite and non-zero.
- At a branch point $x = e_i$ the good coordinate is s with $x - e_i = s^2$, so $y = s\sqrt{f'(e_i) + O(s^2)}$ and

$$\omega = \frac{2s\,\mathrm{d}s}{s\sqrt{f'(e_i)}\,(1+O(s^2))} = \frac{2\,\mathrm{d}s}{\sqrt{f'(e_i)}}\,(1+O(s^2)),$$

finite and non-zero.

- Over $x = \infty$ there are two points ($y \approx \pm x^{p+1}$). With $t = 1/x$, $\mathrm{d}x = -t^{-2}\mathrm{d}t$ and $y \approx \pm t^{-p-1}$, so $\omega \approx \mp t^{p+1}t^{-2}\mathrm{d}t = \mp t^{p-1}\mathrm{d}t$: a zero of order $p-1$ at each point.

Total: $\deg K = 2(p-1) = 2p-2$. ✓ (For $p = 1$ this is the nowhere-vanishing $\mathrm{d}z$ of the torus, since $\mathrm{d}x/y = \mathrm{d}\wp/\wp' = \mathrm{d}z$.)

Nash's calculation

The index theorem for $\bar\partial_E$ on a curve is the Riemann–Roch theorem (Chapter 4, Nash's (4.118)). For $E = K_\Sigma^2$ it reads [Nash p. 163, (5.81)]

$$\operatorname{index}\bar\partial_{K_\Sigma^2} = \dim\operatorname{Ker}\bar\partial_{K_\Sigma^2} - \dim\operatorname{Ker}\bar\partial^*_{K_\Sigma^2} = \int_\Sigma \operatorname{ch}(K_\Sigma^2)\wedge\operatorname{td}(T\Sigma). \tag{5.147}$$

Evaluate the integrand [Nash p. 163, (5.82)]:

$$\begin{aligned}\operatorname{ch}(K_\Sigma^2)\wedge\operatorname{td}(T\Sigma) &\overset{(1)}{=} \big(1 + c_1(K_\Sigma^2)\big)\wedge\big(1 + \tfrac12 c_1(K_\Sigma^*)\big)\\ &\overset{(2)}{=} 1 + c_1(K_\Sigma^2) + \tfrac12 c_1(K_\Sigma^*) + \tfrac12 c_1(K_\Sigma^2)\wedge c_1(K_\Sigma^*)\\ &\overset{(3)}{=} 1 + 2c_1(K_\Sigma) - \tfrac12 c_1(K_\Sigma)\\ &= 1 + \tfrac32\, c_1(K_\Sigma).\end{aligned} \tag{5.148}$$

(1) $\operatorname{ch} = 1 + c_1$ and $\operatorname{td} = 1 + \frac12 c_1$ for line bundles on a surface; $T\Sigma = K_\Sigma^*$.
(2) Multiply out.
(3) The last term is a 4-form on a 2-manifold, so it vanishes; $c_1(K^2) = 2c_1(K)$ and $c_1(K^*) = -c_1(K)$.

Only the 2-form part contributes to the integral:

$$\operatorname{index}\bar\partial_{K_\Sigma^2} \overset{(1)}{=} \tfrac32\int_\Sigma c_1(K_\Sigma) \overset{(2)}{=} -\tfrac32\,(2-2p) = 3p-3. \tag{5.149}$$

(1) Integrate (5.148); the constant 1 is a 0-form and contributes nothing.
(2) Gauss–Bonnet in the form (5.146).

This is Nash's (5.84). In the language of Section 5.6.7,

$$\dim H^0(\Sigma, \mathcal{O}(K^2)) - \dim H^0(\Sigma, \mathcal{O}(K^*)) = 3p-3, \tag{5.150}$$

"b zero modes minus c zero modes". This holds for *every* genus. What we still need is the size of one of the two kernels.

Key idea: Riemann–Roch for every K^q

The same algebra with $E = K^q$ gives

$$\operatorname{index}\bar\partial_{K^q} \overset{(1)}{=} \int_\Sigma \big(1 + q\,c_1(K)\big)\big(1 - \tfrac12 c_1(K)\big) \overset{(2)}{=} \big(q - \tfrac12\big)(2p-2) = (2q-1)(p-1).$$

(1) $\operatorname{ch}(K^q) = 1 + qc_1(K)$, $\operatorname{td}(T\Sigma) = 1 - \frac12 c_1(K)$.
(2) Keep the 2-form part and use $\deg K = 2p-2$.

Equivalently $\operatorname{index}\bar\partial_E = \deg E + 1 - p$ for any line bundle E: this is the classical Riemann–Roch theorem of Chapter 4.

q	object	$\deg K^q$	index $\bar\partial_{K^q}$	meaning
-1	vector fields $V^z\partial_z$	$2-2p$	$3-3p$	CKVs minus moduli
0	functions	0	$1-p$	constants (1) minus $h^1(\mathcal{O})=p$
1	Abelian differentials $\omega(z)\mathrm{d}z$	$2p-2$	$p-1$	p differentials minus 1
2	quadratic differentials	$4p-4$	$3p-3$	moduli minus CKVs
q	q-differentials	$2q(p-1)$	$(2q-1)(p-1)$	

Note the symmetry index $\bar\partial_{K^q} = -\,\mathrm{index}\,\bar\partial_{K^{1-q}}$. It is Serre duality (5.135) again: H^0 and H^1 of K^q are H^1 and H^0 of K^{1-q} (up to duals), so the alternating sums change sign. The rows $q=-1$ and $q=2$ are the same statement, and so are $q=0$ and $q=1$.

Worked example 5.92: Checking Riemann–Roch on the sphere

On $\mathbb{CP}^1$ the bundle K^q is $\mathcal{O}(-2q)$, because $\deg K=-2$. A holomorphic section of $K^{-m}=(K^*)^m$ $(m\ge 0)$ is $V(z)\,\partial_z^{\otimes m}$ with V entire. Near ∞, $\partial_z=-w^2\partial_w$, so

$$V(z)\,\partial_z^{\otimes m} \overset{(1)}{=} (-1)^m\,w^{2m}\,V(1/w)\,\partial_w^{\otimes m}.$$

(1) Substitute $\partial_z=-w^2\partial_w$ in each of the m factors.

This is holomorphic at $w=0$ iff V is a polynomial of degree $\le 2m$. So $h^0(K^{-m})=2m+1$. On the other hand $h^1(K^{-m})=h^0(K^{1+m})=0$ by Example 5.89. Riemann–Roch predicts $(2q-1)(p-1)=(-2m-1)(-1)=2m+1$. ✓ For $m=1$ we recover the three conformal Killing vectors, and index $\bar\partial_{K^2}=0-3=-3$.

5.6.9 Vanishing theorems

Riemann–Roch gives a difference of two dimensions. To get $\dim\mathrm{Ker}\,\bar\partial_{K^2}$ by itself we must show that the other kernel vanishes. The tool is a vanishing theorem.

Working definition 5.49 (Positive and negative line bundles)

A holomorphic line bundle E on a compact complex manifold is **positive** if it carries a Hermitian metric whose curvature form $\frac{i}{2\pi}F$ is a positive $(1,1)$-form, and **negative** if E^* is positive. *Operationally, on a Riemann surface:* E is positive iff $\deg E>0$ and negative iff $\deg E<0$. (Given the degree, one can always choose the metric so that the curvature is a constant multiple of the area form, of the same sign as the degree.) Nash writes this as $c_1(E)>0$.

For the bundles we care about:

$$\deg K^2 = 4p-4, \qquad \deg K^* = 2-2p.$$

So for $p\ge 2$, K^2 is positive and K^* is negative; for $p=0$ it is the other way round; and for $p=1$ both are trivial, neither positive nor negative.

The Kodaira vanishing theorem

The result (Nash calls it the Kodaira vanishing theorem) is [Nash p. 164, (5.85)]:

Key idea: Kodaira vanishing

If E is a positive line bundle on a compact Kähler manifold M of complex dimension n, then

$$H^p\big(M, \Omega^q(E)\big) = 0 \qquad \text{for } p+q > n. \tag{5.151}$$

Here p is the cohomological degree and q the form degree ($\Omega^q(E)$ is the sheaf of holomorphic E-valued q-forms). By Serre duality this is equivalent to Nash's second form [Nash p. 165, (5.89)]: if E is *negative*,

$$H^i\big(M, \Omega^j(E)\big) = 0 \qquad \text{for } i+j < n. \tag{5.152}$$

Nash's (5.88) is the intermediate step. Apply Serre duality (5.134) to (5.85):

$$H^{n-p}\big(M, \Omega^{n-q}(E^*)\big) = 0 \qquad \text{for } p+q > n,$$

then rename $i = n-p$, $j = n-q$ (so $i+j < n$) and note that E^* is negative exactly when E is positive.

On a curve ($n = 1$) the two forms say:

- E positive $\Rightarrow H^1(\Sigma, \Omega^1(E)) = H^1(\Sigma, \mathcal{O}(K \otimes E)) = 0$ $\quad (p = q = 1)$;
- E negative $\Rightarrow H^0(\Sigma, \mathcal{O}(E)) = 0$ $\quad (i = j = 0)$.

Why the negative version is obvious on a curve

The second statement has a one-line proof on a Riemann surface, and it is the one we actually need. Suppose s is a non-zero holomorphic section of E. It has no poles, and its zeros are isolated, each with a positive multiplicity. Then by (5.145)

$$\deg E = \#\{\text{zeros of } s\} \;\geq 0.$$

So if $\deg E < 0$ there is no such s: $H^0(\Sigma, \mathcal{O}(E)) = 0$. Moreover, if $\deg E = 0$ then a non-zero section has no zeros at all, so it trivialises E, and $h^0(E) \leq 1$ with equality iff E is holomorphically trivial.

Why it is true in general: the Weitzenböck mechanism

Nash summarises the general proof in words [Nash p. 164]: write the cohomology as the kernel of a Laplacian; write the Laplacian as a positive "kinetic" term plus a curvature term; positivity of $c_1(E)$ makes the curvature term positive; so the Laplacian is strictly positive and has no kernel. The cleanest place to see every step is a physics problem we already know: a charged particle in a magnetic field.

Worked example 5.93: Landau levels are Kodaira vanishing

Put a uniform magnetic field B on the flat plane (or on a flat torus of area $\mathcal{A}$ with $B\mathcal{A} = 2\pi N$). Use the physicists' covariant derivative $D_a = \partial_a - iA_a$ with real A (in the mathematicians' convention $A_{\text{math}} = -iA$) and symmetric gauge $A = \frac{B}{2}(-y\,\mathrm{d}x + x\,\mathrm{d}y)$, so $F_{xy} = \partial_x A_y - \partial_y A_x = B$. The line bundle has $c_1 = \frac{1}{2\pi} B\,\mathrm{d}x \wedge \mathrm{d}y$ and degree $N = B\mathcal{A}/2\pi$.
Step 1: the operators. Set $D_z = \frac{1}{2}(D_x - iD_y)$ and $D_{\bar z} = \frac{1}{2}(D_x + iD_y)$. Since $A_x + iA_y = \frac{B}{2}(-y + ix) = \frac{iB}{2} z$,

$$D_{\bar z} \overset{(1)}{=} \partial_{\bar z} - \tfrac{i}{2}(A_x + iA_y) \overset{(2)}{=} \partial_{\bar z} + \tfrac{B}{4} z, \qquad D_z = \partial_z - \tfrac{B}{4}\bar z.$$

(1) Definition of $D_{\bar z}$ with $\partial_{\bar z} = \frac{1}{2}(\partial_x + i\partial_y)$.
(2) $-\frac{i}{2}\cdot\frac{iB}{2}z = \frac{B}{4}z$. The formula for D_z is the same computation with $A_x - iA_y = -\frac{iB}{2}\bar z$.

$D_{\bar z}$ is the operator $\bar\partial_E$ of this line bundle.
Step 2: the commutator is the curvature.

$$[D_z, D_{\bar z}] \overset{(1)}{=} [\partial_z, \tfrac{B}{4}z] + [-\tfrac{B}{4}\bar z, \partial_{\bar z}] \overset{(2)}{=} \tfrac{B}{4} + \tfrac{B}{4} = \tfrac{B}{2}.$$

(1) $[\partial_z, \partial_{\bar z}] = 0$ and $[z, \bar z] = 0$.
(2) $[\partial_z, z] = 1$ and $[\bar z, \partial_{\bar z}] = -1$ as operators.

Step 3: adjoints. On $L^2(\mathrm{d}^2 z)$, integration by parts gives $\partial_z^\dagger = -\partial_{\bar z}$, and multiplication by $\bar z$ has adjoint multiplication by z. Hence $D_{\bar z}^\dagger = -D_z$.
Step 4: the Weitzenböck identity. The two Laplacians $\Delta_0 = \bar\partial_E^\dagger\bar\partial_E$ (on sections) and $\Delta_1 = \bar\partial_E\bar\partial_E^\dagger$ (on $(0,1)$-forms, which on the flat plane we identify with sections using the flat frame $\mathrm{d}\bar z$) satisfy

$$\Delta_1 - \Delta_0 \overset{(1)}{=} -D_{\bar z}D_z + D_zD_{\bar z} \overset{(2)}{=} [D_z, D_{\bar z}] \overset{(3)}{=} \tfrac{B}{2}. \tag{5.153}$$

(1) Step 3: $\Delta_0 = -D_zD_{\bar z}$ and $\Delta_1 = -D_{\bar z}D_z$.
(2) Definition of the commutator.
(3) Step 2.

Step 5: vanishing. Both Δ_0 and Δ_1 are non-negative (each is $T^\dagger T$ or $TT^\dagger$). If $B > 0$ then $\Delta_1 = \Delta_0 + \frac{B}{2} \geq \frac{B}{2} > 0$: Δ_1 has no kernel, so $\operatorname{Ker}\bar\partial_E^\dagger = 0$, i.e. $H^1(\mathcal{O}(E)) = 0$. If $B < 0$ then $\Delta_0 = \Delta_1 + \frac{|B|}{2} > 0$: no holomorphic sections, $H^0(\mathcal{O}(E)) = 0$. The sign of the magnetic field decides which kernel is killed.
Step 6: the spectrum. For $B > 0$ put $a = \sqrt{2/B}\,D_{\bar z}$, so $a^\dagger = -\sqrt{2/B}\,D_z$ and $[a, a^\dagger] = -\frac{2}{B}[D_{\bar z}, D_z] = 1$. Then $\Delta_0 = \frac{B}{2}a^\dagger a$ and $\Delta_1 = \frac{B}{2}(a^\dagger a + 1)$. This is a harmonic oscillator: the spectrum of Δ_0 is $\frac{B}{2}\{0, 1, 2, \dots\}$ and that of Δ_1 is $\frac{B}{2}\{1, 2, 3, \dots\}$ (Figure 5.51). The zero modes of $D_{\bar z}$ are $f(z)\,e^{-B|z|^2/4}$ with f holomorphic, the lowest Landau level. On the torus there are exactly N of them (theta functions), and Riemann–Roch with $h^1 = 0$ gives index $= \deg E + 1 - p = N$. ✓

On a curved surface the same computation produces an extra term: the $(0,1)$-forms themselves are sections of $E \otimes \bar K$, and the frame $\mathrm{d}\bar z$ is no longer flat. The curvature that appears in $\Delta_1 - \Delta_0$ is then that of $E \otimes K^{-1}$, not of E. This is why the clean statement is about $\Omega^1(E) = \mathcal{O}(K \otimes E)$, as in (5.151): for $K \otimes E$ the offending K^{-1} cancels.

Watch out: Positive does not mean $H^1(\mathcal{O}(E)) = 0$

It is tempting to read Kodaira as "$H^1(\Sigma, \mathcal{O}(E)) = 0$ for every positive E". That is false on a curve of genus $p \geq 2$. Take $E = [P]$, the degree-one bundle of a point. Serre duality gives $h^1(\mathcal{O}([P])) = h^0(\mathcal{O}(K - P))$, the number of holomorphic differentials vanishing at P, which is $p - 1 \neq 0$ (at most one linear condition on p differentials, and it is a genuine condition because not all differentials vanish at P; see Section 5.7). What is true is $H^1(\mathcal{O}(E)) = 0$ whenever $\deg E > 2p - 2$, because then $K \otimes E^*$ is negative.

5.6.10 Putting it together: $\dim_{\mathbb{C}} \mathcal{M}_p = 3p - 3$ for $p \geq 2$

Now we follow Nash's chain [Nash pp. 164–165, (5.86)–(5.92)].

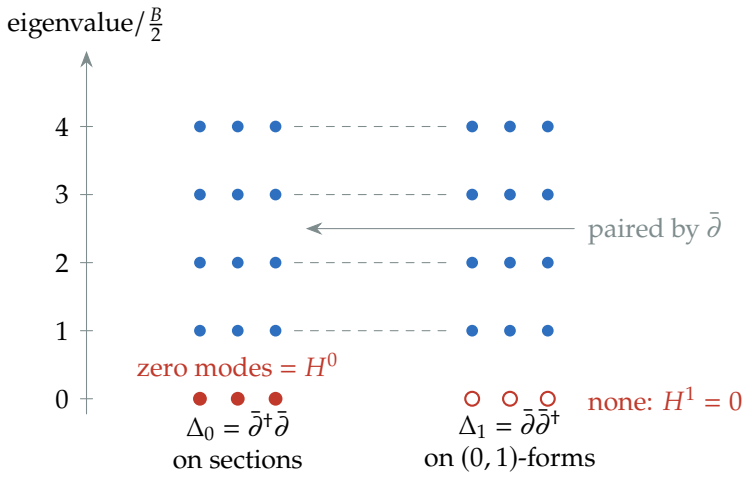

Figure 5.51: The Weitzenböck mechanism for a positive line bundle (Example 5.93, $B > 0$). Every non-zero level of Δ_0 is matched by a level of Δ_1 with the same eigenvalue ($\bar\partial$ maps one eigenspace isomorphically onto the other). The identity $\Delta_1 = \Delta_0 + \frac{B}{2}$ pushes the whole spectrum of Δ_1 up by one unit, so only Δ_0 has zero modes: holomorphic sections exist and H^1 vanishes. For $B < 0$ the picture is reflected.

Step 1: identify the cokernel as a cohomology group. By Hodge theory (Chapter 4, Chapter 3) each Dolbeault class has exactly one representative annihilated by $\bar\partial^*$, so

$$\operatorname{Ker}\bar\partial^*_{K_\Sigma^2} \;\cong\; H^{0,1}_{\bar\partial_{K_\Sigma^2}}(\Sigma) \;\cong\; H^1\big(\Sigma, \mathcal{O}(K_\Sigma^2)\big). \tag{5.154}$$

Step 2: Serre duality.

$$\operatorname{Ker}\bar\partial^*_{K_\Sigma^2} \overset{(1)}{=} H^1\big(\Sigma,\mathcal{O}(K_\Sigma^2)\big) \overset{(2)}{\cong} \big\{H^0\big(\Sigma,\mathcal{O}(K_\Sigma^{-2}\otimes K_\Sigma)\big)\big\}^* \overset{(3)}{=} \big\{H^0\big(\Sigma,\mathcal{O}(K_\Sigma^*)\big)\big\}^* \overset{(4)}{=} \big\{\operatorname{Ker}\bar\partial_{K_\Sigma^*}\big\}^*. \tag{5.155}$$

(1) (5.154).
(2) Serre duality (5.135) with $E = K^2$, $E^* = K^{-2}$.
(3) $K^{-2}\otimes K = K^{-1} = K^*$.
(4) Holomorphic sections are the kernel of $\bar\partial$.

This is the same conclusion as our explicit (5.144). Nash's comment: Serre duality has replaced the *positive* bundle K^2 (for which Kodaira's theorem, in the form Nash uses, gives nothing about $H^1(\mathcal{O}(K^2))$) by the *negative* bundle K^*.

Step 3: vanishing. Apply (5.152) with $E = K^*$, $i = j = 0$, $n = 1$ [Nash p. 165, (5.90)–(5.92)]:

$$H^0\big(\Sigma,\mathcal{O}(K_\Sigma^*)\big) = 0 \quad \text{provided } c_1(K_\Sigma^*) < 0, \qquad c_1(K_\Sigma^*) = 2-2p, \tag{5.156}$$

and $2-2p < 0$ exactly when $p \geq 2$. In words: *a surface of genus $p \geq 2$ has no non-zero holomorphic vector fields*, because such a field would have $2-2p < 0$ zeros. So $\operatorname{Ker}\bar\partial^*_{K^2} = 0$ for $p \geq 2$.

Step 4: conclude.

$$\dim_{\mathbb{C}}\mathcal{M}_p \overset{(1)}{=} \dim\operatorname{Ker}\bar\partial_{K_\Sigma^2} \overset{(2)}{=} \operatorname{index}\bar\partial_{K_\Sigma^2} + \dim\operatorname{Ker}\bar\partial^*_{K_\Sigma^2} \overset{(3)}{=} (3p-3) + 0. \tag{5.157}$$

(1) (5.141).
(2) Definition of the index.
(3) (5.149) and Step 3.

Key idea: The dimension of moduli space (Nash's (5.93))

$$\dim_{\mathbb{C}} \mathcal{M}_p = 3p - 3 \qquad (p \geq 2).$$

Mechanism: the tangent space is $H^{0,1}(K^*)$; its dual is the space of holomorphic quadratic differentials; Riemann–Roch says $h^0(K^2) - h^0(K^*) = 3p - 3$; and $h^0(K^*) = 0$ because a vector field on a surface of negative Euler characteristic must have a negative number of zeros.

Watch out: Nash's "$= \emptyset$"

Nash writes $\operatorname{Ker} \bar{\partial}^*_{K^2_\Sigma} = \emptyset$ and $\operatorname{Ker} \bar{\partial}_{K^2_\Sigma} = \emptyset$. A kernel is a vector space and always contains 0; he means the zero space $\{0\}$, of dimension 0.

A second route, directly through Kodaira

There is a shortcut Nash does not mention. Write $\mathcal{O}(K^2) = \mathcal{O}(K \otimes K) = \Omega^1(K)$. Then

$$H^1\big(\Sigma, \mathcal{O}(K^2)\big) = H^1\big(\Sigma, \Omega^1(K)\big),$$

which has $p + q = 1 + 1 = 2 > 1 = n$. For $p \geq 2$ the bundle K has degree $2p - 2 > 0$, so it is positive, and (5.151) kills this group directly. The two routes agree, as they must: they are Serre duals of each other.

Worked example 5.94: Genus two, by hand

Let us exhibit the $3 \cdot 2 - 3 = 3$ quadratic differentials on a genus-2 surface $y^2 = f(x)$, $\deg f = 6$. The holomorphic differentials are $\omega_0 = \mathrm{d}x/y$ and $\omega_1 = x\,\mathrm{d}x/y$ (Chapter 5; by Example 5.91 ω_0 has simple zeros at the two points over $x = \infty$, and x has simple poles there, so ω_1 is holomorphic too). Products of two holomorphic differentials are holomorphic quadratic differentials:

$$\omega_0^2 = \frac{\mathrm{d}x^2}{y^2}, \qquad \omega_0\omega_1 = \frac{x\,\mathrm{d}x^2}{y^2}, \qquad \omega_1^2 = \frac{x^2\,\mathrm{d}x^2}{y^2}.$$

They are linearly independent (as $1, x, x^2$ are), so $h^0(K^2) \geq 3$; with Riemann–Roch and $h^0(K^*) = 0$, exactly 3. Is there any other candidate, like $x^3\mathrm{d}x^2/y^2$? At a point over ∞, ω_0^2 has a double zero and x^3 a triple pole, so $x^3\omega_0^2$ has a simple pole: not holomorphic. ✓ The count also matches the hyperelliptic parameter count: 6 branch points on $\mathbb{CP}^1$ minus 3 Möbius parameters leaves 3.

5.6.11 Genus zero and genus one

For $p < 2$ the Kodaira argument for K^* fails, and Nash treats the two cases separately [Nash pp. 165–166, (5.94)–(5.99)].

Genus zero

The index is [Nash p. 165, (5.94)]

$$\operatorname{index} \bar{\partial}_{K^2_\Sigma} \overset{(1)}{=} 3 \cdot 0 - 3 = -3, \tag{5.158}$$

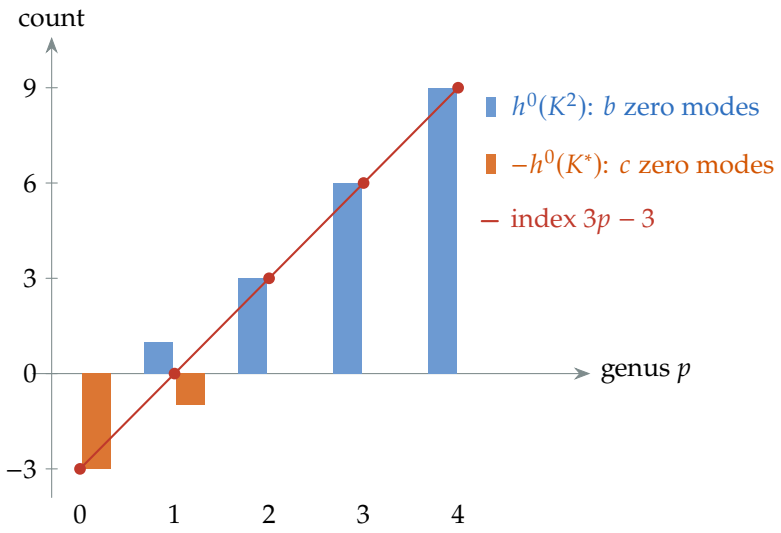

Figure 5.52: Moduli and conformal Killing vectors by genus. Blue bars (up): holomorphic quadratic differentials, $\dim \mathcal{M}_p$. Orange bars (down): holomorphic vector fields, the leftover symmetries. The red line is their difference, the index $3p-3$, which Riemann–Roch computes for every genus. Only for $p \geq 2$ is the orange bar absent, so that the index alone gives the dimension; for $p = 0$ and $p = 1$ we need extra information.

(1) (5.149) with $p = 0$.

so $\dim \operatorname{Ker} \bar\partial^*_{K^2} \geq 3 > 0$. This time we apply the vanishing theorem to the other kernel [Nash (5.95)–(5.96)]:

$$\operatorname{Ker} \bar\partial_{K^2_\Sigma} = H^0\big(\Sigma, \mathcal{O}(K^2_\Sigma)\big) = 0,$$

because $\deg K^2 = 4p - 4 = -4 < 0$: for genus zero, K^2 is a *negative* line bundle. (Example 5.89 proved the same thing with Liouville's theorem.) Hence [Nash (5.97)]

$$\dim_{\mathbb{C}} \mathcal{M}_0 = 0, \tag{5.159}$$

in agreement with Section 5.5: there is only one Riemann sphere. The index is carried entirely by the other kernel: $\dim \operatorname{Ker} \bar\partial^*_{K^2} = 3 = h^0(K^*)$. These are the three conformal Killing vectors (Nash's footnote 7).

Worked example 5.95: The conformal Killing vectors of the sphere form $\mathfrak{sl}(2,\mathbb{C})$

Nash's footnote 7 says the three complex parameters are given by the action of the Möbius group $\mathrm{SL}(2,\mathbb{C})/\{\mp I\}$. Let us exhibit the Lie algebra. Take the basis

$$\ell_{-1} = -\partial_z, \qquad \ell_0 = -z\,\partial_z, \qquad \ell_1 = -z^2\,\partial_z,$$

that is, $\ell_n = -z^{n+1}\partial_z$. Commute two of them, acting on a test function f:

$$\begin{aligned}
[\ell_m, \ell_n] f &\overset{(1)}{=} z^{m+1}\partial_z\big(z^{n+1}f'\big) - z^{n+1}\partial_z\big(z^{m+1}f'\big) \\
&\overset{(2)}{=} (n+1)z^{m+n+1}f' - (m+1)z^{m+n+1}f' \\
&\overset{(3)}{=} (m-n)\,\ell_{m+n} f.
\end{aligned}$$

(1) Definition, with the two minus signs cancelling in each product.
(2) Product rule; the terms with f'' cancel.
(3) $(n-m)z^{m+n+1}f' = (m-n)\cdot(-z^{m+n+1}\partial_z f)$.

So $[\ell_0, \ell_{\pm1}] = \mp\ell_{\pm1}$ and $[\ell_1, \ell_{-1}] = 2\ell_0$: the algebra $\mathfrak{sl}(2,\mathbb{C})$. Compare with the 2×2 matrices

$$\ell_{-1} \leftrightarrow \begin{pmatrix} 0 & -1 \\ 0 & 0 \end{pmatrix}, \quad \ell_0 \leftrightarrow \begin{pmatrix} -\frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{pmatrix}, \quad \ell_1 \leftrightarrow \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix},$$

which generate the Möbius maps $z \mapsto (az+b)/(cz+d)$: for instance $\exp\left(t\left(\begin{smallmatrix} 0 & -1 \\ 0 & 0 \end{smallmatrix}\right)\right) = \left(\begin{smallmatrix} 1 & -t \\ 0 & 1 \end{smallmatrix}\right)$ is $z \mapsto z - t$, the flow of $-\partial_z$. In general the matrix $\left(\begin{smallmatrix} \alpha & \beta \\ \gamma & -\alpha \end{smallmatrix}\right)$ generates the vector field $(\beta + 2\alpha z - \gamma z^2)\partial_z$ (differentiate $((1+t\alpha)z + t\beta)/(t\gamma z + 1 - t\alpha)$ at $t = 0$). The matrix commutators reproduce the relations up to an overall sign, e.g. $[M_1, M_{-1}] = -2M_0$: the map from matrices to vector fields of a *left* action is an anti-homomorphism, a standard sign that one can remove by using $-M^T$ instead. These ℓ_n, $n \in \{-1, 0, 1\}$, are the globally defined members of the Witt algebra $\ell_n = -z^{n+1}\partial_z$, $n \in \mathbb{Z}$, whose central extension is the Virasoro algebra of Chapter 11.

Genus one

For the torus [Nash p. 166, (5.98)]

$$\operatorname{index} \bar\partial_{K_\Sigma^2} = 0 \quad \Longrightarrow \quad \dim \operatorname{Ker} \bar\partial^*_{K_\Sigma^2} = \dim \operatorname{Ker} \bar\partial_{K_\Sigma^2}. \tag{5.160}$$

Both K^2 and K^* are trivial ($\mathrm{d}z$ is a global nowhere-zero section of K), so neither vanishing theorem applies. But we already know the answer from Section 5.5: $\mathcal{T}_1 = \mathbb{C}^+$ is one-dimensional, so $\dim \operatorname{Ker} \bar\partial_{K^2} = 1$ (the quadratic differential $\mathrm{d}z^2$).

Nash then turns the logic around. The index theorem now tells us something new: $\dim \operatorname{Ker} \bar\partial^*_{K^2} = 1$, and that kernel is dual to the space of conformal Killing vectors. His argument, spelled out:

(a) A conformal Killing vector V is one whose flow changes the metric only by a Weyl factor, so it produces $\delta\mu = 0$.

(b) By (5.130), $\delta\mu = \partial_{\bar z} V^z$ locally. So $\partial_{\bar z} V^z = 0$: $V^z\partial_z$ is a holomorphic section of $T\Sigma = K^*$.

(c) These form $H^0(\Sigma, \mathcal{O}(K^*))$, which is dual to $\operatorname{Ker} \bar\partial^*_{K^2}$ by (5.155).

(d) Hence $\dim\{\text{conformal Killing vectors}\} = 1$ for genus one.

This agrees with Example 5.71: the only conformal Killing vectors of a flat torus are the translations $c\,\partial_z$.

Physical picture: What the torus numbers mean for a one-loop amplitude

The one modulus is τ, integrated over the fundamental domain F (Section 5.5.5). The one conformal Killing vector is the translation of the torus. In a one-loop amplitude with n vertex operators it is used to fix the position of one of them; if there are no vertex operators (the vacuum amplitude) nothing can be fixed, and we must divide instead by the volume of the translation group, which is the area of the torus, $\int \mathrm{d}^2 z = \tau_2$. That factor $1/\tau_2$, combined with powers of τ_2 from the determinants, assembles the modular-invariant measure $\mathrm{d}^2\tau/\tau_2^2$ of (5.112).

Summary

Nash's final table [Nash p. 166, (5.99)], with the kernels made explicit:

$$\dim_{\mathbb{C}} \mathcal{M}_p = \begin{cases} 0 & p = 0 \ \ (\mathcal{M}_0 \text{ is a point}), \\ 1 & p = 1, \\ 3p - 3 & p \geq 2. \end{cases} \tag{5.161}$$

p	$h^0(K^2)$ (moduli)	$h^0(K^*)$ (CKVs)	index	which vanishing is used
0	0	3	-3	K^2 negative $\Rightarrow h^0(K^2) = 0$
1	1	1	0	none; use $\mathcal{T}_1 = \mathbb{C}^+$
≥ 2	$3p - 3$	0	$3p - 3$	K^* negative $\Rightarrow h^0(K^*) = 0$

A compact way to remember all three rows: $\dim_{\mathbb{C}} \mathcal{M}_p - \dim_{\mathbb{C}}\{\text{CKVs}\} = 3p - 3$, and at most one of the two terms is non-zero except at $p = 1$.

5.6.12 Beyond Nash: three more ways to see $3p - 3$

The number $3p - 3$ is so important that it is worth seeing it appear from completely different directions. Each of the following is a standard physicist's count.

Punctures: $\dim \mathcal{M}_{p,n} = 3p - 3 + n$

String amplitudes with n external states are computed on surfaces with n marked points (the positions of the vertex operators). The relevant space is $\mathcal{M}_{p,n}$, genus-p Riemann surfaces with n distinct labelled points, up to biholomorphisms carrying marked points to marked points. Each marked point can move over the surface, adding one complex parameter, but for $p = 0$ and $p = 1$ the conformal Killing vectors can be used to fix some of them. The index theorem handles all cases at once. Let $D = P_1 + \cdots + P_n$. The deformations are now counted by quadratic differentials allowed to have simple poles at the P_i, i.e. holomorphic sections of $K^2 \otimes [D]$; the infinitesimal symmetries are vector fields vanishing at the P_i, sections of $K^* \otimes [-D]$. Riemann–Roch:

$$\begin{aligned} h^0(K^2 \otimes [D]) - h^0(K^* \otimes [-D]) &\overset{(1)}{=} \deg(K^2 \otimes [D]) + 1 - p \\ &\overset{(2)}{=} (4p - 4 + n) + 1 - p = 3p - 3 + n. \end{aligned}$$

(1) Riemann–Roch, together with Serre duality $h^1(K^2 \otimes [D]) = h^0(K^{-1} \otimes [-D])$.
(2) $\deg K^2 = 4p - 4$, $\deg[D] = n$.

The vector fields term is zero as soon as $\deg(K^* \otimes [-D]) = 2 - 2p - n < 0$, i.e. $2p - 2 + n > 0$, the condition for a **stable** marked surface. Then $\dim_{\mathbb{C}} \mathcal{M}_{p,n} = 3p - 3 + n$.

Worked example 5.96: Four points on the sphere and the Virasoro–Shapiro amplitude

$\mathcal{M}_{0,4}$ has dimension $0 - 3 + 4 = 1$. Explicitly: a Möbius map can send any three distinct points to $0, 1, \infty$, and it is then unique, so a configuration (z_1, z_2, z_3, z_4) is determined by the image of z_4, the **cross-ratio**

$$\lambda = \frac{(z_4 - z_1)(z_2 - z_3)}{(z_4 - z_3)(z_2 - z_1)},$$

which is invariant under all Möbius maps and sends $(z_1, z_2, z_3) \mapsto (0, 1, \infty)$ when evaluated

at z_4. (Check: $z_4 = z_1$ gives 0, $z_4 = z_2$ gives 1, $z_4 = z_3$ gives ∞.) This is why the tree-level closed-string four-point amplitude (Virasoro–Shapiro) is a single integral over the complex plane,

$$A_4 \propto \int_{\mathbb{C}} \mathrm{d}^2\lambda \; |\lambda|^{\alpha' k_1\cdot k_4}\, |1-\lambda|^{\alpha' k_2\cdot k_4}$$

(for tachyons of momenta k_i, in Polchinski's conventions), with the other three vertex operators fixed at $z_1 = 0$, $z_2 = 1$, $z_3 = \infty$ by the three conformal Killing vectors. Moduli (1) plus conformal Killing vectors (3) equals the number of vertex positions (4).

Pants decompositions

Cut a surface of genus $p \geq 2$ along disjoint simple closed curves until every piece is a **pair of pants** (a sphere with three holes). The Euler characteristic of a pair of pants is -1, and cutting along circles does not change χ (a circle has $\chi = 0$), so

$$\#\{\text{pants}\} = -\chi(\Sigma) = 2p - 2.$$

Each pair of pants has 3 boundary circles and each cut circle is shared by two pants, so

$$\#\{\text{cut curves}\} = \tfrac{3}{2}(2p-2) = 3p - 3.$$

A hyperbolic pair of pants with geodesic boundary is determined up to isometry by its three boundary lengths. When we glue, each cut curve carries two real parameters: its length $\ell_i > 0$ and a **twist** angle θ_i saying how far one side is rotated before gluing. These **Fenchel–Nielsen coordinates** give

$$\dim_{\mathbb{R}} \mathcal{T}_p = 2(3p-3) = 6p - 6,$$

and in fact $\mathcal{T}_p \cong (\mathbb{R}_{>0} \times \mathbb{R})^{3p-3}$, which makes the contractibility quoted in Section 5.5 visible. Twisting by a full 2π gives the same surface with the curves relabelled: that is precisely a Dehn twist (Section 5.5.7), an element of the mapping class group.

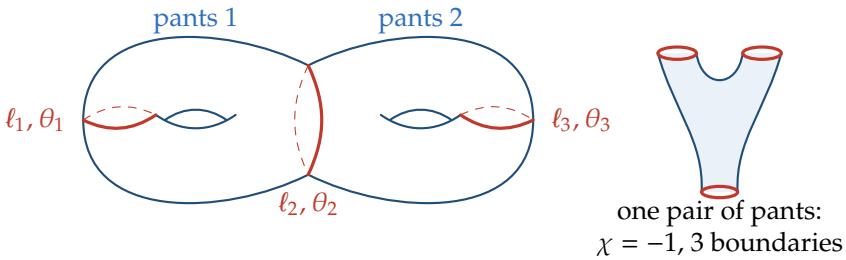

Figure 5.53: A pants decomposition of a genus-2 surface. Cutting along the $3 = 3p - 3$ red curves leaves $2 = 2p - 2$ pairs of pants (right). Each cut curve carries a length ℓ_i and a twist θ_i: $6 = 6p - 6$ real parameters, the Fenchel–Nielsen coordinates on $\mathcal{T}_2$. Twisting θ_i by 2π is a Dehn twist.

Riemann's own count, by branched coverings

Riemann obtained $3p - 3$ in 1857 by counting meromorphic functions. A non-constant meromorphic function f of degree n (it takes each value n times) presents Σ as an n-sheeted cover of $\mathbb{CP}^1$, branched at the points where two sheets meet. For generic f each branch point is simple.

Step 1: the number of branch points (Riemann–Hurwitz). Triangulate $\mathbb{CP}^1$ with the b branch values among the vertices, and lift. Every cell has n preimages, except that each simple branch value has only $n-1$ preimages. So

$$\chi(\Sigma) \overset{(1)}{=} n\,\chi(\mathbb{CP}^1) - b \quad\Longrightarrow\quad 2-2p \overset{(2)}{=} 2n-b \quad\Longrightarrow\quad b = 2n+2p-2. \tag{5.162}$$

(1) Count vertices, edges and faces upstairs: n times the count downstairs, minus one vertex for each simple branch value.
(2) $\chi(\mathbb{CP}^1) = 2$ and $\chi(\Sigma) = 2-2p$.

Step 2: the pairs (Σ, f). By Riemann's existence theorem a branched cover is determined, up to finitely many choices of how the sheets are connected, by its branch values. So the pairs (Σ, f) form a space of complex dimension $b = 2n+2p-2$.

Step 3: functions on a fixed surface. On a fixed Σ, a degree-n function is fixed by its polar divisor D (n points: n parameters) and then by an element of $\mathcal{L}(D)$, the space of functions with poles bounded by D. For $n > 2p-2$ Riemann–Roch gives $\dim \mathcal{L}(D) = n+1-p$ (this is exactly the calculation of Section 5.7 below). So the functions of degree n on a fixed surface form a family of dimension $n + (n+1-p) = 2n+1-p$.

Step 4: subtract.

$$\dim_{\mathbb{C}} \mathcal{M}_p \overset{(1)}{=} b - (2n+1-p) \overset{(2)}{=} (2n+2p-2) - (2n+1-p) = 3p-3.$$

(1) Pairs (Σ, f) fibre over $\mathcal{M}_p$ with fibres the functions on a fixed Σ.
(2) (5.162) and Step 3.

The answer does not depend on the auxiliary degree n, which is a strong consistency check. For the hyperelliptic surfaces of Example 5.94 ($n=2$) the count gives $b-3 = 2p+2-3 = 2p-1$, the dimension of the hyperelliptic locus; for $p=2$ this equals $3p-3=3$, so every genus-2 surface is hyperelliptic, while for $p \geq 3$ ($2p-1 < 3p-3$) most are not. (For $n=2$ the dimension of the functions is not $2n+1-p$, because $n \leq 2p-2$: this is one of the special cases Riemann–Roch warns about, and the reason we subtracted only the 3 Möbius parameters.)

Reading Nash (pp. 157–166, (5.59)–(5.99))

Nash computes $\dim \mathcal{M}_p$ in five moves: (i) write the metric as $\lambda|\mathrm{d}z + \mu\,\mathrm{d}\bar{z}|^2$ (5.59), derive the transformation laws (5.60) and identify $\delta\mu$ as a Beltrami differential (5.61)–(5.65); (ii) remove diffeomorphisms using the Lie derivative (5.66)–(5.73), getting $T\mathcal{M}_p = H^{0,1}_{\bar\partial_{K^*}}$ (5.74)–(5.76); (iii) Serre duality turns this into holomorphic quadratic differentials (5.77)–(5.78), with a worked pairing example on p. 162; (iv) the index of $\bar\partial_{K^2}$ is $3p-3$ by Riemann–Roch and Gauss–Bonnet (5.79)–(5.84); (v) Kodaira vanishing, after Serre duality, kills the cokernel for $p \geq 2$ (5.85)–(5.93), and $p = 0, 1$ are handled separately (5.94)–(5.99). We added: the explicit (λ, μ) decomposition checks, the Cartesian meaning of $\delta\mu$, the torus in Fourier modes, the explicit adjoint (5.143) (which exhibits (5.87) without Serre duality), the Landau-level proof of the vanishing mechanism, the correction that Kodaira on curves concerns $K \otimes E$, the $\mathfrak{sl}(2,\mathbb{C})$ of footnote 7, the genus-2 quadratic differentials, and three independent counts of $3p-3$. Note Nash's factor 2 in (5.72) and his "$= \emptyset$" for the zero space.

Recap

- A tangent vector to $\mathcal{M}_p$ is a Beltrami differential $\delta\mu\,\partial_z \otimes \mathrm{d}\bar{z}$ modulo $\partial_{\bar z} V^z$: $T\mathcal{M}_p = H^{0,1}(K^*)$. On the torus it is the average of $\delta\mu$, i.e. $\delta\tau$.

- Serre duality: $T^*\mathcal{M}_p = H^0(K^2)$, holomorphic quadratic differentials $\phi(z)\mathrm{d}z^2$, paired with $\delta\mu$ by $\int \mu\phi\, \mathrm{d}^2z$.
- Riemann–Roch: $h^0(K^2) - h^0(K^*) = \int \mathrm{ch}(K^2)\,\mathrm{td}(T\Sigma) = 3p-3$ for every p ("b zero modes minus c zero modes").
- Vanishing: a negative line bundle has no holomorphic sections (degree count, or the Weitzenböck/Landau-level argument). For $p \geq 2$, K^* is negative, so $\dim_{\mathbb{C}} \mathcal{M}_p = 3p-3$.
- $p = 0$: 0 moduli, 3 CKVs ($\mathfrak{sl}(2,\mathbb{C})$). $p = 1$: 1 modulus, 1 CKV.
- The same $3p-3$ (or $3p-3+n$ with punctures) comes from pants decompositions and from Riemann's branched-cover count.

5.7 Weierstrass gaps and Weierstrass points

Up to now this part has asked a question about the *collection* of all Riemann surfaces of genus p: how many shapes are there? The answer was a space $\mathcal{M}_p$ of complex dimension $3p-3$. Nash's last section asks a question about *one* surface at a time:

> *Which meromorphic functions can live on a given compact Riemann surface, and in particular, which kinds of pole can a function have if it is allowed only one pole?*

On the complex plane the question is empty: $1/z^n$ has a single pole of order n, for every n. On a compact surface of genus $p \geq 1$ the global topology forbids some of these. A function on a torus, for example, cannot have just one simple pole. The forbidden orders are called **Weierstrass gaps**. There are always exactly p of them, and at most points of the surface they are the first p integers $1, 2, \ldots, p$. The finitely many special points where the pattern is different are the **Weierstrass points**.

Why should a physicist care?

- *Ward identities are pole-counting problems.* In a conformal field theory on a worldsheet Σ, a correlation function $\langle J(z)\,\mathcal{O}_1(z_1)\cdots\mathcal{O}_n(z_n)\rangle$ is, as a function of z, a meromorphic object on Σ with poles only at the insertion points. Whether it is determined by its singular parts, and which singular parts are allowed, is exactly the question of this section. We will see that for a current (a 1-form) the only restriction is the residue theorem, which is charge conservation, and that for the stress tensor (a quadratic differential) the ambiguity is the $3p-3$ quadratic differentials of Section 5.6.
- *Weierstrass points are landmarks.* They are defined by the complex structure alone, so any symmetry of the surface must permute them. Since there are finitely many, a surface of genus $p \geq 2$ has only finitely many symmetries. This is the fact behind the mild (orbifold) singularities of $\mathcal{M}_p$ found in Section 5.5.
- *They reappear in string and conformal field theory* (Chapter 11). Nash notes that the gap theorem constrains correlation functions of conformal field theories on Σ. The determinants of zero-mode wavefunctions of b–c ghost systems, which appear in bosonisation formulas for loop amplitudes, are built from the same Wronskian determinants whose zeros define the Weierstrass points.

The whole section is a single application of the Riemann–Roch theorem, which is the index theorem for $\bar\partial$ that we used in Section 5.6. This time we apply it not to K^2 but to the line bundle of a divisor nz_0.

5.7.1 Poles on the Riemann sphere: no restrictions

Start where everything is allowed. On the sphere $\mathbb{CP}^1 = \mathbb{C} \cup \{\infty\}$ a meromorphic function with a single pole at $z_0 \in \mathbb{C}$ may behave near z_0 like [Nash p. 166, (5.100)]

$$f(z) \;\to\; \frac{c}{(z - z_0)^n} + \cdots, \qquad c \neq 0, \tag{5.163}$$

for *any* $n \geq 1$. The dots are less singular terms.

Watch out: Two sign conventions for the order of a pole

In this section (Nash's footnote 8) a pole of order n has $n > 0$: $1/(z - z_0)^3$ has "a pole of order 3". In the divisor bookkeeping of Chapter 5 the *order* of f at z_0 was a signed integer, negative at poles, so the same function has $\operatorname{ord}_{z_0} f = -3$ and contributes $-3z_0$ to $\operatorname{div} f$. The two are related by

$$f \text{ has a pole of order at most } n \text{ at } z_0 \quad \Longleftrightarrow \quad \operatorname{ord}_{z_0} f \;\geq\; -n.$$

We use the positive convention for pole orders and the signed one inside divisors.

Worked example 5.97: Every pole order occurs on the sphere

Take $f_n(z) = (z - z_0)^{-n}$ with $z_0 \in \mathbb{C}$. On $\mathbb{C}$ it is holomorphic except at z_0, where it has a pole of order n. Is it harmless at ∞? Use the coordinate $w = 1/z$ there:

$$f_n \overset{(1)}{=} \left(\frac{1}{w} - z_0\right)^{-n} \overset{(2)}{=} \frac{w^n}{(1 - z_0 w)^n}.$$

(1) Substitute $z = 1/w$.
(2) Multiply numerator and denominator by w^n.

At $w = 0$ the denominator is 1, so f_n is holomorphic at ∞, with a zero of order n there. So f_n has exactly one pole, of order n, and every $n \geq 1$ is allowed: *the sphere has no gaps*.
What is the full space of functions with a pole of order at most n at z_0 and no other poles? Let f be such a function, and let $P(z) = \sum_{k=1}^{n} a_k (z - z_0)^{-k}$ be its principal part (the singular terms of its Laurent series at z_0). Then:

$$\begin{aligned} f - P \text{ is bounded on } \mathbb{CP}^1 &\overset{(1)}{\Longrightarrow} f - P = a_0 \text{ (a constant)} \\ &\overset{(2)}{\Longrightarrow} f = a_0 + \frac{a_1}{z - z_0} + \cdots + \frac{a_n}{(z - z_0)^n}. \end{aligned}$$

(1) $f - P$ is holomorphic on $\mathbb{C}$ (the singular terms have been removed at z_0) and has a finite limit at ∞ (both f and P do). A bounded entire function is constant: Liouville's theorem.
(2) Rearrange.

So the space is spanned by $1, (z - z_0)^{-1}, \ldots, (z - z_0)^{-n}$, which are linearly independent: its dimension is $n + 1$, and the $n + 1$ Laurent coefficients $a_0, \ldots, a_n$ can be chosen freely. For $z_0 = \infty$ the same space is the space of polynomials of degree at most n.

This "free choice of every coefficient" is exactly what fails at higher genus. It is worth fixing the notation for the space we just computed.

Working definition 5.50 (The space $\mathcal{L}(nz_0)$ and its dimension $\ell(n)$)

For a point z_0 of a compact Riemann surface Σ and an integer $n \geq 0$,

$$\mathcal{L}(nz_0) = \{f \text{ meromorphic on } \Sigma : f \text{ is holomorphic on } \Sigma \setminus \{z_0\} \text{ and has a pole of order} \leq n \text{ at } z_0\}$$

[meromorphic means holomorphic except at isolated poles. A pole of order $\leq n$ means $z^n f$ stays bounded near z_0]. In divisor language $\mathcal{L}(nz_0) = \{f : \operatorname{div} f + nz_0 \geq 0\} \cup \{0\}$ [$\operatorname{div} f$ lists the zeros of f with + their order and the poles with − their order. ≥ 0 says no point is left with a negative count], as in Chapter 5. We write $\ell(n) := \dim_{\mathbb{C}} \mathcal{L}(nz_0)$. *Operationally:* write down the most general Laurent tail $a_0 + a_1 z^{-1} + \cdots + a_n z^{-n}$ in a local coordinate z centred at z_0 ($z(z_0) = 0$) and ask how many of these tails extend to a function on all of Σ with no other poles. On $\mathbb{CP}^1$, $\ell(n) = n + 1$.

The spaces are nested, $\mathcal{L}(0) \subset \mathcal{L}(z_0) \subset \mathcal{L}(2z_0) \subset \cdots$, because a pole of order at most $n - 1$ is in particular a pole of order at most n.

5.7.2 The first restriction: no function has a single simple pole

Nash begins with the simplest gap [Nash p. 167]: on a surface of genus $p \geq 1$ the order $n = 1$ is never allowed. Here are three ways to see it, from the most general to the most explicit.

The degree argument

Key idea: A single simple pole forces genus zero

If a meromorphic function f on a compact Riemann surface Σ has exactly one pole, and that pole is simple, then $f : \Sigma \to \mathbb{CP}^1$ is a biholomorphism, so Σ is a sphere. Hence on a surface of genus $p \geq 1$, the order 1 is a gap at every point.

The mechanism is that "number of zeros equals number of poles" holds not only for f but for $f - c$, for every constant c. Fix $c \in \mathbb{C}$:

$$\#\{\text{zeros of } f - c\} \overset{(1)}{=} \#\{\text{poles of } f - c\} \overset{(2)}{=} \#\{\text{poles of } f\} \overset{(3)}{=} 1.$$

(1) The divisor of a meromorphic function has degree zero (Chapter 5). Recall how: integrate $\mathrm{d}g/g$ with $g = f - c$ around the boundary of the $4p$-gon obtained by cutting Σ open; the sides are glued in pairs with opposite orientation and cancel, so $\frac{1}{2\pi i} \oint \mathrm{d}g/g = \#\text{zeros} - \#\text{poles} = 0$. Both counts include multiplicity.

(2) Subtracting a constant does not move or change the poles.

(3) Assumption: one pole, of order one.

So f takes every finite value c exactly once, counted with multiplicity, and takes the value ∞ exactly once (at z_0). "With multiplicity one" means that $f - c$ has a simple zero, so $f' \neq 0$ there. So f is a bijection $\Sigma \to \mathbb{CP}^1$ with non-vanishing derivative in every local coordinate; its inverse is holomorphic by the inverse function theorem. Therefore $\Sigma \cong \mathbb{CP}^1$ and $p = 0$.

Physical picture: A function is a branched covering

The same count shows more: a function whose poles add up to n (with multiplicity) takes *every* value n times. It presents Σ as an n-sheeted covering of the sphere, branched where

sheets meet. We used this in Riemann's count of $3p-3$ (Section 5.6.12). A 1-sheeted covering is no covering at all: it is the sphere itself. A 2-sheeted covering is a hyperelliptic surface, and we will meet it again as the surfaces whose Weierstrass points are the branch points.

The residue argument on the torus

Nash's argument is via residues. It is cleanest on the torus, where there is a global coordinate z and a global 1-form $\mathrm{d}z$. A meromorphic function on $\Sigma = \mathbb{C}/(\mathbb{Z}\omega_1 \oplus \mathbb{Z}\omega_2)$ is an **elliptic function**: a meromorphic function on $\mathbb{C}$ with $f(z+\omega_1) = f(z+\omega_2) = f(z)$. Choose the orientation so that $\mathrm{Im}(\omega_2/\omega_1) > 0$ (in the notation of Section 5.5, $\omega_1 = 1$ and $\omega_2 = \tau$). Let Π be a fundamental parallelogram with corners a, $a+\omega_1$, $a+\omega_1+\omega_2$, $a+\omega_2$, shifted by a generic a so that no pole lies on its boundary (Figure 5.54).

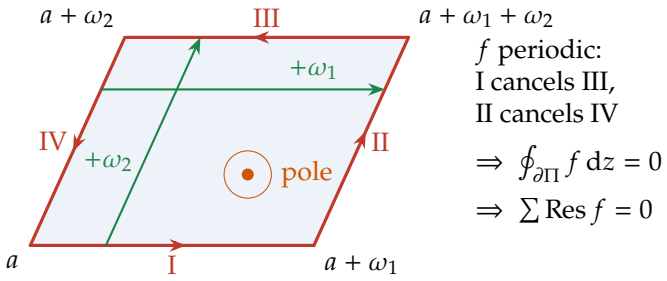

Figure 5.54: The residue theorem on a torus. The boundary of a fundamental parallelogram consists of two pairs of opposite sides. Translation by ω_2 carries side I onto side III, and by ω_1 carries IV onto II. A periodic function takes the same values on both sides of each pair, but the sides are traversed in opposite directions, so their contributions cancel. Hence the residues of an elliptic function add up to zero, and a single simple pole (residue $c \neq 0$) is impossible.

Write the boundary integral side by side:

$$
\begin{aligned}
2\pi i \sum_{\text{poles in } \Pi} \mathrm{Res}\, f &\overset{(1)}{=} \oint_{\partial\Pi} f(z)\,\mathrm{d}z \\
&\overset{(2)}{=} \int_a^{a+\omega_1} f\,\mathrm{d}z + \int_{a+\omega_1}^{a+\omega_1+\omega_2} f\,\mathrm{d}z - \int_{a+\omega_2}^{a+\omega_1+\omega_2} f\,\mathrm{d}z - \int_a^{a+\omega_2} f\,\mathrm{d}z \\
&\overset{(3)}{=} \int_a^{a+\omega_1} \big[f(z) - f(z+\omega_2)\big]\mathrm{d}z + \int_a^{a+\omega_2} \big[f(z+\omega_1) - f(z)\big]\mathrm{d}z \\
&\overset{(4)}{=} 0.
\end{aligned}
\tag{5.164}
$$

(1) The residue theorem of complex analysis for the meromorphic 1-form $f\,\mathrm{d}z$ inside Π.
(2) The boundary is traversed counter-clockwise: I, II, then III and IV backwards.
(3) Shift the variable: on III put $z \to z+\omega_2$, on II put $z \to z+\omega_1$; then pair I with III and II with IV.
(4) Periodicity makes each bracket vanish identically.

If f had only one pole in Π, simple with principal part $c/(z-z_0)$, the left side would be $2\pi i c \neq 0$. Contradiction.

Worked example 5.98: The Weierstrass ζ-function: as close as one can get

Is there anything on $\mathbb{C}$ with a simple pole at each lattice point and no other poles, that is "almost" periodic? Yes. With $\Lambda = \mathbb{Z}\omega_1 \oplus \mathbb{Z}\omega_2$ and $\sum'$ the sum over $\omega \in \Lambda \setminus \{0\}$, let

$$\wp(z) = \frac{1}{z^2} + \sum_{\omega}{}' \Big[\frac{1}{(z-\omega)^2} - \frac{1}{\omega^2} \Big], \qquad \zeta(z) = \frac{1}{z} + \sum_{\omega}{}' \Big[\frac{1}{z-\omega} + \frac{1}{\omega} + \frac{z}{\omega^2} \Big].$$

Both series converge (the terms are $O(|\omega|^{-3})$), and differentiating term by term gives $\zeta' = -\wp$. Since $\wp$ is elliptic, $\frac{\mathrm{d}}{\mathrm{d}z}\big[\zeta(z+\omega_i) - \zeta(z)\big] = -\wp(z+\omega_i) + \wp(z) = 0$, so

$$\zeta(z+\omega_i) = \zeta(z) + \eta_i, \qquad i = 1, 2,$$

with constants η_i. The function ζ has exactly one simple pole per parallelogram, with residue 1, and it is *not* periodic. Run (5.164) for ζ instead of f:

$$\begin{aligned} 2\pi i \cdot 1 &\overset{(1)}{=} \int_a^{a+\omega_1} \big[\zeta(z) - \zeta(z+\omega_2)\big]\mathrm{d}z + \int_a^{a+\omega_2} \big[\zeta(z+\omega_1) - \zeta(z)\big]\mathrm{d}z \\ &\overset{(2)}{=} \int_a^{a+\omega_1} (-\eta_2)\,\mathrm{d}z + \int_a^{a+\omega_2} \eta_1\,\mathrm{d}z \\ &\overset{(3)}{=} \eta_1\omega_2 - \eta_2\omega_1. \end{aligned}$$

(1) Steps (1)–(3) of (5.164), which did not use periodicity; the residue of ζ at its one pole in Π is 1.
(2) Quasi-periodicity.
(3) The integrands are constants.

This is **Legendre's relation** $\eta_1\omega_2 - \eta_2\omega_1 = 2\pi i$. It says precisely that ζ *cannot* be periodic: if $\eta_1 = \eta_2 = 0$ the left side would vanish. The would-be function with one simple pole exists only as a multivalued object, and its failure to be single valued is forced to be exactly the amount the residue demands.
On the other hand the *difference*

$$g(z) = \zeta(z - b_1) - \zeta(z - b_2), \qquad b_1 \neq b_2,$$

is elliptic, because the η_i cancel. It has two simple poles with residues $+1$ and -1, adding to zero as (5.164) requires. So on the torus the pole order 1 is a gap, but the pole divisor $b_1 + b_2$ is allowed; and at a single point, order 2 is allowed: $\wp(z - z_0)$.

Physical picture: Gauss's law on a compact surface

Think of $f\,\mathrm{d}z$ on the torus as the complex electric field of point charges in two dimensions: a simple pole $c/(z - z_0)$ is a point charge (together with a point vortex) of strength $\propto c$. The residue theorem (5.164) says that the total charge on a compact surface is zero, because the flux has nowhere to go. That is the same reason a periodic box in lattice electrostatics needs a neutralising background: a single charge on a torus is inconsistent. A dipole $(\zeta(z - b_1) - \zeta(z - b_2))$ is fine. The quasi-periodic ζ is the field of a single charge *plus* a uniform background, which is not periodic.

What Nash's residue argument means in higher genus

Nash says [Nash p. 167] that the sum of the residues of a meromorphic function on Σ_p is zero, by running the $4p$-gon contour argument of Chapter 5 on f instead of on $\mathrm{d}f/f$. This needs one repair.

Watch out: A residue belongs to a 1-form, not to a function

The residue of f at z_0 is the coefficient of $(z-z_0)^{-1}$ in a local coordinate z, and it *changes* if we change coordinate. Example: $f = 1/z^2$ has residue 0 in the coordinate z; in the coordinate $w = z+z^2$ (so $z = w-w^2+O(w^3)$) it is $f = w^{-2}(1-w+\dots)^{-2} = w^{-2}+2w^{-1}+\dots$, with residue 2. What *is* coordinate independent is the residue of a meromorphic 1-form $\alpha = a(z)\,\mathrm{d}z$, because $\frac{1}{2\pi i}\oint \alpha$ around a small loop does not care about coordinates. The residue theorem on a compact surface is a statement about 1-forms:

$$\sum_P \operatorname{Res}_P \alpha = 0 \qquad \text{for every meromorphic 1-form } \alpha \text{ on } \Sigma.$$

(Proof: α is closed away from its poles; Stokes' theorem on Σ minus small discs around the poles, $\int_\Sigma \mathrm{d}\alpha = 0 = \sum_P \oint_{\partial D_P} \alpha$.) On the torus there is a preferred 1-form $\mathrm{d}z$, and "the residue of f" means the residue of $f\,\mathrm{d}z$. On a surface of higher genus we must pick a holomorphic 1-form ω and apply the theorem to $f\omega$.

With that repair the argument reads as follows. Suppose f has a single simple pole at z_0, $f = c/z + O(1)$ with $c \neq 0$. Take any holomorphic differential $\omega = h(z)\,\mathrm{d}z$. Then $f\omega$ is a meromorphic 1-form with at most a simple pole at z_0 and residue $c\,h(0)$. The residue theorem gives $c\,h(0) = 0$, i.e. *every* holomorphic differential vanishes at z_0. This is a contradiction as soon as some holomorphic differential is non-zero at z_0. On a torus $\omega = \mathrm{d}z$ never vanishes. In genus $p \geq 2$ it is true that the p holomorphic differentials never all vanish at the same point, but that fact is itself equivalent to 1 being a gap, as we will see in Section 5.7.6. The degree argument above avoids this circle.

5.7.3 Gaps, non-gaps and the gap theorem

Nash now states the general result. We first fix the vocabulary.

Working definition 5.51 (Gap, non-gap, gap sequence, weight)

Fix a point z_0 on a compact Riemann surface Σ of genus p [p is the number of handles]. An integer $n \geq 1$ is a **non-gap** at z_0 if there is a meromorphic function on Σ that is holomorphic on $\Sigma \setminus \{z_0\}$ and has a pole of order *exactly* n at z_0. Otherwise n is a **(Weierstrass) gap** at z_0. The list of gaps $n_1 < n_2 < \cdots$ is the **gap sequence** of z_0, and

$$w(z_0) := \sum_{i=1}^{p} (n_i - i)$$

[there are exactly p gaps, by the theorem below. w measures how far they sit above $1, 2, \dots, p$] is its **weight**. *Operational test:* n is a non-gap iff $\ell(n) = \ell(n-1) + 1$ [$\ell(n)$ is the number of independent functions with no poles except one of order $\leq n$ at z_0], i.e. allowing one more order of pole produces a new function (proved in Section 5.7.5).

Key idea: The Weierstrass gap theorem (Nash, p. 167)

Let Σ be a compact Riemann surface of genus $p \geq 1$ and $z_0 \in \Sigma$.

(i) There are exactly p gaps at z_0, and they satisfy

$$1 = n_1 < n_2 < \cdots < n_p \leq 2p - 1.$$

Every $n \geq 2p$ is a non-gap.

(ii) For all but finitely many z_0 the gaps are $1, 2, \ldots, p$ (weight 0). Such z_0 are **normal points**; at them no function with only one pole has a pole of order $\leq p$.

(iii) The finitely many exceptional points, where the gap sequence is anything else (weight > 0), are the **Weierstrass points**. At a Weierstrass point some $n \leq p$ is a non-gap.

For genus 0 there are no gaps; for genus 1 the single gap is $n_1 = 1$ at every point, so every point is normal and there are no Weierstrass points.

The bound $n_p \leq 2p - 1$ is Nash's "$n_p < 2p$". Two quick consequences follow from the multiplicative structure of functions.

Key idea: The non-gaps form a semigroup

If n and m are non-gaps at z_0, so is $n + m$.

Take f and g with single poles of exact orders n and m at z_0. In a local coordinate centred at z_0,

$$f\,g \overset{(1)}{=} \left(az^{-n} + \ldots\right)\left(bz^{-m} + \ldots\right) \overset{(2)}{=} ab\,z^{-(n+m)} + \ldots,$$

(1) Leading terms, with $a \neq 0$, $b \neq 0$; the dots are less singular.
(2) Multiply; $ab \neq 0$.

and fg is holomorphic wherever both f and g are, i.e. away from z_0. So fg has a single pole of order exactly $n + m$. The semigroup property is already a strong constraint.

Worked example 5.99: If 2 is a non-gap, the gaps are the odd numbers

Suppose some function has a single double pole at z_0 (on a surface of genus $p \geq 1$). Then $2, 4, 6, \ldots$ are all non-gaps by the semigroup property. Now count using part (i) of the gap theorem:

$$\#\{\text{gaps}\} \overset{(1)}{=} p,$$

$$\#\{\text{gaps}\} \overset{(2)}{\leq} \#\{\text{odd numbers in } 1, \ldots, 2p-1\} \overset{(3)}{=} p.$$

(1) The gap theorem.
(2) All gaps lie in $\{1, \ldots, 2p-1\}$ and none is even.
(3) The odd numbers there are $1, 3, \ldots, 2p - 1$.

Equality forces the gap sequence to be exactly $1, 3, 5, \ldots, 2p - 1$, with weight

$$w(z_0) = \sum_{i=1}^{p} \left((2i - 1) - i\right) = \sum_{i=1}^{p} (i - 1) = \frac{p(p-1)}{2}.$$

This is the largest weight a point can have (a standard fact we do not prove). For $p = 1$ the weight is 0: on the torus $\wp(z - z_0)$ has a double pole at every point, and the gap sequence

{1} is also the normal one. For $p \geq 2$, a point with non-gap 2 is a Weierstrass point. A function with a single double pole is a degree-2 map to $\mathbb{CP}^1$, so the surface is **hyperelliptic**; we will identify these points as the branch points in Section 5.7.8.

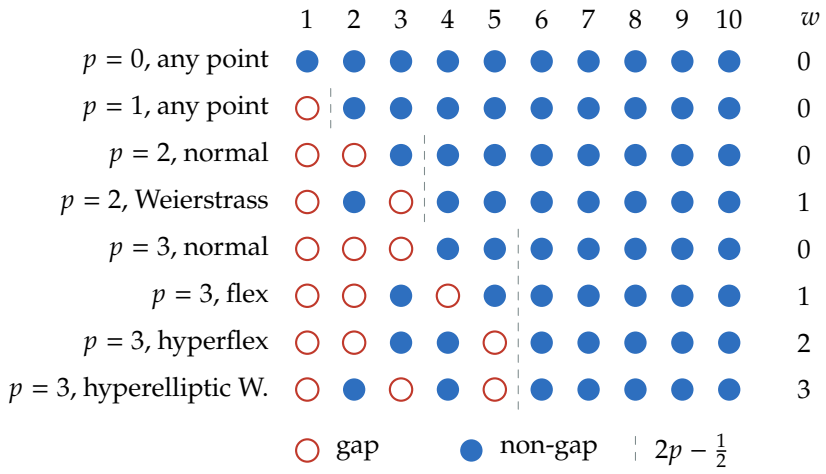

Figure 5.55: Gap sequences. Each row lists the pole orders $n = 1, \ldots, 10$ at one point: open red circles are gaps (no function with only that pole exists), filled blue circles are non-gaps. Every row has exactly p gaps, all to the left of the dashed line at $2p - \frac{1}{2}$, and the gap 1 is always present for $p \geq 1$. Normal points have the gaps packed at the start; at Weierstrass points a gap has moved to the right, and the weight w in the last column measures how far. Every row respects the semigroup property: sums of non-gaps are non-gaps. The genus-2 and genus-3 examples are worked out in Section 5.7.8.

Try it: Which gap sequences are possible in genus 2?

Using only the gap theorem and the semigroup property, list all possible gap sequences in genus 2.
Answer. We need $1 = n_1 < n_2 \leq 3$, so $\{1, 2\}$ or $\{1, 3\}$. Both satisfy the semigroup property: for $\{1, 2\}$ the non-gaps $3, 4, 5, \ldots$ are closed under addition; for $\{1, 3\}$ the non-gaps $2, 4, 5, 6, \ldots$ are too. Both occur (Section 5.7.8).

5.7.4 Counting functions with Riemann–Roch

Nash's outline of the proof [Nash pp. 167–169, (5.101)–(5.110)] turns the question "which f exist?" into "how many holomorphic sections does a certain line bundle have?", and then answers it with the index theorem.

The divisor nz_0 and its line bundle

Let [Nash p. 167, (5.101)]

$$D = nz_0, \qquad n \geq 1, \qquad \deg D = n > 0. \tag{5.165}$$

Recall from Chapter 5 how a divisor defines a line bundle $[D]$. We make it completely explicit for this D.

- *Cover.* Let U_0 be a coordinate disc around z_0, with coordinate z, $z(z_0) = 0$. Cover the rest of Σ by patches U_α ($\alpha \neq 0$) that do not contain z_0.

- *Local equations of D.* On U_0 the divisor is "a zero of order n at $z = 0$", with local equation $f_0 = z^n$. On U_α the divisor is empty, with local equation $f_\alpha = 1$.
- *Transition functions.* $g_{0\alpha} = f_0/f_\alpha = z^n$ on $U_0 \cap U_\alpha$. This is holomorphic and non-zero there, because $z_0 \notin U_\alpha$. The cocycle condition holds automatically, since the g's are ratios.
- *The canonical section.* The local functions $s_0 = z^n$, $s_\alpha = 1$ satisfy $s_0 = g_{0\alpha} s_\alpha$, so they define a global holomorphic section s of $[D]$. It vanishes exactly at z_0, to order n. This is Nash's "s is really the localisation of the divisor D".

In particular $[D]$ has a non-zero holomorphic section; this is Nash's remark that "because the degree of D is positive, $[D]$ has a global holomorphic section". (For a general line bundle of positive degree that is not automatic; here we constructed the section by hand.) Its degree is

$$c_1([nz_0]) = \deg(nz_0) = n,$$

the number of zeros of s (Chapter 5, Nash's (5.11)).

Sections of $[D]$ are functions with a restricted pole

Now let f be meromorphic with its only singularity at z_0, a pole of order at most n. Consider the product fs, with local components

$$(fs)_0 = f \cdot z^n \ \text{ on } U_0, \qquad (fs)_\alpha = f \ \text{ on } U_\alpha.$$

On U_α this is holomorphic because f is. On U_0, $f = O(z^{-n})$, so $z^n f$ is holomorphic too. So fs is a holomorphic section of $[D]$. Conversely, any holomorphic section σ of $[D]$ gives the meromorphic function $f = \sigma/s$ (the ratio of two sections of the same bundle is a function), holomorphic away from z_0 and with a pole of order at most n at z_0 (dividing by z^n). So [Nash p. 168, (5.102)]

$$\mathcal{L}(nz_0) \xrightarrow{\ f \mapsto fs\ } H^0\big(\Sigma_p, \mathcal{O}([D])\big) = H^0\big(\Sigma_p, \mathcal{O}([nz_0])\big) \tag{5.166}$$

is an isomorphism. Two remarks from Nash:

- A function in $\mathcal{L}(nz_0)$ need not be singular. If it is holomorphic at z_0 too, it is holomorphic on a compact surface, so it is constant (maximum modulus principle). Hence the constants are always in $\mathcal{L}(nz_0)$ and $\ell(n) \geq 1$.
- If *all* of $\mathcal{L}(nz_0)$ were holomorphic, $\ell(n)$ would take its minimum value 1.

The naive count and why it is wrong

A function $f \in \mathcal{L}(nz_0)$ has a Laurent expansion at z_0 [Nash (5.103)]

$$f(z) \ \to\ a_0 + \frac{a_1}{z - z_0} + \cdots + \frac{a_n}{(z - z_0)^n} + O(z - z_0). \tag{5.167}$$

It depends on the $n + 1$ parameters $a_0, \ldots, a_n$, and on the sphere the function is determined by them and they are free (Example 5.97). So one might conjecture [Nash (5.104)]

$$\dim \mathcal{L}(nz_0) = \dim H^0\big(\Sigma_p, \mathcal{O}([nz_0])\big) \stackrel{?}{=} n + 1. \tag{5.168}$$

The first half is right: f is determined by its principal part up to a constant, because the difference of two functions in $\mathcal{L}(nz_0)$ with the same principal part is holomorphic, hence

constant. So $\ell(n) \le n+1$. What fails is the *freedom* of the coefficients. The gap theorem contradicts (5.168) in two ways [Nash (5.105)–(5.106)]:

$$\dim \mathcal{L}(nz_0) = 1 \qquad \text{if } n \le p \text{ and } z_0 \text{ is a normal point,} \tag{5.169}$$

$$\dim \mathcal{L}(nz_0) = n+1-p \qquad \text{if } n \ge 2p-1. \tag{5.170}$$

In (5.169) only the constant survives: none of $a_1, \dots, a_n$ can be non-zero. In (5.170) "there are p gaps in the parameters a_i": the $n+1$ coefficients are subject to p independent linear conditions. We will see exactly what these conditions are in Section 5.7.6. First, Nash's derivation of (5.170) from the index theorem.

The index theorem for $\bar\partial_{[nz_0]}$

The space (5.166) is the kernel of the Dolbeault operator $\bar\partial_{[nz_0]}$ of the line bundle, the same kind of operator as $\bar\partial_{K^2}$ in Section 5.6. The Riemann–Roch (index) theorem [Nash p. 169, (5.107)] gives

$$\operatorname{index} \bar\partial_{[nz_0]} = \dim \operatorname{Ker} \bar\partial_{[nz_0]} - \dim \operatorname{Ker} \bar\partial^*_{[nz_0]} = \int_{\Sigma_p} \operatorname{ch}([nz_0]) \wedge \operatorname{td}(T\Sigma_p). \tag{5.171}$$

The integrand is evaluated exactly as in (5.148) [Nash (5.108)]:

$$\begin{aligned} \operatorname{index} \bar\partial_{[nz_0]} &\overset{(1)}{=} \int_{\Sigma_p} \big(1 + c_1([nz_0])\big) \wedge \big(1 + \tfrac{1}{2}c_1(T\Sigma_p)\big) \\ &\overset{(2)}{=} \int_{\Sigma_p} c_1([nz_0]) + \frac{1}{2}\int_{\Sigma_p} c_1(T\Sigma_p) \\ &\overset{(3)}{=} n + \tfrac{1}{2}(2-2p) \\ &= n+1-p. \end{aligned} \tag{5.172}$$

(1) For a line bundle on a surface $\operatorname{ch} = 1 + c_1$ and $\operatorname{td} = 1 + \frac{1}{2}c_1$ (Section 5.6.8).
(2) Only the 2-form part integrates; the product of the two c_1's is a 4-form, zero on a surface.
(3) $\int c_1([nz_0]) = \deg(nz_0) = n$, and Gauss–Bonnet $\int c_1(T\Sigma_p) = \chi(\Sigma_p) = 2-2p$ (5.146).

This is the familiar $\deg D + 1 - p$ of Riemann–Roch.

Killing the cokernel: Serre duality and vanishing

The index is the dimension we want *minus* $\dim \operatorname{Ker} \bar\partial^*_{[nz_0]}$. By Hodge theory that kernel is $H^1(\Sigma_p, \mathcal{O}([nz_0]))$, and then [Nash (5.109)]

$$\begin{aligned} H^1\big(\Sigma_p, \mathcal{O}([nz_0])\big) &\overset{(1)}{\cong} \big\{H^0\big(\Sigma_p, \mathcal{O}(K_{\Sigma_p} \otimes [nz_0]^*)\big)\big\}^*, \\ H^0\big(\Sigma_p, \mathcal{O}(K_{\Sigma_p} \otimes [nz_0]^*)\big) &\overset{(2)}{=} 0 \qquad \text{if } n \ge 2p-1. \end{aligned} \tag{5.173}$$

(1) Serre duality (5.135) with $E = [nz_0]$.
(2) The bundle $K \otimes [nz_0]^*$ has degree $c_1(K) + c_1([nz_0]^*) = (2p-2) - n$, which is negative exactly when $n > 2p-2$, i.e. $n \ge 2p-1$. A line bundle of negative degree has no non-zero holomorphic sections (Section 5.6.9: a section would have a negative number of zeros). Nash quotes this as the Kodaira vanishing theorem for negative line bundles.

What are the sections of $K \otimes [nz_0]^*$ concretely? The bundle $[nz_0]^* = [-nz_0]$ has transition functions z^{-n}, so a section of $K \otimes [-nz_0]$ is a collection of local 1-forms ω_α with $\omega_0 = z^{-n}\omega_\alpha$ on

overlaps; equivalently a global holomorphic 1-form ω (= ω_α away from z_0) such that $z^{-n}\omega$ is still holomorphic at z_0. That is:

$$H^0\big(\Sigma_p, \mathcal{O}(K \otimes [-nz_0])\big) \;\cong\; \big\{\omega \in H^0(\Sigma_p, \mathcal{O}(K)) : \ \omega \text{ vanishes to order} \geq n \text{ at } z_0\big\}, \tag{5.174}$$

whose dimension we call $\kappa(n)$. A holomorphic differential has $\deg K = 2p-2$ zeros, so it cannot vanish to order $n \geq 2p-1$ unless it is zero: this is the vanishing in (5.173) again, seen directly.

Putting (5.172) and (5.173) together gives Nash's (5.110): for $n \geq 2p-1$,

$$\dim H^0\big(\Sigma_p, \mathcal{O}([nz_0])\big) = \dim \mathcal{L}(nz_0) = n+1-p, \tag{5.175}$$

in agreement with (5.170). And for every $n \geq 0$ we have the exact statement

$$\boxed{\ell(n) = n+1-p+\kappa(n)} \tag{5.176}$$

where

$$\kappa(n) = \dim\big\{\omega \text{ holomorphic differential} : \ \omega \text{ vanishes to order} \geq n \text{ at } z_0\big\}.$$

At $n=0$: $\ell(0)=1$ and $\kappa(0)=p$ (all differentials), and indeed $1 = 0+1-p+p$. ✓

Watch out: What the vanishing theorem does and does not give

For $n \leq 2p-2$ the bundle $K \otimes [-nz_0]$ has degree ≥ 0, no vanishing theorem applies, and $\kappa(n)$ genuinely depends on the point z_0. That dependence is the whole content of the distinction between normal points and Weierstrass points. The index theorem alone knows only the topological number $n+1-p$; the fine structure lives in the cokernel.

5.7.5 The staircase: proof of the gap theorem

Nash says "we can outline a proof" and stops at (5.175). The rest of the proof is short, and it is worth writing out because it shows how much information is in the single equation (5.175).

Step 1: the staircase starts at 1. $\ell(0)=1$: a function with no poles on a compact surface is constant.

Step 2: each step has height 0 *or* 1. For $n \geq 1$ consider the linear map "read off the coefficient of z^{-n}":

$$c_n : \ \mathcal{L}(nz_0) \to \mathbb{C}, \qquad f = a_n z^{-n} + \ldots \ \mapsto \ a_n.$$

Its kernel is the set of f whose pole has order at most $n-1$, i.e. $\mathcal{L}((n-1)z_0)$. So

$$\ell(n) \overset{(1)}{=} \dim \operatorname{Ker} c_n + \dim \operatorname{Im} c_n \overset{(2)}{=} \ell(n-1) + \dim \operatorname{Im} c_n \overset{(3)}{\leq} \ell(n-1)+1.$$

(1) Rank–nullity for the linear map c_n.
(2) $\operatorname{Ker} c_n = \mathcal{L}((n-1)z_0)$.
(3) The image is a subspace of $\mathbb{C}$.

Moreover $\dim \operatorname{Im} c_n = 1$ exactly when some $f \in \mathcal{L}(nz_0)$ has $a_n \neq 0$, i.e. has a pole of order exactly n. So

$$n \text{ is a non-gap} \iff \ell(n) = \ell(n-1)+1, \qquad n \text{ is a gap} \iff \ell(n) = \ell(n-1). \tag{5.177}$$

This is the operational test promised in the working definition.

Step 3: count the steps. By (5.175) at $n = 2p-1$, $\ell(2p-1) = (2p-1)+1-p = p$. Between $n = 0$ and $n = 2p-1$ the staircase climbs from 1 to p in $2p-1$ steps of height 0 or 1:

$$\#\{\text{non-gaps in } 1,\dots,2p-1\} \overset{(1)}{=} \sum_{n=1}^{2p-1} \big(\ell(n)-\ell(n-1)\big) \overset{(2)}{=} \ell(2p-1)-\ell(0) \overset{(3)}{=} p-1,$$

$$\#\{\text{gaps in } 1,\dots,2p-1\} \overset{(4)}{=} (2p-1)-(p-1) = p.$$

(1) Each non-gap contributes a step of height 1, each gap a step of height 0, by (5.177).
(2) The sum telescopes.
(3) $\ell(2p-1) = p$ and $\ell(0) = 1$.
(4) Every integer in $1,\dots,2p-1$ is either a gap or a non-gap.

Step 4: no gaps beyond $2p-1$. For $n \geq 2p$ both n and $n-1$ satisfy $\geq 2p-1$, so by (5.175) $\ell(n)-\ell(n-1) = (n+1-p)-(n-p) = 1$: every $n \geq 2p$ is a non-gap.

Step 5: the first gap. 1 is a gap for $p \geq 1$ by Section 5.7.2. (Alternatively: if $\ell(1) = 2$, some function of degree 1 exists, which makes Σ a sphere.)

That proves part (i) of the gap theorem: exactly p gaps, starting at 1, all at most $2p-1$. For $p = 0$ the same argument, with $\ell(n) = n+1$ for all n from (5.176) (there are no differentials, so $\kappa = 0$), shows every step has height one: no gaps.

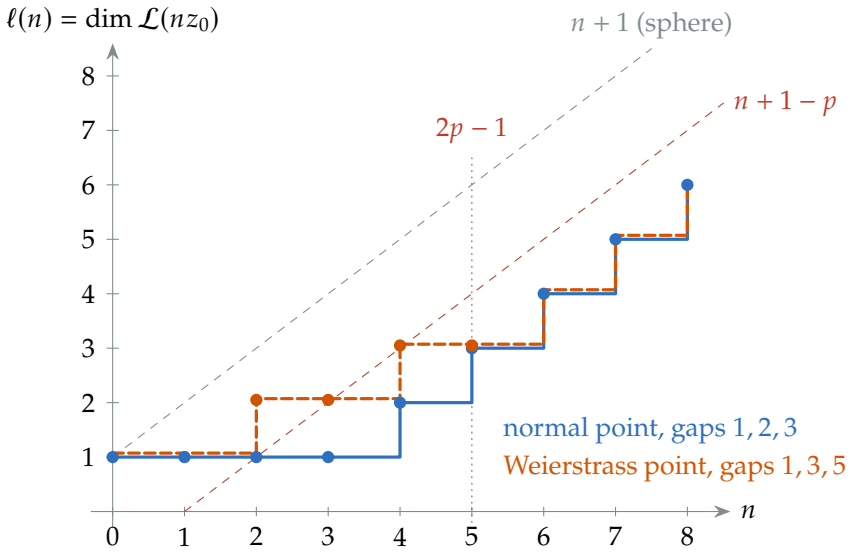

Figure 5.56: The staircase $\ell(n)$ for genus $p = 3$. At each n the staircase either stays flat (a gap) or rises by one (a non-gap). The grey line $n+1$ is the naive count, correct only on the sphere. The red line $n+1-p$ is index $\bar{\partial}_{[nz_0]}$; the staircase lies on or above it, the excess being $\kappa(n)$, and it joins the line for good at $n = 2p-1 = 5$ at the latest, where the cokernel is killed by the vanishing theorem (at a normal point it joins already at $n = p+1$). A normal point (blue) stays flat for the first p steps; a Weierstrass point (orange, here a branch point of a hyperelliptic surface) rises earlier. Both must reach height $p = 3$ at $n = 5$, so both have exactly 3 flat steps.

5.7.6 Where the gaps come from: residues of $f\omega$

We now know how many gaps there are. Which ones they are is decided by the holomorphic differentials, through the residue theorem. This makes Nash's phrase "p gaps in the parameters a_i" precise, and it is the most concrete way to see Riemann–Roch at work.

p conservation laws for the principal part

Let $f \in \mathcal{L}(nz_0)$ with principal part $\sum_{k=1}^{n} a_k z^{-k}$ in a local coordinate z centred at z_0. Let $\omega = h(z)\,dz$ be any holomorphic differential, with Taylor series $h(z) = \sum_{m\geq 0} h_m z^m$ near z_0. Then $f\omega$ is a meromorphic 1-form whose only pole is at z_0, and

$$\begin{aligned} 0 &\overset{(1)}{=} \operatorname{Res}_{z_0}(f\omega) \\ &\overset{(2)}{=} \operatorname{Res}_{z=0}\Big[\Big(\sum_{k=1}^{n} a_k z^{-k} + (\text{holomorphic})\Big)\Big(\sum_{m\geq 0} h_m z^m\Big)dz\Big] \\ &\overset{(3)}{=} \sum_{k=1}^{n} a_k\, h_{k-1}. \end{aligned} \tag{5.178}$$

(1) The residue theorem for the meromorphic 1-form $f\omega$ on the compact surface: the sum of its residues is zero, and it has only one pole.
(2) Insert the Laurent series of f and the Taylor series of h.
(3) The coefficient of z^{-1} comes from $z^{-k}\cdot z^m$ with $m = k-1$; the holomorphic part of f times h has no z^{-1} term.

Choose a basis $\omega_1, \dots, \omega_p$ of holomorphic differentials (Chapter 5: there are exactly p), $\omega_j = h^{(j)}(z)\,dz$. Each gives one linear condition on the principal part. Collect them in the $p \times n$ **residue matrix**

$$R_n = \begin{pmatrix} h_0^{(1)} & h_1^{(1)} & \cdots & h_{n-1}^{(1)} \\ \vdots & & & \vdots \\ h_0^{(p)} & h_1^{(p)} & \cdots & h_{n-1}^{(p)} \end{pmatrix}, \qquad R_n \begin{pmatrix} a_1 \\ \vdots \\ a_n \end{pmatrix} = 0.$$

The (j,k) entry is the $(k-1)$-th Taylor coefficient of the j-th differential at z_0.

Key idea: Riemann–Roch as p conservation laws

A principal part $(a_1, \dots, a_n)$ at z_0 comes from a meromorphic function with no other poles *if and only if* $R_n a = 0$. Hence

$$\ell(n) = 1 + \big(n - \operatorname{rank} R_n\big),$$

the 1 being the constant a_0.

"Only if" is (5.178). "If" is the statement that the residue pairings are the *only* obstruction to solving the Mittag-Leffler problem "find f with a prescribed principal part". On $\mathbb{C}$ there is no obstruction (take f = the principal part). On a compact surface the obstruction lives in $H^1(\Sigma, \mathcal{O})$, and Serre duality (5.135) identifies $H^1(\Sigma, \mathcal{O})$ with the dual of $H^0(\Sigma, \mathcal{O}(K))$, the pairing being exactly $a \mapsto \sum_k a_k h_{k-1}$. So the conditions are necessary by the residue theorem and sufficient by Serre duality. The dimension count matches (5.176): the kernel of R_n^T acting on combinations of the ω_j consists of the differentials with $h_0 = \cdots = h_{n-1} = 0$, i.e. those vanishing to order $\geq n$, so $p - \operatorname{rank} R_n = \kappa(n)$ and $\ell(n) = 1 + n - p + \kappa(n)$. ✓

Physical picture: Each holomorphic differential is a conserved charge

In a conformal field theory with a holomorphic current $j(z)$ (a 1-form), the product $f\omega$ plays the role of j: the residue theorem $\sum \text{Res} = 0$ is the Ward identity for the corresponding charge, which forces the charges of the insertions to add up to zero. A function on Σ multiplied by each of the p holomorphic differentials gives p such conservation laws. On the sphere there are no holomorphic differentials and so no constraints on f; on a torus

there is one ($\omega = \mathrm{d}z$, condition $a_1 = 0$: "no net charge"); in genus p there are p. The number of constraints that are *independent*, rank R_n, depends on where the pole sits, and that is what distinguishes the points of Σ.

Gaps are vanishing orders plus one

Now choose the basis cleverly. Order the differentials by how fast they vanish at z_0. By Gaussian elimination we may assume that their orders of vanishing are all different: if two had the same order m, a suitable combination would vanish to order $> m$. So we get a basis with

$$\omega_j = \big(c_j z^{m_j} + O(z^{m_j+1})\big)\mathrm{d}z, \quad c_j \neq 0, \qquad 0 \le m_1 < m_2 < \cdots < m_p \le 2p-2.$$

The upper bound holds because a non-zero holomorphic differential has exactly $\deg K = 2p-2$ zeros. The integers m_j are the **vanishing orders** of the holomorphic differentials at z_0; they depend only on z_0, not on the basis.

In this basis row j of R_n is $(0,\dots,0,c_j,*,*,\dots)$, with the first non-zero entry in column $k = m_j + 1$. The matrix is in echelon form, and its rank is the number of rows whose pivot fits into the first n columns:

$$\operatorname{rank} R_n = \#\{j : \ m_j + 1 \le n\}.$$

Therefore

$$\ell(n) - \ell(n-1) \overset{(1)}{=} 1 - \big(\operatorname{rank} R_n - \operatorname{rank} R_{n-1}\big) \overset{(2)}{=} 1 - \#\{j : \ m_j + 1 = n\}.$$

(1) The keyidea formula at n and at $n-1$.
(2) The only rows that gain a pivot when the n-th column is added are those with $m_j + 1 = n$; since the m_j are distinct there is at most one.

By (5.177) this is zero exactly when $n = m_j + 1$ for some j.

Key idea: Noether's characterisation of the gaps

n is a gap at z_0 if and only if there is a holomorphic differential vanishing to order *exactly* $n-1$ at z_0. Thus the gap sequence is

$$\{n_1,\dots,n_p\} = \{m_1+1,\ \dots,\ m_p+1\},$$

the vanishing orders of the holomorphic differentials, shifted by one.

This reproves the whole gap theorem in one stroke. There are p gaps because there are p differentials; $n_p \le 2p-1$ because $m_p \le 2p-2$; and $n_1 = 1$ exactly when $m_1 = 0$, i.e. when some differential does not vanish at z_0. (Combined with Section 5.7.2, this shows that for $p \ge 1$ the p differentials never vanish simultaneously: the canonical bundle has no "base points". This is the fact that Nash's residue argument needed.)

It also makes explicit what Nash's "a_i" are doing. Suppose $n = n_j$ is a gap and f had a pole of order exactly n. The condition from ω_j reads

$$0 = \sum_k a_k\, h^{(j)}_{k-1} = c_j\, a_n + \big(\text{terms with } a_k,\ k > n\big) = c_j\, a_n,$$

because $h^{(j)}_{k-1} = 0$ for $k-1 < m_j = n-1$ and $a_k = 0$ for $k > n$. So $a_n = 0$: the pole cannot have order n. In general the j-th condition expresses the coefficient a_{n_j} in terms of the higher coefficients: the p coefficients $a_{n_1},\dots,a_{n_p}$ are not free parameters.

Normal points and Weierstrass points in terms of differentials

A point is normal iff its gaps are $1, \dots, p$, iff the vanishing orders are $0, 1, \dots, p-1$. In other words: *z_0 is a Weierstrass point iff some non-zero holomorphic differential vanishes to order at least p at z_0.* This is a condition we can test with a determinant. With any basis $\omega_j = h_j(z)\,\mathrm{d}z$ (no adaptation needed), a combination $\sum_j \lambda_j \omega_j$ vanishes to order $\geq p$ iff

$$\sum_{j=1}^{p} \lambda_j \, h_j^{(k)}(z_0) = 0 \quad \text{for } k = 0, 1, \dots, p-1, \tag{5.179}$$

where $h_j^{(k)}$ is the k-th derivative. This is p equations in p unknowns; a non-zero solution exists iff the determinant vanishes. So

$$z_0 \text{ is a Weierstrass point} \iff W(z_0) \coloneqq \det \begin{pmatrix} h_1(z_0) & h_2(z_0) & \cdots & h_p(z_0) \\ h_1'(z_0) & h_2'(z_0) & \cdots & h_p'(z_0) \\ \vdots & & & \vdots \\ h_1^{(p-1)}(z_0) & h_2^{(p-1)}(z_0) & \cdots & h_p^{(p-1)}(z_0) \end{pmatrix} = 0. \tag{5.180}$$

W is the **Wronskian** of the p functions h_j. It is a holomorphic function of z_0 in each chart, and it is not identically zero (the Wronskian of linearly independent analytic functions never is). Its zeros are isolated, and on a compact surface there are finitely many of them. That is the finiteness of the set of Weierstrass points, which Nash quotes from Griffiths and Harris. In the next part we turn the Wronskian into a section of a line bundle and count its zeros.

Worked example 5.100: The residue matrix on the torus and in genus two

Torus. $p = 1$, $\omega_1 = \mathrm{d}z$, so $h^{(1)} = 1$: $h_0 = 1$, $h_m = 0$ for $m \geq 1$. At every point

$$R_n = (1, 0, 0, \dots, 0), \qquad R_n a = 0 \iff a_1 = 0.$$

So $\ell(n) = 1 + n - 1 = n$ for $n \geq 1$: the only condition is "zero residue", the only gap is 1, and every point is normal. Explicitly $\mathcal{L}(n z_0)$ is spanned by

$$1,\ \wp(z - z_0),\ \wp'(z - z_0),\ \wp(z - z_0)^2,\ \wp(z - z_0)\wp'(z - z_0),\ \dots$$

with pole orders $0, 2, 3, 4, 5, \dots$: products $\wp^a \wp'^b$ with $b \in \{0, 1\}$ have pole order $2a + 3b$, which takes every value ≥ 2 exactly once. ($\wp'^2$ is not needed: it is a cubic polynomial in $\wp$.)
Genus two at a branch point. Take $y^2 = f(x)$ with $f(x) = \prod_{i=1}^{6}(x - e_i)$, and z_0 the point $(e_1, 0)$. The local coordinate is s with $x - e_1 = s^2$, and $y = s\,u(s)$ with $u(0)^2 = f'(e_1) \neq 0$ (Example 5.91). A basis of holomorphic differentials is $\omega_1 = \mathrm{d}x/y$ and $\omega_2 = (x - e_1)\,\mathrm{d}x/y$. In the coordinate s

$$\omega_1 \overset{(1)}{=} \frac{2s\,\mathrm{d}s}{s\,u(s)} = \frac{2}{u(s)}\,\mathrm{d}s, \qquad \omega_2 \overset{(2)}{=} s^2 \cdot \frac{2}{u(s)}\,\mathrm{d}s.$$

(1) $\mathrm{d}x = 2s\,\mathrm{d}s$ and $y = s\,u(s)$.
(2) $x - e_1 = s^2$.

Now u is even in s (because $y^2/s^2 = f(e_1 + s^2)/s^2$ is a function of s^2), so $2/u(s) = \gamma_0 + \gamma_2 s^2 + O(s^4)$ with $\gamma_0 \neq 0$. The vanishing orders are $m_1 = 0$, $m_2 = 2$, and

$$R_4 = \begin{pmatrix} \gamma_0 & 0 & \gamma_2 & 0 \\ 0 & 0 & \gamma_0 & 0 \end{pmatrix}.$$

The conditions are $\gamma_0 a_1 + \gamma_2 a_3 = 0$ and $\gamma_0 a_3 = 0$, so $a_1 = a_3 = 0$ while a_2, a_4 are free: *the gaps are* 1 *and* 3. Indeed $1/(x - e_1) = s^{-2}$ has a single double pole at z_0 (it vanishes at the two points over $x = \infty$). So branch points are Weierstrass points in genus two, with weight $(1 - 1) + (3 - 2) = 1$.

5.7.7 How many Weierstrass points? The Wronskian as a section

Nash closes his outline with a statement he does not prove [Nash p. 169, (5.111)]: the Weierstrass points are finite in number, which he phrases as

$$\text{if } n \geq p, \qquad \dim \mathcal{L}(n z_0) > 1 \quad \text{for only finitely many } z_0. \tag{5.181}$$

First let us see why this *is* the finiteness of the Weierstrass points. At a normal point the gaps are $1, \dots, p$, so the staircase of Figure 5.56 is flat up to $n = p$ and $\ell(p) = 1$. At a Weierstrass point some $n \leq p$ is a non-gap, so the staircase has risen at least once by $n = p$ and $\ell(p) \geq 2$. Hence

$$\ell(p) = \dim \mathcal{L}(p z_0) > 1 \iff z_0 \text{ is a Weierstrass point},$$

and (5.181) with $n = p$ says there are finitely many of them. (For $n > p$ the statement as Nash prints it is not what he means: once $n \geq p + 1$ we have $\ell(n) \geq n + 1 - p \geq 2$ at *every* point, by the index bound $\ell(n) \geq \operatorname{index} \bar{\partial}_{[n z_0]}$. The meaningful statement is the one at $n = p$.)

Nash refers the proof to Griffiths and Harris, who count singular points of certain curves attached to Σ. We give the argument in the physicist's form: the Weierstrass points are the zeros of one holomorphic object, the Wronskian (5.180), and we can count the zeros of a holomorphic section by computing the degree of its bundle. This is the same move as "$\deg K = 2p - 2$" in Example 5.91: the number of zeros of a section is a Chern number.

Step 1: the order of vanishing of W is the weight

Fix z_0 and a coordinate z centred at z_0. Use the adapted basis of Section 5.7.6,

$$\omega_j = h_j(z)\, \mathrm{d}z, \qquad h_j(z) = c_j z^{m_j}\big(1 + O(z)\big), \qquad c_j \neq 0, \qquad m_1 < \cdots < m_p.$$

First the Wronskian of pure monomials.

Key idea: Wronskian of monomials

For distinct integers $a_1, \dots, a_p \geq 0$,

$$W\big[z^{a_1}, \dots, z^{a_p}\big] = \prod_{i<j} (a_j - a_i)\; z^{\,a_1 + \cdots + a_p - \frac{p(p-1)}{2}}. \tag{5.182}$$

The (k, i) entry of the Wronskian matrix (row $k = 0, \dots, p-1$ for the k-th derivative, column i for the function) is $\frac{\mathrm{d}^k}{\mathrm{d}z^k} z^{a_i} = (a_i)_k\, z^{a_i - k}$, where $(a)_k = a(a-1)\cdots(a-k+1)$ is the falling factorial. Then

$$W \overset{(1)}{=} \det\big[(a_i)_k\, z^{a_i - k}\big] \overset{(2)}{=} z^{\sum_i a_i}\, z^{-\sum_k k}\, \det\big[(a_i)_k\big] \overset{(3)}{=} z^{\sum_i a_i - \frac{p(p-1)}{2}}\, \det\big[a_i^{\,k}\big] \overset{(4)}{=} \prod_{i<j} (a_j - a_i)\; z^{\sum_i a_i - \frac{p(p-1)}{2}}.$$

(1) The entries, differentiated.

(2) Pull the factor z^{a_i} out of column i and z^{-k} out of row k; a determinant is linear in each row and each column.
(3) $\sum_{k=0}^{p-1} k = p(p-1)/2$. The falling factorial $(a)_k$ is a polynomial in a of degree k with leading coefficient 1: $(a)_k = a^k + (\text{lower powers})$. Subtracting suitable multiples of earlier rows from row k removes the lower powers without changing the determinant.
(4) The Vandermonde determinant.

Two checks. For $p = 2$, $a = (0, 2)$: $\det\left(\begin{smallmatrix} 1 & z^2 \\ 0 & 2z \end{smallmatrix}\right) = 2z$, and the formula gives $(2-0)z^{2-1} = 2z$. ✓ For $a = (0, 1, \dots, p-1)$ the exponent is 0: the Wronskian of $1, z, \dots, z^{p-1}$ is the non-zero constant $\prod_{k<p} k!$.

Now the general case. The Wronskian is linear in each function. Expand every h_j in its Taylor series, $h_j = \sum_{b \geq m_j} h_{j,b} z^b$. Then $W[h_1, \dots, h_p]$ is a sum of terms $\left(\prod_j h_{j,b_j}\right) W[z^{b_1}, \dots, z^{b_p}]$ with $b_j \geq m_j$. By (5.182) each such term is zero or has order $\sum_j b_j - \frac{p(p-1)}{2} \geq \sum_j m_j - \frac{p(p-1)}{2}$, with equality only for $b_j = m_j$ for all j. That lowest term is not zero, because the m_j are distinct. So

$$\operatorname{ord}_{z_0} W \overset{(1)}{=} \sum_{j=1}^{p} m_j - \frac{p(p-1)}{2} \overset{(2)}{=} \sum_{j=1}^{p} (n_j - 1) - \sum_{j=1}^{p} (j-1) \overset{(3)}{=} \sum_{j=1}^{p} (n_j - j) = w(z_0). \tag{5.183}$$

(1) The lowest term of the expansion just described.
(2) Noether's characterisation (Section 5.7.6): the gaps are $n_j = m_j + 1$; and $\frac{p(p-1)}{2} = \sum_j (j-1)$.
(3) Combine the sums.

The Wronskian vanishes at z_0 to order exactly the weight of z_0. It is non-zero at normal points (weight 0) and zero at Weierstrass points, as (5.180) already said, but now we know the multiplicity too. Changing the basis multiplies W by the (constant, non-zero) determinant of the change of basis, so the order does not depend on the basis.

Step 2: W transforms like a $\frac{p(p+1)}{2}$-differential

So far W was computed in one chart. How does it change if we use another coordinate w, with $z = z(w)$? In the new chart the same differentials read $\omega_j = h_j(z(w))\, z'(w)\, \mathrm{d}w \coloneqq \tilde{h}_j(w)\, \mathrm{d}w$, and the new Wronskian is built from the $\tilde{h}_j$ and w-derivatives. We need two facts about Wronskians.

(a) *Multiplying all functions by φ:* $W[\varphi f_1, \dots, \varphi f_p] = \varphi^p\, W[f_1, \dots, f_p]$. By the Leibniz rule $(\varphi f)^{(k)} = \varphi f^{(k)} + \sum_{l<k} \binom{k}{l} \varphi^{(k-l)} f^{(l)}$, so the new matrix is (lower-triangular matrix with φ on the diagonal) $\times$ (old matrix). Its determinant is φ^p times the old one.

(b) *Changing the variable:* $W_w[f_1 \circ z, \dots, f_p \circ z] = (z')^{p(p-1)/2}\, W_z[f_1, \dots, f_p] \circ z$. By the chain rule $\frac{\mathrm{d}^k}{\mathrm{d}w^k} f(z(w)) = (z')^k f^{(k)}(z(w)) + \sum_{l<k} (\cdots) f^{(l)}(z(w))$, so again the matrix changes by a lower-triangular factor, now with diagonal $1, z', (z')^2, \dots, (z')^{p-1}$, whose determinant is $(z')^{0+1+\cdots+(p-1)}$.

Therefore

$$\begin{aligned} \tilde{W}(w) &\overset{(1)}{=} W_w\left[z' \cdot (h_1 \circ z), \dots, z' \cdot (h_p \circ z)\right] \\ &\overset{(2)}{=} (z')^p\, W_w\left[h_1 \circ z, \dots, h_p \circ z\right] \\ &\overset{(3)}{=} (z')^p\, (z')^{\frac{p(p-1)}{2}}\, W(z(w)) = \left(\frac{\mathrm{d}z}{\mathrm{d}w}\right)^{\frac{p(p+1)}{2}} W(z(w)). \end{aligned} \tag{5.184}$$

(1) Definition of the new Wronskian, with $\tilde{h}_j = z' \cdot (h_j \circ z)$.

(2) Fact (a) with $\varphi = z'$.
(3) Fact (b).

Compare with the transformation of a q-differential $\phi(z)\,dz^q$ (Nash's footnote 6, Section 5.6.6): $\tilde{\phi}(w) = \phi(z(w))(z')^q$. So (5.184) says exactly that

$$\mathbb{W} := W(z)\,(dz)^{\frac{p(p+1)}{2}} \quad \text{is a global holomorphic section of } K_\Sigma^{\frac{p(p+1)}{2}}. \tag{5.185}$$

It is not identically zero (it is non-zero at any normal point, and normal points exist because the zeros of a non-zero holomorphic function in a chart are isolated).

Step 3: count the zeros

A non-zero holomorphic section of a line bundle L has exactly $\deg L$ zeros, counted with multiplicity (Chapter 5). Then

$$\sum_{z_0\in\Sigma} w(z_0) \overset{(1)}{=} \sum_{z_0\in\Sigma} \operatorname{ord}_{z_0}\mathbb{W} \overset{(2)}{=} \deg K^{\frac{p(p+1)}{2}} \overset{(3)}{=} \frac{p(p+1)}{2}(2p-2) = (p-1)\,p\,(p+1) = p^3 - p. \tag{5.186}$$

(1) (5.183) at every point.
(2) Number of zeros of a holomorphic section = degree.
(3) $\deg K^N = N \deg K$ (transition functions are N-th powers, so c_1 multiplies by N), and $\deg K = 2p-2$.

Key idea: The Weierstrass points are the zeros of a section of $K^{p(p+1)/2}$

On a compact Riemann surface of genus p the Wronskian of a basis of holomorphic differentials is a holomorphic section of $K^{p(p+1)/2}$. It vanishes exactly at the Weierstrass points, to order equal to their weights. Hence the Weierstrass points are finite in number and

$$\sum_{z_0} w(z_0) = p^3 - p.$$

Since $1 \le w(z_0) \le \frac{p(p-1)}{2}$ at a Weierstrass point (Example 5.99), for $p \ge 2$

$$2p+2 = \frac{p^3-p}{p(p-1)/2} \;\le\; \#\{\text{Weierstrass points}\} \;\le\; p^3 - p.$$

For $p = 1$ the count gives 0: no Weierstrass points on a torus, as the gap theorem said. For $p = 0$ it gives 0 again (there are no differentials and nothing to count). For $p = 2$: between 6 and 6 points, so *every* genus-2 surface has exactly six Weierstrass points, each of weight 1. For $p = 3$: between 8 and 24.

Physical picture: Counting zeros by topology, once more

The logic of (5.186) is the logic of this whole chapter: to count the special points of a geometric structure, package the condition as the vanishing of a holomorphic section of a line bundle, and read the count off a Chern number. Poincaré–Hopf counts zeros of a vector field by χ; Gauss–Bonnet counts curvature by χ; here the Weierstrass condition is a determinant, the determinant is a section of a power of K, and the count is $\frac{p(p+1)}{2}\deg K$. Physicists meet the same move when counting zero modes of a Dirac operator by an index, or instantons by $\frac{1}{8\pi^2}\int \operatorname{tr} F \wedge F$.

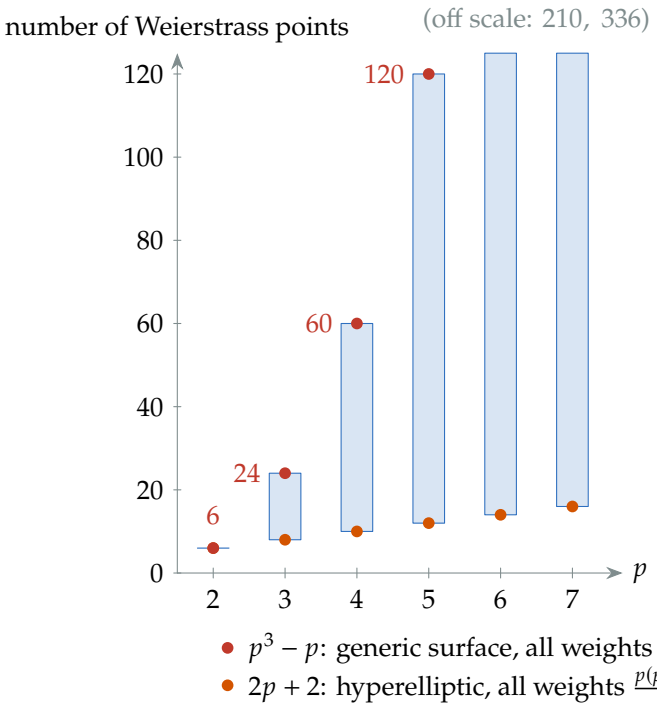

Figure 5.57: The number of Weierstrass points in genus p lies in the shaded range between $2p + 2$ and $p^3 - p$. The upper end is reached when every Weierstrass point has weight 1, which is the case for a generic surface; the lower end exactly for hyperelliptic surfaces, where every Weierstrass point has the maximal weight $p(p-1)/2$. In genus 2 the two ends meet: every genus-2 surface has exactly six Weierstrass points.

Watch out: Two standard facts we quote

Two statements in this subsection are true but not proved here: that $w(z_0) \le p(p-1)/2$ with equality only at the Weierstrass points of a hyperelliptic surface, and that a generic surface has all weights equal to 1. Both are in Griffiths and Harris (Ch. 2, §4). Everything else, in particular the finiteness and the total $p^3 - p$, follows from (5.183)–(5.186), which we derived.

5.7.8 Weierstrass points in examples

The count $p^3 - p$ is a strong check on any explicit calculation. We now find the Weierstrass points of the three classes of surface we know explicitly.

Worked example 5.101: The torus has no Weierstrass points

$p = 1$, one differential $\omega = \mathrm{d}z$, so $h = 1$ and the Wronskian is the 1×1 determinant $W = 1$. It never vanishes, so there are no Weierstrass points, and the count is $\deg K^1 = 0 = 1^3 - 1$. ✓ In terms of functions: at every point z_0 the gap sequence is $\{1\}$, the only obstruction is the single residue condition $a_1 = 0$ of Example 5.100, and $\wp(z - z_0)$ realises the non-gap 2. The torus is homogeneous (translations act transitively), so all its points must look alike: there is no room for special points.

Worked example 5.102: Hyperelliptic surfaces: the branch points

Let Σ be $y^2 = f(x)$ with f a polynomial of degree $2p+2$ with distinct roots $e_1, \dots, e_{2p+2}$ ($p \geq 2$). By Example 5.91, $\mathrm{d}x/y$ has no zeros in the finite part and a zero of order $p-1$ at each of the two points $\infty_\pm$ over $x = \infty$, where x has a simple pole. So

$$\omega_k = x^k \frac{\mathrm{d}x}{y}, \qquad k = 0, 1, \dots, p-1,$$

is holomorphic (order $p-1-k \geq 0$ at $\infty_\pm$), and these are p independent differentials: a basis.

At a branch point $P_i = (e_i, 0)$ use the basis $\omega'_k = (x-e_i)^k\,\mathrm{d}x/y$, $k = 0, \dots, p-1$. It spans the same space, since $(x-e_i)^k$ is a polynomial of degree k in x with leading coefficient 1 (a triangular change of basis). With the local coordinate s, $x - e_i = s^2$, $y = s\,u(s)$, $u(0) \neq 0$ (Example 5.100):

$$\omega'_k \overset{(1)}{=} s^{2k} \cdot \frac{2s\,\mathrm{d}s}{s\,u(s)} \overset{(2)}{=} \frac{2}{u(s)}\, s^{2k}\,\mathrm{d}s.$$

(1) $(x-e_i)^k = s^{2k}$, $\mathrm{d}x = 2s\,\mathrm{d}s$, $y = s\,u(s)$.
(2) Cancel s.

Since $2/u(s)$ is non-zero at $s = 0$, the vanishing orders are $m_k = 2k$: $0, 2, 4, \dots, 2p-2$, all distinct, so this is already the adapted basis. By Noether's characterisation the gaps are

$$1, 3, 5, \dots, 2p-1, \qquad w(P_i) = \sum_{k=0}^{p-1} \big((2k+1) - (k+1)\big) = \sum_{k=0}^{p-1} k = \frac{p(p-1)}{2}.$$

At any other point the pattern is normal. At a finite point $x = a$ with $y \neq 0$ the coordinate is $t = x - a$, $1/y$ is holomorphic and non-zero, and $(x-a)^k \mathrm{d}x/y$ vanishes to order k: orders $0, \dots, p-1$. At $\infty_\pm$ the orders of ω_k are $p-1-k$, again $0, \dots, p-1$. So no other point is a Weierstrass point.

The count.

$$\sum_{z_0} w(z_0) \overset{(1)}{=} (2p+2) \cdot \frac{p(p-1)}{2} \overset{(2)}{=} (p+1)\,p\,(p-1) = p^3 - p. \checkmark$$

(1) $2p+2$ branch points, each of weight $p(p-1)/2$; all other points have weight 0.
(2) Arithmetic.

The functions. The non-gap 2 is realised by $1/(x-e_i) = s^{-2}$: its only pole is the double pole at P_i (at $\infty_\pm$ it vanishes). The odd non-gap $2p+1$ is realised by $y/(x-e_i)^{p+1}$, which behaves like $s\,u/s^{2p+2}$ at P_i and like x^{p+1}/x^{p+1} (finite) at $\infty_\pm$. Products of these give every non-gap, as the semigroup property predicts.

Genus three: plane quartics and their flexes

Most genus-3 surfaces are not hyperelliptic (Section 5.6.12: the hyperelliptic locus has dimension $2p-1 = 5 < 6 = 3p-3$). The generic genus-3 surface is a smooth **plane quartic**, a curve $C = \{F(X,Y,Z) = 0\} \subset \mathbb{CP}^2$ with F homogeneous of degree 4 (Chapter 5: the degree–genus formula gives $\frac{(4-1)(4-2)}{2} = 3$). Its holomorphic differentials have a beautiful description.

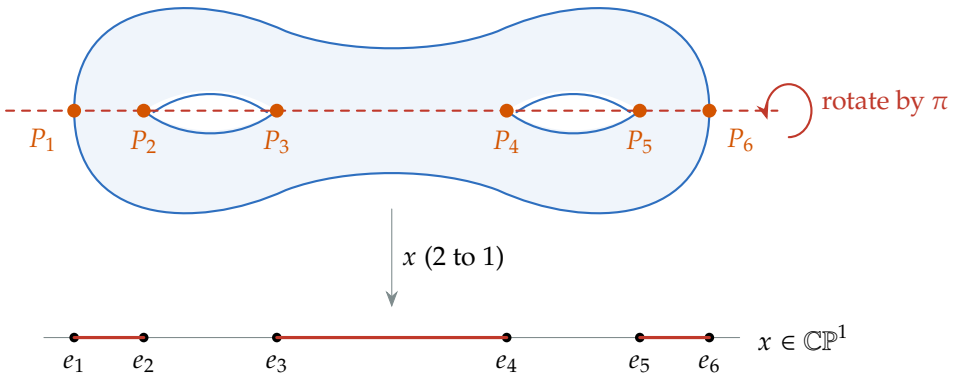

Figure 5.58: A genus-2 surface $y^2 = \prod_{i=1}^{6}(x - e_i)$ drawn so that the hyperelliptic involution $(x, y) \mapsto (x, -y)$ is the rotation by π about the dashed axis. The axis pierces the surface in exactly six points $P_1, \dots, P_6$: the fixed points of the involution, the branch points of the 2-to-1 map x to the sphere (red cuts join them in pairs), and the six Weierstrass points. At each of them $1/(x - e_i)$ is a function with a single double pole, so the gap sequence is $\{1, 3\}$ instead of the normal $\{1, 2\}$. Their weights add up to $6 = 2^3 - 2$.

Key idea: Differentials on a plane quartic are lines

In the affine chart $Z = 1$, with $F(x, y) = F(x, y, 1)$, the holomorphic differentials of a smooth quartic are

$$\omega_P = P(x, y)\,\frac{dx}{\partial F/\partial y}, \qquad P \in \operatorname{span}\{1, x, y\},$$

and the zeros of ω_P are the four intersection points of C with the line $\{P = 0\}$, with multiplicity. So *the order of vanishing of ω_P at z_0 is the order of contact of the line $P = 0$ with C at z_0.*

We take this as known (it is the adjunction formula $K_C = \mathcal{O}(d-3)|_C$ for a plane curve of degree d; see Griffiths and Harris, Ch. 2, §1). Two consistency checks: the space of linear P is $3 = p$ dimensional, and a line meets a quartic in $4 = 2p - 2 = \deg K$ points, by Bézout.

Now read off the vanishing orders at a point $z_0 \in C$. In the 3-dimensional space of lines P:

- a line not through z_0 gives order 0;
- a line through z_0 but not tangent gives order 1;
- the tangent line T_{z_0} gives order 2, or more.

So the vanishing orders are $0, 1, m_3$ with $m_3 =$ the contact order of the tangent line. Three cases:

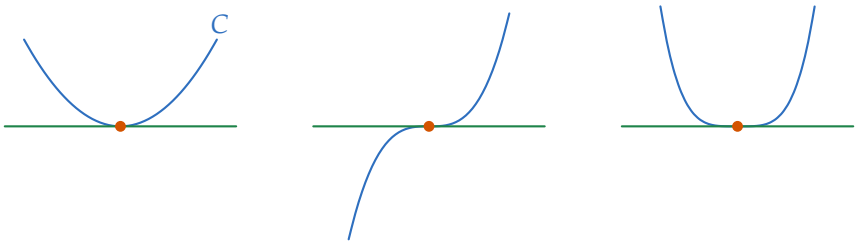
point z_0	tangent line meets C	orders m_j	gaps n_j	weight
ordinary	$2z_0 + Q + R$	0, 1, 2	1, 2, 3	0
flex (inflection point)	$3z_0 + Q$	0, 1, 3	1, 2, 4	1
hyperflex	$4z_0$	0, 1, 4	1, 2, 5	2

The Weierstrass points of a plane quartic are its inflection points. Note that the second vanishing order is always 1, so 2 and 3 are always gaps: no function on a plane quartic has a single pole of order 2, so plane quartics are never hyperelliptic. The classical count of flexes of a plane

curve of degree d is $3d(d-2)$ (intersect C with its Hessian curve, of degree $3(d-2)$, by Bézout), counting a hyperflex twice. For $d = 4$:

$$\#\text{flexes} + 2\,\#\text{hyperflexes} = 3 \cdot 4 \cdot 2 = 24 = 3^3 - 3. \checkmark$$

The Hessian count and the Wronskian count agree, as they must.



ordinary point
contact 2: orders $0, 1, 2$

flex
contact 3: orders $0, 1, 3$

hyperflex
contact 4: orders $0, 1, 4$

Figure 5.59: Real pictures of the three kinds of point on a plane quartic. The green line is the tangent line at the orange point; the differential ω_P attached to it vanishes there to the order of contact. At an ordinary point the curve stays on one side of its tangent (contact 2). At a flex the curve crosses its tangent (contact 3), and at a hyperflex it is flattened to fourth order (contact 4). Flexes and hyperflexes are the Weierstrass points, of weights 1 and 2.

Worked example 5.103: The Fermat quartic: twelve hyperflexes

Take $C: X^4 + Y^4 + Z^4 = 0$. It is smooth: the gradient $(4X^3, 4Y^3, 4Z^3)$ vanishes only at $X = Y = Z = 0$, which is not a point of $\mathbb{CP}^2$. Let ζ be one of the four roots of $\zeta^4 = -1$ and consider the line $X = \zeta Y$. On it,

$$X^4 + Y^4 + Z^4 \overset{(1)}{=} \zeta^4 Y^4 + Y^4 + Z^4 \overset{(2)}{=} Z^4.$$

(1) Substitute $X = \zeta Y$.
(2) $\zeta^4 = -1$.

So the line meets C only where $Z = 0$, i.e. at the single point $[\zeta : 1 : 0]$, and with multiplicity 4 (the restriction of F to the line is Z^4, a fourth-order zero). This point is a hyperflex, and the line is its tangent. The same works with the roles of the coordinates permuted: lines $X = \zeta Z$ and $Y = \zeta Z$. That gives $3 \times 4 = 12$ hyperflexes, each of weight 2:

$$12 \cdot 2 = 24 = 3^3 - 3. \checkmark$$

So the count is exhausted: the Fermat quartic has exactly twelve Weierstrass points, all hyperflexes, and no ordinary flexes. Its automorphisms (permutations of X, Y, Z and multiplication of coordinates by fourth roots of unity, a group of order $6 \cdot 16 = 96$) permute these twelve points, as Section 5.7.11 says they must.

Worked example 5.104: The Klein quartic: twenty-four flexes

The Klein quartic $X^3Y + Y^3Z + Z^3X = 0$ (Example 5.82) has 24 ordinary flexes and no hyperflexes, so it has the generic number $24 = 3^3 - 3$ of Weierstrass points, each of weight 1. Its 168 automorphisms act on these 24 points transitively. The stabiliser of a point then has order $168/24 = 7$. Explicitly, the order-7 symmetry $(X, Y, Z) \mapsto (\epsilon X, \epsilon^4 Y, \epsilon^2 Z)$ with $\epsilon = e^{2\pi i/7}$ maps the curve to itself (each monomial picks up $\epsilon^{3+4} = \epsilon^{12+2} = \epsilon^{6+1} = 1$) and fixes the three points $[1 : 0 : 0], [0 : 1 : 0], [0 : 0 : 1]$. At $[0 : 0 : 1]$, in the chart $Z = 1$, the

curve is $x^3y + y^3 + x = 0$, i.e. $x = -y^3 - x^3y = -y^3 + O(y^{10})$: the tangent line $x = 0$ has contact 3. So this fixed point is a flex. ✓

surface	genus	Weierstrass points	weights
sphere	0	none	–
torus	1	none	–
any genus-2 surface (y^2 = sextic)	2	6 branch points	1 each
hyperelliptic, genus p	p	$2p+2$ branch points	$p(p-1)/2$ each
Klein quartic	3	24 flexes	1 each
Fermat quartic	3	12 hyperflexes	2 each
generic surface of genus p	p	$p^3 - p$	1 each

In every row the weights add up to $p^3 - p$.

Try it: Weierstrass points of the genus-3 hyperelliptic surface

For $y^2 = x^8 - 1$ find the Weierstrass points, their gap sequences, and check the count. *Answer.* $p = 3$. The branch points are the eight points $(\zeta, 0)$, $\zeta^8 = 1$. At each, the vanishing orders of $\mathrm{d}x/y$, $(x-\zeta)\mathrm{d}x/y$, $(x-\zeta)^2\mathrm{d}x/y$ are $0, 2, 4$, so the gaps are $1, 3, 5$ and the weight is $0 + 1 + 2 = 3$. Total $8 \cdot 3 = 24 = 3^3 - 3$. Every other point is normal. So this surface has 8 Weierstrass points, the minimum $2p + 2$ allowed, compared with 24 for the Klein quartic.

5.7.9 q-differentials: the same theorem for every K^q

Nash ends the section with a remark [Nash p. 169]: instead of meromorphic functions one may consider meromorphic q-differentials, and "a very similar proof" gives a gap theorem for them, with the sheaf $\mathcal{O}([nz_0])$ replaced by $\mathcal{O}(K^q \otimes [nz_0])$. Let us carry this out, because one case of it, $q = -1$, is the $3p - 3$ of Section 5.6 seen from a completely different angle.

The count

Recall (Nash's footnote 6, Section 5.6.6) that a **q-differential** is a section of K^q, locally $\phi(z)\,\mathrm{d}z^q$, with $\tilde{\phi}(w) = \phi(z(w))\,(z')^q$. For $q = 0, 1, 2$ these are functions, 1-forms and quadratic differentials; for $q = -1$ they are vector fields $v(z)\,\partial_z$, since $K^{-1} = K^* = T\Sigma$. Let

$$\mathcal{L}_q(nz_0) := \Big\{\text{meromorphic } q\text{-differentials, holomorphic on } \Sigma \setminus \{z_0\},\ \text{with a pole of order} \le n \text{ at } z_0\Big\} \;\cong\; H^0\big(\Sigma, \mathcal{O}(K^q \otimes [nz_0])\big),$$

by the same argument as (5.166): multiply by the canonical section s of $[nz_0]$. Write $\ell_q(n)$ for its dimension. Then

$$\begin{aligned}\ell_q(n) &\overset{(1)}{=} \operatorname{index} \bar{\partial}_{K^q \otimes [nz_0]} + \dim H^1\big(\Sigma, \mathcal{O}(K^q \otimes [nz_0])\big)\\ &\overset{(2)}{=} \deg\big(K^q \otimes [nz_0]\big) + 1 - p + \dim H^0\big(\Sigma, \mathcal{O}(K^{1-q} \otimes [-nz_0])\big)\\ &\overset{(3)}{=} (2q-1)(p-1) + n + \kappa_{1-q}(n). \end{aligned} \tag{5.187}$$

(1) The index is $\dim\ker - \dim\operatorname{coker}$, and the cokernel of $\bar\partial_E$ is $H^1(\Sigma, \mathcal{O}(E))$ (Hodge theory, as in Section 5.6.7).
(2) Riemann–Roch (5.172) for a line bundle of any degree; Serre duality (5.135) with $K \otimes (K^q \otimes [nz_0])^* = K^{1-q} \otimes [-nz_0]$.
(3) $\deg = q(2p-2)+n$, and $q(2p-2)+1-p = (2q-1)(p-1)$. We write $\kappa_{1-q}(n)$ for the dimension of the space of holomorphic $(1-q)$-differentials vanishing to order $\geq n$ at z_0, by the same reasoning as (5.174).

For $q = 0$ this is (5.176), with $\kappa_1 = \kappa$. The staircase argument of Section 5.7.5 goes through word for word (read off the leading coefficient a_n of the pole in a local frame $\mathrm{d}z^q$): each step of ℓ_q has height 0 or 1, and n is a **q-gap** iff $\ell_q(n) = \ell_q(n-1)$. The residue argument of Section 5.7.6 also goes through, because a q-differential times a $(1-q)$-differential is a 1-form, $\phi(z)\mathrm{d}z^q \cdot \psi(z)\mathrm{d}z^{1-q} = \phi\psi\,\mathrm{d}z$, to which the residue theorem applies. The result:

Key idea: Gap theorem for q-differentials

A pole order $n \geq 1$ at z_0 is a gap for meromorphic q-differentials iff some holomorphic $(1-q)$-differential vanishes to order exactly $n-1$ at z_0. So the number of q-gaps is $\dim H^0(\Sigma, \mathcal{O}(K^{1-q}))$, and the gaps are the vanishing orders of the holomorphic $(1-q)$-differentials, plus one.

For $p \geq 2$ this gives the following table (for $p \geq 2$, $\dim H^0(K^r) = (2r-1)(p-1)$ when $r \geq 2$, p when $r = 1$, 1 when $r = 0$, and 0 when $r < 0$, all from (5.187) and vanishing):

q	meromorphic objects with one pole	dual holomorphic objects	number of gaps
$q \geq 2$	q-differentials	$(1-q)$-differentials: none	0
1	1-forms (currents)	functions: constants	1 (namely $n = 1$)
0	functions (Nash's case)	1-forms	p
-1	vector fields	quadratic differentials	$3p-3$
$q \leq -1$	q-differentials	$(1-q)$-differentials	$(1-2q)(p-1)$

Watch out: Where the content of Nash's remark lies

For $q \geq 2$ the "gap theorem" is empty: $K^{1-q} \otimes [-nz_0]$ has negative degree, so $\kappa_{1-q} = 0$ and every pole order occurs. The interesting q-differential gap problems are those with $q \leq 0$, whose gaps are controlled by the holomorphic $(1-q)$-differentials with $1-q \geq 1$. Equivalently, one speaks of the **q-Weierstrass points** of the space $H^0(K^q)$, $q \geq 1$: the points where some holomorphic q-differential vanishes to order at least $\dim H^0(K^q)$. For $q = 1$ these are the ordinary Weierstrass points. Nash's sentence covers both readings.

The case $q = 1$ in the table is the physicist's charge conservation: a meromorphic 1-form (a current $j(z)\mathrm{d}z$) with a single pole must have a pole of order at least 2, because a simple pole carries a residue (a charge) and the total charge on a closed surface vanishes. This is the intuition box of Section 5.7.6, now as a theorem with exactly one gap, dual to the one constant function.

How many q-Weierstrass points?

The Wronskian count generalises directly. Let $d = \dim H^0(K^q)$ and let $\phi_j = h_j(z)\,\mathrm{d}z^q$, $j = 1, \dots, d$, be a basis. The Wronskian $W[h_1, \dots, h_d]$ vanishes at z_0 to order $\sum_j \big(m_j - (j-1)\big)$, the

q-weight of z_0 (the proof of (5.183) did not use $q = 1$). Its transformation law changes in one place only: fact (a) is now used with $\varphi = (z')^q$, giving $(z')^{qd}$. So W is a section of K^N with

$$N = qd + \frac{d(d-1)}{2} = \frac{d\,(2q+d-1)}{2}.$$

For $q \geq 2$ and $p \geq 2$, with $d = (2q-1)(p-1)$:

$$\sum_{z_0} w_q(z_0) \overset{(1)}{=} N\,(2p-2) \overset{(2)}{=} d\,(2q+d-1)\,(p-1)$$

$$\overset{(3)}{=} (2q-1)(p-1)\cdot(2q-1)p\cdot(p-1) = p\,(p-1)^2\,(2q-1)^2. \tag{5.188}$$

(1) Number of zeros of the section $W\,\mathrm{d}z^N$ of K^N.
(2) Insert $N = d(2q+d-1)/2$.
(3) $d = (2q-1)(p-1)$, so $2q+d-1 = (2q-1)+(2q-1)(p-1) = (2q-1)p$.

For $q = 1$ the same line with $d = p$ gives $p(p+1)(p-1)$, which is (5.186). For quadratic differentials ($q = 2$) the total is $9p(p-1)^2$; in genus 2 it is 18.

Worked example 5.105: Quadratic Weierstrass points in genus two

On $y^2 = \prod_{i=1}^{6}(x-e_i)$ the three quadratic differentials are $\mathrm{d}x^2/y^2$, $x\,\mathrm{d}x^2/y^2$, $x^2\,\mathrm{d}x^2/y^2$ (Example 5.94). At the branch point P_1 use instead the basis $(x-e_1)^k\,\mathrm{d}x^2/y^2$, $k = 0,1,2$ (a triangular change). With $x - e_1 = s^2$, $y = s\,u(s)$:

$$(x-e_1)^k\frac{\mathrm{d}x^2}{y^2} \overset{(1)}{=} s^{2k}\,\frac{(2s\,\mathrm{d}s)^2}{s^2u(s)^2} \overset{(2)}{=} \frac{4}{u(s)^2}\,s^{2k}\,\mathrm{d}s^2.$$

(1) Substitute; $\mathrm{d}x^2$ means $\mathrm{d}x\otimes\mathrm{d}x = (2s\,\mathrm{d}s)^2$.
(2) Cancel s^2.

The vanishing orders are $0,2,4$ instead of the normal $0,1,2$, so the $q = 2$ weight is $(0-0)+(2-1)+(4-2) = 3$. The six branch points contribute $6\cdot 3 = 18 = 9\cdot 2\cdot 1^2$: the whole of (5.188). So in genus two the quadratic Weierstrass points are again exactly the six branch points. ✓

5.7.10 Vector fields with one pole: the $3p-3$ moduli as gaps

Take $q = -1$. A meromorphic vector field on Σ with a single pole of order at most n at z_0 lies in $\mathcal{V}(n) := \mathcal{L}_{-1}(nz_0)$, and (5.187) reads

$$\dim\mathcal{V}(n) = n+3-3p+\kappa_2(n), \qquad \kappa_2(n) = \dim\{\phi\in H^0(K^2) :\ \phi \text{ vanishes to order} \geq n \text{ at } z_0\}. \tag{5.189}$$

For $p \geq 2$:

- at $n = 0$: $\dim\mathcal{V}(0) = 3-3p+(3p-3) = 0$. No holomorphic vector fields (Nash's (5.90)). ✓
- for $n \geq 4p-3$: a non-zero quadratic differential has $\deg K^2 = 4p-4$ zeros, so none vanishes to order $\geq 4p-3$, $\kappa_2(n) = 0$, and $\dim\mathcal{V}(n) = n+3-3p$.

The staircase climbs from 0 at $n = 0$ to $(4p-3)+3-3p = p$ at $n = 4p-3$ in $4p-3$ steps of height 0 or 1. So it has p rising steps and

$$(4p-3)-p = 3p-3 \text{ flat steps.}$$

There are exactly $3p-3$ pole orders that no global vector field with a single pole at z_0 can have. By the keyidea above they are the vanishing orders of the $3p-3$ quadratic differentials plus one; at a point where these orders are $0, 1, \dots, 3p-4$ (a "normal point for K^2") the gaps are $1, 2, \dots, 3p-3$.

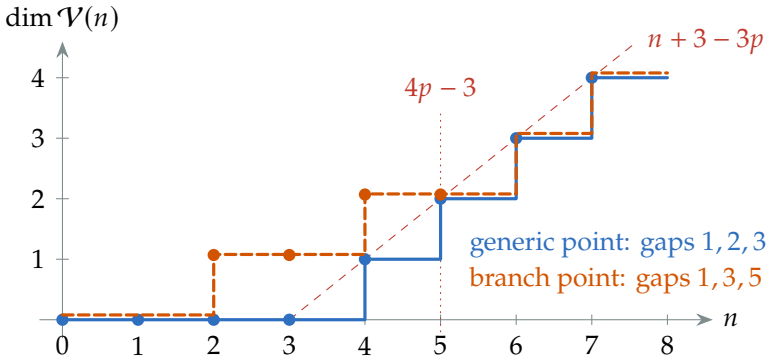


Figure 5.60: Meromorphic vector fields with a single pole on a genus-2 surface. $\dim \mathcal{V}(n)$ starts at 0 (no holomorphic vector fields), and must reach $p=2$ at $n=4p-3=5$, so it has exactly $3=3p-3$ flat steps: three forbidden pole orders, one for each complex modulus. At a generic point the forbidden orders are $1,2,3$; at a branch point of $y^2=$ sextic they are $1,3,5$, and the field $y\,\partial_x/(x-e_1)$ realises the order 2.

Worked example 5.106: Vector fields with one pole in genus two

On $y^2 = f(x) = \prod_{i=1}^{6}(x-e_i)$ consider

$$v_k = \frac{y}{(x-e_1)^k}\,\partial_x, \qquad k \geq 1.$$

Where is it singular? We need ∂_x in good local coordinates.

- *At an ordinary finite point* x is a coordinate, y and $(x-e_1)^{-k}$ are holomorphic (if $x \neq e_1$): no pole.
- *At a branch point* P_i, $x = e_i + s^2$, so $\partial_s = 2s\,\partial_x$ and

$$v_k \overset{(1)}{=} \frac{s\,u(s)}{(e_i-e_1+s^2)^k}\cdot\frac{1}{2s}\,\partial_s \overset{(2)}{=} \frac{u(s)}{2\,(e_i-e_1+s^2)^k}\,\partial_s.$$

  (1) $y = s\,u(s)$ and $\partial_x = (2s)^{-1}\partial_s$.
  (2) Cancel s.

  For $i \neq 1$ this is holomorphic. For $i=1$ it is $\frac{u(s)}{2}s^{-2k}\partial_s$: a pole of order exactly $2k$.
- *At* $\infty_\pm$, $t = 1/x$, $\partial_x = -t^2\partial_t$ and $y \approx \pm x^3 = \pm t^{-3}$, so $v_k \approx \mp t^{-3}\,t^k\,t^2\,\partial_t = \mp t^{k-1}\partial_t$: holomorphic for $k \geq 1$.

So $v_k \in \mathcal{V}(2k)$ has a single pole, of order $2k$, at the branch point P_1. The non-gaps $2,4,6$ are realised, and v_1, v_2, v_3 are independent, in agreement with $\dim \mathcal{V}(6) = 6+3-6+0 = 3$. The odd orders $1,3,5$ are the three gaps, one for each of the three moduli of a genus-2 surface.

The gap modes are the tangent vectors to $\mathcal{M}_p$

Why "one gap for each modulus"? Because the gap modes give an explicit basis of $T_{[\Sigma]}\mathcal{M}_p = H^{0,1}_{\bar\partial_{K^*}}$. The construction is called a **Schiffer variation**. Let D be a coordinate disc around z_0, and χ a smooth cut-off function equal to 1 on $|z| < r_1$ and to 0 on $|z| > r_2$, with $r_1 < r_2$ inside D. For $n \geq 1$ put

$$\mu_n := \bar\partial\big(\chi\, z^{-n}\partial_z\big) = \big(\partial_{\bar z}\chi\big)\, z^{-n}\ \partial_z \otimes \mathrm{d}\bar z. \tag{5.190}$$

This is a smooth Beltrami differential, supported in the annulus $A = \{r_1 < |z| < r_2\}$ (the singular vector field $z^{-n}\partial_z$ is only used where χ has already killed the pole). Its pairing (5.138) with a quadratic differential $\phi = \sum_{m\geq 0}\phi_m z^m\,\mathrm{d}z^2$ is a residue:

$$\begin{aligned}\langle \mu_n, \phi\rangle &\overset{(1)}{=} \int_A \partial_{\bar z}\big(\chi\, z^{-n}\phi(z)\big)\,\mathrm{d}^2z \\ &\overset{(2)}{=} -\frac{i}{2}\oint_{\partial A}\chi\, z^{-n}\phi(z)\,\mathrm{d}z \\ &\overset{(3)}{=} \frac{i}{2}\oint_{|z|=r_1} z^{-n}\phi(z)\,\mathrm{d}z \overset{(4)}{=} \frac{i}{2}\cdot 2\pi i\,\phi_{n-1} = -\pi\,\phi_{n-1}.\end{aligned} \tag{5.191}$$

(1) $z^{-n}\phi$ is holomorphic on A, so $\partial_{\bar z}(\chi z^{-n}\phi) = (\partial_{\bar z}\chi)z^{-n}\phi$; outside A the integrand is zero.
(2) With $\mathrm{d}^2z = \frac{i}{2}\mathrm{d}z\wedge\mathrm{d}\bar z$ and $\mathrm{d}(F\,\mathrm{d}z) = \partial_{\bar z}F\,\mathrm{d}\bar z\wedge\mathrm{d}z$ we have $\partial_{\bar z}F\,\mathrm{d}^2z = -\frac{i}{2}\mathrm{d}(F\,\mathrm{d}z)$; then Stokes.
(3) ∂A is the outer circle (counter-clockwise), where $\chi = 0$, minus the inner circle, where $\chi = 1$.
(4) Residue of $z^{-n}\sum\phi_m z^m$ at 0 is ϕ_{n-1}.

Now take the $3p-3$ gap orders $n_i = m_i + 1$ and the adapted basis $\phi_j = c_j z^{m_j}(1 + O(z))\mathrm{d}z^2$ with $m_1 < m_2 < \cdots$. The matrix of pairings $\langle \mu_{n_i}, \phi_j\rangle = -\pi\,(\phi_j)_{m_i}$ vanishes for $i < j$ (since ϕ_j starts at z^{m_j} and $m_i < m_j$) and equals $-\pi c_j \neq 0$ on the diagonal. A triangular matrix with non-zero diagonal is invertible. Since the pairing is perfect (Section 5.6.6),

Key idea: Moduli from gaps

The $3p-3$ Schiffer variations $\mu_{n_1},\dots,\mu_{n_{3p-3}}$ at the vector-field gaps n_i of any point z_0 form a basis of $T_{[\Sigma]}\mathcal{M}_p$. At a generic point they are the modes $z^{-1}\partial_z,\dots,z^{-(3p-3)}\partial_z$. The non-gap modes give nothing new: if n is a non-gap, a global field $v \in \mathcal{V}(n)$ with leading term $z^{-n}\partial_z$ exists, and μ_n differs from $\bar\partial(\chi(z^{-n}\partial_z - v)) + \bar\partial v$ only by lower modes and the fake $\bar\partial v$... more precisely $\bar\partial v = 0$ away from z_0, so μ_n is cohomologous to a combination of the μ_k with $k < n$.

Physical picture: Cutting, twisting and regluing a disc

A Schiffer variation is a concrete way to change the shape of a surface: cut out a small disc around z_0 and glue it back after moving the rim by the flow of the vector field $\varepsilon z^{-n}\partial_z$, defined on the annulus. The change is trivial if the displacement can be absorbed by moving the disc (a field holomorphic inside) or by moving the rest of the surface (a field holomorphic outside). What cannot be absorbed is exactly one mode per gap. In conformal field theory the vector field $-z^{m+1}\partial_z$ is represented by the Virasoro generator L_m, so the modes $z^{-n}\partial_z$, $n \geq 1$, are the L_{-n-1} ($L_{-2}, L_{-3},\dots$), and a change of moduli is implemented by inserting the corresponding contour integral of the stress tensor $T(z)$ around z_0. This is the germ of the "operator formalism" of string perturbation theory, in which the $3p-3$ moduli of a genus-p worldsheet are generated by $3p-3$ Virasoro modes at a single point.

Worked example 5.107: The torus and the sphere

Torus. K is trivial, so a vector field is $f(z)\partial_z$ with f elliptic, and $\mathcal{V}(n) \cong \mathcal{L}(nz_0)$. Its dimensions are $1, 1, 2, 3, \dots$ for $n = 0, 1, 2, 3, \dots$ (the constant field ∂_z at $n = 0$, the conformal Killing vector of Example 5.71). The only flat step is at $n = 1$: one gap, one modulus. Formula (5.189) agrees: $\kappa_2(0) = 1$ ($\mathrm{d}z^2$) and $\kappa_2(n \geq 1) = 0$, so $\dim \mathcal{V}(n) = n + \kappa_2(n)$. The Schiffer variation μ_1 pairs with $\mathrm{d}z^2$ to $-\pi \neq 0$ by (5.191): it moves τ.
Sphere. There are no quadratic differentials, $\kappa_2 = 0$, and $\dim \mathcal{V}(n) = n + 3$: every step rises, there are no gaps and no moduli. At $n = 0$ we recover the three conformal Killing vectors ∂_z, $z\partial_z$, $z^2\partial_z$ of Example 5.70 (Nash's footnote 7), the Lie algebra of $\mathrm{SL}(2, \mathbb{C})$.

5.7.11 Automorphisms: finiteness and the Hurwitz bound

Nash's final paragraph [Nash p. 169] uses the Weierstrass points to show that a surface of genus $p \geq 2$ has only finitely many automorphisms, at most $84(p-1)$ of them, the bound quoted in Section 5.5. We fill in the argument.

Working definition 5.52 (Automorphism of a Riemann surface)

An **automorphism** of Σ is a biholomorphic map $\varphi : \Sigma \to \Sigma$: in local coordinates $w = \varphi(z)$ is holomorphic with $\varphi' \neq 0$. They form a group $\mathrm{Aut}(\Sigma)$. *Test:* write the surface as an equation (a lattice, a curve in $\mathbb{CP}^2$, $y^2 = f(x)$) and look for coordinate changes that preserve it [e.g. on the torus $\mathbb{C}/\Lambda$, $z \mapsto -z$ sends the lattice Λ to itself, so it is an automorphism].

Automorphisms permute the Weierstrass points

Let $\varphi \in \mathrm{Aut}(\Sigma)$ and ω a holomorphic differential. The pull-back $\varphi^*\omega$ is again a holomorphic differential (in coordinates $\varphi^*(h(w)\mathrm{d}w) = h(\varphi(z))\varphi'(z)\,\mathrm{d}z$), and φ^* is an invertible linear map of $H^0(K)$ to itself. Since φ is a local biholomorphism, orders of vanishing are preserved:

$$\mathrm{ord}_{z_0}(\varphi^*\omega) \overset{(1)}{=} \mathrm{ord}_{z_0}\big(h(\varphi(z))\,\varphi'(z)\big) \overset{(2)}{=} \mathrm{ord}_{z_0}\big(h \circ \varphi\big) \overset{(3)}{=} \mathrm{ord}_{\varphi(z_0)}\, h.$$

(1) The pull-back in coordinates.
(2) $\varphi'(z_0) \neq 0$.
(3) φ is a local coordinate change at z_0, and the order of a zero does not depend on the coordinate.

So the set of vanishing orders $\{m_j\}$ of all holomorphic differentials at $\varphi(z_0)$ equals that at z_0. By Noether's characterisation the gap sequences agree too:

$$\text{gaps at } \varphi(z_0) = \text{gaps at } z_0, \qquad w(\varphi(z_0)) = w(z_0). \tag{5.192}$$

In particular φ maps the finite set $\mathcal{W}$ of Weierstrass points to itself: it permutes them, preserving weights. This is what Nash means by "Weierstrass points are landmarks".

A non-trivial automorphism has few fixed points

Key idea: Fixed-point bound

If $p \geq 1$... more precisely for any genus p, an automorphism $\varphi \neq \mathrm{id}$ of Σ has at most $2p+2$ fixed points.

Pick z_0 with $\varphi(z_0) \neq z_0$ (fixed points of $\varphi \neq \mathrm{id}$ are isolated, so such z_0 exist), and choose a non-constant $f \in \mathcal{L}((p+1)z_0)$. It exists because $\ell(p+1) \geq (p+1)+1-p = 2$, the index lower bound. Put $g = f - f \circ \varphi$.

- $f \circ \varphi$ has its only pole at $\varphi^{-1}(z_0) \neq z_0$, while f has its only pole at z_0. So $g \not\equiv 0$, and g has poles at the two points $z_0, \varphi^{-1}(z_0)$, each of order at most $p+1$: at most $2p+2$ poles in total.

- At a fixed point a of φ (necessarily $a \neq z_0, \varphi^{-1}(z_0)$), $g(a) = f(a) - f(\varphi(a)) = 0$.

Then

$$\#\{\text{fixed points}\} \;\leq\; \#\{\text{zeros of } g\} \overset{(1)}{=} \#\{\text{poles of } g\} \;\leq\; 2p+2,$$

with (1) the degree-zero property of $\operatorname{div} g$. The bound is sharp: the hyperelliptic involution $(x, y) \mapsto (x, -y)$ fixes exactly the $2p+2$ branch points (Figure 5.58).

Finiteness

Argument 1 (Nash's). By (5.192) we have a homomorphism $\mathrm{Aut}(\Sigma) \to \mathrm{Perm}(\mathcal{W})$ into the finite group of permutations of the Weierstrass points. If Σ is not hyperelliptic, then $\#\mathcal{W} > 2p+2$ (the lower bound $2p+2$ is attained only in the hyperelliptic case), and an element of the kernel fixes more than $2p+2$ points, so it is the identity: $\mathrm{Aut}(\Sigma)$ embeds in a finite group. (In the hyperelliptic case the kernel turns out to be $\{\mathrm{id}, J\}$, J the hyperelliptic involution; we do not prove this.)

Argument 2 (with the tools of Sections 5.4 and 5.6). An automorphism maps the unique constant-curvature metric g_c of area $4\pi(p-1)$ in the conformal class to a constant-curvature metric of the same area in the same class, hence to g_c itself: $\mathrm{Aut}(\Sigma)$ is a group of isometries of g_c. The isometry group of a compact Riemannian manifold is a compact Lie group. Its Lie algebra consists of Killing vector fields; those that preserve the complex structure are holomorphic vector fields; and there are none for $p \geq 2$ (Nash's (5.90)). A compact Lie group with zero Lie algebra is discrete and compact, hence finite.

The Hurwitz bound $84(p-1)$

Let $G = \mathrm{Aut}(\Sigma)$, of order N. The quotient $\Sigma' = \Sigma/G$ is a compact Riemann surface of some genus h (near a point with stabiliser of order m the map to the quotient looks like $z \mapsto z^m$, and z^m is a good coordinate downstairs). The projection $\pi : \Sigma \to \Sigma'$ is an N-sheeted branched covering. Let $b_1, \ldots, b_r$ be the branch values, and $m_i \geq 2$ the order of the stabiliser of any point over b_i; over b_i there are N/m_i points instead of N.

Triangulate Σ' with the b_i among the vertices, and lift the triangulation. Faces and edges

have N preimages each; an ordinary vertex has N preimages; b_i has N/m_i. Then

$$\begin{aligned} 2-2p &\overset{(1)}{=} N\,(V-E+F) - \sum_{i=1}^{r}\Big(N - \frac{N}{m_i}\Big) \\ &\overset{(2)}{=} N\,(2-2h) - N\sum_{i=1}^{r}\Big(1-\frac{1}{m_i}\Big), \\ \Longrightarrow \quad 2p-2 &\overset{(3)}{=} N\,R, \qquad R \coloneqq 2h-2+\sum_{i=1}^{r}\Big(1-\frac{1}{m_i}\Big). \end{aligned} \tag{5.193}$$

(1) Euler characteristic upstairs, counted from the lifted triangulation: N copies of everything, minus the missing preimages over each branch value.
(2) $V-E+F=\chi(\Sigma')=2-2h$.
(3) Rearrange, with a sign change.

(This is the Riemann–Hurwitz formula (5.162) for a Galois covering.) For $p \geq 2$ the left side is positive, so $R>0$ and $N=(2p-2)/R$. To bound N we find the *smallest positive* value R can take. Each term $1-\frac{1}{m_i}$ is at least $\frac{1}{2}$.

- $h \geq 2$: $R \geq 2$.
- $h=1$: $R=\sum(1-\frac{1}{m_i})$, positive only if $r \geq 1$, then $R \geq \frac{1}{2}$.
- $h=0$, $r \geq 5$: $R \geq -2+\frac{5}{2}=\frac{1}{2}$.
- $h=0$, $r=4$: $R>0$ excludes $(2,2,2,2)$; the smallest is $(2,2,2,3)$, $R=-2+\frac{3}{2}+\frac{2}{3}=\frac{1}{6}$.
- $h=0$, $r=3$: $R=1-\big(\frac{1}{m_1}+\frac{1}{m_2}+\frac{1}{m_3}\big)$. We want $\frac{1}{m_1}+\frac{1}{m_2}+\frac{1}{m_3}$ as close to 1 as possible but below it. With $m_1 \leq m_2 \leq m_3$: $m_1=2$ (else the sum is at most 1 only with $R \geq 1-\frac{3}{4}\cdot\ldots$, far away); $m_2=3$ (the choice $m_2=4$ gives at best $(2,4,5)$, $R=\frac{1}{20}$); and then the smallest m_3 with $\frac{1}{2}+\frac{1}{3}+\frac{1}{m_3}<1$ is $m_3=7$:

$$R_{\min}=1-\frac{1}{2}-\frac{1}{3}-\frac{1}{7}=\frac{42-21-14-6}{42}=\frac{1}{42}.$$

  For comparison $(2,3,8)$ gives $\frac{1}{24}$, $(3,3,4)$ gives $\frac{1}{12}$.

So $R \geq \frac{1}{42}$ and

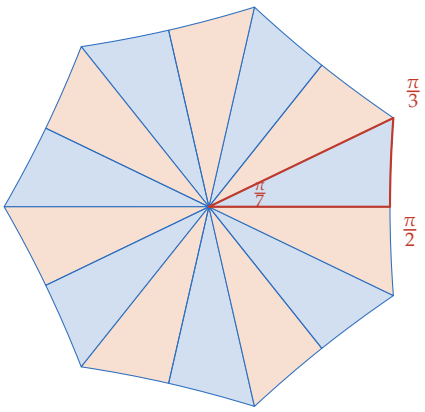
$$\#\operatorname{Aut}(\Sigma)=N=\frac{2p-2}{R} \;\leq\; 42\,(2p-2)=84\,(p-1), \tag{5.194}$$

with equality exactly when $\Sigma \to \Sigma/G$ is a covering of the sphere branched over three points with orders $(2,3,7)$.

The area version in the caption is the same calculation in the language of uniformisation (Section 5.4.6): the Gauss–Bonnet theorem for the hyperbolic metric turns (5.193) into

$$\operatorname{Area}(\Sigma)=|G|\cdot\operatorname{Area}(\Sigma/G), \qquad 4\pi(p-1)=|G|\cdot 2\pi R,$$

and the area of a hyperbolic triangle with angles α,β,γ is $\pi-\alpha-\beta-\gamma$ (Gauss–Bonnet for a geodesic triangle with $K=-1$).



centre of the Poincaré disc $\mathbb{H}$ (magnified)

hyperbolic triangle,
angles $\frac{\pi}{2}, \frac{\pi}{3}, \frac{\pi}{7}$:
area $\pi - \frac{\pi}{2} - \frac{\pi}{3} - \frac{\pi}{7} = \frac{\pi}{42}$

Σ/G has area $\geq 2 \cdot \frac{\pi}{42}$,
Σ has area $4\pi(p-1)$
$\Rightarrow\ |G| \leq 84(p-1)$

Figure 5.61: The Hurwitz bound as an area count. With the constant-curvature metric of curvature -1, a genus-p surface has area $4\pi(p-1)$ (Gauss–Bonnet). Its automorphisms are isometries, and the quotient Σ/G is a hyperbolic orbifold of area $4\pi(p-1)/|G|$, which is $2\pi R$ in the notation of (5.193). The smallest possible orbifold is made of two copies of the $(2,3,7)$ triangle drawn in red (one blue, one orange copy in each kite), of total area $\pi/21$. Fourteen such triangles meet at the vertex with angle $\pi/7$. So $|G| \leq 4\pi(p-1)/(\pi/21) = 84(p-1)$.

Worked example 5.108: The bound in genus 3, and in genus 2

Genus 3. The bound is $84 \cdot 2 = 168$, attained by the Klein quartic: $168/2\ldots$ indeed $NR = 2p-2$ gives $R = 4/168 = 1/42$, so the quotient is the $(2,3,7)$ orbifold. The three branch values have $168/2 = 84$, $168/3 = 56$ and $168/7 = 24$ preimages. The last 24 are the points with stabiliser of order 7: the 24 flexes, i.e. the Weierstrass points of Example 5.104. The Fermat quartic has 96 automorphisms: $R = 4/96 = 1/24$, the $(2,3,8)$ orbifold, and the $96/8 = 12$ points with stabiliser of order 8 are its twelve hyperflexes.
Genus 2. The bound 84 is not attained. The largest group is of order 48, for $y^2 = x(x^4-1)$: $R = 2/48 = 1/24$, again $(2,3,8)$. In every genus-2 case the hyperelliptic involution is in the group and fixes the six Weierstrass points.
Genus 1 and 0: no bound. For $p = 1$, $2p-2 = 0$ and (5.193) gives no constraint: the translations form a continuous group T^2 of automorphisms. For $p = 0$, $\mathrm{Aut}(\mathbb{CP}^1) = \mathrm{SL}(2,\mathbb{C})/\{\pm I\}$. Both reflect the conformal Killing vectors of Section 5.4.5: automorphisms are finite in number exactly when there are no holomorphic vector fields.

5.7.12 Why physicists meet the Wronskian: zero-mode determinants

Nash mentions [Nash p. 318] that the gap theorem constrains correlation functions of conformal field theories on Σ. Here is the simplest instance. Consider a chiral system whose zero modes are the p holomorphic differentials: for instance a b–c system with b of weight 1 and c of weight 0 (a "$\lambda = 1$" ghost system), or a chiral boson current. The path integral over the zero modes of b vanishes unless p fields $b(z_1), \ldots, b(z_p)$ are inserted, and the result is proportional to

$$\big\langle b(z_1)\cdots b(z_p)\big\rangle \ \propto\ \det\big[\, h_i(z_j)\,\big]_{i,j=1}^{p}, \tag{5.195}$$

the determinant of the zero-mode wavefunctions at the insertion points. (This is the Grassmann integral $\int \prod \mathrm{d}\beta_i \ \prod_j (\sum_i \beta_i h_i(z_j))$ over the zero-mode coefficients β_i in $b = \sum_i \beta_i \omega_i + \ldots$.) What happens when all insertions come together at one point z_0? Put $z_j = z_0 + \varepsilon t_j$ with distinct t_j

and expand:

$$\begin{aligned}\det\big[h_i(z_0+\varepsilon t_j)\big] &\overset{(1)}{=} \det\Big[\sum_{k\ge 0}\frac{h_i^{(k)}(z_0)}{k!}\,\varepsilon^k t_j^{\,k}\Big]\\ &\overset{(2)}{=} \det\Big[\frac{h_i^{(k)}(z_0)}{k!}\Big]_{i,\,k<p}\ \det\big[\varepsilon^k t_j^{\,k}\big]_{k<p,\,j}+O\big(\varepsilon^{\frac{p(p-1)}{2}+1}\big)\\ &\overset{(3)}{=} \frac{W(z_0)}{\prod_{k<p}k!}\prod_{i<j}(t_j-t_i)\;\varepsilon^{\frac{p(p-1)}{2}}+O\big(\varepsilon^{\frac{p(p-1)}{2}+1}\big).\end{aligned}\tag{5.196}$$

(1) Taylor expansion of each wavefunction about z_0.

(2) The matrix is a product $B\,C$ with $B_{ik}=h_i^{(k)}/k!$ and $C_{kj}=\varepsilon^k t_j^{\,k}$, $k=0,1,2,\dots$. By the Cauchy–Binet formula its determinant is a sum over p-element sets of rows k of products of minors; the set $\{0,\dots,p-1\}$ has the lowest power of ε, namely $\varepsilon^{0+1+\cdots+(p-1)}$.

(3) The first determinant is the Wronskian with row k divided by $k!$ (and transposed); the second is $\varepsilon^{p(p-1)/2}$ times a Vandermonde determinant.

For $p=2$ this is simply $h_1(z)h_2(z+\varepsilon)-h_2(z)h_1(z+\varepsilon)=\varepsilon\,(h_1h_2'-h_2h_1')+O(\varepsilon^2)=\varepsilon\,W(z)+O(\varepsilon^2)$.

Physical picture: Weierstrass points as places where zero modes pile up

(5.196) says: the leading short-distance behaviour of the zero-mode correlator, as all insertions collide, is the Wronskian. At a normal point it is the generic $\varepsilon^{p(p-1)/2}$ (the Pauli-like repulsion of p fermionic insertions); at a Weierstrass point of weight w it is suppressed by an extra ε^{w}, because a combination of zero modes vanishes to unusually high order there. For the string, the relevant ghost b has weight 2 and its zero modes are the $3p-3$ quadratic differentials; the measure on $\mathcal{M}_p$ contains $\big|\det\phi_i(z_j)\big|^2$, and its coincidence limit is the $q=2$ Wronskian, which vanishes at the quadratic Weierstrass points of (5.188). Bosonisation formulas for loop amplitudes, which trade such determinants for theta functions, keep track of these zeros explicitly (Alvarez-Gaumé, Gomez and Vafa; Verlinde and Verlinde).

Reading Nash (pp. 166–169, (5.100)–(5.111))

Nash's §7 is three pages. (i) On the sphere a pole of any order is allowed (5.100); footnote 8 switches to positive pole orders. (ii) He states the Weierstrass gap theorem: p gaps $1=n_1<\cdots<n_p<2p$, normal points with gaps $1,\dots,p$, finitely many Weierstrass points, none for $p=0,1$. (iii) He explains $n_1=1$ by the residue theorem on the $4p$-gon; we noted that the residue belongs to a 1-form and repaired the argument, and gave the degree argument, which needs no repair. (iv) He outlines the proof by Riemann–Roch: $D=nz_0$ (5.101), $\mathcal{L}(nz_0)=H^0(\mathcal{O}([nz_0]))$ (5.102), the naive count $n+1$ (5.103)–(5.104) contradicted by (5.105)–(5.106), the index $n+1-p$ (5.107)–(5.108), and Serre duality plus vanishing for $n\ge 2p-1$ (5.109)–(5.110). We completed the proof (staircase), identified the p conditions on the Laurent coefficients as residue conditions (Noether), and computed examples. (v) Finiteness (5.111) is quoted from Griffiths and Harris; we proved it with the Wronskian, a section of $K^{p(p+1)/2}$, which also gives the count p^3-p. (vi) The q-differential version with $\mathcal{O}(K^q\otimes[nz_0])$: we worked it out, and for $q=-1$ it recovers the $3p-3$ moduli as gaps of vector fields. (vii) Automorphisms permute the Weierstrass points, so they are finite in number, at most $84(p-1)$: we proved the fixed-point bound, finiteness, and the Hurwitz bound. Note that Nash's (5.111) should be read at $n=p$; for $n>p$, $\dim\mathcal{L}(nz_0)>1$ holds at every point.

Recap: Weierstrass gaps and points

- $\ell(n) = \dim \mathcal{L}(nz_0)$ counts functions with a single pole of order $\leq n$. Riemann–Roch: $\ell(n) = n + 1 - p + \kappa(n)$, where $\kappa(n)$ counts holomorphic differentials vanishing to order $\geq n$ at z_0; $\kappa(n) = 0$ for $n \geq 2p - 1$.
- The staircase $\ell(n)$ rises by 0 or 1; flat steps are the gaps. Exactly p gaps, $1 = n_1 < \cdots < n_p \leq 2p - 1$.
- Gaps = vanishing orders of holomorphic differentials +1 (residue conditions $\sum_k a_k h_{k-1} = 0$). Normal points: gaps $1, \ldots, p$. Weierstrass points: some differential vanishes to order $\geq p$; the Wronskian vanishes.
- The Wronskian is a section of $K^{p(p+1)/2}$; its zeros, weighted, number $p^3 - p$. Between $2p+2$ (hyperelliptic: the branch points) and $p^3 - p$ (generic) Weierstrass points. Plane quartics: the flexes.
- q-differentials: gaps of q-differentials are the vanishing orders of holomorphic $(1-q)$-differentials +1. For vector fields ($q = -1$) there are $3p - 3$ gaps, and the corresponding Schiffer variations form a basis of $T\mathcal{M}_p$.
- Automorphisms permute Weierstrass points; a non-trivial one fixes at most $2p + 2$ points; $|\operatorname{Aut}\Sigma| \leq 84(p-1)$ for $p \geq 2$, from Riemann–Hurwitz and the $(2, 3, 7)$ triangle.
- Physically: residue conditions are Ward identities; the Wronskian is the coincidence limit of zero-mode determinants.

Chapter summary

The chapter asked one question: *what are the possible shapes of a closed string worldsheet, and how many numbers does it take to specify one?* A "shape" here is a complex structure on a closed orientable surface of genus p, because the Polyakov action only sees the metric up to Weyl rescaling and diffeomorphisms. The answer came in two halves.

The first half (§5.1–§5.3) built the tools. A compact Riemann surface is an algebraic curve, so it can be written down as the zero set of polynomials in $\mathbb{CP}^n$. Its holomorphic line bundles are recorded by divisors, bookkeeping for zeros and poles, and their topology is the single integer $\deg D = c_1([D])$. Serre duality and the Riemann–Roch theorem count holomorphic sections. The exponential sequence and the Picard group say which line bundles exist, and Kähler geometry and the Hodge decomposition tie the complex structure to the topology.

The second half (§5.4–§5.7) used the tools. The space of shapes is the Teichmüller space $\mathcal{T}_p$, and dividing by the large diffeomorphisms gives the moduli space $\mathcal{M}_p$. Its dimension is computed by one application of Riemann–Roch, to the quadratic differentials. The Weierstrass points are the places where Riemann–Roch "jumps", and they make the automorphism group finite.

The whole second half fits into one labelled chain, which is worth memorising because every step is one idea of the chapter. For $p \geq 2$:

$$\begin{aligned}\dim_{\mathbb{C}} \mathcal{M}_p &\overset{(1)}{=} \dim_{\mathbb{C}} \frac{\{\text{Beltrami differentials } \mu\, \partial_z \otimes \mathrm{d}\bar{z}\}}{\{\bar{\partial} V : V \text{ a vector field}\}} \overset{(2)}{=} \dim_{\mathbb{C}} H^{0,1}_{\bar{\partial}}(\Sigma, K^*) \\ &\overset{(3)}{=} \dim_{\mathbb{C}} H^0\big(\Sigma, \mathcal{O}(K^2)\big) \overset{(4)}{=} \operatorname{index} \bar{\partial}_{K^2} \\ &\overset{(5)}{=} \deg K^2 + 1 - p \overset{(6)}{=} 2(2p-2) + 1 - p = 3p - 3. \end{aligned} \tag{5.197}$$

(1) A tangent vector to the space of shapes is a change $\delta\mu$ of the Beltrami coefficient of $ds^2 = \lambda\,|dz + \mu\,d\bar{z}|^2$ (Weyl rescalings change only λ), modulo the changes $\delta\mu = 2\,\partial_{\bar{z}} V^z$ produced by infinitesimal diffeomorphisms (Sections 5.6.3 and 5.6.4).
(2) That quotient is by definition the Dolbeault cohomology of $\bar{\partial}$ acting on sections of $K^* = T\Sigma$; every $(0,1)$-form on a curve is $\bar{\partial}$-closed (Section 5.6.5).
(3) Serre duality pairs $H^{0,1}(K^*)$ with the holomorphic sections of $K \otimes (K^*)^* = K^2$: the cotangent space of $\mathcal{M}_p$ is the space of holomorphic quadratic differentials (Section 5.6.6).
(4) The cokernel of $\bar{\partial}_{K^2}$ is dual to the holomorphic vector fields, and there are none for $p \geq 2$ (vanishing theorem, Section 5.6.9), so the kernel is the whole index.
(5) Riemann–Roch, i.e. the index theorem for $\bar{\partial}$ on a line bundle over a curve (Section 5.6.8).
(6) $\deg K = 2p - 2$ by Gauss–Bonnet (Example 5.91).

For $p = 0$ and $p = 1$ step (4) fails: there are 3 and 1 holomorphic vector fields (conformal Killing vectors), the index is -3 and 0, and the true dimensions are 0 and 1 (Section 5.6.11).

Figure 5.62 draws the same argument as a tower of spaces. Each level is obtained from the one above by dividing out a symmetry, and each quotient is "measured" by a piece of the machinery of the chapter.

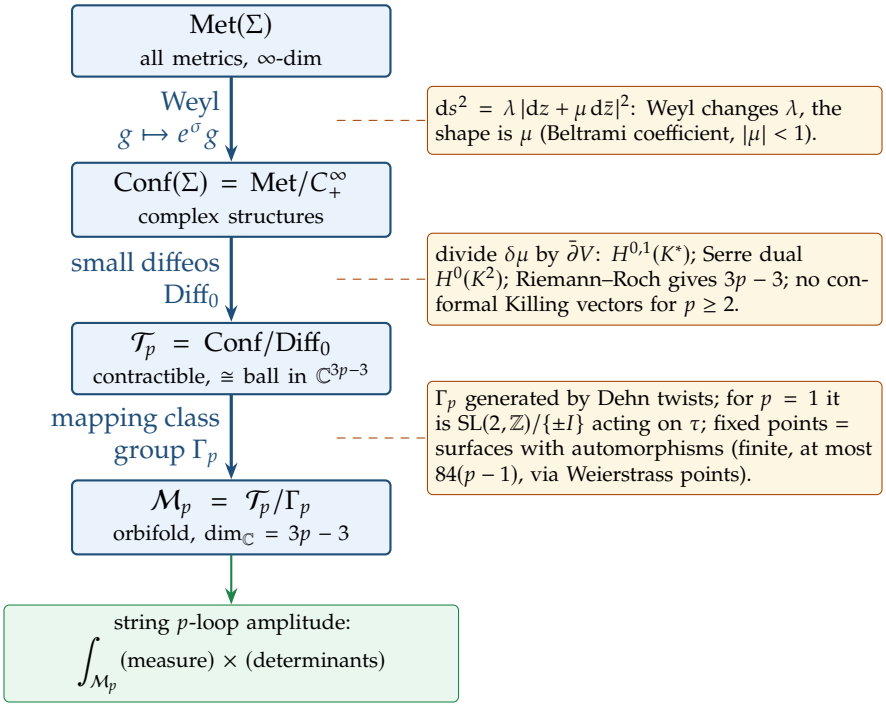


Figure 5.62: The chapter's second half as a tower of quotients. Read down the left: at each arrow a symmetry of the Polyakov path integral is divided out. Read the orange boxes: the tool that measures each quotient. What is left at the bottom is a finite-dimensional orbifold, and the string path integral at p loops becomes an ordinary integral over it (Chapter 9).

The rest of this summary has five parts: a table of every concept of the chapter with its operational meaning and where it returns; the three genus regimes side by side; the important numbers of a genus-p surface; a dictionary to physics with a map of where the chapter goes next; and a self-test.

Every concept, how to use it, and where it returns

The tables follow Nash's sections. The middle column is the *operational* meaning: what we actually do to compute or test the thing. The right column says where in the book the idea comes back. Sections §5.1–§5.3 are the first part of this chapter; §5.4–§5.7 are Sections 5.4 to 5.7.

Nash §1: algebraic varieties

Concept	Operational meaning	Returns in
homogeneous polynomial	every monomial has the same degree d, so $P(\lambda z) = \lambda^d P(z)$ and "$P = 0$" is a well-defined condition on lines through the origin	§5.2, Example 5.103
$\mathbb{CP}^n$	lines in $\mathbb{C}^{n+1}$; charts $U_i = \{z_i \neq 0\}$ with coordinates z_j/z_i, transition functions ratios of coordinates; a compact complex n-manifold	Chapter 8 (twistors, $\mathbb{CP}^1$ models), Chapter 6 (flag manifolds)
projective variety	common zero set of homogeneous $P_1, \dots, P_k$ in $\mathbb{CP}^n$; draw its real points in an affine chart	§5.2 (curves), Section 5.7.8
singular point	a point where the Jacobian $\left[\partial P_i/\partial z_j\right]$ has rank $< k$; if there are none the variety is a complex submanifold of dimension $n - k$	Example 5.104, Chapter 11 (nodal surfaces)
Chow's theorem	a closed complex submanifold of $\mathbb{CP}^n$ is automatically cut out by polynomials: "analytic = algebraic"	§5.2
Kodaira embedding	a compact complex manifold embeds in some $\mathbb{CP}^N$ iff it carries a closed positive $(1,1)$-form with rational (hence, after scaling, integral) class	§5.3 (Kähler), Chapter 10
degree–genus formula	a smooth plane curve of degree d has genus $\frac{1}{2}(d-1)(d-2)$: cubics are tori, quartics have genus 3	Section 5.7.8

Nash §2: Riemann surfaces and divisors

Concept	Operational meaning	Returns in
compact Riemann surface Σ_p	a surface with holomorphic transition functions; topologically a sphere with p handles, $\chi = 2 - 2p$; always an algebraic curve	everywhere below, Chapter 9, Chapter 11
the three regimes	$p = 0$: $\mathbb{CP}^1$; $p = 1$: the cubic $y^2 = x(x-1)(x-\lambda)$, i.e. $\mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$; $p \geq 2$: $3p - 3$ complex moduli	Sections 5.4 and 5.5
holomorphic line bundle	cover by charts, give nowhere-zero holomorphic transition functions $g_{\alpha\beta}$; sections are local holomorphic s_α with $s_\alpha = g_{\alpha\beta} s_\beta$	§5.3, Section 5.6.7
$O(n)$ on $\mathbb{CP}^1$	transition function z^n; holomorphic sections are polynomials of degree $\leq n$, so $n+1$ of them for $n \geq 0$	Example 5.92, Chapter 6 (Borel–Weil)
canonical bundle K	$\Lambda^n T^*M$; on a curve $K = T^*\Sigma$, sections are holomorphic 1-forms $h(z)\,\mathrm{d}z$; $\deg K = 2p - 2$	Section 5.6, Chapter 9, Chapter 10
q-differential	a section of K^q, locally $\phi(z)\,\mathrm{d}z^q$ with $\tilde{\phi} = \phi\,(z')^q$; $q = -1, 0, 1, 2$: vector fields, functions, 1-forms, quadratic differentials	Sections 5.6.6 and 5.7.9, Chapter 11 (primary fields)
divisor $D = \sum n_i P_i$	list the zeros ($n_i > 0$) and poles ($n_i < 0$) of a meromorphic section with their orders; $\deg D = \sum n_i$	Section 5.7.4, Chapter 11
$\deg(\mathrm{div}\, f) = 0$	$\frac{1}{2\pi i}\oint \mathrm{d}f/f$ around the boundary of the cut-open $4p$-gon vanishes because the sides cancel in pairs	Section 5.7.2

Nash §2 (continued): divisors, homology and periods

Concept	Operational meaning	Returns in
linear equivalence	$D_1 \sim D_2$ iff $D_1 - D_2 = \operatorname{div} f$; divisors of different meromorphic sections of one bundle are equivalent	Section 5.7.4
$[D]$ and $c_1([D]) = \deg D$	build transition functions f_α / f_β from local equations of D; its first Chern number is the degree (flux = number of zeros)	Eq. (5.166), Chapter 8 (monopole)
sections and degree	a non-zero holomorphic section forces $\deg \geq 0$ (and a trivial bundle if $\deg = 0$); the converse needs Riemann–Roch ($\deg \geq p$ suffices)	Section 5.6.9
$\mathrm{Div} = H^0(\mathcal{M}^*/\mathcal{O}^*)$	a divisor is a local meromorphic function up to local holomorphic units: the sheaf viewpoint	§5.3 (Picard)
higher-dimensional divisors	formal sums of codimension-one subvarieties; where meromorphic functions have zeros and poles	Chapter 11 (compactification divisor)
a_i, b_i and intersection numbers	$H_1(\Sigma_p;\mathbb{Z}) = \mathbb{Z}^{2p}$ with $a_i \cdot b_j = \delta_{ij}$, $a \cdot a = b \cdot b = 0$; the $4p$-gon $a_1 b_1 a_1^{-1} b_1^{-1} \cdots$	Example 5.81, Section 5.5.7
holomorphic differentials	p independent holomorphic 1-forms ω_i (first kind), normalised by $\oint_{a_i} \omega_j = \delta_{ij}$	Sections 5.7.6 and 5.7.7
period matrix Ω	$\Omega_{ij} = \oint_{b_i} \omega_j$; symmetric with $\operatorname{Im}\Omega > 0$ (Riemann bilinear relations); for $p = 1$ it is τ	Section 5.5.3, Chapter 9, Chapter 10
Jacobian $J(\Sigma) = \mathbb{C}^p/\Lambda$	the lattice of periods; the Abel–Jacobi map $P \mapsto \int^P \omega$; Abel: D is a divisor of a function iff $\deg D = 0$ and its image is 0; Torelli: Ω determines Σ	§5.3 (Pic_0), Chapter 10

Nash §3: Serre duality, line bundles and Kähler manifolds

Concept	Operational meaning	Returns in
(p,q)-forms, ∂, $\bar\partial$	split $\mathrm{d} = \partial + \bar\partial$ by counting $\mathrm{d}z$'s and $\mathrm{d}\bar z$'s; $\bar\partial f = 0$ is the Cauchy–Riemann equation	Section 5.6.5, Chapter 4
Dolbeault cohomology	$H^{p,q}_{\bar\partial}(E) = \operatorname{Ker}\bar\partial/\operatorname{Im}\bar\partial$; isomorphic to sheaf cohomology $H^q(M,\Omega^p(E))$	Eq. (5.133), Chapter 3
Serre duality	$H^q(\Omega^p(E)) \cong H^{n-q}(\Omega^{n-p}(E^*))^*$ by integrating the wedge product; on a curve $H^1(\mathcal{O}(L)) \cong H^0(\mathcal{O}(K\otimes L^*))^*$	Section 5.6.6, Section 5.7.4, Chapter 11
Riemann–Roch	$h^0(L) - h^0(K\otimes L^*) = \deg L + 1 - p$; the index theorem for $\bar\partial_L$	Sections 5.6.8 and 5.7.4, Chapter 9
line bundle as a cocycle	transition functions with $g_{\alpha\beta}g_{\beta\gamma} = g_{\alpha\gamma}$ define a class in $H^1(M;\mathcal{E}^*)$	Chapter 10 (determinant bundles)
exponential sequence	$0 \to \mathbb{Z} \to \mathcal{E} \to \mathcal{E}^* \to 0$ with $f \mapsto e^{2\pi i f}$; the connecting map is c_1; smooth line bundles $\leftrightarrow H^2(M;\mathbb{Z})$	Chapter 8, Chapter 10
Picard group	$\mathrm{Pic}(M) = H^1(M;\mathcal{O}^*)$: holomorphic line bundles; $\mathrm{Pic}_0 = H^1(\mathcal{O})/H^1(\mathbb{Z})$, the Jacobian for a curve; flat U(1) bundles, Wilson lines	Chapter 6 (Borel–Weil), Chapter 10
Kähler manifold	Hermitian $g_{i\bar\jmath}$ with $\omega = \frac{i}{2}g_{i\bar\jmath}\mathrm{d}z^i\wedge\mathrm{d}\bar z^j$ closed; locally $g_{i\bar\jmath} = \partial_i\partial_{\bar\jmath}K$	Section 5.5.1 (Weil–Petersson), Chapter 9, Chapter 10
Fubini–Study metric	$\omega = \frac{i}{2}\partial\bar\partial\ln(1+\lvert z\rvert^2)$ on $\mathbb{CP}^n$; on $\mathbb{CP}^1$ the round sphere	Chapter 8, Chapter 6
submanifolds are Kähler	restrict ω; closedness is inherited, so every projective variety is Kähler	Section 5.7.8
Kähler Hodge theory	$\Delta_d = 2\Delta_{\bar\partial}$, so harmonic forms split by type: $b_k = \sum_{p+q=k} h^{p,q}$, $h^{p,q} = h^{q,p}$, b_{odd} even, $b_2 > 0$	Chapter 7 (SUSY QM), Chapter 11

Nash §4: the Teichmüller space $\mathcal{T}_p$ (Section 5.4)

Concept	Operational meaning	Returns in
metric → complex structure	write $\mathrm{d}s^2 = A\mathrm{d}x^2 + 2B\mathrm{d}x\mathrm{d}y + C\mathrm{d}y^2$ as $\lambda\,\lvert\mathrm{d}z + \mu\mathrm{d}\bar{z}\rvert^2$; solve for $\lambda > 0$ and $\lvert\mu\rvert < 1$ (Eq. (5.79)); μ is the shape	Section 5.6, Chapter 9
Beltrami equation	$f_{\bar{z}} = \mu f_z$: a solution f is a holomorphic (isothermal) coordinate for the metric; infinitesimal circles are ellipses of axis ratio $\frac{1+\lvert\mu\rvert}{1-\lvert\mu\rvert}$	Section 5.6.2
conformal class, Conf	Met/C^∞_+: metrics up to Weyl rescaling $g \mapsto e^\sigma g$; one-to-one with complex structures (given an orientation)	Chapter 9, Chapter 10 (Weyl anomaly)
Diff^+, Diff_0	orientation-preserving diffeomorphisms; those isotopic to the identity ("small"); reversing orientation conjugates the complex structure	Section 5.5
conformal Killing vector	$\mathcal{L}_V g = Cg$, i.e. $\partial_{\bar{z}} V^z = 0$: holomorphic vector fields; 3, 1, 0 of them for $p = 0, 1, \geq 2$ (Table 5.1)	Section 5.6.11, Chapter 9 (ghost zero modes)
uniformisation	$\Sigma = \tilde{\Sigma}/\pi_1$ with $\tilde{\Sigma} = S^2$, $\mathbb{C}$ or $\mathbb{H}$; each conformal class has a constant-curvature metric of sign $\operatorname{sgn}\chi$ (Gauss–Bonnet)	Section 5.5.6, Section 5.7.11
$\mathrm{Met}_{\mathrm{const}}$ and $\mathcal{T}_p$	pick the constant-curvature representative (area 1 for the torus); $\mathcal{T}_p = \mathrm{Conf}/\mathrm{Diff}_0 = \mathrm{Met}_{\mathrm{const}}/\mathrm{Diff}_0$	Chapter 9
$\mathcal{T}_1 = \mathbb{C}^+$	flat unit-area metrics on T^2 modulo small diffeomorphisms $\leftrightarrow \tau$ in the upper half plane $\leftrightarrow \mathrm{SL}(2,\mathbb{R})/\mathrm{SO}(2)$ (Eq. (5.98))	Section 5.5, Chapter 11

Nash §5: the moduli space $\mathcal{M}_p$ (Section 5.5)

Concept	Operational meaning	Returns in
mapping class group Γ_p	$\mathrm{Diff}^+/\mathrm{Diff}_0$: diffeomorphisms up to isotopy; for the torus the integer matrices $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ of determinant 1 acting on H_1	Chapter 9, Chapter 12
$\mathcal{M}_p = \mathcal{T}_p/\Gamma_p$	shapes counted once; $\mathrm{Met}_{\mathrm{const}}/\mathrm{Diff}^+$	Chapter 9, Chapter 11
orbifold	quotient by a group acting with finite stabilisers; locally $\mathbb{C}^n/G$; a cone point of angle $2\pi/\lvert G\rvert$ (Figure 5.41)	Section 5.7.11, Chapter 11
modular group	$\mathrm{SL}(2,\mathbb{Z})/\{\pm I\}$ acting by $\tau \mapsto \frac{a\tau+b}{c\tau+d}$; generated by $S : \tau \mapsto -1/\tau$, $T : \tau \mapsto \tau + 1$	Chapter 11 (modular invariance), Chapter 12
fundamental domain F	$\lvert\Re\tau\rvert \leq \frac{1}{2}$, $\lvert\tau\rvert \geq 1$; reduce any τ into F by the S/T algorithm (Example 5.76); orbifold points i, $e^{i\pi/3}$ and a cusp at $i\infty$	Chapter 9, Chapter 11
invariant measure	$\mathrm{d}^2\tau/\tau_2^2$ (hyperbolic area); $\mathrm{vol}(F) = \pi/3$ (Example 5.79); the one-loop amplitude $\int_F \frac{\mathrm{d}^2\tau}{\tau_2^2}\mathcal{Z}$	Chapter 9, Chapter 10
modular forms	$f(\gamma\tau) = (c\tau + d)^q f(\tau)$: q-differentials on $\mathcal{M}_1$; Eisenstein series G_4	Example 5.90, Chapter 11
Fuchsian group	a discrete subgroup $G \subset \mathrm{SL}(2,\mathbb{R})/\{\pm I\}$ acting freely on $\mathbb{H}$; $\Sigma_p = \mathbb{H}/G$ for $p \geq 2$ with a $4p$-gon fundamental domain	Section 5.7.11
topology of $\mathcal{M}_p$	$\mathcal{T}_p$ is contractible and is the orbifold universal cover; $\pi_1^{\mathrm{orb}}(\mathcal{M}_p) = \Gamma_p$	Chapter 10 (global anomalies)
Dehn twist	cut along a simple closed curve, twist by 2π, reglue; on T^2 the twists about a and b are T and a conjugate of T; they generate Γ_p	Chapter 12 (surgery, framings)
Weil–Petersson metric	$\langle\mu,\nu\rangle = \int \mu\bar{\nu}\, g_{z\bar{z}}\, \mathrm{d}^2 z$ (up to normalisation) on Beltrami differentials; Kähler on $\mathcal{T}_p$	Chapter 9

Nash §6: the dimension of the moduli space (Section 5.6)

Concept	Operational meaning	Returns in
transformation laws of λ, μ	under $z \mapsto w$ holomorphic, $\mu \mapsto \mu\, w'/\overline{w'}$ and $\lambda \mapsto \lambda\, \lvert w' \rvert^{-2}$; so μ is a section of $K^{-1} \otimes \bar{K}$ (Eq. (5.114))	Chapter 9
Beltrami differential	$\mu\, \partial_z \otimes \mathrm{d}\bar{z}$; its variation $\delta\mu = \delta g_{\bar{z}\bar{z}}/g_{z\bar{z}}$ is a tangent vector to the space of shapes (Eq. (5.120))	Chapter 9
diffeomorphism directions	$\delta g = \mathcal{L}_V g$ gives $\delta\mu = 2\partial_{\bar{z}} V^z$ (Eq. (5.130)): the "pure gauge" deformations	Chapter 9 (Faddeev–Popov)
$T_{[g]}\mathcal{M}_p = H^{0,1}(K^*)$	Beltrami differentials modulo $\bar{\partial}$(vector fields); represented by harmonic Beltrami differentials $\bar{\phi}/g_{z\bar{z}}$	Chapter 9
quadratic differentials	holomorphic sections $\phi(z)\mathrm{d}z^2$ of K^2; $T^*\mathcal{M}_p = H^0(K^2)$ via the pairing $\int \mu\phi\, \mathrm{d}^2z$ (Eq. (5.138)); explicit for $p = 0, 1, 2$	Chapter 9 (b-ghost zero modes)
index of $\bar{\partial}_{K^2}$	Riemann–Roch: $\deg K^2 + 1 - p = 3p - 3$; equivalently index $= \int \mathrm{ch}(K^2)\, \mathrm{td}(T\Sigma)$ (Eq. (5.149))	Chapter 9, Chapter 10 (ghost number anomaly)
vanishing theorems	a bundle of negative degree has no holomorphic sections; hence no holomorphic vector fields for $p \geq 2$ and $H^1(K^2) = 0$; Weitzenböck/Landau-level picture	Chapter 6 (Borel–Weil), Chapter 9
$\dim_{\mathbb{C}} \mathcal{M}_p$	$0, 1, 3p - 3$ for $p = 0, 1, \geq 2$; in general $\dim \mathcal{M}_p - \dim(\mathrm{CKV}) = 3p - 3$ (Eq. (5.150))	Chapter 9, Chapter 10 (critical dimension)
other counts of $3p - 3$	branched covers of $\mathbb{CP}^1$ (Riemann), pants decompositions ($3p - 3$ lengths and twists), punctures ($3p - 3 + n$), vector-field gaps	Sections 5.6.12 and 5.7.10, Chapter 11

Nash §7: Weierstrass gaps and points (Section 5.7)

Concept	Operational meaning	Returns in
$\mathcal{L}(nz_0)$, $\ell(n)$	meromorphic functions with a single pole, of order $\le n$, at z_0; $\cong H^0(\mathcal{O}([nz_0]))$ (Eq. (5.166))	Chapter 11
sphere: no restriction	on $\mathbb{CP}^1$ the function $(z-z_0)^{-n}$ exists for every n; $\ell(n) = n+1$ (Eq. (5.163))	Section 5.7.1
no single simple pole	for $p \ge 1$ a function with one simple pole would be a degree-one map to $\mathbb{CP}^1$, an isomorphism; residue theorem for $f\omega$	Section 5.7.2
gap, gap theorem	n is a gap if $\ell(n) = \ell(n-1)$; there are exactly p gaps, $1 = n_1 < \cdots < n_p \le 2p-1$ (the staircase, Figure 5.56)	Chapter 11 (correlator constraints)
Riemann–Roch for $\ell(n)$	$\ell(n) = n+1-p+\kappa(n)$ with $\kappa(n)$ the number of holomorphic differentials vanishing to order $\ge n$ at z_0; $\kappa = 0$ for $n \ge 2p-1$ (Eq. (5.176))	Section 5.7.10
residue conditions	$f = \sum_k a_k (z-z_0)^{-k} + \dots$ exists iff $\sum_k a_k h_{k-1} = 0$ for each differential $h\,\mathrm{d}z$: gaps = vanishing orders +1	Chapter 11 (Ward identities)
normal and Weierstrass points	normal: gaps $1, \dots, p$; Weierstrass: a differential vanishes to order $\ge p$; weight $w = \sum_i (n_i - i)$	Section 5.7.11
Wronskian	$W = \det[h_i^{(k)}]$, a section of $K^{p(p+1)/2}$ vanishing to order w; so $\sum w = p^3 - p$ and there are between $2p+2$ and p^3-p Weierstrass points	Section 5.7.12
examples	torus: none; hyperelliptic: the $2p+2$ branch points, weight $\frac{p(p-1)}{2}$; plane quartics: flexes (24 ordinary or 12 hyperflexes)	Section 5.7.8
q-differential gaps	$\ell_q(n) = (2q-1)(p-1) + n + \kappa_{1-q}(n)$; number of q-Weierstrass points $p(p-1)^2(2q-1)^2$ (Eq. (5.188))	Chapter 11
vector-field gaps	for $q=-1$ there are $3p-3$ forbidden pole orders; their Schiffer variations span $T\mathcal{M}_p$	Chapter 9
automorphisms	permute Weierstrass points, fix $\le 2p+2$ points if non-trivial; hence finite, and $\lvert\mathrm{Aut}\,\Sigma\rvert \le 84(p-1)$ (Hurwitz; equality for the Klein quartic, 168)	Section 5.5.1 (orbifold points), Chapter 9
zero-mode determinants	$\langle b(z_1)\cdots b(z_p)\rangle \propto \det h_i(z_j)$; its coincidence limit is the Wronskian (Eq. (5.196))	Chapter 9, Chapter 11

The three genus regimes side by side

Almost every statement of the chapter splits into the cases $p=0$, $p=1$ and $p \ge 2$. The split is always for the same reason: the sign of $\chi = 2-2p = \deg K^*$, which decides the curvature of the uniformising metric and whether holomorphic vector fields exist.

	$p = 0$	$p = 1$	$p \geq 2$
model	$\mathbb{CP}^1$, $y = \text{const}$	$y^2 = x(x-1)(x-\lambda)$, $\mathbb{C}/(\mathbb{Z}+\tau\mathbb{Z})$	$y^2 =$ degree $2p+2$ (hyperelliptic), plane quartic ($p=3$), $\mathbb{H}/G$
universal cover, curvature	S^2, $+1$	$\mathbb{C}$, 0	$\mathbb{H}$, -1
$\deg K = 2p-2$	-2	0	> 0
holomorphic differentials $h^0(K)$	0	1 (dz)	p
conformal Killing vectors $h^0(K^*)$	3 ($\mathfrak{sl}(2,\mathbb{C})$)	1 (∂_z)	0
quadratic differentials $h^0(K^2)$	0	1 (dz^2)	$3p-3$
index $\bar\partial_{K^2} = 3p-3$	-3	0	$3p-3$
$\mathcal{T}_p$	point	$\mathbb{C}^+$	ball in $\mathbb{C}^{3p-3}$
Γ_p	trivial	$\mathrm{SL}(2,\mathbb{Z})/\{\pm I\}$	generated by Dehn twists
$\mathcal{M}_p$	point	F (Figure 5.44)	orbifold of $\dim_{\mathbb{C}} 3p-3$
$\mathrm{Aut}\,\Sigma$	$\mathrm{SL}(2,\mathbb{C})/\{\pm I\}$	$T^2\rtimes$ (finite)	finite, $\leq 84(p-1)$
Weierstrass points	none	none	$2p+2$ to p^3-p
string amplitude	tree level: fix 3 points	one loop: $\int_F d^2\tau/\tau_2^2$	p loops: $\int_{\mathcal{M}_p}$

Key idea: One sign decides everything

The sign of $\deg T\Sigma = 2-2p$ controls the whole table. If it is positive, $T\Sigma$ has holomorphic sections (a group of automorphisms that is too big and fixes 3 points), and there are no deformations. If it is zero, there is one of each. If it is negative, there are no holomorphic vector fields, automorphisms are finite, and Riemann–Roch counts the deformations exactly: $3p-3$.

The numbers of a genus-p surface

It helps to see the chapter's integers together. Each is a degree or a dimension, and each follows from Riemann–Roch plus Gauss–Bonnet. Figure 5.63 plots them for small p.

quantity	value	where
Euler characteristic χ	$2-2p$	§5.2
$\deg K$, zeros of a holomorphic differential	$2p-2$	Example 5.91
holomorphic differentials $h^0(K)$	p	§5.3
real rank of $H_1(\Sigma;\mathbb{Z})$	$2p$	§5.2
$\dim_{\mathbb{C}} \mathcal{M}_p = h^0(K^2)$	$3p-3$	Eq. (5.157)
$h^0(K^q)$, $q \geq 2$	$(2q-1)(p-1)$	Eq. (5.187)
Weierstrass gaps at any point	p, all $\leq 2p-1$	Section 5.7.5
total Weierstrass weight	p^3-p	Eq. (5.186)
Weierstrass points on a hyperelliptic surface	$2p+2$	Example 5.102
$\lvert\mathrm{Aut}\,\Sigma\rvert$	$\leq 84(p-1)$	Eq. (5.194)
area of the constant-curvature ($K=-1$) metric	$4\pi(p-1)$	Eq. (5.92)

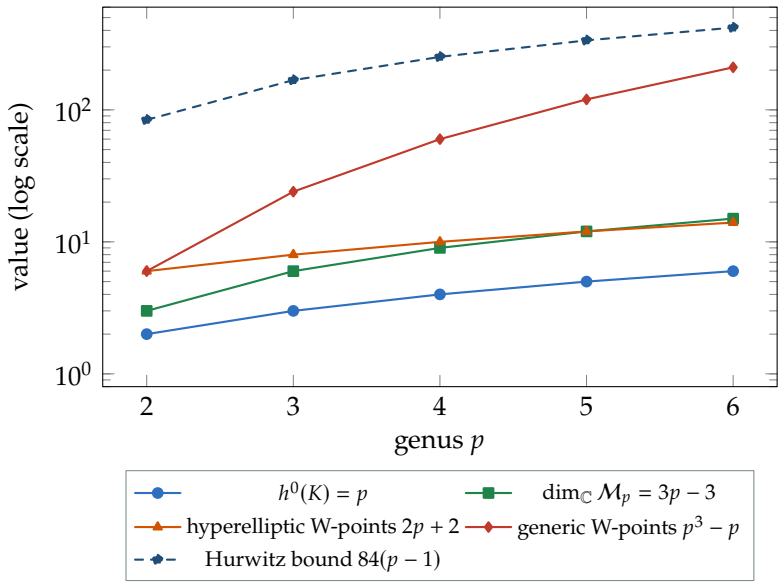

Figure 5.63: The integers of a genus-p surface on a log scale. The linear quantities (p, $3p - 3$, $2p + 2$) are dimensions and degrees. The number of Weierstrass points grows like p^3 because the Wronskian is a section of the high power $K^{p(p+1)/2}$. The Hurwitz bound stays above the generic Weierstrass count only for small p; for $p \geq 9$ the cubic overtakes the linear bound, which is consistent because a generic surface has no automorphisms at all.

Worked example 5.109: Checking the table at genus 2

Take $y^2 = \prod_{i=1}^{6}(x - e_i)$. The holomorphic differentials are $\mathrm{d}x/y$ and $x\,\mathrm{d}x/y$ (Example 5.102), so $h^0(K) = 2 = p$. The quadratic differentials are products of these, $\{\mathrm{d}x^2/y^2,\ x\,\mathrm{d}x^2/y^2,\ x^2\,\mathrm{d}x^2/y^2\}$, and the count agrees with the table:

$$h^0(K^2) \overset{(1)}{=} \deg K^2 + 1 - p \overset{(2)}{=} 4 + 1 - 2 = 3 \overset{(3)}{=} 6 - 3.$$

(1) Riemann–Roch plus vanishing of $H^1(K^2)$ (Section 5.6.9).
(2) $\deg K = 2p - 2 = 2$.
(3) Three complex moduli: the six branch points e_i modulo the three complex parameters of $\mathrm{SL}(2, \mathbb{C})$ acting on x.

The Weierstrass points are the six branch points, each of weight $\frac{p(p-1)}{2} = 1$, total $6 = 2^3 - 2$, so the generic count $p^3 - p$ and the hyperelliptic count $2p + 2$ coincide. The hyperelliptic involution $(x, y) \mapsto (x, -y)$ is an automorphism fixing exactly these six points, the maximum $2p + 2$ allowed, and $|\operatorname{Aut}\Sigma| \leq 84$ is respected (the actual maximum at genus 2 is 48).

Dictionary to physics

The left column is the mathematics of the chapter; the right column is the name the same object carries in string theory and conformal field theory, where Chapters 9 and 11 will use it.

Dictionary: Chapter V for string theorists

Mathematics	Physics
Σ_p, genus p	closed-string worldsheet at p loops
conformal class, Beltrami coefficient μ	the metric modulo Weyl: what the classical Polyakov action sees
Diff_0, $\mathcal{L}_V g$	gauge (reparametrisation) symmetry and its Faddeev–Popov directions
Γ_p, $\mathrm{SL}(2,\mathbb{Z})$	large diffeomorphisms; modular invariance of the torus partition function
$\mathcal{T}_p$, $\mathcal{M}_p$	the integration region of the p-loop amplitude: $\mathcal{T}_p$ overcounts, $\mathcal{M}_p$ counts once
Beltrami differentials $H^{0,1}(K^*)$	moduli insertions $\int \mu\, T$ / $\int \mu\, b$ in the measure
quadratic differentials $H^0(K^2)$	zero modes of the b ghost
conformal Killing vectors $H^0(K^*)$	zero modes of the c ghost; "fix three vertex operators on the sphere"
index $\bar\partial_{K^2} = 3p - 3$	ghost number anomaly: $\#b$ zero modes $-\#c$ zero modes
q-differential	a primary field of conformal weight $(q, 0)$
modular form of weight q	a torus quantity transforming like $(c\tau + d)^q$
$\mathrm{d}^2\tau/\tau_2^2$ on F	one-loop measure; the cusp $\tau_2 \to \infty$ is the infrared (long, thin torus)
Dehn twist	large diffeomorphism; in Chapter 12 a change of framing
residue conditions, gap theorem	Ward identities: which pole structures a correlator may have
Wronskian, Weierstrass points	coincidence limit of zero-mode determinants
Kähler, Weil–Petersson	$\mathcal{M}_p$ carries a natural Kähler metric; holomorphic factorisation of Z_p

Where Chapter V goes next

Figure 5.64 shows where the ideas of this chapter are used later. The main customer is Chapter 9, where the Polyakov integral over metrics is reduced, using exactly the tower of Figure 5.62, to a finite-dimensional integral over $\mathcal{M}_p$. The zero modes of $\bar\partial_{K^2}$ and $\bar\partial_{K^*}$ counted here become the Faddeev–Popov ghost zero modes, and the Weil–Petersson metric on $\mathcal{T}_p$ is built from the Beltrami and quadratic differentials of Section 5.6. Chapter 10 uses the determinant line bundle over $\mathcal{M}_p$ and Riemann–Roch (the Mumford isomorphism) to find the critical dimension 26, and the Kähler structure of $\mathcal{T}_p$ to explain why the partition function is the modulus squared of a holomorphic function (Belavin–Knizhnik). Chapter 11 uses modular invariance of the torus partition function, the Weierstrass gap theorem as a constraint on correlation functions, Serre duality to turn the stress tensor into a connection on a line bundle over $\mathcal{M}_p$, and the compactified moduli space $\overline{\mathcal{M}}_p$ whose boundary, the compactification divisor, consists of surfaces with nodes. Chapter 6 uses the Kodaira vanishing theorem and the exponential sequence on the Kähler manifold G/T to prove the Borel–Weil theorem. Chapter 8 calls the analogy between instanton moduli spaces and Teichmüller theory explicit: in both cases the moduli are counted by the index of a linearised operator. Chapter 12 uses Dehn twists and the mapping class group in surgery and in the modular functor.

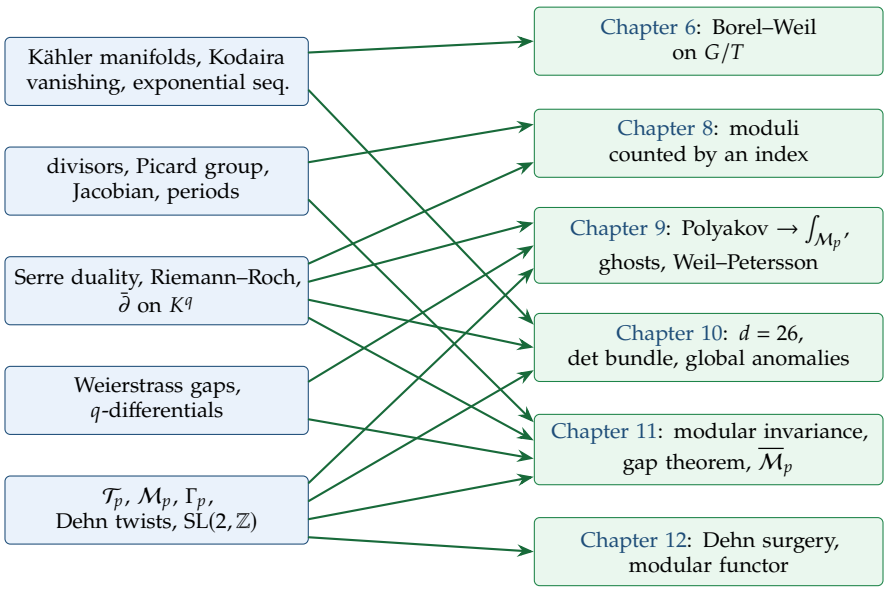

Figure 5.64: Where the chapter goes. Blue: the mathematics of Chapter V. Green: the later chapters that use it. Every route to physics passes through counting holomorphic sections (Riemann–Roch) or through dividing by diffeomorphisms (the tower of Figure 5.62).

Self-test

Try it: Ten questions on Chapter V

1. Why is $x^3 + y^2z - z^3 = 0$ a well-defined curve in $\mathbb{CP}^2$ but $x^3 + y^2 - z = 0$ not?
   Answer: the first is homogeneous of degree 3, so its zero set is a union of lines through 0; the second changes under $(x, y, z) \mapsto \lambda(x, y, z)$ by different powers of λ.

2. A meromorphic function on a torus has poles of order 2 at 0 and nowhere else. How many zeros does it have?
   Answer: two, counted with multiplicity, since $\deg \operatorname{div} f = 0$. ($\wp(z) - c$ is such a function.)

3. What is $\dim H^0(\mathbb{CP}^1, \mathcal{O}(n))$ for $n \geq -1$, and how does Riemann–Roch confirm it?
   Answer: $n + 1$; $\deg +1 - p = n + 1$, and $H^1 = 0$ because its dual $H^0(\mathcal{O}(-2 - n))$ vanishes for $n \geq -1$.

4. Write the metric $\mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}x\,\mathrm{d}y$ as $\lambda\,|\mathrm{d}z + \mu\,\mathrm{d}\bar z|^2$.
   Answer: $A = C = 1$, $B = \frac{1}{2}$, so $2\sqrt{AC - B^2} = \sqrt{3}$, and Eq. (5.79) gives

$$\mu = \frac{A - C + 2iB}{A + C + 2\sqrt{AC - B^2}} = \frac{i}{2 + \sqrt{3}}, \qquad \lambda = \frac{A + C + 2\sqrt{AC - B^2}}{4} = \frac{2 + \sqrt{3}}{4}.$$

   Check: $\lambda(1 + |\mu|^2) = \frac{2+\sqrt{3}}{4} \cdot 4(2 - \sqrt{3}) = 1 = \frac{A+C}{2}$.

5. Reduce $\tau = \frac{3}{10} + \frac{i}{10}$ into the fundamental domain.
   Answer: S: $-1/\tau = -3 + i$; T^3: i. So $\tau \sim i$, the square torus, an orbifold point of order 2.

6. Why does the torus have a 1-dimensional moduli space although the index of $\bar\partial_{K^2}$ is 0?
   Answer: index $= h^0(K^2) - h^0(K^*) = 1 - 1$; the one holomorphic vector field ∂_z cancels the one quadratic differential $\mathrm{d}z^2$ in the index, but not in the dimension.

7. How many real parameters does a pants decomposition of a genus-4 surface give?
Answer: $2p-2=6$ pairs of pants, $3p-3=9$ cuffs, a length and a twist each: $18=6p-6$ real, 9 complex.

8. List the gap sequences at a normal point and at a branch point of a genus-3 hyperelliptic surface.
Answer: $\{1,2,3\}$ and $\{1,3,5\}$; the weight of the latter is $0+1+2=3=\frac{p(p-1)}{2}$.

9. Verify that 8 hyperelliptic Weierstrass points of weight 3 give the total p^3-p at genus 3.
Answer: $8\times 3=24=27-3$.

10. Why must an automorphism group of a genus-$p\geq 2$ surface be finite, in one sentence?
Answer: it permutes the finitely many Weierstrass points, and an automorphism fixing more than $2p+2$ points is the identity, so the group maps to a finite permutation group with a kernel of order at most 2 (the hyperelliptic involution).

Recap: Chapter V in five sentences

- A compact Riemann surface is an algebraic curve; its line bundles are divisors up to equivalence, and their topology is $\deg = c_1$.
- Riemann–Roch $h^0(L)-h^0(K\otimes L^*)=\deg L+1-p$, with Serre duality and vanishing for negative degree, counts every space of holomorphic objects we met.
- The space of worldsheet shapes is $\mathcal{M}_p=\mathrm{Met}/(\mathrm{Weyl}\ltimes\mathrm{Diff}^+)=\mathcal{T}_p/\Gamma_p$; for the torus it is $\mathbb{C}^+/\mathrm{SL}(2,\mathbb{Z})$, the fundamental domain F.
- Its tangent space is $H^{0,1}(K^*)$, its cotangent space the quadratic differentials $H^0(K^2)$, and its dimension $3p-3$ for $p\geq 2$ (with 0 and 1 for $p=0,1$).
- Weierstrass points, where the gap sequence is not $1,\ldots,p$, number between $2p+2$ and p^3-p and make automorphism groups finite ($\leq 84(p-1)$), which is why $\mathcal{M}_p$ is only an orbifold.

Chapter 6

Infinite Dimensional Groups

Where this chapter is going

Every symmetry group we met in a first course on quantum mechanics has a finite number of parameters. A rotation needs three angles. A Lorentz transformation needs six numbers. Quantum field theory, though, keeps producing symmetries with a parameter *at every point of space*. A gauge transformation $g(x)$ is a whole function. So is a change of coordinates $x \mapsto x'(x)$. So is a conformal transformation of a two-dimensional worldsheet $z \mapsto w(z)$. The groups formed by such transformations have infinitely many parameters: they are *infinite-dimensional groups*.

This chapter is a first tour of these groups and of their quantum mechanics. We proceed in three steps, following Nash's three sections.

(1) *The examples* (§6.1). Groups of maps $\mathrm{Map}(X, G)$, with the loop group $LG = \mathrm{Map}(S^1, G)$ as the star; the diffeomorphism group $\mathrm{Diff}(X)$, with $\mathrm{Diff}(S^1)$ and its Lie algebra of vector fields on a circle as the star; and the gauge group $\mathcal{G}$ of a principal bundle. We compute their Lie algebras, count their connected components, and write down explicit bases.

(2) *Extensions* (§6.2). In quantum mechanics a symmetry acts on rays, not on vectors, so the operators multiply only up to phases. For finite-dimensional semisimple groups the phases can always be removed. For loop groups and for $\mathrm{Diff}(S^1)$ they cannot: the commutators acquire a *central term*, a c-number proportional to the identity. This is where the *affine Kac–Moody algebra*, the *Virasoro algebra* with its $\frac{c}{12}(m^3 - m)$, and the *Schwinger term* of current algebra come from. We derive the central terms three ways: from the consistency (cocycle) condition, from normal ordering in free field theories, and from the Sugawara construction.

(3) *Representations* (§6.3). Requiring the energy L_0 to be bounded below forces the central term to be nonzero and leads to highest-weight representations. Unitarity then quantises the central charges: the discrete series $c = 1 - 6/((m+1)(m+2))$ of the Virasoro algebra and the integer level of a Kac–Moody algebra. Finally the Borel–Weil construction realises representations as spaces of holomorphic sections of line bundles, exactly as wavefunctions of the lowest Landau level are holomorphic sections.

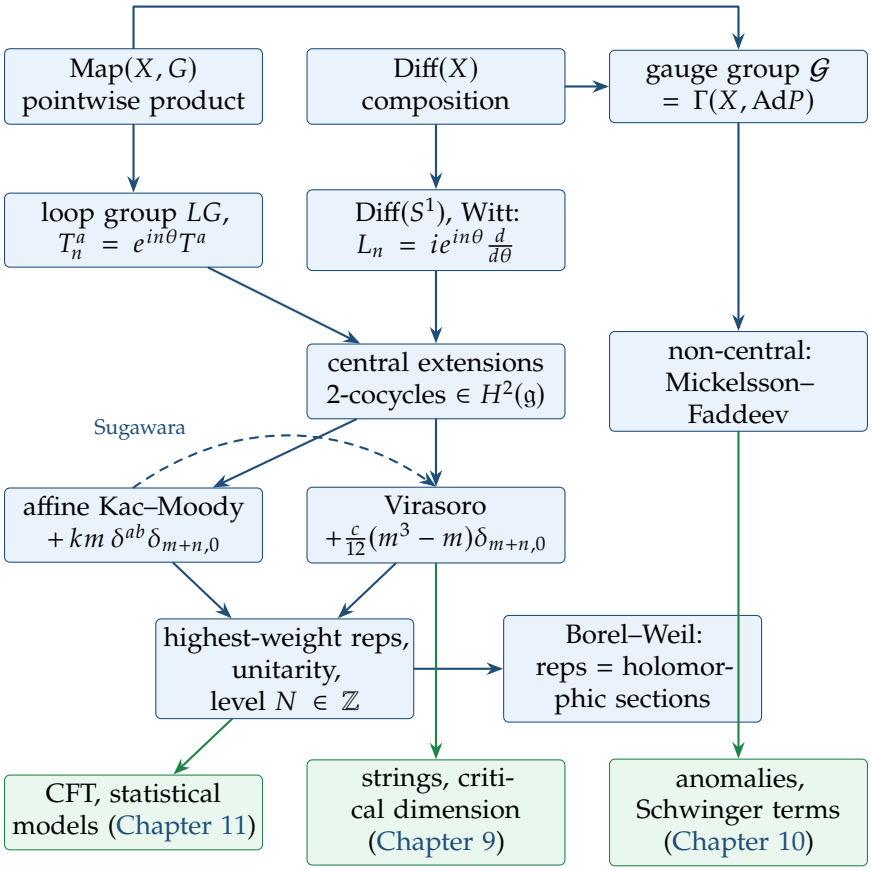

Figure 6.1: The logic of Chapter 6. Top row: three families of infinite-dimensional groups. Middle: in quantum theory their Lie algebras acquire central (or, for Map(X, G) with dim $X > 1$, non-central) terms. Bottom: the representation theory of the centrally extended algebras, and the physics chapters that use it (green).

Dictionary: infinite-dimensional groups for physicists

Mathematics	Physics
Map(X, G), gauge group $\mathcal{G}$	local gauge transformations $g(x)$
Diff(X)	general coordinate transformations
loop algebra Map$(S^1, \mathfrak{g})$	Fourier modes of a current $j^a(\theta)$ on a spatial circle
affine Kac–Moody algebra	equal-time current algebra with Schwinger term
Witt algebra vect(S^1)	classical conformal generators of a closed string
Virasoro algebra, central charge c	quantum conformal generators; c counts degrees of freedom
2-cocycle	the c-number (Schwinger) term in a commutator
central extension	symmetry realised projectively on the Hilbert space
highest-weight representation	spectrum with a lowest-energy state $\lvert h\rangle$
level k	the coefficient of the anomaly/Schwinger term

Watch out: conventions for generators in this chapter

In the toolkit chapters (Chapter T3) and in the gauge theory chapters we use the mathematicians' convention: Lie algebra elements are *anti-Hermitian*, and a gauge field is $A = A_\mu \, \mathrm{d}x^\mu$ with $A_\mu \in \mathfrak{g}$ anti-Hermitian. In this chapter Nash switches to the physicists' convention for generators, and so do we. The basis elements T^a of $\mathfrak{g}$ are *Hermitian*, a group element near the identity is $g = \exp(i\varepsilon_a T^a)$, and

$$[T^a, T^b] = i f^{abc}\, T^c, \qquad f^{abc} \text{ real and totally antisymmetric.}$$

The dictionary is $X_{\text{math}} = iX_{\text{phys}}$: the anti-Hermitian element $i\varepsilon_a T^a$ is what the mathematician calls a Lie algebra element. We always normalise $\operatorname{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ in the defining representation of SU(N); for SU(2), $T^a = \sigma^a/2$ with the Pauli matrices and $f^{abc} = \varepsilon^{abc}$. We set $\hbar = 1$ except in Section 6.2.7, where the powers of $\hbar$ are the point.

6.1 Some infinite dimensional groups

What does it mean for a group to be infinite-dimensional, and where do such groups show up in physics? The short answer is: whenever a symmetry transformation is allowed to depend on position. A global phase rotation $\psi \mapsto e^{i\lambda}\psi$ has one parameter λ. A local one, $\psi(x) \mapsto e^{i\lambda(x)}\psi(x)$, has one parameter *per point*, that is, a whole function $\lambda(x)$. The group of all such local phase rotations is the group of maps from space into U(1). Almost every example in this chapter is, at least locally, a group of maps Map(X, Y) from a finite-dimensional manifold X into a finite-dimensional manifold Y. That observation is our guide.

6.1.1 The groups we already know

Before going infinite, it helps to lay out the finite-dimensional groups that physicists use, since everything below is built out of them.

Type	Examples	Where physics uses them
finite (dimension 0)	point groups, S_n, $\mathbb{Z}_n$	crystallography, identical particles
infinite discrete (dim. 0)	$\mathbb{Z}$, $\mathrm{PSL}(2,\mathbb{Z}) = \mathrm{SL}(2,\mathbb{Z})/\{\pm I\}$	lattice translations; modular invariance of the torus in string theory
compact Lie	$\mathrm{U}(1)$, $\mathrm{U}(n)$, $\mathrm{O}(n)$, $\mathrm{Sp}(n)$, E_6, E_7, E_8, F_4, G_2	internal (gauge, flavour) symmetries, GUTs, heterotic string
non-compact Lie	$\mathrm{SL}(2,\mathbb{C})$, Poincaré, $\mathrm{SL}(2,\mathbb{R})$	Lorentz invariance; conformal symmetry

Worked example 6.1: the modular group, and why $\pm I$ is divided out

A torus is $\mathbb{C}$ modulo the lattice generated by 1 and a complex number τ with $\operatorname{Im}\tau > 0$. A change of lattice basis is a matrix $\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}(2,\mathbb{Z})$, and it changes τ by

$$\tau \;\mapsto\; \tau' \overset{(1)}{=} \frac{a\tau + b}{c\tau + d} \overset{(2)}{=} \frac{(-a)\tau + (-b)}{(-c)\tau + (-d)}.$$

(1) The new basis vectors are $a\tau + b$ and $c\tau + d$; rescaling the lattice so the second becomes 1 gives the new modulus.

(2) Multiplying numerator and denominator by -1 changes nothing.

So M and $-M$ act identically, and the group that acts effectively is $\mathrm{SL}(2,\mathbb{Z})/\{\pm I\}$. It is generated by $T = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ ($\tau \mapsto \tau + 1$) and $S = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ ($\tau \mapsto -1/\tau$). It is infinite but discrete: zero-dimensional. A one-loop string amplitude must be invariant under it (Chapter 9).

These groups have a complete representation theory, especially the compact ones: every unitary irreducible representation of a compact group is finite dimensional and is labelled by a highest weight. For infinite-dimensional groups the theory is much younger. Nash's aim, and ours, is to meet the infinite-dimensional groups that the rest of the book needs, to see their structure concretely, and to learn the basic facts about their representations.

6.1.2 Infinite-dimensional manifolds

A finite-dimensional Lie group is a manifold, so we can talk about curves in it, tangent vectors and a Lie algebra. To do the same for $\mathrm{Map}(X, G)$ we need a notion of an infinite-dimensional manifold. The idea is the obvious one.

Working definition 6.1 (infinite-dimensional manifold)

An **infinite-dimensional manifold M modelled on** a topological vector space E [a vector space, here usually of functions, in which it makes sense to say that two vectors are close]

is a space covered by open sets, each of which is identified (by a chart) with an open set of E, such that the changes of chart are smooth maps between open subsets of E [where two charts overlap, converting one chart's coordinates into the other's is a smooth map]. *Operationally:* near every point you can describe M by "coordinates" that are elements of E, and small moves in M are small vectors in E.

In finite dimensions $E = \mathbb{R}^n$ or $\mathbb{C}^n$. In infinite dimensions there is a choice to make, and the name of the manifold records it:

- a **Hilbert manifold** is modelled on a Hilbert space, for example $L^2(S^1)$, the square-integrable functions on a circle, with $\|f\|^2 = \int_0^{2\pi} |f|^2 \, \mathrm{d}\theta$;
- a **Sobolev manifold** is modelled on a Sobolev space H^s, functions whose first s derivatives are square integrable, $\|f\|_s^2 = \sum_n (1+n^2)^s \, |f_n|^2$ in terms of Fourier coefficients;
- a **Banach manifold** is modelled on a complete normed space, for example $C^k(S^1)$ with $\|f\| = \sum_{j \le k} \sup \left|f^{(j)}\right|$;
- a **Fréchet manifold** is modelled on a complete space whose topology is defined by countably many seminorms. The main example is $C^\infty(S^1)$ with the seminorms $\sup \left|f^{(j)}\right|$, $j = 0, 1, 2, \ldots$ (Nash says "locally convex space").

The smooth maps we care about live naturally in the Fréchet world. The Hilbert and Sobolev versions are technically easier (the inverse function theorem holds), and physicists often work in them without saying so.

Key idea: the Lie algebra is the model space

For a finite-dimensional Lie group, the Lie algebra (the tangent space at the identity) is a copy of the model space $\mathbb{R}^n$. The same holds in infinite dimensions: if M is a Lie group modelled on E, its Lie algebra is E. For groups of maps $\mathrm{Map}(X, G)$ the model space is $\mathrm{Map}(X, \mathfrak{g})$.

6.1.3 The group $\mathrm{Map}(X, G)$

Let X be a compact manifold (space, or spacetime in Euclidean signature) and G a finite-dimensional Lie group. The set $\mathrm{Map}(X, G)$ of smooth maps $\alpha : X \to G$ is a group in the most obvious way: multiply the values.

Working definition 6.2 (pointwise product)

For $\alpha, \beta \in \mathrm{Map}(X, G)$ define

$$(\alpha \bullet \beta)(x) := \alpha(x)\,\beta(x), \qquad \alpha^{-1}(x) := \alpha(x)^{-1}, \qquad e(x) := 1 \text{ for all } x. \tag{6.1}$$

Operationally: to multiply two maps, go to each point x and multiply the two matrices sitting there. This is Nash's (6.1).

The group axioms hold because they hold at each point separately. The product and the inverse are smooth, so $\mathrm{Map}(X, G)$ is an (infinite-dimensional) Lie group.

Worked example 6.2: local phase rotations: $\mathrm{Map}(X, \mathrm{U}(1))$

Take $G = \mathrm{U}(1)$. An element is a function $\alpha(x) = e^{i\lambda(x)}$ with λ real (defined modulo 2π). Then

$$(\alpha \bullet \beta)(x) \overset{(1)}{=} e^{i\lambda(x)} e^{i\mu(x)} \overset{(2)}{=} e^{i(\lambda(x)+\mu(x))}.$$

(1) Definition (6.1) with $\beta = e^{i\mu}$.
(2) Phases commute and add.

The group is abelian and "is" the space of functions $\lambda(x)$, at least near the identity. These are the gauge transformations of electromagnetism. One parameter per point: infinitely many parameters.

Worked example 6.3: a non-abelian group of maps: $\mathrm{Map}(S^2, \mathrm{SU}(2))$

Let $\hat{n}(x)$ be a unit vector field on S^2 and $\phi(x)$ a function. Then $\alpha(x) = \exp\big(i\phi(x)\,\hat{n}(x)\cdot\vec{\sigma}/2\big) = \cos\frac{\phi}{2} + i\sin\frac{\phi}{2}\,\hat{n}\cdot\vec{\sigma}$ is an element of $\mathrm{Map}(S^2, \mathrm{SU}(2))$: at each point a rotation of spinors by angle $\phi(x)$ about the axis $\hat{n}(x)$. Two such maps multiply by multiplying 2×2 matrices at each point, and in general $\alpha \bullet \beta \neq \beta \bullet \alpha$ because the axes differ from point to point.

The Lie algebra of $\mathrm{Map}(X, G)$

The Lie algebra is the tangent space at the identity map e. A curve through e is a family α_t with $\alpha_0 = e$, and its velocity is the function $x \mapsto \frac{d}{dt}\alpha_t(x)\big|_{t=0}$, which at each point is a tangent vector to G at 1, that is an element of $\mathfrak{g}$. So

$$\mathrm{Lie}\ \mathrm{Map}(X, G) = \mathrm{Map}(X, \mathfrak{g}), \tag{6.2}$$

Nash's (6.2). The bracket is also pointwise. We check this by the usual trick: the commutator of two group elements close to the identity. Write $\alpha_s(x) = \exp(s\,\xi(x))$ and $\beta_t(x) = \exp(t\,\eta(x))$ with $\xi, \eta \in \mathrm{Map}(X, \mathfrak{g})$ (anti-Hermitian values, the mathematician's $\mathfrak{g}$). At each point x,

$$\begin{aligned}\big(\alpha_s \bullet \beta_t \bullet \alpha_s^{-1} \bullet \beta_t^{-1}\big)(x) &\overset{(1)}{=} e^{s\xi(x)} e^{t\eta(x)} e^{-s\xi(x)} e^{-t\eta(x)} \\ &\overset{(2)}{=} 1 + st\,\big(\xi(x)\eta(x) - \eta(x)\xi(x)\big) + O(s^2 t, st^2) \\ &\overset{(3)}{=} \exp\big(st\,[\xi(x), \eta(x)]\big) + O(s^2 t, st^2).\end{aligned}$$

(1) The group operations of $\mathrm{Map}(X, G)$ are pointwise, so we just evaluate at x.
(2) Expand each exponential to second order; the terms of order s^2 and t^2 alone cancel between $e^{s\xi}$ and $e^{-s\xi}$ (and similarly for η), leaving the mixed term.
(3) Resum to first order in st.

Hence the bracket on $\mathrm{Map}(X, \mathfrak{g})$ is

$$[\xi, \eta](x) = [\xi(x), \eta(x)]. \tag{6.3}$$

There are no derivatives of ξ or η anywhere: the Lie algebra of a group of maps is a *current algebra* without Schwinger terms, at least classically. The Schwinger terms of §6.2 are a quantum effect.

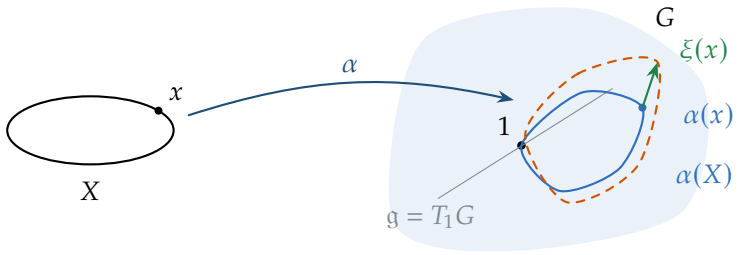

Figure 6.2: A point of $\mathrm{Map}(X, G)$ is a whole map α, drawn as its image (blue) in G. A nearby point (dashed orange) is obtained by moving each $\alpha(x)$ a little, in the direction of a tangent vector $\xi(x)$ (green). A tangent vector to $\mathrm{Map}(X, G)$ is therefore a $\mathfrak{g}$-valued function on X: the model space is $\mathrm{Map}(X, \mathfrak{g})$.

6.1.4 How many pieces does $\mathrm{Map}(X, G)$ have?

A finite-dimensional group like SU(2) is connected: any element can be joined to the identity by a path. A group of maps usually is not. The map $e^{i\theta} : S^1 \to \mathrm{U}(1)$ winds once around the circle, and no continuous deformation can unwind it. Physically, the connected components of the gauge group are the "large gauge transformations", and they are responsible for the θ-vacua of Yang–Mills theory (Chapter 8). Let us count them.

Based maps

Fix a base point $x_0 \in X$. A **based map** is one with $\alpha(x_0) = 1$. The based maps form a subgroup $\mathrm{Map}_0(X, G)$ (Nash introduced it in his Chapter 1). Two based maps are **based-homotopic** if one can be deformed into the other through based maps; the set of classes is written $[X, G]_0$.

The full group splits, as a space, into constants times based maps. For $g \in G$ let α_g denote the constant map $\alpha_g(x) = g$. Given any α, let $g = \alpha(x_0)$. Then

$$\alpha \overset{(1)}{=} \alpha_g \bullet (\alpha_g^{-1} \bullet \alpha),$$
$$(\alpha_g^{-1} \bullet \alpha)(x_0) \overset{(2)}{=} g^{-1}\alpha(x_0) \overset{(3)}{=} g^{-1}g = 1.$$

(1) Insert $\alpha_g \bullet \alpha_g^{-1} = e$ on the left.
(2) Pointwise product evaluated at the base point.
(3) g was defined as $\alpha(x_0)$.

So every α is uniquely "a constant g" times "a based map", and the assignment $\alpha \mapsto (g, \alpha_g^{-1} \bullet \alpha)$ is continuous with continuous inverse. As topological spaces (not as groups),

$$\mathrm{Map}(X, G) \;\cong\; G \times \mathrm{Map}_0(X, G), \tag{6.4}$$

Nash's (6.3). Connected components of a product are pairs of components, so

$$\begin{aligned}\pi_0\big(\mathrm{Map}(X, G)\big) &\overset{(1)}{=} \pi_0(G) \times \pi_0\big(\mathrm{Map}_0(X, G)\big),\\ \pi_0\big(\mathrm{Map}_0(X, G)\big) &\overset{(2)}{=} [S^0, \mathrm{Map}_0(X, G)]_0\\ &\overset{(3)}{=} [S^0 \wedge X, G]_0\\ &\overset{(4)}{=} [X, G]_0.\end{aligned} \tag{6.5}$$

(1) The splitting (6.4). (Nash writes $\oplus$; for the abelian groups that occur below the two notations agree.)

(2) S^0 is two points; a based map from S^0 picks out one point of the target, and based-homotopy classes of such picks are exactly path components.
(3) The adjunction $[A, \mathrm{Map}_0(X, G)]_0 = [A \wedge X, G]_0$: a based map from A into based maps is the same as a based map of two variables, which factors through the smash product $A \wedge X = A \times X/(A \vee X)$ (Nash's (1.18)).
(4) $S^0 \wedge X$ is X itself (smashing with two points, one of which is the base point, changes nothing).

Maps from spheres

For $X = S^m$, based-homotopy classes of maps $S^m \to G$ are by definition the homotopy group $\pi_m(G)$. For $G = \mathrm{U}(n)$, which is connected ($\pi_0(\mathrm{U}(n)) = 0$), we get Nash's (6.5):

$$\pi_0\big(\mathrm{Map}(S^m, \mathrm{U}(n))\big) = \pi_m(\mathrm{U}(n)). \tag{6.6}$$

The standard values (for n large enough, the "stable range" $n > m/2$) are $\pi_m(\mathrm{U}(n)) = \mathbb{Z}$ for m odd and 0 for m even (Bott periodicity). In particular $\pi_3(\mathrm{U}(n)) = \mathbb{Z}$ for $n \geq 2$, so $\mathrm{Map}(S^3, \mathrm{U}(n))$ has infinitely many components, one for each integer. Two explicit examples make the integer visible.

Worked example 6.4: winding number of a loop in $\mathrm{U}(1)$

Take $X = S^1$, $G = \mathrm{U}(1)$ and $\alpha_w(\theta) = e^{iw\theta}$ with $w \in \mathbb{Z}$ (an integer is needed for α_w to be single-valued). Define $W[\alpha] = \frac{1}{2\pi i} \oint \alpha^{-1} \mathrm{d}\alpha$. Then

$$W[\alpha_w] \overset{(1)}{=} \frac{1}{2\pi i} \int_0^{2\pi} e^{-iw\theta}\,(iw)\,e^{iw\theta}\,\mathrm{d}\theta$$
$$\overset{(2)}{=} \frac{1}{2\pi i}\,(iw)(2\pi) = w.$$

(1) $\alpha^{-1}\mathrm{d}\alpha = e^{-iw\theta}\,\mathrm{d}(e^{iw\theta})$ and $\mathrm{d}(e^{iw\theta}) = iw\,e^{iw\theta}\mathrm{d}\theta$.
(2) The integrand is the constant iw.

For a general $\alpha = e^{i\lambda(\theta)}$, $W = \frac{1}{2\pi}\big(\lambda(2\pi) - \lambda(0)\big)$, the number of times the phase goes round. Under a small deformation $\lambda \to \lambda + \delta\lambda$ with $\delta\lambda$ periodic, W changes by $\frac{1}{2\pi}(\delta\lambda(2\pi) - \delta\lambda(0)) = 0$. An integer that cannot change continuously labels the components: $\pi_0(\mathrm{Map}(S^1, \mathrm{U}(1))) = \pi_1(\mathrm{U}(1)) = \mathbb{Z}$.

Worked example 6.5: the degree of a map $S^3 \to \mathrm{SU}(2)$

SU(2) is itself a three-sphere: every element can be written $g = x_4 \mathbb{1} + i\,\vec{x}\cdot\vec{\sigma}$ with $x_4^2 + \big|\vec{x}\big|^2 = 1$. So the identity map $g(x) = x_4 + i\vec{x}\cdot\vec{\sigma}$ is an element of $\mathrm{Map}(S^3, \mathrm{SU}(2))$. Its integer invariant is the degree

$$w[g] = \frac{1}{24\pi^2} \int_{S^3} \mathrm{tr}\big(g^{-1}\mathrm{d}g\big)^3.$$

We evaluate the integrand at the identity element $x = (0, 0, 0, 1)$, where $\vec{x}$ are good local coordinates:

$$g^{-1}\mathrm{d}g\big|_{g=1} \overset{(1)}{=} i\sigma_j\,\mathrm{d}x^j,$$
$$\mathrm{tr}\big(g^{-1}\mathrm{d}g\big)^3\big|_{g=1} \overset{(2)}{=} i^3\,\mathrm{tr}(\sigma_j\sigma_k\sigma_l)\,\mathrm{d}x^j \wedge \mathrm{d}x^k \wedge \mathrm{d}x^l$$

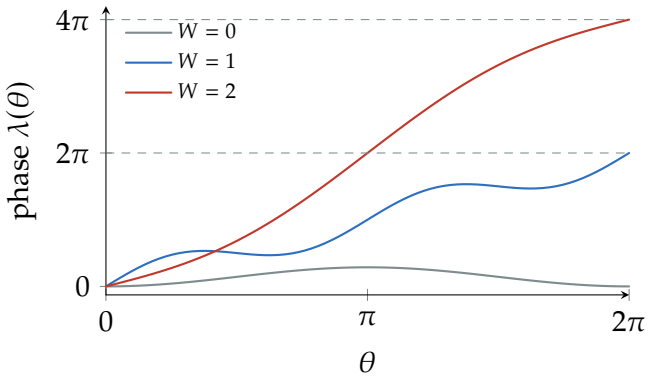

Figure 6.3: Three loops in U(1), drawn as the lifted phase $\lambda(\theta)$ of $\alpha = e^{i\lambda}$. The endpoint $\lambda(2\pi)$ must equal $\lambda(0)$ plus a multiple $2\pi W$. Wiggling a curve (a small deformation) cannot move its endpoint from one dashed line to another, so the winding number W labels the connected components of $LU(1)$.

$$\overset{(3)}{=} (-i)(2i\,\varepsilon_{jkl})\,\mathrm{d}x^j \wedge \mathrm{d}x^k \wedge \mathrm{d}x^l$$
$$\overset{(4)}{=} 12\,\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3.$$

(1) Near $g = 1$, $g \approx 1 + i\vec{x}\cdot\vec{\sigma}$, so $\mathrm{d}g = i\sigma_j \mathrm{d}x^j$ and $g^{-1} \approx 1$.
(2) Cube the matrix-valued 1-form; the wedge makes the coefficient antisymmetric in j, k, l.
(3) $\mathrm{tr}(\sigma_j\sigma_k\sigma_l) = 2i\varepsilon_{jkl}$.
(4) $\varepsilon_{jkl}\mathrm{d}x^j \wedge \mathrm{d}x^k \wedge \mathrm{d}x^l = 6\,\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3$ and $(-i)(2i) = 2$.

The form $\mathrm{tr}(g^{-1}\mathrm{d}g)^3$ is invariant under left multiplication $g \mapsto hg$ (since $(hg)^{-1}\mathrm{d}(hg) = g^{-1}\mathrm{d}g$), so it equals 12×(the volume form of the unit S^3) everywhere. The unit three-sphere has volume $2\pi^2$, hence $w[g] = \frac{1}{24\pi^2}\cdot 12 \cdot 2\pi^2 = 1$. The identity map has degree one, and g^w (pointwise power) has degree w. This is the integer that labels the components of $\mathrm{Map}(S^3, \mathrm{SU}(2))$, and, in Chapter 8, the instanton number.

General X and K-theory

For $G = \mathrm{U}(n)$ and any compact X, Nash rewrites $[X, \mathrm{U}(n)]_0$ in the language of vector bundles. The chain is his (6.6):

$$\begin{aligned}\pi_0\big(\mathrm{Map}(X, \mathrm{U}(n))\big) &\overset{(1)}{=} [S^0 \wedge X, \mathrm{U}(n)]_0 \\ &\overset{(2)}{=} [S^0 \wedge X, \Omega B\mathrm{U}(n)]_0 \\ &\overset{(3)}{=} [SX, B\mathrm{U}(n)]_0 \\ &\overset{(4)}{=} \tilde{K}^{-1}(X) \qquad (n > \tfrac{1}{2}\dim X).\end{aligned} \tag{6.7}$$

(1) Equation (6.5), together with $\pi_0(\mathrm{U}(n)) = 0$.
(2) The classifying space $B\mathrm{U}(n)$ has the property that its based loop space $\Omega B\mathrm{U}(n)$ is homotopy equivalent to $\mathrm{U}(n)$. (A loop in $B\mathrm{U}(n)$ is a way of going round the base of the universal bundle, and its holonomy is an element of $\mathrm{U}(n)$.)
(3) Loop–suspension adjunction: a map from Y into loops of Z is a map from the suspension SY into Z. With $Y = X$ this is $[SX, B\mathrm{U}(n)]_0$.

(4) Maps $SX \to BU(n)$ classify rank-n vector bundles on the suspension. Such a bundle is built by gluing trivial bundles on the two cones of SX along X with a clutching function $X \to U(n)$. In the stable range these bundles, up to isomorphism and adding trivial bundles, form $\tilde{K}(SX)$, which is by definition $\tilde{K}^{-1}(X)$ (Chapter 1).

So the components of the gauge group of a trivial $U(n)$ bundle are counted by odd K-theory. Nash's footnote adds that $\tilde{K}^{-1}(X)$ is a sum of copies of $\mathbb{Z}$ and a finite (torsion) group T, and that the number of copies of $\mathbb{Z}$ is $b_1 + b_3 + b_5 + \cdots$, the sum of the odd Betti numbers of X. (This is the statement that the Chern character identifies $K^{-1}(X) \otimes \mathbb{Q}$ with the odd rational cohomology.) Checks:

X	odd Betti numbers	$\pi_0 \operatorname{Map}(X, U(n))$	the integers are
S^1	$b_1 = 1$	$\mathbb{Z}$	winding of $\det \alpha$ (Example 6.4)
S^2	none	0	$\operatorname{Map}(S^2, U(n))$ connected
S^3	$b_3 = 1$	$\mathbb{Z}$	degree (Example 6.5)
T^2	$b_1 = 2$	$\mathbb{Z}^2$	windings of $\det \alpha$ round the two cycles
T^3	$b_1 = 3,\ b_3 = 1$	$\mathbb{Z}^4$	three windings and one degree

6.1.5 The loop group LG

The simplest nontrivial choice of X is a circle. This case is special enough to have its own name and its own beautiful theory.

Working definition 6.3 (loop group)

The **loop group** of G is

$$LG := \operatorname{Map}(S^1, G), \tag{6.8}$$

smooth loops $\gamma : S^1 \to G$, $\theta \mapsto \gamma(\theta)$, with the pointwise product [$(\gamma_1\gamma_2)(\theta) = \gamma_1(\theta)\gamma_2(\theta)$, multiply the values at each θ] (Nash's (6.7)). *Physically:* a gauge transformation [a choice of group element $\gamma(\theta) \in G$ at each point θ of space] at fixed time in a $(1+1)$-dimensional theory whose space is a circle of circumference 2π.

By (6.5), $\pi_0(LG) = \pi_0(G) \times \pi_1(G)$. For a connected G, the components of LG are the elements of $\pi_1(G)$:

- $G = SU(n), Sp(n), E_8$ (simply connected): LG is connected, as Nash notes;
- $G = U(1)$: $\pi_1 = \mathbb{Z}$, components labelled by the winding number;
- $G = SO(3)$: $\pi_1 = \mathbb{Z}_2$. The loop "rotate by 2π about the z-axis as θ goes round" is not contractible, but going round twice (rotation by 4π) is. This is the same $\mathbb{Z}_2$ that makes spinors change sign under a 2π rotation (Chapter T4).

The loop algebra and its Fourier basis

By (6.2) the Lie algebra of LG is

$$\operatorname{Lie} LG = \operatorname{Map}(S^1, \mathfrak{g}), \tag{6.9}$$

Nash's (6.8), the **loop algebra**. Its elements are $\mathfrak{g}$-valued periodic functions $\xi(\theta)$, so we can Fourier expand them. In the physicists' convention (Hermitian T^a) write

$$T^a_n := e^{in\theta}\, T^a, \qquad n \in \mathbb{Z}, \quad a = 1, \ldots, \dim G, \tag{6.10}$$

which is Nash's (6.10). A general element of the (complexified) loop algebra is $\xi(\theta) = \sum_{n,a} \xi_{a,n} T^a_n$, and it is Hermitian at every θ precisely when $\xi_{a,-n} = \overline{\xi_{a,n}}$. The generators T^a_0 are the *constant* loops; they span a copy of $\mathfrak{g}$. The loops with $n \neq 0$ are the "oscillating" directions, the based part of the splitting (6.4).

The bracket of basis elements follows from (6.3):

$$\begin{aligned}[T^a_m, T^b_n](\theta) &\overset{(1)}{=} [e^{im\theta}T^a,\ e^{in\theta}T^b] \\ &\overset{(2)}{=} e^{i(m+n)\theta}\,[T^a, T^b] \\ &\overset{(3)}{=} i f^{abc}\, e^{i(m+n)\theta} T^c \overset{(4)}{=} i f^{abc}\, T^c_{m+n}(\theta). \end{aligned} \tag{6.11}$$

(1) The bracket is pointwise, so we compute at each θ.
(2) The functions $e^{im\theta}$ are numbers at each θ and pull out of the commutator.
(3) Commutation relations of $\mathfrak{g}$.
(4) Definition (6.10) with index $m + n$.

So the mode numbers simply add. This is the **loop algebra** in its mode form. It is "$\mathfrak{g}$ tensored with Laurent polynomials in $z = e^{i\theta}$": $\mathfrak{g} \otimes \mathbb{C}[z, z^{-1}]$.

Worked example 6.6: the SU(2) loop algebra with Pauli matrices

Let $T^a = \sigma^a/2$, so $f^{abc} = \varepsilon^{abc}$. Then $T^1_m = \frac{1}{2}e^{im\theta}\begin{pmatrix}0&1\\1&0\end{pmatrix}$ and $T^2_n = \frac{1}{2}e^{in\theta}\begin{pmatrix}0&-i\\i&0\end{pmatrix}$, and

$$\begin{aligned}[T^1_m, T^2_n] &\overset{(1)}{=} \tfrac{1}{4}e^{i(m+n)\theta}\left[\begin{pmatrix}0&1\\1&0\end{pmatrix}\begin{pmatrix}0&-i\\i&0\end{pmatrix} - \begin{pmatrix}0&-i\\i&0\end{pmatrix}\begin{pmatrix}0&1\\1&0\end{pmatrix}\right] \\ &\overset{(2)}{=} \tfrac{1}{4}e^{i(m+n)\theta}\left[\begin{pmatrix}i&0\\0&-i\end{pmatrix} - \begin{pmatrix}-i&0\\0&i\end{pmatrix}\right] \\ &\overset{(3)}{=} i\,\tfrac{1}{2}e^{i(m+n)\theta}\begin{pmatrix}1&0\\0&-1\end{pmatrix} = i\,T^3_{m+n}. \end{aligned}$$

(1) Pointwise bracket; the phases multiply.
(2) Matrix multiplication.
(3) The difference is $2i\sigma^3$, and $\frac{1}{4}\cdot 2i = \frac{i}{2}$.

This is (6.11) with $f^{123} = 1$. Note what the modes look like as matrices: T^1_1 is a 2×2 matrix whose entries rotate once round the circle as θ goes from 0 to 2π.

The affine Kac–Moody algebra (first look)

Nash now makes a statement that the rest of the chapter explains: *all the interesting representations of* $\mathrm{Map}(S^1, \mathfrak{g})$ *are really representations of a central extension* $\widetilde{L\mathfrak{g}}$. In the extended algebra the modes obey

$$\boxed{[T^a_m, T^b_n] = i f^{abc}\, T^c_{m+n} + k\, m\, \delta^{ab}\, \delta_{m+n,0}, \qquad m, n \in \mathbb{Z}} \tag{6.12}$$

Nash's (6.9). Here k is a **central element**: it commutes with every T^a_n, and in an irreducible representation it is a number, the **level** (up to normalisation, see Section 6.3.9). This is the **untwisted affine Kac–Moody algebra** $\hat{\mathfrak{g}}$. Three things to notice at once:

- the extra term is present only when $m + n = 0$, and it is proportional to m. So it vanishes when $m = n = 0$: the constant loops T^a_0 still close into an ordinary copy of $\mathfrak{g}$;

- it is antisymmetric, as a commutator must be: swapping (a, m) with (b, n) and using $\delta_{m+n,0}$ turns $km\delta^{ab}$ into $kn\delta^{ab} = -km\delta^{ab}$;
- it is a c-number. In a quantum field theory it is the famous *Schwinger term* (Section 6.1.11).

In §6.2 we show that (6.12) is consistent (it satisfies the Jacobi identity), that the extra term cannot be removed by redefining the generators, and that it appears automatically when the algebra is realised on a Fock space with a Dirac sea.

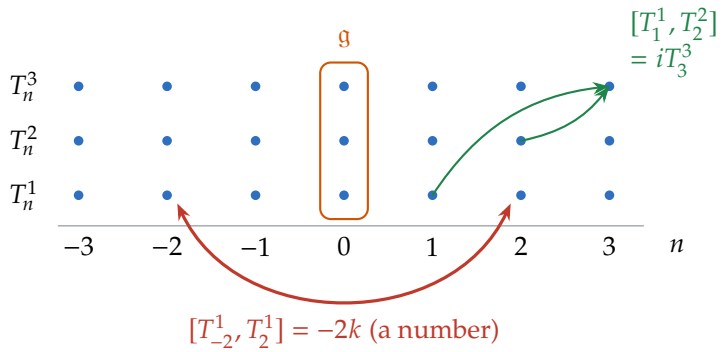

Figure 6.4: The generators of the loop algebra of SU(2) as a lattice: one column per Fourier mode n, one row per direction a in $\mathfrak{g}$. Brackets add mode numbers (green). The column $n = 0$ (orange box) is a copy of $\mathfrak{g}$. In the affine Kac–Moody algebra, a bracket that returns to total mode number zero from a pair $\pm n$ in the same row also produces a c-number (red): the central term $km\,\delta^{ab}\delta_{m+n,0}$.

Reading Nash (pp. 170–174, (6.1)–(6.10))

Nash's treatment of $\mathrm{Map}(X, G)$ and LG is two pages. The formulae (6.1), (6.2), (6.7), (6.8) and (6.10) are the definitions above. His (6.3)–(6.6) are our (6.4)–(6.7); the "using 1.18" refers to the smash-product adjunction of his Chapter 1, and "cf. p. 73 and pp. 74, 76" refers to $\Omega B\mathrm{U}(n) \simeq \mathrm{U}(n)$ and to the definition of $\tilde{K}^{-1}$ by suspension. Nash writes $\pi_3(\mathrm{U}(n)) = \mathbb{Z}$, $n > 1$. The Kac–Moody relations (6.9) are quoted here and justified only in §2; we have followed him in using the same symbol k for the central element and its value. The references he gives for the mathematics and the physics (Pressley and Segal; Kac; Goddard and Olive) are still the standard ones.

Where loop groups turn up

Nash lists the places where loop groups and their Kac–Moody algebras have proved their worth. It is worth pausing on the list, because it explains why a physicist should care about such an abstract-looking object.

- *Two-dimensional statistical mechanics and conformal field theory* (Chapter 11). At a critical point a two-dimensional system with an internal symmetry G (for instance a chain of quantum spins with SU(2) symmetry) has conserved currents $j^a(\theta)$ on a spatial circle. Their Fourier modes obey (6.12). The level k and the central charge of §6.2 are then measurable numbers: they fix the finite-size corrections to the ground-state energy and the critical exponents.
- *Current algebra* (Section 6.1.11). The equal-time commutators of currents, first studied for the strong interactions, are loop-algebra relations with a Schwinger term.
- *String theory* (Chapter 9). A closed string is a loop; a string moving on a group manifold G (the Wess–Zumino–Witten model) has the loop group LG as its symmetry group.

- *Knot invariants* (Chapter 12). The Jones polynomial comes out of the representation theory of the affine SU(2) algebra at integer level, through Chern–Simons theory.

- *Pure mathematics*. Kac–Moody algebras are tied to completely integrable systems (the KdV equation has the Virasoro algebra as its Poisson bracket algebra), to modular forms (characters of Kac–Moody representations are modular forms, which is why string partition functions are modular invariant), and to the Monster, the largest sporadic finite simple group, whose representations are organised by a $c = 24$ conformal field theory.

6.1.6 The diffeomorphism group $\mathrm{Diff}(X)$

Our second family of infinite-dimensional groups has a different product. In $\mathrm{Map}(X, G)$ we multiplied the *values* of two maps. Now the elements are maps of a space to itself, and we multiply them by doing one after the other.

Working definition 6.4 (diffeomorphism group)

A **diffeomorphism** of a manifold X is a smooth map $\alpha : X \to X$ with a smooth inverse. The diffeomorphisms of X form a group $\mathrm{Diff}(X)$ with product *composition*:

$$\alpha \bullet \beta := \alpha \circ \beta, \qquad (\alpha \bullet \beta)(x) = \alpha\big(\beta(x)\big), \tag{6.13}$$

Nash's (6.11). The identity element is the identity map and the inverse is the inverse map. *Physically:* $\mathrm{Diff}(X)$ is the group of general coordinate transformations, the gauge group of general relativity [moving all fields along by the same diffeomorphism does not change the physics]. An active diffeomorphism moves every point of space to a new place.

Note the difference with $\mathrm{Map}(X, G)$. There, the product $\alpha \bullet \beta$ at x only needs the values at x. Here it needs the value of α at the *different* point $\beta(x)$. This nonlocality is what makes $\mathrm{Diff}(X)$ much harder than $\mathrm{Map}(X, G)$, as we will see when we discuss analyticity in Section 6.1.12.

Worked example 6.7: diffeomorphisms of the line and the circle

On $X = \mathbb{R}$, the maps $\alpha_a(x) = x + a$ (translations) and $\delta_\lambda(x) = e^\lambda x$ (dilatations) are diffeomorphisms. Compose them:

$$(\alpha_a \bullet \delta_\lambda)(x) \overset{(1)}{=} \alpha_a(e^\lambda x) = e^\lambda x + a,$$
$$(\delta_\lambda \bullet \alpha_a)(x) \overset{(2)}{=} \delta_\lambda(x + a) = e^\lambda x + e^\lambda a.$$

(1) Definition (6.13): first dilate, then translate.
(2) First translate, then dilate.

The two differ unless $a = 0$ or $\lambda = 0$: the group is non-abelian already for these two one-parameter families. The map $x \mapsto x^3$ is a smooth bijection of $\mathbb{R}$ but not a diffeomorphism, because its inverse $x \mapsto x^{1/3}$ is not differentiable at 0.
On $X = S^1$ with angle θ, a diffeomorphism is a map $\theta \mapsto \alpha(\theta)$ with $\alpha(\theta + 2\pi) = \alpha(\theta) \pm 2\pi$ and $\alpha'(\theta)$ never zero. The rigid rotations $\theta \mapsto \theta + a$ are the simplest. A less rigid example is $\alpha_\varepsilon(\theta) = \theta + \varepsilon \sin\theta$, which is a diffeomorphism for $|\varepsilon| < 1$ because then $\alpha'_\varepsilon = 1 + \varepsilon\cos\theta > 0$. It squeezes the points near $\theta = \pi$ together and spreads out those near $\theta = 0$.

The Lie algebra: vector fields and their flows

What is a diffeomorphism "close to the identity"? It moves every point a little. Record the little displacement at each point: that is a vector at each point, a *vector field*. Conversely, a vector field generates diffeomorphisms by flowing along it.

Working definition 6.5 (flow of a vector field)

Let $V = \sum_i v^i(x)\,\frac{\partial}{\partial x^i}$ be a smooth vector field on X. Its **integral curves** are the solutions of $\dot{x}^i(t) = v^i(x(t))$. The **flow** of V is the family of maps $\alpha_t : X \to X$ that sends each point x to the point reached after time t along the integral curve starting at x. On a compact X [closed and bounded, so no integral curve can run off to infinity in finite time] the flow exists for all t, each α_t is a diffeomorphism, and $\alpha_t \bullet \alpha_s = \alpha_{t+s}$ [flowing for time s and then for time t is the same as flowing for time $t+s$]. We write, with Nash's (6.13),

$$V = \sum_i v^i \frac{\partial}{\partial x^i}, \qquad \alpha_t = \exp[tV]. \tag{6.14}$$

Operationally: to find $\alpha_t(x)$, solve the ODE $\dot{x} = v(x)$ with initial condition x and read off the solution at time t. To first order, $\alpha_t(x) = x + t\,v(x) + O(t^2)$.

Flows give a one-parameter subgroup $t \mapsto \alpha_t$ of $\mathrm{Diff}(X)$ for every vector field, and every smooth one-parameter subgroup arises this way (differentiate it at $t = 0$ to recover V). So the tangent space at the identity is the space of vector fields:

$$\text{Lie Diff}(X) = \text{vect}(X), \tag{6.15}$$

Nash's (6.12). The bracket is the Lie bracket of vector fields,

$$[V, W] = \sum_{i,j} \left(v^j \frac{\partial w^i}{\partial x^j} - w^j \frac{\partial v^i}{\partial x^j} \right) \frac{\partial}{\partial x^i}, \tag{6.16}$$

which is just the commutator $VW - WV$ of the two first-order differential operators (the second derivatives cancel), Chapter T1.

Worked example 6.8: flows on the line: translations, dilatations and a blow-up

We solve $\dot{x} = v(x)$ for three vector fields on $\mathbb{R}$.

$$V_{-1} = \frac{\partial}{\partial x} : \quad \dot{x} = 1 \qquad \Rightarrow \quad \alpha_t(x) \overset{(1)}{=} x + t,$$
$$V_0 = x\frac{\partial}{\partial x} : \quad \dot{x} = x \qquad \Rightarrow \quad \alpha_t(x) \overset{(2)}{=} e^t x,$$
$$V_1 = x^2\frac{\partial}{\partial x} : \quad \dot{x} = x^2 \qquad \Rightarrow \quad \alpha_t(x) \overset{(3)}{=} \frac{x}{1 - tx}.$$

(1) Constant velocity: a translation.

(2) Exponential growth: a dilatation.

(3) Separate variables: $\mathrm{d}x/x^2 = \mathrm{d}t$ gives $-1/x(t) + 1/x = t$, so $x(t) = x/(1 - tx)$. Check: $\frac{d}{dt}\frac{x}{1-tx} = \frac{x^2}{(1-tx)^2} = x(t)^2$.

The third flow sends the point $x = 1/t$ to infinity in finite time, so on $\mathbb{R}$ it is not a diffeomorphism for any $t \neq 0$: $\mathbb{R}$ is not compact, and the vector field $x^2\partial_x$ is not complete. If we add the point at infinity and work on the circle $\mathbb{RP}^1 = \mathbb{R} \cup \{\infty\}$, all three flows are perfectly good diffeomorphisms: they are the Möbius maps $x \mapsto (ax + b)/(cx + d)$. The

brackets are

$$[V_m, V_n] \overset{(4)}{=} x^{m+1}\,(n+1)x^n \frac{\partial}{\partial x} - x^{n+1}(m+1)x^m \frac{\partial}{\partial x}$$
$$= (n-m)\,V_{m+n}, \qquad m,n \in \{-1,0,1\},$$

(4) Formula (6.16) with $V_m = x^{m+1}\partial_x$.

a three-dimensional Lie algebra, which is $\mathfrak{sl}(2,\mathbb{R})$. We will meet exactly this subalgebra inside the Witt algebra below.

Watch out: the sign of the bracket on $\mathrm{vect}(X)$

The Lie algebra bracket obtained from the group commutator of $\mathrm{Diff}(X)$ is *minus* the vector field bracket (6.16). Let us see this in one dimension. Take flows $\alpha_t(x) = x + tv(x) + O(t^2)$ and $\beta_s(x) = x + sw(x) + O(s^2)$. Then, keeping terms up to order ts,

$$(\alpha_t \bullet \beta_s)(x) \overset{(1)}{=} \beta_s(x) + t\,v\big(\beta_s(x)\big) \overset{(2)}{=} x + sw + tv + ts\,v'w,$$
$$(\beta_s \bullet \alpha_t)(x) \overset{(3)}{=} x + tv + sw + ts\,w'v,$$
$$\big(\alpha_t \bullet \beta_s \bullet \alpha_t^{-1} \bullet \beta_s^{-1}\big)(x) \overset{(4)}{=} x + ts\,(v'w - w'v) + \cdots .$$

(1) Apply α_t to the point $\beta_s(x)$.
(2) Taylor expand $v(x+sw) = v + sv'w + \cdots$.
(3) The same with the roles exchanged.
(4) The group commutator is $(\alpha \bullet \beta) \bullet (\beta \bullet \alpha)^{-1}$, which moves points by the difference of the two displacements.

The displacement $v'w - w'v$ is the coefficient of $-[V,W]$ in (6.16). The sign is harmless: the map $V \mapsto -V$ converts one bracket into the other. It also disappears in the way physicists use $\mathrm{Diff}(X)$, namely through its action on functions $f \mapsto f \circ \alpha^{-1}$, whose generator is the differential operator $-V$, and then all commutators are commutators of differential operators. Like Nash, we always use the commutator of differential operators.

6.1.7 Diffeomorphisms of the circle and the Witt algebra

The case $X = S^1$ is to $\mathrm{Diff}(X)$ what the loop group is to $\mathrm{Map}(X,G)$: the simplest case, and the most important one for physics. A closed string at fixed time is a map from a circle into spacetime, and reparametrising the string, $\sigma \mapsto \alpha(\sigma)$, does not change the physical string. So $\mathrm{Diff}(S^1)$ is a gauge group of string theory.

Components

$\mathrm{Diff}(S^1)$ has two components: the orientation-preserving maps $\mathrm{Diff}^+(S^1)$, with $\alpha' > 0$, and the orientation-reversing ones, such as the reflection $\theta \mapsto -\theta$. $\mathrm{Diff}^+(S^1)$ is connected, and in fact it can be deformed onto its subgroup of rigid rotations: the path $\alpha_s(\theta) = (1-s)\alpha(\theta) + s(\theta + \alpha(0))$, $s \in [0,1]$, stays inside $\mathrm{Diff}^+(S^1)$ (a convex combination of two increasing functions is increasing) and ends at a rotation. So, as a space, $\mathrm{Diff}^+(S^1)$ looks like a circle times a contractible piece, and $\pi_1(\mathrm{Diff}^+(S^1)) = \mathbb{Z}$.

The Witt basis

A vector field on S^1 is $v(\theta)\,\frac{d}{d\theta}$ with v periodic. Fourier expand v. The complex basis vector fields, in Nash's normalisation (6.15), are

$$L_n := ie^{in\theta}\,\frac{d}{d\theta}, \qquad n \in \mathbb{Z}. \tag{6.17}$$

It is often convenient to use the complex coordinate $z = e^{i\theta}$ on the unit circle. Then

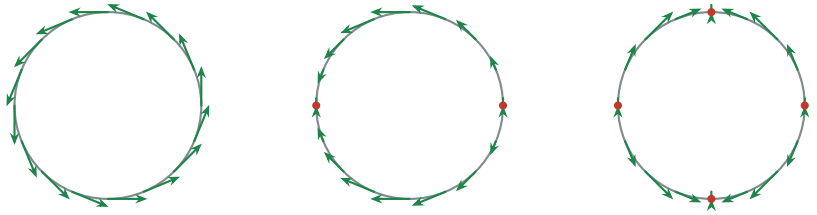
$$\begin{aligned} -z^{n+1}\frac{d}{dz} &\overset{(1)}{=} -z^{n+1}\,\frac{d\theta}{dz}\,\frac{d}{d\theta} \\ &\overset{(2)}{=} -e^{i(n+1)\theta}\,\frac{1}{ie^{i\theta}}\,\frac{d}{d\theta} \\ &\overset{(3)}{=} ie^{in\theta}\,\frac{d}{d\theta} = L_n. \end{aligned} \tag{6.18}$$

(1) Chain rule on the circle $|z| = 1$.
(2) $dz/d\theta = ie^{i\theta}$, so $d\theta/dz = 1/(ie^{i\theta})$.
(3) $-1/i = i$ and $e^{i(n+1)\theta}e^{-i\theta} = e^{in\theta}$.

So $L_n = -z^{n+1}\frac{d}{dz} = ie^{in\theta}\frac{d}{d\theta}$, which is Nash's (6.15). Real vector fields are real combinations:

$$\frac{d}{d\theta} = -iL_0, \qquad \cos n\theta\,\frac{d}{d\theta} = -\tfrac{i}{2}(L_n + L_{-n}), \qquad \sin n\theta\,\frac{d}{d\theta} = -\tfrac{1}{2}(L_n - L_{-n}). \tag{6.19}$$

(Check the last one: $L_n - L_{-n} = i(e^{in\theta} - e^{-in\theta})\frac{d}{d\theta} = i\cdot 2i\sin n\theta\,\frac{d}{d\theta} = -2\sin n\theta\,\frac{d}{d\theta}$.)



$\frac{d}{d\theta}$ $(n=0)$ $\qquad$ $\sin\theta\,\frac{d}{d\theta}$ $(n=1)$ $\qquad$ $\sin 2\theta\,\frac{d}{d\theta}$ $(n=2)$

Figure 6.5: Real vector fields on the circle, drawn as tangent arrows (green) whose length is $v(\theta)$. Left: the rotation generator $-iL_0$, the same at every point. Middle: $\sin\theta\,\frac{d}{d\theta} = -\frac{1}{2}(L_1 - L_{-1})$, which vanishes at $\theta = 0, \pi$ (red) and pushes points from 0 towards π. Right: the $n = 2$ field has four zeros and pushes points towards two of them. In general the mode-n field has $2n$ zeros.

Worked example 6.9: the flow of $\sin\theta\,\frac{d}{d\theta}$ is a Möbius map

Solve $\dot\theta = \sin\theta$. Separate variables:

$$t \overset{(1)}{=} \int_{\theta_0}^{\theta(t)} \frac{\mathrm{d}\theta}{\sin\theta} \overset{(2)}{=} \Big[\ln\tan\tfrac{\theta}{2}\Big]_{\theta_0}^{\theta(t)},$$

$$\tan\frac{\theta(t)}{2} \overset{(3)}{=} e^{t}\,\tan\frac{\theta_0}{2}.$$

(1) $\mathrm{d}t = \mathrm{d}\theta/\sin\theta$ along an integral curve.
(2) $\frac{d}{d\theta}\ln\tan\frac{\theta}{2} = \frac{1}{2}\frac{\sec^2(\theta/2)}{\tan(\theta/2)} = \frac{1}{2\sin(\theta/2)\cos(\theta/2)} = \frac{1}{\sin\theta}$.
(3) Exponentiate.

In the variable $u = \tan(\theta/2)$ (the stereographic coordinate of the circle) the flow is the

dilatation $u \mapsto e^t u$. Points with $0 < \theta_0 < \pi$ approach $\theta = \pi$ ($u \to \infty$) as $t \to \infty$, and the fixed points $\theta = 0, \pi$ stay put, exactly as in Figure 6.5. In the variable $z = e^{i\theta}$ the same map is

$$z \;\mapsto\; \frac{\cosh\frac{t}{2}\, z - \sinh\frac{t}{2}}{-\sinh\frac{t}{2}\, z + \cosh\frac{t}{2}},$$

a Möbius transformation preserving the unit circle. (Check: $u = \tan\frac{\theta}{2} = -i\frac{z-1}{z+1}$, and a dilatation of u is a fractional linear map of z.) This is the circle version of the flow of V_0 in Example 6.8.

The Witt algebra

Now compute the bracket of two basis fields. Using the form $L_n = -z^{n+1}\frac{d}{dz}$ and acting on a test function $f(z)$,

$$\begin{aligned}
[L_m, L_n]f &\overset{(1)}{=} z^{m+1}\frac{d}{dz}\Big(z^{n+1}f'\Big) - z^{n+1}\frac{d}{dz}\Big(z^{m+1}f'\Big) \\
&\overset{(2)}{=} (n+1)z^{m+n+1}f' + z^{m+n+2}f'' - (m+1)z^{m+n+1}f' - z^{m+n+2}f'' \\
&\overset{(3)}{=} (n-m)\,z^{m+n+1}f' \overset{(4)}{=} (m-n)\,L_{m+n}f\,.
\end{aligned} \tag{6.20}$$

(1) $L_mL_nf = (-z^{m+1}\partial_z)(-z^{n+1}\partial_z f)$: the two minus signs cancel.
(2) Product rule.
(3) The second-derivative terms cancel; this is why the commutator of two vector fields is again a vector field.
(4) $z^{m+n+1}f' = -L_{m+n}f$.

So

$$\boxed{[L_m, L_n] = (m-n)\,L_{m+n}}$$

This is the **Witt algebra**, the complexified Lie algebra of $\mathrm{Diff}^+(S^1)$. It is the Virasoro algebra with $c = 0$. Like the loop algebra, it is graded by the mode number: brackets add mode numbers.

Worked example 6.10: the same bracket in the angle variable

It is reassuring to redo (6.20) with $L_n = ie^{in\theta}\partial_\theta$, since this is the form used in the Sugawara construction later. For a test function $f(\theta)$,

$$\begin{aligned}
L_mL_nf &\overset{(1)}{=} ie^{im\theta}\partial_\theta\big(ie^{in\theta}f'\big) \overset{(2)}{=} -e^{im\theta}\big(ine^{in\theta}f' + e^{in\theta}f''\big), \\
[L_m, L_n]f &\overset{(3)}{=} -in\,e^{i(m+n)\theta}f' + im\,e^{i(m+n)\theta}f' \overset{(4)}{=} (m-n)\,ie^{i(m+n)\theta}f' = (m-n)L_{m+n}f\,.
\end{aligned}$$

(1) Definition (6.17), applied twice.
(2) Product rule and $i \cdot i = -1$.
(3) Subtract the same expression with $m \leftrightarrow n$; the f'' terms cancel.
(4) Collect: $-in + im = i(m-n)$.

Key idea: the $\mathfrak{sl}(2)$ inside the Witt algebra

The three generators L_{-1}, L_0, L_1 close among themselves:

$$[L_1, L_{-1}] = 2L_0, \qquad [L_0, L_1] = -L_1, \qquad [L_0, L_{-1}] = L_{-1}.$$

They are the only L_n that extend to holomorphic vector fields on the whole Riemann sphere $\mathbb{C} \cup \{\infty\}$ (see below), and they generate the Möbius transformations $z \mapsto (az+b)/(cz+d)$. In a quantum theory they are the symmetries that even the vacuum respects. Keep an eye on them: the central term of the Virasoro algebra will vanish exactly on this subalgebra.

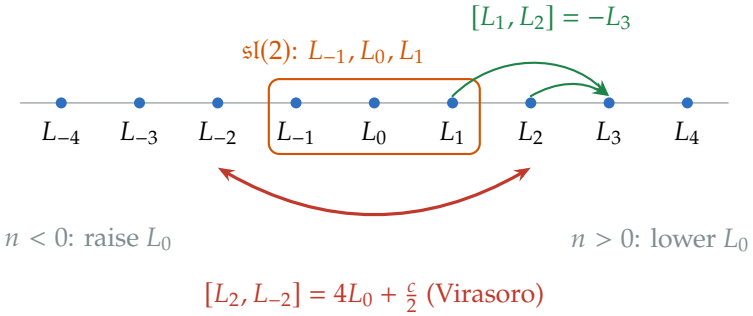


Figure 6.6: The Witt/Virasoro generators as points on a line labelled by mode number. Brackets add mode numbers (green). The orange box is the $\mathfrak{sl}(2)$ of Möbius transformations. The red arc is a bracket of L_n with L_{-n}, which in the Virasoro algebra picks up the c-number $\frac{c}{12}(n^3 - n)$; for $n = 2$ this is $\frac{c}{2}$, and for $n = 0, \pm 1$ it is zero, so the orange box is unaffected. In a quantum theory, $[L_0, L_n] = -nL_n$ says that L_n with $n > 0$ lowers the eigenvalue of L_0 by n and L_{-n} raises it by n.

6.1.8 The Virasoro algebra (first look)

Nash now states the second central actor of the chapter. In string theory the group that matters is not $\mathrm{Diff}(S^1)$ itself but a central extension $\widehat{\mathrm{Diff}(S^1)}$, the **Virasoro group**. Its Lie algebra, the **Virasoro algebra**, has generators L_n ($n \in \mathbb{Z}$) and one extra central element c, with

$$\boxed{[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12}\, m(m^2-1)\,\delta_{m,-n}, \qquad [L_m, c] = 0, \qquad m, n \in \mathbb{Z}} \tag{6.21}$$

Nash's (6.14). The number c (its value in an irreducible representation) is the **central charge**. Compare the Kac–Moody algebra (6.12): again the new term appears only when the mode numbers cancel, and again it is a c-number. Three quick checks:

- *Antisymmetry.* Swapping $m \leftrightarrow n$ with $n = -m$ turns $m(m^2-1)$ into $(-m)(m^2-1)$: the term is odd, as a commutator must be.
- *The $\mathfrak{sl}(2)$ is untouched.* $m(m^2-1) = (m-1)m(m+1)$ vanishes for $m = 0, \pm 1$.
- *Why the $\frac{1}{12}$ and why $m^3 - m$.* Both are forced. In Section 6.2.8 we show that the Jacobi identity allows only $am^3 + bm$, that the bm part can be absorbed in a shift of L_0, and in Section 6.2.9 that one free boson gives exactly $\frac{1}{12}(m^3 - m)$, so that with this normalisation c counts free bosons.

Physically c is a measure of the number of degrees of freedom: a free boson has $c = 1$, a free Majorana fermion $c = \frac{1}{2}$, and D free bosons (a string in D dimensions) have $c = D$.

6.1.9 The conformal group in two dimensions

Why is $\mathrm{Diff}(S^1)$ so closely tied to conformal invariance? In d dimensions a **conformal transformation** is a map that preserves angles; equivalently, it rescales the metric by a positive function, $g_{\mu\nu} \mapsto \Omega(x)^2 g_{\mu\nu}$. For $d \geq 3$ the conformal transformations of flat space form a finite-dimensional group. In $d = 2$ they form an infinite-dimensional one. Here is why.

The conformal Killing equation

An infinitesimal map $x^\mu \mapsto x^\mu + \varepsilon v^\mu(x)$ changes the flat metric $\delta_{\mu\nu}$ by $\varepsilon(\partial_\mu v_\nu + \partial_\nu v_\mu)$. It is conformal if this change is proportional to the metric. Taking the trace fixes the proportionality factor, and we get the **conformal Killing equation**

$$\partial_\mu v_\nu + \partial_\nu v_\mu = \frac{2}{d}\,(\partial\cdot v)\,\delta_{\mu\nu}. \tag{6.22}$$

In $d = 2$ with coordinates (x, y) and $v = (v_1, v_2)$ write out the three independent components:

$$\begin{aligned}
(\mu\nu) = (11): \quad & 2\partial_x v_1 \overset{(1)}{=} \partial_x v_1 + \partial_y v_2 && \Longrightarrow \quad \partial_x v_1 = \partial_y v_2,\\
(\mu\nu) = (22): \quad & 2\partial_y v_2 \overset{(2)}{=} \partial_x v_1 + \partial_y v_2 && \Longrightarrow \quad \text{the same equation},\\
(\mu\nu) = (12): \quad & \partial_x v_2 + \partial_y v_1 \overset{(3)}{=} 0 && \Longrightarrow \quad \partial_y v_1 = -\partial_x v_2.
\end{aligned}$$

(1) Equation (6.22) with $d = 2$ and $\partial\cdot v = \partial_x v_1 + \partial_y v_2$.
(2) The same, for the other diagonal component.
(3) The off-diagonal component: $\delta_{12} = 0$.

These are the *Cauchy–Riemann equations* for the complex function $v(z) = v_1 + iv_2$ of $z = x + iy$. So the conformal vector fields in two dimensions are exactly the holomorphic functions $v(z)$, and the transformations are $z \mapsto z + \varepsilon v(z)$. Finite conformal transformations are the holomorphic maps $z \mapsto w(z)$ with $w' \neq 0$ (and the antiholomorphic ones, which reverse orientation). There are infinitely many of them: $w(z) = z + \varepsilon z^{n+1}$ for every n. In $d \geq 3$, by contrast, (6.22) has only finitely many solutions: translations, rotations, the dilatation and the special conformal transformations, forming $\mathrm{SO}(d+1,1)$ of dimension $\frac{1}{2}(d+1)(d+2)$ (in $d = 4$: $4 + 6 + 1 + 4 = 15$).

Worked example 6.11: a holomorphic map preserves angles

Take $w = z^2$. The coordinate lines $x = \text{const}$ and $y = \text{const}$ meet at right angles, and so do their images. Indeed, with $w = u + iv$, $u = x^2 - y^2$, $v = 2xy$; a small displacement $\mathrm{d}z$ is mapped to

$$\mathrm{d}w \overset{(1)}{=} w'(z)\,\mathrm{d}z \overset{(2)}{=} 2z\,\mathrm{d}z = |2z|\; e^{i\arg(2z)}\,\mathrm{d}z.$$

(1) Holomorphic functions are complex differentiable: the derivative is a single complex number, independent of the direction of $\mathrm{d}z$.
(2) Write the complex number $2z$ in polar form.

Every small displacement at z is stretched by the same factor $|2z|$ and rotated by the same angle $\arg(2z)$. Two displacements are therefore rotated together, and the angle between them is preserved. The metric is rescaled: $|\mathrm{d}w|^2 = |w'|^2\,|\mathrm{d}z|^2$, i.e. $\Omega^2 = |w'(z)|^2$. (At $z = 0$, where $w' = 0$, angles are doubled; the map is not conformal there.)

Two commuting Witt algebras

The complexified conformal vector fields are $v(z)\partial_z$ (holomorphic) and $\bar v(\bar z)\partial_{\bar z}$ (antiholomorphic). Expanding $v(z)$ in a Laurent series gives the basis

$$\ell_n = -z^{n+1}\partial_z, \qquad \bar\ell_n = -\bar z^{n+1}\partial_{\bar z}, \qquad n \in \mathbb{Z}. \tag{6.23}$$

Exactly as in (6.20),

$$[\ell_m, \ell_n] = (m-n)\ell_{m+n}, \qquad [\bar\ell_m, \bar\ell_n] = (m-n)\bar\ell_{m+n}, \qquad [\ell_m, \bar\ell_n] = 0,$$

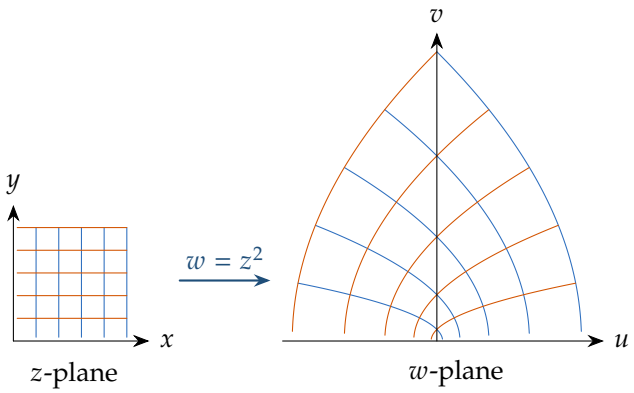

Figure 6.7: A holomorphic map is conformal. The square grid of the z-plane (left) is mapped by $w = z^2$ to a grid of parabolas (right). The cells are curved and of different sizes, but at every crossing the blue and orange curves still meet at a right angle. There is one such map for every holomorphic function, which is why the two-dimensional conformal group is infinite-dimensional.

the last because $\partial_z \bar{z} = 0$ and $\partial_{\bar{z}} z = 0$. So the local conformal algebra in two dimensions is two commuting copies of the Witt algebra: two Virasoro algebras with $c = 0$, as Nash says. In the quantum theory each copy acquires its own central charge, c and $\bar{c}$. For a closed string the two copies are the left-moving and right-moving oscillations.

Boundary values on the circle

Nash's remark that holomorphic maps are "determined by their boundary values on the unit circle" is the reason the conformal algebra reduces to vector fields on S^1. A holomorphic function on an annulus around $|z| = 1$ is determined by its Laurent series $\sum_n v_n z^n$, and the Laurent coefficients are just the Fourier coefficients of its restriction to the circle, $v(e^{i\theta}) = \sum_n v_n e^{in\theta}$. On the unit circle the field ℓ_n becomes exactly $L_n = ie^{in\theta}\partial_\theta$ by (6.18). So the Fourier expansion on S^1 "is" the Laurent expansion in the plane. In radial quantisation, circles $|z| = e^\tau$ are equal-time slices, τ is Euclidean time, and the dilatation $-(\ell_0 + \bar{\ell}_0) = z\partial_z + \bar{z}\partial_{\bar{z}} = \partial_\tau$ generates time translation: $L_0 + \bar{L}_0$ is the Hamiltonian (Chapter 11).

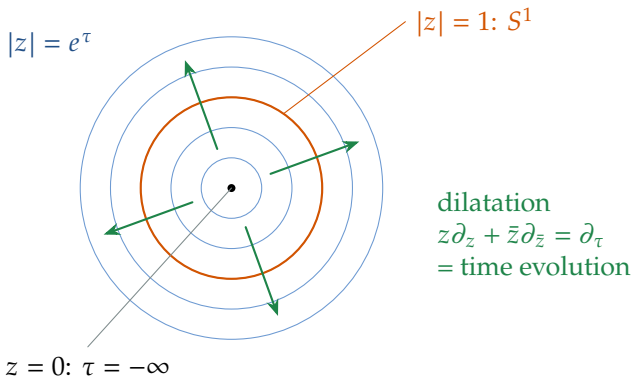

Figure 6.8: Radial quantisation. Map the cylinder (space S^1, Euclidean time τ) to the plane by $z = e^{\tau + i\theta}$. Equal-time circles become concentric circles (blue); the far past is the origin. The generators $L_n = -z^{n+1}\partial_z$ restricted to the unit circle (orange) are the vector fields on S^1, and the radial dilatation (green) is the Hamiltonian.

Watch out: local versus global conformal transformations

The vector fields ℓ_n are holomorphic on $\mathbb{C}\setminus\{0\}$ but most of them are singular somewhere on the Riemann sphere. $\ell_n = -z^{n+1}\partial_z$ is regular at $z=0$ only for $n \geq -1$. Near $z=\infty$ use $w = 1/z$: $\partial_z = -w^2\partial_w$, so $\ell_n = w^{1-n}\partial_w$, regular at $w=0$ only for $n \leq 1$. Only $n = -1, 0, 1$ survive both tests. So the *global* conformal group of the sphere is the finite-dimensional Möbius group $\mathrm{PSL}(2,\mathbb{C})$; the infinite-dimensional Witt algebra consists of *local* conformal transformations, defined on an annulus. For a physicist, local is what matters: Ward identities are local.

6.1.10 The group of gauge transformations

Physicists write a gauge transformation as a function $g(x)$ with values in G, and so it looks like an element of $\mathrm{Map}(X, G)$. That is right locally, but not globally. If the gauge field is a connection on a *nontrivial* principal bundle P (a monopole, an instanton), then there is no global choice of gauge, and a gauge transformation cannot be described by a single function on all of X. We need a description that uses the bundle itself.

Reminder: principal bundles

A **principal G-bundle** $\pi : P \to X$ is a space P with a free right action of G, $p \mapsto pg$, whose orbits are the fibres $P_x = \pi^{-1}(x)$, each a copy of G. Over a small open set $U \subset X$ we can choose a **local section** $s : U \to P$ and then write every point of $\pi^{-1}(U)$ uniquely as $p = s(x)h$; in these *local coordinates* $p = (x, h)$ and the right action is $(x,h)g = (x, hg)$. On an overlap of two patches the sections differ by a **transition function**: $s_j(x) = s_i(x)\, t_{ij}(x)$ with $t_{ij} : U_i \cap U_j \to G$. A connection is a $\mathfrak{g}$-valued 1-form A_i on each patch, glued by $A_j = t_{ij}^{-1} A_i t_{ij} + t_{ij}^{-1}\mathrm{d}t_{ij}$ (Chapter T3).

Dictionary: anti-Hermitian versus Hermitian gauge fields

In this subsection we use the mathematicians' convention of Chapter T3: A is anti-Hermitian, $F = \mathrm{d}A + A\wedge A$, and a gauge transformation acts as $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$. The physicists' Hermitian field is A^a_{phys} with $A_{\text{math}} = -i\, g_{\text{YM}} A^a_{\text{phys}} T^a$ and Hermitian T^a. For $G = \mathrm{U}(1)$ and $g = e^{i\lambda}$, $A_{\text{math}} = -iea$ transforms as $-iea \mapsto -iea + i\mathrm{d}\lambda$, i.e. $a \mapsto a - \frac{1}{e}\mathrm{d}\lambda$, the textbook gauge transformation of electromagnetism.

Bundle automorphisms

A bundle has the same physical content after any transformation that preserves its structure. So the symmetries of a gauge theory built on P are the maps $P \to P$ that respect the G-action.

Working definition 6.6 (bundle automorphism)

A **bundle automorphism** is a diffeomorphism $\alpha : P \to P$ that commutes with the action of G [moving p to pg and then applying α lands at the same point as applying α first and then multiplying by g]. Nash writes the action on the left, $g\cdot p := pg^{-1}$ (his (6.17)), so the condition reads $\alpha(g\cdot p) = g\cdot\alpha(p)$ (his (6.16)); replacing g by g^{-1} this is the same as

$$\alpha(pg) = \alpha(p)\, g \qquad \text{for all } p \in P,\ g \in G, \tag{6.24}$$

his (6.18). The automorphisms form a group $\mathrm{Aut}(P)$ under composition, $(\alpha\bullet\beta)(p) = \alpha(\beta(p))$. *Operationally:* α may move fibres around, but it must map each fibre [$P_x = \pi^{-1}(x)$, the

copy of G over the point x] to a fibre, and it must do so "by left multiplication", so that it commutes with right multiplication.

Why must an automorphism map fibres to fibres? The fibre through p is the orbit $\{pg\}$. By (6.24) its image is $\{\alpha(p)g\}$, the orbit of $\alpha(p)$, which is again a fibre. Hence α induces a map $h(\alpha) : X \to X$ of the base, $h(\alpha)(\pi(p)) := \pi(\alpha(p))$. It is a diffeomorphism, and $h(\alpha \bullet \beta) = h(\alpha) \circ h(\beta)$. So h is a group homomorphism

$$h : \mathrm{Aut}(P) \longrightarrow \mathrm{Diff}(X).$$

Working definition 6.7 (gauge group)

The **group of gauge transformations** is the kernel of h:

$$\bar{\mathcal{G}} := \mathrm{Ker}\, h = \{\alpha \in \mathrm{Aut}(P) : \ \pi(\alpha(p)) = \pi(p) \text{ for all } p\},$$

the automorphisms that map every fibre *to itself*. The **based gauge group** is the subgroup

$$\mathcal{G} := \{\alpha \in \bar{\mathcal{G}} : \ \alpha(p_0) = p_0\},$$

for a fixed point $p_0 \in P$ over a base point $x_0 = \pi(p_0)$. By (6.24), $\alpha(p_0 g) = p_0 g$ for all g, so an element of $\mathcal{G}$ acts as the identity on the whole fibre P_{x_0}.

The based gauge group is used in Chapter 8: unlike $\bar{\mathcal{G}}$, it acts *freely* on the space of connections, so the quotient is a manifold. The quotient $\bar{\mathcal{G}}/\mathcal{G}$ is a copy of G (the value of the gauge transformation at the base point), exactly as in the splitting $\mathrm{Map}(X, G) \cong G \times \mathrm{Map}_0(X, G)$ of (6.4).

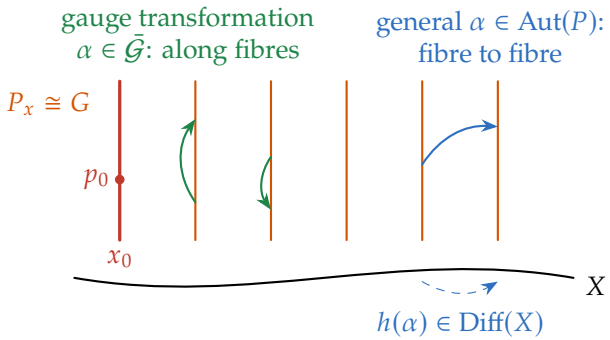

Figure 6.9: The bundle P drawn as fibres (orange) over the base X. A gauge transformation moves points only up and down their own fibre (green). A general automorphism may carry one fibre onto another (blue), and so covers a diffeomorphism of the base (dashed). Based gauge transformations are, in addition, the identity on the fibre over the base point (red).

Key idea: $\mathrm{Aut}(P)$ contains both kinds of invariance

The sequence

$$1 \longrightarrow \bar{\mathcal{G}} \longrightarrow \mathrm{Aut}(P) \xrightarrow{h} \mathrm{Diff}(X) \tag{6.25}$$

is exact: $\bar{\mathcal{G}}$ is exactly what h kills. The group $\mathrm{Aut}(P)$ therefore contains the two invariances of a gauge theory coupled to gravity: *internal* gauge invariance, which transforms the fibres ($\bar{\mathcal{G}}$), and *Einstein's* general coordinate invariance, which transforms the base ($\mathrm{Diff}(X)$). For a trivial bundle $P = X \times G$ every diffeomorphism lifts, $\alpha(x, g) = (\phi(x), g)$, so h is onto and $\mathrm{Aut}(P)$ is the semidirect product $\mathrm{Map}(X, G) \rtimes \mathrm{Diff}(X)$. This is our first example of a *group*

extension, the subject of §6.2.

Gauge transformations as sections of $\mathrm{Ad}P$

Now we describe $\bar{\mathcal{G}}$ concretely. Given $\alpha \in \bar{\mathcal{G}}$, the points p and $\alpha(p)$ lie in the same fibre, so they differ by a unique group element. Define $\hat{\alpha} : P \to G$ by

$$\alpha(p) = p\,\hat{\alpha}(p), \tag{6.26}$$

Nash's (6.19). The equivariance (6.24) becomes a condition on $\hat{\alpha}$:

$$\begin{aligned} (pg)\,\hat{\alpha}(pg) &\overset{(1)}{=} \alpha(pg) \overset{(2)}{=} \alpha(p)\,g \overset{(3)}{=} p\,\hat{\alpha}(p)\,g, \\ \Longrightarrow \quad \hat{\alpha}(pg) &\overset{(4)}{=} g^{-1}\,\hat{\alpha}(p)\,g. \end{aligned} \tag{6.27}$$

(1) Definition (6.26) at the point pg.
(2) Equivariance (6.24).
(3) Definition (6.26) at the point p.
(4) Cancel p (the action is free, so $pa = pb$ implies $a = b$) and multiply by g^{-1} on the left.

This is Nash's (6.20). In local coordinates $p = (x, h)$, i.e. $p = s(x)h$, define $\hat{\alpha}_X(x) := \hat{\alpha}(s(x))$. Then by (6.27) with $p = s(x)$ and $g = h$,

$$\alpha(x,h) \overset{(1)}{=} (x,h)\,\hat{\alpha}(x,h) \overset{(2)}{=} \big(x,\ h\,h^{-1}\hat{\alpha}_X(x)h\big) \overset{(3)}{=} \big(x,\ \hat{\alpha}_X(x)\,h\big). \tag{6.28}$$

(1) Definition (6.26).
(2) Equivariance (6.27) of $\hat{\alpha}$, and the right action $(x,h)g = (x,hg)$.
(3) $hh^{-1} = 1$.

This is Nash's (6.21): *in a local trivialisation, a gauge transformation is left multiplication of the fibre coordinate by a G-valued function $\hat{\alpha}_X(x)$.* That is the physicist's $g(x)$.

What happens when we change patch? Let $s_j = s_i t_{ij}$ on an overlap and write $\phi_i = \hat{\alpha}(s_i)$, $\phi_j = \hat{\alpha}(s_j)$. Then

$$\phi_j(x) \overset{(1)}{=} \hat{\alpha}\big(s_i(x)\,t_{ij}(x)\big) \overset{(2)}{=} t_{ij}(x)^{-1}\,\phi_i(x)\,t_{ij}(x). \tag{6.29}$$

(1) Definition of ϕ_j and $s_j = s_i t_{ij}$.
(2) Equation (6.27) with $g = t_{ij}$.

So the local functions $\phi_i : U_i \to G$ do *not* glue to a single function $X \to G$. They glue by *conjugation* with the transition functions. An object that is locally a G-valued function and glues this way is a section of the **adjoint bundle**

$$\mathrm{Ad}P := P \times_{\mathrm{Ad}} G,$$

the bundle with fibre G whose transition functions act on the fibre by conjugation, $\phi \mapsto t^{-1}\phi t$, rather than by multiplication.

Working definition 6.8 (gauge group as sections)

$$\bar{\mathcal{G}} = \Gamma(X, \mathrm{Ad}P), \qquad \mathrm{Ad}P = P \times_{\mathrm{Ad}} G.$$

[Γ denotes sections, a smooth choice of one point $\phi(x)$ in the fibre over each $x \in X$]

Operationally: a gauge transformation is a collection of functions $\phi_i : U_i \to G$, one per patch, related on overlaps by $\phi_j = t_{ij}^{-1}\phi_i t_{ij}$ [t_{ij} is the transition function, $s_j = s_i t_{ij}$ on the overlap $U_i \cap U_j$]. If G is abelian, conjugation does nothing, $\mathrm{Ad}P = X \times G$, and $\bar{\mathcal{G}} = \mathrm{Map}(X, G)$ whatever P is. If P is trivial [$P = X \times G$, so a single section covers all of X], one patch suffices and again $\bar{\mathcal{G}} = \mathrm{Map}(X, G)$.

The product is still pointwise

Nash checks that composition of automorphisms becomes pointwise multiplication of sections. For $\alpha, \beta \in \bar{\mathcal{G}}$,

$$\alpha\big(\beta(p)\big) \overset{(1)}{=} \alpha\big(p\,\hat{\beta}(p)\big) \overset{(2)}{=} \alpha(p)\,\hat{\beta}(p) \overset{(3)}{=} p\,\hat{\alpha}(p)\,\hat{\beta}(p). \tag{6.30}$$

(1) Definition (6.26) for β.
(2) Equivariance (6.24) of α with $g = \hat{\beta}(p)$.
(3) Definition (6.26) for α.

So $\widehat{\alpha \bullet \beta} = \hat{\alpha}\,\hat{\beta}$, the pointwise product; in local coordinates $\hat{\gamma}_X(x) = \hat{\alpha}_X(x)\hat{\beta}_X(x)$, which is Nash's (6.22)–(6.23). (Nash's version inserts $\hat{\beta}_X\hat{\beta}_X^{-1}$ in the middle; the result is the same.) Differentiating at the identity, the Lie algebra of $\bar{\mathcal{G}}$ is the space of sections of the **adjoint Lie algebra bundle** $\mathrm{ad}P = P \times_{\mathrm{Ad}} \mathfrak{g}$, whose fibre is $\mathfrak{g}$ and whose transition functions act by $\xi \mapsto t^{-1}\xi t$. Summarising (Nash's (6.24)):

$$\boxed{\bar{\mathcal{G}} = \Gamma(X, \mathrm{Ad}P), \quad \mathrm{Ad}P = P \times_{\mathrm{Ad}} G; \qquad \mathrm{Lie}\,\bar{\mathcal{G}} = \Gamma(X, \mathrm{ad}P), \quad \mathrm{ad}P = P \times_{\mathrm{Ad}} \mathfrak{g}.} \tag{6.31}$$

Worked example 6.12: gauge transformations on the instanton bundle

Let P be the SU(2) bundle over S^4 with instanton number 1. Cover S^4 by a northern and a southern patch overlapping near the equator S^3, with transition function $t(x) = x_4 + i\vec{x}\cdot\vec{\sigma}$, the degree-one map of Example 6.5. A gauge transformation is a pair ϕ_N, ϕ_S of SU(2)-valued functions with $\phi_S = t^{-1}\phi_N t$ on the equator.

- The constant pair $\phi_N = \phi_S = -1$ is allowed, because -1 is central and $t^{-1}(-1)t = -1$.
- Take $\phi_N = u = e^{i\lambda\sigma_3}$, constant on the northern patch. On the overlap the rule forces $\phi_S = t^{-1}ut$, which is *not* constant: as x runs over the equator, $t^{-1}ut$ runs over the whole conjugacy class of u, a 2-sphere inside SU(2). This map $S^3 \to \mathrm{SU}(2)$ misses most of SU(2), so it can be contracted and hence extended smoothly over the southern patch. The result is a legitimate gauge transformation, constant in the north and not in the south, and no single function on S^4 describes it.
- The pair $\phi_N = \phi_S = u$ with u a constant non-central element is *not* allowed, because $t^{-1}ut \neq u$ at most points of the equator. So "global" SU(2) rotations are not gauge transformations of this bundle: only the centre $\{\pm 1\}$ survives as constants.

The last point is physical: in an instanton background there is no global colour rotation, only the local gauge transformations. It is also why $\bar{\mathcal{G}}$ is not $\mathrm{Map}(S^4, \mathrm{SU}(2))$ here.

Worked example 6.13: the monopole bundle: abelian, so nothing changes

Let P be the U(1) bundle over S^2 of the Dirac monopole of charge n, with transition function

$t = e^{in\varphi}$ on the equator. A gauge transformation is a pair $\phi_N = e^{i\lambda_N}$, $\phi_S = e^{i\lambda_S}$ with

$$\phi_S \overset{(1)}{=} t^{-1}\phi_N t \overset{(2)}{=} \phi_N .$$

(1) The gluing rule (6.29).
(2) U(1) is abelian.

So the two local functions agree on the overlap and define one function $S^2 \to \mathrm{U}(1)$: $\bar{\mathcal{G}} = \mathrm{Map}(S^2, \mathrm{U}(1))$, although P is nontrivial. Acting on the potential $A_N = -\frac{in}{2}(1-\cos\vartheta)\mathrm{d}\varphi$ (anti-Hermitian convention) it gives $A_N \mapsto A_N + i\,\mathrm{d}\lambda$, the familiar gauge transformation, the same in both patches.

Watch out: large gauge transformations and nontrivial bundles are different things

Two different topological issues are easily confused. (i) $\bar{\mathcal{G}}$ may have many components even for a trivial bundle: $\pi_0(\mathrm{Map}(S^3, \mathrm{SU}(2))) = \mathbb{Z}$ (Example 6.5); these are the large gauge transformations behind the θ-vacuum. (ii) For a nontrivial bundle, $\bar{\mathcal{G}}$ is not a group of maps at all, but a group of sections of $\mathrm{Ad}P$. Both matter in Chapter 8.

6.1.11 Current algebra

The first time an infinite-dimensional Lie algebra appeared in physics was the current algebra of the strong interactions (Adler and Dashen; Gell-Mann and Ne'eman). The idea: even if we cannot solve the dynamics, the *equal-time commutators* of the conserved currents $j^a_\mu(x)$ of an internal symmetry are fixed by the symmetry algebra, and they lead to sum rules and low-energy theorems. The charges $Q^a = \int j^a_0\,\mathrm{d}^3x$ generate the finite group G; the local densities $j^a_0(x)$ generate its gauge group $\mathrm{Map}(\mathbb{R}^3, G)$.

Currents on a circle

Nash's concrete example is two-dimensional spacetime with periodic space, a circle with angle θ. Package the Kac–Moody generators of (6.12) (now thought of as operators on a Hilbert space) into a current density:

$$j^a(\theta) \coloneqq \frac{1}{2\pi}\sum_{n\in\mathbb{Z}} T^a_n\, e^{in\theta}, \qquad T^a_n = \int_0^{2\pi} j^a(\theta)\, e^{-in\theta}\,\mathrm{d}\theta. \tag{6.32}$$

This is Nash's (6.25), where we have put in the factor $\frac{1}{2\pi}$ that makes T^a_n the Fourier coefficients (Nash leaves it out; see below). If $(T^a_n)^\dagger = T^a_{-n}$, which is the case in a unitary representation, then $j^a(\theta)$ is a Hermitian operator at each θ. The total charge is $T^a_0 = \int j^a\,\mathrm{d}\theta$.

To compute the commutator of two currents we need the Fourier series of the delta function on the circle,

$$\sum_{m\in\mathbb{Z}} e^{im(\theta-\varphi)} = 2\pi\,\delta(\theta-\varphi), \qquad \sum_{m\in\mathbb{Z}} m\, e^{im(\theta-\varphi)} = -2\pi i\,\partial_\theta\delta(\theta-\varphi). \tag{6.33}$$

(The first is the completeness of the Fourier basis; the second follows by applying $-i\partial_\theta$ to the

first.) Now

$$
\begin{aligned}
[j^a(\theta), j^b(\varphi)] &\overset{(1)}{=} \frac{1}{4\pi^2}\sum_{m,n} e^{im\theta}e^{in\varphi}\,[T^a_m, T^b_n] \\
&\overset{(2)}{=} \frac{1}{4\pi^2}\sum_{m,n} e^{im\theta+in\varphi}\Big(i f^{abc}T^c_{m+n} + k\,m\,\delta^{ab}\delta_{m+n,0}\Big) \\
&\overset{(3)}{=} \frac{i f^{abc}}{4\pi^2}\sum_p T^c_p e^{ip\varphi}\sum_m e^{im(\theta-\varphi)} + \frac{k\,\delta^{ab}}{4\pi^2}\sum_m m\,e^{im(\theta-\varphi)} \\
&\overset{(4)}{=} i f^{abc}\,j^c(\varphi)\,\delta(\theta-\varphi) - \frac{ik}{2\pi}\,\delta^{ab}\,\partial_\theta\delta(\theta-\varphi). \qquad (6.34)
\end{aligned}
$$

(1) Definition (6.32), twice; the commutator is bilinear.
(2) The Kac–Moody relations (6.12).
(3) In the first term set $p = m + n$, so $e^{im\theta+in\varphi} = e^{ip\varphi}e^{im(\theta-\varphi)}$; in the second the Kronecker delta sets $n = -m$.
(4) The two sums (6.33), and $\frac{1}{2\pi}\sum_p T^c_p e^{ip\varphi} = j^c(\varphi)$.

This is Nash's (6.26), $[j^a(\theta), j^b(\varphi)] = i f^{abc} j^c(\theta)\delta(\theta-\varphi) + ic\,\delta^{ab}\delta'(\theta-\varphi)$, with his constant c equal to $-k/2\pi$ in our normalisation (and $j^c(\theta)\delta(\theta-\varphi) = j^c(\varphi)\delta(\theta-\varphi)$).

Key idea: the central term is the Schwinger term

The first term of (6.34) is the classical, pointwise bracket (6.3) of the gauge algebra: currents at different points commute, and at the same point they rotate into each other. The second term, proportional to the *derivative* of the delta function and to the unit operator, is the **Schwinger term**. It is the central extension of the loop algebra, seen in position space.

Worked example 6.14: smeared currents and the cocycle

Delta functions are awkward; smear them. For real test functions f, g on the circle define $Q^a(f) = \int_0^{2\pi} f(\theta)j^a(\theta)\,\mathrm{d}\theta$. Then

$$
\begin{aligned}
[Q^a(f), Q^b(g)] &\overset{(1)}{=} \int\!\!\int f(\theta)g(\varphi)\,[j^a(\theta), j^b(\varphi)]\,\mathrm{d}\theta\,\mathrm{d}\varphi \\
&\overset{(2)}{=} i f^{abc}\int f g\, j^c\,\mathrm{d}\varphi - \frac{ik}{2\pi}\delta^{ab}\int\!\!\int f(\theta)g(\varphi)\,\partial_\theta\delta(\theta-\varphi)\,\mathrm{d}\theta\,\mathrm{d}\varphi \\
&\overset{(3)}{=} i f^{abc}\,Q^c(fg) + \frac{ik}{2\pi}\,\delta^{ab}\int_0^{2\pi} f'(\varphi)\,g(\varphi)\,\mathrm{d}\varphi.
\end{aligned}
$$

(1) Bilinearity.
(2) Equation (6.34); the delta function does the θ integral in the first term.
(3) Integrate by parts in θ (no boundary on a circle): $\int f(\theta)\partial_\theta\delta(\theta-\varphi)\mathrm{d}\theta = -f'(\varphi)$.

The first term is the loop algebra: the smeared charges multiply their test functions pointwise. The second is a number that depends on f and g only, antisymmetric because $\int f'g = -\int fg'$. It vanishes if f or g is constant, so the global charges $Q^a(1) = T^a_0$ still form $\mathfrak{g}$. This number is the 2-*cocycle* of the extension; we will study exactly this bilinear form in Section 6.2.4. As a check, take $f = e^{im\theta}$, $g = e^{in\theta}$ (complex test functions). Then $Q^a(e^{im\theta}) = T^a_{-m}$ and the central term is $\frac{ik}{2\pi}\,(im)\,2\pi\,\delta_{m+n,0} = -km\,\delta_{m+n,0}$, which is the central term of $[T^a_{-m}, T^b_{-n}]$ in (6.12). ✓

Why the Schwinger term cannot vanish

Schwinger's 1959 argument shows that a term like this is forced on us in any relativistic quantum field theory, in any dimension. Let j_μ be a conserved current, $\partial_0 j_0 = -\partial_1 j_1$ (one space dimension for simplicity), and suppose naively that $[j_0(x), j_1(y)] = 0$ at equal times. Consider the smeared charge density $j_0(f) = \int f(x) j_0(x)\,\mathrm{d}x$ and the vacuum expectation value of a double commutator with the Hamiltonian H, normalised so that $H|0\rangle = 0$:

$$\langle 0|[j_0(f),[H,j_0(f)]]|0\rangle \overset{(1)}{=} 2\sum_n E_n\ |\langle n|j_0(f)|0\rangle|^2\ >\ 0,$$

$$[H,j_0(f)] \overset{(2)}{=} -i\int f\,\partial_0 j_0\,\mathrm{d}x \overset{(3)}{=} i\int f\,\partial_1 j_1\,\mathrm{d}x \overset{(4)}{=} -i\int f'\,j_1\,\mathrm{d}x.$$

(1) Insert a complete set of energy eigenstates; $j_0(f)$ is Hermitian and $E_n \geq 0$. The sum is strictly positive unless $j_0(f)|0\rangle = 0$, which would make the charge density annihilate the vacuum; for any interacting or free theory with charged states it does not.
(2) Heisenberg equation $\partial_0 O = i[H, O]$.
(3) Current conservation.
(4) Integrate by parts.

So $\langle 0|[j_0(f), j_1(f')]|0\rangle \neq 0$, contradicting the naive assumption. The equal-time commutator of j_0 and j_1 must contain a term with a derivative of a delta function, a Schwinger term. In two dimensions, with chiral currents $j = j_0 \pm j_1$, this is precisely the central term of (6.34). We will compute it explicitly for free fermions in Section 6.2.9, where it comes out of the filled Dirac sea.

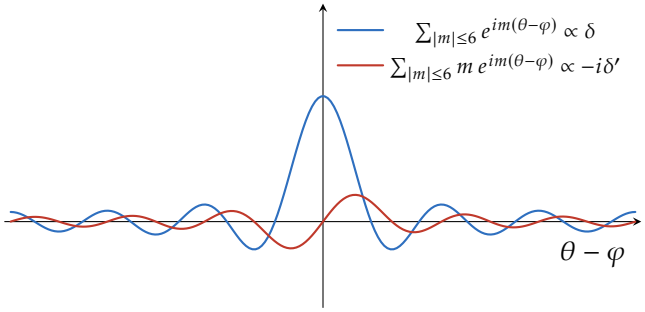

Figure 6.10: Truncated Fourier sums (rescaled for display). The sum of the modes $e^{im(\theta-\varphi)}$ (blue) peaks at $\theta = \varphi$ and tends to $2\pi\delta(\theta-\varphi)$: this gives the pointwise term of the current algebra. Weighting each mode by m, as the central term $km\delta_{m+n,0}$ does, gives an odd function (red; its imaginary part is shown) that tends to $-2\pi i\delta'$: the Schwinger term.

6.1.12 Analyticity, and why $\mathrm{Diff}(X)$ is strange

All the groups above are smooth infinite-dimensional Lie groups. Nash ends the section with a warning: beyond smoothness, the two families behave very differently.

$\mathrm{Map}(X, G)$ is analytic

A finite-dimensional Lie group G is automatically *analytic*: in exponential coordinates $g = g_0 \exp(\xi)$ the group multiplication is given by convergent power series (the Baker–Campbell–Hausdorff series). The group $\mathrm{Map}(X, G)$ inherits this, pointwise. Topologise $\mathrm{Map}(X, G)$ by *uniform convergence of all derivatives*: $\alpha_n \to \alpha$ if $\alpha_n \to \alpha$ uniformly on X and so do all partial

derivatives of all orders. Then charts

$$\begin{aligned}\mathrm{Map}(X,\mathfrak{g}) \supset \{\xi \text{ small}\} &\longrightarrow \mathrm{Map}(X,G),\\ \xi &\longmapsto \alpha_0 \exp(\xi), \qquad (\alpha_0 \exp \xi)(x) = \alpha_0(x)\exp(\xi(x))\end{aligned}$$

cover a neighbourhood of α_0, and the changes of chart and the group law are given, point by point, by the same convergent power series as in G. So $\mathrm{Map}(X,G)$ has an atlas of analytic charts ("Taylor series with no remainder"), and its exponential map $\mathrm{Map}(X,\mathfrak{g}) \to \mathrm{Map}(X,G)$ is a local diffeomorphism near 0, just as for G.

$\mathrm{Diff}(X)$ is not

For $\mathrm{Diff}(X)$ none of this holds (Milnor). The composition $\alpha \circ \beta$ involves α evaluated at a moved point, and Taylor expanding $\alpha(\beta(x))$ in β costs derivatives of α; the power series do not close on any function space. The most striking symptom concerns the exponential map $\exp : \mathrm{vect}(X) \to \mathrm{Diff}(X)$, $V \mapsto \alpha_1$ (the time-one flow).

Key idea: the exponential map of $\mathrm{Diff}(S^1)$ is not a local homeomorphism

There are diffeomorphisms of the circle arbitrarily close to the identity that lie on *no* one-parameter subgroup; and there are diffeomorphisms arbitrarily close to the identity that lie on *several* one-parameter subgroups. So near the identity, exp is neither onto nor one-to-one, and the flows of vector fields do not provide canonical coordinates on $\mathrm{Diff}(X)$. In finite dimensions the inverse function theorem forbids this; in the Fréchet space $\mathrm{vect}(S^1)$ the inverse function theorem fails.

Both halves can be seen with explicit examples. We work on S^1 with angle θ.

Worked example 6.15: close to the identity, but on no one-parameter subgroup

For $n \geq 1$ and a small $\varepsilon > 0$, let

$$f_n(\theta) = \theta + \frac{\pi}{n} + \varepsilon \sin^2(n\theta).$$

As $n \to \infty$ with, say, $\varepsilon = e^{-n}$, f_n and all its derivatives converge uniformly to those of the identity (the k-th derivative of the ε term is at most $\varepsilon(2n)^k \to 0$). So $f_n \to \mathrm{id}$ in $\mathrm{Diff}(S^1)$.
Step 1: f_n has a periodic orbit. Let $\theta_j = j\pi/n$. Then $\sin^2(n\theta_j) = \sin^2(j\pi) = 0$, so

$$f_n(\theta_j) \overset{(1)}{=} \theta_j + \frac{\pi}{n} = \theta_{j+1}, \qquad f_n^{2n}(\theta_0) \overset{(2)}{=} \theta_{2n} = 2\pi \equiv \theta_0.$$

(1) The ε term vanishes at the points θ_j.
(2) Apply this $2n$ times.

Step 2: $f_n^{2n} \neq \mathrm{id}$. Take θ not of the form $j\pi/n$. Since $\varepsilon \sin^2 \geq 0$, and f_n is increasing,

$$f_n^{2n}(\theta) \overset{(1)}{=} f_n^{2n-1}\big(f_n(\theta)\big) \overset{(2)}{\geq} f_n(\theta) + (2n-1)\frac{\pi}{n} \overset{(3)}{>} \theta + 2\pi.$$

(1) Split off the first step.
(2) Each application of f_n adds at least π/n.
(3) $f_n(\theta) = \theta + \pi/n + \varepsilon \sin^2(n\theta) > \theta + \pi/n$ because $\sin(n\theta) \neq 0$.

Step 3: f_n is not $\exp(V)$ for any V. Suppose f_n is the time-one flow of $V = v(\theta)\partial_\theta$. If $v(\theta_*) = 0$ somewhere, θ_* would be fixed by the flow and hence by f_n; but $f_n(\theta) > \theta$ everywhere. So v never vanishes. A nowhere-vanishing vector field on a circle can be straightened: in

the new coordinate $s(\theta) = \lambda \int_0^\theta d\theta'/v(\theta')$, with λ chosen so that s runs from 0 to 2π, the field is the constant $\lambda\,\partial_s$, and its time-one flow is the rigid rotation $s \mapsto s + \lambda$. A rigid rotation that has a periodic orbit of period $2n$ going once round the circle is the rotation by π/n, and then *every* orbit has period $2n$, i.e. its $2n$-th power is the identity. Changing coordinates does not affect this, so $f_n^{2n} = \mathrm{id}$, contradicting Step 2.
So f_n lies on no one-parameter subgroup, however close to the identity it is.

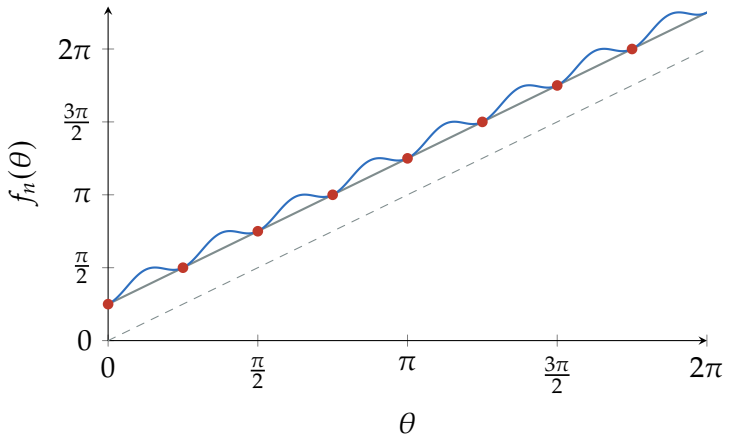

Figure 6.11: Milnor's example with $n = 4$ (and ε exaggerated). The blue graph $f_4(\theta) = \theta + \frac{\pi}{4} + \varepsilon \sin^2 4\theta$ touches the graph of the rigid rotation by $\pi/4$ (grey) exactly at the red points $\theta = j\pi/4$, which form a periodic orbit of period 8. Everywhere else f_4 moves points strictly further, so $f_4^8 \neq \mathrm{id}$. A time-one flow with a period-8 orbit would have $f^8 = \mathrm{id}$; hence f_4 is not the exponential of any vector field. Letting $n \to \infty$ and $\varepsilon \to 0$ gives such maps arbitrarily close to the identity (dashed).

Worked example 6.16: close to the identity, on many one-parameter subgroups

Let R be the rotation $\theta \mapsto \theta + \frac{2\pi}{n}$, the time-one flow of the constant field $V = \frac{2\pi}{n}\partial_\theta$. Let ϕ be any diffeomorphism that commutes with R, for instance $\phi(\theta) = \theta + \delta \sin(n\theta)$ with $|\delta| < 1/n$. Then

$$\phi \circ \exp(tV) \circ \phi^{-1} \overset{(1)}{=} \exp\big(t\,\phi_* V\big),$$
$$\phi \circ R \circ \phi^{-1} \overset{(2)}{=} R.$$

(1) Conjugating a flow by a diffeomorphism gives the flow of the transported vector field $\phi_* V$.
(2) ϕ commutes with R: $\phi(\theta + 2\pi/n) = \theta + 2\pi/n + \delta \sin(n\theta + 2\pi) = \phi(\theta) + 2\pi/n$.

So $R = \exp(V) = \exp(\phi_* V)$ at $t = 1$. The field $\phi_* V = \frac{2\pi}{n}\phi'(\phi^{-1}(\theta))\partial_\theta$ is not constant (it is $\frac{2\pi}{n}(1 + n\delta\cos(n\phi^{-1}(\theta)))\partial_\theta$), so R lies on two different one-parameter subgroups (in fact on a whole family, one for each δ). As $n \to \infty$ both R and the vector fields tend to the identity and to zero. So exp is not one-to-one on any neighbourhood of 0.

Watch out: what this does and does not mean for physics

Nothing here stops us from using $\mathrm{vect}(S^1)$ and its central extension, the Virasoro algebra, in quantum theory: the Lie algebra is perfectly well defined, and its representations are what we construct. What fails is the naive idea that every group element near the identity is $e^{i\sum \varepsilon_n L_n}$. For $\mathrm{Map}(X, G)$ that idea is fine.

Reading Nash (pp. 174–178, (6.11)–(6.26))

Nash's Diff(X) example is (6.11)–(6.13), stated without the flows; our Examples 6.8 and 6.9 and the sign pitfall fill in the details. His Virasoro relations (6.14) are quoted with the reference to Gel'fand–Fuks; we derive them in §6.2. The formula (6.15), $L_n = -z^{n+1}\frac{d}{dz} = e^{in\theta} i\frac{d}{d\theta}$, is our (6.18); the "two commuting Virasoro algebras (with $c = 0$)" are the $\ell_n, \bar{\ell}_n$ of (6.23). For the gauge group, his (6.16)–(6.24) are our (6.24)–(6.31); we have added the gluing rule (6.29), which is the real reason the gauge group is $\Gamma(X, \mathrm{Ad}P)$. In (6.25)–(6.26) Nash drops the factor $\frac{1}{2\pi}$ and leaves the constant in front of δ' unnamed; with our normalisation it is $-k/2\pi$. His analyticity paragraph cites Milnor for the failure of exp; Example 6.15 is the standard example.

Recap: Section 6.1

- Map(X, G): pointwise product; Lie algebra Map($X, \mathfrak{g}$) with pointwise bracket; $\pi_0 = \pi_0(G) \times [X, G]_0$, e.g. $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$ (degree), and $\tilde{K}^{-1}(X)$ in general.
- $LG = \mathrm{Map}(S^1, G)$; basis $T^a_n = e^{in\theta}T^a$ with $[T^a_m, T^b_n] = if^{abc}T^c_{m+n}$; the quantum version adds the central term $km\delta^{ab}\delta_{m+n,0}$ (affine Kac–Moody).
- Diff(X): composition; Lie algebra = vector fields (bracket up to a sign convention); flows $\alpha_t = \exp(tV)$.
- Diff(S^1): $L_n = ie^{in\theta}\partial_\theta = -z^{n+1}\partial_z$, Witt algebra $[L_m, L_n] = (m-n)L_{m+n}$; Virasoro adds $\frac{c}{12}m(m^2-1)\delta_{m+n,0}$; the $\mathfrak{sl}(2)$ of $L_{0,\pm1}$ is untouched.
- 2d conformal group: Cauchy–Riemann, two commuting Witt algebras.
- Gauge group $\bar{\mathcal{G}} = \mathrm{Ker}(\mathrm{Aut}(P) \to \mathrm{Diff}(X)) = \Gamma(X, \mathrm{Ad}P)$, pointwise product; locally $g(x)$ acting by left multiplication.
- Current algebra: $j^a(\theta)$ with Schwinger term $\propto \delta'$ = Kac–Moody central term.
- Map(X, G) is analytic; Diff(S^1) is not, and its exp is neither locally onto nor locally one-to-one.

6.2 Group extensions

In §6.1 we quoted two Lie algebras, the affine Kac–Moody algebra (6.12) and the Virasoro algebra (6.21), in a form with an extra c-number in the commutators. The classical groups LG and Diff(S^1) have no such term: their Lie algebras are $[T^a_m, T^b_n] = if^{abc}T^c_{m+n}$ and $[L_m, L_n] = (m-n)L_{m+n}$. This section answers three questions.

(a) *Where do c-numbers in commutators come from?* From the fact that quantum mechanics represents symmetries on rays, so that operators need only multiply up to a phase. The mathematical name is a *central extension*.

(b) *When can they be removed by redefining the generators?* This is a cohomology question: the c-number is a *2-cocycle*, and it can be removed exactly when it is a *coboundary*. For finite-dimensional semisimple groups it always can. For loop groups and Diff(S^1) it cannot.

(c) *How are the numbers k and c fixed in practice?* By the consistency (Jacobi) condition, which pins down the *form* of the central terms, and by explicit quantum field theories (free

bosons, free fermions, the Sugawara construction), which produce definite values.

6.2.1 Extensions of groups

We start with the group-theoretic language. It is the language of short exact sequences, which we met in Chapter 1.

Working definition 6.9 (group extension)

An **extension** of a group G by a group H is a group $\bar{G}$ together with homomorphisms [maps that respect products, $\alpha(h_1 h_2) = \alpha(h_1)\alpha(h_2)$]

$$1 \longrightarrow H \xrightarrow{\alpha} \bar{G} \xrightarrow{\beta} G \longrightarrow 1 \tag{6.35}$$

forming an **exact sequence** (Nash's (6.27)): at each place the image of the incoming map equals the kernel [the elements sent to the identity 1] of the outgoing one. Concretely:

- α is injective [distinct elements of H have distinct images] (the kernel of $H \to \bar{G}$ is the image of 1), so H sits inside $\bar{G}$ as a subgroup;
- β is surjective (the image of $\bar{G} \to G$ is the kernel of $G \to 1$, which is everything);
- $\alpha(H) = \operatorname{Ker}\beta$: the elements of $\bar{G}$ that "do nothing" in G are exactly those of H.

Operationally: $\bar{G}$ is a bigger group that projects onto G, and the extra information lost in the projection is an element of H.

Three consequences follow at once.

- H is a **normal subgroup** of $\bar{G}$, because a kernel always is: if $\beta(h) = 1$ then $\beta(ghg^{-1}) = \beta(g)\beta(g)^{-1} = 1$.
- $\bar{G}/H \cong G$: the fibres of β are the cosets of H.
- As a *set*, $\bar{G}$ looks like $H \times G$: each element of G has an H's worth of preimages. The group law of $\bar{G}$, however, need not be the product law.

Two special cases have names.

Working definition 6.10 (split and central extensions)

The extension (6.35) **splits** if β has a right inverse that is a homomorphism [$s(g_1 g_2) = s(g_1)s(g_2)$, not just any choice of one preimage of each g], $s : G \to \bar{G}$ with $\beta \circ s = \mathrm{id}$. Then $\bar{G}$ is the **semidirect product** $H \rtimes G$: every element is uniquely $h\, s(g)$, and

$$\big(h_1 s(g_1)\big)\big(h_2 s(g_2)\big) = \big(h_1\, s(g_1) h_2 s(g_1)^{-1}\big)\, s(g_1 g_2),$$

so G acts on H by conjugation. The extension is **central** if $\alpha(H)$ lies in the centre of $\bar{G}$: every element of H commutes with every element of $\bar{G}$. Then H is necessarily abelian.

For quantum mechanics the important case is a central extension by $H = \mathrm{U}(1)$ (or its Lie algebra $\mathbb{R}$): the extra information is a phase.

Worked example 6.17: $\mathrm{SU}(2)$ is a non-split central extension of $\mathrm{SO}(3)$

Every $U \in \mathrm{SU}(2)$ rotates the Pauli matrices, $U\sigma_j U^\dagger = \sum_i R_{ij}(U)\,\sigma_i$, and the rotation matrix is $R_{ij}(U) = \frac{1}{2}\operatorname{tr}(\sigma_i U \sigma_j U^\dagger)$. This defines $\beta : \mathrm{SU}(2) \to \mathrm{SO}(3)$, $U \mapsto R(U)$. Its kernel consists of the U commuting with all three Pauli matrices, i.e. the multiples of the identity in $\mathrm{SU}(2)$, $U = \pm 1$. So

$$1 \longrightarrow \mathbb{Z}_2 \longrightarrow \mathrm{SU}(2) \xrightarrow{\beta} \mathrm{SO}(3) \longrightarrow 1,$$

and the extension is central (± 1 commute with everything). Does it split? Suppose $s : \mathrm{SO}(3) \to \mathrm{SU}(2)$ were a homomorphism with $\beta \circ s = \mathrm{id}$. Let R_π be the rotation by π about the z-axis. Then

$$s(R_\pi)^2 \overset{(1)}{=} s(R_\pi^2) \overset{(2)}{=} s(\mathrm{id}) \overset{(3)}{=} 1,$$
$$s(R_\pi) \overset{(4)}{=} \pm 1, \qquad \text{so} \qquad R_\pi \overset{(5)}{=} \beta\big(s(R_\pi)\big) = \beta(\pm 1) = \mathrm{id}.$$

(1) s is a homomorphism.
(2) Rotating twice by π is rotating by 2π, the identity.
(3) A homomorphism sends the identity to the identity.
(4) If $V \in \mathrm{SU}(2)$ and $V^2 = 1$, the eigenvalues of V are ± 1 with product $\det V = 1$, so both are $+1$ or both are -1; a diagonalisable matrix with equal eigenvalues is a multiple of 1.
(5) $\beta \circ s = \mathrm{id}$, and ± 1 lie in the kernel.

This contradicts $R_\pi \neq \mathrm{id}$. So there is no way to choose the sign of the spin-$\frac{1}{2}$ rotation operators consistently: the physical statement is that a rotation by 2π acts on a spinor as -1.

Worked example 6.18: the Euclidean group is split but not central

The rigid motions of the plane, $x \mapsto Rx + a$ with $R \in \mathrm{SO}(2)$ and $a \in \mathbb{R}^2$, compose as

$$(a, R)\,(b, S) : \; x \overset{(1)}{\longmapsto} R(Sx + b) + a \overset{(2)}{=} (RS)x + (a + Rb).$$

(1) First apply (b, S), then (a, R).
(2) Expand.

So $(a, R)(b, S) = (a + Rb, RS)$. The translations $H = \mathbb{R}^2$ form a normal subgroup, the quotient is $G = \mathrm{SO}(2)$, and $R \mapsto (0, R)$ is a homomorphic section: $E(2) = \mathbb{R}^2 \rtimes \mathrm{SO}(2)$. It is not central, because rotations do not commute with translations. (The Poincaré group $\mathbb{R}^4 \rtimes \mathrm{SO}(3,1)$ and the group $\mathrm{Aut}(X \times G) = \mathrm{Map}(X, G) \rtimes \mathrm{Diff}(X)$ of Section 6.1.10 are of the same kind.)

Worked example 6.19: the Heisenberg group: the simplest central extension

Consider the real upper-triangular matrices

$$M(a, b, c) = \begin{pmatrix} 1 & a & c \\ 0 & 1 & b \\ 0 & 0 & 1 \end{pmatrix}, \qquad a, b, c \in \mathbb{R}.$$

Multiply two of them:

$$M(a,b,c)\,M(a',b',c') \overset{(1)}{=} \begin{pmatrix} 1 & a'+a & c'+ab'+c \\ 0 & 1 & b'+b \\ 0 & 0 & 1 \end{pmatrix} \overset{(2)}{=} M\big(a+a',\, b+b',\, c+c'+ab'\big).$$

(1) Row times column; the only non-obvious entry is the top right one, $1 \cdot c' + a \cdot b' + c \cdot 1$.
(2) Read off the entries.

The elements $M(0,0,c)$ commute with everything (the ab' term only involves a and b'), so $H = \{M(0,0,c)\} \cong \mathbb{R}$ is central. The quotient, forgetting c, is $G = \mathbb{R}^2$ with $(a,b)+(a',b')$: an abelian group. So we have a central extension

$$0 \longrightarrow \mathbb{R} \longrightarrow \mathrm{Heis} \longrightarrow \mathbb{R}^2 \longrightarrow 0.$$

It is not trivial, because Heis is not abelian:

$$M(a,0,0)M(0,b,0) \overset{(3)}{=} M(a,b,ab), \qquad M(0,b,0)M(a,0,0) \overset{(4)}{=} M(a,b,0),$$
$$\Rightarrow \quad M(a,0,0)\,M(0,b,0) \overset{(5)}{=} M(0,0,ab)\;M(0,b,0)\,M(a,0,0).$$

(3) The product rule with $a' = 0$, $b = 0$ renamed: the extra term is $a \cdot b$.
(4) Now the first factor has $a = 0$, so the extra term vanishes.
(5) $M(0,0,ab)$ is central and adds ab to the corner entry.

Two commuting translations of $\mathbb{R}^2$ have lifts that commute only up to a central element. That is what a central extension does. In quantum mechanics this is the canonical commutation relation, as the next subsection shows.

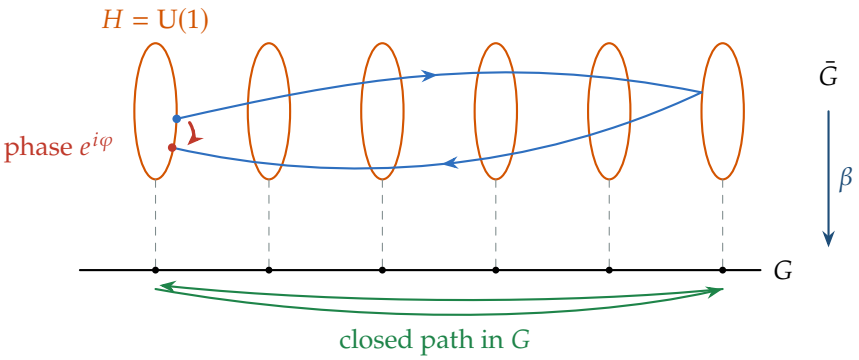

Figure 6.12: A central extension by U(1) pictured as a circle bundle: over each point of G sits a circle of elements of $\bar{G}$ (orange), and β projects each circle to its base point. A closed path in G (green) lifts to a path in $\bar{G}$ (blue) that need not close: it can return to the same fibre rotated by a phase (red). In quantum mechanics this phase is the projective multiplier of the symmetry operators.

6.2.2 Projective representations in quantum mechanics

Why should a physicist expect central extensions? Because of the way symmetries act on quantum states (Wigner). A physical state is not a vector ψ but a *ray*, $\{e^{i\varphi}\psi\}$: all measurable quantities, the transition probabilities $\left|\langle\phi|\psi\rangle\right|^2$, are blind to the phase. A symmetry g is therefore represented by a unitary operator T_g that is determined only up to a phase. When we compose two symmetries, the operators need only agree up to a phase:

Working definition 6.11 (projective representation)

A **projective representation** of a group G is an assignment $g \mapsto T_g$ of unitary operators with

$$T_g\,T_h = c(g,h)\,T_{gh}, \qquad |c(g,h)| = 1. \tag{6.36}$$

This is Nash's (6.56). The function $c : G \times G \to \mathrm{U}(1)$ [U(1) is the set of phases $e^{i\varphi}$] is the **multiplier**. *Operationally:* multiply the operators for g and h and compare with the operator for gh; the ratio is a phase, and that phase is $c(g,h)$.

The multiplier is not arbitrary. Operator multiplication is associative, so the two ways of computing $T_g T_h T_k$ must agree:

$$\begin{aligned} (T_g T_h)\,T_k &\overset{(1)}{=} c(g,h)\,T_{gh}T_k \overset{(2)}{=} c(g,h)\,c(gh,k)\,T_{ghk}, \\ T_g\,(T_h T_k) &\overset{(3)}{=} c(h,k)\,T_g T_{hk} \overset{(4)}{=} c(h,k)\,c(g,hk)\,T_{ghk}, \\ \Longrightarrow \quad c(g,h)\,c(gh,k) &\overset{(5)}{=} c(h,k)\,c(g,hk). \end{aligned} \tag{6.37}$$

(1) Equation (6.36) for the pair (g,h).
(2) Equation (6.36) for the pair (gh,k).
(3) Equation (6.36) for the pair (h,k).
(4) Equation (6.36) for the pair (g,hk).
(5) Associativity of operator products and of the group law; T_{ghk} is invertible, so the coefficients must match.

Equation (6.37) is the **cocycle condition**, and a function obeying it is a **group 2-cocycle** (QFT notes, (2.7.5); there the phases are written $e^{i\phi}$ and the condition is additive modulo 2π).

Some multipliers are fake. If we rephase the operators, $T'_g = \lambda(g)T_g$ with $|\lambda(g)| = 1$, then

$$T'_g T'_h \overset{(1)}{=} \lambda(g)\lambda(h)\,c(g,h)\,T_{gh} \overset{(2)}{=} \frac{\lambda(g)\lambda(h)}{\lambda(gh)}\,c(g,h)\,T'_{gh}. \tag{6.38}$$

(1) Definition of T' and (6.36).
(2) $T_{gh} = \lambda(gh)^{-1}T'_{gh}$.

So c and $c'(g,h) = c(g,h)\lambda(g)\lambda(h)/\lambda(gh)$ describe the same physics. A multiplier of the form $\lambda(g)\lambda(h)/\lambda(gh)$ is a **coboundary**; it can be removed by rephasing. The genuinely projective representations are classified by cocycles modulo coboundaries, the second cohomology group $H^2(G;\mathrm{U}(1))$.

Key idea: a projective representation is a true representation of a central extension

Given a multiplier c, define the group $\bar{G} = \mathrm{U}(1) \times G$ with product

$$(\lambda, g)\cdot(\mu, h) \coloneqq \big(\lambda\mu\,c(g,h),\ gh\big). \tag{6.39}$$

It is associative precisely because of the cocycle condition (6.37), and $\mathrm{U}(1) = \{(\lambda, e)\}$ is central. The operators $\bar{T}_{(\lambda,g)} \coloneqq \lambda T_g$ then obey $\bar{T}_{(\lambda,g)}\bar{T}_{(\mu,h)} = \lambda\mu\,c(g,h)T_{gh} = \bar{T}_{(\lambda,g)(\mu,h)}$: a true representation of $\bar{G}$. So *projective representations of G are the same as true representations of central extensions of G by* U(1). This is the sentence "Of course a projective representation of G is a true representation of the extension $\bar{G}$" of Nash, p. 186.

Let us check associativity of (6.39) once, since everything rests on it:

$$\begin{aligned} \big((\lambda,g)(\mu,h)\big)(\nu,k) &\overset{(1)}{=} \big(\lambda\mu\nu\,c(g,h)\,c(gh,k),\ ghk\big), \\ (\lambda,g)\big((\mu,h)(\nu,k)\big) &\overset{(2)}{=} \big(\lambda\mu\nu\,c(h,k)\,c(g,hk),\ ghk\big), \end{aligned}$$

(1) Apply (6.39) twice, left pair first.

(2) Apply (6.39) twice, right pair first.

and the two agree by (6.37).

There are exactly two ways in which a representation can be intrinsically projective (QFT notes, §2.7): *topologically*, because G is not simply connected, so that a phase can build up around a non-contractible loop; and *algebraically*, because the Lie algebra has central terms that cannot be removed. The three examples below show both.

Worked example 6.20: spin $\frac{1}{2}$: a topological phase

The spin-$\frac{1}{2}$ operators $U(\hat{n},\phi) = \exp(-i\phi\,\hat{n}\cdot\vec{\sigma}/2)$ represent rotations. For the rotation by $\phi = 2\pi$ about any axis,

$$U(\hat{n},2\pi) \overset{(1)}{=} \cos\pi\;\mathbb{1} - i\sin\pi\;\hat{n}\cdot\vec{\sigma} \overset{(2)}{=} -\mathbb{1},$$

(1) $(\hat{n}\cdot\vec{\sigma})^2 = \mathbb{1}$, so the exponential series splits into cosine and sine.
(2) $\cos\pi = -1$, $\sin\pi = 0$.

while in SO(3) the rotation by 2π is the identity. So, as operators on spinors, $T_{R_1}T_{R_2} = \pm T_{R_1R_2}$, with the sign depending on how the path from 1 to R_1R_2 winds around SO(3): $c(g,h) \in \{\pm 1\}$. The phase is removed by passing to the extension SU(2) of Example 6.17, the universal cover. At the Lie algebra level nothing happens: $\mathfrak{su}(2) = \mathfrak{so}(3)$ has no central terms (see Example 6.24 below).

Worked example 6.21: the Galilean group: mass as a central charge

In non-relativistic quantum mechanics a translation by $\vec{A}$ is $e^{-i\vec{P}\cdot\vec{A}}$ and a boost by $\vec{v}$ is $e^{-i\vec{K}\cdot\vec{v}}$. Classically boosts and translations commute (both just shift $\vec{x}$). Quantum mechanically the Galilean algebra contains (QFT notes, (2.4.34))

$$[K_i, P_j] = -iM\,\delta_{ij},$$

where M is the mass operator, which commutes with everything. For operators X, Y whose commutator is central, the Baker–Campbell–Hausdorff formula stops after one term, $e^X e^Y = e^{X+Y+\frac{1}{2}[X,Y]}$. With $X = -i\vec{K}\cdot\vec{v}$ and $Y = -i\vec{P}\cdot\vec{A}$,

$$[X,Y] \overset{(1)}{=} -v_iA_j\,[K_i,P_j] \overset{(2)}{=} -v_iA_j(-iM\delta_{ij}) = iM\,\vec{v}\cdot\vec{A},$$
$$e^{-i\vec{K}\cdot\vec{v}}\,e^{-i\vec{P}\cdot\vec{A}} \overset{(3)}{=} e^{\frac{i}{2}M\vec{v}\cdot\vec{A}}\;e^{-i(\vec{K}\cdot\vec{v}+\vec{P}\cdot\vec{A})}.$$

(1) Bilinearity of the commutator; $(-i)^2 = -1$.
(2) The Galilean commutator.
(3) BCH with a central commutator (QFT notes, (2.4.35)).

The product of a boost and a translation equals the "combined" transformation only up to the phase $e^{\frac{i}{2}M\vec{v}\cdot\vec{A}}$. This cannot be removed by shifting $\vec{K}$ or $\vec{P}$ by constants, because in the Galilean algebra $[K_i,P_j]$ would otherwise be zero, and a shift of generators cannot create a nonzero commutator from a vanishing one. So the Galilean group acts projectively, and the mass is a central charge. (The physical consequence is Bargmann's superselection rule: one cannot superpose states of different mass.)

Worked example 6.22: the canonical commutation relation

Let x and $p = -i\partial_x$ act on wavefunctions $\psi(x)$ (with $\hbar = 1$), so $[x, p] = i$. The translations $U(a) = e^{-iap}$, $U(a)\psi(x) = \psi(x-a)$, and the momentum kicks $V(b) = e^{ibx}$ are two commuting copies of $\mathbb{R}$ as far as their classical action on phase space is concerned. As operators,

$$V(b)U(a)\psi(x) \overset{(1)}{=} e^{ibx}\psi(x-a),$$
$$U(a)V(b)\psi(x) \overset{(2)}{=} e^{ib(x-a)}\psi(x-a) \implies V(b)U(a) = e^{iab}\,U(a)V(b).$$

(1) First translate, then multiply by e^{ibx}.
(2) First multiply, then translate: the phase factor is also shifted.

So $T(a,b) := V(b)U(a)$ is a projective representation of the abelian group $\mathbb{R}^2$, with multiplier $T(a,b)T(a',b') = e^{-iab'}T(a+a', b+b')$ (move $U(a)$ past $V(b')$). The operators $\rho(a,b,c) = e^{-ic}V(b)U(a)$ form a *true* representation of the Heisenberg group of Example 6.19: the phase $e^{-iab'}$ supplies the extra ab' in its product law. The Schrödinger representation is the Heisenberg group in disguise.

Dictionary: projective representations

Mathematics	Physics
ray, projective Hilbert space	physical state up to phase
multiplier $c(g,h)$, 2-cocycle	phase in $T_gT_h = c\,T_{gh}$
coboundary $\lambda(g)\lambda(h)/\lambda(gh)$	phase removable by rephasing T_g
$H^2(G;\mathrm{U}(1)) \neq 0$	intrinsically projective symmetry
central extension $\bar{G}$	enlarged symmetry group acting linearly
central element of $\bar{\mathfrak{g}}$	c-number in a commutator: M, $\hbar$, k, c

6.2.3 Lie algebra extensions and 2-cocycles

Near the identity, a central extension of a Lie group by U(1) becomes a central extension of its Lie algebra by $\mathbb{R}$, and the multiplier becomes a c-number in the commutators. Let us set this up directly for Lie algebras, with a general abelian $\mathfrak{h}$ in place of $\mathbb{R}$.

As a *vector space* the extended algebra is a direct sum, $\bar{\mathfrak{g}} = \mathfrak{g} \oplus \mathfrak{h}$. We write its elements as pairs (U, V) with $U \in \mathfrak{g}$, $V \in \mathfrak{h}$. All the content lies in the bracket. For a central extension, $\mathfrak{h}$ commutes with everything, and the bracket of two elements of $\mathfrak{g}$ is the old bracket plus something in $\mathfrak{h}$:

$$\big[(U_1,V_1),(U_2,V_2)\big] = \big([U_1,U_2],\ c(U_1,U_2)\big), \tag{6.40}$$

Nash's (6.28), with $c : \mathfrak{g}\times\mathfrak{g} \to \mathfrak{h}$ bilinear. Two conditions make this a Lie bracket.

Antisymmetry. The left side changes sign when we swap the two entries, so $c(U_2,U_1) = -c(U_1,U_2)$.

Jacobi identity. Compute a double bracket:

$$\big[(U_1,V_1),[(U_2,V_2),(U_3,V_3)]\big] \overset{(1)}{=} \big[(U_1,V_1),\big([U_2,U_3],c(U_2,U_3)\big)\big]$$
$$\overset{(2)}{=} \Big([U_1,[U_2,U_3]],\ c\big(U_1,[U_2,U_3]\big)\Big).$$

(1) The bracket (6.40) of the inner pair.
(2) The bracket (6.40) again; the $\mathfrak{h}$ entries V_1 and $c(U_2,U_3)$ never appear on the right, because $\mathfrak{h}$ is central.

Summing over cyclic permutations, the $\mathfrak{g}$ entries add up to zero by the Jacobi identity of $\mathfrak{g}$. The $\mathfrak{h}$ entries must also add up to zero:

$$\boxed{c\big([U,V],W\big)+c\big([V,W],U\big)+c\big([W,U],V\big)=0} \tag{6.41}$$

(Nash's (6.29); we used antisymmetry to write $c(U_1,[U_2,U_3])=-c([U_2,U_3],U_1)$.)

Working definition 6.12 (Lie algebra 2-cocycle)

A **2-cocycle** on $\mathfrak{g}$ with values in $\mathfrak{h}$ [the abelian algebra of the central terms. For an extension by U(1), $\mathfrak{h}=\mathbb{R}$ and $c(U,V)$ is a number] is a bilinear [linear in each argument separately], antisymmetric map $c:\mathfrak{g}\times\mathfrak{g}\to\mathfrak{h}$ satisfying the cyclic condition (6.41). *Operationally:* it is the c-number you are allowed to add to the commutators of $\mathfrak{g}$ without spoiling the Jacobi identity.

Watch out: what is and is not required of c

Nash calls c "a G-invariant anti-symmetric form". Antisymmetry and (6.41) are the requirements. Invariance under the adjoint action of G is an extra property that the cocycles we care about happen to have, and that can always be arranged for compact G by averaging; it is not part of the definition.

Trivial cocycles

Some cocycles only look like extensions. Suppose we choose new representatives of $\mathfrak{g}$ inside $\bar{\mathfrak{g}}$, shifting each U by a c-number, $\tilde{U}:=(U,\lambda(U))$ with $\lambda:\mathfrak{g}\to\mathfrak{h}$ linear. Then

$$\begin{aligned}
[\tilde{U}_1,\tilde{U}_2] &\overset{(1)}{=} \big([U_1,U_2],\ c(U_1,U_2)\big)\\
&\overset{(2)}{=} \big([U_1,U_2],\ \lambda([U_1,U_2])\big)+\big(0,\ c(U_1,U_2)-\lambda([U_1,U_2])\big)\\
&\overset{(3)}{=} \widetilde{[U_1,U_2]}+\big(0,\ c'(U_1,U_2)\big), \qquad c'(U_1,U_2):=c(U_1,U_2)-\lambda\big([U_1,U_2]\big).
\end{aligned} \tag{6.42}$$

(1) The bracket (6.40); the shifts $\lambda(U_i)$ are central and drop out.
(2) Add and subtract $\lambda([U_1,U_2])$ in the $\mathfrak{h}$ slot.
(3) Definition of $\widetilde{\ }$ applied to $[U_1,U_2]$.

In the new basis the cocycle is $c'=c-\lambda\circ[\,,\,]$. A cocycle of the form $c(U_1,U_2)=\lambda([U_1,U_2])$ is a **coboundary**: it can be removed completely by shifting generators by constants. This is the Lie-algebra version of rephasing (6.38); in the QFT notes it is (2.7.22)–(2.7.24).

Key idea: extensions are classified by $H^2(\mathfrak{g};\mathfrak{h})$

$$H^2(\mathfrak{g};\mathfrak{h})=\frac{\{\text{2-cocycles}\}}{\{\text{coboundaries } \lambda\circ[\,,\,]\}}.$$

Nontrivial central extensions of $\mathfrak{g}$ by $\mathfrak{h}$ correspond to nonzero classes. A class is a c-number term in the commutators that survives every redefinition of the generators.

This is a genuine cohomology, with a differential, as in de Rham theory (Chapter T2). The **Chevalley–Eilenberg** differential sends a p-cochain (an antisymmetric p-linear map) to a $(p+1)$-cochain; in the lowest degrees, with trivial action on $\mathfrak{h}$,

$$(\delta\lambda)(U,V)=-\lambda([U,V]), \qquad (\delta c)(U,V,W)=-c([U,V],W)-c([V,W],U)-c([W,U],V).$$

So "cocycle" means $\delta c = 0$, which is (6.41), and "coboundary" means $c = \delta(-\lambda)$. Every coboundary is a cocycle:

$$\delta(\delta\lambda)(U,V,W) \overset{(1)}{=} \lambda([[U,V],W]) + \lambda([[V,W],U]) + \lambda([[W,U],V]) \overset{(2)}{=} \lambda(0) = 0.$$

(1) Insert $\delta\lambda$ into the formula for δc; the two minus signs cancel.
(2) λ is linear, and the three double brackets add to zero by the Jacobi identity of $\mathfrak{g}$.

So $\delta^2 = 0$, exactly like $\mathrm{d}^2 = 0$ for forms, and H^2 makes sense.

Worked example 6.23: the Heisenberg algebra: every cocycle is nontrivial

Let $\mathfrak{g} = \mathbb{R}^2$ with basis X, P and the zero bracket (the Lie algebra of the abelian group $\mathbb{R}^2$). Since $[\,,\,] = 0$, the coboundaries $\lambda([U,V])$ all vanish, and (6.41) holds trivially. So every antisymmetric bilinear form is a nontrivial cocycle. On $\mathbb{R}^2$ there is one up to scale, $c(X,P) = -c(P,X) = \hbar$, and it gives

$$[X,P] = \hbar Z, \qquad [X,Z] = [P,Z] = 0,$$

with Z the central generator. In a representation where Z acts as i this is $[x,p] = i\hbar$: *the canonical commutation relation is a central extension of the abelian algebra of phase-space translations*, and $H^2(\mathbb{R}^2;\mathbb{R}) = \mathbb{R}$. The Lie group is the Heisenberg group of Example 6.19. With n degrees of freedom one gets the $(2n+1)$-dimensional Heisenberg algebra; the free boson of Section 6.2.9 is the case $n = \infty$.

Worked example 6.24: no central extensions of $\mathfrak{su}(2)$

Take the physicists' basis $T^a = \sigma^a/2$ with $[T^a, T^b] = i\varepsilon^{abc}T^c$, and try to add central terms: $[T^a,T^b] = i\varepsilon^{abc}T^c + iC^{ab}\mathbb{1}$ with $C^{ab} = -C^{ba}$ real. Every antisymmetric 3×3 matrix can be written $C^{ab} = \varepsilon^{abc}\mu^c$ for a vector μ (namely $\mu^c = \frac{1}{2}\varepsilon^{abc}C^{ab}$). Now shift the generators, $\tilde{T}^a = T^a + \mu^a\mathbb{1}$:

$$[\tilde{T}^a,\tilde{T}^b] \overset{(1)}{=} [T^a,T^b] \overset{(2)}{=} i\varepsilon^{abc}T^c + i\varepsilon^{abc}\mu^c \overset{(3)}{=} i\varepsilon^{abc}\big(\tilde{T}^c - \mu^c\big) + i\varepsilon^{abc}\mu^c = i\varepsilon^{abc}\tilde{T}^c.$$

(1) Multiples of $\mathbb{1}$ commute with everything.
(2) The assumed extended bracket with $C^{ab} = \varepsilon^{abc}\mu^c$.
(3) $T^c = \tilde{T}^c - \mu^c$.

The central term is gone. We did not even need the cocycle condition: for $\mathfrak{su}(2)$ every antisymmetric C is a coboundary, because $[\,,\,]$ is onto. So $H^2(\mathfrak{su}(2);\mathbb{R}) = 0$, and angular momentum admits no c-number in its commutators.

The same is true for every semisimple $\mathfrak{g}$ (**Whitehead's lemma**: $H^2(\mathfrak{g};\mathbb{R}) = 0$). The argument is short enough to give. Let K be the Killing form, which is nondegenerate and invariant, $K([A,B],C) = K(A,[B,C])$. Given a cocycle c, nondegeneracy lets us write $c(U,V) = K(DU,V)$ for a unique linear map $D : \mathfrak{g} \to \mathfrak{g}$, and antisymmetry of c says $K(DU,V) = -K(U,DV)$. The cocycle condition then says that D is a *derivation*:

$$\begin{aligned} 0 &\overset{(1)}{=} K\big(D[U,V],W\big) + K\big(D[V,W],U\big) + K\big(D[W,U],V\big) \\ &\overset{(2)}{=} K\big(D[U,V],W\big) - K\big([DU,V],W\big) - K\big([U,DV],W\big). \end{aligned}$$

(1) The cocycle condition (6.41) with $c(A,B) = K(DA,B)$.

(2) Second term: $K(D[V,W],U) = -K([V,W],DU) = -K(DU,[V,W]) = -K([DU,V],W)$, using antisymmetry of D, symmetry of K and invariance. Third term: $K(D[W,U],V) = -K(DV,[W,U]) = K(DV,[U,W]) = K([DV,U],W) = -K([U,DV],W)$ in the same way.

Since W is arbitrary, $D[U,V] = [DU,V] + [U,DV]$. For semisimple $\mathfrak{g}$ every derivation is inner, $D = \mathrm{ad}_X$ for some $X \in \mathfrak{g}$. Then

$$c(U,V) = K([X,U],V) = K(X,[U,V]) = \lambda([U,V]), \qquad \lambda := K(X,\cdot),$$

a coboundary. *Finite-dimensional semisimple Lie algebras have no central extensions*: every projective representation of a semisimple Lie group comes from topology (the universal cover), never from the algebra. The loop algebra escapes this conclusion, because the Killing form of $\mathrm{Map}(S^1,\mathfrak{g})$ is not a nondegenerate form of the right kind and there are outer derivations, the most important one being $\frac{d}{d\theta}$. We now exhibit its cocycle.

6.2.4 The Kac–Moody cocycle

The loop algebra $\mathrm{Map}(S^1,\mathfrak{g})$ has elements $\xi(\theta) = \xi_a(\theta)T^a$ (Hermitian T^a, real periodic ξ_a, or complex ones in the complexification), with the pointwise bracket $[\xi,\eta](\theta) = [\xi(\theta),\eta(\theta)]$. We now have an outer derivation to play with, the derivative $\xi \mapsto \xi' = \frac{d\xi}{d\theta}$, and an invariant trace. Combine them.

Working definition 6.13 (Kac–Moody cocycle)

For $\xi,\eta \in \mathrm{Map}(S^1,\mathfrak{g})$ put

$$\omega_k(\xi,\eta) := \frac{k}{\pi i}\int_0^{2\pi} \mathrm{tr}\big(\xi'(\theta)\,\eta(\theta)\big)\,\mathrm{d}\theta = \frac{k}{2\pi i}\int_0^{2\pi} \xi_a'(\theta)\,\eta_a(\theta)\,\mathrm{d}\theta, \tag{6.43}$$

where the second form uses $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$. The Kac–Moody algebra (6.12) is the extension (6.40) [$\omega_k(\xi,\eta)$ is added to the bracket as a c-number that commutes with everything] of the loop algebra by this cocycle [the constant k is the level appearing in (6.12)]: $[\xi,\eta]_{\mathrm{KM}} = [\xi,\eta] + \omega_k(\xi,\eta)$. *Operationally:* to find the central term of a commutator, differentiate the first loop, multiply by the second, take the trace and integrate round the circle.

We check four things: that ω_k reproduces the central term of (6.12), that it is antisymmetric, that it is a cocycle, and that it is not a coboundary.

(1) The central term. For $\xi = T^a_m = e^{im\theta}T^a$ and $\eta = T^b_n = e^{in\theta}T^b$ we have $\xi_c = \delta_{ac}e^{im\theta}$, so

$$\omega_k(T^a_m,T^b_n) \overset{(1)}{=} \frac{k}{2\pi i}\int_0^{2\pi} (im)\,e^{im\theta}\,e^{in\theta}\,\delta^{ab}\,\mathrm{d}\theta \overset{(2)}{=} \frac{k}{2\pi i}\,(im)\,2\pi\,\delta_{m+n,0}\,\delta^{ab} = k\,m\,\delta^{ab}\,\delta_{m+n,0}. \tag{6.44}$$

(1) The second form of (6.43); $\frac{d}{d\theta}e^{im\theta} = ime^{im\theta}$.

(2) $\int_0^{2\pi} e^{i(m+n)\theta}\mathrm{d}\theta = 2\pi\delta_{m+n,0}$.

This is exactly the central term of Nash's (6.9).

(2) Antisymmetry. Integrate by parts on the circle, where there is no boundary term:

$$\omega_k(\eta,\xi) \overset{(1)}{=} \frac{k}{\pi i}\int_0^{2\pi} \mathrm{tr}(\eta'\xi)\,\mathrm{d}\theta \overset{(2)}{=} -\frac{k}{\pi i}\int_0^{2\pi} \mathrm{tr}(\eta\,\xi')\,\mathrm{d}\theta \overset{(3)}{=} -\omega_k(\xi,\eta).$$

(1) Definition.

(2) $\int_0^{2\pi} \frac{d}{d\theta}\operatorname{tr}(\eta\xi)\mathrm{d}\theta = 0$ by periodicity, and $\frac{d}{d\theta}\operatorname{tr}(\eta\xi) = \operatorname{tr}(\eta'\xi) + \operatorname{tr}(\eta\xi')$.
(3) Cyclicity of the trace, $\operatorname{tr}(\eta\xi') = \operatorname{tr}(\xi'\eta)$.

(3) The cocycle condition. We need the cyclic sum of $\omega_k([\xi,\eta],\zeta)$ to vanish. Two facts about traces are used repeatedly: $\operatorname{tr}([A,B]C) = \operatorname{tr}(A[B,C])$ (expand and use cyclicity), and the product rule $[\xi,\eta]' = [\xi',\eta] + [\xi,\eta']$. Then

$$\begin{aligned}\operatorname{tr}\big([\xi,\eta]'\,\zeta\big) &\overset{(1)}{=} \operatorname{tr}\big([\xi',\eta]\zeta\big) + \operatorname{tr}\big([\xi,\eta']\zeta\big)\\ &\overset{(2)}{=} \operatorname{tr}\big(\xi'[\eta,\zeta]\big) + \operatorname{tr}\big(\eta'[\zeta,\xi]\big).\end{aligned}$$

(1) Product rule for the pointwise bracket.
(2) First term: $\operatorname{tr}([A,B]C) = \operatorname{tr}(A[B,C])$ with $A = \xi'$. Second term: use $[\xi,\eta'] = -[\eta',\xi]$, then $\operatorname{tr}([A,B]C) = \operatorname{tr}(A[B,C])$ again with $A = \eta'$, then antisymmetry of the bracket once more, to get $\operatorname{tr}(\eta'[\zeta,\xi])$.

Now sum over the three cyclic permutations $(\xi,\eta,\zeta) \to (\eta,\zeta,\xi) \to (\zeta,\xi,\eta)$. The second term on the right is the first term with (ξ,η,ζ) shifted cyclically, so both give the same cyclic sum $S := \operatorname{tr}(\xi'[\eta,\zeta]) + \operatorname{tr}(\eta'[\zeta,\xi]) + \operatorname{tr}(\zeta'[\xi,\eta])$, and

$$\sum_{\text{cyc}} \omega_k\big([\xi,\eta],\zeta\big) \overset{(1)}{=} \frac{k}{\pi i}\int_0^{2\pi} 2S\,\mathrm{d}\theta \overset{(2)}{=} \frac{2k}{\pi i}\int_0^{2\pi} \frac{d}{d\theta}\operatorname{tr}\big(\xi[\eta,\zeta]\big)\,\mathrm{d}\theta \overset{(3)}{=} 0. \tag{6.45}$$

(1) Definition (6.43) and the computation above.
(2) Product rule: $\frac{d}{d\theta}\operatorname{tr}(\xi[\eta,\zeta]) = \operatorname{tr}(\xi'[\eta,\zeta]) + \operatorname{tr}(\xi[\eta',\zeta]) + \operatorname{tr}(\xi[\eta,\zeta'])$, and by $\operatorname{tr}(A[B,C]) = \operatorname{tr}(B[C,A]) = \operatorname{tr}(C[A,B])$ the last two terms are $\operatorname{tr}(\eta'[\zeta,\xi])$ and $\operatorname{tr}(\zeta'[\xi,\eta])$. So the derivative is exactly S.
(3) The integral of a derivative of a periodic function over a period: the fundamental theorem of calculus on a circle, i.e. Stokes' theorem with $\partial S^1 = \varnothing$.

So the Jacobi identity of the Kac–Moody algebra is, at bottom, Stokes' theorem on the circle.

(4) Nontriviality. Suppose $\omega_k = \lambda \circ [\,,\,]$ for some linear λ. Take $\xi = T^3_m$ and $\eta = T^3_{-m}$ with $m \neq 0$. These commute in the loop algebra, $[T^3_m, T^3_{-m}] = if^{33c}T^c_0 = 0$, so $\lambda([\xi,\eta]) = 0$. But $\omega_k(\xi,\eta) = km \neq 0$ by (6.44). Contradiction. So for $k \neq 0$ the extension is nontrivial: no redefinition of generators removes the Kac–Moody central term.

Worked example 6.25: the Jacobi identity in mode form

It is instructive to see (3) directly in the mode basis. Take three generators T^a_l, T^b_m, T^c_n. In $[T^a_l,[T^b_m,T^c_n]]$ the central term comes from the bracket of T^a_l with the $if^{bcd}T^d_{m+n}$ part of the inner bracket:

$$\big[T^a_l,[T^b_m,T^c_n]\big]\Big|_{\text{central}} \overset{(1)}{=} if^{bcd}\,\big[T^a_l,T^d_{m+n}\big]\Big|_{\text{central}} \overset{(2)}{=} if^{bcd}\,k\,l\,\delta^{ad}\,\delta_{l+m+n,0} = ik\,l\,f^{bca}\,\delta_{l+m+n,0}.$$

(1) The inner bracket is $if^{bcd}T^d_{m+n}$ + (central), and a central element commutes with T^a_l.
(2) The central term of (6.12).

Adding the two cyclic permutations, and using $f^{bca} = f^{cab} = f^{abc}$,

$$ik\,\delta_{l+m+n,0}\big(l\,f^{bca} + m\,f^{cab} + n\,f^{abc}\big) = ik\,f^{abc}\,(l+m+n)\,\delta_{l+m+n,0} = 0.$$

The central terms cancel because the mode numbers add up to zero whenever the Kronecker delta is nonzero. (The non-central parts cancel by the Jacobi identity of $\mathfrak{g}$.)

Worked example 6.26: $G = \mathrm{U}(1)$: infinitely many oscillators

For $G = \mathrm{U}(1)$ there is one generator, $T_n = e^{in\theta}$, and $f = 0$. The loop algebra is abelian, and the Kac–Moody algebra is

$$[T_m, T_n] = k\, m\, \delta_{m+n,0}.$$

In a unitary representation with $T_n^\dagger = T_{-n}$ and $k > 0$, set $a_n := T_n/\sqrt{kn}$ for $n > 0$. Then

$$[a_m, a_n^\dagger] \overset{(1)}{=} \frac{[T_m, T_{-n}]}{k\sqrt{mn}} \overset{(2)}{=} \frac{k\, m\, \delta_{m,n}}{k\, m} = \delta_{mn}, \qquad [a_m, a_n] = 0 \quad (m, n > 0).$$

(1) Definition of a_n and $a_n^\dagger = T_{-n}/\sqrt{kn}$.
(2) The central term, with $\delta_{m-n,0}$ forcing $n = m$.

One independent harmonic oscillator for each $n = 1, 2, 3, \ldots$: the U(1) Kac–Moody algebra is the infinite-dimensional Heisenberg algebra of Example 6.23, i.e. the mode algebra of a chiral free boson. We return to it in Section 6.2.9.

Two further properties of ω_k are worth recording. It is invariant under constant gauge rotations, $\omega_k(g\xi g^{-1}, g\eta g^{-1}) = \omega_k(\xi, \eta)$, by cyclicity of the trace; this is the invariance Nash mentions. And it is invariant under rigid rotations of the circle, $\theta \mapsto \theta + a$, because $\mathrm{d}\theta$ is. It is *not* invariant under general diffeomorphisms of the circle, and that is the germ of the Virasoro algebra inside the Kac–Moody algebra (Section 6.2.10).

6.2.5 Cohomology of groups and of their Lie algebras

Nash next relates the Lie algebra cohomology $H^*(\mathfrak{g}; \mathbb{R})$ to the de Rham cohomology of the group. The bridge is the space of left-invariant forms.

Left-invariant forms

A p-form ω on G is **left invariant** if $L_h^* \omega = \omega$ for every left translation $L_h : g \mapsto hg$. Such a form is determined by its value at the identity, which is an antisymmetric p-linear form on $T_1 G = \mathfrak{g}$. So

$$\{\text{left-invariant } p\text{-forms on } G\} \;\cong\; \{\text{antisymmetric } p\text{-linear forms on } \mathfrak{g}\}.$$

The basic example is the **Maurer–Cartan form** $\theta = g^{-1}\mathrm{d}g$, a $\mathfrak{g}$-valued left-invariant 1-form: $(hg)^{-1}\mathrm{d}(hg) = g^{-1}\mathrm{d}g$. It satisfies the Maurer–Cartan equation

$$\mathrm{d}\theta \overset{(1)}{=} \mathrm{d}(g^{-1}) \wedge \mathrm{d}g \overset{(2)}{=} -g^{-1}\mathrm{d}g\, g^{-1} \wedge \mathrm{d}g = -\theta \wedge \theta,$$

(1) $\mathrm{d}(g^{-1}\mathrm{d}g) = \mathrm{d}(g^{-1}) \wedge \mathrm{d}g + g^{-1}\mathrm{d}\mathrm{d}g$ and $\mathrm{d}\mathrm{d}g = 0$.
(2) Differentiate $g^{-1}g = 1$: $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\, g^{-1}$.

Under the identification with forms on $\mathfrak{g}$, the exterior derivative d becomes the Chevalley–Eilenberg differential δ; the Maurer–Cartan equation is the statement that d of a left-invariant 1-form λ evaluates on U, V to $-\lambda([U, V])$, i.e. $\mathrm{d}\lambda = \delta\lambda$ (up to the convention-dependent factor in front). So left-invariant closed forms modulo left-invariant exact forms is exactly $H^*(\mathfrak{g}; \mathbb{R})$.

Key idea: for compact G, $H^*(G; \mathbb{R}) = H^*(\mathfrak{g}; \mathbb{R})$

For compact connected G every de Rham class contains a left-invariant representative: average. If ω is closed, each $L_h^* \omega$ is cohomologous to ω (since L_h can be deformed to

the identity through the path from h to 1, and homotopic maps pull back closed forms to cohomologous ones), so the average $\bar{\omega} = \int_G L_h^* \omega \, \mathrm{d}h$ (normalised Haar measure) is left-invariant and cohomologous to ω. A similar averaging shows that a left-invariant form that is exact is the derivative of a left-invariant form. Hence $H^*(G;\mathbb{R}) = H^*(\mathfrak{g};\mathbb{R})$.

Worked example 6.27: the generator of $H^3(\mathrm{SU}(2))$

The 3-form $\Omega = \mathrm{tr}(g^{-1}\mathrm{d}g)^3$ on SU(2) is left-invariant (it is built from θ) and closed (it is a top form on a 3-manifold). It is not exact, because its integral over the closed manifold $\mathrm{SU}(2) = S^3$ is nonzero: by Example 6.5, $\int_{S^3} \Omega = 24\pi^2$, and an exact form would integrate to zero by Stokes. At the identity it is the 3-cocycle on $\mathfrak{su}(2)$

$$\Omega(U,V,W) \propto \mathrm{tr}\big(U[V,W]\big),$$

the unique invariant antisymmetric trilinear form. In contrast $H^1 = H^2 = 0$: a left-invariant 1-form λ is closed iff $\lambda([U,V]) = 0$ for all U, V, but $[\mathfrak{g},\mathfrak{g}] = \mathfrak{g}$ for semisimple $\mathfrak{g}$, so $\lambda = 0$; and $H^2 = 0$ is Whitehead's lemma (Example 6.24). These agree with $H^*(S^3)$: nonzero only in degrees 0 and 3.

For LG the same statement survives, even though LG is not compact: $H^*(LG;\mathbb{R}) = H^*(\mathrm{Map}(S^1,\mathfrak{g});\mathbb{R})$ (Pressley and Segal). In particular the Kac–Moody cocycle ω_k extends to a left-invariant 2-form on LG, which we also call ω_k, and it is closed because ω_k is a cocycle. For $\mathrm{Map}(X,G)$ with $\dim X > 1$ the statement fails: there are de Rham classes on $\mathrm{Map}(X,G)$ that cannot be made left invariant, so $H^*(\mathrm{Map}(X,G);\mathbb{R})$ is smaller than $H^*(\mathrm{Map}(X,\mathfrak{g});\mathbb{R})$. This is one reason why the extensions of $\mathrm{Map}(X,G)$ in Section 6.2.12 are harder.

Watch out: topology of LG

For simply connected G, $LG \cong G \times \Omega G$ as spaces (constants times based loops, (6.4)), and $\pi_k(\Omega G) = \pi_{k+1}(G)$. So $\pi_1(LG) = \pi_1(G) \oplus \pi_2(G) = 0$ and $\pi_2(LG) = \pi_2(G) \oplus \pi_3(G) = \mathbb{Z}$ for simple G. Hence $H^2(LG;\mathbb{Z}) = \mathbb{Z}$: there is room for exactly one integer's worth of circle bundles over LG. That integer will be the level.

6.2.6 From the Lie algebra to the group: integrality

In finite dimensions every Lie algebra extension integrates to an extension of the simply connected group. In infinite dimensions this fails, and the reason is one that every physicist knows from the Dirac monopole.

A warm-up: magnetic translations and flux quantisation

A charged particle ($e = \hbar = 1$) in a uniform magnetic field B in the plane has *magnetic translation* operators $t(\vec{a}) = e^{-i\vec{a}\cdot\vec{K}}$ that commute with the Hamiltonian; their generators satisfy $[K_1, K_2] = iB$ (up to a sign convention). This is a Heisenberg algebra with central element B. By the BCH formula for central commutators,

$$\begin{aligned} t(\vec{a})\,t(\vec{b}) &\overset{(1)}{=} e^{-i(\vec{a}+\vec{b})\cdot\vec{K}}\, e^{\frac{1}{2}[-i\vec{a}\cdot\vec{K},\,-i\vec{b}\cdot\vec{K}]} \\ &\overset{(2)}{=} e^{-\frac{1}{2}a_i b_j [K_i,K_j]}\, t(\vec{a}+\vec{b}) \overset{(3)}{=} e^{-\frac{i}{2}B(a_1 b_2 - a_2 b_1)}\, t(\vec{a}+\vec{b}), \\ t(\vec{a})\,t(\vec{b}) &\overset{(4)}{=} e^{-iB(\vec{a}\times\vec{b})}\, t(\vec{b})\,t(\vec{a}). \end{aligned} \tag{6.46}$$

(1) $e^X e^Y = e^{X+Y} e^{\frac{1}{2}[X,Y]}$ for central $[X, Y]$.
(2) $(-i)^2 = -1$ and bilinearity.
(3) $a_i b_j [K_i, K_j] = (a_1 b_2 - a_2 b_1)\, iB$.
(4) Write the same for $t(\vec{b})t(\vec{a})$ and divide: the phases differ by $e^{-iB(a_1 b_2 - a_2 b_1)}$.

The phase is $e^{-i\Phi}$, with $\Phi = B\,(\vec{a} \times \vec{b})$ the magnetic flux through the parallelogram spanned by $\vec{a}$ and $\vec{b}$: the Aharonov–Bohm phase of the loop "go along $\vec{a}$, then $\vec{b}$, then back". So far this is just a Lie algebra extension, and B can be anything.

Now put the particle on a torus of side L. Translating by a full period is a symmetry that does nothing to the torus, so $t(L\hat{x})$ and $t(L\hat{y})$ must commute (each acts on the Hilbert space as a phase at most). By (6.46) this requires

$$e^{-iBL^2} = 1 \qquad \Longleftrightarrow \qquad \frac{BL^2}{2\pi} = \frac{\Phi_{\text{total}}}{2\pi} \in \mathbb{Z}.$$

The Lie algebra extension of $\mathbb{R}^2$ by B exists for all B, but it descends to a group extension of the *compact* group T^2 only if the total flux is an integer multiple of 2π: Dirac's quantisation condition.

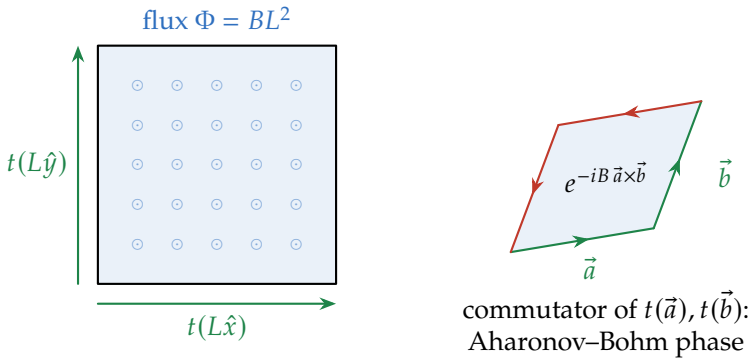

Figure 6.13: Right: two magnetic translations commute only up to the Aharonov–Bohm phase of the flux through the parallelogram they span; this is a Lie algebra cocycle (the 2-form $B\,\mathrm{d}x \wedge \mathrm{d}y$). Left: on a torus the translations by a full period must commute, so the flux through the whole torus must be $2\pi\times$ an integer. Integrating the cocycle 2-form over a closed surface must give $2\pi\mathbb{Z}$: this is the integrality condition for central extensions of groups.

The general statement

The same mechanism controls every central extension by U(1). Topologically, $\bar{G}$ is a principal U(1)-bundle over G (Figure 6.12). The Lie algebra cocycle c defines a left-invariant 2-form ω on G, and ω is the curvature of a natural connection on this bundle: the phase acquired by lifting a small closed loop in G is $e^{i\int \omega}$ over the enclosed surface, exactly as in (6.46). A U(1)-bundle with curvature ω exists if and only if the flux through every closed surface is quantised, i.e. if and only if

$$\left[\frac{\omega}{2\pi}\right] \in H^2(G;\mathbb{Z}) \quad \text{(an integral class)}, \qquad \text{i.e.} \qquad \int_\Sigma \frac{\omega}{2\pi} \in \mathbb{Z} \text{ for every closed surface } \Sigma \subset G. \tag{6.47}$$

The class $[\omega/2\pi]$ is then the first Chern class of the bundle $\bar{G} \to G$, which characterises it completely. The factor 2π is the usual normalisation of characteristic classes as differential forms (Nash's footnote 2; compare $c_1 = \frac{i}{2\pi}\operatorname{tr} F$ in Chapter T2).

Key idea: Lie algebras without groups

The Lie algebra $\mathrm{Map}(S^1,\mathfrak{g})\oplus\mathbb{R}$ with bracket $[\xi,\eta]+\omega_k(\xi,\eta)$ exists for every real k. The group extension $1\to \mathrm{U}(1)\to \widetilde{LG}\to LG\to 1$ exists only when $\omega_k/2\pi$ is an integral class on LG. Since $H^2(LG;\mathbb{Z})=\mathbb{Z}$ for simple simply connected G (the pitfall above), this is one integer condition on k. With our normalisation ($\mathrm{tr}\,T^aT^b=\frac{1}{2}\delta^{ab}$, long roots of length 1 for $\mathrm{SU}(N)$) it reads

$$N=2k\in\mathbb{Z},$$

which is the same quantisation of the level that we will find from representation theory in Section 6.3.9 (Nash's (6.62)). For non-integral N, $\mathrm{Map}(S^1,\mathfrak{g})\oplus\mathbb{R}$ is a Lie algebra that is the Lie algebra of no group.

Watch out: a class, not a form

Integrality is a condition on the cohomology class of $\omega/2\pi$, not on the form itself. Changing c by a coboundary changes ω by an exact form and does not affect (6.47). This is why the integer (the level, the Chern class, the monopole charge) is robust: it cannot change under small deformations, and it cannot be redefined away.

6.2.7 Where the c-numbers come from: counting powers of $\hbar$

So far the central terms have been an algebraic possibility. Nash now explains why a physicist should *expect* them, by keeping track of Planck's constant. In this subsection only, $\hbar\neq 1$.

Classical symmetries and Poisson brackets

In classical mechanics a symmetry group G acts on phase space, and each generator T^a of its Lie algebra is represented by a function on phase space (the conserved charge). The group structure is encoded in the Poisson brackets of these functions,

$$\{T^a,T^b\}=f^{abc}\,T^c, \tag{6.48}$$

Nash's (6.30). Here $\{A,B\}=\sum_i\left(\frac{\partial A}{\partial x_i}\frac{\partial B}{\partial p_i}-\frac{\partial A}{\partial p_i}\frac{\partial B}{\partial x_i}\right)$.

Worked example 6.28: angular momentum as Poisson brackets

Take $L_i=\varepsilon_{ijk}x_jp_k$, so $L_1=x_2p_3-x_3p_2$ and $L_2=x_3p_1-x_1p_3$. The only nonzero basic brackets are $\{x_i,p_j\}=\delta_{ij}$, and the bracket is a derivation in each slot, so

$$\begin{aligned}\{L_1,L_2\}&\overset{(1)}{=}\{x_2p_3,x_3p_1\}-\{x_2p_3,x_1p_3\}-\{x_3p_2,x_3p_1\}+\{x_3p_2,x_1p_3\}\\&\overset{(2)}{=}x_2p_1\{p_3,x_3\}-0-0+p_2x_1\{x_3,p_3\}\\&\overset{(3)}{=}-x_2p_1+x_1p_2\overset{(4)}{=}L_3.\end{aligned}$$

(1) Bilinearity.
(2) Leibniz rule; the middle two brackets contain no conjugate pair (p_3 with no x_3, and x_3 with no p_3).
(3) $\{p_3,x_3\}=-1$, $\{x_3,p_3\}=1$.
(4) $L_3=x_1p_2-x_2p_1$.

So $\{L_i,L_j\}=\varepsilon_{ijk}L_k$: (6.48) with $f^{abc}=\varepsilon^{abc}$.

Quantisation and the first correction

Dirac's rule replaces Poisson brackets by commutators, $\{A,B\} \to \frac{1}{i\hbar}[\hat{A},\hat{B}]$. Applied to (6.48),

$$[T^a, T^b] = i\hbar\, f^{abc}\, T^c, \tag{6.49}$$

which is Nash's (6.31). (Nash phrases the rule as "replace T^a by $i\hbar T^a$"; the effect is the same.) The rule is exact for angular momentum. It is not exact in general: the quantum operator for a product of x's and p's depends on how we order them, and the commutator of two quantised functions differs from $i\hbar$ times the quantised Poisson bracket by terms of higher order in $\hbar$ (Groenewold and van Hove showed that no ordering rule can remove them all). So in general

$$[T^a, T^b] = i\hbar\, f^{abc}\, T^c + O(\hbar^2), \tag{6.50}$$

Nash's (6.32). The simplest possible correction is a c-number:

$$[T^a, T^b] = i\hbar\, f^{abc}\, T^c + i\hbar^2\, c^{ab}\, \mathbb{1}, \tag{6.51}$$

which is Nash's (6.33) (he writes $c\,\delta^{ab}$; for $\mathfrak{g}$ itself c^{ab} must be antisymmetric, and in the loop algebra it becomes the $\delta^{ab} m\, \delta_{m+n,0}$ structure). This is precisely a central extension (6.40), with $\hbar^2 c^{ab}$ as the cocycle.

Worked example 6.29: an $\hbar^2$ c-number from normal ordering

Take one degree of freedom and the complex coordinate $z = (x + ip)/\sqrt{2}$, for which $\{z,\bar z\} = \frac{1}{2}\{x+ip, x-ip\} = \frac{1}{2}(-i-i) = -i$. The three quadratic functions

$$K_+ = \tfrac{1}{2}\bar z^2, \qquad K_- = \tfrac{1}{2} z^2, \qquad K_0 = \tfrac{1}{2}\bar z z$$

generate the symplectic group $\mathrm{Sp}(2,\mathbb{R})$ (squeezing and rotating phase space). Classically

$$\{K_-, K_+\} \overset{(1)}{=} \tfrac{1}{4}\,(2z)(2\bar z)\,\{z,\bar z\} \overset{(2)}{=} -i\, z\bar z = -2i\, K_0.$$

(1) Chain rule: $\{f(z), g(\bar z)\} = f'(z) g'(\bar z)\{z,\bar z\}$.
(2) $\{z,\bar z\} = -i$.

Now quantise with $\hat z = \sqrt{\hbar}\, a$, $\hat{\bar z} = \sqrt{\hbar}\, a^\dagger$, $[a, a^\dagger] = 1$ (check: $[\hat z, \hat{\bar z}] = \hbar = i\hbar\{z,\bar z\}$). Choose the normal-ordered operators $\hat K_+ = \frac{\hbar}{2} a^{\dagger 2}$, $\hat K_- = \frac{\hbar}{2} a^2$, $\hat K_0 = \frac{\hbar}{2} a^\dagger a$. Then

$$[\hat K_-, \hat K_+] \overset{(3)}{=} \tfrac{\hbar^2}{4}\,[a^2, a^{\dagger 2}] \overset{(4)}{=} \tfrac{\hbar^2}{4}\,(4a^\dagger a + 2) \overset{(5)}{=} i\hbar\,(-2i\hat K_0) + \tfrac{\hbar^2}{2}.$$

(3) Definitions.
(4) $[a^2, a^{\dagger 2}] = a[a, a^{\dagger 2}] + [a, a^{\dagger 2}]a = a\,2a^\dagger + 2a^\dagger a = 4a^\dagger a + 2$, using $[a, a^{\dagger 2}] = 2a^\dagger$ and $aa^\dagger = a^\dagger a + 1$.
(5) $\hbar^2 a^\dagger a = 2\hbar \hat K_0$ and $i\hbar(-2i) = 2\hbar$.

So the commutator is $i\hbar$ times the quantised Poisson bracket *plus the c-number* $\hbar^2/2$: exactly the pattern (6.51). Here the c-number is a coboundary: redefining $\hat K_0 \to \hat K_0 + \frac{\hbar}{4}$ (the symmetric ordering $\frac{\hbar}{4}(a^\dagger a + a a^\dagger)$) removes it, as Whitehead's lemma says it must for the semisimple $\mathfrak{sp}(2)$. The point of the example is where it comes from: the reordering needed to make an operator well defined.

In finite dimensions such c-numbers can always be absorbed. The same mechanism in field theory, where the normal-ordering constant is an *infinite* sum and cannot be absorbed, gives the loop-algebra version, Nash's (6.34):

$$[T^a_m, T^b_n] = i\hbar\, f^{abc}\, T^c_{m+n} + c\, m\, \hbar^2\, \delta^{ab}\, \delta_{m,-n}. \tag{6.52}$$

With $\hbar = 1$ and $c = k$ this is the Kac–Moody algebra (6.12).

Physical picture: the central term is a one-loop effect

The power $\hbar^2$ (one more than the classical term) is the signature of a quantum (one-loop) effect. In the free-fermion realisation below, the classical currents Poisson-commute up to the f^{abc} term; the central term comes entirely from filling the Dirac sea, which is a statement about the ground state and has no classical analogue. The same is true of the Virasoro central charge. This is why Nash calls the central term an *anomaly*: a classical symmetry that survives quantisation only projectively.

Watch out: the conformal anomaly and the critical dimension

In string theory $\mathrm{Diff}(S^1)$ (two copies of it, one for each chirality) is a *gauge* symmetry: reparametrising the string does not change the physics. Gauge symmetries must act as true representations on physical states, so the total central charge must vanish. D free bosons (the string coordinates) contribute $c = D$ (Section 6.2.9), and the Faddeev–Popov ghosts of the reparametrisation gauge contribute $c = -26$. So $c_{\text{total}} = D - 26$ vanishes only in the **critical dimension** $D = 26$ (and $D = 10$ for the superstring). Nash returns to this in Chapter 9 and Chapter 10.

6.2.8 The Virasoro cocycle from the Jacobi identity

We now derive the Virasoro algebra (6.21) instead of quoting it. The question is: *what c-numbers can be added to the Witt algebra* $[L_m, L_n] = (m-n)L_{m+n}$ *without spoiling the Jacobi identity, and which of them are genuine?* The answer comes in four steps. We add one central element Z and write the most general central extension,

$$[L_m, L_n] = (m-n)\,L_{m+n} + c(m,n)\,Z, \qquad c(n,m) = -c(m,n). \tag{6.53}$$

Step 1: the cocycle condition

For three generators the cocycle condition (6.41) reads $c([L_k,L_m],L_n) + c([L_m,L_n],L_k) + c([L_n,L_k],L_m) = 0$, where $c([L_k,L_m],L_n)$ means $(k-m)\,c(k+m,n)$. So

$$(k-m)\,c(k+m,n) + (m-n)\,c(m+n,k) + (n-k)\,c(n+k,m) = 0 \qquad \text{for all } k,m,n. \tag{6.54}$$

Step 2: only $m+n=0$ survives

Put $k = 0$ in (6.54):

$$\begin{aligned} 0 &\overset{(1)}{=} -m\,c(m,n) + (m-n)\,c(m+n,0) + n\,c(n,m) \\ &\overset{(2)}{=} -(m+n)\,c(m,n) + (m-n)\,c(m+n,0). \end{aligned} \tag{6.55}$$

(1) $(k-m)c(k+m,n) \to -m\,c(m,n)$; $(m-n)c(m+n,k) \to (m-n)c(m+n,0)$; $(n-k)c(n+k,m) \to n\,c(n,m)$.

(2) Antisymmetry, $c(n,m) = -c(m,n)$.

Now use the freedom to redefine generators. Shifting $L_p \to L'_p = L_p + \lambda_p Z$ changes the cocycle by the coboundary (6.42):

$$c'(m,n) = c(m,n) - (m-n)\,\lambda_{m+n}. \tag{6.56}$$

Choose $\lambda_p = c(p,0)/p$ for every $p \neq 0$. Then $c'(p,0) = c(p,0) - p\lambda_p = 0$ for $p \neq 0$, and (6.55) (which holds for c' as well, since c' is again a cocycle) says $(m+n)\,c'(m,n) = 0$. Hence $c'(m,n) = 0$ unless $m+n = 0$. Dropping the prime,

$$c(m,n) = h(m)\,\delta_{m+n,0}, \qquad h(-m) = -h(m), \quad h(0) = 0. \tag{6.57}$$

We have not yet used λ_0: it remains available.

Step 3: the functional equation

Put $n = -k-m$ in (6.54), so that all three terms are of the form (6.57):

$$\begin{aligned} 0 &\overset{(1)}{=} (k-m)\,h(k+m) + (2m+k)\,c(-k,k) + (-2k-m)\,c(-m,m) \\ &\overset{(2)}{=} (k-m)\,h(k+m) - (k+2m)\,h(k) + (2k+m)\,h(m). \end{aligned} \tag{6.58}$$

(1) $c(k+m,n) = c(k+m,-(k+m)) = h(k+m)$; $m-n = 2m+k$ and $m+n = -k$; $n-k = -2k-m$ and $n+k = -m$.
(2) $c(-k,k) = h(-k) = -h(k)$ and $c(-m,m) = -h(m)$.

This is a linear equation for the function h. Setting $k = 1$ gives a recursion,

$$h(m+1) = \frac{(m+2)\,h(m) - (2m+1)\,h(1)}{m-1} \qquad (m \geq 2),$$

so h is completely determined by the two numbers $h(1)$ and $h(2)$ (for $m = 1$ the equation reads $0 = 0$ and leaves $h(2)$ free). The solution space is therefore at most two-dimensional. Two solutions are easy to verify:

$$\begin{aligned} h(m) = m: &\quad (k-m)(k+m) - (k+2m)k + (2k+m)m \overset{(1)}{=} k^2 - m^2 - k^2 - 2km + 2km + m^2 = 0, \\ h(m) = m^3: &\quad (k-m)(k+m)^3 - (k+2m)k^3 + (2k+m)m^3 \\ &\overset{(2)}{=} \left(k^4 + 2k^3m - 2km^3 - m^4\right) - k^4 - 2k^3m + 2km^3 + m^4 = 0. \end{aligned}$$

(1) Expand.
(2) $(k-m)(k+m)^3 = (k-m)(k^3 + 3k^2m + 3km^2 + m^3) = k^4 + 2k^3m - 2km^3 - m^4$.

They are independent, so the general solution is

$$h(m) = a\,m^3 + b\,m. \tag{6.59}$$

Step 4: which part is genuine

The remaining freedom is λ_0, i.e. $L_0 \to L_0 + \lambda_0 Z$. By (6.56) with $n = -m$ it changes $h(m) \to h(m) - 2m\lambda_0$: it shifts b by $-2\lambda_0$ and leaves a alone. So:

- the linear term bm is a coboundary: it is an artefact of where we put the zero of L_0;
- the cubic term am^3 is *not* a coboundary: coboundaries $\lambda([L_m, L_{-m}]) = 2m\lambda_0$ are all linear in m.

Hence $H^2(\mathrm{Witt};\mathbb{C})$ is one-dimensional: the Witt algebra has exactly one central extension up to equivalence, and it is the Virasoro algebra. The conventional choice of λ_0 is $b = -a$, so

that $h(m) = a(m^3 - m)$ vanishes for $m = 0, \pm 1$ and the $\mathfrak{sl}(2)$ subalgebra of Section 6.1.7 is not extended. Calling $a = c/12$ (and letting Z act as 1), we arrive at

$$[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12}(m^3 - m)\,\delta_{m+n,0},$$

which is (6.21). The factor $\frac{1}{12}$ is a convention, chosen so that a free boson has $c = 1$; we check this in the next subsection.

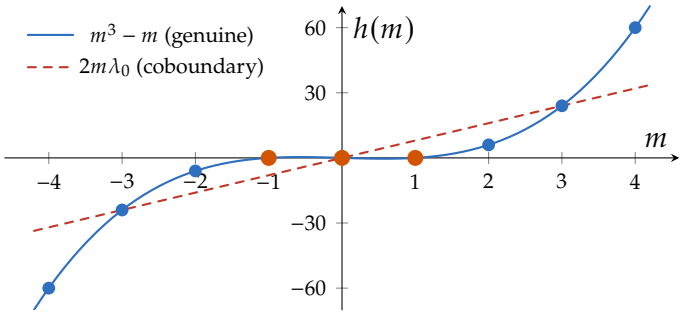

Figure 6.14: The Virasoro cocycle $h(m)$, the c-number in $[L_m, L_{-m}]$. Every central extension of the Witt algebra has $h(m) = am^3 + bm$. The linear part (red, dashed) can be changed at will by shifting L_0 by a constant, so it carries no information. The cubic part cannot. The standard choice $h = \frac{c}{12}(m^3 - m)$ (blue) vanishes at $m = 0, \pm 1$ (orange): the Möbius subalgebra $\mathfrak{sl}(2)$ is left unextended.

Worked example 6.30: the cocycle as an integral: Gel'fand–Fuks

As with the Kac–Moody cocycle (6.43), the Virasoro cocycle can be written for general vector fields $f(\theta)\partial_\theta$, $g(\theta)\partial_\theta$:

$$\omega(f\partial_\theta, g\partial_\theta) = \frac{c}{24\pi i}\int_0^{2\pi} \big(f'''(\theta) + f'(\theta)\big)\, g(\theta)\,\mathrm{d}\theta. \tag{6.60}$$

Check it on $L_m = f_m\partial_\theta$, $f_m = ie^{im\theta}$:

$$f_m''' + f_m' \overset{(1)}{=} i\big((im)^3 + im\big)e^{im\theta} \overset{(2)}{=} (m^3 - m)\,e^{im\theta},$$
$$\omega(L_m, L_n) \overset{(3)}{=} \frac{c}{24\pi i}(m^3 - m)\, i\int_0^{2\pi} e^{i(m+n)\theta}\,\mathrm{d}\theta \overset{(4)}{=} \frac{c}{12}(m^3 - m)\,\delta_{m+n,0}.$$

(1) Each derivative brings down im.
(2) $i(im)^3 = i(-i)m^3 = m^3$ and $i \cdot im = -m$.
(3) $g = f_n = ie^{in\theta}$.
(4) $\int_0^{2\pi} e^{i(m+n)\theta}\mathrm{d}\theta = 2\pi\delta_{m+n,0}$, and $\frac{c\cdot 2\pi i}{24\pi i} = \frac{c}{12}$.

Antisymmetry follows by integrating by parts: odd numbers of derivatives change sign when moved from f to g. And the operator $f \mapsto f''' + f'$ annihilates exactly $1, \cos\theta, \sin\theta$: the three real vector fields of $\mathfrak{sl}(2)$. Compare the Kac–Moody cocycle, which has one derivative and annihilates the constants: in both cases the cocycle measures how much a field fails to be "rigid".

6.2.9 Central terms from normal ordering: free fields

The cocycle condition fixes the *form* of the central terms. Their *values* are fixed by a concrete quantum theory. We compute three: the Virasoro central charge of a free boson ($c = 1$), of a

free Majorana fermion ($c = \frac{1}{2}$), and the Kac–Moody level of the charge current of a free Dirac fermion ($k = 1$). In each case the c-number comes from a single source: the ground state is not annihilated by everything, and the operators must be normal ordered.

A lemma we use three times

Suppose operators A_m on a Hilbert space satisfy: (i) the space is spanned by polynomials in some "building block" operators acting on a vacuum $|0\rangle$ (a *cyclic* vacuum); (ii) an operator D commutes with all the building blocks; (iii) there is a grading operator $L_0 \geq 0$ with $L_0|0\rangle = 0$, whose eigenvalue-0 space is spanned by $|0\rangle$, and $[L_0, D] = -q\,D$. Then $D = \langle 0|D|0\rangle\,\mathbb{1}$ if $q = 0$, and $D|0\rangle = 0$ if $q > 0$. Indeed $D\,P|0\rangle = P\,D|0\rangle$ for any polynomial P in the building blocks, so D is fixed by $D|0\rangle$; and $D|0\rangle$ has L_0-eigenvalue $-q$, which forces $D|0\rangle = 0$ for $q > 0$ and $D|0\rangle \propto |0\rangle$ for $q = 0$. We use this to reduce "compute a commutator" to "compute one vacuum expectation value".

The free boson: $c = 1$

A chiral free boson on a circle has modes α_n, $n \in \mathbb{Z}$, with

$$[\alpha_m, \alpha_n] = m\,\delta_{m+n,0}, \qquad \alpha_n^\dagger = \alpha_{-n}, \qquad \alpha_n|0\rangle = 0\ (n \geq 0). \tag{6.61}$$

This is the U(1) Kac–Moody algebra of Example 6.26 with $k = 1$ (the modes of the current $\partial\phi$). The states $\alpha_{-n_1}\cdots\alpha_{-n_r}|0\rangle$ span the Fock space. Classically the stress tensor is $\frac{1}{2}(\partial\phi)^2$, whose Fourier modes are $\frac{1}{2}\sum_m \alpha_{n-m}\alpha_m$. Quantum mechanically this is ambiguous for $n = 0$:

$$\langle 0|\tfrac{1}{2}\sum_m \alpha_{-m}\alpha_m|0\rangle \overset{(1)}{=} \tfrac{1}{2}\sum_{m>0}\langle 0|\alpha_m\alpha_{-m}|0\rangle \overset{(2)}{=} \tfrac{1}{2}\sum_{m>0} m = \infty. \tag{6.62}$$

(1) For $m \geq 0$ the right factor α_m annihilates $|0\rangle$, so those terms vanish. For $m < 0$ write $m = -m'$ with $m' > 0$: the term is $\alpha_{m'}\alpha_{-m'}$, the annihilator standing on the left. Renaming $m' \to m$ gives the sum over $m > 0$.

(2) $\alpha_m\alpha_{-m}|0\rangle = [\alpha_m, \alpha_{-m}]|0\rangle = m|0\rangle$.

This is the zero-point energy $\frac{1}{2}\hbar\omega$ of infinitely many oscillators with frequencies $\omega = m$. The remedy is **normal ordering**: $:\alpha_m\alpha_n:$ puts the annihilator (α_m with $m \geq 0$) on the right. So we define

$$L_n := \frac{1}{2}\sum_{m\in\mathbb{Z}} :\alpha_{n-m}\alpha_m:, \qquad L_0 = \frac{1}{2}\alpha_0^2 + \sum_{m>0}\alpha_{-m}\alpha_m. \tag{6.63}$$

For $n \neq 0$ normal ordering changes nothing, since α_{n-m} and α_m commute unless $n = 0$. On any Fock state only finitely many terms of the sum are nonzero, so L_n is well defined.

First commutator. For each fixed p, $[\alpha_{n-p}\alpha_p, \alpha_m] = \alpha_{n-p}\,p\,\delta_{p+m,0} + (n-p)\,\delta_{n-p+m,0}\,\alpha_p$. Summing over p and multiplying by $\frac{1}{2}$,

$$[L_n, \alpha_m] \overset{(1)}{=} \tfrac{1}{2}\big((-m)\,\alpha_{n+m} + (-m)\,\alpha_{n+m}\big) \overset{(2)}{=} -m\,\alpha_{m+n}. \tag{6.64}$$

(1) The first delta sets $p = -m$; the second sets $p = n + m$, and then $n - p = -m$. The c-number from normal ordering commutes with α_m and drops out.

(2) Add.

So L_n acts on the modes exactly as the vector field L_n acts on the function $e^{im\theta}$ (compare Section 6.2.10 below).

Second commutator. Let $D_{mn} \coloneqq [L_m, L_n] - (m-n)L_{m+n}$. Using (6.64) twice and the Jacobi identity,

$$\begin{aligned}[D_{mn}, \alpha_p] &\overset{(1)}{=} [L_m, [L_n, \alpha_p]] - [L_n, [L_m, \alpha_p]] - (m-n)[L_{m+n}, \alpha_p] \\ &\overset{(2)}{=} p(n+p)\,\alpha_{m+n+p} - p(m+p)\,\alpha_{m+n+p} + (m-n)p\,\alpha_{m+n+p} \overset{(3)}{=} 0. \end{aligned} \tag{6.65}$$

(1) Jacobi: $[[L_m, L_n], X] = [L_m, [L_n, X]] - [L_n, [L_m, X]]$.
(2) $[L_n, \alpha_p] = -p\alpha_{n+p}$, then $[L_m, -p\alpha_{n+p}] = p(n+p)\alpha_{m+n+p}$; similarly for the second term; the third is $-(m-n)(-p)\alpha_{m+n+p}$.
(3) $p(n+p-m-p+m-n) = 0$.

Also $[L_0, D_{mn}] = -(m+n)D_{mn}$, since D_{mn} is built from modes of total index $m+n$ and $[L_0, \alpha_p] = -p\alpha_p$. The lemma now says that D_{mn} is the c-number $\langle 0|D_{mn}|0\rangle$, which vanishes unless $m+n=0$ (for $m+n<0$ take adjoints: $D_{mn}^\dagger = -D_{-m,-n}$). For $n=-m$, $m>0$:

$$\langle 0|D_{m,-m}|0\rangle \overset{(1)}{=} \langle 0|L_m L_{-m}|0\rangle - \langle 0|L_{-m}L_m|0\rangle - 2m\langle 0|L_0|0\rangle \overset{(2)}{=} \| L_{-m}|0\rangle\|^2 . \tag{6.66}$$

(1) Definition of D.
(2) $L_m|0\rangle = 0$ for $m>0$ (every term of L_m has an annihilator on the right, since the two indices add to $m>0$), $L_0|0\rangle = 0$, and $L_m = L_{-m}^\dagger$.

In $L_{-m}|0\rangle = \frac{1}{2}\sum_p :\alpha_{-m-p}\alpha_p: |0\rangle$ only the terms with both indices negative survive: $-m < p < 0$. Writing $p=-q$,

$$L_{-m}|0\rangle = \tfrac{1}{2}\sum_{q=1}^{m-1} \alpha_{-(m-q)}\,\alpha_{-q}|0\rangle :$$

one term for each way of splitting m into two positive parts (Figure 6.15). Its norm is

$$\begin{aligned}\| L_{-m}|0\rangle\|^2 &\overset{(1)}{=} \tfrac{1}{4}\sum_{q,q'=1}^{m-1} \langle 0|\alpha_{q'}\alpha_{m-q'}\,\alpha_{-(m-q)}\alpha_{-q}|0\rangle \\ &\overset{(2)}{=} \tfrac{1}{4}\sum_{q,q'=1}^{m-1} q(m-q)\big(\delta_{q'q} + \delta_{q',m-q}\big) \overset{(3)}{=} \tfrac{1}{2}\sum_{q=1}^{m-1} q(m-q) \\ &\overset{(4)}{=} \tfrac{1}{2}\Big(m\,\frac{m(m-1)}{2} - \frac{(m-1)m(2m-1)}{6}\Big) \overset{(5)}{=} \frac{m^3-m}{12}. \end{aligned} \tag{6.67}$$

(1) Adjoint of $L_{-m}|0\rangle$, using $\alpha_n^\dagger = \alpha_{-n}$.
(2) Move the annihilators to the right (Wick's theorem): $\alpha_{m-q'}$ contracts either with $\alpha_{-(m-q)}$ (giving $(m-q)\delta_{q'q}$) or with α_{-q} (giving $q\,\delta_{m-q',q}$), and then $\alpha_{q'}$ contracts with the remaining creator.
(3) Each Kronecker delta contributes the same sum.
(4) $\sum_{q=1}^{m-1} q = \frac{m(m-1)}{2}$ and $\sum_{q=1}^{m-1} q^2 = \frac{(m-1)m(2m-1)}{6}$.
(5) $\frac{m(m-1)}{12}\big(3m-(2m-1)\big) = \frac{m(m-1)(m+1)}{12}$.

Comparing with $\frac{c}{12}(m^3-m)$:

Key idea: one free boson has $c=1$

The operators (6.63) satisfy the Virasoro algebra (6.21) with $c=1$. For D independent bosons α_n^μ, $\mu = 1,\dots,D$, the L_n add and so do the central charges: $c=D$. The whole c-number comes from the norm of $L_{-m}|0\rangle$: a classical stress tensor would annihilate the

classical vacuum, but the quantum one creates pairs of quanta out of it.

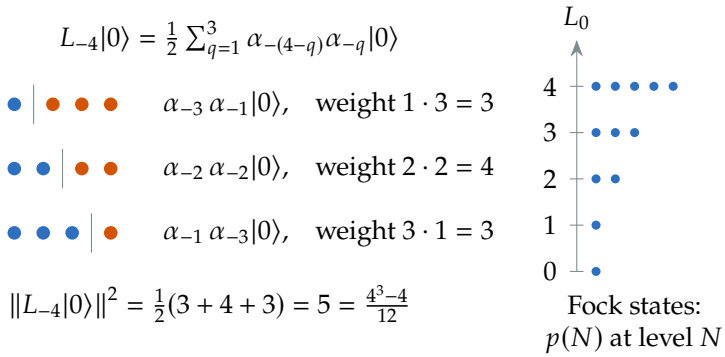

Figure 6.15: Left: $L_{-m}|0\rangle$ is a sum over the ways of splitting m into two positive integers, shown for $m = 4$ (blue dots: q; orange dots: $m-q$). Each splitting contributes $q(m-q)$ to the squared norm, and the total is $\frac{1}{12}(m^3 - m)$: this is the Virasoro central charge $c = 1$. Right: the Fock space of one boson has $p(N)$ states at $L_0 = N$ (p = number of partitions: $1, 1, 2, 3, 5, \ldots$); L_{-m} raises the level by m.

Watch out: the $-\frac{1}{24}$

Dropping the infinite constant (6.62) is not the end of the story. If one regularises it instead, with the zeta function $\sum_{m>0} m \to \zeta(-1) = -\frac{1}{12}$, the zero-point energy is $\frac{1}{2}\zeta(-1) = -\frac{1}{24} = -\frac{c}{24}$. This is the Casimir energy of a boson on a circle, and on a cylinder it is the statement that the Hamiltonian is $L_0 - \frac{c}{24}$. It is also the "bm" freedom of (6.59) in disguise: a shift of L_0 by a constant.

The free Majorana fermion: $c = \frac{1}{2}$

A real (Majorana) chiral fermion with antiperiodic boundary conditions (the Neveu–Schwarz sector) has modes b_r, $r \in \mathbb{Z} + \frac{1}{2}$, with

$$\{b_r, b_s\} = \delta_{r+s,0}, \qquad b_r^\dagger = b_{-r}, \qquad b_r|0\rangle = 0 \ (r > 0).$$

Its Virasoro generators are

$$L_m = \frac{1}{2}\sum_{r\in\mathbb{Z}+\frac{1}{2}} \left(r + \frac{m}{2}\right) :b_{-r}b_{m+r}: . \tag{6.68}$$

The weights $r + \frac{m}{2}$ are fixed by the requirement that the L_m act on the modes as vector fields act on a field of conformal weight $\frac{1}{2}$:

$$[b_{-r}b_{m+r}, b_s] \overset{(1)}{=} b_{-r}\{b_{m+r}, b_s\} - \{b_{-r}, b_s\}b_{m+r} = b_{-r}\,\delta_{m+r+s,0} - \delta_{s-r,0}\,b_{m+r},$$
$$[L_m, b_s] \overset{(2)}{=} \tfrac{1}{2}\left(-s - \tfrac{m}{2}\right)b_{m+s} - \tfrac{1}{2}\left(s + \tfrac{m}{2}\right)b_{m+s} = -\left(s + \frac{m}{2}\right)b_{m+s}.$$

(1) $[AB, C] = A\{B, C\} - \{A, C\}B$ for fermionic A, B, C.
(2) The first delta sets $r = -m - s$, with weight $r + \frac{m}{2} = -s - \frac{m}{2}$; the second sets $r = s$.

The same argument as for the boson shows that $[L_m, L_n] - (m-n)L_{m+n}$ is the c-number $\|L_{-m}|0\rangle\|^2\,\delta_{m+n,0}$. Now $L_{-m}|0\rangle = \frac{1}{2}\sum_r (r - \frac{m}{2})\,:b_{-r}b_{r-m}:\,|0\rangle$, and only $0 < r < m$ survives (both

operators must be creators). The terms r and $m-r$ are equal, because $(m-r-\frac{m}{2})\,b_{-(m-r)}b_{-r} = (\frac{m}{2}-r)(-b_{-r}b_{-(m-r)}) = (r-\frac{m}{2})\,b_{-r}b_{-(m-r)}$. So

$$L_{-m}|0\rangle \overset{(1)}{=} \sum_{0<r<m/2} \left(r-\frac{m}{2}\right) b_{-r}b_{-(m-r)}|0\rangle,$$

$$\|L_{-m}|0\rangle\|^2 \overset{(2)}{=} \sum_{0<r<m/2} \left(\frac{m}{2}-r\right)^2 \overset{(3)}{=} \frac{1}{2}\sum_{i=0}^{m-1}\left(\frac{m-1-2i}{2}\right)^2 \overset{(4)}{=} \frac{1}{8}\cdot\frac{m(m^2-1)}{3} = \frac{1}{2}\cdot\frac{m^3-m}{12}.$$

(1) Pair the terms r and $m-r$; the term $r=\frac{m}{2}$ (if present) has coefficient zero.
(2) The two-fermion states $b_{-r}b_{-s}|0\rangle$ with $r\neq s$ are orthonormal.
(3) Write $r = i+\frac{1}{2}$, $i = 0,\dots,m-1$, and sum over *all* $0<r<m$, which counts each pair twice.
(4) $\sum_{i=0}^{m-1}(m-1-2i)^2 = \frac{m(m^2-1)}{3}$ (the sum of the squares of m equally spaced numbers symmetric about 0; check $m=3$: $4+0+4=8$).

So *a Majorana fermion has* $c=\frac{1}{2}$. (Check at $m=2$: $L_{-2}|0\rangle = -\frac{1}{2}b_{-1/2}b_{-3/2}|0\rangle$, of norm $\frac{1}{4}=\frac{c}{2}$.) This is the central charge of the critical Ising model, which we will meet again as the first member of the unitary discrete series in Section 6.3.6. A complex (Dirac) fermion is two Majoranas and has $c=1$.

The Dirac sea and the Schwinger term: $k=1$

Finally, the Kac–Moody central term itself. Take a complex chiral fermion on a circle with single-particle momenta $p\in\mathbb{Z}+\frac{1}{2}$ and creation and annihilation operators $c_p^\dagger, c_p$, $\{c_p, c_q^\dagger\}=\delta_{pq}$. The ground state $|\Omega\rangle$ is the **Dirac sea**: every level with $p<0$ filled, every level with $p>0$ empty. The Fourier modes of the charge density $\psi^\dagger\psi$ are

$$\rho_n = \sum_p :c_p^\dagger c_{p+n}:\,, \qquad \rho_n^\dagger = \rho_{-n}. \tag{6.69}$$

ρ_n moves one particle from momentum $p+n$ to momentum p, lowering the total momentum by n. Two facts:

- $\rho_n|\Omega\rangle = 0$ for $n>0$: we would need an occupied level $p+n<0$ and an empty level $p>0$ with $p<p+n$, which is impossible.
- Naively $[\rho_m,\rho_n]=0$. Using $[c_a^\dagger c_b, c_c^\dagger c_d] = \delta_{bc}\,c_a^\dagger c_d - \delta_{ad}\,c_c^\dagger c_b$, the double sum gives $\sum_p c_p^\dagger c_{p+m+n} - \sum_q c_q^\dagger c_{q+m+n}$, two copies of the same divergent sum with opposite signs. Shifting the summation variable in an infinite sum of operators that do not annihilate the sea is exactly the illegal step.

The lemma replaces the illegal step by a vacuum expectation value. The commutator $[\rho_m,\rho_n]$ commutes with every c_p (the operator parts do cancel term by term when acting on fermion operators, since each c_p appears in finitely many terms), so it is a c-number, zero unless $m+n=0$. To evaluate it, look at what ρ_{-m} ($m>0$) does to the sea. $\rho_{-m}=\sum_p :c_p^\dagger c_{p-m}:$ moves a particle from $p-m$ up to p. Acting on the sea, it needs $p-m$ occupied ($p-m<0$) and p empty ($p>0$), i.e. $0<p<m$. For $p\in\mathbb{Z}+\frac{1}{2}$ there are exactly m such values, $p=\frac{1}{2},\frac{3}{2},\dots,m-\frac{1}{2}$, and each gives a different particle–hole state of norm 1. So

$$[\rho_m,\rho_n] \overset{(1)}{=} \langle\Omega|[\rho_m,\rho_{-m}]|\Omega\rangle\;\delta_{m+n,0} \overset{(2)}{=} \|\rho_{-m}|\Omega\rangle\|^2\;\delta_{m+n,0} \overset{(3)}{=} m\,\delta_{m+n,0}. \tag{6.70}$$

(1) The commutator is a c-number, nonzero only for $m+n=0$ (the lemma).

(2) $\rho_m|\Omega\rangle = 0$ for $m > 0$ and $\rho_m = \rho_{-m}^\dagger$.
(3) The m orthonormal particle–hole states just counted.

This is the U(1) Kac–Moody algebra at level $k = 1$: the *Schwinger term is the number of ways of lifting a particle out of the Dirac sea by m units of momentum* (Figure 6.16). In position space it is the δ' term of (6.34).

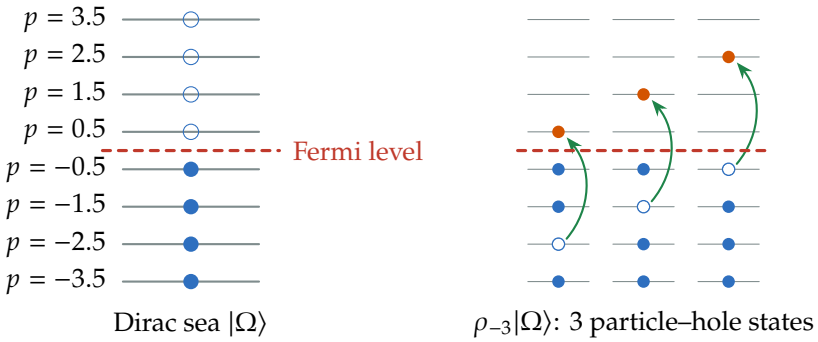

Figure 6.16: The Schwinger term counted. Left: the Dirac sea, all negative momentum levels filled. Right: ρ_{-m} lifts one particle by m units of momentum across the Fermi level; for $m = 3$ there are exactly three ways (green arrows, holes open circles, particles orange). So $\|\rho_{-m}|\Omega\rangle\|^2 = m$ and $[\rho_m, \rho_{-m}] = m$: the U(1) Kac–Moody algebra at level 1. With no Dirac sea (a classical charge density) this number would be 0.

Physical picture: bosons from fermions

Since $[\rho_m, \rho_n] = m\delta_{m+n,0}$ is exactly the boson algebra (6.61), the particle–hole excitations of the Dirac sea *are* the quanta of a chiral boson. This is bosonisation in two dimensions. As a check, the counting matches: the number of states of the Dirac sea (at fixed charge) with momentum N is $p(N)$, the same as the boson Fock space in Figure 6.15. With N_f species of fermion transforming in the fundamental of $\mathrm{U}(N_f)$, the currents $\sum_p :c_p^\dagger T^a c_{p+n}:$ give the $\mathrm{SU}(N_f)$ Kac–Moody algebra at level 1 in the physics normalisation.

6.2.10 The Sugawara construction

Nash's next point is that every Kac–Moody algebra comes with a Virasoro algebra built out of it. The reason is geometric.

Why a Virasoro algebra must be there

$\mathrm{Diff}^+(S^1)$ acts on the loop group by reparametrisation: a diffeomorphism ϕ sends a loop $\alpha(\theta)$ to $\alpha(\phi^{-1}(\theta))$. This is an automorphism of LG (the pointwise product is respected), so the symmetry group of a theory with LG symmetry is the semidirect product $LG \rtimes \mathrm{Diff}^+(S^1)$. Infinitesimally, the vector field $L_n = ie^{in\theta}\partial_\theta$ acts on the loop algebra element $T_m^a = e^{im\theta}T^a$ by differentiation:

$$L_n \cdot T_m^a \overset{(1)}{=} ie^{in\theta}\frac{d}{d\theta}\big(e^{im\theta}\big)T^a \overset{(2)}{=} ie^{in\theta}\,(im)\,e^{im\theta}\,T^a \overset{(3)}{=} -m\,T_{m+n}^a. \tag{6.71}$$

(1) The vector field differentiates the function part of the loop.
(2) $\frac{d}{d\theta}e^{im\theta} = ime^{im\theta}$.
(3) $i \cdot im = -m$, and $e^{i(m+n)\theta}T^a = T_{m+n}^a$.

In a quantum theory we want operators L_n that implement this action on the Hilbert space, i.e. with $[L_n, T^a_m] = -m\,T^a_{m+n}$. Since the Kac–Moody algebra is only a projective representation of LG, we should expect the L_n to form only a projective representation of $\mathrm{Diff}^+(S^1)$: a Virasoro algebra. The surprise is that the L_n can be built from the T^a_n themselves.

The stress tensor as a square of currents

Sugawara (1968) proposed, in four dimensions, that the energy–momentum tensor of a theory of currents be

$$T_{\mu\nu} = j^a_\mu j^a_\nu - \frac{g_{\mu\nu}}{2}\, j^a_\alpha j^{a\alpha}, \tag{6.72}$$

Nash's (6.35). In two dimensions this tensor is automatically traceless, the hallmark of conformal invariance:

$$g^{\mu\nu}T_{\mu\nu} \overset{(1)}{=} j^a_\mu j^{a\mu} - \frac{g^{\mu\nu}g_{\mu\nu}}{2}\, j^a_\alpha j^{a\alpha} \overset{(2)}{=} j^2 - \frac{2}{2}\, j^2 = 0.$$

(1) Contract with the inverse metric.
(2) $g^{\mu\nu}g_{\mu\nu} = \delta^\mu_\mu = 2$ in two dimensions.

In light-cone coordinates $x^\pm = t \pm x$ the only nonzero components are $T_{++} \propto j^a_+ j^a_+$ and $T_{--} \propto j^a_- j^a_-$, each a square of one chiral current. The Fourier modes of T_{++} on a circle are then bilinear in the Kac–Moody generators: $L_n \propto \sum_m T^a_m T^a_{n-m}$. A Lagrangian field theory in which all this happens is the two-dimensional sigma model with values in G and a Wess–Zumino term (Witten), the **WZW model**; the Wess–Zumino term is built from the 3-form $\mathrm{tr}(g^{-1}\mathrm{d}g)^3$ whose integrality we met in Section 6.2.5, and its coefficient is the level.

Why normal ordering is unavoidable

Nash gives the physical reason for normal ordering: products of operators at the same point, $A(x)B(y)$ as $y \to x$, are singular. Let us see it for the current. With $j^a(\theta) = \frac{1}{2\pi}\sum_n T^a_n e^{in\theta}$ (6.32) in a representation with vacuum $|0\rangle$ ($T^a_n|0\rangle = 0$ for $n \geq 0$), the vacuum two-point function of the current, for $u = \theta - \varphi$ with a small negative imaginary part, is

$$\begin{aligned}\langle 0|j^a(\theta)j^b(\varphi)|0\rangle &\overset{(1)}{=} \frac{1}{4\pi^2}\sum_{m>0}\langle 0|T^a_m T^b_{-m}|0\rangle\, e^{im(\theta-\varphi)} \overset{(2)}{=} \frac{k\,\delta^{ab}}{4\pi^2}\sum_{m>0} m\, e^{imu} \\ &\overset{(3)}{=} \frac{k\,\delta^{ab}}{4\pi^2}\,\frac{e^{iu}}{(1-e^{iu})^2} \overset{(4)}{=} -\frac{k\,\delta^{ab}}{16\pi^2\sin^2(u/2)} \xrightarrow{u\to 0} -\frac{k\,\delta^{ab}}{4\pi^2 u^2}.\end{aligned} \tag{6.73}$$

(1) Only $m > 0$, $n = -m$ survives: $T^b_n|0\rangle = 0$ for $n \geq 0$, and $\langle 0|T^a_m = 0$ for $m \leq 0$.
(2) $\langle 0|T^a_m T^b_{-m}|0\rangle = \langle 0|[T^a_m, T^b_{-m}]|0\rangle = km\delta^{ab}$ (the $f^{abc}T^c_0$ term has zero vacuum expectation value).
(3) $\sum_{m>0} m x^m = x\frac{d}{dx}\frac{1}{1-x} = \frac{x}{(1-x)^2}$ for $|x| < 1$.
(4) $1 - e^{iu} = -2ie^{iu/2}\sin\frac{u}{2}$, so $(1-e^{iu})^2 = -4e^{iu}\sin^2\frac{u}{2}$.

So $j^a(\theta)j^a(\theta)$ is infinite: the operator product has a double pole as the points collide, with coefficient proportional to the level. The cure is *point splitting*: define $:j^a j^a:(\theta) = \lim_{\varphi\to\theta}\big(j^a(\theta)j^a(\varphi) - \langle 0|j^a(\theta)j^a(\varphi)|0\rangle\big)$. In modes this subtraction is exactly the normal ordering prescription (6.76) below.

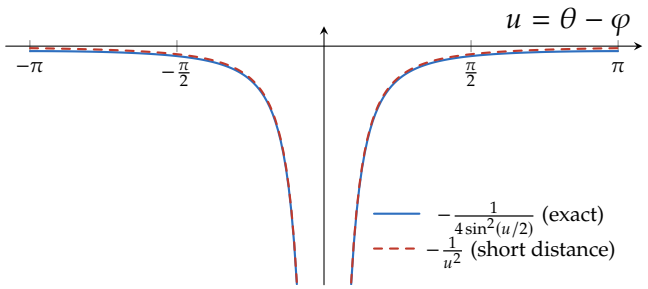

Figure 6.17: The vacuum correlator $\langle 0|j(\theta)j(\varphi)|0\rangle$ of a Kac–Moody current (in units of $k/4\pi^2$), from (6.73). It blows up like $1/u^2$ as the two points collide, so the square $j(\theta)^2$ of the current at one point is not defined. Subtracting this singular c-number is point splitting; in Fourier modes it is normal ordering.

The Sugawara operators

Let C (Nash's $c(G)$) be the value of the quadratic Casimir in the adjoint representation,

$$f^{acd}f^{bcd} = C\,\delta^{ab}, \qquad C = \frac{f^{abc}f^{abc}}{\dim G}. \tag{6.74}$$

(The adjoint generators are $(T^a_{\rm adj})_{bc} = -if^{abc}$, and $(T^a_{\rm adj}T^a_{\rm adj})_{bd} = -f^{abc}f^{acd} = f^{bca}f^{dca} = C\delta^{bd}$.) For SU(2) with $f^{abc} = \varepsilon^{abc}$, $\varepsilon^{acd}\varepsilon^{bcd} = 2\delta^{ab}$, so $C = 2$; for SU(N) in our normalisation $C = N$. Define

$$\boxed{L_n = \frac{1}{2k + C}\sum_{m\in\mathbb{Z}} :T^a_m T^a_{n-m}:} \tag{6.75}$$

(sum over a understood), Nash's (6.36), with the normal ordering of (6.37):

$$:T^a_m T^a_n: = \begin{cases} T^a_n T^a_m, & m \geq 0, \\ T^a_m T^a_n, & m < 0. \end{cases} \tag{6.76}$$

The annihilators ($m \geq 0$) are placed on the right. As for the boson, normal ordering matters only for $n = 0$: for $n \neq 0$, $T^a_m T^a_{n-m} - T^a_{n-m}T^a_m = if^{aac}T^c_n + k\,m\,\delta^{aa}\delta_{n,0} = 0$. On any state of a highest-weight representation (where T^a_m, $m > 0$, lowers L_0 and states have L_0 bounded below) only finitely many terms are nonzero.

Why $2k + C$ and not $2k$? Classically, a Poisson-bracket version of (6.75) with $\frac{1}{2k}$ would work. The extra C is a quantum correction, a shift of the level by (half) the dual Coxeter number, and it comes from the same illegal-shift phenomenon as the Dirac sea. We now compute it.

The key commutator

Let $S_n := \sum_p :T^a_p T^a_{n-p}:$, so that $L_n = S_n/(2k + C)$. We compute $[T^b_m, S_n]$ for $m > 0$ ($m < 0$ follows by taking adjoints, and $m = 0$ gives 0 because S_n is $\mathfrak{g}$-invariant). Because infinite sums must not be reshuffled, we cut the sum off at $|p| \leq M$ and let $M \to \infty$ only at the end, acting on a fixed state $|\psi\rangle$. Normal ordering changes each term by a c-number, which commutes with T^b_m, so we

may drop the colons inside the commutator. Put $q = m + n$.

$$\Big[T^b_m, \sum_{|p|\le M} T^a_p T^a_{n-p}\Big] \overset{(1)}{=} \sum_{|p|\le M} \Big((if^{bac}T^c_{m+p} + km\delta^{ab}\delta_{m+p,0})T^a_{n-p} + T^a_p\big(if^{bac}T^c_{q-p} + km\delta^{ab}\delta_{q-p,0}\big)\Big)$$
$$\overset{(2)}{=} 2km\,T^b_q + if^{bac}\Big(\sum_{p=m-M}^{m+M} T^c_p T^a_{q-p} - \sum_{p=-M}^{M} T^c_p T^a_{q-p}\Big)$$
$$\overset{(3)}{=} 2km\,T^b_q + if^{bac}\Big(\sum_{p=M+1}^{M+m} T^c_p T^a_{q-p} - \sum_{p=-M}^{-M+m-1} T^c_p T^a_{q-p}\Big). \tag{6.77}$$

(1) $[X, YZ] = [X, Y]Z + Y[X, Z]$ and the Kac–Moody relations (6.12).
(2) The two central terms each give kmT^b_q (from $p = -m$ and $p = q$, both inside the cutoff for large M). In the first f-term shift $p \to p - m$. In the second rename $a \leftrightarrow c$ and use $f^{bca} = -f^{bac}$.
(3) The two sums have the same summand and overlap on $m - M \le p \le M$; what is left are m terms at each end.

The naive answer would have been zero for the f-terms. The "end" terms do not vanish, because the operators are not normal ordered there (Figure 6.18). Act on $|\psi\rangle$ and let $M \to \infty$:

- *Lower end*, $p \approx -M$: then $q - p \approx M$ is large and positive, so $T^a_{q-p}|\psi\rangle = 0$ (it would lower L_0 below its minimum). These terms vanish.
- *Upper end*, $p \approx M$: now T^c_p is the annihilator but it stands on the left. Commute it through:

$$if^{bac}\,T^c_p T^a_{q-p}|\psi\rangle \overset{(1)}{=} if^{bac}\big(T^a_{q-p}T^c_p + [T^c_p, T^a_{q-p}]\big)|\psi\rangle \overset{(2)}{=} if^{bac}\,\big(if^{cad}T^d_q + kp\,\delta^{ca}\delta_{q,0}\big)|\psi\rangle$$
$$\overset{(3)}{=} -f^{bac}f^{cad}\,T^d_q|\psi\rangle \overset{(4)}{=} C\,T^b_q|\psi\rangle. \tag{6.78}$$

(1) Reorder.
(2) $T^c_p|\psi\rangle = 0$ for large p; the Kac–Moody relations.
(3) The δ^{ca} term dies against $f^{baa} = 0$.
(4) $f^{bac} = -f^{bca}$ and $f^{cad} = f^{dca}$, so $-f^{bac}f^{cad} = f^{bca}f^{dca} = C\delta^{bd}$ by (6.74).

There are m such terms, so altogether

$$[T^b_m, S_n] = (2k + C)\,m\,T^b_{m+n}, \qquad \text{i.e.} \qquad \boxed{[L_n, T^b_m] = -m\,T^b_{m+n}} \tag{6.79}$$

which is exactly the geometric action (6.71). The normalisation $\frac{1}{2k+C}$ in (6.75) is *forced* by demanding this.

The Virasoro algebra and its central charge

Now the argument we used for the free boson goes through word for word. Let $D_{mn} = [L_m, L_n] - (m - n)L_{m+n}$. By the Jacobi computation (6.65), with α_p replaced by T^b_p and (6.64) by (6.79), D_{mn} commutes with every T^b_p. Work in the vacuum representation: the states are polynomials in the T^a_{-n} acting on a vacuum with $T^a_n|0\rangle = 0$ for $n \ge 0$. By the lemma of Section 6.2.9, $D_{mn} = d_m\,\delta_{m+n,0}\,\mathbb{1}$. The numbers d_m form a cocycle of the Witt algebra (the Jacobi identity of the operators L_n forces (6.54)), so by (6.59) $d_m = am^3 + bm$. Two vacuum expectation values fix a and b.

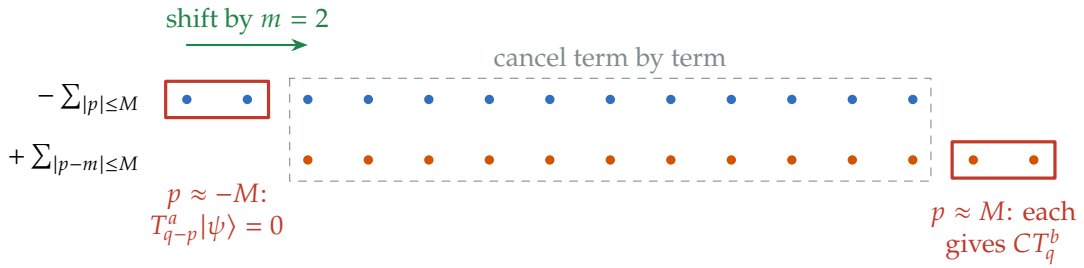

Figure 6.18: Why the Sugawara commutator is not the naive one. The two f^{abc}-sums in (6.77) have the same summand, but one is shifted by m (here $m = 2$). They cancel on the overlap (dashed box), leaving m terms at each end (red boxes). On any state the lower end vanishes, but at the upper end the annihilator stands on the wrong side, and each term leaves behind $C\,T^b_{m+n}$. This is the origin of the C in $2k + C$, and it is the same mechanism as the Dirac-sea counting of Figure 6.16.

$m = 1$. In $L_{-1}|0\rangle = \frac{1}{2k+C}\sum_p :T^a_p T^a_{-1-p}: |0\rangle$ a term survives only if both indices are negative, $p < 0$ and $-1-p < 0$, which is impossible; the borderline terms $p = 0, -1$ contain T^a_0 on the right, which kills the vacuum. So $L_{-1}|0\rangle = 0$, and $d_1 = \langle 0|[L_1, L_{-1}]|0\rangle - 2\langle 0|L_0|0\rangle = 0$: $a + b = 0$.

$m = 2$. Similarly $L_{-2}|0\rangle = \frac{1}{2k+C}\,T^a_{-1}T^a_{-1}|0\rangle$ (only $p = -1$ survives). Write $N_k := 2k + C$. First

$$\begin{aligned} T^b_1\,T^a_{-1}T^a_{-1}|0\rangle &\overset{(1)}{=} [T^b_1, T^a_{-1}]\,T^a_{-1}|0\rangle + T^a_{-1}[T^b_1, T^a_{-1}]|0\rangle \\ &\overset{(2)}{=} \big(if^{bac}T^c_0 + k\delta^{ab}\big)T^a_{-1}|0\rangle + T^a_{-1}\big(if^{bac}T^c_0 + k\delta^{ab}\big)|0\rangle \\ &\overset{(3)}{=} if^{bac}\,if^{cad}\,T^d_{-1}|0\rangle + 2k\,T^b_{-1}|0\rangle \overset{(4)}{=} (C + 2k)\,T^b_{-1}|0\rangle. \end{aligned} \tag{6.80}$$

(1) $T^b_1|0\rangle = 0$, so only the commutators contribute.
(2) Kac–Moody relations with $m = 1$.
(3) $T^c_0|0\rangle = 0$, and $T^c_0T^a_{-1}|0\rangle = [T^c_0, T^a_{-1}]|0\rangle = if^{cad}T^d_{-1}|0\rangle$.
(4) $-f^{bac}f^{cad} = C\delta^{bd}$, as in (6.78).

Hence

$$d_2 \overset{(1)}{=} \||L_{-2}|0\rangle\|^2 \overset{(2)}{=} \frac{1}{N_k^2}\,\langle 0|T^b_1T^b_1\,T^a_{-1}T^a_{-1}|0\rangle \overset{(3)}{=} \frac{1}{N_k}\,\langle 0|T^b_1T^b_{-1}|0\rangle \overset{(4)}{=} \frac{k\dim G}{N_k}.$$

(1) As in (6.66).
(2) $(T^a_{-1}T^a_{-1}|0\rangle)^\dagger = \langle 0|T^a_1T^a_1$.
(3) (6.80).
(4) $\langle 0|T^b_1T^b_{-1}|0\rangle = \langle 0|[T^b_1, T^b_{-1}]|0\rangle = k\delta^{bb} = k\dim G$.

With $d_2 = 8a + 2b = 6a$ we find $a = \frac{k\dim G}{6N_k}$, and writing $a = c/12$:

Key idea: the Sugawara central charge

The operators (6.75) satisfy

$$[L_m, L_n] = (m-n)L_{m+n} + \frac{2k\dim G}{12(2k+C)}\,m(m^2-1)\,\delta_{m,-n}, \qquad c = \frac{2k\dim G}{2k+C}, \tag{6.81}$$

Nash's (6.38). Every Kac–Moody algebra carries a Virasoro algebra, whose central charge is determined by the level.

Worked example 6.31: central charges of some Sugawara theories

In terms of the integer level $N = 2k$ of Section 6.3.9 and the dual Coxeter number $h^\vee$ (for our normalisation $C = h^\vee$ for SU(n)), the formula reads $c = \frac{N \dim G}{N + h^\vee}$.

G	$\dim G$	$h^\vee$	c at level N	$N = 1, 2, 3$
U(1)	1	0	1	1, 1, 1
SU(2)	3	2	$\frac{3N}{N+2}$	1, $\frac{3}{2}$, $\frac{9}{5}$
SU(3)	8	3	$\frac{8N}{N+3}$	2, $\frac{16}{5}$, 4
E_8	248	30	$\frac{248N}{N+30}$	8, $\frac{31}{2}$, $\frac{744}{33}$

Two checks. For U(1) ($f = 0$, $C = 0$), (6.75) is $L_n = \frac{1}{2k} \sum :T_m T_{n-m}:$, which with $\alpha_n = T_n/\sqrt{k}$ is the free boson (6.63), and $c = \frac{2k}{2k} = 1$ as it must be. As $N \to \infty$, $c \to \dim G$: at large level the currents behave like $\dim G$ free bosons (the classical limit). At level 1, c equals the rank (1, 2, 8): these theories are free bosons on the maximal torus in disguise (Frenkel–Kac).

6.2.11 The Casimir operator and the true L_0

Nash gives a second, more mathematical, way to see why normal ordering and the combination $2k + C$ appear (following Pressley and Segal): try to write down the Casimir operator of the loop algebra.

The finite-dimensional Casimir

For a finite-dimensional $\mathfrak{g}$ with orthonormal basis T^a the **Casimir operator** is

$$\Delta = T^a (T^a)^* = T^a T^a, \tag{6.82}$$

Nash's (6.39) (T^* is the adjoint, and our T^a are Hermitian). It commutes with every generator:

$$[T^b, \Delta] \overset{(1)}{=} [T^b, T^a] T^a + T^a [T^b, T^a] \overset{(2)}{=} i f^{bac} \left(T^c T^a + T^a T^c \right) \overset{(3)}{=} 0.$$

(1) Leibniz rule for commutators.
(2) $[T^b, T^a] = i f^{bac} T^c$.
(3) f^{bac} is antisymmetric in a, c, while $T^c T^a + T^a T^c$ is symmetric.

So Δ is a number on each irreducible representation: $j(j+1)$ for spin j of SU(2), C on the adjoint.

The loop version diverges

For the loop algebra the obvious analogue, with $(T^a_n)^* = T^a_{-n}$ in a unitary representation, is

$$\begin{aligned} \tilde{\Delta} &\overset{(1)}{=} \sum_{n \in \mathbb{Z}} T^a_n (T^a_n)^* \overset{(2)}{=} \sum_{n>0} \left(T^a_n T^a_{-n} + T^a_{-n} T^a_n \right) + T^a_0 T^a_0 \\ &\overset{(3)}{=} \sum_{n>0} 2\, T^a_{-n} T^a_n + T^a_0 T^a_0 + k \dim G \sum_{n>0} n. \end{aligned} \tag{6.83}$$

(1) Definition (Nash's (6.40)).
(2) Split into $n > 0$, $n < 0$ and $n = 0$; this is Nash's (6.41).
(3) $T^a_n T^a_{-n} = T^a_{-n} T^a_n + [T^a_n, T^a_{-n}] = T^a_{-n} T^a_n + i f^{aac} T^c_0 + kn\, \delta^{aa} = T^a_{-n} T^a_n + kn \dim G$ (Nash's (6.42)).

The last term is the divergent sum $\sum n$, the same zero-point energy as in (6.62). Dropping it defines

$$\tilde{\Delta}_0 := \sum_{n>0} 2\,T^a_{-n}T^a_n + T^a_0 T^a_0 = \sum_p :T^a_p T^a_{-p}: = S_0, \tag{6.84}$$

Nash's (6.43): it is exactly the normal-ordered operator, and $\tilde{\Delta}_0 = (2k + C)\,L_0$.

Fixing up the Casimir

$\tilde{\Delta}_0$ is not a Casimir operator: by (6.79) with $n = 0$,

$$[T^a_n, \tilde{\Delta}_0] = n\,(2k + C)\,T^a_n, \tag{6.85}$$

Nash's (6.44). (Nash prints a minus sign here; it is inconsistent with his own (6.47) at $n = 0$, which agrees with us.) The failure is proportional to n, which is what a rotation of the circle does. Indeed, for the geometric rotation generator $i\frac{d}{d\theta}$ acting on loops,

$$\left[T^a_n,\, i\frac{d}{d\theta}\right] f \overset{(1)}{=} e^{in\theta}T^a\, if' - i\frac{d}{d\theta}\left(e^{in\theta}T^a f\right) \overset{(2)}{=} -i(in)\,e^{in\theta}T^a f = n\,T^a_n f, \tag{6.86}$$

(1) Act on a test function $f(\theta)$.
(2) Product rule; the if' terms cancel.

which is Nash's (6.45). Subtracting,

$$\left[T^a_n,\ \tilde{\Delta}_0 - (2k + C)\,i\frac{d}{d\theta}\right] = n(2k + C)T^a_n - (2k + C)nT^a_n = 0, \tag{6.87}$$

so the true Casimir is $\tilde{\Delta}_0 - (2k + C)\,i\frac{d}{d\theta}$ (Nash's (6.46), where the sign of the second term follows his sign in (6.44)).

Key idea: the Casimir says "Sugawara L_0 = rotation generator"

To make room for $i\frac{d}{d\theta}$ we must enlarge the group from $\widetilde{LG}$ to the semidirect product $S^1 \ltimes \widetilde{LG}$, where $S^1 \subset \mathrm{Diff}^+(S^1)$ is the group of rigid rotations of the loop. Its Lie algebra is $\mathbb{R} \oplus \mathbb{R} \oplus \mathrm{Map}(S^1, \mathfrak{g})$ (rotation generator, central element, loops). In an irreducible representation the Casimir is a constant, so

$$(2k + C)\left(L_0 - i\frac{d}{d\theta}\right) = \text{const}:$$

up to a constant, the operator L_0 built from the currents *is* the generator of rotations of the circle. Pressley and Segal observe that a "regularised" Casimir must have the form $\tilde{\Delta}_0 + \alpha\, i\frac{d}{d\theta}$ by this argument; the calculation (6.85) fixes $\alpha = -(2k + C)$.

For $n \neq 0$ define $\tilde{\Delta}_n := \sum_m T^a_m T^a_{n-m} = S_n$ (no ordering is needed). Then (6.79) reads

$$[T^a_l, \tilde{\Delta}_n] = l\,(2k + C)\,T^a_{l+n}, \tag{6.88}$$

Nash's (6.47), and the operators

$$L_n = \frac{\tilde{\Delta}_n}{2k + C} \quad (n \neq 0), \qquad L_0 = \frac{1}{2k + C}\left(\sum_{n>0} 2\,T^a_{-n}T^a_n + T^a_0 T^a_0\right) \tag{6.89}$$

(Nash's (6.48)) are the Sugawara operators (6.75). They obey the Virasoro algebra (6.81) (Nash's (6.49)).

Worked example 6.32: the conformal weight of a highest-weight state

Let $|\lambda\rangle$ be a state annihilated by all T^a_n, $n > 0$, and transforming in an irreducible representation V_λ of $\mathfrak{g}$ under the T^a_0. Then only the $T^a_0 T^a_0$ term of L_0 acts:

$$L_0|\lambda\rangle \overset{(1)}{=} \frac{1}{2k+C}\, T^a_0 T^a_0 |\lambda\rangle \overset{(2)}{=} \frac{C_\lambda}{2k+C}\,|\lambda\rangle,$$

(1) The terms $T^a_{-n}T^a_n$ with $n > 0$ annihilate $|\lambda\rangle$.
(2) $T^a_0 T^a_0$ is the Casimir (6.82) of V_λ, with eigenvalue C_λ.

For SU(2) at level $N = 2k$ and spin j: $h_j = \frac{j(j+1)}{N+2}$. At level 1, the spin-$\frac{1}{2}$ state has $h = \frac{3/4}{3} = \frac{1}{4}$: the conformal weight of the operator $e^{i\phi/\sqrt{2}}$ of a free boson, as bosonisation requires.

Reading Nash (pp. 180–183, (6.30)–(6.49))

Nash's (6.30)–(6.34) are our (6.48)–(6.52); the Sp(2) example is ours, added to show a c-number arising at order $\hbar^2$ from ordering. Nash quotes the Virasoro algebra (6.14) and says its central term "gives rise to a conformal anomaly unless the space-time has a certain critical dimension"; we derived the cocycle in Section 6.2.8 and computed c for free fields in Section 6.2.9. His Sugawara formulae (6.35)–(6.38) are (6.72)–(6.81); he states that "these L_n satisfy the Virasoro algebra" without proof, and our (6.77)–(6.80) is the proof. His Casimir discussion (6.39)–(6.49) is Section 6.2.11. Two typographical points: in (6.42)–(6.43) the normal-ordered product should read $2T^a_{-n}T^a_n$ (annihilator on the right), and the sign in (6.44) and (6.46) should be flipped to agree with (6.47). His $c(G)$ is our C.

6.2.12 Extensions of $\mathrm{Map}(X, G)$ when $\dim X > 1$

So far the space on which the maps live has been a circle. Physics in $3+1$ dimensions needs more: a gauge transformation at fixed time is a map $g : X \to G$ from a *three-dimensional* space X. The equal-time commutators of the currents, or of the Gauss law generators, of such a theory may again pick up c-number terms, the higher-dimensional Schwinger terms. So we ask the question of this section once more, now for $\mathrm{Map}(X, G)$ with $\dim X > 1$:

What extensions does $\mathrm{Map}(X, \mathfrak{g})$ *have, and where do they come from?*

The answer comes in two parts. The *central* extensions are all inherited from the loop group by restricting maps to loops in X. But the extensions that actually occur in gauge theory are *not* central: the "c-number" in the commutator turns out to depend on the gauge field. We take the two parts in turn.

Central extensions: restrict to a loop

Nash's recipe is short: pick a loop in X and restrict. Let

$$f : S^1 \longrightarrow X \tag{6.90}$$

be a smooth loop (Nash's (6.50)). A map on X can be restricted to the loop by composing:

$$\hat{f} : \mathrm{Map}(X, \mathfrak{g}) \longrightarrow \mathrm{Map}(S^1, \mathfrak{g}), \qquad \alpha \longmapsto \alpha \circ f, \tag{6.91}$$

Nash's (6.51). In words: $\hat{f}(\alpha)(\theta) = \alpha(f(\theta))$ is the value of α at the point of the loop with parameter θ (Figure 6.19). The same formula defines a group homomorphism $\mathrm{Map}(X, G) \to LG$.

$\hat f$ respects brackets. The bracket in both algebras is pointwise, so at every θ

$$\hat f\big([\alpha,\beta]\big)(\theta) \overset{(1)}{=} [\alpha,\beta]\big(f(\theta)\big) \overset{(2)}{=} \big[\alpha(f(\theta)),\beta(f(\theta))\big] \overset{(3)}{=} \big[\hat f(\alpha),\hat f(\beta)\big](\theta).$$

(1) Definition (6.91) of $\hat f$.
(2) The pointwise bracket (6.3) on $\mathrm{Map}(X,\mathfrak g)$.
(3) Definition of $\hat f$ again, and the pointwise bracket on $\mathrm{Map}(S^1,\mathfrak g)$.

So $\hat f$ is a Lie algebra homomorphism.

Pulling back the cocycle. Any 2-cocycle c on $\mathrm{Map}(S^1,\mathfrak g)$ now gives one on $\mathrm{Map}(X,\mathfrak g)$:

$$(\hat f^{*}c)(\alpha,\beta) \coloneqq c\big(\hat f(\alpha),\hat f(\beta)\big). \tag{6.92}$$

It is antisymmetric because c is. It satisfies the cocycle condition (6.41) because

$$\begin{aligned}(\hat f^{*}c)\big([\alpha,\beta],\gamma\big) + \text{cyclic} &\overset{(1)}{=} c\big(\hat f([\alpha,\beta]),\hat f(\gamma)\big) + \text{cyclic}\\ &\overset{(2)}{=} c\big([\hat f\alpha,\hat f\beta],\hat f\gamma\big) + \text{cyclic} \overset{(3)}{=} 0.\end{aligned}$$

(1) Definition (6.92).
(2) $\hat f$ is a homomorphism (the chain above).
(3) c is a cocycle on $\mathrm{Map}(S^1,\mathfrak g)$, applied to the three loops $\hat f\alpha,\hat f\beta,\hat f\gamma$.

This is a general principle: *a homomorphism pulls cocycles back to cocycles*. With Nash we write $\hat f^{*}c \in H^2(\mathrm{Map}(X,\mathfrak g);\mathbb Z)$ when c is integral; since $\hat f$ is also a homomorphism of groups, the circle bundle $\widetilde{LG} \to LG$ pulls back along $\hat f : \mathrm{Map}(X,G) \to LG$ to a circle bundle over $\mathrm{Map}(X,G)$, and the integrality survives. So the central extension of the group exists too.

What the cocycle looks like. Take $c = \omega_k$, the Kac–Moody cocycle (6.43). The chain rule turns the θ-derivative of the restricted map into the differential of α along the loop:

$$\begin{aligned}(\hat f^{*}\omega_k)(\alpha,\beta) &\overset{(1)}{=} \frac{k}{\pi i}\int_0^{2\pi} \mathrm{tr}\Big(\frac{d}{d\theta}\big(\alpha(f(\theta))\big)\,\beta(f(\theta))\Big)\mathrm d\theta\\ &\overset{(2)}{=} \frac{k}{\pi i}\int_0^{2\pi} \mathrm{tr}\Big(\partial_\mu\alpha\big(f(\theta)\big)\,\frac{df^\mu}{d\theta}\,\beta\big(f(\theta)\big)\Big)\mathrm d\theta \overset{(3)}{=} \frac{k}{\pi i}\oint_f \mathrm{tr}\big(\mathrm d\alpha\;\beta\big).\end{aligned} \tag{6.93}$$

(1) Definitions (6.92) and (6.43).
(2) Chain rule, in local coordinates x^μ on X.
(3) $\partial_\mu\alpha\,\frac{df^\mu}{d\theta}\mathrm d\theta$ is the pull-back $f^{*}(\mathrm d\alpha)$ of the $\mathfrak g$-valued 1-form $\mathrm d\alpha = \partial_\mu\alpha\,\mathrm dx^\mu$, so the integral is the line integral of the 1-form $\mathrm{tr}(\mathrm d\alpha\,\beta)$ round the loop.

So the pulled-back cocycle is a *line integral* over the loop f of the 1-form $\mathrm{tr}(\mathrm d\alpha\,\beta)$ on X. We can now see directly why it is a cocycle: antisymmetry is $\oint_f \mathrm{tr}(\mathrm d\alpha\,\beta + \alpha\,\mathrm d\beta) = \oint_f \mathrm d\,\mathrm{tr}(\alpha\beta) = 0$, and the cocycle condition reduces, as in (6.45), to $\oint_f \mathrm d\,\mathrm{tr}(\alpha[\beta,\gamma]) = 0$. Both are Stokes' theorem on the closed curve $f(S^1)$, which has no boundary.

Worked example 6.33: the two-torus: two levels and a toroidal algebra

Let $X = T^2$ with angles (θ,φ). A basis of the complexified $\mathrm{Map}(T^2,\mathfrak g)$ is

$$T^a_{(m,n)} \coloneqq e^{i(m\theta+n\varphi)}\,T^a, \qquad m,n\in\mathbb Z,$$

with the pointwise bracket $[T^a_{(m,n)},T^b_{(m',n')}] = i f^{abc}T^c_{(m+m',n+n')}$ (multiply the exponentials).

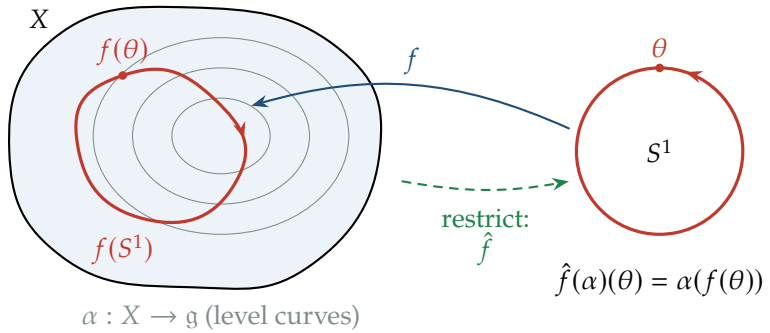

Figure 6.19: Restricting a map α on X (faint level curves) to a loop $f : S^1 \to X$ (red) produces a loop in $\mathfrak{g}$. Because the bracket is pointwise, restriction is a homomorphism $\mathrm{Map}(X,\mathfrak{g}) \to \mathrm{Map}(S^1,\mathfrak{g})$, and any cocycle of the loop algebra pulls back. The pulled-back Kac–Moody cocycle is the line integral $\frac{k}{\pi i}\oint_f \mathrm{tr}(\mathrm{d}\alpha\,\beta)$ along the red curve.

Take the loop $f_{\varphi_0}(\theta) = (\theta, \varphi_0)$, a circle of fixed φ. Then

$$\begin{aligned}\big(\hat{f}^*_{\varphi_0}\omega_k\big)\big(T^a_{(m,n)}, T^b_{(m',n')}\big) &\overset{(1)}{=} \omega_k\big(e^{in\varphi_0}\,T^a_m,\ e^{in'\varphi_0}\,T^b_{m'}\big)\\ &\overset{(2)}{=} e^{i(n+n')\varphi_0}\ k\,m\,\delta^{ab}\,\delta_{m+m',0}.\end{aligned}$$

(1) On the loop, $T^a_{(m,n)}$ restricts to the loop-algebra element $e^{in\varphi_0}e^{im\theta}T^a = e^{in\varphi_0}T^a_m$.
(2) Bilinearity and (6.44).

Each circle gives a cocycle, and so does any superposition of circles. The average over all the circles $\varphi_0 \in [0, 2\pi)$ is

$$c_1\big(T^a_{(m,n)}, T^b_{(m',n')}\big) \overset{(1)}{=} \frac{1}{2\pi}\int_0^{2\pi} e^{i(n+n')\varphi_0}\mathrm{d}\varphi_0\ k\,m\,\delta^{ab}\delta_{m+m',0} \overset{(2)}{=} k\,m\,\delta^{ab}\,\delta_{m+m',0}\,\delta_{n+n',0}.$$

(1) Average the previous result over φ_0.
(2) Orthogonality of Fourier modes.

Doing the same with the circles of fixed θ gives $c_2 = k'\,n\,\delta^{ab}\delta_{m+m',0}\delta_{n+n',0}$. The general combination $c = c_1 + c_2$ defines the extended algebra

$$[T^a_{(m,n)}, T^b_{(m',n')}] = i f^{abc}\,T^c_{(m+m',n+n')} + (k\,m + k'\,n)\,\delta^{ab}\,\delta_{m+m',0}\,\delta_{n+n',0},$$

a **toroidal Lie algebra** with *two* levels, one for each independent cycle of the torus. Restricted to the modes with $n = 0$ it is the ordinary Kac–Moody algebra at level k.

The example shows the general pattern. A single loop, or any superposition of loops, gives a central extension. The linear functionals on 1-forms of the type $\omega \mapsto \sum_i \lambda_i \oint_{f_i}\omega$, and their limits, are what de Rham called *closed 1-currents*. Nash's statement that *all* central extensions of $\mathrm{Map}(X,\mathfrak{g})$ (for simple $\mathfrak{g}$) are obtained in this fashion means: every continuous central 2-cocycle has the form $(\alpha,\beta) \mapsto T\big(\mathrm{tr}(\mathrm{d}\alpha\,\beta)\big)$ for a closed 1-current T on X (Pressley and Segal, §4.2). Because the line integral is sensitive to the 1-form $\mathrm{tr}(\mathrm{d}\alpha\,\beta)$ itself, and not just to its de Rham class, even a small contractible loop gives a nontrivial extension.

Watch out: central extensions are not where the higher-dimensional physics is

A loop in X is a one-dimensional object, and the extensions just found see only what happens along it. Local field theories in $3+1$ dimensions produce Schwinger terms that are local densities over all of space. These do not come from loops. They come from the second construction below, and they are *not central*.

Transgression: from forms on G to forms on $\mathrm{Map}(X,G)$

Nash's second construction produces a 2-form on the group $\mathrm{Map}(X,G)$ from a higher-degree form on G. It is called **transgression**, and it uses two operations we already know well: pull-back and integration.

Let $\dim X = n$, with X compact, oriented and without boundary, and let ω be a closed $(n+2)$-form on G. The **evaluation map**

$$\mathrm{Ev} : X \times \mathrm{Map}(X,G) \longrightarrow G, \qquad (x,\alpha) \longmapsto \alpha(x) \tag{6.94}$$

(Nash's (6.52)) just reads off the value of the map α at the point x. Pull ω back along it and integrate out the X directions:

$$c \coloneqq \int_X \mathrm{Ev}^*\omega, \qquad [c] \in H^2\big(\mathrm{Map}(X,G);\mathbb{R}\big), \tag{6.95}$$

Nash's (6.53). The degree count is: $\mathrm{Ev}^*\omega$ is an $(n+2)$-form on the product; integrating over the n-dimensional fibre X uses up n of its slots and leaves a 2-form on $\mathrm{Map}(X,G)$ (Figure 6.20).

Working definition 6.14 (integration over the fibre)

To evaluate $c = \int_X \mathrm{Ev}^*\omega$ at a point $\alpha \in \mathrm{Map}(X,G)$ on two tangent vectors $\delta_1\alpha, \delta_2\alpha$ (infinitesimal changes of the map), do this at each $x \in X$: feed ω at the point $\alpha(x) \in G$ the two vectors $\delta_1\alpha(x), \delta_2\alpha(x)$ and the n vectors $\partial_1\alpha(x), \dots, \partial_n\alpha(x)$ (the derivatives of α along coordinate directions of X). That gives a density on X [a number at each x times $\mathrm{d}^n x$, ready to be integrated over X]; integrate it:

$$c_\alpha(\delta_1\alpha, \delta_2\alpha) = \int_X \omega_{\alpha(x)}\big(\delta_1\alpha, \delta_2\alpha, \partial_1\alpha, \dots, \partial_n\alpha\big)\, \mathrm{d}^n x.$$

Why c is closed. Exterior derivatives commute with pull-backs, and integration over a fibre without boundary commutes with d (the extra term would be an integral over $\partial X = \varnothing$). So

$$\mathrm{d}c \overset{(1)}{=} \int_X \mathrm{d}\,\mathrm{Ev}^*\omega \overset{(2)}{=} \int_X \mathrm{Ev}^*\mathrm{d}\omega \overset{(3)}{=} 0.$$

(1) $\mathrm{d}\int_X = \int_X \mathrm{d}$ for a closed fibre X: Stokes' theorem on X, with $\partial X = \varnothing$.
(2) d commutes with pull-back (Chapter T1).
(3) ω is closed.

If $\omega = \mathrm{d}\eta$ is exact, the same steps give $c = \mathrm{d}\int_X \mathrm{Ev}^*\eta$, also exact. So transgression is a well-defined map $H^{n+2}(G;\mathbb{R}) \to H^2(\mathrm{Map}(X,G);\mathbb{R})$.

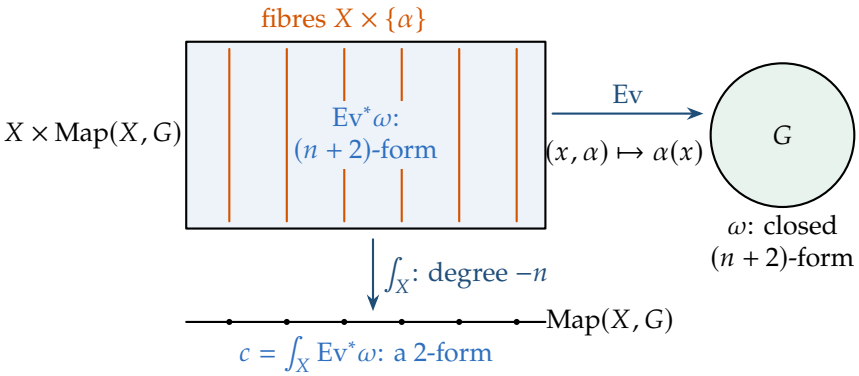

Figure 6.20: Transgression. Pull the $(n+2)$-form ω back from G to the product $X \times \mathrm{Map}(X, G)$ along the evaluation map, then integrate along the fibres X (orange). What is left is a 2-form c on $\mathrm{Map}(X, G)$, closed because X has no boundary.

Worked example 6.34: the case $n = 1$: transgression produces the level

Take $X = S^1$ and G compact, simple and simply connected, for instance SU(2). The group G carries the closed 3-form $\Omega = \mathrm{tr}(g^{-1}\mathrm{d}g)^3$ that generates $H^3(G;\mathbb{R})$ (for SU(2) we met it as the degree density, with $\int_{\mathrm{SU}(2)} \Omega = 24\pi^2$). Its transgression $c = \int_{S^1} \mathrm{Ev}^*\Omega$ is a closed 2-form on LG. Its value on a 2-sphere in LG can be computed without evaluating any form. A map $\Sigma : S^2 \to LG$ is a family of loops, i.e. a map $\hat{\Sigma} : S^1 \times S^2 \to G$, $\hat{\Sigma}(\theta, s) = \Sigma(s)(\theta)$, and

$$\int_{S^2} \Sigma^* c \overset{(1)}{=} \int_{S^1 \times S^2} \hat{\Sigma}^*\Omega \overset{(2)}{=} \deg(\hat{\Sigma}) \int_G \Omega \overset{(3)}{=} 24\pi^2 \deg(\hat{\Sigma}).$$

(1) The definition of c as a fibre integral: integrating first over the circle and then over the sphere is integrating over the product (Fubini), and $\mathrm{Ev} \circ (\mathrm{id} \times \Sigma) = \hat{\Sigma}$.
(2) For a map between closed oriented 3-manifolds, the pull-back of a top form integrates to the degree times the integral of the form (Example 6.5).
(3) The value of $\int_{\mathrm{SU}(2)} \Omega$.

So $c/24\pi^2$ integrates to an integer over every 2-sphere in LG, and since $\pi_2(LG) = \pi_3(G) = \mathbb{Z}$ (the pitfall in Section 6.2.5) there are spheres with degree 1. Therefore $\frac{c}{24\pi^2}$ represents a generator of $H^2(LG;\mathbb{Z}) = \mathbb{Z}$. On the other hand, $H^2(LG;\mathbb{R}) = H^2(\mathrm{Map}(S^1, \mathfrak{g});\mathbb{R})$ is one-dimensional and spanned by the left-invariant Kac–Moody form ω_k. Hence ω_k is cohomologous to a multiple of c, and the integrality condition (6.47) becomes an integrality condition on k. This is the geometric source of the quantised level: *the level of a loop group extension is the degree of a map into G*, just as the winding of the Wess–Zumino term is (Chapter 9).
Notice what did *not* happen: c itself is not left invariant. At the constant loop $\alpha \equiv 1$ the derivative $\partial_\theta \alpha$ vanishes, so by the working definition $c_1 = 0$ there, whereas $\omega_k \neq 0$. For $X = S^1$ this is harmless, because every class on LG has a left-invariant representative. For $\dim X > 1$ it is not harmless, and it is the reason for what follows.

Non-central extensions: cocycles with values in functions

For $\dim X = n > 1$ the 2-form c of (6.95) cannot in general be made left invariant (this is the failure of $H^*(\mathrm{Map}(X, G)) = H^*(\mathrm{Map}(X, \mathfrak{g}))$ noted in Section 6.2.5). Nash's move is to *keep* the non-invariance. Every $\alpha \in \mathrm{Map}(X, \mathfrak{g})$ defines a left-invariant vector field α^L on the group

$\mathrm{Map}(X,G)$, and the value of the 2-form c on two of them,

$$\hat{c}(\alpha,\beta) := c(\alpha^L,\beta^L), \tag{6.96}$$

is not a number but a *function* on $\mathrm{Map}(X,G)$ (Nash's (6.54)). So we get a map

$$\hat{c} : \mathrm{Map}(X,\mathfrak{g}) \times \mathrm{Map}(X,\mathfrak{g}) \longrightarrow \mathcal{H}, \qquad \mathcal{H} = \Omega^0\big(\mathrm{Map}(X,G)\big)$$

into the space $\mathcal{H}$ of functions on the group. (Nash writes $\Omega^0(\mathrm{Map}(X,\mathfrak{g}))$; since the function is on the group, we write G.) What kind of extension does such a thing define?

Working definition 6.15 (extension by a module; cocycle with coefficients)

Let $\mathfrak{g}$ act linearly on an abelian Lie algebra $\mathcal{H}$ [a vector space whose bracket is zero, here the functions on the group]: for each $U \in \mathfrak{g}$ an operator $\rho(U)$ on $\mathcal{H}$ with $[\rho(U),\rho(V)] = \rho([U,V])$. A bilinear antisymmetric $\hat{c} : \mathfrak{g}\times\mathfrak{g} \to \mathcal{H}$ defines a bracket on $\mathfrak{g}\oplus\mathcal{H}$:

$$\big[(U,F),(V,G)\big] = \big([U,V],\ \rho(U)G - \rho(V)F + \hat{c}(U,V)\big). \tag{6.97}$$

It satisfies the Jacobi identity if and only if

$$\sum_{\mathrm{cyc}(U,V,W)} \Big(\rho(U)\,\hat{c}(V,W) - \hat{c}\big([U,V],W\big)\Big) = 0. \tag{6.98}$$

Test for triviality: $\hat{c}$ can be removed by a redefinition $U \mapsto (U,\lambda(U))$ exactly when $\hat{c}(U,V) = \rho(U)\lambda(V) - \rho(V)\lambda(U) - \lambda([U,V])$ for some linear $\lambda : \mathfrak{g} \to \mathcal{H}$. The classes form $H^2(\mathfrak{g};\mathcal{H})$ [cocycles, with two counted as the same when they differ by such a removable term]. When $\rho = 0$ everything reduces to the central case (6.41), (6.42).

The ideal $\mathcal{H}$ is abelian but *not central*: the bracket of $(U,0)$ with $(0,G)$ is $(0,\rho(U)G)$, not zero. This is the price of letting the "c-number" be a function.

Why the cocycle condition is the Jacobi identity. Take three elements $(U,0),(V,0),(W,0)$. Using (6.97) twice,

$$\begin{aligned}\big[[(U,0),(V,0)],(W,0)\big] &\overset{(1)}{=} \big[([U,V],\hat{c}(U,V)),(W,0)\big] \\ &\overset{(2)}{=} \Big([[U,V],W],\ -\rho(W)\hat{c}(U,V) + \hat{c}([U,V],W)\Big).\end{aligned}$$

(1) The inner bracket.
(2) The outer bracket, with $F = \hat{c}(U,V)$ and $G = 0$.

The cyclic sum of the first entries vanishes by the Jacobi identity of $\mathfrak{g}$. The cyclic sum of the second entries is minus the left side of (6.98) (write $\rho(W)\hat{c}(U,V)$ as the cyclic partner of $\rho(U)\hat{c}(V,W)$). General elements (U,F) add only terms that cancel by $[\rho(U),\rho(V)] = \rho([U,V])$.

Why a closed 2-form gives such a cocycle. For a 2-form c and vector fields X,Y,Z on any manifold,

$$\mathrm{d}c(X,Y,Z) = \sum_{\mathrm{cyc}} \Big(X\big(c(Y,Z)\big) - c\big([X,Y],Z\big)\Big).$$

On left-invariant vector fields, $[\alpha^L,\beta^L] = [\alpha,\beta]^L$, and a vector field acts on functions by differentiation, $\rho(\alpha)F = \alpha^L F$. So $\mathrm{d}c = 0$ is literally the cocycle condition (6.98) for $\hat{c}$ with values in the module $\mathcal{H}$ of functions. Nash summarises: the Lie algebra $\mathrm{Map}(X,\mathfrak{g})$ has been extended by $\mathcal{H}$, and $\hat{c} \in H^2(\mathrm{Map}(X,\mathfrak{g});\mathcal{H})$.

The Mickelsson–Faddeev extension

Nash's concrete example is $G = \mathrm{SU}(N)$ with $N \geq 3$ and $X = S^3$. The physics setting is a non-abelian gauge theory with chiral fermions on the spatial 3-sphere. Its states are wave functionals $\Psi[A]$ of the spatial gauge field A, i.e. functions on the space $\mathcal{A}$ of connections on the (trivial) bundle over S^3. The gauge algebra acts on $\mathcal{A}$ by the infinitesimal gauge transformation, so the natural module is $\mathcal{E} = \mathrm{Map}(\mathcal{A}, \mathbb{R})$, not functions on the group.

Conventions for this subsection. We use real components: a basis $e_a = -iT^a$ of anti-Hermitian matrices, so that $[e_a, e_b] = f^{abc} e_c$; the gauge field is $A = A^a\, e_a$ with $A^a = A^a_\mu \, \mathrm{d}x^\mu$ real 1-forms (this is the dictionary $A_{\text{math}} = -iA^a_{\text{phys}} T^a$ with the coupling absorbed), and a gauge parameter is $\alpha = \alpha^a e_a$ with real functions α^a. The infinitesimal gauge transformation $A \mapsto A + \varepsilon\, D_A\alpha$ has components

$$(D_A\alpha)^c = \mathrm{d}\alpha^c + f^{abc} A^a \alpha^b, \tag{6.99}$$

from $\delta A = \mathrm{d}\alpha + [A, \alpha]$. It acts on functionals by the directional derivative $(\rho(\alpha)\Psi)[A] = \frac{d}{d\varepsilon}\Psi[A + \varepsilon D_A\alpha]\big|_{\varepsilon=0}$. This is a Lie algebra action: the vector fields $V_\alpha(A) = D_A\alpha$ on $\mathcal{A}$ obey $[V_\alpha, V_\beta] = V_{[\alpha,\beta]}$ (a two-line check using the Jacobi identity of $\mathfrak{g}$). The only group-theory input we need beyond f^{abc} is the totally symmetric tensor

$$d^{abc} := 2\,\mathrm{tr}\big(T^a\{T^b, T^c\}\big), \tag{6.100}$$

real because the T^a are Hermitian, and *invariant*: $f^{eax} d^{xbc} + f^{ebx} d^{axc} + f^{ecx} d^{abx} = 0$. (Proof: the trace of a commutator vanishes, so $\mathrm{tr}[T^e, T^a\{T^b, T^c\}] = 0$; expanding the commutator by the Leibniz rule and using $[T^e, T^a] = i f^{eax} T^x$ gives the three terms.)

Working definition 6.16 (Mickelsson–Faddeev cocycle)

For $\alpha, \beta \in \mathrm{Map}(S^3, \mathfrak{su}(N))$ and a connection A [the spatial gauge field $A = A^a e_a$ on S^3],

$$\hat{c}(\alpha,\beta)[A] := C \int_{S^3} d^{abc}\, A^c \wedge \mathrm{d}\alpha^a \wedge \mathrm{d}\beta^b = C \int_{S^3} d^{abc}\, \varepsilon^{ijk}\, A^c_k\, \partial_i\alpha^a\, \partial_j\beta^b\, \mathrm{d}^3x, \tag{6.101}$$

a function on $\mathcal{A}$ for each pair (α, β). Operationally: a Schwinger term [an extra term in the commutator of two gauge generators] that is linear in the gauge field and has one derivative on each gauge parameter, glued together with the d-symbol.

Relation to Nash's formula. Nash writes (6.55) as $c(\alpha,\beta) = C\int_{S^3} \mathrm{tr}(\mathrm{d}\alpha \wedge \mathrm{d}\beta \wedge A)$ with matrix-valued forms. A 2-cocycle must be antisymmetric, so this is to be read antisymmetrised in α, β. Then

$$\begin{aligned}
\mathrm{tr}(\mathrm{d}\alpha \wedge \mathrm{d}\beta \wedge A) - \mathrm{tr}(\mathrm{d}\beta \wedge \mathrm{d}\alpha \wedge A) &\overset{(1)}{=} \mathrm{d}\alpha^a \wedge \mathrm{d}\beta^b \wedge A^c \left(\mathrm{tr}(e_a e_b e_c) + \mathrm{tr}(e_b e_a e_c)\right) \\
&\overset{(2)}{=} (-i)^3\, \mathrm{tr}\big(\{T^a, T^b\}T^c\big)\, \mathrm{d}\alpha^a \wedge \mathrm{d}\beta^b \wedge A^c \\
&\overset{(3)}{=} \frac{i}{2}\, d^{abc}\, A^c \wedge \mathrm{d}\alpha^a \wedge \mathrm{d}\beta^b .
\end{aligned}$$

(1) Expand in components; in the second term swap the two real 1-forms, $\mathrm{d}\beta^b \wedge \mathrm{d}\alpha^a = -\mathrm{d}\alpha^a \wedge \mathrm{d}\beta^b$, and rename $a \leftrightarrow b$ so both terms carry the same forms.

(2) $e_a = -iT^a$.

(3) $(-i)^3 = i$; $\mathrm{tr}(\{T^a, T^b\}T^c) = \mathrm{tr}(T^c\{T^a, T^b\}) = \frac{1}{2} d^{cab} = \frac{1}{2} d^{abc}$; a 1-form moves past a 2-form with no sign.

So Nash's formula and (6.101) agree up to the constant, and only the totally symmetric part of the trace, the d-symbol, survives the antisymmetrisation.

Check 1: antisymmetry. Swap $\alpha \leftrightarrow \beta$ in (6.101), rename the summed indices $a \leftrightarrow b$, use $d^{bac} = d^{abc}$ and $\mathrm{d}\beta^a \wedge \mathrm{d}\alpha^b \to \mathrm{d}\beta^b \wedge \mathrm{d}\alpha^a = -\mathrm{d}\alpha^a \wedge \mathrm{d}\beta^b$: the integrand changes sign.

Check 2: the cocycle condition. We must show that

$$\delta\hat{c}(\alpha,\beta,\gamma) \coloneqq \rho(\alpha)\hat{c}(\beta,\gamma) - \rho(\beta)\hat{c}(\alpha,\gamma) + \rho(\gamma)\hat{c}(\alpha,\beta) - \hat{c}([\alpha,\beta],\gamma) + \hat{c}([\alpha,\gamma],\beta) - \hat{c}([\beta,\gamma],\alpha)$$

vanishes (this is (6.98), written out). Each term is an integral of either (i) $\mathrm{d}\alpha\,\mathrm{d}\beta\,\mathrm{d}\gamma$, with no A and no undifferentiated parameter, or (ii) A times two differentiated parameters times one undifferentiated one.

Terms of type (i) come from the $\mathrm{d}\gamma^c$ part of $D_A\gamma$ in $\rho(\gamma)\hat{c}(\alpha,\beta) = C\int d^{abc}(D_A\gamma)^c \wedge \mathrm{d}\alpha^a \wedge \mathrm{d}\beta^b$ and its two partners. Each is the integral of an exact form, e.g. $d^{abc}\mathrm{d}\gamma^c \wedge \mathrm{d}\alpha^a \wedge \mathrm{d}\beta^b = \mathrm{d}\big(d^{abc}\gamma^c\,\mathrm{d}\alpha^a \wedge \mathrm{d}\beta^b\big)$, over the closed manifold S^3: zero by Stokes.

Terms of type (ii) with α undifferentiated come from three places: the $f^{xyc}A^x\alpha^y$ part of $D_A\alpha$ in $\rho(\alpha)\hat{c}(\beta,\gamma)$; the $f^{uvx}\alpha^u\mathrm{d}\beta^v$ part of $\mathrm{d}[\alpha,\beta]^x$ in $-\hat{c}([\alpha,\beta],\gamma)$; and the $f^{uvx}\alpha^u\mathrm{d}\gamma^v$ part of $\mathrm{d}[\alpha,\gamma]^x$ in $+\hat{c}([\alpha,\gamma],\beta)$. Writing all three in the form $C\int(\cdots)A^d\,\alpha^e\,\mathrm{d}\beta^b \wedge \mathrm{d}\gamma^c$,

$$\begin{aligned}\text{coefficient} &\overset{(1)}{=} d^{bcx}f^{dex} \;-\; d^{xcd}f^{ebx} \;-\; d^{xbd}f^{ecx}\\ &\overset{(2)}{=} -\big(f^{edx}d^{bcx} + f^{ebx}d^{xcd} + f^{ecx}d^{bxd}\big) \overset{(3)}{=} 0.\end{aligned}$$

(1) The three sources in order. In the first, $(D_A\alpha)^x \supset f^{dex}A^d\alpha^e$ fills the A slot of $d^{bcx}A^x \wedge \mathrm{d}\beta^b \wedge \mathrm{d}\gamma^c$. In the second, $[\alpha,\beta]^x = f^{uvx}\alpha^u\beta^v$, so $\mathrm{d}[\alpha,\beta]^x \supset f^{ebx}\alpha^e\mathrm{d}\beta^b$ sits in $-d^{xcd}A^d \wedge \mathrm{d}[\alpha,\beta]^x \wedge \mathrm{d}\gamma^c$. In the third, $\mathrm{d}[\alpha,\gamma]^x \supset f^{ecx}\alpha^e\mathrm{d}\gamma^c$ sits in $d^{xbd}A^d \wedge \mathrm{d}[\alpha,\gamma]^x \wedge \mathrm{d}\beta^b$, and $\mathrm{d}\gamma^c \wedge \mathrm{d}\beta^b = -\mathrm{d}\beta^b \wedge \mathrm{d}\gamma^c$ gives the sign.
(2) $f^{dex} = -f^{edx}$, and the d's are totally symmetric.
(3) Invariance of d^{abc} under the adjoint action of T^e.

Since $\delta\hat{c}$ is totally antisymmetric in (α,β,γ), the terms with β or γ undifferentiated cancel in the same way, with the letters permuted. Hence $\delta\hat{c} = 0$: (6.101) is a cocycle, and the Jacobi identity of the extended algebra reduces to two things we trust, *Stokes' theorem on S^3 and the gauge invariance of d^{abc}*.

Key idea: the Mickelsson–Faddeev extension (Nash, pp. 184–185)

The gauge algebra $\mathrm{Map}(S^3,\mathfrak{su}(N))$, $N \geq 3$, has a nontrivial extension by the module $\mathcal{E} = \mathrm{Map}(\mathcal{A},\mathbb{R})$ of functions of the gauge field:

$$[(\alpha,F),(\beta,G)] = \big([\alpha,\beta],\ \rho(\alpha)G - \rho(\beta)F + \hat{c}(\alpha,\beta)\big),$$

with $\hat{c}$ the cocycle (6.101). Since $\mathcal{E}$ is the Lie algebra of the abelian group $\mathrm{Map}(\mathcal{A},S^1)$ (the Lie algebra of S^1 is $\mathbb{R}$), the corresponding group is an extension

$$1 \longrightarrow \mathrm{Map}(\mathcal{A},S^1) \longrightarrow \widehat{\mathrm{Map}(S^3,G)} \longrightarrow \mathrm{Map}(S^3,G) \longrightarrow 1,$$

the **Mickelsson–Faddeev extension**, in which $\mathrm{Map}(S^3,G)$ acts on $\mathrm{Map}(\mathcal{A},S^1)$ through its action on connections. It is the $3+1$ dimensional analogue of the Kac–Moody extension, and it is what chiral fermions produce as a Schwinger term.

Worked example 6.35: why $N \geq 3$: the d-symbol of SU(2) and SU(3)

For SU(2), $T^a = \frac{1}{2}\sigma^a$, and the Pauli matrices anticommute to the identity. So

$$d^{abc} \overset{(1)}{=} 2\,\mathrm{tr}\big(T^a\{T^b, T^c\}\big) \overset{(2)}{=} \tfrac{1}{4}\,\mathrm{tr}\big(\sigma^a\{\sigma^b, \sigma^c\}\big) \overset{(3)}{=} \tfrac{1}{4}\cdot 2\delta^{bc}\,\mathrm{tr}\,\sigma^a \overset{(4)}{=} 0.$$

(1) Definition (6.100).
(2) $T^a = \sigma^a/2$ contributes $(1/2)^3$, times the 2 in front.
(3) $\{\sigma^b, \sigma^c\} = 2\delta^{bc}\mathbb{1}$.
(4) The Pauli matrices are traceless.

So for SU(2) the cocycle (6.101) vanishes identically. For SU(3) it does not: with the Gell-Mann matrices, $T^1 = \frac{1}{2}\lambda^1$ and $T^8 = \frac{1}{2\sqrt{3}}\mathrm{diag}(1,1,-2)$,

$$d^{811} \overset{(1)}{=} 2\,\mathrm{tr}\big(T^8\cdot 2(T^1)^2\big) \overset{(2)}{=} 2\,\mathrm{tr}\Big(\tfrac{1}{2\sqrt{3}}\mathrm{diag}(1,1,-2)\cdot\tfrac{1}{2}\mathrm{diag}(1,1,0)\Big) \overset{(3)}{=} \frac{2}{4\sqrt{3}}\,(1+1) = \frac{1}{\sqrt{3}}.$$

(1) $\{T^1, T^1\} = 2(T^1)^2$.
(2) $\lambda^1 = \begin{pmatrix}0&1&0\\1&0&0\\0&0&0\end{pmatrix}$ squares to $\mathrm{diag}(1,1,0)$, so $(T^1)^2 = \frac{1}{4}\mathrm{diag}(1,1,0)$ and $2(T^1)^2 = \frac{1}{2}\mathrm{diag}(1,1,0)$.
(3) Multiply the diagonals and add.

This is the standard value $d_{118} = 1/\sqrt{3}$. The same dichotomy is topological: the cocycle is the transgression of the 5-form $\mathrm{tr}(g^{-1}\mathrm{d}g)^5$ on G over $X = S^3$ ($n+2 = 5$), and this form represents a nonzero class in $H^5(\mathrm{SU}(N);\mathbb{R})$ exactly when $N \geq 3$. For $\mathrm{SU}(2) = S^3$ there is nothing in degree 5. In homotopy language, $\pi_5(\mathrm{SU}(N)) = \mathbb{Z}$ for $N \geq 3$, while $\pi_5(\mathrm{SU}(2)) = \mathbb{Z}_2$ is torsion and invisible to real cohomology. The d-symbol is also exactly what appears in the triangle anomaly $\propto d^{abc}$ of chiral gauge theories (Chapter 10).

Worked example 6.36: the abelian case: a Schwinger term that can be removed

For $G = \mathrm{U}(1)$ drop all indices ($f = 0$, and the "d-symbol" is 1): $\hat{c}(\alpha,\beta)[A] = \int_{S^3} A\wedge\mathrm{d}\alpha\wedge\mathrm{d}\beta$, with $\rho(\alpha)$ the derivative along $\delta A = \mathrm{d}\alpha$. Try the functional $\lambda(\beta)[A] := \int_{S^3}\beta\,A\wedge\mathrm{d}A$, a gauge parameter times the Chern–Simons density. Its coboundary is

$$(\delta\lambda)(\alpha,\beta) \overset{(1)}{=} \rho(\alpha)\lambda(\beta) - \rho(\beta)\lambda(\alpha) \overset{(2)}{=} \int \beta\,\mathrm{d}\alpha\wedge\mathrm{d}A - \int \alpha\,\mathrm{d}\beta\wedge\mathrm{d}A$$
$$\overset{(3)}{=} -2\int \alpha\,\mathrm{d}\beta\wedge\mathrm{d}A \overset{(4)}{=} -2\int \mathrm{d}\alpha\wedge\mathrm{d}\beta\wedge A \overset{(5)}{=} -2\,\hat{c}(\alpha,\beta).$$

(1) The coboundary formula of the working definition; $[\alpha,\beta] = 0$.
(2) $\rho(\alpha)\int\beta A\,\mathrm{d}A = \int\beta\,(\mathrm{d}\alpha\wedge\mathrm{d}A + A\wedge\mathrm{d}\mathrm{d}\alpha)$ and $\mathrm{d}\mathrm{d}\alpha = 0$.
(3) Stokes: $0 = \int\mathrm{d}(\alpha\beta\,\mathrm{d}A) = \int\beta\,\mathrm{d}\alpha\wedge\mathrm{d}A + \int\alpha\,\mathrm{d}\beta\wedge\mathrm{d}A$.
(4) Stokes again: $\mathrm{d}(\alpha\,\mathrm{d}\beta\wedge A) = \mathrm{d}\alpha\wedge\mathrm{d}\beta\wedge A - \alpha\,\mathrm{d}\beta\wedge\mathrm{d}A$ integrates to zero.
(5) A 1-form moves past a 2-form without sign.

So $\hat{c} = \delta(-\frac{1}{2}\lambda)$ is a coboundary. Physically, the abelian Schwinger term is removed by redefining the Gauss law generator, $G_\alpha \to G_\alpha + \frac{1}{2}\int\alpha\,A\wedge\mathrm{d}A$. In the non-abelian case with $d^{abc} \neq 0$ no such redefinition exists (Mickelsson, Faddeev), and the extension is genuine.

Physical picture: why a non-central Schwinger term signals an anomaly

In a gauge theory in the Hamiltonian formalism, physical states must be gauge invariant: $G_\alpha|\psi\rangle = 0$ for the Gauss law generators G_α (one for each gauge parameter $\alpha(x)$). If the G_α represent the Lie algebra of $\mathrm{Map}(X, G)$ this is consistent. If instead

$$[G_\alpha, G_\beta] = G_{[\alpha,\beta]} + i\,\hat{c}(\alpha,\beta)[A],$$

then applying both sides to a physical state gives $\hat{c}(\alpha,\beta)[A]|\psi\rangle = 0$, which is impossible for a non-vanishing multiplication operator. The Gauss law cannot be imposed; the gauge symmetry is anomalous. This is the Hamiltonian face of the chiral anomaly, and the Mickelsson–Faddeev cocycle is related to the four-dimensional anomaly $\propto d^{abc}$ by the descent equations of Chapter 10. In $1+1$ dimensions the analogous obstruction is the central Kac–Moody term itself.

Reading Nash (pp. 178–180 and 183–185, (6.27)–(6.29), (6.50)–(6.55))

The opening of Nash's §2, the exact sequence (6.27), split and central extensions, the bracket (6.28) and the cocycle condition (6.29), is our Sections 6.2.1 and 6.2.3; the projective representations and the examples (Heisenberg, Galilean, $\mathrm{SU}(2) \to \mathrm{SO}(3)$) are added background. His comparison of $H^*(G)$ with $H^*(\mathfrak{g})$ and the integrality discussion (footnote 2) are Sections 6.2.5 and 6.2.6. On pp. 183–185, (6.50)–(6.51) are our (6.90)–(6.91) and (6.52)–(6.53) are (6.94)–(6.95). Nash writes the coefficient module of (6.54) as $\Omega^0(\mathrm{Map}(X,\mathfrak{g}))$; the functions live on the group $\mathrm{Map}(X, G)$ (or, in the example, on $\mathcal{A}$). His (6.55) must be read antisymmetrised in α, β, which leaves the d-symbol form (6.101). The transgression example for $X = S^1$, the module-cocycle formalism, the verification of the cocycle condition, and the SU(2) and U(1) examples are added.

Recap: Section 6.2

- An extension $1 \to H \to \bar{G} \to G \to 1$ is central if H commutes with everything. Quantum symmetries are projective, $U(g)U(h) = e^{i\phi(g,h)}U(gh)$, so they are true representations of a central extension.
- Lie algebra version: $[U, V] \mapsto ([U, V], c(U, V))$ with c an antisymmetric 2-cocycle, $\sum_{\mathrm{cyc}} c([U, V], W) = 0$; removable iff $c = \lambda \circ [\,,\,]$. Classes: $H^2(\mathfrak{g};\mathfrak{h})$. Semisimple finite-dimensional $\mathfrak{g}$: $H^2 = 0$ (Whitehead).
- Loop algebra: $\omega_k(\xi,\eta) = \frac{k}{\pi i}\oint \mathrm{tr}(\xi'\eta)$ gives $km\delta^{ab}\delta_{m+n,0}$; the cocycle identity is Stokes on S^1. Group extension exists iff $[\omega/2\pi]$ is integral: the level is quantised, $N = 2k \in \mathbb{Z}$.
- Witt algebra: the Jacobi identity allows only $am^3 + bm$; bm is a shift of L_0; $c/12\,(m^3 - m)$ remains. Free boson $c = 1$, Majorana fermion $c = \frac{1}{2}$, Dirac sea gives $k = 1$ (Schwinger term).
- Sugawara: $L_n = \frac{1}{2k+C}\sum :T^a_m T^a_{n-m}:$ obeys Virasoro with $c = \frac{2k\dim G}{2k+C}$; L_0 is the regularised Casimir, equal to rotation of the circle up to a constant.
- $\mathrm{Map}(X, G)$, $\dim X > 1$: central extensions come from loops in X (line integrals of $\mathrm{tr}(\mathrm{d}\alpha\,\beta)$). Transgression $c = \int_X \mathrm{Ev}^*\omega$ gives non-central extensions with values in functions; for $X = S^3$, $G = \mathrm{SU}(N \geq 3)$ this is the Mickelsson–Faddeev cocycle $\int d^{abc}A^c\,\mathrm{d}\alpha^a\,\mathrm{d}\beta^b$, the higher-dimensional Schwinger term.

6.3 Representations

We now have the algebras. The Kac–Moody algebra (6.12) and the Virasoro algebra (6.21) are the Lie algebras of central extensions of LG and $\mathrm{Diff}(S^1)$. The question of this section is the one a physicist asks of any symmetry:

On what Hilbert spaces can these algebras act, and what does the space of states look like?

For SU(2) the answer is the list of spins $j = 0, \frac{1}{2}, 1, \ldots$ and the multiplets $|j, m\rangle$. We want the analogue for the infinite-dimensional algebras.

Nash begins with a warning. The representation theory of infinite-dimensional groups is "still under construction"; it is nothing like as complete as that of compact Lie groups. Two cases are well understood: the loop groups LG and $\mathrm{Diff}(S^1)$. Much less is known for $\mathrm{Map}(X, G)$ with $\dim X > 1$ (Pressley and Segal summarise what is known). Also, as in physics practice, we mostly represent the *Lie algebra* and not the group: we look for operators L_n and T^a_n on a vector space obeying the commutation relations, and worry about exponentiating them only at the end (Section 6.3.10).

The section runs as follows. The single physical requirement that the energy be bounded below leads to *highest-weight representations* (Section 6.3.1). We construct the biggest one, the *Verma module* (Section 6.3.2), find the *null states* inside it and remove them (Sections 6.3.3 and 6.3.4), and see how the inner product decides which states are null (Section 6.3.5). Unitarity then fixes the allowed values of the central charge (Section 6.3.6) and forces the representation to be projective (Section 6.3.7). The same story for the Kac–Moody algebra gives the quantised level (Sections 6.3.8 and 6.3.9). Finally the Borel–Weil theorem shows where the representations live geometrically (Section 6.3.10).

6.3.1 Positive energy and highest weights

Why L_0 is an energy

Recall that on the circle $L_n = ie^{in\theta}\frac{d}{d\theta}$ (6.17), so $L_0 = i\frac{d}{d\theta}$ generates rotations of the circle. In a quantum field theory on a spatial circle, the generator of rotations is the total momentum P (up to sign). Now think of a *chiral* field, a left mover $\phi(t + \theta)$. For such a field, a shift in time and a shift in angle are the same thing, so its momentum and its energy coincide: L_0 *is* the Hamiltonian of the left movers, up to an additive constant. For a closed string or a two-dimensional conformal field theory with both chiralities, $H = L_0 + \bar{L}_0 - \frac{c+\bar{c}}{24}$ and $P = L_0 - \bar{L}_0$ (radial quantisation, Figure 6.8 and Chapter 11). Either way:

Key idea: the positive-energy condition

In every physical application, the spectrum of L_0 is the spectrum of an energy, and so must be *bounded below*. This one condition selects the representations that matter.

Nash makes a point here that we will prove at the end of this section (Section 6.3.7): once L_0 is bounded below, every nontrivial irreducible unitary representation of $\mathrm{vect}(S^1)$ is a representation of the *central extension*, i.e. it has $c \neq 0$. In group language, the representations of $\mathrm{Diff}(S^1)$ we want are *projective*: recall from (6.36) that unitary operators T_g form a projective representation if

$$T_g T_h = c(g, h)\, T_{gh}, \qquad |c(g, h)| = 1, \tag{6.102}$$

Nash's (6.56), and that a projective representation of G is a true representation of the extension $\bar{G}$ (Section 6.2.2). So this is the physics reason to attach more importance to the Virasoro algebra

than to vect(S^1) itself.

Unitarity: $L_n^\dagger = L_{-n}$

A unitary representation of a group represents a *real* Lie algebra element ξ by an anti-Hermitian operator $\rho(\xi)$, because $e^{t\rho(\xi)}$ must be unitary. The real vector fields on the circle are $f(\theta)\frac{d}{d\theta}$ with real f. The L_n are complex combinations of them, and the complex-linear extension of ρ fixes their adjoints:

$$\begin{aligned}\rho(L_n)^\dagger &\overset{(1)}{=} \Big(i\,\rho\big(\cos n\theta\,\tfrac{d}{d\theta}\big) - \rho\big(\sin n\theta\,\tfrac{d}{d\theta}\big)\Big)^\dagger \\ &\overset{(2)}{=} -i\,\rho\big(\cos n\theta\,\tfrac{d}{d\theta}\big)^\dagger - \rho\big(\sin n\theta\,\tfrac{d}{d\theta}\big)^\dagger \\ &\overset{(3)}{=} i\,\rho\big(\cos n\theta\,\tfrac{d}{d\theta}\big) + \rho\big(\sin n\theta\,\tfrac{d}{d\theta}\big) \overset{(4)}{=} \rho(L_{-n}).\end{aligned}$$

(1) $L_n = ie^{in\theta}\frac{d}{d\theta} = i\cos n\theta\,\frac{d}{d\theta} - \sin n\theta\,\frac{d}{d\theta}$, and ρ is complex linear.
(2) The adjoint is antilinear: $(iA)^\dagger = -iA^\dagger$.
(3) The real vector fields are represented by anti-Hermitian operators.
(4) $L_{-n} = ie^{-in\theta}\frac{d}{d\theta} = i\cos n\theta\,\frac{d}{d\theta} + \sin n\theta\,\frac{d}{d\theta}$.

So in a unitary representation

$$L_n^\dagger = L_{-n}, \qquad L_0^\dagger = L_0, \qquad c \in \mathbb{R}. \tag{6.103}$$

(The last because c is a real multiple of the identity; take the adjoint of (6.21).) The free boson (6.63) satisfies this, since $\alpha_n^\dagger = \alpha_{-n}$. This is the Virasoro analogue of $J_\pm^\dagger = J_\mp$ for angular momentum.

Raising and lowering

The commutator with L_0 is the whole story of the spectrum. Setting $m = 0$ in (6.21) gives $[L_0, L_n] = -nL_n$ (the central term vanishes for $m = 0$). Let $|\psi\rangle$ be an eigenvector, $L_0|\psi\rangle = E|\psi\rangle$. Then

$$L_0\big(L_n|\psi\rangle\big) \overset{(1)}{=} [L_0, L_n]|\psi\rangle + L_nL_0|\psi\rangle \overset{(2)}{=} -nL_n|\psi\rangle + E\,L_n|\psi\rangle = (E-n)\,L_n|\psi\rangle. \tag{6.104}$$

(1) Add and subtract $L_nL_0|\psi\rangle$.
(2) $[L_0, L_n] = -nL_n$ and $L_0|\psi\rangle = E|\psi\rangle$.

So L_n with $n > 0$ *lowers* the energy by n, and L_{-n} *raises* it by n, exactly as J_- and J_+ lower and raise J_3 (Figure 6.21).

Working definition 6.17 (highest-weight representation)

A representation is a **highest-weight representation** with **highest weight** (c, h) if the central element [the extra generator of (6.21) that commutes with every L_n] acts as the number c and there is a state $|h\rangle$, the **vacuum** or **highest-weight state**, with

$$L_0|h\rangle = h|h\rangle, \qquad L_n|h\rangle = 0 \quad (n \geq 1), \tag{6.105}$$

Nash's (6.57), such that the whole space is obtained by acting on $|h\rangle$ with the L_{-n} ($|h\rangle$ is **cyclic**). Operationally: find the state of lowest energy; check that every L_n with $n > 0$ kills it; then h is its energy and c is the central charge.

Why the lowest-energy state is killed by the lowering operators. This is Nash's argument. Suppose h is the lowest eigenvalue of L_0 and $L_n|h\rangle \neq 0$ for some $n \geq 1$. By (6.104) with $E = h$, $L_n|h\rangle$ is an eigenvector of L_0 with eigenvalue $h - n < h$. That contradicts the assumption that h is the lowest eigenvalue. So $L_n|h\rangle = 0$ for all $n \geq 1$. The positive-energy condition *forces* (6.105).

The raising operators do not kill it. Nash states that $L_{-n}|h\rangle \neq 0$ "as may be seen by applying the commutation relations". Here is the calculation. In a unitary representation, with $\langle h|h\rangle = 1$,

$$\|L_{-n}|h\rangle\|^2 \overset{(1)}{=} \langle h|L_n L_{-n}|h\rangle \overset{(2)}{=} \langle h|[L_n, L_{-n}]|h\rangle \overset{(3)}{=} \langle h|\Big(2nL_0 + \frac{c}{12}n(n^2-1)\Big)|h\rangle$$
$$\overset{(4)}{=} 2nh + \frac{c}{12}\,n(n^2-1). \tag{6.106}$$

(1) $(L_{-n}|h\rangle)^\dagger = \langle h|L_{-n}^\dagger = \langle h|L_n$ by (6.103).
(2) $L_n|h\rangle = 0$ for $n \geq 1$, so $\langle h|L_{-n}L_n|h\rangle = 0$ may be subtracted.
(3) The Virasoro algebra (6.21) with $m = n$, $n \to -n$: $(n-(-n))L_0 = 2nL_0$ and $\delta_{n,n} = 1$.
(4) $L_0|h\rangle = h|h\rangle$ and $\langle h|h\rangle = 1$.

For $n = 1$ this is $2h$; for $n \geq 2$ the central term enters. Unless h and c are both zero, the right side is nonzero for large n, so $L_{-n}|h\rangle$ cannot vanish. Two immediate consequences, which are the first unitarity conditions:

- $n = 1$: $\|L_{-1}|h\rangle\|^2 = 2h \geq 0$, so $h \geq 0$.
- $n \to \infty$: the cubic term dominates, so $c \geq 0$.

This is why Nash says the highest weight is a pair of *non-negative* numbers (c, h).

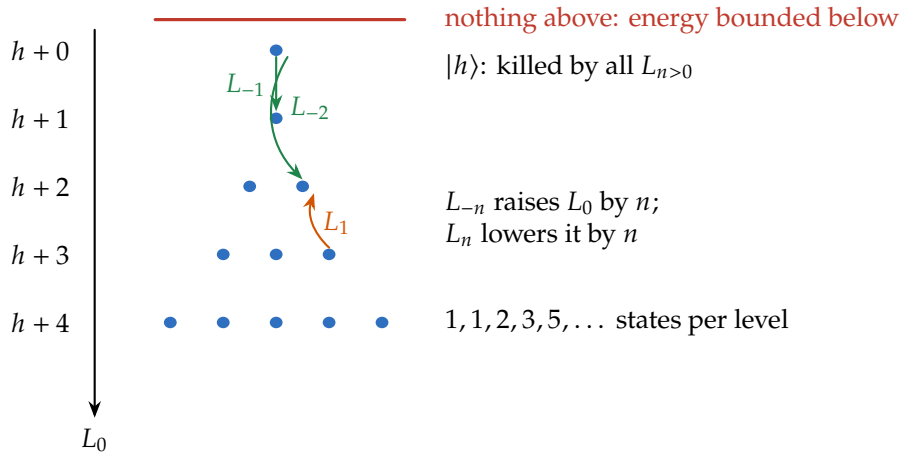

Figure 6.21: The spectrum of L_0 in a highest-weight representation. Each row is an eigenspace of L_0 (drawn downwards, so that the bounded-below end is at the top). The raising operators L_{-n} (green) move down n rows; the lowering operators L_n (orange) move up. The positive-energy condition says there is a top row, and its states are then killed by every L_n with $n > 0$. The number of dots per row is counted in Section 6.3.2.

Watch out: highest weight or lowest weight?

Nash's footnote 4: the name "highest weight" is not ideal, since $|h\rangle$ has the *lowest* eigenvalue of L_0 in the representation. The terms *lowest weight*, *anti-dominant weight* and *positive energy representation* are also used for the same thing. The name comes from Lie theory, where the mode operators $L_{n>0}$ play the role of the positive root vectors (like J_+) and $|h\rangle$ is killed by them, like the state $|j, j\rangle$ of highest J_3. We follow Nash and say "highest weight".

6.3.2 The Verma module: everything a highest-weight state generates

Given (c, h), which representation do we get? We answer this in the way a physicist builds a Fock space: start with a vacuum and apply creation operators. The result is called the Verma module. It is not yet the answer, because some of the states we build can turn out to be "null" and must be thrown away. The whole construction fits in one line:

$$|h\rangle \xrightarrow[\text{descendants}]{\text{generate}} V(c,h) = U(\text{vir}_-)|h\rangle \xrightarrow[\text{submodule } N]{\text{quotient by null}} L(c,h) = V(c,h)/N \tag{6.107}$$

Figure 6.22 shows the three objects. We take the steps one at a time, and at each step we say why the step is legitimate.

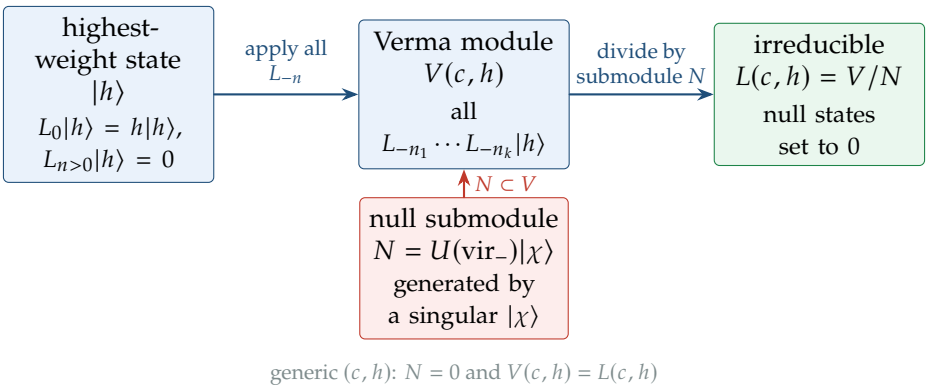

Figure 6.22: The pipeline (6.107). The Verma module (centre) is the largest highest-weight representation with given (c, h). At special values of (c, h) it contains a proper submodule N (red), generated by a singular vector; dividing it out gives the irreducible representation (green), which is the space of states of the physical theory.

A vector space, or a module?

First a word about language, because it is the main source of confusion for a physicist reading the mathematics. We are used to starting with a Hilbert space $\mathcal{H}$ and then asking how the symmetry operators act on it. The highest-weight construction goes the other way: we start from the algebra, and the construction produces the vector space *together with* the action of the algebra on it. Such a pair has a name.

Working definition 6.18 (module)

A **module** over a Lie algebra $\mathfrak{g}$ (a $\mathfrak{g}$-module) is a vector space V together with a linear action $X \mapsto \rho(X)$ of $\mathfrak{g}$ on V that respects brackets:

$$\rho([X,Y]) = \rho(X)\rho(Y) - \rho(Y)\rho(X).$$

Operationally: a module is a *representation space*. "V is a vir-module" means exactly "the L_n act on V as operators obeying the Virasoro algebra". A **submodule** is a subspace $W \subset V$ with $\rho(X)W \subset W$ for all X: an invariant subspace.

Dictionary: modules

Algebra	Physics
module V	representation space; space of states
submodule $W \subset V$	invariant subspace, closed under all L_n
irreducible module	irreducible representation, no invariant subspaces
cyclic vector	a state from which all others are obtained
quotient module V/W	states of V, with those in W declared to be zero
Shapovalov (Kac) form	the inner product $\langle \cdot \mid \cdot \rangle$ on states

Notice what is *not* in the definition of a module: an inner product. The Verma module is built from the algebra alone. The Hilbert space structure enters later, through the rule $L_n^\dagger = L_{-n}$ (Section 6.3.5), and it is the inner product that tells us which states are "null" and must be removed before we have a Hilbert space. Keeping these two things apart is the key to the whole construction.

Step 1: the descendants

The **descendants** of $|h\rangle$ are all the states obtained by acting with the raising operators:

$$|h\rangle, \quad L_{-1}|h\rangle, \quad L_{-2}|h\rangle, \quad L_{-1}^2|h\rangle, \quad L_{-3}|h\rangle, \quad L_{-2}L_{-1}|h\rangle, \quad L_{-1}L_{-2}|h\rangle, \ \ldots$$

Not all orderings are needed. A product in the "wrong" order can be rewritten in the standard order using the commutators, and the commutators of raising operators are again raising operators. For example

$$L_{-1}L_{-2}|h\rangle \overset{(1)}{=} L_{-2}L_{-1}|h\rangle + [L_{-1}, L_{-2}]|h\rangle \overset{(2)}{=} L_{-2}L_{-1}|h\rangle + L_{-3}|h\rangle.$$

(1) Add and subtract $L_{-2}L_{-1}|h\rangle$.
(2) $[L_{-1}, L_{-2}] = (-1+2)L_{-3} = L_{-3}$; no central term since $-1-2 \neq 0$.

In general, repeating this move puts every product in the form

$$L_{-n_1}L_{-n_2}\cdots L_{-n_k}|h\rangle, \qquad n_1 \geq n_2 \geq \cdots \geq n_k \geq 1, \tag{6.108}$$

plus shorter products. (This is the Poincaré–Birkhoff–Witt theorem; for a physicist it is the statement that we may normal order.) The states (6.108) are the analogue of the Fock states $a_{n_1}^\dagger \cdots a_{n_k}^\dagger|0\rangle$.

By (6.104), the state (6.108) has $L_0 = h + N$ with $N = n_1 + \cdots + n_k$. We call N the **level**. The number of states (6.108) at level N is the number of ways of writing N as an unordered sum of positive integers: the **partition number** $p(N)$.

level N	basis of $V(c,h)$ at level N	$p(N)$
0	$\lvert h\rangle$	1
1	$L_{-1}\lvert h\rangle$	1
2	$L_{-2}\lvert h\rangle,\ L_{-1}^2\lvert h\rangle$	2
3	$L_{-3}\lvert h\rangle,\ L_{-2}L_{-1}\lvert h\rangle,\ L_{-1}^3\lvert h\rangle$	3
4	$L_{-4},\ L_{-3}L_{-1},\ L_{-2}^2,\ L_{-2}L_{-1}^2,\ L_{-1}^4$ (on $\lvert h\rangle$)	5
5	$\ldots$	7

All the levels are packaged in the generating function

$$\sum_{N\geq 0} p(N)\, q^N \overset{(1)}{=} \prod_{n\geq 1}\left(1+q^n+q^{2n}+\cdots\right) \overset{(2)}{=} \prod_{n\geq 1}\frac{1}{1-q^n} = 1+q+2q^2+3q^3+5q^4+7q^5+\cdots \tag{6.109}$$

(1) A state (6.108) is fixed by how many times each L_{-n} appears; j copies of L_{-n} contribute q^{jn}.
(2) Geometric series.

The **character** of the Verma module, the trace of q^{L_0}, is then $\chi_{V(c,h)}(q) = q^h \prod_n (1-q^n)^{-1}$. (It is the partition function of one free boson without zero mode, a fact we use below.)

Working definition 6.19 (Verma module)

The **Verma module** $V(c,h)$ is the vector space with basis (6.108) [the states $L_{-n_1}\cdots L_{-n_k}|h\rangle$ with $n_1 \geq \cdots \geq n_k \geq 1$, and $|h\rangle$ itself], with the L_n acting by the rule: *write L_n in front, and use the commutation relations to move it to the right until it hits $|h\rangle$, where $L_{n>0}|h\rangle = 0$, $L_0|h\rangle = h|h\rangle$ and c acts as the number c.* In symbols $V(c,h) = U(\mathrm{vir}_-)|h\rangle$, where $U(\mathrm{vir}_-)$ is the space of all polynomials in the raising operators $L_{-1}, L_{-2}, \ldots$ (the **universal enveloping algebra** of the subalgebra vir_- they span). Formally, $V(c,h) = U(\mathrm{vir}) \otimes_{U(\mathrm{vir}_{\geq 0})} \mathbb{C}_{c,h}$ [$\mathbb{C}_{c,h}$ is the line spanned by $|h\rangle$, on which $L_{n>0}$ act as 0, L_0 as h and the central element as c].

The Verma module contains everything the Virasoro algebra can generate from $|h\rangle$, and it imposes *no relations* beyond the defining ones (6.105). That makes it *universal*: every highest-weight representation with the same (c,h) is a quotient of $V(c,h)$, because every state in it is some polynomial in the L_{-n} acting on its vacuum.

Worked example 6.37: the action of L_1 and L_2 at level 2

We compute the lowering operators on the two states at level 2. These four numbers are all we need for the null vectors below. First L_1:

$$\begin{aligned} L_1L_{-2}|h\rangle &\overset{(1)}{=} [L_1,L_{-2}]|h\rangle \overset{(2)}{=} 3L_{-1}|h\rangle, \\ L_1L_{-1}^2|h\rangle &\overset{(3)}{=} [L_1,L_{-1}]L_{-1}|h\rangle + L_{-1}[L_1,L_{-1}]|h\rangle \overset{(4)}{=} 2L_0L_{-1}|h\rangle + L_{-1}\,2L_0|h\rangle \\ &\overset{(5)}{=} 2(h+1)L_{-1}|h\rangle + 2h\,L_{-1}|h\rangle = (4h+2)\,L_{-1}|h\rangle. \end{aligned}$$

(1) $L_1|h\rangle = 0$, so $L_1L_{-2}|h\rangle = [L_1,L_{-2}]|h\rangle$.
(2) $[L_1,L_{-2}] = (1+2)L_{-1} = 3L_{-1}$; no central term since $1-2\neq 0$.
(3) Move L_1 through the two factors; the term with L_1 on $|h\rangle$ vanishes.
(4) $[L_1,L_{-1}] = 2L_0$; the central term $\frac{c}{12}\cdot 1\cdot 0$ vanishes.
(5) $L_{-1}|h\rangle$ has $L_0 = h+1$.

Then L_2:

$$\begin{aligned} L_2L_{-2}|h\rangle &\overset{(1)}{=} [L_2,L_{-2}]|h\rangle \overset{(2)}{=} \left(4L_0 + \frac{c}{12}\cdot 2\cdot 3\right)|h\rangle = \left(4h+\frac{c}{2}\right)|h\rangle, \\ L_2L_{-1}^2|h\rangle &\overset{(3)}{=} [L_2,L_{-1}]L_{-1}|h\rangle + L_{-1}[L_2,L_{-1}]|h\rangle \overset{(4)}{=} 3L_1L_{-1}|h\rangle + 3L_{-1}L_1|h\rangle \overset{(5)}{=} 6h|h\rangle. \end{aligned}$$

(1) $L_2|h\rangle = 0$.
(2) $[L_2,L_{-2}] = 4L_0 + \frac{c}{12}\,2(2^2-1)$.
(3) Move L_2 through.
(4) $[L_2,L_{-1}] = 3L_1$.
(5) $L_1L_{-1}|h\rangle = [L_1,L_{-1}]|h\rangle = 2h|h\rangle$, and $L_1|h\rangle = 0$.

In the bases $(L_{-2}|h\rangle, L_{-1}^2|h\rangle)$ at level 2, $L_{-1}|h\rangle$ at level 1 and $|h\rangle$ at level 0, the lowering operators are the matrices

$$L_1\big|_{2\to1} = \begin{pmatrix} 3 & 4h+2 \end{pmatrix}, \qquad L_2\big|_{2\to0} = \begin{pmatrix} 4h+\frac{c}{2} & 6h \end{pmatrix}.$$

This is a representation made completely explicit: every matrix element of every L_n on $V(c,h)$ can be computed this way.

Try it: level 3

Show that $L_1L_{-3}|h\rangle = 4L_{-2}|h\rangle$, $L_1L_{-2}L_{-1}|h\rangle = 2h\,L_{-2}|h\rangle + 3L_{-1}^2|h\rangle$ and $L_1L_{-1}^3|h\rangle = (6h+6)L_{-1}^2|h\rangle$. *Answer:* use $[L_1, L_{-n}] = (n+1)L_{1-n}$ and the level-2 results; for the last, $L_1L_{-1}^3 = \sum_{j=0}^{2} L_{-1}^{j}\,2L_0\,L_{-1}^{2-j}$ on $|h\rangle$ gives $2\big((h+2)+(h+1)+h\big) = 6h+6$.

6.3.3 Singular vectors and the null submodule

Step 2: a singular vector can appear

At special values of (c,h) something new happens: a descendant is *itself* killed by all the lowering operators. It then behaves like a second highest-weight state sitting inside $V(c,h)$.

Working definition 6.20 (singular vector)

A state $|\chi\rangle \neq 0$ in $V(c,h)$ at level $N>0$ [$L_0|\chi\rangle = (h+N)|\chi\rangle$] is **singular** if

$$L_n|\chi\rangle = 0 \quad \text{for all } n \geq 1.$$

It is then a highest-weight vector of weight $(c, h+N)$. *Test:* it is enough to check $L_1|\chi\rangle = 0$ and $L_2|\chi\rangle = 0$, because every L_n with $n \geq 3$ is a commutator of these: $[L_2, L_1] = L_3$ and $[L_n, L_1] = (n-1)L_{n+1}$, so $L_1|\chi\rangle = L_2|\chi\rangle = 0$ implies $L_3|\chi\rangle = L_2L_1|\chi\rangle - L_1L_2|\chi\rangle = 0$, and so on by induction.

Level 1. The only candidate is $|\chi\rangle = L_{-1}|h\rangle$. Since $[L_1, L_{-1}] = 2L_0$, we have $L_1L_{-1}|h\rangle = 2h|h\rangle$; and $L_2L_{-1}|h\rangle = 3L_1|h\rangle = 0$ automatically. So $L_{-1}|h\rangle$ is singular exactly when $h=0$. This is the familiar case: the vacuum of a conformal field theory is invariant under L_{-1} (translations), and $L_{-1}|0\rangle$ is the first null vector.

Level 2. The general candidate, normalised so that the coefficient of L_{-2} is 1, is

$$|\chi\rangle = \big(L_{-2} + \alpha\, L_{-1}^2\big)|h\rangle. \tag{6.110}$$

(If the coefficient of L_{-2} vanished, $|\chi\rangle \propto L_{-1}^2|h\rangle$, and $L_1L_{-1}^2|h\rangle = (4h+2)L_{-1}|h\rangle$ would force $h = -\frac{1}{2}$, but then $L_2L_{-1}^2|h\rangle = 6h|h\rangle \neq 0$; so this case never occurs.) Now impose the two conditions, using Example 6.37:

$$L_1|\chi\rangle \overset{(1)}{=} L_1L_{-2}|h\rangle + \alpha\, L_1L_{-1}^2|h\rangle \overset{(2)}{=} \big(3 + \alpha(4h+2)\big)L_{-1}|h\rangle,$$
$$L_2|\chi\rangle \overset{(3)}{=} L_2L_{-2}|h\rangle + \alpha\, L_2L_{-1}^2|h\rangle \overset{(4)}{=} \Big(4h + \frac{c}{2} + 6h\alpha\Big)|h\rangle.$$

(1) Linearity of L_1.
(2) $L_1L_{-2}|h\rangle = 3L_{-1}|h\rangle$ and $L_1L_{-1}^2|h\rangle = (4h+2)L_{-1}|h\rangle$.
(3) Linearity of L_2.

(4) $L_2L_{-2}|h\rangle = (4h + \frac{c}{2})|h\rangle$ and $L_2L_{-1}^2|h\rangle = 6h|h\rangle$.

The first condition fixes α and the second then fixes c in terms of h:

$$L_1|\chi\rangle = 0 \iff \alpha = -\frac{3}{2(2h+1)}, \tag{6.111}$$

and, with this α, $L_2|\chi\rangle = 0$ says

$$\frac{c}{2} \overset{(1)}{=} -4h - 6h\alpha \overset{(2)}{=} -4h + \frac{9h}{2h+1} \overset{(3)}{=} \frac{h(5-8h)}{2h+1}, \qquad \text{i.e.} \quad c = \frac{2h(5-8h)}{2h+1}. \tag{6.112}$$

(1) Set the coefficient $4h + \frac{c}{2} + 6h\alpha$ to zero.
(2) Substitute (6.111): $-6h\alpha = \frac{18h}{2(2h+1)} = \frac{9h}{2h+1}$.
(3) Common denominator: $-4h(2h+1) + 9h = 5h - 8h^2$.

Clearing denominators, (6.112) is the quadratic

$$16h^2 + 2(c-5)h + c = 0, \qquad h_\pm(c) = \frac{5 - c \pm \sqrt{(1-c)(25-c)}}{16}. \tag{6.113}$$

(Check: $c(2h+1) = 10h - 16h^2$ rearranges to $16h^2 + (2c-10)h + c = 0$; the discriminant is $4(c-5)^2 - 64c = 4(c^2 - 26c + 25) = 4(c-1)(c-25)$.) So a level-2 singular vector exists exactly on the two curves $h = h_\pm(c)$ in the (c, h) plane.

Worked example 6.38: the Ising model: $c = \frac{1}{2}$

At $c = \frac{1}{2}$, (6.113) gives

$$h_\pm\Big(\frac{1}{2}\Big) \overset{(1)}{=} \frac{\frac{9}{2} \pm \sqrt{\frac{1}{2}\cdot\frac{49}{2}}}{16} \overset{(2)}{=} \frac{\frac{9}{2} \pm \frac{7}{2}}{16} = \frac{1}{2} \text{ or } \frac{1}{16}.$$

(1) $5 - c = \frac{9}{2}$, $(1-c)(25-c) = \frac{1}{2}\cdot\frac{49}{2}$.
(2) $\sqrt{49/4} = \frac{7}{2}$.

These are the conformal weights of the energy operator ε ($h = \frac{1}{2}$) and the spin operator σ ($h = \frac{1}{16}$) of the two-dimensional Ising model at its critical point (Chapter 11). The singular vectors are, by (6.111),

$$|\chi_\varepsilon\rangle = \Big(L_{-2} - \frac{3}{4}L_{-1}^2\Big)|\tfrac{1}{2}\rangle, \qquad |\chi_\sigma\rangle = \Big(L_{-2} - \frac{4}{3}L_{-1}^2\Big)|\tfrac{1}{16}\rangle.$$

(For $h = \frac{1}{2}$: $\alpha = -\frac{3}{2\cdot 2}$; for $h = \frac{1}{16}$: $\alpha = -\frac{3}{2\cdot\frac{9}{8}} = -\frac{4}{3}$.) In the field theory, setting these states to zero becomes a second-order differential equation for the correlation functions of σ and ε. This is how the Ising correlators are actually computed (Belavin, Polyakov and Zamolodchikov). At $c = 0$ the curves give $h = 0$ and $h = \frac{5}{8}$; at $c = 1$ they meet at $h = \frac{1}{4}$.

A singular vector generates a whole submodule

Here is the central point, and the one most often misunderstood. A single singular vector does not come alone. Since $|\chi\rangle$ is a highest-weight vector, we can apply the raising operators to it, exactly as we did to $|h\rangle$:

$$N \coloneqq U(\mathrm{vir}_-)|\chi\rangle = \mathrm{span}\big\{|\chi\rangle,\ L_{-1}|\chi\rangle,\ L_{-2}|\chi\rangle,\ L_{-1}^2|\chi\rangle,\ L_{-3}|\chi\rangle, \dots\big\}. \tag{6.114}$$

This is a Verma module in its own right, $N \cong V(c, h+2)$, sitting inside $V(c,h)$ with its top at level 2. So N has $p(N'-2)$ states at level N': $1,1,2,3,\ldots$ at levels $2,3,4,5,\ldots$ (Figure 6.23).

N is a submodule. We must check that every L_n maps N into itself. For $n<0$ this is the definition of N. For $n \geq 0$, move L_n to the right through the raising operators. Each commutator produces another Virasoro generator, and when a lowering operator finally reaches $|\chi\rangle$ it gives zero, while L_0 and c give numbers. Two instances:

$$L_1\,L_{-1}|\chi\rangle \overset{(1)}{=} [L_1,L_{-1}]|\chi\rangle + L_{-1}L_1|\chi\rangle \overset{(2)}{=} 2L_0|\chi\rangle \overset{(3)}{=} 2(h+2)|\chi\rangle \;\in N,$$
$$L_2\,L_{-1}|\chi\rangle \overset{(4)}{=} [L_2,L_{-1}]|\chi\rangle + L_{-1}L_2|\chi\rangle \overset{(5)}{=} 3L_1|\chi\rangle \overset{(6)}{=} 0 \;\in N.$$

(1) Add and subtract $L_{-1}L_1|\chi\rangle$.
(2) $[L_1,L_{-1}] = 2L_0$ and $L_1|\chi\rangle = 0$ ($|\chi\rangle$ is singular).
(3) $|\chi\rangle$ is at level 2, so $L_0|\chi\rangle = (h+2)|\chi\rangle$.
(4) As in (1).
(5) $[L_2,L_{-1}] = 3L_1$ and $L_2|\chi\rangle = 0$.
(6) $L_1|\chi\rangle = 0$.

The general case is the same bookkeeping: $L_n\,U(\mathrm{vir}_-)|\chi\rangle$ is a combination of terms $U(\mathrm{vir}_-)\,X|\chi\rangle$ with $X \in \{L_{m>0}, L_0, c\}$, and each $X|\chi\rangle$ is 0 or a multiple of $|\chi\rangle$.

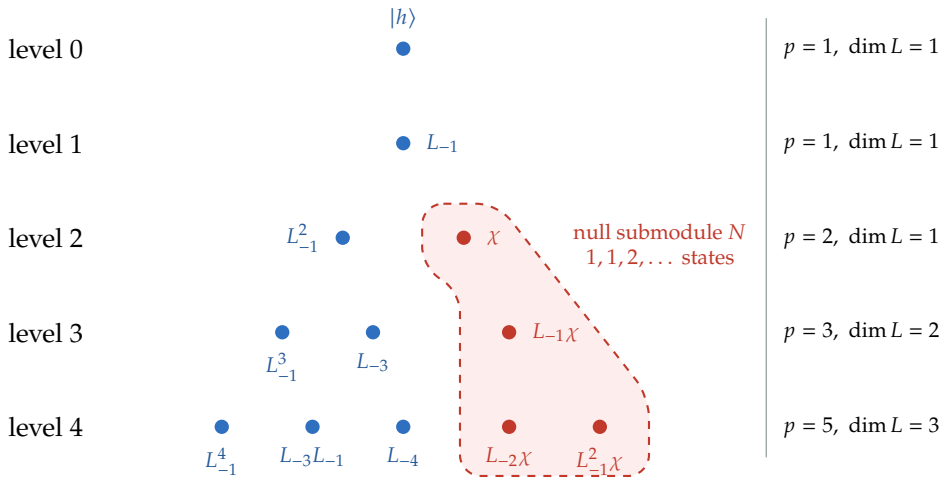

Figure 6.23: The Verma module $V(c,h)$ level by level, with $p(N) = 1,1,2,3,5$ states at levels $0,\ldots,4$, drawn for a point (c,h) on one of the curves (6.113). The red states span the null submodule N generated by the singular vector $|\chi\rangle$ at level 2: $1,1,2$ states at levels $2,3,4$. The blue states are representatives of the quotient $L(c,h) = V/N$, which therefore has $1,1,1,2,3$ states. (The blue labels abbreviate $L_{-1}^2|h\rangle$ etc.; any set of blue states that together with the red ones forms a basis would do.)

We should check that the blue states in Figure 6.23 really complement the red ones. At level 3 the red state is $L_{-1}|\chi\rangle = \big(L_{-1}L_{-2} + \alpha L_{-1}^3\big)|h\rangle = \big(L_{-2}L_{-1} + L_{-3} + \alpha L_{-1}^3\big)|h\rangle$, which contains the basis vector $L_{-2}L_{-1}|h\rangle$ that is not among the blue ones; so $\{L_{-1}^3, L_{-3}, L_{-1}\chi\}$ is a basis. At level 4 a short calculation gives $L_{-1}^2L_{-2} = L_{-2}L_{-1}^2 + 2L_{-3}L_{-1} + 2L_{-4}$, so the red states $L_{-2}|\chi\rangle = (L_{-2}^2 + \alpha L_{-2}L_{-1}^2)|h\rangle$ and $L_{-1}^2|\chi\rangle = (L_{-2}L_{-1}^2 + \alpha L_{-1}^4 + 2L_{-3}L_{-1} + 2L_{-4})|h\rangle$ supply the two missing directions L_{-2}^2 and $L_{-2}L_{-1}^2$.

6.3.4 The quotient: the irreducible representation

Step 3: why quotient?

When $V(c,h)$ contains the submodule N, the representation $V(c,h)$ is *reducible*: N is an invariant subspace. In a physical theory the state $|\chi\rangle$ is not an independent state. We will see in Section 6.3.5 that it has zero norm and is orthogonal to every state, so no measurement can detect it: it is zero in the Hilbert space. And because the algebra acts on it, everything in the sector it generates, $L_{-1}|\chi\rangle$, $L_{-2}|\chi\rangle$, and so on, is equally redundant. So we remove the whole null submodule.

Working definition 6.21 (quotient module)

Given a submodule $N \subset V$ [a subspace that every L_n maps into itself, here all states built on $|\chi\rangle$], declare two states equivalent if they differ by an element of N:

$$v_1 \sim v_2 \iff v_1 - v_2 \in N.$$

The equivalence class of v is $[v] = v + N$. The **quotient module** is the set of classes, V/N, with the action

$$L_n[v] \coloneqq [L_n v]. \tag{6.115}$$

Operationally: compute with the representatives as usual, and at the end set every element of N to zero. In particular $|\chi\rangle \sim 0$, $L_{-1}|\chi\rangle \sim 0$, $L_{-2}|\chi\rangle \sim 0, \ldots$. For the Virasoro algebra, the result is written

$$L(c,h) \coloneqq V(c,h)/N.$$

Step 4: why the quotient is still a Virasoro module

The definition (6.115) uses a representative v of the class. It makes sense only if a different representative gives the same answer. Suppose $[v] = [v']$. Then

$$[L_n v] - [L_n v'] \overset{(1)}{=} [L_n v - L_n v'] \overset{(2)}{=} [L_n(v - v')] \overset{(3)}{=} [0].$$

(1) Classes add like their representatives: $[a] - [b] = [a - b]$.
(2) L_n is linear.
(3) $v - v' \in N$ because $[v] = [v']$, and $L_n(v - v') \in N$ because N is a *submodule*; an element of N has class $[0]$.

So the action on classes is well defined. It also still obeys the algebra:

$$\big(L_m L_n - L_n L_m\big)[v] \overset{(1)}{=} [L_m L_n v - L_n L_m v] \overset{(2)}{=} \Big[(m-n)L_{m+n}v + \tfrac{c}{12}m(m^2-1)\delta_{m,-n}v\Big]$$
$$\overset{(3)}{=} (m-n)L_{m+n}[v] + \tfrac{c}{12}m(m^2-1)\delta_{m,-n}[v].$$

(1) Apply (6.115) twice.
(2) The Virasoro relations hold on V.
(3) (6.115) and linearity of the class map.

Step (3) of the first chain is the only place where anything could go wrong, and it is *exactly* the statement that N is closed under the action. That is why we quotient by a submodule and not by an arbitrary subspace.

Watch out: do not quotient by the single vector

Suppose we tried to remove only $|\chi\rangle$ itself, i.e. to divide by the one-dimensional subspace $W = \mathbb{C}|\chi\rangle$. Then $[|\chi\rangle] = [0]$, and (6.115) would require

$$[0] \overset{(1)}{=} L_{-1}[0] \overset{(2)}{=} L_{-1}[|\chi\rangle] \overset{(3)}{=} [L_{-1}|\chi\rangle] \overset{(4)}{\neq} [0],$$

(1) L_{-1} is linear, so it maps the zero class to the zero class.
(2) $[|\chi\rangle] = [0]$ in V/W.
(3) The definition (6.115).
(4) $L_{-1}|\chi\rangle$ is a nonzero state at level 3, not a multiple of $|\chi\rangle$, so it is not in W.

a contradiction. The action is *not* well defined on V/W: W is not invariant. The smallest invariant subspace containing $|\chi\rangle$ is the whole of $N = U(\mathrm{vir}_-)|\chi\rangle$. Removing a null state means removing its entire tower of descendants.

Step 5: irreducibility

$L(c,h)$ is irreducible when N is the *maximal* proper submodule of $V(c,h)$. At some special points there are several singular vectors (for instance at every level rs in the minimal models below), and then N must be taken to be the sum of all the submodules they generate. A clean characterisation of the maximal proper submodule comes from the inner product (Section 6.3.5): it consists of *all* the null states.

	what it contains	**states per level**
Verma module $V(c,h)$	all descendants $L_{-n_1}\cdots L_{-n_k}\|h\rangle$, no relations beyond (6.105)	$p(N)$: $1,1,2,3,5,7,\ldots$
null submodule N	all descendants of the singular (null) vectors; zero-norm states orthogonal to everything	e.g. level-2 singular vector: $p(N-2)$: $0,0,1,1,2,3,\ldots$
irreducible $L(c,h)$	V/N: the Verma module with the null states set to zero; nondegenerate inner product	$p(N) - \dim N_N$: $1,1,1,2,3,4,\ldots$

Step 6: generically nothing happens

A Verma module need not contain any null state. The level-1 and level-2 conditions are single equations in the (c,h) plane ($h = 0$; $h = h_\pm(c)$), and the conditions at higher levels are more curves of the same kind ((6.119) below). For *generic* (c,h), off all these curves, $N = \{0\}$ and

$$V(c,h) = L(c,h)\,:$$

the Verma module is already irreducible. The Verma module is the universal highest-weight representation built from (c,h); the physical theory's irreducible representation is what remains after imposing the null-state relations, and generically there are none to impose.

6.3.5 Where the inner product enters: the Kac form

So far we have a module but no Hilbert space. The physicist's Hilbert space needs an inner product, and in a unitary representation the inner product must satisfy $L_n^\dagger = L_{-n}$ (6.103). This single rule determines the inner product on the whole Verma module.

Working definition 6.22 (Shapovalov or Kac form)

On $V(c,h)$ define $\langle\cdot|\cdot\rangle$ by $\langle h|h\rangle = 1$ and $L_n^\dagger = L_{-n}$. To compute $\langle v|w\rangle$ for two basis states (6.108): take the adjoint of v, which reverses the order and flips the signs of the mode numbers, $\big(L_{-n_1}\cdots L_{-n_k}|h\rangle\big)^\dagger = \langle h|L_{n_k}\cdots L_{n_1}$; then move the lowering operators [the L_n with $n>0$, each lowers L_0 by n] to the right with the commutation relations until they hit $|h\rangle$. The **Gram matrix** $M_N(c,h)$ at level N is the $p(N)\times p(N)$ matrix of inner products of the basis states at level N. Its determinant is the **Kac determinant** [it vanishes exactly when some nonzero state at level N is orthogonal to every state at that level].

Different levels are orthogonal. If v and w have levels $N \neq N'$, then, since L_0 is Hermitian,

$$(h+N)\langle v|w\rangle \overset{(1)}{=} \langle v|L_0^\dagger|w\rangle \overset{(2)}{=} \langle v|L_0|w\rangle \overset{(3)}{=} (h+N')\langle v|w\rangle,$$

(1) $L_0|v\rangle = (h+N)|v\rangle$ with h real, and $\langle v|L_0^\dagger = (L_0|v\rangle)^\dagger$.
(2) $L_0^\dagger = L_0$.
(3) $L_0|w\rangle = (h+N')|w\rangle$.

so $\langle v|w\rangle = 0$. The form is therefore block diagonal, one block M_N per level, and we only need the Gram matrices.

Worked example 6.39: the Gram matrices at levels 1 and 2

At level 1, $M_1 = \|L_{-1}|h\rangle\|^2 = 2h$ by (6.106). At level 2, in the basis $(L_{-2}|h\rangle, L_{-1}^2|h\rangle)$,

$$\langle h|L_2L_{-2}|h\rangle \overset{(1)}{=} 4h+\tfrac{c}{2}, \qquad \langle h|L_2L_{-1}^2|h\rangle \overset{(2)}{=} 6h,$$
$$\langle h|L_1L_1L_{-1}^2|h\rangle \overset{(3)}{=} (4h+2)\langle h|L_1L_{-1}|h\rangle \overset{(4)}{=} (4h+2)\,2h.$$

(1) Example 6.37.
(2) Example 6.37; the adjoint of $L_{-2}|h\rangle$ is $\langle h|L_2$.
(3) $L_1L_{-1}^2|h\rangle = (4h+2)L_{-1}|h\rangle$ (Example 6.37); the adjoint of $L_{-1}^2|h\rangle$ is $\langle h|L_1L_1$.
(4) $\langle h|L_1L_{-1}|h\rangle = 2h$.

So

$$M_2(c,h) = \begin{pmatrix} 4h+\frac{c}{2} & 6h \\ 6h & 8h^2+4h \end{pmatrix},$$

and its determinant factorises:

$$\det M_2 \overset{(1)}{=} \Big(4h+\frac{c}{2}\Big)(8h^2+4h) - 36h^2 \overset{(2)}{=} 32h^3 - 20h^2 + 4ch^2 + 2ch$$
$$\overset{(3)}{=} 2h\big(16h^2+2(c-5)h+c\big) \overset{(4)}{=} 32\,h\,\big(h-h_+(c)\big)\big(h-h_-(c)\big). \tag{6.116}$$

(1) Determinant of a 2×2 matrix.
(2) Expand: $32h^3+16h^2+4ch^2+2ch-36h^2$.
(3) Take out $2h$.
(4) The roots of the quadratic are $h_\pm(c)$ of (6.113), and its leading coefficient is 16.

The determinant vanishes exactly where there is a singular vector: at $h=0$ (where $L_{-1}|h\rangle$ is singular, and its descendant $L_{-1}^2|h\rangle$ is in the null submodule) and on the curves $h_\pm(c)$ found in (6.113).

Null states are the zero-norm states

A singular vector has zero norm, and is orthogonal to *every* state. For $|\chi\rangle$ at level 2:

$$\langle\chi|\chi\rangle \overset{(1)}{=} \langle h|\big(L_2 + \bar{\alpha}L_1L_1\big)|\chi\rangle \overset{(2)}{=} \langle h|L_2|\chi\rangle + \bar{\alpha}\langle h|L_1\big(L_1|\chi\rangle\big) \overset{(3)}{=} 0.$$

(1) $\langle\chi| = \big((L_{-2} + \alpha L_{-1}^2)|h\rangle\big)^\dagger$ and $L_n^\dagger = L_{-n}$.
(2) Linearity.
(3) $L_2|\chi\rangle = 0$ and $L_1|\chi\rangle = 0$.

The same computation shows $\langle v|\chi\rangle = 0$ for every v at level 2, since $\langle v|$ is $\langle h|$ times a polynomial in lowering operators. Then for any descendant $L_{-m}|\chi\rangle \in N$ and any $v \in V$,

$$\langle v|L_{-m}\chi\rangle \overset{(1)}{=} \langle L_m v|\chi\rangle \overset{(2)}{=} 0,$$

(1) $L_{-m}^\dagger = L_m$.
(2) $L_m v$ is again a state of V, and $|\chi\rangle$ is orthogonal to all of them (both have level 2 or the levels differ).

and by induction every state of N is orthogonal to every state of V. So N lies in the **radical** of the form,

$$\mathrm{Rad} = \{w \in V : \ \langle v|w\rangle = 0 \text{ for all } v \in V\},$$

the null states. Conversely, *every* proper submodule $W \subset V$ consists of null states. Such a W contains no multiple of $|h\rangle$ (otherwise it would contain all descendants and not be proper). For $w \in W$ at level N and a basis state v at level N,

$$\langle v|w\rangle \overset{(1)}{=} \langle h|\, L_{n_k}\cdots L_{n_1}|w\rangle \overset{(2)}{=} 0,$$

(1) The adjoint of $v = L_{-n_1}\cdots L_{-n_k}|h\rangle$.
(2) $L_{n_k}\cdots L_{n_1}|w\rangle$ lies in W (a submodule) and at level 0; but W has nothing at level 0.

So the radical is the *maximal* proper submodule, and the irreducible module is

$$L(c,h) = V(c,h)/\mathrm{Rad}, \tag{6.117}$$

on which the form is nondegenerate. In particular $V(c,h)$ is irreducible if and only if $\det M_N(c,h) \neq 0$ for every level N.

Key idea: why unitarity needs the null states removed

A Hilbert space has a positive definite inner product: the only vector of zero length is 0. A null state $|\chi\rangle \neq 0$ has $\langle\chi|\chi\rangle = 0$ and zero overlap with every state, so all transition amplitudes involving it vanish. It is physically indistinguishable from 0. Keeping it would give a space with a degenerate inner product, which is not a Hilbert space. Removing the whole null submodule, $L = V/\mathrm{Rad}$, is exactly what turns the module into a pre-Hilbert space. Whether the form on L is then *positive* is a further question, the unitarity question.

The Kac determinant formula

The level-2 result generalises. Parametrise the central charge by t:

$$c = 13 - 6\Big(t + \frac{1}{t}\Big), \qquad h_{r,s}(t) = \frac{(r^2-1)\,t}{4} - \frac{rs-1}{2} + \frac{(s^2-1)}{4t}, \quad r,s = 1,2,3,\ldots \tag{6.118}$$

The result, found by Kac and proved by Feigin and Fuchs, is

$$\det M_N(c,h) = \text{const} \times \prod_{\substack{r,s\geq 1\\ rs\leq N}} \big(h - h_{r,s}(c)\big)^{p(N-rs)}, \tag{6.119}$$

with a positive constant. The factor $h - h_{r,s}$ first appears at level rs: there is a singular vector at level rs when $h = h_{r,s}$, and its submodule contributes to all higher levels, with multiplicity $p(N-rs)$.

Check at level 2. The pairs with $rs \leq 2$ are $(1,1)$, $(1,2)$, $(2,1)$. We have $h_{1,1} = 0$, with multiplicity $p(1) = 1$; and

$$h_{1,2} + h_{2,1} \overset{(1)}{=} \left(-\frac{1}{2} + \frac{3}{4t}\right) + \left(\frac{3t}{4} - \frac{1}{2}\right) \overset{(2)}{=} \frac{3}{4}\cdot\frac{13-c}{6} - 1 = \frac{5-c}{8},$$
$$h_{1,2}\,h_{2,1} \overset{(3)}{=} -\frac{3t}{8} + \frac{1}{4} + \frac{9}{16} - \frac{3}{8t} \overset{(4)}{=} \frac{13}{16} - \frac{3}{8}\cdot\frac{13-c}{6} = \frac{c}{16}.$$

(1) (6.118) with $(r,s) = (1,2)$ and $(2,1)$.
(2) $t + \frac{1}{t} = \frac{13-c}{6}$ from (6.118).
(3) Multiply out.
(4) Same substitution.

These are the sum $\frac{5-c}{8}$ and product $\frac{c}{16}$ of the roots of $h^2 + \frac{c-5}{8}h + \frac{c}{16}$, i.e. of (6.113) divided by 16. So $\{h_{1,2}, h_{2,1}\} = \{h_+, h_-\}$ and (6.119) reproduces (6.116).

Worked example 6.40: the Ising Gram matrix at $h = \frac{1}{16}$

At $c = \frac{1}{2}$, $h = \frac{1}{16}$:

$$M_2 = \begin{pmatrix} \frac{1}{4}+\frac{1}{4} & \frac{6}{16} \\ \frac{6}{16} & \frac{8}{256}+\frac{4}{16} \end{pmatrix} = \begin{pmatrix} \frac{1}{2} & \frac{3}{8} \\ \frac{3}{8} & \frac{9}{32} \end{pmatrix}, \qquad \det M_2 = \frac{9}{64} - \frac{9}{64} = 0.$$

The null direction is the singular vector of Example 6.38:

$$M_2 \begin{pmatrix} 1 \\ -\frac{4}{3} \end{pmatrix} \overset{(1)}{=} \begin{pmatrix} \frac{1}{2} - \frac{4}{3}\cdot\frac{3}{8} \\ \frac{3}{8} - \frac{4}{3}\cdot\frac{9}{32} \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} 0 \\ 0 \end{pmatrix}.$$

(1) Matrix times vector; the vector is the components of $|\chi_\sigma\rangle = (L_{-2} - \frac{4}{3}L_{-1}^2)|\frac{1}{16}\rangle$.
(2) $\frac{4}{3}\cdot\frac{3}{8} = \frac{1}{2}$ and $\frac{4}{3}\cdot\frac{9}{32} = \frac{3}{8}$.

The other eigenvalue is $\operatorname{tr} M_2 = \frac{1}{2} + \frac{9}{32} = \frac{25}{32} > 0$. So the form on level 2 is positive *semi*-definite; after removing the null vector, $L(\frac{1}{2}, \frac{1}{16})$ has one state at level 2, and it has positive norm. This is consistent with the Ising model being a unitary theory.

Worked example 6.41: the free boson: a module where the null states are already zero

Take one free boson (6.61)–(6.63) and let $|p\rangle$ be the Fock vacuum with momentum p: $\alpha_0|p\rangle = p|p\rangle$, $\alpha_n|p\rangle = 0$ for $n > 0$. Then $c = 1$ and $L_0|p\rangle = \frac{1}{2}p^2|p\rangle$, $L_n|p\rangle = 0$ $(n > 0)$: $|p\rangle$ is a highest-weight state with $h = \frac{p^2}{2}$. The Fock space F_p, spanned by $\alpha_{-n_1}\cdots\alpha_{-n_k}|p\rangle$, has $p(N)$ states at level N — the same count as $V(1, \frac{p^2}{2})$. Compare the two. We need $[L_n, \alpha_m] = -m\alpha_{m+n}$ (6.64). At level 1,

$$L_{-1}|p\rangle \overset{(1)}{=} \Big(\alpha_{-1}\alpha_0 + \sum_{m\neq 0,-1} \tfrac{1}{2}\alpha_{-1-m}\alpha_m\Big)|p\rangle \overset{(2)}{=} p\,\alpha_{-1}|p\rangle.$$

(1) In $L_{-1} = \frac{1}{2}\sum_m \alpha_{-1-m}\alpha_m$ the terms $m = 0$ and $m = -1$ are equal and together give $\alpha_{-1}\alpha_0$.
(2) For $m \geq 1$ the annihilator α_m stands on the right and kills $|p\rangle$. For $m \leq -2$ the left factor α_{-1-m} is an annihilator ($-1-m \geq 1$); it commutes with α_m because the mode numbers add to $-1 \neq 0$, so it may be moved to the right, where it kills $|p\rangle$.

At $p = 0$ ($h = 0$) this vanishes: the level-1 null vector of $V(1,0)$ is *literally the zero vector* in the Fock space. At level 2, with $L_{-2}|p\rangle = (p\,\alpha_{-2} + \frac{1}{2}\alpha_{-1}^2)|p\rangle$ (same argument) and

$$L_{-1}^2|p\rangle \overset{(1)}{=} p\,L_{-1}\alpha_{-1}|p\rangle \overset{(2)}{=} p\big([L_{-1},\alpha_{-1}] + \alpha_{-1}L_{-1}\big)|p\rangle \overset{(3)}{=} \big(p\,\alpha_{-2} + p^2\alpha_{-1}^2\big)|p\rangle,$$

(1) The level-1 result.
(2) Add and subtract.
(3) $[L_{-1},\alpha_{-1}] = \alpha_{-2}$ and $L_{-1}|p\rangle = p\alpha_{-1}|p\rangle$.

the singular vector of $V(1,h)$ at $h = h_{\pm}(1) = \frac{1}{4}$ (where $\alpha = -1$ by (6.111)) becomes

$$\big(L_{-2} - L_{-1}^2\big)|p\rangle = \Big(\frac{1}{2} - p^2\Big)\alpha_{-1}^2|p\rangle = 0 \qquad \text{at } p^2 = \tfrac{1}{2}.$$

Again the null vector is zero in the Fock space. This is the general situation in a physical theory: the Hilbert space is built with a positive inner product, so the null states are *automatically* zero there. The Virasoro descendants of $|p\rangle$ span only one state at level 2, whereas F_p has two. The second, orthogonal, one is $|v\rangle = (\alpha_{-2} - 2p\,\alpha_{-1}^2)|p\rangle$, and one checks $L_1|v\rangle = (2-4p^2)\alpha_{-1}|p\rangle = 0$ and $L_2|v\rangle = (2p-2p)|p\rangle = 0$: it is a *new* highest-weight vector, with $h = \frac{1}{4} + 2 = \frac{9}{4}$. So at $p^2 = \frac{1}{2}$ the Fock space is a sum of several irreducible Virasoro modules, $F_p = L(1,\frac{1}{4}) \oplus L(1,\frac{9}{4}) \oplus \cdots$, not a single Verma module. For generic p there are no null vectors, and $F_p \cong V(1,\frac{p^2}{2}) = L(1,\frac{p^2}{2})$.

6.3.6 Unitary representations: the Friedan–Qiu–Shenker series

Now we ask which $L(c,h)$ are *unitary*: when is the Kac form on $L(c,h)$ positive definite? Equivalently, when are all the Gram matrices $M_N(c,h)$ positive semi-definite (with the zero eigenvalues exactly the null states)? Nash quotes the answer, due to Friedan, Qiu and Shenker (necessity) and Goddard, Kent and Olive (existence).

Key idea: the FQS classification (Nash's (6.58))

The irreducible highest-weight representation $L(c,h)$ is unitary if and only if either

$$c \geq 1, \quad h \geq 0,$$

or (c,h) belongs to the **discrete series**

$$c = 1 - \frac{6}{(m+1)(m+2)}, \qquad h = h_{p,q} = \frac{\big((m+2)p - (m+1)q\big)^2 - 1}{4(m+1)(m+2)}, \tag{6.120}$$

with $m = 1,2,3,\ldots$ and $1 \leq q \leq p \leq m$.

How the conditions arise

Levels 1 and ∞. We saw after (6.106) that $h \geq 0$ and $c \geq 0$ are necessary.

Level 2. By (6.116), $\det M_2 = 32h(h-h_+)(h-h_-)$. For $0 < c < 1$ both roots $h_\pm(c)$ are real and positive, with $h_- < h_+$. If $h_-(c) < h < h_+(c)$ then $\det M_2 < 0$: the 2×2 matrix M_2 has one positive and one negative eigenvalue, so some state at level 2 has negative norm. That strip is excluded (Figure 6.24). For $c \geq 1$ the roots coincide at $h = \frac{1}{4}$ ($c = 1$), are complex ($1 < c < 25$) or are real and negative ($c \geq 25$), so $\det M_2 \geq 0$ for all $h \geq 0$; since the diagonal entries of M_2 are then positive, M_2 is positive semi-definite.

Higher levels. Each level excludes more of the region $0 < c < 1$, $h > 0$, along the curves $h = h_{r,s}(c)$ of (6.119). FQS showed that what survives, below $c = 1$, is exactly the set of points where many such curves cross, and these are the points (6.120). For $1 < c < 25$ the values $h_{r,s}$ with $r \neq s$ are complex, and $h_{r,r} = \frac{(r^2-1)(1-c)}{24} \leq 0$ (use $t + \frac{1}{t} = \frac{13-c}{6}$); so no Kac determinant vanishes in the region $h > 0$. The determinants are positive for large h (the diagonal terms h^{power} dominate), hence positive throughout $h > 0$, and everything with $h \geq 0$ survives. (For $c \geq 25$ the same conclusion holds.)

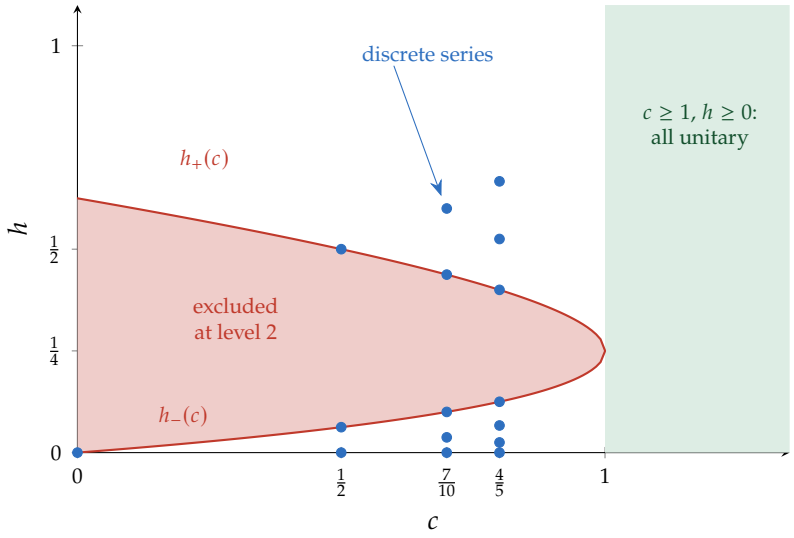

Figure 6.24: The unitarity question in the (c, h) plane. The red strip between the level-2 curves $h_\pm(c)$ of (6.113) is excluded because $\det M_2 < 0$ there. For $c \geq 1$ (green) every $h \geq 0$ is unitary. Below $c = 1$ higher levels exclude everything except the discrete series (blue dots, shown for $m = 1, 2, 3, 4$, i.e. $c = 0, \frac{1}{2}, \frac{7}{10}, \frac{4}{5}$; values $h > 1.1$ are off the picture). Notice that some of the blue dots lie *on* the red curves: these representations have a null vector at level 2, which is removed.

Checking (6.120) *against the Kac formula.* Take $t = \frac{m+2}{m+1}$ in (6.118), and write $a = m+1$, $b = m+2$, so $t = b/a$ and $b - a = 1$. Then

$$c \overset{(1)}{=} 13 - 6\,\frac{a^2+b^2}{ab} \overset{(2)}{=} \frac{13ab - 6(b-a)^2 - 12ab}{ab} \overset{(3)}{=} 1 - \frac{6}{(m+1)(m+2)},$$

$$h_{p,q} \overset{(4)}{=} \frac{(p^2-1)b^2 - 2(pq-1)ab + (q^2-1)a^2}{4ab} \overset{(5)}{=} \frac{(pb-qa)^2 - (b-a)^2}{4ab}$$

$$\overset{(6)}{=} \frac{\big((m+2)p - (m+1)q\big)^2 - 1}{4(m+1)(m+2)}.$$

(1) $t + \frac{1}{t} = \frac{b}{a} + \frac{a}{b} = \frac{a^2+b^2}{ab}$.
(2) $a^2 + b^2 = (b-a)^2 + 2ab$.
(3) $b - a = 1$ and $ab = (m+1)(m+2)$.
(4) (6.118) with $(r, s) = (p, q)$, over the common denominator $4ab$ ($t = b/a$).
(5) Complete the square: $(pb - qa)^2 = p^2b^2 - 2pqab + q^2a^2$, and $-b^2 + 2ab - a^2 = -(b-a)^2$.
(6) $b - a = 1$.

So the discrete series is the set of Kac-table values $h_{p,q}$ at the special central charges (6.120): every unitary representation with $c < 1$ has null vectors, in fact infinitely many.

Worked example 6.42: the first members of the discrete series

Evaluate (6.120) for small m. For $m = 2$, $(m+1)(m+2) = 12$:

$$h_{2,1} \overset{(1)}{=} \frac{(4\cdot 2 - 3\cdot 1)^2 - 1}{48} = \frac{24}{48} = \frac{1}{2}, \qquad h_{2,2} \overset{(2)}{=} \frac{(8-6)^2 - 1}{48} = \frac{1}{16}, \qquad h_{1,1} = 0.$$

(1) $m+2 = 4$, $m+1 = 3$, $(p,q) = (2,1)$.
(2) $(p,q) = (2,2)$.

The full table:

m	c	model	allowed h
1	0	trivial	0
2	$\frac{1}{2}$	Ising	$0,\ \frac{1}{16},\ \frac{1}{2}$
3	$\frac{7}{10}$	tricritical Ising	$0,\ \frac{3}{80},\ \frac{1}{10},\ \frac{7}{16},\ \frac{3}{5},\ \frac{3}{2}$
4	$\frac{4}{5}$	tetracritical Ising / 3-state Potts	$0, \frac{1}{40}, \frac{1}{15}, \frac{1}{8}, \frac{2}{5}, \frac{21}{40}, \frac{2}{3}, \frac{7}{5}, \frac{13}{8}, 3$

At each m there are $\frac{m(m+1)}{2}$ values (one for each $1 \le q \le p \le m$). For $m = 1$ only $h = 0$ survives, and $c = 0$: the trivial representation, in agreement with Section 6.3.7. The Ising values match Example 6.38: both $h = \frac{1}{16}$ and $h = \frac{1}{2}$ lie on the level-2 curves at $c = \frac{1}{2}$, which is why they have level-2 null vectors. The same is true of $\frac{1}{10}, \frac{7}{16}$ at $c = \frac{7}{10}$ and of $\frac{1}{8}, \frac{2}{5}$ at $c = \frac{4}{5}$: check with (6.113), e.g. $h_{\pm}(\frac{4}{5}) = \frac{4.2 \pm \sqrt{0.2\cdot 24.2}}{16} = \frac{4.2 \pm 2.2}{16}$. These discrete-series theories are the **minimal models**; they describe the critical points of two-dimensional statistical models (Chapter 11).

Constructing the discrete series: the GKO coset

Nash says that "representations for all these allowed values can be constructed" (Goddard, Kent and Olive). FQS only showed that nothing *else* can be unitary. The construction uses the Sugawara operators of Section 6.2.10 twice.

Let $\mathfrak{g} \supset \mathfrak{h}$ be a Lie algebra and a subalgebra, and suppose we have a unitary highest-weight representation of the Kac–Moody algebra of $\mathfrak{g}$. The currents of $\mathfrak{h}$ are among those of $\mathfrak{g}$, so we have two Sugawara Virasoro algebras, $L^{\mathfrak{g}}_n$ and $L^{\mathfrak{h}}_n$, with central charges $c_{\mathfrak{g}}$ and $c_{\mathfrak{h}}$. Define

$$K_n := L^{\mathfrak{g}}_n - L^{\mathfrak{h}}_n. \tag{6.121}$$

Step 1: K_n commutes with the $\mathfrak{h}$ currents. Both Sugawara operators act on any current J_m of $\mathfrak{h}$ as the vector field does, $[L^{\mathfrak{g}}_n, J_m] = -mJ_{m+n} = [L^{\mathfrak{h}}_n, J_m]$ (this is Nash's $[L_n, T^a_m] = -mT^a_{n+m}$ in (6.123) below). Subtracting, $[K_n, J_m] = 0$. Since $L^{\mathfrak{h}}_m$ is built from the J's, $[K_n, L^{\mathfrak{h}}_m] = 0$ as well.

Step 2: K_n is a Virasoro algebra.

$$\begin{aligned}
[K_m, K_n] &\overset{(1)}{=} [K_m, L^{\mathfrak{g}}_n] \overset{(2)}{=} [L^{\mathfrak{g}}_m, L^{\mathfrak{g}}_n] - [L^{\mathfrak{h}}_m, L^{\mathfrak{g}}_n] \overset{(3)}{=} [L^{\mathfrak{g}}_m, L^{\mathfrak{g}}_n] - [L^{\mathfrak{h}}_m, L^{\mathfrak{h}}_n] \\
&\overset{(4)}{=} (m-n)\big(L^{\mathfrak{g}}_{m+n} - L^{\mathfrak{h}}_{m+n}\big) + \frac{c_{\mathfrak{g}} - c_{\mathfrak{h}}}{12}\, m(m^2-1)\,\delta_{m,-n} \\
&= (m-n)K_{m+n} + \frac{c_{\mathfrak{g}} - c_{\mathfrak{h}}}{12}\, m(m^2-1)\,\delta_{m,-n}.
\end{aligned}$$

(1) $K_n = L^{\mathfrak{g}}_n - L^{\mathfrak{h}}_n$ and $[K_m, L^{\mathfrak{h}}_n] = 0$ (Step 1).

(2) Expand K_m.
(3) $L^{\mathfrak{g}}_n = K_n + L^{\mathfrak{h}}_n$ and $[L^{\mathfrak{h}}_m, K_n] = -[K_n, L^{\mathfrak{h}}_m] = 0$.
(4) Both are Virasoro algebras, with central charges $c_{\mathfrak{g}}$ and $c_{\mathfrak{h}}$.

So the K_n form a Virasoro algebra with $c = c_{\mathfrak{g}} - c_{\mathfrak{h}}$, the **coset construction**. It is unitary: $K_n^\dagger = K_{-n}$ on the unitary Kac–Moody representation space, whose inner product is positive. One checks that K_0 is also bounded below. Decomposing the space under the K_n therefore gives unitary highest-weight representations of Virasoro with $c = c_{\mathfrak{g}} - c_{\mathfrak{h}}$.

Worked example 6.43: the discrete series from SU(2)

Take $\mathfrak{g} = \mathfrak{su}(2) \oplus \mathfrak{su}(2)$ at levels $(\ell, 1)$ and $\mathfrak{h}$ the diagonal $\mathfrak{su}(2)$, whose currents $J^a_n = T^{a(1)}_n + T^{a(2)}_n$ have level $\ell + 1$ (levels add, because the central terms add). With $c(\mathfrak{su}(2)_\ell) = \frac{3\ell}{\ell+2}$ (Example 6.31),

$$c \overset{(1)}{=} \frac{3\ell}{\ell+2} + 1 - \frac{3(\ell+1)}{\ell+3} \overset{(2)}{=} \frac{3\ell(\ell+3) + (\ell+2)(\ell+3) - 3(\ell+1)(\ell+2)}{(\ell+2)(\ell+3)}$$
$$\overset{(3)}{=} \frac{\ell^2 + 5\ell}{(\ell+2)(\ell+3)} \overset{(4)}{=} 1 - \frac{6}{(\ell+2)(\ell+3)}.$$

(1) $c_{\mathfrak{g}} = c(\ell) + c(1)$ and $c_{\mathfrak{h}} = c(\ell+1)$; $c(1) = \frac{3}{3} = 1$.
(2) Common denominator.
(3) Expand: $3\ell^2 + 9\ell + \ell^2 + 5\ell + 6 - 3\ell^2 - 9\ell - 6$.
(4) $(\ell+2)(\ell+3) - 6 = \ell^2 + 5\ell$.

With $m = \ell + 1$ this is exactly the discrete series (6.120). For $\ell = 1$ it is $c = \frac{1}{2}$: the Ising model is $\frac{\mathrm{SU}(2)_1 \times \mathrm{SU}(2)_1}{\mathrm{SU}(2)_2}$. Every value $c < 1$ allowed by FQS therefore does occur.

The other side: Sugawara gives $c \geq 1$

Nash contrasts the discrete series with the Sugawara construction, which gives unitary representations "of the opposite type". By (6.81) the Sugawara central charge is $c = \frac{2k \dim G}{2k + C}$, and on a unitary Kac–Moody representation (integer level $N = 2k \geq 1$, Section 6.3.9) this is never less than one. For SU(2),

$$c - 1 \overset{(1)}{=} \frac{3N}{N+2} - 1 \overset{(2)}{=} \frac{2(N-1)}{N+2} \overset{(3)}{\geq} 0,$$

(1) $\dim \mathrm{SU}(2) = 3$, $C = 2$, $2k = N$.
(2) Common denominator.
(3) $N \geq 1$.

with equality at level one, where the theory is a single free boson (the bosonisation of Example 6.32). In general Nash notes the bound $c \geq \operatorname{rank} G \geq 1$: at level one for simply laced G the Sugawara theory is rank G free bosons on the root lattice (the Frenkel–Kac construction), and c increases with the level towards $\dim G$.

6.3.7 True representations are trivial (Goddard–Olive)

Finally we prove Nash's claim that the central extension is unavoidable. Suppose the representation is a *true* representation of $\mathrm{vect}(S^1)$ (or of $\mathrm{Diff}(S^1)$), not a projective one. Then the central term is absent: $c = 0$. Assume also that it is unitary, with L_0 bounded below, so that it has a highest-weight vector $|h\rangle$.

Step 1: $c = 0$ forces $h = 0$. This is the result of Goddard and Olive. Consider the two states $L_{-2n}|h\rangle$ and $L_{-n}^2|h\rangle$ at level $2n$. With $c = 0$ the computations of Example 6.39, repeated with n in place of 1, give

$$\langle h|L_{2n}L_{-2n}|h\rangle \overset{(1)}{=} 4nh, \qquad \langle h|L_{2n}L_{-n}^2|h\rangle \overset{(2)}{=} 3n\langle h|L_nL_{-n}|h\rangle = 6n^2h,$$
$$\langle h|L_n^2L_{-n}^2|h\rangle \overset{(3)}{=} \big(2n(h+n)+2nh\big)\langle h|L_nL_{-n}|h\rangle = (4nh+2n^2)\,2nh.$$

(1) (6.106) with $2n$ in place of n and $c = 0$.
(2) $L_{2n}L_{-n}^2|h\rangle = [L_{2n}, L_{-n}]L_{-n}|h\rangle + L_{-n}[L_{2n}, L_{-n}]|h\rangle = 3nL_nL_{-n}|h\rangle + 3nL_{-n}L_n|h\rangle$, and $L_n|h\rangle = 0$.
(3) $L_nL_{-n}^2|h\rangle = [L_n, L_{-n}]L_{-n}|h\rangle + L_{-n}[L_n, L_{-n}]|h\rangle = 2nL_0L_{-n}|h\rangle + 2nh\,L_{-n}|h\rangle$ with $c = 0$, and $L_{-n}|h\rangle$ has $L_0 = h + n$.

The Gram matrix of the two states therefore has determinant

$$\det\begin{pmatrix} 4nh & 6n^2h \\ 6n^2h & 2nh(4nh+2n^2)\end{pmatrix} \overset{(1)}{=} 8n^2h^2(4nh+2n^2) - 36n^4h^2 \overset{(2)}{=} 4n^3h^2\,(8h-5n).$$

(1) 2×2 determinant.
(2) $32n^3h^3 + 16n^4h^2 - 36n^4h^2 = 32n^3h^3 - 20n^4h^2$.

If $h > 0$, choose $n > \frac{8h}{5}$: the determinant is negative, so one of the states has negative norm, contradicting unitarity. Hence $h = 0$.

Step 2: then every $L_{-n}|h\rangle$ vanishes. Nash's (6.59) is (6.106) with $c = h = 0$:

$$\|L_{-n}|h\rangle\|^2 \overset{(1)}{=} \langle h|L_nL_{-n}|h\rangle \overset{(2)}{=} \langle h|[L_n, L_{-n}]|h\rangle \overset{(3)}{=} 0. \tag{6.122}$$

(1) $L_{-n}^\dagger = L_n$.
(2) $L_n|h\rangle = 0$ for $n \geq 1$.
(3) $[L_n, L_{-n}] = 2nL_0 + \frac{c}{12}n(n^2-1)$ and $c = h = 0$.

In a Hilbert space a vector of zero norm is zero, so $L_{-n}|h\rangle = 0$ for every $n \geq 1$.

Step 3: the representation is trivial. The vacuum is cyclic: the representation space is spanned by the vectors $L_{-1}^{a_1}L_{-2}^{a_2}\cdots L_{-s}^{a_s}|h\rangle$. All of these with some $a_i > 0$ vanish by Step 2 (the rightmost raising operator already kills $|h\rangle$). So the space is the single line $\mathbb{C}|h\rangle$, on which every L_n acts as zero.

Key idea: nontrivial positive-energy representations are projective (Nash, p. 187)

A unitary representation of $\mathrm{vect}(S^1)$ with L_0 bounded below and $c = 0$ is trivial. Therefore every nontrivial unitary highest-weight representation has $c > 0$: it is a representation of the Virasoro algebra, and a projective representation of $\mathrm{Diff}(S^1)$. The central charge is not an optional extra; positive energy forces it.

Physical picture: what the argument says physically

In a theory with $c = 0$ and a unique vacuum, $\|L_{-2}|0\rangle\|^2 = \frac{c}{2} = 0$: the stress tensor acting on the vacuum creates nothing. But the stress tensor of any theory with local degrees of freedom creates states from the vacuum, just as the electromagnetic field operator creates photons. So $c > 0$ measures the presence of local degrees of freedom ($c = 1$ for one boson, $c = \frac{1}{2}$ for one Majorana fermion), and $c = 0$ with unitarity means there are none. Non-unitary theories with $c = 0$ do exist (percolation, polymers), and they escape the

argument only by having negative-norm states.

Reading Nash (pp. 185–187, (6.56)–(6.59))

Nash defines a highest-weight representation as a pair of *non-negative* numbers (c, h), his (6.56)–(6.57), with $L_0|h\rangle = h|h\rangle$ and $L_n|h\rangle = 0$ for $n \geq 1$ forced by boundedness below. He states, and we have proved above, that $L_{-n}|h\rangle \neq 0$ "as may be seen by applying the commutation relations" – this is our computation of $\|L_{-n}|h\rangle\|^2$ in (6.106). He then quotes the Friedan–Qiu–Shenker classification (6.58) of unitary (c, h) without derivation; Section 6.3.6 supplies the level-2 half of the argument in full and sketches the rest. Finally he shows, in the computation we reproduce as (6.59), that a true (non-projective) representation of $\mathrm{Diff}(S^1)$ with L_0 bounded below is necessarily trivial – our Section 6.3.7. Nash does not discuss Verma modules, singular vectors or the Kac form by name; Sections 6.3.2 to 6.3.5 make explicit the construction that his brief remarks presuppose.

6.3.8 Representations of the Kac–Moody algebra

We now repeat the story of the Virasoro algebra for the loop group LG. Nash's strategy is the same as before: represent the Lie algebra rather than the group, impose a boundedness condition on the energy, and see what is left. The answer has the same shape, highest-weight vector → big module → quotient by null states, but two new features appear. The lowest energy states now form a whole *multiplet* of the finite-dimensional group G, rather than a single vector. And unitarity quantises the central term k not into a discrete series of fractions but into integers, the *level*.

The full algebra

A physical theory with a loop group symmetry has two sets of operators. It has the currents T^a_m, the Fourier modes of $j^a(\theta)$ (Section 6.1.11). It also has a Hamiltonian and a momentum, which generate rotations of the circle and, in a conformal theory, the whole Virasoro algebra. In the Sugawara construction (Section 6.2.10) the second set is built from the first, and we computed all the commutators there. Collecting them, Nash's (6.60) reads

$$\begin{aligned} [L_m, L_n] &= (m-n)\,L_{m+n} + \frac{2k\dim G}{12(2k+C)}\,m(m^2-1)\,\delta_{m,-n}, \\ [T^a_m, T^b_n] &= i f^{abc}\,T^c_{m+n} + k\,m\,\delta^{ab}\,\delta_{m,-n}, \\ [L_n, T^a_m] &= -m\,T^a_{m+n}, \qquad [L_n, k] = [T^a_m, k] = 0. \end{aligned} \tag{6.123}$$

The first line is the Sugawara Virasoro algebra (6.81). The second is the Kac–Moody algebra (6.12). The third is (6.79), which says that the modes of the current transform under reparametrisations of the circle exactly as the vector fields $L_n = ie^{in\theta}\frac{d}{d\theta}$ act on the functions $e^{im\theta}$ (6.71). The central element k commutes with everything, so in an irreducible representation it is a number (Schur's lemma). Here C is the adjoint Casimir (6.74), Nash's $c(G)$.

Even without Sugawara, the third line holds whenever the L_n implement the action of $\mathrm{Diff}^+(S^1)$ on the loop group. In CFT language it says that $j^a(\theta)$ is a **primary field of conformal weight one**.

Watch out: adjoints

Throughout, the T^a are Hermitian (the physicists' convention of the pitfall at the start of the chapter). A real loop $\xi(\theta) = \sum_n \xi_{a,n} e^{in\theta} T^a$ has $\xi_{a,-n} = \overline{\xi_{a,n}}$. So in a unitary representation

$$(T^a_n)^\dagger = T^a_{-n}, \qquad L_n^\dagger = L_{-n}, \qquad k \in \mathbb{R}, \tag{6.124}$$

exactly as for the Virasoro generators (6.103). We use these rules to compute every norm below.

The boundedness condition

Setting $n = 0$ in the third line of (6.123) gives $[L_0, T^a_m] = -m\, T^a_m$. So T^a_m shifts the energy by $-m$, just as L_m does. Let $L_0|\psi\rangle = E|\psi\rangle$. Then

$$L_0\big(T^a_m|\psi\rangle\big) \overset{(1)}{=} [L_0, T^a_m]|\psi\rangle + T^a_m L_0|\psi\rangle \overset{(2)}{=} -m\, T^a_m|\psi\rangle + E\, T^a_m|\psi\rangle = (E - m)\, T^a_m|\psi\rangle. \tag{6.125}$$

(1) Write $L_0 T^a_m = [L_0, T^a_m] + T^a_m L_0$.
(2) The third line of (6.123) with $n = 0$, and $L_0|\psi\rangle = E|\psi\rangle$.

For $m > 0$ the mode T^a_m *lowers* the energy by m; for $m < 0$ it raises it; and the zero modes T^a_0 do not change the energy at all.

Now impose Nash's criterion: *the spectrum of L_0 is bounded below*. Let h be the lowest eigenvalue and $|h\rangle$ a state with that energy. The state $T^a_n|h\rangle$, $n \geq 1$, would have energy $h - n < h$, which is impossible unless it vanishes. The same holds for $L_n|h\rangle$. Hence Nash's (6.61):

$$\boxed{L_0|h\rangle = h|h\rangle \implies L_n|h\rangle = 0, \quad T^a_n|h\rangle = 0, \qquad n \geq 1.} \tag{6.126}$$

This defines a **highest-weight representation** of the Kac–Moody algebra. (As in Section 6.3.1, "highest" is the mathematicians' word; for a physicist $|h\rangle$ is the state of *lowest* energy.)

The ground states form a multiplet of G

There is a genuinely new feature here. The zero modes T^a_0 commute with L_0:

$$[L_0, T^a_0] \overset{(1)}{=} -0 \cdot T^a_0 = 0, \qquad [T^a_0, T^b_0] \overset{(2)}{=} i f^{abc}\, T^c_0.$$

(1) The third line of (6.123) with $n = m = 0$.
(2) The second line with $m = n = 0$; the central term carries a factor m and vanishes.

So the T^a_0 form an ordinary copy of the finite-dimensional Lie algebra $\mathfrak{g}$ (these are the constant loops), and they map the lowest-energy eigenspace

$$V_0 := \{|\psi\rangle : L_0|\psi\rangle = h|\psi\rangle\}$$

into itself. V_0 is therefore a representation of $\mathfrak{g}$, the **ground-state multiplet**. In a quantum field theory with a global G symmetry this is just the statement that the lowest-energy states come in G-multiplets: the proton and the neutron, the pions, the spin states of an atom. Every state of V_0 satisfies (6.126).

Key idea: the ground-state multiplet is irreducible (Nash, p. 188)

If the Kac–Moody representation is irreducible, then V_0 is an irreducible representation V_λ of $\mathfrak{g}$, labelled by a highest weight λ. The whole representation is determined by two pieces of data: the central term k and the weight λ. Nash writes the pair as (k, λ).

Why is V_0 irreducible? Suppose $V_0 = V' \oplus V''$ with V' a nonzero proper $\mathfrak{g}$-invariant subspace. Let $\mathcal{A} := U(\hat{\mathfrak{g}})$ be all polynomials in the generators. Every such polynomial can be reordered (by the commutation relations) into a sum of products

$$(\text{raising modes } T^a_{-n},\ n \geq 1) \times (\text{zero modes } T^a_0) \times (\text{lowering modes } T^a_n,\ n \geq 1),$$

the Poincaré–Birkhoff–Witt ordering. Acting on V', the lowering modes give zero by (6.126), the zero modes keep us in V', and the raising modes strictly increase the energy. So the energy-h part of $\mathcal{A}V'$ is V' itself, and $\mathcal{A}V'$ is an invariant subspace not containing V'': the representation would be reducible. Hence V_0 is irreducible.

The energy of the ground states is also fixed. With the Sugawara L_0, the Casimir of the finite group sets the energy:

Worked example 6.44: the ground-state energy is a Casimir

By (6.75) and the normal ordering (6.76),

$$L_0 = \frac{1}{2k + C}\Big(T^a_0 T^a_0 + 2\sum_{m>0} T^a_{-m} T^a_m\Big).$$

(The $m = 0$ term of $\sum_m :T^a_m T^a_{-m}:$ is $T^a_0 T^a_0$; the terms m and $-m$ both become $T^a_{-|m|} T^a_{|m|}$.) On $|\psi\rangle \in V_\lambda$,

$$L_0|\psi\rangle \overset{(1)}{=} \frac{1}{2k + C}\, T^a_0 T^a_0 |\psi\rangle \overset{(2)}{=} \frac{C_\lambda}{2k + C}\,|\psi\rangle, \qquad \text{so} \qquad h_\lambda = \frac{C_\lambda}{2k + C}.$$

(1) $T^a_m|\psi\rangle = 0$ for $m > 0$ by (6.126).

(2) $T^a_0 T^a_0$ is the quadratic Casimir of $\mathfrak{g}$; on the irreducible V_λ it is a number C_λ (Schur's lemma).

For SU(2), $T^a_0 T^a_0 = \vec{J}^2 = j(j+1)$ on spin j, $C = 2$ and $2k = N$, so

$$h_j = \frac{j(j+1)}{N+2}. \tag{6.127}$$

At level $N = 1$ and $j = \frac{1}{2}$ this is $h = \frac{3/4}{3} = \frac{1}{4}$, the dimension of the vertex operator $e^{i\phi/\sqrt{2}}$ of a free boson at the self-dual radius (Example 6.31 said that $\mathrm{SU}(2)_1$ is such a boson). At $N = 2$ the values are $h = 0, \frac{3}{16}, \frac{1}{2}$: three Majorana fermions ($c = \frac{3}{2}$), with $\frac{1}{2}$ the fermion itself and $\frac{3}{16} = 3 \times \frac{1}{16}$ the product of three Ising spin fields.

The Cartan–Weyl basis

To go further we need the root decomposition of $\mathfrak{g}$ (a refresher; the Lie theory is in Chapter T3).

Working definition 6.23 (roots and step operators)

Pick a maximal set of commuting Hermitian generators $H^1, \ldots, H^r$ (the **Cartan subalgebra** $\mathfrak{t}$; r is the rank). The rest of $\mathfrak{g}_{\mathbb{C}}$ [complex linear combinations of the generators] splits into

simultaneous eigenvectors E^α of the H^i,

$$[H^i, E^\alpha] = \alpha^i E^\alpha, \qquad (E^\alpha)^\dagger = E^{-\alpha}, \qquad [E^\alpha, E^{-\alpha}] = \alpha \cdot H,$$

labelled by **roots** $\alpha = (\alpha^1, \dots, \alpha^r) \in \mathbb{R}^r$. We normalise with the same inner product that appears in the central term, $(T^a, T^b) = \delta^{ab}$, so that $(H^i, H^j) = \delta^{ij}$ and $(E^\alpha, E^{-\beta}) = \delta_{\alpha\beta}$. A choice of "positive" direction [a vector in $\mathbb{R}^r$ perpendicular to no root. A root is positive when its dot product with this vector is positive] splits the roots into positive (E^α raise the weight) and negative ($E^{-\alpha}$ lower it). In a representation, a **weight** μ is a simultaneous eigenvalue $H^i|\mu\rangle = \mu^i|\mu\rangle$, and the **highest weight** λ is the one killed by all positive E^α. *How to compute:* diagonalise ad H^i [the map $X \mapsto [H^i, X]$] on $\mathfrak{g}_{\mathbb{C}}$.

For SU(2) with $T^a = \sigma^a/2$ the rank is 1, $H = T^3$, and $E^\pm = \frac{1}{\sqrt{2}}(T^1 \pm iT^2)$, i.e. $E^\pm = J^\pm/\sqrt{2}$ in terms of the angular momentum ladder operators $J^\pm = T^1 \pm iT^2$. Then

$$[E^+, E^-] \overset{(1)}{=} \tfrac{1}{2}\big(-i[T^1, T^2] + i[T^2, T^1]\big) \overset{(2)}{=} \tfrac{1}{2}\big(-i \cdot iT^3 + i \cdot (-i)T^3\big) = T^3,$$

(1) Expand $[T^1 + iT^2, T^1 - iT^2]$; the $[T^1, T^1]$ and $[T^2, T^2]$ terms vanish.
(2) $[T^1, T^2] = iT^3$.

so the roots are $\alpha = \pm 1$ and $|\alpha|^2 = 1$. This is the statement "long roots have length 1" in our normalisation, which we used in Section 6.2.6. On spin j the weights are $m = -j, \dots, j$ and $\lambda = j$.

The one fact we need about the finite-dimensional theory is this. For every root α the three operators

$$e_\alpha = \frac{\sqrt{2}}{|\alpha|} E^\alpha, \qquad f_\alpha = \frac{\sqrt{2}}{|\alpha|} E^{-\alpha}, \qquad h_\alpha = \frac{2}{|\alpha|^2}\, \alpha \cdot H \tag{6.128}$$

satisfy the $\mathfrak{sl}(2)$ relations $[h, e] = 2e$, $[h, f] = -2f$, $[e, f] = h$ (check: $[h_\alpha, e_\alpha] = \frac{2}{|\alpha|^2}\, \alpha \cdot \alpha\, e_\alpha = 2e_\alpha$ and $[e_\alpha, f_\alpha] = \frac{2}{|\alpha|^2}[E^\alpha, E^{-\alpha}] = h_\alpha$). For SU(2) they are J^+, J^-, $2J^3$. Everything about levels follows from the representation theory of this $\mathfrak{sl}(2)$.

The $\mathfrak{sl}(2)$ fact we need

Let e, f, h act unitarily ($e^\dagger = f$, $h^\dagger = h$), and let v be a vector with $e\,v = 0$ and $h\,v = n\,v$. First, by induction on j,

$$\begin{aligned} e\, f^j v &\overset{(1)}{=} [e, f]\, f^{j-1} v + f\, e\, f^{j-1} v \overset{(2)}{=} h\, f^{j-1} v + f\,(j-1)(n-j+2)\, f^{j-2} v \\ &\overset{(3)}{=} \big(n - 2(j-1)\big) f^{j-1} v + (j-1)(n-j+2)\, f^{j-1} v \overset{(4)}{=} j\,(n-j+1)\, f^{j-1} v. \end{aligned} \tag{6.129}$$

(1) $ef = [e, f] + fe$.
(2) $[e, f] = h$; the induction hypothesis for $j-1$ (for $j = 1$ the second term is absent because $ev = 0$).
(3) f lowers the h-eigenvalue by 2 ($[h, f] = -2f$), so $hf^{j-1}v = (n - 2j + 2)f^{j-1}v$.
(4) $(n - 2j + 2) + (j-1)(n-j+2) = j(n-j+1)$, as expanding both sides shows.

Hence the norms of the states in the "multiplet" built on v are

$$\big\|f^j v\big\|^2 \overset{(1)}{=} \langle v|\, e^j f^j |v\rangle \overset{(2)}{=} j(n-j+1)\, \big\|f^{j-1} v\big\|^2 \overset{(3)}{=} j!\; n(n-1)\cdots(n-j+1)\; \|v\|^2 . \tag{6.130}$$

(1) $(f^j)^\dagger = e^j$.
(2) Peel off one e with (6.129).
(3) Repeat j times.

Key idea: unitarity quantises n

If every $\left\|f^j v\right\|^2$ is ≥ 0, then n is a non-negative integer, and $f^{n+1}v = 0$.

Why: if $n < 0$ then $\|fv\|^2 = n\,\|v\|^2 < 0$. If $n > 0$ is not an integer, let $j = \lfloor n \rfloor + 2$. The factors $n, n-1, \ldots, n-j+2$ are positive but the last one, $n - j + 1 = n - \lfloor n \rfloor - 1$, is negative, so $\left\|f^j v\right\|^2 < 0$. If n is a non-negative integer, the factor $n - j + 1$ vanishes at $j = n + 1$, so $\left\|f^{n+1}v\right\| = 0$ and, in a Hilbert space, $f^{n+1}v = 0$. This is the familiar statement that $2j$ is an integer and the multiplet stops at $m = -j$.

No representations at $k = 0$

Nash says we "can easily verify that there are no non-trivial highest weight representations of the algebra $\mathrm{Map}(S^1, \mathfrak{g})$ itself". This is the Kac–Moody analogue of Goddard–Olive (Section 6.3.7), and it is a two-line computation. In the loop algebra with the central term, the step-operator modes $E^\alpha_m = e^{im\theta}E^\alpha$ obey

$$[E^\alpha_m, E^{-\alpha}_n] \overset{(1)}{=} \left([E^\alpha, E^{-\alpha}]\right)_{m+n} + k\,m\,(E^\alpha, E^{-\alpha})\,\delta_{m,-n} \overset{(2)}{=} \alpha \cdot H_{m+n} + k\,m\,\delta_{m,-n}. \tag{6.131}$$

(1) The second line of (6.123) is bilinear in the generators: for any $X, Y \in \mathfrak{g}_{\mathbb{C}}$, $[X_m, Y_n] = [X, Y]_{m+n} + km(X, Y)\delta_{m,-n}$.
(2) The Cartan–Weyl relations and the normalisation $(E^\alpha, E^{-\alpha}) = 1$.

Now let $|\lambda\rangle$ be the highest-weight state of the ground multiplet, $H^i_0|\lambda\rangle = \lambda^i|\lambda\rangle$, and let α be a positive root. Two norms:

$$\left\|E^{-\alpha}_0|\lambda\rangle\right\|^2 \overset{(1)}{=} \langle\lambda|[E^\alpha_0, E^{-\alpha}_0]|\lambda\rangle \overset{(2)}{=} \alpha \cdot \lambda, \tag{6.132}$$

$$\left\|E^{\alpha}_{-1}|\lambda\rangle\right\|^2 \overset{(3)}{=} \langle\lambda|[E^{-\alpha}_1, E^{\alpha}_{-1}]|\lambda\rangle \overset{(4)}{=} k - \alpha \cdot \lambda. \tag{6.133}$$

(1) $(E^{-\alpha}_0)^\dagger = E^\alpha_0$, and $E^\alpha_0|\lambda\rangle = 0$ because λ is the highest weight.
(2) (6.131) with $m = n = 0$.
(3) $(E^\alpha_{-1})^\dagger = E^{-\alpha}_1$, and $E^{-\alpha}_1|\lambda\rangle = 0$ by (6.126).
(4) (6.131) with $-\alpha$ in place of α and $m = 1$, $n = -1$: $[E^{-\alpha}_1, E^\alpha_{-1}] = -\alpha \cdot H_0 + k$.

Unitarity needs both to be non-negative:

$$0 \leq \alpha \cdot \lambda \leq k \qquad \text{for every positive root } \alpha. \tag{6.134}$$

Set $k = 0$. Then $\alpha \cdot \lambda = 0$ for all positive roots, so $\lambda = 0$ (the roots span the dual of $\mathfrak{t}$): the ground multiplet is the trivial one-dimensional representation, $V_0 = \mathbb{C}|0\rangle$ with $T^a_0|0\rangle = 0$. Next,

$$\|T^a_{-n}|0\rangle\|^2 \overset{(1)}{=} \langle 0|[T^a_n, T^a_{-n}]|0\rangle \overset{(2)}{=} \langle 0|\left(if^{aac}T^c_0 + kn\right)|0\rangle \overset{(3)}{=} kn = 0 \qquad \text{(no sum over } a\text{)},$$

(1) $(T^a_{-n})^\dagger = T^a_n$ and $T^a_n|0\rangle = 0$ for $n \geq 1$.
(2) The Kac–Moody relation with $b = a$.
(3) $f^{aac} = 0$ by antisymmetry, and $k = 0$.

So every $T^a_{-n}|0\rangle$ vanishes, and since $|0\rangle$ is cyclic the whole representation is the one-dimensional trivial one. Every nontrivial positive-energy unitary representation of the loop algebra is therefore a representation of the *central extension* with $k > 0$ ($k < 0$ is ruled out by $\big\|T^a_{-1}|0\rangle\big\|^2 = k$, or by (6.134)). This is why Nash says "we only consider the centrally extended algebra". As for $\mathrm{Diff}(S^1)$, the central extension is forced by positive energy.

Physical picture: why positive energy needs the Schwinger term

The inequality (6.134) says that the charge $\alpha \cdot \lambda$ carried by the ground state is bounded by the central term. With $k = 0$ no state can carry charge, and the current operators, which should create particle–hole pairs from the Dirac sea, create nothing. It is the Schwinger term that gives the current a nonzero vacuum two-point function (6.73), and hence the ability to create states.

The module: pipeline for the Kac–Moody algebra

We now build the representation space, following the same four steps as for the Virasoro algebra (Sections 6.3.2 to 6.3.4).

$$\underbrace{V_\lambda}_{\text{ground multiplet}} \xrightarrow{\text{apply } T^a_{-n},\ n\geq 1} \underbrace{M(k,\lambda) = U(\hat{\mathfrak{g}}_-)\, V_\lambda}_{\text{generalised Verma module}} \xrightarrow{\text{quotient by the null submodule } N} \underbrace{L(k,\lambda) = M(k,\lambda)/N}_{\text{irreducible}} \tag{6.135}$$

Step 1: the ground multiplet. Start from the irreducible representation V_λ of $\mathfrak{g}$, extended to the non-negative modes by $T^a_n V_\lambda = 0$ for $n \geq 1$ and $k =$ a number. This is a module for the subalgebra $\hat{\mathfrak{g}}_{\geq 0}$ spanned by k and T^a_n, $n \geq 0$.

Step 2: generate descendants. Let $\hat{\mathfrak{g}}_-$ be spanned by the raising modes T^a_{-n}, $n \geq 1$. The **generalised Verma module** $M(k,\lambda)$ is spanned by the ordered monomials

$$T^{a_1}_{-n_1} T^{a_2}_{-n_2} \cdots T^{a_s}_{-n_s} |\lambda, \mu\rangle, \qquad n_1 \geq n_2 \geq \cdots \geq n_s \geq 1, \tag{6.136}$$

(with $a_1 \leq a_2 \leq \ldots$ among equal n's), where $|\lambda,\mu\rangle$ runs over a basis of V_λ. These vectors are declared linearly independent; the algebra acts by commuting generators to the right until they hit V_λ. This is Nash's "we can construct the representation space by application of polynomials in the generators to the vacuum". The word "generalised" means that we start from a whole irreducible multiplet V_λ, rather than from one vector: the null vectors of the finite-dimensional algebra (such as $(J^-)^{2j+1}|j,j\rangle = 0$) have already been removed.

A monomial (6.136) has energy $h_\lambda + \sum n_i$; the integer $\sum n_i$ is its **grade**. Counting monomials grade by grade is counting partitions in which each part comes in $\dim G$ colours:

$$\sum_{\text{grades } N} \dim M(k,\lambda)_N \; q^N = \dim V_\lambda \prod_{n\geq 1} \frac{1}{(1-q^n)^{\dim G}}. \tag{6.137}$$

For SU(2) and $\lambda = 0$ this is $1 + 3q + 9q^2 + 22q^3 + 51q^4 + \cdots$. At grade 2, for instance, there are 3 states $T^a_{-2}|0\rangle$ and 6 symmetric products $T^a_{-1}T^b_{-1}|0\rangle$ (the antisymmetric products are not new: $[T^a_{-1}, T^b_{-1}] = if^{abc}T^c_{-2}$).

Step 3: find the null submodule. The inner product on $M(k,\lambda)$ is fixed by (6.124), $\||\lambda\rangle\| = 1$ and the commutation relations; it is the Kac–Moody version of the Kac form of Section 6.3.5.

A **singular vector** is a state $|\chi\rangle$ of positive grade killed by all lowering operators. As for the Virasoro algebra, $|\chi\rangle$ is orthogonal to every state and has zero norm, and so is everything it generates. The whole generated submodule N is the null submodule. For SU(2) the singular vector, when it exists, is

$$|\chi\rangle = (J_{-1}^{+})^{N-2j+1}|j,j\rangle, \qquad J_n^{\pm} := T_n^1 \pm iT_n^2, \tag{6.138}$$

as we show in Section 6.3.9.

Step 4: quotient. The irreducible representation is $L(k,\lambda) = M(k,\lambda)/N$. The action on classes, $T_n^a[v] = [T_n^a v]$, is well defined for the same reason as in (6.115): if $v - v' \in N$ then $T_n^a v - T_n^a v' = T_n^a(v-v') \in N$, because N is a submodule. The unitary representations are exactly the quotients for which the induced inner product on $L(k,\lambda)$ is positive definite.

	$M(k,\lambda)$	null submodule N	$L(k,\lambda) = M/N$
built from	V_λ by all T_{-n}^a	$\|\chi\rangle$ by all T_{-n}^a	classes $v+N$
grade-N count	(6.137)	starts at the grade of $\|\chi\rangle$	difference
inner product	degenerate if $N \neq 0$	zero norm, $\perp$ everything	nondegenerate
when $N=0$	generic level k	—	$L = M$
unitary?	never for $k>0$ (degenerate or indefinite)	—	iff $N = 2k \in \mathbb{Z}$, $2j \le N$

For generic values of k (in particular non-rational ones) there are no singular vectors, and $M(k,\lambda) = L(k,\lambda)$ (Kac and Kazhdan). But then, as we now show, the inner product is not positive: the unitary representations live exactly at the special values of k where null states appear and are removed.

6.3.9 The level is an integer

Nash states the result without derivation: "just as in the $c<1$ Virasoro case, the central term k can only take certain discrete values":

$$\boxed{N \in \mathbb{Z}, \qquad N = \frac{2k}{l^2}} \tag{6.139}$$

where l is the length of a long root of $\mathfrak{g}$. The integer N is the **level** of the representation. The mechanism is beautifully simple: inside the Kac–Moody algebra there is, for every root, a *second* copy of $\mathfrak{su}(2)$, and its "spin" involves k. Unitarity forces the spin of every $\mathfrak{su}(2)$ to be a half-integer.

The hidden $\mathfrak{su}(2)$

For a root α define, by analogy with (6.128) but using a raising mode of *one* root and a lowering mode of the *opposite* root,

$$\hat{e}_\alpha = \frac{\sqrt{2}}{|\alpha|}E_1^{-\alpha}, \qquad \hat{f}_\alpha = \frac{\sqrt{2}}{|\alpha|}E_{-1}^{\alpha}, \qquad \hat{h}_\alpha = \frac{2k}{|\alpha|^2} - \frac{2}{|\alpha|^2}\,\alpha\cdot H_0. \tag{6.140}$$

Let us verify the $\mathfrak{sl}(2)$ relations:

$$[\hat{e}_\alpha,\hat{f}_\alpha] \overset{(1)}{=} \frac{2}{|\alpha|^2}[E_1^{-\alpha},E_{-1}^{\alpha}] \overset{(2)}{=} \frac{2}{|\alpha|^2}(-\alpha\cdot H_0 + k) = \hat{h}_\alpha,$$

$$[\hat{h}_\alpha,\hat{e}_\alpha] \overset{(3)}{=} -\frac{2}{|\alpha|^2}\cdot\frac{\sqrt{2}}{|\alpha|}[\alpha\cdot H_0, E_1^{-\alpha}] \overset{(4)}{=} -\frac{2}{|\alpha|^2}\cdot\frac{\sqrt{2}}{|\alpha|}(-\alpha\cdot\alpha)\,E_1^{-\alpha} = 2\,\hat{e}_\alpha,$$

(1) Definition (6.140).
(2) (6.131) with $-\alpha$ in place of α, $m = 1$, $n = -1$.
(3) k is central, so only the H_0 term contributes.
(4) $[H_0^i, E_1^{-\alpha}] = -\alpha^i E_1^{-\alpha}$: the zero modes of the Cartan generators act on any mode of $E^{-\alpha}$ as on $E^{-\alpha}$.

and similarly $[\hat{h}_\alpha, \hat{f}_\alpha] = -2\hat{f}_\alpha$. Also $\hat{e}_\alpha^\dagger = \hat{f}_\alpha$ by (6.124). So $(\hat{e}_\alpha, \hat{f}_\alpha, \hat{h}_\alpha)$ is a unitary $\mathfrak{su}(2)$, different from the finite one (6.128): its $\hat{h}$ contains the central term. In the geometric picture of Figure 6.25, $\hat{e}_\alpha$ moves one step in the loop direction and one step down in weight at the same time.

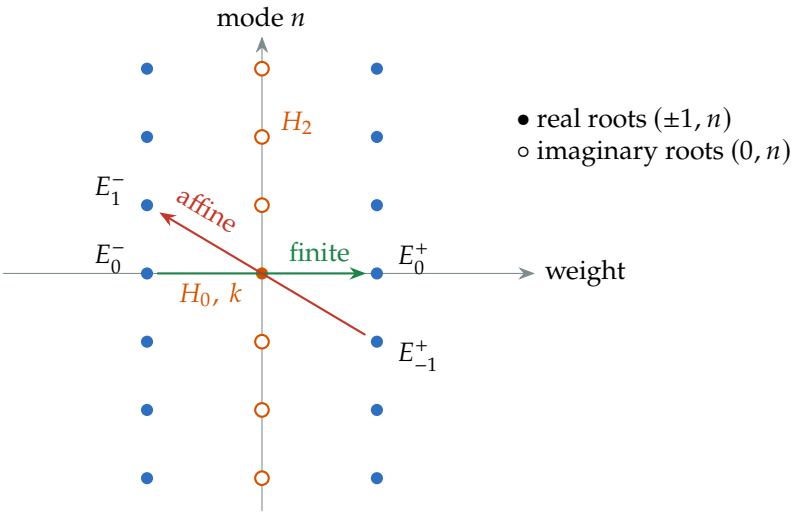

Figure 6.25: The roots of the affine algebra $\widehat{\mathfrak{su}}(2)$. Each generator $E_n^\pm$, H_n is drawn at (its T^3-weight, its mode number). The finite $\mathfrak{su}(2)$ (green) is the horizontal pair $E_0^\pm$. The hidden $\mathfrak{su}(2)$ (red) pairs E_1^- with E_{-1}^+: it is another line through the origin, and its Cartan element $\hat{h} = 2k - 2H_0$ picks up the central term. Every pair $(\pm 1, n)$, $(\mp 1, -n)$ gives an $\mathfrak{su}(2)$ of this kind; the two drawn generate the rest. The points $(0, n)$ are the modes of the Cartan generator (the "imaginary roots").

The quantisation

Apply the $\mathfrak{sl}(2)$ fact to the highest-weight state $v = |\lambda\rangle$ of the ground multiplet and a positive root α. It is killed by $\hat{e}_\alpha \propto E_1^{-\alpha}$ (a lowering mode, (6.126)), and it is an eigenvector of $\hat{h}_\alpha$:

$$\hat{h}_\alpha|\lambda\rangle \overset{(1)}{=} \left(\frac{2k}{|\alpha|^2} - \frac{2\,\alpha\cdot\lambda}{|\alpha|^2}\right)|\lambda\rangle \overset{(2)}{=} \left(\frac{2k}{|\alpha|^2} - \langle\lambda, \alpha^\vee\rangle\right)|\lambda\rangle. \tag{6.141}$$

(1) $H_0^i|\lambda\rangle = \lambda^i|\lambda\rangle$.
(2) Notation: $\langle\lambda, \alpha^\vee\rangle := \frac{2\,\alpha\cdot\lambda}{|\alpha|^2}$ is the eigenvalue of the finite h_α (6.128) on $|\lambda\rangle$.

By the keyidea on unitarity, this eigenvalue is a non-negative integer. The finite $\mathfrak{sl}(2)$ already forces $\langle\lambda, \alpha^\vee\rangle$ to be a non-negative integer (it is "$2j$" of the finite multiplet). Therefore

$$\frac{2k}{|\alpha|^2} \in \mathbb{Z} \qquad \text{and} \qquad \langle\lambda, \alpha^\vee\rangle \le \frac{2k}{|\alpha|^2} \qquad \text{for every positive root } \alpha. \tag{6.142}$$

For a long root $|\alpha| = l$ and the first condition is Nash's (6.62), $N = 2k/l^2 \in \mathbb{Z}$. For a short root $|\alpha|^2 = l^2/p$ with $p = 2$ or 3 (in the non-simply-laced algebras), and $2k/|\alpha|^2 = pN$ is then automatically an integer: the long roots give the strongest condition. The second condition,

applied to the *highest root* θ (which is long), is the strongest of the inequalities:

$$\boxed{\langle \lambda, \theta^\vee \rangle \le N} \tag{6.143}$$

Representations satisfying (6.139) and (6.143) are called **integrable**. They are exactly the unitary highest-weight representations, and exactly the ones that exponentiate to (projective) representations of the loop group (Pressley and Segal). There are finitely many at each level.

Key idea: the level (Nash's (6.62))

In a unitary highest-weight representation of the affine Kac–Moody algebra, $N = 2k/l^2$ is a non-negative integer, and the highest weight of the ground multiplet satisfies $\langle \lambda, \theta^\vee \rangle \le N$. For SU(2) in our normalisation ($l^2 = 1$): $N = 2k \in \mathbb{Z}_{\ge 0}$ and the ground-state spin satisfies

$$j \in \{0, \tfrac{1}{2}, 1, \dots, \tfrac{N}{2}\}.$$

When $\langle \lambda, \theta^\vee \rangle \le N$ the null vector $\hat{f}_\theta^{\,N - \langle \lambda, \theta^\vee \rangle + 1} |\lambda\rangle$ must be quotiented out, which for SU(2) is (6.138).

This is the same integer we met topologically in Section 6.2.6: there the central extension of the *group* LG existed only for $N \in \mathbb{Z}$ (the cocycle had to be an integral class, like the flux of a monopole). Here unitarity of the representation of the *algebra* gives the same condition. The two must agree, because a unitary highest-weight representation of the algebra integrates to a projective representation of the group, i.e. a true representation of the extension.

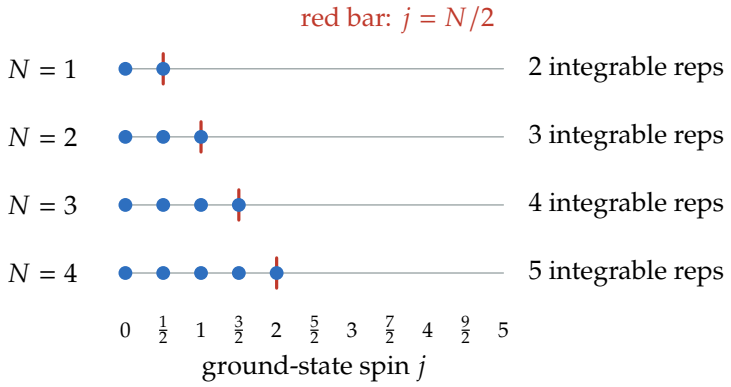

Figure 6.26: The integrable representations of $\widehat{\mathfrak{su}}(2)$ at levels $N = 1, \dots, 4$. Each dot is an allowed spin j of the ground multiplet; the red bar is the bound $2j \le N$ of (6.143). At level N there are $N + 1$ representations, with lowest energies $h_j = j(j+1)/(N+2)$ (6.127). As $N \to \infty$ the bound disappears and every spin of SU(2) is allowed: the classical limit.

Watch out: normalisations of the level

Many CFT books write the Kac–Moody algebra as $[J^a_m, J^b_n] = i f^{abc} J^c_{m+n} + \kappa\, m\, \delta^{ab} \delta_{m+n,0}$ with the generators normalised so that long roots have length^2 2; then κ itself is the integer level. Nash's form $N = 2k/l^2$ is normalisation-independent: rescaling $T^a \to sT^a$ multiplies k by s^2 and l^2 by s^2. In our normalisation ($T^a = \sigma^a/2$ for SU(2), $l^2 = 1$) the integer is $N = 2k$, which is why $c = \frac{3N}{N+2}$ in Example 6.31.

The SU(2) case in detail

For SU(2) the hidden $\mathfrak{su}(2)$ is built from $J_n^{\pm} = T_n^1 \pm iT_n^2$ ($= \sqrt{2}E_n^{\pm}$). First the basic commutator:

$$[J_m^+, J_n^-] \overset{(1)}{=} [T_m^1, T_n^1] + [T_m^2, T_n^2] - i[T_m^1, T_n^2] + i[T_m^2, T_n^1]$$
$$\overset{(2)}{=} 2km\,\delta_{m,-n} - i\big(iT_{m+n}^3\big) + i\big(-iT_{m+n}^3\big) = 2T_{m+n}^3 + 2km\,\delta_{m,-n}. \tag{6.144}$$

(1) Expand $[T_m^1 + iT_m^2,\ T_n^1 - iT_n^2]$ by bilinearity.
(2) The Kac–Moody relations with $f^{abc} = \varepsilon^{abc}$: $[T_m^1, T_n^1] = km\delta_{m,-n}$ (the same for T^2), $[T_m^1, T_n^2] = iT_{m+n}^3$ and $[T_m^2, T_n^1] = -iT_{m+n}^3$ (their central terms vanish, since $\delta^{12} = 0$).

The hidden $\mathfrak{su}(2)$ is $\hat{e} = J_1^-$, $\hat{f} = J_{-1}^+$ and

$$\hat{h} \overset{(1)}{=} [J_1^-, J_{-1}^+] \overset{(2)}{=} -\big(2T_0^3 + 2k\cdot(-1)\big) = 2k - 2T_0^3,$$

(1) The $\mathfrak{sl}(2)$ relation $[\hat{e}, \hat{f}] = \hat{h}$.
(2) $[J_1^-, J_{-1}^+] = -[J_{-1}^+, J_1^-]$ and (6.144) with $m = -1$, $n = 1$.

in agreement with (6.140) for $|\alpha|^2 = 1$. On the top state $|j, j\rangle$ of the ground multiplet, $\hat{h} = 2k - 2j = N - 2j$. So the condition "$\hat{h}$ has non-negative integer eigenvalue" reads $N - 2j \in \mathbb{Z}_{\geq 0}$, and the singular vector is $\hat{f}^{\,N-2j+1}|j, j\rangle = (J_{-1}^+)^{N-2j+1}|j, j\rangle$, which is (6.138). It is killed by all the lowering operators: by $\hat{e} = J_1^-$ because of (6.129) with $j = n + 1$, and by J_0^+ because $[J_0^+, J_{-1}^+] = 0$ and $J_0^+|j, j\rangle = 0$; these two generate all the lowering operators under commutators (for example $[J_0^+, J_1^-] = 2T_1^3$).

Worked example 6.45: the vacuum module of SU(2) at level 1

Take $j = 0$. We compute the lowest grades of $M(k, 0)$ and see where unitarity fails and where null states appear.

Grade 1. The three states $T_{-1}^a|0\rangle$ have norms $\big\|T_{-1}^a|0\rangle\big\|^2 = \langle 0|[T_1^a, T_{-1}^a]|0\rangle = k$ (no sum), positive for $k > 0$.

Grade 2. Consider the top-weight state $(J_{-1}^+)^2|0\rangle$, with $T_0^3 = 2$. Using $\hat{e} = J_1^-$,

$$J_1^-\,(J_{-1}^+)^2|0\rangle \overset{(1)}{=} [J_1^-, J_{-1}^+]\,J_{-1}^+|0\rangle + J_{-1}^+\,[J_1^-, J_{-1}^+]|0\rangle$$
$$\overset{(2)}{=} (2k - 2T_0^3)\,J_{-1}^+|0\rangle + J_{-1}^+\,(2k - 2T_0^3)|0\rangle$$
$$\overset{(3)}{=} (2k-2)\,J_{-1}^+|0\rangle + 2k\,J_{-1}^+|0\rangle = (4k-2)\,J_{-1}^+|0\rangle,$$

(1) $J_1^-|0\rangle = 0$, so only commutators survive.
(2) $[J_1^-, J_{-1}^+] = \hat{h} = 2k - 2T_0^3$.
(3) $J_{-1}^+|0\rangle$ has $T_0^3 = 1$ (because $[T_0^3, J_{-1}^+] = J_{-1}^+$), and $T_0^3|0\rangle = 0$.

so, with $\big\|J_{-1}^+|0\rangle\big\|^2 = \langle 0|[J_1^-, J_{-1}^+]|0\rangle = 2k$,

$$\big\|(J_{-1}^+)^2|0\rangle\big\|^2 \overset{(1)}{=} \langle 0|J_1^-\,J_1^-(J_{-1}^+)^2|0\rangle \overset{(2)}{=} (4k-2)\,\big\|J_{-1}^+|0\rangle\big\|^2 \overset{(3)}{=} 4k\,(2k-1).$$

(1) $\big((J_{-1}^+)^2\big)^\dagger = (J_1^-)^2$.
(2) The previous chain.
(3) $\big\|J_{-1}^+|0\rangle\big\|^2 = 2k$.

This agrees with (6.130): $j = 2$, $n = 2k$, giving $2\cdot 2k(2k-1)$. Read the answer as a function of the level:

- $0 < 2k < 1$: the norm is *negative*. There is no unitary representation. This is level quantisation happening at grade two.
- $2k = 1$: the norm is zero. The state $(J^+_{-1})^2|0\rangle$ is the singular vector (6.138) with $N = 1$, $j = 0$.
- $2k > 1$ but not an integer: positive here, but a higher power $(J^+_{-1})^{\lfloor 2k \rfloor + 2}|0\rangle$ has negative norm.

Now set $N = 1$ and quotient. The null vector has $T^3_0 = 2$, and it is the top state of a spin-2 multiplet under the zero modes T^a_0 (it is killed by J^+_0); all five states $(J^-_0)^r(J^+_{-1})^2|0\rangle$, $r = 0, \dots, 4$, lie in N, since N is a submodule. Under SU(2) the six symmetric products $T^a_{-1}T^b_{-1}|0\rangle$ decompose as $\mathrm{Sym}^2(\mathbf{3}) = \mathbf{5} \oplus \mathbf{1}$, and the $\mathbf{5}$ is exactly this null multiplet. What survives at grade 2 is

$$\underbrace{T^a_{-2}|0\rangle}_{\mathbf{3}} \;\oplus\; \underbrace{T^a_{-1}T^a_{-1}|0\rangle = (2k + C)\,L_{-2}|0\rangle}_{\mathbf{1}\text{ (Sugawara stress tensor)}},$$

four states instead of nine.

The counting can be checked against the free boson. By Example 6.31, $L(1/2, 0)$ is the Fock space of a chiral boson at the self-dual radius, with T^3_0 the momentum $n \in \mathbb{Z}$ and grade n^2 + (oscillator level). So the number of states with $T^3_0 = n$ at grade g is $p(g - n^2)$, with p the partition function:

$$\sum_g \dim L(\tfrac{1}{2}, 0)_g \, q^g = \frac{\sum_{n\in\mathbb{Z}} q^{n^2}}{\prod_{m\geq 1}(1 - q^m)} = 1 + 3q + 4q^2 + 7q^3 + 13q^4 + \cdots . \tag{6.145}$$

Compare the generalised Verma module $1 + 3q + 9q^2 + 22q^3 + 51q^4 + \cdots$: the quotient throws away most of the states. Figure 6.27 shows where the survivors sit.

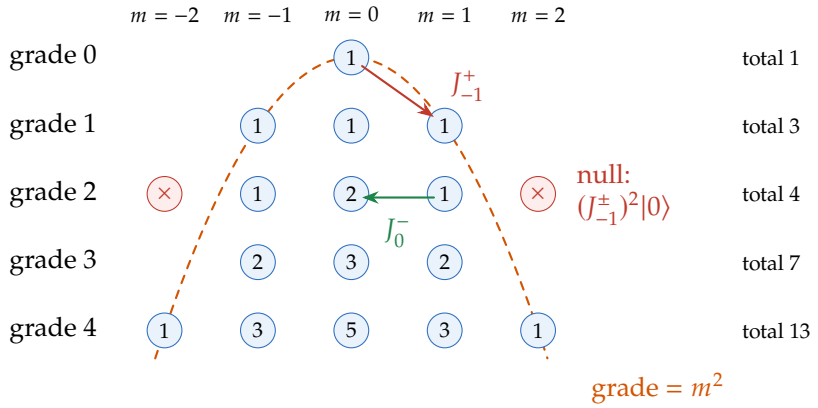

Figure 6.27: The irreducible vacuum module $L(\frac{1}{2}, 0)$ of $\widehat{\mathfrak{su}}(2)$ at level $N = 1$. Horizontal: the T^3_0 weight m; vertical (downwards): the grade. The number in each circle is the multiplicity $p(g - m^2)$. No state lies above the dashed parabola $g = m^2$: to reach weight m one must spend grade at least m^2. The red crosses are the null states $(J^\pm_{-1})^2|0\rangle$, which would have $|m| = 2$ at grade 2 in the generalised Verma module; they, and the whole multiplet and submodule they generate, are removed. The red arrow is the hidden $\mathfrak{su}(2)$ lowering operator $\hat{f} = J^+_{-1}$, the green one a finite $\mathfrak{su}(2)$ step. The total numbers are (6.145).

Physical picture: the parabola

Why must the states lie inside a parabola? The single current $T^3(\theta)$ is itself a U(1) Kac–Moody algebra with central term $k = N/2$, and it has its own Sugawara operator $L_0^{\mathrm{U}(1)} = \frac{1}{2k}(T_0^3)^2 + (\text{oscillators})$, whose lowest value in the sector of charge m is m^2/N. The difference $L_0 - L_0^{\mathrm{U}(1)}$ is a coset Virasoro generator (6.121), and on a unitary representation it is non-negative. So every state of charge m has energy at least m^2/N; for $N = 1$ and $h = 0$ that is grade $\geq m^2$. Physically: to put charge m on a circle you pay an electrostatic energy $m^2/2k$, quadratic in the charge, with the level playing the role of the capacitance.

Try it: level 1, spin one-half

In $L(\frac{1}{2}, \frac{1}{2})$, show that $J_{-1}^+|\frac{1}{2}, \frac{1}{2}\rangle$ is null. *Answer:* $\left\|J_{-1}^+|\frac{1}{2}, \frac{1}{2}\rangle\right\|^2 = \langle\frac{1}{2}, \frac{1}{2}|(2k - 2T_0^3)|\frac{1}{2}, \frac{1}{2}\rangle = 2k - 1 = 0$ at $N = 1$. This is (6.138) with $N - 2j + 1 = 1$. The lowest states of charge $\frac{3}{2}$ therefore sit at grade 2, not 1.

Reading Nash (pp. 187–188, (6.60)–(6.62))

Nash lists the three families of commutators (6.123), states the boundedness criterion (6.126), and asserts that $k = 0$ admits no nontrivial highest-weight representations (we derived it from the norms (6.132)–(6.133)). He notes that the T_0^a act irreducibly on the ground states, so a representation is labelled by (k, λ), and quotes the quantisation $N = 2k/l^2 \in \mathbb{Z}$ with l the length of a long root, referring to Kac and to Pressley–Segal for proofs. The proof is the hidden $\mathfrak{su}(2)$ of (6.140). Nash writes $\delta_{m,-n}$ where we sometimes write $\delta_{m+n,0}$; they are the same.

6.3.10 The Borel–Weil construction

So far we have built representations *algebraically*: start with a highest-weight vector, act with raising operators, throw away the null states. Nash ends the chapter with a second, *geometric* way of producing the same representations. It emphasises the group rather than the algebra, and it looks exactly like quantum mechanics: the representation space is a space of wavefunctions on a manifold.

Here is the question it answers. A physicist already knows one way to manufacture representations of SO(3) out of geometry: take functions on the sphere $S^2 = \mathrm{SO}(3)/\mathrm{SO}(2)$ and let rotations act on them by $(R \cdot \psi)(\vec{x}) = \psi(R^{-1}\vec{x})$. The result is

$$L^2(S^2) = \bigoplus_{l=0}^{\infty} \operatorname{span}\{Y_{lm}\}_{m=-l}^{l},$$

which contains every integer spin, once each. That is too much: we want *one* irreducible representation at a time, and we want the half-integer spins as well. The Borel–Weil construction fixes both problems with two changes.

(a) Replace functions by *sections of a line bundle*: wavefunctions of a particle that carries a charge n under the circle T that we quotiented by. (Physically: put a magnetic monopole inside the sphere.) This lets the half-integer spins in.

(b) Keep only the *holomorphic* sections. This cuts the infinite sum down to a single irreducible representation. (Physically: keep only the lowest Landau level.)

The rest of this subsection makes each step concrete, first for a general compact group in words, then for SU(2) with every formula written out.

$$\underbrace{\lambda : T \to \mathrm{U}(1)}_{\text{a weight}} \xrightarrow{\text{associate}} \underbrace{L_\lambda = G \times_T \mathbb{C} \to G/T}_{\text{a line bundle}} \xrightarrow{G/T = G_{\mathbb{C}}/B} \underbrace{L_\lambda \text{ holomorphic}}_{\text{unique structure}}$$
$$\xrightarrow{\text{take } \Gamma_{\text{hol}}} \underbrace{\Gamma(G/T, \mathcal{O}(L_\lambda)) \cong V_\lambda}_{\text{the irreducible representation}} \tag{6.146}$$

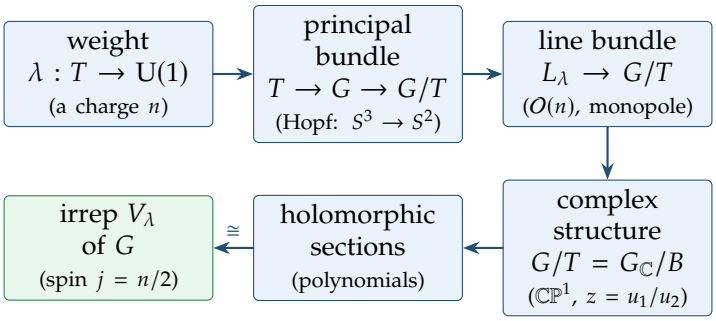

Figure 6.28: The Borel–Weil pipeline (6.146). Read it like the Verma pipeline of Figure 6.22: a small piece of data (here a weight, there a highest weight) is fed into a construction that produces a big space (here all sections, there the Verma module), and a condition (here holomorphicity, there the removal of null states) cuts it down to exactly one irreducible representation. The small type follows the SU(2) example that we work out in full.

Step 1: weights are characters of the torus

Let G be a compact connected Lie group, such as SU(2) or SU(3). A **maximal torus** $T \subset G$ is a maximal connected abelian subgroup. For SU(N) it is the diagonal matrices. Every T is a product of circles, $T \cong \mathrm{U}(1)^r$, and r is the rank.

In a unitary representation of G, the elements of T commute with each other, so they can be diagonalised simultaneously. On the common eigenvectors v_i, each $t \in T$ acts by a phase: $t\, v_i = \lambda_i(t)\, v_i$ with $|\lambda_i(t)| = 1$. Since $(tt')v_i = t(t'v_i)$, the map $\lambda_i : T \to \mathrm{U}(1)$ is a group homomorphism.

Working definition 6.24 (weight as a character)

A **weight** of a representation is a homomorphism $\lambda : T \to \mathrm{U}(1)$ such that some nonzero vector obeys $t\, v = \lambda(t)\, v$ for all $t \in T$. *How to compute:* diagonalise the torus. For $T = \mathrm{U}(1)^r$ every continuous homomorphism is $\lambda(e^{i\phi_1}, \dots, e^{i\phi_r}) = e^{i(n_1\phi_1 + \cdots + n_r\phi_r)}$ with integers n_i, so a weight is a vector of integers. Its derivative $\mathrm{d}\lambda$ at the identity is the "weight" μ of Section 6.3.8 (an eigenvalue of the Cartan generators H^i [the commuting Hermitian generators whose exponentials make up T]).

Why must the exponents be integers? A continuous homomorphism $\lambda : \mathrm{U}(1) \to \mathrm{U}(1)$ has the form $\lambda(e^{i\phi}) = e^{i\kappa\phi}$ for some real κ (it is a one-parameter group of phases). Then

$$1 \overset{(1)}{=} \lambda(1) \overset{(2)}{=} \lambda(e^{2\pi i}) \overset{(3)}{=} e^{2\pi i\kappa} \qquad \Longrightarrow \qquad \kappa \in \mathbb{Z}.$$

(1) A homomorphism sends the identity to the identity.
(2) $e^{2\pi i} = 1$ in U(1).
(3) The formula for λ with $\phi = 2\pi$.

This is the same argument that quantises angular momentum about an axis: a rotation by 2π must act trivially. The lattice of weights is where all the integers of representation theory come from.

Worked example 6.46: the weights of SU(2)

For SU(2) take

$$T = \left\{ t_\phi = \begin{pmatrix} e^{i\phi} & 0 \\ 0 & e^{-i\phi} \end{pmatrix} \right\} \cong \mathrm{U}(1), \qquad \lambda_n(t_\phi) := e^{in\phi}, \quad n \in \mathbb{Z}. \tag{6.147}$$

We find the weights of the spin-j representation. In the fundamental representation $J^3 = \sigma^3/2$, so $t_\phi = e^{i\phi\sigma^3} = e^{2i\phi J^3}$. This identity between group elements holds in every representation, so on the basis $|j, m\rangle$

$$t_\phi |j,m\rangle \overset{(1)}{=} e^{2i\phi J^3}|j,m\rangle \overset{(2)}{=} e^{2im\phi}|j,m\rangle \overset{(3)}{=} \lambda_{2m}(t_\phi)|j,m\rangle.$$

(1) $t_\phi = \exp(2i\phi J^3)$.
(2) $J^3|j,m\rangle = m|j,m\rangle$.
(3) Definition (6.147) with $n = 2m$.

So the weights of spin j are $\lambda_{2j}, \lambda_{2j-2}, \ldots, \lambda_{-2j}$, and the **highest weight** is λ_{2j}. The integer $n = 2m$ is always an integer even when m is a half-integer: this is why the torus of SU(2) (rather than of SO(3), where t would be a rotation by ϕ and not 2ϕ) sees the spinors. The irreducible representation with highest weight λ_n, $n \geq 0$, is spin $j = n/2$.

Watch out: which weight labels the representation

An irreducible representation contains many weights, but only one highest weight (for a fixed choice of which roots are "positive"). Nash writes V_λ for the irreducible representation whose highest weight is λ. For SU(2), V_{λ_n} is spin $n/2$ and has dimension $n+1$. The highest weights that actually occur are the **dominant** ones; for SU(2) this means $n \geq 0$.

Step 2: the principal T-bundle $G \to G/T$

The torus acts on G by right multiplication, $g \mapsto gt$. The orbits are copies of T, and the space of orbits is the homogeneous space G/T. So G is a principal T-bundle over G/T (Nash's (6.63)):

$$T \longrightarrow G \xrightarrow{\pi} G/T. \tag{6.148}$$

(Refresher: a principal T-bundle is a space with a free right T-action whose orbits are the fibres; see Chapters 1 and T3.) The dimension of the base is $\dim G - \dim T$: $3 - 1 = 2$ for SU(2), $8 - 2 = 6$ for SU(3).

Worked example 6.47: $\mathrm{SU}(2) \to S^2$ is the Hopf fibration

Write a general element of SU(2) in terms of its *second* column $u = (u_1, u_2)$:

$$g = \begin{pmatrix} \bar{u}_2 & u_1 \\ -\bar{u}_1 & u_2 \end{pmatrix}, \qquad |u_1|^2 + |u_2|^2 = 1. \tag{6.149}$$

(Check: $\det g = |u_2|^2 + |u_1|^2 = 1$, and the two columns are orthonormal.) So $\mathrm{SU}(2) \cong S^3$, the unit sphere in $\mathbb{C}^2$. Now multiply on the right by the torus:

$$g\,t_\phi \overset{(1)}{=} \begin{pmatrix} \bar{u}_2 & u_1 \\ -\bar{u}_1 & u_2 \end{pmatrix} \begin{pmatrix} e^{i\phi} & 0 \\ 0 & e^{-i\phi} \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} \bar{u}_2 e^{i\phi} & u_1 e^{-i\phi} \\ -\bar{u}_1 e^{i\phi} & u_2 e^{-i\phi} \end{pmatrix}.$$

(1) Definitions (6.147) and (6.149).
(2) Right multiplication by a diagonal matrix scales the columns.

The second column goes to $e^{-i\phi}u$: right multiplication by T is the overall phase rotation of $u \in S^3$. Two elements are in the same orbit iff their second columns are proportional, so the orbit is labelled by the ratio

$$\pi(g) = [u_1 : u_2] \in \mathbb{CP}^1, \qquad z := \frac{u_1}{u_2} \in \mathbb{C} \cup \{\infty\}.$$

Thus $\mathrm{SU}(2)/T = \mathbb{CP}^1 = S^2$ and (6.148) is the Hopf fibration $S^1 \to S^3 \to S^2$ (Figure 6.29). The point z is also a direction in $\mathbb{R}^3$: $\pi(g)$ can be identified with the unit vector $\hat{n} = u^\dagger \vec{\sigma} u$, the direction of the spin of the state u.

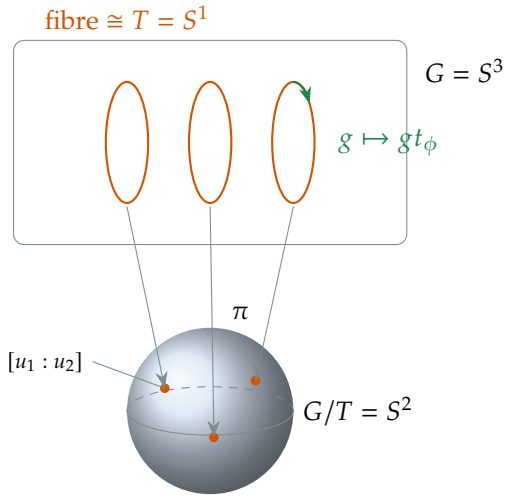

Figure 6.29: The principal T-bundle $G \to G/T$ for $G = \mathrm{SU}(2)$. Each point $[u_1 : u_2]$ of the base sphere has a whole circle of group elements above it, the phases $e^{-i\phi}u$ of the second column; the torus moves points round these circles. This is the Hopf fibration, and the associated line bundles are the monopole bundles over S^2.

Step 3: the associated line bundle L_λ

A weight $\lambda : T \to \mathrm{U}(1)$ lets T act on the complex line $\mathbb{C}$. From a principal bundle and an action on a vector space we can always build an associated vector bundle (Chapter T3): here a complex line bundle.

Working definition 6.25 (the line bundle L_λ and its sections)

$L_\lambda = G \times_T \mathbb{C}$ is the set of pairs $[g, w]$, $g \in G$, $w \in \mathbb{C}$, with the identification $[gt, w] = [g, \lambda(t)w]$. The projection is $[g, w] \mapsto \pi(g)$ [the coset gT, the point of G/T lying below g].
How to compute with it: a section of L_λ [a smooth choice of one point of L_λ over each point

of G/T] is the same thing as a function $f : G \to \mathbb{C}$ obeying

$$f(gt) = \lambda(t)^{-1} f(g) \qquad \text{for all } g \in G,\ t \in T. \tag{6.150}$$

The group acts on sections by left translation, $(h \cdot f)(g) = f(h^{-1}g)$.

The dictionary between sections s and functions f is $s(\pi(g)) = [g, f(g)]$. For this to be well defined, the answer must not depend on which g above the point we used. Replacing g by gt,

$$[gt, f(gt)] \overset{(1)}{=} [g, \lambda(t)\, f(gt)] \overset{(2)}{=} [g, f(g)].$$

(1) The identification rule $[gt, w] = [g, \lambda(t)w]$ with $w = f(gt)$.
(2) The equivariance (6.150): $\lambda(t)f(gt) = f(g)$.

So equivariant functions give sections, and conversely every section gives an equivariant function. Left translation preserves the condition (6.150), because left and right multiplication commute: $(h \cdot f)(gt) = f(h^{-1}gt) = \lambda(t)^{-1} f(h^{-1}g) = \lambda(t)^{-1}(h \cdot f)(g)$. Hence the space of all sections $\Gamma(G/T, L_\lambda)$ is a representation of G. It is infinite-dimensional; the next two steps cut it down.

Physical picture: sections are wavefunctions of a charged particle

A function obeying (6.150) is a wavefunction on the big space G that picks up a definite phase when you move along the fibre. This is exactly the "wavefunction in a fixed gauge" of a particle of charge n in a magnetic field: choosing a representative g over each point is choosing a gauge, and changing $g \to gt$ is a gauge transformation, under which the wavefunction changes by the phase $\lambda(t)^{-1}$. The line bundle L_λ is the bundle whose sections are these wavefunctions, and its first Chern class is the magnetic flux (Example 6.48).

Worked example 6.48: the sections of L_{λ_n} over S^2

Take $G = \mathrm{SU}(2)$ and $\lambda = \lambda_n$. By (6.149) a function on SU(2) is a function $f(u, \bar{u})$ on S^3, and by the example above $g\, t_\phi$ has second column $e^{-i\phi}u$. The condition (6.150) becomes

$$f\left(e^{-i\phi}u,\ e^{i\phi}\bar{u}\right) = e^{-in\phi}\, f(u, \bar{u}). \tag{6.151}$$

The monomial $u_1^p u_2^q \bar{u}_1^r \bar{u}_2^s$ gets the factor $e^{-i(p+q-r-s)\phi}$, so the smooth sections are (limits of) polynomials with $p + q - r - s = n$: "charge" n = (number of u's) − (number of $\bar{u}$'s). For $n = 0$ these are the functions on S^2, i.e. all spherical harmonics. In every case the space is infinite-dimensional.

The Chern class. Choose a representative in each of two patches: $\sigma_N(z)$ with $u_2 > 0$ real (defined where $u_2 \neq 0$, i.e. away from $z = \infty$) and $\sigma_S(z)$ with $u_1 > 0$ real (away from $z = 0$). On the overlap they differ by a torus element: $\sigma_S = \sigma_N\, t_{\phi(z)}$. To find ϕ, compare second columns:

$$e^{-i\phi}\left(\frac{u_1\,\bar{u}_2}{|u_2|},\ |u_2|\right) \overset{(1)}{=} \left(|u_1|,\ \frac{u_2\,\bar{u}_1}{|u_1|}\right) \qquad \Longrightarrow \qquad e^{i\phi} \overset{(2)}{=} \frac{u_1\bar{u}_2}{|u_1|\,|u_2|} \overset{(3)}{=} \frac{z}{|z|}.$$

(1) The second column of σ_N is u rephased to make u_2 positive; that of σ_S is u rephased to make u_1 positive; right multiplication by t_ϕ multiplies the second column by $e^{-i\phi}$.
(2) Solve the first component for $e^{i\phi}$.
(3) $z = u_1/u_2 = u_1\bar{u}_2/|u_2|^2$, so $z/|z| = u_1\bar{u}_2/(|u_1|\,|u_2|)$.

So $\phi(z) = \arg z$. The local wavefunctions $f_N = f \circ \sigma_N$ and $f_S = f \circ \sigma_S$ are then related by

$$f_S = f(\sigma_N t_\phi) = \lambda_n(t_\phi)^{-1} f_N = e^{-in\arg z}\, f_N.$$

The transition function $e^{-in\arg z}$ winds n times (up to orientation) round the equator, which is the definition of a line bundle of Chern number n (Chapter T2): L_{λ_n} is the bundle of a Dirac monopole with $eg = n/2$ (Dirac's condition is $2eg \in \mathbb{Z}$). In algebraic geometry it is called $\mathcal{O}(n)$ (Chapter 5).

Step 4: G/T is a complex manifold

To speak of holomorphic sections, G/T must be a complex manifold. It is, because of a second description (Nash's (6.64)):

$$G/T \;=\; G_{\mathbb{C}}/B. \tag{6.152}$$

Here $G_{\mathbb{C}}$ is the complexification of G ($\mathrm{SL}(2,\mathbb{C})$ for $\mathrm{SU}(2)$, $\mathrm{SL}(N,\mathbb{C})$ for $\mathrm{SU}(N)$), and B is a **Borel subgroup**: for $\mathrm{SL}(N,\mathbb{C})$, the lower-triangular matrices of determinant one. The right-hand side is a quotient of a complex group by a complex subgroup, so it is automatically a complex manifold, and (6.152) transports the complex structure to G/T.

Worked example 6.49: $\mathrm{SL}(2,\mathbb{C})/B = \mathbb{CP}^1 = \mathrm{SU}(2)/T$ by Gram–Schmidt

$\mathrm{SL}(2,\mathbb{C})$ acts on lines in $\mathbb{C}^2$. Let it act on the line $\mathbb{C}e_2$ spanned by $e_2 = (0,1)^T$; then $g\cdot\mathbb{C}e_2$ is the line through the second column of g. The stabiliser of $\mathbb{C}e_2$ is

$$B = \left\{ \begin{pmatrix} \tau^{-1} & 0 \\ s & \tau \end{pmatrix} :\; \tau\in\mathbb{C}^\times,\; s\in\mathbb{C} \right\},$$

the lower-triangular matrices, because $ge_2 = (g_{12}, g_{22})$ lies in $\mathbb{C}e_2$ iff $g_{12} = 0$. Every line is reached, so $\mathrm{SL}(2,\mathbb{C})/B = \mathbb{CP}^1$, the space of lines, with the holomorphic coordinate $z = g_{12}/g_{22}$.
Why is this the same as $\mathrm{SU}(2)/T$? Two facts.

(i) $\mathrm{SU}(2)$ alone already acts transitively on lines: any unit vector u is the second column of the element (6.149). So every $g\in\mathrm{SL}(2,\mathbb{C})$ can be written $g = kb$ with $k\in\mathrm{SU}(2)$, $b\in B$. This is Gram–Schmidt run from the second column: normalise ge_2 to get u, take k as in (6.149); then $k^{-1}g$ maps e_2 into $\mathbb{C}e_2$, i.e. is lower triangular.

(ii) The elements of $\mathrm{SU}(2)$ that fix the line $\mathbb{C}e_2$ are $\mathrm{SU}(2)\cap B$, the unitary lower-triangular matrices. A unitary triangular matrix is diagonal (its columns are orthonormal), so $\mathrm{SU}(2)\cap B = T$.

Together: $\mathrm{SU}(2)/T \to \mathrm{SL}(2,\mathbb{C})/B$, $kT\mapsto kB$, is well defined, onto by (i) and one-to-one by (ii). In coordinates it is $[u_1:u_2]\mapsto z = u_1/u_2$, the coordinate of Example 6.47.

The same argument works in general: Gram–Schmidt (the Iwasawa decomposition) gives $G_{\mathbb{C}} = G\cdot B$, and $G\cap B = T$. For $\mathrm{SU}(3)$, $G_{\mathbb{C}}/B$ is the space of **flags** (a line inside a plane inside $\mathbb{C}^3$), a complex manifold of complex dimension 3.

Key idea: G/T is Kähler

G/T carries a G-invariant Kähler metric: a Riemannian metric compatible with the complex structure whose 2-form ω is closed. For $\mathbb{CP}^1$ it is the round metric, with

$$\omega = \frac{i\,\mathrm{d}z\wedge\mathrm{d}\bar z}{(1+|z|^2)^2}, \qquad \frac{1}{2\pi}\int_{\mathbb{CP}^1}\omega = 1. \tag{6.153}$$

The integral is a two-line check. With $z = re^{i\theta}$, $i\,\mathrm{d}z \wedge \mathrm{d}\bar{z} = 2\,\mathrm{d}x \wedge \mathrm{d}y = 2r\,\mathrm{d}r \wedge \mathrm{d}\theta$, and

$$\frac{1}{2\pi}\int_{\mathbb{CP}^1}\omega \overset{(1)}{=} \frac{1}{2\pi}\int_0^{2\pi}\mathrm{d}\theta\int_0^{\infty}\frac{2r\,\mathrm{d}r}{(1+r^2)^2} \overset{(2)}{=} \int_0^{\infty}\frac{\mathrm{d}s}{(1+s)^2} = 1.$$

(1) The point $z = \infty$ has measure zero, so the chart $\mathbb{C}$ suffices.
(2) The θ integral gives 2π; substitute $s = r^2$.

So $\omega/2\pi$ is an integral class, the Chern class of L_{λ_1}. In the language of classical mechanics, $n\,\omega$ is the symplectic form on the phase space of a classical spin of length $n/2$, and the whole Borel–Weil construction is its quantisation (see the physical picture below).

Step 5: the holomorphic structure is unique

A complex line bundle over a complex manifold may carry many inequivalent holomorphic structures, or none. Nash needs to know that L_λ carries exactly one. The tool is the sheaf-cohomology comparison of Chapter 5 (and Chapter 3): the exponential sequence of sheaves

$$0 \longrightarrow \mathbb{Z} \longrightarrow \mathcal{O} \xrightarrow{\exp(2\pi i\,\cdot)} \mathcal{O}^* \longrightarrow 0$$

gives the exact sequence

$$H^1(M;\mathcal{O}) \longrightarrow H^1(M;\mathcal{O}^*) \xrightarrow{c_1} H^2(M;\mathbb{Z}) \longrightarrow H^2(M;\mathcal{O}). \tag{6.154}$$

Here $H^1(M;\mathcal{O}^*)$ is the group of holomorphic line bundles (a Čech 1-cocycle of nonvanishing holomorphic functions is a set of holomorphic transition functions), and c_1 sends a bundle to its Chern class, which classifies the underlying *smooth* bundle. So the two outer groups measure the difference between holomorphic and smooth line bundles. If both vanish, c_1 is an isomorphism: every smooth line bundle has one and only one holomorphic structure.

For G/T they do vanish. This is Nash's (6.65),

$$H^i(G/T;\mathcal{O}) = 0, \qquad i \geq 1, \tag{6.155}$$

a consequence of the Kodaira vanishing theorem (G/T is Kähler with positive curvature in the right sense). For $\mathbb{CP}^1$ we can see it by hand.

Worked example 6.50: $H^1(\mathbb{CP}^1;\mathcal{O}) = 0$ by Laurent series

Cover $\mathbb{CP}^1$ by $U_0 = \{z \neq \infty\}$ and $U_1 = \{z \neq 0\}$, with $U_0 \cap U_1 = \mathbb{C}^\times$. A Čech 1-cochain is a holomorphic function h on $\mathbb{C}^\times$, i.e. a Laurent series. It is a coboundary if $h = f_0 - f_1$ with f_0 holomorphic on U_0 (a power series in z) and f_1 holomorphic on U_1 (a power series in $w = 1/z$, i.e. in non-positive powers of z). Every Laurent series splits this way:

$$h(z) \overset{(1)}{=} \sum_{k\in\mathbb{Z}} h_k z^k \overset{(2)}{=} \underbrace{\sum_{k\geq 0} h_k z^k}_{f_0,\ \text{hol. on } U_0} \; - \; \underbrace{\Big(-\sum_{k\geq 1} h_{-k} w^k\Big)}_{f_1,\ \text{hol. on } U_1}.$$

(1) Laurent expansion on the annulus $\mathbb{C}^\times$.
(2) Split into non-negative and negative powers; $z^{-k} = w^k$.

So every 1-cochain is a coboundary and $H^1(\mathbb{CP}^1;\mathcal{O}) = 0$. With only two open sets there are no 2-cochains, so $H^2(\mathbb{CP}^1;\mathcal{O}) = 0$ too. By (6.154), $H^1(\mathbb{CP}^1;\mathcal{O}^*) \cong H^2(\mathbb{CP}^1;\mathbb{Z}) = \mathbb{Z}$: holomorphic line bundles on $\mathbb{CP}^1$ are classified by one integer, the degree. The holomorphic

structure on L_{λ_n} is unique, and the bundle is $\mathcal{O}(n)$.

The theorem

Key idea: the Borel–Weil theorem (Nash, p. 189)

Let G be compact and connected, T a maximal torus, and $\lambda : T \to \mathrm{U}(1)$ a weight. The space $\Gamma(G/T, \mathcal{O}(L_\lambda))$ of holomorphic sections of the line bundle L_λ is nonzero if and only if λ is the highest weight of an irreducible representation (i.e. λ is dominant). In that case

$$\Gamma(G/T, \mathcal{O}(L_\lambda)) \;\cong\; V_\lambda$$

as representations of G (acting by left translation). Every irreducible representation of G arises this way, exactly once.

The rest of this subsection makes the theorem plausible in two ways: by an explicit computation for SU(2), and by a general argument (Nash's) that uses the Lie algebra and the Peter–Weyl theorem.

The theorem for SU(2), completely explicit

The holomorphicity condition as a differential equation. By Example 6.48, a section of L_{λ_n} is an equivariant function f on S^3. On the region $u_2 \neq 0$ define

$$F := \frac{f}{u_2^n}.$$

Under $u \to e^{-i\phi}u$ both f and u_2^n get the factor $e^{-in\phi}$, so F is invariant: it is a function on the base, $F = F(z, \bar{z})$. Therefore

$$f(u, \bar{u}) = u_2^n \, F(z, \bar{z}), \qquad z = \frac{u_1}{u_2}. \tag{6.156}$$

The section is **holomorphic** when F is a holomorphic function of the complex coordinate z: $\partial_{\bar{z}} F = 0$. This is the Cauchy–Riemann equation. (Replacing u_2^n by any other nowhere-zero holomorphic local section gives the same condition, because the ratio of two such is holomorphic.)

The holomorphic sections are polynomials. Let f be holomorphic. On $u_2 \neq 0$, $F(z)$ is holomorphic in all of $\mathbb{C}$, so it has a convergent power series $F(z) = \sum_{k \geq 0} a_k z^k$. On the other patch $u_1 \neq 0$ use $w = u_2/u_1 = 1/z$ and the local section u_1^n:

$$f \overset{(1)}{=} u_2^n F(z) \overset{(2)}{=} u_1^n \, w^n F(1/w) \overset{(3)}{=} u_1^n \sum_{k \geq 0} a_k \, w^{\,n-k}.$$

(1) (6.156).
(2) $u_2 = u_1 w$ and $z = 1/w$.
(3) The power series of F.

Holomorphy at $w = 0$ (the point $z = \infty$) requires every exponent $n - k$ to be ≥ 0: $a_k = 0$ for $k > n$. Hence

$$f = u_2^n \sum_{k=0}^{n} a_k \left(\frac{u_1}{u_2}\right)^k = \sum_{k=0}^{n} a_k \, u_1^k u_2^{n-k}, \qquad \dim \Gamma(\mathbb{CP}^1, \mathcal{O}(n)) = \begin{cases} n+1, & n \geq 0, \\ 0, & n < 0. \end{cases} \tag{6.157}$$

The holomorphic sections of L_{λ_n} are exactly the homogeneous polynomials of degree n in (u_1, u_2). For $n < 0$ the conditions leave nothing: there are no holomorphic sections, in agreement with the theorem (λ_n is dominant iff $n \geq 0$).

The group action. We now show that these $n+1$ polynomials carry spin $j = n/2$. Let G act by $(U(h)f)(g) = f(h^{-1}g)$; the second column of $h^{-1}g$ is $h^{-1}u$. With the physicists' convention $U(e^{-i\theta\sigma^a/2}) = e^{-i\theta J^a}$, the generators are

$$J^a f := i\,\frac{\mathrm{d}}{\mathrm{d}\theta}\, f\big(e^{i\theta\sigma^a/2}g\big)\Big|_{\theta=0}.$$

For $a = 3$, $e^{i\theta\sigma^3/2}$ multiplies u_1 by $e^{i\theta/2}$ and u_2 by $e^{-i\theta/2}$:

$$J^3 f \overset{(1)}{=} i\,\frac{\mathrm{d}}{\mathrm{d}\theta}\, f\big(e^{i\theta/2}u_1,\, e^{-i\theta/2}u_2\big)\Big|_0 \overset{(2)}{=} i\cdot\frac{i}{2}\big(u_1\partial_1 - u_2\partial_2\big)f = \tfrac{1}{2}\big(u_2\partial_2 - u_1\partial_1\big)f,$$

(1) The second column of $e^{i\theta\sigma^3/2}g$.
(2) Chain rule, with $\partial_i = \partial/\partial u_i$ (f is holomorphic, so it does not depend on $\bar u$).

For the ladder operators combine $J^\pm = J^1 \pm iJ^2$. Since J^a is linear in σ^a, J^+ is obtained by the same formula with $\sigma^a/2$ replaced by $\sigma^+ = \tfrac{1}{2}(\sigma^1 + i\sigma^2) = \left(\begin{smallmatrix}0&1\\0&0\end{smallmatrix}\right)$ (legitimate on holomorphic f, which extend to $\mathrm{SL}(2,\mathbb{C})$):

$$J^+ f \overset{(1)}{=} i\,\frac{\mathrm{d}}{\mathrm{d}s}\, f\big(u_1 + is\,u_2,\, u_2\big)\Big|_0 \overset{(2)}{=} i\cdot i\,u_2\,\partial_1 f = -u_2\,\partial_1 f,$$

(1) $e^{is\sigma^+} = \mathbb{1} + is\sigma^+$ adds is times the second row to the first, so $u_1 \to u_1 + isu_2$.
(2) Chain rule.

and in the same way (σ^- adds is times the first row to the second) $J^- f = -u_1\,\partial_2 f$. Collecting:

$$J^3 = \tfrac{1}{2}\big(u_2\partial_2 - u_1\partial_1\big), \qquad J^+ = -u_2\,\partial_1, \qquad J^- = -u_1\,\partial_2. \tag{6.158}$$

These are the Schwinger–Jordan ("two-oscillator") realisation of angular momentum. Check one relation:

$$[J^+, J^-] \overset{(1)}{=} [u_2\partial_1,\, u_1\partial_2] \overset{(2)}{=} u_2\partial_2 - u_1\partial_1 \overset{(3)}{=} 2J^3.$$

(1) The two minus signs cancel.
(2) $[u_2\partial_1, u_1\partial_2] = u_2[\partial_1, u_1]\partial_2 + u_1[u_2,\partial_2]\partial_1 = u_2\partial_2 - u_1\partial_1$.
(3) (6.158).

On a monomial,

$$J^3\, u_1^{j-m}u_2^{j+m} = \tfrac{1}{2}\big((j+m) - (j-m)\big)u_1^{j-m}u_2^{j+m} = m\,u_1^{j-m}u_2^{j+m},$$

so with $n = 2j$ the monomials $u_1^{j-m}u_2^{j+m}$, $m = -j, \dots, j$, are the J^3 eigenstates. The top one, u_2^n, is killed by $J^+ = -u_2\partial_1$: it is the highest-weight vector, with weight λ_n. The space (6.157) is V_{λ_n}, spin $n/2$. This is the Borel–Weil theorem for SU(2).

The inner product. The representation is unitary for the L^2 inner product on $\mathrm{SU}(2) = S^3$ with the normalised round (Haar) measure $\mathrm{d}\mu$, which is invariant under left and right multiplication. The norms of the monomials follow from a Gaussian trick. On $\mathbb{C}^2$, with d^4u the Lebesgue measure,

$$\begin{aligned} p!\,q! &\overset{(1)}{=} \int_{\mathbb{C}^2} |u_1|^{2p}\,|u_2|^{2q}\; e^{-|u|^2}\,\frac{\mathrm{d}^4u}{\pi^2} \\ &\overset{(2)}{=} \frac{2\pi^2}{\pi^2}\int_0^\infty r^{2(p+q)+3}e^{-r^2}\,\mathrm{d}r \int_{S^3} |u_1|^{2p}\,|u_2|^{2q}\,\mathrm{d}\mu \\ &\overset{(3)}{=} (p+q+1)!\int_{S^3} |u_1|^{2p}\,|u_2|^{2q}\,\mathrm{d}\mu. \end{aligned} \tag{6.159}$$

(1) The integral factorises into two copies of $\int_{\mathbb{C}} |w|^{2p}\, e^{-|w|^2} \frac{\mathrm{d}^2 w}{\pi} = \int_0^\infty \rho^{2p} e^{-\rho^2}\, 2\rho\, \mathrm{d}\rho = p!$.
(2) Polar coordinates $u = r\hat{u}$ in $\mathbb{R}^4$: $\mathrm{d}^4 u = r^3 \mathrm{d}r\, \mathrm{d}\Omega_3$ with $\int \mathrm{d}\Omega_3 = 2\pi^2$, so $\mathrm{d}\Omega_3 = 2\pi^2\, \mathrm{d}\mu$.
(3) $\int_0^\infty r^{2N+3} e^{-r^2} \mathrm{d}r = \frac{1}{2}\Gamma(N+2) = \frac{1}{2}(N+1)!$ with $N = p + q$.

So $\left\| u_1^p u_2^q \right\|^2 = \frac{p!\, q!}{(p+q+1)!}$, and distinct monomials are orthogonal (integrate over the phases of u_1 and u_2). The orthonormal basis, with the Condon–Shortley phases, is

$$|j, m\rangle \longleftrightarrow e_m \coloneqq (-1)^{j-m} \sqrt{\frac{(2j+1)!}{(j-m)!\,(j+m)!}}\; u_1^{j-m} u_2^{j+m}, \tag{6.160}$$

and (6.158) gives the textbook matrix elements, e.g. $J^+ e_m = \sqrt{(j-m)(j+m+1)}\, e_{m+1}$. (The sign $(-1)^{j-m}$ absorbs the minus sign in $J^+ = -u_2 \partial_1$.)

Worked example 6.51: spin one as quadratic polynomials

Take $n = 2$, $j = 1$. By (6.160)

$$e_1 = \sqrt{3}\, u_2^2, \qquad e_0 = -\sqrt{6}\, u_1 u_2, \qquad e_{-1} = \sqrt{3}\, u_1^2.$$

Their norms are $3 \cdot \frac{0!\,2!}{3!} = 1$, $6 \cdot \frac{1!\,1!}{3!} = 1$, and $3 \cdot \frac{2!\,0!}{3!} = 1$. Apply $J^+ = -u_2 \partial_1$:

$$J^+ e_{-1} \overset{(1)}{=} \sqrt{3}\,(-u_2)(2u_1) = -2\sqrt{3}\, u_1 u_2 \overset{(2)}{=} \sqrt{2}\, e_0,$$
$$J^+ e_0 \overset{(3)}{=} -\sqrt{6}\,(-u_2)\, u_2 = \sqrt{6}\, u_2^2 \overset{(4)}{=} \sqrt{2}\, e_1, \qquad J^+ e_1 \overset{(5)}{=} 0.$$

(1) $\partial_1 u_1^2 = 2u_1$.
(2) $\sqrt{2}\, e_0 = -\sqrt{12}\, u_1 u_2 = -2\sqrt{3}\, u_1 u_2$.
(3) $\partial_1 (u_1 u_2) = u_2$.
(4) $\sqrt{2}\, e_1 = \sqrt{6}\, u_2^2$.
(5) u_2^2 does not depend on u_1.

In the basis (e_1, e_0, e_{-1}),

$$J^3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}, \qquad J^+ = \begin{pmatrix} 0 & \sqrt{2} & 0 \\ 0 & 0 & \sqrt{2} \\ 0 & 0 & 0 \end{pmatrix}, \qquad J^- = (J^+)^T,$$

the standard spin-one matrices, and $[J^+, J^-] = \mathrm{diag}(2, 0, -2) = 2J^3$. Three holomorphic sections of the monopole bundle of charge 1 are a vector of SO(3). For $n = 1$ the two sections $\sqrt{2}\, u_2$ and $-\sqrt{2}\, u_1$ are a spinor. The half-integer spins appear because the element $-\mathbb{1} = t_\pi \in T$ acts on sections of L_{λ_n} by $f(-u) = (-1)^n f(u)$: for odd n the rotation by 2π is -1, so only SU(2), not SO(3), acts.

Where the states live. A section does not have a value in $\mathbb{C}$ at a point, but its length $|f(u)|^2$ is a function on S^2 (it is invariant under $u \to e^{-i\phi} u$). For the basis (6.160), parametrise the point by $z = \tan\frac{\vartheta}{2}\, e^{i\varphi}$, so that $|u_1| = \sin\frac{\vartheta}{2}$ and $|u_2| = \cos\frac{\vartheta}{2}$. Then

$$\sum_{m=-j}^{j} |e_m|^2 \overset{(1)}{=} (2j+1) \sum_m \binom{2j}{j-m} \left(\sin^2\tfrac{\vartheta}{2}\right)^{j-m} \left(\cos^2\tfrac{\vartheta}{2}\right)^{j+m} \overset{(2)}{=} (2j+1) \left(\sin^2\tfrac{\vartheta}{2} + \cos^2\tfrac{\vartheta}{2}\right)^{2j} = 2j+1. \tag{6.161}$$

(1) (6.160): $\frac{(2j+1)!}{(j-m)!(j+m)!} = (2j+1)\binom{2j}{j-m}$.

(2) The binomial theorem.

The total density is uniform over the sphere, as rotational invariance demands (the analogue of Unsöld's theorem $\sum_m |Y_{lm}|^2 = \frac{2l+1}{4\pi}$). The individual states are rings: $|e_m|^2 \propto \sin^{2(j-m)}\frac{\vartheta}{2}\cos^{2(j+m)}\frac{\vartheta}{2}$ peaks where $\cos\vartheta = m/j$, the latitude at which a classical spin of length j has z-component m (Figure 6.30).

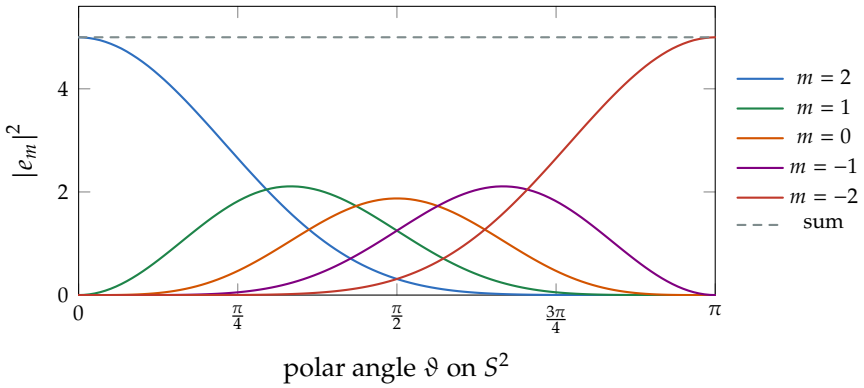

Figure 6.30: The holomorphic sections of $O(4)$ over S^2, the spin-2 representation, drawn as densities $|e_m|^2$ against the polar angle. Each state is a ring around the z-axis, peaked at $\cos\vartheta = m/j$, where a classical spin of length $j = 2$ has $J^3 = m$; the highest-weight state $e_2 = \sqrt{5}\,u_2^4$ sits at the north pole $z = 0$. The sum (dashed) is the constant $2j + 1 = 5$ (6.161).

Physical picture: the lowest Landau level and the quantisation of a spin

Put a charged particle on a sphere around a magnetic monopole with n flux quanta. Its wavefunctions are sections of L_{λ_n} (Example 6.48), and its Hamiltonian is the covariant Laplacian. The states of lowest energy (the **lowest Landau level**) are exactly the holomorphic sections, just as in the plane the lowest Landau level consists of $\psi = F(z)\,e^{-|z|^2/4\ell_B^2}$ with F holomorphic. So:

- the degeneracy of the lowest Landau level is $n + 1$ = (number of flux quanta) +1, which is (6.157) and also the Riemann–Roch / index theorem index $\bar\partial$ = deg +1 on $\mathbb{CP}^1$ (Chapter 4);
- the rotations act on it with spin $j = n/2$, which is the known result that a charge in a monopole field has total angular momentum at least $|eg| = n/2$;
- as $n \to \infty$ at fixed radius the states become sharply localised rings (Figure 6.30), i.e. classical.

Read backwards: the sphere with the area form $n\,\omega$ is the classical phase space of a spin, $\vec S \in \mathbb{R}^3$ with $\left|\vec S\right| = n/2$. The Borel–Weil space is its quantisation, with "holomorphic" playing the role of "functions of q only" and the number of states equal to $\frac{1}{2\pi}\int n\,\omega + 1$ (phase-space area over $2\pi\hbar$, plus a quantum correction). This is **geometric quantisation**, and Borel–Weil is its founding example.

Worked example 6.52: $SU(3)$ **and the flag manifold**

For $G = \mathrm{SU}(3)$, $G/T = G_{\mathbb{C}}/B$ is the space of flags $\ell \subset P \subset \mathbb{C}^3$, a line inside a plane. Record the line by a nonzero vector $x \in \mathbb{C}^3$ (up to scale) and the plane by its normal covector p (up

to scale), with $P = \{v : \ p \cdot v = 0\}$. The condition $\ell \subset P$ is

$$p \cdot x = p_1 x^1 + p_2 x^2 + p_3 x^3 = 0, \tag{6.162}$$

so the flag manifold is the hypersurface (6.162) in $\mathbb{CP}^2 \times \mathbb{CP}^{2*}$, of complex dimension $2 + 2 - 1 = 3$ (real dimension $6 = 8 - 2$, as it should be).
The weights are now pairs of integers (a, b), and the holomorphic sections of the line bundle $L_{(a,b)}$ are the polynomials of degree a in x and b in p, modulo the relation (6.162). Count them. There are $\binom{a+2}{2}$ monomials of degree a in three variables. Multiples of $p \cdot x$ in bidegree (a, b) are $p \cdot x$ times an arbitrary polynomial of bidegree $(a - 1, b - 1)$. So

$$\dim \Gamma(L_{(a,b)}) \overset{(1)}{=} \binom{a+2}{2}\binom{b+2}{2} - \binom{a+1}{2}\binom{b+1}{2} \overset{(2)}{=} \tfrac{1}{2}(a+1)(b+1)(a+b+2).$$

(1) All bihomogeneous polynomials, minus the multiples of $p \cdot x$ (multiplication by $p \cdot x$ is injective on polynomials).
(2) Algebra: $\frac{1}{4}(a+1)(b+1)\big[(a+2)(b+2) - ab\big] = \frac{1}{4}(a+1)(b+1)(2a+2b+4)$.

This is the Weyl dimension formula for SU(3). Check: $(1, 0)$ gives 3 and $(0, 1)$ gives 3 (the coordinates x^i and p_i: the two three-dimensional representations **3** and $\bar{\mathbf{3}}$), $(1, 1)$ gives $9 - 1 = 8$ (all $x^i p_j$ minus the trace $p \cdot x$: the octet), $(2, 0)$ gives 6 and $(3, 0)$ gives 10 (the decuplet). The quark model is a list of holomorphic sections over the flag manifold. For $a < 0$ or $b < 0$ there are no polynomials and no sections, which is the "only if" half of the theorem.

6.3.11 The complex structure of G/T from the Lie algebra

Step 4 gave G/T its complex structure through the identification $G/T = G_{\mathbb{C}}/B$. That is quick, but it hides the answer to a simple question: standing at a point of G/T, which tangent directions are the "holomorphic" ones, and which are their complex conjugates? Nash answers it directly with the Lie algebra (his (6.66)–(6.68)). The answer is the same one a physicist uses every day for angular momentum: split the generators into Cartan generators, raising operators and lowering operators.

The tangent space of G/T

Let $o = eT$ be the base point of G/T. A curve through o is $s \mapsto e^{sX}T$ with $X \in \mathfrak{g}$. If $X \in \mathfrak{t}$, then $e^{sX} \in T$ and the curve does not move. So the tangent space is

$$T_o(G/T) = \mathfrak{g}/\mathfrak{t}.$$

It is convenient to pick a complement of $\mathfrak{t}$ inside $\mathfrak{g}$. Nash's (6.66) is

$$\mathfrak{g} = \mathfrak{t} \oplus \mathfrak{h}, \tag{6.163}$$

where $\mathfrak{h}$ is the orthogonal complement of $\mathfrak{t}$ for the inner product $\langle X, Y\rangle = -\operatorname{tr}(XY)$. Then $T_o(G/T) \cong \mathfrak{h}$ and $\dim G/T = \dim \mathfrak{h} = \dim G - \operatorname{rank} G$. (Here and below $\mathfrak{g}$ means the real Lie algebra of *anti-Hermitian* matrices, the mathematicians' convention of Chapter T3; a physicist's Hermitian generator J corresponds to $iJ \in \mathfrak{g}$.)

Worked example 6.53: the splitting for SU(2) and SU(3)

For SU(2), $\mathfrak{g} = \mathrm{span}_{\mathbb{R}}\{i\sigma^1, i\sigma^2, i\sigma^3\}$, the torus (6.147) has $\mathfrak{t} = \mathrm{span}_{\mathbb{R}}\{i\sigma^3\}$, and $\mathfrak{h} = \mathrm{span}_{\mathbb{R}}\{i\sigma^1, i\sigma^2\}$: two directions, the tangent plane of S^2.
For SU(3), $\mathfrak{t}$ is the traceless diagonal matrices $\mathrm{diag}(i\theta_1, i\theta_2, i\theta_3)$ with $\theta_1 + \theta_2 + \theta_3 = 0$ (two real parameters), and $\mathfrak{h}$ is the off-diagonal anti-Hermitian matrices, fixed by three complex numbers a_{12}, a_{13}, a_{23} above the diagonal (six real parameters). So $\dim G/T = 6$, the flag manifold of Example 6.52.

The torus rotates $\mathfrak{h}$: root spaces

Why does Nash call $\mathfrak{h}$ "the sum of the root spaces"? Because the torus acts on $\mathfrak{g}$ by conjugation, $\mathrm{Ad}(t)X = tXt^{-1}$, and this action fixes $\mathfrak{t}$ pointwise and *rotates* $\mathfrak{h}$. For SU(2),

$$t_\phi\,\sigma^1\,t_\phi^{-1} \overset{(1)}{=} \begin{pmatrix} 0 & e^{2i\phi} \\ e^{-2i\phi} & 0 \end{pmatrix} \overset{(2)}{=} \cos 2\phi\;\sigma^1 - \sin 2\phi\;\sigma^2,$$
$$t_\phi\,\sigma^2\,t_\phi^{-1} \overset{(3)}{=} \begin{pmatrix} 0 & -ie^{2i\phi} \\ ie^{-2i\phi} & 0 \end{pmatrix} \overset{(4)}{=} \sin 2\phi\;\sigma^1 + \cos 2\phi\;\sigma^2.$$

(1) Conjugating by $\mathrm{diag}(e^{i\phi}, e^{-i\phi})$ multiplies the $(1,2)$ entry by $e^{i\phi}\cdot e^{i\phi}$ and the $(2,1)$ entry by $e^{-i\phi}\cdot e^{-i\phi}$.
(2) Compare entries: $\cos 2\phi\,\sigma^1 - \sin 2\phi\,\sigma^2$ has $(1,2)$ entry $\cos 2\phi + i\sin 2\phi = e^{2i\phi}$.
(3) The same rule applied to σ^2, whose $(1,2)$ entry is $-i$.
(4) $(1,2)$ entry of the right side: $\sin 2\phi - i\cos 2\phi = -ie^{2i\phi}$.

So $\mathrm{Ad}(t_\phi)$ turns the plane $\mathfrak{h}$ by the angle -2ϕ. A real rotation has no real eigenvectors, but it has complex ones. That is why Nash complexifies, (6.67):

$$\mathfrak{g}_{\mathbb{C}} = \mathfrak{t}_{\mathbb{C}} \oplus \mathfrak{h}_{\mathbb{C}}. \tag{6.164}$$

In $\mathfrak{h}_{\mathbb{C}}$ the eigenvectors of the rotation are the familiar step operators

$$\sigma^{\pm} = \tfrac{1}{2}(\sigma^1 \pm i\sigma^2), \qquad \sigma^+ = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad \sigma^- = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix},$$

and by the rule in item (1),

$$\mathrm{Ad}(t_\phi)\,\sigma^{\pm} = e^{\pm 2i\phi}\,\sigma^{\pm} = \lambda_{\pm 2}(t_\phi)\,\sigma^{\pm}. \tag{6.165}$$

The eigenvalues are weights, in the sense of Step 1, of the adjoint representation: they are $\lambda_{\pm 2}$, the two nonzero weights of spin 1. These weights of the adjoint representation are the **roots**. Nash's (6.68) splits $\mathfrak{h}_{\mathbb{C}}$ into positive and negative root spaces:

$$\mathfrak{g}_{\mathbb{C}} = \mathfrak{t}_{\mathbb{C}} \oplus \mathfrak{h}^+ \oplus \mathfrak{h}^-, \qquad \mathfrak{h}^+ = \mathbb{C}\sigma^+, \quad \mathfrak{h}^- = \mathbb{C}\sigma^-. \tag{6.166}$$

Working definition 6.26 (roots and a choice of positive roots)

Diagonalise $\mathrm{Ad}(T)$ [conjugation $X \mapsto tXt^{-1}$ by each element t of the torus] on $\mathfrak{g}_{\mathbb{C}}$. The eigenvectors outside $\mathfrak{t}_{\mathbb{C}}$ are the **step operators** E_α, with $\mathrm{Ad}(t)E_\alpha = \alpha(t)E_\alpha$; the characters α [homomorphisms $T \to \mathrm{U}(1)$, exactly as for weights in Step 1] are the **roots**. They come in pairs $\pm\alpha$ (complex conjugation swaps E_α and $E_{-\alpha}$ up to sign). *How to choose the positive ones:* draw a line (a hyperplane) through the origin of the weight space [$\mathbb{R}^r$, with each weight recorded by its vector of integers $(n_1, \ldots, n_r)$] that contains no root, and call positive the

roots on one side of it. The choice is a **Weyl chamber**. Then $\mathfrak{h}^{\pm}$ is spanned by the $E_{\pm\alpha}$ with $\alpha > 0$. For SU(N) with the usual choice, $\mathfrak{h}^{+}$ is the strictly upper-triangular and $\mathfrak{h}^{-}$ the strictly lower-triangular matrices.

For SU(3) the step operators are the matrix units E_{ij}, $i \neq j$ (a 1 in row i, column j). Conjugation by $t = \operatorname{diag}(e^{i\theta_1}, e^{i\theta_2}, e^{i\theta_3})$ gives $\operatorname{Ad}(t)E_{ij} = e^{i(\theta_i-\theta_j)}E_{ij}$, so the roots are $\theta_i - \theta_j$. Name the two **simple roots** $\alpha_1 = \theta_1 - \theta_2$ and $\alpha_2 = \theta_2 - \theta_3$; then $\theta_1 - \theta_3 = \alpha_1 + \alpha_2$. The six roots form a hexagon (Figure 6.31), and the upper-triangular choice is

$$\mathfrak{h}^{+} = \operatorname{span}\{E_{12}, E_{23}, E_{13}\} \quad \longleftrightarrow \quad \{\alpha_1,\ \alpha_2,\ \alpha_1 + \alpha_2\}.$$

Notice that $\mathfrak{t}_{\mathbb{C}} \oplus \mathfrak{h}^{-}$ is the lower-triangular matrices: the Lie algebra $\mathfrak{b}$ of the Borel subgroup B of Step 4. This is the link between Nash's two descriptions of the complex structure.

The holomorphic directions

Now Nash's prescription: *declare the directions in $\mathfrak{h}^{+}$ to be the holomorphic ones.* More precisely, the complexified tangent space at o is $\mathfrak{h}_{\mathbb{C}} = \mathfrak{h}^{+} \oplus \mathfrak{h}^{-}$, and we declare

$$T_o^{1,0}(G/T) = \mathfrak{h}^{+}, \qquad T_o^{0,1}(G/T) = \mathfrak{h}^{-}.$$

Then move this choice to every other point gT by the left translation $g : G/T \to G/T$. The result is well defined because the only ambiguity in the translating element is $g \to gt$, and $\operatorname{Ad}(t)$ maps $\mathfrak{h}^{+}$ to itself by (6.165). A split of the complexified tangent spaces of this kind is the same thing as an **almost complex structure** J, a linear map on each real tangent space with $J^2 = -1$: the $(1,0)$ vectors are $v - iJv$ and the $(0,1)$ vectors are $v + iJv$.

Worked example 6.54: the rule reproduces $z = u_1/u_2$

Take SU(2) and the coordinate $z = g_{12}/g_{22}$ of Example 6.49, which is 0 at o. Move away from o along the two real directions of $\mathfrak{h}$:

$$e^{s\,i\sigma^2} \overset{(1)}{=} \begin{pmatrix} \cos s & \sin s \\ -\sin s & \cos s \end{pmatrix} \qquad \Longrightarrow \quad z = \tan s \approx s,$$

$$e^{s\,i\sigma^1} \overset{(2)}{=} \begin{pmatrix} \cos s & i\sin s \\ i\sin s & \cos s \end{pmatrix} \qquad \Longrightarrow \quad z = i\tan s \approx is.$$

(1) $(i\sigma^2)^2 = -\mathbb{1}$, so $e^{s\,i\sigma^2} = \cos s\,\mathbb{1} + \sin s\,i\sigma^2$, and $i\sigma^2 = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$.

(2) The same with $i\sigma^1 = \left(\begin{smallmatrix} 0 & i \\ i & 0 \end{smallmatrix}\right)$.

So $X_2 = i\sigma^2$ points along the real z-axis and $X_1 = i\sigma^1$ along the imaginary axis. Multiplication by i turns the first into the second, so the complex structure is $JX_2 = X_1$ (and $JX_1 = -X_2$). The $(1,0)$ vector built from X_2 is

$$X_2 - iJX_2 = i\sigma^2 - i\,(i\sigma^1) = \sigma^1 + i\sigma^2 = 2\sigma^{+} \in \mathfrak{h}^{+},$$

exactly as Nash prescribes. Conversely, moving along the complex direction $\sigma^{\pm}$ with a complex parameter s:

$$z\big(e^{s\sigma^{+}}\big) \overset{(1)}{=} \frac{s}{1} = s, \qquad z\big(e^{s\sigma^{-}}\big) \overset{(2)}{=} \frac{0}{1} = 0.$$

(1) $e^{s\sigma^{+}} = \left(\begin{smallmatrix} 1 & s \\ 0 & 1 \end{smallmatrix}\right)$, whose second column is $(s, 1)$.

(2) $e^{s\sigma^{-}} = \left(\begin{smallmatrix} 1 & 0 \\ s & 1 \end{smallmatrix}\right) \in B$ does not move the point o at all.

The step operator σ^{+} moves z holomorphically ($z = s$); the step operator σ^{-} lies in $\mathfrak{b}$ and does nothing to the point.

Integrability: why $\mathfrak{b}^+$ must be closed under brackets

An almost complex structure need not come from complex coordinates. It does exactly when the $(0,1)$ vector fields are closed under the Lie bracket (the **Newlander–Nirenberg theorem**). The necessity of this condition is a one-line physicist's argument. A holomorphic function f is one that is killed by every $(0,1)$ vector field, $\bar{Z}f = 0$. If $\bar{Z}$ and $\bar{W}$ kill f, so does their commutator:

$$[\bar{Z}, \bar{W}]f = \bar{Z}(\bar{W}f) - \bar{W}(\bar{Z}f) = 0.$$

If $[\bar{Z}, \bar{W}]$ had a $(1,0)$ part, the holomorphic functions would be killed by some holomorphic derivative as well, and there would not be enough of them to serve as local coordinates. (The sufficiency is the hard half of the theorem, and we take it on trust.)

For the invariant structure on G/T the $(0,1)$ directions are generated by $\mathfrak{b}^-$ (together with $\mathfrak{t}_{\mathbb{C}}$, which does not move the point), so the condition is that $\mathfrak{b} = \mathfrak{t}_{\mathbb{C}} \oplus \mathfrak{b}^-$ be closed under brackets. Complex conjugation swaps $\mathfrak{b}^+$ and $\mathfrak{b}^-$, so this is the same as Nash's statement that $\mathfrak{b}^+$ is closed. It holds because of how roots add:

$$\mathrm{Ad}(t)\,[E_\alpha, E_\beta] \overset{(1)}{=} [\mathrm{Ad}(t)E_\alpha,\ \mathrm{Ad}(t)E_\beta] \overset{(2)}{=} \alpha(t)\,\beta(t)\,[E_\alpha, E_\beta]. \tag{6.167}$$

(1) Conjugation is a Lie algebra automorphism: $t[X,Y]t^{-1} = [tXt^{-1}, tYt^{-1}]$.
(2) Each E is an eigenvector.

So $[E_\alpha, E_\beta]$ has root $\alpha + \beta$ (in additive notation), or vanishes if $\alpha + \beta$ is not a root. If α and β lie on the positive side of the chosen line, so does $\alpha + \beta$. Hence $[\mathfrak{b}^+, \mathfrak{b}^+] \subset \mathfrak{b}^+$. For SU(3) the only nonzero bracket among the positive step operators is

$$[E_{12}, E_{23}] = E_{12}E_{23} - E_{23}E_{12} = E_{13} - 0 = E_{13},$$

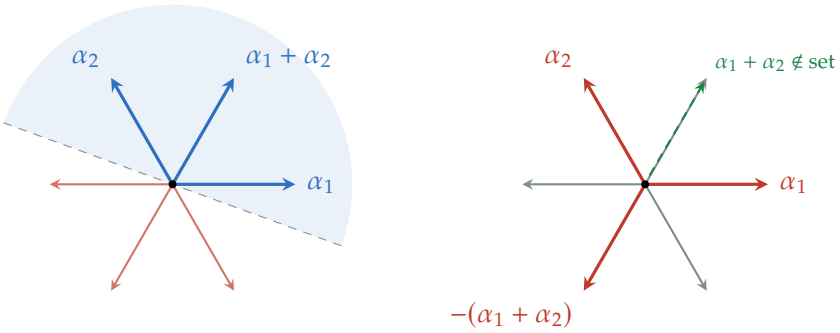
which is root addition $\alpha_1 + \alpha_2$.

Worked example 6.55: an almost complex structure that is not integrable

For SU(3) there are three pairs of roots, so there are $2^3 = 8$ ways to pick one root from each pair and call its step operator "holomorphic". Each choice gives a G-invariant almost complex structure on the flag manifold. Which are integrable? Write the choice as $\{\epsilon_1\alpha_1,\ \epsilon_2\alpha_2,\ \epsilon_3(\alpha_1+\alpha_2)\}$ with signs $\epsilon_i = \pm$. The set must contain the sum of any two of its members whenever that sum is a root. Checking the three possible sums:

- $\epsilon_1\alpha_1 + \epsilon_2\alpha_2$ is a root only if $\epsilon_1 = \epsilon_2$, and then it is $\epsilon_1(\alpha_1+\alpha_2)$: we need $\epsilon_3 = \epsilon_1$;
- $\epsilon_1\alpha_1 + \epsilon_3(\alpha_1+\alpha_2)$ is a root only if $\epsilon_3 = -\epsilon_1$, and then it is $\epsilon_3\alpha_2$: we need $\epsilon_2 = \epsilon_3$;
- $\epsilon_2\alpha_2 + \epsilon_3(\alpha_1+\alpha_2)$ is a root only if $\epsilon_3 = -\epsilon_2$, and then it is $\epsilon_3\alpha_1$: we need $\epsilon_1 = \epsilon_3$.

Run through the eight sign patterns: the only failures are $(+,+,-)$ and $(-,-,+)$, i.e. the choices $\{\alpha_1, \alpha_2, -(\alpha_1+\alpha_2)\}$ and its negative. The other six are the six Weyl chambers (the Weyl group of SU(3) is the permutation group S_3, of order 6), and they all give integrable structures, isomorphic to each other by a permutation of the coordinates of $\mathbb{C}^3$. For the bad choice, $[E_{12}, E_{23}] = E_{13}$ is *not* in $\mathrm{span}\{E_{12}, E_{23}, E_{31}\}$: the almost complex structure is not integrable, and there are no holomorphic coordinates adapted to it. Geometrically (Figure 6.31): the three chosen roots sum to zero, so they cannot all lie on one side of a line.



a Weyl chamber:
$\mathfrak{b}^+$ closed, integrable

three roots summing to zero:
not closed, not integrable

Figure 6.31: The six roots of SU(3). Left: the upper-triangular choice $\mathfrak{b}^+ = \{\alpha_1, \alpha_2, \alpha_1 + \alpha_2\}$ (blue) lies on one side of the dashed line; sums of blue roots stay blue, so $\mathfrak{b}^+$ is closed under brackets and the complex structure on the flag manifold is integrable. Right: the choice $\{\alpha_1, \alpha_2, -(\alpha_1 + \alpha_2)\}$ (red) cannot be put on one side of any line; the bracket of the first two produces $\alpha_1 + \alpha_2$ (green), which is not in the set, so this almost complex structure has no holomorphic coordinates.

Watch out: two meanings of "$\mathfrak{b}$"

Nash's $\mathfrak{b}$ in (6.66) is the complement of the Cartan subalgebra, not the Cartan subalgebra itself (which many physics texts call $\mathfrak{b}$). Here the Cartan subalgebra is $\mathfrak{t}$, and $\mathfrak{b}$ is the span of the step operators.

6.3.12 The Peter–Weyl theorem: Fourier analysis on a group

To prove the Borel–Weil theorem Nash uses a second big theorem, which answers the question: *how do we Fourier-analyse a function on a compact group?* For the circle the answer is Fourier series. The Peter–Weyl theorem is the same statement for any compact G, with the exponentials $e^{in\theta}$ replaced by matrix elements of irreducible representations, the Wigner D-functions of angular momentum theory.

Left and right translations

The group acts on functions on itself in two commuting ways:

$$(L_h f)(g) := f(h^{-1}g), \qquad (R_h f)(g) := f(gh). \tag{6.168}$$

Both are representations: $L_h L_{h'} = L_{hh'}$ (this is why h^{-1} appears) and $(R_h R_{h'} f)(g) = (R_{h'} f)(gh) = f(ghh') = (R_{hh'} f)(g)$. Both are unitary on $L^2(G)$ with the Haar measure $\mathrm{d}\mu$, which is invariant under left and right multiplication (for SU(2) $= S^3$ it is the round measure). The infinitesimal version of R is the derivative along a Lie algebra element,

$$(R_X f)(g) := \frac{\mathrm{d}}{\mathrm{d}s} f\left(g\, e^{sX}\right)\Big|_{s=0}, \tag{6.169}$$

extended complex-linearly to $X \in \mathfrak{g}_{\mathbb{C}}$, $R_{X+iY} := R_X + iR_Y$. Nash's (6.69) is the decomposition of $L^2(G)$ under R into irreducibles,

$$L^2(G) = \bigoplus_{\lambda} c_\lambda\, V_\lambda,$$

with multiplicities c_λ. The theorem says what they are.

Matrix coefficients

Given a finite-dimensional representation V, a vector $v \in V$ and a covector $\xi \in V^*$ (a linear function on V), define the **matrix coefficient**

$$f_{\xi,v}(g) := \xi\big(g^{-1}v\big). \tag{6.170}$$

In a basis, with ξ the i-th dual basis vector and v the j-th basis vector, $f_{\xi,v}(g) = D(g^{-1})_{ij}$: one entry of the representation matrix. Watch what the two translations do to it:

$$(L_h f_{\xi,v})(g) \overset{(1)}{=} \xi\big((h^{-1}g)^{-1}v\big) \overset{(2)}{=} \xi\big(g^{-1}(hv)\big) = f_{\xi,hv}(g), \tag{6.171}$$

$$(R_h f_{\xi,v})(g) \overset{(3)}{=} \xi\big(h^{-1}g^{-1}v\big) \overset{(4)}{=} (h\cdot\xi)\big(g^{-1}v\big) = f_{h\cdot\xi,v}(g). \tag{6.172}$$

(1) Definitions (6.168) and (6.170).
(2) $(h^{-1}g)^{-1} = g^{-1}h$.
(3) $(gh)^{-1} = h^{-1}g^{-1}$.
(4) The **dual representation** on V^* is $(h\cdot\xi)(w) := \xi(h^{-1}w)$.

So left translation moves v and right translation moves ξ. The matrix coefficients of V span a copy of $V \otimes V^*$ inside the functions on G, with $G \times G$ acting by (left, right). This is Nash's (6.70) in the making.

Key idea: the Peter–Weyl theorem (Nash's (6.69), (6.70))

For compact G, the matrix coefficients of the irreducible unitary representations span a dense subspace of $L^2(G)$, and

$$L^2(G) = \widehat{\bigoplus_{\lambda}} V_\lambda \otimes V_\lambda^* \tag{6.173}$$

(the hat means completion) as a representation of $G \times G$, the first factor acting by left and the second by right translation. Each irreducible V_λ occurs exactly once in the pair, so under right translation alone it occurs $c_\lambda = \dim V_\lambda$ times, and the block of V_λ contributes $(\dim V_\lambda)^2$ independent functions. Different irreducibles, and different entries of one, are orthogonal:

$$\int_G \overline{D^\lambda_{ij}(g)}\, D^\mu_{kl}(g)\, \mathrm{d}\mu(g) = \frac{\delta_{\lambda\mu}\,\delta_{ik}\,\delta_{jl}}{\dim V_\lambda} \qquad \Big(\textstyle\int_G \mathrm{d}\mu = 1\Big). \tag{6.174}$$

Why is it true? The orthogonality (6.174) is Schur's lemma: averaging a matrix over the group produces an intertwiner, which is zero between inequivalent irreducibles and a multiple of $\mathbb{1}$ otherwise. Completeness (that nothing is missing) has a physicist's proof via the Laplacian. The Laplacian Δ of a bi-invariant metric on G is a self-adjoint elliptic operator on a compact manifold, so $L^2(G)$ is the orthogonal sum of its eigenspaces, and each eigenspace is finite-dimensional (Chapter 2). Since the metric is bi-invariant, Δ commutes with L_h and R_h, so each eigenspace is a finite-dimensional representation of $G \times G$ inside the functions; a finite-dimensional space of functions invariant under right translations is spanned by matrix coefficients (evaluate at $g = e$). Hence every function is a limit of sums of matrix coefficients. In fact Δ is the quadratic Casimir, so its eigenvalue on $V_\lambda \otimes V_\lambda^*$ is the Casimir of λ.

Worked example 6.56: the circle: Fourier series

For $G = \mathrm{U}(1)$ the irreducible representations are $V_n = \mathbb{C}$ with $e^{i\theta} \mapsto e^{in\theta}$, and the only matrix coefficient is $f(\theta) = e^{-in\theta}$ (from g^{-1}). So (6.173) reads $L^2(S^1) = \widehat{\bigoplus}_{n\in\mathbb{Z}} \mathbb{C}\, e^{in\theta}$: Fourier series. Each irreducible is one-dimensional and occurs once, $(\dim V_n)^2 = 1$; (6.174) is

$\frac{1}{2\pi}\int e^{-im\theta}e^{in\theta}\mathrm{d}\theta = \delta_{mn}$; and the Laplacian $-\frac{\mathrm{d}^2}{\mathrm{d}\theta^2}$ has eigenvalue n^2, the Casimir of U(1).

Worked example 6.57: SU(2) = S^3: hyperspherical harmonics

For SU(2) the irreducibles are the spins $j = 0, \frac{1}{2}, 1, \dots$, so (6.173) predicts that $L^2(S^3)$ contains $(2j+1)^2 = (n+1)^2$ functions (with $n = 2j$) for every $n \geq 0$. Compare with the harmonic analysis of $S^3 \subset \mathbb{R}^4$: the eigenfunctions of the Laplacian are the restrictions of the harmonic homogeneous polynomials on $\mathbb{R}^4$. The polynomials of degree n in 4 variables number $\binom{n+3}{3}$, and the harmonic ones are the kernel of ∇^2, which maps them onto the polynomials of degree $n-2$. So their number is

$$\binom{n+3}{3} - \binom{n+1}{3} \overset{(1)}{=} \frac{(n+3)(n+2)(n+1) - (n+1)n(n-1)}{6} \overset{(2)}{=} \frac{(n+1)\,(6n+6)}{6} = (n+1)^2.$$

(1) Definition of the binomial coefficients.
(2) $(n+3)(n+2) - n(n-1) = n^2 + 5n + 6 - n^2 + n = 6n + 6$.

Exactly as predicted. The eigenvalue matches too: on the unit S^3 the degree-n harmonics have $-\nabla^2_{S^3} = n(n+2)$, and with the unit-length left-invariant vector fields ξ_a (brackets $[\xi_a, \xi_b] = 2\epsilon_{abc}\xi_c$) and $J_a = \frac{i}{2}\xi_a$ (which obey $[J_a, J_b] = i\epsilon_{abc}J_c$),

$$-\nabla^2_{S^3} = -\sum_a \xi_a^2 = 4\sum_a J_a^2 = 4j(j+1) = 2j(2j+2) = n(n+2).$$

The Laplacian on the three-sphere is four times the angular-momentum Casimir. The normalisation (6.174) can also be checked with the moments (6.159): for $j = \frac{1}{2}$ the matrix entries of g are $\pm u_i, \pm\bar{u}_i$, and $\int_{S^3} |u_1|^2\,\mathrm{d}\mu = \frac{1!\,0!}{2!} = \frac{1}{2} = \frac{1}{\dim V_{1/2}}$.

What sits inside $L^2(G)$: functions on G/T, sections, holomorphic sections

The Peter–Weyl theorem now sorts the three spaces of the Borel–Weil story. In each case the condition is a condition on the *right* behaviour of a function, so by (6.172) it is a condition on the covector ξ alone, and v is free.

Sections of L_λ. A section is a function with $f(gt) = \lambda(t)^{-1}f(g)$ (6.150). On a matrix coefficient,

$$f_{\xi,v}(gt) \overset{(1)}{=} f_{t\cdot\xi,v}(g) \overset{(2)}{=} \lambda(t)^{-1}f_{\xi,v}(g) \quad \text{for all } t \in T \iff t\cdot\xi = \lambda(t)^{-1}\xi.$$

(1) (6.172) with $h = t$.
(2) The equivariance condition, which we want to hold.

So ξ must be a weight vector of V^* with weight λ^{-1} (in additive language, $-\lambda$). If e_i is a basis of weight vectors of V with weights μ_i, the dual basis vector e^i has weight μ_i^{-1}, because $(t\cdot e^i)(e_j) = e^i(t^{-1}e_j) = \mu_j(t)^{-1}\delta_{ij}$. Hence

$$\Gamma(G/T, L_\lambda) = \widehat{\bigoplus_\mu} V_\mu \otimes (\text{weight-}\lambda \text{ space of } V_\mu), \tag{6.175}$$

and V_μ appears as often as λ appears among its weights. For λ trivial these are the functions on G/T.

Holomorphic sections. A section is holomorphic when it is killed by the $(0,1)$ directions, i.e. by R_W for every $W \in \mathfrak{h}^-$ (Nash: "it is annihilated by all $W \in \mathfrak{h}^-_{\mathbb{C}}$"). Differentiating (6.172),

$$R_W f_{\xi,v} = f_{W\cdot\xi,v}, \qquad (W\cdot\xi)(w) = -\xi(Ww),$$

so the condition is $W \cdot \xi = 0$ for all $W \in \mathfrak{h}^-$: ξ is killed by all lowering operators. In an irreducible V_μ^* such a vector is unique up to scale. It is the **lowest-weight vector** of V_μ^* (the dual of the highest-weight vector of V_μ), and its weight is μ^{-1}. It satisfies the equivariance condition only if $\mu^{-1} = \lambda^{-1}$. Therefore

$$\begin{aligned}\Gamma\big(G/T, \mathcal{O}(L_\lambda)\big) &= \bigoplus_\mu V_\mu \otimes \big\{\xi \in V_\mu^* : \ \mathfrak{h}^- \cdot \xi = 0, \ \text{weight } \lambda^{-1}\big\} \\ &= \begin{cases} V_\lambda \otimes \mathbb{C}\,\xi_\lambda & \lambda \text{ a highest weight,} \\ 0 & \text{otherwise.} \end{cases}\end{aligned} \tag{6.176}$$

This is the Borel–Weil theorem. Nash's phrasing is that the pulled-back section $\tilde{f}$ is "a lowest weight vector for an irreducible representation": it is a lowest-weight vector for the *right* translations (which act on the V^* factor), and it carries the irreducible representation V_λ under the left translations.

Worked example 6.58: the SU(2) sections are one row of the D-matrix

For spin j, the highest-weight vector of V_j is $|j,j\rangle$ and the covector $\xi_\lambda = \langle j,j|$ is the lowest-weight vector of V_j^* (it is killed by $\langle j,j|J^-$, as $\langle j,j|J^- = (J^+|j,j\rangle)^\dagger = 0$). By (6.176) the holomorphic sections are

$$f_m(g) = \langle j,j|\, g^{-1}\, |j,m\rangle = D^j_{jm}(g^{-1}), \qquad m = -j, \dots, j :$$

one row of the Wigner matrix of g^{-1}. For $j = \frac{1}{2}$ and g as in (6.149), $g^{-1} = g^\dagger = \left(\begin{smallmatrix} u_2 & -u_1 \\ \bar{u}_1 & \bar{u}_2 \end{smallmatrix}\right)$, whose first row is $(u_2, -u_1)$. These are the two holomorphic sections u_2 and $-u_1$ of $\mathcal{O}(1)$ found in (6.157), with the sign of (6.160). By contrast the sections of L_{λ_n} without the holomorphy condition are, by (6.175), all $V_{j'}$ with $j' \geq \frac{|n|}{2}$ and $j' - \frac{n}{2} \in \mathbb{Z}$, each once: these are the **monopole harmonics** of Wu and Yang. For $n = 0$ they are the integer spins $j' = 0, 1, 2, \dots$: the spherical harmonics with which this subsection began.

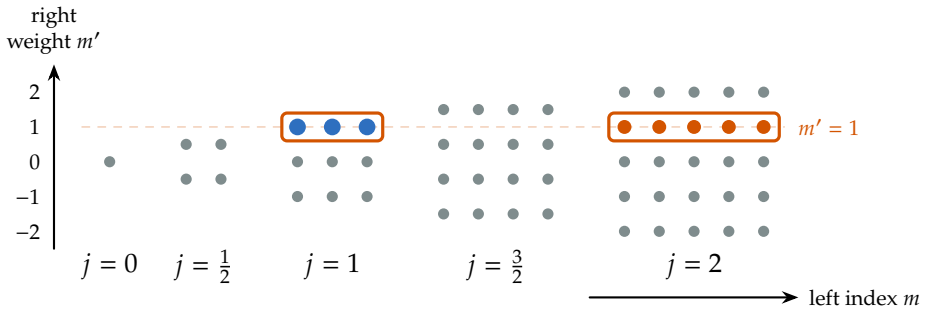


Figure 6.32: Peter–Weyl for SU(2), and the Borel–Weil funnel. Each block of dots is one $V_j \otimes V_j^*$ inside $L^2(S^3)$: $(2j+1)^2$ matrix coefficients, with the left index m running along a row and the height of the row giving the weight m' of the basis vector dual to the covector ξ. The sections of L_{λ_2} are the rows with $m' = 1$, the value fixed by the equivariance (orange frames on the dashed line): one row in each integer spin $j \geq 1$, infinitely many in all (monopole harmonics). The holomorphic sections are the single row (blue) that is *extreme* in its block, killed by all lowering operators: this happens only at $j = 1$, and that row is V_1, spin one.

Borel–Weil and the Verma module

The algebraic construction of Section 6.3.2 and the geometric one are two views of one object, and the SU(2) case shows how they fit. Work on the big cell $u_2 \neq 0$ and write a holomorphic section as $f = u_2^n F(z)$ with $z = u_1/u_2$, as in (6.156). The operators (6.158) become differential operators in z:

$$\begin{aligned} J^+ f &\overset{(1)}{=} -u_2\,\partial_1\big(u_2^n F\big) = -u_2^n\,F'(z), \\ J^- f &\overset{(2)}{=} -u_1\,\partial_2\big(u_2^n F\big) = -u_1\Big(n\,u_2^{n-1}F - u_2^n F'\,\frac{u_1}{u_2^2}\Big) = u_2^n\big(z^2F' - nzF\big), \\ J^3 f &\overset{(3)}{=} \tfrac12\big(u_2\partial_2 - u_1\partial_1\big)\big(u_2^n F\big) = u_2^n\Big(\frac{n}{2}F - zF'\Big). \end{aligned} \tag{6.177}$$

(1) $\partial_1 z = 1/u_2$ and u_2^n does not depend on u_1.
(2) Product rule; $\partial_2 z = -u_1/u_2^2$; then $u_1/u_2 = z$.
(3) $u_2\partial_2(u_2^n F) = u_2^n(nF - zF')$ and $u_1\partial_1(u_2^n F) = u_2^n zF'$.

So on F: $J^+ = -\frac{\mathrm{d}}{\mathrm{d}z}$, $J^- = z^2\frac{\mathrm{d}}{\mathrm{d}z} - nz$, $J^3 = \frac{n}{2} - z\frac{\mathrm{d}}{\mathrm{d}z}$. (Check: $[-\partial_z,\, z^2\partial_z - nz] = -(2z\partial_z - n) = 2J^3$.) On monomials,

$$J^3 z^p = \Big(\frac{n}{2} - p\Big)z^p, \qquad J^+ z^p = -p\,z^{p-1}, \qquad J^- z^p = (p-n)\,z^{p+1}.$$

Read this as a module for the Lie algebra alone, allowing *every* polynomial F, i.e. every function holomorphic on the big cell:

- $F = 1$ has $J^3 = \frac{n}{2}$ and $J^+1 = 0$: a highest-weight vector of weight $j = \frac{n}{2}$. Applying J^- repeatedly gives $z, z^2, z^3, \ldots$ (up to factors): an infinite ladder, one state at each weight $j, j-1, j-2, \ldots$, which is the weight diagram of the Verma module $V(j)$ of $\mathfrak{sl}(2)$.
- If n is a non-negative integer, $J^- z^n = 0$: the ladder is cut, and $\mathrm{span}\{1, z, \ldots, z^n\}$ is a *submodule*, the irreducible spin j.
- The condition that singles out this submodule is holomorphy at $z = \infty$ (the other chart), which by (6.157) means $\deg F \leq n$.

The polynomial module $\mathbb{C}[z]$ is the **dual** (contragredient) Verma module: it has the same weights as $V(j)$, but the arrows are reversed. In the Verma module the irreducible is a *quotient* $L(j) = V(j)/N$, and the null submodule N is generated by the singular vector $(J^-)^{n+1}|j\rangle$. In $\mathbb{C}[z]$ the irreducible is a *submodule*, and $z^{n+1}, z^{n+2}, \ldots$ survive only in the quotient $\mathbb{C}[z]/\mathrm{span}\{1, \ldots, z^n\}$, whose top state $[z^{n+1}]$ has weight $j - (n+1) = -j - 1$, the weight of the singular vector. Global holomorphy on the compact $\mathbb{CP}^1$ does the job that "remove the null states" does in the Verma module.

Watch out: what happens for λ not dominant: Borel–Weil–Bott

For $n < 0$ there are no holomorphic sections, but the representation does not disappear: it moves into higher cohomology. For $\mathbb{CP}^1$, $H^1(\mathbb{CP}^1; \mathcal{O}(n))$ has dimension $-n-1$ for $n \leq -2$ (by the same Laurent-series argument as Example 6.50, now with the transition function z^n), and it carries spin $\frac{-n-2}{2}$; for $n = -1$ everything vanishes. The general statement is the Borel–Weil–Bott theorem, and the shift by -2 (the "ρ-shift") is the same shift that relates the Verma module $V(j)$ to its singular submodule $V(-j-1)$.

6.3.13 Loop groups: holomorphic sections over LG/T

Nash closes the chapter with one sentence: for the loop group, G/T is replaced by LG/T, and the highest-weight representations of $\widetilde{LG}$ are realised as spaces of holomorphic sections of line bundles over LG/T. We now unpack that sentence. The question is: *can the Fock spaces and Kac–Moody modules of Sections 6.2.9 and 6.3.8 be seen as "lowest Landau levels" on an infinite-dimensional manifold?* They can, and for the free boson the whole construction fits on a page.

The homogeneous space LG/T

Here $T \subset G \subset LG$ is the maximal torus of G, embedded as constant loops. LG/T is the space of loops modulo right multiplication by a constant torus element. Evaluating a loop at $\theta = 0$ gives a map $LG/T \to G/T$, $\gamma T \mapsto \gamma(0)T$, whose fibre is the group ΩG of based loops (Section 6.1.4):

$$\Omega G \longrightarrow LG/T \longrightarrow G/T.$$

So LG/T is the finite-dimensional flag manifold G/T with an infinite-dimensional space of loops attached at each point.

The complex structure. Write $z = e^{i\theta}$. The complexified loop algebra has the Fourier basis Xz^n, $X \in \mathfrak{g}_{\mathbb{C}}$, $n \in \mathbb{Z}$ (Section 6.1.5), and the tangent space at the base point is $L\mathfrak{g}_{\mathbb{C}}/\mathfrak{t}_{\mathbb{C}}$. Split it, as in (6.166), into

$$\mathfrak{p}^+ = \mathfrak{h}^+ \oplus \bigoplus_{n>0} \mathfrak{g}_{\mathbb{C}}\, z^n, \qquad \mathfrak{p}^- = \mathfrak{h}^- \oplus \bigoplus_{n<0} \mathfrak{g}_{\mathbb{C}}\, z^n, \tag{6.178}$$

where for $n \neq 0$ the whole of $\mathfrak{g}_{\mathbb{C}}$ (Cartan part included) appears. The positive directions $\mathfrak{p}^+$ are exactly the operators that annihilate a Kac–Moody highest-weight state (6.126): the positive step operators at mode 0 and every mode T^a_n with $n > 0$. Declare $\mathfrak{p}^+$ holomorphic. The integrability condition of Section 6.3.11 holds for the same reason as before: brackets add mode numbers ($[Xz^m, Yz^n] = [X,Y]z^{m+n}$), negative plus negative is negative, and at mode 0 we are back to $[\mathfrak{h}^-, \mathfrak{h}^-] \subset \mathfrak{h}^-$. So $\mathfrak{b}_{\mathrm{loop}} = \mathfrak{t}_{\mathbb{C}} \oplus \mathfrak{p}^-$ is a subalgebra. Its group B_{loop} consists of the loops $\sum_{n\le 0} b_n z^n$ that extend holomorphically to the outside of the unit disc, including $z = \infty$, with value at ∞ in B. Pressley and Segal show that

$$LG/T = LG_{\mathbb{C}}/B_{\mathrm{loop}},$$

the loop analogue of (6.152), so LG/T is a complex manifold. (Pressley and Segal use the mirror convention, with loops holomorphic *inside* the disc; the two differ by $z \to 1/z$.)

The free boson as a lowest Landau level

Take $G = \mathrm{U}(1)$ and restrict to the identity component of the based loops, $\gamma(\theta) = e^{i\varphi(\theta)}$ with φ real, periodic and of zero mean. (The other components are labelled by the winding number, and T is the constant loops; we do not need them.) Expand

$$\varphi(\theta) = \sum_{m\neq 0} \varphi_m\, e^{im\theta}, \qquad \varphi_{-m} = \bar{\varphi}_m. \tag{6.179}$$

The independent coordinates are the complex numbers $\varphi_1, \varphi_2, \dots$. Which are holomorphic? The complexified loop is e^{ψ} with $\psi = \sum \psi_n z^n$ complex, and B_{loop} consists of the e^{ψ} with only $n \le 0$ modes. The group is abelian, so the class of e^{ψ} in $LG_{\mathbb{C}}/B_{\mathrm{loop}}$ is fixed by the positive modes $\psi_1, \psi_2, \dots$ alone. For a real loop $\psi = i\varphi$, so the holomorphic coordinates are φ_m with $m > 0$, and the $\bar{\varphi}_m$ are antiholomorphic.

The line bundle. Its curvature should be the Kac–Moody cocycle, now read as a real 2-form. For U(1) the cocycle (6.43) on real loops is $\omega_k(\xi,\eta) = \frac{k}{2\pi i}\int_0^{2\pi} \xi'\eta\,\mathrm{d}\theta$, which is imaginary; the real 2-form is $\Omega := i\,\omega_k$. In modes, with $\xi = \sum \xi_m e^{im\theta}$ and $\eta = \sum \eta_m e^{im\theta}$ two tangent vectors (variations of φ),

$$\Omega(\xi,\eta) \overset{(1)}{=} \frac{k}{2\pi}\int_0^{2\pi} \xi'(\theta)\,\eta(\theta)\,\mathrm{d}\theta \overset{(2)}{=} k\sum_{m\neq 0}(im)\,\xi_m\,\eta_{-m}$$
$$\overset{(3)}{=} k\sum_{m>0} i\,m\,\big(\xi_m\bar\eta_m - \bar\xi_m\eta_m\big) \overset{(4)}{=} \Big(i\,k\sum_{m>0} m\;\mathrm{d}\varphi_m\wedge\mathrm{d}\bar\varphi_m\Big)(\xi,\eta). \tag{6.180}$$

(1) $\Omega = i\omega_k$.
(2) $\xi' = \sum im\,\xi_m e^{im\theta}$ and $\frac{1}{2\pi}\int e^{i(m+n)\theta}\mathrm{d}\theta = \delta_{m+n,0}$.
(3) Pair the terms m and $-m$, using $\xi_{-m} = \bar\xi_m$ and $\eta_{-m} = \bar\eta_m$ (real loops).
(4) $(\mathrm{d}\varphi_m\wedge\mathrm{d}\bar\varphi_m)(\xi,\eta) = \xi_m\bar\eta_m - \bar\xi_m\eta_m$.

With $\varphi_m = x_m + iy_m$ we have $i\,\mathrm{d}\varphi_m\wedge\mathrm{d}\bar\varphi_m = 2\,\mathrm{d}x_m\wedge\mathrm{d}y_m$, so $\Omega = \sum_{m>0} 2km\,\mathrm{d}x_m\wedge\mathrm{d}y_m$: *each Fourier mode is a plane threaded by a uniform magnetic field, and the field in the m-th plane is proportional to km.* The space of loops is an infinite stack of Landau problems.

A holomorphic line bundle over $\mathbb{C}^\infty$ with curvature $\Omega = i\partial\bar\partial K$ is described by a Kähler potential K; a holomorphic section is a holomorphic function F, and its norm is $\int |F|^2\,e^{-K}$. (This is the same convention as on $\mathbb{CP}^1$, where $\omega = i\partial\bar\partial\log(1+|z|^2)$ and sections of $\mathcal{O}(n)$ have $\|F\|^2 = \int |F|^2\,(1+|z|^2)^{-n}\omega$.) Here

$$K = k\sum_{m>0} m\;|\varphi_m|^2\,,\qquad \|F\|^2 = \int |F(\varphi_1,\varphi_2,\dots)|^2\prod_{m>0} e^{-km|\varphi_m|^2}\,\frac{km\,\mathrm{d}^2\varphi_m}{\pi}, \tag{6.181}$$

since $i\partial\bar\partial\,(km\,|\varphi_m|^2) = ikm\,\mathrm{d}\varphi_m\wedge\mathrm{d}\bar\varphi_m$, which is (6.180). The measure is normalised so that $\|1\| = 1$.

Key idea: holomorphic sections over $LU(1)/U(1)$ are the Fock space

The normalisable holomorphic sections are the polynomials in $\varphi_1,\varphi_2,\varphi_3,\dots$. With

$$T_{-m} := km\,\varphi_m \text{ (multiplication)},\qquad T_m := \frac{\partial}{\partial\varphi_m},\qquad m>0, \tag{6.182}$$

they form the U(1) Kac–Moody module of Example 6.26: the vacuum is $F=1$, and $T_m^\dagger = T_{-m}$ in the inner product (6.181).

Let us check the three claims, one mode at a time. Write $w = \varphi_m$ and $\beta = km$.

The algebra. On any polynomial F,

$$[T_m,T_{-m}]F \overset{(1)}{=} \partial_w\big(\beta w F\big) - \beta w\,\partial_w F \overset{(2)}{=} \beta F = km\,F,$$

(1) Definitions (6.182).
(2) Product rule.

which is $[T_m,T_n] = km\,\delta_{m+n,0}$. Different modes commute because they involve different variables. And $T_m 1 = \partial_w 1 = 0$: the constant function is the vacuum.

The norms and the adjoint. The Gaussian integral

$$\int_{\mathbb{C}} |w|^{2p}\,e^{-\beta|w|^2}\,\frac{\beta\,\mathrm{d}^2w}{\pi} \overset{(1)}{=} \int_0^\infty r^{2p}e^{-\beta r^2}\,2\beta r\,\mathrm{d}r \overset{(2)}{=} \frac{1}{\beta^p}\int_0^\infty s^p e^{-s}\mathrm{d}s = \frac{p!}{\beta^p} \tag{6.183}$$

(1) Polar coordinates, $\mathrm{d}^2w = r\,\mathrm{d}r\,\mathrm{d}\theta$, and the angular integral gives 2π.
(2) Substitute $s = \beta r^2$.

gives $\|w^p\|^2 = p!/\beta^p$, and distinct powers are orthogonal (the angular integral of $e^{i(p-q)\theta}$). Now test the adjoint on monomials:

$$\langle w^{p+1},\, T_{-m}w^p\rangle = \beta\left\|w^{p+1}\right\|^2 = \frac{(p+1)!}{\beta^p}, \qquad \langle T_m w^{p+1},\, w^p\rangle = (p+1)\,\|w^p\|^2 = \frac{(p+1)!}{\beta^p}.$$

They agree, so $T_{-m}^\dagger = T_m$. Finally $\|(T_{-m})^p 1\|^2 = \beta^{2p}\,p!/\beta^p = p!\,(km)^p$, which is the norm of $(a^\dagger)^p|0\rangle$ for an oscillator with $[a, a^\dagger] = km$. Everything matches Example 6.26. Polynomials are exactly the normalisable holomorphic functions (the Bargmann–Fock theorem), so nothing else appears.

Worked example 6.59: the Weyl operators are magnetic translations

Where does the *group* act, and why is it the central extension? A real loop $e^{i\delta\varphi}$ with $\delta\varphi = ae^{im\theta} + \bar{a}e^{-im\theta}$ shifts the m-th coordinate, $w \to w + a$. On sections it acts by the **Weyl operator**

$$(U_a F)(w) := e^{\beta\bar{a}w - \frac{\beta}{2}|a|^2}\,F(w-a). \tag{6.184}$$

The prefactor is needed for unitarity: substituting $w \to w + a$,

$$|(U_aF)(w+a)|^2\,e^{-\beta|w+a|^2} \overset{(1)}{=} |F(w)|^2\;e^{2\beta\,\mathrm{Re}(\bar{a}(w+a)) - \beta|a|^2 - \beta|w+a|^2} \overset{(2)}{=} |F(w)|^2\;e^{-\beta|w|^2},$$

(1) $\left|e^X\right|^2 = e^{2\,\mathrm{Re}X}$.
(2) $|w+a|^2 = |w|^2 + 2\,\mathrm{Re}(\bar{a}w) + |a|^2$, so the exponent is $2\beta\mathrm{Re}(\bar{a}w) + 2\beta\,|a|^2 - \beta\,|a|^2 - \beta\,|w|^2 - 2\beta\mathrm{Re}(\bar{a}w) - \beta\,|a|^2 = -\beta\,|w|^2$.

so $\|U_aF\| = \|F\|$. Now compose two of them:

$$\begin{aligned}(U_aU_bF)(w) &\overset{(1)}{=} e^{\beta\bar{a}w - \frac{\beta}{2}|a|^2}\,e^{\beta\bar{b}(w-a) - \frac{\beta}{2}|b|^2}\,F(w-a-b)\\ &\overset{(2)}{=} e^{\frac{\beta}{2}(\bar{a}b - a\bar{b})}\,e^{\beta(\bar{a}+\bar{b})w - \frac{\beta}{2}|a+b|^2}\,F(w-a-b) \overset{(3)}{=} e^{i\beta\,\mathrm{Im}(\bar{a}b)}\,(U_{a+b}F)(w).\end{aligned}$$

(1) Apply (6.184) twice: U_b first, evaluated at $w - a$.
(2) $-\beta\bar{b}a - \frac{\beta}{2}|a|^2 - \frac{\beta}{2}|b|^2 = -\frac{\beta}{2}|a+b|^2 + \frac{\beta}{2}(\bar{a}b - a\bar{b})$.
(3) $\bar{a}b - a\bar{b} = 2i\,\mathrm{Im}(\bar{a}b)$, and the definition of U_{a+b}.

The translations of the m-th plane are represented only up to a phase: this is the Heisenberg group of Example 6.19, and the phase is the magnetic flux β times the area spanned by a and b, as for the magnetic translations (6.46). Thus the loop group acts on the holomorphic sections through its central extension $\widehat{L\mathrm{U}(1)}$. The infinitesimal Weyl operators along $a = \epsilon$ and $a = i\epsilon$ are $D_1 = \beta w - \partial_w$ and $D_2 = -i(\beta w + \partial_w)$, and their complex combinations are $\frac{1}{2}(D_1 + iD_2) = \beta w = T_{-m}$ and $\frac{1}{2}(D_1 - iD_2) = -\partial_w = -T_m$: the Kac–Moody generators (6.182), up to the sign conventions for the generators.

Energy and the partition function. The rotation $\theta \to \theta + \alpha$ of the circle acts on loops by $\varphi_m \to e^{-im\alpha}\varphi_m$, and on functions its generator is (up to a factor $-i$) the degree operator

$$L_0 = \sum_{m>0} m\,\varphi_m\frac{\partial}{\partial\varphi_m} = \frac{1}{k}\sum_{m>0} T_{-m}T_m,$$

which is the Sugawara form of L_0 for U(1) ((6.75) with $C = 0$ and $T_0 = 0$). A monomial $\varphi_1^{p_1}\varphi_2^{p_2}\cdots$

has $L_0 = \sum m p_m$, so the number of states at energy N is the number of partitions $p(N)$, and $\mathrm{Tr}\, q^{L_0} = \prod_{m\geq 1}(1-q^m)^{-1}$, the same count as (6.109).

Physical picture: the vacuum wave functional of a free field

In the Schrödinger picture the vacuum of a free field is a Gaussian functional of the field configuration, with width $\propto \omega^{-1/2}$ in each normal mode. Here the vacuum is the section $F = 1$, whose density $|F|^2 e^{-K} = \prod_m e^{-km|\varphi_m|^2}$ is precisely such a Gaussian: the loop $\varphi(\theta)$ is the field on the circle, and the m-th mode, with frequency $\propto m$, is squeezed with width $1/\sqrt{km}$ (Figure 6.33). Borel–Weil for $LU(1)$ is the Schrödinger (holomorphic, or Bargmann) representation of the free chiral boson: excited states are the vacuum Gaussian times polynomials in the positive-frequency modes, exactly like the lowest Landau level of each mode plane.

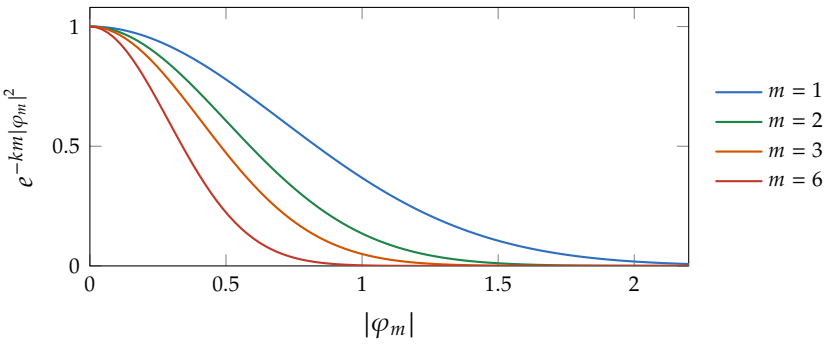

Figure 6.33: The vacuum section of the U(1) loop-group line bundle at level $k = 1$, drawn as the density $e^{-km|\varphi_m|^2}$ in each Fourier-mode plane. Each plane is a Landau problem with field $\propto km$; higher modes feel a stronger field and are squeezed harder. The product over m is the Gaussian vacuum wave functional of the free chiral boson.

Nonabelian G: the level as a Chern class, integrability as positivity

For simple, simply connected G the same picture holds, with two new features.

(1) The line bundles. A homogeneous line bundle over LG/T is now labelled by a weight of G *and* an integer. The weight comes from G/T, as before. The integer is the Chern class along the ΩG fibres: the curvature there is the Kac–Moody 2-form $\Omega = i\omega_k$, and by the integrality condition (6.47) (with $H^2(\Omega G;\mathbb{Z}) = \mathbb{Z}$) its class is the level N. The loop group acts on the bundle only through its central extension: lifting the action of LG on LG/T to the fibres of the line bundle produces phases, exactly as in Example 6.59, and the group of lifts is $\widetilde{LG}$. So the pair (weight, level) labelling a Kac–Moody highest-weight representation (Nash, p. 188) is literally the first Chern class of the bundle.

(2) Which bundles have sections. In the finite case the answer was "λ dominant", i.e. $\langle \lambda, \alpha^\vee\rangle \geq 0$ for the positive roots. For the loop group there is one more $\mathfrak{su}(2)$ to test, the hidden one of (6.140), built from $E_1^{-\alpha}$, E_{-1}^{α} and $\hat{h}_\alpha = \frac{2}{|\alpha|^2}(k - \alpha\cdot H_0)$. It generates a subgroup $\mathrm{SU}(2)_{\hat{\alpha}} \subset \widetilde{LG}$ whose orbit through the base point is a sphere $\mathbb{CP}^1 \subset LG/T$. Restrict the line bundle to that sphere. By Step 3 and (6.157) for this SU(2), the restriction is $\mathcal{O}(d)$, with d the eigenvalue of $\hat{h}_\alpha$ on the highest-weight line:

$$d = \frac{2k}{|\alpha|^2} - \langle \lambda, \alpha^\vee\rangle$$

(this is (6.141)). The highest-weight section does not vanish at the base point (at $g = e$ it equals

$\xi_\lambda(v_\lambda) \neq 0$), so its restriction is a nonzero holomorphic section of $\mathcal{O}(d)$, which requires $d \geq 0$. For the highest root θ this is

$$\langle \lambda, \theta^\vee \rangle \leq N,$$

the integrability condition (6.143), now read as *positivity of a line bundle on a sphere*. For SU(2) at level N the bundles with sections are those with spin $0 \leq j \leq \frac{N}{2}$, the $N+1$ integrable representations of Section 6.3.9. (That these conditions are also sufficient is the Borel–Weil theorem for loop groups, proved by Pressley and Segal.)

	compact G	loop group LG
homogeneous space	$G/T = G_{\mathbb{C}}/B$, compact, $\dim_{\mathbb{C}} = \#\{\alpha > 0\}$	$LG/T = LG_{\mathbb{C}}/B_{\text{loop}}$, infinite-dimensional
holomorphic directions	$\mathfrak{b}^+$ (positive step operators)	$\mathfrak{p}^+$: $\mathfrak{b}^+$ and all modes z^n, $n > 0$
line bundles labelled by	a weight λ (c_1 on G/T)	(λ, N): weight and level (c_1 on ΩG)
group acting on sections	G	the central extension $\widetilde{LG}$
sections exist iff	λ dominant	λ dominant and $\langle \lambda, \theta^\vee \rangle \leq N$ (integrable)
the representation	V_λ, finite-dimensional	integrable highest-weight module, finite-dimensional at each L_0
SU(2) / U(1) example	polynomials of degree n in u_1, u_2 (spin $\frac{n}{2}$)	polynomials in $\varphi_1, \varphi_2, \ldots$ (Fock space)
physics	lowest Landau level on a sphere around a monopole	Gaussian vacuum functional of a chiral field times polynomials

Table 6.1: Borel–Weil for compact groups and for loop groups, side by side.

Reading Nash (pp. 185–191, (6.56)–(6.70))

Nash's §3 begins by noting that the representation theory of infinite-dimensional groups is far from complete: substantial for LG and $\mathrm{Diff}(S^1)$, thin for $\mathrm{Map}(X, G)$ with $\dim X > 1$.

- *Virasoro* (pp. 185–187). The projective representation (6.56) is our (6.102); the highest-weight conditions (6.57) are (6.105), with the ladder argument of Section 6.3.1 supplying Nash's "since L_0 is bounded below". The FQS–GKO classification (6.58) is Section 6.3.6; Nash's $h = \frac{[(m+2)p-(m+1)q]^2-1}{4(m+1)(m+2)}$ is our (6.120). The Verma module, singular vectors, the quotient and the Kac determinant (Sections 6.3.2 to 6.3.5) are background that Nash's statement of (6.58) presupposes. The Goddard–Olive argument (6.59) is Section 6.3.7.

- *Kac–Moody* (pp. 187–188). See the box at the end of Section 6.3.9.

- *Borel–Weil* (pp. 188–191). (6.63) is (6.148), (6.64) is (6.152), (6.65) is (6.155), and the uniqueness of the holomorphic structure via $H^1(\mathcal{O}^*) \cong H^2(\mathbb{Z})$ is Step 5. (6.66)–(6.68) are (6.163), (6.164) and (6.166); (6.69)–(6.70) are (6.173). Nash's closing argument is (6.176). Two small points of translation. Nash says that $\tilde{f}$ is multiplied by $\lambda(Y)$ under "left translation" by $Y \in \mathfrak{t}$; the torus acts on the *right* (it is the fibre action of $G \to G/T$), and with our equivariance convention the factor is $\lambda(t)^{-1}$. And his "lowest weight vector" refers to the right action on V_λ^*; under the left action the same functions carry V_λ with its highest weight λ. The final paragraph on LG/T is Section 6.3.13.

Everything explicit (the SU(2) and SU(3) computations, the Landau level picture, monopole

harmonics, the Verma comparison, Borel–Weil–Bott, and the Fock space over $L\mathrm{U}(1)/\mathrm{U}(1)$) is added.

Recap: Section 6.3

- Positive energy (L_0 bounded below) forces highest-weight representations: $L_0|h\rangle = h|h\rangle$, $L_n|h\rangle = 0$ $(n > 0)$. Unitarity gives $\|L_{-n}|h\rangle\|^2 = 2nh + \frac{c}{12}(n^3 - n) \geq 0$, so $c \geq 0$, $h \geq 0$; a true (non-projective) representation has $c = 0$ and is trivial (Goddard–Olive).
- Pipeline: $|h\rangle \to V(c,h) = U(\mathrm{vir}_-)|h\rangle \to L(c,h) = V(c,h)/N$. V is a module (a representation space), graded by level with $p(N)$ states; N is the submodule generated by singular vectors, the zero-norm states of the Kac form; the quotient is still a module because N is invariant. Generic (c,h): $N = 0$.
- Kac determinant and unitarity: for $c \geq 1$ all $h \geq 0$; for $c < 1$ only $c = 1 - \frac{6}{(m+1)(m+2)}$ with the Kac values $h_{p,q}$ (FQS), all realised by the GKO coset construction.
- Kac–Moody: highest-weight states form an irreducible G-multiplet λ; the hidden $\mathfrak{su}(2)$ built from $E_1^{-\alpha}$ and E_{-1}^{α} forces $N = 2k/l^2 \in \mathbb{Z}_{\geq 0}$ and $\langle \lambda, \theta^\vee \rangle \leq N$ (integrable representations; for SU(2), $j \leq N/2$).
- Borel–Weil: a weight λ gives a line bundle $L_\lambda \to G/T$; $G/T = G_{\mathbb{C}}/B$ is complex with holomorphic directions $\mathfrak{h}^+$; holomorphic sections form V_λ (nonzero iff λ dominant). Proof: Peter–Weyl, $L^2(G) = \bigoplus V_\lambda \otimes V_\lambda^*$, and holomorphy selects the lowest-weight covector. SU(2): polynomials of degree n in u_1, u_2, the lowest Landau level on a sphere with n flux quanta.
- Loop groups: LG/T is complex with holomorphic directions the positive modes; line bundles are labelled by (weight, level); sections carry $\widetilde{LG}$; for U(1) they are the Fock space of the free boson in the Bargmann representation.

Chapter summary

The chapter asked what happens to symmetry when the symmetry group has a parameter at every point: a gauge transformation $g(x)$, a reparametrisation $x \mapsto x'(x)$, a conformal map $z \mapsto w(z)$. The answer came in three layers. First, the groups themselves ($\mathrm{Map}(X,G)$, LG, $\mathrm{Diff}(X)$, the gauge group) are perfectly good infinite-dimensional Lie groups with computable Lie algebras and components. Second, quantum mechanics sees them only projectively, and for these groups the phases cannot be removed: the Lie algebras acquire central terms, the level k of the Kac–Moody algebra and the central charge c of the Virasoro algebra, which appear physically as Schwinger terms and normal-ordering constants. Third, positivity of the energy and of the norm turns these central terms into quantum numbers: the level is an integer, $c < 1$ is quantised, and the representations can be built either algebraically (Verma modules modulo null states) or geometrically (holomorphic sections, Borel–Weil). The tables list every concept, what to do with it, and where it returns.

Section 6.1: the groups

concept	operational meaning	used later
$\mathrm{Map}(X, G)$, Lie algebra $\mathrm{Map}(X, \mathfrak{g})$	multiply maps pointwise; the Lie algebra is $\mathfrak{g}$-valued functions with pointwise bracket	gauge groups (Chapters 8 and 10)
based maps, π_0	$\mathrm{Map} \cong G \times \mathrm{Map}_0$; $\pi_0(\mathrm{Map}_0(S^m, G)) = \pi_m(G)$, e.g. $\pi_3(\mathrm{SU}(n)) = \mathbb{Z}$ counted by the winding integral; general X: $KU^{-1}(X)$	large gauge transformations, θ-vacua (Chapter 8); global anomalies (Chapter 10)
loop group LG	$\mathrm{Map}(S^1, G)$; basis $T^a_n = e^{in\theta}T^a$; connected for simply connected G	WZW models, CFT (Chapter 11)
affine Kac–Moody algebra	$[T^a_m, T^b_n] = if^{abc}T^c_{m+n} + km\delta^{ab}\delta_{m+n,0}$; T^a_0 span $\mathfrak{g}$	currents in CFT (Chapter 11); Chern–Simons, knot invariants (Chapter 12)
$\mathrm{Diff}(X)$, $\mathrm{vect}(X)$	compose maps; the Lie algebra is vector fields, $\alpha_t = \exp(tV)$ the flow, bracket = Lie bracket (up to sign)	reparametrisations of strings (Chapter 9); gravity
Witt algebra	$L_n = -z^{n+1}\partial_z = e^{in\theta}i\partial_\theta$, $[L_m, L_n] = (m-n)L_{m+n}$	conformal symmetry (Chapters 9 and 11)
Virasoro algebra	Witt plus $\frac{c}{12}m(m^2-1)\delta_{m+n,0}$; c = central charge	critical dimension (Chapter 9); minimal models (Chapter 11)
2d conformal group	holomorphic maps; boundary values on S^1; two commuting Witt/Virasoro copies	CFT (Chapter 11)
$\mathrm{Aut}(P)$ and gauge group $\bar{\mathcal{G}}$	$\alpha(pg) = \alpha(p)g$; kernel of $\mathrm{Aut}(P) \to \mathrm{Diff}(X)$; $\mathcal{G} = \Gamma(X, \mathrm{Ad}P)$, $\mathrm{Lie}\,\mathcal{G} = \Gamma(X, \mathrm{ad}P)$; based gauge group acts freely	orbit space $\mathcal{A}/\mathcal{G}$, moduli spaces (Chapter 8); anomalies (Chapter 10)
current algebra	$j^a(\theta) = \sum T^a_n e^{in\theta}$; $[j^a, j^b]$ has the Schwinger term $\propto k\,\delta'(\theta - \phi)$	anomalies (Chapter 10)
analyticity	$\mathrm{Map}(X, G)$ is analytic; $\mathrm{Diff}(X)$ is not, and $\exp : \mathrm{vect} \to \mathrm{Diff}$ is not locally onto	caution in all uses of $\mathrm{Diff}(S^1)$

Section 6.2: extensions

concept	operational meaning	used later
extension $1 \to H \to \bar{G} \to G \to 1$	H normal; split = semidirect product; central if H commutes with all of $\bar{G}$	throughout; $SU(2) \to SO(3)$, Heisenberg, Galilean mass
projective representation	$U(g)U(h) = e^{i\phi(g,h)}U(gh)$; phases form a group 2-cocycle; removable iff a coboundary	spin; anomalies as obstructions (Chapter 10)
Lie algebra 2-cocycle	c antisymmetric with $\sum_{\text{cyc}} c([U,V],W) = 0$; trivial iff $c = \lambda([\,,\,])$; classes $H^2(\mathfrak{g};\mathfrak{h})$	consistency conditions for anomalies (Chapter 10)
Whitehead lemma	semisimple finite-dimensional $\mathfrak{g}$: $H^2 = 0$, so no central charges	why only infinite-dimensional groups have them
Kac–Moody cocycle	$\omega_k(\xi,\eta) = \frac{k}{\pi i}\oint \mathrm{tr}(\xi'\eta)$; cocycle identity is $\oint(\dots)' = 0$	WZW, Chern–Simons (Chapters 11 and 12)
integrality	a group extension by U(1) exists iff $[\omega/2\pi]$ is integral; c_1 of $\widetilde{LG} \to LG$; $N = 2k \in \mathbb{Z}$	quantised levels (Chapter 12)
$\hbar$ expansion	$\{\,,\,\} \to [\,,\,]/i\hbar$; central terms enter at order $\hbar^2$ as c-numbers from reordering	anomalies (Chapter 10)
Virasoro cocycle	Jacobi forces $c(m) = am^3 + bm$; bm is a shift of L_0; Gel'fand–Fuks $\oint u'''v$	strings (Chapter 9)
free fields	boson $c = 1$, Majorana fermion $c = \frac{1}{2}$ via $\|\|L_{-2}\|0\rangle\|\|^2$; Dirac sea gives $k = 1$	$c = 26$ counting (Chapter 9); Ising (Chapter 11)
Sugawara construction	$L_n = \frac{1}{2k+C}\sum_m :T^a_m T^a_{n-m}:$, $c = \frac{2k\dim G}{2k+C}$	WZW, cosets (Chapter 11)
Casimir	$\sum_n T^a_{-n}T^a_n$ diverges by $k\dim G\sum n$; regularised, it is $(2k+C)L_0$	conformal weights (Chapter 11)
extensions of $\mathrm{Map}(X,G)$	central ones pulled back along loops $f: S^1 \to X$; transgression $c = \int_X \mathrm{Ev}^*\omega$; Mickelsson–Faddeev $\propto \int d^{abc}A^c\,\mathrm{d}\alpha^a\,\mathrm{d}\beta^b$	Schwinger terms in 3 + 1 dimensions (Chapter 10)

Section 6.3: representations

concept	operational meaning	used later
positive energy, highest weight	L_0 bounded below $\Rightarrow$ a state with $L_n\|h\rangle = 0$, $n > 0$; labels (c, h)	primary fields (Chapter 11)
Verma module $V(c, h)$	all $L_{-n_1} \cdots L_{-n_r}\|h\rangle$; $p(N)$ states at level N; a module (representation space)	null-vector equations (Chapter 11)
singular vector, null submodule N	$L_1\chi = L_2\chi = 0$; e.g. $(L_{-2} - \frac{3}{2(2h+1)}L_{-1}^2)\|h\rangle$ when $c = \frac{2h(5-8h)}{2h+1}$; N = all its descendants	minimal models (Chapter 11)
irreducible $L(c, h) = V/N$	quotient is a module because N is invariant; generic (c, h): $V = L$	
Kac form and determinant	Gram matrix of level-N states; zeros at $h_{p,q}(c)$; null states have zero norm	unitarity analysis (Chapter 11)
FQS series, GKO	unitary $c < 1$ only at $1 - \frac{6}{(m+1)(m+2)}$, $h = h_{p,q}$; realised as cosets	critical statistical models (Chapter 11)
Goddard–Olive	$c = 0$ unitary $\Rightarrow$ trivial; nontrivial representations are projective	
Kac–Moody representations	ground states form a G-multiplet λ; label (k, λ); $k = 0$ trivial	WZW primaries (Chapter 11)
level, integrability	hidden $\mathfrak{su}(2)$ from $E_1^{-\alpha}, E_{-1}^{\alpha}$: $N = 2k/l^2 \in \mathbb{Z}$, $\langle\lambda, \theta^\vee\rangle \le N$	Verlinde formula, Chern–Simons Hilbert spaces (Chapter 12)
Borel–Weil	weight $\lambda \to L_\lambda \to G/T = G_{\mathbb{C}}/B$; holomorphic sections = V_λ; SU(2): degree-n polynomials	geometric quantisation, Chern–Simons (Chapter 12); Riemann–Roch (Chapter 4)
root complex structure	holomorphic directions $\mathfrak{b}^+$; integrable because positive roots add to positive roots	flag manifolds
Peter–Weyl	$L^2(G) = \bigoplus V_\lambda \otimes V_\lambda^*$; matrix coefficients are the Fourier modes of G	harmonic analysis on groups, lattice gauge theory
LG/T	holomorphic directions = positive modes; line bundles labelled by (weight, level); sections carry $\widetilde{LG}$; U(1): Fock space	conformal blocks (Chapters 11 and 12)

Two threads run through all three tables. The first is the *central term as topology*: the level k is the Chern class of the circle bundle $\widetilde{LG} \to LG$, and the magnetic-translation picture (flux through a plaquette) explains both its integrality and its role as the obstruction to a true representation. The second is *representations as spaces of states built from a vacuum*: either algebraically, by applying lowering operators and removing zero-norm states, or geometrically, as holomorphic wavefunctions in a lowest Landau level. In the chapters on strings, anomalies and conformal and topological field theory the same two ideas reappear as the central charge that must cancel, the Schwinger term that signals an anomaly, and the finite-dimensional spaces of conformal blocks.

Chapter 7

Morse Theory

Where this chapter is going

Every physicist has drawn a potential-energy landscape. There are valleys where a ball comes to rest, peaks where it balances precariously, and mountain passes in between. Now suppose the landscape lives not on a flat plane but on a closed surface such as a sphere or a doughnut. A surprising thing happens: the *shape* of the surface forces the landscape to have a certain minimum number of valleys, passes and peaks, whatever the potential. On a sphere you cannot avoid having at least one peak and one valley. On a doughnut you cannot avoid mountain passes. Turn this around and you get a way to read off the topology of a space by counting the stationary points of one well-chosen function. That two-way street is **Morse theory**.

Physics is full of stationary points: the vacua of a field theory, the classical paths of the action principle, geodesics, instantons, the solutions of the Yang–Mills equations. Morse theory tells us how many there must be, and how their "instability counts" (the number of directions in which they roll downhill) are tied to the topology of the space of all configurations. It is also the mathematics behind the semiclassical approximation: expanding the energy to second order around a stationary point and counting its negative modes is exactly the Hessian and its index, which is where the chapter starts.

The chapter has four sections in Nash. §1 introduces non-degenerate critical points and their index, and the *Morse inequalities* that bound the number of critical points from below by the Betti numbers. §2 allows the critical points to come in whole families (critical submanifolds), which is what symmetric problems always produce. §3 adds a symmetry group G acting on the space and replaces ordinary cohomology by *equivariant cohomology*; this section also looks at the infinite-dimensional case, where the configuration space is a space of paths and the critical points are geodesics. §4 (the next part of these notes) is Witten's reformulation: the Morse inequalities come out of the ground states of a supersymmetric quantum mechanics, and the gradient flow lines between critical points are its instantons. That picture feeds directly into the instanton chapter and into Floer homology in the chapter on topological quantum field theory.

This first part covers Nash's §1–§3. Nash's treatment here is a sequence of statements with very few calculations, so we fill in the geometry he takes for granted: the Hessian and why its index is well defined, the Morse lemma, gradient flows and how a manifold is built by attaching handles, why the inequalities hold, the cohomology of the examples, classifying spaces, and the calculus of variations for geodesics.

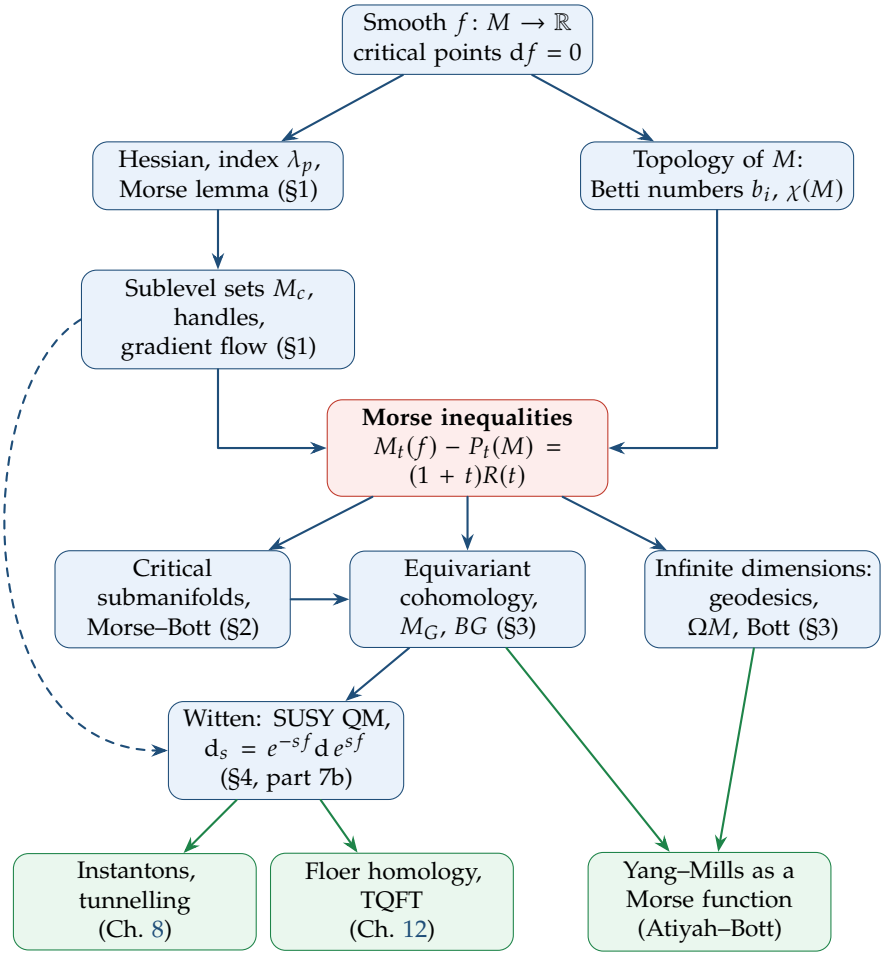

Figure 7.1: The logic of Chapter 7. A single function f on M is examined in two ways: locally, through the Hessian at each critical point (left), and globally, through the cohomology of M (right). The Morse inequalities (red) are where the two meet. The three generalisations in the middle row are all needed for physics: symmetric problems have critical *families*, gauge theories have symmetry groups, and field theories live in infinite dimensions. Witten's supersymmetric picture (dashed arrow: the gradient flow lines become instantons) leads into the physics chapters (green).

7.1 Critical points, the Hessian and the index

Here is the question that starts the subject. We are given a smooth real-valued function on a manifold,

$$f : M \longrightarrow \mathbb{R}, \tag{7.1}$$

where M is compact and (unless we say otherwise) has no boundary [Nash p. 192, (7.1)]. Where is f stationary, and what does f look like near such a point? The answer to the second question turns out to be astonishingly simple: near a "generic" stationary point, f looks like a sum of squares with some plus signs and some minus signs, and the only information is *how many minus signs*. That number, the index, is the atom of Morse theory.

Throughout, $\dim M = n$ and $x^1, \dots, x^n$ are local coordinates. We write $\partial_i = \partial/\partial x^i$.

7.1.1 Critical points

Working definition 7.1 (critical point)

A point $p \in M$ is a **critical point** of f if

$$\mathrm{d}f(p) = 0, \qquad \text{i.e.} \qquad \partial_1 f(p) = \partial_2 f(p) = \cdots = \partial_n f(p) = 0 \tag{7.2}$$

in any (hence every) coordinate chart around p [if all n first partials vanish in one chart, they vanish in every other chart] [Nash p. 193, (7.2)]. The value $f(p)$ is then a **critical value**. *Operational test:* write f in coordinates and solve the n equations $\partial_i f = 0$.

Why "in every chart"? The differential $\mathrm{d}f = \partial_i f \, \mathrm{d}x^i$ is a 1-form, a coordinate-free object (see Chapter T1). In new coordinates y^a its components are

$$\frac{\partial f}{\partial y^a} \overset{(1)}{=} \frac{\partial x^i}{\partial y^a}\,\frac{\partial f}{\partial x^i},$$

(1) Chain rule; the repeated index i is summed.

so the components vanish in one chart exactly when they vanish in the other: the Jacobian matrix $\partial x^i/\partial y^a$ is invertible. Being a critical point is a geometric property of f at p, not of the coordinates.

Physical picture: Equilibria of a potential

If $f = V$ is the potential energy of a particle moving on M, the force is $-\nabla V$. Critical points are exactly the *equilibria*, the points where a particle placed at rest stays at rest. A minimum is a stable equilibrium, a maximum is maximally unstable, and a saddle is stable in some directions and unstable in others. The number of unstable directions is going to be the index.

7.1.2 The Hessian

To see what f looks like near a critical point we Taylor expand to second order. The first-order term vanishes because $\mathrm{d}f(p) = 0$. What is left is

$$f(x) = f(p) + \tfrac{1}{2}\, H_{ij}\, x^i x^j + O(|x|^3), \qquad H_{ij} = \left.\frac{\partial^2 f}{\partial x^i \partial x^j}\right|_p, \tag{7.3}$$

with coordinates centred at p (so p has coordinates $x = 0$).

Working definition 7.2 (Hessian)

The **Hessian** of f at a critical point p is the symmetric $n \times n$ matrix

$$Hf(p) = \left[\partial^2 f/\partial x^i \partial x^j\big|_p\right]_{n\times n} \tag{7.4}$$

[Nash p. 193, (7.3)]. Think of it as a quadratic form [a rule giving one number for each vector v, homogeneous of degree two in v] $v \mapsto H_{ij}v^i v^j$ on the tangent space T_pM [the n-dimensional space of velocity vectors v of curves through p]: it gives the second derivative of f along a curve through p with velocity v.

A matrix of second partial derivatives in one chart does not have to mean anything in another chart. At a critical point it does. Change coordinates $x = x(y)$ with $y = 0$ at p. Then

$$\begin{aligned}\frac{\partial^2 f}{\partial y^a \partial y^b} &\overset{(1)}{=} \frac{\partial}{\partial y^a}\left(\frac{\partial x^j}{\partial y^b}\frac{\partial f}{\partial x^j}\right)\\ &\overset{(2)}{=} \frac{\partial x^i}{\partial y^a}\frac{\partial x^j}{\partial y^b}\frac{\partial^2 f}{\partial x^i \partial x^j} + \frac{\partial^2 x^j}{\partial y^a \partial y^b}\frac{\partial f}{\partial x^j}\\ &\overset{(3)}{=} \frac{\partial x^i}{\partial y^a}\frac{\partial x^j}{\partial y^b}\frac{\partial^2 f}{\partial x^i \partial x^j} \qquad \text{at } p.\end{aligned} \tag{7.5}$$

(1) Chain rule for the first derivative.
(2) Product rule, and the chain rule once more on $\partial f/\partial x^j$.
(3) At a critical point $\partial f/\partial x^j = 0$, so the second term drops out.

In matrix language, with $J = [\partial x^i/\partial y^a]$ the Jacobian,

$$H^{(y)} = J^{\mathsf{T}} H^{(x)} J. \tag{7.6}$$

This is the transformation law of a symmetric bilinear form (a $(0,2)$-tensor), not of a linear map. So at a critical point the Hessian is a genuine geometric object: a quadratic form on T_pM.

Watch out: The Hessian is only tensorial at critical points

Away from a critical point the second term in (7.5) is present, and the matrix of second partials depends on the chart. Example: $f = x$ on $\mathbb{R}$ has zero second derivative, but in the coordinate y with $x = y + y^2$ we get $\mathrm{d}^2 f/\mathrm{d}y^2 = 2$. Nothing is wrong: x has no critical point, so its "Hessian" has no meaning. (With a Riemannian metric one can define a covariant Hessian $\nabla\nabla f$ everywhere; at critical points it agrees with ours.)

7.1.3 Non-degeneracy, index and nullity

The law (7.6) tells us which features of the matrix H are meaningful. Its eigenvalues are *not* (congruence $J^{\mathsf{T}}HJ$ rescales them). What survives is captured by Sylvester's law of inertia.

Key idea: Sylvester's law of inertia

Any real symmetric matrix H can be brought by a congruence $H \mapsto J^{\mathsf{T}}HJ$ (J invertible) to the form $\mathrm{diag}(-1,\dots,-1,+1,\dots,+1,0,\dots,0)$. The numbers of -1's, $+1$'s and 0's do not depend on the choice of J. They equal the numbers of negative, positive and zero eigenvalues of H.

Why is the count of negative signs invariant? It has a basis-free meaning: it is the largest dimension of a subspace on which the quadratic form is negative definite. A subspace on which $H(v, v) < 0$ for all $v \neq 0$ stays such a subspace after any change of basis, so its maximal dimension cannot change.

Working definition 7.3 (non-degenerate, index, nullity)

Let p be a critical point of f with Hessian $H = Hf(p)$.

- p is **non-degenerate** if $\det H \neq 0$ [Nash (7.3)]. Test: compute the determinant of the matrix of second partials in any chart.
- The **index** λ_p is the number of negative eigenvalues of H. Equivalently, it is the dimension of the largest subspace of T_pM on which f decreases to second order [$H_{ij}v^iv^j < 0$ for every nonzero v in the subspace]: the number of independent "downhill directions".
- The **nullity** is $\dim M - \operatorname{rank} H$ [$\operatorname{rank} H$ is the number of independent rows of the matrix H], the number of zero eigenvalues. Non-degenerate means nullity 0.

A function all of whose critical points are non-degenerate is a **Morse function**.

For $n = 2$ there are exactly three kinds of non-degenerate critical point: index 0 (a local minimum), index 1 (a saddle) and index 2 (a local maximum). In general index 0 is a local minimum, index n a local maximum and everything in between is a saddle of some type.

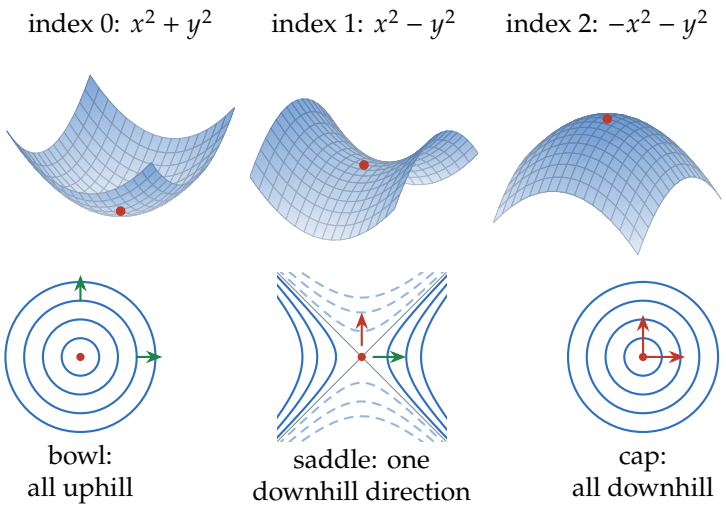

Figure 7.2: The three non-degenerate critical points in two dimensions. Top: graphs of the normal forms. Bottom: their level curves $f = \text{const}$. For the saddle, solid curves are $f > 0$ and dashed curves $f < 0$; the two faint diagonals are the level set $f = 0$ through the critical point. Green arrows point uphill, red arrows downhill. The index is the number of independent red (downhill) directions.

Worked example 7.1: A cubic on the line

Let $f(x) = x^3 - 3x$ on $\mathbb{R}$. Then $f'(x) = 3x^2 - 3$, so the critical points are $x = \pm 1$. The "Hessian" is the 1×1 matrix $f''(x) = 6x$:

$$f''(1) = 6 > 0 \;\Rightarrow\; \text{non-degenerate, index 0 (minimum)},$$
$$f''(-1) = -6 < 0 \;\Rightarrow\; \text{non-degenerate, index 1 (maximum)}.$$

Compare $g(x) = x^3$: the only critical point is $x = 0$, with $g''(0) = 0$. It is degenerate, with nullity 1. It is neither a minimum nor a maximum: an inflection point. We will see in a moment that x^3 is what you get when the two critical points of $x^3 - 3\varepsilon x$ collide as $\varepsilon \to 0$.

Worked example 7.2: Four critical points on the flat torus

Let $T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$, with angles (x, y), and $f(x, y) = \cos x + \cos y$. This is the potential of a particle on a square lattice (a tight-binding band, if you like). Then

$$\partial_x f = -\sin x, \qquad \partial_y f = -\sin y,$$

so critical points need $\sin x = \sin y = 0$: the four points $(x, y) \in \{0, \pi\}^2$. The Hessian is

$$Hf(x, y) \overset{(1)}{=} \begin{pmatrix} \partial_x^2 f & \partial_x\partial_y f \\ \partial_y\partial_x f & \partial_y^2 f \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} -\cos x & 0 \\ 0 & -\cos y \end{pmatrix}.$$

(1) Definition (7.4) with $n = 2$.
(2) $\partial_x^2 \cos x = -\cos x$, and the mixed derivative vanishes because f is a sum of a function of x and a function of y.

Evaluating:

point	Hf	f	index
$(0, 0)$	$\mathrm{diag}(-1, -1)$	2	2 (max)
$(\pi, 0)$	$\mathrm{diag}(+1, -1)$	0	1 (saddle)
$(0, \pi)$	$\mathrm{diag}(-1, +1)$	0	1 (saddle)
(π, π)	$\mathrm{diag}(+1, +1)$	-2	0 (min)

All four are non-degenerate, so f is a Morse function. It has one minimum, two saddles and one maximum. Remember this pattern $(1, 2, 1)$: we will see that the Betti numbers of T^2 are $(b_0, b_1, b_2) = (1, 2, 1)$ and that this is no coincidence.

Worked example 7.3: Degenerate critical points

Three functions on $\mathbb{R}^2$ with a critical point at the origin, all degenerate:

- $f = x^2 + y^3$: $Hf(0) = \mathrm{diag}(2, 0)$, nullity 1. Along the y-axis it behaves like the inflection point y^3.
- $f = x^3 - 3xy^2 = \mathrm{Re}(x + iy)^3$, the **monkey saddle**: all second derivatives vanish at 0, so $Hf(0) = 0$ and the nullity is 2. It has three "valleys" going down (room for a monkey's two legs and tail) instead of the ordinary saddle's two.
- $f = x^2$ (viewed on $\mathbb{R}^2$): $Hf = \mathrm{diag}(2, 0)$ at *every* point of the y-axis. The critical points are not isolated; they fill a whole line. This is the situation of Nash's §2 (Section 7.5), and it is degenerate in a controlled way: non-degenerate in the directions normal to the critical line.

7.1.4 The Morse lemma: the normal form near a critical point

The Taylor expansion (7.3) says f is approximately quadratic near p. The Morse lemma says that for a non-degenerate critical point we can do better: we can choose coordinates in which f is *exactly* quadratic, and after rescaling, exactly a sum of ± squares.

Key idea: The Morse lemma (Nash (7.4))

If p is a non-degenerate critical point of index $\lambda = \lambda_p$, there are coordinates $x^1, \dots, x^n$ centred at p in which

$$f(x) = f(p) \underbrace{- x_1^2 - x_2^2 - \cdots - x_\lambda^2}_{\lambda \text{ terms}} \underbrace{+ x_{\lambda+1}^2 + \cdots + x_n^2}_{n-\lambda \text{ terms}} \tag{7.7}$$

exactly, in a whole neighbourhood of p [Nash p. 193, (7.4)]. (We lower the indices on the coordinates here, as Nash does, to reduce clutter.)

This is a striking statement. It says a non-degenerate critical point has *no local invariants* other than the integer λ: the cubic and higher terms of the Taylor series can all be absorbed by a change of coordinates. The proof is a calculation worth seeing once, because it is just "completing the square" with coefficients that depend on position.

Step 1: f is exactly a quadratic form with variable coefficients. Put p at the origin and subtract the constant so that $f(0) = 0$. For fixed x, consider $\phi(t) = f(tx)$ for $0 \le t \le 1$. Then

$$\begin{aligned} f(x) &\overset{(1)}{=} \phi(1) - \phi(0) \\ &\overset{(2)}{=} \phi'(0) + \int_0^1 (1-t)\,\phi''(t)\,\mathrm{d}t \\ &\overset{(3)}{=} x^i\,\partial_i f(0) + \int_0^1 (1-t)\,x^i x^j\,\partial_i\partial_j f(tx)\,\mathrm{d}t \\ &\overset{(4)}{=} x^i x^j\,h_{ij}(x), \qquad h_{ij}(x) := \int_0^1 (1-t)\,\partial_i\partial_j f(tx)\,\mathrm{d}t. \end{aligned} \tag{7.8}$$

(1) $\phi(1) = f(x)$ and $\phi(0) = f(0) = 0$.

(2) Taylor's theorem with integral remainder, to first order: $\phi(1) = \phi(0) + \phi'(0) + \int_0^1 (1-t)\phi''(t)\,\mathrm{d}t$ (integrate the remainder by parts to check it).

(3) Chain rule: $\phi'(t) = x^i \partial_i f(tx)$ and $\phi''(t) = x^i x^j \partial_i\partial_j f(tx)$.

(4) $\partial_i f(0) = 0$ because 0 is critical; the $x^i x^j$ come out of the t-integral.

The functions $h_{ij}(x)$ are smooth and symmetric, and $h_{ij}(0) = \int_0^1 (1-t)\,\mathrm{d}t\;\partial_i\partial_j f(0) = \frac{1}{2}H_{ij}$. So f is exactly a quadratic form whose coefficient matrix varies smoothly with position and equals half the Hessian at the origin.

Step 2: complete the squares one at a time. Since H is invertible we may (after a linear change of coordinates) assume $h_{11}(0) \neq 0$, hence $h_{11}(x) \neq 0$ near 0. Collect all terms containing x^1:

$$\begin{aligned} x^i x^j h_{ij} &\overset{(1)}{=} h_{11}(x^1)^2 + 2x^1 \sum_{k>1} h_{1k} x^k + \sum_{k,l>1} h_{kl} x^k x^l \\ &\overset{(2)}{=} h_{11}\Big(x^1 + \sum_{k>1} \frac{h_{1k}}{h_{11}} x^k\Big)^2 + \sum_{k,l>1} \Big(h_{kl} - \frac{h_{1k}h_{1l}}{h_{11}}\Big) x^k x^l \\ &\overset{(3)}{=} \pm\,(y^1)^2 + \sum_{k,l>1} \tilde{h}_{kl}(x)\,x^k x^l, \end{aligned}$$

(1) Split the double sum into the $(1,1)$ term, the cross terms (twice, by symmetry) and the rest.

(2) Complete the square. Expanding the square reproduces the first two terms, plus the extra piece $\sum_{k,l>1} h_{1k}h_{1l}\,x^k x^l/h_{11}$, which we then subtract again.
(3) Define the new coordinate

$$y^1 = \sqrt{|h_{11}(x)|}\left(x^1 + \sum_{k>1} \frac{h_{1k}(x)}{h_{11}(x)}\,x^k\right),$$

take the sign $\pm$ to be that of $h_{11}(0)$, and call the remaining coefficients $\tilde{h}_{kl}$.

The map $(x^1,\dots,x^n) \mapsto (y^1, x^2,\dots,x^n)$ has invertible Jacobian at 0 (its $(1,1)$ entry is $\sqrt{|h_{11}(0)|} \neq 0$), so by the inverse function theorem it is a legitimate coordinate change near 0. The leftover form $\tilde{h}_{kl}$ in the $n-1$ variables $x^2,\dots,x^n$ is still non-degenerate at 0 (it is the Schur complement of an invertible matrix). Repeat n times. The result is $f = \pm(y^1)^2 \pm \cdots \pm (y^n)^2$; reorder so the minus signs come first. By Sylvester's law the number of minus signs is the index λ.

Worked example 7.4: Straightening a cubic correction

Let $f(x,y) = x^2 - y^2 + x^3$ near the origin. The Hessian at 0 is $\mathrm{diag}(2,-2)$: non-degenerate, index 1. The Morse lemma promises coordinates with $f = u^2 - v^2$ exactly. Here we can find them by inspection:

$$\begin{aligned} f &\overset{(1)}{=} x^2(1+x) - y^2 \\ &\overset{(2)}{=} \left(x\sqrt{1+x}\right)^2 - y^2 \overset{(3)}{=} u^2 - v^2. \end{aligned}$$

(1) Factor x^2 out of the x-terms.
(2) For $x > -1$ the square root is smooth and positive.
(3) Set $u = x\sqrt{1+x}$ and $v = y$. Since $\partial u/\partial x = 1$ at $x = 0$, this is a valid coordinate change near the origin.

Far from the origin the new coordinates break down (at $x = -1$), and indeed f has a second critical point at $(x,y) = (-\frac{2}{3}, 0)$ which $u^2 - v^2$ knows nothing about. The Morse lemma is a strictly local statement.

Worked example 7.5: Rotating a cross term away

Let $f(x,y) = xy$. The Hessian at 0 is $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, with eigenvalues ± 1: index 1. The coordinates $u = (x+y)/2$, $v = (x-y)/2$ give

$$u^2 - v^2 \overset{(1)}{=} \tfrac{1}{4}\left[(x+y)^2 - (x-y)^2\right] \overset{(2)}{=} xy.$$

(1) Definition of u, v.
(2) $(x+y)^2 - (x-y)^2 = 4xy$.

This is the linear-algebra part of the Morse lemma (diagonalising a constant symmetric matrix) with no higher-order terms to absorb.

7.1.5 Consequences: isolation and finiteness

Two consequences of the normal form (7.7) are used constantly.

Non-degenerate critical points are isolated. In the Morse coordinates, $\partial f/\partial x_i = \pm 2x_i$, which vanishes only at $x = 0$. So a neighbourhood of p contains no other critical point.

A Morse function on a compact manifold has finitely many critical points. Suppose there were

infinitely many, $p_1, p_2, \ldots$. By compactness a subsequence converges to some $q \in M$. By continuity of $\mathrm{d}f$,

$$\mathrm{d}f(q) \overset{(1)}{=} \lim_{k\to\infty} \mathrm{d}f(p_k) \overset{(2)}{=} 0,$$

(1) $\mathrm{d}f$ is continuous and $p_k \to q$ along the subsequence.
(2) Each p_k is critical.

so q is itself a critical point, and every neighbourhood of q contains other critical points p_k. That contradicts isolation. This is the reason Nash gives for the Morse series (7.11) below being a finite sum [Nash p. 193].

7.1.6 Morse functions are everywhere

Is being Morse a strong restriction? No: almost every function is Morse, and any function can be made Morse by an arbitrarily small tilt.

Key idea: Genericity of Morse functions

Let $M \subset \mathbb{R}^N$ be an embedded compact manifold and f any smooth function on it. For almost every vector $a \in \mathbb{R}^N$ (all a outside a set of measure zero) the tilted function

$$f_a(x) = f(x) + a \cdot x$$

is a Morse function. In particular (take $f = 0$) the "height function" $x \mapsto a \cdot x$ in almost every direction a is Morse.

The mechanism is Sard's theorem: the set of critical values of a smooth map has measure zero, and a makes f_a degenerate somewhere exactly when $-a$ is a critical value of a certain smooth map built from $\mathrm{d}f$. At the physicist's level: degeneracy is a coincidence (a determinant vanishing on top of a gradient vanishing), and a random small perturbation destroys coincidences.

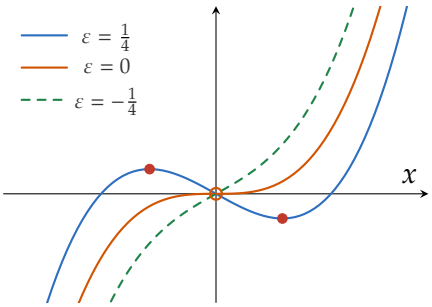

Figure 7.3: The family $f_\varepsilon(x) = x^3 - 3\varepsilon x$. For $\varepsilon > 0$ (blue) there are two non-degenerate critical points (red dots): a maximum of index 1 and a minimum of index 0. As $\varepsilon \to 0$ they approach each other and merge into the degenerate inflection point of x^3 (orange circle). For $\varepsilon < 0$ (green, dashed) they have disappeared. A small perturbation always removes the degenerate case, but it can add or remove critical points *in pairs of adjacent index*. This pair creation and annihilation will explain the factor $(1 + t)$ in the Morse inequalities.

Worked example 7.6: Height functions on the sphere

Let $S^n = \{x \in \mathbb{R}^{n+1} : |x| = 1\}$ and $f_a(x) = a \cdot x$ for a unit vector a. Critical points of the restriction to S^n are points where the gradient of $a \cdot x$ in $\mathbb{R}^{n+1}$, which is the constant vector a, is normal to the sphere, i.e. parallel to x. So $x = \pm a$: the "north and south poles" in

the direction a. Take $a = e_{n+1}$ and use $u = (x_1, \dots, x_n)$ as coordinates near the north pole, where $x_{n+1} = \sqrt{1 - |u|^2}$. Then

$$f \overset{(1)}{=} \sqrt{1 - |u|^2} \overset{(2)}{=} 1 - \tfrac{1}{2}|u|^2 - \tfrac{1}{8}|u|^4 - \dots,$$

(1) On the upper hemisphere the last coordinate is the positive root.
(2) Binomial series $\sqrt{1-s} = 1 - \frac{1}{2}s - \frac{1}{8}s^2 - \dots$ with $s = |u|^2$.

so the Hessian at the north pole is $-\mathbb{1}_n$: non-degenerate, index n (a maximum). Near the south pole $f = -\sqrt{1 - |u|^2}$ and the Hessian is $+\mathbb{1}_n$: index 0 (a minimum). The height function on S^n is a Morse function with exactly two critical points, of index 0 and n.

7.1.7 The height function on an upright torus

This is *the* example of Morse theory, and Nash uses it on p. 196. We set it up explicitly now and use it throughout the part. Take a torus with tube radius r and central-circle radius $R > r$, standing on its end like a tyre on the road, so that its axis of symmetry is horizontal. Coordinates: θ goes around the tube, ϕ around the central circle. The embedding in $\mathbb{R}^3$ is

$$(\theta, \phi) \mapsto \big((R + r\cos\theta)\cos\phi,\ r\sin\theta,\ (R + r\cos\theta)\sin\phi\big), \tag{7.9}$$

with the third coordinate the height. (The central circle lies in the vertical xz-plane, and the axis of symmetry is the horizontal y-axis.) The height function is therefore

$$f(\theta, \phi) = (R + r\cos\theta)\sin\phi. \tag{7.10}$$

Worked example 7.7: Critical points and indices on the upright torus

The first derivatives are

$$\partial_\theta f = -r\sin\theta\,\sin\phi, \qquad \partial_\phi f = (R + r\cos\theta)\cos\phi.$$

Since $R > r$, the factor $R + r\cos\theta$ is never zero, so $\partial_\phi f = 0$ forces $\cos\phi = 0$, i.e. $\phi = \pm\pi/2$. Then $\sin\phi = \pm 1 \neq 0$ and $\partial_\theta f = 0$ forces $\sin\theta = 0$, i.e. $\theta \in \{0, \pi\}$. Four critical points. The second derivatives are

$$\partial_\theta^2 f = -r\cos\theta\sin\phi, \qquad \partial_\phi^2 f = -(R + r\cos\theta)\sin\phi, \qquad \partial_\theta\partial_\phi f = -r\sin\theta\cos\phi,$$

and the mixed derivative vanishes at all four points (where $\sin\theta = 0$). So the Hessians are diagonal:

(θ, ϕ)	where on the tyre	f	Hf	index
$(0, \pi/2)$	top of outer rim	$R + r$	$\mathrm{diag}(-r, -(R + r))$	2
$(\pi, \pi/2)$	top of inner rim	$R - r$	$\mathrm{diag}(+r, -(R - r))$	1
$(\pi, -\pi/2)$	bottom of inner rim	$-(R - r)$	$\mathrm{diag}(-r, +(R - r))$	1
$(0, -\pi/2)$	bottom of outer rim	$-(R + r)$	$\mathrm{diag}(+r, +(R + r))$	0

All four are non-degenerate: the height function on the upright torus is a Morse function with one minimum, two saddles and one maximum, the same $(1, 2, 1)$ pattern as Example 7.2. The two saddles are Nash's "two distinguished points on the inner circle". At the top of the hole, moving along the inner rim (ϕ direction) goes down, while moving around the tube (θ direction, towards the outside) goes up.

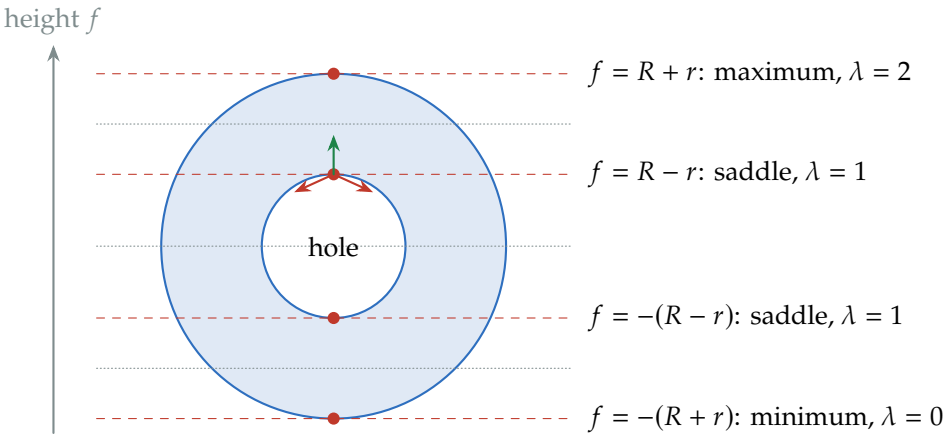

Figure 7.4: The torus standing on its end, seen along its horizontal axis (so it looks like an annulus). The height function has four critical points, all on the vertical line through the centre. Dashed red lines are the four critical levels; dotted lines are ordinary levels. At the upper saddle (top of the hole) the two red arrows, along the inner rim, point downhill; the green arrow, up over the tube, points uphill. One downhill direction: index 1.

Reading Nash (pp. 192–193, (7.1)–(7.4))

Nash states the set-up in a few lines: $f\colon M \to \mathbb{R}$ [Nash (7.1)], critical points $\mathrm{d}f = 0$ [Nash (7.2)], non-degeneracy $\det Hf(p) \neq 0$ [Nash (7.3)], the index λ_p as the number of negative eigenvalues, the normal form [Nash (7.4)] "for suitable coordinates", the nullity $\dim M - \operatorname{rank} Hf(p)$, and Morse functions. What we added: why the Hessian is coordinate-independent at a critical point (7.6), why the index is well defined (Sylvester), a proof of the normal form (the Morse lemma), why non-degenerate critical points are isolated and finitely many, and why Morse functions are generic. Nash's list of applications (infinitely many geodesics on S^n, Bott periodicity, Milnor's exotic 7-spheres, Smale's proof of the Poincaré conjecture in dimensions ≥ 5) we return to in Section 7.8. Milnor's *Morse Theory* is the classic reference Nash recommends.

Recap

- A critical point of f is where $\mathrm{d}f = 0$: an equilibrium of the potential f.
- At a critical point the Hessian $\partial_i \partial_j f$ is a well-defined quadratic form on T_pM (it transforms as $J^{\mathsf{T}} H J$).
- Non-degenerate: $\det H \neq 0$. Index λ_p: the number of negative eigenvalues, i.e. of independent downhill directions.
- Morse lemma: near a non-degenerate critical point, $f = f(p) - x_1^2 - \cdots - x_\lambda^2 + x_{\lambda+1}^2 + \cdots + x_n^2$ exactly.
- Non-degenerate critical points are isolated, so a Morse function on a compact M has finitely many. Morse functions are generic.
- Examples: S^n height (indices $0, n$); torus height and $\cos x + \cos y$ (indices $0, 1, 1, 2$).

7.2 Counting critical points: the Morse inequalities

We now have a local invariant attached to each critical point: its index. The question of this section is global. *Given a compact manifold M, how few critical points of each index can a Morse function on M have?* The answer is controlled by the Betti numbers of M, the numbers of independent "holes" of each dimension. It comes as a list of inequalities, the Morse inequalities, which Nash packages elegantly into a single statement about two polynomials. We first build the two polynomials, then state the inequalities and squeeze every consequence out of them. *Why* they are true is the subject of Section 7.3.

7.2.1 The Morse series: book-keeping for critical points

Let f be a Morse function on a compact M of dimension n. Let

$$m_i := \#\{\text{critical points of } f \text{ of index } i\}, \qquad i = 0, 1, \dots, n.$$

Rather than carry around the list $(m_0, \dots, m_n)$ we put the numbers into a polynomial in a dummy variable t, with the power of t recording the index.

Working definition 7.4 (Morse series)

The **Morse series** (really a polynomial) of f is

$$M_t(f) \;=\; \sum_{\text{critical } p} t^{\lambda_p} \;=\; \sum_{i=0}^{n} m_i\, t^i \tag{7.11}$$

[λ_p is the index of p, its number of independent downhill directions] [Nash p. 193, (7.5)]. *Operational recipe:* find all critical points, compute each index, and write down one monomial t^{λ_p} per critical point.

The two ways of writing (7.11) agree because grouping the monomials t^{λ_p} by their power collects exactly m_i copies of t^i. The sum is finite because a Morse function on a compact manifold has finitely many critical points (Section 7.1.5).

Worked example 7.8: Morse series of the examples so far

Reading off the indices from Section 7.1:

- Height on S^n (Example 7.6): one point of index 0, one of index n, so $M_t = 1 + t^n$.
- $\cos x + \cos y$ on the flat torus (Example 7.2) and the height on the upright torus (Example 7.7): indices $0, 1, 1, 2$, so $M_t = 1 + 2t + t^2$.
- $f(\theta) = \cos\theta$ on the circle S^1: $f' = -\sin\theta$ vanishes at $\theta = 0$ ($f'' = -1$, index 1) and $\theta = \pi$ ($f'' = +1$, index 0), so $M_t = 1 + t$.
- $f(\theta) = \cos 2\theta$ on S^1: critical points at $\theta = 0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}$, with $f'' = -4\cos 2\theta$ equal to $-4, +4, -4, +4$. Two maxima and two minima: $M_t = 2 + 2t$.

The last two examples live on the same manifold but have different Morse series. The Morse series depends on f. What survives every choice of f is what the Morse inequalities are about.

7.2.2 What the topology supplies: Betti numbers and the Poincaré series

Nash writes $P_t(M)$ down in one line. Let us recall what goes into it, since everything in this chapter is measured against it. (For the full story see Chapter 1 and Chapter T2.)

De Rham cohomology in one paragraph. A p-form α is **closed** if $\mathrm{d}\alpha = 0$ and **exact** if $\alpha = \mathrm{d}\beta$ for a globally defined $(p-1)$-form β. Since $\mathrm{d}^2 = 0$, exact forms are closed. The p-th de Rham cohomology is the quotient

$$H^p_{\mathrm{dR}}(M) = \frac{\{\text{closed } p\text{-forms}\}}{\{\text{exact } p\text{-forms}\}},$$

the closed forms that are not derivatives, counted modulo derivatives. By Stokes' theorem an exact form integrates to zero over every closed p-dimensional submanifold, so a closed form with a nonzero integral over some closed p-surface is a nonzero class. For compact M each $H^p_{\mathrm{dR}}(M)$ is finite-dimensional.

Working definition 7.5 (Betti numbers, Poincaré series)

The i-th **Betti number** is $b_i = \dim H^i(M;\mathbb{R})$: the number of independent closed, non-exact i-forms, or equivalently the number of independent i-dimensional "holes" (closed i-surfaces that do not bound [are not the boundary of any $(i+1)$-dimensional region inside M]). The **Poincaré series** (a polynomial for compact M) is

$$P_t(M) = \sum_{i=0}^{n} \dim H^i(M;\mathbb{R})\, t^i = \sum_{i=0}^{n} b_i\, t^i \tag{7.12}$$

[Nash p. 193, (7.6)]. *Operational recipe:* b_0 is the number of connected components; $b_n = 1$ for a connected, closed, orientable M; the rest you compute from a decomposition of M or from the rules below.

Three rules let us compute almost every Poincaré series we need.

- *Poincaré duality.* For M compact, orientable, of dimension n: $b_i = b_{n-i}$. The polynomial P_t is palindromic.
- *Künneth formula.* $P_t(M \times N) = P_t(M)\,P_t(N)$.
- *Euler characteristic.* $\chi(M) = \sum_i (-1)^i b_i = P_{-1}(M)$.

Worked example 7.9: The Betti numbers of the torus, by hand

On $T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$ with angles (x, y), the 1-forms $\mathrm{d}x$ and $\mathrm{d}y$ are globally defined (the angles jump by 2π, their differentials do not) and closed. They are not exact. Let a be the loop $y = 0$, $0 \le x \le 2\pi$, and b the loop $x = 0$. Then

$$\oint_a \mathrm{d}x \overset{(1)}{=} \int_0^{2\pi} \mathrm{d}x = 2\pi \neq 0, \qquad \oint_b \mathrm{d}x \overset{(2)}{=} 0,$$

(1) Along a we can use x itself as parameter.
(2) Along b, x is constant, so $\mathrm{d}x$ restricts to zero.

and similarly $\oint_a \mathrm{d}y = 0$, $\oint_b \mathrm{d}y = 2\pi$. If $\mathrm{d}x = \mathrm{d}g$ for a function g on T^2, Stokes (the fundamental theorem of calculus) would give $\oint_a \mathrm{d}g = 0$. So $[\mathrm{d}x] \neq 0$, and the matrix of periods $\mathrm{diag}(2\pi, 2\pi)$ shows that no combination $c_1\mathrm{d}x + c_2\mathrm{d}y$ with $(c_1, c_2) \neq 0$ is exact either. Hence $b_1 \ge 2$, and in fact $b_1 = 2$. With $b_0 = 1$ (connected) and $b_2 = 1$ (the area form

$\mathrm{d}x \wedge \mathrm{d}y$ has integral $4\pi^2 \neq 0$), we find $P_t(T^2) = 1 + 2t + t^2$. The Künneth formula gives the same answer in one line: $P_t(S^1 \times S^1) = (1 + t)(1 + t)$.

M	$P_t(M)$	$\chi(M) = P_{-1}(M)$
point	1	1
S^1	$1 + t$	0
S^n	$1 + t^n$	$1 + (-1)^n$
$T^2 = S^1 \times S^1$	$1 + 2t + t^2$	0
T^n	$(1 + t)^n$	0
Σ_p (genus p surface)	$1 + 2pt + t^2$	$2 - 2p$
$\mathbb{CP}^n$	$1 + t^2 + t^4 + \cdots + t^{2n}$	$n + 1$
$S^2 \times S^2$	$1 + 2t^2 + t^4$	4
$\mathbb{RP}^2$ (real coefficients)	1	1

The $\mathbb{CP}^n$ line we shall *derive* by Morse theory in Section 7.4. The last line is the first hint that the choice of coefficients matters.

7.2.3 Other coefficient fields, and torsion

Nash immediately generalises to cohomology "with coefficients in a general field $\mathbf{F}$" [Nash p. 194, (7.8)]:

$$P_t(M; \mathbf{F}) = \sum_{i=0}^{n} \dim_{\mathbf{F}} H^i(M; \mathbf{F})\, t^i. \tag{7.13}$$

De Rham theory only produces real coefficients. To get others we describe cohomology combinatorially. Chop M into cells, let C_i be the vector space over $\mathbf{F}$ with one basis vector per i-cell, and let $\partial\colon C_i \to C_{i-1}$ record, with signs and multiplicities, how the boundary of each cell wraps onto the cells one dimension down. Then $\partial^2 = 0$, and $H_i = \operatorname{Ker}\partial/\operatorname{Im}\partial$. (Cohomology is the dual construction; over a field it has the same dimensions.) The only place the field enters is in the *integers* that appear in ∂: a multiplicity 2 is invertible in $\mathbb{R}$ but is zero in $\mathbb{Z}_2$.

Worked example 7.10: The real projective plane with $\mathbb{R}$ and with $\mathbb{Z}_2$ coefficients

$\mathbb{RP}^2$ is the sphere S^2 with antipodal points identified, or equivalently a disc whose boundary circle has antipodal points identified. It has a cell structure with one cell in each dimension: a point e_0, a circle's worth of edge e_1 (half the boundary of the disc; the other half is identified with it) and the open disc e_2. Going around the boundary of the disc we traverse e_1 *twice in the same direction*, and e_1 is a closed loop starting and ending at e_0. So the chain complex is

$$0 \longrightarrow C_2 \xrightarrow{\partial_2 = 2} C_1 \xrightarrow{\partial_1 = 0} C_0 \longrightarrow 0, \qquad C_0 \cong C_1 \cong C_2 \cong \mathbf{F}.$$

Over $\mathbf{F} = \mathbb{R}$: multiplication by 2 is injective, so $\operatorname{Ker}\partial_2 = 0$ and $\operatorname{Im}\partial_2 = C_1$. Hence

$$b_2 \overset{(1)}{=} \dim \operatorname{Ker}\partial_2 = 0, \qquad b_1 \overset{(2)}{=} \dim \operatorname{Ker}\partial_1 - \dim \operatorname{Im}\partial_2 = 1 - 1 = 0, \qquad b_0 = 1.$$

(1) Nothing maps into C_2 from above, so $H_2 = \operatorname{Ker}\partial_2$.
(2) $\partial_1 = 0$ so all of C_1 is closed, but it is all hit by ∂_2.

Over $\mathbf{F} = \mathbb{Z}_2$: now $2 = 0$, so $\partial_2 = 0$ as well, and every C_i contributes: $b_0 = b_1 = b_2 = 1$. So

$$P_t(\mathbb{RP}^2; \mathbb{R}) = 1, \qquad P_t(\mathbb{RP}^2; \mathbb{Z}_2) = 1 + t + t^2. \tag{7.14}$$

Over the integers $H_1(\mathbb{RP}^2; \mathbb{Z}) = \mathbb{Z}/2\mathbb{Z}$: a loop which is not a boundary, but twice which is. This finite piece of the integral cohomology is called **torsion**. Real coefficients are blind to it; $\mathbb{Z}_2$ coefficients see it. Notice that $\chi = 1$ in both cases: the Euler characteristic is the alternating count of cells, $1 - 1 + 1$, whatever the field.

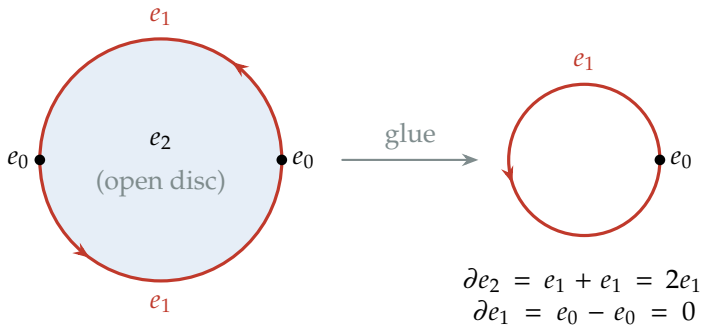

Figure 7.5: $\mathbb{RP}^2$ as a disc with antipodal boundary points identified. The upper and lower red arcs are the same edge e_1, and the arrows show they are glued with the same orientation, so the boundary of the disc runs over e_1 twice: $\partial e_2 = 2e_1$. With real coefficients e_1 is "half a boundary" and dies; with $\mathbb{Z}_2$ coefficients $2e_1 = 0$ and it survives.

7.2.4 The weak Morse inequalities

Here is the fundamental result.

Key idea: The weak Morse inequalities (Nash (7.7)–(7.9))

For any Morse function f on a compact manifold M and any coefficient field $\mathbf{F}$,

$$M_t(f) \;\geq\; P_t(M; \mathbf{F}), \qquad \text{i.e.} \qquad m_i \;\geq\; b_i(\mathbf{F}) \quad \text{for every } i = 0, 1, \ldots, n. \tag{7.15}$$

An inequality between polynomials means: coefficient by coefficient. *A Morse function has at least as many critical points of index i as M has independent i-dimensional holes.*

The second form follows from the first by comparing coefficients of t^i [Nash (7.9)]. The mechanism is the subject of Section 7.3: each critical point of index i attaches one i-dimensional cell to M, and each independent i-dimensional hole must be created by some i-cell. You cannot make a hole of dimension i without an i-cell to span it.

Worked example 7.11: Lower bounds from the weak inequalities

- *Any Morse function on T^2 has at least 4 critical points*, at least one of each index 0 and 2 and at least two saddles, since $P_t(T^2) = 1 + 2t + t^2$. The upright torus height and $\cos x + \cos y$ are optimal.
- *Any Morse function on Σ_p has at least $2p + 2$ critical points*, of which at least $2p$ are saddles.
- *Any Morse function on T^n has at least 2^n critical points*, since the sum of the coefficients

of $(1+t)^n$ is 2^n. The function $\sum_{k=1}^{n} \cos x_k$ has exactly 2^n: the points with every $x_k \in \{0, \pi\}$, and the index is the number of x_k equal to 0.

- *Any Morse function on $\mathbb{RP}^2$ has at least 3 critical points.* Here real coefficients only give $m_0 \geq 1$. Coefficients in $\mathbb{Z}_2$ give $m_0, m_1, m_2 \geq 1$. This is why Nash insists on allowing any field: different fields can give different, stronger bounds.

7.2.5 The strong Morse inequalities

Morse found much more. Look at the difference of the two polynomials.

Key idea: The strong Morse inequalities (Nash (7.10))

For any Morse function f and any field $\mathbf{F}$ there is a polynomial $R(t)$ with *non-negative* integer coefficients such that

$$M_t(f) - P_t(M;\mathbf{F}) = (1+t)\,R(t), \qquad R(t) = \sum_i r_i t^i, \quad r_i \geq 0. \tag{7.16}$$

The surplus critical points (those not forced by topology) always come in pairs of adjacent index, $t^i + t^{i+1} = t^i(1+t)$.

This is the precise form of what Figure 7.3 suggested. When a deformation of f creates critical points, it creates them in pairs of indices $(i, i+1)$; when it destroys them, it destroys them in such pairs. A pair $t^i(1+t)$ can be created or destroyed freely, so it carries no topological information. What cannot be removed is $P_t(M)$. We will see in Section 7.3.8 where the factor $(1+t)$ comes from in the proof: it is the exactness of a long exact sequence.

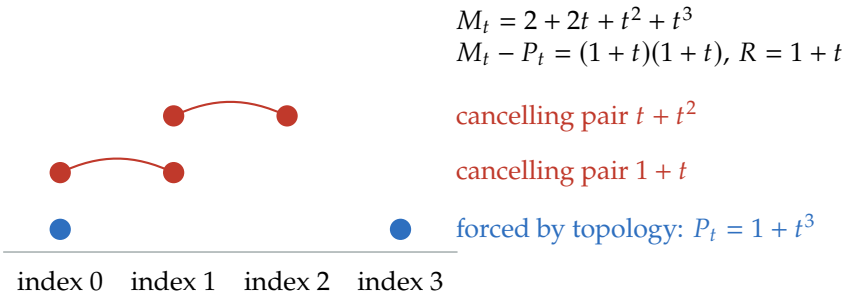

Figure 7.6: The ledger picture of the strong Morse inequalities, for a hypothetical Morse function on S^3 with critical points of indices $0, 0, 1, 1, 2, 3$. Every critical point is a dot in the column of its index. The blue dots are the minimum that the topology demands, $P_t(S^3) = 1 + t^3$. The red surplus can always be paired off, each pair linking *adjacent* columns; each red arc is one factor $t^i(1+t)$ in $(1+t)R(t)$. A surplus that cannot be paired this way is impossible.

Unpacking (7.16) into inequalities. Nash divides by $(1+t)$ and expands the geometric series. Write $\Delta(t) = M_t - P_t$ with coefficients $\Delta_i = m_i - b_i$ (and $\Delta_i = 0$ for $i < 0$ or $i > n$). Then

$$R(t) \overset{(1)}{=} \frac{\Delta(t)}{1+t} \overset{(2)}{=} \Big(\sum_{i=0}^{n} \Delta_i t^i\Big)\Big(\sum_{k=0}^{\infty} (-1)^k t^k\Big)$$

$$\overset{(3)}{=} \sum_{j=0}^{\infty} \Big(\sum_{i=0}^{j} (-1)^{j-i} \Delta_i \Big) t^j. \tag{7.17}$$

(1) Definition (7.16).
(2) $(1+t)^{-1} = 1 - t + t^2 - \dots$ as a formal power series.
(3) Collect the terms with total power $j = i + k$; then $k = j - i$ and i runs from 0 to j.

The coefficient of t^j in R is $r_j \geq 0$. Reading this off:

$$r_j \;=\; \sum_{i=0}^{j} (-1)^{j-i} (m_i - b_i) \;\geq\; 0 \quad\Longleftrightarrow\quad m_j - m_{j-1} + \cdots \pm m_0 \;\geq\; b_j - b_{j-1} + \cdots \pm b_0 \tag{7.18}$$

for every j [Nash p. 194, (7.11)]. Written out for the first few j:

$$\begin{aligned} j = 0: &\quad m_0 \geq b_0, \\ j = 1: &\quad m_1 - m_0 \geq b_1 - b_0, \\ j = 2: &\quad m_2 - m_1 + m_0 \geq b_2 - b_1 + b_0, \\ &\;\;\vdots \\ j = n: &\quad \sum_{i=0}^{n} (-1)^{n-i} m_i = \sum_{i=0}^{n} (-1)^{n-i} b_i. \end{aligned}$$

The last line is an *equality*. Why? $R(t)$ is a polynomial of degree at most $n-1$, because $(1+t)R(t)$ has degree at most n. So $r_n = 0$. The alternating sum in (7.18) for $j = n$ is $\pm$ the Euler characteristic; we return to it in a moment.

Watch out: The strong inequalities imply the weak ones, not conversely

Adding the strong inequalities for j and $j-1$ gives $r_j + r_{j-1} = m_j - b_j \geq 0$: the weak inequality. The strong ones say more, as the next example shows.

Worked example 7.12: Two valleys force a mountain pass

Can a Morse function on S^3 have two minima, two maxima and nothing else? The weak inequalities do not object: $m = (2,0,0,2)$ and $b = (1,0,0,1)$ satisfy $m_i \geq b_i$, and even the Euler characteristic matches, $2 - 0 + 0 - 2 = 0 = \chi(S^3)$. But the strong inequality with $j = 1$ says

$$m_1 - m_0 = 0 - 2 = -2 \;\overset{(1)}{\geq}\; b_1 - b_0 = 0 - 1 = -1,$$

(1) This is (7.18) for $j = 1$; it is violated.

which is false. Equivalently, $M_t - P_t = 1 + t^3 = (1+t)(1 - t + t^2)$, and $R = 1 - t + t^2$ has a negative coefficient. So the function cannot exist. In general, on a connected manifold ($b_0 = 1$, $b_1 = 0$ here), $m_1 \geq m_0 - 1$: k separate valleys need at least $k-1$ passes to connect them. Every hiker knows this.

Worked example 7.13: A non-perfect function on S^2: the two-humped sphere

Deform the round sphere so that it has two peaks, like a camel's back (Figure 7.7). The height function now has two maxima (index 2), one saddle between them (index 1) and

one minimum (index 0):

$$M_t - P_t(S^2) \overset{(1)}{=} (1 + t + 2t^2) - (1 + t^2)$$
$$= t + t^2 \overset{(2)}{=} (1 + t)\, t.$$

(1) Morse series of the humped sphere; Poincaré series of S^2.
(2) Factor out t.

So $R(t) = t$: one cancelling pair of indices $(1, 2)$, namely the extra peak and the saddle. Pushing the extra peak down until it merges with the saddle (a birth–death event run backwards) removes both and gives back the round sphere.

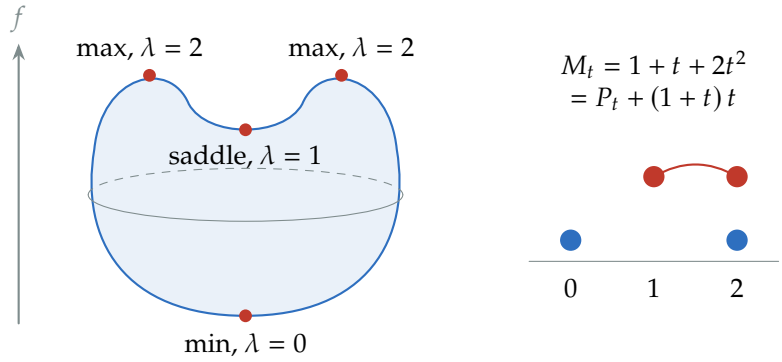

Figure 7.7: A sphere with two humps. Its height function has an extra maximum and an extra saddle compared with the round sphere. Right: the ledger. The blue dots are forced by $P_t(S^2) = 1 + t^2$; the red pair (indices 1 and 2) is the cancelling pair $t(1 + t)$. Nash's example $f = z^2$ on S^2 in Section 7.5 has the same Morse series for a different reason.

7.2.6 Two special values of t: counting and the Euler characteristic

Since $M_t(f)$ and $P_t(M)$ are polynomials, we may evaluate them at numbers. Two values are informative [Nash pp. 194–195, (7.12)–(7.13)].

At $t = 1$ every monomial becomes 1:

$$M_1(f) = \sum_i m_i = \text{total number of critical points of } f. \tag{7.19}$$

This depends strongly on f (2 or 4 on S^1 in Example 7.8), and the weak inequalities bound it below by $P_1(M) = \sum_i b_i$.

At $t = -1$ the factor $(1 + t)$ kills the surplus:

$$M_{-1}(f) \overset{(1)}{=} P_{-1}(M) + (1 + (-1))\, R(-1)$$
$$\overset{(2)}{=} P_{-1}(M) \overset{(3)}{=} \sum_{i=0}^{n} (-1)^i b_i \overset{(4)}{=} \chi(M). \tag{7.20}$$

(1) Set $t = -1$ in the strong inequalities (7.16).
(2) $1 + (-1) = 0$; $R(-1)$ is a finite number because R is a polynomial.
(3) Definition of the Poincaré series at $t = -1$.
(4) Definition of the Euler(–Poincaré) characteristic.

So

$$\sum_{\text{critical } p} (-1)^{\lambda_p} = \chi(M) \qquad \text{for every Morse function } f. \tag{7.21}$$

The left side is computed from f; the right side knows nothing about f. This is the cleanest piece of evidence for the power of the strong inequalities: the weak inequalities alone could never produce an equality.

Worked example 7.14: Checking the Euler count

upright torus: $1-2+1=0=\chi(T^2)$, two-humped S^2: $1-1+2=2=\chi(S^2)$,
$\cos 2\theta$ on S^1: $2-2=0=\chi(S^1)$, height on S^n: $1+(-1)^n=\chi(S^n)$.

The index of a critical point sets the sign $(-1)^{\lambda_p}$, so a saddle on a surface counts -1. A surface of genus p needs $2p$ more saddles than extrema to get $\chi = 2-2p$.

Physical picture: Poincaré–Hopf and Gauss–Bonnet

Equip M with a metric and consider the gradient vector field ∇f. Its zeros are the critical points. Near a critical point of index λ the field is $\nabla f = (-2x_1, \dots, -2x_\lambda, 2x_{\lambda+1}, \dots, 2x_n)$ in Morse coordinates, whose Jacobian has determinant sign $(-1)^\lambda$: this is the *index of the vector field* at that zero. So (7.21) is the Poincaré–Hopf theorem: the sum of the indices of the zeros of any vector field is $\chi(M)$. For surfaces, Gauss–Bonnet gives the same number as $\frac{1}{2\pi}\int_M K\,dA$ (Chapter T2). "You can't comb a hairy ball" is the statement $\chi(S^2) = 2 \neq 0$.

7.2.7 The lacunary principle: when counting is enough

The strong inequalities have a remarkable consequence. If the indices of f never occur in adjacent degrees, there is no room for cancelling pairs, so f must have exactly the minimum number of critical points, and its Morse series *is* the Poincaré series.

Key idea: Morse's lacunary principle (Nash p. 195, (7.14))

If $M_t(f)$ contains no two consecutive powers of t (whenever $m_i \neq 0$, both $m_{i-1} = 0$ and $m_{i+1} = 0$), then for every coefficient field $\mathbf{F}$, $R(t) \equiv 0$ and

$$M_t(f) = P_t(M; \mathbf{F}). \tag{7.22}$$

("Lacunary" means "full of gaps".)

Why. Suppose $R \neq 0$ and let $r_j t^j$ be its *lowest* nonzero term, so $r_j > 0$ and $r_i = 0$ for $i < j$. Look at two coefficients of $M_t = P_t + (1+t)R$:

$$m_j \overset{(1)}{=} b_j + r_j + r_{j-1} \overset{(2)}{=} b_j + r_j \overset{(3)}{>} 0,$$
$$m_{j+1} \overset{(4)}{=} b_{j+1} + r_{j+1} + r_j \overset{(5)}{\geq} r_j > 0.$$

(1) The coefficient of t^j in $(1+t)R(t) = \sum_i r_i(t^i + t^{i+1})$ is $r_j + r_{j-1}$.
(2) $r_{j-1} = 0$ because r_j is the lowest nonzero coefficient.
(3) $b_j \geq 0$ and $r_j > 0$.
(4) The coefficient of t^{j+1} in $(1+t)R$ is $r_{j+1} + r_j$.

(5) $b_{j+1} \geq 0$ and $r_{j+1} \geq 0$.

So t^j and t^{j+1} both occur in $M_t(f)$: two consecutive powers, contradicting the assumption. Hence $R = 0$. The argument used nothing about $\mathbf{F}$ except the strong inequalities, so it holds for every field. (Nash phrases the same argument using the first nonzero power of M_t; the essential point in both versions is that $(1+t)R$ always contains a pair of neighbouring powers.)

Worked example 7.15: Recovering the cohomology of spheres

The height function on S^n has $M_t = 1 + t^n$. For $n \geq 2$ the powers 0 and n are not consecutive, so by the lacunary principle

$$P_t(S^n; \mathbf{F}) = 1 + t^n \qquad \text{for every field } \mathbf{F}.$$

We have computed the cohomology of every sphere $S^{n\geq 2}$ by finding the critical points of one function. For S^1 the powers 0 and 1 are adjacent and the principle is silent. (The answer $1 + t$ is still right; the lacunary principle is sufficient, not necessary.) The torus is another example where it is silent: $1 + 2t + t^2$ has every power, yet the upright height function turns out to be perfect.

7.2.8 Perfect Morse functions and torsion

Working definition 7.6 (perfect Morse function)

A Morse function is **perfect** for the field $\mathbf{F}$ [the numbers used as coefficients in the cohomology, such as $\mathbb{R}$ or $\mathbb{Z}_q$] if $M_t(f) = P_t(M; \mathbf{F})$, i.e. $R \equiv 0$ [$R(t)$ is the polynomial with nonnegative coefficients in the Morse inequalities $M_t - P_t = (1+t)R(t)$]: it has exactly as many critical points of each index as the topology requires. It is *perfect* (with no qualifier) if this holds for every field [Nash p. 195]. *Test:* compare the Morse series with the Poincaré series; if they agree over $\mathbb{R}$ and over every $\mathbb{Z}_q$ (q prime), f is perfect.

Perfect Morse functions are the most economical landscapes a space allows. The lacunary principle says that a function with gaps in its indices is automatically perfect. Nash draws a sharp consequence. Perfection for all fields forces the dimensions $\dim H^i(M; \mathbf{F})$ to be independent of $\mathbf{F}$, and that happens exactly when the integral cohomology $H^*(M; \mathbb{Z})$ has no torsion (torsion like $\mathbb{Z}/q\mathbb{Z}$ is invisible over $\mathbb{R}$ and visible over $\mathbb{Z}_q$, as in Example 7.10). So:

Key idea: Torsion obstructs perfection

If f is perfect for every field then $H^*(M; \mathbb{Z})$ is torsion-free. On a manifold whose integral cohomology has torsion, such as $\mathbb{RP}^n$ ($n \geq 2$), lens spaces or the Klein bottle, *no* Morse function is perfect for every field.

Worked example 7.16: The minimal Morse function on $\mathbb{RP}^2$

On $S^2 \subset \mathbb{R}^3$ take $f = ax^2 + by^2 + cz^2$ with $0 < a < b < c$. Since $f(-x) = f(x)$ it descends to $\mathbb{RP}^2$. Critical points on S^2: points where the gradient $2(ax, by, cz)$ in $\mathbb{R}^3$ is parallel to the position vector (x, y, z). Because a, b, c are distinct this forces two of the coordinates to vanish: the six points $\pm e_1, \pm e_2, \pm e_3$. Near $e_1 = (1, 0, 0)$ use y, z as coordinates, with $x^2 = 1 - y^2 - z^2$:

$$f \overset{(1)}{=} a(1 - y^2 - z^2) + by^2 + cz^2$$

$$\overset{(2)}{=} a + (b-a)\,y^2 + (c-a)\,z^2,$$

(1) Substitute $x^2 = 1 - y^2 - z^2$ on the sphere.
(2) Collect terms.

which is *exactly* in Morse normal form: both coefficients positive, so index 0. The same computation near $\pm e_2$ gives $b + (a-b)x^2 + (c-b)z^2$, index 1, and near $\pm e_3$ gives $c + (a-c)x^2 + (b-c)y^2$, index 2. On S^2:

$$M_t^{S^2} - P_t(S^2) \overset{(1)}{=} (2 + 2t + 2t^2) - (1 + t^2) = 1 + 2t + t^2 \overset{(2)}{=} (1+t)(1+t).$$

(1) Two critical points of each index; $P_t(S^2) = 1 + t^2$.
(2) The surplus factorises with $R = 1 + t \geq 0$, as it must.

On $\mathbb{RP}^2$ the antipodal pairs become single points, so $M_t^{\mathbb{RP}^2} = 1 + t + t^2$. Comparing with (7.14):

$$\begin{aligned} \text{over } \mathbb{Z}_2: &\quad M_t - P_t = 0 \quad \text{(perfect)}, \\ \text{over } \mathbb{R}: &\quad M_t - P_t = t + t^2 = (1+t)\,t \quad \text{(not perfect)}. \end{aligned}$$

Three is the minimum number of critical points on $\mathbb{RP}^2$ (the $\mathbb{Z}_2$ bound), and the function achieving it is perfect over $\mathbb{Z}_2$ but not over $\mathbb{R}$. Keep this function in mind: its complex version is exactly Nash's function on $\mathbb{CP}^n$ in Section 7.4.

Reading Nash (pp. 193–195, (7.5)–(7.14))

Nash defines the Morse series [Nash (7.5)] and Poincaré series [Nash (7.6)], states $M_t(f) \geq P_t(M)$ as "the fundamental result of Morse theory" [Nash (7.7)], generalises to any field [Nash (7.8)], extracts $m_i \geq b_i$ [Nash (7.9)], and gives Morse's strong form $M_t - P_t = (1+t)R(t)$, $r_i \geq 0$ [Nash (7.10)], unpacking it by expanding $(1+t)^{-1}$ [Nash (7.11)]. Then $t = 1$ counts critical points [Nash (7.12)] and $t = -1$ gives $\chi(M)$ [Nash (7.13)]. The lacunary principle is stated as a theorem with a short proof [Nash (7.14)], followed by the definition of perfect Morse functions and the torsion remark. He gives no example in this stretch; we added the S^1, S^3, two-humped S^2 and $\mathbb{RP}^2$ examples, the cellular computation of $\mathbb{RP}^2$ with two coefficient fields, and the Poincaré–Hopf reading of (7.21). Nash does not prove the inequalities; he refers to Nash and Sen. We give the mechanism in Section 7.3.8.

Recap

- Morse series $M_t(f) = \sum_p t^{\lambda_p} = \sum m_i t^i$ counts critical points by index; Poincaré series $P_t(M;\mathbf{F}) = \sum b_i t^i$ counts holes by dimension.
- Weak inequalities: $m_i \geq b_i$. Strong inequalities: $M_t - P_t = (1+t)R(t)$ with $R \geq 0$, equivalently the alternating sums (7.18).
- Surplus critical points come in cancelling pairs of adjacent index.
- $t = -1$: $\sum_p (-1)^{\lambda_p} = \chi(M)$ for every Morse f (Poincaré–Hopf).
- Lacunary principle: no adjacent indices $\Rightarrow M_t = P_t$ for every field. Spheres: $P_t(S^n) = 1 + t^n$.
- Perfect for every field $\Rightarrow$ no torsion. $\mathbb{RP}^2$: three critical points, perfect over $\mathbb{Z}_2$ only.

7.3 How the topology changes at a critical point: sublevel sets, handles and gradient flow

The inequalities of Section 7.2 relate a local count (critical points and their indices) to a global count (Betti numbers). There has to be a mechanism connecting them. Here it is. Imagine flooding the manifold: pour water into the landscape f and watch the region under water, $\{f \le c\}$, as the water level c rises. Nothing interesting happens to the *shape* of the flooded region until the water reaches a critical point. There it changes in a completely standard way: a cell of dimension λ is glued on, where λ is the index. Building M out of cells, one per critical point, is what forces the Morse inequalities.

7.3.1 Level sets and sublevel sets

Working definition 7.7 (level and sublevel sets)

For a real number c, the **level set** of f at c is $f^{-1}(c) = \{x \in M : f(x) = c\}$ and the **sublevel set** (Nash calls it a "half space") is

$$M_c = \{x \in M : f(x) \le c\} \tag{7.23}$$

[Nash p. 195, (7.15)]. If c is not a critical value [$c \neq f(p)$ for every critical point p], $f^{-1}(c)$ is a smooth hypersurface [a submanifold of dimension $n-1$] in M and it is the boundary of M_c.

Why is a level set smooth at a non-critical value? Near a point x with $f(x) = c$ and $\mathrm{d}f(x) \neq 0$, some $\partial_i f(x) \neq 0$, and the implicit function theorem lets us solve $f = c$ for x^i as a smooth function of the other $n-1$ coordinates. So $f^{-1}(c)$ is locally a graph, an $(n-1)$-dimensional submanifold. At a critical point this fails: the level set through a saddle of a surface is a figure eight, with a crossing at the saddle.

The level sets are the higher-dimensional analogue of the contour lines on a map. On the upright torus (Figure 7.4), a level between the minimum and the lower saddle is one small circle around the bottom of the tube; between the two saddles it is two circles, one on each side of the hole; above the upper saddle it is again one circle; and at each saddle it is a figure eight.

7.3.2 Gradient flow

To move points from one level to another we need a direction field. Choose a Riemannian metric g_{ij} on M (any one will do). The **gradient** of f is the vector field

$$(\nabla f)^i = g^{ij}\,\partial_j f, \tag{7.24}$$

the vector "dual" to the 1-form $\mathrm{d}f$. It vanishes exactly at the critical points. The **gradient flow** is the system of ODEs

$$\frac{\mathrm{d}x^i}{\mathrm{d}t} = -(\nabla f)^i(x(t)), \tag{7.25}$$

"roll downhill as steeply as possible" (overdamped motion in the potential f; physically, a particle in a very viscous fluid). Along a solution,

$$\frac{\mathrm{d}}{\mathrm{d}t} f(x(t)) \overset{(1)}{=} \partial_i f\,\frac{\mathrm{d}x^i}{\mathrm{d}t} \overset{(2)}{=} -\partial_i f\, g^{ij} \partial_j f \overset{(3)}{=} -\,|\nabla f|^2 \;\le\; 0. \tag{7.26}$$

(1) Chain rule.

(2) The flow equation (7.25) and the definition (7.24).
(3) $g^{ij}\partial_i f \partial_j f = g_{ij}(\nabla f)^i(\nabla f)^j$ is the squared length of ∇f.

So f strictly decreases along every flow line except at the critical points, where the flow is stationary. On a compact M every flow line therefore comes from a critical point as $t \to -\infty$ and goes to a critical point as $t \to +\infty$. (It cannot decrease f forever, since f is bounded, and it can only slow down where ∇f is small, i.e. near critical points.)

Worked example 7.17: Gradient flow near a critical point of index λ

In Morse coordinates, with the flat metric $g_{ij} = \delta_{ij}$ (we may choose the metric this way near p), $f = f(p) - \sum_{i\le\lambda} x_i^2 + \sum_{i>\lambda} x_i^2$. The flow (7.25) is

$$\dot{x}_i \overset{(1)}{=} -\partial_i f = +2x_i \quad (i \le \lambda), \qquad \dot{x}_i \overset{(2)}{=} -\partial_i f = -2x_i \quad (i > \lambda),$$

(1) $\partial_i(-x_i^2) = -2x_i$ for the downhill coordinates.
(2) $\partial_i(+x_i^2) = +2x_i$ for the uphill coordinates.

with solution $x_i(t) = x_i(0)\,e^{2t}$ for $i \le \lambda$ and $x_i(t) = x_i(0)\,e^{-2t}$ for $i > \lambda$. The points that flow *into* p as $t \to +\infty$ are those with $x_1 = \cdots = x_\lambda = 0$: an $(n-\lambda)$-dimensional disc, the **stable** (ascending) manifold. The points that flow *out of* p (reach p as $t \to -\infty$) have $x_{\lambda+1} = \cdots = x_n = 0$: a λ-dimensional disc, the **unstable** (descending) manifold $W^-(p)$. *The index is the dimension of the set of points that roll away from p.* This is the linear stability analysis of an equilibrium, exactly as in mechanics: λ unstable modes, $n-\lambda$ stable ones.

7.3.3 Nothing happens between critical values

Key idea: Bott–Morse–Smale theorem, part 1 (Nash p. 196)

If $f^{-1}[a,b]$ is compact and contains no critical point, then M_a and M_b are diffeomorphic. In fact M_a is a deformation retract of M_b: M_b can be continuously squeezed onto M_a.

The proof is a flow. On the region $a \le f \le b$ the gradient is nonzero, so we may rescale it to the vector field

$$X = -\frac{\nabla f}{|\nabla f|^2}$$

(cut off smoothly to zero away from $f^{-1}[a,b]$). Along a flow line of X,

$$\frac{\mathrm{d}}{\mathrm{d}s} f(x(s)) \overset{(1)}{=} \partial_i f\, X^i \overset{(2)}{=} -\frac{\partial_i f\, g^{ij}\partial_j f}{|\nabla f|^2} \overset{(3)}{=} -1.$$

(1) Chain rule.
(2) Definition of X and of the gradient.
(3) The numerator is $|\nabla f|^2$.

So flowing along X for a time s lowers f by exactly s. Flowing for time $b-a$ carries the level $f^{-1}(b)$ onto $f^{-1}(a)$ and the whole of M_b into M_a, and the flow for time $-(b-a)$ is the inverse map. Hence $M_b \cong M_a$. Morally: if there are no critical points in the slab, the slab is just a product $f^{-1}(a) \times [a,b]$, a collar that can be absorbed.

7.3.4 Passing a critical point attaches a cell

Key idea: Bott–Morse–Smale theorem, part 2 (Nash p. 196)

If (a, b) contains exactly one critical value, belonging to a single non-degenerate critical point p of index λ, then

$$M_b \simeq M_a \cup e_\lambda, \tag{7.27}$$

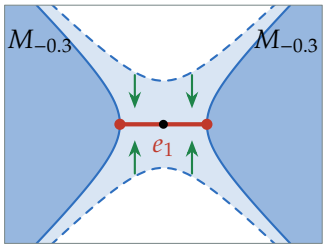
where e_λ is a λ-dimensional cell (a closed disc D^λ) glued to M_a along its boundary sphere $S^{\lambda-1}$, and $\simeq$ means "has the same homotopy type as" (can be deformed into, allowing thickness to be squashed).

We can see this in the local model. Shift so that $f(p) = 0$ and take $a = -\varepsilon$, $b = +\varepsilon$. Split the Morse coordinates as $u = (x_1, \dots, x_\lambda)$ (downhill) and $v = (x_{\lambda+1}, \dots, x_n)$ (uphill), so near p

$$f = -|u|^2 + |v|^2 .$$

- $M_{-\varepsilon}$ near p is $\{|u|^2 \geq |v|^2 + \varepsilon\}$: points with a large downhill displacement. It does not contain p.
- $M_{+\varepsilon}$ near p additionally contains the region $\{-\varepsilon < -|u|^2 + |v|^2 \leq \varepsilon\}$, which includes p.
- The **core** of the new region is the λ-disc $e_\lambda = \{v = 0,\ |u|^2 \leq \varepsilon\}$, a piece of the unstable manifold of p. Its boundary $\{v = 0,\ |u|^2 = \varepsilon\}$ is a sphere $S^{\lambda-1}$ that lies on the level set $f = -\varepsilon$, i.e. on the boundary of $M_{-\varepsilon}$.

The rest of the new region retracts onto the core: slide each point along the v directions towards $v = 0$ (this lowers f, since $|v|^2$ decreases) until it either reaches the core or hits $M_{-\varepsilon}$. So up to homotopy, $M_{+\varepsilon}$ is $M_{-\varepsilon}$ with a λ-disc glued on along its boundary sphere. The same squeeze, done without collapsing the v directions, shows that $M_{+\varepsilon}$ is *diffeomorphic* to $M_{-\varepsilon}$ with a *handle* attached, as follows.



solid: $f = -0.3$
dashed: $f = +0.3$
dark: $M_{-0.3}$
light: added to make $M_{+0.3}$
red: the core cell e_1

u (downhill) horizontal, v (uphill) vertical

Figure 7.8: Crossing a saddle ($n = 2$, $\lambda = 1$, $f = -u^2 + v^2$). Below the critical level, the sublevel set (dark) near p is two separate pieces. Just above it (dark plus light) they are joined through a neck. The green arrows squeeze the neck vertically onto the red segment e_1, whose two endpoints (S^0) lie on the old boundary. So up to homotopy, crossing the saddle glues a 1-cell onto $M_{-\varepsilon}$ along its two ends.

7.3.5 Handles

Working definition 7.8 (λ-handle)

In dimension n, a **λ-handle** is a copy of $D^\lambda \times D^{n-\lambda}$ (a thickened λ-disc) [D^k is the solid ball of dimension k, with boundary sphere S^{k-1}] glued to the boundary of a manifold along $S^{\lambda-1} \times D^{n-\lambda}$ (a thickened copy of its boundary sphere). Its **core** is $D^\lambda \times \{0\}$. Crossing a critical point of index λ attaches exactly one λ-handle: $M_{+\varepsilon} \cong M_{-\varepsilon} \cup (D^\lambda \times D^{n-\lambda})$ [$M_{\pm\varepsilon}$ are the sublevel sets just above and just below the critical value $f(p) = 0$. The symbol $\cong$ means diffeomorphic]. Shrinking the thickening gives (7.27).

In dimension 2 there are three kinds, pictured in Figure 7.9:

- a *0-handle* $D^0 \times D^2$ is a disc glued along $S^{-1} \times D^2 = \varnothing$, i.e. not glued at all: a new component is born (a new lake appears at a minimum);
- a *1-handle* $D^1 \times D^1$ is a strip glued along its two ends $S^0 \times D^1$: a bridge (two lakes merge at a pass, or one lake wraps around and meets itself);
- a *2-handle* $D^2 \times D^0$ is a disc glued along its whole boundary circle: a cap (a hole in the flooded region is plugged at a peak).

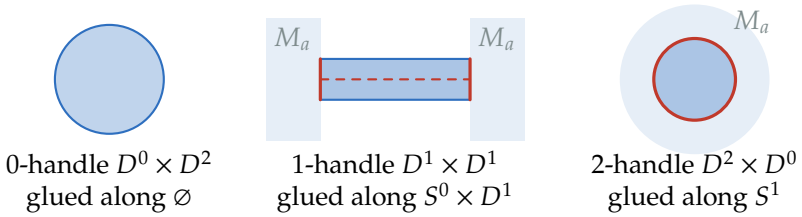


Figure 7.9: The three kinds of handle on a surface. Dark blue: the new handle; light blue: the old sublevel set M_a; red: the attaching region $S^{\lambda-1} \times D^{n-\lambda}$; dashed red: the core of the 1-handle, which is the cell e_1. A minimum starts a new piece, a saddle builds a bridge, a maximum puts on a lid.

7.3.6 The torus, built one critical point at a time

Now we watch the upright torus of Example 7.7 fill with water. The four critical values are $-(R+r) < -(R-r) < R-r < R+r$.

Worked example 7.18: Sublevel sets of the upright torus

1. $c < -(R+r)$: $M_c = \varnothing$.
2. $-(R+r) < c < -(R-r)$: we have passed the minimum (index 0). M_c is a small cap at the bottom of the tyre: a *disc*. A 0-handle.
3. $-(R-r) < c < R-r$: we have passed the lower saddle (index 1). The water now climbs both sides of the hole; M_c is the bottom half of the tyre, a U-shaped tube: a *cylinder*, i.e. a disc with a strip attached. Up to homotopy it is a circle: $e_0 \cup e_1$.
4. $R-r < c < R+r$: we have passed the upper saddle (index 1). The two arms of the U have joined over the top of the hole. M_c is the torus with a small disc around the top removed: a *punctured torus*. Up to homotopy it is a figure eight of two circles, $e_0 \cup e_1 \cup e_1$.

5. $c > R + r$: we have passed the maximum (index 2), which caps off the remaining hole. $M_c = T^2 = e_0 \cup e_1 \cup e_1 \cup e_2$.

One cell per critical point, with dimension equal to the index.

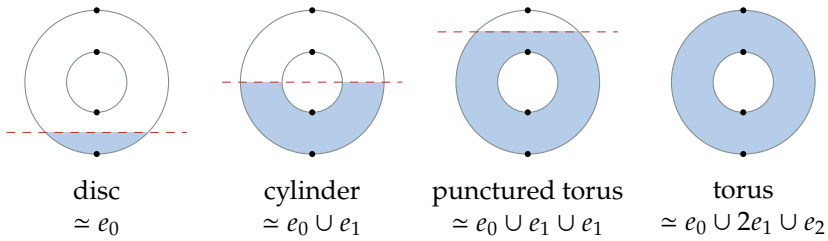

Figure 7.10: Flooding the upright torus (seen along its axis, as in Figure 7.4). Shaded: the sublevel set M_c, for c just above the minimum, between the saddles, above the upper saddle, and above the maximum. The red dashed line is the water level. Each time the water passes a critical point (black dot) one cell is added, of dimension equal to the index: first a disc, then a bridge around the left or right of the hole giving a cylinder, then a second bridge over the top giving a punctured torus, then a lid.

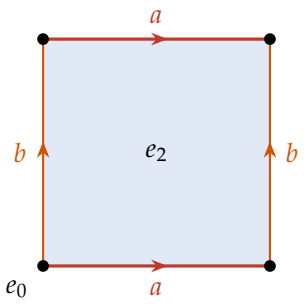
Reading off the Morse series and the Euler characteristic [Nash p. 196, (7.17)–(7.18)]:

$$M_t(f) \overset{(1)}{=} t^0 + t^1 + t^1 + t^2 = 1 + 2t + t^2, \tag{7.28}$$

$$M_{-1}(f) \overset{(2)}{=} 1 - 2 + 1 \overset{(3)}{=} 0 = \chi(T^2). \tag{7.29}$$

(1) One monomial per critical point, indices $0, 1, 1, 2$ (Example 7.7).
(2) Set $t = -1$.
(3) The Euler characteristic of the torus is $b_0 - b_1 + b_2 = 1 - 2 + 1$, or, counting cells, 1 vertex −2 edges +1 face.

Since also $P_t(T^2) = 1 + 2t + t^2$, the height function on the upright torus is a perfect Morse function (over every field: T^2 has no torsion).



one 0-cell: the four corners
two 1-cells: a and b
one 2-cell: the open square
$\partial e_2 = a + b - a - b = 0, \quad \partial a = \partial b = 0$

Figure 7.11: The cell structure $T^2 = e_0 \cup e_1 \cup e_1 \cup e_2$ produced by the height function, drawn as the usual square with opposite sides identified. All boundary maps vanish, so every cell carries a cohomology class and $P_t = 1 + 2t + t^2$ equals the Morse series: the function is perfect. Compare $\mathbb{RP}^2$ in Figure 7.5, where $\partial e_2 = 2e_1 \neq 0$.

7.3.7 Cell decompositions (Nash's "stratification")

Applying (7.27) at every critical value, from the bottom up, builds M up to homotopy as a union of cells, one per critical point:

$$M \simeq \bigcup_{\text{critical } p} e_{\lambda_p} \tag{7.30}$$

[Nash p. 196, (7.16)]. A space built by successively gluing discs along their boundary spheres is a **CW complex**. So a Morse function hands us a CW structure with m_i cells of dimension i. Examples:

$$\begin{aligned} S^n &\simeq e_0 \cup e_n && \text{(height function: } M_t = 1 + t^n\text{)},\\ T^2 &\simeq e_0 \cup e_1 \cup e_1 \cup e_2 && \text{(upright height: } 1 + 2t + t^2\text{)},\\ \mathbb{RP}^2 &\simeq e_0 \cup e_1 \cup e_2 && \text{(Example 7.16: } 1 + t + t^2\text{)},\\ \mathbb{CP}^n &\simeq e_0 \cup e_2 \cup e_4 \cup \cdots \cup e_{2n} && \text{(Section 7.4: } 1 + t^2 + \cdots + t^{2n}\text{)}. \end{aligned}$$

For S^n this is the familiar picture of a sphere as a disc with its whole boundary collapsed to a point.

Watch out: "Stratification"

Nash calls (7.30) a *stratification* of M. In most modern texts that word means a decomposition into smooth pieces (strata) of various dimensions, such as an orbit space broken up by stabiliser type. What Morse theory gives is a *cell decomposition up to homotopy*: the equality in (7.30) is $\simeq$, not $=$. That is enough for computing cohomology, which is all we need.

7.3.8 Why the Morse inequalities are true

We can now prove the strong inequalities (7.16). The idea: each time a λ-cell is attached, *either* it creates a new independent λ-dimensional class (its boundary sphere was already a boundary in M_a, so the cell closes up into a new cycle), *or* it kills an existing $(\lambda-1)$-dimensional class (its boundary sphere was a nontrivial cycle, and now it bounds). In the first case b_λ goes up by one, in the second $b_{\lambda-1}$ goes down by one. The first kind of cell is "needed by the topology"; the second kind comes paired with an earlier $(\lambda-1)$-cell, and the pair contributes $t^{\lambda-1} + t^\lambda = t^{\lambda-1}(1+t)$ to the surplus.

To make this precise we use the cohomology of a pair.

The exact sequence of a pair. For $Y \subset X$ there are relative cohomology groups $H^i(X, Y)$ (forms on X that vanish on Y, roughly) and a **long exact sequence**

$$\cdots \to H^{i-1}(Y) \xrightarrow{\delta} H^i(X, Y) \xrightarrow{j} H^i(X) \xrightarrow{r} H^i(Y) \xrightarrow{\delta} H^{i+1}(X, Y) \to \cdots$$

"Exact" means the image of each map is the kernel of the next. Here r is restriction to Y and δ is the connecting map. For a single cell, $H^i(M_b, M_a) \cong H^i(D^\lambda, S^{\lambda-1})$ (everything outside the new cell cancels; this is called excision), and this is $\mathbf{F}$ for $i = \lambda$ and 0 otherwise. So

$$P_t(M_b, M_a) = t^\lambda. \tag{7.31}$$

Counting ranks. Write $q_i = \operatorname{rank}\big(\delta\colon H^i(Y) \to H^{i+1}(X,Y)\big)$. Exactness at each of the three kinds of spot says that each space splits into the kernel of the outgoing map (which is the image of the incoming map) and a complement mapped isomorphically onto the image:

$$\begin{aligned} \dim H^i(X,Y) &\overset{(1)}{=} q_{i-1} + \operatorname{rank} j_i, \\ \dim H^i(X) &\overset{(2)}{=} \operatorname{rank} j_i + \operatorname{rank} r_i, \\ \dim H^i(Y) &\overset{(3)}{=} \operatorname{rank} r_i + q_i. \end{aligned}$$

(1) Rank–nullity for j_i, with $\operatorname{Ker} j_i = \operatorname{Im} \delta_{i-1}$.
(2) Rank–nullity for r_i, with $\operatorname{Ker} r_i = \operatorname{Im} j_i$.
(3) Rank–nullity for δ_i, with $\operatorname{Ker} \delta_i = \operatorname{Im} r_i$.

Taking the first minus the second plus the third, then multiplying by t^i and summing,

$$\begin{aligned} P_t(X,Y) - P_t(X) + P_t(Y) &\overset{(1)}{=} \sum_i (q_{i-1} + q_i)\, t^i \\ &\overset{(2)}{=} \sum_i q_i\, t^{i+1} + \sum_i q_i\, t^i \overset{(3)}{=} (1+t)\, Q(t), \qquad Q(t) = \sum_i q_i t^i. \end{aligned} \tag{7.32}$$

(1) The rank j_i and rank r_i terms cancel.
(2) Shift the summation index in the first sum.
(3) Factor; Q has non-negative coefficients because ranks are non-negative.

This is where the factor $(1+t)$ comes from: every nonzero connecting map δ links degree i with degree $i+1$.

Summing over the critical points. Order the critical values $c_1 < c_2 < \cdots < c_N$ (perturb f slightly so each level has one critical point) and choose $a_0 < c_1 < a_1 < c_2 < \cdots < c_N < a_N$. Then $M_{a_0} = \varnothing$, $M_{a_N} = M$, and $(M_{a_k}, M_{a_{k-1}})$ contains exactly one critical point, of index λ_k. Apply (7.32) with (7.31) to each step and add:

$$\begin{aligned} &\sum_{k=1}^{N} \big[t^{\lambda_k} - P_t(M_{a_k}) + P_t(M_{a_{k-1}})\big] \overset{(1)}{=} (1+t) \sum_k Q_k(t) \\ &\quad\Longrightarrow\quad M_t(f) - P_t(M) + P_t(\varnothing) \overset{(2)}{=} (1+t)\, R(t), \qquad R := \textstyle\sum_k Q_k. \end{aligned} \tag{7.33}$$

(1) Relation (7.32) for $(X,Y) = (M_{a_k}, M_{a_{k-1}})$, summed over k.
(2) $\sum_k t^{\lambda_k} = M_t(f)$, and the $P_t(M_{a_k})$ terms telescope, leaving $-P_t(M_{a_N}) + P_t(M_{a_0})$.

Since $P_t(\varnothing) = 0$, this is precisely $M_t(f) - P_t(M) = (1+t)R(t)$ with $R \geq 0$: the strong Morse inequalities. Nothing depended on the field $\mathbf{F}$, which is why they hold for every field.

Worked example 7.19: Which cells are paired on the two-humped sphere?

Flood the camel-back sphere of Example 7.13. Order of critical values: minimum, saddle, lower peak, higher peak.

- Minimum ($\lambda = 0$): a disc appears; it creates $b_0 = 1$. No pairing.
- Saddle ($\lambda = 1$): the water reaches the pass. The flooded region was a disc covering the lower part of the sphere; now the strip across the pass turns it into an *annulus* whose two boundary circles surround the two peaks. A new 1-cycle is created (a

loop around one peak): $b_1(M_c) = 1$.

- Lower peak ($\lambda = 2$): the lid over the lower peak closes one boundary circle. The loop around that peak now bounds the lid, so the 1-cycle is *killed*: $\delta \neq 0$, and the peak is paired with the saddle. The flooded region is a disc again.
- Higher peak ($\lambda = 2$): the last lid closes the sphere and creates $b_2 = 1$.

So $R = Q_{\text{lower peak}} = t$, matching $M_t - P_t = (1 + t)\,t$. The pairing is concrete: the saddle and the peak that "undoes" it.

7.3.9 A preview: counting flow lines (the Morse complex)

The proof above uses only the *number* of cells in each dimension. The cells themselves come with more information: the way the boundary of each cell wraps around the lower cells. For a Morse function this information is carried by the gradient flow lines, and it gives a complete way to compute the cohomology from f. This goes beyond Nash's §1–§3, but it is exactly what Witten's §4 (part 7b) reconstructs from supersymmetric quantum mechanics, so we preview it.

Working definition 7.9 (Morse complex, over $\mathbb{Z}_2$)

Let C_i be the $\mathbb{Z}_2$-vector space with one basis vector $\langle p\rangle$ for each critical point of index i. For generic metric [all Riemannian metrics except a thin set, the metric being needed to define ∇f], the flow lines of $-\nabla f$ [curves $\gamma(s)$ with $\dot\gamma = -\nabla f$, leaving p as $s \to -\infty$ and arriving at q as $s \to +\infty$] from a critical point p of index i to a critical point q of index $i-1$ are finite in number. Define

$$\partial\langle p\rangle = \sum_{\lambda_q = i-1} \big(\#\text{flow lines } p \to q \bmod 2\big)\,\langle q\rangle.$$

Then $\partial^2 = 0$, and $\operatorname{Ker}\partial/\operatorname{Im}\partial$ [combinations c with $\partial c = 0$, counted as equal when they differ by some ∂b] is the homology of M with $\mathbb{Z}_2$ coefficients. (Over $\mathbb{Z}$ or $\mathbb{R}$ each flow line carries a sign fixed by orientations.)

Worked example 7.20: The Morse complex of $\cos x + \cos y$ on the torus

For $f = \cos x + \cos y$ with the flat metric, $-\nabla f = (\sin x, \sin y)$. The critical points are the maximum $P = (0,0)$, the saddles $S_1 = (\pi, 0)$ and $S_2 = (0, \pi)$, and the minimum $Q = (\pi, \pi)$ (Example 7.2). The line $y = 0$ is invariant under the flow (since $\sin 0 = 0$), and on it $\dot x = \sin x > 0$ for $0 < x < \pi$ and < 0 for $\pi < x < 2\pi$. So there are exactly two flow lines from P to S_1: rightwards from $x = 0$ and leftwards from $x = 2\pi$ (the same point P). Likewise two from P to S_2 (along $x = 0$), two from S_1 to Q (along $x = \pi$) and two from S_2 to Q (along $y = \pi$). Hence, over $\mathbb{Z}_2$,

$$\partial\langle P\rangle \overset{(1)}{=} 2\langle S_1\rangle + 2\langle S_2\rangle = 0, \qquad \partial\langle S_k\rangle \overset{(2)}{=} 2\langle Q\rangle = 0.$$

(1) Two flow lines from P to each saddle.
(2) Two flow lines from each saddle to the minimum.

All boundary maps vanish, so every critical point gives a homology class: $b_0 = 1$, $b_1 = 2$, $b_2 = 1$. (With signs the two flow lines cancel too, since the torus is orientable; for $\mathbb{RP}^2$ with Example 7.16 the two flow lines from the maximum to the saddle add up to 2, reproducing $\partial e_2 = 2e_1$ of Example 7.10.)

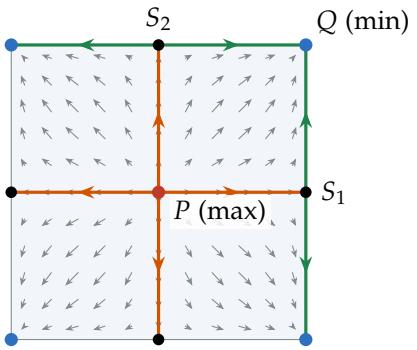


Figure 7.12: The torus as a square $[-\pi,\pi]^2$ with opposite sides identified, centred on the maximum P of $f=\cos x+\cos y$. Grey arrows: the downhill field $-\nabla f=(\sin x,\sin y)$. Orange: the four flow lines leaving P, two to each saddle (the left and right black dots are the same point S_1, the top and bottom ones are S_2). Green: the flow lines from the saddles to the minimum Q (the four corners are one point). Every critical point is joined to each lower neighbour by an *even* number of flow lines, so the Morse differential vanishes and the function is perfect.

Physical picture: Flow lines are tunnelling paths

In Witten's picture (part 7b), critical points are classical vacua of a supersymmetric particle moving on M with potential built from f. The perturbative ground states sit at the critical points, one per critical point, with fermion number equal to the index: that is $M_t(f)$. Instantons (tunnelling paths) are the gradient flow lines between critical points of adjacent index. They lift pairs of would-be ground states to nonzero energy, exactly the cancelling pairs $(1+t)R(t)$. The states that survive are the true supersymmetric ground states, counted by $P_t(M)$. The Morse inequalities become "the true ground states are a subset of the perturbative ones".

Reading Nash (pp. 195–196, (7.15)–(7.18))

Nash introduces the level surfaces $\{f=c\}$ and the "half spaces" M_c [Nash (7.15)], and states the Bott–Morse–Smale theorem in two parts: no critical value in $[a,b]$ gives $M_a\cong M_b$; one critical point of index λ gives $M_b\simeq M_a\cup e_\lambda$. He calls the resulting cell decomposition (7.30) a stratification [Nash (7.16)]. He deliberately does not prove the Morse inequalities ("rather than give another proof we shall just explain the part that [level surfaces] play"). The upright torus example with $M_t=1+2t+t^2$ and $\chi=0$ is [Nash (7.17)–(7.18)]. We have added the gradient flow and the stable/unstable manifolds, the proof of both parts of the theorem in the local model, handles, the flooding picture of the torus, the exact-sequence proof of the strong inequalities, and the Morse complex.

Recap

- $M_c=\{f\le c\}$ keeps its shape until c crosses a critical value (flow along $-\nabla f/|\nabla f|^2$ lowers f at unit rate).
- Crossing a critical point of index λ attaches a λ-handle $D^\lambda\times D^{n-\lambda}$; up to homotopy, a λ-cell whose core is the unstable manifold.
- So $M\simeq\bigcup_p e_{\lambda_p}$: a CW complex with m_i cells of dimension i.
- Each cell either creates a class in degree λ or kills one in degree $\lambda-1$; the exact sequence of a pair turns this into $M_t-P_t=(1+t)R$, $R\ge 0$.

- Upright torus: disc → cylinder → punctured torus → torus; $M_t = 1 + 2t + t^2 = P_t$, $\chi = 0$.
- Flow lines between critical points of adjacent index compute the boundary maps (Morse complex); they are Witten's instantons.

7.4 Three classic calculations: $\mathbb{CP}^n$, surfaces of genus p, and degenerate critical points

So far we have mostly used topology to predict critical points. Now we run the machine the other way. Nash's first showpiece is the complex projective space $\mathbb{CP}^n$: we shall find its complete cohomology by locating the critical points of one quadratic function and counting minus signs, with no cohomology theory at all beyond the lacunary principle. The second example, the surface of genus p, shows the $(1, 2p, 1)$ pattern of saddles. The third asks what survives when we give up non-degeneracy: then critical points can merge into "monkey saddles", the Morse inequalities fall silent, and a different and cruder lower bound, the Lusternik–Schnirelmann category, takes over.

7.4.1 $\mathbb{CP}^n$ as a quotient of an odd sphere

Working definition 7.10 (complex projective space)

$\mathbb{CP}^n$ is the set of complex lines through the origin in $\mathbb{C}^{n+1}$ [each line is $\{\mu z : \mu \in \mathbb{C}\}$ for one nonzero vector z, a copy of $\mathbb{C}$]. A point is written in **homogeneous coordinates** $[z_1 : z_2 : \cdots : z_{n+1}]$, not all z_i zero, with the rule

$$[z_1 : \cdots : z_{n+1}] = [\mu z_1 : \cdots : \mu z_{n+1}] \qquad \text{for every } \mu \in \mathbb{C}^\times = \mathbb{C} \setminus \{0\}.$$

Operational version: use $|\mu|$ to normalise $\sum_i |z_i|^2 = 1$. What is left of μ is a phase $e^{i\theta}$. So

$$\mathbb{CP}^n = S^{2n+1}/\mathrm{U}(1), \qquad S^{2n+1} = \Big\{ z \in \mathbb{C}^{n+1} : \sum_{i=1}^{n+1} z_i \bar{z}_i = 1 \Big\}, \tag{7.34}$$

[points of S^{2n+1} that differ by an overall phase $e^{i\theta}$ count as one point of $\mathbb{CP}^n$] where $\mathrm{U}(1) = S^1$ acts by $e^{i\theta} \cdot (z_1, \ldots, z_{n+1}) = (e^{i\theta} z_1, \ldots, e^{i\theta} z_{n+1})$ [Nash p. 197, (7.19)–(7.20)].

The U(1) action is **free**: if $e^{i\theta} z = z$ with $z \neq 0$ then $e^{i\theta} = 1$. Each orbit is a great circle in S^{2n+1}, and the orbits are exactly the points of $\mathbb{CP}^n$. This free-quotient picture will reappear in Section 7.6, where we compare free and non-free actions.

Charts. On the open set $U_k = \{z_k \neq 0\}$ we may use $\mu = 1/z_k$ to set $z_k = 1$. The remaining n ratios

$$w_j = z_j / z_k \qquad (j \neq k)$$

are arbitrary complex numbers, so $U_k \cong \mathbb{C}^n \cong \mathbb{R}^{2n}$. The $n+1$ charts $U_1, \ldots, U_{n+1}$ cover $\mathbb{CP}^n$ (some z_k is nonzero), so $\mathbb{CP}^n$ is a compact manifold of real dimension $2n$. The complement of U_{n+1} is $\{z_{n+1} = 0\}$, which is a copy of $\mathbb{CP}^{n-1}$. So

$$\mathbb{CP}^n = \mathbb{C}^n \sqcup \mathbb{CP}^{n-1} = \mathbb{C}^n \sqcup \mathbb{C}^{n-1} \sqcup \cdots \sqcup \mathbb{C}^1 \sqcup \mathbb{C}^0. \tag{7.35}$$

Morse theory will tell us that this decomposition is a cell structure with one cell in each even dimension, and hence what the cohomology is.

Worked example 7.21: $\mathbb{CP}^1$ is the two-sphere

The map $\pi\colon S^3 \to \mathbb{R}^3$,

$$\pi(z_1, z_2) = \big(2\,\mathrm{Re}\, z_1\bar{z}_2,\ 2\,\mathrm{Im}\, z_1\bar{z}_2,\ |z_1|^2 - |z_2|^2\big),$$

is unchanged by $z \mapsto e^{i\theta}z$ (each entry is a product of a z and a $\bar{z}$), so it is really a map from $\mathbb{CP}^1$. It lands on the unit sphere:

$$|\pi(z)|^2 \overset{(1)}{=} 4\,|z_1\bar{z}_2|^2 + \big(|z_1|^2 - |z_2|^2\big)^2 \overset{(2)}{=} \big(|z_1|^2 + |z_2|^2\big)^2 \overset{(3)}{=} 1.$$

(1) $(2\,\mathrm{Re}\, c)^2 + (2\,\mathrm{Im}\, c)^2 = 4\,|c|^2$ with $c = z_1\bar{z}_2$.
(2) $4\,|z_1|^2\,|z_2|^2 + (A - B)^2 = (A + B)^2$ with $A = |z_1|^2$, $B = |z_2|^2$.
(3) We are on S^3.

It is a bijection $\mathbb{CP}^1 \to S^2$ (the inverse sends a point of S^2 to its stereographic coordinate $w = z_1/z_2$, the Riemann sphere). This π is the **Hopf map** $S^3 \to S^2$, whose fibres are the U(1) orbits.

7.4.2 The Morse function on $\mathbb{CP}^n$

Pick $n+1$ real numbers $a_1 < a_2 < \cdots < a_{n+1}$ and set

$$\tilde{f}(z) = a_1 z_1\bar{z}_1 + a_2 z_2\bar{z}_2 + \cdots + a_{n+1} z_{n+1}\bar{z}_{n+1} \qquad \text{on } S^{2n+1} \tag{7.36}$$

[Nash p. 197, (7.21)]. Since $\left|e^{i\theta}z_i\right| = |z_i|$ it is constant on orbits, so it defines a function f on $\mathbb{CP}^n$ with $\tilde{f} = f \circ \pi$. In homogeneous coordinates, without normalising,

$$f([z]) = \frac{\sum_i a_i\,|z_i|^2}{\sum_i |z_i|^2}. \tag{7.37}$$

Physically, f is the expectation value $\langle z|A|z\rangle/\langle z|z\rangle$ of the Hermitian matrix $A = \mathrm{diag}(a_1, \dots, a_{n+1})$ in the state $|z\rangle$. Here $\mathbb{CP}^n$ plays the role of the space of pure states of an $(n+1)$-level quantum system (the ray space), and the stationary points of f are exactly the eigenstates of A – this is the Rayleigh–Ritz variational principle.

Where are the critical points? Since π is a submersion, $\mathrm{d}\tilde{f} = \mathrm{d}f \circ \mathrm{d}\pi$ vanishes at z exactly when $\mathrm{d}f$ vanishes at $\pi(z)$. So we find the critical points of $\tilde{f}$ on the sphere, by a Lagrange multiplier μ for the constraint $\sum |z_i|^2 = 1$. Writing $z_i = x_i + iy_i$ and differentiating in x_i and y_i,

$$\mathrm{d}\tilde{f} = \mu\,\mathrm{d}\Big(\sum_i |z_i|^2\Big) \overset{(1)}{=} \iff 2a_i x_i = 2\mu x_i \ \text{ and } \ 2a_i y_i = 2\mu y_i \quad \text{for all } i$$

$$\overset{(2)}{=} \iff (a_i - \mu)\,z_i = 0 \quad \text{for all } i.$$

(1) $\partial_{x_i}(a_i(x_i^2 + y_i^2)) = 2a_i x_i$, and likewise for y_i and for the constraint.
(2) Combine the real and imaginary parts.

Because the a_i are distinct, at most one z_i can be nonzero, and on the sphere exactly one is. So the critical points of f are the $n+1$ *coordinate points*

$$P_k = [0 : \cdots : 0 : \underset{k}{1} : 0 : \cdots : 0], \qquad k = 1, \dots, n+1,$$

with critical values $f(P_k) = a_k$. In the quantum language: the eigenstates of A. Nash: "one for each direction z_i".

The Hessian at P_k. Use the chart U_k, with $z_k = 1$ and $w_j = z_j$ for $j \neq k$. Write $A(w) = \sum_{j\neq k} a_j |w_j|^2$ and $S(w) = \sum_{j\neq k} |w_j|^2$, both quadratic in w. Then

$$\begin{aligned} f(w) &\overset{(1)}{=} \frac{a_k + A(w)}{1 + S(w)} \\ &\overset{(2)}{=} (a_k + A)(1 - S + S^2 - \dots) \\ &\overset{(3)}{=} a_k + A - a_k S + O(|w|^4) \\ &\overset{(4)}{=} a_k + \sum_{j\neq k} (a_j - a_k)\,|w_j|^2 + O(|w|^4). \end{aligned} \tag{7.38}$$

(1) Formula (7.37) with $z_k = 1$, $z_j = w_j$.
(2) Geometric series $1/(1+S) = 1 - S + \dots$, valid for small w.
(3) Keep the terms of order ≤ 2; AS and S^2 are quartic.
(4) Combine $A - a_k S = \sum_{j\neq k}(a_j - a_k)|w_j|^2$.

Now the crucial observation Nash makes. With $w_j = u_j + iv_j$, $|w_j|^2 = u_j^2 + v_j^2$, so each complex direction w_j contributes *two* equal real eigenvalues $2(a_j - a_k)$ to the $2n \times 2n$ real Hessian:

$$Hf(P_k) = \operatorname{diag}\big(\underbrace{2(a_1 - a_k),\, 2(a_1 - a_k)}_{w_1},\ \dots,\ \underbrace{2(a_{n+1} - a_k),\, 2(a_{n+1} - a_k)}_{w_{n+1}}\big) \quad (j \neq k). \tag{7.39}$$

No eigenvalue is zero (the a's are distinct), so f is a Morse function. The negative eigenvalues come from the j with $a_j < a_k$, i.e. $j < k$. There are $k-1$ of them, each counted twice:

$$\lambda_{P_k} = 2(k-1), \qquad k = 1, \dots, n+1. \tag{7.40}$$

Key idea: The cohomology of $\mathbb{CP}^n$ (Nash (7.22)–(7.23))

The Morse series of f is

$$M_t(f) = 1 + t^2 + t^4 + \cdots + t^{2n}. \tag{7.41}$$

Only even powers occur, so no two are consecutive, and the lacunary principle gives, for every coefficient field $\mathbf{F}$,

$$P_t(\mathbb{CP}^n; \mathbf{F}) = 1 + t^2 + t^4 + \cdots + t^{2n} = \frac{1 - t^{2n+2}}{1 - t^2}. \tag{7.42}$$

So $b_{2i}(\mathbb{CP}^n) = 1$ for $0 \le i \le n$ and all odd Betti numbers vanish; $H^*(\mathbb{CP}^n; \mathbb{Z})$ has no torsion; $\chi(\mathbb{CP}^n) = n+1$; and f is perfect.

Worked example 7.22: $\mathbb{CP}^2$ with $a = (0, 1, 2)$

Take $f = (|z_2|^2 + 2|z_3|^2)/(|z_1|^2 + |z_2|^2 + |z_3|^2)$. Apply (7.38) at each coordinate point:

point	chart	f near the point	$f(P_k)$	real Hessian	index
$[1:0:0]$	$z_1 = 1$	$0 + \lvert w_2\rvert^2 + 2\lvert w_3\rvert^2$	0	$\mathrm{diag}(2,2,4,4)$	0
$[0:1:0]$	$z_2 = 1$	$1 - \lvert w_1\rvert^2 + \lvert w_3\rvert^2$	1	$\mathrm{diag}(-2,-2,2,2)$	2
$[0:0:1]$	$z_3 = 1$	$2 - 2\lvert w_1\rvert^2 - \lvert w_2\rvert^2$	2	$\mathrm{diag}(-4,-4,-2,-2)$	4

(Quartic terms omitted.) So $M_t = 1+t^2+t^4$, and by the lacunary principle $P_t(\mathbb{CP}^2) = 1+t^2+t^4$: $\mathbb{CP}^2$ has no 1-dimensional holes ($b_1 = 0$), one 2-cycle (the line $\mathbb{CP}^1 \subset \mathbb{CP}^2$) and a fundamental class in degree 4. The Euler characteristic is 3.

Worked example 7.23: $\mathbb{CP}^1$: the function is the height on S^2

For $n = 1$, on S^3 we have $|z_1|^2 + |z_2|^2 = 1$ and, with x_3 the third component of the Hopf map of Example 7.21, $|z_1|^2 - |z_2|^2 = x_3$. So $|z_1|^2 = (1 + x_3)/2$ and $|z_2|^2 = (1 - x_3)/2$. Then

$$f \overset{(1)}{=} a_1 \frac{1 + x_3}{2} + a_2 \frac{1 - x_3}{2} \overset{(2)}{=} \frac{a_1 + a_2}{2} - \frac{a_2 - a_1}{2} x_3.$$

(1) Substitute into $f = a_1 |z_1|^2 + a_2 |z_2|^2$.
(2) Collect the constant and the x_3 terms.

Since $a_2 > a_1$ this is a positive multiple of *minus* the height, plus a constant. Its minimum is at $x_3 = +1$, which is $P_1 = [1:0]$ (index 0), and its maximum at $x_3 = -1$, which is $P_2 = [0:1]$ (index 2). We recover Example 7.6 for $n = 2$: $M_t = 1 + t^2 = P_t(S^2)$.

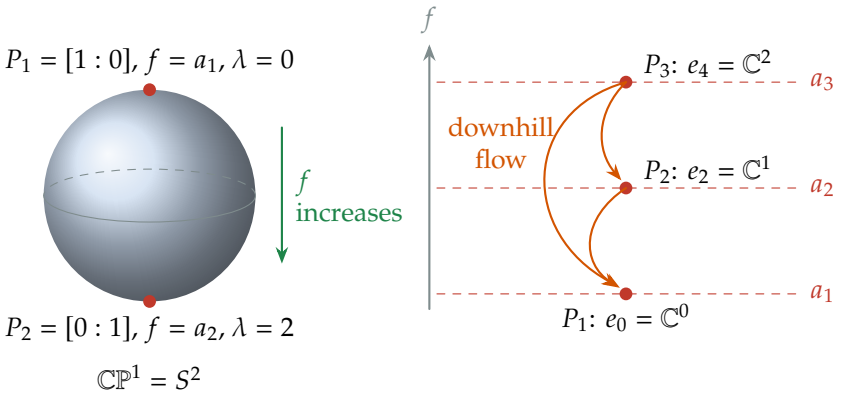

Figure 7.13: Left: on $\mathbb{CP}^1 = S^2$ the function $a_1|z_1|^2 + a_2|z_2|^2$ is (minus) the height, with one minimum and one maximum. Right: the three critical levels of f on $\mathbb{CP}^2$. Each P_k has index $2(k-1)$; the orange downhill flow lines leaving P_k sweep out a copy of $\mathbb{C}^{k-1}$, the cell $e_{2(k-1)}$. There are no odd cells, so there is nothing for a boundary map to connect: every cell is a cohomology class.

The cells, explicitly. We can see the cell decomposition (7.35) emerging from the flow. For the Fubini–Study metric (the natural round metric on $\mathbb{CP}^n$) the downhill gradient flow of f is, up to a positive constant c in the exponent fixed by the normalisation of the metric,

$$[z_1 : \cdots : z_{n+1}] \longmapsto [e^{-ca_1 t} z_1 : \cdots : e^{-ca_{n+1} t} z_{n+1}].$$

As $t \to -\infty$ the component with the largest a_j among the nonzero z_j dominates. So the points that flow out of P_k (the unstable manifold of P_k) are exactly those with $z_k \neq 0$ and $z_j = 0$ for $j > k$:

$$W^-(P_k) = \{[z_1 : \cdots : z_k : 0 : \cdots : 0],\ z_k \neq 0\} \cong \mathbb{C}^{k-1},$$

an open cell of real dimension $2(k-1) = \lambda_{P_k}$, as the general theory of Example 7.17 demands. Together they give $\mathbb{CP}^n = e_0 \cup e_2 \cup \cdots \cup e_{2n}$, and the sublevel set just below the top critical value is (up to homotopy) $\mathbb{CP}^{n-1}$.

Watch out: Nash's labelling of the index

Nash says "the i-th critical point has index $2i$". With his labelling $i = 1, \ldots, n+1$ that would give indices $2, 4, \ldots, 2n+2$, which is off by one step (the maximum index on a $2n$-manifold is $2n$). The correct statement is (7.40): the point where $f = a_k$ has index $2(k-1)$, i.e. index $2i$ if we count $i = 0, 1, \ldots, n$. His formula (7.22) is correct.

Physical picture: Why complex manifolds give even indices

Nash remarks that this "illustrates the point that we can use Morse theory on complex manifolds even though f is a real valued function". There is no choice: a holomorphic function on a compact complex manifold is constant (it attains a maximum of $|F|$, so by the maximum principle it is constant), so Morse functions are always real. What the complex structure does is *pair up the real directions*, $w = u + iv$. Our f is invariant under the phase rotations $z_j \mapsto e^{i\theta_j} z_j$, and a function invariant under a rotation of the (u_j, v_j) plane has equal Hessian eigenvalues in that plane. Hence every index is even, and the lacunary principle applies. (This is the simplest case of a general fact: on a compact symplectic manifold with a circle action, the "moment map" is a Morse–Bott function with even indices and is always perfect. Our f is the moment map of the phase rotations.) By contrast, the real part of a holomorphic function has critical points of index *exactly* half the real dimension: $\mathrm{Re}(z^2) = x^2 - y^2$ has index 1 on $\mathbb{C}$. We use this in Section 7.4.4.

7.4.3 The height function on a surface of genus p

A **surface of genus** p, Σ_p, is a closed orientable surface with p holes: a sphere with p handles attached, or p tori glued in a row. Every closed orientable surface is one of these. Stand Σ_p on its end, with the holes stacked vertically, and let f be the height [Nash p. 197].

Worked example 7.24: Critical points of the upright Σ_p

Reading off from Figure 7.14: a minimum at the bottom (index 0), a maximum at the top (index 2), and for each hole two saddles (index 1), one at the bottom of the hole and one at its top. Each saddle is exactly like those of the upright torus, Example 7.7. So

$$M_t(f) = 1 + 2p\,t + t^2 \tag{7.43}$$

[Nash (7.24)], and

$$\chi(\Sigma_p) \overset{(1)}{=} M_{-1}(f) \overset{(2)}{=} 1 - 2p + 1 = 2 - 2p. \tag{7.44}$$

(1) Relation (7.21): the Euler characteristic is the signed count of critical points.
(2) Set $t = -1$ in (7.43).

Since $P_t(\Sigma_p) = 1 + 2pt + t^2$ (the $2p$ independent loops $a_1, b_1, \ldots, a_p, b_p$ around and through each hole), this height function is perfect. Gauss–Bonnet gives a completely independent

check, $\frac{1}{2\pi}\int_{\Sigma_p} K\,\mathrm{d}A = 2-2p$ (Chapter T2): the saddles are where the surface is negatively curved.

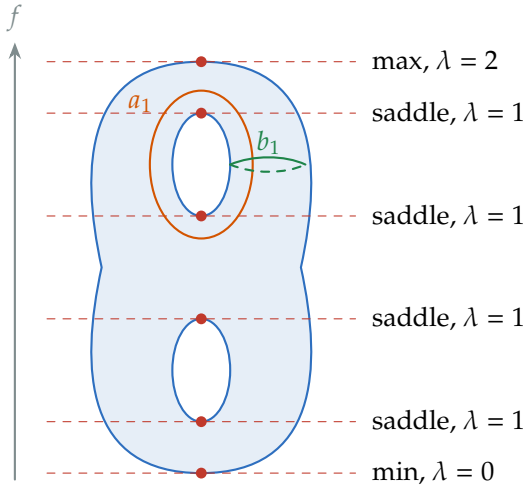

Figure 7.14: A surface of genus 2 standing upright. The height has $2p+2=6$ critical points: a minimum, a maximum, and a saddle at the bottom and the top of each hole. The dashed red lines are the six critical levels. The orange loop a_1 goes around the upper hole and the green loop b_1 goes through the tube beside it; the $2p$ loops a_i, b_i are the $2p$ independent 1-dimensional holes that force the $2p$ saddles.

Try it: Sublevel sets of Σ_2

Flood the surface of Figure 7.14. Describe M_c just above each critical level.
Answer: disc; annulus (cylinder); annulus with its two ends joined over the lower hole, i.e. a punctured torus ($\simeq$ wedge of 2 circles); then the lower saddle of the upper hole adds a strip, giving a torus with two punctures ($\simeq$ wedge of 3 circles); the top saddle of the upper hole gives a punctured genus-2 surface ($\simeq$ wedge of 4 circles); the maximum caps it. Cells: $e_0 \cup 4e_1 \cup e_2$.

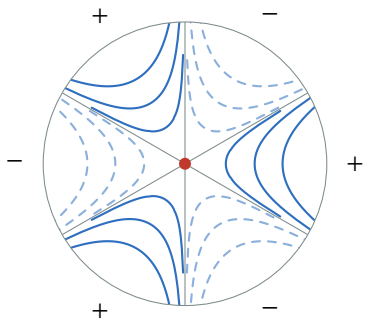
7.4.4 Squashing the saddles together: degenerate critical points

The Morse inequalities say that a Morse function on Σ_p needs at least $2p+2$ critical points. Nash points out that if we drop non-degeneracy we can do much better: *four* critical points suffice for every p, a maximum, a minimum and two degenerate saddles. Deform the upright Σ_p so that the p lower saddles slide together into one point, and likewise the p upper ones. Near the merged saddle, in suitable coordinates (x,y) centred on it,

$$f = \mathrm{Re}(x+iy)^{p+1} = \mathrm{Re}\, z^{p+1} = r^{p+1}\cos\big((p+1)\varphi\big) \tag{7.45}$$

[Nash p. 198], where $z = x+iy = re^{i\varphi}$.

What this looks like. As we go once around the point, $\cos((p+1)\varphi)$ changes sign $2(p+1)$ times: there are $p+1$ "valleys" ($f<0$) and $p+1$ "ridges" ($f>0$) alternating around it. For $p=1$ this is the ordinary saddle x^2-y^2 (two valleys). For $p=2$ it is the monkey saddle x^3-3xy^2 of Example 7.3 (three valleys). All second derivatives of $r^{p+1}\cos((p+1)\varphi)$ vanish at 0 when $p+1\geq 3$, so the Hessian is the zero matrix: the point is as degenerate as possible and has no Morse index.



$\operatorname{Re} z^3$: three ridges (+),
three valleys (−)

Figure 7.15: Level curves of the monkey saddle $f = \operatorname{Re} z^3 = r^3 \cos 3\varphi$ ($p = 2$ in (7.45)). Solid: $f > 0$; dashed: $f < 0$; faint rays: the level $f = 0$, six half-lines through the critical point. Compare the ordinary saddle in Figure 7.2, which has two ridges and two valleys. A monkey saddle is two ordinary saddles squashed into one point.

Counting a degenerate critical point: the gradient winding number. The Morse index is lost, but the Euler count (7.21) must still hold, since χ is topological. The replacement for $(-1)^\lambda$ is the **index of the vector field** ∇f at the zero: the number of times the direction of ∇f turns around as we go once counter-clockwise around a small circle about the point. For a holomorphic $F = f + ig$ the Cauchy–Riemann equations give $\partial_x f = \operatorname{Re} F'$ and $\partial_y f = -\operatorname{Im} F'$. So

$$\begin{aligned} \partial_x f + i\,\partial_y f &\overset{(1)}{=} \operatorname{Re} F'(z) - i \operatorname{Im} F'(z) \\ &\overset{(2)}{=} \overline{F'(z)} \overset{(3)}{=} (p+1)\,\bar{z}^{\,p} \overset{(4)}{=} (p+1)\,r^p e^{-ip\varphi}. \end{aligned} \tag{7.46}$$

(1) The Cauchy–Riemann equations just quoted.
(2) $\operatorname{Re} w - i \operatorname{Im} w = \bar{w}$.
(3) $F = z^{p+1}$, so $F' = (p+1)z^p$.
(4) $z = re^{i\varphi}$.

As φ runs from 0 to 2π the direction $e^{-ip\varphi}$ of ∇f turns p times *clockwise*: the vector-field index is $-p$. Check $p = 1$: an ordinary saddle has index $-1 = (-1)^1$. Now the Euler count on the squashed Σ_p:

$$\chi(\Sigma_p) \overset{(1)}{=} \underbrace{(+1)}_{\max} + \underbrace{(+1)}_{\min} + \underbrace{2 \times (-p)}_{\text{two degenerate saddles}} = 2 - 2p.$$

(1) Poincaré–Hopf: the sum of the indices of the zeros of ∇f is χ. A non-degenerate max or min has vector-field index +1.

It matches. The two degenerate saddles carry all the topology of the $2p$ original saddles.

Unfolding the degeneracy. Nash notes that a small perturbation removes the degeneracy: replace

$$z^{p+1} \longrightarrow F_\varepsilon(z) = (z - \varepsilon_1)(z - \varepsilon_2) \cdots (z - \varepsilon_{p+1}) \tag{7.47}$$

with distinct small ε_i. The critical points of $f_\varepsilon = \operatorname{Re} F_\varepsilon$ are, by (7.46) with F_ε in place of z^{p+1}, the zeros of F'_ε, a polynomial of degree p. For generic ε_i its p roots $\zeta_1, \ldots, \zeta_p$ are distinct and

$F''_\varepsilon(\zeta_m) \neq 0$. Near each root,

$$f_\varepsilon \overset{(1)}{=} \operatorname{Re}\Big[F_\varepsilon(\zeta_m) + \tfrac{1}{2}F''_\varepsilon(\zeta_m)(z-\zeta_m)^2 + \dots\Big]$$
$$\overset{(2)}{=} \text{const} + \tfrac{1}{2}\,|F''_\varepsilon(\zeta_m)|\,\operatorname{Re}(\xi^2) + \dots \overset{(3)}{=} \text{const} + \tfrac{1}{2}\,|F''_\varepsilon(\zeta_m)|\,(\xi_1^2 - \xi_2^2) + \dots$$

(1) Taylor expansion of the holomorphic F_ε; the linear term vanishes because $F'_\varepsilon(\zeta_m) = 0$.
(2) Write $F''_\varepsilon(\zeta_m) = |F''_\varepsilon|\,e^{i\alpha}$ and rotate, $\xi = e^{i\alpha/2}(z-\zeta_m)$.
(3) $\operatorname{Re}\xi^2 = \xi_1^2 - \xi_2^2$ for $\xi = \xi_1 + i\xi_2$.

So each ζ_m is a non-degenerate saddle of index 1. The single degenerate point has *bifurcated* into p ordinary saddles, and the total vector-field index is conserved: $p \times (-1) = -p$. Doing this to both degenerate points restores a Morse function with $2p+2$ critical points.

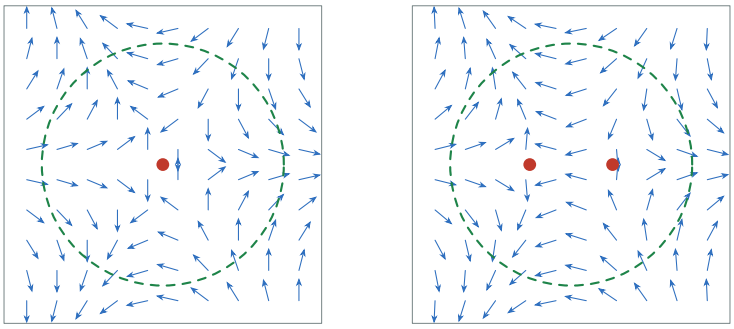
Worked example 7.25: Splitting a monkey saddle

Take $p = 2$ and $F_\varepsilon = z^3 - 3\varepsilon z$ with $\varepsilon > 0$ (this is $(z-\varepsilon_1)(z-\varepsilon_2)(z-\varepsilon_3)$ with $\varepsilon_1+\varepsilon_2+\varepsilon_3 = 0$, a harmless normalisation). Then

$$F'_\varepsilon(z) \overset{(1)}{=} 3(z^2-\varepsilon) \quad\Longrightarrow\quad \zeta_\pm = \pm\sqrt{\varepsilon}, \qquad F''_\varepsilon(\zeta_\pm) \overset{(2)}{=} \pm 6\sqrt{\varepsilon} \neq 0.$$

(1) Differentiate.
(2) $F''_\varepsilon = 6z$.

In real terms $f_\varepsilon = x^3 - 3xy^2 - 3\varepsilon x$, and at $(\pm\sqrt{\varepsilon}, 0)$ the Hessian is $\operatorname{diag}(\pm 6\sqrt{\varepsilon}, \mp 6\sqrt{\varepsilon})$: two non-degenerate saddles. As $\varepsilon \to 0$ they approach each other and merge into the monkey saddle. This is the two-dimensional cousin of the birth–death picture Figure 7.3, except that here two critical points of the *same* index merge, which a Morse function could never do generically.



$\varepsilon = 0$: monkey saddle, index -2 | $\varepsilon = 0.3$: two saddles, index -1 each

Figure 7.16: The direction of ∇f (unit arrows) for $f_\varepsilon = x^3 - 3xy^2 - 3\varepsilon x$. Follow the arrows around the green dashed circle: in both pictures they turn twice clockwise, so the total index inside the circle is -2. On the left it is concentrated in one degenerate point; on the right it is shared by two ordinary saddles (red dots). The perturbation moves the zeros but cannot change the winding number on a circle it does not touch.

Watch out: Degenerate functions have no Morse series

The Morse series (7.11) is only defined for Morse functions: a degenerate critical point has no index to put in the exponent. The Morse inequalities therefore say *nothing* about degenerate functions, and indeed the four-point function on Σ_p violates $M_1(f) \geq 2p+2$.

What survives degeneration is only the Euler count, with vector-field indices in place of $(-1)^\lambda$.

7.4.5 A lower bound for every function: the Lusternik–Schnirelmann category

Since degenerate functions can have fewer critical points, Nash asks: is there any topological lower bound on the number of critical points of an *arbitrary* smooth function? Yes.

Working definition 7.11 (Lusternik–Schnirelmann category)

The **category** $\operatorname{cat}(M)$ is the smallest number k of closed subsets $M_1, \dots, M_k$ with $M = M_1 \cup \cdots \cup M_k$ such that each M_i is contractible in M (it can be shrunk to a point through M) [Nash p. 198]. *Operational use:* upper bounds come from exhibiting a cover [an explicit choice of k such sets, which shows $\operatorname{cat}(M) \le k$]; lower bounds come from cohomology (see below). (Many modern texts subtract one, so that cat of a contractible space is 0; we follow Nash, for whom it is 1.)

Key idea: The Lusternik–Schnirelmann theorem

Every smooth function on a compact manifold M has at least $\operatorname{cat}(M)$ distinct critical points. $\operatorname{cat}(M)$ is a topological invariant.

Why: the minimax principle. Let $\mathcal{A}_j$ be the family of closed sets $A \subset M$ that cannot be covered by fewer than j closed sets contractible in M. Define

$$c_j = \inf_{A \in \mathcal{A}_j} \max_{x \in A} f(x), \qquad j = 1, \dots, \operatorname{cat}(M).$$

$\mathcal{A}_1$ contains single points, so $c_1 = \min f$, and $\mathcal{A}_{\operatorname{cat}(M)}$ contains M, so $c_{\operatorname{cat} M} \le \max f$. The families shrink as j grows, so $c_1 \le c_2 \le \dots$. Each c_j is a critical value: if it were not, the downhill flow of Section 7.3.3 would push the whole of a near-optimal A below c_j, and a deformation cannot lower the category of A, so we would have found a set in $\mathcal{A}_j$ with maximum below c_j, contradicting the definition. If all the c_j are different we have $\operatorname{cat}(M)$ critical values. If two coincide, $c_j = c_{j+1}$, one shows that the critical set at that level cannot be contractible in M, so it is infinite. Either way there are at least $\operatorname{cat}(M)$ critical points. (This is the physicist's familiar "mountain pass" or minimax argument: the lowest pass over which you must climb to get from one valley to another is a saddle point.)

How to compute it. Two estimates bracket $\operatorname{cat}(M)$ for a connected n-manifold:

$$(\text{cup length of } M) + 1 \;\le\; \operatorname{cat}(M) \;\le\; n + 1. \tag{7.48}$$

The **cup length** is the largest number of positive-degree cohomology classes whose wedge (cup) product is nonzero. The lower bound holds because a class of positive degree restricts to zero on a set contractible in M, and a product of classes each vanishing on one of k sets covering M vanishes on their union. The upper bound comes from a fine triangulation.

Worked example 7.26: Categories of the standard examples

- S^n: the two closed hemispheres (slightly enlarged) are contractible, so cat ≤ 2; S^n is not contractible, so cat $\neq 1$. Hence $\operatorname{cat}(S^n) = 2$ [Nash (7.25)], and the height function (two critical points) achieves the bound.

- T^2: $[\mathrm{d}x] \wedge [\mathrm{d}y] = [\mathrm{d}x \wedge \mathrm{d}y] \neq 0$, so the cup length is 2 and cat ≥ 3; also cat ≤ 3 by (7.48). So $\mathrm{cat}(T^2) = 3$.
- Σ_p, $p \geq 1$: the classes dual to a_1 and b_1 have nonzero product (the area class), so again $\mathrm{cat}(\Sigma_p) = 3$ [Nash (7.25)].
- T^n: $[\mathrm{d}x_1] \wedge \cdots \wedge [\mathrm{d}x_n] \neq 0$, so $\mathrm{cat}(T^n) = n + 1$. Compare the Morse bound 2^n.
- $\mathbb{CP}^n$: the generator $u \in H^2$ has $u^n \neq 0$ (it integrates to 1 over $\mathbb{CP}^n$, suitably normalised), so the cup length is n and $\mathrm{cat}(\mathbb{CP}^n) = n + 1$. Here the LS bound equals the Morse bound, and our f achieves it.

Worked example 7.27: A function on the torus with only three critical points

Let $f(x, y) = \sin x + \sin y + \sin(x + y)$ on $T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$. Critical points need

$$\partial_x f = \cos x + \cos(x + y) = 0, \qquad \partial_y f = \cos y + \cos(x + y) = 0.$$

Subtracting, $\cos x = \cos y$, so $y = x$ or $y = -x \pmod{2\pi}$.

- If $y = -x$: $\cos x + \cos 0 = 0$ forces $\cos x = -1$, so $(x, y) = (\pi, \pi)$.
- If $y = x$: $\cos x + \cos 2x = 0$, i.e. $2\cos^2 x + \cos x - 1 = 0$, i.e. $(2\cos x - 1)(\cos x + 1) = 0$. So $x = \pm\pi/3$ or $x = \pi$.

Exactly three critical points: $(\frac{\pi}{3}, \frac{\pi}{3})$ with $f = \frac{3\sqrt{3}}{2}$ (the maximum), $(-\frac{\pi}{3}, -\frac{\pi}{3})$ with $f = -\frac{3\sqrt{3}}{2}$ (the minimum), and (π, π) with $f = 0$. At the last one,

$$\partial_x^2 f \overset{(1)}{=} -\sin x - \sin(x + y) = 0, \quad \partial_y^2 f = 0, \quad \partial_x \partial_y f \overset{(2)}{=} -\sin(x + y) = 0,$$

(1) Differentiate $\partial_x f$ once more; $\sin\pi = \sin 2\pi = 0$.
(2) Differentiate $\partial_x f$ with respect to y.

The Hessian vanishes: it is a monkey saddle, with vector-field index -2, and $1 + 1 - 2 = 0 = \chi(T^2)$. So the LS bound $\mathrm{cat}(T^2) = 3$ is attained. No Morse function could do this; the Morse bound is 4.

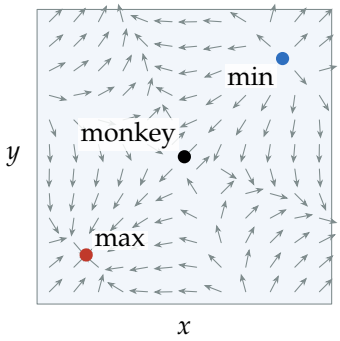


Figure 7.17: The direction of ∇f for $f = \sin x + \sin y + \sin(x + y)$ on the torus $[0, 2\pi]^2$ (opposite sides identified). The arrows flow out of the minimum (blue) and into the maximum (red); around the black point at (π, π) they turn twice clockwise, the signature of a monkey saddle. Three critical points in all, the minimum allowed by the Lusternik–Schnirelmann category.

Reading Nash (pp. 196–198, (7.19)–(7.25))

Nash's $\mathbb{CP}^n$ example: S^{2n+1} [Nash (7.19)], the S^1 action [Nash (7.20)], $\tilde{f} = \sum a_i z_i \bar{z}_i$ [Nash (7.21)], "a straightforward piece of calculus" for the indices (we did it in (7.38)), $M_t = 1+t^2+\cdots+t^{2n}$ [Nash (7.22)] and the lacunary conclusion [Nash (7.23)]. The genus-p height function gives [Nash (7.24)] and $\chi = 2-2p$. Nash then describes the four-point degenerate function, the local form $\mathrm{Re}(x+iy)^{p+1}$, the Lusternik–Schnirelmann category with $\mathrm{cat}(S^2) = 2$, $\mathrm{cat}(\Sigma_p) = 3$ [Nash (7.25)], and the unfolding $z^{p+1} \to \prod(z-\varepsilon_i)$. He also remarks that three critical points can be attained on Σ_p, "but not by any embedding of Σ_p in three dimensions" (i.e. not as a height function); we have not checked this claim and do not use it. What we added: charts and the Hopf map, the Lagrange multiplier and Hessian computations, the explicit cells, the quantum-state reading of f, the gradient winding number and Poincaré–Hopf check, the explicit bifurcation, the minimax mechanism and cup-length bounds, and the three-point function on T^2.

Recap

- $\mathbb{CP}^n = S^{2n+1}/\mathrm{U}(1)$; $f = \sum a_i |z_i|^2 / \sum |z_i|^2$ has $n+1$ critical points (the eigenstates of $\mathrm{diag}(a_i)$) of indices $0, 2, \ldots, 2n$; complex directions double every eigenvalue.
- Lacunary $\Rightarrow P_t(\mathbb{CP}^n) = 1 + t^2 + \cdots + t^{2n}$ over every field; $\mathbb{CP}^n = e_0 \cup e_2 \cup \cdots \cup e_{2n}$.
- Upright Σ_p: $M_t = 1 + 2pt + t^2$, perfect, $\chi = 2 - 2p$.
- Degenerate points: $\mathrm{Re}\, z^{p+1}$ has vector-field index $-p$; perturbing it splits it into p ordinary saddles.
- Any smooth f has $\geq \mathrm{cat}(M)$ critical points; $\mathrm{cat}(S^n) = 2$, $\mathrm{cat}(\Sigma_p) = 3$, $\mathrm{cat}(\mathbb{CP}^n) = n+1$; $\sin x + \sin y + \sin(x+y)$ attains 3 on T^2.

7.5 Critical submanifolds: Morse–Bott theory

Symmetry and isolated critical points do not get on. If a function is invariant under rotations about an axis, then rotating a critical point gives another critical point, and unless the point sits on the axis, it sweeps out a whole circle of them. Physics is full of such families. The minimum of a Mexican-hat potential is a circle of vacua; the classical solutions of a rotationally invariant problem come in orbits; every closed geodesic can be started at any point along itself. A Morse function cannot have any of this: its critical points are isolated. Bott's generalisation, which Nash describes in §2, keeps the whole machine running when the critical points come in smooth families, provided the function is non-degenerate *across* each family. The key new fact is that a critical family C contributes not a monomial t^λ but a whole polynomial $t^{\lambda_C} P_t(C)$.

Physical picture: Vacuum manifolds and Goldstone modes

Take the Mexican hat $V(\phi) = (|\phi|^2 - v^2)^2$ for a complex field $\phi = \phi_1 + i\phi_2$ (constant in space). Its minima form the circle $|\phi| = v$. At a point of the circle, the Hessian has one positive eigenvalue (the radial "Higgs" direction, $\mathrm{mass}^2 = 8v^2$) and one zero eigenvalue, along the circle (the Goldstone mode). The zero mode is not an accident to be perturbed away: it is forced by the U(1) symmetry. Morse–Bott theory is the statement that zero modes of this kind, *exactly tangent to the critical family*, are harmless.

7.5.1 The torus on a dinner plate

Nash's motivating example [Nash p. 199]: the height function on the torus of Section 7.1.7, but now lying flat, as it would on a dinner plate. The embedding is

$$(\theta, \phi) \mapsto \big((R + r\cos\theta)\cos\phi,\ (R + r\cos\theta)\sin\phi,\ r\sin\theta\big), \tag{7.49}$$

with θ around the tube and ϕ around the vertical axis. The height is $f(\theta, \phi) = r\sin\theta$, independent of ϕ.

Worked example 7.28: Critical circles of the flat torus

The derivatives are

$$\partial_\theta f = r\cos\theta, \qquad \partial_\phi f = 0.$$

So $\mathrm{d}f = 0$ exactly when $\cos\theta = 0$: on the two circles

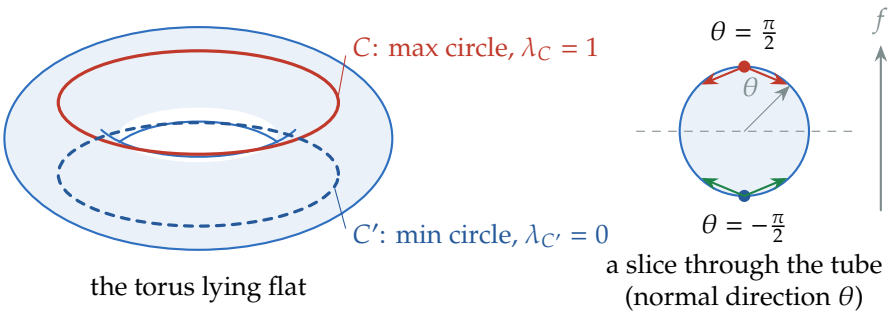
$$C = \{\theta = \tfrac{\pi}{2}\}\ (\text{top}, f = r), \qquad C' = \{\theta = -\tfrac{\pi}{2}\}\ (\text{bottom}, f = -r).$$

The Hessian in the coordinates (θ, ϕ) is

$$Hf \overset{(1)}{=} \begin{pmatrix} -r\sin\theta & 0 \\ 0 & 0 \end{pmatrix} \overset{(2)}{=} \begin{cases} \mathrm{diag}(-r, 0) & \text{on } C, \\ \mathrm{diag}(+r, 0) & \text{on } C'. \end{cases}$$

(1) $\partial_\theta^2(r\sin\theta) = -r\sin\theta$; all derivatives involving ϕ vanish because f does not depend on ϕ.
(2) $\sin(\pm\pi/2) = \pm 1$.

Every critical point is degenerate ($\det Hf = 0$), so f is not a Morse function and the theory of Section 7.2 does not apply. But the degeneracy has a very particular form. The zero eigenvector ∂_ϕ is tangent to the critical circle, and in the one direction *normal* to the circle, ∂_θ, the Hessian is non-degenerate: negative on the top circle (moving off it, over the tube, goes down), positive on the bottom one.



the torus lying flat

a slice through the tube (normal direction θ)

Figure 7.18: Left: the torus lying flat. The height is constant along the top circle C (red) and along the hidden bottom circle C' (blue, dashed), and these are its only critical points. Right: a vertical slice through the tube. In the one normal direction θ, the top of the slice is a maximum (red arrows go downhill) and the bottom a minimum (green arrows go uphill). Along the circles themselves nothing changes: that is the zero eigenvalue.

7.5.2 Non-degenerate critical submanifolds

First a basic fact: along a critical family the tangent directions are *always* in the kernel of the Hessian. Let C be a submanifold on which $\mathrm{d}f = 0$, and let $\gamma(s)$ be a curve in C. For each j, the function $s \mapsto \partial_j f(\gamma(s))$ is identically zero, so

$$0 \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}s}\, \partial_j f(\gamma(s)) \overset{(2)}{=} \partial_i \partial_j f\ \dot\gamma^i \overset{(3)}{=} H_{ji}\, \dot\gamma^i. \tag{7.50}$$

(1) $\partial_j f = 0$ at every point of C, in particular along γ.
(2) Chain rule.
(3) Definition of the Hessian.

So $H\dot\gamma = 0$: every tangent vector to C is a zero eigenvector of the Hessian. The Hessian therefore *must* have at least $\dim C$ zero eigenvalues. Bott's condition asks that it have no more.

Working definition 7.12 (non-degenerate critical submanifold (Bott))

A connected submanifold $C \subset M$ is a **non-degenerate critical manifold** of f if

1. $\mathrm{d}f = 0$ at every point of C, and
2. at every $p \in C$ the kernel of $Hf(p)$ [the vectors v with $H_{ij}v^j = 0$] is exactly T_pC [the velocities of curves that stay inside C].

Equivalently, the Hessian restricted to the directions normal to C [directions leaving C, complementary to T_pC inside T_pM] is non-degenerate [Nash p. 199]. *Operational test:* at each point of C, the nullity $\dim M - \operatorname{rank} Hf(p)$ equals $\dim C$. A function all of whose critical points lie on non-degenerate critical manifolds is a **Morse–Bott function**. (An isolated non-degenerate critical point is the case $\dim C = 0$.)

For the flat torus, $\dim C = 1$ and the nullity is 1 everywhere on C and C': both are non-degenerate critical circles.

The normal bundle and its splitting. At each $p \in C$ the **normal space** $N_p(C)$ is the orthogonal complement of T_pC in T_pM (for some metric; without a metric, take the quotient T_pM/T_pC). Together they form the **normal bundle** $N(C) \to C$, a vector bundle of rank $n - \dim C$. The Hessian is a non-degenerate symmetric form on each fibre N_p, so its eigenvectors split each fibre into a positive and a negative part:

$$N(C) = N^+(C) \oplus N^-(C) \tag{7.51}$$

[Nash p. 199, (7.26)], where N^- is spanned by the eigenvectors of the Hessian with negative eigenvalues and N^+ by those with positive eigenvalues.

Working definition 7.13 (index of a critical manifold)

The **index** of C is $\lambda_C = \operatorname{rank} N^-(C)$, the number of negative eigenvalues of the Hessian at any point of C [this number is the same at every $p \in C$, as shown below]: the number of independent directions in which one can roll off C downhill.

Why does λ_C not depend on the point $p \in C$? The eigenvalues of $Hf(p)$ vary continuously with p. On the normal directions none of them is ever zero, so none can change sign as p moves along the connected manifold C. The number of negative ones is locally constant, hence constant.

Key idea: The Morse–Bott lemma

Near a non-degenerate critical manifold C of index λ_C there are coordinates (c, u, v), with c coordinates along C, $u \in \mathbb{R}^{\lambda_C}$ along the fibres of N^- and v along the fibres of N^+, in which

$$f = f(C) - |u|^2 + |v|^2 . \tag{7.52}$$

The function does not depend on c at all: near C, f is "the Morse lemma in the normal directions, repeated at every point of C".

The proof is the Morse lemma of Section 7.1.4 done with the coordinates c carried along as parameters: Step 1 (writing f as a quadratic form with variable coefficients) only uses the normal coordinates, since f and $\mathrm{d}f$ vanish identically on C, and Step 2 (completing squares) works with c-dependent coefficients because the normal Hessian is invertible everywhere on C.

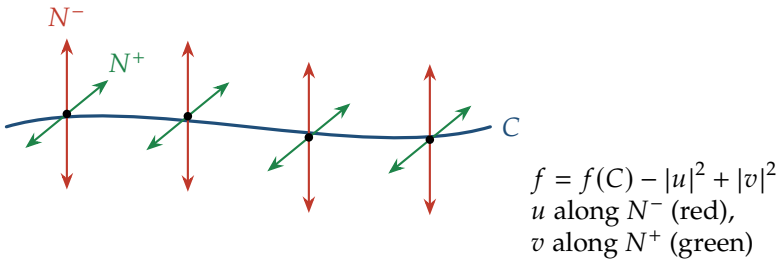


Figure 7.19: The local picture near a critical manifold C. At every point of C the normal space splits into a downhill part N^- (red) and an uphill part N^+ (green); along C itself f is constant. The index λ_C is the number of red directions. As we move along C the fibres twist, which is why N^- is a *bundle*, possibly non-trivial.

7.5.3 What a critical manifold contributes to the Morse series

Key idea: Bott's contribution (Nash (7.27)–(7.28))

A non-degenerate critical manifold C of index λ_C contributes

$$t^{\lambda_C} P_t(C) \tag{7.53}$$

to the Morse series, where $P_t(C)$ is the Poincaré polynomial of C. The **Morse–Bott series** is

$$M_t(f) = \sum_{\text{critical manifolds } C} t^{\lambda_C} P_t(C). \tag{7.54}$$

When C is a point, $P_t(C) = 1$ and we get back t^{λ_p}.

There are two ways to see why the whole Poincaré polynomial of C appears. Both are worth knowing.

Mechanism 1: tilt the function. Let g be a Morse function on C, extended to a small neighbourhood of C so that it does not depend on the normal coordinates. Consider $f_\varepsilon = f + \varepsilon g$. In the Morse–Bott coordinates,

$$f_\varepsilon = f(C) - |u|^2 + |v|^2 + \varepsilon\, g(c).$$

Its critical points near C need $u = v = 0$ (from ∂_u, ∂_v) and $\mathrm{d}g(c) = 0$ (from ∂_c). So they are exactly the critical points q of g on C, and at such a point the Hessian is block diagonal,

$$Hf_\varepsilon(q) = \operatorname{diag}\big(\underbrace{-2,\dots,-2}_{\lambda_C},\ \underbrace{+2,\dots,+2}_{\operatorname{rank} N^+},\ \varepsilon\, Hg(q)\big), \tag{7.55}$$

so the index of q as a critical point of f_ε is $\lambda_C + \lambda_q(g)$. The tilted function is Morse, and C has been replaced by the critical points of g, each shifted up in index by λ_C. Its contribution to $M_t(f_\varepsilon)$ is $t^{\lambda_C} M_t(g)$. If we choose g perfect on C, this is $t^{\lambda_C} P_t(C)$.

Worked example 7.29: Tilting the dinner plate

On the flat torus take $g = x = (R + r\cos\theta)\cos\phi$ (the tilt you get by lifting one side of the plate slightly). On the top circle C, $g = R\cos\phi$, which has a maximum at $\phi = 0$ (index 1 on the circle) and a minimum at $\phi = \pi$ (index 0). Likewise on C'. So the tilted function has four critical points:

circle	λ_C	point on circle	$\lambda_q(g\vert_C)$	index in f_ε
C (top)	1	$\phi = 0$	1	2
C (top)	1	$\phi = \pi$	0	1
C' (bottom)	0	$\phi = 0$	1	1
C' (bottom)	0	$\phi = \pi$	0	0

The indices are $0, 1, 1, 2$, as for the upright torus. That is no surprise: tilting the plate further and further ends with the torus standing on its end. The top circle contributed $t^1 + t^2 = t(1 + t) = t\,P_t(S^1)$ and the bottom one $1 + t = P_t(S^1)$.

Mechanism 2: attach a disc bundle (the Thom isomorphism). Redo the handle argument of Section 7.3.4 with the Morse–Bott normal form. As the level rises through $f(C)$, what gets attached to $M_{f(C)-\varepsilon}$ is no longer a single disc D^λ but a disc D^{λ_C} in the fibre of N^- over *every* point of C: the **disc bundle** $D(N^-)$, glued along its **sphere bundle** $S(N^-)$ (the boundary spheres of the fibre discs). The relative cohomology of this pair is given by the **Thom isomorphism**: if N^- is orientable,

$$H^k\big(D(N^-), S(N^-)\big) \cong H^{k-\lambda_C}(C), \qquad \text{i.e.} \qquad P_t\big(D(N^-), S(N^-)\big) = t^{\lambda_C} P_t(C). \tag{7.56}$$

Each class on C gets "lifted" by λ_C degrees by wedging it with a form on the fibre that integrates to 1 over each disc and vanishes near the boundary (the Thom form). When C is a point this is (7.31). Now substitute (7.56) for (7.31) in the telescoping argument (7.33). Nothing else changes, and out come the Morse–Bott inequalities.

Worked example 7.30: The Thom isomorphism for a circle with a trivial line bundle

Let $C = S^1$ and $N^- = S^1 \times \mathbb{R}$ (rank 1, trivial). Then $X = D(N^-) = S^1 \times [-1, 1]$ is an annulus and $Y = S(N^-) = S^1 \times \{\pm 1\}$ is its two boundary circles. The exact sequence of the pair (Section 7.3.8) reads, with real coefficients,

$$0 \to H^0(X,Y) \to \underbrace{H^0(X)}_{\mathbb{R}} \xrightarrow{r_0} \underbrace{H^0(Y)}_{\mathbb{R}^2} \to H^1(X,Y) \to \underbrace{H^1(X)}_{\mathbb{R}} \xrightarrow{r_1} \underbrace{H^1(Y)}_{\mathbb{R}^2} \to H^2(X,Y) \to 0.$$

Here $r_0(a) = (a, a)$ (a constant restricts to the same constant on both circles) and $r_1(b) = (b, b)$ (the loop around the annulus is homotopic to each boundary circle). Both are injective

with rank 1. So

$$\dim H^0(X,Y) \overset{(1)}{=} 0, \qquad \dim H^1(X,Y) \overset{(2)}{=} (2-1)+0 = 1, \qquad \dim H^2(X,Y) \overset{(3)}{=} 2-1 = 1.$$

(1) $H^0(X,Y)$ is the kernel of r_0, which is injective.
(2) $H^1(X,Y)$ receives the cokernel of r_0 (dimension $2-1$) and maps onto the kernel of r_1 (dimension 0).
(3) $H^2(X,Y)$ is the cokernel of r_1.

Hence $P_t(X,Y) = t + t^2 = t(1+t) = t^1 P_t(S^1)$, exactly (7.56) with $\lambda_C = 1$.

Watch out: The negative bundle must be orientable, or use $\mathbb{Z}_2$

Nash says C is a "connected oriented" submanifold. What matters for (7.56) is really the orientability of N^-. Take instead N^- to be the Möbius line bundle over S^1. Then $X = D(N^-)$ is a Möbius band and $Y = S(N^-)$ is its boundary, a *single* circle that runs twice around the core. Now $r_0 : \mathbb{R} \to \mathbb{R}$ is an isomorphism, and $r_1 : \mathbb{R} \to \mathbb{R}$ is multiplication by 2 (the boundary wraps twice), also an isomorphism over $\mathbb{R}$. Every relative group vanishes: $P_t(X,Y;\mathbb{R}) = 0 \neq t(1+t)$. Over $\mathbb{Z}_2$, multiplication by 2 is zero, so $H^1(X,Y;\mathbb{Z}_2) \cong \mathbb{Z}_2$ and $H^2(X,Y;\mathbb{Z}_2) \cong \mathbb{Z}_2$: $P_t(X,Y;\mathbb{Z}_2) = t + t^2$, as (7.56) predicts. So: with $\mathbb{Z}_2$ coefficients the Morse–Bott formula always holds; with real coefficients it needs N^- orientable (or else $P_t(C)$ must be replaced by the cohomology of C twisted by the orientation of N^-).

7.5.4 The Morse–Bott inequalities and the examples

Key idea: Morse–Bott inequalities (Nash (7.30))

For a Morse–Bott function f on a compact M, and any field $\mathbf{F}$ (provided every $N^-(C)$ is orientable when $\mathbf{F}$ does not have characteristic 2),

$$M_t(f) = \sum_C t^{\lambda_C} P_t(C;\mathbf{F}) \;\geq\; P_t(M;\mathbf{F}), \qquad M_t(f) - P_t(M;\mathbf{F}) = (1+t)R(t),\ R \geq 0. \tag{7.57}$$

Setting $t = -1$: $\sum_C (-1)^{\lambda_C} \chi(C) = \chi(M)$.

Worked example 7.31: The dinner-plate torus is perfect (Nash (7.29))

With $P_t(C) = P_t(C') = 1 + t$, $\lambda_C = 1$, $\lambda_{C'} = 0$:

$$M_t(f) \overset{(1)}{=} t^{\lambda_{C'}} P_t(C') + t^{\lambda_C} P_t(C) \overset{(2)}{=} (1+t) + t(1+t) = 1 + 2t + t^2 \overset{(3)}{=} P_t(T^2).$$

(1) The Morse–Bott series (7.54) with the two critical circles.
(2) $P_t(S^1) = 1 + t$ and the indices from Example 7.28.
(3) Example 7.9.

The degenerate height function is, in Bott's sense, perfect: "the height function is restored to perfection".

Worked example 7.32: The square of the height on S^2 (Nash (7.31)–(7.33))

Let $f = z^2$ on $S^2 = \{x^2 + y^2 + z^2 = 1\}$. Use the cylindrical coordinates (z, ϕ), valid away from the poles. There $\partial_\phi f = 0$ and $\partial_z f = 2z$, so the critical set away from the poles is the

equator $z = 0$. At the poles use (x, y): near $z = \pm 1$, $z^2 = 1 - x^2 - y^2$ exactly, so the poles are critical with Hessian $\mathrm{diag}(-2, -2)$.

- The poles $z = \pm 1$: maxima, index 2, each contributing $t^2 P_t(\mathrm{pt}) = t^2$.
- The equator $E = \{z = 0\}$: in the coordinates (z, ϕ) the Hessian is $\mathrm{diag}(2, 0)$. The zero eigenvector ∂_ϕ is tangent to E and the normal one is positive, so E is a non-degenerate critical circle of index 0 (a circle of minima, $f = 0$), contributing $t^0 P_t(S^1) = 1 + t$.

Therefore

$$M_t(f) \overset{(1)}{=} (1 + t) + t^2 + t^2 = 1 + t + 2t^2, \tag{7.58}$$

$$M_t(f) - P_t(S^2) \overset{(2)}{=} (1 + t + 2t^2) - (1 + t^2) = t + t^2 \overset{(3)}{=} (1 + t)\, t. \tag{7.59}$$

(1) Morse–Bott series: equator plus two poles.
(2) $P_t(S^2) = 1 + t^2$.
(3) Factor.

So $R(t) = t$: the function is *not* perfect, and the surplus is one cancelling pair of indices $(1, 2)$, exactly as the strong inequalities demand. Euler check: $\chi(S^1) + \chi(\mathrm{pt}) + \chi(\mathrm{pt}) = 0 + 1 + 1 = 2 = \chi(S^2)$.

Where is the cancelling pair? Flood the sphere. Just above $f = 0$ the sublevel set $\{z^2 \le c\}$ is a band $|z| \le \sqrt{c}$ around the equator, an annulus: it has $b_0 = 1$ and $b_1 = 1$, the "$1 + t$" of the equator. At $f = 1$ both polar caps are attached at once. The first cap fills in one end of the band and *kills* the 1-cycle (the equator now bounds the cap): that cap is paired with the t from the equator. The second cap closes the sphere and creates $b_2 = 1$. The pair "t from the equator, t^2 from one pole" is the $(1 + t)\, t$ of (7.59). Compare the two-humped sphere (Example 7.13), which had the same Morse series for a different reason.

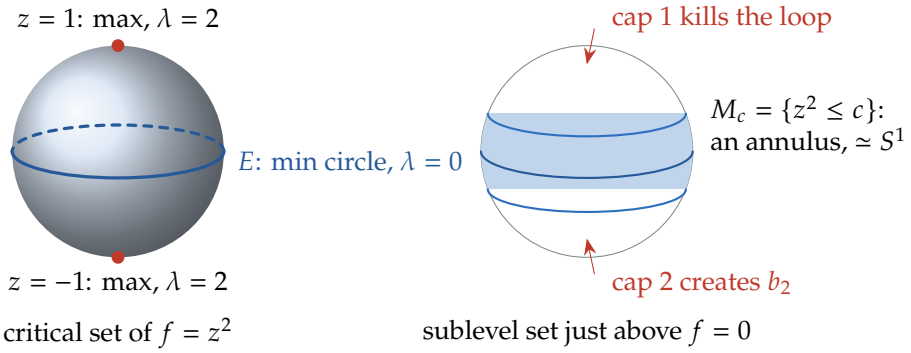

Figure 7.20: The function $f = z^2$ on S^2. Left: its critical set is the equator (a circle of minima, blue) and the two poles (maxima, red). Right: the sublevel set just above the minimum is a band around the equator, which already has a 1-cycle. The two caps added at $f = 1$ play different roles: one kills the 1-cycle (the cancelling pair $t \cdot (1 + t)$), the other creates the 2-cycle.

Worked example 7.33: A degenerate $\mathbb{CP}^2$ function: a critical $\mathbb{CP}^1$

Return to $\mathbb{CP}^2$ and let two of the a's coincide: $f = |z_3|^2 / (|z_1|^2 + |z_2|^2 + |z_3|^2)$, i.e. $a = (0, 0, 1)$. The Lagrange condition $(a_i - \mu) z_i = 0$ of Section 7.4.2 now allows z_1, z_2 both nonzero (with

$\mu = 0$, $z_3 = 0$), or z_3 alone nonzero ($\mu = 1$). So the critical set is

$$C = \{z_3 = 0\} = \{[z_1 : z_2 : 0]\} \cong \mathbb{CP}^1, \qquad f = 0, \qquad \text{and} \qquad P_3 = [0 : 0 : 1], \qquad f = 1.$$

At a point of C, say $[1 : 0 : 0]$, the expansion (7.38) gives $f \approx 0 \cdot |w_2|^2 + 1 \cdot |w_3|^2$: zero along w_2 (tangent to C), positive along w_3 (normal). So C is a non-degenerate critical manifold of index 0 (by the U(2) symmetry mixing z_1, z_2, every point of C looks the same). At P_3 the expansion gives $1 - |w_1|^2 - |w_2|^2$: index 4.

$$M_t(f) \overset{(1)}{=} t^0 P_t(\mathbb{CP}^1) + t^4 \overset{(2)}{=} 1 + t^2 + t^4 = P_t(\mathbb{CP}^2).$$

(1) The Morse–Bott series: the critical $\mathbb{CP}^1$ and the point P_3.
(2) $P_t(\mathbb{CP}^1) = P_t(S^2) = 1 + t^2$.

Perfect. Letting eigenvalues of $A = \operatorname{diag}(a_i)$ coincide turns isolated critical points into critical projective spaces (the eigenspaces), and the Morse–Bott series does not notice.

Worked example 7.34: $f = z^2$ on $\mathbb{RP}^2$: two fields, two answers

$f = z^2$ is even under $x \mapsto -x$, so it descends to $\mathbb{RP}^2 = S^2/\pm$. The two poles become one point (index 2). The equator becomes the equator modulo antipodes, which is again a circle (going halfway round the equator closes up), of index 0. The negative bundle of the circle has rank 0, so orientability is no issue. Then

$$M_t(f) \overset{(1)}{=} (1 + t) + t^2,$$
$$\text{over } \mathbb{Z}_2: \; M_t - P_t \overset{(2)}{=} (1 + t + t^2) - (1 + t + t^2) = 0,$$
$$\text{over } \mathbb{R}: \; M_t - P_t \overset{(3)}{=} (1 + t + t^2) - 1 = t(1 + t).$$

(1) One critical circle of index 0 and one point of index 2.
(2) $P_t(\mathbb{RP}^2; \mathbb{Z}_2) = 1 + t + t^2$ from (7.14).
(3) $P_t(\mathbb{RP}^2; \mathbb{R}) = 1$.

Perfect over $\mathbb{Z}_2$, not over $\mathbb{R}$: the same pattern as the Morse function of Example 7.16, as it must be (torsion obstructs perfection).

Try it: Quadratic functions on S^n

On $S^n \subset \mathbb{R}^{n+1}$ let $f = x_1^2 + \cdots + x_k^2$ with $1 \le k \le n$. Find the critical manifolds, their indices and $R(t)$.
Answer: the minimum set $\{x_1 = \cdots = x_k = 0\} \cong S^{n-k}$ ($f = 0$, index 0) and the maximum set $\{x_{k+1} = \cdots = x_{n+1} = 0\} \cong S^{k-1}$ ($f = 1$, index $n - k + 1$, the codimension). $M_t = (1 + t^{n-k}) + t^{n-k+1}(1 + t^{k-1}) = 1 + t^{n-k} + t^{n-k+1} + t^n$, so $M_t - P_t(S^n) = t^{n-k}(1 + t)$ and $R = t^{n-k}$. For $n = 2$, $k = 1$ this is x^2 on S^2, which is the z^2 example rotated. (For $k = 1$ the maximum set S^0 is two points.)

Worked example 7.35: The extreme case: a constant function

If f is constant, the whole of M is critical, $C = M$, the normal bundle has rank 0, the Hessian is (vacuously) non-degenerate on it, and $\lambda_M = 0$. So $M_t(f) = P_t(M)$: a constant is a perfect Morse–Bott function. This is a useless function, but it is a good check that the

formula (7.54) interpolates correctly between "all critical points isolated" and "everything critical".

Reading Nash (pp. 199–201, (7.26)–(7.33))

Nash motivates §2 with the torus on a dinner plate, defines a non-degenerate critical manifold ("$\mathrm{d}f = 0$ everywhere on C and the Hessian is non-degenerate in the directions normal to C"), splits the normal bundle $N(C) = N^+ \oplus N^-$ [Nash (7.26)] (his text says $N^{\mp}$ is spanned by the positive and negative eigenvectors; the sign labels should be read the other way round, N^- being the negative part, since $\lambda_C = \operatorname{rank} N^-$), and quotes Bott's contribution $t^{\lambda_C} P_t(C)$ [Nash (7.27)] and the series [Nash (7.28)]. The dinner plate gives [Nash (7.29)], the inequalities are [Nash (7.30)], and $f = z^2$ on S^2 is [Nash (7.31)–(7.33)]. We added: why tangent directions are always null (7.50), the constancy of λ_C, the Morse–Bott lemma, both mechanisms for $t^{\lambda_C} P_t(C)$ (tilting and the Thom isomorphism, with the annulus and Möbius computations), the flooding picture of z^2, and the $\mathbb{CP}^2$, $\mathbb{RP}^2$ and S^n examples.

Recap

- Symmetric functions have critical families. Tangent directions to a critical family are always zero modes of the Hessian.
- Non-degenerate critical manifold: the Hessian's kernel is exactly TC. Normal bundle $N = N^+ \oplus N^-$; index $\lambda_C = \operatorname{rank} N^-$.
- Morse–Bott lemma: $f = f(C) - |u|^2 + |v|^2$ near C.
- C contributes $t^{\lambda_C} P_t(C)$: tilt by a perfect g on C, or attach the disc bundle $D(N^-)$ (Thom isomorphism; needs N^- orientable over $\mathbb{R}$).
- Dinner-plate torus: $(1+t) + t(1+t) = P_t(T^2)$, perfect. z^2 on S^2: $1 + t + 2t^2$, $R = t$, not perfect.

7.6 Equivariant cohomology: keeping track of a symmetry

The previous section showed that a symmetry produces critical *families*. There is a second, more ambitious thing one wants to do with a symmetry: *divide by it*. In physics we do this all the time. The configuration space of a gauge theory is the space of gauge potentials modulo gauge transformations; the configuration space of a rigid rotor is a group modulo a subgroup; the phase space of a system with a conserved angular momentum can be reduced by the rotations it generates. If f is invariant under a group G acting on M, then f really lives on the space of orbits M/G, and it is natural to hope that Morse theory on M/G is simpler.

Nash's §3 opens with an example in which this hope fails in the simplest possible way, and then explains the cure, which is due to Borel and was made into a tool for Morse theory by Atiyah and Bott. The cure is to never divide by a group that does not act freely. Instead one first replaces M by a space that has the same cohomology but on which the action *is* free, and divides that. The resulting cohomology is **equivariant cohomology**. This section builds it from scratch: group actions, universal bundles and classifying spaces, the Borel construction, and two complete computations for the rotating sphere. Section 7.7 then puts it to work in Morse theory.

7.6.1 The rotating sphere: a quotient that forgets too much

Take the height function on the unit sphere [Nash p. 201, (7.34)],

$$M = S^2 = \{(x,y,z) : x^2+y^2+z^2 = 1\}, \qquad f(x,y,z) = z. \tag{7.60}$$

We know everything about it (Example 7.6). It has two critical points, the north pole $z=1$ (index 2) and the south pole $z=-1$ (index 0), so $M_t(f) = 1+t^2 = P_t(S^2)$: it is perfect.

It is also symmetric. Let $\mathrm{U}(1) = \{e^{i\alpha}\}$ act by rotation about the z-axis,

$$e^{i\alpha}\cdot\begin{pmatrix}x\\y\\z\end{pmatrix} = \underbrace{\begin{pmatrix}\cos\alpha & -\sin\alpha & 0\\ \sin\alpha & \cos\alpha & 0\\ 0 & 0 & 1\end{pmatrix}}_{R_\alpha}\begin{pmatrix}x\\y\\z\end{pmatrix}. \tag{7.61}$$

Writing $w = x+iy$, this is simply $(w,z)\mapsto(e^{i\alpha}w, z)$. The height is invariant, because the third row of R_α is $(0,0,1)$:

$$f\big(R_\alpha(x,y,z)\big) \overset{(1)}{=} 0\cdot x + 0\cdot y + 1\cdot z = f(x,y,z).$$

(1) The third component of $R_\alpha(x,y,z)^{\mathsf{T}}$ is the third row of R_α applied to (x,y,z).

So f is constant along each orbit, and ought to define a function on the space of orbits. What is that space? Two points lie on the same orbit exactly when they have the same height z (the rotations can move (x,y) anywhere on the circle $x^2+y^2 = 1-z^2$ but cannot change z). So the map

$$q\colon S^2 \to [-1,1], \qquad (x,y,z)\mapsto z, \tag{7.62}$$

identifies the orbit space:

- over $-1<z<1$ the orbit is the latitude circle of radius $\sqrt{1-z^2}$;
- over $z=\pm1$ the orbit is a single point, the pole.

Hence

$$S^2/\mathrm{U}(1) \;\cong\; [-1,1] \;\cong\; [0,1] \tag{7.63}$$

[Nash (7.35)]. An interval is contractible, so

$$P_t\big(S^2/\mathrm{U}(1)\big) = 1. \tag{7.64}$$

The hope is dashed. The quotient has trivial cohomology, and the function $f_G(z) = z$ on $[-1,1]$ has no critical points at all: it is monotonic, and its extreme values sit on the boundary. Morse theory on the quotient knows nothing about the sphere.

Worked example 7.36: Where did the critical points go?

Look near the north pole. Use $w = x+iy$ as a coordinate there, so that $z = \sqrt{1-|w|^2}$. The invariant combination of w and $\bar w$ is $\rho = |w|^2 = w\bar w$; it is a good coordinate on the quotient near the endpoint, with $\rho\ge 0$ and $\rho = 0$ at the pole. Then

$$f \overset{(1)}{=} \sqrt{1-|w|^2} \overset{(2)}{=} 1 - \tfrac12|w|^2 - \tfrac18|w|^4 - \dots \overset{(3)}{=} 1 - \tfrac12\rho - \tfrac18\rho^2 - \dots$$

(1) On the upper hemisphere $z = +\sqrt{1-x^2-y^2}$.

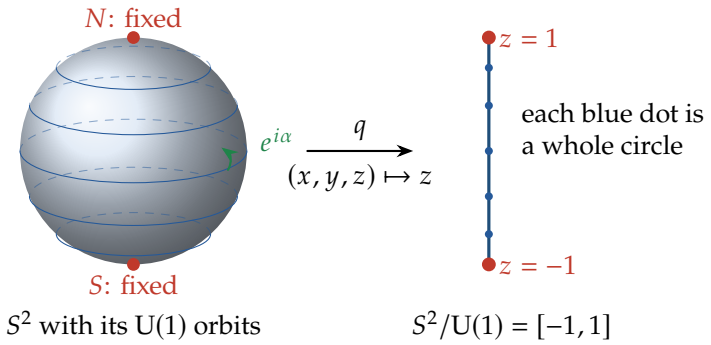

Figure 7.21: Dividing the sphere by rotations. Each latitude circle (an orbit) is collapsed to one point of the interval; the poles, which the rotations do not move, go to the two endpoints. The quotient is contractible, so all the topology of S^2 (its 2-cycle) has been lost. The culprits are the two fixed points.

(2) Taylor series $\sqrt{1-s} = 1 - \frac{1}{2}s - \frac{1}{8}s^2 - \dots$ with $s = |w|^2$.
(3) Substitute the invariant $\rho = |w|^2$.

On S^2 the pole is a non-degenerate maximum: in terms of $w = x + iy$, $f \approx 1 - \frac{1}{2}(x^2 + y^2)$, two negative eigenvalues. On the quotient it is the boundary point $\rho = 0$ of the half-line $\rho \geq 0$, and there $\mathrm{d}f_G/\mathrm{d}\rho = -\frac{1}{2} \neq 0$. *A non-degenerate critical point has turned into a boundary point with a nonzero slope.* The quadratic function $-|w|^2$ is linear in the quotient coordinate $|w|^2$, so the information that it had two negative directions has disappeared.

Physical picture: Gauge fixing near a symmetric configuration

This is the finite-dimensional cartoon of a familiar problem in gauge theory. Gauge-fixing works well near a configuration that the gauge group moves freely. Near a configuration with a nontrivial stabiliser (in gauge theory: a *reducible* connection, such as the trivial connection $A = 0$, which is fixed by all constant gauge transformations), the gauge orbits change dimension, the space of orbits develops a singularity, and naive quotients lose information. The equivariant cohomology built below is the topologists' version of "keep the gauge symmetry and add ghosts" instead of "fix the gauge".

7.6.2 Group actions, orbits and stabilisers

We need a little vocabulary. Throughout, G is a compact Lie group (usually U(1) or a finite group) acting smoothly on M.

Working definition 7.14 (action, orbit, stabiliser, free action)

A (left) [h acts first and then g, as the rule $g \cdot (h \cdot x) = (gh) \cdot x$ below says] **action** of G on M is a smooth map $G \times M \to M$, $(g, x) \mapsto g \cdot x$, with $1 \cdot x = x$ and $g \cdot (h \cdot x) = (gh) \cdot x$. In practice: a group of symmetry transformations, written as explicit matrices or maps.

- The **orbit** of x is $G \cdot x = \{g \cdot x : g \in G\}$: everywhere the symmetry can move x.
- The **stabiliser** (isotropy group) of x is $G_x = \{g : g \cdot x = x\}$: the symmetries that do not move x.
- x is a **fixed point** if $G_x = G$.

- The action is **free** if every stabiliser is trivial, $G_x = \{1\}$: no group element other than 1 fixes any point.
- The **orbit space** M/G is the set of orbits, with the topology in which a set of orbits is open when the union of those orbits is open in M [so orbits passing close to each other in M are close in M/G].

Test for freeness: solve $g \cdot x = x$ for g; if the only solution is $g = 1$ for every x, the action is free.

The map $g \mapsto g \cdot x$ from G onto the orbit takes the same value on g and gh for every $h \in G_x$. So the orbit is a copy of the coset space:

$$G \cdot x \;\cong\; G/G_x, \qquad \dim(G \cdot x) = \dim G - \dim G_x. \tag{7.65}$$

This **orbit–stabiliser relation** explains Figure 7.21: at a generic point of S^2 the stabiliser is trivial and the orbit is a circle ($\mathrm{U}(1)/\{1\}$); at a pole the stabiliser is all of $\mathrm{U}(1)$ and the orbit is a point ($\mathrm{U}(1)/\mathrm{U}(1)$). When the orbit dimension jumps, the quotient cannot be a manifold of one fixed dimension near the jump.

Worked example 7.37: A catalogue of actions

G	acting on	by	stabilisers, quotient
$\mathrm{U}(1)$	S^2	rotation (7.61)	$\mathrm{U}(1)$ at poles; $[-1,1]$
$\mathrm{U}(1)$	$\mathbb{C}$	$z \mapsto e^{i\alpha}z$	$\mathrm{U}(1)$ at 0; $[0,\infty)$ (a cone)
$\mathbb{Z}_2$	$\mathbb{R}$	$x \mapsto -x$	$\mathbb{Z}_2$ at 0; $[0,\infty)$
$\mathbb{Z}_2$	S^n	$x \mapsto -x$	free; $\mathbb{RP}^n$
$\mathrm{U}(1)$	$S^{2n+1} \subset \mathbb{C}^{n+1}$	$z \mapsto e^{i\alpha}z$	free; $\mathbb{CP}^n$
$\mathrm{U}(1)$	S^1	$e^{i\beta} \mapsto e^{i(\alpha+\beta)}$	free; a point
$\mathrm{U}(1)$	$S^3 \subset \mathbb{C}^2$	$(z_1,z_2) \mapsto (e^{i\alpha}z_1, e^{2i\alpha}z_2)$	$\mathbb{Z}_2$ on $z_1 = 0$; a "teardrop"

Two of these deserve a calculation.
The antipodal map is free. If $-x = x$ then $2x = 0$, so $x = 0$, which is not on the sphere. Hence no point is fixed by the non-trivial element.
The weighted action on S^3. Solve $(e^{i\alpha}z_1, e^{2i\alpha}z_2) = (z_1, z_2)$. If $z_1 \neq 0$ we need $e^{i\alpha} = 1$, so the stabiliser is trivial. If $z_1 = 0$ then $|z_2| = 1$ and we only need $e^{2i\alpha} = 1$, i.e. $e^{i\alpha} = \pm 1$: stabiliser $\mathbb{Z}_2$. The quotient is still a topological sphere, but with one conical point (the image of the circle $z_1 = 0$). Finite stabilisers produce mild "orbifold" singularities; positive-dimensional stabilisers, as at the poles of S^2, produce boundaries and cones of lower dimension.

Key idea: Free actions have smooth quotients (cf. Nash Ch. 1 and Ch. 5)

If a compact Lie group G acts smoothly and freely on M, then M/G is a smooth manifold of dimension $\dim M - \dim G$, and the projection $M \to M/G$ is a principal G-bundle: every fibre is a copy of G. If the action has fixed points or other non-trivial stabilisers, M/G is in general singular (boundaries, cones, orbifold points), as the table shows.

For a free action there is no problem in doing Morse theory downstairs [Nash p. 201]. A G-invariant f defines $f_G\colon M/G \to \mathbb{R}$ by $f_G([x]) = f(x)$, which is well defined because f is constant on orbits. In a local trivialisation $M \supset U \cong V \times G$ (with $V \subset M/G$), $f(v,g) = f_G(v)$

does not depend on g. So the critical points of f_G are the orbits on which $\mathrm{d}f = 0$, and each such orbit is a critical manifold of f of dimension $\dim G$, non-degenerate (in Bott's sense) exactly when the critical point of f_G is non-degenerate, and of the same index.

Worked example 7.38: Upstairs on S^{2n+1}, downstairs on $\mathbb{CP}^n$

Take Nash's function on $\mathbb{CP}^n$ (7.36) and read it upstairs, as a U(1)-invariant function on S^{2n+1}:

$$f(z) = \sum_{i=1}^{n+1} a_i \left|z_i\right|^2, \qquad a_1 < a_2 < \cdots < a_{n+1}, \qquad \sum |z_i|^2 = 1.$$

Downstairs we found $n+1$ critical points of index $0, 2, \ldots, 2n$ (Section 7.4.2). Upstairs each of them is a whole orbit: the circle $C_i = \{|z_i| = 1,\ z_j = 0\ (j \neq i)\}$. Near C_i the normal coordinates are z_j, $j \neq i$ ($2n$ real coordinates; the circle direction is tangent and the radial direction in z_i is not on the sphere), and

$$f \overset{(1)}{=} a_i\Big(1 - \sum_{j\neq i} \left|z_j\right|^2\Big) + \sum_{j\neq i} a_j \left|z_j\right|^2 \overset{(2)}{=} a_i + \sum_{j\neq i} (a_j - a_i)\, \left|z_j\right|^2.$$

(1) On the sphere $|z_i|^2 = 1 - \sum_{j\neq i} \left|z_j\right|^2$.
(2) Collect terms: this is already the Morse–Bott normal form (7.52), with no dependence on the phase of z_i (the coordinate along C_i).

The coefficient $a_j - a_i$ is negative for the $i-1$ values $j < i$, each giving two real negative directions, so $\lambda_{C_i} = 2(i-1)$. The Morse–Bott series on S^{2n+1} is

$$M_t(f) \overset{(1)}{=} \sum_{i=1}^{n+1} t^{2(i-1)} P_t(S^1) = (1+t)(1+t^2+\cdots+t^{2n}) = 1 + t + t^2 + \cdots + t^{2n+1},$$

$$M_t(f) - P_t(S^{2n+1}) \overset{(2)}{=} t + t^2 + \cdots + t^{2n} \overset{(3)}{=} (1+t)\,(t + t^3 + \cdots + t^{2n-1}).$$

(1) Each critical circle contributes $t^{\lambda_{C_i}} P_t(S^1)$ (7.54).
(2) $P_t(S^{2n+1}) = 1 + t^{2n+1}$ removes the first and last terms.
(3) Group the terms in pairs $t^{2k-1} + t^{2k} = (1+t)t^{2k-1}$, $k = 1, \ldots, n$.

So upstairs f is far from perfect ($R = t + t^3 + \cdots + t^{2n-1}$), while downstairs f_G is perfect, $M_t(f_G) = 1 + t^2 + \cdots + t^{2n} = P_t(\mathbb{CP}^n)$. Dividing by a *free* action threw away the redundant circle directions and, with them, all the cancelling pairs. This is what we would like to do for non-free actions too.

7.6.3 Universal bundles and classifying spaces

Borel's idea is simple to state. Find a space EG that is

1. *topologically trivial*: contractible, so that $M \times EG$ has the same cohomology as M; and
2. *a free G-space*: G acts on it freely.

Then G acts freely on $M \times EG$ (we check this below), so we can divide $M \times EG$ by G without any singularity, even if the action on M was far from free. The price is that EG is necessarily infinite-dimensional, but it is an entirely explicit space.

Working definition 7.15 (universal bundle, classifying space)

A **universal G-bundle** is a contractible space EG with a free G-action. Its quotient $BG = EG/G$ is the **classifying space** of G, and $EG \to BG$ is a principal G-bundle [the fibre over each point of BG is one orbit, a copy of G] [Nash p. 202]. *In practice*: find a sequence of free G-spaces $E_1 \subset E_2 \subset \cdots$ whose cohomology vanishes in degrees $1, \dots, N$ for E_N, with $N \to \infty$; take EG to be their union.

(In Nash's Chapter 1, BG appears as the space that classifies principal G-bundles: every principal G-bundle $P \to X$ is the pull-back of $EG \to BG$ along some map $X \to BG$, unique up to homotopy. We shall come back to this meaning below; for equivariant cohomology the two properties above are what matter.)

A finite-dimensional sphere is not contractible, but it is "contractible up to its dimension": S^m has no cohomology in degrees $1, \dots, m-1$. So we can use spheres of ever larger dimension and take the limit

$$S^\infty = \bigcup_m S^m = \Big\{(x_1, x_2, \dots) : \text{ finitely many } x_i \neq 0,\ \textstyle\sum x_i^2 = 1\Big\}.$$

Worked example 7.39: The infinite sphere is contractible

In finite dimensions you cannot shrink a sphere to a point within the sphere. In infinite dimensions you can, because there is always a spare direction to move into. Let $S(x_1, x_2, \dots) = (0, x_1, x_2, \dots)$ be the shift, and $e_1 = (1, 0, 0, \dots)$. Consider the two straight-line homotopies, each divided by its length to stay on the sphere,

$$h_s(x) = \frac{(1-s)\,x + s\,Sx}{\|(1-s)\,x + s\,Sx\|}, \qquad k_s(x) = \frac{(1-s)\,Sx + s\,e_1}{\|(1-s)\,Sx + s\,e_1\|}, \qquad 0 \le s \le 1.$$

The first deforms the identity into the shift, the second deforms the shift into the constant map to e_1. Together they contract S^∞ to the point e_1. The only thing to check is that neither numerator ever vanishes.

- For h_s: let x_k be the first nonzero coordinate of x. The k-th coordinate of Sx is $x_{k-1} = 0$, so the k-th coordinate of the numerator is $(1-s)x_k$, nonzero for $s < 1$; at $s = 1$ the numerator is $Sx \neq 0$.
- For k_s: the first coordinate of Sx is 0, so the first coordinate of the numerator is s, and the rest is $(1-s)Sx$. Both vanish only if $s = 0$ and $s = 1$ at once, which is impossible.

In a finite-dimensional sphere the shift is not available (the last coordinate would fall off the end), and indeed S^m is not contractible.

Now let the groups act.

Worked example 7.40: Three classifying spaces

(a) $G = \mathbb{Z}$. $\mathbb{Z}$ acts on $\mathbb{R}$ by translations, $n \cdot x = x + n$. This is free ($x + n = x$ forces $n = 0$) and $\mathbb{R}$ is contractible. So $E\mathbb{Z} = \mathbb{R}$ and $B\mathbb{Z} = \mathbb{R}/\mathbb{Z} = S^1$.
(b) $G = \mathbb{Z}_2$. $\mathbb{Z}_2 = \{\pm 1\}$ acts on S^∞ by $x \mapsto -x$, freely (Example 7.37). So $E\mathbb{Z}_2 = S^\infty$ and $B\mathbb{Z}_2 = S^\infty/\pm = \mathbb{RP}^\infty = \bigcup_n \mathbb{RP}^n$. From the cell structure of $\mathbb{RP}^n$ (one cell in each dimension, Example 7.10),

$$P_t(\mathbb{RP}^\infty; \mathbb{Z}_2) = 1 + t + t^2 + \cdots = \frac{1}{1-t}, \qquad P_t(\mathbb{RP}^\infty; \mathbb{R}) = 1.$$

(c) $G = \mathrm{U}(1)$**.** Regard S^∞ as the unit sphere in $\mathbb{C}^\infty = \bigcup_n \mathbb{C}^{n+1}$, i.e. as the union of the odd spheres $S^1 \subset S^3 \subset S^5 \subset \cdots$. The action $z \mapsto e^{i\alpha}z$ is free on each S^{2n+1} (Example 7.37), hence on the union, and the quotients are the projective spaces of Section 7.4.1. So

$$E\mathrm{U}(1) = S^\infty, \qquad B\mathrm{U}(1) = S^\infty/\mathrm{U}(1) = \mathbb{CP}^\infty = \bigcup_n \mathbb{CP}^n.$$

The Poincaré series of $\mathbb{CP}^\infty$ is the limit of those of $\mathbb{CP}^n$ [Nash p. 204, (7.48)]:

$$P_t(\mathbb{CP}^\infty) \overset{(1)}{=} \lim_{n\to\infty} P_t(\mathbb{CP}^n) \overset{(2)}{=} \lim_{n\to\infty} \left(1 + t^2 + t^4 + \cdots + t^{2n}\right) \overset{(3)}{=} \frac{1}{1-t^2}. \tag{7.66}$$

(1) $\mathbb{CP}^\infty$ is built from the cells of all the $\mathbb{CP}^n$ (one in each even dimension); $H^k(\mathbb{CP}^\infty) = H^k(\mathbb{CP}^n)$ as soon as $2n > k$, since adding cells of dimension $> k+1$ cannot change H^k.
(2) The perfect Morse function on $\mathbb{CP}^n$, (7.42).
(3) Geometric series, read as a formal power series in t.

And the numerators of the same limit tell us that S^∞ really is a universal bundle, as Nash argues [Nash (7.49)]: S^{2n+1} has no cohomology in degrees $1, \ldots, 2n$, and as $n \to \infty$ the first non-zero degree runs away to infinity. Hence

$$B\mathrm{U}(1) = \mathbb{CP}^\infty, \qquad H^*(B\mathrm{U}(1); \mathbb{R}) = \mathbb{R}[u], \quad \deg u = 2, \qquad P_t(B\mathrm{U}(1)) = \frac{1}{1-t^2}. \tag{7.67}$$

Here u is a generator of $H^2(\mathbb{CP}^\infty)$, and u^k generates H^{2k}. (The ring statement, that the powers of u are all nonzero, is the fact that on $\mathbb{CP}^n$ the n-th power of the Fubini–Study Kähler form is a volume form.)

Worked example 7.41: More classifying spaces

(d) $G = \mathrm{SU}(2)$**.** $\mathrm{SU}(2)$ is the group of unit quaternions, $S^3 \subset \mathbb{H}$ (Chapter T3). It acts freely on the unit sphere $S^{4n+3} \subset \mathbb{H}^{n+1}$ by right multiplication, with quotient the quaternionic projective space $\mathbb{HP}^n$, which has one cell in each dimension divisible by 4. As $n \to \infty$:

$$B\mathrm{SU}(2) = \mathbb{HP}^\infty, \qquad P_t(B\mathrm{SU}(2)) = 1 + t^4 + t^8 + \cdots = \frac{1}{1-t^4}.$$

The generator in degree 4 is the second Chern class c_2 of the universal $\mathrm{SU}(2)$-bundle: the characteristic class that counts instantons (Chapter 8).
(e) $G = T^k = \mathrm{U}(1)^k$**.** Take products: $ET^k = (S^\infty)^k$, $BT^k = (\mathbb{CP}^\infty)^k$, $P_t(BT^k) = (1-t^2)^{-k}$.
(f) $G = \mathrm{U}(n)$**.** $B\mathrm{U}(n)$ is the Grassmannian of complex n-planes in $\mathbb{C}^\infty$; $H^*(B\mathrm{U}(n); \mathbb{R}) = \mathbb{R}[c_1, \ldots, c_n]$ with $\deg c_i = 2i$, the universal Chern classes, and $P_t(B\mathrm{U}(n)) = \prod_{i=1}^n (1-t^{2i})^{-1}$.

Why "classifying". Let $P \to X$ be a principal G-bundle. Choose a G-equivariant map $\Phi\colon P \to EG$ (it exists because EG is contractible, and is unique up to homotopy for the same reason). It descends to $\phi\colon X \to BG$, and P is recovered as the pull-back ϕ^*EG. Characteristic classes of P are then pull-backs $\phi^*(c)$ of classes $c \in H^*(BG)$.

Worked example 7.42: The monopole bundle inside the universal bundle

The Hopf bundle $S^3 \to S^2 = \mathbb{CP}^1$ (Example 7.21), the bundle of the Dirac monopole of unit charge, is literally the first stage $S^3 \to \mathbb{CP}^1$ of the universal bundle $S^\infty \to \mathbb{CP}^\infty$. Its classifying map is the inclusion $\phi\colon \mathbb{CP}^1 \hookrightarrow \mathbb{CP}^\infty$. The generator $u \in H^2(\mathbb{CP}^\infty)$ restricts to a

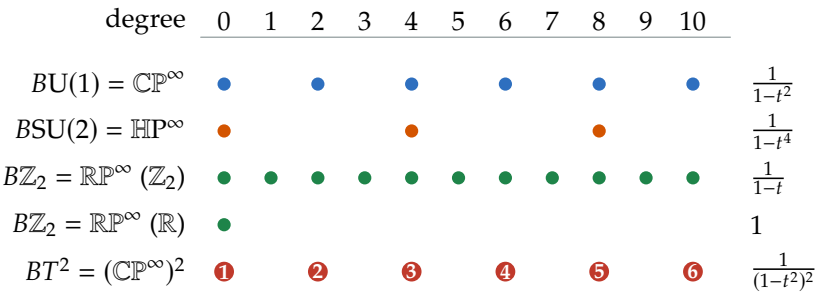

Figure 7.22: Betti numbers of some classifying spaces, degree by degree (a dot means $b_k = 1$; for BT^2 the number in the dot is b_k). Unlike an ordinary compact manifold, BG has cohomology in infinitely many degrees: this is what makes the equivariant cohomology of a single point so rich. Note that $B\mathbb{Z}_2$ is invisible with real coefficients: finite groups have no real equivariant cohomology to speak of.

generator of $H^2(\mathbb{CP}^1) = H^2(S^2)$, i.e. (up to the sign fixed by orientation conventions) to the first Chern class of the monopole bundle:

$$\int_{S^2} \phi^* u = \pm 1.$$

A monopole of charge k corresponds to a map $S^2 \to \mathbb{CP}^\infty$ of "degree" k. So the whole family of monopole bundles over S^2 is organised by the single space $\mathbb{CP}^\infty$.

Watch out: EG is not unique, but BG is unique up to homotopy

Any two contractible free G-spaces give homotopy-equivalent classifying spaces, which is all that cohomology sees. We could equally use a model of EG in which S^∞ is replaced by the unit sphere of a separable Hilbert space. When a statement about BG is proved using the finite approximations $S^{2n+1} \to \mathbb{CP}^n$, it is true in degrees $< 2n+1$ at stage n, and hence in every degree in the limit.

7.6.4 The Borel construction: the homotopy quotient

Now combine M with EG. Let G act on the product by the **diagonal action** [Nash (7.36)]

$$G \times (M \times EG) \to M \times EG, \qquad g \cdot (x, e) = (g \cdot x,\ g \cdot e). \tag{7.68}$$

This action is free, however badly G acts on M:

$$g \cdot (x, e) = (x, e) \overset{(1)}{\Longrightarrow} g \cdot e = e \overset{(2)}{\Longrightarrow} g = 1.$$

(1) Compare second components.
(2) G acts freely on EG.

So the quotient is well behaved:

Working definition 7.16 (homotopy quotient, Borel construction)

The **homotopy quotient** of M by G is

$$M_G = (M \times EG)/G \ = \ M \times_G EG \tag{7.69}$$

[EG is a contractible space on which G acts freely, such as S^∞ for U(1)] [Nash (7.37)], the set of pairs $[x, e]$ with the identification $[g \cdot x, g \cdot e] = [x, e]$. *Recipe:* to compute with M_G, replace EG by a finite approximation (for U(1): S^{2N+1}), which is honest in all degrees below $2N+1$ [it gives the same cohomology of M_G as EG does in those degrees], and let $N \to \infty$.

The space M_G has two natural projections, and each tells us something.

Projection to BG: M_G is an M-bundle. The map $\pi[x, e] = [e] \in EG/G = BG$ is well defined (it forgets x), and the fibre over $[e]$ is $\{[x, e] : x \in M\}$, which is a copy of M (for fixed e, different x give different points, since only $g = 1$ fixes e). So there is a fibre bundle [Nash (7.38)]

$$M \longrightarrow M_G \xrightarrow{\pi} BG. \tag{7.70}$$

When the action on M is trivial, $M_G = M \times BG$. In general M_G is a twisted product, the twisting being the action.

Projection to M/G: the fibres are classifying spaces of the stabilisers. The map $p[x, e] = [x] \in M/G$ is also well defined. Fix a point x in a given orbit. Every point of M_G over that orbit can be written $[x, e]$ for some e (if $[x', e']$ has $x' = g \cdot x$, then $[x', e'] = [x, g^{-1}e']$), and

$$[x, e] = [x, e'] \overset{(1)}{\iff} (x, e') = (h \cdot x, h \cdot e) \text{ for some } h \in G \overset{(2)}{\iff} e' = h \cdot e \text{ for some } h \in G_x.$$

(1) Definition of the quotient by the diagonal action.
(2) $h \cdot x = x$ says exactly that h is in the stabiliser G_x.

So the fibre of p over $[x]$ is EG/G_x. Since G_x acts freely on the contractible EG, this is a model of BG_x:

$$p^{-1}([x]) \;=\; EG/G_x \;\simeq\; BG_x. \tag{7.71}$$

Key idea: What the homotopy quotient remembers

Over a point of M/G where the action is free, M_G has a contractible fibre EG: nothing is added. Over a fixed point, M_G has the fibre BG, with all its cohomology. So

- if G acts freely, $M_G \simeq M/G$ [Nash p. 202];
- if G acts trivially, $M_G = M \times BG$;
- in general, M_G is M/G with the singular orbits "thickened" by the classifying spaces of their stabilisers.

Working definition 7.17 (equivariant cohomology)

The **equivariant cohomology** of a G-space M [a space with a smooth action of G, fixed points allowed] is the ordinary cohomology of its homotopy quotient [Nash (7.39)],

$$H^*_G(M; \mathbf{F}) := H^*(M_G; \mathbf{F}), \tag{7.72}$$

and its **equivariant Poincaré series** is [Nash p. 203, (7.42)]

$$P^G_t(M) = \sum_i \dim H^i_G(M; \mathbf{F})\, t^i = \sum_i \dim H^i(M_G; \mathbf{F})\, t^i = P_t(M_G). \tag{7.73}$$

It is a formal power series [a list of coefficients written as $\sum_i a_i t^i$, with t only a bookkeeping variable, so no convergence is needed], usually with infinitely many terms.

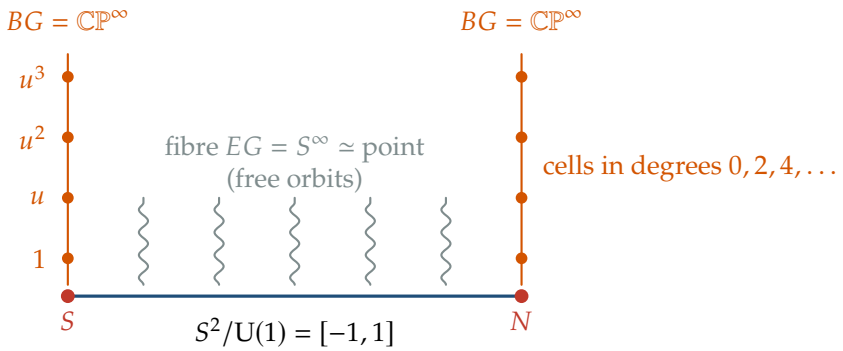

Figure 7.23: The homotopy quotient $S^2_{\mathrm{U}(1)}$ drawn over the naive quotient $[-1, 1]$. Over interior points the fibre is EG, which is contractible and adds nothing. Over each fixed point the fibre is a whole $BG = \mathbb{CP}^\infty$, with a class u^k in every even degree. The equivariant cohomology is built from the two orange columns, glued along the contractible middle: $1 + 2t^2 + 2t^4 + \cdots$.

Worked example 7.43: Four quick computations

A point [Nash (7.40)–(7.41)]. The action on $\{p\}$ is trivial, so

$$\{p\}_G \overset{(1)}{=} (\{p\} \times EG)/G \overset{(2)}{=} EG/G = BG, \qquad H^*_G(\{p\}) = H^*(BG).$$

(1) Definition (7.69).
(2) $\{p\} \times EG$ is just EG, with its own action.

For $G = \mathrm{U}(1)$: $H^*_{\mathrm{U}(1)}(\mathrm{pt}) = \mathbb{R}[u]$, $P_t^{\mathrm{U}(1)}(\mathrm{pt}) = 1/(1 - t^2)$. A point is as topologically trivial as a space can be, yet its equivariant cohomology is infinite. It remembers the symmetry group.

A free orbit. Let $\mathrm{U}(1)$ act on S^1 by rotation. The action is free, so $S^1_{\mathrm{U}(1)} \simeq S^1/\mathrm{U}(1) = \mathrm{pt}$ and $P_t^{\mathrm{U}(1)}(S^1) = 1$. More generally G acting on itself by left multiplication has $G_G = G \times_G EG \cong EG \simeq \mathrm{pt}$.

A free action. $H^*_{\mathrm{U}(1)}(S^{2n+1}) = H^*(\mathbb{CP}^n)$, so $P_t^{\mathrm{U}(1)}(S^{2n+1}) = 1 + t^2 + \cdots + t^{2n}$.

A trivial action. If G acts trivially on M, $M_G = M \times BG$ and by the Künneth formula $P_t^G(M) = P_t(M)\, P_t(BG)$. For instance, $\mathrm{U}(1)$ acting trivially on S^2 gives $(1 + t^2)/(1 - t^2)$.

The equivariant parameter. The projection $\pi\colon M_G \to BG$ pulls back classes from BG, so $H^*_G(M)$ is a module over $H^*(BG)$. For $\mathrm{U}(1)$ this means we can multiply equivariant classes by u (raising the degree by 2). How u acts is a good detector of fixed points. For a free action, $H^*_G(M) = H^*(M/G)$ vanishes in high degrees, so some power of u acts as zero (on $\mathbb{CP}^n$, $u^{n+1} = 0$). For a fixed point, u acts on $H^*_G(\mathrm{pt}) = \mathbb{R}[u]$ with no power ever zero. This is the germ of the **localisation theorem** of Atiyah and Bott: after inverting u, the equivariant cohomology of M only sees the fixed-point set.

7.6.5 The equivariant cohomology of the rotating sphere, twice

We now compute Nash's quantity [Nash (7.45)]

$$P_t^{\mathrm{U}(1)}(S^2) = P_t\big(S^2_{\mathrm{U}(1)}\big), \qquad G = \mathrm{U}(1), \tag{7.74}$$

first by Nash's route (a sphere bundle with vanishing Euler class) and then by cutting the sphere in two (Mayer–Vietoris), which makes Figure 7.23 precise.

Route 1: a sphere bundle over BG

By (7.70), S^2_G is an S^2-bundle over BG. It is the unit-sphere bundle of a vector bundle of rank 3. Write $\mathbb{R}^3 = \mathbb{C} \oplus \mathbb{R}$ with coordinates (w, z); $\mathrm{U}(1)$ acts on $\mathbb{C}$ with weight one and trivially on $\mathbb{R}$. Form

$$V = EG \times_G \mathbb{R}^3 = \underbrace{EG \times_G \mathbb{C}}_{L} \oplus \underbrace{EG \times_G \mathbb{R}}_{\mathbb{R}}, \qquad S^2_G = S(V), \tag{7.75}$$

where $L \to \mathbb{CP}^\infty$ is the universal complex line bundle (a real rank-2 bundle) and the second summand is the trivial line bundle, because G does not act on the z-axis. So S^2_G is the sphere bundle of $V = L \oplus \mathbb{R}$, which has rank 3 [Nash p. 203].

Two standard tools compute the cohomology of a sphere bundle.

Key idea: Euler class, Gysin sequence, Leray–Hirsch

Let $V \to B$ be an oriented real vector bundle of rank m, and $S^{m-1} \to S(V) \xrightarrow{\pi} B$ its unit-sphere bundle.

- Its **Euler class** $e(V) \in H^m(B)$ is the obstruction to a nowhere-vanishing section: if V has a section with no zeros, $e(V) = 0$. (For the tangent bundle of a surface it is the Gauss–Bonnet form, $\int e = \chi$.)
- The **Gysin sequence** is exact:

$$\cdots \to H^{k-m}(B) \xrightarrow{\cup e} H^k(B) \xrightarrow{\pi^*} H^k(S(V)) \longrightarrow H^{k-m+1}(B) \xrightarrow{\cup e} H^{k+1}(B) \to \cdots$$

- **Leray–Hirsch**: if there are classes on the total space E of a fibre bundle $F \to E \to B$ that restrict to a basis of $H^*(F)$ on every fibre, then $H^*(E) \cong H^*(B) \otimes H^*(F)$ as vector spaces, so $P_t(E) = P_t(B)\,P_t(F)$ [Nash (7.46)].

For our $V = L \oplus \mathbb{R}$ the Euler class vanishes, and there are two reasons. The direct one: V has the nowhere-zero section $[e] \mapsto [e, (0,1)]$ (the unit vector along the fixed z-axis, which G does not move). The general one, which Nash quotes: any bundle V_{2k+1} of *odd* rank has $2e(V) = 0$, because the fibrewise map $v \mapsto -v$ is a bundle automorphism that reverses the orientation of odd-dimensional fibres and so sends e to $-e$; with real coefficients, $e = 0$.

With $e = 0$ every map $\cup e$ in the Gysin sequence is zero, and the sequence breaks into short exact pieces:

$$\begin{aligned} \dim H^k(S(V)) &\overset{(1)}{=} \dim H^k(B) + \dim H^{k-m+1}(B), \\ P_t(S(V)) &\overset{(2)}{=} P_t(B) + t^{m-1}P_t(B) = (1 + t^{m-1})\,P_t(B) = P_t(S^{m-1})\,P_t(B). \end{aligned} \tag{7.76}$$

(1) With $\cup e = 0$ the sequence reads $0 \to H^k(B) \to H^k(S(V)) \to H^{k-m+1}(B) \to 0$, and in a short exact sequence of vector spaces the middle dimension is the sum of the other two.
(2) Multiply by t^k and sum over k; the second sum is shifted by $m-1$ degrees.

This is the Leray–Hirsch factorisation [Nash (7.46)]. With $m = 3$, $B = B\mathrm{U}(1)$ and (7.67) we get [Nash p. 204, (7.47)]

$$P_t^{\mathrm{U}(1)}(S^2) \overset{(1)}{=} P_t(S^2)\,P_t(B\mathrm{U}(1)) \overset{(2)}{=} (1+t^2)(1+t^2+t^4+\cdots) \overset{(3)}{=} \frac{1+t^2}{1-t^2} = 1 + 2t^2 + 2t^4 + 2t^6 + \cdots . \tag{7.77}$$

(1) (7.76) with $m = 3$: $S(V) = S^2_G$ and $P_t(S^2) = 1 + t^2$.

(2) (7.67).
(3) Sum the geometric series.

Worked example 7.44: When the Euler class does not vanish: the free circle

For contrast, let U(1) act on the circle $S^1 \subset \mathbb{C}$ by rotation. Then $S^1_G = S(L)$ is the circle bundle of the rank-2 bundle L over $\mathbb{CP}^\infty$, whose Euler class is the generator u (up to sign), and $\cup u \colon H^j(\mathbb{CP}^\infty) \to H^{j+2}(\mathbb{CP}^\infty)$ is an isomorphism for every $j \geq 0$ (it sends u^i to u^{i+1}). The Gysin sequence with $m = 2$ reads

$$H^{k-2}(B) \xrightarrow{\cup u} H^k(B) \to H^k(S(L)) \to H^{k-1}(B) \xrightarrow{\cup u} H^{k+1}(B),$$

so

$$\begin{aligned} H^k(S(L)) &\overset{(1)}{=} \operatorname{Coker}\big(\cup u \colon H^{k-2}(B) \to H^k(B)\big) \oplus \operatorname{Ker}\big(\cup u \colon H^{k-1}(B) \to H^{k+1}(B)\big) \\ &\overset{(2)}{=} \begin{cases} \mathbb{R}, & k = 0, \\ 0, & k \geq 1. \end{cases} \end{aligned}$$

(1) Exactness: $H^k(S(L))$ receives the cokernel of the left map and maps onto the kernel of the right map.
(2) $\cup u$ is injective, so every kernel vanishes; it is onto H^k for $k \geq 2$ and for $k = 1$ ($H^1(B) = 0$), so the only cokernel is $H^0(B) = \mathbb{R}$ (there is no H^{-2}).

So $S^1_G \simeq$ pt, as it must be for a free action (Example 7.43). Indeed $S(L) = S^\infty$ itself. A non-zero Euler class is how the sphere bundle "untwists" the BG direction.

Route 2: cut the sphere at the equator

Let $U = S^2 \setminus \{S\}$ and $V = S^2 \setminus \{N\}$ be the complements of the two poles. Both are U(1)-invariant, $U \cup V = S^2$, and $U \cap V$ is the open band $-1 < z < 1$. Now look at them equivariantly.

- U shrinks onto the north pole along the meridians, and this contraction commutes with the rotations. So $U_G \simeq \{N\}_G = BG$. Likewise $V_G \simeq BG$.
- $U \cap V$ shrinks onto the equator, on which G acts freely. So $(U \cap V)_G \simeq S^1_G \simeq$ pt.

The Mayer–Vietoris sequence of $S^2_G = U_G \cup V_G$ is

$$\cdots \to H^{k-1}\big((U \cap V)_G\big) \to H^k(S^2_G) \to H^k(U_G) \oplus H^k(V_G) \xrightarrow{r} H^k\big((U \cap V)_G\big) \to \cdots$$

with $r(a, b) = a|_{(U\cap V)_G} - b|_{(U\cap V)_G}$ (the difference of the restrictions). In degree 0, $r \colon \mathbb{R} \oplus \mathbb{R} \to \mathbb{R}$, $(a, b) \mapsto a - b$, is onto with one-dimensional kernel; in every other degree $H^k((U \cap V)_G) = 0$. Therefore

$$\begin{aligned} H^0(S^2_G) &\overset{(1)}{=} \operatorname{Ker} r = \{(a, a)\} \cong \mathbb{R}, \\ H^1(S^2_G) &\overset{(2)}{=} 0, \\ H^{2k}(S^2_G) &\overset{(3)}{=} H^{2k}(BG) \oplus H^{2k}(BG) \cong \mathbb{R}^2 \quad (k \geq 1), \qquad H^{\mathrm{odd}}(S^2_G) = 0. \end{aligned}$$

(1) Exactness at H^0: $H^0(S^2_G)$ injects into $H^0(U_G) \oplus H^0(V_G)$ with image $\operatorname{Ker} r$.
(2) $H^1(S^2_G)$ sits between $\operatorname{Coker}(r)$ in degree 0, which is zero because r is onto, and $H^1(U_G) \oplus H^1(V_G) = H^1(BG)^{\oplus 2}$, which is zero because $H^1(\mathbb{CP}^\infty) = 0$.

(3) For $k \geq 1$ both neighbours $H^{k-1}((U\cap V)_G)$ and $H^k((U\cap V)_G)$ vanish, so $H^k(S^2_G) \cong H^k(BG)^{\oplus 2}$, which is $\mathbb{R}^2$ in even degrees and 0 in odd ones.

So

$$P_t^{\mathrm{U}(1)}(S^2) = 1 + 2t^2 + 2t^4 + \cdots \overset{(1)}{=} 1 + \frac{2t^2}{1-t^2} = \frac{1+t^2}{1-t^2},$$

(1) $2t^2 + 2t^4 + \cdots = 2t^2(1 + t^2 + t^4 + \dots)$, a geometric series.

in agreement with (7.77). This route shows *where* the classes live: in positive degrees there is one copy of $H^*(BG)$ at each fixed point, exactly the two orange columns of Figure 7.23, and in degree 0 the two constants are glued through the contractible free part.

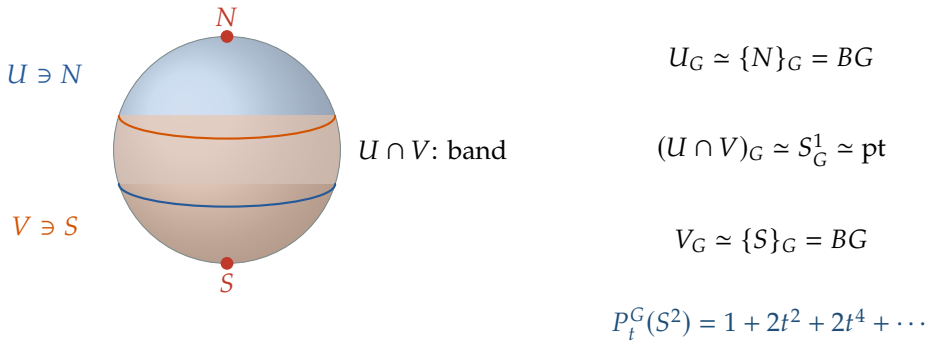

Figure 7.24: The Mayer–Vietoris cover used in Route 2. Each cap contracts equivariantly onto its pole, a fixed point, so each contributes a full copy of $H^*(BG)$. The band contracts onto the equator, where the action is free, so it contributes only a point. The two copies of $H^*(BG)$ are glued only in degree 0.

Watch out: Equivariant cohomology is not the cohomology of the quotient

Compare the three answers for U(1) acting on S^2:

$$P_t(S^2) = 1 + t^2, \qquad P_t(S^2/\mathrm{U}(1)) = 1, \qquad P_t^{\mathrm{U}(1)}(S^2) = \frac{1+t^2}{1-t^2}.$$

The equivariant answer is neither of the others. It equals $P_t(S^2)P_t(BG)$ here (the sphere is **equivariantly formal**), but that is a property of this example, not a general rule: for the free action on S^3, $P_t^{\mathrm{U}(1)}(S^3) = 1 + t^2$, whereas $P_t(S^3)P_t(BG) = (1 + t^3)/(1 - t^2)$.

7.6.6 Equivariant cohomology with differential forms: the Cartan model

The Borel construction is conceptually clean but uses an infinite-dimensional space. For $G = \mathrm{U}(1)$ and real coefficients there is a model built only from forms on M itself. It is the version physicists meet in localisation computations and in topological field theory.

Let X be the vector field that generates the action (for the rotating sphere, $X = \partial_\phi$, i.e. $X = -y\,\partial_x + x\,\partial_y$). Consider U(1)-invariant forms with coefficients that are polynomials in a formal variable u of degree 2:

$$\Omega_G(M) = \big(\Omega^*(M)\big)^{\mathrm{U}(1)} \otimes \mathbb{R}[u], \qquad \mathrm{d}_G = \mathrm{d} - u\,\iota_X, \tag{7.78}$$

where ι_X is the interior product. Both d and $u\,\iota_X$ raise the total degree by one (ι_X lowers the

form degree by 1 and u adds 2). The operator squares to zero on invariant forms:

$$d_G^2 \overset{(1)}{=} d^2 - u\,(d\iota_X + \iota_X d) + u^2\iota_X^2 \overset{(2)}{=} -u\,\mathcal{L}_X \overset{(3)}{=} 0.$$

(1) Expand $(d - u\iota_X)^2$; u is a number-like (even) variable, so it commutes with everything.
(2) $d^2 = 0$, $\iota_X^2 = 0$, and Cartan's formula $\mathcal{L}_X = d\iota_X + \iota_X d$ (Chapter T1).
(3) Invariant forms satisfy $\mathcal{L}_X\alpha = 0$.

Key idea: Cartan's theorem

For a compact connected group acting on M, the cohomology of $(\Omega_G(M), d_G)$ is $H^*_G(M;\mathbb{R})$. For U(1), u corresponds to the generator of $H^2(BU(1))$.

Check it on a point: there are no forms of positive degree and $X = 0$, so $\Omega_G = \mathbb{R}[u]$ with $d_G = 0$, and the cohomology is $\mathbb{R}[u]$, in agreement with (7.67).

Worked example 7.45: The equivariant area form of the sphere and its moment map

On S^2 use z and ϕ (cylindrical coordinates). The area form is

$$\omega = \sin\theta\, d\theta \wedge d\phi = d\phi \wedge dz, \tag{7.79}$$

because $z = \cos\theta$ gives $dz = -\sin\theta\, d\theta$, so $d\phi \wedge dz = -\sin\theta\, d\phi \wedge d\theta = \sin\theta\, d\theta \wedge d\phi$. It is closed but not d_G-closed. Look for a correction $u\,h$ with h a function:

$$\begin{aligned} d_G(\omega + u\,h) &\overset{(1)}{=} d\omega + u\,dh - u\,\iota_X\omega - u^2\iota_X h \\ &\overset{(2)}{=} u\,(dh - \iota_X\omega) \overset{(3)}{=} u\,(dh - dz). \end{aligned}$$

(1) Definition (7.78).
(2) $d\omega = 0$ (a top form) and $\iota_X h = 0$ (a function has no slot for a vector).
(3) $\iota_{\partial_\phi}(d\phi \wedge dz) = dz$.

So $h = z$ works, and

$$\omega_G = \omega + u\,z \tag{7.80}$$

is an equivariantly closed extension of the area form. The function that appears is the *height function*: the Morse function of this whole section. The equation $dz = \iota_X\omega$ says that the rotation is the Hamiltonian flow of z for the symplectic form ω (in classical mechanics: z is the angular momentum L_z that generates rotations about the z-axis). Such an h is called a **moment map**.

The restrictions to the fixed points make the Mayer–Vietoris picture concrete. At a point, forms of positive degree restrict to 0, so

$$\omega_G\big|_N = u \cdot z(N) = u, \qquad \omega_G\big|_S = u \cdot z(S) = -u, \qquad 1\big|_N = 1\big|_S = 1.$$

In degree 2 the classes $u \cdot 1 \mapsto (u, u)$ and $\omega_G \mapsto (u, -u)$ are independent, matching $\dim H^2_G(S^2) = 2$ from (7.77).

Dictionary: Equivariant cohomology in physics language

Mathematics	Physics
G acting on M	a symmetry, or a gauge group acting on configurations
orbit space M/G	physical (gauge-inequivalent) configurations
non-trivial stabiliser	reducible connection; symmetric vacuum
EG, contractible free G-space	auxiliary "gauge-fixing" degrees of freedom that remove the singularities
equivariant parameter $u \in H^2(BG)$	the ghost-for-ghost / Cartan generator ϕ of topological field theory
$\mathrm{d}_G = \mathrm{d} - u\,\iota_X$	equivariant BRST operator; $\mathrm{d}_G^2 = -u\mathcal{L}_X$ is a gauge transformation
moment map h with $\mathrm{d}h = \iota_X\omega$	the conserved charge that generates the symmetry

Watch out: Finite stabilisers are invisible over $\mathbb{R}$

If every stabiliser is finite, then with real coefficients $H^*_G(M;\mathbb{R}) \cong H^*(M/G;\mathbb{R})$, because $H^*(B\Gamma;\mathbb{R}) = \mathbb{R}$ for a finite group Γ (for instance $P_t(\mathbb{RP}^\infty;\mathbb{R}) = 1$). Over $\mathbb{Z}_p$ this is false. The serious trouble that equivariant cohomology repairs comes from positive-dimensional stabilisers, such as the $\mathrm{U}(1)$ fixing the poles of S^2.

Reading Nash (pp. 201–204, (7.34)–(7.42), (7.45)–(7.49))

Nash's §3 starts with the height function on S^2 [Nash (7.34)] and the disappointing quotient $S^2/\mathrm{U}(1) \simeq [0,1]$ [Nash (7.35)], blames the fixed points, recalls that free actions have smooth quotients on which f_G lives, and then, following Atiyah and Bott, defines the diagonal action [Nash (7.36)], the homotopy quotient [Nash (7.37)], the fibration over BG [Nash (7.38)], equivariant cohomology [Nash (7.39)], the point [Nash (7.40)–(7.41)] and the equivariant Poincaré series [Nash (7.42)]. Two misprints: in the diagram [Nash (7.38)] the base of the fibration should be BG, not M; and in [Nash (7.46)] "$H^*(M)$" means the cohomology of the base BG. The isomorphism [Nash (7.46)] is one of vector spaces (the Leray–Hirsch theorem), which is all that Poincaré series need. He computes $P_t^G(S^2)$ by the sphere-bundle argument [Nash (7.45)–(7.47)] and justifies $P_t(B\mathrm{U}(1)) = 1/(1-t^2)$ by a digression on $\mathbb{CP}^\infty$ and S^∞ [Nash (7.48)–(7.49)]. We added: orbits and stabilisers, the catalogue of actions, the pole-to-endpoint computation, the $S^{2n+1} \to \mathbb{CP}^n$ comparison, the contraction of S^∞, the classifying spaces of $\mathbb{Z}$, $\mathbb{Z}_2$, $\mathrm{SU}(2)$, T^k, $\mathrm{U}(n)$, the monopole bundle as a piece of the universal bundle, the two projections of M_G and the fibre BG_x, the Gysin computation for the free circle, the Mayer–Vietoris computation, and the Cartan model with the moment map of the sphere.

Recap

- Dividing by a non-free action loses information: $S^2/\mathrm{U}(1) = [0,1]$, and the critical points become boundary points.
- Orbit $\cong G/G_x$; free actions have smooth quotients; fixed points make cones and

boundaries.

- EG: contractible with a free action; $BG = EG/G$. $B\mathrm{U}(1) = \mathbb{CP}^\infty$, $P_t = 1/(1-t^2)$; $B\mathrm{SU}(2) = \mathbb{HP}^\infty$, $P_t = 1/(1-t^4)$.
- Borel: $M_G = (M \times EG)/G$, an M-bundle over BG, with fibre BG_x over the orbit of x. $H^*_G(M) \coloneqq H^*(M_G)$.
- Point: $H^*(BG)$. Free: $H^*(M/G)$. Trivial action: $H^*(M) \otimes H^*(BG)$.
- Rotating sphere: $P_t^{\mathrm{U}(1)}(S^2) = (1+t^2)/(1-t^2)$, by Gysin (Euler class zero) or by Mayer–Vietoris (one BG per pole).
- Cartan model: $\mathrm{d}_G = \mathrm{d} - u\,\iota_X$; the area form extends to $\omega + u\,z$, and the height is the moment map.

7.7 Equivariant Morse theory

We now have both halves of an equivariant Morse theory. The topological half is the equivariant Poincaré series $P_t^G(M)$ of (7.73). The question of this section is: *what is the equivariant Morse series, and does it satisfy Morse inequalities?* The answer is that one simply does Morse–Bott theory for the function that f induces on the homotopy quotient M_G. Each critical manifold N then contributes $P_t^G(N)\,t^{\lambda_N}$ instead of $P_t(N)\,t^{\lambda_N}$. Fixed points contribute a whole $P_t(BG)$; free orbits contribute only 1. We shall see that this repairs the height function on the rotating sphere, turns the imperfect function z^2 into a perfect one, computes equivariant cohomology by counting fixed points, and leads, via the Cartan model, to an exact stationary-phase formula, the Duistermaat–Heckman formula, which is the simplest example of localisation in physics.

7.7.1 The induced function on the homotopy quotient

Let $f\colon M \to \mathbb{R}$ be G-invariant, $f(g\cdot x) = f(x)$. Define

$$f_G\colon M_G \to \mathbb{R}, \qquad f_G[x,e] = f(x). \tag{7.81}$$

This is well defined, because the two representatives of the same point give the same value:

$$f_G[g\cdot x, g\cdot e] \overset{(1)}{=} f(g\cdot x) \overset{(2)}{=} f(x) = f_G[x,e].$$

(1) Definition (7.81) applied to the representative $(g\cdot x, g\cdot e)$.
(2) f is G-invariant.

On each fibre of $\pi\colon M_G \to BG$ (a copy of M) the function f_G is just f.

To do calculus we use a finite approximation E_N of EG (for $\mathrm{U}(1)$, $E_N = S^{2N+1}$), so that $M \times_G E_N$ is a compact manifold, and let $N \to \infty$ at the end. First pull f back to the product: $F(x,e) = f(x)$ on $M \times E_N$. In product coordinates (x^i, e^a),

$$\mathrm{d}F \overset{(1)}{=} \partial_i f\,\mathrm{d}x^i + 0\cdot \mathrm{d}e^a, \qquad HF(x,e) \overset{(2)}{=} \begin{pmatrix} Hf(x) & 0 \\ 0 & 0 \end{pmatrix}. \tag{7.82}$$

(1) F does not depend on e.
(2) All second derivatives involving e vanish for the same reason.

So the critical set of F is $\mathrm{Crit}(f) \times E_N$, and if N is a non-degenerate critical manifold of f, then $N \times E_N$ is a non-degenerate critical manifold of F. Its tangent directions are $TN \oplus TE_N$, which is exactly the kernel of HF, and the Hessian on the normal directions is that of f. In particular the index is still λ_N.

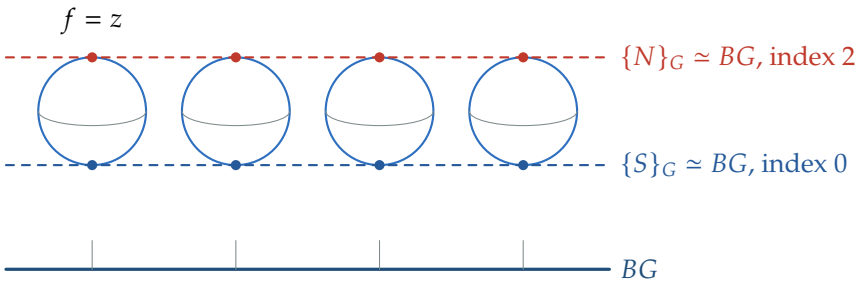
Next divide by G. When G is connected, each critical manifold N of f is G-invariant: $g \cdot N$ is again a critical manifold (since f is invariant), it can be joined to N through the path of group elements from 1 to g, and distinct critical manifolds are disjoint. So $N \times E_N$ is invariant under the free diagonal action, and it descends to

$$N_G = (N \times EG)/G \;\subset\; M_G, \tag{7.83}$$

the homotopy quotient of N by G. Dividing by a free action does not change the normal directions (the group directions are tangent to $N \times E_N$), so:

Key idea: Critical manifolds of f_G (Nash p. 203)

The critical manifolds of f_G on M_G are the homotopy quotients N_G of the critical manifolds N of f. The index of f_G on N_G is the *same* as the index λ_N of f on N.



each fibre is a copy of S^2 carrying f; the critical set of f_G is swept out by the poles

Figure 7.25: The induced function f_G on S^2_G, drawn as a bundle of spheres over BG. On every fibre f_G is the height $f = z$, with its two poles. As the fibre moves over BG the poles sweep out the critical manifolds $\{N\}_G$ and $\{S\}_G$, each a copy of BG (dashed). The normal directions to them are the directions inside a fibre, so the indices are 2 and 0 as before.

7.7.2 The equivariant Morse series and inequalities

Applying the Morse–Bott series (7.54) to f_G gives:

Working definition 7.18 (equivariant Morse series)

For a G-invariant [$f(g \cdot x) = f(x)$ for every $g \in G$] Morse–Bott function f with critical manifolds N,

$$M_t^G(f) = \sum_N P_t(N_G)\, t^{\lambda_N} = \sum_N P_t^G(N)\, t^{\lambda_N} \tag{7.84}$$

[$N_G = (N \times EG)/G$ is the homotopy quotient of N, and λ_N is the number of independent downhill directions normal to N] [Nash (7.43)]. *Recipe*: list the critical manifolds of f with their indices; for each, work out its equivariant Poincaré series (a fixed point: $P_t(BG)$; a free orbit: 1; a manifold N on which G acts freely: $P_t(N/G)$); multiply by t^{λ_N} and add.

Key idea: Equivariant Morse inequalities (Nash (7.44))

For G-invariant Morse–Bott functions,

$$M_t^G(f) - P_t^G(M) = (1+t)\,R(t), \tag{7.85}$$

where $R(t)$ is a formal power series with non-negative coefficients.

Why. Apply the Morse–Bott inequalities (7.57) to f_G on the compact manifold $M \times_G E_N$. Its cohomology agrees with that of M_G in degrees below $2N+1$ (for U(1)), and so do the Poincaré series of the critical manifolds $N \times_G E_N$. Therefore (7.85) holds coefficient by coefficient up to t^{2N}. Since N is arbitrary, it holds for all coefficients. (For real coefficients we also need the negative bundles N_G^- to be orientable; they are in all our examples, where they are complex vector bundles.)

The algebra of Section 7.2 carries over to power series with one exception.

- The weak inequalities $m_i^G \geq b_i^G$ and the alternating forms still hold.
- The *lacunary principle still holds*, with the same proof: if $R \neq 0$, look at its lowest term $r_j t^j$; then $(1+t)R$ contributes to both t^j and t^{j+1} in M_t^G. So if $M_t^G(f)$ has no two consecutive powers, $M_t^G(f) = P_t^G(M)$.
- The value $t = -1$ is *not* available: the series are infinite and need not converge there. There is no equivariant Euler characteristic in this naive sense.

Working definition 7.19 (equivariantly perfect)

f is **equivariantly perfect** if $M_t^G(f) = P_t^G(M)$, i.e. $R \equiv 0$ [$R(t)$ is the series in $M_t^G - P_t^G = (1+t)R(t)$. It vanishes exactly when the two series agree term by term].

7.7.3 The height function on the rotating sphere

Return to $f = z$ on S^2 with the rotation action. The critical points are the two poles, fixed by U(1), with indices 2 (N) and 0 (S). Each is a point on which G acts trivially, so its homotopy quotient is $\{p\}_G = BG$ (7.67). The equivariant Morse series is [Nash p. 204, (7.50)]

$$M_t^G(f) \overset{(1)}{=} P_t^G(\{S\})\,t^0 + P_t^G(\{N\})\,t^2 \overset{(2)}{=} (1+t^2)\,P_t(BG) \overset{(3)}{=} \frac{1+t^2}{1-t^2} \overset{(4)}{=} P_t^G(S^2). \tag{7.86}$$

(1) (7.84) with the two poles.
(2) Each pole is a fixed point, so $P_t^G(\{p\}) = P_t(BG)$.
(3) $P_t(BU(1)) = 1/(1-t^2)$.
(4) (7.77).

The height function is **equivariantly perfect**. (It had to be: the series $(1+t^2)(1+t^2+t^4+\cdots)$ contains only even powers, so the equivariant lacunary principle applies. This gives a third derivation of $P_t^G(S^2)$.) The naive quotient $[0,1]$ lost the poles; the homotopy quotient has kept each of them, fattened into a copy of BG.

7.7.4 The square of the height: equivariantly perfect, not perfect

Now take $f = z^2$ (7.58), which is also U(1)-invariant. The Poincaré side is unchanged, $P_t^G(S^2) = (1+t^2)/(1-t^2)$; only the Morse side must be recomputed [Nash p. 205]. Its critical manifolds are the two poles (index 2) and the equator $E = \{z = 0\}$ (index 0).

- The poles are fixed points. Together they contribute [Nash (7.51)]

$$2\,t^2\,P_t(BU(1)) = \frac{2t^2}{1-t^2}.$$

- The equator is a single free orbit. Since G acts freely, $E_G \simeq E/G$ [Nash (7.52)]:

$$S^1_{U(1)} \simeq S^1/U(1) = \mathrm{pt}, \qquad P_t^G(E) = 1,$$

  so the equator contributes $t^0 \cdot 1 = 1$.

Hence [Nash (7.53)]

$$M_t^G(z^2) \overset{(1)}{=} 1 + \frac{2t^2}{1-t^2} \overset{(2)}{=} \frac{1-t^2+2t^2}{1-t^2} = \frac{1+t^2}{1-t^2} \overset{(3)}{=} P_t^G(S^2). \tag{7.87}$$

(1) Equator plus the two poles.
(2) Common denominator.
(3) (7.77).

So z^2 is *equivariantly perfect* even though it is not perfect (Example 7.32, where $R = t$). Equivariant perfection does not imply ordinary perfection.

What happened to the cancelling pair? In the ordinary theory the surplus was "the t from the equator, cancelled by one of the t^2's from the poles": the equator's 1-cycle was created at $f = 0$ and killed when the first cap was attached (Figure 7.20). Equivariantly, the equator's 1-cycle is precisely the orbit direction, which the homotopy quotient divides out ($E_G \simeq \mathrm{pt}$). So there is nothing for the cap to kill, and each pole instead contributes a fresh copy of $H^*(BG)$ starting in degree 2. The ledger below shows the coefficients.

	t^0	t^1	t^2	t^3	t^4	t^6	
$P_t(S^2)$	1	0	1	0	0	0	
$M_t(z)$	1	0	1	0	0	0	perfect
$M_t(z^2)$	1	1	2	0	0	0	$R = t$
$P_t^G(S^2)$	1	0	2	0	2	2	
$M_t^G(z)$: $\{S\}_G, \{N\}_G$	1	0	$1+1$	0	$1+1$	$1+1$	perfect
$M_t^G(z^2)$: $E_G, 2\{N,S\}_G$	1	0	$0+2$	0	$0+2$	$0+2$	perfect

Figure 7.26: The ordinary and equivariant ledgers for U(1) acting on S^2. Top: ordinary Morse theory, where z^2 has the surplus pair shown in red. Bottom: equivariant Morse theory. For z each pole contributes $1, 1, 1, \ldots$ in degrees $\lambda, \lambda+2, \ldots$ (a copy of $P_t(BG)$). For z^2 the equator contributes only its t^0, the poles contribute 2 in each even degree ≥ 2, and the surplus has gone.

7.7.5 More examples: free actions and fixed points

Worked example 7.46: A free action: equivariant Morse theory is Morse theory on the quotient

Take $f = \sum a_i\,|z_i|^2$ on S^{2n+1} with the free U(1) action, as in Example 7.38. Its critical manifolds are the circles C_i of index $2(i-1)$, each a single free orbit, so $P_t^G(C_i) =$

$P_t(C_i/\mathrm{U}(1)) = 1$:

$$M_t^G(f) \overset{(1)}{=} \sum_{i=1}^{n+1} t^{2(i-1)} \cdot 1 = 1 + t^2 + \cdots + t^{2n} \overset{(2)}{=} P_t(\mathbb{CP}^n) \overset{(3)}{=} P_t^G(S^{2n+1}).$$

(1) (7.84); each critical circle is a free orbit and its homotopy quotient is a point.
(2) (7.42).
(3) Free action: $H_G^*(S^{2n+1}) = H^*(S^{2n+1}/\mathrm{U}(1)) = H^*(\mathbb{CP}^n)$ (Example 7.43).

Upstairs f had $R = t + t^3 + \cdots + t^{2n-1}$; equivariantly $R = 0$. For a free action the equivariant Morse theory of f *is* the ordinary Morse theory of f_G on M/G [Nash p. 201].

Worked example 7.47: Counting fixed points computes $H^*_{\mathrm{U}(1)}(\mathbb{CP}^2)$

Let $\mathrm{U}(1)$ act on $\mathbb{CP}^2$ by

$$e^{i\alpha} \cdot [z_1 : z_2 : z_3] = [z_1 : e^{i\alpha} z_2 : e^{2i\alpha} z_3].$$

Fixed points. $[z]$ is fixed when $(z_1, e^{i\alpha} z_2, e^{2i\alpha} z_3) = \mu(\alpha)\,(z_1, z_2, z_3)$ for every α, i.e. when z is an eigenvector of $\mathrm{diag}(1, e^{i\alpha}, e^{2i\alpha})$. For generic α the three eigenvalues are distinct, so the eigenvectors are the coordinate axes. The fixed points are $P_1 = [1:0:0]$, $P_2 = [0:1:0]$, $P_3 = [0:0:1]$.
The function. Nash's $f = \sum a_i |z_i|^2 / \sum |z_j|^2$ with $a_1 < a_2 < a_3$ (7.36) depends only on the moduli $|z_i|$, so it is invariant. Its critical points are P_1, P_2, P_3 with indices $0, 2, 4$ (Section 7.4.2): exactly the fixed points.
Equivariant Morse series. Each critical point is a fixed point:

$$M_t^G(f) \overset{(1)}{=} (1 + t^2 + t^4)\, P_t(BG) \overset{(2)}{=} \frac{1 + t^2 + t^4}{1 - t^2} = 1 + 2t^2 + 3t^4 + 3t^6 + 3t^8 + \cdots .$$

(1) Three fixed points of indices $0, 2, 4$, each contributing $t^\lambda P_t(BG)$.
(2) $P_t(B\mathrm{U}(1)) = 1/(1 - t^2)$.

Only even powers occur, so by the equivariant lacunary principle

$$P_t^{\mathrm{U}(1)}(\mathbb{CP}^2) = \frac{1 + t^2 + t^4}{1 - t^2} = P_t(\mathbb{CP}^2)\, P_t(BG).$$

We have computed an equivariant cohomology without ever constructing $\mathbb{CP}^2_{\mathrm{U}(1)}$: counting fixed points was enough.
A remark on the choice of f. With $a = (0, 1, 2)$, the weights of the action, f is the moment map of the rotation for the Fubini–Study form, just as z was for S^2 (Example 7.45). Atiyah and Bott, and later Kirwan, showed that this is a general phenomenon: the norm-square of a moment map (and, for a circle, the moment map itself) is an equivariantly perfect Morse–Bott function.

Try it: Two rotating spheres

Let $\mathrm{U}(1)$ rotate both factors of $S^2 \times S^2$ about their z-axes, and let $f = z_1 + 2z_2$. Find the critical points, their indices and $M_t^G(f)$, and deduce $P_t^G(S^2 \times S^2)$.
Answer: the critical points are the four pairs of poles (all fixed): (S, S) index 0; (N, S) and (S, N) index 2; (N, N) index 4. So $M_t^G = (1 + 2t^2 + t^4)/(1 - t^2) = (1 + t^2)^2/(1 - t^2)$. Only

even powers, hence this is $P_t^G(S^2 \times S^2)$, equal to $P_t(S^2 \times S^2)P_t(BG)$.

Watch out: Non-free orbits with finite stabiliser

If a critical orbit has a finite stabiliser Γ, e.g. the circle $z_1 = 0$ of the weighted action on S^3 (Example 7.37), then its homotopy quotient is $B\Gamma$, which is a point for real coefficients but not for $\mathbb{Z}_p$. This matters for closed geodesics (Section 7.8.10): a geodesic traversed k times is fixed by the rotations by $2\pi/k$.

7.7.6 Localisation: an exact stationary-phase formula

Equivariant cohomology has a striking application that every physicist recognises: in favourable cases the *stationary-phase approximation is exact*. Consider the oscillatory integral over the sphere

$$Z(s) = \int_{S^2} e^{isz}\,\omega, \tag{7.88}$$

a toy "path integral" in which z plays the role of the action and s of $1/\hbar$.

Exact evaluation. By (7.79), $\omega = \mathrm{d}\phi \wedge \mathrm{d}z$, so

$$Z(s) \overset{(1)}{=} \int_0^{2\pi} \mathrm{d}\phi \int_{-1}^{1} e^{isz}\,\mathrm{d}z \overset{(2)}{=} 2\pi\,\frac{e^{is} - e^{-is}}{is} \overset{(3)}{=} \frac{4\pi \sin s}{s}.$$

(1) The coordinates (ϕ, z) cover the sphere minus the poles with the standard orientation, and the area form is $\mathrm{d}\phi\,\mathrm{d}z$.

(2) $\int_{-1}^{1} e^{isz}\mathrm{d}z = [e^{isz}/(is)]_{-1}^{1}$.

(3) $e^{is} - e^{-is} = 2i\sin s$.

The first step is Archimedes' theorem: the area of the band of the sphere between two heights depends only on the difference of the heights (Figure 7.27).

Stationary phase. For large s, the integral is dominated by the critical points of the phase z, the poles. Near N, use (x, y): then $z \approx 1 - \tfrac{1}{2}(x^2 + y^2)$ and $\omega \approx \mathrm{d}x \wedge \mathrm{d}y$, so

$$Z_N(s) \overset{(1)}{=} e^{is} \int_{\mathbb{R}^2} e^{-\frac{is}{2}(x^2+y^2)}\,\mathrm{d}x\,\mathrm{d}y \overset{(2)}{=} e^{is}\left(\sqrt{\tfrac{2\pi}{is}}\right)^2 = \frac{2\pi\, e^{is}}{is}.$$

(1) Keep the Hessian (quadratic) term of the phase at the pole and the leading term of the area form; extend the integral to the whole plane.

(2) Fresnel integral $\int e^{-ax^2/2}\mathrm{d}x = \sqrt{2\pi/a}$ with $a = is$ (interpreted by continuation from $\operatorname{Re} a > 0$).

Near S, $z \approx -1 + \tfrac{1}{2}(x^2 + y^2)$, and the same computation with $a = -is$ gives $Z_S(s) = 2\pi e^{-is}/(-is)$. Adding:

$$Z_N(s) + Z_S(s) = \frac{2\pi\,(e^{is} - e^{-is})}{is} \overset{(1)}{=} Z(s) \qquad \text{exactly.}$$

(1) Compare with the exact evaluation above.

The Gaussian approximation at the two critical points has no corrections at all. This is the **Duistermaat–Heckman formula**: if h is the moment map of a circle action on a compact symplectic manifold, then $\int e^{ish}\,\omega^n/n!$ equals its stationary-phase approximation.

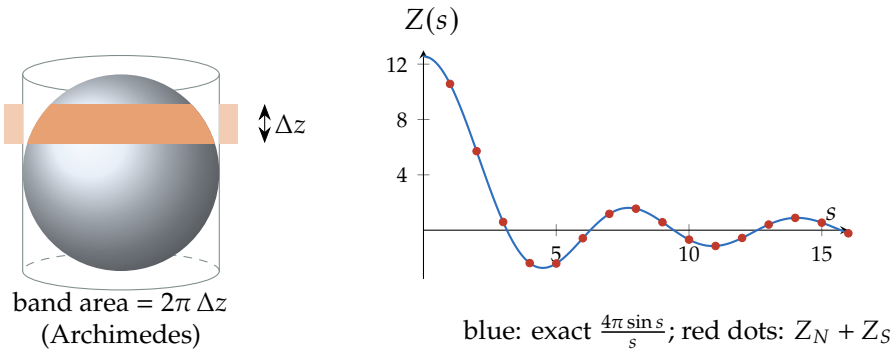


Figure 7.27: Left: Archimedes' theorem. The band of the unit sphere between two heights has the same area as the matching band of the circumscribing cylinder, $2\pi\,\Delta z$. So the pushforward of the area measure to the z-axis is flat, and $Z(s)$ is the Fourier transform of a box. Right: the exact integral $Z(s) = 4\pi \sin s/s$ and the sum of the two stationary-phase contributions from the poles, which agree for every s, not just asymptotically.

Why it is exact: the equivariant mechanism. The integrand is the top-degree part of an equivariantly closed form. With the Cartan model of Section 7.6.6 and $\omega_G = \omega + u\,z$ (7.80),

$$e^{\omega_G} = e^{uz}\big(1+\omega\big), \qquad \int_{S^2} e^{\omega_G} \;:=\; \int_{S^2} \big[e^{\omega_G}\big]_{\text{top}} = \int_{S^2} e^{uz}\,\omega,$$

which is $Z(s)$ at $u = is$. (The series stops at ω since $\omega^2 = 0$ on a surface.) Now the key fact: the integral of an equivariantly closed form α ($\mathrm{d}_G\alpha = 0$) does not change if we multiply it by $e^{\tau\,\mathrm{d}_G\theta}$ for an invariant 1-form θ. Indeed

$$\frac{\mathrm{d}}{\mathrm{d}\tau}\int_M \alpha\, e^{\tau\,\mathrm{d}_G\theta} \overset{(1)}{=} \int_M (\mathrm{d}_G\theta)\,\alpha\, e^{\tau\,\mathrm{d}_G\theta} \overset{(2)}{=} \int_M \mathrm{d}_G\big(\theta\,\alpha\, e^{\tau\,\mathrm{d}_G\theta}\big) \overset{(3)}{=} \int_M \mathrm{d}\big[\theta\,\alpha\, e^{\tau\,\mathrm{d}_G\theta}\big]_{\text{top}-1} \overset{(4)}{=} 0.$$

(1) Differentiate the exponential; $\mathrm{d}_G\theta$ has even degree, so everything commutes.
(2) d_G obeys the Leibniz rule, $\mathrm{d}_G\alpha = 0$, and $\mathrm{d}_G(\mathrm{d}_G\theta) = -u\,\mathcal{L}_X\theta = 0$ because θ is invariant.
(3) Only the top-degree part of the form is integrated; the top part of $\mathrm{d}_G\beta$ is d of the part of β one degree lower, since $u\,\iota_X$ lowers the form degree.
(4) Stokes' theorem on the closed manifold M.

Choose $\theta = g(X,\cdot)$, the metric dual of the generating vector field. Then $\mathrm{d}_G\theta = \mathrm{d}\theta - u\,\iota_X\theta = \mathrm{d}\theta - u\,|X|^2$, so the factor $e^{\tau\mathrm{d}_G\theta}$ contains $e^{-\tau u|X|^2}$. For $\tau \to \infty$ (with u treated as a positive real number, then continued) this suppresses everything except a neighbourhood of the zeros of X: the fixed points, which here are the poles, the critical points of the moment map. There the Gaussian integral is exact. This is the same logic as supersymmetric localisation: add a "Q-exact" term $\tau\,Q\theta$ to the action, note that nothing depends on τ, and send $\tau \to \infty$. Witten's approach to Morse theory (§4, part 7b) is the supersymmetric version of the same idea.

Physical picture: Atiyah–Bott: Yang–Mills as an equivariant Morse function

Nash's reference for equivariant Morse theory is Atiyah and Bott's paper on the Yang–Mills equations over Riemann surfaces. There M is the space $\mathcal{A}$ of all connections on a bundle over a surface Σ, the group is the gauge group $\mathcal{G}$, and the function is the Yang–Mills action $\mathrm{YM}(A) = \int_\Sigma |F_A|^2$, which is gauge invariant. The action of $\mathcal{G}$ is not free: reducible connections, and in particular every connection (via the constant central gauge transformations), have stabilisers. So ordinary Morse theory on $\mathcal{A}/\mathcal{G}$ is hopeless and equivariant Morse theory is the natural tool. Because $\mathcal{A}$ is an affine space, hence

contractible, its equivariant cohomology is simply $H^*(B\mathcal{G})$, which can be computed. The critical points of YM are the Yang–Mills connections; the minimum is the set of flat connections (the moduli space the physicist is interested in), and the higher critical sets are built from reducible connections. Atiyah and Bott showed that YM is equivariantly perfect, so

$$P_t(B\mathcal{G}) = P_t^{\mathcal{G}}(\text{flat connections}) + \sum_{\text{higher } C_\mu} t^{\lambda_\mu} P_t^{\mathcal{G}}(C_\mu),$$

from which they computed the cohomology of the moduli space of flat connections (equivalently, of stable holomorphic bundles). The infinite-dimensional setting is the subject of the next section, and Yang–Mills theory returns in Chapter 8.

Reading Nash (pp. 203–205, (7.42)–(7.44), (7.50)–(7.53))

Nash defines the equivariant Poincaré series [Nash (7.42)] and the equivariant Morse series as the ordinary Morse(–Bott) series of f_G on M_G: a critical manifold N of f gives a critical manifold N_G of f_G of the same index, and [Nash (7.43)] follows; the inequalities are [Nash (7.44)]. After computing $P_t^G(S^2)$ (previous section) he shows that the height function is equivariantly perfect [Nash (7.50)], and that z^2, with the poles contributing $2t^2/(1-t^2)$ [Nash (7.51)] and the free equator only 1 [Nash (7.52)], is equivariantly perfect too [Nash (7.53)]: "equivariant perfection does not imply perfection in the ordinary sense". We added: why f_G is well defined and why N_G has the same index (7.82), the finite-dimensional approximation behind (7.85), the equivariant lacunary principle, the ledger of cancelling pairs, the free-action and $\mathbb{CP}^2$ examples, the Duistermaat–Heckman formula with its localisation argument, and the Atiyah–Bott application that Nash alludes to.

Recap

- A G-invariant f induces $f_G[x,e] = f(x)$ on M_G; its critical manifolds are the N_G, with the same indices.
- $M_t^G(f) = \sum_N P_t^G(N)\, t^{\lambda_N}$: a fixed point gives $P_t(BG)$, a free orbit gives 1.
- $M_t^G - P_t^G = (1+t)R$, $R \geq 0$; the lacunary principle survives, $t = -1$ does not.
- On the rotating S^2: z and z^2 are both equivariantly perfect, $M_t^G = (1+t^2)/(1-t^2)$; z^2 is not perfect.
- Counting fixed points of a circle action computes H_G^* (e.g. $\mathbb{CP}^2$).
- Localisation: $\int_{S^2} e^{isz}\omega = 4\pi \sin s/s$ equals its stationary-phase approximation exactly (Duistermaat–Heckman).

7.8 Infinite dimensions: geodesics, loop spaces and Bott periodicity

Every example so far has had a finite-dimensional M. The problem that created the subject was not of that kind. Morse wanted to count the *geodesics* joining two points of a Riemannian manifold, and for that the "manifold" on which the function lives is the space of all paths from one point to the other. That space is infinite dimensional [Nash p. 205].

A physicist has met this situation many times. The action principle says that classical trajectories are the stationary points of a functional on the space of all paths. The free particle

moving on a curved space M has action $S = \frac{1}{2}\int g_{ij}\dot{x}^i\dot{x}^j\,dt$, whose stationary points are geodesics. The semiclassical expansion of the path integral expands S to second order around each classical path. The resulting quadratic form, the "fluctuation operator", has a finite number of negative modes, and that number enters the answer as a phase. This is exactly the index of Morse theory, now in infinite dimensions.

In this section we set up the calculus of variations for the energy functional, compute its Hessian, and find the index of every geodesic on a round sphere. Then we do Morse theory on the path space of S^n, which proves Morse's theorem that any two points of a sphere, whatever the metric, are joined by infinitely many geodesics. We see how to reduce everything to finite dimensions with broken geodesics (the time-slicing of the path integral), turn to closed geodesics and the free loop space where the circle action of the previous sections reappears, and finish with Bott's use of all this to prove his periodicity theorem, plus the other triumphs that Nash lists at the start of the chapter.

7.8.1 The space of paths and the energy functional

Let (M, g) be a connected Riemannian manifold, and fix two points $p, q \in M$. The **path space** is

$$PM(p,q) = \big\{\gamma\colon [0,1] \to M \;\big|\; \gamma \text{ smooth (or piecewise smooth)},\ \gamma(0) = p,\ \gamma(1) = q\big\}. \tag{7.89}$$

A "point" of $PM(p,q)$ is a whole path. On it Morse puts the **energy functional** [Nash (7.54)]

$$E(\gamma) = \int_0^1 \left|\frac{d\gamma}{dt}\right|^2 dt = \int_0^1 g_{ij}\big(\gamma(t)\big)\,\frac{d\gamma^i}{dt}\frac{d\gamma^j}{dt}\,dt, \tag{7.90}$$

a real-valued function on the path space [Nash (7.55)]:

$$E\colon PM(p,q) \longrightarrow \mathbb{R}, \qquad \gamma \longmapsto E(\gamma). \tag{7.91}$$

Up to a factor 2, E is the action of a free non-relativistic particle of unit mass moving on M for a unit of time. Here $\gamma^i(t)$ are the coordinates of $\gamma(t)$ in a chart and we sum over repeated indices. The metric g and the endpoints are fixed; only the path varies.

Tangent vectors to the path space. To do calculus on $PM(p,q)$ we need to know what a tangent vector is. Take a one-parameter family of paths $\gamma_\varepsilon \in PM(p,q)$ with $\gamma_0 = \gamma$, that is, a map $(t,\varepsilon) \mapsto \gamma_\varepsilon(t)$. Its velocity at $\varepsilon = 0$ is

$$V(t) = \left.\frac{\partial \gamma_\varepsilon(t)}{\partial \varepsilon}\right|_{\varepsilon=0} \in T_{\gamma(t)}M, \qquad V(0) = V(1) = 0. \tag{7.92}$$

The endpoint conditions hold because $\gamma_\varepsilon(0) = p$ and $\gamma_\varepsilon(1) = q$ for all ε. So:

Working definition 7.20 (tangent space of the path space)

A tangent vector to $PM(p,q)$ at γ is a **variation vector field**: a vector field $V(t)$ along γ [one tangent vector $V(t) \in T_{\gamma(t)}M$ at each point of the path] that vanishes at both endpoints. Every such V comes from a variation, for example $\gamma_\varepsilon(t) = \exp_{\gamma(t)}(\varepsilon V(t))$ [the point reached by following the geodesic that leaves $\gamma(t)$ with velocity $\varepsilon V(t)$ for unit time]. *In practice*: to differentiate a functional [a function whose argument is a whole path, such as E] at γ, replace γ by $\gamma + \varepsilon V$ (in a chart) and differentiate in ε at $\varepsilon = 0$.

The tangent space is infinite dimensional. In flat $\mathbb{R}^n$ a basis is given by Fourier sine modes:

$$V(t) = \sum_{k=1}^{\infty} a_k \sin(k\pi t), \qquad a_k \in \mathbb{R}^n, \tag{7.93}$$

since $\sin(k\pi t)$ vanishes at $t = 0, 1$. The coordinates $(a_1, a_2, \dots)$ run over an infinite sequence of vectors. This is the same function space as for a quantum particle in a box.

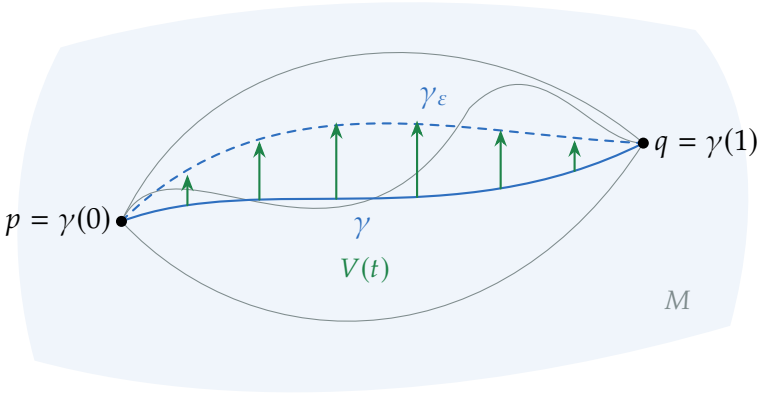

Figure 7.28: The path space $PM(p, q)$. Each curve from p to q (grey, blue) is a single point of this infinite-dimensional space. A tangent vector at γ is a vector field V along γ (green) which vanishes at the two ends, because every nearby path γ_ε (dashed) has the same endpoints. The energy E assigns a number to each curve; its critical points are the geodesics.

Worked example 7.48: Flat space: one critical point, index 0

Let $M = \mathbb{R}^n$ with $g_{ij} = \delta_{ij}$. Write any path from p to q as the straight line plus a deviation that vanishes at the ends: $\gamma(t) = p + t(q - p) + \eta(t)$, $\eta(0) = \eta(1) = 0$. Then

$$\begin{aligned} E(\gamma) &\overset{(1)}{=} \int_0^1 |(q - p) + \dot\eta(t)|^2 \, \mathrm{d}t \\ &\overset{(2)}{=} |q - p|^2 + 2\,(q - p) \cdot \int_0^1 \dot\eta \, \mathrm{d}t + \int_0^1 |\dot\eta|^2 \, \mathrm{d}t \\ &\overset{(3)}{=} |q - p|^2 + \int_0^1 |\dot\eta|^2 \, \mathrm{d}t . \end{aligned}$$

(1) $\dot\gamma = (q - p) + \dot\eta$, and g is the Euclidean dot product.

(2) Expand the square and integrate term by term; $\int_0^1 \mathrm{d}t = 1$.

(3) $\int_0^1 \dot\eta \, \mathrm{d}t = \eta(1) - \eta(0) = 0$.

So E is *exactly* quadratic around the straight line $\eta = 0$. It has a single critical point, the straight line, which is the global minimum with $E = |q - p|^2$. In the sine modes (7.93), $\eta = \sum a_k \sin k\pi t$,

$$\int_0^1 |\dot\eta|^2 \, \mathrm{d}t \overset{(1)}{=} \sum_{k,l} (k\pi)(l\pi)\, a_k \cdot a_l \int_0^1 \cos k\pi t \, \cos l\pi t \, \mathrm{d}t \overset{(2)}{=} \sum_{k \geq 1} \frac{(k\pi)^2}{2} \, |a_k|^2 .$$

(1) Differentiate the series term by term.

(2) $\int_0^1 \cos k\pi t \cos l\pi t \, \mathrm{d}t = \tfrac{1}{2}\delta_{kl}$ for $k, l \geq 1$.

The Hessian is diagonal in the sine modes, with infinitely many eigenvalues, all positive. The index is 0. The Morse series is $M_t(E) = 1$, which is the Poincaré series of a point. This is right: $P\mathbb{R}^n(p, q)$ is contractible (slide every path to the straight line along $\gamma_s = (1 - s)\gamma + s\,\gamma_{\text{line}}$).

7.8.2 First variation: the critical points are geodesics

Nash says that the extrema of E "are easily seen to be the geodesics" and writes the geodesic equation [Nash (7.56)]. Let us see it. Take a variation γ_ε with variation field V, and write $\dot{} = \mathrm{d}/\mathrm{d}t$. In a chart,

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}\varepsilon} E(\gamma_\varepsilon)\Big|_{\varepsilon=0} &\overset{(1)}{=} \int_0^1 \Big[\partial_k g_{ij}\, V^k \dot\gamma^i \dot\gamma^j + 2\, g_{ij}\, \dot\gamma^i \dot V^j \Big] \mathrm{d}t \\
&\overset{(2)}{=} \int_0^1 \Big[\partial_k g_{ij}\, \dot\gamma^i \dot\gamma^j - 2\, \frac{\mathrm{d}}{\mathrm{d}t}\big(g_{kj}\dot\gamma^j\big) \Big] V^k \, \mathrm{d}t \\
&\overset{(3)}{=} \int_0^1 \Big[\partial_k g_{ij}\, \dot\gamma^i \dot\gamma^j - 2\, \partial_i g_{kj}\, \dot\gamma^i \dot\gamma^j - 2\, g_{kj}\, \ddot\gamma^j \Big] V^k \, \mathrm{d}t \\
&\overset{(4)}{=} -2 \int_0^1 \Big[g_{kj}\, \ddot\gamma^j + \Gamma_{kij}\, \dot\gamma^i \dot\gamma^j \Big] V^k \, \mathrm{d}t \\
&\overset{(5)}{=} -2 \int_0^1 g_{kl}\, V^k \Big[\ddot\gamma^l + \Gamma^l_{ij}\, \dot\gamma^i \dot\gamma^j \Big] \mathrm{d}t .
\end{aligned} \tag{7.94}$$

(1) Differentiate under the integral. The metric depends on ε through its argument $\gamma_\varepsilon(t)$, giving $\partial_k g_{ij} V^k$; each velocity gives $\partial_\varepsilon \dot\gamma^i_\varepsilon = \dot V^i$, and the two such terms are equal because g_{ij} is symmetric.

(2) Integrate the second term by parts. The boundary term $2\big[g_{kj}\dot\gamma^j V^k\big]_0^1$ vanishes because $V(0) = V(1) = 0$.

(3) Chain rule: $\frac{\mathrm{d}}{\mathrm{d}t} g_{kj}(\gamma(t)) = \partial_i g_{kj}\, \dot\gamma^i$.

(4) Because $\dot\gamma^i\dot\gamma^j$ is symmetric, $2\partial_i g_{kj}\dot\gamma^i\dot\gamma^j = (\partial_i g_{kj} + \partial_j g_{ki})\dot\gamma^i\dot\gamma^j$. Then the bracket is $-2\Gamma_{kij}\dot\gamma^i\dot\gamma^j$ with the Christoffel symbols of the first kind $\Gamma_{kij} = \tfrac12(\partial_i g_{kj} + \partial_j g_{ki} - \partial_k g_{ij})$.

(5) Raise the index: $\Gamma^l_{ij} = g^{lk}\Gamma_{kij}$, so $\Gamma_{kij} = g_{kl}\Gamma^l_{ij}$.

If this vanishes for *every* variation field V, the bracket must vanish at every t. (If it were non-zero somewhere, choose V to be the bracket times a bump function around that t; then the integrand is ≥ 0 and not identically zero.) So the critical points of E are the solutions of

$$\frac{\mathrm{d}^2\gamma^i}{\mathrm{d}t^2} + \Gamma^i_{jk}\, \frac{\mathrm{d}\gamma^j}{\mathrm{d}t}\frac{\mathrm{d}\gamma^k}{\mathrm{d}t} = 0, \tag{7.95}$$

the **geodesic equation** [Nash (7.56)]. It is the Euler–Lagrange equation of the Lagrangian $g_{ij}\dot x^i \dot x^j$: Newton's law with no force, written in curvilinear coordinates. In invariant language (7.94) reads

$$\mathrm{d}E_\gamma(V) = -2 \int_0^1 \Big\langle V,\ \frac{D\dot\gamma}{\mathrm{d}t} \Big\rangle \mathrm{d}t, \tag{7.96}$$

where $D/\mathrm{d}t$ is the covariant derivative along γ (Levi-Civita connection, Chapter T2). So the "gradient" of E is -2 times the covariant acceleration, and a critical point is an unaccelerated path.

Geodesics have constant speed. Along a solution of (7.95), the speed is constant:

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}t}\big(g_{ij}\dot\gamma^i\dot\gamma^j\big) &\overset{(1)}{=} \partial_k g_{ij}\, \dot\gamma^k\dot\gamma^i\dot\gamma^j + 2\, g_{ij}\, \ddot\gamma^i\dot\gamma^j \\
&\overset{(2)}{=} 2\,\Gamma_{jki}\, \dot\gamma^j\dot\gamma^k\dot\gamma^i + 2\, g_{ij}\, \ddot\gamma^i\dot\gamma^j \\
&\overset{(3)}{=} 2\, g_{ij}\, \dot\gamma^j \big(\ddot\gamma^i + \Gamma^i_{kl}\dot\gamma^k\dot\gamma^l\big) \overset{(4)}{=} 0.
\end{aligned}$$

(1) Chain rule and product rule; the two velocity terms are equal by symmetry of g.
(2) Fully contracted with three velocities, the three terms of $2\Gamma_{jki} = \partial_k g_{ji} + \partial_i g_{jk} - \partial_j g_{ki}$ are all equal to $\partial_k g_{ij}\dot\gamma^k\dot\gamma^i\dot\gamma^j$, so $2\Gamma_{jki}\dot\gamma^j\dot\gamma^k\dot\gamma^i = (1+1-1)\,\partial_k g_{ij}\dot\gamma^k\dot\gamma^i\dot\gamma^j$.
(3) $\Gamma_{jkl} = g_{ji}\Gamma^i_{kl}$; relabel dummy indices.
(4) The geodesic equation (7.95).

This is energy conservation for the free particle. It will matter in a moment.

Worked example 7.49: Great circles on the round sphere

On the unit sphere, $g = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2$, so $g_{\theta\theta} = 1$, $g_{\phi\phi} = \sin^2\theta$, $g_{\theta\phi} = 0$. The only non-constant component is $g_{\phi\phi}$, and it depends only on θ. The non-zero Christoffel symbols are

$$\Gamma^\theta_{\phi\phi} \overset{(1)}{=} \tfrac12 g^{\theta\theta}\big(2\partial_\phi g_{\theta\phi} - \partial_\theta g_{\phi\phi}\big) \overset{(2)}{=} -\tfrac12\,\partial_\theta(\sin^2\theta) = -\sin\theta\cos\theta,$$
$$\Gamma^\phi_{\theta\phi} = \Gamma^\phi_{\phi\theta} \overset{(3)}{=} \tfrac12 g^{\phi\phi}\,\partial_\theta g_{\phi\phi} \overset{(4)}{=} \frac{2\sin\theta\cos\theta}{2\sin^2\theta} = \cot\theta.$$

(1) $\Gamma^i_{jk} = \tfrac12 g^{il}(\partial_j g_{lk} + \partial_k g_{lj} - \partial_l g_{jk})$ with $i=\theta$, $j=k=\phi$; the metric is diagonal so only $l=\theta$ survives.
(2) $g^{\theta\theta} = 1$ and $g_{\theta\phi} = 0$.
(3) Same formula with $i=\phi$, $j=\theta$, $k=\phi$: only the term $\partial_\theta g_{\phi\phi}$ survives.
(4) $g^{\phi\phi} = 1/\sin^2\theta$.

The geodesic equations (7.95) are therefore

$$\ddot\theta - \sin\theta\cos\theta\,\dot\phi^2 = 0, \qquad \ddot\phi + 2\cot\theta\,\dot\theta\,\dot\phi = 0.$$

- A *meridian* $\phi = \phi_0$, $\theta = \theta_0 + ct$: $\ddot\theta = 0$ and $\dot\phi = 0$, so both equations hold. It is a geodesic.
- The *equator* $\theta = \pi/2$, $\phi = ct$: $\ddot\theta = 0$ and $\sin\theta\cos\theta = 0$; $\ddot\phi = 0$ and $\dot\theta = 0$. It is a geodesic.
- A *latitude circle* $\theta = \theta_0 \neq \pi/2$, $\phi = ct$: the first equation gives $-\sin\theta_0\cos\theta_0\,c^2 \neq 0$. It is *not* a geodesic. To keep a particle on it you must push it towards the nearer pole (Figure 7.29).

Since rotations are isometries, rotating a meridian gives all the great circles. These are all the geodesics of the round sphere.

7.8.3 Energy versus length

The obvious functional for geodesics is the *length*

$$L(\gamma) = \int_0^1 \left|\frac{\mathrm{d}\gamma}{\mathrm{d}t}\right| \mathrm{d}t. \tag{7.97}$$

Nash records the relation between the two [Nash (7.57), (7.58)]:

$$E(\gamma) \;\geq\; L(\gamma)^2 \quad \text{for every path,} \qquad E(\gamma) = L(\gamma)^2 \quad \text{if } \gamma \text{ is a geodesic.} \tag{7.98}$$

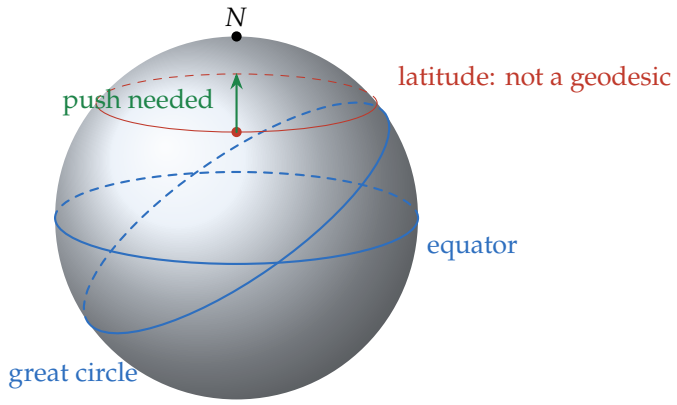

Figure 7.29: Critical points of E on the round sphere. Great circles (blue), such as the equator or a tilted circle, satisfy the geodesic equation. A latitude circle (red) does not: a particle released along it drifts towards the equator, and to keep it on the latitude one must push it towards the pole (green), which is the term $-\sin\theta_0\cos\theta_0\,\dot\phi^2 \neq 0$.

The inequality is the Cauchy–Schwarz inequality for the functions $|\dot\gamma|$ and 1 on $[0,1]$:

$$L(\gamma)^2 \overset{(1)}{=} \left(\int_0^1 |\dot\gamma|\cdot 1\,\mathrm{d}t\right)^2 \overset{(2)}{\leq} \left(\int_0^1 |\dot\gamma|^2\,\mathrm{d}t\right)\left(\int_0^1 1^2\,\mathrm{d}t\right) \overset{(3)}{=} E(\gamma).$$

(1) Definition (7.97), with a factor 1 inserted.
(2) Cauchy–Schwarz, $(\int fh)^2 \leq \int f^2 \int h^2$, with equality if and only if f is a constant multiple of h, i.e. $|\dot\gamma|$ is constant.
(3) Definition (7.90) and $\int_0^1 1\,\mathrm{d}t = 1$.

A geodesic has constant speed, so equality holds: $|\dot\gamma| = L$ and $E = \int_0^1 L^2\mathrm{d}t = L^2$. Consequently the minimum of E on $PM(p,q)$ is $d(p,q)^2$, attained exactly at the shortest geodesics traversed at constant speed.

Why use E and not L? Because L has too much symmetry. If $\varphi\colon[0,1]\to[0,1]$ is an increasing diffeomorphism, then $L(\gamma\circ\varphi) = L(\gamma)$. So every critical point of L comes with an infinite-dimensional family of reparametrised copies, all critical. The Hessian of L has an infinite-dimensional kernel. This is as degenerate as a function can be. E is not reparametrisation invariant: it picks out the constant-speed representative and penalises the others.

Worked example 7.50: Reparametrising a straight line

In $\mathbb{R}^n$ let $\gamma(t) = p + t(q-p)$ and $\tilde\gamma(t) = \gamma(t^2) = p + t^2(q-p)$. Both trace the same segment, so $L(\tilde\gamma) = L(\gamma) = |q-p|$. But

$$E(\tilde\gamma) \overset{(1)}{=} \int_0^1 |2t\,(q-p)|^2\,\mathrm{d}t \overset{(2)}{=} \tfrac{4}{3}\,|q-p|^2 \;>\; |q-p|^2 = E(\gamma).$$

(1) $\dot{\tilde\gamma} = 2t\,(q-p)$.
(2) $\int_0^1 4t^2\mathrm{d}t = \tfrac{4}{3}$.

The slow-then-fast parametrisation costs extra energy, so it is not a critical point of E even though it is one of L.

Dictionary: Length and energy in physics

$L(\gamma)=\int\lvert\dot\gamma\rvert\,\mathrm{d}t$	relativistic point particle, $S=-m\int\mathrm{d}s$: reparametrisation invariant, i.e. a gauge symmetry (worldline diffeomorphisms)
$E(\gamma)=\int\lvert\dot\gamma\rvert^2\,\mathrm{d}t$	the "einbein" or Polyakov form $\frac12\int e^{-1}\dot x^2\mathrm{d}t$ in the gauge $e=1$: the gauge is fixed, only constant-speed paths are critical
$E\geq L^2$, equality on geodesics	eliminating e by its equation of motion returns the square-root action

The same pair (Nambu–Goto area versus Polyakov energy) reappears for strings in Chapter 9.

7.8.4 Second variation: the Hessian of the energy

To do Morse theory we need the index of each critical point. So we need the Hessian of E at a geodesic γ. Nash does not compute it; here it is.

Conventions. $D/\mathrm{d}t$ and $D/\mathrm{d}\varepsilon$ are covariant derivatives along the two-parameter family $\gamma_\varepsilon(t)$ (Levi-Civita connection). The Riemann tensor is $R(X,Y)Z=\nabla_X\nabla_Y Z-\nabla_Y\nabla_X Z-\nabla_{[X,Y]}Z$. We use three facts from Riemannian geometry (Chapter T2):

(a) metric compatibility: $\partial_\varepsilon\langle A,B\rangle=\langle\frac{D}{\mathrm{d}\varepsilon}A,B\rangle+\langle A,\frac{D}{\mathrm{d}\varepsilon}B\rangle$, and the same for t;

(b) no torsion: $\frac{D}{\mathrm{d}\varepsilon}\partial_t\gamma=\frac{D}{\mathrm{d}t}\partial_\varepsilon\gamma$;

(c) curvature measures the failure of the two covariant derivatives to commute: $\frac{D}{\mathrm{d}\varepsilon}\frac{D}{\mathrm{d}t}W-\frac{D}{\mathrm{d}t}\frac{D}{\mathrm{d}\varepsilon}W=R(\partial_\varepsilon\gamma,\partial_t\gamma)W$.

In a two-parameter variation the ε and t coordinate lines commute, which is why no bracket term appears in (c).

Let γ be a geodesic and γ_ε a variation with variation field $V=\partial_\varepsilon\gamma_\varepsilon|_{\varepsilon=0}$, fixed endpoints. Write $\dot\gamma_\varepsilon=\partial_t\gamma_\varepsilon$.

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}\varepsilon}E(\gamma_\varepsilon)&\overset{(1)}{=}2\int_0^1\Big\langle\frac{D}{\mathrm{d}\varepsilon}\dot\gamma_\varepsilon,\dot\gamma_\varepsilon\Big\rangle\mathrm{d}t\overset{(2)}{=}2\int_0^1\Big\langle\frac{D}{\mathrm{d}t}\partial_\varepsilon\gamma_\varepsilon,\dot\gamma_\varepsilon\Big\rangle\mathrm{d}t,\\
\frac{\mathrm{d}^2}{\mathrm{d}\varepsilon^2}E(\gamma_\varepsilon)&\overset{(3)}{=}2\int_0^1\Big[\Big\langle\frac{D}{\mathrm{d}\varepsilon}\frac{D}{\mathrm{d}t}\partial_\varepsilon\gamma_\varepsilon,\dot\gamma_\varepsilon\Big\rangle+\Big\langle\frac{D}{\mathrm{d}t}\partial_\varepsilon\gamma_\varepsilon,\frac{D}{\mathrm{d}t}\partial_\varepsilon\gamma_\varepsilon\Big\rangle\Big]\mathrm{d}t\\
&\overset{(4)}{=}2\int_0^1\Big[\Big\langle\frac{D}{\mathrm{d}t}\frac{D}{\mathrm{d}\varepsilon}\partial_\varepsilon\gamma_\varepsilon+R(\partial_\varepsilon\gamma_\varepsilon,\dot\gamma_\varepsilon)\partial_\varepsilon\gamma_\varepsilon,\dot\gamma_\varepsilon\Big\rangle+\Big|\frac{D}{\mathrm{d}t}\partial_\varepsilon\gamma_\varepsilon\Big|^2\Big]\mathrm{d}t.
\end{aligned}\tag{7.99}$$

(1) Differentiate $\langle\dot\gamma_\varepsilon,\dot\gamma_\varepsilon\rangle$ using (a).
(2) No torsion (b).
(3) Differentiate again using (a); the second factor gives $\frac{D}{\mathrm{d}\varepsilon}\dot\gamma_\varepsilon=\frac{D}{\mathrm{d}t}\partial_\varepsilon\gamma_\varepsilon$ by (b) once more.
(4) Commute the covariant derivatives with (c), $W=\partial_\varepsilon\gamma_\varepsilon$.

Now set $\varepsilon=0$. The first term is a total derivative plus something that vanishes on a geodesic:

$$\int_0^1\Big\langle\frac{D}{\mathrm{d}t}A,\dot\gamma\Big\rangle\mathrm{d}t\overset{(1)}{=}\big[\langle A,\dot\gamma\rangle\big]_0^1-\int_0^1\Big\langle A,\frac{D\dot\gamma}{\mathrm{d}t}\Big\rangle\mathrm{d}t\overset{(2)}{=}0,\qquad A:=\frac{D}{\mathrm{d}\varepsilon}\partial_\varepsilon\gamma_\varepsilon\Big|_{\varepsilon=0}.$$

(1) Integration by parts with metric compatibility (a).
(2) At the endpoints $\gamma_\varepsilon(0) = p$ for all ε, so $\partial_\varepsilon \gamma_\varepsilon$ and its ε-derivative vanish there: $A(0) = A(1) = 0$. And $D\dot\gamma/\mathrm{d}t = 0$ because γ is a geodesic.

The curvature term is rewritten using the antisymmetry of $\langle R(X,Y)Z, W\rangle$ in its last two slots,

$$\big\langle R(V,\dot\gamma)V,\dot\gamma\big\rangle = -\big\langle R(V,\dot\gamma)\dot\gamma, V\big\rangle.$$

Writing $V' = DV/\mathrm{d}t$, we arrive at the **second variation formula**:

$$\boxed{\frac{\mathrm{d}^2}{\mathrm{d}\varepsilon^2}E(\gamma_\varepsilon)\Big|_{\varepsilon=0} = 2\int_0^1 \Big(|V'|^2 - \big\langle R(V,\dot\gamma)\dot\gamma, V\big\rangle\Big)\mathrm{d}t} \tag{7.100}$$

The first term is the flat-space answer of Example 7.48: bending a path costs energy. The second term is the effect of curvature. For positive curvature, $\langle R(V,\dot\gamma)\dot\gamma, V\rangle = K\,|V_\perp|^2\,|\dot\gamma|^2 > 0$ (with K the sectional curvature and $V_\perp$ the part of V normal to $\dot\gamma$). Positive curvature *lowers* the energy of a deformation: nearby geodesics are focused together, as meridians are focused at the south pole.

The Hessian as an operator. Integrating the first term by parts once more (boundary terms vanish as $V(0) = V(1) = 0$) gives

$$\frac{\mathrm{d}^2E}{\mathrm{d}\varepsilon^2} = 2\int_0^1 \big\langle V,\ \mathcal{J}V\big\rangle\mathrm{d}t, \qquad \mathcal{J}V := -\frac{D^2V}{\mathrm{d}t^2} - R(V,\dot\gamma)\dot\gamma. \tag{7.101}$$

$\mathcal{J}$ is the **Jacobi operator**. In a parallel orthonormal frame along γ it is the matrix Schrödinger operator $-\mathrm{d}^2/\mathrm{d}t^2 + U(t)$, with "potential" $U_{ab}(t) = -\langle R(e_a,\dot\gamma)\dot\gamma, e_b\rangle$, acting on vector-valued functions on $[0,1]$ with Dirichlet boundary conditions.

Key idea: The index of a geodesic is finite

The Hessian of E at a geodesic γ is the quadratic form of the Jacobi operator $\mathcal{J}$ with Dirichlet conditions. Its eigenvalues, like those of any Schrödinger operator on a bounded interval, form a discrete list tending to $+\infty$. Only finitely many are negative. So although $PM(p,q)$ is infinite dimensional:

- the **index** λ_γ (number of negative eigenvalues, with multiplicity) is *finite*;
- the **nullity** (dimension of the kernel) is finite, at most $n-1$.

Physical picture: The fluctuation operator of the path integral

In the semiclassical evaluation of the propagator $\langle q|e^{-iHT/\hbar}|p\rangle$ of a particle on M, one expands the action to second order around each classical path. The quadratic part is exactly (7.101), and the Gaussian integral over fluctuations gives $(\det\mathcal{J})^{-1/2}$. Each negative eigenvalue of $\mathcal{J}$ contributes a phase $e^{-i\pi/2}$, so a path of index λ_γ carries the phase $e^{-i\pi\lambda_\gamma/2}$. This is the **Maslov phase** of the Van Vleck–Gutzwiller formula. The Morse index of a geodesic is something quantum mechanics measures.

7.8.5 Jacobi fields, conjugate points and the Morse index theorem

The kernel of $\mathcal{J}$ has a direct geometric meaning.

Working definition 7.21 (Jacobi field, conjugate point)

A **Jacobi field** along a geodesic γ is a solution of $\mathcal{J}V = 0$, i.e.

$$\frac{D^2V}{\mathrm{d}t^2} + R(V, \dot\gamma)\dot\gamma = 0. \tag{7.102}$$

[$D/\mathrm{d}t$ is the covariant derivative along γ. The curvature term $R(V, \dot\gamma)\dot\gamma$ says how nearby geodesics bend towards or away from γ] It is the variation field of a family of *geodesics* (linearise the geodesic equation). The point $\gamma(t_0)$ is **conjugate** to $p = \gamma(0)$ along γ if there is a non-zero Jacobi field with $V(0) = 0$ and $V(t_0) = 0$. The number of independent such fields is the **multiplicity** of the conjugate point. *Test*: send out the geodesics from p with slightly different initial directions; $\gamma(t_0)$ is conjugate if, to first order, they come back together there.

So the nullity of E at γ is the multiplicity of $q = \gamma(1)$ as a conjugate point, and γ is a non-degenerate critical point exactly when q is not conjugate to p along γ. The index is counted by the conjugate points *before* q:

Key idea: Morse index theorem

The index of the geodesic $\gamma\colon [0,1] \to M$ as a critical point of E is

$$\lambda_\gamma = \sum_{0<t_0<1} \big(\text{multiplicity of } \gamma(t_0) \text{ as a point conjugate to } \gamma(0)\big). \tag{7.103}$$

The sum is finite.

Why. Restrict the geodesic to $[0, T]$ and follow the Dirichlet eigenvalues $\mu_k(T)$ of the Jacobi operator on $[0, T]$ as T grows from 0 to 1.

- For very small T the kinetic term wins: $\mu_k(T) \approx (k\pi/T)^2 > 0$. The index starts at 0.
- The eigenvalues decrease as T increases. (Extending an eigenfunction on $[0, T]$ by zero gives a trial function on $[0, T']$; the min–max principle then pushes every eigenvalue down.)
- An eigenvalue is *zero* at time T exactly when there is a Jacobi field vanishing at 0 and T, i.e. when $\gamma(T)$ is conjugate to $\gamma(0)$, and the number of zero eigenvalues is the multiplicity.

So each time T passes a conjugate time, that many eigenvalues cross from positive to negative, and none cross back. Counting crossings up to $T = 1$ gives (7.103). Figure 7.31 shows the crossings on the sphere. (The same reasoning in quantum mechanics is the Sturm oscillation theorem: the kth eigenfunction has $k - 1$ interior nodes.)

Worked example 7.51: Every geodesic of the round sphere S^n

Let γ be a great-circle arc of length L on the unit sphere S^n, starting at p. Use the arc-length parameter $s = Lt \in [0, L]$ and write $'$ for $D/\mathrm{d}s$. (Changing from t to s multiplies the Hessian by a positive constant, which changes no signs.) Choose a parallel orthonormal frame along γ: $e_1 = \gamma'$, and $e_2, \dots, e_n$ normal to it. Write $V = \sum_a v^a(s)\, e_a$; then $V'' = \sum_a v^a{}'' e_a$, because the frame is parallel. The unit sphere has constant curvature

1: $R(X,Y)Z = \langle Y,Z\rangle X - \langle X,Z\rangle Y$. Hence

$$R(V,\gamma')\gamma' \overset{(1)}{=} \langle\gamma',\gamma'\rangle V - \langle V,\gamma'\rangle\gamma' \overset{(2)}{=} V - v^1 e_1 = \sum_{a=2}^{n} v^a e_a,$$

$$\mathcal{J}V \overset{(3)}{=} -v^1{}'' e_1 + \sum_{a=2}^{n}\bigl(-v^a{}'' - v^a\bigr)e_a.$$

(1) Constant curvature formula with $X = V, Y = Z = \gamma'$.
(2) Unit speed, $|\gamma'| = 1$; and $\langle V,\gamma'\rangle = v^1$.
(3) $\mathcal{J}V = -V'' - R(V,\gamma')\gamma'$ (7.101).

The operator splits into n decoupled Sturm–Liouville problems on $[0,L]$ with $v(0) = v(L) = 0$. The eigenfunctions are $\sin(k\pi s/L)$, $k = 1,2,\dots$, with eigenvalues

$$\text{tangential } (a=1): \quad \mu_k = \left(\frac{k\pi}{L}\right)^2 > 0, \qquad \text{normal } (a = 2,\dots,n): \quad \mu_k = \left(\frac{k\pi}{L}\right)^2 - 1.$$

A normal eigenvalue is negative when $k\pi < L$, and each value of k occurs $n-1$ times. Therefore

$$\lambda_\gamma = (n-1)\cdot\#\{k \geq 1 :\ k\pi < L\}, \qquad \text{nullity} = \begin{cases} n-1, & L \in \pi\mathbb{Z}, \\ 0, & \text{otherwise.} \end{cases} \tag{7.104}$$

Check against the index theorem. The Jacobi fields vanishing at $s = 0$ are $V = \sin s\, e_a$ ($a \geq 2$), the variation fields of the great circles through p. They vanish again at $s = \pi, 2\pi, \dots$: the antipode $-p$ and p itself, each conjugate to p with multiplicity $n-1$. All geodesics leaving p refocus there (Figure 7.30). The number of conjugate points strictly inside $(0,L)$, counted with multiplicity, is $(n-1)\cdot\#\{k : k\pi < L\}$, in agreement with (7.104).
For example, on S^2 an arc shorter than a half circle has index 0 (it is the shortest path); an arc of length between π and 2π has index 1: it can be shortened by sliding it off the great circle, over the antipodal point.

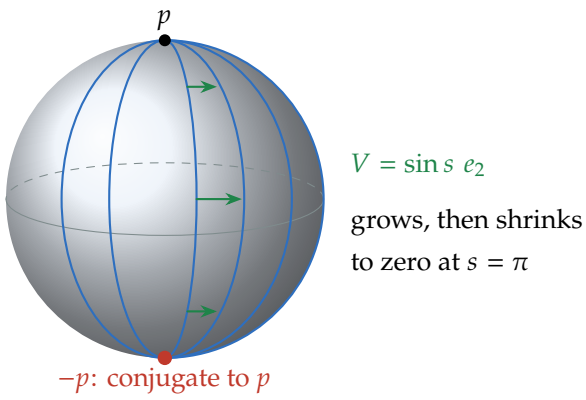

Figure 7.30: Conjugate points on the sphere. The great circles leaving p (blue) spread out and then refocus at the antipode $-p$. The Jacobi field $V = \sin s\, e_2$ (green) measures their separation: it vanishes at $s = 0$ and again at $s = \pi$, so $-p$ is conjugate to p, with multiplicity $n-1$ on S^n (one for each normal direction). A geodesic that passes through $-p$ picks up $n-1$ negative directions.

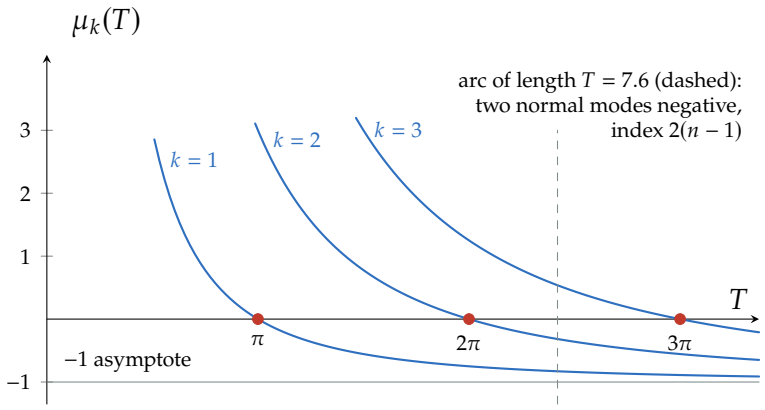

Figure 7.31: Eigenvalues of the normal Jacobi operator $-\mathrm{d}^2/\mathrm{d}s^2 - 1$ on $[0, T]$ for great-circle arcs of the unit sphere, $\mu_k(T) = (k\pi/T)^2 - 1$. As the arc gets longer every eigenvalue decreases; the kth one crosses zero (red dot) exactly when $T = k\pi$, the conjugate times. The index of an arc of length T is the number of curves below the axis (times $n-1$), which is the number of red dots to the left of T: the Morse index theorem.

Worked example 7.52: Flat and negatively curved spaces: every geodesic is a local minimum

If the sectional curvature is ≤ 0, then $\langle R(V,\dot\gamma)\dot\gamma, V\rangle \le 0$, and (7.100) gives

$$\frac{\mathrm{d}^2E}{\mathrm{d}\varepsilon^2} \overset{(1)}{\ge} 2\int_0^1 |V'|^2\,\mathrm{d}t \overset{(2)}{>} 0 \qquad (V \neq 0).$$

(1) The curvature term is non-negative after the minus sign.
(2) If $V' \equiv 0$ then V is parallel, and $V(0) = 0$ forces $V \equiv 0$.

So every geodesic has index 0 and nullity 0: no conjugate points at all. On the flat torus $T^n = \mathbb{R}^n/2\pi\mathbb{Z}^n$ the geodesics from p to q are the straight lines from $\tilde p$ to the lattice translates $\tilde q + 2\pi k$, $k \in \mathbb{Z}^n$: infinitely many geodesics, all local minima, one in each homotopy class of paths.

Try it: A geodesic on the cylinder

On the cylinder $S^1 \times \mathbb{R}$ with the flat metric $\mathrm{d}\phi^2 + \mathrm{d}z^2$, how many geodesics join $(0,0)$ to $(\pi/2, 1)$, and what are their indices?
Answer: lift to the plane: the straight lines to $(\pi/2 + 2\pi m, 1)$, $m \in \mathbb{Z}$. Infinitely many, one for each winding number m, all of index 0 (the cylinder is flat). Their energies are $(\pi/2 + 2\pi m)^2 + 1$.

7.8.6 Loop spaces and path spaces

We now know the critical points of E on $PM(p,q)$ (geodesics) and how to compute their indices (conjugate points). To run the Morse inequalities we also need the other side of the equation: the Betti numbers of the space $PM(p,q)$ itself. This subsection collects what we need about that space.

Working definition 7.22 (based loop space)

Fix a base point $p \in M$. The **based loop space** is

$$\Omega M = \{\gamma\colon [0,1] \to M \mid \gamma(0) = \gamma(1) = p\} = PM(p,p). \tag{7.105}$$

A point of ΩM is a loop that starts and ends at p. Two loops can be multiplied by running first one and then the other at double speed. The *connected components* of ΩM are the homotopy classes of loops [two loops count as one class when one can be deformed continuously into the other, keeping p fixed], i.e. the elements of $\pi_1(M,p)$.

$PM(p,q)$ and ΩM have the same topology. Choose once and for all a path β from q back to p. Then

$$\Phi\colon PM(p,q) \longrightarrow \Omega M, \qquad \gamma \longmapsto \gamma * \beta \quad (\text{first } \gamma,\ \text{then } \beta), \tag{7.106}$$

turns every path from p to q into a loop at p. Composing with the reverse path $\bar\beta$ goes back: $\ell \mapsto \ell * \bar\beta$. Both composites are homotopic to the identity (a path followed by $\beta * \bar\beta$ can be shrunk back to itself by pulling in the "there and back" tail). So

$$PM(p,q) \;\simeq\; \Omega M \tag{7.107}$$

for any p, q in a connected M. In particular they have the same Betti numbers. The advantage of $PM(p,q)$ is that for a well-chosen q the energy is a Morse function; on ΩM itself the constant loop at p is a critical manifold, and p is conjugate to itself along closed geodesics on symmetric spaces, which makes things degenerate.

The homotopy groups shift down by one. A map of a sphere S^k into ΩM is a k-parameter family of loops at p; sweeping out the loop parameter as well gives a map $S^k \times [0,1] \to M$ that sends the ends $S^k \times \{0,1\}$ to p. Collapsing those ends, and the k-parameter family's base point, turns $S^k \times [0,1]$ into S^{k+1}. This is the **suspension** correspondence, and it gives

$$\pi_k(\Omega M) \;\cong\; \pi_{k+1}(M). \tag{7.108}$$

(The more systematic reason: the space $PM(p,\cdot)$ of all paths starting at p is contractible, because every path can be reeled back to p along itself, and the endpoint map $PM(p,\cdot) \to M$ has fibre ΩM. The long exact sequence of this fibration, with a contractible total space, gives (7.108).) This is the reason Morse theory on ΩM can tell us about the homotopy groups of M, which is how Bott will use it.

Worked example 7.53: The loop space of a circle

Let $M = S^1 = \mathbb{R}/2\pi\mathbb{Z}$ with the flat metric, $p = 0$. A loop at 0 lifts to a path in $\mathbb{R}$ from 0 to $2\pi m$ for a unique integer m, the winding number. So

$$\Omega S^1 = \bigsqcup_{m\in\mathbb{Z}} \Omega_m S^1, \qquad \Omega_m S^1 \;\simeq\; P\mathbb{R}(0,2\pi m) \;\simeq\; \text{point}.$$

Each component is contractible by Example 7.48. The energy on $\Omega_m S^1$ has exactly one critical point, the uniform winding $\gamma_m(t) = 2\pi m t$, of index 0 and energy $E = (2\pi m)^2$. The Morse series is $\sum_{m\in\mathbb{Z}} t^0$, an infinite sum of 1's, and $b_0(\Omega S^1) = \infty$: one component for each $m \in \pi_1(S^1) = \mathbb{Z}$. Consistent with (7.108): $\pi_0(\Omega S^1) = \pi_1(S^1) = \mathbb{Z}$ and $\pi_k(\Omega S^1) = \pi_{k+1}(S^1) = 0$ for $k \geq 1$. All the geodesics here are explained by the fundamental group; the interesting case is a simply connected M, where ΩM is connected and the geodesics must be explained by higher Betti numbers.

7.8.7 Morse theory on the path space of the sphere

Take the unit sphere S^n ($n \geq 2$) with the round metric, and two points p, q that are neither equal nor antipodal. Let $\theta = d(p,q) \in (0,\pi)$ be the angle between them. We list all the critical

points of E on $PS^n(p,q)$, their indices, and read off the Morse series.

The critical points. A geodesic from p to q is a great-circle arc (Example 7.49). Because $q \neq \pm p$, exactly one great circle passes through both, the intersection of S^n with the plane spanned by p and q. A geodesic may leave p along it in either direction and may wind around it any number of times before stopping at q:

- towards q, winding k times first: length $L = 2\pi k + \theta$;
- away from q (through $-p$), winding k times first: length $L = 2\pi(k+1) - \theta$.

Order them by length and call them $\gamma_0, \gamma_1, \gamma_2, \ldots$:

$$L(\gamma_{2k}) = 2\pi k + \theta, \qquad L(\gamma_{2k+1}) = 2\pi(k+1) - \theta, \qquad k = 0, 1, 2, \ldots \tag{7.109}$$

Since $0 < \theta < \pi$, these lengths strictly increase with j and none is a multiple of π.

The indices. By (7.104) the index of an arc of length L is $(n-1)$ times the number of positive integers m with $m\pi < L$.

$$\lambda(\gamma_{2k}) \overset{(1)}{=} (n-1)\,\#\{m \geq 1 :\ m\pi < 2\pi k + \theta\} \overset{(2)}{=} (n-1)\cdot 2k,$$
$$\lambda(\gamma_{2k+1}) \overset{(3)}{=} (n-1)\,\#\{m \geq 1 :\ m\pi < 2\pi k + 2\pi - \theta\} \overset{(4)}{=} (n-1)(2k+1).$$

(1) The index formula (7.104) with $L = 2\pi k + \theta$.
(2) $2k\pi < 2\pi k + \theta < (2k+1)\pi$ because $0 < \theta < \pi$, so $m = 1, \ldots, 2k$ qualify and $m = 2k+1$ does not.
(3) The same formula with $L = 2\pi(k+1) - \theta$.
(4) $(2k+1)\pi < 2\pi k + 2\pi - \theta < (2k+2)\pi$, so $m = 1, \ldots, 2k+1$ qualify.

So, in one line,

$$\lambda(\gamma_j) = j\,(n-1), \qquad j = 0, 1, 2, \ldots, \tag{7.110}$$

and every γ_j is non-degenerate, because its length is never a multiple of π, so q is never conjugate to p along it. Geometrically: each time the arc passes through $-p$ or through p itself (the conjugate points, Figure 7.30), it picks up $n-1$ more directions in which it can be shortened. Figure 7.32 shows the first few.

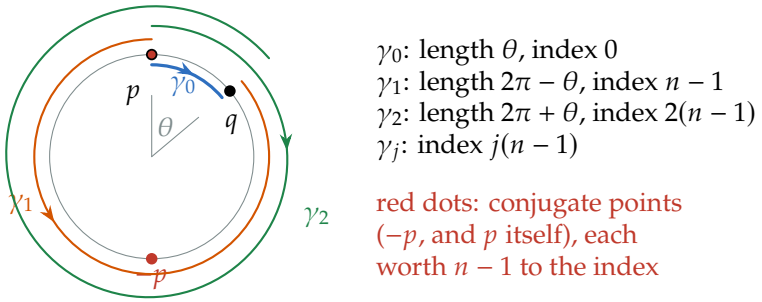

Figure 7.32: All the geodesics from p to q on the round S^n, drawn in the plane of the unique great circle through p and q (the curves are pushed apart radially only so that they can be seen). γ_0 goes the short way, γ_1 the long way through $-p$, γ_2 once around and then the short way, and so on. Every passage through a red conjugate point adds $n-1$ to the index, which gives $\lambda(\gamma_j) = j(n-1)$.

The Morse series. One critical point of each index $j(n-1)$, so

$$M_t(E) = \sum_{j=0}^{\infty} t^{\,j(n-1)} = 1 + t^{n-1} + t^{2(n-1)} + \cdots = \frac{1}{1-t^{n-1}}. \tag{7.111}$$

It is an infinite series, since there are infinitely many critical points, but each coefficient is finite (0 or 1). That is all the Morse inequalities need.

The lacunary principle does the rest. For $n \geq 3$ the gaps between the exponents in (7.111) are $n-1 \geq 2$: no two consecutive powers of t appear. The lacunary principle (Section 7.2.7) works degree by degree, so it applies to an infinite series just as well. Suppose $R(t) = \sum r_i t^i \neq 0$ and let r_i be its first non-zero coefficient. Then $(1+t)R(t)$ has the positive coefficient r_i in degree i and $r_i + r_{i+1} > 0$ in degree $i+1$. So $m_i - b_i > 0$ and $m_{i+1} - b_{i+1} > 0$, which needs $m_i \neq 0$ and $m_{i+1} \neq 0$: two consecutive powers in M_t, which do not exist. Hence $R = 0$, E is perfect, and

$$\boxed{P_t(\Omega S^n) = P_t\big(PS^n(p,q)\big) = \frac{1}{1-t^{n-1}}}, \qquad H^i(\Omega S^n;\mathbb{R}) = \begin{cases} \mathbb{R}, & i = 0,\ n-1,\ 2(n-1), \ldots \\ 0, & \text{otherwise.} \end{cases} \tag{7.112}$$

This is a calculation of the cohomology of an infinite-dimensional space from counting great circles. The same argument works with any coefficient field, so there is no torsion.

The Bott–Morse–Smale picture (Section 7.3.4) tells us more. The energy levels $E(\gamma_j) = L_j^2$ increase with j, so as c increases the sublevel set $\{E \leq c\}$ acquires one cell at a time:

$$\Omega S^n \;\simeq\; e^0 \cup e^{n-1} \cup e^{2(n-1)} \cup e^{3(n-1)} \cup \cdots . \tag{7.113}$$

The first two cells already form a sphere $S^{n-1} = e^0 \cup e^{n-1}$. It has a direct meaning: the loops at p that run once over the sphere through $-p$ along a great circle are labelled by their direction at $-p$, a point of the unit sphere S^{n-1} of directions. (Figure 7.33.)

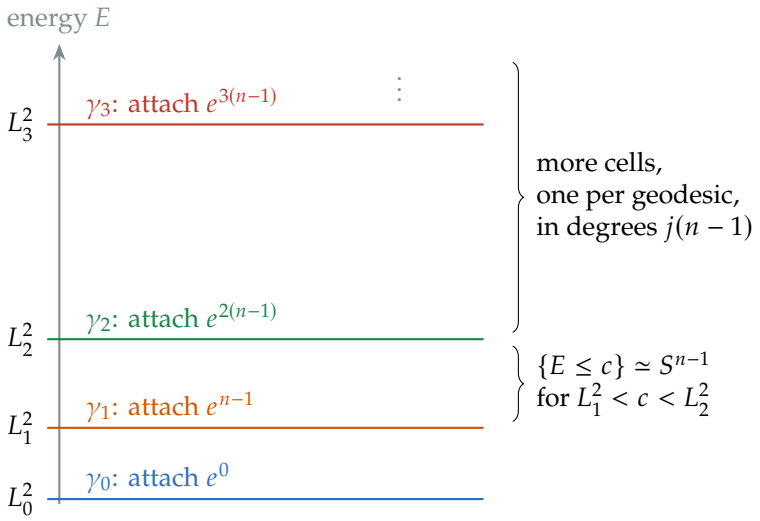

Figure 7.33: The path space of the round S^n, built by raising the energy. Each geodesic γ_j from p to q is a critical level (drawn to scale for $\theta = 1.2$), and crossing it attaches one cell of dimension $\lambda(\gamma_j) = j(n-1)$. Between L_1^2 and L_2^2 the sublevel set is homotopy equivalent to $S^{n-1} = e^0 \cup e^{n-1}$; in the limit one obtains a cell complex with exactly one cell in each degree $j(n-1)$, which is why $P_t(\Omega S^n) = 1/(1-t^{n-1})$.

Worked example 7.54: Checking the answer for S^3 and S^2

S^3. (7.112) gives $P_t(\Omega S^3) = 1 + t^2 + t^4 + \dots$. The lowest non-trivial class is in degree 2. By (7.108) and the Hurewicz theorem (for the simply connected space ΩS^3, the first non-zero homotopy group equals the first non-zero homology group),

$$H_2(\Omega S^3) \overset{(1)}{\cong} \pi_2(\Omega S^3) \overset{(2)}{=} \pi_3(S^3) \overset{(3)}{=} \mathbb{Z}.$$

(1) Hurewicz: ΩS^3 is connected and $\pi_1(\Omega S^3) = \pi_2(S^3) = 0$.
(2) The shift (7.108).
(3) The degree of a map $S^3 \to S^3$; this is the group of instanton numbers of SU(2) gauge theory (Chapter 8).

So $b_2(\Omega S^3) = 1$, as the Morse series says.
S^2. Here $n - 1 = 1$ and (7.111) is $M_t = 1 + t + t^2 + t^3 + \dots$: consecutive powers, so the lacunary principle is silent. An independent calculation settles it. The Hopf fibration $S^1 \to S^3 \to S^2$ gives a homotopy equivalence $\Omega S^2 \simeq S^1 \times \Omega S^3$. (Lift a loop in S^2 to a path in S^3 starting at a fixed point over p; its end lies in the fibre circle S^1 over p. This defines $\Omega S^2 \to S^1$, whose fibre is the space of loops that lift to closed loops, i.e. ΩS^3. The resulting fibration $\Omega S^3 \to \Omega S^2 \to S^1$ is trivial up to homotopy, because a loop of loops mapping once around S^1 exists, and loops in S^2 can be multiplied.) Hence

$$P_t(\Omega S^2) \overset{(1)}{=} P_t(S^1)\, P_t(\Omega S^3) \overset{(2)}{=} \frac{1+t}{1-t^2} \overset{(3)}{=} \frac{1}{1-t} = M_t(E).$$

(1) The Künneth formula for a product.
(2) $P_t(S^1) = 1 + t$ and the S^3 result above.
(3) $1 - t^2 = (1 - t)(1 + t)$.

So the energy is perfect on $PS^2(p, q)$ too, even though counting alone could not show it.

Morse's theorem: infinitely many geodesics for every metric

Now forget the round metric. Put *any* Riemannian metric g on S^n and pick p, q. The Betti numbers of $PS^n(p, q)$ do not know about g: they are those of ΩS^n, computed above using the round metric. For all but a measure-zero set of q, the point q is not conjugate to p along any geodesic (Sard's theorem applied to the exponential map at p: conjugate points are its critical values). Then E is a Morse function on $PS^n(p, q)$ and the weak Morse inequalities give

$$m_{j(n-1)} \;\geq\; b_{j(n-1)}(\Omega S^n) = 1 \qquad \text{for every } j = 0, 1, 2, \dots \tag{7.114}$$

So there is at least one geodesic of each index $j(n - 1)$, and in particular infinitely many.

Key idea: Morse's theorem (Nash p. 192)

For any Riemannian metric on S^n, and any two points p, q that are not conjugate along any geodesic, there are infinitely many geodesics from p to q; at least one has index $j(n - 1)$, for each $j \geq 0$. (With the Lusternik–Schnirelmann version of the argument, Section 7.4.5, the conclusion "infinitely many" survives for conjugate p, q too.)

Picture a potato-shaped S^2. Most of the geodesics we are guaranteed are long curves that wind around it several times; the theorem says that however the potato is shaped, those windings cannot all be undone. The reason is not geometric but topological: the cohomology classes of ΩS^n in degrees $j(n - 1)$ each have to be "carried" by a critical point.

Serre's generalisation. Serre proved in 1951 that for *every* compact simply connected manifold M of positive dimension, infinitely many Betti numbers of ΩM are non-zero (with coefficients in some field). The same inequality then shows: on any compact Riemannian manifold, any two non-conjugate points are joined by infinitely many geodesics. (If M is not simply connected and $\pi_1(M)$ is infinite, the components of ΩM already give infinitely many, as for S^1 in Example 7.53; if π_1 is finite, pass to the universal cover.)

7.8.8 Why Morse theory survives in infinite dimensions

We have used the Morse inequalities on an infinite-dimensional space without comment. Two things could go wrong.

Infinite index. A critical point with infinitely many negative directions would attach an "infinite-dimensional cell", and infinite-dimensional discs can be contracted onto their boundary spheres, so nothing would be detected. The second-variation formula rules this out: the Hessian of E is a Schrödinger operator with finitely many negative eigenvalues (Section 7.8.4). The energy is "bounded below in all but finitely many directions". The action of a *relativistic* string, or the Dirac action, is not of this form; it is unbounded in both directions, and for those problems a different construction (Floer's, Chapter 12) is needed.

Critical points escaping to infinity. This can go wrong even in one dimension, once the space is not compact.

Worked example 7.55: A minimum that runs away

Let $f(x) = e^x$ on $M = \mathbb{R}$. Then $f'(x) = e^x \neq 0$ everywhere: no critical points, $M_t(f) = 0$. But $\mathbb{R}$ is connected, $P_t(\mathbb{R}) = 1$, and the weak inequality $m_0 \geq b_0$ fails. What happened is visible in Figure 7.34: f is bounded below by 0 and wants a minimum, but the minimum has escaped to $x = -\infty$. Along the sequence $x_k = -k$,

$$f(x_k) = e^{-k} \text{ is bounded}, \qquad f'(x_k) = e^{-k} \to 0,$$

yet x_k has no convergent subsequence. It is a "critical point at infinity".

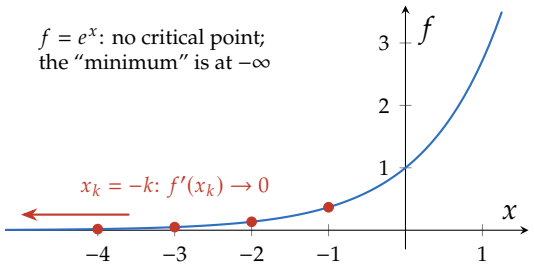

Figure 7.34: The failure mode that the Palais–Smale condition excludes. The function e^x is bounded below and becomes flatter and flatter to the left, but never has a critical point. A sequence along which f stays bounded and $f' \to 0$ (red dots) runs off to infinity instead of converging. On such a space the Morse inequalities fail: $\mathbb{R}$ has $b_0 = 1$ but f has no minimum.

Working definition 7.23 (Palais–Smale condition)

A function f on a (possibly infinite-dimensional, complete [every Cauchy sequence of points converges, so no points are missing]) Riemannian manifold satisfies the **Palais–Smale condition** if every sequence x_k along which $f(x_k)$ is bounded and $|\nabla f(x_k)| \to 0$ has a convergent subsequence. *In words*: approximate critical points at bounded height converge to genuine ones. On a compact finite-dimensional M it holds automatically.

Palais and Smale showed (1964) that with this condition, finite indices and the gradient flow on a complete Hilbert manifold, the whole of finite-dimensional Morse theory goes through: nothing happens between critical values, crossing a critical point of index λ attaches a λ-cell, and the Morse inequalities hold. For the energy one works with paths of finite energy (the Sobolev space H^1 of paths whose velocity is square integrable), which is a complete Hilbert manifold. Then E satisfies Palais–Smale whenever M is compact: a sequence of paths of bounded energy is equicontinuous (by the chain (7.115) below, short time intervals give short arcs), so by Arzelà–Ascoli it has a uniformly convergent subsequence, and $\nabla E \to 0$ upgrades this to convergence in H^1. Physically: a particle of bounded kinetic energy on a compact space cannot run away.

7.8.9 Broken geodesics: a finite-dimensional model (time slicing)

Morse himself avoided infinite-dimensional analysis. His device, which Nash describes for closed loops [Nash p. 206], is to replace paths by *broken geodesics*: chains of short geodesic segments. Any physicist will recognise it as the time-slicing of the path integral, where a path is replaced by its positions $x_1, \dots, x_{k-1}$ at intermediate times.

Bounded energy means short segments. Cut $[0,1]$ into k equal intervals $[t_{i-1}, t_i]$, $t_i = i/k$. Let L_i be the length of the ith piece of a path γ. Then

$$L_i^2 \overset{(1)}{=} \left(\int_{t_{i-1}}^{t_i} |\dot\gamma| \cdot 1 \, \mathrm{d}t \right)^2 \overset{(2)}{\le} (t_i - t_{i-1}) \int_{t_{i-1}}^{t_i} |\dot\gamma|^2 \, \mathrm{d}t \overset{(3)}{\le} \frac{E(\gamma)}{k}. \tag{7.115}$$

(1) Definition of length, with a factor 1 inserted.
(2) Cauchy–Schwarz on the interval $[t_{i-1}, t_i]$, as in (7.98).
(3) $t_i - t_{i-1} = 1/k$, and the integral over one piece is at most the total energy.

Now fix an energy ceiling c. Every compact Riemannian manifold has an $\varepsilon > 0$ (for instance any number below the injectivity radius) such that two points at distance $< \varepsilon$ are joined by a *unique* shortest geodesic, which depends smoothly on its endpoints. Choose $k > c/\varepsilon^2$. Then every path with $E < c$ has all its pieces of length $< \varepsilon$, by (7.115).

Working definition 7.24 (space of broken geodesics)

With k and c as above, a **broken geodesic** is a path that is the unique short geodesic [the one shortest geodesic joining $\gamma(t_{i-1})$ to $\gamma(t_i)$, which exists since their distance is below ε] on each interval $[t_{i-1}, t_i]$. It is determined by its break points $x_i = \gamma(t_i)$, $i = 1, \dots, k-1$ (with $x_0 = p$, $x_k = q$). So the space of broken geodesics with $E < c$ is the finite-dimensional open set

$$B_k(c) = \big\{ (x_1, \dots, x_{k-1}) \in M^{k-1} : \; E < c \big\}, \qquad \dim B_k(c) = (k-1)\, n,$$

on which the energy is the explicit function

$$E_k(x_1,\dots,x_{k-1}) = k\sum_{i=1}^{k} d(x_{i-1},x_i)^2. \tag{7.116}$$

[$d(x,y)$ is the Riemannian distance, the length of the shortest path from x to y].

The formula (7.116) holds because a geodesic segment of length d traversed in time $1/k$ has speed kd, hence energy $\int_0^{1/k}(kd)^2\mathrm{d}t = kd^2$.

Key idea: Broken geodesics carry everything below the ceiling

- Replacing each piece of a path with $E < c$ by the short geodesic with the same endpoints lowers its energy (a geodesic minimises energy among paths with its endpoints and duration). Doing this gradually is a deformation retraction of $\{E < c\} \subset PM(p,q)$ onto $B_k(c)$. So the two have the same topology.
- The critical points of E_k on $B_k(c)$ are exactly the unbroken geodesics from p to q with $E < c$, with the same index and the same nullity as in the full path space.

Thus Morse theory on $PM(p,q)$ below any energy is honest finite-dimensional Morse theory on $B_k(c)$. Letting $c \to \infty$ (and $k \to \infty$ with it) recovers the whole path space.

Why is a critical point of E_k unbroken? Differentiating (7.116) in x_i only affects the two pieces meeting at x_i. The gradient of $d(x_{i-1},x)^2$ at $x = x_i$ is $2d$ times the unit vector pointing away from x_{i-1} along the segment, i.e. $2/k$ times the arriving velocity; that of $d(x,x_{i+1})^2$ is minus $2/k$ times the departing velocity. So

$$\frac{\partial E_k}{\partial x_i} = 2\big(\dot\gamma(t_i^-) - \dot\gamma(t_i^+)\big), \tag{7.117}$$

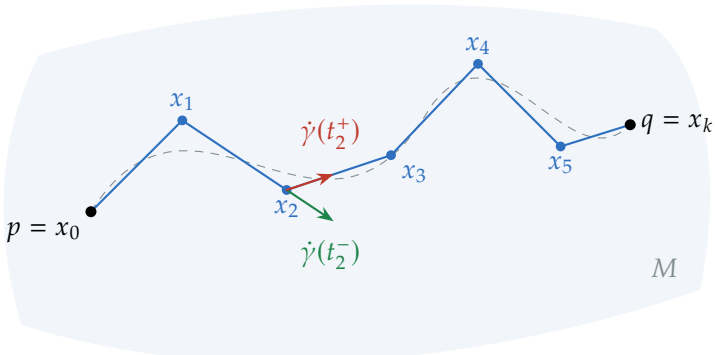
and a critical point has no kink at any x_i: the incoming and outgoing velocities agree, and the broken geodesic is a smooth geodesic. (This is also the first-variation formula (7.96) for a piecewise geodesic: the only contributions are the jumps of velocity at the corners.) Figure 7.35 shows the picture.

Worked example 7.56: Time slicing in flat space

Take $M = \mathbb{R}^n$, where $d(x,y) = |x-y|$ and every k is allowed. Put $x_i = p + \frac{i}{k}(q-p) + \eta_i$ with $\eta_0 = \eta_k = 0$. The same steps as in Example 7.48 give

$$\begin{aligned} E_k &\overset{(1)}{=} k\sum_{i=1}^{k}\Big|\tfrac{1}{k}(q-p)+\eta_i-\eta_{i-1}\Big|^2 \\ &\overset{(2)}{=} |q-p|^2 + 2(q-p)\cdot\sum_{i=1}^{k}(\eta_i-\eta_{i-1}) + k\sum_{i=1}^{k}|\eta_i-\eta_{i-1}|^2 \\ &\overset{(3)}{=} |q-p|^2 + k\sum_{i,j=1}^{k-1} T_{ij}\,\eta_i\cdot\eta_j, \qquad T = \begin{pmatrix} 2 & -1 & & \\ -1 & 2 & -1 & \\ & \ddots & \ddots & \ddots \\ & & -1 & 2 \end{pmatrix}. \end{aligned}$$

(1) (7.116) with $x_i - x_{i-1} = \frac{1}{k}(q-p) + \eta_i - \eta_{i-1}$.



each piece: the unique short geodesic, length $< \varepsilon$, duration $1/k$;
$\partial E_k/\partial x_i = 2(\dot\gamma(t_i^-) - \dot\gamma(t_i^+))$: kinks cost energy

Figure 7.35: A broken geodesic with $k = 6$ pieces. It is fixed by the $k-1$ break points $x_1, \dots, x_5$, so the space of broken geodesics is finite dimensional. Any path of energy $< c$ (dashed) can be pulled tight piece by piece onto a broken geodesic without raising its energy. The gradient of E_k at a break point is the jump in velocity there (green versus red arrows at x_2), so the critical points are the broken geodesics with no kinks: the true geodesics.

(2) Expand the square; the k copies of $k \cdot \frac{1}{k^2}|q-p|^2$ add up to $|q-p|^2$.

(3) The middle sum telescopes to $\eta_k - \eta_0 = 0$; expanding $\sum_i |\eta_i - \eta_{i-1}|^2$ gives $2|\eta_i|^2$ on the diagonal and $-\eta_i \cdot \eta_{i\pm1}$ off it (the discrete Laplacian).

The Hessian is $2kT \otimes \mathbb{1}_n$. The eigenvectors of T are the discrete sine modes $(\eta_i) = (\sin \frac{m\pi i}{k})$, with eigenvalues $4\sin^2 \frac{m\pi}{2k}$, $m = 1, \dots, k-1$ (substitute and use $\sin(a+b) + \sin(a-b) = 2\sin a \cos b$). All are positive, so the index is 0, as in the continuum. For fixed m and large k, $2k \cdot 4\sin^2 \frac{m\pi}{2k} \approx \frac{2(m\pi)^2}{k}$; since $\sum_i |\eta_i|^2 \approx \frac{k}{2}|a_m|^2$ for $\eta_i = a_m \sin \frac{m\pi i}{k}$, the quadratic energy of one mode tends to $\frac{1}{2} \cdot \frac{2(m\pi)^2}{k} \cdot \frac{k}{2}|a_m|^2 = \frac{(m\pi)^2}{2}|a_m|^2$, exactly the continuum value of Example 7.48. The time-sliced action converges mode by mode to the continuum action, which is the statement physicists use when they define the path integral by slicing.

Worked example 7.57: Two-piece broken geodesics on S^2

On the unit S^2 with $d(p,q) = \theta \in (0,\pi)$, take $k = 2$: a single break point x, and

$$E_2(x) = 2\big(d(p,x)^2 + d(x,q)^2\big), \qquad x \in S^2 \setminus \{-p, -q\}$$

(each piece must be shorter than π to be the unique shortest arc). We find its critical points and their Hessians directly, and recover γ_0 and γ_1 with indices 0 and 1.

Coordinates near a point m of the great circle C through p and q. Let s be the displacement along C and y the (small) displacement perpendicular to C. For a point a_0 on C at distance a from m, the spherical theorem of Pythagoras (right angle at the foot of the perpendicular) gives, to second order,

$$\cos d(a_0,x) \overset{(1)}{=} \cos(a \mp s)\cos y \quad\Longrightarrow\quad d(a_0,x) \overset{(2)}{=} a \mp s + \tfrac{1}{2}y^2 \cot a + O(3).$$

(1) Spherical Pythagoras $\cos(\text{hypotenuse}) = \cos(\text{leg}_1)\cos(\text{leg}_2)$, with legs $a \mp s$ along C and y across it (the sign depends on which side of m the point a_0 lies).

(2) Write $d = (a \mp s) + \delta$. Then $\cos(a \mp s) - \delta \sin(a \mp s) \approx \cos(a \mp s)(1 - \frac{1}{2}y^2)$, so $\delta = \frac{1}{2}y^2 \cot(a \mp s) = \frac{1}{2}y^2 \cot a + O(3)$.

Short arc. Let m be the midpoint of the short arc from p to q, so p and q lie on C at distance $a = \theta/2$ from m, on opposite sides. With $Y = \frac{1}{2}y^2 \cot a$,

$$E_2 \overset{(1)}{=} 2\big[(a - s + Y)^2 + (a + s + Y)^2\big] \overset{(2)}{=} 4a^2 + 4s^2 + 8aY + O(3)$$
$$\overset{(3)}{=} \theta^2 + 4s^2 + 2\theta \cot \tfrac{\theta}{2}\; y^2 + O(3).$$

(1) The expansion above for $d(p, x)$ and $d(x, q)$.
(2) Expand, keeping terms of order two (Y is already second order).
(3) $a = \theta/2$ and $8aY = 4a \cot a\; y^2$.

Both coefficients are positive since $\cot \frac{\theta}{2} > 0$: a minimum, index 0, with $E_2 = \theta^2 = L(\gamma_0)^2$.
Long arc. Let m be the midpoint of the long arc (through $-p$ and $-q$). Now $-p$ and $-q$ lie at distance $a = \theta/2$ from m, and $d(p, x) = \pi - d(-p, x)$, $d(q, x) = \pi - d(-q, x)$. So

$$E_2 \overset{(1)}{=} 2\big[(\pi - a - s - Y)^2 + (\pi - a + s - Y)^2\big]$$
$$\overset{(2)}{=} 4(\pi - a)^2 + 4s^2 - 8(\pi - a)Y + O(3) \overset{(3)}{=} (2\pi - \theta)^2 + 4s^2 - 2(2\pi - \theta) \cot \tfrac{\theta}{2}\; y^2 + O(3).$$

(1) Antipodal distances on the unit sphere, then the expansion for $d(-p, x)$ and $d(-q, x)$.
(2) Expand to second order.
(3) $a = \theta/2$ and $8(\pi - a)Y = 4(\pi - a) \cot a\; y^2$.

The y^2 coefficient is negative: one downhill direction, index $1 = n - 1$, with $E_2 = (2\pi - \theta)^2 = L(\gamma_1)^2$. Moving the break point off the great circle shortens both pieces. The reason is that each piece is longer than a quarter circle, and beyond a quarter circle the circles of constant distance from p are shrinking again (they close up at $-p$), so a sideways step moves x to a smaller circle, i.e. closer to p; this is the $-\cot$ sign above. On S^n the same computation has $n - 1$ perpendicular directions y, and gives index $n - 1$.
Longer geodesics are invisible to E_2: γ_2 has length $> 2\pi$ and cannot be built from two pieces shorter than π. To see γ_j one needs $k > L_j/\pi$ break points, which is why the ceiling c and k must grow together.

Try it: An equilateral triangle on a great circle

Nash's version for closed loops uses *geodesic polygons* with n vertices $p_1, \dots, p_n$, with energy $E_n = n \sum_{i=1}^{n} d(p_i, p_{i+1})^2$ ($p_{n+1} = p_1$). Show that three equally spaced points on a great circle of S^2 form a critical point of E_3, with the energy of a once-traversed great circle. Why does $n = 2$ not work?
Answer: each side has length $2\pi/3 < \pi$, so it is the unique short arc; at each vertex the incoming and outgoing directions are both tangent to the great circle and equal, so by (7.117) the gradient vanishes. $E_3 = 3 \cdot 3 \cdot (2\pi/3)^2 = 4\pi^2 = (2\pi)^2$. With $n = 2$ the two vertices would have to be antipodal, at distance π, where the short arc is not unique and d^2 is not smooth.

7.8.10 Closed geodesics and the free loop space

A **closed geodesic** is a geodesic that comes back to its starting point with its starting velocity, so that it can go round again: a periodic orbit of the free particle. To find them, Nash replaces paths with fixed ends by all loops [Nash p. 206, (7.59)]:

$$E\colon LM := \operatorname{Map}(S^1, M) \longrightarrow \mathbb{R}, \qquad E(\gamma) = \int_0^1 |\dot\gamma(t)|^2 \, \mathrm{d}t, \tag{7.118}$$

where a point of the **free loop space** $LM = \mathrm{Map}(S^1, M)$ is a map of the circle $S^1 = [0,1]/(0 \sim 1)$ into M, with no base point imposed.

First variation for loops. The computation (7.94) goes through with one change: $V(0) = V(1)$ need not vanish, only agree. The boundary term from the integration by parts is $2\big[\langle V, \dot\gamma\rangle\big]_0^1 = 2\langle V(0), \dot\gamma(1) - \dot\gamma(0)\rangle$. So the critical points of E on LM satisfy the geodesic equation *and* $\dot\gamma(1) = \dot\gamma(0)$: they are exactly the closed geodesics, together with the constant loops (geodesics of speed zero), which form the absolute minimum $E = 0$.

The relation to the based loop space. Evaluating a loop at $t = 0$ gives a map $LM \to M$, $\gamma \mapsto \gamma(0)$. The loops with $\gamma(0) = p$ are the based loops, so the fibre over p is ΩM:

$$\Omega M \longrightarrow LM \xrightarrow{\gamma \mapsto \gamma(0)} M. \tag{7.119}$$

The constant loops give a section $M \to LM$. This fibration is what Nash means by "the topology of $\mathrm{Map}(S^1, M)$ is closely related to that of ΩM" [Nash p. 206]. It implies the inequality $P_t(LM) \le P_t(M)\,P_t(\Omega M)$ coefficientwise (with field coefficients and M simply connected), with equality in favourable cases. The inequality is the statement that the cohomology of the total space is at most that of "base times fibre"; equality means that, as for a product, every class of the fibre extends over the total space (the Leray–Hirsch situation of Section 7.6.5).

The circle acts, so critical points come in circles. The group U(1) of rotations of the domain circle acts on LM,

$$(e^{2\pi i s} \cdot \gamma)(t) = \gamma(t + s), \tag{7.120}$$

and E is invariant: shifting the time origin does not change the kinetic energy. So E is a U(1)-invariant function, and the equivariant theory of Section 7.7 applies, as Nash remarks. The consequence for the ordinary theory is immediate: a closed geodesic γ is never an isolated critical point, because every rotated copy $\gamma(\cdot + s)$ is also critical, with the same energy. The critical sets are at least circles, and E is at best a Morse–Bott function (Section 7.5). The stabiliser of a closed geodesic traversed k times ($\gamma(t) = \gamma_1(kt)$) is the cyclic group $\mathbb{Z}_k$ of rotations by multiples of $1/k$; its orbit is $S^1/\mathbb{Z}_k$, and for real coefficients the equivariant contribution of such an orbit is that of a point (Section 7.7).

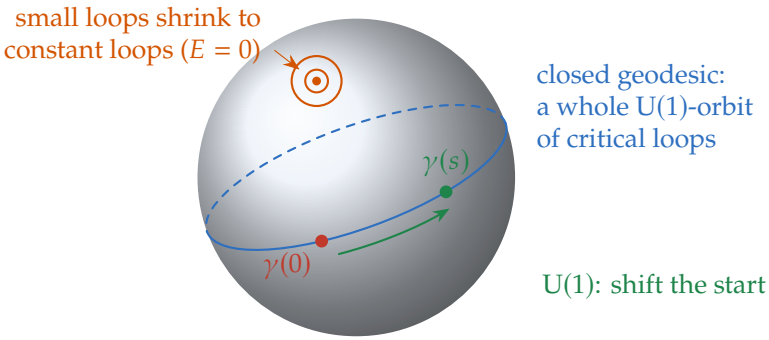


Figure 7.36: Critical points of the energy on the free loop space LS^2. A great circle (blue) is a closed geodesic; but the loop is a parametrised map, and moving the starting point from $\gamma(0)$ (red) to $\gamma(s)$ (green) gives a different point of LS^2 with the same energy. So each closed geodesic is a circle of critical points. Tilting the great circle gives more: the whole family is the unit tangent bundle T^1S^2. At the bottom of the landscape lie the constant loops (orange), a copy of S^2 at $E = 0$.

Worked example 7.58: The flat torus: critical tori

On $T^n = \mathbb{R}^n/2\pi\mathbb{Z}^n$ with the flat metric, a closed loop lifts to a path from $\tilde{x}$ to $\tilde{x} + 2\pi m$, $m \in \mathbb{Z}^n$. The closed geodesics in the class m are the straight loops

$$\gamma_{x,m}(t) = x + 2\pi m\, t, \qquad x \in T^n,$$

one for each starting point x: a critical manifold $C_m \cong T^n$, at energy $E = 4\pi^2 |m|^2$ (for $m = 0$ these are the constant loops). Each has index 0 by Example 7.52. Is C_m non-degenerate in the Morse–Bott sense? The Jacobi operator is $-\mathrm{d}^2/\mathrm{d}t^2$ on periodic vector fields; its kernel is the constant fields $V \equiv v \in \mathbb{R}^n$, which is n-dimensional, exactly the tangent space of C_m (moving x). So yes. The Morse–Bott series is

$$M_t(E) \overset{(1)}{=} \sum_{m\in\mathbb{Z}^n} t^0 P_t(T^n) \overset{(2)}{=} \sum_{m\in\mathbb{Z}^n} (1+t)^n,$$

(1) (7.54) with one critical torus of index 0 in each class m.
(2) $P_t(T^n) = (1+t)^n$ by Künneth.

which is $P_t(LT^n)$: the component of LT^n of class m is homotopy equivalent to T^n (slide the loop to the straight one). The energy is perfect.

Worked example 7.59: The round sphere: iterated great circles

On the unit S^n the closed geodesics are the great circles traversed k times, $k = 1, 2, \ldots$:

$$\gamma(t) = \cos(2\pi k t)\, x + \sin(2\pi k t)\, v, \qquad x, v \in S^n \subset \mathbb{R}^{n+1}, \quad x \perp v,$$

of length $2\pi k$ and energy $(2\pi k)^2$. The pair (x, v), a point and a unit tangent vector there, runs over the unit tangent bundle, so each critical manifold is

$$C_k \cong T^1 S^n, \qquad \dim C_k = n + (n-1) = 2n - 1.$$

Index and nullity. Use arc length $s \in [0, 2\pi k]$ with periodic boundary conditions and the parallel frame of Example 7.51. The Jacobi operator is $-\mathrm{d}^2/\mathrm{d}s^2$ on the tangential component and $-\mathrm{d}^2/\mathrm{d}s^2 - 1$ on each of the $n-1$ normal components. Periodic eigenfunctions are 1, $\cos\frac{ms}{k}$, $\sin\frac{ms}{k}$ ($m \geq 1$), with eigenvalues $(m/k)^2$ and $(m/k)^2 - 1$ respectively. Counting:

$$\lambda_{C_k} \overset{(1)}{=} (n-1)\Big[1 + 2\,\#\{m :\ 1 \leq m \leq k-1\}\Big] \overset{(2)}{=} (2k-1)(n-1),$$

$$\text{nullity} \overset{(3)}{=} 1 + (n-1)\cdot 2 \overset{(4)}{=} 2n - 1 = \dim C_k.$$

(1) Negative normal eigenvalues: $m = 0$ (one function) and $1 \leq m \leq k-1$ (two functions each), since $(m/k)^2 < 1$ exactly for $m < k$. Tangential eigenvalues are never negative.
(2) $1 + 2(k-1) = 2k - 1$.
(3) Zero eigenvalues: the tangential constant (rotating the start point) and the two normal modes with $m = k$, in each of $n-1$ normal directions (tilting the great circle).
(4) So the kernel of the Hessian is exactly the tangent space of C_k: the critical manifold is non-degenerate.

The $m = 0$ normal mode is the familiar one: push the whole great circle towards a latitude circle, which is shorter. The constant loops, $C_0 \cong S^n$, have index 0.
With $\mathbb{Z}_2$ coefficients (so that no orientation of the negative bundles is needed) and $n = 2$,

where $T^1S^2 \cong \mathrm{SO}(3) \cong \mathbb{RP}^3$ has $P_t(\mathbb{RP}^3;\mathbb{Z}_2) = 1 + t + t^2 + t^3$, the Morse–Bott series is

$$M_t(E) \overset{(1)}{=} (1+t^2) + \sum_{k\geq 1} t^{2k-1}(1+t+t^2+t^3)$$
$$\overset{(2)}{=} (1+t^2) + (1+t)(1+t^2)\,\frac{t}{1-t^2} \overset{(3)}{=} (1+t^2)\Big(1+\frac{t}{1-t}\Big) = \frac{1+t^2}{1-t}.$$

(1) Constant loops ($P_t(S^2)$, index 0) plus C_k with index $2k-1$.
(2) $1+t+t^2+t^3 = (1+t)(1+t^2)$, and $\sum_{k\geq 1} t^{2k-1} = t/(1-t^2)$.
(3) $1-t^2 = (1-t)(1+t)$.

Compare with the fibration (7.119): $P_t(S^2)P_t(\Omega S^2) = (1+t^2)/(1-t)$ by Example 7.54. The two agree; this equality is Ziller's theorem that for the round sphere (indeed for every compact symmetric space) E is a perfect Morse–Bott function with $\mathbb{Z}_2$ coefficients.

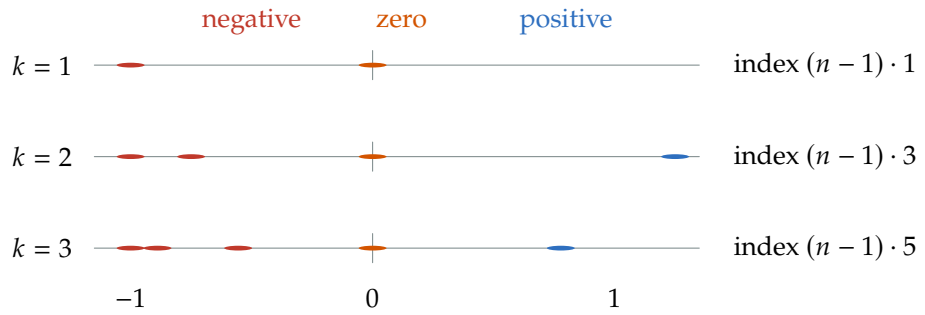

Figure 7.37: The spectrum of the normal Jacobi operator $-\mathrm{d}^2/\mathrm{d}s^2 - 1$ for a great circle traversed k times, one dot per eigenvalue $(m/k)^2 - 1$, $m = 0, 1, 2, \ldots$ (each $m \geq 1$ counts twice: cos and sin). Going round more times packs the eigenvalues more densely, so more of them fall below zero (red): $1, 3, 5, \ldots$ per normal direction. The orange zero modes, $m = k$, tilt the circle, and are tangent to the critical manifold.

How many closed geodesics are there? The trouble with counting closed geodesics by Morse theory is that each one produces infinitely many critical manifolds: all its iterates γ^k. A single closed geodesic, iterated, could in principle carry all the Betti numbers of LM. To conclude that there are infinitely many *geometrically distinct* closed geodesics one must control how the index grows under iteration. The known results:

- *Lusternik–Fet* (1951): every compact Riemannian manifold has at least one non-constant closed geodesic. (Take a non-trivial homotopy class of maps $S^j \to M$, view it as a family of loops, and minimise the maximum energy over the family: a minimax, as in Section 7.4.5.)
- *Lusternik–Schnirelmann*: every metric on S^2 has at least three simple closed geodesics (the three principal "equators" of an ellipsoid are the model).
- *Gromoll–Meyer* (1969): if M is simply connected and the Betti numbers of LM (rational coefficients) are unbounded, there are infinitely many geometrically distinct closed geodesics. The hypothesis fails for spheres, whose loop spaces have bounded Betti numbers (as we just saw).
- *Bangert and Franks* (1992–93): every metric on S^2 has infinitely many closed geodesics. For S^n with $n \geq 3$ and a general metric the question is harder; Nash's sentence about "the existence of an infinite number of closed geodesics on S^k" refers to Klingenberg's programme, and it is best read as a statement about the method.

Physical picture: Periodic orbits in physics

Closed geodesics are periodic orbits of the free particle on M. They are the input of the Gutzwiller trace formula, which expresses the density of quantum energy levels as a sum over classical periodic orbits, each weighted by a phase built from its Morse (Maslov) index. The index growth $\lambda(\gamma^k) \approx k \cdot (\text{const})$ we saw for great circles is the "mean index" that enters there. The U(1) action by time translation is the reason each orbit appears as a whole circle of critical points, and in the trace formula it produces the factor of the primitive period.
A second connection is deeper. Atiyah observed that for the supersymmetric particle on M, the path integral over the free loop space is formally an equivariantly closed integral for the rotation (7.120). Its fixed points are the constant loops, i.e. M itself, and applying the Duistermaat–Heckman localisation of Section 7.7.6 formally to LM gives an integral over M of the $\hat{A}$ genus: the index of the Dirac operator, Chapter 4. The circle action on $\mathrm{Map}(S^1, M)$ that Nash mentions in passing is the reason the index theorem has a one-line path-integral proof.

7.8.11 Loop groups and Bott periodicity

Nash closes his discussion of geodesics with one sentence [Nash p. 207]: replace the sphere S^k by a Lie group G and use Morse theory on ΩG; "this strategy was very successfully employed by Bott in the proof of his periodicity theorems". This subsection unpacks that sentence. It is worth the effort, because the answer is a table that every gauge theorist uses.

The question. Physicists meet the homotopy groups of the unitary groups all the time.

- $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$: flux quantisation, vortices, winding of a phase.
- $\pi_3(\mathrm{SU}(N)) = \mathbb{Z}$ for every $N \geq 2$: the instanton number of SU(N) Yang–Mills theory (Chapter 8), and the baryon number of Skyrmions.
- $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$: Witten's global SU(2) anomaly (Chapter 10).
- $\pi_5(\mathrm{SU}(3)) = \mathbb{Z}$: the quantisation of the Wess–Zumino–Witten term in the chiral Lagrangian of QCD with three flavours.

Two things stand out. Some of these groups do not depend on N once N is large enough: every SU(N) with $N \geq 2$ has the same π_3. And the groups look simple: $\mathbb{Z}$ or 0, apart from a few small-N oddities like $\pi_4(\mathrm{SU}(2))$. Bott's theorem explains both, and it does so by Morse theory on a loop space.

Step 0: stability

Working definition 7.25 (stable homotopy groups of the unitary group)

The group $\mathrm{U}(n+1)$ acts on the unit sphere $S^{2n+1} \subset \mathbb{C}^{n+1}$ by matrix multiplication, transitively [every unit vector is ge_{n+1} for some $g \in \mathrm{U}(n+1)$]. The matrices that fix the last basis vector e_{n+1} form a copy of $\mathrm{U}(n)$ (upper-left block). Hence

$$\mathrm{U}(n) \longrightarrow \mathrm{U}(n+1) \xrightarrow{\;g \mapsto ge_{n+1}\;} S^{2n+1} \tag{7.121}$$

is a fibre bundle: the last column of a unitary matrix is a unit vector, and the other columns can be anything unitary orthogonal to it. For $j \leq 2n-1$ the inclusion $\mathrm{U}(n) \hookrightarrow$

$\mathrm{U}(n+1)$ induces an isomorphism on π_j [maps $S^j \to \mathrm{U}(n)$, up to continuous deformation, correspond one to one with maps $S^j \to \mathrm{U}(n+1)$]. So for fixed j the groups $\pi_j(\mathrm{U}(n))$ stop changing once $2n > j$. The common value is the **stable** homotopy group, written $\pi_j(\mathrm{U})$, where $\mathrm{U} = \bigcup_n \mathrm{U}(n)$ is the infinite unitary group.

Why stability holds. Every fibre bundle $F \to E \to B$ has a long exact sequence of homotopy groups, $\cdots \to \pi_{j+1}(B) \to \pi_j(F) \to \pi_j(E) \to \pi_j(B) \to \dots$ (a sphere in E projects to a sphere in B; a sphere in B lifts to a disc in E whose boundary lies in one fibre). Apply it to (7.121):

$$\underbrace{\pi_{j+1}(S^{2n+1})}_{0} \longrightarrow \pi_j(\mathrm{U}(n)) \longrightarrow \pi_j(\mathrm{U}(n+1)) \longrightarrow \underbrace{\pi_j(S^{2n+1})}_{0} \qquad (j+1 \le 2n).$$

The outer groups vanish because a sphere S^{2n+1} has no homotopy below its dimension: a map $S^i \to S^{2n+1}$ with $i < 2n+1$ misses a point (after a small smoothing) and can then be contracted through the complement, which is a copy of $\mathbb{R}^{2n+1}$. Exactness then forces the middle arrow to be an isomorphism. With $\mathrm{U}(1) = S^1$, $\mathrm{U}(2) \simeq S^1 \times S^3$ (as spaces, $\mathrm{U}(n) = \mathrm{SU}(n) \times \mathrm{U}(1)$ via $g \mapsto (g\,\mathrm{diag}(\det g^{-1}, 1, \dots), \det g)$) and a few known homotopy groups of spheres, the pattern is visible in a table.

	π_1	π_2	π_3	π_4	π_5	π_6
$\mathrm{U}(1)$	$\mathbb{Z}$	0	0	0	0	0
$\mathrm{U}(2)$	$\mathbb{Z}$	0	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_{12}$
$\mathrm{U}(3)$	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	$\mathbb{Z}_6$
$\mathrm{U}(4)$	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0
U (stable)	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0

Table 7.1: Homotopy groups of the unitary groups. An entry $\pi_j(\mathrm{U}(n))$ is in the stable range when $j \le 2n-1$; the red entries are outside it and are "accidents" of small n (for example $\pi_4(\mathrm{U}(2)) = \pi_4(S^3) = \mathbb{Z}_2$). Read the columns downwards: each one settles to the bottom row. Read the bottom row across: it alternates $\mathbb{Z}, 0, \mathbb{Z}, 0, \dots$. Bott's theorem is the statement that this alternation goes on for ever.

Key idea: Bott periodicity, complex case (Nash p. 207)

$$\pi_j(\mathrm{U}) \;\cong\; \pi_{j+2}(\mathrm{U}) \quad \text{for all } j \ge 0, \qquad \text{so} \qquad \pi_j(\mathrm{U}) = \begin{cases} 0, & j \text{ even}, \\ \mathbb{Z}, & j \text{ odd}. \end{cases}$$

Equivalently, in the stable range $\pi_j(\mathrm{U}(n)) = \pi_j(\mathrm{SU}(n))$ for $j \ge 2$ is $\mathbb{Z}$ in odd degrees and 0 in even degrees.

The rest of this subsection is Bott's proof. The plan is shown in Figure 7.38. The only new ingredients are the geometry of a Lie group with an invariant metric (Step 1) and one index computation (Step 3). Everything else is the Morse theory we already have.

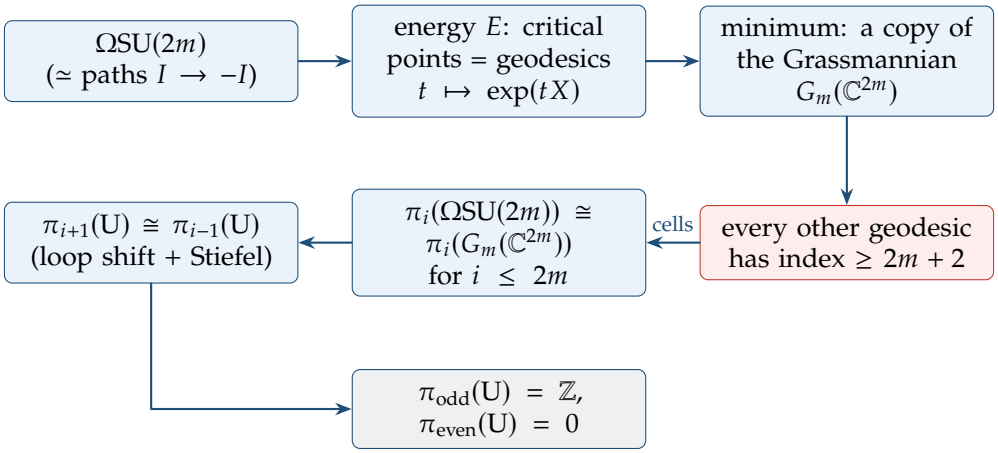

Figure 7.38: The logic of Bott's proof. Morse theory on the loop space of $\mathrm{SU}(2m)$ says that, up to dimension $2m$, the loop space looks like its own minimum set, a finite-dimensional Grassmannian. Two exact sequences then turn this into a statement comparing homotopy groups of the unitary group two degrees apart.

Step 1: geodesics in a Lie group

Working definition 7.26 (bi-invariant metric on $\mathrm{SU}(n)$)

The Lie algebra $\mathfrak{su}(n)$ [the tangent space at the identity I, the velocities of curves in $\mathrm{SU}(n)$ through I] is the space of traceless anti-Hermitian $n \times n$ matrices. On it put

$$\langle X, Y\rangle = -\operatorname{tr}(XY), \qquad |X|^2 = -\operatorname{tr}(X^2) = \sum_{j,l} |X_{jl}|^2 \geq 0. \tag{7.122}$$

Transport it to every tangent space $T_g\mathrm{SU}(n) = g\,\mathfrak{su}(n)$ by left multiplication [declare $\langle gX, gY\rangle := \langle X, Y\rangle$ at the point g]. Because $\operatorname{tr}\big((hXh^{-1})(hYh^{-1})\big) = \operatorname{tr}(XY)$, the result is also invariant under right multiplication: it is a **bi-invariant** metric. Infinitesimally, conjugation invariance says that $\mathrm{ad}_Z = [Z, \cdot\,]$ is skew [its matrix in an orthonormal basis of $\mathfrak{su}(n)$ is antisymmetric]:

$$\langle [Z, X], Y\rangle = -\langle X, [Z, Y]\rangle, \qquad \text{equivalently} \qquad \langle [X, Y], Z\rangle = \langle X, [Y, Z]\rangle. \tag{7.123}$$

Check (7.123) directly: $-\operatorname{tr}([X,Y]Z) = -\operatorname{tr}(XYZ) + \operatorname{tr}(YXZ) = -\operatorname{tr}(XYZ) + \operatorname{tr}(XZY) = -\operatorname{tr}(X[Y,Z])$, using the cyclicity of the trace in the middle step.

The Levi-Civita connection. For left-invariant vector fields X, Y, Z (each determined by its value in $\mathfrak{su}(n)$) all inner products are constant. The Koszul formula for the Levi-Civita connection, $2\langle \nabla_X Y, Z\rangle = X\langle Y,Z\rangle + Y\langle Z,X\rangle - Z\langle X,Y\rangle + \langle [X,Y],Z\rangle - \langle [Y,Z],X\rangle + \langle [Z,X],Y\rangle$, then gives

$$\begin{aligned} 2\langle \nabla_X Y, Z\rangle &\overset{(1)}{=} \langle [X,Y],Z\rangle - \langle [Y,Z],X\rangle + \langle [Z,X],Y\rangle \\ &\overset{(2)}{=} \langle [X,Y],Z\rangle - \langle [X,Y],Z\rangle + \langle [X,Y],Z\rangle \\ &= \langle [X,Y],Z\rangle, \qquad \text{so} \qquad \nabla_X Y = \tfrac{1}{2}[X,Y]. \end{aligned}$$

(1) The three derivative terms vanish because the inner products of left-invariant fields are constant functions on the group.

(2) Cyclic moves with (7.123): $\langle [Y,Z],X\rangle = \langle Y,[Z,X]\rangle = \langle [Z,X],Y\rangle$, and $\langle [Z,X],Y\rangle = \langle Z,[X,Y]\rangle = \langle [X,Y],Z\rangle$.

In particular $\nabla_X X = \tfrac{1}{2}[X,X] = 0$. The integral curves of a left-invariant field are $t \mapsto g\exp(tX)$, so

Key idea: geodesics of a bi-invariant metric

The geodesics through the identity are exactly the one-parameter subgroups $\gamma(t) = \exp(tX)$, $X \in \mathfrak{su}(n)$. The geodesic with $\gamma(0) = I$ and $\gamma(1) = g$ is $\exp(tX)$ with $\exp(X) = g$; it has constant speed $|X|$ and energy $E(\gamma) = \int_0^1 |X|^2\,\mathrm{d}t = |X|^2$ (Nash's normalisation [Nash (7.54)]).

A physicist knows this as the statement that a free symmetric top has constant angular velocity in the body frame: the geodesic equation of the bi-invariant metric is Euler's equation with all moments of inertia equal.

The curvature. For left-invariant fields, $R(X,Y)Z = \nabla_X\nabla_Y Z - \nabla_Y\nabla_X Z - \nabla_{[X,Y]}Z$ (the convention of Section 7.8.4, for which the unit sphere has $R(X,Y)Z = \langle Y,Z\rangle X - \langle X,Z\rangle Y$). Then

$$R(X,Y)Z \overset{(1)}{=} \tfrac{1}{4}[X,[Y,Z]] - \tfrac{1}{4}[Y,[X,Z]] - \tfrac{1}{2}[[X,Y],Z]$$
$$\overset{(2)}{=} \tfrac{1}{4}[[X,Y],Z] - \tfrac{1}{2}[[X,Y],Z] = -\tfrac{1}{4}[[X,Y],Z].$$

(1) Apply $\nabla_X Y = \tfrac{1}{2}[X,Y]$ twice in each of the first two terms, and once in the third.
(2) The Jacobi identity: $[X,[Y,Z]] - [Y,[X,Z]] = [[X,Y],Z]$.

The operator that enters the Jacobi equation along the geodesic $\gamma(t) = \exp(tX)$ is $K_X(V) = R(V,X)X$ (with $\gamma' = X$ in the left-invariant frame, as in the operator $\mathcal{J}$ of (7.101)):

$$K_X(V) = R(V,X)X \overset{(1)}{=} -\tfrac{1}{4}[[V,X],X] \overset{(2)}{=} -\tfrac{1}{4}\,\mathrm{ad}_X^2(V). \tag{7.124}$$

(1) The curvature formula just derived, with $(X,Y,Z) \to (V,X,X)$.
(2) $[[V,X],X] = [X,[X,V]] = \mathrm{ad}_X(\mathrm{ad}_X V)$, using antisymmetry twice.

Since ad_X is skew (7.123), its eigenvalues are imaginary, $\pm i\theta$, and ad_X^2 has eigenvalues $-\theta^2 \le 0$. So K_X is positive semi-definite with eigenvalues $\theta^2/4$: a compact group with a bi-invariant metric has non-negative sectional curvature, and geodesics refocus, as on a sphere.

Conjugate points. A bi-invariant metric makes G a symmetric space, for which the curvature tensor is parallel. So the eigenvectors of K_X can be chosen parallel along γ, and the Jacobi equation $V'' + K_X V = 0$ (7.102) splits into scalar equations

$$v'' + \frac{\theta^2}{4}v = 0, \qquad v(0) = 0 \quad\Longrightarrow\quad v(t) = \sin\frac{\theta t}{2}, \tag{7.125}$$

one for each eigenvector of ad_X^2 with eigenvalue $-\theta^2 < 0$. This solution vanishes again at $t = 2\pi k/\theta$, $k = 1,2,\dots$. The directions with $\theta = 0$ (the centraliser of X) give $v = t$, which never vanishes again. By the Morse index theorem (7.103):

Working definition 7.27 (index of a geodesic in a compact Lie group)

For the geodesic $\gamma(t) = \exp(tX)$, $0 \le t \le 1$:

1. find the eigenvalues $\pm i\theta$ of ad_X on the Lie algebra, with their real multiplicities [the

multiplicity of θ is the real dimension of the eigenspace of ad_X^2 with eigenvalue $-\theta^2$];

2. each $\theta > 0$ contributes $\#\{k \geq 1 : \ 2\pi k/\theta < 1\}$ conjugate points inside $(0, 1)$, each counted with the multiplicity of θ;

3. the index $\lambda(\gamma)$ is the total; the nullity [the number of independent Jacobi fields vanishing at both $t = 0$ and $t = 1$] is the number counted with $2\pi k/\theta = 1$ exactly.

Step 2: a warm-up, $\mathrm{SU}(2) = S^3$

Worked example 7.60: Geodesics from I to $-I$ in $\mathrm{SU}(2)$

A basis of $\mathfrak{su}(2)$ is $i\sigma_1, i\sigma_2, i\sigma_3$, with the Pauli matrices

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \qquad \langle i\sigma_a, i\sigma_b \rangle = -\operatorname{tr}(i\sigma_a\, i\sigma_b) = 2\delta_{ab}.$$

Write $X = i\theta\, \hat{n} \cdot \vec{\sigma}$ with $\hat{n}$ a unit vector and $\theta \geq 0$. Since $(\hat{n} \cdot \vec{\sigma})^2 = I$,

$$\exp(X) \overset{(1)}{=} \sum_{r \geq 0} \frac{(i\theta)^r (\hat{n} \cdot \vec{\sigma})^r}{r!} \overset{(2)}{=} \cos\theta\, I + i \sin\theta\, \hat{n} \cdot \vec{\sigma}.$$

(1) The exponential series.
(2) Even powers of $\hat{n} \cdot \vec{\sigma}$ are I and odd powers are $\hat{n} \cdot \vec{\sigma}$; the even and odd terms sum to $\cos\theta$ and $i \sin\theta$.

So $\exp(X) = -I$ exactly when $\theta = (2l+1)\pi$, $l = 0, 1, 2, \ldots$, with $\hat{n}$ arbitrary. The geodesics from I to $-I$ therefore come in families

$$N_l = \left\{ t \mapsto \exp\bigl(i(2l+1)\pi t\, \hat{n} \cdot \vec{\sigma}\bigr) \;:\; \hat{n} \in S^2 \right\} \;\cong\; S^2, \qquad E(N_l) = |X|^2 = 2(2l+1)^2\pi^2.$$

Index. Take $\hat{n} = \hat{z}$, so $X = i\theta\sigma_3$. From $[\sigma_3, \sigma_\pm] = \pm 2\sigma_\pm$ (with $\sigma_\pm = \frac{1}{2}(\sigma_1 \pm i\sigma_2)$) we get $\mathrm{ad}_X\, \sigma_\pm = \pm 2i\theta\, \sigma_\pm$ and $\mathrm{ad}_X\, \sigma_3 = 0$. So ad_X has the eigenvalue pair $\pm i \cdot 2\theta$ on the real 2-plane spanned by $i\sigma_1, i\sigma_2$, and 0 on $i\sigma_3$. With $2\theta = 2(2l+1)\pi$ the conjugate points sit at

$$t = \frac{2\pi k}{2(2l+1)\pi} = \frac{k}{2l+1}, \qquad k = 1, 2, \ldots,$$

and those inside $(0, 1)$ are $k = 1, \ldots, 2l$, each of multiplicity 2. Hence

$$\lambda(N_l) = 2 \cdot 2l = 4l, \qquad \text{nullity} = 2\ (k = 2l+1) = \dim N_l.$$

The nullity equals the dimension of the critical family: each N_l is a non-degenerate critical manifold in the sense of Section 7.5.

Morse–Bott series. By (7.54),

$$M_t(E) \overset{(1)}{=} \sum_{l \geq 0} t^{\lambda(N_l)} P_t(N_l) \overset{(2)}{=} (1 + t^2) \sum_{l \geq 0} t^{4l} \overset{(3)}{=} \frac{1 + t^2}{1 - t^4} \overset{(4)}{=} \frac{1}{1 - t^2}.$$

(1) Each critical manifold contributes its Poincaré polynomial shifted by its index.
(2) $\lambda(N_l) = 4l$ and $P_t(S^2) = 1 + t^2$.
(3) Geometric series in t^4.
(4) $1 - t^4 = (1 - t^2)(1 + t^2)$.

This is exactly $P_t(\Omega S^3)$ from (7.112) with $n = 3$. The energy is a perfect Morse–Bott function (all exponents are even, so the lacunary argument applies to the expanded series $1 + t^2 + t^4 + \cdots$).

Try it: Closed loops at the identity

Do the same count for geodesic *loops* at I: $\exp(X) = I$. Show that the critical families are the constant loop ($X = 0$, index 0) and 2-spheres N_l' with $\theta = 2l\pi$, $l \geq 1$, of index $4l - 2$, and that $1 + (1 + t^2) \sum_{l \geq 1} t^{4l-2} = 1/(1 - t^2)$ again.

Answer. For $\theta = 2l\pi$ the conjugate points are at $t = k/(2l)$, $k = 1, \ldots, 2l-1$ inside $(0, 1)$, each of multiplicity 2: index $2(2l-1) = 4l-2$. Then $1 + (1+t^2)(t^2 + t^6 + t^{10} + \cdots) = 1 + t^2 + t^4 + t^6 + \cdots$.

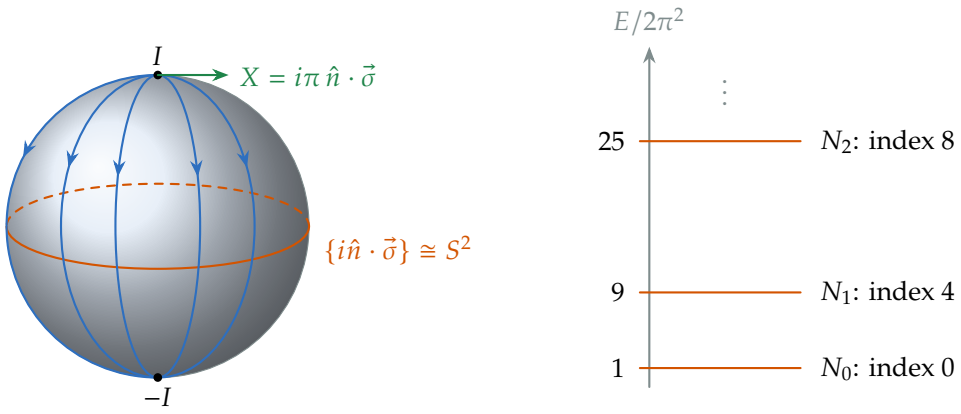

Figure 7.39: Left: SU(2) is a 3-sphere (drawn one dimension down). The shortest geodesics from I to $-I$ are the half great circles $\exp(i\pi t\,\hat{n}\cdot\vec{\sigma})$, one for each direction $\hat{n}$: a whole 2-sphere of minima (orange). Right: the energy levels of the critical families N_l (not to scale). Each is a 2-sphere; the index jumps by 4 from one to the next, because a geodesic that winds $2l+1$ half-turns passes $2l$ conjugate points, each of multiplicity 2.

Step 3: geodesics from I to $-I$ in $\mathrm{SU}(2m)$

Now take $G = \mathrm{SU}(2m)$ and consider the space of paths from I to $-I$. It has the homotopy type of $\Omega\mathrm{SU}(2m)$ by (7.107). A geodesic is $\exp(tX)$ with $\exp(X) = -I$. Diagonalise the anti-Hermitian matrix X by a unitary U:

$$X = U\,\mathrm{diag}\big(i\pi k_1, \dots, i\pi k_{2m}\big)\,U^{-1}, \qquad k_j \text{ odd integers}, \quad \sum_j k_j = 0. \tag{7.126}$$

The k_j must be odd because $\exp(i\pi k_j) = -1$, and they must sum to zero because $\mathrm{tr}\,X = 0$. Their energy is

$$E = |X|^2 = -\,\mathrm{tr}\,X^2 = \pi^2 \sum_{j=1}^{2m} k_j^2. \tag{7.127}$$

The index. The matrix units E_{jl} (a 1 in slot (j,l)) diagonalise the adjoint action of the diagonal matrix $D = \mathrm{diag}(i\pi k_j)$: $[D, E_{jl}] = i\pi(k_j - k_l)E_{jl}$. For each pair $j < l$ the real 2-plane in $\mathfrak{su}(2m)$ spanned by $E_{jl} - E_{lj}$ and $i(E_{jl} + E_{lj})$ carries the eigenvalue pair $\pm i\theta_{jl}$ with $\theta_{jl} = \pi\,|k_j - k_l|$. Using the recipe of Step 1:

$$\lambda(\gamma) \overset{(1)}{=} \sum_{j<l} 2 \cdot \#\Big\{k \geq 1 : \frac{2\pi k}{\pi\,|k_j - k_l|} < 1\Big\} \overset{(2)}{=} \sum_{j<l} 2\Big(\frac{|k_j - k_l|}{2} - 1\Big)_+ \overset{(3)}{=} \sum_{k_j > k_l} (k_j - k_l - 2). \tag{7.128}$$

(1) Each pair $j < l$ is a real 2-dimensional eigenspace; count its conjugate points inside $(0,1)$.
(2) $k_j - k_l$ is even (both are odd), so $2k < |k_j - k_l|$ holds for $k = 1, \dots, |k_j - k_l|/2 - 1$; $(\cdot)_+$ means "or 0 if negative" (for $k_j = k_l$).
(3) Rewrite the sum over unordered pairs with $k_j \neq k_l$ as a sum over ordered pairs with $k_j > k_l$; pairs with $|k_j - k_l| = 2$ contribute 0.

The index depends only on the list (k_j), not on U: the geodesics with a given list form one critical manifold, the orbit of D under conjugation.

The minimum. The energy (7.127) is smallest when every $|k_j| = 1$. Then $\sum k_j = 0$ forces m entries $+1$ and m entries -1:

$$E_{\min} = 2m\pi^2, \qquad \lambda = 0 \ \text{(every difference is 0 or 2)}.$$

Such an X is $i\pi$ on an m-dimensional complex subspace $V = \ker(X - i\pi)$ of $\mathbb{C}^{2m}$ and $-i\pi$ on its orthogonal complement. Conversely every m-dimensional V gives one such X. So

$$\{\text{minimal geodesics } I \to -I\} \;\cong\; G_m(\mathbb{C}^{2m}), \qquad \dim_{\mathbb{R}} G_m(\mathbb{C}^{2m}) = 2m^2, \tag{7.129}$$

the **Grassmannian** of complex m-planes in $\mathbb{C}^{2m}$. As a check of non-degeneracy: the nullity is the number of conjugate points at $t = 1$, which is 2 for each of the $m \cdot m$ pairs with $k_j = +1$, $k_l = -1$, i.e. $2m^2$, the dimension of the Grassmannian. For $m = 1$ this is $G_1(\mathbb{C}^2) = \mathbb{CP}^1 = S^2$, the sphere N_0 of Example 7.60.

The gap. Every non-minimal geodesic has index at least $2m + 2$. Suppose some $|k_j| \geq 3$; by the symmetry $X \to -X$ we may take $k_1 \geq 3$. Let p and q be the numbers of positive and negative entries, $p + q = 2m$.

- If $q \geq m + 1$: each negative $k_l \leq -1$ pairs with k_1 to give $k_1 - k_l - 2 \geq 3 + 1 - 2 = 2$ in (7.128), so $\lambda \geq 2q \geq 2m + 2$.
- If $q \leq m$, then $p \geq m \geq q$. The positive entries add up to at least $3 + (p - 1) = p + 2$, so the negative ones add up to at most $-(p + 2)$; with only $q \leq p$ of them, some $k_l \leq -3$. Each of the p positive entries pairs with this k_l to give at least $1 + 3 - 2 = 2$, and the pair (k_1, k_l) gives at least $3 + 3 - 2 = 4$. So $\lambda \geq 2p + 2 \geq 2m + 2$.

The bound is attained, for instance by $k = (3, \underbrace{1, \dots, 1}_{m-2}, \underbrace{-1, \dots, -1}_{m+1})$ (sum $3 + (m-2) - (m+1) = 0$): only the $m + 1$ pairs $(3, -1)$ contribute, each 2, giving $2m + 2$. See Figure 7.40.

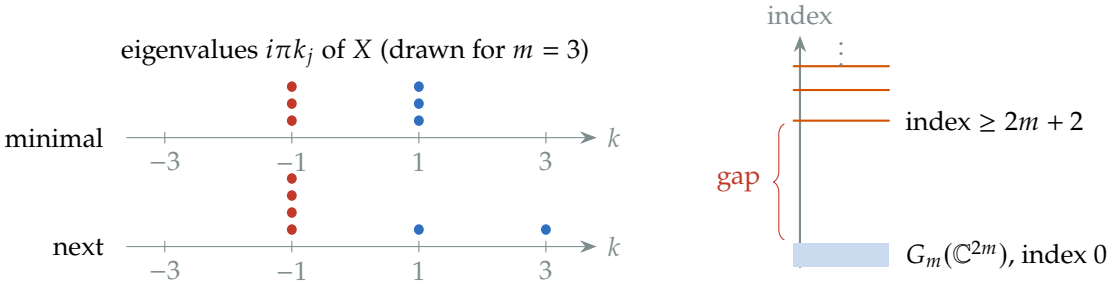

Figure 7.40: Left: the eigenvalue patterns of X for geodesics from I to $-I$ in $\mathrm{SU}(2m)$. The minimal ones have m eigenvalues $+i\pi$ (blue) and m eigenvalues $-i\pi$ (red); the lowest non-minimal ones move one eigenvalue out to $3i\pi$. Right: the resulting Morse–Bott ladder. The bottom rung is the Grassmannian; every other rung sits at index $2m + 2$ or higher, so up to dimension $2m$ the loop space cannot tell itself from the Grassmannian.

Step 4: from the gap to periodicity

What the gap buys. By the Bott–Morse–Smale picture (Section 7.3.4), extended to critical manifolds in Section 7.5.3, raising the energy past a critical manifold of index λ attaches cells of dimension $\geq \lambda$. So

$$\Omega\mathrm{SU}(2m) \;\simeq\; G_m(\mathbb{C}^{2m}) \;\cup\; (\text{cells of dimension } \geq 2m + 2).$$

Attaching a cell e^d cannot change π_i for $i \leq d - 2$: a map $S^i \to X \cup e^d$ with $i < d$ can be pushed off the centre of the cell and then radially out of it into X, and the same works for a homotopy $S^i \times [0, 1]$ between two maps as long as $i + 1 < d$. With $d \geq 2m + 2$:

$$\pi_i\big(\Omega\mathrm{SU}(2m)\big) \;\cong\; \pi_i\big(G_m(\mathbb{C}^{2m})\big) \qquad (i \leq 2m). \tag{7.130}$$

The Grassmannian's homotopy. Let $V_m(\mathbb{C}^{2m})$ be the **Stiefel manifold** of orthonormal m-frames $(v_1, \dots, v_m)$ in $\mathbb{C}^{2m}$. Forgetting the frame but keeping the plane it spans is a bundle

$$\mathrm{U}(m) \longrightarrow V_m(\mathbb{C}^{2m}) \longrightarrow G_m(\mathbb{C}^{2m}), \tag{7.131}$$

whose fibre is the set of orthonormal frames of a fixed m-plane, a copy of $\mathrm{U}(m)$. The Stiefel manifold is highly connected: choosing $v_1 \in S^{4m-1}$, then v_2 in the unit sphere S^{4m-3} of $v_1^{\perp}$, and so on down to $v_m \in S^{2m+1}$, builds it out of spheres of dimension $\geq 2m+1$, so $\pi_i(V_m(\mathbb{C}^{2m})) = 0$ for $i \leq 2m$. The exact sequence of (7.131),

$$\underbrace{\pi_i(V_m)}_{0} \to \pi_i(G_m) \to \pi_{i-1}(\mathrm{U}(m)) \to \underbrace{\pi_{i-1}(V_m)}_{0} \qquad (i \leq 2m),$$

gives $\pi_i(G_m(\mathbb{C}^{2m})) \cong \pi_{i-1}(\mathrm{U}(m))$.

The chain. For $1 \leq i \leq 2m$,

$$\begin{aligned}\pi_{i-1}(\mathrm{U}) &\overset{(1)}{=} \pi_{i-1}(\mathrm{U}(m)) \overset{(2)}{=} \pi_i\big(G_m(\mathbb{C}^{2m})\big) \overset{(3)}{=} \pi_i\big(\Omega\mathrm{SU}(2m)\big) \\ &\overset{(4)}{=} \pi_{i+1}\big(\mathrm{SU}(2m)\big) \overset{(5)}{=} \pi_{i+1}\big(\mathrm{U}(2m)\big) \overset{(6)}{=} \pi_{i+1}(\mathrm{U}).\end{aligned} \tag{7.132}$$

(Every "=" here is an isomorphism of groups.)

(1) Stability: $i-1 \leq 2m-1$ is in the stable range of $\mathrm{U}(m)$.
(2) The Stiefel bundle (7.131).
(3) The gap, (7.130).
(4) The loop shift $\pi_i(\Omega M) \cong \pi_{i+1}(M)$ (7.108).
(5) $\mathrm{U}(2m) \cong \mathrm{SU}(2m) \times S^1$ as a space, and $\pi_{i+1}(S^1) = 0$ for $i+1 \geq 2$.
(6) Stability again: $i+1 \leq 2m+1 \leq 2(2m)-1$.

Taking m as large as we like, $\pi_j(\mathrm{U}) \cong \pi_{j+2}(\mathrm{U})$ for every $j \geq 0$. Two starting values finish the job: $\pi_0(\mathrm{U}) = 0$ ($\mathrm{U}(n)$ is connected: every unitary matrix is exp of an anti-Hermitian one) and $\pi_1(\mathrm{U}) = \mathbb{Z}$ (the winding number of $\det g$, since $\pi_1(\mathrm{SU}(n)) = 0$). Hence $\pi_{\mathrm{even}}(\mathrm{U}) = 0$ and $\pi_{\mathrm{odd}}(\mathrm{U}) = \mathbb{Z}$, the bottom row of Table 7.1.

Worked example 7.61: Checking the chain in low degrees

$m = 1$**.** The gap statement (7.130) reads $\pi_i(\Omega S^3) \cong \pi_i(S^2)$ for $i \leq 2$. Directly: $\pi_1(\Omega S^3) = \pi_2(S^3) = 0 = \pi_1(S^2)$ and $\pi_2(\Omega S^3) = \pi_3(S^3) = \mathbb{Z} = \pi_2(S^2)$. The second is realised by the inclusion of the minimal geodesics: the map $S^2 \to \Omega S^3$ sending a direction $\hat{n}$ to the half great circle $\exp(i\pi t\, \hat{n} \cdot \vec{\sigma})$ (the orange sphere of Figure 7.39) generates $\pi_2(\Omega S^3) = \pi_3(S^3)$. This is the first case of the Freudenthal suspension theorem, $\pi_2(S^2) \cong \pi_3(S^3)$, proved here by counting geodesics.
$m = 2$**,** $i = 2$**.** The chain gives

$$\pi_3(\mathrm{SU}(4)) \overset{(1)}{=} \pi_2(\Omega\mathrm{SU}(4)) \overset{(2)}{=} \pi_2\big(G_2(\mathbb{C}^4)\big) \overset{(3)}{=} \pi_1(\mathrm{U}(2)) \overset{(4)}{=} \mathbb{Z}.$$

(1) Loop shift.
(2) The gap: $i = 2 \leq 2m = 4$.
(3) Stiefel bundle.
(4) $\det\colon \mathrm{U}(2) \to S^1$, with simply connected fibre $\mathrm{SU}(2) = S^3$.

So the instanton number of SU(4) gauge theory is "the same" as the winding number of a U(2) phase: an integer. The class in $\pi_2(G_2(\mathbb{C}^4))$ is the first Chern class of the tautological

2-plane bundle over a 2-sphere in the Grassmannian; this is where the monopole charge of Chapter 1 enters.
$m = 2$, $i = 3$ **and** $i = 4$. $\pi_4(\mathrm{SU}(4)) \cong \pi_2(\mathrm{U}(2)) = 0$ and $\pi_5(\mathrm{SU}(4)) \cong \pi_3(\mathrm{U}(2)) = \pi_3(S^3) = \mathbb{Z}$, matching Table 7.1.

Watch out: Periodicity is a stable statement

Bott's theorem says nothing about $\pi_j(\mathrm{U}(n))$ outside the range $j \le 2n-1$. That is where the physically interesting torsion lives: $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$ (the Witten anomaly), $\pi_6(\mathrm{SU}(3)) = \mathbb{Z}_6$, $\pi_6(\mathrm{SU}(2)) = \mathbb{Z}_{12}$. A theory with gauge group SU(2) in four dimensions is sensitive to $\pi_4(\mathrm{SU}(2))$ precisely because $4 > 2\cdot 2 - 1$: the group is too small to be stable in that degree.

The loop space of a compact group, and the real case

The whole loop space. Bott's analysis gives more than homotopy groups. For a compact simply connected Lie group G with a bi-invariant metric, the closed geodesics at e are $\exp(tX)$ with $\exp(X) = e$; the critical manifolds are conjugacy orbits $G/Z(X)$ ($Z(X)$ the centraliser), which have cohomology only in even degrees; and all indices are even (for $\mathrm{SU}(n)$ this is the $\mathbb{Z}$-valued version of (7.128), where each conjugate point has multiplicity 2). The lacunary principle (Section 7.2.7), in its Morse–Bott form, then says the energy is perfect and $H^{\mathrm{odd}}(\Omega G) = 0$. For $\mathrm{SU}(n)$ the result is

$$P_t\big(\Omega\mathrm{SU}(n)\big) = \prod_{k=1}^{n-1} \frac{1}{1-t^{2k}}, \tag{7.133}$$

which for $n = 2$ is the $1/(1-t^2)$ of Example 7.60. The loop group ΩG, with pointwise multiplication $(\gamma\delta)(t) = \gamma(t)\delta(t)$, is the infinite-dimensional group of Chapter 6; the Morse–Bott structure found here is the starting point of the Atiyah–Pressley and Atiyah–Bott analyses of loop groups and of Yang–Mills theory on Riemann surfaces (the Atiyah–Bott discussion at the end of Section 7.7.6).

The real (orthogonal) case. Bott ran the same argument through a chain of symmetric spaces for the orthogonal group, $\mathrm{O} \to \mathrm{O}/\mathrm{U} \to \mathrm{U}/\mathrm{Sp} \to \cdots$, each the space of minimal geodesics in the loop space of the previous one. After eight steps it returns to O:

$j \bmod 8$	0	1	2	3	4	5	6	7
$\pi_j(\mathrm{O})$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	0	$\mathbb{Z}$	0	0	0	$\mathbb{Z}$

Here $\pi_0(\mathrm{O}) = \mathbb{Z}_2$ counts the two components ($\det = \pm 1$), $\pi_1(\mathrm{SO}(n)) = \mathbb{Z}_2$ for $n \ge 3$ is the reason spinors exist (the double cover $\mathrm{Spin}(n) \to \mathrm{SO}(n)$, Chapter T4), and $\pi_3(\mathrm{O}) = \mathbb{Z}$ is again the instanton number.

Dictionary: Bott periodicity in physics

Physical picture: Why a loop space "remembers" a Grassmannian

Think of a geodesic $\exp(i\pi t P)$ from I to $-I$, where P is $+1$ on a plane V and -1 on $V^\perp$. It rotates the phase of vectors in V by $+\pi$ and of vectors in $V^\perp$ by $-\pi$. A loop of unitary matrices is, after a gauge choice, a way of splitting $\mathbb{C}^{2m}$ into "positive" and "negative frequency" parts; this is the same splitting that defines a Dirac sea. The statement $\Omega\mathrm{U} \simeq \mathbb{Z} \times B\mathrm{U}$ (the infinite Grassmannian, with the integer counting the index) is the mathematical form of the physicists' observation that the Dirac sea has a charge and that families of Dirac seas are classified by vector bundles. It reappears in the treatment of anomalies (Chapter 10) and of the infinite-dimensional Grassmannians of Chapter 6.

7.8.12 Three more triumphs: Reeb, Milnor and Smale

Nash's opening list of the successes of Morse theory [Nash p. 192] has four entries: Morse's infinitely many geodesics on S^n (Section 7.8.7), Bott periodicity (just done), Milnor's exotic spheres, and Smale's proof of the Poincaré conjecture in dimensions ≥ 5. The last two are about finite-dimensional manifolds, and both run on the machinery of Section 7.3: a manifold is built from handles, one per critical point, and the handles can be counted, rearranged and cancelled. We explain the mechanism of each, at the level of "what is the Morse function, and what does it tell us". A common thread is a simple question.

If a closed manifold carries a function with only two critical points, what is it?

Reeb's theorem: two critical points means a sphere

The height function on the round S^n has two critical points, a minimum and a maximum (Example 7.6). The converse is the first result.

Key idea: Reeb's theorem

Let M be a closed n-manifold and $f\colon M \to \mathbb{R}$ a Morse function with exactly two critical points. Then M is *homeomorphic* to the sphere S^n.

First, the homology. This is a one-line use of the weak Morse inequalities.

Worked example 7.62: Two critical points force the homology of a sphere

A Morse function on a closed connected M has at least one minimum and at least one maximum (compactness), so the two critical points are a minimum (index 0) and a maximum (index n). For any coefficient field F and $0 < i < n$,

$$b_i(M;F) \overset{(1)}{\leq} m_i(f) \overset{(2)}{=} 0,$$

(1) The weak Morse inequality (7.15).
(2) The only critical points have index 0 and n.

and $b_0 = b_n = 1$ because M is connected and (by the $t = -1$ check $\chi = 1 + (-1)^n$ of (7.21)) the top Betti number is not lost. So $P_t(M) = 1 + t^n$: the Poincaré series of S^n. In the other direction, the torus can never carry such a function, since $m_1 \geq b_1(T^2) = 2$ forces at least four critical points, as for the upright torus of Section 7.1.7.

Homology alone does not identify a sphere (there are "homology spheres" with the same Betti numbers but a non-trivial fundamental group). Reeb's theorem is stronger, and the reason is geometric: sublevel sets.

Why it is true. Let p be the minimum and q the maximum, and rescale so $f(p) = 0$, $f(q) = 1$.

1. *Near the bottom.* By the Morse lemma (7.7), near p we have $f = x_1^2 + \cdots + x_n^2$. So for small ε the sublevel set $M_\varepsilon = \{f \leq \varepsilon\}$ is the round ball $\{|x|^2 \leq \varepsilon\}$: a closed disc D^n.

2. *The middle.* There are no critical values in $[\varepsilon, 1-\varepsilon]$. By the first half of the Bott–Morse–Smale theorem (Section 7.3.3), the flow of $\nabla f/|\nabla f|^2$ carries M_ε diffeomorphically onto $M_{1-\varepsilon}$. So $M_{1-\varepsilon}$ is also a disc.

3. *Near the top.* By the Morse lemma at q, $f = 1 - |y|^2$ nearby, and $\{f \geq 1-\varepsilon\}$ is again a disc $\{|y|^2 \leq \varepsilon\}$.

So M is two closed discs glued along their boundary spheres:

$$M \;\cong\; D^n \cup_\varphi D^n, \qquad \varphi\colon S^{n-1} \to S^{n-1} \text{ a diffeomorphism.} \tag{7.134}$$

Here φ records how the boundary of the lower disc is matched with the boundary of the upper one; it is produced by the flow, and we have no control over it.

Any such gluing is a topological sphere (the Alexander trick). For $\varphi = \mathrm{id}$, (7.134) is the northern and southern hemispheres: S^n. For a general φ, extend it to the whole upper disc by coning it off,

$$\Phi\colon D^n \to D^n, \qquad \Phi(r\,x) = r\,\varphi(x) \qquad (0 \leq r \leq 1,\ x \in S^{n-1}). \tag{7.135}$$

This is a bijection with inverse $r\,x \mapsto r\,\varphi^{-1}(x)$, and it is continuous with continuous inverse (at $r = 0$ both send small balls to small balls). Using id on the lower disc and Φ on the upper disc defines a homeomorphism $D^n \cup_{\mathrm{id}} D^n \to D^n \cup_\varphi D^n$, i.e. $S^n \to M$.

Watch out: Homeomorphic, not diffeomorphic

The cone (7.135) is smooth everywhere except at the centre $r = 0$. There its derivative would have to be "the derivative of φ at radius zero", which does not exist unless φ is linear. So Reeb's theorem gives a homeomorphism with at most one bad point. That one point is exactly the room in which exotic spheres live: a manifold can be $D^n \cup_\varphi D^n$, hence a topological sphere, and still fail to be *diffeomorphic* to S^n when φ is not isotopic to a rotation. These are Milnor's spheres.

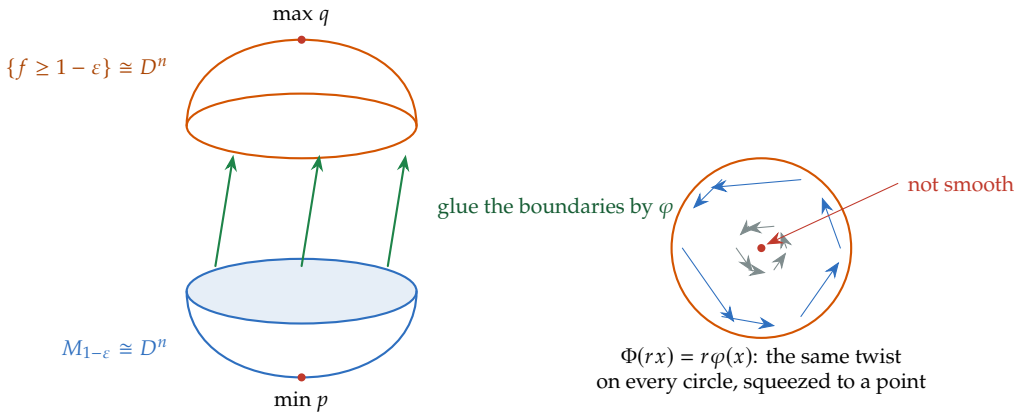

Figure 7.41: Reeb's theorem. Left: the sublevel set below any regular level is a disc (blue), the region above it is another disc (orange), and M is the two glued along their boundary spheres by some map φ. Right: the Alexander trick extends φ from the boundary circle to the whole disc by applying the same twist on every concentric sphere. The result is continuous, but at the centre (red) it is not differentiable. So M is a sphere topologically; smoothly it may not be.

Milnor's exotic 7-spheres

The question. Is there a smooth manifold homeomorphic to S^7 but not diffeomorphic to it? Milnor (1956) said yes, and his proof is a Morse function with two critical points plus a characteristic-class calculation. We give each step, using quaternions, with the physicist's reminder that quaternions are 2×2 matrices.

Working definition 7.28 (Quaternions as SU(2))

A quaternion is $u = u_0 + u_1\mathbf{i} + u_2\mathbf{j} + u_3\mathbf{k}$, $u_\mu \in \mathbb{R}$, with $\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = \mathbf{ijk} = -1$. Represent it as the matrix

$$u \;\longleftrightarrow\; u_0\,\mathbb{1} - i(u_1\sigma_1 + u_2\sigma_2 + u_3\sigma_3) = \begin{pmatrix} u_0 - iu_3 & -iu_1 - u_2 \\ -iu_1 + u_2 & u_0 + iu_3 \end{pmatrix},$$

with σ_a the Pauli matrices [the three 2×2 matrices of spin $\frac{1}{2}$, written out in Example 7.60]. Then $|u|^2 = u_0^2 + \cdots + u_3^2 = \det u$, the real part is $\operatorname{Re} u = u_0 = \frac{1}{2}\operatorname{tr} u$, and the unit quaternions $|u| = 1$ are exactly $\mathrm{SU}(2) = S^3$. The space of all quaternions is $\mathbb{H} \cong \mathbb{R}^4$ [as a real vector space, with coordinates (u_0, u_1, u_2, u_3)].

Step 1: sphere bundles over S^4. The sphere S^4 is $\mathbb{H} \cup \{\infty\}$, covered by two charts $\mathbb{R}^4$ that overlap in $\mathbb{H} \setminus \{0\}$, with transition $u \mapsto u^{-1}$ (the quaternionic version of the Riemann sphere $\mathbb{CP}^1$). A bundle with fibre S^3 over S^4 is two trivial pieces $\mathbb{R}^4 \times S^3$ glued over the overlap by a

transition function (Chapter 1). For integers h, j Milnor takes

$$(u, v) \sim (u', v') = \Big(\frac{u}{|u|^2},\ \frac{u^h\, v\, u^j}{|u|^{h+j}} \Big), \qquad u \in \mathbb{H} \setminus \{0\},\ v \in S^3. \tag{7.136}$$

The fibre map $v \mapsto u^h v u^j / |u|^{h+j}$ is left and right multiplication by unit quaternions, so it preserves $|v| = 1$. Call the total space $M_{h,j}$: a closed smooth 7-manifold. The simplest case $(h, j) = (1, 0)$ is the quaternionic Hopf fibration $S^3 \to S^7 \to S^4$, the SU(2) instanton bundle of Chapter 8.

Step 2: when is $M_{h,j}$ a homotopy sphere? The bundle has two integer invariants read off from the clutching map: the Euler number $h + j$ and the first Pontryagin number $\pm 2(h - j)$. The Euler class controls the cohomology via the Gysin sequence (the same tool as in Section 7.6.5): $H^4(M_{h,j}) = \mathbb{Z}/(h + j)$, and all other cohomology in degrees 1 to 6 vanishes. So set

$$h + j = 1, \qquad h - j = k \quad (k \text{ odd}), \qquad \text{i.e.} \quad h = \tfrac{1+k}{2},\ j = \tfrac{1-k}{2}, \tag{7.137}$$

and write M_k. Then M_k has the cohomology of S^7.

Step 3: a Morse function with two critical points. On the first chart, Milnor takes

$$f(u, v) = \frac{\operatorname{Re} v}{\sqrt{1 + |u|^2}}. \tag{7.138}$$

When $h + j = 1$, a short quaternion computation shows that in the second chart the same function reads $f = \operatorname{Re} u'' / \sqrt{1 + |u''|^2}$, where $u'' = u'(v')^{-1}$ is another quaternion coordinate. That expression has no critical points at all: its derivative in the real direction of u'' is $(1 + |u''|^2 - (\operatorname{Re} u'')^2)/(1 + |u''|^2)^{3/2} > 0$. So all critical points lie in the first chart, where $\partial f / \partial u = 0$ forces $u = 0$ and then v must be critical for $\operatorname{Re} v$ on S^3, i.e. $v = \pm 1$.

Worked example 7.63: The two critical points of Milnor's function are non-degenerate

Near $(u, v) = (0, 1)$ write $v = \sqrt{1 - |w|^2} + w$ with w a small imaginary quaternion ($w \in \mathbb{R}^3$ is the coordinate on S^3 near 1). Then

$$\begin{aligned} f &\overset{(1)}{=} \sqrt{1 - |w|^2}\,\big(1 + |u|^2\big)^{-1/2} \\ &\overset{(2)}{=} \big(1 - \tfrac{1}{2}|w|^2 + \dots\big)\big(1 - \tfrac{1}{2}|u|^2 + \dots\big) \\ &\overset{(3)}{=} 1 - \tfrac{1}{2}|u|^2 - \tfrac{1}{2}|w|^2 + O(4). \end{aligned}$$

(1) $\operatorname{Re} v = \sqrt{1 - |w|^2}$, since w is purely imaginary.
(2) Binomial series for both square roots, as in Example 7.6.
(3) Multiply out and keep the quadratic terms.

The Hessian in the seven coordinates $(u, w) \in \mathbb{R}^4 \times \mathbb{R}^3$ is $-\mathbb{1}_7$: a non-degenerate maximum of index 7. At $(0, -1)$ the same computation with an overall minus sign gives $+\mathbb{1}_7$: a minimum of index 0. So f is a Morse function on M_k with exactly two critical points, and by Reeb's theorem M_k is homeomorphic to S^7 for every odd k.

Step 4: a smooth invariant that tells them apart. Suppose M_k were diffeomorphic to S^7. M_k is the boundary of the associated disc bundle W_k (fibre D^4), an 8-manifold with boundary.

Glue an 8-disc to W_k along $\partial W_k = M_k \cong S^7$: the result $\overline{W}_k$ is a closed smooth 8-manifold. Its topology is simple: $H^4(\overline{W}_k) = \mathbb{Z}$, generated by a class e dual to the zero section S^4, with $e^2[\overline{W}_k] = h + j = 1$ (the zero section meets a small push-off of itself in $h + j$ points; the Euler number). So the intersection form is the 1×1 matrix (1) and the signature is $\sigma = 1$. The first Pontryagin class is $p_1 = 2k\,e$ (sign fixed by orientation). Hirzebruch's signature theorem for an 8-manifold (the L-genus of Chapter 4) reads $\sigma = \frac{1}{45}(7p_2 - p_1^2)[\overline{W}_k]$.

Worked example 7.64: The integrality test

Solve the signature theorem for the Pontryagin number $p_2[\overline{W}_k]$:

$$p_2[\overline{W}_k] \overset{(1)}{=} \frac{45\,\sigma + p_1^2[\overline{W}_k]}{7} \overset{(2)}{=} \frac{45 + (2k)^2\,e^2[\overline{W}_k]}{7} \overset{(3)}{=} \frac{45 + 4k^2}{7}.$$

(1) Rearrange $45\sigma = 7p_2 - p_1^2$.
(2) $\sigma = 1$ and $p_1 = 2k\,e$.
(3) $e^2[\overline{W}_k] = 1$.

A Pontryagin number of a closed smooth manifold is an integer. Check:

- $k = 1$: $(45 + 4)/7 = 7$. An integer, as it must be, since $M_1 = S^7$ (the Hopf fibration) and $\overline{W}_1 = \mathbb{HP}^2$, the quaternionic projective plane.
- $k = 3$: $(45 + 36)/7 = 81/7$. **Not an integer.**

So the assumption was false: M_3 is homeomorphic to S^7 (by Step 3) but not diffeomorphic to it. It is an **exotic sphere**.

Try it

For which odd k does the test fail to detect anything? *Answer:* $(45 + 4k^2)/7 \in \mathbb{Z}$ iff $4k^2 \equiv -45 \equiv 4 \pmod 7$ iff $k^2 \equiv 1 \pmod 7$ iff $k \equiv \pm 1 \pmod 7$. So $k = 1, 13, 15, \ldots$ pass the test, and $k = 3, 5, 7, 9, 11$ are all exotic. (Milnor's finer invariant, $\lambda(M_k) \equiv k^2 - 1 \pmod 7$, is the same calculation packaged as an invariant of M_k alone.)

Kervaire and Milnor later showed that there are exactly 28 smooth structures on S^7 up to orientation-preserving diffeomorphism (Chapter 1 discusses the count, and Chapter 10 meets the same group through $\pi_0\,\mathrm{Diff}(S^n)$). The role of Morse theory was decisive: without Reeb's theorem there was no way to know that the manifolds M_k are spheres at all.

Physical picture: Why the physicist should care

An exotic sphere is a spacetime that no topological measurement can distinguish from a sphere, but on which "smooth" means something different: the space of smooth metrics, of smooth gauge fields, and of solutions of field equations can change. The gravitational instantons and global gravitational anomalies of Chapter 10 are sensitive to exactly this kind of difference, and in four dimensions (exotic $\mathbb{R}^4$, Chapter 1) gauge theory itself is the tool that detects it (Donaldson theory, Chapter 12).

Smale: cancelling handles and the Poincaré conjecture

The generalised Poincaré conjecture says: a closed n-manifold with the homotopy type of S^n is homeomorphic to S^n. Smale (1961) proved it for $n \geq 5$. By Reeb's theorem it would be enough to find a Morse function with only two critical points. Smale's idea is to start with *any* Morse function and remove critical points in pairs until only two are left.

The basic move: cancelling a pair. We have already seen pairs of critical points born or annihilated in the family $x^3 - 3\varepsilon x$ (Figure 7.3). The move is to run that family backwards, on purpose.

Worked example 7.65: A cancelling pair in the plane

Take $f_\varepsilon(x, y) = x^3 - 3\varepsilon x + y^2$ on $\mathbb{R}^2$, with $\varepsilon > 0$. The gradient is $(3x^2 - 3\varepsilon,\, 2y)$, which vanishes at $y = 0$, $x = \pm\sqrt{\varepsilon}$. The Hessians are

$$Hf_\varepsilon(\pm\sqrt{\varepsilon}, 0) \overset{(1)}{=} \begin{pmatrix} 6x & 0 \\ 0 & 2 \end{pmatrix}_{x=\pm\sqrt{\varepsilon}} = \begin{pmatrix} \pm 6\sqrt{\varepsilon} & 0 \\ 0 & 2 \end{pmatrix},$$

(1) Second derivatives $\partial_x^2 f = 6x$, $\partial_y^2 f = 2$, mixed derivative 0.

so $(+\sqrt{\varepsilon}, 0)$ is a minimum (index 0) and $(-\sqrt{\varepsilon}, 0)$ is a saddle (index 1). The critical values are

$$f_\varepsilon(\pm\sqrt{\varepsilon}, 0) \overset{(1)}{=} \pm\varepsilon^{3/2} \mp 3\varepsilon^{3/2} \overset{(2)}{=} \mp 2\varepsilon^{3/2}.$$

(1) Substitute $x = \pm\sqrt{\varepsilon}$, $y = 0$.
(2) Collect terms.

The segment $-\sqrt{\varepsilon} < x < \sqrt{\varepsilon}$, $y = 0$ is a flow line of $-\nabla f$ (since $\partial_y f = 0$ on $y = 0$ and $-\partial_x f = 3(\varepsilon - x^2) > 0$ there): *exactly one* flow line runs from the saddle down to the minimum. As $\varepsilon \to 0$ the two points and their flow line shrink to the origin, and for $\varepsilon < 0$ the gradient $(3x^2 + 3|\varepsilon|, 2y)$ never vanishes. Two critical points, of adjacent index, have disappeared without changing f far away.

Key idea: Handle cancellation (Morse, Smale)

Let p and q be critical points of index $\lambda + 1$ and λ, with no critical values between $f(q)$ and $f(p)$. If exactly one gradient flow line runs from p to q, then f can be modified in a neighbourhood of that flow line to a function with the same critical points except that p and q are gone. In handle language: the $(\lambda + 1)$-handle is attached across the λ-handle exactly once, and together they form a ball glued along a ball, which changes nothing.

This is where the Morse complex of Section 7.3.9 becomes a geometric tool. There, a flow-line count $\partial\langle p\rangle = \pm\langle q\rangle$ was an algebraic statement. Here, "exactly one flow line" is a geometric statement, and the two differ whenever several flow lines with opposite signs cancel algebraically.

The proof strategy, step by step. Let M^n be a closed simply connected manifold with the homology of S^n, $n \geq 6$ (the case $n = 5$ needs an extra argument).

1. Remove two small open discs from M. What is left, W, is a compact manifold with two boundary spheres $\partial_0 W \cong \partial_1 W \cong S^{n-1}$, and the homology of W relative to $\partial_0 W$

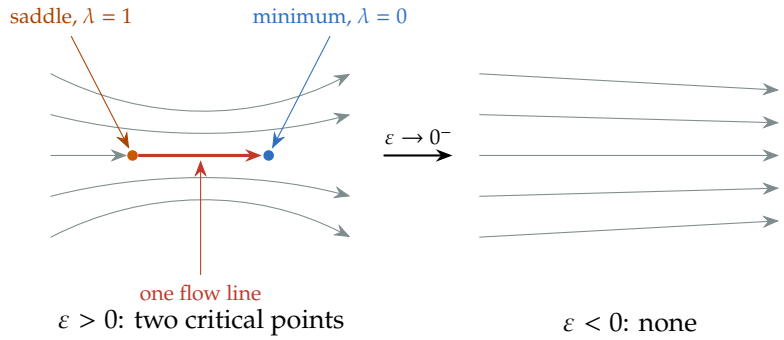

Figure 7.42: Cancelling a pair of critical points, Example 7.65, drawn as the flow of $-\nabla f$ (grey). Left: a saddle (orange) and a minimum (blue) joined by exactly one flow line (red). Right: after the move the flow runs straight through; no critical points are left. The move is local: far from the red segment the flow is unchanged.

vanishes: W looks like a cylinder $S^{n-1} \times [0,1]$ as far as homology can tell. Such a W is an **h-cobordism**.

2. Choose a Morse function $f : W \to [0,1]$ with $f = 0$ on $\partial_0 W$ and $f = 1$ on $\partial_1 W$. Rearrange it so that critical points of lower index have lower critical values (this is always possible: flow lines between critical points of the "wrong" order can be pushed apart).

3. Get rid of indices 0 and 1 (and dually n and $n-1$) using the simple connectivity: each index-0 point cancels against an index-1 point, and extra index-1 points are traded for index-3 points.

4. The Morse complex computes $H_*(W, \partial_0 W) = 0$, so the boundary maps are isomorphisms, and after a change of basis each $\lambda + 1$ critical point is paired with one λ critical point by an algebraic count ± 1.

5. **The Whitney trick.** In a level set between the two, the descending sphere of p (dimension λ) and the ascending sphere of q (dimension $n-1-\lambda$) meet in the points counted by the flow lines. When the algebraic count is ± 1 but the geometric count is larger, pairs of intersection points of opposite sign are removed by pushing one sphere across an embedded 2-disc (a "Whitney disc"). The two spheres have complementary dimensions, $\lambda + (n-1-\lambda) = n-1$, so they meet in isolated points. A generic 2-disc in a d-dimensional manifold is embedded when $2+2 < d$ and misses a k-dimensional submanifold when $2 + k < d$; in the level set, $d = n-1$, and once the low indices are gone both conditions hold for $n - 1 \geq 5$. This is where the dimension enters (the case $n = 5$ needs extra care).

6. Now each pair has exactly one flow line and cancels (Figure 7.42). When nothing is left, f has no critical points, and by Section 7.3.3 $W \cong S^{n-1} \times [0,1]$ (the **h-cobordism theorem**). Putting back the two discs, $M \cong D^n \cup (S^{n-1} \times [0,1]) \cup D^n$: a Morse function with two critical points, and Reeb's theorem finishes the job.

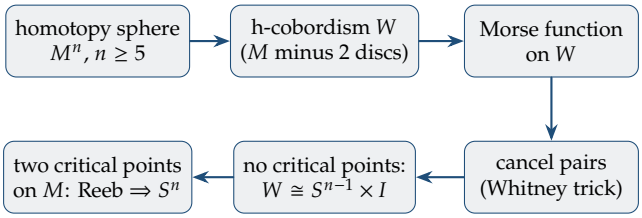

Figure 7.43: The logic of Smale's proof of the Poincaré conjecture in dimensions $n \geq 5$. Every arrow is Morse theory: sublevel sets, handles, the Morse complex, cancellation, and finally Reeb's two-critical-point theorem.

Dictionary: The three triumphs

result	Morse-theory mechanism
Reeb	two critical points $\Rightarrow$ two discs glued $\Rightarrow$ topological sphere
Milnor	explicit f with two critical points on an S^3-bundle over S^4 + a smooth invariant (Pontryagin numbers) $\Rightarrow$ exotic S^7
Smale	cancel handles in pairs (one flow line each) until two critical points remain $\Rightarrow$ Poincaré conjecture, $n \geq 5$
(physics)	Witten's tunnelling picture of §4 (part 7b) and Floer theory (Chapter 12) are the quantum version of counting flow lines

Watch out: Dimensions 3 and 4

The Whitney trick fails in dimension 4 (two 2-discs in a 4-manifold generically meet in points), and this is why low dimensions are different. The 4-dimensional topological Poincaré conjecture was proved by Freedman (1982) by other means; the smooth 4-dimensional one is still open. The 3-dimensional conjecture was proved by Perelman (2003) with Ricci flow, a gradient flow of a different kind. Nash's statement "for dim $M \geq 5$" [Nash p. 192] is the range where Morse theory alone does the job.

Reading Nash (pp. 205–207, (7.54)–(7.59); and p. 192)

Nash's discussion of infinite dimensions is two pages. He defines the energy $E(\gamma) = \int_0^1 g_{ij}\,\dot\gamma^i\dot\gamma^j\,dt$ [Nash (7.54)] on the path space $PM(p,q)$ [Nash (7.55)] (our (7.90), with the same normalisation), says that its extrema are the geodesics [Nash (7.56)] (our first variation, (7.95)), that at a geodesic $E = L^2$ [Nash (7.57)] and in general $E \geq L^2$ [Nash (7.58)] (Section 7.8.3, via Cauchy–Schwarz). For closed geodesics he replaces $PM(p,q)$ by $\mathrm{Map}(S^1, M)$ [Nash (7.59)] and remarks that U(1) acts by rotating the circle, so equivariant Morse theory should be relevant (Section 7.8.10). He sketches Morse's approximation of loops by geodesic polygons, $\mathrm{Map}_n(S^1, S^k)$, and the passage $n \to \infty$ (Section 7.8.9), with Klingenberg as the reference. He closes by saying that replacing S^k by a Lie group G and studying ΩG is Bott's route to periodicity (Section 7.8.11).

What we added: the second variation and the Hessian of E (7.100), Jacobi fields, conjugate points and the Morse index theorem (7.103), the explicit index count on S^n and the Poincaré series of ΩS^n (7.112), the Palais–Smale condition that makes infinite-dimensional Morse theory legitimate, the explicit time-slicing model, the free loop space fibration and the index growth of iterated closed geodesics, the full Morse-theoretic proof of complex Bott

periodicity, and the Reeb–Milnor–Smale applications that Nash lists on p. 192 but does not discuss.
Two remarks on Nash's wording. His sentence that one "eventually deduces ... the existence of an infinite number of closed geodesics on S^k" should be read as describing the programme; the precise known results are the ones listed in Section 7.8.10. And his claim that E is perfect holds for the round metric: on the based path space $PS^k(p,q)$ by the lacunary principle (Section 7.8.7), and on the free loop space as a Morse–Bott function with $\mathbb{Z}_2$ coefficients (Section 7.8.10). For a general metric only the inequalities survive.

Recap

- The energy $E(\gamma) = \int_0^1 |\dot\gamma|^2 \mathrm{d}t$ on the path space $PM(p,q)$ is a Morse function in infinitely many variables. Its critical points are the geodesics from p to q, and $E \geq L^2$ with equality for constant-speed paths, in particular at geodesics.
- Its Hessian is the Jacobi operator $-\nabla_t^2 - R(\cdot,\dot\gamma)\dot\gamma$ with Dirichlet conditions; the index is the number of conjugate points, counted with multiplicity (Morse index theorem). On the round S^n the k-th geodesic has index $k(n-1)$.
- Palais–Smale (or time slicing by broken geodesics) makes Morse theory work in infinite dimensions. Result: $P_t(\Omega S^n) = 1/(1-t^{n-1})$, and every metric on S^n has infinitely many geodesics between two points.
- Closed geodesics are critical points of E on the free loop space $\mathrm{Map}(S^1, M)$, with a U(1) symmetry by rotation: each closed geodesic is a critical circle, a Morse–Bott and equivariant problem.
- Bott: on a compact Lie group, the minimal geodesics from I to $-I$ form a Grassmannian, and all other geodesics have large index. Hence $\Omega\mathrm{SU}(2m) \simeq G_m(\mathbb{C}^{2m})$ (the Grassmannian) up to degree $2m$, and $\pi_j(\mathrm{U}) = \pi_{j+2}(\mathrm{U})$: $\mathbb{Z}$ in odd degrees, 0 in even degrees (period 8 for O).
- Reeb: two critical points $\Rightarrow$ topological sphere. Milnor: such a function on an S^3-bundle over S^4 plus an integrality test gives exotic 7-spheres. Smale: cancelling handles gives the Poincaré conjecture for $n \geq 5$.

7.9 Supersymmetric quantum mechanics and Morse theory: the plan

The first half of this chapter was pure topology. We took a function $f : M \to \mathbb{R}$ on a compact manifold, looked at its critical points, and found that they are forced to be at least as numerous as the "holes" of M. That is the content of the Morse inequalities.

In 1982 Edward Witten gave a completely different explanation of the same inequalities [Nash p. 207]. His explanation uses nothing but quantum mechanics: a Hamiltonian, its ground states, perturbation theory about classical minima, and tunnelling. The question of this section is simple: *what does a quantum-mechanical particle on M have to do with the critical points of a function on M?* We answer it in outline here, and then spend the rest of the chapter filling in every step.

7.9.1 Three facts we will string together

Witten's argument has three ingredients. Each one is a fact a physicist already believes, used in an unfamiliar setting.

1. **Ground states count topology.** There is a quantum system whose wavefunctions are differential forms on M and whose Hamiltonian is the Hodge Laplacian $\Delta = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$. By Hodge theory its zero-energy states in the sector of p-forms are in one-to-one correspondence with the de Rham cohomology $H^p_{\mathrm{dR}}(M)$. So
$$b_p = \#\{\text{zero-energy states made of } p\text{-forms}\}.$$
2. **A potential can be switched on without changing the ground-state count.** Witten deforms the system by a real parameter t, using the Morse function f. The deformation is a similarity transformation of d, so the number of zero-energy states cannot change. But the Hamiltonian now contains a potential $t^2\,|\nabla f|^2$, which is huge except near the critical points of f.
3. **At large t everything localises.** When the potential is huge, low-energy wavefunctions must crowd into its minima, i.e. near the critical points of f. Near each critical point the system is a set of harmonic oscillators. Solving them shows that each critical point of index p supplies exactly one candidate zero-energy p-form. Tunnelling between critical points can lift some candidates away from zero, but it can never create new ones.

Putting the three together:

$$\begin{aligned} b_p &\overset{(1)}{=} \#\{\text{exact zero modes of } H \text{ in degree } p\} \\ &\overset{(2)}{=} \#\{\text{exact zero modes of } H_t \text{ in degree } p\} \\ &\overset{(3)}{\leq} \#\{\text{approximate zero modes of } H_t \text{ in degree } p \text{ at large } t\} \\ &\overset{(4)}{=} \#\{\text{critical points of index } p\} = m_p. \end{aligned} \tag{7.139}$$

(1) Hodge theory: harmonic p-forms represent de Rham cohomology one-to-one (Section 7.11).
(2) Witten's deformation $\mathrm{d}_t = e^{-tf}\mathrm{d}e^{tf}$ is conjugation by an invertible operator, which preserves cohomology (Section 7.12).
(3) Every exact zero mode is in particular a low-lying state, but tunnelling can push some low-lying states up to small nonzero energies (Section 7.15).
(4) The harmonic-oscillator analysis gives exactly one low-lying state per critical point, sitting in the degree equal to the index (Section 7.14).

The inequality $b_p \leq m_p$ is the *weak* Morse inequality. Witten goes further. The operator d_t acts on the low-lying states and squares to zero. Its matrix elements at large t are tunnelling amplitudes, computed by instantons, and those instantons turn out to be the gradient flow lines of f. So the low-lying states form a small cochain complex, one basis vector per critical point, with a differential that counts flow lines. Its cohomology is $H^*(M)$. That is the **Morse–Witten complex**, and it gives the *strong* Morse inequalities as a piece of linear algebra (Section 7.16).

7.9.2 Reminder: the Morse data we need

We collect the facts from the first half of the chapter (Chapter 7) that this half uses. Let M be a compact manifold without boundary, of dimension n, and $f : M \to \mathbb{R}$ smooth.

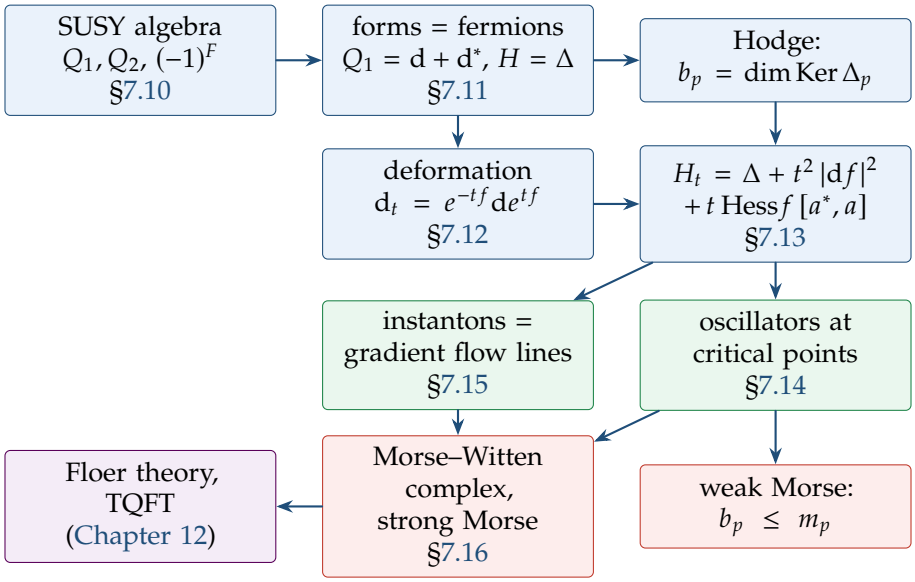

Figure 7.44: The logic of Witten's argument and of this half of the chapter. Blue boxes are algebra and geometry that hold exactly; green boxes are the large-t semiclassical analysis; red boxes are the two conclusions. The instanton box feeds only the *strong* inequalities: the weak ones need no tunnelling at all.

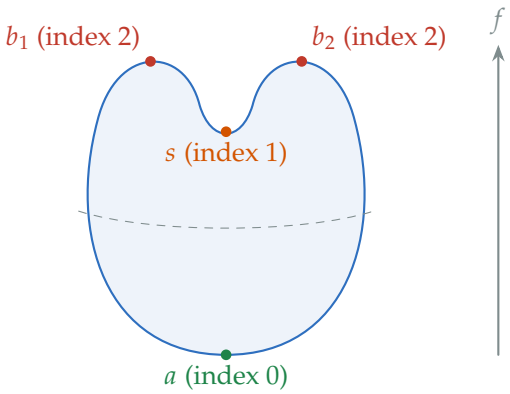
- A **critical point** is a point p where $df = 0$, i.e. all partial derivatives $\partial f/\partial x^i$ vanish.
- At a critical point the **Hessian** is the symmetric matrix $H_{ij} = \partial^2 f/\partial x^i \partial x^j$. The point is **non-degenerate** if $\det H_{ij} \neq 0$. Its **index** λ_p is the number of negative eigenvalues of H_{ij}: the number of independent directions in which f goes *down*.
- f is a **Morse function** if all its critical points are non-degenerate. Then there are finitely many of them. We write m_p for the number of critical points of index p.
- The **Morse lemma**: near a non-degenerate critical point of index λ there are coordinates with $f = f(p) - x_1^2 - \cdots - x_\lambda^2 + x_{\lambda+1}^2 + \cdots + x_n^2$.
- $b_p = \dim H^p_{\mathrm{dR}}(M)$ is the p-th Betti number. The Morse inequalities, written with a dummy variable u, are

$$\sum_p m_p u^p - \sum_p b_p u^p = (1+u)\, R(u), \qquad R(u) = \sum_p r_p u^p,\ r_p \ge 0. \tag{7.140}$$

  Setting $u = -1$ gives $\sum_p (-1)^p m_p = \sum_p (-1)^p b_p = \chi(M)$. Comparing coefficients of u^p gives $m_p - b_p = r_p + r_{p-1} \ge 0$, so in particular the weak inequalities $m_p \ge b_p$.

Watch out: Which letter is t?

Nash uses the letter t twice: for the variable of the Morse and Poincaré polynomials in §§1–3 ($M_t(f)$, $P_t(M)$), and for Witten's deformation parameter in §4. In this half of the chapter t *always* means Witten's parameter, a large positive number. We write the polynomial variable as u, so the Poincaré polynomial is $P_u(M) = \sum_p b_p u^p$ and the Morse polynomial is $M_u(f) = \sum_p m_p u^p$. The letter s will be Euclidean time along an instanton.



degree p	0	1	2
m_p (critical points)	1	1	2
b_p (S^2)	1	0	1
$m_p - b_p$	0	1	1

The saddle and one peak form a "cancelling pair": $m_u - P_u = u + u^2 = (1+u)\,u$, so $R(u) = u$.

Figure 7.45: A two-humped sphere and its height function: one minimum, one saddle, two maxima. Witten's large-t analysis will produce four low-lying states (one per dot, in degree equal to the index). Only two of them are true zero-energy states, matching $b_0 = b_2 = 1$. The saddle state and a combination of the two peak states will be paired up by tunnelling along the flow line joining them (Example 7.93).

7.9.3 What is new compared with the classical proof

Nash stresses one point [Nash p. 207]. The classical proof of the Morse inequalities (attaching a cell each time we pass a critical value) bounds the Betti numbers but does not hand us the cohomology in a usable form. Witten's argument constructs an explicit cochain complex whose generators are the critical points. Its differential is computed by counting gradient flow lines with signs. So the cohomology of M is *built* from the critical points of f and the flows between them.

This idea turned out to be enormously influential. When the manifold M is replaced by an infinite-dimensional space (the space of connections on a 3-manifold, or the loop space of a symplectic manifold), there are no Betti numbers to compare with directly, and ordinary Morse theory breaks down because indices are infinite. But the Morse–Witten complex still makes sense, since it only needs *differences* of indices and counts of flow lines. That is Floer theory, which Nash takes up in Chapter 12.

Dictionary: the whole of this chapter in one table

Mathematics	Physics
differential form on M	wavefunction of a particle on M with spin degrees of freedom
degree p of the form	fermion number F
d, d^*	supercharges
Hodge Laplacian Δ	Hamiltonian
harmonic forms, b_p	supersymmetric ground states
Euler characteristic $\chi(M)$	Witten index $\mathrm{Tr}(-1)^F$
Morse function f	superpotential
critical points of f	classical vacua
index of a critical point	fermion number of the perturbative vacuum
gradient flow line	instanton (tunnelling path)
Morse–Witten differential δ	instanton-corrected supercharge

Reading Nash (p. 207, opening of §4)

Nash introduces the section by saying Witten's paper "provides a new way of looking at Morse theory", that it is the "point of departure for the Floer theory discussed in chapter 12", and that "an important extra feature" of the quantum proof is that "the cohomology of M is also explicitly constructed". Everything in the flowchart of Figure 7.44 is compressed into the next eight pages of Nash (pp. 207–215, equations (7.60)–(7.95)). We take them one step at a time.

Recap

- Witten's proof has three moves: ground states of the Hodge Laplacian count Betti numbers; a deformation by f keeps the count but adds a potential $t^2\,|\nabla f|^2$; at large t the low-lying states sit one per critical point in degree equal to the index.
- Weak inequalities follow from the oscillators alone. Strong inequalities and the cohomology itself follow from tunnelling, i.e. from counting gradient flow lines.
- In this half of the chapter t is Witten's parameter and u is the polynomial variable.

7.10 The supersymmetry algebra

A symmetry of a quantum system is an operator that commutes with the Hamiltonian. It maps energy eigenstates to energy eigenstates of the same energy, so it organises the spectrum into multiplets. Rotations give the $(2l+1)$-fold degeneracy of hydrogen levels; isospin puts the proton and neutron together.

Supersymmetry is a symmetry that maps bosons into fermions and back [Nash p. 207]. It organises the spectrum into boson–fermion pairs. The question of this section is: *what algebra do such symmetries obey, and what can we learn just from that algebra?* The answer will be that the energy is never negative, that every state of positive energy has a partner of the opposite statistics, and that the difference

$$\text{(number of bosonic zero-energy states)} - \text{(number of fermionic zero-energy states)}$$

is unusually robust. It is the Witten index, and in Section 7.11 it will turn out to be the Euler characteristic.

7.10.1 Anticommutators and fermions: a reminder

For two operators A, B we write

$$[A,B] = AB - BA \quad \text{(commutator)}, \qquad \{A,B\} = AB + BA \quad \text{(anticommutator)}.$$

Bosonic creation and annihilation operators obey commutation relations, $[c, c^\dagger] = 1$. Fermionic ones obey anticommutation relations.

Working definition 7.29 (a single fermionic mode)

A **fermionic mode** is a pair of operators $b, b^\dagger$ with

$$\{b, b^\dagger\} = 1, \qquad \{b, b\} = 2b^2 = 0, \qquad (b^\dagger)^2 = 0. \tag{7.141}$$

[$(b^\dagger)^2 = 0$ is the Pauli principle, the mode cannot be filled twice] The **fermion number** is $F = b^\dagger b$ [it has eigenvalue 0 on the empty state and 1 on the occupied state]. *Operational test:* if you can find two operators with these relations, you have a two-state system, empty and occupied.

The relations are realised by 2×2 matrices. Take the basis $|0\rangle = \binom{1}{0}$ (empty) and $|1\rangle = \binom{0}{1}$ (occupied), and

$$b^\dagger = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \qquad b = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}.$$

Then

$$\{b, b^\dagger\} \overset{(1)}{=} \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}\begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$$
$$\overset{(2)}{=} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} = \mathbf{1}, \qquad F = b^\dagger b = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}.$$

(1) Definition of the anticommutator, with the two matrices inserted.
(2) Multiply out: $bb^\dagger$ projects onto $|0\rangle$, $b^\dagger b$ projects onto $|1\rangle$.

And $(b^\dagger)^2 = 0$ because the matrix is strictly lower triangular. That is the Pauli exclusion principle: you cannot put two fermions in the same mode. The operator

$$(-1)^F = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = \sigma_z$$

is $+1$ on the empty state and -1 on the occupied one. It anticommutes with b and $b^\dagger$, since each of them changes F by one: $\sigma_z b = -b\,\sigma_z$, as one checks by multiplying the matrices.

With n independent modes $b_1, \dots, b_n$ (all anticommuting, $\{b_i, b_j^\dagger\} = \delta_{ij}$) we get 2^n states, labelled by which modes are occupied. We will meet exactly this Fock space in Section 7.11, where it will be the exterior algebra.

7.10.2 Supersymmetry generators

A supersymmetry generator (or **supercharge**) is a Hermitian operator Q that changes a boson into a fermion and vice versa. So it is itself "fermionic", and the natural algebraic relations for it are anticommutators. With N supercharges $Q_1, \dots, Q_N$, the first relation is [Nash p. 207, (7.60)]

$$\{Q_i, Q_j\} = Q_i Q_j + Q_j Q_i = 0 \qquad (i \neq j). \tag{7.142}$$

This says nothing about $Q_i^2 = \tfrac{1}{2}\{Q_i, Q_i\}$. The squares are fixed by the physics. In the case Nash considers, a theory in one space and one time dimension with $N = 2$, the squares are [Nash p. 207, (7.61)]

$$Q_1^2 = H + P, \qquad Q_2^2 = H - P, \tag{7.143}$$

where H is the Hamiltonian and P the momentum. This is the defining feature of supersymmetry: *a supercharge is a square root of the energy–momentum*. It is the fermionic analogue of the Dirac operator being a square root of the Laplacian.

Key idea: consequences of the algebra, Nash (7.62)

From (7.142) and (7.143),

$$[Q_i, H] = 0, \qquad H = \tfrac{1}{2}\big(Q_1^2 + Q_2^2\big), \qquad H \geq 0. \tag{7.144}$$

So the supercharges are genuine symmetries, and the energy is never negative.

Here is why. Adding the two equations in (7.143), $Q_1^2 + Q_2^2 = 2H$, which is the middle statement. For the first, take $i = 1$:

$$\begin{aligned}
[Q_1, H] &\overset{(1)}{=} \tfrac{1}{2}\big[Q_1,\, Q_1^2 + Q_2^2\big] \\
&\overset{(2)}{=} \tfrac{1}{2}\big(Q_1Q_2Q_2 - Q_2Q_2Q_1\big) \\
&\overset{(3)}{=} \tfrac{1}{2}\big(-Q_2Q_1Q_2 - Q_2Q_2Q_1\big) \\
&\overset{(4)}{=} \tfrac{1}{2}\big(-Q_2Q_1Q_2 + Q_2Q_1Q_2\big) = 0.
\end{aligned}$$

(1) Insert $H = \frac{1}{2}(Q_1^2 + Q_2^2)$.
(2) Q_1 commutes with its own square, so only the Q_2^2 term survives.
(3) Move Q_1 one place to the right in the first term using $Q_1Q_2 = -Q_2Q_1$ from (7.142).
(4) Do the same in the second term: $Q_2Q_1 = -Q_1Q_2$, so $-Q_2Q_2Q_1 = +Q_2Q_1Q_2$.

The same computation with $1 \leftrightarrow 2$ gives $[Q_2, H] = 0$. For positivity, take any state $|\psi\rangle$ and use $Q_i^\dagger = Q_i$:

$$\begin{aligned}
\langle\psi|H|\psi\rangle &\overset{(1)}{=} \tfrac{1}{2}\big(\langle\psi|Q_1Q_1|\psi\rangle + \langle\psi|Q_2Q_2|\psi\rangle\big) \\
&\overset{(2)}{=} \tfrac{1}{2}\big(\|Q_1|\psi\rangle\|^2 + \|Q_2|\psi\rangle\|^2\big) \overset{(3)}{\geq} 0.
\end{aligned}$$

(1) The middle statement of (7.144).
(2) $\langle\psi|Q_iQ_i|\psi\rangle = \big(Q_i|\psi\rangle\big)^\dagger\big(Q_i|\psi\rangle\big)$ because Q_i is Hermitian.
(3) A squared length is non-negative.

The last line tells us more than positivity. *A state has zero energy if and only if every supercharge annihilates it:* $H|\psi\rangle = 0 \iff Q_1|\psi\rangle = Q_2|\psi\rangle = 0$. We will use this over and over. The same argument applied to $Q_1^2 = H + P$ and $Q_2^2 = H - P$ separately gives $H \pm P \geq 0$, i.e. $H \geq |P|$: supersymmetry forbids anything from moving faster than light, energetically speaking.

7.10.3 Quantum mechanics: $P = 0$ and a nilpotent supercharge

In quantum mechanics (one time dimension and no space) there is no momentum generator, and $P = 0$ [Nash p. 209]. Then $Q_1^2 = Q_2^2 = H$. It is very convenient to combine the two Hermitian supercharges into one complex one:

$$Q = \tfrac{1}{2}(Q_1 - \mathrm{i}Q_2), \qquad Q^\dagger = \tfrac{1}{2}(Q_1 + \mathrm{i}Q_2), \qquad \text{equivalently} \quad Q_1 = Q + Q^\dagger,\ \ Q_2 = \mathrm{i}(Q - Q^\dagger). \tag{7.145}$$

Then

$$\begin{aligned}
Q^2 &\overset{(1)}{=} \tfrac{1}{4}\big(Q_1^2 - \mathrm{i}(Q_1Q_2 + Q_2Q_1) - Q_2^2\big) \\
&\overset{(2)}{=} \tfrac{1}{4}\big((H + P) - 0 - (H - P)\big) = \tfrac{1}{2}P, \\
\{Q, Q^\dagger\} &\overset{(3)}{=} \tfrac{1}{4}\big(2Q_1^2 + 2Q_2^2\big) = H.
\end{aligned} \tag{7.146}$$

(1) Expand $(Q_1 - iQ_2)^2$ keeping the order of the factors.
(2) Use (7.143) and (7.142).
(3) Expand $(Q_1 - iQ_2)(Q_1 + iQ_2) + (Q_1 + iQ_2)(Q_1 - iQ_2)$: the cross terms cancel in the sum, leaving $2Q_1^2 + 2Q_2^2$, which is $4H$.

So Q *squares to zero exactly when* $P = 0$. A nilpotent operator Q with $Q^2 = 0$ whose anticommutator with its adjoint is the Hamiltonian: that is exactly the structure of the exterior derivative d, its adjoint d^*, and the Laplacian $dd^* + d^*d$. We make this precise in Section 7.11.

7.10.4 Bosons, fermions and the block structure

To tell bosons from fermions, introduce the operator $(-1)^F$ ("-1 to the fermion number") [Nash p. 207, (7.63)]:

$$(-1)^F|P\rangle = \begin{cases} -|P\rangle & \text{if } P \text{ is a fermion,} \\ +|P\rangle & \text{if } P \text{ is a boson.} \end{cases} \tag{7.147}$$

It squares to one, and its two eigenspaces split the one-particle Hilbert space [Nash p. 208, (7.64)]:

$$\mathcal{H}_1 = \mathcal{H}_1^B \oplus \mathcal{H}_1^F, \qquad (-1)^F = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix} \tag{7.148}$$

in a basis adapted to the splitting [Nash p. 208, (7.65)]. A space split like this is called a **$\mathbb{Z}_2$-graded** or **super** vector space.

Supercharges turn bosons into fermions. Algebraically, this means they *anticommute* with $(-1)^F$: $\{Q_i, (-1)^F\} = 0$. Write Q_i in blocks and impose this:

$$\begin{aligned} 0 = \{Q_i, (-1)^F\} &\overset{(1)}{=} \begin{pmatrix} A & B \\ C & D \end{pmatrix}\begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix} + \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}\begin{pmatrix} A & B \\ C & D \end{pmatrix} \\ &\overset{(2)}{=} \begin{pmatrix} A & -B \\ C & -D \end{pmatrix} + \begin{pmatrix} A & B \\ -C & -D \end{pmatrix} = \begin{pmatrix} 2A & 0 \\ 0 & -2D \end{pmatrix}. \end{aligned}$$

(1) A general operator in block form, with $A\colon \mathcal{H}^B \to \mathcal{H}^B$, $B\colon \mathcal{H}^F \to \mathcal{H}^B$, $C\colon \mathcal{H}^B \to \mathcal{H}^F$, $D\colon \mathcal{H}^F \to \mathcal{H}^F$.
(2) Right multiplication by $(-1)^F$ flips the sign of the second column; left multiplication flips the sign of the second row.

So $A = D = 0$: the supercharges are block off-diagonal [Nash p. 208, (7.66)–(7.67)]:

$$Q_i = \begin{pmatrix} 0 & Q_i^{BF} \\ Q_i^{FB} & 0 \end{pmatrix}, \qquad Q_i^{BF}\colon \mathcal{H}_1^F \to \mathcal{H}_1^B, \quad Q_i^{FB}\colon \mathcal{H}_1^B \to \mathcal{H}_1^F. \tag{7.149}$$

Hermiticity of Q_i says $Q_i^{BF} = (Q_i^{FB})^\dagger$. The Hamiltonian, being a sum of squares of off-diagonal operators, is block *diagonal*: $H = \operatorname{diag}(Q_i^{BF}Q_i^{FB},\ Q_i^{FB}Q_i^{BF})$ for either i (in the $P = 0$ case). Bosons stay bosons under time evolution, as they must.

Worked example 7.66: the smallest supersymmetric system

Take a single boson state and a single fermion state, both of energy $E > 0$, i.e. $\mathcal{H} = \mathbb{C}^2$ with $(-1)^F = \sigma_z$ and $H = E\,\mathbf{1}$. Let $Q = \sqrt{E}\,b^\dagger$ (it creates the fermion out of the boson). Then

$$Q_1 \overset{(1)}{=} \sqrt{E}\,(b^\dagger + b) = \sqrt{E}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \sqrt{E}\,\sigma_x,$$

$$Q_2 \overset{(2)}{=} \mathrm{i}\sqrt{E}\,(b^\dagger - b) = \sqrt{E}\begin{pmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{pmatrix} = \sqrt{E}\,\sigma_y .$$

(1) $Q_1 = Q + Q^\dagger$ from (7.145), with the matrices of Section 7.10.1.
(2) $Q_2 = \mathrm{i}(Q - Q^\dagger)$; the factor i turns the real antisymmetric matrix into σ_y.

All relations can be read off from the Pauli algebra: $\{\sigma_x, \sigma_y\} = 0$ gives (7.142); $\sigma_x^2 = \sigma_y^2 = \mathbf{1}$ gives $Q_1^2 = Q_2^2 = E = H$; and σ_z anticommutes with σ_x, σ_y, so both supercharges are off-diagonal. The minimal "supermultiplet" is a spin-$\frac{1}{2}$ system in disguise: $Q_1, Q_2, (-1)^F$ are $\sqrt{E}\sigma_x, \sqrt{E}\sigma_y, \sigma_z$. Note that this construction needs $E > 0$: at $E = 0$ we would have $Q_1 = Q_2 = 0$ and nothing pairs the two states.

7.10.5 Supersymmetric quantum mechanics on a line

Here is the example that the whole chapter generalises. A particle on the real line with one fermionic mode. States are pairs of wavefunctions,

$$\Psi = \begin{pmatrix} \varphi_0(x) \\ \varphi_1(x) \end{pmatrix}, \qquad \varphi_0 \in \mathcal{H}^B,\ \varphi_1 \in \mathcal{H}^F,$$

the upper component with the fermion mode empty, the lower one with it occupied. Choose a real function $W(x)$, the **superpotential**, and define

$$A = \frac{\mathrm{d}}{\mathrm{d}x} + W'(x), \qquad A^\dagger = -\frac{\mathrm{d}}{\mathrm{d}x} + W'(x), \qquad Q = \begin{pmatrix} 0 & 0 \\ A & 0 \end{pmatrix}, \quad Q^\dagger = \begin{pmatrix} 0 & A^\dagger \\ 0 & 0 \end{pmatrix}. \tag{7.150}$$

$A^\dagger$ really is the adjoint of A on $L^2(\mathbb{R})$: integrating by parts, $\int \bar\chi\,(\varphi' + W'\varphi)\,\mathrm{d}x = \int \overline{(-\chi' + W'\chi)}\,\varphi\,\mathrm{d}x$ for functions that vanish at infinity. Clearly $Q^2 = 0$ (a strictly lower triangular block matrix). The Hamiltonian is

$$H = \{Q, Q^\dagger\} = \begin{pmatrix} A^\dagger A & 0 \\ 0 & AA^\dagger \end{pmatrix} = \begin{pmatrix} H_B & 0 \\ 0 & H_F \end{pmatrix}. \tag{7.151}$$

Let us compute the two blocks. Acting on a test function φ,

$$\begin{aligned} A^\dagger A\,\varphi &\overset{(1)}{=} \Big(-\frac{\mathrm{d}}{\mathrm{d}x} + W'\Big)\big(\varphi' + W'\varphi\big) \\ &\overset{(2)}{=} -\varphi'' - W''\varphi - W'\varphi' + W'\varphi' + W'^2\varphi \\ &= \Big(-\frac{\mathrm{d}^2}{\mathrm{d}x^2} + W'^2 - W''\Big)\varphi, \end{aligned} \tag{7.152}$$

$$AA^\dagger\,\varphi \overset{(3)}{=} \Big(-\frac{\mathrm{d}^2}{\mathrm{d}x^2} + W'^2 + W''\Big)\varphi. \tag{7.153}$$

(1) Definitions (7.150).
(2) Product rule on $(W'\varphi)'$; the two first-derivative terms $\mp W'\varphi'$ cancel.
(3) The same computation with the signs of the derivative terms swapped; now $+(W'\varphi)' - W'\varphi' = +W''\varphi$.

So the boson and the fermion feel *different* potentials,

$$V_B = W'^2 - W'', \qquad V_F = W'^2 + W'',$$

differing by the "spin–orbit" term $\pm W''$. Supersymmetry guarantees that, apart from zero-energy states, the two Schrödinger operators have exactly the same spectrum. The Hermitian supercharges are $Q_1 = \left(\begin{smallmatrix} 0 & A^\dagger \\ A & 0 \end{smallmatrix}\right)$ and $Q_2 = \left(\begin{smallmatrix} 0 & -\mathrm{i}A^\dagger \\ \mathrm{i}A & 0 \end{smallmatrix}\right)$, so in Nash's notation $Q_1^{FB} = A$ and $Q_1^{BF} = A^\dagger$.

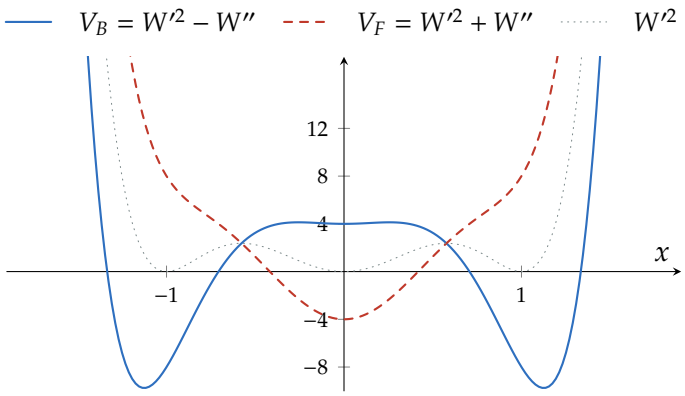


Figure 7.46: The two potentials of supersymmetric quantum mechanics for the double-well superpotential $W = t\left(\frac{1}{4}x^4 - \frac{1}{2}x^2\right)$ at $t = 4$. The boson (solid) sits in deep wells at the minima $x = \pm 1$ of W, where $-W'' < 0$; the fermion (dashed) has its deepest well at the maximum $x = 0$, where $+W'' < 0$. The wells of both are the zeros of W'^2 (dotted), i.e. the critical points of W. This is the one-dimensional picture of the whole chapter.

Worked example 7.67: the supersymmetric harmonic oscillator

Take $W = \frac{1}{2}\omega x^2$ with $\omega > 0$. Then $W' = \omega x$ and $W'' = \omega$, so

$$H_B = -\frac{\mathrm{d}^2}{\mathrm{d}x^2} + \omega^2 x^2 - \omega, \qquad H_F = -\frac{\mathrm{d}^2}{\mathrm{d}x^2} + \omega^2 x^2 + \omega.$$

The operator $-\mathrm{d}^2/\mathrm{d}x^2 + \omega^2 x^2$ is a harmonic oscillator (in units with $\hbar = 1$, $m = \frac{1}{2}$) with levels $\omega(2n+1)$, $n = 0, 1, 2, \ldots$ (we derive this in Section 7.14.1). Hence

$$\operatorname{spec} H_B = \{\omega(2n+1) - \omega\} = \{0,\, 2\omega,\, 4\omega, \ldots\},$$
$$\operatorname{spec} H_F = \{\omega(2n+1) + \omega\} = \{2\omega,\, 4\omega,\, 6\omega, \ldots\}.$$

Every level $2k\omega$ with $k \geq 1$ contains one boson and one fermion; the level 0 contains a single boson, $\varphi_0 \propto e^{-\omega x^2/2}$. The zero-point energy $+\omega$ of the bosonic oscillator is exactly cancelled by the fermionic contribution $-\omega$: the famous cancellation of vacuum energies in supersymmetric theories, in its simplest form.

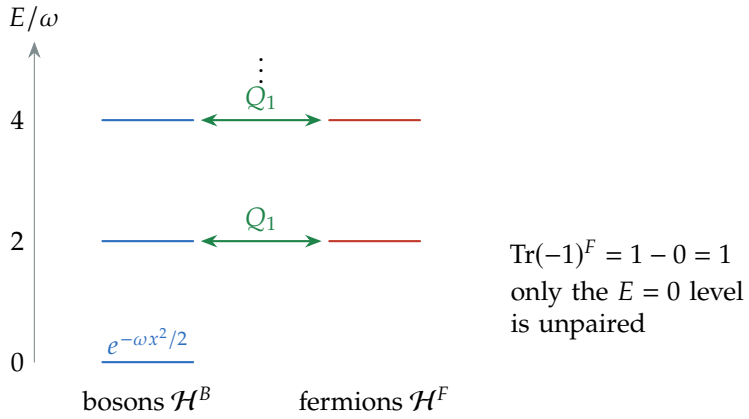

Figure 7.47: Spectrum of the supersymmetric harmonic oscillator. Every positive level is a boson–fermion pair, exchanged by the supercharge Q_1. Only the zero-energy level can be unpaired, and here it is a single boson.

Zero-energy states on the line. A zero-energy state must satisfy $Q\Psi = Q^\dagger\Psi = 0$, i.e. $A\varphi_0 = 0$ and $A^\dagger\varphi_1 = 0$. These are first-order equations:

$$\varphi_0' + W'\varphi_0 = 0 \implies \varphi_0 = C\,e^{-W(x)},$$
$$-\varphi_1' + W'\varphi_1 = 0 \implies \varphi_1 = C'\,e^{+W(x)}.$$

Whether these are physical depends on normalisability, i.e. on how W behaves at $\pm\infty$:

behaviour of W	zero-energy states	$n_B^0 - n_F^0$
$W \to +\infty$ at both ends (e.g. x^2, x^4)	boson e^{-W}	$+1$
$W \to -\infty$ at both ends (e.g. $-x^2$)	fermion e^{+W}	-1
$W \to \pm\infty$ at opposite ends (e.g. x^3)	none	0

In the last case there is no state of zero energy at all: the ground state has $E > 0$, and supersymmetry is **spontaneously broken**. Notice that the answer depends only on the behaviour of W far away, not on its wiggles. That is our first glimpse of a topological invariant.

7.10.6 The Witten index

The last example suggests counting zero-energy states with signs. Define $n_B(E)$ and $n_F(E)$ as the numbers of bosonic and fermionic states of energy E.

Working definition 7.30 (Witten index)

The **Witten index** of a supersymmetric system is

$$\operatorname{Tr}(-1)^F := n_B(0) - n_F(0). \tag{7.154}$$

[$(-1)^F$ is $+1$ on bosonic states and -1 on fermionic states] *Operational recipe:* find all zero-energy states (they are the states killed by every supercharge [the operators Q that turn bosonic states into fermionic ones and back, with H built from them]), and count bosons minus fermions. Equivalently, compute $\operatorname{Tr}\big((-1)^F e^{-\beta H}\big)$ [a sum over all states, of every energy, each weighted by $\pm e^{-\beta E}$] for any $\beta > 0$.

The "equivalently" is the key fact: *all positive-energy states cancel in pairs*. Here is the pairing argument. Let $E > 0$ and let $\mathcal{H}_E = \mathcal{H}_E^B \oplus \mathcal{H}_E^F$ be the eigenspace of H with eigenvalue E (in quantum mechanics, $P = 0$, so $Q_1^2 = H$).

- Q_1 maps $\mathcal{H}_E$ into itself, because $[Q_1, H] = 0$: if $H\psi = E\psi$ then $H(Q_1\psi) = Q_1 H\psi = E\,Q_1\psi$.
- Q_1 maps $\mathcal{H}_E^B$ into $\mathcal{H}_E^F$ and back, because it is off-diagonal (7.149).
- On $\mathcal{H}_E$, $Q_1^2 = H = E$, so Q_1 is invertible there, with inverse Q_1/E.

An invertible linear map between two vector spaces forces them to have the same dimension. Hence $n_B(E) = n_F(E)$ for every $E > 0$, and

$$\operatorname{Tr}\big((-1)^F e^{-\beta H}\big) \overset{(1)}{=} \sum_E e^{-\beta E}\big(n_B(E) - n_F(E)\big)$$
$$\overset{(2)}{=} n_B(0) - n_F(0) = \operatorname{Tr}(-1)^F. \tag{7.155}$$

(1) Evaluate the trace in an eigenbasis of H adapted to the splitting into bosons and fermions: each boson of energy E contributes $+e^{-\beta E}$, each fermion $-e^{-\beta E}$.
(2) Every $E > 0$ term vanishes by the pairing argument; only $E = 0$ is left, where $e^{-\beta\cdot 0} = 1$.

So the regulated trace does not depend on β. One can also see this directly by differentiating:

$$
\begin{aligned}
-\frac{\mathrm{d}}{\mathrm{d}\beta}\operatorname{Tr}\big((-1)^F e^{-\beta H}\big) &\overset{(1)}{=} \operatorname{Tr}\big((-1)^F Q_1 Q_1 e^{-\beta H}\big) \\
&\overset{(2)}{=} -\operatorname{Tr}\big(Q_1 (-1)^F Q_1 e^{-\beta H}\big) \\
&\overset{(3)}{=} -\operatorname{Tr}\big((-1)^F Q_1 e^{-\beta H} Q_1\big) \overset{(4)}{=} -\operatorname{Tr}\big((-1)^F Q_1 Q_1 e^{-\beta H}\big).
\end{aligned}
$$

(1) Differentiate the exponential and write $H = Q_1^2$.
(2) Q_1 anticommutes with $(-1)^F$.
(3) Cyclicity of the trace: move the first Q_1 to the end.
(4) Q_1 commutes with H, hence with $e^{-\beta H}$.

The derivative equals minus itself, so it is zero.

Key idea: why the Witten index is robust

Deform the system continuously while keeping supersymmetry (change the potential, the metric, a coupling constant). Energy levels move, but each positive level carries equal numbers of bosons and fermions, and a state can reach or leave $E = 0$ only together with its partner. So $n_B(0)$ and $n_F(0)$ can each jump, but only by the same amount: $n_B(0) - n_F(0)$ *cannot change*. The only escape is if states come in from or leave to infinity, which on a compact configuration space cannot happen.

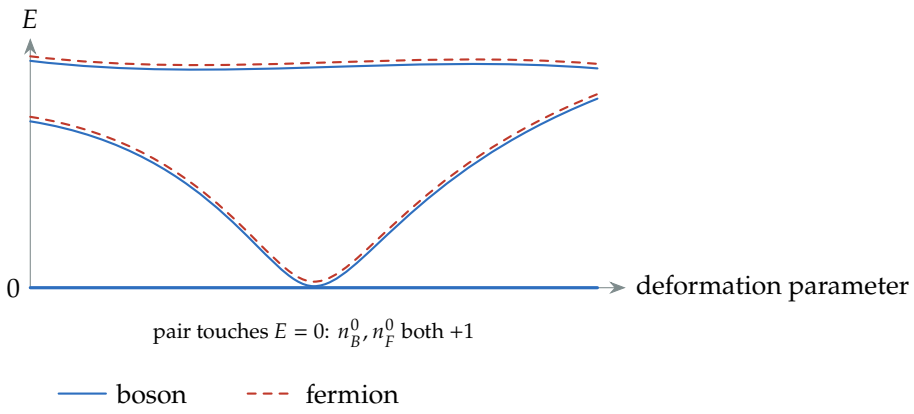

Figure 7.48: Levels of a supersymmetric system under a deformation. Positive levels always carry a boson (solid) and a fermion (dashed) together, so when a level comes down to $E = 0$ it adds one boson *and* one fermion to the zero-energy count. The zero-energy boson on the bottom line never moves. The difference $n_B(0) - n_F(0)$ stays equal to 1 throughout.

Physical picture: the path integral view

$\operatorname{Tr}\big((-1)^F e^{-\beta H}\big)$ is a partition function in Euclidean time β with an insertion of $(-1)^F$. In a path integral, inserting $(-1)^F$ changes the boundary condition of the fermions around the time circle from antiperiodic (the ordinary thermal trace) to *periodic*. With periodic boundary conditions the boson and fermion fluctuation determinants cancel mode by mode, which is the path-integral version of the pairing argument. As $\beta \to 0$ the path

integral reduces to an ordinary integral over the configuration space, and one can compute the index there; this is the route to the index theorems of Chapter 4.

Watch out: not every supersymmetric system has an index

On the line with $W = x^3$ the index is 0 and there is no zero-energy state. If we now deform $W = x^3$ into $W = x^3 - ax$ with $a > 0$, the answer does not change (the behaviour at infinity is the same). But now W has two critical points, a minimum at $x = +\sqrt{a/3}$ and a maximum at $x = -\sqrt{a/3}$, and V_B, V_F each have a deep well at one of them. Perturbation theory around each well predicts a zero-energy boson (at the minimum of W) and a zero-energy fermion (at the maximum), and the prediction is wrong: tunnelling between the wells lifts both to a small positive energy, as a boson–fermion pair. The index is robust; the naive semiclassical count of ground states is not. This is exactly the gap between the weak inequality $b_p \le m_p$ and the equality we will get from the Morse–Witten complex.

Reading Nash (pp. 207–208, (7.60)–(7.67))

Nash states the algebra (7.142)–(7.143) for a $(1+1)$-dimensional theory and deduces (7.144) "showing ... that the Q_i are bona fide symmetry operators, and ... that the Hamiltonian is non-negative"; we filled in both computations. His (7.63)–(7.67) are our (7.147)–(7.149), with the block-off-diagonal form derived from $\{Q_i, (-1)^F\} = 0$. Nash does not name the Witten index or give the pairing argument at this point; we included them because they are the reason the construction computes topology. Nash's "one particle states" $\mathcal{H}_1$ will be the space of all differential forms on M.

Recap

- Supercharges are Hermitian, anticommute with each other and with $(-1)^F$, and square to $H \pm P$. In quantum mechanics $P = 0$, and $Q = \frac{1}{2}(Q_1 - \mathrm{i}Q_2)$ is nilpotent with $\{Q, Q^\dagger\} = H$.
- Consequences: $[Q_i, H] = 0$, $H \ge 0$, and $H\psi = 0$ iff every supercharge kills ψ.
- Positive-energy states come in boson–fermion pairs, so the Witten index $\mathrm{Tr}(-1)^F = n_B(0) - n_F(0) = \mathrm{Tr}(-1)^F e^{-\beta H}$ is independent of β and of continuous deformations.
- On a line, $V_{B,F} = W'^2 \mp W''$; zero modes are $e^{\mp W}$; the index is fixed by the behaviour of W at infinity.

7.11 Supersymmetry from differential forms

The algebra of Section 7.10 needs a Hilbert space with a $\mathbb{Z}_2$-grading and a nilpotent operator Q whose anticommutator with its adjoint is the Hamiltonian. The question of this section is: *is there such a system attached to every Riemannian manifold, built from nothing but its geometry?* There is, and it is so natural that we have met all of its pieces before: the exterior derivative d is Q, the space of all differential forms is the Hilbert space, and the Hodge Laplacian is the Hamiltonian [Nash p. 208]. Along the way we find the first half of Witten's argument: the zero-energy states of this system are the harmonic forms, so they count the Betti numbers.

7.11.1 The Hilbert space of forms and the adjoint d^*

Let M be compact, oriented, without boundary, with a Riemannian metric g. Write $\Omega^p(M)$ for the p-forms. The metric gives the Hodge star $\star\colon \Omega^p \to \Omega^{n-p}$ and with it an inner product (Chapter T1):

$$\langle \alpha, \beta \rangle = \int_M \alpha \wedge \star\beta = \int_M \frac{1}{p!}\, \alpha_{i_1 \dots i_p}\, \beta^{i_1 \dots i_p}\, \sqrt{g}\, \mathrm{d}^n x \qquad (\alpha, \beta \in \Omega^p), \tag{7.156}$$

and forms of different degrees are orthogonal. In an orthonormal frame this is just "sum of products of components, integrated over M". For functions it is $\int \alpha\beta$ vol; for 1-forms $A = A_i \mathrm{d}x^i$ it is $\int A_i B^i$ vol, the L^2 product of the corresponding vector fields. (For complex forms put a complex conjugate on α.) Completing gives the Hilbert space

$$\mathcal{H} = \bigoplus_{p=0}^{n} L^2\Omega^p(M).$$

Working definition 7.31 (the adjoint d^*)

$\mathrm{d}^*\colon \Omega^p \to \Omega^{p-1}$ is defined by $\langle \mathrm{d}^*\alpha, \beta \rangle = \langle \alpha, \mathrm{d}\beta \rangle$ for all β [every $(p-1)$-form β on M]. *Operational formula:*

$$\mathrm{d}^* = (-1)^{n(p+1)+1} \star \mathrm{d} \star \quad \text{on } p\text{-forms}, \qquad (\mathrm{d}^*\alpha)_{i_2 \dots i_p} = -\nabla^i \alpha_{i\, i_2 \dots i_p}. \tag{7.157}$$

[∇ is the Levi-Civita covariant derivative, and the index on ∇^i is raised with g] It is minus a divergence. For a 1-form A, $\mathrm{d}^*A = -\nabla_i A^i = -\operatorname{div} A$.

The minus sign is the one familiar from integration by parts. For $\alpha = A$ a 1-form and $\beta = \phi$ a function on flat $\mathbb{R}^n$,

$$\langle A, \mathrm{d}\phi \rangle \overset{(1)}{=} \int A_i\, \partial_i \phi\, \mathrm{d}^n x \overset{(2)}{=} -\int (\partial_i A_i)\, \phi\, \mathrm{d}^n x \overset{(3)}{=} \langle -\operatorname{div} A, \phi \rangle,$$

(1) The inner product (7.156) on 1-forms, with $\mathrm{d}\phi = \partial_i \phi\, \mathrm{d}x^i$.
(2) Integrate by parts; there is no boundary term on a closed manifold (or for functions that decay at infinity).
(3) Read off the function paired with ϕ.

So $\mathrm{d}^*A = -\operatorname{div} A$: d is the gradient and d^* is minus the divergence, which is the familiar statement that $-\operatorname{div}$ is the adjoint of grad.

7.11.2 Nash's construction

Now define [Nash p. 208, (7.68)]

$$Q_1 = \mathrm{d} + \mathrm{d}^*, \qquad Q_2 = \mathrm{i}(\mathrm{d} - \mathrm{d}^*), \qquad \mathcal{H}_1^B = \bigoplus_{p \geq 0} \Omega^{2p}(M), \qquad \mathcal{H}_1^F = \bigoplus_{p \geq 0} \Omega^{2p+1}(M). \tag{7.158}$$

A particle is a differential form, and the parity of its degree is its statistics: even forms are bosons, odd forms are fermions. So $(-1)^F$ acts on a p-form as $(-1)^p$. Both d and d^* change the degree by one, so both change the parity: Q_1, Q_2 are off-diagonal as they should be. Comparing with (7.145), the complex supercharge is

$$Q = \tfrac{1}{2}(Q_1 - \mathrm{i}Q_2) = \tfrac{1}{2}\big(\mathrm{d} + \mathrm{d}^* + \mathrm{d} - \mathrm{d}^*\big) = \mathrm{d}, \qquad Q^\dagger = \mathrm{d}^*.$$

The supersymmetry algebra follows from a single fact, $\mathrm{d}^2 = 0$, together with its adjoint $(\mathrm{d}^*)^2 = 0$. Here is the anticommutator [Nash p. 208, (7.69)]:

$$\begin{aligned} Q_1 Q_2 &\overset{(1)}{=} \mathrm{i}(\mathrm{d}+\mathrm{d}^*)(\mathrm{d}-\mathrm{d}^*) = \mathrm{i}\big(\mathrm{d}^2 + \mathrm{d}^*\mathrm{d} - \mathrm{d}\mathrm{d}^* - \mathrm{d}^{*2}\big) \\ &\overset{(2)}{=} \mathrm{i}(\mathrm{d}^*\mathrm{d} - \mathrm{d}\mathrm{d}^*), \\ Q_2 Q_1 &\overset{(3)}{=} \mathrm{i}(\mathrm{d}-\mathrm{d}^*)(\mathrm{d}+\mathrm{d}^*) = \mathrm{i}\big(\mathrm{d}^2 - \mathrm{d}^*\mathrm{d} + \mathrm{d}\mathrm{d}^* - \mathrm{d}^{*2}\big) = -\mathrm{i}(\mathrm{d}^*\mathrm{d} - \mathrm{d}\mathrm{d}^*) \\ &\overset{(4)}{=} -Q_1 Q_2. \end{aligned} \tag{7.159}$$

(1) Multiply out, keeping the order of the operators.
(2) $\mathrm{d}^2 = 0$ and $(\mathrm{d}^*)^2 = 0$ (the adjoint of $\mathrm{d}^2 = 0$).
(3) The same with the signs of d^* swapped.
(4) Compare with the second line.

So $\{Q_1, Q_2\} = 0$. The squares:

$$\begin{aligned} Q_1^2 &\overset{(1)}{=} \mathrm{d}^2 + \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d} + \mathrm{d}^{*2} = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}, \\ Q_2^2 &\overset{(2)}{=} -\big(\mathrm{d}^2 - \mathrm{d}\mathrm{d}^* - \mathrm{d}^*\mathrm{d} + \mathrm{d}^{*2}\big) = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}, \\ H &\overset{(3)}{=} \tfrac{1}{2}(Q_1^2 + Q_2^2) = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d} = \bigoplus_{p \geq 0} \Delta_p. \end{aligned} \tag{7.160}$$

(1) Multiply out $(\mathrm{d}+\mathrm{d}^*)^2$ and drop $\mathrm{d}^2, \mathrm{d}^{*2}$.
(2) $\mathrm{i}^2 = -1$, then the same.
(3) Nash's (7.70): average the two; Δ_p is the Laplacian acting on p-forms. It preserves the degree because $\mathrm{d}\mathrm{d}^*$ and $\mathrm{d}^*\mathrm{d}$ each lower and raise it once.

Since $Q_1^2 = Q_2^2$, comparison with (7.143) gives $P = 0$ [Nash p. 209]: this is supersymmetric quantum mechanics, not a field theory. In Nash's words, a "non-relativistic model".

Working definition 7.32 (Hodge Laplacian)

$\Delta = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$ on forms. *Operational formulas.* On functions, $\Delta\phi = \mathrm{d}^*\mathrm{d}\phi = -\nabla^i\nabla_i\phi$, the *positive* Laplacian (minus the usual ∇^2). On forms in flat $\mathbb{R}^n$ with Cartesian coordinates, Δ acts on each component as $-\sum_i \partial_i^2$. On a curved manifold, $\Delta = \nabla^*\nabla + (\text{curvature})$ [$\nabla^*\nabla = -\nabla^i\nabla_i$ acting on every component index] (the Weitzenböck formula); on 1-forms the curvature term is the Ricci tensor [it acts as $A_i \mapsto R_i{}^j A_j$].

Worked example 7.68: Δ on 1-forms in the plane, by hand

Take $A = A_x\mathrm{d}x + A_y\mathrm{d}y$ on $\mathbb{R}^2$. Then

$$\mathrm{d}^*\mathrm{d}A \overset{(1)}{=} \mathrm{d}^*\big((\partial_x A_y - \partial_y A_x)\,\mathrm{d}x \wedge \mathrm{d}y\big) \overset{(2)}{=} -\partial_x B\,\mathrm{d}y + \partial_y B\,\mathrm{d}x, \qquad B := \partial_x A_y - \partial_y A_x,$$

$$\mathrm{d}\mathrm{d}^*A \overset{(3)}{=} \mathrm{d}\big(-\partial_x A_x - \partial_y A_y\big) = -\partial_x(\operatorname{div} A)\,\mathrm{d}x - \partial_y(\operatorname{div} A)\,\mathrm{d}y.$$

(1) $\mathrm{d}A$ is the "magnetic field" B times the area form.
(2) $\mathrm{d}^* = -\star\,\mathrm{d}\star$ in two dimensions; $\star(\mathrm{d}x \wedge \mathrm{d}y) = 1$, $\star\mathrm{d}x = \mathrm{d}y$, $\star\mathrm{d}y = -\mathrm{d}x$.
(3) $\mathrm{d}^*A = -\operatorname{div} A$ from (7.157).

Adding, the $\mathrm{d}x$ component is $\partial_y B - \partial_x \operatorname{div} A = \partial_y\partial_x A_y - \partial_y^2 A_x - \partial_x^2 A_x - \partial_x\partial_y A_y = -(\partial_x^2 + \partial_y^2)A_x$, and similarly for $\mathrm{d}y$. So $\Delta A = -(\nabla^2 A_x)\mathrm{d}x - (\nabla^2 A_y)\mathrm{d}y$: this is the vector identity $\operatorname{curl}\operatorname{curl} - \operatorname{grad}\operatorname{div} = -\nabla^2$ in disguise.

7.11.3 Zero-energy states are harmonic forms

By the positivity argument of Section 7.10.2, a form has zero energy exactly when both supercharges kill it. For forms this reads:

$$\begin{aligned}\langle \alpha, \Delta\alpha\rangle &\overset{(1)}{=} \langle \alpha, \mathrm{d}\mathrm{d}^*\alpha\rangle + \langle \alpha, \mathrm{d}^*\mathrm{d}\alpha\rangle \\ &\overset{(2)}{=} \langle \mathrm{d}^*\alpha, \mathrm{d}^*\alpha\rangle + \langle \mathrm{d}\alpha, \mathrm{d}\alpha\rangle = \|\mathrm{d}^*\alpha\|^2 + \|\mathrm{d}\alpha\|^2 .\end{aligned} \tag{7.161}$$

(1) Definition of Δ.
(2) Move one d or d^* to the left side of each inner product using the definition of the adjoint.

A sum of two squared norms vanishes only if both do. So

$$\Delta\alpha = 0 \iff \mathrm{d}\alpha = 0 \text{ and } \mathrm{d}^*\alpha = 0.$$

Such forms are called **harmonic**. The key theorem of Hodge relates them to cohomology.

Key idea: Hodge theorem, Nash (7.74)

On a compact oriented Riemannian manifold without boundary, every de Rham cohomology class contains exactly one harmonic form. Hence

$$b_p = \dim H^p_{\mathrm{dR}}(M) = \dim \operatorname{Ker} \Delta_p . \tag{7.162}$$

More precisely, $\Omega^p = \operatorname{Ker}\Delta_p \oplus \operatorname{Im}\mathrm{d} \oplus \operatorname{Im}\mathrm{d}^*$ (the **Hodge decomposition**), and the three pieces are orthogonal.

Here is the physicist's reason. Fix a closed form α and look at all forms $\alpha + \mathrm{d}\beta$ in its class. Among them, pick the one of *smallest norm* (an elliptic-PDE fact guarantees a minimiser exists; see Chapter 2). At the minimiser, varying $\beta \to \beta + \epsilon\gamma$ must not change the norm to first order:

$$0 = \frac{\mathrm{d}}{\mathrm{d}\epsilon}\Big|_{\epsilon=0} \|\alpha + \mathrm{d}\beta + \epsilon\,\mathrm{d}\gamma\|^2 \overset{(1)}{=} 2\,\langle \mathrm{d}\gamma,\ \alpha + \mathrm{d}\beta\rangle \overset{(2)}{=} 2\,\langle \gamma,\ \mathrm{d}^*(\alpha + \mathrm{d}\beta)\rangle .$$

(1) Expand the square to first order in ϵ.
(2) Definition of the adjoint.

Since γ is arbitrary, $\mathrm{d}^*(\alpha + \mathrm{d}\beta) = 0$. The minimiser is closed (it is in the class of a closed form) and co-closed, i.e. harmonic. It is unique: if ω and $\omega + \mathrm{d}\beta$ are both harmonic, then $\mathrm{d}\beta$ is harmonic, and $\|\mathrm{d}\beta\|^2 = \langle \beta, \mathrm{d}^*\mathrm{d}\beta\rangle = 0$. So: *the harmonic representative is the minimum-energy representative of the cohomology class*. For the Maxwell field this is familiar: among all vector potentials describing a given field, the one satisfying the Lorenz gauge condition $\mathrm{d}^*A = 0$ is picked out.

Key idea: the Witten index of forms is the Euler characteristic

With $(-1)^F = (-1)^p$ on p-forms,

$$\operatorname{Tr}(-1)^F \overset{(1)}{=} \sum_p (-1)^p \dim \operatorname{Ker}\Delta_p \overset{(2)}{=} \sum_p (-1)^p b_p \overset{(3)}{=} \chi(M). \tag{7.163}$$

(1) Definition (7.154): zero-energy states are harmonic forms, weighted by the parity of their degree.
(2) Hodge theorem (7.162).
(3) Definition of the Euler characteristic.

This is our first "physics computes topology" result. The Witten index is independent of the metric (a continuous deformation), just as the pairing argument predicts. In the language of Chapter 4, it is the index of the elliptic operator $\mathrm{d}+\mathrm{d}^*\colon \Omega^{\text{even}} \to \Omega^{\text{odd}}$.

The pairing, concretely. For forms the boson–fermion pairing of Section 7.10.6 is visible directly. Let α be an eigenform, $\Delta\alpha = \lambda\alpha$ with $\lambda > 0$, and suppose it is co-exact ($\alpha = \mathrm{d}^*\gamma$). Then $\mathrm{d}\alpha \neq 0$ (otherwise α would be harmonic), $\mathrm{d}\alpha$ has one degree more, and $\Delta\mathrm{d}\alpha = \mathrm{d}\Delta\alpha = \lambda\,\mathrm{d}\alpha$ because d commutes with Δ. So every positive eigenvalue appears in degrees p and $p+1$ together. The following examples show this in action.

Worked example 7.69: the spectrum of Δ on the circle

On S^1 with angle $\theta \in [0, 2\pi)$ and metric $\mathrm{d}\theta^2$, a 0-form is a periodic function and a 1-form is $\varphi(\theta)\mathrm{d}\theta$. Δ acts as $-\mathrm{d}^2/\mathrm{d}\theta^2$ on the coefficient in both degrees. Eigenforms are $e^{\mathrm{i}k\theta}$ and $e^{\mathrm{i}k\theta}\mathrm{d}\theta$, $k \in \mathbb{Z}$, with eigenvalue k^2. For $k \neq 0$,

$$\mathrm{d}\big(e^{\mathrm{i}k\theta}\big) = \mathrm{i}k\, e^{\mathrm{i}k\theta}\mathrm{d}\theta,$$

so d maps the bosonic state at level k^2 onto the fermionic one. At $k = 0$ we get 1 and $\mathrm{d}\theta$, both harmonic and unpaired: $b_0 = b_1 = 1$, and $\mathrm{Tr}(-1)^F = 1 - 1 = 0 = \chi(S^1)$.

Worked example 7.70: the spectrum on the flat torus

On $T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$ with coordinates (x, y), the eigenforms are $e^{\mathrm{i}(kx+ly)}$ times one of $1,\ \mathrm{d}x,\ \mathrm{d}y,\ \mathrm{d}x \wedge \mathrm{d}y$, with eigenvalue $k^2 + l^2$ (Δ acts on each Cartesian component as $-\partial_x^2 - \partial_y^2$, by Example 7.68). At each level with $(k, l) \neq (0, 0)$ there are 1 zero-form, 2 one-forms and 1 two-form per Fourier mode, so bosons minus fermions is $1 - 2 + 1 = 0$. At $(k, l) = (0, 0)$ we get the harmonic forms $1, \mathrm{d}x, \mathrm{d}y, \mathrm{d}x \wedge \mathrm{d}y$: $b = (1, 2, 1)$, $\chi(T^2) = 0$.

Worked example 7.71: the spectrum on the round sphere

On the unit S^2, the eigenfunctions of Δ on 0-forms are the spherical harmonics Y_{lm}, with eigenvalue $l(l+1)$ and multiplicity $2l+1$. Since Δ commutes with d and with $\star$, we also get

- 2-forms $Y_{lm}\,\mathrm{vol}$ (apply $\star$), eigenvalue $l(l+1)$, multiplicity $2l+1$;
- 1-forms $\mathrm{d}Y_{lm}$ (exact) and $\star\mathrm{d}Y_{lm}$ (co-exact), $l \geq 1$, eigenvalue $l(l+1)$, multiplicity $2(2l+1)$.

These exhaust the spectrum (Hodge decomposition, and $b_1(S^2) = 0$). Count at level $l(l+1)$ with $l \geq 1$:

$$n_B - n_F \overset{(1)}{=} \big[(2l+1) + (2l+1)\big] - 2(2l+1) = 0,$$

(1) Bosons are the 0-forms and 2-forms, fermions the 1-forms.

At $l = 0$: the constant function and vol, both bosons, both harmonic. So $b = (1, 0, 1)$ and $\mathrm{Tr}(-1)^F = 2 = \chi(S^2)$.

7.11.4 Forms are fermions: the exterior algebra as a Fock space

Nash says that there is a "formal equivalence between exterior and interior multiplication and Fermion creation and annihilation" [Nash p. 210]. We now make this precise, with matrices,

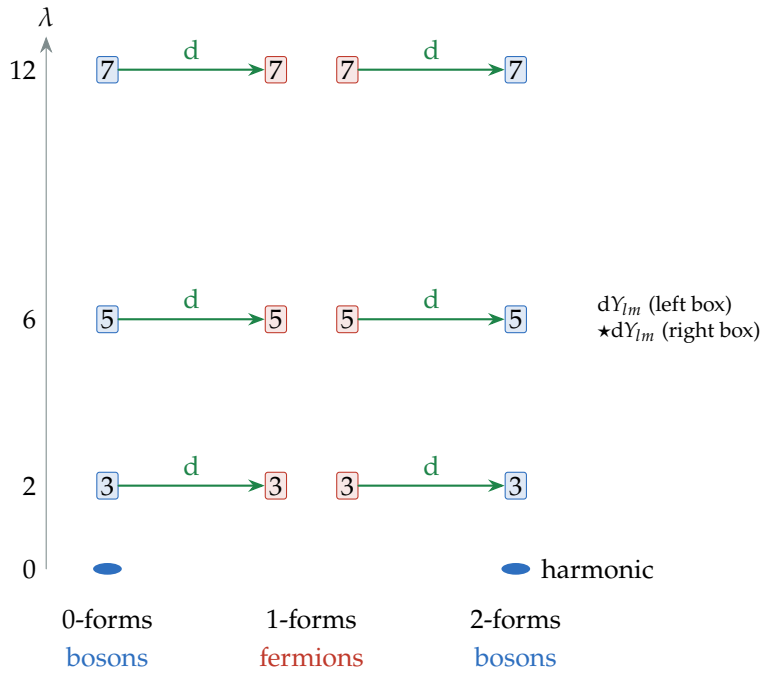

Figure 7.49: The spectrum of the Hodge Laplacian on the round S^2, sorted by degree. Each box is a level $l(l+1)$ with its multiplicity. The exterior derivative (green) maps 0-forms onto exact 1-forms and co-exact 1-forms onto 2-forms, preserving the eigenvalue. Every positive level cancels in $\mathrm{Tr}(-1)^F$; only the two harmonic forms at $\lambda = 0$ survive, and $\chi(S^2) = 2$.

because the Hamiltonian of Section 7.13 is written in this language.

At one point $x \in M$, pick an orthonormal basis $e_1, \dots, e_n$ of T_xM and the dual basis $e^1, \dots, e^n$ of T_x^*M (in flat space, $e_i = \partial_i$ and $e^i = \mathrm{d}x^i$). Nash writes e_i^* for e^i. Define two operators on forms at x:

$$a^{i*}\alpha := e^i \wedge \alpha \quad \text{(exterior multiplication)}, \qquad a^i\alpha := \iota_{e_i}\alpha \quad \text{(interior multiplication)}. \tag{7.164}$$

Here ι_v is contraction with v in the first slot, so $\iota_{e_i}e^j = \delta_i^j$ and $\iota_v(\alpha\wedge\beta) = (\iota_v\alpha)\wedge\beta + (-1)^p\alpha\wedge\iota_v\beta$ for α a p-form.

Key idea: canonical anticommutation relations

$$\{a^i, a^{j*}\} = \delta^{ij}, \qquad \{a^i, a^j\} = 0, \qquad \{a^{i*}, a^{j*}\} = 0. \tag{7.165}$$

These are the relations of n independent fermionic modes. The "vacuum" (no fermions) is the constant function 1; the state with fermions in modes $i_1 < \cdots < i_p$ is $e^{i_1}\wedge\cdots\wedge e^{i_p}$. The fermion number operator $N = \sum_i a^{i*}a^i$ is the *degree*: $N\alpha = p\,\alpha$ on p-forms.

The last two relations say $e^i\wedge e^j = -e^j\wedge e^i$ and $\iota_{e_i}\iota_{e_j} = -\iota_{e_j}\iota_{e_i}$. For the first, use the Leibniz rule for ι with e^j a 1-form:

$$a^i a^{j*}\alpha \overset{(1)}{=} \iota_{e_i}(e^j\wedge\alpha) \overset{(2)}{=} (\iota_{e_i}e^j)\,\alpha - e^j\wedge\iota_{e_i}\alpha \overset{(3)}{=} \delta_i^j\,\alpha - a^{j*}a^i\alpha.$$

(1) Definitions (7.164).
(2) The Leibniz rule for ι, with sign $(-1)^1$ because e^j has degree one.
(3) $\iota_{e_i}e^j = \delta_i^j$ for dual bases.

Moving the last term to the left gives $\{a^i, a^{j*}\} = \delta^{ij}$. And $N = \sum_i e^i\wedge\iota_{e_i}$ applied to $e^{i_1}\wedge\cdots\wedge e^{i_p}$ removes each of the p factors in turn and puts it back in front, returning p copies of the form.

Worked example 7.72: the Fock space of $\Lambda(\mathbb{R}^2)$ as 4×4 matrices

In the plane, order the basis of forms as $(1,\ \mathrm{d}x,\ \mathrm{d}y,\ \mathrm{d}x\wedge\mathrm{d}y)$. Reading off the images of the basis vectors column by column:

$$a^{1*}=\begin{pmatrix}0&0&0&0\\1&0&0&0\\0&0&0&0\\0&0&1&0\end{pmatrix},\qquad a^{2*}=\begin{pmatrix}0&0&0&0\\0&0&0&0\\1&0&0&0\\0&-1&0&0\end{pmatrix},\qquad a^1=\left(a^{1*}\right)^T,\quad a^2=\left(a^{2*}\right)^T.$$

For example, the second column of a^{2*} is $-\mathrm{d}x\wedge\mathrm{d}y$ because $\mathrm{d}y\wedge\mathrm{d}x=-\mathrm{d}x\wedge\mathrm{d}y$; this minus sign is the whole of fermionic statistics. The fermion number and the grading are

$$N=a^{1*}a^1+a^{2*}a^2=\mathrm{diag}(0,1,1,2),\qquad (-1)^F=\mathrm{diag}(1,-1,-1,1).$$

As a check of (7.165): a^1a^{2*} sends $\mathrm{d}x\mapsto\iota_x(-\mathrm{d}x\wedge\mathrm{d}y)=-\mathrm{d}y$ and $a^{2*}a^1$ sends $\mathrm{d}x\mapsto\mathrm{d}y\wedge1=\mathrm{d}y$; all other basis vectors are killed by both, so $\{a^1,a^{2*}\}=0$. Similarly $a^1a^{1*}+a^{1*}a^1=\mathrm{diag}(1,0,1,0)+\mathrm{diag}(0,1,0,1)=\mathbf{1}$.

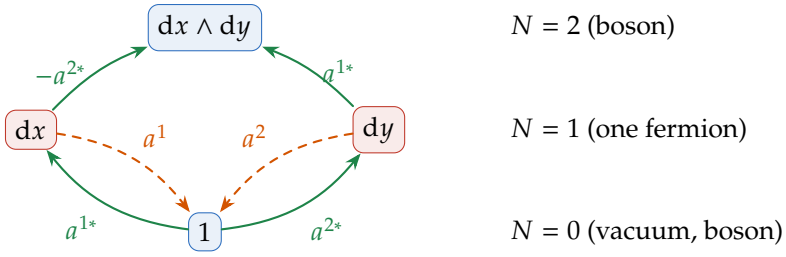

Figure 7.50: The exterior algebra of $\mathbb{R}^2$ as a fermionic Fock space. Exterior multiplication by $\mathrm{d}x^i$ (green) creates a fermion in mode i; interior multiplication by ∂_i (orange, dashed) destroys one. The degree is the fermion number. The minus sign on one path to $\mathrm{d}x\wedge\mathrm{d}y$ is the antisymmetry of fermionic states.

d and d^* as fermion bilinears. In flat space with Cartesian coordinates,

$$\mathrm{d}=\sum_i a^{i*}\,\partial_i,\qquad \mathrm{d}^*=-\sum_i a^i\,\partial_i. \tag{7.166}$$

The first is the definition $\mathrm{d}\alpha=\mathrm{d}x^i\wedge\partial_i\alpha$. The second is its adjoint: $(a^{i*})^\dagger=a^i$ (the matrices above are transposes) and $(\partial_i)^\dagger=-\partial_i$, and a^i commutes with ∂_i. On a curved manifold the same formulas hold with an orthonormal frame and ∂_i replaced by the Levi-Civita covariant derivative ∇_{e_i}. Compare with (7.157): on a 1-form, $-a^i\partial_i(A_j\mathrm{d}x^j)=-\partial_iA_i$, minus the divergence, as it should be.

Clifford operators and the Dirac operator. Two combinations of a and a^* are especially useful:

$$c^i:=a^{i*}-a^i,\qquad \hat{c}^{\,i}:=a^{i*}+a^i. \tag{7.167}$$

From (7.165),

$$\begin{aligned}\{c^i,c^j\}&\overset{(1)}{=}\{a^{i*},a^{j*}\}-\{a^{i*},a^j\}-\{a^i,a^{j*}\}+\{a^i,a^j\}=-2\delta^{ij},\\ \{\hat{c}^{\,i},\hat{c}^{\,j}\}&=+2\delta^{ij},\qquad \{c^i,\hat{c}^{\,j}\}\overset{(2)}{=}-\{a^{i*},a^j\}+\{a^i,a^{j*}\}=0.\end{aligned} \tag{7.168}$$

(1) Expand bilinearly; only the mixed anticommutators are nonzero, each equal to δ^{ij}.
(2) The two mixed terms enter with opposite signs and cancel.

So the c^i generate a Clifford algebra with $(c^i)^2 = -1$, the $\hat{c}^{\,i}$ generate a second Clifford algebra with $(\hat{c}^{\,i})^2 = +1$, and the two anticommute (Chapter T4). The forms $\Lambda(\mathbb{R}^n)$, of dimension 2^n, carry both at once. In flat space

$$Q_1 = \mathrm{d} + \mathrm{d}^* = \sum_i (a^{i*} - a^i)\,\partial_i = \sum_i c^i \partial_i, \tag{7.169}$$

a Dirac operator built with the "gamma matrices" c^i. Squaring it,

$$Q_1^2 = \sum_{i,j} c^i c^j \partial_i \partial_j = \tfrac{1}{2} \sum_{i,j} \{c^i, c^j\} \partial_i \partial_j = -\sum_i \partial_i^2 = \Delta,$$

because $\partial_i \partial_j$ is symmetric. This is the same mechanism by which the Dirac operator squares to the Laplacian. The operator $\mathrm{d} + \mathrm{d}^*$ is sometimes called the **signature** or **Euler** operator, or the Dirac–Kähler operator; in Chapter 4 its index is $\chi(M)$.

Dictionary: forms and fermions

Forms	Fermions
1 (a function)	Fock vacuum $\lvert 0\rangle$
$e^i\wedge$ (exterior mult.)	creation operator $a^{i*} = \psi^{i\dagger}$
ι_{e_i} (interior mult.)	annihilation operator $a^i = \psi^i$
degree p	fermion number F
$(-1)^p$	$(-1)^F$
$e^{i_1} \wedge \cdots \wedge e^{i_p}$	p-fermion state $\psi^{i_1\dagger} \cdots \psi^{i_p\dagger}\lvert 0\rangle$
d, d^*	supercharges Q, $Q^\dagger$
$\mathrm{d} + \mathrm{d}^*$	Dirac operator $c^i \nabla_i$

Reading Nash (pp. 208–209, (7.68)–(7.70), (7.74))

Nash writes the definitions (7.158) and remarks that "a particle is a p-form and the parity of p determines whether it is a Boson or a Fermion". His (7.69) is our (7.159); his (7.70), $H = \mathrm{dd}^* + \mathrm{d}^*\mathrm{d} = \bigoplus_p \Delta_p$, is (7.160); and his (7.74), $b_p = \dim \mathrm{Ker}\,\Delta_p$, is the Hodge theorem (7.162), which he quotes without comment. The fermionic interpretation of $e^i\wedge$ and ι_{e_i}, which Nash mentions on p. 210 as notation borrowed from Witten, is Section 7.11.4.

Recap

- Every compact Riemannian manifold carries a supersymmetric quantum mechanics: $\mathcal{H}$ = forms, $(-1)^F = (-1)^{\text{degree}}$, $Q = \mathrm{d}$, $Q^\dagger = \mathrm{d}^*$, $H = \Delta$.
- Zero-energy states = harmonic forms = cohomology classes (Hodge): $b_p = \dim \mathrm{Ker}\,\Delta_p$. The Witten index is $\chi(M)$.
- Exterior and interior multiplication are fermion creation and annihilation operators; $c^i = a^{i*} - a^i$ are Clifford generators, and $\mathrm{d} + \mathrm{d}^* = c^i \nabla_i$ is a Dirac operator.
- Nonzero eigenvalues of Δ are paired between adjacent degrees by d (circle, torus, sphere examples).

7.12 Witten's deformation of the exterior derivative

So far the manifold M carries a metric, and nothing else. The supersymmetric quantum mechanics of Section 7.11 knows the Betti numbers, but it does not know about any function f, so it cannot know about critical points. The question of this section is: *how do we put a Morse function into the system without spoiling the supersymmetry algebra, and without changing the number of zero-energy states?*

Witten's answer [Nash p. 209, (7.71)] is to conjugate d by the function e^{tf}. It is a one-line idea, but everything later rests on it, so we look at it from several sides: as a formula, as a change of basis that preserves cohomology, as a quantum-mechanical system, and through its exact zero-energy states.

7.12.1 The deformed differential

Let $f : M \to \mathbb{R}$ be smooth and $t \in \mathbb{R}$ a real parameter (later large and positive). Multiplication by the positive function e^{tf} is an invertible operator on forms, with inverse multiplication by e^{-tf}. Define [Nash p. 209, (7.71)]

$$\mathrm{d}_t := e^{-tf}\,\mathrm{d}\,e^{tf}. \tag{7.170}$$

Read it from right to left: multiply the form by e^{tf}, take d, multiply back by e^{-tf}. The result is again a first-order operator raising the degree by one. To see which one, apply it to a p-form α:

$$\begin{aligned} \mathrm{d}_t\alpha &\overset{(1)}{=} e^{-tf}\,\mathrm{d}\big(e^{tf}\alpha\big) \\ &\overset{(2)}{=} e^{-tf}\big(\mathrm{d}(e^{tf})\wedge\alpha + e^{tf}\,\mathrm{d}\alpha\big) \\ &\overset{(3)}{=} e^{-tf}\big(t\,e^{tf}\,\mathrm{d}f\wedge\alpha + e^{tf}\,\mathrm{d}\alpha\big) \\ &= \mathrm{d}\alpha + t\,\mathrm{d}f\wedge\alpha. \end{aligned} \tag{7.171}$$

(1) Definition (7.170).
(2) Leibniz rule for d of a function times a form: $\mathrm{d}(g\alpha) = \mathrm{d}g\wedge\alpha + g\,\mathrm{d}\alpha$.
(3) Chain rule, $\mathrm{d}(e^{tf}) = t\,e^{tf}\,\mathrm{d}f$.

So

$$\boxed{\mathrm{d}_t = \mathrm{d} + t\,\mathrm{d}f\wedge \;=\; \mathrm{d} + t\,\frac{\partial f}{\partial x^i}\,a^{i*}} \tag{7.172}$$

in the fermion notation of Section 7.11.4. The deformation adds a zeroth-order term: exterior multiplication by the 1-form $t\,\mathrm{d}f$.

Physical picture: an imaginary gauge field

On functions, $\mathrm{d}_t\phi = (\partial_i\phi + t\,\partial_i f\,\phi)\,\mathrm{d}x^i$. Compare the covariant derivative of a charged field, $D_i\phi = (\partial_i - \mathrm{i}eA_i)\phi$. The deformation is a covariant derivative with the "gauge field" $A = \mathrm{i}\,t\,\mathrm{d}f/e$: a pure gauge (it is exact), but *imaginary*. A real gauge transformation $e^{\mathrm{i}e\chi}$ is unitary and changes nothing physical. Our "gauge transformation" e^{tf} is real and not unitary, so it will change the spectrum, although, being pure gauge, it cannot change the topology. This is the whole trick in one sentence.

It still squares to zero. The conjugation formula makes this immediate:

$$\mathrm{d}_t^2 \overset{(1)}{=} e^{-tf}\,\mathrm{d}\,e^{tf}\,e^{-tf}\,\mathrm{d}\,e^{tf} \overset{(2)}{=} e^{-tf}\,\mathrm{d}^2\,e^{tf} \overset{(3)}{=} 0.$$

(1) Definition, twice.
(2) The inner factors $e^{tf}e^{-tf}$ cancel.
(3) $\mathrm{d}^2 = 0$.

It is instructive to check it from (7.171) as well, since there the cancellation is less obvious: $\mathrm{d}_t^2\alpha = \mathrm{d}(\mathrm{d}\alpha + t\,\mathrm{d}f\wedge\alpha) + t\,\mathrm{d}f\wedge(\mathrm{d}\alpha + t\,\mathrm{d}f\wedge\alpha)$. The first bracket gives $\mathrm{d}^2\alpha + t\,\mathrm{d}^2 f\wedge\alpha - t\,\mathrm{d}f\wedge\mathrm{d}\alpha$ (the sign from moving d past the 1-form $\mathrm{d}f$), the second gives $t\,\mathrm{d}f\wedge\mathrm{d}\alpha + t^2\,\mathrm{d}f\wedge\mathrm{d}f\wedge\alpha$. Everything cancels: $\mathrm{d}^2 = 0$, $\mathrm{d}^2 f = 0$, the two $\mathrm{d}f\wedge\mathrm{d}\alpha$ terms have opposite signs, and $\mathrm{d}f\wedge\mathrm{d}f = 0$.

7.12.2 The adjoint and the new supercharges

The adjoint of a product is the product of the adjoints in reverse order. Multiplication by a real function is self-adjoint for the L^2 inner product (7.156). Hence

$$\mathrm{d}_t^* \overset{(1)}{=} \left(e^{-tf}\,\mathrm{d}\,e^{tf}\right)^* \overset{(2)}{=} (e^{tf})^*\,\mathrm{d}^*\,(e^{-tf})^* \overset{(3)}{=} e^{tf}\,\mathrm{d}^*\,e^{-tf}, \tag{7.173}$$

(1) Definition (7.170).
(2) $(ABC)^* = C^*B^*A^*$.
(3) $e^{\pm tf}$ is real, so multiplication by it is self-adjoint.

which is Nash's formula for d_t^* [Nash p. 209]. Note the exponents have swapped sign. Explicitly, the adjoint of exterior multiplication by a 1-form ω is interior multiplication by the dual vector $\omega^\sharp$ (in an orthonormal frame, $(a^{i*})^\dagger = a^i$), so

$$\mathrm{d}_t^* = \mathrm{d}^* + t\,\iota_{\nabla f} = \mathrm{d}^* + t\,\frac{\partial f}{\partial x^i}\,a^i, \tag{7.174}$$

where $\nabla f = g^{ij}\partial_j f\,\partial_i$ is the gradient vector field. (One can also derive this from (7.173) using $\mathrm{d}^* = -\iota_{e_i}\nabla_{e_i}$, exactly as we derived (7.171): the derivative hits e^{-tf} and produces $-(-t\,\partial_i f)\,a^i$.)

Now copy (7.158) with d replaced by d_t [Nash p. 209, (7.72)]:

$$Q_1(t) = \mathrm{d}_t + \mathrm{d}_t^*, \qquad Q_2(t) = \mathrm{i}\big(\mathrm{d}_t - \mathrm{d}_t^*\big). \tag{7.175}$$

Nash calls it "a routine matter to verify" that the algebra is unchanged. The verification in (7.159)–(7.160) used *only* two facts: $\mathrm{d}^2 = 0$, and d^* is the adjoint of d. Both hold for d_t: we just showed $\mathrm{d}_t^2 = 0$, and d_t^* is its adjoint by construction, so $(\mathrm{d}_t^*)^2 = (\mathrm{d}_t^2)^* = 0$. Therefore, with no further work,

$$\{Q_1(t), Q_2(t)\} = 0, \qquad Q_1(t)^2 = Q_2(t)^2 = \mathrm{d}_t\mathrm{d}_t^* + \mathrm{d}_t^*\mathrm{d}_t := H_t = \bigoplus_p \Delta_p(t) \tag{7.176}$$

[Nash p. 209, (7.73)]. Each $Q_i(t)$ is Hermitian, anticommutes with $(-1)^F$ (it changes the degree by ± 1) and commutes with H_t. So for every value of t we have a supersymmetric quantum mechanics with complex supercharge $Q = \mathrm{d}_t$, and all the conclusions of Section 7.10 apply to it: $H_t \geq 0$; $H_t\alpha = 0$ iff $\mathrm{d}_t\alpha = \mathrm{d}_t^*\alpha = 0$; positive energy levels pair up; the Witten index is independent of t.

7.12.3 Why the zero-energy states are still counted by the Betti numbers

Nash says that "conjugation by e^{ft} means that the spectrum of H_t depends on t", but "the null spaces of H_t and H clearly coincide", so that [Nash p. 209, (7.75)]

$$b_p = \dim\operatorname{Ker}\Delta_p(t) \qquad \text{for every } t. \tag{7.177}$$

Let us see exactly why, because the word "coincide" hides a subtlety.

Step 1: e^{tf} is a chain isomorphism. Rewrite the definition (7.170) as

$$\mathrm{d} \circ e^{tf} = e^{tf} \circ \mathrm{d}_t. \tag{7.178}$$

So multiplication by e^{tf} carries d_t into d. It maps d_t-closed forms to d-closed forms ($\mathrm{d}_t\alpha = 0 \Rightarrow \mathrm{d}(e^{tf}\alpha) = e^{tf}\mathrm{d}_t\alpha = 0$) and d_t-exact forms to d-exact forms ($\alpha = \mathrm{d}_t\beta \Rightarrow e^{tf}\alpha = \mathrm{d}(e^{tf}\beta)$), and its inverse e^{-tf} does the reverse. Hence it induces an isomorphism

$$H^p(\Omega^*(M), \mathrm{d}_t) = \frac{\operatorname{Ker} \mathrm{d}_t}{\operatorname{Im} \mathrm{d}_t} \xrightarrow[\cong]{e^{tf}} \frac{\operatorname{Ker} \mathrm{d}}{\operatorname{Im} \mathrm{d}} = H^p_{\mathrm{dR}}(M). \tag{7.179}$$

Step 2: Hodge theory for d_t. The argument of Section 7.11.3 used only $\mathrm{d}^2 = 0$, the adjoint, and ellipticity of the Laplacian (which is unaffected by adding lower-order terms). So it works verbatim for d_t: every d_t-cohomology class contains exactly one form killed by $\Delta(t)$, the one of minimal norm. Hence

$$\dim \operatorname{Ker} \Delta_p(t) \overset{(1)}{=} \dim H^p(\Omega^*, \mathrm{d}_t) \overset{(2)}{=} \dim H^p_{\mathrm{dR}}(M) \overset{(3)}{=} b_p.$$

(1) Hodge theorem for the complex (Ω^*, d_t).
(2) The chain isomorphism (7.179).
(3) Definition of the Betti number.

$$\begin{array}{ccccccccc}
\cdots & \xrightarrow{\mathrm{d}_t} & \Omega^{p-1} & \xrightarrow{\mathrm{d}_t} & \Omega^{p} & \xrightarrow{\mathrm{d}_t} & \Omega^{p+1} & \xrightarrow{\mathrm{d}_t} & \cdots \\
 & & \downarrow{\scriptstyle e^{tf}\cong} & & \downarrow{\scriptstyle e^{tf}\cong} & & \downarrow{\scriptstyle e^{tf}\cong} & & \\
\cdots & \xrightarrow{\mathrm{d}} & \Omega^{p-1} & \xrightarrow{\mathrm{d}} & \Omega^{p} & \xrightarrow{\mathrm{d}} & \Omega^{p+1} & \xrightarrow{\mathrm{d}} & \cdots
\end{array}$$

Figure 7.51: Multiplication by e^{tf} (vertical arrows) intertwines the deformed complex (top row) with the de Rham complex (bottom row): every square commutes, by (7.178). So the two rows have the same cohomology, degree by degree, for every t. The vertical maps are not unitary, so the Laplacians built from the two rows have different spectra.

Watch out: "the null spaces coincide" means "have the same dimension"

The harmonic forms of Δ and of $\Delta(t)$ are *different forms*. For example, on functions $\operatorname{Ker} \Delta_0$ is spanned by the constant 1, whereas $\operatorname{Ker} \Delta_0(t)$ is spanned by e^{-tf} (see below). They are related by e^{tf}, but not literally equal, and H_t is not unitarily equivalent to H: *its positive eigenvalues move with t*. That is the point of the deformation. Only the number of zero eigenvalues in each degree is frozen.

7.12.4 The exact zero modes in degree 0 and n

Two zero-energy states of H_t can be written down in closed form, for every f and every t. They are our first look at localisation.

Degree 0. On functions $\mathrm{d}_t^* = 0$ (there are no (-1)-forms), so $H_t\phi = \mathrm{d}_t^*\mathrm{d}_t\phi$, and ϕ is a zero mode iff $\mathrm{d}_t\phi = 0$. Now

$$\mathrm{d}_t\left(e^{-tf}\right) \overset{(1)}{=} e^{-tf}\,\mathrm{d}\left(e^{tf}e^{-tf}\right) \overset{(2)}{=} e^{-tf}\,\mathrm{d}(1) \overset{(3)}{=} 0.$$

(1) Definition (7.170).

(2) The exponentials cancel.
(3) A constant has zero derivative.

So $\phi_0 = e^{-tf}$ spans $\operatorname{Ker}\Delta_0(t)$ on a connected M (it is the image of $1 \in \operatorname{Ker}\Delta_0$ under e^{-tf}).

Degree n. On top forms $\mathrm{d}_t = 0$, so a zero mode needs only $\mathrm{d}_t^*\omega = 0$. By (7.173), $\mathrm{d}_t^*(e^{tf}\,\mathrm{vol}) = e^{tf}\,\mathrm{d}^*(e^{-tf}e^{tf}\mathrm{vol}) = e^{tf}\,\mathrm{d}^*\mathrm{vol} = 0$, because the volume form is harmonic. So $\omega_n = e^{tf}\,\mathrm{vol}$ spans $\operatorname{Ker}\Delta_n(t)$ (for M connected and oriented).

Key idea: localisation of the exact zero modes

As $t \to +\infty$,

$$|\phi_0|^2 = e^{-2tf} \text{ piles up at the global minimum of } f,$$
$$|\omega_n|^2 = e^{2tf} \text{ piles up at the global maximum of } f.$$

A minimum has index 0 and a maximum has index n. So already the two explicit zero modes live at critical points whose index equals their degree. This is the pattern we will establish in general in Section 7.14.

Worked example 7.73: the circle with $f = \cos\theta$

On S^1 with $f = \cos\theta$ there is a maximum at $\theta = 0$ ($f = 1$) and a minimum at $\theta = \pi$ ($f = -1$). A state is a pair $(\phi(\theta), \psi(\theta)\,\mathrm{d}\theta)$. From (7.171) and (7.174), with $f' = -\sin\theta$,

$$\mathrm{d}_t\phi \overset{(1)}{=} (\phi' - t\sin\theta\,\phi)\,\mathrm{d}\theta,$$
$$\mathrm{d}_t^*(\psi\,\mathrm{d}\theta) \overset{(2)}{=} -\psi' - t\sin\theta\,\psi.$$

(1) $\mathrm{d}\phi = \phi'\mathrm{d}\theta$ and $t\,\mathrm{d}f\,\phi = -t\sin\theta\,\phi\,\mathrm{d}\theta$.
(2) $\mathrm{d}^*(\psi\mathrm{d}\theta) = -\psi'$ (minus the divergence), and $t\,\iota_{\nabla f}(\psi\mathrm{d}\theta) = tf'\psi = -t\sin\theta\,\psi$.

The zero modes solve first-order ODEs: $\phi' = t\sin\theta\,\phi$ gives $\phi_0 = e^{-t\cos\theta}$, and $\psi' = -t\sin\theta\,\psi$ gives $\psi_1 = e^{t\cos\theta}$. Both are smooth and periodic, so $\dim\operatorname{Ker}\Delta_0(t) = \dim\operatorname{Ker}\Delta_1(t) = 1 = b_0 = b_1$, as (7.177) demands. At $t = 0$ they are the constants 1 and $\mathrm{d}\theta$ of Example 7.69. As t grows the 0-form concentrates at the minimum $\theta = \pi$ and the 1-form at the maximum $\theta = 0$ (Figure 7.52). The normalised density is

$$\frac{e^{-2t\cos\theta}}{\int_0^{2\pi} e^{-2t\cos\theta}\,\mathrm{d}\theta} = \frac{e^{-2t\cos\theta}}{2\pi I_0(2t)} \approx \sqrt{\frac{t}{\pi}}\,e^{-t(\theta-\pi)^2} \quad (t \gg 1),$$

where I_0 is a modified Bessel function; the last form uses $\cos\theta \approx -1 + \tfrac{1}{2}(\theta-\pi)^2$ and $\int e^{-tu^2}\mathrm{d}u = \sqrt{\pi/t}$. The width of the peak is $1/\sqrt{t}$: this $t^{-1/2}$ localisation length will be a constant companion.

7.12.5 The line: we have seen this system before

Take $M = \mathbb{R}$ with coordinate x (not compact, but it is the local model of everything). A state is $(\phi(x), \psi(x)\,\mathrm{d}x)$ and

$$\mathrm{d}_t\phi = (\phi' + tf'\phi)\mathrm{d}x, \qquad \mathrm{d}_t^*(\psi\,\mathrm{d}x) = -\psi' + tf'\psi.$$

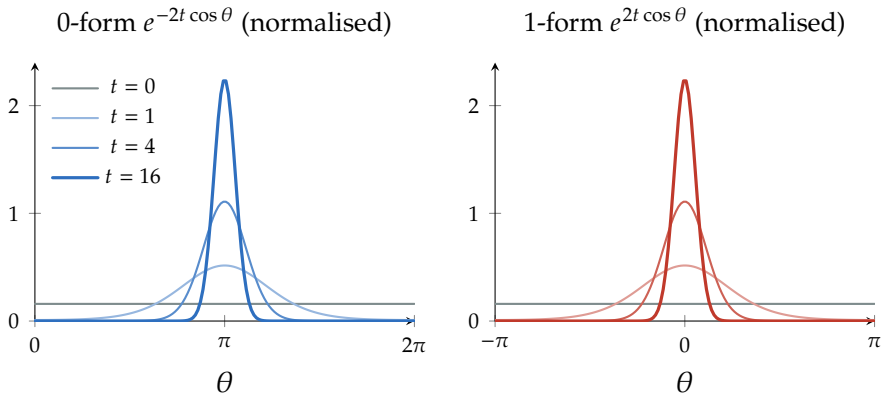

Figure 7.52: The two exact zero-energy states of H_t on the circle with $f = \cos\theta$, as probability densities, for $t = 0, 1, 4, 16$. The bosonic 0-form (left) concentrates at the minimum $\theta = \pi$ of f; the fermionic 1-form (right, plotted on $[-\pi, \pi]$) at the maximum $\theta = 0$. The peak height grows like $\sqrt{t/\pi}$ and the width shrinks like $t^{-1/2}$.

Compare with (7.150): these are exactly $A\phi$ and $A^\dagger\psi$ with superpotential

$$W = t\,f. \tag{7.180}$$

So the supersymmetric quantum mechanics on a line of Section 7.10.5 *is* Witten's deformed de Rham complex of the real line. In particular, reading off (7.152)–(7.153),

$$H_t = \begin{pmatrix} -\dfrac{\mathrm{d}^2}{\mathrm{d}x^2} + t^2 f'^2 - t f'' & 0 \\ 0 & -\dfrac{\mathrm{d}^2}{\mathrm{d}x^2} + t^2 f'^2 + t f'' \end{pmatrix} \quad \text{on} \quad \begin{pmatrix} \text{0-forms} \\ \text{1-forms} \end{pmatrix}. \tag{7.181}$$

The potential $t^2 f'^2$ is large except at the critical points; the "spin" term $\mp t f''$ decides which critical points are good for 0-forms (minima, where $f'' > 0$) and which for 1-forms (maxima). The general version of this formula, on any M, is the subject of Section 7.13.

Worked example 7.74: the double well on the line

Take $f = \frac{1}{4}(x^2 - 1)^2$, with minima at $x = \pm 1$ ($f = 0$, $f'' = 2$) and a maximum at $x = 0$ ($f = \frac{1}{4}$, $f'' = -1$). The zero-mode equations give

$$\phi_0 = e^{-tf} = e^{-t(x^2-1)^2/4} \quad \text{(normalisable)}, \qquad \psi_1 = e^{+tf} \quad \text{(not normalisable)}.$$

So there is one bosonic zero-energy state and no fermionic one. The boson has two bumps, one at each minimum. Naive counting ("one state per critical point, in degree equal to the index") predicts *three* low-energy states: two 0-forms at $x = \pm 1$ and one 1-form at $x = 0$. The exact answer has one. The other two form a boson–fermion pair at a small positive energy: numerically, at $t = 16$ the three lowest 0-form levels are 0, 4.6×10^{-3}, 27.9, and the 1-form sector has a matching level 4.6×10^{-3}. We will compute that small energy from tunnelling in Section 7.15.

7.12.6 Reversing the function and Poincaré duality

Replacing f by $-f$ swaps minima and maxima, and replaces the index λ of each critical point by $n - \lambda$. On the quantum side, the Hodge star swaps d_t with d^*_{-t}, up to sign.

Try it: the Hodge star intertwines H_t and H_{-t}

Using $\mathrm{d}^* = \pm \star \mathrm{d} \star$ and the fact that $\star$ commutes with multiplication by functions, show that $\star \mathrm{d}_t^* = \pm \mathrm{d}_{-t} \star$ and hence $\star \Delta_p(t) = \Delta_{n-p}(-t) \star$. Conclude that $\dim \operatorname{Ker} \Delta_p(t) = \dim \operatorname{Ker} \Delta_{n-p}(-t)$, i.e. $b_p = b_{n-p}$.
Answer. $\star \mathrm{d}_t^* = \star e^{tf} \mathrm{d}^* e^{-tf} = \pm e^{tf} \star \star \mathrm{d} \star e^{-tf} = \pm e^{tf} \mathrm{d} e^{-tf} \star = \pm \mathrm{d}_{-t} \star$ (using $\star\star = \pm 1$). Taking adjoints gives the companion relation, and $\Delta(t) = \mathrm{d}_t \mathrm{d}_t^* + \mathrm{d}_t^* \mathrm{d}_t$ goes over to $\mathrm{d}_{-t}^* \mathrm{d}_{-t} + \mathrm{d}_{-t} \mathrm{d}_{-t}^*$. This is Poincaré duality, seen by Witten's Hamiltonian. In the circle example it maps $e^{-t\cos\theta}$ to $e^{-t\cos\theta} \mathrm{d}\theta$, the 1-form zero mode for $-f$.

Reading Nash (p. 209, (7.71)–(7.75))

Nash introduces $\mathrm{d}_t = e^{-ft} \mathrm{d} e^{ft}$, states $\mathrm{d}_t^* = e^{ft} \mathrm{d}^* e^{-ft}$, defines $Q_1(t)$, $Q_2(t)$ and H_t, and says the algebra is unchanged "as a routine matter"; the routine is that $\mathrm{d}_t^2 = 0$ and d_t^* is its adjoint. His (7.75), $b_p = \dim \operatorname{Ker} \Delta_p(t)$, rests on the chain isomorphism (7.179) plus Hodge theory for d_t. "Coincide" should be read as "are isomorphic via e^{tf}". Nash writes e^{-ft} where we write e^{-tf}; it is the same thing.

Recap

- $\mathrm{d}_t = e^{-tf} \mathrm{d} e^{tf} = \mathrm{d} + t\, \mathrm{d}f\wedge$ and $\mathrm{d}_t^* = e^{tf} \mathrm{d}^* e^{-tf} = \mathrm{d}^* + t\, \iota_{\nabla f}$. Still $\mathrm{d}_t^2 = 0$, so the supersymmetry algebra holds for every t, with $H_t = \mathrm{d}_t \mathrm{d}_t^* + \mathrm{d}_t^* \mathrm{d}_t$.
- e^{tf} is a chain isomorphism, so $\dim \operatorname{Ker} \Delta_p(t) = b_p$ for all t; but e^{tf} is not unitary, so the positive spectrum moves.
- Exact zero modes e^{-tf} (degree 0) and $e^{tf}\,\mathrm{vol}$ (degree n) localise at the minimum and maximum of f, with width $t^{-1/2}$.
- On the line, d_t is supersymmetric quantum mechanics with superpotential $W = tf$.

7.13 The deformed Laplacian: a Schrödinger operator with spin

The deformation leaves the number of zero modes alone, but it changes the Hamiltonian. The question of this section is: *what does H_t look like as a differential operator?* The answer [Nash p. 210, (7.76)] is that it is the ordinary Laplacian plus a potential. The potential has a bosonic part $t^2 |\mathrm{d}f|^2$, which is large except at the critical points, and a "spin" part, linear in t, built from the Hessian of f and the fermion operators. Everything in the rest of the chapter is read off from this formula.

7.13.1 Expanding the product

Write $\varepsilon := \mathrm{d}f\wedge$ (exterior multiplication by $\mathrm{d}f$) and $\iota := \iota_{\nabla f}$ (its adjoint). Then $\mathrm{d}_t = \mathrm{d} + t\varepsilon$ and $\mathrm{d}_t^* = \mathrm{d}^* + t\iota$ by (7.172)–(7.174), and

$$\begin{aligned} H_t &\overset{(1)}{=} (\mathrm{d} + t\varepsilon)(\mathrm{d}^* + t\iota) + (\mathrm{d}^* + t\iota)(\mathrm{d} + t\varepsilon) \\ &\overset{(2)}{=} \big(\mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}\big) + t\big(\{\mathrm{d}, \iota\} + \{\varepsilon, \mathrm{d}^*\}\big) + t^2\{\varepsilon, \iota\} \\ &\overset{(3)}{=} \Delta + t\big(\mathcal{L}_{\nabla f} + \mathcal{L}_{\nabla f}^*\big) + t^2 |\mathrm{d}f|^2 . \end{aligned} \tag{7.182}$$

(1) Definition (7.176) with the explicit forms of d_t and d_t^*.

(2) Multiply out and group by powers of t. The expansion stops at t^2 because d_t is only linear in t.
(3) Three facts, derived below: Cartan's formula $\{\mathrm{d}, \iota_X\} = \mathcal{L}_X$; its adjoint $\{\varepsilon, \mathrm{d}^*\} = \{\iota, \mathrm{d}\}^* = \mathcal{L}_X^*$; and $\{\varepsilon, \iota\} = |\mathrm{d}f|^2$.

The t^2 term: a potential. In an orthonormal frame $\varepsilon = \partial_i f\, a^{i*}$ and $\iota = \partial_j f\, a^j$, so

$$\{\varepsilon, \iota\} \overset{(1)}{=} \partial_i f\, \partial_j f\, \{a^{i*}, a^j\} \overset{(2)}{=} \partial_i f\, \partial_j f\, \delta^{ij} = |\mathrm{d}f|^2 = g^{ij}\partial_i f\, \partial_j f.$$

(1) The coefficients are functions, which commute with the constant matrices a^{i*}, a^j; pull them out.
(2) Canonical anticommutation relations (7.165).

It is multiplication by a function, the same in every degree. This is Nash's $t^2 g^{ij}\, \partial_i f\, \partial_j f$, the "(grad f)^2" of (7.77).

The t term: first derivatives cancel. A priori $\{\mathrm{d}, \iota\}$ is a first-order differential operator: Cartan's formula $\mathrm{d}\iota_X + \iota_X \mathrm{d} = \mathcal{L}_X$ says it is the Lie derivative along the gradient flow, which differentiates. So is its adjoint. But the derivative parts cancel in the sum. On functions, where everything is explicit,

$$\begin{aligned}(\mathcal{L}_X + \mathcal{L}_X^*)\phi &\overset{(1)}{=} X^i\partial_i\phi - \frac{1}{\sqrt{g}}\partial_i\big(\sqrt{g}\, X^i\phi\big)\\ &\overset{(2)}{=} X^i\partial_i\phi - X^i\partial_i\phi - (\operatorname{div} X)\,\phi\\ &\overset{(3)}{=} -(\nabla^2 f)\,\phi.\end{aligned} \tag{7.183}$$

(1) $\mathcal{L}_X\phi = X(\phi)$; the adjoint of $X^i\partial_i$ for the measure $\sqrt{g}\,\mathrm{d}^n x$ is $-\frac{1}{\sqrt{g}}\partial_i\sqrt{g}X^i$ (integrate by parts).
(2) Product rule; $\operatorname{div} X = \frac{1}{\sqrt{g}}\partial_i(\sqrt{g}X^i)$.
(3) $X = \nabla f$, so $\operatorname{div} X = \nabla^2 f$, the ordinary Laplacian of f.

A pure multiplication operator: the derivatives cancelled. This is no accident. A first derivative $X^i\partial_i$ is anti-self-adjoint up to terms without derivatives (think of ∂_x, whose adjoint is $-\partial_x$), so adding it to its own adjoint always kills the derivative part. What survives is built from the first derivatives of X, and for $X = \nabla f$ these are the second derivatives of f.

In every degree the cleanest route is the fermion calculus. In flat space with Cartesian coordinates, using $\mathrm{d} = a^{k*}\partial_k$ and $\mathrm{d}^* = -a^k\partial_k$ from (7.166), and writing $f_j = \partial_j f$, $f_{kj} = \partial_k\partial_j f$:

$$\begin{aligned}\{\mathrm{d}, \iota\} &\overset{(1)}{=} a^{k*}\partial_k\big(f_j a^j\,\cdot\big) + f_j a^j\, a^{k*}\partial_k\\ &\overset{(2)}{=} f_{kj}\, a^{k*}a^j + f_j\big(a^{k*}a^j + a^j a^{k*}\big)\partial_k \overset{(3)}{=} f_{kj}\, a^{k*}a^j + f_k\,\partial_k,\\ \{\varepsilon, \mathrm{d}^*\} &\overset{(4)}{=} -f_i a^{i*}a^k\partial_k - a^k\partial_k\big(f_i a^{i*}\,\cdot\big)\\ &\overset{(5)}{=} -f_i\big(a^{i*}a^k + a^k a^{i*}\big)\partial_k - f_{ki}\, a^k a^{i*} \overset{(6)}{=} -f_k\,\partial_k - f_{kj}\, a^j a^{k*}.\end{aligned} \tag{7.184}$$

(1) Write out the anticommutator; the dot marks where the form being acted on goes.
(2) Product rule: ∂_k hits either the coefficient f_j (giving f_{kj}) or the form.
(3) $\{a^{k*}, a^j\} = \delta^{kj}$.
(4) The same for $\{\varepsilon, \mathrm{d}^*\}$ with $\mathrm{d}^* = -a^k\partial_k$.

(5) Product rule again.
(6) $\{a^{i*}, a^k\} = \delta^{ik}$, and rename $i \to j$ in the last term using $f_{kj} = f_{jk}$.

Adding, the first-derivative terms $\pm f_k \partial_k$ cancel, and

$$\{\mathrm{d}, \iota\} + \{\varepsilon, \mathrm{d}^*\} = f_{kj}\big(a^{k*}a^j - a^j a^{k*}\big) = \frac{\partial^2 f}{\partial x^k \partial x^j}\,\big[a^{k*}, a^j\big]. \tag{7.185}$$

On functions $[a^{k*}, a^j]1 = -a^j a^{k*}1 = -\delta^{jk}$, so this reproduces $-\nabla^2 f$, in agreement with (7.183). On a curved manifold the same computation, done in an orthonormal frame with covariant derivatives, replaces f_{kj} by the **covariant Hessian** $\nabla_k \nabla_j f = \partial_k \partial_j f - \Gamma^l_{kj} \partial_l f$, which Nash writes $D^2 f / Dx^k Dx^j$. (At a critical point the Christoffel term vanishes, so the covariant Hessian is the ordinary one of Chapter 7.)

Key idea: Witten's Hamiltonian, Nash (7.76)

$$H_t = \mathrm{d}_t \mathrm{d}_t^* + \mathrm{d}_t^* \mathrm{d}_t = \Delta \;+\; t^2\, g^{ij} \frac{\partial f}{\partial x^i}\frac{\partial f}{\partial x^j} \;+\; t\, \frac{D^2 f}{Dx^i Dx^j}\,\big[a^{i*}, a^j\big] \;\coloneqq\; \Delta + V. \tag{7.186}$$

It is a Schrödinger operator (Laplacian plus potential) acting on multi-component wavefunctions. The potential V is a matrix in the fermion indices: its t^2 part is a scalar, the same for every degree; its t part couples the Hessian of f to the fermions, like a spin–orbit or Zeeman term.

Watch out: H_t is not a conjugate of Δ

Nash's (7.76) begins "$H_t = \mathrm{d}_t \mathrm{d}_t^* + \mathrm{d}_t^* \mathrm{d}_t = e^{-ft}(\mathrm{dd}^* + \mathrm{d}^*\mathrm{d})e^{ft}$". The second equality is not correct as written. We have $\mathrm{d}_t \mathrm{d}_t^* = e^{-tf}\,\mathrm{d}\,e^{tf}\,e^{tf}\mathrm{d}^* e^{-tf} = e^{-tf}\,\mathrm{d}\,e^{2tf}\,\mathrm{d}^* e^{-tf}$: the two conjugations point in opposite directions, so the exponentials do not cancel in the middle. Were H_t a conjugate of Δ, it would have the same spectrum as Δ, and the whole method would be empty. The correct statement is that the complex (Ω^*, d_t) is conjugate to (Ω^*, d); the Laplacians are not. What *is* true is the rest of Nash's line, the explicit formula (7.186).

7.13.2 The same Hamiltonian in Clifford form

The derivation is shorter, and more illuminating, with the Clifford operators of (7.167): $c^i = a^{i*} - a^i$ and $\hat{c}^{\,i} = a^{i*} + a^i$, with $\{c^i, c^j\} = -2\delta^{ij}$, $\{\hat{c}^{\,i}, \hat{c}^{\,j}\} = 2\delta^{ij}$, $\{c^i, \hat{c}^{\,j}\} = 0$. The supercharge is

$$Q_1(t) \overset{(1)}{=} \big(a^{i*} - a^i\big)\partial_i + t\, f_i \big(a^{i*} + a^i\big) \overset{(2)}{=} c^i \partial_i + t\, f_i\, \hat{c}^{\,i}. \tag{7.187}$$

(1) $\mathrm{d}_t + \mathrm{d}_t^*$ with $\mathrm{d} = a^{i*}\partial_i$, $\mathrm{d}^* = -a^i \partial_i$, $\varepsilon = f_i a^{i*}$, $\iota = f_i a^i$.
(2) Definitions of c^i and $\hat{c}^{\,i}$.

So the undeformed part is a Dirac operator built with the c's, and the deformation is a "mass term" $t\,\mathrm{d}f$ built with the *other* Clifford algebra, the $\hat{c}$'s. Squaring:

$$\begin{aligned} Q_1(t)^2 &\overset{(1)}{=} \big(c^i \partial_i\big)^2 + t^2 \big(f_i \hat{c}^{\,i}\big)^2 + t\big\{c^i \partial_i,\; f_j \hat{c}^{\,j}\big\} \\ &\overset{(2)}{=} -\partial_i \partial_i + t^2 f_i f_i + t\big(c^i \hat{c}^{\,j} f_{ij} + f_j \{c^i, \hat{c}^{\,j}\}\partial_i\big) \\ &\overset{(3)}{=} \Delta + t^2\,|\mathrm{d}f|^2 + t\, f_{ij}\, c^i \hat{c}^{\,j}. \end{aligned} \tag{7.188}$$

(1) $(A + B)^2 = A^2 + B^2 + \{A, B\}$.

(2) $(c^i\partial_i)^2 = \frac{1}{2}\{c^i, c^j\}\partial_i\partial_j = -\partial_i\partial_i$ and $(f_i\hat{c}^{\,i})^2 = \frac{1}{2}\{\hat{c}^{\,i}, \hat{c}^{\,j}\}f_if_j = f_if_i$ (symmetric coefficients pick out the anticommutator). In the cross term, ∂_i either differentiates f_j or passes through, and $c^i\hat{c}^{\,j} + \hat{c}^{\,j}c^i = \{c^i, \hat{c}^{\,j}\}$.

(3) The two Clifford algebras anticommute, so the first-derivative term vanishes identically.

Here the cancellation of first derivatives is one line: *it is the anticommutation of c with $\hat{c}$*. To compare with (7.186), expand for a symmetric matrix f_{ij}:

$$f_{ij}\,c^i\hat{c}^{\,j} \overset{(1)}{=} f_{ij}\big(a^{i*}a^{j*} + a^{i*}a^j - a^ia^{j*} - a^ia^j\big) \overset{(2)}{=} f_{ij}\big(a^{i*}a^j - a^ja^{i*}\big) = f_{ij}\big[a^{i*}, a^j\big].$$

(1) Multiply out $(a^{i*} - a^i)(a^{j*} + a^j)$.

(2) $f_{ij}a^{i*}a^{j*} = 0$ and $f_{ij}a^ia^j = 0$ (symmetric times antisymmetric); in the third term swap the dummy labels $i \leftrightarrow j$.

The two forms agree.

Dictionary: the three ways to write the Hessian term

fermion form	$t\,f_{ij}\,[a^{i*}, a^j] = t\,f_{ij}\,(2a^{i*}a^j - \delta^{ij})$
Clifford form	$t\,f_{ij}\,c^i\hat{c}^{\,j}$
on p-forms, diagonal Hessian	$t\big(\sum_{i\in I}\lambda_i - \sum_{i\notin I}\lambda_i\big)$ on e^I
path integral	$t\,D_iD_jf\;\bar{\psi}^i\psi^j$ (Nash (7.88))

The first line uses $[a^{i*}, a^j] = 2a^{i*}a^j - \{a^j, a^{i*}\} = 2a^{i*}a^j - \delta^{ij}$. The third line follows from it: if $f_{ij} = \mathrm{diag}(\lambda_1, \dots, \lambda_n)$, then $a^{i*}a^i$ is 1 on a basis form $e^I = e^{i_1} \wedge \cdots \wedge e^{i_p}$ if $i \in I$ and 0 otherwise, so $\lambda_i(2a^{i*}a^i - 1)$ is $+\lambda_i$ or $-\lambda_i$.

Worked example 7.75: the Hessian term as a 4×4 matrix in the plane

In the basis $(1, \mathrm{d}x, \mathrm{d}y, \mathrm{d}x \wedge \mathrm{d}y)$ of Example 7.72, take a general symmetric Hessian $\left(\begin{smallmatrix} h_{11} & h_{12} \\ h_{12} & h_{22} \end{smallmatrix}\right)$. From $[a^{i*}, a^j] = 2a^{i*}a^j - \delta^{ij}$ and the matrices of that example, $a^{1*}a^1 = \mathrm{diag}(0,1,0,1)$, $a^{2*}a^2 = \mathrm{diag}(0,0,1,1)$, and $a^{1*}a^2$ sends $\mathrm{d}y \mapsto \mathrm{d}x$ (and kills everything else), $a^{2*}a^1$ sends $\mathrm{d}x \mapsto \mathrm{d}y$. Therefore

$$h_{ij}[a^{i*}, a^j] = \begin{pmatrix} -h_{11} - h_{22} & 0 & 0 & 0 \\ 0 & h_{11} - h_{22} & 2h_{12} & 0 \\ 0 & 2h_{12} & h_{22} - h_{11} & 0 \\ 0 & 0 & 0 & h_{11} + h_{22} \end{pmatrix}.$$

Read it degree by degree.

- On functions: $-\operatorname{tr} h = -\nabla^2 f$.
- On 1-forms: $2h - (\operatorname{tr} h)\mathbf{1}$. Its eigenvalues are $\pm(\lambda_1 - \lambda_2)$, where $\lambda_{1,2}$ are the eigenvalues of h.
- On 2-forms: $+\operatorname{tr} h$.

At a saddle, $\lambda_1 = -1$, $\lambda_2 = +1$ say, the four diagonal entries in an eigenbasis are $0, -2, +2, 0$: the most negative "spin energy" is found on the 1-form $\mathrm{d}x$ along the *downhill* direction. At a minimum ($\lambda_1 = \lambda_2 = 1$) the most negative entry, -2, is on the 0-form; at a maximum it is on the 2-form. This is the index appearing already, before we have solved anything.

Physical picture: Pauli Hamiltonian

In one dimension $c = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$ and $\hat{c} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ in the basis $(1, \mathrm{d}x)$, so $c\hat{c} = \mathrm{diag}(-1, 1) = -\sigma_z$ and

$$H_t = -\frac{\mathrm{d}^2}{\mathrm{d}x^2} + t^2 f'^2 - t f'' \, \sigma_z ,$$

which is (7.181). This is exactly the Pauli Hamiltonian of a spin-$\frac{1}{2}$ particle in a magnetic field $\propto f''$ along z: the spin-up component (0-forms) feels $-t f''$, the spin-down component (1-forms) feels $+t f''$. In n dimensions the "spin" is the 2^n-dimensional fermion Fock space and the "magnetic field" is the Hessian matrix.

7.13.3 Large t: the potential wins

Nash's next observation [Nash p. 210, (7.77)] is that for large t the potential is dominated by its t^2 part,

$$V \longrightarrow t^2 \left|\mathrm{grad}\, f\right|^2 . \tag{7.189}$$

Think of $H_t\psi = E\psi$ as a Schrödinger equation. Wherever $|\mathrm{d}f| \neq 0$, the potential energy is of order t^2, which is enormous. A state of moderate energy cannot afford to be there. The only places where V is not huge are the zeros of $\mathrm{d}f$, the critical points. So as $t \to \infty$ the low-energy eigenfunctions are forced to concentrate near the critical points of f.

Let us make "moderate" quantitative. Suppose f is Morse, and remove a small ball B_r of radius r around each critical point. Outside the balls $|\mathrm{d}f| \geq c > 0$ (a continuous nonvanishing function on a compact set is bounded below), and the Hessian term is bounded by $t\,C$ for some constant C. So outside the balls

$$V \;\geq\; t^2 c^2 - tC \;\xrightarrow{\;t\to\infty\;}\; \infty \quad \text{like } t^2 .$$

Inside a ball, near a critical point x_0, we have $\mathrm{d}f \approx h \cdot (x - x_0)$ and all three pieces of H_t are comparable once we zoom in by the right amount. Set $x - x_0 = y/\sqrt{t}$:

$$\begin{aligned} H_t &\overset{(1)}{=} -t\,\partial_y^2 + t^2\,\frac{(hy)^2}{t} + t\,h_{ij}[a^{i*}, a^j] + O(t^{1/2}) \\ &\overset{(2)}{=} t\Big(-\partial_y^2 + (hy)^2 + h_{ij}[a^{i*}, a^j]\Big) + O(t^{1/2}). \end{aligned} \tag{7.190}$$

(1) $\partial_x = \sqrt{t}\,\partial_y$ and $|\mathrm{d}f|^2 = |h(x - x_0)|^2 + O(|x - x_0|^3)$; the cubic correction becomes $t^2 \cdot t^{-3/2}\,|y|^3 = O(t^{1/2})$. The Hessian is evaluated at x_0 up to a correction of order $|x - x_0| \sim t^{-1/2}$, also giving $O(t^{1/2})$.

(2) Factor out t.

Key idea: the two scales of Witten's analysis

Near each critical point, H_t is t times a *fixed*, t-independent operator, the bracket in (7.190), plus corrections smaller by $t^{-1/2}$. That operator is a set of harmonic oscillators with spin (Section 7.14). So low-lying states have energies of order t (or smaller), and they live in balls of radius of order $t^{-1/2}$ around the critical points. Everything else costs order t^2.

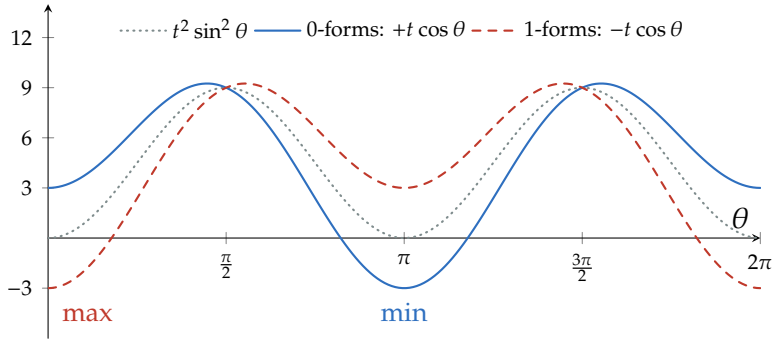

Figure 7.53: Witten's potential on the circle with $f = \cos\theta$, at $t = 3$. The common part $t^2\,|\mathrm{d}f|^2 = t^2\sin^2\theta$ (dotted) vanishes at both critical points. The Hessian term $\mp t f''$ lowers the 0-form potential (solid) at the minimum $\theta = \pi$, to $-t$, and raises it at the maximum. For 1-forms (dashed) it is the other way round. Each sector has a single deep well, at the critical point whose index is its degree; the $-t$ at the bottom is exactly what is needed to cancel the zero-point energy $+t$ of the oscillator there.

Worked example 7.76: the height function on the round S^2

Take the unit sphere and $f = z = \cos\theta$, with its minimum at the south pole and maximum at the north pole. We need $|\mathrm{d}f|^2$ and the covariant Hessian of z.

- $\mathrm{d}z = -\sin\theta\,\mathrm{d}\theta$ and $|\mathrm{d}\theta| = 1$ in the round metric $\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2$, so $|\mathrm{d}f|^2 = \sin^2\theta = 1 - z^2$.
- The coordinate functions restricted to the unit sphere satisfy $\nabla_i\nabla_j z = -z\,g_{ij}$. (Check at the north pole: in the tangent-plane coordinates $z = \sqrt{1-x^2-y^2} \approx 1 - \frac{1}{2}(x^2+y^2)$, so the Hessian is $-\mathbf{1} = -z\,g$ there. The general case follows by rotational symmetry, or from the Gauss formula for the second fundamental form of the sphere.)

Insert $h_{ij} = -z\,\delta_{ij}$ (orthonormal frame) into $h_{ij}[a^{i*}, a^j] = 2h_{ij}a^{i*}a^j - \operatorname{tr} h$:

$$t\,h_{ij}[a^{i*}, a^j] \overset{(1)}{=} t\left(-2z\,a^{i*}a^i + 2z\right) \overset{(2)}{=} 2tz\,(1-N),$$

(1) $h_{ij}a^{i*}a^j = -z\,a^{i*}a^i$ and $\operatorname{tr} h = -2z$ in two dimensions.
(2) $N = a^{i*}a^i$ is the degree.

So, degree by degree,

$$H_t\big|_{\Omega^0} = \Delta + t^2\sin^2\theta + 2t\cos\theta, \qquad H_t\big|_{\Omega^1} = \Delta + t^2\sin^2\theta, \qquad H_t\big|_{\Omega^2} = \Delta + t^2\sin^2\theta - 2t\cos\theta.$$

The 0-forms feel an extra $-2t$ at the south pole ($\cos\theta = -1$), the 2-forms an extra $-2t$ at the north pole, and the 1-forms nothing. Near the south pole the 0-form operator is a two-dimensional oscillator $-\nabla^2 + t^2\rho^2 - 2t$ (with $\rho = \pi - \theta$ small), whose zero-point energy $2\cdot t$ cancels the $-2t$ exactly. The exact zero modes of Section 7.12.4, $e^{-t\cos\theta}$ and $e^{t\cos\theta}\mathrm{vol}$, sit precisely there.

Worked example 7.77: the flat torus: two circles at once

On $T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$ take $f = \cos x + \cos y$. The metric is flat, so the covariant Hessian is

the ordinary one, $h = \operatorname{diag}(-\cos x, -\cos y)$, and $|\mathrm{d}f|^2 = \sin^2 x + \sin^2 y$. Then

$$H_t \overset{(1)}{=} \left(-\partial_x^2 + t^2 \sin^2 x - t \cos x\,[a^{1*}, a^1]\right) + \left(-\partial_y^2 + t^2 \sin^2 y - t \cos y\,[a^{2*}, a^2]\right)$$
$$\overset{(2)}{=} H_t^{(x)} \otimes \mathbf{1} + \mathbf{1} \otimes H_t^{(y)}.$$

(1) (7.186) with a diagonal, coordinate-separated Hessian.
(2) Forms on T^2 are tensor products of forms in x and forms in y ($\mathrm{d}x \wedge \mathrm{d}y = \mathrm{d}x \otimes \mathrm{d}y$), and each bracket acts on one factor only.

The Hamiltonian is the sum of two copies of the circle Hamiltonian of Example 7.73. Its eigenstates are products and its eigenvalues are sums. In particular its exact zero modes are the four products of the circle zero modes,

$$e^{-t\cos x} e^{-t\cos y}, \quad e^{t\cos x} e^{-t\cos y}\,\mathrm{d}x, \quad e^{-t\cos x} e^{t\cos y}\,\mathrm{d}y, \quad e^{t\cos x} e^{t\cos y}\,\mathrm{d}x \wedge \mathrm{d}y,$$

localised at the minimum (π, π), the two saddles $(0, \pi)$ and $(\pi, 0)$, and the maximum $(0, 0)$ respectively: $b = (1, 2, 1)$. This is the Künneth formula $H^*(T^2) = H^*(S^1) \otimes H^*(S^1)$ at the level of supersymmetric ground states.

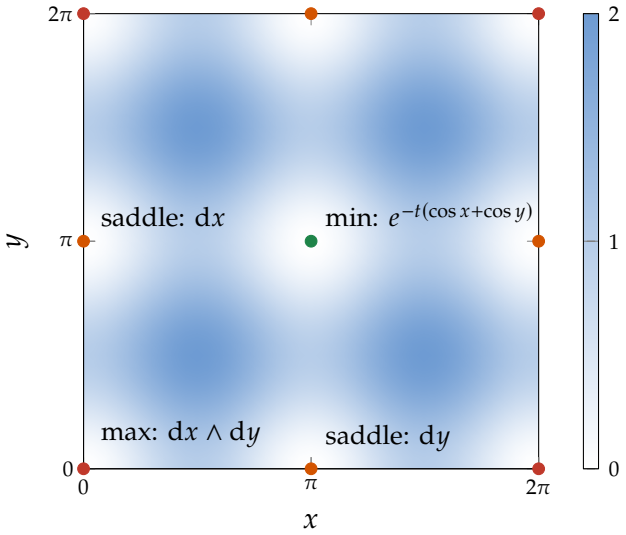

Figure 7.54: The bosonic potential $|\mathrm{d}f|^2 = \sin^2 x + \sin^2 y$ on the flat torus (the square with opposite edges identified; the four red corners are one point). It has four zeros, one per critical point of $f = \cos x + \cos y$: the maximum (red), two saddles (orange) and the minimum (green). At large t the potential $t^2\,|\mathrm{d}f|^2$ confines the low-lying states to these four wells, and the Hessian term selects the degree of the state in each well, which equals the index. Here the four states are exact zero modes, so $b = (1, 2, 1)$.

Reading Nash (p. 210, (7.76)–(7.77))

Nash states (7.186) with "the expansion terminates at the t^2 term" because $\mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$ is second order; more precisely, it terminates because d_t is linear in t. We derived every term: the t^2 term from the anticommutation relations, the t term from the product rule, and the disappearance of first derivatives from $\{c, \hat{c}\} = 0$. Nash writes $[a_i^*, a_j]$ with lower indices; in an orthonormal frame the position of indices does not matter. His remark that "this enormous growth of the potential energy ... will force the eigenfunctions of H_t to be zero"

away from critical points is the estimate $V \geq t^2c^2 - tC$ above.

Recap

- $H_t = \Delta + t^2\,|\mathrm{d}f|^2 + t\,\nabla_i\nabla_j f\,[a^{i*}, a^j]$: a Laplacian, a scalar potential, and a Hessian–fermion coupling.
- In Clifford form $Q_1(t) = c^i\nabla_i + t\,\partial_i f\,\hat{c}^{\,i}$, and $H_t = Q_1(t)^2 = \Delta + t^2\,|\mathrm{d}f|^2 + t\,f_{ij}c^i\hat{c}^{\,j}$; first derivatives cancel because $\{c^i, \hat{c}^{\,j}\} = 0$.
- On a basis form e^I, a diagonal Hessian contributes $t(\sum_{i\in I}\lambda_i - \sum_{i\notin I}\lambda_i)$: most negative when I is the set of downhill directions.
- Large t: states of energy $\ll t^2$ live within $t^{-1/2}$ of the critical points, where $H_t \approx t\times$(oscillators with spin).

7.14 Harmonic oscillators at the critical points: the weak Morse inequalities

At large t the low-lying states of H_t live in tiny balls around the critical points of f, and inside each ball H_t is t times a fixed operator (Section 7.13.3). The question of this section is: *what is the spectrum of that local operator, and in particular how many states of (almost) zero energy does each critical point contribute, and in which degree?* The answer [Nash pp. 210–211, (7.78)–(7.80)] is the heart of Witten's argument: *each critical point of index p supplies exactly one low-lying state, and it is a p-form.* Comparing with the exact count b_p of zero-energy p-forms gives the weak Morse inequalities $b_p \leq m_p$.

The only piece of physics needed is the harmonic oscillator. We first review it in the normalisation used here, then solve the local model, and then explain how the local answers are glued into a global statement.

7.14.1 The harmonic oscillator, by ladder operators

Our oscillators have the form

$$h_\omega = -\frac{\mathrm{d}^2}{\mathrm{d}x^2} + \omega^2x^2, \qquad \omega > 0. \tag{7.191}$$

This is $p^2 + \omega^2x^2$ with $p = -\mathrm{i}\,\mathrm{d}/\mathrm{d}x$: the usual $\frac{p^2}{2m} + \frac{1}{2}m\Omega^2x^2$ with $\hbar = 1$, $m = \frac{1}{2}$ and $\Omega = 2\omega$. So we expect levels spaced by $\hbar\Omega = 2\omega$. Let us derive them without remembering anything. Introduce the first-order operators

$$A = \frac{\mathrm{d}}{\mathrm{d}x} + \omega x, \qquad A^\dagger = -\frac{\mathrm{d}}{\mathrm{d}x} + \omega x.$$

They are the supercharge blocks of (7.150) with superpotential $W = \frac{1}{2}\omega x^2$. Acting on a test function φ,

$$\begin{aligned} A^\dagger A\,\varphi &\overset{(1)}{=} \Big(-\frac{\mathrm{d}}{\mathrm{d}x} + \omega x\Big)\big(\varphi' + \omega x\varphi\big) \\ &\overset{(2)}{=} -\varphi'' - \omega\varphi - \omega x\varphi' + \omega x\varphi' + \omega^2x^2\varphi = (h_\omega - \omega)\,\varphi, \\ AA^\dagger\,\varphi &\overset{(3)}{=} -\varphi'' + \omega\varphi + \omega^2x^2\varphi = (h_\omega + \omega)\,\varphi. \end{aligned} \tag{7.192}$$

(1) Definitions of A and $A^\dagger$.
(2) Product rule on $(\omega x\varphi)' = \omega\varphi + \omega x\varphi'$; the two first-derivative terms cancel.
(3) The same computation with the sign of $\mathrm{d}/\mathrm{d}x$ reversed in both factors; now the product rule gives $+\omega\varphi$.

Subtracting, $[A, A^\dagger] = 2\omega$, and

$$h_\omega = A^\dagger A + \omega, \qquad [h_\omega, A^\dagger] = 2\omega\, A^\dagger, \qquad [h_\omega, A] = -2\omega\, A. \tag{7.193}$$

(For the middle one: $[A^\dagger A, A^\dagger] = A^\dagger[A, A^\dagger] = 2\omega A^\dagger$.) So $A^\dagger$ raises the energy by 2ω and A lowers it by 2ω. Lowering cannot go on for ever, because $\langle\varphi, h_\omega\varphi\rangle = \|A\varphi\|^2 + \omega\,\|\varphi\|^2 \geq \omega\,\|\varphi\|^2$. The ladder must stop at a state with $A\varphi_0 = 0$, a first-order equation:

$$\varphi_0' + \omega x\varphi_0 = 0 \implies \varphi_0(x) = \left(\frac{\omega}{\pi}\right)^{1/4} e^{-\omega x^2/2}, \qquad h_\omega\varphi_0 = \omega\,\varphi_0. \tag{7.194}$$

The normalisation uses $\int_{-\infty}^{\infty} e^{-\omega x^2}\mathrm{d}x = \sqrt{\pi/\omega}$.

Key idea: the oscillator in one line

The spectrum of $h_\omega = -\mathrm{d}^2/\mathrm{d}x^2 + \omega^2 x^2$ is

$$\omega\,(2n+1), \qquad n = 0, 1, 2, \ldots, \tag{7.195}$$

each level non-degenerate, with eigenfunctions $\varphi_n \propto (A^\dagger)^n\varphi_0$. The ground state is a Gaussian of width $\langle x^2\rangle^{1/2} = (2\omega)^{-1/2}$. The *zero-point energy* ω is the price of confining a particle to that width.

For example $\varphi_1 \propto A^\dagger\varphi_0 = \left(-\frac{\mathrm{d}}{\mathrm{d}x} + \omega x\right)e^{-\omega x^2/2} = 2\omega x\, e^{-\omega x^2/2}$, the familiar odd first excited state, with energy 3ω. In n dimensions, $\sum_i\left(-\partial_i^2 + \omega_i^2 x_i^2\right)$ separates into n independent oscillators, with eigenvalues $\sum_i \omega_i(2n_i+1)$ and eigenfunctions $\prod_i \varphi_{n_i}(x_i)$.

7.14.2 Zooming in on one critical point

Fix a non-degenerate critical point x_0 of f, of index k. We want coordinates in which both the metric and f are as simple as possible.

- *The metric.* Riemann normal coordinates centred at x_0 give $g_{ij}(x) = \delta_{ij} + O(|x|^2)$ and $\Gamma^i_{jk}(0) = 0$ (the metric is "flat to second order", as Nash puts it [Nash p. 210]). Rotating these coordinates we may also diagonalise the Hessian at x_0, since a symmetric matrix can be diagonalised by an orthogonal change of basis.

- *The function.* Taylor's theorem then gives

$$f(x) = f(x_0) + \tfrac{1}{2}\left(\lambda_1 x_1^2 + \cdots + \lambda_n x_n^2\right) + O(|x|^3), \tag{7.196}$$

  where $\lambda_1, \ldots, \lambda_n$ are the eigenvalues of the Hessian, all nonzero. Exactly k of them are negative. We order them so that $\lambda_1, \ldots, \lambda_k < 0 < \lambda_{k+1}, \ldots, \lambda_n$.

Nash writes (7.196) with $\lambda_i = \mp 1$ [Nash p. 210, (7.78)] and remarks that the factor $\frac{1}{2}$ is "just chosen for convenience". That is the Morse lemma normal form (Section 7.9.2) rescaled by $\frac{1}{2}$.

Watch out: can we really have $\lambda_i = \pm 1$ *and* a flat metric?

The Morse lemma coordinates, in which f is *exactly* quadratic with coefficients $\pm\frac{1}{2}$, are in general not orthonormal for a given metric. With the metric fixed, the honest statement is (7.196) with arbitrary nonzero λ_i. There are two ways out, and both are fine. (i) Keep general λ_i; we do this below, and only their signs will matter. (ii) Use the freedom to choose the metric: the Betti numbers do not depend on it, so we may take g to be the Euclidean metric of the Morse coordinates near each critical point, glued to anything elsewhere. Then $\lambda_i = \pm 1$ exactly and the cubic remainder vanishes. This is what Nash's (7.78) implicitly does.

7.14.3 The local Hamiltonian separates

Now insert (7.196) into Witten's Hamiltonian (7.186), dropping everything that is small after the rescaling $x = y/\sqrt{t}$ of (7.190). To this order $\partial_i f = \lambda_i x_i$ (no sum), the covariant Hessian is $\operatorname{diag}(\lambda_1, \dots, \lambda_n)$, and the Laplacian is the flat one acting on each component of the form. So

$$\begin{aligned} \widetilde{H}_t &\overset{(1)}{=} -\sum_i \partial_i^2 + t^2 \sum_i (\lambda_i x_i)^2 + t \sum_{i,j} \lambda_i \delta_{ij} \, [a^{i*}, a^j] \\ &\overset{(2)}{=} \sum_{i=1}^{n} \Big\{ -\frac{\partial^2}{\partial x_i^2} + t^2 \lambda_i^2 x_i^2 + t \lambda_i \, [a^{i*}, a^i] \Big\} \;:=\; \sum_{i=1}^{n} h^{(i)}. \end{aligned} \tag{7.197}$$

(1) The three terms of (7.186): $\Delta = -\sum_i \partial_i^2$ on each component in flat Cartesian coordinates (Example 7.68), $g^{ij}\partial_i f \, \partial_j f = \sum_i \lambda_i^2 x_i^2$, and $D^2 f / Dx^i Dx^j = \lambda_i \delta_{ij}$.
(2) Collect the terms belonging to each coordinate direction.

This is Nash's (7.79) [Nash p. 211], with $\lambda_i^2 = 1$ there. It is a sum of n commuting pieces, one per direction. Each piece is a *supersymmetric harmonic oscillator* (Example 7.67) with frequency $\omega_i = t\,|\lambda_i|$: a bosonic oscillator in x_i plus a fermionic "spin" in mode i.

Why do the pieces commute? Different $h^{(i)}$ involve different coordinates, and their fermionic parts are the even operators $[a^{i*}, a^i]$, which commute with each other for different i (moving a pair of fermion operators past another pair produces two minus signs). Within a single $h^{(i)}$, the oscillator part acts only on the coefficient functions and the spin part only on the fermion index, so they commute too. That is Nash's remark that "the harmonic oscillator contribution to H_t commutes with the correction terms".

The spin part has eigenvalues ± 1. For one mode,

$$[a^{i*}, a^i] \overset{(1)}{=} a^{i*}a^i - a^i a^{i*} \overset{(2)}{=} a^{i*}a^i - \big(1 - a^{i*}a^i\big) = 2\, a^{i*}a^i - 1.$$

(1) Definition of the commutator.
(2) $\{a^i, a^{i*}\} = 1$ from (7.165).

The occupation number $a^{i*}a^i$ is 1 on a basis form $e^I = \mathrm{d}x^{i_1} \wedge \cdots \wedge \mathrm{d}x^{i_p}$ if $i \in I$ and 0 if $i \notin I$. So

$$[a^{i*}, a^i]\, e^I = \varepsilon_i \, e^I, \qquad \varepsilon_i = \begin{cases} +1 & i \in I \ (\mathrm{d}x^i \text{ present}), \\ -1 & i \notin I \ (\mathrm{d}x^i \text{ absent}). \end{cases} \tag{7.198}$$

These are Nash's $\varepsilon_i = \mp 1$ [Nash p. 211]: "the simple spectrum ∓ 1".

7.14.4 The spectrum and the unique zero mode

A complete set of eigenstates of (7.197) is

$$\Psi_{n,I} = \varphi_{n_1}(x_1)\cdots\varphi_{n_n}(x_n)\, e^I, \qquad n = (n_1,\dots,n_n)\in\mathbb{N}^n, \quad I\subseteq\{1,\dots,n\}, \tag{7.199}$$

where φ_{n_i} is the n_i-th eigenfunction of the oscillator with $\omega_i = t\,|\lambda_i|$. Each $h^{(i)}$ acts on $\Psi_{n,I}$ by a number, so

$$\begin{aligned}\widetilde{H}_t\,\Psi_{n,I} &\overset{(1)}{=} \sum_i \Big(t\,|\lambda_i|\,(2n_i+1) + t\lambda_i\varepsilon_i\Big)\Psi_{n,I}\\ &\overset{(2)}{=} t\sum_i \Big\{|\lambda_i|\,(1+2n_i) + \lambda_i\varepsilon_i\Big\}\Psi_{n,I}.\end{aligned} \tag{7.200}$$

(1) The oscillator part of $h^{(i)}$ gives $\omega_i(2n_i+1)$ by (7.195); the spin part gives $t\lambda_i\varepsilon_i$ by (7.198).
(2) Factor out t. With $|\lambda_i| = 1$ this is Nash's (7.80), $t\sum_i\{(1+2n_i)+\lambda_i\varepsilon_i\}$.

The degree of $\Psi_{n,I}$ is $p = |I|$, the number of ε_i equal to $+1$. To find the zero eigenvalues in degree p, look at one term of the sum at a time:

$$|\lambda_i|\,(1+2n_i) + \lambda_i\varepsilon_i \overset{(1)}{\geq} |\lambda_i| + \lambda_i\varepsilon_i \overset{(2)}{\geq} |\lambda_i| - |\lambda_i| = 0. \tag{7.201}$$

(1) $n_i \geq 0$, with equality only for $n_i = 0$.
(2) $\lambda_i\varepsilon_i = \pm|\lambda_i|$, with the minus sign exactly when $\varepsilon_i = -\operatorname{sgn}\lambda_i$.

Every term is non-negative, so the total vanishes only if every term does, i.e. only if for every i

$$n_i = 0 \qquad\text{and}\qquad \varepsilon_i = \begin{cases} +1 & \text{if } \lambda_i < 0 \text{ (downhill direction)},\\ -1 & \text{if } \lambda_i > 0 \text{ (uphill direction)}.\end{cases}$$

This fixes n and I completely: $I = \{1,\dots,k\}$, the set of downhill directions, of size k = index.

Key idea: one zero mode per critical point, in degree = index

The local Hamiltonian (7.197) at a critical point of index k has exactly one state of zero energy,

$$\Psi_0 = \prod_{i=1}^n \Big(\frac{t\,|\lambda_i|}{\pi}\Big)^{1/4} \exp\Big(-\frac{t}{2}\sum_{i=1}^n |\lambda_i|\,x_i^2\Big)\,\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^k, \tag{7.202}$$

a Gaussian of width $\sim t^{-1/2}$ times the wedge of the downhill directions. It is a k-form. Every other state has energy at least $2t\,\min_i|\lambda_i|$.

The gap statement follows from (7.201): to move away from the zero mode we must either raise some n_i to 1 (cost $2t\,|\lambda_i|$) or flip some ε_i (cost $2t\,|\lambda_i|$ as well).

A direct check. The zero mode must be annihilated by both supercharges of the local model, $\mathrm{d}_t = \mathrm{d} + t\,\mathrm{d}f\wedge$ and $\mathrm{d}_t^* = \mathrm{d}^* + t\,\iota_{\nabla f}$. Write $\Psi_0 = G\,\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^k$ with $G = \exp(-\frac{t}{2}\sum_j|\lambda_j|\,x_j^2)$, so $\partial_j G = -t\,|\lambda_j|\,x_j G$, and $\partial_j f = \lambda_j x_j$. Then

$$\mathrm{d}_t\Psi_0 \overset{(1)}{=} \sum_{j>k}\big(\partial_j G + t\lambda_j x_j G\big)\,\mathrm{d}x^j\wedge\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^k \overset{(2)}{=} \sum_{j>k}\big(-t\lambda_j x_j + t\lambda_j x_j\big)G\,(\cdots) = 0,$$

$$\mathrm{d}_t^*\Psi_0 \overset{(3)}{=} \sum_{j\leq k}\big(-\partial_j G + t\lambda_j x_j G\big)\,\iota_{\partial_j}\big(\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^k\big) \overset{(4)}{=} \sum_{j\leq k}\big(t\,|\lambda_j| + t\lambda_j\big)x_j G\,(\cdots) = 0.$$

(1) $\mathrm{d}(G\,e^I) = \partial_j G\,\mathrm{d}x^j \wedge e^I$ and $t\,\mathrm{d}f \wedge e^I = t\lambda_j x_j\,\mathrm{d}x^j \wedge e^I$; the terms with $j \le k$ vanish because $\mathrm{d}x^j$ already appears in e^I.
(2) For $j > k$ (uphill), $|\lambda_j| = \lambda_j$, so $\partial_j G = -t\lambda_j x_j G$ cancels the second term.
(3) $\mathrm{d}^* = -\sum_j a^j \partial_j$ from (7.166) and $\iota_{\nabla f} = \sum_j \lambda_j x_j\, a^j$; only $j \le k$ survive, because ι_{∂_j} kills e^I when $\mathrm{d}x^j$ is absent.
(4) For $j \le k$ (downhill), $|\lambda_j| = -\lambda_j$, so the bracket vanishes.

Two first-order equations, both solved. Notice what the Gaussian is: along the uphill directions it is $e^{-t(f-f(x_0))}$, the local version of the 0-form zero mode e^{-tf}; along the downhill directions it is $e^{+t(f-f(x_0))}$ times $\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^k$, the local version of the top-form zero mode $e^{tf}\,\mathrm{vol}$ of Section 7.12.4. Near a critical point of index k, M looks like $\mathbb{R}^k_{\text{down}} \times \mathbb{R}^{n-k}_{\text{up}}$, and the zero mode is the product of the "top form on the first factor" and the "function on the second".

Worked example 7.78: one dimension: a minimum and a maximum

Take $n = 1$ and $f = f(x_0) + \frac{1}{2}\lambda x^2$. The two sectors are $\varepsilon = -1$ (0-forms) and $\varepsilon = +1$ (1-forms). From (7.200):

	0-forms ($\varepsilon = -1$)	1-forms ($\varepsilon = +1$)
minimum, $\lambda > 0$	$t\lambda(2n+1) - t\lambda = 2t\lambda\, n$	$t\lambda(2n+1) + t\lambda = 2t\lambda(n+1)$
maximum, $\lambda < 0$	$t\,\lvert\lambda\rvert\,(2n+1) + t\,\lvert\lambda\rvert = 2t\,\lvert\lambda\rvert\,(n+1)$	$2t\,\lvert\lambda\rvert\; n$

At a minimum the 0-forms have the levels $0, 2t\lambda, 4t\lambda, \ldots$ and the 1-forms $2t\lambda, 4t\lambda, \ldots$: exactly the supersymmetric oscillator of Example 7.67 with $\omega = t\lambda$, whose superpotential is $W = tf$ as in (7.180). The unique zero mode is the 0-form $e^{-t\lambda x^2/2}$. At a maximum the roles are swapped, and the zero mode is the 1-form $e^{-t|\lambda|x^2/2}\mathrm{d}x$. In the language of Figure 7.53: the deep well of the 0-form potential is at the minimum, that of the 1-form potential at the maximum, and in each well the "spin" energy $-t\,|\lambda|$ cancels the zero-point energy $+t\,|\lambda|$.

Worked example 7.79: two dimensions: minimum, saddle, maximum

Take $n = 2$ and $|\lambda_1| = |\lambda_2| = 1$. The four fermion states are $1, \mathrm{d}x, \mathrm{d}y, \mathrm{d}x \wedge \mathrm{d}y$ with $(\varepsilon_1, \varepsilon_2) = (-,-), (+,-), (-,+), (+,+)$. The term $\sum_i \lambda_i \varepsilon_i$ shifts the oscillator energy $t(2 + 2n_1 + 2n_2)$. The shifts, in units of t:

	1	$\mathrm{d}x$	$\mathrm{d}y$	$\mathrm{d}x \wedge \mathrm{d}y$
minimum $(\lambda_1, \lambda_2) = (+1, +1)$, index 0	-2	0	0	$+2$
saddle $(\lambda_1, \lambda_2) = (-1, +1)$, index 1	0	-2	$+2$	0
maximum $(\lambda_1, \lambda_2) = (-1, -1)$, index 2	$+2$	0	0	-2

The lowest level in each sector is $t(2 + \text{shift})$: zero only for the entry -2, and that entry sits in degree 0, 1, 2 respectively. The saddle's zero mode is $e^{-t(x^2+y^2)/2}\,\mathrm{d}x$: a 1-form pointing along the downhill direction x. We met exactly these numbers as the diagonal of the 4×4 Hessian matrix in Example 7.75. The full low-lying spectrum is drawn in Figure 7.55; at every level above zero, bosons (1, $\mathrm{d}x \wedge \mathrm{d}y$) and fermions ($\mathrm{d}x$, $\mathrm{d}y$) are equal in number, as supersymmetry requires.

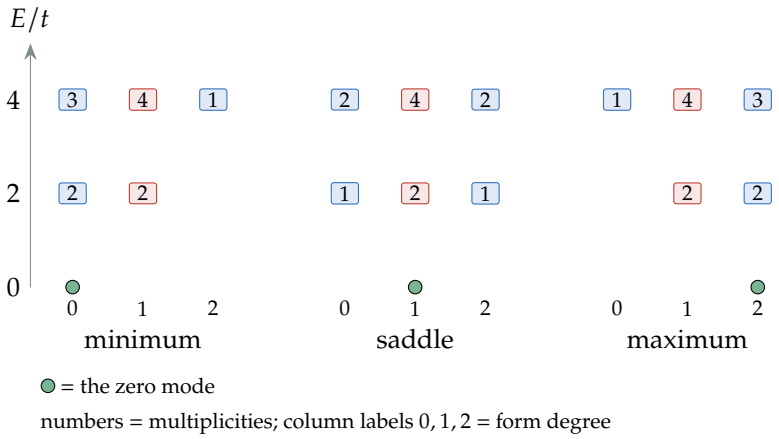

Figure 7.55: Spectrum of the local model $\widetilde{H}_t$ at the three kinds of non-degenerate critical point in two dimensions ($|\lambda_i| = 1$), up to $E = 4t$, sorted by form degree. Blue boxes are bosons (even forms), red boxes fermions (odd forms). Each critical point has a single zero-energy state (green dot), in degree equal to its index; everything else is at least $2t$ above it, and every positive level is boson–fermion balanced.

Worked example 7.80: general eigenvalues, and the round sphere

With general λ_i, the levels near a critical point are $t\sum_i\{|\lambda_i|\,(1+2n_i)+\lambda_i\varepsilon_i\}$. For the height function $f=\cos\theta$ on the unit S^2 at the south pole, $f=-1+\frac{1}{2}\rho^2+O(\rho^4)$ in geodesic polar coordinates, so $\lambda_1=\lambda_2=+1$; at the north pole $\lambda_1=\lambda_2=-1$. The local zero modes are

$$\Psi_{\mathrm{S}}=\sqrt{\tfrac{t}{\pi}}\,e^{-t\rho^2/2},\qquad \Psi_{\mathrm{N}}=\sqrt{\tfrac{t}{\pi}}\,e^{-t\rho'^2/2}\,\mathrm{vol},$$

with ρ, ρ' the geodesic distances from the two poles. Compare the *exact* zero modes $e^{-t\cos\theta}$ and $e^{t\cos\theta}\mathrm{vol}$ of Example 7.76: near the south pole $e^{-t\cos\theta}=e^{t}e^{-t(1-\cos\rho)}\approx e^{t}e^{-t\rho^2/2}$, the same Gaussian up to normalisation. For the sphere the local approximation is therefore accurate: both local zero modes survive as exact ones, matching $b_0=b_2=1$, $b_1=0$. The first excited states at each pole are at $2t$, confirming the gap $2t\min|\lambda_i|$.

7.14.5 From local to global: the weak Morse inequalities

We now have one approximate zero mode per critical point, in degree equal to the index. How do we turn this into a statement about the global operator $\Delta_p(t)$ on M? Define the counting function

$$N_p(t;E):=\#\{\text{eigenvalues of }\Delta_p(t)\text{ in }[0,E]\},\tag{7.203}$$

counted with multiplicity. The precise claim, due to Witten and proved by Simon and by Helffer and Sjöstrand, is:

Key idea: the low-lying spectrum at large t

Fix any constant c with $0<c<2\min|\lambda|$ (the minimum over all Hessian eigenvalues at all critical points). Then for all sufficiently large t,

$$N_p(t;\,ct)=m_p=\#\{\text{critical points of index }p\}.\tag{7.204}$$

In words: at large t the spectrum of $\Delta_p(t)$ splits into m_p **low-lying** eigenvalues that are $o(t)$ and the rest, which are at least of order t. The low-lying eigenfunctions are close to the

local zero modes (7.202), one at each critical point of index p.

The physicist believes this at once: the potential confines the particle to the wells, each well is an oscillator, and the oscillator levels are what we computed. It is worth seeing how the two halves of (7.204) are actually established, because the tools are standard quantum mechanics.

The min–max principle. For a self-adjoint $H \geq 0$ with discrete spectrum $E_1 \leq E_2 \leq \dots$, the k-th eigenvalue is

$$E_k = \min_{\dim V = k} \; \max_{\psi \in V,\, \psi \neq 0} \frac{\langle \psi, H\psi \rangle}{\langle \psi, \psi \rangle}.$$

Two consequences are all we need.

(a) If there is a k-dimensional space of trial states on which the Rayleigh quotient is $\leq E$, then H has at least k eigenvalues $\leq E$.

(b) If $\langle \psi, H\psi \rangle \geq E \, \|\psi\|^2$ for every ψ orthogonal to some k-dimensional space, then H has at most k eigenvalues $< E$.

(For a 2×2 matrix, (a) says that if some vector has Rayleigh quotient $\leq E$ then the smaller eigenvalue is $\leq E$; (b) says that if the quotient is $\geq E$ on the orthogonal complement of one vector, then the larger eigenvalue is $\geq E$.)

At least m_p (trial states). For each critical point x_0 of index p take the local zero mode (7.202), written in normal coordinates around x_0, and multiply it by a smooth cut-off function J equal to 1 in a ball of radius r and 0 outside radius $2r$. The m_p trial states have disjoint supports, so they are orthogonal and H_t, a differential operator, has no matrix elements between them. The Rayleigh quotient of any combination is therefore at most the largest of the individual quotients. Each individual quotient is small: the local zero mode has $\widetilde{H}_t$-energy zero, and the errors come from (i) the cut-off, which only acts where the Gaussian is $e^{-t|\lambda| r^2/2}$, exponentially small, and (ii) the difference $H_t - \widetilde{H}_t$, which on a Gaussian of width $t^{-1/2}$ is $o(t)$ by the scaling (7.190). So by (a), $N_p(t; ct) \geq m_p$ for large t.

At most m_p (localisation). Choose a partition of unity $\sum_k J_k^2 = 1$ on M: one function J_{x_0} supported in a ball $B_{2r}(x_0)$ around each critical point, and one function J_∞ supported away from all critical points. For a Schrödinger operator $H = -\nabla^2 + V$ there is an exact identity (the **IMS localisation formula**)

$$H = \sum_k J_k \, H \, J_k - \sum_k |\nabla J_k|^2 . \tag{7.205}$$

It is proved by expanding a double commutator:

$$\sum_k J_k H J_k \overset{(1)}{=} \sum_k \Big(\tfrac{1}{2}\big(J_k^2 H + H J_k^2\big) - \tfrac{1}{2}\big[J_k, [J_k, H]\big] \Big)$$
$$\overset{(2)}{=} H - \tfrac{1}{2} \sum_k \big[J_k, [J_k, -\nabla^2]\big] \overset{(3)}{=} H + \sum_k |\nabla J_k|^2 .$$

(1) Expand $[J,[J,H]] = J^2 H - 2JHJ + HJ^2$ and solve for JHJ.
(2) $\sum_k J_k^2 = 1$; the potential (a multiplication operator, even a matrix one) commutes with J_k and drops out of the commutator.
(3) $[J, -\nabla^2]\varphi = (\nabla^2 J)\varphi + 2\nabla J \cdot \nabla \varphi$, and commuting once more with J leaves $-2\,|\nabla J|^2\,\varphi$.

Now estimate each piece of (7.205) with $r = t^{-2/5}$ (small, but much larger than the width $t^{-1/2}$ of the Gaussians):

- The localisation error $|\nabla J_k|^2 \sim r^{-2} = t^{4/5}$ is $o(t)$.
- On the support of J_∞, $|\mathrm{d}f| \gtrsim r$, so $V \geq t^2 r^2 c_1 - tC = c_1 t^{6/5} - tC$, which is $\gg t$.
- Inside $B_{2r}(x_0)$, H_t differs from the local model $\widetilde{H}_t$ by terms of size at most $t^2 r^3 + tr = O(t^{4/5})$, again $o(t)$. And $\widetilde{H}_t$ is $\geq 2t \min|\lambda|$ on the orthogonal complement of its single zero mode, in the one degree where it has a zero mode, and $\geq 2t \min|\lambda|$ everywhere in the other degrees.

Putting these into (7.205): on p-forms orthogonal to the m_p cut-off local zero modes, $\langle \psi, H_t \psi \rangle \geq (2 \min|\lambda| \; t - o(t)) \, \|\psi\|^2$. By (b), $N_p(t; ct) \leq m_p$ for large t. Together with the first half this is (7.204).

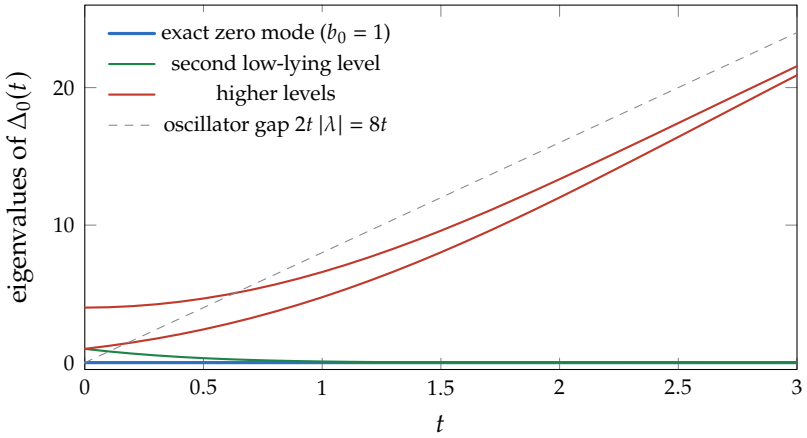

Figure 7.56: The lowest eigenvalues of $\Delta_0(t)$ on the circle for $f = -\cos 2\theta$ (two minima, two maxima, $|\lambda| = 4$), computed numerically in a Fourier basis. At $t = 0$ they are the free levels $0, 1, 1, 4, 4$. As t grows, exactly $m_0 = 2$ levels stay low: the exact zero mode (blue) and a second level (green) that falls to zero exponentially fast. All other levels (red; the upper curve is doubly degenerate) climb with slope close to the oscillator gap $8t$ (dashed). The weak inequality $b_0 = 1 \leq m_0 = 2$ is visible directly; the green level is lifted from zero only by tunnelling (Section 7.15).

Key idea: the weak Morse inequalities, Nash p. 211

For every p,

$$b_p \overset{(1)}{=} \dim \operatorname{Ker} \Delta_p(t) \overset{(2)}{\leq} N_p(t;\, ct) \overset{(3)}{=} m_p. \tag{7.206}$$

(1) Nash's (7.75), (7.177): the number of exact zero modes does not depend on t.
(2) An exact zero mode is in particular an eigenvalue in $[0, ct]$.
(3) (7.204), for t large enough.

Nash's comment is exact: "if our approximation were exact we would know that the number of these zero p-forms is equal to the Betti number b_p. Taking into account the approximation means that some of the zero p forms may disappear in an exact calculation." The inequality in step (2) is where information is lost: the m_p low-lying states include the b_p exact zero modes and possibly some others, at energies that are small but not zero.

7.14.6 The Euler characteristic comes for free

Supersymmetry adds one more piece of information. The low-lying levels that are *not* exactly zero come in boson–fermion pairs, like every positive level (Section 7.10.6). The pairing is done by $Q_1(t)$, which commutes with H_t and changes the degree by one, so it maps the low-lying space into itself. Hence

$$\begin{aligned}\sum_p (-1)^p m_p &\overset{(1)}{=} \sum_p (-1)^p N_p(t;ct)\\ &\overset{(2)}{=} \sum_p (-1)^p \dim\operatorname{Ker}\Delta_p(t) + \sum_{0<E\le ct}\big(n_B(E)-n_F(E)\big)\\ &\overset{(3)}{=} \sum_p (-1)^p b_p = \chi(M).\end{aligned} \tag{7.207}$$

(1) (7.204).
(2) Split the low-lying levels into $E = 0$ and $E > 0$; even degrees are bosons, odd degrees fermions.
(3) The pairing argument kills every $E > 0$ term; the $E = 0$ term is the Witten index (7.163).

This is the Morse-theoretic formula $\chi(M) = \sum_p (-1)^p m_p$ of Chapter 7, now obtained as a statement about ground states: the Witten index computed exactly (Hodge theory) equals the Witten index computed semiclassically (one state per critical point, with sign $(-1)^{\text{index}}$). Physically, $(-1)^{\text{index}}$ is the fermion number parity of the perturbative vacuum at that critical point. For a gradient vector field ∇f it is also the local index of the zero of the vector field, so (7.207) is the Poincaré–Hopf theorem for gradient fields.

Worked example 7.81: counting on familiar examples

The weak inequalities, and the Euler characteristic check, on the examples of this chapter:

M	f	(m_0, m_1, m_2)	(b_0, b_1, b_2)	$\sum(-1)^p m_p = \chi$
S^1	$\cos\theta$	$(1,1)$	$(1,1)$	0
S^1	$-\cos 2\theta$	$(2,2)$	$(1,1)$	0
S^2	height z	$(1,0,1)$	$(1,0,1)$	2
S^2	two-humped height	$(1,1,2)$	$(1,0,1)$	2
T^2	$\cos x + \cos y$	$(1,2,1)$	$(1,2,1)$	0
T^2	upright height	$(1,2,1)$	$(1,2,1)$	0
$\mathbb{RP}^2$	$\frac{x^2+2y^2+3z^2}{x^2+y^2+z^2}$	$(1,1,1)$	$(1,0,0)$	1

When $m_p = b_p$ for all p (a **perfect** Morse function), all the local zero modes must survive as exact zero modes: there is nothing for tunnelling to do. When $m_p > b_p$, some low-lying states must be lifted. On S^1 with $-\cos 2\theta$ one bosonic and one fermionic state are lifted, together; on the two-humped sphere a 1-form and a 2-form. In each case $m_p - b_p$ summed with alternating signs is zero, as (7.207) requires. For $\mathbb{RP}^2$ we use real coefficients, $b = (1,0,0)$; the lifted pairs are in degrees $(1,2)$. We return to $\mathbb{RP}^2$ with integer coefficients in Section 7.16.

Watch out: perturbation theory cannot see the lifting

On the line with the double well $f = \frac{1}{4}(x^2-1)^2$ (Example 7.74) the local analysis gives three approximate zero modes: 0-forms at $x = \pm 1$ and a 1-form at $x = 0$. Only one exact zero mode exists. The other two sit at an energy of about 5×10^{-3} at $t = 16$, which is $\sim e^{-t/2}$. This is smaller than any power of $1/t$, so no order of perturbation theory around the wells can produce it: the anharmonic corrections are power series in $t^{-1/2}$ and never lift a supersymmetric zero mode. The lifting is *non-perturbative*. It comes from tunnelling, and it needs a different tool, the instanton.

Physical picture: why tunnelling must pair a p-state with a $(p+1)$-state

A single approximate zero mode cannot be lifted on its own: positive-energy states come in pairs related by d_t or d_t^*, which change the degree by exactly one. So lifting always takes one low-lying state of degree p and one of degree $p+1$ together, located at critical points whose indices differ by one. The amplitude for this involves the matrix element $\langle b|\mathrm{d}_t|a\rangle$ between the two local states, and that is a tunnelling amplitude from one critical point to the other. The next two sections compute it.

Reading Nash (pp. 210–211, (7.78)–(7.80))

Nash expands the metric "to make it flat to order two in the coordinates" and writes f in the form (7.78) with $\lambda_i = \mp 1$. His (7.79) is our (7.197) and his (7.80), $t\sum_i\{(1+2n_i)+\lambda_i\varepsilon_i\}$, is (7.200). He then argues exactly as we did in (7.201): a zero eigenvalue needs all $n_i = 0$ and "$\varepsilon_i = +1$ precisely when $\lambda_i = -1$", giving "a single zero eigenvalue corresponding to a p-form where p is the index of the critical point". His conclusion $b_p \le m_p$ is (7.206); the passage from the local oscillators to the global spectrum, which he leaves implicit, is Section 7.14.5. Nash ends with "this is as far as one gets with the present asymptotic analysis in t"; the strong inequalities need the complex and the tunnelling of the next two sections.

Recap

- $h_\omega = -\partial_x^2 + \omega^2 x^2$ has levels $\omega(2n+1)$ and Gaussian ground state $e^{-\omega x^2/2}$ of width $\sim \omega^{-1/2}$.
- Near a critical point with Hessian eigenvalues λ_i, $H_t \approx \sum_i\{-\partial_i^2 + t^2\lambda_i^2 x_i^2 + t\lambda_i[a^{i*}, a^i]\}$, with spectrum $t\sum_i\{|\lambda_i|\,(1+2n_i)+\lambda_i\varepsilon_i\}$.
- The unique zero mode is a Gaussian times the wedge of the downhill directions: degree = index. The gap above it is $2t\min|\lambda|$.
- Globally, $\Delta_p(t)$ has exactly m_p eigenvalues below ct at large t (trial states for $\ge$, IMS localisation for $\le$). Hence $b_p \le m_p$, and supersymmetric pairing gives $\sum(-1)^p m_p = \chi(M)$.
- The discrepancy $m_p - b_p$ is due to non-perturbative tunnelling, which lifts states in pairs of adjacent degree.

7.15 Instantons: tunnelling between critical points

The harmonic-oscillator analysis gave us m_p low-lying p-forms, one per critical point of index p. Only b_p of them are true zero modes. The others have been pushed up to small positive energies, by an amount that no order of perturbation theory can see (Section 7.14.6). The question of this section is: *what pushes them up, and by how much?*

The answer is quantum tunnelling. A particle sitting at one critical point can leak through the potential barrier $t^2\,|\nabla f|^2$ to a neighbouring critical point. The amplitude for this is exponentially small in t, and we will compute it twice: first by a direct and elementary calculation in one dimension, then by Witten's route, the Euclidean path integral, where the tunnelling paths turn out to be the gradient flow lines of f [Nash pp. 212–214, (7.83), (7.87)–(7.93)]. The second route is the one that generalises, and it is the physical origin of the Morse–Witten differential of Section 7.16.

7.15.1 What has to be computed

d_t preserves energy. The deformed exterior derivative commutes with the Hamiltonian:

$$H_t\,\mathrm{d}_t \overset{(1)}{=} \big(\mathrm{d}_t\mathrm{d}_t^* + \mathrm{d}_t^*\mathrm{d}_t\big)\mathrm{d}_t \overset{(2)}{=} \mathrm{d}_t\mathrm{d}_t^*\mathrm{d}_t \overset{(3)}{=} \mathrm{d}_t\big(\mathrm{d}_t^*\mathrm{d}_t + \mathrm{d}_t\mathrm{d}_t^*\big) = \mathrm{d}_t\,H_t. \tag{7.208}$$

(1) Definition (7.176) of H_t.
(2) $\mathrm{d}_t^2 = 0$ kills the second term.
(3) Add $\mathrm{d}_t\mathrm{d}_t\mathrm{d}_t^* = 0$, again because $\mathrm{d}_t^2 = 0$.

So if $H_t\psi = E\psi$ then $H_t(\mathrm{d}_t\psi) = E\,(\mathrm{d}_t\psi)$: d_t maps each eigenspace of H_t into itself, raising the degree by one. In particular it maps the **low-lying space**

$$V_p := \mathrm{span}\{\text{eigenforms of } \Delta_p(t) \text{ with eigenvalue} \le ct\}, \qquad \dim V_p = m_p, \tag{7.209}$$

of (7.204) into V_{p+1}. The whole question of which low-lying states are lifted is therefore a question about a *finite* matrix: the matrix of $\mathrm{d}_t : V_p \to V_{p+1}$.

The matrix elements. To leading order, V_p is spanned by the local zero modes $|a\rangle$ of (7.202), one for each critical point a of index p. So we need

$$\langle b|\,\mathrm{d}_t\,|a\rangle, \qquad \mathrm{index}(a) = p, \quad \mathrm{index}(b) = p+1, \tag{7.210}$$

which is Nash's (7.87) [Nash p. 213]. Only critical points whose indices differ by exactly one can appear: $|a\rangle$ is a p-form, $\mathrm{d}_t|a\rangle$ is a $(p+1)$-form, and it can only overlap with local states of degree $p+1$.

Once we know these numbers, the lifted energies follow. Write D_p for the $m_{p+1}\times m_p$ matrix $\langle b|\mathrm{d}_t|a\rangle$. On V_p the Hamiltonian is $H_t = \mathrm{d}_t^*\mathrm{d}_t + \mathrm{d}_t\mathrm{d}_t^*$, so in the (approximately orthonormal) basis of local states

$$H_t\big|_{V_p} \approx D_p^{\mathsf{T}}D_p + D_{p-1}D_{p-1}^{\mathsf{T}}. \tag{7.211}$$

The small eigenvalues are the eigenvalues of this matrix.

Why perturbation theory gives zero. Each local state is a Gaussian of width $t^{-1/2}$ centred on its critical point. d_t is a differential operator, so it does not move a wavefunction anywhere: $\mathrm{d}_t|a\rangle$ is concentrated where $|a\rangle$ is. The overlap $\langle b|\mathrm{d}_t|a\rangle$ therefore comes entirely from the *tails* of the two wavefunctions, far from both critical points. Tails of Gaussians are exponentially

small, so the answer is of the form $e^{-t\,(\text{something})}$, and every power series in $1/t$ misses it. This is exactly the structure of the tunnelling splitting in a double-well potential, which is the standard example of a non-perturbative effect in quantum mechanics.

Physical picture: tunnelling lifts would-be ground states

Think of the symmetric double well of elementary quantum mechanics. Each well alone has a ground state. Tunnelling mixes the two, and the combinations (even and odd) are split by $\Delta E \propto e^{-S_0/\hbar}$, where S_0 is the action of the classical path through the inverted potential. Witten's situation is the same, with one twist: supersymmetry forces the lower of the two combinations to stay at *exactly* zero when it is a true cohomology class, and the upper one moves up. What decides which combinations survive is the topology of M, via the signs of the tunnelling amplitudes.

7.15.2 A one-dimensional calculation without path integrals

In one dimension the amplitude (7.210) can be computed in a few lines, using only the exact zero-mode equations of Section 7.12.4. This calculation already contains every feature of the general answer: the exponential, the prefactor and the sign.

Let M be the line or the circle, with coordinate x and metric $\mathrm{d}x^2$. Let a be a local minimum of f (index 0) and b a neighbouring local maximum (index 1), with no critical point between them. Write $f''(a) > 0$ and $f''(b) < 0$.

Step 1: WKB states. Rather than the Gaussians (7.202), which are only approximate solutions, we use functions that solve the zero-mode equations *exactly* on a large region. Recall from Section 7.12.4 that e^{-tf} solves $\mathrm{d}_t\phi = 0$ and $e^{tf}\,\mathrm{d}x$ solves $\mathrm{d}_t^*\omega = 0$. So we set

$$\psi_a = N_a\,\chi_a(x)\,e^{-t(f(x)-f(a))}, \qquad \psi_b = N_b\,\chi_b(x)\,e^{+t(f(x)-f(b))}\,\mathrm{d}x. \tag{7.212}$$

Here χ_a is a smooth cut-off that equals 1 on the basin of a except near its edges and falls to 0 just before the neighbouring maxima; likewise χ_b equals 1 on the interval between the two minima adjacent to b, except near its ends. (Without cut-offs the functions would blow up away from their own critical point, since $e^{-t(f-f(a))}$ grows where $f < f(a)$.) Both states are sharply peaked: ψ_a at a (where $f - f(a)$ is smallest) and ψ_b at b (where $f - f(b)$ is largest, namely 0). See Figure 7.57.

Step 2: normalisation. Near a, $f(x) - f(a) \approx \tfrac{1}{2}f''(a)(x-a)^2$, so

$$1 = \|\psi_a\|^2 \overset{(1)}{=} N_a^2 \int e^{-2t(f(x)-f(a))}\,\mathrm{d}x \overset{(2)}{=} N_a^2 \int_{-\infty}^{\infty} e^{-tf''(a)(x-a)^2}\,\mathrm{d}x \overset{(3)}{=} N_a^2 \sqrt{\frac{\pi}{tf''(a)}},$$

$$\Longrightarrow \quad N_a = \left(\frac{tf''(a)}{\pi}\right)^{1/4}, \qquad \text{and likewise} \quad N_b = \left(\frac{t\,|f''(b)|}{\pi}\right)^{1/4}. \tag{7.213}$$

(1) Definition (7.212); the cut-off is 1 wherever the integrand is not exponentially small.
(2) Laplace's method: at large t only a neighbourhood of width $t^{-1/2}$ around a contributes, and there f is quadratic (errors are $O(1/t)$ relative).
(3) The Gaussian integral $\int e^{-\alpha y^2}\mathrm{d}y = \sqrt{\pi/\alpha}$ with $\alpha = tf''(a)$.

These are the same normalisations as the oscillator ground states (7.194) with $\omega = t\,|f''|$, as they must be.

Step 3: apply d_t. The exponential in ψ_a is killed by d_t exactly; only the cut-off is differentiated:

$$\mathrm{d}_t\psi_a \overset{(1)}{=} N_a\, e^{-tf}\, \mathrm{d}\big(e^{tf}\,\chi_a e^{-tf}\, e^{tf(a)}\big) \overset{(2)}{=} N_a\, e^{tf(a)}\, e^{-tf}\, \mathrm{d}\chi_a \overset{(3)}{=} N_a\, \chi_a'(x)\, e^{-t(f(x)-f(a))}\, \mathrm{d}x. \tag{7.214}$$

(1) $\mathrm{d}_t = e^{-tf}\,\mathrm{d}\,e^{tf}$, (7.170).
(2) The factors $e^{tf}\,e^{-tf}$ cancel inside; $e^{tf(a)}$ is a constant.
(3) $\mathrm{d}\chi_a = \chi_a'\mathrm{d}x$, and recombine the exponentials.

So $\mathrm{d}_t\psi_a$ is supported only where the cut-off varies: near the maxima that bound the basin of a. This is the precise sense in which tunnelling is a boundary (tail) effect.

Step 4: the overlap. Now take the inner product with ψ_b. The inner product of two 1-forms $u\,\mathrm{d}x, v\,\mathrm{d}x$ is $\int uv\,\mathrm{d}x$.

$$\begin{aligned}\langle b|\mathrm{d}_t|a\rangle &\overset{(1)}{=} N_aN_b \int \chi_b\,\chi_a'\, e^{t(f-f(b))}\, e^{-t(f-f(a))}\,\mathrm{d}x \overset{(2)}{=} N_aN_b\, e^{-t(f(b)-f(a))} \int \chi_b\,\chi_a'\,\mathrm{d}x \\ &\overset{(3)}{=} N_aN_b\, e^{-t(f(b)-f(a))}\,\big[\chi_a\big]_{\text{from } a \text{ to } b} \overset{(4)}{=} \varepsilon_{ba}\, N_aN_b\, e^{-t(f(b)-f(a))}.\end{aligned} \tag{7.215}$$

(1) (7.212) and (7.214); the states are real.
(2) The x-dependent exponentials cancel *exactly*: $e^{tf}e^{-tf} = 1$. What remains is the constant $e^{-tf(b)}e^{tf(a)}$.
(3) $\chi_b = 1$ on the whole region between a and b where χ_a falls from 1 to 0 (and $\chi_b\chi_a' = 0$ elsewhere), so the integral is the total change of χ_a along the segment from a towards b, oriented by $\mathrm{d}x$.
(4) If b lies to the right of a, going from a to b means increasing x and χ_a drops from 1 to 0: the integral is -1. If b lies to the left, the same drop is traversed in the direction of decreasing x, and $\int \chi_a'\mathrm{d}x = +1$. So $\varepsilon_{ba} = -1$ if $b > a$ and $+1$ if $b < a$.

The sign has a clean description. The downhill flow from b to a moves in the direction $+\partial_x$ when a is to the right of b ($\varepsilon = +1$) and $-\partial_x$ when a is to the left ($\varepsilon = -1$). In other words

$$\varepsilon_{ba} = \iota_{\dot\gamma}(\mathrm{d}x)\,/\,|\dot\gamma|\,,$$

where $\dot\gamma$ is the velocity of the descending flow line leaving b and $\mathrm{d}x$ is the orientation we chose for the local 1-form state at b. This is exactly Nash's orientation rule [Nash p. 213], which we develop in general in Section 7.16.4.

Key idea: the one-dimensional tunnelling amplitude

For a minimum a and an adjacent maximum b,

$$\langle b|\,\mathrm{d}_t\,|a\rangle = \varepsilon_{ba}\sqrt{\frac{t}{\pi}}\,\big(f''(a)\;|f''(b)|\big)^{1/4}\, e^{-t\,(f(b)-f(a))}\big(1+O(t^{-1})\big), \qquad \varepsilon_{ba} = \pm 1. \tag{7.216}$$

The exponent is t times the height of the barrier between the two critical points. The sign records the direction of the flow line from b down to a.

Two remarks. First, the computation never needed to know the shape of the cut-offs: all that mattered was that χ_a drops from 1 to 0 somewhere between a and b. The integral of χ_a' is "topological", a boundary term. Second, the product $e^{t(f-f(b))}e^{-t(f-f(a))}$ is constant along the whole segment: the two exponentials are *perfectly* matched, and this is why the answer is so clean. In the path-integral language of the next subsections, the constant $f(b) - f(a)$ will reappear as the instanton action divided by t.

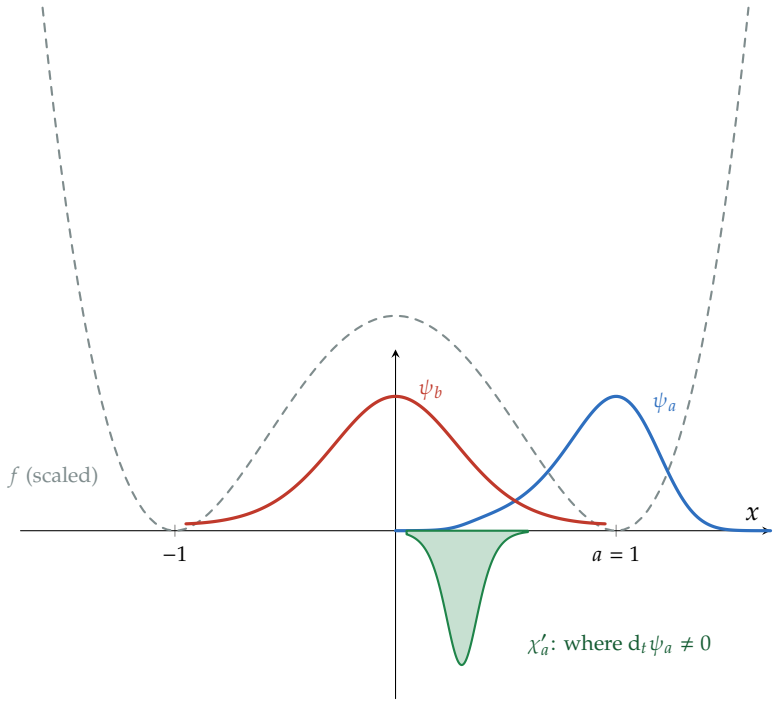

Figure 7.57: The one-dimensional overlap calculation for the double well $f = \frac{1}{4}(x^2-1)^2$ (only the right half of the story is drawn). The WKB state $\psi_a \propto e^{-t(f-f(a))}$ (blue) peaks at the minimum $a = 1$ and is cut off before the maximum; $\psi_b \propto e^{t(f-f(b))}$ (red) peaks at the maximum $b = 0$. $\mathrm{d}_t\psi_a$ is nonzero only where the cut-off varies (green). There ψ_b is not small, and the product of the two exponentials is the constant $e^{-t(f(b)-f(a))}$: the tunnelling amplitude is this constant times the total drop of the cut-off.

Worked example 7.82: the double well on the line: the splitting

Take $f = \frac{1}{4}(x^2-1)^2$ as in Example 7.74: minima $a_\pm = \pm 1$ with $f'' = 2$, $f = 0$; maximum $b = 0$ with $f'' = -1$, $f = \frac{1}{4}$. The low-lying space is $V_0 = \mathrm{span}(\psi_{a_-}, \psi_{a_+})$ and $V_1 = \mathrm{span}(\psi_b)$. By (7.216), with

$$A := \sqrt{\tfrac{t}{\pi}}\,(2\cdot 1)^{1/4} e^{-t/4},$$

the flow line from b to a_+ moves right ($\varepsilon = +1$) and the one from b to a_- moves left ($\varepsilon = -1$). So the 1×2 matrix of d_t and the Hamiltonian on V_0 are

$$D_0 = A\begin{pmatrix}-1 & 1\end{pmatrix}, \qquad H_t\big|_{V_0} \overset{(1)}{=} D_0^{\mathsf{T}} D_0 \overset{(2)}{=} A^2\begin{pmatrix}1 & -1\\ -1 & 1\end{pmatrix}, \qquad H_t\big|_{V_1} \overset{(3)}{=} D_0 D_0^{\mathsf{T}} = 2A^2.$$

(1) (7.211) with $p = 0$ (there is no D_{-1}).
(2) Multiply the column $(-1,1)^{\mathsf{T}}$ by the row $(-1,1)$.
(3) (7.211) with $p = 1$ (there is no D_1 on the line).

The eigenvalues on V_0 are 0, with eigenvector $\psi_{a_-} + \psi_{a_+}$ (the exact zero mode e^{-tf}, which has a bump at each minimum), and

$$E_{\text{lift}} = 2A^2 = 2\sqrt{2}\,\frac{t}{\pi}\,e^{-t/2}, \tag{7.217}$$

with eigenvector $\psi_{a_+} - \psi_{a_-}$. On V_1 the single level is the same $2A^2$: the lifted boson and the lifted fermion are superpartners, as they must be. Compare with a direct numerical diagonalisation of (7.181) (finite differences on $[-2.4, 2.4]$):

t	lifted 0-form level	lifted 1-form level	$2\sqrt{2}\,(t/\pi)e^{-t/2}$	ratio
8	1.191×10^{-1}	1.191×10^{-1}	1.319×10^{-1}	0.903
12	2.485×10^{-2}	2.485×10^{-2}	2.678×10^{-2}	0.928
16	4.574×10^{-3}	4.575×10^{-3}	4.832×10^{-3}	0.947
20	7.821×10^{-4}	7.833×10^{-4}	8.175×10^{-4}	0.957

The ratio tends to 1 like $1-O(1/t)$, the expected size of the corrections to Laplace's method. The next level up (not shown) is at $\approx 2t$ (for example 27.9 at $t=16$), the oscillator gap of the minima.

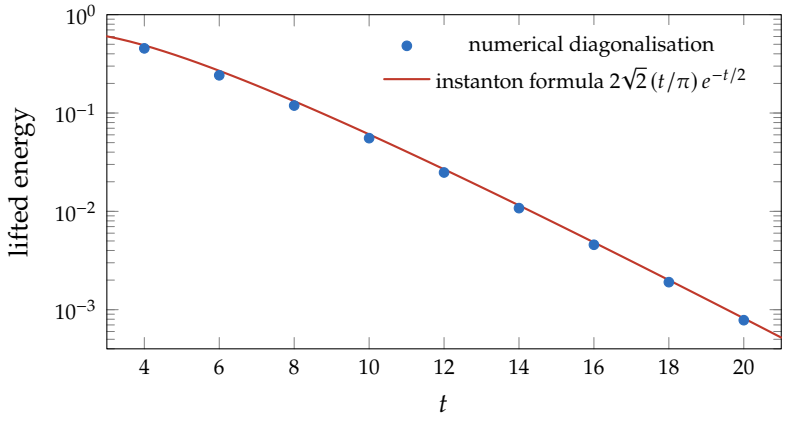

Figure 7.58: The tunnelling splitting of the line double well on a logarithmic scale. The straight-line behaviour is the factor $e^{-t/2}=e^{-2S_0}$ with $S_0=t\,(f(b)-f(a))=t/4$: the energy is the *square* of an amplitude e^{-S_0}. The prefactor t/π is what the Gaussian normalisations contribute. Agreement improves steadily with t.

Worked example 7.83: the circle with two wells, $f=-\cos 2\theta$

On S^1 with $f=-\cos 2\theta$ there are minima $a_1=0$, $a_2=\pi$ ($f=-1$, $f''=4$) and maxima $b_1=\frac{\pi}{2}$, $b_2=\frac{3\pi}{2}$ ($f=1$, $f''=-4$). The barrier height is $f(b)-f(a)=2$, so each amplitude has modulus

$$A=\sqrt{\tfrac{t}{\pi}}\,(4\cdot4)^{1/4}e^{-2t}=2\sqrt{\tfrac{t}{\pi}}\,e^{-2t}.$$

Each minimum is joined to both maxima. Reading off the directions of the descending flow lines (from $b_1=\frac{\pi}{2}$ to $a_1=0$: leftwards, $\varepsilon=-1$; from $b_2=-\frac{\pi}{2}$ to a_1: rightwards, $\varepsilon=+1$; and the reverse for a_2):

$$D_0=A\begin{pmatrix}-1 & +1\\ +1 & -1\end{pmatrix}\begin{matrix}\leftarrow b_1\\ \leftarrow b_2,\end{matrix}\qquad H_t\big|_{V_0}\overset{(1)}{=}D_0^{\mathsf T}D_0\overset{(2)}{=}2A^2\begin{pmatrix}1 & -1\\ -1 & 1\end{pmatrix}.$$

(1) (7.211), $p=0$; the columns of D_0 are labelled by a_1,a_2.
(2) Matrix multiplication: each column has squared length $2A^2$ and the two columns have inner product $-2A^2$.

The eigenvalues are 0 (eigenvector a_1+a_2, the exact zero mode $e^{t\cos 2\theta}$) and

$$E_{\text{lift}}=4A^2=\frac{16\,t}{\pi}\,e^{-4t}.$$

At $t = 2$ this is 3.42×10^{-3}; the numerical value from Figure 7.56 is 3.18×10^{-3}. At $t = 3$ it is 9.39×10^{-5} against 8.97×10^{-5}. The 1-form sector $D_0 D_0^{\mathsf{T}}$ has the same two eigenvalues 0 and $4A^2$: its zero mode $b_1 + b_2$ is the exact harmonic 1-form $e^{-t\cos 2\theta}\mathrm{d}\theta$ at large t, and $b_1 - b_2$ is the superpartner of the lifted boson.

Worked example 7.84: the circle with $f = \cos\theta$: cancelling instantons

Now take $f = \cos\theta$: one maximum $b = 0$ and one minimum $a = \pi$. There are *two* descending flow lines from b to a: one going through $\theta \in (0, \pi)$, moving in the direction $+\partial_\theta$ ($\varepsilon = +1$), and one through $\theta \in (-\pi, 0)$, moving in the direction $-\partial_\theta$ ($\varepsilon = -1$). In the overlap calculation, χ_a now drops from 1 to 0 twice, once near $\theta = 0^+$ and once near $\theta = 0^- = 2\pi^-$, in opposite directions. So

$$\langle b|\mathrm{d}_t|a\rangle = (+1 - 1)\sqrt{\tfrac{t}{\pi}}\, e^{-2t} = 0.$$

Nothing is lifted, in agreement with Example 7.73, where we found exact zero modes $e^{-t\cos\theta}$ and $e^{t\cos\theta}\mathrm{d}\theta$. The two tunnelling paths interfere destructively. This is the simplest example of the cancellations that make the Morse–Witten complex compute cohomology: $b_0 = b_1 = 1$ because the two ways round the circle carry opposite signs.

7.15.3 The Euclidean path integral, briefly

In higher dimensions the local states are not simple exponentials of f, and the direct calculation becomes hard. Witten computes $\langle b|\mathrm{d}_t|a\rangle$ instead by the semiclassical evaluation of a path integral. We recall what that means.

Imaginary time. For a particle with Hamiltonian $H = \tfrac{1}{2}p^2 + U(x)$, the amplitude to go from x_i to x_f in imaginary time T (with $\hbar = 1$) is

$$\langle x_f|e^{-TH}|x_i\rangle = \int_{x(-T/2)=x_i}^{x(T/2)=x_f} \mathcal{D}x\; e^{-S_E[x]}, \qquad S_E[x] = \int_{-T/2}^{T/2} \Big(\tfrac{1}{2}\dot{x}^2 + U(x)\Big)\mathrm{d}s. \tag{7.218}$$

The derivation is the same as in real time. Slice T into N steps $\epsilon = T/N$ and insert complete sets of position states. For one slice,

$$\langle x'|e^{-\epsilon H}|x\rangle \overset{(1)}{=} \langle x'|e^{-\epsilon p^2/2}\, e^{-\epsilon U(\hat{x})}|x\rangle\big(1 + O(\epsilon^2)\big) \overset{(2)}{=} \int \frac{\mathrm{d}p}{2\pi}\, e^{\mathrm{i}p(x'-x)}\, e^{-\epsilon p^2/2}\, e^{-\epsilon U(x)}$$
$$\overset{(3)}{=} \frac{1}{\sqrt{2\pi\epsilon}}\, \exp\!\Big[-\epsilon\Big(\tfrac{1}{2}\Big(\frac{x'-x}{\epsilon}\Big)^2 + U(x)\Big)\Big].$$

(1) Split the exponential (the commutator is higher order in ϵ).
(2) $U(\hat{x})$ acts on $|x\rangle$ by the number $U(x)$; insert $\int \mathrm{d}p\, |p\rangle\langle p|$ with $\langle x'|p\rangle = e^{\mathrm{i}px'}/\sqrt{2\pi}$.
(3) Gaussian integral over p, completing the square.

The exponent is $-\epsilon$ times the Euclidean Lagrangian $\tfrac{1}{2}\dot{x}^2 + U$ at one time step; multiplying the slices and letting $\epsilon \to 0$ gives (7.218). The sign in front of U is $+$, unlike the real-time Lagrangian $\tfrac{1}{2}\dot{x}^2 - U$: going to imaginary time flips the sign of the kinetic term relative to the potential.

Semiclassics. When the action is large, the integral is dominated by the paths that minimise S_E, and

$$\langle x_f | e^{-TH} | x_i \rangle \approx \sum_{\text{minima } x_{\mathrm{cl}}} (\text{fluctuation determinant}) \times e^{-S_E[x_{\mathrm{cl}}]}.$$

A minimum of S_E satisfies the Euler–Lagrange equation

$$\ddot{x} = U'(x), \tag{7.219}$$

which is Newton's law in the *inverted* potential $-U$. It conserves the "Euclidean energy" $\frac{1}{2}\dot{x}^2 - U(x)$ (differentiate: $\dot{x}\ddot{x} - U'\dot{x} = 0$). A path that starts at a zero of U at $s = -\infty$ and ends at another zero at $s = +\infty$ has Euclidean energy 0, so along it

$$\tfrac{1}{2}\dot{x}^2 = U(x). \tag{7.220}$$

Such a finite-action solution, localised in Euclidean time, is an **instanton**. In a double well it is the path that rolls off one hill of $-U$ and comes to rest on the other.

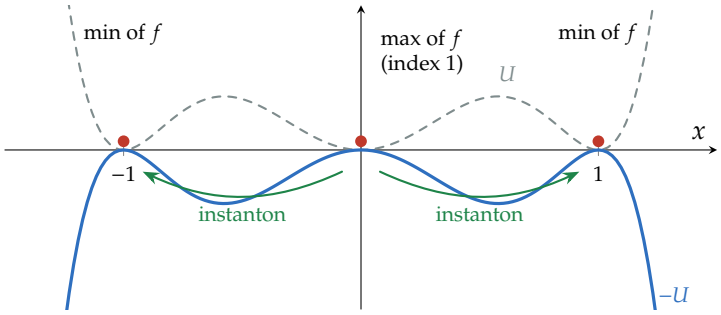

Figure 7.59: The bosonic potential $U = \frac{1}{2}t^2 f'^2$ of the double well (dashed) vanishes at *every* critical point of f, maxima included: all critical points are classical vacua. In Euclidean time the particle moves in the inverted potential $-U$ (blue), whose hilltops are the critical points. A zero-energy trajectory leaves one hilltop at $s = -\infty$ and arrives on the next at $s = +\infty$: that is an instanton. Here the instantons join the maximum of f to each minimum.

7.15.4 Witten's supersymmetric action

The Hamiltonian H_t acts on forms, i.e. on wavefunctions with fermionic degrees of freedom. Its path integral therefore needs fermionic (Grassmann) variables as well as the position $x^i(s)$. Nash quotes the Euclidean action [Nash p. 213, (7.88)]:

$$S = \frac{1}{2}\int \left\{ g_{ij}\frac{\mathrm{d}x^i}{\mathrm{d}s}\frac{\mathrm{d}x^j}{\mathrm{d}s} + t^2 g^{ij}\frac{\partial f}{\partial x^i}\frac{\partial f}{\partial x^j} + \mathrm{i}\,\bar{\psi}^i \frac{D\psi^j}{Ds} g_{ij} + \tfrac{1}{4}R_{ijkl}\bar{\psi}^i\psi^k\bar{\psi}^j\psi^l + t\,\frac{D^2 f}{Dx^i Dx^j}\left[\bar{\psi}^i, \psi^j\right] \right\} \mathrm{d}s. \tag{7.221}$$

Term by term:

- $\frac{1}{2}g_{ij}\dot{x}^i\dot{x}^j$: the kinetic energy of a particle on the Riemannian manifold M. The $x^i(s)$ are the bosonic fields (Nash: "x^i now counting as a Boson field").
- $\frac{1}{2}t^2\,|\nabla f|^2$: the bosonic potential U, the t^2 term of H_t in (7.186).
- $\bar{\psi}^i D\psi^j/Ds$: the fermion kinetic term. The $\psi^i(s)$ and $\bar{\psi}^i(s)$ are anticommuting variables carrying a tangent index, and D/Ds is the covariant derivative along the path, $D\psi^j/Ds = \dot{\psi}^j + \Gamma^j_{kl}\dot{x}^k\psi^l$. It is first order in s, as fermion kinetic terms always are. (The factor i depends on the convention used to continue the fermions to imaginary time; it drops out of everything below.)

- $\frac{1}{4}R_{ijkl}\bar\psi^i\psi^k\bar\psi^j\psi^l$: a four-fermion term built from the Riemann tensor of g. On quantisation it is the curvature part of the Hodge Laplacian on forms (the Weitzenböck term): Δ on p-forms is not just $-\nabla^2$ when M is curved.
- $t\,(D^2f/Dx^iDx^j)[\bar\psi^i,\psi^j]$: the Hessian coupled to a fermion bilinear. On quantisation it becomes the "spin" term $t\,(D^2f/Dx^iDx^j)[a^{i*},a^j]$ of (7.186).

Watch out: two misprints in (7.88)

Nash's last term reads $t\,D^2h/Dx^iDx^j$ with no fermions. The h should be f, the Morse function, and the Hessian multiplies the fermion bilinear $[\bar\psi^i,\psi^j]$ (Witten writes it this way); a Hessian term without fermions would be a t-dependent change of the bosonic potential, and could not produce the $\mp t\lambda_i$ spin energies of (7.200).

Check in one dimension. On $M=\mathbb{R}$ with flat metric the curvature term vanishes and the action becomes

$$S=\int\Big\{\tfrac12\dot x^2+\tfrac12 t^2f'(x)^2+\bar\psi\dot\psi+\tfrac12 t\,f''(x)\,[\bar\psi,\psi]\Big\}\mathrm{d}s. \tag{7.222}$$

(We have absorbed the i and the $\frac12$ of the fermion kinetic term into the normalisation of ψ.) Let us quantise it and recover H_t. A first-order term $\bar\psi\dot\psi$ means that $\bar\psi$ is the momentum conjugate to ψ; for Grassmann variables canonical quantisation imposes an *anti*commutator,

$$\{\psi,\bar\psi\}=1,\qquad \psi^2=\bar\psi^2=0,$$

realised by $\psi\mapsto a$, $\bar\psi\mapsto a^*$ on the two-dimensional fermion space $\{1,\mathrm{d}x\}$ of Section 7.11.4. The Hamiltonian is the Legendre transform: the fermion kinetic term contributes nothing (it is already of the form $p\dot q$), so

$$H\overset{(1)}{=}\tfrac12p^2+\tfrac12t^2f'^2+\tfrac12t\,f''[a^*,a]\overset{(2)}{=}\tfrac12\Big(-\frac{\mathrm{d}^2}{\mathrm{d}x^2}+t^2f'^2+t\,f''[a^*,a]\Big)\overset{(3)}{=}\tfrac12\,H_t. \tag{7.223}$$

(1) Bosonic Legendre transform of $\frac12\dot x^2$ plus the potential terms, with $[\bar\psi,\psi]\mapsto[a^*,a]$.
(2) $p=-\mathrm{i}\,\mathrm{d}/\mathrm{d}x$.
(3) Compare (7.181): $[a^*,a]=-1$ on 0-forms and $+1$ on 1-forms ((7.198)), giving the potentials $t^2f'^2\mp tf''$.

So the action (7.221) generates the evolution $e^{-sH_t/2}$. The factor $\frac12$ is a harmless rescaling of Euclidean time. The dictionary is

path integral	operators on forms
$x^i(s)$	position on M, coefficient functions of forms
$\psi^i,\bar\psi^i$	$a^i=\iota_{e_i}$, $a^{i*}=e^i\wedge$
$\{\psi^i,\bar\psi^j\}=g^{ij}$	canonical anticommutation relations (7.165)
$\bar\psi^i$ insertion	raises form degree by one
fermion number of a path	change of form degree

7.15.5 Bogomolny's trick: instantons are gradient flow lines

The instantons are the minima of the action with the fermions set to zero, because the classical fermion fields vanish. So we minimise the bosonic part [Nash p. 214, (7.89)]. Write $\langle\cdot,\cdot\rangle$ and $\|\cdot\|$ for

the metric inner product integrated over s, and ∇f for the gradient vector field ($(\nabla f)^i = g^{ij}\partial_j f$). Then

$$\begin{aligned} S_B &\overset{(1)}{=} \frac{1}{2}\left\|\frac{\mathrm{d}x}{\mathrm{d}s}\right\|^2 + \frac{t^2}{2}\,\|\nabla f\|^2 \\ &\overset{(2)}{=} \frac{1}{2}\left\|\frac{\mathrm{d}x}{\mathrm{d}s} + t\,\nabla f\right\|^2 - t\left\langle \frac{\mathrm{d}x}{\mathrm{d}s}, \nabla f\right\rangle \\ &\overset{(3)}{=} \frac{1}{2}\left\|\frac{\mathrm{d}x}{\mathrm{d}s} + t\,\nabla f\right\|^2 - t\int_{-\infty}^{\infty} \frac{\mathrm{d}}{\mathrm{d}s} f\big(x(s)\big)\,\mathrm{d}s \\ &\overset{(4)}{=} \frac{1}{2}\left\|\frac{\mathrm{d}x}{\mathrm{d}s} + t\,\nabla f\right\|^2 + t\big(f(x(-\infty)) - f(x(+\infty))\big). \end{aligned} \tag{7.224}$$

(1) The bosonic terms of (7.221), with $g^{ij}\partial_i f\,\partial_j f = |\nabla f|^2$.
(2) Complete the square: $\frac{1}{2}|v + tw|^2 = \frac{1}{2}|v|^2 + \frac{t^2}{2}|w|^2 + t\langle v, w\rangle$.
(3) The chain rule: $\langle \dot{x}, \nabla f\rangle = g_{ij}\dot{x}^i g^{jk}\partial_k f = \dot{x}^k \partial_k f = \mathrm{d}f(x(s))/\mathrm{d}s$.
(4) The fundamental theorem of calculus.

The last term depends only on the endpoints. For a path from $x(-\infty) = b$ to $x(+\infty) = a$ it is $t\,(f(b) - f(a))$, and the first term is non-negative. Hence

$$S_B \;\geq\; t\,\big(f(b) - f(a)\big), \qquad \text{with equality iff} \qquad \frac{\mathrm{d}x}{\mathrm{d}s} = -t\,\nabla f(x). \tag{7.225}$$

This is Nash's (7.90)–(7.91). Absorbing t into s (i.e. writing $\sigma = ts$), the condition becomes $\mathrm{d}x/\mathrm{d}\sigma = -\nabla f$, the equation of steepest descent (7.83), $\mathrm{d}\gamma/\mathrm{d}\sigma = -\operatorname{grad} f(\gamma)$.

Which way round? The bound (7.225) is useful only if $f(b) > f(a)$: the path must go *downhill*. For a path going uphill, from a to b, complete the square the other way, $\frac{1}{2}|\dot{x} - t\nabla f|^2 + t\langle \dot{x}, \nabla f\rangle$, and get $S_B \geq t\,(f(b) - f(a))$ again, with equality iff $\dot{x} = +t\nabla f$: an ascending flow line. This is Nash's remark "by changing f to $-f$, if necessary, we can assume that the inner product $-\langle \mathrm{d}x/\mathrm{d}s, \partial f/\partial x\rangle$ is positive". Either way,

Key idea: instantons = gradient flow lines

The paths of least Euclidean action joining two critical points a and b are the gradient flow lines of f between them, traversed downhill ($\dot{x} = -t\nabla f$) or uphill ($\dot{x} = +t\nabla f$) according to the direction of travel. Every such path has the same action,

$$S_{\text{inst}} = t\;|f(b) - f(a)|\,, \tag{7.226}$$

t times the height difference. It depends on nothing but the critical values.

Two checks. (i) The first-order equation $\dot{x} = \mp t\nabla f$ implies the zero-energy condition (7.220): $\frac{1}{2}|\dot{x}|^2 = \frac{1}{2}t^2|\nabla f|^2 = U$. So the flow lines are indeed the zero-energy solutions of Newton's equation in $-U$. (ii) On a flow line the kinetic and potential terms are equal, so $S_B = \int |\dot{x}|^2\,\mathrm{d}s = \int \dot{x}\cdot(-t\nabla f)\,\mathrm{d}s = -t\int \mathrm{d}f = t(f(b) - f(a))$, as it should.

Watch out: the second-order equation has more solutions

Newton's equation in $-U$ is second order and has many solutions joining the two critical points only if we allow nonzero Euclidean energy or infinite time. Bogomolny's trick selects, among all paths with the given endpoints at $s = \pm\infty$, those satisfying the *first-order*

flow equation. This is the finite-dimensional ancestor of the (anti-)self-duality equations for Yang–Mills instantons, which arise from exactly the same completion of a square (Chapter 8).

Reading Nash (pp. 212–214, (7.83), (7.89)–(7.91))

Nash first introduces the paths of steepest descent (7.83) as a piece of mathematics, needed to define δ, and only later shows (7.90) that they are the instantons. He calls $\mathrm{d}\gamma/\mathrm{d}s = -\operatorname{grad} f$ the "descending gradient flow" and notes that the paths begin and end at critical points because $\operatorname{grad} f$ vanishes there. In (7.89) he writes $\partial f/\partial x$ for the gradient; with a non-flat metric it is $\nabla f = g^{ij}\partial_j f\,\partial_i$. His (7.91) is the action (7.226).

7.15.6 Explicit instantons

The flow equation is first order, so in simple cases we can solve it in closed form. Seeing the solutions makes the abstract statements concrete.

Worked example 7.85: the kink of the double well

For $f = \tfrac{1}{4}(x^2-1)^2$ on $\mathbb{R}$, $f' = x^3 - x$, the downhill flow from the maximum $b = 0$ to the minimum $a = 1$ is $\dot{x} = -t(x^3 - x) = t\,x(1-x^2)$. Put $y = x^2$:

$$\dot{y} \overset{(1)}{=} 2x\dot{x} \overset{(2)}{=} 2t\,x^2(1-x^2) = 2t\,y(1-y) \quad\Longrightarrow\quad y(s) \overset{(3)}{=} \frac{1}{1+e^{-2t(s-s_0)}}.$$

(1) Chain rule.
(2) The flow equation.
(3) The logistic equation $\dot{y} = ky(1-y)$ has solution $1/(1+e^{-k(s-s_0)})$; here $k = 2t$, and s_0 is a free constant.

So

$$x_{\mathrm{cl}}(s) = \left(1 + e^{-2t(s-s_0)}\right)^{-1/2}, \tag{7.227}$$

which goes from 0 at $s = -\infty$ to 1 at $s = +\infty$ (Figure 7.60). The transition takes a Euclidean time of order $1/t$, centred at s_0. Its action is $t\,(f(0) - f(1)) = t/4$, and the splitting (7.217) is $\propto e^{-2\cdot t/4}$: the *square* of the one-instanton factor $e^{-S_{\mathrm{inst}}}$, because an energy is the square of an amplitude ((7.211)). Let us verify the action directly:

$$S_B \overset{(1)}{=} \int \dot{x}_{\mathrm{cl}}^2\,\mathrm{d}s \overset{(2)}{=} \int_0^1 \dot{x}\,\mathrm{d}x \overset{(3)}{=} \int_0^1 t\,x(1-x^2)\,\mathrm{d}x = t\left(\tfrac{1}{2} - \tfrac{1}{4}\right) = \frac{t}{4}.$$

(1) On a flow line the kinetic and potential terms are equal.
(2) Change variable from s to x, $\mathrm{d}x = \dot{x}\,\mathrm{d}s$.
(3) The flow equation expresses $\dot{x}$ as a function of x.

The mirror-image kink $-x_{\mathrm{cl}}(s)$ joins $b = 0$ to $a_- = -1$.

Worked example 7.86: the circle and the sphere: $\theta(s) = 2\arctan e^{ts}$

On the unit circle take $f = \cos\theta$, so $f' = -\sin\theta$ and the downhill flow is $\dot{\theta} = t\sin\theta$. Then

$$\frac{\mathrm{d}}{\mathrm{d}s}\tan\frac{\theta}{2} \overset{(1)}{=} \frac{\dot{\theta}}{2\cos^2(\theta/2)} \overset{(2)}{=} \frac{t\cdot 2\sin(\theta/2)\cos(\theta/2)}{2\cos^2(\theta/2)} = t\tan\frac{\theta}{2},$$

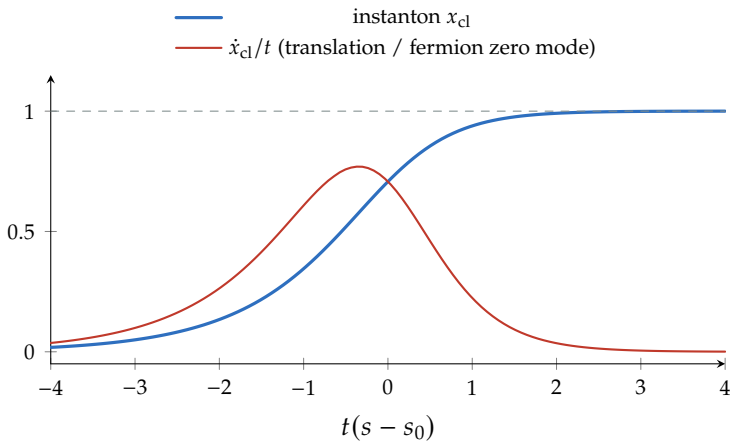

Figure 7.60: The double-well instanton (7.227) from the maximum $x = 0$ to the minimum $x = 1$ (blue), as a function of Euclidean time in units of $1/t$. It spends almost all its time sitting on one critical point or the other and switches over in a time $\sim 1/t$. Its velocity (red, scaled up by 2 for visibility) is a normalisable bump: it is the zero mode of both the bosonic and the fermionic fluctuation operators (Section 7.15.7).

(1) Chain rule, $(\tan u)' = \sec^2 u$.
(2) The flow equation and $\sin\theta = 2\sin\frac{\theta}{2}\cos\frac{\theta}{2}$.

so $\tan(\theta/2) = \pm e^{t(s-s_0)}$ and

$$\theta_\pm(s) = \pm 2\arctan e^{t(s-s_0)}.$$

Both start at the maximum $\theta = 0$ at $s = -\infty$; θ_+ arrives at $\theta = \pi$, θ_- at $\theta = -\pi$, the same point, the minimum. These are the two instantons of Example 7.84, each of action $t\,(f(0) - f(\pi)) = 2t$, moving in opposite directions.

On the round unit sphere take the height $f = \cos\theta$ (polar angle θ). The metric is $\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2$, so $\nabla f = -\sin\theta\,\partial_\theta$, and the downhill flow is $\dot\theta = t\sin\theta$, $\dot\phi = 0$: the same equation. Its solutions are $\theta(s) = 2\arctan e^{t(s-s_0)}$ at *every* fixed longitude ϕ_0. So the instantons from the north pole (index 2) to the south pole (index 0) form a family with two parameters, (s_0, ϕ_0). Up to the time translation s_0 they form a circle S^1 of meridians. The dimension count "2 = index(N) − index(S)" is general (Section 7.16.3): the flow lines from b to a form a family of dimension index(b) − index(a), including the time translation. Because the indices differ by 2, these instantons do not contribute to $\langle b|\mathrm{d}_t|a\rangle$ (which needs a difference of 1); they would contribute to amplitudes of operators that change the degree by two.

Worked example 7.87: the flat torus

On $T^2 = \mathbb{R}^2/2\pi\mathbb{Z}^2$ with $f = \cos x + \cos y$: maximum $P = (0,0)$, saddles $S_1 = (\pi, 0)$ and $S_2 = (0, \pi)$, minimum $Q = (\pi, \pi)$. The downhill flow is $(\dot x, \dot y) = t(\sin x, \sin y)$, which separates. Each coordinate obeys the circle equation of Example 7.86. The instantons between critical points of adjacent index are the ones in which only one coordinate moves:

- $P \to S_1$: $y \equiv 0$, $x = \pm 2\arctan e^{t(s-s_0)}$ (two instantons);
- $P \to S_2$: $x \equiv 0$, $y = \pm 2\arctan e^{t(s-s_0)}$ (two);
- $S_1 \to Q$: $x \equiv \pi$, $y = \pm 2\arctan e^{t(s-s_0)}$ (two);
- $S_2 \to Q$: $y \equiv \pi$, $x = \pm 2\arctan e^{t(s-s_0)}$ (two).

Each has action $2t$. When both coordinates move we get the flow lines from P to Q (index difference 2), a two-parameter family $(x, y) = \big(\pm 2 \arctan e^{t(s-s_1)}, \pm 2 \arctan e^{t(s-s_2)}\big)$, of action $4t$. We will see in Example 7.91 that the two instantons in each pair carry opposite signs.

7.15.7 Fluctuations: why the determinants cancel up to a sign

The semiclassical approximation expands the path integral to second order about each instanton. For a path $x = x_{\mathrm{cl}} + \xi$ and fermions $\psi, \bar\psi$ (which are already "small"), the quadratic action is

$$S \approx S_{\mathrm{inst}} + \tfrac{1}{2}\int \xi\, L_B\, \xi \,\mathrm{d}s + \int \bar\psi\, D_F\, \psi \,\mathrm{d}s,$$

and Gaussian integration gives, schematically,

$$\text{contribution of one instanton} = \frac{\det D_F}{\sqrt{\det L_B}}\, e^{-S_{\mathrm{inst}}}. \tag{7.228}$$

This is Nash's $\det F_{ab}\, \exp[-t(f(b)-f(a))]$ [Nash p. 214, (7.92)]. A Grassmann Gaussian integral gives the determinant ($\int \mathrm{d}\bar\psi \mathrm{d}\psi\, e^{-\bar\psi D \psi} = \det D$), a bosonic one gives the inverse square root of the determinant. Let us compute the two operators in one dimension and see why the ratio is only a sign.

The two operators. From (7.222), the second variation of the bosonic action about x_{cl} is

$$L_B = -\frac{\mathrm{d}^2}{\mathrm{d}s^2} + U''(x_{\mathrm{cl}}(s)), \qquad U = \tfrac{1}{2}t^2 f'^2,$$

and the fermion operator is read off from $\bar\psi\dot\psi + t f''\bar\psi\psi$:

$$D_F = \frac{\mathrm{d}}{\mathrm{d}s} + W(s), \qquad W(s) := t\, f''(x_{\mathrm{cl}}(s)).$$

Now compute $D_F^\dagger D_F$, with $D_F^\dagger = -\mathrm{d}/\mathrm{d}s + W$:

$$\begin{aligned} D_F^\dagger D_F\, \eta &\overset{(1)}{=} \Big(-\frac{\mathrm{d}}{\mathrm{d}s} + W\Big)\big(\dot\eta + W\eta\big) \overset{(2)}{=} -\ddot\eta - \dot W\eta - W\dot\eta + W\dot\eta + W^2\eta \\ &\overset{(3)}{=} -\ddot\eta + \big(t^2 f''^2 - t f'''\, \dot x_{\mathrm{cl}}\big)\eta \overset{(4)}{=} -\ddot\eta + t^2\big(f''^2 + f' f'''\big)\eta \\ &\overset{(5)}{=} -\ddot\eta + U''(x_{\mathrm{cl}})\,\eta = L_B\,\eta. \end{aligned} \tag{7.229}$$

(1) Definitions.
(2) Product rule on $(W\eta)^{\cdot}$; the $W\dot\eta$ terms cancel.
(3) $W^2 = t^2 f''^2$ and $\dot W = t f''' \dot x_{\mathrm{cl}}$ by the chain rule.
(4) On the instanton $\dot x_{\mathrm{cl}} = -t f'$, the flow equation.
(5) $U'' = \tfrac{1}{2}t^2 (f'^2)'' = t^2(f''^2 + f' f''')$.

So *the bosonic fluctuation operator is the square of the fermionic one*: $L_B = D_F^\dagger D_F$. This is supersymmetry at work, in the same way that $H = Q^\dagger Q$ in Section 7.10. Formally $\det L_B = \det D_F^\dagger \det D_F = |\det D_F|^2$, and the ratio (7.228) is

$$\frac{\det D_F}{|\det D_F|} = \pm 1.$$

All the magnitudes cancel. What survives is a sign: Nash's "all that is left is the sign of $\det F_{ab}$".

Zero modes: one boson, one fermion. The instanton has a free parameter, its centre s_0. Differentiating the family $x_{\mathrm{cl}}(s - s_0)$ with respect to s_0 shows that $\dot{x}_{\mathrm{cl}}$ is a zero mode of L_B (moving the centre costs no action). It is also a zero mode of D_F:

$$D_F\,\dot{x}_{\mathrm{cl}} = \ddot{x}_{\mathrm{cl}} + t f''\dot{x}_{\mathrm{cl}} = \frac{\mathrm{d}}{\mathrm{d}s}\big(-t f'(x_{\mathrm{cl}})\big) + t f''\dot{x}_{\mathrm{cl}} = -t f''\dot{x}_{\mathrm{cl}} + t f''\dot{x}_{\mathrm{cl}} = 0.$$

And $D_F^\dagger$ has no normalisable zero mode: $D_F^\dagger \eta = 0$ means $\dot{\eta} = W\eta$, whose solution is $1/\dot{x}_{\mathrm{cl}}$ (check: $(1/\dot{x})^{\cdot} = -\ddot{x}/\dot{x}^2 = t f''/\dot{x}$), and this blows up at both ends. So

$$\dim \operatorname{Ker} D_F - \dim \operatorname{Ker} D_F^\dagger = 1 = \operatorname{index}(b) - \operatorname{index}(a). \tag{7.230}$$

In n dimensions the same holds with $D_F = \nabla_s + t\,\mathrm{Hess} f$ acting on vector fields along the instanton: its index is $\operatorname{index}(b) - \operatorname{index}(a)$, the number of directions that are unstable at b but stable at a.

The zero modes are handled as usual. The bosonic zero mode is traded for an integral over the collective coordinate s_0, which gives a positive Jacobian ($\sqrt{S_{\mathrm{inst}}}$ times constants). The fermionic zero mode is more interesting. A Grassmann integral over a mode that does not appear in the action vanishes, $\int \mathrm{d}\eta_0\, 1 = 0$, unless the integrand contains exactly one factor of that mode. So the instanton contributes only to amplitudes with *one* fermion insertion, i.e. to matrix elements of an operator that changes the fermion number by one. That operator is d_t (or d_t^*), and this is why instantons between critical points whose indices differ by one are precisely what $\langle b|\mathrm{d}_t|a\rangle$ sees.

Physical picture: fermion zero modes as selection rules

In gauge theory a BPST instanton carries fermion zero modes, and they make it violate a chiral charge by a definite amount: the 't Hooft vertex. Here the flow line from b to a carries $\operatorname{index}(b) - \operatorname{index}(a)$ fermion zero modes, so it changes the form degree by exactly that amount. The Morse index plays the role of the chiral charge, and "index difference $= 1$" is the selection rule for the supercharge d_t. The same mechanism (an index theorem for the linearised operator) will count dimensions of instanton moduli spaces in Chapter 8 and gradings in Floer theory (Chapter 12).

The sign. The sign of $\det D_F$ (suitably regularised and with the zero mode removed) is a "relative orientation": it compares the orientation of the fermion zero-mode space with the orientations chosen for the states $|a\rangle$ and $|b\rangle$. In one dimension we computed it directly in (7.215): $\varepsilon = \pm 1$ according to the direction of the flow. In general it is the sign $\varepsilon_{\gamma_{ab}}$ defined by Nash's orientation rule, which we work out in Section 7.16.4.

7.15.8 Assembling the amplitude

Summing over all instantons from b to a:

$$\langle b|\,\mathrm{d}_t\,|a\rangle \;\approx\; \sum_{\gamma_{ab}} \varepsilon_{\gamma_{ab}}\, e^{-t(f(b)-f(a))} \qquad (t \to \infty), \tag{7.231}$$

which is Nash's (7.93), up to a positive prefactor that we suppress (in one dimension it is $\sqrt{t/\pi}\,(f''(a)\,|f''(b)|)^{1/4}$, and with Nash's normalisation $|\lambda_i| = 1$ it is the universal $\sqrt{t/\pi}$). The sum is finite for a generic metric (Section 7.16.3). In terms of the action of d_t on the local states,

$$\mathrm{d}_t|a\rangle \approx \sum_b \Big(\sum_{\gamma_{ab}} \varepsilon_{\gamma_{ab}}\Big) e^{-t(f(b)-f(a))}|b\rangle, \tag{7.232}$$

Nash's (7.94), the sum running over critical points b of index $\operatorname{index}(a) + 1$.

The exponentials are a change of basis. Rescale each local state by a constant, $|\tilde{a}\rangle := e^{-tf(a)}|a\rangle$. Then

$$\mathrm{d}_t|\tilde{a}\rangle \overset{(1)}{=} e^{-tf(a)} \sum_b \varepsilon(a,b)\, e^{-tf(b)} e^{tf(a)}|b\rangle \overset{(2)}{=} \sum_b \varepsilon(a,b)\, e^{-tf(b)}|b\rangle \overset{(3)}{=} \sum_b \varepsilon(a,b)\,|\tilde{b}\rangle, \tag{7.233}$$

(1) (7.232), with $\varepsilon(a,b) := \sum_{\gamma_{ab}} \varepsilon_{\gamma_{ab}}$.
(2) The factors $e^{\pm tf(a)}$ cancel.
(3) Definition of $|\tilde{b}\rangle$.

In the rescaled basis, the matrix of d_t has the *integer* entries $\varepsilon(a,b)$. A change of basis does not change kernels, images or ranks, so the exponentials carry no information about cohomology. This is Witten's observation that "the exponential factors are inessential and can be discarded" [Nash p. 215]. It leads to the definition

$$\delta(a) = \sum_b \varepsilon(a,b)\, b, \tag{7.234}$$

Nash's (7.95), which is the same as the purely mathematical definition (7.86) that we give in Section 7.16. And since $\mathrm{d}_t^2 = 0$ exactly, its shadow on the low-lying space squares to zero too: $\delta^2 = 0$ "is really a consequence of $\mathrm{d}_t^2 = 0$".

Watch out: what "inessential" does and does not mean

The rescaling (7.233) removes the exponentials exactly, and a common positive prefactor (such as $\sqrt{t/\pi}$) is a harmless overall scalar. But the new basis is not orthonormal, so the rescaled matrix is not the matrix of an operator we can square with its adjoint: the lifted *energies* (Example 7.82) do depend on the exponentials. What is preserved is everything linear-algebraic: ranks, kernels, images, and hence cohomology. The step "to leading order, the matrix of d_t on the low-lying space is δ up to change of basis" is made rigorous by the semiclassical analysis of Helffer and Sjöstrand (for a metric satisfying the Morse–Smale condition of Section 7.16.3): for large t the complex $(V_\bullet, \mathrm{d}_t)$ is isomorphic to the Morse–Witten complex with real coefficients.

Reading Nash (pp. 213–215, (7.87)–(7.95))

Nash's physics argument runs: compute the amplitude (7.87); evaluate it at large t by summing over instantons, found from the action (7.88); complete the square (7.89) to identify instantons with steepest-descent paths (7.90), of action (7.91); quote WKB for the contribution (7.92), where fermionic and bosonic determinants "mutually cancel" leaving the sign $\varepsilon_{\gamma_{ab}}$; sum to get (7.93) and the action (7.94) of d_t; discard exponentials to get (7.95). We have filled in the one-dimensional computation of the amplitude with its prefactor (7.216), the canonical quantisation check (7.223), the identity $L_B = D_F^\dagger D_F$ behind the cancellation of determinants, the role of the fermion zero mode, and the explanation of why dropping the exponentials is a change of basis.

Recap

- d_t commutes with H_t, so it maps the m_p-dimensional low-lying space V_p to V_{p+1}. The lifted energies are the eigenvalues of $D^\mathsf{T}D + DD^\mathsf{T}$, where $D = \langle b|\mathrm{d}_t|a\rangle$.
- In one dimension, WKB states make the calculation exact up to Laplace-method corrections: $\langle b|\mathrm{d}_t|a\rangle = \varepsilon\sqrt{t/\pi}\,(f''(a)\,|f''(b)|)^{1/4} e^{-t(f(b)-f(a))}$. The double-well splitting

$2\sqrt{2}(t/\pi)e^{-t/2}$ matches numerics.

- Witten's action has bosons x^i, fermions $\psi^i, \bar\psi^i$ and quantises to $\frac{1}{2}H_t$. Completing the square shows its instantons are gradient flow lines, of action $t\,|f(b)-f(a)|$.
- $L_B = D_F^\dagger D_F$: the determinants cancel up to sign. The instanton has index$(b)-$index(a) fermion zero modes, so only index difference one contributes to $\langle b|\mathrm{d}_t|a\rangle$.
- $\mathrm{d}_t|a\rangle \approx \sum \varepsilon(a,b)e^{-t(f(b)-f(a))}|b\rangle$. Rescaling the basis by e^{-tf} removes the exponentials and leaves the integer matrix $\varepsilon(a,b)$: the Morse–Witten differential δ. Opposite signs cancel (the circle with $\cos\theta$), same signs add.

7.16 The Morse–Witten complex

The last section ended with a finite matrix of integers. For every pair of critical points a, b with index(b) = index$(a)+1$ we have a number $\varepsilon(a,b)$, a signed count of the gradient flow lines running down from b to a, and at large t the operator d_t acts on the low-lying states as

$$\mathrm{d}_t|\tilde a\rangle \approx \sum_b \varepsilon(a,b)\,|\tilde b\rangle$$

((7.233)). This section answers three questions about this matrix.

1. *What does it compute?* It is the differential of a cochain complex, one generator per critical point, and the cohomology of that complex is the cohomology of M. The strong Morse inequalities then follow from a line of linear algebra.
2. *How do we compute it without quantum mechanics?* By looking at the geometry of the gradient flow: stable and unstable manifolds, and Nash's orientation rule for the signs [Nash pp. 212–213, (7.84)–(7.86)].
3. *Why does it square to zero?* Physically because $\mathrm{d}_t^2 = 0$ [Nash p. 215]; geometrically because flow lines between critical points of index difference two break into pairs of flow lines of index difference one.

Along the way we compute the complex for every example of this chapter, and meet one example ($\mathbb{RP}^2$) where the complex sees more than the Betti numbers: it sees torsion.

7.16.1 Cochain complexes and the algebra of the strong inequalities

Nash says that "the additional mathematics is a result which says that if one can form a cohomology complex from the set of critical points of f then this gives the cohomology of M and also implies the strong form of the Morse inequalities" [Nash p. 211]. We first make the second half of this sentence completely explicit, because it is pure linear algebra and it is the reason the whole construction is worth doing.

Working definition 7.33 (cochain complex and its cohomology)

A (finite) **cochain complex** is a list of finite-dimensional vector spaces and linear maps

$$0 \longrightarrow C^0 \xrightarrow{\delta_0} C^1 \xrightarrow{\delta_1} C^2 \xrightarrow{\delta_2} \cdots \xrightarrow{\delta_{n-1}} C^n \longrightarrow 0$$

with $\delta_{p+1} \circ \delta_p = 0$ for every p (written $\delta^2 = 0$). To compute with it, choose a basis of each C^p and write δ_p as a matrix D_p of size $\dim C^{p+1} \times \dim C^p$; the condition is $D_{p+1} D_p = 0$. Its **cohomology** is

$$H^p(C) := \frac{\operatorname{Ker} \delta_p}{\operatorname{Im} \delta_{p-1}}, \qquad \dim H^p(C) = \dim \operatorname{Ker} D_p - \operatorname{rank} D_{p-1}.$$

[vectors $x \in C^p$ with $\delta_p x = 0$, counted as equal when they differ by some $\delta_{p-1} y$. The rank of D_{p-1} is its number of independent columns] Formally, $H^\bullet(C)$ is a sequence of quotient spaces; in practice it is "closed modulo exact", computed by Gaussian elimination.

The quotient makes sense precisely because of $\delta^2 = 0$. For $\operatorname{Ker} \delta_p / \operatorname{Im} \delta_{p-1}$ to be a quotient of a space by a subspace we need $\operatorname{Im} \delta_{p-1} \subseteq \operatorname{Ker} \delta_p$, i.e. $\delta_p(\delta_{p-1} x) = 0$ for all x. That is literally $\delta^2 = 0$. The de Rham complex $(\Omega^\bullet, \mathrm{d})$ is the infinite-dimensional example; the deformed complex $(\Omega^\bullet, \mathrm{d}_t)$ is another (Section 7.12.3); the complexes of this section are finite.

The counting identity. Suppose $\dim C^p = m_p$ and $\dim H^p(C) = b_p$. Write $r_p := \operatorname{rank} \delta_p \geq 0$ (with $r_{-1} = r_n = 0$). Then

$$b_p \overset{(1)}{=} \dim \operatorname{Ker} \delta_p - \dim \operatorname{Im} \delta_{p-1} \overset{(2)}{=} (m_p - r_p) - r_{p-1}, \tag{7.235}$$

(1) Definition of the cohomology as a quotient: the dimension of a quotient is the difference of dimensions.
(2) Rank–nullity for $\delta_p \colon C^p \to C^{p+1}$: $\dim \operatorname{Ker} \delta_p = \dim C^p - \operatorname{rank} \delta_p$; and $\dim \operatorname{Im} \delta_{p-1} = r_{p-1}$ by definition.

so $m_p - b_p = r_p + r_{p-1}$. Multiply by u^p and sum:

$$\begin{aligned} \sum_p m_p u^p - \sum_p b_p u^p &\overset{(1)}{=} \sum_p r_p u^p + \sum_p r_{p-1} u^p \overset{(2)}{=} \sum_p r_p u^p + u \sum_q r_q u^q \\ &\overset{(3)}{=} (1+u)\, R(u), \qquad R(u) := \sum_p r_p u^p. \end{aligned} \tag{7.236}$$

(1) (7.235), multiplied by u^p and summed over p.
(2) Rename $q = p - 1$ in the second sum; $u^p = u \cdot u^q$.
(3) Factor out $\sum_p r_p u^p$.

Since every r_p is a rank, $R(u)$ has non-negative coefficients. This is exactly the form (7.140) of the strong Morse inequalities.

Key idea: the strong inequalities are rank–nullity

Any cochain complex with $\dim C^p = m_p$ whose cohomology has dimensions b_p satisfies

$$M_u - P_u = (1+u) R(u), \qquad R(u) = \sum_p \operatorname{rank}(\delta_p)\, u^p,$$

with all coefficients of R non-negative. So the strong Morse inequalities follow as soon as we find *any* complex with one generator per critical point (in degree equal to the index) and cohomology $H^\bullet(M)$. The coefficient r_p counts how many index-p critical points are "cancelled" against index-$(p+1)$ critical points by the differential.

Worked example 7.88: a two-term complex: the circle with two wells

Take $C^0 = \mathbb{R}^2$, $C^1 = \mathbb{R}^2$ and $D_0 = \begin{pmatrix} -1 & 1 \\ 1 & -1 \end{pmatrix}$ (the matrix of Example 7.83 with the factor A removed). There is only one map, so $\delta^2 = 0$ is automatic. Then

$$\operatorname{rank} D_0 \overset{(1)}{=} 1, \qquad b_0 \overset{(2)}{=} 2 - 1 = 1, \qquad b_1 \overset{(3)}{=} 2 - 1 = 1.$$

(1) The two columns are negatives of each other and nonzero.
(2) $\operatorname{Ker} D_0$ is spanned by $(1,1)^{\mathsf{T}}$: $b_0 = m_0 - r_0$.
(3) $b_1 = m_1 - r_0$ (there is no δ_1 on a 1-manifold).

These are the Betti numbers of S^1. The identity (7.236) reads $(2+2u) - (1+u) = (1+u)\cdot 1$, so $R(u) = 1$: one cancelling pair, in degrees $(0,1)$.

7.16.2 Witten's low-lying complex

Is there such a complex? Quantum mechanics hands us one immediately, before any instanton is computed. Recall the low-lying space V_p of (7.209): the span of the eigenforms of $\Delta_p(t)$ with eigenvalue at most ct. At large t, $\dim V_p = m_p$ ((7.204)), and d_t maps V_p into V_{p+1} ((7.208)). So

$$0 \longrightarrow V_0 \xrightarrow{\mathrm{d}_t} V_1 \xrightarrow{\mathrm{d}_t} \cdots \xrightarrow{\mathrm{d}_t} V_n \longrightarrow 0 \tag{7.237}$$

is a finite cochain complex, since $\mathrm{d}_t^2 = 0$. Its dimensions are the m_p. Its cohomology is the cohomology of M. Here is why.

Positive-energy eigenspaces carry no cohomology. Let E_λ be the space of eigenforms of H_t with eigenvalue λ (all degrees). Both d_t and d_t^* commute with H_t, so each maps E_λ to itself, and $(E_\lambda, \mathrm{d}_t)$ is a complex by itself. If $\lambda > 0$ and $\alpha \in E_\lambda$ is d_t-closed, then

$$\alpha \overset{(1)}{=} \frac{1}{\lambda} H_t\, \alpha \overset{(2)}{=} \frac{1}{\lambda}\left(\mathrm{d}_t \mathrm{d}_t^* \alpha + \mathrm{d}_t^* \mathrm{d}_t \alpha\right) \overset{(3)}{=} \mathrm{d}_t\left(\frac{1}{\lambda}\, \mathrm{d}_t^* \alpha\right), \tag{7.238}$$

(1) $H_t \alpha = \lambda \alpha$ and $\lambda \neq 0$.
(2) Definition (7.176) of H_t.
(3) $\mathrm{d}_t \alpha = 0$ kills the second term.

and $\frac{1}{\lambda}\mathrm{d}_t^*\alpha$ lies in E_λ again. So every closed element of E_λ is exact *within* E_λ: the complex $(E_\lambda, \mathrm{d}_t)$ has zero cohomology. (The operator $K = \mathrm{d}_t^*/\lambda$ is a **contracting homotopy**: $\mathrm{d}_t K + K \mathrm{d}_t = \mathrm{id}$ on E_λ.) Physically this is the statement that positive-energy states come in boson–fermion pairs $(\beta, \mathrm{d}_t\beta)$ and cannot carry a supersymmetric ground state.

Putting the eigenspaces together. The low-lying complex is the direct sum of the eigenspace complexes with $\lambda \leq ct$:

$$H^p\left(V_\bullet, \mathrm{d}_t\right) \overset{(1)}{=} \bigoplus_{\lambda \leq ct} H^p\left(E_\lambda, \mathrm{d}_t\right) \overset{(2)}{=} H^p\left(E_0, \mathrm{d}_t\right) \overset{(3)}{=} \operatorname{Ker} \Delta_p(t) \overset{(4)}{\cong} H^p_{\mathrm{dR}}(M). \tag{7.239}$$

(1) d_t preserves each E_λ, so kernels and images split eigenspace by eigenspace.
(2) (7.238): only $\lambda = 0$ contributes.
(3) On E_0 we have $\mathrm{d}_t = 0$ (a zero mode of H_t satisfies $\mathrm{d}_t\alpha = \mathrm{d}_t^*\alpha = 0$, Section 7.12.3), so every element is closed and none but 0 is exact.
(4) Hodge theory for d_t, (7.177).

Key idea: Witten's first proof of the strong inequalities

At large t the low-lying states of H_t form a cochain complex $(V_\bullet, \mathrm{d}_t)$ with $\dim V_p = m_p$ and cohomology $H^\bullet_{\mathrm{dR}}(M)$. By (7.236),

$$\sum_p m_p u^p - \sum_p b_p u^p = (1+u)R(u), \qquad r_p = \operatorname{rank}\bigl(\mathrm{d}_t : V_p \to V_{p+1}\bigr) \geq 0. \tag{7.240}$$

No instanton calculation is needed for this. The instantons are needed to compute the matrix of d_t on $V_\bullet$, i.e. to *construct* the cohomology of M from f.

The physical meaning of r_p. Decompose V_p orthogonally as

$$V_p = \underbrace{\operatorname{Ker}\Delta_p(t)}_{b_p \text{ exact ground states}} \oplus \underbrace{\mathrm{d}_t V_{p-1}}_{r_{p-1} \text{ lifted}} \oplus \underbrace{\mathrm{d}_t^* V_{p+1}}_{r_p \text{ lifted}}.$$

This is the Hodge decomposition of the finite complex. A lifted state in $\mathrm{d}_t^* V_{p+1}$ is a p-form β with $\mathrm{d}_t\beta \neq 0$; its partner $\mathrm{d}_t\beta$ is a lifted $(p+1)$-form with the same energy. So r_p is the number of boson–fermion pairs that tunnelling lifts *between degrees p and $p+1$*, and the factor $(1+u)$ in the Morse inequalities is the supersymmetric pairing $u^p + u^{p+1}$ of these states. See Figure 7.61.

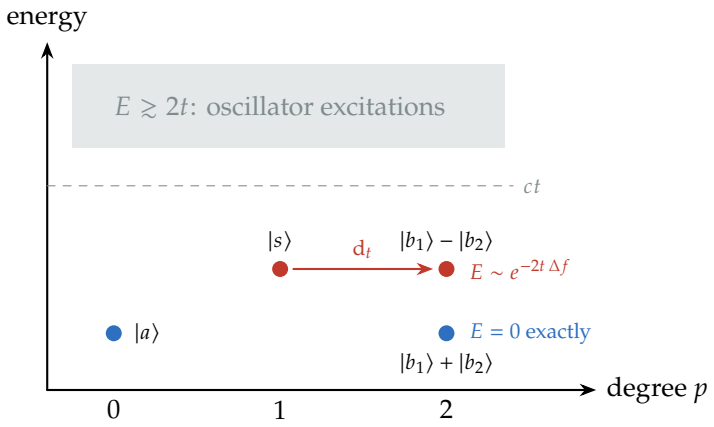

Figure 7.61: The low-lying spectrum of the two-humped sphere of Figure 7.45 at large t (schematic; energies not to scale). The four low-lying states sit one per critical point in degree equal to the index. Two (blue) are exact zero modes, $b_0 = b_2 = 1$. The saddle state and the antisymmetric combination of the two peak states (red) are superpartners, lifted together by tunnelling and joined by d_t. They are the single cancelling pair $r_1 = 1$ of $M_u - P_u = (1+u)\,u$. Everything else is at energies of order t.

Worked example 7.89: the low-lying complex on the circle with two wells

For $f = -\cos 2\theta$ on S^1 (Example 7.83) the low-lying complex is $V_0 \to V_1$ with $\dim V_0 = \dim V_1 = 2$. We computed the matrix of d_t in the basis of local states, $D_0 = A\begin{pmatrix} -1 & 1 \\ 1 & -1 \end{pmatrix}$ with $A = 2\sqrt{t/\pi}\,e^{-2t}$. Its rank is 1 for every t (the factor A is never zero), so $r_0 = 1$, $b_0 = b_1 = 1$, $R(u) = 1$, exactly as in Example 7.88. The exponentially small A does not affect the rank: this is the statement that the exponential factors are "inessential" [Nash p. 215].

Watch out: rank is robust, but only if the matrix is exactly right

The rank of a matrix is not a continuous function of its entries: a tiny perturbation can raise it. In (7.237) this causes no trouble, because d_t on $V_\bullet$ is an *exact* complex whose cohomology we know exactly. But when we replace the true matrix by its semiclassical approximation ((7.232)), we must make sure that approximation errors cannot change ranks. They cannot, because the approximate matrix is itself (after rescaling) an integer matrix with $\delta^2 = 0$ and the corrections are relatively small by powers of $1/t$; Helffer and Sjöstrand showed that for large t the two complexes are isomorphic. The upshot is that we may compute the ranks from the integer matrix $\varepsilon(a,b)$.

7.16.3 Stable and unstable manifolds, and spaces of flow lines

We now turn to the geometry that computes $\varepsilon(a,b)$ without any quantum mechanics. Nash introduces the **descending gradient flow** [Nash p. 212, (7.83)]

$$\frac{\mathrm{d}\gamma}{\mathrm{d}\sigma} = -\nabla f\big(\gamma(\sigma)\big), \qquad (\nabla f)^i = g^{ij}\partial_j f. \tag{7.241}$$

(We write σ for the flow parameter; the instanton of Section 7.15.5 is $\gamma(ts)$.) Two facts make it useful.

f decreases along the flow. Along a solution,

$$\frac{\mathrm{d}}{\mathrm{d}\sigma} f\big(\gamma(\sigma)\big) \overset{(1)}{=} \partial_i f\,\frac{\mathrm{d}\gamma^i}{\mathrm{d}\sigma} \overset{(2)}{=} -\partial_i f\, g^{ij}\partial_j f \overset{(3)}{=} -|\nabla f|^2 \;\le\; 0, \tag{7.242}$$

(1) Chain rule.
(2) The flow equation (7.241).
(3) g^{ij} is positive definite; equality only at critical points.

So f strictly decreases except at critical points. On a compact M the flow exists for all $\sigma \in \mathbb{R}$, and $f(\gamma(\sigma))$ is bounded and monotone, so it has limits as $\sigma \to \pm\infty$. Integrating (7.242) shows $\int |\nabla f|^2\,\mathrm{d}\sigma < \infty$, which forces $\gamma(\sigma)$ to approach points where $\nabla f = 0$. For a Morse function the critical points are isolated, and *every flow line starts at a critical point and ends at a critical point* (Nash: "when grad f vanishes we have a critical point and so there are critical points at the ends of the paths").

The local picture. Near a critical point, in the Morse coordinates of (7.196) with a flat metric, $f = f(c) + \tfrac{1}{2}\sum_i \lambda_i x_i^2$ and the flow is

$$\dot{x}_i = -\lambda_i x_i \quad\Longrightarrow\quad x_i(\sigma) = x_i(0)\,e^{-\lambda_i \sigma}. \tag{7.243}$$

Coordinates with $\lambda_i > 0$ decay as $\sigma \to +\infty$; those with $\lambda_i < 0$ grow. A point flows *into* c as $\sigma \to +\infty$ iff its $\lambda_i < 0$ coordinates vanish, and it came *out of* c at $\sigma = -\infty$ iff its $\lambda_i > 0$ coordinates vanish.

Working definition 7.34 (stable and unstable manifolds)

For a critical point c,

$$W^u(c) := \{x \in M :\ \text{the flow line through } x \text{ tends to } c \text{ as } \sigma \to -\infty\} \quad (\textbf{unstable}),$$
$$W^s(c) := \{x \in M :\ \text{the flow line through } x \text{ tends to } c \text{ as } \sigma \to +\infty\} \quad (\textbf{stable}).$$

[the flow line through x is the solution $\gamma(\sigma)$ of (7.241) with $\gamma(0) = x$] These are the **unstable manifold** and the **stable manifold** of c. Operationally: $W^u(c)$ is everything that can be reached by flowing *downhill* out of c, $W^s(c)$ everything that flows downhill *into* c. By (7.243), $W^u(c)$ is a disc of dimension index(c) [the number of independent downhill directions at c], tangent at c to $T_c^- M$, the span of the Hessian's negative eigenvectors; $W^s(c)$ is a disc of dimension $n - \text{index}(c)$, tangent to $T_c^+ M$.

Nash's $T_b^- M$ in (7.84), "the $(p+1)$-dimensional space corresponding to the $(p+1)$ negative eigenvalues of the Hessian Hf at b", is $T_b\, W^u(b)$. It is also the space of downhill directions whose wedge product is the local zero mode $|b\rangle$ (7.202). Every flow line leaving b lies in $W^u(b)$ and leaves b in a direction of $T_b^- M$.

Flow lines from b to a. A point lies on a flow line from b down to a iff it lies in $W^u(b) \cap W^s(a)$. So the space of *parametrised* flow lines from b to a is

$$\mathcal{M}(b,a) := W^u(b) \cap W^s(a),$$

(each point of the intersection is the value $\gamma(0)$ of one flow line). The flow parameter can be shifted, $\gamma(\sigma) \mapsto \gamma(\sigma + c)$, so the space of *unparametrised* flow lines is $\widehat{\mathcal{M}}(b,a) = \mathcal{M}(b,a)/\mathbb{R}$. Its dimension, when the intersection is transversal, is

$$\begin{aligned} \dim \widehat{\mathcal{M}}(b,a) &\overset{(1)}{=} \dim W^u(b) + \dim W^s(a) - n - 1 \\ &\overset{(2)}{=} \text{index}(b) + \big(n - \text{index}(a)\big) - n - 1 = \text{index}(b) - \text{index}(a) - 1. \end{aligned} \tag{7.244}$$

(1) Two submanifolds of dimensions k and l meeting transversally in an n-manifold meet in a submanifold of dimension $k + l - n$ (count equations: $W^s(a)$ is cut out by $n - l$ equations, and they stay independent on $W^u(b)$). Then subtract 1 for the time translation.

(2) $\dim W^u(b) = \text{index}(b)$, $\dim W^s(a) = n - \text{index}(a)$.

Key idea: finitely many flow lines between adjacent indices

If $\text{index}(b) = \text{index}(a) + 1$ and the intersection is transversal, the unparametrised flow lines from b to a form a 0-dimensional space. It is also compact (a sequence of such flow lines can only degenerate by breaking at an intermediate critical point, which would need a critical point of index strictly between index(a) and index(b)), so it is a *finite* set of points. This is why Nash's sum over "all these paths of steepest descent from b to a" in (7.85) is finite.

Working definition 7.35 (Morse–Smale condition)

The pair (f, g) [the Morse function and the Riemannian metric, both needed to define the flow of $-\nabla f$] is **Morse–Smale** if for all critical points a, b the manifolds $W^u(b)$ and $W^s(a)$ intersect transversally: at every common point their tangent spaces together span $T_x M$. Test: at a point of $W^u(b) \cap W^s(a)$, add up the dimensions of the two tangent spaces and subtract the dimension of their intersection; the result must be n. Smale's theorem: for any Morse function the condition can be achieved by an arbitrarily small change of the metric (or of f).

A consequence worth remembering: under Morse–Smale, flow lines only go *down* in index. Since $\dim \widehat{\mathcal{M}}(b,a) \geq 0$ whenever it is non-empty, a flow line from b to a forces $\text{index}(b) \geq \text{index}(a) + 1$. In particular there are no flow lines between two critical points of the same index.

Worked example 7.90: the round sphere and the flat torus

Sphere, height $f = z$. $W^u(N) = S^2 \setminus \{S\}$ (everything flows out of the north pole), $W^s(S) = S^2 \setminus \{N\}$. Their intersection is $S^2 \setminus \{N, S\}$, of dimension $2 = \text{index}(N) - \text{index}(S)$, and the unparametrised flow lines form the circle of meridians, of dimension $1 = 2 - 0 - 1$, in agreement with Example 7.86. The intersection is transversal because both are open subsets of S^2.
Flat torus, $f = \cos x + \cos y$. At the saddle $S_1 = (\pi, 0)$, $f \approx -(x-\pi)^2/2 \cdot (-1) + \dots$; precisely, $\cos x \approx -1 + \frac{1}{2}(x-\pi)^2$ and $\cos y \approx 1 - \frac{1}{2}y^2$, so the downhill direction is y and the uphill direction is x. Hence $W^u(S_1)$ is the circle $\{x = \pi\}$ minus the point Q, and $W^s(S_1)$ is the circle $\{y = 0\}$ minus P. At S_1 they cross at right angles. The intersection $W^u(P) \cap W^s(S_1) = W^s(S_1) \setminus \{S_1\}$ consists of two open arcs: the two flow lines from P to S_1 of Example 7.87, and $\dim \widehat{\mathcal{M}}(P, S_1) = 0 = 2 - 1 - 1$.

When Morse–Smale fails: the upright torus. Stand the torus on its end, like a tyre on a road, and let f be the height. Its four critical points are the top P (index 2), the top of the hole S_u and the bottom of the hole S_l (index 1), and the bottom Q (index 0). At S_u the downhill directions run along the rim of the hole, and following them we slide down the inside of the hole, left or right, and arrive at S_l. So there are two flow lines from S_u to S_l, *between critical points of the same index*. Here $W^u(S_u)$ and $W^s(S_l)$ are the same curve (the rim of the hole), and two coinciding curves in a surface are not transversal: their tangent spaces span only a line. The count (7.244) predicts $\dim \widehat{\mathcal{M}}(S_u, S_l) = 1 - 1 - 1 = -1$, i.e. generically no such flow lines at all.

Tilting the torus slightly towards us breaks the reflection symmetry that keeps the rim of the hole invariant. The two flow lines leaving S_u now miss S_l, one passing in front and one behind, and continue to the minimum Q; and S_l now receives two flow lines from the top P. Figure 7.62 shows both pictures, computed numerically on the torus of radii 2 and 1 with its induced metric. After the tilt the flow lines between adjacent indices are

$$P \to S_u \ (2), \qquad P \to S_l \ (2), \qquad S_u \to Q \ (2), \qquad S_l \to Q \ (2),$$

exactly the pattern of the flat torus. Saddle-to-saddle connections are destroyed by any small generic perturbation, which is Smale's theorem in action. This is why Nash's upright-torus example [Nash p. 196] is fine for counting critical points but must be tilted before we count flow lines.

Watch out: the upright torus is not a counter-example

For the upright torus the naive Morse–Witten count happens to give the right answer (all the relevant signed counts vanish). That is luck. In general, saddle-to-saddle connections make the counts ill-defined: a small change of the metric changes which flow lines exist. The correct statement is that the complex is defined, and computes $H^\bullet(M)$, for Morse–Smale pairs (f, g); different Morse–Smale pairs give different complexes with the same cohomology. Nash does not mention the condition; it is implicit in his statement that the sum (7.85) is finite.

7.16.4 The signs: Nash's orientation rule

Over $\mathbb{Z}_2$ one could simply count flow lines mod 2 (Chapter 7 previews this). Over $\mathbb{Z}$ or $\mathbb{R}$ each flow line needs a sign, and the examples show that the sign is essential: on the circle with $f = \cos\theta$ the two flow lines from the maximum to the minimum must *cancel* (Example 7.84), because $b_0 = b_1 = 1$ requires $\delta = 0$. Nash's rule [Nash pp. 212–213, (7.84)–(7.85)] produces these signs. We state it, explain each step, and then compute it in examples.

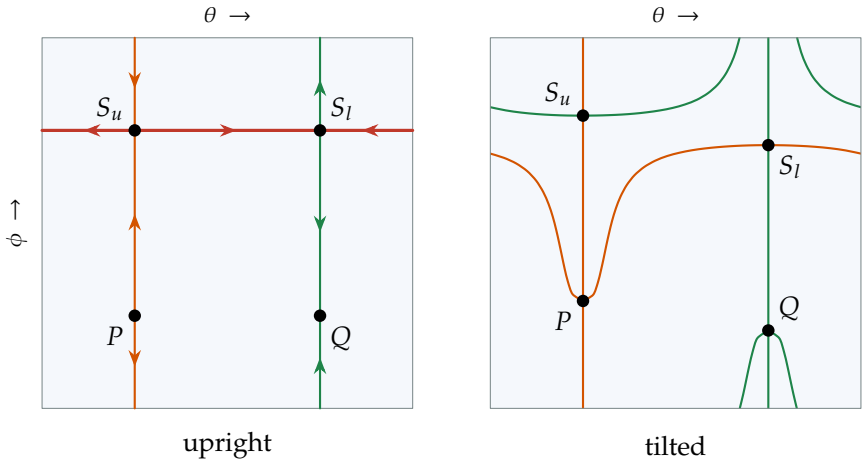

Figure 7.62: Flow lines of the height function on a torus of radii 2 and 1, drawn on the square of angles (θ, ϕ) (opposite sides identified; θ runs around the big circle, ϕ around the tube). Orange: flow lines from the top P into the saddles; green: flow lines from the saddles to the bottom Q. *Left:* the upright torus. The two red flow lines run from the saddle S_u to the saddle S_l, between points of the same index: Morse–Smale fails. *Right:* the same torus tilted by 0.25 radians (numerical solution of $\dot\gamma = -\nabla f$ with the induced metric). The red connection has broken open: the lines leaving S_u now curve away and end at Q, and S_l receives two new lines from P. Every saddle now has exactly two lines in and two lines out.

Orientations are signs of states. The local zero mode at a critical point b of index $p+1$ is ((7.202))

$$|b\rangle \propto e^{-\frac{t}{2}\sum|\lambda_i|x_i^2}\, \mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^{p+1},$$

the wedge of the downhill coordinate differentials. The state is defined only up to a sign: reordering two of the $\mathrm{d}x^i$ flips it. Choosing the sign of $|b\rangle$ is the same as choosing an **orientation** of the $(p+1)$-dimensional space $T_b^- M$: the ordered bases $(v_1, \dots, v_{p+1})$ with $(\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^{p+1})(v_1, \dots, v_{p+1}) > 0$ are declared positive. That is Nash's phrase "using the critical point b thought of as a $(p+1)$-form to orient $T_b^- M$". At a minimum ($p = -1$, i.e. index 0) the local state is a positive Gaussian function, and the orientation of the zero-dimensional space $T_a^- M = \{0\}$ is the number +1.

Working definition 7.36 (the sign ε_γ of a flow line (Nash's rule))

Let γ be a flow line from b (index $p+1$) down to a (index p), and let ω_b, ω_a be the chosen orientation forms on $T_b^- M$ and $T_a^- M$ [top-degree forms, such as $\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^{p+1}$ at b, that fix the signs of $|b\rangle$ and $|a\rangle$].

1. Let $v \in T_b^- M$ be the direction in which γ leaves b (pointing downhill, along γ). Split $T_b^- M = \mathbb{R}v \oplus O_b$ with $O_b \perp v$: Nash's (7.84), $T_b^- M = T_b \gamma_{ab} \oplus O_b$.
2. Orient the p-dimensional O_b by the p-form $\iota_v \omega_b = \omega_b(v, \cdot, \dots, \cdot)$: a basis $(w_1, \dots, w_p)$ of O_b is positive iff $\omega_b(v, w_1, \dots, w_p) > 0$.
3. Transport $(w_1, \dots, w_p)$ along γ with the linearised flow [the derivative of the flow map, carrying a tangent vector at one point of γ to a tangent vector at a later point]. As the flow line approaches a, the transported vectors, projected onto $T_a^- M$, form a basis $(w_1', \dots, w_p')$ of $T_a^- M$.
4. $\varepsilon_\gamma := \operatorname{sgn} \omega_a(w_1', \dots, w_p') = \pm 1$: +1 if the orientations agree, −1 if they disagree.

Then $\varepsilon(a,b) := \sum_{\gamma:\, b \to a} \varepsilon_\gamma$ (Nash's (7.85)).

Why step 3 works. Two things need checking: that the transported vectors end up in (or project isomorphically onto) $T_a^- M$, and that the answer does not depend on how close to a we look. Near a, write a tangent vector as $w = (w_-, w_+)$ with $w_- \in T_a^- M$ (the p directions with $\lambda_i < 0$) and $w_+ \in T_a^+ M$. The linearised flow of (7.243) acts by

$$w_i(\sigma) = e^{-\lambda_i \sigma}\, w_i(0): \qquad w_- \text{ grows like } e^{|\lambda|\sigma}, \qquad w_+ \text{ decays like } e^{-\lambda\sigma}. \tag{7.245}$$

The transported O_b stays inside the tangent spaces of $W^u(b)$, and the Morse–Smale condition says that these meet $T\,W^s(a) \approx T_a^+ M$ only in the direction of γ itself. Hence the transported O_b is complementary to $T_a^+ M$, its projection onto $T_a^- M$ is an isomorphism, and by (7.245) the transported subspace converges to $T_a^- M$ as $\sigma \to \infty$ (the w_+ parts die, the w_- parts are stretched). Projection is continuous and never degenerates along the way, so the sign in step 4 is the same wherever it is evaluated. (This is the "λ-lemma" of dynamical systems in its simplest form.)

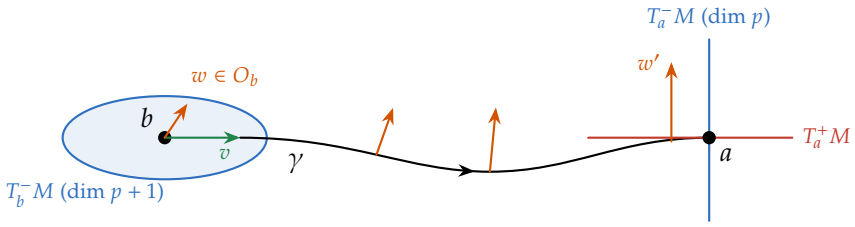

Figure 7.63: Nash's orientation rule. At b the unstable space $T_b^- M$ (blue) contains the exit direction v of the flow line γ and its complement O_b. Interior multiplication by v turns the orientation of $T_b^- M$ into an orientation of O_b. Carried along γ by the linearised flow, the frame of O_b is stretched in the unstable directions of a and squeezed in its stable directions (red), so it lines up with $T_a^- M$ (blue). Comparing with the chosen orientation of $T_a^- M$ gives $\varepsilon_\gamma = \pm 1$.

Check: one dimension. For $p = 0$, b is a local maximum of a function on a line or circle with coordinate x, $\omega_b = \mathrm{d}x$, and $T_b^- M$ is the whole tangent line. Then $O_b = \{0\}$ and step 2 gives the number $\iota_v \mathrm{d}x = \mathrm{d}x(v)$, whose sign is $+1$ if the flow line leaves b in the direction of increasing x and -1 otherwise. At the minimum a, $\omega_a = +1$. So

$$\varepsilon_\gamma = \operatorname{sgn} \mathrm{d}x(v),$$

which is exactly the sign we found by direct computation of $\langle b|\mathrm{d}_t|a\rangle$ in (7.215). Nash's rule is the generalisation of that one-dimensional computation to every dimension.

Worked example 7.91: the flat torus: all pairs cancel

Take $f = \cos x + \cos y$ on the flat torus with orientation $\mathrm{d}x \wedge \mathrm{d}y$. Choose

$$\omega_P = \mathrm{d}x \wedge \mathrm{d}y, \qquad \omega_{S_1} = \mathrm{d}y, \qquad \omega_{S_2} = \mathrm{d}x, \qquad \omega_Q = +1,$$

using the downhill directions found in Example 7.90 (y at $S_1 = (\pi, 0)$; by the same computation x at $S_2 = (0, \pi)$).

From P to S_1. The two flow lines run along $y = 0$, leaving P in the directions $v = \pm\partial_x$. Then

$$\iota_{\pm\partial_x}(\mathrm{d}x \wedge \mathrm{d}y) \overset{(1)}{=} \pm\big(\mathrm{d}x(\partial_x)\,\mathrm{d}y - \mathrm{d}y(\partial_x)\,\mathrm{d}x\big) \overset{(2)}{=} \pm\mathrm{d}y.$$

(1) The interior product of a 2-form, $\iota_v(\alpha \wedge \beta) = \alpha(v)\beta - \beta(v)\alpha$.
(2) $\mathrm{d}x(\partial_x) = 1$, $\mathrm{d}y(\partial_x) = 0$.

So $O_P = \mathbb{R}\partial_y$ is oriented by $\pm\mathrm{d}y$. Along the invariant line $y = 0$ the linearised flow maps ∂_y to a positive multiple of ∂_y (the y-component obeys $\dot{w}_y = \cos(0)\, w_y$ along the line for

the flow $\dot y = \sin y$). At S_1, $T^-_{S_1}M = \mathbb{R}\partial_y$ with $\omega_{S_1} = \mathrm{d}y$. Comparing: the rightward line has $\varepsilon = +1$, the leftward line $\varepsilon = -1$, and $\varepsilon(S_1, P) = 0$.
From P to S_2. Now $v = \pm\partial_y$ and $\iota_{\pm\partial_y}(\mathrm{d}x \wedge \mathrm{d}y) = \mp\mathrm{d}x$: the upward line has $\varepsilon = -1$, the downward line $\varepsilon = +1$, and $\varepsilon(S_2, P) = 0$.
From S_1 and S_2 to Q. From S_1 the lines leave along $v = \pm\partial_y$, and $\iota_{\pm\partial_y}\mathrm{d}y = \pm 1$, compared with $\omega_Q = +1$: $\varepsilon = \pm 1$, total 0. Likewise from S_2 along $\pm\partial_x$: total 0.
So every $\varepsilon(a, b)$ vanishes and $\delta = 0$:

$$H^0 = \mathbb{Z}\,Q, \qquad H^1 = \mathbb{Z}\,S_1 \oplus \mathbb{Z}\,S_2, \qquad H^2 = \mathbb{Z}\,P,$$

the cohomology of T^2. The same signs hold for the tilted torus of Figure 7.62, by continuity of the picture. Physically: every critical point carries an exact supersymmetric ground state, because for each pair of adjacent critical points the two tunnelling paths interfere destructively.

Watch out: conventions for the sign

Authors differ on details of the rule: some contract ω_b with v in the last slot rather than the first, some use the incoming direction at a instead of the outgoing one at b, some work with homology and flow upwards. Each change multiplies all $\varepsilon(a, b)$ with $\mathrm{index}(a) = p$ by a factor depending only on p, or reverses some basis vectors. Both are changes of basis of the C^p, so they do not affect $\delta^2 = 0$ or the cohomology. Likewise, reversing the chosen orientation at a single critical point c replaces the basis vector c by $-c$: a change of basis. Only the combination of choices used in one computation must be consistent. Ours is fixed by agreement with the d_t computation (7.215).

7.16.5 Why $\delta^2 = 0$: broken flow lines

Nash defines δ by [Nash p. 213, (7.86)]

$$\delta(a) = \sum_{b \in C^{p+1}} \varepsilon(a, b)\, b,$$

and then remarks that "a direct calculation [of $\delta^2 = 0$] with the present combinatorial definition is difficult". He sidesteps it with physics: δ is d_t in the rescaled basis (7.233), and $\mathrm{d}_t^2 = 0$. That argument is complete as far as it goes. But it is worth seeing what the "difficult" combinatorial statement actually says, because it is a beautiful piece of geometry, and it is exactly the argument that survives in Floer theory, where there is no d_t to fall back on.

What has to vanish. Apply δ twice to a critical point a of index p:

$$\delta^2(a) \overset{(1)}{=} \delta\Big(\sum_b \varepsilon(a, b)\, b\Big) \overset{(2)}{=} \sum_b \varepsilon(a, b) \sum_c \varepsilon(b, c)\, c \overset{(3)}{=} \sum_c \Big(\sum_b \varepsilon(a, b)\, \varepsilon(b, c)\Big) c. \tag{7.246}$$

(1) Definition (7.86); b runs over critical points of index $p + 1$.
(2) δ is linear; apply (7.86) again to each b, with c running over index $p + 2$.
(3) Exchange the two finite sums.

So $\delta^2 = 0$ says: for every pair (a, c) with $\mathrm{index}(c) = \mathrm{index}(a) + 2$,

$$N(a, c) := \sum_b \varepsilon(a, b)\, \varepsilon(b, c) = \sum_{\substack{\text{broken lines} \\ c \to b \to a}} \varepsilon_{\gamma_{bc}}\, \varepsilon_{\gamma_{ab}} = 0. \tag{7.247}$$

The middle expression expands each ε as a sum over flow lines (7.244): $N(a,c)$ is a signed count of **broken flow lines**, pairs consisting of a flow line from c down to some b followed by a flow line from that b down to a.

Where broken flow lines come from. By the dimension formula (7.244), the unparametrised flow lines from c to a form a space $\widehat{\mathcal{M}}(c,a)$ of dimension $\mathrm{index}(c) - \mathrm{index}(a) - 1 = 1$: a union of curves. A 1-manifold is a union of circles and open intervals. An open interval has two ends, and we can ask what the flow lines do as we run off an end. Three facts, which we take from the analysis of the gradient flow, answer this.

1. *Compactness up to breaking.* A sequence of flow lines from c to a that leaves every compact part of $\widehat{\mathcal{M}}(c,a)$ has a subsequence converging to a broken flow line $c \to b \to a$. (The flow line is spending longer and longer near b. Energy $f(c) - f(a)$ is conserved in the limit; it splits as $(f(c) - f(b)) + (f(b) - f(a))$.)
2. *Gluing.* Conversely, every broken flow line $c \to b \to a$ is the limit of exactly one end of $\widehat{\mathcal{M}}(c,a)$. (Start slightly off the first line, on the side that leads to a; the flow carries you past b and down to a.)
3. *Signs at the ends.* The orientation data that define the ε's also orient each component of $\widehat{\mathcal{M}}(c,a)$, and at the two ends of an interval the products $\varepsilon_{\gamma_{bc}}\varepsilon_{\gamma_{ab}}$ are *opposite*. (One end is "incoming", the other "outgoing", as for the boundary of an oriented interval $\partial[0,1] = \{1\} - \{0\}$.)

Key idea: $\delta^2 = 0$ is Stokes' theorem for an interval

The broken flow lines $c \to b \to a$ are exactly the ends of the one-dimensional space $\widehat{\mathcal{M}}(c,a)$, and each open-interval component contributes two ends with opposite signs. Circles contribute no ends. So

$$N(a,c) = \sum_{\text{intervals}} (+1 - 1) = 0,$$

which is (7.247). This is the same principle as "$\int_{\partial I} 1 = 1 - 1 = 0$": a compact oriented 1-manifold has as many positively as negatively oriented boundary points.

Worked example 7.92: the torus family $P \to Q$ and its broken ends

On the flat torus with $f = \cos x + \cos y$ (Example 7.87), take the flow parameter σ with $t = 1$. In the quadrant $0 < x, y < \pi$ the flow lines from $P = (0,0)$ to $Q = (\pi,\pi)$ are

$$x(\sigma) = 2\arctan e^{\sigma}, \qquad y(\sigma) = 2\arctan e^{\sigma - \Delta}, \qquad \Delta \in \mathbb{R},$$

where we used the time translation to put the x-kink at $\sigma = 0$. The unparametrised flow lines in this quadrant are labelled by the single number Δ, the delay of the y-kink behind the x-kink: an open interval, as the dimension count $2 - 0 - 1 = 1$ predicts. Its two ends are:

- $\Delta \to +\infty$: x jumps from 0 to π long before y moves. The curve hugs $y = 0$ from P to $S_1 = (\pi, 0)$, waits there, then climbs $x = \pi$ to Q: the broken line $P \to S_1 \to Q$.
- $\Delta \to -\infty$: y moves first: the broken line $P \to S_2 \to Q$.

The signs from Example 7.91 are: $P \to S_1$ rightwards $+1$, then $S_1 \to Q$ upwards $+1$ (product $+1$); $P \to S_2$ upwards -1, then $S_2 \to Q$ rightwards $+1$ (product -1). Opposite, as promised. The other three quadrants are the same up to reflections:

quadrant	via S_1	product	via S_2	product
$x>0,\ y>0$	$(+1)(+1)$	$+1$	$(-1)(+1)$	-1
$x<0,\ y>0$	$(-1)(+1)$	-1	$(-1)(-1)$	$+1$
$x<0,\ y<0$	$(-1)(-1)$	$+1$	$(+1)(-1)$	-1
$x>0,\ y<0$	$(+1)(-1)$	-1	$(+1)(+1)$	$+1$

Here "via S_1" lists $\varepsilon_{\gamma_{S_1P}}\,\varepsilon_{\gamma_{QS_1}}$ for the two segments of the broken line. There are $2\times 2=4$ broken lines through S_1 and 4 through S_2; the 8 broken lines are the 8 ends of the 4 intervals, and each interval has one end of each sign. So $N(Q,P)=0$. On the torus this is no surprise, because every single ε already vanishes; but the pairing of ends holds interval by interval, which is the mechanism in general.

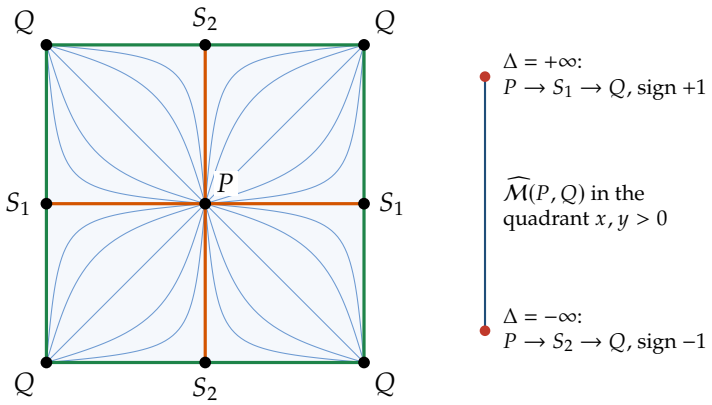

Figure 7.64: Why $\delta^2=0$ on the flat torus (drawn on $[-\pi,\pi]^2$ with $P=(0,0)$ at the centre; the sides are identified, so the four corners are the one minimum Q and the midpoints of opposite sides are the same saddle). Blue: the one-parameter families of flow lines from P to Q, one family per quadrant, labelled by the delay Δ. As $\Delta\to\pm\infty$ a blue curve degenerates to a broken line made of an orange segment ($P\to$ saddle) followed by a green one (saddle $\to Q$). Each family is an open interval (right) whose two ends are broken lines with opposite signs, so the signed count of broken lines, which is the coefficient of P in $\delta^2(Q)$, is zero.

Two proofs, one fact. The physics proof ($\mathrm{d}_t^2=0$ and (7.233)) and the geometric proof (ends of $\widehat{\mathcal{M}}(c,a)$) are the same statement seen from two sides. In the rescaled basis, the matrix element $\langle\tilde{c}|\mathrm{d}_t\mathrm{d}_t|\tilde{a}\rangle$ is a sum over intermediate low-lying states $|\tilde{b}\rangle$, and each term is a product of two single-instanton amplitudes: a broken flow line $c\to b\to a$. That the sum vanishes is guaranteed by $\mathrm{d}_t^2=0$. On the geometric side the same cancellation appears as the pairing of the ends of the one-parameter family of unbroken flow lines from c to a, which are the tunnelling histories that "interpolate" between the broken ones. Stokes' theorem on the moduli space is how the path integral knows that $\mathrm{d}_t^2=0$.

Watch out: breaking needs Morse–Smale

On the upright torus (Figure 7.62, left) the family of flow lines from P to Q is not a union of intervals whose ends are broken lines between adjacent indices: some flow lines leave P, pass through S_u and S_l in turn (two breaks), because of the saddle-to-saddle connection. Transversality is what guarantees that a 1-dimensional family can only break once. This is the second reason (after finiteness of the counts) for insisting on a Morse–Smale pair (f,g).

7.16.6 Worked Morse–Witten complexes

We now have a complete recipe. It is worth stating it as a pipeline, since every example below follows it step by step.

Working definition 7.37 (computing the Morse–Witten complex)

1. *Critical points.* List the critical points of f and their indices. C^p is the free abelian group [all combinations $\sum_c n_c\, c$ with integers n_c, and no relations] (or vector space) with one basis vector for each critical point of index p (Nash's (7.81); "included in C_p are integral linear combinations").
2. *Orientations.* At each critical point c choose an orientation ω_c of $T_c^- M$ (the downhill directions). At a minimum choose +1.
3. *Flow lines.* For each pair (a, b) with $\mathrm{index}(b) = \mathrm{index}(a) + 1$, find the flow lines of $-\nabla f$ from b to a (check Morse–Smale; if it fails, perturb the metric).
4. *Signs.* Give each flow line its sign ε_γ by Nash's rule, and add: $\varepsilon(a, b) = \sum_\gamma \varepsilon_\gamma$.
5. *Differential.* $\delta(a) = \sum_b \varepsilon(a, b)\, b$; write the matrices D_p and check $D_{p+1} D_p = 0$.
6. *Cohomology.* $H^p = \mathrm{Ker}\, D_p / \mathrm{Im}\, D_{p-1}$, by Gaussian elimination (over $\mathbb{Z}$: by the Smith normal form [integer row and column operations that make D_p diagonal. Diagonal entries other than 0 and ±1 give the torsion], which also finds torsion).

Why is step 1 legitimate with integer coefficients? The entries $\varepsilon(a, b)$ are integers, so δ maps integer combinations to integer combinations, and all of the construction makes sense over $\mathbb{Z}$. Witten's d_t acts on real (or complex) forms and sees the complex tensored with $\mathbb{R}$ [the same complex with real instead of integer coefficients]; the integer complex is a refinement that physics does not directly provide but that the geometry of flow lines does.

Worked example 7.93: the two-humped sphere

Take the two-humped sphere of Figure 7.45: a minimum a at the bottom, two peaks b_1 (left) and b_2 (right), and a saddle s on the ridge between them. Near the top use coordinates (x, y) with x running along the ridge from left to right and y running from back to front, and assume the surface is symmetric under $y \mapsto -y$.

Steps 1–2. $C^0 = \mathbb{Z}a$, $C^1 = \mathbb{Z}s$, $C^2 = \mathbb{Z}b_1 \oplus \mathbb{Z}b_2$. Orientations: $\omega_{b_1} = \omega_{b_2} = \mathrm{d}x \wedge \mathrm{d}y$ (the same orientation of the sphere near both peaks), $\omega_s = \mathrm{d}y$ (at the saddle the downhill direction is across the ridge), $\omega_a = +1$.

Step 3. From b_1 exactly one flow line reaches s: the crest of the ridge, moving to the right. From b_2 one flow line, moving left. From s two flow lines descend to a, one down the front and one down the back. Every other flow line from a peak goes straight to a. The pair is Morse–Smale: in two dimensions, any pair (a, b) with adjacent indices involves a maximum or a minimum, whose unstable or stable manifold is open, and an open set meets anything transversally.

Step 4. From s to a: the lines leave s along $v = \pm\partial_y$, and $\iota_{\pm\partial_y}\mathrm{d}y = \pm 1$. So $\varepsilon(a, s) = (+1) + (-1) = 0$. From b_1 to s: $v = +\partial_x$, and

$$\iota_{\partial_x}(\mathrm{d}x \wedge \mathrm{d}y) \overset{(1)}{=} \mathrm{d}x(\partial_x)\,\mathrm{d}y - \mathrm{d}y(\partial_x)\,\mathrm{d}x \overset{(2)}{=} \mathrm{d}y,$$

(1) The interior product of a wedge of two 1-forms.
(2) $\mathrm{d}x(\partial_x) = 1$, $\mathrm{d}y(\partial_x) = 0$.

so $O_{b_1} = \mathbb{R}\partial_y$ is oriented by ∂_y. The reflection $y \mapsto -y$ fixes the crest pointwise and commutes with the flow, so the linearised flow carries ∂_y to a positive multiple of ∂_y. At s we compare with $\omega_s = \mathrm{d}y$: $\varepsilon(s, b_1) = +1$. From b_2 the line leaves along $v = -\partial_x$, $\iota_{-\partial_x}(\mathrm{d}x \wedge \mathrm{d}y) = -\mathrm{d}y$, and $\varepsilon(s, b_2) = -1$.
Steps 5–6.

$$\delta(a) = 0, \qquad \delta(s) = b_1 - b_2, \qquad \delta(b_i) = 0; \qquad D_0 = \begin{pmatrix} \end{pmatrix}, \quad D_1 = \begin{pmatrix} 1 \\ -1 \end{pmatrix}.$$

Then

$$H^0 \overset{(1)}{=} \operatorname{Ker} D_0 = \mathbb{Z}a \cong \mathbb{Z},$$
$$H^1 \overset{(2)}{=} \operatorname{Ker} D_1 / \operatorname{Im} D_0 = 0,$$
$$H^2 \overset{(3)}{=} \frac{\mathbb{Z}b_1 \oplus \mathbb{Z}b_2}{\mathbb{Z}(b_1 - b_2)} \cong \mathbb{Z}.$$

(1) Nothing maps into C^0, and $D_0 = 0$.
(2) D_1 is injective: $D_1(ns) = n(b_1 - b_2) \neq 0$ for $n \neq 0$.
(3) The map $mb_1 + nb_2 \mapsto m + n$ is onto $\mathbb{Z}$ with kernel exactly $\mathbb{Z}(b_1 - b_2)$; so the quotient is $\mathbb{Z}$, generated by the class of b_1 (equal to the class of b_2).

This is $H^\bullet(S^2; \mathbb{Z}) = (\mathbb{Z}, 0, \mathbb{Z})$. The single cancelling pair is $(s,\ b_1 - b_2)$, in degrees $(1, 2)$: $R(u) = u$, as announced in Figure 7.45.
The physics. Back in the unrescaled basis (7.232),

$$\mathrm{d}_t|s\rangle \approx A_1|b_1\rangle - A_2|b_2\rangle, \qquad A_i \propto e^{-t(f(b_i) - f(s))}.$$

The exact 2-form ground state must be orthogonal to $\operatorname{Im} \mathrm{d}_t$, so it is proportional to $A_2|b_1\rangle + A_1|b_2\rangle$. If the peaks have equal height it is the symmetric combination $|b_1\rangle + |b_2\rangle$ of Figure 7.61. If b_1 is higher, then $A_1 \ll A_2$ and the ground state sits almost entirely on b_1: it concentrates on the *highest* peak. That agrees with the exact zero mode e^{tf} vol of Section 7.12, which for large t is dominated by the global maximum of f. The lifted 2-form is the orthogonal combination $A_1|b_1\rangle - A_2|b_2\rangle$, the superpartner of $|s\rangle$.

Worked example 7.94: perfect functions: the round sphere and $\mathbb{CP}^n$

For the height on the round S^2 there are two critical points, of index 0 and 2. $C^1 = 0$, so both maps $\delta_0 \colon C^0 \to C^1$ and $\delta_1 \colon C^1 \to C^2$ vanish, whatever the flow lines are. The complex is $\mathbb{Z} \to 0 \to \mathbb{Z}$ and $H^\bullet = (\mathbb{Z}, 0, \mathbb{Z})$. The circle of meridians from N to S (Example 7.90) plays no role: it connects indices that differ by 2.
The same argument works whenever no two critical indices are adjacent, because then every C^p next to a non-zero $C^{p\pm1}$ is zero. For $f = \sum_i a_i |z_i|^2$ on $\mathbb{CP}^n$ (Chapter 7, the classic example of Nash's §1) the indices are $0, 2, \ldots, 2n$. So $\delta = 0$ identically and $H^{2k}(\mathbb{CP}^n; \mathbb{Z}) = \mathbb{Z}$ for $0 \leq k \leq n$, all other groups zero. This is the Morse–Witten version of the **lacunary principle**: a Morse function whose indices have no two consecutive values is perfect, over every coefficient ring. Physically, every perturbative ground state is exact, because there is no state of adjacent fermion number for it to pair with.

Worked example 7.95: six critical points on the round sphere

Let $f(x,y,z) = x^2 + 2y^2 + 3z^2$ restricted to the unit sphere, with the round metric. Its critical points are the six points $\pm e_1, \pm e_2, \pm e_3$. To avoid writing "$-e_2$" for a basis vector (it would look like the negative of e_2), we name them

$$a_\pm = (\pm 1, 0, 0), \qquad s_\pm = (0, \pm 1, 0), \qquad b_\pm = (0, 0, \pm 1).$$

Indices. Near a_+ use (y,z) as coordinates; then $x^2 = 1 - y^2 - z^2$ and $f = 1 + y^2 + 2z^2$: index 0. Near s_+, with coordinates (x,z), $f = 2 - x^2 + z^2$: index 1, downhill direction ∂_x. Near b_+, with (x,y), $f = 3 - 2x^2 - y^2$: index 2. The same holds at the antipodes. So $m = (2,2,2)$ while $b(S^2) = (1,0,1)$: two cancelling pairs, $M_u - P_u = 1 + 2u + u^2 = (1+u)(1+u)$ and $R(u) = 1 + u$.

The flow, exactly. Write $A = \operatorname{diag}(1,2,3)$, so $f(x) = x \cdot Ax$. The gradient on the unit sphere is the ambient gradient $2Ax$ minus its normal part, $\nabla f = 2\big(Ax - (x \cdot Ax)\, x\big)$. We claim that

$$x(\sigma) = \frac{y(\sigma)}{|y(\sigma)|}, \qquad y(\sigma) = e^{-2A\sigma} x_0,$$

solves $\dot{x} = -\nabla f$. Indeed, with $\dot{y} = -2Ay$,

$$\dot{x} \overset{(1)}{=} \frac{\dot{y}}{|y|} - \frac{y\,(y \cdot \dot{y})}{|y|^3} \overset{(2)}{=} -2Ax + 2x\,\frac{y \cdot Ay}{|y|^2} \overset{(3)}{=} -2\big(Ax - (x \cdot Ax)\, x\big) = -\nabla f.$$

(1) Quotient rule, with $\frac{\mathrm{d}}{\mathrm{d}\sigma}|y| = (y \cdot \dot{y})/|y|$.
(2) $\dot{y} = -2Ay$ and $y/|y| = x$.
(3) $(y \cdot Ay)/|y|^2 = x \cdot Ax$.

So the flow line through $x_0 = (x_0, y_0, z_0)$ is the direction of $(x_0 e^{-2\sigma},\ y_0 e^{-4\sigma},\ z_0 e^{-6\sigma})$. As $\sigma \to +\infty$ the slowest-decaying non-zero component wins: the line ends at $a_\pm$ if $x_0 \neq 0$ (sign of x_0), and at $s_\pm$ if $x_0 = 0$, $y_0 \neq 0$. As $\sigma \to -\infty$ the fastest-growing non-zero component wins: the line starts at $b_\pm$ if $z_0 \neq 0$. Hence the flow lines between adjacent indices are quarter great circles:

- $b_\pm \to s_\pm$ along the great circle $x = 0$ (four lines, one for each pair of signs);
- $s_\pm \to a_\pm$ along the equator $z = 0$ (four lines).

Morse–Smale holds for the same reason as in the previous example.

Orientations. In the ambient coordinates, choose $\omega_{b_\pm} = \mathrm{d}x \wedge \mathrm{d}y$ (the tangent planes at $b_\pm$ are both horizontal), $\omega_{s_\pm} = \mathrm{d}x$, $\omega_{a_\pm} = +1$.

Signs, $s \to a$. The line $s_+ \to a_+$ leaves $s_+ = (0,1,0)$ towards $(1,0,0)$, i.e. along $v = +\partial_x$: $\varepsilon = \mathrm{d}x(\partial_x) = +1$. The line $s_+ \to a_-$ leaves along $-\partial_x$: $\varepsilon = -1$. The same for s_-.

Signs, $b \to s$. The line $b_+ \to s_+$ leaves b_+ along $v = +\partial_y$. Then $\iota_{\partial_y}(\mathrm{d}x \wedge \mathrm{d}y) = -\mathrm{d}x$, so $O_{b_+} = \mathbb{R}\partial_x$ is positively spanned by $w = -\partial_x$. Along the great circle $x = 0$ the vector ∂_x is tangent to the sphere, and the reflection $x \mapsto -x$ (a symmetry of f and g fixing that circle) forces the linearised flow to carry ∂_x to a positive multiple of itself. So w arrives at s_+ as a positive multiple of $-\partial_x$, and $\omega_{s_+}(-\partial_x) = -1$: $\varepsilon = -1$. The line $b_+ \to s_-$ leaves along $-\partial_y$, $\iota_{-\partial_y}(\mathrm{d}x \wedge \mathrm{d}y) = +\mathrm{d}x$, $w = +\partial_x$, $\varepsilon = +1$. The lines from b_- leave in the same ambient directions ($\pm\partial_y$) with the same ω, so they have the same signs.

The complex.

$$\delta(a_+) = s_+ + s_-, \qquad \delta(a_-) = -s_+ - s_-,$$
$$\delta(s_+) = -b_+ - b_-, \qquad \delta(s_-) = b_+ + b_-,$$

$$D_0 = \begin{pmatrix} 1 & -1 \\ 1 & -1 \end{pmatrix} \begin{matrix} \leftarrow s_+ \\ \leftarrow s_- \end{matrix}, \qquad D_1 = \begin{pmatrix} -1 & 1 \\ -1 & 1 \end{pmatrix} \begin{matrix} \leftarrow b_+ \\ \leftarrow b_- \end{matrix},$$

columns labelled (a_+, a_-) and (s_+, s_-) respectively. Check:

$$D_1 D_0 \overset{(1)}{=} \begin{pmatrix} -1\cdot 1 + 1\cdot 1 & -1\cdot(-1) + 1\cdot(-1) \\ -1\cdot 1 + 1\cdot 1 & -1\cdot(-1) + 1\cdot(-1) \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}.$$

(1) Row times column.

Cohomology: $\operatorname{Ker} D_0 = \mathbb{Z}(a_+ + a_-)$, so $H^0 = \mathbb{Z}$. $\operatorname{Ker} D_1 = \mathbb{Z}(s_+ + s_-) = \operatorname{Im} D_0$, so $H^1 = 0$. $H^2 = (\mathbb{Z}b_+ \oplus \mathbb{Z}b_-)/\mathbb{Z}(b_+ + b_-) \cong \mathbb{Z}$, generated by the class of b_+. Again $H^\bullet(S^2;\mathbb{Z})$, from a different complex. The two cancelling pairs are $(a_+ - a_-,\ s_+ + s_-)$ in degrees $(0,1)$ and $(s_+ - s_-,\ b_+ + b_-)$ in degrees $(1,2)$, matching $R(u) = 1 + u$.

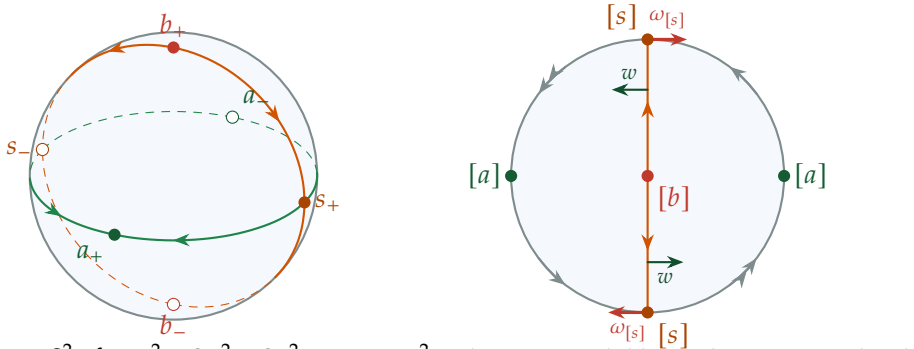

Figure 7.65: *Left:* the six critical points of $f = x^2 + 2y^2 + 3z^2$ on the round sphere (open circles are on the hidden back side, dashed arcs are hidden). Orange quarter circles run from the maxima $b_\pm$ to the saddles $s_\pm$; green ones from the saddles to the minima $a_\pm$. *Right:* the same function on $\mathbb{RP}^2$, drawn as the upper hemisphere seen from above with antipodal boundary points identified. There is one critical point of each index. The two flow lines from $[b]$ reach $[s]$ from opposite sides. The orientation of $[s]$ (red) looks reversed at the two lifts because the gluing map is $v \mapsto -v$. The transported vectors w (green) disagree with it on *both* lines, so the two signs add: $\varepsilon([s],[b]) = -2$.

Worked example 7.96: $\mathbb{RP}^2$: the complex sees torsion

The antipodal map $\tau(x) = -x$ preserves $f = x^2 + 2y^2 + 3z^2$ and the round metric, so f descends to $\mathbb{RP}^2 = S^2/\{\pm 1\}$ (the function in the table of Example 7.81). It has one critical point of each index: $[a] = \{a_\pm\}$, $[s] = \{s_\pm\}$, $[b] = \{b_\pm\}$, and $m = (1,1,1)$.

Orientations. $\mathbb{RP}^2$ is not orientable, but Nash's rule never needs an orientation of M; it needs orientations of the small spaces $T_c^- M$. Choose them at the lifts a_+, s_+, b_+ as before: $+1$, $\mathrm{d}x$, $\mathrm{d}x \wedge \mathrm{d}y$. To compare at the other lift, push forward by τ, whose derivative is $v \mapsto -v$ on ambient vectors:

- at s_- the orientation of $[s]$ is carried by $\tau_* \partial_x = -\partial_x$: it is $-\mathrm{d}x$, opposite to the ω_{s_-} of Example 7.95;
- at b_- it is carried by $(\tau_* \partial_x, \tau_* \partial_y) = (-\partial_x, -\partial_y)$, and $(\mathrm{d}x \wedge \mathrm{d}y)(-\partial_x, -\partial_y) = +1$: it is $+\mathrm{d}x \wedge \mathrm{d}y$, the same as ω_{b_-}.

Flow lines and signs. Each flow line on $\mathbb{RP}^2$ has two lifts; use the one starting at the chosen lift of its upper end.

- $[s] \to [a]$: the lines $s_+ \to a_+$ (sign +1) and $s_+ \to a_-$ (sign −1, compared with +1 at $[a]$). So $\varepsilon([a],[s]) = 0$.
- $[b] \to [s]$: the line $b_+ \to s_+$ has sign −1 (computed above). The line $b_+ \to s_-$ had sign +1 relative to $\omega_{s_-} = \mathrm{d}x$; relative to the orientation $-\mathrm{d}x$ of $[s]$ at s_- it is −1. So $\varepsilon([s],[b]) = -1-1 = -2$.

The complex and its cohomology.

$$0 \to \mathbb{Z}[a] \xrightarrow{0} \mathbb{Z}[s] \xrightarrow{\times(-2)} \mathbb{Z}[b] \to 0.$$

$$H^0 \overset{(1)}{=} \mathbb{Z}, \qquad H^1 \overset{(2)}{=} 0, \qquad H^2 \overset{(3)}{=} \mathbb{Z}/2\mathbb{Z}.$$

(1) $\delta_0 = 0$, so all of C^0 is closed.
(2) Multiplication by −2 on $\mathbb{Z}$ is injective.
(3) $\operatorname{Im}\delta_1 = 2\mathbb{Z}[b]$, and $\mathbb{Z}/2\mathbb{Z}$ is what is left.

This is $H^\bullet(\mathbb{RP}^2;\mathbb{Z}) = (\mathbb{Z},0,\mathbb{Z}_2)$. Change the coefficients:

coefficients	δ_1	(H^0,H^1,H^2)	comment
$\mathbb{Z}$	$\times(-2)$	$(\mathbb{Z},0,\mathbb{Z}_2)$	torsion in H^2
$\mathbb{R}$ (Witten's d_t)	$\times(-2)$, invertible	$(\mathbb{R},0,0)$	$b = (1,0,0)$
$\mathbb{Z}_2$	0	$(\mathbb{Z}_2,\mathbb{Z}_2,\mathbb{Z}_2)$	perfect mod 2
$\mathbb{Z}_3$	$\times 1$, invertible	$(\mathbb{Z}_3,0,0)$	like $\mathbb{R}$

The table reproduces what Chapter 7 says about $\mathbb{RP}^2$: f is perfect over $\mathbb{Z}_2$ and not over $\mathbb{R}$, and no Morse function on $\mathbb{RP}^2$ can be perfect over $\mathbb{Z}$, because the integer cohomology has torsion. The number 2 is visible only to the integer complex; real coefficients, and so the real forms of Witten's quantum mechanics, only see whether it is zero.

The physics of $\mathbb{RP}^2$. Wavefunctions on $\mathbb{RP}^2$ are forms on S^2 invariant under τ. The exact zero modes on S^2 are e^{-tf} and $e^{tf}\mathrm{vol}$; the first is invariant, but $\tau^*\mathrm{vol} = -\mathrm{vol}$ (the antipodal map reverses the orientation of S^2), so the second is not. Hence $\mathbb{RP}^2$ has a single supersymmetric ground state, a bosonic one, and Witten index $1 = \chi(\mathbb{RP}^2)$. In the low-lying complex, the invariant combinations are

$$[a] \leftrightarrow a_+ + a_-, \qquad [s] \leftrightarrow s_+ - s_-, \qquad [b] \leftrightarrow b_+ + b_-,$$

(the relative sign in $[s]$ is the orientation flip found above), and indeed, using Example 7.95,

$$\delta(s_+ - s_-) \overset{(1)}{=} (-b_+ - b_-) - (b_+ + b_-) \overset{(2)}{=} -2(b_+ + b_-).$$

(1) $\delta(s_+) = -b_+ - b_-$ and $\delta(s_-) = b_+ + b_-$.
(2) Collect terms.

The two tunnelling paths from $[b]$ to $[s]$ interfere *constructively*, and the pair $([s],[b])$ is lifted. On the circle with $\cos\theta$ they interfered destructively and nothing was lifted. The τ-odd combinations $a_+ - a_-$, $s_+ + s_-$, $b_+ - b_-$ form the other half of the S^2 complex: $\delta(a_+ - a_-) = 2(s_+ + s_-)$, $\delta(s_+ + s_-) = 0$, and $b_+ - b_-$ carries the odd ground state $e^{tf}\mathrm{vol}$.

Try it

Take $M = S^1 \times S^1$ with the product metric and $f(x, y) = -\cos 2x + \cos y$. List the critical points and indices, find M_u, and guess δ from Examples 7.83 and 7.84. *Answer:* critical points are (minimum or maximum of $-\cos 2x$) $\times$ (maximum or minimum of $\cos y$): $m = (2, 4, 2)$, $M_u = (2 + 2u)(1 + u)$. The differential is built from the circle complexes of the two factors (next subsection): δ_x has rank 1 and $\delta_y = 0$. So $M_u - P_u = (2+2u)(1+u) - (1+u)^2 = (1+u)^2$ and $R(u) = 1 + u$: one pair cancelled in degrees $(0, 1)$ and one in degrees $(1, 2)$.

7.16.7 Products, and why the answer does not depend on f

Two questions remain about the complex as a computational tool. How do we build it for a product manifold from the complexes of the factors? And since it is built from a particular function f and a particular metric g, why is its cohomology independent of both? Both questions have a quantum mechanical answer and a geometric one, and it is instructive to see them agree.

Critical points of a sum. Let $M = M_1 \times M_2$ with the product metric, and let $f(x_1, x_2) = f_1(x_1) + f_2(x_2)$. Then

$$\mathrm{d}f = 0 \overset{(1)}{=} \mathrm{d}f_1 \oplus \mathrm{d}f_2 = 0 \iff \mathrm{d}f_1(x_1) = 0 \text{ and } \mathrm{d}f_2(x_2) = 0,$$
$$Hf(c_1, c_2) \overset{(2)}{=} \begin{pmatrix} Hf_1(c_1) & 0 \\ 0 & Hf_2(c_2) \end{pmatrix}, \qquad \operatorname{index}(c_1, c_2) \overset{(3)}{=} \operatorname{index} c_1 + \operatorname{index} c_2.$$

(1) f_1 depends only on the coordinates of M_1, f_2 only on those of M_2, so the gradient splits into two blocks.
(2) Mixed second derivatives $\partial^2 f / \partial x_1 \partial x_2$ vanish for the same reason.
(3) The negative eigenvalues of a block-diagonal matrix are those of the blocks.

So the critical points of f are the pairs of critical points, and the Morse polynomial multiplies:

$$M_u(f) = \sum_{c_1, c_2} u^{\operatorname{index} c_1 + \operatorname{index} c_2} = \Big(\sum_{c_1} u^{\operatorname{index} c_1}\Big)\Big(\sum_{c_2} u^{\operatorname{index} c_2}\Big) = M_u(f_1)\, M_u(f_2). \tag{7.248}$$

The Poincaré polynomial multiplies too (Künneth formula, over a field): $P_u(M_1 \times M_2) = P_u(M_1) P_u(M_2)$. We now see the complex behind both statements.

The quantum mechanics of a product. A form on $M_1 \times M_2$ is a sum of products $\alpha \wedge \beta$ of forms pulled back from the two factors. Write $\alpha \otimes \beta$ for $\alpha \wedge \beta$ and $(-1)^{F_1}$ for the operator that multiplies α by $(-1)^{\deg \alpha}$. The Leibniz rule $\mathrm{d}(\alpha \wedge \beta) = \mathrm{d}\alpha \wedge \beta + (-1)^{\deg \alpha} \alpha \wedge \mathrm{d}\beta$ says

$$\mathrm{d} = \mathrm{d}^{(1)} \otimes 1 + (-1)^{F_1} \otimes \mathrm{d}^{(2)}.$$

Because $e^{tf} = e^{tf_1} e^{tf_2}$ is a product of functions of the separate factors, conjugating by it conjugates each term separately, and because the L^2 inner product of a product metric factorises (and $(-1)^{F_1}$ is self-adjoint),

$$\mathrm{d}_t = \mathrm{d}_t^{(1)} \otimes 1 + (-1)^{F_1} \otimes \mathrm{d}_t^{(2)}, \qquad \mathrm{d}_t^* = \mathrm{d}_t^{(1)*} \otimes 1 + (-1)^{F_1} \otimes \mathrm{d}_t^{(2)*}. \tag{7.249}$$

Add them: $Q_1(t) = Q^{(1)} \otimes 1 + (-1)^{F_1} \otimes Q^{(2)}$ with $Q^{(i)} = \mathrm{d}_t^{(i)} + \mathrm{d}_t^{(i)*}$. Its square is the Hamiltonian:

$$\begin{aligned} H_t = Q_1(t)^2 &\overset{(1)}{=} \big(Q^{(1)}\big)^2 \otimes 1 + \big((-1)^{F_1}\big)^2 \otimes \big(Q^{(2)}\big)^2 + \big(Q^{(1)}(-1)^{F_1} + (-1)^{F_1} Q^{(1)}\big) \otimes Q^{(2)} \\ &\overset{(2)}{=} H_t^{(1)} \otimes 1 + 1 \otimes H_t^{(2)}. \end{aligned} \tag{7.250}$$

(1) Multiply out $(A\otimes 1 + B\otimes C)^2 = A^2\otimes 1 + B^2\otimes C^2 + (AB+BA)\otimes C$, keeping the order of operators in each factor.
(2) $((-1)^{F_1})^2 = 1$; and $Q^{(1)}$ changes the degree by ± 1, so it *anticommutes* with $(-1)^{F_1}$ and the cross term vanishes. Finally $(Q^{(i)})^2 = H_t^{(i)}$ by (7.73).

This is the supersymmetric version of "the Hamiltonian of two decoupled systems is the sum". The sign $(-1)^{F_1}$ in the supercharge, which looks like a nuisance, is exactly what kills the cross term: without it $Q_1(t)^2$ would contain $2Q^{(1)}\otimes Q^{(2)}$ and would not be a sum of two commuting Hamiltonians. (The same sign is the Jordan–Wigner string that makes fermions on two sites anticommute.)

Consequences, read off from (7.250):

- The spectrum of H_t consists of the sums $E_1 + E_2$. Both are ≥ 0, so $E = 0$ iff $E_1 = E_2 = 0$: the ground states of the product are the products of ground states, and $\ker H_t = \ker H_t^{(1)} \otimes \ker H_t^{(2)}$. That is the Künneth formula for harmonic forms.
- Since $F = F_1 + F_2$, $(-1)^F = (-1)^{F_1}\otimes(-1)^{F_2}$ and the Witten index multiplies: $\chi(M_1\times M_2) = \chi(M_1)\,\chi(M_2)$.
- A low-lying state has $E_1 + E_2 \leq ct$, and since the next levels in each factor are of order t, both factors must be low-lying. So $V(M) = V(M_1)\otimes V(M_2)$ and, by (7.249), the low-lying complex of the product is the tensor product of the low-lying complexes, with the sign $(-1)^{F_1}$.

Worked example 7.97: the four ground states of the flat torus

On the circle with $f = \cos\theta$ the two exact ground states are $e^{-t\cos\theta}$ (a 0-form) and $e^{t\cos\theta}\mathrm{d}\theta$ (a 1-form) (Example 7.73). On T^2 with $f = \cos x + \cos y$ the products are

$$e^{-t\cos x}\,e^{-t\cos y}, \qquad e^{t\cos x}\,e^{-t\cos y}\,\mathrm{d}x, \qquad e^{-t\cos x}\,e^{t\cos y}\,\mathrm{d}y, \qquad e^{t\cos x}\,e^{t\cos y}\,\mathrm{d}x\wedge\mathrm{d}y.$$

Their degrees are $0,1,1,2$, and $b_\bullet(T^2) = (1,2,1)$. We can check one directly with (7.172), $\mathrm{d}_t = \mathrm{d} + t\,\mathrm{d}f\wedge$:

$$\begin{aligned}\mathrm{d}_t\big(e^{t\cos x - t\cos y}\mathrm{d}x\big) &\overset{(1)}{=} \mathrm{d}\big(e^{t\cos x - t\cos y}\big)\wedge\mathrm{d}x + t\,(-\sin x\,\mathrm{d}x - \sin y\,\mathrm{d}y)\wedge e^{t\cos x - t\cos y}\mathrm{d}x\\ &\overset{(2)}{=} e^{t\cos x - t\cos y}\big(t\sin y\,\mathrm{d}y\wedge\mathrm{d}x - t\sin y\,\mathrm{d}y\wedge\mathrm{d}x\big) \overset{(3)}{=} 0.\end{aligned}$$

(1) Definition of d_t with $\mathrm{d}f = -\sin x\,\mathrm{d}x - \sin y\,\mathrm{d}y$.
(2) $\mathrm{d}(e^{t\cos x - t\cos y}) = e^{t\cos x - t\cos y}(-t\sin x\,\mathrm{d}x + t\sin y\,\mathrm{d}y)$, and $\mathrm{d}x\wedge\mathrm{d}x = 0$ removes the x-parts.
(3) The two terms cancel.

A similar computation with $\mathrm{d}_t^* = \mathrm{d}^* + t\,\iota_{\nabla f}$ shows it is also annihilated by d_t^*. Each ground state is localised on one critical point: the first on the minimum Q (where $\cos x = \cos y = -1$), the second on the saddle $(0,\pi)$, the third on the saddle $(\pi,0)$, the last on the maximum P. Every critical point carries an exact ground state, just as the vanishing of the whole complex in Example 7.91 predicted.

The same product rule, from the flow lines. Geometrically, the gradient flow of $f_1 + f_2$ for the product metric is the product of the two flows, run with the same time s: a flow line is a pair $(\gamma_1(s), \gamma_2(s))$, each component a flow line or a constant. The unparametrised flow lines from (b_1, b_2) to (a_1, a_2) form a space of dimension $\Delta_1 + \Delta_2 - 1$, with $\Delta_i = \text{index}\,b_i - \text{index}\,a_i \geq 0$

((7.244), applied to each factor, minus one for the common time shift). For an index difference of one, one of the Δ_i is zero, so *only one factor moves*. The flow lines that count are (γ_1, c_2) and (c_1, γ_2).

Their signs follow from Nash's rule with the product orientation $\omega_{(c_1,c_2)} = \omega_{c_1} \wedge \omega_{c_2}$. If the second factor moves, the exit vector v lies in the second factor and

$$\iota_v\big(\omega_{c_1} \wedge \omega_{b_2}\big) \overset{(1)}{=} (\iota_v \omega_{c_1}) \wedge \omega_{b_2} + (-1)^{\operatorname{index} c_1}\, \omega_{c_1} \wedge \iota_v \omega_{b_2} \overset{(2)}{=} (-1)^{\operatorname{index} c_1}\, \omega_{c_1} \wedge \iota_v \omega_{b_2}.$$

(1) The graded Leibniz rule for the interior product.
(2) ω_{c_1} involves only covectors of the first factor, which vanish on v.

The first-factor vectors sit at the fixed point c_1 and are only stretched by positive factors, so the comparison at the lower end gives $\varepsilon = (-1)^{\operatorname{index} c_1} \varepsilon_{\gamma_2}$. If the first factor moves, ι_v hits ω_{b_1} first and there is no sign. Altogether

$$\delta(c_1 \times c_2) = \delta^{(1)} c_1 \times c_2 + (-1)^{\operatorname{index} c_1}\, c_1 \times \delta^{(2)} c_2, \tag{7.251}$$

which is exactly the tensor product of complexes predicted by (7.249): the geometric orientation sign and the fermionic sign $(-1)^{F_1}$ are the same sign. Its square vanishes for the same reason as the cross term in (7.250):

$$\begin{aligned}\delta^2(c_1 \times c_2) &\overset{(1)}{=} (\delta^{(1)})^2 c_1 \times c_2 + (-1)^{\operatorname{index} c_1 + 1} \delta^{(1)} c_1 \times \delta^{(2)} c_2 \\ &\quad + (-1)^{\operatorname{index} c_1} \delta^{(1)} c_1 \times \delta^{(2)} c_2 + c_1 \times (\delta^{(2)})^2 c_2 \overset{(2)}{=} 0.\end{aligned}$$

(1) Apply (7.251) twice; $\delta^{(1)} c_1$ has index index $c_1 + 1$, and $(-1)^{\operatorname{index} c_1}(-1)^{\operatorname{index} c_1} = 1$.
(2) $(\delta^{(i)})^2 = 0$ in each factor, and the two middle terms have opposite signs.

Worked example 7.98: the torus with $f = -\cos 2x + \cos y$, from the two circles

Let a_1, a_2 (index 0) and b_1, b_2 (index 1) be the critical points of $-\cos 2x$, with $\delta^{(1)} a_1 = -b_1 + b_2$, $\delta^{(1)} a_2 = b_1 - b_2$ (Example 7.83), and let Q' (the minimum $y = \pi$) and P' (the maximum $y = 0$) be those of $\cos y$, with $\delta^{(2)} = 0$ (Example 7.84). The product complex has

$$C^0 = \langle a_1 Q', a_2 Q' \rangle, \qquad C^1 = \langle b_1 Q', b_2 Q', a_1 P', a_2 P' \rangle, \qquad C^2 = \langle b_1 P', b_2 P' \rangle,$$

so $m = (2, 4, 2)$. By (7.251), with $\delta^{(2)} = 0$, $\delta(c_1 c_2) = (\delta^{(1)} c_1) c_2$, and in these bases

$$D_0 = \begin{pmatrix} -1 & 1 \\ 1 & -1 \\ 0 & 0 \\ 0 & 0 \end{pmatrix}, \qquad D_1 = \begin{pmatrix} 0 & 0 & -1 & 1 \\ 0 & 0 & 1 & -1 \end{pmatrix}.$$

Check $D_1 D_0 = 0$: the only nonzero columns of D_1 are the last two, and the last two rows of D_0 vanish. Then

$$b_0 \overset{(1)}{=} 2 - 1 = 1, \qquad b_1 \overset{(2)}{=} (4 - 1) - 1 = 2, \qquad b_2 \overset{(3)}{=} 2 - 1 = 1.$$

(1) $\operatorname{rank} D_0 = 1$; the kernel is spanned by $a_1 Q' + a_2 Q'$.
(2) $\operatorname{rank} D_1 = 1$, so $\dim \operatorname{Ker} D_1 = 3$; subtract $\operatorname{rank} D_0 = 1$.
(3) $\operatorname{Im} D_1$ is spanned by $b_1 P' - b_2 P'$.

Representatives of H^1 are $b_1 Q'$ (equivalently $b_2 Q'$, since $b_1 Q' - b_2 Q' = -\delta(a_1 Q')$) and $a_1 P' + a_2 P'$: the classes $[\mathrm{d}x]$ and $[\mathrm{d}y]$ of the torus, i.e. $H^1(S^1) \otimes H^0(S^1) \oplus H^0(S^1) \otimes H^1(S^1)$. The strong inequality reads $M_u - P_u = (2 + 4u + 2u^2) - (1 + 2u + u^2) = (1 + u)(1 + u)$, so $R(u) = 1 + u$, as found in the exercise above. Physically: each factor-circle has one lifted pair, and the lifted pairs of the torus are (lifted pair)×(ground state of the other factor).

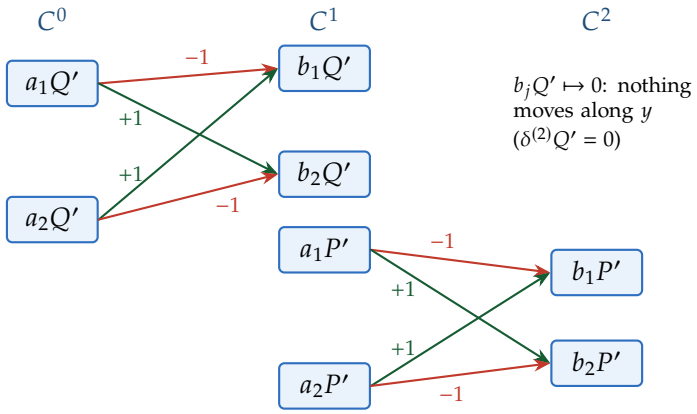

Figure 7.66: The Morse–Witten complex of $f = -\cos 2x + \cos y$ on the torus, as a product. Each arrow is a flow line in which only the x-factor moves; green arrows have $\varepsilon = +1$, red ones $\varepsilon = -1$. The top block is the circle complex of $-\cos 2x$ times the minimum Q' of $\cos y$; the bottom block is the same complex times the maximum P'. The flow lines in the y-direction come in cancelling pairs and are not drawn. The two blocks each kill one pair, leaving $b_\bullet = (1, 2, 1)$.

Why the cohomology does not depend on f or g. The complex $(C^\bullet, \delta)$ certainly depends on the choices: $f = \cos\theta$ and $f = -\cos 2\theta$ on the circle give complexes of different sizes. There are two ways to see that the cohomology does not.

Quantum mechanics. At large t the cohomology of the low-lying complex is the space of exact ground states (7.239), and those have dimension $b_p = \dim H^p_{\mathrm{dR}}(M)$ for *every* t (Section 7.12.3), by the chain isomorphism $e^{tf}\colon (\Omega^\bullet, \mathrm{d}_t) \to (\Omega^\bullet, \mathrm{d})$. The de Rham cohomology knows nothing about f or g. So the complex may change, but only by adding or removing pairs of generators joined by an invertible entry of δ: states that are lifted together.

Geometry: birth and death of pairs. Deform f through a family f_s. For generic families only one thing can happen to the critical points, and it happens in a one-dimensional slice. The local model is

$$f_s(x) = \tfrac{1}{3}x^3 - s\,x, \qquad f_s'(x) = x^2 - s. \tag{7.252}$$

For $s < 0$ there are no critical points. At $s = 0$ there is one degenerate critical point (an inflection). For $s > 0$ there are two:

$$x_\pm = \pm\sqrt{s}, \qquad f_s''(x_\pm) \overset{(1)}{=} \pm 2\sqrt{s}, \qquad f_s(x_-) - f_s(x_+) \overset{(2)}{=} \tfrac{4}{3}\,s^{3/2}.$$

(1) $f_s'' = 2x$. So x_+ is a minimum (index 0) and x_- a maximum (index 1).
(2) $f_s(\pm\sqrt{s}) = \pm\tfrac{1}{3}s^{3/2} \mp s^{3/2} = \mp\tfrac{2}{3}s^{3/2}$.

Exactly one flow line runs from x_- down to x_+, in the direction $+\partial_x$, so $\varepsilon(x_+, x_-) = +1$: $\delta x_+ = x_- + \dots$, an invertible entry. (In n dimensions one adds $\sum \pm y_j^2$ in the other directions; the two new critical points have indices k and $k+1$.) The new pair of generators cancels in cohomology. This is the **birth–death** (or cancellation) of critical points, the geometric fact behind the invariance: Morse theory "with handles" (Chapter 7) says that a cancelling pair of handles can be removed without changing the manifold.

Worked example 7.99: the birth of a pair, in quantum mechanics

On the line, with $f = f_s$ of (7.252), the 0-form Hamiltonian is $H_0 = \mathrm{d}_t^*\mathrm{d}_t = -\partial_x^2 + t^2 f'^2 - t f''$ ((7.181)). Rescale $x = t^{-1/3}y$:

$$H_0 \overset{(1)}{=} t^{2/3}(-\partial_y^2) + t^2\left(t^{-2/3}y^2 - s\right)^2 - 2t\,t^{-1/3}y \overset{(2)}{=} t^{2/3}\left[-\partial_y^2 + (y^2 - \sigma)^2 - 2y\right], \qquad \sigma := s\,t^{2/3}.$$

(1) $\partial_x = t^{1/3}\partial_y$, $f' = x^2 - s$, $f'' = 2x$.
(2) Factor out $t^{2/3}$: $t^2(t^{-2/3}y^2 - s)^2 = t^{2/3}(y^2 - st^{2/3})^2$.

So the whole family depends on the single combination σ, and all energies are $t^{2/3}g(\sigma)$. For $\sigma \gg 1$ the barrier between the two critical points is high, and (7.216) gives the lifted energy of the pair,

$$E \overset{(1)}{=} |\langle x_-|\mathrm{d}_t|x_+\rangle|^2 \overset{(2)}{=} \frac{t}{\pi}\,(2\sqrt{s}\cdot 2\sqrt{s})^{1/2}\,e^{-\frac{8}{3}ts^{3/2}} \overset{(3)}{=} t^{2/3}\cdot\frac{2}{\pi}\sqrt{\sigma}\,e^{-\frac{8}{3}\sigma^{3/2}}.$$

(1) (7.211) with a 1×1 matrix D_0.
(2) (7.216) with $f''(x_+)\,|f''(x_-)| = 4s$ and barrier $\frac{4}{3}s^{3/2}$, squared.
(3) $t\sqrt{s} = t^{2/3}\sqrt{\sigma}$ and $ts^{3/2} = \sigma^{3/2}$.

The numerically computed lowest eigenvalue of the bracket (Figure 7.67) agrees with this for $\sigma \gtrsim 1$. As σ decreases the barrier shrinks, the energy of the pair grows, and for $\sigma < 0$ it has merged with the rest of the spectrum: there is nothing low-lying left. The same energy appears in the 1-form sector (supersymmetric pairing), so the pair never contributes to the Witten index or to cohomology. The birth of two critical points is, in quantum mechanics, a boson–fermion pair descending from the high part of the spectrum.

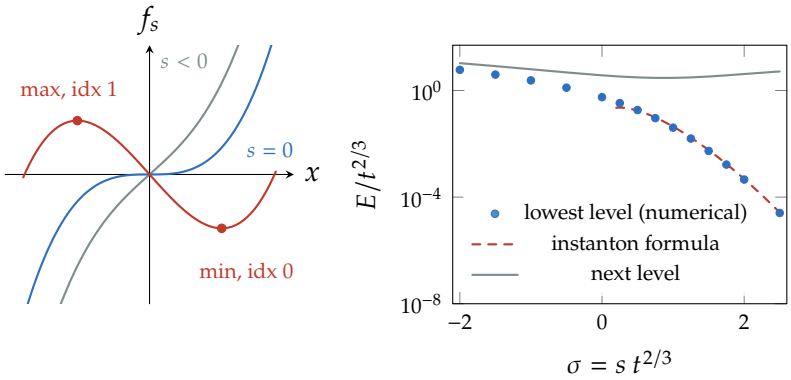

Figure 7.67: Birth of a pair of critical points. *Left:* $f_s = \frac{1}{3}x^3 - sx$ for $s < 0$ (grey, no critical point), $s = 0$ (blue, one degenerate point) and $s > 0$ (red, a maximum and a minimum joined by one flow line). *Right:* the lowest eigenvalue of the rescaled Hamiltonian $-\partial_y^2 + (y^2 - \sigma)^2 - 2y$ (dots), which becomes exponentially small as the pair is born, compared with the instanton formula (dashed). The next level (grey) stays of order one. The pair is always lifted, so the Witten index and the cohomology never notice it.

Continuation maps. There is a third, more constructive argument, which is the one that generalises to Floer theory. Given two Morse–Smale pairs (f_0, g_0) and (f_1, g_1), interpolate by a family f_s, g_s with $f_s = f_0$ for $s \le 0$ and $f_s = f_1$ for $s \ge 1$, and count solutions of the *time-dependent* flow $\dot\gamma(s) = -\nabla_{g_s} f_s(\gamma(s))$ running from a critical point of f_0 (at $s = -\infty$) to one of f_1 of the same index (at $s = +\infty$). Such solutions are isolated (no time-shift symmetry any more), and their signed count is a matrix $\Phi\colon C^\bullet(f_0) \to C^\bullet(f_1)$. Looking at the ends of the one-dimensional families, exactly as in Section 7.16.5, gives $\Phi\delta_0 = \delta_1\Phi$: Φ is a chain map. Running the interpolation backwards gives a chain map the other way, and composing the two is chain-homotopic to the identity. So Φ induces an isomorphism of cohomology. We do not need this in finite dimensions, where de Rham cohomology is available, but in Floer theory it is the only proof that the answer is an invariant.

7.16.8 Where the construction goes next: Floer's infinite-dimensional version

Nash closes the section with the remark that "the instanton ideas employed for this purpose will be useful again in the somewhat analogous infinite dimensional Floer theory" [Nash p. 215]. It is worth seeing now what survives and what breaks when M is replaced by an infinite-dimensional space, because it explains why the flow-line definition of δ, and not the spectral one, is the one that generalises.

The ingredients of the construction, listed. Everything above used four things:

1. a space X and a function $f\colon X \to \mathbb{R}$ whose critical points are isolated and non-degenerate;
2. a grading of the critical points by the index;
3. the spaces of gradient flow lines between critical points, of dimension $\operatorname{index}(b) - \operatorname{index}(a) - 1$, with signs;
4. compactness: families of flow lines can only degenerate by breaking (Section 7.16.5).

Witten's spectral route needs, in addition, the Laplacian Δ_t on forms on X, and so a manifold on which differential forms and a Hodge theory make sense. In infinite dimensions that is exactly what is lost. Items 1–4, on the other hand, can survive.

Floer's example: the Chern–Simons function. Let Y be a closed oriented 3-manifold, $\mathcal{A}$ the space of SU(2) connections on Y (anti-Hermitian $\mathfrak{su}(2)$-valued 1-forms, $F_A = \mathrm{d}A + A \wedge A$), and $\mathcal{G}$ the gauge group. The **Chern–Simons function**

$$\mathrm{CS}(A) = \frac{1}{8\pi^2} \int_Y \operatorname{tr}\Big(A \wedge \mathrm{d}A + \tfrac{2}{3} A \wedge A \wedge A \Big) \tag{7.253}$$

is gauge invariant up to integers, so it is a function (mod $\mathbb{Z}$) on $X = \mathcal{A}/\mathcal{G}$. Its first variation is

$$\left.\frac{\mathrm{d}}{\mathrm{d}\eta}\right|_{\eta=0} \mathrm{CS}(A + \eta\, a) \overset{(1)}{=} \frac{1}{8\pi^2} \int_Y \operatorname{tr}\big(a \wedge \mathrm{d}A + A \wedge \mathrm{d}a + 2\, a \wedge A \wedge A \big) \overset{(2)}{=} \frac{1}{8\pi^2} \int_Y \operatorname{tr}\big(2\, a \wedge \mathrm{d}A + 2\, a \wedge A \wedge A \big) \overset{(3)}{=} \frac{1}{4\pi^2} \int_Y \operatorname{tr}\big(a \wedge F_A \big).$$

(1) Differentiate each term; the cubic term gives three equal terms by cyclicity of the trace (moving a 1-form past a 2-form costs no sign).
(2) Integrate by parts: $\mathrm{d}\operatorname{tr}(A \wedge a) = \operatorname{tr}(\mathrm{d}A \wedge a) - \operatorname{tr}(A \wedge \mathrm{d}a)$ and $\partial Y = \varnothing$, so $\int \operatorname{tr}(A \wedge \mathrm{d}a) = \int \operatorname{tr}(\mathrm{d}A \wedge a) = \int \operatorname{tr}(a \wedge \mathrm{d}A)$.
(3) $F_A = \mathrm{d}A + A \wedge A$.

So the critical points of CS are the **flat connections**, $F_A = 0$, and with the inner product $\langle a, b \rangle = -\int_Y \operatorname{tr}(a \wedge \star b)$ the gradient is $\nabla \mathrm{CS} = \mp \frac{1}{4\pi^2} \star F_A$ (the sign depends on the orientation convention). Two things are new:

- *The Hessian has infinitely many negative and infinitely many positive eigenvalues.* It is the operator $a \mapsto \star \mathrm{d}_A a$ on 1-forms (plus gauge fixing), a first-order elliptic operator like the Dirac operator, whose spectrum is unbounded in both directions. The Morse index is infinite. What is finite is the *difference* of indices between two critical points: the number of eigenvalues that cross zero along a path from one to the other, the **spectral flow**. Floer grades the complex by this relative index, which is all that items 2 and 3 need. Because

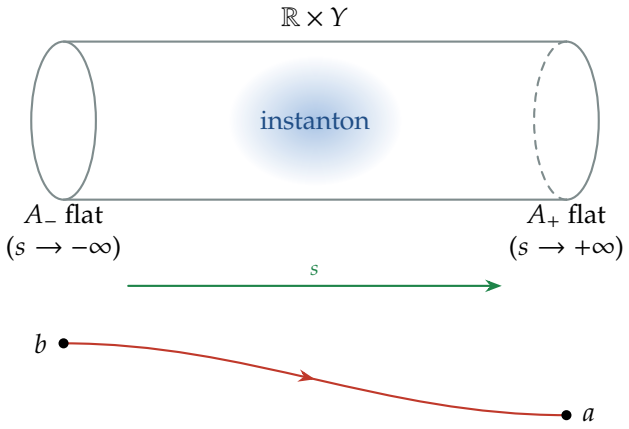
CS is only defined modulo integers on $\mathcal{A}/\mathcal{G}$, a loop in $\mathcal{A}/\mathcal{G}$ can change the relative index; for SU(2) the change is a multiple of 8 (an index-theorem computation), so the grading is by $\mathbb{Z}_8$ and there are eight Floer groups.

- *The flow lines are instantons.* A path $A(s)$ of connections on Y is a connection on the cylinder $\mathbb{R}\times Y$ (in the gauge with no $\mathrm{d}s$ component), with curvature $F = \mathrm{d}s\wedge\partial_s A + F_{A(s)}$. With the orientation $\mathrm{d}s\wedge\mathrm{vol}_Y$, the 4D Hodge star acts as $\star_4(\mathrm{d}s\wedge\alpha) = \star_3\alpha$ and $\star_4\beta = \mathrm{d}s\wedge\star_3\beta$ for a 1-form α and a 2-form β on Y. So

$$F = \mp\star_4 F \iff \partial_s A = \mp\star_3 F_{A(s)}:$$

the (anti-)self-duality equations on the cylinder are the gradient flow of CS (up to a positive constant). The Yang–Mills action of such a flow line is, by the Bogomolny argument of Section 7.15.5, $8\pi^2$ times the drop of CS between its ends: the analogue of (7.91), $S = t(f(b) - f(a))$.

Floer's differential counts these instantons on $\mathbb{R}\times Y$ between flat connections whose relative index is one, and $\delta^2 = 0$ is proved by the broken-flow-line argument of Section 7.16.5, now requiring the compactness theory of instantons (Uhlenbeck) of Chapter 8. The result, **instanton Floer homology** $HF(Y)$, is an invariant of the 3-manifold. It is the space of states of a topological field theory in the sense of Chapter 12: in Witten's language it is the space of supersymmetric ground states of a quantum field theory on $\mathbb{R}\times Y$, exactly as $H^\bullet(M)$ is the space of supersymmetric ground states of the quantum mechanics of this chapter.



gradient flow line of f on M: a quantum-mechanical instanton

Figure 7.68: Floer's dictionary. *Top:* a flow line of the Chern–Simons function is a path of connections $A(s)$ on Y, i.e. a connection on the cylinder $\mathbb{R}\times Y$; the flow equation is the (anti-)self-duality equation, so the flow line is a Yang–Mills instanton, concentrated where $A(s)$ changes, interpolating between flat connections $A_\pm$. *Bottom:* the finite-dimensional template of this section, a tunnelling path from b to a whose action is $t(f(b) - f(a))$.

Dictionary: Witten's quantum mechanics and Floer theory

Morse–Witten (this chapter)	instanton Floer theory (Chapter 12)
compact manifold M	$\mathcal{A}/\mathcal{G}$ for a 3-manifold Y
Morse function f	Chern–Simons function CS
critical points	flat connections
index index(b)	relative index: spectral flow of $\star \mathrm{d}_A$
gradient flow $\dot\gamma = -\nabla f$	anti-self-dual connection on $\mathbb{R}\times Y$
action $t\,(f(b)-f(a))$	$8\pi^2\ \lvert\Delta\mathrm{CS}\rvert$, the instanton number
$\delta^2 = 0$ from broken flow lines	$\delta^2 = 0$ from Uhlenbeck compactness
$H^\bullet(M)$ = SUSY ground states of QM	$HF(Y)$ = SUSY ground states of QFT on $\mathbb{R}\times Y$

The symplectic version. On a symplectic manifold (P,ω) with a time-periodic Hamiltonian H_τ, the **action functional** of classical mechanics, $\mathcal{A}(x) = -\int_D u^*\omega + \int_0^1 H_\tau(x(\tau))\,\mathrm{d}\tau$ on contractible loops x (with u a disc bounding x), has as critical points the 1-periodic orbits of the Hamiltonian flow: this is Hamilton's principle. Its flow lines are maps $u(s,\tau)$ of a cylinder solving a perturbed Cauchy–Riemann equation $\partial_s u + J(\partial_\tau u - X_H) = 0$. Counting them gives symplectic Floer homology, which turns out to be $H^\bullet(P)$. The strong Morse inequalities then say that a non-degenerate Hamiltonian has at least $\sum_p b_p(P)$ periodic orbits: the **Arnold conjecture**, proved by Floer in this way. It is the Morse inequality of this chapter, applied on the loop space of P, and it is the most famous application of the instanton picture of Morse theory.

Reading Nash (pp. 211–213 and 215, (7.81)–(7.86), (7.95))

Nash states the "additional mathematics" in one sentence: if a coboundary $\delta\colon C_p \to C_{p+1}$ with $\delta^2 = 0$ can be built on the integral combinations of critical points (7.81)–(7.82), its cohomology is that of M and the Morse inequalities follow. We made the second half explicit as rank–nullity (7.236). Nash then defines δ geometrically: steepest-descent paths (7.83), the splitting $T_b^- M = T_b\gamma_{ab} \oplus O_b$ (7.84), the sign $\varepsilon_{\gamma_{ab}}$ from orienting O_b by interior multiplication and flowing it to a, the total $\varepsilon(a,b)$ (7.85) and $\delta(a) = \sum_b \varepsilon(a,b)b$ (7.86). He remarks that checking $\delta^2 = 0$ "with the present combinatorial definition is difficult" and appeals to $\mathrm{d}_t^2 = 0$ instead; we gave both that argument (the low-lying complex) and the direct one (broken flow lines). Finally (7.95) recovers (7.86) from the instanton calculation. Nash writes the index as a subscript, C_p, but his δ raises the degree, so it is a cochain complex; and his statement that the complex gives the cohomology of M is true over $\mathbb{Z}$ (for a Morse–Smale metric), which is why the $\mathbb{RP}^2$ example sees the torsion $\mathbb{Z}_2$ that Witten's real forms cannot.

Recap

- Any cochain complex with m_p generators in degree p and cohomology of dimension b_p satisfies $M_u - P_u = (1+u)R(u)$ with $R \geq 0$ (rank–nullity). So the strong Morse inequalities follow from the existence of one such complex.
- Witten's low-lying complex $(V_\bullet, \mathrm{d}_t)$ is such a complex over $\mathbb{R}$. At large t, in the rescaled basis, its matrix is the integer matrix $\varepsilon(a,b)$.
- $\varepsilon(a,b)$ is a signed count of gradient flow lines from b to a (index difference one). The flow lines form a space of dimension index b − index a − 1 for a Morse–Smale metric; the signs come from Nash's orientation rule (interior multiplication by the

exit direction, then transport).

- $\delta^2 = 0$ physically because $\mathrm{d}_t^2 = 0$, geometrically because the ends of one-dimensional families of flow lines are broken flow lines, which cancel in pairs.
- Worked complexes: circles, the flat and tilted torus ($\delta = 0$), the two-humped and six-point spheres (pairs cancel), $\mathbb{RP}^2$ ($\delta_1 = \times(-2)$: torsion over $\mathbb{Z}$, invisible over $\mathbb{R}$).
- Products: $\delta = \delta^{(1)} \otimes 1 + (-1)^{F_1} \otimes \delta^{(2)}$, the same sign as in the supercharge. Changing f creates or annihilates cancelling pairs (birth–death), a boson–fermion pair in the spectrum; the cohomology never changes.
- The flow-line definition generalises to infinite dimensions, where Hodge theory is lost: Floer theory, with Chern–Simons flow lines = instantons on $\mathbb{R} \times Y$.

Chapter summary

The chapter asked one question: *what does the landscape of a single function $f : M \to \mathbb{R}$ know about the shape of M?* The answer is that the critical points of f, counted with their indices, bound the Betti numbers from above, and that the gradient flow lines between them, counted with signs, reconstruct the cohomology exactly.

The first half of the chapter (Nash §§1–3) is classical. The index of a non-degenerate critical point is the number of downhill directions, and passing a critical value of index λ attaches a λ-cell to the sublevel set. Counting cells gives the weak and strong Morse inequalities and the Euler characteristic. Allowing whole critical submanifolds gives the Morse–Bott version; keeping track of a symmetry gives the equivariant version; and allowing M to be a space of paths gives Morse's theory of geodesics and Bott's periodicity theorem.

The second half (Nash §4, Section 7.9 onwards) is Witten's: the same results, and more, from supersymmetric quantum mechanics. The differential forms on M are the states of a particle with fermionic spin, $\mathrm{d} + \mathrm{d}^*$ is the supercharge, the Laplacian is the Hamiltonian, and the zero-energy states are the cohomology. Deforming by e^{tf} localises the low-energy states at the critical points, where they are harmonic oscillators; tunnelling between critical points, computed by instantons, is the Morse–Witten differential.

The two proofs, each as one chain

The whole of Witten's argument fits into one labelled chain. Every step is one section of the second half.

$$b_p \overset{(1)}{=} \dim \operatorname{Ker} \Delta_p \overset{(2)}{=} \dim \operatorname{Ker} \Delta_p(t) \overset{(3)}{=} \dim H^p\left(V_\bullet, \mathrm{d}_t\right)$$
$$\overset{(4)}{=} \dim H^p\left(C^\bullet, \delta\right) \overset{(5)}{=} m_p - r_p - r_{p-1} \overset{(6)}{\leq} m_p. \tag{7.254}$$

(1) The Hodge theorem: every de Rham class has exactly one harmonic representative, and the harmonic forms are the supersymmetric ground states of $H = \mathrm{dd}^* + \mathrm{d}^*\mathrm{d}$ (Section 7.11, Nash (7.74)).

(2) Multiplication by e^{tf} is a chain isomorphism from $(\Omega^\bullet, \mathrm{d}_t)$ to $(\Omega^\bullet, \mathrm{d})$, so the number of zero-energy states does not change with t (Section 7.12, Nash (7.75)).

(3) At large t the spectrum splits into m_p low-lying levels per degree, one per critical point of index p, and levels of order t. d_t preserves the low-lying space $V_\bullet$, and every exact ground state lies in it (Sections 7.14 and 7.16.2).

(4) On $V_\bullet$ the matrix of d_t is a sum over instantons, $\varepsilon(a,b)\,e^{-t(f(b)-f(a))}$, and rescaling the basis removes the exponentials, leaving the integer matrix of δ (Section 7.15, Nash (7.93)–(7.95)).
(5) Rank–nullity, with $r_p = \operatorname{rank}\delta_p$ ((7.235)).
(6) Ranks are non-negative: the weak Morse inequality. Summing $(-1)^p u^p$-weighted versions of step 5 gives the strong form $M_u - P_u = (1+u)R(u)$ ((7.236)).

The classical proof reaches the same inequalities from the other end: the sublevel sets $M_c = \{f \le c\}$ change only at critical values, each change is the attachment of a cell of dimension equal to the index, and the exact sequence of the pair $(M_{c+\varepsilon}, M_{c-\varepsilon})$ changes each Betti number by at most one per cell, in a way that makes the alternating sums subadditive.

The Euler characteristic is the special value where all the cancellations become irrelevant:

$$\chi(M) \overset{(1)}{=} \operatorname{Tr}(-1)^F \overset{(2)}{=} \sum_p (-1)^p b_p \overset{(3)}{=} \sum_p (-1)^p m_p \overset{(4)}{=} M_{-1}(f). \tag{7.255}$$

(1) The Witten index of the de Rham supersymmetric quantum mechanics ((7.163)); $(-1)^F$ is $(-1)^{\text{degree}}$.
(2) Only zero-energy states contribute to the Witten index: states with $E > 0$ come in boson–fermion pairs (Section 7.10.6).
(3) Deformation invariance: at large t each critical point carries one low-lying state of degree equal to its index, and lifted states still pair (Section 7.14.6).
(4) The definition of the Morse polynomial at $u = -1$.

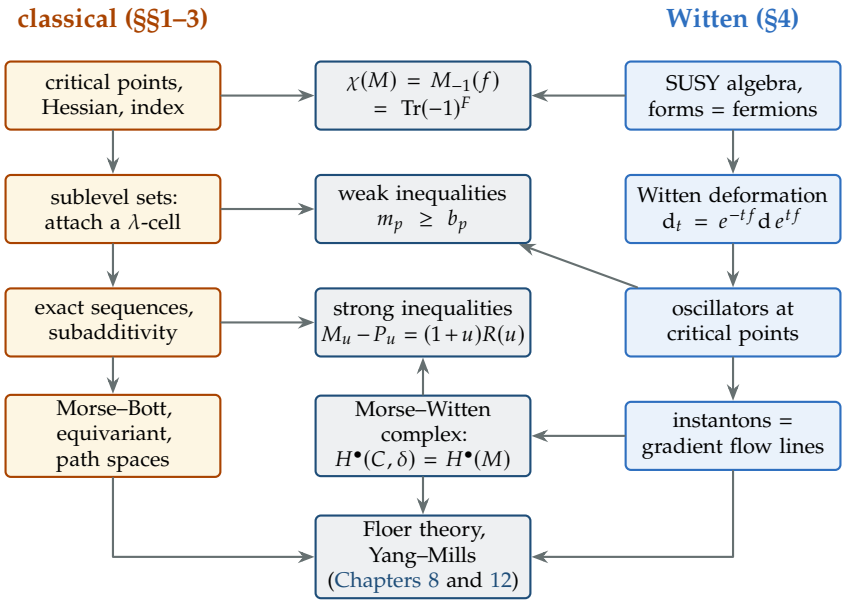


Figure 7.69: The logic of the chapter. The classical route (orange, left) and Witten's quantum route (blue, right) arrive at the same results (middle). The quantum route passes through the Morse–Witten complex, which proves the strong inequalities by linear algebra, and it is the version of the argument that survives in the infinite-dimensional settings of later chapters.

Every concept, how to use it, and where it returns

The tables follow Nash's four sections. The middle column is the *operational* meaning: what we actually do to compute or test the thing. The right column says where the idea is developed further or used again. In this chapter the variable of the Morse and Poincaré polynomials is written t in §§1–3, as in Nash, and u in §4, where t is Witten's deformation parameter.

Nash §1: the topology of critical points

Concept	Operational meaning	Returns in
critical point	a point where $\mathrm{d}f = 0$: solve $\partial_i f = 0$ in a chart	everywhere; Chapter 8 (Yang–Mills solutions)
Hessian, non-degenerate	the matrix $\partial_i \partial_j f$ at a critical point; non-degenerate iff $\det \neq 0$	Section 7.14.2 (oscillator frequencies)
index λ	number of negative eigenvalues of the Hessian (Sylvester: chart independent); number of downhill directions	Section 7.14.4 (degree of the zero mode)
nullity, Morse function	nullity $= n - \operatorname{rank} Hf$; Morse = all critical points non-degenerate; generic: $f + a \cdot x$ is Morse for almost every a	Section 7.16.7 (birth–death)
Morse lemma	near a non-degenerate critical point $f = f(p) - x_1^2 - \cdots - x_\lambda^2 + x_{\lambda+1}^2 + \cdots + x_n^2$	Section 7.14.2, Nash (7.78)
Morse series $M_t(f)$	$\sum_p t^{\lambda_p} = \sum_i m_i t^i$: count critical points by index	Section 7.16.1
Poincaré series $P_t(M)$	$\sum_i b_i t^i$ with $b_i = \dim H^i(M; F)$; depends on the coefficient field F when there is torsion	Example 7.96
weak inequalities	$m_i \geq b_i$ for every i	Section 7.14.5
strong inequalities	$M_t - P_t = (1+t)R(t)$ with $R \geq 0$; equivalently the alternating partial sums $m_j - m_{j-1} + \cdots \geq b_j - b_{j-1} + \ldots$	Section 7.16.1 (rank–nullity)
Euler characteristic	$\chi = M_{-1}(f) = P_{-1}(M)$, the same for every f	Section 7.14.6, Chapter 4 (Gauss–Bonnet, Hopf)
lacunary principle	no two consecutive powers in $M_t \Rightarrow R = 0$ and $M_t = P_t$	Example 7.94
perfect Morse function	$M_t = P_t$; impossible over $\mathbb{Z}$ if $H^\bullet(M; \mathbb{Z})$ has torsion	Example 7.96
sublevel set M_c	$\{f \leq c\}$; changes topology only at critical values	Section 7.16.3
cell attachment, handles	crossing a critical value of index λ attaches a λ-cell ($D^\lambda \times D^{n-\lambda}$ handle); Nash's stratification $M = \bigcup e_\lambda$	Section 7.16.5, Chapter 12 (cobordisms)
gradient flow	$\dot\gamma = -\nabla f$; f decreases along it, and it connects critical points	Section 7.15.5 (instantons)
$\mathbb{CP}^n$, Σ_p, upright torus	$\sum a_i \lvert z_i\rvert^2$ has indices $0, 2, \ldots, 2n$ (lacunary); the height on Σ_p has $M_t = 1 + 2pt + t^2$	Chapter 5, Chapter 9
degenerate critical points	e.g. the monkey saddle $\operatorname{Re} z^3$; perturb to split into non-degenerate ones	Example 7.99
LS category	least number of contractible closed sets covering M; a lower bound for the number of critical points of *any* f	–

Nash §2: critical submanifolds

Concept	Operational meaning	Returns in
non-degenerate critical submanifold	a connected C with $\mathrm{d}f\|_C = 0$ whose Hessian is non-degenerate on the normal bundle $N(C)$	Chapter 8 (critical sets of Yang–Mills)
$N = N^+ \oplus N^-$, index λ_C	split the normal bundle by the sign of the Hessian; $\lambda_C = \operatorname{rank} N^-$	–
Morse–Bott series	$M_t(f) = \sum_C t^{\lambda_C} P_t(C)$ (orientable N^-, or $\mathbb{Z}_2$ coefficients)	Chapter 8 (Atiyah–Bott)
dinner-plate torus, z^2 on S^2	two critical circles give $(1+t)+t(1+t) = P_t(T^2)$ (perfect); z^2 gives $M_t - P_t = t(1+t)$ (not perfect)	–
perturbing to Morse	add a small Morse function on C: each critical point of it of index μ becomes one of index $\lambda_C + \mu$	Section 7.16.7

Nash §3: equivariant Morse theory, and infinite dimensions

Concept	Operational meaning	Returns in
group action, stabiliser	G moves points of M; free iff all stabilisers are trivial; then M/G is a manifold	Chapter 6, Chapter 8 (gauge group)
naive quotient fails	$S^2/\mathrm{U}(1) = [0,1]$ has $P_t = 1$: fixed points are forgotten	–
universal bundle $EG \to BG$	EG contractible with free G-action; $E\mathrm{U}(1) = S^\infty$, $B\mathrm{U}(1) = \mathbb{CP}^\infty$, $B\mathbb{Z}_2 = \mathbb{RP}^\infty$	Chapter 10 (classifying spaces)
homotopy quotient M_G	$(M \times EG)/G$; equals M/G up to homotopy if the action is free	–
equivariant cohomology	$H_G(M) = H(M_G)$; $H_G(\mathrm{pt}) = H(BG)$, $P_t(B\mathrm{U}(1)) = 1/(1-t^2)$	Chapter 12 (localisation)
equivariant Morse series	$\sum_N P_t(N_G)\, t^{\lambda_N}$ over critical manifolds N; inequalities $M_t^G - P_t^G = (1+t)R$	Chapter 8 (Yang–Mills on a Riemann surface is equivariantly perfect)
equivariantly perfect	e.g. z^2 on the rotating S^2: $(1+t^2)/(1-t^2)$ on both sides, though not perfect	–
Cartan model, localisation	equivariantly closed forms $\mathrm{d}\alpha = \iota_X \alpha$-type condition; Duistermaat–Heckman: stationary phase is exact	Chapter 12
energy functional	$E(\gamma) = \int \lvert\dot\gamma\rvert^2$ on paths $p \to q$; critical points are geodesics; $E \geq L^2$	Chapter 9 (Polyakov vs. Nambu–Goto)
second variation, Jacobi fields	Hessian of E is $-\nabla_s^2 - R(\cdot, \dot\gamma)\dot\gamma$; its kernel are the Jacobi fields	–
Morse index theorem	index of a geodesic = number of conjugate points along it, with multiplicity	Chapter 10 (spectral flow)
loop space ΩS^n	$P_t = 1/(1-t^{n-1})$: infinitely many geodesics between two points, for every metric	Chapter 6 (loop groups)
Palais–Smale	the compactness condition that lets Morse theory work in infinite dimensions	Section 7.16.8
closed geodesics	critical points of E on $\mathrm{Map}(S^1, M)$; U(1) rotates the loop, so the theory is equivariant	–
Bott periodicity	minimal geodesics in $\mathrm{SU}(2m)$ are Grassmannians; $\Omega^2\mathrm{U} \simeq \mathbb{Z} \times B\mathrm{U}$ (period 2), period 8 for O	Chapter 10, Chapter 4 (K-theory)
Reeb, Milnor, Smale	two critical points $\Rightarrow$ sphere; exotic 7-spheres; handle cancellation $\Rightarrow$ Poincaré conjecture in dim ≥ 5	Chapter 12

Nash §4: supersymmetric quantum mechanics (Witten)

Concept	Operational meaning	Returns in
supersymmetry algebra	$\{Q_i, Q_j\} = 0$ $(i \neq j)$, $Q_1^2 = H + P$, $Q_2^2 = H - P$; so $H \geq 0$	Section 7.10, Chapter 9, Chapter 12
fermion number $(-1)^F$	$+1$ on bosons, -1 on fermions; the Q_i are off-diagonal in the split $\mathcal{H}^B \oplus \mathcal{H}^F$	Section 7.10.4
nilpotent supercharge	for $P = 0$, $Q = \frac{1}{2}(Q_1 - iQ_2)$ has $Q^2 = 0$; in the forms model $Q = \mathrm{d}$ (or d_t)	Section 7.10.3
SUSY QM on a line	$Q = \partial + W'$ on functions; partner Hamiltonians $-\partial^2 + W'^2 \mp W''$; zero modes $e^{\mp W}$	Section 7.10.5, Section 7.12.5
Witten index	$\mathrm{Tr}(-1)^F = \mathrm{Tr}(-1)^F e^{-\beta H}$ counts ground states with sign; $E > 0$ levels pair; deformation invariant	Section 7.10.6, Chapter 4 (heat-kernel proof), Chapter 10
forms model	$\mathcal{H} = \Omega^\bullet(M)$, $Q_1 = \mathrm{d} + \mathrm{d}^*$, $Q_2 = i(\mathrm{d} - \mathrm{d}^*)$, $H = \Delta$; ground states = harmonic forms	Section 7.11.2, Section 7.11.3
forms as fermions	$a^{i*} = \mathrm{d}x^i \wedge$, $a^i = \iota_{\partial_i}$ obey $\{a^i, a^{j*}\} = \delta^{ij}$; degree = fermion number	Section 7.11.4
Clifford operators	$c^i = a^{i*} - a^i$, $\hat{c}^i = a^{i*} + a^i$; $\mathrm{d} + \mathrm{d}^*$ is a Dirac-type operator	Section 7.13.2, Chapter T4, Chapter 4
Witten deformation	$\mathrm{d}_t = e^{-tf}\,\mathrm{d}\,e^{tf} = \mathrm{d} + t\,\mathrm{d}f\wedge$, $\mathrm{d}_t^* = \mathrm{d}^* + t\,\iota_{\nabla f}$; same Betti numbers	Section 7.12
deformed Laplacian	$H_t = \Delta + t^2\,\lvert\mathrm{d}f\rvert^2 + t\,(D^2 f/Dx^i Dx^j)[a^{i*}, a^j]$: a Schrödinger operator with a spin–Hessian coupling	Section 7.13
local oscillators	at a critical point $H_t \approx \sum_i (-\partial_i^2 + t^2\lambda_i^2 x_i^2 + t\lambda_i[a^{i*}, a^i])$; spectrum $t\sum(\lvert\lambda_i\rvert\,(1 + 2n_i) + \lambda_i\varepsilon_i)$	Section 7.14.4
one zero mode per critical point	Gaussian times $\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^\lambda$ (downhill directions): degree = index	Section 7.14.5
low-lying complex	V_p = span of eigenforms with $E \leq ct$; $\dim V_p = m_p$; $\mathrm{d}_t : V_p \to V_{p+1}$	Section 7.16.2
tunnelling amplitude	$\langle b\rvert\mathrm{d}_t\lvert a\rangle \approx \varepsilon\,\sqrt{t/\pi}\,(f''(a)\,\lvert f''(b)\rvert)^{1/4} e^{-t(f(b)-f(a))}$ in 1D	Section 7.15, Chapter 8
Bogomolny bound	for a path from b down to a, $S_B = \frac{1}{2}\,\lVert\dot{x} + t\nabla f\rVert^2 + t\,(f(b) - f(a)) \geq t\,(f(b) - f(a))$; minimisers are gradient flow lines	Section 7.15.5, Chapter 8 (BPST)
determinant cancellation	bosonic and fermionic fluctuation determinants cancel up to the sign ε_γ; fermion zero modes select index difference one	Chapter 10 (zero modes)
stable/unstable manifolds, Morse–Smale	$W^u(b)$, $W^s(a)$ of dimensions index b, $n -$ index a; transverse $\Rightarrow$ flow lines form a space of dimension index $b -$ index $a - 1$	Section 7.16.3
orientation rule	orient O_b by $\iota_v\omega_b$, transport to a, compare with ω_a: $\varepsilon_\gamma = \pm 1$	Section 7.16.4
Morse–Witten complex	$\delta(a) = \sum_b \varepsilon(a,b)\,b$; $\delta^2 = 0$ by broken flow lines; $H(C,\delta) = H(M;\mathbb{Z})$	Section 7.16, Chapter 12
products, birth–death	$\delta = \delta^{(1)} \otimes 1 + (-1)^{F_1} \otimes \delta^{(2)}$; pairs of critical points appear and disappear together	Section 7.16.7
Floer theory	the same complex for CS on $\mathcal{A}/\mathcal{G}$: relative index by spectral flow, flow lines = instantons on $\mathbb{R} \times Y$	Section 7.16.8, Chapter 12

The examples, side by side

Every example of the chapter is one row of Table 7.2. Reading down the last column is a quick way to recall what each one teaches. (We write the Morse and Poincaré polynomials in u; $R(u) = (M_u - P_u)/(1+u)$ counts the cancelling pairs, and real coefficients are meant unless stated.)

M, f	$M_u(f)$	$P_u(M)$	$R(u)$	what it shows
S^1, $\cos\theta$	$1+u$	$1+u$	0	two instantons with opposite signs cancel (Example 7.84)
S^1, $-\cos 2\theta$	$2+2u$	$1+u$	1	one pair lifted, $E = \frac{16t}{\pi}e^{-4t}$ (Example 7.83)
$\mathbb{R}$, double well	$2+u$	1	1	tunnelling splitting $2\sqrt{2}\frac{t}{\pi}e^{-t/2}$ (Example 7.82)
$\mathbb{R}$, $\frac{1}{3}x^3 - sx$	$1+u$ or 0	1	–	birth–death of a pair (Example 7.99; not compact)
S^2, height	$1+u^2$	$1+u^2$	0	lacunary, perfect; exact zero modes e^{-tf}, $e^{tf}\,\mathrm{vol}$
S^2, two humps	$1+u+2u^2$	$1+u^2$	u	the saddle cancels one peak (Example 7.93)
S^2, $x^2+2y^2+3z^2$	$2+2u+2u^2$	$1+u^2$	$1+u$	two cancelling pairs (Example 7.95)
$\mathbb{RP}^2$, same f	$1+u+u^2$	1 (over $\mathbb{R}$)	u	$\delta_1 = \times(-2)$: $H^2(\mathbb{RP}^2;\mathbb{Z}) = \mathbb{Z}_2$ (Example 7.96)
T^2, $\cos x + \cos y$	$1+2u+u^2$	$1+2u+u^2$	0	$\delta = 0$, four exact ground states (Examples 7.91 and 7.97)
T^2, upright height	$1+2u+u^2$	$1+2u+u^2$	0	perfect, but not Morse–Smale until tilted (Figure 7.62)
T^2, $-\cos 2x + \cos y$	$2+4u+2u^2$	$1+2u+u^2$	$1+u$	product of complexes (Example 7.98)
$\mathbb{CP}^n$, $\sum a_i\lvert z_i\rvert^2$	$1+u^2+\cdots+u^{2n}$	same	0	lacunary: counting is enough
Σ_p, height	$1+2pu+u^2$	same	0	perfect; $\chi = 2-2p$
S^2, z^2 (Morse–Bott)	$1+u+2u^2$	$1+u^2$	u	a critical circle contributes $P_u(S^1)$
$S^2_{\mathrm{U}(1)}$, z^2	$\frac{1+u^2}{1-u^2}$	same	0	equivariantly perfect, though not perfect
ΩS^n, energy	$\frac{1}{1-u^{n-1}}$	same	0	perfect in infinite dimensions; infinitely many geodesics

Table 7.2: Every example of Chapter VII in one table: Morse polynomial, Poincaré polynomial, the cancelling-pair polynomial $R(u)$, and the lesson.

Dictionary: Morse theory and supersymmetric quantum mechanics

The whole of §4 can be compressed into the translation table Table 7.3. Read left to right it says what each piece of Morse theory *is* physically; read right to left it says what each piece of the quantum mechanics computes topologically.

Where Chapter VII goes next

- *Yang–Mills theory* (Chapter 8). The Yang–Mills functional on the space of connections is a Morse function in infinite dimensions. Its minima are the instantons; on a Riemann

Morse theory	supersymmetric quantum mechanics
differential forms on M	wavefunctions of a particle with n fermionic modes
degree p of a form	fermion number
d, d^*	supercharges Q, $Q^\dagger$
Hodge Laplacian Δ	Hamiltonian $H = \{Q, Q^\dagger\}$
harmonic forms, b_p	supersymmetric ground states in the p-fermion sector
Euler characteristic $\chi(M)$	Witten index $\mathrm{Tr}(-1)^F$
Morse function f, deformation e^{tf}	superpotential tf; $t \sim 1/\hbar$
critical point of index λ	classical vacuum; oscillator with λ fermions filled
weak Morse inequalities	perturbative ground states $\geq$ exact ground states
gradient flow line	instanton (tunnelling path)
$\varepsilon(a, b)$	sign of the fermion determinant
Morse–Witten differential δ	d_t restricted to the low-lying states
cancelling pair of critical points	boson–fermion pair lifted by tunnelling
$\delta^2 = 0$	$Q^2 = 0$
birth–death of critical points	a supermultiplet entering or leaving the low-energy spectrum

Table 7.3: The dictionary between Morse theory and supersymmetric quantum mechanics that Chapter VII §4 establishes.

surface Atiyah and Bott showed it is equivariantly perfect with respect to the gauge group, the equivariant Morse theory of Nash §3 in its most famous application. The Bogomolny bound $S \geq 8\pi^2 |k|$ is the gauge-theory version of the completed square of Section 7.15.5.

- *Index theory and anomalies* (Chapters 4 and 10). The Witten index is the index of the Dirac-type operator $\mathrm{d} + \mathrm{d}^*$ from even to odd forms. The same supersymmetric trick, $\mathrm{Tr}(-1)^F e^{-\beta H}$ independent of β, gives the heat-kernel proof of the index theorem. The Morse index theorem and the relative Morse index are instances of spectral flow, which computes anomalies.
- *Loop groups and strings* (Chapters 6 and 9). The energy functional on loop spaces and Bott periodicity return with the loop groups ΩG and with the string action.
- *Topological field theory* (Chapter 12). Floer homology is the Morse–Witten complex of the Chern–Simons function; Witten's interpretation of Donaldson theory treats it as the space of supersymmetric ground states of a twisted $N = 2$ gauge theory, exactly as $H^\bullet(M)$ was the space of ground states here.

Self-test

Try it

1. A Morse function on a closed surface has 3 minima and 2 maxima. How many saddles does it have, if the surface is a torus? a sphere?
2. Why can a Morse function on $\mathbb{RP}^2$ never be perfect over $\mathbb{Z}$, but can be over $\mathbb{Z}_2$?
3. At large t, what is the energy (to leading order) of the local state $\Psi_{n,I}$ at a critical point with Hessian eigenvalues $\lambda = (-1, 2)$, with $n = (0, 0)$ and the fermion in the x_2

direction occupied?

4. Why does $\langle b|\mathrm{d}_t|a\rangle$ vanish unless index b = index a + 1?

5. Why is the cross term in $Q_1(t)^2$ for a product manifold zero?

Answers. (1) $\chi = m_0 - m_1 + m_2$: on T^2, $0 = 3 - m_1 + 2$, so 5 saddles; on S^2, $2 = 3 - m_1 + 2$, so 3 saddles. (2) $H^2(\mathbb{RP}^2;\mathbb{Z}) = \mathbb{Z}_2$ is torsion, and a perfect function would give a complex with $\delta = 0$ and free cohomology; over $\mathbb{Z}_2$ the function $x^2 + 2y^2 + 3z^2$ has $\delta = 0$ mod 2 (Example 7.96). (3) By (7.200), $E = t\{(1\cdot 1 + (-1)(-1)) + (2\cdot 1 + 2\cdot(+1))\} = t(2+4) = 6t$, since the x_1-fermion is empty ($\varepsilon_1 = -1$) and the x_2-fermion is filled ($\varepsilon_2 = +1$). The zero mode instead fills the downhill direction x_1. (4) d_t raises the degree by one and the local state at b has degree index b; in the path integral, the instanton has index b − index a fermion zero modes, and d_t supplies exactly one fermion. (5) The supercharge of the second factor carries a factor $(-1)^{F_1}$, and $Q^{(1)}$ anticommutes with it ((7.250)).

Chapter 8

Instantons and Monopoles

Where this chapter is going

Chapter 8 is about the two most famous classical solutions of non-Abelian gauge theory: *instantons* (finite-action solutions of the Euclidean Yang–Mills equations in four dimensions) and *monopoles* (finite-energy static solutions of Yang–Mills–Higgs theory in three space dimensions). Nash is not mainly interested in writing the solutions down. He wants the *topology*: of the fields, of the gauge group, of the space of all fields modulo gauge transformations, and of the spaces of solutions (the moduli spaces).

The chapter starts from one simple fact: the space $\mathcal{A}$ of all gauge potentials is a vector space in disguise, so it has no topology at all. All the interesting topology comes from dividing by the gauge group $\mathcal{G}$. The quotient $\mathcal{A}/\mathcal{G}$ is the true configuration space of a gauge theory, and it is topologically rich: it is the classifying space $B\mathcal{G}$. On a sphere S^n its homotopy groups are homotopy groups of the Lie group G, shifted in degree. This is where instanton numbers, large gauge transformations, the θ-vacua and the Gribov ambiguity come from. Section 2 then builds explicit differential forms for the cohomology of $\mathcal{G}$ and $\mathcal{A}/\mathcal{G}$ out of the curvature, by the Chern–Simons (transgression) construction. The same Chern–Simons forms give the topologically massive gauge theory in three dimensions, and in Chapter 10 they give the anomalies. Sections 3–6 (the later parts of this chapter) turn to the instanton and monopole moduli spaces and to Morse theory on $\mathcal{A}/\mathcal{G}$.

Reading Nash (pp. 216–227)

Nash's §1 "The topology of gauge fields" runs from p. 216 to the middle of p. 223, equations (8.1)–(8.38). His §2 "Secondary characteristic classes" runs to the top of p. 227, equations (8.39)–(8.62). That is only eleven pages, and nearly every line hides a construction from algebraic topology or a calculation. In these notes we unpack all of them. We also add the physics Nash only alludes to: the winding number of $g^{-1}\mathrm{d}g$ at infinity, large gauge transformations and the θ-vacua.

8.1 The topology of gauge fields

What is the space of all gauge fields, and what does it look like? A physicist usually meets gauge fields one at a time, as solutions of field equations or as integration variables in a path integral. Here we step back and look at the *set* of all of them. There are three reasons to care.

- The path integral $Z = \int \mathcal{D}A\, e^{-S[A]}$ is an integral over this space. If the space has holes or twists, the integral knows about them.

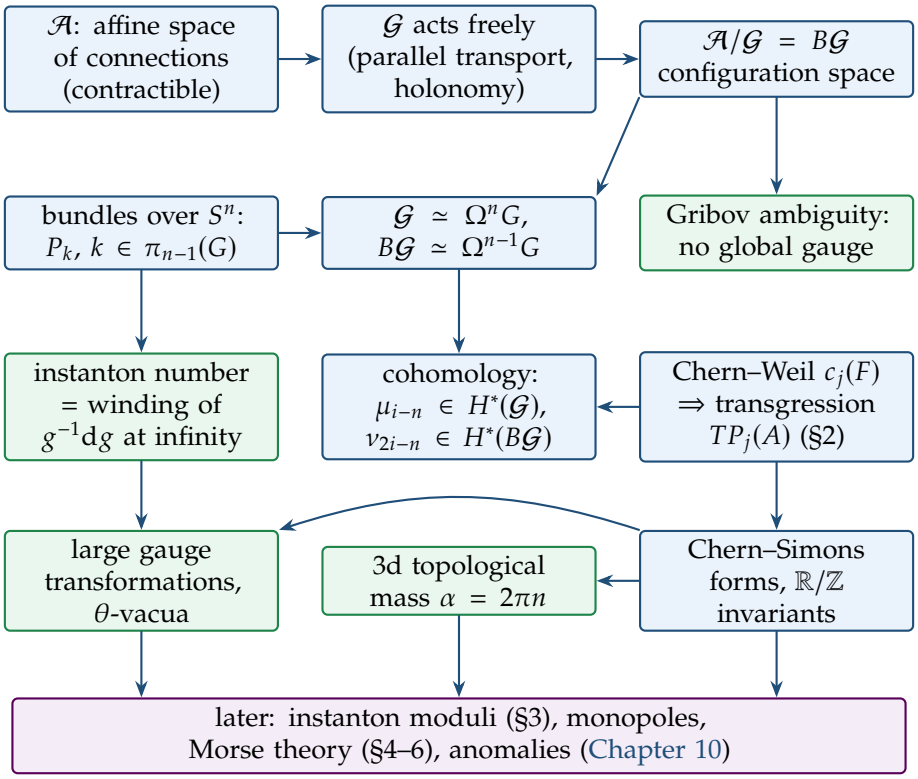

Figure 8.1: The logic of this part (Nash §§1–2) and where it leads. Blue boxes are mathematical constructions, green boxes are their physical consequences. Read the top row first: contractible $\mathcal{A}$, free action of $\mathcal{G}$, and the quotient $B\mathcal{G}$. Everything below it computes the topology of that quotient and gives it a physical meaning.

- Gauge-equivalent potentials describe the same physics. So the physical configuration space is the space of potentials divided by gauge transformations. Dividing can create topology where there was none.

- Topological invariants of gauge fields (instanton number, monopole charge) are exactly the labels of the "pieces" of these spaces.

This section answers four questions in turn. What is the space of connections $\mathcal{A}$? (An affine space, so topologically trivial.) How does the gauge group $\mathcal{G}$ act on it? (Freely, if we use the based gauge group.) What is the quotient $\mathcal{A}/\mathcal{G}$? (The classifying space $B\mathcal{G}$; the bundle $\mathcal{A} \to \mathcal{A}/\mathcal{G}$ is twisted, which is the Gribov ambiguity.) And what are the homotopy and cohomology of $\mathcal{G}$ and $B\mathcal{G}$ when the base is a sphere? (They are those of G, shifted.)

8.1.1 Conventions and a reminder about principal bundles

Throughout this part M is a smooth, connected, oriented manifold of dimension n (in the examples usually S^n or $\mathbb{R}^n$), and G is a compact Lie group, usually $\mathrm{U}(N)$ or $\mathrm{SU}(N)$, realised as a group of $N \times N$ matrices. Its Lie algebra $\mathfrak{g}$ consists of *anti-Hermitian* matrices.

Principal bundles in one paragraph

A **principal G-bundle** $\pi : P \to M$ is a space P with a free right action of G, $p \mapsto pg$, whose orbits are the fibres $P_x = \pi^{-1}(x)$.[1] Each fibre is a copy of G (but without a preferred identity element). Over a small open set $U \subset M$ we choose a **local section** $s : U \to P$. Every point over U can then be written uniquely as $p = s(x)g$, and the pair (x, g) are **local coordinates** on P. Nash writes exactly these coordinates in (8.3). If U_i, U_j are two patches with sections s_i, s_j, then on the overlap

$$s_j(x) = s_i(x)\, t_{ij}(x), \qquad t_{ij} : U_i \cap U_j \to G, \tag{8.1}$$

and the t_{ij} are the **transition functions**. They obey the cocycle condition $t_{ij}t_{jk} = t_{ik}$ on triple overlaps. A bundle is **trivial**, $P \cong M \times G$, exactly when one section can be chosen on all of M. (Many books write g_{ij} or $g_{\alpha\beta}$ for the transition functions; we keep the letter g for gauge transformations.) Figure 8.2 shows every ingredient of this paragraph at once.

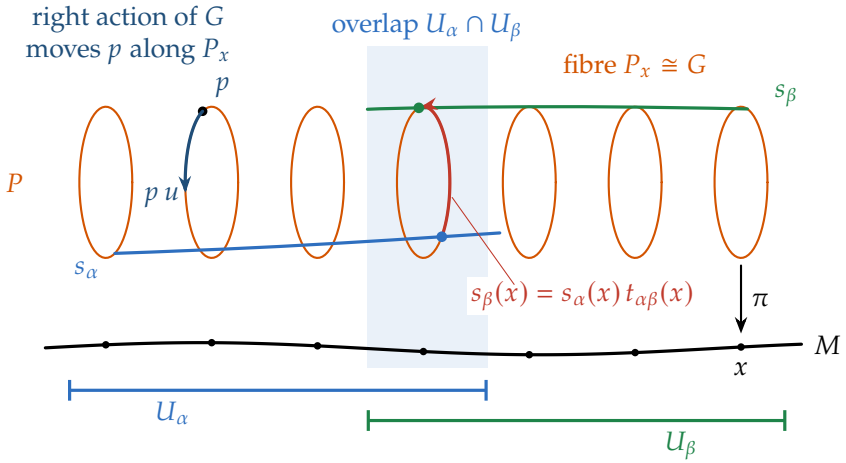

Figure 8.2: A principal bundle $\pi : P \to M$ for $G = \mathrm{U}(1)$, so that every fibre is a circle. What to see: each fibre $P_x = \pi^{-1}(x)$ (orange) is a copy of G sitting over one point x; π squashes the whole fibre to x. The right action of $u \in G$ slides a point p around its own fibre and never leaves it (dark blue arrow). A local section $s_\alpha : U_\alpha \to P$ (blue) picks one point in every fibre over the patch U_α, and so gives the trivialisation $p = s_\alpha(x)u \leftrightarrow (x, u)$; likewise s_β (green) over U_β. On the overlap (shaded) both sections exist, and they differ by the group element $t_{\alpha\beta}(x)$, the transition function (red arrow, often written $g_{\alpha\beta}$). The bundle is twisted exactly when no choice of sections makes all the transition functions equal to $\mathbb{1}$.

Connections: global on P, local on M

A connection can be described in two equivalent ways, and we will need both.

- *On P:* a $\mathfrak{g}$-valued 1-form ω on the total space P which, on vertical vectors (tangent to a fibre), returns the Lie algebra element that generates them, and which transforms as $R_g^*\omega = g^{-1}\omega g$ under the right action. This ω is defined *globally* on P, even when P is twisted.

[1] Vocabulary of fibre bundles (defined in Chapter 1, all drawn in Figure 8.2). The *total space* is P (for a general bundle often called E); the *base* is M; the *projection* $\pi : P \to M$ sends each point to the point of M it sits over. The *fibre over* x is $P_x = \pi^{-1}(x)$, and every fibre is a copy of one *typical fibre* F; for a principal bundle $F = G$. A *local trivialisation* is an identification $\pi^{-1}(U) \cong U \times F$ that respects π. A *(local) section* is a map $s : U \to P$ with $\pi \circ s = \mathrm{id}_U$: a choice of one point in each fibre over U. The *transition functions* compare two trivialisations on an overlap $U_i \cap U_j$; for principal bundles they are the t_{ij} of (8.1).

- *On M:* the pull-backs $A_i = s_i^*\omega$ by the local sections. These are the physicist's gauge potentials. They live on patches and are glued by

$$A_j = t_{ij}^{-1} A_i \, t_{ij} + t_{ij}^{-1} \mathrm{d} t_{ij}. \tag{8.2}$$

In the local coordinates $p = (x, g)$ the two descriptions are related by

$$\omega_{(x,g)} = g^{-1} A_i(x)\, g + g^{-1}\mathrm{d}g. \tag{8.3}$$

The curvature is $F = \mathrm{d}A + A \wedge A$ on each patch, and it transforms covariantly, $F_j = t_{ij}^{-1} F_i t_{ij}$. That is why $\operatorname{tr} F^k$ and all other invariant polynomials in F are globally defined forms on M, even though A is not. We will use this over and over in Section 8.2. For more background see Chapter T3.

Covariant derivatives: the transformation law dictates the formula

We will differentiate several kinds of objects: matter fields ψ, gauge parameters ε, the curvature F. The covariant derivative $D\psi = \mathrm{d}\psi + A\psi$, the transformation law $A \mapsto A^g = g^{-1}Ag + g^{-1}\mathrm{d}g$, its infinitesimal form $\delta A = \mathrm{d}\varepsilon + [A, \varepsilon]$, the curvature as D^2 and the Bianchi identity $DF = 0$ were developed in Section T3.8.3 and the rest of Section T3.8, which also has the dictionary to the Hermitian conventions of physics texts (Section T3.8.9). One rule organises all the formulas: *the covariant derivative of an object must transform exactly as the object does.* The bare d spoils this, because it also differentiates g, so we add terms built from A that cancel the damage. How many terms, and with which signs, depends only on how many factors of g the object carries and on which side.

Key idea: One-sided versus two-sided transformation laws

With $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$,

$$\psi \mapsto g^{-1}\psi \quad\Longrightarrow\quad D\psi = \mathrm{d}\psi + A\psi, \tag{8.4}$$

$$\Phi \mapsto g^{-1}\Phi\, g \quad\Longrightarrow\quad D\Phi = \mathrm{d}\Phi + A\wedge\Phi - (-1)^p\,\Phi\wedge A =: \mathrm{d}\Phi + [A,\Phi]. \tag{8.5}$$

The first line is for a **fundamental** (one-sided) object, such as a quark field. The second is for an **adjoint** (two-sided) p-form, such as F ($p = 2$) or an infinitesimal gauge parameter ε ($p = 0$). The term $+A\wedge\Phi$ repairs the derivative of the *left* factor g^{-1}; the term $-(-1)^p\Phi\wedge A$ repairs the derivative of the *right* factor g.

The fundamental case is checked in Section T3.8.3. Here is the check of the two-sided case, which shows each correction term doing its job. Nothing is needed beyond the product rule and $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\, g^{-1}$. Put $\Phi' = g^{-1}\Phi g$ and $A' = A^g$. Moving d past the p-form Φ costs $(-1)^p$, so $\mathrm{d}(\Phi g) = \mathrm{d}\Phi\, g + (-1)^p\,\Phi\wedge\mathrm{d}g$, and

$$\begin{aligned}
\mathrm{d}\Phi' &\overset{(1)}{=} -g^{-1}\mathrm{d}g\, g^{-1}\wedge\Phi g + g^{-1}\mathrm{d}\Phi\, g + (-1)^p\, g^{-1}\Phi\wedge\mathrm{d}g,\\
A'\wedge\Phi' &\overset{(2)}{=} g^{-1}A\wedge\Phi\, g + g^{-1}\mathrm{d}g\, g^{-1}\wedge\Phi g,\\
\Phi'\wedge A' &\overset{(3)}{=} g^{-1}\Phi\wedge A\, g + g^{-1}\Phi\wedge\mathrm{d}g,\\
\Longrightarrow\quad \mathrm{d}\Phi' + A'\wedge\Phi' - (-1)^p\,\Phi'\wedge A' &\overset{(4)}{=} g^{-1}\big(\mathrm{d}\Phi + A\wedge\Phi - (-1)^p\,\Phi\wedge A\big)g.
\end{aligned} \tag{8.6}$$

(1) Product rule on $g^{-1}\cdot\Phi\cdot g$, with $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\, g^{-1}$ and the sign rule just stated.
(2) Multiply $A' = g^{-1}Ag + g^{-1}\mathrm{d}g$ into $g^{-1}\Phi g$ from the left; the inner gg^{-1} cancel.

(3) Multiply from the right: $g^{-1}\Phi g \wedge g^{-1}Ag = g^{-1}\Phi \wedge Ag$ and $g^{-1}\Phi g \wedge g^{-1}\mathrm{d}g = g^{-1}\Phi \wedge \mathrm{d}g$.
(4) Add the first two lines and subtract $(-1)^p$ times the third. The term $g^{-1}\mathrm{d}g\, g^{-1} \wedge \Phi g$ (from differentiating the left g^{-1}) cancels against the one in $+A' \wedge \Phi'$; the term $(-1)^p g^{-1}\Phi \wedge \mathrm{d}g$ (from differentiating the right g) cancels against the one in $-(-1)^p\Phi' \wedge A'$.

So $D\Phi \mapsto g^{-1}(D\Phi)g$, as it must. For $\Phi = \varepsilon$ ($p = 0$) this is $D\varepsilon = \mathrm{d}\varepsilon + A\varepsilon - \varepsilon A$, the combination in the infinitesimal gauge transformation $A^{e^\varepsilon} \approx A + \mathrm{d}\varepsilon + [A, \varepsilon]$ (Section 8.1.10). For $\Phi = F$ ($p = 2$) it is $DF = \mathrm{d}F + A \wedge F - F \wedge A$, and its vanishing is the Bianchi identity (T3.61); we use it in Section 8.2 as the reason $\mathrm{d}\,\mathrm{tr}\, F^k = 0$. (This way of explaining the signs follows a Physics Stack Exchange answer, question 483197, answer 483214.)

The graded commutator. For a matrix-valued p-form α and q-form β the **graded commutator** is

$$[\alpha, \beta] := \alpha \wedge \beta - (-1)^{pq}\, \beta \wedge \alpha. \tag{8.7}$$

For two 0-forms it is the matrix commutator, and for $\alpha = A$ ($p = 1$) it is exactly the bracket in (8.5). Unlike the ordinary commutator, it does not vanish when $\alpha = \beta$ has odd degree. For the gauge potential, $A = A_\mu \mathrm{d}x^\mu$,

$$\begin{aligned}[A, A] &\overset{(1)}{=} A \wedge A - (-1)^{1\cdot 1} A \wedge A = 2\, A \wedge A \\ &\overset{(2)}{=} 2\, A_\mu A_\nu\, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu \\ &\overset{(3)}{=} [A_\mu, A_\nu]\, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu.\end{aligned}$$

(1) Definition (8.7) with $p = q = 1$.
(2) Expand both factors; the matrices A_μ stay in order, the $\mathrm{d}x$'s are wedged.
(3) Split $A_\mu A_\nu$ into symmetric and antisymmetric parts in $\mu\nu$; the symmetric part dies against the antisymmetric $\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$, leaving $\frac{1}{2}[A_\mu, A_\nu]$, times 2.

So $A \wedge A$ is zero for U(1) and nonzero as soon as the components fail to commute. For SU(2) with $e_k = -i\sigma_k$ (so $e_1 e_2 = -e_2 e_1 = e_3$), the potential $A = e_1\, \mathrm{d}x + e_2\, \mathrm{d}y$ has $A \wedge A = (e_1 e_2 - e_2 e_1)\, \mathrm{d}x \wedge \mathrm{d}y = 2e_3\, \mathrm{d}x \wedge \mathrm{d}y$. In this notation the curvature is

$$F = \mathrm{d}A + A \wedge A = \mathrm{d}A + \tfrac{1}{2}[A, A]. \tag{8.8}$$

Watch out: A is not covariant, and F is not "$D_A A$"

If A were an adjoint 1-form, (8.5) would give its covariant derivative as $\mathrm{d}A + [A, A] = \mathrm{d}A + 2A \wedge A$, which is *not* F. The factor $\frac{1}{2}$ in (8.8) is the sign that something different is going on: A transforms inhomogeneously, $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$, so it is not a two-sided object and the rule of (8.5) does not apply to it; A has no covariant derivative at all. One sometimes sees "$\mathrm{d}_A A = \mathrm{d}A + A \wedge A = F$"; this is only a notation for F, not a covariant derivative of A. What is remarkable is that F, built from the non-covariant A, does transform covariantly, $F \mapsto g^{-1}Fg$: the inhomogeneous pieces cancel between $\mathrm{d}A$ and $A \wedge A$. Differences of connections, $A - A'$, are two-sided (Section 8.1.2), and for them $D(A - A')$ makes perfect sense.

Dictionary: anti-Hermitian (Nash) versus Hermitian (physics) fields

We use Nash's convention: A is anti-Hermitian, $F = \mathrm{d}A + A \wedge A$, and a gauge transformation acts as

$$A \longmapsto g^{-1}Ag + g^{-1}\mathrm{d}g.$$

The physicists' field is Hermitian: $A_{\text{math}} = -i\, g_{\text{YM}}\, A^a_{\text{phys}} T^a$ with Hermitian generators T^a, normalised by $\operatorname{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ for SU(N). Then $F_{\text{math}} = -i\, g_{\text{YM}} F^a_{\text{phys}} T^a$ and

$$-\operatorname{tr}\big(F_{\text{math}} \wedge \star F_{\text{math}}\big) = \tfrac{1}{2}\, g_{\text{YM}}^2\, F^a_{\text{phys}} \wedge \star F^a_{\text{phys}}.$$

For $G = \mathrm{U}(1)$ and $g = e^{i\lambda}$ the rule becomes $A \mapsto A + i\,\mathrm{d}\lambda$, i.e. $a \mapsto a - \mathrm{d}\lambda/e$ for the real potential a with $A = -iea$.

Working definition 8.1 (quaternion notation for SU(2))

We use the conventions of the rest of this chapter for SU(2) [the 2×2 complex matrices g with $g^\dagger g = \mathbb{1}$ and $\det g = 1$]. Write $e_k = -i\sigma_k$ ($k = 1,2,3$) with the Pauli matrices

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

Then $e_1 e_2 = e_3$ (and cyclically) and $e_k^2 = -1$: the e_k are the quaternion units $\mathbf{i}, \mathbf{j}, \mathbf{k}$. A point $x = (x^1, x^2, x^3, x^4) \in \mathbb{R}^4$ is identified with the 2×2 matrix

$$x = x^4\,\mathbb{1} + x^k e_k = \begin{pmatrix} x^4 - ix^3 & -x^2 - ix^1 \\ x^2 - ix^1 & x^4 + ix^3 \end{pmatrix}, \qquad \det x = |x|^2 . \tag{8.9}$$

Its conjugate is $\bar{x} = x^\dagger = x^4\mathbb{1} - x^k e_k$, and $\bar{x}x = |x|^2\,\mathbb{1}$. So the unit sphere $S^3 = \{|x| = 1\}$ *is* the group SU(2). The orientation of $\mathbb{R}^4$ [the choice of which 4-form counts as positive, which fixes the sign of every integral over $\mathbb{R}^4$] is $\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4$.

Watch out: Signs of c_2 and of the instanton number

For SU(N) with anti-Hermitian F, the second Chern class is $c_2(F) = \frac{1}{8\pi^2}\operatorname{tr}(F \wedge F)$. For a self-dual field this is *negative*, because $\operatorname{tr}(e_a e_b) = -2\delta_{ab}$. We follow the rest of this chapter and Nash's formula (8.61) and define the **instanton number**

$$k := -\frac{1}{8\pi^2}\int_M \operatorname{tr}(F \wedge F) = -c_2, \tag{8.10}$$

which is $+1$ for the standard (BPST) instanton. Nash's polynomial $P_2(F) = -\frac{1}{8\pi^2}\operatorname{tr}(F\wedge F)$ in (8.60) is therefore $-c_2$, not c_2. This does not matter for anything topological (a sign never changes whether a class vanishes), but it matters when we compare numbers.

8.1.2 The space of all connections is an affine space

Let $\mathcal{A}$ denote the set of all connections on a fixed bundle $P \to M$. What kind of space is it?

A first guess is "a vector space": gauge potentials are 1-forms, and 1-forms can be added. But this is wrong in an instructive way. If A and A' are connections, then $A + A'$ is *not* a connection. Look at the gluing rule (8.2):

$$\begin{aligned}(A + A')_j &\overset{(1)}{=} \big(t^{-1}A_i t + t^{-1}\mathrm{d}t\big) + \big(t^{-1}A'_i t + t^{-1}\mathrm{d}t\big) \\ &= t^{-1}(A + A')_i\, t + 2\,t^{-1}\mathrm{d}t.\end{aligned}$$

(1) Each of A and A' obeys the gluing rule (8.2) with the same transition function $t = t_{ij}$.

The inhomogeneous term $t^{-1}\mathrm{d}t$ appears twice, so $A + A'$ glues with the wrong rule. Likewise $2A$ is not a connection, and neither is 0 on a nontrivial bundle (the zero potential in one patch is not zero in another).

What *does* work is the difference. Subtracting,

$$\begin{aligned}(A - A')_j &\overset{(1)}{=} \left(t^{-1}A_i t + t^{-1}\mathrm{d}t\right) - \left(t^{-1}A'_i t + t^{-1}\mathrm{d}t\right)\\ &= t^{-1}(A - A')_i\, t.\end{aligned} \tag{8.11}$$

(1) Gluing rule (8.2) for both connections.

The inhomogeneous terms cancel. So $a = A - A'$ transforms like the curvature does, by conjugation only. Such an object is a globally defined 1-form with values in the bundle of Lie algebras $\operatorname{ad} P = P \times_G \mathfrak{g}$ (the adjoint bundle): an element of $\Omega^1(M; \operatorname{ad} P)$. This is an honest vector space.

Working definition 8.2 (affine space)

A set $\mathcal{A}$ is an **affine space** modelled on a vector space V [here $V = \Omega^1(M; \operatorname{ad} P)$, the differences $a = A - A'$ of two connections] if you can subtract two points to get a vector, $A - A' \in V$, and add a vector to a point to get a point, $A + a \in \mathcal{A}$, with the usual rules. *In practice:* an affine space is a vector space in which nobody has told you where the origin is. Choose any point A_0 as an origin; then every point is $A = A_0 + a$ for a unique vector a.

Key idea: The space of connections

The space $\mathcal{A}$ of connections on P is an affine space modelled on $\Omega^1(M; \operatorname{ad} P)$. Choosing a reference connection A_0,

$$\mathcal{A} = \left\{A_0 + a \;:\; a \in \Omega^1(M; \operatorname{ad} P)\right\}. \tag{8.12}$$

This is Nash's first statement. The "origin" A_0 is arbitrary. On a trivial bundle the obvious choice is $A_0 = 0$, and then $\mathcal{A}$ really is the vector space of $\mathfrak{g}$-valued 1-forms. On a nontrivial bundle (a monopole or instanton bundle) there is no such canonical choice.

Straight lines and contractibility

In an affine space we cannot add points, but we can take *weighted averages* whose weights sum to one. Nash's equation (8.1) is exactly this. For two connections A_1, A_2 and $t \in \mathbb{R}$, set

$$A_t := (1 - t)A_1 + tA_2 = A_1 + t\,(A_2 - A_1). \tag{8.13}$$

Is A_t a connection? Check the gluing rule:

$$\begin{aligned}(A_t)_j &\overset{(1)}{=} (1-t)\left(t_{ij}^{-1}A_{1,i}t_{ij} + t_{ij}^{-1}\mathrm{d}t_{ij}\right) + t\left(t_{ij}^{-1}A_{2,i}t_{ij} + t_{ij}^{-1}\mathrm{d}t_{ij}\right)\\ &\overset{(2)}{=} t_{ij}^{-1}\left((1-t)A_{1,i} + tA_{2,i}\right)t_{ij} + \left((1-t)+t\right)t_{ij}^{-1}\mathrm{d}t_{ij}\\ &\overset{(3)}{=} t_{ij}^{-1}(A_t)_i\, t_{ij} + t_{ij}^{-1}\mathrm{d}t_{ij}.\end{aligned}$$

(1) Each A_a glues by (8.2).
(2) Collect the conjugated terms and the inhomogeneous terms separately.
(3) The weights sum to 1, so the inhomogeneous term appears exactly once, which is the correct gluing rule.

So $A_t \in \mathcal{A}$ for every real t: there is a whole straight line through any two connections.

Now fix any $A_0 \in \mathcal{A}$ and define

$$H : \mathcal{A} \times [0,1] \to \mathcal{A}, \qquad H(A,s) = (1-s)A + sA_0. \tag{8.14}$$

At $s = 0$ this is the identity map of $\mathcal{A}$, and at $s = 1$ it sends everything to the single point A_0. It is continuous (it is affine in both arguments). A space with such a map is **contractible**: it can be shrunk continuously to a point. Consequently every loop, every sphere, every closed surface drawn in $\mathcal{A}$ can be shrunk to a point, and

$$\pi_j(\mathcal{A}) = 0 \quad \text{for all } j \geq 0, \qquad H^j(\mathcal{A}) = 0 \quad \text{for all } j \geq 1. \tag{8.15}$$

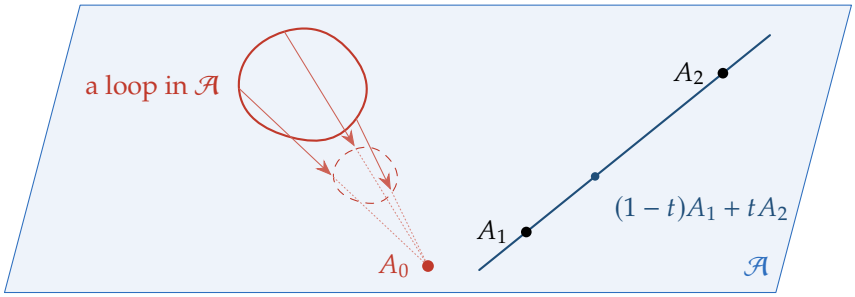

Figure 8.3: The space of connections is a (very large) flat space without an origin. Any two points A_1, A_2 are joined by the straight line (8.1). A loop (red) is shrunk to the point A_0 along straight lines (thin arrows, which end on the dashed loop: the halfway stage $s = \frac{1}{2}$ of (8.14)), so $\mathcal{A}$ has no topology. All the topology in this chapter comes from the gauge group, not from $\mathcal{A}$.

Worked example 8.1: Connections on the trivial U(1) bundle over S^1

Let $M = S^1$ with angle $\phi \in [0, 2\pi)$ and $G = \mathrm{U}(1)$. Every U(1) bundle over S^1 is trivial (a transition function would be a map from a disconnected overlap into the connected group U(1), which can be deformed to 1). A connection is then a single global 1-form

$$A = i\,a(\phi)\,\mathrm{d}\phi, \qquad a : S^1 \to \mathbb{R} \text{ smooth},$$

anti-Hermitian because it is i times a real form. So $\mathcal{A}$ is literally the vector space $C^\infty(S^1;\mathbb{R})$ of periodic real functions, with origin $A_0 = 0$. A straight line is $a_t(\phi) = (1-t)a_1(\phi) + t a_2(\phi)$. Contractibility is obvious: $a \mapsto (1-s)a$ shrinks everything to 0.
This tiny example will reappear several times. It is the simplest place to see a nontrivial quotient $\mathcal{A}/\mathcal{G}$ (Example 8.10).

Worked example 8.2: Why 0 is not a connection on the monopole bundle

Cover S^2 by the northern and southern patches $U_N = S^2 \setminus \{\mathrm{S}\}$ and $U_S = S^2 \setminus \{\mathrm{N}\}$, glued along the equator by $t_{NS}(\phi) = e^{im\phi}$ with $m \in \mathbb{Z}$. The standard Dirac monopole connection is

$$A_N = -\tfrac{im}{2}(1-\cos\theta)\,\mathrm{d}\phi, \qquad A_S = \tfrac{im}{2}(1+\cos\theta)\,\mathrm{d}\phi.$$

Check the gluing rule at the equator:

$$\begin{aligned} t_{NS}^{-1} A_N t_{NS} + t_{NS}^{-1}\mathrm{d}t_{NS} &\overset{(1)}{=} A_N + im\,\mathrm{d}\phi \\ &\overset{(2)}{=} \Big(-\tfrac{im}{2}(1-\cos\theta) + im\Big)\mathrm{d}\phi \\ &= \tfrac{im}{2}(1+\cos\theta)\,\mathrm{d}\phi = A_S. \end{aligned}$$

(1) U(1) is Abelian, so conjugation does nothing, and $e^{-im\phi}\mathrm{d}(e^{im\phi}) = im\,\mathrm{d}\phi$.
(2) Substitute A_N.

Now try the "zero connection" $A_N = 0$, $A_S = 0$. The gluing rule would demand $A_S = 0 + im\,\mathrm{d}\phi$, which is not zero if $m \neq 0$. So on the monopole bundle, zero is not a point of $\mathcal{A}$. Any other connection has the form $A = A_{\text{Dirac}} + a$ with $a = i\,\alpha$ for a *global* real 1-form α on S^2. The curvature is $F = \mathrm{d}A_N = -\frac{im}{2}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi + i\,\mathrm{d}\alpha$, and

$$\int_{S^2}\frac{i}{2\pi}F \overset{(1)}{=} \frac{m}{4\pi}\int_{S^2}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi - \frac{1}{2\pi}\int_{S^2}\mathrm{d}\alpha \overset{(2)}{=} m.$$

(1) Multiply out $\frac{i}{2\pi}\cdot(-\frac{im}{2}) = \frac{m}{4\pi}$ and $\frac{i}{2\pi}\cdot i = -\frac{1}{2\pi}$.
(2) The area of the unit sphere is 4π; the exact form $\mathrm{d}\alpha$ integrates to zero by Stokes, because S^2 has no boundary.

So every point of $\mathcal{A}$ has the same first Chern number m. Moving around in $\mathcal{A}$ never changes the topology of the bundle; the bundle is fixed once and for all when we define $\mathcal{A}$.

Physical picture: Why a physicist should not be surprised

In a path integral we integrate over "all field configurations". For a scalar field that is a vector space, and nobody expects topology there. The statement that $\mathcal{A}$ is affine says the same is true of gauge potentials, *as long as we do not divide by gauge transformations*. Perturbation theory lives happily in $\mathcal{A}$: expand around a background A_0 and integrate over the fluctuation a. The topological effects (instantons, θ-vacua, Gribov copies) appear only once we insist that gauge-equivalent fields be counted once.

Watch out: Infinite dimensions

$\mathcal{A}$ is infinite-dimensional. To make "continuous" and "smooth" precise one completes it in a Sobolev norm (see Chapter 6). For the topology none of this matters: straight-line contractions work in any topological vector space.

8.1.3 Gauge transformations and the two gauge groups

The space $\mathcal{A}$ has no topology of its own. The next ingredient is the group that acts on it. What exactly is a gauge transformation on a bundle that may be twisted?

On a single patch the physicist's answer is familiar: a gauge transformation is a function $g : U \to G$, and it acts on the potential by

$$A \longmapsto A^g := g^{-1}Ag + g^{-1}\mathrm{d}g. \tag{8.16}$$

On a nontrivial bundle we have one such function g_i on each patch U_i. They cannot be chosen independently. The transformed potentials $A_i^{g_i}$ must still glue by the rule (8.2), and that forces

$$g_j = t_{ij}^{-1}\,g_i\,t_{ij} \qquad \text{on } U_i\cap U_j. \tag{8.17}$$

Let us check that (8.17) is enough. Write $t = t_{ij}$ and use $\mathrm{d}(t^{-1}) = -t^{-1}\mathrm{d}t\,t^{-1}$:

$$\begin{aligned} t^{-1}A_i^{g_i}t + t^{-1}\mathrm{d}t &\overset{(1)}{=} t^{-1}g_i^{-1}A_ig_it + t^{-1}g_i^{-1}\mathrm{d}g_i\,t + t^{-1}\mathrm{d}t \\ &\overset{(2)}{=} g_j^{-1}\big(t^{-1}A_it\big)g_j + g_j^{-1}t^{-1}\mathrm{d}g_i\,t + t^{-1}\mathrm{d}t \\ &\overset{(3)}{=} g_j^{-1}\big(A_j - t^{-1}\mathrm{d}t\big)g_j + g_j^{-1}t^{-1}\mathrm{d}g_i\,t + t^{-1}\mathrm{d}t \end{aligned}$$

$$\overset{(4)}{=} g_j^{-1} A_j g_j + g_j^{-1} \mathrm{d} g_j = A_j^{g_j}.$$

(1) Definition (8.16) of $A_i^{g_i}$.
(2) Insert $\mathbb{1} = tt^{-1}$ twice and use $t^{-1} g_i^{\pm 1} t = g_j^{\pm 1}$ from (8.17); in the middle term write $t^{-1} g_i^{-1} = g_j^{-1} t^{-1}$.
(3) The gluing rule (8.2) says $t^{-1} A_i t = A_j - t^{-1} \mathrm{d} t$.
(4) Differentiate $g_j = t^{-1} g_i t$: $\mathrm{d} g_j = -t^{-1} \mathrm{d} t \, g_j + t^{-1} \mathrm{d} g_i \, t + g_j t^{-1} \mathrm{d} t$. Multiply on the left by g_j^{-1}; the three terms are exactly $-g_j^{-1} t^{-1} \mathrm{d} t \, g_j + g_j^{-1} t^{-1} \mathrm{d} g_i \, t + t^{-1} \mathrm{d} t$, which is what stands on the previous line after $g_j^{-1} A_j g_j$.

So the transformed potentials glue correctly. A collection $\{g_i\}$ obeying (8.17) is a section of the bundle $\mathrm{Ad}\, P$, whose fibre is a copy of G on which the transition functions act by *conjugation* (compare P itself, where they act by left multiplication). On a trivial bundle it is simply a map $M \to G$.

Working definition 8.3 (gauge transformation)

A **gauge transformation** of P is a collection of maps $g_i : U_i \to G$ that glue by conjugation [on each overlap $g_j = t_{ij}^{-1} g_i t_{ij}$, with the same transition functions t_{ij} as P], (8.17); equivalently a section of $\mathrm{Ad}\, P = P \times_{\mathrm{Ad}} G$. It acts on connections by (8.16), patch by patch. It acts on the bundle P itself, in the local coordinates $p = (x, u)$, by

$$\alpha(x, u) = \big(x, \; g_i(x)^{-1} u\big). \tag{8.18}$$

Formally: a bundle automorphism $\alpha : P \to P$ with $\alpha(pu) = \alpha(p)u$ that covers the identity map of M [α maps each fibre P_x to itself, so no point of M is moved] (Nash, Ch. 6, p. 176, and Chapter 6).

The rule (8.18) is patch-independent. A point p has coordinates u_i and u_j in the two patches, with $u_i = t_{ij} u_j$ (because $p = s_j u_j = s_i t_{ij} u_j$). Transforming in patch j and converting back,

$$t_{ij}\big(g_j^{-1} u_j\big) \overset{(1)}{=} t_{ij} t_{ij}^{-1} g_i^{-1} t_{ij} u_j \overset{(2)}{=} g_i^{-1} u_i,$$

(1) Invert (8.17): $g_j^{-1} = t_{ij}^{-1} g_i^{-1} t_{ij}$.
(2) Cancel $t_{ij} t_{ij}^{-1}$ and use $t_{ij} u_j = u_i$.

which is the transformation computed in patch i. The action commutes with the right action of G on P (left and right multiplications commute), as a bundle automorphism must. The inverse in (8.18) is chosen so that the action on connections comes out as (8.16); we will see why in Section 8.1.5.

Two gauge groups

Gauge transformations can be multiplied pointwise, $(gh)_i(x) = g_i(x) h_i(x)$, and they form an infinite-dimensional group. Nash uses two versions of it.

Working definition 8.4 (the full and the based gauge groups)

- $\hat{\mathcal{G}}$ is the group of *all* gauge transformations (sections of $\mathrm{Ad}\, P$). For a trivial bundle, $\hat{\mathcal{G}} = \mathrm{Map}(M, G)$.

- Fix a base point $m_0 \in M$. The **based gauge group** $\mathcal{G}$ [the group Nash divides by, because the only element of it that leaves a connection unchanged is $\mathbb{1}$] is the subgroup of gauge transformations that are the identity on the fibre over m_0:

$$\mathcal{G} = \{ g \in \hat{\mathcal{G}} \ : \ g(m_0) = \mathbb{1} \}. \tag{8.19}$$

Evaluating at the base point is a group homomorphism $\mathrm{ev}_{m_0} : \hat{\mathcal{G}} \to G$, $g \mapsto g(m_0)$. It is onto (take constant maps near m_0, cut off smoothly), and its kernel is $\mathcal{G}$. So

$$1 \longrightarrow \mathcal{G} \longrightarrow \hat{\mathcal{G}} \xrightarrow{\mathrm{ev}_{m_0}} G \longrightarrow 1, \qquad \hat{\mathcal{G}}/\mathcal{G} \cong G. \tag{8.20}$$

The based group loses only a finite-dimensional copy of G: the "global" (constant) gauge transformations at one point.

Why bother? Because $\hat{\mathcal{G}}$ does *not* act freely on $\mathcal{A}$, and $\mathcal{G}$ does. An action is **free** if the only group element that fixes any point is the identity. For $\hat{\mathcal{G}}$ this fails in the most blatant way.

Worked example 8.3: Constant gauge transformations fix connections

Let c be a constant element of the centre $Z(G)$ of G, for example $c = -\mathbb{1} \in \mathrm{SU}(2)$ or any $c = e^{i\lambda} \in \mathrm{U}(1)$. Then for every connection A,

$$A^c \overset{(1)}{=} c^{-1} A c + c^{-1} \mathrm{d} c \overset{(2)}{=} A.$$

(1) Definition (8.16).

(2) c commutes with every matrix in $\mathfrak{g}$, so $c^{-1}Ac = A$; and $\mathrm{d}c = 0$ because c is constant.

So *every* point of $\mathcal{A}$ has a nontrivial stabiliser in $\hat{\mathcal{G}}$. For special connections the stabiliser is larger. Take the trivial SU(2) bundle and $A = 0$. Every constant $c \in \mathrm{SU}(2)$ fixes it, so its stabiliser is the whole of SU(2). Take instead the diagonal potential

$$A = \begin{pmatrix} i\,a & 0 \\ 0 & -i\,a \end{pmatrix}, \qquad a \text{ a real 1-form.}$$

It is fixed by the constant diagonal matrices $c = \mathrm{diag}(e^{i\lambda}, e^{-i\lambda})$ (which commute with A), a copy of U(1). None of these c is in $\mathcal{G}$ unless $c = \mathbb{1}$, because $c(m_0) = c$.

The quotient of a space by a group that does not act freely is singular: the orbits have different dimensions, and the quotient is not a manifold near the special points. Passing to the based group removes the problem in one stroke. Nash proves this by an argument with parallel transport. We first need parallel transport in a form that is easy to compute with.

8.1.4 Parallel transport in local coordinates

Parallel transport is the answer to the question: how do we compare "internal directions" at two different points of spacetime? A connection is precisely the rule that tells us. For the toolkit version see Chapter T3; here we set it up the way Nash uses it.

Take two points $a, b \in M$ and a smooth path between them, Nash's (8.2):

$$\gamma_{ab} : [0,1] \to M, \qquad \gamma_{ab}(0) = a, \quad \gamma_{ab}(1) = b. \tag{8.21}$$

A **lift** of γ_{ab} is a path $\hat{\gamma}_{ab}(t)$ in P lying over it, $\pi(\hat{\gamma}_{ab}(t)) = \gamma_{ab}(t)$. In local coordinates it is Nash's (8.3):

$$\hat{\gamma}_{ab}(t) = \big(\gamma_{ab}(t),\, g(t)\big), \qquad g(t) \in G. \tag{8.22}$$

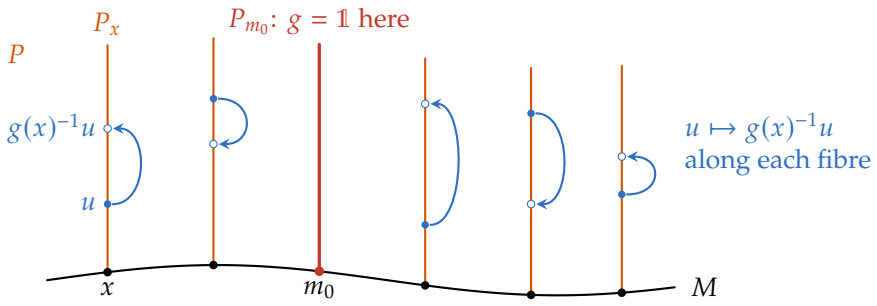

Figure 8.4: A gauge transformation moves each fibre P_x into itself, by left multiplication with $g(x)^{-1}$ in local coordinates, independently at different points (blue arrows). A *based* gauge transformation does nothing on one chosen fibre P_{m_0} (red). This single condition is enough to stop the group from fixing any connection.

There are many lifts: $g(t)$ could be anything. The connection picks out the **horizontal** ones, those whose velocity is annihilated by the connection form ω on P. In local coordinates (8.3) says $\omega = g^{-1}Ag + g^{-1}\mathrm{d}g$. The velocity of the lift is $(\dot\gamma, \dot g)$, so

$$\begin{aligned} 0 &\overset{(1)}{=} \omega\big(\dot\gamma_{ab}\big) \\ &\overset{(2)}{=} g^{-1}A(\dot\gamma_{ab})\,g + g^{-1}\dot g \\ \Longrightarrow \qquad \frac{\mathrm{d}g(t)}{\mathrm{d}t} &\overset{(3)}{=} -A(\dot\gamma_{ab})\,g(t). \end{aligned} \tag{8.23}$$

(1) Definition of a horizontal lift.
(2) Evaluate $\omega = g^{-1}Ag + g^{-1}\mathrm{d}g$ on the vector $(\dot\gamma, \dot g)$: the 1-form A on M eats $\dot\gamma$, and $\mathrm{d}g$ eats $\dot g$.
(3) Multiply on the left by g.

This is Nash's parallel transport equation (8.4), $\dot g + A\dot\gamma_{ab}\,g = 0$. In components, with $A = A_\mu \mathrm{d}x^\mu$, it reads $\dot g = -A_\mu(\gamma(t))\,\dot\gamma^\mu(t)\,g$.

Physical picture: What the equation says

Think of $g(t)$ as the "internal frame" carried along the path. The equation says that the frame changes only as much as the gauge field forces it to. If $A = 0$ the frame stays constant. A physicist meets exactly this equation as the Schrödinger equation of a charged particle's internal state moving along a prescribed path: in the Hermitian convention $A = -iA^a_{\text{phys}}T^a$ it reads $\dot g = iA^a_\mu T^a \dot x^\mu g$, a "time-dependent Hamiltonian" $-A^a_\mu T^a \dot x^\mu$ with t as time.

Solving the equation

Equation (8.23) is a linear, first-order ODE for the matrix $g(t)$. So once $g(0)$ is chosen, $g(t)$ is determined for all t. Moreover, because the equation is linear and g multiplies from the right, the solution has the form

$$g(t) = U(t)\,g(0), \qquad \dot U = -A(\dot\gamma)\,U, \quad U(0) = \mathbb{1}, \tag{8.24}$$

with a single matrix $U(t)$ that does not depend on the initial point. Nash's (8.5)–(8.6) are the endpoints of the lift:

$$\hat\gamma_{ab}(0) = \big(a, g(0)\big), \qquad \hat\gamma_{ab}(1) = \big(b, g(1)\big) = \big(b, U(1)g(0)\big). \tag{8.25}$$

In the *Abelian* case the equation is solved by an exponential. For $G = \mathrm{U}(1)$ write $A = i\,a_\mu \mathrm{d}x^\mu$ with real a_μ. Then

$$\frac{\mathrm{d}}{\mathrm{d}t}\ln U(t) \overset{(1)}{=} -i\,a_\mu(\gamma(t))\dot\gamma^\mu(t)$$
$$\Longrightarrow \quad U(1) \overset{(2)}{=} \exp\!\Big(-i\int_0^1 a_\mu(\gamma(t))\dot\gamma^\mu(t)\,\mathrm{d}t\Big) \overset{(3)}{=} \exp\!\Big(-i\int_{\gamma_{ab}} a\Big).$$

(1) For a 1×1 matrix, $\dot U/U = \frac{\mathrm{d}}{\mathrm{d}t}\ln U$; divide (8.24) by U.
(2) Integrate from 0 to 1 with $U(0) = 1$.
(3) The integral of a 1-form along a path is defined by pulling back to the parameter interval (Chapter T2).

This is the Aharonov–Bohm phase: with $A = -iea$ in terms of the physical potential a and charge e, $U(1) = \exp(ie\int_\gamma a)$.

In the *non-Abelian* case the matrices $A(\dot\gamma(t))$ at different times do not commute and the exponential of the integral is wrong. The fix is to iterate. Integrating (8.24),

$$\begin{aligned} U(t) &\overset{(1)}{=} \mathbb{1} - \int_0^t \mathrm{d}t_1\,\mathsf{A}(t_1)U(t_1) \\ &\overset{(2)}{=} \mathbb{1} - \int_0^t \mathrm{d}t_1\,\mathsf{A}(t_1) + \int_0^t \mathrm{d}t_1 \int_0^{t_1} \mathrm{d}t_2\,\mathsf{A}(t_1)\mathsf{A}(t_2) - \cdots \\ &\overset{(3)}{=} \mathcal{P}\exp\!\Big(-\int_0^t \mathsf{A}(s)\,\mathrm{d}s\Big), \end{aligned} \tag{8.26}$$

(1) Integrate $\dot U = -\mathsf{A}U$ with $U(0) = \mathbb{1}$, where $\mathsf{A}(t) := A_\mu(\gamma(t))\dot\gamma^\mu(t)$ is a matrix-valued function of t.
(2) Substitute the equation into itself repeatedly. The later times always stand to the *left*: $t \geq t_1 \geq t_2 \geq \cdots$.
(3) This is the definition of the path-ordered exponential $\mathcal{P}$ exp: expand the exponential and order each product with later times to the left. It is the same object as the Dyson series of time-dependent perturbation theory.

The series converges for every t (the n-th term is bounded by $(\int\|\mathsf{A}\|)^n/n!$). Its practical meaning is "chop the path into tiny pieces and multiply the tiny exponentials in order":

$$U(1) = \lim_{N\to\infty} e^{-\mathsf{A}(t_N)\Delta t}\cdots e^{-\mathsf{A}(t_2)\Delta t}\,e^{-\mathsf{A}(t_1)\Delta t}, \qquad \Delta t = 1/N. \tag{8.27}$$

Working definition 8.5 (parallel transport map)

The **parallel transport** of the connection A along γ_{ab} is the map from the fibre over a [the copy P_a of G sitting above the point a] to the fibre over b obtained by following horizontal lifts [curves $g(t)$ in P above γ_{ab} that solve $\dot g = -A(\dot\gamma_{ab})\,g$, i.e. (8.23)] (Nash's (8.7)):

$$PT_{\gamma_{ab}}(A) : P_a \longrightarrow P_b, \qquad g(0) \longmapsto g(1) = U_{\gamma_{ab}}(A)\,g(0), \tag{8.28}$$

with $U_{\gamma_{ab}}(A) = \mathcal{P}\exp(-\int_{\gamma_{ab}} A)$. *To compute it:* solve (8.23), or multiply the short-step exponentials (8.27). It commutes with the right action of G [$p \mapsto pu$, multiplying the fibre coordinate by a fixed $u \in G$ from the right]: $PT(pu) = PT(p)u$, because U multiplies from the left.

Two basic properties follow at once from the ODE. Running a path backwards inverts the map, $PT_{\gamma^{-1}} = PT_\gamma^{-1}$. Following γ_1 from a to b and then γ_2 from b to c composes the maps,

$$PT_{\gamma_2 * \gamma_1} = PT_{\gamma_2} \circ PT_{\gamma_1}, \qquad U_{\gamma_2 * \gamma_1} = U_{\gamma_2} U_{\gamma_1}. \tag{8.29}$$

Both are clear from (8.27): the product for the combined path is the product for γ_2 times the product for γ_1, and reversing a path reverses the order of the factors and flips the sign of each exponent.

Worked example 8.4: Holonomy of a small square: curvature appears

Let $M = \mathbb{R}^2$ and take a *constant* non-Abelian potential $A = X\,\mathrm{d}x + Y\,\mathrm{d}y$, where $X, Y \in \mathfrak{g}$ are fixed anti-Hermitian matrices that do not commute. Its curvature is

$$F \overset{(1)}{=} \mathrm{d}A + A \wedge A \overset{(2)}{=} XY\,\mathrm{d}x \wedge \mathrm{d}y + YX\,\mathrm{d}y \wedge \mathrm{d}x \overset{(3)}{=} [X, Y]\,\mathrm{d}x \wedge \mathrm{d}y.$$

(1) Definition of the curvature.
(2) $\mathrm{d}A = 0$ since X, Y are constant; in $A \wedge A$ only the mixed terms survive because $\mathrm{d}x \wedge \mathrm{d}x = 0$.
(3) $\mathrm{d}y \wedge \mathrm{d}x = -\mathrm{d}x \wedge \mathrm{d}y$.

Transport around the square of side ε with corners $(0,0)$, $(\varepsilon,0)$, $(\varepsilon,\varepsilon)$, $(0,\varepsilon)$, traversed anticlockwise. On each leg A is constant, so each leg contributes an honest exponential: $e^{-\varepsilon X}$ for the first leg ($\dot\gamma = \varepsilon\partial_x$), $e^{-\varepsilon Y}$ for the second, $e^{+\varepsilon X}$ and $e^{+\varepsilon Y}$ for the two return legs. By (8.29),

$$\begin{aligned} U_\square &\overset{(1)}{=} e^{\varepsilon Y} e^{\varepsilon X} e^{-\varepsilon Y} e^{-\varepsilon X} \\ &\overset{(2)}{=} \mathbb{1} + \varepsilon^2 [Y, X] + O(\varepsilon^3) \\ &\overset{(3)}{=} \mathbb{1} - \varepsilon^2 F_{xy} + O(\varepsilon^3). \end{aligned}$$

(1) Later legs stand to the left.
(2) Expand each exponential to second order and multiply out: all terms of first order cancel, the squares cancel, and the cross terms leave $\varepsilon^2(YX - XY)$. (This is the group commutator formula $e^a e^b e^{-a} e^{-b} = \mathbb{1} + [a, b] + \cdots$.)
(3) $F_{xy} = [X, Y]$ from the previous calculation.

The transport around a small closed loop differs from the identity by the curvature times the enclosed area. This is the most concrete meaning of F. In the Abelian case X and Y commute, the four exponentials cancel and $U_\square = \mathbb{1}$ exactly; consistently, a constant Abelian potential has $F = 0$. A small loop detects the curvature, not the potential.

8.1.5 Gauge transformations commute with parallel transport

Now we let a gauge transformation α, with local functions g_i, act on everything at once: on the bundle by (8.18) and on the connection by (8.16). Write $\alpha \cdot A$ for A^g, as Nash does. Nash's (8.8) says that transporting and then transforming is the same as transforming and then transporting with the transformed connection. Denote by $\alpha_a : P_a \to P_a$ the restriction of α to a fibre.

Key idea: Gauge covariance of parallel transport, Nash (8.8)

$$\alpha_b \circ PT_{\gamma_{ab}}(A) = PT_{\gamma_{ab}}(\alpha \cdot A) \circ \alpha_a, \qquad U_{\gamma_{ab}}(A^g) = g(b)^{-1}\, U_{\gamma_{ab}}(A)\, g(a). \tag{8.30}$$

Here is the whole argument, which is one calculation. Let $u(t)$ be a horizontal lift for A, so $\dot{u} = -\mathsf{A}\,u$. Transform it pointwise, $h(t) \coloneqq g(\gamma(t))^{-1}u(t)$, and write $g(t)$ for $g(\gamma(t))$. Then

$$\begin{aligned}\dot{h} &\overset{(1)}{=} -g^{-1}\dot{g}\,g^{-1}u + g^{-1}\dot{u}\\ &\overset{(2)}{=} -g^{-1}\dot{g}\,h - g^{-1}\mathsf{A}\,u\\ &\overset{(3)}{=} -\big(g^{-1}\mathsf{A}\,g + g^{-1}\dot{g}\big)h\\ &\overset{(4)}{=} -\big(A^g\big)(\dot{\gamma})\,h.\end{aligned}$$

(1) Product rule, with $\frac{\mathrm{d}}{\mathrm{d}t}g^{-1} = -g^{-1}\dot{g}\,g^{-1}$.
(2) Recognise $g^{-1}u = h$ in the first term; use the transport equation for u in the second.
(3) Write $u = gh$ in the second term.
(4) $g^{-1}\mathsf{A}g + g^{-1}\dot{g}$ is the transformed potential (8.16) evaluated on $\dot{\gamma}$ (since $\dot{g} = \mathrm{d}g(\dot{\gamma})$).

So $h(t)$ is a horizontal lift for the transformed connection A^g. It starts at $h(0) = g(a)^{-1}u(0) = \alpha_a(u(0))$ and ends at $h(1) = g(b)^{-1}u(1) = \alpha_b(u(1))$. Reading this as maps of fibres gives (8.30). (This is also why the inverse appears in (8.18): it makes the action on P match the familiar rule $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$.)

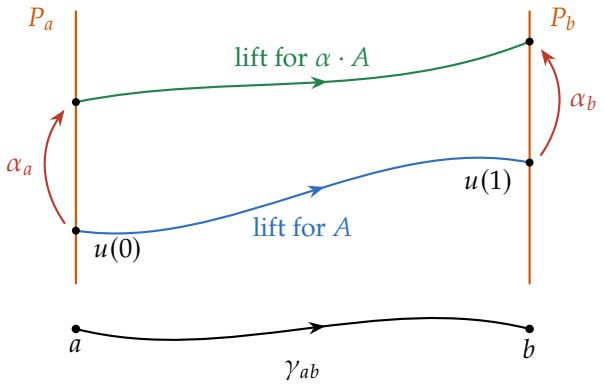

Figure 8.5: Nash's (8.8) as a picture. The blue curve is the horizontal lift for A from $u(0)$ to $u(1)$. The gauge transformation moves every point of it vertically (red arrows at the two ends). The moved curve (green) is again horizontal, for the transformed connection $\alpha \cdot A$. Going round the square either way gives the same point of P_b.

Worked example 8.5: Checking (8.8) for U(1)

For $G = \mathrm{U}(1)$, $g = e^{i\lambda(x)}$ and $A = ia$, the transformed connection is $A^g = ia + i\,\mathrm{d}\lambda$ and

$$\begin{aligned}U_\gamma(A^g) &\overset{(1)}{=} \exp\Big(-i\int_\gamma (a + \mathrm{d}\lambda)\Big) \overset{(2)}{=} e^{-i(\lambda(b)-\lambda(a))}\exp\Big(-i\int_\gamma a\Big)\\ &\overset{(3)}{=} g(b)^{-1}\,U_\gamma(A)\,g(a).\end{aligned}$$

(1) The Abelian solution of the transport equation, applied to A^g.
(2) Fundamental theorem of calculus: $\int_\gamma \mathrm{d}\lambda = \lambda(b) - \lambda(a)$.
(3) $e^{-i\lambda(b)} = g(b)^{-1}$ and $e^{i\lambda(a)} = g(a)$.

This is the statement, familiar from quantum mechanics, that the Aharonov–Bohm phase along an open path is not gauge invariant: it changes by the gauge phases at its two ends. Around a *closed* path the two ends coincide and the phase is invariant.

8.1.6 The based gauge group acts freely

Now the promised result.

Key idea: Nash: $\mathcal{G}$ acts freely on $\mathcal{A}$

If a based gauge transformation $\alpha \in \mathcal{G}$ fixes some connection, $\alpha \cdot A = A$, then α is the identity. Hence $\mathcal{G}$ acts on $\mathcal{A}$ without fixed points.

Why. Take $a = m_0$, the base point. Nash's (8.9) combines the two facts

$$\alpha \cdot A = A \qquad \text{and} \qquad \alpha_{m_0} = I.$$

Put them into (8.30), for any path γ from m_0 to a point b:

$$\alpha_b \circ PT_\gamma(A) \overset{(1)}{=} PT_\gamma(\alpha \cdot A) \circ \alpha_{m_0} \overset{(2)}{=} PT_\gamma(A) \circ I = PT_\gamma(A).$$

(1) Gauge covariance of parallel transport (8.30).
(2) α fixes A, and α is the identity on the base fibre.

Parallel transport is a bijection $P_{m_0} \longrightarrow P_b$ (its inverse is transport backwards), so we can cancel it on the right: $\alpha_b = I$. If M is path connected, every b can be reached from m_0 by a path, so α is the identity everywhere.

The same thing can be seen directly from the equation $A^g = A$. Multiply $g^{-1}Ag + g^{-1}\mathrm{d}g = A$ on the left by g:

$$\mathrm{d}g = gA - Ag, \qquad \text{i.e.} \qquad \mathrm{d}g + [A, g] = 0. \tag{8.31}$$

Along any path this is a linear first-order ODE for $g(\gamma(t))$: $\dot{g} = g\mathsf{A} - \mathsf{A}g$. At $t = 0$ we are at m_0, so $g = \mathbb{1}$. The constant $g \equiv \mathbb{1}$ solves the ODE (since $\mathbb{1}\mathsf{A} - \mathsf{A}\mathbb{1} = 0$) with the same initial value. By uniqueness of solutions, $g \equiv \mathbb{1}$ along the whole path.

Physical picture: Covariantly constant gauge transformations

Equation (8.31) says that a gauge transformation fixing A is *covariantly constant* ($\mathrm{d}_A g = 0$, with g viewed as a section of $\mathrm{Ad}\,P$). A covariantly constant object is determined by its value at one point, just as a solution of $\mathrm{d}f = 0$ is. In $\hat{\mathcal{G}}$ that value can be any element of G that commutes with the holonomy (see below), so there may be many such g. In $\mathcal{G}$ it is pinned to $\mathbb{1}$, so there is only one.

Watch out: Free action needs the base point, not the centre

One might try to cure the non-free action of $\hat{\mathcal{G}}$ by dividing out only its centre (the constant central elements). That removes the stabiliser of a *generic* (irreducible) connection, but not the larger stabilisers of reducible ones such as $A = 0$ in Example 8.3. The based group removes all of them at once, at the price of the leftover global symmetry $G = \hat{\mathcal{G}}/\mathcal{G}$, which still acts on $\mathcal{A}/\mathcal{G}$. Section 3 of this chapter deals with that residual action on instanton moduli spaces.

8.1.7 The holonomy group

Closely related is the **holonomy** of a connection. Let the path close up into a loop γ_a that starts and ends at a. Parallel transport is now a map of one fibre to itself, Nash's (8.10):

$$PT_{\gamma_a}(A) : P_a \longrightarrow P_a, \qquad u \longmapsto U_{\gamma_a}(A)\, u. \tag{8.32}$$

It is generally not the identity: transport around a loop can rotate the internal frame. This is the Aharonov–Bohm effect in the Abelian case and the Wilson loop in the non-Abelian one.

Working definition 8.6 (holonomy group; reducible and irreducible connections)

The **holonomy group** $\mathrm{Hol}_a(A)$ is the set of all matrices $U_{\gamma_a}(A)$ as γ_a runs over all loops based at a. *To compute it:* find the transport matrices of enough loops and see what subgroup of G they generate [all finite products of these matrices and their inverses]. Nash calls A **irreducible** if $\mathrm{Hol}_a(A) = G$ and **reducible** if the holonomy group is a proper subgroup [a subgroup strictly smaller than G, such as a U(1) inside SU(2)].

It is a group because loops can be composed (giving the product, by (8.29)), reversed (giving the inverse) and taken constant (giving $\mathbb{1}$). Changing the base point from a to b conjugates it: if σ is a path from a to b, every loop at b is $\sigma * \gamma_a * \sigma^{-1}$ for a loop γ_a at a, and

$$U_{\sigma*\gamma_a*\sigma^{-1}} = U_\sigma \, U_{\gamma_a} \, U_\sigma^{-1}, \qquad \mathrm{Hol}_b(A) = U_\sigma \, \mathrm{Hol}_a(A) \, U_\sigma^{-1}. \tag{8.33}$$

So on a connected M the holonomy groups at different points are isomorphic, as Nash says. By construction the holonomy group is a subgroup of the structure group G. Under a gauge transformation it is conjugated by $g(a)$, by (8.30): $U_{\gamma_a}(A^g) = g(a)^{-1} U_{\gamma_a}(A) g(a)$. The trace of a holonomy matrix, the **Wilson loop** $W_\gamma(A) = \operatorname{tr} U_\gamma(A)$, is therefore gauge invariant.

The holonomy tells us the stabiliser in the full gauge group $\hat{\mathcal{G}}$. A solution of (8.31) is determined by its value $c = g(a)$. Going around a loop and coming back must reproduce c; by (8.30) with $A^g = A$, this means $U_{\gamma_a} = c^{-1} U_{\gamma_a} c$. So

$$\mathrm{Stab}_{\hat{\mathcal{G}}}(A) \cong \{ c \in G : \; cU = Uc \text{ for all } U \in \mathrm{Hol}_a(A) \}, \tag{8.34}$$

the **centraliser** of the holonomy group. The bigger the holonomy, the smaller the stabiliser. If $\mathrm{Hol}(A) = G$ the stabiliser is the centre $Z(G)$, the minimum possible. (Section 3 of this chapter returns to this.)

Worked example 8.6: Flat U(1) connections on the circle

On S^1 take the constant potential $A = i\,a\,\mathrm{d}\phi$, $a \in \mathbb{R}$. It is flat ($F = \mathrm{d}A = 0$: there are no 2-forms on a circle). The loop going once around has

$$U = \exp\!\left(-i \int_0^{2\pi} a \, \mathrm{d}\phi \right) = e^{-2\pi i a}.$$

Going around n times gives $e^{-2\pi i n a}$. A loop that goes out and comes back without going around gives $\mathbb{1}$. So $\mathrm{Hol}(A) = \{ e^{-2\pi i n a} : n \in \mathbb{Z} \}$.

- $a \in \mathbb{Z}$: Hol $= \{1\}$. The connection is gauge equivalent to $A = 0$ (by $g = e^{-i a \phi}$, a legitimate map $S^1 \to \mathrm{U}(1)$ when a is an integer).
- $a = p/q$ in lowest terms: Hol $= \mathbb{Z}_q$, the q-th roots of unity.
- a irrational: Hol is infinite cyclic and *dense* in U(1), but not all of it.

All of these are reducible in Nash's sense except that none reaches all of U(1). (For U(1) the notion is not very useful; it matters for non-Abelian G.) Note also that $\mathrm{Hol}(A)$ need not be a closed subgroup.

Worked example 8.7: The Dirac monopole: holonomy equals flux

Take the monopole connection of Example 8.2 and the latitude circle at polar angle θ_0, based at a point on it and traversed in the direction of increasing ϕ. Using the northern potential,

$$U \overset{(1)}{=} \exp\Big(-\oint A_N\Big) \overset{(2)}{=} \exp\Big(\frac{im}{2}(1-\cos\theta_0)\cdot 2\pi\Big) \overset{(3)}{=} \exp\Big(\frac{im}{2}\,\Omega(\theta_0)\Big),$$

(1) Abelian transport around a closed loop.
(2) $A_N = -\frac{im}{2}(1-\cos\theta)\mathrm{d}\phi$ is constant on the circle, and $\oint \mathrm{d}\phi = 2\pi$.
(3) $\Omega(\theta_0) = 2\pi(1-\cos\theta_0)$ is the solid angle of the polar cap enclosed by the circle.

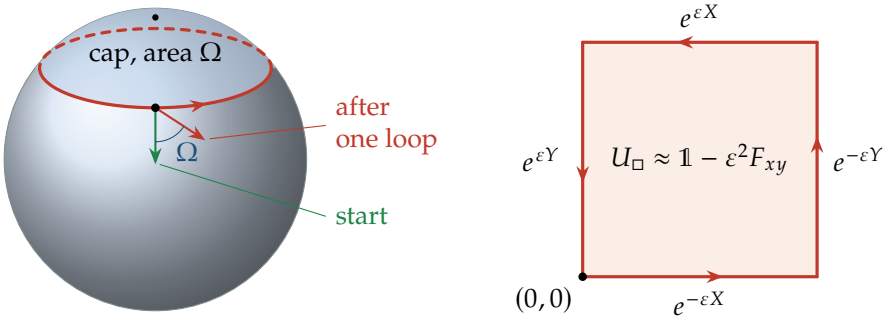
By Stokes, $-\oint A_N = -\int_{\text{cap}} F$: the holonomy is the magnetic flux through the cap, in the form $e^{ie\Phi}$. As θ_0 runs from 0 to π the phase runs over all of U(1) (for $m \neq 0$), so Hol = U(1). As $\theta_0 \to \pi$ the loop shrinks to the south pole and $U \to e^{2\pi i m} = 1$: the Dirac quantisation condition, seen as the statement that a vanishing loop must have trivial holonomy.

Worked example 8.8: Levi-Civita connection on S^2

Parallel transport of tangent vectors on the unit sphere is an SO(2) connection on the frame bundle. Carry a tangent vector around the latitude circle $\theta = \theta_0$. It comes back rotated by the angle $2\pi(1-\cos\theta_0)$, the enclosed area (the curvature is 1, so this is Gauss–Bonnet for the cap, Chapter T2). All angles occur, so Hol = SO(2). For the flat plane the same experiment gives no rotation: Hol = $\{1\}$. See Figure 8.6.

Worked example 8.9: A reducible SU(2) connection

Embed a U(1) connection ia in SU(2) diagonally, $A = \mathrm{diag}(ia, -ia)$. Every transport matrix is $U = \mathrm{diag}(e^{-i\int a}, e^{i\int a})$: the holonomy lies in the diagonal U(1) $\subset$ SU(2), a proper subgroup. So A is reducible. The centraliser of the diagonal U(1) in SU(2) is the diagonal U(1) itself, which matches the stabiliser found in Example 8.3. Conversely, an SU(2) connection whose holonomy contains two non-commuting matrices (say, $e^{\varepsilon e_1}$ and $e^{\varepsilon e_2}$) has centraliser $\{\pm\mathbb{1}\} = Z(\mathrm{SU}(2))$. In the square example Example 8.4 this happens as soon as $[X, Y] \neq 0$.



Levi-Civita on S^2 constant $A = X\mathrm{d}x + Y\mathrm{d}y$, side ε

Figure 8.6: Two ways to see holonomy. Left: a tangent vector carried around a latitude circle on the sphere returns rotated by the enclosed area Ω, so the holonomy group of the round sphere is all of SO(2). Right: the four legs of a small square contribute four matrix exponentials, whose ordered product differs from $\mathbb{1}$ by the curvature times the area (Example 8.4).

Watch out: Two definitions of "irreducible"

Nash defines irreducible as "holonomy group equal to G". Most of the modern literature (and Section 3 of this chapter) uses the weaker condition "stabiliser equal to the centre $Z(G)$", i.e. the centraliser of the holonomy is as small as possible. For SU(2) the two agree in practice: the only closed connected proper subgroups of SU(2) are $\{1\}$ and the circles U(1) (up to conjugation), whose centralisers are SU(2) and U(1), while any subgroup containing two non-commuting elements has centraliser $\{\pm\mathbb{1}\}$. For larger groups, a subgroup can be proper and still have trivial centraliser (for example $\mathrm{SO}(3) \subset \mathrm{SU}(3)$), so the two notions differ.

Reading Nash (pp. 216–218, (8.2)–(8.10))

Nash's (8.2)–(8.7) set up parallel transport in local coordinates (x, g): the ODE (8.4) $\dot{g} + A\dot{\gamma}_{ab}\, g = 0$ is our (8.23), and $PT_{\gamma_{ab}}(A)$ is (8.28). His (8.8) is our (8.30); he states it as "the commutativity of gauge transformations and parallel transport" and does not prove it. The one-line computation of $\dot{h}$ above is the proof. His (8.9) is the free-action argument. The "$\alpha \cdot A$" in Nash is our A^g. Nash's reference to "chapter 6 p. 176" is to the definition of $\mathcal{G}$ as the based subgroup of $\hat{\mathcal{G}} = \ker(\mathrm{Aut}\, P \to \mathrm{Diff}\, M)$.

Recap

- A gauge transformation is a section of $\mathrm{Ad}\, P$: local maps g_i glued by conjugation. $\hat{\mathcal{G}}$ is the group of all of them, $\mathcal{G}$ the subgroup with $g(m_0) = \mathbb{1}$; $\hat{\mathcal{G}}/\mathcal{G} = G$.
- Parallel transport solves $\dot{g} = -A(\dot{\gamma})g$; the solution is a path-ordered exponential. Around a small loop it is $\mathbb{1} - F \cdot (\text{area})$.
- Gauge transformations commute with parallel transport: $U(A^g) = g(b)^{-1} U(A) g(a)$.
- Hence the based group $\mathcal{G}$ acts freely on $\mathcal{A}$; the full group $\hat{\mathcal{G}}$ has stabilisers equal to the centraliser of the holonomy.
- Irreducible: holonomy $= G$ (Nash), or stabiliser $= Z(G)$ (modern).

8.1.8 The quotient $\mathcal{A}/\mathcal{G}$

Since $\mathcal{G}$ acts freely on $\mathcal{A}$, we can divide. The **gauge orbit** of a connection A is the set of everything gauge equivalent to it, $\mathcal{G} \cdot A = \{A^g : g \in \mathcal{G}\}$. The quotient $\mathcal{A}/\mathcal{G}$ is the set of orbits. A point of $\mathcal{A}/\mathcal{G}$ is a gauge field "up to gauge transformations": what a physicist would call a physical field configuration.

Because the action is free, every orbit is a faithful copy of $\mathcal{G}$ (the map $g \mapsto A^g$ is one-to-one). So $\mathcal{A}$ is fibred over $\mathcal{A}/\mathcal{G}$ with every fibre a copy of $\mathcal{G}$. This is Nash's (8.11):

$$\begin{array}{ccc} \mathcal{G} & \longrightarrow & \mathcal{A} \\ & & \big\downarrow \pi \\ & & \mathcal{A}/\mathcal{G} \end{array} \tag{8.35}$$

It is a principal $\mathcal{G}$-bundle: $\mathcal{G}$ acts on the total space $\mathcal{A}$, freely, with the fibres as orbits. (Local triviality needs a local "slice" through each orbit; the Coulomb gauge condition provides one, as Section 3 of this chapter explains. We take it for granted here.)

Worked example 8.10: U(1) on the circle: $\mathcal{A}/\mathcal{G}$ is a circle

Return to Example 8.1: $M = S^1$, $G = \mathrm{U}(1)$, $A = i\,a(\phi)\,\mathrm{d}\phi$ with a a periodic real function. A based gauge transformation is $g = e^{i\lambda(\phi)}$ with $g(0) = 1$. Because g must be single valued, λ need not be periodic: it may wind,

$$\lambda(0) = 0, \qquad \lambda(2\pi) = 2\pi n, \quad n \in \mathbb{Z}.$$

The action is $a \mapsto a + \lambda'$, since $A^g = A + g^{-1}\mathrm{d}g = i(a + \lambda')\mathrm{d}\phi$. When are a and $\tilde{a}$ in the same orbit? We need $\tilde{a} - a = \lambda'$ for an allowed λ. Integrating,

$$\oint (\tilde{a} - a)\,\mathrm{d}\phi \overset{(1)}{=} \int_0^{2\pi} \lambda'(\phi)\,\mathrm{d}\phi \overset{(2)}{=} \lambda(2\pi) - \lambda(0) \overset{(3)}{=} 2\pi n.$$

(1) Assume $\tilde{a} = a + \lambda'$.
(2) Fundamental theorem of calculus.
(3) Boundary conditions on λ.

Conversely, if $\oint(\tilde{a} - a) = 2\pi n$, then $\lambda(\phi) := \int_0^{\phi}(\tilde{a} - a)$ is allowed and does the job. So the only gauge invariant is the total flux modulo 2π, i.e. the holonomy $e^{-i\oint a}$, and

$$\mathcal{A}/\mathcal{G} \;\cong\; \mathbb{R}/2\pi\mathbb{Z} \;\cong\; S^1, \qquad [a] \longmapsto \oint a\,\mathrm{d}\phi \bmod 2\pi. \tag{8.36}$$

The total space $\mathcal{A}$ is contractible, the quotient is a circle, and the fibre $\mathcal{G}$ has infinitely many components labelled by the winding n. Walking once around the circle $\mathcal{A}/\mathcal{G}$ (increasing $\oint a$ from 0 to 2π) and lifting the walk to $\mathcal{A}$, we arrive at a connection that differs from the starting one by a gauge transformation of winding $n = 1$. This is the first appearance of a *large gauge transformation* (Section 8.1.17).

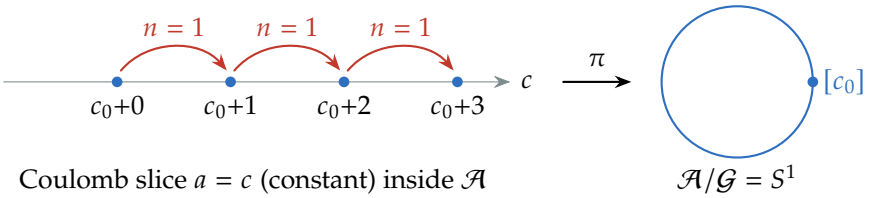


Figure 8.7: The U(1) theory on a circle. The constant potentials $a = c$ form a line inside $\mathcal{A}$ (coordinate $c = \frac{1}{2\pi}\oint a\,\mathrm{d}\phi$) that meets every gauge orbit, but it meets each orbit infinitely often, at $c_0 + n$ (blue dots), related by the winding gauge transformations $e^{in\phi}$ (red arrows). Under the projection π the line wraps infinitely often around the quotient circle. Choosing one representative per orbit continuously is impossible: this is the Gribov problem in miniature.

8.1.9 Universal bundles and classifying spaces

Nash's next sentence, (8.12), is loaded: "since $\mathcal{A}$ is contractible it follows that $\mathcal{A}$ is the total space of a universal $\mathcal{G}$-bundle; hence $\mathcal{A}/\mathcal{G}$ is the classifying space for $\mathcal{G}$ bundles." Let us unpack it.

Working definition 8.7 (universal bundle, classifying space)

Let H be a topological group [here $H = \mathcal{G}$, the based gauge group]. A principal H-bundle $EH \to BH$ [H acts freely on EH and $BH = EH/H$, as $\mathcal{G}$ does on $\mathcal{A}$] whose total space EH is *contractible* [it can be shrunk continuously to one point, as $\mathcal{A}$ can along straight lines to A_0] is called a **universal H-bundle**, and its base BH is a **classifying space** for H. *In practice:* find any contractible space on which H acts freely; the quotient is BH. It is unique up to homotopy equivalence [two answers are related by maps both ways whose composites can be deformed continuously into the identity].

Why the name? Two facts, both standard in algebraic topology.

1. *Classification.* For any (reasonable) space X, principal H-bundles over X correspond one-to-one to homotopy classes of maps $f : X \to BH$. The bundle belonging to f is the pull-back f^*EH. So BH "classifies" H-bundles.
2. *Homotopy.* The homotopy groups of BH are those of H, shifted up by one:

$$\pi_j(BH) \cong \pi_{j-1}(H). \tag{8.37}$$

The second fact is the one we use all the time, and it follows from the long exact sequence of a fibration, which we now recall.

The long exact homotopy sequence

For any fibre bundle $F \to E \to B$ (with B connected) there is a sequence of group homomorphisms

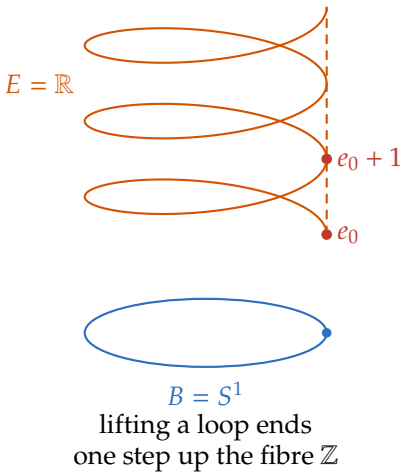
$$\cdots \to \pi_j(F) \xrightarrow{i_*} \pi_j(E) \xrightarrow{\pi_*} \pi_j(B) \xrightarrow{\partial} \pi_{j-1}(F) \xrightarrow{i_*} \pi_{j-1}(E) \to \cdots \to \pi_0(E) \to 0, \tag{8.38}$$

which is **exact**: at each place, the image of the incoming map equals the kernel of the outgoing one. The maps i_* and π_* are induced by the inclusion of a fibre and by the projection. The interesting one is the **boundary map** ∂. Here is how it works for $j = 1$. Take a loop ℓ in B at the base point. Lift it to a path $\hat{\ell}$ in E starting at a chosen point e_0 of the fibre (always possible for a bundle). The lift need not close up: it ends somewhere in the same fibre F. The class of that end point in $\pi_0(F)$ is $\partial[\ell]$. For higher j the same idea applies to a j-dimensional ball whose boundary sphere is squashed to the base point: lift the ball, and look at where its boundary lands, a $(j-1)$-sphere in F.

If E is contractible, all $\pi_j(E) = 0$, and exactness at the two places around ∂ gives $0 \to \pi_j(B) \xrightarrow{\partial} \pi_{j-1}(F) \to 0$: so ∂ is an isomorphism. This is (8.37).

Worked example 8.11: A gallery of classifying spaces

- $H = \mathbb{Z}$ acting on $\mathbb{R}$ by translations. $\mathbb{R}$ is contractible, so $B\mathbb{Z} = \mathbb{R}/\mathbb{Z} = S^1$. Check: $\pi_1(S^1) = \mathbb{Z} = \pi_0(\mathbb{Z})$.
- $H = \mathbb{Z}_2$ acting on the infinite sphere $S^\infty = \bigcup_n S^n$ by $v \mapsto -v$. S^∞ is contractible (every sphere S^n can be shrunk inside S^{n+1}), so $B\mathbb{Z}_2 = \mathbb{RP}^\infty$. Check: $\pi_1(\mathbb{RP}^\infty) = \mathbb{Z}_2$.
- $H = \mathrm{U}(1)$ acting on the unit sphere $S^\infty \subset \mathbb{C}^\infty$ by $v \mapsto e^{i\lambda}v$. So $B\mathrm{U}(1) = \mathbb{CP}^\infty$. Check: $\pi_2(\mathbb{CP}^\infty) = \pi_1(\mathrm{U}(1)) = \mathbb{Z}$, and all other homotopy groups vanish. The finite stage $S^3 \to \mathbb{CP}^1 = S^2$ is the Hopf fibration.



E contractible:

$$\underbrace{\pi_j(E)}_{0} \to \pi_j(B) \xrightarrow{\partial} \pi_{j-1}(F) \to \underbrace{\pi_{j-1}(E)}_{0}$$

$$\Longrightarrow \quad \pi_j(B) \cong \pi_{j-1}(F)$$

here: $\pi_1(S^1) = \mathbb{Z} = \pi_0(\mathbb{Z})$

Figure 8.8: The boundary map of the long exact sequence, in the simplest universal bundle $\mathbb{Z} \to \mathbb{R} \to S^1$ ($x \mapsto e^{2\pi i x}$). A loop going once around the base lifts to a path in $E = \mathbb{R}$ that climbs from e_0 to $e_0 + 1$. The mismatch lives in the fibre. When E is contractible, this mismatch is all the information there is: $\pi_j(B) = \pi_{j-1}(F)$.

- $H = \mathrm{U}(N)$: $B\mathrm{U}(N)$ is the Grassmannian of N-planes in $\mathbb{C}^\infty$. Its cohomology is generated by the universal Chern classes c_i; we use this in Section 8.1.25.

The classification statement in the U(1) case: U(1) bundles over S^2 correspond to $[S^2, \mathbb{CP}^\infty] = \pi_2(\mathbb{CP}^\infty) = \mathbb{Z}$. The integer is the monopole charge m of Example 8.2.

Key idea: Nash (8.12): the configuration space is a classifying space

$\mathcal{A}$ is contractible and $\mathcal{G}$ acts freely on it. Therefore

$$\mathcal{A}/\mathcal{G} = B\mathcal{G}, \qquad \pi_j(\mathcal{A}/\mathcal{G}) \cong \pi_{j-1}(\mathcal{G}) \quad (j \geq 1). \tag{8.39}$$

The whole topology of the configuration space of a gauge theory is the topology of the gauge group, shifted by one degree.

Check it on Example 8.10: $\mathcal{A}/\mathcal{G} = S^1$, so $\pi_1(\mathcal{A}/\mathcal{G}) = \mathbb{Z}$; and $\pi_0(\mathcal{G}) = \mathbb{Z}$, the winding number of λ. The loop in $\mathcal{A}/\mathcal{G}$ that increases $\oint a$ by 2π corresponds, via ∂, to the gauge transformation of winding one, exactly as the figure showed.

8.1.10 Why physicists care: the path integral lives on $\mathcal{A}/\mathcal{G}$

The partition function and the correlation functions of a gauge theory are functional integrals over $\mathcal{A}$,

$$Z = \int_{\mathcal{A}} \mathcal{D}A \; e^{-S[A]}, \qquad \langle O \rangle = \frac{1}{Z} \int_{\mathcal{A}} \mathcal{D}A \; O[A] \, e^{-S[A]}. \tag{8.40}$$

If S and O are gauge invariant, the integrand is constant along each orbit. The integral over the orbit then just produces the (infinite) volume of $\mathcal{G}$, and all the physics is in the integral over the space of orbits $\mathcal{A}/\mathcal{G}$. (Nash's caveat, "in the absence of anomalies", means: as long as the *measure* $\mathcal{D}A$ combined with the fermion determinant is also gauge invariant. When it is not, the integrand is not constant along orbits and the projection fails; that is Chapter 10.)

To perform the projection in practice one **fixes a gauge**: pick a condition $\chi(A) = 0$ that selects one point on each orbit, and integrate only over those points, with the right Jacobian. The

Jacobian is the **Faddeev–Popov determinant**. The procedure is clearest in a finite-dimensional toy model, which also shows its weak spot.

Worked example 8.12: Faddeev–Popov for rotations of the plane

Take the "field space" $\mathbb{R}^2$ with the "gauge group" SO(2) of rotations R_θ, and a rotation-invariant integrand $f(|x|)$. We know the answer: $Z = \int \mathrm{d}^2x\, f = 2\pi \int_0^\infty r\, f(r)\, \mathrm{d}r$. Try the gauge condition $\chi(x) = x_2 = 0$. Along the orbit of $x = (r\cos\phi, r\sin\phi)$,

$$\chi(R_\theta x) = r\sin(\phi+\theta), \qquad \left|\frac{\partial\chi(R_\theta x)}{\partial\theta}\right| = r\left|\cos(\phi+\theta)\right|.$$

The condition has *two* solutions on each orbit, $\theta = -\phi$ and $\theta = \pi - \phi$ (the positive and negative x_1 axis). With the Faddeev–Popov factor $\Delta(x) = r$ (the value of $|\partial_\theta\chi|$ at the solutions),

$$\int_0^{2\pi} \mathrm{d}\theta\; \Delta(x)\,\delta\big(\chi(R_\theta x)\big) \overset{(1)}{=} \sum_{\text{zeros } \theta_*} \frac{\Delta(x)}{|\partial_\theta\chi(R_\theta x)|_{\theta_*}} \overset{(2)}{=} 1 + 1 = 2.$$

(1) $\delta(h(\theta)) = \sum_{\theta_*} \delta(\theta-\theta_*)/|h'(\theta_*)|$ over the zeros of h.
(2) At both zeros $|\cos| = 1$, so each contributes $r/r = 1$.

So "$1 = \int \mathrm{d}\theta\,\Delta\,\delta(\chi)$", the identity that Faddeev–Popov insert into the path integral, is *false* here: the right-hand side is 2. Inserting $1 = \frac{1}{2}\int \mathrm{d}\theta\,\Delta\,\delta(\chi)$ instead,

$$\begin{aligned} Z &\overset{(1)}{=} \tfrac{1}{2}\int_0^{2\pi}\mathrm{d}\theta \int \mathrm{d}^2x\; r\,\delta\big(\chi(R_\theta x)\big) f(|x|) \\ &\overset{(2)}{=} \tfrac{1}{2}\cdot 2\pi \int \mathrm{d}^2x\; r\,\delta(x_2)\, f(|x|) \overset{(3)}{=} \pi\int_{-\infty}^{\infty}\mathrm{d}x_1\; |x_1|\, f(|x_1|) \overset{(4)}{=} 2\pi\int_0^\infty r\, f(r)\,\mathrm{d}r. \end{aligned}$$

(1) Insert the corrected identity and exchange the integrals.
(2) Change variables $x \to R_{-\theta}x$; d^2x, r and f are invariant, so the θ integral gives the group volume 2π.
(3) The δ sets $x_2 = 0$, so $r = |x_1|$.
(4) The integrand is even in x_1.

The right answer, but only after dividing by the number of **Gribov copies** (here 2). In this toy we could have avoided the problem by the better gauge "$x_2 = 0$, $x_1 > 0$", which meets each orbit exactly once. That works because the bundle $\mathbb{R}^2\setminus\{0\} \to (0,\infty)$ of orbits is trivial. In Yang–Mills theory there is no such escape, as we now show.

For Yang–Mills the steps are the same. Near the identity a gauge transformation is $g = e^\varepsilon \approx \mathbb{1} + \varepsilon$ with ε a $\mathfrak{g}$-valued function, and

$$\begin{aligned} A^g &\overset{(1)}{=} (\mathbb{1}-\varepsilon)A(\mathbb{1}+\varepsilon) + (\mathbb{1}-\varepsilon)\,\mathrm{d}\varepsilon + O(\varepsilon^2) \\ &\overset{(2)}{=} A + \mathrm{d}\varepsilon + [A,\varepsilon] + O(\varepsilon^2) \overset{(3)}{=} A + \mathrm{d}_A\varepsilon + O(\varepsilon^2). \end{aligned} \tag{8.41}$$

(1) Definition (8.16) with $g^{-1} \approx \mathbb{1} - \varepsilon$.
(2) Multiply out and drop second-order terms.
(3) $\mathrm{d}_A\varepsilon := \mathrm{d}\varepsilon + [A,\varepsilon]$ is the covariant derivative in the adjoint representation.

For the Lorenz (Landau) gauge $\chi(A) = \partial^\mu A_\mu$ the change of the gauge condition is $\delta\chi = \partial^\mu D_\mu\varepsilon$, so the Faddeev–Popov factor is $\Delta_{\mathrm{FP}}[A] = \left|\det(\partial^\mu D_\mu)\right|$. Writing the determinant with

anticommuting ghost fields $c, \bar{c}$,

$$Z = \int_{\mathcal{A}} \mathcal{D}A\, \mathcal{D}c\, \mathcal{D}\bar{c}\; \delta\big(\partial^\mu A_\mu\big)\, e^{-S[A] - \int \mathrm{tr}(\bar{c}\, \partial^\mu D_\mu c)} \quad (\text{“per Gribov copy”}). \tag{8.42}$$

This is “the familiar Faddeev–Popov ghost Jacobian” of Nash’s text. The derivation assumes that $\partial^\mu A_\mu = 0$ meets each orbit exactly once. Gribov noticed that for large fields it does not: the Coulomb or Lorenz condition has several solutions on one orbit, and the operator $\partial^\mu D_\mu$ acquires zero modes where two copies merge (the **Gribov horizon**). Perturbation theory never notices, since it only explores a neighbourhood of $A = 0$. The question is whether a cleverer gauge condition could do better. Topology says no.

8.1.11 The bundle $\mathcal{A} \to \mathcal{A}/\mathcal{G}$ is not trivial: the Gribov ambiguity

A *global gauge condition* is a rule that picks one connection on each orbit, continuously. In bundle language it is a continuous **section** $s : \mathcal{A}/\mathcal{G} \to \mathcal{A}$ of the bundle (8.35).

Key idea: Sections of principal bundles

A principal bundle has a global section if and only if it is trivial. Given a section s, the map

$$\mathcal{G} \times (\mathcal{A}/\mathcal{G}) \longrightarrow \mathcal{A}, \qquad (g, [A]) \longmapsto s([A])^g \tag{8.43}$$

is a bijection, and it respects the fibration: every point of $\mathcal{A}$ is reached exactly once, since each orbit contains exactly one $s([A])$ and the action is free.

So a global gauge condition exists only if $\mathcal{A} \cong \mathcal{G} \times (\mathcal{A}/\mathcal{G})$, Nash’s (8.13). Nash shows that this cannot be. If the product decomposition held, homotopy groups of a product being products,

$$\pi_j(\mathcal{A}) = \pi_j(\mathcal{G}) \oplus \pi_j(\mathcal{A}/\mathcal{G}), \tag{8.44}$$

which is Nash’s (8.14). Now compare the two sides.

- The left side is 0 for every j, because $\mathcal{A}$ is contractible (8.15).
- The right side contains $\pi_j(\mathcal{G})$, which is *not* zero for many j. For $M = S^4$ we will find $\pi_j(\mathcal{G}) = \pi_{j+4}(G)$ (8.56); for $G = \mathrm{SU}(2)$ this gives $\pi_0(\mathcal{G}) = \pi_4(S^3) = \mathbb{Z}_2$, $\pi_1(\mathcal{G}) = \pi_5(S^3) = \mathbb{Z}_2$, $\pi_2(\mathcal{G}) = \pi_6(S^3) = \mathbb{Z}_{12}$, and so on.

A group of the form $0 = \pi_j(\mathcal{G}) \oplus (\dots)$ with $\pi_j(\mathcal{G}) \neq 0$ is impossible. So the bundle is nontrivial and has no global section.

Key idea: The Gribov ambiguity (Gribov, Singer, Mitter–Viallet)

There is no continuous gauge-fixing condition that selects exactly one representative from every gauge orbit. Any gauge condition either misses some orbits or meets some orbits more than once (Gribov copies), or is discontinuous.

Worked example 8.13: A nontrivial bundle with no global gauge: the Hopf fibration

The Hopf bundle $\mathrm{U}(1) \to S^3 \to S^2$ is the finite-dimensional model of the Gribov problem. Write $S^3 = \{(z_1, z_2) \in \mathbb{C}^2 : |z_1|^2 + |z_2|^2 = 1\}$, with $\mathrm{U}(1)$ acting by $(z_1, z_2) \mapsto (e^{i\lambda} z_1, e^{i\lambda} z_2)$. The orbit space is $\mathbb{CP}^1 = S^2$. A natural gauge condition is “z_2 real and positive”, i.e.

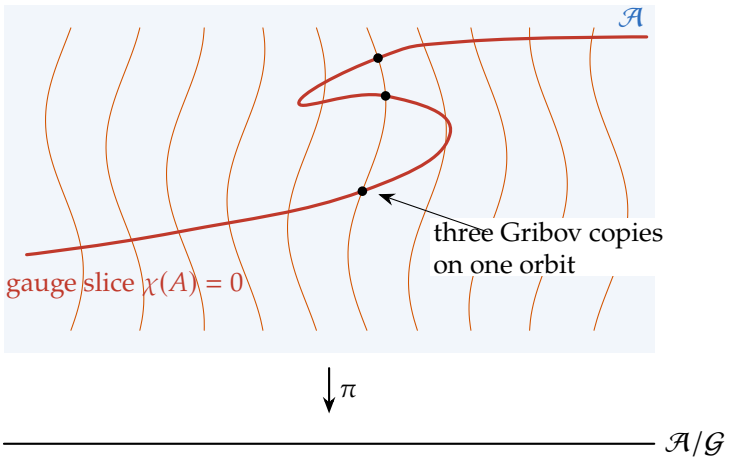


Figure 8.9: Gauge orbits (orange) fibre the space of connections. A gauge condition is a surface (red) that should cut every orbit once. Near $A = 0$ it does (left). For large fields the surface folds back and cuts some orbits several times; where two cuts merge, the Faddeev–Popov operator has a zero mode. The nontriviality of $\mathcal{A} \to \mathcal{A}/\mathcal{G}$ guarantees that *every* continuous choice of surface misbehaves somewhere.

$\arg z_2 = 0$. It picks exactly one point on each orbit with $z_2 \neq 0$, namely

$$s(z_1 : z_2) = \left(\frac{z_1 \bar{z}_2}{|z_2|},\ |z_2| \right).$$

But on the orbit $z_2 = 0$ (one point of S^2, the "north pole") the condition cannot be imposed at all, and near it s is discontinuous: approaching the pole from different directions gives different limits $z_1\bar{z}_2/|z_2|$. Any other choice fails somewhere else. The reason is the same as Nash's, with π_1 in place of π_j: if the bundle were trivial we would have $S^3 \cong \mathrm{U}(1) \times S^2$ and hence $0 = \pi_1(S^3) = \pi_1(\mathrm{U}(1)) \oplus \pi_1(S^2) = \mathbb{Z}$, which is absurd. So the Hopf bundle is nontrivial, and no global gauge exists. Physically this is the Dirac monopole of charge one: no single potential works on all of S^2.

Watch out: What the theorem does and does not say

Singer's theorem does not say that gauge fixing is useless. Locally, near any connection, the Coulomb gauge works perfectly, and perturbation theory is local in this sense. It says the local slices cannot be patched into one global slice, so any exact non-perturbative treatment must either use several patches on $\mathcal{A}/\mathcal{G}$ (as we use several patches on a monopole bundle) or live with Gribov copies. The precise statement needs a compact spacetime (or fields with fixed behaviour at infinity), such as S^4 or S^3; on $\mathbb{R}^n$ with no condition at infinity, $\mathcal{G}$ can be contractible.

Reading Nash (pp. 218–219, (8.11)–(8.14))

Nash gives the argument in four lines: (8.11) the bundle, (8.12) $\mathcal{A}/\mathcal{G} = B\mathcal{G}$ because $\mathcal{A}$ is contractible, (8.13)–(8.14) the product decomposition and its homotopy groups. The non-vanishing of $\pi_j(\mathcal{G})$ is postponed to (8.23), which we reach in Section 8.1.15. His references are Gribov (the Coulomb gauge copies), Singer (the topological theorem) and Mitter–Viallet (the geometry of $\mathcal{A} \to \mathcal{A}/\mathcal{G}$ as a Riemannian submersion).

Recap

- $\mathcal{A} \to \mathcal{A}/\mathcal{G}$ is a principal $\mathcal{G}$-bundle with contractible total space, so $\mathcal{A}/\mathcal{G} = B\mathcal{G}$ and $\pi_j(\mathcal{A}/\mathcal{G}) = \pi_{j-1}(\mathcal{G})$.
- $\mathcal{A}/\mathcal{G}$ is the physical configuration space; the path integral projects onto it (no anomalies), via gauge fixing and the Faddeev–Popov determinant.
- A global gauge condition is a section; it exists only if the bundle is trivial; triviality would force $\pi_j(\mathcal{G}) = 0$; that is false. Hence Gribov copies are unavoidable.
- Toy models: U(1) on S^1 ($\mathcal{A}/\mathcal{G} = S^1$, Coulomb slice meets each orbit infinitely often), rotations of the plane (two copies), the Hopf bundle (no global section).

8.1.12 Bundles over spheres: the clutching construction

To compute anything we now specialise to $M = S^n$. This is the natural setting for instantons: a finite-action field on $\mathbb{R}^4$ extends to the one-point compactification S^4 (Section 3 of this chapter and Section 8.1.16 below). Nash states that a bundle over S^n is determined by "the degree k of a homotopy class in $\pi_{n-1}(G)$". Here is where that comes from.

Cover S^n by two patches, the northern and southern "hemispheres" D_+ and D_-, slightly enlarged so that they overlap in a thin band around the equator. The band retracts onto the equator, which is a sphere S^{n-1}. Each hemisphere is a ball, hence contractible, so any bundle over it is trivial. All the information is therefore in the single transition function on the overlap,

$$t : S^{n-1} \longrightarrow G. \tag{8.45}$$

This way of building a bundle is the **clutching construction**: take two trivial pieces $D_\pm \times G$ and glue them along $S^{n-1} \times G$ by $(x, u) \mapsto (x, t(x)u)$.

Working definition 8.8 (bundles over S^n)

Principal G-bundles over S^n (G connected) correspond to homotopy classes of clutching maps $t : S^{n-1} \to G$ [two clutching maps count as the same when one can be deformed continuously into the other], i.e. to elements of $\pi_{n-1}(G)$ [these classes form a group, for example $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$]. *In practice:* write down one transition function on the equator, and compute its degree or winding number [the integer k counting how many times t wraps S^{n-1} around G]. Deforming t continuously gives an isomorphic bundle, because the deformation can be absorbed into a change of trivialisation [multiplying the fibre coordinate on that hemisphere by a map from it to G] on one hemisphere.

For n even the integer k can also be computed from the curvature, as Nash says, by integrating the Chern class $c_{n/2}$ over S^n. For $n = 2$ we did this in Example 8.2: $\int_{S^2} \frac{i}{2\pi} F = m$, the winding of $t = e^{im\phi}$. For $n = 4$ and $G = \mathrm{SU}(2)$, the analogous statement is that $-\frac{1}{8\pi^2}\int \mathrm{tr}\, F \wedge F$ equals the winding number of $t : S^3 \to \mathrm{SU}(2)$; we derive this in Section 8.1.17. The label k therefore does double duty: a topological class (the homotopy class of t) and an integral of the curvature (the Chern number).

Nash's (8.15) displays all the objects that depend on k:

$$G \to P_k \to S^n, \qquad \mathcal{G}_k \to \mathcal{A}_k \to B\mathcal{G}_k, \qquad c_{n/2}(P_k) = k, \qquad \mathcal{G}_k \subset \mathrm{Aut}(P_k). \tag{8.46}$$

For each k there is a bundle P_k, its space of connections $\mathcal{A}_k$, its (based) gauge group $\mathcal{G}_k$ of automorphisms of P_k, and the quotient $\mathcal{A}_k/\mathcal{G}_k = B\mathcal{G}_k$. (We keep the sign convention of (8.10) for $n = 4$, so strictly $k = -c_2(P_k)$ there; this changes nothing below.)

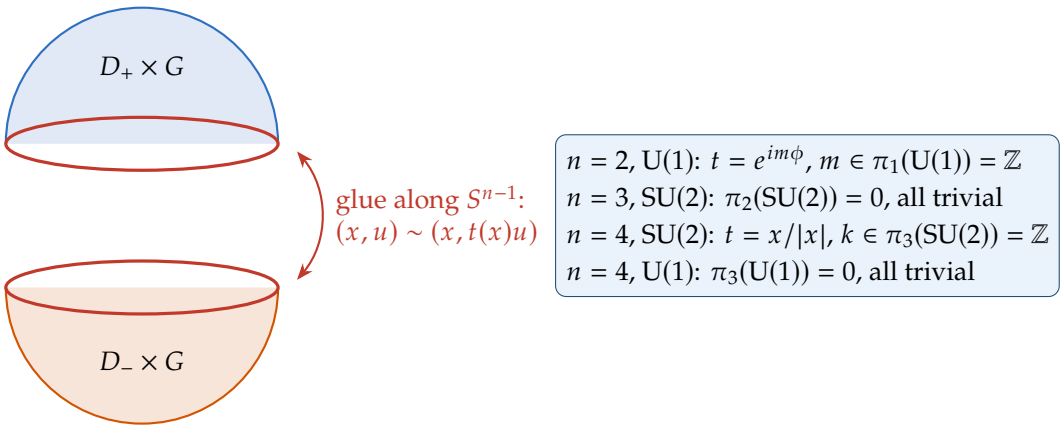

Figure 8.10: The clutching construction. A bundle over S^n is two trivial bundles over the two hemispheres, glued along the equator S^{n-1} (red) by a transition function $t : S^{n-1} \to G$. Only the homotopy class of t matters, so bundles are counted by $\pi_{n-1}(G)$ (examples on the right).

8.1.13 The gauge group is an iterated loop space

The trivial bundle

Start with $k = 0$, the trivial bundle $P_0 = S^n \times G$. A gauge transformation is then just a map $g : S^n \to G$, and a based one sends the base point m_0 to $\mathbb{1}$. This is Nash's (8.16):

$$P_0 = G \times S^n \quad \Longrightarrow \quad \mathcal{G}_0 = \mathrm{Map}_0(S^n, G) \equiv \Omega^n G. \tag{8.47}$$

Here $\mathrm{Map}_0(X, Y)$ denotes base-point-preserving continuous maps, and $\Omega^n G$ is the **n-fold loop space** of G. Let us see why the two are the same.

Working definition 8.9 (loop space)

The **loop space** ΩX of a space X with base point x_0 [a chosen point of X, for gauge groups $x_0 = \mathbb{1} \in G$] is the space of loops $\ell : [0,1] \to X$ with $\ell(0) = \ell(1) = x_0$, i.e. based maps $S^1 \to X$. The iterated loop space is $\Omega^n X = \Omega(\Omega^{n-1} X)$ [loops in the space of loops. Its base point is the constant loop at x_0]. *In practice:* a point of $\Omega^n X$ is a map from the cube $[0,1]^n$ to X that sends the whole boundary of the cube to x_0. Since a cube with its boundary collapsed to a point is a sphere S^n, this is a based map $S^n \to X$:

$$\Omega^n X = \mathrm{Map}_0(S^n, X). \tag{8.48}$$

For $n = 2$: a loop of loops is a one-parameter family $s \mapsto \ell_s$ of loops, each starting and ending at x_0, with ℓ_0 and ℓ_1 the constant loop. Write it as a function of two variables, $f(s,t) = \ell_s(t)$. It is x_0 on all four edges of the square. Collapsing the edges turns the square into a sphere, so f is a based map $S^2 \to X$ (Figure 8.11).

The homotopy groups of loop spaces are shifted:

$$\pi_j(\Omega X) \cong \pi_{j+1}(X), \qquad \pi_j(\Omega^n X) \cong \pi_{j+n}(X). \tag{8.49}$$

The reason is the same picture: a j-sphere's worth of loops is a map of $S^j \times S^1$ to X with enough of it sent to x_0 that it becomes a map of S^{j+1}. In particular $\pi_0(\Omega^n X) = \pi_n(X)$: *the components of $\Omega^n X$ are the homotopy classes of maps $S^n \to X$.*

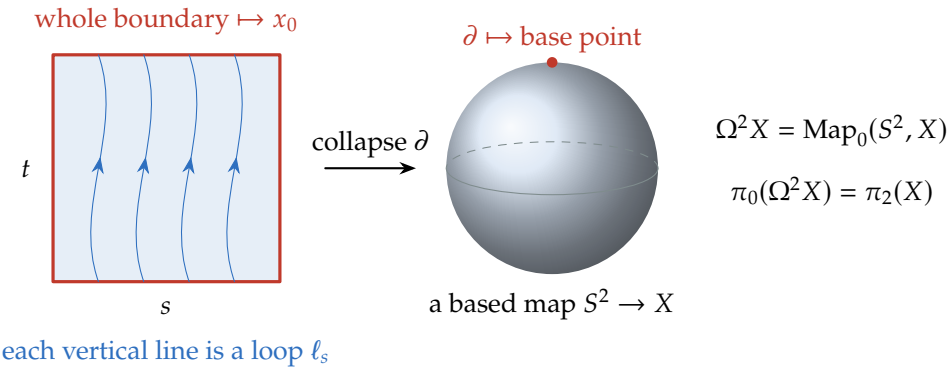

Figure 8.11: A loop of loops is a map from a square whose boundary goes to the base point. Collapsing the boundary turns the square into a sphere, so $\Omega^2 X = \mathrm{Map}_0(S^2, X)$. The same with an n-cube gives $\Omega^n X = \mathrm{Map}_0(S^n, X)$: the based gauge group of the trivial bundle over S^n is $\Omega^n G$.

Independence of k

For $k \neq 0$ the bundle P_k is twisted, and $\mathcal{G}_k$ is the group of sections of the twisted bundle $\mathrm{Ad}\, P_k$. Nash quotes Atiyah and Jones: the homotopy type does not depend on k. So up to homotopy we have Nash's (8.17) and (8.18):

$$\mathcal{G}_k \simeq \mathcal{G}_{k-1} \simeq \cdots \simeq \Omega^n G, \qquad \text{so we write} \quad \mathcal{G} = \Omega^n G. \tag{8.50}$$

Why should this be true? A clean way to see it uses the classifying space and is one line once we have (8.53) below: $B\mathcal{G}_k$ is one connected component of the space $\mathrm{Map}_0(S^n, BG)$, labelled by the bundle type k, and that mapping space is itself a loop space (it equals $\Omega^n BG$). The components of a loop space are all homotopy equivalent to each other: concatenating with a fixed loop of type $-k$ maps the k-component onto the 0-component, with inverse given by concatenating with a loop of type $+k$. So $B\mathcal{G}_k \simeq B\mathcal{G}_0$ for every k, and therefore $\mathcal{G}_k \simeq \Omega B\mathcal{G}_k \simeq \Omega B\mathcal{G}_0 \simeq \mathcal{G}_0$.

Watch out: Components: $B\mathcal{G}_k$ versus $\Omega^{n-1}G$

$\mathcal{A}_k$ is contractible, hence connected, so $B\mathcal{G}_k = \mathcal{A}_k/\mathcal{G}_k$ is *connected*. But $\Omega^{n-1}G$ has components labelled by $\pi_{n-1}(G)$, which is $\mathbb{Z}$ for $n = 4$. The correct statement is that $B\mathcal{G}_k$ is homotopy equivalent to *one* component of $\Omega^{n-1}G$ (all components being alike). Nash's equality $B\mathcal{G} \simeq \Omega^{n-1}G$ in (8.19) should be read this way; equivalently, the union over all k of the $B\mathcal{G}_k$ is $\Omega^{n-1}G$. The formula $\pi_m(B\mathcal{G}) = \pi_{m+n-1}(G)$ below is correct for $m \geq 1$; for $m = 0$ it counts the bundles P_k, not components of a single $B\mathcal{G}_k$.

8.1.14 Ω and B are inverse to each other

Nash now uses "the inverse relationship between the operands Ω and B" (his p. 73). The statement is

$$\Omega BH \simeq H, \qquad B\Omega X \simeq X \quad (X \text{ connected}). \tag{8.51}$$

Why $\Omega BH \simeq H$. Take the universal bundle $EH \to BH$ and a base point $e_0 \in EH$ over $b_0 \in BH$. Given a loop ℓ at b_0, lift it to a path in EH starting at e_0. It ends at a point $e_0 h$ of the same fibre, for a unique $h \in H$. The map $\ell \mapsto h$ is well defined up to homotopy (because EH is contractible, any two lifts are homotopic), and it is a homotopy equivalence $\Omega BH \to H$. This is the boundary map ∂ of Section 8.1.9 "before taking π_0".

Worked example 8.14: Two checks of $\Omega BH \simeq H$

- $H = \mathbb{Z}$, $BH = S^1$. The loops in S^1 fall into components labelled by the winding number $n \in \mathbb{Z}$, and each component is contractible (straight-line homotopy of the lifts in $\mathbb{R}$). So $\Omega S^1 \simeq \mathbb{Z}$.
- $H = \mathrm{U}(1)$, $BH = \mathbb{CP}^\infty$. Then $\pi_j(\Omega\mathbb{CP}^\infty) = \pi_{j+1}(\mathbb{CP}^\infty)$, which is $\mathbb{Z}$ for $j = 1$ and 0 otherwise: the same as the homotopy groups of the circle $\mathrm{U}(1)$.

Why $B\Omega X \simeq X$. Consider the **path fibration** $\Omega X \to PX \to X$, where PX is the space of paths starting at x_0 and the projection takes a path to its end point. The fibre over x_0 is the set of paths that end at x_0, i.e. ΩX. The space PX is contractible (shrink each path back along itself to x_0). Up to homotopy this is a universal ΩX-bundle (loops act on paths by concatenation), so its base X is $B\Omega X$.

Now Nash's chain (8.19) is immediate. With $\mathcal{G} = \Omega^n G = \Omega(\Omega^{n-1}G)$,

$$B\mathcal{G} \overset{(1)}{=} B\Omega^n G \overset{(2)}{=} B\,\Omega\big(\Omega^{n-1}G\big) \overset{(3)}{\simeq} \Omega^{n-1}G. \tag{8.52}$$

(1) The gauge group is $\Omega^n G$, (8.50).
(2) Peel off one Ω.
(3) $B\Omega X \simeq X$ for $X = \Omega^{n-1}G$ (component-wise; see the pitfall above).

And in the other direction, Nash's (8.20), using $G \simeq \Omega BG$:

$$\Omega^{n-1}G \overset{(1)}{\simeq} \Omega^{n-1}\Omega BG \overset{(2)}{=} \Omega^n BG \overset{(3)}{=} \mathrm{Map}_0(S^n, BG) \quad\Longrightarrow\quad B\mathcal{G} \simeq \mathrm{Map}_0(S^n, BG). \tag{8.53}$$

(1) $G \simeq \Omega BG$ from (8.51), applied inside Ω^{n-1}.
(2) $\Omega^{n-1}\Omega = \Omega^n$.
(3) (8.48) with $X = BG$.

This has a pleasing interpretation. Points of $\mathrm{Map}_0(S^n, BG)$ are, by the classification property of BG, G-bundles over S^n (with a trivialisation at the base point). A *connection* modulo gauge transformations is a point of $B\mathcal{G}$. So up to homotopy, "a connection on P modulo based gauge transformations" is the same kind of object as "a map $S^n \to BG$ in the class of P". Indeed, a connection does give such a map, by holonomy; this is the idea behind many constructions in Chapter 10.

Families of bundles, Nash's (8.21)

Iterating once more,

$$\begin{aligned} \Omega^{m+n}BG &\overset{(1)}{=} \Omega^m\Omega^n BG \overset{(2)}{\simeq} \Omega^m B\mathcal{G} \overset{(3)}{=} \mathrm{Map}_0(S^m, B\mathcal{G}), \\ \Longrightarrow\quad \mathrm{Map}_0\big(S^m, \mathrm{Map}_0(S^n, BG)\big) &\simeq \mathrm{Map}_0(S^m, B\mathcal{G}). \end{aligned} \tag{8.54}$$

(1) Split the loop space.
(2) $\Omega^n BG \simeq B\mathcal{G}$ by (8.53).
(3) (8.48) with $X = B\mathcal{G}$.

(Nash writes the left-hand side of (8.21) with the roles of m and n swapped; since $S^m \wedge S^n = S^{m+n}$ is symmetric, both orders give $\Omega^{m+n}BG$.) Read the two sides with the classification property. A map $S^m \to B\mathcal{G}$ is a $\mathcal{G}$-bundle over S^m. A map from S^m into $\mathrm{Map}_0(S^n, BG)$ is an S^m-parametrised family of G-bundles over S^n. So: *a bundle over a parameter sphere S^m with fibre the gauge group is*

the same thing as a family of gauge bundles over spacetime, parametrised by that sphere. This is how families of Dirac operators, parametrised by $\mathcal{A}/\mathcal{G}$, enter the theory of anomalies (Chapter 10, §6).

8.1.15 Homotopy groups of $\mathcal{G}$ and $B\mathcal{G}$

Collecting, Nash's (8.22) is

$$\mathcal{G} \simeq \Omega^n G, \qquad B\mathcal{G} \simeq \Omega^{n-1} G. \tag{8.55}$$

The homotopy groups follow at once from (8.49). This is Nash's (8.23):

$$\pi_m(\mathcal{G}) \overset{(1)}{=} \pi_m(\Omega^n G) \overset{(2)}{=} \pi_{m+n}(G), \tag{8.56}$$

$$\pi_m(B\mathcal{G}) \overset{(3)}{=} \pi_m(\Omega^{n-1} G) \overset{(2)}{=} \pi_{m+n-1}(G) \overset{(4)}{=} \pi_{m-1}(\mathcal{G}). \tag{8.57}$$

(1) $\mathcal{G} \simeq \Omega^n G$.
(2) Homotopy groups of loop spaces are shifted, (8.49).
(3) $B\mathcal{G} \simeq \Omega^{n-1} G$ (for $m \geq 1$).
(4) Compare with (8.56) at $m-1$; this is also (8.39), a good consistency check.

Key idea: Topology of the gauge group on a sphere

On S^n, the m-th homotopy group of the gauge group is the $(m+n)$-th homotopy group of the Lie group: $\pi_m(\mathcal{G}) = \pi_{m+n}(G)$, $\pi_m(\mathcal{A}/\mathcal{G}) = \pi_{m+n-1}(G)$. In particular $\pi_0(\mathcal{G}) = \pi_n(G)$ counts the disconnected pieces of the gauge group (*large* gauge transformations), and $\pi_1(\mathcal{A}/\mathcal{G}) = \pi_n(G)$ counts non-contractible loops of physical field configurations.

To use this we need the homotopy groups of the classical groups. We collect what is needed.

	π_1	π_2	π_3	π_4	π_5	π_6	π_7
$\mathrm{U}(1) = S^1$	$\mathbb{Z}$	0	0	0	0	0	0
$\mathrm{SU}(2) = S^3$	0	0	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_{12}$	$\mathbb{Z}_2$
$\mathrm{U}(2)$	$\mathbb{Z}$	0	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_{12}$	$\mathbb{Z}_2$
$\mathrm{SU}(3)$	0	0	$\mathbb{Z}$	0	$\mathbb{Z}$	$\mathbb{Z}_6$	0
$\mathrm{U}(N)$, $N \geq 3$ (stable, $j < 2N$)	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$

Table 8.1: Homotopy groups of unitary groups. Every Lie group has $\pi_2 = 0$, and every compact simple one has $\pi_3 = \mathbb{Z}$. In the *stable range* $j < 2N$, Bott periodicity gives $\pi_j(\mathrm{U}(N)) = \mathbb{Z}$ for j odd and 0 for j even; the row for $\mathrm{U}(N)$ is valid for the entries with $j < 2N$ (so $\pi_6(\mathrm{U}(3)) = \mathbb{Z}_6$, not 0). The entries for SU(2) are the homotopy groups of the sphere S^3.

A few words on where the table comes from.

- $\mathrm{U}(N) \cong \mathrm{U}(1) \times \mathrm{SU}(N)$ *as a space* (via $u \mapsto (\det u,\ \mathrm{diag}(\det u^{-1}, 1, \ldots, 1)\, u)$), so $\pi_j(\mathrm{U}(N)) = \pi_j(\mathrm{U}(1)) \oplus \pi_j(\mathrm{SU}(N))$, and for $j \geq 2$ this is just $\pi_j(\mathrm{SU}(N))$.
- SU(2) is the 3-sphere (8.9). Its $\pi_3 = \mathbb{Z}$ is the degree of a map $S^3 \to S^3$. $\pi_4(S^3) = \mathbb{Z}_2$ is generated by the suspension of the Hopf map; the "twice" of it can be undone.
- $\mathrm{SU}(N)$ acts transitively on the unit sphere $S^{2N-1} \subset \mathbb{C}^N$ with stabiliser $\mathrm{SU}(N-1)$, giving a fibration $\mathrm{SU}(N-1) \to \mathrm{SU}(N) \to S^{2N-1}$. Its long exact sequence shows $\pi_j(\mathrm{SU}(N-1)) \to \pi_j(\mathrm{SU}(N))$ is an isomorphism for $j < 2N-2$. This is why the groups "stabilise" for large N.

Now Nash's example (8.24): $M = S^4$ and $G = \mathrm{U}(N)$. With $n = 4$,

$$\pi_1(B\mathcal{G}) \overset{(1)}{=} \pi_4(G) = \begin{cases} 0, & N = 1 \\ \mathbb{Z}_2, & N = 2 \\ 0, & N \geq 3 \end{cases} \qquad \pi_2(B\mathcal{G}) \overset{(1)}{=} \pi_5(G) = \begin{cases} 0, & N = 1 \\ \mathbb{Z}_2, & N = 2 \\ \mathbb{Z}, & N \geq 3 \end{cases} \tag{8.58}$$

(1) (8.57) with $n = 4$, then read off Table 8.1: π_4, π_5 of U(1) vanish; those of U(2) are those of S^3; for $N \geq 3$ we are in the stable range $(4, 5 < 2N)$.

By (8.56) the same groups are $\pi_0(\mathcal{G})$ and $\pi_1(\mathcal{G})$.

Worked example 8.15: Checks and interpretations in low dimensions

- $n = 1$, $G = \mathrm{U}(1)$. $\mathcal{G} = \Omega\mathrm{U}(1)$ and $\pi_0(\mathcal{G}) = \pi_1(\mathrm{U}(1)) = \mathbb{Z}$: the winding of λ in Example 8.10. $B\mathcal{G} \simeq \Omega^0\mathrm{U}(1) = \mathrm{U}(1)$: the circle $\mathcal{A}/\mathcal{G}$ we found by hand.
- $n = 2$, $G = \mathrm{U}(1)$. $\pi_m(\mathcal{G}) = \pi_{m+2}(\mathrm{U}(1)) = 0$ for all m, and each $B\mathcal{G}_k$ is contractible. So an Abelian theory on S^2 has no Gribov problem. Directly: the orbit of a is $a + \mathrm{d}\lambda$, and by Hodge theory on S^2 (no harmonic 1-forms) each orbit contains exactly one a with $\mathrm{d}^*a = 0$. The Coulomb gauge works globally, as the topology says it must.
- $n = 4$, $G = \mathrm{SU}(2)$. $\pi_0(\mathcal{G}) = \pi_4(S^3) = \mathbb{Z}_2$: the gauge group on S^4 has two components. A gauge transformation in the other component cannot be deformed to the identity. This $\mathbb{Z}_2$ is the origin of Witten's global SU(2) anomaly (Chapter 10): a theory with an odd number of Weyl doublets has a fermion determinant that changes sign under such a transformation.
- $n = 4$, $G = \mathrm{SU}(3)$. $\pi_2(\mathcal{A}/\mathcal{G}) = \pi_5(\mathrm{SU}(3)) = \mathbb{Z}$: the configuration space has a non-contractible 2-sphere. The integer is detected by the class ν_2 constructed in Section 8.1.25; it is what makes the non-Abelian anomaly possible.
- $n = 3$, G *simple*. $\pi_0(\mathcal{G}) = \pi_3(G) = \mathbb{Z}$. Gauge transformations on S^3 (or on $\mathbb{R}^3$ with $g \to \mathbb{1}$ at infinity) carry an integer winding number. This is the subject of the next section.

Reading Nash (pp. 219–220, (8.15)–(8.24))

Nash compresses the whole of this section into two pages. The "degree k of a homotopy class in $\pi_{n-1}(G)$" is the clutching function (8.45). The Atiyah–Jones independence of k is quoted without reason; we gave the loop-space argument. Nash's p. 73 is where he explains Ω and B. In (8.19)–(8.22) all equalities are homotopy equivalences, and $B\mathcal{G}$ should be read component-wise (pitfall above). The table (8.24) is (8.58); Nash's "with the same results applying to $\pi_0(\mathcal{G})$ and $\pi_1(\mathcal{G})$" is (8.57).

Recap

- Bundles over S^n are clutched by $t : S^{n-1} \to G$ and counted by $\pi_{n-1}(G)$; for n even the class is a Chern number.
- Based gauge group of the trivial bundle: $\mathcal{G} = \mathrm{Map}_0(S^n, G) = \Omega^n G$; up to homotopy the same for every k.
- $\Omega BH \simeq H$ and $B\Omega X \simeq X$ give $B\mathcal{G} \simeq \Omega^{n-1}G \simeq \mathrm{Map}_0(S^n, BG)$.
- $\pi_m(\mathcal{G}) = \pi_{m+n}(G)$, $\pi_m(B\mathcal{G}) = \pi_{m+n-1}(G)$; on S^4 with SU(2): $\pi_0(\mathcal{G}) = \mathbb{Z}_2$; with SU(3):

$\pi_2(B\mathcal{G}) = \mathbb{Z}$.

8.1.16 Finite action and the behaviour at infinity

Nash works on the sphere S^4 and labels bundles by $k \in \pi_3(G)$. A physicist works on flat Euclidean space $\mathbb{R}^4$, where every bundle is trivial. Where does the integer come from on $\mathbb{R}^4$? From the requirement that the action be finite. Finiteness forces the field to become "pure gauge" at infinity, and the gauge transformation it becomes is a map from the 3-sphere at infinity to G. Its winding number is the instanton number.

Finite action forces a flat connection at infinity

The Euclidean Yang–Mills action is (Chapter T3, and Section 3 of this chapter)

$$S[A] = -\int_{\mathbb{R}^4} \operatorname{tr}(F \wedge \star F) = \frac{1}{4}\int_{\mathbb{R}^4} \mathrm{d}^4x \, \sum_{\mu,\nu} \bigl(-\operatorname{tr} F_{\mu\nu}F_{\mu\nu}\bigr), \tag{8.59}$$

and $-\operatorname{tr} F_{\mu\nu}F_{\mu\nu} \geq 0$ because $F_{\mu\nu}$ is anti-Hermitian. In polar coordinates $\mathrm{d}^4x = r^3\,\mathrm{d}r\,\mathrm{d}\Omega_3$. If the curvature fell off only like $|F| \sim 1/r^2$, the integrand would behave like $r^{-4}\cdot r^3 = r^{-1}$ and the r-integral would diverge logarithmically. So a finite-action field must have

$$r^2\,|F| \longrightarrow 0 \qquad (r \to \infty). \tag{8.60}$$

The potential, on the other hand, is allowed to fall off only like $1/r$. Indeed it *must* be allowed to, because the leading $1/r$ piece can have zero curvature. A connection with $F = 0$ is called **flat**.

Key idea: Flat means pure gauge on a simply connected region

If $F = 0$ on a simply connected region U, then there is a map $g : U \to G$ with

$$A = g^{-1}\mathrm{d}g \qquad \text{on } U. \tag{8.61}$$

Equivalently, A is the gauge transform of the zero connection by g: $A = 0^g$.

Why. Fix a point $x_0 \in U$ and, for every $x \in U$, let $U(x)$ be the transport matrix (8.24) along some path from x_0 to x. Two different paths differ by a loop, and a loop in a simply connected region bounds a disc that can be tiled by small squares. For each small square the transport is $\mathbb{1} - \varepsilon^2 F + \cdots = \mathbb{1}$ to second order by Example 8.4; composing the squares, the transport around the whole loop is trivial. So $U(x)$ does not depend on the path. Moving the end point by $\mathrm{d}x$ gives the transport equation $\mathrm{d}U = -AU$. Put $g = U^{-1}$:

$$g^{-1}\mathrm{d}g \overset{(1)}{=} U\,\mathrm{d}\bigl(U^{-1}\bigr) \overset{(2)}{=} U\bigl(-U^{-1}\mathrm{d}U\,U^{-1}\bigr) \overset{(3)}{=} -\mathrm{d}U\,U^{-1} \overset{(4)}{=} A.$$

(1) Substitute $g = U^{-1}$.
(2) $\mathrm{d}(U^{-1}) = -U^{-1}\mathrm{d}U\,U^{-1}$, from differentiating $UU^{-1} = \mathbb{1}$.
(3) $UU^{-1} = \mathbb{1}$.
(4) The transport equation $\mathrm{d}U = -AU$ gives $-\mathrm{d}U\,U^{-1} = A$.

The region $r > R$ of $\mathbb{R}^4$ is $S^3 \times (R, \infty)$, which is simply connected. So at large r a finite-action potential has the form

$$A \;=\; g_\infty^{-1}\mathrm{d}g_\infty + O\Bigl(r^{-1-\delta}\Bigr), \qquad g_\infty : S^3_\infty \longrightarrow G, \tag{8.62}$$

where g_∞ depends only on the angles. (A function of the angles only has a gradient of size $1/r$, which is why the pure-gauge term is $O(1/r)$ while F is smaller.) The map g_∞ is the whole topological content of the field at infinity.

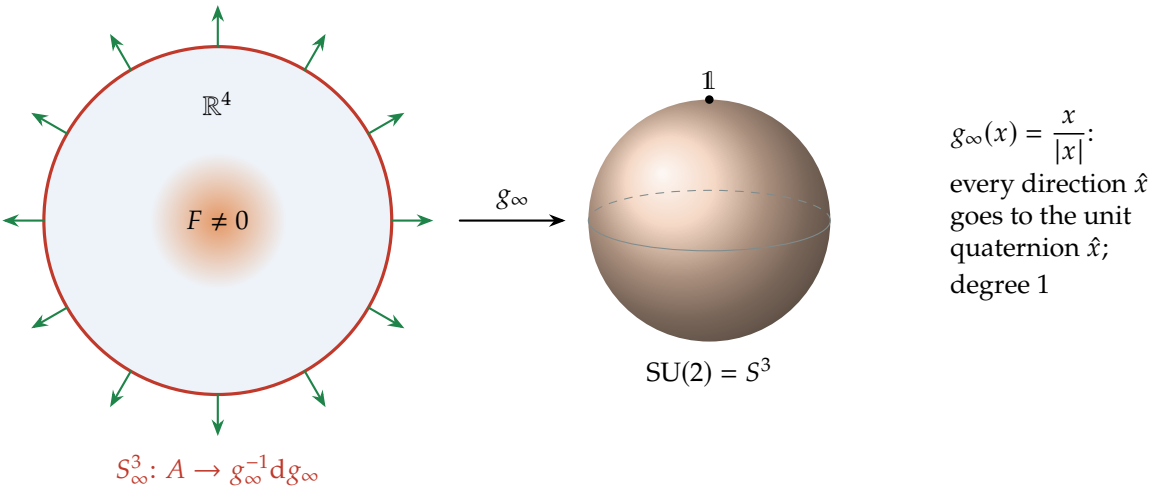

Figure 8.12: A finite-action field on $\mathbb{R}^4$. Its curvature is concentrated in a finite region (orange). Far away $F \to 0$, and the potential becomes a pure gauge $g_\infty^{-1}\mathrm{d}g_\infty$, where g_∞ assigns a group element to each direction (green arrows). For SU(2) the group is itself a 3-sphere, and g_∞ is a map $S^3 \to S^3$; the number of times it covers the target is the instanton number.

From $\mathbb{R}^4$ to a bundle over S^4

Add the point at infinity. $\mathbb{R}^4 \cup \{\infty\} = S^4$ is covered by two patches: the big ball $D_+ = \{|x| < 2R\}$ and the neighbourhood of infinity $D_- = \{|x| > R\} \cup \{\infty\}$. On D_+ use the potential A. On D_- use the gauge-transformed potential

$$A_- := A^{g_\infty^{-1}} = g_\infty A\, g_\infty^{-1} + g_\infty\, \mathrm{d}\big(g_\infty^{-1}\big) \xrightarrow{r\to\infty} 0, \tag{8.63}$$

which tends to zero at infinity (substitute (8.62): the two pure-gauge terms cancel) and so extends smoothly over the added point, after the conformal change of coordinates $y = x/|x|^2$. The two potentials glue by the gauge transformation g_∞ on the overlap, which retracts onto the equatorial S^3. In the language of Section 8.1.12:

Key idea: Finite action on $\mathbb{R}^4$ = connection on a bundle over S^4

A finite-action gauge field on $\mathbb{R}^4$ is a connection on the bundle P_k over S^4 whose clutching function is the asymptotic gauge transformation $g_\infty : S^3 \to G$. Its class $k \in \pi_3(G)$ is the homotopy class of g_∞.

This is why Nash can work on S^4 throughout: the physicist's boundary condition at infinity is the mathematician's choice of bundle.

Worked example 8.16: The two-dimensional version: vortices and $\pi_1(\mathrm{U}(1))$

On $\mathbb{R}^2$ with $G = \mathrm{U}(1)$, finite action again forces $A \to g_\infty^{-1}\mathrm{d}g_\infty$ with $g_\infty : S^1_\infty \to \mathrm{U}(1)$. Take $g_\infty = e^{im\phi}$, $m \in \mathbb{Z}$, and the smooth interpolating potential

$$A = f(r)\, g_\infty^{-1}\mathrm{d}g_\infty = i\, m\, f(r)\, \mathrm{d}\phi, \qquad f(0) = 0, \quad f(\infty) = 1,$$

with $f \sim r^2$ near the origin so that A is smooth there. Then $F = \mathrm{d}A = i\, m\, f'(r)\, \mathrm{d}r \wedge \mathrm{d}\phi$,

and the first Chern number is

$$c_1 = \frac{i}{2\pi}\int_{\mathbb{R}^2} F \overset{(1)}{=} \frac{i}{2\pi}\cdot i\,m\int_0^{2\pi}\mathrm{d}\phi\int_0^{\infty} f'(r)\,\mathrm{d}r$$
$$\overset{(2)}{=} -\frac{m}{2\pi}\cdot 2\pi\,\big(f(\infty)-f(0)\big) \overset{(3)}{=} -m.$$

(1) Substitute F; the orientation $\mathrm{d}x\wedge\mathrm{d}y = r\,\mathrm{d}r\wedge\mathrm{d}\phi$ makes $\mathrm{d}r\wedge\mathrm{d}\phi$ positive.
(2) $i\cdot i=-1$; the ϕ-integral gives 2π; the r-integral is the fundamental theorem of calculus.
(3) Boundary values of f.

The shape of f is irrelevant: only the winding of g_∞ survives. By Stokes the same number is $\frac{i}{2\pi}\oint_{S^1_\infty} A = \frac{i}{2\pi}\oint g_\infty^{-1}\mathrm{d}g_\infty$. The flux of a vortex of the Abelian Higgs model is quantised for exactly this reason. (The minus sign is the orientation bookkeeping of (8.10): with our conventions, the Chern number is minus the winding of g_∞, in two and in four dimensions.)

8.1.17 The winding number of a map $S^3 \to \mathrm{SU}(2)$

How do we compute the homotopy class of $g : S^3 \to G$? For $G = \mathrm{SU}(2) = S^3$ it is the **degree**: the number of times the map covers the target sphere, counted with orientation. Pick a generic target point $h \in \mathrm{SU}(2)$, look at its preimages, and add $+1$ for each preimage where g preserves orientation and -1 where it reverses it. There is also an integral formula, which is the one that connects to curvature.

Working definition 8.10 (winding number of a map into a Lie group)

For $g : S^3 \to G$ (with $G \subset \mathrm{U}(N)$ a matrix group) set $\theta := g^{-1}\mathrm{d}g$, the pull-back of the **Maurer–Cartan form** [the matrix-valued 1-form $h^{-1}\mathrm{d}h$ on G itself, evaluated along $h = g(\sigma)$]. The **winding number** is

$$w(g) := \frac{1}{24\pi^2}\int_{S^3}\mathrm{tr}\big(g^{-1}\mathrm{d}g\big)^3 = \frac{1}{24\pi^2}\int_{S^3}\mathrm{tr}(\theta\wedge\theta\wedge\theta), \tag{8.64}$$

where S^3 carries its orientation as the boundary of the unit ball in $\mathbb{R}^4$ (outward normal first) [a frame (v_1, v_2, v_3) on S^3 is positive when (outward normal, v_1, v_2, v_3) is positive in $\mathbb{R}^4$]. *To compute it:* in coordinates $\sigma^1, \sigma^2, \sigma^3$ on S^3, $\mathrm{tr}\,\theta^3 = \epsilon^{abc}\,\mathrm{tr}(\theta_a\theta_b\theta_c)\,\mathrm{d}\sigma^1\wedge\mathrm{d}\sigma^2\wedge\mathrm{d}\sigma^3$ with $\theta_a = g^{-1}\partial_a g$. It is an integer, equal to the degree for $G = \mathrm{SU}(2)$.

The basic example: the identity map

Let $g(x) = x$ for $x \in S^3$, in the quaternion notation (8.9): $g = x^4\mathbb{1} + x^k e_k$ with $|x| = 1$. It covers SU(2) exactly once, so we expect $w = 1$. Three observations make the integral easy.

(a) $\mathrm{tr}\,\theta^3$ *is left-invariant.* Replacing g by hg with a constant h leaves $\theta = g^{-1}h^{-1}h\,\mathrm{d}g = g^{-1}\mathrm{d}g$ unchanged. The round volume form of S^3 is also invariant under left multiplication (it is a rotation of $\mathbb{R}^4$: $|hx| = |x|$). On a 3-dimensional group, two left-invariant 3-forms are proportional. So $\mathrm{tr}\,\theta^3 = c\cdot\mathrm{vol}_{S^3}$ for a constant c, which we may compute at the identity.

(b) At the identity $x = (0,0,0,1)$, $g = \mathbb{1}$, the tangent space of S^3 is spanned by the x^1, x^2, x^3 directions ($\mathrm{d}x^4 = 0$ there), and $\theta = \mathrm{d}g = e_1\mathrm{d}x^1 + e_2\mathrm{d}x^2 + e_3\mathrm{d}x^3$. Then

$$\theta\wedge\theta\wedge\theta \overset{(1)}{=} \sum_{i,j,k} e_i e_j e_k\;\mathrm{d}x^i\wedge\mathrm{d}x^j\wedge\mathrm{d}x^k$$

$$\overset{(2)}{=} \Big(\sum_{\sigma\in S_3} \operatorname{sgn}(\sigma)\, e_{\sigma(1)}e_{\sigma(2)}e_{\sigma(3)}\Big)\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3$$

$$\overset{(3)}{=} 6\, e_1e_2e_3\ \mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3 \overset{(4)}{=} -6\cdot\mathbb{1}\ \mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3,$$

$$\operatorname{tr}\theta^3\big|_{\mathbb{1}} \overset{(5)}{=} -12\ \mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3. \tag{8.65}$$

(1) Multiply out; the matrices do not commute, so keep their order.
(2) Only distinct i,j,k survive, and $\mathrm{d}x^{\sigma(1)}\wedge\mathrm{d}x^{\sigma(2)}\wedge\mathrm{d}x^{\sigma(3)} = \operatorname{sgn}(\sigma)\,\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3$.
(3) Quaternion relations: $e_ie_j = -e_je_i$ for $i\neq j$, so reordering $e_{\sigma(1)}e_{\sigma(2)}e_{\sigma(3)}$ to $e_1e_2e_3$ costs exactly $\operatorname{sgn}(\sigma)$; the six terms are equal.
(4) $e_1e_2e_3 = e_3e_3 = -\mathbb{1}$.
(5) $\operatorname{tr}\mathbb{1} = 2$.

(c) Orientation. At the point $(0,0,0,1)$ the outward normal is ∂_4. The boundary orientation declares (v_1,v_2,v_3) positive when (∂_4,v_1,v_2,v_3) is positive in $\mathbb{R}^4$. Since $(\partial_4,\partial_1,\partial_2,\partial_3)$ is an odd permutation of $(\partial_1,\dots,\partial_4)$, the positive volume form of S^3 at this point is $\mathrm{vol}_{S^3} = -\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3$.

Putting (a)–(c) together,

$$w(\mathrm{id}) \overset{(1)}{=} \frac{1}{24\pi^2}\int_{S^3} 12\,\mathrm{vol}_{S^3} \overset{(2)}{=} \frac{12\cdot 2\pi^2}{24\pi^2} = 1. \tag{8.66}$$

(1) By (a), $\operatorname{tr}\theta^3 = c\,\mathrm{vol}_{S^3}$ everywhere, and by (b), (c), $c = 12$: $-12\,\mathrm{d}x^{123} = 12\,(-\mathrm{d}x^{123})$.
(2) The volume of the unit 3-sphere is $2\pi^2$.

The mysterious $24\pi^2$ in (8.64) is just $12\times 2\pi^2$, chosen to make this answer 1.

Watch out: Orientation signs

Had we oriented S^3 by $\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3$ at the north pole we would have found $w(\mathrm{id}) = -1$. Many books absorb this sign in different places (Hermitian versus anti-Hermitian θ, x^0 first versus x^4 last). Any consistent choice works; ours makes the BPST instanton, whose potential tends to $g^{-1}\mathrm{d}g$ with $g = x/|x|$, have $k = +1$.

Why the winding number is a topological invariant

Deform g slightly, $g\mapsto g(\mathbb{1}+\xi)$, with ξ a small $\mathfrak{g}$-valued function on S^3. Then $\delta\theta = \mathrm{d}\xi + [\theta,\xi]$, and

$$\delta\operatorname{tr}\theta^3 \overset{(1)}{=} 3\operatorname{tr}\big(\theta^2\,\delta\theta\big) \overset{(2)}{=} 3\operatorname{tr}\big(\theta^2\mathrm{d}\xi\big) + 3\operatorname{tr}\big(\theta^3\xi - \theta^2\xi\theta\big)$$

$$\overset{(3)}{=} 3\operatorname{tr}\big(\theta^2\mathrm{d}\xi\big) \overset{(4)}{=} 3\,\mathrm{d}\operatorname{tr}\big(\theta^2\xi\big) - 3\operatorname{tr}\big(\mathrm{d}(\theta^2)\,\xi\big) \overset{(5)}{=} 3\,\mathrm{d}\operatorname{tr}\big(\theta^2\xi\big). \tag{8.67}$$

(1) Product rule on $\operatorname{tr}(\theta\theta\theta)$; each of the three terms can be cycled to the form $\operatorname{tr}(\theta^2\delta\theta)$, because moving a 1-form past a 2-form under the trace costs the sign $(-1)^{1\cdot 2} = +1$.
(2) Insert $\delta\theta = \mathrm{d}\xi + \theta\xi - \xi\theta$.
(3) Cycle the 1-form θ from the end of $\operatorname{tr}(\theta^2\xi\theta)$ to the front (past the 2-form $\theta^2\xi$, no sign): it equals $\operatorname{tr}(\theta^3\xi)$, so the bracket vanishes.
(4) Product rule: $\mathrm{d}\operatorname{tr}(\theta^2\xi) = \operatorname{tr}(\mathrm{d}(\theta^2)\xi) + \operatorname{tr}(\theta^2\mathrm{d}\xi)$ (moving d past the 2-form θ^2 costs no sign).
(5) The Maurer–Cartan equation $\mathrm{d}\theta = -\theta\wedge\theta$ (differentiate $g^{-1}\mathrm{d}g$) gives $\mathrm{d}(\theta^2) = \mathrm{d}\theta\,\theta - \theta\,\mathrm{d}\theta = -\theta^3 + \theta^3 = 0$.

The change of the integrand is exact, so by Stokes on the closed manifold S^3 the integral does not change. A continuous deformation is a succession of small ones, so $w(g)$ depends only on the homotopy class of g. Being also an integer (it is the degree), it cannot change continuously at all.

Winding numbers add

For two maps $g, h : S^3 \to G$, the pointwise product has

$$w(gh) = w(g) + w(h). \tag{8.68}$$

Write $a = g^{-1}\mathrm{d}g$ and $b = \mathrm{d}h\, h^{-1}$. Then $(gh)^{-1}\mathrm{d}(gh) = h^{-1}(a+b)h$, and

$$\begin{aligned}\operatorname{tr}\big((gh)^{-1}\mathrm{d}(gh)\big)^3 &\overset{(1)}{=} \operatorname{tr}(a+b)^3 \overset{(2)}{=} \operatorname{tr} a^3 + 3\operatorname{tr}(a^2 b) + 3\operatorname{tr}(ab^2) + \operatorname{tr} b^3 \\ &\overset{(3)}{=} \operatorname{tr}\big(g^{-1}\mathrm{d}g\big)^3 + \operatorname{tr}\big(h^{-1}\mathrm{d}h\big)^3 - 3\,\mathrm{d}\operatorname{tr}(ab).\end{aligned}$$

(1) Conjugation by h drops out of the trace.
(2) Expand the eight terms and cycle each to one of these four forms (moving a 1-form past a 2-form under the trace is free).
