(3) $\operatorname{tr} b^3 = \operatorname{tr}(h\,h^{-1}\mathrm{d}h\,h^{-1})^3 = \operatorname{tr}(h^{-1}\mathrm{d}h)^3$; and $\mathrm{d}\operatorname{tr}(ab) = \operatorname{tr}(\mathrm{d}a\,b - a\,\mathrm{d}b) = -\operatorname{tr}(a^2 b) - \operatorname{tr}(ab^2)$ using $\mathrm{d}a = -a^2$ and $\mathrm{d}b = \mathrm{d}h\,\mathrm{d}(h^{-1})\cdot(-1)\cdot(-1) = b^2$.

The exact term integrates to zero. So w is a group homomorphism from $\pi_3(G)$ (with pointwise multiplication) to $\mathbb{Z}$.

Worked example 8.17: Maps of every degree

- $g_n(x) = x^n$ (quaternion power, $|x| = 1$). By (8.68) applied $n-1$ times, $w(g_n) = n\,w(\mathrm{id}) = n$. Likewise $w(\bar{x}) = -1$, because $\bar{x} = x^{-1}$ and $w(x\,x^{-1}) = w(\mathbb{1}) = 0$.
- A constant map has $\theta = 0$ and $w = 0$.
- A map into a U(1) subgroup, $g = \exp(\phi(x)e_3)$, has $\theta = e_3\,\mathrm{d}\phi$ and $\theta\wedge\theta = e_3^2\,\mathrm{d}\phi\wedge\mathrm{d}\phi = 0$. So $w = 0$: an Abelian map is never topologically non-trivial in three dimensions, matching $\pi_3(\mathrm{U}(1)) = 0$.
- For $G = \mathrm{SU}(N)$, embed an SU(2) map in the upper left 2×2 block. The trace in (8.64) is unchanged, so $w = 1$ is still attained, and $\pi_3(\mathrm{SU}(N)) = \mathbb{Z}$ is generated by this embedding.

8.1.18 The instanton number is the winding at infinity

Now connect curvature to winding. The key identity is that $\operatorname{tr} F\wedge F$ is exact, *locally*:

$$\operatorname{tr}(F\wedge F) = \mathrm{d}\,Q_3(A), \qquad Q_3(A) := \operatorname{tr}\Big(A\wedge\mathrm{d}A + \tfrac{2}{3}A\wedge A\wedge A\Big). \tag{8.69}$$

Q_3 is the **Chern–Simons 3-form**. We will meet it again as Nash's $TP_2(A)$ in Section 8.2. The check:

$$\begin{aligned}\mathrm{d}Q_3 &\overset{(1)}{=} \operatorname{tr}\big(\mathrm{d}A\wedge\mathrm{d}A\big) + \tfrac{2}{3}\operatorname{tr}\big(\mathrm{d}A\,A\,A - A\,\mathrm{d}A\,A + A\,A\,\mathrm{d}A\big) \\ &\overset{(2)}{=} \operatorname{tr}\big(\mathrm{d}A\wedge\mathrm{d}A\big) + 2\operatorname{tr}\big(\mathrm{d}A\wedge A\wedge A\big) \\ &\overset{(3)}{=} \operatorname{tr}\big(\mathrm{d}A\,\mathrm{d}A + \mathrm{d}A\,A^2 + A^2\,\mathrm{d}A + A^2A^2\big) \overset{(4)}{=} \operatorname{tr}\big((\mathrm{d}A + A^2)\wedge(\mathrm{d}A + A^2)\big) = \operatorname{tr} F\wedge F.\end{aligned}$$

(1) $\mathrm{d}(A \wedge \mathrm{d}A) = \mathrm{d}A \wedge \mathrm{d}A$ (since $\mathrm{d}\mathrm{d}A = 0$), and the product rule on $A\,A\,A$ with a sign each time d passes a 1-form.
(2) Cycle under the trace: $\mathrm{tr}(A\,\mathrm{d}A\,A)$ moves the last A past the 3-form $A\,\mathrm{d}A$, costing $(-1)^{1\cdot 3} = -1$, so $-\mathrm{tr}(A\,\mathrm{d}A\,A) = +\mathrm{tr}(A^2\mathrm{d}A)$; and $\mathrm{tr}(A^2\mathrm{d}A) = \mathrm{tr}(\mathrm{d}A\,A^2)$ (2-forms commute under the trace). The three terms add to $3\,\mathrm{tr}(\mathrm{d}A\,A^2)$.
(3) Split $2\,\mathrm{tr}(\mathrm{d}A\,A^2) = \mathrm{tr}(\mathrm{d}A\,A^2) + \mathrm{tr}(A^2\mathrm{d}A)$, and add $\mathrm{tr}(A^4) = 0$ (moving one 1-form past a 3-form under the trace gives $\mathrm{tr}(A^4) = -\mathrm{tr}(A^4)$).
(4) Factorise; $F = \mathrm{d}A + A \wedge A$.

Integrate over a large ball B_R and use Stokes. With the instanton number normalised as in (8.10),

$$k \overset{(1)}{=} -\frac{1}{8\pi^2}\lim_{R\to\infty}\int_{B_R}\mathrm{tr}\,F\wedge F \overset{(2)}{=} -\frac{1}{8\pi^2}\lim_{R\to\infty}\int_{S^3_R} Q_3(A)$$
$$\overset{(3)}{=} -\frac{1}{8\pi^2}\int_{S^3} Q_3\big(g_\infty^{-1}\mathrm{d}g_\infty\big) \overset{(4)}{=} -\frac{1}{8\pi^2}\int_{S^3}\Big(-\tfrac{1}{3}\Big)\,\mathrm{tr}\,\theta^3 \overset{(5)}{=} w(g_\infty). \tag{8.70}$$

(1) Definition, with $\mathbb{R}^4$ exhausted by balls.
(2) $\mathrm{tr}\,F^2 = \mathrm{d}Q_3$ on $\mathbb{R}^4$, where A is a single smooth potential; Stokes' theorem with the boundary orientation.
(3) At large R, $A = g_\infty^{-1}\mathrm{d}g_\infty + O(r^{-1-\delta})$; the correction contributes $O(R^{-\delta}) \to 0$ to an integral over a sphere of area $2\pi^2R^3$ of a form of size $R^{-3-\delta}$.
(4) For a pure gauge $A = \theta$: $\mathrm{d}\theta = -\theta^2$, so $Q_3(\theta) = \mathrm{tr}(-\theta^3 + \frac{2}{3}\theta^3) = -\frac{1}{3}\,\mathrm{tr}\,\theta^3$.
(5) $\frac{1}{8\pi^2}\cdot\frac{1}{3} = \frac{1}{24\pi^2}$, and (8.64).

Key idea: Instanton number = winding number

For a finite-action field on $\mathbb{R}^4$,

$$k = -\frac{1}{8\pi^2}\int_{\mathbb{R}^4}\mathrm{tr}\,F\wedge F = \frac{1}{24\pi^2}\int_{S^3_\infty}\mathrm{tr}\big(g_\infty^{-1}\mathrm{d}g_\infty\big)^3 = w(g_\infty) \in \mathbb{Z}.$$

The integral of a local density over all of space is an integer, because it only sees how the field wraps the group at infinity. This is the concrete content of Nash's "$c_{n/2}(P_k) = k$" in (8.15), for $n = 4$.

Worked example 8.18: Where the BPST instanton keeps its charge

The BPST instanton of size ρ centred at the origin (Section 3 of this chapter) is, in our conventions,

$$A = f(r)\,g^{-1}\mathrm{d}g, \qquad g = \frac{x}{|x|}, \qquad f(r) = \frac{r^2}{r^2+\rho^2}.$$

It tends to $g^{-1}\mathrm{d}g$ at infinity, so $k = w(x/|x|) = 1$. How much of this charge lies inside the ball of radius R? Apply the same Stokes argument on B_R. On the sphere S^3_R the function f is constant, so there $\mathrm{d}(f\theta) = f\,\mathrm{d}\theta = -f\theta^2$ and

$$k(R) \overset{(1)}{=} -\frac{1}{8\pi^2}\int_{S^3_R} Q_3(f\theta) \overset{(2)}{=} -\frac{1}{8\pi^2}\int_{S^3_R}\Big(-f^2+\tfrac{2}{3}f^3\Big)\,\mathrm{tr}\,\theta^3$$
$$\overset{(3)}{=} -\frac{24\pi^2}{8\pi^2}\Big(-f^2+\tfrac{2}{3}f^3\Big) \overset{(4)}{=} 3f^2 - 2f^3 = \frac{R^4(R^2+3\rho^2)}{(R^2+\rho^2)^3}, \qquad f = f(R).$$

(1) Stokes on B_R, with A smooth inside (it vanishes like r^2 at the origin, where g itself is undefined).

(2) $Q_3(f\theta) = \operatorname{tr}(f\theta \wedge (-f\theta^2) + \frac{2}{3}f^3\theta^3)$ restricted to the sphere.
(3) $\int_{S^3_R} \operatorname{tr}\theta^3 = 24\pi^2$ for every R (the map $x \mapsto x/|x|$ has winding one on every sphere).
(4) Algebra: $f^2(3-2f)$ with $f = R^2/(R^2+\rho^2)$.

At $R = \rho$, $k = 3/4 - 2/8 = 1/2$: half the charge lies within one instanton radius, and the density falls like ρ^4/r^8 outside. (We checked the density $\operatorname{tr} F \wedge F = -48\rho^4/(r^2+\rho^2)^4\,\mathrm{d}^4x$ symbolically; it integrates to $k = 1$.) See Figure 8.13.

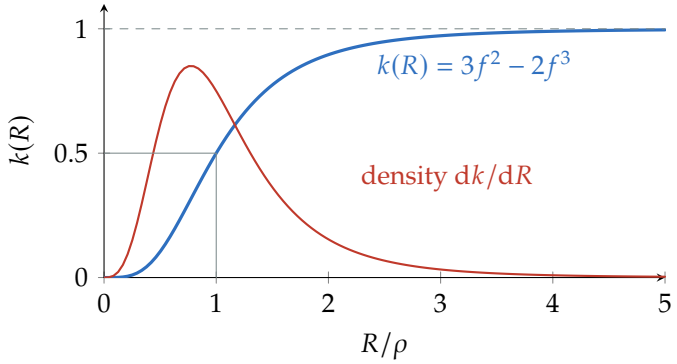

Figure 8.13: The instanton number inside a ball of radius R for the BPST instanton of size ρ (blue), and its radial density (red). Half the charge lies within $R = \rho$, and the total is exactly 1, whatever ρ: the size is a modulus, the charge is topological.

Watch out: The winding can move, but not disappear

Apply the gauge transformation g^{-1} (with $g = x/|x|$) to the BPST potential. Far away the new potential tends to 0; near the origin it has the singular piece $g\,\mathrm{d}(g^{-1})$. This *singular gauge* is popular for multi-instanton ansätze ('t Hooft). The winding has moved from infinity to a small sphere around the origin, where g is singular. The total, computed as the integral of the gauge-invariant density $\operatorname{tr} F \wedge F$, is still 1. What cannot happen is a *smooth* gauge transformation on all of $\mathbb{R}^4$ that changes g_∞'s class, because w of the restriction of a smooth map on the ball to its boundary is zero (the map extends over the ball, so it is null-homotopic).

8.1.19 Large gauge transformations and the Chern–Simons number

Now switch from four-dimensional Euclidean spacetime to the Hamiltonian picture: three-dimensional space, evolving in time. Here $\pi_3(G)$ appears again, this time as π_0 of the gauge group of *space*.

The gauge group of space is disconnected

In the temporal gauge $A_4 = 0$ (Euclidean) or $A_0 = 0$ (Minkowski), the potential is a time-dependent family $A(t) = A_i(t,\vec{x})\,\mathrm{d}x^i$ of connections on space $\mathbb{R}^3$. The gauge transformations that preserve $A_0 = 0$ are the time-independent ones, $g(\vec{x})$. For the Gauss law and the charges to make sense we require $g \to \mathbb{1}$ at spatial infinity. So g is a based map from $\mathbb{R}^3 \cup \{\infty\} = S^3$ to G, and the residual gauge group is

$$\mathcal{G}_{\text{space}} = \operatorname{Map}_0(S^3, G) = \Omega^3 G, \qquad \pi_0(\mathcal{G}_{\text{space}}) = \pi_3(G) = \mathbb{Z}. \tag{8.71}$$

This is Nash's $\mathcal{G}$ with $n = 3$, and (8.56) with $m = 0$. Gauge transformations with $n(g) = 0$ are connected to the identity: **small** gauge transformations. The others are **large**.

Worked example 8.19: An explicit large gauge transformation

Inverse stereographic projection maps $\mathbb{R}^3 \cup \{\infty\}$ onto the unit quaternions. With a length scale $\lambda > 0$ define

$$g_1(\vec{x}) = \frac{(r^2 - \lambda^2)\,\mathbb{1} - 2\lambda\, x^k e_k}{r^2 + \lambda^2}, \qquad r = |\vec{x}|. \tag{8.72}$$

It is unitary: $|g_1|^2 = \big((r^2-\lambda^2)^2 + 4\lambda^2 r^2\big)/(r^2+\lambda^2)^2 = 1$. It tends to $\mathbb{1}$ as $r \to \infty$ and equals $-\mathbb{1}$ at the origin. Every unit quaternion is hit exactly once. Symbolic computation gives

$$\operatorname{tr}\big(g_1^{-1}\mathrm{d}g_1\big)^3 = -\frac{96\,\lambda^3}{(r^2+\lambda^2)^3}\,\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3.$$

At the origin this is easy to check by hand: there $g_1 = -\mathbb{1}$ and $\mathrm{d}g_1 = -(2/\lambda)\,e_k \mathrm{d}x^k$, so $\theta = (2/\lambda) e_k \mathrm{d}x^k$ and, by (8.65), $\operatorname{tr}\theta^3 = (2/\lambda)^3(-12)\,\mathrm{d}x^{123} = -96\lambda^{-3}\mathrm{d}x^{123}$. Integrating,

$$\int_{\mathbb{R}^3} \operatorname{tr}\theta^3 \overset{(1)}{=} -96\lambda^3 \cdot 4\pi \int_0^\infty \frac{r^2\,\mathrm{d}r}{(r^2+\lambda^2)^3} \overset{(2)}{=} -96\lambda^3 \cdot 4\pi \cdot \frac{\pi}{16\lambda^3} = -24\pi^2.$$

(1) The density depends only on r; $\mathrm{d}^3x = 4\pi r^2 \mathrm{d}r$ after the angular integral.

(2) $\int_0^\infty r^2(r^2+\lambda^2)^{-3}\mathrm{d}r = \pi/(16\lambda^3)$ (substitute $r = \lambda\tan u$: the integral becomes $\lambda^{-3}\int_0^{\pi/2}\sin^2 u\cos^2 u\,\mathrm{d}u = \lambda^{-3}\pi/16$).

Working definition 8.11 (winding of a gauge transformation of space)

For $g : \mathbb{R}^3 \to G$ with $g \to \mathbb{1}$ at infinity [so g extends to a map $S^3 \to G$, with the point at infinity sent to $\mathbb{1}$],

$$n(g) := -\frac{1}{24\pi^2}\int_{\mathbb{R}^3} \operatorname{tr}\big(g^{-1}\mathrm{d}g\big)^3, \tag{8.73}$$

with $\mathbb{R}^3$ oriented by $\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3$. So $n(g_1) = +1$. The minus sign is orientation bookkeeping: a slice $\{x^4 = \text{const}\}$, seen as the *top* face of a slab in $\mathbb{R}^4$ oriented by $\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^4$, carries the boundary orientation [outward normal first. On the top face the outward normal is ∂_4, and moving it past three vectors gives a sign -1] $-\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3$ (the same computation as in (c) above). With that orientation (8.73) is exactly (8.64).

The Chern–Simons number and how it changes

Define the **Chern–Simons number** of a spatial configuration,

$$N_{\mathrm{CS}}(A) := \frac{1}{8\pi^2}\int_{\mathbb{R}^3} Q_3(A) = \frac{1}{8\pi^2}\int_{\mathbb{R}^3} \operatorname{tr}\Big(A \wedge \mathrm{d}A + \tfrac{2}{3}A^3\Big). \tag{8.74}$$

It is *not* gauge invariant. Its change under a gauge transformation is the most important formula of this section. Write $b := \mathrm{d}g\,g^{-1}$, so that $A^g = g^{-1}(A+b)g$ and $\theta = g^{-1}\mathrm{d}g = g^{-1}bg$. It is convenient to write $Q_3 = \operatorname{tr}(AF) - \frac{1}{3}\operatorname{tr}A^3$ (substitute $\mathrm{d}A = F - A^2$). Then

$$\begin{aligned} Q_3(A^g) &\overset{(1)}{=} \operatorname{tr}\big((A+b)F\big) - \tfrac{1}{3}\operatorname{tr}(A+b)^3 \\ &\overset{(2)}{=} Q_3(A) + \operatorname{tr}(bF) - \operatorname{tr}(A^2 b) - \operatorname{tr}(Ab^2) - \tfrac{1}{3}\operatorname{tr}b^3 \end{aligned}$$

$$\overset{(3)}{=} Q_3(A) + \operatorname{tr}(b\,\mathrm{d}A) - \operatorname{tr}(Ab^2) - \tfrac{1}{3}\operatorname{tr}\theta^3$$
$$\overset{(4)}{=} Q_3(A) - \mathrm{d}\operatorname{tr}(bA) - \tfrac{1}{3}\operatorname{tr}\theta^3. \tag{8.75}$$

(1) $A^g = g^{-1}(A+b)g$ and $F^g = g^{-1}Fg$; the conjugations drop out of the traces.
(2) Expand $\operatorname{tr}(A+b)^3 = \operatorname{tr}A^3 + 3\operatorname{tr}(A^2b) + 3\operatorname{tr}(Ab^2) + \operatorname{tr}b^3$ as in the proof of (8.68).
(3) $\operatorname{tr}(bF) = \operatorname{tr}(b\,\mathrm{d}A) + \operatorname{tr}(bA^2)$ and $\operatorname{tr}(bA^2) = \operatorname{tr}(A^2b)$ (a 1-form past a 2-form); $\operatorname{tr}b^3 = \operatorname{tr}\theta^3$ by conjugation.
(4) $\mathrm{d}b = \mathrm{d}g\wedge\mathrm{d}g^{-1}\cdot(-1) = b^2$, so $\mathrm{d}\operatorname{tr}(bA) = \operatorname{tr}(b^2A) - \operatorname{tr}(b\,\mathrm{d}A)$, and $\operatorname{tr}(b^2A) = \operatorname{tr}(Ab^2)$.

(We also checked (8.75) symbolically for random non-Abelian A and g.) Integrate over $\mathbb{R}^3$. The exact term gives a surface integral at infinity, which vanishes because $b\to 0$ there. The last term gives the winding:

$$N_{\mathrm{CS}}(A^g) = N_{\mathrm{CS}}(A) - \frac{1}{24\pi^2}\int_{\mathbb{R}^3}\operatorname{tr}\theta^3 = N_{\mathrm{CS}}(A) + n(g). \tag{8.76}$$

Key idea: N_{CS} is gauge invariant modulo integers

Small gauge transformations leave N_{CS} unchanged; a large one of winding n shifts it by the integer n. So N_{CS} mod 1, equivalently $e^{2\pi i N_{\mathrm{CS}}}$, is gauge invariant. This is our first example of a quantity that is only defined in $\mathbb{R}/\mathbb{Z}$: a *secondary* invariant (Section 8.2.7).

Classical vacua and the instanton as a tunnelling path

A classical vacuum of the Hamiltonian theory has zero energy, so zero field strength on space: $F=0$ on $\mathbb{R}^3$. By (8.61) it is a pure gauge, $A = g^{-1}\mathrm{d}g$. Its Chern–Simons number is

$$N_{\mathrm{CS}}\big(g^{-1}\mathrm{d}g\big) \overset{(1)}{=} N_{\mathrm{CS}}(0^g) \overset{(2)}{=} N_{\mathrm{CS}}(0) + n(g) = n(g).$$

(1) A pure gauge is the gauge transform of the zero connection.
(2) (8.76); $Q_3(0)=0$.

So the classical vacua fall into classes $|n\rangle$, $n\in\mathbb{Z}$, labelled by their Chern–Simons number. Vacua in the same class are related by small gauge transformations: they are physically the same state. Vacua in different classes are related only by large gauge transformations. To go from one class to another *continuously* one must pass through configurations with $F\neq 0$, i.e. over an energy barrier (its top is the **sphaleron**).

In Euclidean time the passage is an instanton. Take the slab $[-T,T]\times\mathbb{R}^3$ in temporal gauge, with $A\to\mathbb{1}$-based pure gauges at spatial infinity and at $x^4=\pm T$. Stokes' theorem on the slab gives

$$k \overset{(1)}{=} -\frac{1}{8\pi^2}\int_{\mathrm{slab}}\mathrm{d}Q_3 \overset{(2)}{=} -\frac{1}{8\pi^2}\Big(-\int_{\mathbb{R}^3}Q_3\big|_{x^4=T} + \int_{\mathbb{R}^3}Q_3\big|_{x^4=-T}\Big)$$
$$\overset{(3)}{=} N_{\mathrm{CS}}\big(A(T)\big) - N_{\mathrm{CS}}\big(A(-T)\big) \xrightarrow{T\to\infty} n_+ - n_-. \tag{8.77}$$

(1) $\operatorname{tr}F\wedge F = \mathrm{d}Q_3$ and (8.10).
(2) The boundary of the slab is the top face with orientation $-\mathrm{d}x^{123}$, the bottom face with $+\mathrm{d}x^{123}$, and the sides at spatial infinity, which contribute nothing in temporal gauge ($A_4=0$ and the Q_3 components along $\mathrm{d}x^4$ vanish there).
(3) Definition (8.74); at $x^4=\pm T\to\pm\infty$ the field is a vacuum of class $n_\pm$.

An instanton of charge k is a Euclidean path that tunnels from the vacuum $|n\rangle$ to the vacuum $|n+k\rangle$.

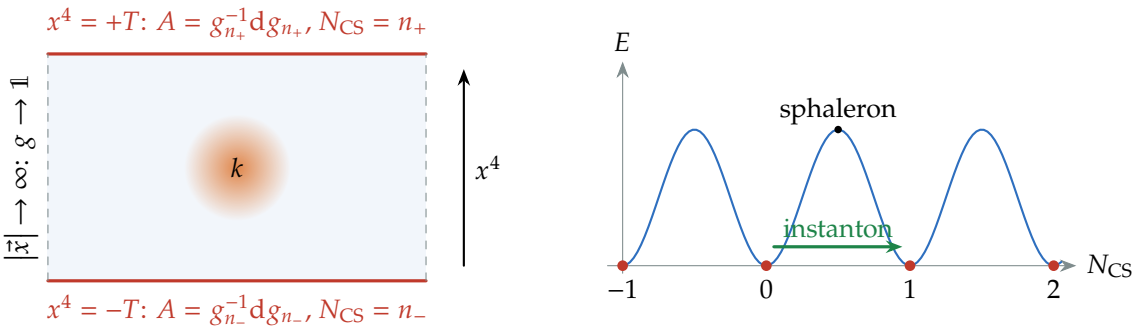

Figure 8.14: Left: an instanton in temporal gauge on the Euclidean slab. The field starts and ends as a pure gauge, and $k = N_{\mathrm{CS}}(+T) - N_{\mathrm{CS}}(-T)$. Right: the potential energy of Yang–Mills theory along a path in configuration space, plotted against the Chern–Simons number. The classical vacua sit at the integers and are related by large gauge transformations. The instanton (green) tunnels under the barrier, whose top is the sphaleron.

Physical picture: A non-contractible loop in configuration space

Walk in $\mathcal{A}$ from $A = 0$ to $A = g_1^{-1}\mathrm{d}g_1$ along any path, for example the straight line. In $\mathcal{A}$ this is an open path. In $\mathcal{A}/\mathcal{G}_{\mathrm{space}}$ its two ends are the same point, because they differ by the gauge transformation g_1. So it is a *loop* in the physical configuration space, and it cannot be contracted, because N_{CS} increases by one along any lift. This is precisely $\pi_1(\mathcal{A}/\mathcal{G}) = \pi_0(\mathcal{G}) = \pi_3(G) = \mathbb{Z}$ for space S^3, from (8.39) and (8.56). The U(1) circle of Example 8.10 is the same phenomenon one dimension down.

8.1.20 θ-vacua

Quantum mechanics on a configuration space with a non-contractible loop has a freedom that classical mechanics does not: a wave function may pick up a phase when it is carried around the loop. For Yang–Mills this phase is the vacuum angle θ. It is cleanest to see it first in the smallest possible example.

Worked example 8.20: A particle on a circle: the θ-angle in quantum mechanics

A particle of moment of inertia I moves on a circle, angle ϕ. Its configuration space is S^1, with $\pi_1(S^1) = \mathbb{Z}$. Work on the covering space $\mathbb{R} \ni \phi$ (the analogue of $\mathcal{A}$) where ϕ and $\phi + 2\pi$ are "gauge equivalent"; the translation $T : \phi \mapsto \phi + 2\pi$ is the analogue of a large gauge transformation. Physical states must be eigenstates of T (it commutes with H), with eigenvalue a phase:

$$\psi(\phi + 2\pi) = e^{i\theta}\,\psi(\phi).$$

The energy eigenstates of $H = -\frac{1}{2I}\partial_\phi^2$ with this twisted periodicity are $\psi_m = e^{i(m+\theta/2\pi)\phi}$, $m \in \mathbb{Z}$, and

$$E_m(\theta) \overset{(1)}{=} \frac{1}{2I}\left(m + \frac{\theta}{2\pi}\right)^2.$$

(1) $-\partial_\phi^2 e^{i\kappa\phi} = \kappa^2 e^{i\kappa\phi}$ with $\kappa = m + \theta/2\pi$; the twisted condition requires $e^{2\pi i\kappa} = e^{i\theta}$.

The spectrum depends on θ and is periodic in it: $\theta \to \theta + 2\pi$ just relabels $m \to m + 1$. Now undo the twist: $\psi = e^{i\theta\phi/2\pi}\chi$ with χ periodic. Then $H\chi = \frac{1}{2I}(-i\partial_\phi + \theta/2\pi)^2\chi$. This

is the Hamiltonian of the Lagrangian

$$L = \frac{I}{2}\dot{\phi}^2 - \frac{\theta}{2\pi}\dot{\phi}.$$

The extra term is a total derivative: it does not change the classical equations of motion. But its integral over a closed Euclidean history is $\theta \times \frac{1}{2\pi}\oint \dot{\phi}\,\mathrm{d}t = \theta \times$ (winding number of the history). So in the path integral histories are weighted by $e^{i\theta\cdot\text{winding}}$. Physically, θ is an Aharonov–Bohm flux threading the ring.

Yang–Mills: large gauge transformations on the Hilbert space

In the quantum theory the Gauss law $D_iE_i = 0$ generates small gauge transformations, and physical states are invariant under them. The large ones are not generated by the Gauss law. Let $\mathcal{T}$ be the unitary operator that implements g_1. It commutes with the Hamiltonian (which is gauge invariant), and on the perturbative vacua

$$\mathcal{T}|n\rangle = |n+1\rangle. \tag{8.78}$$

A physical vacuum must be an eigenstate of $\mathcal{T}$, with a unimodular eigenvalue $e^{i\theta}$. The solution is the Bloch-wave superposition, the **θ-vacuum**

$$|\theta\rangle := \sum_{n\in\mathbb{Z}} e^{-in\theta}|n\rangle. \tag{8.79}$$

Check:

$$\mathcal{T}|\theta\rangle \overset{(1)}{=} \sum_n e^{-in\theta}|n+1\rangle \overset{(2)}{=} \sum_{n'} e^{-i(n'-1)\theta}|n'\rangle \overset{(3)}{=} e^{i\theta}|\theta\rangle.$$

(1) (8.78), term by term.
(2) Relabel $n' = n+1$.
(3) Pull out $e^{i\theta}$.

Gauge-invariant operators commute with $\mathcal{T}$, so they cannot connect different θ: each value of $\theta \in [0, 2\pi)$ labels a separate **superselection sector**, a separate version of the theory.

The θ-term in the path integral

The Euclidean amplitude between perturbative vacua is a path integral over fields that tunnel from n to n', i.e. over the sector with instanton number $k = n' - n$ by (8.77): $\langle n'|e^{-HT}|n\rangle = Z_{n'-n}(T)$, depending only on the difference. Then

$$\begin{aligned}\langle\theta'|e^{-HT}|\theta\rangle &\overset{(1)}{=} \sum_{n,n'} e^{in'\theta'}e^{-in\theta}\,Z_{n'-n}(T) \overset{(2)}{=} \sum_n e^{in(\theta'-\theta)}\sum_k e^{ik\theta'}Z_k(T)\\ &\overset{(3)}{=} 2\pi\,\delta(\theta'-\theta)\sum_{k\in\mathbb{Z}} e^{ik\theta}Z_k(T) \overset{(4)}{=} 2\pi\,\delta(\theta'-\theta)\int_{\mathcal{A}}\mathcal{D}A\; e^{-S[A]+i\theta k[A]}.\end{aligned} \tag{8.80}$$

(1) Expand both θ-states by (8.79); the bra carries the complex conjugate phase.
(2) Substitute $n' = n + k$.
(3) $\sum_n e^{in\alpha} = 2\pi\delta(\alpha)$ on $[0, 2\pi)$; set $\theta' = \theta$ in the remaining sum.
(4) Z_k is the path integral over the sector k; summing sectors with the weight $e^{ik\theta}$ is the same as integrating over all fields with the extra factor $e^{i\theta k[A]}$.

So the θ-vacuum is equivalent to adding a **topological term** to the action:

$$S_\theta[A] = S[A] - i\theta\, k[A] = S[A] + \frac{i\theta}{8\pi^2}\int \operatorname{tr} F\wedge F. \tag{8.81}$$

It is a total derivative ($\operatorname{tr} F\wedge F = \mathrm{d}Q_3$), so it never shows up in perturbation theory or in the classical equations. Yet it changes the physics, because it weights the topologically distinct sectors differently. And θ is an angle: since $k\in\mathbb{Z}$, $\theta\mapsto\theta+2\pi$ does nothing.

Dictionary: the θ-term in physics normalisation

With $A = -ig_{\mathrm{YM}}A^aT^a$, $\operatorname{tr}(T^aT^b)=\frac12\delta^{ab}$, and $\tilde F^{a\mu\nu}=\frac12\epsilon^{\mu\nu\rho\sigma}F^a_{\rho\sigma}$ ($\epsilon^{1234}=1$):

$$k \overset{(1)}{=} -\frac{1}{8\pi^2}\int\left(-g_{\mathrm{YM}}^2\right)\tfrac12 F^a\wedge F^a \overset{(2)}{=} \frac{g_{\mathrm{YM}}^2}{16\pi^2}\int \tfrac14\epsilon^{\mu\nu\rho\sigma}F^a_{\mu\nu}F^a_{\rho\sigma}\,\mathrm{d}^4x \overset{(3)}{=} \frac{g_{\mathrm{YM}}^2}{32\pi^2}\int F^a_{\mu\nu}\tilde F^{a\mu\nu}\mathrm{d}^4x.$$

(1) $\operatorname{tr}(F\wedge F) = (-ig_{\mathrm{YM}})^2F^a\wedge F^b\,\operatorname{tr}(T^aT^b)$.
(2) $F^a=\frac12F^a_{\mu\nu}\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu$, and $\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu\wedge\mathrm{d}x^\rho\wedge\mathrm{d}x^\sigma=\epsilon^{\mu\nu\rho\sigma}\mathrm{d}^4x$.
(3) Definition of $\tilde F$.

So the familiar $\mathcal{L}_\theta=\theta\frac{g^2}{32\pi^2}F\tilde F$ is θ times the instanton density. In QCD it violates P and CP; the neutron electric dipole moment bounds $|\theta|\lesssim 10^{-10}$ (the strong CP problem).

The dilute instanton gas: the vacuum energy depends on θ

How big are the Z_k? The Bogomolny bound (Section 3 of this chapter) says $S\geq 8\pi^2|k|/g_{\mathrm{YM}}^2$ in physics normalisation, with equality for (anti-)instantons. The QFT notes [QFT notes §4.13.4, (4.13.13)–(4.13.14)] make the point that such a sector contributes a factor $e^{-8\pi^2|k|/g^2}$, which is invisible at every order of perturbation theory in g. If instantons are rare and far apart (dilute), a configuration with N instantons and $\bar N$ anti-instantons at arbitrary positions and times contributes $(KVTe^{-S_0})^{N+\bar N}/(N!\bar N!)$, with $S_0=8\pi^2/g^2$, V the volume of space, and K a determinant factor from the small fluctuations. Its instanton number is $k=N-\bar N$. Then

$$\begin{aligned}\sum_k e^{ik\theta}Z_k &\overset{(1)}{=} Z_{\mathrm{pert}}\sum_{N,\bar N\geq 0}\frac{\left(KVTe^{-S_0}e^{i\theta}\right)^N}{N!}\frac{\left(KVTe^{-S_0}e^{-i\theta}\right)^{\bar N}}{\bar N!}\\ &\overset{(2)}{=} Z_{\mathrm{pert}}\exp\left(2KVTe^{-S_0}\cos\theta\right)\overset{(3)}{=} e^{-E(\theta)T},\qquad \frac{E(\theta)}{V}=\frac{E_0}{V}-2Ke^{-8\pi^2/g^2}\cos\theta.\end{aligned} \tag{8.82}$$

(1) Each configuration with N instantons and $\bar N$ anti-instantons has $k=N-\bar N$, so $e^{ik\theta}=(e^{i\theta})^N(e^{-i\theta})^{\bar N}$; the $1/N!\bar N!$ removes the relabellings of identical objects.
(2) Two exponential series; $e^{i\theta}+e^{-i\theta}=2\cos\theta$.
(3) At large T, $\langle\theta|e^{-HT}|\theta\rangle\propto e^{-E(\theta)T}$ defines the vacuum energy; $Z_{\mathrm{pert}}=e^{-E_0T}$.

The vacuum energy density is lowest at $\theta=0$ and depends on θ through a non-perturbatively small term. This is the tight-binding band of a particle in a periodic potential (Figure 8.14), with θ as crystal momentum.

Watch out: No instantons in Abelian theories on $\mathbb{R}^4$

The QFT notes [QFT notes §4.13.4] illustrate instantons with the Abelian action $\frac{1}{g^2}\int\operatorname{tr}F\wedge\star F$ and write $\int\operatorname{tr}F\wedge F\in 8\pi^2\mathbb{Z}$. Read that schematically. For $G=\mathrm{U}(1)$ on $\mathbb{R}^4$ (or S^4) every bundle is trivial, because $\pi_3(\mathrm{U}(1))=0$ (Example 8.17); a finite-action Abelian field has

$\int F \wedge F = 0$. Abelian instantons exist only on 4-manifolds with non-zero H^2, such as T^4 or $\mathbb{CP}^2$. On $\mathbb{R}^4$ one needs a non-Abelian group, and SU(2) is the smallest.

Reading Nash (p. 219, (8.15); p. 220, (8.23) with $n = 3$; p. 227, (8.59))

Nash never writes the winding integral. He states that $P_k \to S^4$ has $c_2(P_k) = k$ and that k is the degree of a class in $\pi_3(G)$; the chain (8.70) is the bridge between the two statements. His formula $\pi_0(\mathcal{G}) = \pi_n(G)$ with $n = 3$ is the statement that large gauge transformations of space exist; he uses it himself in (8.59) for the three-dimensional Chern–Simons theory. The formula (8.75) is the simplest case of the $\mathbb{R}/\mathbb{Z}$ property of secondary classes in his (8.45).

Recap

- Finite action on $\mathbb{R}^4 \Rightarrow A \to g_\infty^{-1}\mathrm{d}g_\infty$, with $g_\infty : S^3_\infty \to G$ the clutching function of a bundle over S^4.
- Winding number $w(g) = \frac{1}{24\pi^2}\int \mathrm{tr}(g^{-1}\mathrm{d}g)^3$: an integer, homotopy invariant (its variation is exact), additive; $w(x/|x|) = 1$.
- $\mathrm{tr}\, F \wedge F = \mathrm{d}\,\mathrm{tr}(A\mathrm{d}A + \frac{2}{3}A^3) \Rightarrow k = -\frac{1}{8\pi^2}\int \mathrm{tr}\, F \wedge F = w(g_\infty)$.
- On space S^3, $\pi_0(\mathcal{G}) = \pi_3(G) = \mathbb{Z}$: large gauge transformations. N_{CS} shifts by $n(g)$ under them; vacua $|n\rangle$; instantons tunnel $n \to n + k$.
- θ-vacua $|\theta\rangle = \sum e^{-in\theta}|n\rangle \Leftrightarrow$ the topological term $e^{i\theta k}$ in the path integral; $E(\theta) \propto -e^{-8\pi^2/g^2}\cos\theta$.

8.1.21 From homotopy to cohomology: why and how

Homotopy groups tell us *that* the gauge group and the configuration space have holes. They do not hand us anything we can integrate. In physics we want more: a differential form on $\mathcal{G}$ or on $\mathcal{A}/\mathcal{G}$ that we can write down, evaluate on a family of fields, and put into a path integral or an effective action. That is what cohomology gives. A de Rham class on $\mathcal{G}$ is a closed form μ; its integral over a closed family of gauge transformations (a loop, a sphere) is a number that does not change when the family is deformed.

The prime physical example is the *non-Abelian anomaly* (Chapter 10). The phase of a chiral fermion determinant changes under an infinitesimal gauge transformation ξ by $\delta_\xi \log\det = i\,\mathcal{G}(\xi)$. Here $\mathcal{G}$ is a 1-form on the gauge group, and the Wess–Zumino consistency condition says exactly that it is closed. If it is exact, $\mathcal{G} = \delta\Gamma$, a local counterterm Γ removes it; if not, it is a genuine anomaly. So "is there an anomaly?" becomes "what is $H^1(\mathcal{G})$?". Nash computes $H^*(\mathcal{G})$ and $H^*(B\mathcal{G})$ in this subsection and gives explicit representatives in Section 8.2.

Free part and torsion

Integer cohomology $H^p(X;\mathbb{Z})$ is a finitely generated Abelian group (for the spaces we meet), so it splits as

$$H^p(X;\mathbb{Z}) \cong \mathbb{Z}^{b_p} \oplus (\text{finite group}).$$

The $\mathbb{Z}^{b_p}$ is the **free part**; b_p is the p-th Betti number. The finite group is the **torsion**. De Rham cohomology sees only the free part: $H^p_{\mathrm{dR}}(X) \cong \mathbb{R}^{b_p}$. The reason is simple. If a class x has $2x = 0$,

then every integral of a representing form over a cycle c satisfies $2\int_c \omega = 0$, so the integral is 0; the class is invisible to integration.

Worked example 8.21: Torsion that forms cannot see

Take $X = \mathbb{RP}^3 = \mathrm{SO}(3)$. Its integral homology is $H_1 = \mathbb{Z}_2$ (a loop that goes once round is not a boundary, twice round is), $H_2 = 0$, $H_3 = \mathbb{Z}$. So $H^1_{\mathrm{dR}}(\mathrm{SO}(3)) = 0$: every closed 1-form on SO(3) is exact, although SO(3) has a non-contractible loop. Concretely, a closed 1-form ω integrates to some number c around the generating loop γ; then γ^2 bounds, so

$$2c \overset{(1)}{=} \oint_{\gamma^2} \omega \overset{(2)}{=} \int_\Sigma \mathrm{d}\omega \overset{(3)}{=} 0,$$

(1) Going round γ twice doubles the integral.
(2) $\gamma^2 = \partial\Sigma$ for a surface Σ, and Stokes.
(3) ω is closed.

so $c = 0$. The physical cousin: in Example 8.15 we found $\pi_0(\mathcal{G}) = \mathbb{Z}_2$ for SU(2) on S^4. No de Rham class on $\mathcal{G}$ can detect the two components as being different in a way stable under products, and indeed Witten's SU(2) anomaly is a torsion ("global") effect, not a local one.

Nash states the division of labour clearly: in this chapter only the free part of $H^*(\mathcal{G})$ is computed, by de Rham forms. The torsion, which needs finer tools, is left to the anomaly chapter.

Rational homotopy

The free part is governed by homotopy groups *up to torsion*. For a finitely generated Abelian group π, the tensor product $\pi \otimes \mathbb{Q}$ keeps the free part and kills the torsion: $\mathbb{Z}\otimes\mathbb{Q} = \mathbb{Q}$, $\mathbb{Z}_k \otimes \mathbb{Q} = 0$ (because $1 \otimes q = 1 \otimes k \cdot (q/k) = k \cdot 1 \otimes q/k = 0$). The groups $\pi_i(X) \otimes \mathbb{Q}$ are the **rational homotopy groups**. Two spaces are **rationally homotopy equivalent**, written $X \sim Y$, if there is a map between them (or a chain of maps) inducing isomorphisms $\pi_i \otimes \mathbb{Q}$ for all i (for the simply connected or H-space case we need). Rationally equivalent spaces have the same cohomology with $\mathbb{Q}$ or $\mathbb{R}$ coefficients, so the same de Rham cohomology.

Working definition 8.12 (rational homotopy groups of spheres)

Serre's theorem: the only non-zero rational homotopy groups of spheres are

$$\pi_i(S^{2k-1}) \otimes \mathbb{Q} = \begin{cases} \mathbb{Q}, & i = 2k-1 \\ 0, & \text{otherwise,} \end{cases} \qquad \pi_i(S^{2k}) \otimes \mathbb{Q} = \begin{cases} \mathbb{Q}, & i = 2k \text{ or } i = 4k-1 \\ 0, & \text{otherwise.} \end{cases}$$

How to use it: every entry of a table of homotopy groups of spheres is finite [a finite group, which becomes 0 after $\otimes\mathbb{Q}$] except $\pi_{2k-1}(S^{2k-1}) = \mathbb{Z}$, $\pi_{2k}(S^{2k}) = \mathbb{Z}$ and the extra $\mathbb{Z}$ in $\pi_{4k-1}(S^{2k})$ (for S^2 this is $\pi_3(S^2) = \mathbb{Z}$, generated by the Hopf map [$S^3 \to S^2$, sending a unit vector $(z_1, z_2) \in \mathbb{C}^2$ to the ratio $z_1/z_2 \in \mathbb{C} \cup \{\infty\}$]). Rationally, an odd sphere looks like it has a single hole, in its own dimension.

Check against Table 8.1: the row of $\mathrm{SU}(2) = S^3$ reads $0, 0, \mathbb{Z}, \mathbb{Z}_2, \mathbb{Z}_2, \mathbb{Z}_{12}, \mathbb{Z}_2$, and only π_3 survives $\otimes\mathbb{Q}$.

8.1.22 The unitary group is rationally a product of odd spheres

Nash's (8.25) is

$$\mathrm{U}(N) \sim S^1 \times S^3 \times S^5 \times \cdots \times S^{2N-1}. \tag{8.83}$$

It is not true as an equivalence of spaces: $\mathrm{U}(2) \cong S^1 \times S^3$ is true, but $\mathrm{SU}(3)$ is not $S^3 \times S^5$ (it is a non-trivial S^3 bundle over S^5; compare $\pi_4(\mathrm{SU}(3)) = 0$ with $\pi_4(S^3 \times S^5) = \mathbb{Z}_2$). It is true after $\otimes\mathbb{Q}$. Here is where it comes from.

The fibration tower

$\mathrm{U}(N)$ acts on $\mathbb{C}^N$ preserving lengths, so it acts on the unit sphere $S^{2N-1} \subset \mathbb{C}^N$. The action is transitive: any unit vector can be rotated to $e_N = (0, \ldots, 0, 1)$. The stabiliser of e_N is the set of unitary matrices of the form $\left(\begin{smallmatrix} u & 0 \\ 0 & 1 \end{smallmatrix}\right)$ with $u \in \mathrm{U}(N-1)$. So the map "last column"

$$\mathrm{U}(N-1) \longrightarrow \mathrm{U}(N) \xrightarrow{u \mapsto u e_N} S^{2N-1} \tag{8.84}$$

is a fibre bundle. For $N = 1$ it is $\mathrm{U}(1) = S^1$. For $N = 2$: a matrix in $\mathrm{U}(2)$ is determined by its last column $(b, d)^T$ (a unit vector in $\mathbb{C}^2$, i.e. a point of S^3) and its determinant $e^{i\phi}$:

$$u = \begin{pmatrix} e^{i\phi}\bar{d} & b \\ -e^{i\phi}\bar{b} & d \end{pmatrix}, \qquad \det u = e^{i\phi}(|d|^2 + |b|^2) = e^{i\phi}.$$

So $\mathrm{U}(2) \cong S^1 \times S^3$ exactly.

For larger N the long exact sequence of (8.84) (Eq. (8.38)) tensored with $\mathbb{Q}$ reads, in the only interesting spot,

$$\cdots \to \pi_i(\mathrm{U}(N-1)) \otimes \mathbb{Q} \to \pi_i(\mathrm{U}(N)) \otimes \mathbb{Q} \to \pi_i(S^{2N-1}) \otimes \mathbb{Q} \to \pi_{i-1}(\mathrm{U}(N-1)) \otimes \mathbb{Q} \to \cdots$$

By induction $\pi_*(\mathrm{U}(N-1)) \otimes \mathbb{Q}$ is $\mathbb{Q}$ in degrees $1, 3, \ldots, 2N-3$ and zero otherwise. The sphere contributes one $\mathbb{Q}$ in degree $2N-1$. The connecting map $\pi_{2N-1}(S^{2N-1}) \otimes \mathbb{Q} \to \pi_{2N-2}(\mathrm{U}(N-1)) \otimes \mathbb{Q}$ goes into an even degree, where the group is zero; so it vanishes and the sequence splits. Hence

$$\pi_i(\mathrm{U}(N)) \otimes \mathbb{Q} = \begin{cases} \mathbb{Q}, & i = 1, 3, 5, \ldots, 2N-1 \\ 0, & \text{otherwise,} \end{cases} \tag{8.85}$$

which is also the rational homotopy of $S^1 \times S^3 \times \cdots \times S^{2N-1}$ (homotopy groups of products are products). That is (8.83). For $\mathrm{SU}(N)$ remove the S^1: $\mathrm{SU}(N) \sim S^3 \times \cdots \times S^{2N-1}$.

The de Rham cohomology of $\mathrm{U}(N)$

Rationally equivalent spaces have the same real cohomology, and the Künneth formula says the cohomology of a product is the tensor product. So (Nash's (8.26))

$$H^*_{\mathrm{dR}}(\mathrm{U}(N)) \cong H^*_{\mathrm{dR}}(S^1) \otimes H^*_{\mathrm{dR}}(S^3) \otimes \cdots \otimes H^*_{\mathrm{dR}}(S^{2N-1}) = \Lambda(\omega_1, \omega_3, \ldots, \omega_{2N-1}). \tag{8.86}$$

Each $H^*_{\mathrm{dR}}(S^{2k-1})$ is $\mathbb{R}$ in degrees 0 and $2k-1$, spanned by 1 and a volume form. So the whole ring is the **exterior algebra** on one generator ω_{2k-1} in each odd degree: products of distinct generators, with $\omega_i \wedge \omega_i = 0$ and $\omega_i \wedge \omega_j = -\omega_j \wedge \omega_i$ (both odd). Its dimension is 2^N and its Poincaré polynomial is

$$P_{\mathrm{U}(N)}(t) := \sum_p \dim H^p_{\mathrm{dR}}\, t^p = (1+t)(1+t^3)(1+t^5)\cdots(1+t^{2N-1}).$$

For $\mathrm{U}(2)$: $1 + t + t^3 + t^4$, i.e. $b_0 = b_1 = b_3 = b_4 = 1$, which matches $S^1 \times S^3$. Setting $t = 1$ gives 2^N; setting $t = -1$ gives 0, the Euler characteristic of a compact Lie group (it has a nowhere-vanishing vector field).

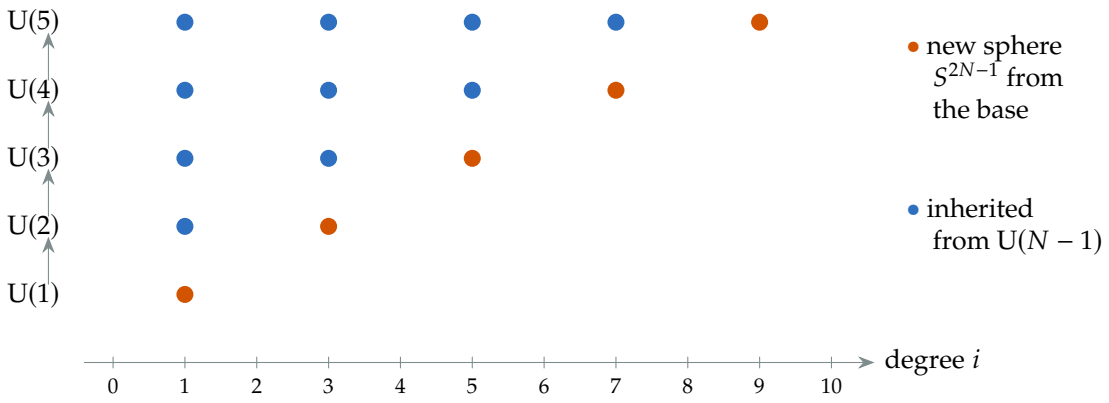

Figure 8.15: Rational homotopy of U(N). Each row lists the degrees i with $\pi_i(\mathrm{U}(N)) \otimes \mathbb{Q} = \mathbb{Q}$. Going up one row (from U($N-1$) to U(N)) the fibration $\mathrm{U}(N-1) \to \mathrm{U}(N) \to S^{2N-1}$ adds exactly one new odd degree, $2N-1$ (orange). All generators sit in odd degrees; that is why nothing can cancel and U(N) looks rationally like $S^1 \times S^3 \times \cdots \times S^{2N-1}$.

Working definition 8.13 (explicit generators ω_{2k-1} on a matrix group)

Let $\theta = g^{-1}\mathrm{d}g$ be the Maurer–Cartan form on $G \subset \mathrm{U}(N)$. The forms

$$\omega_{2k-1} := C_k \operatorname{tr}\!\left(\theta^{2k-1}\right), \qquad k = 1, \dots, N, \tag{8.87}$$

are closed, bi-invariant [unchanged under $g \mapsto hg$ and under $g \mapsto gh$ for any fixed $h \in G$], and represent the generators of (8.86). The constants C_k fix the normalisation; the natural choice, which comes out of the transgression in Section 8.2.5, is

$$C_1 = \frac{i}{2\pi}, \qquad C_2 = \frac{1}{24\pi^2}, \qquad C_3 = -\frac{i}{240\pi^3}.$$

With it, ω_3 is the winding density (8.64). *To test a map* $f : S^{2k-1} \to G$ for non-triviality in $\pi_{2k-1}(G) \otimes \mathbb{Q}$, compute $\int_{S^{2k-1}} f^*\omega_{2k-1}$: it is non-zero exactly when f is rationally non-trivial [no multiple $m[f]$ with $m \neq 0$ is the trivial class, i.e. $[f]$ has infinite order].

Why are the ω_{2k-1} closed? The Maurer–Cartan equation $\mathrm{d}\theta = -\theta^2$ gives

$$\mathrm{d}\operatorname{tr}\theta^m \overset{(1)}{=} \sum_{r=0}^{m-1} (-1)^r \operatorname{tr}\!\left(\theta^r\, \mathrm{d}\theta\, \theta^{m-1-r}\right) \overset{(2)}{=} -\sum_{r=0}^{m-1} (-1)^r \operatorname{tr}\!\left(\theta^{m+1}\right) \overset{(3)}{=} \begin{cases} -\operatorname{tr}\theta^{m+1} = 0, & m \text{ odd} \\ 0, & m \text{ even.} \end{cases}$$

(1) Graded product rule: passing d across r 1-forms costs $(-1)^r$.
(2) $\mathrm{d}\theta = -\theta^2$.
(3) For m odd the alternating sum of m terms is 1, and $\operatorname{tr}\theta^{m+1}$ with $m+1$ even vanishes: cycling one 1-form past the other m (odd degree) costs $(-1)^m = -1$, so $\operatorname{tr}\theta^{m+1} = -\operatorname{tr}\theta^{m+1}$. For m even the alternating sum is 0.

The same cycling argument shows that $\operatorname{tr}\theta^{2k} = 0$: even powers are useless, which is another way to see that only odd generators appear.

Worked example 8.22: The generators of U(1) and U(2) explicitly

U(1). With $g = e^{i\phi}$, $\theta = i\,\mathrm{d}\phi$ and $\omega_1 = \frac{i}{2\pi}\, i\,\mathrm{d}\phi = -\frac{1}{2\pi}\mathrm{d}\phi$. Its integral over the circle is -1. (The sign is the price of the convention $c_1 = \frac{i}{2\pi}F$; we could use $-\omega_1$ as the generator equally well.)

U(2). Write $u = e^{i\phi}h$ with h in SU(2) is not quite possible globally (the pair (ϕ, h) and $(\phi + \pi, -h)$ give the same u), but locally it is fine and $\theta_u = i\,\mathrm{d}\phi\,\mathbb{1} + \theta_h$. Then

$$\omega_1(u) \overset{(1)}{=} \frac{i}{2\pi}\big(2i\,\mathrm{d}\phi + \operatorname{tr}\theta_h\big) \overset{(2)}{=} -\frac{1}{\pi}\mathrm{d}\phi, \qquad \omega_3(u) \overset{(3)}{=} \frac{1}{24\pi^2}\operatorname{tr}\theta_h^3.$$

(1) $\operatorname{tr}\mathbb{1} = 2$.
(2) $\operatorname{tr}\theta_h = \operatorname{tr}(h^{-1}\mathrm{d}h) = \mathrm{d}\log\det h = 0$ for $h \in \mathrm{SU}(2)$.
(3) Expand $(i\,\mathrm{d}\phi\,\mathbb{1} + \theta_h)^3$; every term with two or more $\mathrm{d}\phi$ vanishes, and the terms with one $\mathrm{d}\phi$ give $3i\,\mathrm{d}\phi\operatorname{tr}\theta_h^2 = 0$ (tr of an even power).

So ω_1 measures the phase winding and ω_3 the SU(2) winding, and the ring is $\Lambda(\omega_1, \omega_3)$ with top class $\omega_1 \wedge \omega_3$ in degree $4 = \dim \mathrm{U}(2)$.

8.1.23 The evaluation map and integration over S^n

We now transport the generators ω_i of $H^*_{\mathrm{dR}}(G)$ to the gauge group $\mathcal{G}$. Recall that here $\mathcal{G}$ is the based gauge group of a bundle over $M = S^n$, which is homotopy equivalent to $\mathrm{Map}_0(S^n, G) = \Omega^n G$ (Section 8.1.13), and that Nash takes n even. The tool is the **evaluation map** (Nash's (8.27)):

$$\mathrm{Ev} : S^n \times \mathcal{G} \longrightarrow G, \qquad (x, \alpha) \longmapsto \alpha(x). \tag{8.88}$$

It is the most natural map there is: a point of $\mathcal{G}$ is a map $\alpha : S^n \to G$, and we evaluate it. Pull the generator back (Nash's (8.28)): $\mathrm{Ev}^*\omega_i$ is a closed i-form on the product $S^n \times \mathcal{G}$. Then "divide out" the S^n by integrating over it (Nash's (8.29)):

$$\mu_{i-n} := \int_{S^n} \mathrm{Ev}^*\omega_i \;\in\; H^{i-n}_{\mathrm{dR}}(\mathcal{G}). \tag{8.89}$$

Integration over the fibre

What does $\int_{S^n}$ of a form on $S^n \times Y$ mean? Use coordinates x on S^n and y on Y. Every form on the product is a sum of pieces of **bidegree** (p, q): p legs along S^n, q along Y. We always write the S^n legs first:

$$\beta = \sum f_{IJ}(x, y)\,\mathrm{d}x^I \wedge \mathrm{d}y^J, \qquad |I| = p,\ |J| = q.$$

Working definition 8.14 (integration over the fibre S^n)

For β of total degree r [$p + q = r$ for every piece] on $S^n \times Y$, keep only the part with $p = n$ and integrate out x:

$$\int_{S^n} \beta := \sum_{|J| = r-n} \Big(\int_{S^n} f_{IJ}(x, y)\,\mathrm{d}x^I\Big)\,\mathrm{d}y^J \qquad (|I| = n).$$

The result is an $(r - n)$-form on Y. The pieces with $p < n$ are thrown away (they cannot be integrated over an n-dimensional space).

The one property we need: *integration over a closed fibre commutes with* d (up to a sign), so it maps closed forms to closed forms and exact to exact, and so is well defined on cohomology. Write $\mathrm{d} = \mathrm{d}_x + \mathrm{d}_y$. Then

$$\mathrm{d}_Y \int_{S^n} \beta \overset{(1)}{=} \int_{S^n} (-1)^n\,\mathrm{d}_y\beta \overset{(2)}{=} (-1)^n \int_{S^n} (\mathrm{d}\beta - \mathrm{d}_x\beta) \overset{(3)}{=} (-1)^n \int_{S^n} \mathrm{d}\beta. \tag{8.90}$$

(1) d_y acts on the coefficient functions and on the $\mathrm{d}y^J$; to bring a new $\mathrm{d}y^k$ to the right of the n legs $\mathrm{d}x^I$ costs $(-1)^n$. Differentiation under the integral sign in x is harmless.
(2) $\mathrm{d}_y = \mathrm{d} - \mathrm{d}_x$.
(3) The $(n, *)$ part of $\mathrm{d}_x\beta$ comes from the $(n-1, *)$ part of β and is exact along S^n; its integral over the closed S^n is zero by Stokes ($\partial S^n = \varnothing$).

So $\mathrm{d}\beta = 0$ implies $\mathrm{d}\int_{S^n}\beta = 0$, and $\beta = \mathrm{d}\gamma$ implies $\int\beta = \pm\mathrm{d}\int\gamma$.

Worked example 8.23: Integration over the fibre on a torus

Let $S^1 \times S^1$ have angles x (the fibre) and y. For $\beta = \cos^2 x\,\mathrm{d}x \wedge \mathrm{d}y + \sin y\,\mathrm{d}y$,

$$\int_{S^1_x}\beta \overset{(1)}{=} \Big(\int_0^{2\pi}\cos^2 x\,\mathrm{d}x\Big)\mathrm{d}y \overset{(2)}{=} \pi\,\mathrm{d}y.$$

(1) Only the $(1,1)$ piece has a full fibre leg; the $(0,1)$ piece $\sin y\,\mathrm{d}y$ is discarded.
(2) $\int_0^{2\pi}\cos^2 x\,\mathrm{d}x = \pi$.

β is closed (a top form plus $\mathrm{d}(-\cos y)$), and the result $\pi\,\mathrm{d}y$ is closed too, as (8.90) promises.

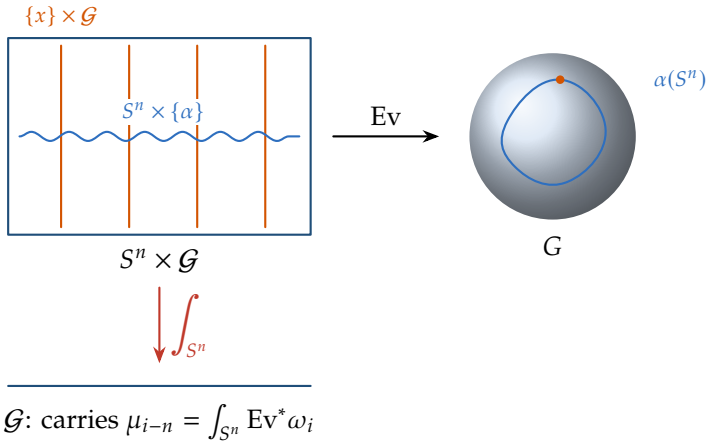

Figure 8.16: The evaluation map. A horizontal slice $S^n \times \{\alpha\}$ of the product is mapped by Ev onto the image $\alpha(S^n)$ of the gauge transformation α; a vertical line $\{x\} \times \mathcal{G}$ records the values of all gauge transformations at one point x. Pulling back an i-form on G and integrating out the n horizontal directions leaves an $(i-n)$-form on $\mathcal{G}$.

What μ_{i-n} measures

Why should μ_{i-n} be non-trivial? Take a family of gauge transformations parametrised by a sphere, $f : S^m \to \mathcal{G}$, $s \mapsto \alpha_s$, with $m = i - n$. By the adjunction of Section 8.1.13 it is the same thing as a single map $F : S^m \times S^n \to G$, $F(s,x) = \alpha_s(x)$, which sends $S^m \times \{x_0\} \cup \{s_0\} \times S^n$ to $\mathbb{1}$ and hence factors through $S^m \wedge S^n = S^{m+n}$. Then

$$\int_{S^m} f^*\mu_m \overset{(1)}{=} \int_{S^m}\int_{S^n}(\mathrm{id}\times f)^*\mathrm{Ev}^*\omega_{m+n} \overset{(2)}{=} \int_{S^n\times S^m} F^*\omega_{m+n} \overset{(3)}{=} \int_{S^{m+n}}\bar{F}^*\omega_{m+n}. \tag{8.91}$$

(1) Definition (8.89); pulling back along f commutes with integrating over the fibre S^n (a change of variables in y only).
(2) Fubini: integrating first over S^n and then over S^m is integrating over the product; $\mathrm{Ev} \circ (\mathrm{id} \times f) = F$.

(3) F factors through the quotient map $S^n \times S^m \to S^{m+n}$, which has degree one, as $F = \bar{F} \circ q$.

The right-hand side is the test of Eq. (8.87) for the element $[\bar{F}] \in \pi_{m+n}(G) = \pi_m(\mathcal{G})$. So μ_m pairs with the rational homotopy of $\mathcal{G}$ exactly as ω_{m+n} pairs with that of G. *Integration over S^n is the cohomological shadow of the shift $\pi_m(\mathcal{G}) = \pi_{m+n}(G)$.*

Worked example 8.24: $n = 1$ and $n = 3$: μ_0 counts windings

Although Nash takes n even, odd n is the best warm-up.
$n = 1$, $G = \mathrm{U}(1)$. $\mathcal{G} = \Omega\mathrm{U}(1)$, the based loops $\alpha : S^1 \to \mathrm{U}(1)$. The only generator is ω_1, so the only μ is

$$\mu_0(\alpha) \overset{(1)}{=} \int_{S^1} \alpha^* \omega_1 \overset{(2)}{=} \frac{i}{2\pi} \oint \alpha^{-1} \mathrm{d}\alpha \overset{(3)}{=} -\frac{1}{2\pi} \oint \mathrm{d}\lambda = -\operatorname{wind}(\alpha),$$

(1) A 0-form on $\mathcal{G}$ is a function; at a point α of $\mathcal{G}$, the slice $S^1 \times \{\alpha\}$ is mapped by α itself.
(2) (8.87) with $C_1 = i/2\pi$.
(3) Write $\alpha = e^{i\lambda(x)}$ locally; $\alpha^{-1}\mathrm{d}\alpha = i\,\mathrm{d}\lambda$.

A closed 0-form is a locally constant function: μ_0 labels the components of $\mathcal{G}$ by the winding number, and $H^0_{\mathrm{dR}}(\mathcal{G})$ is the space of functions on $\pi_0(\mathcal{G}) = \mathbb{Z}$.
$n = 3$, $G = \mathrm{SU}(2)$. Likewise $\mu_0 = \int_{S^3} \alpha^* \omega_3 = w(\alpha)$, the winding number (8.64). This is the label of large gauge transformations in Section 8.1.19, now seen as the simplest of Nash's cohomology classes.

8.1.24 H-spaces, Hopf algebras, and the cohomology of $\mathcal{G}$

Nash next argues that the μ's *generate* the whole cohomology ring, with no relations beyond those of an exterior algebra. The argument has two ingredients: a structure theorem for the cohomology of group-like spaces, and the rational homotopy of $\mathcal{G}$.

H-spaces and Hopf algebras

An **H-space** is a space X with a continuous multiplication $X \times X \to X$ that has a unit up to homotopy. Every topological group is an H-space. So is $\mathcal{G}$ (pointwise multiplication of gauge transformations), and so is every loop space ΩY (concatenation of loops; the constant loop is a unit up to reparametrisation). The multiplication $m : X \times X \to X$ gives, on cohomology, a **coproduct**

$$m^* : H^*(X) \to H^*(X \times X) = H^*(X) \otimes H^*(X).$$

Together with the cup (wedge) product this makes $H^*(X; \mathbb{Q})$ a **Hopf algebra**. A class x is **primitive** if $m^* x = x \otimes 1 + 1 \otimes x$: it behaves additively under multiplication, like a logarithm.

Worked example 8.25: The winding forms are primitive

The winding number is additive, $w(gh) = w(g) + w(h)$ (8.68). At the level of forms, the computation in that proof says $m^*\omega_3 = \omega_3 \otimes 1 + 1 \otimes \omega_3 + \mathrm{d}(\ldots)$. So ω_3 is primitive. The same holds for every ω_{2k-1} and for the μ's. The products $\omega_1 \wedge \omega_3$ and so on are not primitive.

Key idea: Hopf's theorem (as Nash quotes it, with Whitehead)

For a connected H-space X of finite type, the rational cohomology is the free graded-commutative algebra on the dual of the rational homotopy:

$$H^*(X;\mathbb{Q}) \cong S(A) \otimes \Lambda(A), \qquad A^i := (\pi_i(X) \otimes \mathbb{Q})^*, \tag{8.92}$$

where $S(A) = \bigotimes_i S(A^{2i})$ is the polynomial algebra on the even-degree generators and $\Lambda(A) = \bigotimes_i \Lambda(A^{2i-1})$ is the exterior algebra on the odd-degree ones.

Why is it plausible? For an H-space the rational Hurewicz map is injective onto the primitives, so each rational homotopy class of degree i gives one primitive cohomology generator of degree i. Generators of odd degree anticommute with themselves ($x \wedge x = -x \wedge x$), so their squares vanish: exterior. Generators of even degree commute with themselves, and in an H-space nothing forces their powers to vanish: polynomial. The theorem says there are no other relations.

Worked example 8.26: An exterior and a polynomial case

- $X = \mathrm{U}(N)$: $\pi_* \otimes \mathbb{Q}$ in degrees $1, 3, \dots, 2N-1$, all odd, so $H^* = \Lambda(\omega_1, \dots, \omega_{2N-1})$, as in (8.86). The ring is finite dimensional, as it must be for a compact manifold.
- $X = \Omega S^3$ (based loops in SU(2)): $\pi_i(\Omega S^3) = \pi_{i+1}(S^3)$, so the only rational class is in degree 2. Hence $H^*(\Omega S^3;\mathbb{Q}) = \mathbb{Q}[y]$ with $\deg y = 2$: one class in *every* even degree, $1, y, y^2, \dots$. This infinite ladder is exactly what the Morse theory of geodesics on S^3 produces (Chapter 7): the k-th family of closed geodesics has index $2k$.
- $X = \mathbb{CP}^\infty = B\mathrm{U}(1)$: $\pi_2 = \mathbb{Z}$ only; $H^* = \mathbb{Q}[c_1]$, the polynomial ring on the first Chern class. (Every $K(\mathbb{Z},2)$ is an H-space.)

Applying Hopf to $\mathcal{G}$

Now Nash's (8.31)–(8.33). We have $\mathcal{G} \simeq \Omega^n G$ and $G \sim S^1 \times S^3 \times \cdots \times S^{2N-1}$. Loop spaces of products are products of loop spaces, so

$$\pi_i(\mathcal{G}) \otimes \mathbb{Q} \overset{(1)}{=} \pi_{n+i}(G) \otimes \mathbb{Q} \overset{(2)}{=} \bigoplus_{j=1}^{N} \pi_{n+i}(S^{2j-1}) \otimes \mathbb{Q} \overset{(3)}{=} \bigoplus_{j=1}^{N} H^{n+i}(S^{2j-1};\mathbb{Q}). \tag{8.93}$$

(1) $\pi_i(\Omega^n G) = \pi_{n+i}(G)$, (8.56).
(2) (8.83): rationally G is the product of odd spheres, and π_* of a product is the direct sum.
(3) Serre: $\pi_k(S^{2j-1}) \otimes \mathbb{Q}$ is $\mathbb{Q}$ exactly when $k = 2j-1$, which is also exactly when $H^k(S^{2j-1};\mathbb{Q}) = \mathbb{Q}$ ($k > 0$).

So $\pi_i(\mathcal{G}) \otimes \mathbb{Q} \neq 0$ only when $n + i = 2j - 1$ for some $j \leq N$:

$$i = 2j - n - 1, \qquad j = 1, \dots, N, \qquad i \geq 0. \tag{8.94}$$

For n even, i is *odd*. There are no even-degree generators, so the symmetric factor $S(A)$ in (8.92) is trivial and

$$H^*_{\mathrm{dR}}(\mathcal{G}) \cong \Lambda\big(\mu_{2j-1-n} \,:\, 2j-1 \geq n+1,\ j \leq N\big). \tag{8.95}$$

By (8.91) each μ_{2j-1-n} pairs non-trivially with the rational generator of $\pi_{2j-1-n}(\mathcal{G})$, so the μ's built by the evaluation map are precisely a set of generators. This is Nash's conclusion below (8.33).

Watch out: Components of $\mathcal{G}$

Hopf's theorem is for a *connected* H-space, but $\mathcal{G}$ has $\pi_0(\mathcal{G}) = \pi_n(G)$ components. For n even, $\pi_n(G) \otimes \mathbb{Q} = 0$, so there are only finitely many components, all homotopy equivalent (multiply by a fixed element of each component). Apply the theorem to the identity component and take one copy per component; in degree 0 this gives the functions on $\pi_0(\mathcal{G})$. For odd n the case $i = 0$ in (8.94) occurs, and μ_0 counts the infinitely many components (Example 8.24).

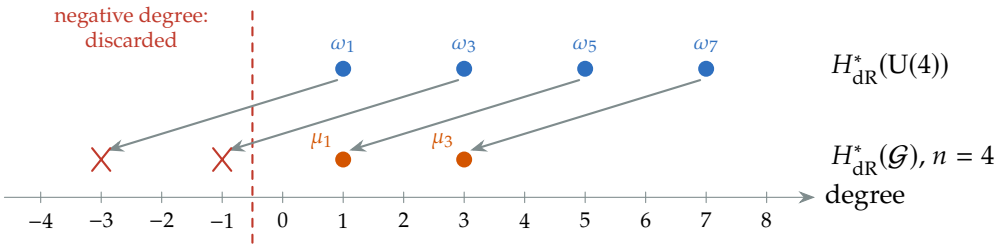

Figure 8.17: Degree shift by integration over S^4, for $G = \mathrm{U}(4)$. Each generator ω_i of the group (blue, degree i) produces μ_{i-4} on the gauge group (orange). Those that would land in negative degree (ω_1, ω_3) give nothing. What survives, μ_1 and μ_3, generates $H^*_{\mathrm{dR}}(\mathcal{G}) = \Lambda(\mu_1, \mu_3)$: Nash's table (8.38).

8.1.25 The cohomology of the configuration space $B\mathcal{G}$

The same method works for $B\mathcal{G} = \mathcal{A}/\mathcal{G}$. Now we use the homotopy equivalence (Nash's (8.34), our (8.53))

$$B\mathcal{G} \simeq \mathrm{Map}_0(S^n, BG),$$

a point of which is (the classifying map of) a G-bundle on S^n together with a connection, up to gauge. The evaluation map is now (Nash's (8.35))

$$\mathrm{Ev} : S^n \times \mathrm{Map}_0(S^n, BG) \longrightarrow BG, \qquad (x, \alpha) \mapsto \alpha(x). \tag{8.96}$$

The cohomology of BG is well known. For $G = \mathrm{U}(N)$ it is the polynomial ring on the universal Chern classes,

$$H^*(B\mathrm{U}(N); \mathbb{Z}) = \mathbb{Z}[c_1, c_2, \ldots, c_N], \qquad c_i \in H^{2i}(B\mathrm{U}(N)).$$

(For $N = 1$ this is $H^*(\mathbb{CP}^\infty) = \mathbb{Z}[c_1]$ of Example 8.26.) "Universal" means: for a bundle $P \to X$ with classifying map $f : X \to BG$, $c_i(P) = f^* c_i$. So we set (Nash's (8.36))

$$\nu_{2i-n} := \int_{S^n} \mathrm{Ev}^* c_i \ \in \ H^{2i-n}_{\mathrm{dR}}(B\mathcal{G}). \tag{8.97}$$

With $n = 2m$ (Nash's (8.37)),

$$\mu_{i-2m} \in H^{i-2m}_{\mathrm{dR}}(\mathcal{G}) \ (i \text{ odd}), \qquad \nu_{2i-2m} \in H^{2i-2m}_{\mathrm{dR}}(B\mathcal{G}). \tag{8.98}$$

The generators of $H^*_{\mathrm{dR}}(\mathcal{G})$ are all of odd degree, those of $H^*_{\mathrm{dR}}(B\mathcal{G})$ all of even degree. This matches the rational homotopy: $\pi_k(B\mathcal{G}) \otimes \mathbb{Q} = \pi_{k-1}(\mathcal{G}) \otimes \mathbb{Q}$ is non-zero only for $k - 1$ odd. For $n \geq 2$, $B\mathcal{G} \simeq \Omega^{n-1} G$ is itself an H-space, so Hopf's theorem applies and gives a *polynomial* ring:

$$H^*_{\mathrm{dR}}(B\mathcal{G}) \cong \mathbb{R}\big[\nu_{2i-n} \ : \ 2i > n, \ i \leq N\big] \quad \text{(on each component)}. \tag{8.99}$$

Worked example 8.27: ν_0 is the instanton number

Take $n = 4$, $G = \mathrm{SU}(N)$ and $i = 2$. Then $\nu_0 = \int_{S^4} \mathrm{Ev}^* c_2$ is a function on $\mathrm{Map}(S^4, BG)$. At a point α (a bundle P with connection A),

$$\nu_0(\alpha) \overset{(1)}{=} \int_{S^4} \alpha^* c_2 \overset{(2)}{=} \int_{S^4} c_2(P) \overset{(3)}{=} \frac{1}{8\pi^2} \int_{S^4} \operatorname{tr} F \wedge F \overset{(4)}{=} -k.$$

(1) On the slice $S^4 \times \{\alpha\}$ the evaluation map is α.
(2) Universality: $\alpha^* c_2 = c_2$ of the bundle classified by α.
(3) Chern–Weil representative of c_2 for $\mathrm{SU}(N)$ (Eq. (8.10)).
(4) Definition of the instanton number.

So ν_0 is locally constant and labels the components $B\mathcal{G}_k$ of the space of all bundles-with-connection by their instanton number. In the text we mostly work on one component, where ν_0 is a constant. (Also $\nu_{-2} = \int_{S^4} c_1 = 0$: an S^4 has no 2-cycles.)

Worked example 8.28: $n = 2$, $G = \mathrm{SU}(2)$: a polynomial ring

Two-dimensional Yang–Mills on S^2. Here $B\mathcal{G} \simeq \Omega S^3$, and the only Chern class is c_2, giving $\nu_{4-2} = \nu_2 = \int_{S^2} \mathrm{Ev}^* c_2 \in H^2(B\mathcal{G})$. By Example 8.26,

$$H^*_{\mathrm{dR}}(\mathcal{A}/\mathcal{G}) = \mathbb{R}[\nu_2] : \quad \mathbb{R} \text{ in every even degree},$$

spanned by $1, \nu_2, \nu_2^2, \ldots$ This is the infinite-dimensional analogue of $\mathbb{CP}^\infty$. (Atiyah and Bott used exactly this ring, via Morse theory of the Yang–Mills functional, to study moduli of flat connections on Riemann surfaces.) Meanwhile $\mathcal{G} \simeq \Omega^2 S^3$ has $\pi_1(\mathcal{G}) = \pi_3(S^3) = \mathbb{Z}$ and $H^*_{\mathrm{dR}}(\mathcal{G}) = \Lambda(\mu_1)$ with $\mu_1 = \int_{S^2} \mathrm{Ev}^* \omega_3$.

Nash's table (8.38): how the answer grows with N

Fix $n = 4$ ($M = S^4$). The group $\mathrm{U}(N)$ has generators $\omega_1, \omega_3, \ldots, \omega_{2N-1}$, giving μ_{i-4} for $i \geq 5$, i.e. $\mu_1, \mu_3, \ldots, \mu_{2N-5}$. The Chern classes $c_1, \ldots, c_N$ give ν_{2i-4} for $i \geq 3$, i.e. $\nu_2, \nu_4, \ldots, \nu_{2N-4}$.

G	generators of $H^*_{\mathrm{dR}}(G)$	generators of $H^*_{\mathrm{dR}}(\mathcal{G})$	$P_{\mathcal{G}}(t)$	generators of $H^*_{\mathrm{dR}}(B\mathcal{G})$
$\mathrm{U}(1)$	ω_1	none	1	none
$\mathrm{U}(2)$	ω_1, ω_3	none	1	none
$\mathrm{U}(3)$	$\omega_1, \omega_3, \omega_5$	μ_1	$1 + t$	ν_2
$\mathrm{U}(4)$	$\omega_1, \ldots, \omega_7$	μ_1, μ_3	$(1 + t)(1 + t^3)$	ν_2, ν_4
$\mathrm{U}(N)$	$\omega_1, \ldots, \omega_{2N-1}$	$\mu_1, \ldots, \mu_{2N-5}$	$\prod_{j=3}^{N}(1 + t^{2j-5})$	$\nu_2, \ldots, \nu_{2N-4}$

Table 8.2: Real cohomology of the (based) gauge group and of the configuration space for $M = S^4$ (Nash's (8.38) completed). U(3) is the first group with any free cohomology in positive degree. Nothing changes if $\mathrm{U}(N)$ is replaced by $\mathrm{SU}(N)$, because the lost generator ω_1 gives nothing on S^4 anyway.

Watch out: "has just" in Nash's table

Nash writes that U(4) "has just $H^1(\mathcal{G}) \neq 0$, $H^3(\mathcal{G}) \neq 0$". He means *generators*. The ring also contains the product $\mu_1 \wedge \mu_3$, so $H^4(\mathcal{G}) \neq 0$ as well. For $B\mathcal{G}$ there are all monomials $\nu_2^a \nu_4^b$, so $H^{2k}(B\mathcal{G}) \neq 0$ for every k once $N \geq 3$.

Three physical remarks.

- SU(2) *on S^4 has no free cohomology at all* (beyond degree 0). The only topology of its gauge group visible to de Rham forms is nothing; the $\mathbb{Z}_2 = \pi_0(\mathcal{G})$ of Example 8.15 is pure torsion. So the perturbative (local) non-Abelian anomaly cannot occur for SU(2); only the global Witten anomaly can. This matches the group theory: the anomaly coefficient $\operatorname{tr} T^a\{T^b, T^c\}$ vanishes for SU(2) (all its representations are pseudo-real).

- SU(3) *(colour) is the first case with $H^1(\mathcal{G}) \neq 0$.* The class μ_1 is the one that represents the four-dimensional non-Abelian anomaly; its partner $\nu_2 \in H^2(\mathcal{A}/\mathcal{G})$ is the first Chern class of the determinant line bundle of the chiral Dirac operator (Chapter 10).

- *The integral in* (8.91) *is an integer multiple of a fixed number.* For SU(3) and the normalisation of Eq. (8.87), a generator of $\pi_5(\mathrm{SU}(3)) = \mathbb{Z}$ gives $\int_{S^5} \omega_5 = \pm 2$, not ± 1 (Bott: the c_3-normalised form is divisible by $(3-1)!$ on spheres). The rational statements do not care.

Reading Nash (pp. 220–223, (8.25)–(8.38))

Nash's "$G \sim S^1 \times \cdots \times S^{2N-1}$" is a rational homotopy equivalence, not a homeomorphism; we derived it from the fibrations (8.84). His (8.27)–(8.29) are our (8.88) and (8.89); the reason the μ's generate is the pairing (8.91), which he leaves implicit. The Hopf–Whitehead structure theorem (8.30) is our (8.92); he writes it for a group $\hat{\mathcal{G}}$ and then applies it to $\mathcal{G}$. His (8.32) contains the isomorphism $\pi_{n+i}(S^{2j-1}) \otimes \mathbb{Q} \cong H^{n+i}(S^{2j-1}; \mathbb{Q})$, which is Serre's theorem for odd spheres. The last sentence of §1 ("no sensitivity to the difference between U(N) and SU(N)") is the remark under Table 8.2.

Recap: cohomology of $\mathcal{G}$ and $B\mathcal{G}$

- De Rham forms see the free part of cohomology, i.e. rational homotopy; torsion (such as Witten's $\mathbb{Z}_2$) needs other tools.
- $\mathrm{U}(N) \sim S^1 \times S^3 \times \cdots \times S^{2N-1}$, so $H^*_{\mathrm{dR}}(\mathrm{U}(N)) = \Lambda(\omega_1, \ldots, \omega_{2N-1})$ with $\omega_{2k-1} \propto \operatorname{tr}(g^{-1}\mathrm{d}g)^{2k-1}$.
- $\mu_{i-n} = \int_{S^n} \mathrm{Ev}^* \omega_i$ and $\nu_{2i-n} = \int_{S^n} \mathrm{Ev}^* c_i$; integration over S^n lowers degrees by n, mirroring $\pi_m(\mathcal{G}) = \pi_{m+n}(G)$.
- For n even: $H^*_{\mathrm{dR}}(\mathcal{G})$ is exterior on odd μ's, $H^*_{\mathrm{dR}}(B\mathcal{G})$ polynomial on even ν's. On S^4: μ_1, ν_2 appear first for U(3).

Summary of Section 8.1

Recap: the topology of gauge fields

- $\mathcal{A}$ is affine, hence contractible; the based gauge group $\mathcal{G}$ acts on it freely (parallel transport commutes with gauge transformations); the holonomy group measures the stabiliser of the full group.
- $\mathcal{G} \to \mathcal{A} \to \mathcal{A}/\mathcal{G}$ is a principal bundle with contractible total space, so $\mathcal{A}/\mathcal{G} = B\mathcal{G}$ and $\pi_k(\mathcal{A}/\mathcal{G}) = \pi_{k-1}(\mathcal{G})$. It is not trivial: no global gauge fixing exists (Gribov).
- On S^n: bundles are clutched by $S^{n-1} \to G$; $\mathcal{G} \simeq \Omega^n G$, $B\mathcal{G} \simeq \Omega^{n-1} G \simeq \mathrm{Map}_0(S^n, BG)$; homotopy groups shift by n.
- On $\mathbb{R}^4$: finite action $\Rightarrow A \to g^{-1}\mathrm{d}g$ at infinity, and the instanton number is the winding $\frac{1}{24\pi^2}\int \mathrm{tr}(g^{-1}\mathrm{d}g)^3$. On $\mathbb{R}^3$: large gauge transformations, N_{CS} shifts by integers, θ-vacua.
- Cohomology: $H^*_{\mathrm{dR}}(\mathcal{G}) = \Lambda(\mu)$, $H^*_{\mathrm{dR}}(B\mathcal{G}) = \mathbb{R}[\nu]$, built by evaluation and integration over S^n.

8.2 Secondary characteristic classes

At the end of Section 8.1 we had the cohomology of the gauge group $\mathcal{G}$ and of the configuration space $B\mathcal{G} = \mathcal{A}/\mathcal{G}$, described by generators μ_{i-n} and ν_{2i-n}. They were built by an abstract recipe: evaluate, pull back a class from G or BG, integrate over S^n. A physicist wants more. Which *differential form*, built from the gauge potential, represents μ_1? How would we write it in a Lagrangian, or recognise it in a Feynman diagram calculation? Nash's Section 2 answers this. The answer is the **Chern–Simons form**, and the construction behind it is Chern's theory of **secondary characteristic classes**.

The central idea fits in one sentence.

Key idea: The principle of secondary classes

When a characteristic class $c_j(F)$ *vanishes*, its vanishing is not the end of the story: the form that makes it vanish (the β with $c_j = \mathrm{d}\beta$) carries new, finer information. That β is a *secondary* class. It is only defined up to integers, so it lives in $\mathbb{R}/\mathbb{Z}$ rather than in $\mathbb{Z}$.

We have met this already twice without naming it. The Chern–Simons number N_{CS} of Section 8.1.19 was gauge invariant only modulo integers. And the phase of an Aharonov–Bohm holonomy is a real number defined modulo 2π. In this section we see that both are instances of one construction. The plan is:

1. a warm-up in one dimension, where everything is elementary;
2. a reminder of invariant polynomials and Chern–Weil theory, the machine that produces $c_j(F)$;
3. the *transgression formula* (Nash's (8.42)): on the total space P of the bundle, every $c_j(F)$ becomes exact, $\pi^* c_j = \mathrm{d}TP_j$;
4. the Chern–Simons forms $TP_j(A)$, written out for $j = 1, 2, 3$;
5. what TP_j does on a single fibre (it gives the generators ω_{2j-1} of $H^*_{\mathrm{dR}}(G)$ from Section 8.1.25);

6. the secondary class and its $\mathbb{R}/\mathbb{Z}$ nature (Nash's (8.43)–(8.45));
7. the formulae for μ and ν (Nash's (8.46)–(8.58)), and the three-dimensional Chern–Simons gauge theory (Nash's (8.59)–(8.62)).

8.2.1 Warm-up: the holonomy of a flat $\mathrm{U}(1)$ connection

Take the simplest possible case: $G = \mathrm{U}(1)$ and $M = S^1$, a circle of circumference L with coordinate $x \in [0, L)$. A connection is $A = i\,a(x)\,\mathrm{d}x$ with a real (anti-Hermitian convention; a is the physicist's vector potential times the charge). Its curvature is a 2-form on a 1-manifold, so $F = 0$: *every* connection on a circle is flat, and the first Chern class $c_1(F) = \frac{i}{2\pi}F$ vanishes identically, as a form.

Does the connection then carry no information? It does carry some: the holonomy around the circle. Parallel transport solves $\mathrm{d}\psi/\mathrm{d}x + a_x\, i\,\psi = 0$ (Section 8.1.7 with $A(\dot\gamma) = ia$), so

$$\mathrm{Hol}(A) = \exp\Big(-\oint_{S^1} A\Big) = \exp\Big(-i\oint a\,\mathrm{d}x\Big), \tag{8.100}$$

the Aharonov–Bohm phase. Now form the first-order expression that Chern–Weil theory would suggest,

$$TP_1(A) \coloneqq \frac{i}{2\pi}A, \qquad \int_{S^1} TP_1(A) = \frac{i}{2\pi}\oint i\,a\,\mathrm{d}x = -\frac{1}{2\pi}\oint a\,\mathrm{d}x. \tag{8.101}$$

It is a *potential* for c_1, in the sense that $\mathrm{d}TP_1(A) = \frac{i}{2\pi}\mathrm{d}A = c_1(F)$. Here $c_1(F) = 0$, so $TP_1(A)$ is closed (every 1-form on a circle is), and its integral is a real number.

How does this number change under a gauge transformation $g = e^{i\lambda(x)}$? The function λ need not be periodic: only $e^{i\lambda}$ must be, so $\lambda(L) - \lambda(0) = 2\pi m$ with $m \in \mathbb{Z}$ the winding number of g. Then $A^g = A + g^{-1}\mathrm{d}g = A + i\,\mathrm{d}\lambda$ and

$$\begin{aligned}\int_{S^1} TP_1(A^g) &\overset{(1)}{=} \frac{i}{2\pi}\oint \big(A + i\,\mathrm{d}\lambda\big) \overset{(2)}{=} \int_{S^1} TP_1(A) - \frac{1}{2\pi}\big(\lambda(L) - \lambda(0)\big)\\ &\overset{(3)}{=} \int_{S^1} TP_1(A) - m.\end{aligned} \tag{8.102}$$

(1) The U(1) transformation law $A \mapsto A + g^{-1}\mathrm{d}g$ with $g^{-1}\mathrm{d}g = i\,\mathrm{d}\lambda$.
(2) $\frac{i}{2\pi}\cdot i = -\frac{1}{2\pi}$, and the fundamental theorem of calculus for $\oint \mathrm{d}\lambda$ on the interval $[0, L]$.
(3) λ winds by $2\pi m$ around the circle.

Worked example 8.29: The number that survives

Take the constant potential $a = \Phi/L$, so $\oint a\,\mathrm{d}x = \Phi$ is the flux threading the ring (in units where the charge is 1). Then $\int TP_1(A) = -\Phi/2\pi$. The large gauge transformation $g = e^{2\pi i m x/L}$ shifts $\Phi \mapsto \Phi + 2\pi m$ and $\int TP_1 \mapsto \int TP_1 - m$. So:

- the real number $\int TP_1(A)$ is *not* gauge invariant;
- its class modulo integers, $\int TP_1(A) \bmod 1 \in \mathbb{R}/\mathbb{Z}$, *is*;
- and $\exp\big(2\pi i \int TP_1(A)\big) = e^{-i\Phi} = \mathrm{Hol}(A)$, the Aharonov–Bohm phase of (8.100).

The rotor of Example 8.20, with its energy levels $\frac{1}{2I}(m + \theta/2\pi)^2$, sees exactly this $\mathbb{R}/\mathbb{Z}$ number: $\theta = -\Phi$ modulo 2π.

This is the whole pattern in miniature. A primary class (c_1) vanishes; the form that trivialises it (TP_1) has a well-defined integral; that integral is gauge invariant only modulo the integer periods of $g^{-1}\mathrm{d}g$; the exponential of $2\pi i$ times it is a physical phase.

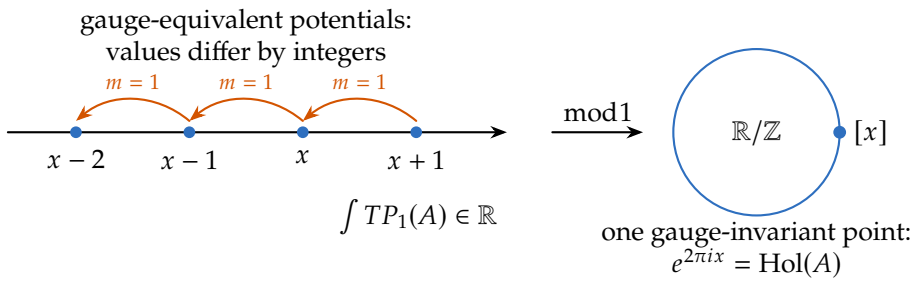

Figure 8.18: Why secondary invariants live in $\mathbb{R}/\mathbb{Z}$. The integral of the Chern–Simons form $TP_1(A) = \frac{i}{2\pi}A$ over a circle takes values that jump by integers under large gauge transformations (orange arrows). Only the image on the circle $\mathbb{R}/\mathbb{Z}$ (right) is physical; its exponential is the Aharonov–Bohm holonomy.

8.2.2 Invariant polynomials and Chern–Weil theory: a reminder

Nash writes (his (8.40))

$$c_j(F) = P_j(\underbrace{F, F, \dots, F}_{j \text{ entries}}),$$

and uses the multilinear object $P_j(\,\cdot\,,\dots,\cdot\,)$ with *different* arguments in the transgression formula. So we need the polynomial in its "polarised" form. This subsection collects what we need; the Chern classes themselves were introduced in Chapter 1.

Working definition 8.15 (invariant polynomial)

An **invariant polynomial** of degree j on the Lie algebra $\mathfrak{g}$ [here anti-Hermitian $N \times N$ matrices, traceless for $\mathrm{SU}(N)$] is a function $P(X_1, \dots, X_j)$ of j matrices $X_i \in \mathfrak{g}$ which is

1. *multilinear* (linear in each slot),
2. *symmetric* (unchanged when two slots are swapped),
3. Ad-*invariant*: $P(hX_1h^{-1}, \dots, hX_jh^{-1}) = P(X_1, \dots, X_j)$ for all $h \in G$.

To build one: take a conjugation-invariant polynomial function $p(X)$ of one matrix, such as $\operatorname{tr} X^j$ or a coefficient of $\det(\mathbb{1} + X)$, and *polarise* it: $P(X_1, \dots, X_j)$ is the coefficient of $t_1 t_2 \cdots t_j$ in $p(t_1X_1 + \cdots + t_jX_j)$, divided by $j!$. For $p = \operatorname{tr} X^j$ this gives the **symmetrised trace**

$$P(X_1, \dots, X_j) = \frac{1}{j!} \sum_{\sigma \in S_j} \operatorname{tr}\big(X_{\sigma(1)} X_{\sigma(2)} \cdots X_{\sigma(j)}\big). \tag{8.103}$$

Inserting forms

The arguments we insert are Lie-algebra-valued *forms*, such as F (a 2-form) or A (a 1-form). Then the entries of the matrices are multiplied with $\wedge$, and the symmetry property picks up the usual sign when two odd forms are swapped. For the arguments that actually occur, one

1-form and several 2-forms, the symmetrisation collapses to a plain trace:

$$P(A,F_1,\dots,F_{j-1}) = \frac{1}{(j-1)!}\sum_{\sigma}\operatorname{tr}\big(A\,F_{\sigma(1)}\cdots F_{\sigma(j-1)}\big), \qquad P(A,F,\dots,F) = \operatorname{tr}\big(A\,F^{j-1}\big)\cdot\kappa_j, \tag{8.104}$$

where κ_j is the overall normalisation of the polynomial. The reason: under the trace, a 2-form can be moved cyclically past anything without a sign, so all orderings in which A sits in a given slot can be cycled to bring A to the front.

The polynomials we use

For $\mathrm{U}(N)$ the Chern classes are defined by the **Chern polynomial**

$$\det\Big(\mathbb{1} + \frac{i}{2\pi}F\Big) = 1 + c_1(F) + c_2(F) + \cdots . \tag{8.105}$$

Expanding the determinant with $X = \frac{i}{2\pi}F$ and $\det(\mathbb{1}+X) = \exp\operatorname{tr}\log(\mathbb{1}+X) = \exp\big(\operatorname{tr}X - \frac{1}{2}\operatorname{tr}X^2 + \frac{1}{3}\operatorname{tr}X^3 - \cdots\big)$,

$$\begin{aligned} c_1 &= \operatorname{tr}X = \frac{i}{2\pi}\operatorname{tr}F, \\ c_2 &= \tfrac{1}{2}\big((\operatorname{tr}X)^2 - \operatorname{tr}X^2\big) = \frac{1}{8\pi^2}\big(\operatorname{tr}F\wedge F - \operatorname{tr}F\wedge\operatorname{tr}F\big), \\ c_3 &= \tfrac{1}{6}(\operatorname{tr}X)^3 - \tfrac{1}{2}\operatorname{tr}X\operatorname{tr}X^2 + \tfrac{1}{3}\operatorname{tr}X^3 \xrightarrow{\operatorname{tr}F=0} \frac{1}{3}\Big(\frac{i}{2\pi}\Big)^3\operatorname{tr}F^3 = -\frac{i}{24\pi^3}\operatorname{tr}(F\wedge F\wedge F). \end{aligned} \tag{8.106}$$

For $\mathrm{SU}(N)$ ($\operatorname{tr}F = 0$) only the single-trace terms survive. Table 8.3 lists them together with Nash's normalisations.

j	$P_j(F,\dots,F)$ used by Nash	relation to c_j	where Nash uses it
1	$\frac{i}{2\pi}\operatorname{tr}F$	$= c_1$	(U(1) holonomy, ω_1)
2	$-\frac{1}{8\pi^2}\operatorname{tr}(F\wedge F)$	$= -c_2$ for $\mathrm{SU}(N)$	(8.60)–(8.61)
3	$-\frac{i}{24\pi^3}\operatorname{tr}(F\wedge F\wedge F)$	$= c_3$ for $\mathrm{SU}(N)$	(8.57)

Table 8.3: The invariant polynomials of this section, for $\mathrm{SU}(N)$ (and U(1) for $j=1$). They are real-valued on anti-Hermitian F: for example $\operatorname{tr}F^2$ is real because $F^\dagger = -F$. Nash's P_2 is $-c_2$, so that $\int_{S^4}P_2(F)$ is the instanton number k of (8.10).

Worked example 8.30: The polynomials on $\mathfrak{su}(2)$

Write $X = X^a e_a$ with the quaternion units $e_a = -i\sigma_a$ of (8.9), which satisfy $e_a e_b = -\delta_{ab}\mathbb{1} + \epsilon_{abc}e_c$. Then

$$\operatorname{tr}(XY) \overset{(1)}{=} X^aY^b\operatorname{tr}(e_ae_b) \overset{(2)}{=} -2\,X^aY^a,$$
$$\operatorname{tr}\big(X\{Y,Z\}\big) \overset{(3)}{=} X^aY^bZ^c\operatorname{tr}\big(e_a(-2\delta_{bc}\mathbb{1})\big) \overset{(4)}{=} 0.$$

(1) Linearity of the trace.
(2) $\operatorname{tr}(e_ae_b) = -\delta_{ab}\operatorname{tr}\mathbb{1} + \epsilon_{abc}\operatorname{tr}e_c = -2\delta_{ab}$ (the e_c are traceless).
(3) $\{e_b,e_c\} = e_be_c + e_ce_b = -2\delta_{bc}\mathbb{1}$: the ϵ terms cancel.
(4) $\operatorname{tr}e_a = 0$.

So P_2 on $\mathfrak{su}(2)$ is (minus) the Euclidean dot product, $P_2(X,Y) \propto X^a Y^a$, while the symmetrised cubic trace vanishes identically: $P_3 \equiv 0$ *for* SU(2). This is the Lie-algebra fact behind the entries "all zero" for U(2) in Nash's table (8.38), and behind the absence of a perturbative SU(2) gauge anomaly. For SU(3) the analogue $\mathrm{tr}(T^a\{T^b,T^c\}) = \frac{1}{2}d^{abc}$ is non-zero.

Two facts about invariant polynomials of forms

(i) d *can be replaced by* D. Differentiate the invariance condition $P(hX_1h^{-1},\dots) = P(X_1,\dots)$ at $h = \mathbb{1}$ along $h = \mathbb{1} + \epsilon Y$: the result is $\sum_i P(X_1,\dots,[Y,X_i],\dots,X_j) = 0$. With forms, and $Y = A$ a 1-form, the same holds with graded commutators and the signs of the graded Leibniz rule. Adding this zero to the ordinary Leibniz rule gives

$$\mathrm{d}P(X_1,\dots,X_j) = \sum_i (-1)^{|X_1|+\cdots+|X_{i-1}|} P(X_1,\dots,DX_i,\dots,X_j), \qquad DX = \mathrm{d}X + [A,X], \quad (8.107)$$

where $|X|$ is the form degree and $[A,X] = AX - (-1)^{|X|}XA$ is the graded commutator of (8.7). (This is the "two-sided" covariant derivative of Section 8.1.1.)

(ii) Chern–Weil: $P_j(F)$ *is closed, and its class does not depend on* A. Closedness is (8.107) with every $X_i = F$ plus the Bianchi identity $DF = 0$. For independence, take two connections A_0, A_1 on the same bundle. By Nash's (8.1) the straight line $A_s = A_0 + s\,a$, $a = A_1 - A_0$, is a path of connections, and a is a globally defined $\mathfrak{g}$-valued 1-form (it transforms two-sidedly). Then $\mathrm{d}F_s/\mathrm{d}s = D_s a$ and

$$\begin{aligned} P_j(F_1) - P_j(F_0) &\overset{(1)}{=} \int_0^1 \frac{\mathrm{d}}{\mathrm{d}s} P_j(F_s,\dots,F_s)\,\mathrm{d}s \overset{(2)}{=} j\int_0^1 P_j(D_s a, F_s,\dots,F_s)\,\mathrm{d}s \\ &\overset{(3)}{=} \mathrm{d}\Big(j\int_0^1 P_j(a,F_s,\dots,F_s)\,\mathrm{d}s \Big). \end{aligned} \quad (8.108)$$

(1) Fundamental theorem of calculus in the parameter s.
(2) Multilinearity and symmetry: differentiating each of the j slots gives the same term; $\frac{\mathrm{d}}{\mathrm{d}s}F_s = \mathrm{d}a + [A_s,a] = D_s a$ (substitute $F_s = F_0 + s\,D_0 a + s^2 a^2$).
(3) (8.107) with $X_1 = a$ and the other slots F_s, whose covariant derivatives vanish by Bianchi.

The form in brackets is built from a and F_s, both tensorial, so it is a *global* form on M: the two Chern–Weil forms differ by an exact form, and define the same class $c_j(P) \in H^{2j}_{\mathrm{dR}}(M)$. This *relative* transgression is the prototype of everything that follows. The trick of Nash's (8.41) is to use it with $A_0 = 0$, which is not a connection on M but is perfectly good on P.

8.2.3 Pulling back to P: the transgression formula

We now follow Nash's (8.39)–(8.42). Let $\pi : P \to M$ be a principal G-bundle (his (8.39)) with a connection.

Why go up to P?

On M a connection is a collection of local potentials A_i on patches U_i, glued by $A_j = g_{ij}^{-1}A_i g_{ij} + g_{ij}^{-1}\mathrm{d}g_{ij}$. There is no global potential unless the bundle is trivial, and so no global way to write $c_j(F) = \mathrm{d}(\text{something built from } A)$. That is as it must be: if $c_j(F)$ were globally exact on M, its integral over closed $2j$-cycles would vanish, and the monopole and the instanton would have zero charge.

On the total space P the situation is different. The connection is a *single global* 1-form ω on P (Section 8.1.1); in a local trivialisation $\pi^{-1}(U) \cong U \times G$, (x, h), it is

$$\omega = h^{-1}A\,h + h^{-1}\mathrm{d}h, \qquad F_\omega := \mathrm{d}\omega + \omega \wedge \omega = h^{-1}F\,h, \tag{8.109}$$

and the gluing rule for the A_i is exactly what makes these local expressions agree on overlaps. Because of Ad-invariance, $P_j(F_\omega, \dots, F_\omega) = P_j(h^{-1}Fh, \dots) = \pi^* P_j(F, \dots, F)$: the Chern–Weil form of F_ω on P *is* the pull-back of $c_j(F)$.

Working definition 8.16 (the family $\omega_t = t\omega$ (Nash's (8.41)))

For $t \in [0, 1]$ put

$$\omega_t := t\,\omega, \qquad F_t := \mathrm{d}\omega_t + \omega_t \wedge \omega_t = t\,\mathrm{d}\omega + t^2\,\omega \wedge \omega. \tag{8.110}$$

At $t = 1$ this is the curvature F_ω; at $t = 0$ it is zero. For $0 < t < 1$, $t\omega$ is *not* a connection (on a fibre [with the point $x \in M$ held fixed, so the $h^{-1}Ah$ term drops out] it restricts to $t\,h^{-1}\mathrm{d}h$, not to the Maurer–Cartan form), but F_t is a perfectly good $\mathfrak{g}$-valued 2-form on P, and that is all we need.

Two algebraic identities hold for *any* $\mathfrak{g}$-valued 1-form, so in particular for ω_t. With $D_t X := \mathrm{d}X + [\omega_t, X]$:

$$\frac{\mathrm{d}F_t}{\mathrm{d}t} \overset{(1)}{=} \mathrm{d}\omega + 2t\,\omega \wedge \omega \overset{(2)}{=} \mathrm{d}\omega + [\omega_t, \omega] = D_t\omega, \tag{8.111}$$

$$D_t F_t \overset{(3)}{=} t^2(\mathrm{d}\omega\,\omega - \omega\,\mathrm{d}\omega) + t^2(\omega\,\mathrm{d}\omega - \mathrm{d}\omega\,\omega) + t^3(\omega^3 - \omega^3) \overset{(4)}{=} 0. \tag{8.112}$$

(1) Differentiate (8.110) in t.

(2) For two 1-forms the graded commutator is an anticommutator: $[t\omega, \omega] = t(\omega\omega + \omega\omega) = 2t\,\omega^2$.

(3) $\mathrm{d}F_t = t^2\mathrm{d}(\omega\omega) = t^2(\mathrm{d}\omega\,\omega - \omega\,\mathrm{d}\omega)$ and $[\omega_t, F_t] = \omega_t F_t - F_t\omega_t$ (a 2-form: commutator); expand.

(4) Everything cancels. This is the Bianchi identity, and it never used that ω_t is a connection.

Key idea: The transgression formula (Nash's (8.42))

On the total space P, every Chern–Weil form becomes exact:

$$\pi^* c_j(F) = \mathrm{d}\,TP_j(\omega), \qquad TP_j(\omega) := j\int_0^1 \mathrm{d}t\; P_j(\omega, F_t, \dots, F_t) \;\in\; \Omega^{2j-1}(P). \tag{8.113}$$

T stands for **transgression**. The $(2j-1)$-form $TP_j(\omega)$ is globally defined on P (it is built from the global ω).

Derivation.

$$\begin{aligned}
\pi^* c_j(F) &\overset{(1)}{=} P_j(F_1, \dots, F_1) - P_j(F_0, \dots, F_0) \overset{(2)}{=} \int_0^1 \frac{\mathrm{d}}{\mathrm{d}t} P_j(F_t, \dots, F_t)\,\mathrm{d}t \\
&\overset{(3)}{=} j\int_0^1 P_j\big(D_t\omega, F_t, \dots, F_t\big)\mathrm{d}t \overset{(4)}{=} j\int_0^1 \mathrm{d}P_j\big(\omega, F_t, \dots, F_t\big)\mathrm{d}t \\
&\overset{(5)}{=} \mathrm{d}\Big(j\int_0^1 P_j(\omega, F_t, \dots, F_t)\,\mathrm{d}t\Big) = \mathrm{d}\,TP_j(\omega).
\end{aligned} \tag{8.114}$$

(1) $F_1 = F_\omega$ and $P_j(F_\omega) = \pi^* c_j(F)$; $F_0 = 0$ gives $P_j(0) = 0$.

(2) Fundamental theorem of calculus in t.
(3) Differentiate each of the j slots (symmetry makes the j terms equal) and use (8.111).
(4) (8.107) for ω_t: $\mathrm{d}P_j(\omega, F_t, \ldots) = P_j(D_t\omega, F_t, \ldots) - \sum P_j(\omega, \ldots, D_tF_t, \ldots)$, and the sum vanishes by (8.112).
(5) d acts on P and commutes with the integral over the parameter t.

This is the same calculation as (8.108) with $A_0 = 0$, $A_1 = \omega$. On M it could not be done, because 0 and A are not two connections on the same bundle; on P it can, because we never needed ω_t to be a connection, only the two identities (8.111)–(8.112).

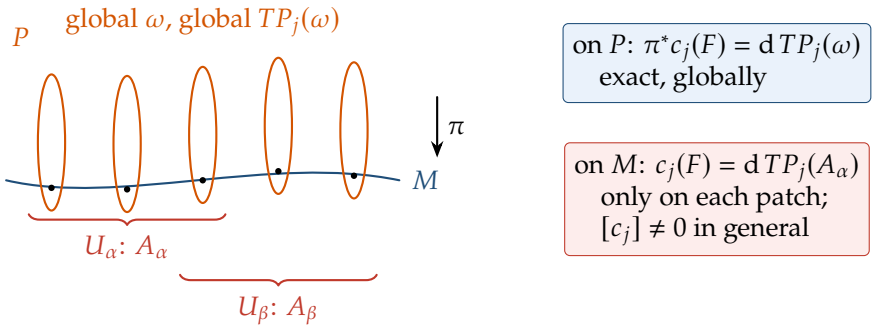

Figure 8.19: Transgression. Upstairs, on the total space P, the connection is one global form ω, and every characteristic form becomes the derivative of the global form $TP_j(\omega)$. Downstairs, on M, only local potentials A_α exist (red braces), so $c_j(F)$ is exact only patch by patch, and its class can be non-zero. The fibres (orange) absorb the difference.

Watch out: Exact on P does not mean trivial

π^*c_j being exact on P says that the class c_j *dies* when pulled back to P. This is a statement about P, not about M: π^* can kill classes. Example: the Hopf bundle $S^3 \to S^2$ below, where $H^2_{\mathrm{dR}}(S^3) = 0$ kills the generator of $H^2_{\mathrm{dR}}(S^2) = \mathbb{R}$. Nash cites Nash and Sen for the general statement.

Worked example 8.31: The Hopf bundle: transgression by hand

$P = S^3 = \{(z_1, z_2) \in \mathbb{C}^2 : |z_1|^2 + |z_2|^2 = 1\}$, $G = \mathrm{U}(1)$ acting by $(z_1, z_2) \cdot \lambda = (z_1\lambda, z_2\lambda)$, $M = S^2 = \mathbb{CP}^1$ with the coordinate $u = z_1/z_2$ away from one point.

- *The connection.* $\omega := \bar{z}_1\mathrm{d}z_1 + \bar{z}_2\mathrm{d}z_2$ restricted to S^3. It is imaginary, as a $\mathfrak{u}(1)$-valued form should be: differentiating $\bar{z}_kz_k = 1$ gives $\bar{z}_k\mathrm{d}z_k = -\overline{\bar{z}_k\mathrm{d}z_k}$. On the fibre direction $\frac{\mathrm{d}}{\mathrm{d}\phi}(ze^{i\phi}) = iz$ it gives $\omega(iz) = i\,|z|^2 = i$, the generator: it restricts to the Maurer–Cartan form $i\,\mathrm{d}\phi$ of $\mathrm{U}(1)$.
- *The curvature.* $F_\omega = \mathrm{d}\omega = \mathrm{d}\bar{z}_1 \wedge \mathrm{d}z_1 + \mathrm{d}\bar{z}_2 \wedge \mathrm{d}z_2$ (Abelian, so $\omega \wedge \omega = 0$).
- *Transgression.* For $j = 1$, $F_t = t\,\mathrm{d}\omega$ and $TP_1(\omega) = 1 \cdot \int_0^1 \mathrm{d}t\,\frac{i}{2\pi}\omega = \frac{i}{2\pi}\omega$. Indeed $\mathrm{d}TP_1(\omega) = \frac{i}{2\pi}F_\omega = \pi^*c_1$: exact on S^3.
- *Down on S^2.* The local section $s(u) = (u, 1)/\sqrt{1 + |u|^2}$ pulls ω back to

$$A = s^*\omega \overset{(1)}{=} \frac{\bar{u}\,\mathrm{d}u - u\,\mathrm{d}\bar{u}}{2(1 + |u|^2)} \overset{(2)}{=} \frac{i\,r^2\,\mathrm{d}\phi}{1 + r^2}, \qquad u = re^{i\phi}.$$

(1) With $\rho = \sqrt{1+|u|^2}$: $\bar z_1 \mathrm{d}z_1 + \bar z_2 \mathrm{d}z_2 = \bar u\,\mathrm{d}u/\rho^2 - (|u|^2+1)\mathrm{d}\rho/\rho^3 = \bar u\,\mathrm{d}u/\rho^2 - \mathrm{d}\rho/\rho$, and $\mathrm{d}\rho/\rho = (\bar u\,\mathrm{d}u + u\,\mathrm{d}\bar u)/2\rho^2$.
(2) $\bar u\,\mathrm{d}u - u\,\mathrm{d}\bar u = 2i\,r^2\,\mathrm{d}\phi$.

Now compute the Chern number by Stokes, using the section on the disc $|u| < R$:

$$\int_{S^2} c_1(F) \overset{(1)}{=} \lim_{R\to\infty} \int_{|u|<R} \mathrm{d}\,TP_1(A) \overset{(2)}{=} \lim_{R\to\infty} \frac{i}{2\pi} \oint_{|u|=R} \frac{i\,R^2\,\mathrm{d}\phi}{1+R^2} \overset{(3)}{=} -1.$$

(1) The disc exhausts S^2 minus the point $u=\infty$ (measure zero); on the disc $c_1 = \mathrm{d}(s^*TP_1(\omega))$.
(2) Stokes, with $\oint \mathrm{d}\phi = 2\pi$.
(3) $\frac{i\cdot i}{2\pi}\cdot 2\pi\cdot 1 = -1$.

Look at what the boundary circle is. As $R\to\infty$, $s(Re^{i\phi}) \to (e^{i\phi}, 0)$: the image of the boundary loop is *one whole fibre*, the fibre over $u=\infty$. So the Chern number equals the integral of $TP_1(\omega)$ over a fibre, $\int_{\mathrm{U}(1)} \frac{i}{2\pi}\, i\,\mathrm{d}\phi = -1$. (The value -1 is the standard answer for the tautological bundle over $\mathbb{CP}^1$ with its complex orientation.) The restriction of the transgression form to a fibre is the subject of Section 8.2.5.

8.2.4 Chern–Simons forms

To get back down to M, pull the transgression formula back with a local section $s: U \to P$. Since $s^*\omega = A$ is the local potential and pull-back commutes with d and $\wedge$,

$$c_j(F) = \mathrm{d}\,TP_j(A) \quad \text{on } U, \qquad TP_j(A) = j\int_0^1 \mathrm{d}t\; P_j(A, F_t, \dots, F_t), \quad F_t = t\,\mathrm{d}A + t^2 A\wedge A. \tag{8.115}$$

This is Nash's (8.42) read on M, and it is how he uses it in (8.56) and (8.61). The local forms $TP_j(A)$ are the **Chern–Simons forms**. The t-integrals are elementary; we do them for $j = 1, 2, 3$.

Worked example 8.32: TP_1, TP_2, TP_3 explicitly

Use the normalisations of Table 8.3 and (8.104).
$j=1$. $TP_1(A) = \int_0^1 \mathrm{d}t\,\frac{i}{2\pi}\operatorname{tr} A = \frac{i}{2\pi}\operatorname{tr} A$.
$j=2$ *(Nash's (8.61)).*

$$\begin{aligned} TP_2(A) &\overset{(1)}{=} 2\int_0^1 \mathrm{d}t\left(-\frac{1}{8\pi^2}\right)\operatorname{tr}\big(A\wedge(t\,\mathrm{d}A + t^2 A\wedge A)\big) \\ &\overset{(2)}{=} -\frac{2}{8\pi^2}\left(\frac{1}{2}\operatorname{tr}(A\wedge\mathrm{d}A) + \frac{1}{3}\operatorname{tr}(A\wedge A\wedge A)\right) \overset{(3)}{=} -\frac{1}{8\pi^2}\operatorname{tr}\left(A\wedge\mathrm{d}A + \frac{2}{3}A\wedge A\wedge A\right). \end{aligned} \tag{8.116}$$

(1) (8.115) with $P_2(X,Y) = -\frac{1}{8\pi^2}\operatorname{tr}(XY)$.
(2) $\int_0^1 t\,\mathrm{d}t = \frac{1}{2}$, $\int_0^1 t^2\mathrm{d}t = \frac{1}{3}$.
(3) Multiply out.

So $TP_2(A) = -\frac{1}{8\pi^2}Q_3(A)$ with Q_3 the Chern–Simons 3-form of (8.69), and $\mathrm{d}TP_2 = -\frac{1}{8\pi^2}\operatorname{tr}F^2 = P_2(F)$, which we verified line by line in Section 8.1.18. (Nash writes $\operatorname{tr}(\mathrm{d}A\wedge A)$ in (8.62); it equals $\operatorname{tr}(A\wedge\mathrm{d}A)$, because moving the 2-form $\mathrm{d}A$ past the 1-form A under the trace costs no sign.)

$j = 3$ *(Nash's (8.56)).* Write $\kappa_3 = -\frac{i}{24\pi^3}$. Then

$$\begin{aligned} TP_3(A) &\overset{(1)}{=} 3\kappa_3 \int_0^1 \mathrm{d}t\ \mathrm{tr}\big(A(t\,\mathrm{d}A + t^2A^2)(t\,\mathrm{d}A + t^2A^2)\big) \\ &\overset{(2)}{=} 3\kappa_3 \int_0^1 \mathrm{d}t\,\Big(t^2\,\mathrm{tr}(A\,\mathrm{d}A\,\mathrm{d}A) + 2t^3\,\mathrm{tr}(A^3\mathrm{d}A) + t^4\,\mathrm{tr}\,A^5\Big) \\ &\overset{(3)}{=} \kappa_3\ \mathrm{tr}\Big(A(\mathrm{d}A)^2 + \frac{3}{2}A^3\,\mathrm{d}A + \frac{3}{5}A^5\Big). \end{aligned} \tag{8.117}$$

(1) (8.115) and (8.104); the factor $j = 3$.
(2) Expand. The two cross terms $\mathrm{tr}(A\,\mathrm{d}A\,A^2)$ and $\mathrm{tr}(A\,A^2\,\mathrm{d}A)$ are equal: cycle the 2-form A^2 from the back of the first to the front.
(3) $\int t^2 = \frac{1}{3}$, $\int t^3 = \frac{1}{4}$, $\int t^4 = \frac{1}{5}$; so $3(\frac{1}{3}, \frac{2}{4}, \frac{1}{5}) = (1, \frac{3}{2}, \frac{3}{5})$.

One can check $\mathrm{d}TP_3 = \kappa_3\,\mathrm{tr}\,F^3$ by the same cycling rules as in Section 8.1.18; it is the five-dimensional Chern–Simons form that governs the four-dimensional anomaly (Section 8.2.8).

Dictionary: Chern–Simons forms in physics notation

With $A = -igA^aT^a$ (Hermitian T^a, $\mathrm{tr}\,T^aT^b = \frac{1}{2}\delta^{ab}$, $[T^a, T^b] = if^{abc}T^c$), the 3-form becomes

$$\mathrm{tr}\Big(A\,\mathrm{d}A + \tfrac{2}{3}A^3\Big) = -\frac{g^2}{2}\Big(A^a \wedge \mathrm{d}A^a + \frac{g}{3}f^{abc}A^a \wedge A^b \wedge A^c\Big),$$

and in components $A^a \wedge \mathrm{d}A^a = \epsilon^{\mu\nu\rho}A^a_\mu\partial_\nu A^a_\rho\,\mathrm{d}^3x$. The Abelian form $\epsilon^{\mu\nu\rho}a_\mu\partial_\nu a_\rho$ is the Chern–Simons term of the quantum Hall effect.

8.2.5 On a fibre: the transgression of the Maurer–Cartan generators

What does $TP_j(\omega)$ look like on a single fibre $\pi^{-1}(x) \cong G$? There A contributes nothing (the fibre is a point of M), and ω restricts to the Maurer–Cartan form $\theta = h^{-1}\mathrm{d}h$. Since pull-back to the fibre commutes with d and $\wedge$, $TP_j(\omega)|_{\text{fibre}} = TP_j(\theta)$, which we can compute. The Maurer–Cartan equation $\mathrm{d}\theta = -\theta^2$ gives

$$F_t\big|_{\text{fibre}} = t\,\mathrm{d}\theta + t^2\theta^2 = (t^2 - t)\,\theta \wedge \theta, \tag{8.118}$$

which vanishes at $t = 0$ and $t = 1$, as it must: the genuine connection on a fibre is flat. With $P_j(X, \ldots, X) = \kappa_j\,\mathrm{tr}\,X^j$,

$$TP_j(\theta) \overset{(1)}{=} j\,\kappa_j \int_0^1 \mathrm{d}t\,(t^2 - t)^{j-1}\,\mathrm{tr}\big(\theta\,(\theta^2)^{j-1}\big) \overset{(2)}{=} j\,\kappa_j\,(-1)^{j-1}\frac{((j-1)!)^2}{(2j-1)!}\,\mathrm{tr}\,\theta^{2j-1}. \tag{8.119}$$

(1) (8.113) with $\omega \to \theta$ and (8.118); by (8.104) the polynomial is a plain trace.
(2) $\int_0^1 (t^2-t)^m \mathrm{d}t = (-1)^m \int_0^1 t^m(1-t)^m \mathrm{d}t = (-1)^m \frac{(m!)^2}{(2m+1)!}$, the Euler Beta integral $B(m+1, m+1)$, with $m = j - 1$.

Explicitly, with the normalisations of Table 8.3:

$$\begin{aligned} &TP_1(\theta) = \frac{i}{2\pi}\,\mathrm{tr}\,\theta, \qquad TP_2(\theta) \overset{(1)}{=} 2\Big(-\frac{1}{8\pi^2}\Big)\Big(-\frac{1}{6}\Big)\,\mathrm{tr}\,\theta^3 = \frac{1}{24\pi^2}\,\mathrm{tr}\,\theta^3, \\ &TP_3(\theta) \overset{(2)}{=} 3\Big(-\frac{i}{24\pi^3}\Big)\frac{1}{30}\,\mathrm{tr}\,\theta^5 = -\frac{i}{240\pi^3}\,\mathrm{tr}\,\theta^5. \end{aligned} \tag{8.120}$$

(1) $j = 2$: the Beta integral is $-\frac{1}{6}$.

(2) $j = 3$: the Beta integral is $\frac{(2!)^2}{5!} = \frac{1}{30}$.

These are exactly the forms $\omega_{2j-1} = C_j \operatorname{tr} \theta^{2j-1}$ of (8.87), with the constants C_1, C_2, C_3 quoted there. In particular $TP_2(\theta)$ is the winding density (8.64).

Key idea: Transgression links $H^*(G)$ and $H^*(BG)$

For each j there is one form $TP_j(\omega)$ on P with

$$\underbrace{TP_j(\omega)\big|_{\text{fibre}} = \omega_{2j-1}}_{\text{generator of } H^{2j-1}_{\mathrm{dR}}(G)} \qquad \text{and} \qquad \underbrace{\mathrm{d}\,TP_j(\omega) = \pi^* c_j}_{\text{generator of } H^{2j}(BG)}.$$

Topologists say that the class $[\omega_{2j-1}]$ of the fibre **transgresses** to the class c_j of the base; this is where Nash's name "T" comes from. For the universal bundle $EG \to BG$ it matches the two rings of Section 8.1 generator by generator: the exterior algebra $\Lambda(\omega_1, \omega_3, \dots, \omega_{2N-1})$ of $\mathrm{U}(N)$ and the polynomial algebra $\mathbb{R}[c_1, c_2, \dots, c_N]$ of $B\mathrm{U}(N)$.

$$G \xrightarrow{\ \iota\ } P \xrightarrow{\ \pi\ } M$$

$$\omega_{2j-1} = C_j \operatorname{tr} \theta^{2j-1} \xleftarrow{\ \iota^*\ } TP_j(\omega) \xmapsto{\ \mathrm{d}\ } \mathrm{d}TP_j(\omega) = \pi^* c_j(F)$$

Figure 8.20: The transgression in one diagram. The single form $TP_j(\omega)$ on the total space restricts on each fibre G to the Maurer–Cartan generator ω_{2j-1} (left), and its derivative is the pull-back of the Chern–Weil form $c_j(F)$ of the base (right). Read left to right, a class of the group "moves" to a class of the base, raising the degree by one.

Worked example 8.33: Chern number = fibre integral, again

The Hopf computation of Example 8.31 was not a coincidence. Let $P \to S^{2j}$ be clutched by $g : S^{2j-1} \to G$ along the equator (Section 8.1.12). Over the northern hemisphere D_+ use a section s_+, over the southern D_- a section s_-, with $s_- = s_+ g$ on the equator. Then

$$\int_{S^{2j}} c_j(F) \overset{(1)}{=} \int_{D_+} \mathrm{d}\, s_+^* TP_j(\omega) + \int_{D_-} \mathrm{d}\, s_-^* TP_j(\omega) \overset{(2)}{=} \int_{S^{2j-1}} (s_+^* - s_-^*) TP_j(\omega)$$
$$\overset{(3)}{=} -\int_{S^{2j-1}} \left(TP_j(A_+^g) - TP_j(A_+) \right) \overset{(4)}{=} -\int_{S^{2j-1}} g^* \omega_{2j-1}.$$

(1) On each hemisphere $c_j = \mathrm{d}TP_j$ of the local potential.

(2) Stokes. The equator is the boundary of D_+ with one orientation and of D_- with the other.

(3) $s_-^* \omega = A_- = A_+^g$, the gauge transform by the clutching function.

(4) The gauge-variation formula (8.122) of the next subsection: the difference is $g^* \omega_{2j-1}$ plus an exact form, which integrates to zero on the closed equator.

So the Chern number is (minus) the Maurer–Cartan period of the clutching function. For $j = 2$, with Nash's $P_2 = -c_2$, this is $k = \int_{S^4} P_2 = \frac{1}{24\pi^2} \int \operatorname{tr}(g^{-1}\mathrm{d}g)^3 = w(g)$, the result (8.70) of Section 8.1.18 (the overall sign depends on which hemisphere is called D_+).

8.2.6 When $c_j(F)$ vanishes: the secondary class

Nash now asks (his (8.43)–(8.44)): what if the form $c_j(F)$ is identically zero? Then the transgression formula reads $\mathrm{d}TP_j(\omega) = 0$. The form $TP_j(\omega)$ is *closed* on P and defines a de Rham class

$$[TP_j(\omega)] \in H^{2j-1}_{\mathrm{dR}}(P) = H^{2j-1}(P;\mathbb{R}), \tag{8.121}$$

of *odd* degree. This is the **secondary characteristic class**, or **Chern–Simons class**, of the connection.

Working definition 8.17 (secondary (Chern–Simons) class)

Given a connection ω with $P_j(F) = 0$ *as a form*, the secondary class is the cohomology class of $TP_j(\omega)$ [the transgression form (8.113), with $\mathrm{d}TP_j(\omega) = P_j(F_\omega)$, so it is closed here] on P. *To compute it:* pull back by a local section [a map $s : U \to P$ with $\pi \circ s = \mathrm{id}$, such as $h = \mathbb{1}$, along which $s^*\omega = A$], $TP_j(A)$, and integrate over closed $(2j-1)$-cycles (for $j = 2$: over closed 3-manifolds in M). *Formally:* the class in $H^{2j-1}(P;\mathbb{R})$ of the transgression form.

When does $c_j(F)$ vanish as a form? Three situations cover the applications.

1. *For dimensional reasons*: $c_j(F)$ is a $2j$-form, so it is zero on any manifold of dimension less than $2j$. On a 3-manifold, $c_2(F) = 0$ for every connection. This is the case of Chern–Simons gauge theory (Section 8.2.10), and of Nash's (8.50) below.
2. *For flat connections*: $F = 0$ kills every $c_j(F)$ with $j \geq 1$. Flat connections are classified by their holonomy, and the secondary classes are then invariants of the holonomy representation, such as the $\mathbb{R}/\mathbb{Z}$ phases of Section 8.2.1.
3. *For algebraic reasons*: $c_j \equiv 0$ for $j > N$ on a rank-N bundle, and $P_3 \equiv 0$ on $\mathfrak{su}(2)$ (Example 8.30).

Watch out: A real class, not an integral one

The primary class $c_j(F)$ is *integral*: its integrals over closed $2j$-cycles are integers. The secondary class TP_j is only *real*: its integrals are arbitrary real numbers (the flux $-\Phi/2\pi$ of Example 8.29 can be anything). That is what makes it interesting. It depends on the connection, not just on the bundle; it is a *geometric* invariant, not merely a topological one. Only its reduction modulo integers is independent of the choice of gauge, as we now show.

8.2.7 Gauge dependence and the $\mathbb{R}/\mathbb{Z}$ class

To integrate the secondary class over a cycle in M we must bring it down from P, and that needs a section. Different sections differ by gauge transformations. How does TP_j change?

Key idea: Gauge variation of the Chern–Simons form

For a gauge transformation $g : U \to G$ and $A^g = g^{-1}Ag + g^{-1}\mathrm{d}g$,

$$TP_j(A^g) = TP_j(A) + g^*\omega_{2j-1} + \mathrm{d}\beta_j(A,g), \qquad g^*\omega_{2j-1} = TP_j(g^{-1}\mathrm{d}g) = C_j\,\mathrm{tr}\big(g^{-1}\mathrm{d}g\big)^{2j-1}, \tag{8.122}$$

for some $(2j-2)$-form β_j built from A and g. For $j = 2$ (Nash's normalisation):

$$TP_2(A^g) = TP_2(A) + \frac{1}{24\pi^2}\,\mathrm{tr}\big(g^{-1}\mathrm{d}g\big)^3 + \frac{1}{8\pi^2}\,\mathrm{d}\,\mathrm{tr}\big(\mathrm{d}g\,g^{-1}\wedge A\big). \tag{8.123}$$

The case $j = 2$. This is (8.75) multiplied by $-\frac{1}{8\pi^2}$:

$$TP_2(A^g) \overset{(1)}{=} -\frac{1}{8\pi^2} Q_3(A^g) \overset{(2)}{=} -\frac{1}{8\pi^2}\Big(Q_3(A) - \mathrm{d}\,\mathrm{tr}(bA) - \tfrac{1}{3}\,\mathrm{tr}\,\theta^3\Big)$$
$$\overset{(3)}{=} TP_2(A) + \frac{1}{8\pi^2}\mathrm{d}\,\mathrm{tr}(bA) + \frac{1}{24\pi^2}\,\mathrm{tr}\,\theta^3,$$

(1) (8.116).
(2) (8.75), with $b = \mathrm{d}g\, g^{-1}$ and $\theta = g^{-1}\mathrm{d}g$.
(3) Distribute the prefactor.

Why the general formula holds. Let $\Delta(A) := TP_j(A^g) - TP_j(A)$ for fixed g.

- $\Delta(A)$ is closed: $\mathrm{d}TP_j(A^g) = P_j(F^g) = P_j(g^{-1}Fg) = P_j(F) = \mathrm{d}TP_j(A)$ by Ad-invariance.
- Δ changes by exact forms when A is deformed. The variation of a Chern–Simons form under $A \to A + \delta A$ is

$$\delta\, TP_j(A) = j\, P_j(\delta A, F, \dots, F) + \mathrm{d}(\dots). \tag{8.124}$$

  For $j = 2$ this is a two-line check: $\delta\,\mathrm{tr}(A\,\mathrm{d}A + \frac{2}{3}A^3) = \mathrm{tr}(\delta A\,\mathrm{d}A + A\,\mathrm{d}\delta A + 2\,\delta A\,A^2) = 2\,\mathrm{tr}(\delta A\,F) - \mathrm{d}\,\mathrm{tr}(A\,\delta A)$, using $\mathrm{tr}(A\,\mathrm{d}\delta A) = \mathrm{tr}(\mathrm{d}A\,\delta A) - \mathrm{d}\,\mathrm{tr}(A\,\delta A)$. For general j the same integration by parts in t works. Now $\delta A^g = g^{-1}\delta A\, g$ and $F^g = g^{-1}Fg$, so the P_j terms in $\delta\Delta$ cancel by Ad-invariance, leaving an exact form.
- Deform A to 0 along sA, $s \in [0,1]$ (fine on a patch). Then $\Delta(A) = \Delta(0) + \mathrm{d}(\dots) = TP_j(0^g) - TP_j(0) + \mathrm{d}(\dots) = TP_j(g^{-1}\mathrm{d}g) + \mathrm{d}(\dots)$, and $TP_j(g^{-1}\mathrm{d}g) = g^*TP_j(\theta) = g^*\omega_{2j-1}$ by (8.120).

The periods of $g^*\omega_{2j-1}$ are integers

Integrate (8.122) over a closed $(2j-1)$-cycle $\Sigma \subset M$ (on which A and A^g are both defined). The exact term drops out by Stokes, and

$$\int_\Sigma TP_j(A^g) - \int_\Sigma TP_j(A) = \int_\Sigma g^*\omega_{2j-1} \in \mathbb{Z}. \tag{8.125}$$

Why an integer? The class $[\omega_{2j-1}]$ is the transgression of the *integral* class c_j (Example 8.33 shows that its periods on spheres are Chern numbers), so it is itself integral: its integral over the image of any closed cycle is an integer. For $j = 1$ this is the winding number of $e^{i\lambda}$ around a circle, (8.102); for $j = 2$ and $\Sigma = S^3$ it is the winding number (8.64); for $j = 2$ and a general closed 3-manifold and $G = \mathrm{SU}(2)$ it is the degree of $g : \Sigma \to S^3$.

Key idea: Nash's (8.45): three classes, three coefficient groups

$$c_j(F) \in H^{2j}(M;\mathbb{Z}), \qquad TP_j(\omega) \in H^{2j-1}(P;\mathbb{R}), \qquad \widehat{TP}_j(A) \in H^{2j-1}(M;\mathbb{R}/\mathbb{Z}).$$

The primary class is integral. The secondary class lives upstairs as a real class. Brought down to M with any local section, it is defined only up to the integer periods (8.125), so on M it is a class with $\mathbb{R}/\mathbb{Z}$ coefficients. Concretely: for every closed $(2j-1)$-cycle Σ, $\int_\Sigma TP_j(A)$ mod 1 is gauge invariant, and so is $\exp\big(2\pi i \int_\Sigma TP_j(A)\big)$.

Worked example 8.34: The Chern–Simons invariant of a flat connection on $\mathbb{RP}^3$

Here is a genuinely fractional value. Identify S^3 with SU(2) as in (8.9), and let $\mathbb{RP}^3 = S^3/\{x \sim -x\}$. On S^3 take the pure gauge potential

$$A = x^{-1}\mathrm{d}x \qquad \text{(the Maurer–Cartan form, with } g(x) = x\text{)}.$$

- *It descends to* $\mathbb{RP}^3$. $(-x)^{-1}\mathrm{d}(-x) = x^{-1}\mathrm{d}x$, so A is a well-defined $\mathfrak{su}(2)$-valued 1-form on $\mathbb{RP}^3$, i.e. a connection on the trivial SU(2) bundle over $\mathbb{RP}^3$.
- *It is flat*, $F = \mathrm{d}\theta + \theta^2 = 0$, so $c_2(F) = 0$ and $TP_2(A)$ is closed.
- *It is not gauge-trivial.* A covariantly constant ψ solves $\mathrm{d}\psi + A\psi = 0$, i.e. $\psi = x^{-1}\psi_0$. Along a path from x to $-x$, which is a closed loop in $\mathbb{RP}^3$, ψ returns as $-\psi$: the holonomy is $-\mathbb{1}$.

Now compute its Chern–Simons invariant. The double cover $S^3 \to \mathbb{RP}^3$ covers each point twice, so

$$\int_{\mathbb{RP}^3} TP_2(A) \overset{(1)}{=} \frac{1}{2}\int_{S^3} TP_2\big(x^{-1}\mathrm{d}x\big) \overset{(2)}{=} \frac{1}{2}\cdot\frac{1}{24\pi^2}\int_{S^3}\operatorname{tr}\theta^3 \overset{(3)}{=} \frac{1}{2}\,w(\mathrm{id}) = \frac{1}{2}.$$

(1) The integral of a pulled-back form over a two-sheeted cover is twice the integral downstairs (orient $\mathbb{RP}^3$ by the orientation of S^3; the antipodal map of S^3 preserves it).
(2) (8.120): for a pure gauge $TP_2(\theta) = \frac{1}{24\pi^2}\operatorname{tr}\theta^3$.
(3) (8.64) and (8.66).

Any gauge transformation $h : \mathbb{RP}^3 \to \mathrm{SU}(2)$ shifts this by the integer $\int_{\mathbb{RP}^3} h^*\omega_3$. So the class $\frac{1}{2}$ mod 1 cannot be removed: the $\mathbb{R}/\mathbb{Z}$ invariant *detects* that this flat connection is not the trivial one, which has invariant 0. (Reversing the orientation gives $-\frac{1}{2}$, which is the same point of $\mathbb{R}/\mathbb{Z}$.)

Defining the invariant with a bounding 4-manifold

There is a second way to see why only the fractional part is meaningful, which is the one used in Chern–Simons theory. Every closed oriented 3-manifold M is the boundary of some compact oriented 4-manifold W. Suppose the bundle and the connection extend over W (for SU(N) this can always be arranged). If the bundle over W is trivial with global potential A, Stokes gives

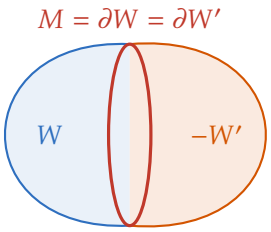
$$\int_M TP_2(A) \overset{(1)}{=} \int_W \mathrm{d}\,TP_2(A) \overset{(2)}{=} \int_W P_2(F), \tag{8.126}$$

(1) Stokes on W with $\partial W = M$.
(2) The transgression formula (8.115).

and one can take the right-hand side as the *definition* of the left in general. Another choice W' gives a closed 4-manifold $X = W \cup_M (-W')$ by gluing along M, and

$$\int_W P_2(F) - \int_{W'} P_2(F') = \int_X P_2 = k(X) \in \mathbb{Z}, \tag{8.127}$$

the instanton number of the glued bundle on the closed 4-manifold X. The Chern–Simons invariant of M is therefore well defined modulo $\mathbb{Z}$: it is "a fraction of an instanton", and the fraction is what the boundary determines. See Figure 8.21.



$$\int_M TP_2(A) = \int_W P_2(F) \pmod{\mathbb{Z}}$$
$$\int_W P_2 - \int_{W'} P_2 = k(W \cup_M -W') \in \mathbb{Z}$$

Figure 8.21: The Chern–Simons invariant of a 3-manifold M (red) computed from a 4-manifold W that it bounds. A different filling W' changes the answer by the instanton number of the closed manifold obtained by gluing W to W' reversed, an integer. So only $\int_M TP_2$ mod 1 is intrinsic to M.

Worked example 8.35: The Chern–Simons number of a pure gauge on S^3

For $M = S^3$ (space compactified, as in Section 8.1.19) and $A = g^{-1}\mathrm{d}g$ with g of winding n, fill S^3 by the ball $W = B^4$. On B^4 take $A_W = f(r)\, g^{-1}\mathrm{d}g$ with $f(0) = 0$, $f(1) = 1$ and g extended radially (singular at the centre, but f tames it, as for the BPST potential in Example 8.18). Then $\int_{S^3} TP_2(g^{-1}\mathrm{d}g) = \int_{B^4} P_2(F_W) = n$: the vacuum of class n has Chern–Simons number n, an integer, and so it is 0 in $\mathbb{R}/\mathbb{Z}$. The $\mathbb{R}/\mathbb{Z}$ invariant cannot tell the classical vacua $|n\rangle$ apart; only the real number can, and the real number is not gauge invariant. This is the $\mathbb{R}/\mathbb{Z}$ way of saying that the $|n\rangle$ are related by large gauge transformations. (N_{CS} of (8.74) is $-\int TP_2$ with the opposite orientation convention, $-\mathrm{d}x^{123}$ versus $\mathrm{d}x^{123}$.)

Watch out: Non-trivial bundles and differential characters

When the bundle over M is not trivial there is no global section, and the recipe "pull TP_j back by a section" has to be carried out patch by patch, with correction terms on overlaps. The clean framework is that of Cheeger–Simons *differential characters*: a secondary invariant assigns to every closed $(2j-1)$-cycle an element of $\mathbb{R}/\mathbb{Z}$, compatibly with $c_j(F)$. In this chapter we only need trivial bundles over 3-manifolds (every SU(N) bundle over a 3-manifold is trivial, because $\pi_2(\mathrm{SU}(N)) = 0$ and $\pi_1(\mathrm{SU}(N)) = 0$), so the naive recipe suffices. Nash's remark that the phenomenon reappears "in chapter 12" refers to Witten's Chern–Simons TQFT (Chapter 12).

Reading Nash (pp. 223–224, (8.39)–(8.45))

Nash states the transgression formula (8.42) without derivation; our (8.114) supplies it, and (8.111)–(8.112) are the two identities it rests on. His "A" in (8.41)–(8.42) is the connection form on P (our ω); the same formula then holds for the local potentials by pull-back. His (8.43)–(8.44) are (8.121). His (8.45) is the keyidea above, and his remark that "the two classes will differ but their difference will be an integral class" is (8.125). The example he promises "in 8.62" is the three-dimensional Chern–Simons action of Section 8.2.10.

Recap: transgression and secondary classes

- Invariant polynomials P_j: symmetric, multilinear, Ad-invariant; $c_j(F) = P_j(F, \dots, F)$ is closed and its class does not depend on A (straight-line homotopy).
- On P: $\pi^* c_j(F) = \mathrm{d}TP_j(\omega)$ with $TP_j = j\int_0^1 P_j(\omega, F_t, \dots, F_t)\,\mathrm{d}t$, $F_t = t\,\mathrm{d}\omega + t^2\omega^2$.
- Chern–Simons forms: $TP_1 = \frac{i}{2\pi}\operatorname{tr} A$, $TP_2 = -\frac{1}{8\pi^2}\operatorname{tr}(A\,\mathrm{d}A + \frac{2}{3}A^3)$, $TP_3 =$

$-\frac{i}{24\pi^3}\operatorname{tr}(A(\mathrm{d}A)^2+\frac{3}{2}A^3\mathrm{d}A+\frac{3}{5}A^5)$.

- On a fibre, TP_j restricts to the generator $\omega_{2j-1}=C_j\operatorname{tr}\theta^{2j-1}$ of $H^*_{\mathrm{dR}}(G)$: transgression.
- If $c_j(F)=0$ as a form, TP_j is closed: a real secondary class on P; on M it is defined modulo the integer periods of $g^*\omega_{2j-1}$, i.e. in $\mathbb{R}/\mathbb{Z}$. Examples: Aharonov–Bohm phase; $\frac{1}{2}$ for the flat connection with holonomy $-\mathbb{1}$ on $\mathbb{RP}^3$.

8.2.8 Secondary classes on the gauge group: an explicit formula for μ

In Section 8.1.23 we built the classes $\mu_{i-n}\in H^{i-n}_{\mathrm{dR}}(\mathcal{G})$ by evaluating gauge transformations, pulling back a generator ω_i of $H^*_{\mathrm{dR}}(G)$ and integrating over S^n. That recipe never mentions the gauge field. But in physics the class μ_1 turns up in a very specific place: as the variation of the effective action of chiral fermions under a gauge transformation (the non-Abelian anomaly, Chapter 10). There it comes out of a Feynman diagram as an explicit polynomial in A and $\mathrm{d}A$. We want the same kind of formula here. Nash's idea is to build μ from the Chern–Simons forms TP_j instead of from ω_{2j-1}. Since TP_j restricts to ω_{2j-1} on each fibre (Section 8.2.5), this should give the same class; and since TP_j is built from the connection, the result will be a formula in A.

Step 1: the evaluation map on $\mathcal{G}\times P$

A gauge transformation $\alpha\in\mathcal{G}$ is a map $\alpha:P\to P$ that moves each point along its own fibre and commutes with the right G-action (a refresher: Section 8.1.3). So there is again an evaluation map, this time with values in P (Nash's (8.46)):

$$\mathrm{Ev}:\mathcal{G}\times P\longrightarrow P,\qquad(\alpha,p)\longmapsto\alpha(p),\qquad\pi\circ\mathrm{Ev}(\alpha,p)=\pi(p).\tag{8.128}$$

The last equation says that Ev does not move the base point, because α covers the identity of $M=S^n$. Pull the Chern–Simons form back (Nash's (8.47)): $\mathrm{Ev}^*TP_j(\omega)$ is a $(2j-1)$-form on the product $\mathcal{G}\times P$.

We do not want forms on $\mathcal{G}\times P$; we want forms on $\mathcal{G}$. The fibres of P are in the way, so we cut them out with a section. Let $s:S^n\to P$ be a section (for the moment assume the bundle is trivial, so that a global one exists; the general case is discussed in the pitfall at the end of this subsection). Define

$$\widehat{\mathrm{Ev}}:S^n\times\mathcal{G}\longrightarrow P,\qquad(x,\alpha)\longmapsto\alpha\big(s(x)\big).\tag{8.129}$$

This is Nash's "restriction of Ev^*TP_j to $\mathcal{G}\times S^n$": we use the section to view S^n as the subset $s(S^n)$ of P. Then (Nash's (8.48))

$$\boxed{\mu_{2j-1-n}:=\int_{S^n}\widehat{\mathrm{Ev}}^*TP_j(\omega)\ \in\ H^{2j-1-n}_{\mathrm{dR}}(\mathcal{G}).}\tag{8.130}$$

Step 2: what TP_j looks like on $S^n\times\mathcal{G}$

Everything is now a computation on the product manifold $S^n\times\mathcal{G}$. We need some bookkeeping for forms on a product.

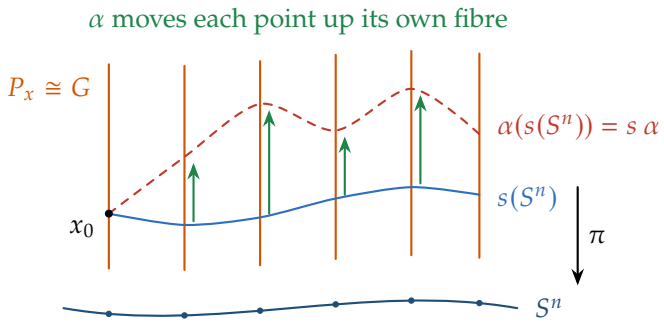


Figure 8.22: The map $\widehat{\mathrm{Ev}}$ of (8.129). A section s (blue) picks one point in each fibre. A gauge transformation α slides every point along its own fibre (green arrows); the image of the section is the new section $s\alpha$ (red, dashed). For the based gauge group α fixes the fibre over x_0. Letting α range over all of $\mathcal{G}$ sweeps out a copy of $S^n \times \mathcal{G}$ inside P (or rather mapped into P), and that is where we pull back TP_j.

Working definition 8.18 (forms on $S^n \times \mathcal{G}$: bidegree and the two derivatives)

- A form on $S^n \times \mathcal{G}$ has legs along S^n (the $\mathrm{d}x^\mu$) and legs along $\mathcal{G}$ [slots that take tangent vectors to $\mathcal{G}$, i.e. infinitesimal gauge transformations]. A form with p legs of the first kind and q of the second has **bidegree** (p, q), and total degree $p + q$.
- The exterior derivative splits as $\mathrm{d}_{\mathrm{tot}} = \mathrm{d} + \delta$: d differentiates along S^n and adds a $\mathrm{d}x$-leg; δ differentiates along $\mathcal{G}$ and adds a $\mathcal{G}$-leg. From $\mathrm{d}_{\mathrm{tot}}^2 = 0$ and the bidegree count, $\mathrm{d}^2 = 0$, $\delta^2 = 0$ and $\mathrm{d}\delta = -\delta\mathrm{d}$.
- Signs follow the *total* degree: a $\mathcal{G}$-leg anticommutes with a $\mathrm{d}x$-leg, and $\delta(\alpha \wedge \beta) = \delta\alpha \wedge \beta + (-1)^{|\alpha|}\alpha \wedge \delta\beta$ with $|\alpha|$ the total degree.
- δ is the familiar "variation". On the space of connections $\mathcal{A}$ the exterior derivative of a functional $\Phi[A]$ is its first variation, $\delta\Phi = \int \frac{\delta\Phi}{\delta A}\,\delta A$; the δA of (8.124) was exactly this.

The key object is a $\mathfrak{g}$-valued 1-form on $\mathcal{G}$, the Maurer–Cartan form of the gauge group:

$$\vartheta := \alpha^{-1}\delta\alpha, \qquad \vartheta_\alpha\Big(\frac{\mathrm{d}}{\mathrm{d}\tau}\alpha_\tau\Big|_{\tau=0}\Big) = \alpha^{-1}(x)\,\frac{\mathrm{d}\alpha_\tau(x)}{\mathrm{d}\tau}\Big|_{\tau=0} := \xi(x). \tag{8.131}$$

In words: feed ϑ a tangent vector to $\mathcal{G}$ at α (a curve of gauge transformations α_τ through α) and it returns the *infinitesimal gauge transformation* $\xi : S^n \to \mathfrak{g}$ that generates the curve, $\alpha_\tau \approx \alpha(\mathbb{1} + \tau\xi)$. So ϑ has bidegree $(0, 1)$: it is a function of x (no $\mathrm{d}x$-legs) and a 1-form on $\mathcal{G}$.

The pulled-back connection. Work in a trivialisation in which the section is $s(x) = (x, \mathbb{1})$ and a gauge transformation acts by $\alpha(s(x)) = s(x)\,\alpha(x)$ for a G-valued function also called $\alpha(x)$. (With the convention (8.18) this function is $g(x)^{-1}$; only the name changes.) Then

$$\begin{aligned}\mathbb{A} := \widehat{\mathrm{Ev}}^*\omega &\overset{(1)}{=} h^{-1}A\,h + h^{-1}\mathrm{d}_{\mathrm{tot}}h\Big|_{h(x,\alpha)=\alpha(x)} \\ &\overset{(2)}{=} \underbrace{\alpha^{-1}A\,\alpha + \alpha^{-1}\mathrm{d}\alpha}_{A^\alpha\text{: bidegree (1,0)}} + \underbrace{\alpha^{-1}\delta\alpha}_{\vartheta\text{: bidegree (0,1)}} = A^\alpha + \vartheta.\end{aligned} \tag{8.132}$$

(1) $\widehat{\mathrm{Ev}}(x, \alpha) = s(x)\,h(x, \alpha)$ with $h = \alpha(x)$, a G-valued function on $S^n \times \mathcal{G}$. By (8.3) the connection form at the point $s(x)h$ is $h^{-1}Ah + h^{-1}\mathrm{d}h$, and pulling back along a map from $S^n \times \mathcal{G}$ replaces d by the exterior derivative of $S^n \times \mathcal{G}$, which is $\mathrm{d}_{\mathrm{tot}}$.

(2) $\mathrm{d}_{\mathrm{tot}} h = \mathrm{d}\alpha + \delta\alpha$; sort by bidegree.

So $\mathbb{A}$ is the gauge transform of A by the function $\alpha(x)$, *with the total derivative*. Its $(1,0)$ part is the ordinary gauge transform A^α; its $(0,1)$ part is ϑ.

Its curvature. The rule $F^g = g^{-1}Fg$ is an algebraic consequence of the Leibniz rule and of $\mathrm{d}(g^{-1}) = -g^{-1}(\mathrm{d}g)g^{-1}$ (Chapter T3), and both hold for $\mathrm{d}_{\mathrm{tot}}$. Hence

$$\mathbb{F} \coloneqq \mathrm{d}_{\mathrm{tot}}\mathbb{A} + \mathbb{A}\wedge\mathbb{A} \overset{(1)}{=} \alpha^{-1}\big(\mathrm{d}_{\mathrm{tot}}A + A\wedge A\big)\alpha \overset{(2)}{=} \alpha^{-1}\big(\mathrm{d}A + A\wedge A\big)\alpha = \alpha^{-1}F\alpha = F^\alpha. \tag{8.133}$$

(1) Gauge covariance of the curvature, applied on $S^n\times\mathcal{G}$ to the gauge transformation $h=\alpha(x)$ with derivative $\mathrm{d}_{\mathrm{tot}}$.
(2) A lives on S^n and does not depend on α, so $\delta A = 0$.

This is the whole secret of the construction. *The curvature $\mathbb{F}$ has no legs along $\mathcal{G}$*: it is purely of bidegree $(2,0)$. The gauge group directions are "flat" directions, because moving along $\mathcal{G}$ does not change the physics.

Physical picture

Think of $S^n\times\mathcal{G}$ as a family of copies of S^n, labelled by α. On the copy labelled α we put the gauge-transformed field A^α. All these fields are gauge equivalent, so they have "the same" curvature, $F^\alpha = \alpha^{-1}F\alpha$. The extra piece ϑ of $\mathbb{A}$ is exactly what is needed to make the family into a single connection on the big space whose curvature does not see the $\mathcal{G}$ directions at all. A family of equivalent fields is a flat family.

Step 3: the forms are closed, and the degree count

Now the two conditions in Nash's (8.49)–(8.50) come out at once.

$$\mathrm{d}_{\mathrm{tot}}\big(\widehat{\mathrm{Ev}}^*TP_j\big) \overset{(1)}{=} \widehat{\mathrm{Ev}}^*\big(\mathrm{d}TP_j\big) \overset{(2)}{=} \widehat{\mathrm{Ev}}^*\pi^*c_j(F) \overset{(3)}{=} \mathrm{pr}^*c_j(F) \overset{(4)}{=} 0 \qquad \text{if } 2j>n. \tag{8.134}$$

(1) Pull-back commutes with the exterior derivative.
(2) The transgression formula (8.113): $\mathrm{d}TP_j(\omega) = \pi^*c_j(F)$ on P.
(3) $\pi\circ\widehat{\mathrm{Ev}}(x,\alpha) = x$, so $\pi\circ\widehat{\mathrm{Ev}}$ is the projection $\mathrm{pr}: S^n\times\mathcal{G}\to S^n$. (Equivalently: the pulled-back c_j is $P_j(\mathbb{F},\dots,\mathbb{F}) = P_j(F^\alpha,\dots) = P_j(F,\dots)$ by (8.133) and Ad-invariance.)
(4) $c_j(F)$ is a $2j$-form on the n-dimensional manifold S^n; if $2j>n$ it vanishes identically.

This is Nash's remark that "we have not yet checked that the characteristic class $c_j(F)$ vanishes but it turns out that this is automatic". The secondary class exists on $S^n\times\mathcal{G}$ precisely because the primary class has no room to live on S^n.

By (8.90), integration over the closed fibre S^n turns the closed $(2j-1)$-form $\widehat{\mathrm{Ev}}^*TP_j$ into a closed form of degree $2j-1-n$ on $\mathcal{G}$. For a non-trivial answer the degree must be non-negative:

$$2j-1-n \;\geq\; 0 \quad\Longleftrightarrow\quad 2j \;\geq\; n+1. \tag{8.135}$$

Since n is even (Nash's standing assumption), $2j\geq n+1$ is the same as $2j>n$, so *whenever μ_{2j-1-n} has a chance of being non-zero, the closedness* (8.134) *is guaranteed*. Figure 8.23 shows the count for $n=2$ and $n=4$.

Step 4: it is the same class as before

Is (8.130) the class (8.89) of Section 8.1.23, or something new? Use the gauge-variation formula (8.122). It was derived on an arbitrary manifold, so it holds on $S^n\times\mathcal{G}$ with $\mathrm{d}\to\mathrm{d}_{\mathrm{tot}}$ and gauge

	$j=1$	$j=2$	$j=3$	$j=4$	$j=5$	$j=6$
$n=2$	-1	μ_1	μ_3	μ_5	μ_7	μ_9
$n=4$	-3	-1	μ_1	μ_3	μ_5	μ_7

generators ω_{2j-1} exist for SU(N) when $2 \le j \le N$

Figure 8.23: The degree $2j-1-n$ of the form μ_{2j-1-n} built from TP_j. Grey boxes (negative degree) give nothing; blue boxes give a class. The red line is the condition $2j \ge n+1$ of (8.135). For $n=4$ the first class is μ_1 from $j=3$, so it needs a group with an independent ω_5, i.e. SU(N) with $N \ge 3$: this is Nash's table (8.38) again.

function $h(x,\alpha)=\alpha(x)$. Note that h, as a map $S^n \times \mathcal{G} \to G$, *is* the evaluation map Ev of (8.88). So

$$\widehat{\mathrm{Ev}}^* TP_j(\omega) \overset{(1)}{=} TP_j\big((\mathrm{pr}^* A)^h\big) \overset{(2)}{=} \mathrm{pr}^* TP_j(A) + h^*\omega_{2j-1} + \mathrm{d}_{\mathrm{tot}}\beta_j \overset{(3)}{=} \mathrm{Ev}^*\omega_{2j-1} + \mathrm{d}_{\mathrm{tot}}\beta_j. \tag{8.136}$$

(1) (8.132): $\mathbb{A}$ is the (total) gauge transform of the pulled-back potential pr^*A by h; and pull-back commutes with building TP_j out of the connection.
(2) (8.122) on the manifold $S^n \times \mathcal{G}$.
(3) $\mathrm{pr}^* TP_j(A)$ has only S^n-legs, and there are $2j-1 > n$ of them: it is zero. And $h = \mathrm{Ev}$.

Integrating over S^n and using (8.90) (with n even, so the sign is +),

$$\int_{S^n} \widehat{\mathrm{Ev}}^* TP_j = \int_{S^n} \mathrm{Ev}^*\omega_{2j-1} + \delta\Big(\int_{S^n} \beta_j\Big).$$

The new μ and the old μ differ by an exact form: *they are the same cohomology class*, as promised. The new one is better for physics: it is an explicit functional of the gauge field.

Step 5: the descent expansion

To read off the form μ_{2j-1-n} explicitly, fix a point (x,α) and abbreviate $B := A^\alpha$ (a $(1,0)$ form) and ϑ (a $(0,1)$ form). By (8.132)–(8.133), $\mathbb{A} = B + \vartheta$ and $\mathbb{F} = F_B$, the curvature of B. The transgression formula needs $\mathbb{F}_t = t\,\mathrm{d}_{\mathrm{tot}}\mathbb{A} + t^2\mathbb{A}^2$, and we rewrite it using $\mathrm{d}_{\mathrm{tot}}\mathbb{A} = \mathbb{F} - \mathbb{A}^2$:

$$\mathbb{F}_t = t\,\mathbb{F} + (t^2 - t)\,\mathbb{A}^2 = t\,F_B + (t^2-t)\big(B^2 + B\vartheta + \vartheta B + \vartheta^2\big). \tag{8.137}$$

This is pointwise algebra: no derivatives of ϑ appear. Now expand the transgression form $TP_j(\mathbb{A}) = j\int_0^1 P_j(\mathbb{A}, \mathbb{F}_t, \dots)\,\mathrm{d}t$ in powers of ϑ:

$$TP_j(\mathbb{A}) = \sum_{k=0}^{2j-1} \Omega^{(k)}_{2j-1-k}, \qquad \Omega^{(k)}_{2j-1-k} \text{ of bidegree } (2j-1-k,\ k). \tag{8.138}$$

The superscript counts the factors of ϑ (the legs along $\mathcal{G}$), the subscript the legs along S^n. Integration over S^n keeps only the terms with exactly n legs along S^n, i.e. $k = 2j-1-n$:

$$\boxed{\mu_{2j-1-n}\Big|_\alpha = \int_{S^n} \Omega_n^{(2j-1-n)}\big(A^\alpha, \vartheta\big).} \tag{8.139}$$

The $k=0$ term is just $TP_j(A^\alpha)$, the Chern–Simons form of the transformed field.

Dictionary: the gauge group Maurer–Cartan form is the ghost

Compute how the two pieces of $\mathbb{A}$ change along $\mathcal{G}$. With $\delta\alpha = \alpha\vartheta$, $\delta(\alpha^{-1}) = -\vartheta\alpha^{-1}$ and $\delta\mathrm{d} = -\mathrm{d}\delta$:

$$\delta\vartheta \overset{(1)}{=} \delta(\alpha^{-1})\,\delta\alpha \overset{(2)}{=} -\vartheta\,\alpha^{-1}\alpha\,\vartheta = -\vartheta^2,$$
$$\delta(\alpha^{-1}\mathrm{d}\alpha) \overset{(3)}{=} -\vartheta\,\alpha^{-1}\mathrm{d}\alpha - \alpha^{-1}\mathrm{d}(\alpha\vartheta) \overset{(4)}{=} -\vartheta\,\theta - \theta\,\vartheta - \mathrm{d}\vartheta, \qquad \theta := \alpha^{-1}\mathrm{d}\alpha,$$
$$\delta(\alpha^{-1}A\alpha) \overset{(5)}{=} -\vartheta\,\alpha^{-1}A\alpha - \alpha^{-1}A\,\delta\alpha = -\vartheta\,(\alpha^{-1}A\alpha) - (\alpha^{-1}A\alpha)\,\vartheta.$$

(1) Leibniz rule; $\delta^2\alpha = 0$.
(2) $\delta(\alpha^{-1}) = -\alpha^{-1}(\delta\alpha)\alpha^{-1}$ and $\delta\alpha = \alpha\vartheta$.
(3) Leibniz rule for δ; $\delta\mathrm{d}\alpha = -\mathrm{d}\delta\alpha = -\mathrm{d}(\alpha\vartheta)$.
(4) $\mathrm{d}(\alpha\vartheta) = \mathrm{d}\alpha\,\vartheta + \alpha\,\mathrm{d}\vartheta$ (α has degree 0).
(5) $\delta A = 0$; moving δ past the 1-form A costs a sign; then insert $\alpha\alpha^{-1}$.

Adding the last two lines, with $B = A^\alpha$ and the graded commutator $[B,\vartheta] = B\vartheta + \vartheta B$ of (8.7),

$$\delta B = -\big(\mathrm{d}\vartheta + [B,\vartheta]\big) = -D_B\vartheta, \qquad \delta\vartheta = -\vartheta^2.$$

These are the **BRST transformations** of a gauge field and of the Faddeev–Popov ghost (in one common sign convention), with $\delta \leftrightarrow s$ (the BRST operator) and $\vartheta \leftrightarrow c$ (the ghost). The ghosts that Section 8.1.10 introduced as a trick to exponentiate a Jacobian are, geometrically, the Maurer–Cartan form of the gauge group. The expansion (8.138) in powers of ϑ is what physicists call the expansion in **ghost number**, and the associated identities are the **Stora–Zumino descent equations** (Chapter 10).

Worked example 8.36: $n = 2$, $G = \mathrm{SU}(2)$: the form μ_1 explicitly

On S^2 the first class is μ_{2j-3} with $j = 2$, i.e. μ_1 built from TP_2 (Figure 8.23). We need the part of $TP_2(\mathbb{A})$ with one ϑ and two $\mathrm{d}x$-legs. Write $P_2(X,Y) = \kappa\ \mathrm{tr}(XY)$ with $\kappa = -\frac{1}{8\pi^2}$ (Table 8.3); for X odd and Y even the symmetrised trace is just $\mathrm{tr}(XY)$, since $\mathrm{tr}(YX) = \mathrm{tr}(XY)$.

$$TP_2(\mathbb{A}) \overset{(1)}{=} 2\kappa \int_0^1 \mathrm{d}t\ \mathrm{tr}\Big((B+\vartheta)\big(tF_B + (t^2-t)(B^2 + B\vartheta + \vartheta B + \vartheta^2)\big)\Big)$$
$$\Omega_2^{(1)} \overset{(2)}{=} 2\kappa \int_0^1 \mathrm{d}t\,\Big[t\ \mathrm{tr}(\vartheta F_B) + (t^2-t)\big(\mathrm{tr}(\vartheta B^2) + \mathrm{tr}(B^2\vartheta) + \mathrm{tr}(B\vartheta B)\big)\Big]$$
$$\overset{(3)}{=} 2\kappa \int_0^1 \mathrm{d}t\,\Big[t\ \mathrm{tr}(\vartheta F_B) + 3(t^2-t)\ \mathrm{tr}(\vartheta B^2)\Big]$$
$$\overset{(4)}{=} 2\kappa\Big[\tfrac{1}{2}\,\mathrm{tr}(\vartheta F_B) - \tfrac{1}{2}\,\mathrm{tr}(\vartheta B^2)\Big] \overset{(5)}{=} \kappa\ \mathrm{tr}(\vartheta\,\mathrm{d}B).$$

(1) Transgression formula (8.113) with (8.137) for $j = 2$.
(2) Keep terms with exactly one ϑ: ϑ from the first slot times $tF_B + (t^2-t)B^2$, or B from the first slot times $(t^2-t)(B\vartheta + \vartheta B)$.
(3) Cyclicity of the graded trace: moving a factor of degree a from the end to the front past a product of degree b costs $(-1)^{ab}$. Moving ϑ past B^2 (degree 2) and B past $B\vartheta$ (degree 2) costs nothing, so all three traces equal $\mathrm{tr}(\vartheta B^2)$.
(4) $\int_0^1 t\,\mathrm{d}t = \frac{1}{2}$ and $\int_0^1 (t^2-t)\,\mathrm{d}t = -\frac{1}{6}$.
(5) $F_B - B^2 = \mathrm{d}B$.

So, feeding in a tangent vector ξ at $\alpha \in \mathcal{G}$ (with $\vartheta(\xi) = \xi$, and putting the $\mathrm{d}x$-legs first, which costs no sign since $\mathrm{d}B$ is even),

$$\mu_1\big|_\alpha(\xi) = -\frac{1}{8\pi^2}\int_{S^2} \mathrm{tr}\big(\xi\, \mathrm{d}A^\alpha\big). \tag{8.140}$$

Check against (8.89). Take $A = 0$, so $B = \alpha^{-1}\mathrm{d}\alpha = \theta$ and $\mathrm{d}B = -\theta^2$ (Maurer–Cartan). Then $\Omega_2^{(1)} = -\kappa\,\mathrm{tr}(\vartheta\theta^2) = \frac{1}{8\pi^2}\,\mathrm{tr}(\vartheta\theta^2)$. On the other hand the Maurer–Cartan form of G pulled back by Ev is $\mathrm{Ev}^*(g^{-1}\mathrm{d}g) = \theta + \vartheta$, and the $(2,1)$ part of $\omega_3 = \frac{1}{24\pi^2}\,\mathrm{tr}(\theta+\vartheta)^3$ is $\frac{3}{24\pi^2}\,\mathrm{tr}(\vartheta\theta^2) = \frac{1}{8\pi^2}\,\mathrm{tr}(\vartheta\theta^2)$ (three placements of ϑ, all equal by cyclicity). The two agree on the nose, as (8.136) predicts (for $A = 0$ the correction β_j vanishes).

Worked example 8.37: A loop of gauge transformations on S^2 with $\oint \mu_1 = \pm 1$

For $M = S^2$ and $G = \mathrm{SU}(2)$, $\pi_1(\mathcal{G}) = \pi_{1+2}(\mathrm{SU}(2)) = \pi_3(S^3) = \mathbb{Z}$ (Eq. (8.56)). Let us exhibit a generator and evaluate μ_1 on it. Identify SU(2) with the unit quaternions, with imaginary units $e_a = -i\sigma_a$, and write a point of S^2 as a unit vector $\hat{n}$, with $\hat{n}\cdot e := n^a e_a$, so that $(\hat{n}\cdot e)^2 = -\mathbb{1}$. For any angle ϕ, $\exp(\phi\,\hat{n}\cdot e) = \cos\phi\,\mathbb{1} + \sin\phi\,\hat{n}\cdot e$. Take the base point $\hat{n}_0$ to be the north pole and define, for $\tau \in [0,1]$,

$$\alpha_\tau(\hat{n}) = \exp\big(\pi\tau\,\hat{n}\cdot e\big)\,\exp\big(-\pi\tau\,\hat{n}_0\cdot e\big).$$

- *Based:* at $\hat{n} = \hat{n}_0$ the two factors cancel, $\alpha_\tau(\hat{n}_0) = \mathbb{1}$.
- *A loop:* $\alpha_0 = \mathbb{1}$, and at $\tau = 1$ each factor is $\cos\pi = -\mathbb{1}$, so $\alpha_1 = (-\mathbb{1})(-\mathbb{1}) = \mathbb{1}$.
- *Degree one:* by (8.91), $\oint \mu_1 = \int_{S^2\times S^1} F^*\omega_3$ with $F(\hat{n},\tau) = \alpha_\tau(\hat{n})$, which is the degree of F as a map to S^3. Count preimages of the point $-\mathbb{1}$: $\alpha_\tau(\hat{n}) = -\mathbb{1}$ means $\exp(\pi\tau\,\hat{n}\cdot e) = -\exp(\pi\tau\,\hat{n}_0\cdot e) = \exp\big(\pi(1-\tau)(-\hat{n}_0)\cdot e\big)$. For $\tau \in (0,1)$ both angles lie in $(0,\pi)$, where the polar form $\cos\phi + \sin\phi\,\hat{m}\cdot e$ is unique; so $\tau = 1-\tau$ and $\hat{n} = -\hat{n}_0$. There is exactly one preimage, $(\hat{n},\tau) = (\text{south pole}, \frac{1}{2})$, so the degree is ± 1.

A direct numerical evaluation of $\frac{1}{24\pi^2}\int \mathrm{tr}\,\theta^3$ with the orientation (polar angle, azimuth, τ) of $S^2\times S^1$ gives -1.000. For comparison, the unbased loop $\tau \mapsto \exp(2\pi\tau\,\hat{n}\cdot e)$ covers S^3 twice (once for $\tau < \frac{1}{2}$, once for $\tau > \frac{1}{2}$ with $\hat{n} \to -\hat{n}$), and gives -2. Physically: in two-dimensional SU(2) gauge theory on a sphere there are closed loops of gauge transformations that cannot be shrunk, and μ_1, the explicit functional (8.140), counts how many times a loop winds.

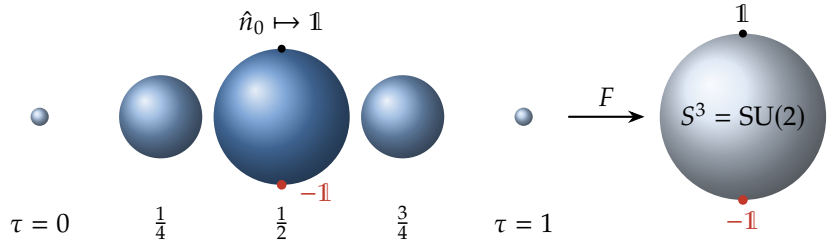

Figure 8.24: The loop of Example 8.37 as a map $F : S^2\times S^1 \to S^3$. Each slice τ is a sphere S^2 mapped into SU(2); the image sphere grows from the point $\mathbb{1}$ at $\tau = 0$, sweeps across S^3, and shrinks back to $\mathbb{1}$ at $\tau = 1$, while the base point $\hat{n}_0$ is always sent to $\mathbb{1}$. Only one point, the south pole at $\tau = \frac{1}{2}$ (red), goes to $-\mathbb{1}$: the map has degree ± 1, so $\oint \mu_1 = \pm 1$ and the loop generates $\pi_1(\mathcal{G}) = \mathbb{Z}$.

Step 6: Nash's example, μ_1 on S^4

Nash's own example (his (8.54)–(8.58)) is the physically important case: four dimensions, $n = 4$, $G = \mathrm{SU}(N)$. By (8.135) the class μ_1 comes from

$$2j - 1 - n = 1 \quad \Longrightarrow \quad j = \frac{2+n}{2} = 3, \tag{8.141}$$

that is, from the third Chern class and its Chern–Simons form (Nash's (8.56))

$$TP_3(A) = 3\int_0^1 \mathrm{d}t\, P_3(A, F_t, F_t).$$

The invariant polynomial (Nash's (8.57)) is the $\mathrm{SU}(N)$ Chern class c_3 of (8.106):

$$P_3(F,F,F) = \frac{1}{3}\Big(\frac{i}{2\pi}\Big)^3 \operatorname{tr} F^3 \overset{(1)}{=} \frac{1}{3}\cdot\frac{-i}{8\pi^3}\operatorname{tr} F^3 = -\frac{i}{24\pi^3}\operatorname{tr}(F\wedge F\wedge F), \tag{8.142}$$

(1) $(i/2\pi)^3 = i^3/(8\pi^3) = -i/(8\pi^3)$.

and its polarisation is $P_3(X,Y,Z) = c\,\mathrm{STr}(X,Y,Z)$ with $c := -\frac{i}{24\pi^3}$, where STr is the graded symmetrised trace (Section 8.2.2). Putting the pieces together (Nash's (8.58)):

$$\mu_1 = 3c\int_0^1 \mathrm{d}t \int_{S^4} \operatorname{tr}\big(\mathbb{A}\wedge\mathbb{F}_t\wedge\mathbb{F}_t\big) = -\frac{i}{(2\pi)^3}\int_0^1 \mathrm{d}t\int_{S^4}\operatorname{tr}\big(\mathbb{A}\wedge\mathbb{F}_t\wedge\mathbb{F}_t\big), \tag{8.143}$$

since $3c = -\frac{i}{8\pi^3} = -\frac{i}{(2\pi)^3}$. Here the first step uses that in $P_3(\mathbb{A},\mathbb{F}_t,\mathbb{F}_t)$, with $\mathbb{F}_t$ of even degree, all orderings are cyclically equal to $\operatorname{tr}(\mathbb{A}\mathbb{F}_t\mathbb{F}_t)$.

Watch out: How to read Nash's (8.58)

Nash writes (8.58) with "A and F the connection and curvature on S^4". Read literally this is zero: $\operatorname{tr}(A\wedge F_t\wedge F_t)$ would be a 5-form on a 4-manifold. The A in (8.58) must be the pulled-back connection $\mathbb{A} = A^\alpha + \vartheta$ on $S^4\times\mathcal{G}$ of (8.132), and F_t is built from it by (8.137). The integral over S^4 then picks out the part with one ϑ, which is a 1-form on $\mathcal{G}$. That is what we now compute.

The computation is the $n = 2$ one of Example 8.36, one step longer. Write $Y := tF_B + s\,B^2$ and $C := s\,(B\vartheta + \vartheta B)$ with $s := t^2 - t$, so that $\mathbb{F}_t = Y + C + s\,\vartheta^2$. The terms of $P_3(\mathbb{A},\mathbb{F}_t,\mathbb{F}_t)$ with one ϑ are

$$P_3(\vartheta,Y,Y) + 2P_3(B,Y,C) = c\Big[\operatorname{tr}(\vartheta Y^2) + \operatorname{tr}(BYC) + \operatorname{tr}(BCY)\Big].$$

(For $P_3(B,Y,C)$: of the six orderings, three are cyclically equal to $\operatorname{tr}(BYC)$ and three to $\operatorname{tr}(BCY)$, all with sign + because Y and C are even; the $\frac{1}{6}$ of the symmetrisation and the factor 2 combine to 1.) Every trace can be brought to the form $\operatorname{tr}(\vartheta W)$ with W a 4-form built from B and F_B: moving a block of degree a from the back to the front past a block of degree b costs $(-1)^{ab}$, and one checks that every move needed here has ab even. Collecting by monomials:

monomial	from $\operatorname{tr}(\vartheta Y^2)$	from $\operatorname{tr}(BYC)+\operatorname{tr}(BCY)$	$3\int_0^1(\cdot)\,\mathrm{d}t$
$\operatorname{tr}(\vartheta F_B^2)$	t^2	–	1
$\operatorname{tr}(\vartheta F_B B^2)$	ts	ts	$-\frac{1}{2}$
$\operatorname{tr}(\vartheta B^2 F_B)$	ts	ts	$-\frac{1}{2}$
$\operatorname{tr}(\vartheta B F_B B)$	–	$2ts$	$-\frac{1}{2}$
$\operatorname{tr}(\vartheta B^4)$	s^2	$4s^2$	$\frac{1}{2}$

using $\int_0^1 t^2\,\mathrm{d}t = \frac{1}{3}$, $\int_0^1 ts\,\mathrm{d}t = \frac{1}{4} - \frac{1}{3} = -\frac{1}{12}$ and $\int_0^1 s^2\,\mathrm{d}t = \frac{1}{5} - \frac{1}{2} + \frac{1}{3} = \frac{1}{30}$. Hence

$$\begin{aligned}\frac{1}{c}\,\Omega_4^{(1)} &\overset{(1)}{=} \operatorname{tr}\Big(\vartheta\big[F_B^2 - \tfrac{1}{2}F_B B^2 - \tfrac{1}{2}B^2F_B - \tfrac{1}{2}BF_BB + \tfrac{1}{2}B^4\big]\Big)\\ &\overset{(2)}{=} \operatorname{tr}\Big(\vartheta\big[(\mathrm{d}B)^2 + \tfrac{1}{2}\big(\mathrm{d}B\,B^2 - B\,\mathrm{d}B\,B + B^2\,\mathrm{d}B\big) + \big(1 - \tfrac{1}{2} - \tfrac{1}{2} - \tfrac{1}{2} + \tfrac{1}{2}\big)B^4\big]\Big)\\ &\overset{(3)}{=} \operatorname{tr}\Big(\vartheta\,\mathrm{d}\big(B\,\mathrm{d}B + \tfrac{1}{2}B^3\big)\Big).\end{aligned} \tag{8.144}$$

(1) The table.
(2) Substitute $F_B = \mathrm{d}B + B^2$: $F_B^2 = (\mathrm{d}B)^2 + \mathrm{d}B\,B^2 + B^2\mathrm{d}B + B^4$, $F_BB^2 = \mathrm{d}B\,B^2 + B^4$, $B^2F_B = B^2\mathrm{d}B + B^4$, $BF_BB = B\,\mathrm{d}B\,B + B^4$, and collect.
(3) $\mathrm{d}(B\,\mathrm{d}B) = (\mathrm{d}B)^2$ and $\mathrm{d}(B^3) = \mathrm{d}B\,B^2 - B\,\mathrm{d}B\,B + B^2\,\mathrm{d}B$ (graded Leibniz rule); the B^4 terms cancel.

(A computer-algebra expansion of $3\int_0^1 P_3(\mathbb{A}, \mathbb{F}_t, \mathbb{F}_t)\,\mathrm{d}t$ in a free graded algebra confirms (8.144), and also confirms that the ϑ-free part is $c\ \operatorname{tr}(B(\mathrm{d}B)^2 + \frac{3}{2}B^3\mathrm{d}B + \frac{3}{5}B^5)$, the Chern–Simons 5-form (8.117).)

Key idea: The explicit μ_1 on S^4

For $G = \mathrm{SU}(N)$ on S^4, at the point $\alpha \in \mathcal{G}$ and on the infinitesimal gauge transformation ξ,

$$\mu_1\big|_\alpha(\xi) = -\frac{i}{24\pi^3}\int_{S^4} \operatorname{tr}\Big(\xi\,\mathrm{d}\big(A^\alpha\,\mathrm{d}A^\alpha + \tfrac{1}{2}(A^\alpha)^3\big)\Big). \tag{8.145}$$

It is linear in ξ, as a 1-form must be, and it has the famous structure $\operatorname{tr}\,\xi\,\mathrm{d}(A\,\mathrm{d}A + \frac{1}{2}A^3)$ of the *consistent non-Abelian anomaly* of a chiral fermion in four dimensions. In Chapter 10 the anomaly is found from Feynman diagrams and is identified, up to a factor involving 2π and the normalisation of the generators, with this class.

Two checks.

1. *Pure gauge, against* (8.89). For $A = 0$, $B = \theta$ and $\mathrm{d}\theta = -\theta^2$:

$$\mathrm{d}\big(\theta\,\mathrm{d}\theta + \tfrac{1}{2}\theta^3\big) \overset{(1)}{=} \mathrm{d}\big(-\theta^3 + \tfrac{1}{2}\theta^3\big) = -\tfrac{1}{2}\,\mathrm{d}(\theta^3) \overset{(2)}{=} -\tfrac{1}{2}\big(\mathrm{d}\theta\,\theta^2 - \theta\,\mathrm{d}\theta\,\theta + \theta^2\mathrm{d}\theta\big) \overset{(3)}{=} \tfrac{1}{2}\,\theta^4.$$

   (1) Maurer–Cartan, $\mathrm{d}\theta = -\theta^2$.
   (2) Graded Leibniz rule for the three factors of θ^3.
   (3) Each $\mathrm{d}\theta$ becomes $-\theta^2$: $-\frac{1}{2}(-\theta^4 + \theta^4 - \theta^4) = \frac{1}{2}\theta^4$.

   So $\Omega_4^{(1)} = \frac{c}{2}\operatorname{tr}(\vartheta\theta^4) = -\frac{i}{48\pi^3}\operatorname{tr}(\vartheta\theta^4)$. The $(4,1)$ part of $\mathrm{Ev}^*\omega_5 = C_3\operatorname{tr}(\theta+\vartheta)^5$ is $5C_3\operatorname{tr}(\vartheta\theta^4) = -\frac{5i}{240\pi^3}\operatorname{tr}(\vartheta\theta^4) = -\frac{i}{48\pi^3}\operatorname{tr}(\vartheta\theta^4)$, with C_3 from (8.87). They agree exactly.

2. *Abelian shadow.* If all matrices commuted (a U(1) factor), $B^2 = 0$, $\mathbb{F}_t = tF$ and $TP_3 = c\,(B + \vartheta)F^2$, whose one-$\vartheta$ part is $c\,\vartheta(\mathrm{d}B)^2 = c\,\vartheta\,\mathrm{d}(B\,\mathrm{d}B)$: the non-Abelian formula with the B^3 term dropped.

Try it

Show that μ_1 vanishes identically for $G = \mathrm{SU}(2)$ on S^4, in agreement with $\pi_1(\mathcal{G}) \otimes \mathbb{Q} = \pi_5(\mathrm{SU}(2)) \otimes \mathbb{Q} = \mathbb{Z}_2 \otimes \mathbb{Q} = 0$.
Answer. P_3 is built from the totally symmetric tensor $d_{abc} \propto \operatorname{tr}(e_a\{e_b, e_c\})$. For $\mathfrak{su}(2)$,

$\{e_b, e_c\} = -2\delta_{bc}\mathbb{1}$, so $d_{abc} \propto \delta_{bc}\,\mathrm{tr}\,e_a = 0$. Every symmetrised trace of three $\mathfrak{su}(2)$-valued forms vanishes, hence $TP_3 = 0$. The torsion class of $\pi_5(\mathrm{SU}(2)) = \mathbb{Z}_2$ is invisible to de Rham cohomology (Example 8.21); it resurfaces as the global SU(2) anomaly (Chapter 10).

Watch out: Non-trivial bundles

For the instanton bundles P_k over S^4 with $k \neq 0$ there is no global section, so (8.129) is only defined over each hemisphere. The recipe still works: on the overlap the two local versions of $\Omega_4^{(1)}$ differ by an exact form plus terms that cancel between the two hemispheres, and (8.145) holds on each patch with the local potential. Since the class μ_1 is defined without sections by (8.89) and by the homotopy equivalence $\mathcal{G}_k \simeq \mathcal{G}_0$ (Eq. (8.50)), nothing depends on these choices.

8.2.9 The classes ν on $\mathcal{A}/\mathcal{G}$ and the double transgression

The ν's live on the configuration space $B\mathcal{G} = \mathcal{A}/\mathcal{G}$. Nash relates them to the μ's through the principal bundle (Nash's (8.51), our (8.35))

$$\mathcal{G} \longrightarrow \mathcal{A} \xrightarrow{\pi} \mathcal{A}/\mathcal{G} = B\mathcal{G}.$$

This is the same shape as the universal bundle $G \to EG \to BG$: a group, a contractible total space, a quotient. For $G \to P \to M$ we saw (Section 8.2.5) that a class on the base pulled up to the total space becomes exact, and that its primitive restricted to a fibre is a class on the group. The same happens here, one level up.

Step 1: pull back to $\mathcal{A}$, where everything is exact

Pull $\nu_{2j} \in H^{2j}_{\mathrm{dR}}(B\mathcal{G})$ back to $\mathcal{A}$. The space $\mathcal{A}$ is affine, hence contractible ((8.14)), and on a contractible space every closed form of positive degree is exact. (Proof of the Poincaré lemma on an affine space: the straight-line homotopy $A_s = A_0 + s(A - A_0)$ gives an explicit primitive, exactly as in the derivation of the transgression formula.) So (Nash's (8.52))

$$\pi^*\nu_{2j} = \delta f_j \qquad \text{for some } f_j \in \Omega^{2j-1}(\mathcal{A}). \tag{8.146}$$

Restrict f_j to one fibre of π, i.e. to one gauge orbit $\mathcal{G}\cdot A$. On the orbit π is constant, so $\pi^*\nu_{2j}$ restricts to zero (the pull-back of a form of positive degree by a constant map vanishes). Hence

$$\delta\big(f_j|_{\mathcal{G}\cdot A}\big) = \big(\pi^*\nu_{2j}\big)\big|_{\mathcal{G}\cdot A} = 0:$$

f_j restricted to an orbit is a closed $(2j-1)$-form on $\mathcal{G}$. Nash's claim (8.53) is that this is μ_{2j-1}. To see it, we make f_j explicit.

Step 2: the universal connection on $S^n \times \mathcal{A}$

Over $S^n \times \mathcal{A}$ there is a tautological bundle with a tautological connection: over the point (x, A) put the fibre P_x, and let the connection in the S^n directions be A itself. What connection should we use in the $\mathcal{A}$ directions? The answer is dictated by the requirement that everything descend to $S^n \times \mathcal{A}/\mathcal{G}$: moving *along* a gauge orbit should be undone by the corresponding gauge transformation. That requires a way of splitting a tangent vector $a \in T_A\mathcal{A} = \Omega^1(M;\mathfrak{g})$ into a part along the orbit and a part across it, i.e. a connection on the principal bundle $\mathcal{A} \to \mathcal{A}/\mathcal{G}$.

Working definition 8.19 (the Coulomb connection on $\mathcal{A} \to \mathcal{A}/\mathcal{G}$)

At $A \in \mathcal{A}$ the orbit directions are the infinitesimal gauge transformations $a = D_A\xi$ (Eq. (8.41)). Declare the *horizontal* directions to be those orthogonal to the orbit in the L^2 inner product [the integral over M of the pointwise inner product of two $\mathfrak{g}$-valued 1-forms], i.e. those with $D_A^* a = 0$ [D_A^* is the adjoint of D_A for this inner product]: the *background Coulomb gauge* condition. The connection 1-form is the Lie($\mathcal{G}$)-valued [its value on a is an infinitesimal gauge transformation ξ] 1-form on $\mathcal{A}$

$$\Theta_A(a) := \left(D_A^* D_A\right)^{-1} D_A^*\, a. \tag{8.147}$$

To use it: to split a variation a of the gauge field, solve the Poisson-type equation [a Laplace equation for ξ. It has exactly one solution when A is irreducible, since then $D_A\xi = 0$ only for $\xi = 0$] $D_A^* D_A \xi = D_A^* a$ for ξ; then $a = D_A\xi + (a - D_A\xi)$ is the vertical plus horizontal decomposition, and $\Theta(a) = \xi$.

It reproduces the generators of the orbit, which is the defining property of a connection form:

$$\Theta_A(D_A\xi) \overset{(1)}{=} \left(D_A^* D_A\right)^{-1}\left(D_A^* D_A\right)\xi \overset{(2)}{=} \xi.$$

(1) Definition (8.147) with $a = D_A\xi$.
(2) $D_A^* D_A$ is invertible when A is irreducible (no covariantly constant ξ; Example 8.3), which is where the gauge group acts freely.

The horizontal subspace $\{D_A^* a = 0\}$ is the tangent space of the local Coulomb slice of Section 8.1.11. That the slice does not extend globally (Gribov) is the statement that the bundle $\mathcal{A} \to \mathcal{A}/\mathcal{G}$ is non-trivial; the connection Θ exists globally all the same, and its *curvature* is what measures the twisting. Figure 8.25 shows the geometry.

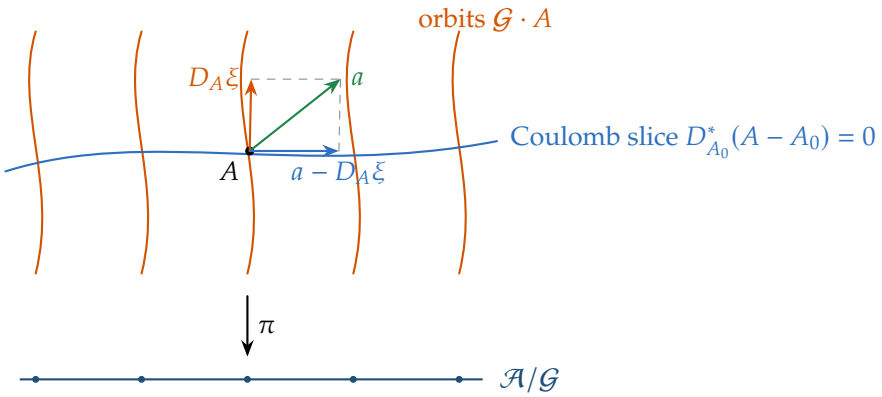

Figure 8.25: The Coulomb connection on $\mathcal{A} \to \mathcal{A}/\mathcal{G}$. Each orbit (orange) projects to a single point of $\mathcal{A}/\mathcal{G}$. A variation a of the gauge field at A (green) splits into a piece $D_A\xi$ along the orbit, which is a gauge transformation and changes nothing physical, and a horizontal piece orthogonal to the orbit (blue). The connection form Θ returns ξ. Horizontal directions are tangent to the Coulomb slice.

The universal connection and its curvature. On $S^n \times \mathcal{A}$ define

$$\mathbb{A}_{\text{univ}} := A + \Theta, \tag{8.148}$$

where A is the tautological $(1,0)$ form (at the point (x, A) it is the value of A at x) and Θ is the $(0,1)$ form (8.147), a $\mathfrak{g}$-valued function of x for each tangent vector. Its curvature, sorted by

bidegree, is

$$\begin{aligned}\mathbb{F}_{\text{univ}} &\overset{(1)}{=} (\mathrm{d}+\delta)(A+\Theta)+(A+\Theta)^2 \\ &\overset{(2)}{=} \underbrace{\mathrm{d}A+A^2}_{(2,0):\,F} + \underbrace{\delta A+\mathrm{d}\Theta+A\Theta+\Theta A}_{(1,1):\,\delta A+D_A\Theta} + \underbrace{\delta\Theta+\Theta^2}_{(0,2):\,\Omega_\Theta}.\end{aligned} \tag{8.149}$$

(1) Definition of curvature with $\mathrm{d}_{\text{tot}} = \mathrm{d}+\delta$.
(2) Expand and sort: $\mathrm{d}A$ and A^2 have two x-legs; δA, $\mathrm{d}\Theta$ and $A\Theta+\Theta A$ have one of each; $\delta\Theta$ and Θ^2 have two $\mathcal{A}$-legs. $D_A\Theta = \mathrm{d}\Theta + [A,\Theta]$ with the graded bracket.

Each piece has a meaning. The $(2,0)$ part is the field strength. The $(0,2)$ part Ω_Θ is the curvature of the Coulomb connection on $\mathcal{A}\to\mathcal{A}/\mathcal{G}$. The $(1,1)$ part, evaluated on a tangent vector a, is (up to the sign conventions of the bigrading) the *horizontal projection* $a - D_A\Theta(a)$. In particular it vanishes on vertical vectors. To check this, restrict to an orbit with the orbit map $o_A:\mathcal{G}\to\mathcal{A}$, $\alpha\mapsto A^\alpha$. By the dictionary box of Section 8.2.8, $o_A^*(\delta A) = \delta(A^\alpha) = -D_{A^\alpha}\vartheta$, and by the defining property of Θ, $o_A^*\Theta = \vartheta$ (the tangent vector to the orbit generated by ξ is $D_{A^\alpha}\xi$, and Θ returns ξ). So

$$\begin{aligned}(\mathrm{id}\times o_A)^*\,\mathbb{A}_{\text{univ}} &\overset{(1)}{=} A^\alpha+\vartheta \overset{(2)}{=} \mathbb{A}, \\ (\mathrm{id}\times o_A)^*\big(\delta A + D_A\Theta\big) &\overset{(3)}{=} -D_{A^\alpha}\vartheta + D_{A^\alpha}\vartheta = 0.\end{aligned} \tag{8.150}$$

(1) The tautological A pulls back to A^α and Θ to ϑ.
(2) This is precisely the connection $\widehat{\mathrm{Ev}}^*\,\omega$ of (8.132).
(3) $o_A^*\delta A = -D_{A^\alpha}\vartheta$ from the dictionary box, and $o_A^*(D_A\Theta) = D_{A^\alpha}\vartheta$.

On an orbit the universal connection is the connection we used to define μ, and its curvature is purely $(2,0)$, in agreement with (8.133).

Step 3: the explicit f_j and Nash's (8.53)

The universal curvature is basic (it descends to $S^n\times\mathcal{A}/\mathcal{G}$, because Θ is a genuine connection), so the Chern–Weil form of the universal bundle over $S^n\times B\mathcal{G}$ pulled back to $S^n\times\mathcal{A}$ is $P_J(\mathbb{F}_{\text{univ}})$. With $J := j+\frac{n}{2}$, so that $2J-n = 2j$, the class ν_{2j} of (8.97) is represented on $\mathcal{A}$ by

$$\pi^*\nu_{2j} \overset{(1)}{=} \int_{S^n} P_J(\mathbb{F}_{\text{univ}},\dots,\mathbb{F}_{\text{univ}}) \overset{(2)}{=} \int_{S^n} \mathrm{d}_{\text{tot}} TP_J(\mathbb{A}_{\text{univ}}) \overset{(3)}{=} \delta\int_{S^n} TP_J(\mathbb{A}_{\text{univ}}). \tag{8.151}$$

(1) Chern–Weil for the universal bundle: c_J is represented by $P_J(\mathbb{F})$, and $\nu_{2j} = \int_{S^n}\mathrm{Ev}^*c_J$ by definition.
(2) The bundle over $S^n\times\mathcal{A}$ is pulled back from S^n (it is pr^*P), so the transgression formula applies there with a section: a section s of P over S^n (trivial bundle, as in Section 8.2.8) is also one over $S^n\times\mathcal{A}$, and pulled back by it, $P_J(\mathbb{F}) = \mathrm{d}_{\text{tot}}TP_J(\mathbb{A})$ as in (8.115).
(3) (8.90) with n even.

So an explicit primitive is

$$f_j = \int_{S^n} TP_{j+n/2}\big(A+\Theta\big), \tag{8.152}$$

and restricted to an orbit, by (8.150),

$$\boxed{f_j\big|_{\mathcal{G}\cdot A} = \int_{S^n} TP_{j+n/2}\big(A^\alpha+\vartheta\big) = \int_{S^n}\widehat{\mathrm{Ev}}^*TP_{j+n/2} = \mu_{2j-1}, \qquad \pi^*\nu_{2j} = \delta f_j.} \tag{8.153}$$

This is Nash's (8.53), with the "adjusted indices": the class $\mu_{2(j+n/2)-1-n}$ of (8.130) is μ_{2j-1}. With the Coulomb connection the coincidence is exact, not merely in cohomology. Any other primitive f_j' of $\pi^*\nu_{2j}$ differs from f_j by a closed, hence exact, form on the contractible $\mathcal{A}$, and restricts to a cohomologous form on the orbit; this is Nash's "coincides cohomologically".

$$\begin{array}{ccccccc} H^{2j-1}_{\mathrm{dR}}(\mathcal{G}) \ni \mu_{2j-1} & \xleftarrow{\text{orbit}} & f_j \in \Omega^{2j-1}(\mathcal{A}) & \xrightarrow{\delta} & \pi^*\nu_{2j} \in \Omega^{2j}(\mathcal{A}) & \xleftarrow{\pi^*} & \nu_{2j} \in H^{2j}_{\mathrm{dR}}(\mathcal{A}/\mathcal{G}) \\ \int_{S^n}\mathrm{Ev}^* \uparrow & & \int_{S^n}\uparrow & & & & \uparrow \int_{S^n}\mathrm{Ev}^* \\ \omega_{2J-1} \in H^{2J-1}_{\mathrm{dR}}(G) & \xleftarrow{\text{fibre}} & TP_J \in \Omega^{2J-1}(P) & \xrightarrow{\mathrm{d}} & \pi^*c_J \in \Omega^{2J}(P) & \xleftarrow{\pi^*} & c_J \in H^{2J}(BG) \end{array}$$

Figure 8.26: The double transgression, with $J = j + \frac{n}{2}$. Bottom row: the transgression for $G \to P \to M$ (Section 8.2.5); the Chern–Simons form TP_J has $\mathrm{d}TP_J = \pi^*c_J$ and restricts to the generator ω_{2J-1} on a fibre. Top row: the same pattern for $\mathcal{G} \to \mathcal{A} \to \mathcal{A}/\mathcal{G}$. Horizontal arrows to the left are restriction to an orbit or a fibre. The vertical arrows are "evaluate and integrate over S^n", which lowers every degree by n. Read the diagram as: *integration over S^n intertwines the two transgressions.*

Step 4: exactness of μ and of ν go together

Nash ends with: if μ_1 is exact the same is true of ν_2, and conversely. One direction is a short chain. Suppose $\nu_{2j} = \delta h$ on $\mathcal{A}/\mathcal{G}$. Then

$$\delta\big(f_j - \pi^*h\big) \overset{(1)}{=} \pi^*\nu_{2j} - \pi^*\nu_{2j} = 0, \qquad f_j - \pi^*h \overset{(2)}{=} \delta k,$$
$$\mu_{2j-1} \overset{(3)}{=} f_j\big|_{\mathcal{G}\cdot A} \overset{(4)}{=} \big(\pi^*h + \delta k\big)\big|_{\mathcal{G}\cdot A} \overset{(5)}{=} \delta\big(k|_{\mathcal{G}\cdot A}\big).$$

(1) (8.146), and δ commutes with pull-back.
(2) A closed form of positive degree on the contractible $\mathcal{A}$ is exact.
(3) (8.153).
(4) The previous line.
(5) π is constant on an orbit, so π^*h restricts to zero.

So ν_{2j} exact $\Rightarrow$ μ_{2j-1} exact. The converse is the statement that for a principal bundle with *contractible* total space the transgression $\mu_{2j-1} \mapsto \nu_{2j}$ is an isomorphism on these generators, exactly as for $G \to EG \to BG$, where $\omega_{2J-1} \mapsto c_J$. In homotopy language: the long exact sequence (8.38) with $\pi_*(\mathcal{A}) = 0$ gives $\pi_k(B\mathcal{G}) \cong \pi_{k-1}(\mathcal{G})$, and rationally the generators correspond one to one; a generator cannot die on one side without dying on the other.

Worked example 8.38: $n = 4$, SU(3): the pair (μ_1, ν_2)

For SU(3) on S^4 the lowest classes are $\mu_1 \in H^1_{\mathrm{dR}}(\mathcal{G})$ and $\nu_2 \in H^2_{\mathrm{dR}}(\mathcal{A}/\mathcal{G})$, both from $J = 3$ (i.e. $j = 1$ in (8.153)):

$$\pi^*\nu_2 = \int_{S^4} P_3(\mathbb{F}_{\mathrm{univ}}) = \delta f_1, \qquad f_1 = \int_{S^4} TP_3(A + \Theta), \qquad f_1\big|_{\mathcal{G}\cdot A} = \mu_1.$$

What does ν_2 look like at a connection A? We need the $(4,2)$ part of $P_3(\mathbb{F}_{\mathrm{univ}}) = c\,\mathrm{tr}\,\mathbb{F}^3$, with $\mathbb{F} = F + \psi + \Omega_\Theta$ split as in (8.149) (ψ the $(1,1)$ part). The terms with four x-legs and two $\mathcal{A}$-legs are F, F, Ω_Θ and F, ψ, ψ; all three placements of each are cyclically equal (all pieces are even), so

$$\pi^*\nu_2 = -\frac{i}{8\pi^3}\int_{S^4} \mathrm{tr}\big(F^2\,\Omega_\Theta + F\,\psi^2\big).$$

On two variations a, b of the gauge field it is a bilinear, antisymmetric expression built from $\mathrm{tr}(F \wedge a_{\mathrm{h}} \wedge b_{\mathrm{h}})$ (with $a_{\mathrm{h}}, b_{\mathrm{h}}$ the horizontal parts) and from $\mathrm{tr}(F \wedge F\, \Omega_\Theta(a,b))$. It is a 2-form on the space of physical configurations. Its non-triviality, $\nu_2 \neq 0$ in $H^2_{\mathrm{dR}}(\mathcal{A}/\mathcal{G})$, is equivalent by Step 4 to $\mu_1 \neq 0$, i.e. to the existence of the anomaly 1-form (8.145); the pair is the "curvature" and the "connection" of one line bundle over $\mathcal{A}/\mathcal{G}$, whose first Chern class is ν_2. In Chapter 10 this line bundle is the determinant line bundle of the chiral Dirac operator.

Reading Nash (pp. 225–226, (8.46)–(8.58))

Nash's (8.46)–(8.48) are our (8.128)–(8.130); the "restriction to $\mathcal{G} \times S^n$" requires the section of (8.129). His (8.49)–(8.50) are (8.135) and (8.134). He writes $\mathcal{G} \times P$ and $\mathcal{G} \times S^n$ with $\mathcal{G}$ first; we put S^n first so that integration over S^n has the sign convention of (8.90). His (8.52) is (8.146); the claim that the restricted f_j "one can easily check coincides cohomologically with μ_{2j-1}" is our (8.150)–(8.153), which uses the Coulomb connection (8.147) that Nash does not write down. His (8.55)–(8.57) are (8.141)–(8.142); his (8.58) is (8.143), and its evaluation (8.145) is not in Nash. His closing sentence ("if μ_1 is exact the same is true for ν_2") is Step 4.

8.2.10 A secondary class in the action: three-dimensional Chern–Simons gauge theory

Up to now secondary classes were cohomology classes: on P, on the gauge group $\mathcal{G}$, on the configuration space $\mathcal{A}/\mathcal{G}$. Nash's last example of the section puts one straight into a Lagrangian. In three dimensions the Chern–Simons form $TP_2(A)$ is a 3-form, so it can be integrated over spacetime and added to the action. This was done by Deser, Jackiw and Templeton (1982) and by Schonfeld (1981). Two things happen, and both are consequences of the $\mathbb{R}/\mathbb{Z}$ nature of the secondary class that we found in Section 8.2.7:

1. the coefficient of the Chern–Simons term must be quantised;
2. the gauge field acquires a mass, without any Higgs field.

The three-dimensional gauge group is disconnected

Take spacetime to be a compact oriented 3-manifold M; the model case is $M = S^3$, Euclidean $\mathbb{R}^3$ with the point at infinity added (fields approach a pure gauge at infinity, as in Section 8.1.16). The based gauge group of the trivial bundle is $\mathcal{G} \simeq \mathrm{Map}_0(S^3, G) = \Omega^3 G$ (Section 8.1.13), and so (Nash's (8.59))

$$\pi_0(\mathcal{G}) \overset{(1)}{=} \pi_0\big(\Omega^3 G\big) \overset{(2)}{=} \big[S^0, \Omega^3 G\big]_* \overset{(3)}{=} \big[S^3, G\big]_* \overset{(4)}{=} \pi_3(G) \overset{(5)}{=} \mathbb{Z}. \tag{8.154}$$

(1) $\mathcal{G} \simeq \Omega^3 G$.
(2) The components of a space X are the based homotopy classes of maps from the two-point space S^0 (one point goes to the base point, the other picks the component).
(3) The adjunction $[\Sigma X, Y]_* = [X, \Omega Y]_*$ used three times, with $\Sigma^3 S^0 = S^3$ (Section 8.1.13).
(4) Definition of π_3.
(5) For every compact, connected, simple Lie group, $\pi_3(G) = \mathbb{Z}$ (Bott). For $G = \mathrm{SU}(2) = S^3$ the integer is the degree; for $\mathrm{SU}(N)$ a generator is the SU(2) identity map placed in the top-left 2×2 block.

So the gauge transformations of a three-dimensional theory fall into infinitely many classes, labelled by the winding number $w(g)$ of (8.64). These are the "large" gauge transformations of Section 8.1.19; there they acted on the spatial S^3 of a four-dimensional theory, here they act on the whole three-dimensional spacetime.

The action

The action is the Yang–Mills action plus a multiple of the Chern–Simons invariant (Nash's (8.60)):

$$S = \|F\|^2 + \alpha \int_M TP_2(A), \qquad \|F\|^2 := -\int_M \operatorname{tr}\big(F \wedge \star F\big). \tag{8.155}$$

The sign of $\|F\|^2$. With anti-Hermitian F the minus sign makes the Yang–Mills term positive. Writing $F = \frac{1}{2}F_{\mu\nu}\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$ on Euclidean M,

$$-\operatorname{tr}\big(F \wedge \star F\big) \overset{(1)}{=} -\tfrac{1}{2}\operatorname{tr}\big(F_{\mu\nu}F_{\mu\nu}\big)\,\mathrm{vol} \overset{(2)}{=} \tfrac{1}{2}\operatorname{tr}\big(F^\dagger_{\mu\nu}F_{\mu\nu}\big)\,\mathrm{vol} \overset{(3)}{=} \tfrac{1}{2}\sum_{\mu,\nu}\sum_{a,b}\big|(F_{\mu\nu})_{ab}\big|^2\,\mathrm{vol} \;\geq\; 0.$$

(1) For 2-forms, $\beta \wedge \star\gamma = \frac{1}{2}\beta_{\mu\nu}\gamma_{\mu\nu}\,\mathrm{vol}$ (Chapter T1); the trace just rides along.
(2) Anti-Hermitian: $F_{\mu\nu} = -F^\dagger_{\mu\nu}$.
(3) $\operatorname{tr}(X^\dagger X)$ is the sum of the squared moduli of the entries of X.

The Chern–Simons 3-form (Nash's (8.61)). With $P_2(X,Y) = -\frac{1}{8\pi^2}\operatorname{tr}(XY)$ and $F_t = t\,\mathrm{d}A + t^2 A\wedge A$,

$$\begin{aligned} TP_2(A) &\overset{(1)}{=} 2\int_0^1 \mathrm{d}t\; P_2(A,F_t) \overset{(2)}{=} -\frac{2}{8\pi^2}\int_0^1 \mathrm{d}t\;\operatorname{tr}\big(A\wedge(t\,\mathrm{d}A + t^2 A\wedge A)\big) \\ &\overset{(3)}{=} -\frac{2}{8\pi^2}\Big(\tfrac{1}{2}\operatorname{tr}(A\wedge\mathrm{d}A) + \tfrac{1}{3}\operatorname{tr}(A\wedge A\wedge A)\Big) \overset{(4)}{=} -\frac{1}{8\pi^2}\operatorname{tr}\Big(A\wedge\mathrm{d}A + \tfrac{2}{3}A\wedge A\wedge A\Big). \end{aligned} \tag{8.156}$$

(1) The transgression formula (8.115) with $j = 2$.
(2) The polynomial P_2 of Table 8.3, polarised; one slot is A, the other F_t.
(3) $\int_0^1 t\,\mathrm{d}t = \frac{1}{2}$, $\int_0^1 t^2\,\mathrm{d}t = \frac{1}{3}$.
(4) Pull out $\frac{1}{2}$.

This is (8.116) again. (The middle line of Nash's (8.61) reads $\operatorname{tr}\{A\wedge(tA\wedge\mathrm{d}A + t^2A\wedge A\wedge A)\}$; the inner bracket should be $F_t = t\,\mathrm{d}A + t^2A\wedge A$, as the last line of (8.61) confirms.)

Putting it into (8.155) gives Nash's (8.62):

$$\begin{aligned} S &\overset{(1)}{=} -\int_M \operatorname{tr}(F\wedge\star F) - \frac{\alpha}{8\pi^2}\int_M \operatorname{tr}\Big(A\wedge\mathrm{d}A + \tfrac{2}{3}A^3\Big) \\ &\overset{(2)}{=} -\operatorname{tr}\int_M \Big\{F\wedge\star F + \frac{\alpha}{8\pi^2}\Big(\mathrm{d}A\wedge A + \tfrac{2}{3}A\wedge A\wedge A\Big)\Big\}. \end{aligned} \tag{8.157}$$

(1) (8.155) and (8.156).
(2) Nash writes $\mathrm{d}A\wedge A$ where we have $A\wedge\mathrm{d}A$. Under the trace they are equal: moving the 2-form $\mathrm{d}A$ past the 1-form A costs $(-1)^{2\cdot1} = +1$, and the trace is cyclic.

In components. The Chern–Simons term uses no metric at all: there is no $\star$ in it. Indeed, with $A = A_\mu\mathrm{d}x^\mu$ and $\mathrm{d}A = \partial_\nu A_\rho\,\mathrm{d}x^\nu\wedge\mathrm{d}x^\rho$,

$$\begin{aligned} \operatorname{tr}\Big(A\,\mathrm{d}A + \tfrac{2}{3}A^3\Big) &\overset{(1)}{=} \operatorname{tr}\Big(A_\mu\partial_\nu A_\rho + \tfrac{2}{3}A_\mu A_\nu A_\rho\Big)\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu\wedge\mathrm{d}x^\rho \\ &\overset{(2)}{=} \epsilon^{\mu\nu\rho}\operatorname{tr}\Big(A_\mu\partial_\nu A_\rho + \tfrac{2}{3}A_\mu A_\nu A_\rho\Big)\mathrm{d}^3x. \end{aligned}$$

(1) Multiply out the forms, keeping the order of the matrix factors.
(2) In three dimensions $\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu \wedge \mathrm{d}x^\rho = \epsilon^{\mu\nu\rho}\,\mathrm{d}^3x$ with $\epsilon^{123} = +1$.

A term that does not see the metric is called **topological**. It does not contribute to the energy–momentum tensor ($T_{\mu\nu} = \frac{2}{\sqrt{g}}\frac{\delta S}{\delta g^{\mu\nu}}$ gets nothing from it), and it is odd under orientation reversal: for an orientation-reversing diffeomorphism ϕ (a reflection $x^1 \to -x^1$), $\int_M \phi^* TP_2 = -\int_M TP_2$. So the Chern–Simons term violates parity.

Gauge variation and the quantisation of α

The Yang–Mills term is gauge invariant: $F^g = g^{-1}Fg$ and $\star(g^{-1}Fg) = g^{-1}(\star F)g$, so the trace does not change. The Chern–Simons term is not. For a gauge transformation $g : M \to G$,

$$\begin{aligned}\int_M TP_2(A^g) &\overset{(1)}{=} \int_M TP_2(A) + \frac{1}{24\pi^2}\int_M \mathrm{tr}\big(g^{-1}\mathrm{d}g\big)^3 + \frac{1}{8\pi^2}\int_M \mathrm{d}\,\mathrm{tr}\big(\mathrm{d}g\, g^{-1}\wedge A\big)\\ &\overset{(2)}{=} \int_M TP_2(A) + w(g).\end{aligned} \tag{8.158}$$

(1) The gauge variation formula (8.123), integrated over M.
(2) Stokes: M is closed, so the exact term integrates to zero. The middle term is the winding number (8.64) (for $M = S^3$; for a general closed M it is the integer of (8.125)).

Hence $S(A^g) = S(A) + \alpha\, w(g)$. *The action itself is not gauge invariant.* It does not have to be: what enters the path integral is the weight e^{iS}. Then

$$e^{iS(A^g)} \overset{(1)}{=} e^{iS(A)}\, e^{i\alpha w(g)}, \qquad e^{i\alpha w} = 1 \ \forall\, w \in \mathbb{Z} \overset{(2)}{\iff} e^{i\alpha} = 1 \iff \alpha \in 2\pi\mathbb{Z}. \tag{8.159}$$

(1) (8.158); the exponential turns a sum into a product.
(2) The case $w = 1$ exists (the generator of (8.154)), and if $e^{i\alpha} = 1$ then $e^{i\alpha w} = (e^{i\alpha})^w = 1$ for all w.

Key idea: Nash's quantisation condition

The weight e^{iS} of the Deser–Jackiw–Templeton theory is gauge invariant if and only if

$$\alpha = 2\pi k, \qquad k \in \mathbb{Z}.$$

The integer k is the **level**. With it the Chern–Simons term takes its standard form

$$\alpha\int_M TP_2(A) = 2\pi k\cdot\Big(-\frac{1}{8\pi^2}\Big)\int_M \mathrm{tr}\Big(A\,\mathrm{d}A + \tfrac{2}{3}A^3\Big) = -\frac{k}{4\pi}\int_M \mathrm{tr}\Big(A\,\mathrm{d}A + \tfrac{2}{3}A^3\Big),$$

and $-\mathrm{tr}$ is positive definite on anti-Hermitian matrices, so this is the familiar "$\frac{k}{4\pi}\int \mathrm{tr}(A\,\mathrm{d}A + \frac{2}{3}A^3)$ with a positive trace". This is the secondary class at work: $\int_M TP_2$ is only defined in $\mathbb{R}/\mathbb{Z}$ as a gauge invariant, and $e^{2\pi i k\int TP_2}$ is exactly the kind of function of an $\mathbb{R}/\mathbb{Z}$-valued quantity that makes sense.

Worked example 8.39: Small gauge transformations cost nothing

For an infinitesimal gauge transformation, $\delta A = D_A\xi$, the change of the Chern–Simons term should vanish (it is a gauge transformation with $w = 0$). Directly, using the variation

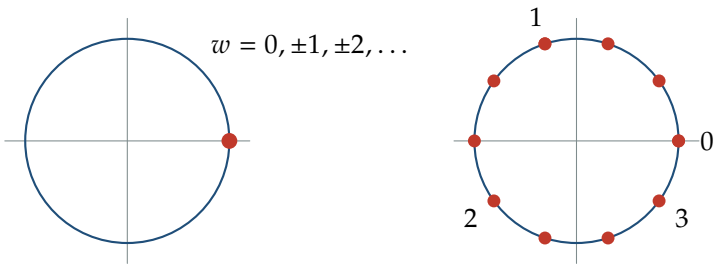

Figure 8.27: The phases $e^{i\alpha w(g)}$ picked up by e^{iS} under large gauge transformations of winding w. For $\alpha \in 2\pi\mathbb{Z}$ (left) they are all 1: the weight is gauge invariant. For any other α (right, $\alpha/2\pi = 0.3$, points labelled by w) different windings give different phases, so gauge-equivalent fields would get different weights and the theory would be inconsistent.

formula (8.124) and writing $\kappa = -\frac{1}{8\pi^2}$:

$$\delta \int_M TP_2(A) \overset{(1)}{=} 2\kappa \int_M \operatorname{tr}\big(\delta A \wedge F\big) + \int_M \mathrm{d}(\ldots) \overset{(2)}{=} 2\kappa \int_M \operatorname{tr}\big(D_A\xi \wedge F\big)$$
$$\overset{(3)}{=} 2\kappa \int_M \Big(\mathrm{d}\operatorname{tr}(\xi F) - \operatorname{tr}(\xi\, D_A F)\Big) \overset{(4)}{=} 2\kappa \int_M \mathrm{d}\operatorname{tr}(\xi F) \overset{(5)}{=} 0.$$

(1) (8.124) with $j = 2$ and $P_2(X, Y) = \kappa \operatorname{tr}(XY)$.
(2) $\delta A = D_A\xi$; the total derivative integrates to zero on closed M.
(3) Covariant Leibniz rule under the trace: $\mathrm{d}\operatorname{tr}(\xi F) = \operatorname{tr}(D_A\xi \wedge F) + \operatorname{tr}(\xi\, D_A F)$ (the commutator terms cancel under the trace; Section 8.1.1).
(4) Bianchi identity $D_A F = 0$.
(5) Stokes, $\partial M = \varnothing$.

So only the *topology* of g can change $\int_M TP_2$: its value mod $\mathbb{Z}$ is a gauge invariant of A. (On a manifold with boundary the last step fails and the Chern–Simons term is gauge variant already under small transformations; this is the origin of the edge modes of the quantum Hall effect.)

Worked example 8.40: The one-dimensional analogue: charge quantisation

Drop two dimensions. On a circle $M = S^1$ of length T (Euclidean time, say) with $G = \mathrm{U}(1)$, write $A = i\,a(t)\,\mathrm{d}t$. The one-dimensional Chern–Simons form is $TP_1(A) = \frac{i}{2\pi}A = -\frac{1}{2\pi}a\,\mathrm{d}t$ (Section 8.2.1). The term $\alpha \int_{S^1} TP_1 = -\frac{\alpha}{2\pi}\oint a\,\mathrm{d}t$ is the coupling of a point charge $q := \alpha/2\pi$ to the gauge field along its world line: a Wilson loop. A large gauge transformation $g(t) = e^{2\pi i n t/T}$ has

$$\int_{S^1} TP_1(A^g) - \int_{S^1} TP_1(A) \overset{(1)}{=} \frac{i}{2\pi}\oint g^{-1}\mathrm{d}g \overset{(2)}{=} \frac{i}{2\pi}\cdot\frac{2\pi i n}{T}\cdot T = -n,$$

(1) For $\mathrm{U}(1)$, $A^g = A + g^{-1}\mathrm{d}g$.
(2) $g^{-1}\mathrm{d}g = \frac{2\pi i n}{T}\mathrm{d}t$.

so $e^{i\alpha\int TP_1}$ changes by $e^{-i\alpha n}$ and is invariant iff $\alpha \in 2\pi\mathbb{Z}$, i.e. $q \in \mathbb{Z}$. *Quantisation of the level in one dimension is quantisation of electric charge*: a Wilson loop $e^{iq\oint a}$ is gauge invariant under all gauge transformations on a circle only for integer q. The three-dimensional statement is the same mechanism one rung up the ladder of Chern–Simons forms.

The topological mass

Why is the Chern–Simons term interesting physically? Because it gives the gauge field a mass while keeping gauge invariance (of e^{iS}). The effect is already visible in the Abelian theory, and the non-Abelian theory reduces to it at quadratic order.

Worked example 8.41: Maxwell–Chern–Simons theory: a massive photon

Work in Minkowski space $\mathbb{R}^{1,2}$ with signature $(+,-,-)$, $\epsilon^{012}=+1$, a real (Hermitian-convention) potential a_μ, $f_{\mu\nu}=\partial_\mu a_\nu-\partial_\nu a_\mu$, and

$$\mathcal{L}=-\frac{1}{4e^2}f_{\mu\nu}f^{\mu\nu}+\frac{\kappa}{2}\,\epsilon^{\mu\nu\rho}a_\mu\partial_\nu a_\rho .$$

Define the dual field strength $\tilde f^\sigma:=\frac12\epsilon^{\sigma\nu\rho}f_{\nu\rho}=\epsilon^{\sigma\nu\rho}\partial_\nu a_\rho$ (in three dimensions a 2-form is dual to a vector: $\tilde f^0$ is the magnetic field, $\tilde f^i$ are the components of the electric field up to signs). It satisfies $\partial_\sigma\tilde f^\sigma=0$ (Bianchi) and $f_{\mu\nu}=\epsilon_{\mu\nu\lambda}\tilde f^\lambda$.

Equation of motion. The Euler–Lagrange equation $\partial_\nu\frac{\partial\mathcal{L}}{\partial(\partial_\nu a_\sigma)}=\frac{\partial\mathcal{L}}{\partial a_\sigma}$ reads

$$-\frac{1}{e^2}\partial_\mu f^{\mu\sigma}+\frac{\kappa}{2}\epsilon^{\mu\nu\sigma}\partial_\nu a_\mu \overset{(1)}{=} \frac{\kappa}{2}\epsilon^{\sigma\nu\rho}\partial_\nu a_\rho \quad\overset{(2)}{\Longrightarrow}\quad \partial_\mu f^{\mu\sigma}=-e^2\kappa\,\tilde f^\sigma .$$

(1) $\partial\mathcal{L}/\partial(\partial_\nu a_\sigma)=-\frac{1}{e^2}f^{\nu\sigma}+\frac{\kappa}{2}\epsilon^{\mu\nu\sigma}a_\mu$ and $\partial\mathcal{L}/\partial a_\sigma=\frac{\kappa}{2}\epsilon^{\sigma\nu\rho}\partial_\nu a_\rho$.

(2) $\epsilon^{\mu\nu\sigma}\partial_\nu a_\mu=\epsilon^{\sigma\mu\nu}\partial_\nu a_\mu=-\epsilon^{\sigma\nu\mu}\partial_\nu a_\mu=-\tilde f^\sigma$; collect the two κ terms and multiply by $-e^2$.

Write $m:=e^2\kappa$. With $f_{\mu\sigma}=\epsilon_{\mu\sigma\lambda}\tilde f^\lambda$ the equation is $\epsilon^{\mu\sigma\lambda}\partial_\mu\tilde f_\lambda=-m\tilde f^\sigma$, a first-order equation for $\tilde f$.

Squaring it. Lowering all indices, the first-order equation reads $\epsilon_{\alpha\beta\sigma}\partial^\alpha\tilde f^\sigma=-m\tilde f_\beta$, equivalently $\epsilon_{\beta\alpha\sigma}\partial^\alpha\tilde f^\sigma=+m\tilde f_\beta$. Apply $\epsilon_{\beta\alpha\sigma}\partial^\alpha$ to $\epsilon^{\mu\sigma\lambda}\partial_\mu\tilde f_\lambda=-m\tilde f^\sigma$:

$$\text{left side:}\quad \epsilon_{\beta\alpha\sigma}\epsilon^{\mu\sigma\lambda}\partial^\alpha\partial_\mu\tilde f_\lambda \overset{(1)}{=} \big(\delta^\lambda_\beta\delta^\mu_\alpha-\delta^\mu_\beta\delta^\lambda_\alpha\big)\partial^\alpha\partial_\mu\tilde f_\lambda=\Box\tilde f_\beta-\partial_\beta(\partial\cdot\tilde f)\overset{(2)}{=}\Box\tilde f_\beta,$$

$$\text{right side:}\quad -\,m\,\epsilon_{\beta\alpha\sigma}\partial^\alpha\tilde f^\sigma \overset{(3)}{=} -m\big(m\tilde f_\beta\big)=-m^2\tilde f_\beta .$$

(1) The contraction identity for the three-dimensional Levi-Civita symbol, $\epsilon_{\beta\alpha\sigma}\epsilon^{\mu\sigma\lambda}=\delta^\lambda_\beta\delta^\mu_\alpha-\delta^\mu_\beta\delta^\lambda_\alpha$ (with $\epsilon_{012}=\det\eta\cdot\epsilon^{012}=+1$; checked by writing out the cases). $\Box=\partial_\alpha\partial^\alpha=\partial_t^2-\nabla^2$.

(2) Bianchi, $\partial\cdot\tilde f=0$.

(3) The equation of motion in its lowered form, quoted above.

Equating the two lines,

$$\big(\Box+m^2\big)\tilde f_\beta=0,\qquad m=e^2\kappa. \tag{8.160}$$

Every component of the field strength obeys the Klein–Gordon equation with mass $|m|$: plane waves have $\omega^2=\vec p^{\,2}+m^2$. Pure Maxwell theory in $2+1$ dimensions has one massless polarisation; with the Chern–Simons term it becomes one massive particle, of spin $+1$ or -1 according to the sign of κ (the first-order equation picks one helicity; that is the parity violation). Nothing was broken: no Higgs field, no gauge-non-invariant $a_\mu a^\mu$ term. The mass is **topological**.

The non-Abelian theory at quadratic order. Restore the coupling in Minkowski signature: $\mathcal{L}=\frac{1}{2g^2}\operatorname{tr}F_{\mu\nu}F^{\mu\nu}+$ (CS term of (8.157)). Expand $A=A^aT_a$ with anti-Hermitian generators

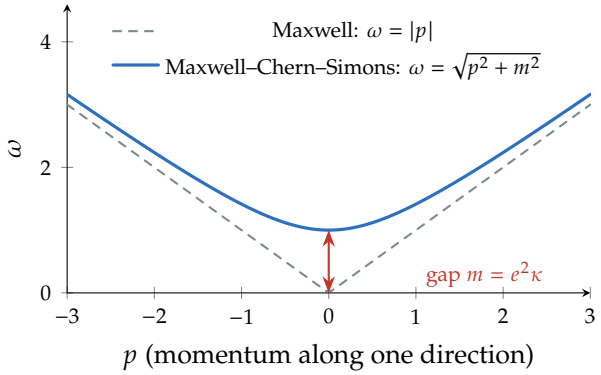

Figure 8.28: Dispersion relations in 2 + 1 dimensions. The Chern–Simons term opens a gap (red): the photon becomes massive, with $m = e^2\kappa$ (here $m = 1$). In the non-Abelian theory $m = g^2\alpha/8\pi^2 = g^2 k/4\pi$ is quantised in units of $g^2/4\pi$.

normalised by $\operatorname{tr}(T_a T_b) = -\tfrac{1}{2}\delta_{ab}$ (for SU(2), $T_a = -\tfrac{i}{2}\sigma_a$). Then

$$\frac{1}{2g^2}\operatorname{tr} F_{\mu\nu}F^{\mu\nu} \overset{(1)}{=} -\frac{1}{4g^2}F^a_{\mu\nu}F^{a\,\mu\nu},$$
$$-\frac{\alpha}{8\pi^2}\operatorname{tr}(A\,\mathrm{d}A) \overset{(2)}{=} \frac{\alpha}{16\pi^2}A^a \wedge \mathrm{d}A^a \overset{(3)}{=} \frac{1}{2}\cdot\frac{\alpha}{8\pi^2}\epsilon^{\mu\nu\rho}A^a_\mu \partial_\nu A^a_\rho \,\mathrm{d}^3x.$$

(1) $\operatorname{tr}(T_a T_b) = -\tfrac{1}{2}\delta_{ab}$.
(2) The same normalisation.
(3) The component formula above.

To quadratic order each colour component is a copy of Example 8.41 with $e^2 \to g^2$ and $\kappa \to \alpha/8\pi^2$, so

$$m = \frac{g^2\alpha}{8\pi^2} = \frac{g^2 k}{4\pi} \qquad (\alpha = 2\pi k). \tag{8.161}$$

In three dimensions g^2 has the dimension of a mass (from $[A] = 1$ and a dimensionless action, $\int \mathrm{d}^3x\, F^2/g^2$ forces $[g^2] = 1$), so m is a mass, and it comes in integer multiples of $g^2/4\pi$. Nash writes the action with $g = 1$, i.e. with the coupling absorbed into the field; then the coefficient of the Chern–Simons term itself carries the dimension of mass, which is his remark that "α has the dimension of a mass: we obtain a 3-dimensional gauge theory with a quantised mass".

Watch out: e^{iS}, Euclidean and Minkowski

Nash writes the weight as $\exp[iS]$ with S containing both $\|F\|^2$ and the Chern–Simons term. The two terms behave differently under Wick rotation $t = -i\tau$. The Yang–Mills term turns into the positive Euclidean action, giving $e^{-\|F\|^2}$. The Chern–Simons term contains exactly one time index ($\epsilon^{\mu\nu\rho}$ with one index 0) and no metric, so it picks up a single factor of i and stays a *phase*: the Euclidean weight is $e^{-\|F\|^2 + i\alpha\int TP_2}$ (up to the orientation sign). Either way, the quantisation condition concerns the coefficient of $\int TP_2$ in the phase, and it is $\alpha \in 2\pi\mathbb{Z}$. Dropping $\|F\|^2$ altogether leaves pure Chern–Simons theory, Witten's topological quantum field theory of knots (Chapter 12).

Higher odd dimensions

Nash closes with the remark that $\mathcal{G}$ is disconnected "for all the larger odd values of dim M". For $M = S^{2j-1}$ and $G = \mathrm{SU}(N)$, $\pi_0(\mathcal{G}) = \pi_{2j-1}(\mathrm{SU}(N)) = \mathbb{Z}$ as soon as $N \geq j$ (the stable range of Bott

periodicity, Table 8.1), and the corresponding Chern–Simons form TP_j is a $(2j-1)$-form that can be put into a $(2j-1)$-dimensional action. The pattern is always the same: the coefficient must be quantised, because $\int TP_j$ changes by the integer $\int g^*\omega_{2j-1}$ under a large gauge transformation, by (8.125).

dim M	Chern–Simons form	$\pi_0(\mathcal{G})$	physics
1	$TP_1 = \frac{i}{2\pi}\operatorname{tr} A$	$\pi_1(\mathrm{U}(1)) = \mathbb{Z}$	charge quantisation (Example 8.40)
3	$TP_2 = -\frac{1}{8\pi^2}\operatorname{tr}(A\,\mathrm{d}A + \frac{2}{3}A^3)$	$\pi_3(\mathrm{SU}(N)) = \mathbb{Z}$	topological mass, level k
5	TP_3 of (8.117)	$\pi_5(\mathrm{SU}(N)) = \mathbb{Z}$, $N \geq 3$	anomaly inflow to 4d
$2j-1$	TP_j	$\pi_{2j-1}(\mathrm{SU}(N)) = \mathbb{Z}$, $N \geq j$	quantised coefficient

The five-dimensional row connects back to Section 8.2.8. The gauge variation of the Chern–Simons 5-form contains, by the descent expansion (8.138), the 4-form $\Omega_4^{(1)}$ of (8.144). On a five-manifold with boundary, the gauge variation of $\int_{M_5} TP_3$ is therefore a boundary term of the form $\int_{\partial M_5} \operatorname{tr}\,\xi\,\mathrm{d}(A\,\mathrm{d}A + \frac{1}{2}A^3)$: exactly the four-dimensional anomaly μ_1. A five-dimensional Chern–Simons term can cancel the anomaly of chiral fermions living on its boundary (**anomaly inflow**, Chapter 10).

Reading Nash (p. 227, (8.59)–(8.62))

Nash's (8.59) is (8.154). His action (8.60) is (8.155), with $\|F\|^2 = -\int \operatorname{tr} F \wedge \star F$. His (8.61) is (8.156); its middle line has a misprint ($tA \wedge \mathrm{d}A$ should be $t\,\mathrm{d}A$). His (8.62) is (8.157), where $\mathrm{d}A \wedge A$ may be read as $A \wedge \mathrm{d}A$ under the trace. His argument that "$TP_2(A)$ changes by an integer under a gauge transformation" is (8.158), and the quantisation $\alpha = 2\pi n$ is (8.159). The "quantised mass" is (8.161), derived in Example 8.41; Nash does not derive it.

Recap: secondary characteristic classes in one page

- *Secondary classes.* On P, $\pi^*c_j(F) = \mathrm{d}TP_j$ with $TP_j = j\int_0^1 P_j(\omega, F_t, \ldots)\,\mathrm{d}t$. When $c_j(F) = 0$ the Chern–Simons form is closed and defines a real class on P, and an $\mathbb{R}/\mathbb{Z}$ class on M: two gauges change it by the integer periods of $g^*\omega_{2j-1}$.
- *μ from Chern–Simons forms.* On $S^n \times \mathcal{G}$ the connection $\mathbb{A} = A^\alpha + \vartheta$ ($\vartheta = \alpha^{-1}\delta\alpha$, the ghost) has curvature F^α with no $\mathcal{G}$-legs. So $\widehat{\mathrm{Ev}}^* TP_j$ is closed when $2j > n$, and $\mu_{2j-1-n} = \int_{S^n} \widehat{\mathrm{Ev}}^* TP_j$ is the old μ plus an exact form.
- *Explicit μ_1.* On S^2: $\mu_1(\xi) = -\frac{1}{8\pi^2}\int \operatorname{tr}(\xi\,\mathrm{d}A)$. On S^4 for SU(N): $\mu_1(\xi) = -\frac{i}{24\pi^3}\int \operatorname{tr}\big(\xi\,\mathrm{d}(A\,\mathrm{d}A + \frac{1}{2}A^3)\big)$, the shape of the non-Abelian anomaly.
- *ν and the double transgression.* With the Coulomb connection Θ on $\mathcal{A} \to \mathcal{A}/\mathcal{G}$, $\mathbb{A}_{\mathrm{univ}} = A + \Theta$; then $\pi^*\nu_{2j} = \delta f_j$ with $f_j = \int_{S^n} TP_{j+n/2}(A + \Theta)$, and f_j restricted to an orbit is μ_{2j-1}. μ_{2j-1} and ν_{2j} are exact or non-exact together.
- *Chern–Simons theory in 3d.* $S = \|F\|^2 + \alpha\int TP_2$; large gauge transformations shift $\int TP_2$ by the winding number, so e^{iS} is invariant iff $\alpha = 2\pi k$; the gauge field gets the quantised topological mass $m = g^2k/4\pi$.

8.3 Instantons: the Yang–Mills action and its critical points

In Euclidean quantum field theory every gauge field configuration A comes with a weight $e^{-S(A)/g^2}$. When the coupling g is small, the path integral is dominated by the configurations where S is stationary. The trivial field $A = 0$ is one such point, and perturbation theory expands around it. But there are others. They sit in different topological sectors, they have finite action, and they contribute effects of order $e^{-8\pi^2/g^2}$, which no Feynman diagram can see. These are the **instantons**.

Nash's Section 3 asks a very concrete question about them: *how many instantons are there?* More precisely, instantons come in continuous families, and we want the number of parameters in a family: the dimension of the **moduli space**. A physicist knows this number by another name. It is the number of *collective coordinates*, or equivalently the number of normalisable bosonic zero modes of the fluctuation operator around the instanton. Each zero mode must be traded for an integral over a collective coordinate in the path integral, so the number matters for every instanton calculation.

The road is long, so here is the plan of this part.

1. Find the equations of motion of the Yang–Mills action (this section).
2. Show that the self-dual fields solve them and are the absolute minima of the action in each topological sector (Section 8.4).
3. Write down the simplest instanton, the BPST solution, completely explicitly (Section 8.5).
4. Understand why gauge invariance spoils ellipticity, and fix a gauge (Section 8.6).
5. Define the moduli space carefully (Section 8.7).
6. Linearise the self-duality equation and package the zero modes into an elliptic complex (Section 8.8).
7. Count the zero modes with the index theorem: $\dim \mathcal{M}_k = 8k - 3$ for SU(2) on S^4 (Section 8.9).
8. Check the count by hand for $k = 1$, and see the ADHM construction (Section 8.10).
9. Look at the global structure and Donaldson's theorem (Section 8.11).

8.3.1 The setting and our conventions

The stage is a **closed** (compact, no boundary), oriented, Riemannian 4-manifold M. The main example is the round sphere S^4. Flat $\mathbb{R}^4$ with fields that fall off at infinity will turn out to be the same thing as S^4, because the action is conformally invariant (Section 8.4.1). Over M we have a principal G-bundle P, with G a compact simple Lie group; our workhorse is $G = \mathrm{SU}(2)$.

A connection on P is, in a local trivialisation, a Lie-algebra-valued 1-form

$$A = A_\mu \, \mathrm{d}x^\mu, \qquad A_\mu(x) \in \mathfrak{g}.$$

We use the mathematicians' (and Nash's) convention: for $G = \mathrm{SU}(N)$ the matrices A_μ are *anti-Hermitian* and traceless. The curvature is

$$F = \mathrm{d}A + A \wedge A, \qquad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + [A_\mu, A_\nu], \tag{8.162}$$

where $F = \frac{1}{2} F_{\mu\nu} \, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$. Under a gauge transformation $g : M \to G$ (locally),

$$A \mapsto A_g = g^{-1} A g + g^{-1} \mathrm{d} g, \qquad F \mapsto g^{-1} F g. \tag{8.163}$$

This is reviewed in Chapter T3; we only need the formulas.

Dictionary: anti-Hermitian versus Hermitian gauge fields

Physics books write $A_\mu^{\text{phys}} = A_\mu^a T^a$ with Hermitian generators T^a, normalised by $\operatorname{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$, and put the coupling into the covariant derivative $D_\mu = \partial_\mu - igA_\mu^{\text{phys}}$. The translation is

$$A_\mu^{\text{math}} = -ig\,A_\mu^a T^a, \qquad F_{\mu\nu}^{\text{math}} = -ig\,F_{\mu\nu}^a T^a, \qquad F_{\mu\nu}^a = \partial_\mu A_\nu^a - \partial_\nu A_\mu^a + g f^{abc} A_\mu^b A_\nu^c.$$

For SU(2), $T^a = \sigma_a/2$. We shall also use the anti-Hermitian basis $e_a = -i\sigma_a$ (so $T^a = \frac{i}{2}e_a$ and $-igA^aT^a = \frac{g}{2}A^a e_a$). With these rules the physicist's action is $\frac{1}{4}\int F_{\mu\nu}^a F_{\mu\nu}^a \,\mathrm{d}^4x = \left\|F^{\text{math}}\right\|^2/g^2$; we check this in the worked example just below.

Lie-algebra-valued forms and the bundle $\operatorname{ad} P$

A **Lie-algebra-valued p-form** is a p-form whose components are matrices in $\mathfrak{g}$. The curvature F is one. So is the difference $a = A' - A$ of two connections. Both transform by conjugation, $a \mapsto g^{-1}ag$, without the inhomogeneous $g^{-1}\mathrm{d}g$ term (the inhomogeneous terms cancel in the difference). Objects that transform by conjugation are sections of the **adjoint bundle** $\operatorname{ad} P$: the vector bundle whose fibre is $\mathfrak{g}$ and whose transition functions act by $X \mapsto g^{-1}Xg$. We write

$$\Omega^p(M, \operatorname{ad} P) = \{\mathfrak{g}\text{-valued } p\text{-forms that transform by conjugation}\}.$$

For SU(2) the fibre $\mathfrak{su}(2)$ is 3-dimensional; $\operatorname{ad} P$ is a real rank-3 vector bundle. It carries the adjoint representation, which is the spin-1 representation, so $\pm g$ act identically on it.

Working definition 8.20 (covariant exterior derivative)

On $\omega \in \Omega^p(M, \operatorname{ad} P)$,

$$\mathrm{d}_A\omega = \mathrm{d}\omega + A \wedge \omega - (-1)^p\,\omega \wedge A. \tag{8.164}$$

The two most used cases are

$$\mathrm{d}_A f = \mathrm{d}f + [A, f] \;\; (p=0), \qquad \mathrm{d}_A a = \mathrm{d}a + A \wedge a + a \wedge A \;\; (p=1).$$

Test: $\mathrm{d}_A\omega$ transforms by conjugation whenever ω does [the $g^{-1}\mathrm{d}g$ terms coming from $\mathrm{d}\omega$ and from the transformed A cancel]. In components, $(\mathrm{d}_A f)_\mu = D_\mu f = \partial_\mu f + [A_\mu, f]$.

The sign $-(-1)^p$ is what makes d_A covariant: moving A past a p-form costs $(-1)^p$, and the combination in (8.164) is the graded commutator $[A, \omega]$. Nash states this formula in a footnote on [Nash p. 235].

Worked example 8.42: The Bianchi identity $\mathrm{d}_A F = 0$

We apply (8.164) with $p = 2$ to $F = \mathrm{d}A + A \wedge A$:

$$\begin{aligned}
\mathrm{d}_A F &\overset{(1)}{=} \mathrm{d}F + A \wedge F - F \wedge A \\
&\overset{(2)}{=} \big(\mathrm{d}A \wedge A - A \wedge \mathrm{d}A\big) + \big(A \wedge \mathrm{d}A + A \wedge A \wedge A \wedge A\big) - \big(\mathrm{d}A \wedge A + A \wedge A \wedge A\big) \\
&\overset{(3)}{=} 0.
\end{aligned}$$

(1) Definition (8.164) with $p = 2$, so $-(-1)^2 = -1$.
(2) $\mathrm{d}(\mathrm{d}A) = 0$, and the graded Leibniz rule gives $\mathrm{d}(A \wedge A) = \mathrm{d}A \wedge A - A \wedge \mathrm{d}A$ (the minus because A is a 1-form); then substitute $F = \mathrm{d}A + A \wedge A$ in the other two terms.

(3) Every term appears once with each sign.

The Bianchi identity is an *identity*: it holds for every connection, not just for solutions. For $G = \mathrm{U}(1)$ it is $\mathrm{d}F = 0$, i.e. the two homogeneous Maxwell equations $\nabla\cdot\vec{B} = 0$, $\nabla\times\vec{E} + \partial_t\vec{B} = 0$.

The inner product and the action

To write an action we need a positive inner product on $\Omega^p(M, \mathrm{ad}\,P)$. Two ingredients combine. The Hodge star $\star$ (Chapter T1) gives, for ordinary forms, $\alpha\wedge\star\beta = \frac{1}{p!}\alpha_{\mu_1\dots\mu_p}\beta_{\mu_1\dots\mu_p}\,\mathrm{vol}$. The trace gives a positive pairing on anti-Hermitian matrices, once we insert a minus sign: $-\operatorname{tr}(X^2) = \operatorname{tr}(X^\dagger X) = \sum_{ij}|X_{ij}|^2 \geq 0$.

Working definition 8.21 (the L^2 inner product)

For $\alpha, \beta \in \Omega^p(M, \mathrm{ad}\,P)$,

$$\langle\alpha,\beta\rangle = -\int_M \operatorname{tr}(\alpha\wedge\star\beta) = -\frac{1}{p!}\int_M \operatorname{tr}(\alpha_{\mu_1\dots\mu_p}\beta_{\mu_1\dots\mu_p})\,\mathrm{d}^4x\sqrt{\det g}, \qquad \|\alpha\|^2 = \langle\alpha,\alpha\rangle \geq 0. \tag{8.165}$$

It is gauge invariant [unchanged when α,β are replaced by $g^{-1}\alpha g$, $g^{-1}\beta g$], because $\operatorname{tr}(g^{-1}Xg\,g^{-1}Yg) = \operatorname{tr}(XY)$.

Key idea: The Yang–Mills action (Nash (8.63))

$$S(A) = \|F\|^2 = -\int_M \operatorname{tr}(F\wedge\star F) = -\frac{1}{2}\int_M \operatorname{tr}(F_{\mu\nu}F_{\mu\nu})\,\mathrm{d}^4x. \tag{8.166}$$

It is non-negative, gauge invariant, and it vanishes exactly when $F = 0$. Instantons are critical points of S with $F \neq 0$.

Worked example 8.43: From Nash's action to the physicist's action

Take $G = \mathrm{SU}(2)$ and $F = \frac{g}{2}F^a e_a$ from the dictionary, with $e_a = -i\sigma_a$. First the trace of two basis elements:

$$\begin{aligned}\operatorname{tr}(e_a e_b) &\overset{(1)}{=} -\operatorname{tr}(\sigma_a\sigma_b)\\ &\overset{(2)}{=} -\operatorname{tr}(\delta_{ab}\mathbb{1} + i\varepsilon_{abc}\sigma_c)\\ &\overset{(3)}{=} -2\delta_{ab}.\end{aligned}$$

(1) $(-i)^2 = -1$.
(2) The Pauli product rule $\sigma_a\sigma_b = \delta_{ab}\mathbb{1} + i\varepsilon_{abc}\sigma_c$.
(3) $\operatorname{tr}\mathbb{1} = 2$ and the Pauli matrices are traceless.

Now the action density:

$$\begin{aligned}-\tfrac{1}{2}\operatorname{tr}(F_{\mu\nu}F_{\mu\nu}) &\overset{(1)}{=} -\tfrac{1}{2}\cdot\tfrac{g^2}{4}F^a_{\mu\nu}F^b_{\mu\nu}\operatorname{tr}(e_a e_b)\\ &\overset{(2)}{=} \tfrac{g^2}{4}F^a_{\mu\nu}F^a_{\mu\nu}.\end{aligned}$$

(1) Substitute $F_{\mu\nu} = \frac{g}{2}F^a_{\mu\nu}e_a$; the trace is linear.
(2) Use $\operatorname{tr}(e_a e_b) = -2\delta_{ab}$.

So $\|F\|^2 = g^2 \cdot \frac{1}{4}\int F^a_{\mu\nu}F^a_{\mu\nu}\,\mathrm{d}^4x = g^2 S_{\text{phys}}$. The Boltzmann weight is $e^{-S_{\text{phys}}} = e^{-\|F\|^2/g^2}$. Nash sets $g = 1$; we restore it when we quote physical numbers such as $e^{-8\pi^2/g^2}$.

8.3.2 Varying the action: the Yang–Mills equations

The space $\mathcal{A}$ of all connections on P is an *affine* space: pick one connection A, and every other one is $A + a$ with $a \in \Omega^1(M, \operatorname{ad} P)$. So we can draw straight lines through A (Figure 8.29):

$$A_t = A + ta, \qquad t \in \mathbb{R}. \tag{8.167}$$

A is a critical point of S if the slope of $S(A_t)$ at $t = 0$ vanishes for every direction a. That is ordinary calculus on a line.

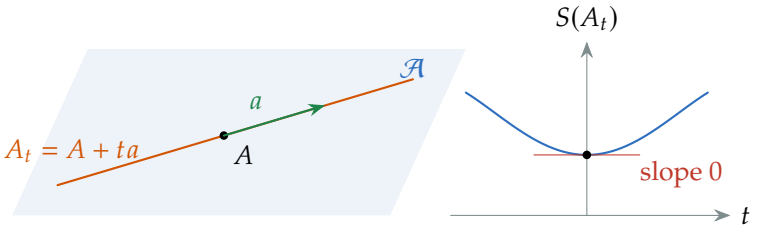

Figure 8.29: Left: the space $\mathcal{A}$ of connections is affine, so through any connection A there is a straight line $A + ta$ in every direction a. Right: A is a critical point when S restricted to every such line has zero slope at $t = 0$. The Yang–Mills equation is this condition, written for all directions a at once.

The curvature along the line

$$\begin{aligned} F(A_t) &\overset{(1)}{=} \mathrm{d}(A + ta) + (A + ta) \wedge (A + ta) \\ &\overset{(2)}{=} \mathrm{d}A + A \wedge A + t\,(\mathrm{d}a + A \wedge a + a \wedge A) + t^2\, a \wedge a \\ &\overset{(3)}{=} F(A) + t\,\mathrm{d}_A a + t^2\, a \wedge a. \end{aligned} \tag{8.168}$$

(1) Definition (8.162) applied to A_t.
(2) Expand and collect powers of t. Keep the order of the wedge products: $A \wedge a$ and $a \wedge A$ are different matrices.
(3) The t^0 terms are $F(A)$; the t^1 terms are $\mathrm{d}_A a$ by (8.164) with $p = 1$.

This is exact, not just to first order: the curvature is quadratic in the connection.

The action along the line

$$\begin{aligned} S(A_t) &\overset{(1)}{=} \langle F + t\,\mathrm{d}_A a + t^2 a \wedge a,\ F + t\,\mathrm{d}_A a + t^2 a \wedge a\rangle \\ &\overset{(2)}{=} \langle F, F\rangle + t\big(\langle \mathrm{d}_A a, F\rangle + \langle F, \mathrm{d}_A a\rangle\big) + O(t^2) \\ &\overset{(3)}{=} S(A) + 2t\,\langle F, \mathrm{d}_A a\rangle + O(t^2). \end{aligned} \tag{8.169}$$

(1) $S = \|F\|^2$ and (8.168).

(2) The inner product is bilinear; collect the terms linear in t.
(3) The inner product is symmetric: $\operatorname{tr}(\alpha \wedge \star\beta) = \operatorname{tr}(\beta \wedge \star\alpha)$ for two 2-forms, since $\alpha \wedge \star\beta$ is $\tfrac{1}{2}\alpha_{\mu\nu}\beta_{\mu\nu}\mathrm{vol}$.

So A is a critical point iff

$$\left.\frac{\mathrm{d}S(A_t)}{\mathrm{d}t}\right|_{t=0} = 2\langle F, \mathrm{d}_A a\rangle = 0 \quad \text{for all } a \in \Omega^1(M, \operatorname{ad} P). \tag{8.170}$$

Moving d_A across: the adjoint d_A^*

To turn (8.170) into a differential equation for A we move the derivative off a, exactly as one integrates by parts to derive the Euler–Lagrange equations. The operator that appears is the **formal adjoint** d_A^*, defined by

$$\langle \mathrm{d}_A \omega, \eta\rangle = \langle \omega, \mathrm{d}_A^* \eta\rangle \quad \text{for all } \omega \in \Omega^{p-1},\ \eta \in \Omega^p. \tag{8.171}$$

With it, (8.170) reads $\langle \mathrm{d}_A^* F, a\rangle = 0$ for all a. Choosing $a = \mathrm{d}_A^* F$ gives $\left\|\mathrm{d}_A^* F\right\|^2 = 0$. Hence:

Key idea: The Yang–Mills equations (Nash (8.69)–(8.70))

A is a critical point of S if and only if

$$\mathrm{d}_A^* F = 0. \tag{8.172}$$

Together with the Bianchi identity, the curvature of a Yang–Mills connection satisfies the pair

$$\mathrm{d}_A F = 0, \qquad \mathrm{d}_A^* F = 0. \tag{8.173}$$

In components, $\mathrm{d}_A^* F = 0$ is $D_\mu F_{\mu\nu} = \partial_\mu F_{\mu\nu} + [A_\mu, F_{\mu\nu}] = 0$ (see the worked example in Section 8.3.3), the Euclidean version of $D_\mu F^{\mu\nu} = j^\nu$ with no sources.

8.3.3 A formula for d_A^* in four dimensions

Nash next proves that on 2-forms in dimension four,

$$\mathrm{d}_A^* = -\star\, \mathrm{d}_A\, \star\,. \tag{8.174}$$

The proof is Stokes' theorem on a well-chosen $(n-1)$-form, the same trick that proves $\int u\, v' = -\int u'\, v$ on a circle. Two small facts about the trace go in first.

Working definition 8.22 (graded trace identities)

For $\mathfrak{g}$-valued forms [forms whose components are matrices in $\mathfrak{g}$] α (degree p) and β (degree q):

(i) $\operatorname{tr}(\alpha \wedge \beta) = (-1)^{pq} \operatorname{tr}(\beta \wedge \alpha)$;
(ii) $\mathrm{d}\, \operatorname{tr}(\alpha \wedge \beta) = \operatorname{tr}(\mathrm{d}_A\alpha \wedge \beta) + (-1)^p \operatorname{tr}(\alpha \wedge \mathrm{d}_A\beta)$.

(i) is cyclicity of the matrix trace [$\operatorname{tr}(XY) = \operatorname{tr}(YX)$ for matrices X, Y], plus the sign from reordering the 1-forms. (ii) says that inside a trace, d_A obeys the same Leibniz rule as d: the extra A-terms cancel.

Let us check (ii), since everything rests on it.

$$\begin{aligned}
&\operatorname{tr}(\mathrm{d}_A\alpha\wedge\beta)+(-1)^p\operatorname{tr}(\alpha\wedge\mathrm{d}_A\beta)\\
&\overset{(1)}{=}\operatorname{tr}(\mathrm{d}\alpha\wedge\beta)+(-1)^p\operatorname{tr}(\alpha\wedge\mathrm{d}\beta)+\operatorname{tr}(A\wedge\alpha\wedge\beta)-(-1)^p\operatorname{tr}(\alpha\wedge A\wedge\beta)\\
&\qquad+(-1)^p\operatorname{tr}(\alpha\wedge A\wedge\beta)-(-1)^{p+q}\operatorname{tr}(\alpha\wedge\beta\wedge A)\\
&\overset{(2)}{=}\mathrm{d}\operatorname{tr}(\alpha\wedge\beta)+\operatorname{tr}(A\wedge\alpha\wedge\beta)-(-1)^{p+q}(-1)^{p+q}\operatorname{tr}(A\wedge\alpha\wedge\beta)\\
&\overset{(3)}{=}\mathrm{d}\operatorname{tr}(\alpha\wedge\beta).
\end{aligned}$$

(1) Expand both d_A's using (8.164), with degree p for α and degree q for β.
(2) The ordinary Leibniz rule for d (the trace commutes with d); the two middle terms cancel; for the last term use (i) with the 1-form A and the $(p+q)$-form $\alpha\wedge\beta$.
(3) $(-1)^{2(p+q)}=1$, so the A-terms cancel.

Now the adjoint. Take $\omega\in\Omega^{p-1}(M,\operatorname{ad}P)$ and $\eta\in\Omega^p(M,\operatorname{ad}P)$ on a closed n-manifold. Then $\omega\wedge\star\eta$ is an $(n-1)$-form, and

$$\begin{aligned}
0&\overset{(1)}{=}\int_M\mathrm{d}\operatorname{tr}(\omega\wedge\star\eta)\\
&\overset{(2)}{=}\int_M\operatorname{tr}(\mathrm{d}_A\omega\wedge\star\eta)+(-1)^{p-1}\int_M\operatorname{tr}(\omega\wedge\mathrm{d}_A\star\eta)\\
&\overset{(3)}{=}-\langle\mathrm{d}_A\omega,\eta\rangle+(-1)^{p-1}(-1)^{(p-1)(n-p+1)}\int_M\operatorname{tr}\big(\omega\wedge\star\star\,\mathrm{d}_A\star\eta\big)\\
&\overset{(4)}{=}-\langle\mathrm{d}_A\omega,\eta\rangle-(-1)^{p-1}(-1)^{(p-1)(n-p+1)}\big\langle\omega,\star\mathrm{d}_A\star\eta\big\rangle.
\end{aligned}\tag{8.175}$$

(1) Stokes: M has no boundary, so the integral of an exact form is zero.
(2) Identity (ii) with $\alpha=\omega$ (degree $p-1$) and $\beta=\star\eta$.
(3) Definition (8.165) for the first term. In the second term, $\mathrm{d}_A\star\eta$ is an $(n-p+1)$-form, and on k-forms $\star\star=(-1)^{k(n-k)}$ in Riemannian signature; with $k=n-p+1$ this is $(-1)^{(p-1)(n-p+1)}$, so we may insert $\star\star$ at the cost of that sign.
(4) Definition (8.165) again, now with the $(p-1)$-forms ω and $\star\mathrm{d}_A\star\eta$.

Comparing with (8.171) we read off, on p-forms,

$$\mathrm{d}_A^{*}=(-1)^p(-1)^{(p-1)(n-p+1)}\ \star\,\mathrm{d}_A\star=(-1)^{n(p+1)+1}\ \star\,\mathrm{d}_A\,\star\,.\tag{8.176}$$

(The second form follows because $p+(p-1)(n-p+1)\equiv n(p+1)+1 \pmod 2$, which you can check by expanding.) In $n=4$ the sign is -1 for every p, and in particular on 2-forms we get (8.174). The Yang–Mills equation (8.172) becomes, after applying $\star$ (which is invertible),

$$\mathrm{d}_A\star F=0.\tag{8.177}$$

This is Nash's (8.75).

Worked example 8.44: d^* in components on $\mathbb{R}^4$

Take the trivial connection and the 2-form $\omega=f\,\mathrm{d}x^1\wedge\mathrm{d}x^2$, i.e. $\omega_{12}=-\omega_{21}=f$ and all other components zero. The orientation is $\mathrm{vol}=\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3\wedge\mathrm{d}x^4$. Then

$$\begin{aligned}
-\star\,\mathrm{d}\star\omega&\overset{(1)}{=}-\star\,\mathrm{d}\big(f\,\mathrm{d}x^3\wedge\mathrm{d}x^4\big)\\
&\overset{(2)}{=}-\star\,\big(\partial_1 f\,\mathrm{d}x^1\wedge\mathrm{d}x^3\wedge\mathrm{d}x^4+\partial_2 f\,\mathrm{d}x^2\wedge\mathrm{d}x^3\wedge\mathrm{d}x^4\big)
\end{aligned}$$

$$\overset{(3)}{=} -(\partial_1 f\, \mathrm{d}x^2 - \partial_2 f\, \mathrm{d}x^1)$$
$$= \partial_2 f\, \mathrm{d}x^1 - \partial_1 f\, \mathrm{d}x^2.$$

(1) $\star(\mathrm{d}x^1 \wedge \mathrm{d}x^2) = \mathrm{d}x^3 \wedge \mathrm{d}x^4$, because $\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4 = \mathrm{vol}$.
(2) Only $\partial_1 f$ and $\partial_2 f$ survive the wedge with $\mathrm{d}x^3 \wedge \mathrm{d}x^4$.
(3) $\star(\mathrm{d}x^1 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4) = \mathrm{d}x^2$ since $\mathrm{d}x^1 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4 \wedge \mathrm{d}x^2 = +\mathrm{vol}$ (two transpositions), and $\star(\mathrm{d}x^2 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4) = -\mathrm{d}x^1$ since $\mathrm{d}x^2 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4 \wedge \mathrm{d}x^1 = -\mathrm{vol}$ (three transpositions).

Compare with $(\mathrm{d}^*\omega)_\nu = -\partial_\mu \omega_{\mu\nu}$: for $\nu = 1$ it gives $-\partial_2\omega_{21} = \partial_2 f$, and for $\nu = 2$ it gives $-\partial_1\omega_{12} = -\partial_1 f$. They agree. So d^* on 2-forms is "minus the divergence on the first index", and with a connection, $(\mathrm{d}_A^* F)_\nu = -D_\mu F_{\mu\nu}$.

8.3.4 A non-linear version of Hodge theory

Compare the pair (8.173) with the definition of a harmonic form (Nash (2.50); see Chapter 2):

$$\mathrm{d}\omega = 0, \qquad \mathrm{d}^*\omega = 0. \tag{8.178}$$

For $G = \mathrm{U}(1)$ the connection is $A = i\mathcal{A}$ with $\mathcal{A}$ a real 1-form, all commutators vanish, $\mathrm{d}_A = \mathrm{d}$, and (8.173) is literally (8.178) for F: the source-free Maxwell equations say the field strength is a harmonic 2-form. Hodge theory then tells us that in each de Rham class there is exactly one harmonic representative. The class of $F/2\pi i$ is fixed by the bundle (it is c_1, see Chapter T2), so on a closed M each U(1) bundle carries exactly one Maxwell field strength, up to gauge. The Maxwell problem is completely linear.

For non-Abelian G, the equations look the same, but d_A itself depends on the unknown A. So (8.173) is a *non-linear* harmonic condition. Two consequences, both visible below: solutions are no longer unique in their topological class, and they come in finite-dimensional families.

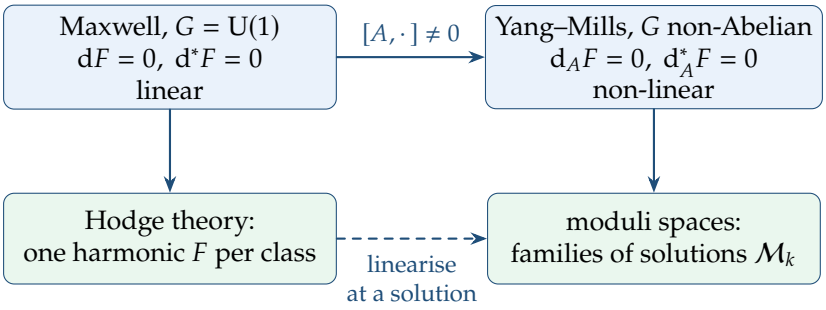

Figure 8.30: The Yang–Mills equations are the non-linear cousin of the harmonic-form equations. In the linear (Maxwell) case each cohomology class has one solution. In the non-linear case we get families of solutions. The tangent space to a family is computed by a *linear* Hodge-type problem at one solution (the dashed arrow), which is how Nash will compute $\dim \mathcal{M}_k$.

Worked example 8.45: Constant non-Abelian fields are not solutions

On the flat torus T^4 (or on $\mathbb{R}^4$), try the simplest non-Abelian ansatz: constant matrices $A_1 = \alpha e_1$, $A_2 = \beta e_2$, $A_3 = A_4 = 0$, with real constants α, β. For a Maxwell field any constant F solves the equations. Here:

$$F_{12} \overset{(1)}{=} [A_1, A_2] = \alpha\beta\,[e_1, e_2]$$
$$\overset{(2)}{=} 2\alpha\beta\, e_3,$$

(1) The fields are constant, so only the commutator term of (8.162) survives.
(2) $e_1e_2 = (-i)^2\sigma_1\sigma_2 = -i\sigma_3 = e_3$ and $e_2e_1 = -e_3$, so $[e_1, e_2] = 2e_3$. (These are the quaternion rules $ij = k = -ji$.)

and every other $F_{\mu\nu}$ with $\mu < \nu$ vanishes. The Yang–Mills equation for $\nu = 2$ is

$$\begin{aligned} -(\mathrm{d}_A^* F)_2 = D_\mu F_{\mu 2} &\overset{(1)}{=} [A_1, F_{12}] \\ &\overset{(2)}{=} 2\alpha^2\beta\,[e_1, e_3] \\ &\overset{(3)}{=} -4\alpha^2\beta\, e_2. \end{aligned}$$

(1) $\partial_\mu F_{\mu 2} = 0$ for constant fields, and only $\mu = 1$ has $F_{\mu 2} \neq 0$.
(2) Substitute A_1 and F_{12}.
(3) $[e_1, e_3] = 2e_1e_3 = -2e_2$ (quaternions: $ik = -j$).

This vanishes only if $\alpha\beta = 0$, i.e. only if the field is Abelian. The self-interaction $[A_\mu, F_{\mu\nu}]$ acts like a source: the gluon field is charged under itself. This is the non-linearity in action.

Try it: The Yang–Mills equations are gauge covariant

Show that if A solves $\mathrm{d}_A^* F = 0$ then so does A_g. *Answer:* $F_{A_g} = g^{-1}Fg$ and $\mathrm{d}_{A_g}(g^{-1}\omega g) = g^{-1}(\mathrm{d}_A\omega)g$, while $\star$ commutes with conjugation. So $\star\mathrm{d}_{A_g} \star F_{A_g} = g^{-1}(\star\mathrm{d}_A \star F)g = 0$. Solutions come in gauge orbits; this is why we will divide by the gauge group.

Reading Nash (pp. 227–229, (8.63)–(8.74))

Nash defines $S = \|F\|^2 = -\int \mathrm{tr}(F \wedge \star F)$ (8.63), varies along $A_t = A + ta$ (8.64)–(8.67), and gets $\mathrm{d}_A^* F = 0$ (8.69), paired with Bianchi (8.70). His (8.72)–(8.74) is the Stokes argument of (8.175). He writes the pairing as $\int \mathrm{tr}(\omega \wedge \star\eta)$ without the minus sign of our (8.165); the sign is an overall factor and does not affect $\mathrm{d}_A^* = -\star\,\mathrm{d}_A\star$. His general sign $(-1)^{1+p+(4-p)p}$ is our (8.176) with $n = 4$ (he labels by the degree of the form d_A^* acts on); it equals -1 for every p. The remark that Yang–Mills is "a kind of non-linear harmonic condition" is Figure 8.30.

Recap

- Conventions: anti-Hermitian A, $F = \mathrm{d}A + A \wedge A$, $\langle\alpha, \beta\rangle = -\int \mathrm{tr}(\alpha \wedge \star\beta)$, $S = \|F\|^2 = g^2 S_{\text{phys}}$.
- Along a line $A + ta$: $F \mapsto F + t\,\mathrm{d}_A a + t^2 a \wedge a$ exactly; $\dot{S}(0) = 2\langle F, \mathrm{d}_A a\rangle$.
- Critical points: $\mathrm{d}_A^* F = 0$; always $\mathrm{d}_A F = 0$. In 4D, $\mathrm{d}_A^* = -\star\,\mathrm{d}_A\star$, so Yang–Mills is $\mathrm{d}_A \star F = 0$.
- Abelian case: F harmonic, one solution per class. Non-Abelian: a non-linear harmonic condition, with families of solutions.

8.4 Self-duality and the Bogomolny bound

The Yang–Mills equation $\mathrm{d}_A \star F = 0$ is a second-order, non-linear partial differential equation for A. Nobody can solve that in general. But Nash observes (just after his (8.75)) that there is a trick. The Bianchi identity $\mathrm{d}_A F = 0$ holds for *every* connection. So if we can arrange $\star F = \pm F$, then $\mathrm{d}_A \star F = \pm \mathrm{d}_A F = 0$ comes for free. The second-order equation has been replaced by a first-order one. Even better, these first-order solutions turn out to be the *absolute minima* of the

action in their topological sector. This section explains both statements. The key player is the Hodge star on 2-forms in four dimensions, which has a special property that holds in no other dimension: it maps 2-forms to 2-forms.

8.4.1 The Hodge star on 2-forms in four dimensions

We work first on $\mathbb{R}^4$ with the flat metric and orientation

$$\mathrm{vol} = \mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4.$$

We abbreviate $\mathrm{d}x^{\mu\nu} = \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$. Recall (Chapter T1) that $\star$ is defined by $\alpha \wedge \star\beta = \langle \alpha, \beta \rangle \,\mathrm{vol}$. For a basis 2-form this means: $\star \mathrm{d}x^{\mu\nu} = \pm \mathrm{d}x^{\rho\sigma}$, where $\{\rho, \sigma\}$ is the complementary pair, and the sign is chosen so that $\mathrm{d}x^{\mu\nu} \wedge \star \mathrm{d}x^{\mu\nu} = +\mathrm{vol}$.

Worked example 8.46: The matrix of $\star$ on $\Lambda^2\mathbb{R}^4$

There are $\binom{4}{2} = 6$ basis 2-forms. Take $\mathrm{d}x^{13}$. Its complement is $\{2, 4\}$, and

$$\begin{aligned} \mathrm{d}x^{13} \wedge \mathrm{d}x^{24} &\overset{(1)}{=} \mathrm{d}x^1 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^4 \\ &\overset{(2)}{=} -\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4 = -\mathrm{vol}, \end{aligned}$$

(1) Definition of the abbreviation.
(2) Swap the adjacent 1-forms $\mathrm{d}x^3$ and $\mathrm{d}x^2$; one transposition costs one minus sign.

so $\star \mathrm{d}x^{13} = -\mathrm{d}x^{24}$. Doing the same for all six:

$$\begin{aligned} &\star \mathrm{d}x^{12} = \mathrm{d}x^{34}, \quad \star \mathrm{d}x^{13} = -\mathrm{d}x^{24}, \quad \star \mathrm{d}x^{14} = \mathrm{d}x^{23}, \\ &\star \mathrm{d}x^{23} = \mathrm{d}x^{14}, \quad \star \mathrm{d}x^{24} = -\mathrm{d}x^{13}, \quad \star \mathrm{d}x^{34} = \mathrm{d}x^{12}. \end{aligned}$$

In the ordered basis $(\mathrm{d}x^{12}, \mathrm{d}x^{13}, \mathrm{d}x^{14}, \mathrm{d}x^{23}, \mathrm{d}x^{24}, \mathrm{d}x^{34})$, the star is the 6×6 matrix

$$\star = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}, \qquad \star^2 = \mathbb{1}_6.$$

The square is the identity: each basis form is sent to its partner and back, with the same sign both times. This agrees with the general rule $\star\star = (-1)^{p(n-p)} = (-1)^4 = +1$ for $p = 2$, $n = 4$.

Since $\star^2 = 1$, the eigenvalues of $\star$ are ± 1, and the 6-dimensional space of 2-forms splits into two 3-dimensional eigenspaces:

$$\Lambda^2 = \Lambda^2_+ \oplus \Lambda^2_-, \qquad \Lambda^2_\pm = \{\omega : \star\omega = \pm\omega\}. \tag{8.179}$$

Forms in Λ^2_+ are called **self-dual** (SD), and forms in Λ^2_- **anti-self-dual** (ASD).

Working definition 8.23 (self-dual and anti-self-dual parts)

Any 2-form [at each point, an element of the 6-dimensional space Λ^2 above] splits as

$\omega = \omega^+ + \omega^-$ with

$$\omega^+ = \pi_+\omega = \tfrac{1}{2}(\omega + \star\omega), \qquad \omega^- = \pi_-\omega = \tfrac{1}{2}(\omega - \star\omega). \tag{8.180}$$

Test: $\star\omega^\pm = \frac{1}{2}(\star\omega \pm \omega) = \pm\omega^\pm$, using $\star^2 = 1$. The maps $\pi_\pm$ are projectors [each keeps its own eigenspace $\Lambda^2_\pm$ unchanged and sends the other one to 0]: $\pi_\pm^2 = \pi_\pm$, $\pi_+\pi_- = 0$, $\pi_+ + \pi_- = 1$. Nash's (8.95) is π_-.

An explicit basis: the 't Hooft symbols

Pairing each $\mathrm{d}x^{a4}$ ($a = 1, 2, 3$) with its complement gives bases of the two eigenspaces:

$$\begin{aligned} \omega_1^+ &= \mathrm{d}x^{14} + \mathrm{d}x^{23}, & \omega_2^+ &= \mathrm{d}x^{24} + \mathrm{d}x^{31}, & \omega_3^+ &= \mathrm{d}x^{34} + \mathrm{d}x^{12}, \\ \omega_1^- &= -\mathrm{d}x^{14} + \mathrm{d}x^{23}, & \omega_2^- &= -\mathrm{d}x^{24} + \mathrm{d}x^{31}, & \omega_3^- &= -\mathrm{d}x^{34} + \mathrm{d}x^{12}. \end{aligned} \tag{8.181}$$

(The table above shows $\star\mathrm{d}x^{14} = \mathrm{d}x^{23}$, and $\star\mathrm{d}x^{24} = -\mathrm{d}x^{13} = \mathrm{d}x^{31}$, so these are indeed eigenvectors.) Physicists write the coefficients as the **'t Hooft symbols**:

$$\omega_a^+ = \tfrac{1}{2}\eta^a_{\mu\nu}\,\mathrm{d}x^{\mu\nu}, \qquad \omega_a^- = \tfrac{1}{2}\bar\eta^a_{\mu\nu}\,\mathrm{d}x^{\mu\nu}, \tag{8.182}$$

$$\eta^a_{jk} = \bar\eta^a_{jk} = \varepsilon_{ajk}, \qquad \eta^a_{j4} = -\eta^a_{4j} = \delta_{aj}, \qquad \bar\eta^a_{j4} = -\bar\eta^a_{4j} = -\delta_{aj} \qquad (j,k = 1,2,3).$$

Each η^a is an antisymmetric 4×4 matrix. For example

$$\eta^1 = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 \\ -1 & 0 & 0 & 0 \end{pmatrix}, \qquad \bar\eta^1 = \begin{pmatrix} 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}.$$

The component form of self-duality is $\frac{1}{2}\varepsilon_{\mu\nu\rho\sigma}\eta^a_{\rho\sigma} = \eta^a_{\mu\nu}$, and similarly with a minus sign for $\bar\eta$. We will use two identities that follow by direct checking of a few components:

$$\eta^a_{\mu\nu}\eta^b_{\mu\nu} = 4\delta^{ab}, \qquad \eta^a_{\mu\nu}\bar\eta^b_{\mu\nu} = 0, \qquad \eta^a_{\mu\nu}\eta^b_{\mu\rho} = \delta^{ab}\delta_{\nu\rho} + \varepsilon^{abc}\eta^c_{\nu\rho}. \tag{8.183}$$

The first says each η^a has four non-zero entries of modulus one; the second is the orthogonality of Λ^2_+ and Λ^2_-; the third says the η^a multiply like quaternions (we will see why in Section 8.5).

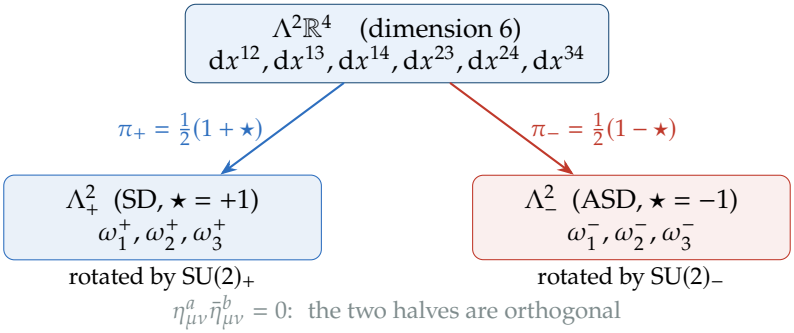

Figure 8.31: The six-dimensional space of 2-forms on $\mathbb{R}^4$ splits into two three-dimensional halves. The rotation group $\mathrm{SO}(4) = (\mathrm{SU}(2)_+ \times \mathrm{SU}(2)_-)/\mathbb{Z}_2$ acts on each half separately, as SO(3); this is the statement $\Lambda^2_\pm \cong$ adjoint of $\mathrm{SU}(2)_\pm$. A self-dual field strength has only three independent components per colour, not six.

Physical picture: self-duality is $\vec{E} = \vec{B}$

Label the components of a Euclidean field strength like the electric and magnetic fields: $E_j = F_{j4}$ and $B_j = \frac{1}{2}\varepsilon_{jkl}F_{kl}$ (so $B_1 = F_{23}$). The basis (8.181) shows

$$F = \sum_j E_j \, \mathrm{d}x^{j4} + \sum_j B_j \, \tfrac{1}{2}\varepsilon_{jkl}\mathrm{d}x^{kl}, \qquad \star F = \sum_j B_j \, \mathrm{d}x^{j4} + \sum_j E_j \, \tfrac{1}{2}\varepsilon_{jkl}\mathrm{d}x^{kl}.$$

So $\star$ swaps $\vec{E}$ and $\vec{B}$, and

$$F = \star F \iff \vec{E} = \vec{B}, \qquad F = -\star F \iff \vec{E} = -\vec{B}.$$

For a non-Abelian field this holds colour by colour: $\vec{E}^a = \pm\vec{B}^a$.

Watch out: There are no real instantons in Minkowski space

In Lorentzian signature $(-,+,+,+)$ the rule is $\star\star = -(-1)^{p(n-p)} = -1$ on 2-forms, so the eigenvalues of $\star$ are $\pm i$ and a real F can satisfy $\star F = \lambda F$ only if $F = 0$. In the $\vec{E}, \vec{B}$ language, the Lorentzian star sends $\vec{E} \mapsto \vec{B}$ and $\vec{B} \mapsto -\vec{E}$, and "self-duality" is $\vec{E} = i\vec{B}$. That is why instantons live in Euclidean signature: they describe tunnelling (imaginary time), not real-time classical motion.

Conformal invariance

On a general Riemannian 4-manifold the star depends on the metric. But on 2-forms in four dimensions it depends only on the *conformal class* of the metric: the metrics g and $\Omega^2 g$ (with $\Omega(x) > 0$ any function) give the same $\star$ on 2-forms.

$$\begin{aligned}(\star_{\Omega^2 g}\,\omega)_{\mu\nu} &\overset{(1)}{=} \tfrac{1}{2}\sqrt{\det(\Omega^2 g)}\;\varepsilon_{\mu\nu\rho\sigma}\,(\Omega^{-2}g^{\rho\alpha})(\Omega^{-2}g^{\sigma\beta})\,\omega_{\alpha\beta}\\ &\overset{(2)}{=} \tfrac{1}{2}\,\Omega^4\sqrt{\det g}\;\Omega^{-4}\,\varepsilon_{\mu\nu\rho\sigma}g^{\rho\alpha}g^{\sigma\beta}\,\omega_{\alpha\beta}\\ &\overset{(3)}{=} (\star_g\,\omega)_{\mu\nu}.\end{aligned}$$

(1) The coordinate formula for the star of a 2-form in four dimensions: raise both indices with the inverse metric, contract with the Levi-Civita symbol, multiply by $\sqrt{\det g}$. The inverse of $\Omega^2 g$ is $\Omega^{-2}g^{-1}$.

(2) $\det(\Omega^2 g) = \Omega^8 \det g$ for a 4×4 matrix, so the square root gives Ω^4; two inverse metrics give Ω^{-4}.

(3) The powers of Ω cancel exactly. In n dimensions on p-forms the leftover power would be Ω^{n-2p}; it vanishes only for $n = 2p$.

The same count shows that the action density $\mathrm{tr}(F \wedge \star F)$ is conformally invariant, so the Yang–Mills action has no scale in four dimensions: *classical Yang–Mills theory in 4D is conformally invariant*.

This matters because the **stereographic projection** $S^4 \setminus \{\text{north pole}\} \to \mathbb{R}^4$ is conformal (Figure 8.32):

$$g_{S^4} = \frac{4}{(1+|x|^2)^2}\, g_{\mathbb{R}^4} \tag{8.184}$$

for the unit sphere. So a self-dual field on $\mathbb{R}^4$ is the same thing as a self-dual field on S^4 minus a point, with the same action. If the action is finite, a theorem of Uhlenbeck (the **removable**

singularity theorem) says the connection extends smoothly, after a gauge transformation, over the missing point. Finite-action instantons on $\mathbb{R}^4$ are therefore exactly instantons on S^4. This is how the compact manifold S^4 of the mathematicians and the flat $\mathbb{R}^4$ of the physicists become the same problem.

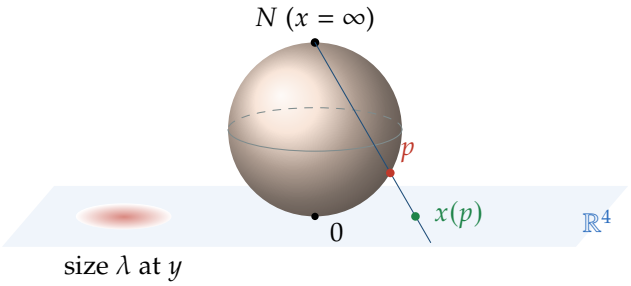

Figure 8.32: Stereographic projection from the north pole N identifies $S^4 \setminus \{N\}$ with $\mathbb{R}^4$. It is conformal, and on 2-forms in 4D the Hodge star sees only the conformal class, so self-duality and the action are the same on both sides. The point at infinity of $\mathbb{R}^4$ is the single point N; finite action is what lets the field extend smoothly over it. An instanton of size λ centred at $y \in \mathbb{R}^4$ is a lump of action density that looks the same, in this sense, on the plane and on the sphere.

8.4.2 Self-dual fields solve the Yang–Mills equations

Everything above is pointwise linear algebra, so it carries over to $\mathfrak{g}$-valued 2-forms on any oriented Riemannian 4-manifold: $\star$ acts on the form part and leaves the matrix part alone. In particular every curvature splits as

$$F = F^+ + F^-, \qquad F^\pm = \tfrac{1}{2}(F \pm \star F). \tag{8.185}$$

Key idea: First order implies second order (Nash, after (8.75))

If $F = \pm \star F$, then A solves the Yang–Mills equations:

$$\begin{aligned} \mathrm{d}_A \star F &\overset{(1)}{=} \mathrm{d}_A(\pm F) \\ &\overset{(2)}{=} \pm\, \mathrm{d}_A F \\ &\overset{(3)}{=} 0. \end{aligned}$$

(1) Apply $\star$ to $F = \pm \star F$ and use $\star^2 = 1$ on 2-forms: $\star F = \pm F$.
(2) d_A is linear.
(3) The Bianchi identity, proved in the worked example of Section 8.3.1.

We have solved a non-linear second-order equation, $\mathrm{d}_A \star F = 0$, by solving a non-linear *first-order* one, $F = \pm \star F$.

The converse is false in general: there are Yang–Mills connections on S^4 that are neither SD nor ASD (Sibner, Sibner and Uhlenbeck, 1989). But the self-dual ones are the most important, because of the energy bound we derive next.

Worked example 8.47: Self-duality in components

Write $F = \frac{1}{2}F_{\mu\nu}\mathrm{d}x^{\mu\nu}$ on $\mathbb{R}^4$. Using the table of the first worked example of Section 8.4.1,

$F = \star F$ means

$$F_{12}\,\mathrm{d}x^{12} + F_{34}\,\mathrm{d}x^{34} + \ldots \overset{(1)}{=} \star\big(F_{12}\,\mathrm{d}x^{12} + F_{34}\,\mathrm{d}x^{34} + \ldots\big) \overset{(2)}{=} F_{12}\,\mathrm{d}x^{34} + F_{34}\,\mathrm{d}x^{12} + \ldots,$$

(1) $F = \sum_{\mu<\nu} F_{\mu\nu}\mathrm{d}x^{\mu\nu}$, written out for the pair $\{12, 34\}$; the other pairs work the same way.
(2) $\star\mathrm{d}x^{12} = \mathrm{d}x^{34}$ and $\star\mathrm{d}x^{34} = \mathrm{d}x^{12}$.

so comparing coefficients, and doing the same for the other two pairs,

$$F_{12} = F_{34}, \qquad F_{13} = -F_{24}, \qquad F_{14} = F_{23}. \tag{8.186}$$

Three matrix equations: they say that the components of F along the three ASD basis forms ω_a^- vanish, i.e. $F^- = 0$. For SU(2) that is $3\times 3 = 9$ real equations on $4\times 3 = 12$ real functions A_μ^a, and 3 of the 12 are gauge. So the count is "9 equations for 9 unknowns": a determined system, as it should be for an elliptic problem. We make this precise in Section 8.8.

8.4.3 The instanton number

Topology enters through the second Chern class. For an SU(N) bundle E the total Chern class is $c(E) = \det\big(1 + \frac{i}{2\pi}F\big)$ (see Chapter T2 and Chapter 4). We need its 4-form part.

$$\begin{aligned}\det\Big(1 + \tfrac{i}{2\pi}F\Big) &\overset{(1)}{=} \exp\operatorname{tr}\log\Big(1 + \tfrac{i}{2\pi}F\Big)\\ &\overset{(2)}{=} \exp\Big(\tfrac{i}{2\pi}\operatorname{tr}F - \tfrac{1}{2}\big(\tfrac{i}{2\pi}\big)^2\operatorname{tr}(F\wedge F) + \ldots\Big)\\ &\overset{(3)}{=} \exp\Big(\tfrac{1}{8\pi^2}\operatorname{tr}(F\wedge F) + \ldots\Big)\\ &\overset{(4)}{=} 1 + \tfrac{1}{8\pi^2}\operatorname{tr}(F\wedge F) + (\text{6-forms and higher}).\end{aligned}$$

(1) The matrix identity det = exp tr log; it is fine for matrices of even forms, which commute with each other.
(2) Expand $\log(1+X) = X - \frac{1}{2}X^2 + \ldots$.
(3) $\operatorname{tr}F = 0$ for $\mathfrak{su}(N)$, and $-\frac{1}{2}(i/2\pi)^2 = \frac{1}{8\pi^2}$.
(4) Expand the exponential; on a 4-manifold nothing beyond 4-forms survives.

So $c_2(E) = \frac{1}{8\pi^2}\operatorname{tr}(F\wedge F)$, and we define the **instanton number**

$$k = -c_2(E)[M] = -\frac{1}{8\pi^2}\int_M \operatorname{tr}(F\wedge F). \tag{8.187}$$

This is an integer, since c_2 is an integral class, and it does not change under continuous deformations of A, since the integrand changes by an exact form (Chapter T2; part 8a derived the transgression formula $\operatorname{tr}(F\wedge F) = \mathrm{d}\,\operatorname{tr}(A\wedge\mathrm{d}A + \frac{2}{3}A\wedge A\wedge A)$). On S^4 the integer k classifies SU(2) bundles completely.

Watch out: The sign of k

Nash's (8.77) writes $k = \frac{1}{8\pi^2}\int\operatorname{tr}(F\wedge F)$ in its first line, then $(\|F^+\|^2 - \|F^-\|^2)/8\pi^2$ in its last. With anti-Hermitian F these two differ by a sign (we show this below), and the first

line is missing a minus sign; his words "k is minus $c_2(F)$" agree with (8.187). With our conventions, orientation dx^{1234} and $k = -c_2$, the BPST instanton of Section 8.5 is self-dual and has $k = +1$.

8.4.4 The action splits; the Bogomolny bound

Two facts do all the work.

Fact 1: SD and ASD forms are orthogonal. Let $\alpha \in \Lambda^2_+$ and $\beta \in \Lambda^2_-$ be $\mathfrak{g}$-valued. Then

$$\begin{aligned}\operatorname{tr}(\alpha \wedge \star\beta) &\overset{(1)}{=} -\operatorname{tr}(\alpha \wedge \beta)\\ &\overset{(2)}{=} -\operatorname{tr}(\beta \wedge \alpha)\\ &\overset{(3)}{=} -\operatorname{tr}(\beta \wedge \star\alpha)\\ &\overset{(4)}{=} -\operatorname{tr}(\alpha \wedge \star\beta),\end{aligned}$$

(1) $\star\beta = -\beta$.
(2) Graded cyclicity of the trace with two 2-forms: sign $(-1)^{2\cdot 2} = +1$.
(3) $\alpha = \star\alpha$.
(4) Symmetry of the pointwise inner product, $\operatorname{tr}(\beta\wedge\star\alpha) = \operatorname{tr}(\alpha\wedge\star\beta)$ (both are $\frac{1}{2}\operatorname{tr}(\alpha_{\mu\nu}\beta_{\mu\nu})\mathrm{vol}$).

A quantity equal to its own negative is zero. So $\langle\alpha,\beta\rangle = 0$, pointwise and after integration.

Fact 2: $\operatorname{tr}(F\wedge F)$ *sees the difference.* Using $F\wedge F = F\wedge\star\star F$ and splitting:

$$\begin{aligned}-\int_M \operatorname{tr}(F\wedge F) &\overset{(1)}{=} -\int_M \operatorname{tr}\big((F^+ + F^-)\wedge(F^+ + F^-)\big)\\ &\overset{(2)}{=} -\int_M \operatorname{tr}(F^+\wedge F^+) - \int_M \operatorname{tr}(F^-\wedge F^-)\\ &\overset{(3)}{=} -\int_M \operatorname{tr}(F^+\wedge\star F^+) + \int_M \operatorname{tr}(F^-\wedge\star F^-)\\ &\overset{(4)}{=} \left\|F^+\right\|^2 - \|F^-\|^2 .\end{aligned} \tag{8.188}$$

(1) The splitting (8.185).
(2) The cross terms are $\operatorname{tr}(F^+\wedge F^-) = -\operatorname{tr}(F^+\wedge\star F^-)$, which vanishes pointwise by Fact 1 (and the same for $F^-\wedge F^+$).
(3) $F^+ = \star F^+$ and $F^- = -\star F^-$.
(4) The definition (8.165) of the norm.

Meanwhile the action itself is a sum:

$$\begin{aligned}S = \|F\|^2 &\overset{(1)}{=} \left\|F^+\right\|^2 + \|F^-\|^2 + 2\langle F^+, F^-\rangle\\ &\overset{(2)}{=} \left\|F^+\right\|^2 + \|F^-\|^2 .\end{aligned} \tag{8.189}$$

(1) Expand the norm of a sum using bilinearity and symmetry.
(2) Fact 1.

This is Nash's (8.76). Combining with (8.187) and (8.188), Nash's (8.77) (with the corrected sign) reads

$$8\pi^2 k = \left\|F^+\right\|^2 - \|F^-\|^2 , \qquad S = \left\|F^+\right\|^2 + \|F^-\|^2 . \tag{8.190}$$

Key idea: The Bogomolny bound (Nash (8.78)–(8.79))

For every connection with instanton number k,

$$S(A) \;\geq\; 8\pi^2|k|, \tag{8.191}$$

with equality if and only if $F^- = 0$ (self-dual, $F = \star F$, possible when $k \geq 0$) or $F^+ = 0$ (anti-self-dual, $F = -\star F$, possible when $k \leq 0$). *Why:* for real numbers $a^2 + b^2 \geq |a^2 - b^2|$, with equality iff $a = 0$ or $b = 0$. Apply it to $a = \|F^+\|$, $b = \|F^-\|$ in (8.190).

So in each topological sector the SD (or ASD) connections are the absolute minima of the action. They are stable: no small deformation lowers the action. In physical units the minimal action is $S_{\text{phys}} = 8\pi^2|k|/g^2$, and each instanton contributes the famous suppression factor $e^{-8\pi^2/g^2}$ to the Euclidean path integral.

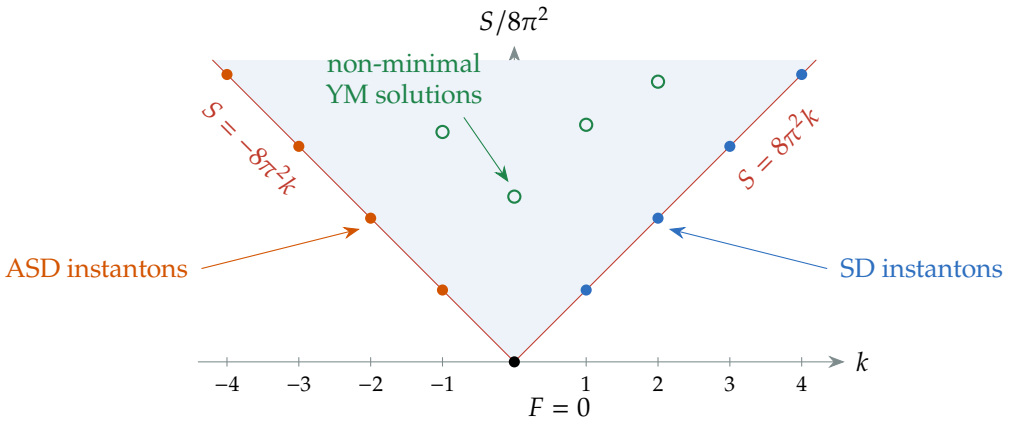

Figure 8.33: The Bogomolny bound. Every connection lies in the shaded wedge $S \geq 8\pi^2|k|$. The solid dots on the edges are the absolute minima: SD instantons for $k > 0$, ASD for $k < 0$, the flat connection at $k = 0$. Hollow circles are Yang–Mills critical points that are neither: they are saddle points of S, not minima. Reversing the orientation of M reflects the picture in the vertical axis.

Worked example 8.48: The Bogomolny trick: completing the square

Physicists usually derive (8.191) in one line, by completing a square. Since $\star$ is an isometry on 2-forms ($\|\star F\| = \|F\|$),

$$\begin{aligned} 0 \overset{(1)}{\leq} \|F - \star F\|^2 &\overset{(2)}{=} \|F\|^2 + \|\star F\|^2 - 2\langle F, \star F\rangle \\ &\overset{(3)}{=} 2S + 2\int_M \operatorname{tr}(F \wedge \star\star F) \\ &\overset{(4)}{=} 2S + 2\int_M \operatorname{tr}(F \wedge F) \\ &\overset{(5)}{=} 2S - 16\pi^2 k. \end{aligned}$$

(1) A norm squared is non-negative; it is zero iff $F = \star F$.
(2) Expand the square.
(3) $\|\star F\|^2 = \|F\|^2 = S$, and $\langle F, \star F\rangle = -\int \operatorname{tr}(F \wedge \star\star F)$ by (8.165).
(4) $\star\star = 1$ on 2-forms.
(5) Definition (8.187) of k.

So $S \geq 8\pi^2 k$, with equality iff F is SD. Replacing $F - \star F$ by $F + \star F$ gives $S \geq -8\pi^2 k$, with

equality iff F is ASD. Together: $S \geq 8\pi^2|k|$.

Worked example 8.49: A $\mathrm{U}(1)$ check with numbers: constant fields on T^4

Let $M = T^4 = \mathbb{R}^4/(L\mathbb{Z})^4$, a flat torus of side L, and $G = \mathrm{U}(1)$. Then $F = if$ with f a real closed 2-form, and there is no trace. Take the constant field

$$f = \frac{2\pi}{L^2}\left(n\,\mathrm{d}x^{12} + m\,\mathrm{d}x^{34}\right), \qquad n, m \in \mathbb{Z}.$$

The integers are forced: the flux of f through the 2-torus in the 12 plane is $\int f = \frac{2\pi}{L^2} n\, L^2 = 2\pi n$, and Dirac quantisation (the first Chern class $[f/2\pi]$ is integral) requires $n \in \mathbb{Z}$; similarly for m. Now compute both sides of the bound. The action is

$$\begin{aligned} S = \int_{T^4} f \wedge \star f &\overset{(1)}{=} \left(\frac{2\pi}{L^2}\right)^2 \int_{T^4} (n\,\mathrm{d}x^{12} + m\,\mathrm{d}x^{34}) \wedge (n\,\mathrm{d}x^{34} + m\,\mathrm{d}x^{12}) \\ &\overset{(2)}{=} \left(\frac{2\pi}{L^2}\right)^2 (n^2 + m^2)\, L^4 \\ &= 4\pi^2(n^2 + m^2). \end{aligned}$$

(1) For U(1), $-\operatorname{tr}(F \wedge \star F) = -(if) \wedge \star(if) = f \wedge \star f$; use $\star \mathrm{d}x^{12} = \mathrm{d}x^{34}$ and $\star \mathrm{d}x^{34} = \mathrm{d}x^{12}$.
(2) $\mathrm{d}x^{12} \wedge \mathrm{d}x^{34} = \mathrm{d}x^{34} \wedge \mathrm{d}x^{12} = \mathrm{vol}$, the other products vanish, and $\int \mathrm{vol} = L^4$.

The topological number is

$$\begin{aligned} k = -\frac{1}{8\pi^2}\int_{T^4} F \wedge F &\overset{(1)}{=} \frac{1}{8\pi^2}\int_{T^4} f \wedge f \\ &\overset{(2)}{=} \frac{1}{8\pi^2}\left(\frac{2\pi}{L^2}\right)^2 2nm\, L^4 = nm. \end{aligned}$$

(1) $F \wedge F = (if) \wedge (if) = -f \wedge f$.
(2) $(n\,\mathrm{d}x^{12} + m\,\mathrm{d}x^{34})^{\wedge 2} = 2nm\,\mathrm{vol}$ (two cross terms).

So $S - 8\pi^2|k| = 4\pi^2(n^2 + m^2 - 2|nm|) = 4\pi^2(|n| - |m|)^2 \geq 0$, with equality exactly when $m = \pm n$, i.e. when $f = \frac{2\pi n}{L^2}(\mathrm{d}x^{12} \pm \mathrm{d}x^{34})$ is SD or ASD. The Bogomolny bound in this case is the inequality $n^2 + m^2 \geq 2|nm|$ between integers.

Worked example 8.50: Self-dual fields carry no energy–momentum

The Euclidean stress tensor of a Yang–Mills field is (physicists' units) $T_{\mu\nu} = F^a_{\mu\rho}F^a_{\nu\rho} - \frac{1}{4}\delta_{\mu\nu}F^a_{\rho\sigma}F^a_{\rho\sigma}$. In terms of $\vec{E}^a$, $\vec{B}^a$ (intuition box above), $F^a_{\rho\sigma}F^a_{\rho\sigma} = 2(|\vec{E}^a|^2 + |\vec{B}^a|^2)$, summed over a. Then

$$\begin{aligned} T_{44} &\overset{(1)}{=} F^a_{4j}F^a_{4j} - \tfrac{1}{2}\left(|\vec{E}|^2 + |\vec{B}|^2\right) \\ &\overset{(2)}{=} \tfrac{1}{2}\left(|\vec{E}|^2 - |\vec{B}|^2\right), \\ T_{j4} &\overset{(3)}{=} F^a_{jk}F^a_{4k} \overset{(4)}{=} -(\vec{E}^a \times \vec{B}^a)_j, \end{aligned}$$

(1) Definition of T with $\mu = \nu = 4$; $F_{44} = 0$.
(2) $F_{4j} = -E_j$, so $F^a_{4j}F^a_{4j} = |\vec{E}|^2$ (sums over a understood).
(3) Definition with $\mu = j$, $\nu = 4$; only $\rho = k$ spatial contributes.
(4) $F_{jk} = \varepsilon_{jkl}B_l$ and $F_{4k} = -E_k$.

If $\vec{E}^a = \pm\vec{B}^a$ for every a then $T_{44} = 0$ and $T_{j4} = 0$, and a similar two-line check gives $T_{jk} = 0$. An instanton exerts no stress. One consequence: an instanton on a curved 4-manifold does not back-react on the metric in Euclidean Einstein–Yang–Mills theory.

Physical picture: instantons as tunnelling

In the temporal gauge, the finite-action configurations on $\mathbb{R}^4$ interpolate between classical vacua $A = g^{-1}\mathrm{d}g$ at $x^4 = -\infty$ and $x^4 = +\infty$ whose winding numbers differ by k (part 8a). The instanton is the dominant tunnelling path between neighbouring vacua, and its amplitude is $e^{-8\pi^2/g^2}$. Adding the topological term $i\theta k$ to the Euclidean action weights the sectors by $e^{i\theta k}$: the θ-vacua. Nash does not discuss this physics, but it is why the moduli spaces we are about to study matter to a physicist: each point of $\mathcal{M}_k$ is a tunnelling path, and integrating over $\mathcal{M}_k$ is summing over them.

Watch out: SD versus ASD is a convention

Reversing the orientation of M changes the sign of $\star$ (the volume form changes sign), swapping Λ^2_+ and Λ^2_-, and also flips the sign of k. Nothing physical changes. Nash, like us, "deems" the minima with $k > 0$ to be self-dual. Much of the mathematical literature (Donaldson, Atiyah–Hitchin–Singer) uses ASD connections with $k > 0$ instead, because it fits the complex geometry of twistor space better. When comparing formulas, swap $+ \leftrightarrow -$ everywhere: for example b_2^- in Nash becomes b_2^+ in Donaldson–Kronheimer.

Reading Nash (pp. 229–230, (8.75)–(8.79); p. 233, (8.95))

After (8.75), Nash notes that $F = \mp\star F$ plus Bianchi solves the Yang–Mills equation, "solving a non-linear second order equation by solving a non-linear first order equation". He splits $F = F^+ + F^-$ (8.76) and asserts that "the crossed terms in the norm contribute zero": this is our Fact 1. (8.77) expresses k as $(\|F^+\|^2 - \|F^-\|^2)/8\pi^2$; see the sign pitfall above. (8.78)–(8.79) is the bound $S \geq 8\pi^2|k|$ from $a^2 + b^2 \geq |a^2 - b^2|$. The projector $\pi_-\omega = \frac{1}{2}(\omega - \star\omega)$ of (8.95) is our (8.180); Nash introduces it only later, to write the SD equation as $\pi_- F = 0$. Nash's wording "$F = \mp \star F$ corresponds to $F^\mp = 0$" uses the opposite pairing of signs to ours in the first formula; the content is the same: the minimum with $k > 0$ has $F^- = 0$.

Recap

- In 4D, $\star$ maps 2-forms to 2-forms with $\star^2 = 1$: $\Lambda^2 = \Lambda^2_+ \oplus \Lambda^2_-$, three dimensions each, bases given by the 't Hooft symbols η^a, $\bar{\eta}^a$.
- On 2-forms in 4D the star (hence the SD equation and the action) is conformally invariant; $\mathbb{R}^4$ and S^4 give the same instantons.
- SD or ASD plus Bianchi implies Yang–Mills.
- $k = -c_2 = -\frac{1}{8\pi^2}\int \mathrm{tr}\, F \wedge F = (\|F^+\|^2 - \|F^-\|^2)/8\pi^2$ and $S = \|F^+\|^2 + \|F^-\|^2$, so $S \geq 8\pi^2|k|$ with equality exactly for SD ($k > 0$) or ASD ($k < 0$) fields.
- Physically: $\vec{E}^a = \pm\vec{B}^a$, zero stress tensor, tunnelling amplitude $e^{-8\pi^2|k|/g^2}$.

8.5 The BPST instanton and the 't Hooft ansatz

The Bogomolny bound tells us where to look: in the sector with instanton number k, the minima of the action are the self-dual connections. But does the sector $k = 1$ contain any self-dual connection at all? Nash takes the answer for granted; he goes straight to the moduli

space $\mathcal{M}_k$ and counts its dimension. Before we follow him, we want an instanton in our hands, as a formula we can differentiate. This section constructs it.

The solution was found by Belavin, Polyakov, Schwarz and Tyupkin in 1975 and is called the **BPST instanton**. The cleanest way to write it uses quaternions, because $\mathbb{R}^4 = \mathbb{H}$ and $\mathrm{SU}(2) = \{\text{unit quaternions}\}$: the spacetime and the gauge group are made of the same stuff. We will

1. set up quaternions as 2×2 matrices, and see the 't Hooft symbols of Section 8.4 fall out of quaternion multiplication;
2. understand why a finite-action field must be "pure gauge at infinity", and how the winding of that gauge transformation is k;
3. write down the BPST connection, compute its curvature line by line, check that it is self-dual, and compute its action $8\pi^2$ (that is, $8\pi^2/g^2$ in physical units) and its charge $k = 1$;
4. move it to the *singular gauge*, and generalise it to k instantons with the *'t Hooft ansatz*.

At the end we count parameters. The BPST instanton has 5 of them (a centre in $\mathbb{R}^4$ and a size), and this is the number $8k-3$ at $k=1$ that Nash computes with the index theorem in Section 8.9.

8.5.1 Quaternions as 2×2 matrices

A quaternion is a number $q = q^4 + q^1\mathbf{i} + q^2\mathbf{j} + q^3\mathbf{k}$ with real q^μ and the rules $\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = \mathbf{ijk} = -1$. We never need the abstract definition, because the quaternions have a concrete matrix representation built from the Pauli matrices.

Working definition 8.24 (quaternions as matrices)

Let

$$e_1 = -i\sigma_1 = \begin{pmatrix} 0 & -i \\ -i & 0 \end{pmatrix}, \quad e_2 = -i\sigma_2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \quad e_3 = -i\sigma_3 = \begin{pmatrix} -i & 0 \\ 0 & i \end{pmatrix}, \quad e_4 = \mathbb{1}.$$

A point $x = (x^1, x^2, x^3, x^4) \in \mathbb{R}^4$ is identified with the matrix

$$x = x^4\mathbb{1} + x^k e_k = \begin{pmatrix} x^4 - ix^3 & -x^2 - ix^1 \\ x^2 - ix^1 & x^4 + ix^3 \end{pmatrix}. \tag{8.192}$$

The **conjugate** is $\bar{x} = x^4\mathbb{1} - x^k e_k = x^\dagger$ (the Hermitian adjoint of the matrix [its complex-conjugate transpose]). The **real part** and **imaginary part** are

$$\operatorname{Re} x = \tfrac{1}{2}(x + \bar{x}) = x^4\mathbb{1}, \qquad \operatorname{Im} x = \tfrac{1}{2}(x - \bar{x}) = x^k e_k.$$

Test: a 2×2 complex matrix is a quaternion iff it has the form $\begin{pmatrix} \alpha & -\bar{\beta} \\ \beta & \bar{\alpha} \end{pmatrix}$. Imaginary quaternions are exactly the matrices of $\mathfrak{su}(2)$: anti-Hermitian and traceless.

Worked example 8.51: The quaternion rules, by matrix multiplication

We check $e_1 e_2 = e_3$:

$$e_1 e_2 \overset{(1)}{=} (-i)^2 \sigma_1\sigma_2$$
$$\overset{(2)}{=} -i\sigma_3$$

$$\overset{(3)}{=} e_3.$$

(1) Definition $e_k = -i\sigma_k$.
(2) Pauli rule $\sigma_1\sigma_2 = i\sigma_3$, and $(-i)^2 = -1$.
(3) Definition of e_3.

In the same way $e_2e_3 = e_1$, $e_3e_1 = e_2$, $e_k^2 = -\sigma_k^2 = -\mathbb{1}$, and $e_je_k = -e_ke_j$ for $j \neq k$. In one line:

$$e_je_k = -\delta_{jk}\mathbb{1} + \varepsilon_{jkl}e_l, \qquad [e_j, e_k] = 2\varepsilon_{jkl}e_l. \tag{8.193}$$

So e_1, e_2, e_3 are $\mathbf{i}, \mathbf{j}, \mathbf{k}$. The commutator form says that $\{e_a\}$ is a basis of $\mathfrak{su}(2)$ with structure constants 2ε.

Two facts make the matrix picture powerful.

Length is a determinant. Multiply out:

$$\begin{aligned}\bar{x}x &\overset{(1)}{=} (x^4 - x^je_j)(x^4 + x^ke_k)\\ &\overset{(2)}{=} (x^4)^2\mathbb{1} - x^jx^ke_je_k + x^4x^k(e_k - e_k)\\ &\overset{(3)}{=} \big((x^4)^2 + x^jx^k\delta_{jk}\big)\mathbb{1} - x^jx^k\varepsilon_{jkl}e_l\\ &\overset{(4)}{=} |x|^2\,\mathbb{1}.\end{aligned}$$

(1) Definitions of x and $\bar{x}$.
(2) Expand the product; the two cross terms $x^4x^ke_k$ and $-x^jx^4e_j$ cancel.
(3) The product rule (8.193).
(4) x^jx^k is symmetric and ε_{jkl} antisymmetric in jk, so the last term vanishes.

Likewise $x\bar{x} = |x|^2\mathbb{1}$, and $\det x = |x|^2$ (check it on (8.192): $(x^4)^2 + (x^3)^2 + (x^1)^2 + (x^2)^2$). So $x^{-1} = \bar{x}/|x|^2$ and $|xy| = |x||y|$.

Unit quaternions are SU(2). If $|x| = 1$ then $x^\dagger x = \bar{x}x = \mathbb{1}$ and $\det x = 1$, so $x \in \mathrm{SU}(2)$. Conversely every SU(2) matrix has the form $\begin{pmatrix}\alpha & -\bar{\beta}\\ \beta & \bar{\alpha}\end{pmatrix}$ with $|\alpha|^2 + |\beta|^2 = 1$, which is a unit quaternion. Hence

$$\mathrm{SU}(2) = \{x \in \mathbb{H} : |x| = 1\} = S^3. \tag{8.194}$$

This is the coincidence at the root of instantons: the sphere at infinity of $\mathbb{R}^4$ is a copy of the gauge group SU(2).

The 't Hooft symbols come from quaternion multiplication

Define the matrix-valued 1-forms $\mathrm{d}x = e_\mu \mathrm{d}x^\mu$ and $\mathrm{d}\bar{x} = \bar{e}_\mu \mathrm{d}x^\mu$ (with $\bar{e}_k = -e_k$, $\bar{e}_4 = \mathbb{1}$). Products of two of them produce the self-dual and anti-self-dual 2-forms.

Worked example 8.52: $\mathrm{d}\bar{x} \wedge \mathrm{d}x$ is self-dual, $\mathrm{d}x \wedge \mathrm{d}\bar{x}$ is anti-self-dual

Since $\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$ is antisymmetric,

$$\begin{aligned}\mathrm{d}\bar{x} \wedge \mathrm{d}x &\overset{(1)}{=} \bar{e}_\mu e_\nu\, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu\\ &\overset{(2)}{=} \sum_{\mu<\nu} (\bar{e}_\mu e_\nu - \bar{e}_\nu e_\mu)\, \mathrm{d}x^{\mu\nu}\end{aligned}$$

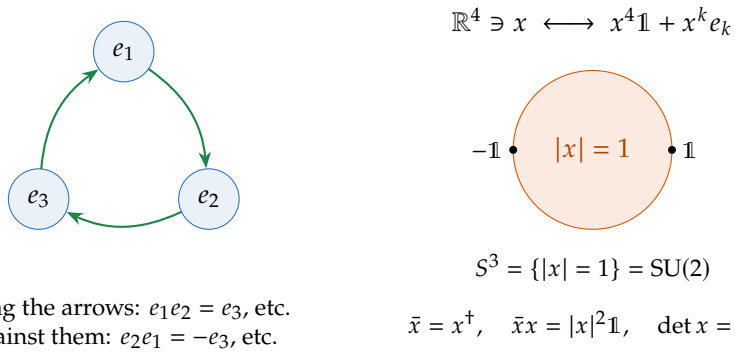

Figure 8.34: Left: the quaternion units multiply cyclically, like the cross product of $\hat{x}, \hat{y}, \hat{z}$; going against the arrow costs a sign. Right: identifying $\mathbb{R}^4$ with 2×2 matrices, the unit sphere S^3 becomes the group SU(2). Every instanton formula below is a statement about multiplying such matrices.

$$\overset{(3)}{=} \sum_k (-e_k - e_k)\,\mathrm{d}x^{k4} + \sum_{j<k} (-e_j e_k + e_k e_j)\,\mathrm{d}x^{jk}$$
$$\overset{(4)}{=} -2\sum_l e_l \left(\mathrm{d}x^{l4} + \tfrac{1}{2}\varepsilon_{ljk}\mathrm{d}x^{jk}\right)$$
$$\overset{(5)}{=} -2\, e_a\, \omega_a^+.$$

(1) Definitions of $\mathrm{d}\bar{x}$ and $\mathrm{d}x$.
(2) Pair the terms (μ,ν) and (ν,μ); $\mathrm{d}x^{\nu\mu} = -\mathrm{d}x^{\mu\nu}$.
(3) For $(\mu,\nu) = (k,4)$: $\bar{e}_k e_4 - \bar{e}_4 e_k = -e_k - e_k$. For spatial (j,k): $\bar{e}_j = -e_j$, $\bar{e}_k = -e_k$.
(4) $-e_j e_k + e_k e_j = -[e_j, e_k] = -2\varepsilon_{jkl}e_l$ by (8.193); then collect the coefficient of each e_l (the sum over $j<k$ equals half the sum over all j,k).
(5) The bracket is ω_l^+ of (8.181): for $l=1$ it is $\mathrm{d}x^{14} + \mathrm{d}x^{23}$.

Since each ω_a^+ is self-dual, so is $\mathrm{d}\bar{x}\wedge\mathrm{d}x$. The same steps with the order reversed give

$$\mathrm{d}\bar{x}\wedge\mathrm{d}x = -2\,e_a\,\omega_a^+ \ \text{(SD)}, \qquad \mathrm{d}x\wedge\mathrm{d}\bar{x} = -2\,e_a\,\omega_a^- \ \text{(ASD)}. \tag{8.195}$$

For the second, the $(k,4)$ coefficient is $e_k\bar{e}_4 - e_4\bar{e}_k = +2e_k$ and the spatial one is again $-2\varepsilon_{jkl}e_l$, and $2e_l\mathrm{d}x^{l4} - 2e_l\frac{1}{2}\varepsilon_{ljk}\mathrm{d}x^{jk} = -2e_l\omega_l^-$.

Reading off components gives a formula for the 't Hooft symbols that we use repeatedly:

$$\mathrm{Im}(\bar{e}_\nu e_\mu) = \eta^a_{\mu\nu}\,e_a, \qquad \mathrm{Im}(e_\mu\bar{e}_\nu) = -\bar{\eta}^a_{\mu\nu}\,e_a. \tag{8.196}$$

Check two entries of the first: $\mathrm{Im}(\bar{e}_4 e_1) = e_1$ and $\eta^1_{14} = 1$; $\mathrm{Im}(\bar{e}_2 e_1) = \mathrm{Im}(-e_2 e_1) = e_3$ and $\eta^3_{12} = \varepsilon_{312} = 1$. Of the second: $\mathrm{Im}(e_1\bar{e}_4) = e_1$ and $-\bar{\eta}^1_{14} = 1$; $\mathrm{Im}(e_1\bar{e}_2) = -e_1e_2 = -e_3$ and $-\bar{\eta}^3_{12} = -1$. The product identities (8.183) are now just associativity of quaternion multiplication, which is why they looked like "η's multiply like quaternions".

Physical picture: why SD 2-forms rotate under only half of SO(4)

Every rotation of $\mathbb{R}^4$ has the form $x \mapsto pxq^{-1}$ with unit quaternions p, q (this is $\mathrm{SO}(4) = (\mathrm{SU}(2)\times\mathrm{SU}(2))/\mathbb{Z}_2$; the pair $(-p,-q)$ gives the same rotation). Then $\mathrm{d}x \mapsto p\,\mathrm{d}x\,q^{-1}$ and $\mathrm{d}\bar{x} \mapsto q\,\mathrm{d}\bar{x}\,p^{-1}$, so

$$\mathrm{d}\bar{x}\wedge\mathrm{d}x \ \mapsto\ q\,(\mathrm{d}\bar{x}\wedge\mathrm{d}x)\,q^{-1}, \qquad \mathrm{d}x\wedge\mathrm{d}\bar{x} \ \mapsto\ p\,(\mathrm{d}x\wedge\mathrm{d}\bar{x})\,p^{-1}.$$

The SD forms feel only q and the ASD forms feel only p: this is the splitting $\mathrm{SU}(2)_+ \times \mathrm{SU}(2)_-$ drawn in Figure 8.31, made explicit.

8.5.2 Pure gauge at infinity and the winding number

We want a connection on $\mathbb{R}^4$ with $k = 1$ and finite action. Finite action constrains its behaviour at large $|x| = r$.

Finite action forces $F \to 0$. In polar coordinates $\mathrm{d}^4x = r^3\,\mathrm{d}r\,\mathrm{d}\Omega_3$, so $\int |F|^2 \mathrm{d}^4x < \infty$ needs $|F|^2$ to decay faster than r^{-4}, that is $|F| = o(r^{-2})$. So at large r the connection is approximately flat. A flat connection is locally pure gauge, $A = g^{-1}\mathrm{d}g$. Therefore

$$A \longrightarrow g^{-1}\mathrm{d}g \quad \text{as } r \to \infty, \qquad g : S^3_\infty \to \mathrm{SU}(2), \tag{8.197}$$

where S^3_∞ is a large sphere $|x| = R$. It is a map from S^3 to $\mathrm{SU}(2) = S^3$, and such maps have a **degree** (winding number): how many times the image wraps around S^3, counted with orientation.

Key idea: The instanton number is a winding number at infinity

For a finite-action $\mathrm{SU}(2)$ connection on $\mathbb{R}^4$ with $A \to g^{-1}\mathrm{d}g$,

$$k = \frac{1}{24\pi^2}\int_{S^3_\infty} \mathrm{tr}\big((g^{-1}\mathrm{d}g)^3\big) = \deg g. \tag{8.198}$$

Here is where it comes from. Part 8a showed that $\mathrm{tr}(F \wedge F) = \mathrm{d}\,\mathrm{CS}(A)$ with $\mathrm{CS}(A) = \mathrm{tr}(A \wedge \mathrm{d}A + \frac{2}{3}A \wedge A \wedge A)$. Then

$$\begin{aligned} k &\overset{(1)}{=} -\frac{1}{8\pi^2}\int_{\mathbb{R}^4} \mathrm{tr}(F \wedge F) \\ &\overset{(2)}{=} -\frac{1}{8\pi^2}\lim_{R\to\infty}\int_{S^3_R} \mathrm{CS}(A) \\ &\overset{(3)}{=} -\frac{1}{8\pi^2}\int_{S^3_\infty} \mathrm{tr}\big(-A^3 + \tfrac{2}{3}A^3\big) \\ &\overset{(4)}{=} \frac{1}{24\pi^2}\int_{S^3_\infty} \mathrm{tr}\big((g^{-1}\mathrm{d}g)^3\big). \end{aligned}$$

(1) Definition (8.187).
(2) $\mathrm{tr}\,F \wedge F = \mathrm{d}\,\mathrm{CS}$ and Stokes on the ball $|x| \le R$ (Chapter T2); the sphere carries the outward orientation.
(3) At infinity $F = \mathrm{d}A + A^2 \to 0$, so $\mathrm{d}A \to -A^2$. We write $A^3 = A \wedge A \wedge A$.
(4) $-1 + \frac{2}{3} = -\frac{1}{3}$, and $-\frac{1}{8\pi^2}\cdot(-\frac{1}{3}) = \frac{1}{24\pi^2}$; insert $A = g^{-1}\mathrm{d}g$.

The normalisation $\frac{1}{24\pi^2}$ is such that the result is an integer, the degree of g. We check it on the most important map.

Worked example 8.53: The identity map $g(x) = x/|x|$ has winding number one

Take $g = x/r$, which sends the sphere $|x| = r$ to $\mathrm{SU}(2)$ by radial projection: it is the identity map $S^3 \to S^3$, so its degree should be 1. First a formula for $g^{-1}\mathrm{d}g$ that we will need again:

$$g^{-1}\mathrm{d}g \overset{(1)}{=} \frac{\bar{x}}{r}\Big(\frac{\mathrm{d}x}{r} - \frac{x\,\mathrm{d}r}{r^2}\Big)$$

$$\begin{aligned} &\overset{(2)}{=} \frac{\bar{x}\,\mathrm{d}x}{r^2} - \frac{\mathrm{d}r}{r}\,\mathbb{1} \\ &\overset{(3)}{=} \frac{\mathrm{Im}(\bar{x}\,\mathrm{d}x)}{r^2}. \end{aligned} \tag{8.199}$$

(1) $g^{-1} = \bar{g} = \bar{x}/r$ for a unit quaternion; product rule for $\mathrm{d}(x/r)$.
(2) $\bar{x}x = r^2\mathbb{1}$.
(3) $\mathrm{Re}(\bar{x}\,\mathrm{d}x) = \frac{1}{2}(\bar{x}\,\mathrm{d}x + \mathrm{d}\bar{x}\,x) = \frac{1}{2}\mathrm{d}(\bar{x}x) = \frac{1}{2}\mathrm{d}(r^2) = r\,\mathrm{d}r$, so subtracting $\mathrm{d}r/r$ removes exactly the real part.

Now evaluate the 3-form $\mathrm{tr}(g^{-1}\mathrm{d}g)^3$ at the point $x = (0,0,0,R)$, where $g = \mathbb{1}$ and the sphere is tangent to the $x^1x^2x^3$ directions:

$$\begin{aligned} \mathrm{tr}\big((g^{-1}\mathrm{d}g)^3\big)\big|_{x=(0,0,0,R)} &\overset{(1)}{=} R^{-3}\,\mathrm{tr}(e_ie_je_k)\,\mathrm{d}x^i\wedge\mathrm{d}x^j\wedge\mathrm{d}x^k \\ &\overset{(2)}{=} R^{-3}\,6\;\mathrm{tr}(e_1e_2e_3)\,\mathrm{d}x^{123} \\ &\overset{(3)}{=} -12\,R^{-3}\,\mathrm{d}x^{123} \\ &\overset{(4)}{=} +12\,\mathrm{vol}_{S^3_R}. \end{aligned}$$

(1) At this point $g^{-1} = \mathbb{1}$ and, along the sphere, $\mathrm{d}g = \mathrm{d}x/R = e_k\mathrm{d}x^k/R$ ($\mathrm{d}x^4$ vanishes on the tangent space).
(2) The six orderings of $(1,2,3)$ each give sign $\times\, e_{\pi(1)}e_{\pi(2)}e_{\pi(3)} = e_1e_2e_3$, because distinct e's anticommute.
(3) $e_1e_2e_3 = e_3e_3 = -\mathbb{1}$, and $\mathrm{tr}\,\mathbb{1} = 2$.
(4) The outward normal at this point is ∂_4, and the boundary orientation is $\iota_{\partial_4}(\mathrm{d}x^{1234}) = -\mathrm{d}x^{123}$. The tangent space is spanned by the orthonormal $\partial_1,\partial_2,\partial_3$, so the positively oriented Riemannian volume form of S^3_R at this point is $\mathrm{vol}_{S^3_R} = -\mathrm{d}x^{123}$.

The form $\mathrm{tr}(g^{-1}\mathrm{d}g)^3$ is invariant under $g \mapsto hg$ for constant $h \in \mathrm{SU}(2)$ (the h's cancel in $g^{-1}\mathrm{d}g$), and left multiplication moves any point of S^3 to any other. So the value $12R^{-3}\mathrm{vol}$ holds everywhere, and

$$\frac{1}{24\pi^2}\int_{S^3_R} 12R^{-3}\,\mathrm{vol}_{S^3_R} = \frac{12\cdot 2\pi^2R^3}{24\pi^2R^3} = 1,$$

using $\mathrm{Vol}(S^3_R) = 2\pi^2R^3$. The identity map has degree one, as it must.

Try it: The winding of g^n

Show that $g(x) = (x/r)^{-1} = \bar{x}/r$ has winding number -1. *Answer:* $g^{-1}\mathrm{d}g = x\,\mathrm{d}\bar{x}/r^2 - \mathrm{d}r/r$, and at $(0,0,0,R)$ it equals $-e_k\mathrm{d}x^k/R$; the cube changes sign. More generally $(x/r)^n$ has winding n: the winding number is additive under pointwise multiplication of maps.

8.5.3 The BPST solution

Now we can guess the instanton. We want A to be smooth at the origin and to approach $g^{-1}\mathrm{d}g$ with $g = x/r$ at infinity. The simplest interpolation multiplies the pure gauge by a function that rises from 0 to 1:

$$A = f(r)\,g^{-1}\mathrm{d}g, \qquad f(0) = 0,\ f(\infty) = 1.$$

Imposing self-duality gives an ordinary differential equation for f, whose solution is $f = r^2/(r^2+\lambda^2)$ for an arbitrary constant $\lambda > 0$. Rather than solve the ODE, we take the answer and *check* it; the check is the useful calculation.

Working definition 8.25 (the BPST instanton)

With $\phi(x) = |x|^2 + \lambda^2$,

$$A = \frac{|x|^2}{|x|^2+\lambda^2}\, g^{-1}\mathrm{d}g = \frac{\operatorname{Im}(\bar{x}\,\mathrm{d}x)}{|x|^2+\lambda^2} = \frac{\eta^a_{\mu\nu}x^\nu}{\phi}\, e_a\,\mathrm{d}x^\mu. \tag{8.200}$$

The second form follows from (8.199) [$g^{-1}\mathrm{d}g = \operatorname{Im}(\bar{x}\,\mathrm{d}x)/|x|^2$ for $g = x/|x|$, the pure gauge that A approaches at infinity]; the third from $\operatorname{Im}(\bar{x}e_\mu) = x^\nu \operatorname{Im}(\bar{e}_\nu e_\mu) = \eta^a_{\mu\nu}x^\nu e_a$ by (8.196) [$\eta^a_{\mu\nu}$ are the 't Hooft symbols, the components of the self-dual basis 2-forms ω^+_a]. The constant λ is the **size** of the instanton, and the origin is its **centre**. Translating, $x \mapsto x - y$, gives an instanton centred at $y \in \mathbb{R}^4$.

In the physicists' language of the dictionary in Section 8.3.1, $A = \frac{g}{2}A^a_\mu e_a \mathrm{d}x^\mu$, so

$$gA^a_\mu = \frac{2\,\eta^a_{\mu\nu}x^\nu}{x^2+\lambda^2},$$

which is the formula printed in every textbook on instantons. As an explicit matrix, the first component is

$$A_1 = \frac{x^\nu \eta^a_{1\nu} e_a}{\phi} = \frac{x^4 e_1 + x^2 e_3 - x^3 e_2}{\phi} = \frac{1}{\phi}\begin{pmatrix} -ix^2 & x^3 - ix^4 \\ -x^3 - ix^4 & ix^2 \end{pmatrix},$$

using $\eta^1_{14} = 1$, $\eta^3_{12} = 1$, $\eta^2_{13} = \varepsilon_{213} = -1$. It is anti-Hermitian and traceless, as a $\mathfrak{su}(2)$ connection must be.

The curvature, line by line

We compute $F = \mathrm{d}A + A \wedge A$ with $A = \phi^{-1}\operatorname{Im}(\bar{x}\,\mathrm{d}x)$. Three small facts first. Since $\phi = \bar{x}x + \lambda^2$,

$$\mathrm{d}\phi = \bar{x}\,\mathrm{d}x + \mathrm{d}\bar{x}\,x, \qquad \operatorname{Im}(\bar{x}\,\mathrm{d}x) = \bar{x}\,\mathrm{d}x - \tfrac{1}{2}\mathrm{d}\phi, \qquad \mathrm{d}\operatorname{Im}(\bar{x}\,\mathrm{d}x) = \mathrm{d}\bar{x}\wedge\mathrm{d}x. \tag{8.201}$$

The first is the product rule. The second says $\operatorname{Re}(\bar{x}\,\mathrm{d}x) = \frac{1}{2}(\bar{x}\,\mathrm{d}x + \mathrm{d}\bar{x}\,x) = \frac{1}{2}\mathrm{d}\phi$. The third: $\mathrm{d}(\bar{x}\,\mathrm{d}x) = \mathrm{d}\bar{x}\wedge\mathrm{d}x$ and $\mathrm{d}(\mathrm{d}\bar{x}\,x) = -\mathrm{d}\bar{x}\wedge\mathrm{d}x$ (moving d past the 1-form $\mathrm{d}\bar{x}$ costs a sign), so $\mathrm{d}\,\frac{1}{2}(\bar{x}\,\mathrm{d}x - \mathrm{d}\bar{x}\,x) = \mathrm{d}\bar{x}\wedge\mathrm{d}x$. Note that $\mathrm{d}\phi$ is an ordinary (scalar) 1-form, so it commutes with every matrix and anticommutes with every matrix-valued 1-form.

Step 1: the quadratic term.

$$\begin{aligned}\phi^2 A\wedge A &\overset{(1)}{=} \left(\bar{x}\,\mathrm{d}x - \tfrac{1}{2}\mathrm{d}\phi\right)\wedge\left(\bar{x}\,\mathrm{d}x - \tfrac{1}{2}\mathrm{d}\phi\right)\\ &\overset{(2)}{=} \bar{x}\,\mathrm{d}x\wedge\bar{x}\,\mathrm{d}x - \tfrac{1}{2}\,\bar{x}\,\mathrm{d}x\wedge\mathrm{d}\phi - \tfrac{1}{2}\,\mathrm{d}\phi\wedge\bar{x}\,\mathrm{d}x + \tfrac{1}{4}\,\mathrm{d}\phi\wedge\mathrm{d}\phi\\ &\overset{(3)}{=} \bar{x}\,\mathrm{d}x\wedge\bar{x}\,\mathrm{d}x.\end{aligned}$$

(1) Second fact of (8.201).
(2) Expand.
(3) $\mathrm{d}\phi\wedge\bar{x}\,\mathrm{d}x = -\bar{x}\,\mathrm{d}x\wedge\mathrm{d}\phi$ (scalar 1-form past a matrix 1-form), so the middle terms cancel; and $\mathrm{d}\phi\wedge\mathrm{d}\phi = 0$.

Step 2: the derivative term.

$$\begin{aligned} \mathrm{d}A &\overset{(1)}{=} \mathrm{d}(\phi^{-1}) \wedge \mathrm{Im}(\bar{x}\,\mathrm{d}x) + \phi^{-1}\,\mathrm{d}\ \mathrm{Im}(\bar{x}\,\mathrm{d}x) \\ &\overset{(2)}{=} -\phi^{-2}\,\mathrm{d}\phi \wedge \left(\bar{x}\,\mathrm{d}x - \tfrac{1}{2}\mathrm{d}\phi\right) + \phi^{-1}\,\mathrm{d}\bar{x} \wedge \mathrm{d}x \\ &\overset{(3)}{=} -\phi^{-2}\,(\bar{x}\,\mathrm{d}x + \mathrm{d}\bar{x}\,x) \wedge \bar{x}\,\mathrm{d}x + \phi^{-1}\,\mathrm{d}\bar{x} \wedge \mathrm{d}x \\ &\overset{(4)}{=} -\phi^{-2}\big(\bar{x}\,\mathrm{d}x \wedge \bar{x}\,\mathrm{d}x + |x|^2\,\mathrm{d}\bar{x} \wedge \mathrm{d}x\big) + \phi^{-1}\,\mathrm{d}\bar{x} \wedge \mathrm{d}x. \end{aligned}$$

(1) Leibniz rule for a function times a 1-form.
(2) $\mathrm{d}(\phi^{-1}) = -\phi^{-2}\mathrm{d}\phi$, and the second and third facts of (8.201).
(3) $\mathrm{d}\phi \wedge \mathrm{d}\phi = 0$, then the first fact.
(4) $\mathrm{d}\bar{x}\,x \wedge \bar{x}\,\mathrm{d}x = \mathrm{d}\bar{x}\,(x\bar{x}) \wedge \mathrm{d}x$ and $x\bar{x} = |x|^2\mathbb{1}$ is a scalar function.

Step 3: add.

$$\begin{aligned} F = \mathrm{d}A + A \wedge A &\overset{(1)}{=} \frac{-\bar{x}\,\mathrm{d}x \wedge \bar{x}\,\mathrm{d}x - |x|^2\,\mathrm{d}\bar{x} \wedge \mathrm{d}x + \phi\,\mathrm{d}\bar{x} \wedge \mathrm{d}x + \bar{x}\,\mathrm{d}x \wedge \bar{x}\,\mathrm{d}x}{\phi^2} \\ &\overset{(2)}{=} \frac{(\phi - |x|^2)\,\mathrm{d}\bar{x} \wedge \mathrm{d}x}{\phi^2} \\ &\overset{(3)}{=} \frac{\lambda^2\,\mathrm{d}\bar{x} \wedge \mathrm{d}x}{(|x|^2+\lambda^2)^2}. \end{aligned} \tag{8.202}$$

(1) Steps 1 and 2, over the common denominator ϕ^2.
(2) The quartic terms $\bar{x}\,\mathrm{d}x \wedge \bar{x}\,\mathrm{d}x$ cancel.
(3) $\phi - |x|^2 = \lambda^2$.

Everything non-linear has cancelled, and what is left is a scalar function times the fixed 2-form $\mathrm{d}\bar{x} \wedge \mathrm{d}x$. By (8.195) that 2-form is self-dual. Hence

Key idea: BPST is self-dual

$$F = \frac{\lambda^2\,\mathrm{d}\bar{x} \wedge \mathrm{d}x}{(|x|^2+\lambda^2)^2} = -\frac{2\lambda^2}{(|x|^2+\lambda^2)^2}\,e_a\,\omega_a^+, \qquad \star F = F.$$

In components $F_{\mu\nu} = -2\lambda^2\eta^a_{\mu\nu}e_a/\phi^2$; in physicists' normalisation $gF^a_{\mu\nu} = -4\lambda^2\eta^a_{\mu\nu}/(x^2+\lambda^2)^2$.

As matrices, for instance,

$$F_{12} = F_{34} = -\frac{2\lambda^2}{\phi^2}e_3 = \frac{2\lambda^2}{\phi^2}\begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}, \qquad F_{14} = F_{23} = -\frac{2\lambda^2}{\phi^2}e_1 = \frac{2\lambda^2}{\phi^2}\begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix},$$

and one sees the self-duality conditions (8.186) directly. The field strength is largest at the centre, where $|F_{\mu\nu}| \sim 2/\lambda^2$, and it decays like λ^2/r^4, safely faster than the r^{-2} required for finite action. By (8.198) and Example 8.53, $k = 1$, since $A \to g^{-1}\mathrm{d}g$ with $g = x/r$ (the prefactor $r^2/\phi \to 1$). We now confirm this, and find the action, by direct integration.

The action and the charge

Worked example 8.54: $S = 8\pi^2$ and $k = 1$ by direct integration

The action density, from (8.166):

$$\begin{aligned} -\tfrac{1}{2}\operatorname{tr}(F_{\mu\nu}F_{\mu\nu}) &\overset{(1)}{=} -\tfrac{1}{2}\cdot\frac{4\lambda^4}{\phi^4}\,\eta^a_{\mu\nu}\eta^b_{\mu\nu}\operatorname{tr}(e_a e_b) \\ &\overset{(2)}{=} -\tfrac{1}{2}\cdot\frac{4\lambda^4}{\phi^4}\cdot 4\delta^{ab}\cdot(-2\delta_{ab}) \\ &\overset{(3)}{=} \frac{48\lambda^4}{(|x|^2+\lambda^2)^4}. \end{aligned}$$

(1) Substitute $F_{\mu\nu} = -2\lambda^2\eta^a_{\mu\nu}e_a/\phi^2$.
(2) $\eta^a_{\mu\nu}\eta^b_{\mu\nu} = 4\delta^{ab}$ (8.183), $\operatorname{tr}(e_a e_b) = -2\delta_{ab}$ (Example 8.43).
(3) $\delta^{ab}\delta_{ab} = 3$, and $\frac{1}{2}\cdot 4\cdot 4\cdot 2\cdot 3 = 48$.

It depends only on $r = |x|$, so we integrate in polar coordinates:

$$\begin{aligned} S &\overset{(1)}{=} \int_0^\infty \frac{48\lambda^4}{(r^2+\lambda^2)^4}\,2\pi^2 r^3\,\mathrm{d}r \\ &\overset{(2)}{=} 48\pi^2\lambda^4\int_0^\infty \frac{u\,\mathrm{d}u}{(u+\lambda^2)^4} \\ &\overset{(3)}{=} 48\pi^2\lambda^4\cdot\frac{1}{6\lambda^4} \\ &= 8\pi^2. \end{aligned}$$

(1) $\mathrm{d}^4x = r^3\mathrm{d}r\,\mathrm{d}\Omega_3$ and $\int\mathrm{d}\Omega_3 = \operatorname{Vol}(S^3) = 2\pi^2$.
(2) Substitute $u = r^2$, $\mathrm{d}u = 2r\,\mathrm{d}r$, so $r^3\mathrm{d}r = \frac{1}{2}u\,\mathrm{d}u$.
(3) Write $u = (u+a) - a$ with $a = \lambda^2$: $\int_0^\infty\left[(u+a)^{-3} - a(u+a)^{-4}\right]\mathrm{d}u = \frac{1}{2a^2} - \frac{a}{3a^3} = \frac{1}{6a^2}$.

Since F is self-dual, $\operatorname{tr}(F\wedge F) = \operatorname{tr}(F\wedge\star F)$, so $-\int\operatorname{tr}(F\wedge F) = S = 8\pi^2$ and

$$k = -\frac{1}{8\pi^2}\int\operatorname{tr}(F\wedge F) = \frac{8\pi^2}{8\pi^2} = 1.$$

The Bogomolny bound $S \geq 8\pi^2|k|$ is saturated. Restoring the coupling (Example 8.43), $S_{\text{phys}} = 8\pi^2/g^2$: the tunnelling amplitude is $e^{-8\pi^2/g^2}$. Notice that λ has dropped out. This is the conformal (in particular scale) invariance of Section 8.4.1: a big instanton and a small one cost the same.

Worked example 8.55: How concentrated is an instanton?

Redo the radial integral only up to $r = R$. With $a = \lambda^2$ and $U = R^2$, the antiderivative of $u(u+a)^{-4}$ is $-\frac{1}{2}(u+a)^{-2} + \frac{a}{3}(u+a)^{-3}$, so

$$\begin{aligned} \frac{S(R)}{8\pi^2} &\overset{(1)}{=} 6a^2\left[-\frac{1}{2(u+a)^2} + \frac{a}{3(u+a)^3}\right]_0^U \\ &\overset{(2)}{=} 6a^2\left[\frac{1}{6a^2} - \frac{1}{2(U+a)^2} + \frac{a}{3(U+a)^3}\right] \end{aligned}$$

$$\overset{(3)}{=} 1 - \frac{3\lambda^4}{(R^2+\lambda^2)^2} + \frac{2\lambda^6}{(R^2+\lambda^2)^3}.$$

(1) The previous example, stopped at $u = U$, divided by $8\pi^2$: $48\pi^2 a^2/8\pi^2 = 6a^2$.
(2) At $u = 0$ the bracket is $-\frac{1}{2a^2} + \frac{1}{3a^2} = -\frac{1}{6a^2}$.
(3) Multiply out and substitute back.

At $R = \lambda$: $1 - \frac{3}{4} + \frac{2}{8} = \frac{1}{2}$. *Half the action lies inside the ball of radius* λ. At $R = 3\lambda$ the fraction is $1 - 0.03 + 0.002 \approx 0.97$. So λ really is the size of a lump of action (Figure 8.35).

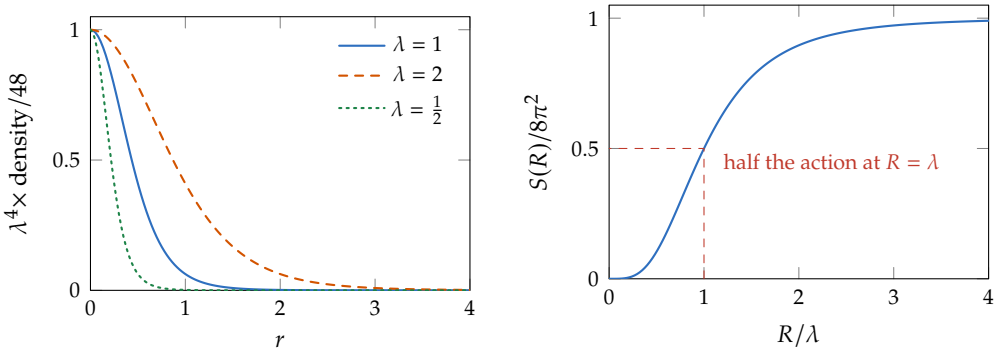

Figure 8.35: Left: the BPST action density $48\lambda^4/(r^2+\lambda^2)^4$, rescaled by $\lambda^4/48$ so that the peak height is 1 for every λ; what changes with λ is only the width. (Without the rescaling a small instanton is a tall narrow spike and a large one a low wide hill, always with the same area $8\pi^2$.) Right: the fraction of the action inside radius R, a universal function of R/λ; half of it sits inside $R = \lambda$.

The anti-instanton and the parameters

Swapping the roles of x and $\bar{x}$ gives the **anti-instanton**

$$\bar{A} = \frac{\operatorname{Im}(x\,\mathrm{d}\bar{x})}{|x|^2+\lambda^2}, \qquad \bar{F} = \frac{\lambda^2\,\mathrm{d}x\wedge\mathrm{d}\bar{x}}{(|x|^2+\lambda^2)^2} = -\frac{2\lambda^2}{\phi^2}\,e_a\,\omega_a^-.$$

The same three steps prove the formula for $\bar{F}$, and (8.195) shows it is ASD. Its pure gauge at infinity is $g = \bar{x}/r$, of winding -1 (the Try-it box above), so $k = -1$ and $S = 8\pi^2$.

How many parameters does the BPST family have? The formula (8.200) was written with centre 0 and a particular orientation in the gauge group. We can

- translate: $x \mapsto x - y$, $y \in \mathbb{R}^4$ (4 parameters);
- rescale: $\lambda > 0$ (1 parameter);
- rotate in colour space by a constant $h \in \mathrm{SU}(2)$: $A \mapsto h^{-1}Ah$ (3 parameters, but h and $-h$ act the same way on $\mathfrak{su}(2)$, so it is really SO(3)).

Rotating $\mathbb{R}^4$ gives nothing new: under $x \mapsto pxq^{-1}$ the BPST connection changes by a constant gauge rotation (by q, from the intuition box above), so spacetime rotations are already among the colour rotations. The constant colour rotations are gauge transformations, so they do not change the physical configuration; but they are the "framing" degrees of freedom that Nash keeps track of in Section 8.7. So:

$$\underbrace{4}_{\text{centre } y} + \underbrace{1}_{\text{size } \lambda} = 5 \text{ gauge-inequivalent parameters}, \qquad 5 + \underbrace{3}_{\text{colour}} = 8 \text{ framed parameters}.$$

The index theorem calculation of Section 8.9 will give $\dim \mathcal{M}_1 = 8k - 3 = 5$, and Section 8.10 shows that the BPST family is all of $\mathcal{M}_1$, so $\mathcal{M}_1 = \mathbb{R}^4 \times \mathbb{R}^+$.

Physical picture: the size modulus and the instanton gas

Because the action does not depend on λ, the classical theory has no preference for any instanton size. In the quantum theory, the one-loop fluctuation determinant around the instanton turns the tunnelling amplitude into an integral over the moduli, schematically $\int \mathrm{d}^4y\,\mathrm{d}\lambda\,\lambda^{-5}\,e^{-8\pi^2/g^2(1/\lambda)}$, where the coupling now runs with the scale $1/\lambda$ (the λ^{-5} is fixed by dimensional analysis: the measure $\mathrm{d}^4y\,\mathrm{d}\lambda$ has length dimension 5). In an asymptotically free theory $g(1/\lambda)$ grows with λ, the suppression $e^{-8\pi^2/g^2}$ weakens, and the integral diverges at large λ. This "infrared problem" of instanton physics is a direct consequence of the non-compact direction $\lambda\to\infty$ of $\mathcal{M}_1$; the other non-compact end $\lambda\to 0$ is the one Donaldson uses (Section 8.11).

8.5.4 The singular gauge

In the form (8.200) the instanton is smooth everywhere, but it falls off only like $1/r$ at infinity (it tends to the pure gauge $g^{-1}\mathrm{d}g$, which is of order $1/r$). This is the **regular gauge**. For superposing several instantons it is better to use a gauge in which A falls off fast at infinity; the price is a singularity at the centre. We apply the gauge transformation $h=g^{-1}=\bar{x}/r$, which is smooth except at $x=0$.

$$\begin{aligned} A_h = h^{-1}Ah + h^{-1}\mathrm{d}h &\overset{(1)}{=} gAg^{-1} + g\,\mathrm{d}(g^{-1}) \\ &\overset{(2)}{=} \frac{r^2}{\phi}\,g(g^{-1}\mathrm{d}g)g^{-1} - \mathrm{d}g\,g^{-1} \\ &\overset{(3)}{=} \Big(\frac{r^2}{\phi}-1\Big)\mathrm{d}g\,g^{-1} \\ &\overset{(4)}{=} -\frac{\lambda^2}{r^2+\lambda^2}\cdot\frac{\mathrm{Im}(\mathrm{d}x\,\bar{x})}{r^2}. \end{aligned} \tag{8.203}$$

(1) $h^{-1}=g$ and $h=g^{-1}$; substitute into (8.163).
(2) First form of (8.200); and $\mathrm{d}(gg^{-1})=0$ gives $g\,\mathrm{d}(g^{-1})=-\mathrm{d}g\,g^{-1}$.
(3) $g\,g^{-1}\mathrm{d}g\,g^{-1}=\mathrm{d}g\,g^{-1}$.
(4) $\frac{r^2}{\phi}-1=-\frac{\lambda^2}{\phi}$, and the same computation as (8.199) with the factors in the other order gives $\mathrm{d}g\,g^{-1}=\mathrm{Im}(\mathrm{d}x\,\bar{x})/r^2$.

In components, $\mathrm{Im}(e_\mu\bar{x})=x^\nu\,\mathrm{Im}(e_\mu\bar{e}_\nu)=-\bar{\eta}^a_{\mu\nu}x^\nu e_a$ by (8.196), so

$$A^{\mathrm{sing}}_\mu = \frac{\lambda^2\,\bar{\eta}^a_{\mu\nu}x^\nu}{r^2(r^2+\lambda^2)}\,e_a. \tag{8.204}$$

Three things to see:

- At large r, $A^{\mathrm{sing}}\sim\lambda^2/r^3$: it falls off fast, and the gauge transformation at infinity is now trivial.
- Near $r=0$, $A^{\mathrm{sing}}\approx -\mathrm{d}g\,g^{-1}=h^{-1}\mathrm{d}h$ with $h=\bar{x}/r$: pure gauge, but singular, with winding. The topology has been moved from the sphere at infinity to an infinitesimal sphere around the centre.
- The curvature is $F_h=h^{-1}Fh=\lambda^2\,x\,(\mathrm{d}\bar{x}\wedge\mathrm{d}x)\,\bar{x}/(r^2\phi^2)$. Conjugation acts on the matrix part only, so F_h is still self-dual, and $\mathrm{tr}\,F_h\wedge F_h=\mathrm{tr}\,F\wedge F$ is the same smooth density. The singularity is in A, not in anything gauge invariant: it is a **gauge singularity**.

Curiously, the self-dual instanton in singular gauge is written with the *anti*-self-dual symbols $\bar\eta$. There is no contradiction: the self-duality of F is a property of the 2-form, not of the symbols used for the 1-form A.

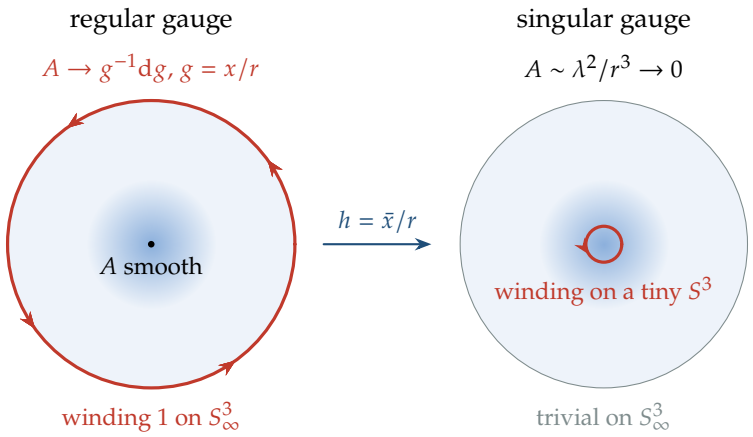

Figure 8.36: The same instanton in two gauges. The blue shading is the action density $48\lambda^4/(r^2+\lambda^2)^4$, identical in both, since it is gauge invariant. The red loop marks where the non-trivial winding of the gauge potential sits: on the sphere at infinity in the regular gauge, on an infinitesimal sphere around the centre in the singular gauge. The gauge transformation h that relates them is itself singular at the origin, which is why it can move the winding.

8.5.5 The 't Hooft ansatz: many instantons at once

Write $\sigma = \ln\rho$ for the function $\rho = 1 + \lambda^2/r^2$. Then $\partial_\nu\sigma = \partial_\nu\rho/\rho = -2\lambda^2 x_\nu/(r^2(r^2+\lambda^2))$, and (8.204) becomes

$$A_\mu = -\tfrac{1}{2}\,\bar\eta^a_{\mu\nu}\,\partial_\nu \ln\rho\; e_a. \tag{8.205}$$

't Hooft's idea was to take (8.205) as an **ansatz** for an arbitrary positive function ρ, and ask what ρ must satisfy for F to be self-dual. The answer is strikingly simple.

Key idea: The 't Hooft ansatz

For the connection (8.205),

$$F^- = \frac{\Box\rho}{4\rho}\; e_a\,\omega^-_a, \qquad \Box = \partial_\mu\partial_\mu. \tag{8.206}$$

So A is self-dual exactly where ρ is harmonic, $\Box\rho = 0$. The self-dual Yang–Mills equations, non-linear in A, have become the *linear* Laplace equation for ρ.

Worked example 8.56: Deriving (8.206)

Write $A_\mu = a^c_\mu e_c$ with $a^c_\mu = -\frac{1}{2}\bar\eta^c_{\mu\lambda}\sigma_\lambda$, where $\sigma_\lambda = \partial_\lambda\sigma$ and $\sigma_{\mu\lambda} = \partial_\mu\partial_\lambda\sigma$. By (8.193), $[A_\mu, A_\nu] = 2\varepsilon_{abc}a^a_\mu a^b_\nu e_c$, so the e_c-component of $F_{\mu\nu}$ is

$$\begin{aligned} F^c_{\mu\nu} &\overset{(1)}{=} \partial_\mu a^c_\nu - \partial_\nu a^c_\mu + 2\varepsilon_{abc}a^a_\mu a^b_\nu \\ &\overset{(2)}{=} -\tfrac{1}{2}\big(\bar\eta^c_{\nu\lambda}\sigma_{\mu\lambda} - \bar\eta^c_{\mu\lambda}\sigma_{\nu\lambda}\big) + \tfrac{1}{2}\varepsilon_{abc}\bar\eta^a_{\mu\lambda}\bar\eta^b_{\nu\kappa}\sigma_\lambda\sigma_\kappa. \end{aligned}$$

(1) $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + [A_\mu, A_\nu]$.
(2) Substitute a^c_μ; $2\cdot(-\tfrac{1}{2})^2 = \tfrac{1}{2}$.

The ASD part of F is the part along the ω_d^- $= \frac{1}{2}\bar\eta^d_{\mu\nu}\mathrm{d}x^{\mu\nu}$. Since $\bar\eta^d_{\mu\nu}\bar\eta^{d'}_{\mu\nu} = 4\delta^{dd'}$ and $\bar\eta^d_{\mu\nu}\eta^{d'}_{\mu\nu} = 0$, the coefficient is $f^{cd} = \frac{1}{4}\bar\eta^d_{\mu\nu}F^c_{\mu\nu}$, i.e. $F^- = f^{cd}e_c\,\omega_d^-$. We need two identities, checked by multiplying out (they hold for η and $\bar\eta$ alike):

$$\text{(I)}\quad \bar\eta^a_{\mu\nu}\bar\eta^b_{\mu\rho} = \delta^{ab}\delta_{\nu\rho} + \varepsilon^{abc}\bar\eta^c_{\nu\rho},$$
$$\text{(II)}\quad \varepsilon_{abc}\bar\eta^a_{\mu\lambda}\bar\eta^b_{\nu\kappa} = \delta_{\mu\nu}\bar\eta^c_{\lambda\kappa} - \delta_{\mu\kappa}\bar\eta^c_{\lambda\nu} - \delta_{\lambda\nu}\bar\eta^c_{\mu\kappa} + \delta_{\lambda\kappa}\bar\eta^c_{\mu\nu}.$$

Derivative terms.

$$-\tfrac{1}{8}\bar\eta^d_{\mu\nu}\big(\bar\eta^c_{\nu\lambda}\sigma_{\mu\lambda} - \bar\eta^c_{\mu\lambda}\sigma_{\nu\lambda}\big) \overset{(1)}{=} -\tfrac{1}{8}\big(-(\delta^{dc}\delta_{\mu\lambda} + \varepsilon^{dce}\bar\eta^e_{\mu\lambda})\sigma_{\mu\lambda} - (\delta^{dc}\delta_{\nu\lambda} + \varepsilon^{dce}\bar\eta^e_{\nu\lambda})\sigma_{\nu\lambda}\big)$$
$$\overset{(2)}{=} \tfrac{1}{4}\,\delta^{cd}\,\Box\sigma.$$

(1) In the first term write $\bar\eta^d_{\mu\nu}\bar\eta^c_{\nu\lambda} = -\bar\eta^d_{\nu\mu}\bar\eta^c_{\nu\lambda}$ and use (I) with summed index ν; the second term is (I) directly with summed index μ.

(2) $\sigma_{\mu\lambda}$ is symmetric and $\bar\eta^e$ antisymmetric, so the ε terms drop; $\delta_{\mu\lambda}\sigma_{\mu\lambda} = \Box\sigma$.

Quadratic terms. First contract (II) with $\sigma_\lambda\sigma_\kappa$:

$$\tfrac{1}{2}\varepsilon_{abc}\bar\eta^a_{\mu\lambda}\bar\eta^b_{\nu\kappa}\sigma_\lambda\sigma_\kappa \overset{(1)}{=} \tfrac{1}{2}\big(0 - \bar\eta^c_{\lambda\nu}\sigma_\lambda\sigma_\mu - \bar\eta^c_{\mu\kappa}\sigma_\nu\sigma_\kappa + \bar\eta^c_{\mu\nu}\,\sigma_\lambda\sigma_\lambda\big),$$

(1) The four terms of (II): $\bar\eta^c_{\lambda\kappa}\sigma_\lambda\sigma_\kappa = 0$ by antisymmetry; the Kronecker deltas set $\kappa = \mu$, $\lambda = \nu$, $\lambda = \kappa$ respectively.

then project with $\frac{1}{4}\bar\eta^d_{\mu\nu}$:

$$\tfrac{1}{8}\bar\eta^d_{\mu\nu}\big(-\bar\eta^c_{\lambda\nu}\sigma_\lambda\sigma_\mu - \bar\eta^c_{\mu\kappa}\sigma_\nu\sigma_\kappa + \bar\eta^c_{\mu\nu}\sigma^2\big) \overset{(1)}{=} \tfrac{1}{8}\big(-\delta^{dc}\sigma^2 - \delta^{dc}\sigma^2 + 4\delta^{dc}\sigma^2\big)$$
$$= \tfrac{1}{4}\,\delta^{cd}\,\sigma_\lambda\sigma_\lambda,$$

(1) Here $\sigma^2 = \sigma_\lambda\sigma_\lambda$. The first term: $\bar\eta^d_{\mu\nu}\bar\eta^c_{\lambda\nu} = \bar\eta^d_{\nu\mu}\bar\eta^c_{\nu\lambda} = \delta^{dc}\delta_{\mu\lambda} + \varepsilon\bar\eta_{\mu\lambda}$ by (I), and the antisymmetric part dies against $\sigma_\lambda\sigma_\mu$. The second term likewise by (I) with summed μ. The third is $\bar\eta^d\cdot\bar\eta^c = 4\delta^{dc}$.

Total.

$$f^{cd} \overset{(1)}{=} \tfrac{1}{4}\delta^{cd}\big(\Box\sigma + \partial_\lambda\sigma\,\partial_\lambda\sigma\big)$$
$$\overset{(2)}{=} \tfrac{1}{4}\delta^{cd}\Big(\frac{\Box\rho}{\rho} - \frac{(\partial\rho)^2}{\rho^2} + \frac{(\partial\rho)^2}{\rho^2}\Big) = \frac{\Box\rho}{4\rho}\,\delta^{cd}.$$

(1) Sum of the two pieces.

(2) $\sigma = \ln\rho$: $\partial\sigma = \partial\rho/\rho$ and $\Box\sigma = \Box\rho/\rho - (\partial\rho)^2/\rho^2$.

So $F^- = \frac{\Box\rho}{4\rho}\sum_c e_c\omega_c^-$, which is (8.206). The magic is the cancellation in the last line: the non-linear term $(\partial\sigma)^2$ from $[A,A]$ is exactly what turns $\Box\ln\rho$ into $\Box\rho/\rho$.

Harmonic functions with poles

Positive harmonic functions on all of $\mathbb{R}^4$ are constant, and a constant ρ gives $A = 0$. So we allow isolated poles. In four dimensions the basic harmonic function with a pole is $1/|x|^2$ (the analogue of $1/r$ in three dimensions):

$$\Box\frac{1}{r^2} \overset{(1)}{=} \frac{1}{r^3}\frac{\mathrm{d}}{\mathrm{d}r}\Big(r^3\frac{\mathrm{d}}{\mathrm{d}r}r^{-2}\Big)$$

$$\overset{(2)}{=} \frac{1}{r^3}\frac{\mathrm{d}}{\mathrm{d}r}(-2) = 0 \qquad (r \neq 0).$$

(1) The Laplacian of a radial function in four dimensions, $\Box f = r^{-3}(r^3 f')'$ (the r^3 is the area factor of S^3_r).
(2) $r^3 \cdot (-2r^{-3}) = -2$, a constant.

(In the sense of distributions, $\Box(1/r^2) = -4\pi^2\delta^4(x)$, the 4D Coulomb law.) Hence

$$\rho(x) = 1 + \sum_{i=1}^{k} \frac{\lambda_i^2}{|x - y_i|^2} \tag{8.207}$$

is harmonic away from the k points y_i, and (8.205) is self-dual there. Near each y_i, $\rho \approx \lambda_i^2/|x-y_i|^2$ and A looks like a singular-gauge BPST instanton centred at y_i: a gauge singularity, removable by a local gauge transformation. So (8.207) describes k instantons of sizes λ_i at positions y_i, which may be anywhere, even overlapping. For $k = 1$ it is exactly the BPST instanton in singular gauge.

	positions y_i	sizes λ_i	relative colour orientations
count	$4k$	k	$3(k-1)$
in the 't Hooft ansatz?	yes	yes	no (all aligned)

Figure 8.37: A 't Hooft multi-instanton: k lumps of action, each with a centre y_i (red: the gauge singularity) and a size λ_i. The ansatz has $5k$ parameters. The full moduli space has dimension $8k - 3 = 5k + 3(k-1)$: the missing $3(k-1)$ are the orientations of the instantons in colour space relative to the first one, which the 't Hooft ansatz freezes. They are supplied by the ADHM construction of Section 8.10.

The action from ρ alone

For the 't Hooft ansatz there is a neat formula (one more page of index gymnastics of the same kind as Example 8.56, which we omit; it can be checked by computer algebra at any point):

$$-\tfrac{1}{2}\operatorname{tr}(F_{\mu\nu}F_{\mu\nu}) = -\tfrac{1}{2}\,\Box\Box \ln\rho \qquad \text{(away from the } y_i\text{)}. \tag{8.208}$$

Worked example 8.57: Checking (8.208) on the BPST instanton

Take $\rho = 1 + \lambda^2/r^2$, so $\ln\rho = \ln(r^2+\lambda^2) - \ln r^2$. The second term is harmonic after one Laplacian: $\Box \ln r^2 = 2\Box \ln r = 4/r^2$ (for $f = \ln r$, $r^{-3}(r^3 \cdot r^{-1})' = 2/r^2$), and $\Box(4/r^2) = 0$. So only the first term matters. With $u = r^2 + \lambda^2$ and the radial formula $\Box f = f'' + \frac{3}{r}f'$:

$$\Box \ln u \overset{(1)}{=} \left(\frac{2}{u} - \frac{4r^2}{u^2}\right) + \frac{3}{r}\cdot\frac{2r}{u}$$
$$\overset{(2)}{=} \frac{8}{u} - \frac{4(u-\lambda^2)}{u^2} = \frac{4}{u} + \frac{4\lambda^2}{u^2},$$

(1) $f = \ln u$ has $f' = 2r/u$ and $f'' = 2/u - 4r^2/u^2$.
(2) $r^2 = u - \lambda^2$.

and applying $\Box$ once more to $h = 4u^{-1} + 4\lambda^2 u^{-2}$:

$$\begin{aligned}\Box h &\overset{(1)}{=} \Big(-\frac{8}{u^2} + \frac{32r^2}{u^3} - \frac{16\lambda^2}{u^3} + \frac{96\lambda^2 r^2}{u^4}\Big) + \frac{3}{r}\Big(-\frac{8r}{u^2} - \frac{16\lambda^2 r}{u^3}\Big)\\ &\overset{(2)}{=} -\frac{32}{u^2} + \frac{32r^2}{u^3} - \frac{64\lambda^2}{u^3} + \frac{96\lambda^2 r^2}{u^4}\\ &\overset{(3)}{=} -\frac{96\lambda^4}{u^4}.\end{aligned}$$

(1) $h' = -8r/u^2 - 16\lambda^2 r/u^3$; differentiate again with $u' = 2r$.
(2) Collect: $-8 - 24 = -32$ and $-16 - 48 = -64$.
(3) Substitute $r^2 = u - \lambda^2$: the u^{-2} terms give $-32 + 32 = 0$, the $\lambda^2 u^{-3}$ terms $-32 - 64 + 96 = 0$, leaving $-96\lambda^4/u^4$.

So $-\frac{1}{2}\Box\Box \ln \rho = 48\lambda^4/(r^2 + \lambda^2)^4$, exactly the density of Example 8.54.

Worked example 8.58: Each pole carries one unit of action

Integrate (8.208) over $\mathbb{R}^4$ minus small balls $B_\varepsilon(y_i)$. Let $u = \Box \ln \rho$.

$$\begin{aligned}S &\overset{(1)}{=} -\tfrac{1}{2}\int_{\mathbb{R}^4 \setminus \cup B_\varepsilon(y_i)} \Box u \, \mathrm{d}^4x\\ &\overset{(2)}{=} -\tfrac{1}{2}\Big(\oint_{S^3_\infty} \partial_r u \, \mathrm{d}S - \sum_i \oint_{S^3_\varepsilon(y_i)} \partial_{r_i} u \, \mathrm{d}S\Big)\\ &\overset{(3)}{=} -\tfrac{1}{2}\Big(0 - \sum_{i=1}^{k} \frac{8}{\varepsilon^3} \cdot 2\pi^2\varepsilon^3\Big)\\ &= 8\pi^2 k.\end{aligned}$$

(1) (8.208). The true density is smooth at y_i (the pole is a gauge artefact), so removing tiny balls changes S by an amount that vanishes as $\varepsilon \to 0$.
(2) Gauss's theorem (Chapter T2). The boundary of the region is the sphere at infinity (outward normal ∂_r) and the small spheres, whose outward normal from the region points *into* the balls, i.e. along $-\partial_{r_i}$ with $r_i = |x - y_i|$.
(3) At infinity $\ln \rho = \sum \lambda_i^2/|x - y_i|^2 + O(r^{-4})$; the first part is harmonic, so $u = O(r^{-6})$ and the flux $r^3 \partial_r u = O(r^{-4}) \to 0$. Near y_i, $\ln \rho = -2 \ln r_i + (\text{smooth})$, so $u = -4/r_i^2 + (\text{bounded})$ and $\partial_{r_i} u = 8/r_i^3 + (\text{bounded})$; the sphere has area $2\pi^2\varepsilon^3$.

Since F is self-dual, k in the Bogomolny sense is also k: $8\pi^2 k = \|F^+\|^2 = S$. Each pole of ρ is one instanton.

Watch out: The 't Hooft ansatz is not the general solution

The ansatz gives $5k$ parameters, but the moduli space has dimension $8k - 3$ (Section 8.9). For $k = 1$ these agree ($5 = 5$). For $k = 2$ the ansatz gives 10 against 13. Jackiw, Nohl and Rebbi noticed that one may drop the "1" and use $\rho = \sum_{i=0}^{k} \lambda_i^2/|x - y_i|^2$, with $k + 1$ poles, which still has instanton number k (the extra pole is a pure gauge artefact); for $k = 2$ this reaches all 13 dimensions, but for $k \geq 3$ it falls short. The complete answer for every k is

the ADHM construction, outlined in Section 8.10. The missing parameters are the relative colour orientations of the lumps (Figure 8.37), which the 't Hooft ansatz fixes to be "all aligned", since every lump uses the same basis e_a.

Try it: Anti-instantons by the same trick

Show that $A_\mu = -\frac{1}{2}\eta^a_{\mu\nu}\partial_\nu \ln\rho\, e_a$ (with η instead of $\bar\eta$) has $F^+ = \frac{\Box\rho}{4\rho} e_a \omega^+_a$, so it is ASD when $\Box\rho = 0$. *Answer:* every step of Example 8.56 goes through with $\eta \leftrightarrow \bar\eta$ and $\omega^- \leftrightarrow \omega^+$, because identities (I) and (II) hold for both kinds of symbol.

Reading Nash (pp. 228–241)

Nash never writes an instanton down in his §3. After the Bogomolny bound (8.78)–(8.79) he says that the minima "are to be deemed self-dual" and moves straight to the moduli space. The explicit solution enters only implicitly, on [Nash p. 241], when he says that for SU(2) on S^4 and $k = 1$ "$\mathcal{M}_1$ is five-dimensional" and has the shape of hyperbolic 5-space. This section supplies what lies behind that sentence: the BPST connection (8.200), its self-dual curvature (8.202), its action $8\pi^2$, and its five parameters (centre and size). Our orientation $\mathrm{d}x^{1234}$ and $k = -c_2$ make it self-dual with $k = +1$, matching Nash's choice that the minima with $k > 0$ are self-dual.

Recap

- Quaternions are the matrices $x^4\mathbb{1} + x^k e_k$, $e_k = -i\sigma_k$; $\bar x x = |x|^2$, unit quaternions form $\mathrm{SU}(2) = S^3$. $\mathrm{d}\bar x \wedge \mathrm{d}x = -2e_a\omega^+_a$ is SD and $\mathrm{d}x \wedge \mathrm{d}\bar x = -2e_a\omega^-_a$ is ASD; the 't Hooft symbols are $\mathrm{Im}(\bar e_\nu e_\mu) = \eta^a_{\mu\nu} e_a$.
- Finite action forces $A \to g^{-1}\mathrm{d}g$ at infinity, and $k = \frac{1}{24\pi^2}\int_{S^3_\infty} \mathrm{tr}(g^{-1}\mathrm{d}g)^3 = \deg g$; the map $g = x/r$ has degree 1.
- BPST: $A = \mathrm{Im}(\bar x\,\mathrm{d}x)/(|x|^2+\lambda^2)$, $F = \lambda^2 \mathrm{d}\bar x \wedge \mathrm{d}x/(|x|^2+\lambda^2)^2$, self-dual, density $48\lambda^4/(r^2+\lambda^2)^4$, action $8\pi^2$ ($8\pi^2/g^2$ physically), $k = 1$, half the action within $r < \lambda$.
- 5 parameters up to gauge (centre, size), 8 with colour orientation.
- Singular gauge: $A \sim \lambda^2/r^3$ at infinity, winding moved to the centre. 't Hooft ansatz $A_\mu = -\frac{1}{2}\bar\eta^a_{\mu\nu}\partial_\nu \ln\rho\, e_a$: $F^- = \frac{\Box\rho}{4\rho} e_a \omega^-_a$, so harmonic $\rho = 1 + \sum \lambda_i^2/|x - y_i|^2$ gives k instantons with $5k$ of the $8k - 3$ moduli.

8.6 Gauge invariance, gauge fixing and ellipticity

We now have one explicit instanton and a family of others. Nash's aim is to describe *all* of them: the space of self-dual connections modulo gauge, and in particular its dimension. The strategy (following Atiyah, Hitchin and Singer) is to linearise the equations around a solution and count the solutions of the linearised problem with the index theorem. The index theorem (Chapter 4) applies to *elliptic* operators. So the first question is: are the Yang–Mills equations elliptic?

They are not, and the reason is gauge invariance. This section explains the failure, cures it by gauge fixing, and in doing so builds the geometric picture (orbits, slices, tangent spaces) that the rest of the part uses. A physicist has met every idea here already, in disguise: the photon propagator does not exist until one fixes a gauge.

8.6.1 A reminder: ellipticity and the symbol

A linear differential operator P of order m acting on vector-valued functions has a **principal symbol** $\sigma_P(x,\xi)$: a matrix-valued function of position x and a covector ξ ("momentum").

Working definition 8.26 (principal symbol and ellipticity)

To compute $\sigma_P(x,\xi)$: keep only the terms of P with the maximal number m of derivatives, and replace each ∂_μ by $i\xi_\mu$. The result is a matrix whose entries are homogeneous polynomials of degree m in ξ [every term contains exactly m factors of ξ]. The operator is **elliptic** if $\sigma_P(x,\xi)$ is an invertible matrix [no nonzero vector v has $\sigma_P(x,\xi)v=0$] for every x and every $\xi\neq 0$. (Formally: $\sigma_P(x,\xi)$ is a linear map between the fibres of the bundles P maps between [the vector spaces at x where the input and the output of P take their values]; see Chapter 2.)

The symbol is what a plane wave $e^{i\xi\cdot x}$ of very high frequency sees: for large ξ, $P(e^{i\xi\cdot x}v)\approx \sigma_P(x,\xi)v\,e^{i\xi\cdot x}$. Ellipticity means that no short-wavelength mode is annihilated. That is what gives the two properties we need:

- *Regularity.* Solutions of $Pu=0$ (and of non-linear elliptic equations) are smooth: no rough high-frequency component can hide in the kernel.
- *Fredholm property.* On a compact manifold $\operatorname{Ker}P$ and $\operatorname{Coker}P$ are finite dimensional, so $\operatorname{index}P=\dim\operatorname{Ker}P-\dim\operatorname{Coker}P$ makes sense and is computed by the index theorem.

Worked example 8.59: Symbols of d, d^* and the Laplacian on $\mathbb{R}^4$

On functions, $\mathrm{d}f=\partial_\mu f\,\mathrm{d}x^\mu$, so $\sigma_{\mathrm{d}}(\xi)f=i\xi_\mu f\,\mathrm{d}x^\mu=i\xi f$. On 1-forms in four dimensions $\mathrm{d}^*=-\star\,\mathrm{d}\star$, which gives $\mathrm{d}^*a=-\partial_\mu a_\mu$, so $\sigma_{\mathrm{d}^*}(\xi)a=-i\,\xi_\mu a_\mu=-i\,\xi\cdot a$. Composing,

$$\begin{aligned}\sigma_{\mathrm{d}^*\mathrm{d}}(\xi)f &\overset{(1)}{=} \sigma_{\mathrm{d}^*}(\xi)\,\sigma_{\mathrm{d}}(\xi)f\\ &\overset{(2)}{=} (-i)(i)\,\xi_\mu\xi_\mu\,f\\ &\overset{(3)}{=} |\xi|^2 f.\end{aligned}$$

(1) The symbol of a composition is the product of the symbols (only the terms where all derivatives hit the exponential survive at leading order).
(2) The two symbols above.
(3) $(-i)(i)=1$.

Indeed $\mathrm{d}^*\mathrm{d}f=-\Box f$. The symbol $|\xi|^2$ is invertible for $\xi\neq 0$: the Laplacian is the model elliptic operator. The covariant version $\mathrm{d}_A^*\mathrm{d}_A f=-D_\mu D_\mu f$ has the same symbol, because A enters without derivatives on f and only affects lower-order terms.

8.6.2 Why the Yang–Mills operator is not elliptic

The Yang–Mills equation $\mathrm{d}_A^*F(A)=0$ is non-linear. For a non-linear equation, ellipticity means ellipticity of its linearisation. Nash writes the operator loosely as "$\mathrm{d}_A^*\mathrm{d}_A$" acting on A; precisely, we perturb $A\to A+ta$ and differentiate at $t=0$.

$$\begin{aligned}\left.\frac{\mathrm{d}}{\mathrm{d}t}\right|_{t=0}\mathrm{d}^*_{A+ta}F(A+ta) &\overset{(1)}{=} \left.\frac{\mathrm{d}}{\mathrm{d}t}\right|_{t=0}\Big(-\star\,\mathrm{d}_{A+ta}\star\big(F+t\,\mathrm{d}_A a+t^2 a\wedge a\big)\Big)\\ &\overset{(2)}{=} -\star\,\mathrm{d}_A\star\,\mathrm{d}_A a-\star[a,\star F]\end{aligned}$$

$$\overset{(3)}{=} \mathrm{d}_A^* \mathrm{d}_A a - \star[a, \star F].$$

(1) $\mathrm{d}_A^* = -\star \mathrm{d}_A \star$ on 2-forms (Section 8.3.3), and the curvature along the line, (8.168).
(2) $\mathrm{d}_{A+ta}\omega = \mathrm{d}_A\omega + t[a,\omega]$, with $[a,\omega]$ the graded commutator $a\wedge\omega - \omega\wedge a$ for a 2-form ω; keep the terms linear in t.
(3) $-\star\mathrm{d}_A\star = \mathrm{d}_A^*$ again.

The second term has no derivatives of a, so the principal symbol comes from $\mathrm{d}_A^*\mathrm{d}_A$ alone. In components on $\mathbb{R}^4$, $(\mathrm{d}^*\mathrm{d}a)_\nu = -\partial_\mu(\partial_\mu a_\nu - \partial_\nu a_\mu) = -\Box a_\nu + \partial_\nu(\partial\cdot a)$, so

$$\sigma_{\mathrm{d}_A^*\mathrm{d}_A}(\xi)_{\nu\mu} = |\xi|^2\delta_{\nu\mu} - \xi_\nu\xi_\mu. \tag{8.209}$$

Worked example 8.60: The symbol as a 4×4 matrix

Take $\xi = (0,0,0,1)$, a wave travelling in the x^4 direction. Then

$$\sigma(\xi) = |\xi|^2\mathbb{1}_4 - \xi\xi^T = \begin{pmatrix} 1&0&0&0\\ 0&1&0&0\\ 0&0&1&0\\ 0&0&0&0\end{pmatrix}.$$

Its kernel is spanned by $a = (0,0,0,1) = \xi$, the *longitudinal* polarisation. For general ξ, $\sigma(\xi) = |\xi|^2(\mathbb{1} - \xi\xi^T/|\xi|^2)$ is $|\xi|^2$ times the projector onto polarisations transverse to ξ. It kills exactly $a \propto \xi$. And $a = \xi f$ is precisely the symbol of a gauge direction: $\sigma_{\mathrm{d}_A}(\xi)f = i\xi f$. So the non-invertibility of the symbol is gauge invariance, seen at high frequency. For SU(2) the full symbol is this matrix tensored with $\mathbb{1}_3$ on the colour index, with a 3-dimensional kernel $\{\xi\otimes f : f\in\mathfrak{su}(2)\}$.

The mechanism is general. If $S(A_g) = S(A)$ for all gauge transformations g, then the gradient of S (the Yang–Mills operator) is constant along gauge orbits, so its linearisation annihilates the tangent vectors to the orbits. Those tangent vectors are $\mathrm{d}_A f$, a first-order expression in an arbitrary function f, so the kernel is infinite-dimensional and contains arbitrarily high frequencies: exactly what ellipticity forbids.

Dictionary: the photon propagator

For $G = \mathrm{U}(1)$ and $A = 0$, (8.209) in momentum space is the kinetic operator of the photon, $k^2\delta_{\mu\nu} - k_\mu k_\nu$. Every QFT course notes that this matrix has no inverse, because it annihilates k_μ, and that one cannot write the propagator until one adds a gauge-fixing term $\frac{1}{\xi}(\partial\cdot A)^2$ to the Lagrangian. In Feynman gauge ($\xi = 1$) the operator becomes $k^2\delta_{\mu\nu}$ with inverse $\delta_{\mu\nu}/k^2$. "The YM operator is not elliptic" is the mathematician's way of saying "the photon propagator does not exist without gauge fixing"; the cure below is the same.

Nash adds a second, more analytic, remark. If A is a smooth solution, so is $A_g = g^{-1}Ag + g^{-1}\mathrm{d}g$ for every gauge transformation g. If g is only, say, continuous, A_g still solves the equation in a weak sense but is not smooth. So without gauge fixing, "solutions are smooth" is simply false: regularity can only hold up to gauge.

8.6.3 Infinitesimal gauge transformations and the orbit

To fix the gauge near a connection A we need to know which directions in the space $\mathcal{A}$ of connections are gauge directions.

Worked example 8.61: Nash (8.80): the tangent to a gauge orbit

Take $g = \exp(tf)$ with $f \in \Omega^0(M, \operatorname{ad} P)$ and t small, so $g \approx \mathbb{1} + tf$ and $g^{-1} \approx \mathbb{1} - tf$.

$$\begin{aligned} A_g &\overset{(1)}{=} g^{-1}Ag + g^{-1}\mathrm{d}g \\ &\overset{(2)}{=} (\mathbb{1} - tf)A(\mathbb{1} + tf) + (\mathbb{1} - tf)\,\mathrm{d}(\mathbb{1} + tf) + O(t^2) \\ &\overset{(3)}{=} A + t(Af - fA) + t\,\mathrm{d}f + O(t^2) \\ &\overset{(4)}{=} A + t\,\mathrm{d}_A f + O(t^2). \end{aligned}$$

(1) The gauge transformation law (8.163).
(2) Expand $\exp(\pm tf)$ to first order.
(3) Multiply out and drop t^2 terms; $\mathrm{d}\mathbb{1} = 0$.
(4) $\mathrm{d}f + [A, f] = \mathrm{d}_A f$ by (8.164) with $p = 0$.

So the velocity of the curve $t \mapsto A_{\exp(tf)}$ at $t = 0$ is $\mathrm{d}_A f$.

Working definition 8.27 (gauge orbit and its tangent space)

The **gauge orbit** of A is $\mathcal{G} \cdot A = \{A_g : g \in \mathcal{G}\}$, all connections gauge equivalent to A. Its tangent space at A is

$$T_A(\mathcal{G} \cdot A) = \operatorname{Im} \mathrm{d}_A = \{\mathrm{d}_A f : f \in \Omega^0(M, \operatorname{ad} P)\} \subset \Omega^1(M, \operatorname{ad} P) = T_A\mathcal{A}. \tag{8.210}$$

Test: a perturbation a is "pure gauge to first order" [a is the velocity at $t = 0$ of a curve $A_{g(t)}$ of gauge transforms of A, with $g(0) = \mathbb{1}$] iff $a = \mathrm{d}_A f$ for some f. This is Nash's (8.83).

Recall that $\mathcal{A}$ is an affine space: any two connections differ by an element of $\Omega^1(M, \operatorname{ad} P)$, so every tangent space $T_A\mathcal{A}$ is $\Omega^1(M, \operatorname{ad} P)$ itself (Figure 8.29).

8.6.4 The slice: $T_A\mathcal{A} = \operatorname{Im} \mathrm{d}_A \oplus \operatorname{Ker} \mathrm{d}_A^*$

Physical (non-gauge) directions should be the directions orthogonal to the orbit. Orthogonality is measured by the inner product (8.165).

$$\begin{aligned} a \perp \operatorname{Im} \mathrm{d}_A &\overset{(1)}{=} \Longleftrightarrow \ \langle \mathrm{d}_A f, a \rangle = 0 \ \text{ for all } f \\ &\overset{(2)}{=} \Longleftrightarrow \ \langle f, \mathrm{d}_A^* a \rangle = 0 \ \text{ for all } f \\ &\overset{(3)}{=} \Longleftrightarrow \ \mathrm{d}_A^* a = 0. \end{aligned}$$

(1) Definition of the orthogonal complement.
(2) Definition (8.171) of the adjoint d_A^*.
(3) Take $f = \mathrm{d}_A^* a$: then $\left\|\mathrm{d}_A^* a\right\|^2 = 0$.

So the orthogonal complement of the orbit directions is $\operatorname{Ker} \mathrm{d}_A^*$. That the two pieces span everything is a statement of Hodge-theory type; we can see it by constructing the splitting explicitly.

Key idea: The gauge-slice decomposition (Nash (8.81), (8.84))

Every $a \in \Omega^1(M, \operatorname{ad} P)$ splits uniquely and orthogonally as

$$a = \underbrace{\mathrm{d}_A f}_{\text{gauge}} + \underbrace{a^\perp}_{\mathrm{d}_A^* a^\perp = 0}, \qquad T_A\mathcal{A} = \operatorname{Im} \mathrm{d}_A \oplus \operatorname{Ker} \mathrm{d}_A^* = T_A(\mathcal{G}\cdot A) \oplus \operatorname{Ker} \mathrm{d}_A^*. \tag{8.211}$$

Recipe: solve the elliptic equation $\mathrm{d}_A^* \mathrm{d}_A f = \mathrm{d}_A^* a$ for f, then set $a^\perp = a - \mathrm{d}_A f$.

Why the recipe works, one step at a time:

1. $\Delta_A = \mathrm{d}_A^* \mathrm{d}_A$ on $\Omega^0(\operatorname{ad} P)$ is the covariant Laplacian, elliptic by Example 8.59, and self-adjoint. On a compact M the equation $\Delta_A f = h$ has a solution iff h is orthogonal to $\operatorname{Ker} \Delta_A$ (the Fredholm alternative).
2. $\operatorname{Ker} \Delta_A = \operatorname{Ker} \mathrm{d}_A$, since $\langle \Delta_A f, f\rangle = \|\mathrm{d}_A f\|^2$.
3. $h = \mathrm{d}_A^* a$ is orthogonal to $\operatorname{Ker} \mathrm{d}_A$: for $\mathrm{d}_A f_0 = 0$, $\langle \mathrm{d}_A^* a, f_0\rangle = \langle a, \mathrm{d}_A f_0\rangle = 0$. So a solution f exists (unique up to adding elements of $\operatorname{Ker} \mathrm{d}_A$, which do not change $\mathrm{d}_A f$).
4. Then $\mathrm{d}_A^* a^\perp = \mathrm{d}_A^* a - \mathrm{d}_A^* \mathrm{d}_A f = 0$, and the two pieces are orthogonal by the chain above. Uniqueness: an element of both pieces is orthogonal to itself.

Worked example 8.62: The splitting in Fourier space: longitudinal and transverse

Take $A = 0$ and $G = \mathrm{U}(1)$ on $\mathbb{R}^4$ (or a torus), so $\mathrm{d}_A = \mathrm{d}$. For a plane wave $a_\mu(x) = \hat{a}_\mu e^{i\xi\cdot x}$ the recipe reads

$$|\xi|^2 \hat{f} \overset{(1)}{=} -i\,\xi\cdot\hat{a}, \qquad \text{so} \qquad \hat{f} = \frac{-i\,\xi\cdot\hat{a}}{|\xi|^2},$$

$$\hat{a}^\perp_\mu \overset{(2)}{=} \hat{a}_\mu - i\xi_\mu \hat{f} \overset{(3)}{=} \hat{a}_\mu - \frac{\xi_\mu\,\xi\cdot\hat{a}}{|\xi|^2}.$$

(1) $\mathrm{d}^*\mathrm{d} f = -\Box f$ becomes $|\xi|^2\hat{f}$ and $\mathrm{d}^* a = -\partial\cdot a$ becomes $-i\xi\cdot\hat{a}$.
(2) $a^\perp = a - \mathrm{d}f$ and $\mathrm{d}f \to i\xi\hat{f}$.
(3) Substitute $\hat{f}$.

This is the familiar split of a vector field into its longitudinal part $\xi(\xi\cdot\hat{a})/|\xi|^2$ (pure gauge) and its transverse part, which satisfies $\xi\cdot\hat{a}^\perp = 0$, the Lorenz (Euclidean: Landau) gauge condition. With numbers: $\xi = (1,0,0,0)$, $\hat{a} = (3,1,0,2)$ gives gauge part $(3,0,0,0)$ and transverse part $(0,1,0,2)$.

The background gauge

The decomposition suggests the gauge condition Nash adopts. For connections $A + a$ near A, impose

$$\mathrm{d}_A^* a = 0 \qquad \big(\text{in components } -D_\mu a_\mu = -(\partial_\mu a_\mu + [A_\mu, a_\mu]) = 0\big). \tag{8.212}$$

This is Nash's (8.82). Physicists call it the **background field gauge** (with A the background); for $A = 0$ it is the ordinary Lorenz condition $\partial\cdot a = 0$. It picks, in each nearby gauge orbit, the representative closest to A (Example 8.63 below). Unlike the temporal gauge $A_4 = 0$ or the axial gauge $A_3 = 0$, it is covariant, which is what makes the resulting equations elliptic.

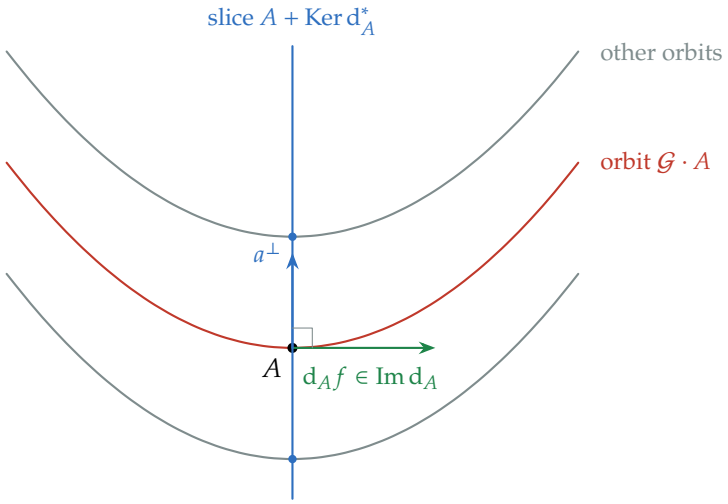

Figure 8.38: The geometry of gauge fixing, drawn in the (infinite-dimensional) space $\mathcal{A}$ of connections. Gauge orbits are the curves: every connection on one curve describes the same physics. At A the tangent to the orbit is $\operatorname{Im} \mathrm{d}_A$ (green). The slice (blue) passes through A orthogonally to the orbit; its tangent directions satisfy the background gauge condition $\mathrm{d}_A^* a = 0$. Near A, each nearby orbit meets the slice exactly once, so points of the slice are local coordinates on $\mathcal{A}/\mathcal{G}$.

Worked example 8.63: The background gauge picks the closest point of the orbit

Fix A and a nearby connection $A + a$. Move $A + a$ along its orbit by an infinitesimal gauge transformation $\exp(t f)$: to first order it becomes $A + a + t\, \mathrm{d}_{A+a} f \approx A + a + t\, \mathrm{d}_A f$ (dropping $t a f$ terms, which are second order in small quantities). The squared distance to A changes as

$$\left.\frac{\mathrm{d}}{\mathrm{d}t}\right|_{t=0} \|a + t\, \mathrm{d}_A f\|^2 \overset{(1)}{=} 2\langle a, \mathrm{d}_A f\rangle \overset{(2)}{=} 2\langle \mathrm{d}_A^* a, f\rangle.$$

(1) Expand the norm squared; bilinearity and symmetry.
(2) Adjoint.

The distance is stationary under all gauge motions iff $\mathrm{d}_A^* a = 0$. So the slice is the set of points of each orbit that are (locally) nearest to A.

8.6.5 The gauge-fixed equations are elliptic

Adding the gauge condition to the Yang–Mills equation gives the system (Nash's (8.85))

$$\mathrm{d}_{A+a}^* F(A + a) = 0, \qquad \mathrm{d}_A^* a = 0.$$

A standard trick packages it as one equation: since $\mathrm{d}_A \mathrm{d}_A^* a$ vanishes when $\mathrm{d}_A^* a = 0$, we may add it. The linearised operator becomes

$$a \longmapsto \mathrm{d}_A^* \mathrm{d}_A a + \mathrm{d}_A \mathrm{d}_A^* a + (\text{zeroth order}),$$

whose principal symbol is

$$\sigma(\xi)_{\nu\mu} \overset{(1)}{=} \left(|\xi|^2 \delta_{\nu\mu} - \xi_\nu \xi_\mu\right) + \xi_\nu \xi_\mu \overset{(2)}{=} |\xi|^2\, \delta_{\nu\mu}.$$

(1) (8.209), plus the symbol of dd^*: $(\mathrm{dd}^* a)_\nu = -\partial_\nu \partial_\mu a_\mu$, so $\sigma = -(i\xi_\nu)(i\xi_\mu) = \xi_\nu \xi_\mu$.
(2) The longitudinal pieces cancel.

This is invertible for $\xi \neq 0$: the gauge-fixed operator is the Hodge Laplacian on 1-forms (plus lower-order terms), the model elliptic operator. In the 4×4 matrix of Example 8.60, the missing 1 in the bottom right corner has been restored. Elliptic regularity then gives Nash's conclusion: the gauge-fixed Yang–Mills equations are an elliptic system, and their solutions are smooth.

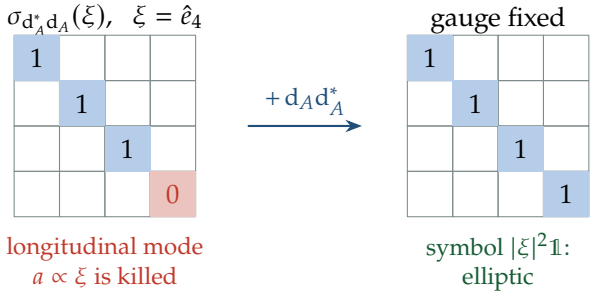

Figure 8.39: The symbol of the linearised Yang–Mills operator for a wave along x^4, before and after gauge fixing. Before: the longitudinal polarisation (the gauge direction) has zero symbol, so the operator is not elliptic. After adding $\mathrm{d}_A \mathrm{d}_A^*$ (the gauge-fixing term, Feynman gauge in physics language) every polarisation has symbol $|\xi|^2$.

Watch out: Gauge fixing is local: the Gribov problem

The slice meets each *nearby* orbit exactly once. Far from A an orbit can cross the slice several times, or be tangent to it; then the condition $\mathrm{d}_A^* a = 0$ does not pick a unique representative. Physicists know this as the **Gribov ambiguity** of the Coulomb and Landau gauges. Singer (1978) showed it is unavoidable for non-Abelian G on S^4: there is no continuous global gauge-fixing section of $\mathcal{A} \to \mathcal{A}/\mathcal{G}$, because the bundle $\mathcal{A} \to \mathcal{A}/\mathcal{G}$ is topologically non-trivial. Nash's word "(local) gauge" is exactly this caveat. For the moduli space it is harmless: we only ever need coordinates near one self-dual connection at a time.

Reading Nash (pp. 230–231, (8.80)–(8.85))

Nash motivates ellipticity by the analogy of Yang–Mills with (non-linear) Hodge theory (Section 8.3.4). He then states that gauge invariance "gives the Yang–Mills operator $\mathrm{d}_A^* \mathrm{d}_A$ a non-invertible symbol, whose kernel is parametrised by the space of gauge transformations": (8.209) and Example 8.60. In his "$\mathrm{d}_A^* \mathrm{d}_A A \equiv \mathrm{d}_A^* F(A)$" the operator notation is loose: the equation is non-linear, and the operator with a symbol is its linearisation. (8.80) is our Example 8.61; (8.81) and (8.84) are (8.211), which he calls "standard linear algebra" (in infinite dimensions it needs the elliptic argument we gave); (8.82) is the background gauge (8.212); (8.83) is (8.210). (8.85) is the elliptic gauge-fixed system. (Nash's "orthogonal compliment" is a typo for complement.)

Recap

- Elliptic means the principal symbol is invertible for $\xi \neq 0$; it gives smooth solutions and finite-dimensional kernels, hence indices.
- The linearised YM operator has symbol $|\xi|^2 \delta - \xi\xi$, which kills the longitudinal (gauge) polarisation: YM is not elliptic, because of gauge invariance. Physics: no photon propagator without gauge fixing.
- Infinitesimal gauge transformations move A by $\mathrm{d}_A f$; the orbit's tangent space is

$\operatorname{Im} \mathrm{d}_A$.

- $T_A\mathcal{A} = \operatorname{Im} \mathrm{d}_A \oplus \operatorname{Ker} \mathrm{d}_A^*$, constructed by solving $\mathrm{d}_A^* \mathrm{d}_A f = \mathrm{d}_A^* a$. The slice $\mathrm{d}_A^* a = 0$ (background gauge) picks the orbit point nearest A.
- With the gauge condition the operator becomes the Hodge Laplacian, symbol $|\xi|^2$: elliptic. Gauge fixing is only local (Gribov, Singer).

8.7 The instanton moduli space and reducible connections

We have an explicit family of instantons: the BPST solution with its centre $y \in \mathbb{R}^4$ and size $\lambda > 0$, and the 't Hooft solutions with $5k$ parameters. Are there others? How many parameters does the most general self-dual connection of charge k have? And in what sense are two instantons "the same"? Physically this is the question of the **collective coordinates** of the instanton. In the semiclassical evaluation of the path integral one integrates over them exactly, and each one comes with a zero mode of the fluctuation operator (Section 8.10). Mathematically it is the question of the **moduli space**.

This section defines the moduli space carefully. The one real subtlety is that the gauge group does not always act freely: some connections are fixed by some gauge transformations. Those connections are called *reducible*, and they produce singularities in the moduli space. We explain what reducibility is, how to test for it, why it causes singularities, and how to avoid it (Nash's two devices: divide by Ad G and restrict to irreducible connections, or keep a framing).

8.7.1 Definition of $\mathcal{M}_k$

Fix the bundle, that is, fix the instanton number k. Write $\mathcal{A}_k$ for the space of all connections on this bundle and $\mathcal{G}_k$ for the group of gauge transformations (locally: maps $g : M \to G$, acting by (8.163)). Two connections related by a gauge transformation describe the same physics, so the *configuration space* of the theory is the quotient $\mathcal{A}_k/\mathcal{G}_k$: the set of gauge orbits.

Working definition 8.28 (instanton moduli space)

The **moduli space** of charge-k instantons is

$$\mathcal{M}_k = \frac{\{A \in \mathcal{A}_k : \star F(A) = F(A)\}}{\mathcal{G}_k} \subset \frac{\mathcal{A}_k}{\mathcal{G}_k}, \tag{8.213}$$

the set of gauge orbits of self-dual connections (Nash's (8.86)–(8.87)). *To compute with it:* pick a self-dual A; nearby points of $\mathcal{M}_k$ are self-dual $A + a$ with a in the slice $\mathrm{d}_A^* a = 0$ [perturbations a that are L^2-orthogonal to the gauge orbit through A] of Section 8.6.4. *To count its dimension:* count the independent solutions a of the linearised self-duality equation [the part of $\star F(A + a) = F(A + a)$ linear in a, which is $(\mathrm{d}_A a)^- = 0$] that are orthogonal to the gauge orbit (Section 8.8).

The whole point of Nash's section is that $\mathcal{M}_k$ is *finite* dimensional, although it sits inside the infinite-dimensional space $\mathcal{A}_k/\mathcal{G}_k$. The self-duality equation is a system of three equations per colour for four unknowns per colour, and the fourth "missing" equation is supplied by gauge invariance; so the system is "determined" and we expect a discrete set of solutions plus finitely many parameters.

Worked example 8.64: Counting the BPST parameters

The BPST connection centred at y with size λ is $A_{y,\lambda} = \operatorname{Im}\big((\bar{x}-\bar{y})\,\mathrm{d}x\big)/(|x-y|^2+\lambda^2)$ (Section 8.5.3). Conjugating by a constant $q \in \mathrm{SU}(2)$ gives another self-dual connection $q^{-1}A_{y,\lambda}\,q$. So in $\mathcal{A}_1$ we see at least $4+1+3=8$ parameters (y,λ,q). How many survive in $\mathcal{M}_1$?

- The constant conjugation *is* a gauge transformation ((8.163) with $\mathrm{d}q=0$). So $q^{-1}Aq$ and A are the same point of $\mathcal{A}_1/\mathcal{G}_1$, and q does not survive.
- Different (y,λ) give genuinely different points: the gauge-invariant action density $s(x) = -\frac{1}{2}\operatorname{tr}F_{\mu\nu}F_{\mu\nu} = 48\lambda^4/(|x-y|^2+\lambda^2)^4$ peaks at $x=y$ with height $48/\lambda^4$, so it remembers both y and λ.

So the BPST family contributes a 5-dimensional piece of $\mathcal{M}_1$, the set of pairs $(y,\lambda)\in\mathbb{R}^4\times\mathbb{R}^+$. The index computation of Section 8.9 will show that $\dim\mathcal{M}_1=5$ exactly, so this piece is (an open subset of, and in fact all of) the moduli space.

Worked example 8.65: A constant rotation of colour is a rotation of space

The last example has a pretty twist. Take $y=0$ and a unit quaternion q (so $q^{-1}=\bar{q}$). Then

$$q^{-1}A\,q \overset{(1)}{=} \frac{\bar{q}\,\operatorname{Im}(\bar{x}\,\mathrm{d}x)\,q}{\phi} \overset{(2)}{=} \frac{\operatorname{Im}\big(\bar{q}\,\bar{x}\,\mathrm{d}x\,q\big)}{\phi} \overset{(3)}{=} \frac{\operatorname{Im}\big(\overline{(xq)}\,\mathrm{d}(xq)\big)}{|xq|^2+\lambda^2}.$$

(1) The BPST formula (8.200), with $\phi=|x|^2+\lambda^2$.

(2) Conjugation by a unit quaternion preserves real parts ($\bar{q}\,1\,q=1$), hence commutes with taking the imaginary part.

(3) $\overline{xq}=\bar{q}\bar{x}$, $\mathrm{d}(xq)=\mathrm{d}x\,q$ because q is constant, and $|xq|=|x|$.

The right-hand side is the BPST connection pulled back by the map $x\mapsto xq$, which is a rotation of $\mathbb{R}^4$ (it preserves $|x|$). So for the instanton a global colour rotation is the same as a spatial rotation. The BPST instanton is invariant under the combined transformation "rotate space by $x\mapsto xq$, then rotate colour back by q". This is the "spin–isospin locking" of the instanton. It is the reason the instanton has only 5 moduli rather than $5+6$ (rotations of $\mathbb{R}^4$ form the 6-dimensional group SO(4)): the rotations either leave it fixed or act on it as gauge transformations.

8.7.2 The residual gauge symmetry: base points and $\mathrm{Ad}\,G$

Nash now points out a remaining invariance. To see it, recall how the gauge group is organised. A gauge transformation is a section g of the bundle of groups $\mathrm{Ad}\,P$ (locally a map $g: M\to G$). Choose a **base point** $p_0\in M$ (on S^4, the point at infinity of $\mathbb{R}^4$ is the natural choice) and evaluate:

$$\mathrm{ev}_{p_0}:\mathcal{G}\to G, \qquad g\mapsto g(p_0).$$

The kernel is the **based gauge group** $\mathcal{G}_0=\{g\in\mathcal{G}:\ g(p_0)=\mathbb{1}\}$. Every g is a based gauge transformation times a constant (on a trivialised neighbourhood of p_0), and $\mathcal{G}/\mathcal{G}_0\cong G$. So the quotient can be taken in two stages:

$$\frac{\mathcal{A}_k}{\mathcal{G}_k} = \frac{\mathcal{A}_k/\mathcal{G}_0}{G}. \tag{8.214}$$

Nash's phrasing is that the action "does not depend on our choice of base point $p_0 \in P_a$": a point of the fibre P_{p_0} is a choice of frame at p_0, the frames at p_0 are permuted by G, and this G still acts on $\mathcal{A}_k/\mathcal{G}_0$. (Here $\mathcal{G}_k$ in Nash's notation is the based group; the distinction matters only in this paragraph.)

Working definition 8.29 (framed connection, framed moduli space)

A **framed connection** is a connection together with a choice of frame (a basis, or equivalently a point of P) at the base point p_0. Gauge transformations in $\mathcal{G}_0$ do not move the frame; constant gauge transformations [equal to one fixed $\alpha \in G$ near p_0, in the trivialisation used there] do. The **framed moduli space** is

$$\mathcal{M}'_k = \frac{\{A \in \mathcal{A}_k : \star F = F\}}{\mathcal{G}_0}, \qquad \text{with} \qquad \mathcal{M}_k = \mathcal{M}'_k/G. \tag{8.215}$$

Physically: $\mathcal{M}'_k$ remembers the orientation of the instanton in colour space [the internal space $\mathbb{C}^2$ on which SU(2) acts] relative to a fixed reference frame at infinity; $\mathcal{M}_k$ forgets it.

Worked example 8.66: The framed $k = 1$ moduli space has dimension 8

For the BPST family, the constant conjugation $q^{-1}Aq$ changes the frame at infinity (it is a gauge transformation with $g(\infty) = q \neq \mathbb{1}$), so in $\mathcal{M}'_1$ the colour orientation q *is* a parameter. The count of Example 8.64 becomes $4 + 1 + 3 = 8$. But the element $q = -\mathbb{1}$ acts trivially ($(-1)^{-1}A(-1) = A$), so the orientation lives in $\mathrm{SU}(2)/\{\pm\mathbb{1}\} = \mathrm{SO}(3)$, and

$$\mathcal{M}'_1 \cong \mathbb{R}^4 \times \mathbb{R}^+ \times \mathrm{SO}(3) \cong \mathbb{R}^4 \times \big(\mathbb{R}^4 \setminus \{0\}\big)/\mathbb{Z}_2.$$

In the last form the size and the orientation are combined into one non-zero quaternion λq (modulus λ, direction q), defined up to sign. We will meet exactly this parameter in the ADHM construction (Section 8.10.6).

The centre acts trivially

Does the residual G act freely on $\mathcal{A}_k/\mathcal{G}_0$? Nash observes that it never does, for a simple reason. G is simple, so its centre $Z(G)$ (the elements commuting with everything) is a finite group. For $G = \mathrm{SU}(N)$, $Z(G) = \{e^{2\pi i m/N}\mathbb{1} : m = 0, \dots, N-1\} \cong \mathbb{Z}_N$; for SU(2) it is $\{\pm\mathbb{1}\}$.

$$\begin{aligned} z \in Z(G) \text{ constant}: \qquad A_z &\overset{(1)}{=} z^{-1}Az + z^{-1}\mathrm{d}z \\ &\overset{(2)}{=} z^{-1}Az \\ &\overset{(3)}{=} A. \end{aligned}$$

(1) The gauge transformation law (8.163).
(2) z is constant, so $\mathrm{d}z = 0$.
(3) z commutes with every matrix in $\mathfrak{g}$ (it is a multiple of the identity for $\mathrm{SU}(N)$).

So the centre fixes every connection. It is harmless: we simply divide it out from the start and let the group

$$\mathrm{Ad}\, G = G/Z(G)$$

act instead. For SU(2), $\operatorname{Ad}\mathrm{SU}(2) = \mathrm{SU}(2)/\mathbb{Z}_2 = \mathrm{SO}(3)$, the group of rotations of $\mathfrak{su}(2) \cong \mathbb{R}^3$ by $X \mapsto g^{-1}Xg$. Nash's new configuration space is (8.88):

$$\left(\mathcal{A}_k^{\mathrm{irred}}/\mathcal{G}_k\right) / \operatorname{Ad} G. \tag{8.216}$$

The superscript "irred" restricts to *irreducible* connections, which are defined next. The reason is that some connections are fixed by more than the centre, and those are the ones to exclude.

8.7.3 Stabilisers, holonomy and reducibility

Working definition 8.30 (stabiliser)

The **stabiliser** (or isotropy group) of a connection is

$$\Gamma_A = \{g \in \mathcal{G} : \; A_g = A\}.$$

Test: $A_g = A$ means $g^{-1}Ag + g^{-1}\mathrm{d}g = A$, i.e.

$$\mathrm{d}g + [A, g] = 0, \qquad \text{i.e.} \qquad \mathrm{d}_A g = 0 : \tag{8.217}$$

g is *covariantly constant* [unchanged by parallel transport along every path], as a section of $\operatorname{Ad} P$. (Multiply $A_g = A$ on the left by g: $Ag + \mathrm{d}g = gA$.)

A covariantly constant object is determined by its value at one point, because we can parallel transport that value everywhere. That is why stabilisers are controlled by *holonomy*. Let us make this precise; it is Nash's (8.89)–(8.90).

Parallel transport and how it changes under gauge transformations

Along a curve $\gamma : [0,1] \to M$ from $a = \gamma(0)$ to $b = \gamma(1)$, the **parallel transport** $U_\gamma(A)$ is the matrix obtained by solving

$$\frac{\mathrm{d}\psi}{\mathrm{d}t} = -A(\dot\gamma)\,\psi, \qquad \psi(0) = \psi_0, \qquad U_\gamma(A)\psi_0 \coloneqq \psi(1),$$

i.e. the path-ordered exponential $U_\gamma(A) = \mathcal{P}\exp\bigl(-\int_\gamma A\bigr)$. Physicists know it as the **Wilson line** (see Chapter T3). For a closed loop based at a, $U_\gamma(A)$ is the **holonomy** around γ; the set of all holonomies around loops at a forms the **holonomy group** $\mathrm{Hol}_a(A) \subset G$.

How does U_γ change under $A \mapsto A_g$? Try $\tilde\psi = g^{-1}\psi$, where ψ solves the transport equation for A:

$$\begin{aligned}
\frac{\mathrm{d}\tilde\psi}{\mathrm{d}t} &\overset{(1)}{=} \frac{\mathrm{d}g^{-1}}{\mathrm{d}t}\psi + g^{-1}\frac{\mathrm{d}\psi}{\mathrm{d}t} \\
&\overset{(2)}{=} -g^{-1}\dot g\, g^{-1}\psi - g^{-1}A(\dot\gamma)\psi \\
&\overset{(3)}{=} -\bigl(g^{-1}\dot g + g^{-1}A(\dot\gamma)g\bigr)\, g^{-1}\psi \\
&\overset{(4)}{=} -A_g(\dot\gamma)\,\tilde\psi.
\end{aligned}$$

(1) Product rule; g is evaluated along γ.
(2) $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\, g^{-1}$ (differentiate $g^{-1}g = \mathbb{1}$), and the transport equation for ψ.
(3) Insert $\mathbb{1} = gg^{-1}$ in the second term and factor.
(4) $A_g = g^{-1}Ag + g^{-1}\mathrm{d}g$ evaluated on $\dot\gamma$; $g^{-1}\dot g = (g^{-1}\mathrm{d}g)(\dot\gamma)$.

So $\tilde{\psi}$ is transported by A_g, and comparing endpoints,

$$U_\gamma(A_g) = g(b)^{-1}\, U_\gamma(A)\, g(a). \tag{8.218}$$

This is Nash's (8.89), $\alpha_b \circ PT_{\gamma_{ab}}(A) = PT_{\gamma_{ab}}(\alpha \cdot A) \circ \alpha_a$, written with our conventions (α_a denotes the value of the gauge transformation at a).

Stabilisers commute with holonomy

Now take a loop γ based at a and a stabiliser element $g \in \Gamma_A$, with value $\alpha = g(a)$ at the base point.

$$\begin{aligned} U_\gamma(A) &\overset{(1)}{=} U_\gamma(A_g) \\ &\overset{(2)}{=} \alpha^{-1}\, U_\gamma(A)\, \alpha, \end{aligned}$$

(1) $A_g = A$ because g is in the stabiliser.
(2) (8.218) with $a = b$, so $g(a) = g(b) = \alpha$.

hence $\alpha\, U_\gamma(A) = U_\gamma(A)\, \alpha$ for every loop: this is (8.90). Conversely, given α commuting with the holonomy group, define $g(x) = U_{\gamma_x}(A)\, \alpha\, U_{\gamma_x}(A)^{-1}$ by transporting along any path γ_x from a to x; the result does not depend on the path (two paths differ by a loop, whose holonomy commutes with α), and it is covariantly constant. So:

Key idea: Stabiliser = centraliser of the holonomy group

Evaluation at the base point identifies

$$\Gamma_A \;\cong\; C_G\big(\mathrm{Hol}(A)\big) = \{\alpha \in G :\ \alpha h = h\alpha \text{ for all } h \in \mathrm{Hol}(A)\}. \tag{8.219}$$

A stabiliser element is fixed by its value at one point. In particular a based gauge transformation ($g(p_0) = \mathbb{1}$) that fixes A is the identity: $\mathcal{G}_0$ *acts freely on all connections.*

Working definition 8.31 (irreducible connection)

A connection is **irreducible** if its stabiliser is as small as possible, namely the centre [the elements of G that commute with all of G, $\pm\mathbb{1}$ for SU(2)]: $\Gamma_A = Z(G)$. Otherwise it is **reducible**. (Nash's formulation: A is irreducible if its holonomy group is all of G; then the centraliser is $Z(G)$. The name comes from representation theory: A is reducible if the holonomy preserves a proper subspace [a nonzero subspace smaller than the whole fibre, such as a line in $\mathbb{C}^2$], i.e. the bundle splits into parallel sub-bundles.) *Infinitesimal test* (Nash's (8.91)): A is reducible iff there is a non-zero $f \in \Omega^0(M, \mathrm{ad}\, P)$ with

$$\mathrm{d}_A f = 0. \tag{8.220}$$

Why the infinitesimal test works: a covariantly constant Lie-algebra element f exponentiates to a one-parameter family of stabiliser elements $g_t = \exp(tf)$, and conversely the stabiliser is a closed subgroup of G (a Lie group), so if it is bigger than the finite group $Z(G)$ it has a non-trivial Lie algebra, whose elements satisfy (8.220). Nash shows the first half by expanding A_g in powers of t, (8.92). We can do better and show that A_{g_t} is exactly constant in t:

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} A_{g_t} &\overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}t}\Big(e^{-tf} A\, e^{tf} + e^{-tf}\, \mathrm{d}\, e^{tf}\Big) \\ &\overset{(2)}{=} e^{-tf}(Af - fA)e^{tf} + \Big(-f\, e^{-tf}\, \mathrm{d}e^{tf} + e^{-tf}\, \mathrm{d}\big(f\, e^{tf}\big)\Big) \end{aligned}$$

$$\overset{(3)}{=} e^{-tf}[A,f]e^{tf} + e^{-tf}(\mathrm{d}f)\,e^{tf}$$
$$\overset{(4)}{=} e^{-tf}\,(\mathrm{d}_A f)\,e^{tf}$$
$$\overset{(5)}{=} 0.$$

(1) The gauge transformation law with $g_t = e^{tf}$.
(2) $\frac{\mathrm{d}}{\mathrm{d}t}e^{\pm tf} = \pm f e^{\pm tf}$, and f commutes with $e^{\pm tf}$.
(3) Leibniz: $\mathrm{d}(fe^{tf}) = (\mathrm{d}f)e^{tf} + f\,\mathrm{d}e^{tf}$; the terms $\mp f e^{-tf}\mathrm{d}e^{tf}$ cancel (again $fe^{-tf} = e^{-tf}f$).
(4) $\mathrm{d}_A f = \mathrm{d}f + [A,f]$.
(5) The assumption (8.220).

So $A_{g_t} = A_{g_0} = A$ for all t. Expanding $e^{-tf}Xe^{tf} = X + t[X,f] + \frac{t^2}{2}[[X,f],f] + \dots$ in the fourth line and integrating reproduces Nash's series $A_g = A + t\,\mathrm{d}_A f + \frac{t^2}{2}[\mathrm{d}_A f, f] + \dots$ term by term.

Worked example 8.67: Three connections and their stabilisers, for $G = \mathrm{SU}(2)$

(a) The trivial connection $A = 0$. Then $\mathrm{d}_A f = \mathrm{d}f$, so every constant $f \in \mathfrak{su}(2)$ is covariantly constant: the space of solutions of (8.220) is 3-dimensional. The holonomy is trivial, its centraliser is all of SU(2), and $\Gamma_A = \mathrm{SU}(2)$ (the constant gauge transformations). This is the "most reducible" connection.
(b) A U(1) *connection.* Let $\alpha = i\alpha_\mu \mathrm{d}x^\mu$ be a U(1) connection (α_μ real) and put

$$A = \begin{pmatrix} \alpha & 0 \\ 0 & -\alpha \end{pmatrix} = i\alpha_\mu\,\sigma_3\,\mathrm{d}x^\mu = -\alpha_\mu\,e_3\,\mathrm{d}x^\mu.$$

It takes values in the diagonal (Cartan) subalgebra. Take $f = i\sigma_3 = -e_3$:

$$\mathrm{d}_A f \overset{(1)}{=} \mathrm{d}f + [A,f]$$
$$\overset{(2)}{=} 0 + \alpha_\mu\,\mathrm{d}x^\mu\,[i\sigma_3, i\sigma_3]$$
$$\overset{(3)}{=} 0.$$

(1) Definition of d_A on 0-forms.
(2) f is constant; $A = \alpha_\mu \mathrm{d}x^\mu\, i\sigma_3$.
(3) A matrix commutes with itself.

So A is reducible; the solutions of (8.220) are the multiples of $i\sigma_3$ (if the curvature of α is non-zero somewhere, $[F,f] = 0$ forces $f \propto i\sigma_3$; see (c)). The stabiliser is the diagonal circle $\{\mathrm{diag}(e^{i\theta}, e^{-i\theta})\} \cong \mathrm{U}(1)$. The bundle splits as $E = L \oplus L^{-1}$, the eigenlines of σ_3, each preserved by parallel transport.
(c) The BPST instanton. Suppose $\mathrm{d}_A f = 0$. Apply d_A again:

$$0 \overset{(1)}{=} \mathrm{d}_A \mathrm{d}_A f$$
$$\overset{(2)}{=} [F,f]$$
$$\overset{(3)}{=} \tfrac{1}{2}\,[F_{\mu\nu}, f]\,\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu.$$

(1) Apply d_A to $\mathrm{d}_A f = 0$.
(2) $\mathrm{d}_A\mathrm{d}_A f = Ff - fF$ for any $f \in \Omega^0(\mathrm{ad}\,P)$; this is Nash's (8.108), which we verify in Section 8.8.4.
(3) Components.

So $f(x)$ must commute with every $F_{\mu\nu}(x)$. For BPST, $F_{\mu\nu} = -2\lambda^2\eta^a_{\mu\nu}e_a/\phi^2$ (Section 8.5.3); at any point, $F_{14} \propto e_1$, $F_{24} \propto e_2$, $F_{34} \propto e_3$. An element of $\mathfrak{su}(2)$ commuting with e_1, e_2 and e_3 is zero, by (8.193). Hence $f = 0$: the BPST instanton is irreducible, $\Gamma_A = \{\pm\mathbb{1}\} = Z(\mathrm{SU}(2))$.

The argument in (c) is a useful general test.

Key idea: A curvature test for irreducibility

If at some point the components $F_{\mu\nu}(x)$ of the curvature generate $\mathfrak{g}$ as a Lie algebra, then A is irreducible. For SU(2): if at some point two components $F_{\mu\nu}(x)$ are not parallel (as vectors in $\mathfrak{su}(2) \cong \mathbb{R}^3$), A is irreducible.

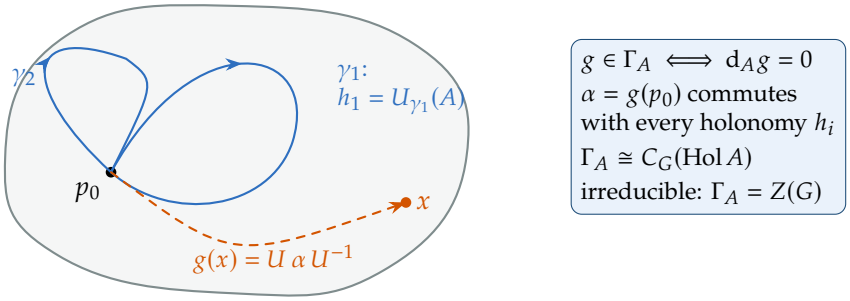

Figure 8.40: Why stabilisers are governed by holonomy. A gauge transformation g fixing A is covariantly constant, so it is determined by its value α at the base point: its value at x is obtained by parallel transport (orange). Transporting around a loop (blue) must bring α back to itself, so α commutes with every holonomy h_i. If the holonomies generate all of G, only central α survive.

With irreducibility in hand we can finish Nash's argument for (8.216). If A is irreducible, its stabiliser in $\mathcal{G}$ is $Z(G)$, and its image in $\mathrm{Ad}\,G = G/Z(G)$ is trivial. So $\mathrm{Ad}\,G$ acts *freely* on the irreducible part of $\mathcal{A}_k/\mathcal{G}_0$, and the quotient (8.216) has no fixed-point singularities. Nash's summary sentence, "a connection with a non-trivial stability group must be reducible", is the contrapositive.

8.7.4 Why reducible connections make singularities

What goes wrong at a reducible connection? The quotient of a space by a group acting with fixed points is not a manifold near the fixed points. The simplest example shows the typical shape: a cone.

Worked example 8.68: The plane divided by rotations is a half-line

Let $\mathrm{U}(1)$ act on $\mathbb{C} = \mathbb{R}^2$ by $z \mapsto e^{i\theta}z$. Every $z \neq 0$ has trivial stabiliser and its orbit is a circle of radius $|z|$; the origin is fixed by the whole group. The orbit space is parametrised by $r = |z|$:

$$\mathbb{C}/\mathrm{U}(1) \cong [0, \infty).$$

Away from $r = 0$ it is a 1-manifold; at $r = 0$ it has a boundary point, which is where the fixed point went. In higher dimensions: $\mathrm{U}(1)$ acting on $\mathbb{C}^n$ by $z \mapsto e^{i\theta}z$ has orbit space

$$\mathbb{C}^n/\mathrm{U}(1) \cong \{t\,w : t \geq 0,\ [w] \in \mathbb{C}^n\setminus 0/\mathrm{U}(1)\} = \text{cone on } S^{2n-1}/\mathrm{U}(1) = \text{cone on } \mathbb{CP}^{n-1}.$$

The link of the singular point (the orbit space of a small sphere around it) is $\mathbb{CP}^{n-1}$ instead of a sphere S^{2n-2}; so the orbit space is not a manifold at the vertex unless $n = 1$.

The same thing happens in $\mathcal{A}/\mathcal{G}$. Near a reducible connection A with stabiliser Γ_A, the slice construction of Section 8.6.4 still works, but the slice is acted on by Γ_A (the gauge transformations that fix A also move points of the slice around). Locally the moduli space looks like

$$\mathcal{M}_k \;\approx\; \frac{\{\text{solutions in the slice through } A\}}{\Gamma_A}.$$

For a U(1)-reducible SU(2) instanton the solutions near A form (in good cases) a copy of $\mathbb{C}^n$ on which $\Gamma_A = \mathrm{U}(1)$ acts with weight one, and $\mathcal{M}_k$ has a cone singularity with link $\mathbb{CP}^{n-1}$. In the case used in Donaldson's theorem ($k = 1$, a 5-dimensional moduli space, $n = 3$), the neighbourhood of each reducible is a *cone on* $\mathbb{CP}^2$ (Section 8.11).

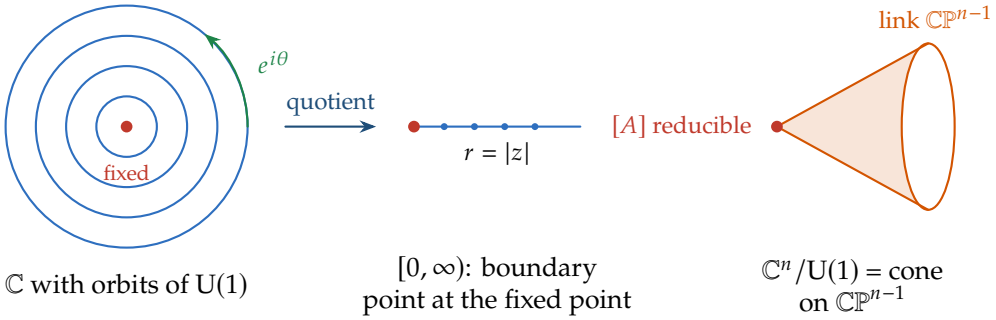

Figure 8.41: Fixed points of a group action produce singularities in the quotient. Left and centre: the rotations of the plane fix only the origin, and the orbit space is a half-line whose end point is the image of the fixed point. Right: in higher dimensions the quotient of $\mathbb{C}^n$ by U(1) is a cone whose cross-section is $\mathbb{CP}^{n-1}$. A reducible instanton, whose stabiliser is U(1), sits at the vertex of such a cone in $\mathcal{M}_k$.

There is also an infinitesimal symptom. The dimension count of the next section uses $h_0 = \dim \operatorname{Ker} \mathrm{d}_A$ on $\Omega^0(\mathrm{ad}\, P)$, the number of infinitesimal stabilisers. At an irreducible connection $h_0 = 0$. At a reducible one $h_0 > 0$, the index formula no longer gives the dimension of the moduli space, and the "expected" dimension is off by exactly the dimension of the stabiliser we have divided by (Example 8.84).

So Nash proceeds with two conventions:

1. $\mathcal{M}_k$ denotes the space of gauge equivalence classes of *irreducible* self-dual connections;
2. if we do not divide by Ad G, we obtain the framed space $\mathcal{M}'_k$, which is fibred over $\mathcal{M}_k$ with fibre Ad G (Figure 8.42).

The framed space has a bonus: since $\mathcal{G}_0$ acts freely on *all* connections (Section 8.7.3), $\mathcal{M}'_k$ has no fixed-point singularities even at reducible points. Over a reducible $[A]$ the fibre is not the full Ad G but Ad G/Γ_A.

8.7.5 Reducible SU(2) instantons and the intersection form

Nash returns to reducibility at the end of the dimension count (his (8.135)–(8.136)). We bring the discussion here, where it belongs logically. The question is: *on which 4-manifolds can an* SU(2) *instanton be reducible?*

For $G = \mathrm{SU}(2)$, a proper subgroup that can be a holonomy group of a non-flat connection is (up to conjugation) the circle $\mathrm{U}(1) = \{\mathrm{diag}(e^{i\theta}, e^{-i\theta})\}$; its centraliser is itself. Holonomy in this circle means that parallel transport preserves the two eigenlines, so the rank-2 bundle E splits:

$$E = L \oplus L^{-1}, \tag{8.221}$$

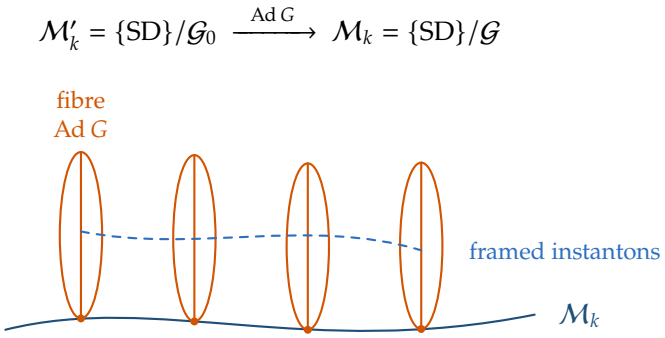

Figure 8.42: The framed moduli space $\mathcal{M}'_k$ is fibred over the moduli space $\mathcal{M}_k$. The fibre over an irreducible instanton is Ad G: all the ways of rotating the instanton in colour space relative to a fixed frame at the base point. For SU(2), $k = 1$ on S^4, the base is the 5-dimensional space of centres and sizes and the fibre is SO(3).

with L a complex line bundle carrying a U(1) connection α and L^{-1} carrying $-\alpha$ (this is Example 8.67(b)). The two lines must be inverse because $\det E$ is trivial for SU(2).

The topology of E is now determined by the topology of L. The total Chern class is multiplicative on direct sums (Chapter 4): writing $e = c_1(L) \in H^2(M;\mathbb{Z})$,

$$\begin{aligned} 1 + c_1(E) + c_2(E) &\overset{(1)}{=} c(L \oplus L^{-1}) \\ &\overset{(2)}{=} c(L)\, c(L^{-1}) \\ &\overset{(3)}{=} (1+e)(1-e) \\ &\overset{(4)}{=} 1 - e^2. \end{aligned}$$

(1) Definition of the total Chern class of E.
(2) Whitney product formula: $c(V \oplus W) = c(V)c(W)$.
(3) For a line bundle $c(L) = 1 + c_1(L)$, and $c_1(L^{-1}) = -c_1(L)$.
(4) Multiply out; $e \cdot e = e \cup e$ is a 4-dimensional class.

Comparing degrees: $c_1(E) = 0$ (as it must be for SU(2)) and $c_2(E) = -e^2$. So

$$k = -c_2(E)[M] = (e \cup e)[M] = q(e,e), \tag{8.222}$$

where q is the **intersection form** of M (Chapter 1): the symmetric bilinear form $q(a,b) = \int_M a \wedge b$ on $H^2(M;\mathbb{Z})$ (for de Rham representatives). Nash writes this $c_2(E) = -c_1(L) \cup c_1(L) = -q(c_1(L), c_1(L)) = -k$.

Key idea: Reducible SU(2) instantons live on classes with $q(e,e) = k$

A reducible charge-k SU(2) connection has $E = L \oplus L^{-1}$ with $e = c_1(L)$ satisfying $q(e,e) = k$. In particular $e \neq 0$, so we need $H^2(M;\mathbb{Z}) \neq 0$. If the connection is also self-dual, the curvature of L is a self-dual harmonic 2-form representing e (up to a factor $2\pi i$), so e lies in the positive part of the intersection form.

Worked example 8.69: No reducible instantons on S^4; some on $\mathbb{CP}^2$

S^4. $H^2(S^4;\mathbb{Z}) = 0$, so there is no non-trivial line bundle and $e = 0$, giving $k = 0$. Every instanton with $k \neq 0$ on S^4 is irreducible. (This is also visible directly: BPST is irreducible by Example 8.67(c).)

$\mathbb{CP}^2$. $H^2(\mathbb{CP}^2;\mathbb{Z}) = \mathbb{Z}$, generated by the hyperplane class h (the Poincaré dual of a line $\mathbb{CP}^1 \subset \mathbb{CP}^2$), with $q(h,h) = 1$: two lines meet in one point. A line bundle is $L = \mathcal{O}(n)$ with $e = nh$, and

$$k = q(nh, nh) = n^2.$$

So reducible SU(2) instantons can exist on $\mathbb{CP}^2$ exactly in the sectors $k = 1, 4, 9, \ldots$. For $k = 1$ the candidates are $n = \pm 1$, and these give the same reducible connection ($L \oplus L^{-1}$ and $L^{-1} \oplus L$ are exchanged by the Weyl reflection $\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \in \mathrm{SU}(2)$). The Fubini–Study metric has a self-dual harmonic 2-form (the Kähler form, with the complex orientation), which is the curvature of such a reducible instanton. So on $\mathbb{CP}^2$ the $k = 1$ moduli space contains exactly one reducible point. This is precisely the case Nash says "is not similarly excluded".

$S^2 \times S^2$. $H^2 = \mathbb{Z}^2$ with $q = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ (the two spheres meet once, and each has self-intersection 0). For $e = (m,n)$, $q(e,e) = 2mn$, so k must be even: reducibles appear only in the even sectors.

Try it: Counting reducibles through the intersection form

On the connected sum $\mathbb{CP}^2 \# \mathbb{CP}^2$, $H^2 = \mathbb{Z}^2$ with $q = \mathrm{diag}(1,1)$. How many reducible points (counted as pairs $\pm e$) does the $k = 1$ moduli space have? *Answer:* $q(e,e) = m^2 + n^2 = 1$ has solutions $\pm(1,0)$ and $\pm(0,1)$: two pairs, hence two reducible points. For the diagonal form $\mathrm{diag}(1,\ldots,1)$ of rank r there are exactly r pairs. This count is the engine of Donaldson's theorem (Section 8.11).

Watch out: Irreducible is not automatic for larger groups

For SU(2) the only way to be reducible is to split off a line bundle, and on S^4 this is impossible. For a big group G, a self-dual connection may have its holonomy in a proper subgroup $H \subset G$ for purely group theoretic reasons, even on S^4: e.g. the BPST instanton embedded in the upper-left 2×2 block of SU(3) has holonomy in $\mathrm{SU}(2) \subset \mathrm{SU}(3)$ and commutes with $\mathrm{diag}(e^{i\theta}, e^{i\theta}, e^{-2i\theta})$. This is why Nash's table of dimensions (8.137) comes with an "irreducibility restriction" column (Section 8.9.8).

Reading Nash (pp. 231–233 and 240, (8.86)–(8.92), (8.135)–(8.136))

Nash defines $\mathcal{M}_k \subset \mathcal{A}_k/\mathcal{G}_k$ ((8.86)–(8.87)) and then notes, citing Atiyah and Jones, that "there is a remaining invariance": change of base point $p_0 \in P_a$, i.e. the residual action of $G = \mathcal{G}/\mathcal{G}_0$ of (8.214). The centre acts trivially, so he uses $\mathrm{Ad}\, G = G/Z(G)$ and restricts to irreducible connections, getting (8.88), our (8.216). (8.89) is our (8.218); (8.90) is the statement that stabilisers commute with holonomy, our (8.219). (8.91)–(8.92) are the infinitesimal test (8.220) and the proof that $\exp(tf)$ then fixes A, which we did exactly rather than as a series. His $\mathcal{M}'_k$ "fibred over $\mathcal{M}_k$ with fibre Ad G" is (8.215). The remark on reducible SU(2) connections, (8.135)–(8.136), is Section 8.7.5.

Recap

- $\mathcal{M}_k$ = self-dual connections of charge k modulo gauge. The BPST family gives 5 parameters (centre, size); colour orientation is a gauge transformation, and for BPST it equals a spatial rotation.
- Gauge group $\mathcal{G}$ = based group $\mathcal{G}_0$ times constants G. The framed space $\mathcal{M}'_k = \{\text{SD}\}/\mathcal{G}_0$ keeps the colour frame at the base point; $\mathcal{M}_k = \mathcal{M}'_k/\operatorname{Ad} G$. For $k = 1$ on S^4: $\dim \mathcal{M}'_1 = 8$, $\dim \mathcal{M}_1 = 5$.
- Stabiliser Γ_A = covariantly constant gauge transformations $\cong$ centraliser of the holonomy group. The centre $Z(G)$ always fixes A; irreducible means nothing else does. Test: no non-zero f with $\mathrm{d}_A f = 0$; sufficient: the $F_{\mu\nu}$ at a point generate $\mathfrak{g}$.
- Reducible connections give cone singularities (link $\mathbb{CP}^{n-1}$ for a U(1) stabiliser). $\mathcal{G}_0$ acts freely, so $\mathcal{M}'_k$ avoids fixed points.
- A reducible SU(2) instanton is $L \oplus L^{-1}$ with $q(c_1 L, c_1 L) = k$: none on S^4; one for $k = 1$ on $\mathbb{CP}^2$; r for the diagonal form of rank r.

8.8 The deformation complex

How many parameters does the general instanton have? Nash answers this the way one computes the dimension of any solution space: work *infinitesimally*. The dimension of a smooth space equals the dimension of its tangent space at any point. So take one instanton A, perturb it to $A + ta$, and ask which perturbations a keep it self-dual (to first order) and are not merely gauge transformations. Those a form the tangent space $T_{[A]}\mathcal{M}_k$. The advantage, as Nash says, is that the dimension of this tangent space can be computed by the index theorem.

The same strategy computes the dimension of the moduli space $\mathcal{M}_p$ of Riemann surfaces of genus p (Chapter 5): there one linearises the condition of being a complex structure and quotients by diffeomorphisms, and Riemann–Roch gives $\dim_{\mathbb{C}} \mathcal{M}_p = 3p - 3$. We compare the two at the end of the section.

The physicist knows this calculation as the counting of **zero modes**. Expand the action around the instanton, $S(A + a) = S(A) + \frac{1}{2}\langle a, \mathcal{K}a\rangle + \dots$; after gauge fixing, the zero eigenvectors of the fluctuation operator $\mathcal{K}$ are exactly the tangent vectors to the moduli space, and their number is the number of collective coordinates.

8.8.1 Tangent vectors: the two requirements

Let $A_t = A + ta$ be a one-parameter family of connections through A. Its velocity $a = \frac{\mathrm{d}}{\mathrm{d}t}A_t|_{t=0}$ is a tangent vector to the space of connections,

$$a \in T_A\mathcal{A}_k = \Omega^1(M, \operatorname{ad} P) \qquad \text{(Nash's (8.93))}.$$

Write $[A]$ for the point of $\mathcal{M}_k$ represented by A. We want to produce from a an element of $T_{[A]}\mathcal{M}_k$ (Nash's (8.94)). Two things must be done:

1. the family must stay self-dual: a must solve the *linearised* self-duality equation;
2. we must throw away the a's that point along the gauge orbit, i.e. those in $T_A(\mathcal{G}\cdot A) = \operatorname{Im} \mathrm{d}_A$ ((8.210)).

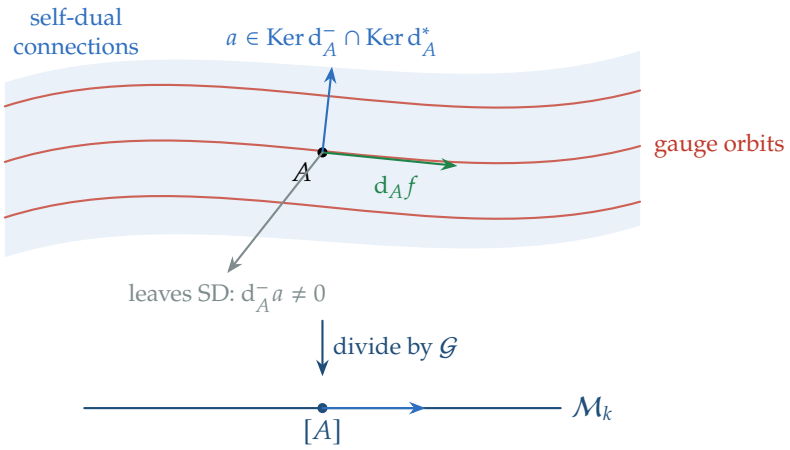

Figure 8.43: The tangent space to the moduli space. Inside the space of connections, the self-dual ones form a (blue) sheet, made of whole gauge orbits (red). A perturbation a of A must stay in the sheet to first order ($\mathrm{d}_A^- a = 0$) and should not point along the orbit. Taking the component orthogonal to the orbit ($\mathrm{d}_A^* a = 0$) gives one representative of each tangent vector of $\mathcal{M}_k$ at $[A]$.

8.8.2 Linearising the self-duality equation

Self-duality says the anti-self-dual part of F vanishes. With the projector $\pi_- \omega = \frac{1}{2}(\omega - \star\omega)$ of (8.180) (Nash's (8.95)), the equation is

$$\pi_- F(A) = 0 \qquad \text{(Nash's (8.96))}. \tag{8.223}$$

Substitute $A + ta$ (Nash's (8.97)) and expand the curvature:

$$\begin{aligned} F(A+ta) &\overset{(1)}{=} \mathrm{d}(A+ta) + (A+ta)\wedge(A+ta) \\ &\overset{(2)}{=} \mathrm{d}A + A\wedge A + t\big(\mathrm{d}a + A\wedge a + a\wedge A\big) + t^2\, a\wedge a \\ &\overset{(3)}{=} F(A) + t\,\mathrm{d}_A a + t^2\, a\wedge a. \end{aligned} \tag{8.224}$$

(1) Definition $F = \mathrm{d}A + A\wedge A$.
(2) Expand; the order of the matrix-valued forms in $A\wedge a$ and $a\wedge A$ must be kept.
(3) $\mathrm{d}_A a = \mathrm{d}a + A\wedge a + a\wedge A$ is (8.164) for $p = 1$.

This is Nash's (8.98) (and our (8.168)). If A and every $A + ta$ are self-dual,

$$\begin{aligned} 0 &\overset{(1)}{=} \pi_- F(A+ta) \\ &\overset{(2)}{=} \pi_- F(A) + t\,\pi_-(\mathrm{d}_A a) + t^2\,\pi_-(a\wedge a) \\ &\overset{(3)}{=} t\,\pi_-(\mathrm{d}_A a) + t^2\,\pi_-(a\wedge a). \end{aligned}$$

(1) $A + ta$ is self-dual.
(2) (8.224) and linearity of π_-.
(3) A is self-dual.

Divide by t and let $t \to 0$ (Nash's (8.99)–(8.100)):

Working definition 8.32 (the linearised self-duality operator)

$$\mathrm{d}_A^- := \pi_- \circ \mathrm{d}_A : \ \Omega^1(M, \mathrm{ad}\, P) \to \Omega^2_-(M, \mathrm{ad}\, P), \qquad \text{tangent vectors satisfy} \qquad \mathrm{d}_A^- a = 0. \tag{8.225}$$

(Nash's (8.101).) *To compute:* form the 2-form $\mathrm{d}_A a$, with components $(\mathrm{d}_A a)_{\mu\nu} = D_\mu a_\nu - D_\nu a_\mu$, and take its anti-self-dual part: three components per colour [for each of the $\mathfrak{su}(2)$ directions e_1, e_2, e_3 separately], along $\omega_1^-, \omega_2^-, \omega_3^-$.

Worked example 8.70: The linearised operator in $\vec{E}, \vec{B}$ language

Take $G = \mathrm{U}(1)$ (or one colour component) and $A = 0$ on $\mathbb{R}^4$, so $\mathrm{d}_A a = \mathrm{d}a = f$ with $f_{\mu\nu} = \partial_\mu a_\nu - \partial_\nu a_\mu$. With $E_j = f_{j4}$ and $B_j = \frac{1}{2}\varepsilon_{jkl} f_{kl}$ as in Section 8.4,

$$\begin{aligned} f &\overset{(1)}{=} \sum_j E_j \, \mathrm{d}x^{j4} + \sum_j B_j \, \tfrac{1}{2}\varepsilon_{jkl} \mathrm{d}x^{kl} \\ &\overset{(2)}{=} \sum_j \Big(E_j \, \tfrac{1}{2}(\omega_j^+ - \omega_j^-) + B_j \, \tfrac{1}{2}(\omega_j^+ + \omega_j^-) \Big) \\ &\overset{(3)}{=} \sum_j \tfrac{1}{2}(E_j + B_j)\, \omega_j^+ + \sum_j \tfrac{1}{2}(B_j - E_j)\, \omega_j^- . \end{aligned}$$

(1) The $\vec{E}, \vec{B}$ decomposition of a 2-form (Section 8.4).
(2) Invert the basis (8.181): $\omega_j^\pm = \pm \mathrm{d}x^{j4} + \frac{1}{2}\varepsilon_{jkl}\mathrm{d}x^{kl}$, so $\mathrm{d}x^{j4} = \frac{1}{2}(\omega_j^+ - \omega_j^-)$ and $\frac{1}{2}\varepsilon_{jkl}\mathrm{d}x^{kl} = \frac{1}{2}(\omega_j^+ + \omega_j^-)$.
(3) Collect.

So $\mathrm{d}^- a = \frac{1}{2}\sum_j (B_j - E_j)\, \omega_j^-$, and the linearised self-duality equation is $\vec{E} = \vec{B}$ for the perturbation: three first-order equations,

$$\partial_j a_4 - \partial_4 a_j = (\nabla \times \vec{a})_j, \qquad j = 1, 2, 3,$$

for four unknown functions $a_1, \ldots, a_4$. The deficit of one equation is made up by the gauge condition, as we shall see.

8.8.3 Removing the gauge directions

The second requirement is to discard perturbations of the form $a = \mathrm{d}_A f$. First, these *do* solve the linearised equation. This is forced by gauge invariance, and it is the key algebraic fact of the section:

$$\mathrm{d}_A^- \circ \mathrm{d}_A = 0 \qquad \text{on } \Omega^0(M, \mathrm{ad}\, P) \qquad \text{(Nash's (8.105))}. \tag{8.226}$$

We check it twice below (Section 8.8.4). Granting it, the space of genuine deformations is the quotient

$$T_{[A]}\mathcal{M}_k \ \cong \ \frac{\mathrm{Ker}\, \mathrm{d}_A^-}{\mathrm{Im}\, \mathrm{d}_A} \qquad \text{(Nash's (8.102))}: \tag{8.227}$$

solutions of the linearised equation, where two solutions are identified if they differ by an infinitesimal gauge transformation.

A quotient is awkward to compute with. The slice of Section 8.6.4 turns it into a subspace:

Key idea: Harmonic representatives of deformations

Each class in $\operatorname{Ker} \mathrm{d}_A^- / \operatorname{Im} \mathrm{d}_A$ has exactly one representative in the background gauge. Hence

$$T_{[A]}\mathcal{M}_k \;\cong\; \operatorname{Ker} \mathrm{d}_A^- \cap \operatorname{Ker} \mathrm{d}_A^* = \{a : \; \mathrm{d}_A^- a = 0, \; \mathrm{d}_A^* a = 0\}. \tag{8.228}$$

These are the *zero modes* of the instanton in background gauge.

Why: let $\mathrm{d}_A^- a = 0$. Split $a = \mathrm{d}_A f + a^\perp$ with $\mathrm{d}_A^* a^\perp = 0$ ((8.211)). Then

$$\begin{aligned} \mathrm{d}_A^- a^\perp &\overset{(1)}{=} \mathrm{d}_A^- a - \mathrm{d}_A^- \mathrm{d}_A f \\ &\overset{(2)}{=} 0 - 0, \end{aligned}$$

(1) Linearity of d_A^- and $a^\perp = a - \mathrm{d}_A f$.
(2) $a \in \operatorname{Ker} \mathrm{d}_A^-$, and (8.226).

so $a^\perp$ is in the intersection and represents the same class as a. It is unique: if $a_1^\perp, a_2^\perp$ are two such representatives, their difference is both in $\operatorname{Im} \mathrm{d}_A$ and in $\operatorname{Ker} \mathrm{d}_A^* = (\operatorname{Im} \mathrm{d}_A)^\perp$, so it is orthogonal to itself and vanishes.

8.8.4 The complex and the check $\mathrm{d}_A^- \circ \mathrm{d}_A = 0$

Let us name the spaces precisely. The perturbation a is a Lie-algebra-valued 1-form that transforms by conjugation, $a \mapsto g^{-1} a g$ (Section 8.3.1). So it is a section of the bundle

$$\operatorname{ad} P \otimes \Lambda^1 T^* M \qquad \text{(Nash's (8.103))} : \tag{8.229}$$

the first factor makes a transform correctly under gauge transformations, the second makes it a 1-form. Write $\Omega^i(M, \operatorname{ad} P) = \Gamma(M, \operatorname{ad} P \otimes \Lambda^i T^* M)$, and $\Omega^2_-(M, \operatorname{ad} P)$ for the anti-self-dual 2-forms. The three operators we have met fit into a sequence:

Key idea: The instanton deformation complex (Nash's (8.104))

$$0 \longrightarrow \Omega^0(M, \operatorname{ad} P) \xrightarrow{\mathrm{d}_A} \Omega^1(M, \operatorname{ad} P) \xrightarrow{\mathrm{d}_A^-} \Omega^2_-(M, \operatorname{ad} P) \longrightarrow 0. \tag{8.230}$$

Reading from left to right: infinitesimal gauge transformations f; perturbations a of the connection; perturbations of the ASD part of the curvature. It is a **complex**: two successive maps compose to zero, (8.226). It is **elliptic**: at the level of symbols, the sequence is exact (Example 8.71).

Check 1: the gauge argument (Nash's (8.107)). $\mathrm{d}_A f$ is the change in A under an infinitesimal gauge transformation e^{tf}, by (8.210). The curvature then changes by conjugation: $F \mapsto e^{-tf} F e^{tf} = F + t[F, f] + O(t^2)$. By (8.224) the same change is $t\, \mathrm{d}_A(\mathrm{d}_A f) + O(t^2)$. A gauge transform of a self-dual curvature is self-dual (because $\star$ acts on the form indices and conjugation on the matrix indices, so they commute). Hence

$$\begin{aligned} 0 &\overset{(1)}{=} \pi_-\left(e^{-tf} F e^{tf}\right) \\ &\overset{(2)}{=} \pi_- F + t\, \pi_-(\mathrm{d}_A \mathrm{d}_A f) + O(t^2) \\ &\overset{(3)}{=} t\, \mathrm{d}_A^- \mathrm{d}_A f + O(t^2), \end{aligned}$$

(1) The gauge-transformed field is still self-dual.

(2) The first-order change of F is $t\,\mathrm{d}_A\mathrm{d}_A f$.
(3) $\pi_- F = 0$, and the definition of d_A^-.

and the coefficient of t must vanish.

Check 2: explicitly (Nash's (8.108)). We use Nash's footnote formula $\mathrm{d}_A\omega = \mathrm{d}\omega + A\wedge\omega + (-1)^{p+1}\omega\wedge A$ for an $\mathrm{ad}\,P$-valued p-form, which is our (8.164).

$$\begin{aligned}
\mathrm{d}_A\mathrm{d}_A f &\overset{(1)}{=} \mathrm{d}(\mathrm{d}_A f) + A\wedge \mathrm{d}_A f + \mathrm{d}_A f\wedge A \\
&\overset{(2)}{=} \mathrm{d}(\mathrm{d}f + Af - fA) + A\wedge(\mathrm{d}f + Af - fA) + (\mathrm{d}f + Af - fA)\wedge A \\
&\overset{(3)}{=} \big(\mathrm{d}A\,f - A\wedge \mathrm{d}f - \mathrm{d}f\wedge A - f\,\mathrm{d}A\big) \\
&\qquad + \big(A\wedge \mathrm{d}f + A\wedge A\,f - A\,f\wedge A\big) + \big(\mathrm{d}f\wedge A + A\,f\wedge A - f\,A\wedge A\big) \\
&\overset{(4)}{=} (\mathrm{d}A + A\wedge A)\,f - f\,(\mathrm{d}A + A\wedge A) \\
&\overset{(5)}{=} Ff - fF = [F, f].
\end{aligned}$$

(1) The formula with $p=1$: $(-1)^{p+1} = +1$.
(2) $\mathrm{d}_A f = \mathrm{d}f + [A, f] = \mathrm{d}f + Af - fA$ (the case $p=0$).
(3) $\mathrm{d}\mathrm{d}f = 0$; Leibniz: $\mathrm{d}(Af) = \mathrm{d}A\,f - A\wedge\mathrm{d}f$ and $\mathrm{d}(fA) = \mathrm{d}f\wedge A + f\,\mathrm{d}A$ (a sign whenever d passes the 1-form A).
(4) Cancel in pairs: $\pm A\wedge\mathrm{d}f$, $\pm\mathrm{d}f\wedge A$, $\pm Af\wedge A$.
(5) Definition of F.

Now project. Since f is a 0-form, π_- acts only on the form part of F, so $\pi_-(Ff - fF) = (\pi_- F)f - f(\pi_- F)$, and

$$\mathrm{d}_A^-\mathrm{d}_A f = [\pi_- F, f] = 0 \qquad \text{because } \pi_- F = 0.$$

The identity $\mathrm{d}_A\mathrm{d}_A = [F, \cdot\,]$ is the covariant version of $\mathrm{d}\mathrm{d} = 0$: *the curvature is the obstruction to* $\mathrm{d}_A^2 = 0$. So the complex (8.230) closes precisely because $F^- = 0$. If we had used the full d_A into all 2-forms, $\mathrm{d}_A\mathrm{d}_A f = [F, f] \neq 0$ and we would not have a complex. This is why instantons (and flat connections) are special.

Worked example 8.71: Ellipticity of the complex: exactness of the symbol sequence

An elliptic complex is one whose symbol sequence is exact for every $\xi \neq 0$ (Chapter 2). Take $\xi = (0,0,0,1)$, i.e. the covector $\mathrm{d}x^4$, and one colour component. The symbols are obtained by replacing d with $i\xi\wedge$:

$$\sigma_0(\xi)f = i\,f\,\mathrm{d}x^4, \qquad \sigma_1(\xi)a = \pi_-\big(i\,\mathrm{d}x^4\wedge a\big).$$

Compute σ_1 on $a = a_\mu \mathrm{d}x^\mu$:

$$\begin{aligned}
\pi_-\big(\mathrm{d}x^4\wedge a\big) &\overset{(1)}{=} \pi_-\Big(\sum_{j=1}^{3} a_j\,\mathrm{d}x^4\wedge\mathrm{d}x^j\Big) \\
&\overset{(2)}{=} -\sum_j a_j\,\pi_-\big(\mathrm{d}x^{j4}\big) \\
&\overset{(3)}{=} -\sum_j a_j\,\pi_-\big(\tfrac12(\omega_j^+ - \omega_j^-)\big) \\
&\overset{(4)}{=} \tfrac12\sum_j a_j\,\omega_j^-.
\end{aligned}$$

(1) $\mathrm{d}x^4 \wedge \mathrm{d}x^4 = 0$ kills the a_4 term.
(2) $\mathrm{d}x^4 \wedge \mathrm{d}x^j = -\mathrm{d}x^{j4}$.
(3) $\mathrm{d}x^{j4} = \tfrac{1}{2}(\omega_j^+ - \omega_j^-)$, as in Example 8.70.
(4) $\pi_- \omega_j^+ = 0$, $\pi_- \omega_j^- = \omega_j^-$.

In the bases $\{1\}$, $\{\mathrm{d}x^1, \dots, \mathrm{d}x^4\}$, $\{\omega_1^-, \omega_2^-, \omega_3^-\}$ the symbol sequence is

$$0 \to \mathbb{C} \xrightarrow{\sigma_0 = i\begin{pmatrix}0\\0\\0\\1\end{pmatrix}} \mathbb{C}^4 \xrightarrow{\sigma_1 = \frac{i}{2}\begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\end{pmatrix}} \mathbb{C}^3 \to 0.$$

- $\sigma_1 \sigma_0 = 0$: the complex property at the symbol level.
- $\operatorname{Ker}\sigma_0 = 0$; $\operatorname{Ker}\sigma_1 = \operatorname{span}(\mathrm{d}x^4) = \operatorname{Im}\sigma_0$; $\operatorname{Im}\sigma_1 = \mathbb{C}^3$. So the sequence is exact everywhere.
- Dimension check: $1 - 4 + 3 = 0$, as it must be for an exact sequence.

Physically: of the four polarisations of a plane wave, one is longitudinal (pure gauge, $\operatorname{Im}\sigma_0$) and three are hit by the linearised equation. None is missed. That is the precise sense in which "self-duality plus gauge fixing" is a determined elliptic system. For SU(2) every space is tensored with $\mathfrak{su}(2) \cong \mathbb{R}^3$: ranks $3 \to 12 \to 9$.

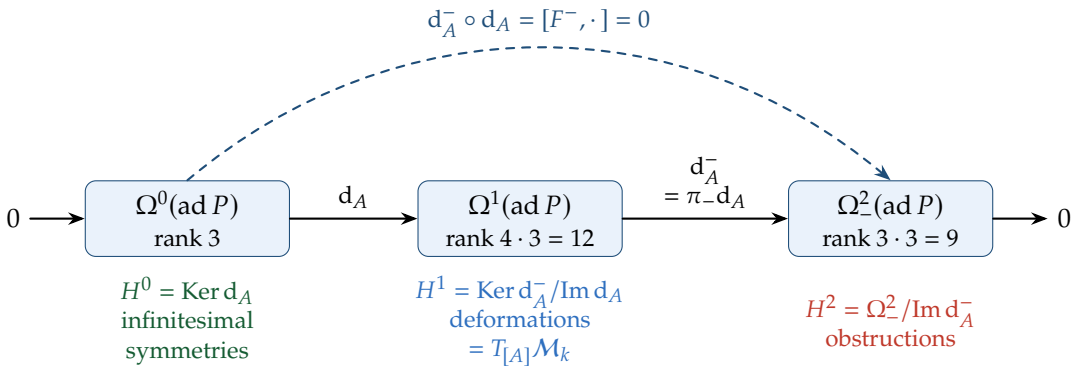

Figure 8.44: The instanton deformation complex for $G = \mathrm{SU}(2)$, with the ranks of the bundles (per point of M). Each cohomology group has a meaning: H^0 counts gauge transformations fixing A (zero when A is irreducible), H^1 is the tangent space to the moduli space, H^2 measures the failure of first-order deformations to extend (zero under the hypotheses of Atiyah–Hitchin–Singer). The composite of the two maps is the anti-self-dual curvature, so the sequence is a complex exactly when A is self-dual.

8.8.5 Cohomology of the complex and the index

Because two successive maps compose to zero, the image of each map lies in the kernel of the next, and we may form quotients. Denote the complex (8.230) by $\Omega_-(M, \mathrm{ad}\,P)$ and write $\mathrm{d}_A^{(p)}$ for d_A acting on $\mathrm{ad}\,P \otimes \Lambda^p T^*M$.

Working definition 8.33 (cohomology of the deformation complex (Nash's (8.109)))

$$H^0 = \operatorname{Ker}\mathrm{d}_A^{(0)}, \qquad h_0 = \dim H^0,$$

$$H^1 = \operatorname{Ker} \mathrm{d}_A^- / \operatorname{Im} \mathrm{d}_A^{(0)}, \qquad h_1 = \dim H^1,$$
$$H^2 = \Omega_-^2(M, \operatorname{ad} P) / \operatorname{Im} \mathrm{d}_A^-, \qquad h_2 = \dim H^2.$$

(Nash writes $H^2 = \operatorname{Ker} \pi_+ / \operatorname{Im} \mathrm{d}_A^-$: the next map in the complex is the zero map $\pi_+ : \Omega_-^2 \to 0$, whose kernel is all of Ω_-^2.) *To compute* each h_i: use harmonic representatives [in each class, the one element L^2-orthogonal to the image of the previous map]. $H^0 = \operatorname{Ker} \mathrm{d}_A$, $H^1 \cong \operatorname{Ker} \mathrm{d}_A^- \cap \operatorname{Ker} \mathrm{d}_A^*$ ((8.228)), and $H^2 \cong \operatorname{Ker}(\mathrm{d}_A^-)^*$ [$(\mathrm{d}_A^-)^*$ is the adjoint of d_A^- for the L^2 inner products] (the orthogonal complement of the image).

We want $h_1 = \dim T_{[A]}\mathcal{M}_k = \dim \mathcal{M}_k$ (Nash's (8.110)). The index theorem does not give h_1 directly; it gives the alternating sum

$$\text{index(complex)} = h_0 - h_1 + h_2 \qquad \text{(Nash's (8.111))}. \tag{8.231}$$

Why an alternating sum? Because the alternating sum is stable: it does not change when the operators are deformed, whereas the individual h_i can jump. The finite-dimensional version shows the mechanism.

Worked example 8.72: Euler characteristic of a finite-dimensional complex

Let $0 \to V_0 \xrightarrow{d_0} V_1 \xrightarrow{d_1} V_2 \to 0$ be finite-dimensional with $d_1 d_0 = 0$. Write $n_i = \dim V_i$, $r_0 = \operatorname{rank} d_0$, $r_1 = \operatorname{rank} d_1$.

$$\begin{aligned} h_0 - h_1 + h_2 &\overset{(1)}{=} (n_0 - r_0) - \big((n_1 - r_1) - r_0\big) + (n_2 - r_1) \\ &\overset{(2)}{=} n_0 - n_1 + n_2. \end{aligned}$$

(1) Rank–nullity: $h_0 = \dim \operatorname{Ker} d_0 = n_0 - r_0$; $h_1 = \dim \operatorname{Ker} d_1 - \dim \operatorname{Im} d_0 = (n_1 - r_1) - r_0$; $h_2 = n_2 - \dim \operatorname{Im} d_1 = n_2 - r_1$.

(2) The ranks cancel.

The alternating sum of cohomology dimensions depends only on the dimensions of the spaces, not on the maps. Concretely, with $V_0 = \mathbb{R}$, $V_1 = \mathbb{R}^3$, $V_2 = \mathbb{R}$, $d_0 = (1,0,0)^T$ and $d_1 = (0, s, 0)$: for $s \neq 0$ we get $(h_0, h_1, h_2) = (0, 1, 0)$; for $s = 0$ we get $(0, 2, 1)$. The individual numbers jump, but $h_0 - h_1 + h_2 = -1 = 1 - 3 + 1$ in both cases. In infinite dimensions the n_i are infinite, and the index theorem is the tool that computes the stable combination anyway.

The moral for instantons: if we can show $h_0 = 0$ and $h_2 = 0$, then $h_1 = -\text{index}$, and the index theorem gives $\dim \mathcal{M}_k$. We now show both vanish, under hypotheses.

Worked example 8.73: Why H^2 is called the obstruction space: a toy model

Consider solving $\Phi(x) = 0$ for a smooth map $\Phi : \mathbb{R}^n \to \mathbb{R}^m$ near a solution x_0. The linearisation $L = \Phi'(x_0)$ plays the role of d_A^-. If L is onto ($\operatorname{Coker} L = 0$), the implicit function theorem says the solutions near x_0 form a manifold of dimension $\dim \operatorname{Ker} L = n - m$. If L is not onto, first-order solutions may fail to extend. The simplest case: $n = m = 1$, $\Phi(x) = x^2$ at $x_0 = 0$. Then $L = 0$, so $\operatorname{Ker} L = \mathbb{R}$ (one first-order deformation) and $\operatorname{Coker} L = \mathbb{R}$ (one obstruction), but the true solution set is the single point $\{0\}$. The second-order term x^2 is what the cokernel measures. Note that $\dim \operatorname{Ker} L - \dim \operatorname{Coker} L = 0 = n - m$ still gives the "expected" dimension correctly. For instantons the second-order term is $\pi_-(a \wedge a)$ in (8.224), and H^2 is where it lives.

8.8.6 The deformation operator as a quaternionic Cauchy–Riemann operator

It helps to see the deformation problem as a single square system. Combine the linearised equation and the gauge condition:

$$\mathcal{D}_A = \mathrm{d}_A^* \oplus \mathrm{d}_A^- : \ \Omega^1(M, \mathrm{ad}\, P) \to \Omega^0(M, \mathrm{ad}\, P) \oplus \Omega^2_-(M, \mathrm{ad}\, P), \qquad T_{[A]}\mathcal{M}_k \cong \operatorname{Ker} \mathcal{D}_A .$$

Four unknowns per colour, $1 + 3 = 4$ equations per colour. Its adjoint $\mathcal{D}_A^* = \mathrm{d}_A + (\mathrm{d}_A^-)^*$ is exactly the operator D that Nash introduces in (8.114) (Section 8.9.1). On flat $\mathbb{R}^4$ with $A = 0$ the operator $\mathcal{D}$ has a beautiful form in quaternions.

Worked example 8.74: The Fueter operator

Package the four components of $a = a_\mu \mathrm{d}x^\mu$ (one colour) into the quaternion $\bar{a} = a_4 \mathbb{1} - a_k e_k$, with the matrices e_k of Section 8.5.1, and define the **Fueter operator** $\mathfrak{D} = \partial_4 + e_j \partial_j$. Then

$$\begin{aligned} \mathfrak{D}\bar{a} &\overset{(1)}{=} (\partial_4 + e_j\partial_j)(a_4 - e_k a_k) \\ &\overset{(2)}{=} \partial_4 a_4 - e_k \partial_4 a_k + e_j \partial_j a_4 - e_j e_k\, \partial_j a_k \\ &\overset{(3)}{=} \partial_4 a_4 + \partial_k a_k + e_l\big(\partial_l a_4 - \partial_4 a_l - \varepsilon_{jkl}\partial_j a_k\big) \\ &\overset{(4)}{=} \partial_\mu a_\mu + e_l\big(E_l - B_l\big). \end{aligned}$$

(1) Definitions.
(2) Expand; the e's are constant.
(3) $e_j e_k = -\delta_{jk}\mathbb{1} + \varepsilon_{jkl} e_l$ by (8.193); rename indices.
(4) $E_l = f_{l4} = \partial_l a_4 - \partial_4 a_l$ and $B_l = \frac{1}{2}\varepsilon_{lmn} f_{mn} = \varepsilon_{lmn}\partial_m a_n = \varepsilon_{jkl}\partial_j a_k$.

The real part is $\partial_\mu a_\mu = -\mathrm{d}^* a$ (the gauge condition) and the imaginary part is $\vec{E} - \vec{B}$, i.e. $-2\times$ the components of $\mathrm{d}^- a$ along ω_l^- (Example 8.70). So

$$\mathcal{D}a = 0 \iff \mathfrak{D}\bar{a} = 0 :$$

the zero modes of a flat-space instanton problem are the solutions of a quaternionic Cauchy–Riemann equation. The analogy with complex analysis is exact: $\partial_{\bar z} = \frac{1}{2}(\partial_x + i\partial_y)$, and a function of z is holomorphic iff it is killed by $\partial_{\bar z}$.
The Fueter operator is elliptic: its symbol $i(\xi_4 + e_j\xi_j)$ is i times a quaternion of length $|\xi|$, invertible for $\xi \neq 0$. And it squares to the Laplacian. With $\bar{\mathfrak{D}} = \partial_4 - e_j\partial_j$,

$$\begin{aligned} \bar{\mathfrak{D}}\mathfrak{D} &\overset{(1)}{=} \partial_4^2 + (e_j - e_j)\partial_4\partial_j - e_j e_k\, \partial_j\partial_k \\ &\overset{(2)}{=} \partial_4^2 + \delta_{jk}\partial_j\partial_k - \varepsilon_{jkl} e_l\, \partial_j\partial_k \\ &\overset{(3)}{=} \Box. \end{aligned}$$

(1) Expand; the e_j are constants.
(2) The product rule (8.193).
(3) $\partial_j\partial_k$ is symmetric and ε_{jkl} antisymmetric.

This is the quaternionic analogue of $4\partial_z\partial_{\bar z} = \partial_x^2 + \partial_y^2$. It is also the Dirac operator in disguise: in the spinor language of Chapter T4, $\Lambda^1 \otimes \mathbb{C} \cong S^+ \otimes S^-$ and $\Lambda^0 \oplus \Lambda^2_- \cong S^- \otimes S^-$, and $\mathcal{D}$ is the Dirac operator acting on S^+ twisted by S^-. We shall use this identification to understand the index formula (Section 8.9.2).

8.8.7 The vanishing theorems: $h_0 = 0$ and $h_2 = 0$

$h_0 = 0$: irreducibility

$H^0 = \operatorname{Ker} d_A^{(0)}$ is the space of covariantly constant sections f of $\operatorname{ad} P$. By Section 8.7.3 a non-zero such f exists exactly when A is reducible. We restrict to irreducible connections, so $h_0 = 0$. On S^4 with $G = \mathrm{SU}(2)$ this costs nothing (Example 8.69).

$h_2 = 0$: a Weitzenböck positivity argument

H^2 is the orthogonal complement of $\operatorname{Im} d_A^-$ in Ω^2_-, i.e. $\operatorname{Ker}(d_A^-)^*$. To show it is zero, Nash follows Atiyah, Hitchin and Singer: show that the Laplacian on $\Omega^2_-(\operatorname{ad} P)$ built from the complex,

$$\Delta_A^{(2)} = d_A^-(d_A^-)^* + \pi_+\pi_+^* \qquad \text{(Nash's (8.112))}, \tag{8.232}$$

is positive definite. (The term $\pi_+\pi_+^*$ is zero: it is the Laplacian term from the zero map $\Omega^2_- \to 0$ at the end of the complex. It is written only to show the pattern "$dd^* + d^*d$".) If $\Delta_A^{(2)}$ is positive then $\operatorname{Ker}\Delta_A^{(2)} = 0$, and since $\langle \Delta_A^{(2)}\omega, \omega\rangle = \left\|(d_A^-)^*\omega\right\|^2$, also $\operatorname{Ker}(d_A^-)^* = 0$, i.e. $h_2 = 0$.

The tool is a **Weitzenböck formula**: an identity expressing a Laplacian built from d's as a "rough" Laplacian $\nabla^*\nabla$ plus curvature terms with no derivatives. The prototype is the Bochner formula on 1-forms, $(\mathrm{dd}^* + \mathrm{d}^*\mathrm{d})\omega = \nabla^*\nabla\omega + \mathrm{Ric}(\omega)$, which shows that a manifold of positive Ricci curvature has no harmonic 1-forms ($b_1 = 0$). For our operator the result is:

Key idea: Weitzenböck formula on $\Omega^2_-(\operatorname{ad} P)$ (Nash's (8.113))

For a self-dual connection A,

$$\Delta_A^{(2)} = d_A^-(d_A^-)^* = \tfrac{1}{2}\nabla_A^*\nabla_A + \frac{R}{6} - W_-. \tag{8.233}$$

Here ∇_A is the covariant derivative on $\operatorname{ad} P \otimes \Lambda^2_-$ built from A and the Levi-Civita connection, $\nabla_A^*\nabla_A = -D_\mu D_\mu$ is the rough Laplacian (a non-negative operator), R is the scalar curvature of M, and W_- is the anti-self-dual part of the Weyl tensor, acting on Λ^2_- as a symmetric traceless 3×3 matrix. A term $[F^-, \cdot\,]$ also appears in general; it vanishes because A is self-dual.

With it, positivity is one line: for $\omega \in \Omega^2_-(\operatorname{ad} P)$,

$$\begin{aligned}
\left\|(d_A^-)^*\omega\right\|^2 &\overset{(1)}{=} \langle \Delta_A^{(2)}\omega, \omega\rangle \\
&\overset{(2)}{=} \tfrac{1}{2}\left\|\nabla_A\omega\right\|^2 + \int_M \frac{R}{6}\,|\omega|^2 - \langle W_-\omega, \omega\rangle \\
&\overset{(3)}{=} \tfrac{1}{2}\left\|\nabla_A\omega\right\|^2 + \int_M \frac{R}{6}\,|\omega|^2 \\
&\overset{(4)}{>} 0 \qquad \text{unless } \omega = 0.
\end{aligned}$$

(1) Definition of the adjoint, $\langle d_A^-(d_A^-)^*\omega, \omega\rangle = \langle (d_A^-)^*\omega, (d_A^-)^*\omega\rangle$.
(2) The Weitzenböck formula, and $\langle \nabla^*\nabla\omega, \omega\rangle = \|\nabla\omega\|^2$.
(3) Assumption: $W_- = 0$ (M is **self-dual**).
(4) Assumption: $R > 0$ everywhere.

So under the two assumptions $W_- = 0$ and $R > 0$, $h_2 = 0$. Nash, following Atiyah–Hitchin–Singer, makes these assumptions from now on.

Worked example 8.75: The flat-space check of the Weitzenböck formula

On $\mathbb{R}^4$ with $A = 0$ we have $R = 0$, $W_- = 0$ and $\nabla^*\nabla = -\Box$, so (8.233) predicts $\mathrm{d}^-(\mathrm{d}^-)^* = -\frac{1}{2}\Box$ on ASD forms. Let ω be an ASD 2-form, $\star\omega = -\omega$. Then $(\mathrm{d}^-)^*\omega = \mathrm{d}^*\omega$ (since π_- is self-adjoint and $\pi_-\omega = \omega$), and

$$\begin{aligned} \mathrm{d}^*\mathrm{d}\,\omega &\overset{(1)}{=} -\star\,\mathrm{d}\star\,\mathrm{d}\omega \\ &\overset{(2)}{=} \star\,\mathrm{d}\,\mathrm{d}^*\star\,\omega \\ &\overset{(3)}{=} -\star\,(\mathrm{d}\mathrm{d}^*\omega), \end{aligned}$$

(1) $\mathrm{d}^* = -\star\,\mathrm{d}\star$ on forms of every degree in four dimensions ((8.176)).
(2) On the 2-form $\star\omega$: $\mathrm{d}^*\star\omega = -\star\mathrm{d}\star\star\omega = -\star\mathrm{d}\omega$, so $\star\mathrm{d}\omega = -\mathrm{d}^*\star\omega$ and $\mathrm{d}\star\mathrm{d}\omega = -\mathrm{d}\mathrm{d}^*\star\omega$.
(3) $\star\omega = -\omega$.

Apply π_-, using $\pi_-\star = -\pi_-$: $\pi_-(\mathrm{d}^*\mathrm{d}\omega) = \pi_-(\mathrm{d}\mathrm{d}^*\omega)$. Adding,

$$2\,\pi_-(\mathrm{d}\mathrm{d}^*\omega) = \pi_-\big((\mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d})\omega\big) = \pi_-(-\Box\omega) = -\Box\omega,$$

because the Hodge Laplacian on flat space is $-\Box$ acting on each component, and it preserves ASD forms. Hence $\mathrm{d}^-(\mathrm{d}^-)^*\omega = \pi_-\mathrm{d}\mathrm{d}^*\omega = -\frac{1}{2}\Box\omega$, as predicted. The factor $\frac{1}{2}$ in Nash's formula is exactly this halving: only half of the Hodge Laplacian is seen on one chirality.

Worked example 8.76: Which manifolds satisfy $W_- = 0$, $R > 0$?

- S^4, *round metric of radius* ρ. Constant sectional curvature $1/\rho^2$, so $R = n(n-1)/\rho^2 = 12/\rho^2 > 0$, and the whole Weyl tensor vanishes (it is conformally flat). Both conditions hold. On Λ^2_- the Weitzenböck potential is $R/6 = 2/\rho^2$.
- $\mathbb{CP}^2$ *with the Fubini–Study metric* and its complex orientation: $W_- = 0$ (it is self-dual, though $W_+ \neq 0$) and $R > 0$. This is the other main example; its intersection form is $(+1)$.
- *The flat torus* T^4: $R = 0$, $W = 0$. The argument gives only $\|(\mathrm{d}^-)^*\omega\|^2 = \frac{1}{2}\|\nabla\omega\|^2 \geq 0$, and indeed for the trivial connection the constant ASD forms ω_a^- are non-zero elements of H^2: the hypothesis $R > 0$ cannot be dropped.

Hitchin showed that among compact Einstein manifolds with $W_- = 0$ and $R > 0$ there are only these two, S^4 and $\mathbb{CP}^2$. For other manifolds one works with generic metrics instead (Freed–Uhlenbeck, Taubes), for which $h_2 = 0$ holds at irreducible instantons after a small perturbation of the metric.

8.8.8 Comparison with the moduli of Riemann surfaces

Nash says the technique is "similar to that used in chapter 5". The dictionary is worth writing out.

	Riemann surfaces of genus p	Instantons of charge k
object	complex structure on a surface Σ	self-dual connection on $P \to M$
equivalence	diffeomorphisms of Σ	gauge transformations
infinitesimal symmetries	$H^0(\Sigma, T\Sigma)$ (holomorphic vector fields)	$H^0 = \operatorname{Ker} \mathrm{d}_A$
deformations	$H^1(\Sigma, T\Sigma)$	$H^1 = \operatorname{Ker} \mathrm{d}_A^- / \operatorname{Im} \mathrm{d}_A$
elliptic operator	$\bar\partial$ on vector fields	$\mathrm{d}_A^* \oplus \mathrm{d}_A^-$ (Fueter type)
vanishing for large genus / irreducible	$H^0 = 0$ for $p \geq 2$	$H^0 = 0$ if irreducible
index theorem	Riemann–Roch: $h^0 - h^1 = 3 - 3p$	Atiyah–Singer: $h_0 - h_1 + h_2 = 3 - 8k$ on S^4
dimension	$\dim_{\mathbb{C}} \mathcal{M}_p = 3p - 3$	$\dim \mathcal{M}_k = 8k - 3$

The difference that matters is linearity. The $\bar\partial$ operator is linear, so the Riemann moduli problem is in a sense a linear one. The instanton equations are non-linear; only their linearisation is an elliptic complex, which is why the extra global conditions of Section 8.11 are needed.

Reading Nash (pp. 233–236, (8.93)–(8.113))

Nash's (8.93)–(8.94) set up $a \in T_A\mathcal{A}_k$ and the target $T_{[A]}\mathcal{M}_k$. (8.95)–(8.101) are Section 8.8.2: π_-, the expansion of $F(A + ta)$ and the operator $\mathrm{d}_A^- = \pi_- \circ \mathrm{d}_A$. (8.102) is the quotient (8.227); we added the harmonic representative (8.228). (8.103)–(8.104) are the bundle $\operatorname{ad} P \otimes \Lambda^1$ and the complex (8.230). The checks (8.105)–(8.108), with the footnote formula for d_A, are Section 8.8.4. (8.109)–(8.111) are Section 8.8.5. (8.112)–(8.113) are the Laplacian and the Weitzenböck formula (8.233), with the AHS hypotheses $W_- = 0$, $R > 0$. Nash does not show that the complex is elliptic; we did this at the symbol level in Example 8.71.

Recap

- Tangent vectors to $\mathcal{M}_k$: perturbations a with $\mathrm{d}_A^- a = \pi_- \mathrm{d}_A a = 0$, modulo gauge directions $\mathrm{d}_A f$; equivalently the zero modes $\mathrm{d}_A^- a = 0 = \mathrm{d}_A^* a$.
- $0 \to \Omega^0 \xrightarrow{\mathrm{d}_A} \Omega^1 \xrightarrow{\mathrm{d}_A^-} \Omega^2_- \to 0$ is a complex because $\mathrm{d}_A^- \mathrm{d}_A f = [F^-, f] = 0$; it is elliptic (symbol sequence $1 \to 4 \to 3$ exact, per colour).
- H^0 = symmetries, H^1 = deformations = $T_{[A]}\mathcal{M}_k$, H^2 = obstructions. The index gives $h_0 - h_1 + h_2$, stable under deformation.
- In flat space, gauge condition + linearised SD = the Fueter equation $(\partial_4 + e_j\partial_j)\bar a = 0$, a quaternionic Cauchy–Riemann (Dirac) equation that squares to $\Box$.
- $h_0 = 0$ for irreducible A; $h_2 = 0$ by the Weitzenböck formula $\mathrm{d}_A^-(\mathrm{d}_A^-)^* = \frac{1}{2}\nabla^*\nabla + R/6 - W_-$ when $W_- = 0$, $R > 0$ (S^4, $\mathbb{CP}^2$). Then $\dim \mathcal{M}_k = h_1 = -\operatorname{index}$.

8.9 Counting the moduli: the index theorem

We now have all the pieces of the zero-mode count. The tangent space to the moduli space at an irreducible instanton is H^1 of the deformation complex, $H^0 = 0$ because A is irreducible, and $H^2 = 0$ by the Weitzenböck argument when $W_- = 0$ and $R > 0$. What is left is arithmetic: compute $h_0 - h_1 + h_2$ with the Atiyah–Singer index theorem and read off h_1.

For a physicist this is a familiar move. One wants the number of zero modes of a fluctuation operator. Counting them directly means solving a partial differential equation. The index theorem replaces that by an integral of a local density (a polynomial in the curvature) over the manifold. The answer comes out in terms of two kinds of topological data:

- the *bundle*: how twisted the gauge field is, through the instanton number k;
- the *manifold*: how twisted spacetime is, through the Euler characteristic $\chi(M)$ and the signature $\tau(M)$.

The final formula for $G = \mathrm{SU}(2)$ on S^4 is $\dim \mathcal{M}_k = 8k - 3$. We derive it line by line, then do the same for other manifolds and other groups.

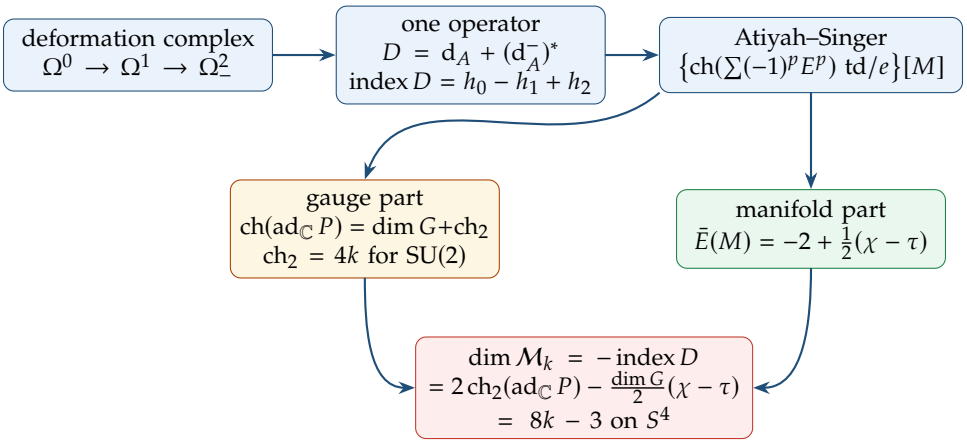

Figure 8.45: The logic of the dimension count. The complex is rolled up into a single elliptic operator D; its index is an integral given by the Atiyah–Singer formula; the integrand factorises into a gauge part (the Chern character of the adjoint bundle) and a manifold part (the index density of the untwisted complex). Only the four-form part of the product survives the integral. The red box is Nash's (8.124) and (8.132).

8.9.1 Rolling the complex up into one operator

The index theorem is a statement about one elliptic operator, not about a complex. The standard trick is to put the even terms of the complex on one side and the odd term on the other. Nash's (8.114) is

Working definition 8.34 (the rolled-up deformation operator)

$$D : \Omega^0(M, \mathrm{ad}\, P) \oplus \Omega^2_-(M, \mathrm{ad}\, P) \longrightarrow \Omega^1(M, \mathrm{ad}\, P), \qquad D(f, \omega) = \mathrm{d}_A f + (\mathrm{d}_A^-)^* \omega. \quad (8.234)$$

Per colour and per point, D maps $1 + 3 = 4$ components to 4 components, so it is a square first-order system [as many equations as unknowns, each with one derivative]. Its adjoint [the L^2 adjoint, with $\langle D(f,\omega), a\rangle = \langle (f,\omega), D^* a\rangle$] is $D^* a = (\mathrm{d}_A^* a,\ \mathrm{d}_A^- a)$, which is the operator $\mathcal{D}_A$ of Section 8.8.6.

The kernel of D. Suppose $D(f,\omega) = 0$. The two pieces of $D(f,\omega)$ are orthogonal, because of the complex property. Indeed,

$$\begin{aligned} \|D(f,\omega)\|^2 &\overset{(1)}{=} \|\mathrm{d}_A f\|^2 + 2\langle \mathrm{d}_A f, (\mathrm{d}_A^-)^*\omega\rangle + \left\|(\mathrm{d}_A^-)^*\omega\right\|^2 \\ &\overset{(2)}{=} \|\mathrm{d}_A f\|^2 + 2\langle \mathrm{d}_A^- \mathrm{d}_A f, \omega\rangle + \left\|(\mathrm{d}_A^-)^*\omega\right\|^2 \\ &\overset{(3)}{=} \|\mathrm{d}_A f\|^2 + \left\|(\mathrm{d}_A^-)^*\omega\right\|^2 . \end{aligned} \quad (8.235)$$

(1) Expand the square of a sum; the inner product (8.165) is real and symmetric.
(2) Move $(\mathrm{d}_A^-)^*$ to the other side of the inner product: this is the definition of the adjoint.
(3) $\mathrm{d}_A^- \mathrm{d}_A f = [F^-, f] = 0$ for a self-dual A ((8.226)).

A sum of two non-negative numbers vanishes only if both do. So $D(f,\omega)=0$ exactly when $\mathrm{d}_A f=0$ and $(\mathrm{d}_A^-)^*\omega=0$:

$$\operatorname{Ker} D=\operatorname{Ker}\mathrm{d}_A^{(0)}\oplus\operatorname{Ker}(\mathrm{d}_A^-)^*\cong H^0\oplus H^2,$$

using the harmonic description of H^2 in Section 8.8.5.

The cokernel of D. The cokernel is the orthogonal complement of the image, which is the kernel of the adjoint:

$$\operatorname{Coker} D\cong\operatorname{Ker} D^*=\{a:\ \mathrm{d}_A^*a=0,\ \mathrm{d}_A^-a=0\}\cong H^1$$

by (8.228). Therefore

$$\begin{aligned}&\operatorname{index} D=\dim\operatorname{Ker} D-\dim\operatorname{Coker} D=h_0+h_2-h_1,\\ &\text{and, when } h_0=h_2=0,\qquad \operatorname{index} D=-h_1=-\dim\mathcal{M}_k.\end{aligned}\tag{8.236}$$

This is Nash's (8.115). The index of the rolled-up operator is the alternating sum $h_0-h_1+h_2$ of the complex, as it must be.

Worked example 8.77: Rolling up the finite-dimensional toy complex

Take the complex of Example 8.72: $V_0=\mathbb{R}$, $V_1=\mathbb{R}^3$, $V_2=\mathbb{R}$, $d_0=(1,0,0)^T$, $d_1=(0,s,0)$. The rolled-up operator $D=d_0\oplus d_1^T: V_0\oplus V_2\to V_1$ is the 3×2 matrix

$$D=\begin{pmatrix}1&0\\0&s\\0&0\end{pmatrix}.$$

- $s\neq 0$: $\operatorname{Ker} D=0$, $\operatorname{Im} D$ is 2-dimensional, $\operatorname{Coker} D$ is 1-dimensional; $\operatorname{index} D=0-1=-1$.
- $s=0$: $\operatorname{Ker} D$ is spanned by $(0,1)$, so it is 1-dimensional; $\operatorname{Im} D$ is 1-dimensional, $\operatorname{Coker} D$ is 2-dimensional; $\operatorname{index} D=1-2=-1$.

In both cases $\operatorname{index} D=h_0+h_2-h_1$ with $(h_0,h_1,h_2)=(0,1,0)$ or $(0,2,1)$, and in both cases it equals $n_0-n_1+n_2=1-3+1$: the index of a map between spaces of dimensions 2 and 3 is always $2-3$. When $s\to 0$ the kernel and cokernel grow *together*. That is the finite model of what the index theorem exploits.

Watch out: Which way does D point?

Nash's D goes from the even terms $\Omega^0\oplus\Omega^2_-$ to the odd term Ω^1, so $\operatorname{index} D=h_0-h_1+h_2$ is *minus* the dimension of the moduli space. Its adjoint $\mathcal{D}_A=D^*$ has index $+h_1$. Nothing deep is involved, but the signs in Nash's (8.124) only make sense once one remembers that $\dim\mathcal{M}_k=-\operatorname{index} D$.

8.9.2 The index formula for an elliptic complex

The formula

In Chapter 4 we met the cohomological form of the index theorem for an elliptic complex $0\to\Gamma(E^0)\to\Gamma(E^1)\to\cdots\to\Gamma(E^m)\to 0$ on a compact oriented manifold of even dimension n (Nash's (4.48), repeated as his (8.116)):

$$\text{index}=(-1)^{n/2}\left\{\frac{\mathrm{ch}\big(\sum_p(-1)^pE^p\big)}{e(M)}\ \mathrm{td}(TM\otimes\mathbb{C})\right\}[M].\tag{8.237}$$

Let us recall what each symbol means and how to compute it.

- $\mathrm{ch}(E)$ is the **Chern character** of a complex vector bundle E with connection: $\mathrm{ch}(E) = \operatorname{tr}\exp(iF_E/2\pi)$, a sum of forms of degrees $0, 2, 4, \dots$. ch of a formal difference is the difference of the ch's.
- $e(M)$ is the **Euler class** of TM; its integral is $\chi(M)$ (Gauss–Bonnet, Chapter T2).
- td is the **Todd class**; for $TM \otimes \mathbb{C}$ it depends only on the Pontryagin classes of M.
- The quotient by $e(M)$ looks alarming, but for an elliptic complex the numerator is always divisible by $e(M)$ as a polynomial in the curvature (we shall see this happen explicitly).
- $\{\cdots\}[M]$ means: keep the part of degree n and integrate it over M.

In our case $n = 4$, so $(-1)^{n/2} = +1$, and only 4-forms matter.

Complexification

The index theorem is stated for complex bundles. Our operators are real: $\operatorname{ad} P$ is a real bundle with fibre $\mathfrak{g}$. We therefore complexify, replacing $\mathfrak{g}$ by $\mathfrak{g} \otimes \mathbb{C}$ and $\operatorname{ad} P$ by $\operatorname{ad}_{\mathbb{C}} P = \operatorname{ad} P \otimes \mathbb{C}$. This does not change the index: a real linear map and its complexification have the same matrix, so $\dim_{\mathbb{R}} \operatorname{Ker} = \dim_{\mathbb{C}} \operatorname{Ker}_{\mathbb{C}}$ and the same for the cokernel. In Nash's (8.117) the bundles of the complex become

$$E^0 = \operatorname{ad}_{\mathbb{C}} P \otimes \Lambda^0 T^*M_{\mathbb{C}}, \qquad E^1 = \operatorname{ad}_{\mathbb{C}} P \otimes \Lambda^1 T^*M_{\mathbb{C}}, \qquad E^2 = \operatorname{ad}_{\mathbb{C}} P \otimes \Lambda^2_- T^*M_{\mathbb{C}}. \tag{8.238}$$

Factorising: the Chern character is multiplicative

Every E^p is "gauge part $\otimes$ form part". The Chern character turns tensor products into products. Here is why, at the level of curvature. On a tensor product $V \otimes W$ the connection acts by the Leibniz rule, so the curvature is $F_{V\otimes W} = F_V \otimes \mathbb{1} + \mathbb{1} \otimes F_W$, and the two terms commute. Then

$$\begin{aligned} \mathrm{ch}(V \otimes W) &\overset{(1)}{=} \operatorname{tr}_{V\otimes W} \exp\Big(\tfrac{i}{2\pi}\big(F_V \otimes \mathbb{1} + \mathbb{1} \otimes F_W\big)\Big) \\ &\overset{(2)}{=} \operatorname{tr}_{V\otimes W}\Big(\exp\big(\tfrac{i}{2\pi}F_V\big) \otimes \exp\big(\tfrac{i}{2\pi}F_W\big)\Big) \\ &\overset{(3)}{=} \operatorname{tr}_V \exp\big(\tfrac{i}{2\pi}F_V\big)\ \operatorname{tr}_W \exp\big(\tfrac{i}{2\pi}F_W\big) = \mathrm{ch}(V)\,\mathrm{ch}(W). \end{aligned} \tag{8.239}$$

(1) Definition of ch and the Leibniz form of the curvature.
(2) $e^{X+Y} = e^X e^Y$ for commuting X, Y (the curvatures are even forms, so they commute as forms too), and $e^{X\otimes\mathbb{1}} = e^X \otimes \mathbb{1}$.
(3) $\operatorname{tr}(X \otimes Y) = \operatorname{tr} X\ \operatorname{tr} Y$ (a Kronecker-product identity).

(In the language of Chapter 4: the Chern roots of $V \otimes W$ are the pairwise sums of the roots of V and of W, and $e^{a+b} = e^a e^b$.) Applying this to each E^p and pulling out the common factor,

$$\operatorname{index} D = \big\{\mathrm{ch}(\operatorname{ad}_{\mathbb{C}} P)\,\bar{E}(M)\big\}[M], \qquad \bar{E}(M) = \frac{\mathrm{ch}\big(\sum_p (-1)^p \bar{E}^p\big)}{e(M)}\ \mathrm{td}(TM_{\mathbb{C}}), \tag{8.240}$$

with $\bar{E}^0 = \Lambda^0 T^*M_{\mathbb{C}}$, $\bar{E}^1 = \Lambda^1 T^*M_{\mathbb{C}}$, $\bar{E}^2 = \Lambda^2_- T^*M_{\mathbb{C}}$ (Nash's (8.118)). The class $\bar{E}(M)$ knows nothing about the gauge field. It is the index density of the *untwisted* complex $\Omega^0 \to \Omega^1 \to \Omega^2_-$, i.e. the same complex for the trivial connection on the trivial line bundle.

Because only the 4-form part of the product is integrated, we need $\mathrm{ch}(\operatorname{ad}_{\mathbb{C}} P)$ and $\bar{E}(M)$ each in degrees 0 and 4 (the degree-2 parts will turn out not to contribute). We compute the two factors in turn.

8.9.3 The gauge factor: $\mathrm{ch}(\mathrm{ad}_{\mathbb{C}}\, P)$

Chern character in terms of Chern classes

Diagonalise the curvature formally: $\frac{i}{2\pi}F_V$ has "eigenvalues" $x_1, \dots, x_r$ (the **Chern roots**, 2-forms), with $r = \mathrm{rk}\, V$. The total Chern class is $c(V) = \prod_i (1 + x_i)$, so $c_1 = \sum_i x_i$ and $c_2 = \sum_{i<j} x_i x_j$. Then

$$\begin{aligned} \mathrm{ch}(V) &\overset{(1)}{=} \sum_{i=1}^{r} e^{x_i} \\ &\overset{(2)}{=} r + \sum_i x_i + \tfrac{1}{2}\sum_i x_i^2 + \dots \\ &\overset{(3)}{=} \mathrm{rk}\, V + c_1(V) + \tfrac{1}{2}\big(c_1(V)^2 - 2c_2(V)\big) + \dots \end{aligned} \tag{8.241}$$

(1) The trace of the exponential of a diagonal matrix.
(2) Expand each exponential; on a 4-manifold, terms of degree > 4 (three or more x's) vanish.
(3) $\sum_i x_i^2 = (\sum_i x_i)^2 - 2\sum_{i<j} x_i x_j = c_1^2 - 2c_2$.

This is Nash's (8.119).

Real bundles: $c_1 = 0$ and the Pontryagin class

$\mathrm{ad}_{\mathbb{C}}\, P$ is the complexification of a real bundle. Two consequences.

- *The rank is* $\dim G$: the fibre is $\mathfrak{g} \otimes \mathbb{C}$.
- $c_1 = 0$. In a real representation the curvature is a real antisymmetric matrix (the adjoint representation of a compact group preserves the Killing form). The eigenvalues of a real antisymmetric matrix come in pairs $\pm i\mu$. So the Chern roots come in pairs $\pm x$, and $c_1 = \sum x_i = 0$. (Nash says this as: a complexified real bundle is *self-conjugate*, $V \cong \bar{V}$, while $c_1(\bar{V}) = -c_1(V)$; so $2c_1 = 0$, which kills c_1 in de Rham cohomology. All odd Chern classes vanish for the same reason.)

Hence

$$\mathrm{ch}(\mathrm{ad}_{\mathbb{C}}\, P) = \dim G + \mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}}\, P), \qquad \mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}}\, P) = -c_2(\mathrm{ad}_{\mathbb{C}}\, P). \tag{8.242}$$

The degree-2 part is zero, which is why degree-2 parts of $\bar{E}(M)$ never contribute.

Watch out: Nash's normalisation of p_1

The standard first Pontryagin class of a real bundle V is $p_1(V) = -c_2(V \otimes \mathbb{C})$. Nash writes $p_1(\mathrm{ad}_{\mathbb{C}}\, P) = -2c_2(\mathrm{ad}_{\mathbb{C}}\, P)$ and hence (8.120), $\mathrm{ch}(\mathrm{ad}_{\mathbb{C}}\, P) = \dim G + \frac{1}{2}p_1$. So *Nash's p_1 is twice the standard one.* The combination that enters the final answer, $-2c_2(\mathrm{ad}_{\mathbb{C}}\, P)$, is unambiguous. We shall write everything in terms of $c_2(\mathrm{ad}_{\mathbb{C}}\, P)$ and $\mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}}\, P) = -c_2(\mathrm{ad}_{\mathbb{C}}\, P)$, and translate to Nash's p_1 at the end: $p_1^{\mathrm{Nash}} = 2\,\mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}}\, P)$.

Worked example 8.78: The adjoint of $\mathrm{SU}(2)$ from the fundamental: $\mathrm{ch}_2(\mathrm{ad}) = 4k$

Let us compute $c_2(\mathrm{ad}_{\mathbb{C}}\, P)$ directly from the curvature, by comparing traces in the two representations. Take an element of $\mathfrak{su}(2)$ in its Cartan direction, $X = \theta e_3 = \mathrm{diag}(-i\theta, i\theta)$.

- Fundamental: eigenvalues $\mp i\theta$, so $\mathrm{tr}_{\mathbf{2}}\, X^2 = -2\theta^2$.

- Adjoint: $\operatorname{ad} X(Y) = [X, Y]$. On the basis e_1, e_2, e_3, using $[e_j, e_k] = 2\varepsilon_{jkl} e_l$ from (8.193),

$$\operatorname{ad} X = \theta \begin{pmatrix} 0 & -2 & 0 \\ 2 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad \text{eigenvalues } 0,\ \pm 2i\theta,$$

so $\operatorname{tr}_{\mathbf{3}}(\operatorname{ad} X)^2 = -8\theta^2$.

(Check the first column: $[e_3, e_1] = 2e_2$, so $\operatorname{ad} X(e_1) = 2\theta e_2$.) Every element of $\mathfrak{su}(2)$ is conjugate to such an X, and both traces are conjugation invariant, so $\operatorname{tr}_{\mathbf{3}}(\operatorname{ad} X)^2 = 4 \operatorname{tr}_{\mathbf{2}} X^2$ for all X. The same holds for the curvature 2-form, since $\operatorname{tr}(F \wedge F)$ is built from $\operatorname{tr}(X^2)$ by polarisation. With Chern–Weil, $c_2 = \frac{1}{8\pi^2} \operatorname{tr}(F \wedge F)$ for a bundle with traceless curvature (from $c(V) = \det(\mathbb{1} + \frac{i}{2\pi} F)$), and so

$$\begin{aligned} \operatorname{ch}_2(\operatorname{ad}_{\mathbb{C}} P)[M] &\overset{(1)}{=} -c_2(\operatorname{ad}_{\mathbb{C}} P)[M] \\ &\overset{(2)}{=} -\frac{1}{8\pi^2} \int_M \operatorname{tr}_{\mathbf{3}}\left(F_{\mathrm{ad}} \wedge F_{\mathrm{ad}}\right) \\ &\overset{(3)}{=} -\frac{4}{8\pi^2} \int_M \operatorname{tr}_{\mathbf{2}}(F \wedge F) \\ &\overset{(4)}{=} 4k. \end{aligned}$$

(1) (8.242).
(2) Chern–Weil for the traceless curvature of $\operatorname{ad}_{\mathbb{C}} P$.
(3) The trace identity $\operatorname{tr}_{\mathbf{3}} = 4 \operatorname{tr}_{\mathbf{2}}$.
(4) The instanton number $k = -\frac{1}{8\pi^2} \int \operatorname{tr}(F \wedge F) = -c_2(E)[M]$ ((8.187), Nash's (8.127)).

For the BPST instanton ($k = 1$) this says $\operatorname{ch}_2(\operatorname{ad}_{\mathbb{C}} P)[S^4] = 4$, i.e. Nash's $p_1(\operatorname{ad}_{\mathbb{C}} P) = 8$. Nash obtains the same number by decomposing $E \otimes E$ (Section 8.9.6); it is worth having both derivations.

8.9.4 The manifold factor: the truncated de Rham complex

Now $\bar{E}(M)$, the index density of $\Omega^0 \xrightarrow{\mathrm{d}} \Omega^1 \xrightarrow{\mathrm{d}^-} \Omega^2_-$ with no gauge field. Nash evaluates it without computing a single characteristic class, by identifying the cohomology of this complex with familiar Betti numbers.

The cohomology of the untwisted complex

Let $b_p = \dim H^p_{\mathrm{dR}}(M)$ be the Betti numbers. Recall (Chapter 1) that the harmonic 2-forms split into self-dual and anti-self-dual ones, of dimensions b_2^+ and b_2^-, and that the intersection form $q(\alpha, \beta) = \int_M \alpha \wedge \beta$ is positive on the first and negative on the second:

$$q(\omega, \omega) = \int_M \omega \wedge \omega = \pm \int_M \omega \wedge \star\omega = \pm \|\omega\|^2 \qquad \text{for } \star\,\omega = \pm\omega.$$

So b_2^+ (b_2^-) is the number of positive (negative) eigenvalues of the matrix of q, and the **signature** is $\tau(M) = b_2^+ - b_2^-$.

We compute the three cohomology groups of the untwisted complex, using harmonic representatives as in Section 8.8.5.

- $H^0 = \operatorname{Ker} \mathrm{d}$ on functions: the locally constant functions. $h_0 = b_0$ (= 1 for connected M).

- $H^1 = \operatorname{Ker} \mathrm{d}^- \cap \operatorname{Ker} \mathrm{d}^*$ on 1-forms. We claim that $\mathrm{d}^- a = 0$ forces $\mathrm{d}a = 0$ on a closed manifold. Split $\mathrm{d}a = (\mathrm{d}a)^+ + (\mathrm{d}a)^-$; then

$$\begin{aligned} \left\|(\mathrm{d}a)^+\right\|^2 - \|(\mathrm{d}a)^-\|^2 &\overset{(1)}{=} \int_M \mathrm{d}a \wedge \mathrm{d}a \\ &\overset{(2)}{=} \int_M \mathrm{d}(a \wedge \mathrm{d}a) \\ &\overset{(3)}{=} 0. \end{aligned}$$

  (1) The self-dual and anti-self-dual parts are orthogonal, and $\omega \wedge \omega = \pm|\omega|^2 \mathrm{vol}$ on each, as above.
  (2) $\mathrm{d}(a \wedge \mathrm{d}a) = \mathrm{d}a \wedge \mathrm{d}a - a \wedge \mathrm{d}\mathrm{d}a$ and $\mathrm{d}^2 = 0$.
  (3) Stokes; $\partial M = \varnothing$.

  So $(\mathrm{d}a)^- = 0$ implies $(\mathrm{d}a)^+ = 0$, i.e. $\mathrm{d}a = 0$. Together with $\mathrm{d}^* a = 0$, a is a harmonic 1-form. Hence $h_1 = b_1$.

- $H^2 = \Omega^2_- / \operatorname{Im} \mathrm{d}^- \cong \operatorname{Ker}(\mathrm{d}^-)^*$ on ASD 2-forms. For an ASD form, $(\mathrm{d}^-)^*\omega = \mathrm{d}^*\omega = -\star\mathrm{d}\star\omega = \star\mathrm{d}\omega$, so $(\mathrm{d}^-)^*\omega = 0$ iff $\mathrm{d}\omega = 0$; then also $\mathrm{d}^*\omega = 0$, and ω is an ASD harmonic form. Hence $h_2 = b_2^-$.

So the index of the untwisted complex is (Nash's (8.121))

$$\bar{E}(M)[M] = b_0 - b_1 + b_2^-.$$

Rewriting in terms of χ and τ

Nash explains that the complex is "the de Rham complex truncated in two ways": the last two terms Ω^3, Ω^4 are missing, and in the middle only Ω^2_- appears instead of all of Ω^2. The missing terms contribute the same as the first two by Poincaré duality, and the middle discrepancy is measured by the signature. In formulas (Nash's (8.122)–(8.123)):

$$\begin{aligned} \chi(M) &\overset{(1)}{=} b_0 - b_1 + b_2 - b_3 + b_4 \\ &\overset{(2)}{=} 2b_0 - 2b_1 + b_2 \\ &\overset{(3)}{=} 2b_0 - 2b_1 + 2b_2^- + (b_2^+ - b_2^-) \\ &\overset{(4)}{=} 2\big(b_0 - b_1 + b_2^-\big) + \tau(M), \end{aligned} \tag{8.243}$$

  (1) The Euler characteristic is the alternating sum of the Betti numbers.
  (2) Poincaré duality on a closed oriented 4-manifold: $b_4 = b_0$, $b_3 = b_1$ (the Hodge star maps harmonic p-forms to harmonic $(4-p)$-forms).
  (3) $b_2 = b_2^+ + b_2^-$, written as $2b_2^- + (b_2^+ - b_2^-)$.
  (4) Definition of τ.

and therefore

$$b_0 - b_1 + b_2^- = \tfrac{1}{2}\big(\chi(M) - \tau(M)\big). \tag{8.244}$$

Worked example 8.79: Checking (8.244) on five manifolds

M	b_0, b_1, b_2^+, b_2^-	χ	τ	$b_0 - b_1 + b_2^-$	$\frac{1}{2}(\chi - \tau)$
S^4	$1, 0, 0, 0$	2	0	1	1
$\mathbb{CP}^2$	$1, 0, 1, 0$	3	1	1	1
$S^2 \times S^2$	$1, 0, 1, 1$	4	0	2	2
T^4	$1, 4, 3, 3$	0	0	0	0
$K3$	$1, 0, 3, 19$	24	-16	20	20

For T^4: $b_1 = 4$ (the forms $\mathrm{d}x^\mu$), $b_2 = 6$ (the $\mathrm{d}x^{\mu\nu}$), split $3 + 3$ into the $\omega_a^\pm$ of Section 8.4, and $\chi = 1 - 4 + 6 - 4 + 1 = 0$. For $S^2 \times S^2$ the intersection form is $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ with eigenvalues ± 1, so $b_2^\pm = 1$. For $K3$ the form is $3H \oplus 2(-E_8)$ in one orientation (Chapter 1), giving $b_2^+ = 3$, $b_2^- = 19$.

The same answer from characteristic classes

It is reassuring, and it shows how the division by $e(M)$ works, to compute $\bar{E}(M)$ directly. By the splitting principle, treat TM as if it were a sum of two oriented planes, rotated with "angles" x_1, x_2 (2-forms). Then the Euler class is $e = x_1 x_2$, the first Pontryagin class is $p_1 = x_1^2 + x_2^2$, and the complexified bundles have the roots

$$\Lambda^0_{\mathbb{C}} : \{0\}, \qquad \Lambda^1_{\mathbb{C}} : \{\pm x_1, \pm x_2\}, \qquad \Lambda^2_{-,\mathbb{C}} : \{0,\ \pm(x_1 - x_2)\}$$

(the self-dual forms carry $\{0, \pm(x_1 + x_2)\}$; we checked in Section 8.4 that $\mathrm{d}x^{13} - \mathrm{d}x^{24}$, which rotates with angle $x_1 + x_2$, is self-dual). The numerator of $\bar{E}(M)$ is, with $\cosh y = 1 + \frac{y^2}{2} + \frac{y^4}{24} + \dots$,

$$\begin{aligned} \mathrm{ch}\big(\Lambda^0 - \Lambda^1 + \Lambda^2_-\big) &\overset{(1)}{=} 1 - \big(2\cosh x_1 + 2\cosh x_2\big) + \big(1 + 2\cosh(x_1 - x_2)\big) \\ &\overset{(2)}{=} \big[-x_1^2 - x_2^2 + (x_1 - x_2)^2\big] + \tfrac{1}{12}\big[(x_1 - x_2)^4 - x_1^4 - x_2^4\big] + \dots \\ &\overset{(3)}{=} -2x_1x_2 + x_1x_2\Big(-\tfrac{1}{3}x_1^2 + \tfrac{1}{2}x_1x_2 - \tfrac{1}{3}x_2^2\Big) + \dots \\ &\overset{(4)}{=} e\left(-2 - \tfrac{1}{3}p_1 + \tfrac{1}{2}e\right) + \dots \end{aligned}$$

(1) ch is the sum of e^{root}; pairs $\pm y$ give $2\cosh y$.
(2) Expand. The constant terms cancel: $1 - 4 + 3 = 0$ (the ranks of the complex, $1 - 4 + 3$).
(3) $(x_1 - x_2)^4 - x_1^4 - x_2^4 = -4x_1^3x_2 + 6x_1^2x_2^2 - 4x_1x_2^3$, and divide by 12.
(4) $e = x_1x_2$, $p_1 = x_1^2 + x_2^2$.

The numerator is divisible by e, as promised. The Todd class of $TM_{\mathbb{C}}$ (roots $\pm x_1, \pm x_2$) is

$$\mathrm{td}(TM_{\mathbb{C}}) = \prod_{i=1}^{2} \frac{x_i}{1 - e^{-x_i}} \cdot \frac{-x_i}{1 - e^{x_i}} = \prod_i \left(1 - \frac{x_i^2}{12} + \dots\right) = 1 - \frac{p_1}{12} + \dots$$

(multiply $1 + \frac{y}{2} + \frac{y^2}{12}$ by $1 - \frac{y}{2} + \frac{y^2}{12}$). Hence

$$\begin{aligned} \bar{E}(M) &\overset{(1)}{=} \left(-2 - \tfrac{1}{3}p_1 + \tfrac{1}{2}e\right)\left(1 - \tfrac{1}{12}p_1\right) \\ &\overset{(2)}{=} -2 + \left(\tfrac{1}{6} - \tfrac{1}{3}\right)p_1 + \tfrac{1}{2}e \\ &\overset{(3)}{=} -2 + \tfrac{1}{2}\left(e - \tfrac{p_1}{3}\right). \end{aligned} \tag{8.245}$$

(1) The two factors just computed.
(2) Keep degree ≤ 4: $(-2)(-\frac{1}{12}p_1) = \frac{1}{6}p_1$.
(3) Collect.

Integrating, $\int_M e = \chi(M)$ (Gauss–Bonnet) and $\int_M \frac{1}{3}p_1 = \tau(M)$ (the Hirzebruch signature theorem, Chapter 4). So the 4-form part integrates to $\frac{1}{2}(\chi - \tau)$, in agreement with (8.244). The new information is the *degree-0 part*, -2. It multiplies $\mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}}\, P)$ in the final formula.

Physical picture: Why -2: the operator is a twisted Dirac operator

In Example 8.74 we saw that, in spinor language, $\Lambda^1_{\mathbb{C}} \cong S^+ \otimes S^-$ and $\Lambda^0_{\mathbb{C}} \oplus \Lambda^2_{-,\mathbb{C}} \cong S^- \otimes S^-$. So the adjoint $\mathcal{D}_A = D^* : \Omega^1 \to \Omega^0 \oplus \Omega^2_-$ is the chiral Dirac operator $S^+ \to S^-$ twisted by the bundle $V = S^- \otimes \mathrm{ad}_{\mathbb{C}}\, P$ of rank $2 \dim G$. By the twisted Dirac index theorem (Chapter 4), index $= \int \hat{A}(M)\,\mathrm{ch}(V)$, and the gauge field enters through $\mathrm{ch}(V) = \mathrm{ch}(S^-)\,\mathrm{ch}(\mathrm{ad}_{\mathbb{C}}\, P)$, whose degree-4 gauge part is $\mathrm{rk}(S^-)\ \mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}}\, P) = 2\,\mathrm{ch}_2$. The "2" is the number of components of a Weyl spinor. It enters index $D = -\,\mathrm{index}\,\mathcal{D}_A$ with a minus sign: that is the -2 in $\bar{E}(M)$.

8.9.5 The dimension formula

Multiply the two factors and keep the 4-form part:

$$\begin{aligned} \mathrm{index}\, D &\overset{(1)}{=} \Big\{ \big(\dim G + \mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}}\, P)\big)\Big(-2 + \tfrac{1}{2}\big(e - \tfrac{p_1}{3}\big)\Big)\Big\}[M] \\ &\overset{(2)}{=} \tfrac{\dim G}{2}\big(\chi(M) - \tau(M)\big) - 2\,\mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}}\, P)[M], \end{aligned} \tag{8.246}$$

(1) (8.240) with (8.242) and (8.245).
(2) The 4-form part is (degree 0)×(degree 4) + (degree 4)×(degree 0); integrate using Gauss–Bonnet and the signature theorem.

and with $\dim \mathcal{M}_k = -\,\mathrm{index}\, D$ from (8.236):

Key idea: Dimension of the instanton moduli space (Nash's (8.124))

For G compact and simple, M compact, oriented, with $W_- = 0$ and $R > 0$, and A irreducible and self-dual,

$$\dim \mathcal{M}_k = 2\,\mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}}\, P)[M] - \frac{\dim G}{2}\big(\chi(M) - \tau(M)\big) = p_1^{\mathrm{Nash}}(\mathrm{ad}_{\mathbb{C}}\, P) - \frac{\dim G}{2}(\chi - \tau). \tag{8.247}$$

Equivalently $\dim \mathcal{M}_k = -2c_2(\mathrm{ad}_{\mathbb{C}}\, P)[M] - \dim G\,(b_0 - b_1 + b_2^-)$. The first term counts the zero modes created by the gauge field; the second subtracts the symmetries and adds the obstructions that the untwisted complex would have.

Nash writes the product as $\{\dim G + \frac{1}{2}p_1\}\{2 - \frac{1}{2}(\chi - \tau)\}$: his second brace is $-\bar{E}(M)$, which absorbs the sign of $\dim \mathcal{M}_k = -\,\mathrm{index}\, D$. Taubes showed the formula holds more generally (for a class of non-self-dual manifolds, and for generic metrics), as Nash notes.

8.9.6 SU(2) instantons on S^4: $\dim \mathcal{M}_k = 8k - 3$

The manifold

S^4 with the round metric has $R > 0$ and $W = 0$ (Example 8.76), so the hypotheses hold. Its Betti numbers are $1, 0, 0, 0, 1$, so (Nash's (8.125))

$$\chi(S^4) = 2, \qquad \tau(S^4) = 0, \qquad \tfrac{1}{2}(\chi - \tau) = 1,$$

and with $\dim \mathrm{SU}(2) = 3$ the formula becomes (Nash's (8.126)) $\dim \mathcal{M}_k = 2\,\mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}} P) - 3$.

The bundle: $E \otimes E = S^2E \oplus \Lambda^2 E$

Let E be the rank-2 complex vector bundle associated with P by the fundamental representation, so $k = -c_2(E)[S^4]$ (Nash's (8.127)). Nash finds $\mathrm{ad}_{\mathbb{C}} P$ inside $E \otimes E$. At the level of representations this is the most familiar decomposition in physics, "spin $\frac{1}{2}\otimes$ spin $\frac{1}{2}$ = spin $1\oplus$ spin 0":

$$E \otimes E = S^2E \oplus \Lambda^2 E, \qquad \mathbf{2} \otimes \mathbf{2} = \mathbf{3} \oplus \mathbf{1} \qquad \text{(Nash's (8.128))}. \tag{8.248}$$

Explicitly, with basis $u_1 = \uparrow$, $u_2 = \downarrow$ of the fibre $\mathbb{C}^2$,

$$S^2E:\ u_1 \otimes u_1,\ \tfrac{1}{\sqrt{2}}(u_1 \otimes u_2 + u_2 \otimes u_1),\ u_2 \otimes u_2; \qquad \Lambda^2 E:\ \tfrac{1}{\sqrt{2}}(u_1 \otimes u_2 - u_2 \otimes u_1).$$

Three facts identify the pieces.

1. *Ranks.* S^2E has rank $2 \cdot 3/2 = 3$ and $\Lambda^2 E$ has rank $\binom{2}{2} = 1$: it is a line bundle.
2. *$\Lambda^2 E$ is trivial.* $g \in \mathrm{SU}(2)$ acts on the singlet by $\det g = 1$. So $\Lambda^2 E = \det E$ is the trivial line bundle, and $\mathrm{ch}(\Lambda^2 E) = 1 + c_1(E) = 1$.
3. *S^2E is the adjoint.* The element $-\mathbb{1} \in \mathrm{SU}(2)$ acts on $E \otimes E$ by $(-1)(-1) = +1$. So $E \otimes E$ is really a representation of $\mathrm{SU}(2)/\mathbb{Z}_2 = \mathrm{SO}(3) = \mathrm{Ad}\,\mathrm{SU}(2)$, and its three-dimensional irreducible piece is the adjoint. Concretely, the weights match: $\mathrm{diag}(e^{-i\theta}, e^{i\theta})$ acts on $u_1 \otimes u_1$, on the symmetric middle vector and on $u_2 \otimes u_2$ by $e^{-2i\theta}, 1, e^{2i\theta}$, which are the eigenvalues of Ad found in Example 8.78 (exponentiated). Hence $S^2E \cong \mathrm{ad}_{\mathbb{C}} P$.

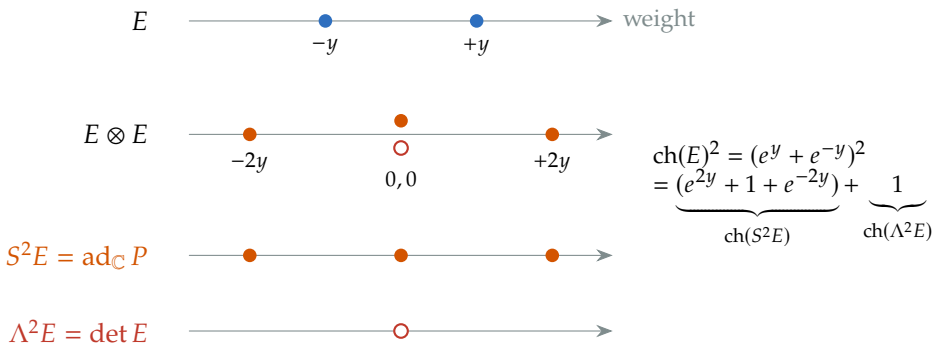

Figure 8.46: Weights (Chern roots) of E, $E \otimes E$ and its two pieces. The roots of a tensor product are the pairwise sums $\pm y \pm y$: this gives $-2y, 0, 0, +2y$. The symmetric part takes $\{-2y, 0, 2y\}$, the same weights as the adjoint representation; the antisymmetric part takes the remaining 0, a trivial line. Squaring the Chern character of E therefore splits into the two Chern characters, which is Nash's (8.129).

The characteristic class computation

Take the Chern character of (8.248). By multiplicativity (8.239), $\mathrm{ch}(E \otimes E) = \mathrm{ch}(E)^2$, so (Nash's (8.129)) $\mathrm{ch}(E)\ \mathrm{ch}(E) = \mathrm{ch}(\mathrm{ad}_{\mathbb{C}} P) + \mathrm{ch}(\Lambda^2 E)$. Expand both sides with (8.241) and keep degree

≤ 4 (Nash's (8.130)–(8.131)):

$$\Big(2 + c_1(E) + \tfrac{1}{2}\big(c_1(E)^2 - 2c_2(E)\big)\Big)^2 \overset{(1)}{=} 3 + \mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}} P) + 1 + c_1(E)$$
$$\Longrightarrow \qquad 4 - 4c_2(E) \overset{(2)}{=} 4 + \mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}} P)$$
$$\Longrightarrow \qquad \mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}} P)[S^4] \overset{(3)}{=} -4c_2(E)[S^4] = 4k. \tag{8.249}$$

(1) Left: (8.241) for the rank-2 bundle E. Right: (8.242) with $\dim G = 3$, plus $\mathrm{ch}(\Lambda^2 E) = 1 + c_1(E)$.
(2) $c_1(E) = 0$ for an SU(2) bundle (traceless curvature), and on S^4 only degrees 0 and 4 exist; squaring $2 - c_2$ gives $4 - 4c_2$ up to degree 8.
(3) Solve, and use $k = -c_2(E)[S^4]$.

In Nash's normalisation, $p_1(\mathrm{ad}_{\mathbb{C}} P) = 2\,\mathrm{ch}_2 = -8c_2(E) = 8k$, his (8.131). The roots give the same thing in one line: if E has roots $\pm y$, then $c_2(E) = -y^2$, and S^2E has roots $\pm 2y, 0$, so $\mathrm{ch}_2(S^2E) = \frac{1}{2}(4y^2 + 4y^2) = 4y^2 = -4c_2(E)$. And it agrees with the trace computation of Example 8.78. Therefore:

Key idea: Nash's (8.132)

$$\dim \mathcal{M}_k = 2 \cdot 4k - 3 \cdot 1 = 8k - 3 \qquad (\mathrm{SU}(2) \text{ instantons on } S^4,\ k \geq 1). \tag{8.250}$$

The framed moduli space $\mathcal{M}'_k$ has dimension $8k$ (add back the 3 dimensions of $\mathrm{Ad}\,\mathrm{SU}(2) = \mathrm{SO}(3)$ acting freely, Section 8.7.2).

Worked example 8.80: Reading $8k - 3$ as collective coordinates

Imagine k BPST instantons so far apart that they do not interact (the **dilute gas**). Each has a position (4), a size (1) and an orientation in colour space (3): 8 parameters each, $8k$ in all. An overall constant colour rotation is a gauge transformation, which removes 3:

$$8k - 3 = \underbrace{4k}_{\text{positions}} + \underbrace{k}_{\text{sizes}} + \underbrace{3(k-1)}_{\text{relative orientations}}.$$

The index theorem says this naive count is exact, not only for far-separated instantons but everywhere in $\mathcal{M}_k$: overlapping instantons do not gain or lose parameters. The 't Hooft ansatz of Section 8.5.5 gives the first two groups, $5k$; it freezes the relative orientations. For $k = 1$ we get 5, the BPST family (y, λ), and for $k = 2$ we get 13.

Worked example 8.81: What the formula says at a reducible connection: $k = 0$

For $k = 0$ the formula gives $8 \cdot 0 - 3 = -3$, which cannot be a dimension. There is no contradiction: the only self-dual connection with $k = 0$ has $\|F\|^2 = 8\pi^2|k| = 0$ (Bogomolny), so it is flat, hence (on the simply connected S^4) the trivial connection. It is maximally reducible: every constant $f \in \mathfrak{su}(2)$ satisfies $\mathrm{d}_A f = \mathrm{d}f = 0$, so $h_0 = 3$. It has no deformations and no obstructions ($h_1 = 0$; $h_2 = 0$ by the Weitzenböck argument, which did not use irreducibility). So

$$h_0 - h_1 + h_2 = 3 - 0 + 0 = 3 = -(8 \cdot 0 - 3),$$

exactly what the index theorem predicts for $\mathrm{index}\, D$. The formula counts $h_1 - h_0 - h_2$, and only equals $\dim \mathcal{M}_k$ when $h_0 = h_2 = 0$. The moduli space $\mathcal{M}_0$ is a single point, of dimension $0 = -3 + h_0$.

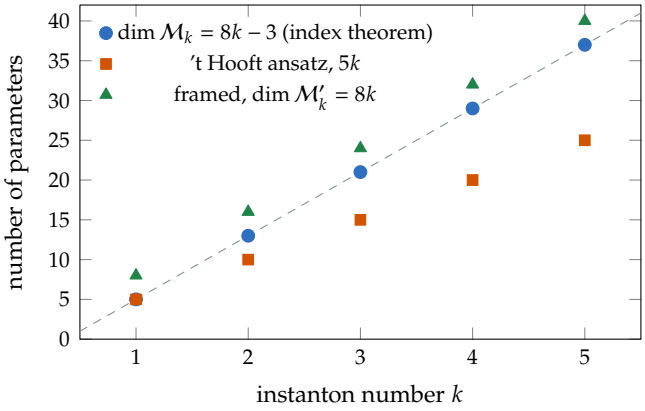

Figure 8.47: Parameter counts for SU(2) instantons on S^4. The index theorem (blue) agrees with the 't Hooft family (orange) only at $k = 1$; the gap $3(k-1)$ is the relative colour orientation of the lumps. The framed count (green) exceeds $\dim \mathcal{M}_k$ by the three global colour rotations.

8.9.7 Other manifolds: Donaldson's class

For $G = \mathrm{SU}(2)$ and a general M (satisfying the hypotheses, or with a generic metric), (8.247) and (8.244) give

$$\dim \mathcal{M}_k = 8k - 3\,(b_0 - b_1 + b_2^-) = 8k - 3\,(1 - b_1 + b_2^-) \tag{8.251}$$

for connected M (the computation of $\mathrm{ch}_2 = 4k$ in (8.249) did not use anything special about S^4). Nash's (8.133)–(8.134) is the special case:

$$\tfrac{1}{2}\big(\chi(M) - \tau(M)\big) \overset{(1)}{=} b_0 - b_1 + b_2^- \overset{(2)}{=} 1 - 0 + 0 = 1, \qquad \text{so} \qquad \dim \mathcal{M}_k = 8k - 3.$$

(1) (8.244).

(2) M connected: $b_0 = 1$. Simply connected: $\pi_1 = 0$, so $H_1(M;\mathbb{Z}) = 0$ and $b_1 = 0$. Positive definite intersection form: no negative eigenvalues, $b_2^- = 0$.

So every simply connected M with positive definite intersection form has the same instanton dimensions as S^4. By Chapter 1, this is exactly the class of manifolds to which Donaldson's theorem applies (Section 8.11).

Worked example 8.82: Expected dimensions on familiar manifolds

Using (8.251) and the Betti numbers of Example 8.79:

M	$1 - b_1 + b_2^-$	$\dim \mathcal{M}_k$	comment
S^4	1	$8k-3$	Nash's (8.132)
$\mathbb{CP}^2$	1	$8k-3$	simply connected, $q = (+1)$
$\mathbb{CP}^2\#\mathbb{CP}^2\#\mathbb{CP}^2$	1	$8k-3$	$q = \mathrm{diag}(1,1,1)$
$S^2 \times S^2$	2	$8k-6$	q indefinite
T^4	0	$8k$	$b_1 = 4$ adds flat directions
$K3$	20	$8k-60$	empty for $k \le 7$ (generic metric)

For $K3$ the "expected dimension" is negative for $k \le 7$: for a generic metric there are no irreducible instantons at all with those charges. The formula is an *expected* dimension; it is the true dimension only at points where $h_0 = h_2 = 0$.

8.9.8 Other gauge groups: Nash's table

For a general compact simple group G the only new input is $\mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}}P)$. Normalise the instanton number so that the BPST instanton, embedded in an SU(2) subgroup of G in the standard way, has $k = 1$. Then the adjoint trace is related to the fundamental one by a number attached to the group, the **dual Coxeter number** $h^\vee$:

$$\mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}}P)[M] = 2h^\vee k, \qquad \text{so on } S^4: \qquad \dim \mathcal{M}_k = 4h^\vee k - \dim G.$$

Worked example 8.83: The $\mathrm{SU}(N)$ row: $\mathrm{tr}_{\mathrm{ad}} = 2N\,\mathrm{tr}_{\mathbf{N}}$

Let X be an $N\times N$ matrix and let $\mathrm{ad}\,X$ act on all matrices Y by $[X,Y]$. Then $(\mathrm{ad}\,X)^2Y = X^2Y - 2XYX + YX^2$. Take the trace of this linear map on the basis E_{ij} (the matrix with a single 1 in place (i,j)):

$$\begin{aligned}\mathrm{tr}_{\mathfrak{gl}(N)}(\mathrm{ad}\,X)^2 &\overset{(1)}{=} \sum_{i,j}\big(X^2E_{ij} - 2XE_{ij}X + E_{ij}X^2\big)_{ij}\\ &\overset{(2)}{=} \sum_{i,j}\big((X^2)_{ii} - 2X_{ii}X_{jj} + (X^2)_{jj}\big)\\ &\overset{(3)}{=} 2N\,\mathrm{tr}(X^2) - 2(\mathrm{tr}\,X)^2.\end{aligned}$$

(1) The trace of a linear map is the sum of the diagonal coefficients $\langle E_{ij}, (\cdot)\rangle$ in the basis E_{ij}.
(2) $(AE_{ij}B)_{ij} = A_{ii}B_{jj}$.
(3) Sum over the free index.

For $X\in\mathfrak{su}(N)$, $\mathrm{tr}\,X = 0$. The identity matrix spans the extra direction of $\mathfrak{gl}(N)$ beyond $\mathfrak{sl}(N)$, and $\mathrm{ad}\,X(\mathbb{1}) = 0$, so it contributes nothing: $\mathrm{tr}_{\mathrm{ad}}(\mathrm{ad}\,X)^2 = 2N\,\mathrm{tr}_{\mathbf{N}}X^2$. For $N = 2$ this is the factor 4 of Example 8.78. Hence $\mathrm{ch}_2(\mathrm{ad}_{\mathbb{C}}P) = 2Nk$, $h^\vee = N$, and

$$\dim\mathcal{M}_k\big(\mathrm{SU}(N), S^4\big) = 4Nk - (N^2-1) = 4Nk - N^2 + 1,$$

the first row of Nash's table.

Doing the same with the other classical and exceptional groups gives Nash's table (8.137), taken from Bernard, Christ, Guth and Weinberg and from Atiyah–Hitchin–Singer. We add the two columns that generate it.

G	$\dim G$	$h^\vee$	$\dim\mathcal{M}_k = 4h^\vee k - \dim G$	irreducible only if
$\mathrm{SU}(N)$	N^2-1	N	$4Nk - N^2 + 1$	$k \ge N/2$
$\mathrm{Spin}(N)$	$N(N-1)/2$	$N-2$	$4(N-2)k - N(N-1)/2$	$k \ge N/4$, $N\ge 7$
$\mathrm{Sp}(N)$	$N(2N+1)$	$N+1$	$4(N+1)k - N(2N+1)$	$k \ge N$
E_6	78	12	$48k - 78$	$k\ge 3$
E_7	133	18	$72k - 133$	$k\ge 3$
E_8	248	30	$120k - 248$	$k\ge 3$
F_4	52	9	$36k - 52$	$k\ge 3$
G_2	14	4	$16k - 14$	$k\ge 2$

Checks: $\mathrm{Sp}(1) = \mathrm{SU}(2) = \mathrm{Spin}(3)$ gives $8k-3$ from the Sp row ($4\cdot 2k - 3$); SU(2) from the SU row gives $8k-3$ too. For $\mathrm{Spin}(N)$ the basic instanton sits in an SU(2) factor of $\mathrm{Spin}(4) = \mathrm{SU}(2)\times\mathrm{SU}(2)\subset\mathrm{Spin}(N)$.

The irreducibility column

Nash stresses that for large G "there may be many subgroups H to which a self-dual connection might reduce" (Section 8.7.3). The last column says when irreducible instantons exist. The mechanism is simple to state for SU(N): a charge-k instanton is built (for example by the ADHM construction of Section 8.10) from k "lumps", each using at most a $\mathbb{C}^2$ of colour space. So its bundle E splits off a trivial flat piece whenever $N > 2k$, and it is then reducible. Irreducible solutions need $N \le 2k$. When the formula is applied below the bound it gives the wrong number, off by h_0:

Worked example 8.84: SU(3) instantons with $k = 1$

The table gives $4 \cdot 3 \cdot 1 - 8 = 4$. But $k = 1 < 3/2$, so every $k = 1$ SU(3) instanton is reducible. In fact every such instanton is a BPST instanton in an SU(2) subgroup, say the upper-left block, and any two are conjugate by a constant element of SU(3). So the true moduli space is again $\{(y, \lambda)\} = \mathbb{R}^4 \times \mathbb{R}^+$, of dimension 5, not 4. The index theorem is not wrong; it computes $h_0 - h_1 + h_2$. At the embedded BPST instanton the stabiliser is the centraliser of the SU(2) block (Section 8.7.3):

$$\left\{\operatorname{diag}(e^{i\theta}, e^{i\theta}, e^{-2i\theta})\right\} \cong \mathrm{U}(1), \qquad h_0 = 1.$$

The obstruction space still vanishes, so

$$h_0 - h_1 + h_2 = 1 - 5 + 0 = -4 = \operatorname{index} D,$$

matching the table's 4 with the sign of (8.236). The same count for SU(4), $k = 1$: the table gives $16 - 15 = 1$; the centraliser of the block $\mathrm{SU}(2) \subset \mathrm{SU}(4)$ is $\{\operatorname{diag}(\mu, \mu, B) : \mu \in \mathrm{U}(1),\ B \in \mathrm{U}(2),\ \mu^2 \det B = 1\}$, of dimension $1 + 4 - 1 = 4$, and $4 - 5 + 0 = -1$. Again right. Framed, the count is uniform: $\dim \mathcal{M}_1' = 4N$ for SU(N) (for $N = 3$: the 5 parameters, plus the SU(3) orbit of the embedded SU(2) frame, $\dim \mathrm{SU}(3) - \dim \mathrm{U}(1) = 7$, total $12 = 4 \cdot 3$).

Reading Nash (pp. 237–241, (8.114)–(8.137))

Nash defines $D = \mathrm{d}_A^{(0)} + (\mathrm{d}_A^-)^*$ (8.114) and states $\operatorname{index} D = -h_1$ (8.115); we proved the kernel/cokernel identification (8.235). (8.116)–(8.118) are (8.237)–(8.240). (8.119)–(8.120) are (8.241)–(8.242), with the warning that Nash's p_1 is twice the usual one. (8.121)–(8.123) are Section 8.9.4; we added the direct characteristic-class evaluation (8.245), which exhibits the degree-0 part -2 that Nash's braces use implicitly. (8.124) is (8.247). (8.125)–(8.132) are Section 8.9.6. (8.133)–(8.134) are Section 8.9.7. (8.137) is the table above, to which we added the columns $\dim G$ and $h^\vee$ that generate it. Nash's reducible-connection remark (8.135)–(8.136) was treated in Section 8.7.5.

Recap

- Roll the complex into $D = \mathrm{d}_A + (\mathrm{d}_A^-)^*$: $\operatorname{Ker} D = H^0 \oplus H^2$, $\operatorname{Coker} D = H^1$, so $\operatorname{index} D = h_0 - h_1 + h_2 = -\dim \mathcal{M}_k$.
- Atiyah–Singer for the complex factorises: $\operatorname{index} D = \{\operatorname{ch}(\mathrm{ad}_{\mathbb{C}} P)\, \bar{E}(M)\}[M]$ with $\operatorname{ch}(\mathrm{ad}_{\mathbb{C}} P) = \dim G + \operatorname{ch}_2$ and $\bar{E}(M) = -2 + \frac{1}{2}(e - \frac{1}{3}p_1)$.
- The untwisted index is $b_0 - b_1 + b_2^- = \frac{1}{2}(\chi - \tau)$ by Poincaré duality.
- $\dim \mathcal{M}_k = 2\operatorname{ch}_2(\mathrm{ad}_{\mathbb{C}} P) - \frac{\dim G}{2}(\chi - \tau)$; $\operatorname{ch}_2 = 4k$ for SU(2) (from $\mathbf{2} \otimes \mathbf{2} = \mathbf{3} \oplus \mathbf{1}$ or from $\mathrm{tr}_3 = 4\,\mathrm{tr}_2$).
- SU(2) on S^4, or on any simply connected positive definite M: $\dim \mathcal{M}_k = 8k - 3 =$

positions + sizes + relative orientations.
- General G on S^4: $4h^\vee k - \dim G$, valid only above the irreducibility bound; below it the count is off by h_0.

8.10 The $k = 1$ moduli space and the ADHM construction

The index theorem told us that $\dim \mathcal{M}_k = 8k - 3$ for SU(2) on S^4. For $k = 1$ that is 5. Nash then makes three further claims in one sentence (p. 241): $\mathcal{M}_1$ is *non-compact*, it has *boundary* S^4, and it is in fact the five-dimensional *hyperbolic space* H^5. He gives no argument. This section supplies one, in four steps.

1. We write down, as explicit formulas, the five tangent vectors to $\mathcal{M}_1$ at the BPST instanton (eight for the framed space $\mathcal{M}_1'$), and check that they solve the linearised equations of Section 8.8. Physicists call them the **zero modes** of the instanton.
2. We find the one mechanism that produces all of them: each zero mode is the response of the instanton to a conformal symmetry of $\mathbb{R}^4$.
3. We compute their lengths. This gives the natural (L^2) metric on $\mathcal{M}_1$, shows that the boundary $\lambda = 0$ is at finite distance, and feeds the collective-coordinate measure of the instanton path integral.
4. We prove that there are no other $k = 1$ instantons, using the **ADHM construction**, which produces every instanton of every charge from finite-dimensional linear algebra.

Throughout, A is the BPST instanton (8.200), $A = \mathrm{Im}(\bar{x}\,\mathrm{d}x)/\phi$ with $\phi = |x|^2 + \lambda^2$, and $F = \lambda^2\,\mathrm{d}\bar{x} \wedge \mathrm{d}x/\phi^2$, so $F_{\mu\nu} = -2\lambda^2\eta^a_{\mu\nu}e_a/\phi^2$ (Section 8.5.3). We work on $\mathbb{R}^4$; by conformal invariance and Uhlenbeck's removable singularity theorem (Section 8.4.1) finite-action instantons on $\mathbb{R}^4$ are the same thing as instantons on S^4.

8.10.1 What a zero mode is

Recall the tangent space to the moduli space (Section 8.8). A tangent vector at $[A]$ is represented by a Lie-algebra-valued 1-form $a = a_\mu\,\mathrm{d}x^\mu$ that

- keeps $A + ta$ self-dual to first order: $\mathrm{d}_A^- a = 0$;
- is orthogonal to the gauge orbit: $\mathrm{d}_A^* a = 0$ (background gauge, (8.212)).

Working definition 8.35 (zero mode)

A **zero mode** of the instanton A is an L^2 [with $\|a\|^2$ finite, so it falls off fast enough at $|x| \to \infty$] 1-form a with values in $\mathfrak{su}(2)$ that satisfies, with $D_\mu = \partial_\mu + [A_\mu, \cdot\,]$,

$$\text{(i)}\quad f_{14} = f_{23},\quad f_{24} = f_{31},\quad f_{34} = f_{12},\qquad \text{where } f_{\mu\nu} = D_\mu a_\nu - D_\nu a_\mu;$$
$$\text{(ii)}\quad D_\mu a_\mu = 0.$$

Condition (i) says the anti-self-dual part of $\mathrm{d}_A a = \tfrac{1}{2} f_{\mu\nu}\,\mathrm{d}x^{\mu\nu}$ vanishes (it is the coefficient of ω_a^- in the basis (8.181)); condition (ii) is $\mathrm{d}_A^* a = -D_\mu a_\mu = 0$. *Test:* four equations (three from (i), one from (ii)) for the four components a_μ, for each of the three colour directions. The space of zero modes is H^1 of the deformation complex [solutions of $\mathrm{d}_A^- a = 0$, with two counted as the same when they differ by a pure gauge $\mathrm{d}_A f$], so its dimension is $h_1 = \dim \mathcal{M}_k$ when $h_0 = h_2 = 0$ (Section 8.8.5).

Why the name? Expand the action around the instanton, $S(A + a) = S(A) + \langle a, \mathcal{K}a\rangle + O(a^3)$,

where in background gauge the fluctuation operator $\mathcal{K}$ is a Laplace-type operator. A zero mode is an eigenvector of $\mathcal{K}$ with eigenvalue 0: a direction in which the action does not change, because it moves us along the valley of minima. In the semiclassical path integral each zero mode must be traded for an integral over a **collective coordinate** (Section 8.10.3).

Watch out: framed and unframed zero modes

For the unframed space $\mathcal{M}_1$ we quotient by all gauge transformations, including those that tend to a non-trivial constant at infinity. For the framed space $\mathcal{M}_1'$ (Section 8.7.2) we quotient only by *based* gauge transformations, $g(\infty) = \mathbb{1}$. So $a = \mathrm{d}_A\Lambda$ with $\Lambda \to 0$ at infinity is never a zero mode, but $a = \mathrm{d}_A\Lambda$ with $\Lambda \to C \neq 0$ at infinity (in a gauge where $A \to 0$ at infinity) is a genuine zero mode of the framed problem. We expect 5 unframed and 8 framed zero modes (Example 8.66).

8.10.2 Zero modes from symmetries

Where do we look for solutions of (i) and (ii)? The instanton is a point in a family; moving along the family is a zero mode. We know two ways to move an instanton: change its parameters, or act on it with a symmetry of the equations. The self-duality equation is invariant under the conformal transformations of $\mathbb{R}^4$ (Section 8.4.1). So every infinitesimal conformal transformation V gives a candidate.

The naive candidate is the Lie derivative $\mathcal{L}_V A$. It is not gauge covariant: under $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$ it does not transform nicely, because $\mathcal{L}_V$ also differentiates g. The fix is to subtract a gauge transformation.

Worked example 8.85: The gauge-covariant derivative of A along V

Let ι_V be the interior product (contraction with V). Then

$$\begin{aligned} \iota_V F &\overset{(1)}{=} \iota_V \mathrm{d}A + \iota_V(A \wedge A) \\ &\overset{(2)}{=} \iota_V \mathrm{d}A + (\iota_V A)\,A - A\,(\iota_V A) \\ &\overset{(3)}{=} \mathcal{L}_V A - \mathrm{d}(\iota_V A) - [A, \iota_V A] \\ &\overset{(4)}{=} \mathcal{L}_V A - \mathrm{d}_A(\iota_V A). \end{aligned} \tag{8.252}$$

(1) $F = \mathrm{d}A + A \wedge A$.
(2) ι_V is an antiderivation: $\iota_V(\alpha \wedge \beta) = (\iota_V\alpha)\beta - \alpha(\iota_V\beta)$ for 1-forms α, β; here $\iota_V A$ is a matrix-valued function.
(3) Cartan's formula $\mathcal{L}_V A = \iota_V \mathrm{d}A + \mathrm{d}\,\iota_V A$ (Chapter T1).
(4) On a matrix-valued function Λ, $\mathrm{d}_A\Lambda = \mathrm{d}\Lambda + [A, \Lambda]$.

So $\iota_V F$ is "move A along the flow of V, then undo the gauge transformation with parameter $\iota_V A$". It is manifestly gauge covariant, because F is. In components, $(\iota_V F)_\mu = V^\nu F_{\nu\mu}$.

Key idea: Which symmetries give zero modes

Let A be self-dual on $\mathbb{R}^4$ and V a conformal Killing vector field. Then $a = \iota_V F$ satisfies the linearised self-duality equation (i). It satisfies the gauge condition (ii) exactly when $F_{\nu\mu}\,\partial_\mu V^\nu = 0$; this holds in particular when the antisymmetric part of the matrix $\partial_\mu V^\nu$ has no self-dual component.

Why (i) holds. Differentiate:

$$\begin{aligned} \mathrm{d}_A(\iota_V F) &\overset{(1)}{=} \mathrm{d}_A(\iota_V F) + \iota_V(\mathrm{d}_A F) \\ &\overset{(2)}{=} \mathrm{d}\iota_V F + \iota_V \mathrm{d}F + [\iota_V A, F] \\ &\overset{(3)}{=} \mathcal{L}_V F + [\iota_V A, F]. \end{aligned}$$

(1) The Bianchi identity $\mathrm{d}_A F = 0$ (Example 8.42); we add zero.
(2) Expand $\mathrm{d}_A\beta = \mathrm{d}\beta + A \wedge \beta + \beta \wedge A$ on the 1-form $\beta = \iota_V F$ and $\mathrm{d}_A F = \mathrm{d}F + A \wedge F - F \wedge A$ on the 2-form F; using the antiderivation rule on $\iota_V(A \wedge F - F \wedge A)$, the terms $A \wedge \iota_V F + \iota_V F \wedge A$ cancel and what survives is $(\iota_V A)F - F(\iota_V A)$.
(3) Cartan's formula on the 2-form F.

Both terms are self-dual. The commutator $[\iota_V A, F]$ multiplies the self-dual 2-form F by a matrix, which does not touch the form part. And $\mathcal{L}_V$ commutes with $\star$ on 2-forms when V is conformal, because the flow of V changes the metric only by a scale factor, and $\star$ on 2-forms in four dimensions does not see that factor. So $\mathcal{L}_V F = \mathcal{L}_V \star F = \star \mathcal{L}_V F$. Hence $\mathrm{d}_A(\iota_V F)$ is self-dual, i.e. $\mathrm{d}_A^-(\iota_V F) = 0$.

When (ii) holds. Take the covariant divergence:

$$\begin{aligned} D_\mu(\iota_V F)_\mu &\overset{(1)}{=} D_\mu\big(V^\nu F_{\nu\mu}\big) \\ &\overset{(2)}{=} (\partial_\mu V^\nu) F_{\nu\mu} + V^\nu D_\mu F_{\nu\mu} \\ &\overset{(3)}{=} (\partial_\mu V^\nu) F_{\nu\mu}. \end{aligned}$$

(1) Components of $\iota_V F$.
(2) Leibniz rule; V^ν is an ordinary function, so D_μ acts on it as ∂_μ.
(3) The Yang–Mills equation $D_\mu F_{\nu\mu} = 0$, which holds for every self-dual field (Section 8.4.2).

Only the antisymmetric part of $\partial_\mu V^\nu$ survives the contraction with $F_{\nu\mu}$. Split it into self-dual and anti-self-dual parts; the anti-self-dual part contracts to zero with the self-dual F by the orthogonality $\eta^a_{\mu\nu}\bar\eta^b_{\mu\nu} = 0$ of (8.183). So (ii) holds when the self-dual part of the "rotation" $\partial_{[\mu}V_{\nu]}$ is orthogonal to F.

The fifteen conformal Killing fields

The conformal Killing fields of $\mathbb{R}^4$ form the Lie algebra $\mathfrak{so}(5,1)$, of dimension 15:

$$\underbrace{P_\nu = \partial_\nu}_{\text{4 translations}}, \qquad \underbrace{D = x^\mu \partial_\mu}_{\text{1 dilation}}, \qquad \underbrace{M_{\mu\nu}}_{\text{6 rotations}}, \qquad \underbrace{K_b = 2(b\cdot x)x^\mu\partial_\mu - |x|^2 b^\mu \partial_\mu}_{\text{4 special conformal}}.$$

Quaternions split the rotations into two halves. Every rotation of $\mathbb{R}^4$ is $x \mapsto p\,x\,\bar q$ with unit quaternions p, q (Section 8.5), so the six rotation generators are

$$V_C^{\mathrm{L}}(x) = Cx \quad \text{(left)}, \qquad V_C^{\mathrm{R}}(x) = xC \quad \text{(right)}, \qquad C \in \operatorname{Im}\mathbb{H}.$$

(Here a vector field on $\mathbb{R}^4 = \mathbb{H}$ is written as a quaternion-valued function.)

Worked example 8.86: Left rotations are anti-self-dual, right rotations self-dual

Take $C = e_1$. With $x = x^4 + x^1 e_1 + x^2 e_2 + x^3 e_3$ and the rules (8.193),

$$\begin{aligned} e_1 x &\overset{(1)}{=} x^4 e_1 + x^1 e_1^2 + x^2 e_1 e_2 + x^3 e_1 e_3 \\ &\overset{(2)}{=} -x^1 + x^4 e_1 - x^3 e_2 + x^2 e_3. \end{aligned}$$

(1) Distribute.
(2) $e_1^2 = -1$, $e_1 e_2 = e_3$, $e_1 e_3 = -e_3 e_1 = -e_2$.

So $V^{\mathrm{L}} = (V^1, V^2, V^3, V^4) = (x^4, -x^3, x^2, -x^1)$. The matrix $\partial_\mu V^\nu$ has entries $\partial_4 V^1 = 1$, $\partial_1 V^4 = -1$, $\partial_3 V^2 = -1$, $\partial_2 V^3 = 1$. As a 2-form $\frac{1}{2}\partial_\mu V_\nu \, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$ this is $-\mathrm{d}x^{14} + \mathrm{d}x^{23} = \omega_1^-$: anti-self-dual. The same computation with $x e_1 = -x^1 + x^4 e_1 + x^3 e_2 - x^2 e_3$ gives $V^{\mathrm{R}} = (x^4, x^3, -x^2, -x^1)$ and the 2-form $-\mathrm{d}x^{14} - \mathrm{d}x^{23} = -\omega_1^+$: self-dual.

Now we run through the list with the BPST instanton.

Worked example 8.87: Translations: four zero modes

$V = P_\nu = \partial_\nu$ has $\partial_\mu V^\nu = 0$, so both (i) and (ii) hold. The mode is

$$a^{(\nu)} = \iota_{\partial_\nu} F = F_{\nu\mu} \, \mathrm{d}x^\mu = -\frac{2\lambda^2 \, \eta^a_{\nu\mu} \, e_a}{\phi^2} \, \mathrm{d}x^\mu.$$

By (8.252), $a^{(\nu)} = \partial_\nu A - \mathrm{d}_A(A_\nu)$. The first term is minus the derivative of the translated instanton $A(x - y)$ with respect to the centre y^ν; the second is an infinitesimal gauge transformation with parameter A_ν, which tends to zero at infinity ($A_\nu = O(1/r)$), so it is a *based* gauge transformation. Up to that correction, $a^{(\nu)}$ is "move the centre". It is in L^2 because $F = O(r^{-4})$. In fact it decays so fast that we can compute its norm at once (next subsection).

Worked example 8.88: The dilation: one zero mode

$V = D = x^\mu \partial_\mu$ has $\partial_\mu V^\nu = \delta^\nu_\mu$, which is symmetric, so (ii) holds. The mode is

$$\begin{aligned} \iota_D F &\overset{(1)}{=} x^\nu F_{\nu\mu} \, \mathrm{d}x^\mu \\ &\overset{(2)}{=} \frac{2\lambda^2}{\phi^2} \, \eta^a_{\mu\nu} x^\nu e_a \, \mathrm{d}x^\mu \\ &\overset{(3)}{=} \frac{2\lambda^2 \, \mathrm{Im}(\bar{x} \, \mathrm{d}x)}{\phi^2} \\ &\overset{(4)}{=} -\lambda \, \frac{\partial A}{\partial \lambda}. \end{aligned}$$

(1) Components of $\iota_V F$ with $V^\nu = x^\nu$.
(2) $F_{\nu\mu} = -2\lambda^2 \eta^a_{\nu\mu} e_a / \phi^2$ and $\eta^a_{\nu\mu} = -\eta^a_{\mu\nu}$.
(3) The third form of (8.200): $\mathrm{Im}(\bar{x} \, \mathrm{d}x) = \eta^a_{\mu\nu} x^\nu e_a \, \mathrm{d}x^\mu$.
(4) $A = \mathrm{Im}(\bar{x} \, \mathrm{d}x)/(|x|^2 + \lambda^2)$, so $\partial_\lambda A = -2\lambda \, \mathrm{Im}(\bar{x} \, \mathrm{d}x)/\phi^2$.

So the dilation mode is exactly the derivative with respect to the size, with no gauge correction. This is no accident: $x \mapsto sx$ maps the instanton of size λ to the one of size λ/s.

One can also check (ii) directly. With $a_\mu = \partial_\lambda A_\mu = h(r)\,\eta^a_{\mu\nu}x^\nu e_a$ and $h = -2\lambda/\phi^2$,

$$\partial_\mu a_\mu = h'(r)\frac{x^\mu}{r}\eta^a_{\mu\nu}x^\nu e_a + h\,\eta^a_{\mu\mu}e_a = 0, \qquad [A_\mu, a_\mu] = h\phi\,[A_\mu, A_\mu] = 0,$$

the first because $\eta^a_{\mu\nu}$ is antisymmetric and $x^\mu x^\nu$ symmetric, the second because $a_\mu = h\phi\,A_\mu$ is a multiple of A_μ for each μ.

Worked example 8.89: Left rotations: three framing modes

Take $V = V^{\mathrm{L}}_C = Cx$ with $C \in \operatorname{Im}\mathbb{H}$. By Example 8.86 the rotation part of V is anti-self-dual, so (ii) holds. To identify the mode, compute the two terms of (8.252). The flow of V is $x \mapsto p_t x$ with $p_t = e^{tC}$ a unit quaternion, and

$$\text{(pull-back of } A \text{ by } x \mapsto p_t x) \overset{(1)}{=} \frac{\operatorname{Im}\big(\overline{p_t x}\,\mathrm{d}(p_t x)\big)}{|p_t x|^2 + \lambda^2} \overset{(2)}{=} \frac{\operatorname{Im}(\bar{x}\,\bar{p}_t p_t\,\mathrm{d}x)}{|x|^2 + \lambda^2} = A.$$

(1) Substitute $p_t x$ for x in (8.200).
(2) $\overline{p_t x} = \bar{x}\bar{p}_t$, $\mathrm{d}(p_t x) = p_t\,\mathrm{d}x$ (p_t is constant), $|p_t x| = |x|$, and $\bar{p}_t p_t = 1$.

So $\mathcal{L}_V A = 0$: the BPST instanton is *literally* invariant under left rotations. Then (8.252) gives

$$\iota_V F = -\mathrm{d}_A \Lambda_C, \qquad \Lambda_C = \iota_V A = \frac{\operatorname{Im}(\bar{x}\,Cx)}{\phi} = \frac{\bar{x}\,C\,x}{|x|^2 + \lambda^2}$$

($\bar{x}Cx$ is already imaginary, since its conjugate is $\bar{x}\bar{C}x = -\bar{x}Cx$). So this mode is an infinitesimal gauge transformation. Is it a based one? At large $|x|$, $\Lambda_C \to \bar{x}Cx/|x|^2$, which is not zero; it is the constant C conjugated by $g = x/|x|$. Transform to the singular gauge (Section 8.5.4), in which $A \to 0$ at infinity; there the gauge parameter becomes

$$\Lambda^{\mathrm{sing}}_C = g\,\Lambda_C\,g^{-1} = \frac{x}{r}\frac{\bar{x}Cx}{\phi}\frac{\bar{x}}{r} = \frac{r^2}{r^2+\lambda^2}\,C \longrightarrow C.$$

So $\iota_V F$ is the infinitesimal gauge transformation that rotates the frame at infinity by C: a zero mode of the *framed* problem, and pure gauge in the unframed one. Three of them, one for each direction of C. Its gauge condition (ii) reads $D_\mu D_\mu \Lambda_C = 0$: Λ_C is a covariantly harmonic function that tends to the constant C at infinity.

Worked example 8.90: Right rotations: no zero modes

Take $V = V^{\mathrm{R}}_C = xC$, with flow $x \mapsto xq_t$, $q_t = e^{tC}$. Now

$$\text{(pull-back of } A) = \frac{\operatorname{Im}(\bar{q}_t\bar{x}\,\mathrm{d}x\,q_t)}{\phi} = \bar{q}_t A q_t,$$

because conjugation by a unit quaternion commutes with taking the imaginary part. Differentiating at $t = 0$, with $q_t \approx 1 + tC$:

$$\iota_V F \overset{(1)}{=} \mathcal{L}_V A - \mathrm{d}_A(\iota_V A) \overset{(2)}{=} [A, C] - \mathrm{d}_A\Big(\frac{\operatorname{Im}(\bar{x}\,xC)}{\phi}\Big)$$

$$\overset{(3)}{=} \mathrm{d}_A C - \mathrm{d}_A\Big(\frac{r^2 C}{\phi}\Big)$$
$$\overset{(4)}{=} \mathrm{d}_A\Big(\frac{\lambda^2}{r^2+\lambda^2}\, C\Big).$$

(1) (8.252).
(2) $\bar{q}_t A q_t \approx (1 - tC)A(1 + tC) = A + t[A, C]$; and $\iota_V A = \mathrm{Im}(\bar{x}V)/\phi$.
(3) C is constant, so $\mathrm{d}_A C = \mathrm{d}C + [A, C] = [A, C]$; and $\bar{x}x = r^2$.
(4) $1 - r^2/\phi = \lambda^2/\phi$.

The gauge parameter $\lambda^2 C/\phi$ vanishes at infinity, in either gauge. So $\iota_V F$ is a *based* gauge transformation: zero in H^1, not a zero mode. Consistently, it fails the gauge condition (ii), since its rotation part is self-dual (Example 8.86) and pairs non-trivially with F. This is the spin–isospin locking of Example 8.65 seen infinitesimally: a right rotation of space is undone by a colour rotation.

Special conformal transformations. For K_b the matrix $\partial_\mu V^\nu = 2b_\mu x^\nu - 2x_\mu b^\nu + 2(b\cdot x)\delta^\nu_\mu$ has an antisymmetric part $2(b_\mu x^\nu - x_\mu b^\nu)$ with both self-dual and anti-self-dual pieces, so (ii) fails. Modulo gauge, K_b moves the instanton the way a translation by $\lambda^2 b$ does; we will see this in Example 8.94. So $P_b - \lambda^{-2}K_b$ fixes the instanton, and the special conformal transformations add nothing new.

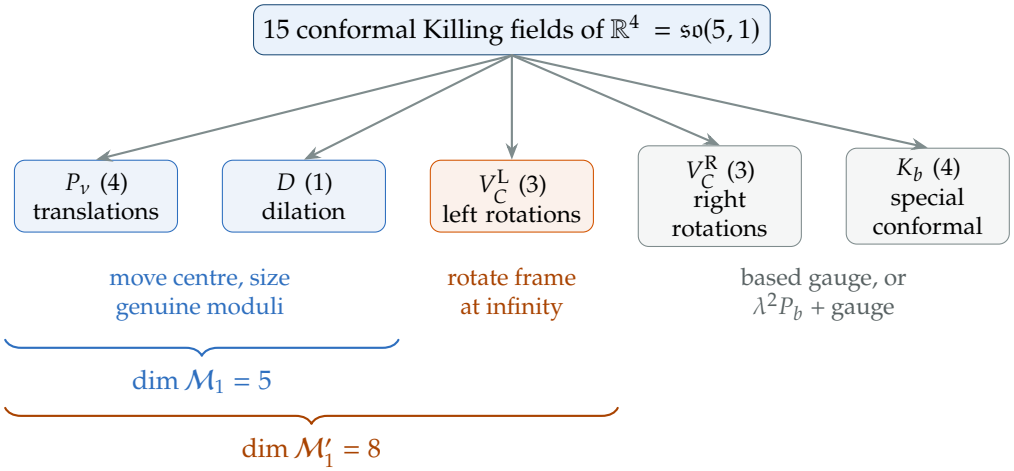

Figure 8.48: Zero-mode bookkeeping for the BPST instanton. Each conformal Killing field V gives the gauge-covariant variation $\iota_V F$. Translations and the dilation give the five genuine moduli; left rotations only turn the frame at infinity, so they count in the framed space $\mathcal{M}_1'$ but not in $\mathcal{M}_1$; the remaining seven generators fix the instanton up to gauge. The index theorem says there are no other zero modes.

Physical picture: the instanton is a highly symmetric object

Out of the 15-dimensional conformal group, a 10-dimensional subgroup (generated by the 6 rotations and the 4 combinations $P_b - \lambda^{-2}K_b$) fixes the unframed instanton. On the unit S^4 with $\lambda = 1$ this subgroup is the rotation group SO(5) of the sphere: the instanton is "round". The orbit of the instanton under the conformal group therefore has dimension $15 - 10 = 5$, which is the whole of $\mathcal{M}_1$. We return to this in Section 8.10.4.

8.10.3 The lengths of the zero modes: the metric on $\mathcal{M}_1$

The space of connections carries the flat L^2 metric $\langle a, b\rangle = -\int \mathrm{tr}(a \wedge \star b) = -\int \mathrm{tr}(a_\mu b_\mu)\,\mathrm{d}^4x$ ((8.165)). Restricting it to zero modes (which are orthogonal to the gauge orbits) gives a Riemannian metric on the moduli space, the L^2 **metric**. We now compute it for $\mathcal{M}_1$ and $\mathcal{M}_1'$.

Two tools. First, $\mathrm{tr}(e_a e_b) = -2\delta_{ab}$ (since $e_a = -i\sigma_a$). Second, contracting the third identity of (8.183) over $a = b$,

$$\eta^a_{\mu\nu}\eta^a_{\mu\rho} = 3\,\delta_{\nu\rho} \tag{8.253}$$

(the ε^{aac} term vanishes). And the radial integrals, with $u = r^2$ and $\mathrm{d}^4x = 2\pi^2 r^3\,\mathrm{d}r$ (the unit S^3 has volume $2\pi^2$):

$$\int_{\mathbb{R}^4} \frac{r^{2m}\,\mathrm{d}^4x}{(r^2+\lambda^2)^4} = \pi^2 \int_0^\infty \frac{u^{m+1}\,\mathrm{d}u}{(u+\lambda^2)^4} = \pi^2\lambda^{2m-4}\,\frac{(m+1)!\,(1-m)!}{3!} \qquad (m = 0, 1), \tag{8.254}$$

by the Beta integral $\int_0^\infty u^{p-1}(u+c)^{-p-q}\,\mathrm{d}u = c^{-q}\,\Gamma(p)\Gamma(q)/\Gamma(p+q)$ with $p = m+2$, $q = 2-m$. So the integral is $\pi^2/(6\lambda^4)$ for $m = 0$ and $\pi^2/(3\lambda^2)$ for $m = 1$.

Worked example 8.91: Norm of a translation mode

For fixed ν,

$$\begin{aligned}
\left\|a^{(\nu)}\right\|^2 &\overset{(1)}{=} -\int \mathrm{tr}\big(F_{\nu\mu}F_{\nu\mu}\big)\mathrm{d}^4x \\
&\overset{(2)}{=} -\int \frac{4\lambda^4}{\phi^4}\,\eta^a_{\nu\mu}\eta^b_{\nu\mu}\,\mathrm{tr}(e_a e_b)\,\mathrm{d}^4x \\
&\overset{(3)}{=} \int \frac{8\lambda^4}{\phi^4}\,\eta^a_{\nu\mu}\eta^a_{\nu\mu}\,\mathrm{d}^4x \\
&\overset{(4)}{=} 24\lambda^4 \int \frac{\mathrm{d}^4x}{(r^2+\lambda^2)^4} \\
&\overset{(5)}{=} 24\lambda^4\cdot\frac{\pi^2}{6\lambda^4} = 4\pi^2.
\end{aligned}$$

(1) Definition of the norm, with $(a^{(\nu)})_\mu = F_{\nu\mu}$ (sum over μ only).
(2) $F_{\nu\mu} = -2\lambda^2\eta^a_{\nu\mu}e_a/\phi^2$.
(3) $\mathrm{tr}(e_a e_b) = -2\delta_{ab}$.
(4) (8.253) with $\nu = \rho$ (no sum over ν): the sum over a, μ is 3.
(5) (8.254) with $m = 0$.

So $\left\|a^{(\nu)}\right\|^2 = 4\pi^2 = \frac{1}{2}S$, half the instanton action. (Sum over ν: $\sum_\nu \left\|a^{(\nu)}\right\|^2 = \|F\|^2\cdot 2 = 16\pi^2$, since $\sum_{\mu\nu} F_{\nu\mu}F_{\nu\mu}$ counts each component twice. A good check.) Different translation modes are orthogonal: $\eta^a_{\nu\mu}\eta^a_{\rho\mu} = 3\delta_{\nu\rho}$.

Worked example 8.92: Norm of the dilation mode

With $a = \partial_\lambda A$, $a_\mu = -2\lambda\,\eta^a_{\mu\nu}x^\nu e_a/\phi^2$:

$$\begin{aligned}
\|\partial_\lambda A\|^2 &\overset{(1)}{=} -\int \frac{4\lambda^2}{\phi^4}\,\eta^a_{\mu\nu}\eta^b_{\mu\rho}x^\nu x^\rho\ \mathrm{tr}(e_a e_b)\,\mathrm{d}^4x \\
&\overset{(2)}{=} \int \frac{8\lambda^2}{\phi^4}\cdot 3\,\delta_{\nu\rho}x^\nu x^\rho\,\mathrm{d}^4x
\end{aligned}$$

$$\overset{(3)}{=} 24\lambda^2 \int \frac{r^2\,\mathrm{d}^4x}{(r^2+\lambda^2)^4}$$
$$\overset{(4)}{=} 24\lambda^2 \cdot \frac{\pi^2}{3\lambda^2} = 8\pi^2.$$

(1) Definition of the norm and the formula for a_μ.
(2) $\operatorname{tr}(e_a e_b) = -2\delta_{ab}$, then (8.253).
(3) $\delta_{\nu\rho}x^\nu x^\rho = r^2$.
(4) (8.254) with $m = 1$.

The dilation mode is orthogonal to each translation mode: the integrand $-\operatorname{tr}(F_{\nu\mu}\partial_\lambda A_\mu)$ is odd under $x \mapsto -x$ (F is even, $\partial_\lambda A$ is odd), so it integrates to zero.

Worked example 8.93: Norm of a framing mode

For $V = Cx$ with $|C| = 1$, the mode is $a = \iota_V F$, $a_\mu = V^\nu F_{\nu\mu} = -2\lambda^2 V^\nu \eta^a_{\nu\mu} e_a/\phi^2$. Then pointwise

$$-\operatorname{tr}(a_\mu a_\mu) \overset{(1)}{=} \frac{8\lambda^4}{\phi^4}\,\eta^a_{\nu\mu}\eta^a_{\rho\mu}V^\nu V^\rho$$
$$\overset{(2)}{=} \frac{24\lambda^4}{\phi^4}\,|V|^2$$
$$\overset{(3)}{=} \frac{24\lambda^4\, r^2}{\phi^4},$$

(1) $\operatorname{tr}(e_a e_b) = -2\delta_{ab}$.
(2) (8.253) (with the antisymmetry of η used twice).
(3) $|V| = |Cx| = |C||x| = r$.

so, by (8.254) with $m = 1$, $\|\iota_V F\|^2 = 24\lambda^4 \cdot \pi^2/(3\lambda^2) = 8\pi^2\lambda^2$.
The same two steps work for *any* two vector fields V, W:

$$-\operatorname{tr}\big((\iota_V F)_\mu (\iota_W F)_\mu\big) = \frac{24\lambda^4}{\phi^4}\,V\cdot W. \tag{8.255}$$

All three norm computations are special cases: $V = W = \partial_\nu$ gives the translation density $24\lambda^4/\phi^4$, and $V = W = x$ (with $\partial_\lambda A = -\iota_x F/\lambda$) gives the dilation density $24\lambda^2 r^2/\phi^4$. It also settles orthogonality. A translation (V constant) against a dilation or framing mode (W linear in x): $V \cdot W$ is odd under $x \mapsto -x$, so the integral vanishes. Dilation against framing: $x \cdot Cx = \operatorname{Re}(\bar{x}\,Cx) = 0$ pointwise. Two framing modes: $Cx \cdot C'x = \operatorname{Re}(\overline{Cx}\,C'x) = r^2\,C\cdot C'$, zero for $C \perp C'$. So the eight modes with $C \in \{e_1, e_2, e_3\}$ are mutually orthogonal.

Key idea: The L^2 metric on the $k = 1$ moduli spaces of $\mathbb{R}^4$

In the coordinates (y, λ) of $\mathcal{M}_1 = \mathbb{R}^4 \times \mathbb{R}^+$, and with the framing $q \in \mathrm{SU}(2)/\{\pm 1\}$ for $\mathcal{M}_1'$,

$$\begin{aligned} \mathrm{d}s^2_{\mathcal{M}_1} &= 4\pi^2\,|\mathrm{d}y|^2 + 8\pi^2\,\mathrm{d}\lambda^2, \\ \mathrm{d}s^2_{\mathcal{M}_1'} &= 4\pi^2\,|\mathrm{d}y|^2 + 8\pi^2\big(\mathrm{d}\lambda^2 + \lambda^2|\mathrm{d}q|^2\big) = 4\pi^2\,|\mathrm{d}y|^2 + 8\pi^2\,|\mathrm{d}(\lambda q)|^2. \end{aligned} \tag{8.256}$$

Both are *flat*. The unframed space is a flat half-space; the framed space is $\mathbb{R}^4$ times the flat cone $\mathbb{H}^\times/\{\pm 1\} = (\mathbb{R}^4 \setminus 0)/\mathbb{Z}_2$, whose tip $\lambda q = 0$ is missing.

Here $|\mathrm{d}q|^2$ is the round metric of the unit $S^3 = \mathrm{SU}(2)$: moving q by $q\,e^{\theta C}$ has speed $|C| = 1$, matching the framing mode of norm $\sqrt{8}\,\pi\lambda$. The combination $\mathrm{d}\lambda^2 + \lambda^2|\mathrm{d}q|^2$ is flat $\mathbb{R}^4$ in polar coordinates, which is why the size and the framing merge into one quaternion λq (Example 8.66); we will meet the same quaternion as ADHM data in Section 8.10.6.

Physical picture: the boundary is at finite distance

In the metric (8.256) the distance from the instanton of size λ_0 to the "instanton of size 0" is $\sqrt{8}\,\pi\lambda_0$: finite. The moduli space is *incomplete*. A path in it can run off the edge in finite time, and what it runs into is a delta function of action density $8\pi^2\delta_y$ sitting at a point y of $\mathbb{R}^4$. This is the concrete meaning of Nash's "$\mathcal{M}_1$ is a non-compact space with boundary S^4". The other end, $\lambda \to \infty$, is at infinite distance.

Watch out: the metric depends on the metric of spacetime

The L^2 norm of a 2-form is conformally invariant in four dimensions, but that of a 1-form is not. So the metric (8.256) is the one induced by flat $\mathbb{R}^4$. On the round S^4 the L^2 metric on $\mathcal{M}_1$ is different (Groisser and Parker computed it): it is still invariant under the rotations SO(5) and still incomplete, with the boundary S^4 at finite distance, but it is neither flat nor the hyperbolic metric. What is canonical is the *action* of the conformal group, which we use next.

Dictionary: collective coordinates in the path integral

In the one-instanton contribution to $\int \mathcal{D}A\, e^{-S/g^2}$, the Gaussian integral over each zero mode would diverge. One changes variables from the zero-mode amplitudes to the moduli. If $\partial_i A$ are the zero modes with norms $\|\partial_i A\|$, the Jacobian is $\prod_i \|\partial_i A\| / (g\sqrt{2\pi})$ (the factor g because the action is S/g^2). For the framed $k = 1$ space, using the norms above,

$$\prod_{i=1}^{8} \frac{\|\partial_i A\|}{g\sqrt{2\pi}} \overset{(1)}{=} \frac{(2\pi)^4\,(\sqrt{8}\,\pi)\,(\sqrt{8}\,\pi\lambda)^3}{g^8(2\pi)^4} \overset{(2)}{=} \frac{64\pi^4\lambda^3}{g^8} = \frac{1}{64\pi^4}\Big(\frac{8\pi^2}{g^2}\Big)^4 \lambda^3.$$

(1) Four translation norms 2π, one dilation norm $\sqrt{8}\pi$, three framing norms $\sqrt{8}\pi\lambda$.
(2) $(\sqrt{8})^4 = 64$.

So the measure on $\mathcal{M}_1'$ is $\propto (8\pi^2/g^2)^4\,\lambda^3\,\mathrm{d}^4y\,\mathrm{d}\lambda\,\mathrm{d}^3q$: one power of $\sqrt{S_0}$ per zero mode, and $\lambda^3\mathrm{d}\lambda\,\mathrm{d}^3q$ is just the flat volume element $\mathrm{d}^4(\lambda q)$ of (8.256). Combined with the determinant of the non-zero modes this becomes 't Hooft's instanton density $\mathrm{d}^4y\,\mathrm{d}\lambda\,\lambda^{-5}\,(8\pi^2/g^2)^4\,e^{-8\pi^2/g^2(1/\lambda)}$, where the running coupling turns $e^{-8\pi^2/g^2}$ into $(\lambda\Lambda_{\mathrm{QCD}})^{22/3}$ for SU(2). The integral over λ then diverges at large λ: this is the infrared problem of Section 8.5.3, and it is the non-compact end $\lambda \to \infty$ of $\mathcal{M}_1$.

8.10.4 The global shape: $\mathcal{M}_1 = \mathbb{R}^4 \times \mathbb{R}^+ = H^5$

Suppose, as the ADHM construction will prove, that every $k = 1$ instanton on S^4 is a BPST instanton, determined up to gauge by its centre $y \in \mathbb{R}^4$ and size $\lambda > 0$ (Example 8.64). Then

$$\mathcal{M}_1 = \{(y, \lambda)\} = \mathbb{R}^4 \times \mathbb{R}^+,$$

the upper half-space of $\mathbb{R}^5$. What does Nash mean by calling it H^5?

Working definition 8.36 (hyperbolic space H^5)

The **upper half-space model** is $\{(y,\lambda)\in\mathbb{R}^4\times\mathbb{R}^+\}$ with the metric

$$\mathrm{d}s^2_{H^5}=\frac{|\mathrm{d}y|^2+\mathrm{d}\lambda^2}{\lambda^2}.$$

Its group of orientation-preserving isometries [maps of the half-space to itself that preserve $\mathrm{d}s^2_{H^5}$ and the orientation] is $\mathrm{SO}_0(5,1)$ (the identity component [the elements that can be joined to $\mathbb{1}$ by a continuous path] of $\mathrm{SO}(5,1)$), generated by translations and rotations of y, the scalings $(y,\lambda)\mapsto(sy,s\lambda)$, and the map $(y,\lambda)\mapsto(\bar y,\lambda)/(|y|^2+\lambda^2)$: the inversion in the unit sphere of $\mathbb{R}^5$ followed by the reflection $y\mapsto\bar y$. The **boundary at infinity** [the limit points, which lie at infinite distance in this metric] is the plane $\lambda=0$ together with one point at infinity: a copy of S^4. *Ball model:* the same space is the open unit ball B^5 with metric $4|\mathrm{d}X|^2/(1-|X|^2)^2$, whose boundary is the unit S^4.

The claim is that the conformal group of S^4 acts on $\mathcal{M}_1$ exactly as the isometry group of H^5 acts on the upper half-space. Translations of $\mathbb{R}^4$ move y. Rotations of $\mathbb{R}^4$ rotate y (and fix λ). The dilation $x\mapsto sx$ maps (y,λ) to $(sy,s\lambda)$. It remains to check an inversion, which together with these generates the conformal group. One care is needed: the inversion $I(x)=x/|x|^2$ *reverses* orientation (its differential is $|x|^{-2}$ times a reflection), so it turns self-dual fields into anti-self-dual ones. The orientation-preserving inversion is $x\mapsto x^{-1}=\bar x/|x|^2$, which is I followed by the reflection $x\mapsto\bar x$ (itself orientation reversing, as it flips three axes).

Worked example 8.94: The inversion acts on (y,λ) as inversion in the unit sphere of $\mathbb{R}^5$

Substitute $x=I(x')=x'/|x'|^2$. The instanton is determined up to gauge by its action density $s\,\mathrm{d}^4x$ with $s=48\lambda^4/(|x-y|^2+\lambda^2)^4$ (Example 8.64). This density is a conformally invariant measure (Section 8.4.1), so under the conformal map I it transforms as $s(x)\,\mathrm{d}^4x\mapsto s(I(x'))\,|\det\mathrm{d}I|\,\mathrm{d}^4x'$. Put $R^2=|y|^2+\lambda^2$, $y'=y/R^2$, $\lambda'=\lambda/R^2$. Then

$$\begin{aligned}|x-y|^2+\lambda^2 &\overset{(1)}{=}\frac{1}{|x'|^2}-\frac{2\,x'\cdot y}{|x'|^2}+R^2\\ &\overset{(2)}{=}\frac{R^2}{|x'|^2}\Big(|x'|^2-\frac{2\,x'\cdot y}{R^2}+\frac{1}{R^2}\Big)\\ &\overset{(3)}{=}\frac{R^2}{|x'|^2}\Big(|x'-y'|^2+\frac{1}{R^2}-\frac{|y|^2}{R^4}\Big)\\ &\overset{(4)}{=}\frac{R^2}{|x'|^2}\big(|x'-y'|^2+\lambda'^2\big).\end{aligned}$$

(1) Expand $|x-y|^2=|x|^2-2x\cdot y+|y|^2$ with $|x|^2=1/|x'|^2$ and $x\cdot y=x'\cdot y/|x'|^2$.
(2) Factor out $R^2/|x'|^2$.
(3) Complete the square: $|x'-y'|^2=|x'|^2-2x'\cdot y/R^2+|y|^2/R^4$.
(4) $1/R^2-|y|^2/R^4=\lambda^2/R^4=\lambda'^2$.

The inversion has $|\det\mathrm{d}I|=|x'|^{-8}$ (it is conformal with scale factor $|x'|^{-2}$, raised to the power 4). So

$$\begin{aligned}\frac{48\lambda^4\,\mathrm{d}^4x}{(|x-y|^2+\lambda^2)^4} &\overset{(1)}{=}\frac{48\lambda^4\,|x'|^8}{R^8\,(|x'-y'|^2+\lambda'^2)^4}\cdot\frac{\mathrm{d}^4x'}{|x'|^8}\\ &\overset{(2)}{=}\frac{48\lambda'^4\,\mathrm{d}^4x'}{(|x'-y'|^2+\lambda'^2)^4}.\end{aligned}$$

(1) The previous chain and the Jacobian.
(2) $\lambda^4/R^8 = (\lambda/R^2)^4 = \lambda'^4$.

So I carries the density of the instanton (y, λ) to the density of the (anti-)instanton with parameters

$$(y', \lambda') = \frac{(y, \lambda)}{|y|^2 + \lambda^2},$$

the inversion of the point $(y, \lambda) \in \mathbb{R}^5$ in the unit sphere. Following it by the reflection $x \mapsto \bar{x}$ restores self-duality and replaces y' by $\bar{y}'$. So the orientation-preserving inversion $x \mapsto x^{-1}$ acts on $\mathcal{M}_1$ by $(y, \lambda) \mapsto (\bar{y}, \lambda)/(|y|^2+\lambda^2)$, an isometry of H^5. For instance the instanton $(0, \lambda)$ goes to $(0, 1/\lambda)$: inversion exchanges small and large instantons, and fixes the instanton of size 1 centred at 0. The special conformal transformation is $K_b = I \circ P_b \circ I$ (two inversions, so orientation is preserved); on $(0, \lambda)$ it gives $(0, \lambda) \mapsto (0, 1/\lambda) \mapsto (\varepsilon b, 1/\lambda) \mapsto (\varepsilon\lambda^2 b, \lambda)+O(\varepsilon^2)$, a translation by $\lambda^2\varepsilon b$, as promised in Section 8.10.2.

Key idea: $\mathcal{M}_1$ is hyperbolic 5-space

The conformal group $\mathrm{SO}(5,1)$ of S^4 acts on $\mathcal{M}_1$ transitively, by the isometries of the hyperbolic metric $(|\mathrm{d}y|^2 + \mathrm{d}\lambda^2)/\lambda^2$. The stabiliser of the instanton $(0, 1)$ is $\mathrm{SO}(5)$. Hence

$$\mathcal{M}_1 \cong \mathrm{SO}(5,1)/\mathrm{SO}(5) = H^5, \qquad \partial\mathcal{M}_1 = S^4.$$

The hyperbolic metric is the unique (up to scale) metric invariant under the conformal group; it is *not* the L^2 metric (Section 8.10.3).

Worked example 8.95: The centre of H^5 is the round instanton

Take $y = 0$, $\lambda = 1$ and carry the instanton to the unit S^4 by stereographic projection, $g_{S^4} = 4(1 + r^2)^{-2} g_{\mathbb{R}^4}$ (8.184). The volume form of S^4 is then $\mathrm{vol}_{S^4} = 16(1 + r^2)^{-4}\mathrm{d}^4x$, so

$$s\,\mathrm{d}^4x \overset{(1)}{=} \frac{48\,\mathrm{d}^4x}{(1 + r^2)^4} \overset{(2)}{=} 3\,\mathrm{vol}_{S^4}.$$

(1) The action density with $\lambda = 1$, $y = 0$.
(2) $48 = 3 \cdot 16$.

The action density is *uniform* on the sphere. Check the total: $3\,\mathrm{Vol}(S^4) = 3 \cdot \frac{8\pi^2}{3} = 8\pi^2$. This is the $\mathrm{SO}(5)$-invariant instanton, the "centre" of H^5. Moving away from the centre towards a boundary point $p \in S^4$ concentrates the density near p.

Try it: Where is the instanton on the sphere?

Donaldson's **centre-of-mass map** sends an instanton on the unit $S^4 \subset \mathbb{R}^5$ to $c(A) = \frac{1}{8\pi^2}\int_{S^4} X\,|F|^2\mathrm{vol}$, where $X \in \mathbb{R}^5$ is the position vector and $|F|^2\mathrm{vol} = -\operatorname{tr}(F \wedge \star F)$. It is a point of the open ball B^5. For the instanton $(0, \lambda)$, only the height $X_5 = (r^2-1)/(r^2+1)$ contributes. Show that $c_5(0) = -1$ (south pole, the image of $x = 0$), $c_5 = 0$ at $\lambda = 1$, and $c_5 \to 1$ as $\lambda \to \infty$. *Answer:* the radial integral gives $c_5(\lambda) = \big(\lambda^8 - 8\lambda^6 + 24\lambda^4 \ln\lambda + 8\lambda^2 - 1\big)/(1 - \lambda^2)^4$, which has the three stated values (at $\lambda = 1$ the numerator vanishes to fifth order and the denominator to fourth, so the limit is 0, as it must be by the symmetry $\lambda \mapsto 1/\lambda$, which

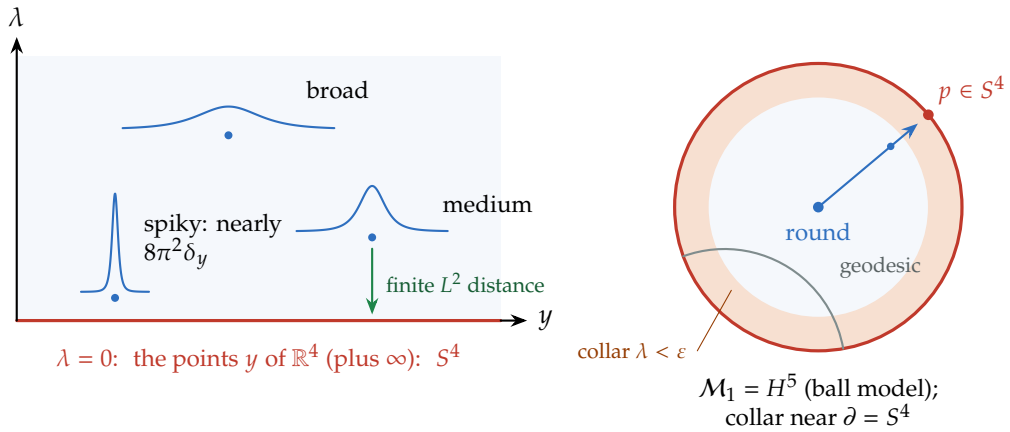

Figure 8.49: Two pictures of $\mathcal{M}_1$. *Left:* the upper half-space, one dimension of y shown. Each point (y, λ) is a BPST instanton, drawn as its action-density profile: broad high up, spiky near the boundary. As $\lambda \to 0$ the density tends to $8\pi^2\delta_y$, so the boundary is a copy of spacetime. *Right:* the ball model. The centre is the round instanton of Example 8.95; moving along a radius towards $p \in S^4$ concentrates the instanton at p. The shaded collar of small instantons is a copy of $S^4 \times (0, \varepsilon)$; it is the part of the picture that Donaldson generalises (Section 8.11).

maps $c_5 \mapsto -c_5$). The map $c : \mathcal{M}_1 \to B^5$ is a diffeomorphism: this is the ball model made concrete.

Watch out: which constant rotations are framings

In the regular gauge, conjugating A by a constant unit quaternion q gives the rotated instanton (Example 8.65), but a constant in the regular gauge is *not* constant near infinity: in the singular gauge it becomes $x\, q\, \bar{x}/r^2$, which depends on the direction of approach. The framing rotations are the gauge transformations that are constant *at infinity in the singular gauge*, like $\Lambda_C^{\text{sing}} \to C$ of Example 8.89. Both descriptions give the same conclusion, $\mathcal{M}_1' = \mathcal{M}_1 \times \mathrm{SO}(3)$, but only the second one is literally a statement about the frame at the base point.

8.10.5 The ADHM construction

We have assumed that every $k = 1$ instanton is BPST. More generally we would like to know *all* instantons. The 't Hooft ansatz of Section 8.5.5 gives $5k$ parameters, short of $8k - 3$ for $k \geq 3$. In 1978 Atiyah, Drinfeld, Hitchin and Manin found a construction that produces every instanton on S^4, for every k, from a few constant matrices. It is the **ADHM construction**. We give it for $\mathrm{SU}(2) = \mathrm{Sp}(1)$, using quaternions, and then say how it looks for $\mathrm{SU}(N)$.

Key idea: The ADHM pipeline

1. *Data.* Constant quaternionic matrices a, b of size $(k+1) \times k$.
2. *A linear family.* $\Delta(x) = a + b\,\bar{x}$, one matrix for each $x \in \mathbb{H} = \mathbb{R}^4$.
3. *ADHM condition.* $\Delta(x)^\dagger \Delta(x)$ is *real* (a real $k \times k$ matrix times the quaternion 1) and invertible, for every x. Write $f(x) = (\Delta^\dagger \Delta)^{-1}$.
4. *A unit vector.* $U(x) \in \mathbb{H}^{k+1}$ with $U^\dagger \Delta = 0$ and $U^\dagger U = 1$.
5. *The connection.* $A = U^\dagger \mathrm{d}U$. It is self-dual, with $F = U^\dagger b\, f\, (\mathrm{d}\bar{x} \wedge \mathrm{d}x)\, b^\dagger U$, and has charge k.

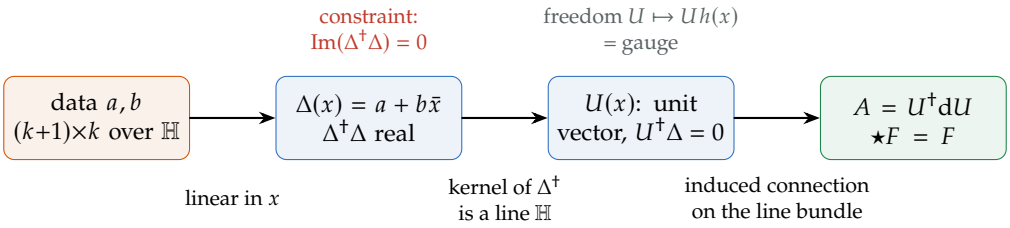

Figure 8.50: The ADHM construction as a pipeline. All the analysis is in the last box and is automatic; the only equation to solve is the algebraic constraint in the second box. The kernel of $\Delta(x)^\dagger$ is a quaternionic line in $\mathbb{H}^{k+1}$ that turns as x moves: this family of lines is the instanton bundle, and $A = U^\dagger \mathrm{d}U$ is the connection it inherits from the flat $\mathbb{H}^{k+1}$.

The idea behind step 5 is one we know from quantum mechanics: a **Berry connection**. If a unit vector $U(x)$ in a fixed vector space depends on parameters x, then $U^\dagger \mathrm{d}U$ is the connection that measures how U turns as x changes. Here the vector is quaternionic, so the connection takes values in $\mathrm{Im}\,\mathbb{H} = \mathfrak{su}(2)$. We now check each step and ask why it is legitimate.

Why U exists and is unique up to a phase. If $\Delta^\dagger\Delta$ is invertible, Δ has trivial kernel, so its image is a k-dimensional (quaternionic) subspace of $\mathbb{H}^{k+1}$. Its orthogonal complement, which is the kernel of $\Delta^\dagger$, is one-dimensional. A unit vector U in it is unique up to $U \mapsto Uh$ with $|h| = 1$, i.e. $h \in \mathrm{Sp}(1) = \mathrm{SU}(2)$.

Why A is $\mathfrak{su}(2)$-valued, and why h is a gauge transformation. Differentiating $U^\dagger U = 1$ gives $\mathrm{d}U^\dagger U + U^\dagger \mathrm{d}U = 0$, so $A = U^\dagger \mathrm{d}U$ satisfies $A^\dagger = -A$: an imaginary quaternion. If $U' = Uh(x)$ then

$$\begin{aligned} A' = U'^\dagger \mathrm{d}U' &\overset{(1)}{=} \bar{h}\, U^\dagger (\mathrm{d}U\, h + U\, \mathrm{d}h) \\ &\overset{(2)}{=} \bar{h} A h + \bar{h}\, \mathrm{d}h = h^{-1} A h + h^{-1} \mathrm{d}h, \end{aligned}$$

(1) Product rule; $(Uh)^\dagger = \bar{h} U^\dagger$.
(2) $U^\dagger U = 1$ and $\bar{h} = h^{-1}$.

which is (8.163).

The completeness relation. The two projectors $UU^\dagger$ (onto the kernel of $\Delta^\dagger$) and $\Delta f \Delta^\dagger$ (onto the image of Δ; check $(\Delta f \Delta^\dagger)^2 = \Delta f (\Delta^\dagger\Delta) f \Delta^\dagger = \Delta f \Delta^\dagger$) project onto complementary orthogonal subspaces. So

$$UU^\dagger + \Delta f \Delta^\dagger = \mathbb{1}_{k+1}. \tag{8.257}$$

Worked example 8.96: The ADHM curvature

$$\begin{aligned} F = \mathrm{d}A + A \wedge A &\overset{(1)}{=} \mathrm{d}U^\dagger \wedge \mathrm{d}U + U^\dagger \mathrm{d}U \wedge U^\dagger \mathrm{d}U \\ &\overset{(2)}{=} \mathrm{d}U^\dagger \wedge \mathrm{d}U - \mathrm{d}U^\dagger U \wedge U^\dagger \mathrm{d}U \\ &\overset{(3)}{=} \mathrm{d}U^\dagger (\mathbb{1} - UU^\dagger) \wedge \mathrm{d}U \\ &\overset{(4)}{=} \mathrm{d}U^\dagger \Delta f \Delta^\dagger \wedge \mathrm{d}U \\ &\overset{(5)}{=} U^\dagger\, \mathrm{d}\Delta\, f \wedge \mathrm{d}\Delta^\dagger\, U \\ &\overset{(6)}{=} U^\dagger b\, f\, (\mathrm{d}\bar{x} \wedge \mathrm{d}x)\, b^\dagger U. \end{aligned}$$

(1) $\mathrm{d}(U^\dagger \mathrm{d}U) = \mathrm{d}U^\dagger \wedge \mathrm{d}U$.
(2) $U^\dagger \mathrm{d}U = -\mathrm{d}U^\dagger U$ (from $U^\dagger U = 1$).

(3) Factor.
(4) The completeness relation (8.257).
(5) Differentiate $U^\dagger\Delta = 0$: $\mathrm{d}U^\dagger\Delta = -U^\dagger\mathrm{d}\Delta$, and similarly $\Delta^\dagger\mathrm{d}U = -\mathrm{d}\Delta^\dagger U$; the two minus signs cancel.
(6) $\mathrm{d}\Delta = b\,\mathrm{d}\bar{x}$, $\mathrm{d}\Delta^\dagger = \mathrm{d}x\,b^\dagger$; take b real (the canonical form below), so b and f commute with the quaternion $\mathrm{d}\bar{x}$, and f can be moved to the left of $\mathrm{d}\bar{x}$.

Now $\mathrm{d}\bar{x}\wedge\mathrm{d}x = -2e_a\omega_a^+$ is self-dual (8.195), and F is a sum of terms $p\,(\mathrm{d}\bar{x}\wedge\mathrm{d}x)\,q$ with quaternions p, q, each a combination of the ω_a^+. So $\star F = F$. The reality of f was essential in step 6: a non-real f would not commute with $\mathrm{d}\bar{x}$, and anti-self-dual pieces could appear.

The ADHM data in canonical form

The data has redundancies: $\Delta \mapsto Q\Delta R$ with $Q \in \mathrm{Sp}(k+1)$ and $R \in \mathrm{GL}(k,\mathbb{R})$ changes nothing essential (it rotates $\mathbb{H}^{k+1}$ and reparametrises the image). Using them one brings b to the form

$$b = \begin{pmatrix} 0 \\ \mathbb{1}_k \end{pmatrix}, \qquad a = \begin{pmatrix} L \\ M \end{pmatrix}, \qquad L \in \mathbb{H}^{1\times k}, \quad M \in \mathbb{H}^{k\times k}.$$

Then $\Delta(x) = \begin{pmatrix} L \\ M + \bar{x}\mathbb{1}_k \end{pmatrix}$.

Worked example 8.97: The ADHM constraint in canonical form

$$\begin{aligned}\Delta^\dagger\Delta &\overset{(1)}{=} L^\dagger L + (M^\dagger + x\mathbb{1})(M + \bar{x}\mathbb{1}) \\ &\overset{(2)}{=} L^\dagger L + M^\dagger M + xM + M^\dagger\bar{x} + |x|^2\mathbb{1}.\end{aligned}$$

(1) Block multiplication; $(\bar{x}\mathbb{1})^\dagger = x\mathbb{1}$.
(2) Expand; $x\bar{x} = |x|^2$.

For this to be real for *all* x, the part linear in x must be real for all x, and the constant part must be real. Entry (i,j) of the linear part is $xM_{ij} + \overline{M_{ji}}\,\bar{x}$. If M is symmetric, $M_{ji} = M_{ij}$, this is $xM_{ij} + \overline{xM_{ij}} = 2\,\mathrm{Re}(xM_{ij})$: real. (Conversely, reality for all x forces $M^T = M$.) So the conditions are

$$M^T = M, \qquad \mathrm{Im}\big(L^\dagger L + M^\dagger M\big) = 0, \tag{8.258}$$

plus non-degeneracy ($\Delta^\dagger\Delta$ invertible for every x). The remaining redundancy preserving the canonical form is $\Delta \mapsto \begin{pmatrix} p & 0 \\ 0 & R \end{pmatrix}\Delta R^{-1}$ with $p \in \mathrm{Sp}(1)$ and $R \in \mathrm{O}(k)$, i.e. $L \mapsto pLR^{-1}$, $M \mapsto RMR^{-1}$.

8.10.6 The case $k = 1$ in full

For $k = 1$, $L = \lambda q$ is a single quaternion and $M = -\bar{y}$ is a single quaternion (a 1×1 matrix is automatically symmetric). The constraint $\mathrm{Im}(|L|^2 + |M|^2) = 0$ is automatic. So the data is simply

$$\Delta(x) = \begin{pmatrix} \lambda q \\ \bar{x} - \bar{y} \end{pmatrix}, \qquad \lambda > 0,\ |q| = 1,\ y \in \mathbb{H},$$

and $\Delta^\dagger\Delta = \lambda^2 + |x-y|^2$ is real and never zero. No equations to solve at all.

Worked example 8.98: ADHM reproduces BPST

Take $q = 1$ and $y = 0$ first. We need $U = (u_1, u_2)^T$ with $U^\dagger \Delta = \bar{u}_1 \lambda + \bar{u}_2 \bar{x} = 0$. Try $u_2 = \lambda/\sqrt{\phi}$; then $\bar{u}_1 \lambda = -\lambda \bar{x}/\sqrt{\phi}$, so $u_1 = -x/\sqrt{\phi}$:

$$U = \frac{1}{\sqrt{\phi}} \begin{pmatrix} -x \\ \lambda \end{pmatrix}, \qquad U^\dagger U = \frac{|x|^2 + \lambda^2}{\phi} = 1.$$

Then

$$\begin{aligned} A = U^\dagger \mathrm{d}U &\overset{(1)}{=} \frac{1}{\sqrt{\phi}} (-\bar{x},\ \lambda) \Big[\frac{1}{\sqrt{\phi}} \begin{pmatrix} -\mathrm{d}x \\ 0 \end{pmatrix} + \mathrm{d}\big(\phi^{-1/2}\big) \begin{pmatrix} -x \\ \lambda \end{pmatrix} \Big] \\ &\overset{(2)}{=} \frac{\bar{x}\, \mathrm{d}x}{\phi} + \sqrt{\phi}\, \mathrm{d}\big(\phi^{-1/2}\big) \\ &\overset{(3)}{=} \frac{\bar{x}\, \mathrm{d}x - \frac{1}{2}\mathrm{d}\phi}{\phi} \\ &\overset{(4)}{=} \frac{\mathrm{Im}(\bar{x}\, \mathrm{d}x)}{|x|^2 + \lambda^2}. \end{aligned}$$

(1) Product rule on $U = \phi^{-1/2}(-x, \lambda)^T$; λ is constant.
(2) First term: $(-\bar{x})(-\mathrm{d}x)/\phi$. Second term: $\phi^{-1/2}(\bar{x}x + \lambda^2)\mathrm{d}(\phi^{-1/2}) = \phi^{1/2}\mathrm{d}(\phi^{-1/2})$.
(3) $\phi^{1/2}\mathrm{d}(\phi^{-1/2}) = -\frac{1}{2}\phi^{-1}\mathrm{d}\phi$.
(4) (8.201): $\bar{x}\, \mathrm{d}x - \frac{1}{2}\mathrm{d}\phi = \mathrm{Im}(\bar{x}\, \mathrm{d}x)$.

This is exactly the BPST instanton (8.200) in the regular gauge. The curvature formula of Example 8.96 gives it in one line: $f = 1/\phi$ and $b^\dagger U = u_2 = \lambda/\sqrt{\phi}$, so $F = \frac{\lambda}{\sqrt{\phi}} \cdot \frac{1}{\phi}\, \mathrm{d}\bar{x} \wedge \mathrm{d}x \cdot \frac{\lambda}{\sqrt{\phi}} = \lambda^2\, \mathrm{d}\bar{x} \wedge \mathrm{d}x/\phi^2$, which is (8.202). With $y \neq 0$, replace x by $x - y$ throughout: the centre is y.

Worked example 8.99: The quaternion λq is size and framing

Now restore q. The data $(\lambda q, \bar{x})$ is obtained from $(\lambda, \bar{x})$ by the canonical-form symmetry with $p = q$, $R = 1$: $\Delta_q = \mathrm{diag}(q, 1)\Delta_1$. Then $U_q = \mathrm{diag}(q, 1)U_1$ solves $U_q^\dagger \Delta_q = U_1^\dagger \Delta_1 = 0$, and

$$A_q = U_q^\dagger \mathrm{d}U_q = U_1^\dagger\, \mathrm{diag}(\bar{q}, 1)\, \mathrm{diag}(q, 1)\mathrm{d}U_1 = A_1.$$

The connection is literally the same. What changes is the identification of the fibre at infinity with $\mathbb{H}$: as $|x| \to \infty$, $U_q \to (-q\, x/|x|, 0)^T$, so the top component, which is how the fibre at infinity is matched to the fixed $\mathbb{H}$ in the first row, is rotated by q. So q is the framing at infinity. The remaining symmetry $R \in \mathrm{O}(1) = \{\pm 1\}$ sends $(\lambda q, \bar{x} - \bar{y}) \mapsto (-\lambda q, \bar{x} - \bar{y})$. Therefore

$$\mathcal{M}_1' = \big\{(y, \lambda q)\big\}/\pm = \mathbb{R}^4 \times \big(\mathbb{H} \setminus \{0\}\big)/\mathbb{Z}_2, \qquad \mathcal{M}_1 = \mathcal{M}_1'/\mathrm{Sp}(1) = \mathbb{R}^4 \times \mathbb{R}^+,$$

in agreement with Example 8.66 and with the flat metric (8.256), in which λq is a Cartesian coordinate.

Since the ADHM construction gives *every* instanton (a theorem we discuss below), and at $k = 1$ it gives only BPST instantons, we have finally proved:

Key idea: Every charge-one $\mathrm{SU}(2)$ instanton on S^4 is BPST

$\mathcal{M}_1 = \{(y,\lambda)\} = \mathbb{R}^4 \times \mathbb{R}^+ \cong H^5$, and $\mathcal{M}_1' = \mathbb{R}^4 \times (\mathbb{R}^4 \setminus 0)/\mathbb{Z}_2$.

8.10.7 General k: counting, 't Hooft, and $\mathrm{SU}(N)$

Worked example 8.100: The ADHM count gives $8k$ and $8k-3$

Count real parameters in the canonical form:

$$\begin{aligned}\dim \mathcal{M}_k' &\overset{(1)}{=} \underbrace{4k}_{L} + \underbrace{4\cdot\tfrac{k(k+1)}{2}}_{M=M^T} - \underbrace{3\cdot\tfrac{k(k-1)}{2}}_{\mathrm{Im}(L^\dagger L + M^\dagger M)=0} - \underbrace{\tfrac{k(k-1)}{2}}_{\mathrm{O}(k)} \\ &\overset{(2)}{=} 4k + 2k^2 + 2k - 2k^2 + 2k \\ &\overset{(3)}{=} 8k.\end{aligned}$$

(1) L has k quaternion entries; a symmetric $k\times k$ quaternionic matrix has $k(k+1)/2$ independent entries. The matrix $X = L^\dagger L + M^\dagger M$ is quaternionic Hermitian, $X_{ji} = \overline{X_{ij}}$, so its imaginary part is antisymmetric: $k(k-1)/2$ independent entries, each with three imaginary components. Finally divide by $\mathrm{O}(k)$, of dimension $k(k-1)/2$ (it acts freely on non-degenerate data).
(2) $3k(k-1)/2 + k(k-1)/2 = 2k(k-1) = 2k^2 - 2k$.
(3) Collect.

Quotienting by the framing $\mathrm{Sp}(1)$ removes 3 more: $\dim \mathcal{M}_k = 8k-3$. The purely algebraic count agrees with the index theorem of Section 8.9. For $k=2$: L gives 8, M (three quaternions) gives 12, the constraint is one imaginary quaternion (3), and $\mathrm{O}(2)$ has dimension 1: $8+12-3-1 = 16 = 8\cdot 2$.

Worked example 8.101: The 't Hooft solutions are ADHM with diagonal M

Take $L = (\lambda_1,\dots,\lambda_k)$ *real* and $M = -\operatorname{diag}(\bar y_1,\dots,\bar y_k)$. Then $M^T = M$, and $L^\dagger L$ (entries $\lambda_i\lambda_j$) and $M^\dagger M$ (entries $|y_i|^2\delta_{ij}$) are real: the constraint holds. Now $\Delta^\dagger\Delta = \operatorname{diag}(r_1^2,\dots,r_k^2) + \lambda\lambda^T$ with $r_i = |x-y_i|$, and the matrix determinant lemma $\det(D+vv^T) = \det D\,(1+v^TD^{-1}v)$ gives

$$\begin{aligned}\det(\Delta^\dagger\Delta) &\overset{(1)}{=} \Big(\prod_i r_i^2\Big)\Big(1+\sum_i \frac{\lambda_i^2}{r_i^2}\Big) \\ &\overset{(2)}{=} \Big(\prod_i r_i^2\Big)\,\rho(x),\end{aligned}$$

(1) Determinant lemma with $D = \operatorname{diag}(r_i^2)$ and $v = \lambda$.
(2) $\rho = 1 + \sum \lambda_i^2/|x-y_i|^2$ is the 't Hooft potential (8.207).

For every ADHM instanton there is a formula of Osborn for the action density,

$$-\tfrac{1}{2}\operatorname{tr}(F_{\mu\nu}F_{\mu\nu}) = -\tfrac{1}{2}\,\Box\Box \ln\det\big(\Delta^\dagger\Delta\big). \tag{8.259}$$

Check it at $k=1$: $\det\Delta^\dagger\Delta = \phi$, and a short radial computation (as in Example 8.57) gives $\Box\Box\ln\phi = -96\lambda^4/\phi^4$, so the right side is $48\lambda^4/\phi^4$, the BPST density. For the diagonal data, $\ln\det = \sum_i \ln r_i^2 + \ln\rho$, and $\Box\Box\ln r_i^2 = \Box(4/r_i^2) = 0$ away from y_i. So the density is

$-\frac{1}{2}\Box\Box \ln \rho$, which is exactly the 't Hooft density (8.208). (A numerical evaluation of both sides at random points for $k = 2$ confirms the agreement.) So the 't Hooft solutions are the ADHM instantons with real L and diagonal M.

The 't Hooft family has real λ_i: all lumps have the same colour orientation. Making the λ_i genuine quaternions $\lambda_i q_i$ breaks the constraint: the off-diagonal entry of $\mathrm{Im}(L^\dagger L)$ is $\mathrm{Im}(\lambda_i \lambda_j \bar{q}_i q_j)$, non-zero when $q_i \neq \pm q_j$. To restore it the off-diagonal entries of M must be switched on. So the relative colour orientations of the lumps, the $3(k-1)$ parameters missing from Figure 8.37, are tied to off-diagonal "positions". For well-separated lumps the off-diagonal entries are small and the y_i are the centres; when the lumps overlap, the notion of individual positions dissolves.

Try it: The complex ADHM data for $\mathrm{SU}(N)$

For $\mathrm{SU}(N)$ the ADHM data are complex matrices B_1, B_2 $(k \times k)$, I $(k \times N)$, J $(N \times k)$, subject to

$$[B_1, B_2] + IJ = 0 \quad \text{(complex)}, \qquad [B_1, B_1^\dagger] + [B_2, B_2^\dagger] + II^\dagger - J^\dagger J = 0 \quad \text{(real)},$$

modulo $\mathrm{U}(k)$. Count the framed dimension, and deduce the first row of Nash's table (8.137). *Answer:* $2(2k^2 + 2kN)$ real parameters, minus $2k^2$ (complex equation) minus k^2 (real equation) minus k^2 ($\mathrm{U}(k)$) gives $\dim \mathcal{M}'_k = 4kN$. Removing the framing $\mathrm{SU}(N)$ gives $4kN - (N^2 - 1) = 4Nk - N^2 + 1$, Nash's entry for $\mathrm{SU}(N)$. At $k = 1$, $N = 2$ it is 5. Moreover the gauge field lives in $\mathbb{C}^N$, but the data only "see" the span of the columns of $I^\dagger$ and J, a subspace of dimension at most $2k$. If $N > 2k$, its orthogonal complement is a trivial flat summand of the bundle, and the instanton is reducible: this is Nash's condition $k \geq N/2$.

Why every instanton arises

The completeness of the construction is a theorem (Atiyah, Drinfeld, Hitchin and Manin, 1978). The route is through **twistor theory**, and we only outline it. There is a fibration $\mathbb{CP}^3 \to S^4$ whose fibres are $\mathbb{CP}^1$'s. The Penrose–Ward correspondence turns a self-dual connection on S^4 into a *holomorphic* vector bundle on $\mathbb{CP}^3$: pull the bundle and its connection back to $\mathbb{CP}^3$ and use the $(0,1)$ part of the pulled-back connection as a $\bar{\partial}$-operator. Self-duality on S^4 is exactly the integrability condition $\bar{\partial}^2 = 0$ that makes this a holomorphic structure; the bundle is then holomorphically trivial on every fibre. Holomorphic bundles on $\mathbb{CP}^3$ of this type can be described by linear algebra (Horrocks' *monads*, which Barth applied to this problem), and unwinding the monad gives exactly the matrix $\Delta(x)$. This is the algebraic geometry of Chapter 5 solving a problem of non-linear partial differential equations: the self-duality equation, which looks hard, becomes a statement about holomorphic objects, which are rigid.

Physical picture: why linear algebra can solve a non-linear PDE

The ADHM ansatz $A = U^\dagger \mathrm{d}U$ builds the instanton as a Berry connection of a moving line inside a fixed flat space $\mathbb{H}^{k+1}$. Every connection can be obtained this way for *some* embedding (this is a theorem of Narasimhan and Ramanan). What ADHM finds is that for self-dual connections on S^4 the embedding can always be chosen *linear in* x, as the kernel of $\Delta(x)^\dagger$. The self-duality equation becomes the algebraic condition that $\Delta^\dagger \Delta$ is real.

Reading Nash (p. 241)

Nash states that for $M = S^4$ the SU(2) moduli space $\mathcal{M}_1$ is five-dimensional, non-compact, with boundary S^4, and "in fact $\mathcal{M}_1$ is the five dimensional hyperbolic space H^5". The dimension is his (8.132) at $k = 1$. The rest is Section 8.10.4: the parameters are (y, λ), the conformal group SO(5, 1) of S^4 acts on them as the isometries of H^5 (Example 8.94), and the boundary $\lambda = 0$ consists of point-like instantons, one for each point of S^4. That there are no other $k = 1$ instantons is the ADHM theorem (Example 8.98). Nash does not mention zero modes or ADHM; they are the standard physicist's and mathematician's ways of making his statement concrete.

Recap

- A zero mode solves $\mathrm{d}_A^- a = 0$ and $\mathrm{d}_A^* a = 0$; it is a tangent vector to the moduli space. For every conformal Killing field V, $\iota_V F = \mathcal{L}_V A - \mathrm{d}_A(\iota_V A)$ solves the first equation, and the second when the rotation part of V has no self-dual component.
- For BPST: 4 translations and 1 dilation give $\mathcal{M}_1$; 3 left rotations rotate the frame at infinity, giving $\mathcal{M}_1'$; right rotations and special conformal maps add nothing.
- Norms: $4\pi^2$, $8\pi^2$, $8\pi^2\lambda^2$. The L^2 metric on $\mathcal{M}_1'$ is flat, $4\pi^2|\mathrm{d}y|^2 + 8\pi^2|\mathrm{d}(\lambda q)|^2$; the boundary $\lambda = 0$ is at finite distance.
- The conformal group acts on (y, λ) as the isometries of the upper half-space: $\mathcal{M}_1 = \mathrm{SO}(5,1)/\mathrm{SO}(5) = H^5$, with boundary S^4 made of point-like instantons.
- ADHM: $\Delta(x) = a + b\bar{x}$ with $\Delta^\dagger\Delta$ real, $U \in \operatorname{Ker}\Delta^\dagger$, $A = U^\dagger \mathrm{d}U$, $F = U^\dagger b f\, \mathrm{d}\bar{x} \wedge \mathrm{d}x\, b^\dagger U$ self-dual. At $k = 1$ it gives BPST and nothing else; in general it gives $8k$ framed parameters, the 't Hooft solutions as diagonal data, and for SU(N) the dimension $4Nk - N^2 + 1$.

8.11 The moduli space as a global object

Nash ends the section with a warning and two outlooks (pp. 240–242). The warning: "the Atiyah–Singer index calculation is an infinitesimal one." It counts tangent vectors at a point $[A]$. It does not tell us that there is a manifold for these vectors to be tangent to. The outlooks: the global moduli space is a powerful tool of *topology* (Donaldson's theorem), and it approximates the *configuration space* of gauge theory (Atiyah–Jones). This section takes them in turn:

1. the three conditions that turn a dimension count into a manifold: existence, integrability, and the Hausdorff property;
2. Donaldson's theorem, previewed through the moduli space $\mathcal{M}_1$ we now know well;
3. Nash's analogy with the moduli of Riemann surfaces;
4. the inclusion $\mathcal{M}_k' \hookrightarrow \mathcal{A}/\mathcal{G}$ and what it says about the topology of the space of all gauge fields.

8.11.1 From a dimension count to a manifold

A finite-dimensional analogy shows what can go wrong. Take a smooth map $\Phi : \mathbb{R}^n \to \mathbb{R}^m$ and its zero set $Z = \Phi^{-1}(0)$. At a point $p \in Z$ the linearisation $\mathrm{d}\Phi_p$ has kernel $\operatorname{Ker}\mathrm{d}\Phi_p$ (the *infinitesimal* solutions) and cokernel $\operatorname{Coker}\mathrm{d}\Phi_p$. The index $\dim\operatorname{Ker} - \dim\operatorname{Coker} = n - m$ is the same at every point. We call it the **expected dimension**. The implicit function theorem says: if $\mathrm{d}\Phi_p$ is *onto* (cokernel zero), then near p the set Z is a manifold of dimension $\dim\operatorname{Ker}\mathrm{d}\Phi_p = n - m$. If the cokernel is not zero, anything can happen.

Worked example 8.102: Three zero sets in the plane

Take $n = 2$, $m = 1$, so the expected dimension is 1, and $p = 0$.

- $\Phi = y - x^2$. $\mathrm{d}\Phi_0 = (0, 1)$ is onto. Z is the parabola, a smooth curve with tangent line $\operatorname{Ker} \mathrm{d}\Phi_0 = \{y = 0\}$.
- $\Phi = xy$. $\mathrm{d}\Phi_0 = (0, 0)$: every vector is an infinitesimal solution ($\operatorname{Ker} = \mathbb{R}^2$) and the cokernel is $\mathbb{R}$. Z is the union of the two axes: not a manifold at 0. The quadratic term xy *obstructs* most infinitesimal solutions: only those along the axes extend to actual curves in Z.
- $\Phi = x^2 + y^2$. Again $\operatorname{Ker} = \mathbb{R}^2$, $\operatorname{Coker} = \mathbb{R}$. Now $Z = \{0\}$: *no* infinitesimal solution extends, and Z has dimension 0, less than expected.

In each case $\dim \operatorname{Ker} - \dim \operatorname{Coker} = 1$, as the index says. What differs is how the cokernel (the **obstruction space**) interacts with the higher-order terms.

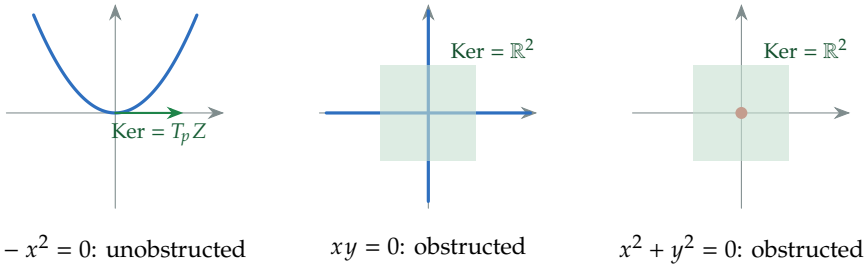

Figure 8.51: Three maps $\mathbb{R}^2 \to \mathbb{R}$ with the same index 1. When the derivative is onto (left) the zero set is a manifold whose tangent space is the kernel. When it is not (middle, right), the kernel (shaded) is larger than the zero set's true tangent directions, and the zero set may be singular or too small. For instantons, the cokernel is H^2 of the deformation complex.

Condition 1: existence

We must first have at least one instanton. On S^4 this is the BPST instanton and its relatives (Sections 8.5 and 8.10); as Nash says, "the first condition is easily met as many instantons are known". On a general M it is a theorem of Taubes (1982): if the intersection form of M has no negative part ($b_2^- = 0$ in our orientation, where instantons are self-dual), then for every $k \geq 1$ there are self-dual SU(2) connections of charge k. They are constructed by *grafting*: take k very small BPST instantons, cut them off far from their centres, glue them into the trivial connection on M at k points, and correct the result to an exact solution. The correction exists because the obstruction to it lies in a space built from self-dual-type harmonic forms on M, which vanishes when $b_2^- = 0$.

Condition 2: integrability, and the Kuranishi picture

Near an instanton A, write a nearby connection in background gauge, $A + a$ with $\mathrm{d}_A^* a = 0$. It is self-dual when

$$\Phi(a) := \pi_- F(A + a) = \mathrm{d}_A^- a + \pi_-(a \wedge a) = 0, \tag{8.260}$$

by the expansion (8.224). This is the infinite-dimensional version of the example above: $\Phi : \{a : \mathrm{d}_A^* a = 0\} \to \Omega^2_-(\mathrm{ad}\, P)$, with linearisation d_A^-, kernel H^1 and cokernel H^2.

Worked example 8.103: Extending a zero mode to second order

Given a zero mode $a_1 \in H^1$, look for a curve of instantons $A(t) = A + ta_1 + t^2 a_2 + O(t^3)$. Substituting into (8.260),

$$\begin{aligned}\pi_- F(A(t)) &\overset{(1)}{=} \pi_-\big(F + t\,\mathrm{d}_A a_1 + t^2\,\mathrm{d}_A a_2 + t^2\, a_1 \wedge a_1\big) + O(t^3)\\ &\overset{(2)}{=} t\,\mathrm{d}_A^- a_1 + t^2\big(\mathrm{d}_A^- a_2 + \pi_-(a_1 \wedge a_1)\big) + O(t^3)\\ &\overset{(3)}{=} t^2\big(\mathrm{d}_A^- a_2 + \pi_-(a_1 \wedge a_1)\big) + O(t^3).\end{aligned}$$

(1) $F(A+b) = F + \mathrm{d}_A b + b \wedge b$ with $b = ta_1 + t^2 a_2$; keep terms up to t^2.
(2) $\pi_- F = 0$ since A is self-dual; $\mathrm{d}_A^- = \pi_- \circ \mathrm{d}_A$.
(3) a_1 is a zero mode.

So we must solve $\mathrm{d}_A^- a_2 = -\pi_-(a_1 \wedge a_1)$. A linear equation $Lx = y$ with L Fredholm is solvable exactly when y is orthogonal to $\operatorname{Coker} L$. Here $\operatorname{Coker} \mathrm{d}_A^- = H^2$. So the *obstruction* to extending a_1 to second order is the H^2-component of $\pi_-(a_1 \wedge a_1)$. If $H^2 = 0$, there is never an obstruction, at this order or any other.

Key idea: The Kuranishi model

Near $[A]$, the moduli space looks like

$$\mathcal{M}_k \;\approx\; \kappa^{-1}(0)\,/\,\Gamma_A, \qquad \kappa : H^1 \to H^2,$$

where κ (the **Kuranishi map**) is a smooth map with $\kappa(0) = 0$ and $\mathrm{d}\kappa_0 = 0$, whose quadratic part is $a \mapsto$ (H^2-component of $\pi_-(a \wedge a)$), and Γ_A is the stabiliser of A (Section 8.7.3). Consequences:

- if $H^2 = 0$ and Γ_A is the centre, $\mathcal{M}_k$ is a manifold near $[A]$ with tangent space H^1: every infinitesimal deformation is tangent to a genuine family (*integrability*);
- if $H^2 = 0$ but Γ_A is bigger, $\mathcal{M}_k$ is locally H^1/Γ_A, e.g. the cone on $\mathbb{CP}^2$ at a reducible point (Section 8.7.4);
- if $H^2 \neq 0$, $\mathcal{M}_k$ can be singular or have the wrong dimension.

This is what Nash calls "an integrability question similar to those that arise in complex analysis when passing from an almost complex structure to a full complex structure": there too an infinitesimal (linear) condition must be promoted to a local (non-linear) one, and the obstruction is a curvature-like quadratic term (the Nijenhuis tensor). On S^4, $H^2 = 0$ at every instanton by the Weitzenböck argument of Section 8.8.7; this is how Atiyah, Hitchin and Singer show that every element of H^1 comes from a one-parameter family $A + ta + O(t^2)$. On a general M one uses a *generic* metric: Freed and Uhlenbeck proved that for almost every Riemannian metric, $H^2 = 0$ at every irreducible instanton, so $\mathcal{M}_k^{\mathrm{irr}}$ is a smooth manifold of the expected dimension.

Condition 3: the Hausdorff property

Local charts must fit into a global space that is *Hausdorff*: two distinct points have disjoint neighbourhoods. A quotient by a group action can fail this badly.

Worked example 8.104: A non-Hausdorff quotient

Let $\mathbb{R}$ act on $\mathbb{R}^2 \setminus \{0\}$ by $t \cdot (x, y) = (e^t x, e^{-t} y)$. The orbits are the branches of the hyperbolas $xy = c$ ($c \neq 0$) and the four open half-axes. Consider the orbits $O_+ = \{x > 0, y = 0\}$ and $O^+ = \{x = 0, y > 0\}$. The points $(1, \varepsilon) \in \{xy = \varepsilon\}$ converge to $(1, 0) \in O_+$, and the points $(\varepsilon, 1)$, which lie on the *same* hyperbola branch, converge to $(0, 1) \in O^+$. So the single sequence of orbits $\{xy = \varepsilon\}$, $\varepsilon \to 0$, converges to both O_+ and O^+ in the quotient. Any neighbourhoods of these two points of the quotient contain the orbit $\{xy = \varepsilon\}$ for small ε, so they intersect: the quotient is not Hausdorff.

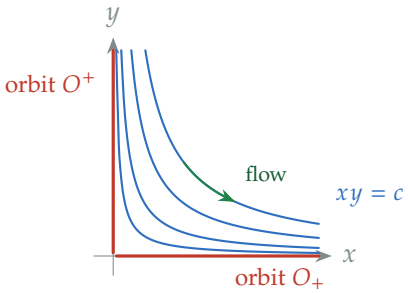

Figure 8.52: The orbits of $(x, y) \mapsto (e^t x, e^{-t} y)$ in the first quadrant. As $c \to 0$ the hyperbola $xy = c$ hugs *both* half-axes, so in the orbit space it converges to two different points at once. The gauge group acting on $\mathcal{A}$ does not behave like this: the estimate $|\mathrm{d}g| \leq |A| + |A_g|$ keeps gauge transformations from escaping to infinity.

What saves the gauge-theory quotient is that the gauge group acts *properly*: gauge transformations relating two nearby connections cannot run off to infinity. The mechanism is a one-line estimate.

Worked example 8.105: Why $\mathcal{A}/\mathcal{G}$ is Hausdorff

Suppose $A_i \to A$ and $g_i \cdot A_i \to B$ (uniformly, say). We want to show $B = g \cdot A$ for some gauge transformation g, so that $[A]$ and $[B]$ are the same point and no two distinct points are "glued" as in Example 8.104. From $A_g = g^{-1} A g + g^{-1} \mathrm{d}g$,

$$\mathrm{d}g_i \overset{(1)}{=} g_i \, (g_i \cdot A_i) - A_i \, g_i$$
$$\overset{(2)}{\Longrightarrow} \quad |\mathrm{d}g_i| \leq |g_i \cdot A_i| + |A_i|,$$

(1) Multiply $g^{-1}\mathrm{d}g = A_g - g^{-1} A g$ on the left by g.

(2) g_i is unitary at each point, so multiplying by it does not change norms; then the triangle inequality.

The right side is bounded uniformly in i, because both sequences converge. So the g_i are uniformly bounded (they are unitary) with uniformly bounded derivatives. By the Arzelà–Ascoli theorem a subsequence converges uniformly to some g, and passing to the limit in step (1) gives $\mathrm{d}g = gB - Ag$, i.e. $B = g \cdot A$. (The honest proof works in Sobolev spaces and bootstraps the regularity of g, but the mechanism is this estimate.)

Key idea: The global moduli space (Nash p. 241)

Existence, integrability and the Hausdorff property all hold for SU(2) instantons on S^4 (Atiyah–Hitchin–Singer): $\mathcal{M}_k$ is a smooth, Hausdorff manifold of dimension $8k - 3$, non-compact, with no singular points. On a simply connected M with positive definite

intersection form and a generic metric, $\mathcal{M}_k$ is a smooth manifold of dimension $8k-3$ away from finitely many cone points, one for each reducible instanton.

8.11.2 Donaldson's theorem: a preview

Nash's remark after (8.134) is the reason the whole section matters for topology: the manifolds for which $\dim \mathcal{M}_k = 8k-3$ by (8.134), simply connected with positive definite intersection form, are "precisely the class of M to which Donaldson's theorem applies". The theorem itself (Chapter 1) is:

Key idea: Donaldson's theorem (1983)

Let M be a smooth, closed, oriented, simply connected 4-manifold whose intersection form q on $H^2(M;\mathbb{Z})$ is positive definite. Then q is *diagonalisable over* $\mathbb{Z}$: there is a basis $e_1,\dots,e_r$ of $H^2(M;\mathbb{Z})$ with $q(e_i,e_j)=\delta_{ij}$.

By Freedman's work (Chapter 1), every unimodular form is the intersection form of some *topological* simply connected 4-manifold. So Donaldson's theorem says that most positive definite forms, for instance the form E_8 of rank 8, belong to topological manifolds that admit *no smooth structure*. A purely topological statement is proved with a moduli space of solutions of a physical field equation. We now describe the proof, using everything we have built. Nash notes (p. 241) that the S^4 space $\mathcal{M}_1$ "is the space used in the proof", and that "the boundary of $\mathcal{M}_1$ is M" for the manifolds of the theorem.

Step 1: the moduli space and its dimension

Take $G=\mathrm{SU}(2)$ and $k=1$. By (8.134), $\dim \mathcal{M}_1 = 8\cdot 1-3=5$. Choose a generic metric on M, so that (Freed–Uhlenbeck) $\mathcal{M}_1$ is a smooth 5-manifold away from the reducible points. Donaldson also proved that it is *orientable*; we need this for Step 5.

Step 2: the reducible points

From Section 8.7.5 (Nash (8.135)–(8.136)), a reducible SU(2) instanton has $E = L\oplus L^{-1}$ and $k=-c_2(E)=q(c_1(L),c_1(L))$. For $k=1$ we need a class $e=c_1(L)$ with $q(e,e)=1$. Conversely, each such e gives exactly one reducible instanton:

- Represent e by its harmonic 2-form ω. Since $b_2^- = 0$, every harmonic 2-form is self-dual, so the U(1) connection on L with curvature $-2\pi i\omega$ is self-dual, and so is the diagonal SU(2) connection on $L\oplus L^{-1}$.
- The U(1) connection with given curvature is unique up to gauge, because the connections differ by closed 1-forms and $H^1(M)=0$ (M is simply connected).
- e and $-e$ give the same reducible: $L\oplus L^{-1}\cong L^{-1}\oplus L$.

So the reducible points of $\mathcal{M}_1$ are in one-to-one correspondence with the pairs $\pm e$ with $q(e,e)=1$. Let m be the number of such pairs.

Step 3: the neighbourhood of a reducible point

At a reducible A the stabiliser is U(1) (Section 8.7.3), so $h_0=1$. With $h_2=0$ (generic metric), the index gives

$$h_0-h_1+h_2=-5 \quad\Longrightarrow\quad h_1=6.$$

The splitting $\operatorname{ad} P = \mathbb{R} \oplus L^2$ (the diagonal and off-diagonal parts of a traceless 2×2 matrix) makes H^1 a complex vector space: the real part contributes $H^1(M;\mathbb{R}) = 0$, and the L^2 part gives $H^1 \cong \mathbb{C}^3$, on which $u \in \mathrm{U}(1)$ acts by u^2. By the Kuranishi model, near $[A]$

$$\mathcal{M}_1 \approx \mathbb{C}^3/\mathrm{U}(1) = \text{cone on } \left(S^5/\mathrm{U}(1)\right) = \text{cone on } \mathbb{CP}^2,$$

exactly as in Section 8.7.4: the unit sphere $S^5 \subset \mathbb{C}^3$ modulo the circle is $\mathbb{CP}^2$ (the Hopf fibration $S^5 \to \mathbb{CP}^2$), and the radius is the cone coordinate.

Step 4: the end of the moduli space, and compactness

For $M = S^4$ we saw that $\mathcal{M}_1 = H^5$ has one end, the boundary $\lambda \to 0$ of point-like instantons, and that this end is a copy of $S^4 \times (0, \varepsilon)$ (Figure 8.49). Two theorems show that the same is true for any M of the theorem.

- *Taubes' gluing.* For each point $x \in M$ and each small λ, graft a BPST instanton of size λ at x (Condition 1). The gluing also involves an identification of the colour frames, an element of SO(3), but it is absorbed by the stabiliser SU(2) of the trivial connection we glue into. So the concentrated instantons form a collar $M \times (0, \varepsilon)$ inside $\mathcal{M}_1$.
- *Uhlenbeck's compactness.* Any sequence of charge-one instantons either has a subsequence converging (modulo gauge) to an instanton, or concentrates: its action density tends to $8\pi^2\delta_x$ at some point x, while away from x it converges to a charge-zero instanton, i.e. a flat connection, which is trivial since $\pi_1(M) = 0$. The concentrating sequences eventually enter the collar.

So, apart from the collar, $\mathcal{M}_1$ is compact. Adding the points $x \in M$ at $\lambda = 0$ closes up the collar with boundary M: this is Nash's "the boundary of $\mathcal{M}_1$ is M".

Step 5: the cobordism

Remove a small open cone neighbourhood of each reducible point, and add the boundary M at the end of the collar. The result is a compact, oriented, smooth 5-manifold W with

$$\partial W = M \sqcup \left(\pm\mathbb{CP}^2\right) \sqcup \cdots \sqcup \left(\pm\mathbb{CP}^2\right) \qquad (m \text{ copies}), \tag{8.261}$$

where the signs are the orientations induced from W. So M is **cobordant** to a disjoint union of m copies of $\pm\mathbb{CP}^2$.

Step 6: the signature

The signature of a boundary vanishes. Here is the Stokes-theorem argument. By the Hirzebruch signature theorem (Chapter 4), $\tau(X) = \frac{1}{3}\int_X p_1(TX)$ for a closed oriented 4-manifold, with p_1 in the standard normalisation (not Nash's, Section 8.9.3).

Worked example 8.106: $\tau(\partial W) = 0$ by Stokes

Let W be a compact oriented 5-manifold with a Riemannian metric that is a product near ∂W, and let P be the Pontryagin 4-form of TW built from its curvature. Then

$$3\,\tau(\partial W) \overset{(1)}{=} \int_{\partial W} p_1(T\partial W) \overset{(2)}{=} \int_{\partial W} P\big|_{\partial W}$$

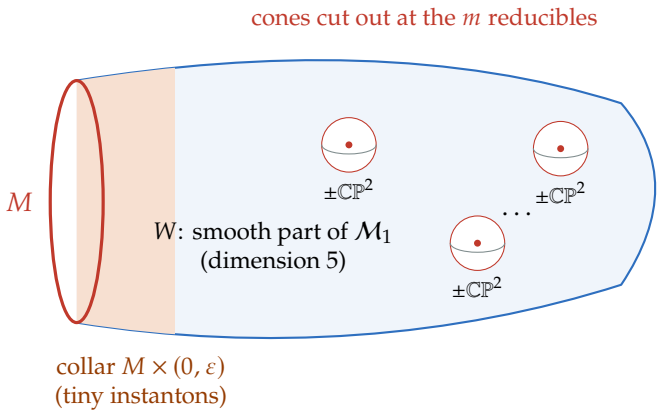

Figure 8.53: The Donaldson cobordism. The 5-dimensional moduli space $\mathcal{M}_1$ has one end, a collar of concentrated instantons whose boundary is a copy of M (left), and m cone points, one per pair $\pm e$ with $q(e,e) = 1$. Cutting out small cones leaves a compact W whose boundary is M together with m copies of $\pm\mathbb{CP}^2$ (the links of the cones). For $M = S^4$ there are no cones and W is the closed 5-ball, the compactified H^5.

$$\overset{(3)}{=} \int_W \mathrm{d}P$$
$$\overset{(4)}{=} 0.$$

(1) The signature theorem on the closed 4-manifold ∂W (its components added with their induced orientations).
(2) Near the boundary $TW = T\partial W \oplus \mathbb{R}$ with a product metric, so the curvature of TW restricted to ∂W is that of $T\partial W$, and the extra trivial line contributes nothing.
(3) Stokes' theorem.
(4) Characteristic forms are closed (Chern–Weil, Chapter T2).

Apply this to (8.261). The signature is additive over disjoint unions and changes sign with orientation, and $\tau(\mathbb{CP}^2) = 1$ (its form is (1)). So

$$0 = \tau(M) + \sum_{i=1}^{m} \varepsilon_i, \qquad \varepsilon_i = \pm 1 \quad \Longrightarrow \quad r = \tau(M) \le m,$$

where $r = \operatorname{rank} H^2(M)$ and $\tau(M) = r$ because q is positive definite.

Step 7: the algebra

Worked example 8.107: A positive definite form has at most r pairs of unit vectors, with equality only if diagonal

Let $e \neq \pm f$ with $q(e,e) = q(f,f) = 1$. Then

$$|q(e,f)| \overset{(1)}{<} \sqrt{q(e,e)\,q(f,f)}$$
$$\overset{(2)}{=} 1,$$

(1) Cauchy–Schwarz for the positive definite q, with strict inequality because e, f are not parallel (parallel integer vectors of equal length are equal up to sign).

(2) Both have length 1.

and $q(e,f)$ is an integer, so $q(e,f)=0$. Choosing one vector from each of the m pairs gives an *orthonormal* set, hence linearly independent: $m \le r$. If $m = r$, the orthonormal vectors span a sublattice Λ' of full rank with $\det(q|_{\Lambda'}) = 1$. Since $\det(q|_{\Lambda'}) = [\Lambda : \Lambda']^2 \det q$ and $\det q = 1$ (unimodularity, Poincaré duality), the index is 1: $\Lambda' = H^2(M;\mathbb{Z})$, and in this basis q is the identity.

Steps 6 and 7 together: $r \le m \le r$, so $m = r$ and q is diagonal. That is Donaldson's theorem.

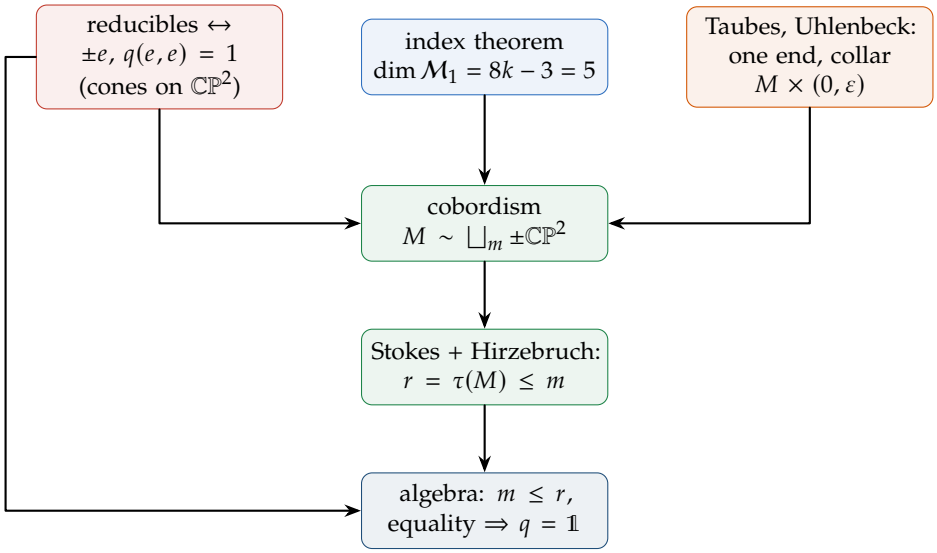

Figure 8.54: The logic of Donaldson's proof. Every ingredient of this section appears: the dimension from the index theorem (Section 8.9), the reducibles and their cones (Section 8.7), the collar of small instantons familiar from H^5 (Section 8.10), and the global structure of this section.

Worked example 8.108: The theorem at work

- $M = S^4$: $r = 0$, $m = 0$. W is the closed 5-ball with boundary S^4, and $\tau(S^4) = 0$. This is the compactified H^5 of Section 8.10.4.
- $M = \mathbb{CP}^2$: $q = (1)$, $m = 1$ (the pair $\pm h$ of Example 8.69). W is a cobordism from $\mathbb{CP}^2$ to one copy of $\mathbb{CP}^2$ (with the opposite induced orientation), and $1 - 1 = 0$. (For the Fubini–Study metric $\mathcal{M}_1$ is known explicitly: it is an open cone on $\mathbb{CP}^2$, with the reducible at the vertex and the collar at the open end.)
- $M = \mathbb{CP}^2 \# \mathbb{CP}^2$: $q = \mathrm{diag}(1,1)$, pairs $\pm(1,0)$, $\pm(0,1)$: $m = 2 = r$.
- A hypothetical smooth M with $q = E_8$: E_8 is even ($q(e,e)$ is even for all e), so it has no vectors with $q(e,e) = 1$, and $m = 0$. Then $\partial W = M$, so $\tau(M) = 0$; but $\tau(E_8) = 8$. Contradiction: the topological E_8 manifold of Freedman has no smooth structure.
- $q = (1) \oplus E_8$, rank 9: the only unit vectors are $\pm(1,0)$, so $m = 1 < 9$; excluded as well.

Physical picture: why a physical equation sees smooth structure

The self-duality equation needs a metric, and a metric needs a smooth structure. The moduli space is built from the equation, so it is a smooth invariant; its ends and singular points, however, are forced by topology (the collar is a copy of M, the cones are counted by q). The cobordism relates the two. A topological manifold that is not smoothable has no instantons to count, and the argument shows that for E_8 there could not be any consistent count.

8.11.3 An analogy: Riemann surfaces and Teichmüller theory

Nash compares Donaldson's use of $\mathcal{M}_k$ with the older theory of moduli of Riemann surfaces (Chapter 5): "In the latter the moduli of a linear elliptic operator—the $\bar\partial$-operator—are used to deduce topological information about Riemann surfaces, the main result being that dim $\mathcal{M}_p$ gives the genus". Let us make this concrete. A Riemann surface of genus p is a surface with a complex structure; its moduli space $\mathcal{M}_p$ parametrises complex structures up to diffeomorphism. The tangent space is computed by the same three-term pattern as for instantons, with the $\bar\partial$-operator on vector fields in place of d_A^-:

$$H^0(\Sigma, T\Sigma) = \{\text{holomorphic vector fields}\} \quad \text{(symmetries)},$$
$$H^1(\Sigma, T\Sigma) = \{\text{infinitesimal deformations of the complex structure}\}.$$

(By Serre duality $H^1(\Sigma, T\Sigma)$ is dual to the space of holomorphic quadratic differentials, which is how Teichmüller described it.)

Worked example 8.109: $\dim_{\mathbb{C}} \mathcal{M}_p = 3p-3$ from Riemann–Roch

For a holomorphic line bundle L on a surface of genus p, Riemann–Roch (the index theorem for $\bar\partial$, Chapter 4) says $h^0(L) - h^1(L) = \deg L + 1 - p$. The tangent bundle has degree $\deg T\Sigma = \chi(\Sigma) = 2 - 2p$ (Gauss–Bonnet or Poincaré–Hopf). So

$$\begin{aligned} h^0(T\Sigma) - h^1(T\Sigma) &\overset{(1)}{=} \deg T\Sigma + 1 - p \\ &\overset{(2)}{=} (2-2p) + 1 - p \\ &\overset{(3)}{=} 3 - 3p. \end{aligned}$$

(1) Riemann–Roch for $L = T\Sigma$.
(2) $\deg T\Sigma = 2 - 2p$.
(3) Collect.

For $p \geq 2$, $T\Sigma$ has negative degree, so it has no holomorphic sections: $h^0 = 0$ (no continuous symmetries), and $\dim_{\mathbb{C}} \mathcal{M}_p = h^1 = 3p - 3$, i.e. $6p - 6$ real dimensions. For $p = 1$: $h^0 = 1$ (translations of the torus), so $h^1 = 1$; the moduli space of tori is one complex dimensional. For $p = 0$: $h^0 = 3$ (the Möbius group $\mathrm{PSL}(2,\mathbb{C})$), $h^1 = 0$; the sphere is rigid. Inverting the first formula, $p = 1 + \dim_{\mathbb{R}} \mathcal{M}_p/6$: the dimension of the moduli space "gives the genus".

Worked example 8.110: The torus: another hyperbolic moduli space

A torus is $\mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$ with $\operatorname{Im}\tau > 0$. Two values of τ give the same torus iff they are related by $\tau \mapsto (a\tau + b)/(c\tau + d)$ with $\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}(2,\mathbb{Z})$, so $\mathcal{M}_1^{\text{tori}} = \mathbb{H}^2/\mathrm{SL}(2,\mathbb{Z})$, where $\mathbb{H}^2$ is the upper half-plane with its hyperbolic metric $(\mathrm{d}x^2 + \mathrm{d}y^2)/y^2$. Like the instanton moduli space $\mathcal{M}_1 = H^5$, it is a quotient of hyperbolic space, and it is non-compact: as $\tau \to i\infty$ the torus becomes infinitely long and thin, and in the limit it pinches to a sphere with two points identified. This degeneration plays the role of the instanton shrinking to a point.

Watch out: Nash's "$d_A^* d_A$"

Nash describes Donaldson's moduli as those of "the operator $d_A^* d_A$". He means the Yang–Mills operator $\mathrm{d}_A^* F_A$ (the equation $\mathrm{d}_A^* F = 0$, whose second-order linearisation is $\mathrm{d}_A^* \mathrm{d}_A$ on 1-forms) restricted to self-dual solutions. The operator whose index we actually

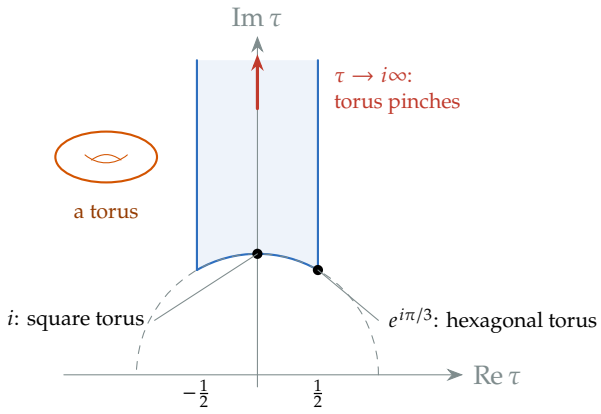

Figure 8.55: The moduli space of complex tori: the shaded fundamental domain of $\mathrm{SL}(2,\mathbb{Z})$ in the upper half-plane (with its sides identified). Each point is a torus $\mathbb{C}/(\mathbb{Z}+\tau\mathbb{Z})$. The space is a quotient of the hyperbolic plane and has one non-compact end, the cusp $\tau \to i\infty$, where the torus degenerates. Compare $\mathcal{M}_1 = H^5$ for instantons, whose end is made of instantons shrinking to points.

	Riemann surfaces	Instantons
object	complex structure on Σ_p	self-dual connection on M^4
operator	$\bar\partial$ on vector fields (linear)	d_A^-, d_A^* around A (linearised)
H^0	holomorphic vector fields	covariantly constant Λ (stabiliser)
H^1	deformations of complex structure	zero modes, $T_{[A]}\mathcal{M}_k$
H^2	none (complex dimension 1)	obstructions Ω^2_-
index	Riemann–Roch: $3-3p$	Atiyah–Singer: $3-8k$ (S^4)
dimension	$6p-6$ (real)	$8k-3$
non-compact end	pinching curves (cusps)	shrinking instantons (collar M)
use	$\dim \mathcal{M}_p$ determines p	$\partial W = M \sqcup m\,\mathbb{CP}^2$ constrains q

Table 8.4: Nash's analogy between Teichmüller theory and Donaldson theory. The same cohomological bookkeeping (H^0 symmetries, H^1 deformations, H^2 obstructions, index = expected dimension) organises both. The difference is linear versus non-linear: for instantons only the linearisation is elliptic, which is why the global conditions of Section 8.11.1 are needed.

computed is the first-order $D = \mathrm{d}_A + (\mathrm{d}_A^-)^*$ of Section 8.9.1.

8.11.4 Instantons and the topology of $\mathcal{A}/\mathcal{G}$: the Atiyah–Jones theorem

The last idea of Nash's section runs in the opposite direction. Instead of using the topology of M to learn about $\mathcal{M}_k$, we use $\mathcal{M}_k$ to learn about the **configuration space** $\mathcal{A}/\mathcal{G}$, the space of all gauge fields up to gauge, over which the Yang–Mills path integral is taken.

The homotopy type of $\mathcal{A}/\mathcal{G}_0$

Work with the based gauge group $\mathcal{G}_0$ (gauge transformations equal to $\mathbb{1}$ at the base point), since it acts freely (Section 8.7.2): if $g \cdot A = A$ then g is covariantly constant (Section 8.7.3), so it is determined by its value at the base point, which is $\mathbb{1}$. Two facts determine the topology.

$\mathcal{A}$ is contractible. It is an affine space: any A can be joined to a fixed A_0 by the straight line $A_0 + t(A - A_0)$, $t \in [0,1]$, and these lines depend continuously on A. So $\mathcal{A}$ deforms to the point A_0.

A contractible space with a free action. When a group $\mathcal{G}_0$ acts freely on a contractible space $\mathcal{A}$, the fibration $\mathcal{G}_0 \to \mathcal{A} \to \mathcal{A}/\mathcal{G}_0$ and the long exact sequence of homotopy groups give

$$\begin{aligned} \pi_i(\mathcal{A}/\mathcal{G}_0) &\overset{(1)}{=} \pi_{i-1}(\mathcal{G}_0) \\ &\overset{(2)}{=} \pi_{i-1}\big(\mathrm{Map}_*(S^4, S^3)\big) \\ &\overset{(3)}{=} \pi_{i+3}(S^3). \end{aligned} \tag{8.262}$$

(1) The exact sequence $\pi_i(\mathcal{A}) \to \pi_i(\mathcal{A}/\mathcal{G}_0) \to \pi_{i-1}(\mathcal{G}_0) \to \pi_{i-1}(\mathcal{A})$ with $\pi_\bullet(\mathcal{A}) = 0$.

(2) On S^4, a based gauge transformation is, up to homotopy, a based map $S^4 \to \mathrm{SU}(2) = S^3$ (trivialise the bundle away from a point; the twisting of P_k does not change the homotopy type of $\mathcal{G}_0$).

(3) A based map $S^j \to \mathrm{Map}_*(S^4, S^3)$ is the same as a based map $S^j \wedge S^4 = S^{j+4} \to S^3$, so $\pi_j(\mathrm{Map}_*(S^4, S^3)) = \pi_{j+4}(S^3)$; put $j = i - 1$.

In the language of loop spaces, $\mathcal{A}_k/\mathcal{G}_0 \simeq \Omega^3_k S^3$, a component of the space of maps $S^3 \to S^3$ (based), the component of degree k. The first few groups are

i	1	2	3	4	5	6
$\pi_i(\mathcal{A}/\mathcal{G}_0) = \pi_{i+3}(S^3)$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_{12}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}_3$

The configuration space of SU(2) gauge theory on S^4 is topologically complicated. For instance $\pi_1 = \pi_4(S^3) = \mathbb{Z}_2$: there is a non-contractible loop of gauge fields. (This loop is behind Witten's global SU(2) anomaly, Chapter 10.) It is also why there is no continuous global gauge slice, the topological root of the Gribov ambiguity (Singer).

The inclusion of the instantons

Every framed instanton is a point of $\mathcal{A}_k/\mathcal{G}_0$, so there is an inclusion (Nash's (8.138))

$$i(k) : \ \mathcal{M}'_k \longrightarrow \mathcal{A}_k/\mathcal{G}_0. \tag{8.263}$$

$\mathcal{M}'_k$ has dimension $8k$ and $\mathcal{A}_k/\mathcal{G}_0$ is infinite dimensional; one cannot expect $i(k)$ to be a homotopy equivalence. But it can capture the topology in low dimensions.

Key idea: The Atiyah–Jones theorem and conjecture

Atiyah and Jones (1978) proved that $i(k)$ induces a surjection $H_q(\mathcal{M}'_k) \to H_q(\mathcal{A}_k/\mathcal{G}_0)$ in a range of dimensions $q < q(k)$ that grows with k. They conjectured that it is an isomorphism in such a range. This *Atiyah–Jones conjecture* was proved for SU(2) on S^4 by Boyer, Hurtubise, Mann and Milgram (1993), with a range growing linearly in k (roughly $q < k/2$). So as $k \to \infty$, "more and more of the homology of $\mathcal{A}/\mathcal{G}$ is captured by that of $\mathcal{M}'_k$": the finite-dimensional space of instantons approximates the infinite-dimensional space of all gauge fields.

Worked example 8.111: Low-dimensional check at $k = 1$

By Example 8.99, $\mathcal{M}'_1 = \mathbb{R}^4 \times (\mathbb{R}^4 \setminus 0)/\mathbb{Z}_2$. Shrinking the $\mathbb{R}^4$ factor to a point and the radial direction λ to $\lambda = 1$ is a deformation retraction, so

$$\mathcal{M}'_1 \simeq S^3/\mathbb{Z}_2 = \mathbb{RP}^3 = \mathrm{SO}(3), \qquad \pi_1(\mathcal{M}'_1) = H_1(\mathcal{M}'_1) = \mathbb{Z}_2.$$

On the other side, $\pi_1(\mathcal{A}_1/\mathcal{G}_0) = \pi_4(S^3) = \mathbb{Z}_2$ by (8.262). So both spaces have fundamental group $\mathbb{Z}_2$, and the candidate generator on the instanton side is the loop that rotates the framing of a single instanton through SO(3). Whether $i(1)$ carries one $\mathbb{Z}_2$ onto the other is exactly the kind of question the theorem answers for large k; at $k = 1$ it needs a separate argument.

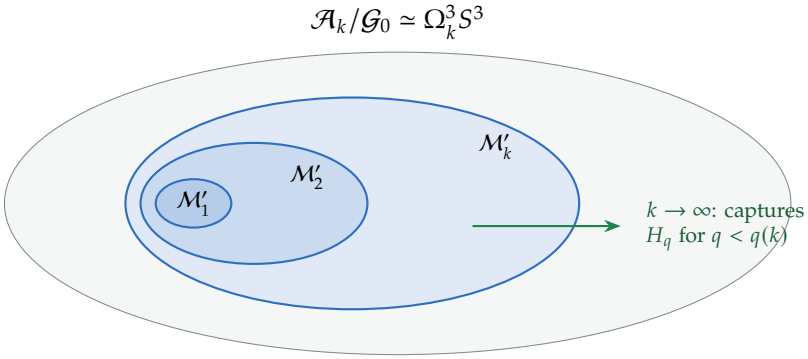

Figure 8.56: The Atiyah–Jones picture, schematically. The framed moduli spaces have dimension $8k$ and sit inside the infinite-dimensional configuration space. (Strictly, the spaces for different k lie in different components $\mathcal{A}_k/\mathcal{G}_0$, all homotopy equivalent to each other.) As k grows, the inclusion captures more and more of the homology of the configuration space: many-instanton configurations explore its topology.

Physical picture: a dilute instanton gas explores configuration space

Why should large k help? A charge-k instanton can be pulled apart into k widely separated, almost independent BPST lumps, each with its own position, size and framing (8 parameters each, matching $8k$). The topology of such configurations is that of k "particles" on S^4 carrying internal SO(3) labels, and configuration spaces of many particles are known to approximate loop spaces as the number of particles grows (this is the mechanism behind the proof). So the "instanton gas" of the semiclassical physicist is also a good model of the topology of the full space of gauge fields.

Reading Nash (pp. 240–242, (8.138))

Nash's warning that the index calculation "is an infinitesimal one" and his three conditions (existence; extending the infinitesimal coordinates at $[A]$ to a neighbourhood; fitting the local coordinates into a global Hausdorff space) are Section 8.11.1; the Kuranishi model and the estimate $|\mathrm{d}g| \le |A| + |A_g|$ are our additions. His references to Atiyah–Hitchin–Singer for S^4 correspond to the keyidea there. His remark that the S^4 space $\mathcal{M}_1$ "is the space used in the proof of Donaldson's theorem" and that "the boundary of $\mathcal{M}_1$ is M" for the other M is Section 8.11.2, where we sketched the whole argument. The Teichmüller analogy is Section 8.11.3 and Table 8.4. The inclusion $i(k) : \mathcal{M}'_k \to \mathcal{A}/\mathcal{G}$ (8.138) and the statement that for large k it "induces a projection of the homology of $\mathcal{M}'_k$ onto part of the homology of $\mathcal{A}/\mathcal{G}$" is the Atiyah–Jones theorem of Section 8.11.4; Nash's $\mathcal{A}/\mathcal{G}$ there means the quotient by the based gauge group, which is why the framed space $\mathcal{M}'_k$ appears.

Recap

- The index gives the *expected* dimension. It is the true dimension near $[A]$ when the obstruction space H^2 vanishes and the stabiliser is the centre; the Kuranishi model $\kappa^{-1}(0)/\Gamma_A$ describes the general case.
- The three global conditions: existence (BPST/ADHM on S^4, Taubes' grafting in general), integrability ($H^2 = 0$: Weitzenböck on S^4, generic metrics in general), Hausdorff (the gauge group acts properly, by $|\mathrm{d}g| \le |A| + |A_g|$).
- Donaldson: for M simply connected with $q > 0$, $\mathcal{M}_1$ is a 5-manifold with a collar end $\cong M \times (0, \varepsilon)$ and m cones on $\mathbb{CP}^2$, $m = \#\{\pm e : q(e,e) = 1\}$. Cobordism and $\tau(\partial W) = 0$ give $r \le m$; algebra gives $m \le r$ with equality iff q is diagonal.
- Teichmüller analogy: the same $H^0/H^1/H^2$ bookkeeping, linear for Riemann surfaces ($\dim_{\mathbb{C}} \mathcal{M}_p = 3p - 3$), non-linear for instantons.
- Atiyah–Jones: $\mathcal{A}_k/\mathcal{G}_0 \simeq \Omega^3_k S^3$ with $\pi_i = \pi_{i+3}(S^3)$, and $\mathcal{M}'_k \hookrightarrow \mathcal{A}_k/\mathcal{G}_0$ captures its homology in a range growing with k.

8.12 Monopoles: the Yang–Mills–Higgs system in three dimensions

So far in this chapter the stage has been four-dimensional and Euclidean, and the stars were instantons: finite-action solutions of $F = \pm \star F$. Now we drop one dimension. Nash opens his Section 4 by remarking that the Yang–Mills equations $\mathrm{d}_A^\star F = 0$ "change considerably" when the dimension of M changes. Here is the physical reason we care about dimension three.

A field configuration in $3 + 1$ dimensions that does not change in time is a field on *space*, which is three-dimensional. Its energy is an integral over $\mathbb{R}^3$. A **soliton** is a static configuration of finite energy that cannot decay, because some integer attached to it (a topological charge) cannot change continuously. Physically it is a particle made out of the fields themselves. The question of this section is:

> *Which gauge theories have solitons in three space dimensions, what integer protects them, and what equations do they satisfy?*

The answer is the **magnetic monopole** of 't Hooft and Polyakov. It needs a Higgs field as well as a gauge field. Its integer is a magnetic charge. The charge turns out to be a Chern number and also a degree of a map between two spheres. In the special "Prasad–Sommerfield" limit the monopoles solve a first-order equation, the **Bogomolny equation**, which is nothing but the self-duality equation of the previous section in disguise. That link, monopoles as symmetric instantons, is the thread that runs through Nash's Sections 4 and 5.

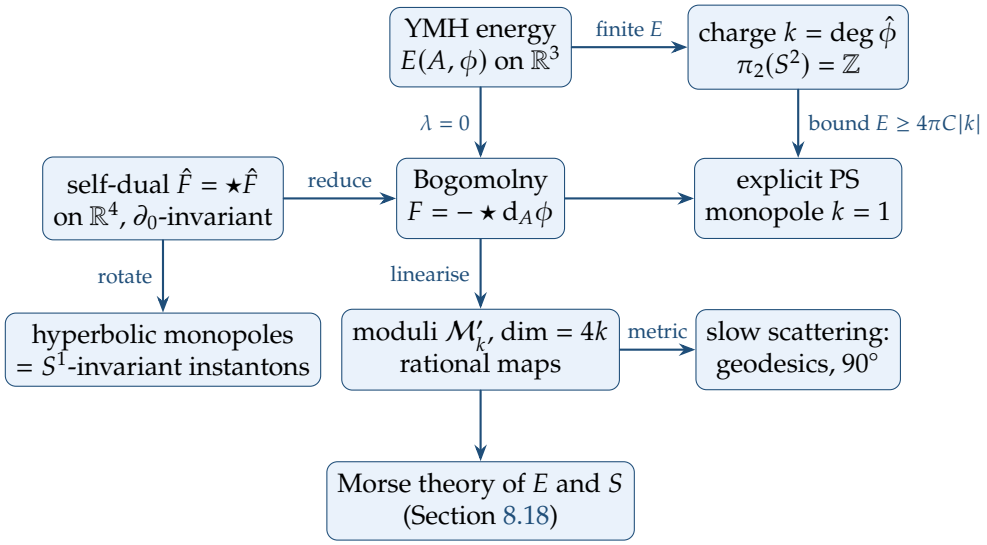

Figure 8.57: The logic of the last three sections of Nash's Chapter 8. Start at the top with the energy of a gauge field plus Higgs field in three dimensions. Follow the arrows: topology forces a charge, the charge bounds the energy, the bound is saturated by solutions of the Bogomolny equation, and those solutions form a finite-dimensional moduli space whose geometry governs how monopoles scatter. The left column shows the link to instantons.

8.12.1 Conventions for this part

We work with $G = \mathrm{SU}(2)$ throughout, as Nash does from p. 244 on. Its Lie algebra $\mathfrak{su}(2)$ is the space of 2×2 anti-Hermitian traceless matrices. We use the basis

$$T_a = -\frac{i}{2}\sigma_a, \qquad T_1 = \frac{1}{2}\begin{pmatrix} 0 & -i \\ -i & 0 \end{pmatrix}, \quad T_2 = \frac{1}{2}\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \quad T_3 = \frac{1}{2}\begin{pmatrix} -i & 0 \\ 0 & i \end{pmatrix}. \tag{8.264}$$

Everything we need about these matrices follows from the Pauli rule $\sigma_a\sigma_b = \delta_{ab}\mathbb{1} + i\varepsilon_{abc}\sigma_c$.

Worked example 8.112: The two facts about T_a we use constantly

First the commutator:

$$\begin{aligned} [T_a, T_b] &\overset{(1)}{=} \left(-\frac{i}{2}\right)^2 [\sigma_a, \sigma_b] \\ &\overset{(2)}{=} -\frac{1}{4}\cdot 2i\varepsilon_{abc}\sigma_c \\ &\overset{(3)}{=} \varepsilon_{abc}\, T_c. \end{aligned}$$

(1) Pull the scalar $-i/2$ out of both factors.
(2) The Pauli rule gives $\sigma_a\sigma_b - \sigma_b\sigma_a = 2i\varepsilon_{abc}\sigma_c$.
(3) $-\frac{i}{2}\sigma_c = T_c$.

Then the trace:

$$\mathrm{tr}(T_aT_b) \overset{(1)}{=} -\frac{1}{4}\,\mathrm{tr}(\sigma_a\sigma_b) \overset{(2)}{=} -\frac{1}{4}(2\delta_{ab}) = -\frac{1}{2}\delta_{ab}.$$

(1) $(-i/2)^2 = -1/4$.
(2) $\mathrm{tr}\,\mathbb{1} = 2$ and $\mathrm{tr}\,\sigma_c = 0$.

So if we write $X = X^aT_a$ and $Y = Y^aT_a$ with real components, then $[X,Y] = (\vec{X}\times\vec{Y})^aT_a$, and $-2\,\mathrm{tr}(XY) = \vec{X}\cdot\vec{Y}$. The Lie algebra $\mathfrak{su}(2)$ *is* $\mathbb{R}^3$ with the cross product.

Working definition 8.37 (pointwise and L^2 inner products in this part)

For $X, Y \in \mathfrak{su}(2)$ we set

$$(X,Y) = -2\,\mathrm{tr}(XY) = \vec{X}\cdot\vec{Y}, \qquad |X|^2 = -2\,\mathrm{tr}(X^2) = \sum_a (X^a)^2. \tag{8.265}$$

For $\mathfrak{su}(2)$-valued p-forms on a Riemannian manifold M [a metric is given, and the Hodge star $\star$ built from it makes $\alpha \wedge \star\beta$ the dot product of α and β times the volume form],

$$\langle \alpha, \beta\rangle = -2\int_M \mathrm{tr}(\alpha\wedge\star\beta) = \sum_a \int_M \alpha^a \wedge \star\beta^a, \qquad \|\alpha\|^2 = \langle\alpha,\alpha\rangle. \tag{8.266}$$

Operational meaning: expand in the basis T_a and use the ordinary dot product of components. $|X|$ is the length of the vector $\vec{X} \in \mathbb{R}^3$.

Watch out: A factor of 2 in Nash's traces

Nash defines $|\phi|^2 = -2\,\mathrm{tr}(\phi^2)$ (just after (8.139)), which agrees with (8.265). But in the energy (8.139), in (8.141) and in (8.148) he writes $-\,\mathrm{tr}$ without the 2. With his normalisation taken literally, the energy of the unit monopole would be 2π instead of the 4π he quotes in (8.191). Using $-2\,\mathrm{tr}$ everywhere, as we do, makes all his final numbers ($E = 4\pi k$, (8.155), $\dim \mathcal{M}'_k = 4k$) come out right. Earlier parts of these notes use $-\,\mathrm{tr}$; the difference is an overall factor of 2 in the definition of the action, and no equation of motion changes.

Gauge fields follow the conventions of the whole book: A is an $\mathfrak{su}(2)$-valued 1-form, $F = \mathrm{d}A + A\wedge A$, and under a gauge transformation $g : M \to \mathrm{SU}(2)$,

$$A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g, \qquad F \mapsto g^{-1}Fg.$$

The Higgs field ϕ is an $\mathfrak{su}(2)$-valued function (a section of $\mathrm{ad}\,P$) and transforms like F, $\phi \mapsto g^{-1}\phi g$. Its covariant derivative is the 1-form

$$\mathrm{d}_A\phi = \mathrm{d}\phi + [A,\phi], \qquad (D_i\phi)^a = \partial_i\phi^a + \varepsilon_{abc}A_i^b\phi^c. \tag{8.267}$$

The component form uses Example 8.112: $[A_i,\phi] = (\vec{A}_i \times \vec{\phi})^a T_a$.

Dictionary: mathematicians' fields versus physicists' fields

A physics text writes the gauge field as A_μ^a with Hermitian generators $\sigma_a/2$ and coupling e, and the Higgs triplet as ϕ^a_{phys} with vacuum value v. The translation is

$$A_\mu^{\text{math}} = -ie\,A_\mu^a\frac{\sigma_a}{2} = e\,A_\mu^a T_a, \qquad \phi^{\text{math}} = e\,\phi^a_{\text{phys}}T_a, \qquad C = e\,v.$$

Then $F^{\text{math}} = eF^aT_a$ with $F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + e\,\varepsilon_{abc}A^b_\mu A^c_\nu$, and the physical energy is $E_{\text{phys}} = E^{\text{math}}/e^2$. So the monopole mass $E = 4\pi C$ that we shall find becomes $M = 4\pi v/e$, the textbook value. We set $e = 1$ from now on.

The Hodge star in three dimensions will appear everywhere. On $\mathbb{R}^3$ with the Euclidean metric and orientation $\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3$,

$$\star\mathrm{d}x^1 = \mathrm{d}x^2\wedge\mathrm{d}x^3, \quad \star\mathrm{d}x^2 = \mathrm{d}x^3\wedge\mathrm{d}x^1, \quad \star\mathrm{d}x^3 = \mathrm{d}x^1\wedge\mathrm{d}x^2, \qquad \star\star = 1. \tag{8.268}$$

In components, a 2-form $F = \tfrac12 F_{ij}\mathrm{d}x^i\wedge\mathrm{d}x^j$ has $\star F = B_i\,\mathrm{d}x^i$ with $B_i = \tfrac12\varepsilon_{ijk}F_{jk}$: the Hodge star turns the "field-strength tensor" into the "magnetic field vector". The formal adjoint of d_A is

$\mathrm{d}_A^\star = -\star\,\mathrm{d}_A\star$ on 1-forms and $\mathrm{d}_A^\star = +\star\,\mathrm{d}_A\star$ on 2-forms in three dimensions (the general rule is $\mathrm{d}^\star = (-1)^{n(p+1)+1}\star\,\mathrm{d}\star$ on p-forms in n dimensions, Chapter T1).

8.12.2 Why pure Yang–Mills theory has no solitons in three dimensions

Why does Nash need a Higgs field at all? Could a pure gauge field on $\mathbb{R}^3$ already form a lump of finite energy? A one-line scaling argument, due to Derrick, says no.

Worked example 8.113: Derrick's scaling argument

Take any static configuration (A, ϕ) on $\mathbb{R}^3$ and squeeze it by a factor $\mu > 0$:

$$A^{(\mu)}(x) = \mu\, A_i(\mu x)\,\mathrm{d}x^i, \qquad \phi^{(\mu)}(x) = \phi(\mu x).$$

(The extra μ in A makes $\mathrm{d} + A$ scale like a derivative.) Then $F_{ij}^{(\mu)}(x) = \mu^2 F_{ij}(\mu x)$ and $D_i^{(\mu)}\phi^{(\mu)}(x) = \mu\,(D_i\phi)(\mu x)$. Write $E = E_F + E_D + E_V$ for the magnetic, gradient and potential energies. Changing variables $y = \mu x$, $\mathrm{d}^3x = \mu^{-3}\mathrm{d}^3y$:

$$E_F^{(\mu)} = \frac{1}{2}\int |B^{(\mu)}(x)|^2\mathrm{d}^3x \overset{(1)}{=} \frac{1}{2}\int \mu^4|B(\mu x)|^2\mathrm{d}^3x \overset{(2)}{=} \mu\, E_F,$$
$$E_D^{(\mu)} = \frac{1}{2}\int |D^{(\mu)}\phi^{(\mu)}(x)|^2\mathrm{d}^3x \overset{(3)}{=} \mu^{-1}E_D, \qquad E_V^{(\mu)} \overset{(4)}{=} \mu^{-3}E_V.$$

(1) Each component of F scales as μ^2, so $|B|^2$ scales as μ^4.
(2) Substitute $y = \mu x$: $\mu^4 \cdot \mu^{-3} = \mu$.
(3) Similarly $\mu^2 \cdot \mu^{-3} = \mu^{-1}$ for the gradient term.
(4) The potential has no derivatives: $\mu^0 \cdot \mu^{-3}$.

A static solution is a critical point of E, so it must be stationary under this particular deformation: $\mathrm{d}E^{(\mu)}/\mathrm{d}\mu|_{\mu=1} = E_F - E_D - 3E_V = 0$. For *pure* Yang–Mills ($\phi = 0$) this says $E_F = 0$, i.e. $F = 0$: no lump. The field can always lower its energy by spreading out. With a Higgs field the gradient term pushes the other way, and a balance $E_F = E_D + 3E_V$ is possible.

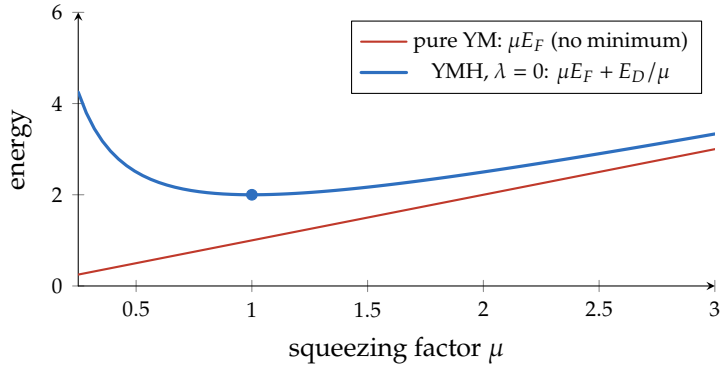

Figure 8.58: Derrick's argument in a picture, with $E_F = E_D = 1$. The pure gauge energy μE_F (red) decreases all the way to $\mu \to 0$: the lump spreads out and disappears. Adding a Higgs gradient term (blue) produces a minimum at $\mu = 1$, where $E_F = E_D$. That equality is exactly what the Bogomolny equation will give.

8.12.3 A warm-up with one gauge field: the Dirac monopole

Before adding the Higgs field, recall the oldest monopole, Dirac's, because the non-abelian monopole will look exactly like it from far away. Maxwell's equation $\nabla \cdot \vec{B} = 0$ forbids magnetic charges *if* $\vec{B}$ is the curl of a vector potential everywhere. Dirac asked what happens if we give up "everywhere".

Place a magnetic charge at the origin: $\vec{B} = g\,\hat{\vec{r}}/r^2$. As a 2-form on $\mathbb{R}^3 \setminus \{0\}$, using spherical coordinates,

$$F^{\text{Maxwell}} = \star(B_i \mathrm{d}x^i) = g\,\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\varphi. \tag{8.269}$$

It is closed, but its integral over any sphere around the origin is $4\pi g \neq 0$, so by Stokes it is not exact: there is no global potential (this is the example in Chapter T2). Locally there are potentials. On the sphere with the south pole removed, and on the sphere with the north pole removed,

$$a_N = g(1-\cos\theta)\,\mathrm{d}\varphi, \qquad a_S = -g(1+\cos\theta)\,\mathrm{d}\varphi, \qquad \mathrm{d}a_N = \mathrm{d}a_S = F^{\text{Maxwell}}. \tag{8.270}$$

Each is singular where the other is fine: a_N blows up at $\theta = \pi$ (the coefficient of $\mathrm{d}\varphi$ does not vanish where the circle shrinks), and a_S at $\theta = 0$. The line where a potential is singular is the **Dirac string**. On the overlap the two differ by $a_N - a_S = 2g\,\mathrm{d}\varphi$, a gauge transformation.

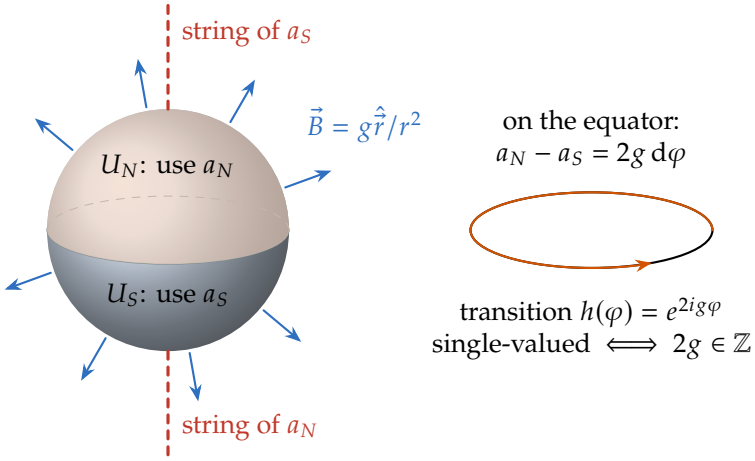

Figure 8.59: The Dirac monopole as two patches. The northern cap uses a_N, the southern cap a_S; each has a string of singularity where the other patch lives, so neither string is ever "seen". On the equatorial overlap the two potentials are related by the U(1) gauge transformation $h = e^{2ig\varphi}$, and this must be a genuine function on the circle.

Worked example 8.114: Dirac quantisation from single-valuedness

A charged wavefunction ψ of unit electric charge couples through $\mathrm{d} - ia$ (physicists' convention for U(1), with a real). If $a_N = a_S + \mathrm{d}\chi$, the wavefunctions in the two patches are related by $\psi_N = e^{i\chi}\psi_S$. Here $\chi = 2g\varphi$. Going once round the equator, $\varphi \to \varphi + 2\pi$, the relation must return to itself:

$$e^{i\chi(\varphi+2\pi)} \overset{(1)}{=} e^{i2g(\varphi+2\pi)} \overset{(2)}{=} e^{i\chi(\varphi)}\,e^{4\pi i g} \overset{(3)}{=} e^{i\chi(\varphi)} \qquad \Longleftrightarrow \qquad 2g = n \in \mathbb{Z}.$$

(1) Insert $\chi = 2g\varphi$.
(2) Split the exponential.
(3) We demand single-valuedness of ψ_N given ψ_S; this holds for every φ exactly when $e^{4\pi i g} = 1$.

The flux is then $\int_{S^2} F^{\text{Maxwell}} = 4\pi g = 2\pi n$. We can recover this from the patches alone, by

Stokes on each hemisphere:

$$\int_{S^2} F^{\text{Maxwell}} \overset{(1)}{=} \int_{U_N} \mathrm{d}a_N + \int_{U_S} \mathrm{d}a_S \overset{(2)}{=} \oint_{\text{eq}} a_N - \oint_{\text{eq}} a_S \overset{(3)}{=} \oint_{\text{eq}} \mathrm{d}\chi = 2\pi n.$$

(1) Split the sphere at the equator and use the regular potential in each half.
(2) Stokes; the equator is the boundary of U_N with the positive orientation and of U_S with the negative one.
(3) $a_N - a_S = \mathrm{d}\chi$; the winding of $\chi = n\varphi$ round the circle is $2\pi n$.

In the language of Chapter 1, $\frac{1}{2\pi}F^{\text{Maxwell}}$ represents the first Chern class of a U(1) bundle over S^2, and $n = c_1$ is an integer because it counts the winding of the transition function. For $n = 1$ the bundle is the Hopf bundle $S^3 \to S^2$.

Two lessons carry over. First, a magnetic charge is a *topological* number: it measures how the patches are glued, not the details of the field. Second, the Dirac monopole is singular at the origin, and its energy $\frac{1}{2}\int |\vec{B}|^2 \mathrm{d}^3x$ diverges there. The 't Hooft–Polyakov monopole cures the singularity by embedding U(1) in SU(2) and letting a Higgs field decide, point by point, which U(1) is "electromagnetism".

8.12.4 The Yang–Mills–Higgs energy

The system Nash studies is a pair (A, ϕ): an SU(2) connection A on a bundle $P \to M$ over a three-manifold M, and a Higgs field ϕ in the adjoint representation. Its energy is Nash's (8.139), written with our trace normalisation:

$$E(A,\phi) = \frac{1}{2}\int_M \Big\{ -2\,\mathrm{tr}(F \wedge \star F) - 2\,\mathrm{tr}(\mathrm{d}_A\phi \wedge \star \mathrm{d}_A\phi) + \lambda\big(|\phi|^2 - C^2\big)^2 \star 1 \Big\}. \tag{8.271}$$

On $\mathbb{R}^3$, in components, this is the familiar

$$E = \int_{\mathbb{R}^3} \Big\{ \frac{1}{2} B_i^a B_i^a + \frac{1}{2} D_i\phi^a \, D_i\phi^a + \frac{\lambda}{2}\big(\phi^a\phi^a - C^2\big)^2 \Big\} \mathrm{d}^3x, \tag{8.272}$$

because $-2\,\mathrm{tr}(F \wedge \star F) = \sum_a F^a \wedge \star F^a = B_i^a B_i^a \, \mathrm{d}^3x$ and similarly for the gradient term.

Read term by term:

- $\frac{1}{2}|B|^2$ is magnetic energy (the fields are static and we work in the gauge $A_0 = 0$, so there is no electric field).
- $\frac{1}{2}|D\phi|^2$ is the gradient energy of the Higgs field; the covariant derivative makes it gauge invariant.
- $\frac{\lambda}{2}(|\phi|^2 - C^2)^2$ is the Mexican-hat potential. It vanishes on the sphere $|\phi| = C$ in $\mathfrak{su}(2) \cong \mathbb{R}^3$.

Each term is non-negative. So the energy vanishes exactly when $F = 0$, $\mathrm{d}_A\phi = 0$ and $|\phi| = C$. On $\mathbb{R}^3$ this means that, up to a gauge transformation, $A = 0$ and ϕ is a constant of length C: the Higgs **vacuum**.

Working definition 8.38 (vacuum manifold)

The **vacuum manifold** is the set of Higgs values of zero potential energy,

$$\mathcal{V} = \{\phi \in \mathfrak{su}(2) : |\phi| = C\} \cong S^2.$$

Operational meaning: it is the set of directions in isospin space [$\mathfrak{su}(2) \cong \mathbb{R}^3$, where the Higgs field takes its values] in which the Higgs field can point at no cost. SU(2) acts on it by conjugation, which rotates $\mathbb{R}^3$. The stabiliser [the elements g with $g^{-1}\phi g = \phi$] of $\phi = CT_3$ is the circle $\{e^{\theta T_3}\} \cong \mathrm{U}(1)$, so $\mathcal{V} \cong \mathrm{SU}(2)/\mathrm{U}(1)$. This unbroken U(1) is electromagnetism.

Physical picture: Symmetry breaking in pictures

Think of $\phi(x)$ as a little arrow in an internal three-dimensional space, attached to each point x. In the vacuum all arrows have length C and are parallel (after a gauge transformation). Rotations about the common arrow do not disturb the vacuum; that is the unbroken U(1). The two gauge fields that rotate the arrow away from its direction get a mass (the $W^\pm$ bosons), and the photon, the gauge field of rotations about the arrow, stays massless.

Worked example 8.115: Masses in the vacuum

Put $\phi = C\,T_3$ and a small gauge field $A = A_i^a T_a \mathrm{d}x^i$. The gradient term is

$$\frac{1}{2}|D_i\phi|^2 \overset{(1)}{=} \frac{1}{2}\big|[A_i, CT_3]\big|^2 \overset{(2)}{=} \frac{C^2}{2}\big|\vec{A}_i \times \hat{\vec{e}}_3\big|^2 \overset{(3)}{=} \frac{C^2}{2}\big((A_i^1)^2 + (A_i^2)^2\big).$$

(1) ϕ is constant, so $\mathrm{d}\phi = 0$.
(2) Commutators are cross products (Example 8.112).
(3) $\vec{A} \times \hat{\vec{e}}_3 = (A^2, -A^1, 0)$.

This is a mass term $\frac{1}{2}m_W^2 A^2$ with $m_W = C$ for A^1, A^2 and no mass for A^3, which is the photon. In physical units $m_W = ev$.

8.12.5 The field equations

The static field equations are the Euler–Lagrange equations of E. We derive them by varying $A \to A + ta$ and $\phi \to \phi + t\eta$, with a, η of compact support, and demanding $\mathrm{d}E/\mathrm{d}t|_{t=0} = 0$. We need the first-order changes

$$F(A + ta) = F + t\,\mathrm{d}_A a + t^2 a \wedge a, \qquad \mathrm{d}_{A+ta}(\phi + t\eta) = \mathrm{d}_A\phi + t\big(\mathrm{d}_A\eta + [a, \phi]\big) + t^2[a, \eta]. \quad (8.273)$$

Worked example 8.116: Deriving Nash's (8.140)

Differentiate E at $t = 0$. Using the symmetry of $\langle\,,\rangle$,

$$\begin{aligned}\frac{\mathrm{d}E}{\mathrm{d}t}\Big|_0 &\overset{(1)}{=} \langle F, \mathrm{d}_A a\rangle + \langle \mathrm{d}_A\phi, \mathrm{d}_A\eta + [a,\phi]\rangle + 2\lambda \int (|\phi|^2 - C^2)(\phi, \eta) \star 1 \\ &\overset{(2)}{=} \langle \mathrm{d}_A^\star F, a\rangle + \langle \mathrm{d}_A^\star \mathrm{d}_A\phi, \eta\rangle + \langle \mathrm{d}_A\phi, [a,\phi]\rangle + \big\langle 2\lambda(|\phi|^2 - C^2)\phi, \eta\big\rangle \\ &\overset{(3)}{=} \big\langle \mathrm{d}_A^\star F - [\mathrm{d}_A\phi, \phi],\, a\big\rangle + \big\langle \mathrm{d}_A^\star \mathrm{d}_A\phi + 2\lambda(|\phi|^2 - C^2)\phi,\, \eta\big\rangle.\end{aligned}$$

(1) Differentiate each square: $\frac{\mathrm{d}}{\mathrm{d}t}\frac{1}{2}\|X + tY\|^2 = \langle X, Y\rangle$; for the potential, $\frac{\mathrm{d}}{\mathrm{d}t}|\phi + t\eta|^2 = 2(\phi, \eta)$, so $\frac{\mathrm{d}}{\mathrm{d}t}\frac{\lambda}{2}(|\phi|^2 - C^2)^2 = 2\lambda(|\phi|^2 - C^2)(\phi, \eta)$.
(2) Move d_A across the inner product as its adjoint $\mathrm{d}_A^\star$ (integration by parts; boundary terms vanish because a, η have compact support).
(3) Pointwise, $(\mathrm{d}_A\phi, [a,\phi]) = \sum_i D_i\vec{\phi} \cdot (\vec{a}_i \times \vec{\phi}) = \sum_i \vec{a}_i \cdot (\vec{\phi} \times D_i\vec{\phi}) = -(a, [\mathrm{d}_A\phi, \phi])$, by the cyclic property of the triple product.

The variation vanishes for all a and η only if

$$\mathrm{d}_A^\star F = [\mathrm{d}_A\phi, \phi], \qquad \mathrm{d}_A^\star \mathrm{d}_A\phi = -2\lambda\,\phi\,(|\phi|^2 - C^2). \tag{8.274}$$

The first equation is the non-abelian Ampère law: the magnetic field is sourced by the current $[\mathrm{d}_A\phi, \phi]$ carried by the charged components of the Higgs field. The second is a covariant nonlinear Klein–Gordon equation; on $\mathbb{R}^3$, since $\mathrm{d}_A^\star \mathrm{d}_A = -D_iD_i$, it reads $D_iD_i\phi = 2\lambda\phi(|\phi|^2 - C^2)$, i.e. "Laplacian of ϕ equals the derivative of the potential".

Watch out: Signs and factors in (8.140)

Nash's (8.140) reads $\mathrm{d}_A^\star \mathrm{d}_A\phi = 4\lambda\phi(|\phi|^2 - C^2)$. The 4 instead of our 2 comes from his use of $-\operatorname{tr}$ rather than $-2\operatorname{tr}$ in the inner product (the gradient term is then half as big relative to the potential). The sign is a slip: $\mathrm{d}_A^\star \mathrm{d}_A$ is a *positive* operator ($\langle\phi, \mathrm{d}_A^\star \mathrm{d}_A\phi\rangle = \|\mathrm{d}_A\phi\|^2 \geq 0$), and for the potential to push $|\phi|$ back towards C the right-hand side must carry a minus sign. Nothing later depends on this, because Nash immediately sets $\lambda = 0$.

These equations are coupled and nonlinear. Nash remarks that they are "difficult to solve explicitly" and refers to the book of Jaffe and Taubes. For $\lambda > 0$ no closed-form monopole is known; existence was proved by variational methods, and numerically the solutions look much like the $\lambda = 0$ solution we shall find in Section 8.13.

8.12.6 Finite energy forces a topological charge

Here is the step that produces the soliton. Finite energy on $\mathbb{R}^3$ requires each term of (8.272) to fall off at infinity. In particular $|\phi| \to C$ as $r \to \infty$ (when $\lambda > 0$ this is forced by the potential term; when $\lambda = 0$ we *impose* it, as Nash does in (8.152)). So at large r the Higgs field defines a map from the sphere at infinity to the vacuum manifold:

$$\hat\phi : S^2_\infty \to S^2 \subset \mathfrak{su}(2), \qquad \hat\phi(\hat{\vec{x}}) = \lim_{r\to\infty} \frac{\phi(r\hat{\vec{x}})}{|\phi(r\hat{\vec{x}})|}. \tag{8.275}$$

Maps between spheres of the same dimension have a **degree**: an integer counting how many times the image wraps round the target (Chapter 1). It cannot change under continuous deformations, and time evolution of finite-energy fields is continuous. Hence the degree is a conserved topological charge.

Working definition 8.39 (degree of a map $S^2 \to S^2$)

For a smooth map $\hat n : S^2 \to S^2 \subset \mathbb{R}^3$, $|\hat n| = 1$,

$$\deg \hat n = \frac{1}{4\pi}\int_{S^2} \hat n^*\omega = \frac{1}{8\pi}\int_{S^2} \varepsilon_{abc}\, n^a\, \mathrm{d}n^b \wedge \mathrm{d}n^c, \tag{8.276}$$

where ω is the area form of the unit sphere [the 2-form whose integral over any region is its area, 4π for all of S^2]. *How to compute:* either do the integral, or pick a generic point y [one at which the derivative of $\hat n$ is invertible at every preimage] of the target and count its preimages with signs (+1 where $\hat n$ preserves orientation, −1 where it reverses it).

The middle and right expressions agree because $\frac{1}{2}\varepsilon_{abc}n^a\mathrm{d}n^b \wedge \mathrm{d}n^c$ is the pullback of the area form: at the north pole $\vec n = (0,0,1)$ of the target it equals $\mathrm{d}n^1 \wedge \mathrm{d}n^2$, which is the area element there.

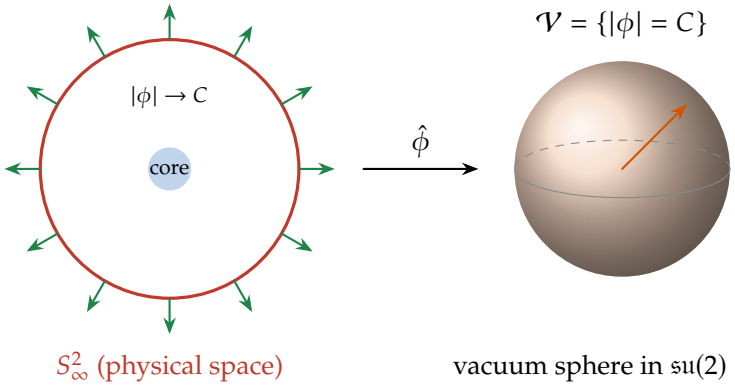

Figure 8.60: At large distance a finite-energy Higgs field lies on the vacuum sphere. Its direction defines a map $\hat{\phi}$ from the sphere at infinity (left) to the vacuum sphere (right). For the "hedgehog" drawn here the Higgs arrow points radially outward, so $\hat{\phi}$ is the identity map and has degree 1. A configuration of degree $k \neq 0$ cannot be deformed into the vacuum (degree 0) without passing through infinite energy.

Worked example 8.117: The degree of $\hat{\vec{n}}_m$ is m

Let $\vec{n}_m(\theta, \varphi) = (\sin\theta\cos m\varphi, \sin\theta\sin m\varphi, \cos\theta)$. It wraps the sphere m times round the vertical axis. The pullback of the area form $\omega = \sin\Theta\, \mathrm{d}\Theta \wedge \mathrm{d}\Phi$ under $\Theta = \theta$, $\Phi = m\varphi$ is

$$\frac{1}{4\pi}\int_{S^2} \vec{n}_m^{\,*}\omega \overset{(1)}{=} \frac{1}{4\pi}\int_{S^2} \sin\theta\, \mathrm{d}\theta \wedge (m\, \mathrm{d}\varphi) \overset{(2)}{=} \frac{m}{4\pi}\cdot 4\pi = m.$$

(1) $\Theta = \theta$ and $\mathrm{d}\Phi = m\, \mathrm{d}\varphi$.
(2) The remaining integral is the area of the unit sphere.

Preimage count: the point $\vec{n} = (1, 0, 0)$ has the m preimages $\theta = \pi/2$, $\varphi = 2\pi j/m$, each orientation-preserving. Both methods give m.

Key idea: The topological charge of a finite-energy configuration

Every finite-energy configuration on $\mathbb{R}^3$ carries an integer $k = \deg\hat{\phi} \in \pi_2(S^2) = \mathbb{Z}$. Configurations with different k lie in disconnected components of the space of finite-energy fields. The vacuum has $k = 0$; a configuration with $k \neq 0$ is a candidate monopole, and it cannot decay into the vacuum.

Two remarks from Nash's first paragraph fit here. First, if M is closed and compact there is no "sphere at infinity", and we shall see in Section 8.13.4 that monopoles on such M are trivial. Second, the charge lives entirely at infinity. The SU(2) bundle over $\mathbb{R}^3$ itself is trivial (Nash, p. 245), because $\mathbb{R}^3$ is contractible; the topology is in the Higgs field's asymptotic direction, not in the bundle.

8.12.7 The 't Hooft–Polyakov hedgehog

The simplest configuration of degree 1 points the Higgs field radially: $\hat{\phi}(\hat{\vec{x}}) = \hat{x}^a T_a$. For finite energy the gauge field must make $\mathrm{d}_A\phi$ vanish at infinity too, so that the gradient energy converges. This fixes the asymptotic gauge field. 't Hooft and Polyakov (1974) made the

spherically symmetric ansatz

$$\phi = h(r)\,\hat{x}^a T_a, \qquad A = \frac{1 - K(r)}{r}\,\varepsilon_{aij}\hat{x}^j\,T_a\,\mathrm{d}x^i, \tag{8.277}$$

with boundary conditions

$$h(0) = 0, \quad K(0) = 1 \qquad \text{(smooth at the origin)}, \qquad h(\infty) = C, \quad K(\infty) = 0 \qquad \text{(finite energy)}. \tag{8.278}$$

The name is visual: the Higgs arrow at $\vec{x}$ points along $\vec{x}$, like the spines of a hedgehog.

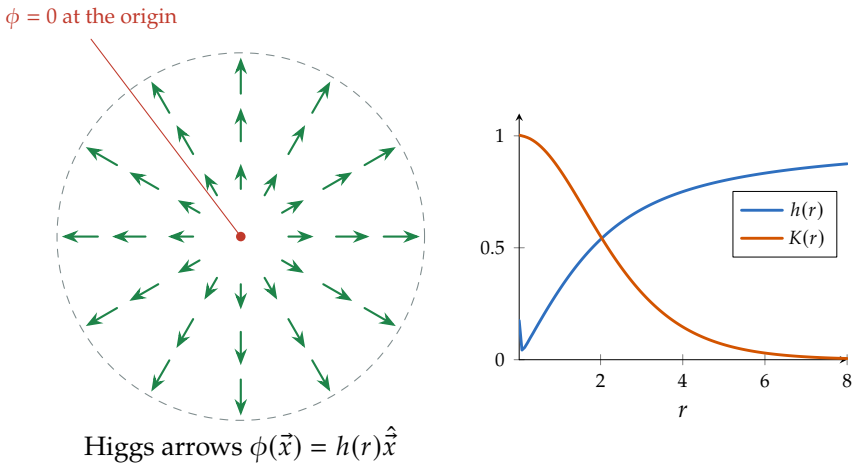

Figure 8.61: Left: the hedgehog. The Higgs field points radially in isospin space, its length grows from 0 at the centre to C far away, and it vanishes only at the origin, which is where the monopole "is". Right: the two profile functions for the Prasad–Sommerfield solution we shall derive in Example 8.123 (with $C = 1$). K controls the gauge field: $K = 1$ is "no gauge field" near the centre, $K = 0$ is the asymptotic monopole field.

Worked example 8.118: The hedgehog has charge one

At infinity $\hat{\phi}(\hat{\vec{x}}) = \hat{x}^a T_a$, whose component vector is $\vec{n} = \hat{\vec{x}}$. So $\hat{\phi}$ is the identity map of S^2, and every point of the target has exactly one orientation-preserving preimage: $\deg\hat{\phi} = 1$. With the integral (8.276), at $\hat{\vec{x}} = (0, 0, 1)$ the integrand $\frac{1}{2}\varepsilon_{abc}n^a\mathrm{d}n^b \wedge \mathrm{d}n^c = \mathrm{d}x^1 \wedge \mathrm{d}x^2$ is the area element, and integrating over the unit sphere gives $4\pi/4\pi = 1$.

To see why the gauge field in (8.277) is forced, compute its asymptotic form: with $K = 0$, $A_\infty = \frac{1}{r}\varepsilon_{aij}\hat{x}^j T_a \mathrm{d}x^i$. The covariant derivative of the unit Higgs field is then

$$\begin{aligned}(D_i\hat{\phi})^a &\overset{(1)}{=} \partial_i\hat{x}^a + \varepsilon_{abc}A_i^b\hat{x}^c \overset{(2)}{=} \frac{\delta_{ai} - \hat{x}_a\hat{x}_i}{r} + \frac{1}{r}\varepsilon_{abc}\varepsilon_{bij}\hat{x}^j\hat{x}^c \\ &\overset{(3)}{=} \frac{\delta_{ai} - \hat{x}_a\hat{x}_i}{r} + \frac{1}{r}\big(\delta_{ci}\delta_{aj} - \delta_{cj}\delta_{ai}\big)\hat{x}^j\hat{x}^c \overset{(4)}{=} \frac{\delta_{ai} - \hat{x}_a\hat{x}_i}{r} + \frac{\hat{x}_a\hat{x}_i - \delta_{ai}}{r} = 0.\end{aligned}$$

(1) Definition (8.267).
(2) $\partial_i(x^a/r) = (\delta_{ai} - \hat{x}_a\hat{x}_i)/r$; insert $A_i^b = \frac{1}{r}\varepsilon_{bij}\hat{x}^j$.
(3) $\varepsilon_{abc}\varepsilon_{bij} = \varepsilon_{bca}\varepsilon_{bij} = \delta_{ci}\delta_{aj} - \delta_{cj}\delta_{ai}$.
(4) Contract, using $\hat{x}^j\hat{x}^j = 1$.

So the asymptotic gauge field is exactly the one that makes the rotating Higgs direction covariantly constant. Its field strength does *not* vanish: it is the magnetic monopole field, as we shall see in Section 8.13.7.

Substituting the ansatz (8.277) into the energy reduces a problem about fields on $\mathbb{R}^3$ to a problem about two functions of r. The covariant derivatives decompose into a "transverse" part proportional to $P^T_{ai} = \delta_{ai} - \hat{x}_a\hat{x}_i$ and a "longitudinal" part proportional to $P^L_{ai} = \hat{x}_a\hat{x}_i$ (a direct computation like the one in Example 8.118, which we checked by computer algebra):

$$B^a_i = \frac{K'}{r}\,P^T_{ai} - \frac{1-K^2}{r^2}\,P^L_{ai}, \qquad D_i\phi^a = \frac{hK}{r}\,P^T_{ai} + h'\,P^L_{ai}. \tag{8.279}$$

Since P^T has trace 2, P^L has trace 1, and $P^TP^L = 0$, the squares are $|B|^2 = 2K'^2/r^2 + (1-K^2)^2/r^4$ and $|D\phi|^2 = 2h^2K^2/r^2 + h'^2$. With $\mathrm{d}^3x = 4\pi r^2\mathrm{d}r$ after the angular integral,

$$E = 4\pi\int_0^\infty \left\{K'^2 + \frac{(1-K^2)^2}{2r^2} + h^2K^2 + \frac{r^2h'^2}{2} + \frac{\lambda}{2}r^2\big(h^2-C^2\big)^2\right\}\mathrm{d}r. \tag{8.280}$$

Every term is non-negative, and the boundary conditions (8.278) make the integral converge at both ends (near $r=0$, $1-K^2 = O(r^2)$ and near $r=\infty$, $K\to 0$ exponentially). Minimising (8.280) over h, K is a two-function ordinary variational problem; for $\lambda > 0$ it is done numerically, and for $\lambda = 0$ we solve it in closed form in the next section.

Try it: The unit of energy

Show that for *any* functions obeying (8.278) the energy (8.280) with $\lambda = 0$ is at least $4\pi C$. *Hint:* complete two squares, $K'^2 + h^2K^2 = (K' + hK)^2 - 2hKK'$ and $\frac{(1-K^2)^2}{2r^2} + \frac{r^2h'^2}{2} = \frac{1}{2}\big(rh' - \frac{1-K^2}{r}\big)^2 + h'(1-K^2)$, and notice that the cross terms add up to $\frac{\mathrm{d}}{\mathrm{d}r}\big[h(1-K^2)\big]$. *Answer:* the total derivative integrates to $h(1-K^2)\big|_0^\infty = C$, so $E = 4\pi C + (\text{squares}) \geq 4\pi C$. We redo this properly in Example 8.123.

Reading Nash (pp. 242–243, (8.139)–(8.140))

Nash's Section 4 opens by listing what changes in three dimensions: monopoles are static, finite-energy critical points of a Yang–Mills–Higgs energy on a three-dimensional M; they carry an integer invariant k; they are trivial on closed compact M; and the usual choice is $M = \mathbb{R}^3$, whose non-compactness brings technical difficulties that "have not proved insurmountable". (8.139) is our (8.271) (with his $-$ tr replaced by -2 tr) and (8.140) is our (8.274). The topology at infinity, which Nash only introduces on p. 245, has been moved forward here because it is what makes k exist at all.

Recap

- In three dimensions pure Yang–Mills has no static lumps (Derrick); a Higgs field in the adjoint representation provides the balancing force.
- The YMH energy is magnetic + gradient + Mexican-hat potential; its vacuum manifold is $S^2 = \mathrm{SU}(2)/\mathrm{U}(1)$, with unbroken U(1) = photon.
- Finite energy forces $|\phi| \to C$ at infinity, so $\hat{\phi} : S^2_\infty \to S^2$ has a degree $k \in \pi_2(S^2) = \mathbb{Z}$: the conserved topological charge.
- The Dirac monopole shows why a magnetic charge is a Chern number; the 't Hooft–Polyakov hedgehog is a smooth, finite-energy version with $k = 1$.

8.13 The Bogomolny equation and the Prasad–Sommerfield monopole

The field equations (8.274) are second order and coupled. For instantons we met a trick that turns such a problem into a first-order one: complete the square in the action, notice that the cross term is topological, and conclude that the absolute minima in each topological sector solve a first-order equation. This section plays the same trick for monopoles. The questions are:

> *When does the monopole problem become first order? What is the first-order equation, what is the minimum energy, and can we solve it explicitly?*

The answers: when the Higgs potential is switched off ($\lambda = 0$); the equation is Bogomolny's $F = \mp \star \mathrm{d}_A\phi$; the minimum energy is $4\pi C|k|$; and for $k = 1$ the solution is the Prasad–Sommerfield monopole, which we write down in closed form.

8.13.1 The Prasad–Sommerfield limit

Nash's next step is to take the limit in which the potential term of (8.271) vanishes, $\lambda \to 0$. The energy becomes

$$E(A,\phi) = -\int_M \Big\{ \mathrm{tr}(F \wedge \star F) + \mathrm{tr}(\mathrm{d}_A\phi \wedge \star \mathrm{d}_A\phi) \Big\} = \frac{1}{2}\Big\{ \|F\|^2 + \big\|\mathrm{d}_A\phi\big\|^2 \Big\}, \tag{8.281}$$

with the norms of (8.266). Setting $\lambda = 0$ in (8.274) gives the field equations

$$\mathrm{d}_A^\star F = [\mathrm{d}_A\phi, \phi], \qquad \mathrm{d}_A^\star \mathrm{d}_A\phi = 0. \tag{8.282}$$

Physical picture: What survives of the potential

Setting $\lambda = 0$ does not mean "no symmetry breaking". We keep the *boundary condition* $|\phi| \to C$ at infinity, which is what the potential was there to enforce. Think of $\lambda \to 0^+$: the potential is infinitely weak, so it no longer shapes the core of the monopole, but it still selects the vacuum sphere at infinity. The price is that the Higgs field is now massless ($m_H^2 \propto \lambda C^2 \to 0$), and its long-range tail will matter when we discuss forces in Section 8.16.

8.13.2 The Bogomolny equation solves the field equations

Bogomolny observed that the first-order equation

$$F = \pm \star \mathrm{d}_A\phi \tag{8.283}$$

implies both equations (8.282). Nash writes the + sign in (8.143); the self-duality reduction below will produce the − sign, and so will the hedgehog. Both signs work, so we check them together. Two facts are needed.

Working definition 8.40 (two identities for d_A in the adjoint)

For an $\mathfrak{su}(2)$-valued function ϕ and an $\mathfrak{su}(2)$-valued 1-form ω,

$$\mathrm{d}_A\omega = \mathrm{d}\omega + A \wedge \omega + \omega \wedge A, \qquad \mathrm{d}_A\mathrm{d}_A\phi = [F,\phi], \qquad \mathrm{d}_A F = 0.$$

The second says "d_A^2 is curvature"; the third is the Bianchi identity [it holds for every connection, not only for solutions] (Chapter T3). *Operational meaning:* a covariant derivative applied twice does not vanish, it multiplies by F (in the adjoint [on $\mathfrak{su}(2)$-valued fields

such as ϕ, where A acts as $[A, \cdot\,]$, by commutator).

Worked example 8.119: Nash's (8.145): $\mathrm{d}_A \mathrm{d}_A \phi = [F, \phi]$ written out

Put $\omega = \mathrm{d}_A\phi = \mathrm{d}\phi + A\phi - \phi A$. Then

$$\begin{aligned}
\mathrm{d}_A\omega &\overset{(1)}{=} \mathrm{d}(\mathrm{d}\phi + A\phi - \phi A) + A \wedge (\mathrm{d}\phi + A\phi - \phi A) + (\mathrm{d}\phi + A\phi - \phi A) \wedge A \\
&\overset{(2)}{=} \big(\mathrm{d}A\,\phi - A \wedge \mathrm{d}\phi - \mathrm{d}\phi \wedge A - \phi\,\mathrm{d}A\big) + \big(A \wedge \mathrm{d}\phi + A \wedge A\,\phi - A\phi \wedge A\big) \\
&\qquad + \big(\mathrm{d}\phi \wedge A + A\phi \wedge A - \phi A \wedge A\big) \\
&\overset{(3)}{=} (\mathrm{d}A + A \wedge A)\phi - \phi(\mathrm{d}A + A \wedge A) \\
&\overset{(4)}{=} F\phi - \phi F = [F, \phi].
\end{aligned}$$

(1) Definition of d_A on an adjoint 1-form.
(2) $\mathrm{d}\mathrm{d}\phi = 0$; the Leibniz rule gives $\mathrm{d}(A\phi) = \mathrm{d}A\,\phi - A \wedge \mathrm{d}\phi$ and $\mathrm{d}(\phi A) = \mathrm{d}\phi \wedge A + \phi\,\mathrm{d}A$ (a 1-form passing d picks up a minus sign).
(3) The terms $\pm A \wedge \mathrm{d}\phi$, $\pm \mathrm{d}\phi \wedge A$ and $\pm A\phi \wedge A$ cancel in pairs.
(4) $F = \mathrm{d}A + A \wedge A$.

Now take $F = \pm \star \mathrm{d}_A\phi$, equivalently $\mathrm{d}_A\phi = \pm \star F$ (because $\star\star = 1$ in three Riemannian dimensions). Recall $\mathrm{d}_A^\star = - \star \mathrm{d}_A \star$ on 1-forms and $\mathrm{d}_A^\star = \star \mathrm{d}_A \star$ on 2-forms. The second field equation:

$$\mathrm{d}_A^\star \mathrm{d}_A \phi \overset{(1)}{=} - \star \mathrm{d}_A \star \mathrm{d}_A \phi \overset{(2)}{=} - \star \mathrm{d}_A \star (\pm \star F) \overset{(3)}{=} \mp \star \mathrm{d}_A F \overset{(4)}{=} 0.$$

(1) Adjoint of d_A on 1-forms in three dimensions.
(2) Bogomolny, in the form $\mathrm{d}_A\phi = \pm \star F$.
(3) $\star\star = 1$.
(4) Bianchi identity. This is Nash's remark that "the second equation just becomes the Bianchi identity" (8.144).

The first field equation:

$$\mathrm{d}_A^\star F \overset{(1)}{=} \star \mathrm{d}_A \star F \overset{(2)}{=} \star \mathrm{d}_A(\pm \mathrm{d}_A\phi) \overset{(3)}{=} \pm \star [F, \phi] \overset{(4)}{=} \big[\pm \star F, \phi\big] \overset{(5)}{=} [\mathrm{d}_A\phi, \phi].$$

(1) Adjoint of d_A on 2-forms in three dimensions.
(2) $\star F = \pm \star \star \mathrm{d}_A\phi = \pm \mathrm{d}_A\phi$.
(3) Example 8.119.
(4) $\star$ acts on the form part only and commutes with bracketing by the function ϕ.
(5) Bogomolny again.

So every solution of (8.283) solves (8.282). The converse is false in general, just as not every Yang–Mills field is self-dual; we return to the non-Bogomolny critical points in Section 8.18.

8.13.3 Completing the square: the Bogomolny bound

Nash notes that it is "much easier" to see why (8.283) is the right equation by completing the square in the energy. Since $\star$ is an isometry, $\big\|\star \mathrm{d}_A\phi\big\| = \big\|\mathrm{d}_A\phi\big\|$, and

$$E \overset{(1)}{=} \frac{1}{2}\Big\{\|F\|^2 + \big\|\star \mathrm{d}_A\phi\big\|^2\Big\}$$

$$\overset{(2)}{=} \frac{1}{2}\Big\{\big\|F \mp \star \mathrm{d}_A\phi\big\|^2 \pm 2\langle F, \star \mathrm{d}_A\phi\rangle\Big\}$$
$$\overset{(3)}{=} \frac{1}{2}\big\|F \mp \star \mathrm{d}_A\phi\big\|^2 \pm \langle F, \star \mathrm{d}_A\phi\rangle. \tag{8.284}$$

(1) Replace $\|\mathrm{d}_A\phi\|$ by $\|\star \mathrm{d}_A\phi\|$.
(2) Expand: $\|F \mp \star \mathrm{d}_A\phi\|^2 = \|F\|^2 + \|\star \mathrm{d}_A\phi\|^2 \mp 2\langle F, \star \mathrm{d}_A\phi\rangle$, so we add back the cross term. This is Nash's (8.146).
(3) Distribute the $\frac{1}{2}$.

The first term is non-negative and vanishes exactly when $F = \pm \star \mathrm{d}_A\phi$. The second term is the one Nash says "looks like a topological charge":

$$\langle F, \star \mathrm{d}_A\phi\rangle = -2\int_M \mathrm{tr}\big(F \wedge \star \star \mathrm{d}_A\phi\big) = -2\int_M \mathrm{tr}(F \wedge \mathrm{d}_A\phi). \tag{8.285}$$

It is indeed a total derivative:

$$\begin{aligned}
\mathrm{d}\ \mathrm{tr}(F\phi) &\overset{(1)}{=} \mathrm{tr}(\mathrm{d}F\,\phi) + \mathrm{tr}(F \wedge \mathrm{d}\phi) \\
&\overset{(2)}{=} \mathrm{tr}\big((\mathrm{d}_A F - A\wedge F + F\wedge A)\phi\big) + \mathrm{tr}\big(F \wedge (\mathrm{d}_A\phi - A\phi + \phi A)\big) \\
&\overset{(3)}{=} \mathrm{tr}(\mathrm{d}_A F\,\phi) + \mathrm{tr}(F \wedge \mathrm{d}_A\phi) + \mathrm{tr}\big(-A\wedge F\phi + F\phi \wedge A\big) \\
&\overset{(4)}{=} \mathrm{tr}(\mathrm{d}_A F\,\phi) + \mathrm{tr}(F \wedge \mathrm{d}_A\phi) \overset{(5)}{=} \mathrm{tr}(F \wedge \mathrm{d}_A\phi).
\end{aligned} \tag{8.286}$$

(1) Leibniz rule; F is a 2-form, so no sign.
(2) Solve $\mathrm{d}_A F = \mathrm{d}F + A\wedge F - F\wedge A$ and $\mathrm{d}_A\phi = \mathrm{d}\phi + A\phi - \phi A$ for $\mathrm{d}F$ and $\mathrm{d}\phi$.
(3) Multiply out; $-\mathrm{tr}(F\wedge A\phi)$ and $+\mathrm{tr}(F\wedge A\phi)$ cancel, leaving the two terms shown.
(4) Graded cyclicity $\mathrm{tr}(\alpha\wedge\beta) = (-1)^{pq}\,\mathrm{tr}(\beta\wedge\alpha)$ with $p=1, q=2$ gives $\mathrm{tr}(A\wedge F\phi) = \mathrm{tr}(F\phi\wedge A)$.
(5) Bianchi identity $\mathrm{d}_A F = 0$. This is Nash's (8.149).

Key idea: The Bogomolny bound

In the Prasad–Sommerfield limit,

$$E(A,\phi) = \tfrac{1}{2}\big\|F \mp \star \mathrm{d}_A\phi\big\|^2 \pm \langle F, \star \mathrm{d}_A\phi\rangle \ \geq\ \pm\langle F, \star \mathrm{d}_A\phi\rangle,$$

and the cross term depends only on boundary values, by (8.286) and Stokes. For fixed boundary data the energy is therefore smallest exactly on solutions of the **Bogomolny equation** $F = \pm \star \mathrm{d}_A\phi$ (Nash's (8.147)). Choose the sign that makes the cross term positive.

This is word for word the argument that produced the instanton bound $S \geq 8\pi^2|k|$ in the previous section: square plus topological term.

8.13.4 On a closed manifold every monopole is trivial

Nash now raises a warning. Suppose M is compact and has no boundary. Then Stokes kills the cross term:

$$\langle F, \star \mathrm{d}_A\phi\rangle \overset{(1)}{=} -2\int_M \mathrm{tr}(F\wedge \mathrm{d}_A\phi) \overset{(2)}{=} -2\int_M \mathrm{d}\ \mathrm{tr}(F\phi) \overset{(3)}{=} -2\int_{\partial M} \mathrm{tr}(F\phi) \overset{(4)}{=} 0. \tag{8.287}$$

(1) (8.285).
(2) (8.286).

(3) Stokes' theorem for the gauge-invariant 2-form $\mathrm{tr}(F\phi)$.
(4) $\partial M = \varnothing$ (Nash's (8.150)).

Hence on a Bogomolny solution $E = 0$, and since E is a sum of squares,

$$F = 0, \qquad \mathrm{d}_A\phi = 0. \tag{8.288}$$

This is Nash's (8.151). The connection is **flat** and the Higgs field is covariantly constant. A flat connection has no local content: near any point it is gauge equivalent to $A = 0$. What remains is global: the holonomy around non-contractible loops (Chapter T3). If M is simply connected there are no such loops, and the "monopole" is gauge equivalent to $A = 0$, $\phi =$ constant: the vacuum.

Worked example 8.120: A flat monopole on the three-torus

Let $M = T^3 = \mathbb{R}^3/(2\pi\mathbb{Z})^3$ with coordinates $x^i \sim x^i + 2\pi$. Take the constant connection and constant Higgs field

$$A = \theta_i\, T_3\, \mathrm{d}x^i, \qquad \phi = C\, T_3, \qquad \theta_i \in \mathbb{R}.$$

Then

$$F \overset{(1)}{=} \mathrm{d}A + A \wedge A \overset{(2)}{=} 0 + \theta_i\theta_j\, T_3T_3\, \mathrm{d}x^i \wedge \mathrm{d}x^j \overset{(3)}{=} 0,$$
$$\mathrm{d}_A\phi \overset{(4)}{=} \mathrm{d}\phi + [A, \phi] \overset{(5)}{=} 0 + C\theta_i[T_3, T_3]\mathrm{d}x^i = 0.$$

(1) Definition of curvature.
(2) The coefficients are constant, so $\mathrm{d}A = 0$.
(3) $\theta_i\theta_j$ is symmetric and $\mathrm{d}x^i \wedge \mathrm{d}x^j$ antisymmetric.
(4) Definition of d_A on the adjoint.
(5) ϕ is constant and T_3 commutes with itself.

So (A, ϕ) solves both Bogomolny equations, with $E = 0$. It is nevertheless *not* gauge equivalent to $A = 0$ when some $\theta_i \notin 4\pi\mathbb{Z}$: the holonomy round the i-th circle is

$$\mathrm{Hol}_i = \exp\Big(-\oint A\Big) = e^{-2\pi\theta_i T_3} = \begin{pmatrix} e^{i\pi\theta_i} & 0 \\ 0 & e^{-i\pi\theta_i} \end{pmatrix},$$

and conjugation cannot change its eigenvalues. This is the only way a closed M can support a nontrivial ground state: through its fundamental group, here $\pi_1(T^3) = \mathbb{Z}^3$.

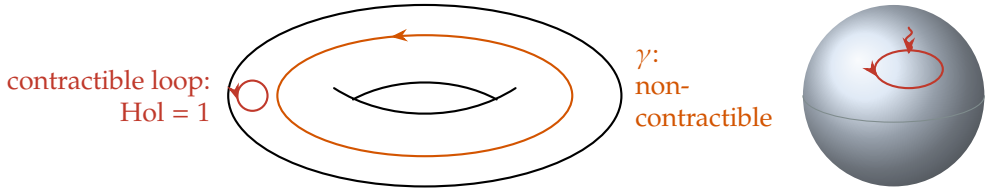

Figure 8.62: Why Bogomolny solutions on a closed M are dull. They are flat, so all their content is holonomy around loops. On the torus (left) a non-contractible loop can carry a holonomy $e^{-2\pi\theta T_3}$ that no gauge transformation removes. On a simply connected space such as S^3 (right, drawn as a ball) every loop can be shrunk to a point, the holonomy is trivial, and the configuration is gauge equivalent to the vacuum.

Key idea: Where non-trivial monopoles can live

Non-trivial monopoles need either a non-compact M or a boundary, so that the cross term $-2\int_{\partial M}\operatorname{tr}(F\phi)$ can be non-zero. Nash considers two cases: $M=\mathbb{R}^3$ with its flat metric (the rest of this section), and $M=H^3$, three-dimensional hyperbolic space (Section 8.14). In both the "boundary" is a sphere at infinity.

8.13.5 Monopoles on $\mathbb{R}^3$: boundary conditions and the magnetic charge

Take $M=\mathbb{R}^3$ with the Euclidean metric and $G=\mathrm{SU}(2)$. To make the energy integrals converge and the variational problem well posed we must specify how the fields behave as $r=|\vec{x}|\to\infty$. Nash's condition (8.152) is

$$|\phi|\to C\quad(r\to\infty),\tag{8.289}$$

together with enough decay of $\mathrm{d}_A\phi$ and F for the energy to be finite; on solutions of the Bogomolny equation the decay of F follows from that of $\mathrm{d}_A\phi$.

Watch out: The rate in (8.152)

Nash writes $|\phi|=C+O(r^{-2})$. That rate is right for a massive Higgs field ($\lambda>0$), whose deviation from C decays exponentially. It is *wrong* for the Bogomolny monopoles that are the subject of the section: the explicit solution below has $|\phi|=C-1/r+$ (exponentially small), and a charge-k monopole has $|\phi|=C-k/r+O(r^{-2})$. The $1/r$ tail is the Coulomb field of the massless Higgs, and it is *forced*, as we shall see: $\mathrm{d}_A\phi=\mp\star F$ ties the Higgs gradient to the magnetic Coulomb field $\sim k/r^2$. The correct condition is simply $|\phi|\to C$ with $|\mathrm{d}_A\phi|=O(r^{-2})$.

With these conditions the cross term becomes an integral over the sphere at infinity. Let S^2_R be the sphere of radius R, oriented by the outward normal. Then

$$-\langle F,\star\mathrm{d}_A\phi\rangle\overset{(1)}{=}2\lim_{R\to\infty}\int_{|x|\le R}\mathrm{d}\,\operatorname{tr}(F\phi)\overset{(2)}{=}2\lim_{R\to\infty}\oint_{S^2_R}\operatorname{tr}(F\phi)\overset{(3)}{=}-\oint_{S^2_\infty}(F,\phi),\tag{8.290}$$

(1) (8.285) and (8.286).
(2) Stokes on the ball.
(3) Pointwise inner product (8.265): $(F,\phi)=-2\operatorname{tr}(F\phi)=F^a\phi^a$, a real 2-form.

Define the **magnetic charge**

$$k=-\frac{1}{4\pi C}\langle F,\star\mathrm{d}_A\phi\rangle=-\frac{1}{4\pi C}\oint_{S^2_\infty}F^a\phi^a=\frac{1}{2\pi C}\oint_{S^2_\infty}\operatorname{tr}(F\phi).\tag{8.291}$$

(Nash's (8.153)–(8.154) have the opposite overall sign and his $-\operatorname{tr}$ normalisation; with our choices the hedgehog of Section 8.12.7 has $k=+1$ and satisfies $F=-\star\,\mathrm{d}_A\phi$, the sign that the self-duality reduction will produce.) In terms of k the Bogomolny bound reads

$$E=\tfrac12\left\|F+\star\mathrm{d}_A\phi\right\|^2+4\pi C\,k\;\ge\;4\pi C\,k,\qquad E=\tfrac12\left\|F-\star\mathrm{d}_A\phi\right\|^2-4\pi C\,k\;\ge\;-4\pi C\,k,\tag{8.292}$$

so $E\ge 4\pi C|k|$, with equality for $k>0$ iff $F=-\star\,\mathrm{d}_A\phi$ (monopoles) and for $k<0$ iff $F=+\star\,\mathrm{d}_A\phi$ (anti-monopoles).

Why is k an integer? Nash gives two interpretations; we make both concrete.

First reading: a Chern number of a $\mathrm{U}(1)$ bundle at infinity

At large r the Higgs field has length C and is covariantly constant to leading order. Its direction $\hat\phi = \phi/|\phi|$ picks out, at each point of S^2_∞, a line in $\mathfrak{su}(2)$ and hence an "unbroken" U(1): the rotations about $\hat\phi$. The component of F along $\hat\phi$,

$$f = (F, \hat\phi) = F^a \hat\phi^a,$$

is the field strength of electromagnetism, and (8.291) says $k = -\frac{1}{4\pi}\oint f$, i.e. k is (minus) the magnetic flux through the sphere at infinity in units of 4π. That this is an integer is the Dirac quantisation of Example 8.114: the U(1) that acts on the two-component (fundamental) fields with charges $\pm\frac12$ is a genuine circle bundle over S^2_∞, and its first Chern class is k. The next example makes this explicit by computing the gauge field at infinity.

Worked example 8.121: The gauge field at infinity is forced, and its curvature is the pulled-back area form

Write $\hat\phi = n^a T_a$ with $|\vec n| = 1$, and suppose $\mathrm{d}_A\hat\phi = 0$ at infinity. Claim: then

$$A = [\mathrm{d}\hat\phi, \hat\phi] + \alpha\,\hat\phi \tag{8.293}$$

for some real 1-form α, and the curvature is

$$F = \big(\mathrm{d}\alpha - \tfrac12 \varepsilon_{abc} n^a \mathrm{d}n^b \wedge \mathrm{d}n^c\big)\hat\phi. \tag{8.294}$$

First, (8.293) does make $\hat\phi$ covariantly constant. In vector notation ($[X,Y] \leftrightarrow \vec X \times \vec Y$),

$$\begin{aligned}\mathrm{d}_A\hat\phi &\overset{(1)}{=} \mathrm{d}\vec n + (\mathrm{d}\vec n \times \vec n)\times\vec n + \alpha\,\vec n\times\vec n \\ &\overset{(2)}{=} \mathrm{d}\vec n - \big(\mathrm{d}\vec n\,(\vec n\cdot\vec n) - \vec n\,(\vec n\cdot\mathrm{d}\vec n)\big) \overset{(3)}{=} \mathrm{d}\vec n - \mathrm{d}\vec n = 0.\end{aligned}$$

(1) $\mathrm{d}_A\hat\phi = \mathrm{d}\hat\phi + [A,\hat\phi]$ with (8.293).
(2) $\vec n\times\vec n = 0$ and $(\vec u\times\vec n)\times\vec n = -\vec n\times(\vec u\times\vec n)$, then "BAC–CAB".
(3) $\vec n\cdot\vec n = 1$, hence $\vec n\cdot\mathrm{d}\vec n = 0$.

Conversely, any A with $\mathrm{d}_A\hat\phi = 0$ differs from $[\mathrm{d}\hat\phi,\hat\phi]$ by a 1-form commuting with $\hat\phi$, i.e. a multiple of $\hat\phi$. So the gauge field at infinity is fixed by the Higgs direction, up to an abelian piece $\alpha\hat\phi$.

For the curvature, check (8.294) at one point, say where $\vec n = (0,0,1)$, using local coordinates (u,v) on S^2_∞ with $\vec n = (u, v, 1 - \frac12(u^2+v^2)) + \dots$ By rotational covariance this suffices. Put $\alpha = 0$ first. Then $A^a = \varepsilon_{abc}\mathrm{d}n^b\, n^c$ and to first order

$$A^1 = \mathrm{d}v + O(2), \qquad A^2 = -\mathrm{d}u + O(2), \qquad A^3 = v\,\mathrm{d}u - u\,\mathrm{d}v.$$

At the point $u = v = 0$:

$$\begin{aligned}F^3 &\overset{(1)}{=} \mathrm{d}A^3 + A^1\wedge A^2 \overset{(2)}{=} (\mathrm{d}v\wedge\mathrm{d}u - \mathrm{d}u\wedge\mathrm{d}v) + \mathrm{d}v\wedge(-\mathrm{d}u) \overset{(3)}{=} -\mathrm{d}u\wedge\mathrm{d}v, \\ F^1 &\overset{(4)}{=} \mathrm{d}A^1 + A^2\wedge A^3 = 0, \qquad F^2 = \mathrm{d}A^2 + A^3\wedge A^1 = 0.\end{aligned}$$

(1) $F^a = \mathrm{d}A^a + \frac12\varepsilon_{abc}A^b\wedge A^c$, the component form of $F = \mathrm{d}A + A\wedge A$ (Example 8.112).
(2) Insert the first-order expressions.
(3) Collect: $-2\,\mathrm{d}u\wedge\mathrm{d}v + \mathrm{d}u\wedge\mathrm{d}v$.
(4) $\mathrm{d}A^1, \mathrm{d}A^2$ vanish at the origin (their coefficients are $O(2)$), and A^3 vanishes there.

At this point $\frac12\varepsilon_{abc}n^a\mathrm{d}n^b\wedge\mathrm{d}n^c = \mathrm{d}n^1\wedge\mathrm{d}n^2 = \mathrm{d}u\wedge\mathrm{d}v$, so $F = -\mathrm{d}u\wedge\mathrm{d}v\,T_3$, which is (8.294). Adding $\alpha\hat\phi$ adds $\mathrm{d}\alpha\,\hat\phi$ (it commutes with everything else at leading order).

Now integrate. The abelian field is $f = (F, \hat{\phi}) = \mathrm{d}\alpha - \frac{1}{2}\varepsilon_{abc} n^a \mathrm{d}n^b \wedge \mathrm{d}n^c$, and

$$k \overset{(1)}{=} -\frac{1}{4\pi}\oint_{S^2_\infty} f \overset{(2)}{=} -\frac{1}{4\pi}\oint_{S^2_\infty} \mathrm{d}\alpha + \frac{1}{8\pi}\oint_{S^2_\infty} \varepsilon_{abc} n^a \mathrm{d}n^b \wedge \mathrm{d}n^c \overset{(3)}{=} \deg \hat{\phi}. \tag{8.295}$$

(1) (8.291) with $\phi = C\hat{\phi}$ at infinity.
(2) (8.294).
(3) $\mathrm{d}\alpha$ integrates to zero over a closed surface (if α is globally defined; if not, it contributes an integer which can be absorbed by a gauge transformation, as in the Dirac construction), and the last term is the degree (8.276).

Second reading: the degree of the Higgs map

This is Nash's (8.155): k is the winding number of $\hat{\phi} : S^2_\infty \to S^2_{\mathfrak{su}(2)}$. He writes it as a matrix integral. We check that his formula agrees with (8.276).

Worked example 8.122: Nash's winding formula in components

With $\hat{\phi} = n^a T_a$,

$$\begin{aligned} -\frac{1}{2\pi}\oint \operatorname{tr}\left(\hat{\phi}\,\mathrm{d}\hat{\phi}\wedge\mathrm{d}\hat{\phi}\right) &\overset{(1)}{=} -\frac{1}{2\pi}\oint n^a\,\mathrm{d}n^b\wedge\mathrm{d}n^c\,\operatorname{tr}(T_aT_bT_c) \\ &\overset{(2)}{=} -\frac{1}{2\pi}\oint n^a\,\mathrm{d}n^b\wedge\mathrm{d}n^c\,\tfrac{1}{2}\varepsilon_{bcd}\operatorname{tr}(T_aT_d) \\ &\overset{(3)}{=} -\frac{1}{2\pi}\oint n^a\,\mathrm{d}n^b\wedge\mathrm{d}n^c\,\tfrac{1}{2}\varepsilon_{bcd}\left(-\tfrac{1}{2}\delta_{ad}\right) \\ &\overset{(4)}{=} \frac{1}{8\pi}\oint \varepsilon_{abc}\,n^a\mathrm{d}n^b\wedge\mathrm{d}n^c \overset{(5)}{=} \deg\hat{\phi}. \end{aligned}$$

(1) Expand in the basis.
(2) $\mathrm{d}n^b \wedge \mathrm{d}n^c$ is antisymmetric in b, c, so only $\frac{1}{2}[T_b, T_c] = \frac{1}{2}\varepsilon_{bcd}T_d$ survives from T_bT_c.
(3) $\operatorname{tr}(T_aT_d) = -\frac{1}{2}\delta_{ad}$ (Example 8.112).
(4) Collect the constants: $(-\frac{1}{2\pi})(\frac{1}{2})(-\frac{1}{2}) = \frac{1}{8\pi}$.
(5) Definition (8.276).

So (8.155) holds exactly in our normalisation. For the hedgehog $\vec{n} = \hat{\vec{x}}$ it gives 1.

Key idea: The magnetic charge is the only topological invariant

For finite-energy SU(2) Yang–Mills–Higgs fields on $\mathbb{R}^3$,

$$k = \text{magnetic flux}/(-4\pi) = c_1(\text{unbroken U(1) bundle over } S^2_\infty) = \deg\left(\hat{\phi} : S^2_\infty \to S^2\right) \in \mathbb{Z}.$$

The SU(2) bundle over $\mathbb{R}^3$ is trivial ($\mathbb{R}^3$ is contractible), so all the topology is in the boundary behaviour of the Higgs field.

Dictionary: monopole charge

Mathematics	Physics
$\deg \hat{\phi} \in \pi_2(S^2)$	winding of the Higgs direction at infinity
c_1 of $L \to S^2_\infty$	quantised magnetic flux (Dirac)
$\langle F, \star \mathrm{d}_A \phi \rangle$	$\int \vec{B}^a \cdot \vec{D}\phi^a \, \mathrm{d}^3x$
Bogomolny bound $E \geq 4\pi C\lvert k\rvert$	BPS mass formula $M \geq 4\pi v\lvert k\rvert/e$

8.13.6 Solving the Bogomolny equation: the Prasad–Sommerfield monopole

Nash does not write down a solution. Here is the classic one, which we derive from scratch. Put the hedgehog ansatz (8.277) into $F = -\star\, \mathrm{d}_A\phi$, i.e. $B_i^a = -D_i\phi^a$, and use the decomposition (8.279) into transverse (P^T) and longitudinal (P^L) parts. Matching coefficients gives two ordinary differential equations.

Worked example 8.123: Deriving and solving the Bogomolny ODEs

From (8.279),

$$B_i^a + D_i\phi^a \overset{(1)}{=} \left(\frac{K'}{r} + \frac{hK}{r}\right)P^T_{ai} + \left(-\frac{1-K^2}{r^2} + h'\right)P^L_{ai} \overset{(2)}{=} 0$$

$$\Longleftrightarrow \qquad \boxed{K' = -hK, \qquad h' = \frac{1-K^2}{r^2}.}$$

(1) Add the two lines of (8.279).

(2) P^T and P^L are linearly independent (they project onto orthogonal subspaces), so each coefficient must vanish.

To solve, write $K = r/g(r)$ and eliminate h. From the first equation, $h = -K'/K = -(\ln K)' = g'/g - 1/r$. Substitute into the second:

$$h' \overset{(1)}{=} \frac{g''g - g'^2}{g^2} + \frac{1}{r^2} \overset{(2)}{=} \frac{1 - r^2/g^2}{r^2} \qquad \Longleftrightarrow \qquad g\,g'' - g'^2 = -1.$$

(1) Differentiate $h = g'/g - 1/r$.

(2) The second Bogomolny ODE with $K^2 = r^2/g^2$; then multiply by g^2 and cancel the $1/r^2$ terms.

The equation $gg'' - g'^2 = -1$ has the solutions $g = r$ (giving $K = 1$, $h = 0$: no monopole), $g = \sin(Cr)/C$ (giving a K that blows up at $r = \pi/C$), and

$$g = \frac{\sinh Cr}{C}: \qquad gg'' - g'^2 = \sinh^2 Cr - \cosh^2 Cr = -1 \;\checkmark. \tag{8.296}$$

Only the last satisfies $K(0) = 1$ and $K(\infty) = 0$. The result is the **Prasad–Sommerfield monopole**:

$$\boxed{h(r) = C\coth(Cr) - \frac{1}{r}, \qquad K(r) = \frac{Cr}{\sinh(Cr)}} \tag{8.297}$$

Check the boundary conditions: $h(r) = \frac{C^2 r}{3} + O(r^3) \to 0$ and $K \to 1$ as $r \to 0$; $h \to C - \frac{1}{r}$ and $K \approx 2Cr\, e^{-Cr} \to 0$ as $r \to \infty$. The profiles are plotted in Figure 8.61.

The asymptotics already tell us a lot. The gauge fields $W^\pm$ (the part of A proportional to K)

die off like e^{-Cr}: they have mass C, as in Example 8.115. The Higgs field approaches its vacuum value like $C - 1/r$: it is massless, with a Coulomb tail. And the magnetic field is $B_i^a \to -\hat{x}_a \hat{x}_i / r^2$: a Coulomb magnetic field along the Higgs direction.

Worked example 8.124: The energy of the PS monopole from its asymptotics

On any Bogomolny solution the energy density is a total Laplacian. With $\varepsilon = \frac{1}{2}(|B|^2 + |D\phi|^2)$ and $B = -D\phi$,

$$\varepsilon \overset{(1)}{=} |D\phi|^2 \overset{(2)}{=} \partial_i(\phi^a D_i \phi^a) - \phi^a D_i D_i \phi^a \overset{(3)}{=} \partial_i(\phi^a D_i \phi^a) \overset{(4)}{=} \tfrac{1}{2}\nabla^2 |\phi|^2.$$

(1) $|B| = |D\phi|$ on a solution.
(2) Leibniz rule for the gauge-invariant product $\partial_i(\vec{\phi} \cdot D_i\vec{\phi}) = D_i\vec{\phi} \cdot D_i\vec{\phi} + \vec{\phi} \cdot D_i D_i \vec{\phi}$.
(3) The second field equation (8.282): $D_i D_i \phi = 0$.
(4) $\phi^a D_i \phi^a = \phi^a \partial_i \phi^a = \frac{1}{2}\partial_i |\phi|^2$, since $\vec{\phi} \cdot (\vec{A}_i \times \vec{\phi}) = 0$.

Then Gauss' divergence theorem gives

$$E \overset{(1)}{=} \frac{1}{2} \lim_{R\to\infty} \oint_{S^2_R} \partial_r |\phi|^2 \, R^2 \mathrm{d}\Omega \overset{(2)}{=} \frac{1}{2} \lim_{R\to\infty} 4\pi R^2 \cdot 2\Big(C - \frac{1}{R}\Big)\frac{1}{R^2} \overset{(3)}{=} 4\pi C.$$

(1) Integrate $\frac{1}{2}\nabla^2|\phi|^2$ over a large ball.
(2) $|\phi| = h \approx C - 1/R$, so $\partial_r |\phi|^2 = 2|\phi|\partial_r|\phi| \approx 2(C - 1/R)/R^2$.
(3) Take the limit.

This is the Bogomolny bound saturated with $k = 1$. Note how the $1/r$ tail of the Higgs field carries the whole answer, which is why Nash's $O(r^{-2})$ cannot be right. At the centre, $h \approx C^2 r/3$ and $K \approx 1$, so $\varepsilon(0) = 2(C^2/3)^2 + (C^2/3)^2 = C^4/3$.

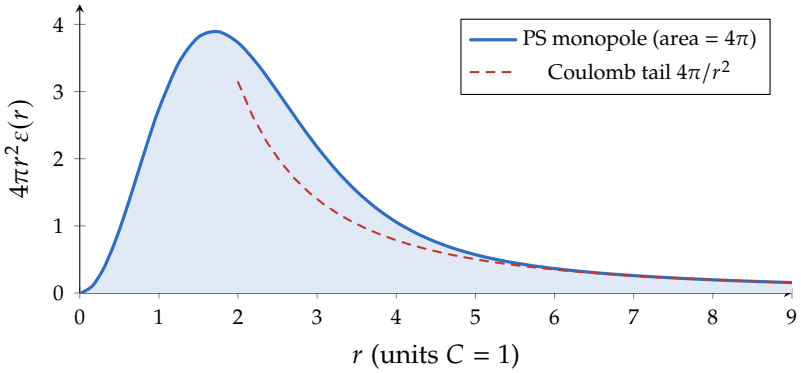

Figure 8.63: Radial energy density of the Prasad–Sommerfield monopole. The shaded area is the total energy $4\pi C$. The monopole has a core of size $\sim 1/C$ (the W Compton wavelength), but no sharp edge: the energy density (here $4\pi r^2 \varepsilon$) falls off only as a power, $4\pi/r^2$ (dashed), because the magnetic field and the massless Higgs field both have Coulomb tails.

Watch out: BPS is not the same as "λ small"

For $\lambda > 0$ the Higgs field is massive, the Higgs tail is exponential, and the energy is strictly above $4\pi C$ (numerically it grows from $4\pi C$ at $\lambda = 0$ to about $1.787 \times 4\pi C$ as $\lambda \to \infty$). The Bogomolny equation holds only at $\lambda = 0$. This distinction will matter for forces: BPS monopoles do not attract or repel at rest, whereas monopoles with $\lambda > 0$ do.

8.13.7 Unitary gauge and the Dirac string

Far from its core the PS monopole should look like a Dirac monopole. To see it, perform a gauge transformation that rotates the Higgs field to a *fixed* direction, $\phi \mapsto T_3$ up to its length. This is **unitary gauge**. In it the unbroken U(1) is the same at every point, and the abelian gauge field can be read off as the T_3 component.

Worked example 8.125: The hedgehog in unitary gauge

Use spherical angles (θ, φ) on S^2_∞ and the gauge transformation

$$g_N(\theta, \varphi) = e^{\varphi T_3}\, e^{\theta T_2}\, e^{-\varphi T_3}.$$

Rotation by $e^{\theta T_2}$ tilts the 3-axis by the angle θ towards the 1-axis, and conjugating by $e^{\varphi T_3}$ turns that tilt to azimuth φ. So $g_N T_3 g_N^{-1} = \hat{x}^a T_a$, i.e. $g_N^{-1}\hat{\phi}\, g_N = T_3$. At infinity the gauge field (8.293) (with $\alpha = 0$) becomes, by direct computation (we checked it by computer algebra),

$$A' = g_N^{-1} A\, g_N + g_N^{-1} \mathrm{d} g_N = -(1-\cos\theta)\,\mathrm{d}\varphi\; T_3, \qquad F' = \mathrm{d}A' = -\sin\theta\,\mathrm{d}\theta \wedge \mathrm{d}\varphi\; T_3. \quad (8.298)$$

Compare with the Dirac potential (8.270): $(A', T_3) = -(1-\cos\theta)\mathrm{d}\varphi = a_N$ with $g = -1$. The flux is $\oint (F', T_3) = -4\pi$, and (8.291) gives $k = +1$.
The gauge transformation g_N is smooth at the north pole ($g_N = 1$ at $\theta = 0$) but not at the south pole: at $\theta = \pi$, $g_N = e^{\varphi T_3}(2T_2)e^{-\varphi T_3}$ still depends on φ. So A' is singular along the negative x^3-axis: the Dirac string. It is a gauge artefact. In the original ("radial") gauge the fields are perfectly smooth; the string appears only because no smooth gauge transformation can rotate a degree-1 map $\hat{\phi}$ to a constant, which is the statement that $\deg \hat{\phi} \neq 0$.

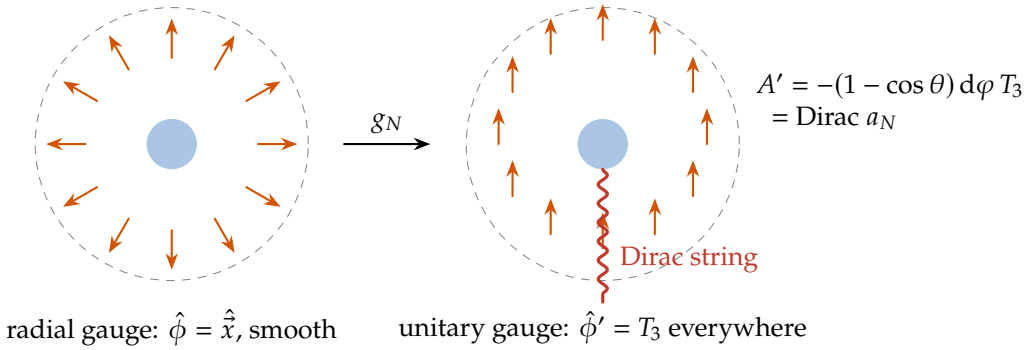

Figure 8.64: The same monopole in two gauges. Left: the Higgs direction (orange) points radially and every field is smooth. Right: after the gauge transformation g_N the Higgs field points "up" everywhere, the unbroken U(1) is the same at each point, and the T_3 part of A is exactly the Dirac potential. The price is a singular line, the Dirac string, where g_N is ill defined.

Try it: Dirac quantisation from the non-abelian side

In unitary gauge a field in the fundamental representation of SU(2) has T_3-eigenvalues $\mp\frac{i}{2}$, i.e. electric charges $q = \pm\frac{1}{2}$ under the unbroken U(1), and the W bosons have $q = \pm 1$. Check Dirac's condition $2qg \in \mathbb{Z}$ of Example 8.114 for the 't Hooft–Polyakov monopole. *Answer:* $g = -1$, so $2qg = \mp 1$ for the doublet and ∓ 2 for $W^\pm$; both are integers. The monopole carries the *minimal* Dirac charge allowed by the doublet, and twice the minimal charge

allowed by the W alone.

Reading Nash (pp. 243–245, (8.141)–(8.155))

Nash takes the Prasad–Sommerfield limit $\lambda = 0$ ((8.141)–(8.142)), states the Bogomolny equation $F = \star \mathrm{d}_A\phi$ (8.143) and checks it against both field equations by the direct calculation (8.144)–(8.145) that we reproduced in Example 8.119. He then completes the square (8.146), identifies the minima (8.147) and the topological cross term (8.148)–(8.149), and observes that on closed M the cross term vanishes (8.150), forcing $F = \mathrm{d}_A\phi = 0$ (8.151). On $\mathbb{R}^3$ he imposes (8.152) (see our pitfall about the rate), defines the magnetic charge (8.153)–(8.154) and rewrites it as a winding number (8.155). We fixed signs so that $k = \deg\hat{\phi}$ and so that the monopole (rather than the anti-monopole) obeys $F = -\star\,\mathrm{d}_A\phi$, which matches his later (8.162). The explicit solution, the energy computation and unitary gauge are not in Nash; they are the standard way to see that the abstract charge is a real magnetic monopole.

Recap

- At $\lambda = 0$ the energy is $\frac{1}{2}(\|F\|^2 + \|\mathrm{d}_A\phi\|^2)$. Completing the square gives $E = \frac{1}{2}\|F \pm \star\mathrm{d}_A\phi\|^2 + 4\pi C(\pm k)$, so $E \geq 4\pi C|k|$.
- The bound is saturated exactly by the first-order Bogomolny equation $F = \mp\star\,\mathrm{d}_A\phi$, which implies the second-order field equations.
- On a closed M the charge is zero and Bogomolny solutions are flat; they are non-trivial only through holonomy.
- On $\mathbb{R}^3$ the charge $k = \deg\hat{\phi} = c_1(L \to S^2_\infty)$ is an integer.
- The Prasad–Sommerfield monopole $h = C\coth Cr - 1/r$, $K = Cr/\sinh Cr$ has $E = 4\pi C$, a massive core of size $1/C$, and Coulomb tails; in unitary gauge it is a Dirac monopole with a gauge-artefact string.

8.14 Monopoles as symmetric instantons

We now have two first-order equations. On $\mathbb{R}^4$ there is the self-duality equation $\hat{F} = \star\hat{F}$ of the instantons. On $\mathbb{R}^3$ there is the Bogomolny equation $F = -\star\,\mathrm{d}_A\phi$ of the monopoles. They were found separately, but they look alike: both come from completing a square, both saturate a topological bound, and both say "one piece of the curvature equals the Hodge dual of another". This section explains the resemblance.

> *Is the Bogomolny equation a special case of the self-duality equation? If so, which symmetry of an instanton turns it into a monopole, and what happens to the topological charges?*

The answers, following Nash (who follows Atiyah):

- An instanton on $\mathbb{R}^4$ that does not depend on one coordinate x^0 is a monopole on $\mathbb{R}^3$. The Higgs field is the fourth component of the gauge field. This is **dimensional reduction**.
- Such an instanton has infinite action, because it is the same at every "time". A better symmetry is a *rotation* in a plane of $\mathbb{R}^4$. A rotation-invariant instanton is a monopole on

hyperbolic space H^3, and now the action is finite. The instanton number is then $c_2 = 2nk$, where k is the magnetic charge and n an integer that fixes the size of the Higgs field at infinity.

- The general mechanism is a conformal equivalence $\mathbb{R}^n \setminus \mathbb{R}^m \simeq S^{n-m-1} \times H^{m+1}$.

8.14.1 Dimensional reduction: time-independent instantons

Let $\hat{A} = \hat{A}_\mu \mathrm{d}x^\mu$ ($\mu = 0,1,2,3$) be an SU(2) connection on $\mathbb{R}^4$ with the Euclidean metric. This is Nash's (8.156). Its curvature has components

$$\hat{F}_{\mu\nu} = \partial_\mu \hat{A}_\nu - \partial_\nu \hat{A}_\mu + [\hat{A}_\mu, \hat{A}_\nu].$$

We use Nash's orientation $\mathrm{d}x^0 \wedge \mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3$, i.e. $\varepsilon_{0123} = +1$. (Part 8b used $\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4$; if we call $x^4 = x^0$ the two orientations differ by a sign, so "self-dual" here is "anti-self-dual" there. Nothing below depends on this beyond an overall sign of the charge.) Self-duality in components is Nash's (8.157):

$$\hat{F}_{\mu\nu} = \tfrac{1}{2}\varepsilon_{\mu\nu\alpha\beta}\hat{F}_{\alpha\beta}. \tag{8.299}$$

Worked example 8.126: Splitting self-duality into space and time: Nash's (8.158)

Take $\mu\nu = ij$ with Latin indices $1,2,3$. In the sum over $\alpha\beta$ one index must be 0 and the other some k:

$$\hat{F}_{ij} \overset{(1)}{=} \tfrac{1}{2}\big(\varepsilon_{ij0k}\hat{F}_{0k} + \varepsilon_{ijk0}\hat{F}_{k0}\big) \overset{(2)}{=} \varepsilon_{ijk0}\hat{F}_{k0} \overset{(3)}{=} -\varepsilon_{0ijk}\hat{F}_{k0} \overset{(4)}{=} -\varepsilon_{ijk}\hat{F}_{k0}.$$

(1) $\varepsilon_{ij\alpha\beta}$ vanishes unless $\{\alpha,\beta\} = \{0,k\}$ for the third spatial index k.
(2) Both terms are equal, since swapping $0 \leftrightarrow k$ flips both ε and $\hat{F}$.
(3) Moving the index 0 from the last slot to the first takes three transpositions: a sign $(-1)^3$.
(4) $\varepsilon_{0ijk} = \varepsilon_{ijk}$ defines the three-dimensional symbol.

Now take $\mu\nu = i0$:

$$\hat{F}_{i0} \overset{(1)}{=} \tfrac{1}{2}\varepsilon_{i0jk}\hat{F}_{jk} \overset{(2)}{=} -\tfrac{1}{2}\varepsilon_{0ijk}\hat{F}_{jk} = -\tfrac{1}{2}\varepsilon_{ijk}\hat{F}_{jk}.$$

(1) Now both α,β must be spatial.
(2) One transposition, $\varepsilon_{i0jk} = -\varepsilon_{0ijk}$.

These are the two halves of (8.158). They say the same thing: contract the first with $\frac{1}{2}\varepsilon_{ijl}$ and use $\varepsilon_{ijl}\varepsilon_{ijk} = 2\delta_{lk}$ to get $\frac{1}{2}\varepsilon_{ijl}\hat{F}_{ij} = -\hat{F}_{l0}$, which is the second. Of the six components of (8.299) only three are independent, as it should be: Λ^2_+ is three-dimensional.

Now impose **x^0-independence**: $\partial_0 \hat{A}_\mu = 0$. Then

$$\hat{F}_{k0} = \partial_k \hat{A}_0 - \partial_0 \hat{A}_k + [\hat{A}_k, \hat{A}_0] = \partial_k \hat{A}_0 + [\hat{A}_k, \hat{A}_0], \tag{8.300}$$

which is Nash's (8.159). This is a covariant derivative of $\hat{A}_0$ with respect to the three-dimensional connection made of the other components. So define, as in Nash's (8.160), the pair on $\mathbb{R}^3$

$$A = \hat{A}_1 \mathrm{d}x^1 + \hat{A}_2 \mathrm{d}x^2 + \hat{A}_3 \mathrm{d}x^3, \qquad \phi = \hat{A}_0. \tag{8.301}$$

Under a gauge transformation $g(x^1,x^2,x^3)$ that is independent of x^0, $\hat{A}_0 \mapsto g^{-1}\hat{A}_0 g$: the fourth component of the gauge field transforms in the adjoint, exactly like a Higgs field. In these

variables $\hat{F}_{ij} = F_{ij}$, and (8.300) says $\hat{F}_{k0} = D_k\phi$. The first half of (8.158) becomes Nash's (8.161):

$$F_{ij} = -\varepsilon_{ijk}\big(\partial_k\phi + [A_k, \phi]\big) = -\varepsilon_{ijk}D_k\phi. \tag{8.302}$$

Apply the three-dimensional Hodge star: $\star F = B_i \mathrm{d}x^i$ with $B_i = \frac{1}{2}\varepsilon_{ijk}F_{jk} = -\frac{1}{2}\varepsilon_{ijk}\varepsilon_{jkl}D_l\phi = -D_i\phi$. So

$$\boxed{F = -\star \mathrm{d}_A\phi} \tag{8.303}$$

which is Nash's (8.162), and exactly the monopole sign we used in Section 8.13. *Self-dual connections on $\mathbb{R}^4$ that are invariant under translations in x^0 are the same thing as solutions of the Bogomolny equation on $\mathbb{R}^3$.*

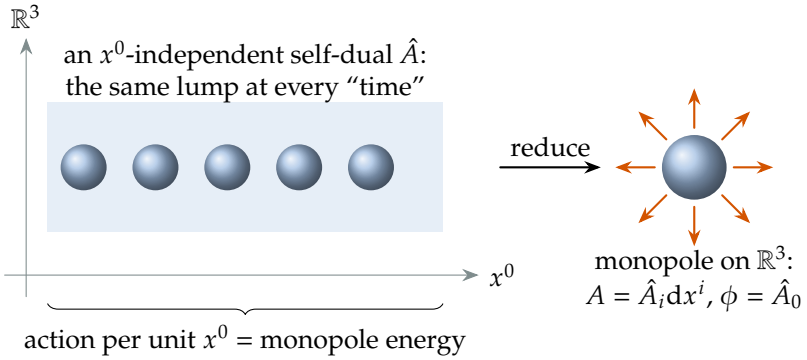

Figure 8.65: Dimensional reduction. A self-dual connection on $\mathbb{R}^4$ that does not depend on x^0 is a "tube" in the x^0 direction. Each slice $x^0 = \text{const}$ carries the same field on $\mathbb{R}^3$, and the component $\hat{A}_0$ becomes an adjoint scalar, the Higgs field. The self-duality equations become the Bogomolny equation, and the four-dimensional action per unit length in x^0 is the three-dimensional energy. The total action is infinite.

Worked example 8.127: What becomes of the action and the instanton number

Write the reduced curvature as a 2-form on $\mathbb{R}^4$. Since $\hat{F}_{k0}\mathrm{d}x^k \wedge \mathrm{d}x^0 = D_k\phi\, \mathrm{d}x^k \wedge \mathrm{d}x^0$,

$$\hat{F} = F + \mathrm{d}_A\phi \wedge \mathrm{d}x^0.$$

Action. With the norm of part 8b, $S = -\int \mathrm{tr}(\hat{F} \wedge \star\hat{F}) = \frac{1}{4}\int \hat{F}^a_{\mu\nu}\hat{F}^a_{\mu\nu}\,\mathrm{d}^4x$, and over a slab $0 \le x^0 \le T$,

$$S_{\text{slab}} \overset{(1)}{=} \frac{1}{2}\int_0^T \mathrm{d}x^0 \int_{\mathbb{R}^3}\Big(\sum_{i<j} F^a_{ij}F^a_{ij} + \sum_k D_k\phi^a D_k\phi^a\Big)\mathrm{d}^3x \overset{(2)}{=} T\cdot\frac{1}{2}\int_{\mathbb{R}^3}\big(|B|^2 + |D\phi|^2\big)\mathrm{d}^3x \overset{(3)}{=} T\,E.$$

(1) $\frac{1}{4}\sum_{\mu,\nu} = \frac{1}{2}\sum_{\mu<\nu}$, and the pairs $\mu < \nu$ are the spatial pairs ij and the pairs $0k$ with $\hat{F}_{0k} = -D_k\phi$.
(2) Nothing depends on x^0; and $\sum_{i<j}(F^a_{ij})^2 = |B|^2$.
(3) The energy (8.281) in components.

Instanton number. In three dimensions $F \wedge F = 0$ (a 4-form) and $\mathrm{d}x^0 \wedge \mathrm{d}x^0 = 0$, so only the cross terms survive:

$$\mathrm{tr}(\hat{F} \wedge \hat{F}) \overset{(1)}{=} 2\ \mathrm{tr}(F \wedge \mathrm{d}_A\phi) \wedge \mathrm{d}x^0 \overset{(2)}{=} -2\,\mathrm{d}x^0 \wedge \mathrm{tr}(F \wedge \mathrm{d}_A\phi) \overset{(3)}{=} -2\,\mathrm{d}x^0 \wedge \mathrm{d}\ \mathrm{tr}(F\phi).$$

(1) The two cross terms are equal by graded cyclicity (a 2-form and a 2-form commute under the trace).
(2) Move the 1-form $\mathrm{d}x^0$ past a 3-form: sign $(-1)^3$.

(3) The total-derivative identity (8.286).

Integrate over the slab with the orientation $\mathrm{d}x^0 \wedge \mathrm{d}^3x$ and use (8.291), $\int_{\mathbb{R}^3} \mathrm{d}\,\mathrm{tr}(F\phi) = \oint \mathrm{tr}(F\phi) = 2\pi C k$:

$$k_{\mathrm{inst}}(\mathrm{slab}) = -\frac{1}{8\pi^2}\int \mathrm{tr}(\hat{F}\wedge\hat{F}) = \frac{2T\cdot 2\pi C k}{8\pi^2} = \frac{C\,T}{2\pi}\,k.$$

So the Bogomolny bound in three dimensions is the instanton bound per unit time: $S_{\mathrm{slab}} \geq 8\pi^2 k_{\mathrm{inst}}$ reads $TE \geq 4\pi C k T$, i.e. $E \geq 4\pi C k$. Both sides are infinite as $T \to \infty$. This is Nash's remark that time-independent instantons are instantons "in a loose sense" only.

Physical picture: Periodic time and calorons

If instead of $\mathbb{R}^4$ we take $S^1_\beta \times \mathbb{R}^3$ with x^0 periodic of period β (finite temperature), x^0-independent configurations have finite action βE. Then the Higgs field is $\hat{A}_0$, whose holonomy $\exp(-\beta\hat{A}_0)$ round the thermal circle is gauge invariant, and the magnetic charge contributes $C\beta k/2\pi$ to the instanton number. Instantons on $S^1 \times \mathbb{R}^3$ (**calorons**) interpolate between instantons (small compared to β) and chains of monopoles (large compared to β). We shall see the same interpolation in the hyperbolic picture below.

8.14.2 Conformal invariance of self-duality

To get finite action we need a symmetry whose orbits are *compact*. The natural candidate is a rotation. The key tool is that self-duality in four dimensions does not see the size of the metric, only its angles.

Working definition 8.41 (conformal change of metric)

A **conformal change** replaces g by $g' = \Omega^2 g$ with Ω a positive function. It rescales lengths by Ω point by point and leaves angles unchanged. *Test:* two metrics are conformally related iff their matrices [the components $g_{\mu\nu}(x)$ in one coordinate system] are proportional at every point.

Worked example 8.128: The Hodge star on middle-degree forms is conformally invariant

Recall $(\star\alpha)_{\nu_1\ldots\nu_{n-p}} = \frac{1}{p!}\sqrt{\det g}\; g^{\mu_1\rho_1}\cdots g^{\mu_p\rho_p}\alpha_{\rho_1\ldots\rho_p}\varepsilon_{\mu_1\ldots\mu_p\nu_1\ldots\nu_{n-p}}$ (Chapter T1). Replace g by $\Omega^2 g$:

$$\star'\alpha \overset{(1)}{=} \left(\Omega^n\sqrt{\det g}\right)\left(\Omega^{-2}\right)^p(\ldots) \overset{(2)}{=} \Omega^{n-2p}\;\star\alpha.$$

(1) $\det(\Omega^2 g) = \Omega^{2n}\det g$, and each inverse metric carries Ω^{-2}; the index structure is unchanged.

(2) Collect the powers.

For $n = 4$ and $p = 2$ the power is $\Omega^0 = 1$. So $\star$ on 2-forms, and with it the equation $\hat{F} = \star\hat{F}$, is the same for g and $\Omega^2 g$. The Yang–Mills action density $\mathrm{tr}(\hat{F}\wedge\star\hat{F})$ is also unchanged, since $\hat{F}$ does not involve the metric at all. So in four dimensions both the equation *and* the action are conformally invariant.

8.14.3 Rotations: $\mathbb{R}^4 \setminus \mathbb{R}^2 \simeq S^1 \times H^3$

Following Nash, look for instantons invariant under rotations of the x^0–x^1 plane. Use polar coordinates (r, θ) in that plane, $x^0 = r\cos\theta$, $x^1 = r\sin\theta$. The flat metric becomes Nash's (8.163):

$$\mathrm{d}s^2 \overset{(1)}{=} \mathrm{d}r^2 + r^2\mathrm{d}\theta^2 + \mathrm{d}x_2^2 + \mathrm{d}x_3^2 \overset{(2)}{=} r^2\Big\{\mathrm{d}\theta^2 + \frac{\mathrm{d}r^2 + \mathrm{d}x_2^2 + \mathrm{d}x_3^2}{r^2}\Big\}. \tag{8.304}$$

(1) The flat metric of the x^0–x^1 plane in polar coordinates.
(2) Factor out r^2, which is legitimate where $r > 0$.

By Example 8.128 we may drop the factor r^2 without changing the self-duality equations. The new metric is Nash's (8.164):

$$\mathrm{d}s'^2 = \mathrm{d}\theta^2 + \frac{\mathrm{d}r^2 + \mathrm{d}x_2^2 + \mathrm{d}x_3^2}{r^2}, \qquad 0 < r < \infty, \quad x_2, x_3 \in \mathbb{R}, \quad \theta \in [0, 2\pi). \tag{8.305}$$

The first term is a circle of radius 1. The second term is the **upper half-space model** of three-dimensional hyperbolic space H^3, with the height coordinate called r.

Working definition 8.42 (hyperbolic space H^3, two models)

Half-space model: $\{(r, x_2, x_3) : r > 0\}$ with $\mathrm{d}s^2 = (\mathrm{d}r^2 + \mathrm{d}x_2^2 + \mathrm{d}x_3^2)/r^2$. *Ball model (radius 2):* $\{\vec{x} \in \mathbb{R}^3 : |\vec{x}| < 2\}$ with

$$\mathrm{d}s^2 = \frac{\mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2}{(1 - \rho^2/4)^2}, \qquad \rho = |\vec{x}|, \tag{8.306}$$

which is Nash's (8.167). Both have constant sectional curvature -1 [every geodesic triangle has angle sum equal to π minus its area]. The **boundary at infinity** ∂H^3 is the plane $r = 0$ plus one point (half-space), or the sphere $\rho = 2$ (ball); it is infinitely far away in the hyperbolic metric but is a perfectly good S^2. *How to recognise it:* a metric that is flat space divided by the square of (a multiple of) the distance to a boundary.

Worked example 8.129: The half-space metric is really at infinite distance from its boundary

Walk up the vertical line $x_2 = x_3 = 0$ from height r_1 to r_2:

$$\text{length} = \int_{r_1}^{r_2} \frac{\mathrm{d}r}{r} = \ln\frac{r_2}{r_1} \to \infty \quad \text{as } r_1 \to 0.$$

So the plane $r = 0$ is infinitely far away. The volume of the region $r > \varepsilon$ above a unit square is $\int_\varepsilon^\infty r^{-3}\mathrm{d}r = 1/(2\varepsilon^2)$, which also diverges at the boundary. This is why the metric (8.305) is "singular at $r = 0$", as Nash puts it: the conformal factor r^{-2} blows up there.

What have we removed from $\mathbb{R}^4$? The coordinates (r, θ) fail at $r = 0$, i.e. $x^0 = x^1 = 0$. That is the plane $\mathbb{R}^2$ spanned by x^2, x^3, the fixed set ("axis") of the rotation. Therefore we have used the conformal equivalence

$$\mathbb{R}^4 \setminus \mathbb{R}^2 \;\simeq\; S^1 \times H^3, \tag{8.307}$$

Nash's (8.165). The axis $\mathbb{R}^2$ has become the boundary at infinity of H^3 (the plane $r = 0$). Adding the point at infinity of $\mathbb{R}^4$, i.e. working on S^4, the axis becomes a 2-sphere and matches $\partial H^3 = S^2$.

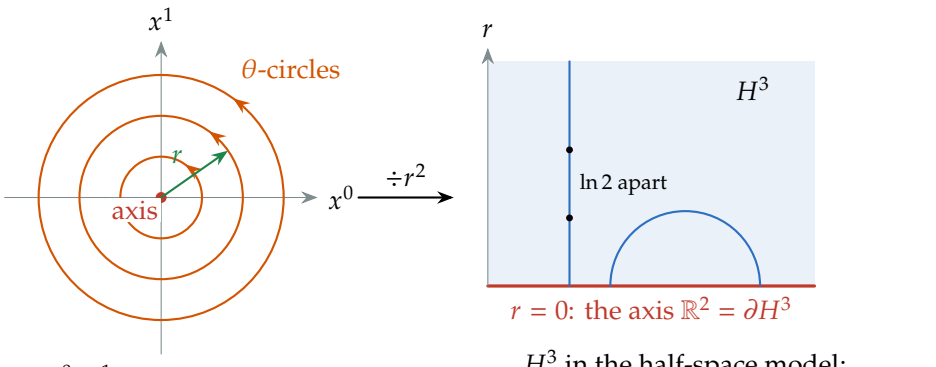

Figure 8.66: Nash's conformal equivalence $\mathbb{R}^4 \setminus \mathbb{R}^2 \simeq S^1 \times H^3$. Left: in the plane of rotation every point except the origin lies on a circle of radius r. Dividing the flat metric by r^2 gives each circle length 2π, and the remaining coordinates (r, x_2, x_3) form hyperbolic space. Right: the axis of rotation ($r = 0$) is pushed off to infinity and becomes the boundary plane of H^3.

8.14.4 Rotation-invariant instantons are hyperbolic monopoles

Now repeat Section 8.14.1 with θ in place of x^0. Take a self-dual $\hat{A}$ on $S^1 \times H^3$ that is invariant under rotations of the circle. In a gauge where nothing depends on θ, write

$$\hat{A} = A + \phi \, \mathrm{d}\theta, \tag{8.308}$$

where A is a connection on H^3 and ϕ an adjoint scalar on H^3. The metric (8.305) is a product with a circle of unit radius, so the computation of Example 8.126 goes through with $x^0 \to \theta$, flat $\mathbb{R}^3 \to H^3$ and the Hodge star of $\mathbb{R}^3$ replaced by that of the hyperbolic metric. The result is Nash's (8.166):

$$\mathrm{d}_A \phi = - \star_H F \qquad (\iff F = - \star_H \mathrm{d}_A \phi, \text{ since } \star_H \star_H = 1). \tag{8.309}$$

This is the Bogomolny equation on H^3, and its solutions are **hyperbolic monopoles**. The boundary condition replacing $|\phi| \to C$ is that $|\phi|$ tends to a constant on ∂H^3. Nash calls it $|\phi|_{\mathrm{as}}$ ("asymptotic").

Worked example 8.130: The hyperbolic Bogomolny equation in the ball, in components

In the ball model the metric is $g = f\,\delta$ with $f = (1 - \rho^2/4)^{-2}$. For a conformally flat metric in three dimensions, $\sqrt{\det g} = f^{3/2}$ and $g^{ij} = f^{-1}\delta^{ij}$, so for a 2-form $F = \frac{1}{2}F_{ij}\mathrm{d}x^i \wedge \mathrm{d}x^j$,

$$(\star_H F)_k \overset{(1)}{=} \tfrac{1}{2}\sqrt{\det g}\; g^{ii'} g^{jj'} F_{i'j'}\, \varepsilon_{ijl}\, g_{lk} \overset{(2)}{=} \tfrac{1}{2} f^{3/2} f^{-2} f\, \varepsilon_{ijk} F_{ij} = \tfrac{1}{2}\sqrt{f}\, \varepsilon_{ijk} F_{ij}.$$

(1) The general formula for $\star$ with the free index lowered.
(2) Insert $g = f\delta$.

So (8.309) reads

$$D_k \phi^a = -\tfrac{1}{2}\sqrt{f}\, \varepsilon_{ijk} F^a_{ij}, \qquad f = \left(1 - \rho^2/4\right)^{-2}. \tag{8.310}$$

Near the centre of the ball $f \approx 1$ and this is the flat Bogomolny equation. Near the boundary $\sqrt{f} \to \infty$: the curvature must fall off fast (in coordinate terms) to keep $\mathrm{d}_A\phi$ finite.

The isometry between the two models

Nash says the ball model is "completely equivalent" to the half-space model via an isometry $T = \alpha^{-1}\beta\alpha$ (his (8.168)), built from stereographic projection α and a quarter-turn β of S^3. We give T explicitly and check it.

Worked example 8.131: An explicit isometry from the ball to the half-space

Let $\vec{x}$ be in the ball $|\vec{x}| < 2$, let $\vec{e}_1 = (1,0,0)$ and $\vec{y} = \vec{x} + 2\vec{e}_1$. Define

$$\vec{w} = T(\vec{x}) = \frac{8\,\vec{y}}{|\vec{y}|^2} - 2\vec{e}_1, \qquad (w_1, w_2, w_3) = (r, x_2, x_3). \tag{8.311}$$

It is an inversion in the sphere of radius $2\sqrt{2}$ about $-2\vec{e}_1$, followed by a shift. First the height w_1:

$$w_1 \overset{(1)}{=} \frac{8(x_1+2) - 2|\vec{y}|^2}{|\vec{y}|^2} \overset{(2)}{=} \frac{8x_1 + 16 - 2\rho^2 - 8x_1 - 8}{|\vec{y}|^2} = \frac{2(4-\rho^2)}{|\vec{y}|^2}.$$

(1) Common denominator.
(2) $|\vec{y}|^2 = \rho^2 + 4x_1 + 4$.

So $w_1 > 0$ exactly when $\rho < 2$: the ball goes to the upper half-space, and the sphere $\rho = 2$ goes to the plane $w_1 = 0$. Now the metric. An inversion $\vec{y} \mapsto \vec{y}/|\vec{y}|^2$ multiplies lengths by $|\vec{y}|^{-2}$, so $|\mathrm{d}\vec{w}|^2 = 64|\mathrm{d}\vec{x}|^2/|\vec{y}|^4$, and

$$\frac{|\mathrm{d}\vec{w}|^2}{w_1^2} \overset{(1)}{=} \frac{64\,|\mathrm{d}\vec{x}|^2}{|\vec{y}|^4} \cdot \frac{|\vec{y}|^4}{4(4-\rho^2)^2} \overset{(2)}{=} \frac{16\,|\mathrm{d}\vec{x}|^2}{(4-\rho^2)^2} \overset{(3)}{=} \frac{|\mathrm{d}\vec{x}|^2}{(1-\rho^2/4)^2}.$$

(1) Insert the two results above.
(2) Cancel $|\vec{y}|^4$.
(3) Divide numerator and denominator by 16.

This is (8.306): T is an isometry. The centre of the ball goes to $T(0) = 8 \cdot 2\vec{e}_1/4 - 2\vec{e}_1 = 2\vec{e}_1$, the point $r = 2$, $x_2 = x_3 = 0$ of the half-space, as Nash states. (We checked the pull-back with computer algebra as well.)

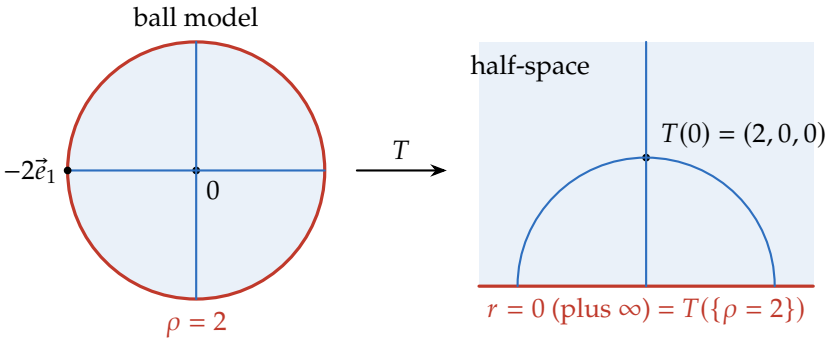

Figure 8.67: The isometry T of Example 8.131, drawn in a plane through the axis. The centre of the ball goes to the point at height 2 above the origin; the boundary sphere goes to the boundary plane (the point $-2\vec{e}_1$ of the sphere goes to infinity). Diameters of the ball (blue lines) become a vertical line and a semicircle, both geodesics.

8.14.5 Finite action, and $c_2 = 2nk$

Here is the difference from the time-independent case: a hyperbolic monopole gives an instanton of *finite* action. Integrating out θ costs only a factor 2π, and by conformal invariance the action on $S^1 \times H^3$ equals the action on $\mathbb{R}^4 \setminus \mathbb{R}^2$, hence on $\mathbb{R}^4$ (a plane has measure zero), and hence on S^4. So we expect an integer relation between three numbers: the instanton number $c_2(V)$ of the rank-2 bundle $V \to S^4$, the magnetic charge k, and the size $|\phi|_{\text{as}}$ of the Higgs field at infinity. Nash explains why the last one is quantised.

The rotation acts on the fibres over the axis. A rotation R_θ in the x^0–x^1 plane moves most points, but it fixes every point of the axis. For $\hat{A}$ to be invariant, the rotation must be lifted to the bundle V. Over a point p of the axis the lift maps the fibre $V_p \cong \mathbb{C}^2$ to itself by an SU(2) matrix M_θ, and $\theta \mapsto M_\theta$ is a group homomorphism $\mathrm{U}(1) \to \mathrm{SU}(2)$. Every such homomorphism can be conjugated into the diagonal torus, and $M_{2\pi} = M_0 = \mathbb{1}$ forces integer weights. So, as in Nash's (8.169),

$$M_\theta = \begin{pmatrix} e^{in\theta} & 0 \\ 0 & e^{-in\theta} \end{pmatrix}, \qquad n \in \mathbb{Z}. \tag{8.312}$$

The Higgs field is the generator of this action. The infinitesimal generator is $\mathrm{d}M_\theta/\mathrm{d}\theta|_0 = \mathrm{diag}(in, -in) = -2n\,T_3$. In the invariant gauge (8.308) the covariant derivative of an invariant section along ∂_θ is (derivative of the lifted action) $+\,\phi$. On the axis the vector field ∂_θ vanishes, so this covariant derivative is zero there, and ϕ must equal (minus) the generator of the fibre action: $\phi|_{\text{axis}}$ is conjugate to $\pm 2nT_3$. Its length in our norm is

$$|\phi|_{\text{as}} = |2nT_3| = 2n. \tag{8.313}$$

Nash, who normalises $|\phi|$ by its eigenvalues $\pm i|\phi|$ rather than by $-2\,\mathrm{tr}\,\phi^2$, writes this as $|\phi|_{\text{as}} = n$. Either way it is quantised.

The bundle over the axis splits. Restrict V to the axis-sphere $S^2 = \partial H^3$; call the restriction V'. The circle acts on each fibre of V' with weights $\pm n$, so V' splits into the two eigenline bundles,

$$V' = L \oplus L^{-1}, \tag{8.314}$$

Nash's (8.170). L is the eigenline of ϕ with eigenvalue $+in$ (in Nash's normalisation). Its Chern class is the degree of the map $\hat{\phi} : \partial H^3 \to S^2$, for exactly the reason of Example 8.121: $c_1(L) = k$, the magnetic charge.

Worked example 8.132: Deriving $c_2(V) = 2nk$

The hyperbolic Bogomolny bound is proved exactly as on $\mathbb{R}^3$ (Section 8.13.3): the energy is a square plus $-\langle F, \star_H \mathrm{d}_A\phi\rangle = 2\oint_{\partial H^3} \mathrm{tr}(F\phi)$, and on the boundary only $|\phi|_{\text{as}}$ and the degree of $\hat{\phi}$ enter. So on a solution, $E_H = 4\pi|\phi|_{\text{as}}\,k$. The instanton number (with the conventions of Example 8.127) is then

$$c_2(V) \overset{(1)}{=} \frac{1}{8\pi^2} S(\hat{A}) \overset{(2)}{=} \frac{1}{8\pi^2}\int_0^{2\pi} \mathrm{d}\theta\; E_H \overset{(3)}{=} \frac{2\pi\cdot 4\pi|\phi|_{\text{as}}k}{8\pi^2} = |\phi|_{\text{as}}\,k \overset{(4)}{=} 2nk.$$

(1) The instanton is self-dual, so it saturates $S = 8\pi^2|c_2|$ (part 8b); and S is conformally invariant (Example 8.128), so we may compute it on $S^1 \times H^3$.
(2) The reduction of Example 8.127, with $\mathrm{d}x^0$ replaced by $\mathrm{d}\theta$ and T by 2π: the action per unit θ is the hyperbolic energy.
(3) The hyperbolic Bogomolny bound, saturated.
(4) (8.313).

This is Nash's (8.171). The three integers k, n and $c_2(V)$ together hold all the topological

data, and they are tied by one relation.

Watch out: Why $|\phi|_{\text{as}}$ must be an integer, and what if it is not

The Bogomolny equation on H^3 makes sense for *any* constant $|\phi|_{\text{as}} > 0$, and hyperbolic monopoles exist for any value. But only for the quantised values of (8.313) does the corresponding θ-invariant connection on $\mathbb{R}^4 \setminus \mathbb{R}^2$ extend smoothly across the axis. For other values the holonomy round a small circle linking the axis, $\exp(-2\pi\phi)$, does not tend to $\mathbb{1}$ as the circle shrinks, so the would-be instanton is singular along the axis and its "instanton number" $|\phi|_{\text{as}}k$ is not an integer (Forgács, Horváth and Palla). So hyperbolic monopoles form a wider class than axially symmetric instantons.

8.14.6 The curvature of H^3 as a parameter, and the flat limit

Nash next inserts a length scale R. Write the flat metric as

$$\mathrm{d}s^2 = \frac{r^2}{R^2}\Big\{R^2\mathrm{d}\theta^2 + \frac{R^2}{r^2}\big(\mathrm{d}r^2 + \mathrm{d}x_2^2 + \mathrm{d}x_3^2\big)\Big\}.$$

Deleting the conformal factor r^2/R^2 leaves $S^1(R) \times H^3(R)$: a circle of radius R times hyperbolic space scaled up by R. Scaling a metric by R^2 divides curvatures by R^2, so $H^3(R)$ has sectional curvature $-1/R^2$ and scalar curvature $3 \cdot 2 \cdot (-1/R^2) = -6/R^2$. Its ball model has radius $2R$ and metric $f_R\,|\mathrm{d}\vec{x}|^2$ with $f_R = (1 - \rho^2/4R^2)^{-2}$ (substitute $\vec{x} \to \vec{x}/R$ in (8.306) and multiply by R^2).

Worked example 8.133: Bogomolny on $S^1(R) \times H^3(R)$

The unit 1-form along the circle is now $R\,\mathrm{d}\theta$. Write $\hat{A} = A + \phi\,\mathrm{d}\theta = A + (\phi/R)(R\,\mathrm{d}\theta)$: the Higgs field seen by an orthonormal frame is $\Phi = \phi/R$. The computation of Example 8.130 with $f \to f_R$ gives $D_k\Phi^a = -\frac{1}{2}\sqrt{f_R}\,\varepsilon_{ijk}F^a_{ij}$, that is

$$D_k\phi^a = -\frac{R}{2}\sqrt{f_R}\,\varepsilon_{ijk}F^a_{ij}, \qquad f_R = \big(1 - \rho^2/4R^2\big)^{-2}. \tag{8.315}$$

As $R \to \infty$ at fixed $\vec{x}$, $f_R \to 1$ and the ball of radius $2R$ fills all of $\mathbb{R}^3$: $H^3(R)$ becomes flat $\mathbb{R}^3$ and (8.315) becomes the flat Bogomolny equation $D_k\Phi = -B_k$ for $\Phi = \phi/R$.

Reading Nash (the factor in (8.172))

Nash prints $D_k\phi^a = -\frac{R}{2\sqrt{f_R}}\varepsilon_{ijk}F^a_{jk}$, with $\sqrt{f_R}$ in the denominator. A direct computation of the Hodge star for $g = f_R\,\delta$ (Example 8.130) puts $\sqrt{f_R}$ in the numerator, as in (8.315). The difference is invisible in the limit $R \to \infty$ that Nash cares about, where $f_R \to 1$.

So flat monopoles are limits of hyperbolic ones, and hyperbolic monopoles with quantised $|\phi|_{\text{as}}$ are instantons. This gives a picture of an $\mathbb{R}^3$ monopole as a limit of instantons (Chakrabarti; Nash).

8.14.7 Where is the monopole? Zeros of the Higgs field

A monopole has no sharp edge (Figure 8.63), so "its position" needs a definition. Nash's is the set of zeros of ϕ. Why must ϕ have zeros at all?

Key idea: A non-zero charge forces zeros of the Higgs field

Let $\hat{\phi} : \partial H^3 \to S^2$ (or $S^2_\infty \to S^2$ on $\mathbb{R}^3$) have degree k. The map $\hat{\phi} = \phi/|\phi|$ extends to a map from the whole closed ball to S^2 without singularity if and only if $k = 0$. Hence if $k \neq 0$, the field ϕ vanishes somewhere. Counted with signs (local degrees), the zeros add up to k.

Why. Suppose ϕ never vanishes on the closed ball B. Then $\hat{\phi}$ is defined on every sphere S_ρ of radius $\rho \leq \rho_{\max}$, and the family $\hat{\phi}|_{S_\rho}$ is a homotopy from the map on the boundary to the map on a tiny sphere around the centre. The latter is nearly constant (it is $\hat{\phi}(0)$ up to a small error), so it has degree 0; degrees are homotopy invariant; so $k = 0$. Conversely, if $k = 0$ the boundary map is homotopic to a constant ($\pi_2(S^2) = \mathbb{Z}$ is detected by the degree), and we can use the homotopy to fill in the ball radially. The signed count follows by applying the same argument to the region outside small spheres around each zero: the boundary degree equals the sum of the degrees on the small spheres.

Worked example 8.134: Local degrees of zeros

Think of $\vec{\phi}(\vec{x})$ as a vector field on $\mathbb{R}^3$ and use complex notation $w = x + iy$ in the xy-plane.

- $\vec{\phi} = (x, y, z)$: one zero at the origin, local degree +1 (the hedgehog).
- $\vec{\phi} = (x, -y, z)$: one zero, local degree −1 (a reflection). This is the Higgs field of an anti-monopole.
- $\vec{\phi} = (\operatorname{Re} w^2, \operatorname{Im} w^2, z)$: the planar part $w \mapsto w^2$ wraps the circle twice, so the boundary map has degree 2; there is a single, degenerate, zero at the origin of local degree 2.
- $\vec{\phi} = (\operatorname{Re}(w^2 - a^2), \operatorname{Im}(w^2 - a^2), z)$ with $a > 0$: two simple zeros at $w = \pm a$, $z = 0$, each of local degree +1 (near $w = a$, $w^2 - a^2 \approx 2a(w - a)$, an orientation-preserving map). The total is again 2.

The last two illustrate how a charge-2 monopole can be two separated unit monopoles or two coincident ones; we meet this again in Section 8.15.

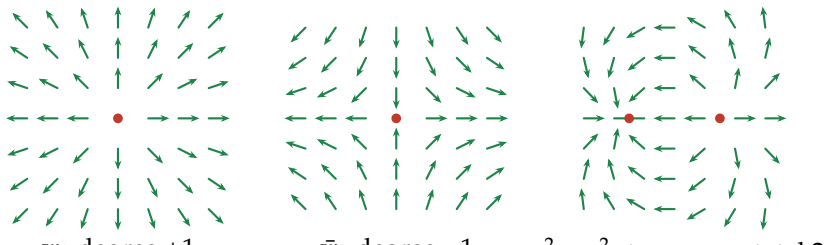

Figure 8.68: The planar part of three Higgs fields, drawn as unit vectors $\hat{\phi}$ in the xy-plane (the z-component is z and vanishes in this plane). Red dots are zeros. Walking once round a large circle, the arrow turns once (left), once backwards (middle) and twice (right). The count of turns at infinity equals the signed count of zeros inside: the monopoles "are" at the red dots.

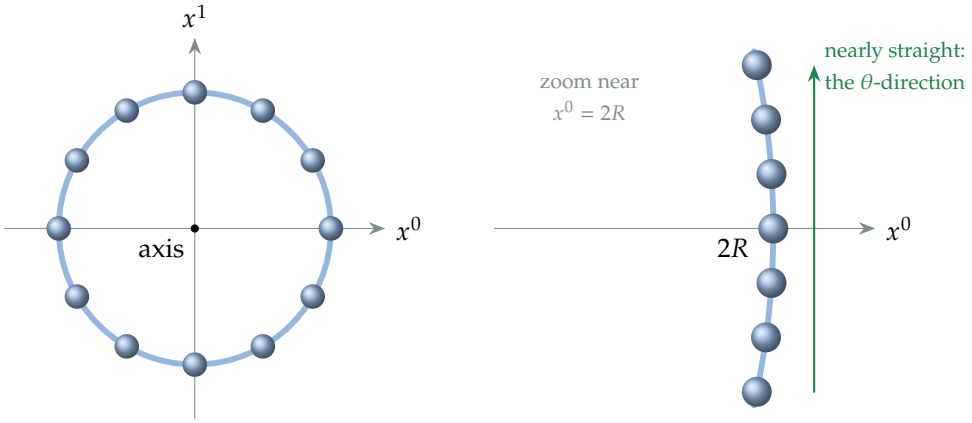
The unit hyperbolic monopole as a ring of instanton

For the simplest hyperbolic monopole, $k = 1$, there is a single zero of ϕ, at the centre of the ball (Nash [1]). What is it in the instanton picture? Follow the zero through the maps:

$$\begin{aligned}\text{centre of the ball} &\xrightarrow{T} (r, x_2, x_3) = (2, 0, 0) \text{ in the half-space} \\ &\xrightarrow{\times S^1} \{x^0 = 2\cos\theta,\ x^1 = 2\sin\theta,\ x^2 = x^3 = 0\} \subset \mathbb{R}^4.\end{aligned}$$

The first arrow is Example 8.131. The second remembers that a point of H^3 stands for a whole θ-circle in $\mathbb{R}^4$, of radius r in the x^0–x^1 plane. So the "location" of the θ-invariant instanton is a circle of radius 2, centred at the origin in the x^0–x^1 plane: a ring of instanton.



$k = 1$, $R = 1$: the zero of ϕ is a circle of radius 2 (a ring of instanton)

$R \to \infty$: the ring becomes a line of instantons, i.e. a static $\mathbb{R}^3$ monopole

Figure 8.69: Instanton pictures of monopoles. Left: the unit hyperbolic monopole corresponds to an axially symmetric instanton "located" on a circle of radius 2 around the axis. Right: as the curvature radius R grows, the relevant part of the circle, of radius $2R$, straightens into a line. Along it (the θ-direction) the field is almost constant; that direction plays the role of time, so the picture is a static monopole. Chakrabarti made this limit precise.

In the limit $R \to \infty$, with larger k, the ring picture becomes a chain of instantons strung out along a line, and the result is an $\mathbb{R}^3$ monopole (Chakrabarti). This is the same interpolation as the calorons of the intuition box after Example 8.127.

8.14.8 The general conformal equivalence

Nash remarks that (8.307) is one case of

$$\mathbb{R}^n \setminus \mathbb{R}^m \ \simeq\ S^{n-m-1} \times H^{m+1}, \qquad m < n. \tag{8.316}$$

Worked example 8.135: Deriving the general equivalence: Nash's (8.174)

Ask for invariance under rotations of the first $l+1$ coordinates, i.e. under $\mathrm{SO}(l+1)$ acting on $(x_1, \dots, x_{l+1})$, with $l < n$. Let $r^2 = x_1^2 + \cdots + x_{l+1}^2$ and let $\mathrm{d}\Omega_l^2$ be the round metric of the unit S^l. Then

$$\begin{aligned}\mathrm{d}s^2 &\overset{(1)}{=} \mathrm{d}x_1^2 + \cdots + \mathrm{d}x_{l+1}^2 + \mathrm{d}x_{l+2}^2 + \cdots + \mathrm{d}x_n^2 \\ &\overset{(2)}{=} \mathrm{d}r^2 + r^2\mathrm{d}\Omega_l^2 + \mathrm{d}x_{l+2}^2 + \cdots + \mathrm{d}x_n^2\end{aligned}$$

$$\overset{(3)}{=} r^2\Big\{\mathrm{d}\Omega_l^2 + \frac{\mathrm{d}r^2 + \mathrm{d}x_{l+2}^2 + \cdots + \mathrm{d}x_n^2}{r^2}\Big\}.$$

(1) The flat metric.
(2) Spherical coordinates in the first $l+1$ variables.
(3) Factor out r^2 where $r > 0$.

The bracket is S^l times the half-space model of H^{n-l} (coordinates $r > 0$ and $x_{l+2}, \dots, x_n$). The removed set $r = 0$ is $\mathbb{R}^{n-l-1}$. So $\mathbb{R}^n \setminus \mathbb{R}^{n-l-1} \simeq S^l \times H^{n-l}$, and with $m = n - l - 1$ this is (8.316).

The cases that matter in four dimensions:

m	removed	result	symmetric instantons become
0	a point	$S^3 \times H^1 = S^3 \times \mathbb{R}$	$\mathbb{R} \ni \tau = \ln\lvert x\rvert$: instantons as tunnelling in "radial time"
1	a line	$S^2 \times H^2$	SO(3)-invariant instantons $\to$ abelian Higgs vortices on H^2
2	a plane	$S^1 \times H^3$	SO(2)-invariant instantons $\to$ hyperbolic monopoles
3	a 3-space	$S^0 \times H^4$	two copies of H^4: nothing is gained

The case $m = 1$ is Nash's (8.175), $\mathbb{R}^4 \setminus \mathbb{R}^1 \simeq S^2 \times H^2$, relevant for SO(3)-symmetric instantons. Here the reduction goes from four dimensions to two. Nash notes (citing Jaffe and Taubes) that SU(2) Yang–Mills reduced from S^4 to H^2 in this way is an *abelian* Yang–Mills–Higgs system with a complex Higgs field and a fixed value of the coupling λ.

Physical picture: Witten's ansatz: instantons as vortices

Why abelian? An SO(3)-invariant SU(2) field on $S^2 \times H^2$ can only use, at each point of H^2, the structures on S^2 that commute with rotations. What survives is a U(1) gauge field a on H^2 (the rotations about the radial direction in isospin space) and a complex scalar χ (the two components of the gauge field tangent to S^2, combined into one complex number). The self-duality equations become the first-order **vortex equations**

$$\bar\partial_a \chi = 0, \qquad \star f_a = \tfrac{1}{2}\big(1 - |\chi|^2\big)$$

(in a suitable normalisation) on H^2. They are the Bogomolny equations of the abelian Higgs model at the special coupling where vortices do not interact. A charge-k instanton becomes k vortices, located at the zeros of χ. This is Witten's 1977 construction of multi-instantons, and the dimension count works: k zeros in H^2 give $2k$ parameters.

Reading Nash (pp. 245–250, (8.156)–(8.175))

Nash shows that the Bogomolny equation is the static version of $F = \star F$ ((8.156)–(8.162)), then uses rotations and the conformal equivalence $\mathbb{R}^4 \setminus \mathbb{R}^2 \simeq S^1 \times H^3$ ((8.163)–(8.165)) to relate axially symmetric instantons to hyperbolic monopoles ((8.166)–(8.168)). He derives $c_2(V) = 2nk$ ((8.169)–(8.171)), introduces the curvature scale R and the limit to $\mathbb{R}^3$ (8.172), discusses zeros of ϕ, and ends with the general equivalence (8.173)–(8.175). We have supplied the component calculations, an explicit isometry T, the computation of the instanton number from the Bogomolny bound, and pictures. Two corrections: our (8.172)

has $\sqrt{f_R}$ in the numerator, and "$|\phi|_{\text{as}} = n$" is in Nash's eigenvalue normalisation (it is $2n$ in ours), which is what makes $c_2 = |\phi|_{\text{as}} k = 2nk$ come out.

Recap

- Dimensional reduction: x^0-independent self-dual fields on $\mathbb{R}^4$ are Bogomolny monopoles on $\mathbb{R}^3$, with $\phi = \hat{A}_0$. Their action per unit time is the monopole energy, so the total action is infinite.
- Self-duality and the action are conformally invariant in four dimensions. With it, $\mathbb{R}^4 \setminus \mathbb{R}^2 \simeq S^1 \times H^3$, and rotation-invariant instantons are monopoles on H^3, now with finite action.
- Over the axis the rotation acts on fibres with weights $\pm n$; this quantises $|\phi|_{\text{as}}$, splits $V|_{\text{axis}} = L \oplus L^{-1}$ with $c_1(L) = k$, and gives $c_2(V) = 2nk$.
- Flat monopoles are the $R \to \infty$ limit of hyperbolic ones. A monopole "is" at the zeros of ϕ, whose signed number is k. The unit hyperbolic monopole is a ring of instanton of radius 2.
- In general $\mathbb{R}^n \setminus \mathbb{R}^m \simeq S^{n-m-1} \times H^{m+1}$; SO(3)-symmetric instantons are vortices on H^2.

8.15 Monopole moduli

We found one explicit monopole, the Prasad–Sommerfield solution with $k = 1$. It sits at the origin. Translating it gives more solutions, so solutions come in families. For instantons (part 8b) we asked how big the family is, and the answer $\dim \mathcal{M}_k = 8k - 3$ came from an index theorem. Nash now asks the same question for monopoles:

> *How many parameters does a charge-k solution of the Bogomolny equation have? What are these parameters physically, and what does the space of all solutions look like as a manifold?*

The answers, which this section derives:

- The **monopole moduli space** $\mathcal{M}'_k$ has dimension $4k$. The count comes from a linearised Bogomolny equation, an elliptic complex, and an index computation, exactly as for instantons.
- Physically, $4k = k \times (3 + 1)$: each unit monopole has three position coordinates and one internal phase.
- Removing the overall phase gives $\mathcal{M}_k$ of dimension $4k - 1$; also fixing the centre gives $\mathcal{M}^0_k$ of dimension $4k - 4$.
- Topologically $\mathcal{M}'_k$ is the space of rational functions of degree k in one complex variable that vanish at infinity (Donaldson).

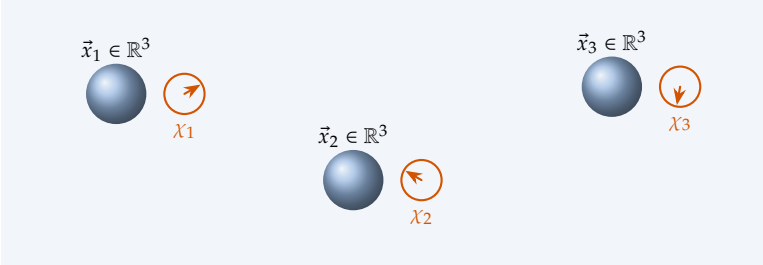
8.15.1 Counting parameters: why one expects $4k$

Before any analysis, here is the physicist's count, due to E. Weinberg. Suppose the k units of charge are far apart. Each then looks like a Prasad–Sommerfield monopole, and each can be moved independently. That gives $3k$ position parameters.

There is one more parameter per monopole. Take a single PS monopole and apply the gauge transformation

$$g_\chi = \exp\Big(\frac{\chi}{C}\,\phi\Big), \qquad \chi \in \mathbb{R}. \tag{8.317}$$

It commutes with ϕ, so ϕ is unchanged, and it changes A only by $g_\chi^{-1}\mathrm{d}g_\chi$, which is non-zero where $|\phi|$ is not constant. At infinity, g_χ is a rotation by the angle χ about the Higgs direction: it does *not* tend to the identity. Physically distinct configurations are those that differ by gauge transformations that are *not* the identity at infinity (Section 8.15.6 explains why). So χ is a genuine parameter, an internal **phase** of the monopole. When one monopole is alone, its phase can be absorbed into a global rotation; when there are several, their *relative* phases are physical. Total: $3k + k = 4k$.



k well-separated unit monopoles: 3 coordinates of position + 1 phase each $\Rightarrow \dim \mathcal{M}'_k = 4k$

Figure 8.70: Weinberg's parameter count. Far apart, a charge-k monopole is k Prasad–Sommerfield lumps (blue). Each has a position in $\mathbb{R}^3$ and an internal phase χ_i (orange dial), the angle of a gauge rotation about its Higgs direction. The index theorem below confirms that no parameters are lost or gained when the lumps come together.

This count is heuristic. When monopoles overlap they are no longer independent lumps. The index theorem makes the count rigorous: the dimension of the solution space cannot change as long as we deform continuously, so the value $4k$ for widely separated monopoles holds everywhere.

8.15.2 Linearising the Bogomolny equation

We follow the method of part 8b. Let (A, ϕ) solve the Bogomolny equation

$$F(A) = -\star\, \mathrm{d}_A\phi \tag{8.318}$$

(our sign, see (8.303); Nash's (8.176)–(8.179) use the opposite sign throughout, which changes a few signs below and nothing else). Deform it along a one-parameter family $(A + ta,\ \phi + t\eta)$, where a is an $\mathfrak{su}(2)$-valued 1-form and η an $\mathfrak{su}(2)$-valued function. This is Nash's (8.176).

Worked example 8.136: Expanding both sides in t

The curvature:

$$\begin{aligned} F(A+ta) &\overset{(1)}{=} \mathrm{d}(A+ta) + (A+ta)\wedge(A+ta) \\ &\overset{(2)}{=} \mathrm{d}A + A\wedge A + t\big(\mathrm{d}a + A\wedge a + a\wedge A\big) + t^2 a\wedge a \\ &\overset{(3)}{=} F(A) + t\,\mathrm{d}_A a + t^2 a\wedge a. \end{aligned}$$

(1) Definition $F = \mathrm{d}A + A\wedge A$.
(2) Multiply out and sort by powers of t.

(3) $\mathrm{d}_A a = \mathrm{d}a + A\wedge a + a\wedge A$ is the covariant derivative of an adjoint 1-form (Section 8.13.2).

The covariant derivative of the Higgs field:

$$\begin{aligned}\mathrm{d}_{A+ta}(\phi+t\eta) &\overset{(1)}{=} \mathrm{d}(\phi+t\eta) + [A+ta, \phi+t\eta]\\ &\overset{(2)}{=} \mathrm{d}_A\phi + t\big(\mathrm{d}_A\eta + [a,\phi]\big) + t^2[a,\eta].\end{aligned}$$

(1) Definition (8.267).
(2) Bilinearity of the bracket; $\mathrm{d}\phi + [A,\phi] = \mathrm{d}_A\phi$ and $\mathrm{d}\eta + [A,\eta] = \mathrm{d}_A\eta$.

Insert both into (8.318). The t^0 terms cancel because (A,ϕ) is a solution. The family is a family of solutions to first order in t iff the t^1 terms agree:

$$\mathrm{d}_A a = -\star\big(\mathrm{d}_A\eta + [a,\phi]\big). \tag{8.319}$$

This is Nash's (8.177) with our sign. In components ($\star$ of a 2-form gives $\frac{1}{2}\varepsilon_{ijk}(\cdot)_{jk}$, and $(\mathrm{d}_A a)_{jk} = D_j a_k - D_k a_j$),

$$\varepsilon_{ijk}D_j a_k + D_i\eta + [a_i,\phi] = 0, \qquad i = 1,2,3. \tag{8.320}$$

Infinitesimal gauge transformations

Some solutions of (8.319) are fake: they only move (A,ϕ) along its gauge orbit. Let $g = \exp(tf)$ with f an $\mathfrak{su}(2)$-valued function. To first order, $g = 1 + tf$ and $g^{-1} = 1 - tf$, so

$$\begin{aligned}g^{-1}Ag + g^{-1}\mathrm{d}g &\overset{(1)}{=} (1-tf)A(1+tf) + (1-tf)\,t\,\mathrm{d}f \overset{(2)}{=} A + t\big(\mathrm{d}f + [A,f]\big) + O(t^2)\\ &= A + t\,\mathrm{d}_A f + O(t^2),\\ g^{-1}\phi\, g &\overset{(3)}{=} \phi + t(\phi f - f\phi) + O(t^2) = \phi + t\,[\phi,f] + O(t^2).\end{aligned}$$

(1) The gauge transformation rule of Section 8.12.1.
(2) Multiply out: $-tfA + tAf = t[A,f]$.
(3) Same for the adjoint scalar.

So the infinitesimal gauge transformation generated by f is

$$(a,\eta) = \big(\mathrm{d}_A f,\ [\phi,f]\big), \tag{8.321}$$

Nash's (8.178).

Watch out: The sign of the Higgs part

Nash writes $(\mathrm{d}_A f, [f,\phi])$ in (8.178) and (8.179). With the gauge rule $\phi \mapsto g^{-1}\phi g$ that he (and we) use, the correct term is $[\phi,f]$. If we used $[f,\phi]$, the pair would not be tangent to the gauge orbit and the check $D_1 D_0 = 0$ below would fail. The slip is harmless for dimension counting.

8.15.3 The deformation complex

Package (8.321) and (8.319) as two operators, Nash's (8.179):

$$\begin{aligned}&D_0 : \Omega^0(\mathbb{R}^3, \mathrm{ad}\,P) \to \Omega^1(\mathbb{R}^3,\mathrm{ad}\,P)\oplus\Omega^0(\mathbb{R}^3,\mathrm{ad}\,P), \qquad f \mapsto \big(\mathrm{d}_A f,\ [\phi,f]\big),\\ &D_1 : \Omega^1(\mathbb{R}^3, \mathrm{ad}\,P)\oplus\Omega^0(\mathbb{R}^3,\mathrm{ad}\,P) \to \Omega^2(\mathbb{R}^3,\mathrm{ad}\,P), \quad (a,\eta)\mapsto \mathrm{d}_A a + \star\mathrm{d}_A\eta + \star[a,\phi].\end{aligned} \tag{8.322}$$

Here ad P is the bundle whose sections are $\mathfrak{su}(2)$-valued functions; over $\mathbb{R}^3$ it is trivial, $\mathbb{R}^3 \times \mathfrak{su}(2)$. The operator D_1 is "Bogomolny linearised": $D_1(a,\eta) = 0$ is (8.319).

Worked example 8.137: Gauge directions solve the linearised equation: $D_1 D_0 = 0$

$$\begin{aligned} D_1 D_0 f &\overset{(1)}{=} \mathrm{d}_A \mathrm{d}_A f + \star \mathrm{d}_A [\phi, f] + \star [\mathrm{d}_A f, \phi] \\ &\overset{(2)}{=} [F, f] + \star\big([\mathrm{d}_A \phi, f] + [\phi, \mathrm{d}_A f]\big) + \star [\mathrm{d}_A f, \phi] \\ &\overset{(3)}{=} [F, f] + \star [\mathrm{d}_A \phi, f] \overset{(4)}{=} \big[F + \star \mathrm{d}_A \phi,\ f\big] \overset{(5)}{=} 0. \end{aligned}$$

(1) Definitions (8.322).
(2) $\mathrm{d}_A \mathrm{d}_A f = [F, f]$ (Example 8.119), and the Leibniz rule for the covariant derivative of a bracket, $\mathrm{d}_A[\phi, f] = [\mathrm{d}_A \phi, f] + [\phi, \mathrm{d}_A f]$.
(3) $[\phi, \mathrm{d}_A f] + [\mathrm{d}_A f, \phi] = 0$.
(4) $\star$ acts only on the form part.
(5) The Bogomolny equation (8.318).

So the image of D_0 lies in the kernel of D_1, but *only* because (A, ϕ) is a solution. That is the typical feature of a deformation complex.

The physical deformations are the solutions of $D_1 = 0$ modulo the gauge directions. This is Nash's (8.180):

$$T_m \mathcal{M}'_k = \frac{\operatorname{Ker} D_1}{\operatorname{Im} D_0}, \tag{8.323}$$

where m is the gauge class of (A, ϕ). We have an **elliptic complex**, Nash's (8.181):

$$0 \longrightarrow \Omega^0(\mathrm{ad}\, P) \xrightarrow{D_0} \Omega^1(\mathrm{ad}\, P) \oplus \Omega^0(\mathrm{ad}\, P) \xrightarrow{D_1} \Omega^2(\mathrm{ad}\, P) \longrightarrow 0, \tag{8.324}$$

with cohomology groups (Nash's (8.182))

$$H^0 = \operatorname{Ker} D_0, \qquad H^1 = \frac{\operatorname{Ker} D_1}{\operatorname{Im} D_0}, \qquad H^2 = \frac{\Omega^2}{\operatorname{Im} D_1}, \qquad \hat{h}_i = \dim H^i. \tag{8.325}$$

Their meaning: H^0 = infinitesimal gauge symmetries of the solution (the stabiliser); H^1 = genuine deformations; H^2 = obstructions, i.e. directions in which the Bogomolny equation cannot be solved by a small deformation.

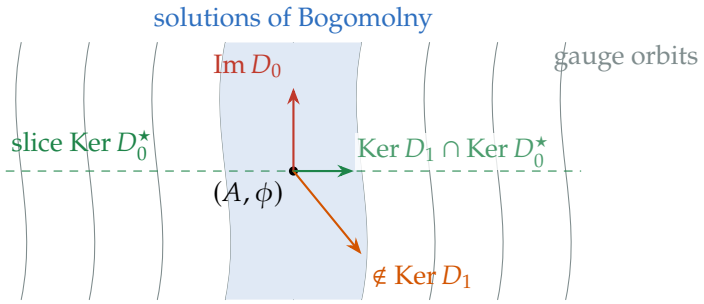


Figure 8.71: The geometry of (8.323), drawn in the infinite-dimensional space $\mathcal{A}_{\mathrm{YMH}}$ of pairs (A, ϕ). Grey curves are gauge orbits; the blue band is the set of solutions, a union of whole orbits. At a solution, tangent vectors along the orbit (Im D_0, red) are trivial; those leaving the band (orange) violate the linearised equation. The physical deformations are best represented by the vectors in Ker D_1 that are orthogonal to the orbit (green): this is the slice condition $D_0^\star(a, \eta) = 0$.

Working definition 8.43 (deformation complex, operationally)

Given a solution, (i) write the linearised equation $D_1 = 0$ [the part of the Bogomolny equation linear in the perturbation (a,η) of (A,ϕ)]; (ii) write the infinitesimal symmetries D_0 [the change of (A,ϕ) under an infinitesimal gauge transformation f]; (iii) check $D_1 D_0 = 0$. The number of parameters is $\hat{h}_1 = \dim(\operatorname{Ker} D_1/\operatorname{Im} D_0)$. To compute it, pick the representative orthogonal to the orbit [L^2-orthogonal to every $D_0 f$], $D_0^\star(a,\eta) = 0$, and count solutions of the *pair* of equations $D_1(a,\eta) = 0$, $D_0^\star(a,\eta) = 0$.

Counting components at a point

The complex (8.324) is elliptic in the usual sense: its symbol sequence is exact. A quick sanity check is that the fibre dimensions have alternating sum zero:

$$\underbrace{3}_{\Lambda^0\otimes\mathfrak{su}(2)} - \underbrace{(3\cdot 3+3)}_{(\Lambda^1\oplus\Lambda^0)\otimes\mathfrak{su}(2)} + \underbrace{3\cdot 3}_{\Lambda^2\otimes\mathfrak{su}(2)} = 3-12+9 = 0.$$

Rolling the complex up gives an operator between bundles of the same rank 12, which we now write down explicitly.

8.15.4 Rolling up: a quaternionic Dirac operator

We need the formal adjoint of D_0. Two facts suffice. First, $\mathrm{d}_A^\star a = -D_i a_i$ on 1-forms (the flat-space formula $\mathrm{d}^\star a = -\partial_i a_i$, made covariant). Second, the map $\mathrm{ad}_\phi = [\phi,\cdot\,]$ is antisymmetric for the inner product (8.265):

$$\big([\phi,X],Y\big) \overset{(1)}{=} -2\operatorname{tr}(\phi XY - X\phi Y) \overset{(2)}{=} -2\operatorname{tr}(XY\phi - X\phi Y) = -2\operatorname{tr}\big(X[Y,\phi]\big) = -\big(X,[\phi,Y]\big).$$

(1) Definition $(X,Y) = -2\operatorname{tr}(XY)$.
(2) Cyclicity of the trace, $\operatorname{tr}(\phi XY) = \operatorname{tr}(XY\phi)$.

(In vector language, $[\phi,X] \leftrightarrow \vec{\phi}\times\vec{X}$ and $(\vec{\phi}\times\vec{X})\cdot\vec{Y} = -\vec{X}\cdot(\vec{\phi}\times\vec{Y})$.) Hence

$$D_0^\star(a,\eta) = \mathrm{d}_A^\star a - [\phi,\eta] = -\big(D_i a_i + [\phi,\eta]\big). \tag{8.326}$$

The **background gauge condition** $D_0^\star(a,\eta) = 0$ is the monopole version of the Coulomb gauge $\mathrm{d}_A^\star a = 0$ of part 8b.

Now combine the four real equations: the gauge condition and the three components (8.320). Collect the unknowns into one quaternion-valued field. Let e_1, e_2, e_3 be the quaternion units $\mathbf{i},\mathbf{j},\mathbf{k}$, with

$$e_i e_j = -\delta_{ij} + \varepsilon_{ijk} e_k, \tag{8.327}$$

and set

$$q = \eta + a_1 e_1 + a_2 e_2 + a_3 e_3 \;\in\; \mathbb{H}\otimes\mathfrak{su}(2) \cong \mathbb{R}^{12}. \tag{8.328}$$

Worked example 8.138: The deformation equations are one quaternionic Dirac equation

Define

$$\mathcal{D}q = \sum_i e_i D_i q + [q,\phi]. \tag{8.329}$$

Expand, using (8.327):

$$\begin{aligned}\mathcal{D}q &\overset{(1)}{=} \sum_i e_i D_i\eta + \sum_{i,k} e_i e_k D_i a_k + [\eta,\phi] + \sum_k [a_k,\phi]e_k \\ &\overset{(2)}{=} \sum_l e_l D_l\eta - \sum_i D_i a_i + \sum_{i,k,l} \varepsilon_{ikl} e_l D_i a_k + [\eta,\phi] + \sum_l [a_l,\phi]e_l \\ &\overset{(3)}{=} -\big(D_i a_i + [\phi,\eta]\big) + \sum_l e_l\big(\varepsilon_{lik} D_i a_k + D_l\eta + [a_l,\phi]\big).\end{aligned}$$

(1) Insert (8.328); D_i acts on the $\mathfrak{su}(2)$ factor and commutes with the constant units e_k.
(2) $e_i e_k = -\delta_{ik} + \varepsilon_{ikl} e_l$.
(3) Sort into the real part and the e_l parts; $\varepsilon_{ikl} = \varepsilon_{lik}$ and $[\eta,\phi] = -[\phi,\eta]$.

The real part is $D_0^\star(a,\eta)$ from (8.326); the e_l part is the l-th component (8.320) of $D_1(a,\eta)$ (after $\star$). So

$$\mathcal{D}q = 0 \iff D_1(a,\eta) = 0 \text{ and } D_0^\star(a,\eta) = 0.$$

$\mathcal{D}$ is the rolled-up operator $D_0^\star + D_1$, and its kernel is H^1. Since $e_i^2 = -1$, the leading part $\sum e_i D_i$ squares to $-\nabla^2$ (plus lower order): it is a Dirac operator in three dimensions, with the quaternion units playing the role of the Pauli matrices $-i\sigma_i$.

Worked example 8.139: The Weitzenböck formula: $\mathcal{D}\mathcal{D}^\dagger = -D^2 - \mathrm{ad}_\phi^2$

Left multiplication by a unit imaginary quaternion is antisymmetric, and so is D_i (integration by parts); they commute, so $e_i D_i$ is symmetric. The map $q \mapsto [q,\phi]$ is antisymmetric. Hence $\mathcal{D}^\dagger q = \sum_i e_i D_i q - [q,\phi]$. Now compute:

$$\begin{aligned}\mathcal{D}\mathcal{D}^\dagger q &\overset{(1)}{=} \sum_{i,j} e_i e_j D_i D_j q - \sum_i e_i\big([D_i q,\phi] + [q, D_i\phi]\big) + \sum_j e_j [D_j q,\phi] - \big[[q,\phi],\phi\big] \\ &\overset{(2)}{=} -\sum_i D_i D_i q + \tfrac{1}{2}\sum_{i,j,k} \varepsilon_{ijk} e_k [F_{ij}, q] - \sum_i e_i [q, D_i\phi] - \big[[q,\phi],\phi\big] \\ &\overset{(3)}{=} -D^2 q + \sum_k e_k [B_k, q] + \sum_k e_k [D_k\phi, q] - \big[[q,\phi],\phi\big] \\ &\overset{(4)}{=} -D^2 q - \mathrm{ad}_\phi^2\, q.\end{aligned}$$

(1) Apply $\mathcal{D}$ to $\mathcal{D}^\dagger q$, using the Leibniz rule $D_i[q,\phi] = [D_i q,\phi] + [q, D_i\phi]$.
(2) Split $e_i e_j = -\delta_{ij} + \varepsilon_{ijk} e_k$; the antisymmetric part of $D_i D_j$ is $\frac{1}{2}[D_i, D_j] = \frac{1}{2}[F_{ij}, \cdot\,]$; the two $[D_i q,\phi]$ terms cancel.
(3) $B_k = \frac{1}{2}\varepsilon_{ijk} F_{ij}$, and $-[q, D_k\phi] = [D_k\phi, q]$.
(4) The Bogomolny equation $B_k = -D_k\phi$ cancels the middle terms; and $[[q,\phi],\phi] = [\phi,[\phi,q]] = \mathrm{ad}_\phi^2\, q$.

Both terms on the right are non-negative operators: $-D^2 = D_i^\dagger D_i$ and $-\mathrm{ad}_\phi^2 = \mathrm{ad}_\phi^\dagger\,\mathrm{ad}_\phi$. So if $\mathcal{D}^\dagger q = 0$ with q square-integrable,

$$0 = \langle q, \mathcal{D}\mathcal{D}^\dagger q\rangle = \sum_i \|D_i q\|^2 + \big\|[\phi,q]\big\|^2 \;\Rightarrow\; D_i q = 0 \;\Rightarrow\; |q| = \text{const} \;\Rightarrow\; q = 0.$$

Therefore $\operatorname{Ker}\mathcal{D}^\dagger = 0$.

Now read off the cohomology. $\operatorname{Ker} \mathcal{D}^\dagger = \operatorname{Ker}(D_0 + D_1^\star)$ consists of pairs $(f, \omega) \in \Omega^0 \oplus \Omega^2$ with $D_0 f + D_1^\star \omega = 0$; pairing with $D_0 f$ and using $D_1 D_0 = 0$ shows $D_0 f = 0$ and $D_1^\star \omega = 0$ separately. So $\operatorname{Ker} \mathcal{D}^\dagger \cong H^0 \oplus H^2$, and the Weitzenböck argument gives

$$\hat{h}_0 = \hat{h}_2 = 0.$$

Nash's (8.183) is then

$$\begin{aligned} \operatorname{index}(D_0 + D_1^\star) &\overset{(1)}{=} \dim \operatorname{Ker}(D_0 + D_1^\star) - \dim \operatorname{Ker}(D_0^\star + D_1) \\ &\overset{(2)}{=} \hat{h}_0 - \hat{h}_1 + \hat{h}_2 \overset{(3)}{=} -\hat{h}_1 = -\dim \mathcal{M}'_k. \end{aligned} \tag{8.330}$$

(1) Definition of the index of an operator: kernel minus cokernel, and the cokernel of $D_0 + D_1^\star$ is the kernel of its adjoint.

(2) $\operatorname{Ker}(D_0 + D_1^\star) = H^0 \oplus H^2$ as just shown, and $\operatorname{Ker}(D_0^\star + D_1) = \operatorname{Ker} \mathcal{D} = H^1$.

(3) $\hat{h}_0 = \hat{h}_2 = 0$ by the Weitzenböck argument; $\hat{h}_1 = \dim T_m \mathcal{M}'_k$.

Watch out: Which kernel vanishes in (8.184)

Nash writes the vanishing theorem as $\operatorname{Ker}(D_0^\star + D_1) = \phi$ (the empty set; he means 0). But $\operatorname{Ker}(D_0^\star + D_1) = H^1$ is the tangent space, which is $4k$-dimensional, not zero. What the Weitzenböck argument kills is the kernel of the *other* operator, $\operatorname{Ker}(D_0 + D_1^\star) = H^0 \oplus H^2$. With that correction, $\hat{h}_0 = \hat{h}_2 = 0$ follows as he says.

Key idea: Dimension of the monopole moduli space (Nash's (8.185))

Taubes (following Callias and E. Weinberg) showed $\operatorname{index}(D_0 + D_1^\star) = -4k$. With $\hat{h}_0 = \hat{h}_2 = 0$,

$$\dim \mathcal{M}'_k = \hat{h}_1 = 4k.$$

Why $4k$, at the physicist's level. The index is unchanged under continuous deformations that keep the operator Fredholm. Deform a charge-k solution into k widely separated unit monopoles. Each has its own zero modes, which we count explicitly below (four of them), and far apart they do not interfere. So the index is 4 per unit of charge. Callias' index theorem for Dirac operators coupled to a Higgs field on odd-dimensional spaces turns this into an exact formula: the index is an integral over the sphere at infinity of an expression in $\hat{\phi}$, proportional to $\deg \hat{\phi} = k$.

Watch out: Why $\mathbb{R}^3$ is harder than S^4

On a compact manifold elliptic operators are automatically Fredholm. On $\mathbb{R}^3$ they need not be: an operator can have continuous spectrum reaching down to 0. Here the term $-\operatorname{ad}_\phi^2$ in Example 8.139 gives the components of q that do *not* commute with ϕ a mass $\approx C$ at infinity, so they decay exponentially. The component along $\hat{\phi}$ (the unbroken U(1), the photon) is massless and decays only like a power. This is why Nash says the index calculation "requires considerable extra analysis": one has to choose function spaces (Taubes uses weighted Sobolev spaces) so that D_0 and D_1 are Fredholm and the cohomology can be built from square-integrable sections. The zero modes that result decay like $1/r^2$, which is square integrable in three dimensions.

8.15.5 The four zero modes of the Prasad–Sommerfield monopole

Let us see the four parameters of a unit monopole as explicit solutions of $\mathcal{D} q = 0$.

Worked example 8.140: Translation zero modes

Translating a solution in the direction x^j gives the tangent vector $(\partial_j A, \partial_j \phi)$. It solves the linearised Bogomolny equation (translations map solutions to solutions), but it is not orthogonal to the gauge orbit. Add the infinitesimal gauge transformation with $f = -A_j$:

$$a_k \overset{(1)}{=} \partial_j A_k - D_k A_j \overset{(2)}{=} \partial_j A_k - \partial_k A_j - [A_k, A_j] \overset{(3)}{=} F_{jk},$$
$$\eta \overset{(4)}{=} \partial_j \phi + [\phi, -A_j] \overset{(5)}{=} D_j \phi.$$

(1) Add $\mathrm{d}_A f$ with $f = -A_j$, from (8.321).
(2) $D_k A_j = \partial_k A_j + [A_k, A_j]$ (the adjoint covariant derivative of the function A_j).
(3) $F_{jk} = \partial_j A_k - \partial_k A_j + [A_j, A_k]$.
(4) Add $[\phi, f]$ with $f = -A_j$.
(5) $[\phi, -A_j] = [A_j, \phi]$ and $D_j \phi = \partial_j \phi + [A_j, \phi]$.

So the translation mode is $(a, \eta) = (\iota_{\partial_j} F,\ D_j \phi)$: gauge-covariant, as it should be. It still solves $D_1 = 0$ (we added a gauge direction, and $D_1 D_0 = 0$). Does it satisfy the gauge condition?

$$D_k a_k + [\phi, \eta] \overset{(1)}{=} D_k F_{jk} + [\phi, D_j \phi] \overset{(2)}{=} [D_j \phi, \phi] + [\phi, D_j \phi] = 0.$$

(1) Insert the mode.
(2) The first field equation (8.282), $\mathrm{d}_A^\star F = [\mathrm{d}_A \phi, \phi]$, in components: $(\mathrm{d}_A^\star F)_j = -D_k F_{kj} = D_k F_{jk}$.

So all three translation modes lie in the slice. (We also verified (8.320) for them numerically on the explicit PS solution.) Their length:

$$\left\| (\iota_{\partial_j} F, D_j \phi) \right\|^2 \overset{(1)}{=} \int \Big(\sum_k |F_{jk}|^2 + |D_j \phi|^2 \Big) \mathrm{d}^3 x \overset{(2)}{=} \frac{1}{3} \int \big(2|B|^2 + |D\phi|^2 \big) \mathrm{d}^3 x$$
$$\overset{(3)}{=} \int |B|^2 \mathrm{d}^3 x \overset{(4)}{=} 4\pi C.$$

(1) The norm (8.266) in components.
(2) Summed over j, $\sum_{j,k} |F_{jk}|^2 = 2|B|^2$ and $\sum_j |D_j \phi|^2 = |D\phi|^2$; for the spherically symmetric PS monopole each j contributes one third.
(3) $|B| = |D\phi|$ on a Bogomolny solution.
(4) $E = \frac{1}{2} \int (|B|^2 + |D\phi|^2) = \int |B|^2 = 4\pi C$.

The squared length of a translation mode is the *mass* of the monopole. We shall see in Section 8.16 that this is no accident.

Worked example 8.141: The phase zero mode

Now apply D_0 to $f = \phi$, the generator of (8.317):

$$D_0 \phi = \big(\mathrm{d}_A \phi, [\phi, \phi] \big) = (\mathrm{d}_A \phi, 0).$$

Check that $(a, \eta) = (\mathrm{d}_A \phi, 0)$ solves both equations:

$$\varepsilon_{ijk} D_j D_k \phi + [D_i \phi, \phi] \overset{(1)}{=} \tfrac{1}{2} \varepsilon_{ijk} [F_{jk}, \phi] + [D_i \phi, \phi] \overset{(2)}{=} [B_i + D_i \phi, \phi] \overset{(3)}{=} 0,$$
$$D_k D_k \phi + [\phi, 0] \overset{(4)}{=} 0.$$

(1) Antisymmetrise: $\varepsilon_{ijk}D_jD_k = \frac{1}{2}\varepsilon_{ijk}[D_j, D_k] = \frac{1}{2}\varepsilon_{ijk}[F_{jk}, \cdot\,]$.
(2) $B_i = \frac{1}{2}\varepsilon_{ijk}F_{jk}$.
(3) Bogomolny, $B_i = -D_i\phi$.
(4) The second field equation (8.282), $\mathrm{d}_A^\star \mathrm{d}_A\phi = -D_kD_k\phi = 0$.

Its length is $\|\mathrm{d}_A\phi\|^2 = \int |D\phi|^2 = 4\pi C$, finite because $|D\phi| \sim r^{-2}$.

The phase mode is peculiar. It has the form $D_0 f$, i.e. it looks like a gauge direction, yet it is a genuine element of H^1. The resolution is that $f = \phi$ is not square integrable ($|\phi| \to C$), so $\phi \notin \Omega^0$ in the L^2 sense of the complex, and $D_0\phi$ is not in the image of D_0 on L^2 functions. In the language of the previous parts: ϕ generates a gauge transformation that is not the identity at infinity, and such transformations are not quotiented out in $\mathcal{M}'_k$.

So for $k = 1$ we have found $3 + 1 = 4 = 4k$ independent zero modes, as the index theorem requires.

8.15.6 From $4k$ to $4k-1$ to $4k-4$

Why keep gauge transformations that are non-trivial at infinity? The situation is exactly that of the framed instanton moduli space of part 8b. The group $\mathcal{G}$ of gauge transformations tending to 1 at infinity acts freely, and dividing by it gives the **framed** (or extended) moduli space $\mathcal{M}'_k$. The leftover global rotations about the Higgs direction at infinity form a circle $S^1 = \{\exp(\chi\phi/C)\}$, and they act on $\mathcal{M}'_k$ as the phase rotation (8.317). Physically, the corresponding momentum is the *electric charge* (Section 8.16.4), so we want to keep this circle when we do dynamics.

Nash's (8.186)–(8.187) record the three spaces:

$$\begin{array}{ccc} S^1 & \to & \mathcal{M}'_k \\ & & \downarrow \\ & & \mathcal{M}_k \end{array} \qquad \mathcal{M}_k = \frac{\mathcal{M}'_k}{S^1}, \qquad \mathcal{M}^0_k = \frac{\mathcal{M}'_k}{S^1 \times \mathbb{R}^3}, \qquad \begin{array}{l} \dim \mathcal{M}'_k = 4k, \\ \dim \mathcal{M}_k = 4k-1, \\ \dim \mathcal{M}^0_k = 4k-4. \end{array} \tag{8.331}$$

Projecting out the one-dimensional subspace spanned by $(\mathrm{d}_A\phi, 0)$ is the passage from $\mathcal{M}'_k$ to $\mathcal{M}_k$. Dividing also by translations (fixing the "centre of mass") gives $\mathcal{M}^0_k$.

Worked example 8.142: $k = 1$: everything explicit

For $k = 1$ there is only one monopole up to translation and phase: the PS monopole, spherically symmetric, with the zero of ϕ at its centre. Its position $\vec{x} \in \mathbb{R}^3$ and phase $\chi \in \mathbb{R}/2\pi\mathbb{Z}$ are all the parameters. So

$$\mathcal{M}'_1 = \mathbb{R}^3 \times S^1, \qquad \mathcal{M}_1 = \mathbb{R}^3, \qquad \mathcal{M}^0_1 = \{\text{point}\}.$$

The phase is periodic with period 2π: $\exp(2\pi\hat{\phi})$, with $\hat{\phi}$ conjugate to $T_3 = \mathrm{diag}(-\frac{i}{2}, \frac{i}{2})$, is $-\mathbb{1}$, which acts trivially in the adjoint representation, where A and ϕ live. Dimensions: $4, 3, 0 = 4k, 4k-1, 4k-4$.

8.15.7 The topology of $\mathcal{M}'_k$: rational maps

Nash quotes a striking theorem of Donaldson.

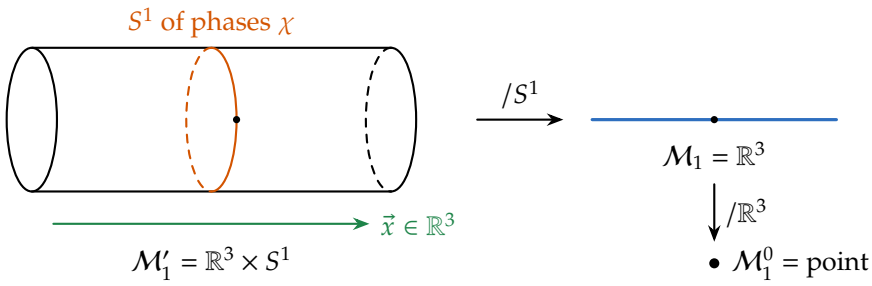

Figure 8.72: The moduli spaces for one monopole (the $\mathbb{R}^3$ drawn as a line). The framed space $\mathcal{M}_1'$ is a cylinder: position times phase. Forgetting the phase gives $\mathcal{M}_1 = \mathbb{R}^3$; forgetting the position as well leaves a single point, the PS monopole at the origin.

Working definition 8.44 (based rational map of degree k)

A **rational map** is a ratio of polynomials $f(z) = p(z)/q(z)$ in one complex variable, viewed as a map $\mathbb{CP}^1 \to \mathbb{CP}^1$ [$\mathbb{CP}^1 = \mathbb{C} \cup \{\infty\}$, a sphere S^2]. It is *based* if $f(\infty) = 0$, which means $\deg p < \deg q$. Its **degree** is $\deg q = k$ when p and q have no common root. Normalise q to be monic [leading coefficient 1]:

$$f(z) = \frac{a_{k-1}z^{k-1} + \cdots + a_1 z + a_0}{z^k + b_{k-1}z^{k-1} + \cdots + b_1 z + b_0}, \qquad a_i, b_i \in \mathbb{C}. \tag{8.332}$$

Operational test: write the fraction in lowest terms and count the poles with multiplicity [a double root of q counts twice]. The count is the degree, and it is also the topological degree of $f : S^2 \to S^2$.

Key idea: Donaldson's theorem (Nash's (8.188))

$\mathcal{M}_k'$ is diffeomorphic to the space Rat_k of based rational maps of degree k.

Parameter count. In (8.332) there are k complex numbers a_i and k complex numbers b_i: $2k$ complex = $4k$ real parameters. The only condition, "no common root", is an open condition, so Rat_k is an open subset of $\mathbb{C}^{2k}$ and has real dimension $4k = \dim \mathcal{M}_k'$. ✓

Where the rational map comes from. Donaldson's construction singles out a direction, say the x^3-axis, and writes $z = x^1 + ix^2$ for the position of a line parallel to it. Along each such line one solves an ordinary differential equation of the form $(D_3 - i\phi)s = 0$ for a section s of the $\mathbb{C}^2$-bundle. Generically the solution that decays as $x^3 \to +\infty$ grows as $x^3 \to -\infty$; the lines along which a solution decays at both ends are "spectral lines", and the scattering data along all lines assemble into a holomorphic function of z, namely f. For well-separated monopoles the spectral lines are the lines through the monopoles, so the poles of f are the positions of the monopoles projected to the z-plane.

Worked example 8.143: One monopole, Nash's (8.189)

For $k = 1$,

$$f(z) = \frac{a_0}{z + b_0}, \qquad a_0 \in \mathbb{C}^\times,\ b_0 \in \mathbb{C}.$$

The coprimality condition says only $a_0 \neq 0$. So $\mathrm{Rat}_1 = \mathbb{C}^\times \times \mathbb{C} \cong (\mathbb{R}_{>0} \times S^1) \times \mathbb{R}^2 \cong \mathbb{R}^3 \times S^1$, which is exactly $\mathcal{M}_1'$ from Example 8.142. The dictionary: the pole $z = -b_0$ is the position $x^1 + ix^2$ of the monopole; $|a_0|$ encodes the height x^3 (with the usual normalisation, $|a_0|$ grows exponentially with x^3, which is why $\mathbb{R}_{>0} \cong \mathbb{R}$ appears); $\arg a_0$ is the phase χ. Nash

notes that $a_0 = 1$, $b_0 = 0$ is the PS monopole at the origin.

Worked example 8.144: Two monopoles and the resultant

For $k = 2$,

$$f(z) = \frac{a_1 z + a_0}{z^2 + b_1 z + b_0}.$$

Numerator and denominator have a common root iff $q(-a_0/a_1) = 0$ (for $a_1 \neq 0$). Clearing the denominator,

$$a_1^2\, q\big(-a_0/a_1\big) \overset{(1)}{=} a_1^2\Big(\frac{a_0^2}{a_1^2} - b_1\frac{a_0}{a_1} + b_0\Big) \overset{(2)}{=} a_0^2 - a_0 a_1 b_1 + a_1^2 b_0 \;=:\; R(f).$$

(1) Evaluate $q(z) = z^2 + b_1 z + b_0$ at the root of the numerator.
(2) Multiply out.

The **resultant** $R(f)$ is also correct when $a_1 = 0$ (then $R = a_0^2$, which vanishes only if the numerator is identically zero). So $\mathrm{Rat}_2 = \{(a_0, a_1, b_0, b_1) \in \mathbb{C}^4 : R \neq 0\}$, the complement of a complex hypersurface in $\mathbb{C}^4$: real dimension $8 = 4k$. *Partial fractions*: if q has distinct roots $\hat{b}_1, \hat{b}_2$,

$$f(z) = \frac{\hat{a}_1}{z - \hat{b}_1} + \frac{\hat{a}_2}{z - \hat{b}_2},$$

the second form in Nash's (8.188). Each term looks like a unit monopole (Example 8.143): this is the approximate superposition of k unit monopoles. When $\hat{b}_1 \to \hat{b}_2$ the partial fraction form breaks down but f does not: coincident monopoles are perfectly regular points of $\mathcal{M}'_k$.

Worked example 8.145: The axially symmetric monopole, Nash's (8.190)

Take $f(z) = 1/z^k$. A rotation by α about the x^3-axis acts on the spectral data by $z \mapsto e^{i\alpha} z$, so $f \mapsto e^{-ik\alpha}/z^k$: the same map up to a phase. A phase can be undone by the S^1 action on $\mathcal{M}'_k$. So the monopole with rational map $1/z^k$ is invariant under rotations about the axis combined with a compensating phase rotation: it is **axially symmetric**. All k poles sit at $z = 0$. For $k = 2$ its energy density is a doughnut (a torus) around the x^3-axis; we will meet it again as the configuration in the middle of 90° scattering.

Finally, the unframed space: $\mathcal{M}_k = \mathcal{M}'_k/S^1$, and on rational maps the circle acts by $f \mapsto e^{i\theta} f$. So $\mathcal{M}_k$ is based rational maps modulo an overall phase of the numerator, as Nash says.

Try it: The topology of Rat_1 and a hint for Rat_2

Show that Rat_1 deformation-retracts onto a circle, so $\pi_1(\mathcal{M}'_1) = \mathbb{Z}$. For Rat_2, show that the map $f \mapsto R(f)/|R(f)| \in S^1$ is well defined and continuous. *Answer:* $\mathbb{C}^\times \times \mathbb{C}$ retracts onto $\{|a_0| = 1\} \times \{0\} = S^1$. For $k = 2$, $R \neq 0$ on Rat_2, so $R/|R|$ is continuous; Segal proved $\pi_1(\mathrm{Rat}_k) = \mathbb{Z}$ for all k, detected by this kind of phase.

Reading Nash (pp. 250–253, (8.176)–(8.190))

Nash linearises the Bogomolny equation ((8.176)–(8.177)), identifies the gauge directions (8.178), defines D_0 and D_1 (8.179), and obtains $T_m\mathcal{M}'_k = \mathrm{Ker}\, D_1/\mathrm{Im}\, D_0$ (8.180) from the elliptic complex (8.181)–(8.182). The index (8.183) is $-4k$ (Taubes) and a Weitzenböck

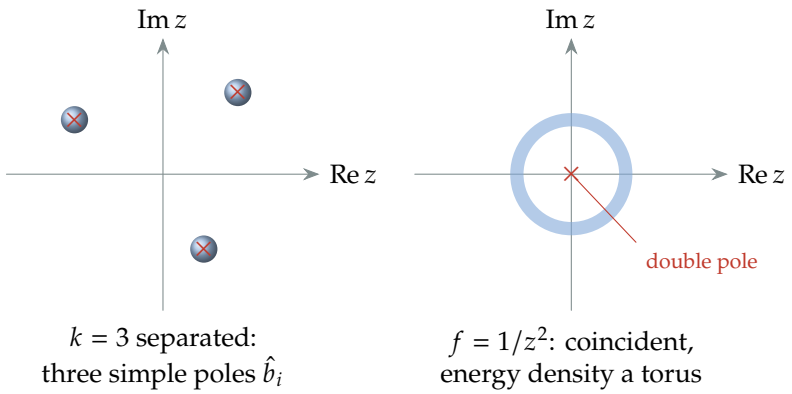

Figure 8.73: Rational maps and monopole positions, seen from above (the x^3-axis points out of the page). Left: for separated monopoles the poles of f (red crosses) sit under the monopoles (blue). Right: for $f = 1/z^2$ both poles coincide at the origin and the energy density is a ring around the axis, not two lumps: the location of the poles says where the monopoles are, not what shape the energy takes.

argument gives $\hat{h}_0 = \hat{h}_2 = 0$ ((8.184), with the kernel corrected as in our pitfall), so $\dim \mathcal{M}'_k = 4k$ (8.185). He explains $4k-1$ (8.186) by the non-L^2 gauge generator ϕ and lists the three spaces (8.187), then quotes Donaldson's rational maps (8.188)–(8.190). We added: the explicit quaternionic form of the operator, the full Weitzenböck computation, the explicit zero modes of the PS monopole and their norms, and the resultant for $k = 2$. Signs: our Bogomolny sign is opposite to Nash's here, and his $[f, \phi]$ should read $[\phi, f]$.

Recap

- Linearising $F = -\star \mathrm{d}_A\phi$ and quotienting by infinitesimal gauge transformations gives an elliptic complex; $T\mathcal{M}'_k = H^1$.
- In quaternionic form the deformation operator is $\mathcal{D}q = e_iD_iq + [q, \phi]$, and $\mathcal{D}\mathcal{D}^\dagger = -D^2 - \mathrm{ad}^2_\phi \geq 0$ forces $H^0 = H^2 = 0$. Taubes' index gives $\dim \mathcal{M}'_k = 4k$.
- For $k = 1$ the four zero modes are three translations $(\iota_j F, D_j\phi)$ and the phase mode $(\mathrm{d}_A\phi, 0)$, each of squared length $4\pi C$.
- $\mathcal{M}'_k \to \mathcal{M}_k = \mathcal{M}'_k/S^1 \to \mathcal{M}^0_k$, of dimensions $4k, 4k-1, 4k-4$; for $k = 1$: $\mathbb{R}^3 \times S^1, \mathbb{R}^3$, point.
- $\mathcal{M}'_k \cong \mathrm{Rat}_k$, based rational maps of degree k; poles $\approx$ monopole positions; $1/z^k$ is the axially symmetric monopole.

8.16 Monopole dynamics: forces and the geodesic approximation

So far every monopole in this part has been static. We found the charge-k solutions and we found that they form a $4k$-dimensional family $\mathcal{M}'_k$. Now we set them in motion. The questions of this section and the next are:

> *Do monopoles exert forces on each other? If two of them are sent towards each other, what comes out? And why does the answer need the geometry of $\mathcal{M}'_k$?*

Nash's answer (pp. 253–256) has three steps, and we follow them.

1. Static BPS monopoles exert *no* net force on each other: the energy $E = 4\pi C k$ does not depend on where they are.
2. Slowly moving monopoles therefore stay close to the bottom of the energy valley, which is $\mathcal{M}'_k$. Their motion is governed by the kinetic energy alone, and kinetic energy is a metric. The motion is a **geodesic** of that metric on $\mathcal{M}'_k$ (Manton).
3. The metric is **hyperkähler**. That property, together with rotational symmetry, fixes the metric for $k = 2$ (Atiyah–Hitchin), and its geodesics show two famous effects: head-on collisions scatter at 90°, and glancing collisions can turn monopoles into dyons.

This section does steps 1 and 2 and the general hyperkähler geometry; the next section does the $k = 2$ case.

8.16.1 The energy is linear in k: no static forces

Recall the Bogomolny bound (Section 8.13.3): with our normalisation, every finite-energy configuration of magnetic charge $k > 0$ obeys $E \geq 4\pi C k$, with equality exactly for solutions of the Bogomolny equation. So *every* point of $\mathcal{M}'_k$ has the same energy,

$$E\big|_{\mathcal{M}'_k} = 4\pi C k, \tag{8.333}$$

Nash's (8.191) (he sets $C = 1$). Two consequences:

- E is linear in k. A charge-k solution weighs exactly as much as k separate unit monopoles. There is no binding energy.
- On the family of k well-separated unit monopoles, E does not depend on the separations. A potential energy that does not depend on position gives no force: $-\partial E/\partial \vec{x}_i = 0$.

This is surprising. Like magnetic charges repel. So something must attract them with exactly the same strength. That something is the Higgs field.

Worked example 8.146: Magnetic repulsion versus Higgs attraction

Put two unit monopoles a large distance d apart. Far from its core, a unit monopole looks like a point source with two long-range fields (Section 8.13.6):

- a Coulomb *magnetic* field along the Higgs direction, $b_i = (B_i, \hat{\phi}) = -\hat{x}_i/r^2$, i.e. a point magnetic charge g with $b = g\,\hat{\vec{x}}/(4\pi r^2)$ (Heaviside–Lorentz units), $|g| = 4\pi$;
- a Coulomb *Higgs* tail, $|\phi| = C - 1/r$, because the Higgs field is massless in the Prasad–Sommerfield limit.

The magnetic interaction energy of two like point poles is the same as that of two like point charges:

$$\begin{aligned} U_{\text{mag}} &\overset{(1)}{=} \int_{\mathbb{R}^3} \vec{b}_1 \cdot \vec{b}_2 \, \mathrm{d}^3x \overset{(2)}{=} \frac{g^2}{16\pi^2} \int_{\mathbb{R}^3} \nabla\frac{1}{r_1} \cdot \nabla\frac{1}{r_2} \, \mathrm{d}^3x \\ &\overset{(3)}{=} \frac{g^2}{16\pi^2} \int_{\mathbb{R}^3} \frac{1}{r_1} \, 4\pi\delta^3(\vec{x} - \vec{x}_2) \, \mathrm{d}^3x \overset{(4)}{=} \frac{g^2}{4\pi d} = \frac{4\pi}{d}. \end{aligned}$$

(1) The field energy is $\frac{1}{2}\int |\vec{b}_1 + \vec{b}_2|^2$; the self-energies do not depend on d, and the cross term is $\int \vec{b}_1 \cdot \vec{b}_2$.
(2) $\vec{b}_j = -\frac{g}{4\pi}\nabla(1/r_j)$ with $r_j = |\vec{x} - \vec{x}_j|$.
(3) Integrate by parts (the boundary term vanishes like $1/R$) and use $-\nabla^2(1/r_2) = 4\pi\delta^3(\vec{x} - \vec{x}_2)$.
(4) Evaluate $1/r_1$ at $\vec{x}_2$, where $r_1 = d$; then $g^2 = 16\pi^2$.

Now the Higgs field. The mass of a monopole is $4\pi C$, and C is the length of the Higgs field at the monopole's location. Monopole 2 sits in the tail of monopole 1, where the Higgs field has length $C - 1/d$. So its mass, and hence the total energy, changes by

$$U_{\text{Higgs}} = 4\pi\left(C - \frac{1}{d}\right) - 4\pi C = -\frac{4\pi}{d}.$$

The total interaction energy is

$$U_{\text{mag}} + U_{\text{Higgs}} = \frac{4\pi}{d} - \frac{4\pi}{d} = 0.$$

In terms of forces: a magnetic repulsion $4\pi/d^2$ and a scalar attraction $4\pi/d^2$, which cancel exactly.

Worked example 8.147: A monopole and an antimonopole attract

Replace monopole 2 by an antimonopole (charge $k = -1$, obtained for instance by reflecting the hedgehog). Its magnetic charge is $-g$, so the magnetic force becomes an attraction of strength $4\pi/d^2$. The Higgs tail is still $|\phi| = C - 1/r$: both objects *lower* the length of the Higgs field near them, since $|\phi| = 0$ in both cores. So the scalar force is still attractive. Total:

$$F = -\frac{4\pi}{d^2} - \frac{4\pi}{d^2} = -\frac{8\pi}{d^2} \qquad \text{(attractive)}.$$

There is no static monopole–antimonopole solution of the Bogomolny equation (it would have $k = 0$ and hence $E = 0$). Whether some *non-minimal* static solution exists in the $k = 0$ sector is a question of critical point theory, and we return to it in Section 8.18.

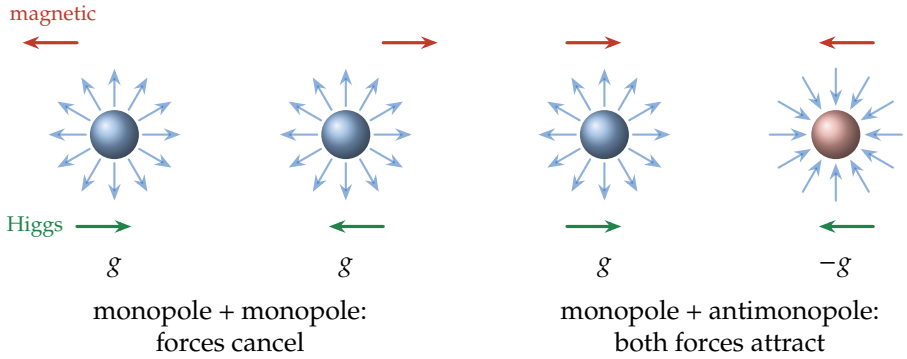

Figure 8.74: Forces between static BPS monopoles at large separation. Red arrows: the magnetic Coulomb force on each object; green arrows: the force from exchange of the massless Higgs field. For two monopoles (left) they have equal size and opposite direction, which is why the energy $4\pi Ck$ does not depend on the positions. For a monopole and an antimonopole (right) both attract.

Physical picture: Why the particle picture breaks down at short distance

The cancellation above is a statement about far-apart monopoles, each seen as a point. When they come within a distance of order $1/C$ (the size of the core, fixed by the W mass C) the cores overlap and there is no longer any sense in which there are "two objects". Nash stresses this: for $k \geq 2$ there are solutions whose charge is localised in one lump, for example the axially symmetric doughnut $f = 1/z^k$ of Example 8.145. Scattering is the process in which k separate lumps merge into such a configuration and then separate again. To describe it we need more than a force law; we need dynamics on the whole of $\mathcal{M}'_k$, including its core region.

8.16.2 Slow motion in a valley: the geodesic approximation

Here is the key idea, due to Manton, in a finite-dimensional setting. Think of a particle moving on a configuration space Q with Lagrangian

$$L = \tfrac{1}{2} G_{IJ}(X)\dot{X}^I \dot{X}^J - V(X),$$

where G_{IJ} is a metric on Q (the "mass matrix") and $V \geq V_0$ is a potential. Suppose the minimum of V is not a point but a whole submanifold $N \subset Q$, a flat-bottomed valley, and $V = V_0$ everywhere on N. Start the particle on N with a small velocity tangent to N. Then:

- it cannot climb the walls of the valley far, since it has little kinetic energy;
- along the bottom there is no force, since V is constant there;
- so it moves along N, driven by nothing except its own inertia.

"Moving by inertia" on a curved space means following a geodesic. We now make this precise.

Worked example 8.148: Kinetic energy on N gives the geodesic equation

Let z^r ($r = 1, \dots, \dim N$) be coordinates on N and $X(z)$ the embedding. A path $z(t)$ on N has velocity $\dot{X}^I = \partial_r X^I \, \dot{z}^r$, so the Lagrangian restricted to N is

$$L_N = \tfrac{1}{2} g_{rs}(z)\dot{z}^r \dot{z}^s - V_0, \qquad g_{rs} = G_{IJ}\, \partial_r X^I \, \partial_s X^J,$$

the **induced metric**. The Euler–Lagrange equation is

$$0 \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L_N}{\partial \dot{z}^r} - \frac{\partial L_N}{\partial z^r} \overset{(2)}{=} \frac{\mathrm{d}}{\mathrm{d}t}\big(g_{rs}\dot{z}^s\big) - \tfrac{1}{2}\,\partial_r g_{st}\,\dot{z}^s\dot{z}^t$$
$$\overset{(3)}{=} g_{rs}\ddot{z}^s + \partial_t g_{rs}\,\dot{z}^t\dot{z}^s - \tfrac{1}{2}\,\partial_r g_{st}\,\dot{z}^s\dot{z}^t \overset{(4)}{=} g_{rs}\ddot{z}^s + \tfrac{1}{2}\big(\partial_t g_{rs} + \partial_s g_{rt} - \partial_r g_{st}\big)\dot{z}^s\dot{z}^t,$$

(1) Euler–Lagrange equation for the coordinate z^r.
(2) $\partial L_N/\partial \dot{z}^r = g_{rs}\dot{z}^s$ (symmetry of g); V_0 is constant and drops out.
(3) Product rule; $\dot{g}_{rs} = \partial_t g_{rs}\dot{z}^t$ (here $\partial_t = \partial/\partial z^t$).
(4) Write $\partial_t g_{rs}\dot{z}^t\dot{z}^s$ as half of itself plus half of the same term with $s \leftrightarrow t$.

Multiplying by the inverse metric g^{ur} gives the geodesic equation

$$\ddot{z}^u + \Gamma^u_{st}\,\dot{z}^s\dot{z}^t = 0, \qquad \Gamma^u_{st} = \tfrac{1}{2}g^{ur}\big(\partial_s g_{rt} + \partial_t g_{rs} - \partial_r g_{st}\big). \tag{8.334}$$

The potential has disappeared completely: only the metric matters.

Worked example 8.149: A ball in a Mexican hat: when is the approximation good?

Take a unit mass in the plane with $V = \frac{\lambda}{4}(|\vec{x}|^2 - 1)^2$. The valley N is the unit circle. Write $\vec{x} = (1+\rho)(\cos\theta, \sin\theta)$. Then

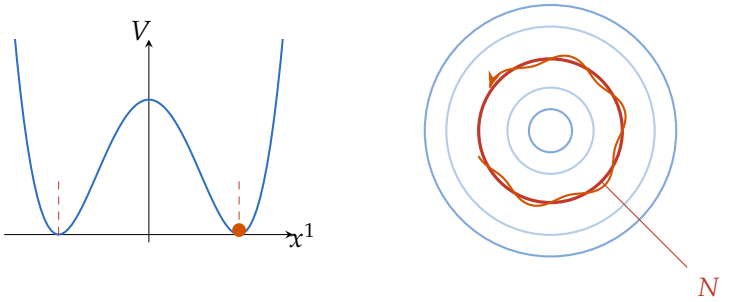
$$L \overset{(1)}{=} \tfrac{1}{2}\big(\dot\rho^2 + (1+\rho)^2\dot\theta^2\big) - \tfrac{\lambda}{4}\big((1+\rho)^2 - 1\big)^2$$
$$\overset{(2)}{=} \tfrac{1}{2}\big(\dot\rho^2 + (1+\rho)^2\dot\theta^2\big) - \lambda\rho^2\big(1 + \tfrac{\rho}{2}\big)^2.$$

(1) The flat metric in polar coordinates is $\mathrm{d}r^2 + r^2\mathrm{d}\theta^2$, with $r = 1+\rho$.
(2) $(1+\rho)^2 - 1 = 2\rho + \rho^2 = 2\rho(1+\rho/2)$.

The radial equation, to first order in ρ, is $\ddot\rho = (1+\rho)\dot\theta^2 - 2\lambda\rho + \dots$ For a uniform rotation $\dot\theta = \omega$ the radius settles at $\rho \approx \omega^2/(2\lambda)$: the centrifugal push is balanced by the stiffness of the wall. The motion on N ($\rho = 0$, $\theta = \omega t$, a geodesic of the circle) is a good approximation when

$$\omega^2 \ll \lambda,$$

i.e. when the speed is small compared with the "frequency" of oscillation across the valley. For monopoles the role of $\sqrt{\lambda}$ is played by the mass gap of the fields that are not zero modes: the W mass C (in units with $c = 1$). So the geodesic approximation should be good for speeds $v \ll 1$ (in units of the speed of light).



top view: orbit hugs the valley

Figure 8.75: The geodesic approximation in miniature. Left: the potential $V = \frac{\lambda}{4}(|\vec{x}|^2 - 1)^2$ along a line through the origin; its minimum set N (red) is a circle, not a point. Right: a slowly moving ball (orange) stays near the bottom of the valley, with small wiggles of amplitude $\omega^2/2\lambda$, and follows a geodesic of N. For monopoles, Q becomes the infinite-dimensional space $\mathcal{A}_{\mathrm{YMH}}/\mathcal{G}$ and N becomes $\mathcal{M}'_k$.

Dictionary: the geodesic approximation

configuration space Q	$\mathcal{A}_{\mathrm{YMH}}/\mathcal{G}$, pairs (A,ϕ) modulo gauge
potential V	static energy $E(A,\phi)$, Nash's (8.194)
valley bottom N, $V = V_0$	moduli space $\mathcal{M}'_k$, $E = 4\pi C k$
mass matrix G_{IJ}	the L^2 metric on field variations, Nash's (8.192)
induced metric g_{rs}	the moduli space metric
motion of the ball	slow monopole scattering

Reading Nash (p. 255, geodesics and the Morse energy functional)

Nash remarks that the equations of motion "are just those for the geodesics on $\mathcal{M}'_k$ . . . (compare with the geodesics giving the critical points of the Morse energy functional on

p. 206)". The link: a path $z(t)$, $0 \le t \le T$, is a geodesic iff it is a critical point of the energy functional $\mathcal{E}(z) = \frac{1}{2}\int_0^T g_{rs}\dot{z}^r\dot{z}^s\,\mathrm{d}t$ with fixed endpoints (the calculation in Example 8.148 is precisely $\delta\mathcal{E} = 0$). This functional is the one whose Morse theory computes the topology of the loop space in Chapter 7. The monopole's action on $\mathcal{M}'_k$ is $\int(L_N)\mathrm{d}t = \mathcal{E} - 4\pi Ck T$.

8.16.3 Kinetic energy on the space of fields and Gauss's law

To apply the idea to monopoles we need their kinetic energy. The static energy $E(A,\phi)$ came from a Lagrangian in $3+1$ dimensions. Write the time component of the gauge field as A_t, and let a dot denote $\partial/\partial t$. The electric field and the time covariant derivative of ϕ are

$$E_i \overset{(1)}{=} F_{ti} = \partial_t A_i - \partial_i A_t + [A_t, A_i] \overset{(2)}{=} \dot{A}_i - D_i A_t,$$
$$D_t\phi \overset{(3)}{=} \dot{\phi} + [A_t,\phi] = \dot{\phi} - [\phi, A_t].$$

(1) $F = \mathrm{d}A + A\wedge A$ in components: $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + [A_\mu, A_\nu]$.
(2) $D_iA_t = \partial_i A_t + [A_i, A_t]$ and $[A_t, A_i] = -[A_i, A_t]$.
(3) Definition of the covariant derivative of an adjoint field.

The Yang–Mills–Higgs Lagrangian (in the Prasad–Sommerfield limit, with signature $(+,-,-,-)$ so that energies are positive) is

$$\mathcal{L} = \tfrac{1}{2}\left(\|E\|^2 + \left\|D_t\phi\right\|^2\right) - \tfrac{1}{2}\left(\|F\|^2 + \left\|\mathrm{d}_A\phi\right\|^2\right) = T - E(A,\phi), \tag{8.335}$$

with the norms of (8.266) taken over $\mathbb{R}^3$ at fixed time. The second bracket is the static energy of Nash's (8.141) and (8.194). The first is the kinetic energy. The two together say $\mathcal{L} = T - V$, as in the finite-dimensional model.

Now look at the formulas for E_i and $D_t\phi$ again. With $\dot{m} = (\dot{A}, \dot{\phi})$ the velocity of the configuration and $D_0 f = (\mathrm{d}_A f, [\phi, f])$ the infinitesimal gauge transformation (8.321),

$$(E,\ D_t\phi) = \dot{m} - D_0 A_t, \qquad T = \tfrac{1}{2}\left\|\dot{m} - D_0 A_t\right\|^2. \tag{8.336}$$

The field A_t has no time derivative in $\mathcal{L}$: it is not dynamical. Its equation of motion is a constraint, obtained by varying $A_t \mapsto A_t + sf$:

$$0 \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}s}\Big|_{s=0} \tfrac{1}{2}\left\|\dot{m} - D_0A_t - sD_0 f\right\|^2 \overset{(2)}{=} -\left\langle \dot{m} - D_0A_t,\ D_0 f\right\rangle \overset{(3)}{=} -\left\langle D_0^\star(\dot{m} - D_0A_t),\ f\right\rangle.$$

(1) Only T contains A_t, through (8.336); D_0 is linear.
(2) Differentiate the square of a norm.
(3) Definition of the adjoint operator $D_0^\star$.

This holds for all f, so $D_0^\star(E, D_t\phi) = 0$. By (8.326) this reads

$$D_iE_i + [\phi, D_t\phi] = 0, \tag{8.337}$$

which is **Gauss's law**: $\nabla\cdot\vec{E} = \rho$, with the charge density $\rho = -[\phi, D_t\phi]$ carried by the moving Higgs field.

Key idea: The meaning of Nash's projection

Gauss's law says that the physical velocity $(E, D_t\phi)$ is *orthogonal to the gauge orbit*. Since T is a positive quadratic function of A_t, the constraint picks the A_t that *minimises* T: $\dot{m} - D_0A_t$

is the part of $\dot m$ orthogonal to $\operatorname{Im} D_0$. So

$$T = \tfrac{1}{2}\,\|P\dot m\|^2\,, \qquad P = \text{orthogonal projection onto } (\operatorname{Im} D_0)^\perp = \operatorname{Ker} D_0^\star .$$

This is the precise meaning of Nash's sentence "this metric descends to the configuration space $\mathcal{A}_{\mathrm{YMH}}/\mathcal{G}$ if we project onto those (a,η) orthogonal to the orbit". The projection is not a choice; it is Gauss's law.

Working definition 8.45 (the moduli space metric, operationally)

Let z^r be coordinates on $\mathcal{M}'_k$ [the framed moduli space, Bogomolny solutions modulo based gauge transformations] and $m(z) = (A(z), \phi(z))$ a family of Bogomolny solutions. For each r:

1. differentiate: $\partial_r m = (\partial A/\partial z^r,\ \partial\phi/\partial z^r)$; it solves the linearised Bogomolny equation, $D_1(\partial_r m) = 0$;
2. add a gauge direction to put it in the slice [the vectors with $D_0^\star(a,\eta) = 0$, orthogonal to the gauge orbit]: $\delta_r m = \partial_r m - D_0\varepsilon_r$ with ε_r chosen so that $D_0^\star \delta_r m = 0$ (Gauss's law);
3. take inner products:

$$g_{rs} = \langle \delta_r m, \delta_s m\rangle = -2\int_{\mathbb{R}^3} \operatorname{tr}\big(\delta_r A \wedge \star\delta_s A\big) - 2\int_{\mathbb{R}^3} \operatorname{tr}\big(\delta_r\phi\,\delta_s\phi\big)\,\mathrm{d}^3x. \tag{8.338}$$

Then $T = \tfrac{1}{2} g_{rs}\dot z^r \dot z^s$. In practice one computes the zero modes of $\mathcal{D}$ in Example 8.138, which already satisfy the slice condition.

Key idea: Manton's geodesic approximation

Slowly moving BPS monopoles of charge k are described, to a good approximation, by a path $z(t)$ in $\mathcal{M}'_k$ with Lagrangian

$$L_{\mathrm{eff}} = \tfrac{1}{2} g_{rs}(z)\,\dot z^r \dot z^s - 4\pi C k.$$

The equations of motion are the geodesic equations (8.334) of the metric (8.338). Monopole scattering at low speeds *is* geodesic motion on $\mathcal{M}'_k$.

Nash's (8.192)–(8.194) write the same thing with coordinates X^I on $\mathcal{A}_{\mathrm{YMH}}$. The approximation was later proved to be valid for small speeds (Stuart): true solutions of the time-dependent field equations with initial data close to $\mathcal{M}'_k$ and small initial velocity stay close, for long times, to the geodesic.

Watch out: Factors in (8.192)–(8.194)

Nash writes $T = \langle \dot m, \dot m\rangle$ in (8.193) without the $\tfrac{1}{2}$ and the inner product with $-\operatorname{tr}$ instead of $-2\operatorname{tr}$. Neither factor affects the geodesics (an overall constant in a metric does not change its geodesics). We keep $T = \tfrac{1}{2}\|P\dot m\|^2$ with (8.266), which is what makes the metric coefficient of a translation equal to the mass of the monopole below.

8.16.4 One monopole: the metric on $\mathbb{R}^3 \times S^1$ and the dyon

We now compute the metric on $\mathcal{M}_1' = \mathbb{R}^3 \times S^1$, and part of it on every $\mathcal{M}_k'$. The zero modes of Section 8.15.5 are all we need.

Worked example 8.150: The translation metric is the total mass, for every k

Let (A, ϕ) be any Bogomolny solution of charge k. The translation zero modes are $\delta_j m = (\iota_{\partial_j} F,\ D_j\phi)$, i.e. $(\delta_j A)_k = F_{jk}$ and $\delta_j\phi = D_j\phi$ (Example 8.140). Then

$$\begin{aligned} g_{jl} &\overset{(1)}{=} \int_{\mathbb{R}^3} \Big(\sum_k (F_{jk}, F_{lk}) + (D_j\phi, D_l\phi) \Big) \mathrm{d}^3x \\ &\overset{(2)}{=} \int_{\mathbb{R}^3} \Big(\sum_k \varepsilon_{jkm}\varepsilon_{lkn}(B_m, B_n) + (B_j, B_l) \Big) \mathrm{d}^3x \\ &\overset{(3)}{=} \int_{\mathbb{R}^3} \Big(\delta_{jl}|B|^2 - (B_l, B_j) + (B_j, B_l) \Big) \mathrm{d}^3x \overset{(4)}{=} \delta_{jl} \int_{\mathbb{R}^3} |B|^2 \, \mathrm{d}^3x \overset{(5)}{=} 4\pi C k \, \delta_{jl}. \end{aligned}$$

(1) The metric (8.338) written with the pointwise product $(X, Y) = -2\,\mathrm{tr}(XY)$ and components.
(2) $F_{jk} = \varepsilon_{jkm} B_m$, and the Bogomolny equation $D_j\phi = -B_j$.
(3) $\varepsilon_{jkm}\varepsilon_{lkn} = \delta_{jl}\delta_{mn} - \delta_{jn}\delta_{ml}$.
(4) The last two terms cancel.
(5) On a Bogomolny solution $|B| = |D\phi|$, so $\int |B|^2 = \frac{1}{2}\int (|B|^2 + |D\phi|^2) = E = 4\pi C k$.

So $\frac{1}{2} g_{jl} \dot{X}^j \dot{X}^l = \frac{1}{2}(4\pi C k)|\dot{\vec{X}}|^2$: the centre of mass $\vec{X}$ moves like a free particle whose inertial mass equals the rest energy $4\pi C k$. This is the "no accident" promised in Example 8.140. It is Einstein's $E = Mc^2$ seen through the moduli space. Notice that we did not need spherical symmetry.

Worked example 8.151: The phase direction, and orthogonality

The phase rotation (8.317) is generated by $f = \phi/C$, so its tangent vector is $\delta_\chi m = D_0(\phi/C) = (\mathrm{d}_A\phi/C,\, 0)$. Its length:

$$g_{\chi\chi} \overset{(1)}{=} \frac{1}{C^2} \int_{\mathbb{R}^3} |D\phi|^2 \, \mathrm{d}^3x \overset{(2)}{=} \frac{4\pi C k}{C^2} = \frac{4\pi k}{C}.$$

(1) Only the A-component is non-zero.
(2) $\int |D\phi|^2 = \int |B|^2 = 4\pi C k$, as in the previous example.

It is orthogonal to the translations:

$$g_{j\chi} \overset{(1)}{=} \frac{1}{C} \int_{\mathbb{R}^3} \sum_k (F_{jk}, D_k\phi)\, \mathrm{d}^3x \overset{(2)}{=} -\frac{1}{C} \int_{\mathbb{R}^3} \varepsilon_{jkm}(D_m\phi, D_k\phi)\, \mathrm{d}^3x \overset{(3)}{=} 0.$$

(1) Pair $(\iota_{\partial_j} F, D_j\phi)$ with $(\mathrm{d}_A\phi/C, 0)$; only the 1-form parts meet.
(2) $F_{jk} = \varepsilon_{jkm} B_m = -\varepsilon_{jkm} D_m\phi$.
(3) ε_{jkm} is antisymmetric in k, m and $(D_m\phi, D_k\phi)$ is symmetric.

For $k = 1$ these four modes span $T\mathcal{M}_1'$, so

$$\boxed{\mathrm{d}s^2_{\mathcal{M}_1'} = 4\pi C\, |\mathrm{d}\vec{X}|^2 + \frac{4\pi}{C}\, \mathrm{d}\chi^2, \qquad \chi \sim \chi + 2\pi} \tag{8.339}$$

a flat metric on $\mathbb{R}^3 \times S^1$, the circle having radius $\sqrt{4\pi/C}$.

For $k \geq 2$ the same four directions (overall translation and overall phase) exist and have the metric $4\pi C k|\mathrm{d}\vec{X}|^2 + (4\pi k/C)\mathrm{d}\chi^2$. The remaining $4k-4$ directions are the *relative* motions, and one can show that they are orthogonal to these four. So, up to a finite covering,

$$\mathcal{M}'_k \cong \mathbb{R}^3 \times S^1 \times \mathcal{M}^0_k \quad \text{(as Riemannian manifolds, up to a } \mathbb{Z}_k \text{ quotient)},$$

with a flat metric on the first two factors. The centre of mass and the overall phase move freely, and all the interesting scattering happens on $\mathcal{M}^0_k$. This is why Nash says "it is the flow on this latter space which contains the interesting scattering information".

Worked example 8.152: Geodesics on $\mathbb{R}^3 \times S^1$: moving monopoles and dyons

Geodesics of the flat metric (8.339) are straight lines: $\vec{X}(t) = \vec{X}_0 + \vec{v}t$ and $\chi(t) = \chi_0 + \omega t$. The first is a monopole moving at constant velocity. What is the second?
Its conserved momentum is $p_\chi = \partial L_{\text{eff}}/\partial\dot{\chi} = (4\pi/C)\,\omega$. To interpret it, look at the fields. In the gauge $A_t = 0$ the velocity is $\dot{m} = \omega\,\delta_\chi m$, so the electric field is

$$E_i = \dot{A}_i = \frac{\omega}{C}\,D_i\phi.$$

It obeys Gauss's law (8.337): $D_iE_i + [\phi, D_t\phi] = \frac{\omega}{C}D_iD_i\phi + 0 = 0$ by the field equation $\mathrm{d}_A^\star \mathrm{d}_A\phi = 0$. Far away, the electric field along the unbroken U(1) is

$$e_i = (E_i, \hat{\phi}) \overset{(1)}{=} \frac{\omega}{C}\,(D_i\phi, \hat{\phi}) \overset{(2)}{=} \frac{\omega}{C}\,\partial_i|\phi| \overset{(3)}{=} \frac{\omega}{C}\,\frac{\hat{x}_i}{r^2}.$$

(1) Take the component of E_i along the unit Higgs direction $\hat{\phi} = \phi/|\phi|$.
(2) $(D_i\phi, \phi) = \frac{1}{2}\partial_i|\phi|^2$, since the bracket term $[A_i, \phi]$ is orthogonal to ϕ.
(3) The Higgs tail $|\phi| = C - 1/r$.

A Coulomb field $e = q\,\hat{\vec{x}}/(4\pi r^2)$ has charge $q = 4\pi\omega/C$. So

$$p_\chi = \frac{4\pi\omega}{C} = q :$$

the momentum conjugate to the phase is the electric charge. A monopole whose phase rotates is a **dyon**, carrying both magnetic and electric charge (Julia–Zee). Its energy is

$$E = 4\pi C + \tfrac{1}{2}\cdot\frac{4\pi}{C}\,\omega^2 = 4\pi C + \frac{C\,q^2}{8\pi}.$$

Compare the exact BPS dyon, whose mass is $C\sqrt{g^2+q^2}$ with $g = 4\pi$:

$$C\sqrt{16\pi^2 + q^2} = 4\pi C\left(1 + \frac{q^2}{16\pi^2}\right)^{1/2} = 4\pi C + \frac{Cq^2}{8\pi} + O(q^4).$$

The geodesic approximation reproduces the first correction exactly, as a non-relativistic expansion should. Finally, χ is periodic, so in quantum mechanics p_χ is an integer (with $\hbar = 1$): *electric charge is quantised because the phase lives on a circle.* The unit is the charge of the W boson.

Watch out: Dyons need the phase to be a genuine coordinate

If the phase rotation were a gauge transformation to be divided out, χ would not be a coordinate and there would be no electric charge. This is exactly why $\mathcal{M}'_k$ keeps the gauge

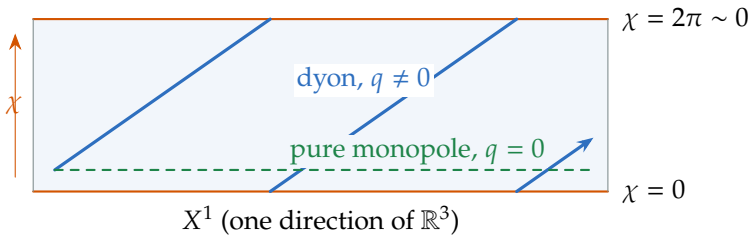


Figure 8.76: Geodesics on $\mathcal{M}_1' = \mathbb{R}^3 \times S^1$, drawn on the flat cylinder obtained by identifying the top and bottom edges. A horizontal line (green) is a monopole moving with constant velocity. A tilted line (blue) also winds around the phase circle: the phase rotates at a constant rate, and the rate is the electric charge. The slope is $\mathrm{d}\chi/\mathrm{d}X^1 = \omega/v = C^2 q/P$, where $P = 4\pi C v$ and q are the two conserved momenta.

transformations that are non-trivial at infinity (Section 8.15.6). Dividing by the circle gives $\mathcal{M}_k$ and forgets the charge; dividing also by $\mathbb{R}^3$ gives $\mathcal{M}_k^0$. For $k = 2$, $\mathcal{M}_2^0$ still contains the *relative* phase, and the relative electric charge will reappear as "spin" in Section 8.17.4.

8.16.5 Hyperkähler manifolds

To go beyond one monopole we need to know more about the metric. Nash's statement is that it is *hyperkähler*. We first recall Kähler metrics (Chapter 5), then build the quaternionic generalisation concretely on $\mathbb{R}^4$, then explain why monopole moduli spaces have it.

Kähler, recalled

A **complex structure** on a real vector space (or on each tangent space of a manifold) is a linear map J with $J^2 = -1$: "multiplication by i". A metric g is **Hermitian** if $g(JX, JY) = g(X, Y)$. Then the **Kähler form** $\omega(X, Y) = g(JX, Y)$ is antisymmetric:

$$\omega(Y, X) \overset{(1)}{=} g(JY, X) \overset{(2)}{=} g(J^2 Y, JX) \overset{(3)}{=} -g(Y, JX) \overset{(4)}{=} -g(JX, Y) = -\omega(X, Y).$$

(1) Definition of ω.
(2) g is Hermitian: apply J to both arguments.
(3) $J^2 = -1$.
(4) g is symmetric.

So ω is a 2-form. The metric is **Kähler** if $\mathrm{d}\omega = 0$ (and J comes from complex coordinates). In complex coordinates, $\omega = \frac{i}{2} g_{j\bar{k}} \mathrm{d}z^j \wedge \mathrm{d}\bar{z}^k$, as Nash writes.

Worked example 8.153: The Kähler form of $\mathbb{C}$

On $\mathbb{C}$ with $z = x + iy$ and $g = \mathrm{d}x^2 + \mathrm{d}y^2$, i.e. $g_{z\bar{z}} = 1$:

$$\tfrac{i}{2} \mathrm{d}z \wedge \mathrm{d}\bar{z} = \tfrac{i}{2} (\mathrm{d}x + i\mathrm{d}y) \wedge (\mathrm{d}x - i\mathrm{d}y) = \tfrac{i}{2}(-2i)\, \mathrm{d}x \wedge \mathrm{d}y = \mathrm{d}x \wedge \mathrm{d}y.$$

Directly: $J\partial_x = \partial_y$, so $\omega(\partial_x, \partial_y) = g(\partial_y, \partial_y) = 1$. The Kähler form is the area form. It is closed trivially (constant coefficients).

Three complex structures: the quaternions

Working definition 8.46 (hyperkähler manifold)

A Riemannian manifold (M, g) is **hyperkähler** if it carries three complex structures [maps I of each tangent space to itself with $I^2 = -1$, like multiplication by i] I, J, K satisfying the quaternion relations, Nash's (8.195),

$$I^2 = J^2 = K^2 = IJK = -1, \tag{8.340}$$

such that g is Hermitian for each [$g(IX, IY) = g(X, Y)$, and likewise for J and K], and the three Kähler forms, Nash's (8.196),

$$\omega_I(X, Y) = g(IX, Y), \qquad \omega_J(X, Y) = g(JX, Y), \qquad \omega_K(X, Y) = g(KX, Y) \tag{8.341}$$

are all closed. *How to test it:* exhibit the three 2-forms and check $\mathrm{d}\omega = 0$ for each. (Equivalently: the holonomy group of g [the rotations of a tangent space produced by parallel transport around loops] lies in $\mathrm{Sp}(n)$ [the length-preserving $n \times n$ quaternionic matrices, with $\dim M = 4n$], and such metrics are automatically Ricci-flat [Ric = 0, the vacuum Einstein equations].)

From (8.340) follow the familiar rules $IJ = K = -JI$, $JK = I = -KJ$, $KI = J = -IK$. For instance, multiplying $IJK = -1$ on the left by I gives $-JK = -I$, so $JK = I$; then $JI = J(JK) = J^2K = -K$. The rules imply that each unit combination is again a complex structure: for $a^2 + b^2 + c^2 = 1$,

$$\begin{aligned}(aI + bJ + cK)^2 &\overset{(1)}{=} a^2I^2 + b^2J^2 + c^2K^2 + ab(IJ + JI) + bc(JK + KJ) + ca(KI + IK) \\ &\overset{(2)}{=} -(a^2 + b^2 + c^2) \overset{(3)}{=} -1.\end{aligned}$$

(1) Multiply out, keeping the order of the non-commuting factors.
(2) $I^2 = J^2 = K^2 = -1$ and the anticommutators vanish.
(3) $a^2 + b^2 + c^2 = 1$.

So a hyperkähler manifold has a whole 2-sphere of complex structures, and is Kähler for each of them (Figure 8.77).

Worked example 8.154: $\mathbb{R}^4 = \mathbb{H}$: the complex structures as 4×4 matrices

Identify $(x^0, x^1, x^2, x^3) \in \mathbb{R}^4$ with the quaternion $q = x^0 + x^1\mathbf{i} + x^2\mathbf{j} + x^3\mathbf{k}$, where $\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = \mathbf{ijk} = -1$ (so $\mathbf{ij} = \mathbf{k}$, $\mathbf{jk} = \mathbf{i}$, $\mathbf{ki} = \mathbf{j}$). Let I, J, K be *left* multiplication by $\mathbf{i}, \mathbf{j}, \mathbf{k}$. Compute I:

$$\mathbf{i}\,q \overset{(1)}{=} x^0\mathbf{i} + x^1\mathbf{i}^2 + x^2\mathbf{ij} + x^3\mathbf{ik} \overset{(2)}{=} -x^1 + x^0\mathbf{i} - x^3\mathbf{j} + x^2\mathbf{k}.$$

(1) Distribute; real numbers commute with everything.
(2) $\mathbf{i}^2 = -1$, $\mathbf{ij} = \mathbf{k}$, $\mathbf{ik} = -\mathbf{ki} = -\mathbf{j}$; sort by units.

Doing the same for $\mathbf{j}$ and $\mathbf{k}$ (using $\mathbf{ji} = -\mathbf{k}$, $\mathbf{jk} = \mathbf{i}$, $\mathbf{ki} = \mathbf{j}$, $\mathbf{kj} = -\mathbf{i}$) gives

$$I = \begin{pmatrix} 0 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{pmatrix}, \quad J = \begin{pmatrix} 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{pmatrix}, \quad K = \begin{pmatrix} 0 & 0 & 0 & -1 \\ 0 & 0 & -1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}.$$

Each is an orthogonal antisymmetric matrix, so $g(IX, IY) = g(X, Y)$ and $I^2 = -I^TI = -1$. Check $IJ = K$ on a basis vector: $Je_0 = e_2$ (third column of J) and $Ie_2 = e_3$, so $IJe_0 = e_3 = Ke_0$;

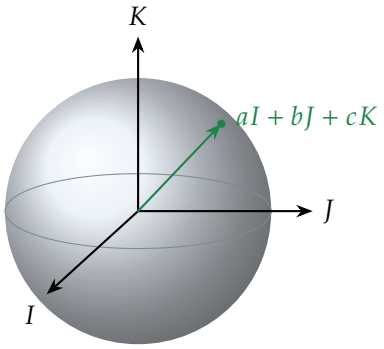
similarly on e_1, e_2, e_3. (Of course: $\mathbf{i}(\mathbf{j}q) = (\mathbf{ij})q = \mathbf{k}q$ by associativity.) The Kähler forms: $\omega_I(e_a, e_b) = g(Ie_a, e_b) = I_{ba}$. From $Ie_0 = e_1$ and $Ie_2 = e_3$,

$$\omega_I = \mathrm{d}x^0 \wedge \mathrm{d}x^1 + \mathrm{d}x^2 \wedge \mathrm{d}x^3,$$
$$\omega_J = \mathrm{d}x^0 \wedge \mathrm{d}x^2 + \mathrm{d}x^3 \wedge \mathrm{d}x^1,$$
$$\omega_K = \mathrm{d}x^0 \wedge \mathrm{d}x^3 + \mathrm{d}x^1 \wedge \mathrm{d}x^2.$$

All three are closed (constant coefficients), so $\mathbb{R}^4$ is hyperkähler. And all three are *self-dual*: $\star(\mathrm{d}x^0 \wedge \mathrm{d}x^1) = \mathrm{d}x^2 \wedge \mathrm{d}x^3$, etc. The three Kähler forms of $\mathbb{R}^4$ are a basis of Λ^2_+, the same space in which the curvature of an instanton lives.

Physical picture: Why hyperkähler means dimension $4n$

One complex structure makes each tangent space a complex vector space, so its real dimension is even. Three complex structures obeying the quaternion relations make it a vector space over the quaternions $\mathbb{H}$, so its real dimension is a multiple of 4: $\dim M = 4n$, as Nash says. This matches $\dim \mathcal{M}'_k = 4k$ and $\dim \mathcal{M}^0_k = 4k-4$. It does *not* fit $\mathcal{M}_k$ (dimension $4k-1$, odd), which is why $\mathcal{M}_k$ is not the space on which one does the geometry.



$a^2 + b^2 + c^2 = 1$: every point of the sphere is a complex structure, and g is Kähler for each.

spatial rotations of $\mathbb{R}^3$ rotate this sphere (Section 8.17.1)

Figure 8.77: The 2-sphere of complex structures of a hyperkähler manifold. The three axes are the quaternion units I, J, K; any unit combination squares to -1. For monopole moduli spaces the three axes correspond to the three components of the Bogomolny equation, so a rotation of physical space rotates the sphere.

Why monopole moduli spaces are hyperkähler

Two facts, one pointwise and one global.

Pointwise: each tangent space is quaternionic. In Example 8.138 we packaged a tangent vector (a, η) into the quaternion-valued field $q = \eta + a_i e_i$ and found that $T_m \mathcal{M}'_k = \operatorname{Ker} \mathcal{D}$ with $\mathcal{D}q = \sum_i e_i D_i q + [q, \phi]$. The operator uses *left* multiplication by the units e_i. Right multiplication by a quaternion commutes with left multiplication (associativity: $(uq)v = u(qv)$), and it commutes with D_i and with $[\,\cdot\,, \phi]$ (which act on the $\mathfrak{su}(2)$ factor). So if $q \in \operatorname{Ker} \mathcal{D}$ then $q\bar{e}_l \in \operatorname{Ker} \mathcal{D}$, where $\bar{e}_l = -e_l$ is the conjugate unit. Define

$$I\,q = q\,\bar{e}_1, \qquad J\,q = q\,\bar{e}_2, \qquad K\,q = q\,\bar{e}_3. \tag{8.342}$$

Then $IJq = q\,\bar{e}_2\bar{e}_1 = q\,e_2e_1 = -q\,e_3 = q\,\bar{e}_3 = Kq$, and $I^2q = q\,\bar{e}_1^2 = -q$: the quaternion relations hold. Right multiplication by a unit quaternion preserves the pointwise length $|q|^2$, so the L^2 metric is Hermitian for all three.

Worked example 8.155: The complex structures on $\mathcal{M}_1'$, explicitly

The phase mode is $(\mathrm{d}_A\phi, 0)$, i.e. $q_0 = \sum_i D_i\phi\, e_i$ (no real part). Apply I:

$$q_0\,\bar{e}_1 \overset{(1)}{=} -\sum_i D_i\phi\, e_i e_1 \overset{(2)}{=} -\sum_i D_i\phi\big(-\delta_{i1} + \varepsilon_{i1k}e_k\big) \overset{(3)}{=} D_1\phi + \sum_{i,k}\varepsilon_{1ik}D_i\phi\, e_k$$
$$\overset{(4)}{=} D_1\phi + \sum_{i,k}\varepsilon_{1ki}B_i\, e_k \overset{(5)}{=} D_1\phi + \sum_k F_{1k}\, e_k.$$

(1) Definition (8.342), $\bar{e}_1 = -e_1$; the real coefficients $D_i\phi$ commute with the units.
(2) Quaternion multiplication (8.327).
(3) The δ_{i1} term gives $D_1\phi$; and $-\varepsilon_{i1k} = \varepsilon_{1ik}$.
(4) Bogomolny, $D_i\phi = -B_i$, and $\varepsilon_{1ik} = -\varepsilon_{1ki}$.
(5) $F_{jk} = \varepsilon_{jkm}B_m$.

The result has real part $\eta = D_1\phi$ and imaginary part $a_k = F_{1k}$: it is exactly the translation mode $(\iota_{\partial_1}F, D_1\phi)$. So

$$I(\text{phase mode}) = \text{translation mode in the } x^1 \text{ direction},$$

and likewise J and K turn the phase mode into translations along x^2 and x^3. In the coordinates $(y, \vec{X})$ with $y = \chi/C$, the metric (8.339) is $4\pi C(\mathrm{d}y^2 + |\mathrm{d}\vec{X}|^2)$ and $I\partial_y = \partial_{X^1}$: this is $\mathbb{R}^4 = \mathbb{H}$ with y as the real coordinate, rolled up along y. So $\mathcal{M}_1'$ is hyperkähler, as the flat quotient $\mathbb{H}/\mathbb{Z}$.

Globally: the forms are closed. Pointwise quaternionic structure is not enough; the three Kähler forms must be closed. The reason is a general construction. Package the four fields into one quaternion-valued field $\mathbb{A} = \phi + A_1e_1 + A_2e_2 + A_3e_3$. The space of all such fields is a *flat* (infinite-dimensional) quaternionic vector space, so its three Kähler forms are constant, hence closed. The gauge group preserves them. For such a symmetry there are three **moment maps** (the "conserved charges" of the three symplectic forms, as angular momentum is for rotations), and here they are the three components of the Bogomolny expression:

$$\mu_i(A,\phi) = B_i + D_i\phi, \qquad i = 1,2,3.$$

So the Bogomolny equation says $\mu_1 = \mu_2 = \mu_3 = 0$.

Key idea: Hyperkähler quotient (Hitchin–Karlhede–Lindström–Roček)

If a group $\mathcal{G}$ acts on a hyperkähler manifold preserving g, I, J, K, with moment maps μ_1, μ_2, μ_3, then $\mu^{-1}(0)/\mathcal{G}$ is again hyperkähler. If the manifold is X, the quotient has dimension $\dim X - 4\dim\mathcal{G}$. Applied to the flat space of fields (A,ϕ) and the gauge group, it gives

$$\mathcal{M}_k' = \{B_i + D_i\phi = 0\}/\mathcal{G} \quad \text{is hyperkähler.}$$

Why dimension drops by 4 per generator: each gauge generator removes 3 dimensions through the three equations $\mu_i = 0$ and 1 more through the quotient. At the level of fields at a point: 4 real fields per Lie algebra direction (ϕ, A_1, A_2, A_3), minus 3 equations, minus 1 gauge freedom, leaves $4 - 3 - 1 = 0$ local degrees of freedom. That is why the solution space is finite-dimensional, and its dimension $4k$ is supplied by the index theorem.

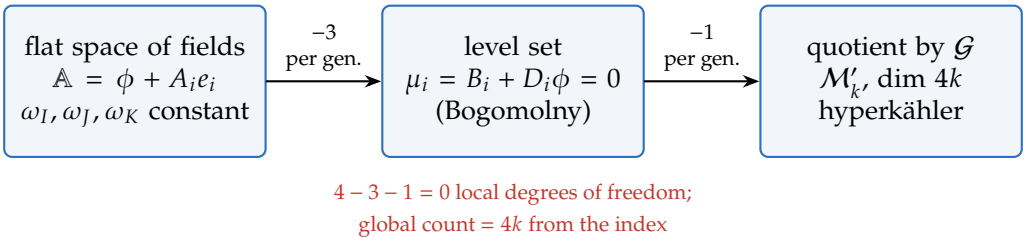


Figure 8.78: The hyperkähler quotient construction of the monopole moduli space. The three components of the Bogomolny equation are the three moment maps of the gauge action; imposing them and dividing by the gauge group preserves the hyperkähler structure.

Watch out: Which spaces are hyperkähler

$\mathcal{M}'_k$ (dimension $4k$) and $\mathcal{M}^0_k$ (dimension $4k-4$) are hyperkähler; $\mathcal{M}_k$ (dimension $4k-1$) cannot be. Nash's statement "the reduced moduli space $\mathcal{M}^0_k$ ... is also hyperkähler" uses the splitting $\mathcal{M}'_k \approx \mathbb{R}^3 \times S^1 \times \mathcal{M}^0_k$ above: the flat factor $\mathbb{R}^3 \times S^1$ is hyperkähler (Example 8.155), and the complement inherits the structure. Geodesics on $\mathcal{M}'_k$ project to geodesics on $\mathcal{M}^0_k$ because the flat factor splits off orthogonally.

Physical picture: Why hyperkähler makes the metric computable

A general metric on a 4-manifold with an SO(3) symmetry depends on several arbitrary functions of one variable. Demanding that it be hyperkähler turns those functions into solutions of a system of first-order ODEs, and demanding the right behaviour at large separation (point monopoles) and regularity picks a unique solution. So the metric on $\mathcal{M}^0_2$ can be found *without* solving the Bogomolny equation for two monopoles. This is what Nash means by "the hyperkählerity of the metric is a key factor in rendering it computable". We do it in the next section.

Reading Nash (pp. 253–255, (8.191)–(8.196))

Nash notes $E = 4\pi k$ (8.191) and deduces the absence of forces between well-separated monopoles, observes that the particle picture breaks down when they come close, and introduces Manton's idea: the L^2 metric (8.192) on $\mathcal{A}_{\mathrm{YMH}}$, projected orthogonally to gauge orbits, the kinetic energy (8.193) and potential energy (8.194), and the conclusion that slow motion is geodesic motion on $\mathcal{M}'_k$. He then recalls Kähler metrics and defines hyperkähler ones by (8.195)–(8.196). We added: the force balance behind (8.191), the derivation of the geodesic equation and the Mexican-hat model, the identification of the projection with Gauss's law, the exact translation and phase metrics, the dyon and charge quantisation, explicit quaternion matrices and Kähler forms, the quaternionic structure of the zero modes, and the hyperkähler quotient.

Recap

- $E = 4\pi C k$ on all of $\mathcal{M}'_k$: magnetic repulsion and Higgs attraction cancel, so static monopoles exert no net force.
- Slow motion stays near the valley bottom $\mathcal{M}'_k$ and follows geodesics of the induced (L^2) metric. The orthogonal projection off gauge orbits is Gauss's law.
- The translation metric is $4\pi C k\, \delta_{jl}$ (inertial mass = rest energy); the phase metric is

$4\pi k/C$. For $k = 1$: flat $\mathbb{R}^3 \times S^1$. Motion around the phase circle is a dyon, with electric charge = momentum of the phase.

- Hyperkähler: three complex structures with quaternion relations and three closed Kähler forms; dimension $4n$. On $\mathbb{R}^4$ they are left multiplication by $\mathbf{i}, \mathbf{j}, \mathbf{k}$ and their forms span Λ^2_+.
- $\mathcal{M}'_k$ is a hyperkähler quotient: the three Bogomolny components are moment maps for the gauge group.

8.17 Two monopoles: the Atiyah–Hitchin manifold and scattering

For $k = 2$ the relative moduli space $\mathcal{M}^0_2$ is four-dimensional. Atiyah and Hitchin found its metric, and its geodesics describe the slow scattering of two monopoles. Nash (pp. 255–256) describes the parameters and the two headline results in words. In this section we

- build the four parameters and the rotational symmetry explicitly;
- write the metric, check its asymptotic form, and plot it;
- derive the 90° scattering of head-on collisions in two independent ways;
- compute the scattering angle as a function of impact parameter;
- explain why glancing collisions produce dyons with spin.

Units: $C = 1$ throughout this section, so each monopole has mass 4π and core size of order 1.

8.17.1 The four parameters and the rotation group

Start with two well-separated monopoles, where the particle picture applies. $\mathcal{M}'_2$ has dimension $8 = 2 \times (3 + 1)$: two positions and two phases. Remove the centre of mass (3 parameters) and the overall phase (1 parameter). Four are left, Nash's description:

- the *relative position*: put the monopoles at $\pm\vec{x}$, so the separation is $2|\vec{x}|$ (3 parameters);
- the *relative phase*: encoded, as Nash says, by a unit vector $\vec{y}$ perpendicular to $\vec{x}$ (1 parameter: $\vec{y}$ lies on a circle in the plane orthogonal to $\vec{x}$).

Two identifications remove redundancy. The monopoles are identical, so $\vec{x}$ and $-\vec{x}$ describe the same configuration. And $\vec{y}$ and $-\vec{y}$ are identified (Nash says "for covering space reasons"): a relative phase $\chi_1 - \chi_2$ is recorded by $\vec{y}$ at *twice* its angle, so turning $\vec{y}$ by π is a full turn of the phase.

Worked example 8.156: The configurations form a space of frames

Given $(\vec{x}, \vec{y})$, set

$$\vec{e}_3 = \hat{\vec{x}}, \qquad \vec{e}_1 = \vec{y}, \qquad \vec{e}_2 = \vec{e}_3 \times \vec{e}_1.$$

This is an oriented orthonormal frame, i.e. a rotation matrix $R = (\vec{e}_1\, \vec{e}_2\, \vec{e}_3) \in \mathrm{SO}(3)$. Conversely a frame and a number $r = 2|\vec{x}|$ give back $(\vec{x}, \vec{y})$. So for well-separated monopoles

$$\mathcal{M}^0_2 \supset \{(r, R)\}/\sim \;=\; (r_{\min}, \infty) \times \mathrm{SO}(3)/D_2,$$

where the identifications $\vec{x} \to -\vec{x}$ (with $\vec{y}$ fixed, and hence $\vec{e}_2 \to -\vec{e}_2$) and $\vec{y} \to -\vec{y}$ (with $\vec{x}$ fixed) generate the group

$$D_2 = \{\mathbb{1},\ \mathrm{diag}(1,-1,-1),\ \mathrm{diag}(-1,1,-1),\ \mathrm{diag}(-1,-1,1)\}$$

acting on the right, i.e. on the frame vectors. Each non-identity element is a rotation by π about one frame axis. Dimension count: $1 + 3 = 4$. ✓

The rotation group SO(3) of physical space acts on $\mathcal{M}_2^0$ by rotating both monopoles: $R \mapsto R_0 R$. This is an isometry of the metric (the energy and the kinetic energy are rotation invariant). So the metric is determined by its values along a single curve transverse to the orbits, parametrised by r. This is the key simplification: *a metric with* SO(3) *symmetry on a 4-manifold with 3-dimensional orbits depends only on functions of one variable.*

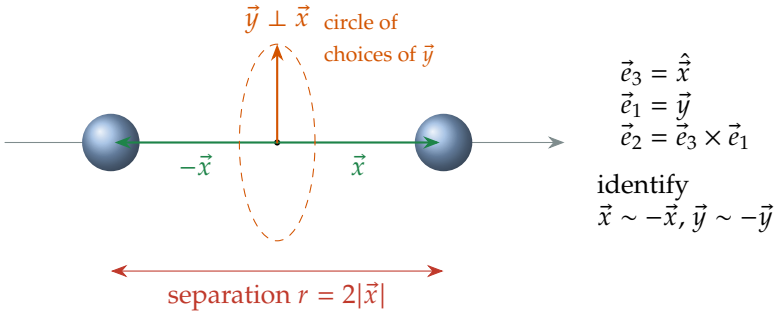

Figure 8.79: Nash's parameters for two well-separated monopoles: the half-separation vector $\vec{x}$ (3 numbers) and a unit vector $\vec{y}$ perpendicular to it (1 number, the relative phase). Together they define an orthonormal frame, so the configuration space is (separation)×SO(3), modulo the four-element group D_2 of sign flips.

The metric

Let $\sigma_1, \sigma_2, \sigma_3$ be the left-invariant 1-forms on SO(3): if $R(t)$ is a path of rotations, $R^{-1}\dot{R}$ is an antisymmetric matrix with entries $\varepsilon_{ijk}\,\omega_k$, and $\sigma_k(\dot{R}) = \omega_k$ is the angular velocity *about the body axis* $\vec{e}_k$. With the sign conventions of Atiyah and Hitchin they satisfy $\mathrm{d}\sigma_1 = \sigma_2 \wedge \sigma_3$ and cyclically. Rotation invariance of the metric under $R \mapsto R_0 R$ means that it is built from $\mathrm{d}r$ and the σ's with coefficients depending only on r. Invariance under the finite group D_2 (which flips the signs of two of the σ's) removes the cross terms. So

$$\mathrm{d}s^2 = f(r)^2\,\mathrm{d}r^2 + a(r)^2\,\sigma_1^2 + b(r)^2\,\sigma_2^2 + c(r)^2\,\sigma_3^2. \tag{8.343}$$

The coefficients a^2, b^2, c^2 are the *moments of inertia* for rotations about the three body axes: a about $\vec{y}$, b about $\vec{e}_2$, c about the line joining the monopoles.

Key idea: The Atiyah–Hitchin metric

The metric (8.343) is hyperkähler, with the SO(3) action rotating the 2-sphere of complex structures (Figure 8.77), if and only if

$$\frac{2bc}{f}\frac{\mathrm{d}a}{\mathrm{d}r} = (b-c)^2 - a^2, \qquad \frac{2ca}{f}\frac{\mathrm{d}b}{\mathrm{d}r} = (c-a)^2 - b^2, \qquad \frac{2ab}{f}\frac{\mathrm{d}c}{\mathrm{d}r} = (a-b)^2 - c^2. \tag{8.344}$$

The function f is a choice of radial coordinate; Atiyah and Hitchin take $f = -b/r$. The unique solution that is smooth and describes two monopoles at large r has

$$a \to 0, \quad b \to \pi, \quad c \to -\pi \qquad (r \to \pi), \tag{8.345}$$

and, up to exponentially small terms as $r \to \infty$,

$$a \approx b \approx r\sqrt{1 - \tfrac{2}{r}}, \qquad c \approx -\frac{2}{\sqrt{1 - 2/r}}. \tag{8.346}$$

Asymptotically r is the separation of the monopoles. The solution can be written with complete elliptic integrals: $r = 2K(\kappa)$, with κ running from 0 (where $K = \pi/2$, the value $r = \pi$) to 1 ($K \to \infty$).

Why the SO(3) *rotates the complex structures.* In the hyperkähler quotient of Section 8.16.5, the three complex structures correspond to the three components $\mu_i = B_i + D_i\phi$ of the Bogomolny equation, i.e. to the three directions of physical space. A rotation of space rotates (μ_1, μ_2, μ_3) as a vector, and so rotates (I, J, K). The three Kähler forms are therefore not individually SO(3)-invariant; they rotate into one another. Demanding that this rotating triple be closed is what produces the equations (8.344). (If the complex structures were fixed instead, one would get the simpler "Euler" system $2\,(bc)' = \dots$ that describes the Eguchi–Hanson and Taub–NUT metrics.)

Worked example 8.157: The asymptotic metric solves the equations exactly

Set $u = 1 - 2/r$, so $u' = 2/r^2$. Take the asymptotic forms as exact trial functions: $a = b = r\sqrt{u}$, $c = -2/\sqrt{u}$, and $f = -b/r = -\sqrt{u}$. The third equation:

$$\frac{2ab}{f}\,c' \overset{(1)}{=} \frac{2r^2u}{-\sqrt{u}} \cdot \frac{2}{r^2u^{3/2}} \overset{(2)}{=} -\frac{4}{u} \overset{(3)}{=} -c^2 \overset{(4)}{=} (a-b)^2 - c^2.$$

(1) $ab = r^2u$; and $c' = -2 \cdot (-\tfrac{1}{2})u^{-3/2}u' = u^{-3/2} \cdot \tfrac{2}{r^2}$.
(2) Collect powers: $u \cdot u^{-1/2} \cdot u^{-3/2} = u^{-1}$.
(3) $c^2 = 4/u$.
(4) $a = b$.

The first equation (the second is the same, since $a = b$):

$$\frac{2bc}{f}\,a' \overset{(1)}{=} \frac{2r\sqrt{u}\,(-2/\sqrt{u})}{-\sqrt{u}} \cdot \frac{r-1}{r\sqrt{u}} \overset{(2)}{=} \frac{4(r-1)}{u},$$

$$(b-c)^2 - a^2 \overset{(3)}{=} c^2 - 2ac \overset{(4)}{=} \frac{4}{u} + 4r \overset{(5)}{=} \frac{4 + 4r - 8}{u} = \frac{4(r-1)}{u}.$$

(1) $a' = \sqrt{u} + \dfrac{ru'}{2\sqrt{u}} = \dfrac{ru+1}{r\sqrt{u}} = \dfrac{r-1}{r\sqrt{u}}$, using $ru = r - 2$.
(2) $2r\sqrt{u} \cdot (-2/\sqrt{u})/(-\sqrt{u}) = 4r/\sqrt{u}$; multiply.
(3) Expand $(a-c)^2 - a^2$ with $b = a$.
(4) $c^2 = 4/u$ and $-2ac = -2\,r\sqrt{u}\,(-2/\sqrt{u}) = 4r$.
(5) $4r = 4ru/u = 4(r-2)/u$.

Both sides agree. So the asymptotic metric is an exact hyperkähler metric by itself:

$$\mathrm{d}s^2_{\mathrm{TN}} = \left(1 - \frac{2}{r}\right)\left(\mathrm{d}r^2 + r^2(\sigma_1^2 + \sigma_2^2)\right) + \frac{4}{1 - 2/r}\,\sigma_3^2, \tag{8.347}$$

the **Taub–NUT metric with negative mass**. It is singular at $r = 2$, which is why the true Atiyah–Hitchin metric, which departs from it at $r \lesssim 6$, is needed.

Physical picture: What the asymptotic metric says physically

At large r, $\sigma_1^2 + \sigma_2^2 = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2$ in terms of the direction (θ, φ) of the separation vector, and $\sigma_3 = \mathrm{d}\psi + \cos\theta\,\mathrm{d}\varphi$ with ψ (half) the relative phase. So (8.347) is the flat metric $\mathrm{d}r^2 + r^2\mathrm{d}\Omega^2$ of the relative position, corrected by the factor $1 - 2/r$, plus a phase circle of radius about 2. The correction is a *velocity-dependent* interaction: the kinetic energy is $\frac{1}{2}(1 - 2/r)v^2$, so the force is of order v^2/r^2. Static monopoles do not interact, moving ones do. This is exactly what one gets by treating the two monopoles as point particles carrying magnetic, electric and scalar charge and keeping terms to order v^2 (Manton; Gibbons–Manton). The term $\cos\theta\,\mathrm{d}\varphi$ is a Dirac monopole potential on the sphere of directions: a moving dyon feels the magnetic field of the other monopole.

Worked example 8.158: Regularity at $r = \pi$: the bolt

Near $r = \pi$ put $\rho = r - \pi$. The first equation at $r = \pi$, with $b = \pi$, $c = -\pi$, $f = -b/r = -1$, $a = 0$:

$$\frac{2\pi(-\pi)}{-1}\,a'(\pi) \overset{(1)}{=} (\pi + \pi)^2 - 0 \quad\Longrightarrow\quad a'(\pi) \overset{(2)}{=} 2.$$

(1) Insert the boundary values (8.345) into (8.344).
(2) $2\pi^2 a'(\pi) = 4\pi^2$.

So $a \approx 2\rho$ and, near $r = \pi$, the metric along the rotations about $\vec{e}_1$ is

$$f^2\mathrm{d}r^2 + a^2\sigma_1^2 \approx \mathrm{d}\rho^2 + 4\rho^2\mathrm{d}\psi_1^2 = \mathrm{d}\rho^2 + \rho^2\mathrm{d}\Theta^2, \qquad \Theta = 2\psi_1,$$

where ψ_1 is the angle of rotation about $\vec{e}_1$ ($\sigma_1 = \mathrm{d}\psi_1$ along such rotations). These are polar coordinates on a plane, smooth at $\rho = 0$ *if and only if* Θ has period 2π, i.e. ψ_1 has period π. And indeed the rotation by π about $\vec{e}_1$ is in D_2. The circle of rotations about $\vec{e}_1$ shrinks to a point at $r = \pi$ (like the angular circle at the origin of polar coordinates), while the σ_2, σ_3 directions keep radius π. The set $r = \pi$ is a 2-dimensional surface, the **bolt**. Its points are configurations invariant under all rotations about $\vec{e}_1$: the axially symmetric doughnuts of Example 8.145, labelled by the direction of their axis $\vec{e}_1$ (up to sign).

8.17.2 Head-on collisions: scattering at right angles

Nash's first result: *when two monopoles collide head-on, they emerge along a line at right angles to the line of approach*. For point particles this would be absurd; a head-on collision of billiard balls or of charges sends them straight back. We give two explanations, one from the metric and one from the rational maps.

From the metric: passing through the bolt

A head-on collision has no angular momentum, and by symmetry the motion stays in the family where only r and the rotation angle ψ_1 about $\vec{e}_1 = \vec{y}$ vary: the separation axis $\vec{e}_3$ turns in the plane perpendicular to $\vec{y}$, and $\vec{y}$ stays fixed (Nash: "y is fixed"). On this family the metric is $f^2\mathrm{d}r^2 + a^2\mathrm{d}\psi_1^2$.

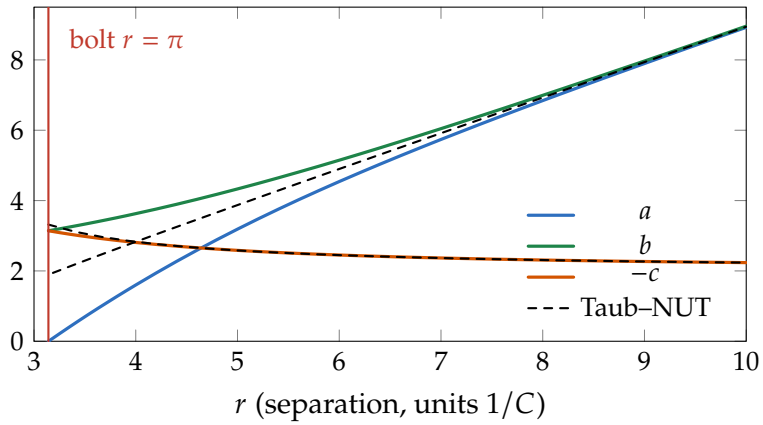

Figure 8.80: The Atiyah–Hitchin coefficients, from a numerical solution of (8.344) starting at the bolt (8.345). At $r = \pi$ the moment of inertia a^2 for rotations about $\vec{e}_1$ vanishes (the doughnut is symmetric about its axis) while $b = -c = \pi$. For $r \gtrsim 6$ the curves merge with the negative-mass Taub–NUT forms (8.346) (dashed): a and b both approach $r\sqrt{1-2/r}$, and $-c$ approaches $2/\sqrt{1-2/r} \to 2$. The differences decay like e^{-r} (at $r = 10$ they are about 0.02, at $r = 20$ about 3×10^{-6}).

Worked example 8.159: Why a radial geodesic turns by 90°

With zero angular momentum the geodesic is radial: ψ_1 is constant and r decreases to π. What happens next is seen in the smooth coordinates of Example 8.158:

$$\begin{aligned} \text{incoming ray: } \Theta = \Theta_0,\ \rho \downarrow 0 &\overset{(1)}{\Longrightarrow} \text{outgoing ray: } \Theta = \Theta_0 + \pi,\ \rho \uparrow \\ &\overset{(2)}{\Longrightarrow} \psi_1 \mapsto \psi_1 + \tfrac{\pi}{2} \\ &\overset{(3)}{\Longrightarrow} \vec{e}_3 \text{ rotated by } 90^\circ \text{ about } \vec{y}. \end{aligned}$$

(1) Near $\rho = 0$ the metric is the flat plane $\mathrm{d}\rho^2 + \rho^2 \mathrm{d}\Theta^2$; a straight line through the origin of a plane leaves along the opposite ray.
(2) $\Theta = 2\psi_1$.
(3) ψ_1 is the angle by which the frame is rotated about $\vec{e}_1$, and $\vec{e}_3$ is the direction of separation.

In the coordinate ψ_1 the geodesic looks as if it bent by 90°; in the smooth coordinate Θ it went straight. The "bending" is the halving $\psi_1 = \Theta/2$, i.e. the fact that the monopoles are identical and the configuration at $\psi_1 + \pi$ is the same as at ψ_1. The result does not depend on the incoming relative phase: every head-on geodesic reaches the bolt.

From rational maps: the poles rotate

The rational maps of Section 8.15.7 give a second, very concrete picture. Recall that the poles of the rational map mark (approximately, for well-separated monopoles) the positions of the monopoles projected on the (x^1, x^2)-plane, with $z = x^1 + ix^2$.

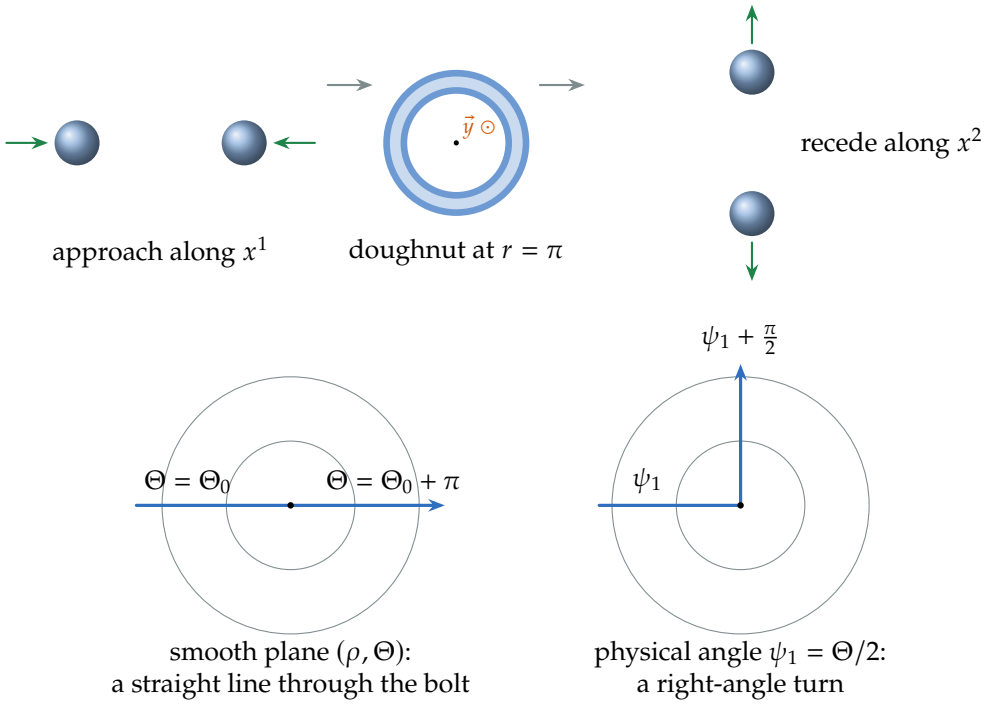

Figure 8.81: Right-angle scattering. Top: two monopoles approach head-on along the x^1-axis, merge into the axially symmetric doughnut (whose axis $\vec{y}$ points out of the page), and separate along the x^2-axis. Bottom: in the smooth coordinates (ρ, Θ) near the bolt the geodesic is a straight line through the origin (left); since the physical angle is $\psi_1 = \Theta/2$, the direction of separation turns by 90° (right).

Worked example 8.160: The family $f_\beta = 1/(z^2 - \beta)$

Consider the one-parameter family of based rational maps of degree 2

$$f_\beta(z) = \frac{1}{z^2 - \beta}, \qquad \beta \in \mathbb{R}.$$

Every member is a legitimate point of Rat_2: numerator 1 and denominator $z^2 - \beta$ have no common root. The poles are the roots of $z^2 = \beta$:

$$\begin{aligned} \beta = +\varepsilon > 0: &\quad z \overset{(1)}{=} \pm\sqrt{\varepsilon} && \text{(monopoles on the } x^1\text{-axis)}, \\ \beta = 0: &\quad z \overset{(2)}{=} 0 \text{ (double)} && \text{(the doughnut } 1/z^2\text{)}, \\ \beta = -\varepsilon < 0: &\quad z \overset{(3)}{=} \pm i\sqrt{\varepsilon} = e^{i\pi/2}\left(\pm\sqrt{\varepsilon}\right) && \text{(monopoles on the } x^2\text{-axis)}. \end{aligned}$$

(1) Real square roots.
(2) $z^2 = 0$.
(3) $\sqrt{-\varepsilon} = i\sqrt{\varepsilon}$, and multiplication by $i = e^{i\pi/2}$ is rotation by 90°.

As β decreases smoothly through 0, the pair of poles comes together along the real axis and leaves along the imaginary axis. A smooth path in the moduli space through the doughnut *is* a right-angle scattering. (The family is picked out by symmetry: it consists of the maps invariant under $z \mapsto -z$ and under complex conjugation, and a fixed set of isometries is totally geodesic, so it contains the head-on geodesic.) Compare with two point particles: their relative position $\pm\sqrt{\varepsilon}$ would have to pass through 0 and continue to $\mp\sqrt{\varepsilon}$, which is the *same* unordered pair, i.e. back-scattering or no scattering. The smooth coordinate on

$\mathcal{M}_2^0$ near coincidence is $\beta = z_1 z_2$-like, a symmetric function of the pole positions, not the positions themselves.

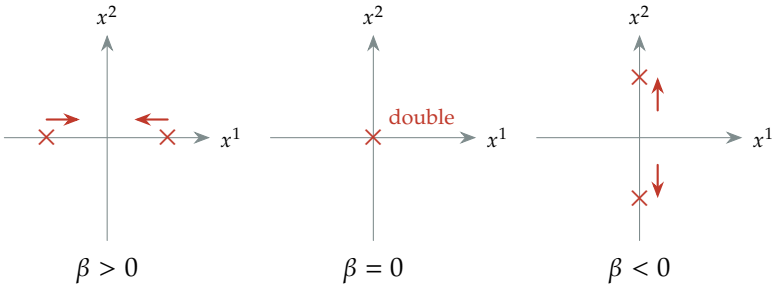

Figure 8.82: The poles of $f_\beta = 1/(z^2 - \beta)$ as β decreases through zero. They meet at the origin (the doughnut) and separate at right angles. The path in the space of rational maps is perfectly smooth: β is a good coordinate, the positions $\pm\sqrt{\beta}$ are not.

8.17.3 Scattering angle and impact parameter

Now give the collision an impact parameter L. We stay in the family of the previous subsection ($\vec{y}$ fixed, motion in the plane perpendicular to it), which is still consistent by symmetry. The metric on it is $f^2 \mathrm{d}r^2 + a^2 \mathrm{d}\psi_1^2$.

Worked example 8.161: The orbit equation

With unit speed and angular momentum ℓ, the Lagrangian $\frac{1}{2}(f^2\dot{r}^2 + a^2\dot{\psi}_1^2)$ gives

$$\ell = a^2\dot{\psi}_1, \qquad f^2\dot{r}^2 + a^2\dot{\psi}_1^2 = 1 \overset{(1)}{\Longrightarrow} \dot{r} = \pm\frac{1}{|f|}\sqrt{1 - \frac{\ell^2}{a^2}}$$
$$\overset{(2)}{\Longrightarrow} \frac{\mathrm{d}\psi_1}{\mathrm{d}r} = \frac{\dot{\psi}_1}{\dot{r}} = \pm\frac{\ell\,|f|}{a\sqrt{a^2 - \ell^2}}.$$

(1) ψ_1 is cyclic, so its momentum ℓ is conserved; substitute $\dot{\psi}_1 = \ell/a^2$ into the energy (speed) equation and solve for $\dot{r}$.

(2) Divide; $\sqrt{1 - \ell^2/a^2} = \sqrt{a^2 - \ell^2}/a$.

The monopoles come in from $r = \infty$ to the turning point r_0 with $a(r_0) = \ell$ and go out again, so the total rotation of the separation axis and the **scattering angle** are

$$\Delta\psi_1 = 2\int_{r_0}^{\infty} \frac{\ell\,|f|\,\mathrm{d}r}{a\sqrt{a^2 - \ell^2}}, \qquad \Theta = \pi - \Delta\psi_1. \tag{8.348}$$

With no interaction the separation vector turns by π (it points from one monopole to the other before and after) and $\Theta = 0$. At large r, $a \approx r$ and $|f| \approx 1$, so $\ell = r^2\dot{\psi}_1$ is the impact parameter times the speed: with unit speed, $\ell = L$.

Worked example 8.162: Taub–NUT scattering is Rutherford scattering

For the asymptotic metric (8.347) restricted to the plane, $(1 - 2/r)(\mathrm{d}r^2 + r^2\mathrm{d}\psi_1^2)$, the integral can be done. Let $u = 1/r$ and $u' = \mathrm{d}u/\mathrm{d}\psi_1$. The conserved quantities are $\ell = (1 - 2u)r^2\dot{\psi}_1$

and $(1-2u)(\dot r^2 + r^2\dot\psi_1^2) = 1$. Then

$$1 \overset{(1)}{=} (1-2u)\Big(\frac{\ell^2 u'^2}{(1-2u)^2} + \frac{\ell^2 u^2}{(1-2u)^2}\Big) \overset{(2)}{\Longrightarrow} \ell^2\big(u'^2+u^2\big) = 1-2u$$

$$\overset{(3)}{\Longrightarrow} u''+u = -\frac{1}{\ell^2} \overset{(4)}{\Longrightarrow} u = A\cos(\psi_1-\psi_0) - \frac{1}{\ell^2}, \qquad A = \frac{\sqrt{1+\ell^2}}{\ell^2}.$$

(1) $\dot\psi_1 = \ell u^2/(1-2u)$ and $\dot r = -u^{-2}u'\dot\psi_1 = -\ell u'/(1-2u)$; also $r^2\dot\psi_1^2 = \ell^2u^2/(1-2u)^2$.
(2) Multiply by $(1-2u)$.
(3) Differentiate with respect to ψ_1 and divide by $2\ell^2 u'$.
(4) General solution of the linear equation; A follows by inserting it back into step 2: $\ell^2A^2 - 2A\cos + \ell^{-2} = 1 - 2A\cos + 2\ell^{-2}$, so $\ell^2A^2 = 1+\ell^{-2}$.

This is a hyperbola: the orbit of a repulsive Coulomb problem. The asymptotes are at $u=0$, i.e. $\cos(\psi_1-\psi_0) = 1/(A\ell^2) = 1/\sqrt{1+\ell^2}$, so $\Delta\psi_1 = 2\arctan\ell$ and, with $\ell = L$,

$$\boxed{\tan\frac{\Theta_{\text{TN}}}{2} = \frac{1}{L}}$$

Rutherford's formula for a repulsive $1/r$ potential. Note that it is independent of the speed: the force is proportional to v^2, so slower monopoles are deflected by the same angle along the same orbit, only more slowly.

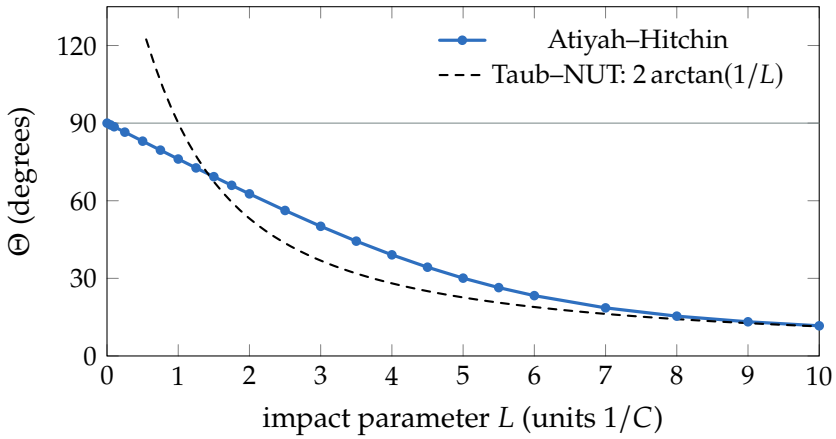

Figure 8.83: Scattering angle against impact parameter for geodesics in the plane perpendicular to $\vec y$, from numerical integration of (8.348) with the Atiyah–Hitchin coefficients. Head-on ($L\to 0$) collisions scatter by 90°. For large L the curve approaches the Rutherford formula of the asymptotic metric (dashed), which would instead give back-scattering (180°) at $L=0$: the 90° is entirely a core effect. Values: $\Theta = 76.1°$ at $L=1$, $62.7°$ at $L=2$, $30.1°$ at $L=5$, $11.7°$ at $L=10$.

8.17.4 Glancing collisions: dyons and spin

Nash's second result: *if the monopoles approach along parallel lines close enough together, the emerging monopoles have spin angular momentum; they are electrically charged, i.e. they have become dyons.* The planar family we used above has the orbital angular momentum along $\vec y = \vec e_1$. In general the incoming orbital angular momentum makes some angle α with $\vec y$ in the plane perpendicular to the line of approach, and then the motion is genuinely four-dimensional.

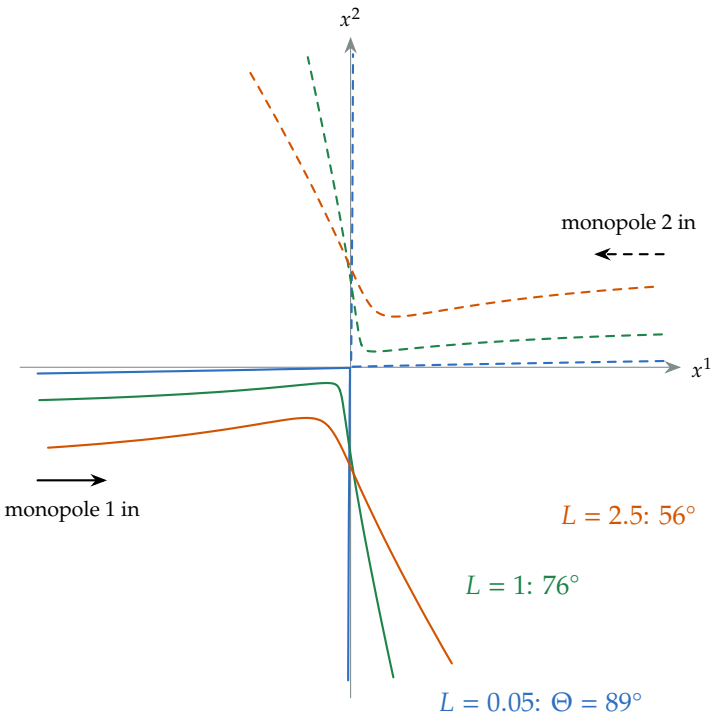

Figure 8.84: Paths of the two monopoles (solid: monopole 1, entering from the left; dashed: monopole 2, entering from the right) for three impact parameters, computed from the Atiyah–Hitchin geodesics. The plotted distance from the origin is $(r - \pi)/2$, a schematic "half-separation" that is exact at large r up to a shift and shrinks to zero at the doughnut; near the centre the monopoles are not separate objects. As $L \to 0$ the paths approach the right-angle cross.

Worked example 8.163: Euler's equations and the exchange of charge

Write the velocity in terms of the body angular velocities $\omega_i = \sigma_i(\dot{R})$. The Lagrangian is that of a rigid body whose moments of inertia $(I_1, I_2, I_3) = (a^2, b^2, c^2)$ depend on r:

$$L = \tfrac{1}{2} f^2 \dot{r}^2 + \tfrac{1}{2}\left(a^2\omega_1^2 + b^2\omega_2^2 + c^2\omega_3^2\right).$$

The body angular momenta $M_i = I_i\omega_i$ obey Euler's equations $\dot{\vec{M}} = \vec{M} \times \vec{\omega}$ (the time dependence of I_i enters only through $\omega_i = M_i/I_i$). In particular

$$\dot{M}_3 \overset{(1)}{=} M_1\omega_2 - M_2\omega_1 \overset{(2)}{=} M_1 M_2\left(\frac{1}{b^2} - \frac{1}{a^2}\right),$$
$$\frac{\mathrm{d}}{\mathrm{d}t}|\vec{M}|^2 \overset{(3)}{=} 2\vec{M}\cdot(\vec{M}\times\vec{\omega}) \overset{(4)}{=} 0.$$

(1) Third component of $\vec{M} \times \vec{\omega}$.
(2) $\omega_i = M_i/I_i$ with $I_1 = a^2$, $I_2 = b^2$.
(3) Differentiate $\vec{M}\cdot\vec{M}$ and use Euler's equation.
(4) $\vec{M} \times \vec{\omega}$ is perpendicular to $\vec{M}$.

Interpretation. M_3 is the angular momentum about the line joining the monopoles. Far apart, the σ_3 direction is the relative phase (Example 8.157), so M_3 is the momentum conjugate to the relative phase: by Example 8.152, the *relative electric charge*. $|\vec{M}|$ is the total angular momentum. Initially $M_3 = 0$ (uncharged monopoles, angular momentum purely orbital, perpendicular to the line joining them). Far away $a = b$ up to exponentially small

terms, so $\dot{M}_3 \approx 0$: charge is conserved while the monopoles are apart. In the core $a \neq b$ (Figure 8.80), and M_3 changes unless $M_1 M_2 = 0$, i.e. unless $\alpha = 0$ or 90° (the two planar families). So generic close encounters convert orbital angular momentum into relative charge.

Numerically integrating the full geodesic equations (Euler's equations plus the radial equation, with the Atiyah–Hitchin coefficients) from separation 30 gives the following fractions $|M_3|/|\vec{M}|$ of the total angular momentum that ends up as relative charge:

impact parameter L	$\alpha = 20^\circ$	$\alpha = 45^\circ$	$\alpha = 70^\circ$
1	0.32	0.68	0.93
2	0.26	0.58	0.88
3	0.18	0.40	0.61
4	0.10	0.21	0.22
6	0.02	0.04	0.03

The effect is large for close encounters and dies off rapidly (exponentially) with the impact parameter, because it is driven by $1/b^2 - 1/a^2$, which is non-zero only in the core. This is Nash's "close enough together".

Worked example 8.164: Why charge means spin: the angular momentum of a charge–monopole pair

Why does Nash call the outgoing angular momentum "spin"? Because a pair of dyons stores angular momentum in its electromagnetic field, even at rest. Take a point charge q at the origin and a point magnetic charge g at $\vec{d}$. The field angular momentum is $\vec{J} = \int \vec{x} \times (\vec{E} \times \vec{B})\, \mathrm{d}^3x$ with $\vec{E} = q\vec{x}/(4\pi r^3)$. Then

$$\vec{J} \overset{(1)}{=} \frac{q}{4\pi} \int \frac{1}{r^3} \big(\vec{x}(\vec{x}\cdot\vec{B}) - r^2\vec{B}\big)\mathrm{d}^3x \overset{(2)}{=} -\frac{q}{4\pi}\int (\vec{B}\cdot\nabla)\hat{\vec{x}}\,\mathrm{d}^3x$$
$$\overset{(3)}{=} \frac{q}{4\pi}\int (\nabla\cdot\vec{B})\,\hat{\vec{x}}\,\mathrm{d}^3x - \frac{q}{4\pi}\oint_\infty \hat{\vec{x}}\,(\vec{B}\cdot\hat{\vec{n}})\,\mathrm{d}S \overset{(4)}{=} \frac{qg}{4\pi}\,\hat{\vec{d}}.$$

(1) $\vec{x}\times(\vec{E}\times\vec{B}) = \vec{E}(\vec{x}\cdot\vec{B}) - \vec{B}(\vec{x}\cdot\vec{E})$ with $\vec{E} \propto \vec{x}$.

(2) $(\vec{B}\cdot\nabla)\hat{x}_i = B_j\partial_j(x_i/r) = (r^2 B_i - x_i\,\vec{x}\cdot\vec{B})/r^3$.

(3) Integrate by parts: $(\vec{B}\cdot\nabla)\hat{\vec{x}} = \nabla\cdot(\vec{B}\,\hat{\vec{x}}) - (\nabla\cdot\vec{B})\hat{\vec{x}}$, and use Gauss's theorem.

(4) $\nabla\cdot\vec{B} = g\,\delta^3(\vec{x}-\vec{d})$ gives $g\,\hat{\vec{d}}$; the surface term is $\frac{g}{4\pi}\oint \hat{\vec{x}}\,\mathrm{d}\Omega = 0$ since $\vec{B} \approx g\hat{\vec{x}}/(4\pi r^2)$ at infinity.

The answer does not depend on the distance $|\vec{d}|$ and points along the line joining the two. For two dyons with equal magnetic charge g and electric charges q_1, q_2, the two cross terms give $\vec{J} = \frac{g}{4\pi}(q_1 - q_2)\hat{\vec{n}}$ along the line joining them (a dyon's own $\vec{E}$ and $\vec{B}$ are parallel and carry no angular momentum). So *relative charge is spin about the line of centres*, exactly the M_3 of Example 8.163. Quantum mechanically this angular momentum must be a multiple of $\hbar/2$, which is Dirac's quantisation condition $qg/4\pi \in \frac{1}{2}\mathbb{Z}$ of Section 8.12.3, seen from the angular-momentum side.

Reading Nash (pp. 255–256)

Nash describes the $k = 2$ parameters (separation $2|x|$, a unit vector $y \perp x$ for the relative phase, $y \sim -y$) and states two results: head-on collisions in which "y is fixed" give scattering at right angles, and collisions along close parallel lines produce dyons with spin. His phrase "the scattering occurs in the x–y plane" is best read as the coordinate plane perpendicular to the fixed vector $\vec{y}$ (if $\vec{y}$ were in the plane of motion it could not stay perpendicular to $\vec{x}$). We supplied the frame description and the D_2 quotient, the metric ansatz and the Atiyah–Hitchin equations with their boundary conditions, the exact Taub–NUT check, the bolt and the 90° derivation, the rational-map picture, the scattering-angle formula with numbers and plots, Rutherford scattering for the asymptotic metric, Euler's equations for charge exchange with numbers, and the field angular momentum of a charge–monopole pair.

Recap

- $\mathcal{M}_2^0$ is 4-dimensional: separation plus an orthonormal frame modulo D_2. SO(3) acts isometrically, so the metric is $f^2\mathrm{d}r^2 + a^2\sigma_1^2 + b^2\sigma_2^2 + c^2\sigma_3^2$.
- Hyperkähler with rotating complex structures $\iff$ the Atiyah–Hitchin ODEs (8.344); smoothness gives the bolt at $r = \pi$ (the doughnuts), and at large r the metric is negative-mass Taub–NUT (velocity-dependent forces).
- Head-on collisions pass through the bolt and scatter by 90°; in rational-map language the poles $\pm\sqrt{\beta}$ rotate by 90° as β changes sign.
- The scattering angle falls from 90° at $L = 0$ to the Rutherford value $2\arctan(1/L)$ at large L.
- Off the planar families, Euler's equations $\dot{M}_3 = M_1 M_2(b^{-2} - a^{-2})$ convert orbital angular momentum into relative charge in the core: glancing collisions make dyons, whose field angular momentum $g(q_1 - q_2)/4\pi$ is the "spin".

8.18 Critical point theory and gauge theories

Everything we have solved in this chapter has been a *minimum*. Instantons are the absolute minima of the Yang–Mills action $S(A)$ in each topological sector, because $S \geq 8\pi^2|k|$ with equality exactly when $F = \pm \star F$. BPS monopoles are the absolute minima of the Yang–Mills–Higgs energy $E(A, \phi)$ in each sector, because $E \geq 4\pi C|k|$ with equality exactly on the Bogomolny equation (Section 8.13.3). In both cases the first-order equation was the *condition for saturating a bound*, and the bound came from completing a square.

But the field equations are second order, and they may have other solutions: saddle points of the action or the energy, which are not minima. In a mechanical system these are the *unstable* equilibria, the top of a pass between two valleys. In quantum field theory they matter a great deal. A saddle of the energy with one unstable direction is the top of the barrier that a tunnelling or thermally activated process must cross. The electroweak *sphaleron*, which mediates baryon-number violation in the early universe, is exactly such a saddle. So Nash asks:

> *Do gauge-theory functionals have non-minimal critical points? How many, of what type (index), and what topological mechanism forces them to exist?*

The tool is Morse theory (Chapter 7): the topology of a space forces a function on it to have

critical points, and the number and indices of those critical points are bounded below by the Betti numbers. The difficulty is that our spaces are infinite-dimensional and have an infinite-dimensional symmetry, the gauge group. We first recall the finite-dimensional theory, then see what breaks in infinite dimensions and how to repair it. Then we treat Nash's three cases in turn: Yang–Mills–Higgs on $\mathbb{R}^3$ (a good Morse function, by Taubes), Yang–Mills on a Riemann surface (an equivariantly perfect Morse function, by Atiyah and Bott), and Yang–Mills on S^4 (no Morse theory at the time Nash wrote, because of conformal invariance).

8.18.1 Morse theory in finite dimensions: a reminder

Let $f : M \to \mathbb{R}$ be a smooth function on a compact manifold of dimension n. A **critical point** is a point x where $\mathrm{d}f = 0$. There the second derivatives form a symmetric matrix, the **Hessian** $H_{ij} = \partial_i \partial_j f(x)$; it is independent of coordinates at a critical point (Chapter 7). The critical point is **non-degenerate** if $\det H \neq 0$, and its **index** $\lambda(x)$ is the number of negative eigenvalues of H: the number of independent directions in which f goes *down*.

Working definition 8.47 (Morse series, Poincaré series, perfect functions)

- Make a list of the critical points $x_1, x_2, \dots$ of f and their indices. The **Morse series** is $M_t(f) = \sum_i t^{\lambda(x_i)}$: the coefficient of t^λ counts the critical points of index λ.
- The **Poincaré series** of M is $P_t(M) = \sum_p b_p\, t^p$, with $b_p = \dim H^p(M)$ the Betti numbers.
- The **Morse inequalities** say $M_t(f) - P_t(M) = (1+t)Q_t$, where Q_t has non-negative coefficients. In particular (setting t to pick coefficients) the number of critical points of index p is at least b_p.
- f is **perfect** if $M_t(f) = P_t(M)$: it has the smallest number of critical points the topology allows.
- If the critical points come in non-degenerate critical manifolds [submanifolds made of critical points, with the Hessian invertible in the directions normal to them] N_j (Morse–Bott case), N_j of index λ_j contributes $t^{\lambda_j} P_t(N_j)$ to M_t.
- If a group G acts and f is invariant, the **equivariant** versions replace $P_t(M)$ by $P_t^G(M) = P_t(M_G)$, the Poincaré series of the homotopy quotient $M_G = M \times_G EG$ [$M \times EG$ divided by G acting on both factors, which G does freely because it acts freely on EG], and a critical orbit $G \cdot x$ with stabiliser [the elements g with $g \cdot x = x$] G_x contributes $t^\lambda P_t(BG_x)$ [BG_x is the classifying space of G_x].

The mechanism behind all of this is the picture of Chapter 7: the sublevel sets $M^a = \{f \leq a\}$ change topology only when a crosses a critical value, and crossing a critical point of index λ glues on a λ-dimensional cell. A space with a rich topology needs many cells, hence many critical points.

Worked example 8.165: Two perfect functions

The upright torus. The height function on a torus standing on its rim has four critical points: a minimum (index 0), two saddles (index 1) and a maximum (index 2). So

$$M_t(f) = 1 + 2t + t^2 = (1+t)^2 = P_t(T^2),$$

and the height function is perfect.

The rotating sphere. Let $U(1)$ rotate S^2 about the z-axis and let $f = z$. The critical points are the poles, a minimum and a maximum, each fixed by the whole $U(1)$. The equivariant Morse series is

$$M_t^{U(1)}(f) \overset{(1)}{=} t^0 P_t(BU(1)) + t^2 P_t(BU(1)) \overset{(2)}{=} \frac{1+t^2}{1-t^2} \overset{(3)}{=} P_t(S^2)\, P_t(BU(1)) \overset{(4)}{=} P_t^{U(1)}(S^2).$$

(1) Each pole is a critical orbit (a single point) with stabiliser $U(1)$ and index 0 or 2.
(2) $BU(1) = \mathbb{CP}^\infty$ has one cell in each even dimension, so $P_t(BU(1)) = 1 + t^2 + t^4 + \cdots = 1/(1-t^2)$.
(3) $P_t(S^2) = 1 + t^2$.
(4) The fibration $S^2 \to S^2_{U(1)} \to BU(1)$ has a spectral sequence that collapses (all cohomology is even), so the Poincaré series multiply (Chapter 7).

So f is *equivariantly* perfect. This little example is the model for the Atiyah–Bott theorem of Section 8.18.9: a function whose critical points are fixed by a symmetry group, each contributing a copy of the cohomology of a classifying space.

8.18.2 What changes in infinite dimensions

In gauge theory the "manifold" is a space of fields, such as the space $\mathcal{A}$ of connections, and the "function" is an action or energy. Three things can go wrong when we copy the finite-dimensional story.

1. The Hessian is a differential operator. In finite dimensions the Hessian is a matrix and its index is automatically finite. In field theory the second variation of an action is a differential operator, with infinitely many eigenvalues. The index (the number of negative eigenvalues) is finite only if the spectrum is discrete and bounded below with finitely many negative values. This is what *ellipticity* guarantees (Chapter 2): an elliptic second-order operator such as $-\nabla^2 + V$ on a compact space has discrete eigenvalues $\mu_1 \le \mu_2 \le \cdots \to +\infty$.

Worked example 8.166: The index of a path: the harmonic oscillator

Take the action of a harmonic oscillator on paths with fixed ends,

$$\mathcal{S}[x] = \frac{1}{2}\int_0^T \left(\dot{x}^2 - \omega^2 x^2\right)\mathrm{d}t, \qquad x(0) = x(T) = 0.$$

The path $x = 0$ is a critical point. Expanding $x = 0 + \varepsilon\,\xi$,

$$\mathcal{S}[\varepsilon\xi] \overset{(1)}{=} \frac{\varepsilon^2}{2}\int_0^T \left(\dot{\xi}^2 - \omega^2\xi^2\right)\mathrm{d}t \overset{(2)}{=} \frac{\varepsilon^2}{2}\int_0^T \xi\left(-\frac{\mathrm{d}^2}{\mathrm{d}t^2} - \omega^2\right)\xi\,\mathrm{d}t \overset{(3)}{=} \frac{\varepsilon^2}{2}\sum_{n\ge 1}\left(\frac{n^2\pi^2}{T^2} - \omega^2\right)c_n^2\,\frac{T}{2}.$$

(1) $\mathcal{S}$ is quadratic, so the expansion stops at order ε^2.
(2) Integrate $\dot{\xi}^2$ by parts; the boundary terms vanish because $\xi(0) = \xi(T) = 0$.
(3) Expand $\xi = \sum_n c_n \sin(n\pi t/T)$, the eigenfunctions of $-\mathrm{d}^2/\mathrm{d}t^2$ with these boundary conditions, and use $\int_0^T \sin^2(n\pi t/T)\mathrm{d}t = T/2$.

The Hessian $-\mathrm{d}^2/\mathrm{d}t^2 - \omega^2$ has eigenvalues $\mu_n = n^2\pi^2/T^2 - \omega^2$, infinitely many, but only finitely many are negative: the index is the number of $n \ge 1$ with $n\pi < \omega T$. Each time ωT passes a multiple of π (a *conjugate point* of the classical path, Chapter 7) the index jumps by one. In the path integral each negative mode contributes a factor i to the square root of the fluctuation determinant: the Maslov phase.

Figure 8.85: The spectrum of the Hessian $-\mathrm{d}^2/\mathrm{d}t^2 - \omega^2$ of Example 8.166 for $\omega T = 7$, in units of $\omega^2/4$. The eigenvalues march off to $+\infty$, so the operator has infinitely many directions but only finitely many (here two, red) negative ones. This is what ellipticity buys in general: a finite index.

2. Compactness can fail. On a compact manifold a function attains its minimum, and a sequence of points along which f becomes "more and more critical" has a convergent subsequence. On an infinite-dimensional or non-compact space this can fail, and critical points that the topology "ought" to force can escape to infinity.

Working definition 8.48 (The Palais–Smale condition)

A **Palais–Smale sequence** for f is a sequence x_n with $f(x_n)$ bounded and $|\nabla f(x_n)| \to 0$: the points look more and more like critical points. The function satisfies the **Palais–Smale condition** (Palais and Smale's "condition (C)") if every such sequence has a convergent subsequence [infinitely many of the x_n, taken in order, that converge to a point of the space]. *Test:* look for a way to send f to a finite value with vanishing gradient while the point runs off to infinity. If you find one, the condition fails.

The theorem of Palais and Smale (the "infinite-dimensional generalisation" Nash cites) is: *a smooth function on a complete Hilbert manifold that is bounded below and satisfies condition (C), whose critical points are non-degenerate with finite index, obeys the Morse inequalities.* The proof is the finite-dimensional one: the gradient flow deforms sublevel sets, and condition (C) is exactly what stops the flow from running off to infinity without reaching a critical point.

Worked example 8.167: Two ways to fail condition (C)

(a) A minimum at infinity. On $\mathbb{R}$ let $f(x) = e^{-x}$. It is bounded below by 0 but never reaches 0. The sequence $x_n = n$ has

$$f(x_n) = e^{-n} \to 0, \qquad f'(x_n) = -e^{-n} \to 0,$$

and no convergent subsequence. The "missing critical point" sits at $x = +\infty$.
(b) A mountain pass with no pass. On $\mathbb{R}^2$ let $f(x, y) = x^2 + (1 - x)^3 y^2$. Its critical points:

$$\partial_y f = 2(1 - x)^3 y = 0 \overset{(1)}{\Longrightarrow} x = 1 \text{ or } y = 0,$$
$$\partial_x f = 2x - 3(1 - x)^2 y^2 \overset{(2)}{\Longrightarrow} (x, y) = (0, 0) \text{ only}.$$

(1) A product vanishes when one factor does.
(2) At $x = 1$ we get $\partial_x f = 2 \neq 0$; at $y = 0$ we need $2x = 0$.

The origin is a strict local minimum ($f \approx x^2 + y^2$ there), and $f(4, 1) = 16 - 27 = -11 < 0$. So the landscape has a valley at the origin surrounded by a ring of positive values, and lower ground beyond it: exactly the geometry in which one expects a pass. Yet there is no second critical point. The would-be pass has escaped to infinity: along paths from $(0, 0)$ to $(4, 1)$ that go out to large $|y|$ near $x = 1$, the maximum height can be made to approach its infimum without any point where $\nabla f = 0$.

3. The symmetry group is infinite-dimensional. Gauge theory functionals are invariant under the gauge group $\mathcal{G}$. Every critical point sits on a whole orbit of critical points, so it is never non-degenerate: the Hessian has a zero eigenvalue for every infinitesimal gauge transformation. We deal with this in Section 8.18.3.

The mountain pass and min-max

The most useful tool for finding non-minimal critical points is the **min-max principle**. Suppose two points p, q lie in two different valleys. Among all paths γ from p to q, consider the highest point of each path and take the lowest such highest point:

$$c = \inf_{\gamma : p \to q} \max_{s \in [0,1]} f(\gamma(s)). \tag{8.349}$$

This is what a hiker does: choose the route whose highest point is as low as possible. The result (the **mountain pass theorem** of Ambrosetti and Rabinowitz): *if c is strictly larger than $f(p)$ and $f(q)$, and f satisfies condition (C), then c is a critical value*, attained at a critical point that is typically of index one. Why: if there were no critical point at height c, the downhill gradient flow would push every path whose maximum is slightly above c to a path whose maximum is below c, contradicting the definition of c. Condition (C) is what makes the flow push by a definite amount near height c; Example 8.167(b) is the counterexample when it fails.

More generally one takes the inf-max over any family of paths, loops or higher spheres that cannot be deformed away, for instance all loops in a fixed non-contractible class. This is Lusternik–Schnirelmann theory (Chapter 7), and it is how Taubes proved the existence of non-minimal monopole solutions.

Worked example 8.168: A mountain pass computed

Let $f(x, y) = (x^2 - 1)^2 + y^2$, with minima $p = (-1, 0)$, $q = (1, 0)$ where $f = 0$. Every path from p to q must cross the line $x = 0$, at some point $(0, y_*)$. Hence

$$\max_s f(\gamma(s)) \overset{(1)}{\geq} f(0, y_*) \overset{(2)}{=} 1 + y_*^2 \overset{(3)}{\geq} 1,$$

(1) The maximum over a path is at least the value at any one of its points.
(2) Substitute $x = 0$.
(3) $y_*^2 \geq 0$.

So $c \geq 1$. The straight path $y = 0$ has maximum $f(0, 0) = 1$, so $c = 1$. The min-max point is $(0, 0)$. Its Hessian is

$$H = \begin{pmatrix} \partial_x^2 f & \partial_x \partial_y f \\ \partial_y \partial_x f & \partial_y^2 f \end{pmatrix}_{(0,0)} = \begin{pmatrix} 12x^2 - 4 & 0 \\ 0 & 2 \end{pmatrix}_{x=0} = \begin{pmatrix} -4 & 0 \\ 0 & 2 \end{pmatrix},$$

with one negative eigenvalue: index one, as promised. The negative direction (x) points along the path, downhill towards the two valleys.

8.18.3 Dividing by the gauge group

A gauge-invariant functional f on a space X of fields has degenerate critical points: if x is critical, so is every $g \cdot x$. Differentiating $f(g_t \cdot x) = f(x)$ twice at a critical point shows that the infinitesimal gauge directions are zero modes of the Hessian. Nash's remark that "large gauge

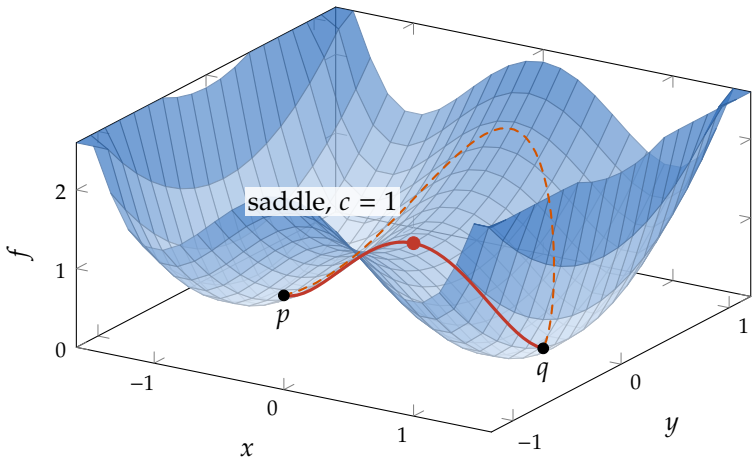

Figure 8.86: The mountain pass of Example 8.168, $f = (x^2 - 1)^2 + y^2$. Two valleys p, q. Every path from one to the other has a highest point; the dashed (orange) path's highest point is higher than that of the solid (red) path, whose highest point is the saddle at height $c = 1$. The saddle is the lowest possible highest point: the min-max critical point, of index one.

invariance . . . will have to be factored out (equivariantly or otherwise)" refers to two ways of dealing with this.

Key idea: Two ways to factor out the gauge group

1. *Quotient by a group that acts freely.* Replace X by $X/\mathcal{G}_0$, where $\mathcal{G}_0$ is a subgroup that acts without fixed points, typically the **based gauge group** of gauge transformations with $g(x_0) = \mathbb{1}$ at a base point x_0 (for us, the point at infinity). Then $X/\mathcal{G}_0$ is (morally) a manifold and f descends to it.

2. *Work equivariantly.* Keep the full group $\mathcal{G}$, including the constant gauge transformations that do have fixed points, and use the equivariant cohomology $H^*_{\mathcal{G}}(X) = H^*(X \times_{\mathcal{G}} E\mathcal{G})$ and the equivariant Morse series of Definition 8.47.

Worked example 8.169: Based gauge transformations act freely

Suppose a gauge transformation g fixes a connection: $g^{-1}Ag + g^{-1}\mathrm{d}g = A$. Then

$$g^{-1}Ag + g^{-1}\mathrm{d}g = A \overset{(1)}{\iff} \mathrm{d}g + Ag - gA = 0 \overset{(2)}{\iff} \mathrm{d}_A g = 0,$$

(1) Multiply on the left by g.
(2) Regard g as a section of the bundle of automorphisms, on which A acts by commutator: $\mathrm{d}_A g = \mathrm{d}g + [A, g]$.

So g is covariantly constant. A covariantly constant section is determined by its value at one point: along any path from x_0 it is parallel transported, $g(x) = \mathrm{hol}_\gamma\, g(x_0)\, \mathrm{hol}_\gamma^{-1}$. If g is based, $g(x_0) = \mathbb{1}$, then $g(x) = \mathbb{1}$ everywhere. So $\mathcal{G}_0$ acts freely. The *unbased* group always has a non-trivial stabiliser, at least the centre (for $U(n)$, the constant scalars $e^{i\theta}\mathbb{1}$), and more at reducible connections (for instance a direct sum of two line bundles is fixed by $\mathrm{U}(1) \times \mathrm{U}(1)$). Stabilisers are why the equivariant route is often more natural.

Watch out: $\mathcal{A}/\mathcal{G}$ versus $B\mathcal{G}$

The space $\mathcal{A}$ of all connections on a bundle is *affine*: given A_0, every other connection is $A_0 + a$ with a an $\mathrm{ad}\,P$-valued 1-form. So $\mathcal{A}$ is contractible (shrink a to zero). If a group acts freely on a contractible space, the quotient is a model of its classifying space. Thus $\mathcal{A}/\mathcal{G}_0 \simeq B\mathcal{G}_0$ exactly. For the full gauge group, which does not act freely, $\mathcal{A}/\mathcal{G}$ is *not* $B\mathcal{G}$; but its equivariant cohomology is, $H^*_{\mathcal{G}}(\mathcal{A}) = H^*(\mathcal{A} \times_{\mathcal{G}} E\mathcal{G}) = H^*(B\mathcal{G})$, because $\mathcal{A}$ is contractible. When Nash writes "$\mathcal{A}/\mathcal{G} = B\mathcal{G}$" he means one of these two statements.

8.18.4 The Yang–Mills–Higgs energy as a Morse function

We return to SU(2) Yang–Mills–Higgs theory on $\mathbb{R}^3$ in the Prasad–Sommerfield limit. The configuration space $\mathcal{A}_{YMH}$ is the space of pairs (A, ϕ) of an SU(2) connection and an adjoint Higgs field with finite energy and the boundary condition $|\phi| \to C$ at infinity (Section 8.13.5). On it lives the energy

$$E(A,\phi) = \frac{1}{2}\Big(\|F(A)\|^2 + \big\|\mathrm{d}_A\phi\big\|^2 \Big), \tag{8.350}$$

Nash's (8.197), with the norms (8.266). We have already found its minima in each sector. Now we treat E as a function on an infinite-dimensional space and ask for all its critical points.

Worked example 8.170: The critical points of E are the Yang–Mills–Higgs equations

Vary $A \to A + ta$ and $\phi \to \phi + t\psi$, with a an $\mathfrak{su}(2)$-valued 1-form and ψ an $\mathfrak{su}(2)$-valued function, both decaying at infinity. To first order in t,

$$F(A+ta) \overset{(1)}{=} F + t\,\mathrm{d}_A a + O(t^2), \qquad \mathrm{d}_{A+ta}(\phi + t\psi) \overset{(2)}{=} \mathrm{d}_A\phi + t\big(\mathrm{d}_A\psi + [a,\phi]\big) + O(t^2).$$

(1) $F(A+ta) = \mathrm{d}(A+ta) + (A+ta)\wedge(A+ta) = F + t(\mathrm{d}a + A\wedge a + a\wedge A) + t^2 a\wedge a$, and $\mathrm{d}a + A\wedge a + a\wedge A = \mathrm{d}_A a$ for an adjoint-valued 1-form.

(2) $\mathrm{d}_{A+ta}\chi = \mathrm{d}\chi + [A+ta,\chi]$; expand with $\chi = \phi + t\psi$.

Hence

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\Big|_{t=0} E &\overset{(1)}{=} \langle F, \mathrm{d}_A a\rangle + \langle \mathrm{d}_A\phi, \mathrm{d}_A\psi + [a,\phi]\rangle \\ &\overset{(2)}{=} \langle \mathrm{d}_A^\star F, a\rangle + \langle \mathrm{d}_A^\star \mathrm{d}_A\phi, \psi\rangle + \langle \mathrm{d}_A\phi, [a,\phi]\rangle \\ &\overset{(3)}{=} \big\langle \mathrm{d}_A^\star F + [\phi, \mathrm{d}_A\phi],\, a\big\rangle + \langle \mathrm{d}_A^\star \mathrm{d}_A\phi, \psi\rangle. \end{aligned}$$

(1) $\frac{\mathrm{d}}{\mathrm{d}t}\frac{1}{2}\|X+tY\|^2 = \langle X, Y\rangle$ at $t=0$.

(2) $\mathrm{d}_A^\star$ is the formal adjoint of d_A; the boundary terms vanish because a, ψ decay.

(3) Pointwise, with $X = D_i\phi$: $-2\,\mathrm{tr}(X[a_i,\phi]) = -2\,\mathrm{tr}(a_i[\phi,X])$ by cyclicity of the trace, so $\langle \mathrm{d}_A\phi, [a,\phi]\rangle = \langle [\phi, \mathrm{d}_A\phi], a\rangle$.

This vanishes for all (a,ψ) if and only if

$$\mathrm{d}_A^\star F = [\mathrm{d}_A\phi, \phi], \qquad \mathrm{d}_A^\star \mathrm{d}_A\phi = 0, \tag{8.351}$$

which is Nash's (8.198), the $\lambda = 0$ case of (8.282).

The quotient and its components

E is gauge invariant, so it descends to the quotient $\mathcal{A}_{YMH}/\mathcal{G}$, where Nash takes $\mathcal{G}$ to be the *base point preserving* gauge transformations, $g \to \mathbb{1}$ at infinity. By Example 8.169 these act freely, so the quotient has no singular points. (They also leave the asymptotic Higgs field $\hat{\phi}_\infty : S^2_\infty \to S^2$ untouched, which matters for the topology below.)

The boundary condition splits the configuration space into pieces. Every finite-energy configuration has an integer magnetic charge $k = \deg \hat{\phi}_\infty$ (Section 8.13.5, (8.295)). So

$$\mathcal{A}_{YMH} = \bigcup_{k\in\mathbb{Z}} \mathcal{A}^k_{YMH}, \qquad \mathcal{A}^k_{YMH} = \left\{(A,\phi) : \; -\frac{1}{4\pi C}\langle F, \star \mathrm{d}_A\phi\rangle = k\right\}, \tag{8.352}$$

Nash's (8.199)–(8.200). Correspondingly the orbit space splits into $\mathcal{C}_k = \mathcal{A}^k_{YMH}/\mathcal{G}$, one for each charge.

Worked example 8.171: Why the pieces are disconnected

Suppose (A_s, ϕ_s), $0 \le s \le 1$, is a continuous path of finite-energy configurations. Then

$$k(s) \overset{(1)}{=} -\frac{1}{4\pi C}\langle F_s, \star \mathrm{d}_{A_s}\phi_s\rangle \overset{(2)}{\text{ is continuous in } s}, \qquad k(s) \overset{(3)}{\in} \mathbb{Z}.$$

(1) Definition (8.291).
(2) The pairing is continuous in the fields (in the finite-energy norm).
(3) k is the degree of $\hat{\phi}_\infty$, an integer (Section 8.13.5).

A continuous integer-valued function on $[0,1]$ is constant (it cannot jump without taking non-integer values in between). So $k(0) = k(1)$: no path joins $\mathcal{A}^k_{YMH}$ to $\mathcal{A}^{k'}_{YMH}$ with $k \neq k'$. Nash's normalisation "$\frac{1}{4\pi}\langle F, \star \mathrm{d}_A\phi\rangle = k$" is ours with $C = 1$ and the opposite sign convention for k (see Section 8.13.5).

The topology of the pieces

Why are the $\mathcal{C}_k$ topologically non-trivial, when each $\mathcal{A}^k_{YMH}$ is built out of a vector space of connections and Higgs fields? Because of the quotient. The based gauge group on $\mathbb{R}^3$ is the group of maps $g : \mathbb{R}^3 \cup \{\infty\} = S^3 \to \mathrm{SU}(2)$ with $g(\infty) = \mathbb{1}$. Such a map has a degree $\deg g \in \pi_3(S^3) = \mathbb{Z}$, and gauge transformations of different degrees cannot be deformed into each other. So $\mathcal{G}$ has infinitely many components, $\pi_0(\mathcal{G}) = \mathbb{Z}$.

Key idea: A non-contractible loop from a large gauge transformation

Let g_1 be a based gauge transformation of degree one, and $x \in \mathcal{A}^k_{YMH}$ any configuration. Join x to $g_1 \cdot x$ by any path γ in $\mathcal{A}^k_{YMH}$ (for example the straight line: the space of fields with given boundary behaviour is affine). In the quotient $\mathcal{C}_k$ the endpoints are the same point, so γ becomes a closed loop $[\gamma]$. *This loop cannot be contracted.* If it could, lifting the contraction to $\mathcal{A}^k_{YMH}$ would deform the endpoint $g_1 \cdot x$ back to x through points of the orbit $\mathcal{G} \cdot x$, i.e. it would give a continuous path in $\mathcal{G}$ from g_1 to $\mathbb{1}$; impossible, since their degrees differ.

In homotopy language: the free action gives a fibration $\mathcal{G} \to \mathcal{A}^k_{YMH} \to \mathcal{C}_k$, and its exact sequence contains $\pi_1(\mathcal{C}_k) \to \pi_0(\mathcal{G}) = \mathbb{Z} \to \pi_0(\mathcal{A}^k_{YMH})$. The loop above maps to the generator $1 \in \mathbb{Z}$. Continuing the exact sequence, the higher homotopy groups $\pi_n(\mathcal{G}) = \pi_{n+3}(S^3)$ (which

are non-zero for infinitely many n: $\mathbb{Z}_2, \mathbb{Z}_2, \mathbb{Z}_{12}, \mathbb{Z}_2, \mathbb{Z}_2, \dots$ for $n = 1, 2, 3, 4, 5$) feed into $\pi_{n+1}(\mathcal{C}_k)$. Together with the topology of the space of asymptotic Higgs fields (maps $S^2 \to S^2$ of degree k), this makes every $\mathcal{C}_k$ topologically rich. Taubes computed the homotopy type precisely; we only need that it is far from contractible.

Physical picture: Tunnelling between vacua

In the $k = 0$ sector take x to be the vacuum, $A = 0$, $\phi = CT_3$. Then $g_1 \cdot x$ is again a vacuum, of the same (zero) energy, but it is a *different point* of $\mathcal{A}^0_{YMH}$, and the only way between them in field space goes over a hill. In the quotient the two vacua are identified and the path becomes a non-contractible loop. The highest point of the best such loop is a saddle point of the energy: a static, unstable, non-minimal solution. This is precisely the logic of the electroweak sphaleron (Manton; Klinkhamer and Manton), whose energy, about 9 TeV, is the height of the barrier between topologically distinct vacua of the Standard Model; crossing it changes baryon number.

The minima as a Morse–Bott critical manifold

What does the Hessian of E look like at a BPS monopole? Use the completed square (8.292): on $\mathcal{A}^k_{YMH}$, with $k > 0$,

$$E(A, \phi) = \frac{1}{2} \left\| F + \star \mathrm{d}_A \phi \right\|^2 + 4\pi C k.$$

Expand around a solution (A, ϕ) of $F = - \star \mathrm{d}_A \phi$ in a direction (a, η):

$$E(A + ta, \phi + t\eta) \overset{(1)}{=} \frac{1}{2} \left\| F + \star \mathrm{d}_A \phi + t\, D_1(a, \eta) + O(t^2) \right\|^2 + 4\pi C k$$
$$\overset{(2)}{=} 4\pi C k + \frac{t^2}{2} \left\| D_1(a, \eta) \right\|^2 + O(t^3).$$

(1) The first-order change of $F + \star \mathrm{d}_A \phi$ is $\mathrm{d}_A a + \star(\mathrm{d}_A \eta + [a, \phi]) = D_1(a, \eta)$, the linearised Bogomolny operator (8.322); k does not change.

(2) At a solution $F + \star \mathrm{d}_A \phi = 0$, so only the square of the first-order term survives at order t^2.

So the Hessian at a monopole is the non-negative operator $D_1^\star D_1$. Its null space is $\ker D_1$; modulo gauge directions (the image of D_0) this is the tangent space to the moduli space, of dimension $4k$ (Section 8.15). In the language of Definition 8.47: the absolute minima of E on $\mathcal{C}_k$ form a critical manifold $\mathcal{M}'_k$ of index 0 and dimension $4k$. The Hessian has no negative directions, and its only normalisable zero modes (modulo gauge) are the $4k$ tangent directions; the Weitzenböck formula $DD^\dagger = -D^2 - \mathrm{ad}^2_\phi$ of Example 8.139 is what rules out any others. One technical caveat, typical of $\mathbb{R}^3$: the unbroken U(1) fields (photon and the massless Higgs mode) are massless, so the spectrum of $D_1^\star D_1$ is continuous down to 0 and there is no spectral gap above the zero modes. This is one of the "technical difficulties" of non-compact M that Nash mentions and that Taubes' weighted function spaces handle.

Taubes' theorems

Nash quotes two results of Taubes on this Morse theory.

Key idea: Taubes: E is a good Morse function

1. In each sector $\mathcal{C}_k$ there are critical points of E that are *not* minima: static solutions of (8.351) that do not satisfy the Bogomolny equation. (The first case Taubes settled was

$k = 0$, below.)

2. There are infinitely many of them, and their energies are unbounded: for every E_0 there is a non-minimal critical point with energy above E_0.

The mechanism is Lusternik–Schnirelmann min-max over the non-trivial topology of C_k. Each homotopy class of non-contractible spheres in C_k gives a min-max value; the rich homotopy described above gives infinitely many classes, and the min-max values of more and more complicated classes grow without bound. The hard analysis is to show that each min-max value is really attained, even though the Palais–Smale condition fails on $\mathbb{R}^3$. We now see concretely how it fails, and why it can be controlled.

8.18.5 Taubes' loop and the monopole–antimonopole saddle

Work in the $k = 0$ sector. Its minimum is the vacuum ($E = 0$). By the key idea above, the loop class $[\gamma]$ built from a degree-one gauge transformation is not contractible. Taubes drew an explicit, physical representative of it:

1. start at the vacuum;
2. create a monopole ($k = +1$) and an antimonopole ($k = -1$) at the origin and pull them apart to a large separation d along an axis;
3. keeping them apart, rotate the internal orientation of the monopole by 2π about that axis, relative to the antimonopole (a relative U(1) phase that winds once, the same phase that becomes the dyon angle in Section 8.16.4);
4. bring them together and annihilate them.

Taubes checks that the fields at the end of this process are not the original vacuum but $g_1 \cdot$ (vacuum) with $\deg g_1 = 1$. Heuristically, the 2π relative rotation leaves behind a gauge transformation that turns once around the axis joining the pair, and the creation and annihilation stages close this up into a map of S^3 onto SU(2) covering it once. So the loop is the non-contractible one of the key idea.

Now apply min-max. Let

$$c = \inf_{\gamma \in [\gamma]} \max_s E(\gamma(s)).$$

Two inequalities make this useful.

Lower bound, $c > 0$. The zero-energy configurations in C_0 are the vacua; up to based gauge transformations they are labelled by the constant asymptotic direction $\hat{\phi}_\infty \in S^2$, so they form a copy of S^2. A loop of very small energy stays close to this vacuum set, and loops near S^2 can be shrunk because $\pi_1(S^2) = 0$. A non-contractible loop must therefore climb to some definite height.

Upper bound, $c < 8\pi C$. Along Taubes' representative the energy is highest while the pair is separated. There the energy is approximately two monopole masses plus the (attractive) interaction energy.

Worked example 8.172: The energy of a separated monopole–antimonopole pair

For a well-separated pair at distance d (in units where the core size $1/C$ is small compared with d), treat each object as a point particle of mass $4\pi C$ carrying magnetic charge $\pm g$ with

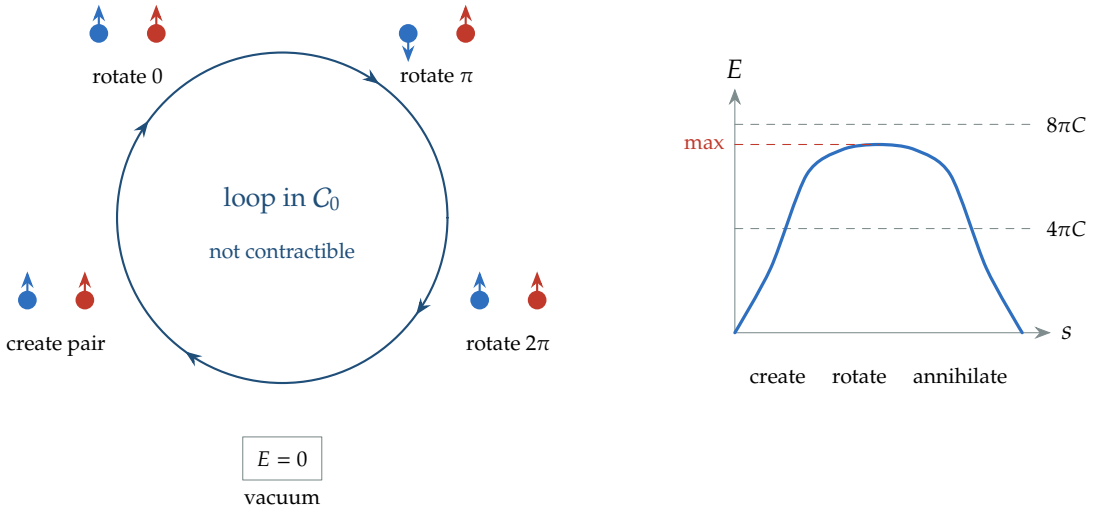

Figure 8.87: Taubes' non-contractible loop in the $k = 0$ configuration space. Left: a monopole (blue) and antimonopole (red) are created from the vacuum, the monopole's internal orientation (arrow) is turned by 2π relative to the antimonopole, and the pair annihilates. Right: the energy along such a loop stays below $8\pi C$, twice the monopole mass, because the pair attracts. Minimising the maximum over all loops in the class gives the monopole–antimonopole saddle point.

$g = 4\pi$ and a scalar charge of the same size (Examples 8.146 and 8.147). Then

$$E(d) \overset{(1)}{=} 4\pi C + 4\pi C + V_{\text{mag}}(d) + V_{\text{Higgs}}(d)$$
$$\overset{(2)}{=} 8\pi C - \frac{g^2}{4\pi d} - \frac{g^2}{4\pi d} \overset{(3)}{=} 8\pi C - \frac{8\pi}{d} + O(e^{-Cd}).$$

(1) Each isolated object has the BPS mass $4\pi C|k|$, $|k| = 1$; add the interaction energies.
(2) Opposite magnetic charges attract with the Coulomb energy $-g^2/(4\pi d)$; the massless Higgs exchange between a monopole and an antimonopole is also attractive with the same strength (Example 8.147).
(3) $g^2/(4\pi) = 4\pi$; the corrections from the massive fields fall off like e^{-Cd}.

The force is $-\mathrm{d}E/\mathrm{d}d = -8\pi/d^2$ (attractive), matching Example 8.147. So $E(d) < 8\pi C$ for every large d, and a rotation of the relative phase at fixed large separation costs only exponentially small energy. Hence loops in the class exist with maximum energy below $8\pi C$, and $c < 8\pi C$.

How the Palais–Smale condition fails, and why it does not matter

Example 8.172 also shows exactly how condition (C) fails for E on $\mathbb{R}^3$. Take the pair at separations $d_n \to \infty$. Then $E \to 8\pi C$ stays bounded, and the configuration becomes ever more nearly a solution: each constituent solves the field equations exactly except for the influence of the other, whose fields at distance d_n are of order $1/d_n$ with gradients of order $1/d_n^2$. So $|\nabla E| \to 0$. But the sequence has no limit: the monopole and antimonopole run off to infinity in opposite directions. It is Example 8.167(a) in field theory: a "critical point at infinity", namely an infinitely separated pair, at level $8\pi C$.

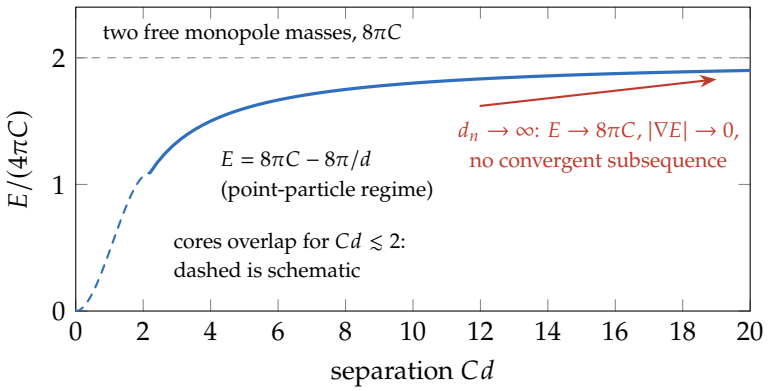

Figure 8.88: Energy of a monopole–antimonopole pair against separation (solid: the point-particle formula of Example 8.172; dashed: schematic behaviour when the cores overlap and the pair can annihilate). Sending the pair apart gives a Palais–Smale sequence at level $8\pi C$ with no limit: condition (C) fails on $\mathbb{R}^3$. Below the threshold $8\pi C$ this cannot happen.

Physical picture: Energy bookkeeping restores compactness

On $\mathbb{R}^3$ the only way a Palais–Smale sequence can fail to converge (up to gauge and translation) is by splitting into pieces that separate to infinity; this is the content of Taubes' analysis. Each piece that carries non-zero magnetic charge costs at least $4\pi C$ (the Bogomolny bound), and in the $k = 0$ sector the charges must add up to zero, so a splitting costs at least $4\pi C + 4\pi C = 8\pi C$ in the limit. The min-max level satisfies $0 < c < 8\pi C$. So a min-max sequence at level c has not enough energy to split, it converges, and its limit is a genuine critical point in C_0 with energy c: a non-minimal static solution of (8.351). Since it comes from a one-parameter family, it is expected to have index one, like the mountain pass.

The saddle point found by Taubes is the **monopole–antimonopole pair**. It has been computed numerically (Rüber; Kleihaus and Kunz): an axially symmetric static solution whose Higgs field has two zeros on the symmetry axis, a monopole and an antimonopole held apart by the balance between their attraction and the twisting of the gauge field between them, with an energy a little below $8\pi C$.

Dictionary: finite-dimensional Morse theory ↔ Yang–Mills–Higgs on $\mathbb{R}^3$

manifold M	orbit space $C_k = \mathcal{A}^k_{YMH}/\mathcal{G}$
function f	energy E of (8.350)
connected components	charge sectors $k \in \mathbb{Z}$
critical points	static solutions of (8.351)
minimum set (Morse–Bott)	BPS moduli space $\mathcal{M}'_k$, dim $= 4k$
index-one saddle	monopole–antimonopole pair (sphaleron-like)
non-contractible loop	path from vacuum to a degree-one gauge transform of it
failure of condition (C)	monopoles escaping to infinity
energy threshold	Bogomolny bound $4\pi C$ per constituent

Reading Nash (pp. 256–257, (8.197)–(8.200))

Nash recalls from Chapter 7 that non-degenerate critical points of a function are tied to the topology of its domain, notes that the gauge-theory examples need the infinite-dimensional generalisations of Palais and of Taubes, and warns that pure Yang–Mills in four dimensions behaves differently from Yang–Mills–Higgs, that two dimensions is special, and that the gauge symmetry must be factored out. For SU(2) Yang–Mills–Higgs on $\mathbb{R}^3$ he writes the energy (8.197), its critical points (8.198), the passage to the orbit space by base point preserving gauge transformations, the decomposition (8.199) by magnetic charge (8.200), and quotes Taubes: each C_k is topologically non-trivial and carries infinitely many non-minimal critical points of unbounded energy, so E has "the properties of a good Morse function". His (8.200), $\frac{1}{4\pi}\langle F, \star \mathrm{d}_A\phi\rangle = k$, is our (8.352) with $C = 1$, his $-\operatorname{tr}$ normalisation and the opposite sign convention for k. We added the finite-dimensional recap, the Palais–Smale condition and its failure (in calculus and for monopoles), the mountain pass, the free action of based gauge transformations, the first-variation calculation, the Morse–Bott structure of the minima, the non-contractible loop and Taubes' monopole–antimonopole saddle.

8.18.6 Yang–Mills theory on a Riemann surface

Nash's second example is pure Yang–Mills theory in *two* dimensions. It is the one gauge theory whose Morse theory is completely understood, and it is "striking" because everything can be computed. The setting: Σ is a closed oriented surface of genus g with a Riemannian metric of total area $\mathcal{A}_\Sigma$, and $P \to \Sigma$ is a principal $\mathrm{U}(n)$ bundle, equivalently a rank-n complex vector bundle E with a Hermitian metric. Its topological type is fixed by one integer, the degree $d = c_1(E) = \frac{i}{2\pi}\int_\Sigma \operatorname{tr} F$ (Chapter T2). The connections are $\mathfrak{u}(n)$-valued 1-forms, i.e. anti-Hermitian $n \times n$ matrices of 1-forms.

Conventions for this subsection. For $\mathrm{U}(n)$ we follow Nash's (8.201) literally and use $-\operatorname{tr}$ without the factor 2 of (8.266):

$$\langle \alpha, \beta\rangle = -\int_\Sigma \operatorname{tr}(\alpha \wedge \star\beta), \qquad S(A) = \|F\|^2 = -\int_\Sigma \operatorname{tr}(F \wedge \star F). \tag{8.353}$$

This is positive. For an anti-Hermitian matrix X ($X^\dagger = -X$),

$$-\operatorname{tr}(X^2) \overset{(1)}{=} \operatorname{tr}(X^\dagger X) \overset{(2)}{=} \sum_{i,j} |X_{ij}|^2 \;\geq\; 0.$$

(1) $X = -X^\dagger$.
(2) $(X^\dagger X)_{jj} = \sum_i \overline{X_{ij}} X_{ij}$.

The Hodge star on a surface, in a local oriented orthonormal coframe e^1, e^2 with area form $\mathrm{vol} = e^1 \wedge e^2$, is

$$\star 1 = \mathrm{vol}, \quad \star \mathrm{vol} = 1, \quad \star e^1 = e^2, \quad \star e^2 = -e^1, \qquad \star\star = -1 \text{ on 1-forms.}$$

The key point is the first two: *the dual of a 2-form is a function.* So $\star F$ is an $\mathrm{ad}\,P$-valued function, which we call $\Phi = \star F$; then $F = \Phi\,\mathrm{vol}$.

Worked example 8.173: The Yang–Mills equations in two dimensions

The critical points of S satisfy $\mathrm{d}_A^\star F = 0$ (the same first-variation calculation as in Example 8.170, without ϕ). In two dimensions the adjoint of d_A on p-forms is $\mathrm{d}_A^\star = (-1)^{n(p+1)+1} \star \mathrm{d}_A \star$ with $n = 2$, i.e. $\mathrm{d}_A^\star = - \star \mathrm{d}_A \star$ for every p. Hence

$$\mathrm{d}_A^\star F = 0 \overset{(1)}{\iff} \star\, \mathrm{d}_A(\star F) = 0 \overset{(2)}{\iff} \mathrm{d}_A(\star F) = 0 \overset{(3)}{\iff} \mathrm{d}\Phi + [A, \Phi] = 0.$$

(1) $\mathrm{d}_A^\star = - \star \mathrm{d}_A \star$; drop the sign.
(2) $\star$ is invertible on 1-forms ($\star\star = -1$).
(3) $\Phi = \star F$ is an adjoint-valued function, and d_A acts on it by commutator.

This is Nash's (8.202). The Yang–Mills equation says simply that the "field strength function" Φ is **covariantly constant**. (There is no Bianchi identity to add: $\mathrm{d}_A F$ is a 3-form, and there are none on a surface.)

Covariant constancy is a strong condition. It makes the eigenvalues of Φ constant, and it splits the bundle.

Worked example 8.174: Covariantly constant Φ: constant eigenvalues and a splitting

Eigenvalues. For each $m \geq 1$,

$$\mathrm{d}\ \mathrm{tr}(\Phi^m) \overset{(1)}{=} \mathrm{tr}\big(\mathrm{d}_A(\Phi^m)\big) \overset{(2)}{=} m\ \mathrm{tr}\big(\Phi^{m-1}\mathrm{d}_A\Phi\big) \overset{(3)}{=} 0.$$

(1) $\mathrm{d}_A(\Phi^m) = \mathrm{d}(\Phi^m) + [A, \Phi^m]$, and the trace of a commutator is zero.
(2) Leibniz rule for d_A, and cyclicity of the trace to collect the m terms.
(3) $\mathrm{d}_A\Phi = 0$.

So all the $\mathrm{tr}\,\Phi^m$ are constant on Σ, hence the characteristic polynomial of Φ is constant, hence its eigenvalues are constant. Since Φ is anti-Hermitian they are imaginary; write them $-i\lambda_1, \dots, -i\lambda_r$ with multiplicities $n_1, \dots, n_r$.
Splitting. Let E_j be the $-i\lambda_j$ eigenbundle. If s is a section of E_j, then

$$\Phi\,(\mathrm{d}_A s) \overset{(1)}{=} \mathrm{d}_A(\Phi s) - (\mathrm{d}_A\Phi)s \overset{(2)}{=} -i\lambda_j\, \mathrm{d}_A s,$$

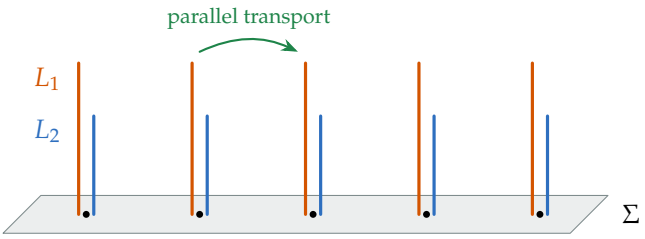
(1) Leibniz: $\mathrm{d}_A(\Phi s) = (\mathrm{d}_A\Phi)s + \Phi\, \mathrm{d}_A s$.
(2) $\Phi s = -i\lambda_j s$ with λ_j constant, and $\mathrm{d}_A\Phi = 0$.

so $\mathrm{d}_A s$ is again E_j-valued. The connection preserves each eigenbundle: $E = E_1 \oplus \cdots \oplus E_r$ and $A = A_1 \oplus \cdots \oplus A_r$ is *reducible*. On each summand the curvature is a constant multiple of the identity, $F_j = -i\lambda_j\, \mathbb{1}_{n_j}$ vol: a **projectively flat**, or constant central curvature, connection.
The constants. Integrate the first Chern class of E_j, of degree d_j and rank n_j:

$$d_j \overset{(1)}{=} \frac{i}{2\pi}\int_\Sigma \mathrm{tr}\, F_j \overset{(2)}{=} \frac{i}{2\pi}(-i\lambda_j)\, n_j\, \mathcal{A}_\Sigma \overset{(3)}{\implies} \lambda_j = \frac{2\pi d_j}{n_j \mathcal{A}_\Sigma}.$$

(1) $c_1 = \frac{i}{2\pi}\,\mathrm{tr}\, F$ (Chapter T2).
(2) $\mathrm{tr}\, F_j = -i\lambda_j n_j$ vol and $\int \mathrm{vol} = \mathcal{A}_\Sigma$.
(3) Solve.

So the eigenvalue λ_j is $2\pi/\mathcal{A}_\Sigma$ times the **slope** $\mu_j = d_j/n_j$ of the summand.



$$E = L_1 \oplus L_2, \quad \star F = \begin{pmatrix} -i\lambda_1 & 0 \\ 0 & -i\lambda_2 \end{pmatrix} \text{constant}, \quad \lambda_j = \frac{2\pi d_j}{\mathcal{A}_\Sigma}$$

Figure 8.89: A Yang–Mills connection on a rank-2 bundle over a surface. The covariantly constant field-strength function $\star F$ has constant eigenvalues, and its eigenlines L_1 (orange) and L_2 (blue) are carried into themselves by parallel transport: the bundle splits, and on each line the curvature is constant. When $\lambda_1 = \lambda_2$ there is no splitting and the connection is projectively flat: a minimum.

Key idea: The critical points of two-dimensional Yang–Mills

A connection on a $\mathrm{U}(n)$ bundle over Σ is Yang–Mills if and only if it is a direct sum of connections with constant central curvature, $E = \bigoplus_j E_j$, $\star F|_{E_j} = -\frac{2\pi i}{\mathcal{A}_\Sigma}\frac{d_j}{n_j}\mathbb{1}$. Its action is

$$S = -\int_\Sigma \operatorname{tr}\Phi^2 \operatorname{vol} = \sum_j n_j \lambda_j^2 \mathcal{A}_\Sigma = \frac{4\pi^2}{\mathcal{A}_\Sigma}\sum_j \frac{d_j^2}{n_j}. \tag{8.354}$$

The critical values are an explicit discrete set, labelled by the ways of writing (n, d) as a sum of (n_j, d_j).

Worked example 8.175: $\mathrm{U}(1)$ on the sphere is the Dirac monopole

For $n = 1$ there is only one summand, so every Yang–Mills connection has constant curvature $F = -i\frac{2\pi d}{\mathcal{A}_\Sigma}\mathrm{vol}$. On the unit sphere ($\mathcal{A}_\Sigma = 4\pi$, $\mathrm{vol} = \sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\varphi$) this is

$$F = -\frac{id}{2}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\varphi,$$

a uniform magnetic field through the sphere with total flux $\int iF = 2\pi d$: exactly the Dirac monopole of charge d of Section 8.12.3, restricted to a sphere around it. Its action is

$$S \overset{(1)}{=} -\int_{S^2}\left(-\frac{id}{2}\right)^2 \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\varphi \overset{(2)}{=} \frac{d^2}{4}\cdot 4\pi = \pi d^2,$$

(1) $\Phi = \star F = -id/2$ is a constant function; $S = -\int \Phi^2 \mathrm{vol}$.

(2) $(-i)^2 = -1$ and $\int \mathrm{vol} = 4\pi$.

in agreement with (8.354): $4\pi^2 d^2/(4\pi) = \pi d^2$. In the $\mathrm{U}(1)$ theory there is exactly one critical value in each degree, and (as we shall see from the Hessian) it is the minimum.

Worked example 8.176: The minimum in each sector: completing the square once more

For any connection on a bundle of rank n and degree d, split $\Phi = \Phi_0 + \frac{1}{n}(\operatorname{tr}\Phi)\mathbb{1}$ into traceless

and central parts. Then

$$S \overset{(1)}{=} -\int \operatorname{tr}\Phi_0^2\,\mathrm{vol} - \frac{1}{n}\int (\operatorname{tr}\Phi)^2\mathrm{vol} \overset{(2)}{\geq} \frac{1}{n}\int |\operatorname{tr}\Phi|^2\mathrm{vol}$$
$$\overset{(3)}{\geq} \frac{1}{n\mathcal{A}_\Sigma}\left|\int \operatorname{tr}\Phi\,\mathrm{vol}\right|^2 \overset{(4)}{=} \frac{4\pi^2 d^2}{n\mathcal{A}_\Sigma}.$$

(1) Expand $\operatorname{tr}\Phi^2$; the cross term is $\frac{2}{n}\operatorname{tr}\Phi\operatorname{tr}\Phi_0 = 0$.
(2) $-\operatorname{tr}\Phi_0^2 \geq 0$ (anti-Hermitian), and $\operatorname{tr}\Phi$ is imaginary so $-(\operatorname{tr}\Phi)^2 = |\operatorname{tr}\Phi|^2$.
(3) Cauchy–Schwarz: $(\int |f|)^2 \leq \mathcal{A}_\Sigma \int |f|^2$.
(4) $\int \operatorname{tr}\Phi\,\mathrm{vol} = \int \operatorname{tr} F = -2\pi i d$.

Equality holds iff $\Phi_0 = 0$ and $\operatorname{tr}\Phi$ is constant: the projectively flat connections, with $r = 1$ summand in the key idea. This is the absolute minimum. Every other Yang–Mills connection (a genuine splitting with unequal slopes) has larger action; for example on a rank-2, degree-0 bundle the splitting into degrees $(m, -m)$ has $S = 8\pi^2 m^2/\mathcal{A}_\Sigma$, compared with the minimum 0.

Holomorphic methods

Nash says the equations "translate into a holomorphic problem". The translation is this. A Riemann surface is a complex curve, and on a complex vector bundle over a complex curve a unitary connection defines a **holomorphic structure**: split $\mathrm{d}_A = \partial_A + \bar\partial_A$ into its $(1,0)$ and $(0,1)$ parts (in a local coordinate z, $\bar\partial_A = \mathrm{d}\bar z\,(\partial_{\bar z} + A_{\bar z})$), and declare a section holomorphic when $\bar\partial_A s = 0$. In higher dimensions this requires $F^{0,2} = 0$; on a curve there are no $(0,2)$-forms, so *every* connection gives a holomorphic bundle. Gauge-equivalent connections give isomorphic holomorphic bundles, and conversely two connections giving isomorphic holomorphic bundles differ by a *complex* gauge transformation. Three classic facts then describe the Yang–Mills critical points in holomorphic terms:

- *Grothendieck.* On $\mathbb{CP}^1$ every holomorphic bundle is a sum of line bundles, $E \cong \mathcal{O}(a_1) \oplus \cdots \oplus \mathcal{O}(a_n)$, with $\mathcal{O}(a)$ the line bundle of degree a (so $\mathcal{O}(-1)$ is the tautological bundle of Chapter 5).

- *Narasimhan–Seshadri* (in the form Donaldson proved it). The minima, the projectively flat connections, correspond to the **polystable** holomorphic bundles, direct sums of stable bundles of the same slope. Here E is **stable** (**semistable**) if every holomorphic subbundle E' has slope $\deg E'/\operatorname{rank} E' < \deg E/\operatorname{rank} E$ ($\leq$). The semistable bundles form the open stratum of connections that flow down to the minimum.

- *Harder–Narasimhan.* Every bundle has a canonical filtration whose quotients are semistable with decreasing slopes; the Yang–Mills critical point that the downward flow from it reaches is (the polystable version of) the direct sum of those quotients. Its slopes (d_j/n_j) label a **stratum** of the space of connections.

So the critical set of S is a union of pieces, each the set of Yang–Mills connections of a given "type" $\mu = (d_1/n_1, \dots)$, and the space $\mathcal{A}$ of connections is stratified accordingly. This is the finite-dimensional-looking structure that makes a Morse theory possible.

8.18.7 The orbit space in two dimensions

Nash: "$S(A)$ is defined on the contractible space $\mathcal{A}$ but it descends to an orbit space whose topology is far from trivial." By the pitfall on $\mathcal{A}/\mathcal{G}$ and $B\mathcal{G}$, the topology of the orbit space is the topology of a classifying space. For the sphere it can be written down.

Worked example 8.177: Genus zero: $\mathcal{A}/\mathcal{G}_0 = \Omega\,\mathrm{SU}(n)$

Take $\Sigma = S^2$ and the based gauge group $\mathcal{G}_0$ (gauge transformations equal to $\mathbb{1}$ at a point). As a space it is the group of based maps $S^2 \to \mathrm{U}(n)$, the double loop space $\Omega^2\mathrm{U}(n)$. Then

$$\mathcal{A}/\mathcal{G}_0 \overset{(1)}{\simeq} B\mathcal{G}_0 \overset{(2)}{\simeq} B\big(\Omega(\Omega\mathrm{U}(n))\big) \overset{(3)}{\simeq} \Omega_0\mathrm{U}(n) \overset{(4)}{\simeq} \Omega\,\mathrm{SU}(n).$$

(1) $\mathcal{G}_0$ acts freely on the contractible space $\mathcal{A}$ (Example 8.169 and the pitfall after it).
(2) A based map of S^2 = (square with boundary collapsed) is a loop of loops.
(3) For any connected space Y, $B(\Omega Y) \simeq Y$: the path fibration $\Omega Y \to PY \to Y$ has contractible total space PY, so it is the universal ΩY-bundle. Here Y is the component $\Omega_0\mathrm{U}(n)$ of contractible loops (a loop of loops based at the constant loop stays in that component).
(4) $\mathrm{U}(n) = \mathrm{U}(1) \times \mathrm{SU}(n)$ as spaces, and the loops in U(1) that are contractible form a contractible space.

This is Nash's "$\mathcal{A}/\mathcal{G} = B\mathcal{G} = \Omega G$". For U(2) it is $\Omega\mathrm{SU}(2) = \Omega S^3$, the space of loops on the three-sphere, whose Morse theory we did in Chapter 7: the energy of paths has critical points (geodesics) of index $0, 2, 4, 6, \ldots$, one of each, and is perfect, so

$$P_t(\Omega S^3) = 1 + t^2 + t^4 + \cdots = \frac{1}{1-t^2}.$$

In general $P_t(\Omega\mathrm{SU}(n)) = \prod_{j=1}^{n-1}(1-t^{2j})^{-1}$ (Bott). A contractible space divided by a gauge group has become a space with infinitely many non-zero Betti numbers: Nash's "rich topology".

For the Atiyah–Bott theorem we need the full gauge group $\mathcal{G}$, whose classifying space is (Atiyah and Bott) the space of maps $\Sigma \to B\mathrm{U}(n)$ in the right homotopy class. For genus 0 and U(2) it has

$$P_t(B\mathcal{G}) \overset{(1)}{=} P_t(B\mathrm{U}(2))\,P_t(\Omega\mathrm{SU}(2)) \overset{(2)}{=} \frac{1}{(1-t^2)(1-t^4)} \cdot \frac{1}{1-t^2} = \frac{1}{(1-t^2)^2(1-t^4)}, \tag{8.355}$$

(1) Evaluation at the base point gives a fibration $\mathcal{G}_0 \to \mathcal{G} \to \mathrm{U}(2)$, hence $B\mathcal{G}_0 \to B\mathcal{G} \to B\mathrm{U}(2)$; all the cohomology is in even degrees, so the spectral sequence collapses and the Poincaré series multiply.
(2) $H^*(B\mathrm{U}(2))$ is polynomial on c_1 (degree 2) and c_2 (degree 4); Example 8.177.

and for genus g Atiyah and Bott found

$$P_t(B\mathcal{G}) = \frac{(1+t)^{2g}(1+t^3)^{2g}}{(1-t^2)^2(1-t^4)} \quad (\mathrm{U}(2)), \qquad P_t(B\mathcal{G}) = \frac{(1+t)^{2g}}{1-t^2} \quad (\mathrm{U}(1)). \tag{8.356}$$

The odd factors come from the $2g$ independent loops on Σ: a gauge transformation can wind around each of them.

8.18.8 The Hessian of the two-dimensional action

To know the *type* of each critical point we need the Hessian. Nash expands the action along a straight line $A_t = A + ta$ in the space of connections.

Worked example 8.178: Expanding the action: Nash's (8.204)–(8.206)

The curvature along the line is exactly quadratic in t:

$$F(A+ta) = \mathrm{d}(A+ta) + (A+ta)\wedge(A+ta) = F + t\,\mathrm{d}_A a + t^2\, a\wedge a.$$

Therefore

$$\begin{aligned} S(A_t) &\overset{(1)}{=} \langle F + t\,\mathrm{d}_A a + t^2 a\wedge a,\ F + t\,\mathrm{d}_A a + t^2 a\wedge a\rangle \\ &\overset{(2)}{=} S(A) + 2t\langle F, \mathrm{d}_A a\rangle + t^2\big\{\langle \mathrm{d}_A a, \mathrm{d}_A a\rangle + \langle a\wedge a, F\rangle + \langle F, a\wedge a\rangle\big\} + O(t^3) \\ &\overset{(3)}{=} S(A) + 2t\langle \mathrm{d}_A^\star F, a\rangle + t^2\big\{\|\mathrm{d}_A a\|^2 + 2\langle F, a\wedge a\rangle\big\} + O(t^3). \end{aligned}$$

(1) $S = \langle F, F\rangle$ with the pairing (8.353).
(2) Multiply out and collect powers of t; the t^3 and t^4 terms are $2t^3\langle \mathrm{d}_A a, a\wedge a\rangle + t^4\,\|a\wedge a\|^2$.
(3) Move d_A across the pairing; the real pairing is symmetric.

At a critical point $\mathrm{d}_A^\star F = 0$, so the t term vanishes, and the t^2 coefficient defines the Hessian. To write it as $\langle a, Ha\rangle$ we express $\langle F, a\wedge a\rangle$ through a. In an orthonormal coframe, $a = a_1 e^1 + a_2 e^2$, $a\wedge a = [a_1, a_2]\,\mathrm{vol}$, $F = \Phi\,\mathrm{vol}$, and $\star a = -a_2 e^1 + a_1 e^2$. Define $K(a) = [\Phi, \star a]$, whose components are $K_1 = -[\Phi, a_2]$, $K_2 = [\Phi, a_1]$. Then

$$\begin{aligned} \langle a, K(a)\rangle &\overset{(1)}{=} -\int \mathrm{tr}\big(-a_1[\Phi, a_2] + a_2[\Phi, a_1]\big)\mathrm{vol} \\ &\overset{(2)}{=} -\int \big(\mathrm{tr}(\Phi[a_1, a_2]) + \mathrm{tr}(\Phi[a_1, a_2])\big)\mathrm{vol} \overset{(3)}{=} 2\langle F, a\wedge a\rangle. \end{aligned}$$

(1) For 1-forms, $\alpha\wedge\star\beta = (\alpha_1\beta_1 + \alpha_2\beta_2)\mathrm{vol}$ (with matrix products in order).
(2) Cyclicity: $\mathrm{tr}(a_1[\Phi, a_2]) = \mathrm{tr}(\Phi a_2 a_1) - \mathrm{tr}(\Phi a_1 a_2) = -\mathrm{tr}(\Phi[a_1, a_2])$, and similarly $\mathrm{tr}(a_2[\Phi, a_1]) = \mathrm{tr}(\Phi[a_1, a_2])$.
(3) $\langle F, a\wedge a\rangle = -\int \mathrm{tr}(\Phi[a_1, a_2])\mathrm{vol}$, since $F\wedge\star(a\wedge a) = \Phi[a_1, a_2]\mathrm{vol}$.

Hence the second-order coefficient is

$$\langle a, Ha\rangle = \langle \mathrm{d}_A a, \mathrm{d}_A a\rangle + \langle a, [\star F, \star a]\rangle, \qquad H = \mathrm{d}_A^\star \mathrm{d}_A + [\star F, \star\,\cdot\,]. \tag{8.357}$$

Nash writes the zeroth-order term as "$\star(\star F(A)\,a)$": since $\star F$ is a function, $\star[\star F, a] = [\star F, \star a]$, and the product must be read as a commutator.

Worked example 8.179: Gauge directions are zero modes

Let ξ be an infinitesimal gauge transformation (an $\mathrm{ad}\,P$-valued function). The connection moves by $a = \mathrm{d}_A\xi$. At a critical point,

$$\begin{aligned} H(\mathrm{d}_A\xi) &\overset{(1)}{=} \mathrm{d}_A^\star\big([F, \xi]\big) + [\Phi, \star\mathrm{d}_A\xi] \overset{(2)}{=} -\star\,\mathrm{d}_A[\Phi, \xi] + [\Phi, \star\mathrm{d}_A\xi] \\ &\overset{(3)}{=} -\star\,\big([\mathrm{d}_A\Phi, \xi] + [\Phi, \mathrm{d}_A\xi]\big) + [\Phi, \star\mathrm{d}_A\xi] \overset{(4)}{=} 0. \end{aligned}$$

(1) $\mathrm{d}_A\mathrm{d}_A\xi = [F, \xi]$ (curvature is the square of the covariant derivative).
(2) $\mathrm{d}_A^\star = -\star\,\mathrm{d}_A\star$ and $\star[F, \xi] = [\Phi, \xi]$.

(3) Leibniz rule.
(4) $\mathrm{d}_A\Phi = 0$ at a critical point, and $\star$ commutes with $[\Phi, \cdot]$.

As expected, the whole tangent space to the gauge orbit, which is infinite-dimensional, lies in the kernel of H.

So, as Nash says, "we must also impose a gauge condition, which we take to be the standard one, $\mathrm{d}_A^\star a = 0$": the directions orthogonal to the orbit, since $\langle a, \mathrm{d}_A\xi\rangle = \langle \mathrm{d}_A^\star a, \xi\rangle$. The **index** of a critical point is then the dimension of a maximal subspace of $\ker \mathrm{d}_A^\star$ on which $\langle a, Ha\rangle < 0$.

Watch out: Why the index is finite

Nash says the index is finite "because ellipticity renders $\ker \mathrm{d}_A^\star$ finite dimensional". Taken literally that is not right: $\ker \mathrm{d}_A^\star$ on 1-forms is infinite-dimensional (it contains all the physical, transverse fluctuations). What is true is this. On $\ker \mathrm{d}_A^\star$, H agrees with

$$H + \mathrm{d}_A\mathrm{d}_A^\star = \left(\mathrm{d}_A^\star\mathrm{d}_A + \mathrm{d}_A\mathrm{d}_A^\star\right) + [\star F, \star\,\cdot\,],$$

a Laplacian plus a bounded zeroth-order term. That operator is elliptic on a compact surface, so its spectrum is discrete and goes to $+\infty$, as in Figure 8.85. Only finitely many eigenvalues are negative: the index is finite.

Worked example 8.180: Abelian critical points are minima

For U(1) all the fields are ordinary imaginary-valued forms and commutators vanish, so $K = 0$ and $H = \mathrm{d}^\star\mathrm{d}$, giving $\langle a, Ha\rangle = \|\mathrm{d}a\|^2 \geq 0$. The index is zero: every U(1) Yang–Mills connection is a minimum. The null directions in the gauge slice are the harmonic 1-forms, $\mathrm{d}a = \mathrm{d}^\star a = 0$, a space of dimension $b_1(\Sigma) = 2g$. They move the connection through the torus $H^1(\Sigma;\mathbb{R})/H^1(\Sigma;\mathbb{Z})$ of constant-curvature connections modulo gauge (the Jacobian of Σ). So in each degree the critical set of the U(1) theory is a torus T^{2g} of minima.

Worked example 8.181: Negative directions at a split U(2) connection

Take $E = L_1 \oplus L_2$ with degrees $d_1 > d_2$, so $\Phi = \mathrm{diag}(-i\lambda_1, -i\lambda_2)$ with $\lambda_1 > \lambda_2$. Write a fluctuation as

$$a = \begin{pmatrix} \alpha_1 & -\bar\beta \\ \beta & \alpha_2 \end{pmatrix},$$

with α_j imaginary 1-forms and β a complex 1-form with values in $\mathrm{Hom}(L_1, L_2)$ (the $(2,1)$ entry maps L_1 to L_2). The diagonal part commutes with Φ and feels only $\mathrm{d}^\star\mathrm{d} \geq 0$, exactly as in the abelian case. For the off-diagonal part, commuting with Φ multiplies the $(2,1)$ entry by $-i\lambda_2 + i\lambda_1$, so $K(a)_{21} = i(\lambda_1 - \lambda_2)\star\beta$. Using $\mathrm{tr}(XY) = -2\,\mathrm{Re}(\bar x y)$ for off-diagonal anti-Hermitian X, Y with lower entries x, y,

$$\langle a, K(a)\rangle_{\mathrm{off}} \overset{(1)}{=} 2(\lambda_1 - \lambda_2)\int \mathrm{Re}\big(i\,\bar\beta_k(\star\beta)_k\big)\mathrm{vol} \overset{(2)}{=} 4(\lambda_1 - \lambda_2)\int \mathrm{Im}(\bar\beta_1\beta_2)\,\mathrm{vol}$$
$$\overset{(3)}{=} 4(\lambda_1 - \lambda_2)\int \left(|\beta_z|^2 - |\beta_{\bar z}|^2\right)\mathrm{vol}.$$

(1) $\langle a, b\rangle = -\int \mathrm{tr}(a_k b_k)\mathrm{vol}$ and the trace formula above.
(2) $(\star\beta)_1 = -\beta_2$, $(\star\beta)_2 = \beta_1$, so $\bar\beta_k(\star\beta)_k = 2i\,\mathrm{Im}(\bar\beta_2\beta_1)$; multiply by i and take the real part.
(3) Write $\beta = \beta_z\mathrm{d}z + \beta_{\bar z}\mathrm{d}\bar z$ with $z = x + iy$, so $\beta_z = \tfrac12(\beta_1 - i\beta_2)$ and $\beta_{\bar z} = \tfrac12(\beta_1 + i\beta_2)$; expanding, $|\beta_z|^2 - |\beta_{\bar z}|^2 = \mathrm{Im}(\bar\beta_1\beta_2)$.

So the $(0,1)$-part of β gets a *negative* potential of strength proportional to $\lambda_1 - \lambda_2$, which is to say to $d_1 - d_2$. These $(0,1)$-forms are precisely the infinitesimal changes of the holomorphic structure $\bar\partial_A$ in the off-diagonal direction. Balancing the negative potential against the kinetic term $\|\mathrm{d}_A a\|^2$ (a Weitzenböck argument that we do not reproduce), the negative eigenspace of H on the gauge slice turns out to be exactly the space of holomorphic deformations $H^{0,1}(\Sigma, \mathrm{Hom}(L_1, L_2)) = H^1(\Sigma, L_1^* \otimes L_2)$.

Worked example 8.182: Counting with Riemann–Roch

Riemann–Roch for a holomorphic line bundle L of degree ℓ on a surface of genus g (Chapters 4 and 5) says $h^0(L) - h^1(L) = \ell + 1 - g$. Apply it to $L = L_1^* \otimes L_2$, of degree $\ell = d_2 - d_1 < 0$:

$$h^1(L_1^* L_2) \overset{(1)}{=} h^0(L_1^* L_2) - (d_2 - d_1) - 1 + g \overset{(2)}{=} d_1 - d_2 + g - 1.$$

(1) Riemann–Roch, solved for h^1.
(2) A line bundle of negative degree has no non-zero holomorphic sections (a section would have $\ell < 0$ zeros counted with multiplicity), so $h^0 = 0$.

Each complex dimension is two real ones, so

$$\mathrm{index}(L_1 \oplus L_2) = 2\,(d_1 - d_2 + g - 1) \qquad (d_1 > d_2). \tag{8.358}$$

On $\mathbb{CP}^1$ ($g = 0$) with $L_1^* L_2 = \mathcal{O}(-m)$, $m = d_1 - d_2$, we can see the $m - 1$ classes directly: by Serre duality $H^1(\mathcal{O}(-m)) \cong H^0(\mathcal{O}(m-2))^*$, the dual of the space of homogeneous polynomials of degree $m-2$ in two variables, which has dimension $m - 1$.
The simplest case is $\mathcal{O}(1) \oplus \mathcal{O}(-1)$ on $\mathbb{CP}^1$, of degree 0: $m = 2$, index 2, action $8\pi^2/\mathcal{A}_\Sigma$. Its single complex unstable direction deforms it into the trivial bundle through the non-split extension

$$0 \to \mathcal{O}(-1) \xrightarrow{s \mapsto (z_0 s,\, z_1 s)} \mathcal{O} \oplus \mathcal{O} \to \mathcal{O}(1) \to 0,$$

the tautological line sitting inside $\mathbb{C}^2$ (Chapter 5). Rolling downhill from $\mathcal{O}(1) \oplus \mathcal{O}(-1)$ along this direction ends at the flat connection on $\mathcal{O} \oplus \mathcal{O}$, with action 0.

Since $d_1 - d_2$ can be as large as we like, there are "critical points of arbitrarily large index", as Nash says; their actions $\frac{4\pi^2}{\mathcal{A}_\Sigma}(d_1^2 + d_2^2)$ grow without bound too.

8.18.9 Atiyah–Bott: the action is equivariantly perfect

We now have all the ingredients of the equivariant Morse series of S with respect to the full gauge group $\mathcal{G}$. Each critical set C_μ (the Yang–Mills connections of type μ) is a $\mathcal{G}$-invariant set of index λ_μ, contributing $t^{\lambda_\mu} P_t^{\mathcal{G}}(C_\mu)$. The theorem Nash records as (8.203) is

$$M_t^{\mathcal{G}}(S) \;:=\; \sum_\mu t^{\lambda_\mu} P_t^{\mathcal{G}}(C_\mu) \;=\; P_t^{\mathcal{G}}(\mathcal{A}) \;=\; P_t(B\mathcal{G}). \tag{8.359}$$

The second equality holds because $\mathcal{A}$ is contractible. The first is the content: the Morse inequalities are equalities.

Key idea: Why no cancellations can occur

In a Morse complex, cancellations between critical points of adjacent index are what make $M_t \neq P_t$. Atiyah and Bott showed they cannot happen here by a criterion that is visible in the rotating sphere of Example 8.165: at each critical set the stabiliser contains a circle that acts on the negative directions *without fixed vectors*. At $L_1 \oplus L_2$, the circle $\mathrm{diag}(e^{i\theta}, 1)$ fixes the connection but acts on the negative directions $\beta \in H^1(L_1^* L_2)$ by $\beta \mapsto e^{-i\theta}\beta$. Then the equivariant Euler class of the negative bundle is not a zero-divisor, each stratum's Thom–Gysin sequence splits into short exact sequences, and the Poincaré series simply add up. At the poles of the rotating sphere the rotation acts on the tangent plane with weight one: the same mechanism, in miniature.

Worked example 8.183: $\mathrm{U}(1)$: perfect in every genus

In each degree there is one critical set, the torus T^{2g} of minima (Example 8.180), with stabiliser the constant $\mathrm{U}(1)$. So

$$M_t^{\mathcal{G}}(S) \overset{(1)}{=} t^0\, P_t(T^{2g})\, P_t(B\mathrm{U}(1)) \overset{(2)}{=} \frac{(1+t)^{2g}}{1-t^2} \overset{(3)}{=} P_t(B\mathcal{G}).$$

(1) The constant $\mathrm{U}(1)$ acts trivially on the connection and $\mathcal{G}/\mathrm{U}(1)$ acts freely, so the equivariant cohomology of the critical set is $H^*(T^{2g}) \otimes H^*(B\mathrm{U}(1))$.
(2) $P_t(T^{2g}) = (1+t)^{2g}$ and $P_t(B\mathrm{U}(1)) = 1/(1-t^2)$.
(3) (8.356).

Worked example 8.184: $\mathrm{U}(2)$ on the sphere: the whole check

Take $\Sigma = S^2$ and a $\mathrm{U}(2)$ bundle of degree d. By Grothendieck and Example 8.174, the critical points are the splittings $\mathcal{O}(d_1) \oplus \mathcal{O}(d_2)$ with $d_1 \geq d_2$, $d_1 + d_2 = d$, each a single gauge orbit. The stabilisers and indices are:

- $d_1 = d_2$ (d even): stabiliser $\mathrm{U}(2)$, index 0, contribution $P_t(B\mathrm{U}(2)) = \dfrac{1}{(1-t^2)(1-t^4)}$;
- $d_1 > d_2$: stabiliser $\mathrm{U}(1) \times \mathrm{U}(1)$, index $2(d_1 - d_2 - 1)$ by (8.358), contribution $\dfrac{t^{2(d_1-d_2-1)}}{(1-t^2)^2}$.

Degree 0. The splittings are $(m, -m)$, $m \geq 0$, with $d_1 - d_2 = 2m$:

$$M_t^{\mathcal{G}} \overset{(1)}{=} \frac{1}{(1-t^2)(1-t^4)} + \sum_{m\geq 1} \frac{t^{2(2m-1)}}{(1-t^2)^2} \overset{(2)}{=} \frac{1}{(1-t^2)(1-t^4)} + \frac{t^2}{(1-t^2)^2(1-t^4)}$$
$$\overset{(3)}{=} \frac{(1-t^2)+t^2}{(1-t^2)^2(1-t^4)} = \frac{1}{(1-t^2)^2(1-t^4)} \overset{(4)}{=} P_t(B\mathcal{G}).$$

(1) The list above.
(2) Geometric series: $\sum_{m\geq 1} t^{4m-2} = t^2/(1-t^4)$.
(3) Common denominator.
(4) (8.355).

Expanding both sides term by term makes the bookkeeping visible:

degree $2j$	0	2	4	6	8
minimum $\mathcal{O}\oplus\mathcal{O}$ (index 0)	1	1	2	2	3
$\mathcal{O}(1)\oplus\mathcal{O}(-1)$ (index 2)	0	1	2	3	4
$\mathcal{O}(2)\oplus\mathcal{O}(-2)$ (index 6)	0	0	0	1	2
$\mathcal{O}(3)\oplus\mathcal{O}(-3)$ (index 10)	0	0	0	0	0
total $= b_{2j}(B\mathcal{G})$	1	2	4	6	9

Degree 1. The splittings are $(m+1,-m)$, $m\geq 0$, with $d_1-d_2=2m+1$ and index $4m$. There is no splitting with $d_1=d_2$, so the minimum is $\mathcal{O}(1)\oplus\mathcal{O}$ (index 0). Then

$$M_t^{\mathcal{G}}=\sum_{m\geq 0}\frac{t^{4m}}{(1-t^2)^2}=\frac{1}{(1-t^2)^2(1-t^4)}=P_t(B\mathcal{G}),$$

perfect again, with a completely different set of critical points.

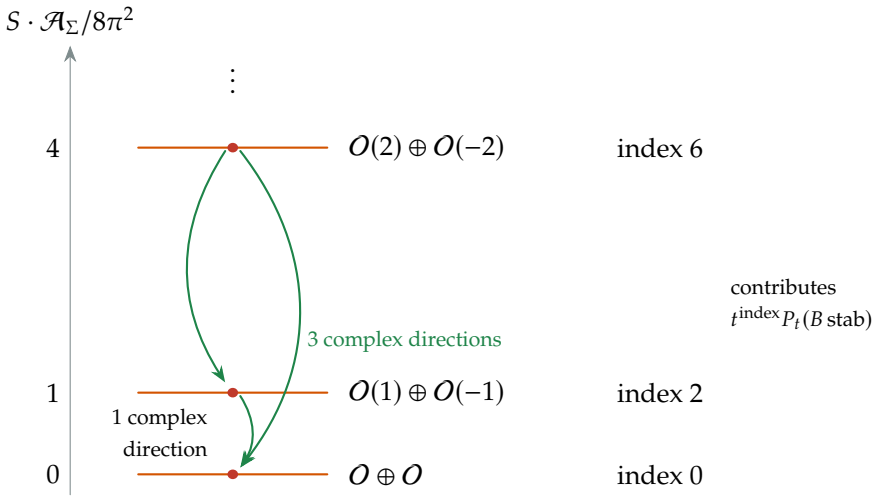


Figure 8.90: The critical points of S for U(2) bundles of degree 0 on the sphere: an infinite ladder of splittings $\mathcal{O}(m)\oplus\mathcal{O}(-m)$ with action $8\pi^2m^2/\mathcal{A}_\Sigma$ and index $2(2m-1)$. Arrows show downhill directions, which deform the splitting into a less unbalanced bundle. Each rung contributes its full equivariant cohomology; nothing cancels, and the ladder adds up to $P_t(B\mathcal{G})$ (Example 8.184).

Worked example 8.185: What perfection buys: the cohomology of a moduli space

Run the argument backwards. For a U(2) bundle of odd degree on a surface of genus g, the lowest stratum is the semistable one, $\mathcal{C}_{ss}$ (the projectively flat connections; for odd degree semistable means stable). The other critical sets are splittings $L_1\oplus L_2$ with $d_1-d_2=2m+1$, $m\geq 0$, of index $2(2m+g)$ by (8.358), each contributing $\left((1+t)^{2g}/(1-t^2)\right)^2$ (two copies of the U(1) answer of Example 8.183). Perfection gives

$$P_t^{\mathcal{G}}(\mathcal{C}_{ss})\overset{(1)}{=}P_t(B\mathcal{G})-\sum_{m\geq 0}t^{2(2m+g)}\frac{(1+t)^{4g}}{(1-t^2)^2}\overset{(2)}{=}\frac{(1+t)^{2g}\left[(1+t^3)^{2g}-t^{2g}(1+t)^{2g}\right]}{(1-t^2)^2(1-t^4)}.$$

(1) (8.359), solved for the bottom stratum.
(2) (8.356) and $\sum_m t^{4m}=1/(1-t^4)$.

The stabiliser on $\mathcal{C}_{ss}$ is just the constant U(1) (stable bundles have only scalar automorphisms), so dividing by $P_t(B\mathrm{U}(1))=1/(1-t^2)$ gives the moduli space of stable bundles,

and removing the Jacobian factor $(1+t)^{2g}$ (fixing the determinant) gives

$$P_t\big(\mathcal{N}_0(2,\text{odd})\big) = \frac{(1+t^3)^{2g} - t^{2g}(1+t)^{2g}}{(1-t^2)(1-t^4)}. \tag{8.360}$$

Checks: for $g=0$ the numerator is $1-1=0$, and indeed there are no stable rank-2 bundles on $\mathbb{CP}^1$ (Grothendieck). For $g=1$ the numerator is $1+2t^3+t^6-t^2-2t^3-t^4=(1-t^2)(1-t^4)$, so $P_t=1$: a single point, Atiyah's unique stable bundle on an elliptic curve. For $g=2$, long division gives $P_t = 1+t^2+4t^3+t^4+t^6$, the Betti numbers of a compact complex threefold (the intersection of two quadrics in $\mathbb{CP}^5$). None of these numbers was put in by hand.

Physical picture: Why two-dimensional Yang–Mills is special

Two-dimensional Yang–Mills has no propagating gluons: a gauge field in two dimensions has no transverse polarisations. Correspondingly its quantum theory is exactly solvable (Migdal, Witten): the partition function on a surface of genus g and area $\mathcal{A}_\Sigma$ is a sum over irreducible representations R of the gauge group, $Z=\sum_R(\dim R)^{2-2g}\exp\!\big(-\frac{e^2\mathcal{A}_\Sigma}{2}C_2(R)\big)$, with C_2 the quadratic Casimir. Witten showed that its weak-coupling limit localises on the Yang–Mills critical points we have just classified, and recovers the Atiyah–Bott results (and the intersection theory of the moduli space) from the path integral. The Morse theory is the classical shadow of an exactly solvable quantum field theory.

Try it: The torus

For U(1) on a flat torus of area $\mathcal{A}$, list the critical points of S, their action and index, and check (8.359).
Answer: in degree d the critical set is the torus T^2 of constant-curvature connections, $S=4\pi^2d^2/\mathcal{A}$, index 0; $M_t^{\mathcal{G}}=(1+t)^2/(1-t^2)=P_t(B\mathcal{G})$ from (8.356) with $g=1$.

8.18.10 Four dimensions: Yang–Mills on S^4

Finally Nash returns to where the chapter began: SU(2) Yang–Mills on S^4. Here the orbit space is again topologically rich, but (in 1983) no Morse theory was available and only the minima, the instantons, were known.

Worked example 8.186: The topology of $\mathcal{A}/\mathcal{G}_0$ on S^4

For a bundle of instanton number k over S^4, the based gauge group is (up to homotopy) the space of based maps $S^4\to \mathrm{SU}(2)=S^3$, i.e. Ω^4S^3. Then

$$\mathcal{A}_k/\mathcal{G}_0 \overset{(1)}{\simeq} B\mathcal{G}_0 \overset{(2)}{\simeq} \Omega^3_kS^3, \qquad \pi_i(\Omega^3S^3) \overset{(3)}{=} \pi_{i+3}(S^3).$$

(1) Free action on the contractible $\mathcal{A}_k$, as in two dimensions.
(2) $B(\Omega Y)\simeq Y$ with $Y=\Omega^3S^3$ (the component labelled by k).
(3) A based map of S^i into Ω^3S^3 is a based map of S^{i+3} into S^3.

The groups $\pi_{i+3}(S^3)$ are $\mathbb{Z}_2,\mathbb{Z}_2,\mathbb{Z}_{12},\mathbb{Z}_2,\mathbb{Z}_2,\mathbb{Z}_3,\mathbb{Z}_{15},\dots$ for $i=1,2,3,\dots$: the homotopy groups of spheres, all non-zero. So $\mathcal{A}_k/\mathcal{G}_0$ has "plenty of cohomology" (mostly torsion; with $\mathbb{Z}_p$ coefficients it is enormous). The Atiyah–Jones conjecture, later proved by Boyer, Hurtubise, Mann and Milgram, says that the instanton moduli space $\mathcal{M}_k$ captures more and more of this topology as k grows: the inclusion $\mathcal{M}_k\to\mathcal{A}_k/\mathcal{G}_0$ is an isomorphism on

homology up to a degree that grows linearly with k.

Yet Nash writes that "no Morse-type results hold". The reason is the symmetry he singles out: *conformal invariance*.

Worked example 8.187: Which actions are conformally invariant

Replace the metric g on an n-manifold by $g' = \Omega^2 g$ with $\Omega > 0$ a function. Inverse metrics scale as Ω^{-2} and the volume form as Ω^n. So

$$\int |F|^2_{g'}\,\mathrm{dvol}_{g'} \overset{(1)}{=} \int \tfrac{1}{2} g'^{\mu\alpha} g'^{\nu\beta} F_{\mu\nu} F_{\alpha\beta}\,\Omega^n \mathrm{dvol}_g \overset{(2)}{=} \int \Omega^{n-4}\,|F|^2_g\,\mathrm{dvol}_g,$$
$$\int |\mathrm{d}\phi|^2_{g'}\,\mathrm{dvol}_{g'} \overset{(3)}{=} \int \Omega^{n-2}\,|\mathrm{d}\phi|^2_g\,\mathrm{dvol}_g.$$

(1) The norm of a 2-form uses two inverse metrics; $\mathrm{dvol}_{g'} = \Omega^n \mathrm{dvol}_g$.
(2) Each inverse metric gives Ω^{-2}.
(3) A 1-form norm uses one inverse metric.

So the Yang–Mills action is conformally invariant exactly in $n = 4$, and the sigma-model energy $\int |\mathrm{d}\phi|^2$ exactly in $n = 2$. In $n = 3$ neither term is invariant, and they scale oppositely (Ω^{-1} and Ω^{+1}): this is Derrick's balance of Section 8.12.2, and the Higgs vacuum value C provides the length scale $1/C$ of a monopole. In $n = 2$ the Yang–Mills action scales as Ω^{-2} and the area $\mathcal{A}_\Sigma$ sets the scale, as in (8.354).

The conformal group of S^4 is non-compact (it contains the dilations $x \mapsto sx$ of $\mathbb{R}^4 = S^4 \setminus \{\infty\}$). Dilating an instanton does not change its action, so one can shrink it to a point. For the BPST instanton of size ρ the action density is $s(r) = 48\rho^4/(r^2+\rho^2)^4$ (normalised so that $\int_{\mathbb{R}^4} s\,\mathrm{d}^4x = 8\pi^2$), and

$$\int_{\mathbb{R}^4} s\,\mathrm{d}^4x \overset{(1)}{=} 2\pi^2 \int_0^\infty \frac{48\rho^4\, r^3}{(r^2+\rho^2)^4}\mathrm{d}r \overset{(2)}{=} 48\pi^2\rho^4 \int_0^\infty \frac{u\,\mathrm{d}u}{(u+\rho^2)^4} \overset{(3)}{=} 48\pi^2\rho^4 \cdot \frac{1}{6\rho^4} = 8\pi^2,$$

(1) Radial integration in $\mathbb{R}^4$: $\mathrm{d}^4x = 2\pi^2 r^3 \mathrm{d}r$.
(2) Substitute $u = r^2$, $\mathrm{d}u = 2r\,\mathrm{d}r$.
(3) $\int_0^\infty u(u+a)^{-4}\mathrm{d}u = a^{-2}\,\Gamma(2)\Gamma(2)/\Gamma(4) = 1/(6a^2)$ with $a = \rho^2$.

independently of ρ. As $\rho \to 0$ the density concentrates at the origin: a family of minima of constant action with no limit among smooth connections. It converges to a flat connection away from the origin plus a "bubble" of action $8\pi^2$ at the origin.

Key idea: Why four dimensions resisted Morse theory

A min-max sequence on $\mathcal{A}_k/\mathcal{G}_0$ over S^4 can lose compactness by bubbling off instantons (or anti-instantons), each carrying action at least $8\pi^2$. Unlike the monopole case, there is no energy threshold below which a non-trivial min-max level is guaranteed to sit: the non-trivial topology of $\Omega^3 S^3$ may be "explained" entirely by configurations near the boundary of the space, where instantons have shrunk to points. So the topology does not force non-minimal critical points in any obvious way, and none were known in 1983.

Two later results fill in the picture. Bourguignon, Lawson and Simons showed that on S^4 every *stable* SU(2) Yang–Mills connection (index zero) is self-dual or anti-self-dual: there are no local minima other than the instantons. And Sibner, Sibner and Uhlenbeck (1989) proved, by a min-max argument made compact by imposing a symmetry that prevents bubbling,

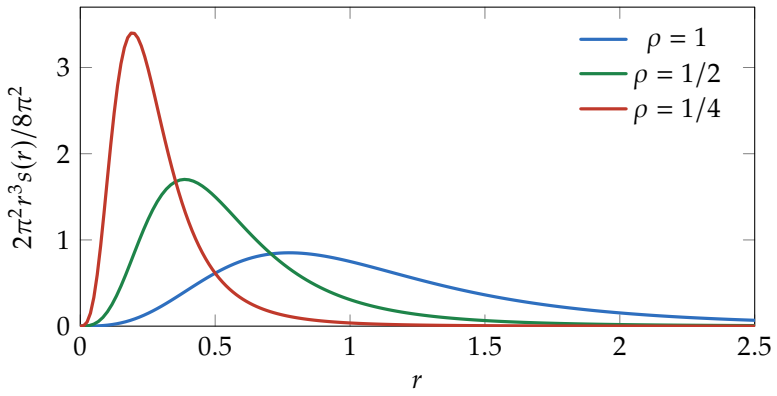

Figure 8.91: Bubbling. The radial distribution of the action of a BPST instanton for three sizes. Each curve has area one (total action $8\pi^2$), but as $\rho \to 0$ the action piles up at the origin. A sequence of shrinking instantons has constant action and zero gradient, yet no smooth limit: the Palais–Smale condition fails in four dimensions, by concentration rather than by escape to infinity.

that non-self-dual solutions of the Yang–Mills equations on S^4 do exist. They are necessarily unstable saddle points.

The two-dimensional sigma model

Nash's last remark is that the two-dimensional sigma model, also conformally invariant (Example 8.187), likewise "only has absolute minima". Take maps $\vec{n} : S^2 \to S^2 \subset \mathbb{R}^3$ with energy $E = \frac{1}{2}\int |\partial_1\vec{n}|^2 + |\partial_2\vec{n}|^2 \,\mathrm{d}^2x$ (the O(3) model; isothermal coordinates x^1, x^2 on the domain), and degree $N = \frac{1}{4\pi}\int \vec{n}\cdot(\partial_1\vec{n}\times\partial_2\vec{n})\,\mathrm{d}^2x$.

Worked example 8.188: The Bogomolny bound of the sigma model

$$0 \le \frac{1}{2}\int |\partial_1\vec{n} \pm \vec{n}\times\partial_2\vec{n}|^2 \mathrm{d}^2x \overset{(1)}{=} \frac{1}{2}\int \left(|\partial_1\vec{n}|^2 + |\partial_2\vec{n}|^2\right)\mathrm{d}^2x \pm \int \partial_1\vec{n}\cdot(\vec{n}\times\partial_2\vec{n})\,\mathrm{d}^2x$$
$$\overset{(2)}{=} E \mp \int \vec{n}\cdot(\partial_1\vec{n}\times\partial_2\vec{n})\,\mathrm{d}^2x \overset{(3)}{=} E \mp 4\pi N.$$

(1) Expand the square; $|\vec{n}\times\partial_2\vec{n}| = |\partial_2\vec{n}|$ because $\vec{n}\cdot\partial_2\vec{n} = 0$ (from $|\vec{n}| = 1$).
(2) Cyclic property of the triple product: $\partial_1\vec{n}\cdot(\vec{n}\times\partial_2\vec{n}) = \vec{n}\cdot(\partial_2\vec{n}\times\partial_1\vec{n}) = -\vec{n}\cdot(\partial_1\vec{n}\times\partial_2\vec{n})$.
(3) Definition of N.

So $E \ge 4\pi|N|$, with equality iff $\partial_1\vec{n} = \mp\vec{n}\times\partial_2\vec{n}$: the Cauchy–Riemann equations for $\vec{n}$ viewed (by stereographic projection) as a function $w(z)$. Holomorphic maps (rational functions of degree N) and antiholomorphic maps are the absolute minima: the exact analogue of instantons and of BPS monopoles.

Worked example 8.189: Every critical point is a minimum

Let $\vec{n}$ be any critical point (a harmonic map). Put $z = x^1 + ix^2$, $\vec{n}_z = \frac{1}{2}(\partial_1\vec{n} - i\partial_2\vec{n})$, and form $\Psi = \vec{n}_z\cdot\vec{n}_z$. Then

$$\partial_{\bar{z}}\Psi \overset{(1)}{=} 2\,\vec{n}_z\cdot\vec{n}_{z\bar{z}} \overset{(2)}{=} 2\,\vec{n}_z\cdot\left(-\tfrac{1}{4}|\nabla\vec{n}|^2\,\vec{n}\right) \overset{(3)}{=} 0.$$

(1) Product rule.

(2) $\vec{n}_{z\bar{z}} = \frac{1}{4}\nabla^2\vec{n}$, and the harmonic map equation for maps into the unit sphere is $\nabla^2\vec{n} = -|\nabla\vec{n}|^2\vec{n}$ (the Laplacian is normal to the sphere).
(3) $\vec{n}\cdot\vec{n}_z = 0$, since $|\vec{n}| = 1$.

So $\Psi\,\mathrm{d}z^2$ is a *holomorphic quadratic differential* on the domain sphere. On S^2 the only one is zero (it would be a holomorphic section of K^2, a line bundle of degree $-4 < 0$). Hence $\Psi = \frac{1}{4}\big(|\partial_1\vec{n}|^2 - |\partial_2\vec{n}|^2 - 2i\,\partial_1\vec{n}\cdot\partial_2\vec{n}\big) = 0$: the map is conformal, so it is holomorphic or antiholomorphic wherever $\mathrm{d}\vec{n} \neq 0$, and it saturates the bound of Example 8.188. *Every* harmonic map $S^2 \to S^2$ is an absolute minimum. (Eells and Wood; Lemaire.)

functional	scale	how condition (C) fails	non-minimal critical points
YMH, $\mathbb{R}^3$, $\lambda = 0$	$1/C$	monopoles escape to infinity	yes: infinitely many, unbounded energy (Taubes)
YM, surface Σ	area $\mathcal{A}_\Sigma$	it does not fail	yes: splittings, arbitrarily large index; equivariantly perfect (Atiyah–Bott)
YM, S^4	none (conformal)	instantons bubble	none known in 1983; exist (Sibner–Sibner–Uhlenbeck 1989)
sigma model, $S^2 \to S^2$	none (conformal)	harmonic spheres bubble	none: every critical point is a minimum

Reading Nash (pp. 257–258, (8.201)–(8.206))

For U(n) Yang–Mills on a Riemann surface Nash writes the action (8.201), the equations (8.202) with the observation that $\star F$ is a covariantly constant section of $\mathrm{ad}\,P$, mentions the holomorphic reformulation, identifies the orbit space for genus zero as $B\mathcal{G} = \Omega G$, and states the Atiyah–Bott equivariant perfection (8.203). He expands the action to second order (8.204), defines the Hessian (8.205) and writes it as $H = \mathrm{d}_A^\star\mathrm{d}_A + \star(\star F(A)\cdot)$ (8.206), which must be read as $\mathrm{d}_A^\star\mathrm{d}_A + [\star F, \star\,\cdot]$; he imposes the gauge $\mathrm{d}_A^\star a = 0$ and notes that the index is finite and can be arbitrarily large. The finiteness comes from ellipticity of H on the slice, not from finite dimensionality of $\ker \mathrm{d}_A^\star$ (see the pitfall above). For SU(2) on S^4 he says no Morse theory is known, only minima, and he links this to conformal invariance, which the two-dimensional sigma model shares. We added the splitting of Yang–Mills connections and their action values, the minimum bound, the holomorphic dictionary (Grothendieck, Narasimhan–Seshadri, Harder–Narasimhan), the loop-space identification, the explicit Hessian with its gauge zero modes and negative directions, the Riemann–Roch index formula, the full U(2) check and the moduli space Poincaré polynomial, the conformal weights, bubbling, the sigma-model bound and the harmonic-map theorem, and the later four-dimensional results.

Recap

- Morse theory: topology forces critical points; $M_t - P_t = (1+t)Q_t$. In infinite dimensions one needs an elliptic Hessian (finite index), the Palais–Smale condition (compactness), and a way of dividing out the gauge group (free action of $\mathcal{G}_0$, or equivariant cohomology).
- Min-max over non-contractible families (the mountain pass) produces saddles.
- YMH on $\mathbb{R}^3$: E descends to $C_k = \mathcal{A}^k_{YMH}/\mathcal{G}$, the sectors are labelled by the magnetic charge, the minima $\mathcal{M}'_k$ form a Morse–Bott critical manifold with Hessian $D_1^\star D_1$,

and $\pi_0(\mathcal{G}) = \pi_3(S^3) = \mathbb{Z}$ gives a non-contractible loop. Min-max over it gives Taubes' monopole–antimonopole saddle at a level below $8\pi C$, where escape to infinity is energetically forbidden. Taubes: infinitely many non-minimal critical points, of unbounded energy.

- YM on a surface: $\mathrm{d}_A(\star F) = 0$, so Yang–Mills connections are sums of constant-curvature pieces with $S = \frac{4\pi^2}{\mathcal{A}_\Sigma} \sum d_j^2/n_j$. The Hessian is $\mathrm{d}_A^\star \mathrm{d}_A + [\star F, \star\,\cdot\,]$; the index of $L_1 \oplus L_2$ is $2(d_1 - d_2 + g - 1)$ by Riemann–Roch. S is equivariantly perfect: $M_t^{\mathcal{G}}(S) = P_t(B\mathcal{G})$, checked in full for U(1) and for U(2) on S^2, and it computes the cohomology of moduli spaces of stable bundles.
- YM on S^4 and the sigma model on S^2 are conformally invariant; compactness fails by bubbling, and only minima were known (for the sigma model, only minima exist).

Chapter summary

This chapter asked one question of gauge theory in several guises: *what does the space of all gauge fields look like, and where on it do the solutions of the field equations sit?* The answers came in three layers.

1. *The arena* (Nash §§1–2). The space $\mathcal{A}$ of connections is affine and therefore contractible, but the gauge group $\mathcal{G}$ is topologically rich: it is an iterated loop space of the structure group, with homotopy groups made of homotopy groups of spheres. So the physical configuration space $\mathcal{A}/\mathcal{G}$ (the space the path integral is really over) is topologically rich too. The integers that label its components, the instanton number and the magnetic charge, are Chern numbers, and they are also winding numbers of gauge transformations or Higgs fields at infinity. Secondary classes (Chern–Simons forms) appear when a characteristic form is exact: they are the "half" of an instanton number that lives on the boundary, and the large gauge transformations that shift them produce θ-vacua.

2. *The special solutions* (Nash §§3–5). Completing a square gives a topological lower bound on the action or energy, saturated exactly by a first-order equation: self-duality $F = \pm \star F$ for instantons (bound $8\pi^2|k|$), the Bogomolny equation $F = -\star \mathrm{d}_A\phi$ for monopoles (bound $4\pi C|k|$). The two are the same equation, the second being the first with a translation (or rotation) symmetry imposed. Their solution spaces are finite-dimensional moduli spaces whose dimensions are indices of elliptic deformation complexes ($8k-3$ for SU(2) instantons on S^4, $4k$ for framed SU(2) monopoles), with explicit descriptions (ADHM for instantons, rational maps for monopoles). The monopole moduli spaces carry a natural hyperkähler metric whose geodesics are the slow motions of monopoles: 90° scattering in head-on collisions.

3. *All the critical points* (Nash §6). The topology of $\mathcal{A}/\mathcal{G}$ forces critical points beyond the minima, provided the functional behaves well enough for Morse theory to apply. For monopoles it does (Taubes), for two-dimensional Yang–Mills it does perfectly (Atiyah–Bott), and for four-dimensional Yang–Mills and the two-dimensional sigma model conformal invariance (bubbling) gets in the way.

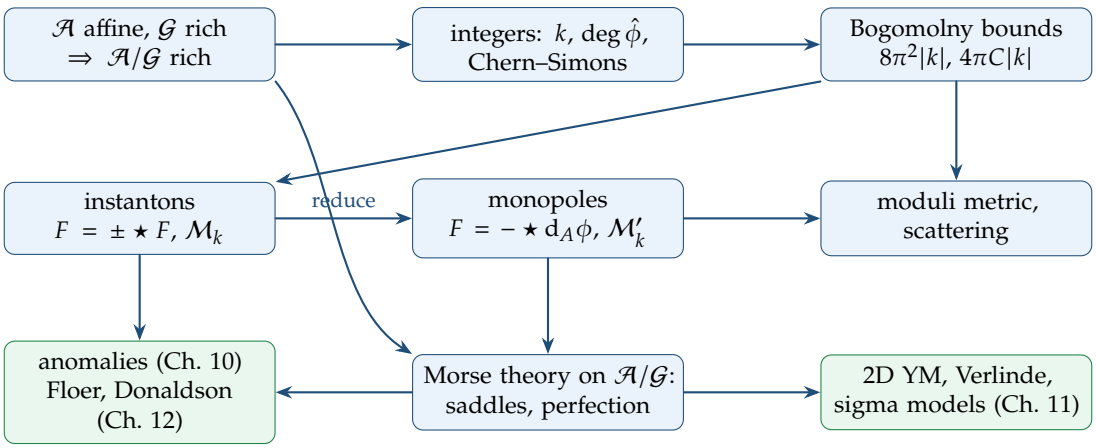

Figure 8.92: How the ideas of Chapter 8 fit together, and where they go next (green).

The tables below list every concept of the chapter, what it means operationally (how you compute or test for it), and where it is used again.

The topology of gauge fields and secondary classes

concept	operational meaning	used later
space of connections $\mathcal{A}$	every connection is $A_0 + a$, a an $\operatorname{ad} P$-valued 1-form; straight lines stay in $\mathcal{A}$, so $\mathcal{A}$ is contractible	Chapter 10 (determinant line over $\mathcal{A}/\mathcal{G}$), Chapter 12
gauge group $\mathcal{G}$, based $\mathcal{G}_0$	sections g of $\operatorname{Ad} P$; $\mathcal{G}_0$ has $g(x_0) = \mathbb{1}$ and acts freely (a fixed point is $\mathrm{d}_A g = 0$, hence $g \equiv \mathbb{1}$)	Chapter 10, Chapter 12
finite action at infinity	$F \to 0$ faster than r^{-2} forces $A \to g^{-1}\mathrm{d}g$: the field is pure gauge on the sphere at infinity	instantons, monopoles; Chapter 12
winding number of $g : S^3 \to \mathrm{SU}(2)$	$\frac{1}{24\pi^2}\int \operatorname{tr}(g^{-1}\mathrm{d}g)^3 \in \mathbb{Z}$; count preimages of a point with signs	Chapter 10 (global anomalies)
instanton number k	$\frac{1}{8\pi^2}\int \operatorname{tr} F \wedge F$ = winding of the gauge at infinity = c_2 (sign by orientation)	Chapter 10 (index of $\not{D}_A$), Chapter 12
large gauge transformation, Chern–Simons number	$\frac{1}{8\pi^2}\int_{S^3} \operatorname{tr}(A\mathrm{d}A + \frac{2}{3}A^3)$ jumps by the winding of g; tunnelling between vacua	Chapter 10, Chapter 12
θ-vacua	superpose the vacua $\lvert n\rangle$ with phases $e^{in\theta}$; adds θk to the action	Chapter 10
Chern–Weil and transgression	invariant polynomial $P(F)$ is closed; on P it is exact, $P(F) = \mathrm{d}\,TP(A)$	Chapter 10 (descent)
Chern–Simons form, secondary class	TP restricted where $P(F) = 0$; defines an $\mathbb{R}/\mathbb{Z}$ class; gauge change shifts it by an integer	Chapter 12 (Chern–Simons theory, Floer)
cohomology of $\mathcal{G}$ and $B\mathcal{G}$	evaluation map $\mathcal{G} \times X \to G$, pull back generators of $H^*(G)$, integrate over cycles of X	Chapter 10
$\mathcal{A}/\mathcal{G}_0 \simeq B\mathcal{G}_0$	free action on a contractible space; on S^4, $\mathcal{A}_k/\mathcal{G}_0 \simeq \Omega^3_k S^3$	Chapter 10, Chapter 12

Instantons and their moduli

concept	operational meaning	used later
Yang–Mills equations	$\mathrm{d}_A^\star F = 0$ from varying $S = \|F\|^2$; with Bianchi $\mathrm{d}_A F = 0$ a non-linear Hodge theory	Chapter 12
gauge fixing, slice	$T_A\mathcal{A} = \operatorname{Im}\mathrm{d}_A \oplus \operatorname{Ker}\mathrm{d}_A^\star$; the gauge-fixed operator is elliptic; Gribov: no global slice	Chapter 10 (Faddeev–Popov)
self-duality and bound	split $F = F^+ + F^-$; $S = \|F^\pm\|^2 \pm 8\pi^2 k \geq 8\pi^2\|k\|$, equality iff $F = \pm \star F$	Chapter 12 (Donaldson)
BPST instanton	$A = \frac{r^2}{r^2+\lambda^2} g^{-1}\mathrm{d}g$ with g the unit quaternion $x/\|x\|$ and size λ; 't Hooft ansatz for many	Chapter 10 (fermion zero modes)
deformation complex	$0 \to \Omega^0 \xrightarrow{\mathrm{d}_A} \Omega^1 \xrightarrow{\mathrm{d}_A^-} \Omega^2_- \to 0$; H^1 = tangent space to $\mathcal{M}_k$	Chapter 12 (Floer, Donaldson)
dimension of $\mathcal{M}_k$	index of the rolled-up complex by Atiyah–Singer: $8k-3$ for SU(2) on S^4	Chapter 12
reducible connections	stabiliser bigger than the centre; cone-like singularities of $\mathcal{M}_k$	Chapter 12 (Donaldson's theorem)
$\mathcal{M}_1$ and ADHM	$\mathcal{M}_1 = \mathbb{R}^4 \times \mathbb{R}^+ = H^5$ (centre and size); ADHM builds all instantons from matrices	Chapter 12

Monopoles and symmetric instantons

concept	operational meaning	used later
Derrick's argument	scale $x \to \lambda x$; pure YM energy in 3D scales as λ^{-1}, so no static solitons without a Higgs field	Section 8.18.10 (conformal weights), Chapter 11
Dirac monopole	U(1) bundle over S^2, patches glued by $e^{in\varphi}$; flux $2\pi n$, $c_1 = n$	Example 8.175; Chapter 10
YMH energy and equations	$E = \frac{1}{2}\int \|F\|^2 + \|\mathrm{d}_A\phi\|^2 + \lambda(\|\phi\|^2 - C^2)^2$; vary to get (8.274)	Section 8.18.4
magnetic charge k	$k = \deg(\hat\phi_\infty : S^2 \to S^2) = c_1$ of the unbroken U(1) at infinity	monopole moduli; Chapter 12
Bogomolny equation and bound	$F = -\star\,\mathrm{d}_A\phi$ (for $k > 0$); $E = \frac{1}{2}\left\|F + \star\mathrm{d}_A\phi\right\|^2 + 4\pi C k$	moduli, Morse theory
compact M is trivial	Stokes kills the boundary term: $k = 0$, $F = 0$, $\mathrm{d}_A\phi = 0$	–
Prasad–Sommerfield monopole	$\phi = \left(C\coth Cr - \frac{1}{r}\right)\hat x^a T_a$, A from $K = Cr/\sinh Cr$; $E = 4\pi C$	zero modes, scattering
unitary gauge, Dirac string	rotate $\hat\phi$ to T_3; the gauge field becomes a Dirac monopole with a string	Chapter 10
dimensional reduction	∂_0-invariant self-dual field on $\mathbb{R}^4$ with $A_0 = \phi$ is a Bogomolny solution	Chapter 12
hyperbolic monopoles	$\mathbb{R}^4 \setminus \mathbb{R}^2 \simeq S^1 \times H^3$ conformally; S^1-invariant instantons are monopoles on H^3, $c_2 = 2nk$	–

Monopole moduli and scattering

concept	operational meaning	used later
monopole deformation complex	$D_0 f = (\mathrm{d}_A f, [\phi, f])$, $D_1(a,\eta) = \mathrm{d}_A a + \star \mathrm{d}_A \eta + \star[a,\phi]$; tangent space $\operatorname{Ker} D_1 \cap \operatorname{Ker} D_0^\star$	Section 8.18.4 (Hessian $D_1^\star D_1$)
quaternionic Dirac operator	roll up $D_0^\star \oplus D_1$ into $\mathcal{D}$; $\mathcal{D}\mathcal{D}^\dagger = -D^2 - \mathrm{ad}_\phi^2 \geq 0$ kills the cokernel	Chapter 10 (Callias index)
$\dim \mathcal{M}_k' = 4k$, $\mathcal{M}_k$, $\mathcal{M}_k^0$	$4k$ framed; drop the phase $(4k-1)$; drop centre and phase $(4k-4)$	scattering
rational maps	Donaldson: $\mathcal{M}_k' \cong$ based rational maps $\mathbb{CP}^1 \to \mathbb{CP}^1$ of degree k	Chapter 12
no static forces	$E = 4\pi C k$ for every k-monopole: magnetic repulsion cancels Higgs attraction	Taubes' saddle
geodesic approximation	slow motion stays near $\mathcal{M}_k'$; kinetic energy restricted there is a metric; motion is geodesic	Chapter 7 (energy of paths)
$k=1$ metric, dyons	$\mathbb{R}^3 \times S^1$ with $4\pi C(\mathrm{d}\vec{x}^2 + C^{-2}\mathrm{d}\chi^2)$; motion in χ is electric charge	–
hyperkähler metric	three complex structures I, J, K with quaternion relations, all Kähler; the moduli metric is hyperkähler	Chapter 12
Atiyah–Hitchin manifold	$\mathcal{M}_2^0$ with metric $f^2\mathrm{d}r^2 + a^2\sigma_1^2 + b^2\sigma_2^2 + c^2\sigma_3^2$ solving the AH ODEs; bolt at $r=\pi$	–
90° scattering, dyon production	head-on geodesics pass through the bolt and turn by 90°; glancing ones convert orbital angular momentum into relative charge	–

Critical point theory

concept	operational meaning	used later
Palais–Smale condition	every sequence with f bounded and $\nabla f \to 0$ has a convergent subsequence; fails by escape or bubbling	Chapter 12 (Floer)
mountain pass, min-max	$c = \inf_\gamma \max f \circ \gamma$ over a non-contractible family is a critical value (index one)	Chapter 12
YMH energy as Morse function	sectors C_k; minima $\mathcal{M}_k'$ Morse–Bott with Hessian $D_1^\star D_1$; Taubes' saddles below $8\pi C$	sphalerons (electroweak)
2D Yang–Mills critical points	$\mathrm{d}_A(\star F) = 0$; sums of constant-curvature bundles, $S = \frac{4\pi^2}{\mathcal{A}_\Sigma}\sum d_j^2/n_j$	Chapter 11 (Verlinde), Chapter 12
Hessian of S	$H = \mathrm{d}_A^\star \mathrm{d}_A + [\star F, \star\,\cdot\,]$ on $\operatorname{Ker}\mathrm{d}_A^\star$; index of $L_1 \oplus L_2$ is $2(d_1 - d_2 + g - 1)$	Chapter 12 (relative Morse index)
Atiyah–Bott perfection	$\sum_\mu t^{\lambda_\mu} P_t^{\mathcal{G}}(C_\mu) = P_t(B\mathcal{G})$; gives the Betti numbers of moduli of stable bundles	Chapter 11, Chapter 12
conformal invariance, bubbling	$\int \lvert F\rvert^2$ invariant in 4D, $\int \lvert\mathrm{d}\phi\rvert^2$ in 2D; shrinking solutions have constant action	Chapter 11, Chapter 12

Key idea: The one sentence to remember from Chapter 8

The configuration space of a gauge theory is a quotient of a contractible space by a topologically rich group; its integers are Chern numbers and winding numbers, its minima are the solutions of first-order (self-duality or Bogomolny) equations with finite-dimensional moduli spaces counted by index theorems, and its topology, through Morse theory, forces further, unstable solutions whenever compactness can be controlled.

Chapter 9

The Elliptic Geometry of Strings

Where this chapter is going

A particle moving through space-time traces out a curve, its world line. A string traces out a surface, its **world sheet**. Quantising a particle by Feynman's recipe means summing e^{-S} over all curves. Quantising a string means summing e^{-S} over all surfaces. This chapter shows that the second sum, which looks hopelessly infinite-dimensional, collapses to an ordinary *finite-dimensional* integral. The collapse is driven entirely by the tools of the earlier chapters. Elliptic operators (Chapter 2) appear as the Laplacian acting on the string's position and as a first-order operator P_1 acting on vector fields. Their zero modes are counted by index theory and Riemann–Roch (Chapters 4 and 5). Their determinants are defined with zeta functions (Chapter 4). And the finite-dimensional space that is left over is the **moduli space** of Riemann surfaces from Chapter 5, now equipped with a natural metric, the **Weil–Petersson metric**.

The logic is the logic of gauge fixing, which a physicist already knows from Yang–Mills theory. The Polyakov action has a huge gauge symmetry: diffeomorphisms of the surface and local rescalings (Weyl transformations) of its metric. Three components of a two-dimensional metric, minus two functions' worth of diffeomorphisms, minus one function's worth of Weyl rescalings, leaves zero local degrees of freedom. So the metric is "pure gauge" up to a finite number of global parameters, the moduli. The Faddeev–Popov procedure turns the integral over metrics into an integral over moduli, weighted by determinants of elliptic operators. Figure 9.1 shows how the pieces fit together. The final formula, Nash's (9.36), is the genus-p contribution to the bosonic string's vacuum amplitude in $d = 26$ dimensions, written as an integral over the moduli space $\mathcal{M}_p$.

Conventions for this chapter.

- The world sheet Σ is a compact, connected, oriented surface without boundary, of genus p (Nash uses p for the genus so that g can denote a metric). Its Euler characteristic is $\chi = 2 - 2p$.
- Local coordinates on Σ are x^a, $a = 1, 2$ (Nash also writes (σ, τ)). The world-sheet metric is g_{ab}, positive definite (Euclidean signature). We write $\sqrt{g} = \sqrt{\det g_{ab}}$ and g^{ab} for the inverse matrix.
- Space-time (the **target space**) is flat Euclidean $\mathbb{R}^d$ with coordinates ϕ^μ, $\mu = 1, \dots, d$, and metric $\delta_{\mu\nu}$. We write $A \cdot B = \delta_{\mu\nu} A^\mu B^\nu$.
- The Laplacian on functions is the *positive* operator $\Delta_g = -\frac{1}{\sqrt{g}} \partial_a \big(\sqrt{g}\, g^{ab} \partial_b \big)$. On flat $\mathbb{R}^2$ it is $-(\partial_1^2 + \partial_2^2)$.

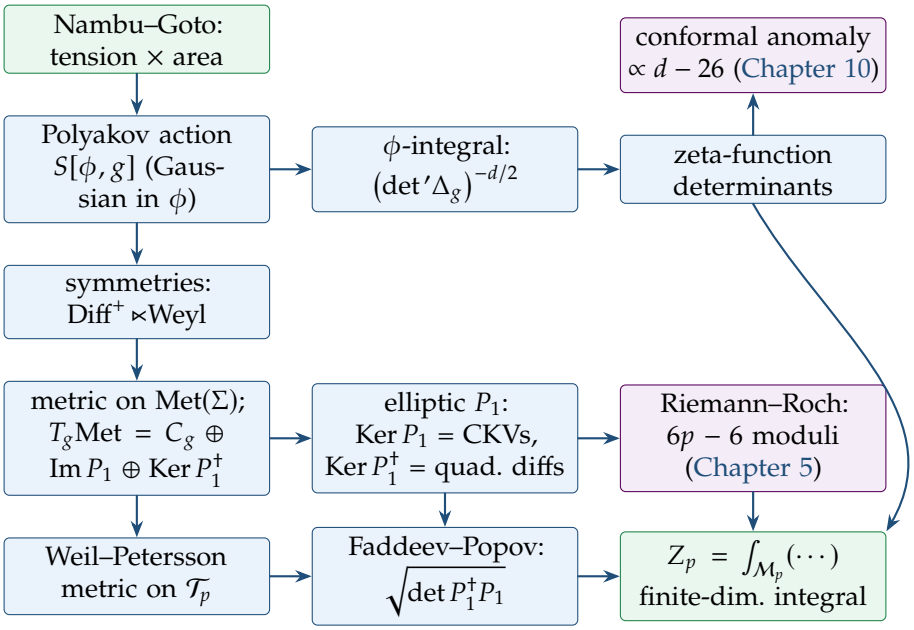

Figure 9.1: The logic of Chapter 9. Green boxes are physics, blue boxes are the machinery built in this chapter, purple boxes are results imported from other chapters. Follow the arrows from the Nambu–Goto area to the final formula for the genus-p partition function Z_p: every arrow is either a Gaussian integral, a symmetry, or a statement about an elliptic operator.

- Complex coordinates are $z = x^1 + ix^2$, $\bar{z} = x^1 - ix^2$, $\partial_z = \frac{1}{2}(\partial_1 - i\partial_2)$, $\partial_{\bar{z}} = \frac{1}{2}(\partial_1 + i\partial_2)$.
- det means a zeta-regularised determinant and det′ means that zero eigenvalues are left out (Section 9.1.10).

9.1 The bosonic string

What is the quantum amplitude for a closed string to appear out of the vacuum, propagate, and disappear again? In a point-particle theory the analogous question is answered by a path integral over closed world lines. For a string the world lines become closed surfaces, and the path integral becomes a sum over surfaces of every shape and every topology. This section sets up that sum. We start from the physics (the action of a relativistic string), rewrite the action in a form that is quadratic in the string's position (Polyakov's trick), identify its symmetries, and do the part of the path integral that is Gaussian. What is left is an integral over the metrics on the world sheet. That integral is the subject of the rest of the chapter.

9.1.1 From world lines to world sheets

Start with a relativistic particle, because every idea we need for the string already appears there in miniature. A particle in $\mathbb{R}^d$ traces out a curve $\tau \mapsto x^\mu(\tau)$. We work in Euclidean signature throughout (the Wick-rotated theory), so the natural action is the mass times the length of the curve:

$$S_{\text{particle}}[x] \;=\; m \int \mathrm{d}\tau\, \sqrt{\dot{x}\cdot\dot{x}}, \qquad \dot{x}^\mu = \frac{\mathrm{d}x^\mu}{\mathrm{d}\tau}. \tag{9.1}$$

Two properties are worth noticing. First, S does not care how we label the points of the curve: a new parameter $\tau' = f(\tau)$ with $f' > 0$ gives the same number. Second, its critical points are the curves of extremal length, the geodesics. In flat space these are straight lines.

Worked example 9.1: Critical points of the length are straight lines

Vary $x \to x + \delta x$ with δx vanishing at the end points. Write $\ell = \sqrt{\dot{x}\cdot\dot{x}}$. Then

$$\begin{aligned}\delta S_{\text{particle}} &\overset{(1)}{=} m\int \mathrm{d}\tau\,\frac{\dot{x}\cdot\delta\dot{x}}{\ell}\\ &\overset{(2)}{=} -m\int \mathrm{d}\tau\,\frac{\mathrm{d}}{\mathrm{d}\tau}\left(\frac{\dot{x}_\mu}{\ell}\right)\delta x^\mu\\ &\overset{(3)}{=} -m\int \mathrm{d}\tau\,\ddot{x}_\mu\,\delta x^\mu \qquad \text{(arc-length parameter)}.\end{aligned}$$

(1) $\delta\sqrt{u} = \delta u/(2\sqrt{u})$ with $u = \dot{x}\cdot\dot{x}$ and $\delta u = 2\dot{x}\cdot\delta\dot{x}$.
(2) Integrate by parts; the boundary term vanishes because $\delta x = 0$ at the end points.
(3) Use the freedom to reparametrise and choose τ to be arc length, so $\ell = 1$ everywhere and $\mathrm{d}/\mathrm{d}\tau$ acts only on $\dot{x}$.

So $\delta S = 0$ for all δx exactly when $\ddot{x} = 0$: a straight line traversed at constant speed.

The square root in (9.1) is awkward. It makes the action non-polynomial, and a path integral of e^{-S} is then not Gaussian. There is a standard trick for removing it, and it is worth seeing here because Polyakov's action is the same trick one dimension up. Introduce an extra positive function $e(\tau)$, called the **einbein**, and the action

$$S_e[x,e] \;=\; \frac{1}{2}\int \mathrm{d}\tau\left(\frac{\dot{x}\cdot\dot{x}}{e} + e\,m^2\right). \tag{9.2}$$

Here e plays the role of a metric on the world line: the invariant line element is $e\,\mathrm{d}\tau$.

Worked example 9.2: Eliminating the einbein gives back the length

The equation of motion of e is algebraic:

$$0 = \frac{\partial}{\partial e}\left(\frac{\dot{x}^2}{e} + e\,m^2\right) \overset{(1)}{=} -\frac{\dot{x}^2}{e^2} + m^2 \quad\Longrightarrow\quad e = \frac{\sqrt{\dot{x}^2}}{m}.$$

(1) Differentiate term by term; $\dot{x}^2$ does not depend on e.

We take the positive root because $e > 0$. Substitute back:

$$\begin{aligned}S_e\left[x,\,\sqrt{\dot{x}^2}/m\right] &\overset{(1)}{=} \frac{1}{2}\int \mathrm{d}\tau\left(m\sqrt{\dot{x}^2} + m\sqrt{\dot{x}^2}\right)\\ &= m\int \mathrm{d}\tau\,\sqrt{\dot{x}^2} \;=\; S_{\text{particle}}[x].\end{aligned}$$

(1) $\dot{x}^2/e = \dot{x}^2\cdot m/\sqrt{\dot{x}^2} = m\sqrt{\dot{x}^2}$, and $e\,m^2 = m\sqrt{\dot{x}^2}$.

At its critical point in e, the quadratic action equals the square-root action. Nash's sentence "at a critical point, the two expressions for the action coincide" (p. 260) is the string version of exactly this computation.

Physical picture: Why the einbein helps

In S_e the particle's position appears quadratically: for fixed e the integral over $x(\tau)$ is Gaussian, and Gaussian integrals are the one kind of infinite-dimensional integral we can do exactly. The price is an extra field e with a gauge symmetry (reparametrisations act on

e as $e\,d\tau = e'\,d\tau'$). The string will pay the same price, with a two-dimensional metric in place of e.

A string is a one-dimensional object. As time goes on it sweeps out a two-dimensional surface Σ in space-time, the world sheet (Figure 9.2). We restrict to **closed** strings (loops) and **oriented** strings (loops with a direction marked on them). A closed string sweeps out a tube; if the tube closes up on itself we get a closed surface. An orientation on the loop, together with the direction of time, orients the tube. So the world sheets we sum over are *closed orientable surfaces*: a sphere, a torus, a surface with p handles.

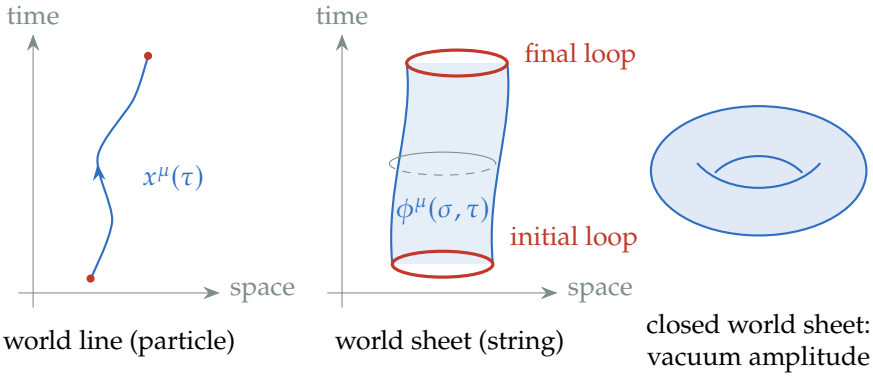

Figure 9.2: Left: a particle's history is a curve. Middle: a closed string's history is a tube $\phi^\mu(\sigma,\tau)$, with σ running around the loop and τ along the tube; its edges (red) are the initial and final loops. Right: if the final loop is glued back onto the initial one, the world sheet becomes a closed surface with no edge. Closed surfaces are what contribute to the vacuum amplitude studied in this chapter.

9.1.2 The Nambu–Goto action: tension times area

Label the points of the world sheet by two coordinates (σ,τ): σ runs around the string, τ runs along its history. The position of the string in space-time is a map

$$\phi : \Sigma \to \mathbb{R}^d, \qquad (\sigma,\tau) \mapsto \phi^\mu(\sigma,\tau), \quad \mu = 1,\dots,d.$$

The natural generalisation of "mass times length" is "tension times area". To compute the area of the image surface we need its **induced metric** (also called the pull-back metric). The two tangent vectors $\partial_\sigma\phi$ and $\partial_\tau\phi$ span a little parallelogram in $\mathbb{R}^d$ (Figure 9.3). Its squared lengths and angles are recorded by the 2×2 matrix

$$h_{ab} \;=\; \partial_a\phi\cdot\partial_b\phi \;=\; \begin{pmatrix} \partial_\sigma\phi\cdot\partial_\sigma\phi & \partial_\sigma\phi\cdot\partial_\tau\phi \\ \partial_\tau\phi\cdot\partial_\sigma\phi & \partial_\tau\phi\cdot\partial_\tau\phi \end{pmatrix}, \qquad a,b\in\{\sigma,\tau\}. \tag{9.3}$$

This is the metric that a creature living on the world sheet would measure with rulers borrowed from space-time.

Working definition 9.1 (Nambu–Goto action)

The **Nambu–Goto action** of an embedded surface $\phi : \Sigma \to \mathbb{R}^d$ is

$$S_{\mathrm{NG}}[\phi] \;=\; T\int_\Sigma d\sigma\,d\tau\,\sqrt{\det h} \;=\; T\int_\Sigma d\sigma\,d\tau\,\sqrt{(\partial_\sigma\phi\cdot\partial_\sigma\phi)(\partial_\tau\phi\cdot\partial_\tau\phi)-(\partial_\sigma\phi\cdot\partial_\tau\phi)^2}\,. \tag{9.4}$$

The constant T is the **string tension** (energy per unit length). To compute it: find the induced metric (9.3), take the square root of its determinant [the area of the little parallelogram spanned by $\partial_\sigma\phi$ and $\partial_\tau\phi$], integrate. The result is T times the area of the image.

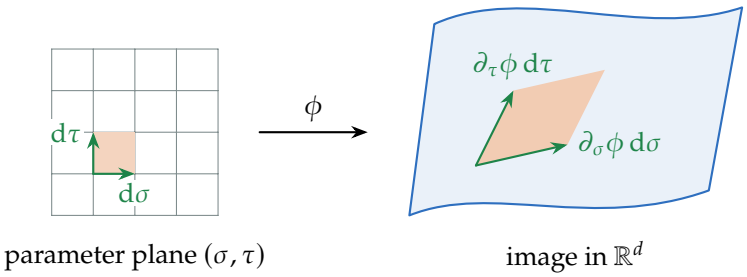

Figure 9.3: The map ϕ sends a small coordinate rectangle to a small parallelogram spanned by $\partial_\sigma\phi\,\mathrm{d}\sigma$ and $\partial_\tau\phi\,\mathrm{d}\tau$ (orange). Its area is $\sqrt{\det h}\,\mathrm{d}\sigma\,\mathrm{d}\tau$, where h is the Gram matrix of the two tangent vectors. Adding up these areas gives the Nambu–Goto action.

Why is $\sqrt{\det h}$ the area of the parallelogram? For two vectors A, B in $\mathbb{R}^3$ we know that the area is $|A \times B|$, and

$$\begin{aligned} |A\times B|^2 &\overset{(1)}{=} |A|^2\,|B|^2 \sin^2\theta \\ &\overset{(2)}{=} |A|^2\,|B|^2 - |A|^2\,|B|^2\cos^2\theta \\ &\overset{(3)}{=} (A\cdot A)(B\cdot B) - (A\cdot B)^2 \;=\; \det\begin{pmatrix} A\cdot A & A\cdot B \\ B\cdot A & B\cdot B\end{pmatrix}. \end{aligned}$$

(1) The magnitude of a cross product is the product of the lengths times the sine of the angle θ between the vectors.
(2) $\sin^2\theta = 1 - \cos^2\theta$.
(3) $A\cdot B = |A|\,|B|\cos\theta$.

The final expression, the **Gram determinant**, makes sense in any dimension d, which is why Nash writes the action (9.4) with dot products rather than cross products. With $A = \partial_\sigma\phi$ and $B = \partial_\tau\phi$ it is exactly $\det h$.

Worked example 9.3: A straight cylinder

Let a circular string of radius R move rigidly along the ϕ^3 axis in $\mathbb{R}^3$ for a Euclidean time $\tau \in [0, \mathcal{T}]$:

$$\phi(\sigma,\tau) = (R\cos\sigma,\; R\sin\sigma,\; \tau), \qquad \sigma \in [0, 2\pi).$$

Then $\partial_\sigma\phi = (-R\sin\sigma, R\cos\sigma, 0)$ and $\partial_\tau\phi = (0,0,1)$, so

$$\begin{aligned} S_{\mathrm{NG}} &\overset{(1)}{=} T\int_0^{\mathcal{T}}\mathrm{d}\tau\int_0^{2\pi}\mathrm{d}\sigma\,\sqrt{R^2\cdot 1 - 0^2} \\ &\overset{(2)}{=} T\cdot 2\pi R\cdot\mathcal{T}. \end{aligned}$$

(1) $\partial_\sigma\phi\cdot\partial_\sigma\phi = R^2(\sin^2\sigma + \cos^2\sigma) = R^2$, $\partial_\tau\phi\cdot\partial_\tau\phi = 1$, and the two tangent vectors are orthogonal.
(2) The integrand is the constant R.

This is tension × circumference × time, which is energy × time: the Euclidean action of a static object whose energy is T times its length. A physicist reads off from this that a string

loop wants to shrink: the action grows linearly with its size.

The critical points of the Nambu–Goto action are the surfaces whose area does not change to first order under small deformations: **minimal surfaces** (more precisely, extremal surfaces), such as soap films. They are the two-dimensional analogue of geodesics. So far the story parallels the particle exactly. And, as for the particle, the square root makes the quantum theory difficult. Polyakov's reformulation removes it.

9.1.3 The Polyakov action

Give the world sheet its own metric $g_{ab}(x)$, a positive-definite symmetric 2×2 matrix at each point, which is *independent* of the embedding. It is the two-dimensional analogue of the einbein. Rename the world-sheet coordinates x^a, $a = 1, 2$ (so $x^1 = \sigma$, $x^2 = \tau$).

Working definition 9.2 (Polyakov action)

The **Polyakov action** of a pair (embedding ϕ, world-sheet metric g) is

$$S[\phi, g] \;=\; \frac{T}{2}\int_\Sigma \mathrm{d}^2x\,\sqrt{g}\,g^{ab}\,\partial_a\phi^\mu\,\partial_b\phi_\mu, \tag{9.5}$$

where $\sqrt{g} = \sqrt{\det g_{ab}}$, g^{ab} is the inverse matrix of g_{ab}, and the index μ is summed with the flat metric of $\mathbb{R}^d$. For fixed g this is the action of d free massless scalar fields ϕ^μ [each ϕ^μ is a real function on Σ, and the action contains only its gradient squared, with no mass or interaction term] living on the curved surface (Σ, g). *How to use it:* for fixed g it is quadratic in ϕ, so every ϕ-integral is Gaussian [done like $\int \mathrm{d}x\, e^{-ax^2/2} = \sqrt{2\pi/a}$, with the number a replaced by an operator].

Watch out: The sign in front of Nash's (9.2)

Nash writes $S = -\frac{T}{2}\int \mathrm{d}^2x\sqrt{g}\,g^{ab}\partial_a\phi^\mu\partial_b\phi_\mu$ with a minus sign. That sign is a relic of Lorentzian world sheets, where g_{ab} has signature $(-,+)$ and $\sqrt{g}$ means $\sqrt{-\det g}$. In the Euclidean theory used everywhere else in the chapter (positive g_{ab}, weight e^{-S}), the action must be positive so that e^{-S} damps large fluctuations. Nash's own (9.3) writes $\exp[-\frac{T}{2}\int\cdots]$, which is the positive-action convention. We use (9.5) with a plus sign throughout.

Now the claim: *at its critical point in g, the Polyakov action equals the Nambu–Goto action.* To see this we need two formulae for how $\sqrt{g}$ and g^{ab} respond to a small change δg_{ab} of the metric.

Worked example 9.4: Varying the determinant and the inverse

For any invertible symmetric matrix g,

$$\begin{aligned}\delta\sqrt{\det g} &\overset{(1)}{=} \tfrac{1}{2}(\det g)^{-1/2}\,\delta\det g\\ &\overset{(2)}{=} \tfrac{1}{2}(\det g)^{-1/2}\,\det g\;\operatorname{tr}(g^{-1}\delta g)\\ &= \tfrac{1}{2}\sqrt{g}\;g^{ab}\,\delta g_{ab},\end{aligned}$$

(1) Chain rule for the square root.

(2) Jacobi's formula $\delta\det g = \det g\,\operatorname{tr}(g^{-1}\delta g)$, which follows from $\det(g+\delta g) = \det g\,\det(1+g^{-1}\delta g)$ and $\det(1+\epsilon) = 1+\operatorname{tr}\epsilon+O(\epsilon^2)$.

and, differentiating $g^{ac}g_{cb} = \delta^a{}_b$,

$$0 = \delta(g^{ac}g_{cb}) \overset{(1)}{=} \delta g^{ac}\, g_{cb} + g^{ac}\,\delta g_{cb} \quad\Longrightarrow\quad \delta g^{ab} = -g^{ac}\,g^{bd}\,\delta g_{cd}.$$

(1) Product rule; then multiply on the right by g^{bd} to isolate δg^{ad} and rename indices.

A quick check on a diagonal metric $g = \mathrm{diag}(\lambda_1, \lambda_2)$: $\sqrt{g} = \sqrt{\lambda_1\lambda_2}$, so $\delta\sqrt{g} = \frac{1}{2}\sqrt{\lambda_1\lambda_2}\,(\delta\lambda_1/\lambda_1 + \delta\lambda_2/\lambda_2)$, which is $\frac{1}{2}\sqrt{g}\,g^{ab}\delta g_{ab}$ as claimed.

Write $h_{ab} = \partial_a\phi\cdot\partial_b\phi$ for the induced metric (9.3), so the Polyakov Lagrangian is $\frac{T}{2}\sqrt{g}\,g^{ab}h_{ab}$. Vary g with ϕ fixed:

$$\begin{aligned}
\delta S &\overset{(1)}{=} \frac{T}{2}\int \mathrm{d}^2x\,\Big(\delta\sqrt{g}\;g^{ab}h_{ab} + \sqrt{g}\;\delta g^{ab}\;h_{ab}\Big)\\
&\overset{(2)}{=} \frac{T}{2}\int \mathrm{d}^2x\,\sqrt{g}\,\Big(\tfrac{1}{2}g^{cd}\,g^{ab}h_{ab} - g^{ca}g^{db}h_{ab}\Big)\delta g_{cd}\\
&\overset{(3)}{=} -\frac{T}{2}\int \mathrm{d}^2x\,\sqrt{g}\;g^{ca}g^{db}\,\Big(h_{ab} - \tfrac{1}{2}g_{ab}\,g^{ef}h_{ef}\Big)\,\delta g_{cd}.
\end{aligned} \tag{9.6}$$

(1) Product rule; h_{ab} does not depend on g.
(2) Insert the two formulae of Example 9.4.
(3) Factor out $g^{ca}g^{db}$, using $g^{cd} = g^{ca}g^{db}g_{ab}$.

The quantity in brackets is (up to normalisation) the world-sheet **energy–momentum tensor**:

$$T_{ab} \;\propto\; h_{ab} - \tfrac{1}{2}\,g_{ab}\,g^{cd}h_{cd} \;=\; \partial_a\phi\cdot\partial_b\phi - \tfrac{1}{2}\,g_{ab}\,g^{cd}\,\partial_c\phi\cdot\partial_d\phi. \tag{9.7}$$

The metric's equation of motion is $T_{ab} = 0$. Two things follow at once.

- T_{ab} is *traceless*: $g^{ab}T_{ab} \propto g^{ab}h_{ab} - \frac{1}{2}\cdot 2\cdot g^{cd}h_{cd} = 0$, using $g^{ab}g_{ab} = 2$ in two dimensions. We will see in a moment that tracelessness is the Noether identity of Weyl invariance.
- $T_{ab} = 0$ says $h_{ab} = \frac{1}{2}(g^{cd}h_{cd})\,g_{ab}$: the induced metric is a *positive multiple* of g. Equivalently $g_{ab} = \Omega(x)\,h_{ab}$ for some positive function Ω.

Worked example 9.5: At the critical metric, Polyakov = Nambu–Goto

Put $g_{ab} = \Omega\,h_{ab}$ into (9.5):

$$\begin{aligned}
S[\phi,\Omega h] &\overset{(1)}{=} \frac{T}{2}\int \mathrm{d}^2x\,\big(\Omega\sqrt{h}\big)\big(\Omega^{-1}h^{ab}\big)h_{ab}\\
&\overset{(2)}{=} \frac{T}{2}\int \mathrm{d}^2x\,\sqrt{h}\cdot 2\\
&\overset{(3)}{=} T\int \mathrm{d}^2x\,\sqrt{\det h} \;=\; S_{\mathrm{NG}}[\phi].
\end{aligned}$$

(1) For a 2×2 matrix, $\det(\Omega h) = \Omega^2\det h$, so $\sqrt{\det(\Omega h)} = \Omega\sqrt{h}$; and $(\Omega h)^{-1} = \Omega^{-1}h^{-1}$.
(2) The factors of Ω cancel, and $h^{ab}h_{ab} = \mathrm{tr}(h^{-1}h) = 2$.
(3) This is (9.4).

Notice that the undetermined function Ω dropped out completely. The equation of motion fixes g only up to a local rescaling. That is the first sign of the Weyl symmetry discussed next.

Worked example 9.6: A non-critical metric on the cylinder

Take the cylinder of Example 9.3, where $h = \operatorname{diag}(R^2, 1)$, and choose instead the flat world-sheet metric $g = \operatorname{diag}(1, 1)$. Then

$$S[\phi, g] \overset{(1)}{=} \frac{T}{2} \int_0^{\mathcal{T}} d\tau \int_0^{2\pi} d\sigma \, (h_{\sigma\sigma} + h_{\tau\tau})$$
$$\overset{(2)}{=} \frac{T}{2} \cdot 2\pi\mathcal{T} \, (R^2 + 1) \overset{(3)}{\geq} T \cdot 2\pi\mathcal{T} R = S_{\mathrm{NG}}.$$

(1) With $g = \mathbf{1}$: $\sqrt{g} = 1$ and $g^{ab} h_{ab} = h_{11} + h_{22}$.
(2) Both entries of h are constant.
(3) $\frac{1}{2}(R^2 + 1) \geq R$ is the inequality $(R - 1)^2 \geq 0$ between arithmetic and geometric means.

Equality holds exactly when $R = 1$, that is, exactly when $h \propto g$. In general, for a fixed embedding, $\frac{1}{2}\sqrt{g}\, g^{ab} h_{ab} \geq \sqrt{h}$ with equality iff $g \propto h$ (apply the same AM–GM inequality to the eigenvalues of $g^{-1}h$). So the Nambu–Goto area is the *minimum* of the Polyakov action over world-sheet metrics.

Dictionary: World-sheet and target-space language

String physics	Geometry
world sheet Σ	closed oriented surface of genus p
string position $\phi^\mu(x)$	a map $\Sigma \to \mathbb{R}^d$ (d scalar fields)
world-sheet metric g_{ab}	a Riemannian metric on Σ
induced metric h_{ab}	pull-back $\phi^* \delta$ of the flat metric
string tension T, Regge slope α'	$T = 1/(2\pi\alpha')$
Polyakov action	Dirichlet energy of ϕ w.r.t. g
classical string	harmonic, conformal map = minimal surface

9.1.4 The symmetries of the Polyakov action

The whole chapter is about what the symmetries of $S[\phi, g]$ do to the path integral, so we verify each of them by hand.

Weyl rescalings. Multiply the metric by a positive function,

$$g_{ab}(x) \longmapsto f(x)\, g_{ab}(x) = e^{2\omega(x)} g_{ab}(x), \qquad f > 0, \tag{9.8}$$

and leave ϕ alone. (Writing $f = e^{2\omega}$ is convenient for infinitesimal work: $\delta g_{ab} = 2\,\delta\omega\, g_{ab}$.) Such a change is called a **Weyl transformation** or **conformal rescaling**. It changes lengths but not angles: two vectors that are orthogonal for g are orthogonal for $f g$, and the ratio of their lengths is unchanged.

Worked example 9.7: Weyl invariance works only in two dimensions

Do the computation on an n-dimensional world volume, to see where $n = 2$ enters. Under $g \mapsto f g$,

$$\sqrt{\det(f g)}\, (f g)^{ab} \overset{(1)}{=} \left(f^{n/2}\sqrt{g}\right)\left(f^{-1} g^{ab}\right)$$
$$\overset{(2)}{=} f^{(n-2)/2} \sqrt{g}\, g^{ab}$$

$$\overset{(3)}{=} \sqrt{g}\, g^{ab} \qquad \text{if } n = 2.$$

(1) $\det(f\,g) = f^n \det g$ for an $n \times n$ matrix, and the inverse of $f\,g$ is $f^{-1}g^{-1}$.
(2) Collect the powers of f.
(3) $f^0 = 1$.

So for a world sheet ($n = 2$) the density $\sqrt{g}\, g^{ab}$ is Weyl invariant and $S[\phi, f\,g] = S[\phi, g]$. For a membrane ($n = 3$) the analogous action picks up $\sqrt{f}$, and there is no Weyl symmetry. This is one reason strings are special.

The infinitesimal version gives the tracelessness of T_{ab} found above. With $\delta g_{cd} = 2\,\delta\omega\, g_{cd}$ in (9.6),

$$\delta_{\text{Weyl}} S \overset{(1)}{=} -\frac{T}{2} \int \mathrm{d}^2x\, \sqrt{g}\, g^{ca} g^{db}\, T_{ab}\, 2\,\delta\omega\, g_{cd}$$
$$\overset{(2)}{=} -T \int \mathrm{d}^2x\, \sqrt{g}\, g^{ab} T_{ab}\, \delta\omega \overset{(3)}{=} 0,$$

(1) Insert the Weyl variation; here T_{ab} stands for the bracket in (9.6).
(2) $g^{ca} g^{db} g_{cd} = g^{ab}$.
(3) T_{ab} is traceless, identically in ϕ and g.

Classically, then, "Weyl invariance" and "$g^{ab}T_{ab} = 0$" are the same statement. The **conformal anomaly** is the discovery that quantum mechanically $\langle g^{ab}T_{ab}\rangle \neq 0$ unless $d = 26$ (Section 9.2.11 and Chapter 10).

Diffeomorphisms. Let $\alpha : \Sigma \to \Sigma$ be a diffeomorphism (a smooth invertible change of points, with smooth inverse). It acts on both fields by **pull-back**:

$$(\alpha^*\phi)(x) = \phi(\alpha(x)), \qquad (\alpha^* g)_{ab}(x) = \frac{\partial \alpha^c}{\partial x^a} \frac{\partial \alpha^d}{\partial x^b}\, g_{cd}(\alpha(x)). \tag{9.9}$$

The first formula says "the string at the new point x is where the string used to be at $\alpha(x)$". The second is the tensor transformation law: it is what makes the line element $g_{cd}\,\mathrm{d}y^c \mathrm{d}y^d$ agree with $(\alpha^* g)_{ab}\mathrm{d}x^a \mathrm{d}x^b$ when $y = \alpha(x)$. Nash abbreviates both to $(\phi(\alpha(x)), g(\alpha(x)))$, with the Jacobian factors in the metric understood.

Worked example 9.8: Diffeomorphism invariance is a change of variables

Write $J^c{}_a = \partial\alpha^c/\partial x^a$ for the Jacobian matrix and $y = \alpha(x)$. Evaluate the three ingredients of the Lagrangian for the transformed fields:

$$\sqrt{\det(\alpha^* g)}(x) \overset{(1)}{=} |\det J|\ \sqrt{g}\,(y),$$
$$(\alpha^* g)^{ab}(x) \overset{(2)}{=} (J^{-1})^a{}_c\, (J^{-1})^b{}_d\, g^{cd}(y),$$
$$\partial_a(\phi \circ \alpha)(x) \overset{(3)}{=} J^c{}_a\, (\partial_c \phi)(y).$$

(1) In matrix form $\alpha^* g = J^{\mathsf{T}}(g \circ \alpha)J$, and $\det(J^{\mathsf{T}} g J) = (\det J)^2 \det g$.
(2) Invert the matrix product: $(J^{\mathsf{T}} g J)^{-1} = J^{-1} g^{-1} J^{-\mathsf{T}}$.
(3) The chain rule.

Now multiply them together and integrate:

$$S[\alpha^*\phi, \alpha^* g] \overset{(1)}{=} \frac{T}{2}\int \mathrm{d}^2x\ |\det J|\ \sqrt{g}(y)\, g^{cd}(y)\, \partial_c\phi(y)\cdot\partial_d\phi(y)$$
$$\overset{(2)}{=} \frac{T}{2}\int \mathrm{d}^2y\ \sqrt{g}\, g^{cd}\, \partial_c\phi\cdot\partial_d\phi \ = \ S[\phi, g].$$

(1) The J^{-1} from the inverse metric cancel the J from the two derivatives: $(J^{-1})^a{}_c J^{c'}{}_a = \delta^{c'}_c$.
(2) Change the integration variable from x to $y = \alpha(x)$; $\mathrm{d}^2y = |\det J|\ \mathrm{d}^2x$, and α is a bijection of Σ.

The action is a coordinate-free object, so relabelling the points of Σ cannot change it.

Watch out: Why only orientation-preserving diffeomorphisms?

The computation above works for *every* diffeomorphism, since only $|\det J|$ appeared. Nash nevertheless restricts to the group $\mathrm{Diff}^+(\Sigma)$ of **orientation-preserving** diffeomorphisms ($\det J > 0$). The reason is not the action but the complex structure: a metric on an oriented surface determines a complex structure (Section 9.1.6), and an orientation-reversing map turns it into its complex conjugate. Since the world sheets are oriented, we identify only configurations related by $\mathrm{Diff}^+(\Sigma)$ (compare [Nash p. 150]).

Space-time symmetries. Finally, S only involves derivatives of ϕ, so it is unchanged by **translations** $\phi^\mu \mapsto \phi^\mu + a^\mu$, $a \in \mathbb{R}^d$. It is also unchanged by rotations $\phi \mapsto R\phi$, $R \in \mathrm{SO}(d)$, because it uses the dot product of $\mathbb{R}^d$. These are global symmetries acting on the target, not gauge symmetries of the world sheet, and their only role in this chapter is the zero mode of Section 9.1.9.

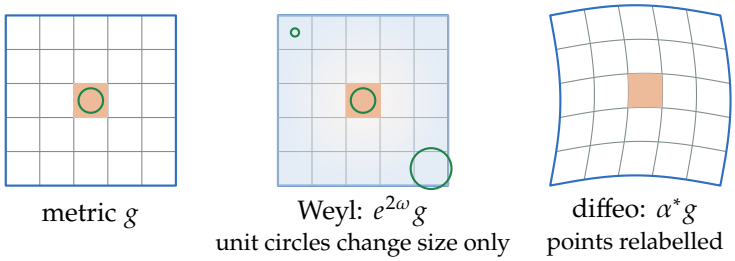

Figure 9.4: The two gauge symmetries of the Polyakov action. Middle: a Weyl rescaling multiplies all lengths near a point by the same factor e^ω, so small circles stay circles (green) and only their size varies from place to place. Right: a diffeomorphism slides the points of the surface around and drags the coordinate grid with it; it changes the *description* of the metric but not the geometry. Neither operation changes $S[\phi, g]$.

Physical picture: Two-dimensional gravity has nothing to propagate

Count functions. A symmetric 2×2 metric has three independent components g_{11}, g_{12}, g_{22} at each point. Diffeomorphisms of a surface are generated by vector fields, which have two components. Weyl rescalings are generated by one function ω. Three minus two minus one is zero: locally, *every* metric can be brought to the flat metric δ_{ab} by a diffeomorphism and a Weyl rescaling. (This is the existence of isothermal coordinates, Section 9.3.6.) The metric carries no local information at all, only a finite number of global parameters that cannot be removed. These are the moduli. The whole chapter is the careful version of this counting.

9.1.5 The functional integral and the vacuum amplitude

To quantise the string we follow Feynman: sum e^{-S} over all configurations of all the variables that appear in the action. For the Polyakov action there are two such variables, the embedding ϕ and the metric g. The basic object is therefore

$$Z_p \;=\; \int \mathcal{D}g\,\mathcal{D}\phi\;\exp\Big[-\frac{T}{2}\int_\Sigma \mathrm{d}^2x\,\sqrt{g}\,g^{ab}\,\partial_a\phi^\mu\,\partial_b\phi_\mu\Big], \tag{9.10}$$

where Σ is a closed oriented surface of genus p, $\mathcal{D}g$ is a (so far formal) integration over all metrics on Σ, and $\mathcal{D}\phi$ is a (so far formal) integration over all maps $\phi:\Sigma\to\mathbb{R}^d$. This is Nash's (9.3). We abbreviate ϕ^μ to ϕ and g_{ab} to g.

Watch out: Embeddings or maps?

Nash says ϕ "should be thought of as specifying an embedding of Σ in space-time". In the path integral we actually integrate over *all* smooth maps $\phi:\Sigma\to\mathbb{R}^d$, including ones that fold the surface over itself or crush it to a point (the constant map $\phi=$ const is the most important configuration of all, see Section 9.1.9). The word "embedding" describes the classical picture, not the domain of integration.

What does (9.10) compute? Nash calls it "a contribution to the partition function" and explains it as a vacuum-to-vacuum amplitude and as a trace. Both readings are familiar from quantum mechanics, so let us recall them there first.

Working definition 9.3 (Partition function as a sum over closed histories)

In quantum mechanics with Hamiltonian H, the **partition function**

$$Z(\beta)=\operatorname{Tr}e^{-\beta H}=\sum_n e^{-\beta E_n}$$

[E_n are the energy levels, the eigenvalues of H] is computed by a path integral over *periodic* paths, $x(0)=x(\beta)$. *How to see it:* the kernel $\langle y|e^{-\beta H}|x\rangle$ [the amplitude to go from x to y in Euclidean time β] is a path integral over paths from x to y; taking the trace sets $y=x$ and integrates over x, so the initial and final points are glued together and the world line closes into a circle.

Worked example 9.9: The free particle: a trace, and a volume factor

Take $H=p^2/2m$ on a line of length L (with $\hbar=1$, and L so large that we can ignore what happens at its ends). The Euclidean propagator is the heat kernel

$$\langle y|e^{-\beta H}|x\rangle=\sqrt{\frac{m}{2\pi\beta}}\;\exp\Big[-\frac{m(x-y)^2}{2\beta}\Big].$$

Then

$$\begin{aligned} Z(\beta) &\overset{(1)}{=} \int_0^L \mathrm{d}x\,\langle x|e^{-\beta H}|x\rangle \\ &\overset{(2)}{=} \int_0^L \mathrm{d}x\,\sqrt{\frac{m}{2\pi\beta}} \\ &= L\sqrt{\frac{m}{2\pi\beta}}. \end{aligned}$$

(1) The trace of an operator is the integral of its diagonal kernel.
(2) At $y = x$ the Gaussian factor is 1.

The factor L is the *volume of space*. It appears because the closed path can sit anywhere: translating a closed world line gives another closed world line with the same action. Exactly the same thing will happen for the string, where the volume of $\mathbb{R}^d$ appears because a closed world sheet can be translated anywhere in space-time. Nash removes it by a "compactness cutoff", which is our L.

Now the string. A state of a closed string at one instant is a loop in space. The amplitude to go from one loop configuration to another is a sum over tubes connecting them (Figure 9.2). The *trace* over string states identifies the final loop with the initial loop, gluing the two edge circles of the tube together. The result is a closed surface, with no edge at all. This is why the world sheets in (9.10) are closed. The simplest surface you get by gluing the two ends of a tube is a torus (Figure 9.5). Nash's other description, "a quantum object is emitted by the vacuum only to disappear by combining with itself", is the same picture read in time: a string pops out of the vacuum, propagates around, and annihilates with itself.

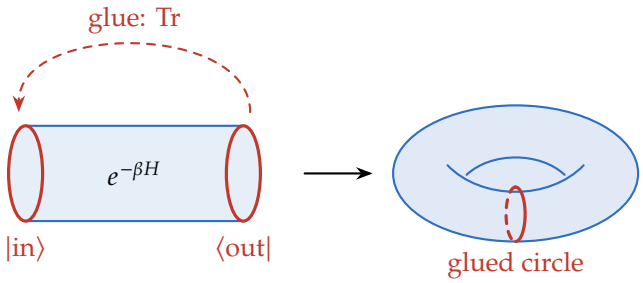

Figure 9.5: Why the world sheets are closed. A tube is the amplitude to evolve a string state for Euclidean time β. Taking the trace glues the outgoing circle onto the incoming one. The result is a torus, the genus-one term of the vacuum amplitude. The red circle on the torus is where the gluing happened; it is no longer a boundary.

The sum over topologies. A given closed surface has a definite genus p, but the string does not care about topology: every closed surface is a legitimate history. So the complete vacuum amplitude also sums over all topologies. The classification of surfaces says that every closed, connected, orientable surface is diffeomorphic to exactly one of the standard surfaces Σ_p, a sphere with p handles (Figure 9.6). Hence

$$Z \;=\; \sum_{\text{genera}} \int \mathcal{D}g\, \mathcal{D}\phi\; e^{-S[\phi,g]} \;=\; \sum_{p=0}^{\infty} Z_p, \tag{9.11}$$

Nash's (9.5) (with $T = 1$, see below).

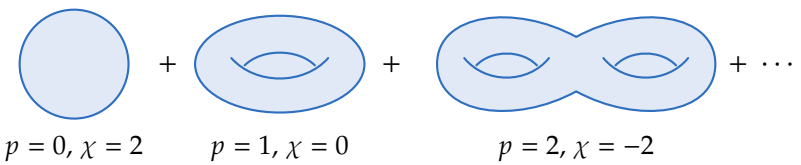

Figure 9.6: The sum over topologies in (9.11). Each term is a closed oriented surface, a sphere with p handles. In string perturbation theory each handle is a closed-string loop, so this is the string analogue of the loop expansion of Feynman diagrams, with one "diagram" per genus.

Physical picture: The genus expansion is the loop expansion

In field theory, the vacuum amplitude is a sum over Feynman diagrams, organised by the number of loops. In string theory there is exactly one world sheet per genus, and the genus plays the role of the number of loops. Each handle is a virtual closed string emitted and reabsorbed. A local vertex of Feynman diagrams is smeared out into smooth geometry, which is one reason string amplitudes are so much softer in the ultraviolet.

Worked example 9.10: Weighting the genera: the Euler characteristic is an action

Nash's sum (9.11) gives every genus the same weight. One may add to S a second term allowed by all the symmetries, the two-dimensional Einstein–Hilbert action

$$S_\lambda = \frac{\lambda}{4\pi}\int_\Sigma \mathrm{d}^2x\,\sqrt{g}\,R,$$

with $R = 2K$ the scalar curvature and K the Gauss curvature. It adds nothing to the dynamics, because it is a topological invariant: by Gauss–Bonnet (Chapter T2),

$$\frac{1}{4\pi}\int_\Sigma \mathrm{d}^2x\,\sqrt{g}\,R \overset{(1)}{=} \frac{1}{2\pi}\int_\Sigma K\,\mathrm{d}A \overset{(2)}{=} \chi(\Sigma) = 2-2p.$$

(1) $R = 2K$ in two dimensions and $\mathrm{d}A = \sqrt{g}\,\mathrm{d}^2x$.
(2) Gauss–Bonnet theorem.

Check it on a round sphere of radius r: $K = 1/r^2$ everywhere and the area is $4\pi r^2$, so $\frac{1}{2\pi}\cdot\frac{1}{r^2}\cdot 4\pi r^2 = 2 = \chi(S^2)$, independent of r. So $e^{-S_\lambda} = e^{-\lambda\chi} = (e^{\lambda})^{2p-2}$, and each extra handle costs a factor g_s^2 with $g_s = e^{\lambda}$, the **string coupling**. This term is Weyl and diffeomorphism invariant and changes none of the analysis of this chapter; it only reweights the Z_p.

9.1.6 A metric is a complex structure

A metric on an oriented surface does more than measure lengths. It singles out which coordinate systems are "holomorphic", that is, it gives the surface the structure of a **Riemann surface** (a one-dimensional complex manifold, Chapter 5). Two conformally related metrics, g and $e^{2\omega}g$, give the *same* complex structure. This is why Nash can pass freely between "metrics up to Weyl rescaling" and "complex structures".

The recipe. A complex structure at a point is the operation "rotate a tangent vector by +90°". To rotate by 90° we need to know angles (the metric, up to scale) and which way is positive (the orientation). So a conformal class of metrics plus an orientation gives a rotation J on every tangent plane, with $J^2 = -1$. Holomorphic functions are those whose differential commutes with J. Algebraically, the recipe is:

Working definition 9.4 (Beltrami coefficient of a metric)

Write a metric in real coordinates (x, y) and in terms of $z = x + iy$:

$$\mathrm{d}s^2 = A\,\mathrm{d}x^2 + 2B\,\mathrm{d}x\,\mathrm{d}y + C\,\mathrm{d}y^2 \;=\; \lambda\,|\mathrm{d}z + \mu\,\mathrm{d}\bar z|^2\,, \qquad \lambda>0,\ |\mu|<1. \tag{9.12}$$

The complex function μ is the **Beltrami coefficient**; it depends only on the conformal class [the metric up to multiplication by a positive function, $g \sim e^{2\omega}g$], while λ carries the scale.

A coordinate w is *holomorphic* for this metric [rotating by $+90°$ in this metric is multiplying $\mathrm{d}w$ by i] iff $\mathrm{d}w \propto \mathrm{d}z + \mu\,\mathrm{d}\bar{z}$, that is iff it solves the **Beltrami equation** $\partial_{\bar{z}} w = \mu\,\partial_z w$. In such a coordinate $\mathrm{d}s^2 = \lambda'\,|\mathrm{d}w|^2$.

Worked example 9.11: Solving for λ and μ

Expand the right side of (9.12) and compare coefficients. With $\mu = \mu_1 + i\mu_2$, and using the symmetric products $\mathrm{d}z\,\mathrm{d}\bar{z} = \mathrm{d}x^2 + \mathrm{d}y^2$ and $\mathrm{d}z^2 = \mathrm{d}x^2 - \mathrm{d}y^2 + 2i\,\mathrm{d}x\,\mathrm{d}y$:

$$\begin{aligned} |\mathrm{d}z + \mu\,\mathrm{d}\bar{z}|^2 &\overset{(1)}{=} (\mathrm{d}z + \mu\,\mathrm{d}\bar{z})(\mathrm{d}\bar{z} + \bar{\mu}\,\mathrm{d}z) \\ &\overset{(2)}{=} (1 + |\mu|^2)\,\mathrm{d}z\,\mathrm{d}\bar{z} + 2\,\mathrm{Re}\big(\bar{\mu}\,\mathrm{d}z^2\big) \\ &\overset{(3)}{=} (1 + |\mu|^2 + 2\mu_1)\,\mathrm{d}x^2 + 4\mu_2\,\mathrm{d}x\,\mathrm{d}y + (1 + |\mu|^2 - 2\mu_1)\,\mathrm{d}y^2. \end{aligned}$$

(1) $|w|^2 = w\bar{w}$, and the conjugate of $\mathrm{d}z$ is $\mathrm{d}\bar{z}$.
(2) Multiply out; the cross terms $\bar{\mu}\,\mathrm{d}z^2$ and $\mu\,\mathrm{d}\bar{z}^2$ are complex conjugates.
(3) $\mathrm{Re}\big((\mu_1 - i\mu_2)(\mathrm{d}x^2 - \mathrm{d}y^2 + 2i\,\mathrm{d}x\,\mathrm{d}y)\big) = \mu_1(\mathrm{d}x^2 - \mathrm{d}y^2) + 2\mu_2\,\mathrm{d}x\,\mathrm{d}y$.

Comparing with $A\,\mathrm{d}x^2 + 2B\,\mathrm{d}x\,\mathrm{d}y + C\,\mathrm{d}y^2$ gives $A + C = 2\lambda(1 + |\mu|^2)$, $A - C = 4\lambda\mu_1$, $B = 2\lambda\mu_2$. The determinant is $AC - B^2 = \lambda^2(1 - |\mu|^2)^2$. Solving,

$$\lambda = \frac{A + C + 2\sqrt{AC - B^2}}{4}, \qquad \mu = \frac{A - C + 2iB}{A + C + 2\sqrt{AC - B^2}}. \tag{9.13}$$

Two checks. (i) The Euclidean metric $A = C = 1$, $B = 0$ gives $\lambda = 1$, $\mu = 0$: z itself is holomorphic. (ii) Multiplying A, B, C by a positive f multiplies λ by f and leaves μ unchanged: a Weyl rescaling does not change the complex structure. For instance $\mathrm{d}s^2 = 4\,\mathrm{d}x^2 + \mathrm{d}y^2$ gives $\lambda = \frac{9}{4}$, $\mu = \frac{1}{3}$, and $w = \frac{3}{2}x + \frac{i}{2}\cdot\ldots$ is easiest found directly: $\mathrm{d}s^2 = |2\mathrm{d}x + i\,\mathrm{d}y|^2$, so $w = 2x + iy$ is a holomorphic coordinate, and indeed $\partial_{\bar{z}} w = \frac{1}{2}(2 - 1) = \frac{1}{2}$, $\partial_z w = \frac{1}{2}(2 + 1) = \frac{3}{2}$, ratio $\frac{1}{3} = \mu$.

The existence of a holomorphic coordinate w near every point (a local solution of the Beltrami equation) is a genuine theorem, the existence of **isothermal coordinates**. We use it freely: *every metric on a surface is locally of the form* $e^{2\omega}\,|\mathrm{d}w|^2$. We come back to it when we discuss the conformal gauge in Section 9.3.6. Nash records the same fact in [Nash p. 149, (5.35)].

The action in complex coordinates. In an isothermal coordinate $z = x^1 + ix^2$ write

$$\mathrm{d}s^2 = e^{2\omega}\big((\mathrm{d}x^1)^2 + (\mathrm{d}x^2)^2\big) = e^{2\omega}\,\mathrm{d}z\,\mathrm{d}\bar{z}, \qquad g_{ab} = e^{2\omega}\delta_{ab}. \tag{9.14}$$

In complex components the only non-zero metric entries are $g_{z\bar{z}} = g_{\bar{z}z} = \frac{1}{2}e^{2\omega}$, with inverse $g^{z\bar{z}} = g^{\bar{z}z} = 2e^{-2\omega}$. The Polyakov Lagrangian becomes very simple:

$$\begin{aligned} \sqrt{g}\,g^{ab}\,\partial_a\phi\cdot\partial_b\phi &\overset{(1)}{=} e^{2\omega}\,e^{-2\omega}\,\delta^{ab}\,\partial_a\phi\cdot\partial_b\phi \\ &\overset{(2)}{=} (\partial_1\phi)^2 + (\partial_2\phi)^2 \\ &\overset{(3)}{=} 4\,\partial_z\phi\cdot\partial_{\bar{z}}\phi. \end{aligned} \tag{9.15}$$

(1) $\sqrt{\det(e^{2\omega}\delta)} = e^{2\omega}$ and $g^{ab} = e^{-2\omega}\delta^{ab}$ (the Weyl invariance of Example 9.7 in action).
(2) Sum over a.

(3) $\partial_z\phi\,\partial_{\bar z}\phi = \tfrac14(\partial_1 - i\partial_2)\phi\,(\partial_1 + i\partial_2)\phi = \tfrac14\big((\partial_1\phi)^2 + (\partial_2\phi)^2\big)$ for real ϕ.

The conformal factor $e^{2\omega}$ has disappeared. Only the complex structure (which coordinates are isothermal) matters to the action.

The action as $\langle\phi, \Delta_g\phi\rangle$. Integrating by parts turns the action into a quadratic form of the Laplacian, which is the form we need for the Gaussian integral. Set $T = 1$ from now on (Nash does the same; it can be restored by rescaling $\phi \to \sqrt{T}\phi$). Then, on a closed surface,

$$\begin{aligned} S[\phi, g] &\overset{(1)}{=} \frac12 \int_\Sigma \mathrm{d}^2x\,\sqrt{g}\,g^{ab}\,\partial_a\phi\cdot\partial_b\phi \\ &\overset{(2)}{=} -\frac12 \int_\Sigma \mathrm{d}^2x\,\phi\cdot\partial_a\big(\sqrt{g}\,g^{ab}\partial_b\phi\big) \\ &\overset{(3)}{=} \frac12 \int_\Sigma \mathrm{d}^2x\,\sqrt{g}\,\phi\cdot\Delta_g\phi \;=\; \frac12\,\langle\phi, \Delta_g\phi\rangle_g, \end{aligned} \tag{9.16}$$

(1) The Polyakov action (9.5) with $T = 1$.
(2) Integrate by parts in x^a. There is no boundary term: Σ is closed (Stokes' theorem with $\partial\Sigma = \varnothing$, Chapter T2).
(3) Definition of the Laplacian, $\Delta_g = -\frac{1}{\sqrt{g}}\partial_a(\sqrt{g}\,g^{ab}\partial_b)$, and of the L^2 inner product $\langle u, v\rangle_g = \int \mathrm{d}^2x\sqrt{g}\,u\,v$.

In the isothermal coordinate (9.14) the Laplacian is

$$\Delta_g = -e^{-2\omega}\big(\partial_1^2 + \partial_2^2\big) = -4\,e^{-2\omega}\,\partial_z\partial_{\bar z}. \tag{9.17}$$

The same chain shows why Δ_g is a *positive* operator: $\langle\phi, \Delta_g\phi\rangle_g = \int\sqrt{g}\,\big|\nabla\phi\big|^2 \geq 0$, with equality only for constant ϕ.

Worked example 9.12: The Laplacian of the round sphere in a complex coordinate

Stereographic projection from the north pole gives the unit sphere the metric

$$\mathrm{d}s^2 = \frac{4\,\mathrm{d}z\,\mathrm{d}\bar z}{(1+|z|^2)^2}, \qquad e^{2\omega} = \frac{4}{(1+|z|^2)^2},$$

so by (9.17), $\Delta = -(1+|z|^2)^2\partial_z\partial_{\bar z}$. The height function of the sphere is $u = \cos\theta = (1-|z|^2)/(1+|z|^2)$. Write $r^2 = z\bar z$. Then

$$\begin{aligned} \partial_{\bar z}u &\overset{(1)}{=} \frac{-z(1+r^2) - (1-r^2)z}{(1+r^2)^2} = \frac{-2z}{(1+r^2)^2}, \\ \partial_z\partial_{\bar z}u &\overset{(2)}{=} \frac{-2(1+r^2)^2 + 2z\cdot 2(1+r^2)\bar z}{(1+r^2)^4} = \frac{-2(1+r^2)+4r^2}{(1+r^2)^3} = \frac{-2(1-r^2)}{(1+r^2)^3}, \\ \Delta u &\overset{(3)}{=} (1+r^2)^2\cdot\frac{2(1-r^2)}{(1+r^2)^3} = 2\,u. \end{aligned}$$

(1) Quotient rule, with $\partial_{\bar z}(z\bar z) = z$.
(2) Quotient rule again, with $\partial_z(1+z\bar z)^2 = 2(1+r^2)\bar z$.
(3) Multiply by $-(1+r^2)^2$.

So $\cos\theta$ is an eigenfunction with eigenvalue $2 = \ell(\ell+1)$ for $\ell = 1$, exactly as the spherical harmonics say. The complex-coordinate formula for Δ works, and the sign convention makes the eigenvalues positive.

Watch out: Nash's (9.4): signs and the symbol ∂

Nash writes $S = (-1/2)\int_\Sigma \langle \partial\phi, \partial\phi\rangle_g = (1/2)\int_\Sigma \langle \phi, \Delta_g \phi\rangle$ with $\langle \partial\phi, \partial\phi\rangle_g = g^{ab}\partial_a\phi^\mu \partial_b \phi_\mu \sqrt{g}\, \mathrm{d}z\, \mathrm{d}\bar{z}$ and $\Delta_g = \partial\partial^* + \partial^*\partial$. Three remarks.

(i) The two expressions differ by an integration by parts, which gives $+\int \langle \mathrm{d}\phi, \mathrm{d}\phi\rangle = +\int \langle \phi, \mathrm{d}^*\mathrm{d}\phi\rangle$ with no sign change; the minus sign in front of the first expression should be dropped (or absorbed into the orientation convention for $\mathrm{d}z\,\mathrm{d}\bar{z} = -2i\,\mathrm{d}x \wedge \mathrm{d}y$). Our (9.16) is the correct Euclidean statement.

(ii) In $\langle \partial\phi, \partial\phi\rangle_g$ the symbol ∂ is the full gradient d (the formula has $g^{ab}\partial_a\partial_b$ with both indices summed). With $\partial = \mathrm{d}$, $\Delta_g = \mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$ is the Hodge Laplacian (Chapter 2).

(iii) On functions the term $\mathrm{d}\mathrm{d}^*$ contributes nothing, as Nash notes: d^* lowers form degree, and there are no (-1)-forms, so $\mathrm{d}^*\phi = 0$ for a function ϕ. Hence $\Delta_g\phi = \mathrm{d}^*\mathrm{d}\phi$, which in coordinates is our $-\frac{1}{\sqrt{g}}\partial_a(\sqrt{g}g^{ab}\partial_b\phi)$. (If instead ∂ is read as the holomorphic Dolbeault operator, then on a Riemann surface $\partial^*\partial = \frac{1}{2}\mathrm{d}^*\mathrm{d}$ on functions; the factor $\frac{1}{2}$ only rescales determinants, see Example 9.26.)

9.1.7 The configuration space and its symmetry group

From now on space-time is flat Euclidean $\mathbb{R}^d$. The two variables of the Polyakov action live in two big spaces:

- $\mathrm{Map}(\Sigma, \mathbb{R}^d)$, the space of all smooth maps $\phi : \Sigma \to \mathbb{R}^d$. It is simply a vector space: d copies of the space $C^\infty(\Sigma)$ of smooth real functions.
- $\mathrm{Met}(\Sigma)$, the space of all Riemannian metrics on Σ.

Nash calls their product the **string configuration space**

$$B = \mathrm{Map}(\Sigma, \mathbb{R}^d) \times \mathrm{Met}(\Sigma), \tag{9.18}$$

and regards the action as a function $S : B \to \mathbb{R}$, $(\phi, g) \mapsto S(\phi, g)$. The path integral (9.10) is an integral over B.

What does $\mathrm{Met}(\Sigma)$ look like? At each point x a metric is a symmetric 2×2 matrix

$$g(x) = \begin{pmatrix} a & b \\ b & c \end{pmatrix}, \qquad a > 0, \quad ac - b^2 > 0.$$

The set of such matrices, call it $\mathrm{Pos}(2)$, is an open cone in the three-dimensional space $\{(a, b, c)\}$ of symmetric matrices: if g and g' are positive definite, so are tg for $t > 0$ and $g + g'$. So $\mathrm{Met}(\Sigma)$ is "one copy of this three-dimensional cone at each point of Σ". In particular it is an open convex subset of the vector space of symmetric tensor fields, and hence its tangent space at any metric g is that whole vector space:

$$T_g\mathrm{Met}(\Sigma) = \{\text{symmetric tensor fields } \delta g_{ab}(x) \text{ on } \Sigma\}. \tag{9.19}$$

A tangent vector to Met is "a small change of metric", which is a symmetric tensor field. This is the fact behind Nash's remark (p. 263) that tangent vectors to $\mathrm{Met}(\Sigma)$ "can be thought of both as tangents to $\mathrm{Met}(\Sigma)$ and as tensor fields on Σ".

The gauge group. We have found two groups that leave S invariant (Section 9.1.4).

- The **Weyl group** $C^\infty_+(\Sigma)$: the smooth *positive* functions on Σ, with pointwise multiplication as the group law. It is abelian. It acts by $g \mapsto f g$ and does not touch ϕ. Its Lie algebra is all of $C^\infty(\Sigma)$, via $f = e^{2\omega}$.
- The group $\mathrm{Diff}^+(\Sigma)$ of orientation-preserving diffeomorphisms, with composition as the group law. It acts on both variables by pull-back (9.9).

Nash writes the combined action as the map (his (9.6))

$$A : \big(\mathrm{Diff}^+(\Sigma) \ltimes C^\infty_+(\Sigma)\big) \times B \longrightarrow B, \qquad \big((\alpha, f), (\phi, g)\big) \longmapsto \big(\alpha^*\phi,\ f \cdot \alpha^* g\big), \tag{9.20}$$

that is, $(\phi(\alpha(x)),\ f(x)\, g(\alpha(x)))$ in Nash's shorthand, where $g(\alpha(x))$ is understood to include the Jacobian factors. The symbol $\ltimes$ says that the two groups do *not* simply commute. Let us see exactly how they fail to commute, by composing two such transformations.

Worked example 9.13: The group law of the semidirect product

Write $T_{(\alpha,f)}$ for the transformation (9.20). Apply $T_{(\alpha_2,f_2)}$ first and then $T_{(\alpha_1,f_1)}$:

$$\begin{aligned} T_{(\alpha_1,f_1)}\, T_{(\alpha_2,f_2)}(\phi, g) &\overset{(1)}{=} T_{(\alpha_1,f_1)}\big(\alpha_2^*\phi,\ f_2\, \alpha_2^* g\big) \\ &\overset{(2)}{=} \big(\alpha_1^*\alpha_2^*\phi,\ f_1\, \alpha_1^*\big(f_2\, \alpha_2^* g\big)\big) \\ &\overset{(3)}{=} \big((\alpha_2 \circ \alpha_1)^*\phi,\ f_1\, (f_2 \circ \alpha_1)\, (\alpha_2 \circ \alpha_1)^* g\big) \\ &\overset{(4)}{=} T_{(\alpha_2\circ\alpha_1,\ f_1\cdot(f_2\circ\alpha_1))}(\phi, g). \end{aligned}$$

(1) Definition of $T_{(\alpha_2,f_2)}$.
(2) Definition of $T_{(\alpha_1,f_1)}$, applied to the new pair.
(3) Pull-back reverses the order of composition, $\alpha_1^*\alpha_2^* = (\alpha_2 \circ \alpha_1)^*$ (check on a function: $\alpha_1^*(\alpha_2^*\phi)(x) = \phi(\alpha_2(\alpha_1(x)))$), and the pull-back of a product is the product of pull-backs, $\alpha_1^* f_2 = f_2 \circ \alpha_1$.
(4) Read off the result as a single transformation of the same type.

So the product in the gauge group is

$$(\alpha_1, f_1) \cdot (\alpha_2, f_2) = \big(\alpha_2 \circ \alpha_1,\ f_1 \cdot (f_2 \circ \alpha_1)\big). \tag{9.21}$$

The diffeomorphism α_1 acts on the Weyl factor f_2 by moving it around the surface. That twist is what the word "semidirect" means. The identity is $(\mathrm{id}, 1)$, and the inverse of (α, f) is $(\alpha^{-1},\ 1/(f \circ \alpha^{-1}))$: indeed $(\alpha, f) \cdot (\alpha^{-1}, h) = (\mathrm{id},\ f \cdot (h \circ \alpha))$, which is $(\mathrm{id}, 1)$ exactly when $h \circ \alpha = 1/f$.

Worked example 9.14: Weyl rescalings form a normal subgroup

Conjugate a pure Weyl rescaling (id, f) by a pure diffeomorphism $(\alpha, 1)$. Using (9.21) twice,

$$\begin{aligned} (\alpha, 1)^{-1} \cdot (\mathrm{id}, f) \cdot (\alpha, 1) &\overset{(1)}{=} (\alpha^{-1}, 1) \cdot (\mathrm{id}, f) \cdot (\alpha, 1) \\ &\overset{(2)}{=} (\alpha^{-1},\ f \circ \alpha^{-1}) \cdot (\alpha, 1) \\ &\overset{(3)}{=} (\mathrm{id},\ f \circ \alpha^{-1}). \end{aligned}$$

(1) The inverse of $(\alpha, 1)$ is $(\alpha^{-1}, 1)$ by the formula above.
(2) $(\alpha^{-1}, 1) \cdot (\mathrm{id}, f) = (\mathrm{id} \circ \alpha^{-1},\ 1 \cdot (f \circ \alpha^{-1}))$.
(3) $(\alpha^{-1}, f \circ \alpha^{-1}) \cdot (\alpha, 1) = (\alpha \circ \alpha^{-1},\ (f \circ \alpha^{-1}) \cdot 1)$.

A conjugated Weyl rescaling is again a Weyl rescaling, by the moved function $f \circ \alpha^{-1}$. So $C^\infty_+(\Sigma)$ is a **normal subgroup**, and the quotient by it is $\mathrm{Diff}^+(\Sigma)$. The diffeomorphisms, on the other hand, do not form a normal subgroup. (In $\ltimes$ the normal factor sits on the side of the open triangle; conventions for the symbol vary between books, so it is safest to remember "Weyl is normal".)

Worked example 9.15: A finite-dimensional semidirect product you already know

The affine maps of the line, $x \mapsto ax + b$ with $a > 0$, form a group. Represent (a, b) by the matrix $\begin{pmatrix} a & b \\ 0 & 1 \end{pmatrix}$ acting on $\begin{pmatrix} x \\ 1 \end{pmatrix}$. Multiplying matrices,

$$\begin{pmatrix} a_1 & b_1 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} a_2 & b_2 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} a_1 a_2 & a_1 b_2 + b_1 \\ 0 & 1 \end{pmatrix}.$$

The dilation a_1 acts on the translation b_2 before the translations are added: the same twist as $f_2 \mapsto f_2 \circ \alpha_1$ above. Translations $(1, b)$ are normal (conjugating a translation by a dilation gives a translation by b/a or ab), dilations are not. The Euclidean group $\mathbb{R}^n \rtimes \mathrm{SO}(n)$ and the Poincaré group are built the same way.

Worked example 9.16: A diffeomorphism changes the components but not the geometry

On the square torus $\mathbb{R}^2/\mathbb{Z}^2$ with the flat metric $g = \mathbf{1}$, take the diffeomorphism $\alpha(x, y) = (x + \varepsilon \sin 2\pi y,\ y)$, which slides each horizontal circle sideways by an amount depending on its height. Its Jacobian and the pulled-back metric are

$$J = \begin{pmatrix} 1 & 2\pi\varepsilon \cos 2\pi y \\ 0 & 1 \end{pmatrix}, \qquad \alpha^* g \overset{(1)}{=} J^{\mathsf{T}} J \overset{(2)}{=} \begin{pmatrix} 1 & 2\pi\varepsilon \cos 2\pi y \\ 2\pi\varepsilon \cos 2\pi y & 1 + 4\pi^2\varepsilon^2 \cos^2 2\pi y \end{pmatrix}.$$

(1) $(\alpha^* g)_{ab} = J^c{}_a J^d{}_b\, g_{cd}$ with $g_{cd} = \delta_{cd}$.
(2) Multiply out the matrices.

The new metric looks quite different: it has an off-diagonal term and a position-dependent entry. But it is the old flat metric in disguise, since $\det(\alpha^* g) = 1$ and its curvature is zero. By (9.13) its Beltrami coefficient is $\mu = \frac{-\varepsilon'^2 + 2i\varepsilon'}{4 + \varepsilon'^2} \neq 0$ with $\varepsilon' = 2\pi\varepsilon \cos 2\pi y$: the diffeomorphism also changes which coordinates are holomorphic. The path integral must not count g and $\alpha^* g$ as two different configurations.

Physical picture: The orbits are infinite-dimensional, the slice almost is not

Each orbit is a copy of the gauge group, so it is infinite-dimensional. By the function counting of Section 9.1.4, the slice through $\mathrm{Met}(\Sigma)$ is *finite*-dimensional: it is parametrised by the moduli. The slice through $\mathrm{Map}(\Sigma, \mathbb{R}^d)$ is still infinite-dimensional (a string can wiggle in any way), but there the integral is Gaussian. That is the division of labour for the rest of the chapter: Gaussian integral over ϕ now, finite-dimensional integral over metrics

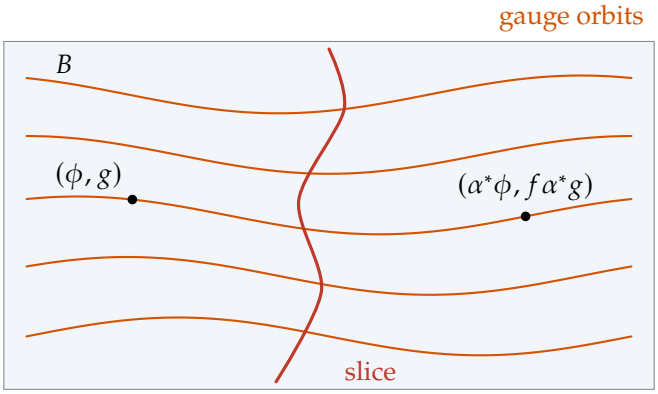

Figure 9.7: The configuration space $B = \mathrm{Map}(\Sigma, \mathbb{R}^d) \times \mathrm{Met}(\Sigma)$ is sliced into *orbits* (orange) of the gauge group $\mathrm{Diff}^+ \ltimes C^\infty_+$. All points on one orbit have the same action and describe the same physics. Integrating over all of B counts each physical configuration an infinite number of times (once per point of its orbit). The cure, carried out in Sections 9.2 and 9.3, is to integrate over a *slice* (red) that meets each orbit once, with a Jacobian that records the size of the orbit.

later.

9.1.8 The integral over the embeddings is Gaussian

For fixed g the action (9.16) is $S = \frac{1}{2}\langle\phi, \Delta_g \phi\rangle_g$, a quadratic form. So the ϕ-integral in (9.10) is an infinite-dimensional Gaussian integral. We first recall the finite-dimensional version in full, because every step of the infinite-dimensional one is a copy of it.

Key idea: The Gaussian integral

For a real symmetric positive-definite $n \times n$ matrix M,

$$\int_{\mathbb{R}^n} \mathrm{d}^n x \; e^{-\frac{1}{2}x^{\mathsf{T}} M x} = \frac{(2\pi)^{n/2}}{\sqrt{\det M}}. \tag{9.22}$$

To see it, rotate to the eigenbasis of M:

$$\begin{aligned}\int_{\mathbb{R}^n} \mathrm{d}^n x \; e^{-\frac{1}{2}x^{\mathsf{T}} M x} &\overset{(1)}{=} \int_{\mathbb{R}^n} \mathrm{d}^n c \; e^{-\frac{1}{2}\sum_k \lambda_k c_k^2} \\ &\overset{(2)}{=} \prod_{k=1}^{n} \int_{-\infty}^{\infty} \mathrm{d}c_k \; e^{-\frac{1}{2}\lambda_k c_k^2} \\ &\overset{(3)}{=} \prod_{k=1}^{n} \sqrt{\frac{2\pi}{\lambda_k}} \overset{(4)}{=} \frac{(2\pi)^{n/2}}{\sqrt{\det M}}.\end{aligned}$$

(1) Write $x = \sum_k c_k e_k$ with e_k an orthonormal eigenbasis, $M e_k = \lambda_k e_k$. The change of variables is a rotation, so $\mathrm{d}^n x = \mathrm{d}^n c$, and $x^{\mathsf{T}} M x = \sum \lambda_k c_k^2$.
(2) The exponential of a sum is a product of exponentials, and the integral factorises.
(3) The one-dimensional Gaussian $\int \mathrm{d}c \; e^{-\lambda c^2/2} = \sqrt{2\pi/\lambda}$.
(4) The determinant is the product of the eigenvalues.

Worked example 9.17: A 2×2 check

Let $M = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$, with eigenvalues 3 (eigenvector $(1,1)/\sqrt{2}$) and 1 (eigenvector $(1,-1)/\sqrt{2}$), so $\det M = 3$. The formula predicts $2\pi/\sqrt{3} \approx 3.628$. Directly, completing the square,

$$\int \mathrm{d}x\,\mathrm{d}y\; e^{-(x^2+xy+y^2)} \overset{(1)}{=} \int \mathrm{d}y\, e^{-\frac{3}{4}y^2} \int \mathrm{d}x\, e^{-(x+y/2)^2}$$
$$\overset{(2)}{=} \sqrt{\frac{4\pi}{3}} \cdot \sqrt{\pi} = \frac{2\pi}{\sqrt{3}}.$$

(1) $\frac{1}{2}x^{\mathsf{T}}Mx = x^2 + xy + y^2 = (x + \frac{y}{2})^2 + \frac{3}{4}y^2$.
(2) Shift x in the inner integral; then use $\int e^{-ac^2}\mathrm{d}c = \sqrt{\pi/a}$ twice.

The normalisation of the measure. The factors of 2π in (9.22) carry no physics, and in infinite dimensions their product would be meaningless. Nash's formula (9.7) has $\det(\Delta_g/2)$ instead of $\det \Delta_g$, which corresponds to normalising the measure so that each mode contributes $\int \frac{\mathrm{d}c}{\sqrt{\pi}}\, e^{-\lambda c^2/2} = (\lambda/2)^{-1/2}$. Equivalently, the measure $\mathcal{D}\phi$ is normalised by $\int \mathcal{D}\phi\, e^{-\langle\phi,\phi\rangle_g} = 1$. Either choice changes the answer by a constant, and we will see in Example 9.26 that for zeta determinants the constant depends only on the genus.

Where the metric g enters. To define $\mathcal{D}\phi$ we need orthonormal coordinates on the space of functions, and "orthonormal" requires an inner product. The natural one is

$$\langle u, v\rangle_g = \int_\Sigma \mathrm{d}^2x\, \sqrt{g}\, u(x)\, v(x). \tag{9.23}$$

So the measure $\mathcal{D}\phi$ itself depends on the metric. This matters: a Weyl rescaling $g \to e^{2\omega}g$ leaves the action invariant but changes $\sqrt{g}$ in (9.23), and hence changes the measure. That is the origin of the conformal anomaly (Section 9.2.11).

The infinite-dimensional Gaussian. Because Σ is compact and Δ_g is elliptic, Δ_g has a complete orthonormal set of eigenfunctions (Chapter 2),

$$\Delta_g e_n = \lambda_n e_n, \qquad \langle e_m, e_n\rangle_g = \delta_{mn}, \qquad 0 = \lambda_0 < \lambda_1 \le \lambda_2 \le \cdots \to \infty. \tag{9.24}$$

Ellipticity is what guarantees that the spectrum is a discrete list with finite multiplicities, growing without bound. The growth rate is given by **Weyl's law**: the number of eigenvalues below λ is $N(\lambda) \approx \frac{\mathrm{Area}}{4\pi}\lambda$ for large λ, so $\lambda_n \approx 4\pi n/\mathrm{Area}$.

Worked example 9.18: The spectrum of the round sphere and Weyl's law

On the unit sphere the eigenfunctions of Δ are the spherical harmonics $Y_{\ell m}$ with $\Delta Y_{\ell m} = \ell(\ell+1)Y_{\ell m}$, $m = -\ell, \dots, \ell$ (we checked $\ell = 1$ in Example 9.12). Count the eigenvalues up to $\Lambda = L(L+1)$:

$$N\big(L(L+1)\big) \overset{(1)}{=} \sum_{\ell=0}^{L} (2\ell+1)$$
$$\overset{(2)}{=} (L+1)^2 \;\approx\; L(L+1) = \frac{4\pi}{4\pi}\Lambda.$$

(1) Each ℓ contributes $2\ell + 1$ eigenfunctions.
(2) The sum of the first $L + 1$ odd numbers is $(L + 1)^2$; for large L this is $L(L + 1)$ up to lower-order terms.

With Area $= 4\pi$ this is exactly Weyl's law. Figure 9.8 shows the spectrum. The single eigenvalue 0 (the constants) is the zero mode.

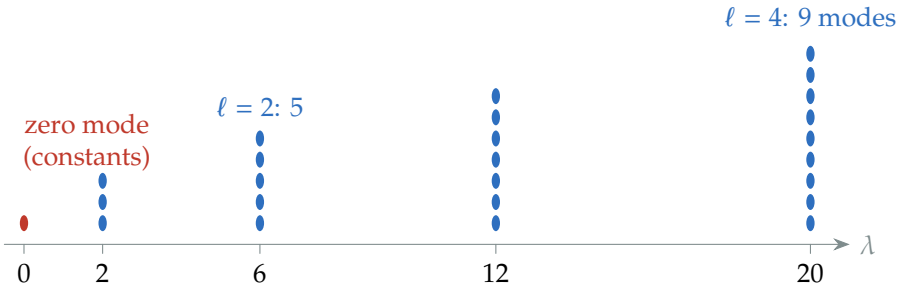

Figure 9.8: The spectrum of the Laplacian on the unit sphere: eigenvalue $\ell(\ell + 1)$ stacked with its multiplicity $2\ell + 1$. The eigenvalues grow without bound and the stacks grow linearly, so the total count grows like λ (Weyl's law). The red dot at $\lambda = 0$ is the constant function: the zero mode that must be treated separately in the Gaussian integral.

Expand each component of the embedding in the eigenfunctions, $\phi^\mu = \sum_n c_n^\mu e_n$. Then

$$S = \tfrac{1}{2}\langle \phi, \Delta_g \phi \rangle_g = \tfrac{1}{2} \sum_{\mu=1}^{d} \sum_{n \geq 0} \lambda_n \, (c_n^\mu)^2, \tag{9.25}$$

by orthonormality, and the measure is $\mathcal{D}\phi = \prod_{\mu,n} \mathrm{d}c_n^\mu / \sqrt{\pi}$. Each non-zero mode gives a factor $(\lambda_n/2)^{-1/2}$, and there are d components. Formally,

$$\int \mathcal{D}\phi \; e^{-S} \;=\; \underbrace{\Big(\int \prod_{\mu} \frac{\mathrm{d}c_0^\mu}{\sqrt{\pi}} \Big)}_{\text{zero mode}} \prod_{n \geq 1} \Big(\frac{\lambda_n}{2} \Big)^{-d/2} \;=\; (\text{zero-mode factor}) \times \Big(\det{}' \frac{\Delta_g}{2} \Big)^{-d/2}. \tag{9.26}$$

Two things need attention. The infinite product $\prod_n \lambda_n$ diverges, since $\lambda_n \to \infty$; it will be defined by a zeta function in Section 9.1.10. And the zero mode gives an infinite factor of a different kind, which we treat now.

9.1.9 The zero mode and the factor $(1, 1)_g$

The eigenvalue $\lambda_0 = 0$ belongs to the constant functions. A constant embedding $\phi^\mu(x) = \phi_0^\mu$ maps the whole world sheet to one point of space-time. It has zero action, and so does $\phi + \phi_0$ for any ϕ: this is translation invariance in $\mathbb{R}^d$. The Gaussian has a flat direction (Figure 9.9), and its integral is proportional to the volume of $\mathbb{R}^d$.

We need to be careful about one thing: the normalised zero mode is not the function 1 but $e_0 = 1/\sqrt{A_g}$, where

$$A_g \;=\; (1, 1)_g \;=\; \int_\Sigma \mathrm{d}^2 x \, \sqrt{g} \tag{9.27}$$

is the area of (Σ, g). (Nash writes $(1, 1)_g$ for the L^2 inner product of the constant function 1 with itself, which is the area.) So the coefficient c_0^μ of the zero mode is related to the physical position ϕ_0^μ of the string's "centre of mass" by $\phi_0^\mu = c_0^\mu / \sqrt{A_g}$.

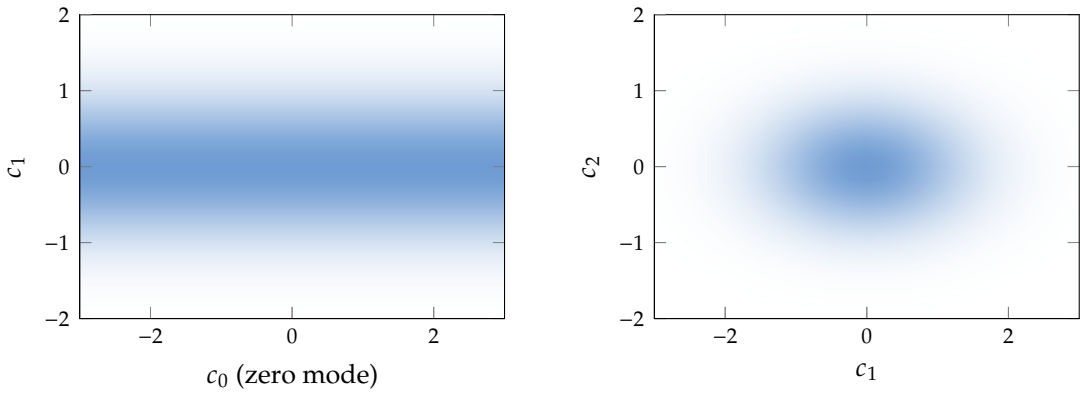

Figure 9.9: Shading shows e^{-S} on a two-dimensional slice of field space. Right: two non-zero modes; the Gaussian is a hill in every direction and its integral is finite, $\propto (\lambda_1\lambda_2)^{-1/2}$. Left: one direction is the zero mode; e^{-S} is constant along it, a ridge running off to infinity. The integral along the ridge is the length of the ridge, which for the string is the volume of space-time.

Worked example 9.19: Where the area comes from

Integrate over the zero mode of one component, with a box of side L in space-time as cutoff (Nash's "compactness cutoff"):

$$\int \frac{\mathrm{d}c_0}{\sqrt{\pi}} \overset{(1)}{=} \int_0^L \frac{\sqrt{A_g}\,\mathrm{d}\phi_0}{\sqrt{\pi}} \overset{(2)}{=} \frac{L}{\sqrt{\pi}}\,A_g^{1/2}.$$

(1) Change variables $c_0 = \sqrt{A_g}\,\phi_0$, and restrict the position ϕ_0 of the string to the box $[0, L]$.
(2) Nothing depends on ϕ_0.

With d components the zero-mode factor is $(L/\sqrt{\pi})^d\,A_g^{d/2} = (\text{volume of the box})\times\pi^{-d/2}\,A_g^{d/2}$. The volume L^d is the same for every metric, so it is an overall constant: we divide by it ("the cutoff may then be discarded"). But the factor $A_g^{d/2}$ *depends on the metric* and must be kept. It is not optional: without it the answer would not be invariant under constant rescalings of g, as we will verify in Example 9.26.

Worked example 9.20: A two-site toy model with a zero mode

Replace Σ by two points, and the Laplacian by the 2×2 matrix $M = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}$, so that $S = \frac{1}{2}(x_1 - x_2)^2$ depends only on the difference. Its eigenvalues are 0 (eigenvector $(1,1)/\sqrt{2}$) and 2 (eigenvector $(1,-1)/\sqrt{2}$). The "area" is $\langle (1,1),(1,1)\rangle = 2$, the number of sites. Restrict the centre of mass $m = \frac{1}{2}(x_1 + x_2)$ to $[0, L]$:

$$\begin{aligned}\int \mathrm{d}x_1\,\mathrm{d}x_2\,e^{-\frac{1}{2}(x_1-x_2)^2} &\overset{(1)}{=} \int \mathrm{d}u\,\mathrm{d}v\,e^{-v^2} \\ &\overset{(2)}{=} \left(\sqrt{2}\int_0^L \mathrm{d}m\right)\sqrt{\pi} \\ &= \sqrt{2\pi}\,L\end{aligned}$$

$$\overset{(3)}{=} L \cdot 2^{1/2} \cdot (2\pi)^{1/2} \cdot 2^{-1/2}.$$

(1) Rotate to $u = (x_1+x_2)/\sqrt{2}$, $v = (x_1-x_2)/\sqrt{2}$; then $\frac{1}{2}(x_1-x_2)^2 = v^2$ and $\mathrm{d}x_1\mathrm{d}x_2 = \mathrm{d}u\,\mathrm{d}v$.
(2) $u = \sqrt{2}\,m$, so $\mathrm{d}u = \sqrt{2}\,\mathrm{d}m$; and $\int e^{-v^2}\mathrm{d}v = \sqrt{\pi}$.
(3) Rewrite $\sqrt{2\pi}\,L$ to display its structure: $L \times (\text{area})^{1/2} \times (2\pi)^{(n-1)/2} \times (\det{}'M)^{-1/2}$ with $n = 2$, area $= 2$, $\det{}'M = 2$.

This is (9.22) with the zero eigenvalue left out of the determinant and replaced by (volume)×(area)$^{1/2}$: exactly the structure of Nash's (9.7).

Worked example 9.21: The string on a lattice circle: $\det'$ by hand

Discretise a circle into n sites with the nearest-neighbour Laplacian $(Mx)_j = 2x_j - x_{j+1} - x_{j-1}$ (indices mod n). Its eigenvectors are the discrete Fourier modes $x_j = e^{2\pi i k j/n}$, with eigenvalues

$$\lambda_k \overset{(1)}{=} 2 - e^{2\pi i k/n} - e^{-2\pi i k/n}$$
$$\overset{(2)}{=} 2 - 2\cos\frac{2\pi k}{n} = 4\sin^2\frac{\pi k}{n}, \qquad k = 0, 1, \dots, n-1.$$

(1) Substitute the Fourier mode into $(Mx)_j$ and divide by x_j.
(2) $e^{i\theta} + e^{-i\theta} = 2\cos\theta$ and $1 - \cos\theta = 2\sin^2(\theta/2)$.

The zero mode is $k = 0$, the constant vector. The product of the non-zero eigenvalues is

$$\det{}'M = \prod_{k=1}^{n-1} 4\sin^2\frac{\pi k}{n} = n^2,$$

a classical trigonometric identity. Check: for $n = 3$ the eigenvalues are $3, 3$ and the product is 9; for $n = 4$ they are $2, 4, 2$ with product 16. (This is also Kirchhoff's matrix-tree theorem: $\det{}'M = n\times$(number of spanning trees of the n-cycle), and the n-cycle has n spanning trees.) Keep this n^2 in mind: the zeta-function determinant of the continuum circle will come out as L^2 in Example 9.23.

The result. Put the Gaussian (9.26) and the zero-mode factor of Example 9.19 together, and drop the constant $(L/\sqrt{\pi})^d$:

Key idea: The embedding integral, Nash's (9.7)

$$Z_p = \int_{\mathrm{Met}(\Sigma)} \mathcal{D}g \left(\frac{\det{}'(\Delta_g/2)}{(1,1)_g}\right)^{-d/2}. \tag{9.28}$$

Each of the d scalar fields ϕ^μ contributes $\left(\det{}'(\Delta_g/2)\right)^{-1/2}$ from its non-zero modes and $(1,1)_g^{1/2} = A_g^{1/2}$ from its zero mode.

Nash writes det rather than det′ and explains in words that the determinant is "restricted to the strictly positive subspace"; we write the prime to make that visible.

Watch out: Two different infinities

The zero mode and the infinite product are infinite for different reasons. The zero mode is an *infrared* infinity: it comes from the infinite volume of space-time, and it is physical (the vacuum amplitude really is proportional to the volume, as for the free particle in Example 9.9). The product $\prod_n \lambda_n$ is an *ultraviolet* infinity: it comes from arbitrarily short-wavelength wiggles of the string, and it is removed by regularisation. Nash's footnote handles the second with a zeta function.

9.1.10 Zeta-function determinants

We now have to give a meaning to $\det{}'\Delta_g = \prod_{n\geq 1}\lambda_n$, a product of infinitely many numbers that grow without bound. Nash's footnote (p. 261) does it in one line: "$\zeta_P(s)$ is always regular at the origin and this means that a regularised determinant of P can be defined as $\exp[-\zeta_P'(0)]$". Here is where that line comes from, and what it gives in examples.

The idea. For a finite list of positive numbers, the logarithm of the product is the sum of the logarithms, and a logarithm is a derivative of a power:

$$\log\lambda = -\frac{\mathrm{d}}{\mathrm{d}s}\lambda^{-s}\Big|_{s=0}.$$

So $\log\prod_n\lambda_n = -\frac{\mathrm{d}}{\mathrm{d}s}\sum_n\lambda_n^{-s}\big|_{s=0}$. The sum $\sum_n\lambda_n^{-s}$ still makes sense for an infinite list, provided s is large enough that the terms decay fast; and then we can try to continue it to $s=0$.

Working definition 9.5 (Zeta function and zeta-regularised determinant)

Let P be a positive elliptic operator (such as Δ_g) [its eigenvalues are real, ≥ 0 and discrete, and they grow without bound] on a compact manifold, with non-zero eigenvalues $0<\lambda_1\leq\lambda_2\leq\cdots$ listed with multiplicity [an eigenvalue with k independent eigenfunctions appears k times]. Its **zeta function** is

$$\zeta_P(s) = \sum_{n\geq 1}\lambda_n^{-s}. \tag{9.29}$$

The sum converges for $\operatorname{Re}s > \frac{\dim M}{\operatorname{ord}P}$ [$\operatorname{ord}P$ is the number of derivatives in P, 2 for Δ_g] (for Δ_g on a surface: $\operatorname{Re}s>1$, by Weyl's law $\lambda_n\approx 4\pi n/A$). It continues to a meromorphic function of s [there is exactly one function, analytic except at isolated poles, that equals the sum wherever the sum converges] that is regular at $s=0$. The **zeta-regularised determinant** is

$$\det{}'P = \exp\bigl[-\zeta_P'(0)\bigr]. \tag{9.30}$$

How to compute it: find the spectrum, write ζ_P in terms of a known zeta function (Riemann, Hurwitz, Epstein), and differentiate at $s=0$.

Worked example 9.22: For a matrix, nothing new

Let $P=\operatorname{diag}(2,3)$. Then $\zeta_P(s)=2^{-s}+3^{-s}$ and

$$\exp\bigl[-\zeta_P'(0)\bigr] \overset{(1)}{=} \exp\bigl[\log 2\cdot 2^{-0}+\log 3\cdot 3^{-0}\bigr]$$
$$\overset{(2)}{=} e^{\log 6} = 6 = \det P.$$

(1) $\frac{\mathrm{d}}{\mathrm{d}s}\lambda^{-s} = -\log\lambda\,\lambda^{-s}$.

(2) $\log 2 + \log 3 = \log 6$.

Note also $\zeta_P(0) = 2$, the number of eigenvalues. For a genuine operator $\zeta_P(0)$ is a finite "regularised number of eigenvalues", and it reappears in the scaling law of Example 9.26.

Two values of the Riemann zeta function. Everything on the circle and the torus reduces to the Riemann zeta function $\zeta(s) = \sum_{n\geq 1} n^{-s}$ (convergent for $\operatorname{Re} s > 1$), and we need its value and slope at $s = 0$:

$$\zeta(0) = -\tfrac{1}{2}, \qquad \zeta'(0) = -\tfrac{1}{2}\log(2\pi). \tag{9.31}$$

Here is a physicist's derivation. Use the alternating version $\eta(s) = \sum_{n\geq 1}(-1)^{n+1}n^{-s}$, which converges for $\operatorname{Re} s > 0$ and is better behaved. Subtracting twice the even terms from ζ,

$$\eta(s) \overset{(1)}{=} \sum_{n\geq 1} n^{-s} - 2\sum_{n\geq 1}(2n)^{-s} \overset{(2)}{=} (1 - 2^{1-s})\,\zeta(s).$$

(1) $1 - 2^{-s} + 3^{-s} - \cdots$ is the full sum minus twice the even terms.
(2) $(2n)^{-s} = 2^{-s}n^{-s}$.

This identity continues ζ to $\operatorname{Re} s > 0$ (except $s = 1$), and η itself continues further. At $s = 0$, $\eta(0) = 1 - 1 + 1 - \cdots = \frac{1}{2}$ in the sense of Abel summation ($\sum(-x)^n \to \frac{1}{1+x} \to \frac{1}{2}$), so $\zeta(0) = \eta(0)/(1-2) = -\frac{1}{2}$. Differentiating the identity at $s = 0$,

$$\eta'(0) \overset{(1)}{=} 2\log 2\;\zeta(0) + (1-2)\,\zeta'(0) \overset{(2)}{=} -\log 2 - \zeta'(0).$$

(1) Product rule, with $\frac{\mathrm{d}}{\mathrm{d}s}(1 - 2^{1-s}) = 2^{1-s}\log 2$, equal to $2\log 2$ at $s = 0$.
(2) $\zeta(0) = -\frac{1}{2}$.

Finally $\eta'(0) = \sum_{n\geq 1}(-1)^n \log n = \log\frac{2}{1} + \log\frac{4}{3} + \log\frac{6}{5} + \cdots$, and pairing the terms against Wallis' product $\prod_{k\geq 1}\frac{(2k)^2}{(2k-1)(2k+1)} = \frac{\pi}{2}$ gives $\eta'(0) = \frac{1}{2}\log\frac{\pi}{2}$. (The partial sums oscillate; their average converges to this value.) Hence $\zeta'(0) = -\log 2 - \frac{1}{2}\log\frac{\pi}{2} = -\frac{1}{2}\log(2\pi)$.

Watch out: This is not "$1 + 1 + 1 + \cdots = -\frac{1}{2}$"

$\zeta(0) = -\frac{1}{2}$ is a statement about the analytic continuation of a function, not about the divergent sum. What the zeta recipe does, in effect, is throw away terms that are *local* in the ultraviolet (terms that could be cancelled by counterterms in the action) and keep a finite remainder. The lattice comparison in Example 9.23 shows this explicitly.

Worked example 9.23: The Laplacian on a circle: $\det'\Delta = L^2$

Let S^1_L be a circle of circumference L and $\Delta = -\mathrm{d}^2/\mathrm{d}\theta^2$. The eigenfunctions are $e^{2\pi i n\theta/L}$, $n \in \mathbb{Z}$, with eigenvalue $(2\pi n/L)^2$. The value 0 ($n = 0$) is the zero mode, and every non-zero eigenvalue occurs twice ($\pm n$). So

$$\zeta_\Delta(s) \overset{(1)}{=} 2\sum_{n\geq 1}\left(\frac{2\pi n}{L}\right)^{-2s} \overset{(2)}{=} 2\left(\frac{L}{2\pi}\right)^{2s}\zeta(2s).$$

(1) Sum over $n \neq 0$; the terms for n and $-n$ are equal.

(2) Pull out $(2\pi/L)^{-2s}$ and recognise $\sum n^{-2s} = \zeta(2s)$.

Now differentiate and set $s = 0$:

$$\begin{aligned}\zeta'_\Delta(0) &\overset{(1)}{=} 2 \cdot 2\log\frac{L}{2\pi}\cdot\zeta(0) + 2\cdot 2\,\zeta'(0)\\ &\overset{(2)}{=} -2\log\frac{L}{2\pi} - 2\log(2\pi)\\ &= -2\log L.\end{aligned}$$

(1) Product rule: $\frac{\mathrm{d}}{\mathrm{d}s}(L/2\pi)^{2s} = 2\log(L/2\pi)(L/2\pi)^{2s}$ and $\frac{\mathrm{d}}{\mathrm{d}s}\zeta(2s) = 2\zeta'(2s)$; then set $s = 0$.
(2) The two Riemann values (9.31).

Therefore

$$\det{}'\Delta_{S^1_L} = e^{2\log L} = L^2, \qquad \zeta_\Delta(0) = 2\zeta(0) = -1. \tag{9.32}$$

Compare the lattice circle of Example 9.21, with n sites and spacing $a = L/n$. The lattice Laplacian with the correct units is M/a^2, so

$$\begin{aligned}\det{}'\Big(\frac{M}{a^2}\Big) &\overset{(1)}{=} a^{-2(n-1)}\,n^2\\ &\overset{(2)}{=} L^2\cdot a^{-2n} \;=\; L^2\cdot\exp\Big[-\frac{2\log a}{a}\,L\Big].\end{aligned}$$

(1) $n-1$ non-zero eigenvalues, each divided by a^2, and $\det{}'M = n^2$.
(2) $n^2a^{-2(n-1)} = (na)^2a^{-2n} = L^2a^{-2n}$, and $n = L/a$.

The lattice answer is the zeta answer L^2 times a factor that diverges as $a \to 0$. The divergent factor is the exponential of (a constant)×(the length L): the same form as the exponential of a local term $\mu\int \mathrm{d}s$ in the action (a "cosmological constant" on the world line), so it can be cancelled by a counterterm. The zeta function silently removes it. This is the precise sense of the pitfall above.

Worked example 9.24: The harmonic oscillator: $\det(\Delta+\omega^2) = 4\sinh^2(\omega\beta/2)$

A test with a known answer. The partition function of a harmonic oscillator of frequency ω at inverse temperature β is $\operatorname{Tr} e^{-\beta H} = \sum_{n\ge0} e^{-\beta\omega(n+1/2)} = \frac{1}{2\sinh(\beta\omega/2)}$. As a Euclidean path integral over periodic paths of period β (a circle of length $L = \beta$) it is $\big(\det(\Delta+\omega^2)\big)^{-1/2}$. There is no zero mode now. The eigenvalues are $(2\pi n/\beta)^2 + \omega^2$, $n \in \mathbb{Z}$. Compare with the massless case, where the ratio of products converges:

$$\begin{aligned}\frac{\det(\Delta+\omega^2)}{\det{}'\Delta} &\overset{(1)}{=} \omega^2\prod_{n\neq0}\frac{(2\pi n/\beta)^2+\omega^2}{(2\pi n/\beta)^2}\\ &\overset{(2)}{=} \omega^2\left[\prod_{n\ge1}\Big(1+\frac{(\omega\beta/2)^2}{\pi^2n^2}\Big)\right]^2\\ &\overset{(3)}{=} \omega^2\Big(\frac{\sinh(\omega\beta/2)}{\omega\beta/2}\Big)^2.\end{aligned}$$

(1) The $n = 0$ eigenvalue ω^2 has no partner in $\det{}'\Delta$; the others are divided pairwise. (For zeta determinants this multiplicativity holds here because the ratio product converges absolutely.)
(2) n and $-n$ give equal factors, and $\omega^2/(2\pi n/\beta)^2 = (\omega\beta/2)^2/(\pi n)^2$.

(3) Euler's product $\frac{\sinh x}{x} = \prod_{n\geq 1}\left(1+\frac{x^2}{\pi^2 n^2}\right)$.

With $\det'\Delta = \beta^2$ from (9.32), $\det(\Delta+\omega^2) = \omega^2\beta^2 \cdot \frac{4\sinh^2(\omega\beta/2)}{\omega^2\beta^2} = 4\sinh^2(\omega\beta/2)$, and so $\big(\det(\Delta+\omega^2)\big)^{-1/2} = \frac{1}{2\sinh(\omega\beta/2)}$, exactly the oscillator's partition function, *including the zero-point energy* $\frac{1}{2}\omega$ (visible as $e^{-\beta\omega/2}$ at large β). The zeta recipe gets the physically correct normalisation.

Why ζ_P is regular at $s=0$: the heat kernel. The analytic continuation, and the value $\zeta_P(0)$, come from the **heat trace** $K(t) = \operatorname{Tr} e^{-tP} = \sum_{n\geq 0} e^{-t\lambda_n}$ (Chapter 4). Its small-t behaviour is local and universal; on a surface, for the Laplacian,

$$K(t) = \frac{A_g}{4\pi t} + \frac{1}{4\pi}\int_\Sigma \mathrm{d}^2x\,\sqrt{g}\,\frac{R}{6} + O(t) = \frac{A_g}{4\pi t} + \frac{\chi(\Sigma)}{6} + O(t), \tag{9.33}$$

where the second form used Gauss–Bonnet, $\int\sqrt{g}\,R = 4\pi\chi$. The bridge between K and ζ is the integral $\lambda^{-s} = \frac{1}{\Gamma(s)}\int_0^\infty t^{s-1}e^{-t\lambda}\,\mathrm{d}t$, which gives

$$\zeta_P(s) = \frac{1}{\Gamma(s)}\int_0^\infty t^{s-1}\big(K(t)-n_0\big)\,\mathrm{d}t, \tag{9.34}$$

with $n_0 = \dim\operatorname{Ker} P$ (here $n_0 = 1$) subtracted so that only non-zero eigenvalues are counted.

Worked example 9.25: $\zeta_\Delta(0) = \frac{\chi}{6} - 1$ from the heat kernel

Split (9.34) at $t=1$. The part from 1 to ∞ converges for every s (the integrand decays like $e^{-\lambda_1 t}$). In the part from 0 to 1 insert $K(t) - n_0 = \frac{a_{-1}}{t} + (a_0 - n_0) + O(t)$:

$$\int_0^1 t^{s-1}\big(K(t)-n_0\big)\mathrm{d}t \overset{(1)}{=} \frac{a_{-1}}{s-1} + \frac{a_0-n_0}{s} + (\text{regular at } s=0).$$

(1) $\int_0^1 t^{s-2}\mathrm{d}t = \frac{1}{s-1}$ and $\int_0^1 t^{s-1}\mathrm{d}t = \frac{1}{s}$; the $O(t)$ terms give functions regular near $s=0$.

Near $s=0$, $\frac{1}{\Gamma(s)} = s + O(s^2)$. Multiplying, the pole $\frac{1}{s}$ is cancelled, ζ_P is regular at 0, and

$$\zeta_P(0) = a_0 - n_0.$$

For the Laplacian on a surface, $\zeta_\Delta(0) = \frac{\chi}{6} - 1$. Checks: the unit sphere has $K(t) = \sum_\ell (2\ell+1)e^{-t\ell(\ell+1)} = \frac{1}{t} + \frac{1}{3} + O(t)$ (Euler–Maclaurin, or a quick numerical sum at $t = 0.001$), so $\zeta(0) = \frac{1}{3} - 1 = -\frac{2}{3}$. For the circle there is no constant term ($K(t) \approx L/\sqrt{4\pi t}$ up to exponentially small corrections, Figure 9.10), so $\zeta(0) = 0 - 1 = -1$, agreeing with (9.32).

Worked example 9.26: Rescaling an operator: $\det'(cP) = c^{\zeta_P(0)}\det'P$

For a constant $c>0$ the eigenvalues of cP are $c\lambda_n$, so $\zeta_{cP}(s) = c^{-s}\zeta_P(s)$ and

$$\begin{aligned}\det'(cP) &\overset{(1)}{=} \exp\Big[-\frac{\mathrm{d}}{\mathrm{d}s}\big(c^{-s}\zeta_P(s)\big)\Big|_{s=0}\Big]\\ &\overset{(2)}{=} \exp\big[\log c\;\zeta_P(0) - \zeta_P'(0)\big]\\ &= c^{\zeta_P(0)}\,\det'P.\end{aligned}$$

(1) Definition (9.30) applied to cP.

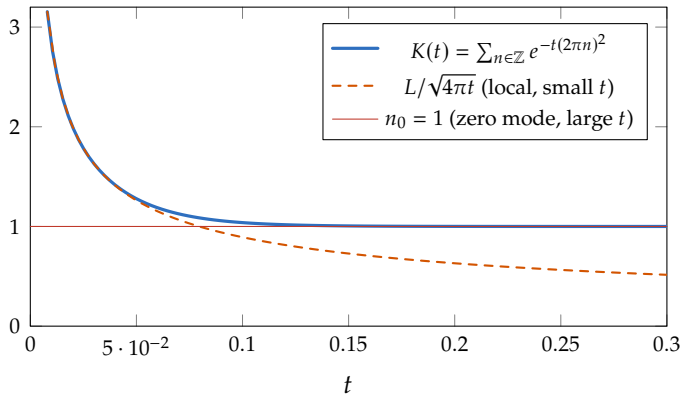

Figure 9.10: The heat trace of the circle of length $L = 1$. For small t it is indistinguishable from the local term $L/\sqrt{4\pi t}$: short times probe only short distances, where the circle looks like a line. For large t only the zero mode survives and $K \to 1$. The zeta function is the Mellin transform (9.34) of $K - 1$; the absence of a t^0 term at small t is why $\zeta_\Delta(0) = 0 - 1 = -1$.

(2) Product rule: $\frac{\mathrm{d}}{\mathrm{d}s} c^{-s} = -\log c\, c^{-s}$.

For a matrix $\zeta_P(0) = n$ and this is $\det(cP) = c^n \det P$. For an operator the "number of eigenvalues" is replaced by $\zeta_P(0)$. Two consequences.
(i) Nash's factor $\frac{1}{2}$. $\det'(\Delta_g/2) = 2^{-\zeta(0)} \det'\Delta_g = 2^{1-\chi/6} \det'\Delta_g$. The factor depends only on the genus, so it is a harmless constant in each Z_p.
(ii) Constant rescalings of the metric. Replace g by λg with $\lambda > 0$ constant. Then $\Delta_{\lambda g} = \lambda^{-1}\Delta_g$ and the area becomes λA_g, so

$$\frac{\det'\Delta_{\lambda g}}{A_{\lambda g}} \overset{(1)}{=} \frac{\lambda^{-\zeta(0)} \det'\Delta_g}{\lambda A_g} \overset{(2)}{=} \lambda^{-\chi/6} \frac{\det'\Delta_g}{A_g}.$$

(1) The scaling law with $c = \lambda^{-1}$.
(2) $-\zeta(0) - 1 = -(\chi/6 - 1) - 1 = -\chi/6$.

Without the area factor we would have had $\lambda^{1-\chi/6}$; the zero mode's A_g removes the "-1" coming from n_0. What remains, $\lambda^{-\chi/6}$, is the first appearance of the conformal anomaly: even a *constant* Weyl rescaling changes the matter determinant, except on the torus ($\chi = 0$). With $\lambda = e^{2\omega}$, the factor $(\det'\Delta/A)^{-d/2}$ in Z_p is multiplied by $e^{d\chi\omega/6}$. We return to this in Section 9.2.11.

Figure 9.11: Two circle spectra used in this subsection (horizontal positions schematic). Top: the massless Laplacian, with a zero mode (red) and doubly degenerate eigenvalues; $\det'\Delta = L^2$. Bottom: adding ω^2 shifts every eigenvalue, lifts the zero mode, and gives $\det(\Delta + \omega^2) = 4\sinh^2(\omega L/2)$, the harmonic oscillator.

Reading Nash (pp. 259–262, (9.1)–(9.7))

- (9.1) is the Nambu–Goto action (9.4); (9.2) the Polyakov action (9.5), whose minus sign we dropped (Euclidean world sheet). "At a critical point the two expressions coincide" is Example 9.5.
- (9.3) is (9.10); "vacuum-to-vacuum amplitude" and "trace" are Figure 9.5; (9.5) is the genus sum (9.11).
- (9.4) is (9.16), with the remarks on signs and on $\partial\partial^*$ in the pitfall after Example 9.12.
- (9.6), the map A, is (9.20); the group law of the semidirect product is (9.21).
- (9.7) is (9.28). "Restriction of $\Delta_g/2$ to its strictly positive subspace" is our det′; the "volume of $\mathbb{R}^d$" and the factor $(1,1)_g$ are Example 9.19; footnote 1 is Section 9.1.10.

Recap: Section

- The Polyakov action $S = \frac{1}{2}\int \sqrt{g}\, g^{ab}\partial_a\phi\cdot\partial_b\phi$ is quadratic in ϕ; eliminating g gives back the Nambu–Goto area.
- It is invariant under $\mathrm{Diff}^+(\Sigma) \ltimes C^\infty_+(\Sigma)$ (Weyl invariance is special to two dimensions) and under translations of $\mathbb{R}^d$.
- Closed world sheets compute the vacuum amplitude (a trace); summing over genus is the string loop expansion.
- A metric on an oriented surface is a complex structure plus a scale; in isothermal coordinates $S = 2\int \partial_z\phi\cdot\partial_{\bar z}\phi\,\mathrm{d}^2x$.
- The ϕ integral is Gaussian: $Z_p = \int \mathcal{D}g\,\left(\det{}'(\Delta_g/2)/A_g\right)^{-d/2}$, the area coming from the zero mode.
- $\det{}'P = e^{-\zeta_P'(0)}$; on the circle $\det{}'\Delta = L^2$; $\zeta_\Delta(0) = \chi/6 - 1$ on a surface; $\det{}'(cP) = c^{\zeta_P(0)}\det{}'P$.

9.2 The space of metrics

After the Gaussian integral, Nash's formula (9.28) still contains an integral over *all* metrics on Σ. How do we integrate over an infinite-dimensional space whose points are mostly related by gauge transformations? The answer is the one familiar from Yang–Mills theory: divide by the volume of the gauge group, pick a slice, and pay a Jacobian. In this section we set up the geometry needed to do that: a metric on the space of metrics, the infinitesimal gauge transformations, and an orthogonal decomposition of the tangent space $T_g\mathrm{Met}(\Sigma)$ into "Weyl", "diffeomorphism" and "moduli" directions. The moduli directions turn out to be the kernel of an elliptic operator, so there are finitely many of them.

9.2.1 What is left to do

Nash's plan (p. 262) has three steps.

1. Split the metrics into conformal classes (metrics related by Weyl rescalings). A conformal class on an oriented surface is the same thing as a complex structure (Section 9.1.6).

2. Identify complex structures related by diffeomorphisms. What is left is the moduli space $\mathcal{M}_p$ of Riemann surfaces of genus p from Chapter 5, which is finite-dimensional.

3. Express Z_p as an integral over $\mathcal{M}_p$, with the right Jacobian.

Watch out: Why $d = 26$?

Step 1 presupposes that the integrand does not depend on the Weyl factor. The classical action does not, but the quantum measure does (Example 9.26): the dependence cancels only when $d = 26$. This is the **conformal anomaly**, treated in Chapter 10 and previewed in Section 9.2.11. Following Nash we set $d = 26$ from now on, so that the Weyl group really is a symmetry of the quantum theory and can be divided out.

Dividing by the gauge group is expressed by Nash's formal definition (9.8):

$$\mathcal{D}g = \frac{\mathcal{D}\mathrm{Met}(\Sigma)}{\mathrm{vol}\big(C^\infty_+(\Sigma)\big)\ \mathrm{vol}\big(\mathrm{Diff}^+(\Sigma)\big)}. \tag{9.35}$$

Here $\mathcal{D}$Met is a (yet to be defined) measure on all of Met(Σ), and the denominator is the volume of a gauge orbit. Such a measure is "supported on the quotient": it integrates over one representative per orbit. Before doing this in infinite dimensions, let us do it once in two dimensions.

9.2.2 Gauge fixing in finite dimensions

Worked example 9.27: Dividing by rotations: polar coordinates as gauge fixing

Let $F(x)$ be a rotation-invariant function on $\mathbb{R}^2$, $F(x) = F(|x|)$. The "gauge group" is SO(2), the "gauge orbits" are the circles $|x| = r$, and a "slice" is the positive x^1-axis, which meets each orbit once (Figure 9.12). The generator of rotations moves the point $(r, 0)$ of the slice with velocity

$$A(\dot\theta) = \dot\theta\,(-x^2, x^1)\big|_{(r,0)} = \dot\theta\,(0, r),$$

a linear map $A : \mathfrak{so}(2) = \mathbb{R} \to T_{(r,0)}\mathbb{R}^2$. Now

$$\begin{aligned}\frac{1}{\mathrm{vol}\,\mathrm{SO}(2)}\int_{\mathbb{R}^2} \mathrm{d}^2x\, F(|x|) &\overset{(1)}{=} \frac{1}{2\pi}\int_0^\infty \mathrm{d}r \int_0^{2\pi} \mathrm{d}\theta\; r\, F(r)\\ &\overset{(2)}{=} \int_0^\infty \mathrm{d}r\, \sqrt{\det(A^\mathsf{T}A)}\, F(r).\end{aligned}$$

(1) Polar coordinates, with $\mathrm{vol}\,\mathrm{SO}(2) = \int_0^{2\pi}\mathrm{d}\theta = 2\pi$.
(2) The θ integral cancels the group volume. The Jacobian r is the length of the velocity $A(1) = (0, r)$, i.e. $\sqrt{A^\mathsf{T}A} = \sqrt{r^2}$.

Three features carry over verbatim to strings. (a) Dividing by the gauge volume leaves an integral over the slice. (b) The slice integral carries a Jacobian, $\sqrt{\det A^\mathsf{T}A}$, where A maps the Lie algebra of the gauge group to the directions along the orbit: this is the **Faddeev–Popov determinant**. (c) At $r = 0$ the orbit is a single point; the rotations do not move it at all ($A = 0$), the Jacobian vanishes, and the action of the group is not free there. For strings the analogue of $r = 0$ is a metric with conformal Killing vectors.

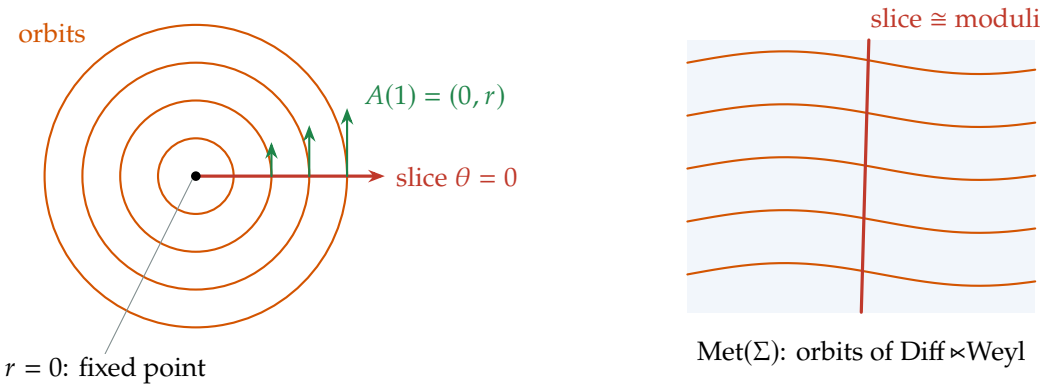

Figure 9.12: Left: gauge fixing for rotations of the plane. The orbits are circles; the slice is a ray; the Jacobian is the speed r with which the group moves the slice point, which vanishes at the fixed point $r = 0$. Right: the same picture for metrics. The orbits of $\mathrm{Diff}^+ \ltimes C^\infty_+$ are infinite-dimensional, the slice is finite-dimensional, and the Jacobian will be $\sqrt{\det{}' P_1^\dagger P_1}$.

9.2.3 Reminder: Teichmüller space and moduli space

The quotient we need was constructed in Chapter 5 (Nash §5.4–5.5, pp. 148–166). Here is what we use from it.

Three groups of diffeomorphisms. $\mathrm{Diff}^+(\Sigma)$ is the group of orientation-preserving diffeomorphisms. Its identity component $\mathrm{Diff}_0(\Sigma)$ consists of the diffeomorphisms that can be continuously deformed to the identity, for example flows $\exp[tV]$ of vector fields. The quotient

$$\Gamma_\Sigma = \mathrm{Diff}^+(\Sigma)/\mathrm{Diff}_0(\Sigma) \tag{9.36}$$

is the **mapping class group**, a discrete group. For the torus $\mathbb{R}^2/\mathbb{Z}^2$ it is $\mathrm{SL}(2,\mathbb{Z})$: the linear map $(x, y) \mapsto (x + y, y)$ (a **Dehn twist**) is a diffeomorphism of the torus, since it maps $\mathbb{Z}^2$ to itself, but it cannot be deformed to the identity, because it changes which loops are which in $\pi_1(T^2) = \mathbb{Z}^2$.

Uniformisation and constant-curvature metrics. Every metric on a closed surface is conformal to a metric of constant Gauss curvature K (Riemann's uniformisation theorem): $+1$ for the sphere, 0 for the torus, -1 for $p \geq 2$. The constant-curvature representative is unique for $p \neq 1$; for the torus we fix the scale by demanding area 1. Nash's (5.42) collects these representatives into

$$\mathrm{Met}_{\mathrm{const}}(\Sigma) = \begin{cases} \{g : K(g) = +1\}, & p = 0, \\ \{g : K(g) = 0,\ \mathrm{Area} = 1\}, & p = 1, \\ \{g : K(g) = -1\}, & p \geq 2. \end{cases} \tag{9.37}$$

So $\mathrm{Met}_{\mathrm{const}}$ is a slice for the Weyl group: every conformal class meets it once. (For $p \geq 2$ the area is then fixed by Gauss–Bonnet: $-\mathrm{Area} = \int K \, \mathrm{d}A = 2\pi\chi$, so $\mathrm{Area} = 4\pi(p-1)$.)

The quotients. The **Teichmüller space** and the **moduli space** are

$$\mathcal{T}_p = \frac{\mathrm{Met}_{\mathrm{const}}(\Sigma)}{\mathrm{Diff}_0(\Sigma)}, \qquad \mathcal{M}_p = \frac{\mathrm{Met}_{\mathrm{const}}(\Sigma)}{\mathrm{Diff}^+(\Sigma)} = \frac{\mathcal{T}_p}{\Gamma_\Sigma}. \tag{9.38}$$

$\mathcal{T}_p$ is a smooth manifold (a ball); $\mathcal{M}_p$ is an orbifold, because Γ_Σ has fixed points on $\mathcal{T}_p$. Their real dimensions are

$$\dim_{\mathbb{R}} \mathcal{M}_p = \begin{cases} 0, & p = 0, \\ 2, & p = 1, \\ 6p - 6, & p \geq 2, \end{cases} \tag{9.39}$$

(complex dimensions $0, 1, 3p-3$). For the torus, $\mathcal{T}_1$ is the upper half-plane $\{\tau : \operatorname{Im}\tau > 0\}$ and $\mathcal{M}_1 = \mathcal{T}_1/\mathrm{SL}(2,\mathbb{Z})$. We rederive (9.39) from the operator P_1 in Section 9.2.9.

$$\underset{\text{all metrics}}{\operatorname{Met}(\Sigma)} \xrightarrow{/\,C^\infty_+} \underset{\text{complex structures}}{\operatorname{Conf}(\Sigma) \cong \operatorname{Met}_{\text{const}}(\Sigma)} \xrightarrow{/\,\mathrm{Diff}_0} \underset{\text{Teichmüller, a ball}}{\mathcal{T}_p} \xrightarrow{/\,\Gamma_\Sigma} \underset{\text{moduli, an orbifold}}{\mathcal{M}_p}$$

$$\infty \text{ (3 fns)} \qquad \infty \text{ (2 fns)} \qquad 6p-6 \qquad 6p-6$$

Figure 9.13: The tower of quotients (Nash §5.4–5.5). Each arrow divides by a group; the bottom row is the real dimension ("3 fns" means three functions' worth). Dividing by the two-function-worth group Diff_0 takes an infinite-dimensional space to a finite-dimensional one: the moduli are what the counting "$3-1-2=0$" leaves behind globally.

Watch out: Why Nash switches from Met to $\mathrm{Met}_{\text{const}}$ and from Diff^+ to Diff_0

Two technical problems are hidden in (9.35). First, Diff^+ does not act freely: the discrete part Γ_Σ has fixed points, so one first divides by the connected group Diff_0 and deals with Γ_Σ at the end (it produces the factor $1/|\Gamma_\Sigma|$ in (9.35)). Second, for $p = 0, 1$ even Diff_0 does not act freely on conformal classes: there are diffeomorphisms (flows of conformal Killing vectors, Section 9.2.5) that map a metric to a conformally equivalent one. This is the $r = 0$ problem of Example 9.27, and it is why Nash quotients $\mathrm{Met}_{\text{const}}$ rather than Met directly.

9.2.4 A Riemannian metric on the space of metrics

To define a measure $\mathcal{D}\mathrm{Met}$ we copy the finite-dimensional recipe. On a Riemannian manifold with metric G, coordinates x^i and coordinate basis $e_i = \partial/\partial x^i$, the invariant volume element is

$$\mathrm{dvol} = \sqrt{\det\langle e_i, e_j\rangle_G}\, \mathrm{d}^n x = \sqrt{G}\, \mathrm{d}^n x. \tag{9.40}$$

For the unit sphere in coordinates (θ, φ), $\langle e_\theta, e_\theta\rangle = 1$, $\langle e_\varphi, e_\varphi\rangle = \sin^2\theta$, $\langle e_\theta, e_\varphi\rangle = 0$, so $\mathrm{dvol} = \sin\theta\, \mathrm{d}\theta\, \mathrm{d}\varphi$. The lesson: *a metric gives a measure*. So we look for a metric on $\mathrm{Met}(\Sigma)$.

A tangent vector at g is a symmetric tensor field (9.19). Nash writes tangent vectors in "coordinates" g^I on Met, where the index I runs over the pairs (ab) *and* the points x of Σ (his (9.9)):

$$X = X^I \frac{\partial}{\partial g^I} = X_{ab}(x) \frac{\partial}{\partial g_{ab}(x)}, \qquad Y = Y_{ab}(x) \frac{\partial}{\partial g_{ab}(x)},$$

with a sum over $a \leq b$ and an "integral" over x understood.

Working definition 9.6 (The natural metric on $\mathrm{Met}(\Sigma)$)

For $X, Y \in T_g\mathrm{Met}(\Sigma)$ [symmetric tensor fields $X_{ab}(x)$, the small changes $g \to g + \epsilon X$ of

the metric] (Nash's (9.10)–(9.11)),

$$\langle X, Y\rangle_{\mathrm{met}} = \int_\Sigma \mathrm{d}^2x\,\sqrt{g}\,\langle X, Y\rangle_{g(x)},$$
$$\langle X, Y\rangle_{g(x)} = g^{ac}(x)\,g^{bd}(x)\,X_{ab}(x)\,Y_{cd}(x) = \mathrm{tr}\big(g^{-1}Xg^{-1}Y\big). \tag{9.41}$$

How to use it: at each point, raise both indices of X with g, contract with Y (a matrix trace), and integrate with the Riemannian area element of g.

Worked example 9.28: The pointwise metric in components

At a point where $g = \mathbf{1}$, write $X = \begin{pmatrix} x_1 & x_2 \\ x_2 & x_3 \end{pmatrix}$. Then

$$\langle X, X\rangle_{\mathbf{1}} \overset{(1)}{=} \mathrm{tr}(X^2)$$
$$\overset{(2)}{=} x_1^2 + 2x_2^2 + x_3^2.$$

(1) $g^{-1} = \mathbf{1}$.
(2) $\mathrm{tr}(X^2) = \sum_{a,b} X_{ab}X_{ba}$; the off-diagonal entry appears twice.

Split X into its trace and traceless parts, $X = \frac{x_1+x_3}{2}\mathbf{1} + \begin{pmatrix} u & x_2 \\ x_2 & -u \end{pmatrix}$ with $u = \frac{x_1-x_3}{2}$. The two parts are orthogonal, $\mathrm{tr}\big(\mathbf{1}\cdot\left(\begin{smallmatrix} u & x_2 \\ x_2 & -u \end{smallmatrix}\right)\big) = 0$, and $\langle X, X\rangle = \frac{(x_1+x_3)^2}{2} + 2(u^2 + x_2^2)$. At a general point where $g = \mathrm{diag}(\lambda_1, \lambda_2)$, $\langle X, X\rangle_g = \frac{x_1^2}{\lambda_1^2} + \frac{2x_2^2}{\lambda_1\lambda_2} + \frac{x_3^2}{\lambda_2^2}$: a change of metric counts as large when it is large *relative to* g.

Watch out: Other choices are possible

The most general ultralocal (no derivatives) metric on Met that is invariant under diffeomorphisms is the **DeWitt metric** $\int \sqrt{g}\,\big(\mathrm{tr}(g^{-1}Xg^{-1}Y) + u\ \mathrm{tr}(g^{-1}X)\,\mathrm{tr}(g^{-1}Y)\big)$, with a constant $u > -\frac{1}{2}$. Nash takes $u = 0$. Since we will divide out the trace directions anyway (they are the Weyl directions), the choice of u only changes the normalisation of the Weyl-group volume, not the final integrand.

Worked example 9.29: Diffeomorphisms are isometries of Met

A diffeomorphism α acts on Met by $g \mapsto \alpha^*g$, and on tangent vectors by $X \mapsto \alpha^*X$ (a tangent vector is a symmetric tensor, and pulls back the same way). With J the Jacobian and $y = \alpha(x)$, in matrix notation $\alpha^*g = J^{\mathsf{T}}gJ$ and $\alpha^*X = J^{\mathsf{T}}XJ$ (evaluated at y). Then

$$\langle \alpha^*X, \alpha^*Y\rangle_{\alpha^*g} \overset{(1)}{=} \int \mathrm{d}^2x\ |\det J|\,\sqrt{g}\ \mathrm{tr}\big(J^{-1}g^{-1}J^{-\mathsf{T}}J^{\mathsf{T}}XJ\,J^{-1}g^{-1}J^{-\mathsf{T}}J^{\mathsf{T}}YJ\big)$$
$$\overset{(2)}{=} \int \mathrm{d}^2x\ |\det J|\,\sqrt{g}\ \mathrm{tr}\big(J^{-1}g^{-1}Xg^{-1}YJ\big)$$
$$\overset{(3)}{=} \int \mathrm{d}^2y\,\sqrt{g}\ \mathrm{tr}\big(g^{-1}Xg^{-1}Y\big) = \langle X, Y\rangle_g.$$

(1) Insert $\sqrt{\det(J^{\mathsf{T}}gJ)} = |\det J|\,\sqrt{g}$ and $(J^{\mathsf{T}}gJ)^{-1} = J^{-1}g^{-1}J^{-\mathsf{T}}$.
(2) $J^{-\mathsf{T}}J^{\mathsf{T}} = \mathbf{1}$ and $JJ^{-1} = \mathbf{1}$ inside the product.
(3) Cyclicity of the trace removes $J^{-1}\cdots J$; then change variables $\mathrm{d}^2y = |\det J|\,\mathrm{d}^2x$.

This is the property Nash uses in §3 (his footnote 3).
Weyl rescalings, by contrast, are *not* isometries: under $g \mapsto fg$, $X \mapsto fX$, the integrand picks up $f \cdot f^{-2} \cdot f^2 = f$ (from $\sqrt{g}$, the two inverse metrics, and X, Y). So the measure on Met "knows" about the conformal factor, one more source of the conformal anomaly.

A toy model: one point of Σ. To see the geometry of (9.41), forget the integral over Σ and look at the three-dimensional space Pos(2) of positive symmetric 2×2 matrices with the metric $ds^2 = \operatorname{tr}(g^{-1}dg\, g^{-1}dg)$. Every g can be written uniquely as a scale times a unimodular matrix, $g = \lambda\hat{g}$ with $\lambda = \sqrt{\det g}$ and $\det\hat{g} = 1$. This is the pointwise version of "conformal factor times conformal class" (Figure 9.14).

Worked example 9.30: $\mathrm{Pos}(2) = \mathbb{R}_+ \times$ (**hyperbolic plane**)

First, the scale separates:

$$\begin{aligned}\operatorname{tr}\big(g^{-1}dg\, g^{-1}dg\big) &\overset{(1)}{=} \operatorname{tr}\Big[\Big(\frac{d\lambda}{\lambda}\mathbf{1} + \hat{g}^{-1}d\hat{g}\Big)^2\Big]\\ &\overset{(2)}{=} 2\Big(\frac{d\lambda}{\lambda}\Big)^2 + 2\frac{d\lambda}{\lambda}\operatorname{tr}\big(\hat{g}^{-1}d\hat{g}\big) + \operatorname{tr}\big(\hat{g}^{-1}d\hat{g}\,\hat{g}^{-1}d\hat{g}\big)\\ &\overset{(3)}{=} 2\Big(\frac{d\lambda}{\lambda}\Big)^2 + \operatorname{tr}\big(\hat{g}^{-1}d\hat{g}\,\hat{g}^{-1}d\hat{g}\big).\end{aligned}$$

(1) $g^{-1}dg = \lambda^{-1}\hat{g}^{-1}(d\lambda\,\hat{g} + \lambda\, d\hat{g})$.
(2) Expand the square; $\operatorname{tr}\mathbf{1} = 2$.
(3) $\operatorname{tr}(\hat{g}^{-1}d\hat{g}) = d\log\det\hat{g} = 0$ (Jacobi's formula, $\det\hat{g} = 1$).

So the scale direction is orthogonal to the unimodular directions. Next, parametrise the unimodular matrices by a point $\tau = \tau_1 + i\tau_2$ of the upper half-plane:

$$\hat{g}_\tau = \frac{1}{\tau_2}\begin{pmatrix}1 & \tau_1\\ \tau_1 & |\tau|^2\end{pmatrix}, \qquad \det\hat{g}_\tau = \frac{|\tau|^2 - \tau_1^2}{\tau_2^2} = 1. \tag{9.42}$$

This is the matrix of the quadratic form $\frac{1}{\tau_2}|dx + \tau\, dy|^2$. A direct computation (differentiate the entries, multiply the 2×2 matrices, take traces) gives

$$\operatorname{tr}\big(\hat{g}^{-1}\partial_{\tau_i}\hat{g}\;\hat{g}^{-1}\partial_{\tau_j}\hat{g}\big) = \frac{2\,\delta_{ij}}{\tau_2^2}, \qquad \text{i.e.} \qquad \operatorname{tr}\big(\hat{g}^{-1}d\hat{g}\,\hat{g}^{-1}d\hat{g}\big) = \frac{2(d\tau_1^2 + d\tau_2^2)}{\tau_2^2}. \tag{9.43}$$

For instance, at $\tau = i$ we have $\hat{g} = \mathbf{1}$, $\partial_{\tau_1}\hat{g} = \left(\begin{smallmatrix}0&1\\1&0\end{smallmatrix}\right)$, $\partial_{\tau_2}\hat{g} = \left(\begin{smallmatrix}-1&0\\0&1\end{smallmatrix}\right)$, and both have $\operatorname{tr}(X^2) = 2$ while $\operatorname{tr}(XY) = 0$, as claimed. The unimodular part is the **hyperbolic plane** with (twice) its Poincaré metric. The same metric will reappear as the Weil–Petersson metric on the moduli space of the torus (Example 9.42).

A metric on vector fields. We will also need to measure the size of an infinitesimal diffeomorphism, that is, of a vector field. The space $\mathrm{vect}(\Sigma)$ of smooth vector fields gets the L^2 metric (Nash's (9.12))

$$\langle V, W\rangle_{\mathrm{vect}} = \int_\Sigma d^2x\,\sqrt{g}\,\langle V(x), W(x)\rangle_{g(x)} = \int_\Sigma d^2x\,\sqrt{g}\; g_{ab}V^aW^b. \tag{9.44}$$

It depends on g too; we suppress this in the notation.

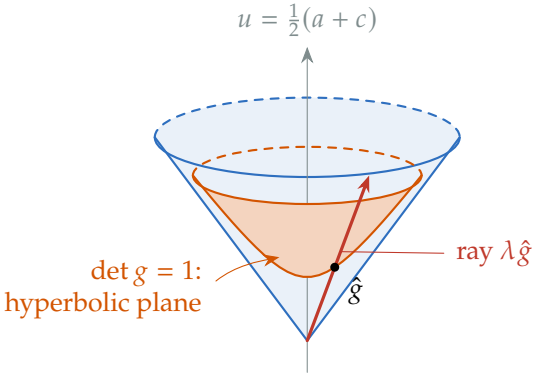

Figure 9.14: The space of positive 2×2 matrices $\begin{pmatrix} a & b \\ b & c \end{pmatrix}$ is an open cone (the horizontal directions are $\frac{1}{2}(a-c)$ and b). The rays through the origin (red) are the Weyl orbits, one point at a time. The surface $\det g = 1$ (orange) meets every ray once: it is the space of conformal structures at a point, and with the metric (9.41) it is a hyperbolic plane, orthogonal to the rays.

9.2.5 Infinitesimal diffeomorphisms: the Lie derivative of the metric

The Lie algebra of $\mathrm{Diff}_0(\Sigma)$ is $\mathrm{vect}(\Sigma)$. A vector field V generates the one-parameter family $\alpha_t = \exp[tV]$ of diffeomorphisms obtained by flowing along V for time t; for small t, $\alpha_t(x)^a = x^a + tV^a(x) + O(t^2)$. The metric moves along the orbit as $\alpha_t^* g = g + t\,\mathcal{L}_V g + O(t^2)$, which defines the **Lie derivative** $\mathcal{L}_V g \in T_g\mathrm{Met}$ (Nash's (9.13)). So $\mathcal{L}_V g$ is the tangent vector to the Diff_0 orbit through g in the direction V.

Worked example 9.31: Computing $\mathcal{L}_V g$ from the pull-back

Use (9.9) with α_t, whose Jacobian is $\partial_a \alpha_t^c = \delta_a^c + t\,\partial_a V^c$:

$$\begin{aligned}(\alpha_t^* g)_{ab}(x) &\overset{(1)}{=} (\delta_a^c + t\,\partial_a V^c)(\delta_b^d + t\,\partial_b V^d)\, g_{cd}(x+tV) \\ &\overset{(2)}{=} g_{ab} + t\big(V^c \partial_c g_{ab} + g_{cb}\,\partial_a V^c + g_{ac}\,\partial_b V^c\big) + O(t^2).\end{aligned}$$

(1) The pull-back formula with $\alpha_t(x) = x + tV + O(t^2)$.
(2) Taylor-expand $g_{cd}(x+tV) = g_{cd} + tV^e \partial_e g_{cd}$ and keep terms of order t.

Hence

$$(\mathcal{L}_V g)_{ab} = V^c \partial_c g_{ab} + g_{cb}\,\partial_a V^c + g_{ac}\,\partial_b V^c. \tag{9.45}$$

Nash's footnote 2 writes this covariantly. With the Levi-Civita connection, $\nabla_a V_b = \partial_a V_b - \Gamma^c_{ab} V_c$, $V_b = g_{bc}V^c$ and $\Gamma^c_{ab} g_{cd} = \frac{1}{2}(\partial_a g_{db} + \partial_b g_{da} - \partial_d g_{ab})$:

$$\begin{aligned}\nabla_a V_b + \nabla_b V_a &\overset{(1)}{=} \partial_a(g_{bc}V^c) + \partial_b(g_{ac}V^c) - 2\Gamma^d_{ab} g_{dc} V^c \\ &\overset{(2)}{=} g_{bc}\partial_a V^c + g_{ac}\partial_b V^c + V^c(\partial_a g_{bc} + \partial_b g_{ac}) - V^c(\partial_a g_{cb} + \partial_b g_{ca} - \partial_c g_{ab}) \\ &\overset{(3)}{=} g_{bc}\partial_a V^c + g_{ac}\partial_b V^c + V^c \partial_c g_{ab} = (\mathcal{L}_V g)_{ab}.\end{aligned}$$

(1) Definition of ∇; the Christoffel symbol is symmetric in a, b, so the two connection terms are equal.
(2) Product rule in the first two terms; the Christoffel formula in the last.
(3) The derivatives of g cancel in pairs except $\partial_c g_{ab}$; compare (9.45).

So $\mathcal{L}_V g_{ab} = \nabla_a V_b + \nabla_b V_a$, and its trace is $g^{ab}\mathcal{L}_V g_{ab} = 2\nabla_a V^a = 2\,\nabla \cdot V$.

Working definition 9.7 (Killing and conformal Killing vectors)

A vector field V is a **Killing vector** of g if $\mathcal{L}_V g = 0$ [$\mathcal{L}_V g$ is the first-order change of g when every point is moved a small distance along V]: its flow [the map that moves every point for a time t along V] is a symmetry (isometry) of g. It is a **conformal Killing vector** (CKV) if $\mathcal{L}_V g = f\, g$ for some function f (necessarily $f = \nabla \cdot V$): its flow changes g only by a Weyl rescaling [multiplication by a positive function, $g \to e^{2\omega} g$]. *Test:* compute (9.45) and check whether the traceless part $\mathcal{L}_V g - \frac{1}{2}\operatorname{tr}(\mathcal{L}_V g)\, g$ vanishes.

Worked example 9.32: Killing and conformal Killing vectors of the flat plane

For $g = \delta$, (9.45) is just $(\mathcal{L}_V g)_{ab} = \partial_a V_b + \partial_b V_a$.

- Translations $V = \partial_x$: $\mathcal{L}_V \delta = 0$. Killing.
- Rotation $V = -y\,\partial_x + x\,\partial_y$: $\partial_x V_x = 0$, $\partial_y V_y = 0$, $\partial_x V_y + \partial_y V_x = 1 - 1 = 0$. Killing.
- Dilation $V = x\,\partial_x + y\,\partial_y$: $\mathcal{L}_V \delta = 2\delta$. Conformal Killing with $f = 2 = \nabla \cdot V$, not Killing.
- Shear $V = y\,\partial_x$: $\mathcal{L}_V \delta = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, which is traceless and non-zero. Not conformal Killing.

The complex coordinate makes the pattern obvious. Write a vector field as $V = V^z \partial_z + V^{\bar z} \partial_{\bar z}$ with $V^{\bar z} = \overline{V^z}$ (for real $V = V^x \partial_x + V^y \partial_y$, $V^z = V^x + i V^y$), and a conformal metric as $g = \rho\, \mathrm{d}z\, \mathrm{d}\bar z$ (symmetric product, so $\rho\, \mathrm{d}z\, \mathrm{d}\bar z = \rho(\mathrm{d}x^2 + \mathrm{d}y^2)$).

Worked example 9.33: $\mathcal{L}_V g$ in complex coordinates

The Lie derivative obeys the Leibniz rule and commutes with d, and $\mathcal{L}_V \mathrm{d}z = \mathrm{d}(V^z)$:

$$\begin{aligned} \mathcal{L}_V\big(\rho\, \mathrm{d}z\, \mathrm{d}\bar z\big) &\overset{(1)}{=} V(\rho)\, \mathrm{d}z\, \mathrm{d}\bar z + \rho\, \mathrm{d}V^z\, \mathrm{d}\bar z + \rho\, \mathrm{d}z\, \mathrm{d}V^{\bar z} \\ &\overset{(2)}{=} \big(V(\rho) + \rho\, \partial_z V^z + \rho\, \partial_{\bar z} V^{\bar z}\big) \mathrm{d}z\, \mathrm{d}\bar z + \rho\, \partial_{\bar z} V^z\, \mathrm{d}\bar z^2 + \rho\, \partial_z V^{\bar z}\, \mathrm{d}z^2. \end{aligned}$$

(1) Leibniz rule; $\mathcal{L}_V \rho = V(\rho)$ for a function, and $\mathcal{L}_V \mathrm{d}z = \mathrm{d}\, \iota_V \mathrm{d}z = \mathrm{d}V^z$ (Cartan's formula, Chapter T1).
(2) Expand $\mathrm{d}V^z = \partial_z V^z\, \mathrm{d}z + \partial_{\bar z} V^z\, \mathrm{d}\bar z$ and similarly for $V^{\bar z}$, then collect terms.

The $\mathrm{d}z\, \mathrm{d}\bar z$ term is a multiple of g: the Weyl part. The $\mathrm{d}z^2$ and $\mathrm{d}\bar z^2$ terms are the traceless part. So

$$V \text{ is a conformal Killing vector} \iff \partial_{\bar z} V^z = 0 \iff V^z \text{ is holomorphic.}$$

In the flat case: ∂_x has $V^z = 1$, the rotation has $V^z = iz$, the dilation $V^z = z$ (all holomorphic), and the shear $V^z = y = \frac{z - \bar z}{2i}$ (not holomorphic).

Worked example 9.34: CKVs on the sphere, the torus, and higher genus

Whether V^z is holomorphic does not depend on the conformal factor ρ, so we may use any conformal coordinate.
Sphere. Cover $S^2 = \mathbb{C} \cup \{\infty\}$ by z and $w = 1/z$. A holomorphic $V^z(z)$ on $\mathbb{C}$ must also be holomorphic at ∞ in the coordinate w:

$$V^w \overset{(1)}{=} \frac{\mathrm{d}w}{\mathrm{d}z}\, V^z = -\frac{1}{z^2} V^z(z)$$

$$\overset{(2)}{=} -w^2\, V^z(1/w).$$

(1) Components of a vector transform with the Jacobian.
(2) Substitute $z = 1/w$.

If $V^z = \sum_k a_k z^k$, then $V^w = -\sum_k a_k w^{2-k}$, which is regular at $w = 0$ iff $a_k = 0$ for $k > 2$. So $V^z = a_0 + a_1 z + a_2 z^2$: *three complex, six real* CKVs. They generate the Möbius transformations $z \mapsto \frac{az+b}{cz+d}$, the group PSL(2, $\mathbb{C}$) of Nash's footnote (p. 165). Three of the six real ones are Killing vectors of the round metric (the rotations SO(3): $V^z = iz$ and $V^z = a - \bar{a}z^2$).

Torus. A holomorphic function on a compact surface is constant (Liouville), so V^z = const: *one complex, two real* CKVs, the translations of $\mathbb{C}/\Lambda$. They are Killing vectors of the flat metric.

Genus $p \geq 2$. There are none. We prove this in Example 9.39 with a curvature argument; in the holomorphic language, $V^z\partial_z$ is a holomorphic section of the tangent bundle K_Σ^{-1}, whose degree $2 - 2p$ is negative, and a line bundle of negative degree has no holomorphic sections (Chapter 5).

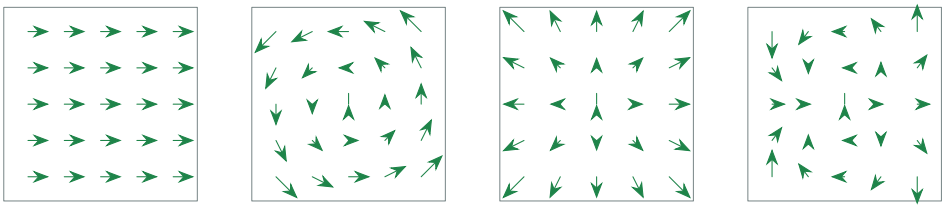

Figure 9.15: The four kinds of conformal Killing vector of the Riemann sphere, drawn in the plane $z = x + iy$ (arrows show the real vector field with $V^x + iV^y = V^z$). Real and imaginary multiples of these give all six. Translations and rotations are Killing for the flat metric; dilations and special conformal transformations only rescale it. On the round sphere the rotations iz and $1 - z^2$, $i(1 + z^2)$ are Killing. None of these fields exists on a surface of genus ≥ 2.

Physical picture: Why CKVs are a problem

A conformal Killing vector is a gauge transformation (a diffeomorphism) that acts on the metric *like another gauge transformation* (a Weyl rescaling). So the combined gauge group $\mathrm{Diff}_0 \ltimes C^\infty_+$ does not act freely: a one-parameter subgroup (the CKV flow combined with the compensating Weyl rescaling) leaves g fixed. In the Faddeev–Popov Jacobian this shows up as a zero mode, exactly like $r = 0$ in Example 9.27.

9.2.6 Splitting off the Weyl directions

We now have two kinds of gauge motion through a point $g \in \mathrm{Met}(\Sigma)$. A Weyl rescaling $g \mapsto e^{2\omega} g$ moves g in the direction $2\omega\, g$. A diffeomorphism generated by V moves g in the direction $\mathcal{L}_V g$. Both directions live in the same space $T_g\mathrm{Met}(\Sigma)$ of symmetric tensors, and we want to know how they sit relative to each other and what is left over. The tool is the metric $\langle\ ,\ \rangle_{\mathrm{met}}$: with a metric we can talk about orthogonal complements.

Working definition 9.8 (The conformal subspace C_g)

$C_g \subset T_g\mathrm{Met}(\Sigma)$ [the small changes $g \to g + \epsilon X$ of the metric, X a symmetric tensor field] is the set of tangent vectors of the form $\alpha\, g$, with α an arbitrary smooth function on Σ. It is the tangent space at g to the Weyl orbit $\{f g : f \in C^\infty_+(\Sigma)\}$ [f runs over the smooth functions with $f > 0$ everywhere]: differentiating $f_t = e^{t\alpha}$ at $t = 0$ gives $\frac{\mathrm{d}}{\mathrm{d}t}(f_t g) = \alpha g$. *Test:* a tangent vector X is in C_g iff at every point the matrix $g^{-1}X$ is a multiple of the identity.

The metric gives an orthogonal decomposition (Nash's (9.14))

$$T_g\mathrm{Met}(\Sigma) = C_g \oplus C_g^{\perp}. \tag{9.46}$$

What is $C_g^{\perp}$? A vector h is orthogonal to all of C_g iff $\langle \alpha g, h\rangle_{\mathrm{met}} = 0$ for every function α. We compute this inner product exactly as Nash does in (9.16):

$$\begin{aligned}
\langle \alpha g, h\rangle_{\mathrm{met}} &\overset{(1)}{=} \int_\Sigma \mathrm{d}^2x\, \sqrt{g}\; g^{a_1a_2} g^{b_1b_2}\, \alpha\, g_{a_1b_1}\, h_{a_2b_2} \\
&\overset{(2)}{=} \int_\Sigma \mathrm{d}^2x\, \sqrt{g}\; \alpha\; \delta^{a_2}_{b_1}\, g^{b_1b_2}\, h_{a_2b_2} \\
&\overset{(3)}{=} \int_\Sigma \mathrm{d}^2x\, \sqrt{g}\; \alpha\; g^{a_2b_2} h_{a_2b_2} \\
&\overset{(4)}{=} \int_\Sigma \mathrm{d}^2x\, \sqrt{g}\; \alpha\; \mathrm{tr}\, h.
\end{aligned} \tag{9.47}$$

(1) Definition (9.41) with $X = \alpha g$ and $Y = h$, written with Nash's index names.
(2) $g^{a_1a_2} g_{a_1b_1} = \delta^{a_2}_{b_1}$: the inverse metric undoes the metric.
(3) Sum over b_1 with the Kronecker delta.
(4) Define $\mathrm{tr}\, h = g^{ab} h_{ab}$, the trace of the matrix $g^{-1}h$.

Since α is arbitrary, (9.47) vanishes for all α iff $\mathrm{tr}\, h = 0$ at every point. (Take $\alpha = \mathrm{tr}\, h$: then the integral is $\int \sqrt{g}\,(\mathrm{tr}\, h)^2$, which is zero only if $\mathrm{tr}\, h \equiv 0$.) So

$$C_g^{\perp} = \{h \in T_g\mathrm{Met} :\ \mathrm{tr}\, h = g^{ab} h_{ab} = 0\} = \text{traceless symmetric tensors}. \tag{9.48}$$

In two dimensions a traceless symmetric 2×2 matrix has two independent entries. So, pointwise, C_g is one-dimensional and $C_g^{\perp}$ is two-dimensional: $1 + 2 = 3$ components of a metric. This is the infinitesimal version of the cone picture Figure 9.14: the ray direction is C_g, the hyperbolic-plane directions are $C_g^{\perp}$.

Splitting a Lie derivative. Apply this to the diffeomorphism direction $\mathcal{L}_V g$. Every symmetric tensor splits uniquely as "trace part plus traceless part":

$$\mathcal{L}_V g = \underbrace{\frac{\mathrm{tr}(\mathcal{L}_V g)}{2}\, g}_{\alpha g \in C_g} + \underbrace{\left\{\mathcal{L}_V g - \frac{\mathrm{tr}(\mathcal{L}_V g)}{2}\, g\right\}}_{h \in C_g^{\perp}} \tag{9.49}$$

(Nash's (9.17)). The first piece is in C_g by definition. The second is traceless because $\mathrm{tr}\, g = g^{ab} g_{ab} = \delta^a_a = 2$, so $\mathrm{tr}\, h = \mathrm{tr}(\mathcal{L}_V g) - \frac{\mathrm{tr}(\mathcal{L}_V g)}{2} \cdot 2 = 0$. This is Nash's (9.18):

$$h = \mathcal{L}_V g - \tfrac{1}{2}\,\mathrm{tr}(\mathcal{L}_V g)\, g, \qquad \alpha = \tfrac{1}{2}\,\mathrm{tr}(\mathcal{L}_V g). \tag{9.50}$$

With the covariant formula of Example 9.31, $\mathcal{L}_V g_{ab} = \nabla_a V_b + \nabla_b V_a$ and $\mathrm{tr}\, \mathcal{L}_V g = 2\nabla_c V^c$, so (Nash's footnote 2)

$$h_{ab} = \nabla_a V_b + \nabla_b V_a - (\nabla_c V^c)\, g_{ab}, \qquad \alpha = \nabla_c V^c. \tag{9.51}$$

Worked example 9.35: Splitting three flat-space vector fields

Take $g = \delta$ on $\mathbb{R}^2$ (or on a flat torus). Then $\nabla = \partial$ and (9.51) reads, in matrix form with $V = (u, v)$,

$$\alpha = u_x + v_y, \qquad h = \begin{pmatrix} u_x - v_y & u_y + v_x \\ u_y + v_x & -(u_x - v_y) \end{pmatrix}. \tag{9.52}$$

- Dilation $V = (x, y)$: $\alpha = 2$, $h = 0$. The flow only rescales the metric.
- Rotation $V = (-y, x)$: $\alpha = 0$, $h = 0$. The flow does not change the metric at all.
- Shear $V = (y, 0)$: $\alpha = 0$, $h = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. The flow changes the *shape* of the metric, not its size.

The shear is the interesting one: it produces a genuinely non-conformal change. Whether such a change is "gauge" (produced by some diffeomorphism) or "physical" (a change of modulus) is exactly the question we answer next.

9.2.7 The operator P_1

The traceless part h of $\mathcal{L}_V g$ depends linearly on V, and it involves one derivative of V. So it is a first-order linear differential operator from vector fields to traceless symmetric tensors.

Working definition 9.9 (The operator $A_g = P_1$)

(Nash's (9.19).)

$$P_1 = A_g : \ \mathrm{vect}(\Sigma) \longrightarrow C_g^{\perp}, \qquad (P_1 V)_{ab} = \nabla_a V_b + \nabla_b V_a - (\nabla_c V^c)\, g_{ab}. \tag{9.53}$$

[vect(Σ) is the smooth vector fields V on Σ. $C_g^{\perp}$ is the traceless symmetric tensors, orthogonal to every αg] It measures how much the flow of V changes the *conformal class* of g [g up to multiplication by a positive function]. *How to compute it:* take $\mathcal{L}_V g$ from (9.45) and throw away its trace. Physicists call it P_1; Nash calls it A_g to stress that it depends on g. Its kernel [the V with $P_1 V = 0$] is the space of conformal Killing vectors.

P_1 is the Cauchy–Riemann operator. In flat coordinates, (9.52) says that $P_1 V = 0$ iff

$$u_x = v_y, \qquad u_y = -v_x, \tag{9.54}$$

the Cauchy–Riemann equations for $u + iv$. In the complex coordinate of Example 9.33, with $g = \rho\, \mathrm{d}z\, \mathrm{d}\bar{z}$ (so $g_{z\bar{z}} = \rho/2$), a traceless symmetric tensor has only the components h_{zz} and $h_{\bar{z}\bar{z}} = \overline{h_{zz}}$, because $h_{z\bar{z}} \propto \mathrm{tr}\, h = 0$. Reading off the coefficients of $\mathrm{d}z^2$ and $\mathrm{d}\bar{z}^2$ in Example 9.33,

$$(P_1 V)_{\bar{z}\bar{z}} = \rho\, \partial_{\bar{z}} V^z, \qquad (P_1 V)_{zz} = \rho\, \partial_z V^{\bar{z}} = \overline{(P_1 V)_{\bar{z}\bar{z}}}. \tag{9.55}$$

So, up to the harmless factor ρ, P_1 *is* the operator $\partial_{\bar{z}}$ acting on the component V^z. We can check that the two descriptions agree in the flat case $\rho = 1$:

$$\begin{aligned} (P_1 V)_{\bar{z}\bar{z}} &\overset{(1)}{=} \tfrac{1}{2}(\partial_x + i\partial_y)(u + iv) \\ &\overset{(2)}{=} \tfrac{1}{2}\big[(u_x - v_y) + i(u_y + v_x)\big] \\ &\overset{(3)}{=} \tfrac{1}{2}\big(h_{11} + i h_{12}\big) \overset{(4)}{=} h(\partial_{\bar{z}}, \partial_{\bar{z}}). \end{aligned}$$

(1) $\partial_{\bar{z}} = \frac{1}{2}(\partial_x + i\partial_y)$ and $V^z = u + iv$.

(2) Multiply out and collect real and imaginary parts.
(3) Compare with (9.52).
(4) $h_{\bar z\bar z} = h(\partial_{\bar z}, \partial_{\bar z}) = \frac{1}{4}(h_{11} + 2ih_{12} - h_{22})$, and $h_{22} = -h_{11}$.

P_1 is elliptic. The principal symbol of a first-order operator is obtained by replacing each derivative ∂_a by $i\xi_a$ and keeping the top-order terms (Chapter 2). For (9.52), as a map from (u, v) to the two independent entries (h_{11}, h_{12}) of a traceless tensor,

$$\sigma_{P_1}(\xi) = i\begin{pmatrix} \xi_1 & -\xi_2 \\ \xi_2 & \xi_1 \end{pmatrix}, \qquad \det \sigma_{P_1}(\xi) = i^2(\xi_1^2 + \xi_2^2) = -\,|\xi|^2\,. \tag{9.56}$$

The matrix is i times the matrix of multiplication by the complex number $\xi_1 + i\xi_2$, and it is invertible for every $\xi \neq 0$. That is what **elliptic** means: P_1 maps a rank-2 bundle (tangent vectors) to a rank-2 bundle (traceless symmetric tensors) and its symbol is an isomorphism off the zero section. (On a curved surface the lower-order Christoffel terms change nothing, because the symbol only sees the highest derivatives.)

Watch out: Why the trace must be removed first

The full map $V \mapsto \mathcal{L}_V g$ goes from a rank-2 bundle to the rank-3 bundle of all symmetric tensors. Its symbol $\xi \otimes V + V \otimes \xi$ is injective but cannot be surjective ($2 < 3$), so this map is *not* elliptic, and its "cokernel" is infinite-dimensional (it contains all of C_g). Removing the trace is what makes the counting work. This is special to two dimensions: in dimension n the traceless symmetric tensors have rank $\frac{n(n+1)}{2} - 1$, which equals n only for $n = 2$.

The adjoint. Nash's next step uses the adjoint $A_g^* = P_1^\dagger$, defined by $\langle h, P_1 V\rangle_{\text{met}} = \langle P_1^\dagger h, V\rangle_{\text{vect}}$ for all traceless h and all V. We compute it by integrating by parts.

$$\begin{aligned}
\langle h, P_1 V\rangle_{\text{met}} &\overset{(1)}{=} \int_\Sigma \mathrm{d}^2x\,\sqrt{g}\; h^{ab}\big(\nabla_a V_b + \nabla_b V_a - g_{ab}\nabla_c V^c\big) \\
&\overset{(2)}{=} 2\int_\Sigma \mathrm{d}^2x\,\sqrt{g}\; h^{ab}\,\nabla_a V_b \\
&\overset{(3)}{=} -2\int_\Sigma \mathrm{d}^2x\,\sqrt{g}\;(\nabla_a h^{ab})\,V_b \\
&\overset{(4)}{=} \Big\langle -2\nabla^a h_{a\,\cdot}\,,\, V\Big\rangle_{\text{vect}}.
\end{aligned} \tag{9.57}$$

(1) Definition (9.41); indices of h raised with g.
(2) h^{ab} is symmetric, so the first two terms are equal; h is traceless, so $h^{ab}g_{ab} = 0$ kills the third.
(3) Integrate by parts. $\sqrt{g}\,\nabla_a(h^{ab}V_b)$ is the divergence of a vector field, whose integral over the closed surface Σ vanishes by Stokes' theorem (Chapter T2).
(4) Definition (9.44) of $\langle\ ,\ \rangle_{\text{vect}}$.

So

$$(P_1^\dagger h)_b = -2\,\nabla^a h_{ab}, \qquad \text{and in complex form} \qquad (P_1^\dagger h)_z = -2g^{z\bar z}\,\partial_{\bar z} h_{zz} = -\frac{4}{\rho}\,\partial_{\bar z} h_{zz}. \tag{9.58}$$

For the complex form: $\nabla^a h_{az} = g^{z\bar z}\nabla_{\bar z} h_{zz} + g^{\bar z z}\nabla_z h_{\bar z z}$; the second term vanishes because $h_{\bar z z} = 0$ and the only non-zero Christoffel symbols of a conformal metric are $\Gamma^z_{zz} = \partial_z \log\rho$ and $\Gamma^{\bar z}_{\bar z\bar z} = \partial_{\bar z}\log\rho$; for the same reason $\nabla_{\bar z} h_{zz} = \partial_{\bar z} h_{zz}$.

Key idea: The kernel of $P_1^\dagger$: holomorphic quadratic differentials

A traceless h is in $\operatorname{Ker} P_1^\dagger$ iff it is divergence-free, $\nabla^a h_{ab} = 0$, iff its component h_{zz} is holomorphic, $\partial_{\bar z} h_{zz} = 0$. The object $\varphi = h_{zz}\,\mathrm{d}z^2$, which transforms under $z \mapsto w$ as $h_{ww} = h_{zz}(\mathrm{d}z/\mathrm{d}w)^2$, is a **holomorphic quadratic differential**: a holomorphic section of K^2, where K is the canonical bundle (Chapter 5). Nash: "it is easy to see that $\operatorname{Ker} A_g^*$ can be identified with the space of quadratic differentials" (p. 265). The identification is (9.58).

Dictionary: the operator P_1

Nash	physics / complex geometry
A_g	P_1, the "conformal Killing operator"
A_g^*	$P_1^\dagger = -2\,\mathrm{div}$; on h_{zz} it is $\propto \partial_{\bar z}$
$\operatorname{Ker} A_g$	conformal Killing vectors; holomorphic vector fields $V^z\partial_z$
$\operatorname{Ker} A_g^*$	holomorphic quadratic differentials $h_{zz}\mathrm{d}z^2$
$A_g^* A_g$	$-2(\nabla^2 + K)$ on vector fields; ghost kinetic operator
$\operatorname{Ker} A_g$, $\operatorname{Ker} A_g^*$	in the path integral: c-ghost and b-ghost zero modes

Worked example 9.36: No quadratic differentials on the sphere, one on the torus

Sphere. Use z on $\mathbb{C}$ and $w = 1/z$ near ∞. If $h_{zz}(z) = \sum_k b_k z^k$ is holomorphic on $\mathbb{C}$, then near $w = 0$

$$h_{ww} \overset{(1)}{=} h_{zz}\left(\frac{\mathrm{d}z}{\mathrm{d}w}\right)^2 \overset{(2)}{=} h_{zz}(1/w)\,\frac{1}{w^4} = \sum_{k\geq 0} b_k\, w^{-k-4}.$$

(1) A quadratic differential has two lower indices, each transforming with one factor of the Jacobian.
(2) $z = 1/w$, so $\mathrm{d}z/\mathrm{d}w = -1/w^2$, whose square is w^{-4}.

Every term has a negative power of w, so h_{ww} is regular at $w = 0$ only if all $b_k = 0$. The sphere has *no* holomorphic quadratic differentials, so $\operatorname{Ker} P_1^\dagger = 0$: no moduli, consistent with $\dim \mathcal{M}_0 = 0$. Compare the vector field count of Example 9.34: there the Jacobian came with the opposite power, w^{+2}, and three coefficients survived.
Torus $\mathbb{C}/\Lambda$. A holomorphic function on a compact surface is constant, so $h_{zz} = b$ and $\varphi = b\,\mathrm{d}z^2$: one complex, two real parameters, matching $\dim_{\mathbb{R}} \mathcal{M}_1 = 2$.

9.2.8 The orthogonal decomposition of $T_g\mathrm{Met}$

The last ingredient is a fact from linear algebra.

Key idea: Range plus cokernel (Nash's (9.20))

For a linear map $A : V \to W$ between inner product spaces, with adjoint A^*,

$$W = \operatorname{Range} A \;\oplus\; \operatorname{Ker} A^*, \qquad \text{orthogonally.} \tag{9.59}$$

Why: $w \perp \operatorname{Range} A$ iff $\langle w, Av\rangle = 0$ for all v iff $\langle A^* w, v\rangle = 0$ for all v iff $A^* w = 0$. So $\operatorname{Ker} A^*$ is exactly the orthogonal complement of the range.

Worked example 9.37: A 3×2 matrix

Let $A = \begin{pmatrix} 1 & 1 \\ 1 & 1 \\ 0 & 0 \end{pmatrix} : \mathbb{R}^2 \to \mathbb{R}^3$. Its range is the line spanned by $(1,1,0)$. Its adjoint is $A^{\mathsf{T}} = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \end{pmatrix}$, whose kernel is $\{(a,b,c) : a+b=0\}$, the plane spanned by $(1,-1,0)$ and $(0,0,1)$. The line and the plane are orthogonal and together span $\mathbb{R}^3$: $1+2=3$. Note also that $\operatorname{Ker} A$ is the line spanned by $(1,-1)$: A is neither injective nor surjective, and both defects are visible separately. The **index** of A is $\dim \operatorname{Ker} A - \dim \operatorname{Ker} A^* = 1-2 = -1 = \dim V - \dim W$.

In infinite dimensions (9.59) can fail, because a range need not be closed. For elliptic operators on compact manifolds it holds: the range is closed and both kernels are finite-dimensional (Chapter 2). Applying it with $A = P_1$ and $W = C_g^{\perp}$, and combining with (9.46), gives Nash's (9.21):

Key idea: The decomposition of the tangent space to the space of metrics

$$T_g \mathrm{Met}(\Sigma) = \underbrace{C_g}_{\text{Weyl}} \oplus \underbrace{\operatorname{Range} P_1}_{\text{diffeomorphisms}} \oplus \underbrace{\operatorname{Ker} P_1^{\dagger}}_{\text{moduli}}. \tag{9.60}$$

Every infinitesimal change of metric is, uniquely, a Weyl rescaling plus the traceless part of an infinitesimal diffeomorphism plus a holomorphic quadratic differential. The first two are gauge; only the third changes the point of Teichmüller space.

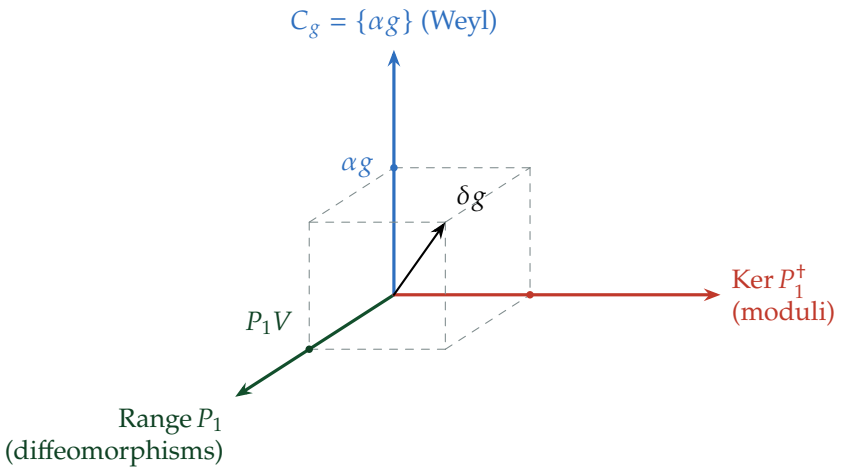

Figure 9.16: The three-way orthogonal splitting (9.60) of $T_g\mathrm{Met}(\Sigma)$. The picture is schematic: the blue and green axes each stand for an infinite-dimensional space, while the red direction $\operatorname{Ker} P_1^{\dagger}$ has finite dimension $6p-6$ (for $p \geq 2$). A general change of metric δg is resolved into a Weyl part (blue), a diffeomorphism part (green) and a modulus (red). Only the red component survives the quotient by the gauge group.

Worked example 9.38: The decomposition on the flat torus, mode by mode

Take $\Sigma = \mathbb{R}^2/\mathbb{Z}^2$ with $g = \delta$ ($\tau = i$, the square torus). Any traceless h is described by the complex function $h_{zz} = \frac{1}{2}(h_{11} + ih_{12})$, which we expand in Fourier modes $e^{2\pi i(nx+my)}$. By

(9.55), $(P_1V)_{\bar z\bar z} = \partial_{\bar z} V^z$, and on a Fourier mode

$$\partial_{\bar z}\, e^{2\pi i(nx+my)} \overset{(1)}{=} \tfrac{1}{2}(\partial_x + i\partial_y)\, e^{2\pi i(nx+my)} \overset{(2)}{=} \pi i\,(n+im)\, e^{2\pi i(nx+my)}.$$

(1) Definition of $\partial_{\bar z}$.
(2) $\partial_x \to 2\pi i n$, $\partial_y \to 2\pi i m$, and $\tfrac{1}{2}(2\pi i n + i\cdot 2\pi i m) = \pi i(n+im)$.

So P_1 is diagonal in Fourier space and multiplies the (n,m) mode by $\pi i(n+im)$. This number vanishes only for $(n,m)=(0,0)$. Hence:

- $\operatorname{Ker} P_1$: constant V^z, the two translations (the CKVs of the torus).
- $\operatorname{Range} P_1$: every traceless h with zero average. Given such an h, the vector field $V^z = \sum_{(n,m)\neq 0} \frac{\hat h(n,m)}{\pi i(n+im)} e^{2\pi i(nx+my)}$ solves $P_1 V = h$.
- $\operatorname{Ker} P_1^\dagger$: the constant traceless tensors, which are orthogonal to every mode with $(n,m)\neq 0$. Two real parameters, the moduli.

A concrete gauge deformation: $\delta g = \varepsilon\cos(2\pi y)\,(\mathrm{d}x^2 - \mathrm{d}y^2)$ has $h_{\bar z\bar z} = \frac{\varepsilon}{2}\cos 2\pi y$ and zero average, so it is pure gauge. Solving $\frac{i}{2}\partial_y V^z = \frac{\varepsilon}{2}\cos 2\pi y$ gives $V^z = -\frac{i\varepsilon}{2\pi}\sin 2\pi y$, i.e. $V = (0, v)$ with $v = -\frac{\varepsilon}{2\pi}\sin 2\pi y$. Then $\mathcal{L}_V\delta = 2v'\,\mathrm{d}y^2 = -2\varepsilon\cos(2\pi y)\,\mathrm{d}y^2$ and

$$\delta g = \mathcal{L}_V \delta + \varepsilon\cos(2\pi y)\,\delta,$$

a diffeomorphism plus a Weyl rescaling, as promised. By contrast the *constant* deformation $\delta g = \varepsilon(\mathrm{d}x^2 - \mathrm{d}y^2)$ would need $v' = -\varepsilon$, i.e. $v = -\varepsilon y$, which is not periodic: it is not gauge. It stretches the square torus into a rectangle, changing $\tau = i$ to $\tau \approx i(1-\varepsilon)$ (compare $\partial_{\tau_2}\hat g = \operatorname{diag}(-1,1)$ in Example 9.30).

9.2.9 How many conformal Killing vectors and moduli?

We have met $\operatorname{Ker} P_1$ (CKVs) and $\operatorname{Ker} P_1^\dagger$ (quadratic differentials) separately. Two further tools pin down their dimensions for every genus: a curvature identity that kills $\operatorname{Ker} P_1$ for $p \geq 2$, and the index theorem, which fixes the *difference* of the two dimensions.

Worked example 9.39: The Weitzenböck formula $P_1^\dagger P_1 = -2(\nabla^2 + K)$

Compose (9.53) and (9.58):

$$\begin{aligned}(P_1^\dagger P_1 V)_b &\overset{(1)}{=} -2\nabla^a\big(\nabla_a V_b + \nabla_b V_a - g_{ab}\nabla_c V^c\big)\\ &\overset{(2)}{=} -2\big(\nabla^2 V_b + \nabla^a\nabla_b V_a - \nabla_b\nabla_c V^c\big)\\ &\overset{(3)}{=} -2\big(\nabla^2 V_b + \nabla_b\nabla^a V_a + R_{bc}V^c - \nabla_b\nabla_c V^c\big)\\ &\overset{(4)}{=} -2\big(\nabla^2 V_b + K\,V_b\big).\end{aligned}$$

(1) Apply $P_1^\dagger = -2\nabla^a(\cdot)_{ab}$ to $h = P_1 V$.
(2) Distribute; $\nabla g = 0$, and $\nabla^2 = \nabla^a\nabla_a$.
(3) Commute the covariant derivatives: $[\nabla_a, \nabla_b]V^a = R_{bc}V^c$, the definition of the Ricci tensor.

(4) The divergence terms cancel, and in two dimensions the Ricci tensor is $R_{bc} = K\, g_{bc}$ with K the Gauss curvature (every 2D metric is an "Einstein metric" pointwise).

Now pair with V and integrate by parts once:

$$\|P_1 V\|^2_{\text{met}} \overset{(1)}{=} \langle V, P_1^\dagger P_1 V\rangle_{\text{vect}} \overset{(2)}{=} 2\int_\Sigma \sqrt{g}\,\nabla_a V_b\,\nabla^a V^b - 2\int_\Sigma \sqrt{g}\,K\,|V|^2 .$$

(1) Definition of the adjoint.

(2) $-\int \sqrt{g}\,V^b\nabla^2 V_b = +\int \sqrt{g}\,|\nabla V|^2$ by Stokes.

Three consequences.

- $p \geq 2$, $K = -1$: $\|P_1 V\|^2 = 2\,\|\nabla V\|^2 + 2\,\|V\|^2$, which is zero only for $V = 0$. *No CKVs* on a hyperbolic surface.
- $p = 1$, $K = 0$: $\|P_1 V\|^2 = 2\,\|\nabla V\|^2$, zero iff $\nabla V = 0$, i.e. V is covariantly constant: the two translations.
- $p = 0$, $K = +1$: the formula allows a kernel, and indeed the six CKVs of Example 9.34 satisfy $\nabla^2 V = -V$ on the unit sphere (for the three Killing vectors this is the standard identity $\nabla^2 V_b = -R_{bc}V^c$).

Note also that $P_1^\dagger P_1$ is minus twice a Laplacian plus a potential: a Laplace-type elliptic operator on vector fields, to which the zeta-function technology of Section 9.1.10 applies.

Key idea: The index of P_1 (Riemann–Roch)

$$\operatorname{index} P_1 = \dim_{\mathbb{R}} \operatorname{Ker} P_1 - \dim_{\mathbb{R}} \operatorname{Ker} P_1^\dagger = 3\chi(\Sigma) = 6 - 6p. \tag{9.61}$$

Why: by (9.55) and (9.58), P_1 is the operator $\bar\partial$ acting on sections $V^z\partial_z$ of the holomorphic tangent bundle $T^{1,0}\Sigma = K^{-1}$, and its cokernel is $H^0(K^2)$. The Riemann–Roch theorem (Chapters 4 and 5) says, for a holomorphic line bundle L,

$$\dim_{\mathbb{C}} H^0(L) - \dim_{\mathbb{C}} H^0(K\otimes L^{-1}) = \deg L - p + 1.$$

With $L = K^{-1}$, $\deg L = 2-2p$ and $K\otimes L^{-1} = K^2$: $\dim_{\mathbb{C}} H^0(K^{-1}) - \dim_{\mathbb{C}} H^0(K^2) = (2-2p) - p + 1 = 3 - 3p$. Doubling to real dimensions gives $6 - 6p = 3\chi$.

The index does not depend on the metric: it is a topological invariant, as the Atiyah–Singer theorem guarantees (Chapter 4). Combined with the vanishing results above, it fixes both dimensions for every genus. For $p \geq 2$ the number of real moduli is $-(6-6p) = 6p - 6$, recovering (9.39). The table and Figure 9.17 collect the answers.

genus	$\dim_{\mathbb{R}} \operatorname{Ker} P_1$ (CKVs)	$\dim_{\mathbb{R}} \operatorname{Ker} P_1^\dagger$ (moduli)	index	3χ
$p = 0$ (sphere)	6 ($\mathrm{PSL}(2,\mathbb{C})$)	0	6	6
$p = 1$ (torus)	2 (translations)	2 (τ)	0	0
$p \geq 2$	0	$6p - 6$	$6 - 6p$	$6 - 6p$

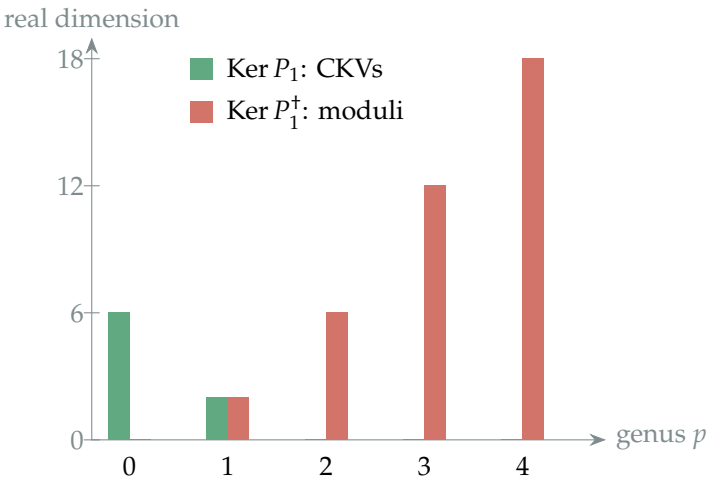

Figure 9.17: Kernel (green) and cokernel (red) of P_1 as the genus grows. The green bar minus the red bar is always $6-6p$, the index. For the sphere all the freedom is in the CKVs; for the torus the two exactly balance; from genus 2 onwards there are no CKVs and $6p-6$ moduli.

Physical picture: Counting degrees of freedom, globally

Locally a 2D metric has 3 functions, the Weyl group removes 1 and diffeomorphisms remove 2: $3-1-2=0$. Globally the count is corrected by finitely many modes on each side. Diffeomorphisms that do nothing to the conformal class (CKVs) mean we removed "too much", and deformations that no diffeomorphism can produce (moduli) mean we removed "too little". The index theorem says #moduli − #CKVs $= -3\chi$: a topological correction to naive counting, exactly like zero-mode counting for the Dirac operator in an instanton background (Chapter 8).

9.2.10 Teichmüller space from the decomposition

Now divide by the gauge groups. Dividing by the Weyl group removes C_g; dividing by Diff_0 removes Range P_1. What survives at the point $[g]$ of the quotient is Ker $P_1^\dagger$. Using the constant-curvature slice to divide by the Weyl group, this is Nash's (9.22),

$$\mathcal{T}_p = \mathrm{Met}_{\mathrm{const}}(\Sigma)/\mathrm{Diff}_0(\Sigma), \qquad T_{[g]}\mathcal{T}_p \;\cong\; \mathrm{Ker}\,P_1^\dagger \;=\; H^0(\Sigma, K^2) \text{ (as a real vector space).} \quad (9.62)$$

One point needs checking: the moduli directions $h \in \mathrm{Ker}\,P_1^\dagger$ really are tangent to the slice $\mathrm{Met}_{\mathrm{const}}$, so that moving along them keeps the curvature constant.

Worked example 9.40: Moduli deformations preserve constant curvature

The first-order change in the scalar curvature $R = 2K$ under $g \to g + h$ is the standard formula (derived by varying the Christoffel symbols; see Chapter T2 for R in terms of the connection)

$$\delta R = -R^{ab}h_{ab} + \nabla^a\nabla^b h_{ab} - \nabla^2\big(g^{ab}h_{ab}\big).$$

For $h \in \mathrm{Ker}\,P_1^\dagger$,

$$\delta R \overset{(1)}{=} -\tfrac{R}{2}\,g^{ab}h_{ab} + \nabla^a\big(\nabla^b h_{ab}\big) - \nabla^2(\mathrm{tr}\,h)$$
$$\overset{(2)}{=} 0 - 0 - 0 = 0.$$

(1) In two dimensions $R^{ab} = \frac{R}{2}g^{ab}$.

(2) h is traceless, so the first and third terms vanish; h is divergence-free, so the middle one does.

So the curvature, and with it the area (by Gauss–Bonnet), is unchanged to first order: $\operatorname{Ker} P_1^\dagger \subset T_g\mathrm{Met}_{\mathrm{const}}$. For the torus this is the statement that the deformation $\partial_\tau \hat g_\tau$ of (9.42) stays flat, which is obvious since all its entries are constant.

9.2.11 Preview: the conformal anomaly and the number 26

Nash's instruction "set $d = 26$" deserves a word of explanation now, even though the full story is Chapter 10. The division by $\operatorname{vol} C_+^\infty$ in (9.35) is legitimate only if the integrand does not depend on the Weyl factor. The classical action does not (Example 9.7), but the determinants do.

Key idea: The Weyl variation of the matter determinant

Under $g = e^{2\omega}\hat g$ (quoted from Chapter 10; it is the Polyakov–Alvarez formula),

$$\log \frac{\det' \Delta_g}{A_g} = \log \frac{\det' \Delta_{\hat g}}{A_{\hat g}} - \frac{1}{12\pi}\int_\Sigma \mathrm{d}^2x \sqrt{\hat g}\,\big(\hat g^{ab}\partial_a\omega\,\partial_b\omega + \hat R\,\omega\big). \tag{9.63}$$

For an infinitesimal $\delta\omega$ the linear term gives $\delta \log(\det'\Delta/A) = -\frac{1}{12\pi}\int \sqrt{g}\,R\,\delta\omega$.

We can test the formula against our own calculation. For *constant* ω the gradient term drops out and

$$\log \frac{\det' \Delta_{e^{2\omega}\hat g}}{A_{e^{2\omega}\hat g}} - \log \frac{\det' \Delta_{\hat g}}{A_{\hat g}} \overset{(1)}{=} -\frac{\omega}{12\pi}\int_\Sigma \sqrt{\hat g}\,\hat R \overset{(2)}{=} -\frac{\omega}{12\pi}\cdot 4\pi\chi = -\frac{\chi}{3}\,\omega,$$

(1) (9.63) with $\partial_a\omega = 0$.
(2) Gauss–Bonnet: $\int \sqrt{g}\,K = 2\pi\chi$ and $R = 2K$.

and $e^{-\chi\omega/3} = \lambda^{-\chi/6}$ with $\lambda = e^{2\omega}$: exactly the scaling found in Example 9.26(ii) from $\zeta_\Delta(0) = \chi/6 - 1$. The constant part of the anomaly is the heat-kernel coefficient; the local formula refines it point by point.

The d matter fields contribute $(\det'\Delta/A)^{-d/2}$, so their Weyl variation is $\delta \log Z_{\mathrm{matter}} = +\frac{d}{24\pi}\int \sqrt{g}\,R\,\delta\omega$. The Faddeev–Popov factor $\sqrt{\det' P_1^\dagger P_1}$ that we are about to derive has its own Weyl variation, with the *same* structure and the coefficient $-\frac{26}{24\pi}$ (Chapter 10). The total is

$$\delta_\omega \log\big(\text{integrand of } Z_p\big) = \frac{d-26}{24\pi}\int_\Sigma \mathrm{d}^2x\,\sqrt{g}\,R\,\delta\omega. \tag{9.64}$$

For $d = 26$ the integrand is Weyl invariant, the Weyl group decouples, and its volume can be divided out. For $d \neq 26$ the Weyl factor becomes a dynamical field (the Liouville field, with the action in (9.63)), and the reduction to a finite-dimensional integral fails. In conformal field theory language (Chapter 11), d is the central charge of the matter and -26 that of the ghosts. On a curved target with metric $G_{\mu\nu}$, Weyl invariance also demands $\alpha' R_{\mu\nu} = 0$ at one loop. That is derived in Section T5.7.1.

Watch out: The torus is anomaly-blind to constant rescalings, not to local ones

For $\chi = 0$ the constant part of (9.64) vanishes, so a *uniform* rescaling of a flat torus changes nothing in any dimension. The condition $d = 26$ is still needed on the torus, because a *non-constant* $\delta\omega$ sees the local curvature R of a non-flat representative metric.

Reading Nash (pp. 262–265, (9.8)–(9.22))

- "Z_p can be expressed as a finite dimensional integral over the moduli space" is the plan of Section 9.2.1; the aside on $d = 26$ is Section 9.2.11.
- (9.8) is (9.35). The remark that Diff^+ does not act freely, and the switch to Diff_0 and $\mathrm{Met}_{\mathrm{const}}$, are the pitfall after Figure 9.13.
- The finite-dimensional volume element $\sqrt{\det\langle e_i, e_j\rangle}\, \mathrm{d}^n x$ is (9.40); (9.9)–(9.11) are (9.41); (9.12) is (9.44); (9.13) is Example 9.31.
- (9.14)–(9.18) are (9.46)–(9.50); (9.16) is the chain (9.47); footnote 2 is (9.51). Nash's sentence "$\mathrm{tr}(h) = 0$ implies (9.15)" should be read as "is equivalent to".
- (9.19) is (9.53); (9.20) is (9.59); (9.21) is (9.60). "A_g can be seen to be elliptic" is (9.56); "it is easy to see that $\mathrm{Ker}\, A_g^*$ can be identified with the space of quadratic differentials" is (9.58) and the key idea after it.
- (9.22) is (9.62).

Recap: Section

- $\mathcal{D}g = \mathcal{D}\mathrm{Met}/(\mathrm{vol}\,\mathrm{Weyl} \cdot \mathrm{vol}\,\mathrm{Diff})$; gauge fixing means integrating over a slice with a Jacobian $\sqrt{\det A^{\mathsf{T}} A}$ (polar coordinates).
- $\mathrm{Met}(\Sigma)$ has the natural metric $\int \sqrt{g}\ \mathrm{tr}(g^{-1}Xg^{-1}Y)$, invariant under diffeomorphisms; at one point it is $\mathbb{R}_+\times$ (hyperbolic plane).
- $\mathcal{L}_V g = \nabla_a V_b + \nabla_b V_a$; CKVs are the V with traceless part zero, i.e. holomorphic V^z: six on S^2, two on T^2, none for $p \geq 2$.
- $T_g\mathrm{Met} = C_g \oplus \mathrm{Range}\, P_1 \oplus \mathrm{Ker}\, P_1^\dagger$, with $P_1 V$ = traceless part of $\mathcal{L}_V g$ (a Cauchy–Riemann operator, elliptic) and $P_1^\dagger = -2\,\mathrm{div}$.
- $\mathrm{Ker}\, P_1^\dagger$ = holomorphic quadratic differentials = $T\mathcal{T}_p$; $\mathrm{index}\, P_1 = 3\chi$ by Riemann–Roch; $P_1^\dagger P_1 = -2(\nabla^2 + K)$.
- Weyl invariance of the quantum integrand requires $d = 26$.

9.3 The Weil–Petersson metric

We now know that the moduli directions at g are the holomorphic quadratic differentials $\mathrm{Ker}\, P_1^\dagger$. To integrate over moduli space we need a *volume element* on it, and the cleanest way to get a volume element is from a metric ((9.40)). Nash's §3 builds that metric. The idea is simple: $\mathrm{Met}(\Sigma)$ already has a metric, the gauge group acts on it by isometries, and a quotient by isometries inherits a metric. The result is the **Weil–Petersson metric** on $\mathcal{T}_p$ and $\mathcal{M}_p$. We first see how quotient metrics work in a case we can draw.

9.3.1 Quotient metrics in finite dimensions

Worked example 9.41: The sphere divided by rotations about an axis

Let $M = S^2$ with the round metric $\mathrm{d}s^2 = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2$, and let $G = \mathrm{SO}(2)$ act by $\varphi \mapsto \varphi + c$. These rotations are isometries. The orbits are the circles of latitude, and the quotient M/G is the interval $\theta \in [0, \pi]$.

To measure the length of a tangent vector $U = \dot\theta\,\partial_\theta$ to the quotient, lift it to a tangent vector X on M that projects to U. There are many lifts, $X = \dot\theta\,\partial_\theta + c\,\partial_\varphi$ for any c, because adding a vector along the orbit does not change the projection. The natural choice is the **horizontal lift**, the one orthogonal to the orbit: $c = 0$. Then

$$|U|^2_{M/G} \overset{(1)}{=} |X^{\mathrm{hor}}|^2_M \overset{(2)}{=} \dot\theta^2.$$

(1) Definition of the quotient metric: the length of the horizontal lift.
(2) $\langle \partial_\theta, \partial_\theta \rangle = 1$.

So the quotient metric is $\mathrm{d}\theta^2$: the length of the interval is π, the distance from pole to pole. If we had used a non-horizontal lift, we would have got $\dot\theta^2 + c^2\sin^2\theta$, which depends on the arbitrary c. Now compare volumes:

$$\mathrm{vol}(S^2) \overset{(1)}{=} \int_0^\pi \mathrm{d}\theta \int_0^{2\pi} \mathrm{d}\varphi\, \sin\theta \overset{(2)}{=} \int_0^\pi \underbrace{\mathrm{d}\theta}_{\text{quotient volume}} \underbrace{2\pi\sin\theta}_{\text{orbit length}} = 4\pi.$$

(1) The Riemannian volume element $\sqrt{\det G}\,\mathrm{d}\theta\,\mathrm{d}\varphi = \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\varphi$.
(2) Do the φ integral first: it is the length of the orbit through θ.

The total volume is "quotient volume times orbit volume". The orbit volume is not constant: it is $2\pi\sin\theta = \mathrm{vol}(G) \times \sin\theta$, and the factor $\sin\theta$ is the length of the vector ∂_φ by which the Lie algebra of G moves the point. That factor is the Faddeev–Popov Jacobian of Example 9.27 again, now on a curved space.

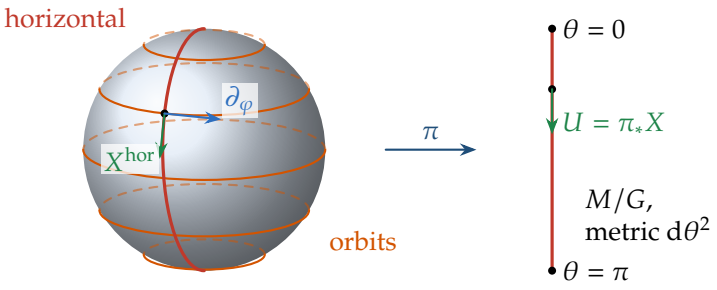

Figure 9.18: A quotient metric. The rotation group moves points along the orange orbits. A tangent vector U to the quotient has many lifts; the horizontal one (along a meridian, orthogonal to the orbits) is unique, and its length defines $|U|$. The Weil–Petersson metric is this construction applied to $\mathrm{Met}_{\mathrm{const}}(\Sigma) \to \mathcal{T}_p$, with the orbits of Diff_0 in place of the latitude circles.

Working definition 9.10 (Quotient (submersion) metric)

Let a group G act on a Riemannian manifold M by isometries [each group element preserves the length of every tangent vector], freely [no group element other than the identity fixes any point], with quotient map $\pi : M \to M/G$. For $U \in T_{\pi(m)}(M/G)$:

1. pick any point m in the fibre over $\pi(m)$ [the orbit $G \cdot m$, all the points that π sends to $\pi(m)$];
2. lift U to the unique $X \in T_m M$ with $\pi_* X = U$ [if X is the velocity of a curve in M, then $\pi_* X$ is the velocity of its image in M/G] that is orthogonal to the orbit $G \cdot m$;
3. set $|U|_{M/G} = |X|_M$.

Step 1 is harmless because G acts by isometries (it carries horizontal lifts at m to horizontal lifts at $g \cdot m$ without changing their length); step 2 is where the choice of lift is made canonical.

9.3.2 The metric on $\mathrm{Met}_{\mathrm{const}}$ and its isometries

$\mathrm{Met}_{\mathrm{const}}(\Sigma) \subset \mathrm{Met}(\Sigma)$ is a submanifold (the constant-curvature metrics (9.37)). Any submanifold of a Riemannian manifold inherits a metric by restriction: to measure a tangent vector to the submanifold, measure it as a vector in the big space. This is how the unit sphere in $\mathbb{R}^3$ gets its round metric from the Euclidean one. Nash denotes the restricted metric by

$$\langle X, Y \rangle_{\mathrm{const}} = \langle X, Y \rangle_{\mathrm{met}} \quad \text{for } X, Y \in T_g \mathrm{Met}_{\mathrm{const}}(\Sigma). \tag{9.65}$$

Diff_0 preserves $\mathrm{Met}_{\mathrm{const}}$ and acts on it by isometries. The pull-back of a metric of constant curvature K by a diffeomorphism again has constant curvature K (curvature is defined geometrically, so $K(\alpha^* g) = \alpha^* K(g) = K(g)$ when $K(g)$ is constant) and the same area. So α^* maps $\mathrm{Met}_{\mathrm{const}}$ to itself. That it preserves $\langle\ ,\ \rangle_{\mathrm{const}}$ is Example 9.29, restricted to tangent vectors of $\mathrm{Met}_{\mathrm{const}}$.

Watch out: Isometries of $\mathrm{Met}_{\mathrm{const}}$, not of Σ (Nash's footnote 3)

Two different statements are easy to confuse.

- α is an isometry *of the surface* (Σ, g) if $\alpha^* g = g$. Only special α do this (the Killing flows).
- α acts as an isometry *of the space of metrics*: $\langle \alpha^* X, \alpha^* Y \rangle_{\alpha^* g} = \langle X, Y \rangle_g$. Every diffeomorphism does this.

Nash means the second. Example: the Dehn twist $\alpha(x, y) = (x + y, y)$ on the square torus maps $g = \mathrm{d}x^2 + \mathrm{d}y^2$ to $\alpha^* g = (\mathrm{d}x + \mathrm{d}y)^2 + \mathrm{d}y^2 \neq g$, so it is not an isometry of the torus. But it maps the point g of $\mathrm{Met}_{\mathrm{const}}$ to the different point $\alpha^* g$, and the tangent spaces at the two points isometrically onto each other.

9.3.3 Definition of the Weil–Petersson metric

Following Nash, let

$$\pi : \mathrm{Met}_{\mathrm{const}}(\Sigma) \longrightarrow \mathrm{Met}_{\mathrm{const}}(\Sigma)/\mathrm{Diff}_0(\Sigma) = \mathcal{T}_p \tag{9.66}$$

be the projection (Nash's (9.23)), write $[g_{\mathrm{const}}]$ for the equivalence class of g_{const} (a point of $\mathcal{T}_p$), and $T_{[g_{\mathrm{const}}]}\mathcal{T}_p$ for the tangent space there (Nash's (9.24)).

Working definition 9.11 (Weil–Petersson metric (Nash's (9.25)))

For $U, V \in T_{[g]}\mathcal{T}_p$ choose a representative metric g and lifts $X, Y \in T_g\mathrm{Met}_{\mathrm{const}}$ with $\pi_* X = U$, $\pi_* Y = V$, horizontal (orthogonal to the Diff_0 orbit through g [all metrics $\alpha^* g$ with α a diffeomorphism that can be continuously deformed to the identity]). Then

$$\langle U, V\rangle_{\mathrm{wp}} = \langle X, Y\rangle_{\mathrm{const}} = \int_\Sigma \mathrm{d}^2x\sqrt{g}\ \mathrm{tr}\big(g^{-1}Xg^{-1}Y\big). \tag{9.67}$$

How to compute it: represent the tangent vectors to $\mathcal{T}_p$ by holomorphic quadratic differentials [tensors $q(z)\,\mathrm{d}z^2$ with q holomorphic in every local complex coordinate z] (they are the horizontal vectors, see below), and evaluate the L^2 inner product (9.69).

Two things must be checked: that the horizontal lifts are what we think they are, and that the answer does not depend on the representative g.

The horizontal vectors are the quadratic differentials. The tangent space to the Diff_0 orbit through g is $\{\mathcal{L}_V g\}$. A vector X is horizontal iff $\langle X, \mathcal{L}_V g\rangle_{\mathrm{met}} = 0$ for all V. The same integration by parts as in (9.57), now without assuming X traceless, gives $\langle X, \mathcal{L}_V g\rangle_{\mathrm{met}} = \langle -2\nabla^a X_{a\,\cdot}, V\rangle_{\mathrm{vect}}$, so horizontal means *divergence-free*, $\nabla^a X_{ab} = 0$. Take $p \geq 2$ and split $X = \beta g + h$ with h traceless. Two conditions constrain β:

$$\begin{aligned} 0 &\overset{(1)}{=} \nabla^a(\beta g_{ab} + h_{ab}) = \nabla_b\beta + \nabla^a h_{ab} \quad\Longrightarrow\quad \nabla^a\nabla^b h_{ab} = -\nabla^2\beta, \\ 0 &\overset{(2)}{=} \delta R = -\tfrac{R}{2}(2\beta) + \nabla^a\nabla^b(\beta g_{ab} + h_{ab}) - \nabla^2(2\beta) \\ &\overset{(3)}{=} -R\beta + \nabla^2\beta - \nabla^2\beta - 2\nabla^2\beta \overset{(4)}{=} 2\beta + 2\Delta\beta. \end{aligned}$$

(1) X is horizontal (divergence-free); take a further divergence.
(2) X is tangent to $\mathrm{Met}_{\mathrm{const}}$, so the curvature does not change; use the formula for δR of Example 9.40 with $\mathrm{tr}\, X = 2\beta$.
(3) $\nabla^a\nabla^b(\beta g_{ab}) = \nabla^2\beta$, and substitute the result of (1).
(4) $R = 2K = -2$ for $p \geq 2$, and $\Delta = -\nabla^2$ is the positive Laplacian.

Pairing $(1 + \Delta)\beta = 0$ with β gives $\|\beta\|^2 + \|\nabla\beta\|^2 = 0$, so $\beta = 0$. Hence a horizontal tangent vector to $\mathrm{Met}_{\mathrm{const}}$ is traceless and divergence-free: it lies in $\mathrm{Ker}\, P_1^\dagger$. Conversely every element of $\mathrm{Ker}\, P_1^\dagger$ is horizontal and tangent to $\mathrm{Met}_{\mathrm{const}}$ (Example 9.40). So

$$(\text{horizontal subspace at } g) = \mathrm{Ker}\, P_1^\dagger \cong T_{[g]}\mathcal{T}_p. \tag{9.68}$$

Independence of the representative (Nash's (9.26)–(9.29)). Suppose $[g'] = [g]$, so $g' = \alpha^* g$ for some $\alpha \in \mathrm{Diff}_0$ (Nash writes α_*). Let X, Y be the horizontal lifts of U, V at g. Then $\alpha^* X, \alpha^* Y$ are tangent to $\mathrm{Met}_{\mathrm{const}}$ at g', project to the same U, V (since $\pi \circ \alpha^* = \pi$), and are horizontal (since α^* is an isometry mapping orbits to orbits, it maps the orthogonal complement of one orbit's tangent space to that of the other). So they are *the* horizontal lifts at g', and

$$\begin{aligned} \langle U, V\rangle_{\mathrm{wp}}\big|_{\text{computed at } g'} &\overset{(1)}{=} \langle \alpha^* X, \alpha^* Y\rangle_{\mathrm{const},\, g'} \\ &\overset{(2)}{=} \langle X, Y\rangle_{\mathrm{const},\, g} \overset{(3)}{=} \langle U, V\rangle_{\mathrm{wp}}\big|_{\text{computed at } g}. \end{aligned}$$

(1) Definition (9.67) at g', with the lifts just found.
(2) α^* is an isometry of $\mathrm{Met}_{\mathrm{const}}$ (Example 9.29).
(3) Definition at g.

Watch out: Which lift?

Nash says that $X' = \alpha_* X$ follows "from the fibration". That is true for *horizontal* lifts only. A general lift is ambiguous up to adding a vertical vector $\mathcal{L}_W g$, and $\langle X + \mathcal{L}_W g, X + \mathcal{L}_W g\rangle \neq \langle X, X\rangle$ in general, exactly as $\dot\theta^2 + c^2 \sin^2\theta \neq \dot\theta^2$ in Example 9.41. An equivalent recipe that works with *any* lift is to first project orthogonally onto $\operatorname{Ker} P_1^\dagger$: $\langle U, V\rangle_{\mathrm{wp}} = \langle \Pi X, \Pi Y\rangle_{\mathrm{met}}$, where Π is the orthogonal projector of (9.60).

The Weil–Petersson metric in complex form. Write a horizontal vector as $h = \varphi\,\mathrm{d}z^2 + \bar\varphi\,\mathrm{d}\bar z^2$, with $\varphi = h_{zz}$ holomorphic, and the metric as $g = \rho\,\mathrm{d}z\,\mathrm{d}\bar z$ (so $g_{z\bar z} = \rho/2$, $g^{z\bar z} = 2/\rho$, $\sqrt{g} = \rho$ in the coordinates x, y). Then

$$\begin{aligned}\langle h, h'\rangle_{\mathrm{met}} &\overset{(1)}{=} \int \mathrm{d}^2x\,\rho\,\big(g^{z\bar z}g^{z\bar z}h_{zz}h'_{\bar z\bar z} + g^{\bar z z}g^{\bar z z}h_{\bar z\bar z}h'_{zz}\big)\\ &\overset{(2)}{=} \int \mathrm{d}^2x\,\rho\,\frac{4}{\rho^2}\big(\varphi\bar\varphi' + \bar\varphi\varphi'\big)\\ &\overset{(3)}{=} 8\,\mathrm{Re}\int_\Sigma \mathrm{d}^2x\,\frac{\varphi\,\bar\varphi'}{\rho}.\end{aligned} \tag{9.69}$$

(1) Evaluate $g^{ac}g^{bd}h_{ab}h'_{cd}$ in the complex basis; only $g^{z\bar z}$ is non-zero, and h has only zz and $\bar z\bar z$ components, so only two terms survive.
(2) $g^{z\bar z} = 2/\rho$ and $h'_{\bar z\bar z} = \bar\varphi'$.
(3) The two terms are complex conjugates.

The integral $\int \varphi\bar\varphi'\rho^{-1}\,\mathrm{d}^2x$ is the **Petersson inner product** of two quadratic differentials (the integrand is a well-defined 2-form because $\varphi\bar\varphi'$ has weight $(2,2)$ and ρ^{-1} has weight $(-1,-1)$). Weil's idea was to use it as a metric on Teichmüller space; hence the name.

Physical picture: What the Weil–Petersson distance measures

The WP length of a path in $\mathcal{T}_p$ is the L^2 size of the *shape change* of the surface along the path, after all size changes (Weyl) and all reparametrisations (diffeomorphisms) have been projected out. It is the unique "kinetic energy" for moving through the space of Riemann surfaces that is inherited from the obvious kinetic energy on metrics. Standard facts (quoted): it is Kähler, it is invariant under the mapping class group, so it descends to $\mathcal{M}_p$, and $\mathcal{M}_p$ has finite WP volume.

9.3.4 The torus: Weil–Petersson = hyperbolic

Worked example 9.42: The WP metric on $\mathcal{T}_1$

Every flat metric of area 1 on the torus $\mathbb{R}^2/\mathbb{Z}^2$ is, up to a diffeomorphism isotopic to the identity, one of

$$\hat g_\tau = \frac{1}{\tau_2}\,|\mathrm{d}x + \tau\,\mathrm{d}y|^2, \qquad \tau = \tau_1 + i\tau_2,\ \tau_2 > 0,$$

the metric (9.42) made constant over the torus. Its area is $\int \sqrt{\det \hat g_\tau}\,\mathrm{d}x\,\mathrm{d}y = 1$. So $\mathcal{T}_1$ is the upper half-plane, with coordinate τ. The coordinate vectors $\partial_{\tau_i}\hat g_\tau$ are constant in x, y, traceless (because $\det \hat g_\tau = 1$ and $\operatorname{tr}(\hat g^{-1}\partial\hat g) = \partial \log\det \hat g = 0$) and therefore divergence-free:

they are horizontal (Example 9.38). Hence

$$\langle \partial_{\tau_i}, \partial_{\tau_j} \rangle_{\mathrm{wp}} \overset{(1)}{=} \int_0^1 \int_0^1 \mathrm{d}x\,\mathrm{d}y\ \sqrt{\det \hat{g}_\tau}\ \operatorname{tr}\big(\hat{g}_\tau^{-1}\partial_{\tau_i}\hat{g}_\tau\ \hat{g}_\tau^{-1}\partial_{\tau_j}\hat{g}_\tau\big)$$
$$\overset{(2)}{=} 1 \cdot 1 \cdot \frac{2\,\delta_{ij}}{\tau_2^2},$$

(1) Definition (9.67); the lifts are horizontal.
(2) The integrand is constant; $\det \hat{g}_\tau = 1$; the trace is (9.43); the coordinate area of the unit square is 1.

so

$$\mathrm{d}s^2_{\mathrm{wp}} = \frac{2\,(\mathrm{d}\tau_1^2 + \mathrm{d}\tau_2^2)}{\tau_2^2} = \frac{2\,|\mathrm{d}\tau|^2}{(\operatorname{Im}\tau)^2}, \qquad \mathrm{d}\mu(\mathcal{T}_1) = \frac{2\,\mathrm{d}\tau_1\,\mathrm{d}\tau_2}{\tau_2^2}. \tag{9.70}$$

The Weil–Petersson metric of the torus is twice the Poincaré metric of the upper half-plane. *Check with the complex formula.* At $\tau = i$, $\hat{g} = \delta$, $\rho = 1$, and $\partial_{\tau_1}\hat{g} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, i.e. $h = 2\,\mathrm{d}x\,\mathrm{d}y$. Its zz component is $\varphi = h(\partial_z, \partial_z) = \frac{1}{4}(h_{11} - 2ih_{12} - h_{22}) = -\frac{i}{2}$, and (9.69) gives $8 \cdot |\varphi|^2 \cdot 1 = 8 \cdot \frac{1}{4} = 2$, in agreement with $2/\tau_2^2$ at $\tau_2 = 1$.

The mapping class group acts by Möbius transformations. A matrix $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in \mathrm{SL}(2,\mathbb{Z})$ defines a linear diffeomorphism of $\mathbb{R}^2/\mathbb{Z}^2$ (it maps $\mathbb{Z}^2$ to itself, and so does its inverse). Pull back $\hat{g}_\tau$ by $(x, y) = (dx' + by',\ cx' + ay')$:

$$\mathrm{d}x + \tau\,\mathrm{d}y \overset{(1)}{=} (d + c\tau)\,\mathrm{d}x' + (b + a\tau)\,\mathrm{d}y'$$
$$\overset{(2)}{=} (c\tau + d)\,\big(\mathrm{d}x' + \tau'\,\mathrm{d}y'\big), \qquad \tau' = \frac{a\tau + b}{c\tau + d},$$
$$\operatorname{Im}\tau' \overset{(3)}{=} \frac{\operatorname{Im}\big((a\tau + b)(c\bar{\tau} + d)\big)}{|c\tau + d|^2} \overset{(4)}{=} \frac{\tau_2}{|c\tau + d|^2}.$$

(1) Substitute $\mathrm{d}x = d\,\mathrm{d}x' + b\,\mathrm{d}y'$ and $\mathrm{d}y = c\,\mathrm{d}x' + a\,\mathrm{d}y'$.
(2) Factor out $(c\tau + d)$.
(3) Multiply numerator and denominator by $\overline{c\tau + d}$.
(4) $\operatorname{Im}\big(ad\,\tau + bc\,\bar{\tau}\big) = (ad - bc)\tau_2 = \tau_2$.

So $\hat{g}_\tau$ pulls back to $\frac{|c\tau+d|^2}{\tau_2}\,|\mathrm{d}x' + \tau'\mathrm{d}y'|^2 = \frac{1}{\tau_2'}\,|\mathrm{d}x' + \tau'\mathrm{d}y'|^2 = \hat{g}_{\tau'}$. The mapping class group $\Gamma_{T^2} = \mathrm{SL}(2,\mathbb{Z})$ acts on $\mathcal{T}_1$ by $\tau \mapsto \frac{a\tau+b}{c\tau+d}$. The matrix $-\mathbf{1}$ acts trivially (it is $(x, y) \mapsto (-x, -y)$, an isometry of every flat torus), so the effective group is $\mathrm{PSL}(2,\mathbb{Z})$. It is generated by

$$T:\ \tau \mapsto \tau + 1 \text{ (the Dehn twist)}, \qquad S:\ \tau \mapsto -\frac{1}{\tau} \text{ (exchange the two cycles)}.$$

These are WP isometries, as they must be:

$$\frac{|\mathrm{d}\tau'|^2}{(\operatorname{Im}\tau')^2} \overset{(1)}{=} \frac{|\mathrm{d}\tau|^2\,/|c\tau + d|^4}{\tau_2^2/|c\tau + d|^4} = \frac{|\mathrm{d}\tau|^2}{\tau_2^2}.$$

(1) $\mathrm{d}\tau' = \frac{a(c\tau+d)-c(a\tau+b)}{(c\tau+d)^2}\mathrm{d}\tau = \frac{\mathrm{d}\tau}{(c\tau+d)^2}$, and the formula for $\operatorname{Im}\tau'$ above.

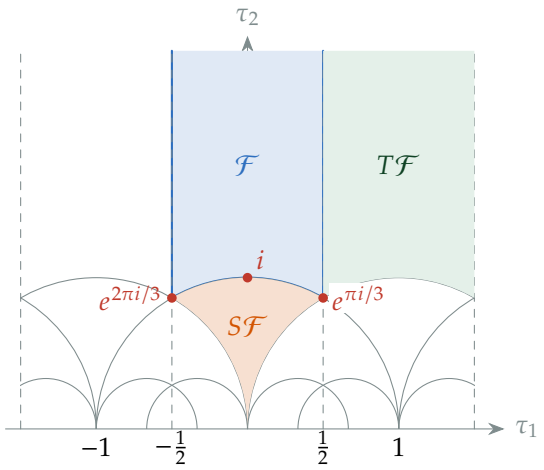

Figure 9.19: Teichmüller space $\mathcal{T}_1$ is the upper half-plane with the hyperbolic (Weil–Petersson) metric. The mapping class group $\mathrm{PSL}(2,\mathbb{Z})$ tiles it by copies of the fundamental domain $\mathcal{F} = \{|\tau_1| \le \frac{1}{2},\ |\tau| \ge 1\}$ (blue): T shifts it sideways (green) and S inverts it in the unit circle (orange). Each point of $\mathcal{M}_1 = \mathcal{T}_1/\mathrm{PSL}(2,\mathbb{Z})$ appears once in $\mathcal{F}$, up to boundary identifications. The red points are fixed by a finite subgroup ($\tau = i$ by S, $\tau = e^{2\pi i/3}$ by ST): the square and hexagonal tori have extra symmetry, which is why $\mathcal{M}_1$ is an orbifold rather than a manifold.

Worked example 9.43: The Weil–Petersson volume of $\mathcal{M}_1$

Integrate (9.70) over $\mathcal{F}$:

$$\begin{aligned}\mathrm{vol}_{\mathrm{wp}}(\mathcal{M}_1) &\overset{(1)}{=} \int_{-1/2}^{1/2} \mathrm{d}\tau_1 \int_{\sqrt{1-\tau_1^2}}^{\infty} \frac{2\,\mathrm{d}\tau_2}{\tau_2^2} \\ &\overset{(2)}{=} \int_{-1/2}^{1/2} \frac{2\,\mathrm{d}\tau_1}{\sqrt{1-\tau_1^2}} \\ &\overset{(3)}{=} 2\big[\arcsin\tau_1\big]_{-1/2}^{1/2} = 2\cdot\frac{\pi}{3} = \frac{2\pi}{3}.\end{aligned}$$

(1) The lower boundary of $\mathcal{F}$ is the unit circle $\tau_2 = \sqrt{1-\tau_1^2}$.

(2) $\int_a^\infty \mathrm{d}\tau_2/\tau_2^2 = 1/a$.

(3) $\int \mathrm{d}u/\sqrt{1-u^2} = \arcsin u$, and $\arcsin\frac{1}{2} = \frac{\pi}{6}$.

The moduli space of tori is non-compact (the cusp $\tau_2 \to \infty$, a very long thin torus) but has *finite* volume. Whether the string amplitude converges in the cusp is then a question about the integrand, which we meet in Example 9.56.

Watch out: Integrating over $\mathcal{T}_p$ versus $\mathcal{M}_p$

The integrand of Z_p is invariant under the whole Diff^+, so it is constant along Γ_Σ-orbits in $\mathcal{T}_p$. An integral over $\mathcal{T}_p$ therefore counts each point of $\mathcal{M}_p$ $|\Gamma_\Sigma|$ times, and $\frac{1}{|\Gamma_\Sigma|}\int_{\mathcal{T}_p} = \int_{\mathcal{M}_p}$. For $p \ge 1$ the group Γ_Σ is infinite, so this is a formal way of saying "integrate over a fundamental domain"; it is the form in which Nash writes (9.35).

9.3.5 The partition function as an integral over moduli

We now have every ingredient, and Nash's last step (pp. 267–268) assembles them. The question is: *what does the formal integral* $\int \mathcal{D}g\,(\cdots)$ *over all metrics become, once we use coordinates adapted to the gauge symmetry?* The answer is a finite-dimensional integral over Teichmüller space, with two Jacobian factors: the Weil–Petersson volume element, and the determinant $\sqrt{\det{}' P_1^\dagger P_1}$. The logic is exactly that of the polar-coordinate example Example 9.27, done once more in infinite dimensions. We go slowly, because every factor in the final formula (9.35) has a specific origin.

Watch out: Two meanings of the letter A

Nash writes A_g for the operator that we call P_1. Earlier in this chapter we used A_g for the area $(1,1)_g = \int_\Sigma \sqrt{g}$. From here on we write P_1 (and $P_1^\dagger = A_g^*$) for the operator and $(1,1)_g$ for the area, and we reserve the letter A for finite-dimensional matrices in toy models.

9.3.6 Coordinates adapted to the gauge symmetry: the conformal gauge

In Section 9.1.6 we used a local fact: near every point, every metric on a surface can be written $e^{2\omega}\,|\mathrm{d}w|^2$ in a suitable coordinate w (isothermal coordinates). The global version of that statement is what makes the gauge fixing work.

Key idea: Global conformal gauge

Choose, for each point $t = (t^1, \dots, t^n)$ of Teichmüller space $\mathcal{T}_p$ ($n = \dim_{\mathbb{R}} \mathcal{T}_p$), one constant-curvature metric $\hat{g}_t \in \mathrm{Met}_{\mathrm{const}}(\Sigma)$ in the class t, depending smoothly on t. Then every metric on Σ can be written as

$$g = \alpha^*\big(e^{\sigma}\,\hat{g}_t\big), \qquad \sigma \in C^\infty(\Sigma), \quad \alpha \in \mathrm{Diff}_0(\Sigma), \quad t \in \mathcal{T}_p. \tag{9.71}$$

Physicists call the choice of representatives $\hat{g}_t$ the **conformal gauge**: the metric is fixed to be "a Weyl factor times a reference metric", and the only gauge-invariant data left are the n numbers t^i.

Why is (9.71) *true?* Read the tower of quotients Figure 9.13 backwards. Given g, uniformisation gives a unique σ_1 with $e^{-\sigma_1} g \in \mathrm{Met}_{\mathrm{const}}$. Its class in $\mathcal{T}_p = \mathrm{Met}_{\mathrm{const}}/\mathrm{Diff}_0$ is some point t, and $\hat{g}_t$ is in the same class, so $e^{-\sigma_1} g = \alpha^* \hat{g}_t$ for some $\alpha \in \mathrm{Diff}_0$. Then $g = e^{\sigma_1}\alpha^*\hat{g}_t = \alpha^*\big(e^{\sigma}\hat{g}_t\big)$ with $\sigma = \sigma_1 \circ \alpha^{-1}$. A smooth choice $t \mapsto \hat{g}_t$ exists globally because $\mathcal{T}_p$ is a ball (a section of a bundle over a contractible base always exists). This is also why we work with $\mathcal{T}_p$ and Diff_0 first, and bring in the mapping class group only at the very end: over $\mathcal{M}_p$, which has orbifold points, no such smooth choice is possible.

Worked example 9.44: Putting a torus metric into conformal gauge

Let $\Sigma = \mathbb{R}^2/\mathbb{Z}^2$ and $g = \mathrm{d}x^2 + f(y)^2\,\mathrm{d}y^2$, where $f > 0$ is any smooth function of period 1. This metric is flat (it is $\mathrm{d}x^2 + \mathrm{d}u^2$ in the local coordinate $u = \int f\,\mathrm{d}y$) but it is not obviously one of the $\hat{g}_\tau = \frac{1}{\tau_2}\,|\mathrm{d}x + \tau\,\mathrm{d}y|^2$ of (9.42). Let

$$c = \int_0^1 f(y)\,\mathrm{d}y, \qquad Y(y) = \frac{1}{c}\int_0^y f(s)\,\mathrm{d}s.$$

Then $Y(y+1) = Y(y) + 1$ and $Y' = f/c > 0$, so $\alpha(x,y) = (x, Y(y))$ is a diffeomorphism of the torus. It lies in Diff_0: the family $Y_s = (1-s)\,y + s\,Y(y)$, $0 \le s \le 1$, consists of

diffeomorphisms (each has $Y_s' > 0$ and $Y_s(y+1) = Y_s(y) + 1$) joining the identity to α. Now

$$\begin{aligned} g &\overset{(1)}{=} \mathrm{d}x^2 + c^2\,\mathrm{d}Y^2 \\ &\overset{(2)}{=} c \cdot \frac{1}{c}\,|\mathrm{d}x + ic\,\mathrm{d}Y|^2 \\ &\overset{(3)}{=} \alpha^*\big(e^\sigma\,\hat{g}_\tau\big), \qquad e^\sigma = c, \quad \tau = ic. \end{aligned}$$

(1) $\mathrm{d}Y = \frac{f}{c}\,\mathrm{d}y$, so $f^2\mathrm{d}y^2 = c^2\mathrm{d}Y^2$.
(2) $|\mathrm{d}x + ic\,\mathrm{d}Y|^2 = \mathrm{d}x^2 + c^2\mathrm{d}Y^2$; multiply and divide by c.
(3) Compare with $\hat{g}_\tau = \frac{1}{\tau_2}\,|\mathrm{d}x + \tau\mathrm{d}y|^2$ at $\tau = ic$, written in the coordinates $(x, Y) = \alpha(x, y)$.

So the modulus is $\tau = i\int_0^1 f$, and the Weyl factor is the constant c, equal to the area of g. Two special cases make the point:

- $f = 1 + \varepsilon\cos 2\pi y$: then $c = 1$ and $\tau = i$. The wiggly metric is the square torus in disguise; the wiggle is pure gauge. (At first order this is the deformation that Example 9.38 showed to be "diffeomorphism plus Weyl".)
- $f = 2$: then $\tau = 2i$, the 1×2 rectangular torus. No choice of $\alpha \in \mathrm{Diff}_0$ and σ can turn this into the square torus.

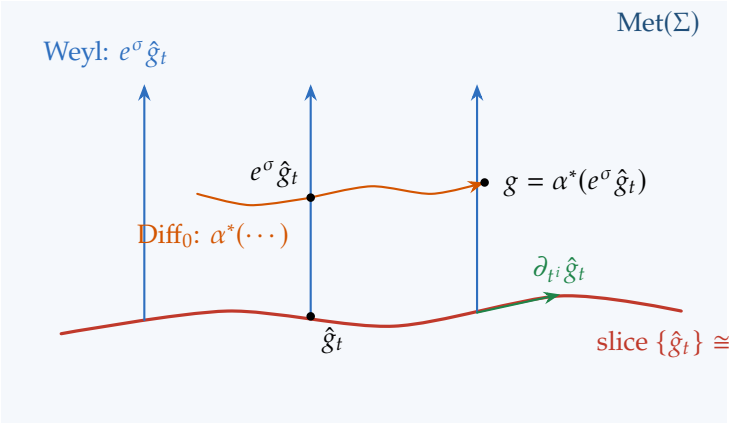

Figure 9.20: The coordinates (σ, α, t) of (9.71). Start on the finite-dimensional slice (red) at the reference metric $\hat{g}_t$; move up a Weyl line (blue) to $e^\sigma\,\hat{g}_t$; then move along a diffeomorphism orbit (orange) to g. Every metric is reached, and for $p \geq 2$ it is reached exactly once. The green arrow is a moduli direction: moving along the slice changes the conformal class.

Nash's (9.30)–(9.31). Infinitesimally, the three coordinates correspond to the three summands of the decomposition (9.60), which Nash repeats as (9.30):

$$T_g\mathrm{Met}(\Sigma) = C_g \oplus \mathrm{Range}\,P_1 \oplus \mathrm{Ker}\,P_1^\dagger.$$

Nash calls the coordinates $\{\sigma\}$ (with $f = e^\sigma \in C^\infty_+$), $\{P_1V\}$ (he writes $\{A_gV\}$) and $\{\mathcal{T}_p\}$, and writes the measure as

$$\mathcal{D}\mathrm{Met}(\Sigma) = N(f, P_1V, \mathcal{T}_p)\;\mathcal{D}\sigma\;\mathcal{D}(P_1V)\;\mathrm{d}\mathcal{T}_p, \tag{9.72}$$

with N "an appropriate normalising factor depending on the frames used". Two things need explaining: how $\mathcal{D}(P_1V)$ is related to a measure on vector fields (this produces the determinant), and what exactly $\mathrm{d}\mathcal{T}_p$ is (this produces the Weil–Petersson measure). Both come from one finite-dimensional fact about volumes.

9.3.7 The volume of the image of a linear map

Key idea: Image measure

Let $A : \mathbb{R}^k \to \mathbb{R}^n$ be linear and injective, $k \le n$. The image $A(\mathbb{R}^k)$ is a k-dimensional subspace, with the length measure inherited from $\mathbb{R}^n$. Then

$$\mathrm{d}^k(Av) = \sqrt{\det\bigl(A^{\mathsf{T}}A\bigr)}\,\mathrm{d}^k v\,: \tag{9.73}$$

the unit cube in $\mathbb{R}^k$ is mapped to a parallelepiped of k-volume $\sqrt{\det A^{\mathsf{T}}A}$.

Why: the image of the unit cube is spanned by the columns $a_1, \dots, a_k$ of A. The k-volume of a parallelepiped is the square root of the Gram determinant $\det\langle a_i, a_j\rangle$ (for $k = n$ this is $|\det A|$; for $k = 1$ it is the length $|a_1|$; in general it is what (9.40) says, for the induced metric on the image). And $\langle a_i, a_j\rangle = (A^{\mathsf{T}}A)_{ij}$.

Worked example 9.45: Two image volumes

(a) $A = \begin{pmatrix}1\\1\end{pmatrix} : \mathbb{R} \to \mathbb{R}^2$. The unit interval maps to the segment from $(0,0)$ to $(1,1)$, of length $\sqrt{2}$, and indeed $A^{\mathsf{T}}A = 2$.

(b) $A = \begin{pmatrix}1 & 0\\ 0 & 1\\ 1 & 1\end{pmatrix} : \mathbb{R}^2 \to \mathbb{R}^3$. The columns are $a_1 = (1,0,1)$ and $a_2 = (0,1,1)$. The area of the parallelogram they span is the length of the cross product,

$$|a_1 \times a_2| \overset{(1)}{=} |(0\cdot 1 - 1\cdot 1,\ 1\cdot 0 - 1\cdot 1,\ 1\cdot 1 - 0\cdot 0)| = |(-1,-1,1)| = \sqrt{3},$$

$$\sqrt{\det A^{\mathsf{T}}A} \overset{(2)}{=} \sqrt{\det\begin{pmatrix}2 & 1\\ 1 & 2\end{pmatrix}} = \sqrt{4-1} = \sqrt{3}.$$

(1) Cross product in components, $(a_1 \times a_2)_1 = a_{1,2}a_{2,3} - a_{1,3}a_{2,2}$ and cyclically.
(2) $\langle a_1, a_1\rangle = \langle a_2, a_2\rangle = 2$ and $\langle a_1, a_2\rangle = 1$.

The two answers agree, as (9.73) promised.

Nash's (9.32). Apply (9.73) with $A = P_1$, $\mathbb{R}^k = \mathrm{vect}(\Sigma)$ with the metric $\langle\ ,\ \rangle_{\mathrm{vect}}$, and $\mathbb{R}^n = C_g^{\perp}$ with $\langle\ ,\ \rangle_{\mathrm{met}}$:

$$\mathcal{D}(P_1 V) = \sqrt{\det\bigl(P_1^{\dagger}P_1\bigr)}\,\mathcal{D}V. \tag{9.74}$$

Here $P_1^{\dagger}$ is the adjoint computed in (9.58), the infinite-dimensional version of A^{T}, and the determinant is zeta-regularised: $P_1^{\dagger}P_1 = -2(\nabla^2 + K)$ is a positive Laplace-type operator (Example 9.39), so Section 9.1.10 applies to it. Formula (9.74) needs P_1 to be injective, i.e. $\operatorname{Ker} P_1 = 0$. By the Weitzenböck argument this holds for $p \ge 2$, and fails for the sphere and the torus (Section 9.3.10 below).

Watch out: What is being measured

$\mathcal{D}(P_1 V)$ is a measure on the *subspace* $\operatorname{Range} P_1$ of $C_g^{\perp}$. $\mathcal{D}V$ is a measure on $\mathrm{vect}(\Sigma)$, i.e. on the Lie algebra of Diff_0, and after exponentiation on Diff_0 itself. The determinant converts one into the other. It is *not* the Jacobian of a map from a space to itself, which is why it

comes as a square root of $\det P_1^\dagger P_1$ rather than as $\det P_1$ (the latter would not even make sense: P_1 maps between two different spaces).

9.3.8 The Jacobian is triangular

Now compute the Jacobian of the change of variables $(\sigma, \alpha, t) \mapsto g$ in (9.71). Because of the gauge invariance of the integrand, we only need it at $\alpha = \mathrm{id}$, $\sigma = 0$, i.e. at the point $g = \hat{g}_t$ of the slice. (At other points it is obtained by transporting with the gauge group, which acts by isometries of $\langle\ ,\ \rangle_{\mathrm{met}}$, Example 9.29; we come back to the σ-dependence in the normalisation N below.) First a finite-dimensional warm-up.

Worked example 9.46: A triangular Jacobian in $\mathbb{R}^3$

Let $e_1 = (1,0,0)$, $a = (c,r,0)$ and $b = (u,w,m)$ be three vectors in $\mathbb{R}^3$, and use (s,v,t) as coordinates via $x = s\,e_1 + v\,a + t\,b$. The Jacobian is

$$\left|\det \frac{\partial x}{\partial(s,v,t)}\right| \overset{(1)}{=} \left|\det \begin{pmatrix} 1 & c & u \\ 0 & r & w \\ 0 & 0 & m \end{pmatrix}\right| \overset{(2)}{=} |r\,m|\,.$$

(1) The columns are e_1, a and b.
(2) The determinant of a triangular matrix is the product of its diagonal entries.

The off-diagonal entries c, u, w do not matter. Geometrically, $1 = |e_1|$; r is the component of a orthogonal to e_1; and m is the component of b orthogonal to the plane of e_1 and a. So *the volume element is the product of the "new" orthogonal components*, taken in order.

The dictionary with strings: e_1 is the Weyl direction, a is a diffeomorphism direction (which has a Weyl component c, its trace), and b is a moduli direction (which may have both a Weyl component u and a diffeomorphism component w). Let us check that the infinite-dimensional Jacobian has exactly this triangular form.

At $g = \hat{g}_t$, a small change $(\delta\sigma, \delta V, \delta t)$ of the coordinates changes the metric by

$$\begin{aligned} \delta g &\overset{(1)}{=} \delta\sigma\, g + \mathcal{L}_{\delta V} g + \delta t^i\, \partial_i \hat{g}_t \\ &\overset{(2)}{=} \Big[\delta\sigma + \nabla_c \delta V^c + \tfrac{1}{2}\,\delta t^i\, \mathrm{tr}(\partial_i \hat{g}_t)\Big] g \;+\; P_1\big(\delta V + \delta t^i W_i\big) \;+\; \delta t^i\, \Pi\, \partial_i \hat{g}_t . \end{aligned} \tag{9.75}$$

(1) Differentiate $\alpha^*(e^\sigma \hat{g}_t)$: at $\sigma = 0$, $e^{\delta\sigma} = 1 + \delta\sigma$; the flow of δV changes g by $\mathcal{L}_{\delta V} g$ (Section 9.2.5); and $\partial_i = \partial/\partial t^i$.
(2) Split each term with (9.60). For the Lie derivative, (9.51) gives $\mathcal{L}_V g = (\nabla_c V^c)\, g + P_1 V$. For the moduli direction, the trace part is $\frac{1}{2}\,\mathrm{tr}(\partial_i \hat{g}_t)\, g$, the projection Π onto $\mathrm{Ker}\, P_1^\dagger$ gives the moduli part, and what is left is traceless and orthogonal to $\mathrm{Ker}\, P_1^\dagger$, hence in $\mathrm{Range}\, P_1$ by (9.59): it equals $P_1 W_i$ for some vector field W_i.

In block form, with rows labelled by the three orthogonal summands and columns by the three kinds of coordinate change,

$$\begin{pmatrix} [\delta g]_{C_g} \\ [\delta g]_{\mathrm{Range}\, P_1} \\ [\delta g]_{\mathrm{Ker}\, P_1^\dagger} \end{pmatrix} = \begin{pmatrix} \mathbf{1} & \nabla_c(\cdot)^c & \frac{1}{2}\,\mathrm{tr}\,\partial_i \hat{g} \\ 0 & P_1 & P_1 W_i \\ 0 & 0 & \Pi\,\partial_i \hat{g} \end{pmatrix} \begin{pmatrix} \delta\sigma \\ \delta V \\ \delta t^i \end{pmatrix}. \tag{9.76}$$

It is block upper triangular, exactly as in Example 9.46. So the volume element is the product of the three diagonal "volumes":

- the C_g block is the identity (times g): it gives $\mathcal{D}\sigma$, with the normalisation fixed by the metric $\langle \delta\sigma\, g, \delta\sigma\, g\rangle_{\text{met}} = 2\int \sqrt{g}\,(\delta\sigma)^2$;
- the Range P_1 block is P_1: by (9.74) it gives $\sqrt{\det P_1^\dagger P_1}\;\mathcal{D}V$;
- the $\operatorname{Ker} P_1^\dagger$ block is the finite matrix of vectors $\Pi\,\partial_i \hat{g}_t$, $i = 1, \dots, n$: by (9.73) it gives $\sqrt{\det\langle \Pi\partial_i \hat{g}_t, \Pi\partial_j \hat{g}_t\rangle_{\text{met}}}\;\mathrm{d}^n t$.

Key idea: The moduli volume element is the Weil–Petersson volume

By the pitfall "Which lift?" after the Weil–Petersson definition, $\langle \Pi X, \Pi Y\rangle_{\text{met}}$ is the Weil–Petersson inner product of the projected vectors. So the moduli block contributes

$$\mathrm{d}\mu(\mathcal{T}_p) = \sqrt{\det\big(G^{\text{wp}}_{ij}(t)\big)}\;\mathrm{d}^n t, \qquad G^{\text{wp}}_{ij} = \langle \partial_{t^i}, \partial_{t^j}\rangle_{\text{wp}} = \langle \Pi\partial_i \hat{g}_t, \Pi\partial_j \hat{g}_t\rangle_{\text{met}}, \tag{9.77}$$

the Riemannian volume element (9.40) of the Weil–Petersson metric. This is the measure Nash calls $\mathrm{d}\mu(\mathcal{T}_p)$ (he writes $\mathrm{d}\mathcal{T}_p$ in (9.31)). It does not depend on how the representatives $\hat{g}_t$ were chosen: changing the choice changes $\partial_i \hat{g}_t$ only by gauge directions, which Π kills.

Worked example 9.47: The moduli block for the torus

For $\hat{g}_\tau$ of (9.42), with $t = (\tau_1, \tau_2)$: the tangent vectors $\partial_{\tau_i}\hat{g}_\tau$ are constant on the torus and traceless, so $\operatorname{tr}(\partial_i \hat{g}) = 0$, $W_i = 0$ and $\Pi\partial_i \hat{g} = \partial_i \hat{g}$. The matrix (9.76) is then block *diagonal* in its last column, and

$$\sqrt{\det G^{\text{wp}}}\;\mathrm{d}\tau_1\mathrm{d}\tau_2 = \sqrt{\det\begin{pmatrix} 2/\tau_2^2 & 0 \\ 0 & 2/\tau_2^2 \end{pmatrix}}\,\mathrm{d}\tau_1\mathrm{d}\tau_2 = \frac{2\,\mathrm{d}\tau_1\,\mathrm{d}\tau_2}{\tau_2^2},$$

using (9.70). This is the hyperbolic area element (times 2).

The normalising factor N. The flat measures $\mathcal{D}\sigma$ and $\mathcal{D}V$ are defined by the metrics $2\int \sqrt{g}\,(\delta\sigma)^2$ and $\int \sqrt{g}\, g_{ab}\delta V^a \delta V^b$, and *both depend on the metric* g, through $\sqrt{g}$ and g_{ab}. When we move off the slice by a Weyl rescaling, these measures change. That change is what Nash hides in $N(f, P_1 V, \mathcal{T}_p)$. It is not innocent: it is one of the two sources (with the Weyl dependence of the determinants) of the conformal anomaly of Section 9.2.11. With $d = 26$ all the σ-dependence cancels, and N can be taken to be a constant, which we drop.

9.3.9 Dividing out the gauge volumes

We can now do the integral. Write the integrand of (9.28) with $d = 26$ as

$$F(g) = \left(\frac{\det'(\Delta_g/2)}{(1,1)_g}\right)^{-13}.$$

It is invariant under diffeomorphisms (the spectrum of Δ_g and the area do not change when g is pulled back by a diffeomorphism), and, for $d = 26$, the combination of F with the measure is invariant under Weyl rescalings. Take first $p \geq 2$, where $\operatorname{Ker} P_1 = 0$ and Diff_0 acts freely.

$$
\begin{aligned}
Z_p &\overset{(1)}{=} \frac{1}{\operatorname{vol}(C_+^\infty)\,\operatorname{vol}(\mathrm{Diff}^+)} \int_{\mathrm{Met}(\Sigma)} \mathcal{D}\mathrm{Met}\; F(g) \\
&\overset{(2)}{=} \frac{1}{\operatorname{vol}(C_+^\infty)\,\operatorname{vol}(\mathrm{Diff}^+)} \int \mathcal{D}\sigma \int_{\mathrm{Diff}_0} \mathcal{D}V \int_{\mathcal{T}_p} \mathrm{d}\mu(\mathcal{T}_p)\, \sqrt{\det P_1^\dagger P_1}\; F(\hat{g}_t) \\
&\overset{(3)}{=} \frac{\operatorname{vol}(C_+^\infty)\,\operatorname{vol}(\mathrm{Diff}_0)}{\operatorname{vol}(C_+^\infty)\,\operatorname{vol}(\mathrm{Diff}^+)} \int_{\mathcal{T}_p} \mathrm{d}\mu(\mathcal{T}_p)\, \sqrt{\det P_1^\dagger P_1}\; F(\hat{g}_t) \\
&\overset{(4)}{=} \frac{1}{|\Gamma_\Sigma|} \int_{\mathcal{T}_p} \mathrm{d}\mu(\mathcal{T}_p) \left(\frac{\det{}'(\Delta_g/2)}{(1,1)_g} \right)^{-13} \sqrt{\det P_1^\dagger P_1} \\
&\overset{(5)}{=} \int_{\mathcal{M}_p} \mathrm{d}\mu(\mathcal{M}_p) \left(\frac{\det{}'(\Delta_g/2)}{(1,1)_g} \right)^{-13} \sqrt{\det P_1^\dagger P_1}. \qquad (9.78)
\end{aligned}
$$

(1) Nash's definition (9.34), which repeats (9.8) = (9.35).
(2) Change variables to (σ, α, t) with the triangular Jacobian of Section 9.3.8; by gauge invariance the integrand and the Jacobian at $\alpha^*(e^\sigma \hat{g}_t)$ equal those at $\hat{g}_t$; the map $(\sigma, \alpha, t) \mapsto g$ is one-to-one for $p \geq 2$.
(3) Nothing depends on σ or α any more, so these integrals give the volumes of the Weyl group and of Diff_0.
(4) Diff^+ is the disjoint union of $|\Gamma_\Sigma|$ cosets of Diff_0, one for each element of the mapping class group (9.36), each with the same volume; so $\operatorname{vol}(\mathrm{Diff}^+) = |\Gamma_\Sigma| \operatorname{vol}(\mathrm{Diff}_0)$. Write g for $\hat{g}_t$.
(5) The integrand is Diff^+-invariant, hence constant on Γ_Σ-orbits in $\mathcal{T}_p$, so the integral over $\mathcal{T}_p$ is $|\Gamma_\Sigma|$ copies of the integral over a fundamental domain $\cong \mathcal{M}_p$ (the pitfall at the end of Section 9.3.4).

Every infinite volume has cancelled between numerator and denominator, and what is left is an integral over a space of dimension $6p - 6$.

Physical picture: Where each factor came from

Look at (9.78) factor by factor. $(\det{}'\Delta_g/(1,1)_g)^{-13}$ is the Gaussian integral over the 26 embedding fields, with their zero modes. $\sqrt{\det P_1^\dagger P_1}$ is the "speed" with which diffeomorphisms move metrics off the slice, the Faddeev–Popov determinant, the r of polar coordinates. $\mathrm{d}\mu(\mathcal{T}_p)$ is the volume of the slice itself, measured with the only metric available, and $1/|\Gamma_\Sigma|$ undoes the overcounting of metrics related by diffeomorphisms that cannot be deformed to the identity.

9.3.10 When P_1 has a kernel: conformal Killing vectors

For the sphere and the torus the argument breaks at one point: $\operatorname{Ker} P_1 \neq 0$. Nash puts it as follows. If $V \in \operatorname{Ker} P_1$ then

$$
P_1 V = 0 \quad \Longleftrightarrow \quad \mathcal{L}_V g = f\, g, \qquad f = \tfrac{1}{2} \operatorname{tr}(\mathcal{L}_V g) = \nabla_c V^c, \qquad (9.79)
$$

which is (9.49) with vanishing traceless part: the flow of V changes g only by a Weyl factor. Such V are the conformal Killing vectors (CKVs) of Section 9.2.5. They generate a finite-dimensional group, the **conformal Killing group** $\mathrm{CKG}(g)$: $\mathrm{PSL}(2, \mathbb{C})$ for the round sphere, the translations $U(1) \times U(1)$ for a flat torus.

Two things go wrong. First, $P_1^\dagger P_1$ has zero modes, so $\det P_1^\dagger P_1 = 0$ and (9.74) is useless as it stands. Second, the map $(\sigma, \alpha, t) \mapsto g$ is no longer one-to-one: if $\beta \in \mathrm{CKG}$, then $\beta^* \hat{g}_t = e^{\sigma_\beta} \hat{g}_t$

for some function σ_β, and (σ, α, t) and $(\sigma', \beta \circ \alpha, t)$ (with a suitably shifted σ') give the same metric. Each metric is hit once for every element of CKG.

Nash's cure (9.33) is to split the Lie algebra orthogonally,

$$\operatorname{vect}(\Sigma) = T_e \operatorname{Diff}_0(\Sigma) = \operatorname{Ker} P_1 \oplus \operatorname{Ker}^{\perp} P_1, \tag{9.80}$$

using $\langle\ ,\ \rangle_{\mathrm{vect}}$, and to treat the two pieces separately: on $\operatorname{Ker}^{\perp} P_1$ the operator is injective and (9.74) holds with the determinant restricted to non-zero modes; the $\operatorname{Ker} P_1$ directions are integrated separately and give the volume of CKG. The finite-dimensional model is a group acting with a stabiliser.

Worked example 9.48: Dividing by $\mathrm{SO}(3)$: a stabiliser appears

Let $F(x) = F(|x|)$ on $\mathbb{R}^3$ and divide by $G = \mathrm{SO}(3)$. Normalise the metric on G so that each rotation by angle θ about a fixed axis is a path of length θ; then $\operatorname{vol}\mathrm{SO}(3) = 8\pi^2$ and the stabiliser of a point, the rotations about one axis, has $\operatorname{vol}\mathrm{SO}(2) = 2\pi$. The slice is the positive x^3-axis, $x = (0, 0, r)$. The infinitesimal action is $A : \mathfrak{so}(3) = \mathbb{R}^3 \to \mathbb{R}^3$, $A(\omega) = \omega \times x$:

$$A(\omega) \overset{(1)}{=} (\omega_2\, r,\ -\omega_1\, r,\ 0), \qquad A^{\mathsf{T}}A = \begin{pmatrix} r^2 & 0 & 0 \\ 0 & r^2 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

$$\sqrt{\det{}' A^{\mathsf{T}}A} \overset{(2)}{=} \sqrt{r^2 \cdot r^2} = r^2.$$

(1) $\omega \times (0, 0, r) = (\omega_2 r - \omega_3 \cdot 0,\ \omega_3 \cdot 0 - \omega_1 r,\ 0)$. Rotations about the x^3-axis (ω_3) do not move the point: $\operatorname{Ker} A$ is the Lie algebra of the stabiliser.

(2) $\det'$ is the product of the non-zero eigenvalues.

Now compare the two sides of the gauge-fixed formula:

$$\begin{aligned} \frac{1}{\operatorname{vol}\mathrm{SO}(3)} \int_{\mathbb{R}^3} \mathrm{d}^3x\, F(|x|) &\overset{(1)}{=} \frac{1}{8\pi^2} \int_0^\infty 4\pi r^2 F(r)\, \mathrm{d}r \\ &\overset{(2)}{=} \frac{1}{2\pi} \int_0^\infty r^2 F(r)\, \mathrm{d}r \\ &\overset{(3)}{=} \frac{1}{\operatorname{vol}(\text{stabiliser})} \int_{\text{slice}} \mathrm{d}r\ \sqrt{\det{}' A^{\mathsf{T}}A}\ F(r). \end{aligned}$$

(1) Spherical coordinates: the orbit through $(0, 0, r)$ is a sphere of area $4\pi r^2$.

(2) $4\pi/8\pi^2 = 1/2\pi$.

(3) 2π is the volume of the stabiliser $\mathrm{SO}(2)$, and $r^2 = \sqrt{\det{}' A^{\mathsf{T}}A}$.

So when the group has a stabiliser, the gauge-fixed integral contains the *primed* Faddeev–Popov determinant and a factor $1/\operatorname{vol}(\text{stabiliser})$.

For strings the stabiliser is $\mathrm{CKG}(\hat{g}_t)$, its Lie algebra is $\operatorname{Ker} P_1$, and the same bookkeeping gives, for $p = 0, 1$,

$$Z_p = \frac{1}{|\Gamma_\Sigma|} \int_{\mathcal{T}_p} \mathrm{d}\mu(\mathcal{T}_p)\ \frac{1}{\operatorname{vol}\mathrm{CKG}(\hat{g}_t)} \left(\frac{\det'(\Delta_g/2)}{(1,1)_g} \right)^{-13} \sqrt{\det{}' P_1^{\dagger} P_1}, \tag{9.81}$$

with the volume of CKG computed with the metric $\langle\ ,\ \rangle_{\mathrm{vect}}$ restricted to $\operatorname{Ker} P_1$. Nash writes $\tilde{A}_g$ for "P_1 restricted to $\operatorname{Ker}^{\perp} P_1$", so that $\det(\tilde{A}_g^{*}\tilde{A}_g) = \det' P_1^{\dagger} P_1$, and absorbs the volume factor into the measure.

Worked example 9.49: The conformal Killing group of a flat torus has volume $(1,1)_g$

On $\mathbb{R}^2/\mathbb{Z}^2$ with the flat metric $\hat{g}_\tau$, the CKVs are the constant vector fields $V = v^1\partial_x + v^2\partial_y$ (Example 9.39), and they generate the translations $(x,y) \mapsto (x+v^1, y+v^2)$. Translating by $v \in \mathbb{Z}^2$ is the identity map, so the group is $\{v\}/\mathbb{Z}^2$, a torus of parameters $v \in [0,1)^2$. Its volume in the metric $\langle V, V\rangle_{\text{vect}}$ is

$$\begin{aligned}\operatorname{vol}\mathrm{CKG} &\overset{(1)}{=} \int_{[0,1)^2} \mathrm{d}^2v\, \sqrt{\det\big(\langle\partial_{v^a}, \partial_{v^b}\rangle_{\text{vect}}\big)} \\ &\overset{(2)}{=} \int_{[0,1)^2} \mathrm{d}^2v\, \sqrt{\det\Big((1,1)_{\hat{g}}\,\hat{g}_{ab}\Big)} \\ &\overset{(3)}{=} (1,1)_{\hat{g}}\,\sqrt{\det\hat{g}_{ab}} = 1.\end{aligned}$$

(1) Riemannian volume (9.40) on the group, with coordinates v^a.

(2) For constant V, $\langle V, W\rangle_{\text{vect}} = \int \sqrt{\hat{g}}\,\hat{g}_{ab}V^aW^b = (1,1)_{\hat{g}}\,\hat{g}_{ab}V^aW^b$, since $\hat{g}_{ab}$ is constant.

(3) det of the 2×2 matrix $(1,1)\hat{g}_{ab}$ is $(1,1)^2 \det\hat{g}$; and $(1,1)_{\hat{g}} = 1 = \det\hat{g}_{ab}$ for $\hat{g}_\tau$.

For a torus of area $(1,1)_g$ (i.e. $g = c\,\hat{g}_\tau$, $c = (1,1)_g$) the same computation gives $\operatorname{vol}\mathrm{CKG} = c\cdot c = (1,1)_g^2$ up to the normalisation of $\mathcal{D}V$. In the slice $\mathrm{Met}_{\text{const}}$ we have fixed the area to 1, so for the torus the CKG factor is simply 1.

Watch out: The sphere has an infinite conformal Killing group

For $p = 0$, CKG = PSL$(2,\mathbb{C})$, a non-compact six-dimensional group. Its volume is infinite, so (9.81) says $Z_0 = 0$ (or, more honestly, is undefined). This is not a mistake: the sphere with no insertions has no moduli, and the residual gauge symmetry cannot be fixed. Physically meaningful sphere amplitudes have at least three vertex operators, whose positions absorb the six real CKV parameters (Example 9.58). Nash's formula is written for all p, but it is the genus $p \geq 1$ terms that make sense as they stand.

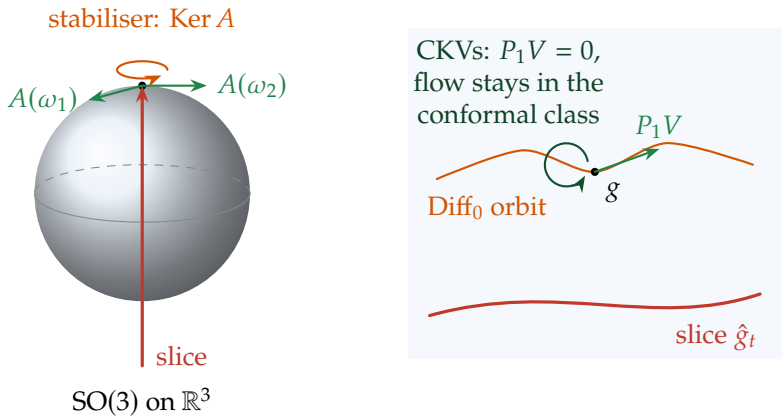

Figure 9.21: Stabilisers. Left: rotations about the vertical axis do not move the north pole; they span Ker A and must be integrated separately, giving $1/\mathrm{vol}(\mathrm{SO}(2))$. Right: for the sphere and the torus, the flows of conformal Killing vectors move g only inside its Weyl orbit (they are not seen by P_1); they span Ker P_1, and the path integral picks up $1/\operatorname{vol}\mathrm{CKG}$ and a primed determinant.

9.3.11 The Faddeev–Popov determinant as a ghost integral

Physicists rarely write $\sqrt{\det{}' P_1^\dagger P_1}$ as it stands. They write it as a Gaussian integral over anticommuting fields, the Faddeev–Popov **ghosts**. This makes the determinant look like one more field theory living on the world sheet, which is what allows it to be treated with the same tools (conformal field theory, Chapter 11) as the matter fields. Here is why it works.

Grassmann integration in one line. Anticommuting variables $\theta_i, \bar\theta_i$ satisfy $\theta_i\theta_j = -\theta_j\theta_i$ (so $\theta_i^2 = 0$), and the Berezin integral is defined by $\int \mathrm{d}\theta\, 1 = 0$, $\int \mathrm{d}\theta\, \theta = 1$, and likewise for $\bar\theta$. For one pair and a number λ,

$$\int \mathrm{d}\bar\theta\, \mathrm{d}\theta\; e^{-\bar\theta\lambda\theta} \overset{(1)}{=} \int \mathrm{d}\bar\theta\, \mathrm{d}\theta\; (1 - \lambda\,\bar\theta\theta) \overset{(2)}{=} \int \mathrm{d}\bar\theta\, \mathrm{d}\theta\; (1 + \lambda\,\theta\bar\theta) \overset{(3)}{=} \lambda.$$

(1) The power series of the exponential stops after the linear term, because $(\bar\theta\theta)^2 = \bar\theta\theta\bar\theta\theta = -\bar\theta\bar\theta\theta\theta = 0$.
(2) Anticommute: $\bar\theta\theta = -\theta\bar\theta$.
(3) $\int \mathrm{d}\theta\, \theta = 1$ does the inner integral, leaving $\int \mathrm{d}\bar\theta\, \bar\theta = 1$; the constant 1 integrates to zero.

Compare the ordinary Gaussian $\int \mathrm{d}\bar z\, \mathrm{d}z\, e^{-\bar z \lambda z} \propto \lambda^{-1}$: the Grassmann integral gives the determinant in the *numerator*.

Worked example 9.50: The 2×2 Grassmann Gaussian

Let M be a 2×2 matrix and $S = \bar\theta_i M_{ij} \theta_j$. Only the term of the exponential containing all four generators survives the integral, and it comes from $\frac{1}{2}S^2$. Its coefficient is

$$\begin{aligned} \tfrac{1}{2}S^2 &\overset{(1)}{=} \tfrac{1}{2} \sum_{i,j,k,l} M_{ij}M_{kl}\, \bar\theta_i\theta_j\bar\theta_k\theta_l \\ &\overset{(2)}{=} \left(M_{11}M_{22}\, \bar\theta_1\theta_1\bar\theta_2\theta_2 + M_{12}M_{21}\, \bar\theta_1\theta_2\bar\theta_2\theta_1\right) + \cdots \\ &\overset{(3)}{=} \left(M_{11}M_{22} - M_{12}M_{21}\right) \bar\theta_1\theta_1\bar\theta_2\theta_2 + \cdots = \det M\; \bar\theta_1\theta_1\bar\theta_2\theta_2 + \cdots . \end{aligned}$$

(1) Square the sum.
(2) Keep terms with $\{i,k\} = \{1,2\}$ and $\{j,l\} = \{1,2\}$. The terms with $i = 2, k = 1$ equal those with $i = 1, k = 2$ (the bilinears $\bar\theta_i\theta_j$ are even, so they commute), which cancels the $\frac{1}{2}$. The dots are terms with a repeated generator, which vanish.
(3) Move θ_1 two places to the left (two sign changes), then swap $\theta_2\bar\theta_2 = -\bar\theta_2\theta_2$: one net minus sign.

With $\int \mathrm{d}\bar\theta_1\mathrm{d}\theta_1\mathrm{d}\bar\theta_2\mathrm{d}\theta_2\; \bar\theta_1\theta_1\bar\theta_2\theta_2 = 1$ (the normalisation fixed by the one-pair case), the integral is $\det M$. The same bookkeeping gives $\det M$ for any $n\times n$ matrix.

Key idea: The b, c ghosts

Introduce an anticommuting vector field c^a (the **c-ghost**, living in the space $\mathrm{vect}(\Sigma)$ of the gauge parameters) and an anticommuting traceless symmetric tensor b_{ab} (the **b-ghost**,

living in $C_g^{\perp}$ where the gauge directions point). Then, formally,

$$\sqrt{\det{}' P_1^\dagger P_1} = \int \mathcal{D}b\,\mathcal{D}c\ \exp\Big[-\frac{1}{4\pi}\int_\Sigma \mathrm{d}^2x\,\sqrt{g}\ b^{ab}(P_1 c)_{ab}\Big] \quad \text{(non-zero modes only)}, \tag{9.82}$$

up to a constant. The exponent is $\langle b, P_1 c\rangle_{\text{met}}$: in an orthonormal basis of $\mathrm{Ker}^{\perp} P_1$ and a matching one of $\mathrm{Range}\, P_1$, P_1 is a square matrix whose determinant has absolute value $\sqrt{\det P_1^\dagger P_1}$. The normalisation $\frac{1}{4\pi}$ is the conventional one; it only rescales the result by a constant. In complex coordinates the ghost action is $\frac{1}{2\pi}\int \mathrm{d}^2z\,(b_{zz}\partial_{\bar z}c^z + \text{c.c.})$, which is the first-order "bc system" of conformal field theory (Chapter 11).

Physical picture: Ghost zero modes are CKVs and moduli

A Grassmann integral over a variable that does not appear in the exponent is zero: $\int \mathrm{d}\theta\, 1 = 0$. So if we did not remove the zero modes, the ghost integral would vanish. The zero modes of c are the solutions of $P_1 c = 0$, the CKVs; those of b are the solutions of $P_1^\dagger b = 0$, the holomorphic quadratic differentials, i.e. the moduli directions. In the ghost language, the c zero modes are soaked up by fixing the positions of vertex operators (Example 9.58), and the b zero modes are soaked up by the moduli integral: pairing b with the moduli deformations $\partial_i \hat g_t$ reproduces the Weil–Petersson (or rather the equivalent Gram-determinant) factor. This is the dictionary row "$\mathrm{Ker}\, A_g, \mathrm{Ker}\, A_g^* \leftrightarrow$ ghost zero modes" of Section 9.2.7, and it is the reason why the index $\dim\mathrm{Ker}\, P_1 - \dim\mathrm{Ker}\, P_1^\dagger = 3\chi$ counts the "ghost number anomaly".

9.3.12 Real versus complex determinants: Nash's (9.36)

Nash ends with a remark: P_1 ($= A_g$) is a *real* operator, but in terms of the $\bar\partial$-operators of Chapter 5,

$$\det\big(\tilde A_g^* \tilde A_g\big) = \big(\det(\bar\partial_{K_\Sigma}^* \bar\partial_{K_\Sigma^*})\big)^2, \tag{9.83}$$

so that $\sqrt{\det \tilde A_g^* \tilde A_g} = \det \bar\partial_{K^*}^* \bar\partial_{K^*}$. Here K_Σ is the canonical bundle (the holomorphic cotangent bundle, spanned locally by $\mathrm{d}z$), and $K_\Sigma^* = K_\Sigma^{-1}$ is its dual, the holomorphic tangent bundle, spanned by ∂_z. Two facts combine to give (9.83).

Fact 1: P_1 is complex-linear. Identify a real vector field $V = V^a\partial_a$ with its holomorphic component V^z, a section of K^{-1} (the real vector field is $V^z\partial_z + \overline{V^z}\partial_{\bar z}$). Identify a traceless tensor h with its component $h_{\bar z\bar z}$. By (9.55), $(P_1 V)_{\bar z\bar z} = \rho\,\partial_{\bar z} V^z$: in these complex variables P_1 is ρ times $\bar\partial_{K^{-1}}$, and multiplying V^z by i (rotating the vector field by 90°) multiplies $P_1 V$ by i. So P_1, and with it $P_1^\dagger P_1$, is a complex-linear operator on the complex line bundle K^{-1}.

Fact 2: a complex operator has real determinant $|\det|^2$.

Worked example 9.51: Real determinant of a complex matrix

One dimension. Multiplication by $\lambda = a + ib$ on $\mathbb{C} \cong \mathbb{R}^2$ sends $x + iy$ to $(ax - by) + i(bx + ay)$, so its real matrix and determinant are

$$\begin{pmatrix} a & -b \\ b & a \end{pmatrix}, \qquad \det_{\mathbb{R}} = a^2 + b^2 = |\lambda|^2 = |\det_{\mathbb{C}}\lambda|^2 .$$

n dimensions. Triangularise a complex $n \times n$ matrix L by a unitary change of basis (Schur): $L = UTU^{-1}$ with T upper triangular, diagonal entries $\lambda_1, \dots, \lambda_n$. As a real $2n \times 2n$ matrix, T is block upper triangular with the 2×2 blocks above on the diagonal, and U becomes a rotation of $\mathbb{R}^{2n}$ (determinant 1). Hence

$$\det_{\mathbb{R}} L \overset{(1)}{=} \det_{\mathbb{R}} T \overset{(2)}{=} \prod_{k=1}^{n} |\lambda_k|^2 \overset{(3)}{=} |\det_{\mathbb{C}} L|^2 .$$

(1) Similar matrices have equal determinants.
(2) A block triangular matrix has determinant the product of the determinants of its diagonal blocks, each $|\lambda_k|^2$.
(3) $\det_{\mathbb{C}} L = \prod_k \lambda_k$.

If L is Hermitian and positive, $\det_{\mathbb{C}} L > 0$ and $\det_{\mathbb{R}} L = (\det_{\mathbb{C}} L)^2$.

Apply this to the positive self-adjoint complex operator $P_1^\dagger P_1$ on $\operatorname{Ker}^\perp P_1$ (every eigenvalue appears twice as a real operator: V^z and iV^z are real-independent eigenvectors with the same eigenvalue). The zeta functions obey $\zeta^{\mathbb{R}}(s) = 2\zeta^{\mathbb{C}}(s)$, so $\det'_{\mathbb{R}} = \exp(-2\zeta^{\mathbb{C}\prime}(0)) = (\det'_{\mathbb{C}})^2$. That is Nash's statement, with $\bar\partial^*_{K^*}\bar\partial_{K^*}$ standing for the complex operator $P_1^\dagger P_1$ (up to the factor ρ and a constant, which rescale the determinant in a controlled way, Example 9.26).

Worked example 9.52: Checking on the flat square torus

Take $\hat g = \delta$ on $\mathbb{R}^2/\mathbb{Z}^2$ ($\rho = 1$). By Example 9.39, $P_1^\dagger P_1 = -2\nabla^2 = 2\Delta$ acting on each Cartesian component of V. On the Fourier mode $V^z = e^{2\pi i(nx+my)}$,

$$P_1^\dagger P_1 V^z \overset{(1)}{=} 2\Delta\, e^{2\pi i(nx+my)} \overset{(2)}{=} 8\pi^2(n^2+m^2)\, V^z .$$

(1) Flat metric, $K = 0$, so $P_1^\dagger P_1 = -2(\partial_x^2 + \partial_y^2)$ on components.
(2) $-\partial_x^2 - \partial_y^2$ multiplies the mode by $4\pi^2(n^2+m^2)$.

On the other hand, $\bar\partial^\dagger\bar\partial$ on functions, with $\langle f, f'\rangle = \int f\bar f'$: integrating by parts, $\int (\partial_{\bar z} f)\,\overline{f'} = -\int f\,\partial_{\bar z}\overline{f'} = -\int f\,\overline{\partial_z f'}$, so $\bar\partial^\dagger = -\partial_z$ and

$$\bar\partial^\dagger\bar\partial \overset{(1)}{=} -\partial_z\partial_{\bar z} \overset{(2)}{=} -\tfrac14(\partial_x^2+\partial_y^2) = \tfrac14\Delta.$$

(1) The adjoint just computed.
(2) $\partial_z\partial_{\bar z} = \frac14(\partial_x - i\partial_y)(\partial_x + i\partial_y) = \frac14(\partial_x^2+\partial_y^2)$.

So on the flat torus $P_1^\dagger P_1 = 8\,\bar\partial^\dagger\bar\partial$ as complex operators, and the complex eigenvalues $8\pi^2(n^2+m^2)$, $(n,m) \neq (0,0)$, each appear once in the complex count and twice in the real count. The excluded mode $(0,0)$ is the complex one-dimensional (real two-dimensional) space of CKVs.

Key idea: The final formula (Nash's (9.35)–(9.36))

With $d = 26$,

$$Z = \sum_p Z_p = \sum_p \int_{\mathcal{M}_p} \mathrm{d}\mu(\mathcal{M}_p) \left(\frac{\det'(\Delta_g/2)}{(1,1)_g} \right)^{-13} \det'\big(\bar\partial^*_{K^*_\Sigma} \bar\partial_{K^*_\Sigma}\big), \tag{9.84}$$

where g is the constant-curvature metric representing the point of $\mathcal{M}_p$, $\mathrm{d}\mu(\mathcal{M}_p)$ is the Weil–Petersson volume element, and for $p = 0, 1$ the determinant is restricted to the orthogonal complement of the conformal Killing vectors (with the factor $1/\mathrm{vol}\,\mathrm{CKG}$ understood). The integral over all surfaces and all embeddings has become, genus by genus, an integral over a finite-dimensional space of dimension $6p - 6$ (or 2 for the torus), of a function built from determinants of two elliptic operators.

Watch out: What (9.36) does and does not say

Nash writes det where we write det′: both determinants omit zero modes. The measure $\mathrm{d}\mu(\mathcal{M}_p)$ in (9.36) is the same as in (9.35); only the ghost factor has been rewritten. And the formula leaves out the string coupling: if the action includes the Euler characteristic term of Section 9.1.5, each Z_p is weighted by g_s^{2p-2}, and Z is the perturbation series of closed string theory. Finally, (9.36) is a *formal* result for $p \geq 2$: the integrals over $\mathcal{M}_p$ diverge near its boundary (where the surface degenerates), which is the string version of the infrared divergences caused by the tachyon, as the torus computation below shows.

9.3.13 The formula at work: the torus amplitude

Nash stops at (9.36). The formula looks forbidding: an integral over a moduli space of a ratio of zeta-regularised determinants. Is it ever a number? For the torus, yes, and computing it is the best way to see that every piece of the chapter does real work. The question for this subsection is: *what is Z_1, explicitly, as a function on the fundamental domain of Figure 9.19?* We will find

$$Z_1 = 2^{-13} \int_{\mathcal{F}} \frac{\mathrm{d}\tau_1\,\mathrm{d}\tau_2}{\tau_2^2}\, \tau_2^{-12}\, |\eta(\tau)|^{-48}, \tag{9.85}$$

where η is the Dedekind eta function defined below. On the way we meet the string's Casimir energy $-\frac{1}{24}$, the tachyon, and the reason string theory has no ultraviolet divergences.

The ingredients, genus by genus. Specialise (9.81) to $p = 1$ on the slice $\hat g_\tau$ of (9.42) (flat, area 1). We need four things:

(a) the measure $\mathrm{d}\mu(\mathcal{T}_1) = 2\,\mathrm{d}\tau_1\mathrm{d}\tau_2/\tau_2^2$ (Example 9.47);

(b) the conformal Killing group volume, which is 1 on the area-1 slice (Example 9.49);

(c) the matter factor $\big(\det'(\Delta_{\hat g_\tau}/2)/(1,1)_{\hat g_\tau}\big)^{-13}$;

(d) the ghost factor $\sqrt{\det' P_1^\dagger P_1}$.

The first two are done. The last two both reduce to a single number: the zeta-regularised determinant of the scalar Laplacian on a flat torus.

Step 1: the spectrum of the flat torus

Worked example 9.53: Eigenvalues of Δ on the torus $\hat{g}_\tau$

The torus is $\mathbb{R}^2/\mathbb{Z}^2$ with coordinates $(x, y) \sim (x+1, y) \sim (x, y+1)$ and the constant metric $\hat{g}_\tau$. The inverse of the matrix (9.42) is

$$\hat{g}_\tau^{-1} = \frac{1}{\tau_2}\begin{pmatrix} |\tau|^2 & -\tau_1 \\ -\tau_1 & 1 \end{pmatrix},$$

as one checks by multiplying: the product is $\tau_2^{-2}\,\mathrm{diag}(|\tau|^2-\tau_1^2, |\tau|^2-\tau_1^2) = \mathbf{1}$. Because the metric is constant, the Laplacian is $\Delta = -\hat{g}^{ab}\partial_a\partial_b$ (no Christoffel symbols), and the periodic functions $f_{n,m} = e^{2\pi i(nx+my)}$, $(n,m) \in \mathbb{Z}^2$, are eigenfunctions:

$$\begin{aligned} \Delta f_{n,m} &\overset{(1)}{=} -\hat{g}^{ab}\,(2\pi i k_a)(2\pi i k_b)\, f_{n,m}, \qquad k = (n,m), \\ &\overset{(2)}{=} \frac{4\pi^2}{\tau_2}\big(|\tau|^2 n^2 - 2\tau_1 nm + m^2\big) f_{n,m} \\ &\overset{(3)}{=} \frac{4\pi^2}{\tau_2}\,|m - n\tau|^2\, f_{n,m}. \end{aligned} \tag{9.86}$$

(1) Each derivative ∂_a brings down $2\pi i k_a$.
(2) Contract with the inverse metric displayed above.
(3) $|m-n\tau|^2 = (m-n\tau_1)^2 + n^2\tau_2^2 = m^2 - 2mn\tau_1 + n^2|\tau|^2$.

The Fourier modes are complete, so this is the whole spectrum. Relabelling $n \to -n$, the non-zero eigenvalues are

$$\lambda_{n,m} = \frac{4\pi^2}{\tau_2}\,|m + n\tau|^2\,, \qquad (n,m) \in \mathbb{Z}^2 \setminus \{(0,0)\}, \tag{9.87}$$

each with multiplicity one, and there is a single zero mode (the constants). *Sanity checks.* (i) At $\tau = i$ (square torus, $\hat{g} = \delta$), $\lambda = 4\pi^2(n^2+m^2)$, the familiar spectrum of $-\partial_x^2 - \partial_y^2$. (ii) Under $\tau \mapsto \tau + 1$ the set $\{m + n\tau\}$ is unchanged (replace m by $m-n$), and under $\tau \mapsto -1/\tau$ we get $|m - n/\tau|^2 / (\tau_2/|\tau|^2) = |m\tau - n|^2/\tau_2$, the same set again. The spectrum is modular invariant, as it must be: modular transformations are diffeomorphisms (Section 9.3.4), and isometric manifolds have the same spectrum.

Step 2: one row at a time, a twisted massive circle

Fix n. The row of eigenvalues is

$$\lambda_{n,m} = \frac{4\pi^2}{\tau_2}\Big[(m+b)^2 + c^2\Big], \qquad b = n\tau_1, \quad c = |n|\,\tau_2, \qquad m \in \mathbb{Z}.$$

For $n = 0$ this is ($m \neq 0$) the spectrum $(2\pi m/L)^2$ of the Laplacian on a circle of length $L = \sqrt{\tau_2}$. For $n \neq 0$ it is a circle Laplacian with a mass c and a shift b of the momentum. The shift is the Dehn twist τ_1 of the torus seen from the row: going once around the y-cycle, the x-coordinate is shifted by τ_1.

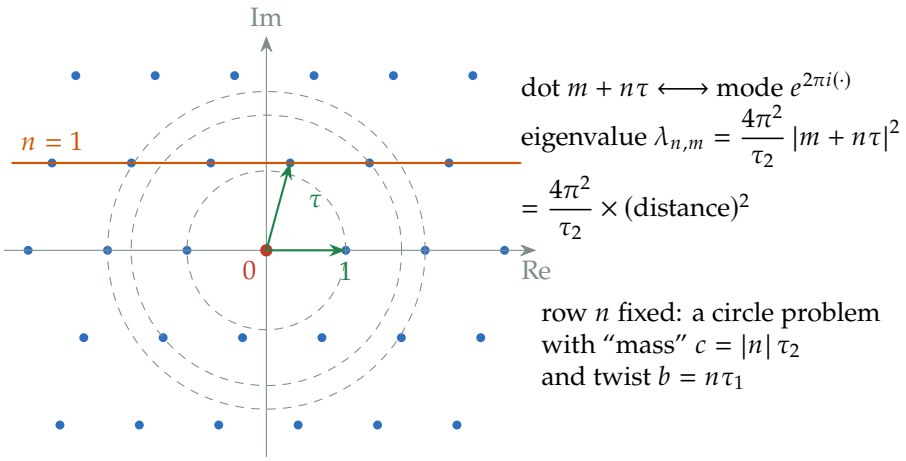

Figure 9.22: The spectrum of the flat torus is a lattice. Each dot $m + n\tau$ of the lattice $\mathbb{Z} + \tau\mathbb{Z}$ (blue) is one eigenfunction, and its eigenvalue is $4\pi^2/\tau_2$ times its squared distance from the origin; the dashed circles are eigenvalue shells. The red origin is the zero mode, dropped from det′. We compute the determinant row by row: each horizontal row (orange, fixed n) is the spectrum of a massive, twisted circle.

Worked example 9.54: The twisted massive circle: $\prod_m \left((m+b)^2 + c^2\right) = 4\,|\sin \pi(b + ic)|^2$

Let $D(b, c)$ be the zeta-regularised product of $(m + b)^2 + c^2$ over $m \in \mathbb{Z}$, with $c > 0$. We compute it in three moves.

Move 1: the untwisted case. For $b = 0$ this is the oscillator of Example 9.24 with $\beta = 2\pi$ and $\omega = c$: the eigenvalues $(2\pi m/\beta)^2 + \omega^2$ become $m^2 + c^2$, so $D(0, c) = 4\sinh^2(\omega\beta/2) = 4\sinh^2(\pi c)$.

Move 2: the twist as a convergent ratio. Write $w = b + ic$, so that $(m + b)^2 + c^2 = |m + w|^2$ and $m^2 + c^2 = |m + ic|^2$. The ratio of the two products converges once m and $-m$ are paired, so (as in Example 9.24)

$$\begin{aligned}\frac{D(b,c)}{D(0,c)} &\overset{(1)}{=} \frac{|w|^2}{c^2}\prod_{m\geq 1}\frac{|(w+m)(w-m)|^2}{|(ic+m)(ic-m)|^2}\\ &\overset{(2)}{=} \frac{|w|^2\prod_{m\geq 1}\left|1 - w^2/m^2\right|^2}{c^2\prod_{m\geq 1}\left(1 + c^2/m^2\right)^2}\\ &\overset{(3)}{=} \frac{|\sin \pi w|^2/\pi^2}{\sinh^2(\pi c)/\pi^2} = \frac{|\sin \pi w|^2}{\sinh^2(\pi c)}.\end{aligned}$$

(1) Separate the $m = 0$ factor $|w|^2/|ic|^2$, and pair m with $-m$ for $m \geq 1$.

(2) $(w + m)(w - m) = w^2 - m^2 = -m^2(1 - w^2/m^2)$ and $(ic + m)(ic - m) = -m^2(1 + c^2/m^2)$; the factors m^4 cancel between numerator and denominator.

(3) Euler's product $\sin \pi w = \pi w \prod_{m\geq 1}(1 - w^2/m^2)$, used at w and at $w = ic$, where $\sin(i\pi c) = i\sinh(\pi c)$.

Move 3: combine and rewrite. Multiplying, $D(b, c) = 4\,|\sin \pi w|^2$, and

$$\begin{aligned}D(b,c) &\overset{(1)}{=} \left|e^{i\pi w} - e^{-i\pi w}\right|^2\\ &\overset{(2)}{=} \left|e^{-i\pi w}\right|^2\,\left|1 - e^{2\pi i w}\right|^2\\ &\overset{(3)}{=} e^{2\pi c}\,\left|1 - e^{2\pi i(b+ic)}\right|^2.\end{aligned} \tag{9.88}$$

(1) $2i\sin\pi w = e^{i\pi w} - e^{-i\pi w}$, and $|2i|^2 = 4$.
(2) Factor out $e^{-i\pi w}$.
(3) $\left|e^{-i\pi(b+ic)}\right| = e^{\pi c}$.

The overall constant. The row eigenvalues carry the prefactor $a = 4\pi^2/\tau_2$. By the scaling law of Example 9.26, it contributes $a^{\zeta_{\mathrm{row}}(0)}$, and $\zeta_{\mathrm{row}}(0) = 0$ for a massive circle: the heat trace $\sum_m e^{-t((m+b)^2+c^2)} = \sqrt{\pi/t}\, e^{-tc^2} +$ (exponentially small) (Poisson summation) has no t^0 term, and by (9.34) the value $\zeta(0)$ is exactly the t^0 coefficient (minus the number of zero modes, here none). This is also why the oscillator answer did not depend on β through the prefactor $(2\pi/\beta)^2$. So a massive row contributes $D(b,c)$ with no extra constant.

Physical picture: What the twisted circle computes

$D(b,c)^{-1/2} = e^{-\pi c}\left|1 - e^{2\pi i(b+ic)}\right|^{-1}$ is the modulus of a *twisted* oscillator trace. For an oscillator of frequency ω with a phase $e^{i\theta}$ inserted per quantum,

$$\mathrm{Tr}\left(e^{-\beta H}e^{i\theta N}\right) = \sum_{k\geq 0} e^{-\beta\omega(k+\frac{1}{2})}e^{i\theta k} = \frac{e^{-\beta\omega/2}}{1 - e^{-\beta\omega+i\theta}},$$

and with $\beta\omega = 2\pi c$, $\theta = 2\pi b$ its modulus is exactly $D(b,c)^{-1/2}$. So the twist b of the torus becomes a phase per quantum. In the string, the rows n and $-n$ are the left- and right-moving oscillators of frequency n, and the Dehn twist τ_1 enters the Hamiltonian trace as the phase $e^{2\pi i\tau_1(L_0-\bar{L}_0)}$, a translation around the string.

Step 3: assemble the rows; the Dedekind eta function

Working definition 9.12 (Dedekind eta function)

For τ in the upper half-plane [$\tau = \tau_1 + i\tau_2$ with $\tau_2 > 0$, the shape of the flat torus] put $q = e^{2\pi i\tau}$ (so $|q| = e^{-2\pi\tau_2} < 1$) and

$$\eta(\tau) = q^{1/24}\prod_{n=1}^{\infty}(1-q^n), \qquad q^{1/24} := e^{2\pi i\tau/24}.$$

How to compute it: the product converges very fast; at $\tau = i$, $q = e^{-2\pi} \approx 0.00187$, and three factors already give $\eta(i) \approx 0.76823$. *Its two symmetry laws* [$\tau \to \tau + 1$ is the Dehn twist, $\tau \to -1/\tau$ exchanges the roles of the two basic loops of the torus], which we derive below from geometry: $\eta(\tau+1) = e^{i\pi/12}\eta(\tau)$ (read off from $q^{1/24}$), and $|\eta(-1/\tau)| = |\tau|^{1/2}\,|\eta(\tau)|$.

Worked example 9.55: $\det'\Delta_{\hat{g}_\tau} = \tau_2\,|\eta(\tau)|^4$

Multiply the rows of Figure 9.22. The row $n = 0$ (zero mode removed) is a circle of length $L = \sqrt{\tau_2}$, so it gives $L^2 = \tau_2$ by (9.32). For the row $n \geq 1$ we have $b + ic = n\tau_1 + in\tau_2 = n\tau$, so $e^{2\pi i(b+ic)} = q^n$; for the row $-n \leq -1$ we have $b + ic = -n\tau_1 + in\tau_2 = -n\bar{\tau}$, so $e^{2\pi i(b+ic)} = \bar{q}^{\,n}$. Hence

$$\det'\Delta_{\hat{g}_\tau} \overset{(1)}{=} \tau_2 \prod_{n\geq 1} D(n\tau_1, n\tau_2)\, D(-n\tau_1, n\tau_2)$$

$$\begin{aligned}
&\overset{(2)}{=} \tau_2 \prod_{n\geq 1} e^{2\pi n\tau_2}\,|1-q^n|^2 \cdot e^{2\pi n\tau_2}\,|1-\bar{q}^{\,n}|^2 \\
&\overset{(3)}{=} \tau_2\ \exp\Big(4\pi\tau_2 \sum_{n\geq 1} n\Big) \prod_{n\geq 1} |1-q^n|^4 \\
&\overset{(4)}{=} \tau_2\, e^{-\pi\tau_2/3} \prod_{n\geq 1} |1-q^n|^4 \\
&\overset{(5)}{=} \tau_2\ |\eta(\tau)|^4 \,. \qquad (9.89)
\end{aligned}$$

(1) The determinant is the product over rows; the $n=0$ row gives τ_2 and each massive row contributes $D(b,c)$ with no extra constant (Example 9.54).
(2) Formula (9.88) with $c = n\tau_2$ in both rows.
(3) $|1-\bar{q}^{\,n}| = |1-q^n|$, and collect the exponentials.
(4) Zeta-regularise the divergent sum: $\sum_{n\geq 1} n = \zeta_R(-1) = -\frac{1}{12}$ (the Riemann zeta value of (9.31)), so the exponent is $-\frac{4\pi\tau_2}{12}$.
(5) $|q|^{1/6} = e^{-2\pi\tau_2/6} = e^{-\pi\tau_2/3}$, and $|\eta|^4 = |q|^{4/24}\prod|1-q^n|^4$.

Checks. (i) The square torus: $\tau = i$ gives $\det'\Delta = \eta(i)^4 \approx 0.348$. (ii) Modular invariance: the determinant is a spectral invariant and the spectrum is modular invariant (Example 9.53), so $\tau_2\,|\eta(\tau)|^4$ must be too. Under $\tau \mapsto -1/\tau$, $\tau_2 \mapsto \tau_2/|\tau|^2$; invariance therefore *forces* $|\eta(-1/\tau)|^4 = |\tau|^2\,|\eta(\tau)|^4$, which is the second symmetry law in the working definition. A non-obvious identity of a q-series has been proved by the statement "isometric tori have the same spectrum".

Watch out: Iterated regularisation, and how to trust it

Step (4) regularised the product over rows separately from the products inside each row. Zeta regularisation is not guaranteed to commute with such rearrangements (a double sum regularised "row by row" can differ from the same double sum regularised all at once by a local polynomial term). Here it does not, and the proof is a classical formula. The torus zeta function is $\zeta_\Delta(s) = (4\pi^2)^{-s}E(\tau,s)$ with the **Epstein zeta function** $E(\tau,s) = \sum_{(n,m)\neq 0} \tau_2^s/|m+n\tau|^{2s}$, and **Kronecker's first limit formula** gives, near $s=1$, $E(\tau,s) = \frac{\pi}{s-1} + 2\pi\big(\gamma - \log 2 - \log(\sqrt{\tau_2}\,|\eta(\tau)|^2)\big) + O(s-1)$. The functional equation $\pi^{-s}\Gamma(s)E(\tau,s) = \pi^{s-1}\Gamma(1-s)E(\tau,1-s)$ carries this to $s=0$, where it says $E(\tau,0) = -1$ and $\partial_s E(\tau,0) = -\log\big(4\pi^2\tau_2\,|\eta|^4\big)$. Then

$$\begin{aligned}
-\zeta_\Delta'(0) &\overset{(1)}{=} \log(4\pi^2)\,E(\tau,0) - \partial_s E(\tau,0) \\
&\overset{(2)}{=} -\log(4\pi^2) + \log(4\pi^2) + \log\big(\tau_2\,|\eta|^4\big) = \log\big(\tau_2\,|\eta(\tau)|^4\big),
\end{aligned}$$

(1) Differentiate $(4\pi^2)^{-s}E(\tau,s)$ at $s=0$.
(2) The two values just quoted.

in agreement with (9.89). Note also $\zeta_\Delta(0) = E(\tau,0) = -1 = \chi(T^2)/6 - 1$, exactly as the heat kernel predicted in Example 9.25.

Physical picture: The $-\frac{1}{24}$ is a Casimir energy

Read the matter factor for one scalar field in Hamiltonian language. With $(1,1)=1$,

$$\left(\det{}'\Delta_{\hat{g}_\tau}\right)^{-1/2} = \tau_2^{-1/2}\,|q|^{-1/12}\prod_{n\geq 1}|1-q^n|^{-2} = \tau_2^{-1/2}\,q^{-1/24}\bar{q}^{-1/24}\prod_{n\geq 1}\frac{1}{1-q^n}\,\frac{1}{1-\bar{q}^n}.$$

The torus is a closed string propagating for Euclidean time $2\pi\tau_2$ and then glued back with a twist $2\pi\tau_1$ (Figure 9.5). Each factor $1/(1-q^n)=\sum_k q^{nk}$ is the trace over the Fock space of one oscillator of frequency n moving to the left, and $1/(1-\bar{q}^n)$ likewise for the right movers. The factor $\tau_2^{-1/2}$ is the integral over the centre-of-mass momentum. And $q^{-1/24}$ is $e^{-2\pi\tau_2 E_0}$ with the zero-point energy $E_0=\frac{1}{2}\sum_{n\geq 1} n=\frac{1}{2}\zeta_R(-1)=-\frac{1}{24}$ of the left movers: the same $\zeta_R(-1)$ as in step (4). The oscillator of Example 9.24 kept its $\frac{1}{2}\omega$; the string keeps its $-\frac{1}{24}$ per field.

Step 4: the ghost factor and the torus amplitude

Worked example 9.56: The torus amplitude Z_1

Ghosts. On the flat torus the Weitzenböck formula gives $P_1^\dagger P_1=-2(\nabla^2+K)=2\Delta$ acting on each of the two components V^1,V^2 (Example 9.39, with $K=0$ and no Christoffel symbols in the affine coordinates x,y). So the spectrum of $P_1^\dagger P_1$ is that of 2Δ with every eigenvalue doubled in multiplicity, and its kernel is the two constant vector fields (the CKVs). Therefore $\zeta_{P_1^\dagger P_1}=2\,\zeta_{2\Delta}$ and

$$\sqrt{\det{}'P_1^\dagger P_1}\overset{(1)}{=}\sqrt{\left(\det{}'(2\Delta)\right)^2}=\det{}'(2\Delta)$$
$$\overset{(2)}{=}2^{\zeta_\Delta(0)}\det{}'\Delta\overset{(3)}{=}\tfrac{1}{2}\,\tau_2\,|\eta(\tau)|^4\,.$$

(1) $\det'=\exp(-\zeta'(0))$ and $\zeta_{P_1^\dagger P_1}=2\zeta_{2\Delta}$ square the determinant.
(2) Scaling law of Example 9.26.
(3) $\zeta_\Delta(0)=-1$ and (9.89).

Matter. In the same way $\det'(\Delta/2)=2^{-\zeta_\Delta(0)}\det'\Delta=2\tau_2\,|\eta|^4$ (this is item (i) of Example 9.26 with $\chi=0$), and $(1,1)_{\hat{g}_\tau}=1$.

Assemble. Insert (a)–(d) into (9.81), with $\frac{1}{|\Gamma_\Sigma|}\int_{\mathcal{T}_1}=\int_{\mathcal{F}}$:

$$Z_1\overset{(1)}{=}\int_{\mathcal{F}}\frac{2\,\mathrm{d}\tau_1\mathrm{d}\tau_2}{\tau_2^2}\cdot 1\cdot\left(2\tau_2\,|\eta(\tau)|^4\right)^{-13}\cdot\tfrac{1}{2}\tau_2\,|\eta(\tau)|^4$$
$$\overset{(2)}{=}2^{-13}\int_{\mathcal{F}}\frac{\mathrm{d}\tau_1\mathrm{d}\tau_2}{\tau_2^2}\,\tau_2^{-12}\,|\eta(\tau)|^{-48}\,. \tag{9.90}$$

(1) Measure (a), CKG volume (b), matter factor (c), ghost factor (d).
(2) Powers of 2: $2\cdot 2^{-13}\cdot\frac{1}{2}=2^{-13}$. Powers of τ_2: $\tau_2^{-13}\cdot\tau_2=\tau_2^{-12}$. Powers of $|\eta|$: $-52+4=-48$.

Modular invariance. The measure $\mathrm{d}\tau_1\mathrm{d}\tau_2/\tau_2^2$ is $\mathrm{PSL}(2,\mathbb{Z})$-invariant (Section 9.3.4), and the integrand is $\tau_2^{-12}\,|\eta|^{-48}=\left(\tau_2\,|\eta|^4\right)^{-12}$, a power of the invariant of Example 9.55. So the integrand is a genuine function on $\mathcal{M}_1$, and integrating over $\mathcal{F}$ is legitimate. Notice how the exponent came out: 26 scalars give -13, the ghosts give $+1$, so the net power of the modular invariant $\tau_2\,|\eta|^4$ is $-13+1=-12=-(26-2)/2$. The $26-2=24$ is the number

of transverse directions of the string; the ghosts cancel two of the 26 fields. (Standard references write the same result as $\int_{\mathcal{F}} \frac{\mathrm{d}^2\tau}{\tau_2^2}(\sqrt{\tau_2}\,|\eta|^2)^{-24}$, times the space-time volume V_{26} from the zero mode of Section 9.1.9 and constants depending on α'.)

Watch out: The element -1 and other constants

$\mathrm{SL}(2,\mathbb{Z})$ contains $-\mathbf{1}$, which is the diffeomorphism $(x,y)\mapsto(-x,-y)$. It fixes every point of $\mathcal{T}_1$, and it is not a conformal Killing *flow* (it is not connected to the identity), so it is not divided out by $1/\mathrm{vol}\,\mathrm{CKG}$. Dividing by the whole symmetry group therefore gives an extra factor $\frac{1}{2}$ in front of (9.90). Such overall constants (together with V_{26}, the normalisation of $\mathcal{D}V$ and the N of (9.72)) are fixed in the end by unitarity; they do not affect the τ-dependence.

Step 5: what the answer means: the string spectrum and the tachyon

Expand the integrand in powers of q. Write $\prod_{n\geq1}(1-q^n)^{-24}=\sum_{N\geq0}d_N q^N$. The coefficients are

$$d_0=1,\quad d_1=24,\quad d_2=324,\quad d_3=3200,\quad d_4=25650,\ \ldots \tag{9.91}$$

and d_N counts the ways of distributing N units of excitation among 24 species of oscillator, one of each frequency $n\geq1$.

Worked example 9.57: Counting states: $d_1=24$, $d_2=324$

Expand each factor: $(1-q^n)^{-24}=\left(\sum_k q^{nk}\right)^{24}$. Up to q^2,

$$\begin{aligned}\prod_{n\geq1}(1-q^n)^{-24} &\overset{(1)}{=}(1-q)^{-24}(1-q^2)^{-24}+O(q^3)\\ &\overset{(2)}{=}\left(1+24q+\tbinom{25}{2}q^2\right)\left(1+24q^2\right)+O(q^3)\\ &\overset{(3)}{=}1+24q+(300+24)q^2+O(q^3).\end{aligned}$$

(1) Factors with $n\geq3$ start at q^3.
(2) $(1-q)^{-24}=\sum_k\binom{k+23}{23}q^k$ (choose k quanta among 24 oscillators α^μ_{-1}), so the q^2 coefficient is $\binom{25}{2}=300$; $(1-q^2)^{-24}=1+24q^2+\cdots$.
(3) Multiply out.

In oscillator language: level 1 is $\alpha^\mu_{-1}|0\rangle$ (24 states); level 2 is $\alpha^\mu_{-2}|0\rangle$ (24) or $\alpha^\mu_{-1}\alpha^\nu_{-1}|0\rangle$ (symmetric, 300).

With $|\eta|^{-48}=|q|^{-2}\sum_{N,\tilde N}d_N d_{\tilde N}q^N\bar q^{\tilde N}$ and $q^N\bar q^{\tilde N}=e^{2\pi i\tau_1(N-\tilde N)}e^{-2\pi\tau_2(N+\tilde N)}$, the part of $\mathcal{F}$ with $\tau_2>1$ (where $\mathcal{F}$ is simply the strip $|\tau_1|\leq\frac{1}{2}$) gives

$$\begin{aligned}Z_1\Big|_{\tau_2>1} &\overset{(1)}{=}2^{-13}\int_1^\infty \mathrm{d}\tau_2\,\tau_2^{-14}\sum_{N,\tilde N}d_N d_{\tilde N}\,e^{4\pi\tau_2}e^{-2\pi\tau_2(N+\tilde N)}\int_{-1/2}^{1/2}\mathrm{d}\tau_1\,e^{2\pi i\tau_1(N-\tilde N)}\\ &\overset{(2)}{=}2^{-13}\int_1^\infty \mathrm{d}\tau_2\,\tau_2^{-14}\sum_{N\geq0}d_N^2\,e^{-4\pi\tau_2(N-1)}.\end{aligned}\tag{9.92}$$

(1) Insert the expansion; $|q|^{-2}=e^{4\pi\tau_2}$; $\tau_2^{-2}\tau_2^{-12}=\tau_2^{-14}$.
(2) The τ_1 integral is $\delta_{N\tilde N}$: the integral over the twist projects onto states with equal left and right excitation (**level matching**, $L_0=\bar L_0$).

Now read the terms one by one.

- $N = 0$: $\int^{\infty} \mathrm{d}\tau_2\, \tau_2^{-14} e^{+4\pi\tau_2}$ *diverges*. The integrand grows exponentially in the cusp. This state has "negative mass squared": it is the **tachyon** of the bosonic string.

- $N = 1$: $d_1^2 = 576$ states with no exponential, $\int_1^{\infty} \tau_2^{-14} \mathrm{d}\tau_2 = \frac{1}{13}$, finite. These are the massless states $\alpha_{-1}^{\mu} \tilde{\alpha}_{-1}^{\nu} |0\rangle$: a 24×24 matrix, which splits into symmetric traceless (299, the graviton), antisymmetric (276, the Kalb–Ramond field $B_{\mu\nu}$) and trace (1, the dilaton); $299 + 276 + 1 = 576$.

- $N \geq 2$: exponentially convergent: massive states.

Physical picture: The torus is a sum of particle loops, without the ultraviolet

For one real scalar particle of mass m in $D = 26$ Euclidean dimensions, the one-loop vacuum amplitude is, by the proper-time (Schwinger) representation $\log \lambda = -\int_0^{\infty} \frac{\mathrm{d}t}{t} e^{-t\lambda} + \text{const}$,

$$-\tfrac{1}{2} \log \det\bigl(-\partial^2 + m^2\bigr) \overset{(1)}{=} \tfrac{1}{2} \int_0^{\infty} \frac{\mathrm{d}t}{t}\, \operatorname{Tr} e^{-t(-\partial^2 + m^2)}$$
$$\overset{(2)}{=} \tfrac{1}{2}\, V_{26} \int_0^{\infty} \frac{\mathrm{d}t}{t}\, (4\pi t)^{-13}\, e^{-tm^2}.$$

(1) Apply the proper-time formula to each eigenvalue and sum; the constant is dropped.
(2) $\operatorname{Tr} e^{t\partial^2} = V_{26} \int \frac{\mathrm{d}^{26}k}{(2\pi)^{26}} e^{-tk^2} = V_{26}(4\pi t)^{-13}$.

The integrand is $t^{-14} e^{-m^2 t}$, exactly the shape of (9.92) with $t \propto \tau_2$ and $m^2 \propto 4(N-1)$ (in conventional units, $t = \pi\alpha'\tau_2$ and $m^2 = 4(N-1)/\alpha'$). So in the cusp the string amplitude is a sum of particle vacuum loops, one for each level-matched state. The difference is the region of integration. For a particle, $t \to 0$ (short proper time, high momentum) gives the ultraviolet divergence $\int_0 \mathrm{d}t\, t^{-14}$. For the string, modular invariance restricts τ to $\mathcal{F}$, where $\tau_2 \geq \sqrt{3}/2$: the would-be ultraviolet region is not a separate region at all, it is a copy of the cusp under S. The only divergence left is the infrared one from the tachyon.

Try it: The integrand near $\tau = i$

Using $\eta(i) = \Gamma(\frac{1}{4})/(2\pi^{3/4}) \approx 0.76823$, evaluate the integrand of (9.90) (without the measure) at the square torus. *Answer:* $2^{-13}\,(\eta(i)^4)^{-12} = 2^{-13}\,\eta(i)^{-48} \approx 2^{-13} \times 3.1 \times 10^5 \approx 38$. Compare the cusp, where at $\tau_2 = 3$ the tachyon term alone is $2^{-13}\, 3^{-14} e^{12\pi} \approx 6 \times 10^5$ and growing: the integral is dominated by the cusp.

9.3.14 The sphere: fixing three points

For the sphere, (9.35) has no moduli integral ($\mathcal{M}_0$ is a point) but an infinite factor $1/\mathrm{vol}\,\mathrm{PSL}(2,\mathbb{C})$ (Section 9.3.10). The question is: *how does a physically meaningful sphere amplitude get rid of it?* Answer: scattering amplitudes contain vertex operators $\mathcal{V}_i$ inserted at points z_i of the world sheet, integrated over their positions. The conformal Killing group moves the points, and three points are exactly enough to use it up.

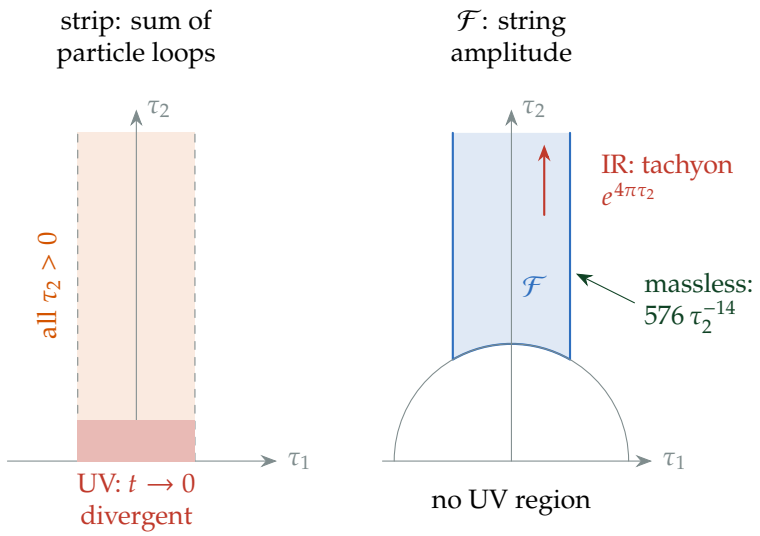

Figure 9.23: Where divergences live. Left: a sum of point-particle loops integrates the proper time $t \propto \tau_2$ over the whole strip, including $t \to 0$ (red), which is the ultraviolet divergence of field theory. Right: the torus amplitude integrates only over the fundamental domain $\mathcal{F}$; the region $\tau_2 \to 0$ has been mapped by $S : \tau \mapsto -1/\tau$ into the cusp and is not counted again. The remaining divergence is in the cusp $\tau_2 \to \infty$ (infrared), where the tachyon term grows like $e^{4\pi\tau_2}$; the massless term decays like τ_2^{-14} and is harmless.

Worked example 9.58: Three points absorb the conformal Killing group

A sphere amplitude with n insertions has the form

$$\mathcal{A}_n = \frac{1}{\operatorname{vol}\mathrm{PSL}(2,\mathbb{C})} \int \prod_{i=1}^{n} \mathrm{d}^2 z_i \; F(z_1, \ldots, z_n),$$

where F (the correlation function of the vertex operators, computed with the determinants of (9.35)) is such that $\prod \mathrm{d}^2 z_i \, F$ is invariant under Möbius maps. We trade the positions z_1, z_2, z_3 for the group. Near the identity, the CKV $V^z = a_0 + a_1 z + a_2 z^2$ of Example 9.34 moves the three points by $\delta z_i = a_0 + a_1 z_i + a_2 z_i^2$, i.e.

$$\begin{pmatrix} \delta z_1 \\ \delta z_2 \\ \delta z_3 \end{pmatrix} = \underbrace{\begin{pmatrix} 1 & z_1 & z_1^2 \\ 1 & z_2 & z_2^2 \\ 1 & z_3 & z_3^2 \end{pmatrix}}_{M} \begin{pmatrix} a_0 \\ a_1 \\ a_2 \end{pmatrix}.$$

This is a Vandermonde matrix. Its determinant, by row reduction:

$$\begin{aligned} \det M &\overset{(1)}{=} \det \begin{pmatrix} 1 & z_1 & z_1^2 \\ 0 & z_2 - z_1 & z_2^2 - z_1^2 \\ 0 & z_3 - z_1 & z_3^2 - z_1^2 \end{pmatrix} \\ &\overset{(2)}{=} (z_2 - z_1)(z_3 - z_1) \det \begin{pmatrix} 1 & z_2 + z_1 \\ 1 & z_3 + z_1 \end{pmatrix} \\ &\overset{(3)}{=} (z_2 - z_1)(z_3 - z_1)(z_3 - z_2). \end{aligned}$$

(1) Subtract row 1 from rows 2 and 3 (determinant unchanged).
(2) Expand along the first column, and pull the factors $z_2 - z_1$ and $z_3 - z_1$ out of rows 2 and 3, using $z_j^2 - z_1^2 = (z_j - z_1)(z_j + z_1)$.

(3) The 2×2 determinant is $(z_3+z_1)-(z_2+z_1)$.

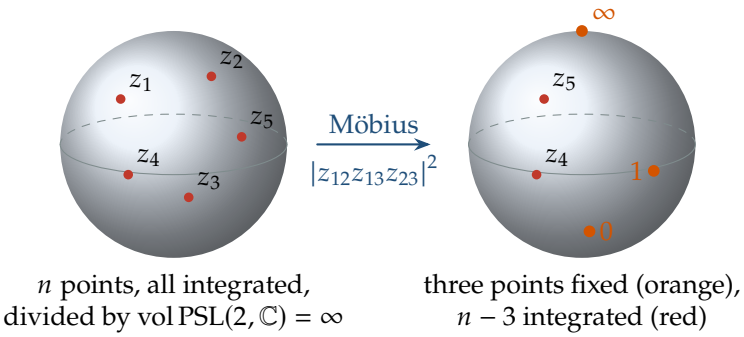
M is a complex-linear map $\mathbb{C}^3\to\mathbb{C}^3$; as a real map $\mathbb{R}^6\to\mathbb{R}^6$ its determinant is $|\det M|^2$ (Example 9.51). Hence, near the identity, $\mathrm{d}^2z_1\,\mathrm{d}^2z_2\,\mathrm{d}^2z_3 = |z_{12}z_{13}z_{23}|^2\,\mathrm{d}(\text{group})$ with $z_{ij}=z_i-z_j$ and $\mathrm{d}(\text{group})$ the (left-invariant) volume element on $\mathrm{PSL}(2,\mathbb{C})$ whose value at the identity is $\mathrm{d}^2a_0\,\mathrm{d}^2a_1\,\mathrm{d}^2a_2$. Since any three distinct points can be moved to any other three by exactly one Möbius map (for example to $0,1,\infty$ by $z\mapsto\frac{(z-z_1)(z_2-z_3)}{(z-z_3)(z_2-z_1)}$), the orbit of a triple is a copy of the group, and

$$\mathcal{A}_n=\int\prod_{i=4}^{n}\mathrm{d}^2z_i\;|z_{12}z_{13}z_{23}|^2\;F(z_1,\dots,z_n)\Big|_{z_1,z_2,z_3\text{ fixed}}. \tag{9.93}$$

The infinite volume has cancelled against the three integrals. The factor $|z_{12}z_{13}z_{23}|^2$ is the Faddeev–Popov determinant for this gauge fixing; in the ghost language of Section 9.3.11 it is the correlator $|\langle c(z_1)c(z_2)c(z_3)\rangle|^2$, the three c zero modes soaked up by the three fixed points.

Try it: The measure is Möbius invariant

Show that $\dfrac{\mathrm{d}z_1\,\mathrm{d}z_2\,\mathrm{d}z_3}{z_{12}\,z_{13}\,z_{23}}$ is invariant under $z\mapsto z'=\frac{az+b}{cz+d}$, $ad-bc=1$. *Answer:* $\mathrm{d}z_i'=\mathrm{d}z_i/(cz_i+d)^2$ and $z_i'-z_j'=(z_i-z_j)/\big((cz_i+d)(cz_j+d)\big)$. Each index i appears in two of the three differences, so the denominator acquires $\prod_i(cz_i+d)^{-2}$, which cancels the numerator's. Hence the invariant volume element on the group, written in terms of three points, is $|z_{12}z_{13}z_{23}|^{-2}\prod_{i=1}^3\mathrm{d}^2z_i$, consistent with (9.93).



n points, all integrated, divided by $\mathrm{vol}\,\mathrm{PSL}(2,\mathbb{C})=\infty$

three points fixed (orange), $n-3$ integrated (red)

Figure 9.24: Gauge fixing the conformal Killing group of the sphere. A Möbius map is fixed uniquely by where it sends three points, so the six real directions of $\mathrm{PSL}(2,\mathbb{C})$ can be traded for the positions of z_1,z_2,z_3, placed at $0,1,\infty$. The Jacobian of the trade is $|z_{12}z_{13}z_{23}|^2$; the remaining $n-3$ positions (and nothing else) are the moduli of the punctured sphere.

Punctures count as moduli. The same count works on every surface. Adding a puncture adds two real parameters (its position) and removes nothing, unless there are CKVs to absorb it. So the real dimension of the moduli space $\mathcal{M}_{p,n}$ of genus-p surfaces with n marked points is

$$\dim_{\mathbb{R}}\mathcal{M}_{p,n}=\underbrace{6p-6}_{-3\chi=-\,\mathrm{index}\,P_1}+2n, \tag{9.94}$$

valid whenever it is ≥ 0 and the CKVs are all used up, i.e. $2p-2+n>0$.

	$n=0$	$n=1$	$n=3$	$n=4$
$p=0$	(CKG dim 6 left)	(CKG dim 4 left)	0 (a point)	2 (cross-ratio)
$p=1$	2 (CKG dim 2 left)	2	6	8
$p=2$	6	8	12	14

For $p=0, n=4$ the single complex modulus is the cross-ratio $x=\frac{z_{12}z_{34}}{z_{13}z_{24}}$, the only Möbius invariant of four points; the four-tachyon amplitude becomes an integral $\int \mathrm{d}^2x\ |x|^A\,|1-x|^B$ over the sphere, the Virasoro–Shapiro amplitude. For $p=1$, $n=0$ the torus keeps its translations, as we saw in Example 9.49; with one puncture, the translations are used to put the puncture at $z=0$.

9.3.15 Higher genus: what the formula becomes

For $p\geq 2$ there are no CKVs (Example 9.34), and (9.35) holds as written: an integral over the $(6p-6)$-dimensional $\mathcal{M}_p$. Two developments, both quoted here without derivation, show how far the elliptic-operator form of the answer can be pushed. They are the "further reading" behind Nash's reference to D'Hoker and Phong.

Determinants as Selberg zeta values. A constant-curvature metric of genus $p\geq 2$ is hyperbolic: $\Sigma=\mathbb{H}/\Gamma$ with $\Gamma\subset \mathrm{PSL}(2,\mathbb{R})$ (Section 9.2.3). Its closed geodesics γ have lengths ℓ_γ, and the **Selberg zeta function** is $Z(s)=\prod_{\gamma\ \text{primitive}}\prod_{k\geq 0}\left(1-e^{-(s+k)\ell_\gamma}\right)$. The Selberg trace formula relates the spectrum of Δ to the lengths ℓ_γ, just as Poisson summation related the rows of Figure 9.22 to the lattice. D'Hoker and Phong showed that, with constants c_p, c_p' depending only on the genus,

$$\det{}'\Delta_g = c_p\, Z'(1), \qquad \det P_1^\dagger P_1 = c_p'\, Z(2). \tag{9.95}$$

So the integrand of (9.35) is a function of the length spectrum of the surface, $Z(2)^{1/2}\,Z'(1)^{-13}$ up to constants. The torus analogue is (9.89): there the "geodesics" are the lattice vectors, and the role of Z is played by $\prod(1-q^n)$.

Holomorphic factorisation. In the torus answer the integrand was $\tau_2^{-14}\left|\eta(\tau)^{24}\right|^{-2}$: a power of τ_2 times the squared modulus of a *holomorphic* function of τ (the cusp form η^{24}). Belavin and Knizhnik showed that the same happens in every genus, and that it happens *only* when $d=26$. Mathematically it is the Mumford isomorphism $\lambda_2\cong\lambda_1^{13}$ between two holomorphic line bundles over $\mathcal{M}_p$: λ_1 is the determinant line of the holomorphic 1-forms (from the matter determinant) and λ_2 that of the quadratic differentials (from the ghost determinant). The exponent 13 is the same $13=26/2$ as in (9.35). For $p=2$, in terms of the period matrix Ω (a 2×2 symmetric matrix with positive imaginary part, three complex moduli), the result is $\mathrm{d}\mu\propto(\det \mathrm{Im}\,\Omega)^{-13}\,|\chi_{10}(\Omega)|^{-2}\prod_{i\leq j}\mathrm{d}^2\Omega_{ij}$, with χ_{10} a Siegel cusp form of weight 10. The anomaly that decides $d=26$ (Section 9.2.11, Chapter 10) is the same obstruction that spoils holomorphic factorisation when $d\neq 26$.

Try it: Weight counting at genus 1 and 2

Under $\tau\mapsto\frac{a\tau+b}{c\tau+d}$: $\tau_2\mapsto\tau_2\,|c\tau+d|^{-2}$, $\mathrm{d}^2\tau\mapsto\mathrm{d}^2\tau\,|c\tau+d|^{-4}$ and $\eta^{24}\mapsto(c\tau+d)^{12}\eta^{24}$. Check that $\tau_2^{-14}\left|\eta^{24}\right|^{-2}\mathrm{d}^2\tau$ is invariant. At genus 2, with $\det\mathrm{Im}\,\Omega\mapsto|\det(C\Omega+D)|^{-2}\det\mathrm{Im}\,\Omega$, $\prod\mathrm{d}^2\Omega_{ij}\mapsto|\det(C\Omega+D)|^{-6}\prod\mathrm{d}^2\Omega_{ij}$ and $\chi_{10}\mapsto\det(C\Omega+D)^{10}\chi_{10}$, check the genus-2 measure. *Answer:* genus 1: $|c\tau+d|^{28-4-24}=1$. Genus 2: $|\det(C\Omega+D)|^{26-6-20}=1$. The extra power of τ_2 at genus 1 is the conformal Killing group of the torus.

Reading Nash (pp. 265–268, (9.23)–(9.36))

p. 265. $\mathrm{Met}_{\mathrm{const}}(\Sigma)$ is a Riemannian submanifold of $\mathrm{Met}(\Sigma)$, and Diff_0 acts on it by isometries (footnote 3: isometries of $\mathrm{Met}_{\mathrm{const}}$, not of Σ). This is Section 9.3.2. **pp. 265–267, (9.23)–(9.29).** The projection π, the tangent space at a class $[g_{\mathrm{const}}]$, the definition of $\langle\,,\,\rangle_{\mathrm{wp}}$ by lifting tangent vectors, and the check that the answer does not depend on the lift or on the representative: Section 9.3.3, where the lift is taken horizontal ($\operatorname{Ker} P_1^\dagger$). Nash does not compute an example; ours is the torus, $\mathrm{d}s^2_{\mathrm{wp}} = 2\,|\mathrm{d}\tau|^2/\tau_2^2$ (Example 9.42), with volume $2\pi/3$ for $\mathcal{M}_1$ (Example 9.43). **p. 267, (9.30)–(9.34).** The decomposition $T_g\mathrm{Met} = C_g \oplus \operatorname{Range} A_g \oplus \operatorname{Ker} A_g^*$, the coordinates $\{\sigma\}, \{A_g V\}, \{\mathcal{T}_p\}$, the factor N, the Jacobian $\sqrt{\det A_g^* A_g}$ and its failure when $\operatorname{Ker} A_g \neq 0$ (CKVs, $p = 0, 1$), and the split vect $= \operatorname{Ker} A_g \oplus \operatorname{Ker}^\perp A_g$. In our notation $A_g = P_1$: Sections 9.3.6 to 9.3.10. **pp. 267–268, (9.35)–(9.36).** The final formulae. Nash's det is our det′ (zero modes removed); $\tilde{A}_g$ is P_1 restricted to $\operatorname{Ker}^\perp P_1$; the $1/|\Gamma_\Sigma|$ converts $\int_{\mathcal{T}_p}$ into $\int_{\mathcal{M}_p}$; the real-versus-complex identity $\det \tilde{A}_g^* \tilde{A}_g = (\det \bar{\partial}_{K^*}^* \bar{\partial}_{K^*})^2$ is "easy to verify" in Nash, and verified in Section 9.3.12. Nash's chapter ends here; the torus computation Example 9.56 and the sphere gauge fixing Example 9.58 show the formula producing numbers.

Recap: Section

- Teichmüller space inherits a metric from $\mathrm{Met}_{\mathrm{const}}$ because Diff_0 acts by isometries: lift a tangent vector horizontally (to a holomorphic quadratic differential) and measure it with $\langle\,,\,\rangle_{\mathrm{met}}$. This is the Weil–Petersson metric.
- For the torus, $\mathcal{T}_1$ is the upper half-plane, WP is twice the hyperbolic metric, $\Gamma_{T^2} = \mathrm{PSL}(2,\mathbb{Z})$ acts by Möbius maps, and $\mathcal{M}_1 = \mathcal{F}$ has WP volume $2\pi/3$.
- In conformal-gauge coordinates $g = e^{2\sigma}\alpha^*\hat{g}_t$, the measure on Met factorises into Weyl, diffeomorphism and moduli pieces; the Jacobian is triangular, and its diagonal blocks are the Weyl factor, $\sqrt{\det' P_1^\dagger P_1}$ and the WP volume element.
- Dividing by the gauge volumes leaves Z_p as an integral over $\mathcal{M}_p$ of $(\det'(\Delta/2)/(1,1))^{-13}\sqrt{\det' P_1^\dagger P_1}$; conformal Killing vectors contribute $1/\mathrm{vol}\,\mathrm{CKG}$; ghosts rewrite the determinant as a Grassmann integral; as a complex operator the ghost determinant is $\det' \bar{\partial}_{K^*}^* \bar{\partial}_{K^*}$.
- For the torus everything is explicit: $\det'\Delta = \tau_2\,|\eta|^4$ and $Z_1 = 2^{-13}\int_{\mathcal{F}} \mathrm{d}^2\tau\, \tau_2^{-14}\,|\eta|^{-48}$, modular invariant, UV finite, divergent only through the tachyon in the cusp.
- For the sphere, three vertex-operator positions absorb $\mathrm{PSL}(2,\mathbb{C})$ with Jacobian $|z_{12}z_{13}z_{23}|^2$; each extra puncture adds one complex modulus.

Chapter summary

This chapter asked one question: *what does it mean to integrate over all surfaces?* The Polyakov path integral sums e^{-S} over pairs (embedding ϕ, world-sheet metric g). Both spaces are infinite-dimensional, and the symmetry group is infinite-dimensional too. The answer was that almost everything is gauge. Once the embeddings have been integrated out (a Gaussian) and the gauge group has been divided out (Faddeev–Popov), what is left is an *ordinary integral*

over a finite-dimensional space, the moduli space $\mathcal{M}_p$ of Riemann surfaces of genus p. The price of the reduction is a pair of determinants of elliptic operators, and the measure on $\mathcal{M}_p$ is the volume form of the Weil–Petersson metric.

The story, in ten sentences:

1. A string sweeps out a surface. Its natural action is tension times area (Nambu–Goto), which has a square root. Adding an independent world-sheet metric g removes the square root (Polyakov). The action becomes d free massless scalars on (Σ, g), and eliminating g by its equation of motion $T_{ab} = 0$ gives back the area.
2. The Polyakov action is invariant under $\mathrm{Diff}^+(\Sigma)$ (relabelling points) and, in two dimensions only, under the Weyl group $C^\infty_+(\Sigma)$ (rescaling lengths pointwise). Together they form the semidirect product $\mathrm{Diff}^+ \ltimes C^\infty_+$.
3. A metric on an oriented surface is the same as a complex structure plus a scale. So summing over metrics up to Weyl rescaling is summing over Riemann surfaces.
4. The ϕ integral is Gaussian. It gives $\bigl(\det{}'(\Delta_g/2)/(1,1)_g\bigr)^{-d/2}$, where the zero mode (the centre of mass) contributes the area $(1,1)_g$ and the volume of space-time.
5. Infinite products of eigenvalues are defined by zeta functions: $\det{}'P = e^{-\zeta'_P(0)}$. On a circle of length L this gives $\det{}'\Delta = L^2$, and the heat kernel gives $\zeta_\Delta(0) = \chi/6 - 1$ on a closed surface.
6. The space $\mathrm{Met}(\Sigma)$ carries a natural diffeomorphism-invariant metric, $\int \sqrt{g}\ \mathrm{tr}(g^{-1}Xg^{-1}Y)$. With it, each tangent space splits orthogonally into Weyl directions C_g, diffeomorphism directions $\mathrm{Range}\, P_1$ and moduli $\mathrm{Ker}\, P_1^\dagger$.
7. The operator $P_1 V =$ (traceless part of $\mathcal{L}_V g$) is a Cauchy–Riemann operator, $\partial_{\bar z}$ acting on V^z. So it is elliptic. Its kernel consists of the conformal Killing vectors, and its cokernel of the holomorphic quadratic differentials. Riemann–Roch gives $\mathrm{index}\, P_1 = 3\chi$.
8. Teichmüller space $\mathcal{T}_p = \mathrm{Met}_{\mathrm{const}}/\mathrm{Diff}_0$ has tangent space $\mathrm{Ker}\, P_1^\dagger$, and so real dimension $6p - 6$ for $p \geq 2$ (2 for the torus, 0 for the sphere). It inherits the Weil–Petersson metric by horizontal lifting; for the torus this is twice the Poincaré metric.
9. In the conformal-gauge coordinates $g = \alpha^*(e^\sigma \hat g_t)$ the Jacobian is triangular. Its diagonal blocks are a Weyl factor, the Faddeev–Popov determinant $\sqrt{\det{}' P_1^\dagger P_1}$ and the Weil–Petersson volume element. Dividing by the gauge volumes leaves an integral over $\mathcal{M}_p = \mathcal{T}_p/\Gamma_\Sigma$.
10. The division by the Weyl volume is legitimate only when the integrand is Weyl invariant. The matter and ghost anomalies are proportional to d and -26, so this happens exactly in $d = 26$. The result is Nash's (9.36), $Z_p = \int_{\mathcal{M}_p} \mathrm{d}\mu_{\mathrm{wp}}\, (\det{}'(\Delta/2)/(1,1))^{-13} \det{}' \bar\partial^*_{K^*} \bar\partial_{K^*}$.

One surface through every lens: the flat torus

Every construction of the chapter can be carried out on the torus $\mathbb{R}^2/\mathbb{Z}^2$ with the flat metric $\hat g_\tau = \frac{1}{\tau_2}\,|\mathrm{d}x + \tau\,\mathrm{d}y|^2$, and every number is explicit. Table 9.1 collects the facts. Four of the entries are worth deriving once more, because together they show the whole mechanism at work: a determinant, a count, a symmetry and an anomaly.

The determinant: the circle again. The torus determinant is built out of circle determinants (Example 9.54), and the circle is where the zeta recipe is easiest to see. For $\Delta = -\mathrm{d}^2/\mathrm{d}\theta^2$ on a

Concept	On the flat torus $(\mathbb{R}^2/\mathbb{Z}^2, \hat{g}_\tau)$
complex structure	$z = x + \tau y$; Beltrami coefficient 0 in this coordinate; $\hat{g}_\tau = \tau_2^{-1} \lvert \mathrm{d}z \rvert^2$
area $(1,1)_g$	$\sqrt{\det \hat{g}_\tau} = 1$, so the area is 1 for every τ
Laplacian spectrum	$\lambda_{n,m} = \frac{4\pi^2}{\tau_2} \lvert m + n\tau \rvert^2$, $(n,m) \neq (0,0)$; one zero mode
$\zeta_\Delta(0)$	$\chi/6 - 1 = -1$
$\det' \Delta$	$\tau_2 \lvert \eta(\tau) \rvert^4$ (Example 9.55); $\det'(\Delta/2) = 2\tau_2 \lvert \eta \rvert^4$
CKVs, $\operatorname{Ker} P_1$	the constant vector fields $v^1 \partial_x + v^2 \partial_y$: real dimension 2
conformal Killing group	translations $\mathbb{R}^2/\mathbb{Z}^2$, the torus itself; volume $(1,1)_g = 1$
quadratic differentials	$\operatorname{Ker} P_1^\dagger = \{c\, \mathrm{d}z^2\}$, $c \in \mathbb{C}$: real dimension 2
index of P_1	$2 - 2 = 0 = 3\chi(T^2)$
$P_1^\dagger P_1$	2Δ on each of the two components of V; $\sqrt{\det' P_1^\dagger P_1} = \frac{1}{2}\tau_2 \lvert \eta \rvert^4$
Teichmüller space	$\mathcal{T}_1 = \{\tau : \tau_2 > 0\}$, the upper half-plane
mapping class group	$\Gamma_{T^2} = \mathrm{SL}(2,\mathbb{Z})$ acting by $\tau \mapsto \frac{a\tau+b}{c\tau+d}$ (effectively $\mathrm{PSL}(2,\mathbb{Z})$)
moduli space	$\mathcal{M}_1 = \mathcal{F}$: $\lvert \tau_1 \rvert \leq \frac{1}{2}$, $\lvert \tau \rvert \geq 1$
Weil–Petersson metric	$\mathrm{d}s^2_{\mathrm{wp}} = 2 \lvert \mathrm{d}\tau \rvert^2 / \tau_2^2$, twice Poincaré; $\mathrm{vol}_{\mathrm{wp}} \mathcal{M}_1 = 2\pi/3$
amplitude	$Z_1 = 2^{-13} \int_{\mathcal{F}} \mathrm{d}^2\tau\, \tau_2^{-14} \lvert \eta(\tau) \rvert^{-48}$
spectrum of states	$\lvert \eta \rvert^{-48} = \lvert q \rvert^{-2} \sum_{N,\tilde{N}} d_N d_{\tilde{N}} q^N \bar{q}^{\tilde{N}}$, $d_1 = 24$: tachyon at $N = 0$, 576 massless states at $N = 1$

Table 9.1: The flat torus as a one-page model of Chapter 9. Every row is a concept of the chapter, evaluated explicitly. The only genuinely hard entry is $\det' \Delta$, which needs the product formula for sin and the value $\zeta_R(-1) = -\frac{1}{12}$.

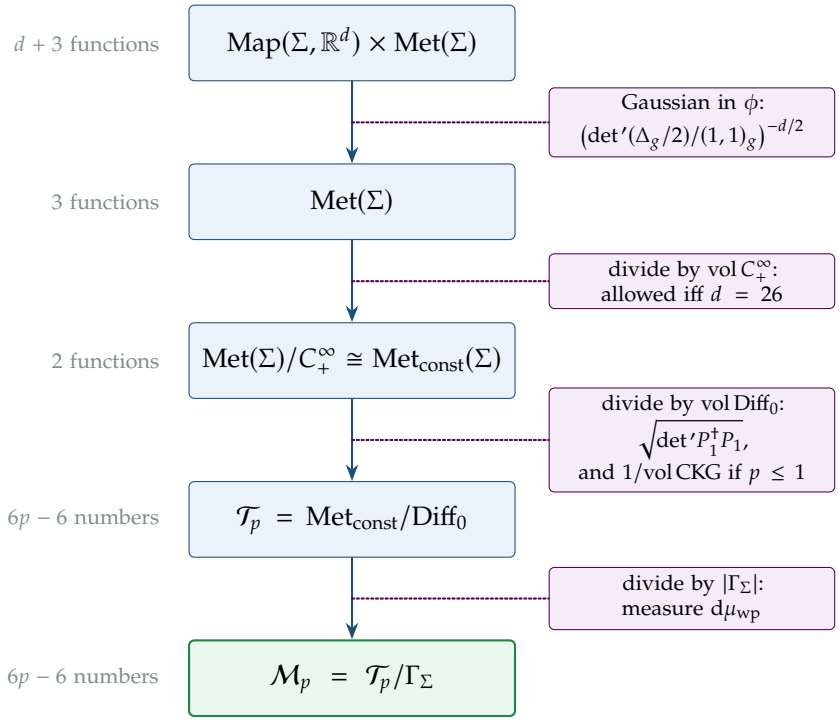


Figure 9.25: The chapter as a funnel. Each arrow integrates out or divides out one piece of the configuration space. The purple boxes show what the step leaves behind in the integrand. The grey counts on the left give the local and global size of each space: the three components of a two-dimensional metric are used up by one Weyl function and two diffeomorphism functions, and only the $6p-6$ moduli survive (2 for the torus, none for the sphere).

circle of length L, the eigenfunctions $e^{2\pi i n\theta/L}$ have eigenvalues $(2\pi n/L)^2$, and each non-zero value occurs twice ($\pm n$). So

$$\zeta_\Delta(s)\overset{(1)}{=}2\sum_{n\ge1}\Big(\frac{2\pi n}{L}\Big)^{-2s}\overset{(2)}{=}2\Big(\frac{L}{2\pi}\Big)^{2s}\zeta_R(2s),$$

$$\zeta'_\Delta(0)\overset{(3)}{=}4\log\Big(\frac{L}{2\pi}\Big)\zeta_R(0)+4\zeta'_R(0)\overset{(4)}{=}-2\log\Big(\frac{L}{2\pi}\Big)-2\log(2\pi)=-2\log L,$$

$$\det'\Delta\overset{(5)}{=}e^{-\zeta'_\Delta(0)}=L^2.$$

(1) Sum over the non-zero eigenvalues, with multiplicity 2.
(2) Pull out $(L/2\pi)^{2s}$ and recognise $\sum n^{-2s}=\zeta_R(2s)$.
(3) Product rule at $s=0$: $\frac{\mathrm{d}}{\mathrm{d}s}(L/2\pi)^{2s}=2\log(L/2\pi)(L/2\pi)^{2s}$ and $\frac{\mathrm{d}}{\mathrm{d}s}\zeta_R(2s)=2\zeta'_R(2s)$.
(4) The Riemann values $\zeta_R(0)=-\frac12$, $\zeta'_R(0)=-\frac12\log 2\pi$ (9.31).
(5) Definition (9.30) of the zeta-regularised determinant.

The same value $\zeta_\Delta(0)=2\zeta_R(0)=-1$ tells us how the determinant scales: replacing L by cL multiplies every eigenvalue by c^{-2} and the determinant by $(c^{-2})^{\zeta(0)}=c^2$, consistent with L^2. In the naive product, $\prod(\text{const})$ would be meaningless. The zeta function turns "infinitely many factors of c^{-2}" into the finite power $c^{-2\zeta(0)}$.

The count: moduli minus Killing vectors. Riemann–Roch (9.61) predicts $\dim\ker P_1-\dim\ker P_1^\dagger=3\chi$. On the three basic surfaces,

$$S^2:\quad \dim\ker P_1-\dim\ker P_1^\dagger\overset{(1)}{=}6-0=6=3\cdot 2,$$

$$T^2: \quad \dim\operatorname{Ker} P_1 - \dim\operatorname{Ker} P_1^\dagger \overset{(2)}{=} 2 - 2 = 0 = 3\cdot 0,$$
$$\Sigma_p,\ p\geq 2: \quad \dim\operatorname{Ker} P_1 - \dim\operatorname{Ker} P_1^\dagger \overset{(3)}{=} 0 - (6p-6) = 3(2-2p).$$

(1) On the sphere, $P_1 V = 0$ means V^z is holomorphic on $\mathbb{CP}^1$ including ∞, so $V^z = a_0 + a_1 z + a_2 z^2$ with $a_i \in \mathbb{C}$: the Lie algebra of $\mathrm{PSL}(2,\mathbb{C})$, six real dimensions. There are no holomorphic quadratic differentials on the sphere ($\mathrm{d}z^2$ has a pole of order 4 at ∞).
(2) On the torus, holomorphic V^z and holomorphic $\varphi\,\mathrm{d}z^2$ are both constant (a holomorphic function on a compact surface is constant), one complex dimension each.
(3) For $p \geq 2$ the curvature is negative, so the Weitzenböck formula $P_1^\dagger P_1 = -2(\nabla^2 + K)$ is a positive operator with no kernel (Example 9.39); the cokernel then has dimension $-3\chi = 6p - 6$ by Riemann–Roch.

So the index is the same topological number whichever way the individual dimensions happen to fall. Moduli and conformal Killing vectors are the two ways a surface can fail to be "pure gauge", and only their difference is topological.

The symmetry: modular invariance of Z_1. The torus amplitude must not depend on which point of $\mathcal{T}_1$ we choose to represent a conformal class, so its integrand must be invariant under $\mathrm{SL}(2,\mathbb{Z})$. The group is generated by $T:\tau\mapsto\tau+1$ and $S:\tau\mapsto -1/\tau$, and the Dedekind function obeys $\eta(\tau+1) = e^{i\pi/12}\eta(\tau)$ and $\eta(-1/\tau) = \sqrt{-i\tau}\,\eta(\tau)$. Write the integrand as $\frac{\mathrm{d}^2\tau}{\tau_2^2}\big(\tau_2\,|\eta|^4\big)^{-12}$. Under S, with $\tau' = -1/\tau$,

$$\tau_2' \overset{(1)}{=} \operatorname{Im}\!\left(-\frac{\bar\tau}{|\tau|^2}\right) = \frac{\tau_2}{|\tau|^2}, \qquad |\eta(\tau')|^4 \overset{(2)}{=} |-i\tau|^2\,|\eta(\tau)|^4 = |\tau|^2\,|\eta(\tau)|^4,$$
$$\tau_2'\,|\eta(\tau')|^4 \overset{(3)}{=} \tau_2\,|\eta(\tau)|^4,$$
$$\frac{\mathrm{d}^2\tau'}{\tau_2'^2} \overset{(4)}{=} \frac{|\tau|^{-4}\,\mathrm{d}^2\tau}{\tau_2^2\,|\tau|^{-4}} = \frac{\mathrm{d}^2\tau}{\tau_2^2}.$$

(1) Multiply numerator and denominator of $-1/\tau$ by $\bar\tau$; $\operatorname{Im}(-\bar\tau) = \tau_2$.
(2) The modular transformation of η, raised to the fourth power in absolute value: $\left|\sqrt{-i\tau}\right|^4 = |\tau|^2$.
(3) Multiply the two results of the first line: the factors $|\tau|^{\pm 2}$ cancel.
(4) $\mathrm{d}\tau'/\mathrm{d}\tau = \tau^{-2}$, so areas scale by $|\tau|^{-4}$; and $\tau_2'^2 = \tau_2^2\,|\tau|^{-4}$ by line 1.

Under T, τ_2 is unchanged and $|\eta|$ only picks up the phase $\left|e^{i\pi/12}\right| = 1$. So both factors are invariant separately: $\tau_2\,|\eta|^4$ is a modular invariant (it is $\det'\Delta$, which depends only on the metric, not on the choice of τ representing it), and $\mathrm{d}^2\tau/\tau_2^2$ is the invariant hyperbolic area. The integral over the fundamental domain $\mathcal{F}$ is therefore well defined: this is the $1/|\Gamma_\Sigma|$ of (9.78) at work.

The anomaly: a constant rescaling checks the coefficient. The Weyl variation formula (9.63) says $\delta\log(\det'\Delta/A) = -\frac{1}{12\pi}\int\sqrt{g}\,R\,\delta\omega$. We can check its coefficient with nothing more than $\zeta_\Delta(0)$, by taking ω constant. Then $g\mapsto e^{2\omega}g$ sends $\Delta\mapsto e^{-2\omega}\Delta$ and $A\mapsto e^{2\omega}A$, so

$$\log\frac{\det'(e^{-2\omega}\Delta)}{e^{2\omega}A} \overset{(1)}{=} -2\omega\,\zeta_\Delta(0) + \log\det'\Delta - 2\omega - \log A$$
$$\overset{(2)}{=} \log\frac{\det'\Delta}{A} - 2\omega\left(\frac{\chi}{6} - 1\right) - 2\omega = \log\frac{\det'\Delta}{A} - \frac{\chi}{3}\,\omega,$$

$$-\frac{1}{12\pi}\int_\Sigma \sqrt{g}\,R\,\omega \overset{(3)}{=} -\frac{\omega}{12\pi}\cdot 4\pi\chi = -\frac{\chi}{3}\,\omega.$$

(1) The scaling law $\det'(cP) = c^{\zeta_P(0)}\det' P$ of Example 9.26, with $c = e^{-2\omega}$.
(2) The heat-kernel value $\zeta_\Delta(0) = \chi/6 - 1$ (Example 9.25).
(3) Gauss–Bonnet $\int\sqrt{g}\,R = 4\pi\chi$ (with $R = 2K$).

The two sides agree. So the conformal anomaly of one scalar field is, at its crudest, the statement that $\zeta_\Delta(0)$ is not zero. For d scalars the matter factor $(\det'\Delta/A)^{-d/2}$ varies by $+\frac{d}{24\pi}\int\sqrt{g}\,R\,\delta\omega$. The ghost factor varies with $-\frac{26}{24\pi}$, and the total (9.64) vanishes only for $d = 26$. (On the torus $\chi = 0$, so constant rescalings are harmless in any dimension. And since $\tau_2\,|\eta|^4$ is modular invariant by itself, the torus integrand is modular invariant for every d. So on the torus the number 26 does not show up as a consistency condition. It shows up in the spectrum instead: the exponent $-48 = -2(d-2)$ of $|\eta|$ in Z_1 counts $d-2 = 24$ oscillator species, which is why $d_1 = 24$, and the leading $|q|^{-2} = \left|q^{-(d-2)/24}\right|^2$ is what puts the graviton exactly at the massless level $N = 1$.)

Every concept of the chapter

The tables below list every concept introduced in Chapter 9, one table per section of Nash, plus one for the explicit amplitudes we computed beyond Nash. The middle column is the *operational* meaning: how to compute it or test for it. The last column says where the concept is used later in the book (or where it came from, when it was imported).

Nash §1, The bosonic string (Nash pp. 259–262): actions and symmetries

Concept	Operational meaning	Used later
world line, einbein	$S_e = \frac{1}{2}\int(\dot{x}^2/e + em^2)\,\mathrm{d}\tau$; eliminating e gives $m\times$length	model for the Polyakov trick
world sheet	the surface $\phi:\Sigma\to\mathbb{R}^d$ swept by a string; closed and oriented here	Chapter 11
induced metric	$h_{ab} = \partial_a\phi\cdot\partial_b\phi$, lengths measured with space-time rulers	Nambu–Goto area
Nambu–Goto action	$T\int\sqrt{\det h}$: tension times area; Gram determinant	classical string, minimal surfaces
Polyakov action	$\frac{T}{2}\int\sqrt{g}\,g^{ab}\partial_a\phi\cdot\partial_b\phi$: d free scalars on (Σ, g)	all of Chapter 9, Chapter 10, Chapter 11
energy–momentum tensor	$T_{ab} = \partial_a\phi\cdot\partial_b\phi - \frac{1}{2}g_{ab}(\partial\phi)^2$; traceless; $T_{ab} = 0$ is the g equation	Virasoro algebra, c (Chapter 11)
classical equivalence	at $T_{ab} = 0$, $g \propto h$ and $S_{\mathrm{P}} = S_{\mathrm{NG}}$	
Weyl transformation	$g\mapsto e^{2\omega}g$; $\sqrt{g}\,g^{ab}$ unchanged in 2D only	conformal anomaly (Chapter 10)
diffeomorphism action	pull back: $\phi\mapsto\alpha^*\phi = \phi\circ\alpha$, $g\mapsto\alpha^*g$	gauge group of gravity
target translations	$\phi^\mu\mapsto\phi^\mu + a^\mu$; source of the zero mode	momentum conservation
configuration space B	$\mathrm{Map}(\Sigma,\mathbb{R}^d)\times\mathrm{Met}(\Sigma)$, Nash's domain of S	
gauge group	$\mathrm{Diff}^+\ltimes C^\infty_+$, law $(\alpha_1, f_1)(\alpha_2, f_2) = (\alpha_2\circ\alpha_1, f_1\,(f_2\circ\alpha_1))$	Faddeev–Popov (Section 9.2)
normal subgroup	C^∞_+ is normal: α conjugates a Weyl factor to $f\circ\alpha^{-1}$	quotient in two steps

Nash §1, The bosonic string (Nash pp. 259–262): path integral and determinants

Concept	Operational meaning	Used later
Z_p, vacuum amplitude	$\int \mathcal{D}g\,\mathcal{D}\phi\, e^{-S}$ over genus-p surfaces; closed surfaces compute a trace	Chapter 10, Chapter 12
genus expansion	$Z = \sum_p Z_p$; the Euler term weights each handle by g_s^2	string perturbation theory
Riemann surface	a metric up to scale = a complex structure; Beltrami μ from $\mathrm{d}s^2 = \lambda\,\lvert\mathrm{d}z + \mu\mathrm{d}\bar{z}\rvert^2$	Chapter 5, Chapter 11
isothermal coordinates	solve $\partial_{\bar{z}} w = \mu\,\partial_z w$; then $g = \rho\,\lvert\mathrm{d}w\rvert^2$	conformal gauge
action as $\langle\phi, \Delta\phi\rangle$	$S = \frac{1}{2}(\phi, \Delta_g\phi)$, $\Delta_g = -\frac{1}{\sqrt{g}}\partial_a\sqrt{g}g^{ab}\partial_b$; $= 2\int \partial\phi\cdot\bar{\partial}\phi$	Gaussian integral
Gaussian integral	$\int \mathrm{d}^n x\, e^{-x^{\mathsf{T}}Mx} = \pi^{n/2}(\det M)^{-1/2}$; mode by mode for Δ_g	every one-loop determinant
Weyl's law	$N(\lambda) \approx A\lambda/4\pi$; so $\sum \lambda_n^{-s}$ converges for $\mathrm{Re}\, s > 1$	heat kernel
zero mode, $(1,1)_g$	constants in $\mathrm{Ker}\,\Delta_g$; the centre-of-mass integral gives $\mathrm{vol}(\mathbb{R}^d)\cdot A_g^{d/2}$	momentum δ-function
det′	product of non-zero eigenvalues; lattice circle: $\det' M = n^2$	(9.7), (9.35)
zeta function	$\zeta_P(s) = \sum \lambda_n^{-s}$, continued to $s = 0$	Chapter 10, Chapter 12
zeta determinant	$\det' P = e^{-\zeta_P'(0)}$; circle: L^2; oscillator: $4\sinh^2(\beta\omega/2)$	Ray–Singer torsion (Chapter 12)
heat trace	$\mathrm{Tr}\, e^{-t\Delta} = \frac{A}{4\pi t} + \frac{\chi}{6} + O(t)$; Mellin transform gives ζ	index theorem (Chapter 4)
$\zeta_\Delta(0)$	$\chi/6 - 1$: the constant term of the heat trace minus the zero mode	scaling law, anomaly
scaling law	$\det'(cP) = c^{\zeta_P(0)}\det' P$	constant Weyl anomaly

Nash §2, The space of metrics (Nash pp. 262–265): quotients and metrics

Concept	Operational meaning	Used later
$\mathcal{D}g$, Nash's (9.8)	$\mathcal{D}\mathrm{Met}/(\mathrm{vol}\, C^\infty_+ \,\mathrm{vol}\,\mathrm{Diff}^+)$: one representative per orbit	(9.35)
Faddeev–Popov (finite)	polar coordinates: $\mathrm{d}^2x = r\,\mathrm{d}r\,\mathrm{d}\theta$; the Jacobian is the orbit's size	Yang–Mills gauge fixing (Chapter 8)
Diff_0, Γ_Σ	diffeos isotopic to the identity; mapping class group $\mathrm{Diff}^+/\mathrm{Diff}_0$ ($\mathrm{SL}(2,\mathbb{Z})$ for T^2)	global anomalies (Chapter 10)
$\mathrm{Met}_{\mathrm{const}}$	metrics of constant curvature $+1, 0, -1$ (area 1 for T^2): the Weyl slice	
Teichmüller, moduli	$\mathcal{T}_p = \mathrm{Met}_{\mathrm{const}}/\mathrm{Diff}_0$, $\mathcal{M}_p = \mathcal{T}_p/\Gamma_\Sigma$; $\dim_{\mathbb{R}} = 0, 2, 6p-6$	Chapter 5, Chapter 11
Riemannian volume	$\sqrt{\det\langle e_i, e_j\rangle}\,\mathrm{d}^n x$ in any frame	WP measure
metric on Met	$\langle X, Y\rangle_{\mathrm{met}} = \int \sqrt{g}\,\mathrm{tr}(g^{-1}Xg^{-1}Y)$ (Nash (9.10)–(9.11)); DeWitt family	Chapter 10
diffeo invariance	$\langle \alpha^* X, \alpha^* Y\rangle_{\alpha^* g} = \langle X, Y\rangle_g$: change of variables	WP well defined
Pos(2)	positive 2×2 matrices $= \mathbb{R}_+ \times$ hyperbolic plane under $\mathrm{tr}(g^{-1}\mathrm{d}g)^2$	torus WP metric
metric on vect	$\langle V, W\rangle_{\mathrm{vect}} = \int \sqrt{g}\, g_{ab} V^a W^b$ (Nash (9.12))	ghost measure
Lie derivative	$\mathcal{L}_V g = \nabla_a V_b + \nabla_b V_a$ (Nash (9.13)); infinitesimal diffeo	Chapter T1, Chapter 11
Killing, conformal Killing	$\mathcal{L}_V g = 0$; $\mathcal{L}_V g = f g$. CKVs: V^z holomorphic. 6, 2, 0 real for $p = 0, 1, \geq 2$	Virasoro L_{-1}, L_0, L_1 (Chapter 11)

Nash §2, The space of metrics (Nash pp. 262–265): the operator P_1

Concept	Operational meaning	Used later
C_g, $C_g^\perp$	$C_g = \{\alpha g\}$ (Weyl directions); $C_g^\perp$ = traceless tensors; test: $\mathrm{tr}(g^{-1}X)$ (Nash (9.14)–(9.16))	
split of $\mathcal{L}_V g$	$\alpha = \nabla_c V^c$ and $h = \mathcal{L}_V g - \alpha g$ (Nash (9.17)–(9.18))	
$P_1 = A_g$	$(P_1 V)_{ab} = \nabla_a V_b + \nabla_b V_a - g_{ab}\nabla_c V^c$ (Nash (9.19))	Chapter 10
Cauchy–Riemann form	$(P_1 V)_{\bar z\bar z} = \rho\,\partial_{\bar z} V^z$: P_1 is $\bar\partial$ on K^{-1}	determinant line bundles
ellipticity of P_1	principal symbol $\propto \xi_{\bar z}$, invertible for $\xi \neq 0$ (Chapter 2)	Fredholm, finite index
$P_1^\dagger$	$(P_1^\dagger h)_b = -2\nabla^a h_{ab}$, i.e. $-\frac{4}{\rho}\partial_{\bar z} h_{zz}$	
quadratic differentials	$\mathrm{Ker}\, P_1^\dagger = \{\varphi(z)\mathrm{d}z^2, \varphi \text{ holomorphic}\} = H^0(K^2)$	Beltrami differentials, b zero modes
Range $\oplus$ Ker	$W = \mathrm{Range}\, A \oplus \mathrm{Ker}\, A^*$ orthogonally (Nash (9.20))	Hodge-type decompositions
three-way split	$T_g\mathrm{Met} = C_g \oplus \mathrm{Range}\, P_1 \oplus \mathrm{Ker}\, P_1^\dagger$ (Nash (9.21))	conformal gauge
Weitzenböck	$P_1^\dagger P_1 = -2(\nabla^2 + K)$ on vector fields; no kernel if $K < 0$	ζ-determinant of ghosts
index of P_1	$\dim\mathrm{Ker}\, P_1 - \dim\mathrm{Ker}\, P_1^\dagger = 3\chi$ (Riemann–Roch for K^{-1})	Chapter 4, Chapter 10
$T\mathcal{T}_p$	$T_{[g]}\mathcal{T}_p \cong \mathrm{Ker}\, P_1^\dagger$ (Nash (9.22))	WP metric
conformal anomaly	$\delta_\omega \log(\text{integrand}) = \frac{d-26}{24\pi}\int \sqrt{g} R\,\delta\omega$	Chapter 10 ($d = 26$), Chapter 11

Nash §3, The Weil–Petersson metric (Nash pp. 265–268)

Concept	Operational meaning	Used later
quotient metric	length of $\pi_* X$:= length of the horizontal lift of it (e.g. $S^2/\mathrm{SO}(2)$)	
$\langle\ ,\ \rangle_{\mathrm{const}}$	restriction of $\langle\ ,\ \rangle_{\mathrm{met}}$ to $\mathrm{Met}_{\mathrm{const}}$; Diff_0 acts by isometries	
Weil–Petersson metric	lift $U, V \in T\mathcal{T}_p$ horizontally to $\mathrm{Ker}\, P_1^\dagger$ and take $\langle\ ,\ \rangle_{\mathrm{met}}$ (Nash (9.25))	measure on $\mathcal{M}_p$
independence	different lifts differ by $\mathrm{Range}\, P_1$; different representatives by an isometry (Nash (9.26)–(9.29))	
Petersson form	$8\,\mathrm{Re}\int \varphi\bar{\varphi}'/\rho\, \mathrm{d}^2x$ for $h = \varphi \mathrm{d}z^2 + \text{c.c.}$	
torus WP	$2\,\lvert \mathrm{d}\tau\rvert^2/\tau_2^2$ on the upper half-plane	Chapter 11 (modular forms)
modular group	$\tau \mapsto (a\tau + b)/(c\tau + d)$, generated by T, S; isometries of WP	Chapter 11, Chapter 10
fundamental domain	$\mathcal{F} = \{\lvert\tau_1\rvert \le \frac{1}{2}, \lvert\tau\rvert \ge 1\}$; WP volume $2\pi/3$	torus amplitudes
conformal gauge	$g = \alpha^*(e^\sigma \hat{g}_t)$ (Nash (9.30)–(9.31))	Chapter 11
image measure	$\mathrm{d}^k(Av) = \sqrt{\det A^{\mathsf{T}} A}\, \mathrm{d}^k v$ (Nash (9.32))	Faddeev–Popov
triangular Jacobian	only diagonal blocks count: Weyl, $\sqrt{\det P_1^\dagger P_1}$, WP	
Z_p, $p \ge 2$	$\int_{\mathcal{M}_p} \mathrm{d}\mu_{\mathrm{wp}} (\det'(\Delta/2)/(1,1))^{-13} \sqrt{\det P_1^\dagger P_1}$ (Nash (9.35))	Chapter 10
CKVs in Z_p	$\det \to \det'$ and a factor $1/\mathrm{vol}\,\mathrm{CKG}$ for $p = 0, 1$ (Nash (9.33)–(9.34))	sphere amplitudes
ghosts b, c	$\sqrt{\det' P_1^\dagger P_1} = \int \mathcal{D}b\, \mathcal{D}c\, e^{-\frac{1}{4\pi}\int b P_1 c}$	$c = -26$ (Chapter 11), BRST
real vs complex	$\det \tilde{A}_g^* \tilde{A}_g = (\det \bar{\partial}_{K^*}^* \bar{\partial}_{K^*})^2$ (Nash (9.36))	Quillen metric (Chapter 10)

Beyond Nash: the formula producing numbers

Concept	Operational meaning	Used later
twisted circle	$\prod_m \lvert m + w\rvert^2$ regularised $= 4\,\lvert\sin \pi w\rvert^2 = e^{2\pi c}\left\lvert 1 - e^{2\pi i(b+ic)}\right\rvert^2$	torus determinants
Dedekind η	$\eta(\tau) = q^{1/24}\prod_{n\ge1}(1-q^n)$, $q = e^{2\pi i\tau}$; weight $\frac{1}{2}$	Chapter 11
$\det'\Delta$ on T^2	$\tau_2\,\lvert\eta(\tau)\rvert^4$; equivalently Kronecker's first limit formula	Chapter 11
Casimir energy	$\frac{1}{2}\sum n = \frac{1}{2}\zeta_R(-1) = -\frac{1}{24}$ per field: the $q^{-1/24}$	$L_0 - \frac{c}{24}$ (Chapter 11)
Z_1	$2^{-13}\int_{\mathcal{F}} \mathrm{d}^2\tau\, \tau_2^{-14}\,\lvert\eta\rvert^{-48}$: modular invariant, UV finite	Chapter 11
level matching	$\int \mathrm{d}\tau_1$ projects onto $N = \tilde{N}$	closed-string spectrum
tachyon, massless states	$N = 0$: $e^{4\pi\tau_2}$ divergence; $N = 1$: $24^2 = 576 = 299 + 276 + 1$ (graviton, B, dilaton)	
sphere gauge fixing	fix z_1, z_2, z_3; Jacobian $\lvert z_{12}z_{13}z_{23}\rvert^2 = \lvert\langle ccc\rangle\rvert^2$	vertex operators (Chapter 11)
punctured moduli	$\dim_{\mathbb{R}} \mathcal{M}_{p,n} = 6p - 6 + 2n$ when $2p - 2 + n > 0$	
higher genus	$\det'\Delta \propto Z'(1)$, $\det P_1^\dagger P_1 \propto Z(2)$ (Selberg zeta); Belavin–Knizhnik	Chapter 10

Formulas to keep at your fingertips

F1. *Polyakov.* $S[\phi, g] = \frac{T}{2}\int_\Sigma \mathrm{d}^2x\sqrt{g}\, g^{ab}\partial_a\phi\cdot\partial_b\phi$; $T_{ab} = \partial_a\phi\cdot\partial_b\phi - \frac{1}{2}g_{ab}(\partial\phi)^2$, $g^{ab}T_{ab} = 0$.

F2. *Gauge group.* $(\alpha, f)\cdot(\phi, g) = (\alpha^*\phi, f\,\alpha^*g)$; $(\alpha_1, f_1)(\alpha_2, f_2) = (\alpha_2\circ\alpha_1, f_1\,(f_2\circ\alpha_1))$.

F3. *Embedding integral.* $\int \mathcal{D}\phi\, e^{-S} \propto \left(\det{}'(\Delta_g/2)/(1,1)_g\right)^{-d/2}$, with $(1,1)_g = \int\sqrt{g}$.

F4. *Zeta determinant.* $\zeta_P(s) = \sum\lambda_n^{-s}$, $\det{}'P = e^{-\zeta_P'(0)}$, $\det{}'(cP) = c^{\zeta_P(0)}\det{}'P$; circle: $\det{}'\Delta = L^2$.

F5. *Heat kernel.* $\operatorname{Tr} e^{-t\Delta} = \frac{A}{4\pi t} + \frac{\chi}{6} + O(t)$, so $\zeta_\Delta(0) = \frac{\chi}{6} - 1$.

F6. *Metrics.* $\langle X, Y\rangle_{\mathrm{met}} = \int\sqrt{g}\,\operatorname{tr}(g^{-1}Xg^{-1}Y)$, $\langle V, W\rangle_{\mathrm{vect}} = \int\sqrt{g}\,g_{ab}V^aW^b$.

F7. *The operator P_1.* $(P_1V)_{ab} = \nabla_aV_b + \nabla_bV_a - g_{ab}\nabla_cV^c$, $(P_1^\dagger h)_b = -2\nabla^a h_{ab}$, $P_1^\dagger P_1 = -2(\nabla^2 + K)$.

F8. *Decomposition.* $T_g\mathrm{Met} = C_g \oplus \operatorname{Range}P_1 \oplus \operatorname{Ker}P_1^\dagger$, and $T_{[g]}\mathcal{T}_p \cong \operatorname{Ker}P_1^\dagger = H^0(K^2)$.

F9. *Index.* $\dim_{\mathbb{R}}\operatorname{Ker}P_1 - \dim_{\mathbb{R}}\operatorname{Ker}P_1^\dagger = 3\chi = 6 - 6p$.

F10. *Weil–Petersson.* $\langle U, V\rangle_{\mathrm{wp}} = \langle X^{\mathrm{hor}}, Y^{\mathrm{hor}}\rangle_{\mathrm{met}}$; torus: $2\,|\mathrm{d}\tau|^2/\tau_2^2$.

F11. *Image measure.* $\mathrm{d}^k(Av) = \sqrt{\det A^{\mathsf{T}}A}\,\mathrm{d}^kv$, so $\mathcal{D}(P_1V) = \sqrt{\det P_1^\dagger P_1}\,\mathcal{D}V$.

F12. *The amplitude.* In $d = 26$, $Z_p = \int_{\mathcal{M}_p}\mathrm{d}\mu_{\mathrm{wp}}\left(\det{}'(\Delta/2)/(1,1)\right)^{-13}\det{}'\bar\partial_{K^*}^*\bar\partial_{K^*}$, with $1/\mathrm{vol}\,\mathrm{CKG}$ for $p \le 1$.

F13. *Anomaly.* $\delta_\omega\log(\text{integrand}) = \frac{d-26}{24\pi}\int\sqrt{g}\,R\,\delta\omega$.

F14. *Torus.* $\det{}'\Delta = \tau_2\,|\eta|^4$, $Z_1 = 2^{-13}\int_{\mathcal{F}}\mathrm{d}^2\tau\,\tau_2^{-14}\,|\eta|^{-48}$.

Where the chapter comes from and where it is used later

This chapter is a meeting point. It imports the analysis of elliptic operators, the index theorem and the geometry of Riemann surfaces, and it exports the conformal anomaly, the ghost system and the torus partition function. Figure 9.26 shows the main routes.

- **The critical dimension.** The division by $\mathrm{vol}\,C_+^\infty$ was allowed only in $d = 26$. Chapter 10 derives the number 26 in three ways: by the heat-kernel computation of the Weyl variation previewed in Section 9.2.11, by the first Chern class of the determinant line bundle of $\bar\partial_{K^*}$ over $\mathcal{M}_p$ (families index theorem), and by Mumford's isomorphism.
- **Global anomalies and large diffeomorphisms.** The mapping class group Γ_Σ, which we divided out to pass from $\mathcal{T}_p$ to $\mathcal{M}_p$, is the prototype of a group of large gauge transformations. Modular invariance of Z_1 is the statement that the theory has no global anomaly under it (Chapter 10).
- **Conformal field theory.** In conformal gauge the residual symmetry is generated by the traceless T_{ab}; its modes form the Virasoro algebra, and T_{zz} of the b, c ghosts has central charge -26. The torus partition function $\tau_2^{-1/2}\,|\eta|^{-2}$ of one free boson, the Casimir shift $-\frac{c}{24}$ and modular invariance are the starting point of Chapter 11.
- **Gluing and topological field theory.** The trace picture of the vacuum amplitude (cutting a torus along a circle gives $\operatorname{Tr}e^{-\beta H}$) is the germ of the axioms of Chapter 12, where

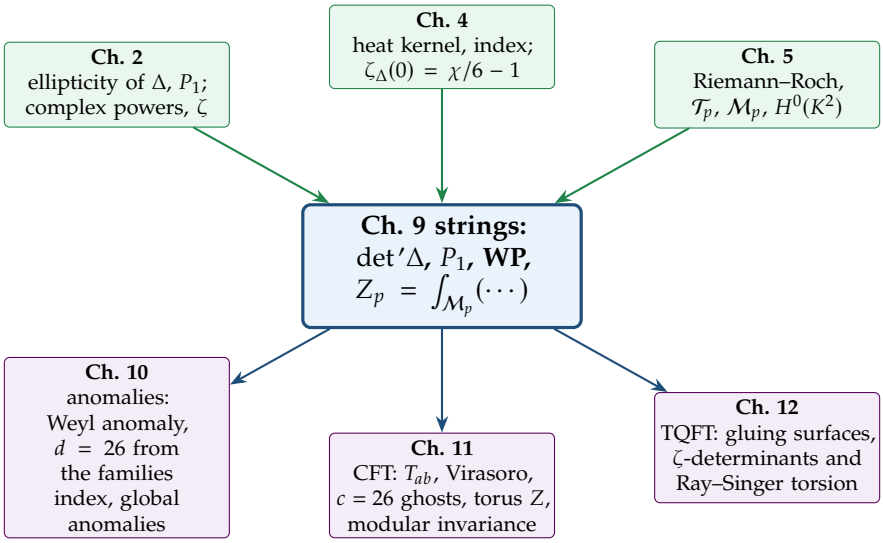

Figure 9.26: Where Chapter 9 comes from (green, above) and where it is used (purple, below). The three imports are exactly the three ingredients of Nash's formula: an elliptic operator theory to define the determinants, the heat kernel to evaluate them, and Riemann–Roch to count the moduli. The three exports are the three things the formula forces on us: the anomaly that fixes $d = 26$, the conformal field theory of the matter and ghost fields, and the idea of building amplitudes by gluing surfaces.

amplitudes are assigned to surfaces and glued along boundaries. The zeta-regularised determinants of this chapter reappear there as Ray–Singer torsion.

Watch out: The six confusions of this chapter

1. *The letter g.* Nash writes g for the metric and p for the genus. The Euler characteristic is $\chi = 2 - 2p$. In most physics texts g is the genus.
2. Diff$^+$ *versus* Diff$_0$. Dividing Met$_{\text{const}}$ by Diff$_0$ gives Teichmüller space, a smooth ball; dividing by all of Diff$^+$ gives the moduli space, which has orbifold points ($\tau = i$, $\tau = e^{i\pi/3}$). The difference is the discrete group Γ_Σ, and in the path integral it appears only as the factor $1/|\Gamma_\Sigma|$ that restricts $\int_{\mathcal{T}_p}$ to a fundamental domain.
3. det *versus* det$'$. Both Δ_g and (for $p \le 1$) P_1 have kernels. Their determinants are always primed, and the zero modes reappear elsewhere: the area $(1,1)_g$ and the volume of space-time for Δ, the factor $1/\operatorname{vol}\mathrm{CKG}$ for P_1. Forgetting either gives a wrong τ-dependence (for the torus) or an infinite answer (for the sphere).
4. *Classical versus quantum Weyl invariance.* The action is Weyl invariant in any d; the measure is not. Nash sets $d = 26$ at the point where he divides by $\operatorname{vol} C^\infty_+$. Everything after (9.8) assumes it.
5. *Real versus complex determinants.* P_1 is a real operator on real vector fields. As a complex operator it is $\bar\partial_{K^*}$ on one complex function V^z. Each complex eigenvalue appears twice among the real ones, so $\sqrt{\det P_1^\dagger P_1}$ (real) equals $\det \bar\partial^* \bar\partial$ (complex), up to the constant rescaling of the operator.
6. *Normalisations.* The factor 2 in the Weil–Petersson metric of the torus, the $\frac{1}{2}$ in $\Delta_g/2$ and the 2^{-13} in Z_1 are all conventions (the choice of $\langle\ ,\ \rangle_{\text{met}}$ and of T). They change overall constants, never the τ-dependence. The scaling law $\det'(cP) = c^{\zeta_P(0)} \det' P$ keeps track of them.

Try it: Test yourself on the chapter

(a) Why is Weyl invariance special to two dimensions?
Answer: under $g \mapsto fg$ in n dimensions, $\sqrt{g} \mapsto f^{n/2}\sqrt{g}$ and $g^{ab} \mapsto f^{-1}g^{ab}$, so $\sqrt{g}\,g^{ab} \mapsto f^{n/2-1}\sqrt{g}\,g^{ab}$, which is unchanged only for $n = 2$.

(b) How many real moduli does a genus-3 surface with 2 punctures have?
Answer: $6 \cdot 3 - 6 + 2 \cdot 2 = 16$.

(c) Compute $\det'(4\Delta)$ on a circle of length L.
Answer: $4^{\zeta_\Delta(0)}L^2 = 4^{-1}L^2 = L^2/4$, which is the determinant of Δ on a circle of length $L/2$, as it should be.

(d) Why is there no Faddeev–Popov factor $1/\mathrm{vol}\,\mathrm{CKG}$ for $p \geq 2$?
Answer: $K < 0$ makes $P_1^\dagger P_1 = -2(\nabla^2 + K)$ strictly positive, so $\mathrm{Ker}\,P_1 = 0$: there are no conformal Killing vectors, and Diff_0 acts freely on $\mathrm{Met}_{\mathrm{const}}$.

(e) Show that the hyperbolic area of $\mathcal{F}$ is $\pi/3$.
Answer: $\int_{-1/2}^{1/2} \mathrm{d}\tau_1 \int_{\sqrt{1-\tau_1^2}}^{\infty} \frac{\mathrm{d}\tau_2}{\tau_2^2} = \int_{-1/2}^{1/2} \frac{\mathrm{d}\tau_1}{\sqrt{1-\tau_1^2}} = 2\arcsin\frac{1}{2} = \frac{\pi}{3}$; the WP volume is twice this.

Chapter 10

Anomalies

Where this chapter is going

A symmetry of a classical action need not survive quantisation. When it does not, we say the theory has an **anomaly**. This chapter is about the anomalies of chiral fermions, and about the surprising fact that every one of them is a piece of topology. The chain of ideas is short. The fermion path integral produces a determinant, $\det \not{D}_A$. The symmetry we care about (gauge invariance, coordinate invariance, conformal invariance) acts on the background field A or on the metric ρ. The anomaly is the failure of the determinant to be invariant. The index theorem tells us when a determinant is forced to vanish; the *families* index theorem, applied to the whole family $\{\not{D}_A\}$, tells us when the determinant cannot even be defined as an invariant function. The answer is a cohomology class: a closed 1-form on the symmetry group $\mathcal{G}$, or equivalently a first Chern class of a line bundle over the orbit space $\mathcal{A}/\mathcal{G}$. Nash's §§1–3, which we expand into Sections 10.1 to 10.3 and 10.5 to 10.7, do this for gauge fields and for gravity. His §4 applies it to the string worldsheet and finds $d = 26$. His §5 treats *global* anomalies, which are torsion classes invisible to de Rham cohomology. His §6 retells the whole story in Hamiltonian language, where the anomaly becomes a failure of Gauss's law.

10.1 Introduction: what an anomaly is

Here is the puzzle that started it all. The neutral pion π^0 decays into two photons with a lifetime of about 8×10^{-17} s. In the late 1960s the best theory of pions, current algebra with an exactly conserved axial current, predicted that this decay should be *forbidden* for massless quarks (Sutherland and Veltman). Nature disagreed by many orders of magnitude. The resolution, due to Adler and to Bell and Jackiw, is that the axial current is conserved in the classical theory but *not* in the quantum theory. A single fermion loop, the triangle graph, spoils the conservation law, and the rate it predicts is the observed one.

That was the first **anomaly**. It is not a mistake in the calculation. It is a genuine feature of quantum field theory: the path-integral measure for chiral fermions cannot be made invariant under every classical symmetry at once. In this section we make that sentence precise, set up our conventions, and preview why the answer turns out to be topological.

Reading Nash (p. 269, §1)

Nash's introduction is one page. He says that the word "anomaly" "usually has to do with strange or even pathological behaviour of chiral fermions when coupled to gauge fields", names the Adler–Bell–Jackiw triangle anomaly for $G = \mathrm{U}(1)$, lists the later generalisations (Yang–Mills, gravity with $\mathrm{Diff}^+(M)$ in place of $\mathcal{G}$, the conformal anomaly

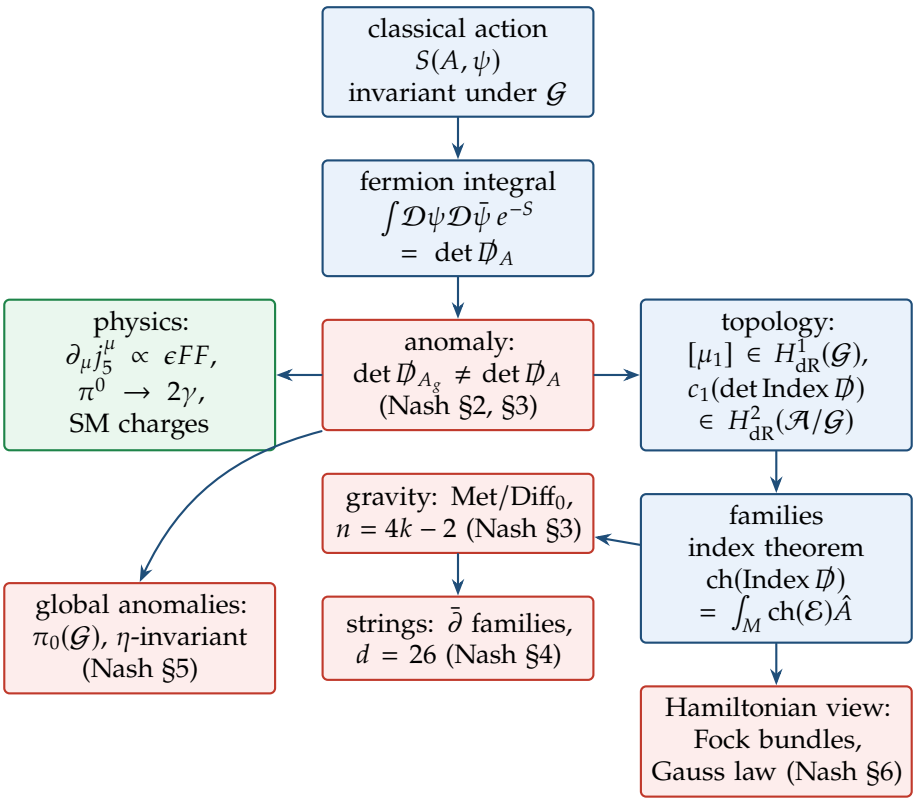

Figure 10.1: The logic of Chapter 10. Blue boxes are the mathematical spine (determinants, cohomology, the families index theorem); red boxes are the kinds of anomaly the chapter treats; the green box is where the anomaly touches experiment. Every red box is obtained by feeding a different family of elliptic operators into the same blue machine.

of the bosonic string, the Hamiltonian view), and then gives his definition: an anomaly is "some obstruction to the defining of a quantum theory with the same invariance groups as its underlying classical theory". The obstruction has a topological origin: it lives in the cohomology $H^*(\mathcal{G})$ of the invariance group. Everything in this part unpacks these statements.

10.1.1 Conventions: Euclidean spinors in two and four dimensions

Nash works on a compact Riemannian (Euclidean) manifold M of even dimension $n = 2m$. We do the same, and we fix the representation of every object now, because the sign of an anomaly depends on it.

Gamma matrices. In n Euclidean dimensions we use Hermitian matrices obeying

$$\gamma_\mu \gamma_\nu + \gamma_\nu \gamma_\mu = 2\delta_{\mu\nu}\,\mathbf{1}, \qquad \gamma_\mu^\dagger = \gamma_\mu, \tag{10.1}$$

so $\gamma_\mu^2 = \mathbf{1}$ for each μ (no sum). Indices are raised and lowered with $\delta_{\mu\nu}$, so $\gamma^\mu = \gamma_\mu$. The reminder of the general theory is in Chapter T4; here we only need two explicit cases.

- $n = 2$**.** Take $\gamma_1 = \sigma_1$, $\gamma_2 = \sigma_2$ (Pauli matrices).
- $n = 4$**.** Take, in 2×2 blocks,

$$\gamma_j = \begin{pmatrix} 0 & i\sigma_j \\ -i\sigma_j & 0 \end{pmatrix} \ (j = 1,2,3), \qquad \gamma_4 = \begin{pmatrix} 0 & \mathbf{1} \\ \mathbf{1} & 0 \end{pmatrix}. \tag{10.2}$$

Chirality. In $n = 2m$ dimensions the **chirality operator** is

$$\gamma_5 := (-i)^m\, \gamma_1 \gamma_2 \cdots \gamma_{2m}. \tag{10.3}$$

(Nash and most physicists write γ_5 in every even dimension; in $n = 2$ it is often called γ_3.) It squares to $\mathbf{1}$, is Hermitian, and anticommutes with every γ_μ. Its ± 1 eigenspaces are the positive and negative **chirality** spinors, the spaces $E^\pm$ of Nash's (10.2).

Worked example 10.1: The chirality matrix in two and four dimensions

For $n = 2$:

$$\begin{aligned} \gamma_5 &\overset{(1)}{=} -i\,\sigma_1\sigma_2 \\ &\overset{(2)}{=} -i\,(i\sigma_3) \\ &= \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \end{aligned}$$

(1) Definition (10.3) with $m = 1$.
(2) The Pauli identity $\sigma_1\sigma_2 = i\sigma_3$.

So positive chirality is the upper component. For $n = 4$, multiply the blocks of (10.2). A product of two block-off-diagonal matrices is block diagonal: $\left(\begin{smallmatrix} 0 & a \\ b & 0 \end{smallmatrix}\right)\left(\begin{smallmatrix} 0 & c \\ d & 0 \end{smallmatrix}\right) = \left(\begin{smallmatrix} ad & 0 \\ 0 & bc \end{smallmatrix}\right)$. Hence

$$\gamma_1\gamma_2\gamma_3\gamma_4 \overset{(1)}{=} \begin{pmatrix} (i\sigma_1)(-i\sigma_2) & 0 \\ 0 & (-i\sigma_1)(i\sigma_2) \end{pmatrix} \begin{pmatrix} (i\sigma_3)(\mathbf{1}) & 0 \\ 0 & (-i\sigma_3)(\mathbf{1}) \end{pmatrix}$$

$$\overset{(2)}{=} \begin{pmatrix} \sigma_1\sigma_2 \cdot i\sigma_3 & 0 \\ 0 & \sigma_1\sigma_2 \cdot (-i\sigma_3) \end{pmatrix}$$
$$\overset{(3)}{=} \begin{pmatrix} i\sigma_3 \cdot i\sigma_3 & 0 \\ 0 & i\sigma_3 \cdot (-i\sigma_3) \end{pmatrix} = \begin{pmatrix} -\mathbf{1} & 0 \\ 0 & \mathbf{1} \end{pmatrix}.$$

(1) Pair up $(\gamma_1\gamma_2)$ and $(\gamma_3\gamma_4)$ and use the block rule.
(2) $(i)(-i) = 1$ in both entries of the first factor.
(3) $\sigma_1\sigma_2 = i\sigma_3$ and $\sigma_3^2 = \mathbf{1}$.

Therefore $\gamma_5 = (-i)^2\gamma_1\gamma_2\gamma_3\gamma_4 = \operatorname{diag}(\mathbf{1}, -\mathbf{1})$: again positive chirality is the upper two components. A four-component spinor is a pair $\psi = (\psi_+, \psi_-)$ of two-component **Weyl spinors**.

Gauge fields. We follow Nash and the mathematicians: the gauge potential $A = A_\mu \, \mathrm{d}x^\mu$ is a 1-form with values in the Lie algebra $\mathfrak{g}$ of *anti-Hermitian* matrices, the covariant derivative is $D_\mu = \partial_\mu + A_\mu$, the curvature is $F = \mathrm{d}A + A \wedge A$ with components $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + [A_\mu, A_\nu]$, and a gauge transformation $g : M \to G$ acts by

$$A \mapsto A_g = g^{-1}Ag + g^{-1}\mathrm{d}g, \qquad \psi \mapsto g^{-1}\psi, \qquad F \mapsto g^{-1}Fg. \tag{10.4}$$

The (Euclidean) Dirac operator is

$$\not{D}_A = \gamma^\mu D_\mu = \gamma^\mu(\partial_\mu + A_\mu). \tag{10.5}$$

Because γ^μ is Hermitian and D_μ is anti-self-adjoint, $\not{D}_A$ is *anti*-self-adjoint, so $i\not{D}_A$ is self-adjoint with real eigenvalues and $\not{D}_A^2 = -(i\not{D}_A)^2 \le 0$. Since γ_5 anticommutes with every γ^μ and commutes with A_μ, $\not{D}_A$ exchanges chiralities: it maps E^+ to E^- and back.

Dictionary: mathematicians' and physicists' gauge fields

Physicists write a Hermitian potential $\mathsf{A}_\mu = \mathsf{A}_\mu^a T^a$ and a coupling e (or g), with $D_\mu = \partial_\mu - ie\mathsf{A}_\mu$. The two conventions are related by

$$A_\mu^{\text{math}} = -ie\,\mathsf{A}_\mu^{\text{phys}}, \qquad F_{\mu\nu}^{\text{math}} = -ie\,\mathsf{F}_{\mu\nu}^{\text{phys}}.$$

For QED with a fermion of charge e, $A_\mu = -ie\,a_\mu$ with a_μ the real electromagnetic potential, and $F_{\mu\nu} = -ie\,f_{\mu\nu}$. Anything quadratic in F therefore picks up $(-ie)^2 = -e^2$: keep this in mind when comparing our formulas with a QFT textbook.

10.1.2 Classical symmetries of massless fermions

Take the Euclidean action of a fermion in a fixed background gauge field,

$$S_F = \int_M \mathrm{d}^n x \, \bar\psi \not{D}_A \psi. \tag{10.6}$$

(In Euclidean signature ψ and $\bar\psi$ are *independent* Grassmann variables; $\bar\psi$ is not $\psi^\dagger\gamma^0$.) This action has two global U(1) symmetries.

- The **vector** rotation $\psi \mapsto e^{i\alpha}\psi$, $\bar\psi \mapsto \bar\psi e^{-i\alpha}$. It rotates both chiralities by the same phase. Its current is $j^\mu = \bar\psi\gamma^\mu\psi$, and its charge is fermion number.
- The **axial** (chiral) rotation $\psi \mapsto e^{i\alpha\gamma_5}\psi$, $\bar\psi \mapsto \bar\psi e^{i\alpha\gamma_5}$. It rotates positive and negative chirality by opposite phases. Its current is $j_5^\mu = \bar\psi\gamma^\mu\gamma_5\psi$, and its charge counts $N_+ - N_-$.

Why the axial rotation is a symmetry. The Noether trick is to let the parameter depend on position and see what the action does. With $\alpha = \alpha(x)$ infinitesimal, $\delta\psi = i\alpha\gamma_5\psi$ and $\delta\bar\psi = i\alpha\bar\psi\gamma_5$, and

$$\begin{aligned}\delta S_F &\overset{(1)}{=} \int \mathrm{d}^n x \left[i\alpha\,\bar\psi\gamma_5 \not{D}_A\psi + \bar\psi\,\not{D}_A(i\alpha\gamma_5\psi)\right] \\ &\overset{(2)}{=} \int \mathrm{d}^n x \left[i\alpha\,\bar\psi\gamma_5 \not{D}_A\psi + i(\partial_\mu\alpha)\bar\psi\gamma^\mu\gamma_5\psi + i\alpha\,\bar\psi\,\not{D}_A\gamma_5\psi\right] \\ &\overset{(3)}{=} i\int \mathrm{d}^n x\,(\partial_\mu\alpha)\,j_5^\mu \overset{(4)}{=} -i\int \mathrm{d}^n x\,\alpha\,\partial_\mu j_5^\mu .\end{aligned} \tag{10.7}$$

(1) Vary $\bar\psi$ and ψ in (10.6).
(2) Leibniz: $\not{D}_A(\alpha\chi) = \gamma^\mu(\partial_\mu\alpha)\chi + \alpha\not{D}_A\chi$.
(3) $\not{D}_A\gamma_5 = -\gamma_5\not{D}_A$, so the first and third terms cancel.
(4) Integrate by parts; M is closed, so Stokes' theorem gives no boundary term.

For constant α the variation vanishes: that is the symmetry. On solutions of the equations of motion $\delta S_F = 0$ for *every* $\alpha(x)$, so classically

$$\partial_\mu j^\mu = 0, \qquad \partial_\mu j_5^\mu = 0. \tag{10.8}$$

The same computation with the vector rotation gives the first equation. Both would fail if we added a mass term $m\bar\psi\psi$: the vector rotation leaves it alone, but $\delta(m\bar\psi\psi) = 2im\alpha\,\bar\psi\gamma_5\psi$, so a mass breaks the axial symmetry *explicitly*. An anomaly is a breaking of a different kind. It is present even at $m = 0$, and it comes from quantisation.

Physical picture: Chirality as direction of motion in $1+1$ dimensions

Rotate back to $1+1$ Minkowski space for a moment (coordinates t, x). The massless Dirac equation splits into $(\partial_t + \partial_x)\psi_+ = 0$ and $(\partial_t - \partial_x)\psi_- = 0$ [QFT notes (22.2.10)]. So $\psi_+(t,x) = f(x-t)$ moves right at the speed of light and $\psi_-(t,x) = h(x+t)$ moves left. Classically the two species never talk to each other, so N_+ and N_- are separately conserved. The anomaly will say: in an electric field, right-movers are converted into left-movers, and $N_+ - N_-$ changes by an amount fixed by the flux.

10.1.3 The first anomaly: Adler, Bell and Jackiw

Couple a massless Dirac fermion to electromagnetism in four dimensions. Both currents in (10.8) are conserved classically. Quantum mechanically, the vector current stays conserved (it must: the photon couples to it, and gauge invariance needs $\partial_\mu j^\mu = 0$), but the axial current obeys

$$\partial_\mu j_5^\mu = \frac{e^2}{16\pi^2}\,\epsilon^{\mu\nu\rho\sigma} f_{\mu\nu} f_{\rho\sigma} = \frac{e^2}{2\pi^2}\,\mathbf{E}\cdot\mathbf{B} \qquad \text{(Euclidean; Minkowski signs differ, see Section 10.4.1).} \tag{10.9}$$

This is the **Adler–Bell–Jackiw (ABJ) anomaly**. We will derive it four ways in Section 10.3: from the vacuum polarisation in two dimensions, from a gauge-invariant point-split current, from the triangle graph, and from Fujikawa's analysis of the path-integral measure. The last route will show that the *integrated* anomaly is twice the index of the Dirac operator, which is where topology enters.

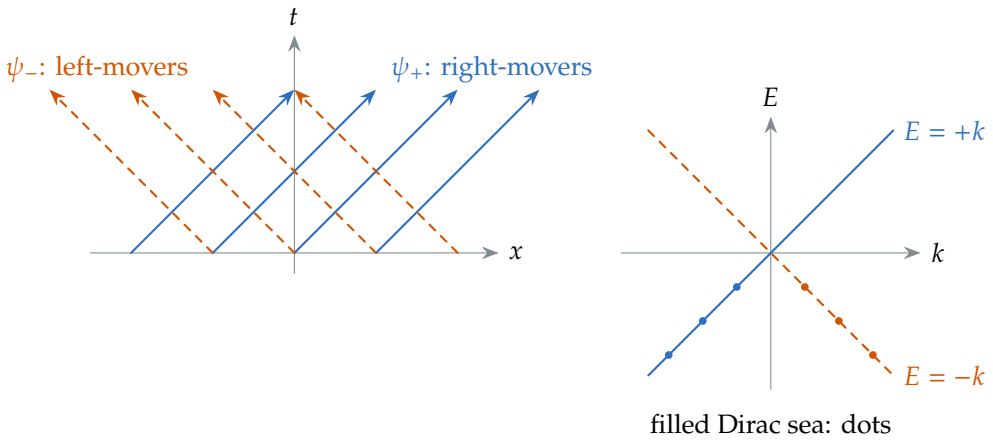

Figure 10.2: Left: in 1 + 1 dimensions a massless positive-chirality fermion moves right and a negative-chirality one moves left, along light rays. Right: their dispersion relations $E = \pm k$. The vacuum fills every negative-energy level of both branches (dots). The anomaly (Section 10.3.5) is the statement that an electric field slides the dots along the lines, pushing one branch's levels up through $E = 0$ and the other's down.

Physical picture: Why $\pi^0 \to \gamma\gamma$ needs the anomaly

The π^0 is (approximately) the Goldstone boson of the spontaneously broken axial isospin symmetry of the u and d quarks. Its field is proportional to the divergence of the corresponding axial current, $\partial_\mu j_5^{\mu 3} \approx f_\pi m_\pi^2 \pi^0$. If that current were conserved at the quantum level, the amplitude for $\pi^0 \to \gamma\gamma$ would vanish as $m_\pi \to 0$. The anomaly adds to $\partial_\mu j_5^{\mu 3}$ an $\epsilon f f$ term whose coefficient is $N_c\,(Q_u^2 - Q_d^2) = 3\left(\frac{4}{9} - \frac{1}{9}\right) = 1$. The resulting width,

$$\Gamma(\pi^0 \to \gamma\gamma) = \frac{\alpha^2 m_\pi^3}{64\pi^3 f_\pi^2} \approx 7.7\ \text{eV} \qquad (f_\pi \approx 92\ \text{MeV}),$$

agrees with experiment, and the factor $N_c = 3$ was one of the early pieces of evidence for colour [QFT notes §22.6.6].

10.1.4 Anomalies as obstructions

Nash's definition is more general than "a current that is not conserved".

Working definition 10.1 (anomaly)

Let a classical theory with fields Φ and action $S[\Phi]$ be invariant under a group Γ acting on the fields. The theory has an **anomaly** under Γ if the quantum theory cannot be defined so that its generating functional [the path integral Z as a function of the background fields, e.g. $Z_F[A]$ as a function of A] is Γ-invariant. *Operational test:* integrate out the fermions [do the $\psi, \bar\psi$ path integral with A held fixed] in a background field A to get $Z_F[A] = \det \not{D}_A$ (suitably regularised). Transform the background, $A \mapsto A_g$. If $Z_F[A_g] \neq Z_F[A]$, and *no* choice of local counterterm [an integral over M of a polynomial in A and its derivatives, added by hand. This is the freedom in choosing the regularisation] added to $\ln Z_F$ restores equality, there is an anomaly.

Two things about this definition matter.

1. The group Γ can be anything that acts on the fields. The cases in this chapter are listed in Table 10.1. The same mathematics handles all of them, because in each case the fermions see the symmetry through a family of Dirac-type operators.

2. The obstruction is *global on the group*. For gauge symmetry it is not enough to look at one gauge transformation; we must ask whether $\ln Z_F$ can be made into a function on the orbit space. This is a question about loops in $\mathcal{G}$ and about line bundles over $\mathcal{A}/\mathcal{G}$.

anomaly	group Γ	operators	where
chiral (ABJ)	global $\mathrm{U}(1)_A$	$\not{D}_A$, A fixed	Section 10.3; harmless, even useful
gauge (local)	$\mathcal{G} = \mathrm{Map}(M, G)$	$\{\not{D}_A\}_{A\in\mathcal{A}}$	Sections 10.5 and 10.6; must cancel
gravitational	$\mathrm{Diff}_0(M)$	$\{\not{D}_\rho\}_{\rho\in\mathrm{Met}(M)}$	Section 10.7; exists in $n = 4k-2$
Lorentz	$\mathcal{G}_L = \mathrm{Map}(M, \mathrm{SO}(n))$	vielbein rotations	Section 10.7.5; tradeable for the above
conformal	Weyl rescalings	$\{\bar\partial_g\}$ on the worldsheet	Nash §4; fixes $d = 26$
global	$\pi_0(\mathcal{G})$, $\pi_0(\mathrm{Diff}^+)$	S^1-families, η-invariant	Nash §5

Table 10.1: The kinds of anomaly in Chapter 10. The first two columns say what symmetry fails; the third says which family of operators the fermions see; the fourth says where it is treated and what physics does with it. Only anomalies in *gauged* symmetries (rows 2–6) are inconsistencies; an anomaly in a global symmetry (row 1) is just a prediction.

Watch out: Global symmetry anomalies are allowed; gauge anomalies are not

The ABJ anomaly breaks a *global* symmetry. That is fine: it just means the symmetry is not there, and the world ($\pi^0 \to \gamma\gamma$) shows it. An anomaly in a *gauge* symmetry is fatal. Gauge invariance is what removes the unphysical polarisations of the gauge field and makes the theory unitary and renormalisable; without it, the quantum theory is inconsistent. So for gauge anomalies the job is to arrange the fermion content so that they *cancel*. The Standard Model does this (Section 10.5.7).

10.1.5 Where the topology comes from: a preview

Why should topology have anything to do with this? Here is the idea in four steps. The rest of this part fills in each one.

1. **The fermions give a determinant.** Integrating out ψ and $\bar\psi$ gives $Z_F[A] = \det \not{D}_A$ (Section 10.2.5). For a chiral fermion $\not{D}_A : \Gamma(E^+) \to \Gamma(E^-)$ maps one space to a *different* one, so its determinant is not a number but an element of a line (Section 10.6.3).

2. **Determinants can vanish, and the index says when.** If $\ker \not{D}_A \neq 0$ the determinant is zero. The index $\dim\ker \not{D}_A - \dim \mathrm{Coker}\, \not{D}_A$ is topological, so for nonzero index the zero is forced (Section 10.2.4).

3. **The anomaly is a winding.** Along a loop $g(t)$ in the gauge group, $\det \not{D}_{A_{g(t)}}$ is a loop in $\mathbb{C}\setminus\{0\}$ (after removing zero modes). If it winds around the origin, $\ln\det$ cannot be a gauge invariant function. The winding is measured by a closed but not exact 1-form μ_1 on $\mathcal{G}$ (Section 10.6.2).

4. **The winding is a Chern class.** Equivalently, the determinants form a line bundle over $\mathcal{A}/\mathcal{G}$, and the anomaly is its first Chern class, which the families index theorem computes as $\int_M \mathrm{ch}(\mathcal{E})\hat{A}$ (Section 10.6.4).

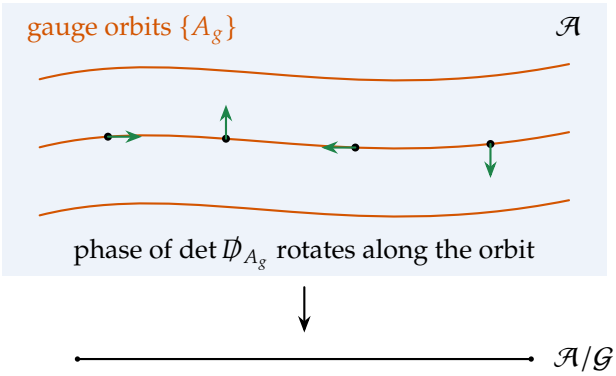

Figure 10.3: The picture behind every local anomaly. The space $\mathcal{A}$ of gauge fields is foliated by gauge orbits (orange). The classical action is constant along each orbit, so the path integral should descend to the quotient $\mathcal{A}/\mathcal{G}$ (bottom). The fermion determinant is not constant along the orbits: its phase (green arrows) rotates as we move along one. When the phase winds by a nonzero amount around a closed loop in the orbit, no redefinition can make it constant.

Recap

- An anomaly is a classical symmetry that the quantum theory cannot keep. For fermions it comes from the path-integral measure, i.e. from the determinant of the Dirac operator.
- Conventions: Hermitian Euclidean γ_μ, $\gamma_5 = (-i)^m \gamma_1 \cdots \gamma_{2m}$ (= σ_3 in 2D, diag($\mathbf{1}, -\mathbf{1}$) in 4D with (10.2)); anti-Hermitian A, $D = \mathrm{d} + A$, $\not{D}_A = \gamma^\mu D_\mu$ is anti-self-adjoint and flips chirality.
- Classically the vector and axial currents are both conserved (10.8). Quantum mechanically the axial current obeys the ABJ equation (10.9).
- Anomalies in global symmetries are predictions; anomalies in gauge symmetries must cancel.
- Topology enters through determinants, indices, windings of phases along loops in $\mathcal{G}$, and Chern classes of line bundles over $\mathcal{A}/\mathcal{G}$.

10.2 Anomalies and Yang–Mills theories I: chiral fermions, the index and the determinant

Nash's §2 is long, and it does three different jobs. It sets up a chiral gauge theory and its path integral; it shows that the fermion determinant is not gauge invariant, and explains what that means for currents and Feynman graphs; and it reinterprets the failure as a cohomology class. We split it into four sections. This one does the set-up. The question it answers is: *what exactly is the object whose gauge invariance fails?* The answer will be the fermion determinant, and we shall see already here that the index of the Dirac operator controls whether that determinant is zero.

Nash first separates two kinds of anomaly.

- A **local** (or **perturbative**) anomaly is visible in an *infinitesimal* gauge transformation $g = e^{tf}$ with $t \to 0$. It shows up in Feynman graphs, and in the non-conservation of a current. It is measured by a de Rham class, i.e. by derivatives.
- A **global** anomaly is visible only under gauge transformations that are *not* connected to

the identity. It is invisible to any derivative, hence to perturbation theory.

Until the global anomalies of Nash's §5 (treated in the second half of this chapter), "anomaly" means a local anomaly.

10.2.1 The action of a chiral gauge theory

We work on a compact Riemannian manifold M of even dimension $n = 2m$, with gauge group G (think U(1), SU(2) or SU(N)). Nash's action is

$$S(A,\psi) = \|F\|^2 + \langle \psi, \not{D}_A \psi\rangle = -\int_M \operatorname{tr}(F\wedge\star F) + \frac{1}{2}\int_M \bar\psi(x)\gamma_\mu\big(\partial^\mu + \Gamma^\mu + A^\mu\big)(1+\gamma_5)\psi(x), \quad (10.10)$$

[Nash p. 270, (10.1)]. Let us take it apart.

The Yang–Mills term is positive. With anti-Hermitian F, the trace $\operatorname{tr}(F_{\mu\nu}F_{\mu\nu})$ is *negative*, which is why Nash puts a minus sign in front. In components,

$$\begin{aligned} -\operatorname{tr}(F\wedge\star F) &\overset{(1)}{=} -\tfrac{1}{4}\operatorname{tr}(F_{\mu\nu}F_{\rho\sigma})\,\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu\wedge\star(\mathrm{d}x^\rho\wedge\mathrm{d}x^\sigma) \\ &\overset{(2)}{=} -\tfrac{1}{2}\operatorname{tr}(F_{\mu\nu}F_{\mu\nu})\,\mathrm{dvol} \\ &\overset{(3)}{=} \tfrac{1}{2}\sum_{\mu,\nu}\operatorname{tr}\big(F^\dagger_{\mu\nu}F_{\mu\nu}\big)\,\mathrm{dvol} \;\geq\; 0. \end{aligned} \quad (10.11)$$

(1) Write $F = \frac{1}{2}F_{\mu\nu}\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu$ and the same for $\star F$.
(2) For an orthonormal frame, $\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu\wedge\star(\mathrm{d}x^\rho\wedge\mathrm{d}x^\sigma) = (\delta^{\mu\rho}\delta^{\nu\sigma} - \delta^{\mu\sigma}\delta^{\nu\rho})\,\mathrm{dvol}$, which is the defining property of the Hodge star (Chapter T1); the two terms give equal contributions, doubling $\frac{1}{4}$ to $\frac{1}{2}$.
(3) $F^\dagger_{\mu\nu} = -F_{\mu\nu}$, and $\operatorname{tr}(X^\dagger X) = \sum_{ij}|X_{ij}|^2 \geq 0$.

So $\|F\|^2 = \int \frac{1}{2}\sum \operatorname{tr}(F^\dagger_{\mu\nu}F_{\mu\nu})$ is the usual positive Euclidean Yang–Mills action. In the physicists' convention of the dictionary in Section 10.1.1, $F = -ig\,\mathsf{F}^a T^a$ with $\operatorname{tr} T^aT^b = \frac{1}{2}\delta^{ab}$ and it becomes $\frac{g^2}{4}\int \mathsf{F}^a_{\mu\nu}\mathsf{F}^a_{\mu\nu}$, the familiar $\frac{1}{4}F^2$ after rescaling $\mathsf{A}\to\mathsf{A}/g$.

The fermion term. The operator in (10.10) contains three connections at once:

- ∂^μ is the flat derivative;
- Γ^μ is the **spin connection**, built from the Levi-Civita connection of the metric. It tells a spinor how to parallel transport on a curved M (Chapter T4); on flat $\mathbb{R}^n$ or a flat torus it vanishes;
- A^μ is the Yang–Mills connection, acting on the colour index of ψ.

The factor $(1+\gamma_5)$ is (twice) the **chiral projector**:

$$P_\pm := \tfrac{1}{2}(1\pm\gamma_5), \qquad P_\pm^2 = P_\pm, \quad P_+P_- = 0, \quad P_+ + P_- = \mathbf{1}. \quad (10.12)$$

Since $\gamma_5^2 = \mathbf{1}$, these relations follow by multiplying out, e.g. $P_+^2 = \frac{1}{4}(1+2\gamma_5+\gamma_5^2) = \frac{1}{2}(1+\gamma_5)$. In the basis of Example 10.1, $P_+ = \operatorname{diag}(\mathbf{1},0)$ picks the upper (Weyl) components. So the fermion term is

$$\begin{aligned} \tfrac{1}{2}\bar\psi\,\not{D}_A(1+\gamma_5)\psi &\overset{(1)}{=} \bar\psi\,\not{D}_A P_+\psi \\ &\overset{(2)}{=} \bar\psi\,P_-\not{D}_A P_+\psi. \end{aligned} \quad (10.13)$$

(1) Definition (10.12).
(2) $\not{D}_A\gamma_5 = -\gamma_5\not{D}_A$ gives $\not{D}_A P_+ = P_-\not{D}_A$, and $P_-^2 = P_-$, so $\not{D}_A P_+ = P_-\not{D}_A P_+$.

Only the positive-chirality part $\psi_+ = P_+\psi$ of ψ and the negative-chirality part $\bar\psi P_-$ of $\bar\psi$ appear. That is what "chiral fermion" means: a Weyl fermion, one chirality only, coupled to the gauge field.

Watch out: Factors of two and the sign of γ_5

Nash writes $\frac{1}{2}\gamma_\mu(\dots)(1+\gamma_5)$, i.e. $\not{D}_A P_+$. Many QFT books use $\frac{1}{2}(1-\gamma_5)$ for left-handed fields, and Minkowski γ_5 conventions differ by factors of i. None of this changes the physics; it changes the overall sign of the anomaly. In this chapter the chiral fermion is always ψ_+ with $\gamma_5\psi_+ = +\psi_+$ and γ_5 as in (10.3).

Dictionary: Weyl fermions in Euclidean and Minkowski language

In Minkowski space a single left-handed Weyl fermion χ_L is a two-component spinor with action $i\chi_L^\dagger\bar\sigma^\mu D_\mu\chi_L$ [QFT notes §22.7.1]. Its Euclidean continuation is our $\bar\psi P_-\not{D}_A P_+\psi$: $\bar\psi P_-$ plays the role of $\chi_L^\dagger$, and the Euclidean $\bar\psi$ is an *independent* variable, so nothing forces $\bar\psi P_-$ to be the conjugate of $P_+\psi$. The choice ψ_+ versus ψ_- corresponds to left- versus right-handed, depending on conventions.

10.2.2 Why M must be a spin manifold

To write $\bar\psi\not{D}\psi$ on a curved M we need spinors, i.e. sections of a spinor bundle. Locally that is easy: pick an orthonormal frame (vielbein) on each coordinate patch and use constant gamma matrices in that frame. On an overlap the two frames differ by a rotation $h_{\alpha\beta}(x) \in \mathrm{SO}(n)$. A spinor must transform by a matrix $\tilde h_{\alpha\beta}(x) \in \mathrm{Spin}(n)$ that covers $h_{\alpha\beta}$ under the double cover $\mathrm{Spin}(n) \to \mathrm{SO}(n)$. The lifts are only determined up to sign, and the question is whether the signs can be chosen consistently on triple overlaps, $\tilde h_{\alpha\beta}\tilde h_{\beta\gamma}\tilde h_{\gamma\alpha} = +\mathbf{1}$.

Working definition 10.2 (spin manifold)

M is **spin** if it is orientable [the frames can be chosen with one handedness everywhere, so every $h_{\alpha\beta}$ lies in $\mathrm{SO}(n)$] and the frame transition functions can be lifted to $\mathrm{Spin}(n)$ with the cocycle condition [$\tilde h_{\alpha\beta}\tilde h_{\beta\gamma}\tilde h_{\gamma\alpha} = +\mathbf{1}$ on every triple overlap] intact. *Test:* compute the **Stiefel–Whitney classes** $w_1(TM), w_2(TM) \in H^*(M;\mathbb{Z}_2)$ [obstruction classes with coefficients in $\mathbb{Z}_2 = \{0,1\}$, where $1+1=0$. w_1 detects failure to give all frames one handedness, w_2 detects failure to fix the signs of the lifts consistently]. The manifold is orientable iff $w_1 = 0$, and an orientable manifold is spin iff also $w_2 = 0$. (Formally, w_2 is the $\mathbb{Z}_2$-valued Čech cocycle $\tilde h_{\alpha\beta}\tilde h_{\beta\gamma}\tilde h_{\gamma\alpha} = \pm\mathbf{1}$.)

Worked example 10.2: Which manifolds are spin

- S^n for $n \geq 3$: $H^1(S^n;\mathbb{Z}_2) = H^2(S^n;\mathbb{Z}_2) = 0$, so $w_1 = w_2 = 0$ automatically.
- S^2: now $H^2(S^2;\mathbb{Z}_2) = \mathbb{Z}_2$ is not zero, so we must compute. For an oriented surface w_2 is the Euler class mod 2, and

$$w_2(TS^2) \overset{(1)}{=} \chi(S^2) \bmod 2 \overset{(2)}{=} 2 \bmod 2 = 0.$$

(1) For an oriented rank-2 bundle, w_2 is the mod-2 reduction of the Euler class, whose integral over the surface is the Euler characteristic.

(2) $\chi(S^2) = 2$ (Gauss–Bonnet, Chapter T2).

Every oriented surface has even $\chi = 2 - 2g$, so every oriented surface is spin.

- $\mathbb{CP}^2$ is *not* spin: $w_2(\mathbb{CP}^2)$ is the generator of $H^2(\mathbb{CP}^2;\mathbb{Z}_2) = \mathbb{Z}_2$. (Its signature is 1, while Rokhlin's theorem forces the signature of a closed spin 4-manifold to be divisible by 16.)

So Nash's working example $M = S^{2m}$ is always allowed: "this is not too severe a requirement and is true for S^n".

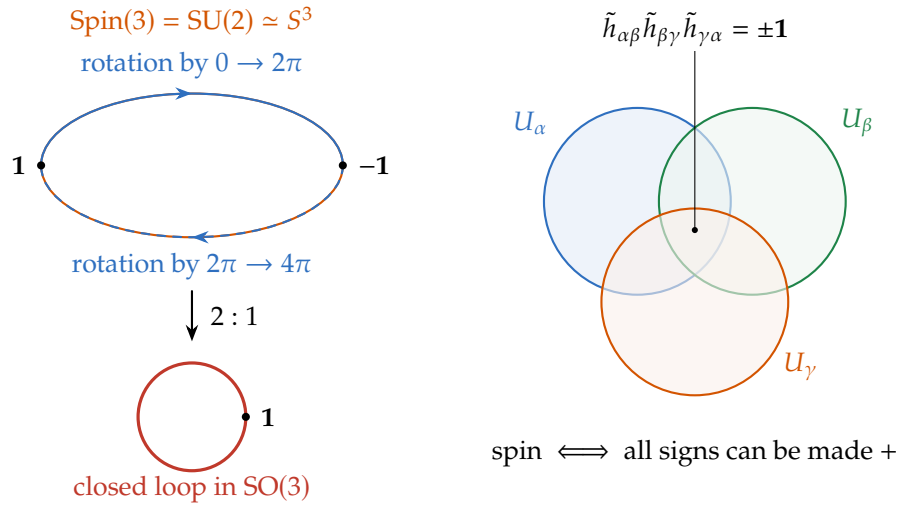

Figure 10.4: Left: a rotation through 2π is a closed loop in SO(3), but it lifts to a path from $\mathbf{1}$ to $-\mathbf{1}$ in Spin(3) = SU(2); only a rotation through 4π closes up. Spinors see this sign. Right: on a triple overlap of coordinate patches the lifted transition functions multiply to $\pm\mathbf{1}$. The manifold is spin when the signs can all be chosen to be +; the obstruction is the class w_2.

10.2.3 The chiral Dirac operator as a map between two spaces

Since $\not{D}_A$ anticommutes with γ_5, it swaps the two chiralities. If $E^{\pm}$ are the positive and negative spinor bundles and F the vector bundle on which the gauge field acts (the "colour" bundle), then

$$\not{D}_A : \Gamma(M, E^+ \otimes F) \longrightarrow \Gamma(M, E^- \otimes F), \tag{10.14}$$

[Nash p. 270, (10.2)]. We write D_A^+ for this map when we need to distinguish it from the full $\not{D}_A$. In a chiral basis the full Dirac operator is block off-diagonal,

$$\not{D}_A = \begin{pmatrix} 0 & D_A^- \\ D_A^+ & 0 \end{pmatrix}, \qquad D_A^+ : E^+ \to E^-, \quad D_A^- : E^- \to E^+, \qquad D_A^- = -(D_A^+)^\dagger. \tag{10.15}$$

The last relation is the anti-self-adjointness of $\not{D}_A$. Nash writes $\not{D}_A^*$ for the adjoint $(D_A^+)^\dagger : E^- \to E^+$.

Worked example 10.3: The blocks in two and four dimensions

Two dimensions. With $\gamma_1 = \sigma_1$, $\gamma_2 = \sigma_2$,

$$\not{D}_A = \sigma_1 D_1 + \sigma_2 D_2 \overset{(1)}{=} \begin{pmatrix} 0 & D_1 \\ D_1 & 0 \end{pmatrix} + \begin{pmatrix} 0 & -iD_2 \\ iD_2 & 0 \end{pmatrix}$$

$$\overset{(2)}{=} \begin{pmatrix} 0 & D_1 - iD_2 \\ D_1 + iD_2 & 0 \end{pmatrix}.$$

(1) $\sigma_1 = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, $\sigma_2 = \left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right)$.
(2) Add entrywise.

So $D_A^+ = D_1 + iD_2$. With $z = x_1 + ix_2$ and $\partial_{\bar z} = \frac{1}{2}(\partial_1 + i\partial_2)$, the free operator is $D_0^+ = 2\partial_{\bar z}$: *a positive-chirality zero mode is a holomorphic function*. This is the reason the two-dimensional Dirac operator is a Cauchy–Riemann operator, which is what Nash exploits for strings in §4.

Four dimensions. With (10.2),

$$\not{D}_A = \gamma_j D_j + \gamma_4 D_4 \overset{(1)}{=} \begin{pmatrix} 0 & i\sigma_j D_j + D_4 \\ -i\sigma_j D_j + D_4 & 0 \end{pmatrix},$$

(1) Insert the blocks of (10.2); σ_j acts on spin and D_j on space and colour, so they commute.

so $D_A^+ = D_4 - i\sigma_j D_j$ and $D_A^- = D_4 + i\sigma_j D_j$. Check the adjoint relation: since $D_\mu^\dagger = -D_\mu$ and $\sigma_j^\dagger = \sigma_j$, we have $(-i\sigma_j D_j)^\dagger = D_j^\dagger \sigma_j (+i) = -i\sigma_j D_j$, hence $(D_4 - i\sigma_j D_j)^\dagger = -D_4 - i\sigma_j D_j = -D_A^-$. These are the quaternionic "$\partial_4 \mp i\vec\sigma\cdot\vec\partial$" operators familiar from instanton calculus.

10.2.4 The index counts chiral zero modes

Let $n_+ = \dim \operatorname{Ker} D_A^+$ be the number of positive-chirality zero modes and $n_- = \dim \operatorname{Ker} D_A^- = \dim \operatorname{Ker}(D_A^+)^\dagger$ the number of negative-chirality ones. The index theorem for the twisted Dirac operator (Chapter 4) says

$$\begin{aligned} \operatorname{index} \not{D}_A &\overset{(1)}{=} n_+ - n_- \\ &\overset{(2)}{=} \int_M \hat A(M) \wedge \operatorname{ch}(F) \\ &\overset{(3)}{=} \int_{S^{2m}} \operatorname{ch}(F) \qquad \text{for } M = S^{2m} \\ &\overset{(4)}{=} k. \end{aligned} \tag{10.16}$$

(1) Definition: $\operatorname{index} D^+ = \dim \operatorname{Ker} D^+ - \dim \operatorname{Coker} D^+$, and $\operatorname{Coker} D^+ \cong \operatorname{Ker}(D^+)^\dagger$.
(2) The Atiyah–Singer formula for the Dirac operator twisted by F [Nash p. 270, (10.3); (4.122)]: only the top-degree ($2m$-form) part of the integrand contributes.
(3) $\hat A$ is a polynomial in the Pontrjagin classes, $\hat A = 1 - \frac{1}{24}p_1 + \frac{1}{5760}(7p_1^2 - 4p_2) + \cdots$, and every $p_i(S^n) = 0$, so $\hat A(S^{2m}) = 1$.
(4) Nash's name k for the resulting integer.

Why do the Pontrjagin classes of a sphere vanish? Because $TS^n \oplus \underline{\mathbb{R}}$ is the trivial bundle $S^n \times \mathbb{R}^{n+1}$ (split $\mathbb{R}^{n+1}$ at each point of S^n into the tangent plane and the normal line). Characteristic classes are unchanged by adding a trivial bundle, and all classes of a trivial bundle vanish.

Only the top form of $\operatorname{ch}(F) = \operatorname{tr}\exp(iF/2\pi)$ survives the integral, so

$$k = \int_{S^{2m}} \operatorname{ch}_m(F) = \frac{1}{m!}\left(\frac{i}{2\pi}\right)^m \int_{S^{2m}} \operatorname{tr} F^m. \tag{10.17}$$

For $m = 1$ this is the first Chern number $\int c_1(F)$, the monopole charge. For $m = 2$ and $G = \mathrm{SU}(N)$, where $c_1 = 0$, it is $\int \operatorname{ch}_2 = \int (\frac{1}{2}c_1^2 - c_2) = -\int c_2$, so $-k = \int c_2 = \frac{1}{8\pi^2}\int \operatorname{tr} F \wedge F$ is the

instanton number, as Nash says. On S^{2m} the class ch_m is (up to a nonzero integer factor) the only characteristic class there is, which is why Nash also calls k the "$c_m(F)$ which classifies bundles over S^{2m}".

Key idea: Chiral asymmetry

If $k \neq 0$, then $n_+ \neq n_-$: the massless chiral fermions have a forced excess of zero modes of one chirality. Since generic gauge fields on a sphere have $k \neq 0$ (only one bundle out of $\mathbb{Z}$ has $k = 0$), this is the typical situation. It is the first sign that chirality and topology are tied together.

Worked example 10.4: Zero modes in a magnetic field: Aharonov–Casher

Take $n = 2$, $G = \mathrm{U}(1)$, and a fermion of charge e in a magnetic field $B(x)$ on the plane, with total flux $\Phi = \int B\,\mathrm{d}^2x$. Choose the gauge $ea_1 = -\partial_2\phi$, $ea_2 = \partial_1\phi$ for a real function ϕ; then $eB = e(\partial_1 a_2 - \partial_2 a_1) = \nabla^2\phi$. In the mathematicians' convention $A_j = -iea_j$, and the positive-chirality equation is

$$\begin{aligned} 0 = D_A^+\psi_+ &\overset{(1)}{=} \big[(\partial_1 + i\partial_2) - ie(a_1 + ia_2)\big]\psi_+ \\ &\overset{(2)}{=} \big[2\partial_{\bar z} - i(-\partial_2\phi + i\partial_1\phi)\big]\psi_+ \\ &\overset{(3)}{=} \big[2\partial_{\bar z} + (\partial_1 + i\partial_2)\phi\big]\psi_+ \overset{(4)}{=} 2\big[\partial_{\bar z} + (\partial_{\bar z}\phi)\big]\psi_+. \end{aligned}$$

(1) $D_A^+ = D_1 + iD_2$ from Example 10.3, with $D_j = \partial_j - iea_j$.
(2) Insert the gauge choice.
(3) $-i\cdot(-\partial_2\phi) = i\partial_2\phi$ and $-i\cdot i\partial_1\phi = \partial_1\phi$.
(4) $\partial_1 + i\partial_2 = 2\partial_{\bar z}$.

The solutions are $\psi_+ = e^{-\phi}f(z)$ with f *holomorphic*: indeed $\partial_{\bar z}(e^{-\phi}f) = -(\partial_{\bar z}\phi)e^{-\phi}f$. Far away, Gauss's theorem on a large disc gives $2\pi r\,\phi'(r) \approx e\Phi$, so $\phi \approx \frac{e\Phi}{2\pi}\ln r$ and

$$|\psi_+| \approx r^{-e\Phi/2\pi}\,|f(z)|.$$

With $f = z^j$ this is square integrable ($\int |\psi_+|^2 r\,\mathrm{d}r < \infty$) iff $2j - e\Phi/\pi + 2 < 0$, i.e. $j < \frac{e\Phi}{2\pi} - 1$. The negative-chirality equation $D_A^-\psi_- = 0$ gives $\psi_- = e^{+\phi}g(\bar z)$, which grows and is never normalisable when $e\Phi > 0$. So for $e\Phi/2\pi = N$ a positive integer there are $N - 1$ modes on the plane and none of the other chirality. On the *sphere* (compactify the plane, the flux becoming a monopole of charge N) one extra mode becomes normalisable and the count is exactly

$$n_+ - n_- = N = \frac{e\Phi}{2\pi} = \int_{S^2}\frac{i}{2\pi}F = \int_{S^2}\mathrm{ch}_1(F),$$

in agreement with (10.16). (In the math convention $F = -ief$, so $\frac{i}{2\pi}F = \frac{e}{2\pi}f$.) All zero modes sit in the chirality that the field "prefers"; reversing the field reverses it.

Worked example 10.5: The instanton zero mode on S^4

For the SU(2) BPST instanton on S^4 (Chapter 8), the instanton number is $\int c_2 = 1$, so $k = \int \mathrm{ch}_2 = -1$ and $n_+ - n_- = -1$ for fermions in the fundamental (2-dimensional) representation. A vanishing theorem (the Weitzenböck formula $-\not{D}_A^2 = -D^\mu D_\mu + \frac{R}{4} - \frac{1}{2}\gamma^\mu\gamma^\nu F_{\mu\nu}$ with $R > 0$ on S^4 and F anti-self-dual or self-dual acting on only one chirality) kills the kernel of one chirality altogether. Hence there is exactly one zero mode, and it has

negative chirality with our conventions: this is 't Hooft's zero mode. For fermions in the adjoint (3-dimensional) representation, ch_2 of the adjoint bundle is 4 times as large, $k = -4$, and there are four zero modes (in supersymmetric Yang–Mills theory, where these are the gluino zero modes, two are generated by supersymmetry and two by superconformal transformations).

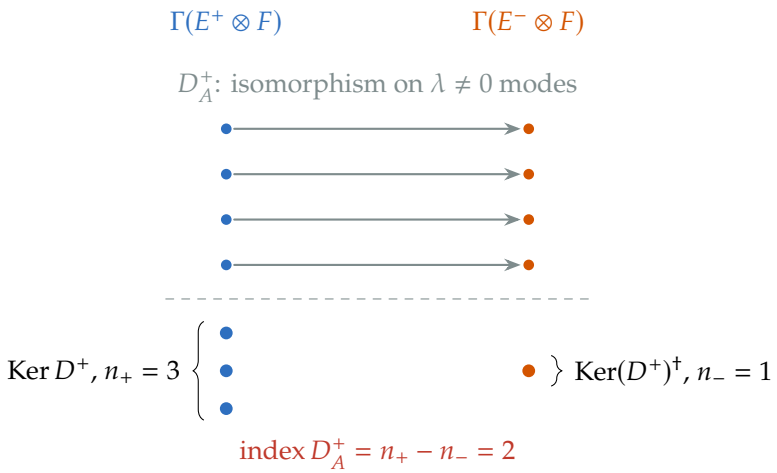

Figure 10.5: Why the index is robust. The non-zero modes of $-\not{D}_A^2$ come in pairs: if $(D^+)^\dagger D^+ u = \lambda u$ with $\lambda > 0$, then $v = D^+ u$ satisfies $D^+(D^+)^\dagger v = \lambda v$, and the grey arrows are bijections. Only the zero modes below the dashed line can be unpaired. When the gauge field is deformed, zero modes can appear or disappear only in $(+,-)$ pairs, so $n_+ - n_-$ never changes.

10.2.5 Integrating out the fermions: Grassmann integrals give determinants

The partition function of the theory is [Nash p. 271, (10.4)]

$$Z = \int \mathcal{D}A\, \mathcal{D}\psi\, \mathcal{D}\bar{\psi}\, \exp\!\left[- \|F\|^2 - \langle \psi, \not{D}_A \psi \rangle \right]. \tag{10.18}$$

The fermions appear quadratically, so their integral can be done exactly. We need the rules of Grassmann integration. Here they are, in finite dimensions.

Working definition 10.3 (Berezin integral)

Grassmann variables [the stand-ins for the fermion fields $\psi, \bar{\psi}$ in the path integral] anticommute: $\theta_i \theta_j = -\theta_j \theta_i$, so $\theta_i^2 = 0$ and every function is a polynomial of degree at most one in each variable. The integral [it picks out the coefficient of θ] is defined by

$$\int \mathrm{d}\theta\, 1 = 0, \qquad \int \mathrm{d}\theta\, \theta = 1,$$

with the $\mathrm{d}\theta_i$ also anticommuting among themselves and with the θ_j. *To compute:* expand the integrand, keep only the term containing every variable exactly once, and move the variables next to their differentials.

Worked example 10.6: Gaussian Grassmann integrals are determinants

One pair. Take independent variables $\theta, \bar\theta$ and a number a. First, $\int \mathrm{d}\bar\theta\,\mathrm{d}\theta\,\theta\bar\theta = \int \mathrm{d}\bar\theta\,\bar\theta = 1$ (inner integral first), so $\int \mathrm{d}\bar\theta\,\mathrm{d}\theta\,\bar\theta\theta = -1$. Then

$$\int \mathrm{d}\bar\theta\,\mathrm{d}\theta\, e^{-\bar\theta a\theta} \overset{(1)}{=} \int \mathrm{d}\bar\theta\,\mathrm{d}\theta\,(1 - a\bar\theta\theta) \overset{(2)}{=} -a\int \mathrm{d}\bar\theta\,\mathrm{d}\theta\,\bar\theta\theta \overset{(3)}{=} a.$$

(1) $(\bar\theta\theta)^2 = 0$, so the exponential series stops.
(2) $\int \mathrm{d}\bar\theta\,\mathrm{d}\theta\,1 = 0$.
(3) The value just computed.

Compare the bosonic $\int \mathrm{d}\bar z\,\mathrm{d}z\, e^{-\bar z a z} \propto a^{-1}$: fermions give the determinant upstairs, bosons downstairs.

Two pairs. With $\bar\theta M\theta = \sum_{ij}\bar\theta_i M_{ij}\theta_j$, only the second-order term of the exponential contains all four variables:

$$\begin{aligned}\int \prod_{i=1}^{2}\mathrm{d}\bar\theta_i\,\mathrm{d}\theta_i\; e^{-\bar\theta M\theta} &\overset{(1)}{=} \frac{1}{2}\int \prod_i \mathrm{d}\bar\theta_i\,\mathrm{d}\theta_i\,(\bar\theta M\theta)^2 \\ &\overset{(2)}{=} \int \prod_i \mathrm{d}\bar\theta_i\,\mathrm{d}\theta_i\,\left(M_{11}M_{22}\,\bar\theta_1\theta_1\bar\theta_2\theta_2 + M_{12}M_{21}\,\bar\theta_1\theta_2\bar\theta_2\theta_1\right) \\ &\overset{(3)}{=} M_{11}M_{22} - M_{12}M_{21} = \det M.\end{aligned}$$

(1) Terms of order 0 and 1 lack some variables and integrate to zero.
(2) Of the 16 terms in $(\bar\theta M\theta)^2$ only those using each of $\bar\theta_1, \bar\theta_2, \theta_1, \theta_2$ once survive; they come in two equal pairs (the order of the two bilinears is immaterial, as bilinears commute), cancelling the $\frac{1}{2}$.
(3) Moving θ_1 two places to the left (sign $+$) and then swapping $\theta_2\bar\theta_2$ (sign $-$) gives $\bar\theta_1\theta_2\bar\theta_2\theta_1 = -\bar\theta_1\theta_1\bar\theta_2\theta_2$. The bilinears $\bar\theta_i\theta_i$ and the pairs $\mathrm{d}\bar\theta_i\mathrm{d}\theta_i$ are even, so the integral factorises into two blocks $\int \mathrm{d}\bar\theta_i\mathrm{d}\theta_i\,\bar\theta_i\theta_i = -1$, whose product is $+1$.

In general $\int \prod \mathrm{d}\bar\theta_i\mathrm{d}\theta_i\, e^{-\bar\theta M\theta} = \det M$ for any $N\times N$ matrix M. The proof is the same bookkeeping: the terms that survive are indexed by permutations, with the sign of the permutation.

Applied formally to (10.18), with $M = \not{D}_A$ an operator on spinor fields, this says $\int \mathcal{D}\psi\mathcal{D}\bar\psi\, e^{-\langle\psi,\not{D}_A\psi\rangle} = \det\not{D}_A$. But Nash writes something slightly different [Nash p. 271, (10.5)]:

$$\int \mathcal{D}\psi\mathcal{D}\bar\psi\,\exp\left[-\langle\psi,\not{D}_A\psi\rangle\right] = \sqrt{\det(\not{D}_A^*\not{D}_A)}. \tag{10.19}$$

Where does the square root come from? From chirality. For a *chiral* fermion the operator in the action is $D_A^+ : E^+ \to E^-$. Its "determinant" is not a number: det of a map between two different spaces depends on the bases chosen in each (Section 10.6.3 makes this precise). What *is* a number is its modulus,

$$|\det D_A^+| = \sqrt{\det\big((D_A^+)^\dagger D_A^+\big)},$$

because $(D_A^+)^\dagger D_A^+$ maps E^+ to itself. That is Nash's (10.19) with $\not{D}_A^*\not{D}_A$ read as $(D_A^+)^\dagger D_A^+$. The next example checks, in finite dimensions, that a chiral fermion is "half" of a Dirac fermion.

Worked example 10.7: A Dirac fermion is two chiral fermions

Let L be a $k\times k$ matrix standing for D^+, and build the block operator $\mathcal{D} = \left(\begin{smallmatrix} 0 & -L^\dagger \\ L & 0 \end{smallmatrix}\right)$ modelling the full anti-self-adjoint $\not{D}$ of (10.15). Then

$$\det \mathcal{D} \overset{(1)}{=} (-1)^k \det(-L^\dagger) \det L \overset{(2)}{=} (-1)^k(-1)^k \overline{\det L} \det L \overset{(3)}{=} |\det L|^2 = \det(L^\dagger L).$$

(1) Moving the k lower rows above the k upper rows takes k^2 adjacent swaps, and $(-1)^{k^2} = (-1)^k$; the result is block diagonal.
(2) $\det(-X) = (-1)^k \det X$ and $\det L^\dagger = \overline{\det L}$.
(3) $(-1)^{2k} = 1$.

For $k = 1$: $\det\left(\begin{smallmatrix} 0 & -\bar{l} \\ l & 0 \end{smallmatrix}\right) = 0 - (-\bar{l})l = |l|^2$. So the Dirac determinant is $|\det D^+|^2$, and a single Weyl fermion contributes the square root of it, *times a phase*. The phase is the subtle part. It is exactly what (10.19) leaves out, and exactly where the anomaly will live.

With (10.19) the partition function becomes [Nash p. 271, (10.6)]

$$Z = \int \mathcal{D}A \sqrt{\det(\not{D}_A^* \not{D}_A)}\, \exp\left[-\|F\|^2\right]. \tag{10.20}$$

10.2.6 Gauge invariance of the integrand, and why it can fail

The next step in evaluating (10.20) would be to use gauge invariance. If the integrand were constant along each gauge orbit $\{A_g : g \in \mathcal{G}\}$, we could divide out the (infinite) volume of $\mathcal{G}$ and integrate only over the orbit space $\mathcal{A}/\mathcal{G}$, which is the classifying space $B\mathcal{G}$ when $\mathcal{G}$ acts freely (Chapter 6). This is the Faddeev–Popov procedure. The Yang–Mills term is manifestly invariant: $F_g = g^{-1}Fg$ and the trace is cyclic, so $\operatorname{tr}(F_g \wedge \star F_g) = \operatorname{tr}(F \wedge \star F)$. The trouble is the determinant. In general [Nash p. 271, (10.7)]

$$\det(\not{D}_{A_g}^* \not{D}_{A_g}) \neq \det(\not{D}_A^* \not{D}_A), \tag{10.21}$$

and when this happens we say an **anomaly** has arisen. It is surprising, because the operator itself transforms covariantly [Nash p. 271, (10.8)]:

$$\not{D}_{A_g} = g^{-1} \not{D}_A\, g. \tag{10.22}$$

Let us check this. For any spinor χ,

$$g^{-1}\not{D}_A(g\chi) \overset{(1)}{=} g^{-1}\gamma^\mu\big(\partial_\mu(g\chi) + A_\mu g\chi\big) \overset{(2)}{=} \gamma^\mu\big(g^{-1}(\partial_\mu g)\chi + \partial_\mu\chi + g^{-1}A_\mu g\,\chi\big) \overset{(3)}{=} \gamma^\mu\big(\partial_\mu + (A_g)_\mu\big)\chi = \not{D}_{A_g}\chi.$$

(1) Definition (10.5) of $\not{D}_A$.
(2) Leibniz rule; g acts on colour, γ^μ on spin, so they commute.
(3) $(A_g)_\mu = g^{-1}A_\mu g + g^{-1}\partial_\mu g$, from (10.4).

So $\not{D}_{A_g}$ and $\not{D}_A$ are conjugate, and conjugate matrices have equal determinants: $\det(g^{-1}Xg) = \det g^{-1} \det X \det g = \det X$. The catch is in the middle step, which uses $\det(XY) = \det X \det Y$.

In infinite dimensions a determinant must be *regularised*, and regularised determinants need not be multiplicative. There is a further catch for chiral fermions, explained in the pitfall below: in $D^+_{A_g} = g^{-1} D^+_A g$, the g on the right acts on E^+ and the g^{-1} on the left acts on E^-, two different spaces, and there is no reason for a regularisation to treat them the same way.

Watch out: The modulus is invariant; the phase is not

Read literally, (10.21) is too strong. The operator $\not{D}^*_{A_g}\not{D}_{A_g} = g^{-1}(\not{D}^*_A \not{D}_A)g$ is conjugate to $\not{D}^*_A\not{D}_A$ by a *unitary* map of a single space $E^+ \otimes F$ to itself, so the two have the same eigenvalues, the same zeta function, and the same zeta-regularised determinant. The modulus $|\det D^+_A|$ is gauge invariant. What is not gauge invariant is the *phase* of the chiral determinant, which $\sqrt{\det \not{D}^*\not{D}}$ does not see. That is why Nash (following Atiyah and Singer) soon replaces $\not{D}^*_{A_g}\not{D}_{A_g}$ by the "mixed" operator $T_g = \not{D}^*_A \not{D}_{A_g}$ (10.153): formally $\det T_g = \overline{\det D^+_A} \cdot \det D^+_{A_g}$, which does record the relative phase. Keep in mind throughout: "the determinant is not gauge invariant" means "its phase changes under gauge transformations in a way no local counterterm can undo".

10.2.7 Regularised determinants

Nash's footnote 1 mentions two ways to give an infinite determinant a meaning.

Operators close to the identity. If $X = \mathbf{1} + K$ with K of **trace class**, meaning that the sum of the singular values of K is finite, $\operatorname{tr}\sqrt{K^\dagger K} < \infty$, then the product $\prod_n (1+\kappa_n)$ over the eigenvalues κ_n of K converges absolutely. The determinant is then defined without any regularisation, and it is multiplicative: $\det(XY) = \det X \, \det Y$.

Worked example 10.8: A convergent infinite determinant

Let K be diagonal with eigenvalues $1/n^2$, $n = 1, 2, \dots$. Then $\sum_n 1/n^2 = \pi^2/6 < \infty$, so K is trace class, and

$$\det(\mathbf{1}+K) \overset{(1)}{=} \prod_{n=1}^{\infty}\Big(1+\frac{1}{n^2}\Big) \overset{(2)}{=} \frac{\sinh \pi}{\pi} \approx 3.676.$$

(1) The determinant of a diagonal operator is the product of its entries.
(2) Euler's product $\sinh(\pi x) = \pi x \prod_n (1 + x^2/n^2)$ at $x = 1$.

The operators in field theory are not of this kind. $\not{D}^*_A\not{D}_A$ is a second-order elliptic operator whose eigenvalues grow like $\lambda_j \sim j^{2/n}$ (Weyl's law), so $\prod \lambda_j$ diverges wildly. The standard cure is the zeta function (Chapter 2; Nash p. 261).

Working definition 10.4 (zeta-regularised determinant)

Let T be an elliptic operator [an operator such as $\not{D}^*_A\not{D}_A$ on the compact M, whose eigenvalues are discrete and grow like a power of j, so their product diverges] with eigenvalues λ_j, none zero, with positive real parts (or at least avoiding a ray from the origin, Section 10.6.1). Define

$$\zeta_T(s) := \sum_j \lambda_j^{-s}.$$

The sum converges for $\operatorname{Re} s > n/2$ (for T of second order in n dimensions), and continues

[there is exactly one function, analytic except at isolated poles, that equals the sum wherever the sum converges] to a function that is analytic at $s = 0$. Since formally $-\zeta_T'(0) = \sum_j \ln \lambda_j = \ln \prod_j \lambda_j$, define

$$\det T := \exp\bigl[-\zeta_T'(0)\bigr].$$

To compute: find the spectrum, express ζ_T in terms of known functions (Riemann, Hurwitz, Epstein zeta functions [$\sum_{n\geq 1} n^{-s}$, $\sum_{n\geq 0}(n+a)^{-s}$, and a sum of $|m|^{-2s}$ over the points $m \neq 0$ of a lattice]), and differentiate at $s = 0$.

Worked example 10.9: The Laplacian on a circle, and a multiplicative anomaly

On the circle $\theta \sim \theta + 2\pi$ take $T = -\mathrm{d}^2/\mathrm{d}\theta^2$, with eigenfunctions $e^{in\theta}$ and eigenvalues n^2. Drop the zero mode $n = 0$ (write det′). Each n^2 with $n \neq 0$ occurs twice ($\pm n$), so

$$\zeta_T(s) \overset{(1)}{=} 2\sum_{n=1}^{\infty} n^{-2s} \overset{(2)}{=} 2\zeta_R(2s),$$

$$\ln \det' T = -\zeta_T'(0) \overset{(3)}{=} -4\zeta_R'(0) \overset{(4)}{=} 2\ln(2\pi), \qquad \text{so} \quad \det' T = 4\pi^2.$$

(1) Count the degenerate pairs.
(2) Riemann's $\zeta_R(s) = \sum_{n\geq 1} n^{-s}$.
(3) Chain rule: $\frac{\mathrm{d}}{\mathrm{d}s} 2\zeta_R(2s) = 4\zeta_R'(2s)$.
(4) The classical value $\zeta_R'(0) = -\frac{1}{2}\ln(2\pi)$.

A divergent product $\prod_{n\neq 0} n^2$ has been given the finite value $4\pi^2$. Now rescale T by a constant $c > 0$. Naively $\det(cT) = c^{\infty} \det T$. The zeta function says:

$$\zeta_{cT}(s) \overset{(1)}{=} c^{-s}\zeta_T(s),$$

$$-\zeta_{cT}'(0) \overset{(2)}{=} \ln c\ \zeta_T(0) - \zeta_T'(0), \qquad \text{so} \quad \det'(cT) = c^{\zeta_T(0)} \det' T \overset{(3)}{=} c^{-1} \det' T.$$

(1) $(c\lambda)^{-s} = c^{-s}\lambda^{-s}$.
(2) Differentiate the product at $s = 0$: $\frac{\mathrm{d}}{\mathrm{d}s} c^{-s} = -\ln c\ c^{-s}$.
(3) $\zeta_T(0) = 2\zeta_R(0) = 2 \cdot (-\frac{1}{2}) = -1$.

But $cT = (c\mathbf{1})T$, and "$\det(c\mathbf{1})$" on an infinite-dimensional space is meaningless or, if regularised by its own zeta function $\sum_j c^{-s}$, not equal to c^{-1}. So $\det(XY) \neq \det X \det Y$ for zeta determinants in general. This **multiplicative anomaly** is the mechanism by which "conjugate operators have the same determinant" can fail once the two sides of the conjugation act on different spaces.

Physical picture: What regularisation does to a symmetry

Every regularisation of $\det D_A^+$ has to cut off high-frequency modes. "High frequency" must be measured by some operator, and for a chiral fermion there is no operator that is simultaneously gauge covariant and maps E^+ to E^+ built from D_A^+ alone: $(D_A^+)^\dagger D_A^+$ and $D_A^+(D_A^+)^\dagger$ live on different spaces. A cutoff that respects gauge invariance on one side breaks it on the other. The anomaly is the finite remainder of this mismatch that survives as the cutoff is removed. We will see this explicitly in the Fujikawa calculation of Section 10.4.1.

Reading Nash (pp. 270–271, (10.1)–(10.8))

Nash's Γ_μ and A_μ are the Levi-Civita (spin) and Yang–Mills connections. His requirement "$w_1(TM) = w_2(TM) = 0$" is the spin condition of Definition 10.2. In (10.3) he uses the index formula "4.122" of his Chapter 4 and the vanishing of the Pontrjagin classes of spheres "(p. 85)". His "$\mathcal{A}/\mathcal{G} = B\mathcal{G}$" is the identification of the orbit space with the classifying space of the gauge group (valid where $\mathcal{G}$ acts freely, e.g. after restricting to based gauge transformations). His footnote on regularisation is Section 10.2.7. Note that in (10.5) the square root of $\det(\not{D}_A^*\not{D}_A)$ is the modulus of the chiral determinant; its phase is where the anomaly lives (see the pitfall in Section 10.2.6).

Recap

- A chiral gauge theory couples only $\psi_+ = P_+\psi$ to A; the action is $\|F\|^2 + \int \bar\psi P_- \not{D}_A P_+ \psi$, with $\|F\|^2 \geq 0$ for anti-Hermitian F.
- M must be spin ($w_1 = w_2 = 0$); all spheres qualify, $\mathbb{CP}^2$ does not.
- $D_A^+ : \Gamma(E^+ \otimes F) \to \Gamma(E^- \otimes F)$; in 2D it is $2\partial_{\bar z} + \ldots$, in 4D $D_4 - i\vec\sigma\cdot\vec D$.
- $\operatorname{index} D_A^+ = n_+ - n_- = \int \hat A\, \operatorname{ch}(F) = \int_{S^{2m}} \operatorname{ch}_m(F) = k$; e.g. N zero modes for a charge-N monopole on S^2, one for the BPST instanton.
- Grassmann Gaussians give determinants; a chiral fermion gives $\det D_A^+$, whose modulus is $\sqrt{\det(\not{D}_A^*\not{D}_A)}$.
- $\not{D}_{A_g} = g^{-1}\not{D}_A g$ formally implies invariance, but regularised determinants are not multiplicative ($\det'(cT) = c^{\zeta_T(0)}\det' T$). The phase of the chiral determinant can change: that is the anomaly.

10.3 Anomalies and Yang–Mills theories II: the anomalous Ward identity, computed

In Section 10.2 we found the object whose gauge invariance is in question: the fermion determinant. Nash now does two things in quick succession [Nash pp. 272–273]. He differentiates the determinant along a gauge orbit and shows that the derivative is the vacuum expectation value of the divergence of a current. Then he says, in one sentence each, that "a direct perturbative way" to see that this is nonzero is the triangle graph, and that Fujikawa found the same thing in the path-integral measure. Those two sentences stand for a large amount of physics. This section and the next one do the calculations.

The question this section answers is: *how do we actually see, in a Feynman-graph calculation, that a classically conserved current is not conserved?* We do it first in two dimensions, where everything can be computed in a few lines and in three different ways, and then in four, where the triangle graph appears.

10.3.1 Varying the determinant along a gauge orbit

Take a one-parameter family of gauge transformations

$$g(t) = \exp(tf), \qquad f \in \operatorname{Lie}\mathcal{G}, \qquad f(x) = T^a f^a(x),$$

where T^a is a basis of anti-Hermitian matrices for the Lie algebra $\mathfrak{g}$ of G in the representation carried by the fermions, and the $f^a(x)$ are real functions on M. (Nash writes t^a for the generators; we use T^a to avoid a clash with the parameter t.) We want $\frac{\mathrm{d}}{\mathrm{d}t}$ of the fermion integral at $A_{g(t)}$, at $t = 0$.

Step 1: how A moves. To first order in t,

$$\begin{aligned} A_{g(t)} &\overset{(1)}{=} (1 - tf)A(1 + tf) + (1 - tf)\,\mathrm{d}(1 + tf) + O(t^2) \\ &\overset{(2)}{=} A + t\big(\mathrm{d}f + Af - fA\big) + O(t^2) \\ &\overset{(3)}{=} A + t\,D_A f + O(t^2), \qquad D_A f \coloneqq \mathrm{d}f + [A, f]. \end{aligned} \tag{10.23}$$

(1) The gauge transformation (10.4) with $g = 1 + tf + O(t^2)$ and $g^{-1} = 1 - tf + O(t^2)$.
(2) Multiply out and drop t^2.
(3) $D_A f$ is the covariant derivative of f in the adjoint representation; in components $(D_\mu f)^a = \partial_\mu f^a + f^{abc} A^b_\mu f^c$ when $[T^b, T^c] = f^{bca} T^a$. Nash writes this operator ∇^{ab}_μ.

So an infinitesimal gauge transformation moves A in the direction $D_A f$: this is the tangent vector to the gauge orbit through A.

Step 2: how the action moves. Only the fermion term depends on A, through $\not{D}_A P_+ = \gamma^\mu(\partial_\mu + A_\mu)P_+$. Define the **chiral (gauge) current**

$$J^{a\mu} \coloneqq \bar\psi\,\gamma^\mu T^a P_+ \psi = \tfrac{1}{2}\,\bar\psi\,\gamma^\mu(1 + \gamma_5)T^a\psi, \tag{10.24}$$

which is Nash's $j_5^{a\mu}$ [Nash p. 272, (10.9)]. Then, holding ψ and $\bar\psi$ fixed,

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} S_F[A_{g(t)}]\Big|_{t=0} &\overset{(1)}{=} \int_M \bar\psi\,\gamma^\mu (D_\mu f) P_+ \psi \\ &\overset{(2)}{=} \int_M (D_\mu f)^a\, J^{a\mu} \\ &\overset{(3)}{=} -\int_M f^a\,(D_\mu J^\mu)^a. \end{aligned} \tag{10.25}$$

(1) Only A_μ changes, by $t\,D_\mu f$ (10.23).
(2) Expand $D_\mu f = (D_\mu f)^a T^a$ and use the definition (10.24).
(3) Integrate by parts. The covariant derivative obeys a Leibniz rule for the invariant pairing $(D_\mu f)^a J^{a\mu} = \partial_\mu(f^a J^{a\mu}) - f^a (D_\mu J^\mu)^a$, and the total derivative integrates to zero on the closed manifold M by Stokes' theorem; this is the "Stokes' theorem" in Nash's sentence.

Step 3: how the fermion integral moves, if the measure does not. If the measure $\mathcal{D}\psi\mathcal{D}\bar\psi$ is held fixed, differentiating under the integral sign gives

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\int \mathcal{D}\psi\mathcal{D}\bar\psi\, e^{-S_F[A_{g(t)}]}\Big|_{t=0} &\overset{(1)}{=} -\int \mathcal{D}\psi\mathcal{D}\bar\psi\, e^{-S_F[A]}\,\frac{\mathrm{d}S_F}{\mathrm{d}t}\Big|_{t=0} \\ &\overset{(2)}{=} \int \mathcal{D}\psi\mathcal{D}\bar\psi\, e^{-S_F[A]} \int_M f^a(x)\,(D_\mu J^\mu)^a(x). \end{aligned} \tag{10.26}$$

(1) Chain rule on the exponential.
(2) Insert (10.25); the two minus signs cancel.

This is Nash's unnumbered equation on p. 272 (with his $\sqrt{\det}$ in place of the fermion integral). Dividing by the fermion integral itself (Nash's "standard normalisation factor", which removes vacuum graphs) turns the right side into an expectation value [Nash p. 272, (10.10)]:

$$\frac{\mathrm{d}}{\mathrm{d}t}\ln Z_F[A_{g(t)}]\Big|_{t=0} = \Big\langle \int_M f^a\,(D_\mu J^\mu)^a \Big\rangle_A, \qquad Z_F[A] := \int \mathcal{D}\psi\mathcal{D}\bar\psi\, e^{-S_F[A]}. \tag{10.27}$$

Key idea: Anomaly = non-conservation of the gauge current

The left side of (10.27) is the change of $\ln Z_F$ along the gauge orbit, in the direction f. The right side is the smeared divergence of the current the gauge field couples to. So

$$\ln Z_F \text{ gauge invariant} \iff \langle D_\mu J^{a\mu}(x)\rangle_A = 0 \text{ for all } x, a \qquad \text{[Nash (10.11)].}$$

The *classical* equations of motion give $D_\mu J^{a\mu} = 0$ (the same computation as (10.7)). The quantum statement fails exactly when an anomaly is present.

For $G = \mathrm{U}(1)$ the generator T is a number ($T = -ie$ for charge e), D_μ reduces to ∂_μ, and the statement is about the ordinary divergence of a U(1) current. Nash calls it the "singlet axial current" $\frac{1}{2}\bar\psi\gamma^\mu(1+\gamma_5)\psi$. It is worth untangling the names. With $j^\mu = \bar\psi\gamma^\mu\psi$ and $j_5^\mu = \bar\psi\gamma^\mu\gamma_5\psi$,

$$j_\pm^\mu := \bar\psi\gamma^\mu P_\pm\psi = \tfrac{1}{2}\big(j^\mu \pm j_5^\mu\big), \qquad j^\mu = j_+^\mu + j_-^\mu, \qquad j_5^\mu = j_+^\mu - j_-^\mu. \tag{10.28}$$

In a *vector-like* theory (QED) the photon couples to j^μ and the axial current j_5^μ is a global current; in a *chiral* theory the gauge field couples to j_+^μ alone. The anomaly calculations below are done for QED, where they are cleanest, and the translation to the chiral theory is made in Sections 10.4.1 and 10.5.

Watch out: Why the measure matters

Equation (10.26) assumed the measure does not change. But there is a second way to compute the left side: substitute $\psi \to g\psi$, $\bar\psi \to \bar\psi g^{-1}$ in the integral for $Z_F[A_g]$. By (10.22) this turns the action back into $S_F[A]$, so if the measure were invariant we would get $Z_F[A_g] = Z_F[A]$ exactly, and hence $\langle D_\mu J^\mu\rangle = 0$. Either the current is conserved or the measure is not invariant. Fujikawa's insight (Section 10.4.1) is that the second alternative is what happens, and that the Jacobian of the change of variables *is* the anomaly.

10.3.2 Tools for one-loop integrals

The explicit anomaly calculations below are one-loop Feynman integrals. They use five standard tools, and we collect them here once, with their derivations, so that every later step can point back to a formula on this page. The reader who knows them can skip to Section 10.3.3.

Notation. In this subsection and the next four we work in Minkowski space of dimension d, with metric $\eta = \mathrm{diag}(+1,-1,\dots,-1)$. For a vector v^μ we write $v^2 = \eta_{\mu\nu}v^\mu v^\nu$ and $v\cdot w = \eta_{\mu\nu}v^\mu w^\nu$. The gamma matrices obey the Clifford relation

$$\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2\eta^{\mu\nu}\mathbf{1}, \tag{10.29}$$

and the **slash** of a vector is $\not{v} := \gamma^\mu v_\mu$. We write N_d for the size of the gamma matrices: $N_2 = 2$, $N_4 = 4$.

Tool 1: gamma-matrix traces

Everything follows from (10.29) and cyclicity of the trace, $\mathrm{tr}(XY) = \mathrm{tr}(YX)$.

(a) The slash of a vector squares to its length.

$$\not{v}\not{v} \overset{(1)}{=} v_\mu v_\nu \gamma^\mu \gamma^\nu \overset{(2)}{=} \tfrac{1}{2} v_\mu v_\nu \big(\gamma^\mu \gamma^\nu + \gamma^\nu \gamma^\mu\big) \overset{(3)}{=} v_\mu v_\nu \eta^{\mu\nu} \mathbf{1} = v^2\, \mathbf{1}. \tag{10.30}$$

(1) Definition of the slash.
(2) $v_\mu v_\nu$ is symmetric in μ, ν, so only the symmetric part of $\gamma^\mu \gamma^\nu$ survives.
(3) The Clifford relation (10.29).

So $\not{v}$ is invertible when $v^2 \neq 0$, with $\not{v}^{-1} = \not{v}/v^2$. This is why the massless fermion propagator can be written either as $1/\not{p}$ or as $\not{p}/p^2$.

(b) The trace of two.

$$\mathrm{tr}(\gamma^\mu \gamma^\nu) \overset{(1)}{=} \tfrac{1}{2}\,\mathrm{tr}\big(\gamma^\mu \gamma^\nu + \gamma^\nu \gamma^\mu\big) \overset{(2)}{=} \tfrac{1}{2}\,\mathrm{tr}\big(2\eta^{\mu\nu}\mathbf{1}\big) = N_d\, \eta^{\mu\nu}. \tag{10.31}$$

(1) Cyclicity: $\mathrm{tr}(\gamma^\mu \gamma^\nu) = \mathrm{tr}(\gamma^\nu \gamma^\mu)$, so the trace equals the average of the two.
(2) Clifford relation; $\mathrm{tr}\,\mathbf{1} = N_d$.

(c) The trace of four. Move γ^μ from the far left to the far right, anticommuting it past one matrix at a time; each step produces an η and a sign:

$$\begin{aligned}
\mathrm{tr}(\gamma^\mu \gamma^\alpha \gamma^\nu \gamma^\beta) &\overset{(1)}{=} 2\eta^{\mu\alpha}\,\mathrm{tr}(\gamma^\nu \gamma^\beta) - \mathrm{tr}(\gamma^\alpha \gamma^\mu \gamma^\nu \gamma^\beta) \\
&\overset{(2)}{=} 2\eta^{\mu\alpha}\,\mathrm{tr}(\gamma^\nu \gamma^\beta) - 2\eta^{\mu\nu}\,\mathrm{tr}(\gamma^\alpha \gamma^\beta) + \mathrm{tr}(\gamma^\alpha \gamma^\nu \gamma^\mu \gamma^\beta) \\
&\overset{(3)}{=} 2\eta^{\mu\alpha}\,\mathrm{tr}(\gamma^\nu \gamma^\beta) - 2\eta^{\mu\nu}\,\mathrm{tr}(\gamma^\alpha \gamma^\beta) + 2\eta^{\mu\beta}\,\mathrm{tr}(\gamma^\alpha \gamma^\nu) - \mathrm{tr}(\gamma^\alpha \gamma^\nu \gamma^\beta \gamma^\mu) \\
&\overset{(4)}{=} \eta^{\mu\alpha}\,\mathrm{tr}(\gamma^\nu \gamma^\beta) - \eta^{\mu\nu}\,\mathrm{tr}(\gamma^\alpha \gamma^\beta) + \eta^{\mu\beta}\,\mathrm{tr}(\gamma^\alpha \gamma^\nu) \\
&\overset{(5)}{=} N_d\big(\eta^{\mu\alpha}\eta^{\nu\beta} - \eta^{\mu\nu}\eta^{\alpha\beta} + \eta^{\mu\beta}\eta^{\alpha\nu}\big).
\end{aligned} \tag{10.32}$$

(1) $\gamma^\mu \gamma^\alpha = 2\eta^{\mu\alpha} - \gamma^\alpha \gamma^\mu$.
(2) $\gamma^\mu \gamma^\nu = 2\eta^{\mu\nu} - \gamma^\nu \gamma^\mu$ inside the last trace.
(3) $\gamma^\mu \gamma^\beta = 2\eta^{\mu\beta} - \gamma^\beta \gamma^\mu$ inside the last trace.
(4) By cyclicity the last trace equals the left-hand side; move it over and divide by 2.
(5) The trace of two, (10.31).

Contracting with vectors, $\mathrm{tr}(\not{a}\not{b}\not{c}\not{d}) = N_d\big[(a\cdot b)(c\cdot d) - (a\cdot c)(b\cdot d) + (a\cdot d)(b\cdot c)\big]$.

(d) Two contraction identities. With $\eta^\mu{}_\mu = d$,

$$\gamma^\rho \gamma^\mu \gamma_\rho \overset{(1)}{=} \big(2\eta^{\rho\mu} - \gamma^\mu \gamma^\rho\big)\gamma_\rho \overset{(2)}{=} 2\gamma^\mu - d\,\gamma^\mu = (2-d)\gamma^\mu, \tag{10.33}$$

$$\not{p}\gamma^\lambda \not{p} \overset{(3)}{=} \big(2p^\lambda - \gamma^\lambda \not{p}\big)\not{p} \overset{(4)}{=} 2p^\lambda \not{p} - p^2 \gamma^\lambda. \tag{10.34}$$

(1) Clifford relation for $\gamma^\rho \gamma^\mu$.
(2) $\eta^{\rho\mu}\gamma_\rho = \gamma^\mu$, and $\gamma^\rho \gamma_\rho = \tfrac{1}{2}\eta_{\rho\sigma}\{\gamma^\rho, \gamma^\sigma\} = \eta_{\rho\sigma}\eta^{\rho\sigma} = d$.
(3) $\not{p}\gamma^\lambda = p_\rho \gamma^\rho \gamma^\lambda = p_\rho(2\eta^{\rho\lambda} - \gamma^\lambda \gamma^\rho) = 2p^\lambda - \gamma^\lambda \not{p}$.
(4) $\not{p}\not{p} = p^2$ by (10.30).

(e) Odd traces vanish, and traces with γ^5. In even dimension there is a matrix γ^5 with $(\gamma^5)^2 = \mathbf{1}$ that anticommutes with every γ^μ (we write it down in each dimension below). For an odd

number $2r+1$ of gamma matrices,

$$\operatorname{tr}(\gamma^{\mu_1}\cdots\gamma^{\mu_{2r+1}}) \overset{(1)}{=} \operatorname{tr}(\gamma^5\gamma^5\gamma^{\mu_1}\cdots\gamma^{\mu_{2r+1}}) \overset{(2)}{=} (-1)^{2r+1}\operatorname{tr}(\gamma^5\gamma^{\mu_1}\cdots\gamma^{\mu_{2r+1}}\gamma^5)$$
$$\overset{(3)}{=} -\operatorname{tr}(\gamma^5\gamma^5\gamma^{\mu_1}\cdots\gamma^{\mu_{2r+1}}) = -\operatorname{tr}(\gamma^{\mu_1}\cdots\gamma^{\mu_{2r+1}}), \tag{10.35}$$

(1) Insert $\mathbf{1} = (\gamma^5)^2$.
(2) Move the second γ^5 to the far right, past $2r+1$ matrices, each giving a sign.
(3) Cyclicity moves the last γ^5 back to the front.

so the trace is zero. A similar trick shows $\operatorname{tr}\gamma^5 = \operatorname{tr}(\gamma^0\gamma^0\gamma^5) = -\operatorname{tr}(\gamma^0\gamma^5\gamma^0) = -\operatorname{tr}\gamma^5$, so $\operatorname{tr}\gamma^5 = 0$ (use $(\gamma^0)^2 = \mathbf{1}$, anticommute, then cycle); inserting instead $\gamma^\rho\gamma^\rho/\eta^{\rho\rho}$ with ρ different from α,β shows in the same way that $\operatorname{tr}(\gamma^5\gamma^\alpha\gamma^\beta) = 0$ in four dimensions. In four dimensions, with $\gamma^5 := i\gamma^0\gamma^1\gamma^2\gamma^3$ and $\epsilon^{0123} := +1$,

$$\operatorname{tr}(\gamma^5) = \operatorname{tr}(\gamma^5\gamma^\alpha\gamma^\beta) = 0, \qquad \operatorname{tr}(\gamma^5\gamma^\alpha\gamma^\beta\gamma^\gamma\gamma^\delta) = -4i\,\epsilon^{\alpha\beta\gamma\delta}. \tag{10.36}$$

Why: $\gamma^5\gamma^\alpha\gamma^\beta\gamma^\gamma\gamma^\delta$ can have nonzero trace only if the product contains each of $\gamma^0,\gamma^1,\gamma^2,\gamma^3$ an even number of times in total, so $\alpha\beta\gamma\delta$ must be a permutation of 0123; the trace is then antisymmetric, and one value fixes it:

$$\operatorname{tr}(\gamma^5\gamma^0\gamma^1\gamma^2\gamma^3) \overset{(1)}{=} \operatorname{tr}\big(\gamma^5\cdot(-i\gamma^5)\big) \overset{(2)}{=} -i\operatorname{tr}\mathbf{1} = -4i.$$

(1) $\gamma^0\gamma^1\gamma^2\gamma^3 = -i\gamma^5$, from the definition of γ^5 and $1/i = -i$.
(2) $(\gamma^5)^2 = \mathbf{1}$; this holds because $(\gamma^0\gamma^1\gamma^2\gamma^3)^2 = -\mathbf{1}$ (six anticommutations and $(\gamma^0)^2 = -(\gamma^j)^2 = \mathbf{1}$), so $(\gamma^5)^2 = i^2\cdot(-\mathbf{1}) = \mathbf{1}$.

Two consequences we use constantly: (i) $\operatorname{tr}(\gamma^5 \not{a}\not{b}\not{c}\not{d}) = -4i\,\epsilon^{\alpha\beta\gamma\delta}a_\alpha b_\beta c_\gamma d_\delta$ is *totally antisymmetric* in the four slots, so it vanishes if two slots hold the same vector; (ii) the four slots may be cyclically rotated only with a sign, because a cyclic shift of four objects is an odd permutation.

Tool 2: Feynman parameters

Products of propagator denominators are combined into a single power. The cleanest derivation uses the **Schwinger parameter** representation $\frac{1}{A} = \int_0^\infty \mathrm{d}s\, e^{-sA}$ (valid for $\operatorname{Re}A > 0$; the final identities are algebraic and continue to hold whenever the parameter integrals make sense, e.g. for denominators carrying Feynman's $+i0$). For two factors:

$$\frac{1}{AB} \overset{(1)}{=} \int_0^\infty \mathrm{d}s_1 \int_0^\infty \mathrm{d}s_2\, e^{-s_1A - s_2B}$$
$$\overset{(2)}{=} \int_0^\infty \mathrm{d}s\; s\int_0^1 \mathrm{d}x\; e^{-s[xA+(1-x)B]} \overset{(3)}{=} \int_0^1 \frac{\mathrm{d}x}{\big[xA+(1-x)B\big]^2}. \tag{10.37}$$

(1) One Schwinger integral for each factor.
(2) Change variables $s_1 = sx$, $s_2 = s(1-x)$ with $s\in[0,\infty)$, $x\in[0,1]$; the Jacobian is $\big|\partial(s_1,s_2)/\partial(s,x)\big| = \big|\det\left(\begin{smallmatrix} x & s \\ 1-x & -s\end{smallmatrix}\right)\big| = s$.
(3) $\int_0^\infty \mathrm{d}s\, s\, e^{-sX} = 1/X^2$ (integrate by parts once).

For three factors the same change of variables, $s_i = sx_i$ with $x_1+x_2+x_3 = 1$, has Jacobian s^2, and $\int_0^\infty \mathrm{d}s\, s^2 e^{-sX} = 2/X^3$, so

$$\frac{1}{ABC} = 2\int_0^1\mathrm{d}x\int_0^1\mathrm{d}y\int_0^1\mathrm{d}z\;\frac{\delta(1-x-y-z)}{\big[xA+yB+zC\big]^3}, \qquad \int \mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z\;\delta(1-x-y-z) = \tfrac{1}{2}. \tag{10.38}$$

(The last integral is the area of the triangle $x,y\ge 0$, $x+y\le 1$.) A quick test of (10.37): at $A = B$ it reads $1/A^2 = \int_0^1 \mathrm{d}x/A^2$, which is true.

Tool 3: Wick rotation

A Minkowski loop integral $\int \mathrm{d}^d\ell\, f(\ell^2)$ has its poles at $\ell^0 = \pm(\sqrt{\boldsymbol{\ell}^2+\Delta} - i0)$: just below the positive real axis and just above the negative one (Figure 10.6). The contour along the real ℓ^0 axis can therefore be rotated anticlockwise by 90° onto the imaginary axis without crossing a pole, and the arcs at infinity contribute nothing when f falls off fast enough. Set

$$\ell^0 = i\ell_E^0, \qquad \boldsymbol{\ell} = \boldsymbol{\ell}_E, \qquad \ell^2 = -\ell_E^2, \qquad \mathrm{d}^d\ell = i\,\mathrm{d}^d\ell_E, \tag{10.39}$$

where $\ell_E^2 = (\ell_E^0)^2 + \boldsymbol{\ell}^2$ is a Euclidean length.

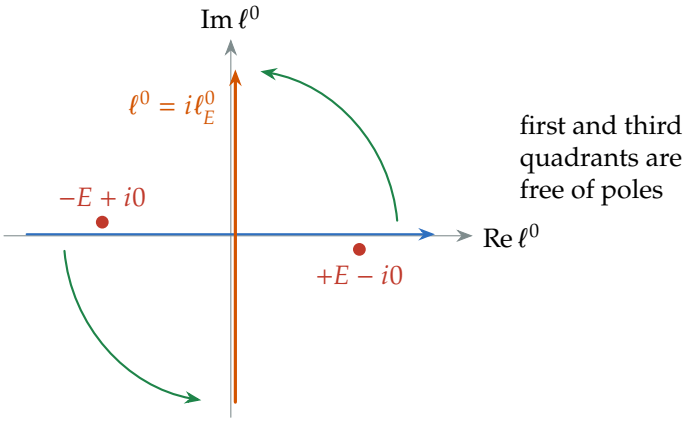

Figure 10.6: Wick rotation. The poles of a Feynman propagator (red, with $E = \sqrt{\boldsymbol{\ell}^2+\Delta}$) sit in the second and fourth quadrants. Rotating the integration contour anticlockwise (green arrows) from the real axis (blue) to the imaginary axis (orange) sweeps only the empty first and third quadrants, so the integral does not change. On the imaginary axis the Minkowski ℓ^2 becomes minus a Euclidean length.

Tool 4: the master integrals

With Wick rotation, a Schwinger parameter and a Gaussian integral we can do every integral we need. The Gaussian integral in d Euclidean dimensions is $\int \mathrm{d}^d\ell_E\, e^{-s\ell_E^2} = (\pi/s)^{d/2}$, the product of d one-dimensional ones. Then, for $\Delta > 0$,

$$\begin{aligned}
\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\frac{1}{(\ell^2-\Delta)^n} &\overset{(1)}{=} i\int \frac{\mathrm{d}^d\ell_E}{(2\pi)^d}\frac{(-1)^n}{(\ell_E^2+\Delta)^n} \\
&\overset{(2)}{=} \frac{i(-1)^n}{(2\pi)^d\,\Gamma(n)}\int_0^\infty \mathrm{d}s\; s^{n-1}e^{-s\Delta}\int \mathrm{d}^d\ell_E\, e^{-s\ell_E^2} \\
&\overset{(3)}{=} \frac{i(-1)^n\pi^{d/2}}{(2\pi)^d\,\Gamma(n)}\int_0^\infty \mathrm{d}s\; s^{n-1-d/2}e^{-s\Delta} \\
&\overset{(4)}{=} \frac{(-1)^n\, i}{(4\pi)^{d/2}}\,\frac{\Gamma(n-\frac{d}{2})}{\Gamma(n)}\,\Delta^{d/2-n}.
\end{aligned} \tag{10.40}$$

(1) Wick rotation (10.39): $\mathrm{d}^d\ell = i\,\mathrm{d}^d\ell_E$ and $\ell^2 - \Delta = -(\ell_E^2+\Delta)$.

(2) $X^{-n} = \frac{1}{\Gamma(n)}\int_0^\infty \mathrm{d}s\; s^{n-1}e^{-sX}$, the definition of the Gamma function after rescaling $s \to s/X$.

(3) The Gaussian integral.

(4) $\int_0^\infty \mathrm{d}s\; s^{m-1}e^{-s\Delta} = \Gamma(m)\Delta^{-m}$ with $m = n - \frac{d}{2}$, and $\pi^{d/2}/(2\pi)^d = (4\pi)^{-d/2}$.

The same steps with an extra $\ell^2 = -\ell_E^2$ in the numerator, using $\int \mathrm{d}^d\ell_E\, \ell_E^2 e^{-s\ell_E^2} = -\partial_s(\pi/s)^{d/2} = \frac{d}{2s}(\pi/s)^{d/2}$, give

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\frac{\ell^2}{(\ell^2-\Delta)^n} = \frac{(-1)^{n-1}\,i}{(4\pi)^{d/2}}\,\frac{d}{2}\,\frac{\Gamma(n-\frac{d}{2}-1)}{\Gamma(n)}\,\Delta^{d/2-n+1}. \tag{10.41}$$

Finally, **symmetric integration**: inside an integral whose other factors depend on ℓ only through ℓ^2,

$$\ell^\mu \to 0, \qquad \ell^\mu\ell^\nu \to \frac{\ell^2}{d}\,\eta^{\mu\nu}, \qquad \ell^\mu\ell^\nu\ell^\rho \to 0. \tag{10.42}$$

Odd powers vanish because $\ell \to -\ell$ is a symmetry of the rest of the integrand. For the even one, Lorentz invariance forces $\int \ell^\mu\ell^\nu f(\ell^2) = c\,\eta^{\mu\nu}$; contracting with $\eta_{\mu\nu}$ gives $\int \ell^2 f = c\,d$, so $c = \frac{1}{d}\int \ell^2 f$.

Tool 5: dimensional regularisation and the Gamma function

When an integral diverges in $d = 2$ or $d = 4$, **dimensional regularisation** evaluates it with (10.40)–(10.42) for general complex d, where the right-hand sides make sense, and takes $d \to 2$ or 4 at the end. Divergences show up as poles of the Gamma function. The facts we need are

$$\Gamma(z+1) = z\,\Gamma(z), \qquad \Gamma(1) = 1, \qquad \Gamma(\epsilon) = \frac{1}{\epsilon} - \gamma_E + O(\epsilon), \tag{10.43}$$

with $\gamma_E \approx 0.577$ the Euler constant. Two features matter for anomalies:

- Shifting the loop momentum, $\ell \to \ell + a$, is always allowed, because the formulas above depend only on ℓ^2 after completing the square. This is what makes dimensional regularisation respect gauge invariance.
- Factors of d from $\eta^\mu{}_\mu = d$ and from (10.42) are kept as d until the end. A factor $(d-2)$ or $(d-4)$ multiplying a pole $\Gamma(1-\frac{d}{2})$ or $\Gamma(2-\frac{d}{2})$ leaves a *finite* remainder: for instance $(1-\frac{d}{2})\Gamma(1-\frac{d}{2}) = \Gamma(2-\frac{d}{2}) \to 1$ as $d \to 2$. This "$0\times\infty$" is how every anomaly below appears.

10.3.3 Two dimensions: QED$_2$ and the vacuum polarisation

Two-dimensional massless QED (the **Schwinger model**) is the simplest theory with an anomaly. We use Minkowski signature here, because the physical interpretation (Section 10.3.5) is Hamiltonian, and we follow the conventions of [QFT notes §22.2]:

$$\eta = \mathrm{diag}(+1,-1), \qquad \gamma^0 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \gamma^1 = \begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix}, \quad \gamma^5 := \gamma^0\gamma^1 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$
$$\mathcal{L} = \bar\psi\, i\gamma^\mu(\partial_\mu + ieA_\mu)\psi - \tfrac{1}{4}F_{\mu\nu}F^{\mu\nu}, \qquad \epsilon^{01} = +1. \tag{10.44}$$

(One checks $(\gamma^0)^2 = \mathbf{1}$, $(\gamma^1)^2 = -\mathbf{1}$, $\gamma^0\gamma^1 = -\gamma^1\gamma^0$ by multiplying the matrices. The interaction term is $-eA_\mu j^\mu$.)

A two-dimensional miracle: the axial current is the dual of the vector current. In two dimensions,

$$\gamma^\mu\gamma^5 = -\epsilon^{\mu\nu}\gamma_\nu, \qquad \text{hence} \qquad j_5^\mu = -\epsilon^{\mu\nu}j_\nu. \tag{10.45}$$

We check the first identity component by component:

$$\gamma^0\gamma^5 \overset{(1)}{=} \gamma^0\gamma^0\gamma^1 \overset{(2)}{=} \gamma^1, \qquad -\epsilon^{0\nu}\gamma_\nu \overset{(3)}{=} -\gamma_1 \overset{(4)}{=} \gamma^1,$$
$$\gamma^1\gamma^5 \overset{(1)}{=} \gamma^1\gamma^0\gamma^1 \overset{(5)}{=} -\gamma^0(\gamma^1)^2 = \gamma^0, \qquad -\epsilon^{1\nu}\gamma_\nu \overset{(3)}{=} +\gamma_0 = \gamma^0.$$

(1) Definition $\gamma^5 = \gamma^0\gamma^1$.
(2) $(\gamma^0)^2 = \mathbf{1}$.
(3) Only one term survives, with $\epsilon^{01} = 1 = -\epsilon^{10}$.
(4) Lowering a spatial index flips its sign: $\gamma_1 = \eta_{11}\gamma^1 = -\gamma^1$.
(5) Anticommute γ^1 past γ^0, then $(\gamma^1)^2 = -\mathbf{1}$.

Sandwiching between $\bar\psi$ and ψ gives the second identity. It means that in two dimensions *any* statement about j^μ is also a statement about j_5^μ.

The vacuum polarisation. Put the fermions in a weak background field A_μ. To first order, the induced current is linear in A: $\langle j^\mu(q)\rangle = -\frac{1}{e}\Pi^{\mu\nu}(q)A_\nu(q)$, where $i\Pi^{\mu\nu}(q)$ is the one-loop photon self-energy [QFT notes (22.2.15)–(22.2.23)]. By Lorentz invariance

$$\Pi^{\mu\nu}(q) = \mathsf{a}\,\eta^{\mu\nu} - \mathsf{b}\,\frac{q^\mu q^\nu}{q^2} \tag{10.46}$$

for two numbers a, b (in two dimensions both are dimensionless, times e^2, so no other structure is possible). Now observe:

$$q_\mu\langle j^\mu\rangle \overset{(1)}{=} -\tfrac{1}{e}(\mathsf{a}-\mathsf{b})q^\nu A_\nu,$$
$$q_\mu\langle j_5^\mu\rangle \overset{(2)}{=} \tfrac{1}{e}\,\epsilon^{\mu\nu}q_\mu\Big(\mathsf{a}A_\nu - \mathsf{b}\frac{q_\nu\, q\cdot A}{q^2}\Big) \overset{(3)}{=} \tfrac{\mathsf{a}}{e}\,\epsilon^{\mu\nu}q_\mu A_\nu. \tag{10.47}$$

(1) Contract (10.46) with q_μ: $q_\mu\eta^{\mu\nu} = q^\nu$ and $q_\mu q^\mu q^\nu/q^2 = q^\nu$.
(2) Use $j_5^\mu = -\epsilon^{\mu\nu}j_\nu$ from (10.45).
(3) $\epsilon^{\mu\nu}q_\mu q_\nu = 0$ by antisymmetry.

So the vector current is conserved iff $\mathsf{a} = \mathsf{b}$, and the axial current is conserved iff $\mathsf{a} = 0$. *Both* are conserved only if $\mathsf{a} = \mathsf{b} = 0$. The whole question is therefore: is b zero?

Worked example 10.10: Computing b: it is finite and nonzero

The integral. The Feynman rules of QED (in the conventions (10.44)) are: a vertex $-ie\gamma^\mu$ for each photon, a propagator $i/\not\ell = i\not\ell/\ell^2$ for each fermion line (Tool 1(a)), a factor -1 and a trace for the closed fermion loop, and $\int \mathrm{d}^2\ell/(2\pi)^2$ over the undetermined loop momentum ℓ. The loop has one propagator with momentum ℓ and one with $\ell + q$. So

$$i\Pi^{\mu\nu}(q) \overset{(1)}{=} (-1)\int \frac{\mathrm{d}^2\ell}{(2\pi)^2}\,\mathrm{tr}\Big[(-ie\gamma^\mu)\frac{i\not\ell}{\ell^2}(-ie\gamma^\nu)\frac{i(\not\ell+\not q)}{(\ell+q)^2}\Big]$$
$$\overset{(2)}{=} -e^2\int \frac{\mathrm{d}^2\ell}{(2\pi)^2}\,\frac{\mathrm{tr}\big[\gamma^\mu\not\ell\,\gamma^\nu(\not\ell+\not q)\big]}{\ell^2(\ell+q)^2}. \tag{10.48}$$

(1) The Feynman rules just listed.

(2) Collect the constants: $(-1)\cdot(-ie)^2\cdot i^2 = (-1)(-e^2)(-1) = -e^2$.

The numerator. By the trace of four (10.32) with $N_2 = 2$, $a = \ell$ in the second slot and $b = \ell + q$ in the fourth,

$$\operatorname{tr}\big[\gamma^\mu \ell \gamma^\nu (\ell\!\!\!/ + q\!\!\!/)\big] = 2\big[\ell^\mu(\ell+q)^\nu + \ell^\nu(\ell+q)^\mu - \eta^{\mu\nu}\,\ell\cdot(\ell+q)\big]. \tag{10.49}$$

The denominator. Use (10.37) with $A = (\ell+q)^2$, $B = \ell^2$ and complete the square:

$$\begin{aligned} xA + (1-x)B &\overset{(1)}{=} x\big(\ell^2 + 2\ell\cdot q + q^2\big) + (1-x)\ell^2 \overset{(2)}{=} \ell^2 + 2x\,\ell\cdot q + xq^2 \\ &\overset{(3)}{=} (\ell + xq)^2 - x^2q^2 + xq^2 \overset{(4)}{=} r^2 - \Delta, \qquad r := \ell + xq, \quad \Delta := -x(1-x)q^2. \end{aligned} \tag{10.50}$$

(1) Expand $(\ell+q)^2$.
(2) The $x\ell^2$ terms combine with $(1-x)\ell^2$ to ℓ^2.
(3) $(\ell+xq)^2 = \ell^2 + 2x\ell\cdot q + x^2q^2$.
(4) $xq^2 - x^2q^2 = x(1-x)q^2 = -\Delta$.

(For spacelike q, $q^2 < 0$, so $\Delta > 0$ and (10.40) applies directly; other q follow by analytic continuation.) We now shift the integration variable from ℓ to r; the integral we are shifting will turn out to be at most logarithmically divergent in $d = 2$, so in dimensional regularisation the shift is certainly allowed.

The numerator in terms of r. With $\ell = r - xq$ and $\ell + q = r + (1-x)q$,

$$\begin{aligned} \ell^\mu(\ell+q)^\nu &\overset{(1)}{=} r^\mu r^\nu + (1-x)r^\mu q^\nu - x\,q^\mu r^\nu - x(1-x)q^\mu q^\nu, \\ \ell\cdot(\ell+q) &\overset{(2)}{=} r^2 + (1-2x)\,r\cdot q - x(1-x)q^2. \end{aligned} \tag{10.51}$$

(1) Multiply out $(r-xq)^\mu(r+(1-x)q)^\nu$.
(2) Contract the same product with $\eta_{\mu\nu}$.

The terms linear in r vanish after integration by (10.42). Keeping the even terms, (10.49) becomes

$$2\Big[\underbrace{2r^\mu r^\nu - \eta^{\mu\nu}r^2}_{\text{divergent}} \;\underbrace{-2x(1-x)\,q^\mu q^\nu}_{\text{gives b}} \;\underbrace{+x(1-x)q^2\,\eta^{\mu\nu}}_{\text{finite part of a}}\Big], \tag{10.52}$$

where we added (10.51) to itself with $\mu \leftrightarrow \nu$ for the first two terms of (10.49). Altogether

$$i\Pi^{\mu\nu}(q) = -e^2\int_0^1 \mathrm{d}x \int \frac{\mathrm{d}^d r}{(2\pi)^d}\,\frac{2\big[2r^\mu r^\nu - \eta^{\mu\nu}r^2 - 2x(1-x)q^\mu q^\nu + x(1-x)q^2\eta^{\mu\nu}\big]}{(r^2-\Delta)^2}, \tag{10.53}$$

with $d = 2$ for the convergent terms.

The $q^\mu q^\nu$ term.

$$\begin{aligned} i\Pi^{\mu\nu}\big|_{q^\mu q^\nu} &\overset{(1)}{=} -e^2\int_0^1 \mathrm{d}x\,\big(-4x(1-x)\big)q^\mu q^\nu \int \frac{\mathrm{d}^2 r}{(2\pi)^2}\frac{1}{(r^2-\Delta)^2} \\ &\overset{(2)}{=} -e^2\int_0^1 \mathrm{d}x\,\big(-4x(1-x)\big)q^\mu q^\nu\,\frac{i}{4\pi\Delta} \\ &\overset{(3)}{=} -e^2\int_0^1 \mathrm{d}x\,\frac{-4x(1-x)\,i}{4\pi\big(-x(1-x)q^2\big)}\,q^\mu q^\nu \overset{(4)}{=} -\frac{ie^2}{\pi}\,\frac{q^\mu q^\nu}{q^2}\int_0^1 \mathrm{d}x = -\frac{ie^2}{\pi}\frac{q^\mu q^\nu}{q^2}. \end{aligned}$$

(1) The $q^\mu q^\nu$ term of (10.53): $2\times(-2x(1-x)) = -4x(1-x)$.

(2) Master integral (10.40) at $d = 2$, $n = 2$: $(-1)^2\, i\, (4\pi)^{-1}\Gamma(1)/\Gamma(2)\, \Delta^{-1}$. It is finite.
(3) Insert $\Delta = -x(1-x)q^2$.
(4) The $x(1-x)$ cancels (a coincidence of $d = 2$), and $\frac{-4i}{-4\pi} = \frac{i}{\pi}$.

Comparing with (10.46), $-\mathsf{b} = -e^2/\pi$, i.e. $\mathsf{b} = e^2/\pi$. It came from a *convergent* integral, so no regularisation can change it.

The coefficient a is where regularisation enters. The $\eta^{\mu\nu}$ part of (10.53) has two pieces. The *finite piece* is the same in every scheme:

$$i\Pi^{\mu\nu}\big|_{\text{finite},\,\eta} \overset{(1)}{=} -e^2 \int_0^1 \mathrm{d}x\; 2x(1-x)q^2\,\eta^{\mu\nu}\,\frac{i}{4\pi\Delta} \overset{(2)}{=} -e^2\int_0^1 \mathrm{d}x\;\frac{2x(1-x)q^2\,i}{4\pi(-x(1-x)q^2)}\,\eta^{\mu\nu} \overset{(3)}{=} \frac{ie^2}{2\pi}\,\eta^{\mu\nu}. \tag{10.54}$$

(1) The last term of (10.53), and the master integral (10.40) at $d = 2$, $n = 2$.
(2) Insert Δ.
(3) Cancel $x(1-x)q^2$; $-e^2\cdot\frac{2i}{-4\pi} = \frac{ie^2}{2\pi}$; $\int_0^1 \mathrm{d}x = 1$.

The *divergent piece* $2r^\mu r^\nu - \eta^{\mu\nu}r^2$ has numerator $\sim r^2$ against denominator $\sim r^4$ in two dimensions: logarithmically divergent. Its value depends on how we define it.

Procedure 1: naive symmetric integration in exactly $d = 2$. Replace $r^\mu r^\nu \to \frac{1}{2}\eta^{\mu\nu}r^2$ by (10.42) with $d = 2$. Then $2r^\mu r^\nu - \eta^{\mu\nu}r^2 \to \eta^{\mu\nu}r^2 - \eta^{\mu\nu}r^2 = 0$ *before* anyone has asked whether the integral converges. Only (10.54) survives: $i\Pi|_\eta = \frac{ie^2}{2\pi}\eta^{\mu\nu}$, so $\mathsf{a} = e^2/2\pi = \frac{1}{2}\mathsf{b}$. By (10.47) neither current is conserved.

Procedure 2: dimensional regularisation. Keep d general until the end:

$$\begin{aligned} i\Pi^{\mu\nu}\big|_{\text{div}} &\overset{(1)}{=} -2e^2\int_0^1\mathrm{d}x\int\frac{\mathrm{d}^d r}{(2\pi)^d}\,\frac{(\frac{2}{d}-1)\eta^{\mu\nu}r^2}{(r^2-\Delta)^2} \overset{(2)}{=} -2e^2\,\frac{2-d}{d}\,\eta^{\mu\nu}\int_0^1\mathrm{d}x\int\frac{\mathrm{d}^d r}{(2\pi)^d}\,\frac{r^2}{(r^2-\Delta)^2} \\ &\overset{(3)}{=} -2e^2\,\frac{2-d}{d}\,\eta^{\mu\nu}\int_0^1\mathrm{d}x\,\frac{(-1)\,i}{(4\pi)^{d/2}}\,\frac{d}{2}\,\frac{\Gamma(1-\frac{d}{2})}{\Gamma(2)}\,\Delta^{d/2-1} \\ &\overset{(4)}{=} 2ie^2\,\eta^{\mu\nu}\int_0^1\mathrm{d}x\,\frac{(1-\frac{d}{2})\Gamma(1-\frac{d}{2})}{(4\pi)^{d/2}}\,\Delta^{d/2-1} \overset{(5)}{=} 2ie^2\,\eta^{\mu\nu}\int_0^1\mathrm{d}x\,\frac{\Gamma(2-\frac{d}{2})}{(4\pi)^{d/2}}\,\Delta^{d/2-1} \\ &\overset{(6)}{=} \frac{2ie^2}{4\pi}\,\eta^{\mu\nu} = \frac{ie^2}{2\pi}\,\eta^{\mu\nu} \qquad (d\to 2). \end{aligned} \tag{10.55}$$

(1) Symmetric integration in d dimensions, $r^\mu r^\nu \to \frac{1}{d}\eta^{\mu\nu}r^2$ (10.42), so $2r^\mu r^\nu - \eta^{\mu\nu}r^2 \to (\frac{2}{d}-1)\eta^{\mu\nu}r^2$; the overall 2 of (10.53) is pulled out.
(2) $\frac{2}{d} - 1 = \frac{2-d}{d}$.
(3) Master integral with r^2 in the numerator (10.41) at $n = 2$: $(-1)^{n-1} = -1$. At $d = 2$ it has a pole, $\Gamma(1-\frac{d}{2}) \to \infty$.
(4) Collect: $-2e^2\cdot\frac{2-d}{d}\cdot(-i)\cdot\frac{d}{2} = ie^2(2-d) = 2ie^2(1-\frac{d}{2})$.
(5) $z\Gamma(z) = \Gamma(z+1)$ with $z = 1-\frac{d}{2}$ (10.43). The vanishing factor has eaten the pole exactly.
(6) At $d = 2$: $\Gamma(1) = 1$, $(4\pi)^{d/2} = 4\pi$, $\Delta^0 = 1$, $\int_0^1 \mathrm{d}x = 1$.

The divergent piece is not zero: it is a finite "$0\times\infty$" remainder equal to the finite piece. Adding (10.54) and (10.55), $i\Pi|_\eta = \frac{ie^2}{\pi}\eta^{\mu\nu}$, so $\mathsf{a} = e^2/\pi = \mathsf{b}$. Dimensional regularisation respects gauge invariance, and it produces $\mathsf{a} = \mathsf{b}$: the vector current is conserved, and then

$$\Pi^{\mu\nu}(q) = \frac{e^2}{\pi}\Big(\eta^{\mu\nu} - \frac{q^\mu q^\nu}{q^2}\Big), \qquad \langle j^\mu\rangle = -\frac{e}{\pi}\Big(\eta^{\mu\nu} - \frac{\partial^\mu\partial^\nu}{\Box}\Big)A_\nu, \tag{10.56}$$

in agreement with [QFT notes (22.2.18), (22.2.23)]. To return to position space, write $A_\nu(x) = \int \frac{d^2q}{(2\pi)^2} e^{-iq\cdot x}\tilde{A}_\nu(q)$ and similarly for the current; then ∂_μ acting on $e^{-iq\cdot x}$ brings down $-iq_\mu$. Multiplying the second line of (10.47) by $-i$,

$$(-iq_\mu)\langle \tilde{j}_5^\mu\rangle \overset{(1)}{=} \frac{\mathsf{a}}{e}\,\epsilon^{\mu\nu}(-iq_\mu)\tilde{A}_\nu \quad\Longrightarrow\quad \partial_\mu\langle j_5^\mu\rangle \overset{(2)}{=} \frac{\mathsf{a}}{e}\,\epsilon^{\mu\nu}\partial_\mu A_\nu \overset{(3)}{=} \frac{e}{\pi}\,\epsilon^{\mu\nu}\partial_\mu A_\nu,$$

(1) Both sides contain exactly one factor of q, so one factor of $-i$ goes to each.
(2) Replace $-iq_\mu \to \partial_\mu$ under the Fourier integral.
(3) $\mathsf{a} = e^2/\pi$.

that is,

$$\boxed{\partial_\mu\langle j_5^\mu\rangle = \frac{e}{\pi}\,\epsilon^{\mu\nu}\partial_\mu A_\nu = \frac{e}{2\pi}\,\epsilon^{\mu\nu}F_{\mu\nu}} \qquad \text{[QFT notes (22.2.27)].} \tag{10.57}$$

The last step is $\epsilon^{\mu\nu}F_{\mu\nu} = \epsilon^{\mu\nu}(\partial_\mu A_\nu - \partial_\nu A_\mu) = 2\epsilon^{\mu\nu}\partial_\mu A_\nu$, by relabelling $\mu \leftrightarrow \nu$ in the second term.

Physical picture: The photon gets a mass

Put (10.56) into Maxwell's equation $\partial_\mu F^{\mu\nu} = e\langle j^\nu\rangle$. In Lorenz gauge $\partial\cdot A = 0$ it reads $\Box A^\nu = -\frac{e^2}{\pi}A^\nu$, i.e. $(\Box + m^2)A^\nu = 0$ with

$$m_\gamma^2 = \frac{e^2}{\pi}.$$

The photon of the Schwinger model is massive, and this one-loop result is exact [QFT notes (22.2.21)]. The pole $1/q^2$ in $\Pi(q^2) = e^2/\pi q^2$ is the reason: in two dimensions a massless fermion–antifermion pair moving in the same direction behaves like a single massless particle, which the photon eats. The anomaly and the photon mass are the same number, $\mathsf{b} = e^2/\pi$.

Watch out: Which current is "anomalous" is a choice

Equation (10.47) leaves a one-parameter family of possibilities. Setting $\mathsf{a} = 0$ instead would conserve j_5^μ and break j^μ: $q_\mu\langle j^\mu\rangle = (e/\pi)\,q\cdot A$ [QFT notes p. 1371]. What is *not* a choice is that $\mathsf{b} = e^2/\pi \neq 0$, so one of them must go. We keep the vector current because the photon couples to it: breaking it would make the physics depend on the gauge. Nash's phrase "the lack of gauge invariance must occur somewhere" is this statement.

10.3.4 Two dimensions again: the point-split current

The vacuum-polarisation argument shows *that* there is an anomaly. The operator argument shows *where* it comes from: the current $j_5^\mu(x)$ is a product of two fields at the same point, and such products are singular.

Working definition 10.5 (gauge-invariant point splitting)

Define the current as a limit of fields at two nearby points, joined by a Wilson line [the phase factor $\exp[-ie\int A]$ along the short segment between the two points. Under a gauge transformation it picks up the phases of both ends] so that the combination is gauge invariant [QFT notes (22.2.31)]:

$$j_5^\mu(x) := \operatorname*{s\text{-}lim}_{\varepsilon\to 0}\ \bar{\psi}\big(x+\tfrac{\varepsilon}{2}\big)\,\gamma^\mu\gamma^5\,\exp\Big[-ie\int_{x-\varepsilon/2}^{x+\varepsilon/2} dz^\sigma A_\sigma(z)\Big]\,\psi\big(x-\tfrac{\varepsilon}{2}\big).$$

The **symmetric limit** averages over the direction of ε: s-lim $\varepsilon^\mu/\varepsilon^2 = 0$ and s-lim $\varepsilon^\mu\varepsilon^\nu/\varepsilon^2 = \eta^{\mu\nu}/d$. *Test of the definition:* under $\psi \to e^{-ie\alpha}\psi$, $A \to A + \mathrm{d}\alpha$, the Wilson line picks up $e^{-ie[\alpha(x+\varepsilon/2)-\alpha(x-\varepsilon/2)]}$, which cancels the phases of the two fermion fields.

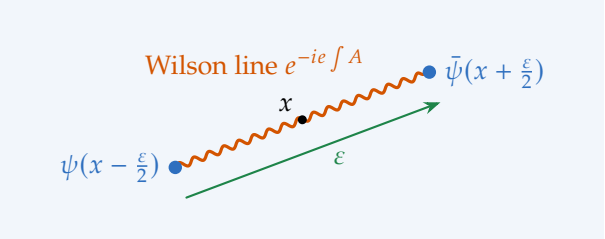

Figure 10.7: Point splitting. The two fermion fields sit a distance ε apart and are joined by a Wilson line to keep the product gauge invariant. Differentiating the Wilson line produces a factor $\varepsilon^\nu F_{\mu\nu}$, which vanishes as $\varepsilon \to 0$; but the fermion pair has a $1/\varepsilon$ singularity. The product of "zero" and "infinity" is finite and nonzero: that is the anomaly.

Differentiating the split current. Write $x_\pm := x \pm \frac{\varepsilon}{2}$ and $W := \exp\!\big[-ie\int_{x_-}^{x_+} \mathrm{d}z^\sigma A_\sigma(z)\big]$, and take ε along a fixed direction while we differentiate with respect to x. We need three ingredients.

(i) The equations of motion. The Dirac equation from (10.44) is $i\gamma^\mu(\partial_\mu + ieA_\mu)\psi = 0$, i.e. $\gamma^\mu\partial_\mu\psi = -ie\not{A}\psi$. Its Dirac conjugate (take the Hermitian conjugate, multiply by γ^0 on the right, and use $\gamma^0\gamma^{\mu\dagger}\gamma^0 = \gamma^\mu$) is $(\partial_\mu\bar\psi)\gamma^\mu = ie\,\bar\psi\not{A}$.

(ii) The derivative of the Wilson line. Parametrise the straight segment as $z = x + s\varepsilon$, $s \in [-\frac12, \frac12]$, so $\mathrm{d}z^\sigma = \varepsilon^\sigma \mathrm{d}s$. Then

$$\begin{aligned}
\partial_\mu W &\overset{(1)}{=} W\cdot(-ie)\,\partial_\mu \int_{-1/2}^{1/2} \mathrm{d}s\ \varepsilon^\sigma A_\sigma(x+s\varepsilon) \\
&\overset{(2)}{=} W\cdot(-ie)\int_{-1/2}^{1/2} \mathrm{d}s\ \varepsilon^\sigma\big[\partial_\mu A_\sigma(x) + s\,\varepsilon^\tau\partial_\tau\partial_\mu A_\sigma(x) + \cdots\big] \\
&\overset{(3)}{=} -ie\,\varepsilon^\sigma\partial_\mu A_\sigma(x)\,W + O(\varepsilon^3) \overset{(4)}{=} -ie\,\varepsilon^\sigma\partial_\mu A_\sigma(x) + O(\varepsilon^2).
\end{aligned} \tag{10.58}$$

(1) Chain rule on the exponential; the endpoints move with x, and this is taken into account by writing the integral in the variable s, whose range is fixed.
(2) Taylor expand A_σ about x.
(3) $\int_{-1/2}^{1/2}\mathrm{d}s = 1$ and $\int_{-1/2}^{1/2} s\,\mathrm{d}s = 0$; the next surviving term is $O(\varepsilon^3)$.
(4) $W = 1 + O(\varepsilon)$.

(iii) Moving γ^5. In two dimensions $\gamma^5 = \gamma^0\gamma^1$ anticommutes with γ^0 and γ^1 (check: $\gamma^0\gamma^5 = \gamma^1$ while $\gamma^5\gamma^0 = \gamma^0\gamma^1\gamma^0 = -\gamma^1$), hence with every $\not{\phi}$.

Now apply the product rule. W is a number (a phase), so it commutes with all matrices.

$$\begin{aligned}
\partial_\mu\big[\bar\psi(x_+)\gamma^\mu\gamma^5 W\psi(x_-)\big] &\overset{(1)}{=} (\partial_\mu\bar\psi)(x_+)\gamma^\mu\gamma^5 W\psi(x_-) + \bar\psi(x_+)\gamma^\mu\gamma^5(\partial_\mu W)\psi(x_-) \\
&\quad + \bar\psi(x_+)\gamma^\mu\gamma^5 W(\partial_\mu\psi)(x_-) \\
&\overset{(2)}{=} ie\,\bar\psi\not{A}(x_+)\gamma^5 W\psi + \bar\psi\gamma^\mu\gamma^5(\partial_\mu W)\psi - \bar\psi\gamma^5 W\gamma^\mu(\partial_\mu\psi)(x_-) \\
&\overset{(3)}{=} ie\,\bar\psi\not{A}(x_+)\gamma^5 W\psi + \bar\psi\gamma^\mu\gamma^5(\partial_\mu W)\psi + ie\,\bar\psi\gamma^5\not{A}(x_-)W\psi \\
&\overset{(4)}{=} ie\,\bar\psi\big[\not{A}(x_+) - \not{A}(x_-)\big]\gamma^5 W\psi + \bar\psi\gamma^\mu\gamma^5(\partial_\mu W)\psi
\end{aligned}$$

$$\overset{(5)}{=} ie\,\varepsilon^\nu \partial_\nu A_\mu\ \bar\psi\gamma^\mu\gamma^5\psi - ie\,\varepsilon^\nu\partial_\mu A_\nu\ \bar\psi\gamma^\mu\gamma^5\psi + O(\varepsilon^2)$$
$$\overset{(6)}{=} -ie\,\varepsilon^\nu F_{\mu\nu}\ \bar\psi(x_+)\gamma^\mu\gamma^5\psi(x_-) + O(\varepsilon^2). \tag{10.59}$$

(1) Product rule: ∂_μ hits $\bar\psi(x_+)$, W, or $\psi(x_-)$. (We abbreviate $\bar\psi = \bar\psi(x_+)$ and $\psi = \psi(x_-)$ from now on.)
(2) First term: equation of motion for $\bar\psi$ from (i). Third term: anticommute γ^μ past γ^5 by (iii), which costs a minus sign.
(3) Third term: $\gamma^\mu\partial_\mu\psi = -ie\not{A}\psi$ from (i); the two minus signs give $+ie$.
(4) Third term: $\gamma^5\not{A} = -\not{A}\gamma^5$ by (iii), and the first and third terms combine.
(5) First term: Taylor expand $A_\mu(x_+) - A_\mu(x_-) = \varepsilon^\nu\partial_\nu A_\mu(x) + O(\varepsilon^3)$ and set $W = 1$ since the prefactor is already $O(\varepsilon)$. Second term: (10.58).
(6) $\partial_\nu A_\mu - \partial_\mu A_\nu = -(\partial_\mu A_\nu - \partial_\nu A_\mu) = -F_{\mu\nu}$.

Classically we would now set $\varepsilon = 0$ and get zero. Quantum mechanically the fermion bilinear has a vacuum expectation value that blows up as $\varepsilon \to 0$.

The singular fermion bilinear. We need the free massless propagator in two dimensions. In momentum space it is $i\not{k}/(k^2 + i0)$. Write it as $i\not{\partial}$ acting on the scalar propagator $D(x) = \int \frac{d^2k}{(2\pi)^2}\frac{i}{k^2+i0}e^{-ik\cdot x}$, since $i\partial_\mu e^{-ik\cdot x} = k_\mu e^{-ik\cdot x}$. The two-dimensional massless scalar propagator is $D(x) = -\frac{1}{4\pi}\ln(-\mu^2x^2 + i0)$, with μ an infrared scale that drops out of derivatives. (Check: in Euclidean signature it is the familiar $-\frac{1}{2\pi}\ln|x|$, the Green's function of $-\nabla^2$ in the plane.) So

$$\langle\psi(x)\bar\psi(y)\rangle \overset{(1)}{=} i\gamma^\mu\partial_\mu D(x-y) \overset{(2)}{=} i\gamma^\mu\left(-\frac{1}{4\pi}\right)\frac{2(x-y)_\mu}{(x-y)^2} = -\frac{i}{2\pi}\,\frac{\gamma^\mu(x-y)_\mu}{(x-y)^2} \qquad \text{[QFT notes (22.2.39)]}. \tag{10.60}$$

(1) The Fourier representation just described.
(2) $\partial_\mu\ln(-x^2) = 2x_\mu/x^2$.

For any 2×2 matrix Γ,

$$\langle\bar\psi(x_+)\Gamma\psi(x_-)\rangle \overset{(1)}{=} \Gamma_{\alpha\beta}\,\langle\bar\psi_\alpha(x_+)\psi_\beta(x_-)\rangle \overset{(2)}{=} -\Gamma_{\alpha\beta}\,\langle\psi_\beta(x_-)\bar\psi_\alpha(x_+)\rangle$$
$$\overset{(3)}{=} -\Gamma_{\alpha\beta}\left(-\frac{i}{2\pi}\right)\frac{(\gamma^\sigma)_{\beta\alpha}(-\varepsilon_\sigma)}{\varepsilon^2} \overset{(4)}{=} -\frac{i}{2\pi}\,\frac{\mathrm{tr}(\Gamma\gamma^\sigma)\,\varepsilon_\sigma}{\varepsilon^2}. \tag{10.61}$$

(1) Write out the spinor indices; $\Gamma_{\alpha\beta}$ is a number.
(2) Fermion fields anticommute (inside the time-ordered product).
(3) The propagator (10.60) with $x - y = x_- - x_+ = -\varepsilon$ and $(x-y)^2 = \varepsilon^2$.
(4) $(-1)(-1) = 1$, and $\Gamma_{\alpha\beta}(\gamma^\sigma)_{\beta\alpha} = \mathrm{tr}(\Gamma\gamma^\sigma)$.

With $\Gamma = \gamma^\mu\gamma^5$ we need one trace:

$$\mathrm{tr}(\gamma^\mu\gamma^5\gamma^\sigma) \overset{(1)}{=} \mathrm{tr}(\gamma^\sigma\gamma^\mu\gamma^5) \overset{(2)}{=} -\epsilon^{\mu\nu}\,\mathrm{tr}(\gamma^\sigma\gamma_\nu) \overset{(3)}{=} -2\epsilon^{\mu\nu}\delta^\sigma_\nu = -2\epsilon^{\mu\sigma}.$$

(1) Cyclicity.
(2) $\gamma^\mu\gamma^5 = -\epsilon^{\mu\nu}\gamma_\nu$ (10.45).
(3) The trace of two (10.31) with $N_2 = 2$: $\mathrm{tr}(\gamma^\sigma\gamma_\nu) = 2\delta^\sigma_\nu$.

(Check at $\mu = 0$, $\sigma = 1$: $\mathrm{tr}(\gamma^0\gamma^0\gamma^1\gamma^1) = \mathrm{tr}(\mathbf{1}\cdot(-\mathbf{1})) = -2 = -2\epsilon^{01}$.)

The symmetric limit. Averaging $\varepsilon^\nu \varepsilon_\sigma/\varepsilon^2$ over the directions of ε gives a Lorentz-invariant tensor, hence $c\,\delta^\nu_\sigma$; taking the trace ($\nu = \sigma$, summed) gives $1 = c\,d$. So

$$\operatorname*{s-lim}_{\varepsilon\to 0} \frac{\varepsilon^\nu \varepsilon_\sigma}{\varepsilon^2} = \frac{\delta^\nu_\sigma}{d}, \qquad \operatorname*{s-lim}_{\varepsilon\to 0} \frac{\varepsilon^\nu}{\varepsilon^2} = 0, \tag{10.62}$$

the second because it is odd under $\varepsilon \to -\varepsilon$. This is the position-space twin of the symmetric integration rule (10.42).

Putting everything together,

$$\begin{aligned} \partial_\mu \langle j^\mu_5 \rangle &\overset{(1)}{=} \operatorname*{s-lim}\big(-ie\,\varepsilon^\nu F_{\mu\nu}\big)\Big(-\frac{i}{2\pi}\Big)\frac{(-2\epsilon^{\mu\sigma})\varepsilon_\sigma}{\varepsilon^2} \\ &\overset{(2)}{=} \frac{e}{\pi}\,\epsilon^{\mu\sigma}F_{\mu\nu}\operatorname*{s-lim}\frac{\varepsilon^\nu\varepsilon_\sigma}{\varepsilon^2} \overset{(3)}{=} \frac{e}{\pi}\,\epsilon^{\mu\sigma}F_{\mu\nu}\,\frac{\delta^\nu_\sigma}{2} \overset{(4)}{=} \frac{e}{2\pi}\,\epsilon^{\mu\nu}F_{\mu\nu}. \end{aligned} \tag{10.63}$$

(1) Take the expectation value of (10.59) and insert (10.61) with the trace just computed; F is a background field, so it comes out of the expectation value. The $O(\varepsilon^2)$ terms times $1/\varepsilon$ vanish in the limit.
(2) The constants: $(-ie)\cdot\big(-\frac{i}{2\pi}\big)\cdot(-2) = \frac{e}{\pi}\cdot(-i)(-i)(-1) = \frac{e}{\pi}\cdot(-1)(-1) = \frac{e}{\pi}$.
(3) The symmetric limit (10.62) with $d = 2$.
(4) δ^ν_σ sets $\sigma = \nu$.

This is (10.57) again [QFT notes (22.2.45)]. The Wilson line was essential. Without it (or with the opposite sign in its exponent, which breaks gauge invariance) the same steps give $\partial_\mu j^\mu_5 = 0$ and a non-conserved vector current.

10.3.5 Spectral flow: where the chiral charge goes

The anomaly equation (10.57) is a local statement. Here is its global meaning, which is the physical picture behind everything in this chapter [QFT notes §22.2.4].

Put the fermions on a circle of length L (periodic boundary conditions), with $A_0 = 0$ and a spatially constant $A^1 =: a(t)$ that changes slowly in time. The Dirac equation $i\gamma^\mu D_\mu\psi = 0$, multiplied by γ^0, is $i\partial_t\psi = -i\gamma^5(\partial_1 + ieA_1)\psi$. For $\psi_\pm \propto e^{ikx}$ with $\gamma^5\psi_\pm = \pm\psi_\pm$:

$$E_\pm(k) \overset{(1)}{=} \pm(-i)(ik + ieA_1) \overset{(2)}{=} \pm(k - e\,a), \qquad k = k_n = \frac{2\pi n}{L},\ n \in \mathbb{Z}. \tag{10.64}$$

(1) Replace $\partial_1 \to ik$ and $\gamma^5 \to \pm 1$.
(2) $A_1 = \eta_{11}A^1 = -a$.

So positive chirality fermions are right-movers with energy $k - ea$ (the kinetic momentum), negative chirality fermions left-movers with energy $-(k - ea)$. The Dirac vacuum fills every level with $E < 0$ in both towers.

Counting. Increase a by $\Delta a = 2\pi/(eL)$. The set of levels is the same as before (the Wilson loop $e^{ie\oint A^1 dx}$ has returned to its value), but each level has moved by one spacing, as in Figure 10.8. Levels move slowly, so their occupation does not change. One empty right-mover level has sunk below zero and one filled left-mover level has risen above zero. Measured from the new vacuum, $\Delta N_+ = -1$, $\Delta N_- = +1$, and $\Delta Q_5 = \Delta(N_+ - N_-) = -2$, while $\Delta Q = \Delta(N_+ + N_-) = 0$: charge is conserved, chirality is not.

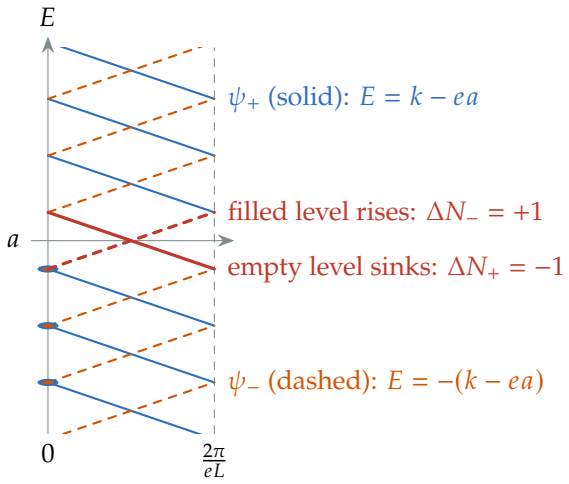

Figure 10.8: Spectral flow on a circle. As the constant potential a increases by $2\pi/eL$ the spectrum returns to itself, but every right-mover level (solid) has moved down one step and every left-mover level (dashed) up one step. The red levels cross $E = 0$. Occupations are preserved by the adiabatic theorem, so relative to the new vacuum one right-mover is missing and one extra left-mover is present: $\Delta(N_+ - N_-) = -2$, exactly what the anomaly equation predicts.

The anomaly predicts exactly this. Integrate (10.57) over the spacetime slab $[0,T]\times S^1$:

$$\Delta Q_5 \overset{(1)}{=} \int_0^T \mathrm{d}t \oint \mathrm{d}x\, \partial_\mu j_5^\mu \overset{(2)}{=} \frac{e}{2\pi}\int \mathrm{d}t\,\mathrm{d}x\, 2F_{01} \overset{(3)}{=} \frac{e}{\pi}\int \mathrm{d}t\,\mathrm{d}x\,\partial_0 A_1$$
$$\overset{(4)}{=} -\frac{e}{\pi}L\,\Delta a \overset{(5)}{=} -\frac{e}{\pi}L\,\frac{2\pi}{eL} = -2. \tag{10.65}$$

(1) $Q_5 = \oint j_5^0\,\mathrm{d}x$; the spatial divergence integrates to zero on the circle.
(2) $\epsilon^{\mu\nu}F_{\mu\nu} = \epsilon^{01}F_{01} + \epsilon^{10}F_{10} = 2F_{01}$.
(3) $F_{01} = \partial_0 A_1 - \partial_1 A_0 = \partial_0 A_1$ because $A_0 = 0$.
(4) $A_1 = -a$ is constant in x, so $\oint \mathrm{d}x = L$ and $\int \mathrm{d}t\,\partial_0 A_1 = -\Delta a$.
(5) The value of Δa that brings the spectrum back to itself.

The two counts agree.

Physical picture: An electric field pumps chirality

In terms of the electric field $E = -\partial_t a$, the anomaly says $\dot{Q}_5 = \frac{e}{\pi}L\,E$. Here is the elementary version. A force eE shifts every momentum at the rate $\dot{k} = eE$. The levels are spaced by $2\pi/L$, so each Fermi point sweeps through $eEL/2\pi$ levels per unit time. Right-movers gain particles at that rate and left-movers lose them: $\dot{N}_\pm = \pm eEL/2\pi$, so $\dot{Q}_5 = eEL/\pi$. The "creation from nothing" is really a rearrangement of the infinitely deep Dirac sea, which is why a regularisation (a way of saying what happens at $E \to -\infty$) is needed to see it, and why gauge invariance (charge conservation) decides which way the answer comes out.

Watch out: Levels crossing zero are an index

The number of levels that cross $E = 0$ in one direction minus the number crossing in the other is called the **spectral flow**. It is an integer and it is topological: small deformations of the path $a(t)$ cannot change it. In Euclidean language, the slab $[0,T]\times S^1$ with the ends identified (since the spectrum came back) is a torus carrying one unit of flux, $\frac{e}{2\pi}\int f = 1$, and the spectral flow of the one-dimensional Hamiltonian equals the index of the two-

dimensional Dirac operator on that torus. This is our first example of "integrated anomaly = index" (Section 10.4.5).

10.3.6 Four dimensions: the point-split current

We now repeat the point-splitting calculation in four dimensions (still Minkowski, $\eta = \mathrm{diag}(+,-,-,-)$, following [QFT notes §22.3]). The conventions are those of Tool 1(e): $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$, $\epsilon^{0123} = +1$ and $\mathrm{tr}(\gamma^5\gamma^\alpha\gamma^\beta\gamma^\gamma\gamma^\delta) = -4i\epsilon^{\alpha\beta\gamma\delta}$. The derivation of the operator identity (10.59) used only three things: the equations of motion, the derivative of the Wilson line, and the fact that γ^5 anticommutes with every γ^μ. All three hold in four dimensions (for the last, $\gamma^5\gamma^\mu = -\gamma^\mu\gamma^5$ because moving γ^μ through $\gamma^0\gamma^1\gamma^2\gamma^3$ costs three signs and one $(\gamma^\mu)^2$ that commutes back). So

$$\partial_\mu j_5^\mu = \operatorname*{s\text{-}lim}_{\varepsilon\to 0} \left(-ie\,\varepsilon^\nu F_{\mu\nu}\right) \bar\psi(x_+)\gamma^\mu\gamma^5\psi(x_-) \tag{10.66}$$

holds unchanged. What changes is the singular bilinear.

Step 1: the free propagator gives nothing. The four-dimensional scalar propagator is $D_4(x) = \int \frac{\mathrm{d}^4k}{(2\pi)^4}\frac{i\,e^{-ik\cdot x}}{k^2+i0} = -\frac{1}{4\pi^2(x^2-i0)}$ (in Euclidean signature this is $1/4\pi^2x_E^2$, the Green's function of $-\nabla^2$ in $\mathbb{R}^4$). Hence, exactly as in (10.60),

$$S(x-y) := \langle\psi(x)\bar\psi(y)\rangle_0 \overset{(1)}{=} i\gamma^\mu\partial_\mu D_4(x-y) \overset{(2)}{=} \frac{i}{2\pi^2}\,\frac{\gamma^\mu(x-y)_\mu}{(x-y)^4}. \tag{10.67}$$

(1) $i\not\partial e^{-ik\cdot x} = \not k\, e^{-ik\cdot x}$, so the Fourier transform of $i\not k/k^2$ is $i\not\partial D_4$.
(2) $\partial_\mu(-1/4\pi^2x^2) = 2x_\mu/4\pi^2x^4$.

By (10.61), whose derivation did not depend on the dimension, the free bilinear is

$$-\,\mathrm{tr}\big(\gamma^\mu\gamma^5 S(-\varepsilon)\big) \propto \mathrm{tr}(\gamma^5\gamma^\sigma\gamma^\mu)\,\frac{\varepsilon_\sigma}{\varepsilon^4},$$

which is *zero* by (10.36): a trace of γ^5 needs four other gamma matrices. The same is true with the Wilson line expanded to first order, since W is a number.

Step 2: the propagator in the background field, to first order. Let $G(x,y) = \langle\psi(x)\bar\psi(y)\rangle_A$ be the propagator in the background A. It obeys the Dirac equation with a source, $(i\not\partial_x - e\not A(x))G(x,y) = i\delta^4(x-y)$, and the free one obeys $i\not\partial_x S(x-y) = i\delta^4(x-y)$. Try $G = S + G_1$ with G_1 of first order in e:

$$\begin{aligned}(i\not\partial_x - e\not A)(S+G_1) &\overset{(1)}{=} i\delta^4(x-y) - e\not A(x)S(x-y) + i\not\partial_x G_1(x,y) + O(e^2)\\ \Longrightarrow\quad G_1(x,y) &\overset{(2)}{=} \int \mathrm{d}^4z\; S(x-z)\left(-ie\not A(z)\right)S(z-y).\end{aligned} \tag{10.68}$$

(1) Use the free equation; $e\not A G_1$ is second order.
(2) Setting the first-order terms to zero requires $i\not\partial_x G_1 = e\not A S$. Applying $i\not\partial_x$ to the proposed G_1 gives $\int \mathrm{d}^4z\, i\delta^4(x-z)(-ie\not A(z))S(z-y) = e\not A(x)S(x-y)$, as required.

This is the diagram of Figure 10.9: a free line, one interaction with the background (vertex $-ie\gamma^\alpha$), another free line.

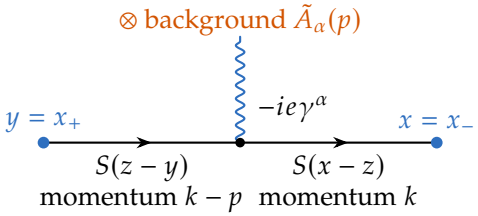

Figure 10.9: The first-order propagator G_1 of (10.68). The fermion line runs from $\bar\psi$ at x_+ to ψ at x_- and absorbs momentum p from the background field once. Compared with the free line it has one more propagator (less singular by one power of ε) but two more gamma matrices (γ^α and a second $\not k$), which is exactly what the trace with γ^5 needs.

Now go to momentum space: $A_\alpha(z) = \int_p e^{-ip\cdot z}\tilde A_\alpha(p)$ and $S(x) = \int_k \frac{i\not k}{k^2}e^{-ik\cdot x}$, with the shorthand $\int_k := \int \frac{\mathrm{d}^4k}{(2\pi)^4}$. Then

$$\begin{aligned} G_1(x,y) &\overset{(1)}{=} \int_p\int_k\int_{k'}\int \mathrm{d}^4z\; e^{-ik\cdot(x-z)}e^{-ip\cdot z}e^{-ik'\cdot(z-y)}\,\frac{i\not k}{k^2}\big(-ie\not{\tilde A}(p)\big)\frac{i\not k'}{k'^2} \\ &\overset{(2)}{=} \int_p\int_k e^{-ik\cdot x+i(k-p)\cdot y}\,\frac{i\not k\,(-ie\not{\tilde A}(p))\,i(\not k-\not p)}{k^2(k-p)^2} \\ &\overset{(3)}{=} ie\int_p\int_k e^{-ik\cdot x+i(k-p)\cdot y}\,\frac{\not k\,\not{\tilde A}(p)\,(\not k-\not p)}{k^2(k-p)^2}. \end{aligned} \tag{10.69}$$

(1) Insert the Fourier representations into (10.68).
(2) The z integral gives $(2\pi)^4\delta^4(k-p-k')$, which sets $k' = k-p$ (momentum conservation at the vertex) and cancels one $(2\pi)^4$.
(3) $i\cdot(-ie)\cdot i = -i^3e = ie$.

We need $G_1(x_-,x_+)$, i.e. $x = x_- = x - \frac{\varepsilon}{2}$ and $y = x_+ = x + \frac{\varepsilon}{2}$ in (10.69). The phase becomes

$$-ik\cdot\left(x-\tfrac{\varepsilon}{2}\right) + i(k-p)\cdot\left(x+\tfrac{\varepsilon}{2}\right) \overset{(1)}{=} -ip\cdot x + ik\cdot\varepsilon - \tfrac{i}{2}p\cdot\varepsilon.$$

(1) Multiply out: the $\pm ik\cdot x$ cancel, and $\frac{i}{2}k\cdot\varepsilon + \frac{i}{2}k\cdot\varepsilon = ik\cdot\varepsilon$.

Step 3: the trace. The bilinear is $B^\mu := \langle\bar\psi(x_+)\gamma^\mu\gamma^5\psi(x_-)\rangle = -\operatorname{tr}[\gamma^\mu\gamma^5 G(x_-,x_+)]$ by steps (1)–(2) of (10.61). The trace that appears is

$$\operatorname{tr}\big[\gamma^\mu\gamma^5\not k\gamma^\alpha(\not k-\not p)\big] \overset{(1)}{=} \operatorname{tr}\big[\gamma^5\not k\gamma^\alpha\not k\gamma^\mu\big] - \operatorname{tr}\big[\gamma^5\not k\gamma^\alpha\not p\gamma^\mu\big] \overset{(2)}{=} 0 + 4i\,\epsilon^{\kappa\alpha\pi\mu}k_\kappa p_\pi. \tag{10.70}$$

(1) Cyclicity moves γ^μ to the end; split $\not k - \not p$.
(2) (10.36): the first trace is $-4i\epsilon^{\kappa\alpha\lambda\mu}k_\kappa k_\lambda = 0$ (antisymmetric ϵ against symmetric $k_\kappa k_\lambda$); the second is $-4i\epsilon^{\kappa\alpha\pi\mu}k_\kappa p_\pi$.

Every term is therefore at least linear in p, i.e. in a derivative of A. As $\varepsilon\to 0$ the singular behaviour comes from large loop momenta, $|k|\sim 1/|\varepsilon| \gg |p|$. There we may set $(k-p)^2\to k^2$ and $e^{-\frac{i}{2}p\cdot\varepsilon}\to 1$: the corrections carry extra powers of $p\varepsilon$, i.e. more derivatives of A and more

powers of ε, and vanish in the limit. So

$$\begin{aligned} B^\mu &\overset{(1)}{=} -ie \int_p e^{-ip\cdot x}\tilde{A}_\alpha(p) \int_k e^{ik\cdot\varepsilon}\, \frac{4i\,\epsilon^{\kappa\alpha\pi\mu}k_\kappa p_\pi}{k^4} \\ &\overset{(2)}{=} 4e\,\epsilon^{\kappa\alpha\pi\mu}\Big[\int_p e^{-ip\cdot x}p_\pi\tilde{A}_\alpha(p)\Big] I_\kappa(\varepsilon), \qquad I_\kappa(\varepsilon) \coloneqq \int_k \frac{k_\kappa\, e^{ik\cdot\varepsilon}}{(k^2+i0)^2} \\ &\overset{(3)}{=} 4ie\,\epsilon^{\kappa\alpha\pi\mu}\,\partial_\pi A_\alpha(x)\, I_\kappa(\varepsilon) \overset{(4)}{=} 2ie\,\epsilon^{\kappa\alpha\pi\mu}F_{\pi\alpha}(x)\, I_\kappa(\varepsilon). \end{aligned} \tag{10.71}$$

(1) $B^\mu = -\operatorname{tr}[\gamma^\mu\gamma^5 G_1(x_-,x_+)]$ with (10.69), the phase, and the trace (10.70); the leading large-k form of the denominator is k^4.
(2) $(-ie)(4i) = 4e$; separate the p and k integrals.
(3) $p_\pi e^{-ip\cdot x} = i\partial_\pi e^{-ip\cdot x}$, so the bracket is $i\partial_\pi A_\alpha(x)$.
(4) $\epsilon^{\kappa\alpha\pi\mu}$ is antisymmetric in $\alpha\pi$, so only the antisymmetric part of $\partial_\pi A_\alpha$ survives: $\epsilon^{\kappa\alpha\pi\mu}\partial_\pi A_\alpha = \frac{1}{2}\epsilon^{\kappa\alpha\pi\mu}(\partial_\pi A_\alpha - \partial_\alpha A_\pi) = \frac{1}{2}\epsilon^{\kappa\alpha\pi\mu}F_{\pi\alpha}$.

The answer depends only on F, as gauge invariance demands.

Step 4: the Fourier integral. Write $I_\kappa = -i\,\partial_{\varepsilon^\kappa} J(\varepsilon)$ with $J(\varepsilon) \coloneqq \int_k e^{ik\cdot\varepsilon}/(k^2+i0)^2$, since $\partial_{\varepsilon^\kappa} e^{ik\cdot\varepsilon} = ik_\kappa e^{ik\cdot\varepsilon}$. Take ε spacelike (e.g. purely spatial), so that $k\cdot\varepsilon = -k_E\cdot\varepsilon_E$ after Wick rotation and $\varepsilon^2 = -\varepsilon_E^2$. Then

$$\begin{aligned} J(\varepsilon) &\overset{(1)}{=} i\int \frac{\mathrm{d}^4k_E}{(2\pi)^4}\,\frac{e^{-ik_E\cdot\varepsilon_E}}{k_E^4} \overset{(2)}{=} i\,G_E(\varepsilon_E), \qquad G_E(x) \coloneqq \int \frac{\mathrm{d}^4k_E}{(2\pi)^4}\,\frac{e^{ik_E\cdot x}}{k_E^4} \\ &\overset{(3)}{=} -\frac{i}{8\pi^2}\ln\big(\mu|\varepsilon_E|\big) \overset{(4)}{=} -\frac{i}{16\pi^2}\ln\big(-\mu^2\varepsilon^2\big). \end{aligned} \tag{10.72}$$

(1) Wick rotation (10.39): $\mathrm{d}^4k = i\,\mathrm{d}^4k_E$ and $(k^2)^2 = (-k_E^2)^2 = k_E^4$.
(2) $k_E \to -k_E$ flips the sign in the exponent.
(3) G_E solves $(\nabla^2)^2 G_E = \delta^4$ (apply $(\nabla^2)^2$ under the integral: $(\nabla^2)^2 e^{ik\cdot x} = k^4 e^{ik\cdot x}$). In four dimensions, with $r = |x|$, $\nabla^2\ln r = \frac{1}{r^3}\partial_r(r^3\cdot\frac{1}{r}) = \frac{2}{r^2}$ and $\nabla^2\frac{1}{r^2} = -4\pi^2\delta^4$ (Step 1). Hence $(\nabla^2)^2\big(-\frac{1}{8\pi^2}\ln r\big) = -\frac{2}{8\pi^2}(-4\pi^2)\delta^4 = \delta^4$. The constant μ is an infrared scale (the integral diverges logarithmically at small k); it drops out of derivatives.
(4) $\ln|\varepsilon_E| = \frac{1}{2}\ln\varepsilon_E^2$ and $\varepsilon_E^2 = -\varepsilon^2$.

Differentiating,

$$I_\kappa(\varepsilon) \overset{(1)}{=} -i\,\partial_{\varepsilon^\kappa}\Big(-\frac{i}{16\pi^2}\ln(-\mu^2\varepsilon^2)\Big) \overset{(2)}{=} -\frac{1}{16\pi^2}\,\frac{2\varepsilon_\kappa}{\varepsilon^2} = -\frac{1}{8\pi^2}\,\frac{\varepsilon_\kappa}{\varepsilon^2}. \tag{10.73}$$

(1) $I_\kappa = -i\partial_\kappa J$ with (10.72).
(2) $(-i)(-i) = -1$ and $\partial_\kappa\ln(-\varepsilon^2) = 2\varepsilon_\kappa/\varepsilon^2$.

Inserting (10.73) in (10.71),

$$B^\mu \overset{(1)}{=} -\frac{ie}{4\pi^2}\,\epsilon^{\kappa\alpha\pi\mu}F_{\pi\alpha}\,\frac{\varepsilon_\kappa}{\varepsilon^2} \overset{(2)}{=} -\frac{ie}{4\pi^2}\,\epsilon^{\mu\sigma\rho\tau}F_{\sigma\rho}\,\frac{\varepsilon_\tau}{\varepsilon^2} \qquad \text{[QFT notes (22.3.12)]}. \tag{10.74}$$

(1) $2ie\cdot(-\frac{1}{8\pi^2}) = -\frac{ie}{4\pi^2}$.
(2) Rename $\pi\to\sigma$, $\alpha\to\rho$, $\kappa\to\tau$; then $\epsilon^{\tau\rho\sigma\mu} = \epsilon^{\mu\sigma\rho\tau}$, because reversing the order of four indices is two transpositions (swap the outer pair and the inner pair).

It is singular like $1/\varepsilon$, one power less than the free bilinear, but it is not zero.

Step 5: the anomaly. Now

$$\partial_\mu\langle j_5^\mu\rangle \overset{(1)}{=} \text{s-lim}\big(-ie\,\varepsilon^\nu F_{\mu\nu}\big)\Big(-\frac{ie}{4\pi^2}\epsilon^{\mu\sigma\rho\tau}F_{\sigma\rho}\frac{\varepsilon_\tau}{\varepsilon^2}\Big) \overset{(2)}{=} -\frac{e^2}{4\pi^2}\,\epsilon^{\mu\sigma\rho\tau}F_{\mu\nu}F_{\sigma\rho}\,\text{s-lim}\,\frac{\varepsilon^\nu\varepsilon_\tau}{\varepsilon^2}$$
$$\overset{(3)}{=} -\frac{e^2}{4\pi^2}\,\epsilon^{\mu\sigma\rho\tau}F_{\mu\nu}F_{\sigma\rho}\,\frac{\delta^\nu_\tau}{4} \overset{(4)}{=} -\frac{e^2}{16\pi^2}\,\epsilon^{\mu\sigma\rho\nu}F_{\mu\nu}F_{\sigma\rho} \overset{(5)}{=} -\frac{e^2}{16\pi^2}\,\epsilon^{\mu\nu\sigma\rho}F_{\mu\nu}F_{\sigma\rho}. \tag{10.75}$$

(1) Expectation value of (10.66), with the bilinear (10.74).
(2) $(-ie)(-ie) = i^2e^2 = -e^2$.
(3) The symmetric limit (10.62) in $d = 4$.
(4) δ^ν_τ sets $\tau = \nu$.
(5) $(\sigma\rho\nu) \to (\nu\sigma\rho)$ is a cyclic permutation of three indices, which is even.

This is the **Adler–Bell–Jackiw anomaly** in Minkowski form [QFT notes (22.3.15)]. To see what it means, write it with $\mathbf{E}$ and $\mathbf{B}$. With $A^\mu = (\phi, \mathbf{A})$, $A_i = -A^i$, $\mathbf{E} = -\nabla\phi - \partial_t\mathbf{A}$ and $\mathbf{B} = \nabla\times\mathbf{A}$, the field strength is $F_{0i} = \partial_0 A_i - \partial_i A_0 = E_i$ and $F_{ij} = -(\partial_i A^j - \partial_j A^i) = -\epsilon_{ijk}B_k$. Then

$$\epsilon^{\mu\nu\sigma\rho}F_{\mu\nu}F_{\sigma\rho} \overset{(1)}{=} 4\,\epsilon^{0ijk}F_{0i}F_{jk} \overset{(2)}{=} 4\,\epsilon_{ijk}E_i\big(-\epsilon_{jkl}B_l\big) \overset{(3)}{=} -4\cdot 2\delta_{il}E_iB_l = -8\,\mathbf{E}\cdot\mathbf{B}, \tag{10.76}$$

(1) Exactly one of the four indices is 0. It can sit in either slot of either pair (4 choices), and each choice gives the same term after using the antisymmetry of both ϵ and F.
(2) $\epsilon^{0ijk} = \epsilon_{ijk}$ (with $\epsilon^{0123} = +1 = \epsilon_{123}$), and the field strengths above.
(3) $\epsilon_{ijk}\epsilon_{ljk} = 2\delta_{il}$.

so the anomaly equation reads

$$\partial_\mu\langle j_5^\mu\rangle = \frac{e^2}{2\pi^2}\,\mathbf{E}\cdot\mathbf{B}. \tag{10.77}$$

Parallel electric and magnetic fields create chirality. This is the four-dimensional version of Figure 10.8: the magnetic field organises the fermions into Landau levels, the lowest of which is a one-dimensional chiral fermion moving along $\mathbf{B}$ with $eB/2\pi$ states per unit transverse area, and the electric field then pumps it exactly as in two dimensions, $\dot n_5 = 2\cdot\frac{eE}{2\pi}\cdot\frac{eB}{2\pi} = \frac{e^2}{2\pi^2}EB$.

10.3.7 Four dimensions: the triangle graph

Nash's "direct perturbative way" is to expand (10.27) in powers of the coupling. At one loop, the matrix element of j_5^λ between the vacuum and a two-photon state is the sum of two **triangle graphs** (Figure 10.10). They are linearly divergent, and that is the whole story.

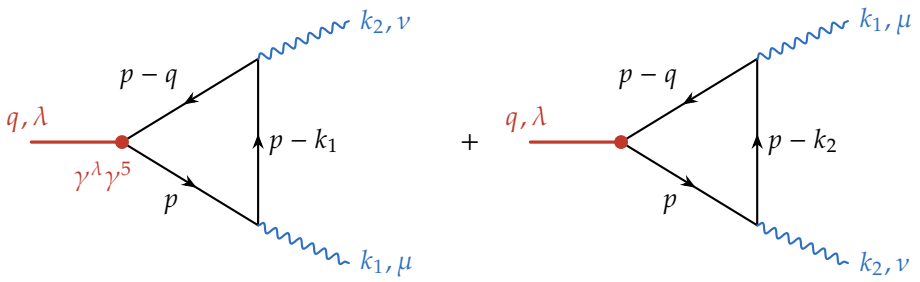

Figure 10.10: The two triangle graphs for $\langle k_1, k_2|j_5^\lambda|0\rangle$. The axial vertex (red) injects momentum $q = k_1 + k_2$; the two photons (blue) leave. The second graph is the first with the photons exchanged. Each graph is linearly divergent: three propagators $\sim 1/p^3$ against d^4p.

The amplitude. Let $|k_1,\epsilon_1;k_2,\epsilon_2\rangle$ be a state of two photons with momenta k_1,k_2 and polarisation vectors ϵ_1,ϵ_2, and write $\langle k_1,\epsilon_1;k_2,\epsilon_2|j_5^\lambda(0)|0\rangle = \epsilon_{1\mu}^*\epsilon_{2\nu}^*\,\mathcal{M}^{\mu\nu\lambda}$. The Feynman rules are as in Example 10.10: the operator $j_5^\lambda=\bar\psi\gamma^\lambda\gamma^5\psi$ contributes the matrix $\gamma^\lambda\gamma^5$ (no coupling constant: it is inserted, not exponentiated), each photon a vertex $-ie\gamma$, each fermion line a propagator $i/\not p$, and the loop a factor -1 and a trace. The fermion loop can run round the triangle in two orientations, which are the two graphs of Figure 10.10. Reading each trace against the fermion arrows,

$$\begin{aligned}\mathcal{M}^{\mu\nu\lambda} &\overset{(1)}{=} (-1)(-ie)^2\,i^3\int\frac{\mathrm{d}^4p}{(2\pi)^4}\Big\{\mathrm{tr}\big[S(p)\gamma^\lambda\gamma^5S(p-q)\gamma^\nu S(p-k_1)\gamma^\mu\big]+(k_1,\mu\leftrightarrow k_2,\nu)\Big\}\\ &\overset{(2)}{=} ie^2\,T^{\mu\nu\lambda}(k_1,k_2),\end{aligned}\tag{10.78}$$

(1) Here $S(p):=1/\not p=\not p/p^2$ (Tool 1(a)), so each propagator is iS. In the first graph the fermion with momentum p enters the μ vertex and leaves with $p-k_1$ (photon k_1 emitted), then leaves the ν vertex with $p-k_1-k_2=p-q$, and the axial vertex injects $q=k_1+k_2$ to bring it back to p.
(2) $(-1)(-e^2)(-i)=-ie^2$; we define T with the opposite sign, below.

where, with the couplings stripped off [QFT notes (22.5.2)],

$$\begin{aligned}T^{\mu\nu\lambda}(k_1,k_2):=-\int\frac{\mathrm{d}^4p}{(2\pi)^4}\Big\{&\mathrm{tr}\big[S(p)\gamma^\lambda\gamma^5S(p-q)\gamma^\nu S(p-k_1)\gamma^\mu\big]\\&+\mathrm{tr}\big[S(p)\gamma^\lambda\gamma^5S(p-q)\gamma^\mu S(p-k_2)\gamma^\nu\big]\Big\}.\end{aligned}\tag{10.79}$$

Since $\langle f|O(x)|0\rangle=e^{i(k_1+k_2)\cdot x}\langle f|O(0)|0\rangle$ (translate with $e^{iP\cdot x}$), a divergence ∂_λ becomes iq_λ. And gauge invariance of the photon couplings means that replacing a polarisation by its momentum, $\epsilon_1\to k_1$, gives zero. So the Ward identities we would like are

$$q_\lambda T^{\mu\nu\lambda}=0\quad\text{(axial)},\qquad k_{1\mu}T^{\mu\nu\lambda}=0=k_{2\nu}T^{\mu\nu\lambda}\quad\text{(vector)}.\tag{10.80}$$

Two algebraic identities. The first converts $\not q\gamma^5$ into a difference of inverse propagators:

$$\begin{aligned}S(p)\,\not q\gamma^5\,S(p-q)&\overset{(1)}{=}S(p)\big[\not p\gamma^5-(\not p-\not q)\gamma^5\big]S(p-q)\overset{(2)}{=}S(p)\big[\not p\gamma^5+\gamma^5(\not p-\not q)\big]S(p-q)\\&\overset{(3)}{=}\gamma^5S(p-q)+S(p)\gamma^5.\end{aligned}\tag{10.81}$$

(1) $\not q=\not p-(\not p-\not q)$.
(2) $\not\phi\gamma^5=-\gamma^5\not\phi$ for any vector v (Tool 1(e)).
(3) $S(p)\not p=\mathbf{1}$ and $(\not p-\not q)S(p-q)=\mathbf{1}$.

The second does the same for a photon vertex. From $S(u)\not u=\mathbf{1}=\not vS(v)$ we get $S(u)(\not v-\not u)S(v)=S(u)-S(v)$ for any u,v, and two instances of it are

$$S(p-k_1)\not k_1\,S(p)=S(p-k_1)-S(p),\qquad S(p-q)\not k_1\,S(p-k_2)=S(p-q)-S(p-k_2),\tag{10.82}$$

with $(u,v)=(p-k_1,p)$ in the first, where $v-u=k_1$, and $(u,v)=(p-q,p-k_2)$ in the second, where $v-u=q-k_2=k_1$.

The naive argument that both Ward identities hold. Contract (10.79) with q_λ and use (10.81) in each graph. Define

$$A_1(p):=\mathrm{tr}\big[\gamma^5S(p-q)\gamma^\nu S(p-k_1)\gamma^\mu\big],\qquad A_2(p):=\mathrm{tr}\big[\gamma^5S(p-q)\gamma^\mu S(p-k_2)\gamma^\nu\big].\tag{10.83}$$

Then

$$
\begin{aligned}
q_\lambda T^{\mu\nu\lambda} &\overset{(1)}{=} -\int \frac{\mathrm{d}^4p}{(2\pi)^4}\Big\{A_1(p) + \mathrm{tr}\big[S(p)\gamma^5\gamma^\nu S(p-k_1)\gamma^\mu\big] + A_2(p) + \mathrm{tr}\big[S(p)\gamma^5\gamma^\mu S(p-k_2)\gamma^\nu\big]\Big\} \\
&\overset{(2)}{=} -\int \frac{\mathrm{d}^4p}{(2\pi)^4}\Big\{A_1(p) - A_2(p+k_2) + A_2(p) - A_1(p+k_1)\Big\} \\
&\overset{(3)}{=} \int \frac{\mathrm{d}^4p}{(2\pi)^4}\big[A_1(p+k_1) - A_1(p)\big] + \int \frac{\mathrm{d}^4p}{(2\pi)^4}\big[A_2(p+k_2) - A_2(p)\big]. \qquad (10.84)
\end{aligned}
$$

(1) (10.81), with the $\gamma^5 S(p-q)$ term giving $A_{1,2}$ directly.
(2) For the fourth term: by cyclicity it is $\mathrm{tr}[\gamma^5\gamma^\mu S(p-k_2)\gamma^\nu S(p)]$, whose numerator is $-4i\epsilon^{\mu\alpha\nu\beta}(p-k_2)_\alpha p_\beta$ by (10.36). Also $A_1(p+k_1) = \mathrm{tr}[\gamma^5 S(p-k_2)\gamma^\nu S(p)\gamma^\mu]$ has numerator $-4i\epsilon^{\alpha\nu\beta\mu}(p-k_2)_\alpha p_\beta$ and the same denominator $(p-k_2)^2p^2$. Since $(\mu\alpha\nu\beta) \to (\alpha\nu\beta\mu)$ is a cyclic shift of four slots (odd), $\epsilon^{\mu\alpha\nu\beta} = -\epsilon^{\alpha\nu\beta\mu}$: the fourth term is $-A_1(p+k_1)$. The second term is $-A_2(p+k_2)$ in the same way.
(3) Regroup.

If we could shift $p \to p - k_1$ in $\int A_1(p+k_1)$, the first bracket would vanish, and likewise the second: $q_\lambda T = 0$. The vector identity works the same way:

$$
\begin{aligned}
k_{1\mu} T^{\mu\nu\lambda} &\overset{(1)}{=} -\int \frac{\mathrm{d}^4p}{(2\pi)^4}\Big\{\mathrm{tr}\big[\gamma^\lambda\gamma^5 S(p-q)\gamma^\nu S(p-k_1)\big] - \mathrm{tr}\big[\gamma^\lambda\gamma^5 S(p-q)\gamma^\nu S(p)\big] \\
&\qquad\qquad + \mathrm{tr}\big[S(p)\gamma^\lambda\gamma^5 S(p-q)\gamma^\nu\big] - \mathrm{tr}\big[S(p)\gamma^\lambda\gamma^5 S(p-k_2)\gamma^\nu\big]\Big\} \\
&\overset{(2)}{=} -\int \frac{\mathrm{d}^4p}{(2\pi)^4}\Big\{\mathrm{tr}\big[\gamma^\lambda\gamma^5 S(p-q)\gamma^\nu S(p-k_1)\big] - \mathrm{tr}\big[S(p)\gamma^\lambda\gamma^5 S(p-k_2)\gamma^\nu\big]\Big\} \\
&\overset{(3)}{=} -\int \frac{\mathrm{d}^4p}{(2\pi)^4}\big[B(p-k_1) - B(p)\big], \qquad B(p) \coloneqq \mathrm{tr}\big[S(p)\gamma^\lambda\gamma^5 S(p-k_2)\gamma^\nu\big]. \qquad (10.85)
\end{aligned}
$$

(1) First graph: cycle $S(p)$ to the end and use the first identity of (10.82). Second graph: the second identity of (10.82).
(2) The second and third terms are equal by cyclicity and cancel.
(3) $B(p-k_1) = \mathrm{tr}[S(p-k_1)\gamma^\lambda\gamma^5 S(p-q)\gamma^\nu]$, which is the first term after cycling $S(p-k_1)$ to the end.

Again a shift $p \to p + k_1$ would give zero. So: *if shifts were allowed, there would be no anomaly* [QFT notes (22.3.20)–(22.3.24)].

Shifting a linearly divergent integral. In one dimension, for an integrand with $f(\pm\infty)$ finite,

$$
\begin{aligned}
\int_{-\infty}^{\infty}\big[f(x+a) - f(x)\big]\mathrm{d}x &\overset{(1)}{=} \int_{-\infty}^{\infty}\big[af'(x) + \tfrac{1}{2}a^2 f''(x) + \cdots\big]\mathrm{d}x \\
&\overset{(2)}{=} a\big[f(+\infty) - f(-\infty)\big]. \qquad (10.86)
\end{aligned}
$$

(1) Taylor expand.
(2) The fundamental theorem of calculus; $f'(\pm\infty) = 0$ kills the higher terms.

If $\int f$ converges, $f(\pm\infty) = 0$ and the shift is harmless; if $\int f$ diverges linearly, $f(\pm\infty)$ can be nonzero and the shift costs a finite *surface term*. In four dimensions the same Taylor expansion plus Gauss's theorem on a large sphere give the formula we need [QFT notes (22.5.9)–(22.5.11)].

Suppose $f(p) \sim |p|^{-3}$ at large p (linear divergence). Then

$$\begin{aligned}\int \mathrm{d}^4p\,\big[f(p+a)-f(p)\big] &\overset{(1)}{=} \int \mathrm{d}^4p\,\big[a^\tau\partial_\tau f(p)+\tfrac{1}{2}a^\tau a^\sigma\partial_\tau\partial_\sigma f(p)+\cdots\big] \overset{(2)}{=} a^\tau\int \mathrm{d}^4p\,\partial_\tau f(p)\\ &\overset{(3)}{=} i\,a_E^\tau\int_{|p_E|<P}\mathrm{d}^4p_E\,\partial_\tau^E f \overset{(4)}{=} i\,a_E^\tau\oint_{|p_E|=P}\mathrm{d}S\,\frac{p_{E\tau}}{P}\,f \overset{(5)}{=} 2i\pi^2\,a_E^\tau\big\langle P^2 p_{E\tau} f\big\rangle_{|p_E|=P}\\ &\overset{(6)}{=} 2i\pi^2\lim_{P\to\infty}\big\langle p^2\,(a\cdot p)\,f(p)\big\rangle_{\text{angles}}. \end{aligned} \tag{10.87}$$

(1) Taylor expansion in a.
(2) The second-order term is a total derivative of $\partial f \sim P^{-4}$, whose surface integral $\sim P^3\cdot P^{-4}\to 0$; the higher ones fall off faster still.
(3) Wick rotate (10.39) ($\mathrm{d}^4p = i\,\mathrm{d}^4p_E$; the scalar $a^\tau\partial_\tau$ becomes $a_E^\tau\partial_\tau^E$), and cut the integral off at $|p_E| = P$, to be sent to infinity.
(4) Gauss's theorem in $\mathbb{R}^4$: the outward unit normal on the sphere is p_E/P.
(5) The 3-sphere of radius P has area $2\pi^2P^3$; $\langle\cdots\rangle$ is the average over the sphere.
(6) Back to Minkowski components: $a_E\cdot p_E = -a\cdot p$ and $P^2 = p_E^2 = -p^2$; the two signs cancel.

We also need the angular average $\langle p_\tau p_\alpha\rangle = \frac{1}{4}\eta_{\tau\alpha}p^2$, which is (10.42) at $d = 4$ (four equivalent directions). Combining, for any integrand whose leading term is $f(p)\to C^\alpha p_\alpha/p^4$,

$$\int\frac{\mathrm{d}^4p}{(2\pi)^4}\big[f(p+a)-f(p)\big] = \frac{2i\pi^2}{16\pi^4}\,a^\tau C^\alpha\left\langle\frac{p_\tau p_\alpha}{p^2}\right\rangle = \frac{i}{32\pi^2}\,a\cdot C. \tag{10.88}$$

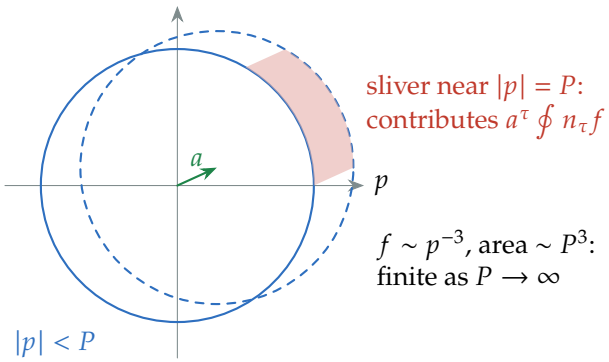

Figure 10.11: Why shifting a linearly divergent integral is not free. The integral over a ball of radius P and over the same ball shifted by a differ by the integral over a thin crescent near the surface. Its thickness is $\sim a$, its area $\sim P^3$, and the integrand $\sim P^{-3}$: the difference stays finite as $P\to\infty$. For a log-divergent or convergent integrand it would vanish.

Step 1: the axial Ward identity with the routing of (10.79). We need the leading large-p behaviour of A_1. Its denominator is $(p-q)^2(p-k_1)^2\to p^4$. Its numerator is

$$\begin{aligned}\mathrm{tr}\big[\gamma^5(\not p-\not q)\gamma^\nu(\not p-\not k_1)\gamma^\mu\big] &\overset{(1)}{=} -4i\,\epsilon^{\alpha\nu\beta\mu}(p-q)_\alpha(p-k_1)_\beta\\ &\overset{(2)}{=} -4i\,\epsilon^{\alpha\nu\beta\mu}\big[p_\alpha p_\beta - q_\alpha p_\beta - p_\alpha k_{1\beta} + q_\alpha k_{1\beta}\big]\\ &\overset{(3)}{=} -4i\,\epsilon^{\alpha\nu\beta\mu}\big[-q_\alpha p_\beta + k_{1\alpha}p_\beta\big] + (\text{const}) \overset{(4)}{=} 4i\,\epsilon^{\alpha\nu\beta\mu}k_{2\alpha}p_\beta + (\text{const}).\end{aligned} \tag{10.89}$$

(1) The γ^5 trace (10.36).

(2) Multiply out.
(3) $\epsilon^{\alpha\nu\beta\mu}p_\alpha p_\beta = 0$ (antisymmetric against symmetric). In the third term relabel $\alpha \leftrightarrow \beta$ and use $\epsilon^{\beta\nu\alpha\mu} = -\epsilon^{\alpha\nu\beta\mu}$. The constant term gives $A_1 \sim p^{-4}$, no surface term.
(4) $q - k_1 = k_2$.

So $A_1 \to C_1^\beta p_\beta/p^4$ with $C_1^\beta = 4i\epsilon^{\alpha\nu\beta\mu}k_{2\alpha}$. Then

$$\int \frac{\mathrm{d}^4p}{(2\pi)^4}\big[A_1(p+k_1) - A_1(p)\big] \overset{(1)}{=} \frac{i}{32\pi^2}\,k_{1\beta}\,4i\,\epsilon^{\alpha\nu\beta\mu}k_{2\alpha} \overset{(2)}{=} -\frac{1}{8\pi^2}\,\epsilon^{\alpha\nu\beta\mu}k_{2\alpha}k_{1\beta} \overset{(3)}{=} \frac{1}{8\pi^2}\,\epsilon^{\mu\nu\rho\sigma}k_{1\rho}k_{2\sigma}. \tag{10.90}$$

(1) The surface rule (10.88) with $a = k_1$.
(2) $\frac{i\cdot 4i}{32\pi^2} = -\frac{1}{8\pi^2}$.
(3) Rename $\alpha \to \sigma$, $\beta \to \rho$: $\epsilon^{\sigma\nu\rho\mu} = -\epsilon^{\mu\nu\rho\sigma}$ (swap the first and last slots).

The second graph is the first with $(k_1, \mu) \leftrightarrow (k_2, \nu)$, so its surface term is $-\frac{1}{8\pi^2}\epsilon^{\alpha\mu\beta\nu}k_{1\alpha}k_{2\beta} = -\frac{1}{8\pi^2}\epsilon^{\rho\mu\sigma\nu}k_{1\rho}k_{2\sigma} = +\frac{1}{8\pi^2}\epsilon^{\mu\nu\rho\sigma}k_{1\rho}k_{2\sigma}$ (three transpositions: $\rho\mu\sigma\nu \to \mu\rho\sigma\nu \to \mu\nu\sigma\rho \to \mu\nu\rho\sigma$). By (10.84),

$$q_\lambda T^{\mu\nu\lambda}\big|_{\text{routing of (10.79)}} = \frac{1}{8\pi^2}\epsilon^{\mu\nu\rho\sigma}k_{1\rho}k_{2\sigma} + \frac{1}{8\pi^2}\epsilon^{\mu\nu\rho\sigma}k_{1\rho}k_{2\sigma} = \frac{1}{4\pi^2}\,\epsilon^{\mu\nu\rho\sigma}k_{1\rho}k_{2\sigma}. \tag{10.91}$$

So with this routing the axial identity already fails. But we have not yet checked the vector identities, and the routing was arbitrary.

Step 2: the routing ambiguity. Since each graph is linearly divergent, the amplitude depends on how we label the loop momentum. Shift $p \to p + a$ in the first graph and, to preserve the symmetry between the photons, $p \to p + a'$ in the second, with a' obtained from a by $k_1 \leftrightarrow k_2$. A shift must be built from the external momenta, so the most general choice is $a = \alpha k_1 + (\alpha - \beta)k_2$ for two numbers α, β [QFT notes (22.5.12)]. Write $T(\beta)$ for the amplitude with the shifted routing. We need the leading large-p integrand of the first graph, including the minus sign in (10.79):

$$-\frac{\mathrm{tr}[\not p\gamma^\lambda\gamma^5\not p\gamma^\nu\not p\gamma^\mu]}{p^6} \overset{(1)}{=} \frac{\mathrm{tr}[\not p\gamma^\lambda\not p\,\gamma^5\gamma^\nu\not p\gamma^\mu]}{p^6} \overset{(2)}{=} \frac{2p^\lambda\,\mathrm{tr}[\not p\gamma^5\gamma^\nu\not p\gamma^\mu] - p^2\,\mathrm{tr}[\gamma^\lambda\gamma^5\gamma^\nu\not p\gamma^\mu]}{p^6}$$
$$\overset{(3)}{=} \frac{0 - p^2\,(-4i)\,\epsilon^{\nu\alpha\mu\lambda}p_\alpha}{p^6} \overset{(4)}{=} -4i\,\frac{\epsilon^{\lambda\nu\alpha\mu}p_\alpha}{p^4}. \tag{10.92}$$

(1) Move γ^5 to the right past $\not p$: one sign.
(2) The sandwich identity (10.34), $\not p\gamma^\lambda\not p = 2p^\lambda\not p - p^2\gamma^\lambda$.
(3) Cycle γ^5 to the front and use (10.36): the first trace is $-4i\epsilon^{\nu\alpha\mu\beta}p_\alpha p_\beta = 0$; the second is $\mathrm{tr}[\gamma^5\gamma^\nu\not p\gamma^\mu\gamma^\lambda] = -4i\epsilon^{\nu\alpha\mu\lambda}p_\alpha$.
(4) $\epsilon^{\nu\alpha\mu\lambda} = -\epsilon^{\lambda\nu\alpha\mu}$ (a cyclic shift of four slots is odd).

The second graph's leading integrand is the same with $\mu \leftrightarrow \nu$, i.e. $+4i\epsilon^{\lambda\nu\alpha\mu}p_\alpha/p^4$. Hence, by the surface rule (10.88),

$$T^{\mu\nu\lambda}(\beta) - T^{\mu\nu\lambda}(0) \overset{(1)}{=} \frac{i}{32\pi^2}(-4i)\,\epsilon^{\lambda\nu\alpha\mu}a_\alpha + \frac{i}{32\pi^2}(+4i)\,\epsilon^{\lambda\nu\alpha\mu}a'_\alpha \overset{(2)}{=} \frac{1}{8\pi^2}\,\epsilon^{\lambda\nu\alpha\mu}(a-a')_\alpha$$
$$\overset{(3)}{=} \frac{\beta}{8\pi^2}\,\epsilon^{\lambda\nu\alpha\mu}(k_1-k_2)_\alpha \overset{(4)}{=} \frac{\beta}{8\pi^2}\,\epsilon^{\mu\nu\lambda\alpha}(k_1-k_2)_\alpha. \tag{10.93}$$

(1) The surface rule for each graph, with $C^\alpha = \mp 4i\epsilon^{\lambda\nu\alpha\mu}$ and shifts a, a'.
(2) $\frac{i(-4i)}{32\pi^2} = \frac{1}{8\pi^2}$.

(3) $a - a' = \alpha k_1 + (\alpha - \beta)k_2 - \alpha k_2 - (\alpha - \beta)k_1 = \beta(k_1 - k_2)$: the α-dependence (a common shift of both graphs by αq) cancels.
(4) $(\lambda\nu\alpha\mu) \to (\mu\nu\alpha\lambda) \to (\mu\nu\lambda\alpha)$: two transpositions.

The triangle is defined only up to this one-parameter family: the momentum routing is not physics, so β must be fixed by a physical requirement.

Step 3: the vector Ward identity at $\beta = 0$. From (10.85) we need the leading behaviour of $B(p) = \mathrm{tr}[S(p)\gamma^\lambda\gamma^5 S(p - k_2)\gamma^\nu]$. Its numerator is

$$\mathrm{tr}\big[\not p\gamma^\lambda\gamma^5(\not p - \not k_2)\gamma^\nu\big] \overset{(1)}{=} \mathrm{tr}\big[\gamma^5(\not p - \not k_2)\gamma^\nu\not p\gamma^\lambda\big] \overset{(2)}{=} -4i\,\epsilon^{\alpha\nu\beta\lambda}(p - k_2)_\alpha p_\beta \overset{(3)}{=} 4i\,\epsilon^{\alpha\nu\beta\lambda}k_{2\alpha}p_\beta,$$

(1) Cyclicity, moving $\not p\gamma^\lambda$ to the end.
(2) (10.36).
(3) $\epsilon^{\alpha\nu\beta\lambda}p_\alpha p_\beta = 0$.

over $p^2(p - k_2)^2 \to p^4$. So $C^\beta = 4i\epsilon^{\alpha\nu\beta\lambda}k_{2\alpha}$ and the shift in (10.85) is $a = -k_1$:

$$k_{1\mu}T^{\mu\nu\lambda}(0) \overset{(1)}{=} -\frac{i}{32\pi^2}(-k_{1\beta})\,4i\,\epsilon^{\alpha\nu\beta\lambda}k_{2\alpha} \overset{(2)}{=} -\frac{1}{8\pi^2}\,\epsilon^{\alpha\nu\beta\lambda}k_{2\alpha}k_{1\beta} \overset{(3)}{=} -\frac{1}{8\pi^2}\,\epsilon^{\nu\lambda\rho\sigma}k_{1\rho}k_{2\sigma}. \tag{10.94}$$

(1) (10.85) (note its overall minus sign) with the surface rule.
(2) $-\frac{i\cdot(-1)\cdot 4i}{32\pi^2} = \frac{4i^2}{32\pi^2} = -\frac{1}{8\pi^2}$.
(3) Rename $\alpha \to \sigma$, $\beta \to \rho$; $(\sigma\nu\rho\lambda) \to (\nu\sigma\rho\lambda) \to (\nu\lambda\rho\sigma)$ is two transpositions, so $\epsilon^{\sigma\nu\rho\lambda} = \epsilon^{\nu\lambda\rho\sigma}$.

The vector identity also fails with the routing of (10.79).

Step 4: the anomaly budget. Contract the routing change (10.93) with q_λ and with $k_{1\mu}$:

$$\begin{aligned}
q_\lambda\big[T(\beta) - T(0)\big]^{\mu\nu\lambda} &\overset{(1)}{=} \frac{\beta}{8\pi^2}\,\epsilon^{\mu\nu\lambda\alpha}(k_1 + k_2)_\lambda(k_1 - k_2)_\alpha \\
&\overset{(2)}{=} \frac{\beta}{8\pi^2}\big(-\epsilon^{\mu\nu\lambda\alpha}k_{1\lambda}k_{2\alpha} + \epsilon^{\mu\nu\lambda\alpha}k_{2\lambda}k_{1\alpha}\big) \overset{(3)}{=} -\frac{\beta}{4\pi^2}\,\epsilon^{\mu\nu\rho\sigma}k_{1\rho}k_{2\sigma}, \\
k_{1\mu}\big[T(\beta) - T(0)\big]^{\mu\nu\lambda} &\overset{(4)}{=} \frac{\beta}{8\pi^2}\,\epsilon^{\mu\nu\lambda\alpha}k_{1\mu}(k_1 - k_2)_\alpha \\
&\overset{(5)}{=} -\frac{\beta}{8\pi^2}\,\epsilon^{\mu\nu\lambda\alpha}k_{1\mu}k_{2\alpha} \overset{(6)}{=} -\frac{\beta}{8\pi^2}\,\epsilon^{\nu\lambda\rho\sigma}k_{1\rho}k_{2\sigma}.
\end{aligned} \tag{10.95}$$

(1) $q = k_1 + k_2$.
(2) Multiply out; ϵkk with the same k twice vanishes.
(3) In the second term relabel $\lambda \leftrightarrow \alpha$ and use antisymmetry; it equals the first. Then rename $\lambda, \alpha \to \rho, \sigma$.
(4) $k_{1\mu}$ times (10.93).
(5) $\epsilon^{\mu\nu\lambda\alpha}k_{1\mu}k_{1\alpha} = 0$.
(6) Rename $\mu \to \rho$, $\alpha \to \sigma$: $\epsilon^{\rho\nu\lambda\sigma} = \epsilon^{\nu\lambda\rho\sigma}$ (a cyclic permutation of the first three slots, which is even).

Adding these to (10.91) and (10.94):

$$\begin{aligned}
q_\lambda T^{\mu\nu\lambda}(\beta) &= \frac{1 - \beta}{4\pi^2}\,\epsilon^{\mu\nu\rho\sigma}k_{1\rho}k_{2\sigma}, \\
k_{1\mu}T^{\mu\nu\lambda}(\beta) &= -\frac{1 + \beta}{8\pi^2}\,\epsilon^{\nu\lambda\rho\sigma}k_{1\rho}k_{2\sigma},
\end{aligned} \tag{10.96}$$

and $k_{2\nu}T^{\mu\nu\lambda}(\beta)$ follows from the second line by the photon exchange symmetry. The QFT notes obtain the same structure, $(1-\beta)$ and $(1+\beta)$, [QFT notes (22.5.21), (22.5.26)]. The axial identity needs $\beta=+1$; the vector identities need $\beta=-1$. *No routing satisfies both.*

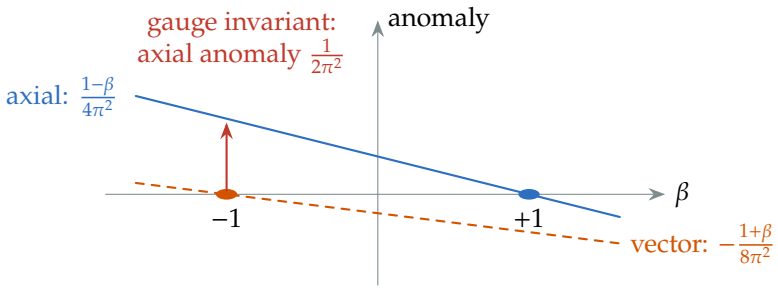

Figure 10.12: The anomaly budget of the triangle graph (in units of ϵkk). Changing the momentum routing β moves the anomaly between the axial current (solid) and the vector current (dashed). The two lines never vanish at the same β. Gauge invariance of electromagnetism forces $\beta=-1$ (orange dot), and the whole anomaly lands in the axial current.

At $\beta=-1$ the vector currents are conserved and

$$q_\lambda T^{\mu\nu\lambda}=\frac{1-(-1)}{4\pi^2}\,\epsilon^{\mu\nu\rho\sigma}k_{1\rho}k_{2\sigma}=\frac{1}{2\pi^2}\,\epsilon^{\mu\nu\rho\sigma}k_{1\rho}k_{2\sigma}. \tag{10.97}$$

Step 5: from the amplitude to the operator equation. Abbreviate $X\coloneqq\epsilon^{\mu\nu\rho\sigma}\epsilon^*_{1\mu}\epsilon^*_{2\nu}k_{1\rho}k_{2\sigma}$. The left side of the anomaly equation, between the two-photon state and the vacuum, is

$$\langle k_1,k_2|\partial_\lambda j^\lambda_5(0)|0\rangle\overset{(1)}{=}iq_\lambda\,\epsilon^*_{1\mu}\epsilon^*_{2\nu}\mathcal{M}^{\mu\nu\lambda}\overset{(2)}{=}i\cdot ie^2\,\epsilon^*_{1\mu}\epsilon^*_{2\nu}\,q_\lambda T^{\mu\nu\lambda}\overset{(3)}{=}-\frac{e^2}{2\pi^2}\,X. \tag{10.98}$$

(1) Translation invariance: $\partial_\lambda\to iq_\lambda$ (see below (10.79)).
(2) (10.78).
(3) $i^2=-1$ and (10.97).

For the right side we need the two-photon matrix element of ϵFF at lowest order. A free photon field obeys $\langle k,\epsilon|A_\beta(x)|0\rangle=\epsilon^*_\beta e^{ik\cdot x}$, so $\langle k,\epsilon|F_{\alpha\beta}(x)|0\rangle=i(k_\alpha\epsilon^*_\beta-k_\beta\epsilon^*_\alpha)e^{ik\cdot x}$. Then

$$\begin{aligned}\langle k_1,k_2|\epsilon^{\alpha\beta\gamma\delta}F_{\alpha\beta}F_{\gamma\delta}(0)|0\rangle&\overset{(1)}{=}2\,\epsilon^{\alpha\beta\gamma\delta}\,\langle k_1|F_{\alpha\beta}|0\rangle\langle k_2|F_{\gamma\delta}|0\rangle\overset{(2)}{=}2\,(2i)(2i)\,\epsilon^{\alpha\beta\gamma\delta}k_{1\alpha}\epsilon^*_{1\beta}k_{2\gamma}\epsilon^*_{2\delta}\\&\overset{(3)}{=}-8\,\epsilon^{\rho\mu\sigma\nu}k_{1\rho}\epsilon^*_{1\mu}k_{2\sigma}\epsilon^*_{2\nu}\overset{(4)}{=}+8X.\end{aligned} \tag{10.99}$$

(1) Either photon can be absorbed by either F (Wick's theorem for the free field), and the two assignments are equal because $\epsilon^{\alpha\beta\gamma\delta}=\epsilon^{\gamma\delta\alpha\beta}$.
(2) $\epsilon^{\alpha\beta\gamma\delta}(k_\alpha\epsilon^*_\beta-k_\beta\epsilon^*_\alpha)=2\epsilon^{\alpha\beta\gamma\delta}k_\alpha\epsilon^*_\beta$ by antisymmetry, for each factor.
(3) Rename $\alpha\beta\gamma\delta\to\rho\mu\sigma\nu$.
(4) $\epsilon^{\rho\mu\sigma\nu}=-\epsilon^{\mu\nu\rho\sigma}$ (three transpositions, as above).

Comparing, $-\frac{e^2}{2\pi^2}X=-\frac{e^2}{16\pi^2}\cdot 8X$, so the triangle says

$$\partial_\lambda j^\lambda_5=-\frac{e^2}{16\pi^2}\,\epsilon^{\alpha\beta\gamma\delta}F_{\alpha\beta}F_{\gamma\delta}\qquad\text{[QFT notes (22.3.46), (22.5.28)]}, \tag{10.100}$$

exactly the point-splitting result (10.75), sign and all. Two completely different calculations, one in position space with a Wilson line, one in momentum space with a surface term, agree. A fermion mass adds the classical term $2im\bar\psi\gamma^5\psi$ to the right side and changes nothing else.

Worked example 10.11: The same anomaly in dimensional regularisation

Dimensional regularisation fixes the routing problem automatically, because shifts are legal in d dimensions (Tool 5). The calculation (10.85) then gives $k_{1\mu}T^{\mu\nu\lambda} = 0$ with no surface term: the vector current is conserved. The price is paid by γ^5, which is intrinsically four-dimensional.

The 't Hooft–Veltman γ^5 [QFT notes (22.3.25)]. Keep $\gamma^5 := i\gamma^0\gamma^1\gamma^2\gamma^3$ in d dimensions. It anticommutes with $\gamma^0, \dots, \gamma^3$ as before, but *commutes* with the extra matrices $\gamma^4, \dots, \gamma^{d-1}$, since moving one of those through four anticommuting matrices gives $(-1)^4 = +1$. Split every loop vector into its four-dimensional part and the rest, $p = \bar{p} + p_\perp$; the external momenta k_1, k_2, q and indices μ, ν, λ are four-dimensional. Then $\not{p}\gamma^5 = -\gamma^5\not{\bar{p}} + \gamma^5\not{p}_\perp$, i.e.

$$\not{p}\,\gamma^5 = -\gamma^5\not{p} + 2\gamma^5\not{p}_\perp, \tag{10.101}$$

and the γ^5 traces (10.36) still hold with only the four-dimensional components contributing (an extra-dimensional γ^a must occur an even number of times for a nonzero trace).

Step (a): the modified identity. Redo (10.81):

$$\begin{aligned} S(p)\not{q}\gamma^5 S(p-q) &\overset{(1)}{=} S(p)\big[\not{p}\gamma^5 - (\not{p}-\not{q})\gamma^5\big]S(p-q) \overset{(2)}{=} S(p)\big[\not{p}\gamma^5 + \gamma^5(\not{p}-\not{q}) - 2\gamma^5\not{p}_\perp\big]S(p-q) \\ &\overset{(3)}{=} \gamma^5 S(p-q) + S(p)\gamma^5 - 2S(p)\gamma^5\not{p}_\perp S(p-q). \end{aligned} \tag{10.102}$$

(1) $\not{q} = \not{p} - (\not{p} - \not{q})$.
(2) (10.101) for the vector $p - q$, whose extra-dimensional part is $p_\perp$ since $q_\perp = 0$.
(3) $S(p)\not{p} = \mathbf{1} = (\not{p} - \not{q})S(p - q)$.

The first two terms give (10.84), whose derivation used only cyclicity and (10.36); now the shifts are legal, so they vanish. What remains, with the -1 of (10.79), is

$$\begin{aligned} q_\lambda T^{\mu\nu\lambda} &= 2\int \frac{\mathrm{d}^d p}{(2\pi)^d}\,\frac{N_1}{p^2(p-q)^2(p-k_1)^2} + (k_1, \mu \leftrightarrow k_2, \nu), \\ N_1 &:= \operatorname{tr}\big[\not{p}\gamma^5\not{p}_\perp(\not{p}-\not{q})\gamma^\nu(\not{p}-\not{k}_1)\gamma^\mu\big]. \end{aligned} \tag{10.103}$$

Step (b): the numerator. Only terms with an even number of $\perp$ vectors survive, and at most two, since the γ^5 trace needs four four-dimensional gamma matrices and only γ^μ, γ^ν are guaranteed. Using $\gamma^5\not{p}_\perp = \not{p}_\perp\gamma^5$ and $\not{p}\not{p}_\perp = \not{\bar{p}}\not{p}_\perp + p_\perp^2$ (by (10.30)),

$$\begin{aligned} N_1 &\overset{(1)}{=} p_\perp^2\ \operatorname{tr}\big[\gamma^5(\not{\bar{p}}-\not{q})\gamma^\nu(\not{\bar{p}}-\not{k}_1)\gamma^\mu\big] + \operatorname{tr}\big[\not{\bar{p}}\not{p}_\perp\gamma^5(\not{p}-\not{q})\gamma^\nu(\not{p}-\not{k}_1)\gamma^\mu\big] \\ &\overset{(2)}{=} p_\perp^2\ \operatorname{tr}\big[\gamma^5(\not{\bar{p}}-\not{q})\gamma^\nu(\not{\bar{p}}-\not{k}_1)\gamma^\mu\big] + \operatorname{tr}\big[\not{\bar{p}}\not{p}_\perp\gamma^5\not{p}_\perp\gamma^\nu(\not{\bar{p}}-\not{k}_1)\gamma^\mu\big] \\ &\qquad + \operatorname{tr}\big[\not{\bar{p}}\not{p}_\perp\gamma^5(\not{\bar{p}}-\not{q})\gamma^\nu\not{p}_\perp\gamma^\mu\big] + (\text{odd in } p_\perp) \\ &\overset{(3)}{=} p_\perp^2\Big\{\operatorname{tr}\big[\gamma^5(\not{\bar{p}}-\not{q})\gamma^\nu(\not{\bar{p}}-\not{k}_1)\gamma^\mu\big] + \operatorname{tr}\big[\not{\bar{p}}\gamma^5\gamma^\nu(\not{\bar{p}}-\not{k}_1)\gamma^\mu\big] + \operatorname{tr}\big[\not{\bar{p}}\gamma^5(\not{\bar{p}}-\not{q})\gamma^\nu\gamma^\mu\big]\Big\} + \cdots \\ &\overset{(4)}{=} -4i\,p_\perp^2\Big\{\epsilon\big(\bar{p}-q, \nu, \bar{p}-k_1, \mu\big) + \epsilon\big(\nu, \bar{p}-k_1, \mu, \bar{p}\big) + \epsilon\big(\bar{p}-q, \nu, \mu, \bar{p}\big)\Big\} + \cdots. \end{aligned} \tag{10.104}$$

(1) $\not{p}\gamma^5\not{p}_\perp = \not{p}\not{p}_\perp\gamma^5 = (\not{\bar{p}}\not{p}_\perp + p_\perp^2)\gamma^5$. In the $p_\perp^2$ term a further $\perp$ part would make four, so only $\bar{p}$ remains there.
(2) In the second trace the lone $\not{p}_\perp$ needs a partner: take the $\perp$ part of either $\not{p} - \not{q}$ or $\not{p} - \not{k}_1$ (both equal $\not{p}_\perp$). Taking both gives three: odd.
(3) Second trace: $\not{p}_\perp\gamma^5\not{p}_\perp = \not{p}_\perp\not{p}_\perp\gamma^5 = p_\perp^2\gamma^5$. Third trace: move the second $\not{p}_\perp$ left past γ^ν (-1), $\not{\bar{p}} - \not{q}$ (-1) and γ^5 ($+1$), then $\not{p}_\perp\not{p}_\perp = p_\perp^2$.

(4) Cycle γ^5 to the front of each trace and use (10.36); $\epsilon(a,b,c,d)$ denotes $\epsilon^{\alpha\beta\gamma\delta}$ contracted with the four slots.

Step (c): Feynman parameters and the shift. With (10.38), $A=(p-k_1)^2$, $B=(p-q)^2$, $C=p^2$:

$$xA+yB+zC \overset{(1)}{=} p^2-2p\cdot(xk_1+yq)+xk_1^2+yq^2 \overset{(2)}{=} (p-c)^2-\Delta,$$
$$c:=xk_1+yq, \qquad \Delta:=c^2-xk_1^2-yq^2.$$

(1) Expand, using $x+y+z=1$ for the p^2 terms.
(2) Complete the square.

Shift $p=\ell+c$ (legal). Since c is four-dimensional, $p_\perp=\ell_\perp$ and $\bar p=\bar\ell+c$. In the braces of (10.104), terms linear in $\bar\ell$ vanish by symmetric integration, and terms quadratic in $\bar\ell$ give $\epsilon(\bar\ell,\cdot,\bar\ell,\cdot)\to\eta\cdot\epsilon=0$. So we may replace $\bar p\to c$. Write $c=a\,k_1+b\,k_2$ with $a=x+y$, $b=y$, and note that for $u=u_1k_1+u_2k_2$, $v=v_1k_1+v_2k_2$, $\epsilon(u,\nu,v,\mu)=(u_1v_2-u_2v_1)\,E_0$ with $E_0:=\epsilon(k_1,\nu,k_2,\mu)$. Then

$$\begin{aligned}
\epsilon(c-q,\nu,c-k_1,\mu) &\overset{(1)}{=} \big[(a-1)b-(b-1)(a-1)\big]E_0=(a-1)E_0,\\
\epsilon(\nu,c-k_1,\mu,c) &\overset{(2)}{=} \epsilon(c-k_1,\nu,c,\mu)\\
&= \big[(a-1)b-ba\big]E_0=-b\,E_0,\\
\epsilon(c-q,\nu,\mu,c) &\overset{(3)}{=} -\epsilon(c-q,\nu,c,\mu)\\
&= -\big[(a-1)b-(b-1)a\big]E_0=-(a-b)E_0.
\end{aligned}$$

(1) $c-q=(a-1)k_1+(b-1)k_2$ and $c-k_1=(a-1)k_1+bk_2$.
(2) Swapping slots $1\leftrightarrow2$ and $3\leftrightarrow4$ is even; $c-k_1=(a-1,b)$, $c=(a,b)$.
(3) Swap the last two slots (odd).

The sum is $\big[(a-1)-b-(a-b)\big]E_0=-E_0$: all dependence on the Feynman parameters has cancelled. So after the shift the numerator is $-4i\,\ell_\perp^2\cdot(-E_0)=4i\,\ell_\perp^2E_0$.

Step (d): the integral.

$$\begin{aligned}
I:=\int\frac{\mathrm{d}^d\ell}{(2\pi)^d}\frac{\ell_\perp^2}{(\ell^2-\Delta)^3} &\overset{(1)}{=} \frac{d-4}{d}\int\frac{\mathrm{d}^d\ell}{(2\pi)^d}\frac{\ell^2}{(\ell^2-\Delta)^3}\\
&\overset{(2)}{=} \frac{d-4}{d}\cdot\frac{(-1)^2\,i}{(4\pi)^{d/2}}\cdot\frac{d}{2}\cdot\frac{\Gamma(2-\frac{d}{2})}{\Gamma(3)}\,\Delta^{d/2-2} \overset{(3)}{=} \frac{i\,(d-4)\,\Gamma(2-\frac{d}{2})}{4\,(4\pi)^{d/2}}\,\Delta^{d/2-2}\\
&\overset{(4)}{=} -\frac{i\,\Gamma(3-\frac{d}{2})}{2\,(4\pi)^{d/2}}\,\Delta^{d/2-2} \overset{(5)}{=} -\frac{i}{2(4\pi)^2}=-\frac{i}{32\pi^2}\quad(d\to4).
\end{aligned}$$

(1) Symmetric integration (10.42): $\ell_\perp^2=\sum_{a\ge4}\eta_{aa}\ell^a\ell^a\to\frac{\ell^2}{d}\sum_{a\ge4}\eta_{aa}\eta^{aa}=\frac{d-4}{d}\ell^2$.
(2) Master integral (10.41) with $n=3$.
(3) $\Gamma(3)=2$; collect.
(4) $(d-4)\Gamma(2-\frac{d}{2})=-2(2-\frac{d}{2})\Gamma(2-\frac{d}{2})=-2\Gamma(3-\frac{d}{2})$ by (10.43): the vanishing factor eats the pole.
(5) At $d=4$: $\Gamma(1)=1$ and $\Delta^0=1$, so the answer does not depend on Δ.

Step (e): assemble. For the first graph,

$$\begin{aligned}
2\int\frac{\mathrm{d}^dp}{(2\pi)^d}\frac{N_1}{p^2(p-q)^2(p-k_1)^2} &\overset{(1)}{=} 2\cdot2\int\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z\,\delta(1-x-y-z)\;4iE_0\,I\\
&\overset{(2)}{=} 2\cdot2\cdot\tfrac12\cdot4iE_0\cdot\Big(-\frac{i}{32\pi^2}\Big) \overset{(3)}{=} \frac{E_0}{4\pi^2} \overset{(4)}{=} \frac{1}{4\pi^2}\,\epsilon^{\mu\nu\rho\sigma}k_{1\rho}k_{2\sigma}.
\end{aligned}$$

(1) (10.38) and Steps (b)–(c).
(2) I is independent of the Feynman parameters, whose integral is $\frac{1}{2}$.
(3) $8i \cdot (-i)/32\pi^2 = 8/32\pi^2$.
(4) $E_0 = \epsilon^{\rho\nu\sigma\mu} k_{1\rho} k_{2\sigma}$ and $(\rho\nu\sigma\mu) \to (\mu\nu\sigma\rho) \to (\mu\nu\rho\sigma)$ is two transpositions.

The second graph gives the same (exchange $(k_1, \mu) \leftrightarrow (k_2, \nu)$: two sign flips of ϵ). Hence

$$q_\lambda T^{\mu\nu\lambda}\big|_{\text{dim reg}} = \frac{1}{2\pi^2}\, \epsilon^{\mu\nu\rho\sigma} k_{1\rho} k_{2\sigma},$$

exactly (10.97): dimensional regularisation automatically chooses the gauge-invariant routing $\beta = -1$ and puts the whole anomaly into the axial current [QFT notes (22.3.41)–(22.3.44)]. The pattern is the same as in the a coefficient of Section 10.3.3: a regulator that respects gauge invariance leaves behind "$0 \times \infty$ = finite", here $(d-4) \times \Gamma(2 - \frac{d}{2}) = -2$.

Physical picture: Why the anomaly is one-loop exact

The anomaly came from a surface term, i.e. from the fact that the one-loop triangle is only linearly divergent and depends on the routing. Graphs with more loops (photon lines dressing the triangle) have more propagators, converge better, and allow free shifts; they cannot contribute. This heuristic is the **Adler–Bardeen theorem**: the coefficient $e^2/16\pi^2$ receives no higher-order corrections [QFT notes §22.8]. It is the perturbative shadow of the fact, to be established in Section 10.4.5, that the integrated anomaly is an integer.

Reading Nash (pp. 272–273, (10.9)–(10.11))

Nash's "routine calculation" is our (10.23)–(10.26). His ∇_μ^{ab} is the adjoint covariant derivative D_μ, his $j_5^{b\mu}$ is our chiral current $J^{b\mu}$ of (10.24), and his (10.10) is our (10.27). The "celebrated divergent triangle graph" is Figure 10.10; "divergent" is the key word, since the anomaly is a surface term of a linearly divergent integral. Nash then cites Fujikawa [1] for the statement that the measure $\mathcal{D}\psi\mathcal{D}\bar{\psi}$ is not gauge invariant; we do that computation next.

Recap

- Along a gauge orbit, $\frac{\mathrm{d}}{\mathrm{d}t} \ln Z_F = \langle \int f^a D_\mu J^{a\mu} \rangle$: the determinant is gauge invariant iff the gauge current is conserved in the quantum theory.
- QED$_2$: $\Pi^{\mu\nu} = \mathsf{a}\eta^{\mu\nu} - \mathsf{b} q^\mu q^\nu/q^2$ with $\mathsf{b} = e^2/\pi$ finite. Vector conservation needs $\mathsf{a} = \mathsf{b}$, axial needs $\mathsf{a} = 0$. Gauge invariance wins: $\partial_\mu j_5^\mu = \frac{e}{2\pi}\epsilon^{\mu\nu}F_{\mu\nu}$, and $m_\gamma^2 = e^2/\pi$.
- Point splitting: $\varepsilon F \times \frac{1}{\varepsilon}$ is finite. Spectral flow on a circle: one flux quantum converts one right-mover into one left-mover, $\Delta Q_5 = -2$.
- QED$_4$: the triangle is linearly divergent; routing ambiguity $\frac{\beta}{8\pi^2}\epsilon(k_1 - k_2)$; axial WI needs $\beta = 1$, vector WI $\beta = -1$. With $\beta = -1$: $\partial_\mu j_5^\mu = -\frac{e^2}{16\pi^2}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$ (Minkowski).
- Every method finds the anomaly as "$0 \times \infty$": a vanishing factor $(\varepsilon, d-4, 2-d)$ times a divergence, left behind by a gauge-invariant regulator.

10.4 Anomalies and Yang–Mills theories III: the measure, the heat kernel and the index

In Section 10.3 we found the anomaly three times, and each time it came out of a regularised product of fields at one point. Nash's sentence on p. 273 points to a fourth derivation, due to Fujikawa, which generalises to every even dimension and connects directly to topology: "the Fermionic 'measure' $\mathcal{D}\psi\mathcal{D}\bar\psi$ is not gauge invariant". The question this section answers is: *if the action is invariant and the anomaly is real, which part of the path integral changes, and by how much?* The answer is the measure. Its change is a Jacobian determinant, which we shall compute exactly. Integrated over spacetime, the same Jacobian turns out to be the index of the Dirac operator.

We work in Euclidean signature on a compact M of dimension $n = 2m$, with the conventions of Section 10.1.1: Hermitian γ_μ, $\gamma_5 = (-i)^m\gamma_1\cdots\gamma_{2m}$, anti-Hermitian A, $D_\mu = \partial_\mu + A_\mu$, and $\not{D}_A = \gamma^\mu D_\mu$ anti-self-adjoint. The orientation is fixed by $\epsilon_{12\cdots n} = +1$. For the local computations we may take M flat (a large torus): the answer is local, and curvature only adds terms that we treat in Section 10.7.

10.4.1 Fujikawa's idea: the Jacobian of a chiral rotation

The logic in one paragraph. Take a Dirac fermion in a fixed background A,

$$Z_F[A] = \int \mathcal{D}\psi\,\mathcal{D}\bar\psi\; e^{-S_F[\psi,\bar\psi]}, \qquad S_F = \int_M \mathrm{d}^n x\,\bar\psi\,\not{D}_A\psi. \tag{10.105}$$

The integration variables are dummies, so renaming them cannot change Z_F. Rename them by an infinitesimal *local* chiral rotation,

$$\psi' = (1 + i\alpha(x)\gamma_5)\psi, \qquad \bar\psi' = \bar\psi\,(1 + i\alpha(x)\gamma_5), \tag{10.106}$$

with $\alpha(x)$ a small real function. Two things happen: the action changes by the Noether term (10.7), and the measure changes by a Jacobian J. Since the total change is zero, the expectation value of the Noether term equals minus the log of the Jacobian. If J were 1 we would get $\langle\partial_\mu j^\mu_5\rangle = 0$. Fujikawa's discovery is that $J \neq 1$.

Step 1: a basis for the fields. To speak of a Jacobian we need coordinates on the space of fields. The operator $i\not{D}_A$ is self-adjoint (Section 10.1.1), so it has real eigenvalues λ_n and an orthonormal basis of eigenspinors,

$$i\not{D}_A\,\varphi_n = \lambda_n\varphi_n, \qquad \int_M \mathrm{d}^n x\,\varphi_n^\dagger(x)\varphi_k(x) = \delta_{nk}, \qquad \sum_n \varphi_n(x)\varphi_n^\dagger(y) = \delta^{(n)}(x-y)\,\mathbf{1}. \tag{10.107}$$

Here $\varphi_n(x)$ is a column vector (spin $\otimes$ colour) and $\mathbf{1}$ is the identity on spin $\otimes$ colour; the last relation is completeness. Expand

$$\psi(x) = \sum_n a_n\varphi_n(x), \qquad \bar\psi(x) = \sum_n b_n\varphi_n^\dagger(x), \tag{10.108}$$

with Grassmann coefficients a_n, b_n (independent, since in Euclidean signature $\bar\psi$ is not the conjugate of ψ), and *define* the measure as $\mathcal{D}\psi\mathcal{D}\bar\psi := \prod_n \mathrm{d}a_n\,\mathrm{d}b_n$ [QFT notes (22.3.54)]. In this basis the action is diagonal: $S_F = \sum_n b_n(-i\lambda_n)a_n$, because $\not{D}_A\varphi_n = -i\lambda_n\varphi_n$.

Step 2: how Grassmann measures change. This is the one place where fermions differ from bosons, and it is the source of the anomaly's sign.

Working definition 10.6 (change of Grassmann variables)

If $\theta_i' = \sum_j M_{ij}\theta_j$ for Grassmann variables $\theta_1, \dots, \theta_N$ [anticommuting variables, here the coefficients a_n, b_n of ψ and $\bar\psi$ in the eigenbasis], then

$$\prod_i \mathrm{d}\theta_i' = (\det M)^{-1} \prod_i \mathrm{d}\theta_i.$$

The Jacobian [the factor multiplying the measure $\prod_i \mathrm{d}\theta_i$] is the *inverse* of the bosonic one [for ordinary commuting variables $x' = Mx$, $\prod_i \mathrm{d}x_i' = \det M \prod_i \mathrm{d}x_i$].

Why: for one variable, $\theta' = c\,\theta$, and both $\int \mathrm{d}\theta'\,\theta' = 1$ and $\int \mathrm{d}\theta\,\theta = 1$ must hold. So

$$1 = \int \mathrm{d}\theta'\,\theta' \overset{(1)}{=} \int \mathrm{d}\theta'\,c\,\theta \overset{(2)}{=} c \cdot \big(\text{factor in } \mathrm{d}\theta' = \kappa\,\mathrm{d}\theta\big) \int \mathrm{d}\theta\,\theta = c\,\kappa,$$

(1) Substitute $\theta' = c\theta$.
(2) Write $\mathrm{d}\theta' = \kappa\,\mathrm{d}\theta$ and pull out the constants.

hence $\kappa = 1/c$. For N variables, antisymmetry gives $\theta_1'\theta_2'\cdots\theta_N' = (\det M)\,\theta_1\theta_2\cdots\theta_N$ (the same bookkeeping as in Example 10.6: only terms with distinct θ's survive, each with the sign of its permutation), and the same argument gives $(\det M)^{-1}$.

Step 3: the transformed coefficients. Insert (10.108) into (10.106) and project onto φ_n with the orthonormality (10.107):

$$\begin{aligned} a_n' &\overset{(1)}{=} \int \mathrm{d}^n x\,\varphi_n^\dagger\,\psi' \overset{(2)}{=} \sum_k \int \mathrm{d}^n x\,\varphi_n^\dagger(1 + i\alpha\gamma_5)\varphi_k\; a_k \overset{(3)}{=} \sum_k \big(\delta_{nk} + C_{nk}\big)a_k, \\ b_n' &\overset{(4)}{=} \int \mathrm{d}^n x\,\bar\psi'\varphi_n \overset{(5)}{=} \sum_k b_k \int \mathrm{d}^n x\,\varphi_k^\dagger(1 + i\alpha\gamma_5)\varphi_n = \sum_k b_k\big(\delta_{kn} + C_{kn}\big), \end{aligned} \tag{10.109}$$

with

$$C_{nk} := i\int_M \mathrm{d}^n x\,\alpha(x)\,\varphi_n^\dagger(x)\gamma_5\varphi_k(x). \tag{10.110}$$

(1) The coefficient of φ_n in any spinor χ is $\int \varphi_n^\dagger\chi$, by orthonormality.
(2) Insert $\psi' = (1 + i\alpha\gamma_5)\sum_k a_k\varphi_k$; the Grassmann a_k are constants and come out.
(3) $\int \varphi_n^\dagger\varphi_k = \delta_{nk}$; the rest is the definition of C_{nk}.
(4) The coefficient of $\varphi_n^\dagger$ in a row spinor $\bar\chi$ is $\int \bar\chi\varphi_n$.
(5) Insert $\bar\psi' = \sum_k b_k\varphi_k^\dagger(1 + i\alpha\gamma_5)$.

So $a' = (1 + C)a$ and $b' = (1 + C)^{\mathsf T}b$. By Definition 10.6, and $\det(1 + C)^{\mathsf T} = \det(1 + C)$,

$$\mathcal{D}\psi'\mathcal{D}\bar\psi' = \det(1 + C)^{-2}\,\mathcal{D}\psi\mathcal{D}\bar\psi. \tag{10.111}$$

Step 4: the determinant to first order. For an infinitesimal matrix C,

$$\begin{aligned} \det(1 + C)^{-2} &\overset{(1)}{=} \exp\big[-2\,\mathrm{Tr}\ln(1 + C)\big] \overset{(2)}{=} \exp\big[-2\,\mathrm{Tr}\,C + O(\alpha^2)\big] \\ &\overset{(3)}{=} \exp\Big[-2i\int_M \mathrm{d}^n x\,\alpha(x)\sum_n \varphi_n^\dagger(x)\gamma_5\varphi_n(x)\Big]. \end{aligned} \tag{10.112}$$

(1) $\det X = \exp\mathrm{Tr}\ln X$: true for diagonalisable X (product of eigenvalues = exponential of the sum of their logs), and by continuity for all X near 1.

(2) $\ln(1+C) = C - \frac{1}{2}C^2 + \cdots$, and C is first order in α.
(3) $\operatorname{Tr} C = \sum_n C_{nn}$ with (10.110).

The factor 2 counts ψ and $\bar\psi$, which rotate by the same $e^{i\alpha\gamma_5}$. For a *vector* rotation $\psi' = (1+i\alpha)\psi$, $\bar\psi' = \bar\psi(1-i\alpha)$ the two Jacobians are $\det(1+C_V)^{-1}$ and $\det(1-C_V)^{-1}$ with C_V the same matrix without γ_5, and to first order they cancel: *the measure is invariant under vector rotations*, so the vector current is conserved.

Step 5: the anomalous Ward identity. Define the **anomaly density**

$$\mathscr{A}(x) := \sum_n \varphi_n^\dagger(x)\gamma_5\varphi_n(x) \qquad \text{(to be regularised).} \tag{10.113}$$

Then

$$\begin{aligned} Z_F &\overset{(1)}{=} \int \mathcal{D}\psi'\mathcal{D}\bar\psi'\; e^{-S_F[\psi',\bar\psi']} \\ &\overset{(2)}{=} \int \mathcal{D}\psi\mathcal{D}\bar\psi\; e^{-2i\int\alpha\mathscr{A}}\; e^{-S_F[\psi,\bar\psi]+i\int\alpha\,\partial_\mu j_5^\mu} \\ &\overset{(3)}{=} Z_F + \int \mathcal{D}\psi\mathcal{D}\bar\psi\; e^{-S_F}\Big(-2i\int\alpha\mathscr{A} + i\int\alpha\,\partial_\mu j_5^\mu\Big) + O(\alpha^2). \end{aligned} \tag{10.114}$$

(1) Rename the dummy variables $\psi \to \psi'$, $\bar\psi \to \bar\psi'$.
(2) Express $\psi', \bar\psi'$ through $\psi, \bar\psi$: the measure gives (10.112), and the action gives $S_F[\psi'] = S_F[\psi] + \delta S_F$ with $\delta S_F = -i\int\alpha\,\partial_\mu j_5^\mu$ from (10.7) (the background A was already included there).
(3) Expand both exponentials to first order in α.

The first-order term must vanish for every $\alpha(x)$. Dividing by Z_F,

$$\boxed{\langle \partial_\mu j_5^\mu(x)\rangle_A = 2\,\mathscr{A}(x)} \tag{10.115}$$

The classical conservation law has become an equation whose right side is the Jacobian of the measure. Everything now depends on the value of $\mathscr{A}(x)$.

Watch out: $0\times\infty$ once more

Naively $\mathscr{A}(x) = \sum_n \varphi_n^\dagger\gamma_5\varphi_n = \operatorname{tr}\big[\gamma_5\sum_n \varphi_n(x)\varphi_n^\dagger(x)\big] = \operatorname{tr}(\gamma_5)\,\delta^{(n)}(0)$ by completeness. The first factor is 0 (γ_5 is traceless) and the second is ∞. The product is undefined and must be regularised. A regularisation cuts off large $|\lambda_n|$, and to keep gauge invariance the cutoff must be defined by the gauge-covariant operator $\not{D}_A$ itself, not by the free $\not{\partial}$.

10.4.2 The heat-kernel regulator, computed step by step

Following Fujikawa [QFT notes (22.3.62)], we define

$$\mathscr{A}(x) := \lim_{M\to\infty}\sum_n \varphi_n^\dagger(x)\gamma_5\, e^{-\lambda_n^2/M^2}\varphi_n(x). \tag{10.116}$$

The damping factor makes the sum converge (Weyl's law: the number of modes with $|\lambda| < \Lambda$ grows like Λ^n, while $e^{-\lambda^2/M^2}$ decays faster than any power). We now evaluate (10.116) in seven short steps.

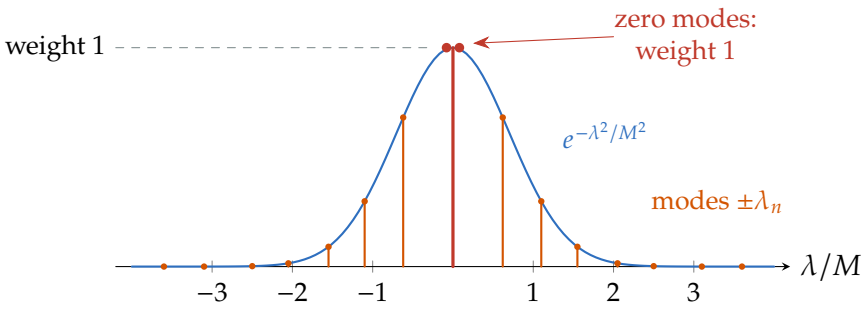

Figure 10.13: Fujikawa's regulator. Each eigenmode of $i\not{D}_A$ (orange sticks; they come in pairs $\pm\lambda_n$, see Section 10.4.5) is weighted by $e^{-\lambda_n^2/M^2}$, and each stick is drawn as tall as its weight. Modes with $|\lambda_n| \ll M$ keep weight ≈ 1; modes with $|\lambda_n| \gg M$ are switched off. Since the weight is a function of $\not{D}_A$, it is gauge covariant. Zero modes (red) always have weight 1: that is why the integrated anomaly will not depend on M.

Step 1: from modes to an operator kernel. Since $\not{D}_A\varphi_n = -i\lambda_n\varphi_n$, we have $\not{D}_A^2\varphi_n = -\lambda_n^2\varphi_n$ and so $e^{\not{D}_A^2/M^2}\varphi_n = e^{-\lambda_n^2/M^2}\varphi_n$. Hence

$$\sum_n \varphi_n^\dagger(x)\gamma_5 e^{-\lambda_n^2/M^2}\varphi_n(x) \overset{(1)}{=} \sum_n \operatorname{tr}\Big[\gamma_5\, e^{\not{D}_A^2/M^2}\varphi_n(x)\varphi_n^\dagger(y)\Big]_{y=x}$$
$$\overset{(2)}{=} \operatorname{tr}\Big[\gamma_5\, e^{\not{D}_A^2/M^2}\delta^{(n)}(x-y)\Big]_{y=x} =: \operatorname{tr}\,\langle x|\gamma_5\, e^{\not{D}_A^2/M^2}|x\rangle. \tag{10.117}$$

(1) $\chi^\dagger\gamma_5\chi = \operatorname{tr}(\gamma_5\chi\chi^\dagger)$ for a column vector χ; the operator $e^{\not{D}_A^2/M^2}$ acts on the x-dependence.
(2) Completeness (10.107). The trace is over spin and colour.

The object $\langle x|e^{t\not{D}_A^2}|y\rangle$ is the **heat kernel** of the operator $-\not{D}_A^2$ at "time" $t = 1/M^2$: it solves $\partial_t K = \not{D}_A^2 K$ with $K \to \delta$ as $t \to 0$. Fujikawa's regulator is the heat kernel at coincident points, at small time.

Step 2: the square of the Dirac operator. We need $\not{D}_A^2$ explicitly ([QFT notes (22.3.64)] in Minkowski form):

$$\not{D}_A^2 = \gamma^\mu\gamma^\nu D_\mu D_\nu \overset{(1)}{=} \tfrac{1}{2}\{\gamma^\mu,\gamma^\nu\}D_\mu D_\nu + \tfrac{1}{2}[\gamma^\mu,\gamma^\nu]D_\mu D_\nu$$
$$\overset{(2)}{=} D_\mu D_\mu + \tfrac{1}{4}[\gamma^\mu,\gamma^\nu][D_\mu,D_\nu]$$
$$\overset{(3)}{=} D_\mu D_\mu + \tfrac{1}{2}\gamma^\mu\gamma^\nu F_{\mu\nu}. \tag{10.118}$$

(1) Split $\gamma^\mu\gamma^\nu$ into its symmetric and antisymmetric parts.
(2) Clifford relation $\{\gamma^\mu,\gamma^\nu\} = 2\delta^{\mu\nu}$; in the second term only the part of $D_\mu D_\nu$ antisymmetric in $\mu\nu$ survives, which is $\frac{1}{2}[D_\mu,D_\nu]$.
(3) $[D_\mu,D_\nu] = \partial_\mu A_\nu - \partial_\nu A_\mu + [A_\mu,A_\nu] = F_{\mu\nu}$, and $\frac{1}{4}[\gamma^\mu,\gamma^\nu]F_{\mu\nu} = \frac{1}{2}\gamma^\mu\gamma^\nu F_{\mu\nu}$ since $F_{\mu\nu}$ is antisymmetric.

Write $\Phi := \frac{1}{2}\gamma^\mu\gamma^\nu F_{\mu\nu}$. It is a matrix acting on spin (through the γ's) and colour (through F), with no derivatives. It is the only place where γ-matrices appear in $\not{D}_A^2$.

Step 3: plane waves. On flat $\mathbb{R}^n$ (or a large torus) plane waves are complete: $\delta^{(n)}(x-y) = \int \frac{\mathrm{d}^n k}{(2\pi)^n} e^{ik\cdot(x-y)}$. For any operator O built from D_μ and multiplication operators,

$$\langle x|O|x\rangle \overset{(1)}{=} \int \frac{\mathrm{d}^n k}{(2\pi)^n}\, e^{-ik\cdot x}\, O\, e^{ik\cdot x} \overset{(2)}{=} \int \frac{\mathrm{d}^n k}{(2\pi)^n}\, O\big|_{D_\mu\to D_\mu+ik_\mu}\cdot\mathbf{1}. \tag{10.119}$$

(1) Act with $\mathcal{O}$ on $\delta(x-y)$ written as a Fourier integral, and set $y=x$.
(2) $e^{-ik\cdot x}D_\mu\big(e^{ik\cdot x}\chi\big)=(D_\mu+ik_\mu)\chi$ by the Leibniz rule; repeat for every factor of D_μ. The final "$\cdot\mathbf{1}$" means the operator acts on the constant function (with values the identity matrix).

Under $D\to D+ik$ the pieces of (10.118) become

$$(D_\mu+ik_\mu)(D_\mu+ik_\mu)=-k^2+2ik_\mu D_\mu+D_\mu D_\mu,\qquad [D_\mu+ik_\mu,D_\nu+ik_\nu]=F_{\mu\nu},\tag{10.120}$$

because the numbers k_μ commute with everything. So Φ is unchanged and

$$\mathscr{A}(x)=\lim_{M\to\infty}\int\frac{\mathrm{d}^nk}{(2\pi)^n}\ \mathrm{tr}\ \gamma_5\exp\Big[\frac{-k^2+2ik\cdot D+D^2+\Phi}{M^2}\Big]\cdot\mathbf{1}.\tag{10.121}$$

Step 4: rescale the momentum. Put $k=M\kappa$, so $\mathrm{d}^nk=M^n\mathrm{d}^n\kappa$:

$$\begin{aligned}\mathscr{A}(x)&\overset{(1)}{=}\lim_{M\to\infty}M^n\int\frac{\mathrm{d}^n\kappa}{(2\pi)^n}\ \mathrm{tr}\ \gamma_5\exp\Big[-\kappa^2+\frac{X_1}{M}+\frac{X_2}{M^2}\Big]\cdot\mathbf{1}\\&\overset{(2)}{=}\lim_{M\to\infty}M^n\int\frac{\mathrm{d}^n\kappa}{(2\pi)^n}\,e^{-\kappa^2}\ \mathrm{tr}\ \gamma_5\exp\Big[\frac{X_1}{M}+\frac{X_2}{M^2}\Big]\cdot\mathbf{1},\end{aligned}\tag{10.122}$$

with $X_1\coloneqq 2i\kappa_\mu D_\mu$ and $X_2\coloneqq D^2+\Phi$.

(1) Substitute $k=M\kappa$ in (10.121).
(2) $-\kappa^2$ is a number times the identity, so it commutes with X_1, X_2 and $e^{-\kappa^2+Y}=e^{-\kappa^2}e^{Y}$ exactly. (This is why no ordering subtlety arises.)

Step 5: power counting. Expand $e^{Y}=\sum_{j\ge0}Y^j/j!$ with $Y=X_1/M+X_2/M^2$. A product containing a factors of X_1 and b factors of X_2 carries M^{-a-2b}, so with the prefactor it is of order $M^{n-a-2b}=M^{2m-a-2b}$. Now use two facts:

- Only Φ contains γ-matrices, two per factor.
- $\mathrm{tr}(\gamma_5\times$ a product of fewer than $2m$ γ's$)=0$ (proved in Step 7).

So a nonzero trace needs at least m factors of Φ, hence $b\ge m$ and the order is at most $M^{2m-a-2b}\le M^0$. Equality needs $a=0$, $b=m$, and every one of the m factors of X_2 equal to Φ (a factor D^2 in place of a Φ would force $b\ge m+1$). Every other term vanishes as $M\to\infty$. The terms that would have *diverged*, $M^{2m}\,\mathrm{tr}\,\gamma_5$, $M^{2m-2}\,\mathrm{tr}(\gamma_5\Phi)$, …, all have too few γ's and vanish identically. Therefore

$$\mathscr{A}(x)=\int\frac{\mathrm{d}^n\kappa}{(2\pi)^n}\,e^{-\kappa^2}\,\frac{1}{m!}\,\mathrm{tr}\big(\gamma_5\,\Phi^m\big).\tag{10.123}$$

The coefficient $1/m!$ comes from the term $Y^m/m!$, the only one containing $(X_2)^m$ with no X_1.

Step 6: the Gaussian integral.

$$\int\frac{\mathrm{d}^n\kappa}{(2\pi)^n}\,e^{-\kappa^2}\overset{(1)}{=}\frac{1}{(2\pi)^n}\Big(\int_{-\infty}^{\infty}e^{-u^2}\mathrm{d}u\Big)^n\overset{(2)}{=}\frac{\pi^{n/2}}{(2\pi)^n}\overset{(3)}{=}\frac{1}{(4\pi)^m}.\tag{10.124}$$

(1) The integrand factorises over the n Cartesian components of κ.
(2) $\int e^{-u^2}\mathrm{d}u=\sqrt{\pi}$.
(3) $n=2m$: $\pi^m/(4^m\pi^{2m})=(4\pi)^{-m}$.

For $n=4$ this is $1/16\pi^2$; restoring M, it is the statement $\langle x|e^{\partial^2/M^2}|x\rangle=M^4/16\pi^2$ [QFT notes (22.3.69)].

Step 7: the γ_5 trace. We need

$$\operatorname{tr}\big(\gamma_5\gamma^{\mu_1}\gamma^{\mu_2}\cdots\gamma^{\mu_{2m}}\big) = (2i)^m\,\epsilon^{\mu_1\mu_2\cdots\mu_{2m}}, \tag{10.125}$$

and that the trace of γ_5 with fewer γ's vanishes. The argument has three parts.

1. *Products of distinct γ's are traceless.* Let P be a product of j distinct γ's, $1 \le j \le 2m$. If j is even, write $P = \gamma_a Q$ with Q the other $j-1$ factors; then $\gamma_a Q = (-1)^{j-1} Q\gamma_a = -Q\gamma_a$, and cyclicity gives $\operatorname{tr} P = \operatorname{tr}(\gamma_a Q) = \operatorname{tr}(Q\gamma_a) = -\operatorname{tr} P$. If j is odd and $j < 2m$, pick γ_c not in P; then $\gamma_c P \gamma_c = (-1)^j P = -P$ and $\operatorname{tr} P = \operatorname{tr}(\gamma_c\gamma_c P) = \operatorname{tr}(\gamma_c P\gamma_c) = -\operatorname{tr} P$. Either way $\operatorname{tr} P = 0$.

2. *Fewer than $2m$ γ's.* Use $\gamma_\mu\gamma_\mu = \mathbf{1}$ and anticommutation to remove repeated indices; γ_5 times what is left is $\pm$(a nonzero power of i) times a product of distinct γ's, which is traceless by part 1 unless it is the identity. It is the identity only if all $2m$ directions appeared, which needs at least $2m$ factors.

3. *Exactly $2m$ γ's.* If two indices coincide, part 2 gives zero; this matches $\epsilon = 0$. If all are distinct, reorder them to $\gamma_1\cdots\gamma_{2m}$, which costs the sign of the permutation, i.e. $\epsilon^{\mu_1\cdots\mu_{2m}}$. Finally $\gamma_1\cdots\gamma_{2m} = i^m\gamma_5$ (multiply (10.3) by i^m and use $(i)^m(-i)^m = 1$), so $\operatorname{tr}(\gamma_5\gamma_1\cdots\gamma_{2m}) = i^m\operatorname{tr}(\gamma_5^2) = i^m\,2^m$, since spinors have 2^m components.

Check: for $m=1$, $\operatorname{tr}(\gamma_5\gamma_1\gamma_2) = \operatorname{tr}(\sigma_3\sigma_1\sigma_2) = \operatorname{tr}(\sigma_3\cdot i\sigma_3) = 2i = (2i)^1$. For $m=2$, (10.125) gives $\operatorname{tr}(\gamma_5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = -4\epsilon^{\mu\nu\rho\sigma}$; with $\gamma_1\gamma_2\gamma_3\gamma_4 = -\gamma_5$ from Example 10.1, indeed $\operatorname{tr}(\gamma_5\gamma_1\gamma_2\gamma_3\gamma_4) = -\operatorname{tr}\mathbf{1} = -4$.

The result. Put Steps 5–7 together:

$$\begin{aligned}\mathscr{A}(x) &\overset{(1)}{=} \frac{1}{(4\pi)^m}\,\frac{1}{m!}\,\frac{1}{2^m}\,\operatorname{tr}_{\text{spin}}\big(\gamma_5\gamma^{\mu_1}\gamma^{\mu_2}\cdots\gamma^{\mu_{2m}}\big)\,\operatorname{tr}_{\text{col}}\big(F_{\mu_1\mu_2}\cdots F_{\mu_{2m-1}\mu_{2m}}\big)\\ &\overset{(2)}{=} \frac{1}{m!}\Big(\frac{i}{4\pi}\Big)^m\,\epsilon^{\mu_1\cdots\mu_{2m}}\,\operatorname{tr}\big(F_{\mu_1\mu_2}\cdots F_{\mu_{2m-1}\mu_{2m}}\big).\end{aligned} \tag{10.126}$$

(1) (10.124) and $\Phi^m = 2^{-m}\gamma^{\mu_1}\gamma^{\mu_2}\cdots\gamma^{\mu_{2m}}F_{\mu_1\mu_2}\cdots F_{\mu_{2m-1}\mu_{2m}}$; the γ's and F's act on different indices, so the trace factorises.
(2) (10.125): $(2i)^m/(2^m(4\pi)^m) = (i/4\pi)^m$.

Key idea: The Fujikawa Jacobian is the Chern character

Compare with the Chern character form $\operatorname{ch}_m(F) = \frac{1}{m!}\big(\frac{i}{2\pi}\big)^m\operatorname{tr}F^m$. Since $F = \frac12 F_{\mu\nu}\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu$,

$$\operatorname{tr}F^m = \frac{1}{2^m}\,\epsilon^{\mu_1\cdots\mu_{2m}}\operatorname{tr}\big(F_{\mu_1\mu_2}\cdots F_{\mu_{2m-1}\mu_{2m}}\big)\,\mathrm{d}^n x,$$

so $\operatorname{ch}_m(F) = \frac{1}{m!}\big(\frac{i}{4\pi}\big)^m\epsilon\operatorname{tr}(F\cdots F)\,\mathrm{d}^n x$, and

$$\mathscr{A}(x)\,\mathrm{d}^n x = \operatorname{ch}_m(F), \qquad \langle\partial_\mu j_5^\mu\rangle\,\mathrm{d}^n x = 2\,\operatorname{ch}_m(F). \tag{10.127}$$

The anomaly density is the top-degree Chern–Weil form of the gauge field.

Worked example 10.12: Four dimensions, written out

For $m=2$ the chain (10.126) reads

$$\mathscr{A} \overset{(1)}{=} \frac{1}{16\pi^2}\cdot\frac12\cdot\frac14\,\operatorname{tr}(\gamma_5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma)\,\operatorname{tr}(F_{\mu\nu}F_{\rho\sigma}) \overset{(2)}{=} \frac{1}{128\pi^2}(-4)\,\epsilon^{\mu\nu\rho\sigma}\operatorname{tr}(F_{\mu\nu}F_{\rho\sigma})$$

$$= -\frac{1}{32\pi^2}\,\epsilon^{\mu\nu\rho\sigma}\,\mathrm{tr}(F_{\mu\nu}F_{\rho\sigma}).$$

(1) Gaussian $1/16\pi^2$, the $1/2!$ from $Y^2/2!$, and $\Phi^2 = \frac{1}{4}\gamma\gamma\gamma\gamma FF$.
(2) The four-dimensional trace $-4\epsilon^{\mu\nu\rho\sigma}$.

For QED, $A_\mu = -iea_\mu$ and $F_{\mu\nu} = -ief_{\mu\nu}$ (dictionary in Section 10.1.1), so $\mathrm{tr}(F_{\mu\nu}F_{\rho\sigma}) = -e^2 f_{\mu\nu}f_{\rho\sigma}$ and

$$\langle \partial_\mu j_5^\mu \rangle = 2\mathscr{A} = \frac{e^2}{16\pi^2}\,\epsilon^{\mu\nu\rho\sigma} f_{\mu\nu}f_{\rho\sigma} \qquad \text{(Euclidean)},$$

which is (10.9). The Minkowski computation of the QFT notes [QFT notes (22.3.70)–(22.3.74)] follows the same seven steps and gives $\partial_\mu j_5^\mu = -\frac{e^2}{16\pi^2}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$ with $\epsilon^{0123} = +1$, the same result as the point-split and triangle computations (10.75).

Watch out: Signs between Euclidean and Minkowski

The two forms of the ABJ equation differ by a sign, and that is not a contradiction. In Minkowski signature with $\epsilon^{0123} = +1$, $F_{0i} = E_i$ and $F_{ij} = -\epsilon_{ijk}B_k$, the chain (10.76) gives $\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma} = -8\,\mathbf{E}\cdot\mathbf{B}$, so both statements say $\partial_\mu j_5^\mu = \frac{e^2}{2\pi^2}\mathbf{E}\cdot\mathbf{B}$. The Wick rotation $x^0 = -ix^4$ changes ϵ, the components of F, and the relation between j_5^0 and j_5^4, each by a factor of $\pm i$ or ± 1. When comparing with a book, compare $\mathbf{E}\cdot\mathbf{B}$ or the integrated (index) form, never the raw ϵFF.

10.4.3 Why the answer does not depend on the regulator

The Gaussian $e^{-\lambda^2/M^2}$ looks arbitrary. Replace it by $f(\lambda^2/M^2)$ with any smooth f such that $f(0) = 1$ and $f(u) \to 0$ fast as $u \to \infty$. Steps 1–5 go through with $e^{-\kappa^2+Y}$ replaced by $f(\kappa^2 - Y)$, where now $-\not{D}^2/M^2 \to \kappa^2 - Y$. (Here κ^2 commutes with Y, so Taylor expansion in Y is legitimate.) The surviving term is the one with Φ^m:

$$\begin{aligned}
\mathscr{A}_f &\overset{(1)}{=} \int \frac{\mathrm{d}^n\kappa}{(2\pi)^n}\,\frac{(-1)^m f^{(m)}(\kappa^2)}{m!}\,\mathrm{tr}(\gamma_5\Phi^m)\\
&\overset{(2)}{=} \frac{\pi^m}{(2\pi)^{2m}\,(m-1)!}\int_0^\infty \mathrm{d}u\; u^{m-1}(-1)^m f^{(m)}(u)\cdot\frac{\mathrm{tr}(\gamma_5\Phi^m)}{m!}\\
&\overset{(3)}{=} \frac{\pi^m}{(2\pi)^{2m}\,(m-1)!}\,(m-1)!\,\big[f(0)-f(\infty)\big]\frac{\mathrm{tr}(\gamma_5\Phi^m)}{m!} = \frac{1}{(4\pi)^m}\frac{\mathrm{tr}(\gamma_5\Phi^m)}{m!}.
\end{aligned} \tag{10.128}$$

(1) Taylor expand $f(\kappa^2 - Y)$ to order m in Y and keep $(-\Phi)^m/M^{2m}$, as in Step 5; the factor is $f^{(m)}(\kappa^2)(-1)^m/m!$.
(2) Polar coordinates in $n = 2m$ dimensions with $u = \kappa^2$: $\mathrm{d}^n\kappa = \frac{\pi^m}{(m-1)!}u^{m-1}\mathrm{d}u$ (the unit sphere S^{2m-1} has area $2\pi^m/(m-1)!$, and $\kappa^{2m-1}\mathrm{d}\kappa = \frac{1}{2}u^{m-1}\mathrm{d}u$).
(3) Integrate by parts $m-1$ times; each time the boundary terms vanish (u^j kills $u = 0$, decay kills $u = \infty$), giving $\int_0^\infty u^{m-1}(-1)^m f^{(m)}\mathrm{d}u = (m-1)!\int_0^\infty(-f')\mathrm{d}u = (m-1)!\,[f(0) - f(\infty)]$.

Only $f(0) = 1$ and $f(\infty) = 0$ matter: the anomaly is insensitive to how the cutoff is shaped. It only knows that low modes are kept and high modes removed. For $f(u) = e^{-u}$ we recover (10.123); a sharp cutoff $f = \theta(1-u)$ or the Pauli–Villars choice $f(u) = 1/(1+u)$ give the same.

Physical picture: Pauli–Villars in one sentence

A Pauli–Villars regulator adds a heavy fermion of mass M with the wrong statistics. Its mass term $M\bar\chi\chi$ breaks the chiral symmetry explicitly, by the term $2iM\bar\chi\gamma_5\chi$, and as $M\to\infty$ the expectation value of that term does not go to zero: it tends to a finite limit, which reproduces $2\mathscr{A}$. The anomaly is the ghost of the regulator's mass, which cannot be removed because a mass is the only gauge-invariant way to make a fermion heavy.

10.4.4 QED in $2k$ dimensions

The computation (10.126) was done in every even dimension at once. For QED, $F=-ief$ and tr is trivial:

$$\begin{aligned}\langle\partial_\mu j_5^\mu\rangle &\overset{(1)}{=} \frac{2}{m!}\Big(\frac{i}{4\pi}\Big)^m(-ie)^m\,\epsilon^{\mu_1\cdots\mu_{2m}}f_{\mu_1\mu_2}\cdots f_{\mu_{2m-1}\mu_{2m}}\\ &\overset{(2)}{=} \frac{2}{m!}\Big(\frac{e}{4\pi}\Big)^m\,\epsilon^{\mu_1\cdots\mu_{2m}}f_{\mu_1\mu_2}\cdots f_{\mu_{2m-1}\mu_{2m}}\qquad\text{(Euclidean).}\end{aligned}\tag{10.129}$$

(1) (10.115) with (10.126) and $F_{\mu\nu}=-ief_{\mu\nu}$.
(2) $i^m(-i)^m=1$.

This is [QFT notes (22.4.1)], which in Minkowski signature carries an extra $(-1)^{m+1}$ (and writes k for our m). Table 10.2 lists the first cases.

$n=2m$	$\mathscr{A}\,\mathrm{d}^nx=\mathrm{ch}_m(F)$	$\langle\partial_\mu j_5^\mu\rangle$ (QED, Euclidean)	needs
2	$\frac{i}{2\pi}\,\mathrm{tr}\,F$	$\frac{e}{2\pi}\,\epsilon^{\mu\nu}f_{\mu\nu}=\frac{e}{\pi}f_{12}$	$\mathrm{tr}(\gamma_5\gamma\gamma)$
4	$-\frac{1}{8\pi^2}\,\mathrm{tr}\,F^2$	$\frac{e^2}{16\pi^2}\,\epsilon^{\mu\nu\rho\sigma}f_{\mu\nu}f_{\rho\sigma}$	$\mathrm{tr}(\gamma_5\gamma\gamma\gamma\gamma)$
6	$-\frac{i}{48\pi^3}\,\mathrm{tr}\,F^3$	$\frac{e^3}{192\pi^3}\,\epsilon^{\mu\nu\rho\sigma\alpha\beta}f_{\mu\nu}f_{\rho\sigma}f_{\alpha\beta}$	six γ's
$2m$	$\frac{1}{m!}\big(\frac{i}{2\pi}\big)^m\,\mathrm{tr}\,F^m$	$\frac{2}{m!}\big(\frac{e}{4\pi}\big)^m\epsilon f\cdots f$	$2m$ γ's

Table 10.2: The chiral anomaly in $n=2m$ dimensions. The anomaly is always the top Chern character form; its tensor structure is forced by the fact that γ_5 needs $2m$ other γ's to have a nonzero trace, and each F supplies two.

Worked example 10.13: Two dimensions, and agreement with the vacuum polarisation

For $m=1$, (10.126) gives

$$\mathscr{A}\overset{(1)}{=}\frac{i}{4\pi}\,\epsilon^{\mu\nu}F_{\mu\nu}\overset{(2)}{=}\frac{i}{4\pi}\,(F_{12}-F_{21})=\frac{i}{2\pi}F_{12}\overset{(3)}{=}\frac{e}{2\pi}f_{12}.$$

(1) (10.126) with $m=1$ and abelian F.
(2) $\epsilon^{12}=1=-\epsilon^{21}$.
(3) $F_{12}=-ief_{12}$.

So $\langle\partial_\mu j_5^\mu\rangle=\frac{e}{\pi}f_{12}$. Directly from the modes: in a constant field $f_{12}=B>0$ on a torus of area L^2 the Landau levels of $-\not{D}^2$ are $2eB\ell$, $\ell=0,1,2,\dots$, each with degeneracy $eBL^2/2\pi$, and the lowest level ($\ell=0$) consists only of positive-chirality zero modes (Example 10.4). All higher levels contain both chiralities equally. The regulated sum (10.116) is therefore the zero-mode density $(eBL^2/2\pi)/L^2=eB/2\pi$, for every M. This agrees with $\mathscr{A}=\frac{e}{2\pi}f_{12}$. In Minkowski form this is (10.57).

Worked example 10.14: Six dimensions

For $m = 3$: $\mathscr{A} = \frac{1}{3!}\left(\frac{i}{4\pi}\right)^3 \epsilon^{\mu\nu\rho\sigma\alpha\beta}\,\mathrm{tr}(F_{\mu\nu}F_{\rho\sigma}F_{\alpha\beta}) = -\frac{i}{384\pi^3}\epsilon\,\mathrm{tr}(FFF)$, and in form language $\mathscr{A}\,\mathrm{d}^6x = \mathrm{ch}_3(F) = -\frac{i}{48\pi^3}\,\mathrm{tr}\,F^3$ (check: $\mathrm{tr}\,F^3 = \frac{1}{8}\epsilon\,\mathrm{tr}(FFF)\mathrm{d}^6x$ and $\frac{1}{48\cdot 8} = \frac{1}{384}$). For QED, $(-ie)^3\cdot(-i) = -e^3$, so $\langle\partial_\mu j_5^\mu\rangle = 2\mathscr{A} = \frac{e^3}{192\pi^3}\epsilon fff$, the entry in Table 10.2. The six-dimensional anomaly matters in Section 10.5: it is the polynomial whose descent gives the four-dimensional non-abelian anomaly.

10.4.5 The integrated anomaly is the index

Now integrate (10.116) over M *before* taking $M \to \infty$:

$$\int_M \mathrm{d}^n x \sum_n \varphi_n^\dagger \gamma_5 e^{-\lambda_n^2/M^2}\varphi_n = \sum_n e^{-\lambda_n^2/M^2}\,\langle\varphi_n, \gamma_5\varphi_n\rangle. \tag{10.130}$$

Two facts about the modes do the rest.

1. *Nonzero modes pair up and cancel.* If $i\not{D}_A\varphi_n = \lambda_n\varphi_n$ with $\lambda_n \neq 0$, then

$$i\not{D}_A(\gamma_5\varphi_n) \overset{(1)}{=} -\gamma_5\, i\not{D}_A\varphi_n \overset{(2)}{=} -\lambda_n\,\gamma_5\varphi_n.$$

   (1) γ_5 anticommutes with every γ^μ and commutes with D_μ.
   (2) The eigenvalue equation.

   So $\gamma_5\varphi_n$ is an eigenvector with the *different* eigenvalue $-\lambda_n$, hence orthogonal to φ_n (eigenvectors of a self-adjoint operator with different eigenvalues are orthogonal): $\langle\varphi_n, \gamma_5\varphi_n\rangle = 0$.

2. *Zero modes have definite chirality.* γ_5 maps $\ker\not{D}_A$ to itself, so we may choose a basis of the kernel consisting of n_+ spinors with $\gamma_5 = +1$ and n_- with $\gamma_5 = -1$. For them $e^{-0} = 1$ and $\langle\varphi, \gamma_5\varphi\rangle = \pm 1$.

Hence, for *every* M,

$$\int_M \mathscr{A}\,\mathrm{d}^n x = n_+ - n_- = \mathrm{index}\,D_A^+, \tag{10.131}$$

and combining with (10.127),

$$\boxed{\int_M \langle\partial_\mu j_5^\mu\rangle\,\mathrm{d}^n x = 2\,\mathrm{index}\,D_A^+ = 2\int_M \mathrm{ch}_m(F)} \tag{10.132}$$

This is Nash's (10.3) in integrated-anomaly form [Nash p. 270]: the left side is the total change of chiral charge, and the right side is twice the number of forced zero modes. (On a curved M, the $\hat{A}$-genus appears as well; Section 10.7.) The argument is the physicist's proof of the index theorem in this setting: the left side of (10.131) is an integer for every M, and as $M \to \infty$ it becomes a local integral that we computed. (It is the McKean–Singer formula $\mathrm{index}\,D^+ = \mathrm{Tr}\,\gamma_5 e^{t\not{D}^2}$ of Chapter 4, at $t = 1/M^2$.)

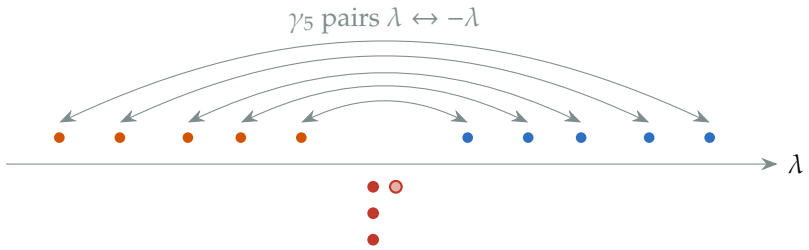

Figure 10.14: Why the integrated anomaly is an integer. The nonzero eigenvalues of $i\not{D}_A$ come in pairs $\pm\lambda$ related by γ_5 (grey arcs); each pair contributes $\langle\varphi, \gamma_5\varphi\rangle = 0$ to the regulated trace. Only the zero modes (red) survive, and they count $n_+ - n_-$. The local formula $\int \mathrm{ch}_m(F)$ must therefore give an integer.

Worked example 10.15: Flux on a torus: the anomaly counts Landau zero modes

On a two-torus with N units of flux, $\int \frac{e}{2\pi} f = N$. Then

$$\int \langle \partial_\mu j_5^\mu \rangle \, \mathrm{d}^2x \overset{(1)}{=} 2 \int \mathrm{ch}_1(F) \overset{(2)}{=} 2 \int \frac{i}{2\pi} F \overset{(3)}{=} 2 \int \frac{e}{2\pi} f = 2N.$$

(1) (10.132).
(2) $\mathrm{ch}_1 = \frac{i}{2\pi} \operatorname{tr} F$ for a line bundle.
(3) $F = -ief$.

On the other side, the lowest Landau level of Example 10.13 has N positive-chirality zero modes and nothing else, so index $D^+ = N$. Read in Minkowski time (the torus being the "periodic slab" of Section 10.3.5), $2N$ is the total change of Q_5 when N flux quanta are threaded: N steps of the spectral flow of Figure 10.8, each changing Q_5 by 2 in magnitude.

Worked example 10.16: The instanton flips chirality: 't Hooft's vertex

For the SU(2) BPST instanton on S^4 with one Dirac fermion in the fundamental representation, Example 10.5 gave index $D_A^+ = k = -1$: a single zero mode, of negative chirality. So

$$\int \langle \partial_\mu j_5^\mu \rangle \, \mathrm{d}^4x = 2k = -2.$$

In Minkowski language an instanton is a tunnelling event between gauge vacua, and in it the axial charge changes by $2|k|$ per Dirac flavour. With N_f flavours the path integral in the instanton background vanishes unless $2N_f$ fermion fields are inserted to soak up the zero modes: the **'t Hooft vertex**. In QCD this is why the axial U(1) is not a symmetry and the η' is heavy. In the electroweak theory, each of the 12 left-handed SU(2) doublets of the three generations (3×3 colours of quark doublets plus 3 lepton doublets) has one zero mode, so an electroweak instanton is a 12-fermion vertex with $\Delta B = \Delta L = 3$. Its amplitude carries the tunnelling factor $e^{-8\pi^2/g^2} = e^{-2\pi/\alpha_W} \approx 10^{-81}$, which is why protons do not decay this way.

Physical picture: Why the anomaly coefficient cannot be renormalised

The integrated anomaly is an integer for every background. A coefficient that depended on the coupling, $e^2/16\pi^2 \times (1 + c\,e^2 + \cdots)$, would make $\int \langle \partial j_5 \rangle$ non-integral for a unit instanton. So the one-loop coefficient is exact: this is the topological face of the Adler–Bardeen theorem mentioned at the end of Section 10.3.7.

10.4.6 The measure of a Weyl fermion and the covariant anomaly

So far the fermion was a Dirac fermion coupled *vectorially*, and the anomaly was in a global symmetry. Nash's concern is the chiral theory (10.13), in which only ψ_+ couples to A and the anomaly would be in the *gauge* symmetry itself. Here is how Fujikawa's method applies to it, and where it runs into trouble.

The difficulty. The operator in the action, $D_A^+ : \Gamma(E^+ \otimes F) \to \Gamma(E^- \otimes F)$, maps one space to another, so it has no eigenvalue problem, and there is no single basis in which to expand both ψ_+ and $\bar\psi_-$. We use two bases:

$$(D_A^+)^\dagger D_A^+ u_n = \mu_n u_n \text{ on } E^+, \qquad D_A^+ (D_A^+)^\dagger w_n = \mu_n w_n \text{ on } E^-, \tag{10.133}$$

orthonormal in their own spaces (for $\mu_n \neq 0$ one can take $w_n = D_A^+ u_n / \sqrt{\mu_n}$). Expand $\psi_+ = \sum a_n u_n$, $\bar\psi_- = \sum b_n w_n^\dagger$, and set $\mathcal{D}\psi_+ \mathcal{D}\bar\psi_- = \prod \mathrm{d}a_n \mathrm{d}b_n$.

The Jacobian of a gauge transformation. Let $g = e^{tv}$ with $v(x) \in \mathfrak{g}$. By (10.22), $Z_F[A_g] = \int \mathcal{D}\psi_+ \mathcal{D}\bar\psi_- \exp(-\int \bar\psi_- g^{-1} D_A^+ g \psi_+)$. Substitute $\chi = g\psi_+$, $\bar\chi = \bar\psi_- g^{-1}$; the action becomes $\int \bar\chi D_A^+ \chi$, and

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} \ln Z_F[A_{g(t)}]\Big|_{t=0} &\overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}t} \ln \Big[\det(1 + tV^+)\, \det(1 - tV^-) \Big]_{t=0} \\ &\overset{(2)}{=} \operatorname{Tr} V^+ - \operatorname{Tr} V^- \overset{(3)}{=} \sum_n \int u_n^\dagger v\, u_n - \sum_n \int w_n^\dagger v\, w_n , \end{aligned} \tag{10.134}$$

where $V^+_{nk} = \int u_n^\dagger v u_k$ and $V^-_{nk} = \int w_n^\dagger v w_k$.

(1) As in (10.109): $\chi = (1+tv)\psi_+$ has coefficients $(1+tV^+)a$ and $\bar\chi = \bar\psi_-(1-tv)$ has coefficients $(1-tV^-)^{\mathsf{T}} b$; by Definition 10.6, $\mathcal{D}\psi_+\mathcal{D}\bar\psi_- = \det(1+tV^+)\det(1-tV^-)\,\mathcal{D}\chi\mathcal{D}\bar\chi$, and the χ-integral is $Z_F[A]$.
(2) $\frac{\mathrm{d}}{\mathrm{d}t} \ln\det(1+tV)|_0 = \operatorname{Tr} V$.
(3) Definitions of the matrix elements.

Regularise with the Dirac square. By (10.15), $\not{D}_A^2 = \operatorname{diag}\big(-(D_A^+)^\dagger D_A^+,\, -D_A^+ (D_A^+)^\dagger\big)$ on $E^+ \oplus E^-$, so cutting off each sum with $e^{-\mu_n/M^2}$ packages the difference of the two traces as a single trace with γ_5:

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} \ln Z_F\Big|_{t=0} &\overset{(1)}{=} \lim_{M\to\infty} \int_M \mathrm{d}^n x\ \operatorname{tr} \langle x|\, v\, \gamma_5\, e^{\not{D}_A^2/M^2} |x\rangle \\ &\overset{(2)}{=} \int_M \frac{1}{m!} \Big(\frac{i}{4\pi}\Big)^m \epsilon^{\mu_1 \cdots \mu_{2m}} \operatorname{tr}\big(v\, F_{\mu_1\mu_2} \cdots F_{\mu_{2m-1}\mu_{2m}}\big) \mathrm{d}^n x = \int_M \operatorname{tr}\Big[v\, \frac{1}{m!} \Big(\frac{i}{2\pi}\Big)^m F^m \Big]. \end{aligned} \tag{10.135}$$

(1) $\gamma_5 = +1$ on E^+ and -1 on E^- gives the relative sign in (10.134); the colour matrix $v(x)$ is a multiplication operator and sits inside the trace.

(2) Steps 1–7 of Section 10.4.2 go through unchanged: v carries no γ's and no derivatives, so it just rides along inside the colour trace.

Comparing with (10.27) and writing $v = T^a f^a$,

$$\langle (D_\mu J^\mu)^a \rangle_{\text{cov}}\, \mathrm{d}^n x = \operatorname{tr}\Big[T^a \, \frac{1}{m!} \Big(\frac{i}{2\pi} \Big)^m F^m \Big]. \tag{10.136}$$

This is the **covariant anomaly**: it is built from F and transforms under gauge transformations like F does. For $G = \mathrm{U}(1)$ with charge e it is exactly half of the Dirac-fermion ABJ anomaly, as it should be: $j_+ = \frac{1}{2}(j + j_5)$.

Watch out: The covariant anomaly is not the variation of anything

The regulator in (10.135) uses $e^{-(D^+)^\dagger D^+/M^2}$ on ψ_+ and $e^{-D^+(D^+)^\dagger/M^2}$ on $\bar\psi_-$: two *different* A-dependent cutoffs on two different spaces (the intuition box of Section 10.2.7). Because the definition of the measure itself depends on A, the Jacobian computed this way is not the derivative of a single well-defined functional $\ln Z_F[A]$. We shall see in Section 10.5.2 that (10.135) fails the integrability condition that any true variation $\delta_v \ln Z_F$ must satisfy. The true variation, the **consistent anomaly**, has the same topological content but a different normalisation: for U(1) in $n = 2m$ dimensions it is $\frac{1}{m+1}$ of the covariant one.

Dictionary: three anomalies with similar names

- *ABJ (axial, singlet) anomaly*: $\partial_\mu j_5^\mu = 2\mathscr{A}$ for a Dirac fermion; a global symmetry fails; no inconsistency.
- *Covariant gauge anomaly*: $\langle (D \cdot J)^a \rangle$ of a chiral gauge current computed with covariant regulators, (10.136); gauge covariant, not integrable.
- *Consistent gauge anomaly*: $\delta_v \ln Z_F$ for a genuinely defined Z_F; satisfies the Wess–Zumino condition; computed by descent in Section 10.5.5. This is Nash's μ_1 (10.13) and (10.33).

Reading Nash (p. 273, Fujikawa; p. 270, (10.3))

Nash's one-line reference to Fujikawa is Sections 10.4.1 and 10.4.2: "the Fermionic 'measure' $\mathcal{D}\psi\mathcal{D}\bar\psi$ is not gauge invariant" is (10.111) with $C \neq 0$, and the non-invariance is computed by the heat kernel as the Chern character (10.127). Integrating gives back his index formula (10.3), now in the form (10.132). For the chiral theory the same Jacobian gives the covariant anomaly (10.136); Nash's cohomological μ_1 is the consistent version, which we derive next.

Recap

- Expand fields in eigenmodes of $i\not{D}_A$. A local chiral rotation changes the Grassmann measure by $\det(1 + C)^{-2} = \exp[-2i \int \alpha\, \mathscr{A}]$, so $\langle \partial_\mu j_5^\mu \rangle = 2\mathscr{A}$.
- With the gauge-covariant heat-kernel regulator, $\mathscr{A} = \lim \operatorname{tr}\langle x | \gamma_5 e^{\not{D}_A^2/M^2} | x \rangle = \frac{1}{m!}(\frac{i}{4\pi})^m \epsilon \operatorname{tr}(F \cdots F)$, i.e. $\mathscr{A}\, \mathrm{d}^n x = \mathrm{ch}_m(F)$. Only the Φ^m term survives, because $\operatorname{tr} \gamma_5$ needs $2m$ γ's.
- The result does not depend on the shape of the cutoff, only on $f(0) = 1$, $f(\infty) = 0$.
- QED_{2k}: $\langle \partial j_5 \rangle = \frac{2}{m!}(\frac{e}{4\pi})^m \epsilon f \cdots f$; $\frac{e}{\pi} f_{12}$ in 2D, $\frac{e^2}{16\pi^2} \epsilon f f$ in 4D.

- Integrated: $\int \mathscr{A} = n_+ - n_-$ for every M (paired modes cancel), so $\int \langle \partial j_5 \rangle = 2\,\mathrm{index}\, D_A^+ = 2\int \mathrm{ch}_m(F)$.
- A Weyl fermion with covariant regulators gives the covariant anomaly $\mathrm{tr}[T^a\,\mathrm{ch}_m(F)]$; the consistent anomaly differs and is the subject of the next section.

10.5 Anomalies and Yang–Mills theories IV: non-abelian anomalies, consistency and descent

So far the anomaly has been a statement about a U(1) current. Nash's set-up [Nash pp. 270–273] is a chiral fermion coupled to a general compact gauge group G, and for such a theory the anomaly is not just a nuisance: it is an inconsistency, because the gauge current is the current the gauge field couples to. The question this section answers is: *what exactly is* $\delta_v \ln Z_F[A]$ *for a non-abelian chiral gauge theory, and when does it vanish?* Three facts will do the work.

1. *Algebra.* Gauge transformations form a group, so the variations δ_v must close into a Lie algebra. This forces the anomaly to obey the **Wess–Zumino consistency condition**. The covariant anomaly of Section 10.4.6 fails it.
2. *Topology.* The solutions of the consistency condition are produced by the **descent equations** from the characteristic class $\mathrm{ch}_{m+1}(F)$ in two dimensions *more* than spacetime. This is the origin of the Chern–Simons forms and of Nash's formula (10.33).
3. *One number.* The overall coefficient is fixed by a single abelian graph, and Bose symmetry gives it: $\frac{1}{m+1}$ of the covariant anomaly.

The upshot is a purely group-theoretic cancellation condition, $\mathrm{Str}(T^aT^bT^c) = 0$ in four dimensions, which the Standard Model satisfies generation by generation.

10.5.1 Toolkit: Lie-algebra-valued forms and their traces

We use the conventions of Section 10.1.1 (and Chapter T3): $A = A_\mu \mathrm{d}x^\mu$ is a 1-form whose components are anti-Hermitian matrices in the representation carried by the fermions, $F = \mathrm{d}A + A \wedge A$, and a finite gauge transformation is $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$. We usually drop the wedge sign: $A^2 \coloneqq A \wedge A$, $A\mathrm{d}A \coloneqq A \wedge \mathrm{d}A$. A gauge parameter is a Lie-algebra-valued function $v(x) = T^a v^a(x)$, and the infinitesimal gauge transformation is (10.23),

$$\delta_v A = D_A v = \mathrm{d}v + [A, v] = \mathrm{d}v + Av - vA. \tag{10.137}$$

(The physicist's dictionary: $A = -ig\,A^a_{\mathrm{phys}} t^a$ with t^a Hermitian, $T^a = -it^a$; for U(1) with charge e, $A = -ie\,a$.)

Graded rules. A matrix-valued p-form times a matrix-valued q-form is a matrix of $(p+q)$-forms. Two rules are used constantly.

- *Graded commutator.* $[X, Y] \coloneqq XY - (-1)^{pq}YX$. For two 1-forms it is an *anti*commutator: $[A, A] = 2A^2$, which is why $A^2 \neq 0$ although $\mathrm{d}x^\mu \wedge \mathrm{d}x^\mu = 0$.
- *Graded cyclicity.* $\mathrm{tr}(XY) = (-1)^{pq}\,\mathrm{tr}(YX)$.

The second rule is worth one line of proof, for two 1-forms:

$$\operatorname{tr}(XY) \overset{(1)}{=} \operatorname{tr}(X_\mu Y_\nu)\,\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu \overset{(2)}{=} \operatorname{tr}(Y_\nu X_\mu)\,\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu \overset{(3)}{=} -\operatorname{tr}(Y_\nu X_\mu)\,\mathrm{d}x^\nu \wedge \mathrm{d}x^\mu = -\operatorname{tr}(YX).$$

(1) Write out the components; the matrices and the forms are multiplied separately.
(2) Ordinary cyclicity of the matrix trace.
(3) Swap the two 1-forms: $\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu = -\mathrm{d}x^\nu \wedge \mathrm{d}x^\mu$.

In general the matrices contribute no sign and the forms contribute $(-1)^{pq}$. For example $\operatorname{tr}(A^4) = \operatorname{tr}(A \cdot A^3) = (-1)^{1\cdot 3}\operatorname{tr}(A^3 \cdot A) = -\operatorname{tr}(A^4)$, so $\operatorname{tr} A^{2k} = 0$ for every $k \geq 1$. The Leibniz rule is $\mathrm{d}(XY) = (\mathrm{d}X)Y + (-1)^p X\,\mathrm{d}Y$.

How F transforms, and the Bianchi identity. Two short chains that we use again and again:

$$\begin{aligned}
\delta_v F &\overset{(1)}{=} \mathrm{d}(\delta_v A) + (\delta_v A)A + A(\delta_v A) \\
&\overset{(2)}{=} \big(\mathrm{d}A\, v - A\,\mathrm{d}v - \mathrm{d}v\, A - v\,\mathrm{d}A\big) \\
&\qquad + \big(\mathrm{d}v\, A + AvA - vA^2\big) + \big(A\,\mathrm{d}v + A^2 v - AvA\big) \\
&\overset{(3)}{=} (\mathrm{d}A + A^2)v - v(\mathrm{d}A + A^2) = [F, v], \qquad (10.138)
\end{aligned}$$

$$\begin{aligned}
D_A F \coloneqq \mathrm{d}F + [A, F] &\overset{(4)}{=} \big(\mathrm{d}A\, A - A\,\mathrm{d}A\big) \\
&\qquad + \big(A\,\mathrm{d}A + A^3 - \mathrm{d}A\, A - A^3\big) = 0. \qquad (10.139)
\end{aligned}$$

(1) Vary $F = \mathrm{d}A + A^2$: $\delta(A^2) = (\delta A)A + A(\delta A)$ (no sign, as δ does not change form degree).
(2) Insert $\delta_v A = \mathrm{d}v + Av - vA$; use $\mathrm{d}(Av) = \mathrm{d}A\, v - A\,\mathrm{d}v$ and $\mathrm{d}(vA) = \mathrm{d}v\, A + v\,\mathrm{d}A$.
(3) The $\mathrm{d}v$ terms cancel in pairs and so do the AvA terms.
(4) $\mathrm{d}F = \mathrm{d}(A^2) = \mathrm{d}A\, A - A\,\mathrm{d}A$, and $[A, F] = AF - FA$ (a 1-form and a 2-form).

So under gauge transformations F rotates, $\delta_v F = [F, v]$, like the finite law $F \mapsto g^{-1}Fg$; it does not shift.

Invariant polynomials. The traces $\operatorname{tr} F^k$ are closed and gauge invariant:

$$\begin{aligned}
\delta_v \operatorname{tr} F^k &\overset{(1)}{=} \sum_j \operatorname{tr}\big(F^j [F, v] F^{k-1-j}\big) \overset{(2)}{=} \operatorname{tr}\big(F^k v - v F^k\big) \overset{(3)}{=} 0, \\
\mathrm{d} \operatorname{tr} F^k &\overset{(4)}{=} -\sum_j \operatorname{tr}\big(F^j [A, F] F^{k-1-j}\big) \overset{(5)}{=} -\operatorname{tr}\big(AF^k - F^k A\big) \overset{(6)}{=} 0. \qquad (10.140)
\end{aligned}$$

(1) Leibniz for δ_v and (10.138).
(2) The sum telescopes: $F^j(Fv - vF)F^{k-1-j} = F^{j+1}vF^{k-1-j} - F^j v F^{k-j}$.
(3) Cyclicity; v is a 0-form, so no sign.
(4) Bianchi (10.139): $\mathrm{d}F = -[A, F]$; F is even, so d passes it without sign.
(5) Telescoping again.
(6) Graded cyclicity: $\operatorname{tr}(F^k A) = (-1)^{2k\cdot 1}\operatorname{tr}(AF^k)$.

This is the Chern–Weil theorem in its computational form (Chapter T2): $\operatorname{tr} F^k$ defines a de Rham class, and (10.140) is why the Chern character $\operatorname{ch}(F) = \operatorname{tr}\exp(iF/2\pi)$ is built from these traces.

Worked example 10.17: SU(2) in the mathematicians' convention

Take $T^a = -\frac{i}{2}\sigma^a$. Then

$$[T^1,T^2] \overset{(1)}{=} \left(-\frac{i}{2}\right)^2 [\sigma^1,\sigma^2] \overset{(2)}{=} -\frac{1}{4}\cdot 2i\sigma^3 \overset{(3)}{=} -\frac{i}{2}\sigma^3 = T^3,$$

(1) Bilinearity of the commutator.
(2) $\sigma^1\sigma^2 = i\sigma^3 = -\sigma^2\sigma^1$, so $[\sigma^1,\sigma^2] = 2i\sigma^3$.
(3) Rewrite.

and cyclically, so $[T^a,T^b] = \epsilon^{abc}T^c$: the structure constants are $f^{abc} = \epsilon^{abc}$. With $A = A^aT^a$,

$$F = \mathrm{d}A^a\,T^a + A^bA^c\,T^bT^c = \left(\mathrm{d}A^a + \tfrac{1}{2}\epsilon^{abc}A^bA^c\right)T^a,$$

because A^bA^c is antisymmetric in b,c (two 1-forms), so only $\frac{1}{2}[T^b,T^c]$ survives. The symmetric invariant that will control the anomaly is

$$d^{abc} \coloneqq \operatorname{tr}\big(T^a\{T^b,T^c\}\big) \overset{(1)}{=} \left(-\frac{i}{2}\right)^3 \operatorname{tr}\big(\sigma^a\{\sigma^b,\sigma^c\}\big) \overset{(2)}{=} \frac{i}{8}\cdot 2\delta^{bc}\operatorname{tr}\sigma^a \overset{(3)}{=} 0.$$

(1) Factor out the constants.
(2) $\{\sigma^b,\sigma^c\} = 2\delta^{bc}\mathbf{1}$, and $(-i/2)^3 = i/8$.
(3) Pauli matrices are traceless.

We shall see that this one line is why SU(2) gauge theories never have perturbative anomalies [QFT notes (22.7.30)].

10.5.2 The consistent anomaly and the Wess–Zumino condition

Let $Z_F[A]$ be the chiral fermion integral of Section 10.2, however it is regularised, provided only that it is a genuine functional of A. Define the **consistent anomaly** as its gauge variation:

$$\mathcal{A}[v;A] \coloneqq \delta_v \ln Z_F[A] \coloneqq \frac{\mathrm{d}}{\mathrm{d}t}\ln Z_F[A+tD_Av]\Big|_{t=0} = \left\langle \int_M v^a (D_\mu J^\mu)^a \right\rangle_A, \tag{10.141}$$

the last equality being (10.27). It is linear in v, and we write $\mathcal{A}[v] = \int_M v^a\,G^a$ with $G^a(x) = \langle (D_\mu J^\mu)^a(x)\rangle$.

Step 1: gauge variations close. Think of δ_v as a vector field on the space $\mathcal{A}$ of connections, $X_v = \int (D_Av)^a_\mu\,\delta/\delta A^a_\mu$, acting on functionals $\Phi[A]$. Then for any Φ

$$\begin{aligned}
\delta_v\big(\delta_w\Phi\big) &\overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}s}\left[\int (D_{A+sD_Av}w)\cdot\frac{\delta\Phi}{\delta A}\Big|_{A+sD_Av}\right]_{s=0} \\
&\overset{(2)}{=} \int [D_Av,w]\cdot\frac{\delta\Phi}{\delta A} + \iint (D_Aw)(D_Av)\cdot\frac{\delta^2\Phi}{\delta A\,\delta A}, \\
[\delta_v,\delta_w]\Phi &\overset{(3)}{=} \int \big([D_Av,w]-[D_Aw,v]\big)\cdot\frac{\delta\Phi}{\delta A} \overset{(4)}{=} \int D_A[v,w]\cdot\frac{\delta\Phi}{\delta A} = \delta_{[v,w]}\Phi.
\end{aligned} \tag{10.142}$$

(1) $\delta_w\Phi[A] = \int (D_Aw)\cdot\delta\Phi/\delta A$ is itself a functional of A; now move A in the direction D_Av.
(2) $D_{A+sD_Av}w = D_Aw + s[D_Av,w]$; the derivative of $\delta\Phi/\delta A$ gives the second functional derivative.
(3) Antisymmetrise in $v \leftrightarrow w$; the second-derivative term is symmetric and drops out.

(4) D_A is a derivation of the bracket: $D_A[v,w] = [D_A v, w] + [v, D_A w]$, and $[v, D_A w] = -[D_A w, v]$.

This is the infinitesimal form of the group law $(A_g)_h = A_{gh}$.

Step 2: the consistency condition. Apply (10.142) to $\Phi = \ln Z_F$:

$$\delta_v \mathcal{A}[w] - \delta_w \mathcal{A}[v] \overset{(1)}{=} \delta_v \delta_w \ln Z_F - \delta_w \delta_v \ln Z_F \overset{(2)}{=} \delta_{[v,w]} \ln Z_F \overset{(3)}{=} \mathcal{A}\big[[v,w]\big]. \tag{10.143}$$

(1) Definition (10.141), for parameters v, w that do not depend on A.
(2) (10.142).
(3) Definition again.

Equation (10.143) is the **Wess–Zumino consistency condition**. It uses nothing about fermions: *any* anomaly that is the variation of *some* functional must obey it.

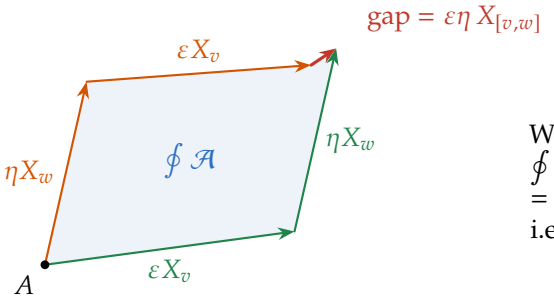
Working definition 10.7 (consistent anomaly)

A **consistent anomaly** is a local expression $\mathcal{A}[v;A] = \int_M v^a G^a(A)$ [a candidate for $\delta_v \ln Z_F$, the change of $\ln Z_F$ under the infinitesimal gauge transformation with parameter v], linear in v, built from A and its derivatives, that satisfies (10.143) [the Wess–Zumino condition $\delta_v \mathcal{A}[w] - \delta_w \mathcal{A}[v] = \mathcal{A}[[v,w]]$]. *To test a candidate:* compute $\delta_v \mathcal{A}[w] - \delta_w \mathcal{A}[v]$ using $\delta_v A = D_A v$ and $\delta_v F = [F, v]$, integrate by parts, and compare with $\mathcal{A}[[v,w]]$. It is **trivial** if $\mathcal{A}[v] = \delta_v \Phi_{\mathrm{loc}}[A]$ for a local functional Φ_{loc}; a trivial anomaly is removed by adding the counterterm [a local term added by hand, allowed because it only changes the regularisation] $-\Phi_{\mathrm{loc}}$ to $\ln Z_F$.

Geometric meaning: a closed 1-form. On a manifold, a 1-form μ and two vector fields obey $\mathrm{d}\mu(X,Y) = X\big(\mu(Y)\big) - Y\big(\mu(X)\big) - \mu([X,Y])$ (Chapter T1). Regard $\mathcal{A}$ as the 1-form on a gauge orbit whose value on the vector field X_v is $\mathcal{A}[v]$. Since $[X_v, X_w] = X_{[v,w]}$ by (10.142),

$$\mathrm{d}\mathcal{A}(X_v, X_w) = \delta_v \mathcal{A}[w] - \delta_w \mathcal{A}[v] - \mathcal{A}\big[[v,w]\big],$$

so *the Wess–Zumino condition says the anomaly is a closed* 1*-form on the gauge orbit*. A trivial anomaly is an *exact* one, $\mathcal{A} = \mathrm{d}\Phi_{\mathrm{loc}}$. This is precisely the cohomological statement of Nash [Nash p. 273]: the variation of $\ln Z_F$ "can be identified with an element of $H^1_{\mathrm{dR}}(\mathcal{G})$"; we return to it in Section 10.6.2.



Wess–Zumino:
$\oint \mathcal{A}$ round the small loop
$= \mathcal{A}$ along the gap,
i.e. $\mathrm{d}\mathcal{A} = 0$ on the orbit.

Figure 10.15: Two infinitesimal gauge transformations done in the two possible orders. The end points differ by the gauge transformation $[v,w]$ (red), because gauge transformations do not commute. The change of $\ln Z_F$ must be the same along both routes plus the gap; that bookkeeping is the Wess–Zumino condition (10.143).

Worked example 10.18: The covariant anomaly is not consistent

In two dimensions the covariant anomaly of (10.135) is $\mathcal{A}_{\mathrm{cov}}[v] = \frac{i}{2\pi}\int_M \mathrm{tr}(vF)$. Test it:

$$\delta_w \mathcal{A}_{\mathrm{cov}}[v] \overset{(1)}{=} \frac{i}{2\pi}\int \mathrm{tr}\big(v[F,w]\big) \overset{(2)}{=} \frac{i}{2\pi}\int \mathrm{tr}\big(vFw - vwF\big) \overset{(3)}{=} \frac{i}{2\pi}\int \mathrm{tr}\big([w,v]F\big),$$

$$\delta_v \mathcal{A}_{\mathrm{cov}}[w] - \delta_w \mathcal{A}_{\mathrm{cov}}[v] \overset{(4)}{=} \frac{i}{2\pi}\int \mathrm{tr}\big([v,w]F - [w,v]F\big)$$

$$\overset{(5)}{=} 2\cdot\frac{i}{2\pi}\int \mathrm{tr}\big([v,w]F\big) = 2\,\mathcal{A}_{\mathrm{cov}}\big[[v,w]\big].$$

(1) v does not depend on A; only F varies, by (10.138).
(2) Expand the commutator.
(3) Cyclicity: $\mathrm{tr}(vFw) = \mathrm{tr}(wvF)$.
(4) Use line 3 twice, with $v \leftrightarrow w$.
(5) $[w,v] = -[v,w]$.

The left side is *twice* the right side of (10.143). For G abelian both sides are zero and there is no contradiction; for non-abelian G the covariant anomaly cannot be the variation of any functional. It is not wrong: it is the divergence of a different current (the covariant current, which is not $\delta \ln Z_F/\delta A$).

Worked example 10.19: A consistent anomaly in two dimensions

Now test $\mathcal{A}_2[v] = \frac{i}{4\pi}\int_M \mathrm{tr}(v\,\mathrm{d}A)$. Since $\mathrm{d}\mathrm{d}w = 0$, $\delta_w(\mathrm{d}A) = \mathrm{d}[A,w]$. First, a useful integration by parts: for 0-forms v, w,

$$\int \mathrm{tr}\big(w\{A,\mathrm{d}v\}\big) \overset{(1)}{=} \int \big[\mathrm{tr}(\mathrm{d}w\,A\,v) - \mathrm{tr}(\mathrm{d}w\,v\,A)\big] + \int \big[\mathrm{tr}(w\,\mathrm{d}A\,v) - \mathrm{tr}(w\,v\,\mathrm{d}A)\big]$$

$$\overset{(2)}{=} \int \mathrm{tr}\big(v\{A,\mathrm{d}w\}\big) + \int \mathrm{tr}\big([v,w]\,\mathrm{d}A\big). \tag{10.144}$$

(1) $\{A,\mathrm{d}v\} = A\,\mathrm{d}v + \mathrm{d}v\,A$ (graded commutator of two 1-forms). Integrate each term by parts using the Leibniz rule: $\mathrm{d}\,\mathrm{tr}(wAv) = \mathrm{tr}(\mathrm{d}w\,Av) + \mathrm{tr}(w\,\mathrm{d}A\,v) - \mathrm{tr}(wA\,\mathrm{d}v)$ and $\mathrm{d}\,\mathrm{tr}(wvA) = \mathrm{tr}(\mathrm{d}w\,vA) + \mathrm{tr}(w\,\mathrm{d}v\,A) + \mathrm{tr}(wv\,\mathrm{d}A)$; total derivatives integrate to zero on closed M (Stokes).
(2) Cyclicity: $\mathrm{tr}(\mathrm{d}w\,Av) = \mathrm{tr}(v\,\mathrm{d}w\,A)$ and $\mathrm{tr}(\mathrm{d}w\,vA) = -\mathrm{tr}(A\,\mathrm{d}w\,v) = -\mathrm{tr}(vA\,\mathrm{d}w)$ (moving the 1-form A past the 1-form $\mathrm{d}w\,v$); and $\mathrm{tr}(w\,\mathrm{d}A\,v) - \mathrm{tr}(wv\,\mathrm{d}A) = \mathrm{tr}((vw-wv)\mathrm{d}A)$.

Next, expand the variation:

$$\mathrm{tr}\big(v\,\mathrm{d}[A,w]\big) \overset{(1)}{=} \mathrm{tr}\big(v(\mathrm{d}A\,w - A\,\mathrm{d}w - \mathrm{d}w\,A - w\,\mathrm{d}A)\big) \overset{(2)}{=} \mathrm{tr}\big([w,v]\mathrm{d}A\big) - \mathrm{tr}\big(v\{A,\mathrm{d}w\}\big).$$

(1) Leibniz: $\mathrm{d}(Aw) = \mathrm{d}A\,w - A\,\mathrm{d}w$ and $\mathrm{d}(wA) = \mathrm{d}w\,A + w\,\mathrm{d}A$.
(2) $\mathrm{tr}(v\,\mathrm{d}A\,w) = \mathrm{tr}(wv\,\mathrm{d}A)$ by cyclicity; collect.

So $\delta_w\mathcal{A}_2[v] = \frac{i}{4\pi}\int[\mathrm{tr}([w,v]\mathrm{d}A) - \mathrm{tr}(v\{A,\mathrm{d}w\})]$, and

$$\delta_v\mathcal{A}_2[w] - \delta_w\mathcal{A}_2[v] \overset{(1)}{=} \frac{i}{4\pi}\int\Big[2\,\mathrm{tr}([v,w]\mathrm{d}A) - \mathrm{tr}(w\{A,\mathrm{d}v\}) + \mathrm{tr}(v\{A,\mathrm{d}w\})\Big]$$

$$\overset{(2)}{=} \frac{i}{4\pi}\int\Big[2\,\mathrm{tr}([v,w]\mathrm{d}A) - \mathrm{tr}([v,w]\mathrm{d}A)\Big]$$

$$= \frac{i}{4\pi}\int \mathrm{tr}\big([v,w]\mathrm{d}A\big) = \mathcal{A}_2\big[[v,w]\big].$$

(1) The previous line with $v \leftrightarrow w$, subtracted; $[w,v] \to [v,w]$ gives the factor 2.
(2) (10.144).

It passes. Note what happened: $\mathcal{A}_2$ is *not* gauge covariant (dA is not F), and that is the price of consistency. In the abelian case $\mathcal{A}_2 = \frac{1}{2}\mathcal{A}_{\text{cov}}$.

10.5.3 Consistent versus covariant: Bose symmetry fixes the factor

Why should the consistent anomaly be *half* of the covariant one in two dimensions? Because in the consistent version every current in a correlation function is treated alike. We check this against explicit graphs in two and four dimensions.

Worked example 10.20: The chiral Schwinger model: one Weyl fermion in two dimensions

Use the Minkowski conventions of (10.44) and couple only the positive-chirality current $j_R^\mu := j_+^\mu = \frac{1}{2}(j^\mu + j_5^\mu)$ of (10.28) to A, with interaction $-eA_\mu j_R^\mu$. (Subscript R is the chirality; superscripts ± below are light-cone components.)
Light-cone components. For a vector V put $V^\pm = V^0 \pm V^1$ and $V_\pm = \frac{1}{2}(V_0 \pm V_1)$. Then

$$V\cdot W = V^0W^0 - V^1W^1 \overset{(1)}{=} \tfrac{1}{2}\big(V^+W^- + V^-W^+\big) \overset{(2)}{=} V_+W^+ + V_-W^-,$$
$$\epsilon^{\mu\nu}q_\mu A_\nu = q_0A_1 - q_1A_0 \overset{(3)}{=} 2\big(q_-A_+ - q_+A_-\big), \qquad q^\mu A_\mu \overset{(4)}{=} 2\big(q_-A_+ + q_+A_-\big).$$

(1) Expand $(V^0+V^1)(W^0-W^1) + (V^0-V^1)(W^0+W^1) = 2(V^0W^0 - V^1W^1)$.
(2) $V_\pm = \frac{1}{2}(V_0 \pm V_1) = \frac{1}{2}(V^0 \mp V^1) = \frac{1}{2}V^\mp$, using $V_1 = -V^1$.
(3) Substitute $q_0 = q_+ + q_-$, $q_1 = q_+ - q_-$ and similarly for A, and expand.
(4) Line (2) with $V = q$, $W = A$ read the other way round: $q^\mu A_\mu = q_+A^+ + q_-A^-$, and $A^\pm = 2A_\mp$.

In this basis $\eta^{++} = \eta^{--} = 0$, $\eta^{+-} = \eta^{-+} = 2$, and $q^2 = q^+q^-$.
Only one component couples. From $j_5^\mu = -\epsilon^{\mu\nu}j_\nu$ (10.45), $j_5^0 = -\epsilon^{01}j_1 = j^1$ and $j_5^1 = -\epsilon^{10}j_0 = j^0$, so

$$j_5^+ = j^1 + j^0 = j^+, \qquad j_5^- = j^1 - j^0 = -j^-, \qquad \text{hence} \qquad j_R^+ = j^+, \quad j_R^- = 0.$$

The chiral current has a single light-cone component, and the interaction is $-eA_\mu j_R^\mu = -eA_+j^+$. This is the interaction of an ordinary *Dirac* fermion in the background $\hat{A}$ with $\hat{A}_+ = A_+$, $\hat{A}_- = 0$: the negative-chirality fermions do not see $\hat{A}$ at all.
The induced current. So we may borrow the Dirac vacuum polarisation (10.46) with its unknown a:

$$\langle j_R^+\rangle \overset{(1)}{=} -\frac{1}{e}\,\Pi^{+\nu}\hat{A}_\nu \overset{(2)}{=} -\frac{1}{e}\,\Pi^{++}A_+ \overset{(3)}{=} -\frac{1}{e}\Big(\mathsf{a}\,\eta^{++} - \mathsf{b}\,\frac{q^+q^+}{q^+q^-}\Big)A_+ \overset{(4)}{=} \frac{\mathsf{b}}{e}\,\frac{q^+}{q^-}\,A_+.$$

(1) Linear response, as in Section 10.3.3.
(2) $\hat{A}_- = 0$, and $\Pi^{+\nu}\hat{A}_\nu = \Pi^{++}\hat{A}_+ + \Pi^{+-}\hat{A}_-$.
(3) (10.46) in light-cone components.
(4) $\eta^{++} = 0$: *the ambiguous coefficient* a *drops out*.

Because this current is the functional derivative of the (unambiguous) effective action of A_+, it is the consistent current. Its divergence is

$$q_\mu\langle j_R^\mu\rangle \overset{(1)}{=} q_+\langle j_R^+\rangle \overset{(2)}{=} \frac{q^-}{2}\,\frac{\mathsf{b}}{e}\,\frac{q^+}{q^-}A_+ \overset{(3)}{=} \frac{\mathsf{b}}{e}\,q_-A_+ \overset{(4)}{=} \frac{e}{4\pi}\big(\epsilon^{\mu\nu}q_\mu A_\nu + q^\mu A_\mu\big).$$

(1) $q \cdot j = q_+ j^+ + q_- j^-$ and $j_R^- = 0$.
(2) $q_+ = \frac{1}{2} q^-$.
(3) $q^+ = 2 q_-$.
(4) Add the two light-cone formulas: $\epsilon q A + q \cdot A = 4 q_- A_+$; and $\mathsf{b} = e^2/\pi$ (Example 10.10).

Compare with the covariant anomaly. The gauge-invariant Dirac scheme $\mathsf{a} = \mathsf{b}$ gives $q \cdot \langle j \rangle = 0$ and $q \cdot \langle j_5 \rangle = \frac{\mathsf{b}}{e} \epsilon q A$ (10.47), so $q \cdot \langle j_R \rangle_{\text{cov}} = \frac{1}{2}(0 + \frac{\mathsf{b}}{e} \epsilon q A) = \frac{e}{2\pi} \epsilon q A$. The two results differ in two ways.

- The term $\frac{e}{4\pi} q^\mu A_\mu$ is *trivial*: under $\delta A_\mu = \partial_\mu \lambda$ the local functional $\int A_\mu A^\mu$ changes by $2 \int A^\mu \partial_\mu \lambda = -2 \int \lambda \, \partial \cdot A$, so a counterterm $c \int A_\mu A^\mu$ with suitable real c removes it. (It uses A_-, which the fermions do not see but which is part of the gauge field.)
- The term $\frac{e}{4\pi} \epsilon^{\mu\nu} q_\mu A_\nu$ is *not* removable: the only local, Lorentz-invariant quadratic functionals of A of the right dimension are $\int A_\mu A^\mu$ and $\int \epsilon^{\mu\nu} A_\mu A_\nu = 0$.

So, after the best local counterterm,

$$\partial_\mu \langle j_R^\mu \rangle_{\text{consistent}} = \frac{1}{2} \partial_\mu \langle j_R^\mu \rangle_{\text{cov}} = \frac{e}{4\pi} \epsilon^{\mu\nu} \partial_\mu A_\nu .$$

The mechanism is visible in the graph: the vacuum polarisation has *two* identical chiral vertices, and the non-removable part of the anomaly is shared equally between them.

Worked example 10.21: The factor $\frac{1}{3}$ from the triangle budget

In four dimensions, couple a single Weyl fermion to a U(1) field through $\gamma^\mu P_+$ at every vertex. In a triangle,

$$\begin{aligned} \gamma^\lambda P_+ S(p_1) \gamma^\nu P_+ S(p_2) \gamma^\mu P_+ S(p_3) &\overset{(1)}{=} \gamma^\lambda S(p_1) P_- \gamma^\nu P_+ S(p_2) \gamma^\mu P_+ S(p_3) \\ &\overset{(2)}{=} \gamma^\lambda S(p_1) \gamma^\nu P_+ S(p_2) \gamma^\mu P_+ S(p_3) \\ &\overset{(3)}{=} \gamma^\lambda S(p_1) \gamma^\nu S(p_2) \gamma^\mu S(p_3) \, P_- \\ &\to \tfrac{1}{2}[\text{vector}] - \tfrac{1}{2}[\text{one-}\gamma^5]. \end{aligned}$$

(1) $S(p) = \not{p}/p^2$ contains one γ, so $P_+ S = S P_-$.
(2) $P_- \gamma^\nu = \gamma^\nu P_+$, and $P_+^2 = P_+$.
(3) Repeat to push all projectors to the right; they collapse to one $P_- = \frac{1}{2}(1 - \gamma^5)$ (a single $P_\pm$ in either case; which one depends on the position we push to).

So the part that can be anomalous is $\frac{1}{2}$ of the one-γ^5 triangle $T^{\mu\nu\lambda}$ of (10.79), with the γ^5 now at no preferred vertex. In (10.96) write each vertex's anomaly in a common form: with all momenta incoming (q at the axial vertex, $-k_1$ and $-k_2$ at the others), the divergence at vertex i is $c_i \, \epsilon^{(\cdot)(\cdot)\rho\sigma} p_{j\rho} p_{k\sigma}$ with (i, j, k) cyclic. Then

$$c_0 \overset{(1)}{=} \frac{1-\beta}{4\pi^2}, \qquad c_1 = c_2 \overset{(2)}{=} \frac{1+\beta}{8\pi^2}, \qquad c_0 + c_1 + c_2 \overset{(3)}{=} \frac{1}{2\pi^2} \quad \text{for every } \beta.$$

(1) The first line of (10.96).
(2) The second line of (10.96), times -1 for the incoming momentum $-k_1$, with $\epsilon^{\nu\lambda\rho\sigma}(-k_2)_\rho q_\sigma = \epsilon^{\nu\lambda\rho\sigma} k_{1\rho} k_{2\sigma}$; vertex 2 by the photon-exchange symmetry.
(3) $\frac{2(1-\beta)+(1+\beta)+(1+\beta)}{8\pi^2} = \frac{4}{8\pi^2}$.

The total is the *anomaly budget*; routing only redistributes it. The covariant (and ABJ) answer puts it all on one vertex ($\beta = -1$: $c_0 = \frac{1}{2\pi^2}$). With three identical chiral currents, Bose symmetry demands $c_0 = c_1 = c_2$, i.e. $\beta = \frac{1}{3}$, and each vertex gets $\frac{1}{6\pi^2}$:

$$\frac{\text{consistent}}{\text{covariant}} = \frac{c_0(\beta = \frac{1}{3})}{c_0(\beta = -1)} = \frac{1/6\pi^2}{1/2\pi^2} = \frac{1}{3}.$$

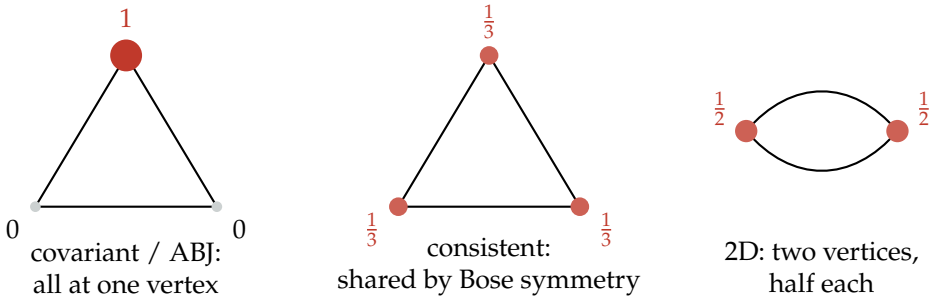


Figure 10.16: The anomaly budget of a one-loop polygon, drawn as the size of the red dot at each current vertex. The total is fixed and regulator independent. The covariant anomaly asks for all of it at the vertex we are looking at. A genuine effective action treats identical currents alike, so the $m+1$ vertices of the relevant polygon in $2m$ dimensions share it equally: the consistent anomaly is $\frac{1}{m+1}$ of the covariant one.

Key idea: Consistent = $\frac{1}{m+1}\times$ covariant, for U(1)

In $2m$ dimensions the anomaly of a U(1) Weyl fermion comes from the one-loop polygon with $m+1$ current vertices: the smallest loop with enough γ-matrices to produce $\epsilon^{\mu_1\cdots\mu_{2m}}$, with superficial degree of divergence $2m-(m+1) = m-1$ (logarithmic in two dimensions, linear in four). The covariant anomaly is the whole budget at one vertex; the consistent anomaly is the Bose-symmetric share, $\frac{1}{m+1}$ of it. For non-abelian G the two differ also in their A-dependence, as Examples 10.18 and 10.19 show, and the consistent one is found by descent.

10.5.4 Chern–Simons forms

The closed forms $\operatorname{tr} F^k$ of (10.140) are *locally exact*: on any region where A is a globally defined 1-form (for instance on all of $\mathbb{R}^n$, or on a ball) there is an explicit $(2k-1)$-form $Q_{2k-1}(A)$ with $\mathrm{d}Q_{2k-1} = \operatorname{tr} F^k$. It is found by switching the gauge field on slowly. Let

$$A_t := tA, \qquad F_t := F(A_t) = t\,\mathrm{d}A + t^2A^2, \qquad 0 \le t \le 1,$$

so $F_0 = 0$ and $F_1 = F$. Then

$$\begin{aligned}
\frac{\mathrm{d}F_t}{\mathrm{d}t} &\overset{(1)}{=} \mathrm{d}A + 2tA^2 \overset{(2)}{=} D_tA, \qquad D_t := D_{A_t} = \mathrm{d} + [tA, \cdot\,], \\
\frac{\mathrm{d}}{\mathrm{d}t}\operatorname{tr} F_t^k &\overset{(3)}{=} k\,\operatorname{tr}\Big(\frac{\mathrm{d}F_t}{\mathrm{d}t}F_t^{k-1}\Big) \overset{(4)}{=} k\,\operatorname{tr}\big((D_tA)F_t^{k-1}\big) \overset{(5)}{=} k\,\mathrm{d}\operatorname{tr}\big(AF_t^{k-1}\big), \\
\operatorname{tr} F^k &\overset{(6)}{=} \int_0^1 \mathrm{d}t\,\frac{\mathrm{d}}{\mathrm{d}t}\operatorname{tr} F_t^k \overset{(7)}{=} \mathrm{d}Q_{2k-1}(A), \qquad Q_{2k-1}(A) := k\int_0^1 \mathrm{d}t\,\operatorname{tr}\big(A\,F_t^{k-1}\big).
\end{aligned} \tag{10.145}$$

(1) Differentiate $t\,\mathrm{d}A + t^2A^2$.

(2) $[tA, A] = t(AA + AA) = 2tA^2$ (graded commutator of 1-forms).
(3) Leibniz, and cyclicity to bring each $\dot{F}_t$ to the front (F_t is even: no signs).
(4) Line 1.
(5) $\mathrm{d}\,\mathrm{tr}(X) = \mathrm{tr}(D_t X)$ for any matrix-valued form (the commutator part is traceless), then Leibniz for D_t: $D_t(AF_t^{k-1}) = (D_tA)F_t^{k-1} - A\,D_t(F_t^{k-1})$, and the Bianchi identity $D_tF_t = 0$.
(6) $F_0 = 0$ and $\mathrm{tr}\,F_0^k = 0$.
(7) Line 5 integrated; d commutes with $\int \mathrm{d}t$.

Q_{2k-1} is the **Chern–Simons form**. Two cases by hand.

Worked example 10.22: Q_3 and Q_5

$k = 2$.

$$Q_3 = 2\int_0^1 \mathrm{d}t\ \mathrm{tr}\big(A(t\,\mathrm{d}A + t^2A^2)\big) \overset{(1)}{=} 2\Big[\tfrac{1}{2}\mathrm{tr}(A\,\mathrm{d}A) + \tfrac{1}{3}\mathrm{tr}\,A^3\Big] = \mathrm{tr}\Big(A\,\mathrm{d}A + \tfrac{2}{3}A^3\Big).$$

(1) $\int_0^1 t\,\mathrm{d}t = \frac{1}{2}$, $\int_0^1 t^2\mathrm{d}t = \frac{1}{3}$.

Check: $\mathrm{d}\,\mathrm{tr}(A\,\mathrm{d}A) = \mathrm{tr}(\mathrm{d}A\,\mathrm{d}A)$, and $\mathrm{d}\,\mathrm{tr}\,A^3 = \mathrm{tr}(\mathrm{d}A\,A^2) - \mathrm{tr}(A\,\mathrm{d}A\,A) + \mathrm{tr}(A^2\mathrm{d}A) = 3\,\mathrm{tr}(\mathrm{d}A\,A^2)$ (move the lone A in the middle term to the end, sign $(-1)^{1\cdot3}$; move $\mathrm{d}A$ in the last to the front, sign +). So $\mathrm{d}Q_3 = \mathrm{tr}(\mathrm{d}A)^2 + 2\,\mathrm{tr}(\mathrm{d}A\,A^2)$. On the other hand $\mathrm{tr}\,F^2 = \mathrm{tr}(\mathrm{d}A)^2 + \mathrm{tr}(\mathrm{d}A\,A^2) + \mathrm{tr}(A^2\mathrm{d}A) + \mathrm{tr}\,A^4 = \mathrm{tr}(\mathrm{d}A)^2 + 2\,\mathrm{tr}(\mathrm{d}A\,A^2)$, since $\mathrm{tr}\,A^4 = 0$. They agree.

$k = 3$. Expand $F_t^2 = t^2(\mathrm{d}A)^2 + t^3(\mathrm{d}A\,A^2 + A^2\mathrm{d}A) + t^4A^4$. Then

$$\begin{aligned}\mathrm{tr}(AF_t^2) &\overset{(1)}{=} t^2\,\mathrm{tr}\big(A(\mathrm{d}A)^2\big) + t^3\big[\mathrm{tr}(A\,\mathrm{d}A\,A^2) + \mathrm{tr}(A^3\mathrm{d}A)\big] + t^4\,\mathrm{tr}\,A^5\\ &\overset{(2)}{=} t^2\,\mathrm{tr}\big(A(\mathrm{d}A)^2\big) + 2t^3\,\mathrm{tr}(A^3\mathrm{d}A) + t^4\,\mathrm{tr}\,A^5,\end{aligned}$$

$$Q_5 = 3\int_0^1 \mathrm{d}t\ \mathrm{tr}(AF_t^2) \overset{(3)}{=} \mathrm{tr}\Big(A(\mathrm{d}A)^2 + \tfrac{3}{2}A^3\mathrm{d}A + \tfrac{3}{5}A^5\Big).$$

(1) Multiply out.
(2) $\mathrm{tr}(A\,\mathrm{d}A\,A^2) = \mathrm{tr}(A^2\cdot A\,\mathrm{d}A)$: moving the even form A^2 from the back to the front costs no sign.
(3) $3\cdot\frac{1}{3} = 1$, $3\cdot2\cdot\frac{1}{4} = \frac{3}{2}$, $3\cdot\frac{1}{5} = \frac{3}{5}$.

Worked example 10.23: A pure gauge counts windings

If $A = g^{-1}\mathrm{d}g$ then $F = 0$, so $\mathrm{d}Q_3 = 0$, but Q_3 need not be exact. With $\mathrm{d}(g^{-1}\mathrm{d}g) = -g^{-1}\mathrm{d}g\,g^{-1}\mathrm{d}g = -A^2$ (from $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\,g^{-1}$),

$$Q_3(g^{-1}\mathrm{d}g) = \mathrm{tr}\big(A(-A^2) + \tfrac{2}{3}A^3\big) = -\tfrac{1}{3}\,\mathrm{tr}\big(g^{-1}\mathrm{d}g\big)^3.$$

For $g : S^3 \to \mathrm{SU}(2)$, $\frac{1}{24\pi^2}\int_{S^3}\mathrm{tr}(g^{-1}\mathrm{d}g)^3$ is (up to sign) the winding number, an integer (Chapter 8). So a Chern–Simons form evaluated on a gauge transformation measures $\pi_3(G)$. In the same way $Q_5(g^{-1}\mathrm{d}g) = \frac{1}{10}\,\mathrm{tr}(g^{-1}\mathrm{d}g)^5$ measures $\pi_5(G)$, the group that appears in Nash's (10.18). (For the last formula: with $A = g^{-1}\mathrm{d}g$, $\mathrm{d}A = -A^2$, so $Q_5 = \mathrm{tr}(A^5 - \frac{3}{2}A^5 + \frac{3}{5}A^5) = \frac{10-15+6}{10}\,\mathrm{tr}\,A^5 = \frac{1}{10}\,\mathrm{tr}\,A^5$.)

10.5.5 The Stora–Zumino descent equations

Here is the construction that turns a characteristic class in dimension $2m+2$ into an anomaly in dimension $2m$. Start with

$$\Omega_{2m+2} \coloneqq \mathrm{ch}_{m+1}(F) = \frac{1}{(m+1)!}\Big(\frac{i}{2\pi}\Big)^{m+1} \operatorname{tr} F^{m+1}, \tag{10.146}$$

a closed, gauge-invariant $(2m+2)$-form built from A. (It is a form on an imagined $(2m+2)$-dimensional space; on our $2m$-dimensional M it vanishes identically, but its *algebraic* structure is what matters.)

1. *Descent 1.* $\Omega_{2m+2} = \mathrm{d}\omega^0_{2m+1}$ with $\omega^0_{2m+1} = \frac{1}{(m+1)!}(\frac{i}{2\pi})^{m+1} Q_{2m+1}(A)$, by (10.145).

2. *Descent 2.* $\mathrm{d}(\delta_v \omega^0_{2m+1}) = \delta_v \Omega_{2m+2} = 0$ by (10.140) (and δ_v commutes with d). A closed form built polynomially from A, v and their derivatives is exact in the same class of forms (the algebraic Poincaré lemma), so

$$\delta_v \omega^0_{2m+1} = \mathrm{d}\omega^1_{2m}(v, A),$$

   with ω^1_{2m} a $2m$-form, linear in v.

3. *The anomaly.* $\int_M \omega^1_{2m}(v, A)$ is a consistent anomaly on the $2m$-dimensional M.

The superscript counts the number of gauge parameters; the subscript is the form degree. The pattern (one more δ, one less form degree) is the **descent**.

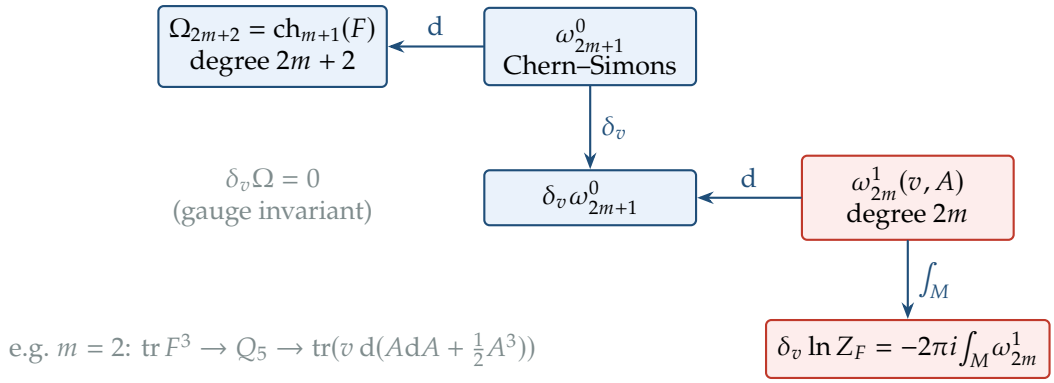

Figure 10.17: The descent ladder. Moving right lowers the form degree by one (d^{-1}); moving down applies one gauge variation. The anomaly in $2m$ dimensions is two steps from the characteristic class in $2m+2$ dimensions.

Step 1: how a Chern–Simons form varies under an arbitrary δA. We need a formula for δQ_{2k-1} valid for any variation, and then specialise to $\delta A = D_A v$. With $F_t = F(tA)$, $\delta F_t = D_t(t\,\delta A)$. We claim

$$\delta Q_{2k-1} = k\,\operatorname{tr}\big(\delta A\, F^{k-1}\big) - \mathrm{d}\Big[k \int_0^1 \mathrm{d}t\; t \sum_{j=0}^{k-2} \operatorname{tr}\big(A\, F_t^j\, \delta A\, F_t^{k-2-j}\big)\Big]. \tag{10.147}$$

Derivation: vary the integrand of (10.145),

$$\begin{aligned}
\delta \operatorname{tr}(A F_t^{k-1}) &\overset{(1)}{=} \operatorname{tr}(\delta A\, F_t^{k-1}) + t \sum_j \operatorname{tr}\big(A F_t^{j} (D_t \delta A) F_t^{k-2-j}\big) \\
&\overset{(2)}{=} \operatorname{tr}(\delta A\, F_t^{k-1}) + t \sum_j \operatorname{tr}\big((D_t A) F_t^{j}\, \delta A\, F_t^{k-2-j}\big) - t\, \mathrm{d} \sum_j \operatorname{tr}\big(A F_t^{j}\, \delta A\, F_t^{k-2-j}\big) \\
&\overset{(3)}{=} \operatorname{tr}(\delta A\, F_t^{k-1}) + t \sum_j \operatorname{tr}\big(\delta A\, F_t^{j}\, \dot F_t\, F_t^{k-2-j}\big) - t\, \mathrm{d} \sum_j \operatorname{tr}\big(A F_t^{j}\, \delta A\, F_t^{k-2-j}\big) \\
&\overset{(4)}{=} \frac{\mathrm{d}}{\mathrm{d}t}\Big[t\ \operatorname{tr}\big(\delta A\, F_t^{k-1}\big)\Big] - t\, \mathrm{d} \sum_j \operatorname{tr}\big(A F_t^{j}\, \delta A\, F_t^{k-2-j}\big).
\end{aligned}$$

(1) Leibniz; $\delta F_t = t\, D_t \delta A$.

(2) Integrate D_t by parts inside the trace: $\mathrm{d}\operatorname{tr}(A F_t^j \delta A F_t^{k-2-j}) = \operatorname{tr}((D_t A) F_t^j \delta A F_t^{k-2-j}) - \operatorname{tr}(A F_t^j (D_t \delta A) F_t^{k-2-j})$, using $D_t F_t = 0$; the sign is that of moving D_t past the 1-form A.

(3) $D_t A = \dot F_t$ from (10.145); then cyclically move the odd block $\delta A\, F_t^{k-2-j}$ to the front past the even block $\dot F_t F_t^j$ (no sign), and relabel $j \to k-2-j$.

(4) $\frac{\mathrm{d}}{\mathrm{d}t}[t \operatorname{tr}(\delta A F_t^{k-1})] = \operatorname{tr}(\delta A F_t^{k-1}) + t \sum_j \operatorname{tr}(\delta A\, F_t^j \dot F_t F_t^{k-2-j})$.

Multiplying by k and integrating over $t \in [0,1]$ (the boundary term is $1 \cdot \operatorname{tr}(\delta A F^{k-1}) - 0$) gives (10.147). For $k=2$ it reads $\delta Q_3 = 2\operatorname{tr}(\delta A\, F) - \mathrm{d}\operatorname{tr}(A\,\delta A)$, which one can confirm directly from $Q_3 = \operatorname{tr}(A\mathrm{d}A + \frac{2}{3}A^3)$.

Step 2: specialise to a gauge variation. For $\delta A = D_A v$ the first term is exact:

$$\operatorname{tr}\big((D_A v) F^{k-1}\big) \overset{(1)}{=} \operatorname{tr}\big(D_A (v F^{k-1})\big) \overset{(2)}{=} \mathrm{d}\operatorname{tr}\big(v F^{k-1}\big).$$

(1) Leibniz for D_A and Bianchi $D_A F = 0$.

(2) The trace of a commutator $[A, X]$ vanishes by graded cyclicity.

Hence $\delta_v Q_{2k-1} = \mathrm{d} Q^1_{2k-2}$ with

$$Q^1_{2k-2}(v, A) = k\ \operatorname{tr}\big(v F^{k-1}\big) - k \int_0^1 \mathrm{d}t\ t \sum_{j=0}^{k-2} \operatorname{tr}\big(A\, F_t^{j}\, (D_A v)\, F_t^{k-2-j}\big) \quad (\text{mod d-exact}). \tag{10.148}$$

Worked example 10.24: Descent in two dimensions: $\operatorname{tr} F^2 \to Q_3 \to \operatorname{tr}(v\,\mathrm{d}A)$

Put $k=2$ in (10.148):

$$\begin{aligned}
Q_2^1 &\overset{(1)}{=} 2\operatorname{tr}(vF) - 2\int_0^1 t\,\mathrm{d}t\ \ \operatorname{tr}(A\, D_A v) \overset{(2)}{=} 2\operatorname{tr}(v\,\mathrm{d}A) + 2\operatorname{tr}(vA^2) - \operatorname{tr}(A\,\mathrm{d}v) - \operatorname{tr}(A[A,v]) \\
&\overset{(3)}{=} 2\operatorname{tr}(v\,\mathrm{d}A) + 2\operatorname{tr}(vA^2) - \operatorname{tr}(A\,\mathrm{d}v) - 2\operatorname{tr}(vA^2) \overset{(4)}{=} 2\operatorname{tr}(v\,\mathrm{d}A) - \operatorname{tr}(v\,\mathrm{d}A) + \mathrm{d}\operatorname{tr}(vA) \\
&\equiv \operatorname{tr}(v\,\mathrm{d}A) \quad (\text{mod d-exact}).
\end{aligned}$$

(1) (10.148); the sum has the single term $j=0$.

(2) $F = \mathrm{d}A + A^2$, $\int_0^1 t\,\mathrm{d}t = \frac{1}{2}$, $D_A v = \mathrm{d}v + [A, v]$.

(3) $\operatorname{tr}(A[A,v]) = \operatorname{tr}(A^2 v) - \operatorname{tr}(AvA)$ and $\operatorname{tr}(AvA) = -\operatorname{tr}(A^2 v)$ (move the last A to the front past the 1-form Av), so $\operatorname{tr}(A[A,v]) = 2\operatorname{tr}(vA^2)$.

(4) $\mathrm{d}\,\mathrm{tr}(vA) = \mathrm{tr}(\mathrm{d}v\,A) + \mathrm{tr}(v\,\mathrm{d}A)$ and $\mathrm{tr}(A\,\mathrm{d}v) = -\mathrm{tr}(\mathrm{d}v\,A)$, so $\mathrm{tr}(A\,\mathrm{d}v) = \mathrm{tr}(v\,\mathrm{d}A) - \mathrm{d}\,\mathrm{tr}(vA)$.

Therefore

$$\omega_2^1 = \frac{1}{2}\Big(\frac{i}{2\pi}\Big)^2 \mathrm{tr}(v\,\mathrm{d}A) = -\frac{1}{8\pi^2}\,\mathrm{tr}(v\,\mathrm{d}A), \qquad -2\pi i\int_M \omega_2^1 = \frac{i}{4\pi}\int_M \mathrm{tr}(v\,\mathrm{d}A),$$

which is exactly the consistent anomaly $\mathcal{A}_2$ of Example 10.19. For U(1) ($A = -ie\,a$, $v = -ie\lambda$) this is $\frac{i}{4\pi}(-ie)^2\int \lambda\,\mathrm{d}a = -\frac{ie^2}{4\pi}\int \lambda\,\mathrm{d}a$, half of the covariant $\frac{i}{2\pi}\int \mathrm{tr}(vF) = -\frac{ie^2}{2\pi}\int \lambda\,\mathrm{d}a$, as the chiral Schwinger model demanded.

Worked example 10.25: Descent in four dimensions: $\mathrm{tr}\,F^3 \to Q_5 \to \mathrm{tr}(v\,\mathrm{d}(A\mathrm{d}A + \frac{1}{2}A^3))$

Put $k = 3$ in (10.148) and write $X := D_A v = \mathrm{d}v + Av - vA$. With $F_t = t\,\mathrm{d}A + t^2A^2$ and $\int_0^1 t^2\mathrm{d}t = \frac{1}{3}$, $\int_0^1 t^3\mathrm{d}t = \frac{1}{4}$,

$$Q_4^1 = \underbrace{3\,\mathrm{tr}(vF^2)}_{\text{(i)}} - \underbrace{\big[\mathrm{tr}(AX\mathrm{d}A) + \mathrm{tr}(A\,\mathrm{d}A\,X)\big]}_{\text{(ii)}} - \tfrac{3}{4}\underbrace{\big[\mathrm{tr}(AXA^2) + \mathrm{tr}(A^3X)\big]}_{\text{(iii)}}.$$

We bring every term to the form $\mathrm{tr}(v\cdots)$, working modulo exact forms, and use $\int \mathrm{tr}(\mathrm{d}v\,Y) = -\int \mathrm{tr}(v\,\mathrm{d}Y)$ for a 3-form Y (Leibniz and Stokes).

Term (i). $3\,\mathrm{tr}(vF^2) = 3\,\mathrm{tr}\big(v(\mathrm{d}A)^2\big) + 3\,\mathrm{tr}(v\,\mathrm{d}A\,A^2) + 3\,\mathrm{tr}(vA^2\mathrm{d}A) + 3\,\mathrm{tr}(vA^4)$.

Term (ii). Insert X:

$$\begin{aligned}
&\mathrm{tr}(A\,\mathrm{d}v\,\mathrm{d}A) + \mathrm{tr}(A\,\mathrm{d}A\,\mathrm{d}v) \overset{(1)}{=} -\mathrm{tr}\big(\mathrm{d}v\,(\mathrm{d}A\,A + A\,\mathrm{d}A)\big) \overset{(2)}{=} 2\,\mathrm{tr}\big(v(\mathrm{d}A)^2\big),\\
&\mathrm{tr}(AAv\,\mathrm{d}A) - \mathrm{tr}(AvA\,\mathrm{d}A)\\
&+\mathrm{tr}(A\,\mathrm{d}A\,Av) - \mathrm{tr}(A\,\mathrm{d}A\,vA)\\
&\qquad\qquad \overset{(3)}{=} \mathrm{tr}(v\,\mathrm{d}A\,A^2) + \mathrm{tr}(vA\,\mathrm{d}A\,A) + \mathrm{tr}(vA\,\mathrm{d}A\,A) + \mathrm{tr}(vA^2\mathrm{d}A).
\end{aligned}$$

(1) Move the leading A to the back past the 3-form $\mathrm{d}v\,\mathrm{d}A$ (sign $-$); move the trailing $\mathrm{d}v$ to the front past the 3-form $A\,\mathrm{d}A$ (sign $-$).

(2) Integrate by parts with $Y = \mathrm{d}A\,A + A\,\mathrm{d}A$, whose derivative is $\mathrm{d}Y = (\mathrm{d}A)^2 + (\mathrm{d}A)^2$.

(3) Term by term: $\mathrm{tr}(A^2\cdot v\mathrm{d}A) = \mathrm{tr}(v\,\mathrm{d}A\,A^2)$ (even block, no sign); $\mathrm{tr}(A\cdot vA\mathrm{d}A) = (-1)^{1\cdot 3}\,\mathrm{tr}(vA\,\mathrm{d}A\cdot A)$ (the 1-form A moved to the back past a 3-form), so $-\mathrm{tr}(AvA\,\mathrm{d}A) = +\mathrm{tr}(vA\,\mathrm{d}A\,A)$; $\mathrm{tr}(A\,\mathrm{d}A\,A\,v) = \mathrm{tr}(vA\,\mathrm{d}A\,A)$; $-\mathrm{tr}(A\mathrm{d}Av\cdot A) = +\mathrm{tr}(A\cdot A\mathrm{d}Av) = \mathrm{tr}(vA^2\mathrm{d}A)$.

So (ii) $\equiv 2\,\mathrm{tr}(v(\mathrm{d}A)^2) + \mathrm{tr}(v\,\mathrm{d}A\,A^2) + 2\,\mathrm{tr}(vA\,\mathrm{d}A\,A) + \mathrm{tr}(vA^2\mathrm{d}A)$.

Term (iii). Insert X:

$$\begin{aligned}
&\mathrm{tr}(A\,\mathrm{d}v\,A^2) + \mathrm{tr}(A^3\mathrm{d}v) \overset{(1)}{=} -2\,\mathrm{tr}(\mathrm{d}v\,A^3) \overset{(2)}{=} 2\,\mathrm{tr}\big(v\,\mathrm{d}(A^3)\big)\\
&\qquad\qquad \overset{(3)}{=} 2\,\mathrm{tr}(v\,\mathrm{d}A\,A^2) - 2\,\mathrm{tr}(vA\,\mathrm{d}A\,A) + 2\,\mathrm{tr}(vA^2\mathrm{d}A),\\
&\mathrm{tr}(A^2vA^2) - \mathrm{tr}(AvA^3)\\
&+\mathrm{tr}(A^4v) - \mathrm{tr}(A^3vA) \overset{(4)}{=} 4\,\mathrm{tr}(vA^4).
\end{aligned}$$

(1) Move A (front) to the back past the 3-form $\mathrm{d}vA^2$: sign $-$; move $\mathrm{d}v$ (back) to the front past A^3: sign $-$.

(2) Integration by parts.

(3) $\mathrm{d}(A^3) = \mathrm{d}A\,A^2 - A\,\mathrm{d}A\,A + A^2\mathrm{d}A$.
(4) Each term becomes $\pm\,\mathrm{tr}(vA^4)$ by cyclic moves, and the two minus signs are cancelled by the signs $(-1)^{1\cdot 3}$ of moving a single A past A^3.

Collect $Q_4^1 \equiv$ (i) $-$ (ii) $-\,\frac{3}{4}$(iii), coefficient by coefficient:

	(i)	−(ii)	$-\frac{3}{4}$(iii)	total
$\mathrm{tr}(v(\mathrm{d}A)^2)$	3	−2	0	1
$\mathrm{tr}(v\,\mathrm{d}A\,A^2)$	3	−1	$-\frac{3}{2}$	$\frac{1}{2}$
$\mathrm{tr}(vA\,\mathrm{d}A\,A)$	0	−2	$+\frac{3}{2}$	$-\frac{1}{2}$
$\mathrm{tr}(vA^2\mathrm{d}A)$	3	−1	$-\frac{3}{2}$	$\frac{1}{2}$
$\mathrm{tr}(vA^4)$	3	0	−3	0

The totals are $\mathrm{tr}(v(\mathrm{d}A)^2) + \frac{1}{2}\,\mathrm{tr}\big(v(\mathrm{d}A\,A^2 - A\,\mathrm{d}A\,A + A^2\mathrm{d}A)\big)$. Since $\mathrm{d}(A\,\mathrm{d}A) = (\mathrm{d}A)^2$ and $\mathrm{d}(A^3) = \mathrm{d}A\,A^2 - A\,\mathrm{d}A\,A + A^2\mathrm{d}A$,

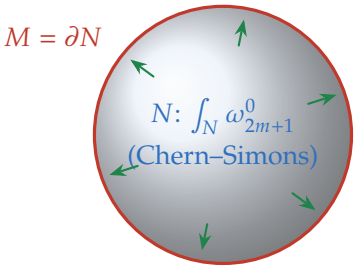
$$Q_4^1(v,A) \equiv \mathrm{tr}\Big(v\,\mathrm{d}\Big(A\,\mathrm{d}A + \tfrac{1}{2}A^3\Big)\Big), \qquad \omega_4^1 = \frac{1}{3!}\Big(\frac{i}{2\pi}\Big)^3 Q_4^1 = -\frac{i}{48\pi^3}\,\mathrm{tr}\Big(v\,\mathrm{d}\Big(A\,\mathrm{d}A + \tfrac{1}{2}A^3\Big)\Big). \tag{10.149}$$

Why $\int_M \omega^1$ is automatically consistent: anomaly inflow. Let N be a $(2m+1)$-manifold with boundary $\partial N = M$ (for $M = S^{2m}$ take N the ball B^{2m+1}), and extend A and v smoothly to $\tilde{A}$, $\tilde{v}$ on N. Consider the Chern–Simons action $\Gamma_N[\tilde{A}] := \int_N \omega^0_{2m+1}(\tilde{A})$. Then

$$\delta_{\tilde{v}}\Gamma_N \overset{(1)}{=} \int_N \delta_{\tilde{v}}\omega^0_{2m+1} \overset{(2)}{=} \int_N \mathrm{d}\omega^1_{2m}(\tilde{v},\tilde{A}) \overset{(3)}{=} \int_M \omega^1_{2m}(v,A), \tag{10.150}$$

(1) Vary under the integral.
(2) Descent 2.
(3) Stokes' theorem on N; on $\partial N = M$ the extensions restrict to A and v.

So the descent anomaly on M is literally the gauge variation of a functional (of the bulk extension), and (10.142) applied to Γ_N gives the Wess–Zumino condition (10.143) with no further computation. The right side depends only on boundary data, even though Γ_N does not.



$\delta_v\Gamma_N = \int_M \omega^1_{2m}$: the Chern–Simons bulk is not gauge invariant, and its failure is a pure boundary term. A chiral fermion on M with the *opposite* anomaly makes the total invariant. Charge flowing in from the bulk (green) is the anomalous non-conservation seen on the boundary.

Figure 10.18: Anomaly inflow. The descent equation $\delta_v\omega^0 = \mathrm{d}\omega^1$ says that the gauge variation of a Chern–Simons action on N lives entirely on ∂N. This is why the descent anomaly obeys the Wess–Zumino condition, and it is the mechanism behind the edge states of the quantum Hall effect.

Key idea: The consistent anomaly (Nash's μ_1), with its normalisation

For a Weyl fermion of positive chirality in a representation with anti-Hermitian generators,

on a $2m$-dimensional M,

$$\begin{aligned} \delta_v \ln Z_F[A] &= -2\pi i \int_M \omega^1_{2m}(v, A) \quad \text{(mod trivial anomalies)}, \\ \Omega_{2m+2} = \mathrm{ch}_{m+1}(F) &= \mathrm{d}\omega^0_{2m+1}, \qquad \delta_v \omega^0_{2m+1} = \mathrm{d}\omega^1_{2m}. \end{aligned} \tag{10.151}$$

Explicitly,

$$\begin{aligned} n = 2: &\quad \delta_v \ln Z_F = \frac{i}{4\pi} \int_M \mathrm{tr}(v\, \mathrm{d}A), \\ n = 4: &\quad \delta_v \ln Z_F = -\frac{1}{24\pi^2} \int_M \mathrm{tr}\Big(v\, \mathrm{d}\Big(A\, \mathrm{d}A + \tfrac{1}{2}A^3\Big)\Big). \end{aligned}$$

Why is this the right normalisation? The consistency condition fixes the *form* of the anomaly (the relevant cohomology is one-dimensional for each independent invariant polynomial), so only the overall number needs checking, and it suffices to check the abelian case against Section 10.5.3:

$$\begin{aligned} -2\pi i\, \omega^1_{2m}\big|_{\text{abelian}} &\overset{(1)}{=} -2\pi i\, \frac{1}{(m+1)!}\Big(\frac{i}{2\pi}\Big)^{m+1} v\, F^m \overset{(2)}{=} \frac{1}{(m+1)!}\Big(\frac{i}{2\pi}\Big)^{m} v\, F^m \\ &\overset{(3)}{=} \frac{1}{m+1}\ \mathrm{tr}\Big[v\, \frac{1}{m!}\Big(\frac{i}{2\pi}\Big)^{m} F^m\Big]. \end{aligned}$$

(1) For abelian A: $Q_{2m+1} = AF^m$ (all $F_t^m = t^m F^m$ commute, $(m+1)\int t^m \mathrm{d}t = 1$), and $\delta_v(AF^m) = \mathrm{d}v\, F^m = \mathrm{d}(vF^m)$ because $\mathrm{d}F = 0$; so $Q^1_{2m} = vF^m$.

(2) $-2\pi i \cdot \frac{i}{2\pi} = 1$.

(3) $\frac{1}{(m+1)!} = \frac{1}{m+1} \cdot \frac{1}{m!}$. The bracket is the covariant anomaly (10.135).

This is the $\frac{1}{m+1}$ of the key idea in Section 10.5.3: $\frac{1}{2}$ in two dimensions (Example 10.20) and $\frac{1}{3}$ in four (Example 10.21). The anomaly thus obeys the Wess–Zumino condition, is local, is not removable by local counterterms when $\mathrm{tr}\, F^{m+1} \not\equiv 0$, and is normalised by a single one-loop graph.

Reading Nash (p. 278, (10.33))

Nash quotes, for $M = S^4$ and $G = \mathrm{SU}(N)$, $\mu_1 = -\frac{i}{(2\pi)^3}\int_0^1 \mathrm{d}t \int_{S^4} \mathrm{tr}(A \wedge F_t \wedge F_t)$, $F_t = t\, \mathrm{d}A + t^2 A \wedge A$, "the expression for the anomaly found in Bardeen [1]". Compare with (10.145): the integrand $\int_0^1 \mathrm{d}t\, \mathrm{tr}(AF_t^2) = \frac{1}{3}Q_5$ is the five-dimensional Chern–Simons form. A 5-form cannot be integrated over S^4 as it stands; Nash's notation ("as used in chapter 8") is that A is the connection on $S^4 \times \mathcal{G}$ whose component along $\mathcal{G}$ is the Maurer–Cartan form $g^{-1}\delta g$. Integrating the part of Q_5 of degree 4 along S^4 and 1 along $\mathcal{G}$ over S^4 leaves a 1-form on $\mathcal{G}$, and that part is exactly the descent term ω^1_4 of (10.149), with v the value of $g^{-1}\delta g$ on the tangent vector. So (10.33) is our (10.151). Overall constants differ between references (Nash's prefactor is $2\omega^0_5$ in our normalisation, reflecting whether one tracks $\det T_g$ or the chiral determinant, and where one puts $2\pi i$); the structure, and in particular the vanishing criterion, do not. The combination $\mathrm{tr}(v\, \mathrm{d}(A\mathrm{d}A + \frac{1}{2}A^3))$ is the **Bardeen** (or minimal consistent) anomaly.

Dictionary: BRST language

Much of the literature writes the gauge parameter as a Grassmann-odd **ghost** $c(x) \in \mathfrak{g}$ and the gauge variation as a nilpotent operator s: $sA = -D_A c$, $sc = -c^2$, $s^2 = 0$ (with s anticommuting with d and with odd objects). The Wess–Zumino condition becomes $s\int_M \omega^1_{2m}(c, A) = 0$, and the descent equations collapse into the **Russian formula** $(\mathrm{d} + s)(A + c) + (A + c)^2 = F$, i.e. "the curvature of $A + c$ has no ghost components". Geometrically c is the Maurer–Cartan form $g^{-1}\delta g$ on $\mathcal{G}$, s is the exterior derivative on $\mathcal{G}$, $sc = -c^2$ is the Maurer–Cartan equation, and $s\mathcal{A} = 0$ is our statement $\mathrm{d}\mathcal{A} = 0$ (Figure 10.15). Nash's $H^1_{\mathrm{dR}}(\mathcal{G})$ is the cohomology of this s.

10.5.6 When does the anomaly vanish? The symmetric invariant

In four dimensions everything in ω^1_4 is controlled by one tensor. Write $A = A^a T^a$, $F_t = F_t^a T^a$. Then

$$\operatorname{tr}(AF_tF_t) \overset{(1)}{=} A^a F_t^b F_t^c \operatorname{tr}(T^a T^b T^c) \overset{(2)}{=} A^a F_t^b F_t^c \tfrac{1}{2}\operatorname{tr}\big(T^a\{T^b, T^c\}\big) \overset{(3)}{=} \tfrac{1}{2} d^{abc} A^a F_t^b F_t^c,$$
$$d^{abc} := \operatorname{tr}\big(T^a\{T^b, T^c\}\big) = 2\operatorname{Str}(T^a T^b T^c). \tag{10.152}$$

(1) Expand in components; the component forms are ordinary (matrix-free) forms.
(2) $F_t^b F_t^c$ is symmetric in $b \leftrightarrow c$ (2-forms commute), so only the symmetric part of $\operatorname{tr}(T^a T^b T^c)$ in b, c survives.
(3) Definition. d^{abc} is symmetric in all three indices: by cyclicity $\operatorname{tr}(T^b\{T^a, T^c\}) = \operatorname{tr}(T^b T^a T^c + T^b T^c T^a) = \operatorname{tr}(T^a T^c T^b + T^a T^b T^c) = d^{abc}$ [QFT notes (22.7.28)].

So $Q_5 = \frac{3}{2} d^{abc}\int_0^1 \mathrm{d}t\, A^a F_t^b F_t^c$, and Q_4^1 (derived from it) is proportional to d^{abc} too. Hence:

Key idea: The four-dimensional cancellation condition

A four-dimensional gauge theory of Weyl fermions is free of perturbative gauge anomalies iff

$$\sum_{\text{positive chirality}} d^{abc}(R) - \sum_{\text{negative chirality}} d^{abc}(R) = 0,$$

equivalently (writing every field as a left-handed Weyl fermion, below) $\sum_R d^{abc}(R) = 0$. For $G = \mathrm{U}(1)$ with charges q_i this is $\sum_i q_i^3 = 0$.

(The relative minus sign: the negative-chirality anomaly comes with $-\gamma_5$ in the Jacobian of Section 10.4.6.)

Conjugate and real representations. With anti-Hermitian generators the conjugate representation $\bar{R}$ has generators $\bar{T}^a = (T^a)^* = -(T^a)^{\mathsf{T}}$. Then

$$d^{abc}(\bar{R}) \overset{(1)}{=} -\operatorname{tr}\big((T^a)^{\mathsf{T}}\{(T^b)^{\mathsf{T}}, (T^c)^{\mathsf{T}}\}\big) \overset{(2)}{=} -\operatorname{tr}\big(\{T^c, T^b\}T^a\big)^{\mathsf{T}} \overset{(3)}{=} -d^{abc}(R).$$

(1) $(-1)^3 = -1$.
(2) $X^{\mathsf{T}}Y^{\mathsf{T}} = (YX)^{\mathsf{T}}$ for each product.
(3) $\operatorname{tr} Z^{\mathsf{T}} = \operatorname{tr} Z$, then cyclicity.

A *real* (or pseudoreal) representation is equivalent to its conjugate, $\bar{R} = URU^{-1}$, and d^{abc} is unchanged by conjugation, so $d^{abc}(R) = -d^{abc}(R) = 0$. In particular a Dirac fermion, whose two chiralities carry the same R, is never anomalous: this is why QED and QCD are safe

[QFT notes (22.7.34)]. Since every representation of SU(2) is real or pseudoreal, SU(2) is safe, as Example 10.17 found by hand.

Worked example 10.26: SU(3) triplets are anomalous; anomaly coefficients

For SU(N), $N \geq 3$, the fundamental has $d^{abc} \neq 0$. With the Hermitian Gell-Mann generator $t^8 = \frac{1}{2\sqrt{3}}\,\mathrm{diag}(1,1,-2)$,

$$\mathrm{tr}\big(t^8\{t^8,t^8\}\big) = 2\,\mathrm{tr}(t^8)^3 \overset{(1)}{=} 2\cdot\frac{1}{(2\sqrt{3})^3}\big(1+1-8\big) \overset{(2)}{=} -\frac{1}{2\sqrt{3}} \neq 0.$$

(1) The cube of a diagonal matrix is the cube of its entries.
(2) $(2\sqrt{3})^3 = 24\sqrt{3}$ and $2\cdot(-6)/(24\sqrt{3}) = -1/(2\sqrt{3})$.

Because SU(N) has only one symmetric invariant of this type, $d^{abc}(R) = A(R)\,d^{abc}(\mathbf{N})$ for a number $A(R)$, the **anomaly coefficient**: $A(\mathbf{N}) = 1$, $A(\bar{\mathbf{N}}) = -1$, $A(\text{adjoint}) = 0$. To compute $A(R)$ it is enough to compare $\mathrm{tr}_R\, X^3$ with $\mathrm{tr}_{\mathbf{N}}\, X^3$ for a single generic generator X. For the antisymmetric square $\Lambda^2\mathbf{N}$, use characters: $\mathrm{tr}_{\Lambda^2} e^{sX} = \frac{1}{2}[(\mathrm{tr}\, e^{sX})^2 - \mathrm{tr}\, e^{2sX}]$. Expanding to order s^3, with $\mathrm{tr}\, X = 0$,

$$\tfrac{1}{6}\,\mathrm{tr}_{\Lambda^2} X^3 \overset{(1)}{=} \tfrac{1}{2}\Big[2N\cdot\tfrac{1}{6}\,\mathrm{tr}\,X^3 - \tfrac{8}{6}\,\mathrm{tr}\,X^3\Big] \overset{(2)}{=} \frac{N-4}{6}\,\mathrm{tr}\,X^3, \qquad \text{so} \qquad A(\Lambda^2\mathbf{N}) = N-4.$$

(1) $(\mathrm{tr}\, e^{sX})^2 = (N + \frac{s^2}{2}\,\mathrm{tr}\,X^2 + \frac{s^3}{6}\,\mathrm{tr}\,X^3 + \dots)^2$ has s^3 coefficient $2N\cdot\frac{1}{6}\,\mathrm{tr}\,X^3$; and $\mathrm{tr}\, e^{2sX}$ has s^3 coefficient $\frac{8}{6}\,\mathrm{tr}\,X^3$.
(2) Simplify.

The same computation with a plus sign gives $A(\mathrm{Sym}^2\,\mathbf{N}) = N+4$ [QFT notes (22.7.39)]. For the SU(5) grand unified theory, one generation is $\bar{\mathbf{5}} \oplus \mathbf{10}$ (left-handed), with $\mathbf{10} = \Lambda^2\mathbf{5}$: $A = -1 + (5-4) = 0$. The generation is anomaly free, and this is part of the appeal of SU(5).

group	possible $d^{abc} \neq 0$?	reason
U(1)	yes: $\sum q^3$	abelian, $\mathrm{tr}\, F^3 = F^3$
SU(2), Sp(n), SO(n) ($n \neq 6$), $G_2, F_4, E_{6,7,8}$	no	no cubic Casimir (all representations real, or no symmetric invariant)
SU(N), $N \geq 3$	yes: $\sum A(R)$	cubic Casimir d^{abc}
SO(6) $\cong$ SU(4)	yes	same as SU(4)

(For product groups one also needs the mixed conditions below, and in the presence of gravity the linear condition $\sum q = 0$ for each U(1), Section 10.7.)

10.5.7 Anomaly cancellation in the Standard Model

The Standard Model is a chiral gauge theory with $G = \mathrm{SU}(3)\times\mathrm{SU}(2)\times\mathrm{U}(1)_Y$: left- and right-handed quarks and leptons carry different representations. Its consistency therefore rests on (10.152) summing to zero for every choice of three generators. We follow [QFT notes §23.4].

Writing everything as left-handed. A right-handed Weyl field ψ_R in a representation r is equivalent to a left-handed field $\psi'_L = \sigma^2\psi_R^*$ in the conjugate representation $\bar{r}$ [QFT notes (22.7.15)–(22.7.21)]; its hypercharge flips sign. We use the convention $Q = T_3 + Y$, with Hermitian

generators t^a normalised by $\mathrm{tr}(t^a t^b) = \frac{1}{2}\delta^{ab}$ in the fundamentals of SU(3) and SU(2). One generation is:

left-handed field	SU(3)	SU(2)	Y	number of Weyl components
$Q = (u_L, d_L)$	$\mathbf{3}$	$\mathbf{2}$	$+\frac{1}{6}$	6
u^c $(= \overline{u_R})$	$\bar{\mathbf{3}}$	$\mathbf{1}$	$-\frac{2}{3}$	3
d^c $(= \overline{d_R})$	$\bar{\mathbf{3}}$	$\mathbf{1}$	$+\frac{1}{3}$	3
$L = (\nu_L, e_L)$	$\mathbf{1}$	$\mathbf{2}$	$-\frac{1}{2}$	2
e^c $(= \overline{e_R})$	$\mathbf{1}$	$\mathbf{1}$	$+1$	1

(Check a charge: u_L has $T_3 = \frac{1}{2}$, so $Q = \frac{1}{2} + \frac{1}{6} = \frac{2}{3}$; u_R must have the same Q with $T_3 = 0$, so $Y(u_R) = \frac{2}{3}$ and $Y(u^c) = -\frac{2}{3}$.)

The list of triangles. Each of the three vertices carries a generator of one factor. A triangle containing exactly one SU(3) or exactly one SU(2) generator vanishes, because the other two generators act on different indices and leave a factor $\mathrm{tr}\, t^a = 0$. The remaining conditions are (Figure 10.19):

$$\mathrm{SU}(3)^3: \quad \sum A(r_3)\,\dim r_2 \overset{(1)}{=} \underbrace{1\cdot 2}_{Q} + \underbrace{(-1)\cdot 1}_{u^c} + \underbrace{(-1)\cdot 1}_{d^c} = 0,$$

$$\mathrm{SU}(2)^3: \quad d^{abc}(\mathrm{SU}(2)) = 0 \text{ identically (Example 10.17)},$$

$$\mathrm{SU}(3)^2\,\mathrm{U}(1): \quad \sum_{\text{coloured}} \tfrac{1}{2}\dim r_2\, Y \overset{(2)}{=} \tfrac{1}{2}\Big[2\cdot\tfrac{1}{6} + 1\cdot\big(-\tfrac{2}{3}\big) + 1\cdot\tfrac{1}{3}\Big] = \tfrac{1}{2}\Big[\tfrac{1}{3} - \tfrac{1}{3}\Big] = 0,$$

$$\mathrm{SU}(2)^2\,\mathrm{U}(1): \quad \sum_{\text{doublets}} \tfrac{1}{2}\dim r_3\, Y \overset{(3)}{=} \tfrac{1}{2}\Big[3\cdot\tfrac{1}{6} + 1\cdot\big(-\tfrac{1}{2}\big)\Big] = 0,$$

$$\mathrm{U}(1)^3: \quad \sum(\text{components})\, Y^3 \overset{(4)}{=} 6\cdot\tfrac{1}{216} + 3\cdot\big(-\tfrac{8}{27}\big) + 3\cdot\tfrac{1}{27} + 2\cdot\big(-\tfrac{1}{8}\big) + 1 = \tfrac{1-32+4-9+36}{36} = 0,$$

$$\mathrm{U}(1)\,(\mathrm{grav})^2: \quad \sum(\text{components})\, Y \overset{(5)}{=} 6\cdot\tfrac{1}{6} + 3\cdot\big(-\tfrac{2}{3}\big) + 3\cdot\tfrac{1}{3} + 2\cdot\big(-\tfrac{1}{2}\big) + 1 = 1 - 2 + 1 - 1 + 1 = 0.$$

(1) d^{abc} factorises: the SU(3) trace gives $A(r_3)d^{abc}(\mathbf{3})$ and the SU(2) indices give a factor $\dim r_2$. Q is two triplets; u^c, d^c are antitriplets with $A = -1$.

(2) $\mathrm{tr}_{r_3}(t^a t^b Y) = \frac{1}{2}\delta^{ab}\, Y \dim r_2$ for $r_3 = \mathbf{3}$ or $\bar{\mathbf{3}}$ (the $\bar{\mathbf{3}}$ generators $-t^{a\mathsf{T}}$ have the same $\mathrm{tr}(t^a t^b)$); the common $\frac{1}{2}\delta^{ab}$ is factored out. Colour singlets do not contribute.

(3) Only Q (three colours) and L are doublets.

(4) $d^{YYY} = 2\sum Y^3$ summed over all 15 Weyl components: $(\frac{1}{6})^3 = \frac{1}{216}$, $(-\frac{2}{3})^3 = -\frac{8}{27}$, $(\frac{1}{3})^3 = \frac{1}{27}$, $(-\frac{1}{2})^3 = -\frac{1}{8}$; over the common denominator 36: $\frac{6}{216} = \frac{1}{36}$, $-\frac{24}{27} = -\frac{32}{36}$, $\frac{3}{27} = \frac{4}{36}$, $-\frac{1}{4} = -\frac{9}{36}$.

(5) The mixed gauge–gravitational triangle is proportional to $\mathrm{tr}\, Y$ ([QFT notes (22.8.1)], Section 10.7).

Every condition holds. The QFT notes do the same sums with right-handed fields kept as they are and a factor -1 for left, $+1$ for right [QFT notes (23.4.2)–(23.4.5)]; since $Y(\psi^c) = -Y(\psi_R)$ and Y^3, Y are odd, the two bookkeepings agree term by term.

Worked example 10.27: Anomaly cancellation nearly fixes the hypercharges

Keep the SU(3) × SU(2) assignments of the table but treat the five hypercharges y_Q, y_u, y_d, y_L, y_e (of Q, u^c, d^c, L, e^c) as unknowns. The four conditions read

$$\mathrm{SU}(3)^2\mathrm{U}(1): 2y_Q + y_u + y_d = 0, \qquad \mathrm{SU}(2)^2\mathrm{U}(1): 3y_Q + y_L = 0,$$

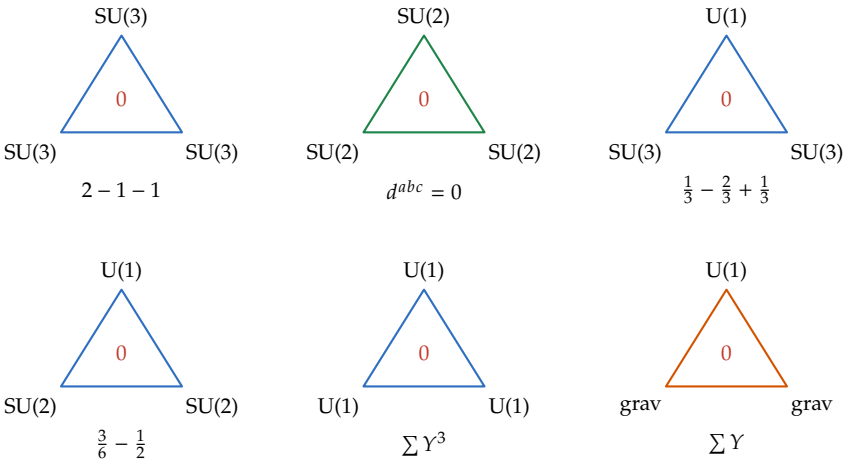


Figure 10.19: The six triangle conditions of the Standard Model that are not trivially zero. Blue: cancel between quarks and leptons, or between left and right, only because of the specific hypercharges and the three colours; green: automatic for SU(2); orange: the mixed gravitational condition. Triangles with a single SU(3) or single SU(2) vertex vanish because generators are traceless.

$$\text{grav}^2\text{U}(1) : 6y_Q + 3y_u + 3y_d + 2y_L + y_e = 0,$$
$$\text{U}(1)^3 : 6y_Q^3 + 3y_u^3 + 3y_d^3 + 2y_L^3 + y_e^3 = 0.$$

Solve them in turn:

$$y_L \overset{(1)}{=} -3y_Q, \qquad y_u + y_d \overset{(2)}{=} -2y_Q, \qquad y_e \overset{(3)}{=} -6y_Q - 3(-2y_Q) - 2(-3y_Q) = 6y_Q,$$
$$y_u^3 + y_d^3 \overset{(4)}{=} -\tfrac{1}{3}\big(6y_Q^3 + 2(-3y_Q)^3 + (6y_Q)^3\big) = -\tfrac{1}{3}\big(6 - 54 + 216\big)y_Q^3 = -56\,y_Q^3,$$
$$y_u y_d \overset{(5)}{=} \frac{(y_u + y_d)^3 - (y_u^3 + y_d^3)}{3(y_u + y_d)} = \frac{-8y_Q^3 + 56y_Q^3}{-6y_Q} = -8y_Q^2,$$
$$\{y_u, y_d\} \overset{(6)}{=} \text{roots of } z^2 + 2y_Q z - 8y_Q^2 = 0 = \{-4y_Q,\ 2y_Q\}.$$

(1) The $\text{SU}(2)^2\text{U}(1)$ condition.
(2) The $\text{SU}(3)^2\text{U}(1)$ condition.
(3) The gravitational condition with (1) and (2).
(4) The cubic condition with (1) and (3).
(5) The identity $a^3 + b^3 = (a + b)^3 - 3ab(a + b)$, assuming $y_Q \neq 0$.
(6) A pair with given sum $-2y_Q$ and product $-8y_Q^2$; the discriminant is $4y_Q^2 + 32y_Q^2 = 36y_Q^2$, so $z = -y_Q \pm 3y_Q$.

With $y_Q = \frac{1}{6}$ this gives $y_L = -\frac{1}{2}$, $y_e = 1$ and $\{y_u, y_d\} = \{-\frac{2}{3}, \frac{1}{3}\}$: exactly the table. The overall scale of Y is a convention, so *anomaly cancellation determines all the hypercharge ratios of a generation*, up to the label swap $u \leftrightarrow d$. In particular it forces $Q(e) = -Q(\nu) - 1$ and $Q(\text{proton}) = -Q(e)$: charge quantisation, from the consistency of the gauge theory.

Physical picture: Quarks and leptons need each other

The gravitational condition happens to cancel separately among leptons $(-1 + 1)$ and among quarks $(1 - 2 + 1)$, but the others do not. For $\text{SU}(2)^2\text{U}(1)$ the quarks give $3 \cdot \frac{1}{6} = +\frac{1}{2}$

and the leptons $-\frac{1}{2}$; for $\mathrm{U}(1)^3$ the quarks give $\frac{1-32+4}{36} = -\frac{3}{4}$ and the leptons $\frac{-9+36}{36} = +\frac{3}{4}$. So neither tower is consistent alone: cancellation needs a complete generation and exactly three colours. A theory with only one of the two towers, or with a different number of colours and the same charges, would be inconsistent: the gauge current would not be conserved and unphysical polarisations of the gauge bosons would not decouple. This is why, once the b quark and the τ lepton were found, a top quark completing the third generation was expected long before it was seen.

Watch out: Perturbative versus global

The triangle conditions are all *perturbative* (local) anomalies. There is one more, non-perturbative, condition: an SU(2) gauge theory must contain an even number of Weyl doublets (Witten's global anomaly, $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$), invisible to d^{abc} because SU(2) has none. Each Standard Model generation has four doublets (three coloured Q's and one L), so it passes. This is a torsion phenomenon in the topology of $\mathcal{G}$, treated in Nash's §5.

Reading Nash (pp. 272–273 and 278)

Nash states the anomaly as the non-vanishing of $\nabla^{ab}_{\mu} j_5^{b\mu}$ [Nash (10.11)] and later gives its cohomological form μ_1 [Nash (10.13), (10.33)]. Between these he does not write down the non-abelian anomaly explicitly, nor the consistency condition, nor its cancellation. This section is that missing middle: (10.143) is the statement that μ_1 is closed, (10.151) with (10.149) is his (10.33), the "trivial anomalies" $\delta_v \Phi_{\mathrm{loc}}$ are the exact forms whose subtlety he raises on p. 279 (local versus de Rham cohomology, Section 10.6.6), and the Standard Model table is the physical reason the question matters.

Recap

- The consistent anomaly $\mathcal{A}[v] = \delta_v \ln Z_F$ obeys the Wess–Zumino condition $\delta_v \mathcal{A}[w] - \delta_w \mathcal{A}[v] = \mathcal{A}[[v, w]]$, because $[\delta_v, \delta_w] = \delta_{[v,w]}$. Geometrically: $\mathcal{A}$ is a closed 1-form on the gauge orbit.
- The covariant anomaly $\mathrm{tr}[v\, \mathrm{ch}_m(F)]$ fails it (by a factor 2 in the commutator term, in 2D).
- Bose symmetry of identical currents: consistent $= \frac{1}{m+1} \times$ covariant for U(1) ($\frac{1}{2}$ from the chiral Schwinger model, $\frac{1}{3}$ from the triangle budget).
- Chern–Simons: $\mathrm{tr}\, F^k = \mathrm{d}Q_{2k-1}$, $Q_{2k-1} = k \int_0^1 \mathrm{tr}(A F_t^{k-1}) \mathrm{d}t$; $Q_3 = \mathrm{tr}(A\mathrm{d}A + \frac{2}{3}A^3)$, $Q_5 = \mathrm{tr}(A(\mathrm{d}A)^2 + \frac{3}{2}A^3 \mathrm{d}A + \frac{3}{5}A^5)$.
- Descent: $\mathrm{ch}_{m+1} = \mathrm{d}\omega^0$, $\delta_v \omega^0 = \mathrm{d}\omega^1$, $\delta_v \ln Z_F = -2\pi i \int \omega^1$: $\frac{i}{4\pi} \int \mathrm{tr}(v \mathrm{d}A)$ in 2D, $-\frac{1}{24\pi^2} \int \mathrm{tr}(v \mathrm{d}(A\mathrm{d}A + \frac{1}{2}A^3))$ in 4D. Inflow from a Chern–Simons bulk makes consistency automatic.
- 4D anomalies $\propto d^{abc} = \mathrm{tr}(T^a\{T^b, T^c\})$; real representations and SU(2) are safe; $A(\Lambda^2 \mathbf{N}) = N - 4$ makes $\bar{\mathbf{5}} \oplus \mathbf{10}$ safe.
- The Standard Model cancels all six nontrivial triangles within each generation, and the conditions fix the hypercharge ratios.

10.6 Anomalies and Yang–Mills theories V: the topology of the anomaly

We now have the anomaly as a formula. Nash's aim in the second half of §2 is to show that the formula is the shadow of a topological invariant [Nash p. 273]: "The rest of this section is devoted to a topological interpretation of the anomaly. This is made up of two parts." The question this section answers is: *what topological object does the anomaly measure, and how does the index theorem for families compute it?* The answer comes in two pictures that turn out to be the same.

1. *On the gauge group $\mathcal{G}$.* The variation of the (phase of the) determinant is a closed 1-form μ_1 on $\mathcal{G}$. It is exact precisely when there is no anomaly; a nontrivial class $[\mu_1] \in H^1_{\mathrm{dR}}(\mathcal{G})$ needs loops in $\mathcal{G}$, i.e. $\pi_1(\mathcal{G}) \neq 0$.
2. *On the orbit space $\mathcal{A}/\mathcal{G}$.* The determinant is not a function but a section of a line bundle, $\det \operatorname{Index} \not{D}$. There is no anomaly precisely when this bundle is trivial, which is detected by its first Chern class. The families index theorem computes that class.

10.6.1 The operator T_g and its determinant

Following Atiyah and Singer, Nash compares the chiral operator at A with the one at A_g through

$$T_g := \not{D}_A^{*}\, \not{D}_{A_g} \qquad \text{[Nash (10.12)]}, \tag{10.153}$$

where, as in Section 10.2.3, $\not{D}_A$ stands for the chiral operator $D_A^+ : \Gamma(E^+ \otimes F) \to \Gamma(E^- \otimes F)$ and $\not{D}_A^{*} = (D_A^+)^\dagger$ maps back. So $T_g : \Gamma(E^+ \otimes F) \to \Gamma(E^+ \otimes F)$ maps a space *to itself*, and its determinant is a number. Formally,

$$\det T_g \text{ "=" } \overline{\det D_A^+} \cdot \det D_{A_g}^+, \tag{10.154}$$

so as a function of g with A fixed it records how the chiral determinant changes along the orbit, the first factor being a fixed normalisation. For $g = 1$, $T_1 = (D_A^+)^\dagger D_A^+ \geq 0$ and $\det T_1 = |\det D_A^+|^2$.

T_g is elliptic [Nash (10.14)]. The leading symbol of a differential operator is obtained by keeping the highest derivatives and replacing $\partial_\mu \to i p_\mu$ (Chapter 2). For the chiral Dirac operator $D_A^+ = \gamma^\mu(\partial_\mu + A_\mu)P_+$ and its adjoint $-\gamma^\mu(\partial_\mu + A_\mu)P_-$ (recall $\partial_\mu^\dagger = -\partial_\mu$ and γ^μ Hermitian),

$$\sigma(T_g)(x,p) \overset{(1)}{=} \sigma(\not{D}_A^{*})\,\sigma(\not{D}_{A_g}) \overset{(2)}{=} \big(-i\gamma^\mu p_\mu\big)\big(g^{-1}\, i\gamma^\nu p_\nu\, g\big) \overset{(3)}{=} \gamma^\mu\gamma^\nu p_\mu p_\nu$$
$$\overset{(4)}{=} \tfrac{1}{2}\{\gamma^\mu,\gamma^\nu\}p_\mu p_\nu \overset{(5)}{=} g^{\mu\nu}p_\mu p_\nu\, \mathbf{1}.$$

(1) The leading symbol of a composition is the product of leading symbols.
(2) $\not{D}_{A_g} = g^{-1}\not{D}_A g$ (10.22); multiplication by g has symbol g (order 0), and A, A_g are lower order.
(3) $(-i)(i) = 1$; g acts on colour and $\gamma^\nu p_\nu$ on spin, so they commute and $g^{-1}g = 1$.
(4) $p_\mu p_\nu$ is symmetric, so only the symmetric part of $\gamma^\mu\gamma^\nu$ survives.
(5) The Clifford relation $\{\gamma^\mu,\gamma^\nu\} = 2g^{\mu\nu}$ (Euclidean, Riemannian metric).

This is Nash's "$g_{\mu\nu}p^\mu p^\nu I$". It is invertible for $p \neq 0$ because the metric is positive definite: T_g is elliptic, with the same leading symbol as a Laplacian.

But T_g need not be positive. The lower-order terms contain $g^{-1}\mathrm{d}g$, and they can push finitely many eigenvalues off the positive real axis. Elliptic theory (Seeley) guarantees that all but finitely many eigenvalues lie in a wedge around the positive real axis. The next example shows this happening.

Worked example 10.28: T_g on a circle: negative eigenvalues and a sign

On $M = S^1$ with coordinate $x \sim x + 2\pi$, take the "chiral" operator $D_a = \frac{\mathrm{d}}{\mathrm{d}x} + ia$ acting on functions, with a a real constant, $0 < a < 1$. Its adjoint is $D_a^\dagger = -\frac{\mathrm{d}}{\mathrm{d}x} - ia$. A gauge transformation $g(x) = e^{ikx}$, $k \in \mathbb{Z}$, shifts a:

$$g^{-1} D_a \, g \overset{(1)}{=} e^{-ikx}\Big(\frac{\mathrm{d}}{\mathrm{d}x} + ia\Big)e^{ikx} \overset{(2)}{=} \frac{\mathrm{d}}{\mathrm{d}x} + ik + ia = D_{a+k}.$$

(1) Definition of the conjugated operator, acting on a test function.
(2) Leibniz: $\frac{\mathrm{d}}{\mathrm{d}x}(e^{ikx} f) = e^{ikx}(f' + ikf)$.

On the Fourier modes e^{inx} both operators are diagonal:

$$\begin{aligned} T_g \, e^{inx} = D_a^\dagger D_{a+k} \, e^{inx} &\overset{(1)}{=} D_a^\dagger \, i(n+a+k) \, e^{inx} \overset{(2)}{=} (-i)(n+a)\, i(n+a+k)\, e^{inx} \\ &= (n+a)(n+a+k)\, e^{inx}. \end{aligned}$$

(1) $\frac{\mathrm{d}}{\mathrm{d}x} e^{inx} = in\, e^{inx}$.
(2) $D_a^\dagger e^{inx} = (-in - ia) e^{inx}$.

The eigenvalue $\lambda_n = (n+a)(n+a+k)$ is negative exactly when $n + a$ lies strictly between $-k$ and 0 (for $k > 0$), i.e. for $n = -1, -2, \dots, -k$: *exactly k negative eigenvalues*, all the rest positive and growing like n^2. This is Nash's "finite number of negative eigenvalues", and here it is g, not A, that causes it. The zeta-regularised determinant [Nash (10.15)] is

$$\det T_g = \big(\lambda_1^- \cdots \lambda_k^-\big) \, \exp\big[-\zeta'_{\hat{T}_g}(0)\big],$$

where $\hat{T}_g$ is T_g restricted to the positive eigenvalues, whose zeta function is defined as in Definition 10.4. Its sign is $(-1)^k$. Using the standard zeta-regularised product $|\prod_{n\in\mathbb{Z}}(n+a)| = 2|\sin \pi a|$ (from Lerch's formula $\prod_{n\geq 0}(n+a) = \sqrt{2\pi}/\Gamma(a)$ and $\Gamma(a)\Gamma(1-a) = \pi/\sin\pi a$) for each factor, the modulus is $4\sin^2 \pi a$, independent of k: the modulus is gauge invariant, as the pitfall of Section 10.2.6 said, and the gauge transformation shows up only in the sign,

$$\frac{\det D_{a+k}}{\det D_a} = \frac{\sin \pi(a+k)}{\sin \pi a} = (-1)^k.$$

A large gauge transformation (one that winds round U(1)) flips the sign of the chiral determinant when k is odd. This is a first glimpse of a *global* anomaly (Nash §5): invisible to any infinitesimal variation, since e^{ikx} with $k \neq 0$ is not connected to the identity.

Zero modes [Nash p. 274]. If T_g has a zero eigenvalue, $\det T_g = 0$ and its logarithm is useless. Nash distinguishes two cases.

- index $D_A^+ = 0$. Then zero modes are not forced. The index is unchanged by small perturbations (Chapter 4), and a generic small perturbation of A removes the kernel of D_A^+; since g is invertible, $\ker D_{A_g}^+ = g^{-1} \ker D_A^+$ is then empty too, and $\ker(D_A^+)^\dagger$ is empty because the index is zero. In the finite-dimensional model a square matrix is generically invertible. In Example 10.28, $a \in \mathbb{Z}$ gives a zero mode, and moving a off the integers removes it.

- index $D_A^+ \neq 0$. Then zero modes are forced: a $k \times (k+1)$ matrix always has a kernel. Say index $D_A^+ > 0$. We can perturb A so that $\ker(D_A^+)^\dagger = 0$, but $\ker D_{A_g}^+ \neq 0$ for every g. We

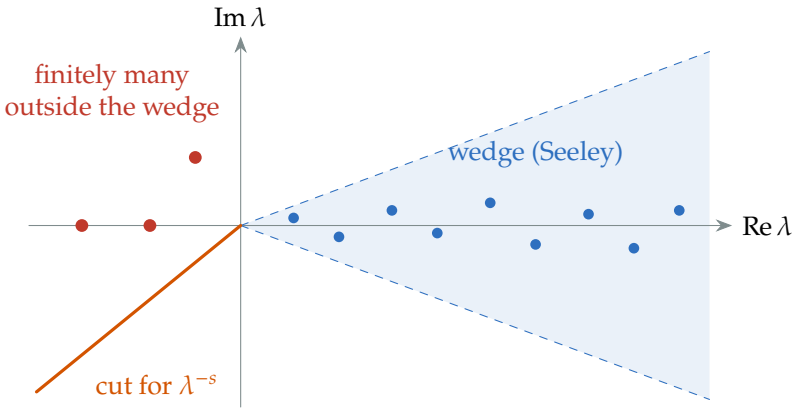

Figure 10.20: The spectrum of the non-self-adjoint elliptic operator T_g. Almost all eigenvalues (blue) lie in a wedge around the positive real axis, because the leading symbol is that of a Laplacian. Finitely many (red), produced by the lower-order terms containing $g^{-1}\mathrm{d}g$, may lie elsewhere, e.g. on the negative axis as in Example 10.28. To define $\lambda^{-s} = e^{-s\ln\lambda}$ one picks a branch cut (orange) outside the wedge; the finitely many stray eigenvalues are multiplied in by hand, as in (10.15).

restrict T_g to the orthogonal complement of $\ker D^+_{A_g}$, where it has no zero eigenvalue. As g varies, $\ker D^+_{A_g} = g^{-1}\ker D^+_A$ sweeps out a vector bundle over the orbit $\{A_g\}$, of rank index D^+_A.

Either way, $\det T_g$ is now a nowhere-vanishing function of $g \in \mathcal{G}$.

10.6.2 The anomaly as a 1-form on the gauge group

Define, with d the exterior derivative on the infinite-dimensional manifold $\mathcal{G}$,

$$\mu_1 := \frac{\mathrm{d}\,\det T_g}{\det T_g} \qquad \text{[Nash (10.13), (10.16)].} \tag{10.155}$$

Its value on the tangent vector at g generated by $v \in \mathfrak{g}$ (the curve $t \mapsto g e^{tv}$) is

$$\mu_1(X_v)\big|_g \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}t}\ln\det T_{ge^{tv}}\Big|_{t=0} \overset{(2)}{=} \frac{\mathrm{d}}{\mathrm{d}t}\ln\det D^+_{(A_g)_{e^{tv}}}\Big|_{t=0} \overset{(3)}{=} \delta_v \ln Z_F[A_g] \overset{(4)}{=} \mathcal{A}[v;A_g]. \tag{10.156}$$

(1) The derivative of $\ln f$ along a curve is $f^{-1}\,\mathrm{d}f/\mathrm{d}t$.
(2) (10.154): only the second factor depends on g; and $A_{ge^{tv}} = (A_g)_{e^{tv}}$.
(3) $Z_F = \det D^+$ and the definition (10.141) of δ_v at the point A_g.
(4) The consistent anomaly, computed in Section 10.5.5.

So μ_1 *is the consistent anomaly*, viewed as a 1-form on $\mathcal{G}$. Being $\mathrm{d}f/f$, it is closed wherever $f \neq 0$ (locally $\mu_1 = \mathrm{d}\ln f$ and $\mathrm{d}\mathrm{d} = 0$); closedness on the orbit is the Wess–Zumino condition of Section 10.5.2.

When is μ_1 exact? If a global logarithm $\ln\det T_g$ existed on $\mathcal{G}$, then $\mu_1 = \mathrm{d}\ln\det T_g$ would be exact and we could redefine the fermion determinant by a g-independent phase (in the local version, a counterterm) to make it invariant. A logarithm of a nowhere-zero complex function $f : W \to \mathbb{C}\setminus\{0\}$ exists iff no loop in W is mapped by f to a loop encircling 0. The standard example:

Worked example 10.29: The winding number obstructs the logarithm

On $W = S^1$, $f(\theta) = e^{in\theta}$ with $n \in \mathbb{Z}$. Then

$$\frac{\mathrm{d}f}{f} \overset{(1)}{=} in\,\mathrm{d}\theta, \qquad \oint_{S^1} \frac{\mathrm{d}f}{f} \overset{(2)}{=} 2\pi i\, n.$$

(1) $\mathrm{d}e^{in\theta} = in\, e^{in\theta}\mathrm{d}\theta$.
(2) $\oint \mathrm{d}\theta = 2\pi$.

If $\mathrm{d}f/f = \mathrm{d}h$ for a single-valued h, Stokes would give $\oint \mathrm{d}h = 0$ (a closed curve has no boundary). So for $n \neq 0$ there is no logarithm, even though $\mathrm{d}f/f$ is closed. The integer $\frac{1}{2\pi i}\oint \mathrm{d}f/f$ is the winding number of f around 0, and $[\mathrm{d}f/f] \in H^1_{\mathrm{dR}}(S^1) \cong \mathbb{R}$ is in times the generator. The same thing in finite-dimensional matrix language: $U(t) = \mathrm{diag}(e^{2\pi i t}, 1) \in \mathrm{U}(2)$, $t \in [0,1]$, is a loop with $\oint \mathrm{d}\ln\det U = 2\pi i$; the determinant detects the generator of $\pi_1(\mathrm{U}(2)) = \mathbb{Z}$.

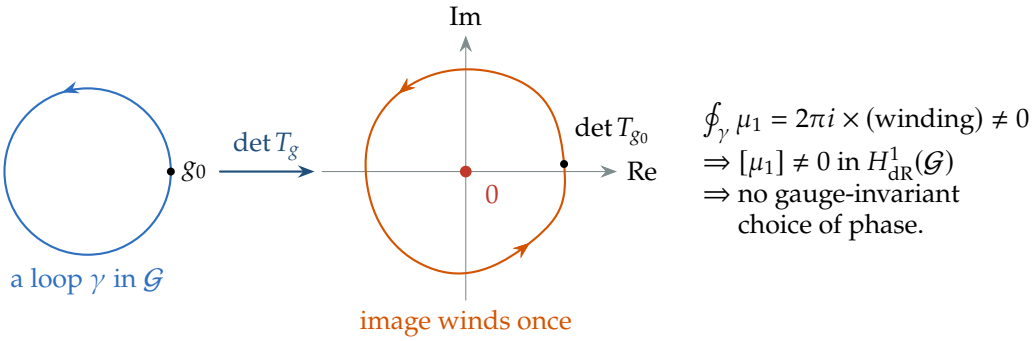

Figure 10.21: Nash's criterion for exactness of μ_1. A loop in the gauge group is mapped by the determinant to a loop in $\mathbb{C} \setminus \{0\}$. If the image winds round the origin, $\ln\det T_g$ cannot be defined continuously and μ_1 is not exact. Such loops exist only if $\pi_1(\mathcal{G}) \neq 0$.

Loops in $\mathcal{G}$ [Nash (10.17)–(10.18)]. If $\mathcal{G}$ is simply connected, every loop can be shrunk, the winding is zero, and μ_1 is exact. So topology enters through $\pi_1(\mathcal{G})$. Take $M = S^{2m}$ and (to make the action free) the *based* gauge group $\mathcal{G} = \mathrm{Map}_*(S^{2m}, G)$, maps sending a base point to 1. A loop in $\mathcal{G}$ is a family $g_t(x)$, $t \in S^1$, i.e. a map $S^1 \times S^{2m} \to G$ that is 1 whenever $t = 0$ or x is the base point. Collapsing $S^1 \times \{*\} \cup \{0\} \times S^{2m}$ to a point turns $S^1 \times S^{2m}$ into the sphere S^{2m+1} (the smash product $S^1 \wedge S^{2m}$). Hence

$$\pi_1(\mathcal{G}) = \pi_{2m+1}(G).$$

(Nash writes π_{2n+1}, with his n equal to our m, half the dimension of M.) For $M = S^4$ and $G = \mathrm{U}(N)$:

- $N = 1$: $\pi_5(\mathrm{U}(1)) = 0$, because $\mathrm{U}(1) = S^1$ has the contractible universal cover $\mathbb{R}$, so all its higher homotopy groups vanish.
- $N = 2$: $\pi_5(\mathrm{U}(2)) = \pi_5(\mathrm{SU}(2)) = \pi_5(S^3) = \mathbb{Z}_2$, a torsion group, which de Rham cohomology cannot see (H^1_{dR} is a real vector space).
- $N \geq 3$: $\pi_5(\mathrm{U}(N)) = \mathbb{Z}$ (Bott periodicity: $\pi_{2k-1}(\mathrm{U}(N)) = \mathbb{Z}$ once $N \geq k$). A generator is detected by the integral $\int_{S^5} \mathrm{tr}(g^{-1}\mathrm{d}g)^5$ (the Q_5 of a pure gauge, Example 10.23).

So for $N \geq 3$ there is room for $[\mu_1] \neq 0$ in $H^1_{\mathrm{dR}}(\mathcal{G})$, and indeed it is nonzero: integrating μ_1 round the generating loop gives $2\pi i$ times a nonzero integer proportional to the anomaly

coefficient d^{abc} of the fermion representation. This matches Section 10.5.6: SU($N \geq 3$) with a triplet-type representation is anomalous, SU(2) is not (perturbatively), and U(1) is a puzzle to which we return in Section 10.6.6.

10.6.3 Determinants in linear algebra: the determinant line

The second picture needs a precise notion of the determinant of a map between two *different* spaces. Let $O : V \to W$ be linear with $\dim V = \dim W = k$. The top exterior powers $\Lambda^k V$, $\Lambda^k W$ are one-dimensional and O induces a map between them,

$$\Lambda^k O : \; v_1 \wedge \cdots \wedge v_k \;\longmapsto\; Ov_1 \wedge \cdots \wedge Ov_k. \tag{10.157}$$

A linear map between one-dimensional spaces is "a number times an identification", i.e. an element of $\mathrm{Hom}(\Lambda^k V, \Lambda^k W) \cong (\Lambda^k V)^* \otimes \Lambda^k W$ [Nash (10.21)]. That element is $\det O$.

Worked example 10.30: The 2×2 determinant as a wedge product

Let $V = W = \mathbb{C}^2$ with basis e_1, e_2 and $O = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$, so $Oe_1 = ae_1 + ce_2$, $Oe_2 = be_1 + de_2$. Then

$$Oe_1 \wedge Oe_2 \overset{(1)}{=} ab\, e_1 \wedge e_1 + ad\, e_1 \wedge e_2 + cb\, e_2 \wedge e_1 + cd\, e_2 \wedge e_2 \overset{(2)}{=} (ad - bc)\, e_1 \wedge e_2.$$

(1) Bilinearity of $\wedge$.
(2) $e_i \wedge e_i = 0$ and $e_2 \wedge e_1 = -e_1 \wedge e_2$.

So $\Lambda^2 O = (ad - bc)\,(e_1 \wedge e_2)^* \otimes (e_1 \wedge e_2)$. If $V \neq W$ and we rescale the basis of W alone, $e_i' = 2e_i$, the *number* in front changes ($e_1 \wedge e_2 = \frac{1}{4} e_1' \wedge e_2'$), but the element of the line $(\Lambda^2 V)^* \otimes \Lambda^2 W$ does not. For a chiral Dirac operator $V = \Gamma(E^+)$ and $W = \Gamma(E^-)$ are different, so its determinant is canonically a vector in a line, not a number. This is the precise meaning of the remark in Section 10.2.5.

Unequal dimensions and kernels. If $\dim V \neq \dim W$, or O is not invertible, we split off the kernels. With inner products on V and W and the adjoint O^*,

$$V = \mathrm{Range}\, O^* \oplus \ker O, \qquad W = \mathrm{Range}\, O \oplus \ker O^* \quad \text{[Nash (10.22)]}. \tag{10.158}$$

The first holds because $\ker O$ is exactly the orthogonal complement of $\mathrm{Range}\, O^*$:

$$v \in \ker O \overset{(1)}{\iff} \langle Ov, w\rangle = 0 \;\; \forall w \in W \overset{(2)}{\iff} \langle v, O^* w\rangle = 0 \;\; \forall w \iff v \perp \mathrm{Range}\, O^*,$$

(1) A vector is zero iff it is orthogonal to everything.
(2) Definition of the adjoint.

and the second is the same statement for O^*. Next, top powers of direct sums factorise:

$$\Lambda^{\max}(X \oplus Y) \cong \Lambda^{\max} X \otimes \Lambda^{\max} Y, \qquad (x_1 \wedge \cdots \wedge x_p) \wedge (y_1 \wedge \cdots \wedge y_q) \leftrightarrow (x_1 \wedge \cdots \wedge x_p) \otimes (y_1 \wedge \cdots \wedge y_q), \tag{10.159}$$

since a basis of X followed by a basis of Y is a basis of $X \oplus Y$. Therefore [Nash (10.23)]

$$(\Lambda^{\max} V)^* \otimes \Lambda^{\max} W \overset{(1)}{=} \left(\Lambda^{\max} \mathrm{Range}\, O^*\right)^* \otimes (\Lambda^{\max} \ker O)^* \otimes \Lambda^{\max} \mathrm{Range}\, O \otimes \Lambda^{\max} \ker O^*.$$

(1) (10.158) and (10.159), with $(X \otimes Y)^* = X^* \otimes Y^*$ for lines.

On the ranges, O restricts to an *isomorphism* $\mathrm{Range}\, O^* \to \mathrm{Range}\, O$ (it is injective there, since the kernel has been removed, and the two ranges have the same dimension, the rank). So its

determinant is a *nonzero* element of $(\Lambda^{\max}\operatorname{Range} O^*)^* \otimes \Lambda^{\max}\operatorname{Range} O$, and we may use it to identify that line with $\mathbb{C}$. What remains is Nash's refined determinant line [Nash (10.24)]:

$$\det O \;\in\; (\Lambda^{\max}\ker O)^* \otimes (\Lambda^{\max}\ker O^*). \tag{10.160}$$

When $\ker O = 0 = \ker O^*$ both factors are $\Lambda^0 = \mathbb{C}$ canonically and $\det O$ is a nonzero number: this is the normalisation in Nash's footnote 2.

Worked example 10.31: Kernels that jump, a line that does not

Take $O_y : \mathbb{C}^2 \to \mathbb{C}^2$, $O_y = \left(\begin{smallmatrix} y & 0 \\ 0 & 0 \end{smallmatrix}\right)$, $y \in \mathbb{C}$.

- For $y \neq 0$: $\ker O_y = \ker O_y^* = \mathbb{C}e_2$, so (10.160) is the line $(\mathbb{C}e_2)^* \otimes \mathbb{C}e_2$, and the refined determinant is $y\, e_2^* \otimes e_2$: the determinant of the invertible part $y : \mathbb{C}e_1 \to \mathbb{C}e_1$ times the kernel line.
- For $y = 0$: $\ker O_0 = \ker O_0^* = \mathbb{C}^2$, and the line is $(\Lambda^2\mathbb{C}^2)^* \otimes \Lambda^2\mathbb{C}^2$.

The kernels jump from dimension 1 to 2, but both lines are canonically $\mathbb{C}$, and the determinant $y \mapsto y$ is a continuous (indeed holomorphic) section of a smooth line bundle over the y-plane, vanishing at $y = 0$. The general rule: if both kernels grow by the same space U, the line $(\Lambda^{\max}(K \oplus U))^* \otimes \Lambda^{\max}(K' \oplus U) \cong (\Lambda^{\max}K)^* \otimes (\Lambda^{\max}U)^* \otimes \Lambda^{\max}U \otimes \Lambda^{\max}K'$ is canonically $(\Lambda^{\max}K)^* \otimes \Lambda^{\max}K'$, because $(\Lambda^{\max}U)^* \otimes \Lambda^{\max}U = \mathbb{C}$ canonically (pair a vector with its dual). Kernels jump; the index (here $1 - 1 = 0$) and the determinant line do not.

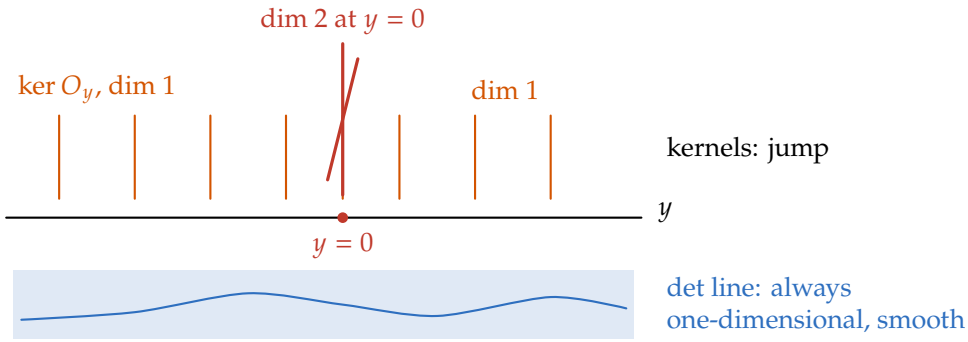

Figure 10.22: The kernel of a family of operators can jump in dimension at special parameter values (red), so $y \mapsto \ker O_y$ is not a vector bundle. The determinant line $(\Lambda^{\max}\ker O)^* \otimes \Lambda^{\max}\ker O^*$ is: extra kernel in $\ker O$ is matched by extra kernel in $\ker O^*$ (the index is constant), and the two cancel in the line.

10.6.4 Families of Dirac operators and the determinant line bundle

Now the whole partition function [Nash (10.19)] $Z = \int_{\mathcal{A}} \mathcal{D}A\, \sqrt{\det(\not{D}_A^*\not{D}_A)}\, e^{-\|F\|^2}$ involves not one Dirac operator but the whole family $\{D_A^+\}_{A\in\mathcal{A}}$. Chapter 4 (Chapter 4) attaches to a family of elliptic operators parametrised by a space Y an *index bundle* in the K-theory of Y:

$$\operatorname{Index}\not{D} = \{\ker D_A^+ : A \in \mathcal{A}\} - \{\ker(D_A^+)^\dagger : A \in \mathcal{A}\} = [\ker\not{D}] - [\ker\not{D}^*] \in K(\mathcal{A}) \qquad \text{[Nash (10.20)]}. \tag{10.161}$$

(Reminder: $K(Y)$ consists of formal differences $[V] - [W]$ of vector bundles over Y, with $[V]-[W] = [V']-[W']$ when $V \oplus W' \oplus U \cong V' \oplus W \oplus U$ for some U. The individual kernels are not bundles, since they jump, but their difference is well defined: add a fixed finite-dimensional space to the target to kill the cokernel locally, as in Example 10.31.) Because $D^+_{A_g} = g^{-1}D_A^+ g$

(10.22), the kernels at A and A_g are identified by g, and the index bundle descends to an element of $K(\mathcal{A}/\mathcal{G})$.

The determinant line of a K-theory class [Nash (10.25)–(10.28)]. To a vector bundle E of rank k associate its **determinant bundle** $\det E$, the line bundle with fibre $\Lambda^k E_y$ (Nash's footnote 3). To a K-theory element $[V]-[W]$ associate $(\det V)^* \otimes \det W$ [Nash (10.27)]. This does not depend on the representative:

$$\big(\det(V\oplus U)\big)^* \otimes \det(W\oplus U) \overset{(1)}{=} (\det V)^* \otimes (\det U)^* \otimes \det W \otimes \det U \overset{(2)}{=} (\det V)^* \otimes \det W,$$

(1) (10.159) fibre by fibre.
(2) $(\det U)^* \otimes \det U$ is canonically trivial.

and $[V\oplus U]-[W\oplus U]=[V]-[W]$ is the only freedom in the representative. Applied to the Dirac family,

$$\det \mathrm{Index}\, \not{D} = (\det\ker \not{D})^* \otimes (\det \ker \not{D}^*) \quad \text{over } \mathcal{A}/\mathcal{G} \qquad \text{[Nash (10.28)]}, \tag{10.162}$$

and (10.160) says that the chiral determinant $\det D_A^+$ is a *section* of this line bundle.

Working definition 10.8 (determinant line bundle)

The **determinant line bundle** of a family of Fredholm operators $\{O_y\}_{y\in Y}$ [operators that can have zero modes, i.e. nonzero solutions $\psi\neq 0$ of $O_y\psi=0$. How many independent zero modes there are can change as y varies] is the line bundle over Y [a copy of $\mathbb{C}$ attached to each point y] whose fibre at y is $(\Lambda^{\max}\ker O_y)^* \otimes \Lambda^{\max}\ker O_y^*$ [the line at y where $\det O_y$ lives. Every such line looks like $\mathbb{C}$, but only when O_y has no zero modes is there a natural way to read $\det O_y$ as an ordinary number], glued across jumps of the kernels as in Example 10.31. The determinant $y\mapsto \det O_y$ is a section [it picks one point from each of these copies], vanishing exactly where O_y has zero modes. *To test for an anomaly:* compute c_1 [an integer measuring how much the copies of $\mathbb{C}$ twist as one goes around Y] with the families index theorem below. If $c_1\neq 0$, no nowhere-vanishing section compatible with the gauge identifications exists, so the determinant cannot be made gauge invariant.

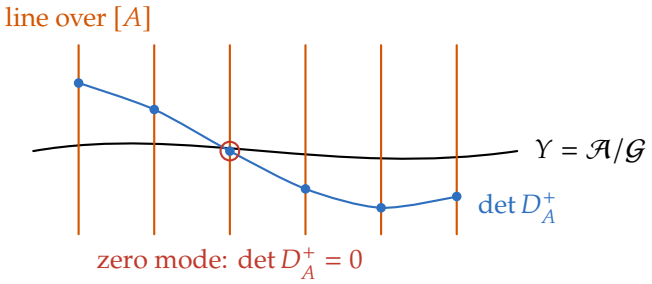

Figure 10.23: The determinant line bundle. Over each gauge field $[A]$ stands a line (orange). The chiral determinant picks a point on every line (blue), so it is a section. The base curve is where each line has its zero, and the section crosses it where D_A^+ has a zero mode (red). If the lines are glued with a twist ($c_1\neq 0$), every section must cross zero and no gauge-invariant choice of the determinant exists: the anomaly.

The Chern class of a determinant bundle. We need $c_1(\det E)=c_1(E)$. For a direct sum of line bundles $E=L_1\oplus L_2$ we have $\det E=L_1\otimes L_2$, and c_1 adds under tensor products, so

$c_1(\det E) = c_1(L_1) + c_1(L_2) = c_1(E)$. In curvature language (the general case, which the splitting principle reduces to this one): the induced connection on $\Lambda^k E$ has curvature $\operatorname{tr} F_E$, so

$$c_1(\det E) \overset{(1)}{=} \frac{i}{2\pi} F_{\det E} \overset{(2)}{=} \frac{i}{2\pi} \operatorname{tr} F_E \overset{(3)}{=} c_1(E),$$

(1) Definition of c_1 for a line bundle.
(2) On $e_1 \wedge \cdots \wedge e_k$ the curvature acts by the Leibniz rule, $\sum_i e_1 \wedge \cdots \wedge F_E e_i \wedge \cdots \wedge e_k = (\operatorname{tr} F_E)\, e_1 \wedge \cdots \wedge e_k$.
(3) Definition of $c_1(E)$ (Chapter T2).

and by linearity $c_1(\det \operatorname{Index} \not{D}) = c_1(\operatorname{Index} \not{D})$.

The families index theorem [Nash (10.29)–(10.30)]. Chapter 4's formula (Nash's (4.126)) for the Chern character of the index bundle, specialised to the spin complex on an even-dimensional M, reads

$$\operatorname{ch}(\operatorname{Index} \not{D}) = \int_M \operatorname{ch}(\mathcal{E})\, \hat{A}(M) \overset{M=S^n}{=} \int_{S^n} \operatorname{ch}(\mathcal{E}). \tag{10.163}$$

Here $\mathcal{E}$ is the **universal bundle** over $Z = M \times \mathcal{A}/\mathcal{G}$: over the point $(x, [A])$ its fibre is the fibre F_x of the colour bundle, and it carries a natural connection whose restriction to $M \times \{[A]\}$ is A. (Construct it as $(F \times \mathcal{A})/\mathcal{G}$; its curvature $\mathbb{F}$ has a $(2,0)$ part F_A along M, a $(1,1)$ part mixing M and $\mathcal{A}/\mathcal{G}$, and a $(0,2)$ part along $\mathcal{A}/\mathcal{G}$.) The integral $\int_M$ lowers the degree by n: the degree-$2j$ part of the left side comes from the degree-$(n+2j)$ part of $\operatorname{ch}(\mathcal{E})\hat{A}$. For c_1 we need $j = 1$:

$$c_1(\det \operatorname{Index} \not{D}) = \int_M \big[\operatorname{ch}(\mathcal{E})\hat{A}\big]_{(n+2)} \overset{M=S^{2m}}{=} \int_{S^{2m}} \operatorname{ch}_{m+1}(\mathbb{F}) \in H^2_{\mathrm{dR}}(\mathcal{A}/\mathcal{G}). \tag{10.164}$$

This is the moment to look back at the descent equations: ch_{m+1} is the Ω_{2m+2} of (10.146). The "imagined $(2m+2)$-dimensional space" on which it lived is $M \times \Sigma$ for a 2-cycle Σ of gauge orbits: the characteristic class that seeds the descent is exactly the one that measures the determinant line bundle.

Worked example 10.32: Flat connections on a torus: a determinant line bundle with $|c_1| = 1$

Let $M = T^2 = \mathbb{R}^2/\mathbb{Z}^2$ with coordinates $x_1, x_2 \in [0,1)$ and flat metric, and a single positive-chirality fermion of charge one. Consider the two-parameter family of flat connections

$$A_\theta = 2\pi i\,(\theta_1 \mathrm{d}x_1 + \theta_2 \mathrm{d}x_2), \qquad \theta = (\theta_1, \theta_2) \in \mathbb{R}^2.$$

The orbit space. The gauge transformation $g_n = e^{2\pi i(n_1 x_1 + n_2 x_2)}$, $n \in \mathbb{Z}^2$, is well defined on T^2 and gives $(A_\theta)_{g_n} = A_\theta + g_n^{-1}\mathrm{d}g_n = A_{\theta+n}$. So the flat connections modulo gauge form the dual torus $\hat{T}^2 = \mathbb{R}^2/\mathbb{Z}^2 \ni \theta$, a two-dimensional piece of $\mathcal{A}/\mathcal{G}$.
The spectrum. By Example 10.3, $D^+_\theta = D_1 + iD_2 = \partial_1 + i\partial_2 + 2\pi i(\theta_1 + i\theta_2)$. On the plane waves $e_k = e^{2\pi i(k_1 x_1 + k_2 x_2)}$, $k \in \mathbb{Z}^2$,

$$D^+_\theta e_k \overset{(1)}{=} \big[2\pi i k_1 + i \cdot 2\pi i k_2 + 2\pi i(\theta_1 + i\theta_2)\big] e_k \overset{(2)}{=} 2\pi i\,(k + \theta)\, e_k,$$

(1) $\partial_j e_k = 2\pi i k_j e_k$.
(2) Complex notation $k = k_1 + ik_2$, $\theta = \theta_1 + i\theta_2$.

So "$\det D^+_\theta = \prod_{k \in \mathbb{Z}[i]} 2\pi i(k+\theta)$" (regularised by the zeta function of $(D^+)^\dagger D^+$, with eigenvalues $4\pi^2|k+\theta|^2$). The kernels are nonzero only when $k + \theta = 0$ for some k, i.e. at the single point $\theta \equiv 0$ of $\hat{T}^2$, where $\ker D^+ = \ker(D^+)^\dagger = \mathbb{C} \cdot 1$: the index is $1 - 1 = 0$ everywhere, as it must be for a trivial bundle ($\int_{T^2} \operatorname{ch}_1 = 0$), but the kernels jump at one point.

The determinant is a section, not a function. Each factor $k+\theta$ depends holomorphically on θ, and the regularised determinant is a holomorphic object with a single simple zero on $\hat{T}^2$. It cannot be a function on $\hat{T}^2$: a holomorphic function on a compact torus is constant, and this one has a zero. It is a section of the determinant line bundle, periodic in θ only up to a multiplier ($\det D^+_{\theta+n} = \chi_n(\theta)\det D^+_\theta$), exactly like a Jacobi theta function. For a holomorphic section of a holomorphic line bundle on a compact Riemann surface, the number of zeros (with multiplicity) equals the degree c_1. Hence $|c_1(\det \mathrm{Index})| = 1$ and the bundle is not trivial.

The families index agrees. On $T^2 \times \hat{T}^2$ the universal connection is $\mathbb{A} = 2\pi i(\theta_1 \mathrm{d}x_1 + \theta_2 \mathrm{d}x_2)$, now with θ a coordinate too (the gluing by g_n makes the bundle over $T^2 \times \hat{T}^2$ the Poincaré bundle). Then

$$\mathbb{F} = \mathrm{d}\mathbb{A} \overset{(1)}{=} 2\pi i\,(\mathrm{d}\theta_1 \wedge \mathrm{d}x_1 + \mathrm{d}\theta_2 \wedge \mathrm{d}x_2),$$

$$\mathrm{ch}_2(\mathbb{F}) = \frac{1}{2}\Big(\frac{i}{2\pi}\mathbb{F}\Big)^2 \overset{(2)}{=} \frac{1}{2}\big(\mathrm{d}\theta_1\mathrm{d}x_1 + \mathrm{d}\theta_2\mathrm{d}x_2\big)^2 \overset{(3)}{=} \mathrm{d}\theta_1\mathrm{d}x_1\mathrm{d}\theta_2\mathrm{d}x_2 \overset{(4)}{=} -\mathrm{d}x_1\mathrm{d}x_2\,\mathrm{d}\theta_1\mathrm{d}\theta_2,$$

$$c_1(\det \mathrm{Index}) = \int_{T^2} \mathrm{ch}_2(\mathbb{F}) \overset{(5)}{=} -\mathrm{d}\theta_1 \wedge \mathrm{d}\theta_2, \qquad \int_{\hat{T}^2} c_1 \overset{(6)}{=} -1.$$

(1) d acts on θ as well: $\mathrm{d}(\theta_j \mathrm{d}x_j) = \mathrm{d}\theta_j \wedge \mathrm{d}x_j$.

(2) $\frac{i}{2\pi}\cdot 2\pi i = -1$, and the sign disappears on squaring.

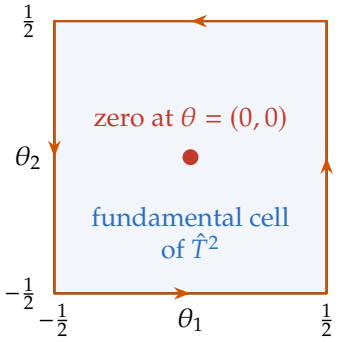
(3) The squares $(\mathrm{d}\theta_1\mathrm{d}x_1)^2$ vanish; the two cross terms are equal (2-forms commute), cancelling the $\frac{1}{2}$.

(4) Reordering $(\theta_1, x_1, \theta_2, x_2) \to (x_1, x_2, \theta_1, \theta_2)$ is an odd permutation (three transpositions).

(5) (10.164) with $\hat{A}(T^2) = 1$ (flat); integrate over $M = T^2$ with $\int \mathrm{d}x_1\mathrm{d}x_2 = 1$.

(6) $\int_{\hat{T}^2} \mathrm{d}\theta_1\mathrm{d}\theta_2 = 1$.

So $|c_1| = 1$, in agreement with the count of zeros. (The sign depends on orientation conventions and on whether one uses Nash's $(\det\ker)^* \otimes \det\ker^*$ or its dual; the magnitude does not.) The chiral U(1) theory on T^2 is anomalous, as the two-dimensional anomaly $\frac{i}{4\pi}\int \mathrm{tr}(v\,\mathrm{d}A) \neq 0$ predicted.



Going round the boundary of the cell, the phase of $\det D^+_\theta$ (measured against the multipliers that glue opposite sides) winds once: one zero inside, $|c_1(\det \mathrm{Index})| = 1$. A gauge-invariant, nowhere-vanishing choice of $\det D^+_\theta$ is impossible.

Figure 10.24: The determinant line bundle over the dual torus of flat U(1) connections on T^2 (Example 10.32). The kernel jumps only at $\theta \equiv 0$; that is where the section $\det D^+_\theta$ vanishes. Counting zeros of a holomorphic section computes c_1, and the families index theorem computes the same number from $\int_{T^2} \mathrm{ch}_2$ of the universal bundle.

10.6.5 The two pictures are one [Nash (10.31)–(10.34)]

We now have two classes [Nash (10.31)]:

$$[\mu_1] = \left[\frac{\mathrm{d}\,\det T_g}{\det T_g}\right] \in H^1_{\mathrm{dR}}(\mathcal{G}) \qquad \text{and} \qquad c_1(\det \operatorname{Index} \not{D}) \in H^2_{\mathrm{dR}}(\mathcal{A}/\mathcal{G}),$$

and Nash asserts (using his Chapter 8, Chapter 8) that [Nash (10.32)]

$$\mu_1 = 0 \iff c_1(\det \operatorname{Index} \not{D}) = 0.$$

Here is why. The space $\mathcal{A}$ of connections is an affine space (any two connections differ by a 1-form, and $A_0 + s(A_1 - A_0)$ is a connection for all s), hence contractible. So:

1. The pull-back of $\det \operatorname{Index} \not{D}$ to $\mathcal{A}$ is trivial (every bundle over a contractible space is), and the chiral determinant $A \mapsto \det D_A^+$ is simply a function on $\mathcal{A}$.
2. Along a gauge orbit this function is not invariant: $\det D^+_{A_g} = \chi(A, g)\, \det D_A^+$ for a nowhere-zero **multiplier** χ. This is how a line bundle over the quotient $\mathcal{A}/\mathcal{G}$ is described upstairs, exactly as theta functions describe line bundles over a torus by their multipliers under the lattice.
3. $\mathrm{d}_g \ln \chi$ is μ_1. Changing the trivialisation upstairs (multiplying $\det D_A^+$ by a nowhere-zero function $e^{\Phi(A)}$) changes μ_1 by the exact form $\mathrm{d}\Phi$. The bundle downstairs is trivial iff χ can be made $\equiv 1$, i.e. iff μ_1 is exact.

In topological language this is the isomorphism $\pi_1(\mathcal{G}) \cong \pi_2(\mathcal{A}/\mathcal{G})$ from the exact homotopy sequence of $\mathcal{G} \to \mathcal{A} \to \mathcal{A}/\mathcal{G}$ with $\mathcal{A}$ contractible (so $\mathcal{A}/\mathcal{G} = B\mathcal{G}$, the classifying space): a loop in $\mathcal{G}$ is the "equator" of a 2-sphere in $\mathcal{A}/\mathcal{G}$, and the winding of det round the loop equals c_1 on the sphere. (A familiar finite-dimensional instance: for the Hopf bundle $S^1 \to S^3 \to S^2$, the winding of a section's phase round the equator equals $c_1 = \pm 1$ on S^2.)

No anomaly $\Rightarrow$ a global section [Nash (10.34)]. Suppose there is no anomaly, so that $\det D_A^+$ can be chosen gauge invariant. Then the integrand of Z is constant on orbits and the integral over $\mathcal{A}$ reduces to an integral over $\mathcal{A}/\mathcal{G}$ (Faddeev–Popov):

$$\int_{\mathcal{A}} \mathcal{D}A\ \det(\not{D})\, e^{-\|F\|^2} = \int_{\mathcal{A}/\mathcal{G}} \mathcal{D}A_{\mathcal{G}}\ \mathrm{Jac}\ \det(\not{D})\, e^{-\|F\|^2},$$

with $\mathcal{D}A_{\mathcal{G}}$ the measure on orbits, Jac the Faddeev–Popov Jacobian (and the constant volume of $\mathcal{G}$ dropped). A finite-dimensional picture of the Jacobian:

Worked example 10.33: Integrating over orbits in the plane

Let U(1) act on $\mathbb{R}^2$ by rotations, and let $f(\vec{x}) = f(r)$ be invariant. The orbits are circles, the orbit space is $[0, \infty) \ni r$, and

$$\int_{\mathbb{R}^2} f\, \mathrm{d}^2x \overset{(1)}{=} \int_0^\infty \int_0^{2\pi} f(r)\, r\, \mathrm{d}\phi\, \mathrm{d}r \overset{(2)}{=} 2\pi \int_0^\infty \mathrm{d}r \underbrace{r}_{\mathrm{Jac}} f(r).$$

(1) Polar coordinates: $\mathrm{d}^2x = r\, \mathrm{d}r\, \mathrm{d}\phi$.
(2) The ϕ-integral is the volume of the group, 2π; the leftover r is the size of the orbit, the Jacobian.

The origin, a fixed point, is where the action is not free: the analogue of reducible connections (and of the isometries of Section 10.7), which is why Nash restricts to based gauge transformations.

In (10.162) language, a gauge-invariant $\det(\not{D})$ on $\mathcal{A}/\mathcal{G}$ is a *global* section of $\det \operatorname{Index} \not{D}$, nowhere vanishing (after the perturbations of Section 10.6.1); a line bundle with a nowhere-vanishing global section is trivial, so $c_1 = 0$. Contrapositive: $c_1(\det \operatorname{Index} \not{D}) \neq 0$ *implies an anomaly.* The index theorem for families thus "brings out very succinctly the anomaly as an obstacle to the definition of a gauge invariant determinant".

10.6.6 Local versus de Rham cohomology

There is a puzzle in (10.155) for $G = \mathrm{U}(1)$ on S^4: $\pi_1(\mathcal{G}) = \pi_5(\mathrm{U}(1)) = 0$, so $H^1_{\mathrm{dR}}(\mathcal{G}) = 0$ and μ_1 is exact, yet the triangle graph shows an anomaly that no counterterm removes. Nash's resolution [Nash p. 279]: $\mu_1 = \mathrm{d}\Phi$ with Φ *non-local*. The explicit counterterm makes this concrete.

Worked example 10.34: A non-local counterterm for the abelian anomaly

Take the four-dimensional U(1) consistent anomaly in the form $\mathcal{A}[\lambda] = c\int \lambda\, \epsilon^{\mu\nu\rho\sigma}\partial_\mu a_\nu \partial_\rho a_\sigma \,\mathrm{d}^4x$ (with $\delta a_\mu = \partial_\mu \lambda$ and a constant c), and let $\Box = \partial_\mu\partial_\mu$ with inverse $\Box^{-1}$ (convolution with the Green's function). Put

$$\Phi[a] := c\int (\partial_\mu a_\mu)\, \Box^{-1}\big(\epsilon^{\alpha\beta\gamma\delta}\partial_\alpha a_\beta \partial_\gamma a_\delta\big)\,\mathrm{d}^4x.$$

Then

$$\delta_\lambda \Phi \overset{(1)}{=} c\int (\partial_\mu\partial_\mu\lambda)\,\Box^{-1}\big(\epsilon\, \partial a\, \partial a\big) \overset{(2)}{=} c\int \lambda\, \Box\,\Box^{-1}\big(\epsilon\, \partial a\, \partial a\big) \overset{(3)}{=} c\int \lambda\, \epsilon\, \partial a\, \partial a = \mathcal{A}[\lambda].$$

(1) $\epsilon\, \partial a\, \partial a = \frac{1}{4}\epsilon f f$ is gauge invariant, so only $\partial \cdot a$ varies: $\delta(\partial_\mu a_\mu) = \Box\lambda$.
(2) Integrate $\Box$ by parts twice (it is symmetric).
(3) $\Box\Box^{-1} = 1$.

So $\ln Z_F - \Phi$ is gauge invariant: the anomaly is "d of something", as $H^1_{\mathrm{dR}}(\mathcal{G}) = 0$ demands. But Φ involves $\Box^{-1}$, i.e. it couples fields at distant points with a $1/|x-y|^2$ kernel. No *local* Φ (a polynomial in a and finitely many derivatives) works: the only parity-odd local 4-forms built from an abelian a are multiples of $a\,\mathrm{d}a\,\wedge(\cdot)$ with $a\wedge a = 0$, and $\int \mathrm{d}a\wedge \mathrm{d}a$ is gauge invariant. The same construction in two dimensions, $\Phi = c\int(\partial\cdot a)\Box^{-1}(\epsilon^{\mu\nu}\partial_\mu a_\nu)$, reproduces the chiral Schwinger model's non-local effective action.

Working definition 10.9 (local cohomology)

The **local cohomology** $H^1_{\mathrm{loc}}(\mathcal{G})$ is the space of local functionals $\mathcal{A}[v;A]$ (integrals of polynomials in v, A and finitely many derivatives) satisfying the Wess–Zumino condition [$\delta_v\mathcal{A}[w] - \delta_w\mathcal{A}[v] = \mathcal{A}[[v,w]]$], modulo those of the form $\delta_v\Phi_{\mathrm{loc}}$ with Φ_{loc} local [two anomalies count as the same if they differ by such a term, since a local counterterm removes it]. A physical anomaly is a nonzero class in H^1_{loc}. *To compute:* run the descent [write the polynomial as $\mathrm{d}\omega^0_{2m+1}$, then $\delta_v\omega^0_{2m+1} = \mathrm{d}\omega^1_{2m}$. The anomaly is $\int_M \omega^1_{2m}$] from each independent invariant polynomial of degree $m+1$ [a gauge-invariant polynomial in the curvature, such as $\operatorname{tr} F^{m+1}$]; each gives one class.

G on S^4	$\pi_1(\mathcal{G}) = \pi_5(G)$	$H^1_{\mathrm{dR}}(\mathcal{G})$	$H^1_{\mathrm{loc}}(\mathcal{G})$
U(1)	0	0	$\neq 0$: triangle anomaly $\propto \sum q^3$
SU(2)	$\mathbb{Z}_2$	0	0 (no d^{abc}); global anomaly in Nash §5
SU(N), $N \geq 3$	$\mathbb{Z}$	$\mathbb{R}$	$\neq 0$: $\propto d^{abc}$

The table shows that neither cohomology contains the other's information: de Rham cohomology misses the U(1) anomaly (which lives in the difference between "exact" and "exact with a local primitive"), and misses the SU(2) torsion. Nash cites Bonora and Cotta-Ramusino for the systematic theory; in physics language it is the BRST cohomology of local functionals, and the descent equations compute it.

Reading Nash (pp. 273–279, (10.12)–(10.34))

Nash's "first part" is Sections 10.6.1 and 10.6.2: the operator T_g (10.12), its elliptic symbol (10.14), the zeta determinant with finitely many negative eigenvalues (10.15), the 1-form μ_1 (10.13), (10.16), and the homotopy input (10.17)–(10.18). His "second part" is Sections 10.6.3 to 10.6.5: the index bundle (10.20), determinant lines (10.21)–(10.28), the families index theorem (10.29)–(10.30), and the equivalence (10.32). Two points he leaves implicit: μ_1 is exactly the consistent anomaly of Section 10.5.5 (10.156), and the ch_{m+1} that computes c_1 in (10.30) is exactly the polynomial that seeds the descent. His final paragraph (local cohomology) is Section 10.6.6. In (10.17) his n is half the dimension of M.

Recap

- $T_g = \not{D}^*_A \not{D}_{A_g}$ is elliptic (symbol $|p|^2\mathbf{1}$) but not positive; its zeta determinant multiplies in the finitely many stray eigenvalues. On S^1: $\lambda_n = (n+a)(n+a+k)$, k negative eigenvalues, sign $(-1)^k$.
- $\mu_1 = \mathrm{d}\ln\det T_g$ is the consistent anomaly as a closed 1-form on $\mathcal{G}$; it is exact iff det has no winding round loops of $\mathcal{G}$; $\pi_1(\mathcal{G}) = \pi_{2m+1}(G)$; $\pi_5(\mathrm{U}(N)) = 0, \mathbb{Z}_2, \mathbb{Z}$.
- The determinant of $O : V \to W$ lives in $(\Lambda^{\max} \ker O)^* \otimes \Lambda^{\max} \ker O^*$; kernels jump, the line does not.
- For the Dirac family: det Index $\not{D}$ over $\mathcal{A}/\mathcal{G}$, $c_1(\det \mathrm{Index}) = \int_M [\mathrm{ch}(\mathcal{E})\hat{A}]_{(n+2)}$; on T^2 with flat U(1) connections $|c_1| = 1$ (one zero of the determinant).
- $[\mu_1] \in H^1_{\mathrm{dR}}(\mathcal{G})$ and $c_1 \in H^2_{\mathrm{dR}}(\mathcal{A}/\mathcal{G})$ vanish together ($\mathcal{A}$ contractible); no anomaly $\Rightarrow$ global section $\Rightarrow c_1 = 0$.
- U(1): $H^1_{\mathrm{dR}} = 0$ yet anomalous, because the primitive is non-local; the physical object is local cohomology.

10.7 Gravitational anomalies

Gauge fields are not the only background a chiral fermion can feel. It also feels the metric, through the gamma matrices and the spin connection, and coordinate invariance plays the role of gauge invariance. The question this section answers is Nash's [Nash p. 279]: *can the fermion determinant, viewed as a function of the metric, fail to be invariant under diffeomorphisms, and if so in which dimensions?* The analysis is "analogous to that of the preceding section with $\mathcal{A}$ and $\mathcal{A}/\mathcal{G}$ replaced by $\mathrm{Met}(M)$ and $\mathrm{Met}(M)/\mathrm{Diff}_0(M)$", and the answer, due to Alvarez-Gaumé and

Witten, is: only in dimensions $n = 4k - 2$, i.e. $2, 6, 10, \ldots$

10.7.1 The Dirac operator depends on the metric

To concentrate on gravity we drop the Yang–Mills field. The chiral Dirac operator is then Nash's $\frac{1}{2}\gamma_\mu(\partial^\mu + \Gamma^\mu)(1+\gamma_5)$, where Γ_μ is the spin connection. Both ingredients depend on the metric $\rho \in \mathrm{Met}(M)$ (the space of all Riemannian metrics on M).

- *The gamma matrices.* The Clifford relation $\{\gamma^\mu, \gamma^\nu\} = 2g^{\mu\nu}$ involves the metric. In practice we fix constant matrices γ^a with $\{\gamma^a, \gamma^b\} = 2\delta^{ab}$ and an orthonormal frame (vielbein) $e_a = e_a{}^\mu \partial_\mu$, $g(e_a, e_b) = \delta_{ab}$, and put $\gamma^\mu = e_a{}^\mu \gamma^a$ (Chapter T4).
- *The spin connection.* With the dual coframe $e^a = e^a{}_\mu \mathrm{d}x^\mu$, the Levi-Civita connection in the frame is the antisymmetric matrix of 1-forms $\omega^a{}_b$ fixed by Cartan's first structure equation $\mathrm{d}e^a + \omega^a{}_b \wedge e^b = 0$ (Chapter T2). On spinors it acts through the spin representation: $\nabla_\mu = \partial_\mu + \frac{1}{4}\omega_\mu{}^{ab}\gamma_a\gamma_b$, i.e. Nash's $\Gamma_\mu = \frac{1}{4}\omega_\mu{}^{ab}\gamma_a\gamma_b$.

So $\not{D}_\rho = \gamma^a e_a{}^\mu \nabla_\mu$, and we write D^+_ρ for its chiral part.

Worked example 10.35: The Dirac operator of a conformally flat surface

Let M be two-dimensional with $g = e^{2\sigma(x)}(\mathrm{d}x_1^2 + \mathrm{d}x_2^2)$, and $\gamma^1 = \sigma_1$, $\gamma^2 = \sigma_2$ as in Example 10.3.

Frame and spin connection. $e^a = e^\sigma \mathrm{d}x^a$, $e_a = e^{-\sigma}\partial_a$. The only independent component is $\omega := \omega^1{}_2 = -\omega^2{}_1$, and we claim $\omega = \partial_2\sigma\,\mathrm{d}x_1 - \partial_1\sigma\,\mathrm{d}x_2$:

$$\begin{aligned}\mathrm{d}e^1 + \omega^1{}_2 \wedge e^2 &\overset{(1)}{=} \partial_2\sigma\, e^\sigma \mathrm{d}x_2 \wedge \mathrm{d}x_1 + (\partial_2\sigma\,\mathrm{d}x_1 - \partial_1\sigma\,\mathrm{d}x_2) \wedge e^\sigma \mathrm{d}x_2 \\ &\overset{(2)}{=} e^\sigma \partial_2\sigma\,(-1+1)\,\mathrm{d}x_1 \wedge \mathrm{d}x_2 = 0,\end{aligned}$$

$$\begin{aligned}\mathrm{d}e^2 + \omega^2{}_1 \wedge e^1 &\overset{(3)}{=} \partial_1\sigma\, e^\sigma \mathrm{d}x_1 \wedge \mathrm{d}x_2 - (\partial_2\sigma\,\mathrm{d}x_1 - \partial_1\sigma\,\mathrm{d}x_2) \wedge e^\sigma \mathrm{d}x_1 \\ &\overset{(4)}{=} e^\sigma \partial_1\sigma\,(1-1)\,\mathrm{d}x_1 \wedge \mathrm{d}x_2 = 0.\end{aligned}$$

(1) $\mathrm{d}(e^\sigma \mathrm{d}x_1) = e^\sigma \partial_2\sigma\,\mathrm{d}x_2 \wedge \mathrm{d}x_1$.
(2) $\mathrm{d}x_2 \wedge \mathrm{d}x_1 = -\mathrm{d}x_1 \wedge \mathrm{d}x_2$; $\mathrm{d}x_2 \wedge \mathrm{d}x_2 = 0$.
(3) $\mathrm{d}(e^\sigma \mathrm{d}x_2) = e^\sigma \partial_1\sigma\,\mathrm{d}x_1 \wedge \mathrm{d}x_2$ and $\omega^2{}_1 = -\omega$.
(4) $\mathrm{d}x_1 \wedge \mathrm{d}x_1 = 0$ and $-(-\partial_1\sigma)\mathrm{d}x_2 \wedge \mathrm{d}x_1 = -\partial_1\sigma\,\mathrm{d}x_1 \wedge \mathrm{d}x_2$.

The curvature is $R^1{}_2 = \mathrm{d}\omega = -(\partial_1^2 + \partial_2^2)\sigma\,\mathrm{d}x_1 \wedge \mathrm{d}x_2$; dividing by the area form $e^{2\sigma}\mathrm{d}x_1 \wedge \mathrm{d}x_2$ gives the Gaussian curvature $K = -e^{-2\sigma}\Delta\sigma$, the classical formula.

The Dirac operator. $\frac{1}{4}\omega_\mu{}^{ab}\gamma_a\gamma_b = \frac{1}{2}\omega_\mu\gamma_1\gamma_2 = \frac{i}{2}\omega_\mu\sigma_3$ (from $\sigma_1\sigma_2 = i\sigma_3$), so with $\omega_1 = \partial_2\sigma$, $\omega_2 = -\partial_1\sigma$,

$$\begin{aligned}\not{D}_g\psi &\overset{(1)}{=} e^{-\sigma}\Big[\sigma_a\partial_a\psi + \tfrac{i}{2}\big(\omega_1\sigma_1\sigma_3 + \omega_2\sigma_2\sigma_3\big)\psi\Big] \overset{(2)}{=} e^{-\sigma}\Big[\sigma_a\partial_a\psi + \tfrac{1}{2}\big(\partial_1\sigma\,\sigma_1 + \partial_2\sigma\,\sigma_2\big)\psi\Big] \\ &\overset{(3)}{=} e^{-3\sigma/2}\,\sigma_a\partial_a\big(e^{\sigma/2}\psi\big) = e^{-3\sigma/2}\not{D}_{\mathrm{flat}}\,e^{\sigma/2}\psi.\end{aligned}$$

(1) $\gamma^\mu = e^{-\sigma}\sigma_\mu$ and the spin connection term.
(2) $\sigma_1\sigma_3 = -i\sigma_2$ and $\sigma_2\sigma_3 = i\sigma_1$, so $\frac{i}{2}(\partial_2\sigma(-i\sigma_2) - \partial_1\sigma(i\sigma_1)) = \frac{1}{2}(\partial_2\sigma\,\sigma_2 + \partial_1\sigma\,\sigma_1)$.
(3) Leibniz: $\sigma_a\partial_a(e^{\sigma/2}\psi) = e^{\sigma/2}(\sigma_a\partial_a\psi + \frac{1}{2}\sigma_a\partial_a\sigma\,\psi)$.

So the Dirac operator of a conformally flat metric is the flat one, conjugated and rescaled. In particular zero modes are unchanged by σ (the index is a topological invariant), but the *spectrum* changes, and so does the regularised determinant.

Diffeomorphisms act covariantly [Nash (10.35)]. An orientation-preserving diffeomorphism $h \in \mathrm{Diff}^+(M)$ acts on metrics by pull-back, $h \cdot \rho = h^*\rho$, and (after lifting $\mathrm{d}h$ to the spin bundle, which is possible for h in the identity component) on spinor fields by pull-back. Since every ingredient of $\not{D}$ is constructed naturally from the metric,

$$\not{D}_{h\cdot\rho} = h^{-1}\,\not{D}_{\rho}\,h. \tag{10.165}$$

This is the analogue of $\not{D}_{A_g} = g^{-1}\not{D}_A g$: coordinate invariance says the operator at the transformed metric is conjugate to the original one. As before, the conjugation relates operators on *different* spaces (E^+ and E^- for the chiral operator), and the regularised determinant need not be invariant.

10.7.2 The space of metrics modulo diffeomorphisms

We want the determinant to descend from $\mathrm{Met}(M)$ to $\mathrm{Met}(M)/\mathrm{Diff}^+(M)$, the space of geometries. As in Chapter 6 (and Nash's Chapter 5), this quotient is singular where the action is not free: a metric with isometries (Killing vectors) is fixed by a subgroup of $\mathrm{Diff}^+(M)$. The cure is to restrict to the subgroup $\mathrm{Diff}_0(M)$ of diffeomorphisms in the identity component that fix a point $x_0 \in M$ and a frame at x_0. An isometry fixing a point and a frame there is the identity (it commutes with the exponential map, so it fixes every geodesic from x_0), so $\mathrm{Diff}_0(M)$ acts freely and $\mathrm{Met}(M)/\mathrm{Diff}_0(M)$ is well behaved.

Worked example 10.36: Metrics on a circle modulo diffeomorphisms

Every metric on $S^1 = [0,1]/(0 \sim 1)$ has the form $\rho = f(x)\,\mathrm{d}x^2$ with $f > 0$ periodic. Put $L = \int_0^1 \sqrt{f}\,\mathrm{d}x$ (the length) and $\phi(x) = \frac{1}{L}\int_0^x \sqrt{f(y)}\,\mathrm{d}y$. Then $\phi : S^1 \to S^1$ is a diffeomorphism fixing 0, and

$$\phi^*\big(L^2\mathrm{d}\phi^2\big) \overset{(1)}{=} L^2\phi'(x)^2\,\mathrm{d}x^2 \overset{(2)}{=} L^2\cdot\frac{f(x)}{L^2}\,\mathrm{d}x^2 = \rho.$$

(1) Pull-back of $\mathrm{d}\phi^2$ is $\phi'(x)^2\mathrm{d}x^2$.

(2) Fundamental theorem of calculus: $\phi'(x) = \sqrt{f(x)}/L$.

So every metric is equivalent to the constant metric of the same length: $\mathrm{Met}(S^1)/\mathrm{Diff}_0(S^1) \cong (0,\infty)$, one number. The rotations of the circle are isometries of $L^2\mathrm{d}\phi^2$; requiring the diffeomorphism to fix 0 removes them, which is Nash's reason for passing to Diff_0. (In two dimensions the same reasoning leaves the conformal factor and finitely many moduli: Nash's Chapter 9 and §4.)

The index bundle and its determinant [Nash (10.36)–(10.38)]. Exactly as for gauge fields,

$$\begin{aligned}\mathrm{Index}\,\not{D}_{\mathrm{grav}} &= \big\{\ker D^+_\rho : \rho \in \mathrm{Met}(M)\big\} - \big\{\ker (D^+_\rho)^\dagger : \rho \in \mathrm{Met}(M)\big\} \\ &= [\ker \not{D}_{\mathrm{grav}}] - [\ker \not{D}^*_{\mathrm{grav}}] \in K\big(\mathrm{Met}(M)/\mathrm{Diff}_0(M)\big), \qquad (10.166)\\ \det\mathrm{Index}\,\not{D}_{\mathrm{grav}} &= (\det\ker \not{D}_{\mathrm{grav}})^* \otimes (\det\ker \not{D}^*_{\mathrm{grav}}), \qquad (10.167)\end{aligned}$$

and the families index theorem, now with no gauge bundle ($\mathrm{ch}(\mathcal{E}) \to 1$) but with M fibred over the family, gives

$$\mathrm{ch}\big(\mathrm{Index}\,\not{D}_{\mathrm{grav}}\big) = \int_M \hat{A}. \tag{10.168}$$

Here $\hat{A}$ is the $\hat{A}$-genus of the *vertical tangent bundle* of the family $M \to Z \to \mathrm{Met}/\mathrm{Diff}_0$, a cohomology class on the total space Z. As always, $c_1(\det\mathrm{Index})$ is its degree-2 part.

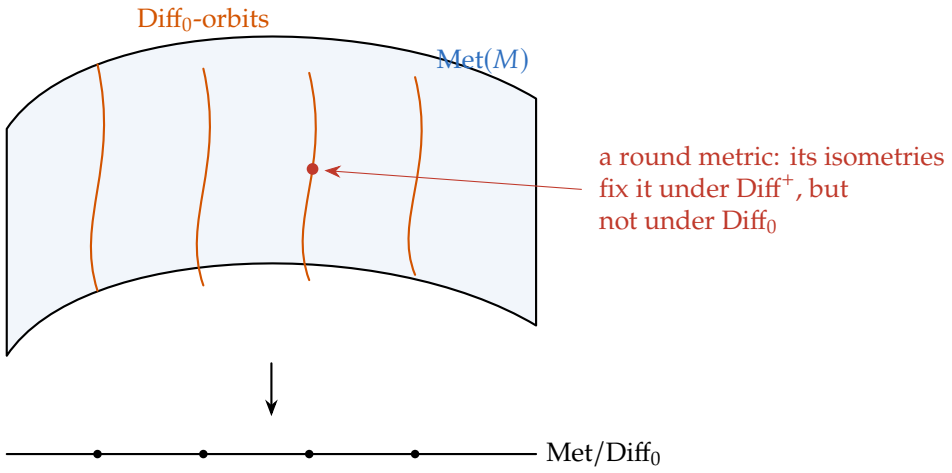


Figure 10.25: The gravitational analogue of Figure 10.3. Diffeomorphisms move a metric along an orbit (orange); the determinant of D_ρ^+ should be constant along each orbit if it is to descend to the space of geometries below. Metrics with isometries are fixed points of Diff$^+$; restricting to Diff$_0$ (fixing a point and a frame) makes the action free.

10.7.3 Why only $n = 4k - 2$

The $\hat{A}$-genus is a power series in the Pontrjagin classes, and p_j has degree $4j$. Let us see the first terms (Chapter 4). With formal Chern roots $\pm x_j$ of the tangent bundle, $\hat{A} = \prod_j \frac{x_j/2}{\sinh(x_j/2)}$ and $p_1 = \sum_j x_j^2$, $p_2 = \sum_{i<j} x_i^2 x_j^2$.

$$\frac{y}{\sinh y} \overset{(1)}{=} \left(1 + \frac{y^2}{6} + \frac{y^4}{120} + \cdots\right)^{-1} \overset{(2)}{=} 1 - \frac{y^2}{6} + \left(\frac{1}{36} - \frac{1}{120}\right)y^4 + \cdots = 1 - \frac{y^2}{6} + \frac{7y^4}{360} + \cdots,$$

$$\frac{x/2}{\sinh(x/2)} \overset{(3)}{=} 1 - \frac{x^2}{24} + \frac{7x^4}{5760} + \cdots,$$

$$\hat{A} \overset{(4)}{=} 1 - \frac{1}{24}\sum_j x_j^2 + \frac{7}{5760}\sum_j x_j^4 + \frac{1}{576}\sum_{i<j} x_i^2 x_j^2 + \cdots \overset{(5)}{=} 1 - \frac{p_1}{24} + \frac{7p_1^2 - 4p_2}{5760} + \cdots.$$

(1) Taylor series of $\sinh y / y$.

(2) $(1+u)^{-1} = 1 - u + u^2 - \cdots$ with $u = \frac{y^2}{6} + \frac{y^4}{120}$; the y^4 terms are $\frac{y^4}{36} - \frac{y^4}{120}$.

(3) $y = x/2$: $\frac{1}{6\cdot 4} = \frac{1}{24}$ and $\frac{7}{360\cdot 16} = \frac{7}{5760}$.

(4) Multiply the factors; the cross terms of degree 8 are $\frac{1}{24^2} x_i^2 x_j^2$.

(5) $\sum x_j^4 = p_1^2 - 2p_2$, so the degree-8 part is $\frac{7(p_1^2 - 2p_2) + 10p_2}{5760}$.

Only degrees $0, 4, 8, \ldots$ occur. Now, the integral over the n-dimensional fibre M lowers degree by n, so $\int_M \hat{A}$ has components only in degrees $4k - n$. For c_1 we need degree 2:

$$4k - n = 2 \iff n = 4k - 2 \qquad \text{[Nash (10.39)]}. \tag{10.169}$$

In $n = 4$ (our world) there is no purely gravitational perturbative anomaly for spin-$\frac{1}{2}$ fermions; in $n = 2, 6, 10$ there can be.

The cohomology of Diff$_0$**.** In the $H^1_{\mathrm{dR}}(\mathcal{G})$ picture, a gravitational anomaly is a nonzero class in $H^1_{\mathrm{dR}}(\mathrm{Diff}_0(M))$; for $M = S^{4k-2}$ Nash reports that $H^1_{\mathrm{dR}}(\mathrm{Diff}_0(S^{4k-2}))$ is known to vanish for $k = 1$ and $k > 6$ (Alvarez, Singer and Zumino) and is conjectured to vanish for all k. As

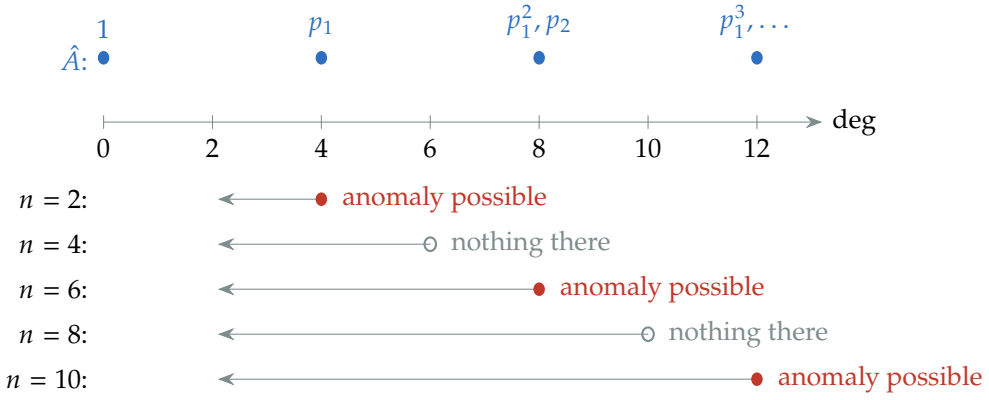

Figure 10.26: The degree count behind Nash's (10.39). A c_1 on the space of geometries needs the degree-$(n+2)$ part of $\hat{A}$ (red dot when it exists), which $\int_M$ lowers to degree 2 (grey arrow). Since $\hat{A}$ lives only in degrees divisible by 4, this happens exactly for $n = 2, 6, 10, \dots$

with U(1) in Section 10.6.6, this does not mean there is no anomaly: the relevant object is $H^1_{\mathrm{loc}}(\mathrm{Diff}_0(S^{4k-2}))$, which is not expected to vanish, and indeed the descent below produces nontrivial local anomalies in every dimension $4k-2$.

10.7.4 Anomaly polynomials and descent for gravity

The recipe of Section 10.5.5 carries over word for word, with the gauge field replaced by the spin connection ω (an $\mathfrak{so}(n)$-valued 1-form) and gauge transformations by local frame rotations $\theta(x) \in \mathfrak{so}(n)$: $\delta_\theta \omega = \mathrm{d}\theta + [\omega, \theta]$, $R = \mathrm{d}\omega + \omega^2$. The seed is the degree-$(n+2)$ part of the index density,

$$I_{n+2} = \left[\hat{A}(R)\ \mathrm{ch}(F)\right]_{n+2}, \tag{10.170}$$

which for a pure spin-$\frac{1}{2}$ field is $[\hat{A}]_{n+2}$. For $\mathfrak{so}(n)$ with real antisymmetric curvature matrices $p_1 = -\frac{1}{8\pi^2}\,\mathrm{tr}\,R^2$.

Worked example 10.37: The two-dimensional Lorentz anomaly by descent

For $n = 2$: $I_4 = -\frac{p_1}{24} = \frac{1}{192\pi^2}\,\mathrm{tr}\,R^2$. In two dimensions $\omega = w\,J$ with $J = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ and $w = \omega^1{}_2$ a real 1-form, and a local Lorentz rotation is $\theta = \vartheta J$. Descent exactly as in Example 10.24, with $\mathrm{tr}(\cdot)$ now over the vector representation:

$$\omega_3^0 \overset{(1)}{=} \frac{1}{192\pi^2}\,\mathrm{tr}\left(\omega\,\mathrm{d}\omega + \tfrac{2}{3}\omega^3\right) \overset{(2)}{=} \frac{1}{192\pi^2}\,(-2)\,w\,\mathrm{d}w,$$

$$\omega_2^1 \overset{(3)}{=} \frac{1}{192\pi^2}\,\mathrm{tr}(\theta\,\mathrm{d}\omega) \overset{(4)}{=} -\frac{1}{96\pi^2}\,\vartheta\,\mathrm{d}w,$$

$$\delta_\vartheta \ln Z_F \overset{(5)}{=} -2\pi i \int_M \omega_2^1 \overset{(6)}{=} \frac{i}{48\pi}\int_M \vartheta\,\mathrm{d}w \overset{(7)}{=} \frac{i}{48\pi}\int_M \vartheta\,K\,\mathrm{d}A.$$

(1) Example 10.22 with $A \to \omega$, times the normalisation of I_4.
(2) $J^2 = -\mathbf{1}$ so $\mathrm{tr}\,J^2 = -2$; $\omega^3 = w \wedge w \wedge w\,J^3 = 0$.
(3) Example 10.24 with $v \to \theta$.
(4) $\mathrm{tr}(\vartheta J\,\mathrm{d}w\,J) = \vartheta\,\mathrm{d}w\,\mathrm{tr}\,J^2$.
(5) The normalisation (10.151).
(6) $-2\pi i \cdot (-\frac{1}{96\pi^2}) = \frac{i}{48\pi}$.
(7) $\mathrm{d}w = R^1{}_2 = K\,\mathrm{d}A$ with K the Gaussian curvature and $\mathrm{d}A$ the area form (Example 10.35).

A single Weyl fermion on a curved surface therefore has a Lorentz anomaly proportional to the curvature: rotating the frames by $\vartheta(x)$ changes the phase of the determinant by $\frac{1}{48\pi}\int \vartheta K \mathrm{d}A$. A Weyl fermion of the opposite chirality contributes the opposite sign, so a Dirac fermion is safe. In conformal-field-theory language the coefficient is proportional to $c_L - c_R$, the difference of the left and right central charges (Nash Ch. 11).

Other chiral fields (Alvarez-Gaumé and Witten). Chiral fermions are not the only chiral fields. A spin-$\frac{3}{2}$ field (gravitino) and an antisymmetric tensor field with self-dual field strength also have chiral determinants, and the same analysis gives their anomaly polynomials:

$$I_{1/2} = \big[\hat{A}(R)\big]_{n+2}, \qquad I_{3/2} = \big[\hat{A}(R)\big(\operatorname{tr} e^{iR/2\pi} - 1\big)\big]_{n+2}, \qquad I_A = -\tfrac{1}{8}\big[L(R)\big]_{n+2},$$

where $\operatorname{tr} e^{iR/2\pi}$ is over the vector representation (n-dimensional) and $L = 1 + \frac{p_1}{3} + \cdots$ is Hirzebruch's L-genus (whose integral is the signature). We quote these (they are derived from index theorems for the Rarita–Schwinger and signature operators) and check them in two dimensions, where $p_1 = x^2$ for the single Chern root x of TM:

$$\begin{aligned} I_{1/2} &\overset{(1)}{=} -\frac{x^2}{24}, \\ I_{3/2} &\overset{(2)}{=} \Big[\Big(1 - \frac{x^2}{24}\Big)\big(e^{x} + e^{-x} - 1\big)\Big]_4 \overset{(3)}{=} \Big[\Big(1 - \frac{x^2}{24}\Big)(1 + x^2)\Big]_4 = \frac{23}{24}x^2, \\ I_A &\overset{(4)}{=} -\frac{1}{8}\cdot\frac{x^2}{3} = -\frac{x^2}{24}. \end{aligned}$$

(1) The degree-4 part of $\hat{A}$.
(2) In the vector representation of $\mathfrak{so}(2)$ the matrix $\frac{i}{2\pi}R$ has eigenvalues $\pm x$ (this is what "Chern root" means), so $\operatorname{tr} e^{iR/2\pi} = e^{x} + e^{-x}$.
(3) $e^{x} + e^{-x} - 1 = 1 + x^2 + \cdots$.
(4) $L = 1 + \frac{p_1}{3}$.

Two lovely checks: $I_A = I_{1/2}$, i.e. a chiral boson has the same gravitational anomaly as a Weyl fermion, as bosonisation says it must; and $I_{3/2} = -23\, I_{1/2}$: a gravitino counts as -23 Weyl fermions. In ten dimensions Alvarez-Gaumé and Witten found that the chiral content of type IIB supergravity (a gravitino, a spin-$\frac{1}{2}$ field of the other chirality and a self-dual 4-form) has $I_{3/2} - I_{1/2} + I_A = 0$ at degree 12: an anomaly cancellation among fields of different spin. For type I and heterotic strings the degree-12 polynomial with gauge group SO(32) or $E_8 \times E_8$ factorises as $I_{12} \propto (\operatorname{tr} R^2 - \frac{1}{30}\operatorname{Tr} F^2)\, X_8$, which allows the Green–Schwarz counterterm to cancel it.

Mixed anomalies in four dimensions. In $n = 4$ the degree-6 part of $\hat{A}\operatorname{ch}(F)$ contains a mixed term,

$$\big[\hat{A}\ \operatorname{ch}(F)\big]_6 = \operatorname{ch}_3(F) + \operatorname{ch}_1(F)\Big(-\frac{p_1}{24}\Big) = \operatorname{ch}_3(F) + \frac{1}{192\pi^2}\,\frac{i}{2\pi}\operatorname{tr} F\ \operatorname{tr} R^2.$$

For non-abelian G, $\operatorname{tr} F = 0$. For each U(1) factor it is $\propto \sum q$: this is the "U(1)–graviton–graviton triangle" of Section 10.5.7, and the reason the Standard Model needs $\sum Y = 0$ [QFT notes (22.8.1)].

10.7.5 Lorentz anomalies and the automorphism group $\mathrm{Aut}(P)$

The Lorentz anomaly of Example 10.37 is a failure of invariance under frame rotations, not under diffeomorphisms. Nash's closing paragraph of §3 [Nash pp. 280–281] explains how the two fit together.

The larger symmetry group. Choosing a vielbein amounts to choosing a section of the frame bundle, a principal $\mathrm{SO}(n)$-bundle P (for spinors, its $\mathrm{Spin}(n)$ lift). The full symmetry of a theory written with vielbeins is the group $\mathrm{Aut}(P)$ of bundle automorphisms (Chapter 6): maps $P \to P$ commuting with the $\mathrm{SO}(n)$ action. Each covers a diffeomorphism of M, and those covering the identity are the vertical automorphisms, the local Lorentz transformations $\mathcal{G}_L = \mathrm{Map}(M, \mathrm{SO}(n))$. This is an exact sequence

$$1 \longrightarrow \mathcal{G}_L \longrightarrow \mathrm{Aut}(P) \longrightarrow \mathrm{Diff}_0(M) \longrightarrow 1,$$

and since the frame bundle of M has a canonical lift of diffeomorphisms (h acts on frames by $\mathrm{d}h$), it splits: $\mathrm{Aut}(P) = \mathcal{G}_L \rtimes \mathrm{Diff}_0(M)$, a semidirect product in which Diff_0 acts on $\mathcal{G}_L$ by transporting the local rotation, $(\lambda_1, h_1)(\lambda_2, h_2) = (\lambda_1 \cdot (h_1 \cdot \lambda_2),\ h_1 h_2)$ with $(h \cdot \lambda)(x) = \lambda(h^{-1}(x))$ (read in frames carried along by $\mathrm{d}h$). (For P Nash takes an $\mathrm{SO}(4k-2)$-bundle, since $n = 4k-2$.) The full anomaly is a class in $H^1(\mathrm{Aut}(P))$.

Trading one anomaly for the other. The polynomial $\operatorname{tr} R^2$ (more generally I_{n+2}) can be written with the spin connection ω, which transforms under $\mathcal{G}_L$ and is inert (a scalar) under diffeomorphisms, or with the Levi-Civita connection $\Gamma^\mu{}_\nu$ in a coordinate basis, a $\mathfrak{gl}(n)$-valued 1-form that transforms under diffeomorphisms and knows nothing of frames. The two are related by a $\mathrm{GL}(n)$ gauge transformation by the vielbein matrix $e = (e^a{}_\mu)$,

$$\Gamma = e^{-1}\omega\, e + e^{-1}\mathrm{d}e,$$

so their Chern–Simons forms differ by an exact form plus a *local* functional of e (Example 10.23 with $g \to e$). Descending with ω puts the anomaly entirely in $\mathcal{G}_L$ (a Lorentz anomaly, Einstein's diffeomorphism invariance intact); descending with Γ puts it entirely in Diff_0 (a gravitational anomaly, the stress tensor symmetric but not conserved). The local counterterm built from e moves it from one to the other (Alvarez-Gaumé and Ginsparg; Bardeen and Zumino). It can be moved, but not removed.

Key idea: Gravitational anomalies

A chiral field on M^n coupled to a metric has determinant $\det D_\rho^+$, a section of $\det \mathrm{Index}\, \not{D}_{\mathrm{grav}}$ over $\mathrm{Met}(M)/\mathrm{Diff}_0(M)$ with $\mathrm{ch} = \int_M \hat{A}$ (10.38). Because $\hat{A}$ has only degrees $4k$, c_1 can be nonzero only for $n = 4k-2$ (10.39). Locally the anomaly follows from descent of $I_{n+2} = [\hat{A}\,\mathrm{ch}\,F]_{n+2}$ with $A \to \omega$; it can be placed in local Lorentz transformations or in diffeomorphisms, but a nonzero I_{n+2} cannot be removed. Finally one may vary the Yang–Mills connection and the metric together; then the mixed terms of $\hat{A}\,\mathrm{ch}(F)$ (such as $\operatorname{tr} F\ \operatorname{tr} R^2$) must cancel as well.

Reading Nash (pp. 279–281, (10.35)–(10.39))

Nash's Dirac operator "$(1/2)\gamma_\mu(\partial^\mu + \Gamma^\mu)(1+\gamma_5)$" is our D_ρ^+ with $\Gamma_\mu = \frac{1}{4}\omega_\mu{}^{ab}\gamma_a\gamma_b$ (Example 10.35 computes it for a conformally flat surface). (10.35) is (10.165). His $\mathrm{Diff}_0(M)$ (identity component, fixing a frame at a point) is justified in Example 10.36 and Figure 10.25. (10.36)–(10.38) are (10.166)–(10.168); the degree count (10.39) is Figure 10.26. His remark that $H^1_{\mathrm{dR}}(\mathrm{Diff}_0(S^{4k-2}))$ vanishes for $k = 1$ and $k > 6$ but H^1_{local} is not expected to vanish is the gravitational version of Section 10.6.6; the explicit local anomaly in $n = 2$ is Example 10.37. The Lorentz anomaly, $\mathrm{Aut}(P) = \mathcal{G}_L \rtimes \mathrm{Diff}_0(M)$, and the trading between the two are Section 10.7.5.

Recap

- The Dirac operator depends on the metric through $\gamma^\mu = e_a{}^\mu \gamma^a$ and the spin connection; for $g = e^{2\sigma}\delta$ in 2D, $\not{D}_g = e^{-3\sigma/2}\not{D}_{\text{flat}}e^{\sigma/2}$. Diffeomorphisms act by conjugation, $\not{D}_{h\cdot\rho} = h^{-1}\not{D}_\rho h$.
- Metrics modulo Diff_0 (fixing a point and a frame, to kill isometries); on S^1 only the length survives.
- $\text{ch}(\det \text{Index}\, \not{D}_{\text{grav}}) = \int_M \hat{A}$ with $\hat{A} = 1 - \frac{p_1}{24} + \frac{7p_1^2 - 4p_2}{5760} - \cdots$; degree count gives $n = 4k - 2$.
- In 2D: $I_4 = \frac{1}{192\pi^2}\,\text{tr}\, R^2$, Lorentz anomaly $\frac{i}{48\pi}\int \vartheta K \mathrm{d}A$; chiral boson = Weyl fermion; gravitino = $-23\times$.
- In 4D no pure gravitational anomaly, but the mixed U(1)–gravity anomaly $\propto \sum q$.
- $\text{Aut}(P) = \mathcal{G}_L \rtimes \text{Diff}_0$: the anomaly can be shifted between Lorentz and diffeomorphisms by a local counterterm, not removed.

10.8 The critical dimension for strings

Why does the bosonic string want to live in exactly 26 dimensions? Of all the numbers in theoretical physics, this is one of the strangest. It is not put in by hand. Nobody chooses it for aesthetic reasons. It is *forced*, and the thing that forces it is an anomaly.

Here is the logic in one paragraph. The Polyakov action of a string is invariant under two groups acting on the worldsheet metric: coordinate changes $\text{Diff}^+(\Sigma)$ and local rescalings $g \mapsto e^{2\sigma}g$ (the **Weyl group** $C^\infty_+(\Sigma)$ of positive functions). To turn the path integral over all metrics into a finite-dimensional integral over the moduli space of Riemann surfaces (Chapter 9), we divide by the volumes of both groups. That division only makes sense if the integrand is constant along the orbits of both groups. The integrand is a product of two functional determinants: one from the d embedding coordinates X^μ, one from the Faddeev–Popov ghosts. Each determinant, separately, fails to be Weyl invariant. The failures are proportional to d and to -26 respectively. They cancel exactly when $d = 26$. That value of d is the **critical dimension**.

Nash does this in two pages with the families index theorem. We will do it three ways, because each teaches something different:

1. a direct heat-kernel computation of how a determinant changes under $g \mapsto e^{2\sigma}g$ (this subsection and the next): this is the physicist's *local* anomaly, $\langle T^a{}_a \rangle = -\frac{c}{12}R$;
2. Nash's computation: the first Chern class of a determinant line bundle, obtained from the families index theorem with Chern characters and Todd classes (Section 10.8.6);
3. two quick cross-checks physicists use every day: the central charge of the ghost system from an operator product, and the light-cone zero-point energy with $\zeta(-1) = -\frac{1}{12}$ (Section 10.8.8).

The three computations produce the same polynomial, $6j^2 - 6j + 1$, in three different guises. That coincidence is not a coincidence; it is the index theorem.

Reading Nash (p. 281, §4, (10.40))

Nash opens §4 with the sentence: "For the Bosonic string the critical dimension may be characterised as the only dimension for which the conformal anomaly vanishes. Instead of having a family of Dirac operators one has a family of Cauchy–Riemann operators." The Cauchy–Riemann operator is $\bar\partial = \partial/\partial\bar z$ acting on sections of a holomorphic line bundle over the worldsheet. The family is parametrised by the worldsheet metric. Everything below unpacks these two sentences.

10.8.1 The integrand we must keep invariant

We first recall the objects from Chapter 9, stating conventions as we go. The worldsheet Σ is a compact oriented surface of genus p without boundary, with a Riemannian metric g_{ab} and local coordinates x^a, $a = 1, 2$. The string's position in flat Euclidean space-time $\mathbb{R}^d$ is a map $\phi = (\phi^1, \dots, \phi^d) : \Sigma \to \mathbb{R}^d$. (Nash writes ϕ; physicists write X^μ.) The Polyakov action with unit tension is

$$S[\phi, g] = \frac{1}{2}\int_\Sigma \mathrm{d}^2x\, \sqrt{g}\, g^{ab}\, \partial_a\phi^\mu\, \partial_b\phi_\mu = \frac{1}{2}\int_\Sigma \mathrm{d}^2x \sqrt{g}\, \phi^\mu\, \Delta_g \phi_\mu, \tag{10.171}$$

where the scalar Laplacian is the *positive* operator

$$\Delta_g = -\frac{1}{\sqrt{g}}\,\partial_a\big(\sqrt{g}\, g^{ab}\partial_b\big). \tag{10.172}$$

The second form of (10.171) follows from the first by one integration by parts; there is no boundary term because $\partial\Sigma = \varnothing$.

The two symmetries. A diffeomorphism α moves both the metric and the fields, $(\phi, g) \mapsto (\phi \circ \alpha, \alpha^* g)$, and S is an integral of a scalar density, so it is unchanged. The more special symmetry is the Weyl rescaling. Let $f = e^{2\sigma}$ be a positive function and replace g_{ab} by $e^{2\sigma} g_{ab}$ without touching ϕ:

$$\begin{aligned}\sqrt{g}\, g^{ab} \;\mapsto\; \sqrt{\det(e^{2\sigma} g)}\, \big(e^{2\sigma} g\big)^{ab} &\overset{(1)}{=} \big(e^{2\sigma}\sqrt{g}\big)\big(e^{-2\sigma} g^{ab}\big) \\ &= \sqrt{g}\, g^{ab}.\end{aligned} \tag{10.173}$$

(1) In two dimensions $\det(e^{2\sigma} g) = e^{4\sigma} \det g$, so $\sqrt{\det}$ gains $e^{2\sigma}$; the inverse metric gains $e^{-2\sigma}$.

The combination that appears in S is untouched, so S is Weyl invariant. This works *only* in two dimensions: in D worldsheet dimensions $\sqrt{g}$ would gain $e^{D\sigma}$. Two consequences of (10.173) will be used repeatedly:

$$\Delta_{e^{2\sigma} g} = e^{-2\sigma}\Delta_g, \qquad \sqrt{g} \;\mapsto\; e^{2\sigma}\sqrt{g}. \tag{10.174}$$

The first holds because in (10.172) only the prefactor $1/\sqrt{g}$ feels the rescaling.

Doing the Gaussian integral over ϕ. For a positive symmetric $N \times N$ matrix M we have the familiar

$$\int_{\mathbb{R}^N} \mathrm{d}^N x\; e^{-\frac{1}{2}x^{\mathsf T} M x} = (2\pi)^{N/2} (\det M)^{-1/2}.$$

The field ϕ^μ is an infinite vector, expanded in the orthonormal eigenfunctions u_k of Δ_g, $\phi^\mu = \sum_k c_k^\mu u_k$, and $S = \frac{1}{2}\sum_k \lambda_k (c_k)^2$. There is one snag: $\lambda_0 = 0$ for the constant eigenfunction $u_0 = 1/\sqrt{A}$, where $A = \int_\Sigma \sqrt{g}\, \mathrm{d}^2x = \langle 1, 1\rangle_g$ is the area. The constant mode is the centre of

mass x_0^μ of the string, and it is not damped at all: its integral gives the volume of $\mathbb{R}^d$. Writing $c_0^\mu = \sqrt{A}\, x_0^\mu$ we find (dropping 2π's, which are metric independent)

$$\int \mathcal{D}\phi\; e^{-S[\phi,g]} = \mathrm{vol}(\mathbb{R}^d) \left(\frac{\det' \Delta_g}{A} \right)^{-d/2}, \tag{10.175}$$

where det′ means the product of the *non-zero* eigenvalues, defined with a ζ-function below. This is Nash's $\big(\det(\Delta_g/2)/\langle 1,1\rangle_g\big)^{-d/2}$ of (9.7), with $d = 26$ giving the exponent -13 in (9.35) and (10.40). The factor $1/2$ inside the determinant is harmless; see Section 10.8.3.

The ghost determinant. The division by the volume of $\mathrm{Diff}_0(\Sigma)$ is done with the Faddeev–Popov trick (Chapter 9, Nash (9.30)–(9.36)). The operator that appears is Nash's A_g (physicists call it P_1):

$$A_g : V \mapsto \mathcal{L}_V g - \tfrac{1}{2}\,\mathrm{tr}(\mathcal{L}_V g)\, g, \qquad (A_g V)_{ab} = \nabla_a V_b + \nabla_b V_a - g_{ab} \nabla_c V^c, \tag{10.176}$$

which sends a vector field to a symmetric *traceless* tensor. It is worth seeing what A_g is in complex coordinates, because this is how the Cauchy–Riemann operator enters. Choose a local complex coordinate $z = x^1 + i x^2$ with $g = e^{2\omega}\, \mathrm{d}z\, \mathrm{d}\bar{z}$, so $g_{z\bar{z}} = \frac{1}{2} e^{2\omega}$ and $g_{zz} = g_{\bar{z}\bar{z}} = 0$. A traceless symmetric tensor has only the components h_{zz} and $h_{\bar{z}\bar{z}}$ (the trace is $2 g^{z\bar{z}} h_{z\bar{z}}$). Then

$$\begin{aligned} (A_g V)_{\bar{z}\bar{z}} &\overset{(1)}{=} 2 \nabla_{\bar{z}} V_{\bar{z}} \\ &\overset{(2)}{=} 2\big(\partial_{\bar{z}} V_{\bar{z}} - \Gamma^{\bar{z}}_{\bar{z}\bar{z}} V_{\bar{z}} \big) \\ &\overset{(3)}{=} 2\big(\partial_{\bar{z}} (g_{\bar{z}z} V^z) - 2 \partial_{\bar{z}} \omega\; g_{\bar{z}z} V^z \big) \\ &\overset{(4)}{=} e^{2\omega}\, \partial_{\bar{z}} V^z . \end{aligned} \tag{10.177}$$

(1) Take the $\bar{z}\bar{z}$ component of (10.176); the trace term drops because $g_{\bar{z}\bar{z}} = 0$.
(2) Definition of the covariant derivative of a covector.
(3) Lower the index, $V_{\bar{z}} = g_{\bar{z}z} V^z$. For a conformal metric the only non-zero Christoffel symbols are $\Gamma^z_{zz} = \partial_z \ln g_{z\bar{z}} = 2\partial_z \omega$ and $\Gamma^{\bar{z}}_{\bar{z}\bar{z}} = 2\partial_{\bar{z}}\omega$.
(4) $g_{\bar{z}z} = \frac{1}{2} e^{2\omega}$, and $\partial_{\bar{z}}(e^{2\omega} V^z) = e^{2\omega}(\partial_{\bar{z}} V^z + 2\partial_{\bar{z}}\omega\, V^z)$: the second term cancels the Christoffel term exactly.

The component V^z is a section of the holomorphic tangent bundle, and the Christoffel symbol has dropped out: what is left is the bare Cauchy–Riemann derivative $\partial_{\bar{z}}$ (times a positive factor, which is where the metric enters the adjoint). So A_g is, up to conjugation and harmless factors, the Cauchy–Riemann operator $\bar{\partial}$ acting on sections of the holomorphic tangent bundle $T^{1,0}\Sigma$, which is the dual K_Σ^* of the canonical bundle $K_\Sigma = T^{*1,0}\Sigma$ (the line bundle of $(1,0)$-forms $f(z)\,\mathrm{d}z$). Nash records this as $\det(\tilde{A}_g^* \tilde{A}_g) = \big(\det \bar{\partial}^*_{K^*} \bar{\partial}_{K^*}\big)^2$, so the square root in the Faddeev–Popov factor gives exactly one power of $\det \bar{\partial}^*_{K^*} \bar{\partial}_{K^*}$.

Key idea: The integrand of the string partition function

Putting the matter and ghost factors together, the contribution of genus $p \geq 2$ to the string partition function is (Nash (10.40), with 26 replaced by a general d)

$$Z_p = \int_{\mathcal{M}_p} \mathrm{d}\mu(\mathcal{M}_p) \underbrace{\left(\frac{\det'(\Delta_g/2)}{\langle 1,1\rangle_g} \right)^{-d/2}}_{d \text{ free bosons}} \underbrace{\det\big(\bar{\partial}^*_{K^*} \bar{\partial}_{K^*}\big)}_{\text{ghosts}} . \tag{10.178}$$

The integral is over the finite-dimensional moduli space $\mathcal{M}_p$. For this to be legitimate, the integrand, which is computed from a metric g, must depend only on the *conformal class* of g, i.e. it must be unchanged under $g \mapsto e^{2\sigma} g$.

Reading Nash (p. 281, footnote 4)

Nash restricts to genus $p > 1$. For $p = 0$ (the sphere) and $p = 1$ (the torus) the Weyl and diffeomorphism groups do not act freely: there are conformal Killing vectors ($\ker A_g \neq 0$), six real ones on S^2 and two on T^2, and the quotient $\mathrm{Met}(\Sigma)/C^\infty_+(\Sigma)$ is singular. The anomaly computation below is local on Σ and does not care, but the clean statement "the determinant line bundle over the quotient" does.

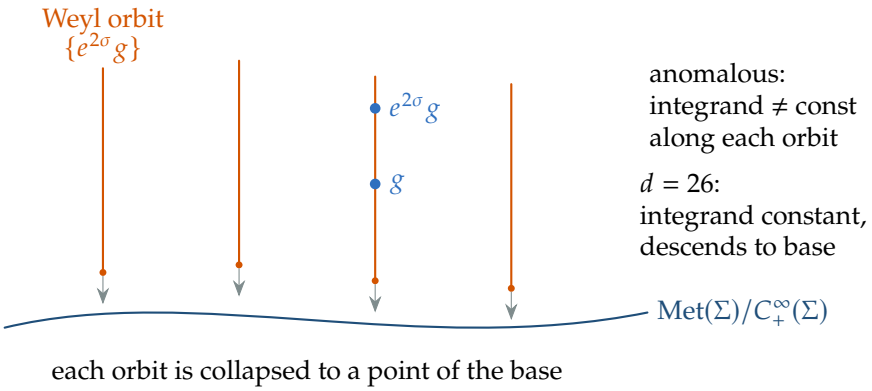

Figure 10.27: The space of metrics is fibred by Weyl orbits (orange). The string integrand is computed at a metric g in some fibre. Dividing by the volume of the Weyl group replaces each fibre by a point of the base; that is only meaningful if the integrand takes the same value all the way up the fibre. The conformal anomaly measures how much it changes.

10.8.2 Zeta-function determinants and the heat kernel

To see whether (10.178) is Weyl invariant we must know how a functional determinant responds to a change of metric. We first recall the definition (Nash p. 261 footnote, and Chapter 4).

Working definition 10.10 (ζ-regularised determinant)

Let P be a positive elliptic operator [here $\Delta_g/2$ or $\bar\partial^*_{K^*}\bar\partial_{K^*}$ from Z_p: built from the metric g, with eigenvalues growing without bound] with eigenvalues $0 < \lambda_1 \le \lambda_2 \le \cdots$ (zero modes discarded). Its **zeta function** is

$$\zeta_P(s) = \sum_k \lambda_k^{-s} = \frac{1}{\Gamma(s)} \int_0^\infty t^{s-1} \big(\mathrm{Tr}\, e^{-tP} - \dim \mathrm{Ker}\, P \big)\, \mathrm{d}t ,$$

convergent for $\mathrm{Re}\, s > \frac{\dim \Sigma}{\text{order}}$ and continued meromorphically [the function given by the sum where it converges extends to all s, with only isolated poles]; it is regular at $s = 0$. Since $\frac{\mathrm{d}}{\mathrm{d}s}\lambda^{-s}\big|_{s=0} = -\ln\lambda$, the formal $\ln \prod \lambda_k = \sum \ln \lambda_k$ equals $-\zeta_P'(0)$. So we *define*

$$\det{}' P := e^{-\zeta_P'(0)} .$$

How to compute it: know the spectrum (or the small-t behaviour of the heat trace [$\mathrm{Tr}\, e^{-tP} = \sum_k e^{-t\lambda_k}$]), build ζ_P, differentiate at 0.

The second equality in the definition is the Mellin transform $\lambda^{-s} = \frac{1}{\Gamma(s)}\int_0^\infty t^{s-1}e^{-t\lambda}\mathrm{d}t$, summed over eigenvalues. It makes the small-t behaviour of the heat trace $\operatorname{Tr} e^{-tP}$ the key input. We need a slightly more general object, the heat trace weighted by a function f on Σ:

$$\operatorname{Tr}\big(f\, e^{-t\Delta}\big) = \int_\Sigma \mathrm{d}^2x\sqrt{g}\; f(x)\, K_t(x,x),$$

where $K_t(x,y)$ is the heat kernel of Δ_g.

Key idea: Heat kernel on a surface, first two terms

For the scalar Laplacian on a surface, as $t \to 0^+$,

$$K_t(x,x) = \frac{1}{4\pi t}\Big(1 + \frac{t}{6}R(x) + O(t^2)\Big), \tag{10.179}$$

where R is the scalar curvature ($R = 2/r^2$ on a round sphere of radius r; $R = 2K$ with K the Gauss curvature).

Why these two terms? The leading term is the flat-space heat kernel $(4\pi t)^{-1}e^{-|x-y|^2/4t}$ at $x = y$: for small t the heat has spread only a distance $\sqrt{t}$, over which the surface looks flat. The correction is first order in the curvature and has dimension (length)$^{-2}$, so by dimensional analysis it must be $c\,tR$ for a pure number c. The number $c = \frac{1}{6}$ is the classic Minakshisundaram–Pleijel coefficient; we will *check* it on the round sphere in Example 10.38. Integrating (10.179) over Σ and using Gauss–Bonnet, $\int_\Sigma \sqrt{g}\,R = 4\pi\chi(\Sigma)$ (Chapter T2), the constant term of the heat trace is topological:

$$\operatorname{Tr} e^{-t\Delta} = \frac{A}{4\pi t} + \frac{\chi(\Sigma)}{6} + O(t). \tag{10.180}$$

Now the lemma that turns heat coefficients into ζ values.

Key idea: ζ at the origin reads off the t^0 heat coefficient

Let $\zeta(s;f) = \operatorname{Tr}'(f\Delta^{-s})$, the prime meaning that the zero mode is removed. Then $\zeta(s;f)$ is regular at $s = 0$ and

$$\zeta(0;f) = \frac{1}{24\pi}\int_\Sigma \sqrt{g}\,R\,f \;-\; \frac{1}{A}\int_\Sigma \sqrt{g}\,f. \tag{10.181}$$

Here is the calculation. Removing the zero mode $u_0 = 1/\sqrt{A}$ from the trace subtracts $\langle u_0, f u_0\rangle = \frac{1}{A}\int\sqrt{g}f =: P_f$. Split the Mellin integral at $t = 1$:

$$\begin{aligned}
\zeta(s;f) &\overset{(1)}{=} \frac{1}{\Gamma(s)}\int_0^1 t^{s-1}\Big(\frac{a_{-1}}{t} + a_0 - P_f + O(t)\Big)\mathrm{d}t + \frac{1}{\Gamma(s)}E(s)\\
&\overset{(2)}{=} \frac{1}{\Gamma(s)}\Big(\frac{a_{-1}}{s-1} + \frac{a_0 - P_f}{s} + (\text{regular at } 0)\Big) + \frac{E(s)}{\Gamma(s)}\\
&\overset{(3)}{=} \big(s + O(s^2)\big)\Big(\frac{a_0 - P_f}{s} + \text{regular}\Big)\\
&\xrightarrow{s\to 0} a_0 - P_f.
\end{aligned} \tag{10.182}$$

(1) Insert the small-t expansion $\operatorname{Tr}(fe^{-t\Delta}) = a_{-1}t^{-1} + a_0 + O(t)$ on $[0,1]$, with $a_{-1} = \frac{1}{4\pi}\int\sqrt{g}f$ and $a_0 = \frac{1}{24\pi}\int\sqrt{g}Rf$ from (10.179); $E(s)$ is the integral over $[1,\infty)$, which converges for every s because the non-zero spectrum is bounded away from 0 (exponential decay), so E is entire.

(2) $\int_0^1 t^{s-2}\mathrm{d}t = \frac{1}{s-1}$ and $\int_0^1 t^{s-1}\mathrm{d}t = \frac{1}{s}$.
(3) $1/\Gamma(s) = s + \gamma s^2 + \cdots$ has a simple zero at $s = 0$; it kills every regular term and $E(s)$ at $s = 0$.

This proves (10.181). With $f = 1$ it gives the useful special case

$$\zeta_\Delta(0) = \frac{\chi(\Sigma)}{6} - 1. \tag{10.183}$$

Worked example 10.38: $\zeta(0)$ on the round sphere: checking the coefficient $\frac{1}{6}$

On the unit sphere, Δ has eigenvalues $l(l+1)$ with multiplicity $2l+1$, $l = 0, 1, 2, \ldots$ (spherical harmonics Y_{lm}). The prediction (10.183) with $\chi(S^2) = 2$ is $\zeta(0) = \frac{2}{6} - 1 = -\frac{2}{3}$. Let us compute it directly. Write $\nu = l + \frac{1}{2}$, so $l(l+1) = \nu^2 - \frac{1}{4}$ and $2l + 1 = 2\nu$. Then

$$\begin{aligned}\zeta(s) = \sum_{l\geq 1} \frac{2l+1}{\big(l(l+1)\big)^s} &\overset{(1)}{=} \sum_{l\geq 1} 2\nu\, \nu^{-2s}\Big(1 - \frac{1}{4\nu^2}\Big)^{-s} \\ &\overset{(2)}{=} 2\sum_{l\geq 1} \nu^{1-2s} + \frac{s}{2}\sum_{l\geq 1} \nu^{-1-2s} + s\,G(s) \\ &\overset{(3)}{=} 2\,\zeta_H\big(2s-1, \tfrac{3}{2}\big) + \frac{s}{2}\,\zeta_H\big(2s+1, \tfrac{3}{2}\big) + s\,G(s).\end{aligned}$$

(1) Substitute $\nu = l + \frac{1}{2}$.
(2) Binomial expansion $(1-u)^{-s} = 1 + su + O(s\,u^2)$ with $u = 1/4\nu^2$; the remainder is s times a sum $G(s) = \sum O(\nu^{-3-2s})$ that converges near $s = 0$.
(3) Hurwitz zeta function $\zeta_H(s, a) = \sum_{n\geq 0}(n+a)^{-s}$; the sum over $l \geq 1$ starts at $\nu = \frac{3}{2}$.

Now use two standard facts: $\zeta_H(-1, a) = -\frac{1}{2}B_2(a) = -\frac{1}{2}(a^2 - a + \frac{1}{6})$, and $\zeta_H(1+2s, a) = \frac{1}{2s} + O(1)$. At $s = 0$:

$$\begin{aligned}\zeta(0) &\overset{(1)}{=} 2\cdot\Big(-\tfrac{1}{2}\Big)\Big(\tfrac{9}{4} - \tfrac{3}{2} + \tfrac{1}{6}\Big) + \frac{s}{2}\cdot\frac{1}{2s}\Big|_{s\to 0} \\ &= -\tfrac{11}{12} + \tfrac{1}{4} = -\tfrac{2}{3}.\end{aligned}$$

(1) The two facts just quoted with $a = \frac{3}{2}$; the $sG(s)$ term vanishes at $s = 0$.

The direct spectral computation agrees with the heat-kernel prediction. This checks the coefficient $\frac{1}{6}$ in (10.179): had it been c, we would have predicted $\zeta(0) = 2c - 1$.

10.8.3 The Weyl anomaly of d free bosons

We now vary the metric by an infinitesimal Weyl rescaling, $\delta g_{ab} = 2\delta\sigma\, g_{ab}$, and compute the change in the matter factor of (10.178). By (10.174), $\delta\Delta = -2\,\delta\sigma\,\Delta$.

$$\begin{aligned}\delta\zeta_\Delta(s) &\overset{(1)}{=} -s\ \mathrm{Tr}'\big(\delta\Delta\ \Delta^{-s-1}\big) \\ &\overset{(2)}{=} 2s\ \mathrm{Tr}'\big(\delta\sigma\ \Delta^{-s}\big) = 2s\,\zeta(s; \delta\sigma), \\ \delta\big(-\ln\det{}'\Delta\big) = \delta\zeta_\Delta'(0) &\overset{(3)}{=} 2\,\zeta(0; \delta\sigma) \\ &\overset{(4)}{=} \frac{1}{12\pi}\int_\Sigma \sqrt{g}\,R\,\delta\sigma - \frac{2}{A}\int_\Sigma \sqrt{g}\,\delta\sigma.\end{aligned} \tag{10.184}$$

(1) First-order perturbation theory for eigenvalues, $\delta(\lambda^{-s}) = -s\lambda^{-s-1}\delta\lambda$ with $\delta\lambda_k = \langle u_k, \delta\Delta\, u_k\rangle$; summing over k gives the trace.

(2) $\delta\Delta = -2\delta\sigma\Delta$ and cyclicity of the trace.
(3) Differentiate $2s\,\zeta(s;\delta\sigma)$ at $s=0$; since $\zeta(s;\delta\sigma)$ is regular there, only $2\zeta(0;\delta\sigma)$ survives.
(4) Formula (10.181) with $f=\delta\sigma$.

The area changes by $\delta A = \int \delta\sqrt{g} = 2\int\sqrt{g}\,\delta\sigma$, so $\delta\ln A = \frac{2}{A}\int\sqrt{g}\,\delta\sigma$, which exactly cancels the zero-mode term. Therefore

$$\boxed{\delta\ln\frac{\det'\Delta_g}{A} = -\frac{1}{12\pi}\int_\Sigma \sqrt{g}\,R\,\delta\sigma} \tag{10.185}$$

and for the matter factor of (10.178),

$$\delta\ln\left(\frac{\det'\Delta_g}{A}\right)^{-d/2} = +\frac{d}{24\pi}\int_\Sigma\sqrt{g}\,R\,\delta\sigma. \tag{10.186}$$

The right side is not zero unless $\delta\sigma$ is orthogonal to R. So the matter determinant is *not* Weyl invariant, even though the action is. This is the **conformal anomaly** (or Weyl anomaly, or trace anomaly).

Physical picture: Where the anomaly comes from

Classically nothing depends on σ. Quantum mechanically we must regularise the product of infinitely many eigenvalues, and every regulator brings in a length scale: here, the heat-kernel time t, which is a (length)^2 measured *with the metric* g. Rescaling g rescales the cutoff. The only memory the regulator keeps is the local term $R/6$ in the heat kernel: the anomaly is local, as every perturbative anomaly is.

Dictionary: Weyl anomaly ↔ trace anomaly ↔ central charge

Define the stress tensor by $T_{ab} = -\frac{4\pi}{\sqrt{g}}\frac{\delta S}{\delta g^{ab}}$ (Polchinski's normalisation). A Weyl rescaling $\delta g^{ab} = -2\delta\sigma g^{ab}$ changes $\ln Z$ by $-\langle\delta S\rangle = -\frac{1}{2\pi}\int\sqrt{g}\,\delta\sigma\,\langle T^a{}_a\rangle$. Comparing with (10.186):

$$\delta_\sigma \ln Z = \frac{c}{24\pi}\int\sqrt{g}\,R\,\delta\sigma \quad\Longleftrightarrow\quad \langle T^a{}_a\rangle = -\frac{c}{12}R,$$

with $c=d$ for d free bosons. The number c is the **central charge**: each free boson contributes 1. The classical tracelessness $T^a{}_a=0$ (the Noether statement of Weyl invariance) fails in the quantum theory by a c-number proportional to the curvature.

Watch out: The factor $1/2$ in $\det(\Delta_g/2)$

Nash writes $\det(\Delta_g/2)$ because (Nash (5.32)) $\Delta_g/2 = \bar\partial^*\bar\partial$ on functions. A constant factor c changes the ζ-determinant by $\det'(cP) = c^{\zeta_P(0)}\det' P$ (differentiate $c^{-s}\zeta_P(s)$ at 0). By (10.183), $\zeta_\Delta(0) = \chi/6 - 1$ is the same for every metric on Σ, so the factor is a constant: it can never contribute to the Weyl anomaly. It is a reminder, though, that ζ-determinants are *not* multiplicative: $\det(cP)\neq c^\infty\det P$.

Worked example 10.39: Constant rescaling: the anomaly is Gauss–Bonnet

Take $\delta\sigma=\sigma_0$ constant. The eigenvalues all scale by $e^{-2\sigma_0}$, so we can compute the change exactly, without (10.179). With $g'=e^{2\sigma_0}g$:

$$\ln\det{}'\Delta_{g'} - \ln\det{}'\Delta_g \overset{(1)}{=} \ln\det{}'\big(e^{-2\sigma_0}\Delta_g\big) - \ln\det{}'\Delta_g$$

$$\overset{(2)}{=} -2\sigma_0\,\zeta_\Delta(0)$$
$$\overset{(3)}{=} -2\sigma_0\Big(\frac{\chi}{6}-1\Big),$$
$$\ln A_{g'} - \ln A_g = 2\sigma_0,$$
$$\Rightarrow \quad \Delta \ln \frac{\det'\Delta}{A} = -\frac{\chi}{3}\,\sigma_0.$$

(1) (10.174) with constant σ.
(2) The scaling rule of Section 10.8.3 with $c = e^{-2\sigma_0}$.
(3) (10.183).

The general formula (10.185) gives $-\frac{1}{12\pi}\sigma_0\int\sqrt{g}R = -\frac{1}{12\pi}\sigma_0\cdot 4\pi\chi = -\frac{\chi}{3}\sigma_0$. They agree. On the sphere the partition function of a free boson depends on the *radius* $r = e^{\sigma_0}$ of the sphere: $\ln Z = -\frac{d}{2}\ln(\det'\Delta/A)$ changes by $+\frac{d}{2}\cdot\frac{\chi}{3}\sigma_0 = \frac{d}{3}\ln r$ (with $\chi = 2$), so $Z \propto r^{d/3}$. This is the famous statement that a CFT on a sphere knows its central charge through its size dependence, $Z \propto r^{c/3}$, with $c = d$ here.

10.8.4 The Liouville action: integrating the anomaly

The infinitesimal statement (10.185) can be integrated along the path $g_\tau = e^{2\tau\sigma}\hat{g}$, $\tau\in[0,1]$, to give the change under a *finite* rescaling. We need one formula from Riemannian geometry: for $g = e^{2\sigma}\hat{g}$ in two dimensions,

$$\sqrt{g}\,R = \sqrt{\hat{g}}\,\big(\hat{R} - 2\hat{\nabla}^2\sigma\big), \tag{10.187}$$

where $\hat{\nabla}^2 = -\hat{\Delta}$ is the ordinary (negative) Laplacian of $\hat{g}$.

Worked example 10.40: Checking (10.187): the sphere from the plane

Stereographic projection writes the unit sphere as the plane with $g = e^{2\sigma}(\mathrm{d}x^2+\mathrm{d}y^2)$, $e^{2\sigma} = 4/(1+r^2)^2$. Here $\hat{R}=0$ and $\sigma = \ln 2 - \ln(1+r^2)$. Then

$$\hat{\nabla}^2\ln(1+r^2) \overset{(1)}{=} \frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\Big(r\cdot\frac{2r}{1+r^2}\Big) = \frac{1}{r}\cdot\frac{4r}{(1+r^2)^2} = \frac{4}{(1+r^2)^2},$$
$$R \overset{(2)}{=} e^{-2\sigma}\big(0 - 2\hat{\nabla}^2\sigma\big) = \frac{(1+r^2)^2}{4}\cdot\frac{8}{(1+r^2)^2} = 2.$$

(1) Radial Laplacian $\frac{1}{r}\partial_r(r\partial_r)$.
(2) (10.187) divided by $\sqrt{g} = e^{2\sigma}\sqrt{\hat{g}}$.

$R = 2$ is correct for the unit sphere ($R = 2/r^2$, $r=1$). See Figure 10.28.

Now integrate (10.186) along g_τ, for which $\delta\sigma = \sigma\,\mathrm{d}\tau$ and $\sqrt{g_\tau}R_\tau = \sqrt{\hat{g}}(\hat{R} - 2\tau\hat{\nabla}^2\sigma)$:

$$\ln Z[e^{2\sigma}\hat{g}] - \ln Z[\hat{g}] \overset{(1)}{=} \frac{c}{24\pi}\int_0^1 \mathrm{d}\tau\int_\Sigma \sqrt{\hat{g}}\,\big(\hat{R} - 2\tau\hat{\nabla}^2\sigma\big)\sigma$$
$$\overset{(2)}{=} \frac{c}{24\pi}\int_\Sigma \sqrt{\hat{g}}\,\big(\hat{R}\sigma - \sigma\hat{\nabla}^2\sigma\big)$$
$$\overset{(3)}{=} \frac{c}{24\pi}\int_\Sigma \sqrt{\hat{g}}\,\big(\hat{g}^{ab}\partial_a\sigma\,\partial_b\sigma + \hat{R}\,\sigma\big). \tag{10.188}$$

(1) The infinitesimal anomaly $\frac{c}{24\pi}\int\sqrt{g}R\,\delta\sigma$ at each τ, with (10.187) for the metric $e^{2\tau\sigma}\hat{g}$.

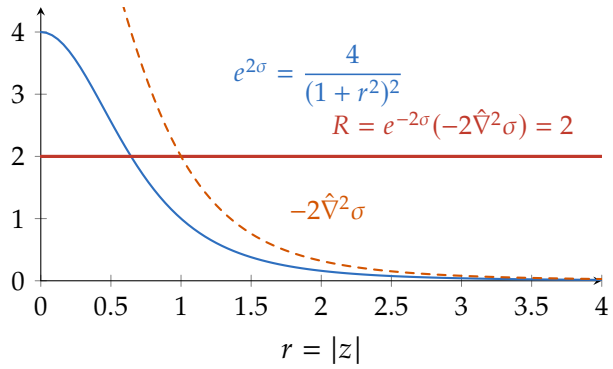

Figure 10.28: The round sphere as the flat plane with a conformal factor. The flat curvature is $\hat{R} = 0$; all the curvature comes from the Laplacian of σ (dashed). Dividing by $e^{2\sigma}$ (blue) gives the constant $R = 2$ (red). This is the mechanism by which the anomaly, which is linear in R, becomes a functional of σ.

(2) $\int_0^1 \mathrm{d}\tau = 1$ and $\int_0^1 2\tau\,\mathrm{d}\tau = 1$.
(3) Integrate $-\sigma\hat{\nabla}^2\sigma$ by parts on the closed surface.

The functional on the right is the **Liouville action**. If $c \neq 0$, the conformal factor σ does not drop out of the path integral: it becomes a dynamical field with this action (Polyakov's non-critical string). If $c = 0$ it decouples, and the integral over the Weyl orbit is just a volume we can divide out.

Recap: Weyl anomaly of the matter

- det′ is defined by ζ-functions; its Weyl variation is read off from the t^0 heat coefficient, $\frac{1}{24\pi}\int \sqrt{g}Rf$.
- d free bosons: $\delta \ln Z = \frac{d}{24\pi}\int \sqrt{g}R\,\delta\sigma$, i.e. central charge $c = d$, $\langle T^a{}_a \rangle = -\frac{c}{12}R$.
- Integrated form: the Liouville action (10.188).
- Checks: $\zeta(0) = -\frac{2}{3}$ on the round sphere; constant rescaling reproduces Gauss–Bonnet.
- Still to do: the ghost factor, which must supply $c = -26$.

10.8.5 Reminder: determinant line bundles and the families index

The heat-kernel computation of Section 10.8.3 is local and concrete. Nash's route is global and topological. It rests on two tools that were set up earlier in this chapter (Nash §2) and in Chapter 4. We recall both in the form we need.

The determinant line of a linear map. Let $O : V \to W$ be a linear map between finite-dimensional complex vector spaces. If $\dim V = \dim W = k$, the top exterior powers $\Lambda^k V$ and $\Lambda^k W$ are one-dimensional, and O induces a map between them, $v_1 \wedge \cdots \wedge v_k \mapsto Ov_1 \wedge \cdots \wedge Ov_k$. In bases, that map is multiplication by the number $\det O$. Without bases, $\det O$ is an element of the line $(\Lambda^k V)^* \otimes \Lambda^k W$. If the dimensions differ, or if O has a kernel, one keeps only what is left after cancelling the parts on which O is invertible:

$$\det O \;\in\; \mathcal{L}_O := \big(\Lambda^{\max} \operatorname{Ker} O\big)^* \otimes \Lambda^{\max} \operatorname{Coker} O. \tag{10.189}$$

(Nash (10.21)–(10.24); $\operatorname{Coker} O \cong \operatorname{Ker} O^*$.) When O is invertible both kernels vanish, $\Lambda^{\max}$ of the zero space is $\mathbb{C}$, and $\det O$ is an honest number.

The determinant line bundle. If O_y depends on a parameter $y \in Y$, the lines $\mathcal{L}_{O_y}$ fit together into a line bundle $\det \operatorname{Index} O_Y$ over Y, even though $\operatorname{Ker} O_y$ and $\operatorname{Coker} O_y$ can jump in dimension. The reason is that it depends only on the index bundle $\operatorname{Index} O_Y = [\operatorname{Ker} O] - [\operatorname{Coker} O] \in K(Y)$, and det turns sums into tensor products: $\det(E \oplus F) = \det E \otimes \det F$, so $\det([E] - [F]) = \det E \otimes (\det F)^*$. The function $y \mapsto \det O_y$ is a *section* of this bundle. It vanishes exactly where O_y has a kernel. If the bundle is non-trivial, no nowhere-zero section exists, and $\det O_y$ cannot be made into an ordinary function on Y.

Worked example 10.41: A family of 1×1 matrices over the sphere

Let $Y = \mathbb{CP}^1$ with homogeneous coordinates $[y_0 : y_1]$, and let O_y be "multiply by y_1/y_0" on the northern patch. As a function this blows up at $y_0 = 0$. But we may instead regard $O_y : \mathbb{C} \to L_y$ with $L = \mathcal{O}(1)$ the hyperplane bundle, $O_y(1) = y_1$ (a linear form in y, i.e. a section of $\mathcal{O}(1)$). Then $\det O_y = y_1$ is a perfectly good section of $\det \operatorname{Index} O = \mathcal{O}(1)$, with exactly one zero (at $y_1 = 0$), and

$$c_1(\det \operatorname{Index} O)[\mathbb{CP}^1] \overset{(1)}{=} \#\{\text{zeros of a generic section}\} \overset{(2)}{=} 1.$$

(1) The first Chern number of a line bundle over a closed surface counts the zeros (with multiplicity and sign) of a generic section; this is the line-bundle version of Poincaré–Hopf.
(2) y_1 vanishes once, simply.

So "the determinant is a section, not a function" is a statement with content: the zero cannot be removed by any choice of phase conventions, because its number is a Chern number.

The families index theorem for $\bar\partial$. For a family of Cauchy–Riemann operators $\bar\partial_E$ acting on a holomorphic vector bundle E over the fibres Σ of a family $Z \to Y$, the cohomological index formula (Nash (4.126), specialised to the Dolbeault complex; in algebraic geometry this is the Grothendieck–Riemann–Roch theorem) reads

$$\operatorname{ch}\big(\operatorname{Index} \bar\partial_E\big) = \int_\Sigma \operatorname{ch}(E)\ \operatorname{td}(T_{\mathrm{v}}), \tag{10.190}$$

where T_{v} is the bundle of tangent vectors along the fibres (the "vertical" tangent bundle) and $\int_\Sigma$ is integration over the fibre: it turns a form of degree k on Z into a form of degree $k-2$ on Y. Its degree-0 part is the ordinary Riemann–Roch theorem on one surface; its degree-2 part is

$$c_1\big(\det \operatorname{Index} \bar\partial_E\big) \overset{(1)}{=} c_1\big(\operatorname{Index} \bar\partial_E\big) \overset{(2)}{=} \Big[\int_\Sigma \operatorname{ch}(E)\operatorname{td}(T_{\mathrm{v}})\Big]_{(2)}. \tag{10.191}$$

(1) For any (virtual) bundle $c_1(\det E) = c_1(E)$: split E into line bundles L_i; then $\det E = \bigotimes L_i$ and both sides equal $\sum_i c_1(L_i)$.
(2) The degree-2 component of (10.190); the Chern character begins $\operatorname{ch} = \operatorname{rank} + c_1 + \cdots$.

So c_1 of the determinant bundle comes from the *degree*-4 part of the integrand $\operatorname{ch}(E)\operatorname{td}(T_{\mathrm{v}})$ on Z. On a single surface every 4-form vanishes; in a family it need not. This is the whole point.

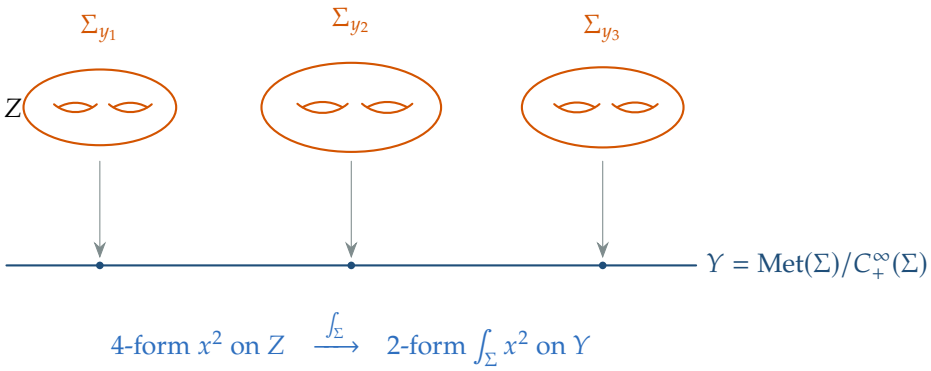

Figure 10.29: The universal family $Z \to Y$: over each point y of the base sits a surface Σ_y carrying the complex structure defined by y. Integrating a form over the fibres lowers its degree by two. The first Chern class of the determinant bundle lives on Y, so it comes from a *4-form* on Z, which is invisible on any single surface.

10.8.6 Nash's computation of 26

We now follow Nash's pp. 282–283 line by line, supplying each step.

Step 1: the scalar Laplacian is $2\bar\partial^*\bar\partial$. Nash quotes (5.32): $\Delta_g/2 = \bar\partial^*\bar\partial$ on functions. Let us check it for the flat metric $g = \mathrm{d}x^2 + \mathrm{d}y^2$ on a torus (the conformal factor goes through unchanged because both sides scale as $e^{-2\sigma}$). With $\partial_{\bar z} = \tfrac12(\partial_x + i\partial_y)$ we have $\bar\partial f = \partial_{\bar z} f\,\mathrm{d}\bar z$ and $|\mathrm{d}\bar z|^2 = |\mathrm{d}x|^2 + |\mathrm{d}y|^2 = 2$. For a complex function f,

$$\begin{aligned}
\langle f, \Delta f\rangle &\overset{(1)}{=} \int \left(|\partial_x f|^2 + |\partial_y f|^2\right)\mathrm{d}^2x \\
&\overset{(2)}{=} 2\int \left(|\partial_z f|^2 + |\partial_{\bar z} f|^2\right)\mathrm{d}^2x \\
&\overset{(3)}{=} 4\int |\partial_{\bar z} f|^2\,\mathrm{d}^2x \\
&\overset{(4)}{=} 2\,\langle \bar\partial f, \bar\partial f\rangle = \langle f, 2\bar\partial^*\bar\partial f\rangle .
\end{aligned}$$

(1) Integrate $\langle f, -\nabla^2 f\rangle$ by parts on the closed torus.
(2) Expand $\partial_x = \partial_z + \partial_{\bar z}$, $\partial_y = i(\partial_z - \partial_{\bar z})$; the cross terms cancel.
(3) $\int |\partial_z f|^2 = \int |\partial_{\bar z} f|^2$: integrate by parts twice, using $\partial_z\partial_{\bar z} = \partial_{\bar z}\partial_z$.
(4) $\|\partial_{\bar z} f\,\mathrm{d}\bar z\|^2 = \int 2|\partial_{\bar z} f|^2$.

So $\Delta = 2\bar\partial^*\bar\partial$, and the matter factor $\det(\Delta_g/2)^{-d/2} = \det(\bar\partial^*\bar\partial)^{-d/2}$ is built from a Cauchy–Riemann operator on the *trivial* bundle $I = \Sigma \times \mathbb{C}$, just as the ghost factor is built from one on K^*_Σ.

Step 2: a determinant is a section. For each metric g we have an operator $\bar\partial_g$. Nash says that "$\det(\bar\partial^*\bar\partial)$ can be thought of as a section of the determinant bundle $\det\mathrm{Index}\,\bar\partial$ over $\mathrm{Met}(\Sigma)/C^\infty_+(\Sigma)$". Strictly, the section is $\det\bar\partial$, and $\det(\bar\partial^*\bar\partial) = \|\det\bar\partial\|^2$ is its length squared in a metric on the line bundle (the Quillen metric of Section 10.8.9). The Weyl anomaly is the statement that this length is not constant along Weyl orbits; the topological statement is that the bundle on the *quotient* is not trivial.

Watch out: Why the base is Met/C^∞_+ and not Met

The space $\mathrm{Met}(\Sigma)$ of all metrics is convex, hence contractible, and every bundle over it is trivial. A trivial bundle has no Chern class. The anomaly is detected only after we ask the determinant to descend to the quotient by the symmetry we want to preserve. Exactly the same thing happened for gauge anomalies, where $\mathcal{A}$ is contractible but $\mathcal{A}/\mathcal{G}$ is not.

Step 3: raising to the power $-d/2$ is tensoring with $-(d/2)I$. If s is a section of a line bundle L, then s^m is a section of $L^{\otimes m}$, for positive or negative m (negative powers are sections of the dual). Now $L = \det \mathrm{Index}\,\bar\partial_I$, and det turns sums of index bundles into products, so

$$\left(\det \mathrm{Index}\,\bar\partial_I\right)^{\otimes m} = \det\left(m \cdot \mathrm{Index}\,\bar\partial_I\right) = \det \mathrm{Index}\,\bar\partial_{mI}. \tag{10.192}$$

For $m = -d/2$ the "bundle" mI has negative rank. It is not a vector bundle but an element of K-theory, a formal difference, and $\bar\partial$ with coefficients in it is Nash's $\bar\partial_{-(d/2)}$. Everything we need from it (its Chern character, its determinant line) is additive, so formal differences are harmless.

Watch out: Half-integer powers

If d is odd, $d/2$ is not an integer and $-(d/2)I$ is not even an element of $K(Y)$; it lives in $K(Y)\otimes\mathbb{Q}$. The first Chern class is still defined in rational cohomology, and the conclusion "$c_1 = 0$ iff $d = 26$" is unaffected. For d even the element is genuinely integral.

Step 4: one operator for the whole integrand. The ghost factor is $\det(\bar\partial^*\bar\partial)$ on K^*_Σ to the power $+1$, a section of $\det \mathrm{Index}\,\bar\partial_{K^*}$. Multiplying the two factors multiplies the line bundles, which by (10.192) adds the coefficient bundles. So the integrand of (10.178) is (the norm of) a section of the determinant bundle of a single family:

$$\bar\partial_Y := \bar\partial_{K^*_\Sigma - (d/2)I}, \qquad \det \mathrm{Index}\,\bar\partial_Y = \det \mathrm{Index}\,\bar\partial_{K^*} \otimes \left(\det \mathrm{Index}\,\bar\partial_I\right)^{-d/2}. \tag{10.193}$$

The integrand is Weyl invariant (can be made so by a local counterterm) exactly when this bundle is trivial on Y, which for a line bundle means $c_1 = 0$.

Step 5: the characteristic classes (Nash (10.41)–(10.42)). Let $x = c_1(K^*_\Sigma) = c_1(T_{\mathrm{v}})$ be the first Chern class of the vertical tangent line bundle on Z. For a line bundle with curvature F (anti-Hermitian, a $\mathfrak{u}(1) = i\mathbb{R}$-valued 2-form) the Chern–Weil representative is $x = \frac{i}{2\pi}F$ (Nash writes $\mathrm{tr}(iF/2\pi)$; the trace of a 1×1 matrix is the entry). The Todd class and Chern character of a line bundle are the power series

$$\begin{aligned}
\mathrm{td}(L) = \frac{x}{1-e^{-x}} &\overset{(1)}{=} \frac{x}{x - \frac{x^2}{2} + \frac{x^3}{6} - \cdots} = \left(1 - \frac{x}{2} + \frac{x^2}{6} - \cdots\right)^{-1} \\
&\overset{(2)}{=} 1 + \left(\frac{x}{2} - \frac{x^2}{6}\right) + \left(\frac{x}{2}\right)^2 + O(x^3) \\
&= 1 + \frac{x}{2} + \frac{x^2}{12} + O(x^3), \qquad\qquad (10.194)\\
\mathrm{ch}(L) = e^x &= 1 + x + \frac{x^2}{2} + O(x^3), \qquad \mathrm{ch}(mI) = m.
\end{aligned}$$

(1) Taylor-expand e^{-x} and divide numerator and denominator by x.

(2) $(1-u)^{-1} = 1 + u + u^2 + \cdots$ with $u = \frac{x}{2} - \frac{x^2}{6} + \cdots$, kept to second order: $u + u^2 = \frac{x}{2} - \frac{x^2}{6} + \frac{x^2}{4} + O(x^3)$.

For a surface, T_{v} restricted to each fibre is the line bundle K_Σ^* itself, so $\mathrm{td}(\Sigma) = \mathrm{td}(K_\Sigma^*)$; that is Nash's remark that the splitting principle is trivial here (there is only one Chern root). The Chern character is additive: $\mathrm{ch}(K^* - \frac{d}{2}I) = e^x - \frac{d}{2}$.

Step 6: multiply and integrate (Nash (10.43)).

$$\begin{aligned}\mathrm{ch}(\mathrm{Index}\,\bar\partial_Y) &\overset{(1)}{=} \int_\Sigma \Big(1 - \frac{d}{2} + x + \frac{x^2}{2} + \cdots\Big)\Big(1 + \frac{x}{2} + \frac{x^2}{12} + \cdots\Big) \\ &\overset{(2)}{=} \int_\Sigma \Big[\Big(1 - \frac{d}{2}\Big) + \Big(\frac{3}{2} - \frac{d}{4}\Big)x + \Big(\frac{1}{12}\Big(1 - \frac{d}{2}\Big) + \frac{1}{2} + \frac{1}{2}\Big)x^2 + \cdots\Big] \\ &\overset{(3)}{=} \Big(\frac{3}{2} - \frac{d}{4}\Big)\int_\Sigma x \;+\; \frac{26-d}{24}\int_\Sigma x^2 + \cdots \end{aligned} \tag{10.195}$$

(1) The families index theorem (10.190) with $E = K^* - \frac{d}{2}I$ and (10.194).

(2) Collect by degree. Degree 2: $x \cdot 1 + (1 - \frac{d}{2}) \cdot \frac{x}{2}$. Degree 4: $(1 - \frac{d}{2})\frac{x^2}{12} + x \cdot \frac{x}{2} + \frac{x^2}{2} \cdot 1$.

(3) The degree-0 term is a function on Z and integrates to zero over a 2-dimensional fibre. For the x^2 coefficient: $\frac{1}{12} - \frac{d}{24} + 1 = \frac{2-d+24}{24}$.

The first term is a number (a 0-form on Y): the virtual rank of the index bundle. The second is a 2-form on Y: the first Chern class. Hence

Key idea: Nash's (10.43): the critical dimension

$$c_1\big(\det \mathrm{Index}\,\bar\partial_Y\big) = \frac{26-d}{24}\int_\Sigma x^2 = \frac{26-d}{24}\,\kappa_1, \tag{10.196}$$

where $\kappa_1 := \int_\Sigma c_1(T_{\mathrm{v}})^2$ is a fixed, non-zero class on moduli space (the first Mumford–Morita–Miller class). The determinant bundle is trivial, and the conformal anomaly absent, precisely when $d = 26$.

Worked example 10.42: The degree-0 term is Riemann–Roch, and it counts moduli

The first term of (10.195) should be the virtual rank dim Ker − dim Coker of the family on one surface. Check it. Gauss–Bonnet says $\int_\Sigma x = \int_\Sigma c_1(T\Sigma) = \chi(\Sigma) = 2 - 2p$. So

$$\begin{aligned}\Big(\frac{3}{2} - \frac{d}{4}\Big)(2-2p) &\overset{(1)}{=} (3-3p) - \frac{d}{2}(1-p) \\ &\overset{(2)}{=} \mathrm{index}\,\bar\partial_{K^*} - \frac{d}{2}\,\mathrm{index}\,\bar\partial_I.\end{aligned}$$

(1) Arithmetic.

(2) Riemann–Roch for a line bundle L of degree $\deg L$ on a genus-p surface: $\mathrm{index}\,\bar\partial_L = h^0(L) - h^1(L) = \deg L + 1 - p$. For $L = I$, deg = 0, index $1 - p$; for $L = K^*$, deg $= 2 - 2p$, index $3 - 3p$.

Now interpret. On functions: $h^0(I) = 1$ (constants: the zero mode of Δ, i.e. the centre of mass that we treated separately in (10.175)) and $h^1(I) = p$ (the p holomorphic 1-forms). On vector fields, for $p \geq 2$: $h^0(K^*) = 0$ (a holomorphic vector field would be a conformal Killing vector, and there are none) and $h^1(K^*) = 3p - 3$. The cokernel of the ghost operator A_g is the space of *quadratic differentials*, the deformations of the complex structure not generated by diffeomorphisms or Weyl rescalings. So Riemann–Roch reproduces

$$\dim_{\mathbb{C}} \mathcal{M}_p = 3p - 3 \qquad (p \geq 2),$$

the complex dimension of the moduli space of Riemann surfaces. For $p = 2$: 3 complex

moduli; for $p = 3$: 6. This is why the ghost determinant and the measure $\mathrm{d}\mu(\mathcal{M}_p)$ in (10.178) come together: the zero modes of A_g^* are exactly the tangent directions of $\mathcal{M}_p$.

Worked example 10.43: x on the round sphere: Gauss–Bonnet as a Chern number

On the unit sphere with complex coordinate z (stereographic), $g = \frac{4\,\mathrm{d}z\,\mathrm{d}\bar z}{(1+|z|^2)^2}$, the holomorphic tangent bundle has fibre metric $h = g_{z\bar z} = \frac{2}{(1+|z|^2)^2}$ on the section ∂_z. The Chern connection of a holomorphic line bundle with metric h has curvature $F = \bar\partial\partial \ln h$. Then

$$\begin{aligned}\int_{S^2} x = \frac{i}{2\pi}\int_{S^2}\bar\partial\partial\ln h &\overset{(1)}{=} \frac{i}{2\pi}\int \partial_{\bar z}\partial_z\big(-2\ln(1+|z|^2)\big)\,\mathrm{d}\bar z\wedge\mathrm{d}z\\ &\overset{(2)}{=} \frac{i}{2\pi}\int\frac{-2}{(1+|z|^2)^2}\,\mathrm{d}\bar z\wedge\mathrm{d}z\\ &\overset{(3)}{=} \frac{i}{2\pi}\cdot(-2)\cdot 2i\int\frac{\mathrm{d}x\,\mathrm{d}y}{(1+r^2)^2}\\ &\overset{(4)}{=} \frac{2}{\pi}\cdot\pi = 2 = \chi(S^2).\end{aligned}$$

(1) The constant $\ln 2$ in $\ln h$ is killed by the derivatives.
(2) $\partial_z \ln(1+z\bar z) = \bar z/(1+z\bar z)$ and $\partial_{\bar z}\big(\bar z/(1+z\bar z)\big) = 1/(1+z\bar z)^2$.
(3) $\mathrm{d}\bar z\wedge\mathrm{d}z = 2i\,\mathrm{d}x\wedge\mathrm{d}y$.
(4) $\int_{\mathbb{R}^2}\frac{\mathrm{d}x\mathrm{d}y}{(1+r^2)^2} = 2\pi\int_0^\infty\frac{r\,\mathrm{d}r}{(1+r^2)^2} = \pi$.

So the class x really is the Euler class of the surface, and $\int_\Sigma x = \chi$. On one surface $x^2 = 0$; in a family, $\int_\Sigma x^2$ measures how the curvature of the fibres twists as we move in the base.

Reading Nash (pp. 282–283, (10.41)–(10.43))

Nash's (10.43) is written "ch(det Index $\bar\partial_Y$) = $\int_\Sigma(\cdots)(\cdots)$". Read the left side as ch(Index $\bar\partial_Y$); its degree-2 part is $c_1(\text{Index}) = c_1(\det\text{Index})$ by (10.191). The printed second factor "$(1+\frac{x}{2}+\frac{x^2}{12})$" is the Todd class and the first is ch$(K^*-\frac{d}{2}I)$, as in (10.42). His conclusion "the determinant bundle vanishes precisely when $d = 26$" means "is trivial" (has vanishing first Chern class), not that the bundle is zero.

10.8.7 The same polynomial for every weight: Mumford's formula

The computation generalises at once, and the generalisation explains the numbers. Let j be any integer (or half-integer, once a spin structure is chosen) and consider $\bar\partial$ on K^j, the bundle of **j-differentials** $f(z)\,(\mathrm{d}z)^j$. Physicists call a field with values in K^j a field of conformal weight j. Since $c_1(K^j) = -jx$,

$$\begin{aligned}c_1\big(\det\text{Index}\,\bar\partial_{K^j}\big) &\overset{(1)}{=} \Big[\int_\Sigma\Big(1-jx+\frac{j^2x^2}{2}\Big)\Big(1+\frac{x}{2}+\frac{x^2}{12}\Big)\Big]_{(2)}\\ &\overset{(2)}{=} \Big(\frac{j^2}{2}-\frac{j}{2}+\frac{1}{12}\Big)\int_\Sigma x^2 = \frac{6j^2-6j+1}{12}\,\kappa_1.\end{aligned}\tag{10.197}$$

(1) (10.191) with ch$(K^j) = e^{-jx}$.
(2) Degree-4 terms: $\frac{j^2x^2}{2} + (-jx)\frac{x}{2} + \frac{x^2}{12}$.

This is **Mumford's formula**. It contains every number of the bosonic and supersymmetric string.

field	weight j	statistics	power of $\det\bar\partial_{K^j}$	$\frac{6j^2-6j+1}{12}$	contribution to c_1/κ_1
X^μ, d real bosons	0	boson	$-d/2$	$\frac{1}{12}$	$-\frac{d}{24}$
b,c ghosts	$2,-1$	fermion	$+1$	$\frac{13}{12}$	$+\frac{26}{24}$
ψ^μ, d Majorana–Weyl	$\frac{1}{2}$	fermion	$+d/2$	$-\frac{1}{24}$	$-\frac{d}{48}$
β,γ superghosts	$\frac{3}{2},-\frac{1}{2}$	boson	-1	$\frac{11}{24}$	$-\frac{11}{24}$

Table 10.3: Mumford's coefficient for the fields of string theory. A complex fermionic pair of weights $(j,1-j)$ contributes one power of $\det\bar\partial_{K^{1-j}}$ (equivalently of K^j, by Serre duality); a real field contributes half a power; bosons contribute negative powers. The last column is always $-c/24$, where c is the central charge of the field.

Reading the table. *Bosonic string:* $-\frac{d}{24}+\frac{26}{24}=\frac{26-d}{24}$, the result (10.196) again. *Superstring:* add the worldsheet fermions and superghosts:

$$-\frac{d}{24}+\frac{26}{24}-\frac{d}{48}-\frac{11}{24}=\frac{-2d+52-d-22}{48}=\frac{30-3d}{48},$$

which vanishes at $d=10$. The critical dimension of the superstring comes out of the same one-line formula.

The symmetry $j\leftrightarrow 1-j$. The polynomial satisfies $6(1-j)^2-6(1-j)+1=6j^2-6j+1$. This is Serre duality: $H^1(K^j)\cong H^0(K^{1-j})^*$, so $\bar\partial_{K^j}$ and $\bar\partial_{K^{1-j}}$ have opposite index bundles, and a pair of fields of weights j and $1-j$ (like b and c) is really one system. The polynomial is smallest at $j=\frac{1}{2}$, the self-dual point, where the field is a spinor.

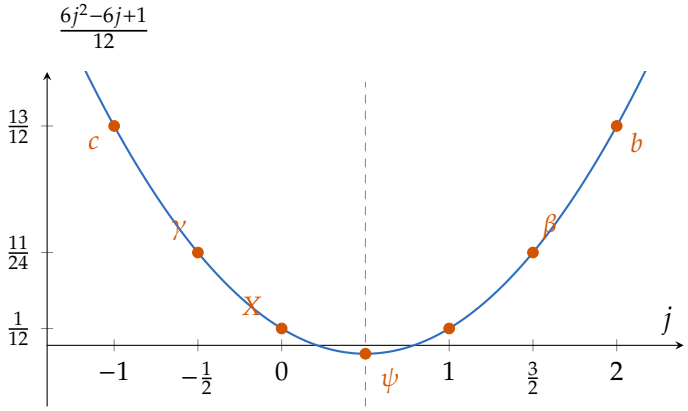

Figure 10.30: Mumford's polynomial is a parabola symmetric about the spinor point $j=\frac{1}{2}$ (dashed): Serre duality pairs weight j with $1-j$. The ghosts b,c sit high up at $j=2,-1$; the embedding coordinates at $j=0$. One ghost pair outweighs 26 half-units of X, which is where 26 comes from.

The local version. The Weyl-variation computation of Section 10.8.3 can be repeated for the Laplacian $\bar\partial^*_{K^j}\bar\partial_{K^j}$ on j-differentials, now with the twisted heat kernel (whose t^0 coefficient involves both $R/6$ and the curvature $-jR/2$ of K^j). The result (O. Alvarez 1983) is the local counterpart of (10.197):

$$\delta_\sigma \ln\frac{\det'\big(\bar\partial^*\bar\partial\big)_{K^j}}{\det\langle\text{zero modes}\rangle}=-\frac{6j^2-6j+1}{12\pi}\int_\Sigma\sqrt{g}\,R\,\delta\sigma. \tag{10.198}$$

For $j = 0$ this is exactly (10.185): the operator $\bar\partial^*\bar\partial = \Delta/2$ on complex functions has the same eigenvalues, with the same (complex) multiplicities, as $\Delta/2$ on real functions, and the zero-mode factor is the area. Assembling the partition function,

$$\begin{aligned}\delta_\sigma \ln Z_p &\overset{(1)}{=} \frac{d}{24\pi}\int \sqrt{g}R\,\delta\sigma - \frac{13}{12\pi}\int \sqrt{g}R\,\delta\sigma \\ &= \frac{d-26}{24\pi}\int_\Sigma \sqrt{g}\,R\,\delta\sigma .\end{aligned}$$

(1) Matter from (10.186); ghosts from (10.198) with $j = -1$ ($6 + 6 + 1 = 13$), with power $+1$ because the ghosts are fermions.

In the language of Section 10.8.3: the total central charge is $c_{\text{tot}} = d - 26$, and the Liouville field decouples iff $d = 26$.

10.8.8 Two cross-checks physicists use every day

(a) The ghost central charge from an operator product

In conformal field theory (Chapter 11) the central charge appears in the operator product of the stress tensor with itself,

$$T(z)T(w) \sim \frac{c/2}{(z-w)^4} + \frac{2T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w}. \tag{10.199}$$

For a fermionic pair b (weight λ) and c (weight $1-\lambda$) with $b(z)c(w) \sim \frac{1}{z-w}$, the stress tensor is

$$T = -\lambda\,{:}b\,\partial c{:} + (1-\lambda)\,{:}\partial b\,c{:}.$$

We compute the fourth-order pole of $T(z)T(w)$ directly.

Recall (Wick's theorem for operator products). The singular part of a product of two normal-ordered free-field expressions is the sum over all ways of contracting fields of the first with fields of the second, each contraction replaced by its two-point function and each fermion interchange giving a sign. A *double* contraction of two bilinears leaves no operator, and it is the only source of the highest pole.

The contractions we need. From $b(z)c(w) \sim \frac{1}{z-w}$ and the fermionic sign, $c(z)b(w) = -b(w)c(z) \sim -\frac{1}{w-z} = \frac{1}{z-w}$. Differentiating,

$$\begin{aligned}
\langle b(z)\,\partial c(w)\rangle &= \partial_w \tfrac{1}{z-w} = \tfrac{1}{(z-w)^2}, & \langle \partial b(z)\,c(w)\rangle &= \partial_z \tfrac{1}{z-w} = -\tfrac{1}{(z-w)^2},\\
\langle \partial c(z)\,b(w)\rangle &= -\tfrac{1}{(z-w)^2}, & \langle c(z)\,\partial b(w)\rangle &= \tfrac{1}{(z-w)^2},\\
\langle \partial b(z)\,\partial c(w)\rangle &= \partial_z \tfrac{1}{(z-w)^2} = -\tfrac{2}{(z-w)^3}, & \langle \partial c(z)\,\partial b(w)\rangle &= -\tfrac{2}{(z-w)^3}.
\end{aligned}$$

The double contraction of two bilinears. In $\beta_1\gamma_1(z)\,\beta_2\gamma_2(w)$ (with β's b-type and γ's c-type, all fermionic) contract γ_1 with β_2 and β_1 with γ_2. Bringing γ_2 next to β_1 moves it past the pair $\gamma_1\beta_2$, which is even, so there is no sign: the double contraction is $\langle\gamma_1(z)\beta_2(w)\rangle\langle\beta_1(z)\gamma_2(w)\rangle$. Now

expand $T(z)T(w)$ into its four products and doubly contract each:

$$\lambda^2 :b\partial c:(z)\,:b\partial c:(w) \overset{(1)}{=} \lambda^2\,\langle \partial c(z) b(w)\rangle\langle b(z)\partial c(w)\rangle = -\frac{\lambda^2}{(z-w)^4},$$

$$(1-\lambda)^2 :\partial b\, c:(z)\,:\partial b\, c:(w) \overset{(2)}{=} (1-\lambda)^2\langle c(z)\partial b(w)\rangle\langle \partial b(z) c(w)\rangle = -\frac{(1-\lambda)^2}{(z-w)^4},$$

$$-\lambda(1-\lambda) :b\partial c:(z)\,:\partial b\, c:(w) \overset{(3)}{=} -\lambda(1-\lambda)\langle \partial c(z)\partial b(w)\rangle\langle b(z) c(w)\rangle = \frac{2\lambda(1-\lambda)}{(z-w)^4},$$

$$-\lambda(1-\lambda) :\partial b\, c:(z)\,:b\partial c:(w) \overset{(4)}{=} -\lambda(1-\lambda)\langle c(z) b(w)\rangle\langle \partial b(z)\partial c(w)\rangle = \frac{2\lambda(1-\lambda)}{(z-w)^4}.$$

(1) The rule above with $\beta_1 = \beta_2 = b$, $\gamma_1 = \gamma_2 = \partial c$; the two contractions are $-\frac{1}{(z-w)^2}$ and $\frac{1}{(z-w)^2}$.
(2) $\beta = \partial b$, $\gamma = c$; contractions $\frac{1}{(z-w)^2}$ and $-\frac{1}{(z-w)^2}$.
(3) Contractions $-\frac{2}{(z-w)^3}$ and $\frac{1}{z-w}$; the coefficient of this cross term in $T\,T$ is $(-\lambda)(1-\lambda)$.
(4) Contractions $\frac{1}{z-w}$ and $-\frac{2}{(z-w)^3}$.

Adding the four lines and comparing with (10.199):

$$\frac{c_\lambda}{2} \overset{(1)}{=} -\lambda^2 - (1-\lambda)^2 + 4\lambda(1-\lambda) \overset{(2)}{=} -\lambda^2 - 1 + 2\lambda - \lambda^2 + 4\lambda - 4\lambda^2 = -(6\lambda^2 - 6\lambda + 1),$$
$$c_\lambda = -2\big(6\lambda^2 - 6\lambda + 1\big).$$

(1) The coefficient of $(z-w)^{-4}$ in the sum of the four lines.
(2) Expand $(1-\lambda)^2$ and $4\lambda(1-\lambda)$.

Check: $\lambda = \frac{1}{2}$ is a single complex (Dirac) fermion, $c = -2(\frac{3}{2} - 3 + 1) = 1$, as it should be. For the reparametrisation ghosts $\lambda = 2$: $c = -2(24 - 12 + 1) = -26$. For the superghosts (bosonic, so every contraction loop has the opposite sign and the overall sign flips) $\lambda = \frac{3}{2}$: $c = +2(\frac{27}{2} - 9 + 1) = 11$. And the polynomial $6\lambda^2 - 6\lambda + 1$ is Mumford's: $c = -24\times$ (coefficient in Table 10.3). The operator product and the Grothendieck–Riemann–Roch integral compute the same number.

(b) The light-cone zero-point energy

In light-cone gauge only the $d-2$ transverse oscillators survive. Each is a string of harmonic oscillators with frequencies $n = 1, 2, 3, \ldots$ (in units where the string length is fixed), each with zero-point energy $\frac{n}{2}$. The ground-state energy of the open string is therefore

$$a = \frac{d-2}{2}\sum_{n=1}^{\infty} n.$$

The sum diverges, but its divergence is a cutoff-dependent term that is absorbed in the (bare) string tension; the finite remainder is universal. Regulate with $e^{-\epsilon n}$:

$$\begin{aligned}\sum_{n=1}^{\infty} n\, e^{-\epsilon n} &\overset{(1)}{=} -\frac{\mathrm{d}}{\mathrm{d}\epsilon}\,\frac{1}{e^{\epsilon}-1} \\ &\overset{(2)}{=} -\frac{\mathrm{d}}{\mathrm{d}\epsilon}\Big(\frac{1}{\epsilon} - \frac{1}{2} + \frac{\epsilon}{12} + O(\epsilon^3)\Big) \\ &= \frac{1}{\epsilon^2} - \frac{1}{12} + O(\epsilon^2).\end{aligned}$$

(1) Geometric series $\sum_{n\geq 1} e^{-\epsilon n} = \frac{1}{e^{\epsilon}-1}$, and differentiate it term by term.
(2) $\frac{\epsilon}{e^{\epsilon}-1} = \sum_k B_k \frac{\epsilon^k}{k!} = 1 - \frac{\epsilon}{2} + \frac{\epsilon^2}{12} - \cdots$ (Bernoulli numbers $B_2 = \frac{1}{6}$).

The finite part is $-\frac{1}{12} = \zeta(-1)$; the same number the ζ-function gives directly. So $a = -\frac{d-2}{24}$. The first excited states $\alpha^i_{-1}|0\rangle$ form a vector of the transverse rotation group $\mathrm{SO}(d-2)$, with $d-2$ components. A massive vector in d dimensions needs $d-1$ components (a vector of the little group $\mathrm{SO}(d-1)$), so Lorentz invariance forces this state to be massless, $1 + a = 0$:

$$-\frac{d-2}{24} = -1 \quad \Longleftrightarrow \quad d = 26.$$

For the superstring (Neveu–Schwarz sector) each of the $d-2$ transverse fermions has modes $r = \frac{1}{2}, \frac{3}{2}, \ldots$ and zero-point energy $-\frac{r}{2}$ per mode (the opposite sign to a boson). Regulate as before:

$$\sum_{r=\frac{1}{2},\frac{3}{2},\ldots} r\, e^{-\epsilon r} \overset{(1)}{=} -\frac{\mathrm{d}}{\mathrm{d}\epsilon}\frac{e^{-\epsilon/2}}{1-e^{-\epsilon}} \overset{(2)}{=} -\frac{\mathrm{d}}{\mathrm{d}\epsilon}\frac{1}{2\sinh(\epsilon/2)} \overset{(3)}{=} -\frac{\mathrm{d}}{\mathrm{d}\epsilon}\left(\frac{1}{\epsilon} - \frac{\epsilon}{24} + O(\epsilon^3)\right) = \frac{1}{\epsilon^2} + \frac{1}{24} + O(\epsilon^2).$$

(1) Geometric series $\sum_{k\geq 0} e^{-\epsilon(k+\frac{1}{2})} = e^{-\epsilon/2}/(1-e^{-\epsilon})$, differentiated term by term.
(2) Multiply numerator and denominator by $e^{\epsilon/2}$.
(3) $2\sinh(\epsilon/2) = \epsilon + \epsilon^3/24 + \ldots$, so its inverse is $\epsilon^{-1}(1 - \epsilon^2/24 + \ldots)$.

The finite part is $+\frac{1}{24}$ (the Hurwitz value $\zeta_H(-1, \frac{1}{2})$), so each fermion contributes $-\frac{1}{2}\cdot\frac{1}{24} = -\frac{1}{48}$ and

$$a_{\mathrm{NS}} = (d-2)\left(-\frac{1}{24} - \frac{1}{48}\right) = -\frac{d-2}{16}.$$

The massless vector is now $\psi^i_{-1/2}|0\rangle$ at level $\frac{1}{2}$, so $a_{\mathrm{NS}} = -\frac{1}{2}$, i.e. $d = 10$.

Physical picture: Why a Casimir energy knows about an anomaly

The $-\frac{1}{12}$ in the light-cone count and the $\frac{1}{12}$ in the Todd class are the same Bernoulli number $B_2 = \frac{1}{6}$ (halved). In the heat kernel it is the coefficient $\frac{1}{6}$ of R. The Todd class $\frac{x}{1-e^{-x}}$ and the regulated sum $\frac{\epsilon}{e^{\epsilon}-1}$ are the same generating function. Casimir energy, conformal anomaly and index theory are three faces of one Bernoulli number.

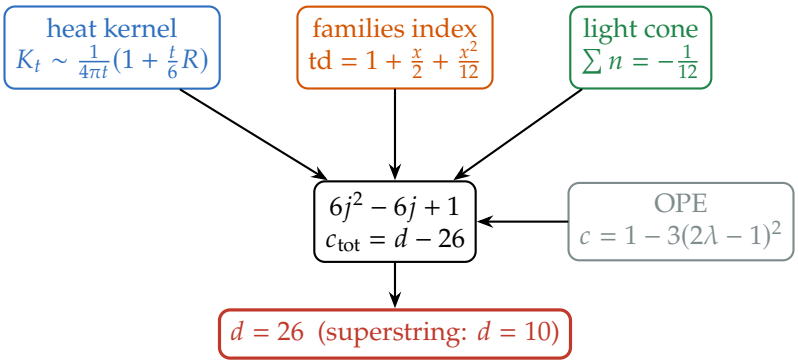

Figure 10.31: Four independent computations feed the same polynomial and the same critical dimension: the local Weyl anomaly (heat kernel), Nash's families index computation, the conformal-field-theory operator product, and the light-cone Casimir energy.

10.8.9 Quillen's metric, holomorphic factorisation and theta functions

Nash ends §4 with three results, each of which deserves a paragraph.

Quillen's metric. A line bundle has a first Chern class, but to write $\det(\bar\partial^*\bar\partial)$ as the *length* of the section $\det\bar\partial$ we need a metric on it. On a fibre where $\bar\partial$ has kernel H^0 and cokernel H^1, the line is $(\Lambda^{\max}H^0)^*\otimes\Lambda^{\max}H^1$ and inherits an L^2 metric $\|\cdot\|_{L^2}$ from the inner products of zero modes. That metric jumps when the kernel jumps. Quillen's fix is to multiply by the ζ-determinant of the Laplacian on the non-zero modes:

$$\|\cdot\|_{\mathrm{Q}}^2 := \|\cdot\|_{L^2}^2\cdot\det{}'\big(\bar\partial^*\bar\partial\big). \tag{10.200}$$

When an eigenvalue $\lambda\to 0$, the L^2 factor gains a zero mode and the $\det'$ factor loses the factor λ; the two changes compensate and $\|\cdot\|_{\mathrm{Q}}$ is smooth. Quillen proved that the curvature of the associated connection is the 2-form representing $c_1(\det\mathrm{Index})$ given by the families index formula at the level of forms. So the anomaly is literally the curvature of the Quillen metric: $d=26$ makes the bundle flat and (on simply connected pieces) trivial with a trivialising section of constant Quillen length.

Belavin–Knizhnik holomorphic factorisation. In the critical dimension the integrand of (10.178) is the Quillen norm squared of a section of a trivial bundle. Belavin and Knizhnik showed that then

$$Z_p=\int_{\mathcal{M}_p} f\,\bar f, \qquad f \text{ holomorphic on (the Teichmüller space covering) } \mathcal{M}_p. \tag{10.201}$$

The algebraic-geometry content is **Mumford's isomorphism**: in (10.197) the weight-2 bundle has coefficient $\frac{13}{12}$ and the weight-1 bundle (the Hodge bundle λ_1, $j=1$) has coefficient $\frac{1}{12}$, so $\lambda_2\cong\lambda_1^{\otimes 13}$; the holomorphic section implementing this isomorphism is f (times the holomorphic volume on moduli). The bosonic string measure is $|\text{Mumford form}|^2$.

Worked example 10.44: The one-loop torus, where everything is explicit

Take Σ a flat torus $\mathbb{C}/(\mathbb{Z}+\tau\mathbb{Z})$, $\tau=\tau_1+i\tau_2$ in the upper half plane. (Genus one is outside Nash's $p>1$, but the formulas are the cleanest illustration.) The non-zero eigenvalues of Δ are $\frac{4\pi^2}{\tau_2^2}|m+n\tau|^2$, and Kronecker's first limit formula evaluates the ζ-determinant:

$$\frac{\det'\Delta}{A}\ \propto\ \tau_2\,|\eta(\tau)|^4, \qquad \eta(\tau)=q^{1/24}\prod_{n\ge1}(1-q^n),\quad q=e^{2\pi i\tau},$$

with a τ-independent constant. The ghosts cancel two of the d bosons (the same $d-2$ as in light-cone gauge), and the measure on moduli is $\mathrm{d}^2\tau/\tau_2^2$. So

$$\begin{aligned} Z_1 &\overset{(1)}{=} \int_{\mathcal{F}}\frac{\mathrm{d}^2\tau}{\tau_2^2}\,\big(\tau_2|\eta(\tau)|^4\big)^{-(d-2)/2}\\ &\overset{(2)}{=} \int_{\mathcal{F}}\frac{\mathrm{d}^2\tau}{\tau_2^2}\,\tau_2^{-12}\,\eta(\tau)^{-24}\,\overline{\eta(\tau)^{-24}} \qquad (d=26), \end{aligned}$$

(1) (10.178) at genus one with the Kronecker formula; the integral is over a fundamental domain $\mathcal{F}$ of $\mathrm{SL}(2,\mathbb{Z})$.

(2) Put $d-2=24$.

The τ-dependence (apart from the powers of τ_2, which come from the zero modes and the non-compact momentum integral) has factorised into $f\bar f$ with $f=\eta^{-24}$ holomorphic. Expanding,

$$\eta(\tau)^{-24}=q^{-1}\prod_{n\ge1}(1-q^n)^{-24}=q^{-1}+24+324\,q+3200\,q^2+\cdots,$$

the coefficients count states: q^{-1} is the tachyon (the ground-state energy $a = -1$ again), and the 24 at order q^0 is the $d - 2 = 24$ oscillators α^i_{-1}, the massless vector. Modular invariance works because $\tau_2^{1/2}|\eta|^2$ is invariant under $\tau \mapsto -1/\tau$ ($\eta(-1/\tau) = \sqrt{-i\tau}\,\eta(\tau)$, $\tau_2 \mapsto \tau_2/|\tau|^2$).

Manin: theta functions. Manin showed that at higher genus the holomorphic f can be written with Riemann theta functions, $\vartheta[\delta](0,\Omega) = \sum_{n\in\mathbb{Z}^p} \exp\bigl(\pi i(n+a)^{\mathsf{T}}\Omega(n+a) + 2\pi i(n+a)^{\mathsf{T}}b\bigr)$, $\delta = (a,b)$ a characteristic, Ω the $p \times p$ period matrix. At genus one the relevant object is $\eta(\tau)^{24} \propto \vartheta_2\vartheta_3\vartheta_4(0,\tau)^8$ (Jacobi); at genus two it is the product of the ten even theta constants squared (the Siegel cusp form χ_{10}), and the genus-two bosonic string measure is proportional to $1/\chi_{10}$. Theta functions are the higher-genus generalisation of η.

Recap: Section 4

- The string integrand is a section of $\det \operatorname{Index} \bar\partial_Y$ with $\bar\partial_Y = \bar\partial_{K^*-(d/2)I}$ over Met/C^∞_+; powers of determinants are tensor powers, i.e. multiples in K-theory.
- Families index theorem with $\mathrm{td} = 1 + \frac{x}{2} + \frac{x^2}{12}$: $c_1 = \frac{26-d}{24}\kappa_1$. The anomaly vanishes iff $d = 26$.
- The degree-0 part of the same computation is Riemann–Roch and gives $\dim_{\mathbb{C}} \mathcal{M}_p = 3p - 3$.
- Mumford's polynomial $\frac{6j^2-6j+1}{12}$ gives the ghost central charge -26, the superghost $+11$ and the superstring dimension 10.
- Cross-checks: the TT operator product and the light-cone Casimir energy $\zeta(-1) = -\frac{1}{12}$.
- At $d = 26$: the Quillen connection is flat, $Z_p = \int f\bar f$ with f holomorphic (Belavin–Knizhnik), expressible by theta functions (Manin); at genus one $f = \eta^{-24}$.

10.9 Global anomalies

Everything so far in this chapter has been *infinitesimal*. We varied the gauge field by $\delta A = \nabla f$ with f in the Lie algebra, or the metric by $\delta g = 2\delta\sigma\, g$, and computed the first-order change of $\ln\det$. That is a derivative, and derivatives only see the part of the symmetry group that is connected to the identity. Suppose the group has several connected components. Then a function can be perfectly invariant under every infinitesimal transformation and still take different values on different components. The question of this section: *can the fermion determinant be invariant under all small gauge transformations and yet change sign under a large one?* Witten showed that the answer is yes, for the most innocent-looking theory imaginable: SU(2) Yang–Mills theory with a single left-handed fermion doublet. Such a change is a **global anomaly**.

Reading Nash (p. 281 top: the end of §3)

Before §4, Nash finishes the gravitational discussion. For a theory with fermions and gravity in $n = 4k - 2$ dimensions one works on the frame bundle P, an $\mathrm{SO}(4k-2)$-bundle, and the relevant symmetry group is $\mathrm{Aut}(P)$, the semi-direct product $\mathcal{G}_L \rtimes \mathrm{Diff}_0(M)$ of local Lorentz rotations and diffeomorphisms. The anomaly is then a class in $H^1(\mathrm{Aut}(P))$ mixing

the two. A local counterterm moves it back and forth between a Lorentz anomaly and a diffeomorphism anomaly (Alvarez-Gaumé and Ginsparg), much as a counterterm moves the U(1) anomaly between the vector and axial currents in QED_2 [QFT notes §22.2.2]. We will not need this below, except as a reminder that the "anomaly" is a property of the full symmetry group, not of one presentation of it.

10.9.1 Local versus global: invisible to derivatives

Here is the distinction in the smallest possible setting. Let G be a group and $\mathcal{Z} : G \to \mathbb{C}^\times$ a function (think: the determinant evaluated on gauge-transformed fields, divided by its value at the identity). A *local* anomaly is a non-zero derivative, $\mathrm{d}\ln\mathcal{Z} \neq 0$ at the identity. It is detected by a 1-form, and Nash's §2 packaged it as a de Rham class in $H^1_{\mathrm{dR}}(\mathcal{G})$. A *global* anomaly is the situation where $\mathrm{d}\ln\mathcal{Z} = 0$ everywhere, so $\mathcal{Z}$ is constant on each connected component, but the constants are different.

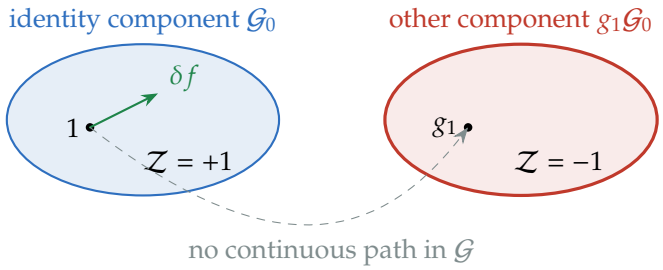

Figure 10.32: A global anomaly. The fermion determinant $\mathcal{Z}$ is invariant under every infinitesimal gauge transformation (green arrow), so it is constant on each component of $\mathcal{G}$. It is nevertheless not invariant: on the component that does not contain the identity it has the opposite sign. No derivative computed at 1 can see this.

The analogy with torsion. Nash compares this with torsion in homology. De Rham cohomology is built from differential forms, and a differential form can only measure things with real (or integer) values that vary smoothly. A torsion class, such as the generator of $H_1(\mathbb{RP}^2;\mathbb{Z}) = \mathbb{Z}_2$, is a loop that is not a boundary, but twice it is. No closed 1-form can integrate to something non-zero on it: if $\oint_\gamma \omega = c$ then $2c = \oint_{2\gamma}\omega = 0$, so $c = 0$. Forms are blind to torsion, and global anomalies turn out to be torsion classes (Section 10.9.6).

10.9.2 A global anomaly you can compute by hand: one fermion on a circle

Before Witten's four-dimensional example, here is the whole mechanism in $0+1$ dimensions, where every step is explicit. Take a single complex fermion $\psi(\tau)$ on a Euclidean time circle of length β, coupled to a U(1) gauge field $A = A(\tau)\,\mathrm{d}\tau$:

$$S = \int_0^\beta \mathrm{d}\tau\; \bar\psi\,(\partial_\tau - iA)\,\psi, \qquad \psi(\tau+\beta) = -\psi(\tau).$$

A gauge transformation $\psi \mapsto e^{i\alpha}\psi$, $A \mapsto A + \partial_\tau\alpha$ leaves S invariant. The function $e^{i\alpha(\tau)}$ must be single valued, so $\alpha(\beta) = \alpha(0) + 2\pi w$ with $w \in \mathbb{Z}$ the winding number. The gauge group has components labelled by w: $\pi_0(\mathcal{G}) = \mathbb{Z}$. Transformations with $w \neq 0$ are the **large** gauge transformations. The only gauge-invariant quantity built from A is the holonomy e^{ia}, $a = \oint A$; a large gauge transformation shifts $a \mapsto a + 2\pi w$.

Worked example 10.45: $Z = 2\cos(a/2)$ and its sign flip

Gauge-fix $A = a/\beta$ (constant). Antiperiodic eigenfunctions are $e^{i\omega_n\tau}$ with $\omega_n = \frac{2\pi}{\beta}(n+\frac{1}{2})$, and the operator $\partial_\tau - ia/\beta$ has eigenvalues $\lambda_n = \frac{i}{\beta}\big(2\pi(n+\frac{1}{2}) - a\big)$, $n \in \mathbb{Z}$. Pair the eigenvalue n with $-n-1$ and normalise by the value at $a = 0$:

$$\begin{aligned}\frac{Z(a)}{Z(0)} &\overset{(1)}{=} \prod_{n\geq 0} \frac{\lambda_n \lambda_{-n-1}\big|_a}{\lambda_n \lambda_{-n-1}\big|_0} = \prod_{n\geq 0} \frac{(2\pi(n+\frac{1}{2}))^2 - a^2}{(2\pi(n+\frac{1}{2}))^2} \\ &\overset{(2)}{=} \prod_{n\geq 0}\Big(1 - \frac{a^2}{(2n+1)^2\pi^2}\Big) \\ &\overset{(3)}{=} \cos\frac{a}{2}.\end{aligned}$$

(1) The Grassmann integral is $\det(\partial_\tau - iA) = \prod_n \lambda_n$; grouping n with $-n-1$ makes each factor $-\beta^{-2}\big((2\pi(n+\frac{1}{2}))^2 - a^2\big)$, and the a-independent prefactors cancel in the ratio. (This pairing is a choice of regularisation that respects charge conjugation $a \mapsto -a$.)

(2) Divide numerator and denominator by $(2\pi(n+\frac{1}{2}))^2 = (2n+1)^2\pi^2$.

(3) Euler's product $\cos x = \prod_{n\geq 0}\big(1 - \frac{4x^2}{(2n+1)^2\pi^2}\big)$ with $x = a/2$.

With $Z(0) = 2$ (the trace over the two states, empty and filled), $Z(a) = 2\cos(a/2)$. Now perform a large gauge transformation, $a \mapsto a + 2\pi$:

$$Z(a+2\pi) = 2\cos\Big(\frac{a}{2} + \pi\Big) = -Z(a).$$

The partition function changes sign under a gauge transformation, although it is perfectly invariant under small ones (it depends only on a). The Hamiltonian reading: the two states have charges $Q = \pm\frac{1}{2}$, and $Z = \operatorname{Tr} e^{iaQ} = e^{ia/2} + e^{-ia/2}$; half-integer charges are not single-valued under $a \mapsto a + 2\pi$.

Where the sign comes from: one eigenvalue crosses zero. As a increases from 0 to 2π, each eigenvalue $\lambda_n \propto (2\pi(n+\frac{1}{2}) - a)$ moves down by 2π, i.e. to the position of its neighbour λ_{n-1}. The spectrum as a set is unchanged (it had to be; a and $a + 2\pi$ are gauge equivalent), but exactly one eigenvalue, λ_0, has passed through zero, at $a = \pi$. In the paired product this is the factor $(\pi^2 - a^2)$ changing sign. This is the prototype of everything in this section: *a gauge-invariant spectrum, a gauge-non-invariant product, and the difference is a count of eigenvalues crossing zero.* Figure 10.33 shows it.

Try it: Two fermions, and a counterterm

(a) Show that with two identical fermions $Z = 4\cos^2(a/2)$ is invariant under $a \mapsto a + 2\pi$. (b) Show that multiplying Z by the "Chern–Simons" counterterm $e^{ia/2}$ gives a gauge-invariant $1 + e^{ia}$, but that this is no longer invariant under charge conjugation $a \mapsto -a$. *Answer:* (a) $\cos^2$ is π-periodic. (b) $e^{ia/2}\cdot 2\cos(a/2) = 1 + e^{ia}$; $1 + e^{-ia} \neq 1 + e^{ia}$. One can trade the global anomaly for the loss of a discrete symmetry, but one cannot keep both. An even number of fermions has no anomaly at all: the same pattern as Witten's "p even".

10.9.3 Counting components: $\pi_0(\mathcal{G}) = \pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$

Now the four-dimensional theory. Space-time is $M = S^4$ (or $\mathbb{R}^4$ with fields approaching a constant at infinity, which is the same thing by stereographic projection). A gauge transformation

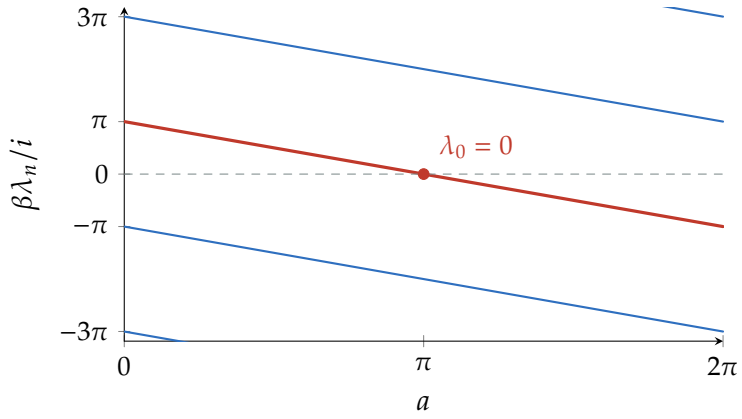

Figure 10.33: Spectral flow in the 0 + 1 toy model. As the holonomy a runs from 0 to 2π, every eigenvalue slides down one step; the spectrum at $a = 2\pi$ is the same set as at $a = 0$. One eigenvalue (red) crosses zero, so the product of eigenvalues, and with it Z, changes sign.

is a map $g : S^4 \to G$, and we fix $g(\infty) = 1$ (these are the transformations that act freely; the constant ones are global symmetries). The gauge group is then the based mapping space $\Omega^4 G$, and its components are homotopy classes of maps $S^4 \to G$ (Nash (10.44)):

$$\pi_0(\mathcal{G}) = \pi_0\big(\Omega^{2m} G\big) = \pi_{2m}(G), \qquad M = S^{2m}. \tag{10.202}$$

Two gauge transformations are in the same component iff one can be deformed into the other; that is exactly a homotopy of maps of spheres.

SU(2) **is the 3-sphere.** Every $g \in \mathrm{SU}(2)$ can be written

$$g = x_0\,\mathbb{1} + i\,x_k\sigma_k = \begin{pmatrix} x_0 + ix_3 & ix_1 + x_2 \\ ix_1 - x_2 & x_0 - ix_3 \end{pmatrix}, \qquad x_0^2 + x_1^2 + x_2^2 + x_3^2 = 1, \tag{10.203}$$

with σ_k the Pauli matrices. The determinant is $x_0^2 + x_3^2 + x_1^2 + x_2^2 = 1$, and unitarity follows from $\sigma_k^\dagger = \sigma_k$ and $\{\sigma_j, \sigma_k\} = 2\delta_{jk}$. So $\mathrm{SU}(2) \cong S^3$, and $\pi_4(\mathrm{SU}(2)) = \pi_4(S^3)$.

Key idea: Nash (10.45)

$$\pi_0(\mathcal{G}) = \pi_4(\mathrm{SU}(2)) = \pi_4(S^3) = \mathbb{Z}_2.$$

There is exactly one class of gauge transformations on S^4 that cannot be deformed to the identity, and doing it twice can.

Why $\mathbb{Z}_2$: framed circles and the belt trick. The Pontryagin–Thom construction turns maps $S^{n+k} \to S^n$ into geometry. Pick a regular value $y \in S^n$; its preimage is a k-dimensional submanifold of S^{n+k}, and the derivative of the map identifies the normal space at each preimage point with $T_y S^n$: a **framing** of the normal bundle. Homotopic maps give framed submanifolds that are framed-cobordant, and conversely. For $S^4 \to S^3$ ($n = 3$, $k = 1$) the preimage is a collection of circles in S^4, each carrying three normal vector fields. In S^4 any circle can be unknotted and shrunk, so only the framing matters. Going once round the circle, the normal frame traces a loop in SO(3), and $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$: a frame rotated by 2π is not deformable to the unrotated one, but a frame rotated by 4π is (Dirac's belt trick). Hence

$$\pi_4(S^3) \cong \{\text{framed circles}\}/\text{cobordism} \cong \pi_1(\mathrm{SO}(3))/(\text{shift}) \cong \mathbb{Z}_2.$$

(The "shift" is a bookkeeping subtlety: the framing induced by bounding a disc is taken as the zero; the result is the same $\mathbb{Z}_2$.) The generator is also the suspension $\Sigma\eta$ of the Hopf map $\eta : S^3 \to S^2$ (Chapter 1).

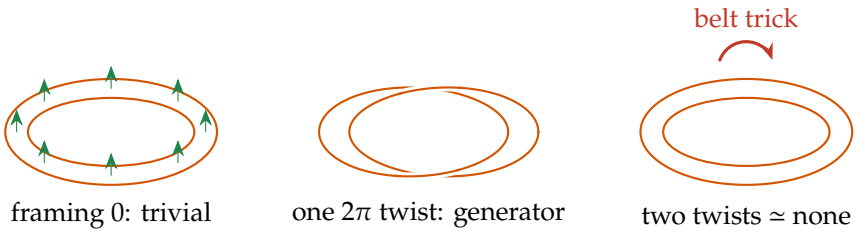

Figure 10.34: Maps $S^4 \to S^3$ as framed circles (Pontryagin–Thom). The only invariant is how many times the normal frame (drawn as a ribbon) twists going round, counted in $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$. One twist cannot be undone; two twists can, exactly as in Dirac's belt trick. This is why $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$.

Worked example 10.46: Which groups have a π_4?

From the tables of homotopy groups (Chapter 1):

$$\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2, \qquad \pi_4(\mathrm{SU}(N)) = 0\ (N \geq 3), \qquad \pi_4(\mathrm{Sp}(n)) = \mathbb{Z}_2, \qquad \pi_4(\mathrm{SO}(4)) = \mathbb{Z}_2 \oplus \mathbb{Z}_2.$$

Since $\mathrm{Sp}(1) = \mathrm{SU}(2)$, the symplectic groups inherit the anomaly; $\mathrm{SO}(4) = (\mathrm{SU}(2) \times \mathrm{SU}(2))/\mathbb{Z}_2$ has one copy for each factor. For SU(3) the large transformation of SU(2) becomes small once SU(2) is embedded in SU(3): there is now room to unwind it. We return to this below.

10.9.4 Why the determinant has a sign: pseudo-reality and Pfaffians

Nash writes that the fermionic integral produces $\sqrt{\det(\not{D}_A^\dagger \not{D}_A)}$ and that global gauge transformations "change the sign" of this square root. A positive square root of a positive number cannot change sign, so we must first understand which square root is meant. The answer is a Pfaffian, and it exists because the doublet of SU(2) is **pseudo-real**.

Pseudo-reality in one line. Let $\varepsilon = i\sigma_2 = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$. Then for the Pauli matrices

$$\begin{aligned} & \varepsilon\, \sigma_k^*\, \varepsilon^{-1} \overset{(1)}{=} -\sigma_k, \qquad k = 1,2,3, \\ \Rightarrow \quad & \varepsilon\, g^*\, \varepsilon^{-1} \overset{(2)}{=} g \qquad \text{for all } g \in \mathrm{SU}(2). \end{aligned} \tag{10.204}$$

(1) Check each: $\sigma_1^* = \sigma_1$, $\sigma_2^* = -\sigma_2$, $\sigma_3^* = \sigma_3$, and conjugation by ε flips the sign of σ_1, σ_3 and fixes σ_2; in all three cases the net effect is $-\sigma_k$.

(2) Write $g = x_0 + i x_k \sigma_k$ as in (10.203). Then $g^* = x_0 - i x_k \sigma_k^*$ and $\varepsilon g^* \varepsilon^{-1} = x_0 - i x_k(-\sigma_k) = g$.

So the doublet is equivalent to its complex conjugate, via a matrix ε with $\varepsilon\varepsilon^* = -1$. That minus sign is what "pseudo-real" (as opposed to real) means. The anti-linear map $J = \varepsilon K$ (K = complex conjugation) commutes with every g and satisfies $J^2 = \varepsilon\varepsilon^* = -1$.

The Weyl operator is real. The same structure exists on spinors: in four Euclidean dimensions the chiral spinors $S^\pm$ are also pseudo-real, with a charge-conjugation map C, $C^2 = -1$ on each chirality (Clifford algebra details in Chapter T4). On a left-handed doublet, $\psi \in \Gamma(S^+ \otimes \mathbb{C}^2)$, the combined anti-linear map $\mathcal{J} = C \otimes J$ squares to $(-1)(-1) = +1$ and commutes with the coupled Dirac operator. An anti-linear map squaring to $+1$ is a *real structure*: the fixed points of $\mathcal{J}$ form

a real vector space, and $\not{D}_A$ restricts to a real operator on it. This is Nash's statement that "$i\not{D}_A$ coupled to an SU(2) doublet can be taken to be a real skew-adjoint operator". In practice this means: a single Weyl doublet is like a Majorana fermion, and its path integral is a Pfaffian,

$$\int \mathcal{D}\psi \; e^{-\frac{1}{2}\int \psi^{\mathsf{T}} C \not{D}_A \psi} = \mathrm{Pf}(C\not{D}_A), \qquad \mathrm{Pf}(\cdot)^2 = \det(\cdot). \tag{10.205}$$

Working definition 10.11 (Pfaffian)

For a real antisymmetric $2N \times 2N$ matrix B, the **Pfaffian** is the polynomial $\mathrm{Pf}(B) = \frac{1}{2^N N!}\sum_\pi \mathrm{sgn}(\pi)\prod_{i=1}^{N} B_{\pi(2i-1)\pi(2i)}$ [a sum over all permutations π of $1,\dots,2N$. Each way of pairing up the indices appears $2^N N!$ times, hence the prefactor. For 2×2 it is just B_{12}], and it satisfies $\mathrm{Pf}(B)^2 = \det B$. *How to compute it:* bring B to block form $\bigoplus_k \left(\begin{smallmatrix} 0 & \lambda_k \\ -\lambda_k & 0 \end{smallmatrix}\right)$ by a rotation $R \in \mathrm{SO}(2N)$; then $\mathrm{Pf}(B) = \prod_k \lambda_k$. The Grassmann integral [keep only the term containing every θ_i exactly once] $\int \mathrm{d}^{2N}\theta \, e^{-\frac{1}{2}\theta^{\mathsf{T}} B \theta} = \mathrm{Pf}(B)$.

Worked example 10.47: 2×2 and 4×4 Pfaffians

For $B = \left(\begin{smallmatrix} 0 & b \\ -b & 0 \end{smallmatrix}\right)$, $\mathrm{Pf}\, B = b$ and $\det B = b^2$. For a 4×4 antisymmetric B,

$$\mathrm{Pf}\, B = B_{12}B_{34} - B_{13}B_{24} + B_{14}B_{23},$$

and one checks $\det B = (B_{12}B_{34} - B_{13}B_{24} + B_{14}B_{23})^2$ by expanding. The point: $\det B$ is a perfect square *as a polynomial*, and $\mathrm{Pf}\, B$ is its square root *with a definite sign*, a polynomial in the entries. Along a path $B(t)$ the Pfaffian is a smooth function that can pass through zero and change sign, while $\sqrt{\det}$ would have a kink. The sign of the Pfaffian is not a matter of convention once it is fixed at one point: it is determined by continuity.

Kramers pairs. The Pfaffian has a spectral description that makes the sign flip visible. The Hermitian operator $H = i\not{D}_A$ on the full (both chiralities) doublet space commutes with the anti-unitary J, $J^2 = -1$. By Kramers' theorem every eigenvalue is doubly degenerate: if $H\psi = \lambda\psi$ then $HJ\psi = \lambda J\psi$ (λ is real and J commutes with H), and $J\psi \perp \psi$. For the last claim use the defining property of an anti-unitary map, $\langle Ja, Jb\rangle = \langle b, a\rangle$:

$$\langle J\psi, \psi\rangle \overset{(1)}{=} -\langle J\psi, J^2\psi\rangle \overset{(2)}{=} -\langle J\psi, \psi\rangle \quad\Longrightarrow\quad \langle J\psi, \psi\rangle = 0.$$

(1) $J^2 = -1$, so $\psi = -J^2\psi$.
(2) Anti-unitarity with $a = \psi$, $b = J\psi$.

So each eigenvalue of $i\not{D}_A$ on the doublet comes as a Kramers pair $\{\psi, J\psi\}$. In addition γ_5 anticommutes with $\not{D}_A$, so the spectrum is symmetric: λ and $-\lambda$ both occur. Hence $\det(\not{D}_A^{*}\not{D}_A) = \prod_k \lambda_k^4$, the product running over the distinct positive eigenvalues λ_k (each counted once), while the Weyl-doublet integral is

$$\mathrm{Pf}(A) = \prod_k \lambda_k, \tag{10.206}$$

one factor for each Kramers pair in the positive half of the spectrum. Squaring gives $\prod_k \lambda_k^2$, which is $\sqrt{\det(\not{D}_A^{*}\not{D}_A)}$, as it should be. The expression $\prod_k \lambda_k$ with all $\lambda_k > 0$ is of course positive; the point is that "which half is the positive half" is only defined when no eigenvalue vanishes. Follow a continuous path of gauge fields: each factor is a continuous function $\lambda_k(t)$, and the product is defined by continuity from a reference configuration. If one Kramers pair crosses zero along the path, its factor changes sign and so does Pf.

Watch out: There is no perturbative $\mathrm{SU}(2)$ anomaly

The local anomaly of a Weyl fermion in representation R is proportional to $d^{abc} = \operatorname{tr}_R\big(T^a\{T^b,T^c\}\big)$. For the doublet, $T^a = \frac{1}{2}\sigma_a$ and $d^{abc} = \frac{1}{8}\operatorname{tr}\big(\sigma_a\{\sigma_b,\sigma_c\}\big) = \frac{1}{4}\delta_{bc}\operatorname{tr}\sigma_a = 0$. More generally $d^{abc} = 0$ for every pseudo-real or real representation. Nash expresses this topologically: the local anomaly lives in $H^1_{\mathrm{dR}}(\mathcal{G})$, and $\pi_1(\mathcal{G}) = \pi_5(\mathrm{SU}(2)) = \mathbb{Z}_2$ is pure torsion, so $H^1_{\mathrm{dR}}(\mathcal{G}) = 0$. The families argument of §2 therefore has nothing to say. Whatever is wrong with the theory must be global.

10.9.5 The mod-2 index and spectral flow

Real skew-adjoint operators have a $\mathbb{Z}_2$ index. Let D be a real skew-adjoint Fredholm operator, $D^{\mathsf{T}} = -D$. Its non-zero eigenvalues (over $\mathbb{C}$) come in pairs $\pm i\lambda$, and the real invariant subspaces are 2-planes on which D acts as $\left(\begin{smallmatrix}0 & \lambda\\ -\lambda & 0\end{smallmatrix}\right)$. The ordinary index is useless: $\operatorname{index} D = \dim\operatorname{Ker} D - \dim\operatorname{Ker} D^* = 0$ since $D^* = -D$. But the kernel can only change by two dimensions at a time: an eigenvalue $i\lambda$ can reach zero only together with its partner $-i\lambda$, and then a whole 2-plane joins the kernel.

Working definition 10.12 (mod-2 index)

For a real skew-adjoint Fredholm operator D [$D\psi = 0$ has only finitely many independent solutions $\psi \neq 0$], the **mod-2 index** is

$$\operatorname{index}_2 D := \dim\operatorname{Ker} D \pmod 2 \in \mathbb{Z}_2.$$

It is unchanged by continuous deformations [moving D along a path of such operators, e.g. $\not{D}_{A_t}$ as the gauge field moves. Independent zero modes then appear or disappear two at a time]. *How to compute it:* find the kernel in one convenient member of the deformation class [all operators reachable from D by such a path] and count.

Worked example 10.48: Finite matrices and the circle

(a) $D(t) = \left(\begin{smallmatrix}0 & t\\ -t & 0\end{smallmatrix}\right)$ on $\mathbb{R}^2$: $\dim\operatorname{Ker} = 2$ at $t = 0$, 0 otherwise; $\operatorname{index}_2 = 0$ throughout. A real skew 3×3 matrix always has a kernel of odd dimension (its non-zero spectrum is paired, and 3 is odd), so $\operatorname{index}_2 = 1$: in finite dimensions the mod-2 index is just the parity of the dimension. (b) Infinite dimensions, where it is interesting: $D = \frac{\mathrm{d}}{\mathrm{d}x}$ on real functions on the circle $x \in [0, 2\pi]$. It is real and skew (integrate by parts). With *periodic* boundary conditions the kernel is the constants, $\dim\operatorname{Ker} = 1$, so $\operatorname{index}_2 D = 1$. With *antiperiodic* boundary conditions ($f(x+2\pi) = -f(x)$) the Fourier modes are $\cos(n+\frac{1}{2})x$, $\sin(n+\frac{1}{2})x$ and none is constant: $\operatorname{index}_2 D = 0$. The two spin structures on S^1 are distinguished by the mod-2 index of their Dirac operators; no continuous deformation of the operator can change one into the other.

Families over a circle. Now the key idea (Nash p. 284). A loop of gauge fields $A_t = (1-t)A + tA^g$, $t \in [0,1]$, runs from A to its gauge transform A^g (this is a straight line in the affine space $\mathcal{A}$, but a closed loop in $\mathcal{A}/\mathcal{G}$). At the two ends the operators are conjugate, $\not{D}_{A^g} = g^{-1}\not{D}_A g$, so they have the same spectrum. The Pfaffian at the two ends differs by $(-1)^N$, with N the number of Kramers pairs that crossed zero along the way (Figure 10.35):

$$\operatorname{Pf}(A^g) = (-1)^N \operatorname{Pf}(A), \qquad N = \text{spectral flow of the family} \pmod 2. \tag{10.207}$$

Witten's step is to reinterpret the family as *one* operator in five dimensions. On $S^4 \times [0,1]$ with t the fifth coordinate, glue the ends using g (the **mapping torus**); the operator $\mathcal{D}_5 = \partial_t + \not{D}_{A_t}$ is a real skew-adjoint operator on this five-manifold, and its zero modes correspond, in the adiabatic limit of a slowly varying A_t, to the level crossings. So

$$N \equiv \operatorname{index}_2 \mathcal{D}_5 \pmod 2.$$

The right side is topological: it depends only on the component of g in $\pi_4(\mathrm{SU}(2))$. Witten computed it for the generator and found 1.

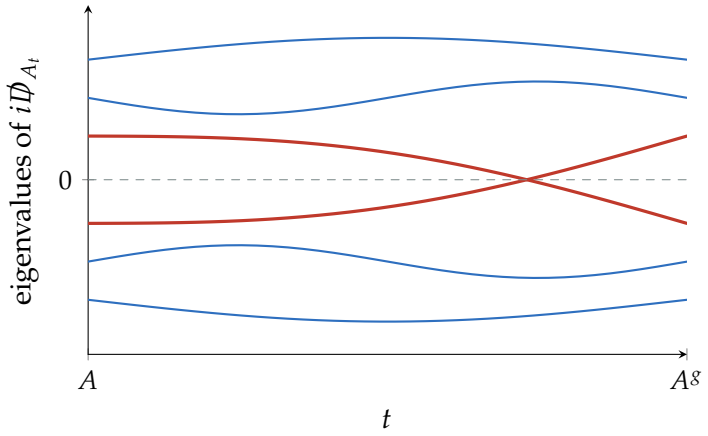

Figure 10.35: Witten's spectral flow. Each curve is a Kramers pair (doubly degenerate); the spectrum is symmetric about 0. Along the path from A to A^g the spectrum returns to itself, but one Kramers pair (red) has crossed from positive to negative while its mirror crossed the other way. The Pfaffian, the product over the positive branch, has lost one positive factor and gained one negative one: it has changed sign.

Key idea: Witten's SU(2) anomaly

For SU(2) gauge theory on S^4 with p left-handed Weyl doublets and g the generator of $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$,

$$Z_\psi(A^g) = (-1)^p\, Z_\psi(A), \qquad Z_\psi = \mathrm{Pf}(C\not{D}_A)^p .$$

For odd p the fermion integral is odd under a gauge transformation, so the integral over gauge fields vanishes identically, $\int \mathcal{D}A\, e^{-S_{\mathrm{YM}}} Z_\psi(A) = 0$ (the contributions of A and A^g cancel), and so do all gauge-invariant correlation functions. The theory is inconsistent. For even p it is fine.

Which representations are anomalous? The same argument applies to any pseudo-real representation R of SU(2), i.e. half-integer isospin j. The parity of the spectral flow turns out to equal the parity of the number of zero modes of a Weyl fermion in R in a one-instanton background, i.e. of the index $\operatorname{index} \not{D}_A = 2T(R)$, with $T(\frac{1}{2}) = \frac{1}{2}$:

$$2T(j) = \tfrac{2}{3}\, j(j+1)(2j+1): \qquad j = \tfrac{1}{2} \mapsto 1, \quad j = \tfrac{3}{2} \mapsto 10, \quad j = \tfrac{5}{2} \mapsto 35, \quad j = \tfrac{7}{2} \mapsto 84.$$

So isospin $\frac{1}{2}, \frac{5}{2}, \frac{9}{2}, \ldots$ are anomalous and $\frac{3}{2}, \frac{7}{2}, \ldots$ are not. Physically: in an instanton transition, fermion number changes by the index ('t Hooft). If that number is odd, the fermion parity $(-1)^F$, which is the gauge transformation $g = -1 \in \mathrm{SU}(2)$ acting on the fermions, cannot be a good symmetry of the gauge-invariant states, and the theory cannot be consistently quantised.

The $(-1)^F$ argument, step by step. This last argument uses only facts we have already computed, so we give it in full. Quantise on space S^3 with p Weyl doublets.

1. $(-1)^F$ *is a gauge transformation.* The constant gauge transformation $g = -\mathbb{1} \in \mathrm{SU}(2)$ acts on every doublet field by $\psi \mapsto -\psi$. On Fock states it therefore acts as $(-1)^F$, where F is the number of doublet quanta (particles and antiparticles each flip sign).

2. *It is a small gauge transformation.* The path $g_s = \exp(i\pi s\sigma_3) = \mathrm{diag}(e^{i\pi s}, e^{-i\pi s})$, $s \in [0,1]$, runs from $\mathbb{1}$ to $-\mathbb{1}$ through constant gauge transformations. So $-\mathbb{1}$ lies in the identity component of the gauge group on S^3, and Gauss's law (which imposes invariance under the identity component) requires

$$(-1)^F|\mathrm{phys}\rangle = |\mathrm{phys}\rangle$$

   for every physical state.

3. *Instantons change F by the index.* In a one-instanton background each doublet has index $\not{D}_A = 2T(\frac{1}{2}) = 1$ zero mode (Chapter 10). The Grassmann integral over a zero mode vanishes unless the mode appears in the integrand, so an amplitude in the one-instanton sector is non-zero only if it contains one extra ψ for each doublet. Hence tunnelling from an initial state $|i\rangle$ to a final state $|f\rangle$ obeys $F_f - F_i \equiv p \pmod 2$.

4. *Contradiction for odd p.* Combine 2 and 3:

$$(-1)^{F_f} \overset{(1)}{=} (-1)^{F_i+p} \overset{(2)}{=} (-1)^p\,(-1)^{F_i} \overset{(3)}{=} -(-1)^{F_i} \qquad (p \text{ odd}).$$

   (1) Step 3.
   (2) Arithmetic of signs.
   (3) p odd.

   So if $|i\rangle$ is physical ($(-1)^{F_i} = 1$), $|f\rangle$ is not. The gauge-invariant Hamiltonian would map physical states to unphysical ones, which is impossible. For even p no contradiction arises.

The Euclidean statement (the Pfaffian changes sign along the path from A to A^g) and this Hamiltonian statement are the same fact. The bridge is the Atiyah–Singer mod-2 index theorem, which identifies the parity of the spectral flow along a loop in the class of $g \in \pi_4(\mathrm{SU}(2))$ with the parity of the instanton index; we do not reproduce its proof.

Worked example 10.49: The Standard Model passes

The weak gauge group of the Standard Model is $\mathrm{SU}(2)_L$. Per generation, the left-handed doublets are the lepton doublet $(\nu_e, e)_L$ and the quark doublet $(u, d)_L$ in each of three colours:

$$p = 1 + 3 = 4 \qquad \text{per generation.}$$

Even, so there is no Witten anomaly, and this is automatic once the perturbative anomalies cancel (they require the same quark–lepton balance; [QFT notes §23.4, pp. 1458–1461]). A hypothetical fourth generation of leptons alone ($p = 1$) would be inconsistent; so would one extra colour of quark.

The SU(3) cross-check. Embed $\mathrm{SU}(2) \subset \mathrm{SU}(3)$ as the upper-left block. The triplet of SU(3) restricts to a doublet plus a singlet. Since $\pi_4(\mathrm{SU}(3)) = 0$, the large SU(2) transformation g is small in SU(3): there is a path g_s in $\mathcal{G}_{\mathrm{SU}(3)}$ from 1 to g. Along that path the SU(3) triplet has a *perturbative* anomaly (its $d^{abc} \neq 0$), and integrating the infinitesimal anomaly along the path

gives a phase $e^{i\pi} = -1$. Witten observed that this is the same sign: a single SU(2) doublet is anomalous because a single SU(3) triplet is. Anomalies are consistent under embedding, the global one of the subgroup being a remnant of the local one of the larger group.

10.9.6 The topology: a torsion class and a Möbius bundle

Nash reformulates Witten's result in the language of determinant bundles, which is what connects it to the rest of the chapter.

Pulling back along a loop. Let $Y = \mathcal{A}/\mathcal{G}$ and choose a map $\alpha : S^1 \to Y$. The family $\not{D}_Y$ over Y pulls back to a family over S^1, and so do its index and determinant bundles (Nash (10.46)):

$$\alpha^* \det \operatorname{Index} \not{D}_Y = \det \operatorname{Index} \not{D}_{S^1} = (\operatorname{Ker} \not{D}_{S^1})^* \otimes (\operatorname{Ker} \not{D}^*_{S^1}). \tag{10.208}$$

(For a determinant bundle the kernels mean their top exterior powers.) Up to isomorphism the pull-back depends only on the homotopy class of α, an element of $\pi_1(Y)$.

$\pi_1(\mathcal{A}/\mathcal{G})$. $\mathcal{A}$ is an affine space (any two connections differ by a Lie-algebra-valued 1-form), so it is contractible, and $\mathcal{G}$ acts freely on it (based gauge transformations). The fibration $\mathcal{G} \to \mathcal{A} \to \mathcal{A}/\mathcal{G}$ has the long exact homotopy sequence $\cdots \to \pi_1(\mathcal{A}) \to \pi_1(\mathcal{A}/\mathcal{G}) \to \pi_0(\mathcal{G}) \to \pi_0(\mathcal{A}) \to \cdots$, and with $\pi_k(\mathcal{A}) = 0$:

$$\pi_1(\mathcal{A}/\mathcal{G}) \overset{(1)}{=} \pi_0(\mathcal{G}) \overset{(2)}{=} \mathbb{Z}_2, \qquad H_1(\mathcal{A}/\mathcal{G};\mathbb{Z}) \overset{(3)}{=} \mathbb{Z}_2. \tag{10.209}$$

(1) Exactness with contractible $\mathcal{A}$. Concretely: a loop in $\mathcal{A}/\mathcal{G}$ lifts to a path in $\mathcal{A}$ from A to some A^g; the component of g is the invariant.
(2) (10.202) and Nash (10.45).
(3) Hurewicz: H_1 is the abelianisation of π_1, and $\mathbb{Z}_2$ is already abelian.

The universal coefficient theorem. To get a class for a line bundle we need H^2, not H_1. The universal coefficient theorem (Nash (10.48), Bott–Tu) relates them: write $H_i(M;\mathbb{Z}) = F_i \oplus T_i$ with F_i free and T_i torsion. Then

$$H^i(M;\mathbb{Z}) \cong F_i \oplus T_{i-1}. \tag{10.210}$$

Torsion moves *up one degree* from homology to cohomology.

Worked example 10.50: The universal coefficient theorem for $\mathbb{RP}^2$ and $\mathbb{RP}^3$

$\mathbb{RP}^2$ has $H_0 = \mathbb{Z}, H_1 = \mathbb{Z}_2, H_2 = 0$ (it is non-orientable). By (10.210): $H^0 = \mathbb{Z}, H^1 = F_1 \oplus T_0 = 0$, $H^2 = F_2 \oplus T_1 = \mathbb{Z}_2$. Check $H^1 = 0$ directly: $H^1(M;\mathbb{Z}) = \operatorname{Hom}(H_1, \mathbb{Z})$, and there is no non-zero homomorphism $\mathbb{Z}_2 \to \mathbb{Z}$. And $H^2(\mathbb{RP}^2;\mathbb{Z}) = \mathbb{Z}_2$ is generated by the first Chern class of the complexified tautological line bundle, a line bundle with $2c_1 = 0$ but $c_1 \neq 0$. For $\mathbb{RP}^3$: $H_* = (\mathbb{Z}, \mathbb{Z}_2, 0, \mathbb{Z})$ and $H^* = (\mathbb{Z}, 0, \mathbb{Z}_2, \mathbb{Z})$. The same shift.

For $\mathcal{A}/\mathcal{G}$, Nash's (10.49):

$$F_1(\mathcal{A}/\mathcal{G}) = 0, \quad F_2(\mathcal{A}/\mathcal{G}) = 0, \quad T_1(\mathcal{A}/\mathcal{G}) = \mathbb{Z}_2 \quad \Longrightarrow \quad H^2(\mathcal{A}/\mathcal{G};\mathbb{Z}) \supseteq T_1 = \mathbb{Z}_2. \tag{10.211}$$

($F_2 = 0$ because $H^2_{\mathrm{dR}}(\mathcal{A}/\mathcal{G}) = 0$ in this case: there is no local anomaly.) So every line bundle L on $\mathcal{A}/\mathcal{G}$ has $c_1(L)$ torsion: $2c_1(L) = 0$. No curvature form can detect it (its de Rham image is zero), which is the precise sense in which the global anomaly is invisible to the methods of §2.

The real determinant bundle is a Möbius band. Because $\not{D}_{S^1}$ is a family of *real* operators, its determinant bundle is a *real* line bundle. The structure group of a real line bundle (with a metric) is $\mathrm{O}(1) = \{\pm 1\} = \mathbb{Z}_2$. Over S^1 there are exactly two real line bundles, since $\pi_0(\mathrm{O}(1)) = \mathbb{Z}_2$ classifies the transition function across one cut: the cylinder (+1) and the Möbius band (−1).

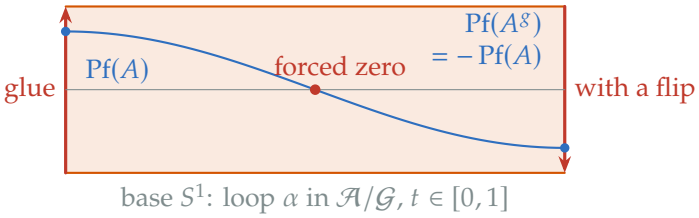

Figure 10.36: The determinant line bundle of the real family over the loop α is a Möbius band. A section (blue) that starts at $+\mathrm{Pf}(A)$ must arrive at the glued edge as $-\mathrm{Pf}(A)$ to be continuous across the twisted gluing, so it must vanish somewhere: that zero is the level crossing. A global section with no zero, i.e. a gauge-invariant non-vanishing fermion determinant, does not exist.

Now put the pieces together, as Nash does on p. 285. Try to define a trivialising section "$\det \not{D}$" of $\det \mathrm{Index}\, \not{D}_{S^1}$. Going once round S^1 it is not periodic: it comes back multiplied by the non-trivial element -1 of the structure group. So $\det \mathrm{Index}\, \not{D}_{S^1}$ is the Möbius bundle, and this reflects the non-trivial torsion class $c_1 \in H^2(\mathcal{A}/\mathcal{G};\mathbb{Z}) = \mathbb{Z}_2$ of the determinant bundle on $\mathcal{A}/\mathcal{G}$; which in turn is the sign change of the Pfaffian under the large gauge transformation. With p doublets the bundle is the p-th tensor power. The Möbius transition function is -1, and $(-1)^p = 1$ iff p is even: the tensor square of a Möbius band is a cylinder. Hence

$$\left(\det \mathrm{Index}\, \not{D}_{S^1}\right)^{\otimes p} \text{ trivial} \iff p \text{ even}.$$

Reading Nash (pp. 283–285, (10.44)–(10.49))

Nash's "$\sqrt{\det(\not{D}_A^* \not{D}_A)}$ changes sign" should be read as: the Pfaffian (10.205), a canonically defined square root up to one overall sign fixed by continuity, changes sign. His "$\not{D}_A$ can be taken to be a real skew-adjoint operator" refers to the real structure $\mathcal{J}$ built from the pseudo-reality of the doublet and of the chiral spinors. The five-dimensional operator and its mod-2 index are Witten's; Nash postpones spectral flow to §6 and adiabatic limits to the gravitational discussion. In (10.49) his $F_2(\mathcal{A}/\mathcal{G}) = 0$ is justified by $H^2_{\mathrm{dR}} = 0$, not by the displayed "$H^2_{\text{de Rham}}(\mathcal{A}/\mathcal{G}) = 0$" alone, but the two statements are the same.

Recap: Witten's SU(2) anomaly

- Global anomaly: invariance under the identity component of $\mathcal{G}$ but not under the other components; invisible to derivatives, to curvature and to de Rham cohomology.
- Toy model: one fermion in $0+1$ dimensions, $Z = 2\cos(a/2) \mapsto -Z$ under $a \mapsto a + 2\pi$; one eigenvalue crosses zero.
- $\pi_0(\mathcal{G}) = \pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$ (framed circles, the belt trick).
- The doublet is pseudo-real, the Weyl operator is real, the fermion integral is a Pfaffian with a sign fixed by continuity.
- Sign change $= (-1)^{\text{spectral flow}} = (-1)^{\mathrm{index}_2 \not{D}_5}$; it is -1 for one doublet. With p doublets: consistent iff p even. The Standard Model has $p = 4$ per generation.

- Topology: $\pi_1(\mathcal{A}/\mathcal{G}) = \mathbb{Z}_2$, $H^2(\mathcal{A}/\mathcal{G};\mathbb{Z}) \supseteq \mathbb{Z}_2$ by the universal coefficient theorem; the real determinant bundle over the loop is a Möbius band.

10.9.7 Global gravitational anomalies: large diffeomorphisms

Everything we just did for gauge transformations has a gravitational twin. In §3 the symmetry group was $\mathrm{Diff}^+(M)$, the orientation-preserving diffeomorphisms of space-time, acting on the space $\mathrm{Met}(M)$ of metrics. The local (perturbative) gravitational anomaly was a class in H^1_{dR} of (the identity component of) this group. The question now is the one we asked for SU(2): *is the fermion determinant invariant under diffeomorphisms that cannot be continuously deformed to the identity?* Such diffeomorphisms are called **large diffeomorphisms**, and they exist exactly when $\pi_0(\mathrm{Diff}^+(M)) \neq 0$. Nash (following Witten) takes the case $M = S^n$.

A large diffeomorphism you can see: the Dehn twist. Before spheres, the simplest example. On the torus $T^2 = \mathbb{R}^2/\mathbb{Z}^2$, the linear map

$$\tau = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} : \ (x, y) \mapsto (x + y, \ y)$$

maps the lattice $\mathbb{Z}^2$ to itself, so it descends to a diffeomorphism of T^2. Its effect on the two basic loops a (the x-circle) and b (the y-circle) is $a \mapsto a$, $b \mapsto a + b$ (Figure 10.37). A diffeomorphism connected to the identity acts trivially on $H_1(T^2;\mathbb{Z}) = \mathbb{Z}^2$, because homotopic maps induce the same map on homology. τ acts by a non-identity matrix, so it is not connected to the identity. In fact $\pi_0(\mathrm{Diff}^+(T^2)) = \mathrm{SL}(2,\mathbb{Z})$, the **modular group** of the torus, whose role in the string partition function was the subject of Example 10.44 (invariance under $\tau \mapsto \tau + 1$ and $\tau \mapsto -1/\tau$). There, modular invariance of the torus amplitude was a global gravitational anomaly-freedom condition in disguise.

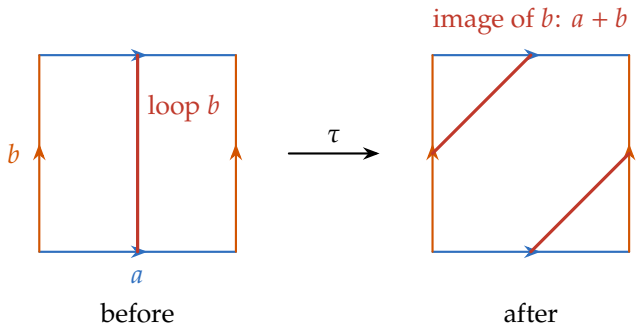

Figure 10.37: The Dehn twist $(x, y) \mapsto (x + y, y)$ on the torus (opposite sides of the square are identified). The vertical loop b (red, left) is carried to a loop that winds once around a as it goes once around b (red, right). Because it changes the homology class of a loop, the twist cannot be deformed to the identity: it is a large diffeomorphism, an element of $\pi_0(\mathrm{Diff}^+(T^2)) = \mathrm{SL}(2,\mathbb{Z})$.

For spheres there are no loops to twist ($H_1(S^n) = 0$ for $n \geq 2$), and it is much less obvious that large diffeomorphisms exist at all. They do, and they are intimately tied to exotic spheres.

10.9.8 Large diffeomorphisms of spheres and exotic spheres

Recall from Chapter 1 that an **exotic sphere** is a smooth manifold that is homeomorphic to S^n but not diffeomorphic to it: the same topological space, a different notion of which functions are smooth. Milnor found the first ones in $n = 7$.

The clutching construction. Here is how to build a candidate n-sphere from a diffeomorphism. Cut S^n along its equator S^{n-1} into the northern and southern hemispheres H^+ and H^-, each a closed n-ball with boundary S^{n-1}. Pick $f \in \mathrm{Diff}^+(S^{n-1})$. Glue H^+ back to H^- by identifying $x \in \partial H^-$ with $f(x) \in \partial H^+$:

$$S^n_f := H^- \cup_f H^+, \qquad \partial H^- \ni x \;\sim\; f(x) \in \partial H^+. \tag{10.212}$$

The result is always homeomorphic to S^n: a homeomorphism of S^{n-1} extends to a homeomorphism of the ball by "coning" ($rx \mapsto rf(x)$ for $0 \le r \le 1$), so we can undo the twist topologically. But the cone of a diffeomorphism is not smooth at the centre, $r = 0$. So the smooth structure of S^n_f can be exotic.

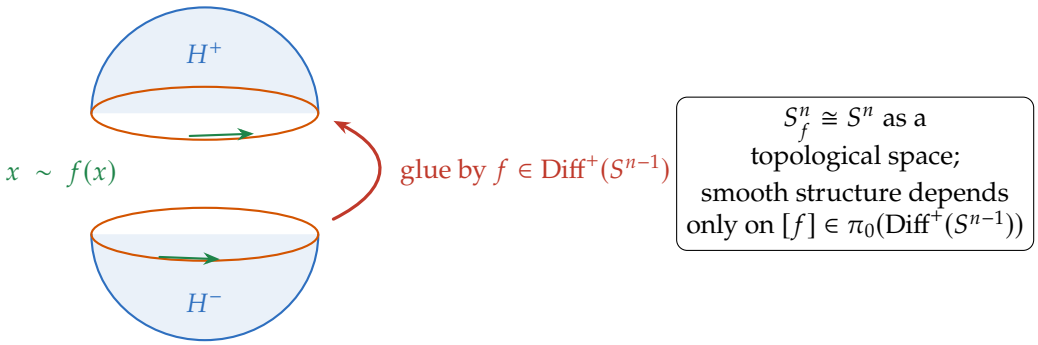

Figure 10.38: Building an n-sphere from two balls glued along their boundary spheres (orange) with a twist f. Topologically the twist can always be undone, so the result is a sphere. Smoothly it can be undone only if f extends to a diffeomorphism of the ball; if not, S^n_f is an exotic sphere. Deforming f within its component does not change S^n_f.

Key idea: Nash p. 285–286; Cerf

Two such spheres S^n_f and S^n_g are diffeomorphic precisely when f and g lie in the same component of $\mathrm{Diff}^+(S^{n-1})$. The components of $\mathrm{Diff}^+(S^{n-1})$ correspond exactly to the smooth structures on the n-sphere (for $n \ge 6$ or so, which is all we need). In symbols, with Θ_n the group of exotic n-spheres (under connected sum),

$$\pi_0\big(\mathrm{Diff}^+(S^{n-1})\big) \;\cong\; \Theta_n.$$

Why is "deforming f does not change the result" true? If f_s is a smooth path from f_0 to f_1, glue a collar $S^{n-1} \times [0,1]$ into the seam, using f_s on the slice $S^{n-1} \times \{s\}$; this gives a diffeomorphism $S^n_{f_0} \cong S^n_{f_1}$. The converse direction is Cerf's hard theorem ("pseudo-isotopy implies isotopy").

Worked example 10.51: The numbers: Kervaire–Milnor

Kervaire and Milnor computed Θ_n. The first few are

n	≤ 6	7	8	9	10	11	12	15
Θ_n	0	$\mathbb{Z}_{28}$	$\mathbb{Z}_2$	$\mathbb{Z}_2^3$	$\mathbb{Z}_6$	$\mathbb{Z}_{992}$	0	$\mathbb{Z}_{16256} \oplus \mathbb{Z}_2$

(for $n = 4$ the smooth question is open; "0" there means only that no exotic S^4 is known). Reading the table through Cerf's theorem:

- $\Theta_7 = \mathbb{Z}_{28}$, so $\pi_0(\mathrm{Diff}^+(S^6)) = \mathbb{Z}_{28}$: the first sphere with large diffeomorphisms, as Nash says, is S^6;

- $\Theta_{11} = \mathbb{Z}_{992}$, so $\pi_0(\mathrm{Diff}^+(S^{10})) = \mathbb{Z}_{992}$. Of these 992 smooth structures one is the standard sphere and 991 are exotic. This is Nash's (10.50).

The number 992 has a formula: it is the order of the subgroup bP_{12} of spheres that bound parallelisable 12-manifolds, $|bP_{4k}| = 2^{2k-2}(2^{2k-1}-1)\cdot \mathrm{num}(4B_{2k}/k)$, which for $k=3$ gives $2^4\cdot 31\cdot 2 = 992$ (with $B_6 = \frac{1}{42}$, $4B_6/3 = \frac{2}{63}$). That Bernoulli numbers appear is a first hint that these numbers are secretly $\hat{A}$-genus computations, which is what the anomaly calculation will be.

10.9.9 Superstrings in ten dimensions: what needs checking

Why should a physicist care about $\pi_0(\mathrm{Diff}^+(S^{10}))$? Because ten is the critical dimension of the superstring (the superstring analogue of 26; Section 10.8.7). Green and Schwarz discovered in 1984 that the $N=1$ supersymmetric string theories in $d=10$ are free of *local* gauge, gravitational and mixed anomalies provided the gauge group is one of the two 496-dimensional groups

$$E_8\times E_8 \quad (\dim = 248+248 = 496) \qquad \text{or} \qquad \mathrm{SO}(32) \quad \Big(\dim = \tfrac{32\cdot 31}{2} = 496\Big).$$

First, local gravitational anomalies really are possible here: §3 showed they need $n = 4k-2$, and $10 = 4\cdot 3 - 2$. Local cancellation leaves the *global* question open. Witten answered it; Nash describes how.

Global gauge anomalies are absent. By (10.202), on $M = S^{10}$ the gauge group has $\pi_0(\mathcal{G}) = \pi_{10}(G)$. For E_8, the homotopy groups vanish in degrees $1 \le i \le 14$ except $\pi_3 = \mathbb{Z}$, so $\pi_{10}(E_8) = 0$. For SO(32) we are in the stable range ($10 < 31$), and Bott periodicity gives $\pi_{10}(\mathrm{SO}) = \pi_2(\mathrm{SO}) = 0$ (the real Bott sequence $\pi_i(\mathrm{O}) = \mathbb{Z}_2, \mathbb{Z}_2, 0, \mathbb{Z}, 0, 0, 0, \mathbb{Z}$ for $i \equiv 0,\dots,7 \bmod 8$). So

$$\pi_0(\mathcal{G}) = \pi_{10}(G) = 0 \qquad \text{for } G = E_8\times E_8 \text{ or } \mathrm{SO}(32):$$

every gauge transformation is small, and there is nothing global to check. Only the gravitational case remains.

The topology of the gravitational parameter space. The parameter space is

$$Y = \mathrm{Met}(S^{10})/\mathrm{Diff}^+(S^{10}).$$

The group acts on the contractible space $\mathrm{Met}(S^{10})$ (a convex cone in a vector space: $(1-t)\rho_0 + t\rho_1$ is a metric if ρ_0, ρ_1 are), so we have the fibre homotopy exact sequence (Nash (10.52))

$$\cdots \to \pi_i\big(\mathrm{Diff}^+\big) \to \pi_i\big(\mathrm{Met}\big) \to \pi_i(Y) \to \pi_{i-1}\big(\mathrm{Diff}^+\big) \to \pi_{i-1}\big(\mathrm{Met}\big) \to \cdots$$

(here we pretend, as Nash does, that the action is free; the proper treatment uses the based diffeomorphisms of §3 and changes nothing below).

$$\pi_1(Y) \overset{(1)}{=} \pi_0\big(\mathrm{Diff}^+(S^{10})\big) \overset{(2)}{=} \mathbb{Z}_{992},$$
$$H_1(Y;\mathbb{Z}) \overset{(3)}{=} \mathbb{Z}_{992}, \qquad H^2(Y;\mathbb{Z}) \overset{(4)}{=} F_2 \oplus T_1 \overset{(5)}{=} \mathbb{Z}_{992}. \tag{10.213}$$

(1) Exactness, with $\pi_1(\mathrm{Met}) = \pi_0(\mathrm{Met}) = 0$ because Met is contractible.
(2) Cerf and Kervaire–Milnor, Nash (10.50).
(3) Hurewicz: H_1 is the abelianisation of π_1.

(4) The universal coefficient theorem (10.210).
(5) $F_2 = 0$ because there is no free part in H_2 (the local anomaly has cancelled, $H^2_{\mathrm{dR}}(Y) = 0$), and $T_1 = \mathbb{Z}_{992}$ by (3). This is Nash's (10.51).

Hence (Nash (10.53)) the determinant line bundle of the gravitational Dirac family has a first Chern class that is *pure torsion*:

$$c_1\big(\det \operatorname{Index} \not{D}_{\mathrm{grav}}\big) \in H^2\big(\mathrm{Met}(S^{10})/\mathrm{Diff}^+(S^{10}); \mathbb{Z}\big) = \mathbb{Z}_{992}.$$

It could be any of 992 values, and we must compute which. De Rham methods, curvature, and the families index density are all blind to it.

10.9.10 Witten's construction: the mapping torus

Let ρ be a metric on S^{10} and f a large diffeomorphism. The question is how $\det(\not{D}^*_\rho \not{D}_\rho)$ (really its square root, the chiral determinant) changes under $\rho \mapsto f \cdot \rho$, the pulled-back metric. We interpolate (Nash (10.54)):

$$\rho^t = (1-t)\rho + t\, f\cdot\rho, \qquad t \in [0,1]. \tag{10.214}$$

Each ρ^t is a metric (a convex combination of positive-definite forms is positive definite), $\rho^0 = \rho$ and $\rho^1 = f\cdot\rho$. In $\mathrm{Met}(S^{10})$ this is a path; in Y it is a closed loop, because its endpoints are related by a diffeomorphism. It is the gravitational twin of the path $A_t = (1-t)A + tA^g$ we used for SU(2).

One metric instead of a family. Witten's trick, which we already used in the SU(2) case, is to trade the one-parameter family of ten-dimensional metrics for a single metric on an eleven-dimensional manifold N, with line element (Nash (10.55))

$$ds^2 = dt^2 + \rho^t_{ij}(x)\, dx^i dx^j. \tag{10.215}$$

Which N? Start with the cylinder $S^{10}\times[0,1]$. Its boundary is $S^{10}\times\{0\} \cup S^{10}\times\{1\}$. Glue the two ends together, but with a twist by f:

$$N = S^{10}\times[0,1]\big/\big((x,1)\sim(f(x),0)\big). \tag{10.216}$$

The metric (10.215) is smooth across the seam precisely because $\rho^1 = f\cdot\rho = f^*\rho^0$: the metric at $t=1$ is the pull-back by the gluing map of the metric at $t=0$. N is a closed 11-manifold, a fibre bundle over the circle (the t direction) with fibre S^{10} and structure group $\mathrm{Diff}^+(S^{10})$. It is called the **mapping torus** of f. A bundle over S^1 is determined by its one transition function, up to deformation, so there are exactly 992 such N, one for each element of $\pi_0(\mathrm{Diff}^+(S^{10}))$.

N as a pull-back. Nash adds a second description. The families index theorem of Chapter 4 is formulated for a fibre bundle $Z \to Y$ with fibre M and structure group $\mathrm{Diff}^+(M)$ (the "universal" family: over the point $[\rho]\in Y$ sits M with the metric ρ). Given a loop $\alpha : S^1 \to Y$, the pull-back α^*Z is a bundle over S^1 with fibre M. Take $M = S^{10}$ and α the loop $t \mapsto [\rho^t]$: then $\alpha^*Z = N$. The mapping torus is the universal family restricted to our loop, exactly as the Möbius band of Figure 10.36 was the determinant bundle restricted to a loop.

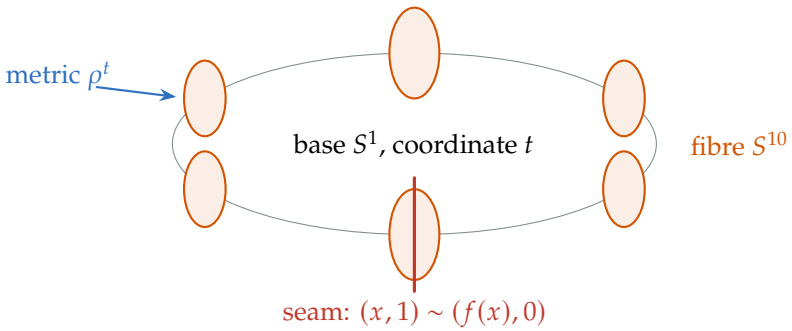

Figure 10.39: The mapping torus N of Nash (10.55). Over each point t of a circle sits a copy of S^{10} (orange) carrying the metric ρ^t. Going once around, the fibre is glued back to itself by the large diffeomorphism f (red seam). The whole family of ten-dimensional metrics has become one eleven-dimensional geometry, and f is now built into the topology of N.

10.9.11 Eta invariants: the phase of a determinant

On the odd-dimensional manifold N there is no chirality. The Weyl operator of ten dimensions is replaced by the full Dirac operator $\mathcal{D}$ (Nash's footnote 5), which is self-adjoint, so it has a real spectrum $\{\lambda_k\}$ that is *not* symmetric about zero. The spectral asymmetry is measured by the eta function.

Working definition 10.13 (eta invariant)

For a self-adjoint elliptic operator $\mathcal{D}$ [such as the Dirac operator on N: its eigenvalues are real, of both signs, and grow in size] with eigenvalues λ_k,

$$\eta_{\mathcal{D}}(s) \coloneqq \sum_{\lambda_k \neq 0} \frac{\operatorname{sgn} \lambda_k}{|\lambda_k|^s} = \sum_{\lambda_k > 0} \lambda_k^{-s} - \sum_{\lambda_k < 0} |\lambda_k|^{-s},$$

defined for $\Re s$ large and continued to $s = 0$ [there is exactly one function, analytic except at isolated poles, that equals the sum where the sum converges, and it has no pole at $s = 0$]. The number $\eta_{\mathcal{D}}(0)$ is "the number of positive eigenvalues minus the number of negative ones", made finite. Also let $h = \dim \operatorname{Ker} \mathcal{D}$. *How to compute it:* split the spectrum into its positive and negative parts, write each as a Hurwitz-type zeta function [a sum $\sum_{n \geq 0} (n + a)^{-s}$ over evenly spaced eigenvalues], and evaluate at $s = 0$. Note $\eta_{c\mathcal{D}}(0) = \eta_{\mathcal{D}}(0)$ for any $c > 0$: rescaling the operator (or the metric) does not change it.

Why the eta invariant is the phase. For a self-adjoint $\mathcal{D}$ with no zero modes, $\det \mathcal{D} = \prod_k \lambda_k = \prod_k |\lambda_k| \cdot \prod_{\lambda_k < 0} (-1)$. Writing $-1 = e^{i\pi}$ and regularising the count of negative eigenvalues with the same zeta-function recipe as the modulus:

$$\begin{aligned} \det \mathcal{D} &\overset{(1)}{=} \left|\det \mathcal{D}\right| \, \exp\!\left(i\pi N_-\right), \qquad N_- = \sum_{\lambda_k < 0} 1 \\ &\overset{(2)}{=} \left|\det \mathcal{D}\right| \, \exp\!\left(i\pi \lim_{s \to 0} \tfrac{1}{2}\Big[\sum_k |\lambda_k|^{-s} - \sum_k \operatorname{sgn}\lambda_k |\lambda_k|^{-s}\Big]\right) \\ &\overset{(3)}{=} \left|\det \mathcal{D}\right| \, \exp\!\left(\tfrac{i\pi}{2}\left[\zeta_{|\mathcal{D}|}(0) - \eta_{\mathcal{D}}(0)\right]\right). \end{aligned} \tag{10.217}$$

(1) Each negative eigenvalue contributes a factor $-1 = e^{i\pi}$ to the product (this choice of branch is a convention; see the pitfall below).

(2) For each k, $|\lambda_k|^{-s} - \operatorname{sgn}\lambda_k |\lambda_k|^{-s}$ is 0 if $\lambda_k > 0$ and $2|\lambda_k|^{-s}$ if $\lambda_k < 0$. So half the bracket counts negative eigenvalues, weighted by $|\lambda_k|^{-s}$, and the $s \to 0$ limit (by analytic continuation) is the regularised count.
(3) Definitions of $\zeta_{|\mathcal{D}|}(s) = \sum |\lambda_k|^{-s}$ and of $\eta_{\mathcal{D}}(s)$.

On a closed odd-dimensional manifold, $\zeta_{|\mathcal{D}|}(0)$ is given by a local heat-kernel coefficient, as in (10.181), and for Dirac operators in odd dimensions that coefficient vanishes, so $\zeta_{|\mathcal{D}|}(0) = -h$. The phase of the determinant is therefore $\exp(-\frac{i\pi}{2}(\eta + h))$: *the phase of a fermion determinant in odd dimensions is the eta invariant*.

Worked example 10.52: The eta invariant on a circle, computed

Take $\mathcal{D}_a = -i\frac{\mathrm{d}}{\mathrm{d}\theta} + a$ on periodic functions on S^1, i.e. the Dirac operator of a charged particle on a circle in the constant gauge field a. Eigenfunctions $e^{in\theta}$ give eigenvalues $\lambda_n = n + a$, $n \in \mathbb{Z}$. Let $0 < a < 1$. The positive eigenvalues are $n + a$ ($n \geq 0$), the negative ones are $-(m + 1 - a)$ ($m \geq 0$). With the Hurwitz zeta function $\zeta_H(s, a) = \sum_{n\geq 0}(n + a)^{-s}$:

$$\begin{aligned}\eta_{\mathcal{D}_a}(0) &\overset{(1)}{=} \zeta_H(0, a) - \zeta_H(0, 1 - a)\\ &\overset{(2)}{=} \left(\tfrac{1}{2} - a\right) - \left(\tfrac{1}{2} - (1 - a)\right)\\ &= 1 - 2a.\end{aligned}$$

(1) Split the sum defining η into the positive and the negative eigenvalues.
(2) $\zeta_H(0, b) = \frac{1}{2} - b$, proved just below.

Proof of $\zeta_H(0, b) = \frac{1}{2} - b$. This is the same heat-kernel argument as (10.182). The "heat trace" of the spectrum $\{n + b\}_{n\geq 0}$ is a geometric series:

$$\sum_{n\geq 0} e^{-t(n+b)} \overset{(1)}{=} \frac{e^{-tb}}{1 - e^{-t}} \overset{(2)}{=} \frac{1 - tb + O(t^2)}{t\left(1 - \frac{t}{2} + O(t^2)\right)} \overset{(3)}{=} \frac{1}{t} + \left(\frac{1}{2} - b\right) + O(t),$$

$$\zeta_H(0, b) \overset{(4)}{=} \text{the } t^0 \text{ coefficient} = \tfrac{1}{2} - b.$$

(1) Sum of a geometric series with ratio e^{-t}.
(2) Expand e^{-tb} and $1 - e^{-t} = t - \frac{t^2}{2} + \cdots$.
(3) $\frac{1}{1-t/2} = 1 + \frac{t}{2} + \cdots$, and multiply out.
(4) $\Gamma(s)\zeta_H(s, b) = \int_0^\infty t^{s-1} \sum_n e^{-t(n+b)}\mathrm{d}t$; the $1/t$ term produces a pole at $s = 1$, the constant term c produces c/s near $s = 0$, and $\Gamma(s) \approx 1/s$, so $\zeta_H(0, b) = c$.

For the two endpoints: at $a = 0$ the spectrum $\mathbb{Z}$ is symmetric, $\eta = 0$, and $h = 1$ (the constant function). The combination $\xi(a) := \frac{1}{2}(\eta + h)$ is

$$\xi(a) = \tfrac{1}{2} - a \quad (0 < a < 1), \qquad \xi(0) = \tfrac{1}{2}, \qquad \xi(a + 1) = \xi(a) \text{ (same spectrum).}$$

So ξ decreases smoothly with slope -1 and jumps up by 1 at every integer, exactly when an eigenvalue $n + a$ passes from negative, through zero, to positive (Figure 10.40).

This one example contains the whole anatomy of the eta invariant:

1. its *variation* along a smooth family, away from crossings, is local, an integral of a curvature density (here $\mathrm{d}\xi/\mathrm{d}a = -1$);

2. it *jumps by integers* (by 2 for η, by 1 for ξ) when eigenvalues cross zero;

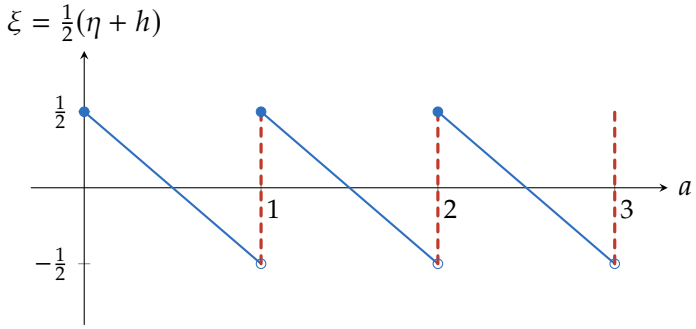

Figure 10.40: The reduced eta invariant $\xi = \frac{1}{2}(\eta + h)$ of $-i\,\mathrm{d}/\mathrm{d}\theta + a$ on a circle. Between integers it changes smoothly (slope -1): that part is *local*, the integral of the field strength. At each integer one eigenvalue crosses zero and ξ jumps by exactly 1 (red dashes): that part counts spectral flow. So $\exp(2\pi i\xi)$ is smooth, while $\exp(i\pi\xi)$ flips sign at every crossing.

3. going round a closed loop of operators, the smooth part changes by an amount that is minus the net spectral flow (here -1 for one circuit $a \to a+1$).

Worked example 10.53: The phase of a one-dimensional determinant

Put Example 10.52 into (10.217). For $0 < a < 1$, $\zeta_{|\mathcal{D}|}(0) = \zeta_H(0,a) + \zeta_H(0,1-a) = 0$ and $\eta = 1-2a$. For the modulus, Lerch's formula $\prod_{n\geq 0}(n+b) = \sqrt{2\pi}/\Gamma(b)$ (the zeta-regularised product) gives

$$\begin{aligned}\det \mathcal{D}_a &\overset{(1)}{=} \frac{\sqrt{2\pi}}{\Gamma(a)} \cdot \frac{\sqrt{2\pi}}{\Gamma(1-a)} \cdot e^{-\frac{i\pi}{2}(1-2a)} \\ &\overset{(2)}{=} 2\sin(\pi a)\, e^{i\pi(a-\frac{1}{2})} \\ &\overset{(3)}{=} 1 - e^{2\pi i a}.\end{aligned}$$

(1) The modulus is the product over positive eigenvalues $n+a$ times the product over |negative| eigenvalues $m+1-a$; the phase is (10.217) with $\zeta_{|\mathcal{D}|}(0) = 0$.
(2) The reflection formula $\Gamma(a)\Gamma(1-a) = \pi/\sin(\pi a)$.
(3) $2\sin(\pi a) = -i(e^{i\pi a} - e^{-i\pi a})$ and $e^{-i\pi/2} = -i$; multiply out.

Look at the two factors in line (2). The real factor $2\sin(\pi a)$, continued smoothly past $a = 1$, changes sign under $a \mapsto a+1$: this is the analogue of the Pfaffian's sign flip, a global anomaly. The phase factor $e^{i\pi(a-1/2)} = -i\exp\left(\frac{i}{2}\oint A\right)$ (with $\oint A = 2\pi a$) also flips sign, so the product $1 - e^{2\pi i a}$ is periodic. The factor $\exp(\frac{i}{2}\oint A)$ is a one-dimensional Chern–Simons term, a *local* functional of the gauge field. The zeta-function regularisation has silently added it, trading the global anomaly for a term that is not invariant under $a \mapsto -a$. This is exactly the trade-off of the "Try it" after Example 10.45, now produced by the eta invariant, and it is the one-dimensional version of the **parity anomaly** of odd-dimensional fermions.

Watch out: The sign convention in the phase

Choosing $-1 = e^{-i\pi}$ instead of $e^{+i\pi}$ in step (1) of (10.217) flips the sign of the exponent. The two choices differ by $e^{i\pi(\zeta-\eta)}$, a local counterterm times an integer power of -1. Different papers use different conventions; what is convention independent is the change of the phase around a closed loop, modulo the local part.

10.9.12 The adiabatic limit and Witten's formula

Now back to the eleven-manifold N. We want the change of the ten-dimensional chiral determinant as ρ^t runs from ρ to $f\cdot\rho$. The idea is that when t is a very slow variable, a spinor on N is approximately (a function of t)×(an eigenspinor of the ten-dimensional operator at time t), and the eleven-dimensional Dirac operator becomes ∂_t plus the ten-dimensional one, as in the SU(2) case, $\mathcal{D}_5=\partial_t+\not{D}_{A_t}$.

Working definition 10.14 (adiabatic limit)

Replace the family ρ^t on S^{10} by $\varepsilon\rho^t$ and let $\varepsilon\to 0$ (Nash p. 288). Equivalently, since $ds^2=dt^2+\varepsilon\rho^t dx^2=\varepsilon\,(dt^2/\varepsilon+\rho^t dx^2)$ and η does not see an overall scale, stretch the circle: $ds^2=dt^2/\varepsilon+\rho^t dx^2$ with $\varepsilon\to 0$ (Nash (10.63)). The circle has length $1/\sqrt{\varepsilon}\to\infty$, so the metric varies slowly along it. Then compute $\eta_{\mathcal{D}}(0)$ [the number of positive minus the number of negative eigenvalues of $\mathcal{D}$, made finite] and h [how many independent solutions $\psi\neq 0$ of $\mathcal{D}\psi=0$ there are, $\dim\operatorname{Ker}\mathcal{D}$] of the Dirac operator on N by expanding in powers of ε.

Key idea: Witten's formula, Nash (10.56)–(10.58)

Under the large diffeomorphism $\rho\mapsto f\cdot\rho$,

$$\det\bigl(\not{D}^*_\rho\not{D}_\rho\bigr)\longmapsto\det\bigl(\not{D}^*_{f\cdot\rho}\not{D}_{f\cdot\rho}\bigr)=C\,\det\bigl(\not{D}^*_\rho\not{D}_\rho\bigr),\qquad C=\exp\bigl[i\pi\,\eta_{\mathcal{D}}(0)\bigr],$$

with $\eta_{\mathcal{D}}$ the eta invariant of the Dirac operator on N (in the adiabatic limit). The path integral contains the square root, so the fermion effective action $S_\psi=\ln\sqrt{\det(\not{D}^*_\rho\not{D}_\rho)}$ changes by $\Delta S_\psi=\frac{i\pi}{2}\eta_{\mathcal{D}}(0)$, and

$$\begin{aligned}\text{no global anomaly}\ &\Longleftrightarrow\ \sqrt{C}=\exp\Bigl[\frac{i\pi}{2}\eta_{\mathcal{D}}(0)\Bigr]=1\\ &\Longleftrightarrow\ \eta_{\mathcal{D}}(0)=4k\ \Longleftrightarrow\ \Delta S_\psi=2\pi i k,\quad k\in\mathbb{Z}.\end{aligned}$$

Why is this plausible? The ten-dimensional chiral determinant, followed continuously along the loop ρ^t, has a modulus that returns to itself (it is diffeomorphism invariant) and a phase that may not. By (10.217), the phase of the eleven-dimensional determinant is $e^{\mp i\pi\eta/2}$, and in the adiabatic limit the eleven-dimensional determinant on N "is" the product over the loop of the ten-dimensional ones, with the end glued to the beginning by f. So the total phase accumulated going round the loop is $e^{\mp i\pi\eta/2}$. In Example 10.53 we saw exactly this in one dimension lower: the phase of the determinant along $a\in[0,1]$ changes by $e^{i\pi}$, which is $e^{-i\pi\Delta\eta/2}$ for the smooth change $\Delta\eta=-2$.

But $\eta(0)$ is not computable from the spectrum. Nobody can diagonalise the Dirac operator on an eleven-dimensional mapping torus. The way out is that eta invariants appear in index theorems for manifolds with boundary.

10.9.13 The Atiyah–Patodi–Singer theorem computes η

Recall from Chapter 4 the index theorem for a manifold with boundary. Let X be a compact 12-dimensional spin manifold with $\partial X=N$, with a metric that is a product $dt^2+\bar{\rho}$ near the boundary. Impose the Atiyah–Patodi–Singer (global, spectral) boundary condition, which projects out the non-negative modes of the boundary operator. Then the chiral Dirac operator

$\not{D}_X$ is Fredholm and (Nash (10.59))

$$\operatorname{index} \not{D}_X = \int_X \hat{A}(X) - \frac{h + \eta_{\mathcal{D}}(0)}{2}, \tag{10.218}$$

where $\mathcal{D}$ is the Dirac operator on N and $h = \dim \operatorname{Ker} \mathcal{D}$. The bulk term is the familiar local index density; the boundary correction $\xi = \frac{1}{2}(h + \eta)$ is exactly the combination whose jumps we watched in Figure 10.40. The formula is consistent: $\int_X \hat{A}$ changes smoothly under deformations of the metric, ξ changes smoothly except for integer jumps, and the index changes by the same integers.

Physical picture: Why a boundary term must be non-local

If X were closed, $\operatorname{index} \not{D}_X = \int_X \hat{A}$ would be an integer. With a boundary, $\int_X \hat{A}$ is some real number that depends on the metric near ∂X. The index is still an integer. Something must make up the fractional difference, and it cannot be a local boundary integral (local boundary integrals can be changed continuously while keeping the bulk fixed, and a continuous function cannot compensate the jump of an integer). The spectral asymmetry η of the boundary operator is the global object that does the job.

Using APS to compute the anomaly. Suppose N bounds a 12-manifold X. Then (10.218) gives $\frac{1}{2}\eta_{\mathcal{D}}(0) = \int_X \hat{A} - \operatorname{index} \not{D}_X - \frac{h}{2}$, and so (Nash (10.60))

$$\Delta S_\psi \overset{(1)}{=} \frac{i\pi}{2}\,\eta_{\mathcal{D}}(0) \overset{(2)}{=} i\pi\Big\{\int_X \hat{A} - \operatorname{index} \not{D}_X - \frac{h}{2}\Big\}. \tag{10.219}$$

(1) Witten's formula.
(2) Solve (10.218) for $\eta/2$ and multiply by $i\pi$.

In twelve dimensions the index of the Dirac operator is always *even*. The reason is the pseudo-reality we met for SU(2): in dimensions $8k + 4$ the chiral spinor representations are quaternionic, so the kernel and cokernel of $\not{D}_X$ carry an anti-linear J with $J^2 = -1$ and their complex dimensions are even (Kramers). Hence $i\pi \operatorname{index} \not{D}_X \in 2\pi i\mathbb{Z}$ and drops out of $e^{\Delta S}$. What remains is a *local* bulk integral (plus the harmless h): the global anomaly has been computed from characteristic classes on a twelve-manifold, one dimension above N, two above space-time.

Watch out: What if N bounds no X?

The argument needs $N = \partial X$. For the mapping tori of S^{10} this is fine (the relevant spin cobordism group vanishes, and in fact one can build X by filling in the fibre spheres). For a general space-time M this is a genuine hypothesis, and the modern theory of anomalies (Dai–Freed, Witten) treats the eta invariant itself as the fundamental object.

10.9.14 All the fields of the superstring

A superstring theory has more than spin-$\frac{1}{2}$ fields, and all of them must be included, both to cancel the local anomalies (Green–Schwarz) and to cancel the global one. Nash lists three kinds of chiral field in ten dimensions:

- spin-$\frac{1}{2}$ Weyl fermions, with operator the Dirac operator $\mathcal{D}$, number n_d (counted with sign: left minus right);

- spin-$\frac{3}{2}$ Rarita–Schwinger fields (gravitini), number n_{rs}. Their operator acts on vector-spinors ψ_μ. A vector-spinor contains a spin-$\frac{1}{2}$ part that is a gauge artefact (removed by the ghosts of local supersymmetry), so the physical contribution is $\eta_{rs} - \eta_{\mathcal{D}}$;
- self-dual antisymmetric tensor fields, number n_{sd}, with an operator of signature type; being "half" of an ordinary field (only the self-dual half propagates), they come with an extra factor $\frac{1}{2}$.

The total phase is (Nash (10.61))

$$\Delta S = \frac{\pi i}{2}\Big\{ n_d\,\eta_{\mathcal{D}}(0) + n_{rs}\big(\eta_{rs}(0) - \eta_{\mathcal{D}}(0)\big) - \frac{n_{sd}}{2}\,\eta_{sd}(0)\Big\}. \tag{10.220}$$

Worked example 10.54: Counting fields in the $E_8 \times E_8$ and $\mathrm{SO}(32)$ theories

The $N = 1$ supergravity multiplet coupled to super Yang–Mills in ten dimensions contains:

field	chirality	number
gravitino ψ_μ	left	1
dilatino λ	right	1
gauginos χ^a (adjoint of G)	left	$\dim G = 496$
self-dual tensor	–	0 (the 2-form B is not self-dual)

Hence $n_{rs} = 1$, $n_{sd} = 0$, and the net number of left-handed spin-$\frac{1}{2}$ fields is $n_d = 496 - 1 = 495$, which is Nash's value. Inserting into (10.220) gives the fermionic phase. Then one must add the change of the remaining term in the action, the Green–Schwarz counterterm $\int B \wedge X_8(F,R)$ that was introduced to cancel the local anomaly (the 12-form anomaly polynomial factorises as $X_4 \wedge X_8$ for exactly these two groups). With it, Witten found that the complete change is $\Delta S = 2\pi i k$: the theories have no global gravitational anomaly on S^{10}. The same calculation for type IIB supergravity, which has $n_{rs} = 2$, $n_d = -2$ and $n_{sd} = 1$, also gives $2\pi i k$.

10.9.15 Global anomalies are holonomies: Bismut and Freed

There is a geometrical statement behind (10.56). It completes the picture of the whole chapter: *local anomaly = curvature, global anomaly = holonomy* of a natural connection on the determinant line bundle.

The connection. The determinant line bundle $\det \operatorname{Index} \not{D}$ over Y carries the Quillen metric of Section 10.8.9 (zeta-regularised norm of the section $\det \not{D}$), and Bismut and Freed constructed a compatible unitary connection ∇^{BF}. Its connection 1-form, pulled back to the space of fields, is the variation of the effective action, $\mathrm{d} \ln \det$, i.e. the anomaly 1-form of §2. Two facts:

1. The *curvature* of ∇^{BF} is the degree-two component of the families index density $\int_M \hat{A}\,\mathrm{ch}$. It is the de Rham representative of $c_1(\det \operatorname{Index} \not{D})$: the local anomaly.
2. The *holonomy* of ∇^{BF} around a loop $\alpha : S^1 \to Y$ is (Nash (10.62)) $\exp\big[\int_{S^1} \alpha^* A\big]$, where A is the connection 1-form. When the curvature vanishes it depends only on the homotopy class of α: it is the global anomaly.

Key idea: Bismut–Freed holonomy formula, Nash (10.64)

Let $\alpha : S^1 \to Y$ be a loop, $N = \alpha^* Z$ the corresponding mapping torus, and give it the metric $ds^2 = dt^2/\varepsilon + \rho^t dx^2$ (Nash (10.63); "blowing up the metric" of the base circle). Then

$$\mathrm{hol}_\alpha\big(\nabla^{\mathrm{BF}}\big) = \exp\Big[\int_{S^1} \alpha^* A\Big] = (-1)^{\mathrm{index}\, \not{D}_\rho} \lim_{\varepsilon\to 0} \exp\big[-\pi i\,(h_\varepsilon + \eta_\varepsilon(0))\big],$$

with h_ε and η_ε those of the Dirac operator on N for the metric with parameter ε, and index $\not{D}_\rho$ the index of the chiral Dirac operator on the fibre. (Nash writes the exponent with $+\pi i$; the two signs differ by the convention of the pitfall above.) The holonomy is the global anomaly.

Physical picture: The Aharonov–Bohm effect of the space of fields

A charged particle going around a solenoid feels no magnetic field (zero curvature) along its path, yet its wavefunction returns with the phase $e^{ie\Phi}$ (holonomy). The effective action of the fermions is the "wavefunction" of the space of fields Y, and the determinant line bundle is the bundle it lives in. When the local anomaly cancels, the Bismut–Freed connection is flat, like the vector potential outside the solenoid, but its holonomy around a non-contractible loop in Y (a large gauge transformation or diffeomorphism) can still be non-trivial. That is a global anomaly. The "solenoid" is the non-trivial $\pi_1(Y)$ (Figure 10.41).

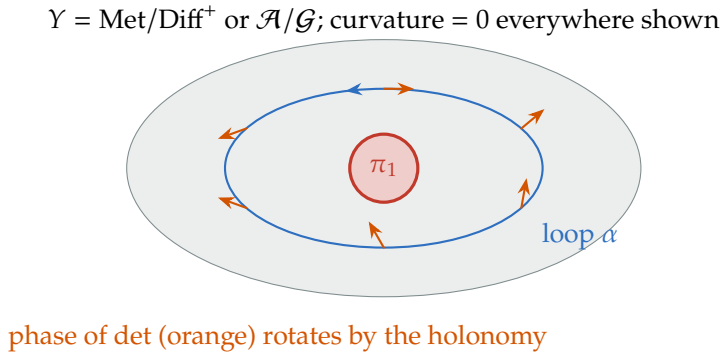

Figure 10.41: Local versus global anomaly as curvature versus holonomy. When the local anomaly cancels, the Bismut–Freed connection on the determinant line is flat on Y (grey), yet transporting the phase of the determinant (orange arrows) around a non-contractible loop α need not bring it back to itself, because the loop encircles a "hole" of Y (red), a non-trivial element of $\pi_1(Y)$. The mismatch is the global anomaly.

Torsion Chern classes are flat bundles with holonomy. This also explains the torsion classes of (10.211) and (10.213). A complex line bundle whose c_1 is torsion has a flat connection, and a flat line bundle is determined by its holonomy, a homomorphism $\pi_1(Y) \to \mathrm{U}(1)$. Such homomorphisms factor through $H_1(Y;\mathbb{Z})$.

Worked example 10.55: Flat line bundles when $\pi_1(Y) = \mathbb{Z}_N$

If $H_1(Y;\mathbb{Z}) = \mathbb{Z}_N$, a homomorphism $\chi : \mathbb{Z}_N \to \mathrm{U}(1)$ is fixed by $\chi(1) = \lambda$ with $\lambda^N = \chi(N\cdot 1) = \chi(0) = 1$. So the possible holonomies are the N-th roots of unity $\lambda = e^{2\pi i m/N}$, $m \in \mathbb{Z}_N$, and they match the elements of $T_1 = \mathbb{Z}_N \subseteq H^2(Y;\mathbb{Z})$ one for one.

- SU(2) on S^4: $N = 2$, the holonomy is ± 1; the real (Möbius) determinant bundle of

Figure 10.36 has holonomy -1 for one Weyl doublet, $(-1)^p$ for p doublets.

- Gravity on S^{10}: $N = 992$; a priori the holonomy of the determinant bundle could be any 992nd root of unity. Witten's computation shows that for the full superstring field content it is 1.

Beyond spheres and Dirac operators. Nash closes the discussion (p. 290) by noting that nothing was special about S^{10}: for any even-dimensional M and any first-order elliptic operator L on it, one builds the mapping torus N of a large diffeomorphism (and, if needed, a bounding X), blows up the metric of the circle, and finds that the global anomaly of L is the phase $\exp\left[\frac{\pi i}{2}\eta_{L_N}(0)\right]$, with L_N the operator on N induced by L.

Reading Nash (pp. 285–290, (10.50)–(10.64))

Nash's "991 exotic spheres in 11 dimensions" and "$\pi_0(\mathrm{Diff}^+(S^{10})) = \mathbb{Z}_{992}$" are the same fact (992 smooth structures, one standard). His (10.53) places the gravitational anomaly in $\mathbb{Z}_{992}$; (10.56) is Witten's adiabatic formula; (10.59) is the APS theorem (his Theorem 4.164 of Chapter 4), for a 12-manifold X with $\partial X = N$. In (10.61) the subtraction $\eta_{rs} - \eta_{\mathcal{D}}$ removes the gauge (ghost) spinor contained in ψ_μ, and $n_d = 495 = 496 - 1$ is gauginos minus dilatino. (10.62)–(10.64) are Bismut–Freed; the operator in the exponent is on the eleven-manifold N with the "blown-up" metric, and the sign in the exponent depends on orientation conventions.

10.9.16 Example: complex anomalies

Nash ends §5 with an example of a different kind of global effect. Anomalies of the global type force us to distinguish manifolds that are homeomorphic but not diffeomorphic (exotic spheres). One can go one step further and distinguish different *complex structures* on the same smooth manifold, as one must in string theory, where the worldsheet (and, in compactifications, space-time) is a complex manifold. The first examples where characteristic numbers tell complex structures apart occur in complex dimension five.

The manifold. Let (Nash (10.65))

$$M = \frac{\mathrm{U}(4)}{\mathrm{U}(2)\times\mathrm{U}(1)\times\mathrm{U}(1)} = \frac{G}{H}. \tag{10.221}$$

It is the space of flags $\{V_2 \subset V_3 \subset \mathbb{C}^4\}$ with $\dim V_k = k$ (equivalently, orthogonal decompositions $\mathbb{C}^4 = W_2 \oplus W_1 \oplus W_1'$ into subspaces of dimensions $2, 1, 1$). Its real dimension is

$$\dim_{\mathbb{R}} M = \dim \mathrm{U}(4) - \dim \mathrm{U}(2) - 2\dim \mathrm{U}(1) = 16 - 4 - 1 - 1 = 10,$$

so $\dim_{\mathbb{C}} M = 5$.

Complex structures from roots. The roots of U(4) are $e_i - e_j$ ($i \neq j$), where e_i picks out the i-th diagonal entry of the Cartan subalgebra; the root space of $e_i - e_j$ is spanned by the matrix unit E_{ij}. The roots of H are $\pm(e_1 - e_2)$ (the U(2) block on indices $1, 2$). The tangent space of M at the base point is spanned by the remaining root spaces, the $12 - 2 = 10$ roots $e_i - e_j$ with i, j in different blocks $\{1,2\}, \{3\}, \{4\}$. As in the treatment of G/T in Chapter 6, an invariant complex structure is fixed by declaring which half of these roots are "holomorphic" ($\bar\partial$ kills them): a choice of positive roots, i.e. of a Weyl chamber, or a lexicographic ordering. For a flag manifold

this amounts to *ordering the three blocks*: a root $e_i - e_j$ is positive if the block of i comes before the block of j. There are $3! = 6$ orderings. Reversing the order gives the complex conjugate structure, and swapping the two U(1) blocks is a symmetry of M, so up to equivalence there are two cases:

$$M_1 : \{1,2\} < \{3\} < \{4\} \quad \text{(U(2) block at the end)},$$
$$M_2 : \{3\} < \{1,2\} < \{4\} \quad \text{(U(2) block in the middle)}.$$

M_1 and M_2 are the same smooth manifold (hence certainly homeomorphic), with two different complex structures.

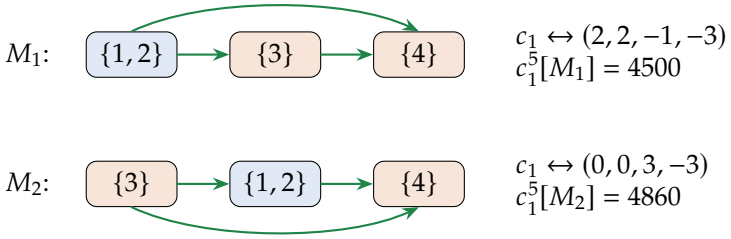

Figure 10.42: Two invariant complex structures on $\mathrm{U}(4)/(\mathrm{U}(2)\times\mathrm{U}(1)\times\mathrm{U}(1))$. An arrow from block B to block B' means the roots $e_i - e_j$ with $i \in B$, $j \in B'$ are holomorphic (positive); there are $2+2+1=5$ of them in each case, one for each complex dimension. Moving the U(2) block (blue) from the end to the middle changes which roots are holomorphic, and changes the Chern number c_1^5.

Computing c_1^5 by hand. Nash quotes (10.66), $c_1^5(M_1) = 4500$ and $c_1^5(M_2) = 4860$, citing his own paper. We can check it with a tool every physicist knows: counting states. Let $L = K^{-1}$ be the anticanonical line bundle (its c_1 is $c_1(M)$). Three facts:

1. (Riemann–Roch, large m) For an ample line bundle, $\dim H^0(M, L^m) = \int_M \mathrm{ch}(L^m)\,\mathrm{td}(M) = \frac{m^5}{5!}\,c_1(L)^5[M] + O(m^4)$, the higher cohomology vanishing (Kodaira).
2. (Borel–Weil) $H^0(G/H, L_\lambda)$ is the irreducible representation of U(4) with highest weight λ, for the positive system defined by the complex structure. For $L = K^{-1}$ the weight is the sum of the positive complementary roots.
3. (Weyl) Its dimension is $\prod_{\alpha>0} \frac{\langle \lambda+\rho,\alpha\rangle}{\langle \rho,\alpha\rangle}$, with ρ half the sum of all positive roots of U(4).

For $\lambda \to m\lambda$ with m large, the factor for the root $\alpha = e_1 - e_2$ of H is 1 (since $\langle \lambda, e_1 - e_2\rangle = 0$), and each of the five complementary roots contributes $m\langle\lambda,\alpha\rangle/\langle\rho,\alpha\rangle$. Comparing with fact 1:

$$c_1^5[M] = 5! \prod_{\alpha\in\Delta^+\setminus\Delta_H} \frac{\langle\lambda,\alpha\rangle}{\langle\rho,\alpha\rangle}. \tag{10.222}$$

Worked example 10.56: Warm-up: $\mathbb{CP}^1$ and $\mathbb{CP}^2$

$\mathbb{CP}^1 = \mathrm{U}(2)/(\mathrm{U}(1)\times\mathrm{U}(1))$: one complementary positive root $e_1 - e_2$, $\lambda = e_1 - e_2 \leftrightarrow (1,-1)$, $\rho = (\frac{1}{2}, -\frac{1}{2})$, so $c_1[\mathbb{CP}^1] = 1! \cdot \frac{2}{1} = 2$, the Euler characteristic of the sphere. ✓
$\mathbb{CP}^2 = \mathrm{U}(3)/(\mathrm{U}(1)\times\mathrm{U}(2))$, blocks $\{1\} < \{2,3\}$: complementary positive roots $e_1 - e_2$, $e_1 - e_3$; $\lambda = 2e_1 - e_2 - e_3 \leftrightarrow (2,-1,-1)$; $\rho = (1,0,-1)$. Then $\langle\lambda, e_1 - e_2\rangle = 3$, $\langle\rho, e_1 - e_2\rangle = 1$,

$\langle\lambda, e_1 - e_3\rangle = 3$, $\langle\rho, e_1 - e_3\rangle = 2$, and

$$c_1^2[\mathbb{CP}^2] = 2! \cdot \frac{3 \cdot 3}{1 \cdot 2} = 9,$$

the known value ($c_1 = 3H$, $H^2 = 1$). ✓

Worked example 10.57: $c_1^5(M_1) = 4500$ and $c_1^5(M_2) = 4860$

M_1: order $\{1,2\} < \{3\} < \{4\}$. The positive system of U(4) is the standard one, $e_i - e_j$ with $i < j$, so $\rho = (\frac{3}{2}, \frac{1}{2}, -\frac{1}{2}, -\frac{3}{2})$. The complementary positive roots are $e_1 - e_3, e_1 - e_4, e_2 - e_3, e_2 - e_4, e_3 - e_4$, whose sum is $\lambda = (2, 2, -1, -3)$. Tabulate:

α	$e_1 - e_3$	$e_1 - e_4$	$e_2 - e_3$	$e_2 - e_4$	$e_3 - e_4$
$\langle\lambda, \alpha\rangle$	3	5	3	5	2
$\langle\rho, \alpha\rangle$	2	3	1	2	1

$$c_1^5[M_1] \overset{(1)}{=} 120 \cdot \frac{3 \cdot 5 \cdot 3 \cdot 5 \cdot 2}{2 \cdot 3 \cdot 1 \cdot 2 \cdot 1} = 120 \cdot \frac{450}{12} = 4500.$$

(1) Formula (10.222) with $5! = 120$ and the tabulated pairings (the pairing is $\langle \sum_i c_i e_i, e_j - e_k\rangle = c_j - c_k$).

M_2: order $\{3\} < \{1,2\} < \{4\}$. Now the positive system orders the indices as $3, 1, 2, 4$, so ρ assigns $\frac{3}{2}, \frac{1}{2}, -\frac{1}{2}, -\frac{3}{2}$ to e_3, e_1, e_2, e_4. The complementary positive roots are $e_3 - e_1, e_3 - e_2, e_3 - e_4, e_1 - e_4, e_2 - e_4$, with sum $\lambda = 3e_3 - 3e_4 \leftrightarrow (0, 0, 3, -3)$.

α	$e_3 - e_1$	$e_3 - e_2$	$e_3 - e_4$	$e_1 - e_4$	$e_2 - e_4$
$\langle\lambda, \alpha\rangle$	3	3	6	3	3
$\langle\rho, \alpha\rangle$	1	2	3	2	1

$$c_1^5[M_2] \overset{(1)}{=} 120 \cdot \frac{3 \cdot 3 \cdot 6 \cdot 3 \cdot 3}{1 \cdot 2 \cdot 3 \cdot 2 \cdot 1} = 120 \cdot \frac{486}{12} = 4860.$$

(1) Formula (10.222) with $5! = 120$ and the tabulated pairings (the pairing is $\langle \sum_i c_i e_i, e_j - e_k\rangle = c_j - c_k$).

Both agree with Nash's (10.66), and they differ by $4860 - 4500 = 360$. (The same numbers come out of the Atiyah–Bott localisation formula, summing c_1^5/e over the 12 torus-fixed points of M.)

The physics: an action that sees the complex structure. Nash's toy model has action

$$S = \frac{i}{(2\pi)^5} \int_M (\operatorname{tr} F)^5,$$

with F the curvature of the (Hermitian) tangent bundle of the Kähler manifold M. Up to the conventional factor, $\frac{i}{2\pi} \operatorname{tr} F$ is the Chern–Weil representative of c_1, so S is (a constant times) the Chern number $c_1^5[M]$ of the complex structure in use. It is diffeomorphism invariant for a fixed complex structure: it is a topological number. Now let g and $\tilde{g}$ be the Kähler metrics adapted to the two complex structures (both invariant under U(4)). They are related by a smooth path g^t of metrics ($g^0 = g$, $g^1 = \tilde{g}$), but not by a holomorphic change of coordinates. Along the path

the complex structure jumps from one type to the other, and the action does not return to its value: it changes by

$$\Delta S = c_1^5[M_2] - c_1^5[M_1] = 360.$$

The example is not meant as a realistic physical model; it shows how an action built from characteristic classes of the complex structure can fail to be invariant under a deformation that is perfectly smooth from the real point of view, a potential "complex anomaly".

Recap: Global gravitational and complex anomalies

- Large diffeomorphisms: $\pi_0(\mathrm{Diff}^+(M)) \neq 0$. On T^2 this is the modular group $\mathrm{SL}(2,\mathbb{Z})$; on spheres it is the group of exotic spheres, $\pi_0(\mathrm{Diff}^+(S^{n-1})) \cong \Theta_n$ (clutching and Cerf).
- In the ten-dimensional superstring, $\pi_{10}(G) = 0$ kills global gauge anomalies; $\pi_0(\mathrm{Diff}^+(S^{10})) = \mathbb{Z}_{992}$ leaves a possible torsion class $c_1(\det \mathrm{Index}\, \not{D}_{\mathrm{grav}}) \in \mathbb{Z}_{992}$.
- Witten: use the interpolating metrics ρ^t to build the mapping torus N; in the adiabatic limit the phase change is $\exp(\frac{i\pi}{2}\eta_{\mathcal{D}}(0))$; no anomaly iff $\eta = 4k$.
- The eta invariant is the phase of an odd-dimensional determinant; on S^1, $\eta(-i\partial_\theta + a) = 1 - 2a$, and $\frac{1}{2}(\eta + h)$ jumps by the spectral flow.
- APS turns η into a local integral $\int_X \hat{A}$ on a bounding 12-manifold, the index being even; with all fields ($n_d = 495$, $n_{rs} = 1$) and the Green–Schwarz term, $\Delta S = 2\pi i k$.
- Bismut–Freed: local anomaly = curvature, global anomaly = holonomy of the determinant line bundle; torsion c_1 = flat bundle with root-of-unity holonomy.
- Complex anomalies: the flag manifold $\mathrm{U}(4)/(\mathrm{U}(2)\times\mathrm{U}(1)^2)$ has two complex structures with $c_1^5 = 4500$ and 4860; an action $\propto \int (\mathrm{tr}\, F)^5$ changes by 360.

10.10 Anomalies from a Hamiltonian perspective

Everything so far in this chapter has been Euclidean. We integrated over fermions in a path integral, obtained a determinant, and asked whether the determinant is gauge invariant. A physicist who learned quantum field theory from canonical quantisation will ask a fair question: *where is the anomaly in the Hamiltonian?* In canonical quantisation there is no determinant. There is a Hilbert space of states, a Hamiltonian, and a set of operators that generate gauge transformations. If gauge invariance is anomalous, something must go wrong with those operators.

The answer, which this section builds up step by step, is:

1. The one-particle Dirac Hamiltonians H_A form a family over the space of spatial gauge fields. Going round a loop of gauge fields, eigenvalues of H_A can cross zero: **spectral flow**.
2. The vacuum is the "filled Dirac sea" of negative-energy states. As A varies, the vacuum states form a *line bundle*, and this bundle has a curvature, exactly like the Berry phase of a spin in a slowly rotating magnetic field.
3. Because of the zero crossings, the Fock spaces are only well defined up to a phase. The gauge group then acts on states only *projectively*: $U(g)U(h) = \lambda\, U(gh)$ with a phase λ.

4. The infinitesimal version of that phase is an extra term in the commutator of gauge generators, the **Schwinger term**. With it, Gauss's law $G(\xi)|\text{phys}\rangle = 0$ has no solutions.

The topology that controls all this is the topology of spaces of Fredholm operators, and the bookkeeping rule that makes the Euclidean and the Hamiltonian pictures agree is: *only $n + p$ matters*, where n is the dimension of the manifold and p the number of parameters of the family.

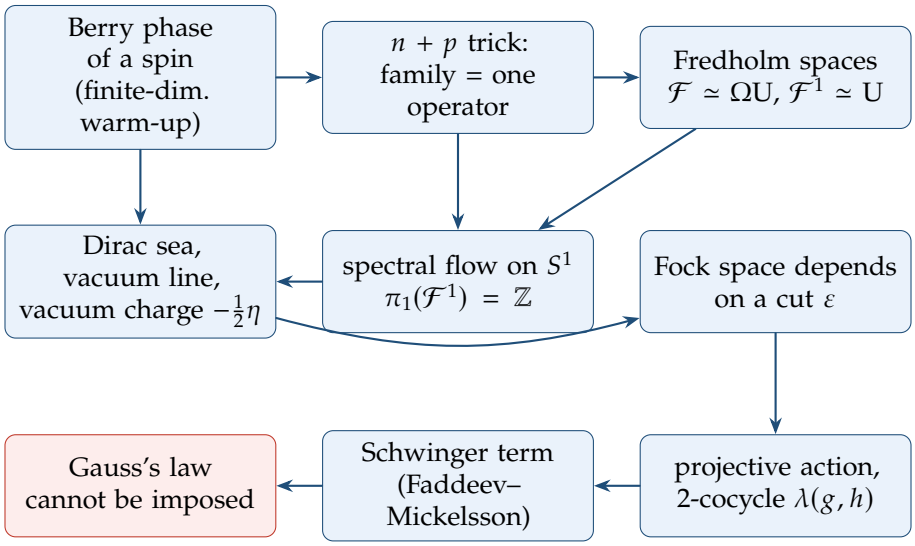

Figure 10.43: The logic of this section. Read along the arrows: a finite-dimensional warm-up (top left), the topology of families (top row), the concrete two-dimensional example (middle), and the second-quantised consequences (bottom row), ending at the physical statement in red: an anomalous gauge symmetry cannot be imposed as a constraint on states.

Reading Nash (p. 291, the opening of §6)

Nash starts §6 with the remark that "anomalies should not disappear in an alternative formulation, though they may manifest themselves in slightly different ways", and that "the central idea is still to use families of Dirac operators". The difference is which operators: in the Euclidean picture the chiral Dirac operator of the whole n-dimensional spacetime; in the Hamiltonian picture the self-adjoint Dirac Hamiltonian of $(n-1)$-dimensional space. The warm-up below (Berry's phase) is not in Nash, but it is the finite-dimensional model of every step in his §6.

10.10.1 Warm-up: the Berry phase of a spin in a magnetic field

Before any field theory, consider the simplest quantum system whose Hamiltonian depends on parameters: a spin-$\frac{1}{2}$ in a magnetic field. Everything we meet later (a family of Hamiltonians, a bundle of ground states, a curvature, a topological obstruction to choosing phases, and a degeneracy that is the source of it all) is already here in a 2×2 matrix.

The family. Let the field be $\vec{B} = B\,\vec{n}$ with $B > 0$ fixed and the unit vector

$$\vec{n} = (\sin\theta\cos\phi,\ \sin\theta\sin\phi,\ \cos\theta)$$

free. The parameter space is the sphere S^2 of field directions. Take

$$H(\vec{n}) = -B\,\vec{n}\cdot\vec{\sigma} = -B\begin{pmatrix} \cos\theta & \sin\theta\, e^{-i\phi} \\ \sin\theta\, e^{i\phi} & -\cos\theta \end{pmatrix},$$

with the Pauli matrices $\sigma_1 = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, $\sigma_2 = \left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right)$, $\sigma_3 = \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$. Since $(\vec{n}\cdot\vec{\sigma})^2 = \mathbb{1}$, the eigenvalues are $\mp B$. The ground state (energy $-B$) is spin up along $\vec{n}$:

$$|\psi_N(\vec{n})\rangle = \begin{pmatrix} \cos\frac{\theta}{2} \\ e^{i\phi}\sin\frac{\theta}{2} \end{pmatrix}. \tag{10.223}$$

Check it: the first component of $(\vec{n}\cdot\vec{\sigma})|\psi_N\rangle$ is $\cos\theta\cos\frac{\theta}{2} + \sin\theta\sin\frac{\theta}{2} = \cos(\theta - \frac{\theta}{2}) = \cos\frac{\theta}{2}$, and the second is $e^{i\phi}(\sin\theta\cos\frac{\theta}{2} - \cos\theta\sin\frac{\theta}{2}) = e^{i\phi}\sin\frac{\theta}{2}$. So $\vec{n}\cdot\vec{\sigma}|\psi_N\rangle = |\psi_N\rangle$ and $H|\psi_N\rangle = -B|\psi_N\rangle$.

The vector (10.223) is smooth everywhere except at the south pole $\theta = \pi$, where it becomes $(0, e^{i\phi})$, which depends on the direction ϕ from which we approach the pole. Multiplying by the phase $e^{-i\phi}$ gives

$$|\psi_S(\vec{n})\rangle = e^{-i\phi}|\psi_N(\vec{n})\rangle = \begin{pmatrix} e^{-i\phi}\cos\frac{\theta}{2} \\ \sin\frac{\theta}{2} \end{pmatrix},$$

which is smooth at the south pole but not at the north pole. We will see that no choice of phase is smooth everywhere.

The adiabatic theorem produces a phase. Now let the direction move slowly along a closed loop $\vec{n}(t)$, $0 \le t \le T$, with $\vec{n}(T) = \vec{n}(0)$. If the motion is slow compared with the gap $2B$, the state stays in the instantaneous ground state up to a phase: $|\Psi(t)\rangle = c(t)\,e^{-i\int_0^t E\,\mathrm{d}t'}|\psi(\vec{n}(t))\rangle$ with $E = -B$ and $|\psi\rangle$ any smooth choice of phase along the loop. Put this into the Schrödinger equation ($\hbar = 1$):

$$\begin{aligned} i\partial_t|\Psi\rangle = H|\Psi\rangle &\overset{(1)}{=} i\dot{c}|\psi\rangle + Ec|\psi\rangle + ic\,\partial_t|\psi\rangle = Ec|\psi\rangle \quad \text{(times the common factor } e^{-i\int E}\text{)} \\ &\implies \dot{c} \overset{(2)}{=} -c\,\langle\psi|\partial_t\psi\rangle \\ &\implies c(T) \overset{(3)}{=} \exp\Big(-\oint\langle\psi|\mathrm{d}\psi\rangle\Big) \overset{(4)}{=} \exp\Big(i\oint\mathcal{A}\Big), \qquad \mathcal{A} \coloneqq i\langle\psi|\mathrm{d}\psi\rangle. \end{aligned} \tag{10.224}$$

(1) Differentiate the product; $H|\psi\rangle = E|\psi\rangle$ on the right.

(2) Take the inner product with $\langle\psi|$ and use $\langle\psi|\psi\rangle = 1$. (We have dropped the components of $\partial_t|\psi\rangle$ along the excited state: that is the adiabatic approximation.)

(3) Integrate the linear equation, with $c(0) = 1$; the time integral of $\langle\psi|\partial_t\psi\rangle\mathrm{d}t$ is the line integral of the 1-form $\langle\psi|\mathrm{d}\psi\rangle$ on parameter space.

(4) Definition of $\mathcal{A}$. Differentiating $\langle\psi|\psi\rangle = 1$ gives $\langle\psi|\mathrm{d}\psi\rangle + \overline{\langle\psi|\mathrm{d}\psi\rangle} = 0$, so $\langle\psi|\mathrm{d}\psi\rangle$ is imaginary and $\mathcal{A}$ is real.

The extra phase $\gamma = \oint\mathcal{A}$ is the **Berry phase**. It depends only on the path in parameter space, not on how fast it is traversed. Under a change of phase $|\psi\rangle \to e^{i\chi}|\psi\rangle$ the 1-form shifts by $\mathcal{A} \to \mathcal{A} - \mathrm{d}\chi$: it is a U(1) gauge field on parameter space, the **Berry connection**.

Worked example 10.58: The Berry phase of spin-$\frac{1}{2}$ is minus half the solid angle

In the north gauge (10.223):

$$\begin{aligned} \langle\psi_N|\mathrm{d}\psi_N\rangle &\overset{(1)}{=} \cos\tfrac{\theta}{2}\,\mathrm{d}\big(\cos\tfrac{\theta}{2}\big) + \sin\tfrac{\theta}{2}\,e^{-i\phi}\,\mathrm{d}\big(e^{i\phi}\sin\tfrac{\theta}{2}\big) \\ &\overset{(2)}{=} -\tfrac{1}{2}\cos\tfrac{\theta}{2}\sin\tfrac{\theta}{2}\,\mathrm{d}\theta + \tfrac{1}{2}\sin\tfrac{\theta}{2}\cos\tfrac{\theta}{2}\,\mathrm{d}\theta + i\sin^2\tfrac{\theta}{2}\,\mathrm{d}\phi \\ &= i\sin^2\tfrac{\theta}{2}\,\mathrm{d}\phi, \\ \mathcal{A}_N &\overset{(3)}{=} -\sin^2\tfrac{\theta}{2}\,\mathrm{d}\phi \overset{(4)}{=} -\tfrac{1}{2}(1-\cos\theta)\,\mathrm{d}\phi. \end{aligned}$$

(1) The components of $|\psi_N\rangle$ are real and $e^{i\phi}\sin\frac{\theta}{2}$; the bra conjugates the second.

(2) Product rule: $\mathrm{d}\cos\frac{\theta}{2} = -\frac{1}{2}\sin\frac{\theta}{2}\mathrm{d}\theta$, $\mathrm{d}(e^{i\phi}\sin\frac{\theta}{2}) = e^{i\phi}(\frac{1}{2}\cos\frac{\theta}{2}\mathrm{d}\theta + i\sin\frac{\theta}{2}\mathrm{d}\phi)$.
(3) $\mathcal{A} = i\langle\psi|\mathrm{d}\psi\rangle$ and $i\cdot i = -1$.
(4) Half-angle formula $\sin^2\frac{\theta}{2} = \frac{1}{2}(1-\cos\theta)$.

For a loop at fixed latitude θ_0, traversed once in the direction of increasing ϕ,

$$\gamma = \oint \mathcal{A}_N = -\tfrac{1}{2}(1-\cos\theta_0)\cdot 2\pi = -\tfrac{1}{2}\,\Omega(\theta_0), \qquad \Omega(\theta_0) = 2\pi(1-\cos\theta_0),$$

where Ω is the solid angle of the cap enclosed by the loop. The curvature is

$$\mathcal{F} = \mathrm{d}\mathcal{A}_N = -\tfrac{1}{2}\sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi,$$

minus one half of the area form of the unit sphere: the field of a magnetic monopole of "charge $-\frac{1}{2}$" sitting at $\vec{B}=0$. In the south gauge, $\mathcal{A}_S = i\langle\psi_S|\mathrm{d}\psi_S\rangle = \mathcal{A}_N + \mathrm{d}\phi = \frac{1}{2}(1+\cos\theta)\mathrm{d}\phi$, which is regular at $\theta=\pi$ (where $1+\cos\theta=0$). The two gauges differ by the transition function $e^{-i\phi}$ on the equator. The total flux is

$$\int_{S^2}\mathcal{F} \overset{(1)}{=} \int_{\text{north}}\mathrm{d}\mathcal{A}_N + \int_{\text{south}}\mathrm{d}\mathcal{A}_S \overset{(2)}{=} \oint_{\text{eq}}\mathcal{A}_N - \oint_{\text{eq}}\mathcal{A}_S$$
$$\overset{(3)}{=} -\oint_{\text{eq}}\mathrm{d}\phi = -2\pi, \qquad \text{so} \qquad \frac{1}{2\pi}\int_{S^2}\mathcal{F} = -1.$$

(1) Cut the sphere along the equator and use, on each half, the gauge that is regular there ($\mathcal{F}$ is gauge invariant).
(2) Stokes' theorem on each hemisphere; the equator is the boundary of the northern cap with the orientation of increasing ϕ, and of the southern cap with the opposite orientation.
(3) $\mathcal{A}_N - \mathcal{A}_S = -\mathrm{d}\phi$.

The integer -1 is the first Chern number of the **ground-state line bundle** $L \to S^2$ whose fibre over $\vec{n}$ is the line spanned by $|\psi(\vec{n})\rangle$. (With the conventions of Chapter T2, the connection 1-form of L is the imaginary $\omega = \langle\psi|\mathrm{d}\psi\rangle = -i\mathcal{A}$, and $c_1 = \frac{i}{2\pi}\int\mathrm{d}\omega = \frac{1}{2\pi}\int\mathcal{F}$.) The line spanned by $|\psi(\vec{n})\rangle$ in $\mathbb{C}^2$ is a point of $\mathbb{CP}^1$, so L is the tautological line bundle over $\mathbb{CP}^1 \cong S^2$, whose Chern number is indeed -1. The excited states form the complementary bundle with Chern number $+1$; the two together make the trivial bundle $S^2\times\mathbb{C}^2$, and $-1+1=0$.

Try it: Higher spin

For spin j in the state $|j,m\rangle$ along $\vec{n}$ (energy $-Bm$ in the field $H=-B\,\vec{n}\cdot\vec{J}$), show that the Berry phase is $\gamma = -m\,\Omega$ and the Chern number of that bundle is $-2m$. *Answer:* rotate $|j,m\rangle_{\hat{z}}$ by $e^{-i\phi J_3}e^{-i\theta J_2}e^{i\phi J_3}$; the same computation gives $\mathcal{A}_N = -m(1-\cos\theta)\mathrm{d}\phi$, so $\gamma = -m\Omega$ and $\frac{1}{2\pi}\int\mathcal{F} = -m\cdot 2 = -2m$. The Chern numbers over all $2j+1$ states add up to $-2\sum_m m = 0$.

What the warm-up teaches. Line up the ingredients with the anomaly problem:

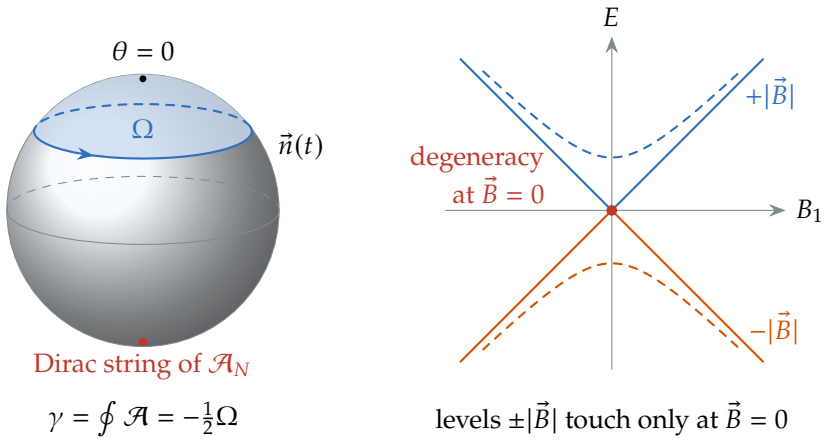

Figure 10.44: Left: the parameter space of the spin is the sphere of field directions. A slow loop $\vec{n}(t)$ encloses a cap of solid angle Ω and the ground state returns multiplied by $e^{-i\Omega/2}$. The north-gauge phase is singular at the south pole (red): that point is the end of a Dirac string, and it cannot be removed, because the Berry flux through the sphere is -2π. Right: a slice of the spectrum as a function of the field. The two levels meet only at $\vec{B} = 0$ (a "diabolical point"); a slice that misses $\vec{B} = 0$ (dashed) sees them repel. This degeneracy is the monopole whose flux the sphere measures.

Dictionary: Berry phase ↔ Hamiltonian anomaly

spin in a field	chiral fermions in a gauge field
parameter space S^2 of directions	space of gauge fields $\mathcal{A}$, or $\mathcal{A}/\mathcal{G}$
Hamiltonian $H(\vec{n})$	one-particle Dirac Hamiltonian H_A
ground state $\lvert\psi(\vec{n})\rangle$	Dirac sea (Fock vacuum) $\lvert\Omega(A)\rangle$
ground-state line bundle L	vacuum line bundle = a determinant line bundle
Berry curvature $\mathcal{F}$	local anomaly, Schwinger term
$c_1(L) = -1 \neq 0$: no global phase choice	no gauge-invariant choice of vacuum phase
degeneracy at $\vec{B} = 0$	zero modes of H_A (spectral flow)

The ground-state bundle is only defined on the space of *gapped* Hamiltonians. If we allowed $\vec{B} = 0$ the parameter space would be all of $\mathbb{R}^3$, which is contractible, and all topology would disappear. The topology is created by removing the degeneracy. The same is true for Dirac operators: all the topology of the anomaly comes from how zero modes sit in the space of gauge fields. To handle that in infinite dimensions we need the right spaces of operators: the Fredholm operators.

10.10.2 A family is a single operator in more dimensions

Let $\not{D}_t^{(n)}$ be a family of Dirac operators on an n-dimensional spin manifold M, depending on p real parameters $t = (t_1, \ldots, t_p)$ [Nash p. 292, (10.67)]:

$$\not{D}^{(n)}_{(t_1,\ldots,t_p)}.$$

Typically t are coordinates on a p-sphere S^p inside $\mathcal{A}/\mathcal{G}$ (as in Chapter 10, §2, where the local anomaly was detected on a 2-sphere of gauge orbits). Out of this family we can build one Dirac

operator on the $(n+p)$-dimensional manifold $M \times$ (parameter space) [Nash (10.68)]:

$$\not{D}^{(n+p)} = \not{D}^{(n)}_{(t_1,\dots,t_p)} + \sum_{i=1}^{p} \gamma_i \frac{\partial}{\partial t_i}, \tag{10.225}$$

where $\gamma_1, \dots, \gamma_p$ are the extra gamma matrices needed in $n+p$ dimensions. The parameters have become coordinates.

Why this is the right operator. Square it. If the new gamma matrices anticommute with the old ones and with each other ($\gamma_i\gamma_j + \gamma_j\gamma_i = -2\delta_{ij}$ in the convention where $(\gamma_i\partial_i)^2 = -\partial_i^2$, and γ_i anticommutes with the γ's inside $\not{D}^{(n)}$):

$$\begin{aligned}\big(\not{D}^{(n+p)}\big)^2 &\overset{(1)}{=} \big(\not{D}^{(n)}_t\big)^2 + \sum_i \big(\not{D}^{(n)}_t \gamma_i\partial_i + \gamma_i\partial_i \not{D}^{(n)}_t\big) + \sum_{i,j} \gamma_i\gamma_j\partial_i\partial_j \\ &\overset{(2)}{=} \big(\not{D}^{(n)}_t\big)^2 - \sum_i \partial_i^2 + \sum_i \gamma_i \big(\partial_i \not{D}^{(n)}_t\big).\end{aligned}$$

(1) Expand the square of a sum; γ_i are constant matrices.

(2) In the cross term, $\gamma_i\partial_i(\not{D}\,\psi) = \gamma_i(\partial_i\not{D})\psi + \gamma_i\not{D}\partial_i\psi$ and $\not{D}\gamma_i = -\gamma_i\not{D}$, so only the derivative of the family survives; in the last term only $i = j$ survives the symmetric sum, giving $\gamma_i^2\partial_i^2 = -\partial_i^2$.

So the $(n+p)$-dimensional Laplacian-type operator is "the square of the family, plus the Laplacian in the parameter directions, plus a term that knows how fast the family changes". When the family changes slowly, the last term is small, and the low-lying spectrum of $\not{D}^{(n+p)}$ is governed by the low-lying spectrum of $\not{D}^{(n)}_t$ as t moves: this is the same adiabatic idea as in the Berry phase and in Witten's global gravitational anomaly (Section 10.9.12).

Worked example 10.59: From a circle to a torus: $n = 1, p = 1$

Take $M = S^1$ with coordinate θ, and the family $D_t = -i\frac{\mathrm{d}}{\mathrm{d}\theta} + kt$ ($k \in \mathbb{Z}$, $0 \le t \le 1$), which will be Nash's example in Section 10.10.7. In two dimensions use $\gamma^\theta = \sigma_1$, $\gamma^t = \sigma_2$ and chirality σ_3. The two-dimensional Dirac operator on the (t,θ) cylinder is

$$\begin{aligned}\mathcal{D} &\overset{(1)}{=} \sigma_1\big(-i\partial_\theta + kt\big) + \sigma_2\big(-i\partial_t\big) \\ &\overset{(2)}{=} \begin{pmatrix} 0 & D_t - \partial_t \\ D_t + \partial_t & 0 \end{pmatrix}.\end{aligned}$$

(1) The Dirac operator $\gamma^\mu(-i\partial_\mu + a_\mu)$ with the gauge field $a = kt\,\mathrm{d}\theta$ (so $a_\theta = kt$, $a_t = 0$).

(2) $\sigma_1(\cdot)$ puts D_t in both off-diagonal slots; $\sigma_2(-i\partial_t) = \left(\begin{smallmatrix} 0 & -\partial_t \\ \partial_t & 0 \end{smallmatrix}\right)$.

The lower-left block $D_A := \partial_t + D_t$ maps positive-chirality spinors to negative-chirality ones: it is Nash's operator (10.85), the chiral Dirac operator on the torus for the field strength $F = \mathrm{d}a = k\,\mathrm{d}t \wedge \mathrm{d}\theta$. This is (10.225) with $n = p = 1$ and the single extra gamma matrix acting as "∂_t in the chiral block". So a one-parameter family of 1-dimensional operators *is* a single 2-dimensional operator.

The Hamiltonian version. Nash adds a second reading of the same trick. In a Hamiltonian treatment spacetime is $\mathbb{R}_{\text{time}} \times \Sigma^{n-1}$, and the object that matters is the Dirac Hamiltonian on the $(n-1)$-dimensional space Σ. A p-parameter family of n-dimensional Euclidean operators

becomes a $(p+1)$-parameter family $\not{D}_t^{(n-1)}$ of $(n-1)$-dimensional Hamiltonians, the extra parameter being time. The totals are equal:

$$n + p = (n-1) + (p+1).$$

Nash's claim is that the anomaly depends only on this total. We now make the claim precise with Fredholm operators.

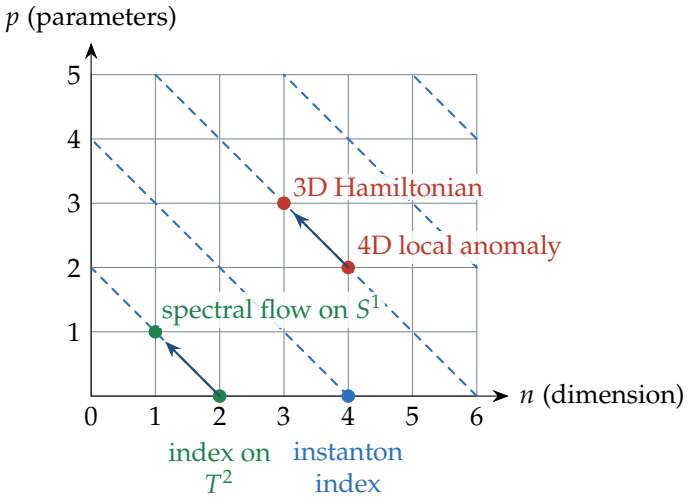

Figure 10.45: Bookkeeping of families. A point (n, p) is a p-parameter family of n-dimensional Dirac operators. The anomaly group depends only on the diagonal $n + p$ it lies on; it is $\mathbb{Z}$ on the dashed diagonals $n + p$ even and 0 in between. The arrows are the step from the Euclidean picture to the Hamiltonian one, $(n, p) \mapsto (n-1, p+1)$: the 4D local anomaly on a 2-sphere of gauge orbits becomes a 3-sphere family of 3D Hamiltonians, and the index on the torus becomes spectral flow on the circle.

10.10.3 Fredholm operators and the index map

Nash now recalls that elliptic operators on compact manifolds are *Fredholm* (Chapter 2) and that the space of Fredholm operators is related to K-theory (Chapter 3). We rebuild both facts here in the form we need.

Working definition 10.15 (Fredholm operator and its index)

A bounded operator [$\|T\psi\| \le C\,\|\psi\|$ for a fixed C. The last sentence shows how a Dirac operator is made so] $T : H \to H'$ between Hilbert spaces is **Fredholm** if $\dim \ker T < \infty$ and $\dim \operatorname{Coker} T < \infty$, where $\operatorname{Coker} T = H'/\operatorname{Im} T$ [H' with the range of T divided out, so its dimension counts the independent directions that T cannot reach] (the range is then automatically closed, and $\operatorname{Coker} T \cong \ker T^*$). Its **index** is

$$\operatorname{index} T = \dim \ker T - \dim \ker T^*.$$

How to test it: count the solutions of $T\psi = 0$ and of $T^*\chi = 0$. *Key property:* the index does not change under continuous deformations of T through Fredholm operators, nor under adding a compact operator [a norm limit of finite-rank operators, i.e. up to an arbitrarily small error it acts on only finitely many independent directions]. We write $\mathcal{F}(H)$ for the space of Fredholm operators $H \to H$ with the norm topology [two operators are close when $\|T - T'\|$ is small]. An unbounded elliptic operator such as a Dirac operator is made bounded without changing its kernel or the signs of its eigenvalues by $D \mapsto D(1 + D^*D)^{-1/2}$.

Worked example 10.60: Three Fredholm operators with their indices

(a) Finite dimensions. Every linear map $T : \mathbb{C}^a \to \mathbb{C}^b$ is Fredholm, and

$$\operatorname{index} T \overset{(1)}{=} \dim \operatorname{Ker} T - \dim \operatorname{Ker} T^* \overset{(2)}{=} (a - \operatorname{rank} T) - (b - \operatorname{rank} T) = a - b.$$

(1) Definition.
(2) Rank–nullity for T and for $T^* : \mathbb{C}^b \to \mathbb{C}^a$, which has the same rank.

The index does not depend on T at all, only on the dimensions: the simplest instance of "the index is a topological invariant". In infinite dimensions $a - b$ becomes $\infty - \infty$, and the index is the finite number that survives.
(b) The shift. On $\ell^2 = \{(c_0, c_1, c_2, \dots)\}$ with basis $e_0, e_1, \dots$, let $S e_j = e_{j+1}$. As a matrix,

$$S = \begin{pmatrix} 0 & 0 & 0 & \cdots \\ 1 & 0 & 0 & \cdots \\ 0 & 1 & 0 & \cdots \\ \vdots & & \ddots & \ddots \end{pmatrix}, \qquad S^*S = \mathbb{1}, \qquad SS^* = \mathbb{1} - |e_0\rangle\langle e_0|.$$

S is injective, so $\operatorname{Ker} S = 0$; its range misses e_0, and $\operatorname{Ker} S^* = \mathbb{C}e_0$. So index $S = 0 - 1 = -1$, index $S^* = +1$, and index $S^k = -k$. Every integer occurs as an index. Note that S is "almost invertible": S^* is an inverse up to the rank-one (compact) operator $|e_0\rangle\langle e_0|$. That is the general picture: T is Fredholm exactly when it is invertible modulo compact operators.
(c) A Dirac operator. $D_a = -i\frac{\mathrm{d}}{\mathrm{d}\theta} + a$ on S^1 has eigenvalues $n + a$, $n \in \mathbb{Z}$, on $e^{in\theta}$. It is self-adjoint, so $\operatorname{Ker} D_a = \operatorname{Ker} D_a^*$ and index $D_a = 0$; the kernel is $\mathbb{C}e^{-ia\theta}$ when $a \in \mathbb{Z}$ and zero otherwise. The index is 0 although the kernel jumps: kernel and cokernel jump together.

Families and the index bundle. Now let X be a compact space and [Nash (10.70)]

$$\alpha : X \to \mathcal{F}(H), \qquad x \mapsto \alpha(x),$$

a continuous map. This is a *family* α_X of Fredholm operators parametrised by X. For each x we have two finite-dimensional spaces $\operatorname{Ker} \alpha(x)$ and $\operatorname{Ker} \alpha(x)^*$. If their dimensions do not jump, they are the fibres of two vector bundles $\operatorname{Ker} \alpha$ and $\operatorname{Ker} \alpha^*$ over X, and [Nash (10.71)]

$$\operatorname{Index} \alpha_X := [\operatorname{Ker} \alpha] - [\operatorname{Ker} \alpha^*] \in K(X)$$

is a formal difference of bundles, an element of the K-theory of X. This is the index bundle of Chapter 10, §2, for an abstract family.

When the dimensions do jump, the formula needs a small repair, and the repair is worth seeing because it is the same idea as the "cut at ε" that will appear in the Fock-space construction.

Worked example 10.61: Repairing a jumping kernel

Take $X = [-1, 1]$ and the family of 1×1 matrices $T(x) = x : \mathbb{C} \to \mathbb{C}$. At $x \neq 0$ kernel and cokernel are zero; at $x = 0$ both are $\mathbb{C}$. Naively $[\operatorname{Ker}] - [\operatorname{Ker}^*]$ is "$0 - 0$" away from 0 and "$\mathbb{C} - \mathbb{C}$" at 0: the difference is the same but neither term is a bundle. Repair: add a fixed extra dimension to the source,

$$\tilde{T}(x) : \mathbb{C} \oplus \mathbb{C} \to \mathbb{C}, \qquad (v, w) \mapsto xv + w.$$

Now $\tilde{T}(x)$ is surjective for every x (take w), so $\operatorname{Ker}\tilde{T}^* = 0$, and

$$\operatorname{Ker}\tilde{T}(x) = \{(v, -xv)\} \cong \mathbb{C}$$

has constant dimension 1: a genuine (trivial) line bundle. The index bundle is $[\operatorname{Ker}\tilde{T}] - [\mathbb{C}_{\text{extra}}] = 1 - 1 = 0$, as it should be. In general one picks a finite-dimensional space W so that $\alpha(x) \oplus$ (inclusion of W) is onto for all x (possible because X is compact); the kernels then form a bundle, and $\operatorname{Index}\alpha_X = [\text{kernel bundle}] - [W]$.

Worked example 10.62: The Berry bundle is an index bundle

Over $X = S^2$ let $\alpha(\vec{n}) : \mathbb{C}^2 \to \mathbb{C}$ be $v \mapsto \langle\psi_\perp(\vec{n})|v\rangle$, the component along the excited state of Example 10.58 (well defined up to a phase, which does not change kernels). Each $\alpha(\vec{n})$ is onto, so $\operatorname{Ker}\alpha^* = 0$, and $\operatorname{Ker}\alpha(\vec{n}) = \mathbb{C}|\psi(\vec{n})\rangle$ is the ground-state line. Hence

$$\operatorname{Index}\alpha_{S^2} = [L] \in K(S^2), \qquad \text{rank } 1, \quad c_1 = -1.$$

The ordinary index (the rank, $2 - 1 = 1$) sees nothing. The first Chern class sees the Berry monopole. Anomalies live in exactly this extra information.

The Atiyah–Jänich theorem. The index bundle depends only on the homotopy class of α, and every element of $K(X)$ arises. That is [Nash (10.69), (10.72)]:

$$\operatorname{Index} : [X, \mathcal{F}(H)] \xrightarrow{\cong} K(X), \qquad [\alpha] \mapsto [\operatorname{Ker}\alpha] - [\operatorname{Ker}\alpha^*] = \operatorname{Index}\alpha_X. \tag{10.226}$$

Here $[X, Y]$ means homotopy classes of maps. Nash's name for this: $\mathcal{F}(H)$ is a **classifying space** for K-theory.

Working definition 10.16 (classifying space)

A space B *classifies* a kind of object $\mathcal{E}$ over spaces X if the objects over X [here: K-theory classes $[V] - [W]$ over X, with $B = \mathcal{F}(H)$], up to isomorphism, correspond to homotopy classes of maps $X \to B$ [maps counted as the same when one can be deformed continuously into the other]. *How to use it:* to classify objects over a sphere S^p it is enough to know the homotopy group $\pi_p(B)$ [maps $S^p \to B$ sending a chosen point of S^p to a chosen point of B, up to continuous deformation] (for connected B; in general, based maps).

Nash's footnote 6 recalls the model case from Chapter 1: $[X, \mathrm{Gr}(k, \infty)] \cong \mathrm{Vect}_k(X)$. The Grassmannian of k-planes in $\mathbb{C}^\infty$ classifies rank-k bundles. The map sends x to the fibre E_x, viewed as a k-plane in a big $\mathbb{C}^N$. For $k = 1$, $\mathrm{Gr}(1, \infty) = \mathbb{CP}^\infty$, and line bundles over S^2 are classified by $\pi_2(\mathbb{CP}^\infty) = \mathbb{Z}$, the Chern number. The Berry bundle is the map $\vec{n} \mapsto [\psi(\vec{n})] \in \mathbb{CP}^1 \subset \mathbb{CP}^\infty$, the identification $S^2 \cong \mathbb{CP}^1$, a map of degree one (the sign -1 of c_1 is the convention that the tautological bundle has $c_1 = -1$).

The homotopy type of $\mathcal{F}(H)$. Three facts pin down $\mathcal{F}(H)$ [Nash (10.73)]:

1. $\pi_0(\mathcal{F}) = \mathbb{Z}$, via the index: two Fredholm operators can be joined by a path of Fredholm operators if and only if they have the same index. (One direction is the stability of the index. The other uses the next fact.)

2. **Kuiper's theorem**: the unitary group $\mathrm{U}(H)$ of an infinite-dimensional Hilbert space is contractible. This is very unlike $\mathrm{U}(N)$, and it is why "every component looks the same":

each component of $\mathcal{F}$ is homotopy equivalent to $BU = \lim_N \mathrm{Gr}(N, 2N)$, the classifying space of stable bundles. Altogether $\mathcal{F} \simeq \mathbb{Z} \times BU$.

3. **Bott periodicity**: $\Omega U(\infty) \simeq \mathbb{Z} \times BU$, where $U(\infty) = \bigcup_N U(N)$ and Ω means based loops.

Combining the last two gives Nash's (10.73):

$$\mathcal{F}(H) \simeq \Omega U(\infty). \tag{10.227}$$

Worked example 10.63: A loop of unitaries gives a Fredholm operator: Toeplitz

The equivalence (10.227) can be made explicit. Let $H = L^2(S^1)$ with basis $z^j = e^{ij\theta}$, $j \in \mathbb{Z}$, and let $H_+ = \overline{\mathrm{span}}\{z^j : j \geq 0\}$ with orthogonal projection P_+. A loop $\gamma : S^1 \to U(1)$ acts on H by multiplication. Its **Toeplitz operator** is $T_\gamma = P_+ \gamma P_+ : H_+ \to H_+$. For $\gamma(z) = z$:

$$T_z(z^j) \overset{(1)}{=} P_+(z^{j+1}) = z^{j+1} \quad (j \geq 0),$$
$$\mathrm{index}\, T_z \overset{(2)}{=} \mathrm{index}\, S = -1 = -\,\mathrm{wind}(\gamma).$$

(1) Multiplying by z raises the power; the result is still in H_+.
(2) In the basis $z^0, z^1, \ldots$ this is exactly the shift S of Example 10.60(b); the winding number of $z \mapsto z$ is 1.

In general $\mathrm{index}\, T_\gamma = -\,\mathrm{wind}(\det \gamma)$ for loops in $U(N)$ (with $H_+ \otimes \mathbb{C}^N$). So the map "loop $\mapsto$ Toeplitz operator" takes the winding number, which labels $\pi_0(\Omega U) = \pi_1(U) = \mathbb{Z}$, to minus the index, which labels $\pi_0(\mathcal{F}) = \mathbb{Z}$.

10.10.4 Self-adjoint Fredholm operators and spectral flow

In odd dimensions there is no chirality, and the Dirac operator is self-adjoint. So we need the space $\mathcal{F}^1(H)$ of *self-adjoint* Fredholm operators. Its index is always zero ($\mathrm{Ker}\, T = \mathrm{Ker}\, T^*$), so the index cannot be the invariant. The invariant is subtler.

A self-adjoint Fredholm operator has real spectrum. Near zero there are only finitely many eigenvalues, each of finite multiplicity (otherwise the kernel of a small perturbation would be infinite-dimensional). Far from zero the spectrum may accumulate (for bounded operators) or run off to infinity (for the unbounded originals). The **essential spectrum** is where it accumulates. It splits $\mathcal{F}^1$ into three pieces [Nash p. 293]:

- $\mathcal{F}^1_+$: essential spectrum only positive; finitely many negative eigenvalues. Example: the Laplacian $-\mathrm{d}^2/\mathrm{d}\theta^2$ on S^1 (after bounding), or $\mathbb{1}$.
- $\mathcal{F}^1_-$: essential spectrum only negative; example: $-\mathbb{1}$.
- $\mathcal{F}^1_*$: essential spectrum on both sides; infinitely many eigenvalues of each sign. Example: every Dirac operator $-i\mathrm{d}/\mathrm{d}\theta + a$ on S^1, and every Dirac operator in odd dimensions.

Why $\mathcal{F}^1_\pm$ are contractible. If $T \in \mathcal{F}^1_+$, the straight-line path $T_s = (1-s)T + s\mathbb{1}$, $0 \leq s \leq 1$, stays inside $\mathcal{F}^1_+$: each T_s is self-adjoint, and its essential spectrum is $(1-s)\,\mathrm{ess}(T) + s$, still positive and away from 0. So the whole of $\mathcal{F}^1_+$ contracts to the point $\mathbb{1}$. The same with $-\mathbb{1}$ for $\mathcal{F}^1_-$. Physically: an operator that is bounded below cannot have spectral flow, because there is nowhere for eigenvalues to flow *from*. Nash stresses this at the end of his example (p. 296): "if the Dirac operator had a lowest bound no flow could take place".

The interesting piece. All the topology is in $\mathcal{F}^1_*$. Atiyah and Singer showed [Nash (10.74)–(10.75)]

$$\mathcal{F}^1 \simeq \mathcal{F}^1_* \simeq \Omega\mathcal{F}(H) \simeq \Omega(\Omega\mathrm{U}(\infty)) \simeq \mathrm{U}(\infty), \tag{10.228}$$

the last step being Bott periodicity again, $\Omega^2\mathrm{U} \simeq \mathrm{U}$.

The equivalence $\mathcal{F}^1_* \simeq \mathrm{U}(\infty)$ has a transparent picture. Bound the operator so its spectrum lies in $[-1,1]$, then push the essential spectrum to the two ends ±1 (this is a homotopy). Now map

$$T \longmapsto U_T = -\exp(i\pi T).$$

U_T is unitary. On the essential spectrum ±1 it equals $-e^{\pm i\pi} = 1$, so $U_T - \mathbb{1}$ is compact: U_T lies in the stable unitary group, which is a model of $\mathrm{U}(\infty)$. An eigenvalue λ of T becomes the point $-e^{i\pi\lambda}$ on the unit circle; $\lambda = 0$ goes to -1. *An eigenvalue crossing zero becomes an eigenvalue of U_T crossing -1* (Figure 10.46).

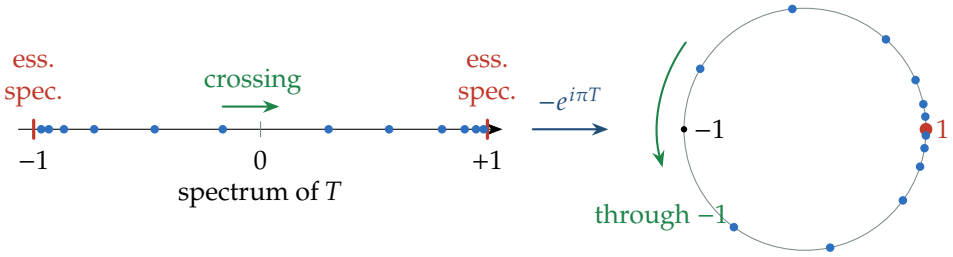

Figure 10.46: The map $T \mapsto -e^{i\pi T}$ from self-adjoint Fredholm operators (spectrum in $[-1,1]$, essential spectrum at the red ends) to unitaries differing from $\mathbb{1}$ by a compact operator. The essential spectrum goes to 1; zero goes to -1. A zero crossing of T (green) becomes a passage of an eigenvalue of U_T through -1, so spectral flow round a loop of T's is a winding number of unitaries.

Worked example 10.64: Spectral flow is a winding number: a telescoping sum

Take the loop $D_t = -i\frac{\mathrm{d}}{\mathrm{d}\theta} + t$, $0 \le t \le 1$ (the case $k = 1$ of Example 10.59). The eigenvalues are $\lambda_n(t) = n + t$. Bound them with $f(\lambda) = \lambda/\sqrt{1+\lambda^2} \in (-1,1)$. Then $U_t = -\exp(i\pi f(D_t))$ has eigenvalues $-e^{i\pi f(n+t)}$, and the change of the total phase of its (regularised) determinant over the loop is

$$\Delta \arg\det U_t \overset{(1)}{=} \pi \sum_{n\in\mathbb{Z}} \big[f(\lambda_n(1)) - f(\lambda_n(0))\big] \overset{(2)}{=} \pi \sum_{n\in\mathbb{Z}} \big[f(n+1) - f(n)\big]$$
$$\overset{(3)}{=} \pi\Big[\lim_{N\to\infty} f(N+1) - \lim_{N\to\infty} f(-N)\Big] \overset{(4)}{=} \pi\,[1-(-1)] = 2\pi.$$

(1) The phase of $\det U$ is the sum of the phases of the eigenvalues; follow each eigenvalue continuously in t.
(2) $\lambda_n(1) = n+1$ and $\lambda_n(0) = n$.
(3) The sum telescopes (sum from $-N$ to N and let $N \to \infty$).
(4) $f(\lambda) \to \pm1$ as $\lambda \to \pm\infty$.

So the loop of unitaries winds once: the element of $\pi_1(\mathrm{U}(\infty)) = \mathbb{Z}$ is 1. The spectrum of D_1 is the same set as that of D_0, but every eigenvalue has moved up one slot, and one of them crossed zero. The telescoping sum only "sees" the two ends of the spectrum. That is why spectral flow needs a spectrum unbounded in both directions: if the spectrum had a bottom, the second limit would be a fixed finite eigenvalue and the flow would be zero.

Homotopy groups. With $\mathcal{F} \simeq \Omega\mathrm{U}$ and $\mathcal{F}^1 \simeq \mathrm{U}$ we can read off the homotopy groups from those of the stable unitary group, $\pi_k(\mathrm{U}(\infty)) = \mathbb{Z}$ for k odd and 0 for k even (Bott; for small

k: $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$ is the winding number, $\pi_3(\mathrm{SU}(2)) = \pi_3(S^3) = \mathbb{Z}$ is the instanton number, $\pi_2(\mathrm{U}(N)) = 0$). Hence [Nash (10.76)]:

$$\pi_k(\mathcal{F}(H)) \overset{(1)}{=} \pi_k(\Omega\mathrm{U}) \overset{(2)}{=} \pi_{k+1}(\mathrm{U}) = \begin{cases} \mathbb{Z} & k \text{ even} \\ 0 & k \text{ odd} \end{cases} \tag{10.229}$$

$$\pi_k(\mathcal{F}^1(H)) \overset{(3)}{=} \pi_k(\mathrm{U}) = \begin{cases} 0 & k \text{ even} \\ \mathbb{Z} & k \text{ odd} \end{cases} \tag{10.230}$$

(1) The homotopy equivalence (10.227).
(2) A map $S^k \to \Omega Y$ is the same as a map $S^k \times S^1 \to Y$ sending the based circles to the base point, i.e. a map $S^{k+1} \to Y$: $\pi_k(\Omega Y) = \pi_{k+1}(Y)$.
(3) The homotopy equivalence (10.228).

k	0	1	2	3	4	5
$\pi_k(\mathrm{U}(\infty))$	0	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$
$\pi_k(\mathcal{F})$	$\mathbb{Z}$ (index)	0	$\mathbb{Z}$ (c_1 of index bundle)	0	$\mathbb{Z}$	0
$\pi_k(\mathcal{F}^1)$	0	$\mathbb{Z}$ (spectral flow)	0	$\mathbb{Z}$	0	$\mathbb{Z}$

The first entries have physical names. $\pi_0(\mathcal{F}) = \mathbb{Z}$ is the ordinary index (zero modes of an instanton). $\pi_1(\mathcal{F}^1) = \mathbb{Z}$ is spectral flow round a loop. $\pi_2(\mathcal{F}) = \mathbb{Z}$ is the first Chern class of the index bundle over a 2-sphere, which is how the local anomaly was detected in Chapter 10, §2, and which (Example 10.62) is the Berry monopole.

Watch out: Berry bundles and $\pi_2(\mathcal{F}^1) = 0$

The Berry example is a 2-sphere family of self-adjoint 2×2 matrices with a nontrivial Chern number, yet $\pi_2(\mathcal{F}^1) = 0$. There is no contradiction. The Berry bundle is defined over the space of *invertible* (gapped) self-adjoint operators, and records how the negative-energy subspace twists. Inside all of $\mathcal{F}^1$ the same sphere can be shrunk by passing through operators with zero modes, as the sphere $|\vec{B}| = 1$ shrinks to $\vec{B} = 0$ through the degeneracy. In infinite dimensions the gapped self-adjoint operators in $\mathcal{F}^1_*$ form a space homotopy equivalent to $\mathcal{F} \simeq \mathbb{Z} \times B\mathrm{U}$ (the "restricted Grassmannian" of negative-energy subspaces). Its π_2 is $\mathbb{Z}$: this is where the vacuum line bundles of Section 10.10.12 live.

10.10.5 Only $n + p$ matters

Back to anomalies. Restrict the parameter space to a sphere, $X = S^p$. Then [Nash (10.77)]

$$\not{D}^{(n)}_{(t_1,\dots,t_p)} \in \begin{cases} \mathcal{F}(H) & n \text{ even (the chiral operator } E^+ \to E^-), \\ \mathcal{F}^1(H) & n \text{ odd (the self-adjoint Dirac operator),} \end{cases}$$

and the topology of the anomaly is in the index bundle over S^p, i.e. in the homotopy class of the map $S^p \to \mathcal{F}$ or $S^p \to \mathcal{F}^1$ [Nash (10.78)]:

$$\pi_p(\mathcal{F}(H)) \quad (n \text{ even}), \qquad \pi_p(\mathcal{F}^1(H)) \quad (n \text{ odd}).$$

Now use the table.

- $n + p$ even. Then n, p are both even or both odd. If both even: $\pi_p(\mathcal{F}) = \mathbb{Z}$. If both odd: $\pi_p(\mathcal{F}^1) = \mathbb{Z}$. Either way $\mathbb{Z}$.

- $n+p$ odd. Then one is even and one odd. If n even, p odd: $\pi_p(\mathcal{F}) = 0$. If n odd, p even: $\pi_p(\mathcal{F}^1) = 0$. Either way 0.

A single formula covers all cases [Nash (10.79)]:

$$\text{anomaly group} \overset{(1)}{=} \begin{cases} \pi_p(\Omega \mathrm{U}) = \pi_{p+1}(\mathrm{U}) & n \text{ even} \\ \pi_p(\mathrm{U}) & n \text{ odd} \end{cases} \overset{(2)}{=} \pi_{n+p+1}(\mathrm{U}(\infty)) \overset{(3)}{=} \pi_{n+p}(\Omega \mathrm{U}(\infty)). \quad (10.231)$$

(1) (10.227) and (10.228).
(2) Bott periodicity makes $\pi_k(\mathrm{U})$ depend only on k mod 2. For n even $p+1 \equiv n+p+1$; for n odd $p \equiv n+p+1 \pmod 2$.
(3) $\pi_k(\Omega Y) = \pi_{k+1}(Y)$.

It is $\mathbb{Z}$ for $n+p$ even and 0 for $n+p$ odd. The Euclidean (n,p) and the Hamiltonian $(n-1,p+1)$ descriptions of the same anomaly lie on the same diagonal of Figure 10.45 and so have the same anomaly group.

Worked example 10.65: Checking the diagonal on three cases

(i) Instantons, $(n,p) = (4,0)$. A single chiral Dirac operator on S^4: $\pi_0(\mathcal{F}) = \mathbb{Z}$, the index = instanton number (Chapter 8). *(ii) The 4D local anomaly,* $(4,2)$*, and its Hamiltonian form* $(3,3)$. In §2 the anomaly of SU(N) on S^4 was the Chern class of the determinant bundle over a 2-sphere in $\mathcal{A}/\mathcal{G}$: $\pi_2(\mathcal{F}) = \mathbb{Z}$. In the Hamiltonian picture space is S^3, the Dirac Hamiltonian is self-adjoint, and the family is over a 3-sphere: $\pi_3(\mathcal{F}^1) = \mathbb{Z}$. Same diagonal $n+p=6$. *(iii) The torus and the circle,* $(2,0)$ *and* $(1,1)$. The chiral operator D_A on T^2 has an index ($\pi_0(\mathcal{F}) = \mathbb{Z}$). Its Hamiltonian version is the loop D_t of self-adjoint operators on S^1, whose invariant is spectral flow ($\pi_1(\mathcal{F}^1) = \mathbb{Z}$). This pair is Nash's worked example, done in full in Section 10.10.7, where we will see that the index on T^2 and the spectral flow on S^1 are the same integer k.

Physical picture: Why the parity of $n+p$

Each step up in dimension adds one gamma matrix; each extra parameter, through (10.225), also adds one. Chirality (and hence the distinction between $\mathcal{F}$ and $\mathcal{F}^1$) depends on whether the total number of gamma matrices is even or odd. So a parameter and a dimension are interchangeable, and only their total counts. The same count explains the familiar descent: a $2m$-dimensional anomaly comes from a $(2m+2)$-form ch_{m+1}, i.e. from "two more dimensions".

10.10.6 The real case and Witten's SU(2) anomaly again

Global anomalies can involve *real* operators. In Section 10.9.5 we saw that for an SU(2) doublet the pseudo-real structure makes the Weyl operator equivalent to a real skew-adjoint operator, whose kernel dimension is invariant only mod 2. So we should redo the Fredholm analysis on a real Hilbert space H_r [Nash p. 294].

Replacing H by H_r replaces U(∞) by the infinite orthogonal group O(∞), and complex K-theory K by real K-theory KO:

- $\mathcal{F}(H_r)$ classifies KO: $[X, \mathcal{F}(H_r)] \cong KO(X)$, by the real version of the index map (10.226).
- The space $\mathcal{F}^1_{\text{skew}}(H_r)$ of real skew-adjoint Fredholm operators is homotopy equivalent to O(∞) (Atiyah and Singer).

The global anomaly is captured by

$$\pi_0\big(\mathcal{F}^1_{\text{skew}}(H_r)\big) = \pi_0(\mathrm{O}(\infty)) = \mathbb{Z}_2,$$

in agreement with Witten's $\mathbb{Z}_2$ of Section 10.9. The two components of $\mathrm{O}(N)$ are det $= \pm 1$, and the corresponding invariant of a real skew operator is the parity of dim Ker.

Worked example 10.66: Why only the parity of the kernel survives

A real skew-symmetric matrix K ($K^T = -K$) has eigenvalues in pairs $\pm i\mu$ ($\mu > 0$) plus zeros. For $K = \left(\begin{smallmatrix} 0 & \mu \\ -\mu & 0 \end{smallmatrix}\right)$, the characteristic polynomial is $\lambda^2 + \mu^2$, roots $\pm i\mu$. Deforming K can move a pair $\pm i\mu$ to 0 (as $\mu \to 0$, two zero modes appear) or split two zero modes into a pair, but can never create or destroy a *single* zero mode. So

$$\dim \mathrm{Ker}\, K \bmod 2$$

is a deformation invariant: the **mod-2 index**. An odd-size real skew matrix always has a kernel ($\det K = \det K^T = (-1)^N \det K$ forces $\det K = 0$ for N odd). In Witten's argument, the five-dimensional operator built from a loop of four-dimensional SU(2) operators by (10.225) is of this kind, and its mod-2 index is 1 for the non-trivial loop: that is the sign flip of the Pfaffian.

k mod 8	0	1	2	3	4	5	6	7
$\pi_k(\mathrm{O}(\infty))$	$\mathbb{Z}_2$	$\mathbb{Z}_2$	0	$\mathbb{Z}$	0	0	0	$\mathbb{Z}$

Real Bott periodicity has period 8. The $\mathbb{Z}_2$'s in this table are the source of every mod-2 global anomaly; the $\mathbb{Z}_2$ at $k = 0$ is the one Nash uses.

Reading Nash (pp. 291–295, (10.67)–(10.79))

(10.67)–(10.68) are the $n + p$ trick of Section 10.10.2. (10.69) and (10.72) are the Atiyah–Jänich theorem; Nash writes the index map as $[\alpha] \mapsto [\mathrm{Ker}\,\alpha] - [\mathrm{Ker}\,\alpha^*]$, which is literally correct only when the kernel dimensions are constant; Example 10.61 shows the general repair. (10.73) is $\mathcal{F} \simeq \Omega\mathrm{U}(\infty)$: Kuiper plus Bott. In the text before (10.74) Nash's $\mathcal{F}^1_+$ is the part with "only a finite number of negative eigenvalues" and $\mathcal{F}^1_-$ the part with finitely many positive ones; both are contractible, so the topology is carried by $\mathcal{F}^1_*$. (10.74)–(10.75) are Atiyah–Singer plus Bott. (10.76) is our table. (10.77)–(10.79) is the parity count of Section 10.10.5; note that Nash's (10.79) is stated with $\Omega\mathrm{U}(\infty)$, i.e. it is $\pi_{n+p}(\mathcal{F})$. On p. 294–295 he treats the real case with $\mathrm{O}(\infty)$ and $\mathcal{F}^1_{\text{skew}}(H_r)$.

10.10.7 Example: spectral flow and an anomaly in two dimensions

We now do Nash's first example completely. It is the smallest system in which every idea of the section can be seen with explicit functions: an abelian U(1) gauge theory on the two-dimensional torus $T^2 = S^1 \times S^1$. We look at it twice. First as a Euclidean space-time, where the relevant object is the *index* of one chiral Dirac operator. Then as "space = circle, time = the other circle", where the relevant object is the *spectral flow* of a loop of self-adjoint operators. The diagonal of Figure 10.45 predicts that the two numbers agree, since $(n, p) = (2, 0)$ and $(1, 1)$ both have $n + p = 2$. We shall check that they do, and see *why* they do.

The Euclidean side. On the even-dimensional torus we have chirality, so we have a chiral Dirac operator $\not{D}_A$ coupled to a U(1) connection A. In two dimensions the local anomaly

computed in §2 is a two-form, $\propto \mathrm{d}(\text{gauge parameter}\cdot A)$, and on a single line bundle it integrates to something with no topology; what is left is the fact that the torus carries *non-trivial* U(1) bundles [Nash p. 295]. These are the two-dimensional abelian "instantons". Line bundles over T^2 are classified by one integer, the first Chern number

$$k = c_1(L)[T^2] = \frac{1}{2\pi}\int_{T^2} F \in \mathbb{Z},$$

(here in the physicists' convention with a real field strength F; in the anti-Hermitian convention $F_{\text{math}} = -iF$ and $c_1 = \frac{i}{2\pi}F_{\text{math}}$), and the index theorem of Chapter 4 gives

$$\operatorname{index} \not{D}_A = \int_{T^2} \operatorname{ch}(F)\,\hat{A}(T^2) = \int_{T^2} \frac{F}{2\pi} = k,$$

because the flat torus has $\hat{A} = 1$, and only the degree-two part $\operatorname{ch}_1 = F/2\pi$ of $\operatorname{ch}(F)$ can be integrated over a surface. In the language of Fredholm families this is the case where the parameter space X is a point: the index map $[X, \mathcal{F}(H)] \to K(X)$ becomes $\pi_0(\mathcal{F}) \to K(\text{point}) = \mathbb{Z}$, which is just "a Fredholm operator $\mapsto$ its index".

Worked example 10.67: The line bundle of charge k on the torus, explicitly

Use coordinates (t, θ) with $t \in [0,1]$ and $\theta \in [0, 2\pi]$. A section of a line bundle over T^2 is a function $\psi(t,\theta)$, 2π-periodic in θ, that returns to itself after $t \mapsto t+1$ only *up to a transition function*. Take

$$\psi(t+1,\theta) = e^{-ik\theta}\,\psi(t,\theta), \qquad a = kt\,\mathrm{d}\theta, \tag{10.232}$$

where a is the gauge field, entering the covariant derivative as $\mathrm{d} + ia$ (physicists' convention, charge 1). Check that the pair is consistent and compute the Chern number:

$$a(t+1) \overset{(1)}{=} a(t) + k\,\mathrm{d}\theta \overset{(2)}{=} a(t) + \mathrm{d}(k\theta),$$
$$F \overset{(3)}{=} \mathrm{d}a = k\,\mathrm{d}t \wedge \mathrm{d}\theta,$$
$$\frac{1}{2\pi}\int_{T^2} F \overset{(4)}{=} \frac{k}{2\pi}\int_0^1 \mathrm{d}t \int_0^{2\pi} \mathrm{d}\theta = k.$$

(1) Substitute $t+1$ in $a = kt\,\mathrm{d}\theta$.

(2) So the two ends of the t-interval differ by the gauge transformation with parameter $\chi = k\theta$. Under $\psi \mapsto e^{-i\chi}\psi$, $a \mapsto a + \mathrm{d}\chi$ the covariant derivative is covariant: $(\mathrm{d} + i(a + \mathrm{d}\chi))(e^{-i\chi}\psi) = e^{-i\chi}(\mathrm{d} + ia)\psi$. This is exactly the gluing (10.232). The function $e^{-ik\theta}$ is single valued on the circle only because $k \in \mathbb{Z}$: that is why the Chern number is an integer.

(3) $\mathrm{d}(kt\,\mathrm{d}\theta) = k\,\mathrm{d}t \wedge \mathrm{d}\theta$; the field is uniform.

(4) Orient the torus by $\mathrm{d}t \wedge \mathrm{d}\theta$.

The bundle is trivial exactly when $k = 0$. For $k \neq 0$ it has no nowhere-vanishing section: a section would have to wind k times round the θ-circle between $t = 0$ and $t = 1$, which forces a zero.

The Hamiltonian side. Now we switch viewpoint [Nash p. 295]. Declare the θ-circle to be *space* and t to be a parameter. On the spatial circle the Dirac operator is self-adjoint (there is no chirality in one dimension), and with the gauge field $a = kt\,\mathrm{d}\theta$ it is simply [Nash (10.80)]

$$\not{D}^1_t = -i\frac{\mathrm{d}}{\mathrm{d}\theta} + kt, \qquad 0 \le t \le 1, \quad k \in \mathbb{Z}. \tag{10.233}$$

This is the Dirac Hamiltonian of a charged particle of one chirality (a right mover) on a ring threaded by the magnetic flux $\oint a = 2\pi kt$. As t goes from 0 to 1 the flux grows by $2\pi k$, i.e. by k flux quanta. Since the other circle of the torus is no longer Euclidean time but a parameter, we are looking at a one-parameter family of one-dimensional operators: $n = 1$, $p = 1$. By (10.230) the anomaly is measured by an element of $\pi_1(\mathcal{F}^1(H)) = \mathbb{Z}$, and the integer is computed by the spectral flow technique of Atiyah and Lusztig (and of Atiyah–Patodi–Singer).

The spectrum. The functions $e^{in\theta}$, $n \in \mathbb{Z}$, are eigenfunctions:

$$\not{D}_t^1 \, e^{in\theta} = \big(-i \cdot in + kt\big) e^{in\theta} = (n + kt)\, e^{in\theta}.$$

So the eigenvalues are [Nash (10.81)]

$$\lambda_n(t) = n + kt, \qquad n = \dots, -1, 0, 1, \dots \tag{10.234}$$

At the two ends of the family [Nash (10.82)],

$$\operatorname{spec} \not{D}_0^1 = \{n : n \in \mathbb{Z}\}, \qquad \operatorname{spec} \not{D}_1^1 = \{n + k : n \in \mathbb{Z}\} = \mathbb{Z}.$$

As sets the two spectra coincide. But if we follow each eigenvalue continuously, we find [Nash (10.83)]

$$\lambda_n(1) = \lambda_n(0) + k : \tag{10.235}$$

every eigenvalue has moved up k places. In particular the k eigenvalues $\lambda_{-1}, \dots, \lambda_{-k}$, which were negative at $t = 0$, are positive (or zero) at $t = 1$. They have crossed zero.

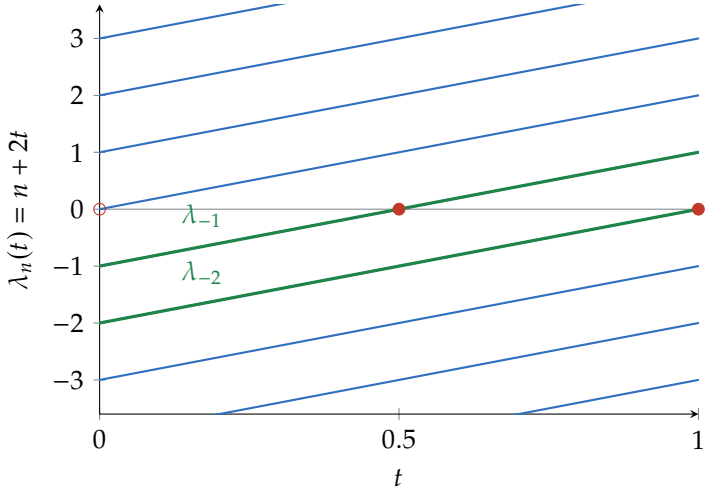

Figure 10.47: Spectral flow of $\not{D}_t^1 = -i\,\mathrm{d}/\mathrm{d}\theta + kt$ for $k = 2$. Each eigenvalue is a straight line of slope k. The set of eigenvalues is the same at $t = 0$ and $t = 1$ (all integers), but each line has climbed two places. Two lines (green) cross zero during the circuit, at the red dots $t = \frac{1}{2}$ and $t = 1$. The line through the open dot at $t = 0$ is the one that the next circuit counts at $t = 1$. The spectral flow is $2 = k$. The spectrum is unbounded in both directions, which is what makes a net upward drift possible.

Working definition 10.17 (spectral flow)

Let D_t, $0 \le t \le 1$, be a continuous family of self-adjoint Fredholm operators [real eigenvalues, with only finitely many independent zero modes and no pile-up of eigenvalues near 0, so the crossings of zero can be counted] whose end points have the same spectrum.

Follow the eigenvalues continuously in t. The **spectral flow** is

$$\mathrm{sf}(D_t) = \#\{\text{crossings from } <0 \text{ to } >0\} - \#\{\text{crossings from } >0 \text{ to } <0\}.$$

How to compute it: plot the eigenvalues against t (a "spectral-flow diagram" like Figure 10.47) and count signed crossings of the axis $\lambda = 0$. *Convention at the end points:* if some eigenvalue is exactly 0 at $t = 0$ (as here), replace D_t by $D_t - \delta$ with a small $\delta > 0$ that is not an eigenvalue; this does not change the answer for a closed loop and makes the count unambiguous. For Nash's family, with δ small, the crossings are at $t = (\delta - n)/k$ for $n = 0, -1, \dots, -(k-1)$: exactly k of them in $[0, 1]$.

The count is a (signed) integer, and in this example it is k [Nash p. 296]. Nash stresses two general points. First, in more complicated families both kinds of crossings happen, and only the net number is an invariant: a pair of crossings in opposite directions can be created or destroyed by a deformation of the family, a single crossing cannot. Second, *the spectrum must be unbounded in both directions*. The next example shows why.

Worked example 10.68: A loop of finite matrices has no spectral flow

Let D_t be a loop of Hermitian $N \times N$ matrices, $D_1 = D_0$. Let $N_-(t)$ be the number of negative eigenvalues. It changes only at crossings: it drops by one each time an eigenvalue goes from negative to positive and rises by one for each crossing the other way. So

$$\begin{aligned}\mathrm{sf}(D_t) &\overset{(1)}{=} \big[\text{number of } (- \to +)\big] - \big[\text{number of } (+ \to -)\big] \\ &\overset{(2)}{=} N_-(0) - N_-(1) \overset{(3)}{=} 0.\end{aligned}$$

(1) Definition of spectral flow.
(2) Each $(- \to +)$ crossing lowers N_- by one, each $(+ \to -)$ raises it by one; add up the changes along the path.
(3) $D_1 = D_0$, so they have the same number of negative eigenvalues.

A concrete loop with crossings: $D_t = \left(\begin{smallmatrix} \cos 2\pi t & 0 \\ 0 & -\cos 2\pi t \end{smallmatrix}\right)$. Its eigenvalues $\pm\cos 2\pi t$ cross zero at $t = \frac{1}{4}$ and $t = \frac{3}{4}$, once in each direction for each line: net flow 0. In infinite dimensions the argument fails because $N_- = \infty$ and "$\infty - \infty$" can be any integer. Nash's family is the simplest case: every eigenvalue climbs by k, and there is no bottom rung to push the spectrum against. For an operator bounded below (in $\mathcal{F}_+^1$) the argument above applies with N_- finite, so the spectral flow vanishes; this is the physical content of the contractibility of $\mathcal{F}_\pm^1$ in Section 10.10.4.

The family is a loop up to a gauge transformation. The family (10.233) is not periodic in t: $\not{D}_1^1 \neq \not{D}_0^1$ as operators. But the two end points are related by conjugation [Nash (10.84)]:

$$\not{D}_1^1 = e^{-ik\theta}\, \not{D}_0^1\, e^{ik\theta}. \tag{10.236}$$

Let us verify it on a test function $f(\theta)$:

$$\begin{aligned}e^{-ik\theta}\not{D}_0^1\big(e^{ik\theta}f\big) &\overset{(1)}{=} e^{-ik\theta}(-i)\frac{\mathrm{d}}{\mathrm{d}\theta}\big(e^{ik\theta}f\big) \\ &\overset{(2)}{=} e^{-ik\theta}(-i)\big(ik\,e^{ik\theta}f + e^{ik\theta}f'\big) \\ &\overset{(3)}{=} -if' + kf \overset{(4)}{=} \not{D}_1^1 f.\end{aligned}$$

(1) $\not{D}^1_0 = -i\,\mathrm{d}/\mathrm{d}\theta$.
(2) Product rule.
(3) Cancel $e^{-ik\theta}e^{ik\theta} = 1$; $(-i)(ik) = k$.
(4) $\not{D}^1_1 = -i\,\mathrm{d}/\mathrm{d}\theta + k$ by (10.233) at $t = 1$.

This is the familiar gauge covariance of the Dirac operator, $\not{D}_{A_g} = g^{-1}\not{D}_A g$ of §2, for the gauge transformation $g = e^{ik\theta}$, which is a map $S^1 \to \mathrm{U}(1)$ of winding number k: a *large* gauge transformation. So the path $t \mapsto \not{D}^1_t$ in the space of operators becomes a *closed loop* once we identify gauge equivalent operators, i.e. a loop in $\mathcal{A}/\mathcal{G}$ for the circle, and it is this loop whose class in $\pi_1(\mathcal{F}^1(H)) = \mathbb{Z}$ Nash computes.

If we prefer an honest loop inside $\mathcal{F}^1(H)$ itself, Kuiper's theorem (Section 10.10.3) supplies one. The unitary group of H is contractible, so there is a path U_s in $\mathrm{U}(H)$ from $U_0 = \mathbb{1}$ to $U_1 = e^{ik\theta}$ (it cannot consist of multiplication operators, since $e^{ik\theta}$ has winding number k, but it exists among all unitaries). Close the family by returning from $\not{D}^1_1$ to $\not{D}^1_0$ along $s \mapsto U_s^{-1}\cdots$, precisely $s \mapsto U_s \not{D}^1_1 U_s^{-1}$ run from $s = 0$ to $s = 1$: at $s = 0$ it is $\not{D}^1_1$ and at $s = 1$ it is $e^{ik\theta}\not{D}^1_1 e^{-ik\theta} = \not{D}^1_0$. Every operator on the return path is unitarily equivalent to $\not{D}^1_1$, so its spectrum does not move at all, and the return path contributes no spectral flow. The closed loop therefore has spectral flow k, and represents k times the generator of $\pi_1(\mathcal{F}^1) = \mathbb{Z}$.

Physical picture: What the gauge transformation does to the eigenvectors

Under conjugation by $e^{ik\theta}$ the eigenvector $e^{in\theta}$ of $\not{D}^1_0$ (eigenvalue n) becomes the eigenvector $e^{-ik\theta}e^{in\theta} = e^{i(n-k)\theta}$ of $\not{D}^1_1$, with eigenvalue $(n-k)+k = n$. So the gauge transformation matches the two ends of the family eigenvalue by eigenvalue, but it relabels the eigenvectors, shifting the label by k. The spectral flow is this relabelling made visible: following the eigenvector $e^{in\theta}$ continuously in t takes eigenvalue n to $n+k$, while the gauge identification says "eigenvalue $n+k$ at $t = 1$ is the same state as eigenvalue $n+k$ at $t = 0$". The mismatch is k rungs of an infinite ladder.

10.10.8 The index on the torus, computed

Nash ends his example with the remark that the integer k "is also the index of the chiral Dirac operator $\not{D}_A$ on the torus. To check this explicitly one would have to calculate the null spaces of $\not{D}_A$ and $\not{D}^*_A$ on the torus using" [Nash (10.85)]

$$\not{D}_A = \not{D}^1_t + \frac{\partial}{\partial t} = \frac{\partial}{\partial t} - i\frac{\partial}{\partial \theta} + kt. \tag{10.237}$$

This is the $n+p$ operator (10.225) for our family, as we saw in Example 10.59. It acts on sections of the charge-k line bundle of Example 10.67, so its domain is functions obeying the twisted periodicity (10.232). We now do the calculation.

Worked example 10.69: The zero modes of $\not{D}_A$ are theta functions

Step 1: reduce to ordinary differential equations. Expand in Fourier modes of the spatial circle, $\psi(t,\theta) = \sum_{n\in\mathbb{Z}} c_n(t)e^{in\theta}$. Then

$$\not{D}_A\psi = 0 \overset{(1)}{=} \sum_n \big(\dot{c}_n + (n+kt)c_n\big)e^{in\theta} = 0$$

$$\iff \dot{c}_n \overset{(2)}{=} -\lambda_n(t)\,c_n$$

$$\Longleftrightarrow\quad c_n(t) \overset{(3)}{=} a_n \exp\!\Big(-\frac{(n+kt)^2}{2k}\Big) \qquad (k\neq 0).$$

(1) Apply (10.237) term by term; $e^{in\theta}$ is an eigenfunction of $-i\partial_\theta + kt$ with eigenvalue $\lambda_n(t) = n + kt$.
(2) The exponentials are independent, so each coefficient vanishes. Each Fourier mode evolves in t with its own instantaneous eigenvalue.
(3) Integrate: $-\int \lambda_n \mathrm{d}t = -(nt + \frac{k}{2}t^2) = -\frac{(n+kt)^2}{2k} + \frac{n^2}{2k}$; absorb the constant $e^{n^2/2k}$ into the constant a_n.

Step 2: impose the twisted periodicity. The condition $\psi(t+1,\theta) = e^{-ik\theta}\psi(t,\theta)$ reads

$$\sum_n c_n(t+1)e^{in\theta} \overset{(1)}{=} \sum_m c_m(t)e^{i(m-k)\theta} \overset{(2)}{=} \sum_n c_{n+k}(t)e^{in\theta},$$

$$\text{so}\quad c_n(t+1) = c_{n+k}(t) \quad\Longleftrightarrow\quad a_n e^{-(n+k+kt)^2/2k} \overset{(3)}{=} a_{n+k}e^{-(n+k+kt)^2/2k}.$$

(1) Multiply the Fourier series by $e^{-ik\theta}$.
(2) Rename $m = n + k$.
(3) Insert the solution of Step 1: in $c_n(t+1)$ the exponent contains $n+k(t+1) = (n+k)+kt$, the same as in $c_{n+k}(t)$.

So $a_{n+k} = a_n$: the coefficients depend only on n mod k. For $k > 0$ there are exactly k free constants $a_0, \dots, a_{k-1}$, giving k solutions

$$\psi_r(t,\theta) = \sum_{j\in\mathbb{Z}} \exp\!\Big(-\frac{(r+jk+kt)^2}{2k}\Big)\, e^{i(r+jk)\theta}, \qquad r = 0,1,\dots,k-1. \tag{10.238}$$

Step 3: they are normalisable. Using $|e^{i(r+jk)\theta}| = 1$ and the orthogonality of different Fourier modes,

$$\|\psi_r\|^2 \overset{(1)}{=} 2\pi \sum_{j\in\mathbb{Z}} \int_0^1 \exp\!\Big(-\frac{(r+jk+kt)^2}{k}\Big)\mathrm{d}t \overset{(2)}{=} 2\pi \int_{-\infty}^{\infty} \exp\!\Big(-\frac{(r+ks)^2}{k}\Big)\mathrm{d}s \overset{(3)}{=} 2\pi\sqrt{\frac{\pi}{k}}.$$

(1) Integrate $|\psi_r|^2$ over $\theta \in [0, 2\pi]$: cross terms between different j integrate to zero.
(2) Put $s = t + j$: the sum over j of integrals over unit intervals is one integral over the whole line.
(3) Gaussian integral: substitute $u = r + ks$, $\int e^{-u^2/k}\mathrm{d}u/k = \sqrt{\pi k}/k$.

Step 4: the adjoint. $\not{D}_A^* = -\partial_t - i\partial_\theta + kt$ (the t-derivative changes sign, $\not{D}_t^1$ is self-adjoint). The same steps give $\dot{c}_n = +\lambda_n c_n$, i.e. $c_n \propto \exp(+(n+kt)^2/2k)$, which grows like a Gaussian in the wrong direction: for $k > 0$ the sum does not converge and there is no normalisable solution. Hence

$$\operatorname{index}\not{D}_A = \dim\operatorname{Ker}\not{D}_A - \dim\operatorname{Ker}\not{D}_A^* = k - 0 = k \qquad (k > 0).$$

For $k < 0$ the roles swap: $\operatorname{Ker}\not{D}_A = 0$ and $\dim\operatorname{Ker}\not{D}_A^* = |k|$, so again $\operatorname{index}\not{D}_A = k$. For $k = 0$ the bundle is trivial, both kernels are the constants, and the index is 0. In every case the index is the Chern number, as the index theorem said, and it equals the spectral flow of the Hamiltonian family.

Why they are called theta functions. Write $w = \theta + it$. Expanding the square in (10.238),

$$\psi_r = e^{-kt^2/2} \sum_{n \equiv r \ (k)} e^{-n^2/2k}\, e^{in(\theta+it)} = e^{-kt^2/2} \sum_{n \equiv r \ (k)} e^{-n^2/2k}\, e^{inw}.$$

Apart from the Gaussian prefactor, this is a holomorphic function of w, a **Jacobi theta function** with characteristic r/k. That is no accident: in the complex coordinate w the chiral Dirac operator on a surface is a $\bar\partial$-operator, $\partial_t - i\partial_\theta = 2i\,\partial_{\bar w}$ (check: $\partial_{\bar w} = \frac{1}{2}(\partial_\theta + i\partial_t)$), so its zero modes are holomorphic sections of the line bundle. The prefactor $e^{-kt^2/2}$ accounts for the term kt in (10.237): it is the change of trivialisation from the unitary gauge $a = kt\,\mathrm{d}\theta$ to a holomorphic one. The Riemann–Roch count of holomorphic sections of a degree k line bundle on a torus, $\dim H^0 = k$ (Chapter 5), is our count of k theta functions.

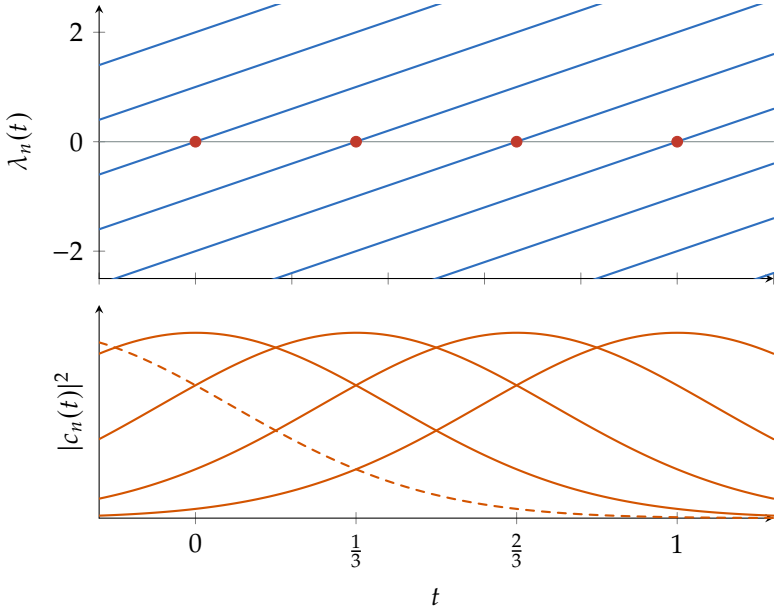

Figure 10.48: Index = spectral flow, seen in the zero modes ($k = 3$). Top: the spectral-flow diagram of $\not{D}^1_t$; eigenvalues cross zero at $t = 0, \frac{1}{3}, \frac{2}{3}, 1, \ldots$ (red). Bottom: the Fourier coefficients $|c_n(t)|^2 = e^{-(n+kt)^2/k}$ of the zero modes of $\not{D}_A$ on the torus. Each is a Gaussian centred exactly at the time when its eigenvalue $\lambda_n(t)$ crosses zero. One period of t contains k crossings, and the twisted periodicity glues the Gaussians into k independent theta functions.

10.10.9 Why the index equals the spectral flow

The picture in Figure 10.48 is general. Let D_t be a family of self-adjoint operators on a compact $(n-1)$-manifold M, depending on $t \in \mathbb{R}$ and approaching fixed invertible operators $D_\pm$ as $t \to \pm\infty$. On the cylinder $\mathbb{R} \times M$ consider

$$\mathcal{D} = \frac{\partial}{\partial t} + D_t.$$

Key idea: Index = spectral flow (Atiyah–Patodi–Singer)

index $\mathcal{D}$ = sf(D_t): the index of the n-dimensional operator $\partial_t + D_t$ is the net number of eigenvalues of the $(n-1)$-dimensional family that cross zero from below. For a loop (or a loop up to gauge transformation, as in Nash's example) the same holds on $S^1 \times M$, with the twisted boundary condition.

Why it is true (the adiabatic argument). Suppose first that D_t changes slowly and that its eigenvectors $\phi_n(t)$ (eigenvalues $\lambda_n(t)$) change slowly too. Look for zero modes of the form $\psi = c(t)\phi_n(t)$, neglecting $\dot\phi_n$ (the adiabatic approximation, as in the Berry-phase calculation (10.224)):

$$\mathcal{D}\psi = 0 \overset{(1)}{=} \dot c\,\phi_n + c\,\lambda_n(t)\phi_n \approx 0 \quad\Longrightarrow\quad c(t) \overset{(2)}{=} c(0)\exp\Big(-\int_0^t \lambda_n(t')\,\mathrm{d}t'\Big).$$

(1) $\partial_t(c\phi_n) = \dot c\phi_n + c\dot\phi_n$, and we drop $c\dot\phi_n$; $D_t\phi_n = \lambda_n\phi_n$.
(2) Solve the linear equation $\dot c = -\lambda_n c$.

When is c square integrable on $\mathbb{R}$? The exponent is $-\int\lambda_n$. As $t\to+\infty$ it must go to $-\infty$, so we need $\lambda_n > 0$ at late times; as $t\to-\infty$ we need $\int_0^t\lambda_n\to+\infty$ for $t\to-\infty$, which requires $\lambda_n<0$ at early times. So:

- a zero mode of $\mathcal{D}$ for every eigenvalue that goes from negative to positive;
- a zero mode of $\mathcal{D}^* = -\partial_t + D_t$ (where $c = e^{+\int\lambda_n}$) for every eigenvalue that goes from positive to negative;
- nothing for eigenvalues that do not change sign (the Gaussian grows at one end).

Subtracting, $\operatorname{index}\mathcal{D} = \#(-\to+) - \#(+\to-) = \operatorname{sf}(D_t)$. The simplest case $\lambda(t) = kt$ gives $c = e^{-kt^2/2}$: exactly the Gaussians of Example 10.69. The general statement (no adiabatic assumption) follows because both sides are deformation invariant: we may always deform the family to a slowly varying one without changing either the index or the spectral flow.

Watch out: Which way is "positive"?

The sign of the answer depends on writing $\partial_t + D_t$ rather than $\partial_t - D_t$, and on the orientation $\mathrm{d}t\wedge\mathrm{d}\theta$ of the torus. Flip either and the index becomes $-\operatorname{sf}$. What is convention independent is the equality of two integers, up to one overall sign fixed once and for all. With our choices, Nash's example gives index $=$ sf $= c_1 = k$.

10.10.10 The Dirac sea: spectral flow creates charge

So far the fermions were first quantised: $\not{D}^1_t$ is a one-particle Hamiltonian. To see the anomaly as a physicist does, we second quantise, and the spectral flow turns into a *non-conservation of charge*: the Hamiltonian form of the Adler–Bell–Jackiw anomaly.

The Dirac sea. Let H be the one-particle Hilbert space with a self-adjoint Hamiltonian h whose spectrum has no zero. Split $H = H^+\oplus H^-$ into the positive and negative spectral subspaces. Dirac's prescription for the ground state of many non-interacting fermions is: *fill every negative-energy level, leave every positive-energy level empty*. For a finite-dimensional H with H^- spanned by orthonormal eigenvectors $\phi_1,\dots,\phi_m$, the many-body ground state is the Slater determinant

$$|\Omega\rangle = \phi_1\wedge\phi_2\wedge\cdots\wedge\phi_m \in \Lambda^m(H).$$

Changing the basis of H^- by a unitary matrix u multiplies $|\Omega\rangle$ by $\det u$; so the *line* through $|\Omega\rangle$ is canonical, it is the line $\Lambda^m(H^-) = \det H^-$, but the vector is not. This is the first appearance of a determinant line in the Hamiltonian picture, and it is the many-body version of the Berry line of Example 10.58. (For a single spin, $H=\mathbb{C}^2$ and $m=1$: the "sea" is the ground state $|\psi(\vec n)\rangle$ itself.)

Adiabatic evolution with spectral flow. Now let the one-particle Hamiltonian be Nash's $\not{D}_t^1$ with t slowly increasing from 0 to 1. Start in the Dirac sea of $\not{D}_0^1$: modes with $\lambda_n(0) = n < 0$ filled. (Resolve the zero mode at $t = 0$ with the δ-shift of the working definition: the mode $n = 0$ is empty.) By the adiabatic theorem each one-particle level is carried along with its occupation number. At $t = 1$:

- the levels $n \le -k-1$ have $\lambda_n(1) = n + k \le -1$: still negative, still filled;
- the k levels $n = -k, \dots, -1$ have $\lambda_n(1) = n + k \in \{0, \dots, k-1\}$: now non-negative, but *still filled*;
- the levels $n \ge 0$ are positive and empty.

The Dirac sea of $\not{D}_1^1$ would have every negative level filled and every non-negative level empty. So the evolved state is the new vacuum *plus* k *particles* in the lowest k positive levels. The field has created k units of charge out of the vacuum (Figure 10.49).

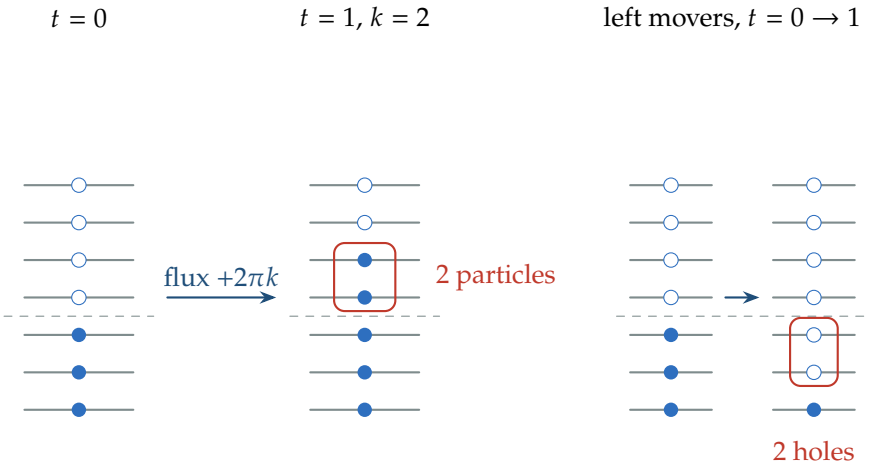

Figure 10.49: The Dirac sea under spectral flow. Levels are drawn by energy (the dashed line is zero energy); filled dots are occupied. Right movers (left two columns): every level climbs $k = 2$ rungs and keeps its occupation, so two occupied levels end up above zero, i.e. two particles are created. Left movers (right panel): the levels move down, two empty levels end up below zero, i.e. two holes (antiparticles) are created. The total charge $N_R + N_L$ is conserved, the chiral charge $N_R - N_L$ changes by $2k$.

Worked example 10.70: The anomaly equation of QED$_2$ from counting levels

Take a massless Dirac fermion on a spatial circle of length 2π: a right mover with $h_R = -i\partial_\theta + a$ and a left mover with $h_L = +i\partial_\theta - a$, where $a(t)$ is the (spatially constant) gauge potential, so the electric field is $E = \dot{a}$ (up to a convention-dependent sign that we fix this way). Let a grow from 0 to k. Count the charges:

$$\Delta N_R \overset{(1)}{=} \mathrm{sf}(h_R) = +k, \qquad \Delta N_L \overset{(2)}{=} \mathrm{sf}(h_L) = -k,$$
$$\Delta Q = \Delta N_R + \Delta N_L = 0, \qquad \Delta Q_5 = \Delta N_R - \Delta N_L = 2k,$$
$$2k \overset{(3)}{=} 2 \cdot \frac{1}{2\pi} \int \mathrm{d}t \oint \mathrm{d}\theta\, \dot{a} \overset{(4)}{=} \frac{1}{\pi} \int \mathrm{d}t \oint \mathrm{d}\theta\, E.$$

(1) h_R is Nash's family, with eigenvalues $n + a$ rising by k; by the adiabatic argument each $(- \to +)$ crossing puts one particle above the new sea.

(2) The eigenvalues of h_L are $-n - a$: they *fall* by k. Each $(+ \to -)$ crossing counts -1 in

sf and takes an empty level below zero, creating a hole, which is charge -1 relative to the new sea. So $\Delta N_L = \mathrm{sf}(h_L) = -k$.

(3) $\oint \mathrm{d}\theta \int \dot{a}\,\mathrm{d}t = 2\pi\,\Delta a = 2\pi k$.

(4) Definition $E = \dot{a}$.

So the vector charge is conserved and the axial charge obeys $\Delta Q_5 = \frac{1}{\pi}\int E$, the integrated form of the local law $\partial_\mu j_5^\mu = \frac{e}{\pi}E = \frac{e}{2\pi}\epsilon^{\mu\nu}F_{\mu\nu}$ (with $e = 1$), which the QFT notes derive from the vacuum polarisation diagram [QFT notes §22.2, (22.2.27)]. No Feynman diagram was needed: the anomaly *is* the spectral flow. If only the right mover were present and coupled to a (a chiral gauge theory), the gauge charge itself would not be conserved: that is a gauge anomaly, and it is the situation that the rest of this section analyses.

The vacuum charge and the eta invariant. How can a charge "appear" in an adiabatic process where every level keeps its occupation? Because the charge of an infinite Dirac sea is itself an infinite quantity that must be regularised, and the regularised value changes continuously. The charge operator, ordered symmetrically between particles and holes, is

$$Q = \tfrac{1}{2}\sum_n \left(a_n^\dagger a_n - a_n a_n^\dagger\right),$$

where a_n annihilates a fermion in the level λ_n. On the Dirac sea each filled level contributes $+\frac{1}{2}$ and each empty level $-\frac{1}{2}$:

$$Q_{\mathrm{vac}} \overset{(1)}{=} \tfrac{1}{2}\sum_{\lambda_n<0} 1 - \tfrac{1}{2}\sum_{\lambda_n>0} 1 \overset{(2)}{=} -\tfrac{1}{2}\sum_n \mathrm{sgn}(\lambda_n) \overset{(3)}{=} -\tfrac{1}{2}\,\eta_h(0). \tag{10.239}$$

(1) For a filled level $a^\dagger a = 1$, $aa^\dagger = 0$; for an empty level the reverse.

(2) Collect the two sums (no zero modes).

(3) Regularise the sum of signs by the eta function, exactly as in Section 10.9.11: $\sum \mathrm{sgn}\,\lambda_n |\lambda_n|^{-s}$ at $s = 0$.

For the right mover $h_R = -i\partial_\theta + a$ with $0 < a < 1$, Example 10.52 gave $\eta = 1 - 2a$, so

$$Q_{\mathrm{vac}}(a) = a - \tfrac{1}{2} \qquad (0 < a < 1).$$

Follow the adiabatically evolved state from $a = 0^+$ to $a = 1^-$: its charge rises smoothly from $-\frac{1}{2}$ to $+\frac{1}{2}$. At $a = 1$ an eigenvalue crosses zero, the ground state of $h_R(1)$ is again a sea of charge $-\frac{1}{2}$, and the evolved state, still of charge $+\frac{1}{2}$, is that new vacuum plus one particle (Figure 10.50). The smooth part of Q is *local*, $\mathrm{d}Q_{\mathrm{vac}}/\mathrm{d}a = 1 = \frac{1}{2\pi}\oint \mathrm{d}\theta$, the density of the anomaly; the integer jumps are the spectral flow.

Watch out: Charge is created, but nothing is non-unitary

Nothing in the evolution violates quantum mechanics. The many-body state evolves unitarily; only the *labelling* of states as "sea" or "particle" is tied to the instantaneous Hamiltonian, and after a spectral flow the old sea is not the new sea. In a vector-like theory (both chiralities with the same charge) the creation of right-moving particles is compensated by the creation of left-moving holes. In a chiral theory it is not, and the gauge charge is not conserved. Then Gauss's law, which says that the charge in a region equals the electric flux out of it, cannot hold as an operator statement. The rest of this section turns that sentence into mathematics.

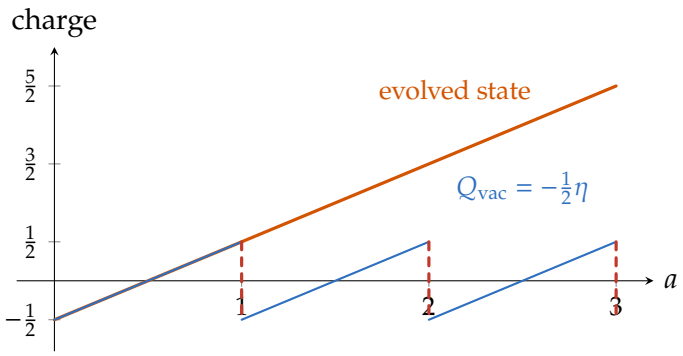

Figure 10.50: Charge of the Dirac sea of $h_R = -i\,\mathrm{d}/\mathrm{d}\theta + a$ as the flux a grows. Blue: the regularised vacuum charge $-\frac{1}{2}\eta(a)$, a sawtooth that drops back by one unit (red) each time an eigenvalue crosses zero. Orange: the charge of the state obtained by adiabatic evolution from the vacuum at $a = 0$; it rises steadily, one unit per flux quantum. The gap between the orange line and the blue sawtooth is the number of particles created: the spectral flow.

Reading Nash (pp. 295–296, (10.80)–(10.85))

Nash's example is "Spectral flow and an anomaly in two dimensions". (10.80) is our (10.233); (10.81)–(10.83) are (10.234)–(10.235); his remark that "k of the negative eigenvalues of $\not{D}_0^1$ have flowed up and become positive eigenvalues of $\not{D}_1^1$" is Figure 10.47. (10.84) is the gauge covariance (10.236); his sentence "if we quotient by this gauge transformation the family descends to a periodic family" is our loop up to gauge, closed in $\mathcal{F}^1$ by Kuiper's theorem. For (10.85) Nash only says that one "would have to calculate the null spaces"; we did so in Example 10.69. His closing warning, "if the Dirac operator had a lowest bound no flow could take place", is Example 10.68. The Dirac-sea interpretation, the QED_2 anomaly and the vacuum charge are not in Nash; they are the physics that makes his statement "anomalies should not disappear in an alternative formulation" concrete.

10.10.11 Example: Fock space and Gauss's law. The set-up

The two-dimensional example gave a *one*-parameter family and the group $\pi_1(\mathcal{F}^1) = \mathbb{Z}$. Nash's second example [Nash p. 297] is the four-dimensional non-abelian anomaly of Chapter 10's §2, seen from both sides. The question it answers is the one we started this section with: in canonical quantisation, what exactly goes wrong?

Two ways of seeing the same integer. Take a gauge group $K = \mathrm{SU}(N)$ with $N \geq 3$ and chiral fermions in the fundamental representation.

- **Euclidean.** Spacetime is S^4 ($n = 4$). The anomaly of §2 was the first Chern class of the determinant line bundle, evaluated on a 2-sphere in $\mathcal{A}/\mathcal{G}$. So we need a family of chiral Dirac operators $\not{D}_y^{(4)}$ with $y \in S^2$ ($p = 2$). The family is a map $S^2 \to \mathcal{F}$, and its class lives in $\pi_2(\mathcal{F}) = \mathbb{Z}$.
- **Hamiltonian.** Space is S^3 and time is extra ($n - 1 = 3$). The operators are the self-adjoint Dirac Hamiltonians $\not{D}_A^{(3)}$ on S^3, so a family is a map into $\mathcal{F}^1$, and to see an integer we need $\pi_p(\mathcal{F}^1) = \mathbb{Z}$, i.e. p odd. Nash takes $p = 3$: a family over $S^3 \subset \mathcal{A}_3/\mathcal{G}_3$.

The bookkeeping rule of Section 10.10.5 says these must agree: $n + p = 4 + 2 = 6$ in the Euclidean picture and $(n - 1) + p = 3 + 3 = 6$ in the Hamiltonian one. Both are measured by

$\pi_6(\Omega U(\infty)) = \pi_7(U(\infty)) = \mathbb{Z}$. Nash's summary is that "the cohomology generators shift from even to odd dimensions and the 2-sphere in $\mathcal{A}/\mathcal{G}$ becomes a 3-sphere".

Why a 2-sphere becomes a 3-sphere. The gauge-theory side of the same statement can be computed directly. Let $\mathcal{G}_m = \mathrm{Map}_*(S^m, K)$ be the based gauge group on S^m (gauge transformations equal to $\mathbb{1}$ at a base point, so that $\mathcal{G}_m$ acts freely on the connections $\mathcal{A}_m$). Then

$$\begin{aligned} \pi_2(\mathcal{A}_4/\mathcal{G}_4) &\overset{(1)}{=} \pi_1(\mathcal{G}_4) \overset{(2)}{=} \pi_1\big(\mathrm{Map}_*(S^4, K)\big) \overset{(3)}{=} \pi_5(K) \overset{(4)}{=} \mathbb{Z}, \\ \pi_3(\mathcal{A}_3/\mathcal{G}_3) &\overset{(5)}{=} \pi_2(\mathcal{G}_3) \overset{(6)}{=} \pi_2\big(\mathrm{Map}_*(S^3, K)\big) \overset{(7)}{=} \pi_5(K) = \mathbb{Z}. \end{aligned} \tag{10.240}$$

(1) The fibration $\mathcal{G} \to \mathcal{A} \to \mathcal{A}/\mathcal{G}$ has contractible total space ($\mathcal{A}$ is an affine space), so its long exact homotopy sequence collapses to $\pi_k(\mathcal{A}/\mathcal{G}) \cong \pi_{k-1}(\mathcal{G})$.
(2) Definition of $\mathcal{G}_4$.
(3) A based loop of based maps $S^4 \to K$ is a based map $S^1 \wedge S^4 = S^5 \to K$: $\pi_k(\mathrm{Map}_*(S^m, K)) = \pi_{k+m}(K)$.
(4) Bott: $\pi_5(\mathrm{SU}(N)) = \mathbb{Z}$ for $N \geq 3$ (the stable range, since $\pi_5(\mathrm{U}(\infty)) = \mathbb{Z}$).
(5) As in step 1, now on S^3.
(6) Definition of $\mathcal{G}_3$.
(7) As in step 3, with $k = 2$, $m = 3$: $2 + 3 = 5$.

So the same group $\pi_5(\mathrm{SU}(N))$, whose generator is behind the non-abelian anomaly in four dimensions, appears once as a 2-sphere in the Euclidean orbit space and once as a 3-sphere in the Hamiltonian one. The dimension of space went down by one, the dimension of the sphere went up by one, and the sum stayed fixed. This is the $n + p$ rule seen from the gauge group rather than from the operators. (For $K = \mathrm{SU}(2)$, $\pi_5(\mathrm{SU}(2)) = \mathbb{Z}_2$: no integer, so no perturbative anomaly, in line with Section 10.9.)

Physical picture: What "anomaly" will mean in the Hamiltonian picture

In the Euclidean picture the anomaly was a *line bundle* over $\mathcal{A}/\mathcal{G}$ with a non-zero Chern class in H^2. In the Hamiltonian picture Nash will find a *projective* bundle of Fock spaces over $\mathcal{A}/\mathcal{G}$ whose obstruction lives in $H^3(\mathcal{A}/\mathcal{G}; \mathbb{Z}) = \mathbb{Z}$ (one degree higher, matching the 3-sphere of (10.240)). Seen from the gauge group, it is a 2-cocycle on $\mathcal{G}$: the gauge group acts on states only up to phases. Infinitesimally, it is a Schwinger term. Physically, Gauss's law cannot be imposed.

10.10.12 The fermionic Fock space

In canonical quantisation of a gauge theory in temporal gauge $A_0 = 0$, the bosonic degree of freedom is the spatial connection $A \in \mathcal{A}$ on space (here S^3). A state is a wave functional $\Psi[A]$, just as a state of a particle is a wave function $\psi(x)$. With fermions present, $\Psi[A]$ is not a number: for each A it is a vector in the space of states of the fermions moving in the background A. That space is the fermionic Fock space $\mathfrak{F}(A)$ built on the one-particle Dirac Hamiltonian $\not{D}_A$. So we need Fock spaces first. We build them in finite dimensions, where every step is a matrix computation, and then see what changes when the one-particle space is infinite-dimensional.

Exterior algebras are many-fermion spaces. For a finite-dimensional one-particle space V with orthonormal basis $e_1, \dots, e_d$, the state with fermions in the levels $i_1 < \cdots < i_k$ is the antisymmetrised product $e_{i_1} \wedge \cdots \wedge e_{i_k}$. The Pauli principle is $e_i \wedge e_i = 0$. So the space of

k-fermion states is $\Lambda^k(V)$, of dimension $\binom{d}{k}$, and the space of all states is the exterior algebra

$$\Lambda^*(V) = \bigoplus_{k=0}^{d} \Lambda^k(V), \qquad \dim \Lambda^*(V) = 2^d.$$

Creation and annihilation operators are wedging and contracting: $a^\dagger(v)\omega = v \wedge \omega$ and $a(v) = \iota_v$, the contraction with $\langle v, \cdot \rangle$. They obey the canonical anticommutation relations $\{a(u), a^\dagger(v)\} = \langle u|v\rangle$, $\{a(u), a(v)\} = 0$. (Check on $V = \mathbb{C}$: $a^\dagger$ maps $1 \mapsto e$ and $e \mapsto 0$, a maps $e \mapsto 1$ and $1 \mapsto 0$, so $aa^\dagger + a^\dagger a = \mathbb{1}$: the 2×2 matrices $\left(\begin{smallmatrix}0&0\\1&0\end{smallmatrix}\right)$ and $\left(\begin{smallmatrix}0&1\\0&0\end{smallmatrix}\right)$ in the basis $(1, e)$.)

Particles and antiparticles. Now let $V = H$ carry a one-particle Hamiltonian h with no zero eigenvalue and split $H = H^+ \oplus H^-$ into its positive and negative spectral subspaces [Nash (10.86)]. Dirac's ground state fills H^-. Relative to it, an excitation is either a fermion added to a level of H^+ (a particle) or a fermion removed from a level of H^- (a hole, i.e. an antiparticle). Holes are described by the *complex conjugate* space $\bar{H}^-$: if the level $w \in H^-$ has the wave function $w(x)$, the hole has $\overline{w(x)}$, the opposite charge and the energy $-\lambda > 0$. The particle–antiparticle Fock space is Nash's (10.87):

Working definition 10.18 (Fermionic Fock space of a polarised Hilbert space)

Given $H = H^+ \oplus H^-$ (a **polarisation** [the split of the one-particle states into the positive-energy levels H^+ and negative-energy levels H^- of h]),

$$\mathfrak{F} = \Lambda^*\big(H^+ \oplus \bar{H}^-\big) = \bigoplus_{p,q\geq 0} \Lambda^p(H^+) \otimes \Lambda^q(\bar{H}^-). \tag{10.241}$$

The summand $\Lambda^p(H^+) \otimes \Lambda^q(\bar{H}^-)$ holds the states with p particles and q antiparticles. Its charge is $Q = p - q$, its energy is $\sum_{\text{particles}} \lambda + \sum_{\text{holes}} |\lambda|$, and the vacuum $|0\rangle = 1 \otimes 1 \in \Lambda^0 \otimes \Lambda^0$ is the unique state of lowest energy. To compute with it: pick an eigenbasis of h; a basis of $\mathfrak{F}$ is labelled by a finite set of occupied positive levels and a finite set of empty negative levels.

The second equality in (10.241) is the exterior algebra of a direct sum, $\Lambda^k(U \oplus W) = \bigoplus_{p+q=k} \Lambda^p(U) \otimes \Lambda^q(W)$: a basis k-vector of $U \oplus W$ is a wedge of p basis vectors of U and q of W, and can be reordered (up to sign) with the U factors first.

Worked example 10.71: A three-level Dirac sea

Let $H = \mathbb{C}^3$ with $h = \mathrm{diag}(-2, -1, +1)$ and eigenbasis e_1, e_2, e_3. Then $H^- = \mathrm{span}(e_1, e_2)$ and $H^+ = \mathrm{span}(e_3)$. The Fock space (10.241) decomposes by (p, q) with $p \in \{0, 1\}$, $q \in \{0, 1, 2\}$:

(p,q)	basis	dim	$Q = p - q$	energy	in $\Lambda^*(H)$
$(0,0)$	1	1	0	0	$e_1 \wedge e_2$
$(0,1)$	$\bar{e}_1,\ \bar{e}_2$	2	-1	2, 1	$e_2,\ -e_1$
$(0,2)$	$\bar{e}_1 \wedge \bar{e}_2$	1	-2	3	1
$(1,0)$	e_3	1	$+1$	1	$e_3 \wedge e_1 \wedge e_2$
$(1,1)$	$e_3 \otimes \bar{e}_1,\ e_3 \otimes \bar{e}_2$	2	0	3, 2	$e_3 \wedge e_2,\ -e_3 \wedge e_1$
$(1,2)$	$e_3 \otimes \bar{e}_1 \wedge \bar{e}_2$	1	-1	4	e_3

The total dimension is $1 + 2 + 1 + 1 + 2 + 1 = 8 = 2^3 = \dim \Lambda^*(\mathbb{C}^3)$. The last column shows the same state written as "which levels are occupied" in the exterior algebra of the whole of H, obtained by starting from the sea $e_1 \wedge e_2$ and removing the holes (contracting) and

adding the particles (wedging). Grouping by charge: $Q = -2, -1, 0, 1$ has dimensions $1, 3, 3, 1$, the dimensions of $\Lambda^0, \Lambda^1, \Lambda^2, \Lambda^3$ of H, as it must be, since "charge Q relative to a sea of 2" means "$2 + Q$ fermions".

The dependence on the sea is a line. The last column of the table used the sea vector $\Omega = e_1 \wedge e_2$. Had we used another orthonormal basis of H^-, related by $u \in \mathrm{U}(2)$, the sea vector would be $(\det u)\,\Omega$. So what is canonical is a map that needs one vector of the line $\det H^- = \Lambda^{\mathrm{top}}(H^-)$ as input:

$$\Lambda^p(H^+) \otimes \Lambda^q(\bar{H}^-) \otimes \det H^- \overset{(1)}{\cong} \Lambda^p(H^+) \otimes \Lambda^{m-q}(H^-) \xrightarrow{\wedge} \Lambda^{p+m-q}(H),$$

$$\text{so} \quad \mathfrak{F} \otimes \det H^- \overset{(2)}{\cong} \Lambda^*(H) \qquad (m = \dim H^-). \tag{10.242}$$

(1) Contracting a top form of H^- with q hole vectors $\bar{w}_1, \dots, \bar{w}_q$ (i.e. with $\iota_{w_1} \cdots \iota_{w_q}$) leaves an $(m-q)$-vector in H^-: "the sea with q levels emptied". This is an isomorphism because $\bar{H}^- \cong (H^-)^*$ via the inner product, and $\Lambda^q(V^*) \otimes \det V \cong \Lambda^{m-q}(V)$ is the Hodge-type duality of an m-dimensional space.

(2) Wedging with the particles and summing over p, q gives every degree $k = p+m-q$ of $\Lambda^*(H)$ exactly once, with matching dimensions $\sum_{p-q=k-m} \binom{\dim H^+}{p}\binom{m}{q} = \binom{\dim H}{k}$ (Vandermonde's identity).

So in finite dimensions $\mathfrak{F} \cong \Lambda^*(H) \otimes (\det H^-)^{-1}$: the particle–antiparticle Fock space is the "which levels are filled" space, tensored with a line. The line is the space of possible vacuum vectors. Projectively, $\mathfrak{F}$ and $\Lambda^*(H)$ are the same, and the same for every polarisation.

What changes in infinite dimensions. For a Dirac Hamiltonian H^- is infinite-dimensional (the spectrum is unbounded below), and "$e_1 \wedge e_2 \wedge \cdots$" with infinitely many factors is not a vector of any Hilbert space; nor is $\det H^-$ a well-defined line. So $\Lambda^*(H)$ is meaningless, and (10.241) is the only definition available. It depends on the polarisation: two splittings $H_1^+ \oplus H_1^-$ and $H_2^+ \oplus H_2^-$ give Fock spaces that can be compared only if the two negative subspaces are "close" (we make this precise in Section 10.10.18). When they differ by a finite-dimensional space, the comparison costs exactly the finite-dimensional line of the last paragraph. This is the whole mechanism of Nash's argument.

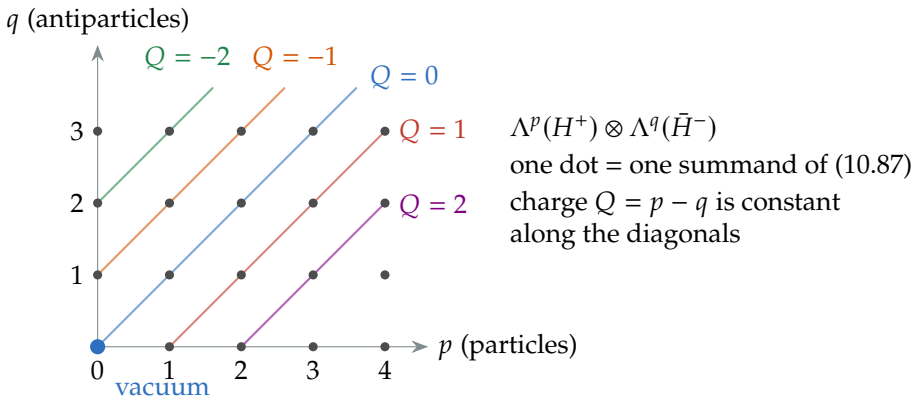

Figure 10.51: The Fock space (10.241) as a grid. Each dot (p, q) is the summand with p particles and q antiparticles; the vacuum is the blue dot at the origin. States of fixed charge lie on the coloured diagonals, and each diagonal is infinite: charge 0 contains the vacuum, all particle–hole pairs, and so on. Changing the polarisation by a k-dimensional space relabels the charges: every diagonal moves by k (Example 10.73).

Fock spaces over the space of connections. Put back the gauge field. For each spatial connection A, the one-particle Hamiltonian is the self-adjoint Dirac operator $\not{D}_A$ on S^3. Suppose for the moment that $\ker \not{D}_A = 0$. Then (10.241) with $H^{\pm} = H^{\pm}(A)$ gives a Fock space $\mathfrak{F}(A)$, and as A varies they form a bundle over $\mathcal{A}$. A gauge transformation $g \in \mathcal{G}$ maps A to $g \cdot A$ and conjugates the Dirac operator, $\not{D}_{g\cdot A} = g\, \not{D}_A\, g^{-1}$, so it maps eigenvectors of $\not{D}_A$ to eigenvectors of $\not{D}_{g\cdot A}$ with the same eigenvalues, and therefore maps $H^{\pm}(A) \to H^{\pm}(g \cdot A)$ and $\mathfrak{F}(A) \to \mathfrak{F}(g \cdot A)$. So we can hope to quotient [Nash (10.88)]:

$$\begin{array}{ccc} \mathfrak{F} & & \mathfrak{F}/\mathcal{G} \\ \downarrow & & \downarrow \\ \mathcal{A} & & \mathcal{A}/\mathcal{G} \end{array} \tag{10.243}$$

The physical states should be the square-integrable sections of $\mathfrak{F}/\mathcal{G} \to \mathcal{A}/\mathcal{G}$.

Dictionary: Why "sections of $\mathfrak{F}/\mathcal{G}$" is Gauss's law

physics	geometry
wave functional $\Psi[A]$ with values in fermion states	section of $\mathfrak{F} \to \mathcal{A}$
electric field $E = -i\,\delta/\delta A$	derivative along $\mathcal{A}$
Gauss's law $(D \cdot E - \rho)\Psi = 0$	Ψ constant along gauge orbits: $\Psi[g \cdot A] = U(g)\Psi[A]$
gauge-invariant wave functionals	sections of $\mathfrak{F}/\mathcal{G} \to \mathcal{A}/\mathcal{G}$

The middle row is the familiar statement that Gauss's law generates gauge transformations: the generator $G(\xi) = \int \operatorname{tr}\, \xi\,(D_i E_i - \rho)$ moves A by $D\xi$ (through $E = -i\delta/\delta A$) and rotates the fermions by ξ (through the charge density ρ). Requiring $G(\xi)\Psi = 0$ for all ξ says that Ψ is invariant under the combined transformation, i.e. that Ψ descends to the quotient. For this to make sense $\mathcal{G}$ must *act* on the Fock bundle: $U(g)U(h) = U(gh)$. Nash's point is that it does not.

10.10.13 The flaw: zero modes, and cutting the spectrum at ε

The construction assumed $\ker \not{D}_A = 0$. As A varies we cannot avoid connections where an eigenvalue passes through zero: that is exactly the spectral flow of Section 10.10.7, and it happens along a codimension-one wall in $\mathcal{A}$. On the wall the split $H = H^+ \oplus H^-$ is undefined, and across it $H^+(A)$ jumps by the crossing eigenvector. So the Fock spaces $\mathfrak{F}(A)$ do not form a smooth bundle over the whole of $\mathcal{A}$ [Nash p. 298].

Worked example 10.72: Where the polarisation jumps

Take Nash's circle family $\not{D}^1_t = -i\,\mathrm{d}/\mathrm{d}\theta + t$ with $k = 1$, so $\lambda_n(t) = n + t$. For $0 < t < 1$ the negative levels are $n \le -1$ and $H^+(t) = \overline{\operatorname{span}}\{e^{in\theta} : n \ge 0\}$. At $t = 1$ the level $n = -1$ reaches zero; for $1 < t < 2$ it is positive and $H^+(t) = \overline{\operatorname{span}}\{e^{in\theta} : n \ge -1\}$. So

$$H^+(1.5) = H^+(0.5) \oplus \mathbb{C}\, e^{-i\theta}.$$

The subspace jumps by one dimension at the wall $t = 1$, and nothing smooth connects the two Fock spaces through it. Everywhere else the subspace is constant (in this family the eigenvectors do not even move).

Nash's cure: move the cut. Nothing forces us to split the spectrum at zero. Choose a real number ε that is not an eigenvalue of $\not{D}_A$ and define [Nash (10.89)]

$$H_\varepsilon^+ = \text{span of eigenvectors with } \lambda > \varepsilon, \qquad H_\varepsilon^- = \text{span of eigenvectors with } \lambda < \varepsilon,$$

and the Fock space [Nash (10.90)]

$$\mathfrak{F}_\varepsilon(A) = \Lambda^*\big(H_\varepsilon^+ \oplus \bar{H}_\varepsilon^-\big). \tag{10.244}$$

The key observation is that this is smooth on a whole open set. Let

$$U_\varepsilon = \{A \in \mathcal{A} : \ \varepsilon \notin \operatorname{spec} \not{D}_A\}.$$

Eigenvalues depend continuously on A, so if ε is not an eigenvalue of $\not{D}_A$ it is not one for nearby A either: U_ε is open. On U_ε the spectral projection

$$P_\varepsilon^+(A) = \frac{1}{2\pi i} \oint_\Gamma \frac{\mathrm{d}z}{z - \not{D}_A}$$

(where Γ encircles the part of the spectrum above ε, crossing the real axis at ε and at $+\infty$) depends smoothly on A, because the contour stays away from the spectrum. So $H_\varepsilon^\pm(A)$ and $\mathfrak{F}_\varepsilon(A)$ form smooth bundles over U_ε. As ε ranges over $\mathbb{R}$ the sets U_ε cover $\mathcal{A}$: every A has a discrete spectrum, so some ε misses it.

Two cuts. On the overlap $U_\varepsilon \cap U_{\varepsilon'}$ we have two decompositions [Nash (10.89)], $H = H_\varepsilon^+ \oplus H_\varepsilon^- = H_{\varepsilon'}^+ \oplus H_{\varepsilon'}^-$, and two Fock spaces. Take $\varepsilon < \varepsilon'$ and let

$$J_{\varepsilon\varepsilon'}(A) = \text{span of eigenvectors of } \not{D}_A \text{ with } \varepsilon < \lambda < \varepsilon'.$$

It is *finite-dimensional*: $\not{D}_A$ is elliptic on a compact manifold, so it has only finitely many eigenvalues in a bounded interval (Chapter 2). Then:

$$H_\varepsilon^+ \overset{(1)}{=} H_{\varepsilon'}^+ \oplus J_{\varepsilon\varepsilon'}, \qquad H_{\varepsilon'}^- \overset{(2)}{=} H_\varepsilon^- \oplus J_{\varepsilon\varepsilon'},$$

$$\Longrightarrow \ H \overset{(3)}{=} H_{\varepsilon'}^+ \oplus J_{\varepsilon\varepsilon'} \oplus H_\varepsilon^-, \tag{10.245}$$

$$\mathfrak{F}_\varepsilon(A) \overset{(4)}{=} \Lambda^*\big(H_{\varepsilon'}^+ \oplus J_{\varepsilon\varepsilon'} \oplus \bar{H}_\varepsilon^-\big) \overset{(5)}{=} \Lambda^*(J_{\varepsilon\varepsilon'}) \otimes \Lambda^*\big(H_{\varepsilon'}^+ \oplus \bar{H}_\varepsilon^-\big), \tag{10.246}$$

$$\mathfrak{F}_{\varepsilon'}(A) \overset{(6)}{=} \Lambda^*\big(H_{\varepsilon'}^+ \oplus \bar{J}_{\varepsilon\varepsilon'} \oplus \bar{H}_\varepsilon^-\big) \overset{(7)}{=} \Lambda^*(\bar{J}_{\varepsilon\varepsilon'}) \otimes \Lambda^*\big(H_{\varepsilon'}^+ \oplus \bar{H}_\varepsilon^-\big). \tag{10.247}$$

(1) An eigenvalue above ε is either above ε' or in $(\varepsilon, \varepsilon')$; Nash's (10.91).
(2) An eigenvalue below ε' is either below ε or in $(\varepsilon, \varepsilon')$.
(3) Combine; the three pieces are mutually orthogonal (eigenspaces of a self-adjoint operator).
(4) Definition (10.244) with step 1.
(5) $\Lambda^*(U \oplus W) \cong \Lambda^*(U) \otimes \Lambda^*(W)$; Nash's (10.92).
(6) Definition with ε': now the J-levels are *below* the cut, so they are part of the sea, and their excitations are holes, described by $\bar{J}$. This is Nash's (10.93).
(7) As in step 5.

So the two Fock spaces share the big factor $\Lambda^*(H_{\varepsilon'}^+ \oplus \bar{H}_\varepsilon^-)$, and differ only in a finite factor: $\Lambda^*(J)$ versus $\Lambda^*(\bar{J})$ [Nash p. 299].

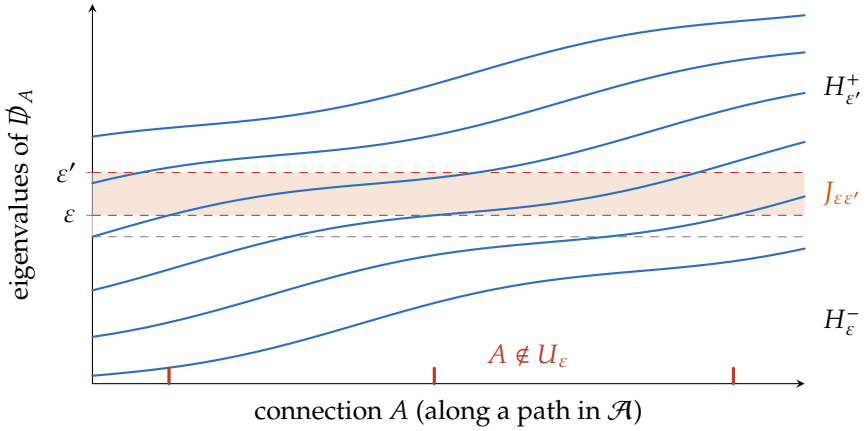

Figure 10.52: Eigenvalues of $\not{D}_A$ (blue) along a path of connections. A cut at ε (dashed red) defines a Fock space $\mathfrak{F}_\varepsilon(A)$ that is smooth as long as no eigenvalue touches the cut; the red ticks on the axis mark the connections where a line crosses ε, which are exactly the points outside U_ε. Between two cuts $\varepsilon < \varepsilon'$ lies the orange window: its eigenvectors span the finite-dimensional space $J_{\varepsilon\varepsilon'}(A)$. The number of lines in the window changes as lines enter and leave, but only where a line crosses one of the two cuts.

Watch out: The cut at ε is not "the vacuum".

For $\varepsilon \neq 0$ the vacuum $|0\rangle_\varepsilon$ of $\mathfrak{F}_\varepsilon$ is not the lowest energy state: if there are levels in $(0, \varepsilon)$ they are empty in $|0\rangle_\varepsilon$ but would be filled in the true ground state, or vice versa for $\varepsilon < 0$. That is harmless. We are not trying to identify the ground state; we are trying to build a smooth bundle of *state spaces*. The state space $\mathfrak{F}_\varepsilon$ contains the true ground state as one of its vectors (a state with finitely many particles or holes in the window).

10.10.14 Changing the cut costs a line: projective Fock spaces

We must compare $\Lambda^*(J)$ with $\Lambda^*(\bar{J})$, where $n = \dim J$. They are the Fock spaces of the *same* n levels, described once as "empty unless occupied" (particles above the cut ε) and once as "filled unless emptied" (holes below the cut ε'). A physical configuration of the n levels, "the levels in the set S are filled and the rest are empty", is described in the first language by the p particles $e_S = e_{s_1} \wedge \cdots \wedge e_{s_p} \in \Lambda^p(J)$ ($|S| = p$), and in the second by the $n - p$ holes $\bar{e}_{S^c} \in \Lambda^{n-p}(\bar{J})$ in the complementary levels. So the dictionary should send $\Lambda^p(J) \to \Lambda^{n-p}(\bar{J})$, and $e_S \mapsto (\text{number}) \cdot \bar{e}_{S^c}$. The only question is which number.

Working definition 10.19 (The isomorphism I^λ (Nash's (10.94)))

Let $e_1, \ldots, e_n$ be an orthonormal eigenbasis of $J = J_{\varepsilon\varepsilon'}(A)$ [the span of the eigenvectors of $\not{D}_A$ with eigenvalues between the two cuts ε and ε'] and choose a non-zero element of the line $\Lambda^n(J)$ [the multiples of $e_1 \wedge \cdots \wedge e_n$, the state with all n window levels filled], $\lambda = c\, e_1 \wedge \cdots \wedge e_n$ with $c \in \mathbb{C}^\times$. For each subset S define the sign $\sigma(S)$ by $e_{S^c} \wedge e_S = \sigma(S)\, e_1 \wedge \cdots \wedge e_n$, and set

$$I^\lambda_p : \Lambda^p(J) \to \Lambda^{n-p}(\bar{J}), \qquad I^\lambda_p(e_S) = c\, \sigma(S)\, \bar{e}_{S^c}, \tag{10.248}$$

extended linearly. Reading $\bar{e}_j$ as e_j, this is exactly Nash's condition $I^\lambda_p(\omega) \wedge \omega = \lambda$ on basis vectors $\omega = e_S$. It is an isomorphism (it maps a basis to a basis up to non-zero factors). Tensoring with the identity on the common factor [the levels outside the window, which both Fock spaces describe in the same way] gives $I^\lambda \otimes \mathbb{1} : \mathfrak{F}_\varepsilon(A) \to \mathfrak{F}_{\varepsilon'}(A)$.

Worked example 10.73: One level crosses the window

Let $n = \dim J = 1$, $J = \mathbb{C}e_1$. Then $\Lambda^*(J) = \mathrm{span}(1, e_1)$ and $\Lambda^*(\bar{J}) = \mathrm{span}(1, \bar{e}_1)$, and (10.248) gives

$$I^\lambda(1) = c\,\bar{e}_1, \qquad I^\lambda(e_1) = c \cdot 1.$$

In words: "the level is empty" (the ε-vacuum) is "one hole in the level" in the ε' description, and "one particle in the level" is the ε'-vacuum. Charges, counted relative to each vacuum, compare as

$$Q_{\varepsilon'}\big(I^\lambda(e_S \otimes \phi)\big) \overset{(1)}{=} Q(\phi) - (n-p) \overset{(2)}{=} \big(Q(\phi) + p\big) - n \overset{(3)}{=} Q_\varepsilon(e_S \otimes \phi) - \dim J.$$

(1) The ε'-state has the charge $Q(\phi)$ of the common factor $\phi \in \Lambda^*(H^+_{\varepsilon'} \oplus \bar{H}^-_{\varepsilon'})$ plus $n - p$ holes of charge -1.
(2) Rearrange.
(3) The ε-state has the same ϕ plus p particles.

So moving the cut up by a window containing $\dim J$ levels shifts every charge by $-\dim J$ (all the diagonals of Figure 10.51 move). This is the Fock-space version of the vacuum-charge sawtooth of Figure 10.50: the *label* "charge relative to the vacuum" depends on the cut, the physics does not.

Worked example 10.74: Two levels in the window: signs

For $n = 2$, $\lambda = c\, e_1 \wedge e_2$. The signs are $\sigma(\varnothing) = 1$ ($e_1 \wedge e_2 \wedge 1$), $\sigma(\{1\}) = -1$ ($e_2 \wedge e_1 = -e_1 \wedge e_2$), $\sigma(\{2\}) = +1$ ($e_1 \wedge e_2$), $\sigma(\{1,2\}) = 1$. Hence

$$I^\lambda(1) = c\,\bar{e}_1 \wedge \bar{e}_2, \quad I^\lambda(e_1) = -c\,\bar{e}_2, \quad I^\lambda(e_2) = c\,\bar{e}_1, \quad I^\lambda(e_1 \wedge e_2) = c.$$

As a matrix from the basis $(1, e_1, e_2, e_1 \wedge e_2)$ to $(\bar{e}_1 \wedge \bar{e}_2, \bar{e}_2, \bar{e}_1, 1)$ this is $c\ \mathrm{diag}(1, -1, 1, 1)$. Now change the orthonormal basis of J by $u \in \mathrm{U}(2)$. The wedge $e_1 \wedge e_2$ becomes $(\det u)\, e_1 \wedge e_2$. If we keep the *same* λ, then c becomes $c/\det u$ and the map I^λ is unchanged (it depends on λ, not on the basis). If instead we keep the same c, I changes by the phase $\det u$. Either way: the isomorphism is fixed by a vector of the line $\Lambda^2(J)$, and different choices differ by a non-zero complex number.

The ambiguity is a line; projectively it disappears. The last two examples show that I^λ depends on λ only through an overall factor: $I^{z\lambda} = z\, I^\lambda$ for $z \in \mathbb{C}^\times$. There is no canonical choice of λ in the line $\Lambda^n(J)$. But the induced map of *projective* spaces (rays),

$$\mathbb{P}\mathfrak{F}_\varepsilon(A) \xrightarrow{[I^\lambda]} \mathbb{P}\mathfrak{F}_{\varepsilon'}(A),$$

is the same for every λ [Nash p. 299]. Quantum states are rays anyway: $|\psi\rangle$ and $z|\psi\rangle$ are the same physical state. So we drop the label ε and write $\mathfrak{FP}(A)$ for the projective Fock space, canonically defined for every A, zero modes or not. The projective Fock spaces form a bundle over all of $\mathcal{A}$ [Nash (10.95)]:

$$\mathfrak{FP} = \{\mathfrak{FP}(A) : A \in \mathcal{A}\}, \tag{10.249}$$

glued on each overlap $U_\varepsilon \cap U_{\varepsilon'}$ by $[I^\lambda]$. Consistency on triple overlaps $\varepsilon < \varepsilon' < \varepsilon''$ holds because $J_{\varepsilon\varepsilon''} = J_{\varepsilon\varepsilon'} \oplus J_{\varepsilon'\varepsilon''}$, so $\Lambda^{\mathrm{top}} J_{\varepsilon\varepsilon''} = \Lambda^{\mathrm{top}} J_{\varepsilon\varepsilon'} \otimes \Lambda^{\mathrm{top}} J_{\varepsilon'\varepsilon''}$ and the composite of two I's is an I up to a scalar. And now gauge transformations cause no trouble: g maps each $J_{\varepsilon\varepsilon'}(A)$ to $J_{\varepsilon\varepsilon'}(g \cdot A)$ (same eigenvalues), hence commutes with the gluing up to scalars, so $\mathcal{G}$ acts smoothly on $\mathfrak{FP}$ and the quotient [Nash (10.96)]

$$\mathfrak{FP}/\mathcal{G} \longrightarrow \mathcal{A}/\mathcal{G} \tag{10.250}$$

is a perfectly good bundle of projective spaces.

Key idea: Where the anomaly now sits

The line bundles $\det J_{\varepsilon\varepsilon'} \to U_\varepsilon \cap U_{\varepsilon'}$ are the Hamiltonian determinant lines. Choosing the λ's is choosing sections of them. Over $\mathcal{A}$ (contractible) these choices can be made consistently, and $\mathfrak{F}\mathfrak{P}$ lifts to an honest vector bundle $\mathfrak{F}$ of Fock spaces. The question is whether this can be done *compatibly with* $\mathcal{G}$, i.e. whether the projective bundle $\mathfrak{F}\mathfrak{P}/\mathcal{G}$ over $\mathcal{A}/\mathcal{G}$ is the projectivisation of a vector bundle. The obstruction is a class in $H^3(\mathcal{A}/\mathcal{G};\mathbb{Z})$; for chiral fermions on S^3 it is the generator of $H^3(\mathcal{A}_3/\mathcal{G}_3;\mathbb{Z}) = \mathbb{Z}$ dual to the 3-sphere of (10.240). Seen from $\mathcal{G}$, it is a 2-cocycle.

Why projective bundles are classified by H^3. A reminder of the one-degree-up pattern (Chapter 1). Complex line bundles, i.e. U(1)-bundles, are classified by $H^2(X;\mathbb{Z})$ through c_1. The reason is that U(1) is a circle, whose classifying space $\mathbb{CP}^\infty$ has only $\pi_2 = \mathbb{Z}$. A bundle of projective Hilbert spaces has structure group $\mathrm{PU}(H) = \mathrm{U}(H)/\mathrm{U}(1)$. By Kuiper's theorem $\mathrm{U}(H)$ is contractible, so $\mathrm{PU}(H)$ has the homotopy of $B\mathrm{U}(1) = \mathbb{CP}^\infty$: only $\pi_2 = \mathbb{Z}$. Its classifying space $B\mathrm{PU}(H)$ therefore has only $\pi_3 = \mathbb{Z}$, and projective bundles over X are classified by $H^3(X;\mathbb{Z})$, the **Dixmier–Douady class**. The class vanishes exactly when the projective bundle comes from a vector bundle. For Nash's bundle, $X = \mathcal{A}/\mathcal{G}$, and the class is the anomaly.

From $H^3(\mathcal{A}/\mathcal{G})$ to $H^2(\mathcal{G})$: transgression. Nash phrases the obstruction as "a cocycle in $H^2(\mathcal{G})$ which corresponds under transgression to an element of $H^3(\mathcal{A}/\mathcal{G})$". The geometric content is the same as step 1 of (10.240). Take a 3-sphere Σ in $\mathcal{A}/\mathcal{G}$. Cut it open at one point. What remains is a 3-ball, and a 3-ball lifts to $\mathcal{A}$ (it is contractible, so the bundle $\mathcal{A} \to \mathcal{A}/\mathcal{G}$ is trivial over it). The lifted ball $B^3 \subset \mathcal{A}$ has its boundary 2-sphere inside a single gauge orbit, because the whole boundary was glued to one point of $\mathcal{A}/\mathcal{G}$. A gauge orbit is a copy of $\mathcal{G}$, so ∂B^3 is a 2-sphere in $\mathcal{G}$ (Figure 10.53). Integrating a closed 3-form Θ on $\mathcal{A}/\mathcal{G}$ over Σ and using Stokes' theorem on the ball turns the answer into an integral of a 2-form over a 2-sphere in the group:

$$\int_\Sigma \Theta \overset{(1)}{=} \int_{B^3} \pi^*\Theta \overset{(2)}{=} \int_{B^3} \mathrm{d}\beta \overset{(3)}{=} \int_{\partial B^3} \beta \overset{(4)}{=} \int_{S^2\subset\mathcal{G}} \beta\big|_{\text{orbit}}. \tag{10.251}$$

(1) $\pi : \mathcal{A} \to \mathcal{A}/\mathcal{G}$ maps B^3 onto Σ, one-to-one except on the boundary, which is collapsed to a point (measure zero).
(2) $\mathcal{A}$ is contractible, so the closed form $\pi^*\Theta$ is exact: $\pi^*\Theta = \mathrm{d}\beta$ (Poincaré lemma, Chapter T2).
(3) Stokes' theorem.
(4) ∂B^3 lies in one orbit $\cong \mathcal{G}$; restricted to it, β is closed ($\mathrm{d}\beta = \pi^*\Theta$ vanishes on vectors tangent to an orbit, since π kills them), so it defines a class in $H^2(\mathcal{G})$.

This is **transgression**: a degree-3 class downstairs becomes a degree-2 class on the fibre. In the Euclidean picture of §2 the same move turned $c_1 \in H^2(\mathcal{A}/\mathcal{G})$ into a class in $H^1(\mathcal{G})$, whose Lie-algebra version was the consistent anomaly, a 1-cocycle. Here the Lie-algebra version of the $H^2(\mathcal{G})$ class will be a 2-cocycle, the Schwinger term.

10.10.15 Symmetries that act only up to phases

The projective Fock bundle $\mathfrak{F}\mathfrak{P}/\mathcal{G}$ of (10.250) is a perfectly good bundle, and $\mathcal{G}$ acts on it. But a quantum state is a *vector*, not a ray, as soon as we want to add two states or ask whether a state is invariant. So the question Nash asks next is: when we lift the action of $\mathcal{G}$ from the rays back to the vectors, what goes wrong? The answer is a phase, and the phase is the anomaly. Before we meet it on Fock space we meet it where every step is a 2×2 matrix.

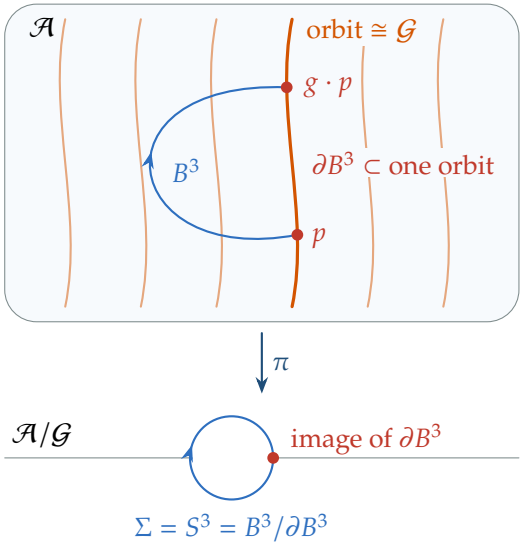

Figure 10.53: Transgression, drawn with every dimension lowered by two. The 3-sphere Σ in the orbit space (bottom) becomes a loop, and its lift, the 3-ball B^3 in the contractible space $\mathcal{A}$ (blue, top), becomes a path. The path starts at p and ends at $g \cdot p$ on the same gauge orbit (orange): its whole boundary (red; really a 2-sphere) lies in one orbit and is collapsed to one point by π. So a 3-sphere in $\mathcal{A}/\mathcal{G}$ is the same as a 2-sphere in $\mathcal{G}$, and $H^3(\mathcal{A}/\mathcal{G})$ corresponds to $H^2(\mathcal{G})$ by Stokes' theorem (10.251).

Why only rays are physical. Two unit vectors ψ and $e^{i\theta}\psi$ give the same probabilities $\left|\langle\phi|\psi\rangle\right|^2$ for every ϕ. So the physical content of a state is its ray $[\psi] = \{e^{i\theta}\psi\}$. A symmetry is a map on rays that preserves the transition probabilities. Wigner's theorem says that every such map comes from a unitary (or antiunitary) operator U on vectors, and that U is unique *up to a phase*. So if a group G acts by symmetries, each $g \in G$ gives an operator $U(g)$ that we may multiply by any phase we like. The group law $g \cdot h = gh$ then only requires that $U(g)U(h)$ and $U(gh)$ give the same map on rays:

Working definition 10.20 (Projective representation and its multiplier)

A **projective representation** of a group G on a Hilbert space is an assignment $g \mapsto U(g)$ of unitary operators such that

$$U(g)\,U(h) = \omega(g,h)\,U(gh), \qquad |\omega(g,h)| = 1. \tag{10.252}$$

The function $\omega : G \times G \to \mathrm{U}(1)$ is the **multiplier** (or **2-cocycle** [it obeys $\omega(g,h)\,\omega(gh,k) = \omega(h,k)\,\omega(g,hk)$, because $(U(g)U(h))U(k) = U(g)(U(h)U(k))$]). *How to compute it:* choose one operator $U(g)$ for every g, multiply two of them, and read off the phase by which the product differs from the chosen $U(gh)$. *How to test whether it is removable* [can be made 1 by changing each $U(g)$ by a phase, $U(g) \to \beta(g)U(g)$]: for every pair of commuting elements $gh = hg$, compute the **commutator phase** $\omega(g,h)/\omega(h,g)$. If one of them is not 1, no choice of phases turns U into an honest representation [one with $U(g)U(h) = U(gh)$ exactly].

The cocycle condition. The multiplier is not an arbitrary function. Operator products are associative, so the two ways of evaluating $U(g)U(h)U(k)$ must agree:

$$\big(U(g)U(h)\big)U(k) \overset{(1)}{=} \omega(g,h)\,U(gh)\,U(k) \overset{(2)}{=} \omega(g,h)\,\omega(gh,k)\,U(ghk),$$

$$U(g)\big(U(h)U(k)\big) \overset{(3)}{=} \omega(h,k)\,U(g)\,U(hk) \overset{(4)}{=} \omega(h,k)\,\omega(g,hk)\,U(ghk).$$

(1) (10.252) for the pair (g,h); the phase is a number and moves to the front.
(2) (10.252) for the pair (gh,k).
(3) (10.252) for the pair (h,k).
(4) (10.252) for the pair (g,hk).

Since $U(ghk)$ is invertible, the two phases are equal:

$$\omega(g,h)\,\omega(gh,k) = \omega(h,k)\,\omega(g,hk) \qquad \text{for all } g,h,k \in G. \tag{10.253}$$

This is the **2-cocycle condition**. It is the multiplicative version of the condition $\delta\omega = 0$ in group cohomology, and it plays for projective representations the role that $\mathrm{d}\omega = 0$ plays for forms.

Changing the phases: coboundaries. We were free to choose the phases. Replace $U(g)$ by $U'(g) = \beta(g)U(g)$ with any function $\beta : G \to \mathrm{U}(1)$. Then

$$U'(g)U'(h) \overset{(1)}{=} \beta(g)\beta(h)\,U(g)U(h) \overset{(2)}{=} \beta(g)\beta(h)\,\omega(g,h)\,U(gh) \overset{(3)}{=} \frac{\beta(g)\beta(h)}{\beta(gh)}\,\omega(g,h)\,U'(gh). \tag{10.254}$$

(1) Definition of U'; the numbers β move to the front.
(2) (10.252).
(3) $U(gh) = \beta(gh)^{-1}U'(gh)$.

So the new multiplier is $\omega' = \omega \cdot \beta(g)\beta(h)/\beta(gh)$. A multiplier of the form $\beta(g)\beta(h)/\beta(gh)$ is a **coboundary**: it can be removed completely by rephasing. The classes of cocycles modulo coboundaries form the group $H^2(G;\mathrm{U}(1))$, and a projective representation can be made into an honest one exactly when its class is zero. The commutator phase is a good detector because it is unchanged by rephasing: if $gh = hg$, then $\beta(g)\beta(h)/\beta(gh) = \beta(h)\beta(g)/\beta(hg)$, so the factor cancels in $\omega'(g,h)/\omega'(h,g)$.

Worked example 10.75: The Pauli matrices represent $\mathbb{Z}_2 \times \mathbb{Z}_2$ projectively

Let $G = \mathbb{Z}_2 \times \mathbb{Z}_2 = \{e,a,b,ab\}$, with $a^2 = b^2 = e$ and $ab = ba$. It is abelian, so every honest irreducible representation is one-dimensional. Choose

$$U(e) = \mathbb{1}, \quad U(a) = \sigma_x, \quad U(b) = \sigma_z, \quad U(ab) = \sigma_y,$$

with $\sigma_x = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, $\sigma_y = \left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right)$, $\sigma_z = \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$. Multiply the matrices out:

$$U(a)U(b) = \sigma_x\sigma_z = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \overset{(1)}{=} -i\,\sigma_y = -i\,U(ab),$$

$$U(b)U(a) = \sigma_z\sigma_x = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \overset{(2)}{=} +i\,\sigma_y = +i\,U(ab).$$

(1) $-i\sigma_y = -i\left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$.
(2) $i\sigma_y = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$.

Doing the same for all pairs (using $\sigma_x\sigma_y = i\sigma_z$, $\sigma_y\sigma_z = i\sigma_x$, $\sigma_z\sigma_x = i\sigma_y$ and $\sigma_j^2 = \mathbb{1}$) gives the whole multiplier:

$\omega(g,h)$	$h=e$	a	b	ab
$g=e$	1	1	1	1
a	1	1	$-i$	i
b	1	i	1	$-i$
ab	1	$-i$	i	1

For instance $\omega(a,ab)$: $U(a)U(ab)=\sigma_x\sigma_y=i\sigma_z=iU(b)$ and $a\cdot ab=b$, so $\omega(a,ab)=i$. The commutator phase of the commuting pair (a,b) is

$$\frac{\omega(a,b)}{\omega(b,a)}=\frac{-i}{i}=-1\neq 1.$$

So the class is non-trivial: σ_x and σ_z anticommute, and no choice of phases can make them commute. The "honest" group that does act is generated by σ_x,σ_z and the phases: it is a non-abelian extension of the abelian $\mathbb{Z}_2\times\mathbb{Z}_2$ (the Pauli group).

Worked example 10.76: No invariant vector: a toy Gauss law

Suppose we demand a state invariant under the whole group, even allowing each element to act with its own phase: $\sigma_x\psi=\lambda\psi$ and $\sigma_z\psi=\mu\psi$. Then

$$\lambda\mu\,\psi\overset{(1)}{=}\sigma_x\sigma_z\psi\overset{(2)}{=}-\sigma_z\sigma_x\psi\overset{(3)}{=}-\mu\lambda\,\psi,$$

(1) Apply σ_z, then σ_x, using the two eigenvalue equations.
(2) $\sigma_x\sigma_z=-i\sigma_y=-\sigma_z\sigma_x$ from Example 10.75.
(3) Apply σ_x, then σ_z.

so $2\lambda\mu\psi=0$, and since $|\lambda|=|\mu|=1$, $\psi=0$. A non-trivial multiplier forbids invariant states. This two-line argument is, in miniature, why Gauss's law fails in an anomalous gauge theory (Section 10.10.20).

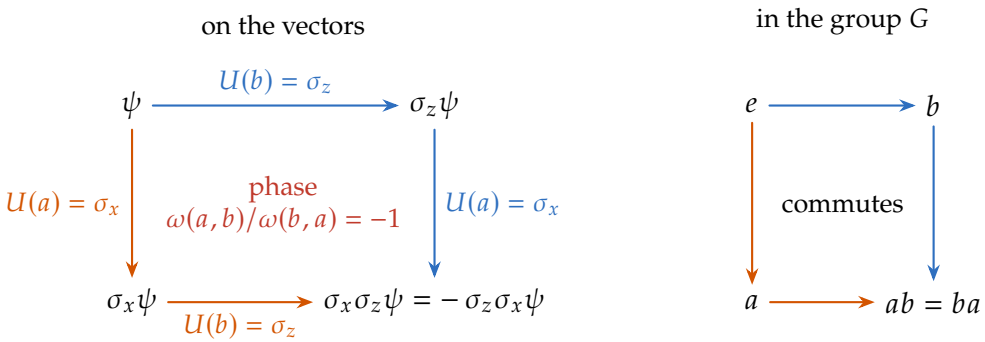

Figure 10.54: A projective representation, drawn as a square. In the group (right) going "b then a" or "a then b" lands on the same element. On the vectors (left) the two routes land on vectors that differ by the commutator phase, here -1. The phase does not depend on how the individual operators were phased, so it is an invariant of the projective representation; it is the simplest picture of a 2-cocycle.

Worked example 10.77: Spin $\frac{1}{2}$ is a projective representation of SO(3)

The rotation by angle φ about the unit vector $\vec{n}$ acts on a spin-$\frac{1}{2}$ state by $U(R_{\vec{n}}(\varphi)) = \exp(-\frac{i}{2}\varphi\,\vec{n}\cdot\vec{\sigma})$. Take $\vec{n} = \hat{z}$, so the operator is $\mathrm{diag}(e^{-i\varphi/2}, e^{i\varphi/2})$. The rotation by π composed with itself is the rotation by 2π, which is the identity of SO(3). But

$$U(R_z(\pi))\,U(R_z(\pi)) \overset{(1)}{=} \mathrm{diag}(e^{-i\pi/2}, e^{i\pi/2})^2 = \mathrm{diag}(e^{-i\pi}, e^{i\pi}) \overset{(2)}{=} -\mathbb{1} \overset{(3)}{=} -U(R_z(2\pi) = e),$$

(1) The formula for U at $\varphi = \pi$.
(2) $e^{\pm i\pi} = -1$.
(3) We chose $U(e) = \mathbb{1}$.

so $\omega(R_z(\pi), R_z(\pi)) = -1$. This multiplier takes only the values ± 1 and cannot be removed by any continuous choice of phases: its class is the generator of $H^2(\mathrm{SO}(3); \mathrm{U}(1)) = \mathbb{Z}_2$, which is the statement that the double cover $\mathrm{SU}(2) \to \mathrm{SO}(3)$ is non-trivial (Chapter T4). The honest group acting on spinors is the extension SU(2).

The extension that acts honestly. Every projective representation is an honest representation of a bigger group. On the set $\widehat{G} = \mathrm{U}(1) \times G$ define the product

$$(\lambda, g)\cdot(\mu, h) = \big(\lambda\mu\,\omega(g,h),\ gh\big). \tag{10.255}$$

It is associative exactly because of the cocycle condition:

$$\begin{aligned}\big((\lambda,g)(\mu,h)\big)(\nu,k) &\overset{(1)}{=} \big(\lambda\mu\nu\,\omega(g,h)\,\omega(gh,k),\ ghk\big)\\ &\overset{(2)}{=} \big(\lambda\mu\nu\,\omega(h,k)\,\omega(g,hk),\ ghk\big) \overset{(3)}{=} (\lambda,g)\big((\mu,h)(\nu,k)\big).\end{aligned}$$

(1) Apply (10.255) twice, left pair first.
(2) The cocycle condition (10.253).
(3) Apply (10.255) twice, right pair first.

And $(\lambda, g) \mapsto \lambda U(g)$ is an honest representation, because $\lambda U(g)\,\mu U(h) = \lambda\mu\,\omega(g,h)U(gh)$, which is the operator assigned to the product (10.255). The subgroup $\{(\lambda, e)\} \cong \mathrm{U}(1)$ commutes with everything (it is **central**), and dividing by it gives back G: $1 \to \mathrm{U}(1) \to \widehat{G} \to G \to 1$. For Example 10.77 the relevant part of $\widehat{G}$ is SU(2); for Example 10.75 it is the Pauli group.

10.10.16 Infinitesimal version: Lie-algebra cocycles

For a Lie group we can phase each one-parameter subgroup so that $U(e^{tX}) = e^{t\rho(X)}$ with $\rho(X)$ anti-Hermitian (a generator). What does the multiplier do to the commutation relations of the generators? Take X, Y in the Lie algebra and small s, t. In the group, $e^{sX}e^{tY}e^{-sX}e^{-tY} = e^{st[X,Y]+\cdots}$, where the dots are of third order. On the vectors the same product equals a phase times $U(e^{st[X,Y]})$. Write that phase as $1 + st\,c(X,Y) + \ldots$ with $c(X,Y) \in i\mathbb{R}$ and expand both sides to order st:

$$\begin{aligned}e^{s\rho(X)}e^{t\rho(Y)}e^{-s\rho(X)}e^{-t\rho(Y)} &\overset{(1)}{=} \mathbb{1} + st\,[\rho(X),\rho(Y)] + \ldots,\\ \big(1 + st\,c(X,Y)\big)\big(\mathbb{1} + st\,\rho([X,Y])\big) &\overset{(2)}{=} \mathbb{1} + st\,\big(\rho([X,Y]) + c(X,Y)\big) + \ldots\end{aligned}$$

(1) Expand each exponential to first order; the terms of order s^2 and t^2 cancel in pairs, and the surviving cross terms are $st(\rho(X)\rho(Y) - \rho(Y)\rho(X))$.

(2) Multiply out and keep order st.

Comparing,

$$[\rho(X),\rho(Y)] = \rho([X,Y]) + c(X,Y)\,\mathbb{1}. \tag{10.256}$$

The number $c(X,Y)$ is a **central term**. It is antisymmetric (swap X and Y in (10.256)) and bilinear. The Jacobi identity for the commutators of operators forces a cocycle condition:

$$0 \overset{(1)}{=} \sum_{\text{cyc}} \big[[\rho(X),\rho(Y)],\rho(Z)\big] \overset{(2)}{=} \sum_{\text{cyc}} \big[\rho([X,Y]) + c(X,Y),\ \rho(Z)\big]$$
$$\overset{(3)}{=} \sum_{\text{cyc}} \Big(\rho\big([[X,Y],Z]\big) + c([X,Y],Z)\Big) \overset{(4)}{=} \sum_{\text{cyc}} c([X,Y],Z),$$

(1) Jacobi identity for operators; "cyc" sums over the three cyclic permutations of (X,Y,Z).
(2) (10.256).
(3) The number $c(X,Y)$ commutes with $\rho(Z)$; then (10.256) again.
(4) Jacobi identity in the Lie algebra, $\sum_{\text{cyc}}[[X,Y],Z] = 0$, and linearity of ρ.

So $c([X,Y],Z) + c([Y,Z],X) + c([Z,X],Y) = 0$: a **Lie-algebra 2-cocycle**. Redefining the generators by constants, $\rho'(X) = \rho(X) + \alpha(X)$ with α linear, changes $c'(X,Y) = c(X,Y) - \alpha([X,Y])$: the commutator of the ρ' is that of the ρ, while $\rho([X,Y]) = \rho'([X,Y]) - \alpha([X,Y])$. So c is trivial (a coboundary) when it has the form $\alpha([X,Y])$.

Worked example 10.78: The Heisenberg group: canonical commutators are a cocycle

Let $G = \mathbb{R}^2$, the abelian group of phase-space translations (a,b), acting on wave functions $\psi(x)$ on the line by $W(a,b) = \exp\big(i(b\hat{x} - a\hat{p})\big)$ (units $\hbar = 1$, $[\hat{x},\hat{p}] = i$). Separately, $W(a,0) = e^{-ia\hat{p}}$ translates, $(W(a,0)\psi)(x) = \psi(x-a)$, and $W(0,b) = e^{ib\hat{x}}$ boosts the momentum. We need one standard identity.

Recall (the Baker–Campbell–Hausdorff formula when the commutator is central). If $[P,Q]$ commutes with P and Q, then $e^P e^Q = e^{P+Q+\frac{1}{2}[P,Q]}$. Proof: $F(t) = e^{tP}e^{tQ}$ obeys $F' = (P + e^{tP}Qe^{-tP})F = (P + Q + t[P,Q])F$, because the series $e^{tP}Qe^{-tP} = Q + t[P,Q] + \frac{t^2}{2}[P,[P,Q]] + \dots$ stops after two terms. Since $P+Q$ commutes with $[P,Q]$, the solution with $F(0) = \mathbb{1}$ is $F(t) = e^{t(P+Q)+\frac{t^2}{2}[P,Q]}$; differentiate to check. Set $t = 1$.

Now take $P = i(b\hat{x} - a\hat{p})$, $Q = i(b'\hat{x} - a'\hat{p})$:

$$[P,Q] \overset{(1)}{=} -\big[b\hat{x} - a\hat{p},\ b'\hat{x} - a'\hat{p}\big] \overset{(2)}{=} -\big(-ba'[\hat{x},\hat{p}] - ab'[\hat{p},\hat{x}]\big) \overset{(3)}{=} -i\,(ab' - ba'),$$
$$W(a,b)\,W(a',b') \overset{(4)}{=} e^{-\frac{i}{2}(ab'-ba')}\,W(a+a',\,b+b').$$

(1) $i \cdot i = -1$.
(2) Bilinearity; $[\hat{x},\hat{x}] = [\hat{p},\hat{p}] = 0$.
(3) $[\hat{x},\hat{p}] = i$ and $[\hat{p},\hat{x}] = -i$, so the bracket is $-ba'i + ab'i$.
(4) The BCH formula above; $P + Q = i((b+b')\hat{x} - (a+a')\hat{p})$.

So $\omega\big((a,b),(a',b')\big) = e^{-\frac{i}{2}(ab'-ba')}$. The group $\mathbb{R}^2$ is abelian, but the commutator phase of a translation and a boost is

$$\frac{\omega((a,0),(0,b))}{\omega((0,b),(a,0))} = \frac{e^{-\frac{i}{2}ab}}{e^{+\frac{i}{2}ab}} = e^{-iab} \neq 1.$$

Check it directly on a wave function: $W(a,0)W(0,b)\psi(x) = e^{ib(x-a)}\psi(x-a)$ while $W(0,b)W(a,0)\psi(x) = e^{ibx}\psi(x-a)$; the ratio is e^{-iab}. At the Lie algebra level the generators are $\rho(e_1) = -i\hat{p}$ and $\rho(e_2) = i\hat{x}$, and $[\rho(e_1),\rho(e_2)] = [\hat{p},\hat{x}] = -i$, while $[e_1,e_2] = 0$.

So (10.256) holds with $c(e_1, e_2) = -i$. Because the Lie algebra is abelian, $\alpha([e_1, e_2]) = 0$ for every α, and the central term cannot be removed. The canonical commutation relation *is* a non-trivial Lie-algebra 2-cocycle; the honest group is the Heisenberg group. The toy Gauss law fails here too: $\hat{x}\psi = 0$ and $\hat{p}\psi = 0$ would give $i\psi = [\hat{x}, \hat{p}]\psi = 0$.

Dictionary: Group cocycles and Lie-algebra cocycles

group level	**Lie-algebra level**
multiplier $\omega(g, h) \in \mathrm{U}(1)$	central term $c(X, Y) \in i\mathbb{R}$
$\omega(g, h)\omega(gh, k) = \omega(h, k)\omega(g, hk)$	$\sum_{\mathrm{cyc}} c([X, Y], Z) = 0$
rephasing $\beta(g)$	shift $\alpha(X)$
coboundary $\beta(g)\beta(h)/\beta(gh)$	coboundary $-\alpha([X, Y])$
central extension $\widehat{G}$	extended algebra $\mathfrak{g} \oplus i\mathbb{R}$
commutator phase of commuting g, h	$c(X, Y)$ for commuting X, Y

10.10.17 Gauge transformations on the Fock bundle: Nash's (10.97)

Now the real thing. Over each connection A on space we have a Fock space $\mathfrak{F}(A)$, defined up to the choice of a line (Section 10.10.14), and the projective spaces $\mathfrak{FP}(A)$ fit into a bundle on which $\mathcal{G}$ acts. A gauge transformation g maps the Dirac Hamiltonian at A to the Dirac Hamiltonian at $g \cdot A$ (they are unitarily equivalent by (10.236) and its non-abelian analogue), so it maps rays in $\mathfrak{FP}(A)$ to rays in $\mathfrak{FP}(g \cdot A)$. Lift this to vectors: for every g and every A choose a unitary

$$U_A(g) : \mathfrak{F}(A) \longrightarrow \mathfrak{F}(g \cdot A)$$

covering the action on rays. As for Wigner's theorem, each $U_A(g)$ is fixed up to a phase, but now the phase may depend on A.

The multiplier is a function of A. Compose two lifts. $U_A(h)$ goes from $\mathfrak{F}(A)$ to $\mathfrak{F}(h \cdot A)$, and $U_{h\cdot A}(g)$ continues to $\mathfrak{F}(gh \cdot A)$. The composite covers the same map of rays as $U_A(gh)$, so

$$U_{h\cdot A}(g)\, U_A(h) = \omega(g, h; A)\, U_A(gh), \qquad \omega(g, h; \cdot) \in \mathrm{Map}(\mathcal{A}, \mathrm{U}(1)). \tag{10.257}$$

This is Nash's (10.97), $g \cdot (h \cdot f_A) = \lambda(A)(gh) \cdot f_A$, with $\lambda(A) = \omega(\cdot, \cdot; A)$. The new feature compared with (10.252) is that the phase is a *function on the space of connections*.

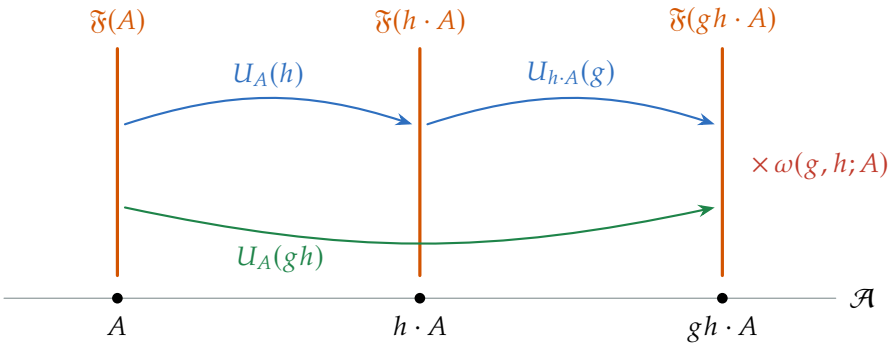

Figure 10.55: Nash's (10.97). The lifted gauge transformations carry the Fock space over A to the Fock spaces over the gauge-equivalent connections (orange fibres). Going in two steps (blue) or in one step (green) lands on the same ray; the vectors differ by a phase $\omega(g, h; A)$, which is a function of the starting point A.

The twisted cocycle condition. Associativity again, but now we must keep track of where each operator acts. Evaluate $U_{hk\cdot A}(g)\,U_{k\cdot A}(h)\,U_A(k)$, a map from $\mathfrak{F}(A)$ to $\mathfrak{F}(ghk\cdot A)$, in the two possible ways:

$$\big(U_{hk\cdot A}(g)\,U_{k\cdot A}(h)\big)U_A(k) \overset{(1)}{=} \omega(g,h;k\cdot A)\,U_{k\cdot A}(gh)\,U_A(k) \overset{(2)}{=} \omega(g,h;k\cdot A)\,\omega(gh,k;A)\,U_A(ghk),$$
$$U_{hk\cdot A}(g)\big(U_{k\cdot A}(h)\,U_A(k)\big) \overset{(3)}{=} \omega(h,k;A)\,U_{hk\cdot A}(g)\,U_A(hk) \overset{(4)}{=} \omega(h,k;A)\,\omega(g,hk;A)\,U_A(ghk).$$

(1) (10.257) with base point $k\cdot A$ (the pair g,h acts on the fibre over $k\cdot A$).
(2) (10.257) for the pair (gh,k) at base point A.
(3) (10.257) for the pair (h,k) at base point A.
(4) (10.257) for the pair (g,hk) at base point A.

Hence

$$\omega(g,h;k\cdot A)\,\omega(gh,k;A) = \omega(h,k;A)\,\omega(g,hk;A). \tag{10.258}$$

If ω does not depend on A this is (10.253). In general the first factor is evaluated at a moved point: $\mathcal{G}$ acts on the functions $\mathrm{Map}(\mathcal{A},\mathrm{U}(1))$ by moving their argument, and (10.258) is the cocycle condition of group cohomology *with coefficients in the $\mathcal{G}$-module* $\mathrm{Map}(\mathcal{A},\mathrm{U}(1))$. Rephasing $U'_A(g)=\beta(g;A)U_A(g)$ gives, exactly as in (10.254) but keeping track of base points,

$$U'_{h\cdot A}(g)\,U'_A(h) \overset{(1)}{=} \beta(g;h\cdot A)\,\beta(h;A)\,U_{h\cdot A}(g)\,U_A(h) \overset{(2)}{=} \frac{\beta(g;h\cdot A)\,\beta(h;A)}{\beta(gh;A)}\,\omega(g,h;A)\,U'_A(gh),$$

(1) Definition of U'; the lift of g acts at the point $h\cdot A$.
(2) (10.257), then $U_A(gh)=\beta(gh;A)^{-1}U'_A(gh)$.

so the removable multipliers are $\beta(g;h\cdot A)\beta(h;A)/\beta(gh;A)$ with β an arbitrary function of g and A. This is a much larger freedom than before, which is why a multiplier that looks non-trivial can sometimes be removed by an A-dependent rephasing. We will see an instance in Example 10.83.

The extension $\widehat{\mathcal{G}}$. The operators that act on sections Ψ of the Fock bundle ($\Psi(A)\in\mathfrak{F}(A)$) are the lifts $(\widehat{U}(g)\Psi)(g\cdot A)=U_A(g)\Psi(A)$ and the multiplications $(M_f\Psi)(A)=f(A)\Psi(A)$ by functions $f\in\mathrm{Map}(\mathcal{A},\mathrm{U}(1))$. A one-line computation shows that they do not commute:

$$(\widehat{U}(g)M_f\Psi)(g\cdot A) \overset{(1)}{=} U_A(g)\,f(A)\Psi(A) \overset{(2)}{=} f(A)\,(\widehat{U}(g)\Psi)(g\cdot A) \overset{(3)}{=} (M_{f\circ g^{-1}}\widehat{U}(g)\Psi)(g\cdot A),$$

(1) Definitions of $\widehat{U}(g)$ and M_f.
(2) $f(A)$ is a number; definition of $\widehat{U}(g)$.
(3) Write $f(A)=(f\circ g^{-1})(g\cdot A)$, where $(f\circ g^{-1})(B)=f(g^{-1}\cdot B)$.

so $\widehat{U}(g)M_f = M_{f\circ g^{-1}}\widehat{U}(g)$. The group generated by the $\widehat{U}(g)$ and the M_f is the extension

$$1\longrightarrow \mathrm{Map}(\mathcal{A},\mathrm{U}(1))\longrightarrow \widehat{\mathcal{G}}\longrightarrow \mathcal{G}\longrightarrow 1,$$

and the subgroup $\mathrm{Map}(\mathcal{A},\mathrm{U}(1))$ is *not* central: $\widehat{U}(g)$ moves the argument of f. This is the non-central extension of the gauge group met in Chapter 6, and it is what Nash means by "an extension of the group $\mathcal{G}$ by the group of projective multipliers $\lambda(A)$, which clearly belong to $\mathrm{Map}(\mathcal{A},S^1)$". When all the multipliers can be chosen constant, the extension is central and we are back in the situation of (10.255).

The infinitesimal version: Gauss generators and their algebra. Differentiate along one-parameter subgroups $g = e^{tX}$, $X \in \mathcal{LG}$ (a Lie-algebra-valued function on space). The lift becomes a first-order operator on sections,

$$\widehat{G}(X) = L_X + \widehat{\rho}_A(X), \tag{10.259}$$

where L_X differentiates a section along the infinitesimal gauge direction and $\widehat{\rho}_A(X)$ is the fermionic generator acting inside each fibre. We use the convention that e^{tX} moves A by

$$\delta_X A = \mathrm{d}X + [A, X] = D_A X, \tag{10.260}$$

the infinitesimal form of $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$ with $g = e^{tX}$ (expand to first order: $g^{-1}\mathrm{d}g \approx t\,\mathrm{d}X$ and $g^{-1}Ag \approx (\mathbb{1} - tX)A(\mathbb{1} + tX) \approx A + t[A, X]$). This is the right action $A \mapsto A^g$; in the left-action notation $g \cdot A$ of (10.257) it is the action of g^{-1}. We use it because with this sign the L_X are an honest representation of the Lie algebra, as we now check. On a function f of A, $(L_X f)(A) = \frac{\mathrm{d}}{\mathrm{d}t} f(A + t\,\delta_X A)|_{t=0}$.

The L_X represent the Lie algebra. We check $[L_X, L_Y] = L_{[X,Y]}$ on a function f. Write $\mathrm{D}f_A(\cdot)$ for the derivative of f at A. Then $L_Y f(A) = \mathrm{D}f_A(\delta_Y A)$, and $\delta_Y A = \mathrm{d}Y + [A, Y]$ itself depends on A, with derivative $[\delta_X A, Y]$ in the direction $\delta_X A$. So

$$\begin{aligned}
[L_X, L_Y]f &\overset{(1)}{=} \mathrm{D}f_A\big([\delta_X A, Y] - [\delta_Y A, X]\big) \\
&\overset{(2)}{=} \mathrm{D}f_A\big([\mathrm{d}X, Y] + [[A, X], Y] - [\mathrm{d}Y, X] - [[A, Y], X]\big) \\
&\overset{(3)}{=} \mathrm{D}f_A\big(\mathrm{d}[X, Y] + [A, [X, Y]]\big) \overset{(4)}{=} L_{[X,Y]}f.
\end{aligned}$$

(1) Product rule: $L_X L_Y f$ is the second derivative $\mathrm{D}^2 f_A(\delta_X A, \delta_Y A)$, which is symmetric and cancels in the commutator, plus $\mathrm{D}f_A$ of the derivative of $\delta_Y A$ along $\delta_X A$.
(2) (10.260) for $\delta_X A$ and $\delta_Y A$.
(3) $\mathrm{d}[X, Y] = [\mathrm{d}X, Y] + [X, \mathrm{d}Y] = [\mathrm{d}X, Y] - [\mathrm{d}Y, X]$; and $[[A, X], Y] - [[A, Y], X] = [[A, X], Y] + [[Y, A], X] = -[[X, Y], A] = [A, [X, Y]]$ by the Jacobi identity.
(4) (10.260) for $[X, Y]$.

Commutators with multiplication operators. For a function f of A (acting by multiplication) and any section Ψ, the product rule $L_Z(f\Psi) = (L_Z f)\Psi + f L_Z \Psi$ gives

$$[f, \widehat{G}(Z)] = -(L_Z f), \tag{10.261}$$

since $\widehat{\rho}_A(Z)$ acts fibrewise and commutes with multiplication by a number.

Working definition 10.21 (Schwinger term)

If the lifts [the operators $\widehat{U}(g)$ carrying the Fock space at A to the one at $g \cdot A$] are projective with an A-dependent multiplier [$\widehat{U}(g)\widehat{U}(h)$ differs from $\widehat{U}(gh)$ by a phase that depends on A], the generators [the infinitesimal lifts $\widehat{G}(X) = L_X + \widehat{\rho}_A(X)$, for $g = e^{tX}$] obey

$$[\widehat{G}(X), \widehat{G}(Y)] = \widehat{G}([X, Y]) + c(A; X, Y), \tag{10.262}$$

where $c(A; X, Y)$ is a function on $\mathcal{A}$ (acting by multiplication), bilinear and antisymmetric in X, Y. It is the **Schwinger term**. *How to compute it:* calculate the commutator of the regularised charge densities [the fermion bilinears with their infinite Dirac-sea value subtracted, i.e. normal ordered] of the fermions in the background A, and subtract $\widehat{G}([X, Y])$. *How to test it:* it is removable [can be made zero by shifting $\widehat{G}(X) \to \widehat{G}(X) + \alpha(X)$] iff $c = -(\delta\alpha)$ for some function $\alpha(A; X)$ linear in X, in the sense of (10.264) below.

The Jacobi identity now gives a cocycle condition that involves L_X:

$$0 \overset{(1)}{=} \sum_{\text{cyc}} \big[[\widehat{G}(X),\widehat{G}(Y)],\widehat{G}(Z)\big] \overset{(2)}{=} \sum_{\text{cyc}} \Big(\big[\widehat{G}([X,Y]),\widehat{G}(Z)\big] + \big[c(X,Y),\widehat{G}(Z)\big]\Big)$$
$$\overset{(3)}{=} \sum_{\text{cyc}} \Big(\widehat{G}\big([[X,Y],Z]\big) + c([X,Y],Z) - L_Z c(X,Y)\Big) \overset{(4)}{=} \sum_{\text{cyc}} \Big(c([X,Y],Z) - L_Z c(X,Y)\Big).$$

(1) Jacobi identity for operators.
(2) (10.262) for the inner commutator.
(3) (10.262) for the first term; (10.261) with $f = c(X,Y)$ for the second.
(4) Jacobi identity in $\mathcal{LG}$ and linearity of $\widehat{G}$.

Writing out the cyclic sum and using $c(Z,X) = -c(X,Z)$,

$$(\delta c)(X,Y,Z) \coloneqq L_X c(Y,Z) - L_Y c(X,Z) + L_Z c(X,Y) - c([X,Y],Z) + c([X,Z],Y) - c([Y,Z],X) = 0. \tag{10.263}$$

This is the Lie-algebra version of (10.258): the Chevalley–Eilenberg coboundary with coefficients in functions on $\mathcal{A}$. The L terms are new compared with Section 10.10.16; they are there because $\mathcal{G}$ acts on the coefficients.

Coboundaries. Shift the generators by functions, $\widehat{G}'(X) = \widehat{G}(X) + \alpha(X)$ with $\alpha(X) = \alpha(A;X)$ linear in X:

$$\begin{aligned}[\widehat{G}'(X),\widehat{G}'(Y)] &\overset{(1)}{=} [\widehat{G}(X),\widehat{G}(Y)] + [\widehat{G}(X),\alpha(Y)] + [\alpha(X),\widehat{G}(Y)] \\ &\overset{(2)}{=} \widehat{G}([X,Y]) + c(X,Y) + L_X\alpha(Y) - L_Y\alpha(X) \\ &\overset{(3)}{=} \widehat{G}'([X,Y]) + \underbrace{c(X,Y) + L_X\alpha(Y) - L_Y\alpha(X) - \alpha([X,Y])}_{c'(X,Y)}.\end{aligned} \tag{10.264}$$

(1) Bilinearity; $[\alpha(X),\alpha(Y)] = 0$ since both are multiplication operators.
(2) (10.262); (10.261) in the form $[\widehat{G}(X), f] = L_X f$.
(3) $\widehat{G}([X,Y]) = \widehat{G}'([X,Y]) - \alpha([X,Y])$.

So c can be removed iff $c = -(\delta\alpha)$ with $(\delta\alpha)(X,Y) = L_X\alpha(Y) - L_Y\alpha(X) - \alpha([X,Y])$. The anomaly is the class of c in this cohomology. Nash's obstruction, the class in $H^2(\mathcal{G})$ which transgresses to $H^3(\mathcal{A}/\mathcal{G};\mathbb{Z})$ ((10.251)), is its global form.

10.10.18 Schwinger terms from the anticommutation relations

Where does a Schwinger term come from in practice? From second quantisation of one-particle operators relative to a Dirac sea. The calculation is short and completely explicit, and it shows in one line why the answer is zero in finite dimensions "up to a coboundary", and non-zero in infinite dimensions.

Second quantisation of a one-particle operator. Let H have orthonormal basis e_i and let $a_i, a_i^\dagger$ obey the canonical anticommutation relations (CAR) $\{a_i, a_j^\dagger\} = \delta_{ij}$, $\{a_i, a_j\} = \{a_i^\dagger, a_j^\dagger\} = 0$. For a one-particle operator X with matrix $X_{ij} = \langle e_i | X e_j\rangle$ put

$$\widehat{X} = \sum_{i,j} X_{ij}\, a_i^\dagger a_j. \tag{10.265}$$

(For $X = \mathbb{1}$ this is the number operator; for $X = f(x)$ a multiplication operator it is the smeared density $\int f\,\psi^\dagger\psi$.) First the basic commutator:

$$\begin{aligned}[a_i^\dagger a_j,\, a_k^\dagger a_l] &\overset{(1)}{=} a_i^\dagger(\delta_{jk} - a_k^\dagger a_j)a_l - a_k^\dagger(\delta_{li} - a_i^\dagger a_l)a_j \\ &\overset{(2)}{=} \delta_{jk}\, a_i^\dagger a_l - \delta_{il}\, a_k^\dagger a_j - a_i^\dagger a_k^\dagger a_j a_l + a_k^\dagger a_i^\dagger a_l a_j \\ &\overset{(3)}{=} \delta_{jk}\, a_i^\dagger a_l - \delta_{il}\, a_k^\dagger a_j. \end{aligned} \tag{10.266}$$

(1) Write the commutator as $a_i^\dagger a_j a_k^\dagger a_l - a_k^\dagger a_l a_i^\dagger a_j$ and use the CAR $a_j a_k^\dagger = \delta_{jk} - a_k^\dagger a_j$ and $a_l a_i^\dagger = \delta_{li} - a_i^\dagger a_l$.
(2) Multiply out.
(3) $a_k^\dagger a_i^\dagger = -a_i^\dagger a_k^\dagger$ and $a_l a_j = -a_j a_l$, so the last term equals $+a_i^\dagger a_k^\dagger a_j a_l$ and cancels the one before it.

Multiplying by $X_{ij}Y_{kl}$ and summing:

$$[\widehat{X}, \widehat{Y}] \overset{(1)}{=} \sum_{i,l}\Big(\sum_j X_{ij}Y_{jl}\Big)a_i^\dagger a_l - \sum_{k,j}\Big(\sum_i Y_{ki}X_{ij}\Big)a_k^\dagger a_j \overset{(2)}{=} \widehat{[X,Y]}.$$

(1) (10.266); the δ's set $k = j$ in the first term and $l = i$ in the second.
(2) The brackets are $(XY)_{il}$ and $(YX)_{kj}$; rename the indices and use (10.265).

So second quantisation is an honest Lie-algebra homomorphism: no central term. In finite dimensions nothing more needs to be said.

Normal ordering relative to a Dirac sea. Now let $H = H^+ \oplus H^-$ be polarised by a one-particle Hamiltonian, and let the e_i be eigenvectors, with occupation numbers $n_i = 1$ for $e_i \in H^-$ (filled) and $n_i = 0$ for $e_i \in H^+$ (empty) in the Dirac sea $|\Omega\rangle$. Then $\langle\Omega|a_i^\dagger a_j|\Omega\rangle = \delta_{ij}n_i$. If H is infinite-dimensional, $\widehat{X}$ does not make sense on the sea: for $X = \mathbb{1}$, $\widehat{X}|\Omega\rangle = (\text{number of filled levels})|\Omega\rangle = \infty$. The cure is to subtract the vacuum value, i.e. to **normal order**:

$$:a_i^\dagger a_j: = a_i^\dagger a_j - \delta_{ij}n_i, \qquad :\widehat{X}: = \sum_{i,j} X_{ij}\,:a_i^\dagger a_j:. \tag{10.267}$$

In finite dimensions this is $\widehat{X} - \mathrm{tr}(P_- X)$, with P_- the projector onto H^-. Substitute $a^\dagger a = :a^\dagger a: + \delta n$ into (10.266):

$$\begin{aligned}[:a_i^\dagger a_j:, :a_k^\dagger a_l:] &\overset{(1)}{=} \delta_{jk}(:a_i^\dagger a_l: + \delta_{il}n_i) - \delta_{il}(:a_k^\dagger a_j: + \delta_{kj}n_k) \\ &\overset{(2)}{=} \delta_{jk}\,:a_i^\dagger a_l: - \delta_{il}\,:a_k^\dagger a_j: + \delta_{jk}\delta_{il}\,(n_i - n_j). \end{aligned} \tag{10.268}$$

(1) The numbers $\delta_{ij}n_i$ commute with everything, so the commutator of normal-ordered bilinears equals that of the bare ones, (10.266); then re-express the result in normal-ordered form.
(2) In the last term $k = j$ is enforced by δ_{kj}, so $n_k = n_j$.

The last term is new: a number. Multiplying by $X_{ij}Y_{kl}$ and summing, the operator parts give $:\widehat{[X,Y]}:$ as before, and

$$[:\widehat{X}:, :\widehat{Y}:] = :\widehat{[X,Y]}: + c(X,Y), \qquad c(X,Y) = \sum_{i,j} X_{ij}Y_{ji}\,(n_i - n_j). \tag{10.269}$$

Only pairs with one level filled and one empty contribute. With the block notation $X_{+-} = P_+ X P_-$ (from H^- to H^+) and $X_{-+} = P_- X P_+$,

$$c(X,Y) \overset{(1)}{=} \sum_{i\in -,\, j\in +} X_{ij}Y_{ji} - \sum_{i\in +,\, j\in -} X_{ij}Y_{ji} \overset{(2)}{=} \operatorname{tr}\big(X_{-+}Y_{+-}\big) - \operatorname{tr}\big(X_{+-}Y_{-+}\big) \overset{(3)}{=} \tfrac{1}{4}\operatorname{tr}\big(\epsilon\,[\epsilon,X]\,[\epsilon,Y]\big). \tag{10.270}$$

(1) $n_i - n_j = +1$ if i is filled and j empty, -1 in the reverse case, 0 otherwise.
(2) Matrix multiplication of the blocks.
(3) With $\epsilon = P_+ - P_-$ (the sign of the Hamiltonian), in block form $[\epsilon, X] = \left(\begin{smallmatrix} 0 & 2X_{+-} \\ -2X_{-+} & 0 \end{smallmatrix}\right)$, so $\epsilon[\epsilon,X][\epsilon,Y] = \left(\begin{smallmatrix} -4X_{+-}Y_{-+} & 0 \\ 0 & 4X_{-+}Y_{+-} \end{smallmatrix}\right)$; take $\frac{1}{4}$ of the trace.

Key idea: Why the Schwinger term is zero in finite dimensions and not in infinite ones

In finite dimensions, $c(X,Y) = \operatorname{tr}(P_-[X,Y])$ (the $--$ block of $[X,Y]$ contributes $\operatorname{tr}(X_{--}Y_{--} - Y_{--}X_{--}) = 0$). That is the coboundary $-\alpha([X,Y])$ of $\alpha(X) = -\operatorname{tr}(P_-X)$, and indeed $:\widehat{X}: = \widehat{X} - \operatorname{tr}(P_-X)$ is just a constant shift of an honest homomorphism. In infinite dimensions $\operatorname{tr}(P_-X)$ is infinite, so this α does not exist, but (10.270) is still finite whenever the off-diagonal blocks X_{+-}, X_{-+} are Hilbert–Schmidt (the product of two Hilbert–Schmidt operators is trace class). The Schwinger term is the finite remainder of a difference of two infinite traces. This form of the cocycle is due to Lundberg.

Worked example 10.79: The U(1) current algebra on a circle

Take one right-moving Weyl fermion on the circle: $H = L^2(S^1)$, $h = -i\,\mathrm{d}/\mathrm{d}\theta$, eigenvectors $e_k = e^{ik\theta}/\sqrt{2\pi}$ with eigenvalue $k \in \mathbb{Z}$. Fill $k \le -1$ and leave $k \ge 0$ empty (the zero mode is empty, as in Section 10.10.10): $n_k = 1$ for $k \le -1$. The density operators are the second-quantised multiplication operators. Multiplication by $e^{im\theta}$ has matrix

$$\big(e^{im\theta}\big)_{jk} = \langle e_j | e^{im\theta} e_k \rangle = \delta_{j,k+m},$$

since it moves e_k to e_{k+m}. Define the Fourier modes of the charge density by $\rho_m = :\widehat{e^{-im\theta}}: = \sum_k :a^\dagger_{k-m}a_k:$. Multiplication operators commute, $[e^{-im\theta}, e^{-in\theta}] = 0$, so the naive answer is $[\rho_m,\rho_n] = 0$. The correct answer is (10.269):

$$[\rho_m,\rho_n] \overset{(1)}{=} \sum_{i,j} \delta_{i,j-m}\,\delta_{j,i-n}\,(n_i - n_j) \overset{(2)}{=} \delta_{m+n,0} \sum_j \big(n_{j-m} - n_j\big) \overset{(3)}{=} m\,\delta_{m+n,0}.$$

(1) (10.269) with $X_{ij} = \delta_{i,j-m}$ and $Y_{ji} = \delta_{j,i-n}$; the operator part vanishes because $[X,Y] = 0$.
(2) The first δ sets $i = j - m$; then the second demands $j = j - m - n$.
(3) Count, for $m > 0$: $n_{j-m} - n_j$ is $+1$ exactly when $j - m \le -1$ and $j \ge 0$, i.e. for $j = 0, 1, \ldots, m-1$: m values, and 0 otherwise. For $m < 0$ the same count gives $-|m| = m$. For $m = 0$ it is 0.

So $[\rho_m,\rho_{-m}] = m$: for $m > 0$, $\rho_m/\sqrt{m}$ and $\rho_{-m}/\sqrt{m}$ obey the commutation relation of an annihilation and a creation operator. Indeed $\rho_m|\Omega\rangle = 0$ for $m > 0$ (the term $a^\dagger_{k-m}a_k$ needs k filled and $k-m$ empty, impossible), and $\|\rho_{-m}|\Omega\rangle\|^2 = \langle\Omega|\rho_m\rho_{-m}|\Omega\rangle = \langle\Omega|[\rho_m,\rho_{-m}]|\Omega\rangle = m$: the state $\rho_{-m}|\Omega\rangle$ is a superposition of the m particle–hole pairs that straddle the Fermi level (Figure 10.56). This is the starting point of bosonisation.

Position space. For real functions $f = \sum_m f_m e^{im\theta}$ and g put $\rho(f) = :\widehat{f}: = \sum_m f_m \rho_{-m}$. Then

$$[\rho(f), \rho(g)] \overset{(1)}{=} \sum_{m,n} f_m g_n \, [\rho_{-m}, \rho_{-n}] \overset{(2)}{=} -\sum_m m \, f_m g_{-m} \overset{(3)}{=} \frac{1}{2\pi i} \int_0^{2\pi} f \, g' \, \mathrm{d}\theta,$$

(1) Bilinearity.

(2) The result above with $(m, n) \to (-m, -n)$: $[\rho_{-m}, \rho_{-n}] = -m \, \delta_{m+n,0}$.

(3) $\int_0^{2\pi} f g' \mathrm{d}\theta = \sum_{m,n} f_m g_n (in) \, 2\pi \delta_{m+n,0} = -2\pi i \sum_m m f_m g_{-m}$.

which is the smeared form of $[\rho(\theta), \rho(\theta')] = \frac{1}{2\pi i} \, \delta'(\theta - \theta')$ (derivative with respect to θ; check by inserting into $\iint f(\theta) g(\theta') [\rho(\theta), \rho(\theta')]$ and integrating by parts). This is the classic Schwinger term of a chiral fermion in $1 + 1$ dimensions.

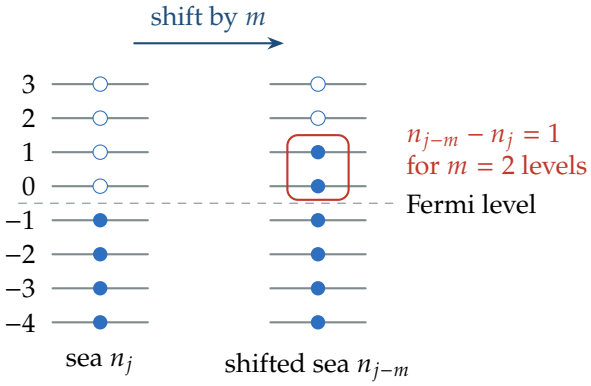

Figure 10.56: Where the m in $[\rho_m, \rho_{-m}] = m$ comes from. Left: the Dirac sea, levels $j \le -1$ filled. Right: the same occupation pattern shifted up by $m = 2$. Each of the two infinite sums $\sum_j n_j$ and $\sum_j n_{j-m}$ diverges, but their difference is finite: exactly the m levels just above the Fermi level (red box). The "trace of a commutator of two multiplication operators" is $\infty - \infty = m$.

Watch out: Chiral versus vector Schwinger terms

A left mover, $h_L = +i \, \mathrm{d}/\mathrm{d}\theta$, has energy $-k$ on e_k, so its sea fills $k \ge 1$. The same count as in step (3) gives $\sum_j (n_{j-m} - n_j) = -m$: the left-moving densities obey $[\rho^L_m, \rho^L_n] = -m \, \delta_{m+n,0}$. For a Dirac fermion the vector density $\rho = \rho^R + \rho^L$ therefore has *no* Schwinger term, while the axial density $\rho_5 = \rho^R - \rho^L$ has $[\rho_5(f), \rho(g)] = \frac{2}{2\pi i} \int f g' \, \mathrm{d}\theta$. The central term is a property of *chiral* charges. In a vector-like gauge theory the gauge generators are built from ρ, and the gauge algebra closes; in a chiral theory they are built from ρ^R alone, and it does not. The same bookkeeping produced $\Delta Q = 0$, $\Delta Q_5 = 2k$ in Example 10.70.

Worked example 10.80: Non-abelian currents in $1 + 1$: the Kac–Moody algebra

Give the right mover N colour components, $H = L^2(S^1) \otimes \mathbb{C}^N$, and let X, Y be $\mathfrak{u}(N)$-valued functions on the circle, $X = \sum_m X_m e^{im\theta}$ with X_m an $N \times N$ matrix. The sea is the same in each colour, so (10.269) gives the U(1) answer with a colour trace. For $X = X_m e^{im\theta}$ and $Y = Y_n e^{in\theta}$ the count of the previous example gives $c(X, Y) = -m \, \delta_{m+n,0} \, \mathrm{tr}(X_m Y_n)$, and summing over modes exactly as in the position-space step,

$$c(X, Y) = -\sum_m m \, \mathrm{tr}(X_m Y_{-m}) = \frac{1}{2\pi i} \int_0^{2\pi} \mathrm{tr}\big(X \, \partial_\theta Y\big) \mathrm{d}\theta. \tag{10.271}$$

This does not depend on any background connection: it is a genuine central term, and (10.269) with it is the level-one Kac–Moody (affine) algebra. At the group level it is the central extension of the loop group $\mathrm{Map}(S^1, \mathrm{U}(N))$ constructed in Chapter 6. The Lie-algebra cocycle condition of Section 10.10.16 can be checked by hand: $\oint \mathrm{tr}([X,Y]\,Z')$ summed cyclically vanishes, because $\mathrm{tr}([X,Y]Z') + \mathrm{tr}([Y,Z]X') + \mathrm{tr}([Z,X]Y') = \partial_\theta \,\mathrm{tr}(XYZ - YXZ)$ (expand both sides with the product rule and cyclicity of the trace), and a derivative integrates to zero on the circle.

When does normal ordering work? The Hilbert–Schmidt test. The state

$$:\widehat{X}:|\Omega\rangle = \sum_{i\in+,\, j\in-} X_{ij}\, a_i^\dagger a_j |\Omega\rangle$$

is a superposition of particle–hole pairs. (On the sea, $a_i^\dagger a_j|\Omega\rangle = 0$ if j is empty, since a_j finds nothing to remove, and also if $i \neq j$ is filled, since $a_i^\dagger$ is blocked by the Pauli principle; for $i = j$ filled it gives $|\Omega\rangle$, which the subtraction $\delta_{ij} n_i$ cancels. Only i empty and j filled survive.) Its squared norm is

$$\left\| :\widehat{X}:|\Omega\rangle \right\|^2 = \sum_{i\in+,\, j\in-} \left|X_{ij}\right|^2 = \|X_{+-}\|_{\mathrm{HS}}^2 \,. \tag{10.272}$$

(Distinct pairs (i,j) give orthogonal states of norm one.) So $:\widehat{X}:$ makes sense on the Fock space built on this sea exactly when X_{+-} is **Hilbert–Schmidt**, i.e. when the sum of the squares of its matrix elements converges. The same is true at the group level (the **Shale–Stinespring theorem**): a unitary U on H is implemented by a unitary on Fock space iff its off-diagonal blocks are Hilbert–Schmidt, and then the implementer is unique up to a phase. The implementable unitaries form the **restricted unitary group** $\mathrm{U}_{\mathrm{res}}(H)$, and the phases of the implementers give a *central* extension of it, whose Lie-algebra cocycle is (10.270).

Worked example 10.81: One space dimension passes, three fail

$d = 1$. Take $h = -i\,\mathrm{d}/\mathrm{d}\theta$ and X multiplication by a smooth $f = \sum_m f_m e^{im\theta}$. Then $X_{ij} = f_{i-j}$, and

$$\|X_{+-}\|_{\mathrm{HS}}^2 \overset{(1)}{=} \sum_{i\geq 0}\sum_{j\leq -1} \left|f_{i-j}\right|^2 \overset{(2)}{=} \sum_{m\geq 1} m\ |f_m|^2 < \infty.$$

(1) (10.272) with $H^+ = \{i \geq 0\}$ and $H^- = \{j \leq -1\}$.

(2) Group the terms by $m = i - j \geq 1$; the number of pairs with a given m is m (namely $j = -1, \ldots, -m$). Smooth f has rapidly decreasing f_m.

So every smooth gauge transformation on the circle is implementable, the extension is central, and the Schwinger term is the constant (10.271).

$d = 3$. Take a Weyl fermion on the 3-torus, $h = \vec{\sigma}\cdot\vec{p}$ with $\vec{p} \in \mathbb{Z}^3$. For each $\vec{p} \neq 0$ there is one positive-energy spinor $u_+(\vec{p})$ (spin along $\hat{\vec{p}}$) and one negative-energy spinor $u_-(\vec{p})$ (spin against $\hat{\vec{p}}$). Multiplication by $e^{i\vec{m}\cdot\vec{x}}$ maps momentum $\vec{p}$ to $\vec{p} + \vec{m}$; its $+-$ block has matrix elements $\langle u_+(\vec{p}+\vec{m})|u_-(\vec{p})\rangle$. We need the overlap of two spin states. Let $|\vec{n},+\rangle$ be the spin-$\frac{1}{2}$ state pointing along the unit vector $\vec{n}$ (the state $|\psi_N(\vec{n})\rangle$ of the Berry-phase example, Example 10.58). Its projector is $|\vec{n},+\rangle\langle\vec{n},+| = \frac{1}{2}(\mathbb{1} + \vec{n}\cdot\vec{\sigma})$: both sides are Hermitian with trace 1, and $\frac{1}{2}(\mathbb{1} + \vec{n}\cdot\vec{\sigma})$ has eigenvalue 1 on $|\vec{n},+\rangle$ (because $(\vec{n}\cdot\vec{\sigma})|\vec{n},+\rangle = |\vec{n},+\rangle$) and 0 on the orthogonal state. Then

$$\left|\langle\vec{n}_1,+|\vec{n}_2,+\rangle\right|^2 \overset{(1)}{=} \mathrm{tr}\big(|\vec{n}_1,+\rangle\langle\vec{n}_1,+|\,|\vec{n}_2,+\rangle\langle\vec{n}_2,+|\big)$$

$$\overset{(2)}{=} \tfrac{1}{4}\operatorname{tr}\big((\mathbb{1}+\vec{n}_1\cdot\vec{\sigma})(\mathbb{1}+\vec{n}_2\cdot\vec{\sigma})\big) \overset{(3)}{=} \tfrac{1}{2}\big(1+\vec{n}_1\cdot\vec{n}_2\big).$$

(1) $\operatorname{tr}(|a\rangle\langle a|b\rangle\langle b|) = \langle a|b\rangle\langle b|a\rangle = |\langle a|b\rangle|^2$.
(2) The projector formula.
(3) $\operatorname{tr}\mathbb{1} = 2$, $\operatorname{tr}\sigma_i = 0$, $\operatorname{tr}(\sigma_i\sigma_j) = 2\delta_{ij}$.

The negative-energy state at $\vec{p}$ points against $\hat{\vec{p}}$: $u_-(\vec{p}) = |-\hat{\vec{p}},+\rangle$. So

$$\|X_{+-}\|_{\mathrm{HS}}^2 \overset{(1)}{=} \sum_{\vec{p}} \tfrac{1}{2}\big(1-\hat{\vec{p}}\cdot\widehat{\vec{p}+\vec{m}}\big) \overset{(2)}{=} \sum_{\vec{p}}\Big(\frac{|\vec{m}_\perp|^2}{4|\vec{p}|^2} + O(|\vec{p}|^{-3})\Big) \overset{(3)}{=} \infty.$$

(1) The overlap formula with $\vec{n}_1 = \widehat{\vec{p}+\vec{m}}$ and $\vec{n}_2 = -\hat{\vec{p}}$.
(2) For large $|\vec{p}|$ the angle ϑ between $\vec{p}$ and $\vec{p}+\vec{m}$ is $|\vec{m}_\perp|/|\vec{p}|$ to leading order, where $\vec{m}_\perp$ is the part of $\vec{m}$ perpendicular to $\vec{p}$; and $1-\cos\vartheta \approx \vartheta^2/2$.
(3) The number of lattice points with $|\vec{p}| \approx P$ grows like $4\pi P^2$, so the sum behaves like $\int^\Lambda 4\pi P^2\,\mathrm{d}P/P^2 \propto \Lambda$: linearly divergent.

In one dimension only finitely many levels near the Fermi point are disturbed by f (Figure 10.56). In three dimensions a gauge transformation tilts the spin of *every* level by a small angle, and the small tilts add up to an infinite number of pairs. The sum $\sum|\vec{p}|^{-2}$ diverges while $\sum|\vec{p}|^{-4}$ converges, so X_{+-} is in the Schatten class $\mathcal{L}_4$ but not in $\mathcal{L}_2$.

Key idea: The dimension of space decides the type of extension

In $1+1$ dimensions the gauge group on space lies inside $\mathrm{U}_{\mathrm{res}}$ of a fixed polarisation: the Fock space can be built once and for all, the extension is *central*, and the Schwinger term is the constant (10.271). In $3+1$ dimensions it does not: there is no single Fock space on which all gauge transformations act. One must use a separate Fock space $\mathfrak{F}(A)$ for each background connection, built on the polarisation of $\not{D}_A$ itself (Section 10.10.12). Then the phases of the implementers depend on A, the extension is by $\mathrm{Map}(\mathcal{A},\mathrm{U}(1))$ and is non-central, as in (10.257), and the Schwinger term is a non-constant function on $\mathcal{A}$. This is precisely the situation Nash describes, and the next subsection computes that function.

10.10.19 The Faddeev–Mickelsson cocycle

We now want the function $c(A;X,Y)$ for chiral fermions on S^3. A direct Hamiltonian computation is possible (it is Mickelsson's: renormalise the charge densities separately on each $\mathfrak{F}(A)$ and compute their commutators), but it is long. Faddeev found the answer faster, by noticing that the Schwinger term is the next rung of the same *descent ladder* that produced the Euclidean anomaly in Chapter 10. We follow that route and do every step.

Ghosts: a bookkeeping device for cochains. A cochain of degree g on the gauge Lie algebra is a function $c(A;X_1,\dots,X_g)$, multilinear and antisymmetric in the X's. A compact way to handle antisymmetric multilinear functions is to replace the X's by a single anticommuting variable, the **ghost** $v = v^a T_a$, whose components $v^a(x)$ are Grassmann numbers. A ghost-number-g expression, a polynomial of degree g in v and its derivatives, determines a g-cochain: to evaluate it on $(X_1,\dots,X_g)$ replace each product $v^{a_1}\cdots v^{a_g}$ of ghost components by the antisymmetrised product $\sum_\pi \operatorname{sgn}(\pi) X^{a_1}_{\pi(1)}\cdots X^{a_g}_{\pi(g)}$. For $g=2$: $v^a v^b \mapsto X^a Y^b - Y^a X^b$. For example (up to an

overall sign that depends on how ghosts are ordered against $\mathrm{d}x^\mu$),

$$\operatorname{tr}(A\,\mathrm{d}v\,\mathrm{d}v) \;\longmapsto\; \operatorname{tr}\big(A\,(\mathrm{d}X\,\mathrm{d}Y - \mathrm{d}Y\,\mathrm{d}X)\big), \tag{10.273}$$

where $\mathrm{d}X\,\mathrm{d}Y$ means the wedge product of the matrix-valued 1-forms $\mathrm{d}X$ and $\mathrm{d}Y$ (the order of the matrices matters). Under this dictionary the BRST operator s becomes (up to sign) the coboundary δ of (10.263), and $s^2 = 0$ becomes $\delta^2 = 0$.

Conventions. All objects are graded by (form degree + ghost number) mod 2: A and v are odd, $\mathrm{d}A$ and $\mathrm{d}v$ are even. The operators d and s are odd derivations, $\mathrm{d}(xy) = (\mathrm{d}x)y + (-1)^{|x|}x\,\mathrm{d}y$ and the same for s, with $\mathrm{d}^2 = s^2 = 0$ and $s\mathrm{d} + \mathrm{d}s = 0$. The trace is graded-cyclic: $\operatorname{tr}(xy) = (-1)^{|x||y|}\operatorname{tr}(yx)$. The action of s is fixed by the **Russian formula** $(\mathrm{d}+s)(A+v) + (A+v)^2 = F$; sorting it by (form, ghost) degree gives $\mathrm{d}A + A^2 = F$ at $(2,0)$, and

$$\begin{aligned} (1,1):&\quad sA + \mathrm{d}v + Av + vA = 0 \implies sA = -\mathrm{d}v - Av - vA,\\ (0,2):&\quad sv + v^2 = 0 \implies sv = -v^2. \end{aligned} \tag{10.274}$$

(With v replaced by tX, $sA = -D_A v$ is minus the infinitesimal gauge transformation (10.260); the sign is the standard one for BRST.) From these, using $s\mathrm{d} = -\mathrm{d}s$:

$$\begin{aligned} s(\mathrm{d}A) &\overset{(1)}{=} -\mathrm{d}(sA) \overset{(2)}{=} \mathrm{d}(\mathrm{d}v + Av + vA) \overset{(3)}{=} \mathrm{d}A\,v - A\,\mathrm{d}v + \mathrm{d}v\,A - v\,\mathrm{d}A,\\ s(\mathrm{d}v) &\overset{(4)}{=} -\mathrm{d}(sv) \overset{(5)}{=} \mathrm{d}(v^2) \overset{(6)}{=} \mathrm{d}v\,v - v\,\mathrm{d}v. \end{aligned}$$

(1) $s\mathrm{d} = -\mathrm{d}s$.
(2) (10.274).
(3) $\mathrm{d}^2 v = 0$; $\mathrm{d}(Av) = \mathrm{d}A\,v - A\,\mathrm{d}v$ and $\mathrm{d}(vA) = \mathrm{d}v\,A - v\,\mathrm{d}A$ (graded Leibniz, A and v odd).
(4) $s\mathrm{d} = -\mathrm{d}s$.
(5) (10.274).
(6) Graded Leibniz with v odd.

(Check: $s^2 v = -s(v^2) = -(sv)v + v(sv) = v^3 - v^3 = 0$.)

The rung we need. In Chapter 10 (§2) the consistent non-abelian anomaly in four dimensions came out as a multiple of

$$\omega_4^1 = \operatorname{tr}\big(v\,\mathrm{d}\Phi\big), \qquad \Phi = A\,\mathrm{d}A + \tfrac{1}{2}A^3, \tag{10.275}$$

with normalisation $\frac{1}{24\pi^2}$ (up to convention-dependent factors of i), obtained by descent from $\operatorname{tr} F^3$ in six dimensions. The descent equations continue one more step: there is a 3-form ω_3^2 of ghost number 2 with

$$s\,\omega_4^1 + \mathrm{d}\,\omega_3^2 = 0. \tag{10.276}$$

We find it. Three short computations.

Step 1: move the derivative off the ghost.

$$\mathrm{d}\,\operatorname{tr}(v\Phi) \overset{(1)}{=} \operatorname{tr}(\mathrm{d}v\,\Phi) - \operatorname{tr}(v\,\mathrm{d}\Phi) \quad\Longrightarrow\quad \omega_4^1 \overset{(2)}{=} \operatorname{tr}(\mathrm{d}v\,\Phi) - \mathrm{d}\,\operatorname{tr}(v\Phi).$$

(1) Graded Leibniz; v is odd, and d commutes with the trace.
(2) Rearrange; definition (10.275).

Step 2: the BRST variation of Φ. Using (10.274) and the formula for $s(\mathrm{d}A)$,

$$\begin{aligned} s(A\,\mathrm{d}A) &\overset{(1)}{=} (sA)\,\mathrm{d}A - A\,s(\mathrm{d}A) \\ &\overset{(2)}{=} \big(-\mathrm{d}v - Av - vA\big)\mathrm{d}A - A\big(\mathrm{d}A\,v - A\,\mathrm{d}v + \mathrm{d}v\,A - v\,\mathrm{d}A\big) \\ &\overset{(3)}{=} -\mathrm{d}v\,\mathrm{d}A - vA\,\mathrm{d}A - A\,\mathrm{d}A\,v + A^2\mathrm{d}v - A\,\mathrm{d}v\,A, \\ s(A^3) &\overset{(4)}{=} (sA)A^2 - A(sA)A + A^2(sA) \\ &\overset{(5)}{=} -\mathrm{d}v\,A^2 - AvA^2 - vA^3 + A\,\mathrm{d}v\,A + A^2vA + AvA^2 - A^2\mathrm{d}v - A^3v - A^2vA \\ &\overset{(6)}{=} -\mathrm{d}v\,A^2 - vA^3 + A\,\mathrm{d}v\,A - A^2\mathrm{d}v - A^3v. \end{aligned}$$

(1) Graded Leibniz; A is odd.
(2) Insert sA and $s(\mathrm{d}A)$.
(3) Multiply out; the terms $-Av\,\mathrm{d}A$ and $+Av\,\mathrm{d}A$ cancel.
(4) Graded Leibniz twice; each A passed by s gives a sign.
(5) Insert sA in each slot and multiply out.
(6) $-AvA^2$ cancels $+AvA^2$ and $+A^2vA$ cancels $-A^2vA$.

Adding $s(A\,\mathrm{d}A) + \frac{1}{2}s(A^3)$:

$$s\Phi = -\mathrm{d}v\,\mathrm{d}A - vA\,\mathrm{d}A - A\,\mathrm{d}A\,v + \tfrac{1}{2}A^2\mathrm{d}v - \tfrac{1}{2}A\,\mathrm{d}v\,A - \tfrac{1}{2}\mathrm{d}v\,A^2 - \tfrac{1}{2}vA^3 - \tfrac{1}{2}A^3v. \tag{10.277}$$

Step 3: vary $\operatorname{tr}(\mathrm{d}v\,\Phi)$. Since $\mathrm{d}v$ is even, $s\,\operatorname{tr}(\mathrm{d}v\,\Phi) = \operatorname{tr}\big(s(\mathrm{d}v)\Phi\big) + \operatorname{tr}\big(\mathrm{d}v\,s\Phi\big)$. The two pieces are

$$\begin{aligned} \operatorname{tr}\big(s(\mathrm{d}v)\Phi\big) &= \operatorname{tr}(\mathrm{d}v\,vA\,\mathrm{d}A) - \operatorname{tr}(v\,\mathrm{d}v\,A\,\mathrm{d}A) + \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,vA^3) - \tfrac{1}{2}\operatorname{tr}(v\,\mathrm{d}v\,A^3), \\ \operatorname{tr}\big(\mathrm{d}v\,s\Phi\big) &= -\operatorname{tr}(\mathrm{d}v\,\mathrm{d}v\,\mathrm{d}A) - \operatorname{tr}(\mathrm{d}v\,vA\,\mathrm{d}A) - \operatorname{tr}(\mathrm{d}v\,A\,\mathrm{d}A\,v) + \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,A^2\mathrm{d}v) \\ &\quad - \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,A\,\mathrm{d}v\,A) - \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,\mathrm{d}v\,A^2) - \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,vA^3) - \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,A^3v). \end{aligned}$$

Now add them and simplify term by term:

$$\begin{aligned} s\,\operatorname{tr}(\mathrm{d}v\,\Phi) &\overset{(1)}{=} -\operatorname{tr}(v\,\mathrm{d}v\,A\,\mathrm{d}A) - \tfrac{1}{2}\operatorname{tr}(v\,\mathrm{d}v\,A^3) - \operatorname{tr}(\mathrm{d}v\,\mathrm{d}v\,\mathrm{d}A) - \operatorname{tr}(\mathrm{d}v\,A\,\mathrm{d}A\,v) \\ &\qquad + \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,A^2\mathrm{d}v) - \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,A\,\mathrm{d}v\,A) - \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,\mathrm{d}v\,A^2) - \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,A^3v) \\ &\overset{(2)}{=} -\operatorname{tr}(\mathrm{d}v\,\mathrm{d}v\,\mathrm{d}A) + \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,A^2\mathrm{d}v) - \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,\mathrm{d}v\,A^2) - \tfrac{1}{2}\operatorname{tr}(\mathrm{d}v\,A\,\mathrm{d}v\,A) \\ &\overset{(3)}{=} -\operatorname{tr}(\mathrm{d}v\,\mathrm{d}v\,\mathrm{d}A) \overset{(4)}{=} -\operatorname{tr}(\mathrm{d}A\,\mathrm{d}v\,\mathrm{d}v). \end{aligned}$$

(1) The terms $\pm\operatorname{tr}(\mathrm{d}v\,vA\,\mathrm{d}A)$ cancel, and so do $\pm\frac{1}{2}\operatorname{tr}(\mathrm{d}v\,vA^3)$.
(2) Graded cyclicity: moving the odd v from the end to the front past the odd block $\mathrm{d}v\,A\,\mathrm{d}A$ (parity $0+1+0$) costs a sign, so $\operatorname{tr}(\mathrm{d}v\,A\,\mathrm{d}A\,v) = -\operatorname{tr}(v\,\mathrm{d}v\,A\,\mathrm{d}A)$, and the pair cancels; in the same way $\operatorname{tr}(\mathrm{d}v\,A^3v) = -\operatorname{tr}(v\,\mathrm{d}v\,A^3)$ cancels its partner.
(3) $\operatorname{tr}(\mathrm{d}v\,A^2\mathrm{d}v) = \operatorname{tr}(\mathrm{d}v\,\mathrm{d}v\,A^2)$ (move the even $\mathrm{d}v$ from the end to the front), so those two cancel. And $\operatorname{tr}(\mathrm{d}v\,A\,\mathrm{d}v\,A) = 0$: moving the last (odd) A to the front past the odd block $\mathrm{d}v\,A\,\mathrm{d}v$ gives $-\operatorname{tr}(A\,\mathrm{d}v\,A\,\mathrm{d}v)$, and moving the last (even) $\mathrm{d}v$ of that to the front gives back $-\operatorname{tr}(\mathrm{d}v\,A\,\mathrm{d}v\,A)$; a quantity equal to minus itself is zero.
(4) Move the even $\mathrm{d}A$ to the front.

And finally $\mathrm{d}\,\operatorname{tr}(A\,\mathrm{d}v\,\mathrm{d}v) = \operatorname{tr}(\mathrm{d}A\,\mathrm{d}v\,\mathrm{d}v) - \operatorname{tr}\big(A\,\mathrm{d}(\mathrm{d}v\,\mathrm{d}v)\big) = \operatorname{tr}(\mathrm{d}A\,\mathrm{d}v\,\mathrm{d}v)$, since $\mathrm{d}^2v = 0$. Putting

the steps together:

$$\begin{aligned} s\,\omega_4^1 &\overset{(1)}{=} s\ \mathrm{tr}(\mathrm{d}v\,\Phi) - s\,\mathrm{d}\ \mathrm{tr}(v\Phi) \overset{(2)}{=} -\mathrm{tr}(\mathrm{d}A\,\mathrm{d}v\,\mathrm{d}v) + \mathrm{d}\,s\ \mathrm{tr}(v\Phi) \\ &\overset{(3)}{=} -\mathrm{d}\Big(\mathrm{tr}(A\,\mathrm{d}v\,\mathrm{d}v) - s\ \mathrm{tr}(v\Phi)\Big). \end{aligned} \tag{10.278}$$

(1) Step 1.
(2) Step 3, and $s\mathrm{d} = -\mathrm{d}s$.
(3) $\mathrm{tr}(\mathrm{d}A\,\mathrm{d}v\,\mathrm{d}v) = \mathrm{d}\ \mathrm{tr}(A\,\mathrm{d}v\,\mathrm{d}v)$.

So (10.276) holds with $\omega_3^2 = \mathrm{tr}(A\,\mathrm{d}v\,\mathrm{d}v) - s\ \mathrm{tr}(v\Phi)$. The second term is s-exact: in cochain language it is the coboundary of the local 1-cochain $\alpha(X) \propto \int \mathrm{tr}(X\Phi)$, and by (10.264) it can be dropped. (We checked (10.278) independently by implementing the graded algebra on a computer.)

Why the next rung is the Schwinger term. Integrate (10.276) over a four-dimensional slab $M = [t_0, t_1] \times S^3$ of spacetime:

$$s\int_M \omega_4^1 \;=\; -\int_M \mathrm{d}\,\omega_3^2 \;=\; -\int_{\{t_1\}\times S^3} \omega_3^2 + \int_{\{t_0\}\times S^3} \omega_3^2.$$

On a closed four-manifold the right side is zero: that is the Wess–Zumino consistency condition, $\delta a = 0$ for the anomaly $a = \int \omega_4^1$ (Chapter 10). On a slab it fails by terms that live on the initial and final *spatial* slices, and depend only on the fields there. In the Hamiltonian language the slices carry the states, and the failure of the gauge transformations acting on them to compose properly is exactly what the Schwinger term measures. So the Schwinger term on S^3 is the integral of ω_3^2 over space, translated into a 2-cochain by (10.273). (Matching the overall constant requires the full Hamiltonian computation; we quote it.)

Key idea: The Faddeev–Mickelsson cocycle

For chiral fermions on S^3 coupled to a connection A, the Schwinger term of the Gauss generators is

$$c(A; X, Y) = N\int_{S^3} \mathrm{tr}\big(A\,(\mathrm{d}X\,\mathrm{d}Y - \mathrm{d}Y\,\mathrm{d}X)\big), \qquad N = \frac{1}{24\pi^2}\ \text{(up to a factor of } i \text{ and a sign)}, \tag{10.279}$$

the Faddeev–Mickelsson cocycle. It is linear in A, so it is a *non-constant* function on $\mathcal{A}$: the extension it defines is by $\mathrm{Map}(\mathcal{A}, \mathrm{U}(1))$, not by $\mathrm{U}(1)$, as Nash says.

In components. Write $\mathrm{d}X = \partial_j X\,\mathrm{d}x^j$. Then

$$\begin{aligned} \mathrm{d}X\,\mathrm{d}Y - \mathrm{d}Y\,\mathrm{d}X &\overset{(1)}{=} \big(\partial_j X\,\partial_k Y - \partial_j Y\,\partial_k X\big)\mathrm{d}x^j \wedge \mathrm{d}x^k \overset{(2)}{=} \big(\partial_j X\,\partial_k Y + \partial_k Y\,\partial_j X\big)\mathrm{d}x^j \wedge \mathrm{d}x^k, \\ c(A; X, Y) &\overset{(3)}{=} N\int_{S^3} \epsilon^{ijk}\ \mathrm{tr}\big(A_i\,\{\partial_j X, \partial_k Y\}\big)\,\mathrm{d}^3x. \end{aligned}$$

(1) Definition of the wedge product of matrix-valued 1-forms: the matrices keep their order, the $\mathrm{d}x$'s are wedged.
(2) In the second term swap the dummy indices $j \leftrightarrow k$ and use $\mathrm{d}x^k \wedge \mathrm{d}x^j = -\mathrm{d}x^j \wedge \mathrm{d}x^k$.
(3) $A = A_i\,\mathrm{d}x^i$ and $\mathrm{d}x^i \wedge \mathrm{d}x^j \wedge \mathrm{d}x^k = \epsilon^{ijk}\mathrm{d}^3x$.

So only the *anticommutator* of the Lie-algebra matrices enters. This is the key to which groups are anomalous.

Worked example 10.82: SU(2) has no Faddeev–Mickelsson term; SU(3) has one

Expand in a basis of anti-Hermitian generators T_a: $\operatorname{tr}(A_i\{\partial_j X, \partial_k Y\}) = A_i^c\,\partial_j X^a\,\partial_k Y^b\,\operatorname{tr}\big(T_c\{T_a, T_b\}\big)$.

- SU(2), $T_a = -\frac{i}{2}\sigma_a$: $\{T_a, T_b\} = -\frac{1}{4}\{\sigma_a, \sigma_b\} = -\frac{1}{2}\delta_{ab}\mathbb{1}$, using $\{\sigma_a, \sigma_b\} = 2\delta_{ab}\mathbb{1}$. Then $\operatorname{tr}(T_c\{T_a, T_b\}) = -\frac{1}{2}\delta_{ab}\operatorname{tr} T_c = 0$. So $c \equiv 0$. This matches $\pi_5(\mathrm{SU}(2)) = \mathbb{Z}_2$: there is no integer class, so no perturbative anomaly, only Witten's global one (Section 10.9).
- SU(3), $T_a = -\frac{i}{2}\lambda_a$ (Gell-Mann matrices, with $\{\lambda_a, \lambda_b\} = \frac{4}{3}\delta_{ab}\mathbb{1} + 2d_{abe}\lambda_e$ and $\operatorname{tr}(\lambda_a\lambda_b) = 2\delta_{ab}$):

$$\operatorname{tr}\big(T_c\{T_a, T_b\}\big) \overset{(1)}{=} \Big(-\tfrac{i}{2}\Big)^3 \operatorname{tr}\big(\lambda_c\{\lambda_a, \lambda_b\}\big) \overset{(2)}{=} \tfrac{i}{8}\big(\tfrac{4}{3}\delta_{ab}\operatorname{tr}\lambda_c + 2d_{abe}\operatorname{tr}(\lambda_c\lambda_e)\big) \overset{(3)}{=} \tfrac{i}{2}\,d_{abc}.$$

  (1) Definition of T_a.
  (2) $(-\frac{i}{2})^3 = \frac{i}{8}$; the anticommutator formula.
  (3) $\operatorname{tr}\lambda_c = 0$ and $\operatorname{tr}(\lambda_c\lambda_e) = 2\delta_{ce}$.

  So $c(A; X, Y) = \frac{iN}{2}\int \epsilon^{ijk} d_{abc}\,A_i^c\,\partial_j X^a\,\partial_k Y^b\,\mathrm{d}^3x$, which is not zero (take $d_{888} = -1/\sqrt{3}$).

The totally symmetric symbol $d_{abc} = \frac{1}{4}\operatorname{tr}(\lambda_c\{\lambda_a, \lambda_b\})$ is the same one that controls the Euclidean anomaly in Chapter 10. With several species of fermions in representations R, the cocycles add, and the total is proportional to $\sum_R \pm \operatorname{tr}_R\big(T_c\{T_a, T_b\}\big)$, the sign depending on chirality. It vanishes exactly when the Euclidean anomaly cancels: the Hamiltonian and Lagrangian cancellation conditions are the same, as they must be.

Checking the cocycle identity by hand. Nash's statement that the multipliers define an extension requires c to obey (10.263). For (10.279) this can be verified directly, and the verification shows what each term does. Put $B(\beta; Y, Z) = \operatorname{tr}\big(\beta\,(\mathrm{d}Y\,\mathrm{d}Z - \mathrm{d}Z\,\mathrm{d}Y)\big)$ for a matrix 1-form β, so $c(A; Y, Z) = N\int B(A; Y, Z)$. Since c is linear in A and $\delta_X A = \mathrm{d}X + [A, X]$, $L_X c(Y, Z) = N\int B(\mathrm{d}X + [A, X]; Y, Z)$. The integrand of $(\delta c)(X, Y, Z)/N$ splits into a part without A and a part linear in A.

The part without A. Put $P = \operatorname{tr}(\mathrm{d}X\,\mathrm{d}Y\,\mathrm{d}Z)$ and $Q = \operatorname{tr}(\mathrm{d}X\,\mathrm{d}Z\,\mathrm{d}Y)$. Cyclicity for 1-forms, $\operatorname{tr}(\alpha\,\beta\gamma) = \operatorname{tr}(\beta\gamma\,\alpha)$ (moving a 1-form past a 2-form costs no sign), gives $\operatorname{tr}(\mathrm{d}Y\,\mathrm{d}Z\,\mathrm{d}X) = \operatorname{tr}(\mathrm{d}Z\,\mathrm{d}X\,\mathrm{d}Y) = P$ and $\operatorname{tr}(\mathrm{d}Y\,\mathrm{d}X\,\mathrm{d}Z) = \operatorname{tr}(\mathrm{d}Z\,\mathrm{d}Y\,\mathrm{d}X) = Q$. Then

$$\begin{aligned} &B(\mathrm{d}X; Y, Z) - B(\mathrm{d}Y; X, Z) + B(\mathrm{d}Z; X, Y) \\ &\overset{(1)}{=} (P - Q) - (Q - P) + (P - Q) \overset{(2)}{=} 3(P - Q) \overset{(3)}{=} 3\,\mathrm{d}\Big(\operatorname{tr}(X\,\mathrm{d}Y\,\mathrm{d}Z) - \operatorname{tr}(X\,\mathrm{d}Z\,\mathrm{d}Y)\Big). \end{aligned}$$

(1) Definition of B and the cyclic identities just listed.
(2) Arithmetic.
(3) $\mathrm{d}\operatorname{tr}(X\,\mathrm{d}Y\,\mathrm{d}Z) = \operatorname{tr}(\mathrm{d}X\,\mathrm{d}Y\,\mathrm{d}Z)$ because $\mathrm{d}^2 = 0$, and similarly for Q.

It is exact, so it integrates to zero on the closed S^3 (Stokes).

The part linear in A. It collects the $[A, \cdot\,]$ pieces of the L terms and the three bracket terms $-c([X, Y], Z) + c([X, Z], Y) - c([Y, Z], X)$, in which $\mathrm{d}[X, Y] = \mathrm{d}X\,Y - Y\,\mathrm{d}X + X\,\mathrm{d}Y - \mathrm{d}Y\,X$. Every term contains one undifferentiated X, Y or Z. Look at the terms with an undifferentiated X (the other two groups are the same computation with the letters permuted). From $L_X c(Y, Z)$:

$$\operatorname{tr}\big([A, X](\mathrm{d}Y\mathrm{d}Z - \mathrm{d}Z\mathrm{d}Y)\big) = \operatorname{tr}(AX\mathrm{d}Y\mathrm{d}Z) - \operatorname{tr}(XA\mathrm{d}Y\mathrm{d}Z) - \operatorname{tr}(AX\mathrm{d}Z\mathrm{d}Y) + \operatorname{tr}(XA\mathrm{d}Z\mathrm{d}Y).$$

From $-c([X, Y], Z)$ and $+c([X, Z], Y)$, keeping only the pieces $X\,\mathrm{d}Y - \mathrm{d}Y\,X$ of $\mathrm{d}[X, Y]$ and

$X\,\mathrm{d}Z - \mathrm{d}Z\,X$ of $\mathrm{d}[X,Z]$:

$$\begin{aligned}&-\operatorname{tr}\big(A(X\mathrm{d}Y - \mathrm{d}YX)\mathrm{d}Z\big) + \operatorname{tr}\big(A\,\mathrm{d}Z(X\mathrm{d}Y - \mathrm{d}YX)\big)\\ &\qquad + \operatorname{tr}\big(A(X\mathrm{d}Z - \mathrm{d}ZX)\mathrm{d}Y\big) - \operatorname{tr}\big(A\,\mathrm{d}Y(X\mathrm{d}Z - \mathrm{d}ZX)\big)\\ &\overset{(1)}{=} -\operatorname{tr}(AX\mathrm{d}Y\mathrm{d}Z) + \operatorname{tr}(AX\mathrm{d}Z\mathrm{d}Y) - \operatorname{tr}(A\,\mathrm{d}Z\mathrm{d}YX) + \operatorname{tr}(A\,\mathrm{d}Y\mathrm{d}ZX).\end{aligned}$$

(1) Multiply out. The terms $+\operatorname{tr}(A\,\mathrm{d}YX\mathrm{d}Z)$ and $-\operatorname{tr}(A\,\mathrm{d}YX\mathrm{d}Z)$ cancel, and so do $\pm\operatorname{tr}(A\,\mathrm{d}ZX\mathrm{d}Y)$.

Adding the two displays, the $\operatorname{tr}(AX\cdots)$ terms cancel, leaving

$$-\operatorname{tr}(XA\,\mathrm{d}Y\mathrm{d}Z) + \operatorname{tr}(XA\,\mathrm{d}Z\mathrm{d}Y) - \operatorname{tr}(A\,\mathrm{d}Z\mathrm{d}YX) + \operatorname{tr}(A\,\mathrm{d}Y\mathrm{d}ZX) \overset{(1)}{=} 0,$$

(1) Cyclicity moves the 0-form X from the end to the front with no sign: $\operatorname{tr}(A\,\mathrm{d}Y\mathrm{d}ZX) = \operatorname{tr}(XA\,\mathrm{d}Y\mathrm{d}Z)$ and $\operatorname{tr}(A\,\mathrm{d}Z\mathrm{d}YX) = \operatorname{tr}(XA\,\mathrm{d}Z\mathrm{d}Y)$.

So $\delta c = 0$: (10.279) is a cocycle. (A numerical check with random $\mathfrak{su}(3)$-valued fields on a lattice confirms it to rounding error.)

Worked example 10.83: The abelian Faddeev–Mickelsson term is a coboundary

For $K = \mathrm{U}(1)$ everything commutes, and the 1-forms anticommute: $\mathrm{d}Y\,\mathrm{d}X = -\mathrm{d}X\,\mathrm{d}Y$. So (10.279) becomes

$$c(A;X,Y) \overset{(1)}{=} 2N\int A\,\mathrm{d}X\,\mathrm{d}Y \overset{(2)}{=} 2N\int X\,\mathrm{d}A\,\mathrm{d}Y \overset{(3)}{=} 2N\int X\,\mathrm{d}Y\,\mathrm{d}A.$$

(1) $\mathrm{d}X\mathrm{d}Y - \mathrm{d}Y\mathrm{d}X = 2\,\mathrm{d}X\mathrm{d}Y$.
(2) $\mathrm{d}(XA\,\mathrm{d}Y) = \mathrm{d}X\,A\,\mathrm{d}Y + X\,\mathrm{d}A\,\mathrm{d}Y = -A\,\mathrm{d}X\mathrm{d}Y + X\,\mathrm{d}A\,\mathrm{d}Y$; integrate over the closed S^3 (Stokes).
(3) A 2-form commutes with a 1-form.

It is not constant, but it is trivial. Try $\alpha(X) = \beta\int X\,A\,\mathrm{d}A$. Under $A \mapsto A + t\,\mathrm{d}X$ only the undifferentiated A changes (to first order $\mathrm{d}A$ is unchanged), so

$$(\delta\alpha)(X,Y) \overset{(1)}{=} L_X\alpha(Y) - L_Y\alpha(X) \overset{(2)}{=} \beta\int\big(Y\,\mathrm{d}X\,\mathrm{d}A - X\,\mathrm{d}Y\,\mathrm{d}A\big) \overset{(3)}{=} -2\beta\int X\,\mathrm{d}Y\,\mathrm{d}A.$$

(1) Definition of $\delta\alpha$; $[X,Y] = 0$.
(2) $L_X\alpha(Y) = \beta\int Y\,\mathrm{d}X\,\mathrm{d}A$, and similarly for $L_Y\alpha(X)$.
(3) $\mathrm{d}(YX\,\mathrm{d}A) = (\mathrm{d}Y\,X + Y\,\mathrm{d}X)\mathrm{d}A$ integrates to zero, so $\int Y\,\mathrm{d}X\,\mathrm{d}A = -\int X\,\mathrm{d}Y\,\mathrm{d}A$.

With $\beta = N$, $c + \delta\alpha = 0$, so by (10.264) the redefined generators $\widehat{G}(X) + N\int XA\,\mathrm{d}A$ close without a Schwinger term. The same happens in $1+1$ dimensions: for U(1) the central term $K\int X\,\mathrm{d}Y$ of Example 10.79 equals $-\delta\alpha$ for $\alpha(X) = \frac{K}{2}\int XA$ (the same two-line computation with $\mathrm{d}A$ removed). An A-dependent redefinition can remove what no constant can. In both abelian cases the topology agrees: $\pi_3(\mathrm{U}(1)) = \pi_5(\mathrm{U}(1)) = 0$, so $H^3(\mathcal{A}/\mathcal{G};\mathbb{Z})$ has no class to carry an obstruction. (For abelian theories the Euclidean anomaly is also invisible to the topology of $\mathcal{G}$; it lives in *local* cohomology, as Nash remarks in §2. On the Hamiltonian side the price of the redefinition is that the new generators contain a Chern–Simons-like functional of A, so they no longer generate the plain gauge transformations.)

space	Schwinger term	extension	topology	obstruction?
S^1, U(1)	$\frac{1}{2\pi i}\int X\,\mathrm{d}Y$ (const.)	central	$\pi_3(\mathrm{U}(1)) = 0$	no
S^1, SU(N)	$\frac{1}{2\pi i}\int \mathrm{tr}(X\,\mathrm{d}Y)$ (const.)	central	$\pi_3 = \mathbb{Z}$	yes
S^3, U(1)	$2N\int X\,\mathrm{d}Y\,\mathrm{d}A$	by Map($\mathcal{A}$, U(1))	$\pi_5(\mathrm{U}(1)) = 0$	no
S^3, SU(2)	0	–	$\pi_5 = \mathbb{Z}_2$	only global
S^3, SU($N \geq 3$)	(10.279), $\propto d_{abc}$	by Map($\mathcal{A}$, U(1))	$\pi_5 = \mathbb{Z}$	yes

The fourth column is (10.240) in general form: on S^d, $\pi_3(\mathcal{A}/\mathcal{G}) = \pi_2(\mathcal{G}) = \pi_{d+2}(K)$.

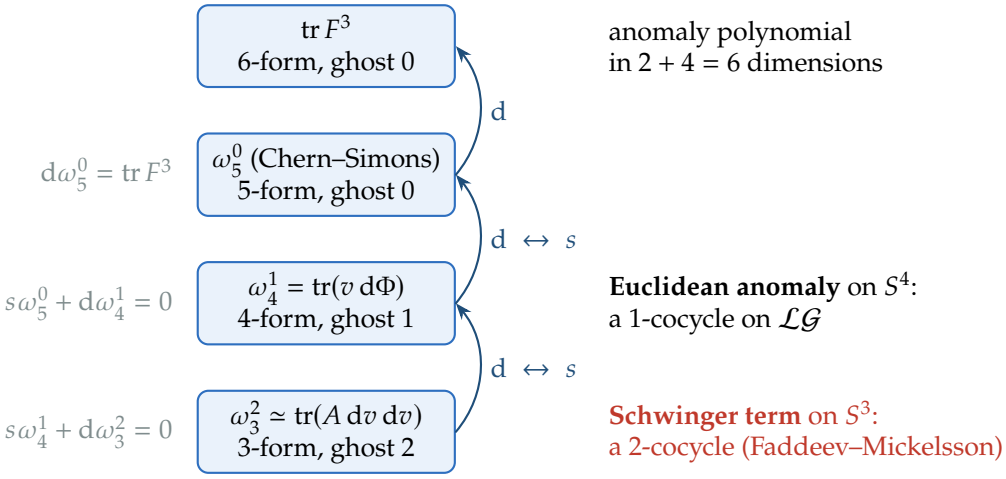

Figure 10.57: The descent ladder. Each rung loses one form degree and gains one ghost number; the equations on the left link neighbouring rungs. Read as cochains, the 4-form rung is the Euclidean (Lagrangian) anomaly in four dimensions, and the 3-form rung below it is the Hamiltonian anomaly, the Schwinger term, on three-dimensional space. This is the cohomological form of Nash's "$n + p$" bookkeeping: the degree of the anomaly polynomial is fixed, and it can be spent on spacetime or on parameters.

10.10.20 Gauss's law cannot be imposed

Nash ends the chapter with a physical consequence: "Gauss's law is violated for theories with this anomaly". We now make the statement precise.

Gauss's law as an operator statement. In temporal gauge $A_0 = 0$ the classical equations of a Yang–Mills field coupled to a charge density ρ^a include one without time derivatives, Gauss's law $(D_iE_i)^a = \rho^a$. Time evolution preserves it but cannot impose it, so in the quantum theory it becomes a condition on states. The electric field is the momentum conjugate to A: $E_i^a(x) = -i\,\delta/\delta A_i^a(x)$ acting on wave functionals $\Psi[A]$. The bosonic generator of gauge transformations is then

$$L_X \overset{(1)}{=} \int \mathrm{d}^3x\,(D_iX)^a\,\frac{\delta}{\delta A_i^a} \overset{(2)}{=} i\int \mathrm{d}^3x\,(D_iX)^a\,E_i^a \overset{(3)}{=} -i\int \mathrm{d}^3x\,X^a\,(D_iE_i)^a,$$

(1) The derivative along $\delta_X A = D_A X$, (10.260), written in components.

(2) $\delta/\delta A = iE$.

(3) Integrate by parts on the closed S^3. The derivative part is ordinary integration by parts; for the commutator part, with real structure constants $[T_b, T_c] = f_{bca}T_a$ totally antisymmetric, $f_{abc}A_i^bX^cE_i^a = -X^c\,f_{cba}A_i^bE_i^a$, which is $-X^c$ times the commutator part of $(D_iE_i)^c$.

so L_X is ($-i$ times) the smeared generator $\int X \cdot D \cdot E$. The full Gauss generator also rotates the fermions: $\widehat{G}(X) = L_X + :\widehat{\rho}_A(X)$: as in (10.259), the second term being the regularised fermion charge density smeared with X. **Gauss's law** is the requirement

$$\widehat{G}(X)\,\Psi = 0 \qquad \text{for all } X \in \mathcal{LG}. \tag{10.280}$$

Exponentiating, it says that Ψ is invariant under every gauge transformation in the identity component of $\mathcal{G}$: physical states are gauge-invariant wave functionals, i.e. they are really functions on $\mathcal{A}/\mathcal{G}$ (sections of $\mathfrak{F}/\mathcal{G}$, in Nash's language). This is how the configuration space $\mathcal{A}/\mathcal{G}$ of Chapter 10 enters the Hamiltonian picture.

The obstruction. Suppose (10.280) holds. Apply two generators:

$$0 \overset{(1)}{=} \widehat{G}(X)\widehat{G}(Y)\Psi - \widehat{G}(Y)\widehat{G}(X)\Psi \overset{(2)}{=} \widehat{G}([X,Y])\Psi + c(X,Y)\Psi \overset{(3)}{=} c(X,Y)\,\Psi.$$

(1) Each term is zero by (10.280).
(2) The commutator (10.262).
(3) (10.280) for the element $[X, Y]$.

Since $c(X, Y)$ acts by multiplication by the function $c(A; X, Y)$, this says $c(A; X, Y)\,\Psi[A] = 0$ for every A, X, Y. So $\Psi[A] = 0$ wherever $c(A; \cdot, \cdot) \neq 0$. For SU(3) and the cocycle of Example 10.82: choosing X and Y concentrated near a point x_0, with prescribed gradients there, shows that $c(A; \cdot, \cdot) = 0$ forces $d_{abc}A^c_i(x_0) = 0$ for all a, b, i. That forces $A_i(x_0) = 0$: if $x = A_i(x_0)$ (a traceless anti-Hermitian matrix) had $\mathrm{tr}(T_c\{T_a, x\}) = 0$ for all a, c, then the traceless part of $\{T_a, x\}$ would vanish for all a; taking $T_a \propto x$ gives $x^2 \propto \mathbb{1}$. The eigenvalues of the anti-Hermitian x are $i\mu_1, i\mu_2, i\mu_3$ with μ_k real, so $x^2 \propto \mathbb{1}$ means $|\mu_1| = |\mu_2| = |\mu_3|$; but three numbers $\pm\mu$ cannot sum to zero (as $\mathrm{tr}\,x = 0$ requires) unless $\mu = 0$. So Ψ vanishes at every $A \neq 0$, and by continuity everywhere. *There are no physical states.* This is the infinite-dimensional version of Example 10.76, and of the impossibility of $\hat{x}\psi = \hat{p}\psi = 0$ in Example 10.78.

The escape routes are exactly the two of Section 10.10.17. If c is a coboundary, $c = -\delta\alpha$, impose instead the modified law $(\widehat{G}(X) + \alpha(X))\Psi = 0$, whose generators close; this is what happens in Example 10.83. If c is not a coboundary, there is no consistent Gauss law and the gauge theory does not exist as a quantum theory, unless the fermion content is changed so that the cocycles of the different species cancel.

Nash's group-level phrasing. Nash says: "the non-triviality of the extension cocycle means that the identity of $\mathcal{G}$ is covered by a non-trivial element of $\mathrm{Map}(\mathcal{A}, S^1)$ ... the identity element acts non-trivially and will change the vacuum". Here is that sentence as a computation. Take two gauge transformations g, h that commute in $\mathcal{G}$. Then $gh = hg$, and (10.257) applied twice gives two lifts of the same element:

$$U_{h\cdot A}(g)\,U_A(h) \overset{(1)}{=} \omega(g,h;A)\,U_A(gh) \overset{(2)}{=} \frac{\omega(g,h;A)}{\omega(h,g;A)}\,U_{g\cdot A}(h)\,U_A(g).$$

(1) (10.257) for the pair (g, h).
(2) (10.257) for the pair (h, g) reads $U_{g\cdot A}(h)U_A(g) = \omega(h, g; A)U_A(hg)$, and $U_A(hg) = U_A(gh)$.

So the lifted group commutator $\widehat{U}(g)\widehat{U}(h)\widehat{U}(g)^{-1}\widehat{U}(h)^{-1}$, which lies over the *identity* of $\mathcal{G}$, acts on the fibre over $gh \cdot A$ by the phase $\omega(g, h; A)/\omega(h, g; A)$. If this is not identically 1, a wave functional invariant under all the $\widehat{U}$ would have to satisfy $\Psi = \frac{\omega(g,h;\cdot)}{\omega(h,g;\cdot)}\Psi$, hence vanish wherever the phase differs from 1. The identity of the gauge group, lifted to the Fock bundle, is not the

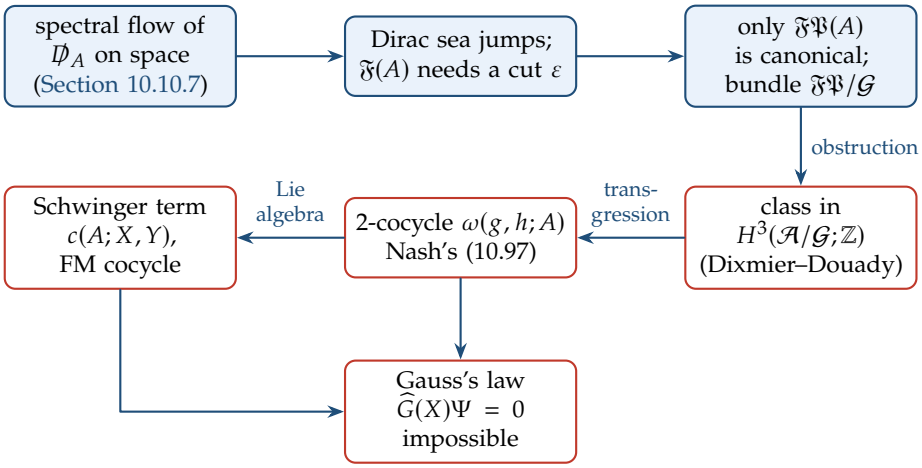

Figure 10.58: The logic of the Hamiltonian picture of anomalies, in the order Nash presents it. Blue boxes are constructions, red boxes are the anomaly in its successive disguises: a degree-3 class on the orbit space, a multiplier on the gauge group, a Schwinger term in the current algebra, and finally the failure of Gauss's law.

identity operator: it multiplies states by a non-constant phase. Infinitesimally, with $g = e^{sX}$ and $h = e^{tY}$, the phase is $1 + st\,c(A;X,Y) + \dots$ and we are back to the Schwinger term.

Reading Nash (pp. 297–300, (10.86)–(10.97))

Nash's example "Fock space and Gauss's law" starts with the counting $n+p = 4+2 = 3+3$ of (10.240). (10.86)–(10.88) are the polarisation, the Fock space (10.241) and the Fock bundles (10.243). His "flaw" (zero eigenvalues make the decomposition jump) and the cure by cuts at ε, ε', (10.89)–(10.93), are Section 10.10.13 and (10.245)–(10.247); the isomorphism I_p^λ of (10.94) is (10.248), worked out in Examples 10.73 and 10.74. The projective bundle (10.95)–(10.96) is (10.249)–(10.250). His (10.97), $g\cdot(h\cdot f_A) = \lambda(A)(gh)\cdot f_A$, is our (10.257) with $\lambda(A) = \omega(\cdot,\cdot;A)$. Nash states without computation that this gives the non-central extension of Chapter 6 and that it is "responsible for the Schwinger term" in the current algebra; we derived the twisted cocycle condition (10.258), its Lie-algebra form (10.263), computed Schwinger terms from the CAR (Section 10.10.18) and obtained the Faddeev–Mickelsson cocycle (10.279) by descent. His final paragraph on Gauss's law (p. 300) is Section 10.10.20. Nash refers to Pressley and Segal for the Fock-space constructions, and to Faddeev, Mickelsson and Segal for the cocycle.

Recap: Section 6: anomalies from a Hamiltonian perspective

- A Berry phase is the holonomy of a line bundle of ground states (Example 10.58); anomalies in the Hamiltonian picture are the same phenomenon for a Dirac sea.
- A p-parameter family of n-dimensional Dirac operators is one operator in $n+p$ dimensions (10.225); only $n+p$ matters, and the anomaly is measured by $\pi_{n+p}(\Omega\mathrm{U}(\infty))$.
- Fredholm operators classify K-theory, $[X,\mathcal{F}] = K(X)$ (10.226); self-adjoint ones are the odd partner, $\mathcal{F}^1 \simeq \mathrm{U}(\infty)$, with $\pi_1(\mathcal{F}^1) = \mathbb{Z}$ given by spectral flow; the real case gives $\mathbb{Z}_2$ and Witten's anomaly.
- On the circle, $-i\,\mathrm{d}/\mathrm{d}\theta + kt$ has spectral flow k, equal to the index on the torus (computed with theta functions) and to the number of particles created from the Dirac sea; the vacuum charge is $-\frac{1}{2}\eta$.

- Fock spaces $\Lambda^*(H^+ \oplus \bar{H}^-)$ depend on a polarisation; changing the cut changes them by a determinant line, so only the projective Fock bundle $\mathfrak{F}\mathfrak{P}/\mathcal{G}$ is canonical. Its obstruction to being a vector bundle is a class in $H^3(\mathcal{A}/\mathcal{G};\mathbb{Z})$.
- Lifting gauge transformations to vectors gives multipliers $\omega(g,h;A)$ obeying the twisted cocycle condition (10.258): an extension of $\mathcal{G}$ by $\mathrm{Map}(\mathcal{A},\mathrm{U}(1))$. Infinitesimally, a Schwinger term $c(A;X,Y)$ obeying (10.263).
- Schwinger terms are finite remainders of infinite traces, $c(X,Y) = \sum X_{ij}Y_{ji}(n_i - n_j)$. In $1+1$ they are constant (Kac–Moody); in $3+1$ they depend on A (Faddeev–Mickelsson, $\propto d_{abc}$), because gauge transformations fail the Hilbert–Schmidt test.
- A non-trivial cocycle forbids Gauss's law: $c(X,Y)\Psi = 0$ forces $\Psi = 0$. Anomaly cancellation is the same d_{abc} condition as in the Euclidean picture.

Chapter summary

This chapter asked one question in several guises: *can a symmetry of the classical theory survive quantisation?* For chiral fermions the quantum theory is built from a determinant (Euclidean picture) or from a Dirac sea (Hamiltonian picture), and both are defined only up to choices that the symmetry group may be unable to make consistently. An anomaly is the obstruction, and it is topological. The answers came in four layers.

1. *Local anomalies* (Nash §§1–3). The fermion integral gives $\sqrt{\det(\not{D}_A^* \not{D}_A)}$, a function of the gauge field that should be gauge invariant but, after regularisation, is not. Its variation along a gauge orbit is the anomalous Ward identity, computed by the triangle graph, by point splitting, or by Fujikawa's Jacobian with a heat-kernel regulator; its integral is the index of the Dirac operator. Topologically the determinant is a section of the determinant line bundle $\det \operatorname{Index} \not{D}$ over $\mathcal{A}/\mathcal{G}$, whose first Chern class is computed by the families index theorem; the anomaly is that class, or equivalently the 1-cocycle μ_1 on $\mathcal{G}$. Gravity is the same story with $\mathrm{Met}(M)/\mathrm{Diff}(M)$ in place of $\mathcal{A}/\mathcal{G}$ and $\hat{A}$ in place of ch, possible only in dimensions $4k-2$.

2. *The conformal anomaly and the critical dimension* (Nash §4). For the bosonic string the relevant group is the Weyl group $C^\infty_+(\Sigma)$ and the relevant family is the family of $\bar\partial$-operators over $\mathrm{Met}(\Sigma)/C^\infty_+$. The matter and ghost determinants together form a section of a determinant line whose first Chern class is $\frac{26-d}{24}\int x^2$: it vanishes exactly for $d = 26$. The same number comes out of the heat kernel, the central charge, Mumford's formula and the light-cone zero-point energy.

3. *Global anomalies* (Nash §5). When the symmetry group is disconnected, a determinant can change sign (or phase) between components while being invariant under infinitesimal transformations. For SU(2), $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$, a mod-2 index and a spectral flow make $\sqrt{\det}$ change sign, and an odd number of doublets is inconsistent. For gravity, large diffeomorphisms (linked to exotic spheres) are tested with the eta invariant of a mapping torus, computed by Atiyah–Patodi–Singer; Bismut and Freed identified global anomalies with holonomies of the determinant line.

4. *The Hamiltonian picture* (Nash §6). A p-parameter family in n dimensions is one operator in $n + p$ dimensions, and the anomaly is classified by $\pi_{n+p}(\Omega\mathrm{U}(\infty))$ through Fredholm operators. In canonical quantisation spectral flow moves levels across the Dirac sea, Fock spaces are defined only projectively, and the gauge group acts only up to phases depending on A: a 2-cocycle, infinitesimally the Schwinger term (constant Kac–Moody term in 1 + 1, Faddeev–Mickelsson term in 3 + 1). A non-trivial cocycle forbids Gauss's law.

The tables below list every concept of the chapter, what it means operationally (how to compute it or test for it), and where it is used again.

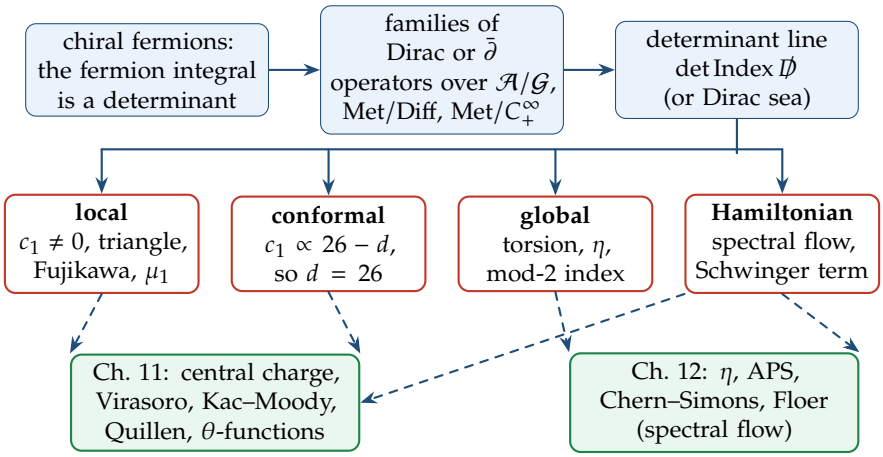

Figure 10.59: The chapter in one picture. Integrating out chiral fermions produces determinants of families of operators; these are sections of a determinant line bundle, and every kind of anomaly (red) is a topological property of that bundle or of its Hamiltonian counterpart. Dashed arrows point to the chapters where the same structures return.

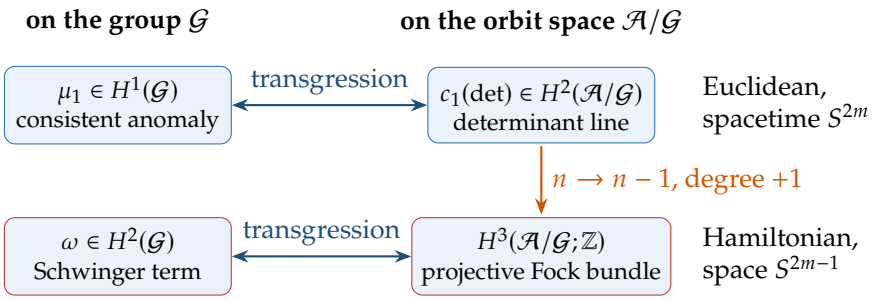

Figure 10.60: Where the anomaly lives, in the two pictures. Horizontally, transgression (Stokes' theorem on a lifted ball, Figure 10.53) trades a class on the orbit space for a class one degree lower on the group. Vertically, passing from spacetime to space lowers the dimension by one and raises the degree by one, keeping $n + p$ fixed.

Local anomalies in gauge theory (Nash §§1–2)

concept	operational meaning	used later
anomaly	a classical symmetry whose quantum (regularised) version cannot be kept; test: vary $\log Z$ along the symmetry and find a non-zero local term that no counterterm removes	throughout; Chapter 11, Chapter 12
chirality, γ_5, Weyl spinors	$\gamma_5 = (-i)^m \gamma_1 \cdots \gamma_{2m}$ splits spinors into ± 1 eigenspaces; explicit 2×2 and 4×4 matrices	Chapter 11 (chiral fields)
ABJ anomaly	$\partial_\mu j_5^\mu \propto \epsilon FF$; explains $\pi^0 \to 2\gamma$	Chapter 12 (instanton effects)
chiral Dirac operator	$\not{D}_A : \Gamma(E^+ \otimes F) \to \Gamma(E^- \otimes F)$, needs a spin structure ($w_1 = w_2 = 0$)	Chapter 12
index of $\not{D}_A$	$n_+ - n_- = \int \hat{A}\ \mathrm{ch}(F)$; on S^{2m} just $\int \mathrm{ch}_m(F) = k$	Chapter 12 (Donaldson)
Grassmann integral	$\int \mathrm{d}\bar\psi\, \mathrm{d}\psi\, e^{-\bar\psi M \psi} = \det M$; fermions give determinants	Chapter 11
gauge covariance	$\not{D}_{A^g} = g^{-1} \not{D}_A g$, so formally det is invariant; regularisation spoils it	
zeta-function determinant	$\det \Delta = e^{-\zeta'_\Delta(0)}$; not multiplicative	Chapter 11 (Quillen metric)
anomalous Ward identity	$\delta_f \log Z = \int f^a \langle (\nabla_\mu j_5^\mu)^a \rangle$, non-zero	
triangle graph, point splitting	one-loop computations of $\langle \partial j_5 \rangle$; the surface term of a linearly divergent integral	
Fujikawa Jacobian	$\lim_{M\to\infty} \mathrm{tr}\, \gamma_5 e^{\not{D}^2/M^2}$ = index density (heat kernel)	Chapter 12
integrated anomaly	$\int \langle \partial j_5 \rangle = 2\,$index: the anomaly counts zero modes	
consistent vs covariant anomaly	Wess–Zumino consistent ($\delta a = 0$) vs gauge covariant; differ by a local polynomial	
BRST and descent	$\mathrm{tr}\, F^{m+1} \to \omega^0_{2m+1} \to \omega^1_{2m} \to \omega^2_{2m-1}$ by d and s; the rung ω^1_{2m} is the anomaly	Chapter 12 (Chern–Simons)
anomaly cancellation	$\sum_R \pm \mathrm{tr}_R(T_a\{T_b, T_c\}) = 0$ (d_{abc} condition); holds in the Standard Model generation by generation	
T_g and μ_1	$\mu_1 = \mathrm{d}\log\det T_g$ on $\mathcal{G}$; closed; exact iff no anomaly; $[\mu_1] \in H^1(\mathcal{G})$	
$\pi_1(\mathcal{G}) = \pi_{n+1}(K)$	on S^4: $\pi_5(\mathrm{U}(N)) = 0, \mathbb{Z}_2, \mathbb{Z}$ for $N = 1, 2, \geq 3$	global anomalies (§5)
determinant line of a map	$\det O \in (\Lambda^{\max} \ker O)^* \otimes \Lambda^{\max} \ker O^*$; defined even when ker jumps	Chapter 11
det Index $\not{D}$	line bundle over $\mathcal{A}/\mathcal{G}$ whose sections are "determinants"; anomaly-free iff trivial	Chapter 11, Chapter 12
families index theorem	$\mathrm{ch}(\mathrm{Index}\, \not{D}) = \int_M \mathrm{ch}(E)\hat{A}$; gives $c_1(\det)$	Chapter 11
local cohomology	anomalies modulo local counterterms; sees the abelian anomaly that $H^*(\mathcal{G})$ misses	

Gravitational anomalies (Nash §3)

concept	operational meaning	used later
$\not{D}_\rho$ on $\mathrm{Met}(M)$	Dirac operator of the metric ρ; $\not{D}_{h\cdot\rho} = h^{-1}\not{D}_\rho h$ for $h \in \mathrm{Diff}_+(M)$	§5 (global)
$\mathrm{Met}(M)/\mathrm{Diff}_0(M)$	the gravitational orbit space; Diff_0 fixes a frame at a point so the action is free	Chapter 11 (moduli of surfaces)
gravitational anomaly	$\mathrm{ch}(\det \mathrm{Index}) = \int_M \hat{A}$; degree 2 only if $n = 4k-2$	
spin-$\frac{3}{2}$, self-dual forms	further anomaly polynomials (Alvarez-Gaumé–Witten); needed for cancellation	§5 (superstring)
2D gravitational anomaly	$\propto c_L - c_R$	Chapter 11
Lorentz anomaly	trade Diff for local frame rotations $\mathcal{G}_L$ in $\mathrm{Aut}(P) = \mathcal{G}_L \rtimes \mathrm{Diff}_0$	
Green–Schwarz mechanism	for SO(32) and $E_8 \times E_8$ the 12-form factorises and is cancelled by a 2-form field	§5

The critical dimension of strings (Nash §4)

concept	operational meaning	used later
Polyakov action, Weyl symmetry	$S = \frac{1}{2}\int \sqrt{g}\, g^{ab}\partial_a X \cdot \partial_b X$ is invariant under $g \to e^{2\sigma} g$ in 2D	Chapter 11
conformal (Weyl) anomaly	$\delta_\sigma \log \det{}'\Delta_g \neq 0$; for d bosons $\delta \log Z = \frac{d}{24\pi}\int \sqrt{g}\,\sigma R$	Chapter 11 (central charge)
heat kernel, $\zeta(0)$	$\mathrm{tr}\, e^{-t\Delta} \sim \frac{A}{4\pi t} + \frac{\chi}{6} + \ldots$; $\zeta_\Delta(0) = \frac{\chi}{6} - \dim\ker$ ($= -\frac{2}{3}$ on S^2)	Chapter 11, Chapter 12
Liouville action	integrate the anomaly: $\log Z[e^{2\sigma}g] - \log Z[g] \propto \int(\lvert\nabla\sigma\rvert^2 + R\sigma)$	Chapter 11
ghost determinant	$\det(\bar\partial^*\bar\partial)$ on K^* from gauge fixing; contributes -26	Chapter 11 (bc system)
bc central charge	$c = -2(6\lambda^2 - 6\lambda + 1)$; $\lambda = 2$ gives -26	Chapter 11
virtual bundle $K^* - \frac{d}{2}I$	raising a determinant to a power = tensoring the family with a virtual bundle	
Nash's families computation	$c_1(\det \mathrm{Index}\,\bar\partial_Y) = \int \mathrm{ch}(K^* - \frac{d}{2})\,\mathrm{td} = \frac{26-d}{24}\int x^2$	
Mumford's formula	$\lambda_j = \lambda_1^{6j^2-6j+1}$ on moduli space; same polynomial as c	Chapter 11
superstring $d = 10$	add fermions and superghosts: $\frac{3}{2}d - 15 = 0$	Chapter 11
light-cone route	$\frac{d-2}{2}\sum n = -\frac{d-2}{24}$ with $\zeta(-1) = -\frac{1}{12}$; massless vector needs $d = 26$	Chapter 11
Quillen metric	zeta-regularised norm on the determinant line; curvature = families index form	Chapter 11
Belavin–Knizhnik, Manin	in $d = 26$ the measure is $\lvert f\rvert^2$, f holomorphic; f via theta functions; torus: $\lvert\eta(\tau)\rvert^{-48}$	Chapter 11 (modular invariance)

Global anomalies (Nash §5)

concept	operational meaning	used later
global anomaly	Z changes under a gauge transformation not connected to $\mathbb{1}$; invisible to derivatives and de Rham cohomology	Chapter 12
$\pi_0(\mathcal{G}) = \pi_{2m}(K)$	components of the gauge group on S^{2m}; $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$ (suspended Hopf map, framed circles)	
toy global anomaly	charge-$\frac{1}{2}$ fermion on a circle: $Z = 2\cos\frac{a}{2}$ changes sign under $a \to a + 2\pi$	
pseudo-reality, Pfaffian	$J = i\sigma_2 K$ pairs eigenvalues (Kramers); $\sqrt{\det}$ is a Pfaffian, with a sign	
mod-2 index	dim ker mod2 of a real skew operator; deformation invariant	Chapter 12
spectral flow	net number of eigenvalues crossing 0 along a path; for Witten's loop it is odd	Chapter 12 (Floer)
Witten's SU(2) anomaly	odd number of doublets (more generally $\sum 2T(R)$ odd) is inconsistent	
torsion, UCT, Möbius bundle	$H^2(\mathcal{A}/\mathcal{G};\mathbb{Z}) = \mathbb{Z}_2$ is pure torsion; the real determinant line is a Möbius bundle	
large diffeomorphisms	$\pi_0(\mathrm{Diff}_+(S^n))$ = exotic $(n+1)$-spheres (Kervaire–Milnor); $\mathbb{Z}_{992}$ for $n = 10$	
mapping torus	glue $M \times [0,1]$ by f; the path of metrics becomes one metric on an $(n+1)$-manifold	Chapter 12
eta invariant	$\eta(0) = \sum \operatorname{sgn}\lambda\lvert\lambda\rvert^{-s}\big\rvert_{s=0}$; phase of a determinant $e^{i\pi\eta/2}$	Chapter 12 (Chern–Simons phase)
APS theorem	index $= \int_X \hat{A} - \frac{h+\eta}{2}$ on a manifold with boundary	Chapter 12
adiabatic limit, Witten's formula	scale the fibre metric; $\Delta S = \frac{i\pi}{2}\eta$ of the mapping torus	
superstring global check	$n_d = 495$, $n_{rs} = 1$, $n_{sd} = 0$: $\Delta S = 2\pi i k$, no anomaly	
Bismut–Freed	global anomaly = holonomy of the natural connection on det; computed by $\lim e^{i\pi(h+\eta)}$	Chapter 12
complex anomalies	distinct complex structures on $\mathrm{U}(4)/(\mathrm{U}(2)\times\mathrm{U}(1)^2)$ with $c_1^5 = 4500, 4860$; $\Delta S = 360$	

The Hamiltonian picture (Nash §6)

concept	operational meaning	used later
Berry phase	$\gamma = \oint i\langle\psi\|\mathrm{d}\psi\rangle$; for spin $\frac{1}{2}$, $-\frac{1}{2}\times$solid angle; holonomy of the ground-state line	Chapter 12
$n+p$ rule	a p-parameter family in n dimensions = one operator $\not{D}_t^{(n)} + \sum \gamma_i \partial_{t_i}$ in $n+p$	
Fredholm operators $\mathcal{F}(H)$	finite kernel and cokernel; $[X, \mathcal{F}] = K(X)$ (Atiyah–Jänich); $\mathcal{F} \simeq \Omega\mathrm{U}(\infty)$	Chapter 12
self-adjoint Fredholm $\mathcal{F}^1$	$\mathcal{F}^1_* \simeq \mathrm{U}(\infty)$; $\pi_k(\mathcal{F}) = \mathbb{Z}, 0$ and $\pi_k(\mathcal{F}^1) = 0, \mathbb{Z}$ (k even, odd)	Chapter 12
real case	$\mathcal{F}^1_{\mathrm{skew}}(H_r) \simeq \mathrm{O}(\infty)$, $\pi_0 = \mathbb{Z}_2$: Witten's anomaly again	
spectral flow on the circle	$-i\partial_\theta + kt$: eigenvalues $n + kt$, flow k = index on T^2 (theta functions)	Chapter 11
Dirac sea, vacuum charge	fill negative levels; $Q_{\mathrm{vac}} = -\frac{1}{2}\eta$; spectral flow creates k particles	Chapter 11
Fock space	$\Lambda^*(H^+ \oplus \bar{H}^-)$ for a polarisation; changing the cut costs $\Lambda^{\mathrm{top}} J_{\varepsilon\varepsilon'}$	Chapter 11
projective Fock bundle	$\mathfrak{F}\mathfrak{P}/\mathcal{G} \to \mathcal{A}/\mathcal{G}$; obstruction to lifting = Dixmier–Douady class in H^3	
transgression	$H^3(\mathcal{A}/\mathcal{G}) \to H^2(\mathcal{G})$ by Stokes on a lifted ball	
projective representation	$U(g)U(h) = \omega(g,h)U(gh)$; test: commutator phase $\neq 1$ (Pauli, spin $\frac{1}{2}$, Heisenberg)	Chapter 11
Nash's (10.97)	A-dependent multipliers; twisted cocycle; extension of $\mathcal{G}$ by $\mathrm{Map}(\mathcal{A}, \mathrm{U}(1))$	Chapter 11
Schwinger term	$[\widehat{G}(X), \widehat{G}(Y)] = \widehat{G}([X,Y]) + c(A;X,Y)$; $c = \sum X_{ij}Y_{ji}(n_i - n_j)$	Chapter 11 (Virasoro)
U(1) current algebra, Kac–Moody	$[\rho_m, \rho_n] = m\delta_{m+n,0}$; $c = \frac{1}{2\pi i}\oint \mathrm{tr}(X\,\mathrm{d}Y)$	Chapter 11 (WZW)
Shale–Stinespring, HS test	implementable iff off-diagonal blocks Hilbert–Schmidt; passes in 1 + 1, fails in 3 + 1	Chapter 11
Faddeev–Mickelsson cocycle	$N\int \mathrm{tr}(A(\mathrm{d}X\mathrm{d}Y - \mathrm{d}Y\mathrm{d}X))$; next rung of descent; $\propto d_{abc}$; zero for SU(2), trivial for U(1)	
Gauss's law obstruction	$\widehat{G}(X)\Psi = 0$ for all X forces $c\,\Psi = 0$, so $\Psi = 0$ when c is non-trivial	

Key idea: The one sentence to remember from Chapter 10

Integrating out chiral fermions turns a gauge (or diffeomorphism, or Weyl) symmetry into a question about the determinant line bundle of a family of elliptic operators over the orbit space; the anomaly is its topology, computed by the families index theorem (local anomalies, the critical dimension 26), by eta invariants and mod-2 indices (global anomalies), or, in the Hamiltonian picture, by spectral flow and the Schwinger 2-cocycle, and it must cancel for the quantum theory to exist.

Chapter 11

Conformal Quantum Field Theories

Where this chapter is going

Most of this book has been about topology leaking into quantum field theory: winding numbers, indices, anomalies. This chapter is about a *symmetry* that is so strong in two dimensions that it almost solves the theory by itself. The symmetry is **conformal invariance**: invariance under maps that preserve angles but may stretch lengths by a position-dependent amount. In d dimensions such maps form a finite-dimensional group. In two dimensions every holomorphic function is such a map, so the symmetry is infinite dimensional. Its Lie algebra is (a central extension of) the algebra of vector fields on the circle, the **Virasoro algebra** we met in Chapter 6. The single number c in its central term, the **central charge**, turns out to control everything: which operators can exist, what their scaling dimensions are, and, via statistical mechanics, the critical exponents of real magnets.

The logic runs as follows. First (§1) we ask why a physicist should care: critical points of statistical systems and short-distance limits of quantum field theories have no length scale, and scale invariance comes with conformal invariance. We meet Wilson's operator product expansion (OPE), the tool that turns "no length scale" into algebra. Next (§2) we go to two dimensions and use complex coordinates. The central objects are **primary fields**, which transform like tensors of weight $(h, \bar{h})$, and the stress tensor $T(z)$. Conformal Ward identities turn into contour integrals, and the Ward identities become OPEs such as $T(w)\phi(z) \sim h\phi/(w-z)^2 + \partial\phi/(w-z)$. The OPE of T with itself contains c. Then (§3) we expand $T(z)$ in modes L_n and find that they obey the Virasoro algebra. States of the theory are built by acting with L_{-n} on **highest-weight states** $|h\rangle = \phi(0)|0\rangle$. Demanding positive norms (the Kac determinant) forces c and h onto a discrete list when $c < 1$: the **unitary minimal models**, among them the critical Ising model. Later sections of Nash's chapter (§4–§5, the next part of these notes) put the theory on a torus, where modular invariance ties the representations together, and then discuss fusion rules and the axiomatic picture that feeds into knot theory in Chapter 12. This part covers §1–§3. Figure 11.1 shows how the pieces connect.

One physical thread runs through everything. In a theory without a length scale, the only thing a two-point function can be is a power law, $\langle A(x)A(0)\rangle \propto 1/|x|^{2\Delta}$. The exponent Δ (the **scaling dimension**) is the basic datum. The whole chapter is a machine for computing the allowed values of Δ and the rules for multiplying operators. In two dimensions the machine is powerful enough that for $c < 1$ it produces the complete list.

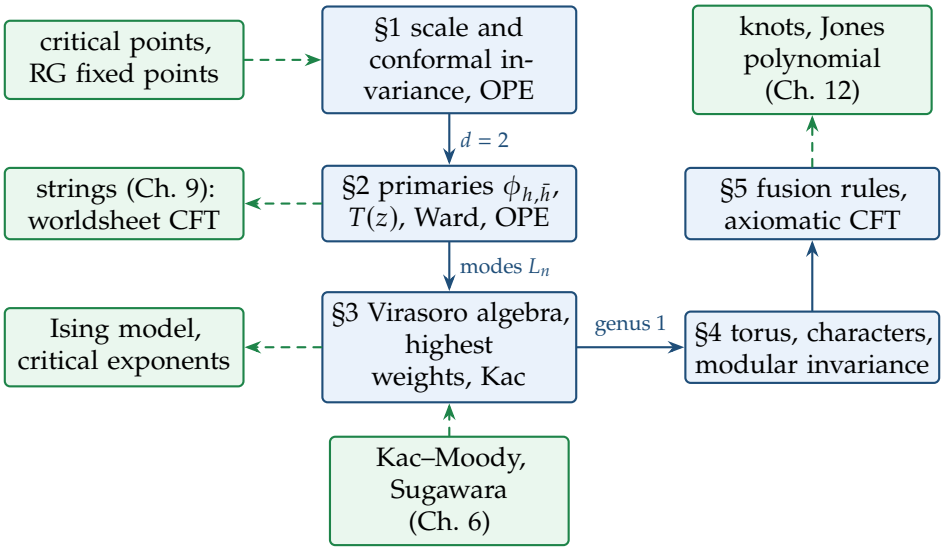

Figure 11.1: The logic of Chapter XI. Blue boxes are Nash's sections; green boxes are the physics they come from or feed. The left column (§1–§3) is this part: from "no length scale" to the Virasoro algebra and its unitary representations. The right column (§4–§5) puts the theory on a torus and on general Riemann surfaces.

Dictionary: the words of this chapter

maths	physics
conformal map	angle-preserving change of coordinates; local rescaling
holomorphic function $z \mapsto f(z)$	2D conformal transformation
weight $(h, \bar{h})$	scaling dimension $h + \bar{h}$, spin $h - \bar{h}$
Virasoro algebra, central charge c	algebra of modes of T; c counts degrees of freedom and measures the Casimir energy
highest-weight (Verma) module	conformal family: a primary and its descendants
unitary representation	theory with positive-norm Hilbert space
Kac determinant	Gram determinant of descendant states

11.1 Conformal invariance and quantum field theory

Nash opens with a remark that sounds negative: a conformally invariant universe would have no masses, so conformal invariance is not a symmetry of the real world. Why then study it? Because there are two regimes where the masses genuinely drop out. One is a statistical system at a second-order phase transition. The other is any quantum field theory probed at distances much shorter than all Compton wavelengths. In both regimes the theory has no length scale, and the absence of a length scale is an extraordinarily strong constraint. This section explains what "no length scale" means operationally, why it tends to upgrade itself to conformal invariance, and what tool (Wilson's operator product expansion) turns it into computable algebra. We end with the conformal group in d dimensions and see why $d = 2$ is special.

11.1.1 Scale transformations and scaling dimensions

Start with dimensional analysis. In units $\hbar = c = 1$ every quantity has a dimension that is a power of length. A mass m has dimension (length)$^{-1}$. A field has a dimension fixed by requiring that the action be dimensionless.

Worked example 11.1: Canonical dimension of a free scalar

The Euclidean action of a free massless scalar in d dimensions is $S = \frac{1}{2}\int \mathrm{d}^d x\, (\partial_\mu \varphi)^2$. We write $[X]$ for the mass dimension of X (so $[x] = -1$, $[\partial] = 1$, $[m] = 1$). Then

$$0 = [S] \overset{(1)}{=} [\mathrm{d}^d x] + 2[\partial] + 2[\varphi] \overset{(2)}{=} -d + 2 + 2[\varphi],$$

(1) The action is a pure number, and dimensions add under multiplication.
(2) $[\mathrm{d}^d x] = -d$ and $[\partial_\mu] = +1$.

So $[\varphi] = (d-2)/2$: dimension 1 in four dimensions, $1/2$ in three, and 0 in two. This is the **canonical dimension** d^c_φ. In two dimensions a free scalar is dimensionless, a fact Nash uses in §2.

A **scale transformation** (or **dilation**) is $x \mapsto \lambda x$ with a constant $\lambda > 0$. In a theory without dimensionful parameters, rescaling lengths must map the theory to itself, provided each field is rescaled by the appropriate power of λ.

Working definition 11.1 (scaling dimension)

A local field $A(x)$ has **scaling dimension** d_A (also written Δ_A) if the unitary operator $U(\lambda)$ implementing dilations [the operator on the space of states that carries out $x \mapsto \lambda x$] acts as

$$U(\lambda)\, A(x)\, U(\lambda)^{-1} = \lambda^{d_A}\, A(\lambda x). \tag{11.1}$$

Operational test: compute the two-point function; if the theory is scale invariant it is a pure power, $\langle A(x)A(0)\rangle = C/|x|^{2d_A}$, and the exponent is $2d_A$. The difference $\gamma_A = d_A - d^c_A$ between the true and the canonical dimension [the value read off from the action by dimensional analysis, $(d-2)/2$ for a scalar] is the **anomalous dimension** [the shift produced by interactions. It is zero in a free theory].

Why does the two-point function have to be a power? Suppose the vacuum is invariant, $U(\lambda)|0\rangle = |0\rangle$. Then

$$\langle A(x)A(0)\rangle \overset{(1)}{=} \langle 0|U(\lambda)^{-1}\,U(\lambda)A(x)U(\lambda)^{-1}\,U(\lambda)A(0)U(\lambda)^{-1}\,U(\lambda)|0\rangle \overset{(2)}{=} \lambda^{2d_A}\,\langle 0|A(\lambda x)A(0)|0\rangle = \lambda^{2d_A}\langle A(\lambda x)A(0)\rangle. \tag{11.2}$$

(1) Insert $1 = U^{-1}U$ three times; the outer factors act on the invariant vacuum and drop out.
(2) Apply (11.1) to each field; note $\lambda \cdot 0 = 0$.

If also rotations are a symmetry, $\langle A(x)A(0)\rangle = G(|x|)$ with $G(r) = \lambda^{2d_A} G(\lambda r)$ for every λ. Choosing $\lambda = 1/r$ gives $G(r) = G(1)\, r^{-2d_A}$: a pure power law. There is no room for an exponential $e^{-r/\xi}$, because ξ would be a length.

Nash's footnote describes $U(\lambda)$ as $\exp[\ln\lambda\,(x\,\partial/\partial x)]$. Here is what that operator does to a

function, which is the reason for the formula. Let $t = \ln\lambda$ and act on a monomial x^n:

$$\exp\!\left[t\,x\frac{\mathrm{d}}{\mathrm{d}x}\right]x^n \overset{(1)}{=} \sum_{k=0}^{\infty}\frac{t^k}{k!}\left(x\frac{\mathrm{d}}{\mathrm{d}x}\right)^k x^n \overset{(2)}{=} \sum_{k=0}^{\infty}\frac{(nt)^k}{k!}\,x^n$$
$$= e^{nt}x^n \overset{(3)}{=} (\lambda x)^n .$$

(1) Definition of the exponential of an operator as its power series.
(2) $x\,\mathrm{d}/\mathrm{d}x$ is the "degree counter": $x\,\mathrm{d}(x^n)/\mathrm{d}x = nx^n$, so x^n is an eigenfunction with eigenvalue n.
(3) $e^{nt} = \lambda^n$.

By linearity, $\exp[\ln\lambda\; x\,\mathrm{d}/\mathrm{d}x]\,f(x) = f(\lambda x)$ for any power series f. So the **dilation generator** is $D = x^\mu\partial_\mu$ (on functions), just as $P_\mu = \partial_\mu$ generates translations, $e^{a\cdot\partial}f(x) = f(x+a)$.

Worked example 11.2: Masses break scale invariance

The Euclidean propagator of a free scalar of mass m in three dimensions is the Yukawa potential $G_m(r) = e^{-mr}/(4\pi r)$. Rescale the separation:

$$G_m(\lambda r) = \frac{e^{-m\lambda r}}{4\pi\lambda r} \overset{(1)}{=} \lambda^{-1}\,\frac{e^{-(\lambda m)r}}{4\pi r} = \lambda^{-1}G_{\lambda m}(r).$$

(1) Regroup $m\lambda r$ as $(\lambda m)r$.

Scale invariance would require $G_m(\lambda r) = \lambda^{-2d_\varphi}G_m(r)$ with the *same* m. This holds for all λ only if $\lambda m = m$, that is $m = 0$. Then $G_0(r) = 1/(4\pi r)$, a power law with $2d_\varphi = 1$, matching the canonical dimension $1/2$ found above. A mass is a length scale (the Compton wavelength $1/m$), and a length scale is exactly what a scale-invariant theory cannot have.

11.1.2 Critical phenomena: where the length scale disappears

Take a ferromagnet, idealised as the **Ising model**: spins $\sigma_i = \pm 1$ on a square lattice with energy $E = -J\sum_{\langle ij\rangle}\sigma_i\sigma_j$. At high temperature the spins are disordered; at low temperature they align. In two dimensions there is a sharp transition at a critical temperature T_c (Onsager: $\sinh(2J/k_BT_c) = 1$). Measure the spin–spin correlation function at large separation r. Away from T_c it decays exponentially,

$$\langle\sigma(r)\sigma(0)\rangle - \langle\sigma\rangle^2 \;\sim\; \frac{e^{-r/\xi}}{r^{\,d-2+\eta}}, \qquad \xi \sim |T - T_c|^{-\nu}. \tag{11.3}$$

The length ξ is the **correlation length**: the size of a typical region of aligned spins. The exponents ν and η are **critical exponents**. As $T \to T_c$, $\xi \to \infty$. At T_c the only lengths left are the lattice spacing a (far too small to matter at large r) and r itself, so the correlator becomes a pure power.

Worked example 11.3: Reading off scaling dimensions from critical exponents

Onsager's solution of the 2D Ising model gives $\eta = 1/4$ and $\nu = 1$. At $T = T_c$, (11.3) with $\xi = \infty$ and $d = 2$ reads $\langle\sigma(r)\sigma(0)\rangle \propto r^{-1/4}$. Compare with the scale-invariant form $r^{-2\Delta_\sigma}$:

$$2\Delta_\sigma \overset{(1)}{=} d - 2 + \eta \overset{(2)}{=} \tfrac{1}{4} \quad\Longrightarrow\quad \Delta_\sigma = \tfrac{1}{8}.$$

(1) Match the power of r in (11.3) at $\xi = \infty$ with (11.2).
(2) $d = 2$, $\eta = 1/4$.

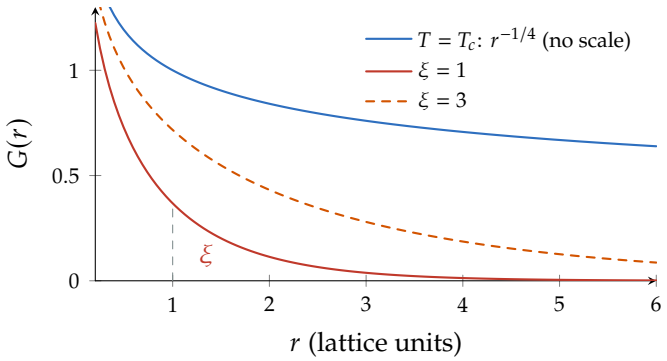

Figure 11.2: Spin–spin correlation of the 2D Ising model (schematic, using the exact exponent $\eta = 1/4$). Away from T_c (red, orange) the correlation dies off after a distance of order ξ. At T_c (blue) $\xi = \infty$ and the decay is a pure power: zooming in or out of the blue curve gives the same shape up to an overall factor. That self-similarity *is* scale invariance.

Now the energy operator ε (the local version of $\sigma_i\sigma_j$). Moving off criticality adds a term $t\int \mathrm{d}^2x\, \varepsilon(x)$ to the action, with $t \propto T - T_c$. The action is dimensionless, so $[t] = d - \Delta_\varepsilon$ in mass units. The only length that can be built from t is $\xi \propto t^{-1/(d-\Delta_\varepsilon)}$. Comparing with $\xi \propto t^{-\nu}$:

$$\nu \overset{(1)}{=} \frac{1}{d-\Delta_\varepsilon} \quad\Longrightarrow\quad \Delta_\varepsilon \overset{(2)}{=} d - \frac{1}{\nu} = 2 - 1 = 1.$$

(1) Dimensional analysis: $t^{1/(d-\Delta_\varepsilon)}$ has dimension of mass, so its inverse is a length.
(2) Solve for Δ_ε and insert $d = 2$, $\nu = 1$.

We will see in §3 that these two numbers, $\frac{1}{8}$ and 1, reappear as $2h$ with $h = \frac{1}{16}$ and $h = \frac{1}{2}$: the weights of the unitary minimal model with $c = \frac{1}{2}$. The critical exponents of a real magnet come out of the representation theory of the Virasoro algebra.

Nash adds a stronger statement: in two dimensions the critical theory is not just scale invariant but *conformally* invariant. Conformal transformations are those that look locally like a rotation times a rescaling, with the rescaling factor allowed to vary from point to point (the precise definition is in Section 11.1.5).

Physical picture: why local physics upgrades scale to conformal

A critical system has no preferred length anywhere. If the physics is also *local* (built from short-range couplings), then different regions do not know about each other's choice of units. So one should be able to rescale by different amounts in different places, as long as the map is locally a rescaling and a rotation and does not shear. Such maps are precisely the conformal maps. Polchinski turned this into a theorem for 2D unitary theories with a discrete spectrum of dimensions: scale plus rotation invariance imply conformal invariance. In higher dimensions it is believed but not proved in general.

11.1.3 Short distances, renormalisation and fixed points

The second regime is the short-distance limit of a massive quantum field theory. Nash states that the product $\varphi(x)\varphi(0)$ becomes independent of the mass as $x \to 0$. Here is what this means in the simplest case.

Worked example 11.4: The mass drops out at short distance

Expand the 3D Yukawa propagator for $mr \ll 1$:

$$G_m(r) = \frac{e^{-mr}}{4\pi r} \overset{(1)}{=} \frac{1}{4\pi r}\left(1 - mr + \tfrac{1}{2}m^2r^2 - \cdots\right)$$
$$= \underbrace{\frac{1}{4\pi r}}_{\text{massless, singular}} - \frac{m}{4\pi} + \frac{m^2 r}{8\pi} - \cdots .$$

(1) Taylor series of e^{-mr}.

The singular part, which dominates as $r \to 0$, is exactly the massless propagator. The mass only appears in terms that are finite or vanishing at $r = 0$. In four dimensions the same thing happens: $G_m(r) = mK_1(mr)/(4\pi^2 r) = 1/(4\pi^2 r^2) + \frac{m^2}{8\pi^2}\ln(mr) + \cdots$, using $K_1(u) = 1/u + \frac{u}{2}\ln(u/2) + \cdots$ for small u. The leading singularity is mass independent. Physically, at distances far below the Compton wavelength a particle does not know it is massive.

For an interacting theory the story is subtler, because the coupling constant itself changes with the scale at which we look: this is the **renormalisation group** (RG). Let us recall just enough of it (see [QFT notes §15.3–15.4] for a full treatment). Renormalised correlation functions depend on an arbitrary renormalisation scale M. Physics cannot depend on M, so changing M must be compensated by changing the renormalised coupling g and the normalisation of the fields. For the n-point function $G^{(n)}$ of a field φ this gives the **Callan–Symanzik equation**

$$\left[M\frac{\partial}{\partial M} + \beta(g)\frac{\partial}{\partial g} + n\,\gamma(g)\right]G^{(n)}(x_1, \ldots, x_n; M, g) = 0, \tag{11.4}$$

where $\beta(g) = M\,\mathrm{d}g/\mathrm{d}M$ says how the coupling runs and $\gamma(g)$ is the anomalous dimension of φ.

Working definition 11.2 (RG fixed point)

A **fixed point** is a value g^* with $\beta(g^*) = 0$: there the coupling stops running. *Operational test:* compute $\beta(g)$ (in perturbation theory, as a power series) and find its zeros. At a fixed point the theory has no intrinsic scale [no length or mass is singled out, so rescaling $x \mapsto \lambda x$ maps the theory to itself].

Let us see that a fixed point produces power laws with shifted exponents. Take the two-point function in a massless theory at $g = g^*$. By rotation invariance and dimensional analysis it has the form $G^{(2)}(x; M) = |x|^{-2d^c}F(M|x|)$, with d^c the canonical dimension and F a dimensionless function of the only dimensionless combination $M|x|$. Then

$$0 \overset{(1)}{=} \left[M\frac{\partial}{\partial M} + 2\gamma^*\right]|x|^{-2d^c}F(M|x|)$$
$$\overset{(2)}{=} |x|^{-2d^c}\left[uF'(u) + 2\gamma^* F(u)\right]_{u=M|x|},$$

(1) The Callan–Symanzik equation (11.4) with $n = 2$; the β term vanishes at the fixed point, and $\gamma^* = \gamma(g^*)$.

(2) Chain rule: $M\,\partial_M F(M|x|) = M|x|\,F'(M|x|)$.

so $uF' = -2\gamma^* F$, whose solution is $F(u) = C\,u^{-2\gamma^*}$. Hence

$$G^{(2)}(x) = C\,M^{-2\gamma^*}\,|x|^{-2(d^c+\gamma^*)}. \tag{11.5}$$

This is a pure power law with scaling dimension $d_\varphi = d^c + \gamma^*$. The anomalous dimension is literally an anomalous shift of the exponent. This is the content of Nash's footnote: "when the scale dimension differs from the canonical dimension the difference is the anomalous dimension γ_A".

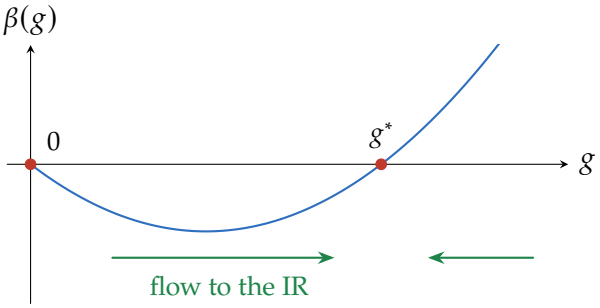

Figure 11.3: A β-function with two zeros. At each zero the coupling stops running and the theory is scale invariant. Since $\beta = M\,\mathrm{d}g/\mathrm{d}M$, lowering M moves g against the sign of β. With $\beta < 0$ between the zeros and $\beta > 0$ beyond g^*, the coupling approaches g^* from both sides at long distances (green arrows): g^* is an infrared-stable fixed point. This is the shape of $\beta(g) = -\varepsilon g + b g^2$ for φ^4 theory in $4-\varepsilon$ dimensions, whose Wilson–Fisher point describes critical magnets. The free point $g = 0$ is the ultraviolet end of the flow.

Watch out: a zero of β is necessary, not sufficient

Nash says a fixed point is a "necessary, but insufficient" condition for conformal invariance. Necessary: without $\beta(g^*) = 0$ the coupling runs and there is a scale (for QCD, Λ_{QCD}). Insufficient: a fixed point gives scale invariance, and scale invariance is weaker than conformal invariance. There are (rare, somewhat pathological) scale-invariant but not conformal theories, for example the theory of elasticity in two dimensions, which is not reflection positive. In practice, unitary, local fixed points are conformal.

11.1.4 Wilson's operator product expansion

Products of quantum fields at the same point are singular. The product $\varphi(x)\varphi(0)$ blows up as $x \to 0$, as the propagators above show. Wilson's idea was to organise the singularity. Seen from far away, the pair of operators at x and 0 looks like a single local disturbance at 0. Any local disturbance can be expanded in a basis of local operators $\mathcal{O}_n(0)$ at that point. The coefficients carry all the x dependence.

Working definition 11.3 (operator product expansion (OPE))

For two local fields A, B there are local operators $\mathcal{O}_n$ [fields sitting at the single point 0, such as $\varphi^2(0)$ or $\partial\varphi(0)$] and c-number functions $C_n(x)$ [ordinary numerical functions of x, not operators] such that, inside any correlation function with other fields placed far from 0,

$$A(x)B(0) \;\longrightarrow\; \sum_n C_n(x)\,\mathcal{O}_n(0) \qquad (x \to 0). \tag{11.6}$$

Operational recipe: for free fields, apply Wick's theorem [the product equals its normal-ordered form plus every way of replacing pairs of fields by their propagator] to $A(x)B(0)$, keep the contractions as c-number coefficients, and Taylor-expand the leftover normal-ordered operators [the uncontracted fields, with annihilation parts to the right, so their vacuum expectation value is zero] about 0. The C_n are singular at $x = 0$; ordering the $\mathcal{O}_n$

by dimension [in a scale-invariant theory $C_n(x)$ scales as $|x|^{d_n - d_A - d_B}$, so a smaller scaling dimension d_n means a stronger singularity] orders the terms from most to least singular.

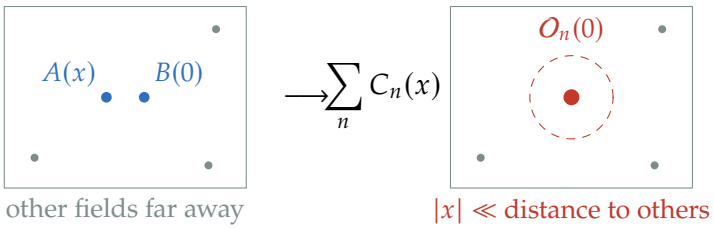

Figure 11.4: The OPE. Two operators close together (left), seen from far away, are indistinguishable from a combination of single local operators at one point (right). The coefficients $C_n(x)$ record how the pair's separation enters. The expansion is valid as long as no other field comes inside the dashed circle.

Worked example 11.5: OPE of a free massless scalar in four dimensions

Let φ be a free massless scalar with $\langle \varphi(x)\varphi(0)\rangle = 1/(4\pi^2 x^2)$. Wick's theorem writes the product as the contraction plus the normal-ordered product,

$$\varphi(x)\varphi(0) \overset{(1)}{=} \langle \varphi(x)\varphi(0)\rangle\, \mathbb{1} + :\varphi(x)\varphi(0):$$
$$\overset{(2)}{=} \frac{1}{4\pi^2 x^2}\,\mathbb{1} + :\varphi^2:(0) + x^\mu :\partial_\mu\varphi\;\varphi:(0) + \tfrac{1}{2}x^\mu x^\nu :\partial_\mu\partial_\nu\varphi\;\varphi:(0) + \cdots$$

(1) Wick's theorem for two free fields: one contraction or none.
(2) The normal-ordered product has no singularity, so we may Taylor-expand $\varphi(x)$ about 0 inside it.

So $\mathcal{O}_0 = \mathbb{1}$ with $C_0 = 1/(4\pi^2 x^2)$, $\mathcal{O}_1 = :\varphi^2:$ with $C_1 = 1$, $\mathcal{O}_{2,\mu} = :\partial_\mu\varphi\;\varphi:$ with $C_2^\mu = x^\mu$, and so on. Let us check the dimension bookkeeping (derived in general just below). With $d_\varphi = 1$: the identity has dimension 0 and $C_0 \sim |x|^{-2}$; $:\varphi^2:$ has dimension 2 and $C_1 \sim |x|^0$; $:\partial\varphi\;\varphi:$ has dimension 3 and $C_2 \sim |x|^{+1}$. In each case (power of $1/|x|$) $= d_\varphi + d_\varphi - d_{\mathcal{O}_n}$.

Now let us derive that bookkeeping rule in a scale-invariant theory. Nash defines the *strength* S_{C_n} of the singularity of C_n by

$$C_n(\lambda x) = \frac{C_n(x)}{\lambda^{S_{C_n}}}, \tag{11.7}$$

so that $C_n(x) \propto |x|^{-S_{C_n}}$. Conjugate the OPE (11.6) by $U(\lambda)$:

$$\lambda^{d_A+d_B}\, A(\lambda x)B(0) \overset{(1)}{=} U(\lambda)\, A(x)B(0)\, U(\lambda)^{-1} \overset{(2)}{=} \sum_n C_n(x)\, U(\lambda)\mathcal{O}_n(0)U(\lambda)^{-1}$$
$$\overset{(3)}{=} \sum_n C_n(x)\, \lambda^{d_{\mathcal{O}_n}}\mathcal{O}_n(0),$$
$$\lambda^{d_A+d_B}\, A(\lambda x)B(0) \overset{(4)}{=} \lambda^{d_A+d_B}\sum_n C_n(\lambda x)\,\mathcal{O}_n(0) \overset{(5)}{=} \sum_n \lambda^{d_A+d_B-S_{C_n}} C_n(x)\,\mathcal{O}_n(0).$$

(1) (11.1) for A and for B (at the origin), with UBU^{-1} and UAU^{-1} multiplied.
(2) Apply the OPE to $A(x)B(0)$; the C_n are numbers and commute with U.
(3) (11.1) for each $\mathcal{O}_n$ at the origin.

(4) Apply the OPE directly to $A(\lambda x)B(0)$.
(5) Definition (11.7).

The $\mathcal{O}_n$ are independent, so the coefficients must agree term by term:

$$d_A + d_B = d_{\mathcal{O}_n} + S_{C_n} \qquad \text{for each } n, \qquad \text{i.e.} \qquad C_n(x) \propto |x|^{d_{\mathcal{O}_n} - d_A - d_B}. \tag{11.8}$$

The most singular term comes from the operator of lowest dimension (usually the identity), and operators of higher dimension come with less singular or vanishing coefficients.

Watch out: a sign in Nash's (11.3)

Nash prints (11.3) as $d_A + d_B = d_{\mathcal{O}_n} - S_{C_n}$. With his own definition (11.2) of S_{C_n} the sign should be +, as derived above. The free-field example confirms it: for $\varphi\varphi \to \mathbb{1}$ in four dimensions, $d_A + d_B = 2$, $d_{\mathbb{1}} = 0$ and $C_0 \propto |x|^{-2}$ has $S = 2$; so $2 = 0 + 2$, whereas the printed sign would give $2 = 0 - 2$.

Nash remarks that the OPE "plays a prominent part" in two-dimensional conformal field theory. That is an understatement. In two dimensions the OPE of the stress tensor with any field *is* the conformal Ward identity (Section 11.3), and the OPE of the stress tensor with itself *is* the Virasoro algebra (Section 11.4).

11.1.5 The conformal group in d dimensions

We have been using the phrase "conformal transformation". Let us define it and find all of them.

Working definition 11.4 (conformal transformation)

A smooth invertible map $x \mapsto x'(x)$ of (a region of) $\mathbb{R}^d$ with the flat metric $\delta_{\mu\nu}$ is **conformal** if it rescales the metric by a position-dependent factor [a short step $\mathrm{d}x$ at x is mapped to a step $\Omega(x)$ times as long, the same factor in every direction],

$$\delta_{\rho\sigma}\,\frac{\partial x'^{\rho}}{\partial x^{\mu}}\,\frac{\partial x'^{\sigma}}{\partial x^{\nu}} = \Omega(x)^2\,\delta_{\mu\nu}. \tag{11.9}$$

Operational test: compute the Jacobian matrix $J = \partial x'/\partial x$ and check that $J^T J$ is a multiple of the identity at every point. Equivalently, $J(x)$ is a rotation (or reflection) times a scalar, so the map preserves angles between curves but not lengths.

Infinitesimally, write $x'^{\mu} = x^{\mu} + \epsilon^{\mu}(x)$ with ϵ small. Then $J = \mathbb{1} + \partial\epsilon$ and, to first order,

$$\delta_{\rho\sigma}\big(\delta^{\rho}_{\mu} + \partial_{\mu}\epsilon^{\rho}\big)\big(\delta^{\sigma}_{\nu} + \partial_{\nu}\epsilon^{\sigma}\big) \overset{(1)}{=} \delta_{\mu\nu} + \partial_{\mu}\epsilon_{\nu} + \partial_{\nu}\epsilon_{\mu} + O(\epsilon^2) \overset{(2)}{=} (1 + 2\sigma(x))\,\delta_{\mu\nu},$$

(1) Multiply out; indices are raised and lowered with δ, so $\epsilon_{\nu} = \epsilon^{\nu}$.
(2) Write $\Omega^2 = 1 + 2\sigma$ with σ small.

Taking the trace of $\partial_{\mu}\epsilon_{\nu} + \partial_{\nu}\epsilon_{\mu} = 2\sigma\delta_{\mu\nu}$ fixes $2\sigma = \frac{2}{d}\,\partial\cdot\epsilon$. So an infinitesimal conformal transformation satisfies the **conformal Killing equation**

$$\partial_{\mu}\epsilon_{\nu} + \partial_{\nu}\epsilon_{\mu} = \frac{2}{d}\,(\partial\cdot\epsilon)\,\delta_{\mu\nu}. \tag{11.10}$$

Solving the conformal Killing equation for $d > 2$. We show that ϵ is at most quadratic in x. Contract (11.10) with ∂^{ν}:

$$\Box\epsilon_{\mu} + \partial_{\mu}(\partial\cdot\epsilon) = \frac{2}{d}\,\partial_{\mu}(\partial\cdot\epsilon) \quad\Longrightarrow\quad \Box\epsilon_{\mu} = \Big(\frac{2}{d} - 1\Big)\partial_{\mu}(\partial\cdot\epsilon). \tag{11.11}$$

Now apply $\Box$ to (11.10) and use (11.11):

$$\frac{2}{d}\,\delta_{\mu\nu}\Box(\partial\cdot\epsilon) \overset{(1)}{=} \partial_\mu\Box\epsilon_\nu + \partial_\nu\Box\epsilon_\mu \overset{(2)}{=} 2\Big(\frac{2}{d}-1\Big)\partial_\mu\partial_\nu(\partial\cdot\epsilon).$$

(1) $\Box$ commutes with ∂_μ.
(2) Substitute (11.11); the two terms are equal because partial derivatives commute.

Taking the trace ($\mu=\nu$, summed with $\delta_{\mu\mu}=d$) of the two ends of this chain gives

$$2\,\Box(\partial\cdot\epsilon) \overset{(1)}{=} 2\Big(\frac{2}{d}-1\Big)\Box(\partial\cdot\epsilon) \quad\Longrightarrow\quad \frac{2(d-1)}{d}\,\Box(\partial\cdot\epsilon) \overset{(2)}{=} 0.$$

(1) Left: $\frac{2}{d}\delta_{\mu\mu}=2$. Right: $\partial_\mu\partial_\mu=\Box$.
(2) Move everything to one side: $2-2(\frac{2}{d}-1)=4-\frac{4}{d}=\frac{4(d-1)}{d}$; divide by 2.

So for $d\geq 2$, $\Box(\partial\cdot\epsilon)=0$. Then the left end of the chain vanishes, and the right end gives

$$(2-d)\,\partial_\mu\partial_\nu(\partial\cdot\epsilon)=0. \tag{11.12}$$

For $d>2$ this says $\partial\cdot\epsilon$ is at most linear in x. Next, the identity

$$\begin{aligned}2\partial_\mu\partial_\nu\epsilon_\rho &\overset{(1)}{=} \partial_\mu(\partial_\nu\epsilon_\rho+\partial_\rho\epsilon_\nu)+\partial_\nu(\partial_\mu\epsilon_\rho+\partial_\rho\epsilon_\mu)-\partial_\rho(\partial_\mu\epsilon_\nu+\partial_\nu\epsilon_\mu)\\ &\overset{(2)}{=} \frac{2}{d}\big(\delta_{\nu\rho}\partial_\mu+\delta_{\mu\rho}\partial_\nu-\delta_{\mu\nu}\partial_\rho\big)(\partial\cdot\epsilon)\end{aligned}$$

(1) Expand the right side: six terms, four cancel in pairs because partial derivatives commute, leaving $2\partial_\mu\partial_\nu\epsilon_\rho$.
(2) Replace each bracket using (11.10).

shows that the second derivatives of ϵ are constants (since $\partial\cdot\epsilon$ is linear). So ϵ is a polynomial of degree at most 2. Substituting the general quadratic into (11.10) and sorting the solutions gives exactly four types:

$$\begin{aligned}&\text{translation:} && \epsilon^\mu = a^\mu,\\ &\text{rotation:} && \epsilon^\mu = \omega^\mu{}_\nu x^\nu, \quad \omega_{\mu\nu}=-\omega_{\nu\mu},\\ &\text{dilation:} && \epsilon^\mu = \lambda\, x^\mu,\\ &\text{special conformal (SCT):} && \epsilon^\mu = 2(b\cdot x)x^\mu - b^\mu x^2.\end{aligned} \tag{11.13}$$

Worked example 11.6: The special conformal transformation satisfies (11.10)

For $\epsilon_\nu = 2(b\cdot x)x_\nu - b_\nu x^2$,

$$\begin{aligned}\partial_\mu\epsilon_\nu &\overset{(1)}{=} 2b_\mu x_\nu + 2(b\cdot x)\delta_{\mu\nu} - 2b_\nu x_\mu,\\ \partial_\mu\epsilon_\nu+\partial_\nu\epsilon_\mu &\overset{(2)}{=} 4(b\cdot x)\,\delta_{\mu\nu},\\ \partial\cdot\epsilon &\overset{(3)}{=} 2(b\cdot x)+2d\,(b\cdot x)-2(b\cdot x)=2d\,(b\cdot x).\end{aligned}$$

(1) Product rule; $\partial_\mu(b\cdot x)=b_\mu$, $\partial_\mu x_\nu=\delta_{\mu\nu}$, $\partial_\mu x^2=2x_\mu$.
(2) Symmetrise: the terms $2b_\mu x_\nu - 2b_\nu x_\mu$ are antisymmetric and cancel.
(3) Set $\mu=\nu$ in the first line and sum: $\delta_{\mu\mu}=d$.

So the right side of (11.10) is $\frac{2}{d}\cdot 2d(b\cdot x)\delta_{\mu\nu}=4(b\cdot x)\delta_{\mu\nu}$, equal to the left side. The local scale factor is $\sigma=\frac{1}{d}\partial\cdot\epsilon=2b\cdot x$: it varies from point to point, which is what distinguishes an SCT from a dilation.

Count the parameters: d translations, $d(d-1)/2$ rotations, one dilation and d special conformal transformations, in total

$$d + \frac{d(d-1)}{2} + 1 + d = \frac{(d+1)(d+2)}{2} = \dim \mathrm{SO}(d+1,1). \tag{11.14}$$

The conformal group of Euclidean $\mathbb{R}^d$ (with a point at infinity added) is indeed $\mathrm{SO}(d+1,1)$; in Minkowski signature it is $\mathrm{SO}(d,2)$. For $d=4$ this is the 15-dimensional group $\mathrm{SO}(4,2)$ of Maxwell's equations and of massless QCD at the classical level.

The finite SCT is best understood through the **inversion** $I : x^\mu \mapsto x^\mu/x^2$. An SCT is "invert, translate by $-b$, invert again":

$$x'^\mu = \frac{x^\mu - b^\mu x^2}{1 - 2\,b\cdot x + b^2 x^2}. \tag{11.15}$$

Expanding to first order in b gives $x'^\mu \approx x^\mu - b^\mu x^2 + 2(b\cdot x)x^\mu$, matching (11.13).

Worked example 11.7: Inversion is conformal

Let $x'^\mu = x^\mu/x^2$. Its Jacobian is

$$\frac{\partial x'^\mu}{\partial x^\nu} \overset{(1)}{=} \frac{\delta^\mu_\nu}{x^2} - \frac{2x^\mu x_\nu}{x^4} = \frac{1}{x^2}\,R^\mu{}_\nu, \qquad R^\mu{}_\nu := \delta^\mu_\nu - 2\frac{x^\mu x_\nu}{x^2}.$$

(1) Quotient rule, with $\partial_\nu (x^2)^{-1} = -2x_\nu/x^4$.

The matrix R is the reflection in the hyperplane orthogonal to x: it sends $x \mapsto -x$ and fixes every vector orthogonal to x. So $R^T R = \mathbb{1}$, and $J^T J = x^{-4}\mathbb{1}$: the inversion is conformal with $\Omega = 1/x^2$. (It reverses orientation, so it is not in the identity component; but composing two inversions with a translation in between gives the orientation-preserving SCT.)

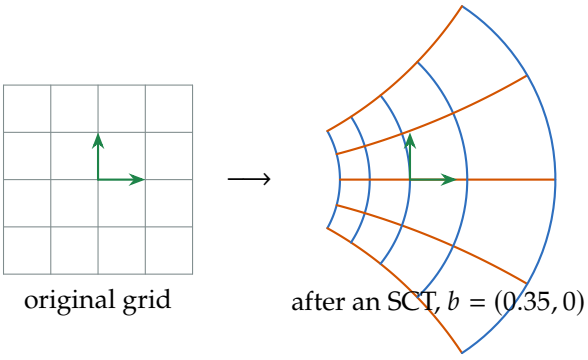

Figure 11.5: A special conformal transformation (11.15) in two dimensions. Straight grid lines become circular arcs, and the cells grow towards the right. But every crossing is still a right angle, and small cells stay square. Locally the map is a rotation times a rescaling; the rescaling factor $\Omega(x)$ changes from point to point.

Why scale invariance plus a traceless stress tensor gives conformal invariance. Here is the field-theory version of the upgrade from scale to conformal invariance. If we change coordinates by $\epsilon^\mu(x)$ depending on position, a translation-invariant action changes by an amount proportional to $\partial\epsilon$. The coefficient defines the (symmetric) stress tensor: $\delta S = -\int \mathrm{d}^d x\, T^{\mu\nu}\partial_\mu \epsilon_\nu$ (the overall sign and normalisation are conventions; see Section 11.3.10). For a conformal ϵ,

$$\delta S \overset{(1)}{=} -\frac{1}{2}\int \mathrm{d}^d x\, T^{\mu\nu}(\partial_\mu\epsilon_\nu + \partial_\nu\epsilon_\mu) \overset{(2)}{=} -\frac{1}{d}\int \mathrm{d}^d x\, T^\mu{}_\mu\,(\partial\cdot\epsilon). \tag{11.16}$$

(1) $T^{\mu\nu}$ is symmetric, so only the symmetric part of $\partial_\mu \epsilon_\nu$ contributes.
(2) The conformal Killing equation (11.10).

So a theory whose stress tensor is traceless, $T^\mu{}_\mu = 0$, is invariant under *all* conformal transformations, not just under dilations (for which $\partial \cdot \epsilon = d\lambda$ is constant). Scale invariance only requires $T^\mu{}_\mu$ to be a total divergence; tracelessness is the extra local condition.

Worked example 11.8: The 2D free boson has a traceless stress tensor

For $S = \frac{g}{2}\int \mathrm{d}^d x\,(\partial\varphi)^2$ the canonical symmetric stress tensor is $T_{\mu\nu} = g\big(\partial_\mu\varphi\,\partial_\nu\varphi - \frac{1}{2}\delta_{\mu\nu}(\partial\varphi)^2\big)$. Its trace is

$$T^\mu{}_\mu \overset{(1)}{=} g\left((\partial\varphi)^2 - \frac{d}{2}(\partial\varphi)^2\right) = g\,\frac{2-d}{2}\,(\partial\varphi)^2.$$

(1) $\delta_{\mu\mu} = d$.

In $d = 2$ this vanishes identically: the free massless boson in two dimensions is conformally invariant with no further work. In $d = 4$ the canonical tensor is not traceless; one must add the "improvement term" $-\frac{g}{6}(\partial_\mu\partial_\nu - \delta_{\mu\nu}\Box)\varphi^2$, which does not change the conserved charges but removes the trace on shell.

11.1.6 Why two dimensions is different

Go back to (11.12). For $d = 2$ the factor $(2-d)$ vanishes and the equation imposes no constraint at all. Write the conformal Killing equation out in components for $d = 2$:

$$\begin{aligned} \mu = \nu = 1: &\quad 2\partial_1\epsilon_1 = \partial_1\epsilon_1 + \partial_2\epsilon_2 \implies \partial_1\epsilon_1 = \partial_2\epsilon_2, \\ \mu = 1, \nu = 2: &\quad \partial_1\epsilon_2 + \partial_2\epsilon_1 = 0. \end{aligned}$$

These are the **Cauchy–Riemann equations** for the complex function $\epsilon(z) = \epsilon_1 + i\epsilon_2$ of $z = x_1 + ix_2$: the real part $u = \epsilon_1$ and imaginary part $v = \epsilon_2$ obey $u_x = v_y$, $u_y = -v_x$. So in two dimensions *every holomorphic function* $\epsilon(z)$ gives an infinitesimal conformal transformation. Holomorphic functions are specified by infinitely many Taylor or Laurent coefficients, so the local conformal algebra is infinite dimensional. Only a six-dimensional part of it, corresponding to $\mathrm{SO}(3,1) \cong \mathrm{SL}(2,\mathbb{C})/\mathbb{Z}_2$ by (11.14) with $d = 2$, consists of transformations that are defined and invertible on the whole plane plus the point at infinity. We will see this explicitly in Section 11.3.3.

Key idea: the leverage of two dimensions

In $d > 2$ conformal symmetry is a finite-dimensional group: it fixes two- and three-point functions but little more. In $d = 2$ it is infinite dimensional: there are infinitely many conserved charges, one for each holomorphic vector field. That is why "in two dimensions the situation is somewhat better" (Nash), and why exactly solvable interacting conformal theories exist there.

Nash lists where two-dimensional conformal theories occur: the worldsheet theory of string theory (Chapter 9), where conformal invariance is a gauge symmetry and c must cancel against the ghost contribution; the critical points of two-dimensional statistical systems; and the quantum field theory approach to knot invariants of Chapter 12. The original reference for everything in this chapter is Belavin, Polyakov and Zamolodchikov (BPZ, 1984).

Reading Nash (pp. 301–302, (11.1)–(11.3))

§1 is two pages of motivation. Nash mentions critical phenomena, the mass independence of $\varphi(x)\varphi(0)$ at short distance, the Callan–Symanzik equation and the need for a zero of $\beta(g)$, and states Wilson's OPE (11.1) with the scaling rule (11.2)–(11.3). His footnote 1 defines the scale dimension via $U(\lambda)A(x)U^{-1}(\lambda) = \lambda^{d_A}A(\lambda x)$ with $U(\lambda) = \exp[\ln\lambda\,(x\,\partial/\partial x)]$, and the anomalous dimension $\gamma_A = d_A - d_A^c$ (he writes $d_A^c - d_A$, a sign convention; with the Callan–Symanzik form (11.5) the natural sign is ours). We have added the derivation of power laws from scale invariance and from the Callan–Symanzik equation, the free-field OPE, the corrected sign in (11.3), and the whole of the conformal group in d dimensions, which Nash does not discuss but which explains his remark that the conformal group is infinite dimensional only in two dimensions.

Recap

- A mass is a length scale; theories without length scales have power-law correlators $\langle AA\rangle \propto |x|^{-2d_A}$.
- Critical points ($\xi = \infty$) and RG fixed points ($\beta(g^*) = 0$) are scale invariant; the scaling dimension is canonical plus anomalous, $d_\varphi = d^c + \gamma^*$.
- The OPE $A(x)B(0) = \sum_n C_n(x)\mathcal{O}_n(0)$ has $C_n \propto |x|^{d_{\mathcal{O}_n} - d_A - d_B}$.
- Conformal maps rescale the metric locally; in $d > 2$ they form $\mathrm{SO}(d+1,1)$ (translations, rotations, dilation, SCTs), in $d = 2$ they are all holomorphic maps.
- A traceless symmetric stress tensor means invariance under all conformal maps. In 2D the free boson qualifies directly.
- 2D Ising: $\Delta_\sigma = 1/8$, $\Delta_\varepsilon = 1$ from $\eta = 1/4$, $\nu = 1$; these will be explained by the Virasoro algebra.

11.2 Weyl rescalings versus conformal transformations

In Section 11.1.5 a conformal transformation was a change of coordinates $x \mapsto x'$ that rescales the flat metric by a factor $\Omega(x)^2$. Many books, and many conversations, use a second operation with almost the same formula: multiply the metric by $\Omega(x)^2$ and do nothing else. That second operation is a *Weyl rescaling*. The two are easy to confuse, because both put a factor Ω^2 in front of $g_{\mu\nu}$. They are not the same. A conformal transformation moves points around inside one fixed geometry. A Weyl rescaling leaves every point where it is and changes the geometry itself: a flat plane can become a sphere, and flat $\mathbb{R}^d$ can become a cylinder.

This section answers four questions. What exactly is the relation between the two operations? How does a primary field transform, and why does the exponent $-\Delta$ appear? How can we read off Δ without moving any point? And what does demanding invariance under *local* Weyl rescalings buy us? The last answer is concrete: it forces a free scalar in curved space to couple to the curvature as $\frac{1}{2}\xi R\varphi^2$ with $\xi = \frac{1}{6}$ in four dimensions, and it explains the "improvement term" of Example 11.8.

Conventions for this section. We work in Euclidean signature on a d-dimensional manifold M with metric $g_{\mu\nu}$, $\sqrt{g} := \sqrt{\det g_{\mu\nu}}$, and ∇_μ the covariant derivative of g (a reminder of Christoffel symbols and curvature is in Chapter T2). For a function f we write $(\nabla f)^2 := g^{\mu\nu}\partial_\mu f\,\partial_\nu f$ and

$\Box f := g^{\mu\nu}\nabla_\mu\nabla_\nu f = \frac{1}{\sqrt{g}}\partial_\mu\big(\sqrt{g}\,g^{\mu\nu}\partial_\nu f\big)$. The curvature convention is

$$R^\rho{}_{\sigma\mu\nu} = \partial_\mu\Gamma^\rho_{\nu\sigma} - \partial_\nu\Gamma^\rho_{\mu\sigma} + \Gamma^\rho_{\mu\lambda}\Gamma^\lambda_{\nu\sigma} - \Gamma^\rho_{\nu\lambda}\Gamma^\lambda_{\mu\sigma}, \qquad R_{\sigma\nu} = R^\mu{}_{\sigma\mu\nu}, \qquad R = g^{\sigma\nu}R_{\sigma\nu}, \tag{11.17}$$

for which a round sphere S^d of radius a has $R = d(d-1)/a^2 > 0$ (we check $d = 2$ below). Rescaling factors are written $\Omega = e^\sigma$, so $\sigma = \ln\Omega$. For small σ this is the σ of Section 11.1.5, where $\Omega^2 = 1 + 2\sigma$.

11.2.1 Two operations: moving the points, or changing the ruler

A conformal transformation moves points. Recall (11.9): a map $x \mapsto x' = f(x)$ of flat $\mathbb{R}^d$ is conformal if its Jacobian matrix $J = \partial x'/\partial x$ obeys $J^T J = \Omega(x)^2\,\mathbb{1}$. Read it as a statement about lengths. A short step $\mathrm{d}x$ at x is carried by the map to the step $\mathrm{d}x' = J\,\mathrm{d}x$ at x', and

$$|\mathrm{d}x'|^2 \overset{(1)}{=} \mathrm{d}x^T J^T J\,\mathrm{d}x \overset{(2)}{=} \Omega(x)^2\;|\mathrm{d}x|^2\,.$$

(1) $|\mathrm{d}x'|^2 = (\mathrm{d}x')^T\mathrm{d}x'$ and $\mathrm{d}x' = J\,\mathrm{d}x$.
(2) The conformal condition $J^T J = \Omega^2\mathbb{1}$.

Every short step near x is stretched by the same factor $\Omega(x)$, whatever its direction. So angles survive, small squares go to small squares, and only their size changes, by an amount that varies from point to point. The points themselves have moved: the point that was at x is now at x'.

A Weyl rescaling changes the ruler. Now keep every point fixed and replace the metric by

$$g_{\mu\nu}(x) \;\longmapsto\; \bar{g}_{\mu\nu}(x) = \Omega(x)^2\,g_{\mu\nu}(x) = e^{2\sigma(x)}g_{\mu\nu}(x). \tag{11.18}$$

Nothing moves. What changes is the reading of the ruler: a coordinate step $\mathrm{d}x$ at x used to have length $\sqrt{g_{\mu\nu}\mathrm{d}x^\mu\mathrm{d}x^\nu}$ and now has length $\Omega(x)$ times that. If Ω is constant, this is a change of units, like measuring in centimetres instead of metres. If Ω varies, it is a different change of units at every point, and in general it produces a different geometry. Figure 11.6 shows the two operations side by side.

When is the second operation secretly the first one? Suppose that after the Weyl rescaling we are allowed to relabel the points, by some smooth invertible map f (a **diffeomorphism**). If some relabelling makes the new rulers read exactly like the old ones, then nobody can tell that anything happened to the geometry, and the whole effect was just a change of coordinates. That is precisely the conformal case.

Working definition 11.5 (Weyl rescaling, and when it is conformal)

A **Weyl rescaling** is the replacement $g_{\mu\nu}(x) \mapsto \Omega(x)^2 g_{\mu\nu}(x)$ with $\Omega > 0$ [every point stays where it is, and a short step $\mathrm{d}x$ at x that used to measure ℓ now measures $\Omega(x)\,\ell$], made together with $\phi(x) \mapsto \Omega(x)^{-\Delta}\phi(x)$ for each field of scaling dimension Δ [a field that carries Δ powers of inverse length is re-expressed in the new local unit of length]. It is **conformal** when $\Omega^2 g$ is **diffeomorphic** to g [some smooth relabelling of the points, $x \mapsto x' = f(x)$, makes the new rulers read exactly like the old ones], that is, when

$$(f^*g)_{\mu\nu}(x) := g_{\rho\sigma}\big(f(x)\big)\,\frac{\partial f^\rho}{\partial x^\mu}\frac{\partial f^\sigma}{\partial x^\nu} = \Omega(x)^2\,g_{\mu\nu}(x) \tag{11.19}$$

[moving the points with f and then measuring with the old ruler gives the same lengths as measuring the unmoved points with the new ruler]. The map f is then a **conformal**

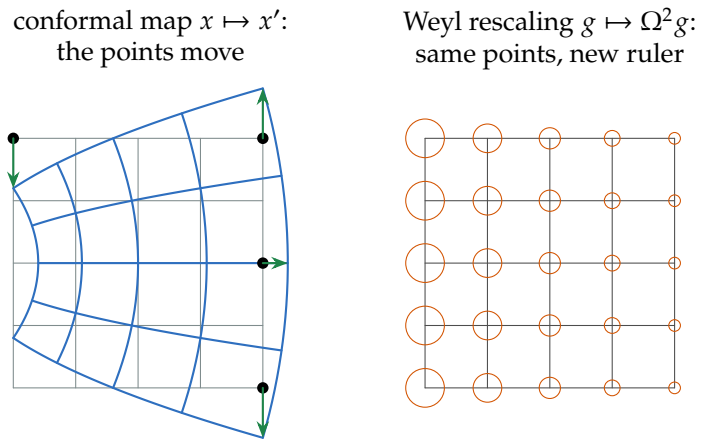

Figure 11.6: Left: the conformal map $z \mapsto z + 0.2\,z^2$ of the plane (grey grid before, blue grid after). The green arrows show four points being carried to new positions. The blue cells are still little squares with right-angled corners, but they are bigger on the right than on the left. Right: a Weyl rescaling with $\Omega = e^{0.6x}$. The grid does not move at all. Each orange circle is the set of points at one fixed *new* distance from the grid point at its centre. On the right, where Ω is large, the new ruler reads every step as long, so the circle of fixed new radius is small.

transformation of (M, g) [for flat $g = \delta$ this is exactly (11.9)]. *To test a given* Ω*:* compute the curvature of $\Omega^2 g$. Curvature cannot be changed by relabelling points, so if $\Omega^2 g$ and g have different curvature the rescaling is not conformal. For flat g the rescaling is conformal (at least locally) exactly when $\Omega^2 g$ is flat as well [its Riemann tensor is zero everywhere]. In $d = 2$ this is the single condition $\Box \ln \Omega = 0$ (see (11.34)).

Farnsworth, Luty and Prilepina put it in one sentence: "Conformal transformations are special Weyl transformations such that the transformed metric is diffeomorphic to the original metric." Most Weyl rescalings are not of this kind. A general $\Omega(x)$ is an arbitrary positive function, while in $d > 2$ the conformal Ω's form the finite-dimensional family found in Section 11.1.5. Figure 11.7 draws this as a picture of the space of all metrics.

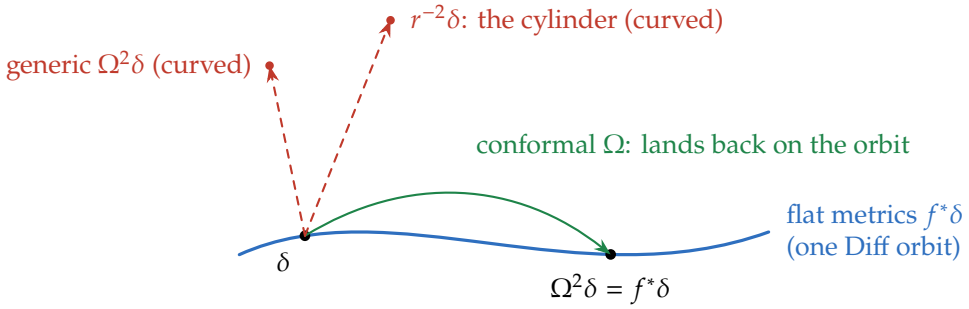

Figure 11.7: The space of all metrics on $\mathbb{R}^d$, drawn as a plane. The blue curve is the set of metrics obtained from the flat metric δ by relabelling points, $f^*\delta$: they all describe the same flat geometry. A Weyl rescaling moves us from δ to $\Omega^2\delta$. For a conformal Ω (green) we land back on the blue curve, so the rescaling can be undone by a diffeomorphism. For every other Ω (red) we land on a genuinely curved metric, for example the cylinder of Example 11.13, and no relabelling brings us back.

Why Weyl invariance implies conformal invariance. Let $S[g, \phi]$ be an action built covariantly from a metric and a scalar field, so that relabelling points does not change it: $S[f^*g, f^*\phi] =$

$S[g,\phi]$, where $(f^*\phi)(x) = \phi(f(x))$. Suppose it is also **Weyl invariant**: $S[\Omega^2 g, \Omega^{-\Delta}\phi] = S[g,\phi]$ for every positive function Ω. Take a conformal map f of flat space, with $f^*\delta = \Omega^2\delta$, and define the transformed field ϕ' by

$$\phi'\big(f(x)\big) = \Omega(x)^{-\Delta}\phi(x). \tag{11.20}$$

Then

$$S[\delta,\phi'] \overset{(1)}{=} S[f^*\delta,\ f^*\phi'] \overset{(2)}{=} S[\Omega^2\delta,\ \Omega^{-\Delta}\phi] \overset{(3)}{=} S[\delta,\phi]. \tag{11.21}$$

(1) Relabelling the points by f does not change a covariant action.
(2) $f^*\delta = \Omega^2\delta$ because f is conformal, and $(f^*\phi')(x) = \phi'(f(x)) = \Omega(x)^{-\Delta}\phi(x)$ by (11.20).
(3) Weyl invariance, used only for this special Ω.

So the flat-space action is unchanged when ϕ is replaced by ϕ': the theory is conformally invariant in flat space. The chain also shows what a conformal transformation *is* on fields: a Weyl rescaling (step 3, read backwards) followed by the relabelling f that undoes it (step 1). Steps 1 and 2 hold for any covariant action. So flat-space conformal invariance is exactly Weyl invariance tested only on the special Ω's of conformal maps, evaluated at $g = \delta$. That is why the converse can fail: a theory may pass the test for these few Ω's and fail it for the others. We return to this in Section 11.2.5.

11.2.2 Primary fields in d dimensions

In two dimensions a primary field was defined in Section 11.3.5 by its response to holomorphic maps. In d dimensions the definition has the same spirit. Under a conformal map the Jacobian is, by the operational test of (11.9),

$$\frac{\partial x'^{\mu}}{\partial x^{\nu}} = \Omega(x)\, R^{\mu}{}_{\nu}(x), \qquad R^T R = \mathbb{1}, \tag{11.22}$$

a rescaling by $\Omega(x)$ times a rotation (or reflection) $R(x)$. A primary field is one that responds to each of these two pieces in the simplest possible way: it is rescaled by a power of Ω and its indices are rotated by R.

Working definition 11.6 (primary tensor of rank (n,m) and dimension Δ)

A field $T^{\mu_1\cdots\mu_n}{}_{\nu_1\cdots\nu_m}$ with n upper and m lower indices is a **primary** of **dimension** Δ if under every conformal map $x \mapsto x'$ [a relabelling of points that stretches every short step near x by the same factor $\Omega(x)$] it transforms as

$$T'^{\mu_1\cdots\mu_n}{}_{\nu_1\cdots\nu_m}(x') = \left|\frac{\partial x'}{\partial x}\right|^{-(\Delta+n-m)/d} \frac{\partial x'^{\mu_1}}{\partial x^{\alpha_1}}\cdots\frac{\partial x'^{\mu_n}}{\partial x^{\alpha_n}}\,\frac{\partial x^{\beta_1}}{\partial x'^{\nu_1}}\cdots\frac{\partial x^{\beta_m}}{\partial x'^{\nu_m}}\, T^{\alpha_1\cdots\alpha_n}{}_{\beta_1\cdots\beta_m}(x) \tag{11.23}$$

[the usual tensor rule for a change of coordinates, times an extra power of the Jacobian determinant]. Here $|\partial x'/\partial x|$ is the absolute value of the Jacobian determinant [the factor by which the map multiplies small volumes]. *To test it:* check that the correlators of T at the new points equal the correlators of the right-hand side, for translations, rotations, the dilation and the inversion.

The power of the determinant looks odd until we evaluate it. The determinant of (11.22) is

$$\left|\frac{\partial x'}{\partial x}\right| \overset{(1)}{=} |\det(\Omega R)| \overset{(2)}{=} \Omega^d\ |\det R| \overset{(3)}{=} \Omega^d.$$

(1) The Jacobian is ΩR by (11.22).

(2) A $d \times d$ matrix multiplied by the number Ω has its determinant multiplied by Ω^d.
(3) $R^T R = \mathbb{1}$ gives $(\det R)^2 = 1$.

So the prefactor in (11.23) is $\Omega^{-(\Delta+n-m)}$. Each upper index brings one factor of the Jacobian, ΩR, and each lower index one factor of the inverse Jacobian, $\Omega^{-1} R^T$ (indices are raised and lowered with δ, and $R^{-1} = R^T$). In total

$$T'(x') \overset{(1)}{=} \Omega^{-(\Delta+n-m)}\, \Omega^n\, \Omega^{-m}\, (R \cdots R)(R^T \cdots R^T)\, T(x)$$
$$\overset{(2)}{=} \Omega(x)^{-\Delta}\, (R \cdots R)(R^T \cdots R^T)\, T(x), \tag{11.24}$$

(1) The determinant gives $\Omega^{-(\Delta+n-m)}$, the n Jacobians give Ω^n and the m inverse Jacobians give Ω^{-m}.
(2) $-(\Delta + n - m) + n - m = -\Delta$.

with one rotation matrix acting on each index. This is the meaning of the definition: *every primary, whatever its indices, is multiplied by* $\Omega^{-\Delta}$ *and rotated.* The index-dependent part of the exponent, $n - m$, is there only to cancel the powers of Ω hidden in the Jacobians.

The scalar case and the sign of the exponent. For a scalar, $n = m = 0$, and (11.24) reads

$$\phi'(x') = \left|\frac{\partial x'}{\partial x}\right|^{-\Delta/d} \phi(x) = \Omega(x)^{-\Delta}\, \phi(x). \tag{11.25}$$

Our convention is therefore: Ω is the factor by which the map *stretches* lengths at x ($\Omega > 1$ where it expands), and a primary of positive dimension is *weakened* by $\Omega^{-\Delta}$ where the map stretches. Let us check that this sign gives the right two-point function. Conformal invariance means that the new field ϕ' has the same correlators as ϕ, so $\langle \phi(x_1')\phi(x_2')\rangle = \langle \phi'(x_1')\phi'(x_2')\rangle = \Omega(x_1)^{-\Delta}\Omega(x_2)^{-\Delta}\langle \phi(x_1)\phi(x_2)\rangle$. Try $\langle \phi(x_1)\phi(x_2)\rangle = C/|x_1 - x_2|^{2\Delta}$.

- *Dilation* $x' = \lambda x$, $\Omega = \lambda$. The left side is $C/(\lambda\,|x_1 - x_2|)^{2\Delta}$, and the right side is $\lambda^{-\Delta}\lambda^{-\Delta} C/|x_1 - x_2|^{2\Delta}$. They agree. This is also (11.2).

- *Inversion* $x' = x/x^2$, $\Omega = 1/x^2$ (Example 11.7). First

$$\left|x_1' - x_2'\right|^2 \overset{(1)}{=} \frac{1}{x_1^2} - \frac{2\,x_1 \cdot x_2}{x_1^2 x_2^2} + \frac{1}{x_2^2} \overset{(2)}{=} \frac{|x_1 - x_2|^2}{x_1^2\, x_2^2}.$$

  (1) Expand $\left|x_1/x_1^2 - x_2/x_2^2\right|^2$ and use $x_i \cdot x_i = x_i^2$.
  (2) Put everything over the common denominator $x_1^2 x_2^2$: the numerator is $x_2^2 - 2x_1 \cdot x_2 + x_1^2 = |x_1 - x_2|^2$.

  So the left side is $C\,(x_1^2 x_2^2)^{\Delta}/|x_1 - x_2|^{2\Delta}$, and the right side is $(x_1^2)^{\Delta}(x_2^2)^{\Delta}\, C/|x_1 - x_2|^{2\Delta}$. They agree.

With the opposite sign, $\Omega^{+\Delta}$, both checks would fail. In $d = 2$ a holomorphic map $z' = f(z)$ has $\Omega = |f'(z)|$, so (11.25) is $\phi'(z') = |f'|^{-\Delta}\,\phi(z)$. This is (11.60) with $h = \bar{h} = \Delta/2$, since $(f')^{-h}(\bar{f}')^{-\bar{h}} = |f'|^{-2h}$. For $h \neq \bar{h}$ the leftover phase $(f'/|f'|)^{-(h-\bar{h})}$ is the rotation R acting on a field of spin $h - \bar{h}$.

The same law seen as a Weyl rescaling. By (11.21), a conformal transformation is a Weyl rescaling followed by the relabelling f. The relabelling is the ordinary tensor rule, which supplies the Jacobian factors in (11.23). Everything else must come from the Weyl step. So under a pure Weyl rescaling, with no point moving, a primary of rank (n, m) transforms as

$$T \longmapsto \Omega^{-w}\, T, \qquad w = \Delta + n - m \quad \text{(the \textbf{Weyl weight})}. \tag{11.26}$$

For a scalar the Weyl weight is the dimension. For a vector potential A_μ in four dimensions, $\Delta = 1$ and $(n, m) = (0, 1)$, so $w = 0$: A_μ does not change at all under a Weyl rescaling, which we will use in Example 11.12.

11.2.3 The scaling dimension from a constant Weyl rescaling

We now find Δ for the free scalar without moving a single point. Couple the massless scalar to a metric in the simplest covariant way,

$$S_{\text{kin}}[g, \varphi] = \frac{1}{2} \int \mathrm{d}^d x\, \sqrt{g}\, g^{\mu\nu}\, \partial_\mu \varphi\, \partial_\nu \varphi, \tag{11.27}$$

which is the action of Section 11.1.1 when $g = \delta$. Rescale the metric by a constant, $g \mapsto \lambda^2 g$, and the field by $\varphi \mapsto \lambda^{-\Delta}\varphi$. The coordinates x, and so $\mathrm{d}^d x$, do not change. The three metric-dependent pieces change as follows:

$$\sqrt{\det(\lambda^2 g)} \overset{(1)}{=} \lambda^d \sqrt{g}, \qquad (\lambda^2 g)^{\mu\nu} \overset{(2)}{=} \lambda^{-2} g^{\mu\nu}, \qquad \partial_\mu(\lambda^{-\Delta}\varphi) \overset{(3)}{=} \lambda^{-\Delta}\partial_\mu \varphi.$$

(1) Multiplying a $d \times d$ matrix by λ^2 multiplies its determinant by λ^{2d}.
(2) The inverse of $\lambda^2 g$ is $\lambda^{-2} g^{-1}$.
(3) λ is constant, so it passes through the derivative.

Therefore

$$S_{\text{kin}}[\lambda^2 g, \lambda^{-\Delta}\varphi] \overset{(1)}{=} \frac{1}{2} \int \mathrm{d}^d x\, \lambda^d \sqrt{g}\, \lambda^{-2} g^{\mu\nu}\, \lambda^{-2\Delta} \partial_\mu \varphi\, \partial_\nu \varphi \overset{(2)}{=} \lambda^{d-2-2\Delta}\, S_{\text{kin}}[g, \varphi]. \tag{11.28}$$

(1) Substitute the three rules above. $\mathrm{d}^d x$ is unchanged because no point moves.
(2) Collect the powers of λ: $d - 2 - 2\Delta$.

Invariance for every λ requires $d - 2 - 2\Delta = 0$:

$$\boxed{\Delta = \frac{d-2}{2}} \tag{11.29}$$

This is the canonical dimension of Section 11.1.1: 1 in $d = 4$, $\frac{1}{2}$ in $d = 3$, 0 in $d = 2$.

The same number comes out of the dilation $x \mapsto \lambda x$ with $\varphi'(x') = \lambda^{-\Delta}\varphi(x)$, in flat space. There the metric stays δ and instead $\mathrm{d}^d x' = \lambda^d \mathrm{d}^d x$ and $\partial'_\mu = \lambda^{-1}\partial_\mu$, and the action again scales as $\lambda^{d-2-2\Delta}$. The two calculations agree for a reason: pulling the flat metric back by the dilation $f(x) = \lambda x$ gives $f^*\delta = \lambda^2 \delta$, so a *constant* Weyl rescaling of flat space is always conformal, undone by a dilation. A constant λ cannot detect the difference between Weyl and conformal. The difference appears only when Ω varies from point to point.

Worked example 11.9: The field equation alone also fixes Δ

A symmetry must map solutions of the field equation $\partial^2\Phi = 0$ (flat space) to solutions. The infinitesimal dilation and special conformal transformation of a primary scalar are $\delta_D\Phi = (x\cdot\partial + \Delta)\Phi$ and $\delta_{K_\mu}\Phi = (K_\mu + 2\Delta x_\mu)\Phi$ with $K_\mu = 2x_\mu\, x\cdot\partial - x^2\partial_\mu$. (These are $\delta\Phi(x) := \Phi(x) - \Phi'(x)$, computed from (11.25) for $x' = x + \epsilon$ with $\Omega = 1 + \sigma$, where $\sigma = \lambda$ for the dilation and $\sigma = 2b\cdot x$ for the SCT, see Example 11.6.) We need three commutators, each checked by acting on a test function u:

$$
\begin{aligned}
[\partial^2, x_\mu]u &\overset{(1)}{=} 2\partial_\mu u,\\
[\partial^2, x\cdot\partial]u &\overset{(2)}{=} 2\partial^2 u,\\
[\partial^2, K_\mu]u &\overset{(3)}{=} 4x_\mu\partial^2 u + 2(2-d)\,\partial_\mu u.
\end{aligned}
$$

(1) $\partial^2(x_\mu u) = x_\mu\partial^2 u + 2\partial_\mu u$, since $\partial_\nu x_\mu = \delta_{\mu\nu}$ and $\partial^2 x_\mu = 0$.
(2) $\partial^2(x^\nu\partial_\nu u) = x^\nu\partial_\nu\partial^2 u + 2\partial^\nu\partial_\nu u$, by the same rule applied to each x^ν.
(3) Write $K_\mu = 2x_\mu x^\nu\partial_\nu - x^2\partial_\mu$. Using (1) twice, $[\partial^2, 2x_\mu x^\nu\partial_\nu]u = 4\partial_\mu u + 4x^\nu\partial_\nu\partial_\mu u + 4x_\mu\partial^2 u$. Also $[\partial^2, x^2]v = 2d\,v + 4x\cdot\partial v$, so $[\partial^2, x^2\partial_\mu]u = 2d\,\partial_\mu u + 4x^\nu\partial_\nu\partial_\mu u$. Subtract: the $x\cdot\partial\,\partial_\mu u$ terms cancel.

Now apply ∂^2 to the transformed field of a solution ($\partial^2\Phi = 0$):

$$
\begin{aligned}
\partial^2(\delta_D\Phi) &\overset{(1)}{=} (x\cdot\partial + 2 + \Delta)\,\partial^2\Phi = 0,\\
\partial^2(\delta_{K_\mu}\Phi) &\overset{(2)}{=} (K_\mu + 4x_\mu + 2\Delta x_\mu)\,\partial^2\Phi + \big[2(2-d) + 4\Delta\big]\partial_\mu\Phi \overset{(3)}{=} \big[2(2-d) + 4\Delta\big]\partial_\mu\Phi.
\end{aligned}
$$

(1) Move ∂^2 to the right with commutator (2).
(2) Move ∂^2 to the right with commutators (3) and (1).
(3) $\partial^2\Phi = 0$.

The dilation maps solutions to solutions for every Δ. The special conformal transformation does so only if $2(2-d) + 4\Delta = 0$, that is $\Delta = (d-2)/2$. So the field equation knows the dimension through the SCT, just as the action knows it through the (constant) rescaling.

11.2.4 Local Weyl invariance fixes the curvature coupling

With $\Delta = (d-2)/2$ the action (11.27) is invariant under *constant* rescalings. Is it invariant when $\sigma(x) = \ln\Omega(x)$ varies? The derivative of $e^{-\Delta\sigma}\varphi$ now hits σ too, and the answer is no. The cure is to add the only other term with two derivatives and two powers of φ that a metric allows,

$$
S[g,\varphi] = \frac{1}{2}\int \mathrm{d}^d x\,\sqrt{g}\,\Big(g^{\mu\nu}\partial_\mu\varphi\,\partial_\nu\varphi + \xi\,R\,\varphi^2\Big), \tag{11.30}
$$

where R is the scalar curvature (two derivatives of the metric) and ξ is a number to be found. In flat space $R = 0$ and the new term is invisible. To use it we first need to know how R responds to a Weyl rescaling.

Step 1: the Laplacian of a Weyl-rescaled metric. For $\bar g = e^{2\sigma}g$ and any function u,

$$
\begin{aligned}
\bar\Box u &\overset{(1)}{=} \frac{1}{\sqrt{\bar g}}\partial_\mu\big(\sqrt{\bar g}\,\bar g^{\mu\nu}\partial_\nu u\big) \overset{(2)}{=} \frac{e^{-d\sigma}}{\sqrt{g}}\,\partial_\mu\big(e^{(d-2)\sigma}\sqrt{g}\,g^{\mu\nu}\partial_\nu u\big)\\
&\overset{(3)}{=} e^{-2\sigma}\Big[\Box u + (d-2)\,g^{\mu\nu}\partial_\mu\sigma\,\partial_\nu u\Big].
\end{aligned} \tag{11.31}
$$

(1) The Laplacian on functions, written with $\sqrt{g}$ (conventions above).
(2) $\sqrt{\bar{g}} = e^{d\sigma}\sqrt{g}$ (the determinant of $e^{2\sigma}g$ is $e^{2d\sigma}\det g$) and $\bar{g}^{\mu\nu} = e^{-2\sigma}g^{\mu\nu}$.
(3) Product rule on $e^{(d-2)\sigma}$, whose derivative is $(d-2)e^{(d-2)\sigma}\partial_\mu\sigma$.

Step 2: the curvature under an infinitesimal rescaling. Let $\delta g_{\mu\nu} = 2\sigma g_{\mu\nu}$ with σ small, so $\delta g^{\mu\nu} = -2\sigma g^{\mu\nu}$. The change of the Christoffel symbols is a tensor (a difference of two connections), and we can compute it at a point in coordinates where $\Gamma = 0$, where $\nabla = \partial$:

$$\delta\Gamma^\lambda_{\mu\nu} \overset{(1)}{=} \tfrac{1}{2}g^{\lambda\kappa}\big(\nabla_\mu\delta g_{\nu\kappa} + \nabla_\nu\delta g_{\mu\kappa} - \nabla_\kappa\delta g_{\mu\nu}\big) \overset{(2)}{=} \delta^\lambda_\nu\partial_\mu\sigma + \delta^\lambda_\mu\partial_\nu\sigma - g_{\mu\nu}\nabla^\lambda\sigma.$$

(1) Vary $\Gamma^\lambda_{\mu\nu} = \frac{1}{2}g^{\lambda\kappa}(\partial_\mu g_{\nu\kappa} + \partial_\nu g_{\mu\kappa} - \partial_\kappa g_{\mu\nu})$ at a point where $\Gamma = 0$. The term with $\delta g^{\lambda\kappa}$ multiplies Γ and drops out, and there $\partial = \nabla$.
(2) $\nabla_\mu\delta g_{\nu\kappa} = 2(\partial_\mu\sigma)g_{\nu\kappa}$ because $\nabla g = 0$. Then contract with $\frac{1}{2}g^{\lambda\kappa}$.

Two contractions of this are needed:

$$g^{\mu\nu}\delta\Gamma^\lambda_{\mu\nu} \overset{(1)}{=} \nabla^\lambda\sigma + \nabla^\lambda\sigma - d\,\nabla^\lambda\sigma = (2-d)\nabla^\lambda\sigma, \qquad \delta\Gamma^\lambda_{\lambda\nu} \overset{(2)}{=} \partial_\nu\sigma + d\,\partial_\nu\sigma - \partial_\nu\sigma = d\,\partial_\nu\sigma.$$

(1) $g^{\mu\nu}g_{\mu\nu} = d$.
(2) $\delta^\lambda_\lambda = d$.

In coordinates with $\Gamma = 0$ at the point, (11.17) gives $R_{\mu\nu} = \partial_\lambda\Gamma^\lambda_{\mu\nu} - \partial_\nu\Gamma^\lambda_{\lambda\mu} + (\Gamma\Gamma)$, and the $\Gamma\Gamma$ terms have zero variation there. So $\delta R_{\mu\nu} = \nabla_\lambda\delta\Gamma^\lambda_{\mu\nu} - \nabla_\nu\delta\Gamma^\lambda_{\lambda\mu}$ (the **Palatini identity**). It is an equation between tensors, so it holds in every coordinate system. Now

$$\begin{aligned}\delta R &\overset{(1)}{=} \delta g^{\mu\nu}\,R_{\mu\nu} + g^{\mu\nu}\,\delta R_{\mu\nu} \overset{(2)}{=} -2\sigma R + \nabla_\lambda\big(g^{\mu\nu}\delta\Gamma^\lambda_{\mu\nu}\big) - \nabla^\mu\big(\delta\Gamma^\lambda_{\lambda\mu}\big)\\ &\overset{(3)}{=} -2\sigma R + (2-d)\Box\sigma - d\,\Box\sigma = -2\sigma R - 2(d-1)\,\Box\sigma. \end{aligned} \tag{11.32}$$

(1) $R = g^{\mu\nu}R_{\mu\nu}$ and the product rule.
(2) $\delta g^{\mu\nu} = -2\sigma g^{\mu\nu}$, and the Palatini identity, with $g^{\mu\nu}$ moved through ∇ (allowed since $\nabla g = 0$).
(3) The two contractions above.

Step 3: the finite rescaling. Build the finite rescaling $\bar{g} = e^{2\sigma}g$ out of many small ones along the path $g_t = e^{2t\sigma}g$, $0 \le t \le 1$. Going from t to $t + \mathrm{d}t$ is the small rescaling $g_{t+\mathrm{d}t} = e^{2\sigma\,\mathrm{d}t}g_t$ of the metric g_t. So (11.32), applied at the metric g_t with small parameter $\sigma\,\mathrm{d}t$, gives the rate of change of $R_t := R[g_t]$. Write $R_t = e^{-2t\sigma}u_t$. Then

$$\begin{aligned}&\frac{\mathrm{d}R_t}{\mathrm{d}t} \overset{(1)}{=} -2\sigma R_t - 2(d-1)\,\Box_t\sigma \overset{(2)}{=} -2\sigma R_t - 2(d-1)\,e^{-2t\sigma}\big[\Box\sigma + (d-2)\,t\,(\nabla\sigma)^2\big],\\ &\frac{\mathrm{d}R_t}{\mathrm{d}t} \overset{(3)}{=} -2\sigma R_t + e^{-2t\sigma}\frac{\mathrm{d}u_t}{\mathrm{d}t} \quad\Longrightarrow\quad \frac{\mathrm{d}u_t}{\mathrm{d}t} \overset{(4)}{=} -2(d-1)\big[\Box\sigma + (d-2)\,t\,(\nabla\sigma)^2\big].\end{aligned}$$

(1) (11.32) at the metric g_t, with $\Box_t$ its Laplacian.
(2) (11.31) with $\sigma \to t\sigma$ and $u = \sigma$. Here $\Box$ and $(\nabla\sigma)^2$ belong to the original g.
(3) Product rule on $R_t = e^{-2t\sigma}u_t$ (σ does not depend on t).
(4) Compare the two lines: the terms $-2\sigma R_t$ cancel, then divide by $e^{-2t\sigma}$.

The right side of the last equation is a polynomial in t, so we integrate from $u_0 = R$ to $t = 1$ and get $u_1 = R - 2(d-1)\Box\sigma - (d-1)(d-2)(\nabla\sigma)^2$. Hence

$$\boxed{\bar{R} = e^{-2\sigma}\Big[R - 2(d-1)\,\Box\sigma - (d-1)(d-2)\,(\nabla\sigma)^2\Big] \quad \text{for } \bar{g} = e^{2\sigma}g} \tag{11.33}$$

This is the standard formula (for example Wald, *General Relativity*, Appendix D). It is exact, not just first order in σ.

Worked example 11.10: Check in $d = 2$: a flat plane becomes a round sphere

In $d = 2$ the formula (11.33) loses its last term:

$$\bar{R} = e^{-2\sigma}\big(R - 2\,\Box\sigma\big) \qquad (d = 2). \tag{11.34}$$

Take flat $g = \delta$ ($R = 0$) and $e^{\sigma} = 2/(1 + r^2)$, with $r^2 = x_1^2 + x_2^2$. The metric $\bar{g} = 4(\mathrm{d}x_1^2 + \mathrm{d}x_2^2)/(1 + r^2)^2$ is the unit sphere written in stereographic coordinates, so we expect $\bar{R} = 2$. With $\sigma = \ln 2 - \ln(1 + r^2)$ and the flat Laplacian in polar coordinates, $\Box u = \frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}(r\frac{\mathrm{d}u}{\mathrm{d}r})$ for $u(r)$:

$$\Box \ln(1 + r^2) \overset{(1)}{=} \frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\Big(\frac{2r^2}{1 + r^2}\Big) \overset{(2)}{=} \frac{1}{r}\cdot\frac{4r(1 + r^2) - 2r^2\cdot 2r}{(1 + r^2)^2} = \frac{4}{(1 + r^2)^2},$$
$$\bar{R} \overset{(3)}{=} -2e^{-2\sigma}\Box\sigma \overset{(4)}{=} 2\cdot\frac{(1 + r^2)^2}{4}\cdot\frac{4}{(1 + r^2)^2} = 2.$$

(1) $\frac{\mathrm{d}}{\mathrm{d}r}\ln(1 + r^2) = \frac{2r}{1+r^2}$, then multiply by r.
(2) Quotient rule. The numerator simplifies to $4r$.
(3) (11.34) with $R = 0$.
(4) $\Box\sigma = -\Box\ln(1 + r^2) = -4/(1 + r^2)^2$ and $e^{-2\sigma} = (1 + r^2)^2/4$.

The unit sphere has $\bar{R} = 2 = d(d - 1)/a^2$ with $d = 2$, $a = 1$, which confirms both the formula and the sign convention. The integral also checks Gauss–Bonnet (Chapter T2): $\int\sqrt{\bar{g}}\,\bar{R} = 2\cdot 4\pi = 4\pi\chi(S^2)$. And (11.34) gives the test promised in Definition 11.5: in $d = 2$, $e^{2\sigma}\delta$ is flat exactly when $\Box\sigma = 0$. For a holomorphic map f, $\sigma = \ln|f'| = \mathrm{Re}\ln f'$ is the real part of a holomorphic function, hence harmonic, as it must be.

Route 1: fix Δ first, then find ξ. Take $\Delta = (d - 2)/2$ from (11.29), and apply the finite rescaling $\bar{g} = e^{2\sigma}g$, $\bar{\varphi} = e^{-\Delta\sigma}\varphi$ to (11.30). The derivative of the rescaled field is

$$\partial_\mu\bar{\varphi} \overset{(1)}{=} e^{-\Delta\sigma}\partial_\mu\varphi - \Delta\, e^{-\Delta\sigma}\varphi\,\partial_\mu\sigma = e^{-\Delta\sigma}\big(\partial_\mu\varphi - \Delta\,\varphi\,\partial_\mu\sigma\big).$$

(1) Product rule. The factor $e^{-\Delta\sigma}$ now depends on x.

The kinetic density becomes

$$\sqrt{\bar{g}}\,\bar{g}^{\mu\nu}\partial_\mu\bar{\varphi}\,\partial_\nu\bar{\varphi} \overset{(1)}{=} e^{d\sigma}\sqrt{g}\;e^{-2\sigma}g^{\mu\nu}\;e^{-2\Delta\sigma}(\partial_\mu\varphi - \Delta\varphi\partial_\mu\sigma)(\partial_\nu\varphi - \Delta\varphi\partial_\nu\sigma)$$
$$\overset{(2)}{=} \sqrt{g}\,\Big[(\nabla\varphi)^2 - 2\Delta\,\varphi\,g^{\mu\nu}\partial_\mu\varphi\,\partial_\nu\sigma + \Delta^2\varphi^2(\nabla\sigma)^2\Big]. \tag{11.35}$$

(1) $\sqrt{\bar{g}} = e^{d\sigma}\sqrt{g}$, $\bar{g}^{\mu\nu} = e^{-2\sigma}g^{\mu\nu}$, and the derivative just computed.
(2) The exponents add to $(d - 2 - 2\Delta)\sigma = 0$. Then multiply out the bracket, using the symmetry of $g^{\mu\nu}$ for the two cross terms.

The middle term is a total derivative in disguise. Since $2\varphi\,\partial_\mu\varphi = \partial_\mu(\varphi^2)$,

$$\int \mathrm{d}^d x\,\sqrt{g}\,\big(-2\Delta\varphi\,g^{\mu\nu}\partial_\mu\varphi\,\partial_\nu\sigma\big) \overset{(1)}{=} -\Delta\int \mathrm{d}^d x\,\sqrt{g}\,g^{\mu\nu}\partial_\mu(\varphi^2)\,\partial_\nu\sigma \overset{(2)}{=} +\Delta\int \mathrm{d}^d x\,\sqrt{g}\,\varphi^2\,\Box\sigma. \tag{11.36}$$

(1) $2\varphi\partial_\mu\varphi = \partial_\mu(\varphi^2)$.

(2) Integrate by parts: $\partial_\mu(\varphi^2)\sqrt{g}g^{\mu\nu}\partial_\nu\sigma = \partial_\mu\big(\varphi^2\sqrt{g}g^{\mu\nu}\partial_\nu\sigma\big) - \varphi^2\,\partial_\mu(\sqrt{g}g^{\mu\nu}\partial_\nu\sigma)$. The first term integrates to zero (M closed, or fields decaying at infinity), and the second is $-\varphi^2\sqrt{g}\,\Box\sigma$.

So the kinetic term changes by

$$S_{\text{kin}}[\bar g,\bar\varphi] - S_{\text{kin}}[g,\varphi] = \frac{1}{2}\int \mathrm{d}^d x\,\sqrt{g}\,\Big[\Delta\,\varphi^2\,\Box\sigma + \Delta^2\varphi^2(\nabla\sigma)^2\Big]. \tag{11.37}$$

Now the curvature term, $S_\xi = \frac{\xi}{2}\int\sqrt{g}\,R\varphi^2$:

$$\begin{aligned} S_\xi[\bar g,\bar\varphi] &\overset{(1)}{=} \frac{\xi}{2}\int \mathrm{d}^d x\,e^{d\sigma}\sqrt{g}\;e^{-2\sigma}\big[R - 2(d-1)\Box\sigma - (d-1)(d-2)(\nabla\sigma)^2\big]\;e^{-2\Delta\sigma}\varphi^2 \\ &\overset{(2)}{=} S_\xi[g,\varphi] + \frac{1}{2}\int \mathrm{d}^d x\,\sqrt{g}\,\Big[-2\xi(d-1)\,\varphi^2\,\Box\sigma - \xi(d-1)(d-2)\,\varphi^2(\nabla\sigma)^2\Big]. \end{aligned} \tag{11.38}$$

(1) $\sqrt{\bar g} = e^{d\sigma}\sqrt{g}$, the formula (11.33) for $\bar R$, and $\bar\varphi^2 = e^{-2\Delta\sigma}\varphi^2$.
(2) The exponents again add to $(d - 2 - 2\Delta)\sigma = 0$. The R term reproduces $S_\xi[g,\varphi]$.

Adding (11.37) and (11.38), the total change of (11.30) is

$$S[\bar g,\bar\varphi] - S[g,\varphi] = \frac{1}{2}\int \mathrm{d}^d x\,\sqrt{g}\,\varphi^2\Big\{\big[\Delta - 2\xi(d-1)\big]\Box\sigma + \big[\Delta^2 - \xi(d-1)(d-2)\big](\nabla\sigma)^2\Big\}. \tag{11.39}$$

The two brackets must vanish separately. (Replace σ by $\epsilon\sigma$: the $\Box\sigma$ term is proportional to ϵ and the $(\nabla\sigma)^2$ term to ϵ^2, and the sum must vanish for every ϵ.) The $\Box\sigma$ bracket fixes ξ:

$$\boxed{\xi = \frac{\Delta}{2(d-1)} = \frac{d-2}{4(d-1)}} \tag{11.40}$$

Nothing is left to choose. Yet the $(\nabla\sigma)^2$ bracket must still vanish, and it does:

$$\Delta^2 - \xi(d-1)(d-2) \overset{(1)}{=} \Delta^2 - \frac{\Delta}{2(d-1)}(d-1)(d-2) \overset{(2)}{=} \Delta\Big(\Delta - \frac{d-2}{2}\Big) \overset{(3)}{=} 0. \tag{11.41}$$

(1) Insert $\xi = \Delta/(2(d-1))$ from (11.40).
(2) Cancel $(d-1)$ and take out the common factor Δ.
(3) $\Delta = (d-2)/2$ by (11.29).

So the action (11.30) with $\xi = (d-2)/(4(d-1))$ is exactly invariant under every finite local Weyl rescaling.

Why did the second condition come for free? Because Weyl rescalings compose: doing $e^{2\sigma_1}$ and then $e^{2\sigma_2}$ is doing $e^{2(\sigma_1+\sigma_2)}$. The $\Box\sigma$ bracket is all that survives to first order in σ, and first-order invariance at *every* metric already implies finite invariance. Indeed $F(t) := S[e^{2t\sigma}g, e^{-t\Delta\sigma}\varphi]$ has $\mathrm{d}F/\mathrm{d}t$ equal to a first-order variation of S about the configuration $(e^{2t\sigma}g, e^{-t\Delta\sigma}\varphi)$, which is zero. So $F(1) = F(0)$, and the $(\nabla\sigma)^2$ terms had to cancel.

Route 2: fix Δ and ξ at the same time. We can also leave Δ unknown and demand invariance under an infinitesimal rescaling $\delta g_{\mu\nu} = 2\sigma g_{\mu\nu}$, $\delta\varphi = -\Delta\sigma\varphi$ with an arbitrary small $\sigma(x)$. Then $\delta\sqrt{g} = d\,\sigma\sqrt{g}$ and $\delta g^{\mu\nu} = -2\sigma g^{\mu\nu}$. For the kinetic term,

$$\begin{aligned} \delta S_{\text{kin}} &\overset{(1)}{=} \frac{1}{2}\int \mathrm{d}^d x\,\sqrt{g}\,\Big[(d-2)\,\sigma\,(\nabla\varphi)^2 - 2\Delta\,g^{\mu\nu}\partial_\mu\varphi\,\partial_\nu(\sigma\varphi)\Big] \\ &\overset{(2)}{=} \int \mathrm{d}^d x\,\sqrt{g}\,\sigma\Big[\frac{d-2}{2}(\nabla\varphi)^2 + \Delta\,\varphi\,\Box\varphi\Big]. \end{aligned} \tag{11.42}$$

(1) The variations of $\sqrt{g}$ and $g^{\mu\nu}$ give $(d-2)\sigma$. The variation of $\partial_\mu\varphi\,\partial_\nu\varphi$ gives twice $\partial_\mu\varphi\,\partial_\nu(\delta\varphi)$, with $\delta\varphi = -\Delta\sigma\varphi$.
(2) Integrate by parts in the second term, moving ∂_ν off $\sigma\varphi$: $-\int\sqrt{g}\,g^{\mu\nu}\partial_\mu\varphi\,\partial_\nu(\sigma\varphi) = +\int\sqrt{g}\,\sigma\varphi\,\Box\varphi$.

For the curvature term we use (11.32):

$$\begin{aligned}\delta S_\xi &\overset{(1)}{=} \frac{\xi}{2}\int \mathrm{d}^d x\,\sqrt{g}\,\Big[(d-2\Delta)\,\sigma R\varphi^2 + \varphi^2\big(-2\sigma R - 2(d-1)\Box\sigma\big)\Big]\\ &\overset{(2)}{=} \frac{\xi}{2}\int \mathrm{d}^d x\,\sqrt{g}\,\sigma\Big[(d-2-2\Delta)R\varphi^2 - 2(d-1)\,\Box(\varphi^2)\Big]\\ &\overset{(3)}{=} \frac{\xi}{2}\int \mathrm{d}^d x\,\sqrt{g}\,\sigma\Big[(d-2-2\Delta)R\varphi^2 - 4(d-1)(\nabla\varphi)^2 - 4(d-1)\,\varphi\,\Box\varphi\Big].\end{aligned} \tag{11.43}$$

(1) $\delta\sqrt{g} = d\sigma\sqrt{g}$, $\delta(\varphi^2) = -2\Delta\sigma\varphi^2$, and δR from (11.32).
(2) Collect the $\sigma R\varphi^2$ terms. Integrate the $\Box\sigma$ term by parts twice, $\int\sqrt{g}\,\varphi^2\Box\sigma = \int\sqrt{g}\,\sigma\,\Box(\varphi^2)$.
(3) $\Box(\varphi^2) = 2(\nabla\varphi)^2 + 2\varphi\Box\varphi$.

Adding the two,

$$\delta S = \int \mathrm{d}^d x\,\sqrt{g}\,\sigma\Big[\underbrace{\Big(\tfrac{d-2}{2} - 2\xi(d-1)\Big)}_{A}(\nabla\varphi)^2 + \underbrace{\big(\Delta - 2\xi(d-1)\big)}_{B}\,\varphi\,\Box\varphi + \underbrace{\tfrac{\xi}{2}\big(d-2-2\Delta\big)}_{C}\,R\varphi^2\Big]. \tag{11.44}$$

Since $\sigma(x)$ is arbitrary, the bracket must vanish at every point, for every φ and every metric. The three structures can be varied independently at a point, so $A = B = C = 0$. Then $A = 0$ gives $\xi = (d-2)/(4(d-1))$, $B = 0$ gives $\Delta = 2\xi(d-1) = (d-2)/2$, and $C = 0$ is then automatic. Both numbers come out of one requirement.

The two routes are the same calculation sorted in two ways. Route 1 keeps σ undifferentiated only in the overall factor $e^{(d-2-2\Delta)\sigma}$ and sorts the rest by derivatives of σ. Route 2 moves every derivative off σ and sorts by what multiplies σ. To first order in σ, with Δ left free, Route 1 gives

$$\begin{aligned}\delta S &\overset{(1)}{=} \frac{1}{2}\int\sqrt{g}\,\Big\{(d-2-2\Delta)\,\sigma\big[(\nabla\varphi)^2 + \xi R\varphi^2\big] + \big[\Delta - 2\xi(d-1)\big]\varphi^2\,\Box\sigma\Big\}\\ &\overset{(2)}{=} \int\sqrt{g}\,\sigma\Big\{\tfrac{d-2-2\Delta}{2}(\nabla\varphi)^2 + C\,R\varphi^2 + B\big[(\nabla\varphi)^2 + \varphi\,\Box\varphi\big]\Big\}\\ &\overset{(3)}{=} \int\sqrt{g}\,\sigma\big[A(\nabla\varphi)^2 + B\,\varphi\Box\varphi + C\,R\varphi^2\big].\end{aligned}$$

(1) Expand $e^{(d-2-2\Delta)\sigma} \approx 1 + (d-2-2\Delta)\sigma$ in the first lines of (11.35) and (11.38) (before the exponent was set to zero), use (11.36), and drop the $(\nabla\sigma)^2$ terms, which are second order.
(2) Move $\Box$ from σ to φ^2 and use $\frac{1}{2}\Box(\varphi^2) = (\nabla\varphi)^2 + \varphi\Box\varphi$.
(3) $\frac{d-2-2\Delta}{2} + \Delta - 2\xi(d-1) = \frac{d-2}{2} - 2\xi(d-1) = A$.

This is exactly (11.44).

The conformally coupled scalar. In $d = 4$ the result is

$$\Delta = 1, \qquad \xi = \frac{4-2}{4\cdot 3} = \frac{1}{6}. \tag{11.45}$$

A scalar with the action (11.30) and $\xi = (d-2)/(4(d-1))$ is called a **conformally coupled scalar**: it is coupled to the curvature in exactly the way that makes it invariant under local

Weyl rescalings with $\varphi \mapsto \Omega^{-(d-2)/2}\varphi$. (With $\xi = 0$ it is called **minimally coupled**.) Its field equation is $E \coloneqq \frac{1}{\sqrt{g}}\frac{\delta S}{\delta \varphi} = -\Box\varphi + \xi R\varphi = 0$ (vary (11.30) and integrate by parts once). The operator $-\Box + \frac{d-2}{4(d-1)}R$ is the **conformal Laplacian**, and Weyl invariance of the action makes it transform neatly. Vary φ by η on both sides of $S[\bar{g},\bar{\varphi}] = S[g,\varphi]$ (with $\bar{\eta} = \Omega^{-\Delta}\eta$):

$$\int \mathrm{d}^d x\,\sqrt{g}\,E\,\eta \overset{(1)}{=} \int \mathrm{d}^d x\,\sqrt{\bar{g}}\,\bar{E}\,\bar{\eta} \overset{(2)}{=} \int \mathrm{d}^d x\,\sqrt{g}\,\Omega^{d-\Delta}\,\bar{E}\,\eta \quad\Longrightarrow\quad \bar{E} \overset{(3)}{=} \Omega^{-(d+2)/2}E.$$

(1) The first-order change of each side, with $\bar{E}$ the field-equation expression built from $\bar{g}$ and $\bar{\varphi}$.
(2) $\sqrt{\bar{g}} = \Omega^d\sqrt{g}$ and $\bar{\eta} = \Omega^{-\Delta}\eta$.
(3) η is arbitrary, and $d - \Delta = (d+2)/2$.

So φ solves the field equation in the metric g exactly when $\Omega^{-(d-2)/2}\varphi$ solves it in $\Omega^2 g$. For example, a spatially flat expanding universe has a metric of the form $a(\eta)^2\times$(flat), so a massless conformally coupled field in it obeys the flat-space wave equation after the rescaling (Parker's classic observation that such a field is not produced by the expansion).

d	2	3	4	6	10	$d \to \infty$
$\Delta = \frac{d-2}{2}$	0	$\frac{1}{2}$	1	2	4	∞
$\xi = \frac{d-2}{4(d-1)}$	0	$\frac{1}{8}$	$\frac{1}{6}$	$\frac{1}{5}$	$\frac{2}{9}$	$\to \frac{1}{4}$

11.2.5 Why it matters

Weyl implies conformal, and the converse needs more. Chain (11.21) showed that Weyl invariance in curved space implies conformal invariance in flat space. It is instructive to see how little the flat-space test actually probes, on the free scalar. Infinitesimally, a conformal map $x' = x + \epsilon(x)$ has $\Omega = 1 + \bar{\sigma}$ with $\bar{\sigma} = \frac{1}{d}\partial\cdot\epsilon$ (Section 11.1.5). By steps 1 and 2 of (11.21), the change of the flat action under the conformal map equals the change under the Weyl rescaling $\bar{\sigma}$ at $g = \delta$. So by (11.44) with $R = 0$ and $\Delta = (d-2)/2$,

$$\begin{aligned}\delta_{\mathrm{conf}}S &\overset{(1)}{=} \int \mathrm{d}^d x\,\bar{\sigma}\Big[\big(\tfrac{d-2}{2} - 2\xi(d-1)\big)(\partial\varphi)^2 + \big(\tfrac{d-2}{2} - 2\xi(d-1)\big)\varphi\,\partial^2\varphi\Big] \\ &\overset{(2)}{=} \Big(\tfrac{d-2}{4} - \xi(d-1)\Big)\int \mathrm{d}^d x\,\bar{\sigma}\,\partial^2(\varphi^2) \overset{(3)}{=} \Big(\tfrac{d-2}{4} - \xi(d-1)\Big)\int \mathrm{d}^d x\,(\partial^2\bar{\sigma})\,\varphi^2 \overset{(4)}{=} 0. \end{aligned} \tag{11.46}$$

(1) (11.44) at $g = \delta$ with $\Delta = \frac{d-2}{2}$, where the R term is absent.
(2) $(\partial\varphi)^2 + \varphi\partial^2\varphi = \frac{1}{2}\partial^2(\varphi^2)$.
(3) Integrate by parts twice.
(4) $\partial\cdot\epsilon$ is at most linear in x for $d > 2$ (this was shown in Section 11.1.5), and harmonic in $d = 2$ (Cauchy–Riemann), so $\partial^2\bar{\sigma} = 0$ in every case.

The result is zero *for every* ξ. The conformal $\bar{\sigma}$'s have $\partial^2\bar{\sigma} = 0$, so they never feel the $\Box\sigma$ term that fixed ξ. The flat-space theory is conformal with or without the curvature coupling. Weyl invariance is a strictly stronger demand: it needs the extra ingredient $\xi R\varphi^2$, which happens to exist.

For some theories no such ingredient exists. Karananas and Monin, and Farnsworth, Luty and Prilepina, discuss the higher-derivative free scalars $S = \frac{1}{2}\int \varphi\,\Box^k\varphi$ (up to sign), with $\Delta_\varphi = (d-2k)/2$. In flat space they are conformally invariant, but when d is even and $d < 2k$ there is no Weyl-invariant curved-space version. The simplest case with the full conformal group is $k = 3$ in $d = 4$, $\mathcal{L} = \frac{1}{2}(\partial_\mu\Box\varphi)^2$: the curvature terms needed for Weyl invariance come

with coefficients that diverge at $d = 4$. All these examples have $\Delta_\varphi < 0$, so they are not unitary (their two-point functions grow with distance).

Key idea: when a conformal theory can be coupled Weyl-invariantly (Farnsworth–Luty–Prilepina)

Let a quantum field theory in flat space be conformally invariant, and suppose that (i) it can be coupled to a background metric so that relabelling points is a symmetry, (ii) its conformal charges are integrals of local currents, (iii) it is unitary, and (iv) $d \le 10$. Then it can be placed on any curved background so that $T^\mu{}_\mu = 0$ as an operator, up to c-number curvature terms (the trace anomaly below). Equivalently it is Weyl invariant, with scalar primaries transforming as $\mathcal{O} \mapsto \Omega^{-\Delta}\mathcal{O}$ (proved for operators of low dimension and spin).

Their argument has three steps, and each is something we have already met.

1. *Flat space: improve.* Condition (ii) forces the trace of the stress tensor to be a double derivative, $T^\mu{}_\mu = \partial_\mu\partial_\nu L^{\mu\nu}$, of a local operator $L^{\mu\nu}$ of dimension $d-2$. Adding curvature couplings $\xi R L + \xi' R_{\mu\nu}L^{\mu\nu}$ to the curved-space action (invisible in flat space) changes $T_{\mu\nu}$ by second derivatives of L and makes $T^\mu{}_\mu = 0$ in flat space. For the free scalar, $L^{\mu\nu} \propto \delta^{\mu\nu}\varphi^2$, and this is our $\xi R\varphi^2$.

2. *Curved space: what could be left.* The leftover trace vanishes in flat space, so it must contain at least one power of curvature. Curvature has dimension 2 and $T^\mu{}_\mu$ has dimension d, so the first candidate is $T^\mu{}_\mu = RX$ with X a scalar of dimension $d-2$. Unitarity requires scalar primaries to have $\Delta \ge (d-2)/2$. The next candidates, (curvature)$^2 \times Y$, need $\Delta_Y = d-4 \ge (d-2)/2$, that is $d \ge 6$. So for $d < 6$ only RX is possible.

3. *Weyl rescalings commute.* If $T^\mu{}_\mu = RX$, the theory is invariant under $\delta g_{\mu\nu} = 2\sigma g_{\mu\nu}$ combined with a shift of the source ρ_X that couples to X, $\delta\rho_X = \sigma R$. Two such transformations must commute on g (they do) and on ρ_X. Using (11.32),

$$
\begin{aligned}
[\delta_{\sigma_1}, \delta_{\sigma_2}]\rho_X &\overset{(1)}{=} \sigma_2\,\delta_{\sigma_1}R - \sigma_1\,\delta_{\sigma_2}R \overset{(2)}{=} \sigma_2\big(-2\sigma_1 R - 2(d-1)\Box\sigma_1\big) - \sigma_1\big(-2\sigma_2 R - 2(d-1)\Box\sigma_2\big) \\
&= 2(d-1)\big(\sigma_1\Box\sigma_2 - \sigma_2\Box\sigma_1\big).
\end{aligned}
$$

   (1) $\delta_{\sigma_1}(\sigma_2 R) = \sigma_2\,\delta_{\sigma_1}R$, since σ_2 is a fixed function. Subtract the same with $1 \leftrightarrow 2$.
   (2) (11.32).

   With $\sigma_1 = 1$ this is $2(d-1)\Box\sigma_2$, an arbitrary function. So the theory would be unchanged by an arbitrary shift of ρ_X alone, which means X has vanishing correlators: $X = 0$, and $T^\mu{}_\mu = 0$ after all. Higher d needs more bookkeeping of the same kind.

Every possible obstruction needs an operator of a special dimension ($d-2$, $d-4$, and so on). The non-unitary $\Box^k$ theories escape through exactly this door.

The improved stress tensor: the flat-space shadow of Weyl invariance. Define the stress tensor by varying the metric,

$$
T_{\mu\nu} := \frac{2}{\sqrt{g}}\frac{\delta S}{\delta g^{\mu\nu}}. \tag{11.47}
$$

For S_{kin} at $g = \delta$ this gives $\partial_\mu\varphi\partial_\nu\varphi - \frac{1}{2}\delta_{\mu\nu}(\partial\varphi)^2$, the canonical tensor of Example 11.8 with $g = 1$. Under an infinitesimal Weyl rescaling, $\delta g^{\mu\nu} = -2\sigma g^{\mu\nu}$ and $\delta\varphi = -\Delta\sigma\varphi$, so

$$
\delta S \overset{(1)}{=} \int \mathrm{d}^d x\,\frac{\delta S}{\delta g^{\mu\nu}}\,\delta g^{\mu\nu} + \int \mathrm{d}^d x\,\frac{\delta S}{\delta\varphi}\,\delta\varphi \overset{(2)}{=} -\int \mathrm{d}^d x\,\sqrt{g}\,\sigma\left(T^\mu{}_\mu + \Delta\,\varphi\,E\right). \tag{11.48}
$$

(1) Chain rule for the change of $S[g,\varphi]$.
(2) $\frac{\delta S}{\delta g^{\mu\nu}} = \frac{\sqrt{g}}{2} T_{\mu\nu}$ and $g^{\mu\nu}T_{\mu\nu} = T^{\mu}{}_{\mu}$. Also $\frac{\delta S}{\delta \varphi} = \sqrt{g}\,E$.

If S is Weyl invariant, this vanishes for every σ, so $T^{\mu}{}_{\mu} = -\Delta\varphi E$, which is zero on solutions ($E = 0$), in every background and in particular in flat space. This is the statement of Section 11.1.5 that tracelessness gives conformal invariance, now traced back to its origin.

For the scalar the ξ term contributes to $T_{\mu\nu}$ even in flat space, where the term itself vanishes. To see it we need δR for a general $\delta g^{\mu\nu}$. Write $h_{\mu\nu} = \delta g_{\mu\nu}$, $h = g^{\mu\nu}h_{\mu\nu}$, and repeat the Palatini computation:

$$g^{\mu\nu}\delta R_{\mu\nu} \overset{(1)}{=} \nabla_\lambda\big(g^{\mu\nu}\delta\Gamma^{\lambda}_{\mu\nu} - g^{\lambda\nu}\delta\Gamma^{\mu}_{\mu\nu}\big) \overset{(2)}{=} \nabla_\lambda\big(\nabla_\mu h^{\mu\lambda} - \tfrac{1}{2}\nabla^\lambda h - \tfrac{1}{2}\nabla^\lambda h\big) \overset{(3)}{=} g_{\mu\nu}\Box\,\delta g^{\mu\nu} - \nabla_\mu\nabla_\nu\,\delta g^{\mu\nu}.$$

(1) The Palatini identity, contracted with $g^{\mu\nu}$.
(2) From $\delta\Gamma^{\lambda}_{\mu\nu} = \frac{1}{2}g^{\lambda\kappa}(\nabla_\mu h_{\nu\kappa} + \nabla_\nu h_{\mu\kappa} - \nabla_\kappa h_{\mu\nu})$: the first contraction is $\nabla_\mu h^{\mu\lambda} - \frac{1}{2}\nabla^\lambda h$ and $\delta\Gamma^{\mu}_{\mu\nu} = \frac{1}{2}\nabla_\nu h$.
(3) $h^{\mu\nu} = -\delta g^{\mu\nu}$ (vary $g^{\mu\lambda}g_{\lambda\nu} = \delta^{\mu}_{\nu}$) and $h = -g_{\mu\nu}\delta g^{\mu\nu}$.

So $\delta R = R_{\mu\nu}\delta g^{\mu\nu} + g_{\mu\nu}\Box\delta g^{\mu\nu} - \nabla_\mu\nabla_\nu\delta g^{\mu\nu}$. (Check: with $\delta g^{\mu\nu} = -2\sigma g^{\mu\nu}$ it gives $-2\sigma R - 2d\,\Box\sigma + 2\Box\sigma$, which is (11.32).) In flat space only the derivative terms survive, and

$$\delta S_\xi\big|_{g=\delta} \overset{(1)}{=} \frac{\xi}{2}\int \mathrm{d}^d x\,\varphi^2\big(\delta_{\mu\nu}\partial^2 - \partial_\mu\partial_\nu\big)\delta g^{\mu\nu} \overset{(2)}{=} \frac{\xi}{2}\int \mathrm{d}^d x\,\delta g^{\mu\nu}\big(\delta_{\mu\nu}\partial^2 - \partial_\mu\partial_\nu\big)\varphi^2,$$

(1) $R = R_{\mu\nu} = 0$ in flat space, so neither $\delta\sqrt{g}\,R$ nor $R_{\mu\nu}\delta g^{\mu\nu}$ contributes.
(2) Integrate by parts twice.

so by (11.47) the flat-space stress tensor is

$$\Theta_{\mu\nu} = \partial_\mu\varphi\,\partial_\nu\varphi - \tfrac{1}{2}\delta_{\mu\nu}(\partial\varphi)^2 - \xi\big(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2\big)\varphi^2. \tag{11.49}$$

The last term is the **improvement term**. With $\xi = \frac{1}{6}$ in $d = 4$ it is exactly the term quoted in Example 11.8, and for general d it is the improvement found from the virial current in Chapter T5 (section "Fixed points are conformal field theories"). Its trace vanishes on shell:

$$\begin{aligned}\Theta^{\mu}{}_{\mu} &\overset{(1)}{=} \Big(1 - \frac{d}{2}\Big)(\partial\varphi)^2 + \xi(d-1)\,\partial^2(\varphi^2)\\ &\overset{(2)}{=} \frac{2-d}{2}(\partial\varphi)^2 + 2\xi(d-1)\big[(\partial\varphi)^2 + \varphi\,\partial^2\varphi\big]\\ &\overset{(3)}{=} \frac{d-2}{2}\,\varphi\,\partial^2\varphi.\end{aligned}$$

(1) $\delta^{\mu}{}_{\mu} = d$, so the improvement contributes $-\xi(1-d)\partial^2\varphi^2$.
(2) $\partial^2(\varphi^2) = 2(\partial\varphi)^2 + 2\varphi\partial^2\varphi$.
(3) $2\xi(d-1) = \frac{d-2}{2}$ by (11.40), so the $(\partial\varphi)^2$ terms cancel.

This is $-\Delta\varphi E$ with $E = -\partial^2\varphi$, as (11.48) predicted, and it is zero on shell. The improvement term is conserved identically and does not change the charges (Chapter T5), so flat-space physics cannot see ξ except through the trace. In short: the curvature coupling that Weyl invariance demands in curved space leaves behind, in flat space, exactly the improvement that makes $T_{\mu\nu}$ traceless.

The trace anomaly. Everything so far is classical. In the quantum theory the path integral must be regularised, and every regulator introduces a length measured with the metric g. A

Weyl rescaling rescales that length, so Weyl invariance can fail by a local c-number built from curvature. In $d = 2$ the result is $\langle T^{\mu}{}_{\mu} \rangle \propto c\, R$ with c the central charge. This **trace anomaly** (or Weyl anomaly) is computed for free bosons from the heat kernel in Chapter 10 (section "The Weyl anomaly of d free bosons"). It is the "c-number curvature terms" allowed in the Farnsworth–Luty–Prilepina statement above.

11.2.6 Examples

Worked example 11.11: The two-dimensional free boson: $\Delta = 0$ and $\xi = 0$

In $d = 2$ the formulae give $\Delta = (2-2)/2 = 0$ and $\xi = 0/(4 \cdot 1) = 0$. The reason is visible directly. The combination $\sqrt{g}\, g^{\mu\nu}$ is Weyl invariant in two dimensions:

$$\sqrt{\bar{g}}\, \bar{g}^{\mu\nu} \overset{(1)}{=} e^{2\sigma} \sqrt{g}\, e^{-2\sigma} g^{\mu\nu} = \sqrt{g}\, g^{\mu\nu}.$$

(1) $\sqrt{\bar{g}} = e^{d\sigma}\sqrt{g}$ with $d = 2$, and $\bar{g}^{\mu\nu} = e^{-2\sigma} g^{\mu\nu}$.

So $S_{\text{kin}} = \frac{1}{2}\int \sqrt{g}\, g^{\mu\nu}\partial_\mu\varphi\partial_\nu\varphi$ is unchanged with φ left alone ($\Delta = 0$). No derivative ever hits σ, so no $\Box\sigma$ appears, and no curvature term is needed. In fact a curvature term would *spoil* the invariance: by (11.34),

$$\begin{aligned} \frac{\xi}{2}\int \mathrm{d}^2x\, \sqrt{\bar{g}}\, \bar{R}\, \varphi^2 &\overset{(1)}{=} \frac{\xi}{2}\int \mathrm{d}^2x\, e^{2\sigma}\sqrt{g}\, e^{-2\sigma}(R - 2\Box\sigma)\, \varphi^2 \\ &= \frac{\xi}{2}\int \mathrm{d}^2x\, \sqrt{g}\, R\, \varphi^2 - \xi \int \mathrm{d}^2x\, \sqrt{g}\, \varphi^2\, \Box\sigma, \end{aligned}$$

(1) $\sqrt{\bar{g}} = e^{2\sigma}\sqrt{g}$, (11.34), and $\bar{\varphi} = \varphi$.

and the last term is not zero for general φ unless $\xi = 0$. (Without φ^2, the integral $\int \sqrt{g}\, R = 4\pi\chi$ is Weyl invariant, because $\int \sqrt{g}\, \Box\sigma = 0$ on a closed surface: Gauss–Bonnet again.)

Two remarks connect this with earlier sections. First, $\Delta = 0$ does not make φ a primary: its two-point function is a logarithm (see the discussion after (11.69)). Weyl weight zero is a statement about the action. Second, $\partial_\mu\varphi$ is a rank $(0,1)$ field with $\Delta = 1$, so by (11.26) its Weyl weight is $1 + 0 - 1 = 0$, which agrees with φ being unchanged. Quantum mechanically this theory has the trace anomaly with $c = 1$.

Worked example 11.12: Maxwell theory: Weyl invariant in $d = 4$ only

The curved-space Maxwell action is

$$S = \frac{1}{4}\int \mathrm{d}^d x\, \sqrt{g}\, g^{\mu\alpha} g^{\nu\beta} F_{\mu\nu} F_{\alpha\beta}, \qquad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu.$$

The field strength needs no metric: the Christoffel symbols in $\nabla_\mu A_\nu - \nabla_\nu A_\mu$ cancel because they are symmetric in $\mu\nu$. Rescale $g \mapsto e^{2\sigma} g$ and leave A_μ alone:

$$\sqrt{\bar{g}}\, \bar{g}^{\mu\alpha}\bar{g}^{\nu\beta} F_{\mu\nu}F_{\alpha\beta} \overset{(1)}{=} e^{d\sigma} e^{-2\sigma} e^{-2\sigma} \sqrt{g}\, g^{\mu\alpha} g^{\nu\beta} F_{\mu\nu}F_{\alpha\beta} = e^{(d-4)\sigma} \sqrt{g}\, g^{\mu\alpha} g^{\nu\beta} F_{\mu\nu}F_{\alpha\beta}.$$

(1) $\sqrt{\bar{g}} = e^{d\sigma}\sqrt{g}$ and two inverse metrics, each $e^{-2\sigma} g^{-1}$. F is unchanged because A is.

In $d = 4$ the factor is 1 for every $\sigma(x)$: Maxwell theory is exactly Weyl invariant, with A_μ of Weyl weight 0. That is the value predicted by (11.26) for $\Delta_A = 1$, $(n, m) = (0, 1)$. No curvature term is needed, and none would be allowed, since a term like $R A_\mu A^\mu$ is not gauge invariant.

In $d \neq 4$ a *constant* rescaling can still be compensated, by $A \mapsto \lambda^{-w} A$ with $w = \frac{d-4}{2}$ (then $\Delta_A = w + 1 = \frac{d-2}{2}$). For a local σ, however,

$$\partial_\mu\big(e^{-w\sigma}A_\nu\big) - \partial_\nu\big(e^{-w\sigma}A_\mu\big) \overset{(1)}{=} e^{-w\sigma}\Big[F_{\mu\nu} - w\big(\partial_\mu\sigma\, A_\nu - \partial_\nu\sigma\, A_\mu\big)\Big].$$

(1) Product rule on each term.

The extra piece contains A_μ itself, not just F, so it changes under a gauge transformation $A \mapsto A + \partial\chi$. Any curvature term that could cancel it would also contain undifferentiated A and break gauge invariance. So Maxwell theory in $d \neq 4$ has no Weyl-invariant form. By the contrapositive of (11.21) this is consistent with what Chapter T5 finds in flat space: for $d \neq 4$ free Maxwell theory is scale invariant but not conformally invariant. Farnsworth, Luty and Prilepina note the general version: free p-form gauge fields with $d \neq 2(p+1)$ are scale invariant without being conformal. The flat-space trace, $T^\mu{}_\mu = (1 - \frac{d}{4})F^2$, vanishes precisely in $d = 4$.

Worked example 11.13: A Weyl rescaling that is not conformal: the plane becomes a cylinder

In polar coordinates on $\mathbb{R}^d$, $\delta = \mathrm{d}r^2 + r^2\mathrm{d}\Omega_{d-1}^2$, where $\mathrm{d}\Omega_{d-1}^2$ is the metric of the unit sphere S^{d-1}. With $\tau = \ln r$, $\mathrm{d}r = r\,\mathrm{d}\tau$, so

$$\delta = r^2\big(\mathrm{d}\tau^2 + \mathrm{d}\Omega_{d-1}^2\big) \qquad \Longrightarrow \qquad r^{-2}\,\delta = \mathrm{d}\tau^2 + \mathrm{d}\Omega_{d-1}^2.$$

The Weyl rescaling with $\Omega = 1/r$, that is $\sigma = -\ln r$, turns flat space (minus the origin) into the cylinder $\mathbb{R} \times S^{d-1}$. Every point stays where it is. The sphere of radius r becomes a sphere of radius 1 at height $\tau = \ln r$ (Figure 11.8). Is this rescaling conformal? Compute the curvature with (11.33), $R = 0$. We need, for $r \neq 0$,

$$\partial_\mu\sigma \overset{(1)}{=} -\frac{x_\mu}{r^2}, \qquad (\nabla\sigma)^2 = \frac{1}{r^2}, \qquad \Box\sigma \overset{(2)}{=} -\frac{1}{r^{d-1}}\frac{\mathrm{d}}{\mathrm{d}r}\Big(r^{d-1}\cdot\frac{1}{r}\Big) = -\frac{d-2}{r^2}.$$

(1) $\partial_\mu r = x_\mu/r$.

(2) The radial part of the flat Laplacian in d dimensions is $r^{1-d}\frac{\mathrm{d}}{\mathrm{d}r}(r^{d-1}\frac{\mathrm{d}}{\mathrm{d}r})$, and $\frac{\mathrm{d}}{\mathrm{d}r}\ln r = \frac{1}{r}$.

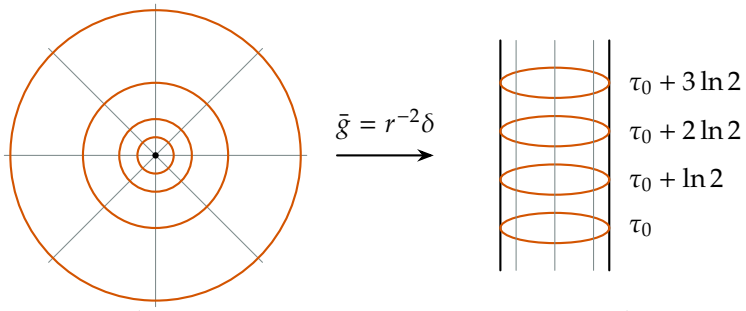
Then

$$\bar{R} \overset{(1)}{=} r^2\Big[-2(d-1)\Big(-\frac{d-2}{r^2}\Big) - (d-1)(d-2)\frac{1}{r^2}\Big] \overset{(2)}{=} (d-1)(d-2).$$

(1) (11.33) with $R = 0$ and $e^{-2\sigma} = r^2$.

(2) $2(d-1)(d-2) - (d-1)(d-2) = (d-1)(d-2)$.

This is the scalar curvature of the unit sphere S^{d-1}, as it should be for $\mathbb{R} \times S^{d-1}$. For $d > 2$ it is not zero, so the cylinder is curved and the rescaling is *not* conformal: no relabelling of points turns it back into flat space. For $d = 2$, $\bar{R} = 0$: the cylinder $\mathbb{R} \times S^1$ is flat, and the rescaling is undone by the conformal map $w = \ln z$, the cylinder map used in Example 11.34 and Section 11.4.3. For $d > 2$ this Weyl rescaling is what replaces that map in radial quantisation: a Weyl-invariant theory on flat space is the same as the theory on the cylinder, and dilations $r \mapsto \lambda r$ become time translations $\tau \mapsto \tau + \ln\lambda$.



flat $\mathbb{R}^d$ (a slice): spheres of radius $r_0, 2r_0, 4r_0, 8r_0$

cylinder $\mathbb{R} \times S^{d-1}$: unit spheres at height $\tau = \ln r$

Figure 11.8: The Weyl rescaling $\bar{g} = r^{-2}\delta$ of Example 11.13. On the left, concentric spheres in flat space, each twice the radius of the one inside it, and a few radial lines. The new ruler shrinks every length at distance r by the factor $1/r$, so all the spheres become unit spheres, stacked at equal spacing $\ln 2$ along the cylinder on the right (heights $\tau = \ln r$, with $\tau_0 = \ln r_0$), and the radial lines become straight lines along the cylinder. No point has moved. For $d > 2$ the cylinder is curved, so this rescaling is not a conformal map.

Try it: the conformal coupling in other dimensions

Show that in $d = 3$ the conformally coupled scalar has $\Delta = \frac{1}{2}$ and $\xi = \frac{1}{8}$, and in $d = 6$ it has $\Delta = 2$ and $\xi = \frac{1}{5}$. Then check (11.41) directly in $d = 3$. *Answer:* $\xi = \frac{d-2}{4(d-1)}$ gives $\frac{1}{8}$ and $\frac{4}{20} = \frac{1}{5}$. In $d = 3$, $\Delta^2 - \xi(d-1)(d-2) = \frac{1}{4} - \frac{1}{8} \cdot 2 \cdot 1 = 0$.

Watch out: Weyl is not conformal, and other traps

- *Different operations.* A conformal transformation moves points and keeps the geometry. A Weyl rescaling keeps the points and changes the geometry, usually from flat to curved (Example 11.13). Only the rescalings that a relabelling can undo are conformal (Definition 11.5). Writing "conformal transformation $g \mapsto \Omega^2 g$" for a general Ω is common and is exactly this confusion.
- *Weyl implies conformal, not conversely.* Chain (11.21) goes one way. The free scalar is conformal in flat space for any ξ (11.46), but Weyl invariant only for $\xi = \frac{d-2}{4(d-1)}$, and the non-unitary $\Box^k$ theories are conformal without any Weyl-invariant version.
- *The sign of R.* With our convention (11.17) spheres have $R > 0$, the Euclidean action is $\frac{1}{2}\int \sqrt{g}\,[(\nabla\varphi)^2 + \xi R\varphi^2]$, and the conformal operator is $-\Box + \xi R$ with $\xi = +\frac{1}{6}$ in $d = 4$. Books that define the Ricci tensor with the opposite sign (so spheres have $R < 0$) write $-\xi R\varphi^2$ for the same physics. Check any source on the round sphere before copying a sign. The derivation never used the signature: in Lorentzian signature the Weyl-invariant combination is still $g^{\mu\nu}\partial_\mu\varphi\,\partial_\nu\varphi + \xi R\varphi^2$, with R computed from (11.17) and $\sqrt{|g|}$ in place of $\sqrt{g}$, whatever overall sign the action carries.
- *How Ω is written.* We write $g \mapsto \Omega^2 g = e^{2\sigma} g$. Some papers write $g \mapsto \Omega\, g$ (Karananas–Monin), or give only the infinitesimal form $\delta g_{\mu\nu} = 2\sigma g_{\mu\nu}$ (Farnsworth–Luty–Prilepina). The exponent in $\phi \mapsto \Omega^{-\Delta}\phi$ changes accordingly, so convert before comparing.
- *Weyl weight is not dimension for tensors.* Under a pure Weyl rescaling a primary of rank (n, m) scales as $\Omega^{-(\Delta+n-m)}$ (11.26), not $\Omega^{-\Delta}$. The Maxwell field has $\Delta = 1$ but does not change at all.

Recap

- A conformal map $x \mapsto x'$ moves points and stretches every short step near x by $\Omega(x)$. A Weyl rescaling $g \mapsto \Omega^2 g$ moves nothing and changes the ruler.
- Conformal transformations are the Weyl rescalings that a diffeomorphism undoes, $f^* g = \Omega^2 g$. In flat space: $\Omega^2 \delta$ must be flat (in $d = 2$, $\Box \ln \Omega = 0$).
- A primary of rank (n, m) and dimension Δ transforms by (11.23). Net effect: multiplied by $\Omega^{-\Delta}$ and rotated. Scalar: $\phi'(x') = \Omega^{-\Delta}\phi(x)$, checked on the dilation and the inversion. Weyl weight $\Delta + n - m$.
- A constant rescaling of $\frac{1}{2}\int \sqrt{g}(\nabla\varphi)^2$ gives $\lambda^{d-2-2\Delta}$, so $\Delta = \frac{d-2}{2}$.
- $\bar{R} = e^{-2\sigma}[R - 2(d-1)\Box\sigma - (d-1)(d-2)(\nabla\sigma)^2]$. Local Weyl invariance of $\frac{1}{2}\int \sqrt{g}[(\nabla\varphi)^2 + \xi R\varphi^2]$: the $\Box\sigma$ terms fix $\xi = \frac{d-2}{4(d-1)}$ ($\frac{1}{6}$ in $d = 4$), and the $(\nabla\sigma)^2$ terms then cancel automatically. Doing it infinitesimally with Δ unknown fixes both numbers at once.
- Weyl invariance gives $T^\mu{}_\mu = 0$ on shell. In flat space the ξ term survives as the improvement term $-\xi(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2)\varphi^2$. Quantum mechanically the trace anomaly $\propto cR$ appears (Chapter 10).
- Farnsworth–Luty–Prilepina: local, unitary conformal theories with local conformal currents in $d \leq 10$ are Weyl invariant. Counterexamples are non-unitary ($\Box^k$ with d even, $d < 2k$).
- Examples: 2D boson ($\Delta = \xi = 0$, $\sqrt{g}g^{\mu\nu}$ invariant), Maxwell (Weyl invariant only in $d = 4$), plane to cylinder (Weyl but not conformal for $d > 2$).

11.3 Conformal field theories in two dimensions

We now know that in two dimensions the conformal transformations are the holomorphic maps. This section turns that fact into a working toolkit. The questions are: how do fields transform under a holomorphic change of coordinates? What does conformal symmetry force the correlation functions to be? And what plays the role of the conserved current, the object whose charges generate the symmetry? The answers are, in order: *primary fields* transform like tensors with two weights $(h, \bar{h})$; two-point functions are fixed up to a constant; and the generator is the holomorphic component $T(z)$ of the stress tensor, whose operator product with any field encodes the whole conformal Ward identity. Along the way we meet the two simplest conformal field theories, the free Majorana fermion and the free boson, and use them to check every formula.

Nash works on the complex plane $\mathbb{C}$ or on the Riemann sphere $\mathbb{C} \cup \{\infty\}$. General Riemann surfaces appear only in §5 of his chapter (the next part of these notes). We do the same.

11.3.1 Complex coordinates on the plane

Two-dimensional Euclidean space has coordinates (x_1, x_2) and metric $\mathrm{d}s^2 = \mathrm{d}x_1^2 + \mathrm{d}x_2^2$. Trade them for

$$z = x_1 + ix_2, \qquad \bar{z} = x_1 - ix_2. \tag{11.50}$$

For a real point, $\bar{z}$ is the complex conjugate of z. But in most calculations we treat z and $\bar{z}$ as *independent* variables, as if x_1, x_2 were complex. This is the trick that makes two-dimensional

conformal field theory work: a function of (x_1, x_2) becomes a function of $(z, \bar{z})$, and holomorphic means "depends on z only".

The derivatives dual to $z, \bar{z}$ are

$$\partial \equiv \partial_z = \tfrac{1}{2}(\partial_1 - i\partial_2), \qquad \bar{\partial} \equiv \partial_{\bar{z}} = \tfrac{1}{2}(\partial_1 + i\partial_2). \tag{11.51}$$

Check: $\partial z = \frac{1}{2}(1 - i \cdot i) = 1$ and $\partial \bar{z} = \frac{1}{2}(1 + i \cdot i) = 0$, and similarly $\bar{\partial}\bar{z} = 1$, $\bar{\partial} z = 0$. The Laplacian factorises,

$$4\partial\bar{\partial} \overset{(1)}{=} (\partial_1 - i\partial_2)(\partial_1 + i\partial_2) \overset{(2)}{=} \partial_1^2 + \partial_2^2 = \nabla^2. \tag{11.52}$$

(1) Definition (11.51); the two factors of $\frac{1}{2}$ give $\frac{1}{4}$, cancelled by the 4.
(2) Multiply out: the cross terms $i\partial_1\partial_2 - i\partial_2\partial_1$ cancel because partial derivatives commute.

The metric and the measure. Substituting $\mathrm{d}x_1 = \frac{1}{2}(\mathrm{d}z + \mathrm{d}\bar{z})$ and $\mathrm{d}x_2 = \frac{1}{2i}(\mathrm{d}z - \mathrm{d}\bar{z})$,

$$\mathrm{d}s^2 \overset{(1)}{=} \tfrac{1}{4}(\mathrm{d}z + \mathrm{d}\bar{z})^2 - \tfrac{1}{4}(\mathrm{d}z - \mathrm{d}\bar{z})^2 \overset{(2)}{=} \mathrm{d}z\,\mathrm{d}\bar{z}.$$

(1) $(\frac{1}{2i})^2 = -\frac{1}{4}$.
(2) The squares $\mathrm{d}z^2$ and $\mathrm{d}\bar{z}^2$ cancel; the cross terms add to $\frac{1}{4} \cdot 4\,\mathrm{d}z\,\mathrm{d}\bar{z}$.

So the metric components are $g_{z\bar{z}} = g_{\bar{z}z} = \frac{1}{2}$ and $g_{zz} = g_{\bar{z}\bar{z}} = 0$ (the symmetric tensor $\mathrm{d}z\,\mathrm{d}\bar{z}$ is $\frac{1}{2}(\mathrm{d}z \otimes \mathrm{d}\bar{z} + \mathrm{d}\bar{z} \otimes \mathrm{d}z)$). The inverse metric has $g^{z\bar{z}} = 2$. Indices are lowered with g: for a vector v, $v_z = g_{z\bar{z}} v^{\bar{z}} = \frac{1}{2} v^{\bar{z}}$.

For the area element, use forms (Chapter T1):

$$\mathrm{d}z \wedge \mathrm{d}\bar{z} \overset{(1)}{=} (\mathrm{d}x_1 + i\,\mathrm{d}x_2) \wedge (\mathrm{d}x_1 - i\,\mathrm{d}x_2) \overset{(2)}{=} -2i\,\mathrm{d}x_1 \wedge \mathrm{d}x_2. \tag{11.53}$$

(1) Definition (11.50).
(2) $\mathrm{d}x_1 \wedge \mathrm{d}x_1 = 0$; the cross terms are $-i\,\mathrm{d}x_1 \wedge \mathrm{d}x_2 + i\,\mathrm{d}x_2 \wedge \mathrm{d}x_1 = -2i\,\mathrm{d}x_1 \wedge \mathrm{d}x_2$.

In CFT texts "$\mathrm{d}z\,\mathrm{d}\bar{z}$" or "$\mathrm{d}^2 z$" usually means the positive measure $|\mathrm{d}z \wedge \mathrm{d}\bar{z}| = 2\,\mathrm{d}^2 x$, where $\mathrm{d}^2 x = \mathrm{d}x_1 \mathrm{d}x_2$. Conventions differ by this factor 2 from book to book. To stay safe we write all actions and integrals with $\mathrm{d}^2 x$.

Tensors in complex components. A tensor $T_{\mu\nu}$ has complex components obtained by the chain rule, $T_{zz} = \frac{\partial x^\mu}{\partial z}\frac{\partial x^\nu}{\partial z} T_{\mu\nu}$, with $\partial x_1/\partial z = \frac{1}{2}$ and $\partial x_2/\partial z = \frac{1}{2i}$. We compute these explicitly for the stress tensor in Section 11.3.10.

The key distributional identity. The function $1/z$ is holomorphic away from 0, so $\bar{\partial}(1/z) = 0$ for $z \neq 0$. At $z = 0$ it has a pole, and $\bar{\partial}(1/z)$ is a delta function:

$$\bar{\partial}\,\frac{1}{z} = \pi\,\delta^2(x), \qquad \partial\bar{\partial}\,\ln|z|^2 = \pi\,\delta^2(x). \tag{11.54}$$

Worked example 11.14: Why $\bar{\partial}(1/z) = \pi\delta^2(x)$: Stokes in the plane

A distribution is defined by what it does to a smooth test function $g(x)$ that vanishes outside a large disc D. The derivative of a distribution is defined by moving the derivative onto g with a minus sign. We also need Stokes' theorem (Chapter T2) in complex form: for

any function F, $\mathrm{d}(F\,\mathrm{d}z) = \bar\partial F\,\mathrm{d}\bar z \wedge \mathrm{d}z = 2i\,\bar\partial F\,\mathrm{d}^2x$ by (11.53), so $\int_R \mathrm{d}^2x\,\bar\partial F = \frac{1}{2i}\oint_{\partial R} F\,\mathrm{d}z$. Let D_ϵ be the disc of radius ϵ about 0. Then

$$\begin{aligned}\left\langle \bar\partial\frac{1}{z},\, g\right\rangle &\overset{(1)}{=} -\lim_{\epsilon\to0}\int_{D\setminus D_\epsilon} \mathrm{d}^2x\;\frac{\bar\partial g}{z} \overset{(2)}{=} -\lim_{\epsilon\to0}\int_{D\setminus D_\epsilon} \mathrm{d}^2x\;\bar\partial\Big(\frac{g}{z}\Big)\\ &\overset{(3)}{=} -\lim_{\epsilon\to0}\frac{1}{2i}\oint_{\partial(D\setminus D_\epsilon)}\frac{g}{z}\,\mathrm{d}z \overset{(4)}{=} \lim_{\epsilon\to0}\frac{1}{2i}\oint_{|z|=\epsilon}\frac{g}{z}\,\mathrm{d}z\\ &\overset{(5)}{=} \frac{1}{2i}\,2\pi i\,g(0) = \pi\,g(0).\end{aligned}$$

(1) Definition of the distributional derivative; $1/z$ is integrable in 2D, so removing a small disc changes nothing in the limit.
(2) Product rule: $\bar\partial(g/z) = (\bar\partial g)/z + g\,\bar\partial(1/z)$, and $\bar\partial(1/z) = 0$ away from the origin.
(3) Stokes' theorem in the complex form just stated.
(4) $g = 0$ on the outer circle. The inner circle is part of the boundary traversed clockwise; writing it counter-clockwise flips the sign.
(5) On $|z| = \epsilon$, $z = \epsilon e^{i\theta}$ and $\mathrm{d}z/z = i\,\mathrm{d}\theta$; as $\epsilon \to 0$, $g \to g(0)$ and $\oint i\,\mathrm{d}\theta = 2\pi i$.

So $\bar\partial(1/z) = \pi\delta^2(x)$. The second form in (11.54) follows from $\partial \ln|z|^2 = \partial(\ln z + \ln\bar z) = 1/z$. As a cross-check, $\nabla^2 \ln r = 2\pi\delta^2(x)$ is Gauss's law for a line charge in 2D, and $4\partial\bar\partial \ln|z|^2 = \nabla^2(2\ln r) = 4\pi\delta^2(x)$, consistent with (11.52).

11.3.2 Conformal maps are holomorphic maps

We saw in Section 11.1.6 that infinitesimal conformal maps are holomorphic. The finite statement is just as direct. Let $w = f(z)$ be holomorphic, $f = u + iv$. The Cauchy–Riemann equations $u_1 = v_2$, $u_2 = -v_1$ make the Jacobian matrix

$$J = \begin{pmatrix} u_1 & u_2 \\ v_1 & v_2 \end{pmatrix} = \begin{pmatrix} a & -b \\ b & a \end{pmatrix} = |f'(z)| \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}, \qquad f'(z) = a + ib = |f'|e^{i\theta}. \tag{11.55}$$

It is a rotation by $\arg f'$ times a stretch by $|f'|$. So $J^TJ = |f'|^2\mathbb{1}$, and in the language of (11.9), $\Omega = |f'(z)|$. Equivalently $\mathrm{d}w\,\mathrm{d}\bar w = |f'(z)|^2\mathrm{d}z\,\mathrm{d}\bar z$. Holomorphic maps preserve orientation; antiholomorphic maps $\bar f(\bar z)$ are conformal but reverse orientation.

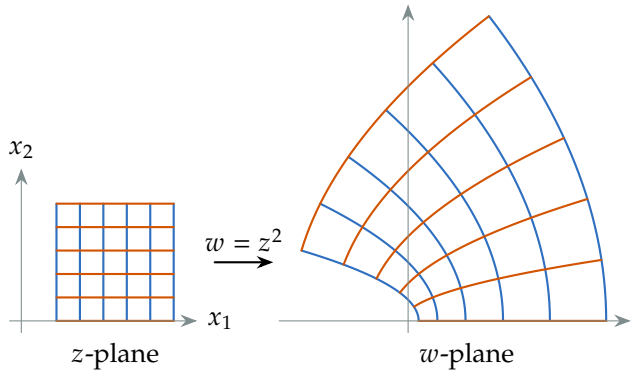


Figure 11.9: The holomorphic map $w = z^2$ applied to a rectangular grid. Vertical lines (blue) and horizontal lines (orange) become two families of parabolas. The images are curved and stretched, but they still cross at right angles: the Jacobian (11.55) is a rotation times a scale at every point. Where $|f'| = 2|z|$ is larger (far from the origin) the cells are bigger.

Worked example 11.15: Two maps we will use constantly

(a) *Rotation and dilation*: $f(z) = \lambda z$ with $\lambda = \rho e^{i\theta}$ complex. Then $f' = \lambda$, so the map rotates by θ and scales by ρ. In real coordinates this is the 2×2 matrix $\rho\left(\begin{smallmatrix}\cos\theta & -\sin\theta \\ \sin\theta & \cos\theta\end{smallmatrix}\right)$: one complex parameter packages a dilation and a rotation.
(b) *The exponential map*: $z = e^w$ with $w = \tau + i\sigma$. Then $|z| = e^\tau$ and $\arg z = \sigma$. The line $\tau =$ const is a circle of radius e^τ; the line $\sigma =$ const is a ray. Since $\sigma \sim \sigma + 2\pi$ gives the same z, the w-plane is really a cylinder of circumference 2π, with τ running along it. The far past $\tau \to -\infty$ is the origin $z = 0$, the far future $\tau \to +\infty$ is $z = \infty$. Here $f'(w) = e^w = z$, so a unit cell on the cylinder is stretched by $|z|$: circles far from the origin are bigger. This map is the basis of radial quantisation in Section 11.4.3.

11.3.3 The local conformal algebra: the Witt algebra

An infinitesimal holomorphic map is $z \mapsto z + \epsilon(z)$ with ϵ holomorphic in some region. Expand in a Laurent series, $\epsilon(z) = -\sum_n \epsilon_n z^{n+1}$. The map acts on functions through the vector field $\epsilon(z)\partial_z$, and it is natural to use the basis

$$\ell_n = -z^{n+1}\partial_z, \qquad \bar{\ell}_n = -\bar{z}^{n+1}\partial_{\bar{z}}, \qquad n \in \mathbb{Z}. \tag{11.56}$$

(The minus sign and the power $n+1$ are chosen so that the commutator comes out clean and so that ℓ_n lowers the power of z by n.)

Worked example 11.16: The Witt algebra commutator

Act on a test function $g(z)$:

$$\begin{aligned}[\ell_m, \ell_n]g &\overset{(1)}{=} z^{m+1}\partial\big(z^{n+1}\partial g\big) - z^{n+1}\partial\big(z^{m+1}\partial g\big) \\ &\overset{(2)}{=} z^{m+1}\big((n+1)z^n\partial g + z^{n+1}\partial^2 g\big) - z^{n+1}\big((m+1)z^m\partial g + z^{m+1}\partial^2 g\big) \\ &\overset{(3)}{=} (n-m)\, z^{m+n+1}\partial g \overset{(4)}{=} (m-n)\,\ell_{m+n}\, g.\end{aligned}$$

(1) $\ell_m\ell_n g = (-z^{m+1}\partial)(-z^{n+1}\partial g)$: the two minus signs cancel.
(2) Product rule.
(3) The second-derivative terms cancel; collect the first-derivative terms, $(n+1)-(m+1) = n-m$.
(4) $\ell_{m+n} = -z^{m+n+1}\partial$, so $z^{m+n+1}\partial = -\ell_{m+n}$.

So

$$[\ell_m, \ell_n] = (m-n)\,\ell_{m+n}, \qquad [\bar{\ell}_m, \bar{\ell}_n] = (m-n)\,\bar{\ell}_{m+n}, \qquad [\ell_m, \bar{\ell}_n] = 0. \tag{11.57}$$

This is the **Witt algebra** (two commuting copies). It is the Virasoro algebra (11.102) with $c = 0$. The central term will appear only in the quantum theory.

Which generators are global? The vector field $\ell_n = -z^{n+1}\partial_z$ is regular at $z = 0$ only if $n \geq -1$. To test $z = \infty$, use the coordinate $u = 1/z$ near infinity. Then $\partial_z = \frac{\mathrm{d}u}{\mathrm{d}z}\partial_u = -u^2\partial_u$, so

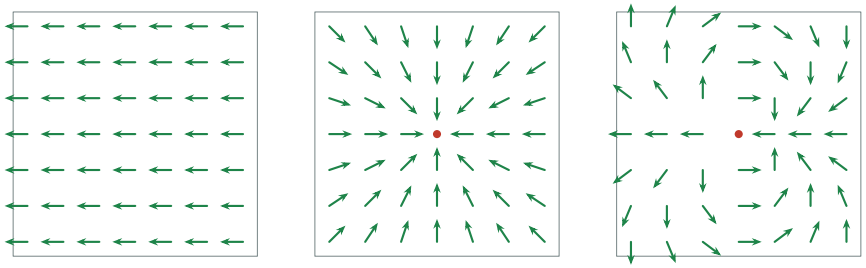
$$\ell_n = -z^{n+1}\partial_z \overset{(1)}{=} -u^{-n-1}(-u^2\partial_u) = u^{1-n}\partial_u,$$

(1) Substitute $z = 1/u$ and $\partial_z = -u^2\partial_u$.

which is regular at $u = 0$ only if $n \leq 1$. So on the whole Riemann sphere only

$$\ell_{-1} = -\partial_z, \qquad \ell_0 = -z\partial_z, \qquad \ell_1 = -z^2\partial_z \tag{11.58}$$

(and their barred partners) are globally defined. Their meaning: ℓ_{-1} generates translations, $\ell_0 + \bar{\ell}_0$ dilations, $i(\ell_0 - \bar{\ell}_0)$ rotations, and ℓ_1 special conformal transformations. That is $3 + 3 = 6$ real generators, matching $\dim \mathrm{SO}(3,1) = 6$ from (11.14). The other ℓ_n are perfectly good *local* symmetries (they are conformal Killing vectors on any annulus), and in quantum field theory, where the Ward identities are local, they constrain the theory just as much.



$\ell_{-1} = -\partial_z$: translation $\quad$ $\ell_0 = -z\partial_z$: dilation $\quad$ $\ell_1 = -z^2\partial_z$: SCT

Figure 11.10: The three global conformal vector fields on the plane, drawn as the flow $\dot{z} = \epsilon(z) = -z^{n+1}$ (arrows show direction only). Left: a uniform shift. Middle: everything flows radially into the fixed point 0 (red dot); multiplying by i would give rotation about 0 instead. Right: the field $-z^2$ has a double zero at the origin; its flow lines are circles through the origin, the images of straight lines under the inversion $z \mapsto 1/z$. Only these three (and i times them) extend smoothly to $z = \infty$.

Watch out: vector fields versus coordinate changes

The flow of $\ell_n = -z^{n+1}\partial_z$ moves points by $\delta z = -\epsilon_n z^{n+1}$ when we write the transformation as $\exp(\epsilon_n \ell_n)$. Some authors put the minus sign elsewhere. Nothing physical depends on it; what matters is that the commutator (11.57) has the sign $(m - n)$, which with our conventions it does.

11.3.4 The global conformal group: Möbius transformations

Exponentiating the three global generators gives the **Möbius transformations**

$$z \mapsto f(z) = \frac{az + b}{cz + d}, \qquad a, b, c, d \in \mathbb{C}, \quad ad - bc = 1. \tag{11.59}$$

They are the only one-to-one holomorphic maps of the Riemann sphere to itself. (A holomorphic map of the sphere is a rational function; to be one-to-one it must have exactly one pole and one zero, so it is of degree one.) Each one is conformal everywhere: $f'(z) = (ad - bc)/(cz + d)^2 = 1/(cz + d)^2$, which never vanishes.

The nicest fact about them is that composition is matrix multiplication. Represent f by the matrix $M_f = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in \mathrm{SL}(2, \mathbb{C})$ and write z as the ratio $z = z_1/z_2$ of a column vector $(z_1, z_2)^T$.

Worked example 11.17: Composition is matrix multiplication

Let $f \leftrightarrow \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ and $g \leftrightarrow \left(\begin{smallmatrix} a' & b' \\ c' & d' \end{smallmatrix}\right)$. Then

$$f(g(z)) \overset{(1)}{=} \frac{a\,\frac{a'z+b'}{c'z+d'} + b}{c\,\frac{a'z+b'}{c'z+d'} + d} \overset{(2)}{=} \frac{a(a'z+b') + b(c'z+d')}{c(a'z+b') + d(c'z+d')}$$
$$\overset{(3)}{=} \frac{(aa' + bc')z + (ab' + bd')}{(ca' + dc')z + (cb' + dd')},$$

(1) Substitute $g(z)$ into f.
(2) Multiply numerator and denominator by $c'z + d'$.

(3) Collect powers of z.

and the coefficients are exactly the entries of the matrix product $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)\left(\begin{smallmatrix} a' & b' \\ c' & d' \end{smallmatrix}\right)$. The matrices M and $-M$ give the same map, since the signs cancel in the ratio. So the Möbius group is

$$\mathrm{SL}(2,\mathbb{C})/\{\pm\mathbb{1}\} \;\cong\; \mathrm{SO}^{+}(3,1),$$

of real dimension 6 (4 complex entries minus 1 complex condition). Its elements are generated by translations $\left(\begin{smallmatrix} 1 & b \\ 0 & 1 \end{smallmatrix}\right)$, rotation-dilations $\left(\begin{smallmatrix} \lambda^{1/2} & 0 \\ 0 & \lambda^{-1/2} \end{smallmatrix}\right)$ (giving $z \mapsto \lambda z$), and the inversion $\left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$ (giving $z \mapsto -1/z$). The SCT is $\left(\begin{smallmatrix} 1 & 0 \\ -\beta & 1 \end{smallmatrix}\right)$: $z \mapsto z/(1-\beta z)$, which is the complex form of (11.15) with $\beta = b_1 - ib_2$.

The infinitesimal generators as 2×2 matrices. Near the identity, $M = \mathbb{1} + \epsilon X$ with $\operatorname{tr} X = 0$. The map is $z \mapsto z + \epsilon(X_{12} + (X_{11} - X_{22})z - X_{21}z^2)$ to first order. So

$$\ell_{-1} \leftrightarrow \begin{pmatrix} 0 & -1 \\ 0 & 0 \end{pmatrix}, \quad \ell_0 \leftrightarrow \begin{pmatrix} -\frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{pmatrix}, \quad \ell_1 \leftrightarrow \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}.$$

(For example ℓ_1 moves z by $-\epsilon z^2$, which is $-X_{21}z^2$ with $X_{21} = 1$.) One checks directly that these matrices obey $[\ell_m, \ell_n] = (m-n)\ell_{m+n}$ with a minus sign overall: the map from vector fields to matrices is an anti-homomorphism, the usual price for letting matrices act on coordinates from the left. For instance $[X_{\ell_1}, X_{\ell_{-1}}] = \left(\begin{smallmatrix} 0 & 0 \\ 1 & 0 \end{smallmatrix}\right)\left(\begin{smallmatrix} 0 & -1 \\ 0 & 0 \end{smallmatrix}\right) - \left(\begin{smallmatrix} 0 & -1 \\ 0 & 0 \end{smallmatrix}\right)\left(\begin{smallmatrix} 0 & 0 \\ 1 & 0 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right) = -2X_{\ell_0}$, while (11.57) gives $[\ell_1, \ell_{-1}] = 2\ell_0$. This is the algebra $\mathfrak{sl}(2,\mathbb{C})$, which returns in Section 11.4.13.

Worked example 11.18: Three points fix a Möbius map

Given three distinct points z_1, z_2, z_3, the map

$$f(z) = \frac{(z-z_1)(z_2-z_3)}{(z-z_3)(z_2-z_1)}$$

is Möbius (after normalising $ad - bc = 1$) and sends $z_1 \mapsto 0$, $z_2 \mapsto 1$, $z_3 \mapsto \infty$: read off the zero, check $f(z_2) = 1$, read off the pole. Since six real parameters can be used to fix three complex points, a Möbius map is completely determined by where it sends three points. With four points $z_1, \dots, z_4$ one invariant survives: the image of z_4,

$$\eta = f(z_4) = \frac{z_{41}z_{23}}{z_{43}z_{21}}, \qquad z_{ij} = z_i - z_j,$$

the **cross-ratio**. This is why conformal symmetry fixes two- and three-point functions completely but leaves four-point functions depending on one variable.

11.3.5 Primary fields

In a conformal field theory, how does a field respond to a holomorphic change of coordinates $z \mapsto z' = f(z)$? The simplest possibility is that it behaves like a tensor with h lower z indices and $\bar{h}$ lower $\bar{z}$ indices: like $\phi_{zz\cdots z\bar{z}\cdots\bar{z}}(\mathrm{d}z)^h(\mathrm{d}\bar{z})^{\bar{h}}$, with the number of indices allowed to be any real number.

Working definition 11.7 (primary field of weight $(h,\bar{h})$)

A field $\phi(z,\bar{z})$ is **primary** with **conformal weights** $(h,\bar{h})$ if under every conformal map $z \mapsto z'(z)$ [a holomorphic change of coordinate, so z' depends on z but not on $\bar{z}$] the

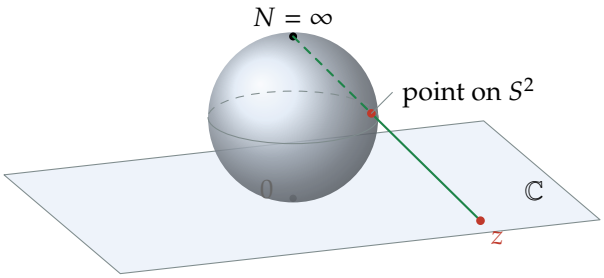


Figure 11.11: The Riemann sphere $\mathbb{C} \cup \{\infty\}$ by stereographic projection: the line from the north pole N through a point of the sphere meets the plane at z. As z runs off to infinity in any direction, the point on the sphere approaches N. On the sphere ∞ is an ordinary point, and a vector field is "globally defined" if it is smooth at N too; that is the test $u = 1/z$ applied to ℓ_n above.

transformed field ϕ' is related to ϕ by

$$\phi(z,\bar z) = \left(\frac{\mathrm{d}z'}{\mathrm{d}z}\right)^{h}\left(\frac{\mathrm{d}\bar z'}{\mathrm{d}\bar z}\right)^{\bar h}\phi'(z',\bar z'), \qquad \text{equivalently} \qquad \phi(z,\bar z)\,\mathrm{d}z^{h}\mathrm{d}\bar z^{\bar h} \text{ is invariant.} \tag{11.60}$$

Here $h, \bar h$ are real, and $\bar h$ is *not* the complex conjugate of h; they are independent labels. *Operational test:* compute the change of ϕ under an infinitesimal $z \mapsto z + \epsilon f(z)$; a primary gives $\delta\phi = \epsilon\big(hf'\phi + f\partial\phi\big)$ plus the barred analogue, for *every* holomorphic f (see (11.63)). If the formula holds only for the Möbius f (degree ≤ 2) [$f = 1, z, z^2$, which generate translations, rotations with dilations, and special conformal maps], the field is called **quasi-primary**.

The two weights package the two quantum numbers that a physicist knows.

Scaling dimension. Take $z' = \lambda z$ with $\lambda > 0$ real. Then $\mathrm{d}z'/\mathrm{d}z = \mathrm{d}\bar z'/\mathrm{d}\bar z = \lambda$ and (11.60) reads $\phi(z,\bar z) = \lambda^{h+\bar h}\phi'(\lambda z, \lambda\bar z)$. Comparing with (11.1), the scaling dimension is

$$\Delta = h + \bar h. \tag{11.61}$$

Spin. Take a rotation $z' = e^{i\theta}z$, $\bar z' = e^{-i\theta}\bar z$. Then $\phi(z,\bar z) = e^{i\theta(h-\bar h)}\phi'(z',\bar z')$. A field that picks up $e^{is\theta}$ under rotation by θ has spin s, so

$$s = h - \bar h. \tag{11.62}$$

Examples: a scalar has $h = \bar h$; a holomorphic current $J(z)$ has $(1,0)$, spin 1; the stress tensor $T(z)$ has $(2,0)$, spin 2 (the two indices of T_{zz}); a chiral fermion has $(\frac12, 0)$, spin $\frac12$.

Nash says that $h - \bar h$ is "therefore restricted to integer or half-integer values". The reason is the rotation by 2π: $e^{2\pi i s}$ must be 1 (bosons) or, allowing a sign, -1 (fermions, which are defined only up to sign). So $s \in \frac12\mathbb{Z}$. We see the same condition from the two-point function below.

Infinitesimal form. Let $z' = z + \epsilon f(z)$, so $\mathrm{d}z'/\mathrm{d}z = 1 + \epsilon f'(z)$. We define the variation of a field as the difference between the old and the new field at the *same* coordinate value, $\delta\phi(z) \coloneqq \phi(z) - \phi'(z)$. Working to first order in ϵ and showing only the holomorphic dependence:

$$\begin{aligned}\phi'(z) &\overset{(1)}{=} \phi'(z') - \epsilon f(z)\,\partial\phi'(z') \overset{(2)}{=} (1+\epsilon f')^{-h}\phi(z) - \epsilon f\,\partial\phi(z)\\ &\overset{(3)}{=} \phi(z) - \epsilon\big(hf'(z)\phi(z) + f(z)\partial\phi(z)\big),\\ \delta\phi(z,\bar z) &\overset{(4)}{=} \epsilon\big(hf'(z)\phi + f(z)\partial\phi\big) + \bar\epsilon\big(\bar h\bar f'(\bar z)\phi + \bar f(\bar z)\bar\partial\phi\big).\end{aligned} \tag{11.63}$$

(1) Taylor expand: $z = z' - \epsilon f(z)$, so $\phi'(z) = \phi'(z' - \epsilon f)$.
(2) The primary law (11.60) gives $\phi'(z') = (1 + \epsilon f')^{-h}\phi(z)$; in the $O(\epsilon)$ term we may replace ϕ' by ϕ.
(3) $(1 + \epsilon f')^{-h} = 1 - h\epsilon f' + O(\epsilon^2)$.
(4) Subtract from $\phi(z)$, and add the identical antiholomorphic calculation (independent parameter $\bar{\epsilon}$ and function $\bar{f}$).

This is Nash's (11.20). The term $f\partial\phi$ is the "transport" of the field, present for any scalar; the term $hf'\phi$ is the response of the h lower indices to the local rotation-and-scaling f'.

Watch out: which $\delta\phi$?

Nash defines $\delta\phi(x)$ as $\phi'(x') - \phi(x)$. With the primary law (11.60) that combination equals $-\epsilon h f'\phi$, without the transport term, and with the opposite sign to his (11.20). What he actually uses in (11.20) and the Ward identity is our $\delta\phi = \phi(z) - \phi'(z)$ (the "active" change of the field at a fixed point). The overall sign is a convention; what matters is that the same $\delta\phi$ appears on both sides of the Ward identity. We check the sign on the free boson in Example 11.26.

11.3.6 Conformal symmetry fixes the two-point function

Suppose ϕ_1, ϕ_2 are primary (quasi-primary is enough) with weights $(h_1, \bar{h}_1)$ and $(h_2, \bar{h}_2)$, and the vacuum is invariant under the global conformal group. Invariance means that correlators of the transformed fields equal correlators of the old fields, so from (11.60)

$$\langle \phi_1(z_1,\bar{z}_1)\phi_2(z_2,\bar{z}_2)\rangle = \prod_{i=1}^{2} f'(z_i)^{h_i}\,\bar{f}'(\bar{z}_i)^{\bar{h}_i}\,\langle \phi_1(f(z_1),\bar{f}(\bar{z}_1))\,\phi_2(f(z_2),\bar{f}(\bar{z}_2))\rangle \tag{11.64}$$

for every Möbius map f. Call the left side $G(z_1, z_2)$ (suppressing $\bar{z}$'s). We use the three kinds of Möbius map one at a time.

Worked example 11.19: Deriving the two-point function

Translations $f(z) = z + a$: $f' = 1$, so $G(z_1, z_2) = G(z_1 + a, z_2 + a)$ and G depends only on $z_{12} = z_1 - z_2$ (and $\bar{z}_{12}$).
Rotation-dilations $f(z) = \lambda z$: $f' = \lambda$, so $G(z_{12}) = \lambda^{h_1+h_2}\bar{\lambda}^{\bar{h}_1+\bar{h}_2}G(\lambda z_{12})$. Choosing $\lambda = 1/z_{12}$ gives

$$G = \frac{C_{12}}{z_{12}^{\,h_1+h_2}\,\bar{z}_{12}^{\,\bar{h}_1+\bar{h}_2}}, \qquad C_{12} = G(1).$$

Inversion $f(z) = -1/z$: $f'(z) = 1/z^2$ and $f(z_1) - f(z_2) = -\frac{1}{z_1} + \frac{1}{z_2} = \frac{z_{12}}{z_1 z_2}$. Look at the holomorphic factors of the right side of (11.64):

$$z_1^{-2h_1} z_2^{-2h_2}\,\frac{C_{12}}{(z_{12}/z_1 z_2)^{h_1+h_2}} \overset{(1)}{=} C_{12}\,\frac{z_1^{h_2-h_1}\,z_2^{h_1-h_2}}{z_{12}^{\,h_1+h_2}}.$$

(1) Collect the powers: $z_1^{-2h_1+h_1+h_2} = z_1^{h_2-h_1}$, similarly for z_2.

This must equal $C_{12}/z_{12}^{h_1+h_2}$ for all z_1, z_2. That is possible only if $h_1 = h_2$ (and likewise $\bar{h}_1 = \bar{h}_2$), or else $C_{12} = 0$. Therefore

$$\langle \phi_1(z_1,\bar{z}_1)\phi_2(z_2,\bar{z}_2)\rangle = \begin{cases} \dfrac{C_{12}}{z_{12}^{2h}\,\bar{z}_{12}^{2\bar{h}}} & h_1 = h_2 = h,\ \bar{h}_1 = \bar{h}_2 = \bar{h}, \\ 0 & \text{otherwise.} \end{cases} \tag{11.65}$$

In polar form $z_{12} = re^{i\theta}$, (11.65) is $C\, r^{-2(h+\bar{h})} e^{-2i\theta(h-\bar{h})}$. The modulus is the power law $r^{-2\Delta}$ of Section 11.1.1. The phase must return to itself (up to the fermionic sign) when $\theta \to \theta + 2\pi$, so $2(h-\bar{h}) \in \mathbb{Z}$: the spin is integer or half-integer, as claimed.

Watch out: the exponent in Nash's (11.9)

Nash prints (11.9) as $\langle \phi(z,\bar{z})\phi(0,0)\rangle = C/z^h\bar{z}^{\bar{h}}$. The exponents should be $2h$ and $2\bar{h}$, as derived above. The check is the free fermion (11.6): $\langle \psi(z)\psi(0)\rangle = C/z$ with $h = \frac{1}{2}$, so the exponent is $1 = 2h$, not h.

Try it: the three-point function

Repeat the argument for three quasi-primaries. Show that translations and rotation-dilations allow $\prod_{i<j} z_{ij}^{-a_{ij}}$ with $a_{12} + a_{13} = 2h_1$ etc. (exponents chosen so each field carries total weight h_i after inversion), and deduce

$$\langle \phi_1\phi_2\phi_3\rangle = \frac{C_{123}}{z_{12}^{h_1+h_2-h_3}\, z_{23}^{h_2+h_3-h_1}\, z_{13}^{h_1+h_3-h_2}} \times (\text{same with bars}).$$

Answer sketch: under inversion each $z_{ij} \mapsto z_{ij}/(z_i z_j)$, so the right side picks up $z_1^{a_{12}+a_{13}}\cdots$, which cancels the $z_1^{-2h_1}$ from $f'(z_1)^{h_1}$ exactly when $a_{12} + a_{13} = 2h_1$. Three linear equations for three unknowns give the exponents shown. The number C_{123} is a genuine dynamical datum of the theory: the OPE coefficient.

11.3.7 Example: the free Majorana fermion

The simplest interacting-looking conformal field theory is actually free: a two-dimensional Majorana (real) fermion. Let us build it from the Dirac equation, with an explicit representation.

Gamma matrices in two Euclidean dimensions. Take $\gamma^1 = \sigma^1$, $\gamma^2 = \sigma^2$ (the Pauli matrices), so $\{\gamma^\mu, \gamma^\nu\} = 2\delta^{\mu\nu}$ (Chapter T4). The Dirac operator is

$$\gamma^\mu\partial_\mu = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\partial_1 + \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}\partial_2 \overset{(1)}{=} \begin{pmatrix} 0 & \partial_1 - i\partial_2 \\ \partial_1 + i\partial_2 & 0 \end{pmatrix} \overset{(2)}{=} 2\begin{pmatrix} 0 & \partial \\ \bar{\partial} & 0 \end{pmatrix}. \tag{11.66}$$

(1) Add the matrices entry by entry.
(2) Definition (11.51) of $\partial, \bar{\partial}$.

Writing the two-component spinor as $\Psi = (\psi, \bar{\psi})^T$, the massless Dirac equation $\gamma^\mu\partial_\mu\Psi = 0$ splits into $2\partial\bar{\psi} = 0$ (first row) and $2\bar{\partial}\psi = 0$ (second row). The upper component is holomorphic, the lower one antiholomorphic. The chirality matrix $\gamma^3 = -i\gamma^1\gamma^2 = -i(i\sigma^3) = \sigma^3$ is diagonal in this basis, so "holomorphic" and "chirality +1" are the same statement. A **Majorana** fermion has real Grassmann components; for it the action is a sum of two decoupled chiral pieces. We look at the holomorphic piece.

The action and its conformal invariance. Nash's (11.5) is $S = \int \mathrm{d}z\mathrm{d}\bar{z}\, \psi\bar{\partial}\psi$ with an unspecified normalisation. We take

$$S_\psi = \frac{1}{2\pi}\int \mathrm{d}^2x\ \psi\,\bar{\partial}\psi. \tag{11.67}$$

Since ψ is Grassmann, $\psi\bar{\partial}\psi$ is not a total derivative (for a commuting field it would be $\frac{1}{2}\bar{\partial}(\psi^2)$). Let us check that S_ψ is invariant under any holomorphic map $z' = f(z)$ if ψ is primary of weight $(\frac{1}{2}, 0)$, that is $\psi'(z') = f'(z)^{-1/2}\psi(z)$:

$$\int \mathrm{d}^2x'\ \psi'\bar{\partial}'\psi' \overset{(1)}{=} \int |f'|^2\mathrm{d}^2x\ f'^{-1/2}\psi\ \bar{f}'^{-1}\bar{\partial}\big(f'^{-1/2}\psi\big)$$
$$\overset{(2)}{=} \int |f'|^2\mathrm{d}^2x\ f'^{-1/2}f'^{-1/2}\bar{f}'^{-1}\ \psi\bar{\partial}\psi \overset{(3)}{=} \int \mathrm{d}^2x\ \psi\,\bar{\partial}\psi.$$

(1) $\mathrm{d}^2x' = |f'|^2\mathrm{d}^2x$ (the Jacobian determinant of (11.55)); $\partial_{\bar{z}'} = (\mathrm{d}\bar{z}'/\mathrm{d}\bar{z})^{-1}\partial_{\bar{z}} = \bar{f}'^{-1}\bar{\partial}$; the transformation of ψ.
(2) f' is holomorphic, so $\bar{\partial}f'^{-1/2} = 0$ and it passes through the derivative.
(3) $|f'|^2 = f'\bar{f}'$ cancels all the factors.

The weight $\frac{1}{2}$ is forced: one $\bar{f}'$ from the measure is eaten by $\bar{\partial}$, and the remaining f' must be shared equally between two ψ's.

Worked example 11.20: The fermion propagator $\langle\psi(z)\psi(w)\rangle = 1/(z-w)$

For a Gaussian Grassmann integral with $S = \frac{1}{2}\int \psi K\psi$ and antisymmetric kernel K, the propagator is K^{-1}. Here (11.67) is $\frac{1}{2}\int \psi\,(\frac{1}{\pi}\bar{\partial})\psi$, so $K = \frac{1}{\pi}\bar{\partial}$ (antisymmetric, since integration by parts flips the sign of $\bar{\partial}$). The propagator $G(z,w) = \langle\psi(z)\psi(w)\rangle$ therefore solves

$$\frac{1}{\pi}\,\bar{\partial}_z G(z,w) = \delta^2(z-w) \quad\Longrightarrow\quad G(z,w) \overset{(1)}{=} \frac{1}{z-w},$$

(1) By (11.54), $\bar{\partial}\frac{1}{z-w} = \pi\delta^2(z-w)$; the solution is unique among functions that vanish at infinity (a bounded entire function is constant, by Liouville).

This is Nash's (11.6) with $C = 1$. Compare with (11.65): $\bar{h} = 0$ and $2h = 1$, so ψ is primary of weight $(\frac{1}{2}, 0)$, exactly the weight that made the action invariant. Consistency check: $1/(z-w)$ is antisymmetric under $z \leftrightarrow w$, as it must be for anticommuting fields (a commuting field would need a symmetric propagator). The half-integer spin shows up in the transformation law: under a rotation $f(z) = e^{i\theta}z$ we have $\psi' = e^{-i\theta/2}\psi$, and at $\theta = 2\pi$ this is $-\psi$. A fermion changes sign under a full turn.

11.3.8 Example: the free boson

Now a real scalar field $\varphi(z,\bar{z})$. Nash's (11.7) is $S = \frac{1}{4\pi}\int \mathrm{d}z\mathrm{d}\bar{z}\,\partial\varphi\bar{\partial}\varphi$. We fix the normalisation as

$$S_\varphi = \frac{1}{4\pi}\int \mathrm{d}^2x\ (\partial_\mu\varphi)^2 = \frac{1}{\pi}\int \mathrm{d}^2x\ \partial\varphi\,\bar{\partial}\varphi, \tag{11.68}$$

using $(\partial_\mu\varphi)^2 = 4\partial\varphi\bar{\partial}\varphi$ (from $\partial_1 = \partial + \bar{\partial}$, $\partial_2 = i(\partial - \bar{\partial})$). This normalisation makes the stress tensor exactly Nash's $T = -(\partial\varphi)^2$ in (11.28); see Example 11.31. The action is conformally invariant with φ of weight $(0,0)$: $\partial\varphi\,\bar{\partial}\varphi\,\mathrm{d}^2x$ picks up $f'^{-1}\bar{f}'^{-1}|f'|^2 = 1$. (In $d = 2$ a scalar is dimensionless: see Section 11.1.1.)

Worked example 11.21: The boson propagator is a logarithm

Integrate by parts: $S_\varphi = \frac{1}{2}\int \mathrm{d}^2x\,\varphi K\varphi$ with $K = -\frac{1}{2\pi}\nabla^2$. The propagator $G = \langle\varphi(x)\varphi(y)\rangle$ solves $KG = \delta^2(x-y)$:

$$-\frac{1}{2\pi}\nabla^2 G = \delta^2(x-y) \quad\Longrightarrow\quad G \overset{(1)}{=} -\ln|x-y| + \text{const} \overset{(2)}{=} -\tfrac{1}{2}\ln|z-w|^2 + \text{const}.$$

(1) Gauss's law in two dimensions: $\nabla^2 \ln r = 2\pi\delta^2(x)$.
(2) $|x-y|^2 = |z-w|^2 = (z-w)(\bar z - \bar w)$.

So

$$\langle\varphi(z,\bar z)\varphi(w,\bar w)\rangle = -\tfrac{1}{2}\ln(z-w) - \tfrac{1}{2}\ln(\bar z - \bar w) + \text{const}, \tag{11.69}$$

which is Nash's (11.8), $C\ln(z\bar z)$, with $C = -\frac{1}{2}$. The additive constant is an infrared ambiguity: the zero mode $\varphi \to \varphi+$const costs no action, so the massless propagator in 2D is defined only up to a constant (it needs an IR cutoff L: $-\ln(|x-y|/L)$).

A logarithm is not a power: $\ln(\lambda z) = \ln z + \ln\lambda$ shifts instead of scaling. So φ is *not* a primary field. As Nash says, this could have been anticipated: φ is dimensionless, so a primary φ would have $h = \bar h = 0$ and a constant two-point function, but the Laplacian needs a nonconstant Green function. The primary fields of the free boson are built from φ in two ways: by differentiating, and by exponentiating.

Worked example 11.22: $\partial\varphi$ is primary of weight $(1,0)$

Differentiate (11.69):

$$\langle\partial\varphi(z)\,\partial\varphi(w)\rangle \overset{(1)}{=} \partial_z\partial_w\left(-\tfrac{1}{2}\ln(z-w)\right) \overset{(2)}{=} \partial_z\left(\frac{1}{2(z-w)}\right) = -\frac{1}{2(z-w)^2}. \tag{11.70}$$

(1) The antiholomorphic and constant terms are killed by ∂_z.
(2) $\partial_w \ln(z-w) = -1/(z-w)$.

By (11.65) this is the two-point function of a field with $2h = 2$, $\bar h = 0$: $\partial\varphi$ has weight $(1,0)$. It is holomorphic by the equation of motion $\partial\bar\partial\varphi = 0$. It is the conserved U(1) current of the shift symmetry $\varphi \to \varphi + a$. The normalised current $J(z) := i\sqrt{2}\,\partial\varphi(z)$ has $\langle J(z)J(w)\rangle = 1/(z-w)^2$.

11.3.9 Free-field toolkit: normal ordering and Wick's theorem

For the free boson and fermion all correlation functions follow from the propagator by Wick's theorem. We will use it constantly, so let us set it up.

Working definition 11.8 (normal ordering and contraction)

For free fields, the **normal-ordered product** $:A_1\cdots A_n:$ of fields is the product with all self-contractions [propagators joining two fields inside the same product] removed; its vacuum expectation value is zero, and it is regular when two of the points coincide. The **contraction** of two fields is their propagator, e.g. the contraction of $\varphi(z)$ with $\varphi(w)$ is $\langle\varphi(z)\varphi(w)\rangle$. *Wick's theorem:* a product of normal-ordered clusters [factors such as $:\varphi(z)\varphi(z):$, each normal-ordered by itself] equals the sum over all ways of contracting pairs of fields from *different* clusters, each term being the product of the contractions times the normal-ordered product of what is left. Fermion contractions carry the sign of the

permutation needed to bring the pair together.

For example, with two clusters of two fields each,

$$:AB:(z)\,:CD:(w) = :ABCD: + \langle AC\rangle :BD: + \langle AD\rangle :BC: + \langle BC\rangle :AD: + \langle BD\rangle :AC: + \langle AC\rangle\langle BD\rangle + \langle AD\rangle\langle BC\rangle,$$

with no terms containing $\langle AB\rangle$ or $\langle CD\rangle$. We use this formula to compute $T(z)T(w)$ in Section 11.3.13.

Worked example 11.23: Vertex operators $e^{i\alpha\varphi}$ are primary with $h = \alpha^2/4$

Let $V_\alpha = :e^{i\alpha\varphi}:$. For a Gaussian variable X with $\langle X\rangle = 0$, $\langle e^X\rangle = e^{\frac{1}{2}\langle X^2\rangle}$ (complete the square). Normal ordering removes the self-contractions $\langle\varphi(z)^2\rangle$, which are infinite. So

$$\langle V_\alpha(z)V_{-\alpha}(w)\rangle \overset{(1)}{=} \exp\Big(\tfrac{1}{2}\big\langle(i\alpha\varphi(z) - i\alpha\varphi(w))^2\big\rangle\Big)\Big|_{\text{no self-contractions}} \overset{(2)}{=} \exp\big(\alpha^2\langle\varphi(z)\varphi(w)\rangle\big) \overset{(3)}{=} \exp\big(-\tfrac{\alpha^2}{2}\ln|z-w|^2\big) = \frac{1}{(z-w)^{\alpha^2/2}(\bar z-\bar w)^{\alpha^2/2}}.$$

(1) $X = i\alpha\varphi(z) - i\alpha\varphi(w)$ is Gaussian with mean zero.
(2) Expand the square, $-\alpha^2(\varphi_z^2 - 2\varphi_z\varphi_w + \varphi_w^2)$; drop the self-contractions φ_z^2, φ_w^2; the cross term gives $\frac{1}{2}\cdot 2\alpha^2\langle\varphi_z\varphi_w\rangle$.
(3) The propagator (11.69), with the constant set to zero.

Compare with (11.65): $2h = 2\bar h = \alpha^2/2$, so

$$V_\alpha = :e^{i\alpha\varphi}: \text{ has weights } (h,\bar h) = \Big(\frac{\alpha^2}{4}, \frac{\alpha^2}{4}\Big). \tag{11.71}$$

Also the charges must balance: $\langle V_\alpha V_\beta\rangle = 0$ unless $\alpha + \beta = 0$, because the shift symmetry $\varphi \to \varphi + a$ multiplies $V_\alpha V_\beta$ by $e^{i(\alpha+\beta)a}$. So a single free boson contains a continuous family of primaries with arbitrary $h \geq 0$: a theory with $c = 1$ and no bound on the number of primaries, unlike the minimal models of Section 11.4.12. We confirm $h = \alpha^2/4$ from the OPE with T in Example 11.28.

Physical picture: Coulomb gas

$\langle\prod_i V_{\alpha_i}(z_i)\rangle = \prod_{i<j}|z_i - z_j|^{\alpha_i\alpha_j}$ (for $\sum\alpha_i = 0$) is the Boltzmann weight $e^{-\beta E}$ of point charges α_i in two dimensions, where the Coulomb energy is logarithmic. The free boson is a two-dimensional electrostatics problem, and the charge neutrality condition is Gauss's law on the compact sphere.

Reading Nash (pp. 302–303, (11.4)–(11.9))

Nash defines primary fields by (11.4), identifies $h+\bar h$ as the scale dimension and $h-\bar h$ as the spin, and gives two examples. The Majorana fermion (11.5)–(11.6) has $\langle\psi(z)\psi(0)\rangle = C/z$ and is primary of weight $(\frac{1}{2},0)$; we derived $C = 1$ from the normalisation (11.67) and checked conformal invariance of the action. The boson (11.7)–(11.8) has a logarithmic propagator and is not primary; we found its primaries $\partial\varphi$ and $:e^{i\alpha\varphi}:$. Nash's (11.9) says scale invariance "alone" constrains the two-point function; in fact scale plus rotation invariance give $C/z^{h_1+h_2}\bar z^{\bar h_1+\bar h_2}$, and one needs the special conformal transformation (inversion) to force $h_1 = h_2$. His exponents $h, \bar h$ should read $2h, 2\bar h$.

11.3.10 The stress tensor in complex coordinates

Every continuous symmetry has a conserved current, and the charges built from the current generate the symmetry on the fields. For translations the current is the stress (energy–momentum) tensor $T_{\mu\nu}$. Conformal transformations are position-dependent translations, $x^\mu \mapsto x^\mu + \epsilon^\mu(x)$, so we expect the stress tensor to generate them too. This subsection sets up $T_{\mu\nu}$ with a definite normalisation, turns it into complex components, and shows that in a conformal theory it collapses to one holomorphic function $T(z)$ and one antiholomorphic function $\bar{T}(\bar{z})$.

The stress tensor as the response to a local translation. Take any field theory that is invariant under translations. Now let the translation depend on position, $\epsilon^\mu = \epsilon^\mu(x)$, with ϵ small and vanishing outside a bounded region. Each field changes by its "active" variation $\delta\phi = \phi(x) - \phi'(x)$ as in Section 11.3.5. For a scalar this is $\delta\phi = \epsilon^\mu \partial_\mu \phi$. If ϵ were constant the action would not change. So for x-dependent ϵ the change of the action can only involve derivatives of ϵ, and to first order it is linear in them.

Working definition 11.9 (stress tensor)

The **stress tensor** $T^{\mu\nu}$ is the coefficient of $\partial_\mu \epsilon_\nu$ in the change of the action under a position-dependent translation:

$$\delta S = \int \mathrm{d}^2x \; T^{\mu\nu}(x)\, \partial_\mu \epsilon_\nu(x) \qquad (\delta\phi = \epsilon^\mu \partial_\mu \phi + \dots). \tag{11.72}$$

Operational recipe: vary the action with $\delta\phi = \epsilon^\mu(x)\partial_\mu\phi$ (plus the spin terms for fields with spin [extra pieces that rotate the components of a vector or spinor field. A scalar has none]), integrate by parts until no derivative acts on anything except ϵ, and read off the coefficient. For theories with a Lorentz-invariant action it can be chosen symmetric, $T^{\mu\nu} = T^{\nu\mu}$. Setting ϵ constant inside a region shows that $\partial_\mu T^{\mu\nu} = 0$ on shell [when the fields obey their equations of motion].

Worked example 11.24: The stress tensor of the free boson

Take $S = \frac{g}{2}\int \mathrm{d}^2x\, \partial_\nu\varphi\, \partial_\nu\varphi$ with $g = \frac{1}{2\pi}$, which is (11.68). With $\delta\varphi = \epsilon^\mu\partial_\mu\varphi$,

$$\begin{aligned}
\delta S &\overset{(1)}{=} g \int \mathrm{d}^2x \; \partial_\nu\varphi\, \partial_\nu\big(\epsilon^\mu \partial_\mu\varphi\big) \\
&\overset{(2)}{=} g \int \mathrm{d}^2x \; \Big[(\partial_\nu\epsilon^\mu)\,\partial_\nu\varphi\,\partial_\mu\varphi + \epsilon^\mu\, \tfrac{1}{2}\partial_\mu\big(\partial_\nu\varphi\,\partial_\nu\varphi\big)\Big] \\
&\overset{(3)}{=} g \int \mathrm{d}^2x \; (\partial_\nu\epsilon^\mu)\Big[\partial_\nu\varphi\,\partial_\mu\varphi - \tfrac{1}{2}\delta_{\mu\nu}(\partial\varphi)^2\Big].
\end{aligned}$$

(1) Vary the two factors; they give equal contributions, cancelling the $\frac{1}{2}$.

(2) Product rule; in the second term $\partial_\nu\varphi\,\partial_\nu\partial_\mu\varphi = \frac{1}{2}\partial_\mu(\partial\varphi)^2$.

(3) Integrate the second term by parts (ϵ vanishes far away): $\int \epsilon^\mu \partial_\mu X = -\int(\partial_\mu\epsilon^\mu)X = -\int(\partial_\nu\epsilon^\mu)\delta_{\mu\nu}X$.

So $T_{\mu\nu} = g\big(\partial_\mu\varphi\,\partial_\nu\varphi - \frac{1}{2}\delta_{\mu\nu}(\partial\varphi)^2\big)$, the tensor of Example 11.8, symmetric and traceless in two dimensions.

Watch out: the sign of δS

In (11.16) we wrote $\delta S = -\int T^{\mu\nu}\partial_\mu \epsilon_\nu$. That was for the passive shift $\phi'(x) = \phi(x-\epsilon)$. Here we use the active variation $\delta\phi = \phi(x) - \phi'(x)$, which flips the sign of ϵ. Both give the same $T^{\mu\nu}$. The conclusion of (11.16), that a traceless T means invariance under all conformal maps, is insensitive to the sign.

Tracelessness. In a conformal theory $\delta S = 0$ for every conformal ϵ. By (11.16) this means $\int T^\mu{}_\mu\, \partial\cdot\epsilon = 0$ for all conformal ϵ. In two dimensions $\partial\cdot\epsilon$ for a holomorphic ϵ is $2\,\mathrm{Re}\,\epsilon'(z)$, which can be any harmonic function; that is enough freedom to conclude that $T^\mu{}_\mu$ vanishes (up to contact terms at the positions of other operators). So

$$T_{11} + T_{22} = 0, \tag{11.73}$$

which is Nash's (11.11). A symmetric traceless 2×2 tensor has only two independent components, for example $T_{11} = -T_{22}$ and T_{12}.

Complex components. As in Section 11.3.1, T_{ab} with $a, b \in \{z, \bar z\}$ is obtained by the chain rule with $\partial x_1/\partial z = \frac12$, $\partial x_2/\partial z = \frac{1}{2i} = -\frac{i}{2}$, $\partial x_1/\partial\bar z = \frac12$, $\partial x_2/\partial\bar z = \frac{i}{2}$:

$$\begin{aligned} T_{zz} &\overset{(1)}{=} \left(\tfrac12\right)^2 T_{11} + 2\cdot\tfrac12\cdot\left(-\tfrac{i}{2}\right)T_{12} + \left(-\tfrac{i}{2}\right)^2 T_{22} = \tfrac14\big(T_{11} - T_{22} - 2iT_{12}\big), \\ T_{\bar z\bar z} &\overset{(2)}{=} \tfrac14\big(T_{11} - T_{22} + 2iT_{12}\big), \\ T_{z\bar z} = T_{\bar z z} &\overset{(3)}{=} \tfrac12\cdot\tfrac12\, T_{11} + \tfrac12\cdot\tfrac{i}{2}\, T_{12} - \tfrac{i}{2}\cdot\tfrac12\, T_{21} - \tfrac{i}{2}\cdot\tfrac{i}{2}\, T_{22} = \tfrac14\big(T_{11} + T_{22}\big) = 0. \end{aligned} \tag{11.74}$$

(1) $T_{zz} = \frac{\partial x^\mu}{\partial z}\frac{\partial x^\nu}{\partial z} T_{\mu\nu}$; the two cross terms T_{12} and T_{21} are equal.
(2) Same computation with $\partial x_2/\partial\bar z = +\frac{i}{2}$ (complex conjugate coefficients).
(3) One index z, one index $\bar z$; the T_{12} terms cancel, $-\frac{i}{2}\cdot\frac{i}{2} = +\frac14$, and we use (11.73).

Watch out: a factor $\frac14$ in Nash's (11.12)

Nash writes $T_{zz} = T_{11} - T_{22} - 2iT_{12}$ and $T_{z\bar z} = T_{11} + T_{22}$, without the $\frac14$. This only rescales T, and Nash never uses the absolute normalisation of T_{zz}: he fixes the normalisation of $T(z)$ later, through the OPE (11.25). But if you check his formulas against a Lagrangian, you need the $\frac14$.

Conservation makes T_{zz} holomorphic. Raise the index with $g^{z\bar z} = g^{\bar z z} = 2$ and $g^{zz} = g^{\bar z\bar z} = 0$ (Section 11.3.1). The z component of the conservation law $\partial^\mu T_{\mu\nu} = 0$ reads

$$0 = g^{\mu\rho}\partial_\rho T_{\mu z} \overset{(1)}{=} g^{z\bar z}\partial_{\bar z} T_{zz} + g^{\bar z z}\partial_z T_{\bar z z} \overset{(2)}{=} 2\,\bar\partial T_{zz}, \tag{11.75}$$

(1) Only the off-diagonal inverse metric components are nonzero.
(2) $T_{\bar z z} = 0$ by tracelessness (11.74).

and similarly the $\bar z$ component gives $\partial T_{\bar z\bar z} = 0$. This is Nash's (11.13). So T_{zz} depends on z only and $T_{\bar z\bar z}$ on $\bar z$ only (away from other operator insertions).

Working definition 11.10 (the holomorphic stress tensor)

Define

$$T(z) := -2\pi\, T_{zz}(z), \qquad \bar{T}(\bar{z}) := -2\pi\, T_{\bar{z}\bar{z}}(\bar{z}). \tag{11.76}$$

Nash's (11.14) sets $T = T_{zz}$; the factor -2π is the standard choice that makes the Ward identity (11.83) [a contour integral of $f(w)T(w)$ around the fields gives their change under $z \mapsto z + \epsilon f(z)$] and the OPE (11.87) come out without stray constants. It is what Nash's formulas implicitly assume: with it, the free boson has $T = -(\partial\varphi)^2$, exactly his (11.28). *Operational test:* $T(z)$ is correctly normalised if its OPE with any primary field [a field for which $\phi\, \mathrm{d}z^h \mathrm{d}\bar{z}^{\bar{h}}$ is invariant] has the leading term $h\phi/(w-z)^2$ with the weight h read off from the two-point function.

Worked example 11.25: $T(z)$ for the free boson and the free fermion

Boson. From Example 11.24,

$$T_{zz} \overset{(1)}{=} \tfrac{g}{4}\left[(\partial_1\varphi)^2 - (\partial_2\varphi)^2 - 2i\,\partial_1\varphi\,\partial_2\varphi\right] \overset{(2)}{=} \tfrac{g}{4}\left(\partial_1\varphi - i\partial_2\varphi\right)^2 \overset{(3)}{=} g\,(\partial\varphi)^2,$$

(1) (11.74); the $\delta_{\mu\nu}$ term drops out of $T_{11} - T_{22}$ and does not contribute to T_{12}.
(2) The bracket is a perfect square.
(3) $\partial_1 - i\partial_2 = 2\partial$ by (11.51).

With $g = \frac{1}{2\pi}$ we get $T(z) = -2\pi\cdot\frac{1}{2\pi}(\partial\varphi)^2 = -(\partial\varphi)^2$, and in the quantum theory $T = -{:}\partial\varphi\,\partial\varphi{:}$. The classical equation of motion $\partial\bar{\partial}\varphi = 0$ shows directly that $\bar{\partial}T = -2\,\partial\varphi\,\partial\bar{\partial}\varphi = 0$.

Fermion. For $S_\psi = \frac{1}{2\pi}\int \mathrm{d}^2x\,\psi\bar{\partial}\psi$ it is quickest to vary with a purely holomorphic-index translation $\epsilon^z(z,\bar{z})$, $\epsilon^{\bar{z}} = 0$, under which the weight-$\frac{1}{2}$ field changes by $\delta\psi = \epsilon^z\partial\psi + \frac{1}{2}(\partial\epsilon^z)\psi$. The general formula (11.72) with a symmetric traceless T becomes, for such ϵ (lower the index: $\epsilon_{\bar{z}} = g_{\bar{z}z}\epsilon^z = \frac{1}{2}\epsilon^z$, and $T^{\bar{z}\bar{z}} = 4T_{zz}$),

$$\delta S = \int \mathrm{d}^2x\; T^{\bar{z}\bar{z}}\,\partial_{\bar{z}}\epsilon_{\bar{z}} = 2\int \mathrm{d}^2x\; T_{zz}\,\bar{\partial}\epsilon^z = -\frac{1}{\pi}\int \mathrm{d}^2x\; T(z)\,\bar{\partial}\epsilon^z. \tag{11.77}$$

Now compute δS_ψ directly:

$$\begin{aligned}
\delta S_\psi &\overset{(1)}{=} \frac{1}{\pi}\int \mathrm{d}^2x\;\delta\psi\,\bar{\partial}\psi \overset{(2)}{=} \frac{1}{\pi}\int \mathrm{d}^2x\,\Big(\epsilon\,\partial\psi + \tfrac{1}{2}(\partial\epsilon)\psi\Big)\bar{\partial}\psi \\
&\overset{(3)}{=} \frac{1}{\pi}\int \mathrm{d}^2x\;\epsilon\Big(\tfrac{1}{2}\partial\psi\,\bar{\partial}\psi - \tfrac{1}{2}\psi\,\partial\bar{\partial}\psi\Big) \overset{(4)}{=} \frac{1}{\pi}\int \mathrm{d}^2x\;\epsilon\Big(-\tfrac{1}{2}\bar{\partial}(\psi\,\partial\psi)\Big) \\
&\overset{(5)}{=} \frac{1}{2\pi}\int \mathrm{d}^2x\;(\bar{\partial}\epsilon)\,\psi\,\partial\psi.
\end{aligned}$$

(1) $\delta(\psi\bar{\partial}\psi) = \delta\psi\,\bar{\partial}\psi + \psi\,\bar{\partial}\delta\psi$; integrating the second term by parts and anticommuting the two Grassmann factors gives $+\delta\psi\,\bar{\partial}\psi$ again.
(2) Insert $\delta\psi$ (we write ϵ for ϵ^z).
(3) Integrate the $\partial\epsilon$ term by parts: $\frac{1}{2}(\partial\epsilon)\psi\bar{\partial}\psi \to -\frac{1}{2}\epsilon(\partial\psi\,\bar{\partial}\psi + \psi\,\partial\bar{\partial}\psi)$; combine with the first term.
(4) $\bar{\partial}(\psi\partial\psi) = \bar{\partial}\psi\,\partial\psi + \psi\,\partial\bar{\partial}\psi = -\partial\psi\,\bar{\partial}\psi + \psi\,\partial\bar{\partial}\psi$ (Grassmann sign), so the bracket is $-\frac{1}{2}\bar{\partial}(\psi\partial\psi)$.
(5) Integrate by parts once more.

Comparing with (11.77): $-\frac{1}{\pi}T = \frac{1}{2\pi}\psi\partial\psi$, so

$$T_\psi(z) = -\tfrac{1}{2}\,{:}\psi\,\partial\psi{:}(z), \qquad T_\varphi(z) = -{:}\partial\varphi\,\partial\varphi{:}(z). \tag{11.78}$$

(The same shortcut, applied to the boson with $\delta\varphi = \epsilon^z\partial\varphi$, gives $\delta S_\varphi = \frac{1}{\pi}\int(\bar\partial\epsilon)(\partial\varphi)^2$, hence again $T = -(\partial\varphi)^2$.)

11.3.11 The conformal Ward identity

We now derive the statement that T generates conformal transformations. The tool is the simplest fact about path integrals: renaming the integration variable does not change the integral.

Ward identities from a change of variables. Let $X = \phi_1(x_1)\cdots\phi_n(x_n)$, with path-integral average

$$\langle X\rangle = \frac{1}{Z}\int \mathcal{D}\phi\, X\, e^{-S[\phi]}.$$

Substitute $\phi = \tilde\phi + \delta\tilde\phi$, where δ is a transformation with a position-dependent parameter, and assume the measure is invariant ($\mathcal{D}\phi = \mathcal{D}\tilde\phi$; for conformal transformations this is where the central charge will eventually hide, but the Ward identity for T is unaffected). Then

$$\int \mathcal{D}\phi\; X[\phi]\, e^{-S[\phi]} \overset{(1)}{=} \int \mathcal{D}\tilde\phi\; X[\tilde\phi+\delta\tilde\phi]\, e^{-S[\tilde\phi+\delta\tilde\phi]} \overset{(2)}{=} \int \mathcal{D}\tilde\phi\; \big(X+\delta X\big)\big(1-\delta S\big)e^{-S}.$$

(1) Change of integration variable; the Jacobian is 1 by assumption.
(2) Expand to first order in the transformation.

The left side is the same as the zeroth-order term on the right, so the first-order terms must cancel:

$$\langle\delta X\rangle = \langle\delta S\; X\rangle, \qquad \delta X = \sum_{i=1}^{n}\phi_1(x_1)\cdots\delta\phi_i(x_i)\cdots\phi_n(x_n). \tag{11.79}$$

With (11.72) this is

$$\sum_i\langle\phi_1(x_1)\cdots\delta\phi_i(x_i)\cdots\phi_n(x_n)\rangle = \int \mathrm{d}^2x\;\partial_\mu\epsilon_\nu(x)\,\langle T^{\mu\nu}(x)\,\phi_1(x_1)\cdots\phi_n(x_n)\rangle. \tag{11.80}$$

Cutting off the transformation: Nash's (11.16). Now choose the transformation to be a genuine conformal map inside a region R that contains all the points x_i, and to be switched off outside: $\epsilon^\nu(x) = \epsilon f^\nu(x)\,\theta_R(x)$, where θ_R is 1 on R and 0 outside. Then $\partial_\mu\epsilon_\nu = \epsilon\,\theta_R\,\partial_\mu f_\nu + \epsilon f_\nu\,\partial_\mu\theta_R$, and $\partial_\mu\theta_R = -n_\mu\,\delta_{\partial R}$ is a delta function on the boundary with the outward normal n_μ. So (11.80) splits into a bulk and a boundary term:

$$\sum_i\langle\cdots\delta\phi_i\cdots\rangle = \epsilon\int_R \mathrm{d}^2x\;\partial^\mu f^\nu\,\langle T_{\mu\nu}\,X\rangle - \epsilon\oint_{\partial R}\mathrm{d}l\;n^\mu f^\nu\,\langle T_{\mu\nu}\,X\rangle. \tag{11.81}$$

Nash writes the boundary term as $\int_{\partial R}\mathrm{d}l_\mu\,\epsilon^{\mu\nu}\langle T_{\nu\sigma}X\rangle f^\sigma$ with the permutation symbol: for a boundary traversed counterclockwise, the outward normal times $\mathrm{d}l$ is the tangent rotated by $90°$, $n_\mu\mathrm{d}l = \epsilon_{\mu\nu}\mathrm{d}x^\nu$. Up to the sign, which depends on orientation conventions, this is (11.16).

If f is conformal, the bulk term vanishes: T is symmetric, so only the symmetric part of $\partial^\mu f^\nu$ contributes; by the conformal Killing equation (11.10) that part is $\frac{1}{2}(\partial\cdot f)\delta^{\mu\nu}$; and T is traceless. Only the boundary term survives. Nash says exactly this after (11.17).

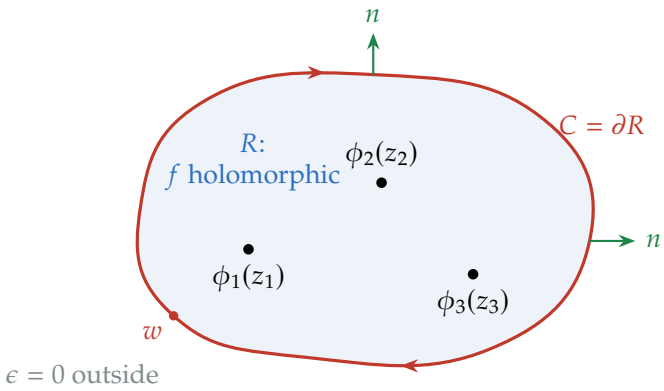

Figure 11.12: The geometry of the Ward identity. Inside R we perform the conformal transformation $z \mapsto z + \epsilon f(z)$; outside R we do nothing. The change of the fields at the insertion points (black) is balanced by the "flux" of the stress tensor through the edge C where the transformation is switched off. Since $T(w)$ is holomorphic away from the insertions, the contour C can be moved freely as long as it does not cross an insertion.

The boundary term in complex form: Nash's (11.17)–(11.18). Rather than convert $n^\mu f^\nu T_{\mu\nu}$ by brute force, go back to (11.77), which (together with its antiholomorphic partner) is (11.72) for a symmetric traceless T: $\delta S = -\frac{1}{\pi}\int \mathrm{d}^2x \left(T\,\bar\partial\epsilon^z + \bar T\,\partial\epsilon^{\bar z}\right)$. Take $\epsilon^z = \epsilon f(z)\theta_R$ with f holomorphic on and near R. We need one formula: for a function g that is smooth near ∂R,

$$\int \mathrm{d}^2x\; g\,\bar\partial\theta_R = -\frac{1}{2i}\oint_{\partial R} g\,\mathrm{d}z, \qquad \int \mathrm{d}^2x\; g\,\partial\theta_R = +\frac{1}{2i}\oint_{\partial R} g\,\mathrm{d}\bar z. \tag{11.82}$$

This follows by moving the derivative onto g (minus sign) and applying the complex Stokes formula $\int_R \mathrm{d}^2x\,\bar\partial F = \frac{1}{2i}\oint_{\partial R} F\mathrm{d}z$ of Example 11.14; for the second, $\mathrm{d}(F\mathrm{d}\bar z) = \partial F\,\mathrm{d}z\wedge\mathrm{d}\bar z = -2i\,\partial F\,\mathrm{d}^2x$ gives $\int_R \mathrm{d}^2x\,\partial F = -\frac{1}{2i}\oint F\mathrm{d}\bar z$. So, for the holomorphic half,

$$\delta S \overset{(1)}{=} -\frac{\epsilon}{\pi}\int \mathrm{d}^2x\; T(w)\,f(w)\,\bar\partial\theta_R \overset{(2)}{=} -\frac{\epsilon}{\pi}\left(-\frac{1}{2i}\right)\oint_{\partial R}\mathrm{d}w\; f(w)\,T(w) = \frac{\epsilon}{2\pi i}\oint_C \mathrm{d}w\; f(w)\,T(w),$$

(1) $\bar\partial(f\theta_R) = f\,\bar\partial\theta_R$ because f is holomorphic.
(2) (11.82) with $g = fT$; T is smooth near the boundary because no operators sit there.

and the antiholomorphic half gives $-\frac{\epsilon}{2\pi i}\oint_C \mathrm{d}\bar w\,\bar f(\bar w)\bar T(\bar w)$, with $C = \partial R$ counterclockwise. Inserting into (11.79):

$$\boxed{\sum_i \langle\cdots\delta\phi_i(z_i,\bar z_i)\cdots\rangle = \frac{\epsilon}{2\pi i}\oint_C \mathrm{d}w\, f(w)\,\langle T(w)\,X\rangle - \frac{\epsilon}{2\pi i}\oint_C \mathrm{d}\bar w\,\bar f(\bar w)\,\langle\bar T(\bar w)\,X\rangle} \tag{11.83}$$

This is Nash's (11.18).

Watch out: the orientation of the $\mathrm{d}\bar w$ integral

Nash writes both terms of (11.18) with a plus sign. The two versions agree: for an antiholomorphic integrand the counterclockwise integral $\oint \mathrm{d}\bar w/(\bar w - \bar z)$ equals $-2\pi i$ (take the complex conjugate of $\oint \mathrm{d}w/(w-z) = 2\pi i$). So "$-\oint_{\text{ccw}}\mathrm{d}\bar w$" is the same as "$+\oint$ with the residue in $\bar w$ counted positively", which is what Nash means. In practice: *evaluate the $\bar w$ contour by taking the residue in $\bar w$ with a plus sign*, exactly as for w.

From correlators to an operator statement: Nash's (11.19). The integrand $\langle T(w)X\rangle$ is holomorphic in w except at the insertion points z_i. By Cauchy's theorem the contour C around all the points can be shrunk to a sum of small circles C_i, one around each z_i (Figure 11.13). The variation on the left is also a sum over i. Since the points are arbitrary, the equality must hold term by term: the small circle around z_i gives $\delta\phi_i$. Dropping the other fields, which are spectators, we get an *operator* identity for the holomorphic part $\delta^h\phi$ of the variation:

$$\delta^h\phi(z,\bar z) = \frac{\epsilon}{2\pi i}\oint_z \mathrm{d}w\; f(w)\,T(w)\,\phi(z,\bar z), \tag{11.84}$$

the contour now being a small circle around z. This is Nash's (11.19). It is the precise meaning of "T generates conformal transformations": the conserved charge $Q_f = \frac{1}{2\pi i}\oint f(w)T(w)\mathrm{d}w$ acts on a field by circling it.

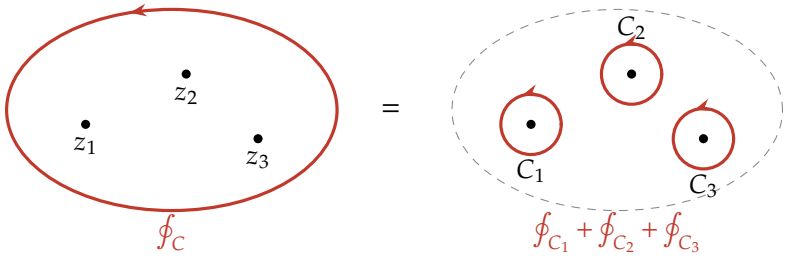

Figure 11.13: Contour deformation. The integrand $f(w)\langle T(w)X\rangle$ is holomorphic except at the insertion points. The big contour (left) can be shrunk until it hugs each point separately (right); in between, the integrand has no singularities, so nothing changes. Each small circle C_i computes the variation of the one field it encloses, and this is how the global identity (11.83) becomes the local operator statement (11.84).

11.3.12 The operator product of T with a primary field

We now have two expressions for the change of a primary field under $z \mapsto z + \epsilon f(z)$. One is the transformation law (11.63), $\delta^h\phi = \epsilon(hf'\phi + f\partial\phi)$ (Nash's (11.20)). The other is the contour integral (11.84). Equating them (Nash's (11.21)):

$$h\,f'(z)\,\phi(z,\bar z) + f(z)\,\partial\phi(z,\bar z) = \frac{1}{2\pi i}\oint_z \mathrm{d}w\; f(w)\,T(w)\,\phi(z,\bar z) \qquad \text{for every holomorphic } f. \tag{11.85}$$

Since f is arbitrary, this determines the singular part of the product $T(w)\phi(z)$. Nash's way of extracting it is to expand everything in powers of $w - z$.

The expansions (Nash's (11.22)). Expand f about z and the product $T(w)\phi(z)$ in a Laurent series about $w = z$, with operator-valued coefficients:

$$f(w) = \sum_{k\ge 0} \hat f_k(z)\,(w-z)^k, \qquad \hat f_k(z) = \frac{f^{(k)}(z)}{k!},$$

$$T(w)\phi(z,\bar z) = \sum_{n\in\mathbb{Z}} \frac{T_n(\phi)(z,\bar z)}{(w-z)^{n+2}} = \cdots + \frac{T_2(\phi)}{(w-z)^4} + \frac{T_1(\phi)}{(w-z)^3} + \frac{T_0(\phi)}{(w-z)^2} + \frac{T_{-1}(\phi)}{w-z} + T_{-2}(\phi) + \cdots$$

We label the coefficient of $(w-z)^{-n-2}$ by $T_n(\phi)$; this is the labelling of the Virasoro modes in §3, where $T_n(\phi)$ becomes $L_n\phi$.

Watch out: Nash's labels in (11.22)

Nash's (11.22) writes the coefficients of $(w-z)^{-2}$ and $(w-z)^{-1}$ as $T_{-2}(\phi)$ and $T_{-1}(\phi)$, and in (11.24) concludes $T_{-1}(\phi)=\partial\phi$, $T_{-2}(\phi)=h\phi$, $T_{-3}=T_{-4}=\cdots=0$. That is a different (and not quite consistent) labelling: in his (11.23) the index runs so that T_{-k-1} multiplies $\hat{f}_k$. We keep the §3 labelling throughout, in which the same results read $T_{-1}(\phi)=\partial\phi$, $T_0(\phi)=h\phi$ and $T_n(\phi)=0$ for $n\geq 1$. The content is identical.

Matching coefficients (Nash's (11.23)–(11.24)). Insert the expansions into the right side of (11.85). The residue theorem, $\frac{1}{2\pi i}\oint_z \mathrm{d}w\,(w-z)^m=\delta_{m,-1}$, picks out the terms where the total power of $(w-z)$ is -1:

$$\frac{1}{2\pi i}\oint_z \mathrm{d}w\, f(w)T(w)\phi(z) \overset{(1)}{=} \sum_{k\geq 0}\sum_{n} \hat{f}_k(z)\,T_n(\phi)\,\frac{1}{2\pi i}\oint_z \mathrm{d}w\,(w-z)^{k-n-2}$$
$$\overset{(2)}{=} \sum_{k\geq 0}\hat{f}_k(z)\,T_{k-1}(\phi)=\hat{f}_0\,T_{-1}(\phi)+\hat{f}_1\,T_0(\phi)+\hat{f}_2\,T_1(\phi)+\hat{f}_3\,T_2(\phi)+\cdots$$

(1) Multiply the two series and integrate term by term.
(2) The integral is 1 exactly when $k-n-2=-1$, i.e. $n=k-1$.

The left side of (11.85) is $\hat{f}_0\,\partial\phi+h\,\hat{f}_1\,\phi$, since $\hat{f}_0=f(z)$ and $\hat{f}_1=f'(z)$. At a fixed point z the numbers $\hat{f}_0,\hat{f}_1,\hat{f}_2,\ldots$ can be chosen independently (take $f(w)=(w-z)^k$ for one k at a time). Comparing coefficients:

$$T_{-1}(\phi)=\partial\phi,\qquad T_0(\phi)=h\,\phi,\qquad T_1(\phi)=T_2(\phi)=\cdots=0. \tag{11.86}$$

Nash does the matching at $z=0$, where $\hat{f}_k(0)=f_k$ are the Taylor coefficients of f; the result is the same at any z.

Key idea: the $T\phi$ OPE is the conformal Ward identity

For a primary field ϕ of weights $(h,\bar{h})$,

$$\begin{aligned} T(w)\,\phi(z,\bar{z}) &= \frac{h\,\phi(z,\bar{z})}{(w-z)^2}+\frac{\partial\phi(z,\bar{z})}{w-z}+\text{regular},\\ \bar{T}(\bar{w})\,\phi(z,\bar{z}) &= \frac{\bar{h}\,\phi(z,\bar{z})}{(\bar{w}-\bar{z})^2}+\frac{\bar{\partial}\phi(z,\bar{z})}{\bar{w}-\bar{z}}+\text{regular}. \end{aligned} \tag{11.87}$$

These are Nash's (11.25)–(11.27). The double pole carries the weight, the simple pole carries the derivative (the translation), and nothing more singular appears. Conversely, if a field has this OPE with T, then it is primary. The OPE is shorthand: the symbol $\sim$ ("equal up to regular terms") is often used, and all OPEs are understood inside correlation functions with other fields placed away from z.

The regular term $R(w-z)$ of Nash's (11.25)–(11.26) contains $T_{-2}(\phi)$, $T_{-3}(\phi)$, and so on. These are new fields: the descendants of §3. They are not fixed by the Ward identity, which only involves the singular part.

Worked example 11.26: Checking the Ward normalisation on the free boson

The boson φ has weight 0 but is not primary, so the check is to compute $T(w)\varphi(z)$ with $T=-{:}\partial\varphi\,\partial\varphi{:}$ and compare with $\delta\varphi=\epsilon f\partial\varphi$. Wick's theorem (Section 11.3.9) needs the

contraction

$$\langle \partial\varphi(w)\,\varphi(z)\rangle = \partial_w\big(-\tfrac{1}{2}\ln(w-z)\big) = -\frac{1}{2(w-z)}.$$

There is one field $\varphi(z)$ to contract, with either of the two $\partial\varphi(w)$:

$$T(w)\varphi(z) \overset{(1)}{=} -2\,\langle\partial\varphi(w)\varphi(z)\rangle\,\partial\varphi(w) + :\cdots: \overset{(2)}{=} \frac{\partial\varphi(w)}{w-z} + \text{reg.} \overset{(3)}{=} \frac{\partial\varphi(z)}{w-z} + \text{reg.}$$

(1) Two equivalent contractions; the leftover normal-ordered term is regular.
(2) Insert the contraction: $-2\cdot(-\frac{1}{2}) = 1$.
(3) Taylor expand $\partial\varphi(w) = \partial\varphi(z) + (w-z)\partial^2\varphi(z) + \cdots$; only the first term is singular.

There is no double pole, consistent with $h = 0$. Then (11.84) gives $\delta\varphi = \frac{\epsilon}{2\pi i}\oint \mathrm{d}w\, f(w)\frac{\partial\varphi(z)}{w-z} = \epsilon f(z)\partial\varphi(z)$, exactly the change of a scalar. The factor -2π in (11.76) is doing its job: with Nash's literal $T = T_{zz}$ we would have found $\delta\varphi = -\frac{1}{2\pi}\,\epsilon f\partial\varphi$.
Why is φ not primary, then? Because φ is not a well-defined local operator in the first place (its two-point function has the infrared constant), and the higher Ward identities with other fields detect this. The fields built from it, $\partial\varphi$ and $:e^{i\alpha\varphi}:$, are primary, as we now check.

Worked example 11.27: $T(w)\,\partial\varphi(z)$: a weight-one primary

Now the contraction is $\langle\partial\varphi(w)\partial\varphi(z)\rangle = -\frac{1}{2(w-z)^2}$, from (11.70).

$$T(w)\,\partial\varphi(z) \overset{(1)}{=} -2\,\langle\partial\varphi(w)\partial\varphi(z)\rangle\,\partial\varphi(w) + \text{reg.} \overset{(2)}{=} \frac{\partial\varphi(w)}{(w-z)^2} + \text{reg.}$$
$$\overset{(3)}{=} \frac{\partial\varphi(z)}{(w-z)^2} + \frac{\partial^2\varphi(z)}{w-z} + \text{reg.}$$

(1) Two ways to contract, as before.
(2) $-2\cdot(-\frac{1}{2}) = 1$.
(3) Taylor expand $\partial\varphi(w)$ to first order; the second-order term is regular.

This is (11.87) with $h = 1$ and $\phi = \partial\varphi$, confirming the weight $(1,0)$ found from the two-point function in Example 11.22.

Worked example 11.28: $T(w)\,V_\alpha(z)$: the vertex operator has $h = \alpha^2/4$

Let $V_\alpha = :e^{i\alpha\varphi}:$. Contract $\partial\varphi(w)$ with $\varphi(z)$ in the exponent: each contraction brings down a factor $i\alpha\langle\partial\varphi(w)\varphi(z)\rangle = -\frac{i\alpha}{2(w-z)}$ (think of $e^{i\alpha\varphi}$ as its power series; contracting one of the n factors of φ in $\varphi^n/n!$ leaves $\varphi^{n-1}/(n-1)!$, which resums to the exponential). T contains two $\partial\varphi$'s, so there are single and double contractions:

$$T(w)V_\alpha(z) \overset{(1)}{=} -\Big(-\frac{i\alpha}{2(w-z)}\Big)^2 V_\alpha(z) - 2\Big(-\frac{i\alpha}{2(w-z)}\Big):\partial\varphi(w)V_\alpha(z):$$
$$\overset{(2)}{=} \frac{\alpha^2/4}{(w-z)^2}\,V_\alpha(z) + \frac{i\alpha\,:\partial\varphi\,V_\alpha:(z)}{w-z} + \text{reg.} \overset{(3)}{=} \frac{\alpha^2/4}{(w-z)^2}\,V_\alpha(z) + \frac{\partial V_\alpha(z)}{w-z} + \text{reg.}$$

(1) Double contraction (both $\partial\varphi(w)$'s with the exponent) and single contraction (one of the two).
(2) $-(-i\alpha/2)^2 = -(-\alpha^2/4) = \alpha^2/4$ and $-2(-i\alpha/2) = i\alpha$; replace $\partial\varphi(w)$ by $\partial\varphi(z)$ in the singular term.
(3) $\partial V_\alpha = :i\alpha\,\partial\varphi\,e^{i\alpha\varphi}:$ by the chain rule.

So V_α is primary with $h = \alpha^2/4$ (and $\bar{h} = \alpha^2/4$ from $\bar{T}$), agreeing with the two-point function (11.71). Two independent methods, one answer: the normalisation of T is right.

Worked example 11.29: $T(w)\,\psi(z)$: the fermion has $h = \frac{1}{2}$

With $T = -\frac{1}{2}{:}\psi\partial\psi{:}$ and $\langle\psi(w)\psi(z)\rangle = \frac{1}{w-z}$, the two contractions of $\psi(z)$ with the factors of $T(w)$ are $\langle\psi(w)\psi(z)\rangle = \frac{1}{w-z}$ and $\langle\partial\psi(w)\psi(z)\rangle = -\frac{1}{(w-z)^2}$. Bringing $\psi(z)$ next to the field it contracts with costs a sign when it passes an odd number of fermions:

$$T(w)\psi(z) \overset{(1)}{=} -\tfrac{1}{2}\Big[-\langle\psi(w)\psi(z)\rangle\,\partial\psi(w) + \psi(w)\,\langle\partial\psi(w)\psi(z)\rangle\Big]$$
$$\overset{(2)}{=} \frac{\partial\psi(w)}{2(w-z)} + \frac{\psi(w)}{2(w-z)^2} \overset{(3)}{=} \frac{\frac{1}{2}\psi(z)}{(w-z)^2} + \frac{\partial\psi(z)}{w-z} + \text{reg.}$$

(1) In $\psi(w)\partial\psi(w)\psi(z)$, contracting $\psi(w)$ with $\psi(z)$ requires moving $\psi(z)$ past $\partial\psi(w)$: one sign. Contracting $\partial\psi(w)$ with $\psi(z)$ needs no move.
(2) Insert the contractions: $-\frac{1}{2}(-1) = \frac{1}{2}$ and $-\frac{1}{2}\cdot(-1) = \frac{1}{2}$.
(3) Expand $\psi(w) = \psi(z) + (w-z)\partial\psi(z) + \cdots$ in the double pole: it contributes $\frac{1}{2}\psi/(w-z)^2 + \frac{1}{2}\partial\psi/(w-z)$; add the other $\frac{1}{2}\partial\psi/(w-z)$.

So ψ is primary with $h = \frac{1}{2}$, as the propagator said (Example 11.20).

The Ward identity for correlation functions. Combining (11.83) with the OPE gives the most useful form of the Ward identity. The function $w \mapsto \langle T(w)\phi_1(z_1)\cdots\phi_n(z_n)\rangle$ is meromorphic, with poles only at the z_i given by the OPE, and (as we show in Section 11.4.13) it decays like w^{-4} at infinity. A meromorphic function on the sphere is fixed by its poles, so

$$\langle T(w)\,\phi_1(z_1)\cdots\phi_n(z_n)\rangle = \sum_{i=1}^{n}\Big(\frac{h_i}{(w-z_i)^2} + \frac{1}{w-z_i}\,\frac{\partial}{\partial z_i}\Big)\langle\phi_1(z_1)\cdots\phi_n(z_n)\rangle. \tag{11.88}$$

Worked example 11.30: The Ward identity on a two-point function

Take $G = \langle\phi(z_1)\phi(z_2)\rangle = z_{12}^{-2h}$ (suppressing the $\bar{z}$ dependence). Then $\partial_1 G = -2hG/z_{12}$ and $\partial_2 G = +2hG/z_{12}$. Write $a = w - z_1$, $b = w - z_2$, so $b - a = z_{12}$.

$$\langle T(w)\phi(z_1)\phi(z_2)\rangle \overset{(1)}{=} hG\Big[\frac{1}{a^2} + \frac{1}{b^2} - \frac{2}{z_{12}\,a} + \frac{2}{z_{12}\,b}\Big] \overset{(2)}{=} hG\Big[\frac{1}{a^2} + \frac{1}{b^2} - \frac{2}{ab}\Big]$$
$$\overset{(3)}{=} hG\Big(\frac{b-a}{ab}\Big)^2 = \frac{h\,z_{12}^{2-2h}}{(w-z_1)^2(w-z_2)^2}.$$

(1) (11.88) with the derivatives just computed.
(2) $\frac{1}{b} - \frac{1}{a} = \frac{a-b}{ab} = -\frac{z_{12}}{ab}$, so the last two terms are $\frac{2}{z_{12}}\cdot\big(-\frac{z_{12}}{ab}\big) = -\frac{2}{ab}$.
(3) A perfect square.

Three checks: the result has double poles at z_1 and z_2 with residue structure dictated by the OPE; it falls off like w^{-4} as $w \to \infty$ (the w^{-2} and w^{-3} terms have cancelled, which is precisely the statement that G is invariant under L_{-1}, L_0, L_1); and it vanishes if $h = 0$. For the free fermion ($h = \frac{1}{2}$, $G = 1/z_{12}$) one can verify it independently by Wick's theorem.

11.3.13 The operator product $T(w)T(z)$ and the central charge

The stress tensor is itself a field of the theory. Its holomorphic part $T(z)$ has, by the scaling argument, weight $(2,0)$: it is a component of a tensor with two lower z indices. Is it primary? Let us compute its OPE with itself in the free boson.

Worked example 11.31: The TT OPE of the free boson: $c = 1$

Let $T = -{:}\partial\varphi\,\partial\varphi{:}$ and write $u = w - z$ and $\langle\partial\varphi(w)\partial\varphi(z)\rangle = -\frac{1}{2u^2}$. Apply the four-field Wick formula of Section 11.3.9 with $A = B = \partial\varphi(w)$ and $C = D = \partial\varphi(z)$:

$$
\begin{aligned}
T(w)T(z) &\overset{(1)}{=} (-1)^2\Big[\,2\Big(-\frac{1}{2u^2}\Big)^2 + 4\Big(-\frac{1}{2u^2}\Big){:}\partial\varphi(w)\partial\varphi(z){:} + {:}\partial\varphi(w)^2\partial\varphi(z)^2{:}\Big] \\
&\overset{(2)}{=} \frac{1}{2u^4} - \frac{2}{u^2}\,{:}\partial\varphi(w)\partial\varphi(z){:} + \text{reg.} \\
&\overset{(3)}{=} \frac{1}{2u^4} - \frac{2}{u^2}\,{:}\partial\varphi\,\partial\varphi{:}(z) - \frac{2}{u}\,{:}\partial^2\varphi\,\partial\varphi{:}(z) + \text{reg.} \\
&\overset{(4)}{=} \frac{1/2}{(w-z)^4} + \frac{2\,T(z)}{(w-z)^2} + \frac{\partial T(z)}{w-z} + \text{reg.}
\end{aligned}
$$

(1) Two full contractions ($AC\,BD$ and $AD\,BC$) and four single contractions (AC, AD, BC, BD), all equal because $A = B$ and $C = D$.

(2) $2 \cdot \frac{1}{4u^4} = \frac{1}{2u^4}$ and $4 \cdot (-\frac{1}{2}) = -2$.

(3) Taylor expand $\partial\varphi(w) = \partial\varphi(z) + u\,\partial^2\varphi(z) + \frac{1}{2}u^2\partial^3\varphi(z) + \cdots$ inside the normal ordering; terms of order u^0 and higher are regular.

(4) ${-}{:}\partial\varphi\partial\varphi{:} = T$, and $\partial T = -2{:}\partial^2\varphi\,\partial\varphi{:}$.

This is Nash's (11.28), with the roles of w and z as he has them. The first term is a c-number times the identity operator I: it comes from the double contraction and is there in any theory with a T.

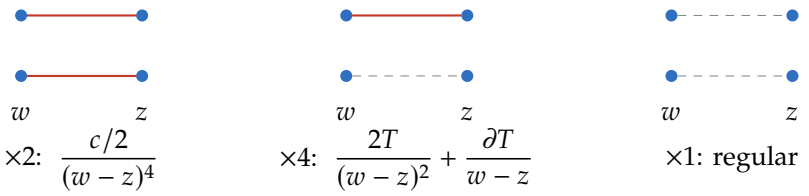

Figure 11.14: The Wick contractions in $T(w)T(z)$ for a free field. Each T is a pair of fields (blue dots); a red line is a propagator. Two propagators (left) leave no operator: a pure number, the central term. One propagator (middle) leaves one field at w and one at z, whose Taylor expansion gives the T and ∂T terms. No propagator (right) is the regular normal-ordered product. The central charge c is literally the sum of "vacuum bubbles" between the two T's, so for N independent free bosons it is N.

Working definition 11.11 (central charge)

In any conformal field theory the TT OPE has the form (Nash's (11.29))

$$
T(w)\,T(z) = \frac{c/2}{(w-z)^4} + \frac{2\,T(z)}{(w-z)^2} + \frac{\partial T(z)}{w-z} + \text{regular}. \tag{11.89}
$$

Here "regular" [terms that stay finite as $w \to z$]. The number c is the **central charge** [one number fixed by the theory, $c = 1$ for a free boson and $c = \frac{1}{2}$ for a free fermion]. *Operational*

recipe: compute the two-point function of T; by (11.89) $\langle T(w)T(z)\rangle = \frac{c/2}{(w-z)^4}$, so c is twice the coefficient of $(w-z)^{-4}$.

Why this form? The terms $2T/(w-z)^2 + \partial T/(w-z)$ are forced: they say that T has weight 2 and that T generates translations of itself, exactly as for any field in (11.87). Scaling allows one more singular term, a field of weight 0 at $(w-z)^{-4}$; the only weight-0 field in a unitary theory is the identity. A term at $(w-z)^{-3}$ would need a weight-1 field, and it is forbidden by the symmetry of the OPE under $w \leftrightarrow z$ (a $(w-z)^{-3}$ term is odd). So the only free datum is c.

Worked example 11.32: The free fermion has $c = \frac{1}{2}$

Nash's footnote 2 invites us to check $c = \frac{1}{2}$. Let $T = -\frac{1}{2}{:}\psi\partial\psi{:}$ and $u = w - z$. Name the four fields $A = \psi(w)$, $B = \partial\psi(w)$, $C = \psi(z)$, $D = \partial\psi(z)$. The contractions are

$$\langle AC\rangle = \frac{1}{u}, \qquad \langle AD\rangle = \partial_z \frac{1}{w-z} = \frac{1}{u^2},$$
$$\langle BC\rangle = \partial_w \frac{1}{w-z} = -\frac{1}{u^2}, \qquad \langle BD\rangle = \partial_w\partial_z \frac{1}{w-z} = -\frac{2}{u^3}.$$

Full contractions. To contract A with C and B with D in $ABCD$ we must swap B and C: one sign. To contract A with D and B with C we move D past C and B: two signs.

$$\tfrac{1}{4}\big[-\langle AC\rangle\langle BD\rangle + \langle AD\rangle\langle BC\rangle\big] \overset{(1)}{=} \tfrac{1}{4}\Big[\frac{2}{u^4} - \frac{1}{u^4}\Big] = \frac{1/4}{u^4}.$$

(1) $-\frac{1}{u}\cdot(-\frac{2}{u^3}) = \frac{2}{u^4}$ and $\frac{1}{u^2}\cdot(-\frac{1}{u^2}) = -\frac{1}{u^4}$; the prefactor is $(-\frac{1}{2})^2 = \frac{1}{4}$.

Comparing with $\frac{c/2}{u^4}$ gives $c = \frac{1}{2}$.

Single contractions. With the same sign rule, and writing ψ, ψ', ψ'' for $\psi(z)$ and its derivatives,

$$\begin{aligned}\tfrac{1}{4}\big[&-\langle AC\rangle{:}BD{:} + \langle AD\rangle{:}BC{:} + \langle BC\rangle{:}AD{:} - \langle BD\rangle{:}AC{:}\big]\\ &\overset{(1)}{=} \tfrac{1}{4}\Big[\frac{{:}\psi'\psi{:}}{u^2} + \frac{{:}\psi''\psi{:}}{u} - \frac{{:}\psi\psi'{:}}{u^2} + \frac{2{:}\psi'\psi{:}}{u^2} + \frac{{:}\psi''\psi{:}}{u}\Big] + \text{reg.}\\ &\overset{(2)}{=} \tfrac{1}{4}\Big[-\frac{4\,{:}\psi\psi'{:}}{u^2} - \frac{2\,{:}\psi\psi''{:}}{u}\Big] \overset{(3)}{=} \frac{2T(z)}{u^2} + \frac{\partial T(z)}{u}.\end{aligned}$$

(1) Expand the fields at w about z: $A = \psi + u\psi' + \cdots$, $B = \psi' + u\psi'' + \cdots$. The AC term is regular (it has only $1/u$ times ${:}\psi'\psi'{:} = 0$). The AD term gives $\frac{1}{u^2}{:}(\psi' + u\psi'')\psi{:}$. The BC term gives $-\frac{1}{u^2}{:}(\psi + u\psi')\psi'{:}$, whose $1/u$ part vanishes since ${:}\psi'\psi'{:} = 0$. The BD term gives $\frac{2}{u^3}{:}(\psi + u\psi' + \frac{1}{2}u^2\psi'')\psi{:}$, and ${:}\psi\psi{:} = 0$.

(2) Collect, using ${:}\psi'\psi{:} = -{:}\psi\psi'{:}$ and ${:}\psi''\psi{:} = -{:}\psi\psi''{:}$.

(3) $T = -\frac{1}{2}{:}\psi\psi'{:}$, so $2T = -{:}\psi\psi'{:}$; and $\partial T = -\frac{1}{2}({:}\psi'\psi'{:} + {:}\psi\psi''{:}) = -\frac{1}{2}{:}\psi\psi''{:}$.

So the fermion satisfies (11.89) with $c = \frac{1}{2}$. As Nash remarks, the value of c distinguishes theories: a single boson has $c = 1$, a single Majorana fermion $c = \frac{1}{2}$, and N decoupled copies of anything have N times the central charge (the T's add and the cross terms do not contract).

Physical picture: what c measures

The coefficient c counts degrees of freedom: a real boson counts 1, a Majorana fermion $\frac{1}{2}$ (half of a Dirac fermion, which is equivalent to a boson in two dimensions and has $c = 1$).

It also measures how the theory responds to the geometry. On a curved surface the trace of T no longer vanishes but becomes $\langle T^{\mu}{}_{\mu}\rangle = -\frac{c}{12}R$ (the **trace anomaly**, in Polchinski's conventions), and on a cylinder of circumference L the ground-state energy is shifted by $-\pi c/(6L)$, the Casimir energy we compute in Example 11.34. In string theory (Chapter 9) the requirement that the total c of matter plus ghosts vanish gives the critical dimension 26.

11.3.14 How T transforms: the Schwarzian derivative

The central term means T is not quite a primary field. Let us see exactly how it transforms.

Infinitesimal transformation (Nash's (11.30)). Apply the operator Ward identity (11.84) to $\phi = T$ and use (11.89):

$$\begin{aligned}\delta T(z) &\overset{(1)}{=} \frac{\epsilon}{2\pi i}\oint_z dw\, f(w)\Big[\frac{c/2}{(w-z)^4}+\frac{2T(z)}{(w-z)^2}+\frac{\partial T(z)}{w-z}\Big]\\ &\overset{(2)}{=} \epsilon\Big[\frac{c}{2}\frac{f'''(z)}{3!}+2f'(z)\,T(z)+f(z)\,\partial T(z)\Big] = \epsilon\Big[2f'T+f\,\partial T+\frac{c}{12}f'''\Big].\end{aligned} \tag{11.90}$$

(1) Operator Ward identity with the TT OPE.

(2) Cauchy's formula $\frac{1}{2\pi i}\oint_z \frac{f(w)}{(w-z)^{k+1}}dw = \frac{f^{(k)}(z)}{k!}$ for $k = 3, 1, 0$.

Without the last term this is the law (11.63) for a primary of weight 2. The extra term is a c-number, independent of the fields. It vanishes if and only if $f''' = 0$, that is, for $f = a + bz + cz^2$: the three global generators $\ell_{-1}, \ell_0, \ell_1$. So T is a **quasi-primary** field of weight 2: primary under Möbius maps only.

Finite transformation (Nash's (11.31)). The finite version is

$$T(z) = \Big(\frac{dz'}{dz}\Big)^2 T'(z') + \frac{c}{12}\{z', z\}, \qquad \{z', z\} := \frac{z'''}{z'} - \frac{3}{2}\Big(\frac{z''}{z'}\Big)^2, \tag{11.91}$$

where primes on z' mean derivatives with respect to z. The combination $\{z', z\}$ is the **Schwarzian derivative**.

Worked example 11.33: The finite law reproduces the infinitesimal one

Take $z' = z + \epsilon f(z)$. Then $dz'/dz = 1 + \epsilon f'$, $z'' = \epsilon f''$, $z''' = \epsilon f'''$, and

$$\{z', z\} = \frac{\epsilon f'''}{1+\epsilon f'} - \frac{3}{2}\Big(\frac{\epsilon f''}{1+\epsilon f'}\Big)^2 = \epsilon f''' + O(\epsilon^2).$$

Solve (11.91) for the new field and evaluate it at the old coordinate value:

$$\begin{aligned}T'(z) &\overset{(1)}{=} T'(z') - \epsilon f\,\partial T'(z') \overset{(2)}{=} (1+\epsilon f')^{-2}\Big[T(z) - \frac{c}{12}\epsilon f'''\Big] - \epsilon f\,\partial T(z)\\ &\overset{(3)}{=} T(z) - \epsilon\Big[2f'T + f\,\partial T + \frac{c}{12}f'''\Big] + O(\epsilon^2).\end{aligned}$$

(1) Taylor expand, since $z = z' - \epsilon f$.

(2) Solve (11.91) for $T'(z')$; in the $O(\epsilon)$ term replace T' by T.

(3) $(1+\epsilon f')^{-2} = 1 - 2\epsilon f' + \cdots$.

So $\delta T = T(z) - T'(z) = \epsilon[2f'T + f\partial T + \frac{c}{12}f''']$, which is (11.90).

Why the Schwarzian? The composition law. Transformation laws must compose: doing $z \to u \to w$ in two steps must give the same answer as doing $z \to w$ at once. For the tensorial part this is the chain rule, $(\mathrm{d}w/\mathrm{d}z)^2 = (\mathrm{d}w/\mathrm{d}u)^2(\mathrm{d}u/\mathrm{d}z)^2$. The extra term must therefore satisfy

$$\{w,z\} = \left(\frac{\mathrm{d}u}{\mathrm{d}z}\right)^2 \{w,u\} + \{u,z\}. \tag{11.92}$$

Let us verify that the Schwarzian does this. Write $S[w] = \{w,z\}$. The quickest route is the identity $\{w,z\} = \big(\ln w'\big)'' - \frac{1}{2}\big((\ln w')'\big)^2$, which follows from $(\ln w')' = w''/w'$ and $(\ln w')'' = w'''/w' - (w''/w')^2$. For $w(u(z))$ we have $\ln w'(z) = \ln w_u(u) + \ln u'(z)$, where $w_u = \mathrm{d}w/\mathrm{d}u$. Let $A = (\ln w_u)_u$ (a function of u) and $B = (\ln u')'$. Then

$$\begin{aligned}
(\ln w')' &\overset{(1)}{=} u'A + B, \qquad (\ln w')'' \overset{(2)}{=} u'^2 A_u + u''A + B', \\
\{w,z\} &\overset{(3)}{=} u'^2 A_u + u''A + B' - \tfrac{1}{2}\big(u'^2A^2 + 2u'AB + B^2\big) \\
&\overset{(4)}{=} u'^2\big(A_u - \tfrac{1}{2}A^2\big) + \big(B' - \tfrac{1}{2}B^2\big) + A\big(u'' - u'B\big) \overset{(5)}{=} u'^2\{w,u\} + \{u,z\}.
\end{aligned}$$

(1) Chain rule: $\frac{\mathrm{d}}{\mathrm{d}z}\ln w_u(u(z)) = u'A$.
(2) Differentiate again; $\frac{\mathrm{d}}{\mathrm{d}z}A = u'A_u$.
(3) Insert into the identity for the Schwarzian.
(4) Regroup.
(5) $u'B = u' \cdot u''/u' = u''$, so the last bracket vanishes; the other two brackets are the Schwarzians by the same identity.

So the Schwarzian is exactly the extra term that composes correctly. (In the language of Chapter 6, it is a one-cocycle on the group of diffeomorphisms; its infinitesimal version f''' is the Gelfand–Fuks cocycle that defines the Virasoro central extension.)

The Schwarzian vanishes exactly on Möbius maps (Nash's (11.32)). *Möbius* $\Rightarrow \{f,z\} = 0$. For $f = \frac{az+b}{cz+d}$ with $ad - bc = 1$:

$$f' = \frac{1}{(cz+d)^2}, \quad f'' = \frac{-2c}{(cz+d)^3}, \quad f''' = \frac{6c^2}{(cz+d)^4}, \qquad \{f,z\} \overset{(1)}{=} \frac{6c^2}{(cz+d)^2} - \frac{3}{2}\cdot\frac{4c^2}{(cz+d)^2} = 0.$$

(1) $f'''/f' = 6c^2/(cz+d)^2$ and $(f''/f')^2 = 4c^2/(cz+d)^2$.

$\{f,z\} = 0 \Rightarrow$ *Möbius.* This is Nash's chain (11.32), with the steps filled in. Let $g = f'$ (assume g is not constant; the constant case $f = az + b$ is Möbius with $c = 0$). Then

$$\begin{aligned}
0 = \{f,z\} &\overset{(1)}{=} \frac{g''}{g} - \frac{3}{2}\frac{g'^2}{g^2} \quad\Longrightarrow\quad \frac{g''}{g'} \overset{(2)}{=} \frac{3}{2}\frac{g'}{g} \quad\Longrightarrow\quad \ln g' \overset{(3)}{=} \tfrac{3}{2}\ln g + A \\
&\Longrightarrow\quad g^{-3/2}\,g' \overset{(4)}{=} e^A \quad\Longrightarrow\quad -2g^{-1/2} \overset{(5)}{=} e^A z + B' \quad\Longrightarrow\quad g \overset{(6)}{=} \frac{4}{(e^A z + B')^2}, \\
f &\overset{(7)}{=} -\frac{4e^{-A}}{e^A z + B'} + D \overset{(8)}{=} \frac{De^A z + (DB' - 4e^{-A})}{e^A z + B'}.
\end{aligned}$$

(1) $f'''/f' = g''/g$ and $f''/f' = g'/g$.
(2) Multiply by g/g'.
(3) Both sides are logarithmic derivatives; integrate, with constant A.
(4) Exponentiate.
(5) $\frac{\mathrm{d}}{\mathrm{d}z}(-2g^{-1/2}) = g^{-3/2}g'$; integrate, constant B'.
(6) Solve for g.

(7) Integrate g, constant D.
(8) Common denominator.

This is $(az+b)/(cz+d)$ with $a = De^{A}$, $b = DB' - 4e^{-A}$, $c = e^{A}$, $d = B'$, and $ad - bc = De^{A}B' - (DB' - 4e^{-A})e^{A} = 4$. Dividing a, b, c, d by 2 normalises $ad - bc = 1$. The three integration constants A, B', D of the third-order equation are the three complex parameters of $\mathrm{SL}(2,\mathbb{C})/\{\pm 1\}$.

Watch out: the constant in Nash's (11.32)

Nash's last line is $f = C\,\frac{az+b}{cz+d}$ with "C an undetermined constant". The undetermined constant actually enters additively (our D), and it is absorbed into a and b. A multiplicative constant is also harmless, since $z \mapsto Cz$ is itself Möbius. Either way the conclusion is the same: the solutions of $\{f, z\} = 0$ are exactly the Möbius maps.

Worked example 11.34: From the plane to the cylinder: the Casimir energy

Use the map of Example 11.15(b), $z = e^{w}$ with $w = \tau + i\sigma$ on a cylinder of circumference 2π. We want the stress tensor $T_{\mathrm{cyl}}(w)$ in the w coordinate. Apply (11.91) with the "old" coordinate w and the "new" one z:

$$T_{\mathrm{cyl}}(w) \overset{(1)}{=} \left(\frac{\mathrm{d}z}{\mathrm{d}w}\right)^{2} T(z) + \frac{c}{12}\{z, w\} \overset{(2)}{=} z^{2}\,T(z) + \frac{c}{12}\left(1 - \frac{3}{2}\right) = z^{2}\,T(z) - \frac{c}{24}.$$

(1) (11.91), with T_{cyl} the field in the w frame and T the field in the z frame.
(2) $\mathrm{d}z/\mathrm{d}w = z'' = z''' = e^{w} = z$, so $z'''/z' = 1$ and $(z''/z')^{2} = 1$.

On the plane the vacuum has $\langle T(z)\rangle = 0$ (by rotation and translation invariance: $\langle T(z)\rangle$ would have to be a constant of weight 2). On the cylinder, therefore, $\langle T_{\mathrm{cyl}}\rangle = -c/24$. The energy density on the cylinder is proportional to $T_{\mathrm{cyl}} + \bar{T}_{\mathrm{cyl}}$, and we will see in Section 11.4.3 that the Hamiltonian is $H = L_0 + \bar{L}_0 - \frac{c}{12}$. Restoring a circumference L multiplies energies by $2\pi/L$: the vacuum energy is $E_0 = -\frac{\pi c}{6L}$. This is the two-dimensional Casimir effect, and measuring E_0 in a numerical simulation of a lattice model is a standard way to determine c.

Reading Nash (pp. 303–307, (11.10)–(11.32))

Nash's aim here is the OPE of T with a primary field. He introduces the stress tensor, uses tracelessness and conservation to reduce it to $T(z)$ and $\bar{T}(\bar{z})$ ((11.10)–(11.14); his (11.12) lacks a factor $\frac{1}{4}$). He quotes the Ward identity (11.16) with a bulk and a boundary term, specialises to conformal f so only the boundary term survives, and obtains the contour form (11.18) and the operator equation (11.19). We derived all of these from a change of variables in the path integral and fixed the normalisation $T = -2\pi T_{zz}$, which Nash leaves implicit. Equating (11.19) with the transformation law (11.20) of a primary gives (11.21); matching the Laurent expansions (11.22)–(11.23) gives (11.24) and hence the OPEs (11.25)–(11.27). Nash then states the free-boson TT OPE (11.28) ("it is easy to calculate"; we computed it, and the fermion's too), the general form (11.29) with the central charge (footnote 2: $c = 1$ for the boson, $c = \frac{1}{2}$ for the fermion), the transformation (11.30) of T, the finite law (11.31) with the Schwarzian derivative, and the proof (11.32) that the Schwarzian vanishes only for Möbius maps. We added the stress tensors of the free fields, the Ward identity for correlators and its check on a two-point function, the explicit OPEs of T with $\partial\varphi$, $:e^{i\alpha\varphi}:$ and ψ, the composition law of the Schwarzian and the cylinder map.

Recap: Section 11.3

- In complex coordinates $z = x_1 + ix_2$, conformal maps are holomorphic maps. Locally they form the Witt algebra $[\ell_m, \ell_n] = (m-n)\ell_{m+n}$; globally on the sphere only $\ell_{-1}, \ell_0, \ell_1$ survive, generating the Möbius group $\mathrm{SL}(2,\mathbb{C})/\{\pm 1\}$.
- A primary field of weights $(h, \bar{h})$ transforms as $\phi\, \mathrm{d}z^h \mathrm{d}\bar{z}^{\bar{h}}$; $\Delta = h + \bar{h}$, $s = h - \bar{h}$. Its two-point function is $C/z_{12}^{2h}\bar{z}_{12}^{2\bar{h}}$.
- Free fermion: $\langle\psi\psi\rangle = 1/z$, $h = \frac{1}{2}$. Free boson: $\langle\varphi\varphi\rangle = -\frac{1}{2}\ln|z|^2$, not primary; $\partial\varphi$ has $h = 1$, $:e^{i\alpha\varphi}:$ has $h = \bar{h} = \alpha^2/4$.
- $T(z) = -2\pi T_{zz}$ is holomorphic; it generates conformal maps by $\delta\phi = \frac{\epsilon}{2\pi i}\oint f(w)T(w)\phi(z)\mathrm{d}w$.
- Primary $\Leftrightarrow T(w)\phi(z) \sim \frac{h\phi}{(w-z)^2} + \frac{\partial\phi}{w-z}$.
- $T(w)T(z) \sim \frac{c/2}{(w-z)^4} + \frac{2T}{(w-z)^2} + \frac{\partial T}{w-z}$; $c = 1$ (boson), $\frac{1}{2}$ (fermion).
- T transforms with the Schwarzian: $T = (z'_z)^2 T' + \frac{c}{12}\{z', z\}$, which vanishes only for Möbius maps; on the cylinder $\langle T_{\mathrm{cyl}}\rangle = -c/24$.

11.4 Relation to the Virasoro algebra

In Section 11.3 everything was phrased with correlation functions and contour integrals. A physicist also wants the Hamiltonian picture: a Hilbert space of states, operators acting on it, and the commutation relations of the symmetry generators. Two questions organise this section.

(a) The conserved charges built from $T(z)$ generate conformal maps. What algebra do they obey? The classical answer is the Witt algebra (11.57). The quantum answer is the **Virasoro algebra**, and the extra term in it is exactly the central charge c of the TT OPE.

(b) How are the states of a conformal field theory organised? The answer is that every primary field ϕ produces a state $|h\rangle$, the Virasoro generators with negative index build a tower of states on top of it, and demanding that all these states have positive norm puts strong restrictions on c and h.

The second question is the representation theory of the Virasoro algebra, which we met from the group side in Chapter 6. Here we see where the representations come from physically.

11.4.1 Two copies of $\mathrm{Diff}(S^1)$

Nash begins §3 by recalling that the two-dimensional conformal group "consists of the group of holomorphic and anti-holomorphic transformations" and that it can be realised as $\mathrm{Diff}(S^1) \times \mathrm{Diff}(S^1)$. Let us see what this means concretely, and where the statement needs a caveat.

Vector fields on the circle. A diffeomorphism of the circle close to the identity is $\theta \mapsto \theta + \epsilon v(\theta)$ with v a smooth real 2π-periodic function. Its generator is the vector field $v(\theta)\partial_\theta$. Expand v in

a Fourier series. A convenient complex basis of vector fields on the circle is

$$\ell_n\big|_{S^1} = i\,e^{in\theta}\,\partial_\theta, \qquad n \in \mathbb{Z}. \tag{11.93}$$

The name is deliberate: it is the restriction of the Witt generator $\ell_n = -z^{n+1}\partial_z$ of (11.56) to the unit circle $z = e^{i\theta}$.

$$\ell_n = -z^{n+1}\partial_z \overset{(1)}{=} -z^n\,(z\,\partial_z) \overset{(2)}{=} -e^{in\theta}\big(-i\,\partial_\theta\big) = i\,e^{in\theta}\partial_\theta.$$

(1) Split off one factor of z.
(2) On functions of $z = e^{i\theta}$ we have $\partial_\theta = \frac{\mathrm{d}z}{\mathrm{d}\theta}\partial_z = iz\,\partial_z$, so $z\partial_z = -i\partial_\theta$.

So the commutator $[\ell_m, \ell_n] = (m-n)\ell_{m+n}$ holds on the circle as well (you can check it directly with ∂_θ, exactly as in Example 11.16). The *real* vector fields are the real combinations

$$-\partial_\theta = i\ell_0, \qquad \cos n\theta\,\partial_\theta = -\tfrac{i}{2}\big(\ell_n + \ell_{-n}\big), \qquad \sin n\theta\,\partial_\theta = -\tfrac{1}{2}\big(\ell_n - \ell_{-n}\big).$$

So the Lie algebra $\mathrm{Vect}(S^1)$ of $\mathrm{Diff}(S^1)$ is a real form of the Witt algebra: the Witt algebra is its complexification. Figure 11.15 shows three of these vector fields.

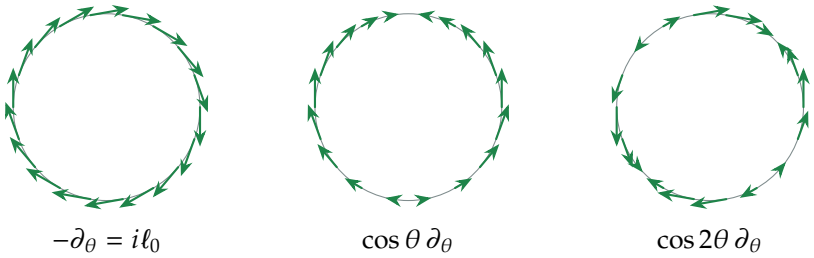

Figure 11.15: Three real vector fields on the circle. Left: rigid rotation (all arrows equal). Middle: $\cos\theta\,\partial_\theta$ moves points counterclockwise on the right half of the circle and clockwise on the left half, so the flow runs from the repelling zero at $\theta = 3\pi/2$ (bottom) to the attracting zero at $\theta = \pi/2$ (top). Right: $\cos 2\theta\,\partial_\theta$ has four zeros; it is a genuinely "local" deformation of the circle. The first two (together with $\sin\theta\,\partial_\theta$) generate the Möbius maps that preserve the unit disc; the $n \geq 2$ fields are the infinitely many extra directions of $\mathrm{Diff}(S^1)$.

Why boundary values? A holomorphic map defined on a neighbourhood of the unit circle (an annulus) is determined by its values on the circle, by Cauchy's formula. Restricting the holomorphic vector field $\epsilon(z)\partial_z$ to the circle therefore loses nothing. The antiholomorphic vector fields $\bar\epsilon(\bar z)\partial_{\bar z}$ give a second, independent copy. This is the sense of Nash's "$\mathrm{Diff}(S^1) \times \mathrm{Diff}(S^1)$: one S^1 corresponds to the boundary values of the holomorphic transformations and the other to the boundary values of the anti-holomorphic transformations."

Watch out: what "$\mathrm{Diff}(S^1) \times \mathrm{Diff}(S^1)$" really means

The statement is true at the level of Lie algebras after complexification:

$$\big(\text{local conformal algebra}\big) = \mathrm{Witt} \oplus \overline{\mathrm{Witt}} = \mathrm{Vect}(S^1)_{\mathbb{C}} \oplus \mathrm{Vect}(S^1)_{\mathbb{C}}.$$

It is *not* literally true at the level of groups, for two reasons. First, the group $\mathrm{Diff}(S^1)$ has no complexification: there is no Lie group whose Lie algebra is $\mathrm{Vect}(S^1)_{\mathbb{C}}$ (see Chapter 6). Second, in Euclidean signature z and $\bar z$ are complex conjugates, so a single real conformal map is one holomorphic function, not a pair. The two copies become genuinely independent only after continuing to Minkowski signature, where $z, \bar z \to x^0 \pm x^1$ are the two real light-cone coordinates and each light-cone circle carries its own $\mathrm{Diff}(S^1)$. For the quantum

theory, which only uses the Lie algebra and its representations, the statement is exactly right.

11.4.2 The modes of $T(z)$

The stress tensor $T(z)$ is holomorphic away from operator insertions. Put the only insertions at 0 and ∞ (we will see in a moment that this is the natural setting). Then T is holomorphic on the punctured plane and has a Laurent expansion. Since T has weight 2, it is natural to shift the powers by 2 so that the label n counts how much the mode changes the scaling dimension:

$$T(z) = \sum_{n\in\mathbb{Z}} L_n\, z^{-n-2}, \qquad L_n = \oint_0 \frac{\mathrm{d}w}{2\pi i}\, w^{n+1}\, T(w). \tag{11.94}$$

This is Nash's (11.33). The inversion formula follows from the residue theorem:

$$\oint_0 \frac{\mathrm{d}w}{2\pi i}\, w^{n+1} T(w) \overset{(1)}{=} \sum_{m\in\mathbb{Z}} L_m \oint_0 \frac{\mathrm{d}w}{2\pi i}\, w^{n+1-m-2} \overset{(2)}{=} \sum_{m\in\mathbb{Z}} L_m\, \delta_{n-m-1,-1} = L_n .$$

(1) Insert the Laurent series and integrate term by term (the series converges uniformly on the contour).

(2) $\oint_0 \frac{\mathrm{d}w}{2\pi i} w^k = \delta_{k,-1}$: only $k=-1$ has a residue.

The same formulas hold for $\bar T$ (Nash's (11.35)):

$$\bar T(\bar z) = \sum_{n\in\mathbb{Z}} \bar L_n\, \bar z^{-n-2}, \qquad \bar L_n = \oint_0 \frac{\mathrm{d}\bar w}{2\pi i}\, \bar w^{n+1}\, \bar T(\bar w), \tag{11.95}$$

with the $\bar w$ residue counted positively, as in the pitfall after (11.83).

The modes are the conformal charges. The operator Ward identity (11.84) says that the transformation $z \mapsto z + \epsilon f(z)$ is generated by $Q_f = \oint \frac{\mathrm{d}w}{2\pi i} f(w)T(w)$. For $f(w) = w^{n+1}$, the transformation $z \mapsto z + \epsilon z^{n+1}$ is the flow of $-\ell_n$, and the charge is exactly L_n. So

$$Q_f = \sum_n f_n\, L_{n-1} \quad \text{for} \quad f(w) = \sum_n f_n w^n, \tag{11.96}$$

and each mode L_n is the quantum generator of one of the Witt vector fields. (The sign relating L_n to ℓ_n is a convention about active versus passive maps and never matters below; what matters is that the L_n realise the algebra of the ℓ_n, up to a central term.)

Dictionary: which mode does what

mode	$f(w)$	transformation
L_{-1}	1	translation $z \mapsto z+\epsilon$
L_0	w	dilation and rotation $z \mapsto (1+\epsilon)z$
L_1	w^2	special conformal $z \mapsto z + \epsilon z^2$
L_n, $\lvert n\rvert \geq 2$	w^{n+1}	local conformal map, not globally defined

11.4.3 Radial quantisation

To talk about commutators of the L_n we need operators acting on a Hilbert space, which means we need a notion of time. Nash states the answer in two sentences: the Hamiltonian is the generator of dilations, $L_0 + \bar L_0$, and time ordering becomes radial ordering. Let us see why.

The plane is a cylinder. Recall the map $z = e^w$, $w = \tau + i\sigma$, of Example 11.15(b). A field theory on a spatial circle of circumference 2π evolving in Euclidean time τ lives on the cylinder $\mathbb{R} \times S^1$. The exponential map sends it to the punctured plane:

- a circle of constant time τ goes to the circle $|z| = e^\tau$;
- the infinite past $\tau \to -\infty$ goes to the origin $z = 0$;
- the infinite future $\tau \to +\infty$ goes to the point $z = \infty$;
- time translation $\tau \mapsto \tau + a$ goes to the dilation $z \mapsto e^a z$;
- space translation $\sigma \mapsto \sigma + b$ goes to the rotation $z \mapsto e^{ib} z$.

Since the map is conformal, a conformal field theory on the cylinder is the same thing as a conformal field theory on the plane.

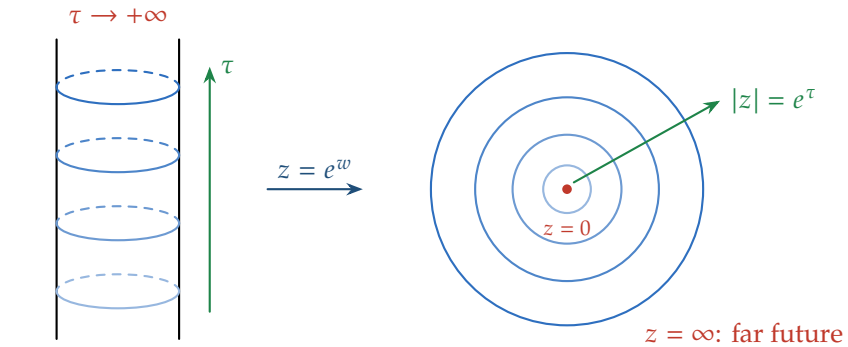

Figure 11.16: Radial quantisation. Circles of constant time on the cylinder (left) become concentric circles on the plane (right), with later times at larger radius. The infinite past shrinks to the single point $z = 0$, so an initial state is prepared by whatever operator we put at the origin: this is the state–operator correspondence. Time evolution is dilation, so the Hamiltonian is the dilation generator $L_0 + \bar{L}_0$.

The Hamiltonian. The Hamiltonian generates translations in τ, which on the plane are dilations $z \mapsto (1+\epsilon)z$, i.e. $f(z) = z$ in (11.96), and the same for $\bar{z}$. So on the plane H is represented by $L_0 + \bar{L}_0$. On the cylinder itself we can be more precise, using the transformation law of T with its Schwarzian. From Example 11.34, $T_{\text{cyl}}(w) = z^2 T(z) - \frac{c}{24}$. The charge generating $w \mapsto w + \epsilon$ on a circle of constant τ, where $\mathrm{d}w = i\,\mathrm{d}\sigma$, is

$$\oint \frac{\mathrm{d}w}{2\pi i}\, T_{\text{cyl}}(w) \overset{(1)}{=} \frac{1}{2\pi}\int_0^{2\pi} \mathrm{d}\sigma \left(z^2 \sum_n L_n z^{-n-2} - \frac{c}{24} \right) \overset{(2)}{=} \frac{1}{2\pi}\int_0^{2\pi} \mathrm{d}\sigma \left(\sum_n L_n\, e^{-n\tau} e^{-in\sigma} - \frac{c}{24} \right)$$
$$\overset{(3)}{=} L_0 - \frac{c}{24}. \tag{11.97}$$

(1) $\mathrm{d}w/(2\pi i) = \mathrm{d}\sigma/(2\pi)$ at fixed τ; insert the Schwarzian law and the mode expansion.
(2) $z = e^{\tau + i\sigma}$, so $z^{-n} = e^{-n\tau} e^{-in\sigma}$.
(3) $\int_0^{2\pi} e^{-in\sigma}\mathrm{d}\sigma = 2\pi\delta_{n,0}$.

Adding the antiholomorphic half,

$$H_{\text{cyl}} = L_0 + \bar{L}_0 - \frac{c}{12}, \qquad P_{\text{cyl}} = L_0 - \bar{L}_0. \tag{11.98}$$

The momentum P generates σ-translations, i.e. rotations of the plane, whose charge is $L_0 - \bar{L}_0$: the rotation $z \mapsto e^{i\epsilon} z$ has $f(z) = iz$ and $\bar{f}(\bar{z}) = -i\bar{z}$, so its charge is $i(L_0 - \bar{L}_0)$. An eigenstate of L_0 and $\bar{L}_0$ with eigenvalues $h, \bar{h}$ has energy $h + \bar{h} - \frac{c}{12}$ and momentum $h - \bar{h}$: the scaling dimension is the energy and the spin is the momentum. Why these, rather than mass and spin, are the right labels of a state is the subject of Section 11.4.6.

Time ordering becomes radial ordering. In the operator formalism, a Euclidean correlation function is a vacuum expectation value of a *time-ordered* product: operators at later times stand to the left. On the plane "later" means "further from the origin". So

$$\langle \phi_1(z_1) \cdots \phi_n(z_n) \rangle = \langle 0 | \, R\big(\phi_1(z_1) \cdots \phi_n(z_n)\big) | 0 \rangle, \qquad R\big(A(z)B(w)\big) = \begin{cases} A(z)B(w), & |z| > |w|, \\ \pm B(w)A(z), & |w| > |z|, \end{cases} \tag{11.99}$$

with the minus sign when both operators are fermionic. This is Nash's remark that "the points $z_1, \ldots, z_n$ in a correlation function are ordered by their differences $|z_i - z_j|$"; more precisely they are ordered by their distances $|z_i|$ from the origin, where the in-state sits. All the OPEs of Section 11.3 are statements about radially ordered products.

Commutators are contour integrals. Here is the one computational trick of this section. Let $A(w)$ be holomorphic and let $B(z)$ be any field. Consider the charge $A_C = \oint_C \frac{\mathrm{d}w}{2\pi i} A(w)$ on a circle C centred at 0. Then

$$\begin{aligned} \big[A_C, B(z)\big] &\overset{(1)}{=} \oint_{|w|>|z|} \frac{\mathrm{d}w}{2\pi i} A(w)B(z) - \oint_{|w|<|z|} \frac{\mathrm{d}w}{2\pi i} B(z)A(w) \\ &\overset{(2)}{=} \oint_{|w|>|z|} \frac{\mathrm{d}w}{2\pi i} R\big(A(w)B(z)\big) - \oint_{|w|<|z|} \frac{\mathrm{d}w}{2\pi i} R\big(A(w)B(z)\big) \\ &\overset{(3)}{=} \oint_z \frac{\mathrm{d}w}{2\pi i} A(w)B(z). \end{aligned} \tag{11.100}$$

(1) As operators, $A_C B(z)$ only makes sense (inside a correlator) when the charge acts at a later time than B, i.e. $|w| > |z|$, and $B(z)A_C$ when $|w| < |z|$. The charge is conserved, so the radius of the contour does not matter as long as it does not cross z.

(2) In each region the operator product is the radially ordered one.

(3) The radially ordered product is a single holomorphic function of w away from z (this is the content of the OPE). The difference of the two circles is a small circle around z (Figure 11.17).

So the commutator of a charge with a field is computed by the singular part of their OPE. For a double contour integral we apply the trick twice: first around z for fixed z, then around 0.

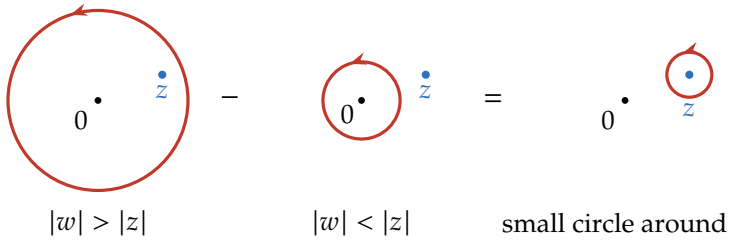

Figure 11.17: Why a commutator is a contour integral. The charge $\oint A$ acting after $B(z)$ is a circle outside z; acting before $B(z)$ it is a circle inside z. Their difference encloses only the point z, so only the singular terms of the OPE $A(w)B(z)$ contribute.

Worked example 11.35: The commutator of L_n with a primary field

Take $A = w^{n+1}T(w)$ and $B = \phi(z,\bar z)$ primary of weight $(h,\bar h)$.

$$[L_n,\phi(z,\bar z)] \overset{(1)}{=} \oint_z \frac{dw}{2\pi i}\, w^{n+1}\Big(\frac{h\,\phi(z,\bar z)}{(w-z)^2}+\frac{\partial\phi(z,\bar z)}{w-z}\Big)$$
$$\overset{(2)}{=} h(n+1)z^n\,\phi(z,\bar z)+z^{n+1}\,\partial\phi(z,\bar z). \tag{11.101}$$

(1) (11.100) with the $T\phi$ OPE (11.87); the regular terms have no residue.

(2) Cauchy: $\oint_z \frac{dw}{2\pi i}\frac{g(w)}{(w-z)^2} = g'(z)$ and $\oint_z \frac{dw}{2\pi i}\frac{g(w)}{w-z} = g(z)$, with $g = w^{n+1}$.

Check with $n=-1$: $[L_{-1},\phi]=\partial\phi$, so L_{-1} generates translations. With $n=0$: $[L_0,\phi(z)] = (h+z\partial)\phi$; at $z=0$ this is $h\phi(0)$, so L_0 measures the weight of a field sitting at the origin.

11.4.4 The Virasoro algebra from the TT OPE

Nash says: "If we combine this with the operator product expansion 11.29 we can verify that these generators have the commutation relations (11.34)." Here is the verification in full. It is the most important calculation of the chapter.

$$[L_m,L_n] \overset{(1)}{=} \oint_0 \frac{dz}{2\pi i}\, z^{n+1}\oint_z \frac{dw}{2\pi i}\, w^{m+1}\,T(w)T(z)$$
$$\overset{(2)}{=} \oint_0 \frac{dz}{2\pi i}\, z^{n+1}\oint_z \frac{dw}{2\pi i}\, w^{m+1}\Big[\frac{c/2}{(w-z)^4}+\frac{2T(z)}{(w-z)^2}+\frac{\partial T(z)}{w-z}\Big]$$
$$\overset{(3)}{=} \oint_0 \frac{dz}{2\pi i}\, z^{n+1}\Big[\frac{c}{2}\cdot\frac{(m+1)m(m-1)}{3!}z^{m-2}+2(m+1)z^m\,T(z)+z^{m+1}\,\partial T(z)\Big]$$
$$\overset{(4)}{=} \frac{c}{12}(m+1)m(m-1)\,\delta_{m+n,0}+2(m+1)\,L_{m+n}-(m+n+2)\,L_{m+n}$$
$$\overset{(5)}{=} (m-n)\,L_{m+n}+\frac{c}{12}\,m(m^2-1)\,\delta_{m+n,0}. \tag{11.102}$$

(1) Write $L_m = \oint \frac{dw}{2\pi i} w^{m+1}T(w)$ and $L_n = \oint \frac{dz}{2\pi i} z^{n+1}T(z)$. For fixed z, the commutator $[L_m,T(z)]$ is the w contour around z by (11.100); then integrate over z around 0.

(2) Insert the TT OPE (11.89); regular terms do not contribute to the w integral.

(3) Cauchy's formula $\oint_z \frac{dw}{2\pi i}\frac{g(w)}{(w-z)^{k+1}} = \frac{g^{(k)}(z)}{k!}$ with $g(w)=w^{m+1}$: $g'''=(m+1)m(m-1)w^{m-2}$, $g'=(m+1)w^m$, $g=w^{m+1}$.

(4) First term: $\oint \frac{dz}{2\pi i} z^{m+n-1} = \delta_{m+n,0}$. Second: $\oint \frac{dz}{2\pi i} z^{m+n+1}T(z) = L_{m+n}$ by (11.94). Third: integrate by parts on the closed contour, $\oint z^{m+n+2}\partial T = -(m+n+2)\oint z^{m+n+1}T$.

(5) $2(m+1)-(m+n+2) = m-n$, and $(m+1)m(m-1) = m(m^2-1)$.

Key idea: the Virasoro algebra (Nash's (11.34)–(11.35))

The modes of the stress tensor of any two-dimensional conformal field theory obey

$$[L_m,L_n] = (m-n)L_{m+n}+\frac{c}{12}m(m^2-1)\delta_{m+n,0},$$
$$[\bar L_m,\bar L_n] = (m-n)\bar L_{m+n}+\frac{c}{12}m(m^2-1)\delta_{m+n,0},$$

and $[L_m,\bar L_n]=0$. Each set spans a copy of the **Virasoro algebra** *Vir*: the Witt algebra plus one extra generator, the central element c, which commutes with everything (so in an

irreducible representation it is a number). The $\bar{L}_n$ commute with the L_n because $T(w)\bar{T}(\bar{z})$ has no singular terms: T is holomorphic and $\bar{T}$ antiholomorphic, so their product is regular.

The central term vanishes for $m \in \{-1, 0, 1\}$. So L_{-1}, L_0, L_1 close on themselves without any central term:

$$[L_0, L_{\pm 1}] = \mp L_{\pm 1}, \qquad [L_1, L_{-1}] = 2L_0. \tag{11.103}$$

This is $\mathfrak{sl}(2, \mathbb{C})$, the Lie algebra of the Möbius group, exactly the global part of the Witt algebra. The central charge is invisible to the global conformal group; it only shows up in the local transformations.

Physical picture: where the central term comes from

Classically the ℓ_n are vector fields and satisfy the Witt algebra exactly. The quantum L_n are quadratic in the fields ($T = -{:}\partial\varphi\partial\varphi{:}$), and normal ordering them requires subtracting an infinite constant. The subtraction cannot be made compatible with all the commutators at once; what is left over is the c-number $\frac{c}{12}m(m^2-1)$. In the contour calculation it is the $(w-z)^{-4}$ term, i.e. the double contraction of Figure 11.14. It is the same mechanism as an anomaly (Chapter 10): a classical symmetry algebra that the quantum theory realises only projectively.

Worked example 11.36: Which central terms are genuine?

Suppose we only knew that the L_n satisfy the Witt algebra up to a c-number, $[L_m, L_n] = (m-n)L_{m+n} + C(m)\delta_{m+n,0}$, with $C(-m) = -C(m)$ by antisymmetry. What can C be? The Jacobi identity $[[L_k, L_n], L_m] + [[L_n, L_m], L_k] + [[L_m, L_k], L_n] = 0$ with $k + n + m = 0$ gives, after the operator terms cancel (they obey the Witt Jacobi identity),

$$\begin{aligned} 0 &\overset{(1)}{=} (k-n)\,C(k+n) + (n-m)\,C(n+m) + (m-k)\,C(m+k) \\ &\overset{(2)}{=} -(k-n)\,C(m) - (n-m)\,C(k) - (m-k)\,C(n). \end{aligned}$$

(1) $[[L_k, L_n], L_m] = (k-n)[L_{k+n}, L_m]$, whose c-number part is $(k-n)C(k+n)\delta_{k+n+m,0}$; similarly for the other two.

(2) $k + n = -m$ and C is odd, so $C(k+n) = -C(m)$, and cyclically.

Take $n = 1$ and $k = -m-1$:

$$\begin{aligned} 0 &\overset{(1)}{=} (m+2)\,C(m) + (m-1)\,C(-m-1) - (2m+1)\,C(1) \\ &\overset{(2)}{=} (m+2)\,C(m) - (m-1)\,C(m+1) - (2m+1)\,C(1), \end{aligned}$$

(1) Substitute into the coefficients: $-(k-n) = m+2$, $-(n-m) = m-1$ (multiplying $C(k) = C(-m-1)$) and $-(m-k) = -(2m+1)$ (multiplying $C(n) = C(1)$).

(2) $C(-m-1) = -C(m+1)$.

that is, $(m-1)\,C(m+1) = (m+2)\,C(m) - (2m+1)\,C(1)$. For $m \geq 2$ this is a recursion that fixes every $C(m)$ once $C(1)$ and $C(2)$ are given. So the solutions form a two-dimensional space. Two solutions are $C(m) = m$ and $C(m) = m^3$:

$$\begin{aligned} C = m: &\quad (m-1)(m+1) = m^2 - 1, \qquad (m+2)m - (2m+1) = m^2 - 1 \ \checkmark \\ C = m^3: &\quad (m-1)(m+1)^3 = m^4 + 2m^3 - 2m - 1, \\ &\quad (m+2)m^3 - (2m+1) = m^4 + 2m^3 - 2m - 1 \ \checkmark \end{aligned}$$

Hence $C(m) = \alpha m^3 + \beta m$. The linear part is not genuine: shifting $L_0 \to L_0 + a$ changes $[L_m, L_{-m}] = 2mL_0 + C(m)$ into $2m(L_0 + a) + C(m) - 2ma$, i.e. $C(m) \to C(m) - 2am$. The standard choice fixes the shift by requiring $C(1) = 0$, so that $L_{\pm1}, L_0$ close into $\mathfrak{sl}(2)$; then $C(m) = \alpha(m^3 - m)$, and $\alpha = c/12$ is the convention. So the Virasoro algebra is the *unique* nontrivial central extension of the Witt algebra, and the one number c is all the freedom there is.

Watch out: the L_0 ambiguity and the Casimir energy

The freedom $L_0 \to L_0 + a$ is not just algebra. On the cylinder the natural generator is $L_0 - \frac{c}{24}$ (11.97), and in that basis the central term reads $\frac{c}{12}m^3$ with no linear piece. The plane generator L_0, with $L_0|0\rangle = 0$, is the one for which $\mathfrak{sl}(2)$ closes. The difference, $-\frac{c}{24}$, is the Casimir energy of Example 11.34. Different books use different L_0's; always check whether the vacuum has $L_0 = 0$ or $L_0 = -c/24$.

11.4.5 The free boson in modes: $c = 1$ by hand

The central charge of the free boson was found in Example 11.31 from the OPE. Now we see the same number in the Hilbert space, by building the L_n out of harmonic oscillators. This is the most concrete representation of the Virasoro algebra there is.

The current and its modes. With our normalisation $\langle \partial\varphi(w)\partial\varphi(z)\rangle = -\frac{1}{2(w-z)^2}$ ((11.70)), it is convenient to define the U(1) current

$$j(z) := i\sqrt{2}\,\partial\varphi(z), \qquad j(w)j(z) = \frac{1}{(w-z)^2} + \text{reg.}, \qquad T(z) = -{:}\partial\varphi\,\partial\varphi{:} = \tfrac{1}{2}{:}j\,j{:}(z). \tag{11.104}$$

(Check: $(i\sqrt{2})^2 \cdot (-\frac{1}{2}) = 1$, and $-(j/i\sqrt{2})^2 = \frac{1}{2}j^2$.) The current is a primary of weight 1 (Example 11.27), so its modes are labelled with a shift of 1:

$$j(z) = \sum_{n\in\mathbb{Z}} a_n\, z^{-n-1}, \qquad a_n = \oint_0 \frac{\mathrm{d}z}{2\pi i}\, z^n\, j(z). \tag{11.105}$$

Worked example 11.37: The oscillator algebra from the jj OPE

$$[a_m, a_n] \overset{(1)}{=} \oint_0 \frac{\mathrm{d}z}{2\pi i} z^n \oint_z \frac{\mathrm{d}w}{2\pi i} w^m \frac{1}{(w-z)^2} \overset{(2)}{=} \oint_0 \frac{\mathrm{d}z}{2\pi i} z^n\, m\, z^{m-1} \overset{(3)}{=} m\,\delta_{m+n,0}.$$

(1) The double-contour trick (11.100) with the OPE (11.104).
(2) Cauchy: the residue of $w^m/(w-z)^2$ at $w = z$ is $\frac{\mathrm{d}}{\mathrm{d}w}w^m = mw^{m-1}$.
(3) $\oint z^{m+n-1}\frac{\mathrm{d}z}{2\pi i} = \delta_{m+n,0}$.

So a_0 commutes with everything (it is the U(1) charge, the momentum of the zero mode), and for $n > 0$ the pairs (a_n, a_{-n}) are harmonic oscillators: $b_n = a_n/\sqrt{n}$ and $b_n^\dagger = a_{-n}/\sqrt{n}$ satisfy $[b_n, b_n^\dagger] = 1$. With $a_n^\dagger = a_{-n}$ (the factor i in j is what makes j Hermitian in radial quantisation), the Fock space built by the a_{-n} on a state annihilated by all $a_{n>0}$ has a positive inner product.

The Virasoro generators as oscillator bilinears. Insert (11.105) into $T = \frac{1}{2}{:}jj{:}$ and collect the coefficient of z^{-n-2}:

$$L_n = \frac{1}{2}\sum_{k\in\mathbb{Z}} {:}a_{n-k}\,a_k{:}, \qquad L_0 = \frac{1}{2}a_0^2 + \sum_{k\geq 1} a_{-k}\,a_k. \tag{11.106}$$

Normal ordering puts the annihilators $a_{k>0}$ to the right. It only matters for L_0: for $n \neq 0$ the two factors a_{n-k} and a_k commute (since $[a_{n-k}, a_k] = (n-k)\delta_{n,0} = 0$). In L_0 the unordered sum would be $\frac{1}{2}a_0^2 + \frac{1}{2}\sum_{k\geq 1}(a_{-k}a_k + a_k a_{-k}) = \frac{1}{2}a_0^2 + \sum_{k\geq 1} a_{-k}a_k + \frac{1}{2}\sum_{k\geq 1} k$, and the divergent constant $\frac{1}{2}\sum k$ is precisely the zero-point energy that normal ordering throws away. (Regularised as $\zeta(-1) = -\frac{1}{12}$, it gives $-\frac{1}{24}$: the Casimir energy $-c/24$ with $c = 1$ again.)

Worked example 11.38: The action of L_n on the oscillators

Since j is primary of weight 1, (11.101) gives $[L_m, j(z)] = (m+1)z^m j(z) + z^{m+1}\partial j(z)$. Taking the z^n moment:

$$[L_m, a_n] \overset{(1)}{=} \oint_0 \frac{\mathrm{d}z}{2\pi i}\, z^n\big((m+1)z^m\, j + z^{m+1}\partial j\big) \overset{(2)}{=} (m+1)\,a_{m+n} - (m+n+1)\,a_{m+n} = -n\,a_{m+n}.$$

(1) $a_n = \oint z^n j$, and L_m commutes with the c-number z^n.

(2) First term: definition of a_{m+n}. Second: integrate by parts, $\oint z^{m+n+1}\partial j = -(m+n+1)\oint z^{m+n} j$.

In particular $[L_0, a_{-n}] = n\,a_{-n}$: each creation operator a_{-n} raises the L_0 eigenvalue by n. One can check the same relation directly from (11.106) and $[a_m, a_n] = m\delta_{m+n,0}$.

Worked example 11.39: The central charge from a norm: $c = 1$

The vacuum $|0\rangle$ satisfies $a_n|0\rangle = 0$ for $n \geq 0$. The Virasoro algebra predicts, for $m \geq 2$,

$$\langle 0|L_m L_{-m}|0\rangle \overset{(1)}{=} \langle 0|[L_m, L_{-m}]|0\rangle \overset{(2)}{=} 2m\langle 0|L_0|0\rangle + \frac{c}{12}m(m^2-1) \overset{(3)}{=} \frac{c}{12}m(m^2-1).$$

(1) $L_m|0\rangle = 0$ for $m \geq -1$ (Section 11.4.7 below; for the boson it is visible from (11.106), since every term of L_m contains an annihilator or a_0).

(2) The Virasoro algebra (11.102).

(3) $L_0|0\rangle = 0$.

Now compute the left side with oscillators. In $L_{-m}|0\rangle = \frac{1}{2}\sum_k {:}a_{-m-k}a_k{:}|0\rangle$ only the terms with both factors creation operators survive: $k = -1, \ldots, -(m-1)$. Relabelling,

$$L_{-m}|0\rangle = \frac{1}{2}\sum_{k=1}^{m-1} a_{-k}\,a_{-(m-k)}|0\rangle.$$

For example $L_{-2}|0\rangle = \frac{1}{2}a_{-1}^2|0\rangle$ and $L_{-3}|0\rangle = a_{-1}a_{-2}|0\rangle$. The norm is

$$\langle 0|L_m L_{-m}|0\rangle \overset{(1)}{=} \frac{1}{4}\sum_{k,l=1}^{m-1}\langle 0|a_{m-l}\,a_l\,a_{-k}\,a_{-(m-k)}|0\rangle \overset{(2)}{=} \frac{1}{4}\sum_{k,l=1}^{m-1} l(m-l)\big(\delta_{l,k} + \delta_{l,m-k}\big)$$
$$\overset{(3)}{=} \frac{1}{2}\sum_{k=1}^{m-1} k(m-k) \overset{(4)}{=} \frac{1}{2}\Big(m\cdot\frac{m(m-1)}{2} - \frac{(m-1)m(2m-1)}{6}\Big) \overset{(5)}{=} \frac{m(m^2-1)}{12}.$$

(1) $L_m = L_{-m}^\dagger$ (Section 11.4.7), so the bra is $\frac{1}{2}\sum_l \langle 0|a_{m-l}a_l$.

(2) Move the annihilators to the right. Each must be absorbed by a creation operator with the opposite index, and $[a_p, a_{-p}] = p$: a_l pairs with a_{-k} ($l = k$) or with $a_{-(m-k)}$ ($l = m-k$), and a_{m-l} with the other.
(3) Both deltas give $k(m-k)$.
(4) $\sum_{k=1}^{m-1} k = \frac{m(m-1)}{2}$ and $\sum_{k=1}^{m-1} k^2 = \frac{(m-1)m(2m-1)}{6}$.
(5) $m(m-1)\left[\frac{m}{2} - \frac{2m-1}{6}\right] = m(m-1)\frac{m+1}{6}$, times $\frac{1}{2}$.

Comparing: $\frac{c}{12}m(m^2-1) = \frac{m(m^2-1)}{12}$ for every m, so $c = 1$. For $m = 2$: $\|L_{-2}|0\rangle\|^2 = \frac{1}{4}\left\|a_{-1}^2|0\rangle\right\|^2 = \frac{1}{4}\cdot 2 = \frac{1}{2} = \frac{c}{2}$.

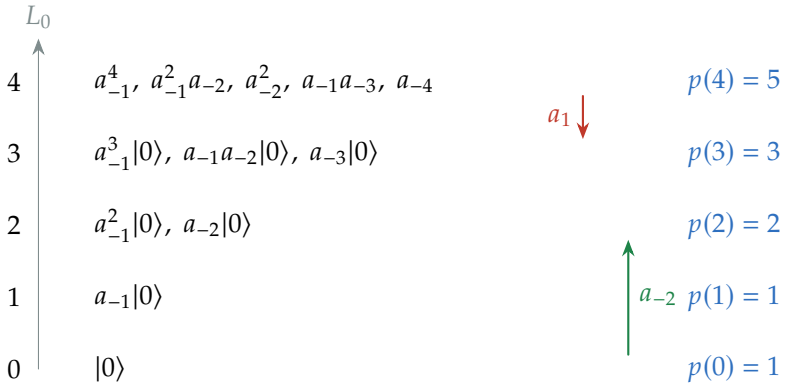

Figure 11.18: The Fock space of one free boson (zero U(1) charge), graded by L_0. A state at level N is a product of creation operators whose indices add up to N, so the number of states is the number $p(N)$ of partitions of N: $1, 1, 2, 3, 5, 7, 11, \ldots$. Creation operators a_{-n} move up by n, annihilators a_n down by n. The same counting will reappear for the Virasoro descendants of a generic highest-weight state.

Try it: the vertex-operator states

The state $|\alpha\rangle = V_\alpha(0)|0\rangle$ of Example 11.28 satisfies $a_n|\alpha\rangle = 0$ for $n > 0$ and $a_0|\alpha\rangle = \frac{\alpha}{\sqrt{2}}|\alpha\rangle$. Use (11.106) to find $L_0|\alpha\rangle$ and compare with the weight $h = \alpha^2/4$.
Answer: $L_0|\alpha\rangle = \frac{1}{2}a_0^2|\alpha\rangle = \frac{1}{2}\cdot\frac{\alpha^2}{2}|\alpha\rangle = \frac{\alpha^2}{4}|\alpha\rangle$. (The a_0 eigenvalue comes from the simple pole of $j(w)V_\alpha(z)$: one contraction gives $i\sqrt{2}\cdot i\alpha\cdot(-\frac{1}{2(w-z)}) = \frac{\alpha/\sqrt{2}}{w-z}$.)

11.4.6 How states are labelled: mass and spin versus dimension and spin

Radial quantisation gave us a Hilbert space and a Hamiltonian. Before we build states in it, we should ask what the *labels* of a state are. In ordinary quantum field theory we never hesitate: a one-particle state is labelled by its mass and its spin. In a conformal field theory these labels are replaced by the scaling dimension Δ and the spin s. This subsection explains why the old labels fail and why the new ones work.

Ordinary QFT: Wigner's classification. In a Poincaré-invariant theory (signature $(+,-,-,-)$ for this paragraph) the symmetry generators are the momenta P_μ and the Lorentz generators $J_{\mu\nu}$. A one-particle state is, by definition, a state in an **irreducible representation** of the Poincaré group: a space of states that the group maps into itself and that has no smaller invariant subspace. By Schur's lemma, an operator that commutes with every generator acts as a number

on an irreducible representation. Such operators are the **Casimirs**. The Poincaré group has two:

$$P^2 = P_\mu P^\mu, \qquad W^2 = W_\mu W^\mu, \quad W_\mu \coloneqq \tfrac{1}{2}\,\epsilon_{\mu\nu\rho\sigma} J^{\nu\rho} P^\sigma, \tag{11.107}$$

where W_μ is the **Pauli–Lubanski vector**. Their values label the representation. For a massive particle go to the rest frame, $p^\mu = (m,0,0,0)$, and write $J_i = \frac{1}{2}\epsilon_{ijk}J^{jk}$ for the angular momentum:

$$\begin{aligned} W_0 &\overset{(1)}{=} \tfrac{1}{2}\,\epsilon_{0\nu\rho0} J^{\nu\rho} m = 0, \\ W_i &\overset{(2)}{=} \tfrac{1}{2}\,\epsilon_{ijk0} J^{jk} m \overset{(3)}{=} -\tfrac{1}{2}\,\epsilon_{0ijk} J^{jk} m \overset{(4)}{=} -m\,J_i, \\ W^2 &\overset{(5)}{=} W_0^2 - \textstyle\sum_i W_i^2 = -m^2\,\vec{J}^{\,2} \overset{(6)}{=} -m^2\, s(s+1). \end{aligned}$$

(1) In the rest frame only $P^0 = m$ is nonzero, so $\sigma = 0$; then $\epsilon_{0\nu\rho0}$ has a repeated index and vanishes.
(2) Again only $\sigma = 0$ survives, and ν, ρ must be spatial.
(3) Moving the index 0 from the last slot to the first passes it through three others: an odd permutation, so a minus sign.
(4) $\epsilon_{0ijk} = \epsilon_{ijk}$ and the definition of J_i.
(5) Mostly-minus signature.
(6) On a spin-s multiplet $\vec{J}^{\,2} = s(s+1)$.

So a particle is labelled by (m^2, s), and its states $|p,\sigma\rangle$ run over the mass shell $p^2 = m^2$ and the $2s+1$ spin projections σ. (For $m = 0$ the rest frame does not exist and s is replaced by the helicity.) This is **Wigner's classification**.

Why mass fails in a CFT. A conformal theory contains the dilatation. Write the generators as Hermitian differential operators on functions,

$$P_\mu = -i\partial_\mu, \qquad D = -i\,x^\nu\partial_\nu, \qquad K_\mu = -i\big(2x_\mu\, x^\nu\partial_\nu - x^2\partial_\mu\big), \tag{11.108}$$

which are $-i$ times the real generators of Section 11.1.1 and (11.13). The key commutator is

$$\begin{aligned} [D, P_\mu] f &\overset{(1)}{=} (-i)^2\big(x^\nu\partial_\nu\partial_\mu f - \partial_\mu(x^\nu\partial_\nu f)\big) \overset{(2)}{=} -\big(x^\nu\partial_\nu\partial_\mu f - \delta^\nu_\mu\partial_\nu f - x^\nu\partial_\mu\partial_\nu f\big) \\ &\overset{(3)}{=} \partial_\mu f \overset{(4)}{=} i\,P_\mu f. \end{aligned} \tag{11.109}$$

(1) Definitions (11.108); $(-i)(-i) = -1$.
(2) Product rule: $\partial_\mu(x^\nu\partial_\nu f) = \delta^\nu_\mu\partial_\nu f + x^\nu\partial_\mu\partial_\nu f$.
(3) Partial derivatives commute, so the first and last terms cancel.
(4) $\partial_\mu = iP_\mu$.

In the same way (the coefficient of ∂ in K_μ has degree 2 in x instead of 0) one finds

$$[D, P_\mu] = iP_\mu, \qquad [D, K_\mu] = -iK_\mu, \qquad [K_\mu, P_\nu] = 2i\big(\eta_{\mu\nu}D - M_{\mu\nu}\big), \tag{11.110}$$

with $M_{\mu\nu} = i(x_\mu\partial_\nu - x_\nu\partial_\mu)$ the rotation generators. Now suppose $|p\rangle$ were a state of definite momentum, $P_\mu|p\rangle = p_\mu|p\rangle$ with $p^2 = m^2$. Conjugate P_μ by a finite dilatation:

$$\begin{aligned} e^{i\alpha D} P_\mu e^{-i\alpha D} &\overset{(1)}{=} P_\mu + [i\alpha D, P_\mu] + \tfrac{1}{2!}\big[i\alpha D, [i\alpha D, P_\mu]\big] + \cdots \\ &\overset{(2)}{=} P_\mu\Big(1 - \alpha + \tfrac{\alpha^2}{2!} - \cdots\Big) = e^{-\alpha} P_\mu, \end{aligned}$$

(1) The expansion $e^X Y e^{-X} = Y + [X,Y] + \frac{1}{2!}[X,[X,Y]] + \cdots$.

(2) $[i\alpha D, P_\mu] = i\alpha \cdot iP_\mu = -\alpha P_\mu$ by (11.109), and each further commutator gives another factor $-\alpha$.

and therefore

$$P_\mu\big(e^{-i\alpha D}|p\rangle\big) \overset{(1)}{=} e^{-i\alpha D}\big(e^{i\alpha D}P_\mu e^{-i\alpha D}\big)|p\rangle \overset{(2)}{=} e^{-\alpha}p_\mu\,\big(e^{-i\alpha D}|p\rangle\big).$$

(1) Insert $e^{-i\alpha D}e^{i\alpha D} = \mathbb{1}$ to the left of P_μ.
(2) The conjugation just computed, then $P_\mu|p\rangle = p_\mu|p\rangle$.

The dilated state has momentum $e^{-\alpha}p_\mu$ and mass squared $e^{-2\alpha}m^2$. So if one value $m^2 > 0$ occurs in the spectrum of P^2, every positive value occurs: the spectrum of P^2 is either $\{0\}$ or a continuum, and there is no discrete mass to label anything. Moreover D does not commute with P^2 (it rescales it), so P^2 is not a Casimir of the conformal group and cannot label its irreducible representations at all. And states of definite P_μ are plane waves, which are not normalisable. In an ordinary theory we cure this with wave packets around a sharp mass shell; in a CFT there is no mass shell to build them around.

Physical picture: no particles, only a continuum

The Fourier transform of a two-point function of dimension Δ in d dimensions is $\langle \mathcal{O}\mathcal{O}\rangle(p) \propto (p^2)^{\Delta-d/2}$. An ordinary particle shows up as a pole $1/(p^2-m^2)$. A power $(p^2)^{\Delta-d/2}$ has no pole, only a branch cut starting at $p^2 = 0$: a continuum of "masses". The one exception is $\Delta = \frac{d-2}{2}$, where the power is $(p^2)^{-1}$: a massless pole, i.e. a free massless field such as our free boson.

The CFT answer: diagonalise the dilatation. Instead of P_μ we diagonalise D. Radial quantisation makes this natural: on the cylinder $\mathbb{R}\times S^{d-1}$ the dilatation *is* the time translation, so its eigenstates are energy eigenstates. Space is now the compact sphere S^{d-1}, so the spectrum is discrete and the eigenstates are normalisable, just as a particle in a box has discrete, normalisable energy levels while a free particle on a line does not. It is convenient to use the generator with real eigenvalues in radial quantisation,

$$\mathcal{D} := -iD, \qquad [\mathcal{D}, P_\mu] = P_\mu, \qquad [\mathcal{D}, K_\mu] = -K_\mu, \qquad \mathcal{D}|\Delta\rangle = \Delta|\Delta\rangle, \tag{11.111}$$

where the commutators follow from (11.110): $[-iD, P_\mu] = -i\cdot iP_\mu = P_\mu$. (In radial quantisation Hermitian conjugation includes the inversion of (11.118), and it is $\mathcal{D}$, not D, that is Hermitian there.) Now the ladder:

$$\begin{aligned}\mathcal{D}\big(P_\mu|\Delta\rangle\big) &\overset{(1)}{=} \big(P_\mu\mathcal{D} + [\mathcal{D}, P_\mu]\big)|\Delta\rangle \overset{(2)}{=} (\Delta+1)\,P_\mu|\Delta\rangle,\\ \mathcal{D}\big(K_\mu|\Delta\rangle\big) &\overset{(3)}{=} \big(K_\mu\mathcal{D} + [\mathcal{D}, K_\mu]\big)|\Delta\rangle \overset{(4)}{=} (\Delta-1)\,K_\mu|\Delta\rangle.\end{aligned} \tag{11.112}$$

(1) Reorder: $\mathcal{D}P_\mu = P_\mu\mathcal{D} + [\mathcal{D}, P_\mu]$.
(2) $\mathcal{D}|\Delta\rangle = \Delta|\Delta\rangle$ and $[\mathcal{D}, P_\mu] = P_\mu$ from (11.111).
(3) The same reordering for K_μ.
(4) $[\mathcal{D}, K_\mu] = -K_\mu$.

So P_μ raises the dimension by one and K_μ lowers it by one, exactly like $a^\dagger$ and a for the harmonic oscillator. Physically, $P_\mu|\Delta\rangle$ is the state of the field $\partial_\mu\mathcal{O}$, and a derivative adds one unit of inverse length. If dimensions are bounded below (unitarity demands it, Section 11.4.11), repeated lowering must stop: there is a state with

$$K_\mu|\Delta\rangle = 0 \quad \text{for all } \mu. \tag{11.113}$$

This lowest state is the state of a **primary** operator, and the states $P_{\mu_1}\cdots P_{\mu_n}|\Delta\rangle$ above it are its **descendants**. The representation is labelled by the dimension Δ of the bottom state and by its spin under the rotations $M_{\mu\nu}$, which commute with $\mathcal{D}$.

The same structure in two dimensions. In $d=2$ the dictionary is

$$\mathcal{D} = L_0 + \bar{L}_0, \qquad \text{rotation} = L_0 - \bar{L}_0, \qquad P \leftrightarrow L_{-1},\ \bar{L}_{-1}, \qquad K \leftrightarrow L_1,\ \bar{L}_1. \tag{11.114}$$

Indeed $\ell_{-1} = -\partial_z$ is a translation and $\ell_1 = -z^2\partial_z$ is a special conformal transformation (Section 11.3), and the Virasoro algebra (11.102) gives $[L_0, L_{\mp 1}] = \pm L_{\mp 1}$, the two-dimensional form of (11.111). A state with L_0 and $\bar{L}_0$ eigenvalues $(h, \bar{h})$ is labelled by

$$\Delta = h + \bar{h} \quad \text{(scaling dimension)}, \qquad s = h - \bar{h} \quad \text{(spin)}, \tag{11.115}$$

and by (11.98) its energy on the cylinder is $\Delta - \frac{c}{12}$ and its momentum is s. What is new in two dimensions is that every L_{-n} with $n \geq 1$ raises the weight, not just L_{-1}. For a state $|h\rangle$ with $L_0|h\rangle = h|h\rangle$,

$$L_0\big(L_{-n}|h\rangle\big) \overset{(1)}{=} \big(L_{-n}L_0 + [L_0, L_{-n}]\big)|h\rangle \overset{(2)}{=} \big(h\,L_{-n} + n\,L_{-n}\big)|h\rangle = (h+n)\,L_{-n}|h\rangle. \tag{11.116}$$

(1) Reorder.
(2) (11.102) with $(m,n) \to (0,-n)$: $[L_0, L_{-n}] = (0-(-n))L_{-n} + \frac{c}{12}\cdot 0 = nL_{-n}$ (the central term has a factor $m = 0$).

So L_{-n} raises h by n and, by the same computation, L_n lowers it by n. The two-dimensional primary is annihilated by all the lowering operators,

$$L_n|h\rangle = 0 \quad (n > 0),$$

the infinite-dimensional version of (11.113). This is precisely the highest-weight condition of the next subsection. A state annihilated only by L_1 (the true K) is called **quasi-primary**: it is primary for the global group but not for the whole Virasoro algebra. T itself is the standard example: its state $L_{-2}|0\rangle$ obeys $L_1L_{-2}|0\rangle = [L_1, L_{-2}]|0\rangle = 3L_{-1}|0\rangle = 0$, but $L_2L_{-2}|0\rangle = [L_2, L_{-2}]|0\rangle = (4L_0 + \frac{c}{2})|0\rangle = \frac{c}{2}|0\rangle \neq 0$.

Worked example 11.40: The quadratic Casimir: labels are still Casimir values

The labels Δ, s are not a break with Wigner's idea; they are Casimir values of the global conformal group. For the global algebra $\{L_{-1}, L_0, L_1\}$, with $[L_1, L_{-1}] = 2L_0$, take $C := L_0^2 - \frac{1}{2}(L_1L_{-1} + L_{-1}L_1)$. It commutes with L_1:

$$\begin{aligned}[C, L_1] &\overset{(1)}{=} L_0[L_0, L_1] + [L_0, L_1]L_0 - \tfrac{1}{2}\big(L_1[L_{-1}, L_1] + [L_{-1}, L_1]L_1\big) \\ &\overset{(2)}{=} -(L_0L_1 + L_1L_0) - \tfrac{1}{2}\big(-2L_1L_0 - 2L_0L_1\big) = 0.\end{aligned}$$

(1) $[AB, C] = A[B, C] + [A, C]B$, and $[L_1, L_1] = 0$ removes the other two terms.
(2) $[L_0, L_1] = -L_1$ and $[L_{-1}, L_1] = -2L_0$.

The same computation with L_{-1} (all signs flipped) and the obvious $[C, L_0] = 0$ (each term of C has total weight zero) show that C commutes with all three generators, so it is constant on an irreducible representation. Evaluate it on the primary:

$$C|h\rangle \overset{(1)}{=} \Big(h^2 - \tfrac{1}{2}L_1L_{-1}\Big)|h\rangle \overset{(2)}{=} \Big(h^2 - \tfrac{1}{2}\big(L_{-1}L_1 + 2L_0\big)\Big)|h\rangle \overset{(3)}{=} h(h-1)|h\rangle.$$

(1) $L_0^2|h\rangle = h^2|h\rangle$, and $L_{-1}L_1|h\rangle = 0$ because $L_1|h\rangle = 0$.

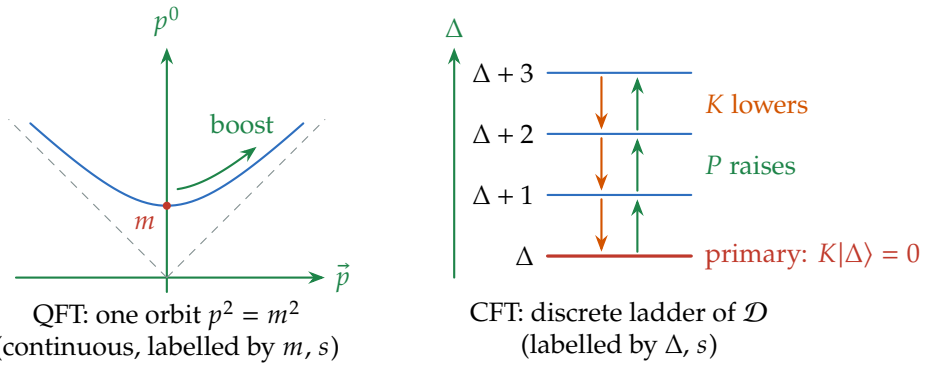
(2) $L_1 L_{-1} = L_{-1}L_1 + [L_1, L_{-1}] = L_{-1}L_1 + 2L_0$.
(3) $L_1|h\rangle = 0$ again, and $L_0|h\rangle = h|h\rangle$.

Adding the antiholomorphic copy, the Casimir of the full global group is

$$2\big(h(h-1) + \bar{h}(\bar{h}-1)\big) \overset{(1)}{=} (\Delta^2 + s^2) - 2\Delta = \Delta(\Delta-2) + s^2.$$

(1) $h = \frac{1}{2}(\Delta + s)$, $\bar{h} = \frac{1}{2}(\Delta - s)$, so $2(h^2 + \bar{h}^2) = \Delta^2 + s^2$ and $2(h + \bar{h}) = 2\Delta$.

This is the $d = 2$ case of the general $\mathrm{SO}(d+1,1)$ Casimir $\Delta(\Delta - d) + \ell(\ell + d - 2)$ with $\ell = |s|$. So a CFT representation is labelled by Casimir eigenvalues just as a particle is. The difference is which Casimirs: those of the conformal group, whose eigenvalues are functions of (Δ, s), rather than P^2 and W^2.



QFT: one orbit $p^2 = m^2$ (continuous, labelled by m, s)

CFT: discrete ladder of $\mathcal{D}$ (labelled by Δ, s)

Figure 11.19: Two ways of labelling states. Left: in a Poincaré-invariant theory a particle's states fill one mass hyperboloid $p^2 = m^2$; boosts move along it and the Casimirs $P^2 = m^2$, W^2 label the whole orbit. A dilatation would move the hyperboloid itself, so in a CFT no single m survives. Right: in a CFT we diagonalise the dilatation instead. Its spectrum is discrete; P_μ climbs the ladder by one unit, K_μ descends, and the bottom rung, killed by K_μ, is the primary.

	ordinary QFT	CFT (in $d = 2$ where specified)
symmetry group	Poincaré: P_μ, $J_{\mu\nu}$	conformal $\mathrm{SO}(d+1,1)$: P_μ, $M_{\mu\nu}$, D, K_μ; in $d = 2$ two copies of Virasoro
labels	Casimirs $P^2 = m^2$ and $W^2 = -m^2 s(s+1)$ (or helicity)	eigenvalues of $\mathcal{D}$ and rotation: $\Delta = h + \bar{h}$, $s = h - \bar{h}$ (Casimir $\Delta(\Delta - d) + \ell(\ell + d - 2)$)
spectrum of the label	m discrete, p_μ continuous	Δ discrete; P^2 continuous with no gap
basic object	a particle: the orbit $\lvert p, \sigma\rangle$ on the mass shell	a primary $\lvert h, \bar{h}\rangle = \phi(0)\lvert 0\rangle$ with K_μ (in 2D all $L_{n>0}$) annihilating it, plus its tower of descendants
moving within the representation	boosts and translations, at fixed m	P_μ raises Δ by 1, K_μ lowers it by 1; in 2D L_{-n} raises h by n
generator of time evolution	$H = P^0$ on $\mathbb{R}^{d-1}$	$\mathcal{D}$ on the sphere S^{d-1}; in 2D $H_{\mathrm{cyl}} = L_0 + \bar{L}_0 - \frac{c}{12}$
states are	asymptotic particles	local operators at the origin (state–operator correspondence)

Table 11.1: Labelling states in ordinary QFT and in CFT.

11.4.7 States from fields: highest-weight states

The vacuum. The vacuum $|0\rangle$ is the state on the cylinder at $\tau \to -\infty$ with nothing inserted, i.e. nothing at $z = 0$. So correlation functions with $|0\rangle$ as the in-state must be regular at the origin. Apply this to T itself:

$$T(z)|0\rangle = \sum_{n\in\mathbb{Z}} L_n|0\rangle\, z^{-n-2}$$

must be regular as $z \to 0$. The powers z^{-n-2} with $n \geq -1$ are singular, so

$$L_n|0\rangle = 0 \quad \text{for } n \geq -1, \qquad \text{in particular} \quad L_{-1}|0\rangle = L_0|0\rangle = L_1|0\rangle = 0. \tag{11.117}$$

The vacuum is invariant under the global conformal group. (Nash's (11.46) states the last part; we come back to it in Section 11.4.13.) The first nontrivial state is $L_{-2}|0\rangle = T(0)|0\rangle$, the state made by the stress tensor itself.

Hermitian conjugation. On the cylinder, Hermitian conjugation of a Euclidean field theory includes time reversal $\tau \to -\tau$. On the plane, $\tau \to -\tau$ with σ fixed is $z = e^{\tau+i\sigma} \mapsto e^{-\tau+i\sigma} = 1/\bar{z}$. For a primary of weights $(h, \bar{h})$ with real correlators, the conjugate is defined by

$$\phi(z,\bar{z})^\dagger = \bar{z}^{-2h}\, z^{-2\bar{h}}\, \phi\big(1/\bar{z}, 1/z\big). \tag{11.118}$$

The prefactor is the conformal factor of the map $z \mapsto 1/\bar{z}$, as in the primary law (11.60). Apply it to T, which has $(h, \bar{h}) = (2, 0)$:

$$\sum_n L_n^\dagger\, \bar{z}^{-n-2} \overset{(1)}{=} T(z)^\dagger \overset{(2)}{=} \bar{z}^{-4}\, T(1/\bar{z}) \overset{(3)}{=} \bar{z}^{-4} \sum_m L_m\, \bar{z}^{m+2} = \sum_m L_m\, \bar{z}^{m-2}.$$

(1) Conjugate the mode expansion; $(z^{-n-2})^* = \bar{z}^{-n-2}$.
(2) (11.118) for T.
(3) Mode expansion at the point $1/\bar{z}$.

Matching powers of $\bar{z}$, $-n-2 = m-2$, i.e. $m = -n$:

$$L_n^\dagger = L_{-n}, \qquad \bar{L}_n^\dagger = \bar{L}_{-n}. \tag{11.119}$$

This is what makes L_0 Hermitian (so its eigenvalues, the energies, are real) and what turns lowering operators into the adjoints of raising operators. It is the input for all the norm computations below. In particular the Virasoro algebra with c real is compatible with (11.119): taking the adjoint of (11.102) gives $[L_{-n}, L_{-m}] = (m-n)L_{-m-n} + \frac{c}{12}m(m^2-1)\delta_{m+n,0}$, which is (11.102) again with $(m, n) \to (-n, -m)$.

The state of a primary field (Nash's (11.36)–(11.38)). The field at the origin prepares a state at $\tau = -\infty$. Define, as Nash does,

$$|h\rangle := \phi(0)|0\rangle, \qquad |h,\bar{h}\rangle := \phi(0,0)|0\rangle. \tag{11.120}$$

Its properties follow from (11.101) and (11.117):

$$\begin{aligned} L_n|h\rangle &\overset{(1)}{=} [L_n, \phi(0)]|0\rangle + \phi(0)L_n|0\rangle \overset{(2)}{=} \big(h(n+1)z^n\phi(z) + z^{n+1}\partial\phi(z)\big)\big|_{z=0}|0\rangle \\ &\overset{(3)}{=} \begin{cases} h|h\rangle, & n = 0, \\ 0, & n \geq 1, \\ \partial\phi(0)|0\rangle, & n = -1. \end{cases} \end{aligned} \tag{11.121}$$

(1) Write $L_n\phi = [L_n, \phi] + \phi L_n$.
(2) (11.101) at $z = 0$; the second term vanishes for $n \geq -1$ by (11.117).
(3) For $n \geq 1$ both z^n and z^{n+1} vanish at $z = 0$; for $n = 0$ only $h\phi(0)$ survives; for $n = -1$ only $\partial\phi(0)$ survives.

So $L_0|h\rangle = h|h\rangle$ and $L_n|h\rangle = 0$ for $n \geq 1$: Nash's (11.37), which is exactly the defining property (6.57) of the highest-weight vector of Chapter 6. With $\bar{T}$ as well, $|h, \bar{h}\rangle$ is simultaneously highest weight for *Vir* and $\overline{Vir}$ (Nash's (11.38)), and the two towers built on it give a representation of $Vir \oplus \overline{Vir}$. Nash asks for a "single valued" primary: under a rotation by 2π a field picks up $e^{2\pi i(h-\bar{h})}$, so single-valuedness means integer spin $h - \bar{h}$ (fermions such as ψ, with spin $\frac{1}{2}$, need a sign and a choice of boundary condition).

Working definition 11.12 (highest-weight state)

A state $|h\rangle$ is a **highest-weight state** of weight h for a representation of *Vir* with central charge c [a space of states on which the L_n act with $[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12}m(m^2-1)\delta_{m+n,0}$] if

$$L_0|h\rangle = h|h\rangle, \qquad L_n|h\rangle = 0 \quad (n \geq 1).$$

Operational test: a state is highest weight if and only if it is annihilated by L_1 and L_2 (every L_n with $n \geq 3$ is a multiple of a commutator of these: $L_3 = -[L_1, L_2]$, $L_4 = -\frac{1}{2}[L_1, L_3]$, and so on by (11.102)). *State–operator form:* highest-weight states are exactly the states $\phi(0)|0\rangle$ of primary fields [fields for which $\phi\, dz^h d\bar{z}^{\bar{h}}$ is invariant under conformal maps].

Watch out: highest or lowest?

$|h\rangle$ has the *lowest* L_0 eigenvalue in its tower, since $[L_0, L_{-n}] = nL_{-n}$ makes every L_{-n} raise the energy. Physicists still call it "highest weight" because the roles of raising and lowering are reversed compared with, say, SU(2): the annihilation conditions $L_{n>0}|h\rangle = 0$ look like those of a highest-weight vector. Nash's footnote in Chapter 6 makes the same remark.

Why $L_n|h\rangle = 0$ is forced (the Chapter 6 argument). There is an independent argument, which Nash uses in Chapter 6. From the algebra, $[L_0, L_n] = -nL_n$, so

$$L_0\big(L_n|h\rangle\big) \overset{(1)}{=} \big(L_nL_0 + [L_0, L_n]\big)|h\rangle \overset{(2)}{=} (h-n)\,L_n|h\rangle.$$

(1) Reorder.
(2) $L_0|h\rangle = h|h\rangle$ and $[L_0, L_n] = (0-n)L_n$ from (11.102).

If $L_n|h\rangle$ were nonzero for some $n \geq 1$ it would have energy $h - n < h$. In a physical theory the energy $L_0 + \bar{L}_0$ is bounded below, and a state of lowest energy in its tower must therefore be annihilated by all $L_{n\geq 1}$. Both routes lead to the same place: the field-theory route shows that primary fields produce highest-weight states; the algebraic route shows that boundedness from below demands them.

Inner products and the out-state. The bra corresponding to $|h\rangle$ is, by (11.118),

$$\langle h| = \big(\phi(0,0)|0\rangle\big)^\dagger \overset{(1)}{=} \lim_{z\to 0}\langle 0|\,\bar{z}^{-2h}z^{-2\bar{h}}\,\phi\big(1/\bar{z}, 1/z\big) \overset{(2)}{=} \lim_{w\to\infty} w^{2h}\bar{w}^{2\bar{h}}\,\langle 0|\,\phi(w,\bar{w}).$$

(1) (11.118); the adjoint reverses the order, so $\langle 0|$ stands on the left.
(2) Set $w = 1/\bar{z}$, so $\bar{w} = 1/z$, $\bar{z}^{-2h} = w^{2h}$ and $z^{-2\bar{h}} = \bar{w}^{2\bar{h}}$.

In words: the out-state is made by putting ϕ at infinity and multiplying by the conformal factor that compensates the decay of the two-point function. Concretely,

$$\langle h|h\rangle \overset{(1)}{=} \lim_{w\to\infty} w^{2h}\bar{w}^{2\bar{h}}\,\langle\phi(w,\bar{w})\,\phi(0,0)\rangle \overset{(2)}{=} \lim_{w\to\infty} w^{2h}\bar{w}^{2\bar{h}}\,\frac{C}{w^{2h}\bar{w}^{2\bar{h}}} = C.$$

(1) The out-state is prepared by the operator at $z=\infty$, rescaled by its conformal factor.
(2) The two-point function (11.65).

We normalise primaries so that $C=1$, i.e. $\langle h|h\rangle = 1$. Positivity of the two-point coefficient is the first unitarity condition: it is the norm of a state.

11.4.8 Descendants and conformal families

Descendant states (Nash's (11.39)). The highest-weight conditions say that $L_{n\geq 1}$ kill $|h\rangle$ and L_0 multiplies it by h. The only operators that produce new states are the L_{-n} with $n\geq 1$ (Nash notes that "the condition $n<0$ follows from 11.37"). Acting repeatedly gives the **descendant** (or **secondary**) states

$$L_{-n_1}L_{-n_2}\cdots L_{-n_k}|h\rangle, \qquad n_1\geq n_2\geq\cdots\geq n_k\geq 1. \tag{11.122}$$

Nash writes the same states as $L_{-1}^{\alpha_1}L_{-2}^{\alpha_2}\cdots L_{-s}^{\alpha_s}|h\rangle$. The ordering does not matter for which states we get: any product of L_{-n}'s can be reordered into a fixed order using (11.102), at the cost of terms with fewer L's, which are again of the same form. So either ordering gives a spanning set.

The level. Each L_{-n} raises L_0 by n:

$$\begin{aligned} L_0\,L_{-n_1}\cdots L_{-n_k}|h\rangle &\overset{(1)}{=} \Big(\sum_{j=1}^{k} L_{-n_1}\cdots[L_0,L_{-n_j}]\cdots L_{-n_k} + L_{-n_1}\cdots L_{-n_k}L_0\Big)|h\rangle \\ &\overset{(2)}{=} \Big(\sum_j n_j + h\Big)\,L_{-n_1}\cdots L_{-n_k}|h\rangle. \end{aligned} \tag{11.123}$$

(1) Move L_0 to the right through each factor, picking up one commutator each time.
(2) $[L_0,L_{-n}]=nL_{-n}$ and $L_0|h\rangle = h|h\rangle$.

In Nash's notation (11.44), L_0 has eigenvalue $h+\sum_i i\alpha_i$ on $L_{-1}^{\alpha_1}\cdots L_{-s}^{\alpha_s}|h\rangle$. The integer $N=\sum_j n_j=\sum_i i\alpha_i$ is the **level** of the descendant.

Different levels are orthogonal. Nash: "Since the Virasoro algebra representation is unitary, the eigenvectors of L_0 are mutually orthogonal." The fact needed is only that L_0 is Hermitian, which is (11.119). For $|a\rangle, |b\rangle$ at levels $N_a\neq N_b$:

$$(h+N_a)\langle b|a\rangle \overset{(1)}{=} \langle b|L_0|a\rangle \overset{(2)}{=} \big(\langle a|L_0^\dagger|b\rangle\big)^* \overset{(3)}{=} \big(\langle a|L_0|b\rangle\big)^* \overset{(4)}{=} (h+N_b)\langle b|a\rangle,$$

(1) $|a\rangle$ is an L_0 eigenvector.
(2) Definition of the adjoint.
(3) $L_0^\dagger = L_0$.
(4) $|b\rangle$ is an eigenvector with real eigenvalue $h+N_b$.

so $(N_a-N_b)\langle b|a\rangle = 0$ and $\langle b|a\rangle = 0$. The space of descendants is therefore an orthogonal direct sum of finite-dimensional *levels*. This is the "grading" of Nash's footnote 3: $[\phi] = \bigoplus_{N\geq 0}[\phi]^N$.

How many states per level? At level N the states (11.122) correspond to the ways of writing $N = n_1 + \cdots + n_k$ with $n_1 \geq \cdots \geq n_k \geq 1$: the partitions of N. So at most $p(N)$ independent states:

N	states	$p(N)$
0	$\|h\rangle$	1
1	$L_{-1}\|h\rangle$	1
2	$L_{-2}\|h\rangle$, $L_{-1}^2\|h\rangle$	2
3	$L_{-3}\|h\rangle$, $L_{-2}L_{-1}\|h\rangle$, $L_{-1}^3\|h\rangle$	3
4	L_{-4}, $L_{-3}L_{-1}$, L_{-2}^2, $L_{-2}L_{-1}^2$, L_{-1}^4 (on $\|h\rangle$)	5

The generating function is $\sum_N p(N)q^N = \prod_{n\geq 1}(1-q^n)^{-1}$, the same as for the boson Fock space of Figure 11.18: each L_{-n} is like an independent oscillator of frequency n. Whether these $p(N)$ states are really linearly independent, and whether they have positive norm, depends on (c, h). That question occupies Sections 11.4.9 and 11.4.10.

Descendant fields (Nash's (11.40)–(11.42)). Every state is made by a field. The field that makes $L_{-n}|h\rangle$ is found by moving the contour of L_{-n} from around 0 to around the insertion point z of ϕ. Define, for any field ϕ at z,

$$\big(L_n\phi\big)(z) \equiv L_n(z)\phi(z) := \oint_z \frac{\mathrm{d}w}{2\pi i}\,(w-z)^{n+1}\,T(w)\,\phi(z), \tag{11.124}$$

Nash's (11.41). At $z = 0$ this is the L_n of (11.94) acting on $\phi(0)$, $L_n(0) = L_n$, and applying it to $|0\rangle$ gives the state: $(L_{-n}\phi)(0)|0\rangle = L_{-n}|h\rangle$. Comparing (11.124) with the Laurent expansion of Section 11.3.12, $(L_n\phi)(z)$ is just the coefficient $T_n(\phi)$ of $(w-z)^{-n-2}$ in $T(w)\phi(z)$. So the full OPE of T with ϕ is

$$T(w)\,\phi(z) = \sum_{n\in\mathbb{Z}} \frac{(L_n\phi)(z)}{(w-z)^{n+2}} = \frac{h\,\phi(z)}{(w-z)^2} + \frac{(L_{-1}\phi)(z)}{w-z} + (L_{-2}\phi)(z) + (w-z)(L_{-3}\phi)(z) + \cdots \tag{11.125}$$

for a primary (where $L_{n\geq 1}\phi = 0$). This is Nash's (11.45), and its first two terms are (11.26). The whole OPE of T with ϕ, including the regular part, is a list of the descendants of ϕ.

Watch out: the summation in Nash's (11.45)

Nash prints (11.45) as $\sum_{n=0}^{\infty}(w-z)^{-n-2}L_n(w)\phi(z)$. Read literally (sum over $n \geq 0$) that would contain only $L_0, L_1, L_2, \ldots$, i.e. only $h\phi/(w-z)^2$ for a primary, and lose the derivative term. The correct range is $n \in \mathbb{Z}$ (equivalently $n \leq 0$ for a primary, i.e. $\sum_{k\geq 0}(w-z)^{k-2}L_{-k}\phi$), with the argument z, not w, in L_n, as in (11.125).

Worked example 11.41: The first descendants, as fields

(a) L_{-1} is the derivative. From (11.124) with $n = -1$ and the OPE,

$$(L_{-1}\phi)(z) \overset{(1)}{=} \oint_z \frac{\mathrm{d}w}{2\pi i}\,T(w)\phi(z) \overset{(2)}{=} \oint_z \frac{\mathrm{d}w}{2\pi i}\left(\frac{h\phi}{(w-z)^2} + \frac{\partial\phi}{w-z}\right) = \partial\phi(z).$$

(1) $(w-z)^{n+1} = 1$ for $n = -1$.
(2) Only the simple pole has a residue.

So the derivative of a primary is its level-1 descendant. It is not itself primary (Nash: "the derivative of a primary field is not primary"): by (11.102), $L_1L_{-1}|h\rangle = [L_1, L_{-1}]|h\rangle = 2L_0|h\rangle = 2h|h\rangle \neq 0$ unless $h = 0$.
(b) The descendants of the identity. The identity field I has $h = 0$, and $T(w)I = T(w)$ has no

singular terms. Taylor expanding $T(w) = \sum_{k\ge 0} \frac{(w-z)^k}{k!}\partial^k T(z)$,

$$(L_{-n}I)(z) \overset{(1)}{=} \oint_z \frac{\mathrm{d}w}{2\pi i}\,(w-z)^{-n+1}\,T(w) \overset{(2)}{=} \sum_{k\ge 0} \frac{\partial^k T(z)}{k!} \oint_z \frac{\mathrm{d}w}{2\pi i}\,(w-z)^{k-n+1}$$
$$\overset{(3)}{=} \frac{\partial^{n-2}T(z)}{(n-2)!} \quad (n \ge 2),$$

(1) (11.124) with $\phi = I$.
(2) Taylor series.
(3) The integral is 1 when $k - n + 1 = -1$, i.e. $k = n - 2$.

and $(L_{-1}I) = 0$, $L_0 I = 0$. So $T = L_{-2}I$ is a descendant of the identity, and so are all its derivatives: Nash's remark that "$T(z)$ is a secondary field belonging to $[I]$". In the state language this is $L_{-2}|0\rangle = T(0)|0\rangle$.

(c) A level-2 descendant of the boson. In the free boson take $\phi = j = i\sqrt{2}\partial\varphi$ ($h = 1$). Its state is $a_{-1}|0\rangle$ (since $j(0)|0\rangle = \sum_n a_n z^{-n-1}|0\rangle|_{z=0}$ keeps only a_{-1}). Then

$$L_{-1}a_{-1}|0\rangle \overset{(1)}{=} [L_{-1}, a_{-1}]|0\rangle + a_{-1}L_{-1}|0\rangle \overset{(2)}{=} a_{-2}|0\rangle,$$
$$L_{-2}a_{-1}|0\rangle \overset{(3)}{=} [L_{-2}, a_{-1}]|0\rangle + a_{-1}L_{-2}|0\rangle \overset{(4)}{=} a_{-3}|0\rangle + \tfrac{1}{2}a_{-1}^3|0\rangle.$$

(1) Commute L_{-1} to the right.
(2) $[L_m, a_n] = -n a_{m+n}$ gives $[L_{-1}, a_{-1}] = a_{-2}$; and $L_{-1}|0\rangle = 0$.
(3) Same move.
(4) $[L_{-2}, a_{-1}] = a_{-3}$ and $L_{-2}|0\rangle = \frac{1}{2}a_{-1}^2|0\rangle$ (Example 11.39).

The first is the state of ∂j, as it must be. The Virasoro descendants of j are particular combinations of Fock states.

Descendant fields in general (Nash's (11.42)–(11.43)). Iterating (11.124), the field of the state $L_{-n_1}\cdots L_{-n_k}|h\rangle$ is $(L_{-n_1}\cdots L_{-n_k}\phi)(z)$, defined by nested contours, the innermost (L_{-n_k}) closest to z. Including the antiholomorphic generators,

$$\big(\bar L_{-\bar n_1}\cdots \bar L_{-\bar n_l}\, L_{-n_1}\cdots L_{-n_k}\phi\big)(z,\bar z) \quad\longleftrightarrow\quad \bar L_{-\bar n_1}\cdots \bar L_{-\bar n_l}\, L_{-n_1}\cdots L_{-n_k}|h,\bar h\rangle,$$

of weights $(h + \sum n_i,\ \bar h + \sum \bar n_j)$. The set of all of these, the primary together with all its descendants, is the **conformal family** $[\phi]$.

Working definition 11.13 (conformal family)

The **conformal family** $[\phi]$ of a primary field ϕ of weights $(h,\bar h)$ is the set of fields $(\bar L_{-\bar n_1}\cdots L_{-n_1}\cdots\phi)$; equivalently the representation of $Vir \oplus \overline{Vir}$ spanned by $|h,\bar h\rangle$ and its descendants [the states made from $|h,\bar h\rangle$ by any string of L_{-n} and $\bar L_{-\bar n}$ with $n,\bar n \ge 1$]. *Operational use:* the Ward identities [they trade each L_{-n} acting on a field for derivatives in the positions of the other fields] express every correlation function of descendants as a differential operator acting on the correlation function of the primaries, so a CFT is specified by its primaries and their correlators.

Operator products inside families. Nash remarks that the product of fields in a conformal family is again expressible through fields in the family, using $T(w)T(z)$ as the example. The precise statement, which is what the TT example shows, is that *fields of the identity family* $[I]$ (that

is, T, its derivatives and its normal-ordered products) act on any family $[\phi]$ without leaving it: the OPE (11.125) of T with ϕ involves only descendants of ϕ, and the TT OPE (11.89) involves only I, T and ∂T, all in $[I]$.

Watch out: two fields from the same family

Nash's sentence "if we take any two fields A and B in the same conformal family $[\phi]$ then the product $A(w)B(z)$ is expressible in a like manner over the fields in $[\phi]$" is true for $[\phi] = [I]$ but not in general. In the Ising model the spin field σ (weight $\frac{1}{16}$) has $\sigma \times \sigma = [I] + [\varepsilon]$: its OPE with itself contains the identity family and the energy family, not the family $[\sigma]$. In general the families appearing in $[\phi_i] \times [\phi_j]$ are governed by the **fusion rules**, which are the subject of Nash's §5 (the next part of these notes). What is always true is that $[I] \times [\phi] = [\phi]$.

Reading Nash (pp. 307–310, (11.33)–(11.45))

Nash defines the modes L_n (11.33), states that the TT OPE implies the Virasoro algebra (11.34) (we did the contour computation, showed via the Jacobi identity that c is the only possible central term, and verified $c = 1$ with oscillators), and adds the second copy (11.35). He identifies the Hamiltonian with $L_0 + \bar{L}_0$ and replaces time ordering by radial ordering in one sentence; we set up radial quantisation, the contour commutator trick, Hermitian conjugation $L_n^\dagger = L_{-n}$ and the cylinder Hamiltonian $L_0 + \bar{L}_0 - c/12$. His (11.36)–(11.38) define $|h\rangle = \phi(0)|0\rangle$ and assert (11.37); we derived it from the $T\phi$ OPE and the regularity of the vacuum, and also from boundedness of the energy as in his Chapter 6. (11.39)–(11.44) introduce descendant states and fields, the operators $L_n(z)$, the conformal family and the level; (11.45) is the full $T\phi$ OPE, whose printed summation range should be $n \in \mathbb{Z}$.

11.4.9 Verma modules: from one state to a representation

Nash's sentence is short: the tower of states $L_{-1}^{\alpha_1} \cdots L_{-s}^{\alpha_s}|h\rangle$ "comprise[s] an irreducible representation of the Virasoro algebra". Two pages later he adds that "there exist non-trivial null states which have zero norm" and that these "must be projected out in order to obtain an irreducible representation". These two statements pull in different directions. The first says the tower is irreducible. The second says that sometimes it is not, and something has to be removed. This subsection makes the construction precise. It is the most important piece of algebra in the chapter, so we go slowly and do one thing at a time.

A change of viewpoint: from a vector space to a module. In quantum mechanics we are used to starting from a Hilbert space $\mathcal{H}$ and then asking which operators act on it. For SU(2), for instance, we are handed the space $\mathbb{C}^{2j+1}$ and the spin matrices on it. The highest-weight construction runs the other way. We start with the *algebra* and one vector $|h\rangle$, and we *build* the space: it is whatever the algebra can produce from $|h\rangle$. What comes out is not a bare vector space. It is a vector space together with a rule saying how every element of the algebra acts on it. Mathematicians call such a thing a module.

Working definition 11.14 (module = representation space)

Let $\mathfrak{g}$ be a Lie algebra [in this chapter the Virasoro algebra, spanned by the L_n and c with their commutators]. A **$\mathfrak{g}$-module** is a complex vector space V together with a linear map $X \mapsto \rho(X) \in \mathrm{End}(V)$ [a linear operator from V to itself, a matrix once a basis is chosen]

such that

$$\rho\big([X,Y]\big) = \rho(X)\rho(Y) - \rho(Y)\rho(X) \qquad \text{for all } X, Y \in \mathfrak{g}.$$

Operational test: write down the action of each generator on a basis, and check that the commutators of the resulting matrices reproduce the brackets of $\mathfrak{g}$. A **submodule** is a subspace $W \subset V$ with $\rho(X)W \subset W$ for all X [acting with any generator on a vector of W gives a vector still in W]. A module is **irreducible** if its only submodules are $\{0\}$ and V.

Dictionary: the same object, two names

mathematician	physicist
$\mathfrak{g}$-module V	representation space; space of states on which $\mathfrak{g}$ acts
submodule	invariant subspace
irreducible module	irreducible representation (irrep)
module homomorphism	intertwiner; linear map commuting with $\mathfrak{g}$
cyclic vector	a state from which all others are reached by the generators

The point to keep in mind is that *a module need not come with an inner product*. The Virasoro relations, $L_0|h\rangle = h|h\rangle$ and $L_n|h\rangle = 0$ for $n \geq 1$, say nothing about lengths of vectors. The inner product is an extra structure that we add later, in Step 4 below, and it is at that step that the physics of positive norms (and hence of Hilbert spaces) enters. Keeping the two layers apart is what makes null states easy to understand.

Key idea: the pipeline

$$\underbrace{|h\rangle}_{\substack{\text{highest-weight}\\ \text{state}}} \xrightarrow{\substack{\text{generate}\\ \text{descendants}}} \underbrace{V(c,h) = U(vir_-)|h\rangle}_{\text{Verma module}} \xrightarrow{\substack{\text{quotient by the}\\ \text{null submodule } N}} \underbrace{L(c,h) = V(c,h)/N}_{\text{irreducible module}} .$$

The Verma module contains everything the Virasoro algebra can generate from $|h\rangle$, subject only to the highest-weight conditions. At special values of (c,h) it contains a *singular vector*, a descendant that is itself highest weight. That vector generates a whole submodule N of zero-norm states. We remove the entire submodule, not just the one vector, and what is left is the irreducible representation $L(c,h)$ that a CFT actually uses. For generic (c,h) there is nothing to remove and $V(c,h) = L(c,h)$.

Step 1: the Verma module

Split the Virasoro generators into three groups according to the sign of the index:

$$vir_- = \text{span}\{L_{-1}, L_{-2}, L_{-3}, \dots\}, \qquad vir_0 = \text{span}\{L_0, c\}, \qquad vir_+ = \text{span}\{L_1, L_2, L_3, \dots\}. \tag{11.126}$$

Each piece is a Lie subalgebra (for instance $[L_{-m}, L_{-n}] = (n-m)L_{-m-n}$ has negative index again, and the central term never appears because $-m-n \neq 0$). On a highest-weight state, vir_+ acts as zero and vir_0 acts by the numbers h and c. Only vir_- produces anything new.

The enveloping algebra, concretely. $U(vir_-)$, the **universal enveloping algebra** of vir_-, is a precise name for "all polynomials in the L_{-n}". Its elements are linear combinations of products

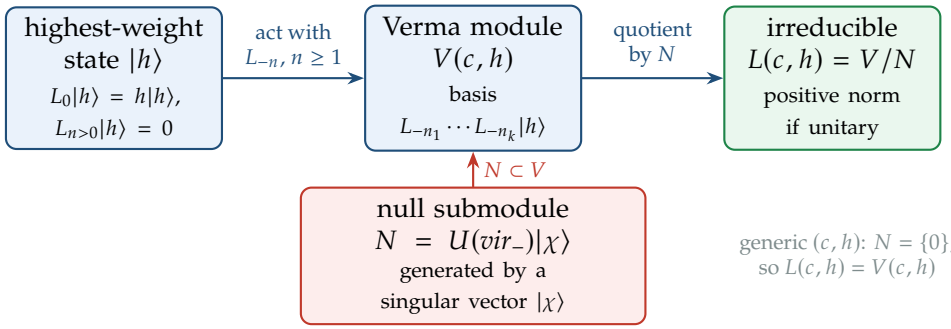


Figure 11.20: The construction of an irreducible highest-weight representation of the Virasoro algebra, in three stages. Read left to right. The only choice we make is (c,h). The Verma module is then completely determined, and the null submodule N (red) is whatever part of it happens to have zero norm. Removing N gives the representation that appears in a conformal field theory.

$L_{-n_1}L_{-n_2}\cdots L_{-n_k}$, and the only rule for manipulating them is that we may swap two neighbours at the cost of their commutator, $L_{-m}L_{-n} = L_{-n}L_{-m} + (n-m)L_{-m-n}$. Using this rule repeatedly, any product can be rewritten as a combination of *ordered* products with $n_1 \geq n_2 \geq \cdots \geq n_k$. For example

$$L_{-1}L_{-2} \overset{(1)}{=} L_{-2}L_{-1} + [L_{-1}, L_{-2}] \overset{(2)}{=} L_{-2}L_{-1} + L_{-3}.$$

(1) Swap the two factors and add the commutator.
(2) $[L_{-1}, L_{-2}] = (-1+2)L_{-3}$ by (11.102).

The **Poincaré–Birkhoff–Witt theorem** says that the ordered products are linearly independent in $U(vir_-)$: there are no relations among them other than those that follow from the commutators. So they form a basis.

Working definition 11.15 (Verma module)

Fix numbers c and h. The **Verma module** $V(c,h)$ is the vector space with basis

$$|h\rangle, \qquad L_{-n_1}L_{-n_2}\cdots L_{-n_k}|h\rangle \quad (n_1 \geq n_2 \geq \cdots \geq n_k \geq 1),$$

on which the Virasoro algebra acts as follows: L_{-n} $(n \geq 1)$ acts by multiplying on the left and then reordering [using $L_{-m}L_{-n} = L_{-n}L_{-m} + (n-m)L_{-m-n}$ until the indices decrease]; L_0 and $L_{n\geq 1}$ act by commuting them to the right with (11.102) until they hit $|h\rangle$, where $L_0|h\rangle = h|h\rangle$ and $L_{n\geq 1}|h\rangle = 0$; the central element acts as the number c. In one line, $V(c,h) = U(vir_-)|h\rangle$. *Operational test:* the dimension of the level-N subspace V_N [spanned by the basis vectors with $n_1 + \cdots + n_k = N$, all with L_0 eigenvalue $h + N$] is the number of partitions $p(N)$ [$p(1) = 1$, $p(2) = 2$, $p(3) = 3$, $p(4) = 5$], since the basis vectors at level N are labelled by partitions $N = n_1 + \cdots + n_k$.
Formal definition, for reference: $V(c,h) = U(Vir) \otimes_{U(vir_0 \oplus vir_+)} \mathbb{C}_{c,h}$ [all products of generators applied to one vector, where any L_0, $L_{n\geq 1}$ or c reaching that vector is replaced by its number], where $\mathbb{C}_{c,h}$ is the one-dimensional module on which vir_+ acts as 0, L_0 as h and the central element as c.

Worked example 11.42: The Verma module at levels 0, 1, 2, written out

Let us exhibit the representation. At levels $0, 1, 2$ the bases are

$$V_0 : |h\rangle, \qquad V_1 : L_{-1}|h\rangle, \qquad V_2 : L_{-2}|h\rangle,\ L_{-1}^2|h\rangle.$$

L_{-1} and L_{-2} just stack on the left. The interesting part is the action of the lowering operators

L_1 and L_2, which we compute by commuting them to the right. First L_1 on level 1:

$$L_1L_{-1}|h\rangle \overset{(1)}{=} [L_1, L_{-1}]|h\rangle + L_{-1}L_1|h\rangle \overset{(2)}{=} 2L_0|h\rangle = 2h|h\rangle.$$

(1) Commute L_1 to the right.
(2) $[L_1, L_{-1}] = 2L_0$ and $L_1|h\rangle = 0$.

Next L_1 on the two level-2 states:

$$L_1L_{-2}|h\rangle \overset{(1)}{=} [L_1, L_{-2}]|h\rangle \overset{(2)}{=} 3L_{-1}|h\rangle,$$
$$L_1L_{-1}^2|h\rangle \overset{(3)}{=} [L_1, L_{-1}]L_{-1}|h\rangle + L_{-1}L_1L_{-1}|h\rangle \overset{(4)}{=} 2L_0L_{-1}|h\rangle + 2h\,L_{-1}|h\rangle \overset{(5)}{=} (4h+2)\,L_{-1}|h\rangle.$$

(1) $L_1|h\rangle = 0$, so only the commutator survives.
(2) $[L_1, L_{-2}] = (1+2)L_{-1}$.
(3) Commute L_1 past the first L_{-1}.
(4) $[L_1, L_{-1}] = 2L_0$, and the previous computation for $L_1L_{-1}|h\rangle$.
(5) $L_0L_{-1}|h\rangle = (h+1)L_{-1}|h\rangle$ by (11.123).

And L_2 on the level-2 states:

$$L_2L_{-2}|h\rangle \overset{(1)}{=} [L_2, L_{-2}]|h\rangle \overset{(2)}{=} \left(4L_0 + \frac{c}{12}\cdot 2\cdot 3\right)|h\rangle = \left(4h + \frac{c}{2}\right)|h\rangle,$$
$$L_2L_{-1}^2|h\rangle \overset{(3)}{=} [L_2, L_{-1}]L_{-1}|h\rangle + L_{-1}[L_2, L_{-1}]|h\rangle \overset{(4)}{=} 3L_1L_{-1}|h\rangle + 3L_{-1}L_1|h\rangle \overset{(5)}{=} 6h|h\rangle.$$

(1) $L_2|h\rangle = 0$.
(2) $[L_2, L_{-2}] = 4L_0 + \frac{c}{12}\,2(2^2-1)$.
(3) Commute L_2 through both factors; the term $L_{-1}^2L_2|h\rangle$ vanishes.
(4) $[L_2, L_{-1}] = 3L_1$.
(5) $L_1L_{-1}|h\rangle = 2h|h\rangle$ and $L_1|h\rangle = 0$.

In matrix form, with the ordered bases above,

$$L_1\big|_{V_1\to V_0} = \begin{pmatrix} 2h \end{pmatrix}, \qquad L_1\big|_{V_2\to V_1} = \begin{pmatrix} 3 & 4h+2 \end{pmatrix}, \qquad L_2\big|_{V_2\to V_0} = \begin{pmatrix} 4h+\frac{c}{2} & 6h \end{pmatrix},$$

while $L_{-1}\big|_{V_1\to V_2} = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$ and $L_{-2}\big|_{V_0\to V_2} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$. As a check of the representation property, compare $[L_1, L_{-1}]$ with $2L_0$ on V_1:

$$\big(L_1L_{-1} - L_{-1}L_1\big)L_{-1}|h\rangle \overset{(1)}{=} L_1L_{-1}^2|h\rangle - L_{-1}\,(2h|h\rangle) \overset{(2)}{=} (4h+2-2h)\,L_{-1}|h\rangle \overset{(3)}{=} 2L_0\,L_{-1}|h\rangle.$$

(1) Definitions of the two products.
(2) The matrices above.
(3) $2L_0 = 2(h+1)$ on V_1.

Why "universal". Suppose W is *any* representation of *Vir* with central charge c containing a highest-weight vector $|h\rangle_W$. Then there is a map

$$\pi : V(c,h) \to W, \qquad L_{-n_1}\cdots L_{-n_k}|h\rangle \mapsto L_{-n_1}\cdots L_{-n_k}|h\rangle_W.$$

It is well defined because the basis of V has no relations to respect, and it commutes with the Virasoro action because both sides are computed by the same commutators. Its image is the submodule of W generated by $|h\rangle_W$. So every highest-weight representation is a quotient of

the Verma module: $V(c,h)$ is the biggest possible one, and all others are obtained from it by setting some combinations to zero. The remaining steps find out which combinations.

Step 2: singular vectors

Working definition 11.16 (singular vector)

A nonzero vector $|\chi\rangle \in V(c,h)$ at level $N \geq 1$ [a combination of basis vectors $L_{-n_1}\cdots L_{-n_k}|h\rangle$ with $n_1+\cdots+n_k = N$] is a **singular vector** (or null vector [once the inner product is defined, it is orthogonal to every vector of $V(c,h)$, itself included]) if it is itself highest weight:

$$L_n|\chi\rangle = 0 \quad (n \geq 1), \qquad L_0|\chi\rangle = (h+N)|\chi\rangle.$$

Operational test: it is enough to check $L_1|\chi\rangle = 0$ and $L_2|\chi\rangle = 0$, because L_1 and L_2 generate all of vir_+ [every L_n with $n \geq 3$ is a repeated commutator of L_1 and L_2] (see the working definition of a highest-weight state in Section 11.4.7). The L_0 condition is automatic for a vector of definite level.

Level 1. The only candidate is $|\chi\rangle = L_{-1}|h\rangle$. It is annihilated by L_2 automatically ($L_2L_{-1}|h\rangle = 3L_1|h\rangle = 0$), and $L_1L_{-1}|h\rangle = 2h|h\rangle$. So $L_{-1}|h\rangle$ is singular exactly when $h = 0$. This is the vacuum: we will see in Section 11.4.13 that $L_{-1}|0\rangle$ is the null vector Nash computes in (11.47).

Level 2. The general level-2 vector is, up to normalisation,

$$|\chi\rangle = \big(L_{-2} + \alpha\, L_{-1}^2\big)|h\rangle. \tag{11.127}$$

(The other possibility, a pure $L_{-1}^2|h\rangle$, is singular only if $h = 0$ and then it is a descendant of the level-1 singular vector.) Impose the two conditions, using the matrices of Example 11.42:

$$L_1|\chi\rangle \overset{(1)}{=} L_1L_{-2}|h\rangle + \alpha\, L_1L_{-1}^2|h\rangle \overset{(2)}{=} \big(3+\alpha(4h+2)\big)L_{-1}|h\rangle, \tag{11.128}$$

$$L_2|\chi\rangle \overset{(3)}{=} L_2L_{-2}|h\rangle + \alpha\, L_2L_{-1}^2|h\rangle \overset{(4)}{=} \Big(4h + \frac{c}{2} + 6\alpha h\Big)|h\rangle. \tag{11.129}$$

(1) Linearity.
(2) $L_1L_{-2}|h\rangle = 3L_{-1}|h\rangle$ and $L_1L_{-1}^2|h\rangle = (4h+2)L_{-1}|h\rangle$.
(3) Linearity.
(4) $L_2L_{-2}|h\rangle = (4h+\frac{c}{2})|h\rangle$ and $L_2L_{-1}^2|h\rangle = 6h|h\rangle$.

Both must vanish. The first fixes α, the second then fixes c in terms of h:

$$3+\alpha(4h+2) = 0 \overset{(1)}{\Rightarrow} \alpha = -\frac{3}{2(2h+1)}, \tag{11.130}$$

$$4h + \frac{c}{2} + 6\alpha h = 0 \overset{(2)}{\Rightarrow} \frac{c}{2} = -4h + \frac{9h}{2h+1} \overset{(3)}{\Rightarrow} c = \frac{2h(5-8h)}{2h+1}. \tag{11.131}$$

(1) Solve the linear equation ($h \neq -\frac{1}{2}$).
(2) Insert α: $6\alpha h = -\frac{9h}{2h+1}$.
(3) Multiply by 2 and use the common denominator $2h+1$: $c = \frac{2\left(-4h(2h+1)+9h\right)}{2h+1} = \frac{2(5h-8h^2)}{2h+1}$.

Equivalently, clearing the denominator,

$$16h^2 + 2(c-5)h + c = 0. \tag{11.132}$$

So a level-2 singular vector exists precisely on this curve in the (c,h) plane. For each c there are two roots h; we will meet them again as $h_{1,2}(c)$ and $h_{2,1}(c)$ in the Kac determinant.

Worked example 11.43: The two Ising weights lie on the level-2 curve

Put $c = \frac{1}{2}$ into (11.132):

$$16h^2 - 9h + \tfrac{1}{2} = 0 \overset{(1)}{=} h = \frac{9 \pm \sqrt{81 - 32}}{32} \overset{(2)}{=} h = \frac{9 \pm 7}{32} = \tfrac{1}{2} \text{ or } \tfrac{1}{16}.$$

(1) Quadratic formula for $16h^2 - 9h + \frac{1}{2} = 0$; the discriminant is $81 - 4 \cdot 16 \cdot \frac{1}{2} = 49$.
(2) $\sqrt{49} = 7$.

These are exactly the weights of the energy field ε ($h = \frac{1}{2}$) and the spin field σ ($h = \frac{1}{16}$) of the critical Ising model, whose scaling dimensions $2h = 1$ and $2h = \frac{1}{8}$ we extracted from the critical exponents in Example 11.3. The corresponding singular vectors are, from (11.130),

$$|\chi_\varepsilon\rangle = \left(L_{-2} - \tfrac{3}{4}L_{-1}^2\right)|\tfrac{1}{2}\rangle, \qquad |\chi_\sigma\rangle = \left(L_{-2} - \tfrac{4}{3}L_{-1}^2\right)|\tfrac{1}{16}\rangle.$$

A singular vector generates a whole submodule. A singular vector behaves in every respect like a new highest-weight state of weight $h + N$. So we can run Step 1 again starting from it: the negative modes acting on $|\chi\rangle$ produce

$$N_\chi := U(vir_-)|\chi\rangle = \text{span}\{|\chi\rangle,\ L_{-1}|\chi\rangle,\ L_{-2}|\chi\rangle,\ L_{-1}^2|\chi\rangle,\ L_{-3}|\chi\rangle, \dots\} \subset V(c,h). \tag{11.133}$$

This is a submodule: it is closed under all of *Vir*, not only under vir_-. For a positive mode acting on a typical element,

$$\begin{aligned} L_n\, L_{-k_1} \cdots L_{-k_j}|\chi\rangle &\overset{(1)}{=} \left(\sum_{i=1}^{j} L_{-k_1} \cdots [L_n, L_{-k_i}] \cdots L_{-k_j} + L_{-k_1} \cdots L_{-k_j}\, L_n\right)|\chi\rangle \\ &\overset{(2)}{=} \sum_{i=1}^{j} L_{-k_1} \cdots \left((n+k_i)L_{n-k_i} + \tfrac{c}{12}n(n^2-1)\delta_{n,k_i}\right) \cdots L_{-k_j}|\chi\rangle \\ &\overset{(3)}{=} (\text{an element of } U(vir_-))\,|\chi\rangle \ \in N_\chi. \end{aligned}$$

(1) Move L_n to the right, one commutator per factor.
(2) The Virasoro algebra, and $L_n|\chi\rangle = 0$.
(3) Each term again contains fewer lowering operators and one mode L_{n-k_i}. If $n - k_i < 0$ it is a lowering operator; if $n - k_i \geq 0$ we repeat the procedure, which terminates because each round reduces the number of factors. Whenever $L_{m\geq 1}$ reaches $|\chi\rangle$ it gives zero, L_0 gives the number $h + N$, and the central element gives c.

For example, at the first level of N_χ:

$$L_1 L_{-1}|\chi\rangle = 2L_0|\chi\rangle = 2(h+2)|\chi\rangle, \qquad L_2 L_{-1}|\chi\rangle = 3L_1|\chi\rangle = 0.$$

So a single singular vector is the seed of a whole copy of a highest-weight module, sitting inside $V(c,h)$ and starting at level N.

Step 3: the quotient, and why it is still a module

If $|\chi\rangle$ is a null state in the physical theory, it is not an independent state. Worse, since the algebra acts on it, all of $L_{-1}|\chi\rangle, L_{-2}|\chi\rangle, \dots$ are equally redundant. The whole submodule has to go. The mathematical tool for "setting a subspace to zero" is the quotient.

Working definition 11.17 (quotient module)

Let $N \subset V$ be a submodule [for example N_χ, spanned by all $L_{-k_1}\cdots L_{-k_j}|\chi\rangle$, which no L_n can leave]. Declare $v \sim v'$ if $v - v' \in N$. The equivalence classes $[v] = v + N$ [$[v]$ is the set of all vectors that differ from v by an element of N] form the vector space V/N, with $[v] + [w] = [v + w]$ and $\lambda[v] = [\lambda v]$. The algebra acts by

$$L_n[v] := [L_n v]. \tag{11.134}$$

Operational use: to compute in V/N, compute in V and then drop everything in N. In the example, $|\chi\rangle \sim 0$, $L_{-1}|\chi\rangle \sim 0$, $L_{-2}|\chi\rangle \sim 0$, and so on; in particular $L_{-2}|h\rangle \sim -\alpha\, L_{-1}^2|h\rangle$.

The definition (11.134) hides a question: the class $[v]$ has many representatives, so is $[L_n v]$ independent of which one we pick? It is, precisely because N is a submodule. Let $v \sim v'$. Then

$$L_n v - L_n v' \overset{(1)}{=} L_n(v - v') \overset{(2)}{\in} L_n N \overset{(3)}{\subset} N, \qquad \text{so} \qquad [L_n v] \overset{(4)}{=} [L_n v'].$$

(1) L_n is linear.
(2) $v - v' \in N$ by definition of $v \sim v'$.
(3) N is a submodule, i.e. closed under every L_n (and under c).
(4) Two vectors whose difference lies in N define the same class.

The commutation relations survive too, since they hold in V before we take classes:

$$L_m L_n[v] - L_n L_m[v] \overset{(1)}{=} [L_m L_n v - L_n L_m v] \overset{(2)}{=} \Big[(m-n)L_{m+n}v + \tfrac{c}{12}m(m^2-1)\delta_{m+n,0}\, v\Big]$$
$$\overset{(3)}{=} (m-n)L_{m+n}[v] + \tfrac{c}{12}m(m^2-1)\delta_{m+n,0}\,[v].$$

(1) Apply (11.134) twice, and linearity of $[\,\cdot\,]$.
(2) The Virasoro algebra holds on V.
(3) (11.134) again.

So V/N is a Virasoro module. Had we quotiented by the single vector $|\chi\rangle$ (the one-dimensional subspace $\mathbb{C}|\chi\rangle$), step (3) would fail: $L_{-1}|\chi\rangle \notin \mathbb{C}|\chi\rangle$, so L_{-1} would send the class $[0] = [|\chi\rangle]$ to two different classes, $[0]$ and $[L_{-1}|\chi\rangle] \neq [0]$. The action would not be defined. That is why we quotient by the submodule *generated* by the singular vector.

Step 4: where the inner product enters

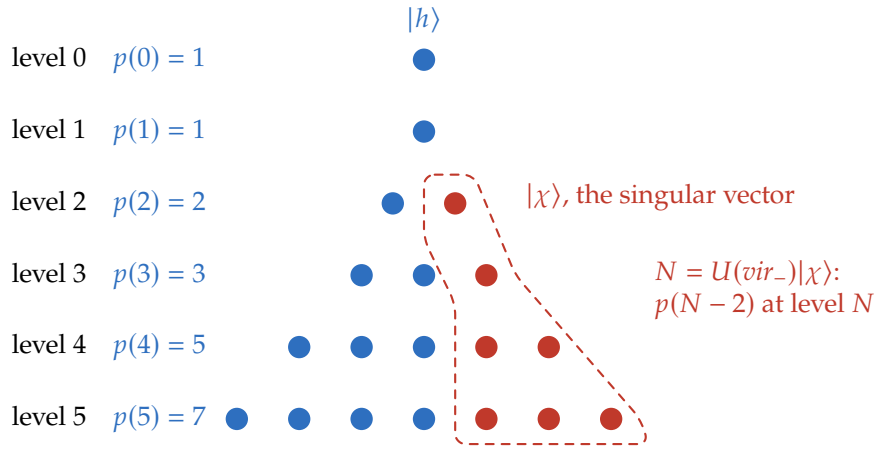
So far there has been no inner product anywhere. Now we add it. The physics input is the Hermiticity property $L_n^\dagger = L_{-n}$ that we derived from radial quantisation (11.119), and the normalisation $\langle h|h\rangle = 1$.

Working definition 11.18 (Shapovalov form)

The **Shapovalov form** (or Kac form) on $V(c,h)$ is the Hermitian form [a pairing $\langle u|v\rangle$, linear in v, with $\langle v|u\rangle = \overline{\langle u|v\rangle}$, but not assumed positive] defined on basis vectors by

$$\big\langle L_{-m_1}\cdots L_{-m_j}h \,\big|\, L_{-n_1}\cdots L_{-n_k}h\big\rangle := \langle h|\, L_{m_j}\cdots L_{m_1}\, L_{-n_1}\cdots L_{-n_k}|h\rangle,$$

where the right side is evaluated by commuting the raising operators L_m [the L_m with $m \geq 1$. Each lowers the level by m and kills $|h\rangle$] to the right until the result is a multiple of $|h\rangle$, and taking that multiple (with $\langle h|h\rangle = 1$). It is the unique Hermitian form with $\langle h|h\rangle = 1$ for which $L_n^\dagger = L_{-n}$ [an L_{-n} on the ket side can be moved to the bra side, where



$$\dim V_N = p(N) = 1, 1, 2, 3, 5, 7, \quad \dim N_N = 0, 0, 1, 1, 2, 3, \quad \dim L_N = 1, 1, 1, 2, 3, 4$$

Figure 11.21: The weight diagram of a Verma module $V(c,h)$, level by level, for (c,h) on the level-2 curve (11.132) but otherwise generic. Each dot is a basis state; level N has $p(N)$ of them. The red dots span the null submodule N generated by the level-2 singular vector $|\chi\rangle$: it looks like a second Verma module whose top sits at level 2, with $p(N-2)$ states at level N. The irreducible module $L(c,h) = V/N$ keeps only the blue dots. (At the minimal-model points, such as $c = \frac{1}{2}$, more singular vectors appear and N is larger; see Example 11.45.)

it becomes L_n]. *Operational use:* the matrices of this form, level by level, are the Gram matrices of Section 11.4.10.

The Shapovalov form is defined by algebra alone. Nothing guarantees that it is positive, or even nondegenerate. Two facts about it are the heart of the matter.

Fact 1: singular vectors have zero norm, and are orthogonal to everything. Let $|\chi\rangle$ be singular at level $N \geq 1$ and let $w = L_{-m_1} \cdots L_{-m_j}|h\rangle$ be any basis vector. If $j \geq 1$,

$$\langle w|\chi\rangle \overset{(1)}{=} \langle h| L_{m_j} \cdots L_{m_2} \left(L_{m_1}|\chi\rangle\right) \overset{(2)}{=} 0.$$

(1) Definition of the form; the adjoint of $L_{-m_1} \cdots L_{-m_j}$ is $L_{m_j} \cdots L_{m_1}$, and L_{m_1} acts first.
(2) $m_1 \geq 1$ and $|\chi\rangle$ is annihilated by every positive mode.

If $j = 0$, $w = |h\rangle$ is at level $0 \neq N$, and states at different levels are orthogonal (Section 11.4.8). So $\langle w|\chi\rangle = 0$ for every w, and in particular $\langle\chi|\chi\rangle = 0$. The same holds for every vector of the submodule N_χ: for $v = L_{-I}|\chi\rangle \in N_\chi$, $\langle w|v\rangle = \langle L_I w|\chi\rangle$ with L_I a product of raising operators, and $L_I w$ is again a combination of basis vectors, so the previous computation applies. A null submodule is a subspace of vectors orthogonal to the whole of V.

Fact 2: the vectors orthogonal to everything form the largest proper submodule. Define the **radical**

$$\mathrm{Rad}\, V := \{v \in V : \langle w|v\rangle = 0 \text{ for all } w \in V\}.$$

It is a submodule: for $v \in \mathrm{Rad}\, V$ and any w,

$$\langle w|L_n v\rangle \overset{(1)}{=} \langle L_{-n} w|v\rangle \overset{(2)}{=} 0.$$

(1) $L_n^\dagger = L_{-n}$.

(2) $L_{-n}w$ is another vector of V, and v is orthogonal to all of them.

Conversely, every proper submodule $M \subsetneq V$ lies inside the radical. The reason is a short chain. First, M is spanned by L_0-eigenvectors (since L_0 acts diagonalisably with finite-dimensional eigenspaces, and M is L_0-invariant), so it splits into levels, $M = \bigoplus_N M_N$. Second, $M_0 = 0$: if M contained $|h\rangle$ it would contain everything, $M = V$. Now take $v \in M_N$ with $N \geq 1$, and a basis vector $w = L_{-I}|h\rangle$ at level N (vectors at other levels are orthogonal to v anyway). Then

$$\langle w|v\rangle \overset{(1)}{=} \langle h|\left(L_I^{\dagger\dagger}\, v\right) \overset{(2)}{=} \langle h|\,(\text{an element of } M_0) \overset{(3)}{=} 0.$$

(1) Definition of the form: $\langle w|v\rangle = \langle h|(L_{-I})^\dagger v$, where $(L_{-I})^\dagger$ is a product of raising operators lowering the level by N.
(2) M is a submodule, so applying modes to $v \in M$ stays in M, and the result is at level 0.
(3) $M_0 = 0$.

So $\operatorname{Rad} V$ contains every proper submodule, and it is itself a proper submodule ($|h\rangle \notin \operatorname{Rad} V$ since $\langle h|h\rangle = 1$). It is the *maximal* proper submodule, and we take $N := \operatorname{Rad} V$.

Key idea: the irreducible module and its inner product

Let $N = \operatorname{Rad} V(c,h)$ be the null submodule. Then

(i) $L(c,h) = V(c,h)/N$ is irreducible: a submodule of the quotient pulls back to a submodule of V containing N, which by maximality is N or V.

(ii) The Shapovalov form descends to $L(c,h)$, by $\langle [w]|[v]\rangle := \langle w|v\rangle$. This is well defined because changing v by an element $n \in N$ changes $\langle w|v\rangle$ by $\langle w|n\rangle = 0$.

(iii) On $L(c,h)$ the form is *nondegenerate*: a class orthogonal to all classes has a representative in $\operatorname{Rad} V = N$, i.e. it is the class $[0]$.

Why unitarity needs the quotient. In a Hilbert space, $\|v\|^2 = 0$ forces $v = 0$. A physical state space therefore cannot contain a nonzero vector of zero norm. If the CFT contains a primary of weight h at a point (c,h) where $V(c,h)$ has singular vectors, the space of states built on ϕ cannot be $V(c,h)$: it must be a quotient in which all of N is zero. This is what Nash means by "projected out". In the field language, the field that would create $|\chi\rangle$ vanishes identically, for example $\left(L_{-2} - \frac{3}{2(2h+1)}L_{-1}^2\right)\phi = 0$ as an operator equation. Then:

- if the descended form on $L(c,h)$ is positive definite, its completion is a Hilbert space and we have a unitary representation;
- if the form on $L(c,h)$ still has a negative-norm vector, no quotient can cure it (the form is already nondegenerate), and the pair (c,h) is excluded from any unitary theory. This is the second half of Nash's remark: "states of negative squared norm can also occur and are disallowed."

The generic case. For generic (c,h) there is no singular vector at any level, the radical is $\{0\}$, and $V(c,h) = L(c,h)$ is already irreducible. We will see in Section 11.4.10 exactly which (c,h) are non-generic: they lie on countably many curves $h = h_{r,s}(c)$ in the (c,h) plane, the zeros of the Kac determinant. Nash's statement that the tower "comprise[s] an irreducible representation" is exactly right off these curves.

	Verma module $V(c,h)$	null submodule N	irreducible module $L(c,h)$
what it is	all formal descendants $L_{-n_1}\cdots L_{-n_k}\|h\rangle$	descendants of the singular vector(s); $=\operatorname{Rad} V$	V/N: Verma module with the null states set to zero
relations imposed	only $L_0\|h\rangle = h\|h\rangle$, $L_{n>0}\|h\rangle = 0$	—	in addition $\|\chi\rangle = 0$ and all its descendants
states at level N	$p(N)$	$\sum$ over singular vectors, e.g. $p(N-2)$ for one at level 2	$p(N) - \dim N_N$
Shapovalov form	may be degenerate or indefinite	identically zero (orthogonal to all of V)	nondegenerate; positive iff unitary
irreducible?	only for generic (c,h)	is itself a highest-weight module	always
role in physics	bookkeeping device, universal object	redundant, unphysical states	the space of states of one conformal family

Table 11.2: The three objects of the construction, side by side.

Worked example 11.44: The vacuum module: quotient by $L_{-1}|0\rangle$

Take $h = 0$. The level-1 computation above shows that $|\chi\rangle = L_{-1}|0\rangle$ is singular. It generates $N_\chi = U(vir_-)L_{-1}|0\rangle$, which has $p(N-1)$ states at level N. For generic c this is the whole radical (it matches the factor $h^{p(N-1)}$ in the Kac determinant, Section 11.4.10), so

$$\dim L(c,0)_N = p(N) - p(N-1):$$

N	0	1	2	3	4	5	6	7
$p(N)$	1	1	2	3	5	7	11	15
$p(N-1)$	0	1	1	2	3	5	7	11
$\dim L(c,0)_N$	1	0	1	1	2	2	4	4

A basis of the quotient is given by the ordered products with no L_{-1} at all, $L_{-n_1}\cdots L_{-n_k}|0\rangle$ with every $n_i \geq 2$: at level 4 these are $L_{-4}|0\rangle$ and $L_{-2}^2|0\rangle$. In field language they are $\frac{1}{2}\partial^2 T$ and $:TT:$, the level-4 fields of the identity family $[I]$ (Example 11.41(b)). The generating function of the dimensions is $\prod_{n\geq 2}(1-q^n)^{-1}$: the factor $(1-q)^{-1}$ that L_{-1} would have contributed is gone.

Worked example 11.45: The free fermion realises the Ising null vector

The free Majorana fermion has $c = \frac{1}{2}$ and contains the primary ψ of weight $\frac{1}{2}$ (Example 11.29). By Example 11.43, the Verma module $V(\frac{1}{2},\frac{1}{2})$ has the singular vector $|\chi_\varepsilon\rangle = (L_{-2} - \frac{3}{4}L_{-1}^2)|\frac{1}{2}\rangle$. In a genuine Hilbert space this vector must be *zero*. Let us check that the fermion Fock space does this automatically.

Modes. Since ψ has weight $\frac{1}{2}$, expand $\psi(z) = \sum_r \psi_r z^{-r-1/2}$, $\psi_r = \oint_0 \frac{dz}{2\pi i} z^{r-1/2}\psi(z)$. Regularity of $\psi(z)|0\rangle$ at $z=0$ requires $\psi_r|0\rangle = 0$ for $r > -\frac{1}{2}$, and single-valuedness around the origin (the Neveu–Schwarz sector, which contains the vacuum) makes $r \in \mathbb{Z} + \frac{1}{2}$. The contour trick (11.100), with an anticommutator because both operators are fermionic, and the OPE $\psi(w)\psi(z) \sim \frac{1}{w-z}$ give

$$\{\psi_r,\psi_s\} \overset{(1)}{=} \oint_0 \frac{dz}{2\pi i} z^{s-1/2} \oint_z \frac{dw}{2\pi i} \frac{w^{r-1/2}}{w-z} \overset{(2)}{=} \oint_0 \frac{dz}{2\pi i} z^{r+s-1} \overset{(3)}{=} \delta_{r+s,0}.$$

(1) Double-contour trick; the radial ordering of two fermions carries the sign that turns the commutator into an anticommutator.

(2) Residue of $w^{r-1/2}/(w-z)$ at $w=z$.
(3) Only z^{-1} has a residue.

In particular $\psi_{-1/2}^2 = \frac{1}{2}\{\psi_{-1/2},\psi_{-1/2}\} = \frac{1}{2}\delta_{-1,0} = 0$. The state of ψ is $|\tfrac{1}{2}\rangle = \psi(0)|0\rangle = \psi_{-1/2}|0\rangle$.

Action of L_m on the modes. Since ψ is primary of weight $\frac{1}{2}$, (11.101) gives $[L_m,\psi(z)] = \frac{1}{2}(m+1)z^m\psi + z^{m+1}\partial\psi$. Taking the $z^{r-1/2}$ moment exactly as in Example 11.38,

$$[L_m,\psi_r] \overset{(1)}{=} \tfrac{1}{2}(m+1)\,\psi_{m+r} - \left(m+r+\tfrac{1}{2}\right)\psi_{m+r} = -\left(r+\frac{m}{2}\right)\psi_{m+r}.$$

(1) The first term is the definition of ψ_{m+r}; the second is integration by parts, $\oint z^{m+r+1/2}\partial\psi = -(m+r+\frac{1}{2})\oint z^{m+r-1/2}\psi$.

The descendants. Using $L_{-1}|0\rangle = 0$:

$$L_{-1}|\tfrac{1}{2}\rangle \overset{(1)}{=} [L_{-1},\psi_{-1/2}]|0\rangle \overset{(2)}{=} \psi_{-3/2}|0\rangle,$$

$$L_{-1}^2|\tfrac{1}{2}\rangle \overset{(3)}{=} [L_{-1},\psi_{-3/2}]|0\rangle \overset{(4)}{=} 2\,\psi_{-5/2}|0\rangle,$$

$$L_{-2}|\tfrac{1}{2}\rangle \overset{(5)}{=} [L_{-2},\psi_{-1/2}]|0\rangle + \psi_{-1/2}L_{-2}|0\rangle \overset{(6)}{=} \tfrac{3}{2}\,\psi_{-5/2}|0\rangle + \beta\,\psi_{-1/2}\psi_{-3/2}\psi_{-1/2}|0\rangle \overset{(7)}{=} \tfrac{3}{2}\,\psi_{-5/2}|0\rangle.$$

(1) Commute L_{-1} to the right; $L_{-1}|0\rangle = 0$.
(2) $-(r+\frac{m}{2}) = -(-\frac{1}{2}-\frac{1}{2}) = 1$ for $m=-1$, $r=-\frac{1}{2}$.
(3) The same step once more.
(4) $-(-\frac{3}{2}-\frac{1}{2}) = 2$.
(5) Commute L_{-2} to the right; now $L_{-2}|0\rangle \neq 0$.
(6) $-(-\frac{1}{2}-1) = \frac{3}{2}$. For the second term: $L_{-2}|0\rangle = T(0)|0\rangle$ is bilinear in ψ, so it is a state of weight 2 with an even number of fermion modes; the only one is $\psi_{-3/2}\psi_{-1/2}|0\rangle$ (two distinct modes with $r_1+r_2=2$), so $L_{-2}|0\rangle = \beta\,\psi_{-3/2}\psi_{-1/2}|0\rangle$ for some number β.
(7) $\psi_{-1/2}\psi_{-3/2}\psi_{-1/2} = -\psi_{-3/2}\psi_{-1/2}^2 = 0$.

Hence

$$|\chi_\varepsilon\rangle = \left(L_{-2} - \tfrac{3}{4}L_{-1}^2\right)|\tfrac{1}{2}\rangle = \left(\tfrac{3}{2} - \tfrac{3}{4}\cdot 2\right)\psi_{-5/2}|0\rangle = 0.$$

The null vector is not merely orthogonal to everything; in the fermion Fock space it simply *is* zero. So the space of states of the free fermion built on ψ is not the Verma module $V(\frac{1}{2},\frac{1}{2})$ but a quotient of it. Counting confirms this. States of odd fermion number built on $|0\rangle$ at weight $\frac{1}{2}+N$ are

N	0	1	2	3	4
states	$\psi_{-1/2}$	$\psi_{-3/2}$	$\psi_{-5/2}$	$\psi_{-7/2}$	$\psi_{-9/2}$, $\psi_{-5/2}\psi_{-3/2}\psi_{-1/2}$
number	1	1	1	1	2
$p(N)$	1	1	2	3	5

(all acting on $|0\rangle$). The level-2 deficit of one state is $|\chi_\varepsilon\rangle$. At level 3 the deficit is two: $L_{-1}|\chi_\varepsilon\rangle$ and a second singular vector at level 3, which exists because $\frac{1}{2}$ is also a root of the level-3 factor of the Kac determinant (Section 11.4.10). This is the typical situation in a minimal model: the null submodule is generated by two singular vectors, and $L(c,h)$ is much smaller than $V(c,h)$. (As a check on β: $\|L_{-2}|0\rangle\|^2 = \frac{c}{2} = \frac{1}{4}$ from Example 11.39, and $\left\|\psi_{-3/2}\psi_{-1/2}|0\rangle\right\|^2 = 1$ with $\psi_r^\dagger = \psi_{-r}$, so $|\beta| = \frac{1}{2}$, consistent with $c=\frac{1}{2}$.)

Watch out: "irreducible" in Nash's sentence

Nash says the tower $L_{-1}^{\alpha_1}\cdots L_{-s}^{\alpha_s}|h\rangle$ comprises an irreducible representation. As a statement about *the space spanned by these vectors inside a Hilbert space* it is correct: in a unitary theory null vectors are automatically zero, so the span is $L(c,h)$, which is irreducible. As a statement about the Verma module, where the tower is taken as a formal basis, it is correct only off the Kac curves. The two readings differ exactly by the null submodule.

11.4.10 The Gram matrix and the Kac determinant

We now make Step 4 computable. The question is: for which (c,h) does the Shapovalov form have zero or negative directions? Since different levels are orthogonal, the form is block diagonal, one finite block per level. So the question reduces to linear algebra on finite matrices.

Working definition 11.19 (Gram matrix)

The **Gram matrix** at level N is the $p(N)\times p(N)$ matrix of inner products of the basis vectors of V_N,

$$M^{(N)}_{IJ}(c,h) = \big\langle L_{-I}h \,\big|\, L_{-J}h\big\rangle, \qquad L_{-I} = L_{-i_1}\cdots L_{-i_k}, \quad i_1\geq\cdots\geq i_k, \quad \textstyle\sum i = N.$$

Operational use: (i) $\det M^{(N)} = 0$ iff $V(c,h)$ has a null vector [a nonzero vector of V_N orthogonal to every vector of V_N] at level N; (ii) $M^{(N)}$ has a negative eigenvalue iff there is a negative-norm state [a vector v with $\langle v|v\rangle<0$] at level N; (iii) the representation can be unitary [every state has $\langle v|v\rangle\geq 0$, as a physical space of states requires] only if $M^{(N)}$ is positive semi-definite for every N.

The entries are polynomials in c and h, computed by commuting raising operators to the right. Level 1 is a single number:

$$M^{(1)} = \langle h|L_1L_{-1}|h\rangle \overset{(1)}{=} \langle h|[L_1,L_{-1}]|h\rangle \overset{(2)}{=} 2h. \tag{11.135}$$

(1) $L_1|h\rangle = 0$.
(2) $[L_1,L_{-1}] = 2L_0$ and $\langle h|h\rangle = 1$.

At level 2 the entries are read off from Example 11.42: each is $\langle h|$ applied to one of the computed vectors.

$$\langle h|L_2L_{-2}|h\rangle \overset{(1)}{=} 4h+\tfrac{c}{2}, \qquad \langle h|L_2L_{-1}^2|h\rangle \overset{(2)}{=} 6h,$$
$$\langle h|L_1^2L_{-2}|h\rangle \overset{(3)}{=} \langle h|L_1\,3L_{-1}|h\rangle = 6h, \qquad \langle h|L_1^2L_{-1}^2|h\rangle \overset{(4)}{=} (4h+2)\langle h|L_1L_{-1}|h\rangle = 4h(2h+1).$$

(1) $L_2L_{-2}|h\rangle = (4h+\frac{c}{2})|h\rangle$.
(2) $L_2L_{-1}^2|h\rangle = 6h|h\rangle$.
(3) $L_1L_{-2}|h\rangle = 3L_{-1}|h\rangle$, then (11.135).
(4) $L_1L_{-1}^2|h\rangle = (4h+2)L_{-1}|h\rangle$, then (11.135).

(The two off-diagonal entries agree, as they must for a Hermitian form with real c,h.) So, in the basis $(L_{-2}|h\rangle,\ L_{-1}^2|h\rangle)$,

$$M^{(2)} = \begin{pmatrix} 4h+\frac{c}{2} & 6h \\ 6h & 4h(2h+1)\end{pmatrix}, \qquad \det M^{(2)} = 2h\big(16h^2+2(c-5)h+c\big). \tag{11.136}$$

The determinant:

$$\det M^{(2)} \overset{(1)}{=} \Big(4h+\frac{c}{2}\Big)4h(2h+1)-36h^2 \overset{(2)}{=} 2h\Big[(8h+c)(2h+1)-18h\Big]$$
$$\overset{(3)}{=} 2h\big(16h^2+2ch+c-10h\big).$$

(1) $ad-bc$.
(2) Factor out $2h$: $(4h+\frac{c}{2})\cdot 4h(2h+1) = 2h(8h+c)(2h+1)$ and $36h^2 = 2h\cdot 18h$.
(3) Expand $(8h+c)(2h+1) = 16h^2+8h+2ch+c$ and subtract $18h$.

Look at the two factors. The factor $2h$ is $M^{(1)}$: it vanishes when $L_{-1}|h\rangle$ is null, and then its descendant $L_{-1}^2|h\rangle$ is null too. The second factor is *exactly* the level-2 curve (11.132) that we found by demanding $L_1|\chi\rangle = L_2|\chi\rangle = 0$. The determinant knows about singular vectors.

Level 3. The basis is $(L_{-3}|h\rangle,\ L_{-2}L_{-1}|h\rangle,\ L_{-1}^3|h\rangle)$. One entry as a sample; the others are computed the same way.

$$\langle h|L_1L_2\,L_{-2}L_{-1}|h\rangle \overset{(1)}{=} \langle h|L_1\Big([L_2,L_{-2}]L_{-1}+L_{-2}[L_2,L_{-1}]\Big)|h\rangle \overset{(2)}{=} \langle h|L_1\Big(\big(4L_0+\tfrac{c}{2}\big)L_{-1}+3L_{-2}L_1\Big)|h\rangle$$
$$\overset{(3)}{=} \Big(4(h+1)+\frac{c}{2}\Big)\langle h|L_1L_{-1}|h\rangle \overset{(4)}{=} h\,(8h+8+c).$$

(1) The adjoint of $L_{-2}L_{-1}$ is L_1L_2; commute L_2 to the right ($L_2|h\rangle = 0$).
(2) $[L_2,L_{-2}] = 4L_0+\frac{c}{2}$ and $[L_2,L_{-1}] = 3L_1$.
(3) $L_0L_{-1}|h\rangle = (h+1)L_{-1}|h\rangle$ and $L_1|h\rangle = 0$.
(4) (11.135): $\big(4h+4+\frac{c}{2}\big)2h$.

The full matrix and its determinant are

$$M^{(3)} = \begin{pmatrix} 6h+2c & 10h & 24h \\ 10h & h(8h+8+c) & 12h(3h+1) \\ 24h & 12h(3h+1) & 24h(h+1)(2h+1) \end{pmatrix}, \tag{11.137}$$

$$\det M^{(3)} = 48\,h^2\,\big(16h^2+2(c-5)h+c\big)\big(3h^2+(c-7)h+c+2\big). \tag{11.138}$$

(We checked these entries, and the determinants at levels 2, 3 and 4, by implementing the commutation rules on a computer; doing one or two entries by hand, as above, is the best way to trust them.) Read the factors:

- h^2: at $h=0$ the level-1 null vector $L_{-1}|h\rangle$ has $p(3-1)=2$ descendants at level 3 ($L_{-2}L_{-1}|h\rangle$ and $L_{-1}^3|h\rangle$), so the factor h appears twice.
- $16h^2+2(c-5)h+c$: the level-2 singular vector has $p(1)=1$ descendant at level 3, $L_{-1}|\chi\rangle$, so this factor appears once.
- $3h^2+(c-7)h+c+2$: new. It vanishes where a singular vector first appears at level 3.

At $c=\frac{1}{2}$ the new factor is $3h^2-\frac{13}{2}h+\frac{5}{2} = 3(h-\frac{1}{2})(h-\frac{5}{3})$. Its root $h=\frac{1}{2}$ is the second singular vector of the Ising energy field that we found by counting fermion states in Example 11.45.

The pattern: the Kac determinant. The structure we just saw continues at every level. A singular vector first appearing at level K contributes a factor that shows up at every level $N\geq K$, raised to the power equal to the number of its descendants at level N, which is $p(N-K)$. Kac found that the new singular vectors appear at levels $K=rs$, labelled by pairs of positive integers (r,s).

Key idea: the Kac determinant formula

$$\det M^{(N)}(c,h) = \alpha_N \prod_{\substack{r,s\geq 1\\ rs\leq N}} \big(h - h_{r,s}(c)\big)^{p(N-rs)}, \tag{11.139}$$

where $\alpha_N > 0$ is a constant independent of c and h, and the zeros are

$$h_{r,s}(c) = \frac{(r\,t-s)^2-(t-1)^2}{4t}, \qquad c = 13 - 6\Big(t+\frac{1}{t}\Big). \tag{11.140}$$

For each c the parameter t solves a quadratic; the two roots t and $1/t$ exchange $h_{r,s} \leftrightarrow h_{s,r}$, so the *set* of zeros depends only on c. For $c < 1$ it is convenient to write $t = \frac{m+1}{m}$ with $m > 0$ real; then

$$c = 1 - \frac{6}{m(m+1)}, \qquad h_{r,s} = \frac{\big((m+1)r - ms\big)^2 - 1}{4m(m+1)}. \tag{11.141}$$

What it means: $V(c,h)$ has a singular vector at level rs if and only if $h = h_{r,s}(c)$ for some $r, s \geq 1$.

Let us check that (11.141) follows from (11.140). With $t = \frac{m+1}{m}$,

$$c \overset{(1)}{=} 13 - 6\Big(\frac{m+1}{m} + \frac{m}{m+1}\Big) \overset{(2)}{=} 13 - 6\,\frac{2m^2+2m+1}{m(m+1)} \overset{(3)}{=} 13 - 12 - \frac{6}{m(m+1)},$$

$$h_{r,s} \overset{(4)}{=} \frac{\big(\frac{(m+1)r}{m} - s\big)^2 - \frac{1}{m^2}}{4\frac{m+1}{m}} \overset{(5)}{=} \frac{\big((m+1)r-ms\big)^2-1}{m^2}\cdot\frac{m}{4(m+1)} = \frac{\big((m+1)r-ms\big)^2-1}{4m(m+1)}.$$

(1) Insert t.
(2) Common denominator: $(m+1)^2 + m^2 = 2m^2 + 2m + 1$.
(3) $6(2m^2+2m)/(m(m+1)) = 12$.
(4) Insert t; $t - 1 = \frac{1}{m}$.
(5) Multiply numerator and denominator by m^2.

And a check against the level-2 factor: with (11.140), $h_{1,2} = \frac{3-2t}{4t}$ and $h_{2,1} = \frac{3t-2}{4}$, so

$$h_{1,2} + h_{2,1} \overset{(1)}{=} \frac{3t^2-4t+3}{4t} \overset{(2)}{=} \frac{5-c}{8}, \qquad h_{1,2}\,h_{2,1} \overset{(3)}{=} \frac{-6t^2+13t-6}{16t} \overset{(4)}{=} \frac{c}{16},$$

(1) Common denominator $4t$: $(3-2t) + t(3t-2)$.
(2) $5 - c = 5 - 13 + 6t + 6/t = (6t^2 - 8t + 6)/t$, and half of that over 4 is the left side.
(3) $(3-2t)(3t-2) = 9t - 6 - 6t^2 + 4t$.
(4) $c = (13t - 6t^2 - 6)/t$.

These are the sum and product of the roots of $16h^2 + 2(c-5)h + c$, so $16h^2 + 2(c-5)h + c = 16(h - h_{1,2})(h - h_{2,1})$, and (11.136) is (11.139) with $\alpha_2 = 32$ and $h_{1,1} = 0$. The level-4 determinant, computed the same way, contains the new factors $c + 8h - 1 = 8(h - h_{2,2})$ (indeed $h_{2,2} = \frac{1-c}{8}$) and $h - h_{1,4}$, $h - h_{4,1}$, together with $h^3(h-h_{1,2})^2(h-h_{2,1})^2(h-h_{1,3})(h-h_{3,1})$: the powers are $p(3) = 3$, $p(2) = 2$ and $p(1) = 1$, exactly as (11.139) predicts.

Why the formula has this shape (a sketch). Two facts make (11.139) plausible without the full proof. *Degree.* For large h, the diagonal entry for $L_{-I}|h\rangle$ with k factors grows like h^k and dominates its row, so $\det M^{(N)}$ is a polynomial in h of degree $\sum_{I\vdash N} k(I)$ (the total number of parts in all partitions of N). One checks that this equals $\sum_{rs\leq N} p(N-rs)$, the degree of the right-hand side. *Zeros.* Each zero $h_{r,s}$ comes with a singular vector at level rs, whose

descendants account for the multiplicity $p(N - rs)$. The location of the zeros is the hard part. Kac obtained it by exhibiting the singular vectors in free-field (Coulomb gas) realisations, which produce the square-completed form $(rt - s)^2$; Feigin and Fuchs proved the structure of the resulting submodules.

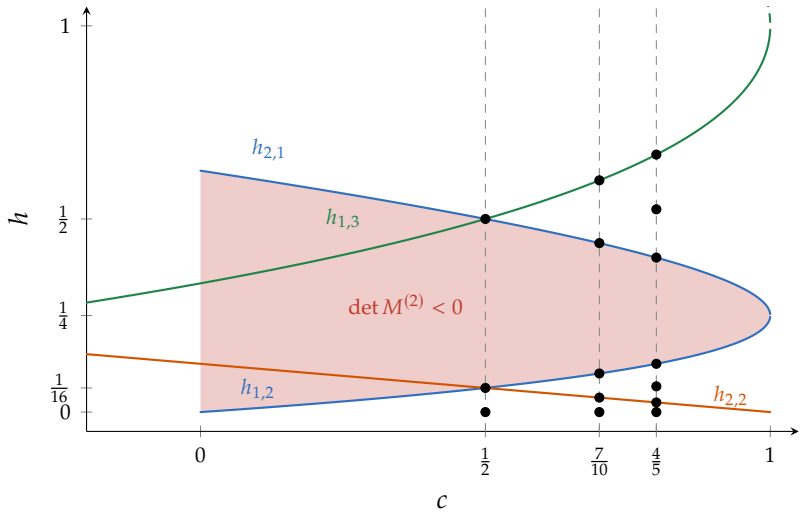


Figure 11.22: Zeros of the Kac determinant in the region $0 \le c < 1$: the curves $h_{1,2}$, $h_{2,1}$ (blue, level 2), $h_{1,3}$ (green) and $h_{3,1}$ (green dashed, level 3; it lies above the top of the plot except very near $c = 1$) and $h_{2,2}$ (orange, level 4). As $c \to 1$ every curve tends to $h_{r,s} \to (r-s)^2/4$: the blue curves meet at $h = \frac{1}{4}$, the green ones at $h = 1$, and $h_{2,2}$ (like every $h_{r,r}$) runs into $h = 0$. The shaded region between $h_{1,2}$ and $h_{2,1}$ is where $\det M^{(2)} < 0$, so there is a negative-norm state at level 2 and the representation cannot be unitary. The black dots on the dashed lines $c = \frac{1}{2}, \frac{7}{10}, \frac{4}{5}$ are the unitary minimal models of Section 11.4.12. Each one lies on two Kac curves at once, because $h_{r,s} = h_{m-r,\,m+1-s}$ (only a few of these curves are drawn), and none lies inside the shaded region.

Try it: the Kac zeros at $c = 1$ and the free boson

At $c = 1$, show that $t = 1$ and $h_{r,s} = \frac{(r-s)^2}{4}$. Compare with the weights $h = \alpha^2/4$ of the vertex operators $:e^{i\alpha\varphi}:$ of Example 11.23: which vertex operators sit at the degenerate values? *Answer:* $c = 13 - 6(t + 1/t) = 1$ gives $t + 1/t = 2$, so $t = 1$, and then $h_{r,s} = \frac{(r-s)^2-0}{4}$. The degenerate weights are $h = n^2/4$, $n \in \mathbb{Z}$, which are the vertex operators with $\alpha = \pm n$ (and $\partial\varphi$, with $h = 1$, is at $n = 2$). For these special charges the $c = 1$ Verma modules have singular vectors, and the boson Fock space realises the quotient.

11.4.11 Unitarity: which (c, h) can live in a Hilbert space?

The Kac determinant tells us where the Shapovalov form is *degenerate*. A physicist wants to know something slightly different: where is it *positive*? Nash puts it in one sentence (p. 310): "the need to construct the representation on a Hilbert space of positive norm plays an important part in finding those values of c and h which give rise to unitary irreducible representations of *Vir*." In Chapter 6 he quotes the answer, due to Friedan, Qiu and Shenker, as his (6.58). In this subsection we derive as much of that answer as can be done by hand. We also draw a picture of the rest, computed from the Gram matrices themselves.

Here is the question in operational form. A conformal family $[\phi]$ of a unitary CFT gives an irreducible module $L(c, h)$ whose inner product is positive definite. By Section 11.4.10, the

inner product is block diagonal by level. So the requirement is

$$\text{unitary} \iff M^{(N)}(c,h) \text{ is positive semi-definite for every level } N, \tag{11.142}$$

with the zero eigenvalues (the null states) then quotiented away, as in Step 4 of Section 11.4.9. A single negative eigenvalue at a single level is enough to rule out the pair (c,h). Such a state cannot be quotiented away, because it is not orthogonal to everything.

Physical picture: why negative norms are fatal

In quantum mechanics $\langle\psi|\psi\rangle$ is the total probability. If a state has $\langle\psi|\psi\rangle < 0$, then the Born rule assigns negative probabilities. Gauge theories do meet negative-norm states (the timelike photon in covariant gauge), but there a constraint such as the Gupta–Bleuler condition removes them. Here nothing removes them: the Virasoro generators *are* the symmetry, and the negative-norm state is produced from a physical state by applying the symmetry. A theory that contains $|h\rangle$ also contains $L_{-2}|h\rangle - L_{-1}^2|h\rangle$.

We now go through the (c,h) plane region by region. The result is summarised in Figure 11.23 and Figure 11.24.

The first two conditions: $h \geq 0$ and $c \geq 0$

The simplest descendants are the single-mode states $L_{-n}|h\rangle$, with $n \geq 1$. Their norms are

$$\begin{aligned} \|L_{-n}|h\rangle\|^2 &\overset{(1)}{=} \langle h|L_n L_{-n}|h\rangle \overset{(2)}{=} \langle h|\,[L_n, L_{-n}]\,|h\rangle \\ &\overset{(3)}{=} \langle h|\Big(2n\,L_0 + \frac{c}{12}\,n(n^2-1)\Big)|h\rangle \overset{(4)}{=} 2n\,h + \frac{c}{12}\,n(n^2-1). \end{aligned} \tag{11.143}$$

(1) The adjoint of L_{-n} is L_n, by (11.119).
(2) $L_n|h\rangle = 0$ for $n \geq 1$ (the highest-weight condition (11.121)), so $L_nL_{-n}|h\rangle = [L_n, L_{-n}]|h\rangle$.
(3) The Virasoro algebra (11.102) with $m = n$ and $n \to -n$: $(n-(-n))L_0 + \frac{c}{12}n(n^2-1)$.
(4) $L_0|h\rangle = h|h\rangle$ and $\langle h|h\rangle = 1$.

Two consequences follow at once.

$h \geq 0$. Put $n = 1$. The central term vanishes, and $\|L_{-1}|h\rangle\|^2 = 2h$. So a unitary highest-weight module has $h \geq 0$. Moreover, if $h = 0$ then $L_{-1}|h\rangle$ has zero norm. In a Hilbert space a zero-norm vector is zero, so $L_{-1}|h\rangle = 0$. In field language this says $\partial\phi(0)|0\rangle = 0$: the field does not depend on z. A holomorphic weight-zero primary in a unitary theory is therefore a constant, i.e. a multiple of the identity. In a unitary CFT the vacuum is the *only* state with $h = \bar{h} = 0$ (assuming a unique vacuum).

$c \geq 0$. Now let n grow at fixed h. The term $\frac{c}{12}n^3$ eventually dominates $2nh$. If $c < 0$ then $\|L_{-n}|h\rangle\|^2 < 0$ for all large n. So a unitary theory has $c \geq 0$. The cleanest case is the vacuum itself, $h = 0$, at $n = 2$:

$$\|L_{-2}|0\rangle\|^2 = \frac{c}{2}. \tag{11.144}$$

In field language $L_{-2}|0\rangle = T(0)|0\rangle$, and (11.144) is the statement that the two-point function of the stress tensor, $\langle T(z)T(0)\rangle = \frac{c/2}{z^4}$, has a positive coefficient. (We derive that two-point function in Section 11.4.13.) The central charge measures how strongly the stress tensor fluctuates, and positivity of that fluctuation is positivity of c.

Worked example 11.46: Negative central charge: the ghosts of string theory

The Faddeev–Popov ghosts of the bosonic string (Chapter 9) form a CFT with $c = -26$. Its vacuum module already contains a negative-norm state:

$$\|L_{-2}|0\rangle\|^2 \overset{(1)}{=} \frac{c}{2} = -13 < 0, \qquad \|L_{-3}|0\rangle\|^2 \overset{(2)}{=} \frac{c}{12}\cdot 3\cdot 8 = 2c = -52 < 0.$$

(1) (11.144) with $c = -26$.
(2) (11.143) with $h = 0$, $n = 3$: $n(n^2-1) = 24$.

This does not make string theory inconsistent. The ghosts are not physical particles. The matter CFT has $c = +26$, and the total central charge $26 - 26 = 0$ is what the BRST construction needs. The physical states are BRST cohomology classes, and on them the inner product is positive. The lesson is that negative central charges occur in useful non-unitary CFTs. They just never describe a space of physical states on their own.

$c = 0$ allows only the trivial theory. At $c = 0$ the single-mode norms $2nh$ are all positive for $h > 0$. We need a two-dimensional subspace to see the problem. Fix $N \geq 1$ and consider the two states $L_{-2N}|h\rangle$ and $L_{-N}^2|h\rangle$ at level $2N$. Write $c_N := \frac{c}{12}N(N^2-1)$, so that $[L_N, L_{-N}] = 2NL_0 + c_N$. The entries of their Gram matrix are

$$\begin{aligned}
\langle h|L_{2N}L_{-2N}|h\rangle &\overset{(1)}{=} 4Nh + c_{2N},\\
L_{2N}L_{-N}^2|h\rangle &\overset{(2)}{=} [L_{2N}, L_{-N}]\,L_{-N}|h\rangle \overset{(3)}{=} 3N\,L_NL_{-N}|h\rangle \overset{(4)}{=} 3N\,(2Nh + c_N)|h\rangle,\\
L_NL_{-N}^2|h\rangle &\overset{(5)}{=} \big([L_N, L_{-N}]L_{-N} + L_{-N}[L_N, L_{-N}]\big)|h\rangle \overset{(6)}{=} \big(2N(h+N) + c_N + 2Nh + c_N\big)L_{-N}|h\rangle,
\end{aligned}$$

(1) (11.143) with $n = 2N$.
(2) $L_{2N}|h\rangle = 0$, so only the commutator with the first L_{-N} survives, and then L_{2N} hits $L_{-N}|h\rangle$, whose level N is too low for L_{2N}: $L_{2N}L_{-N}|h\rangle = [L_{2N}, L_{-N}]|h\rangle = 3NL_N|h\rangle = 0$.
(3) $[L_{2N}, L_{-N}] = (2N+N)L_N$; no central term since $2N - N \neq 0$.
(4) $L_NL_{-N}|h\rangle = [L_N, L_{-N}]|h\rangle = (2Nh + c_N)|h\rangle$.
(5) Commute L_N through both factors; $L_N|h\rangle = 0$.
(6) L_0 acting on $L_{-N}|h\rangle$ gives $h + N$, and acting on $|h\rangle$ gives h.

So $\big\|L_{-N}^2|h\rangle\big\|^2 = (4Nh + 2N^2 + 2c_N)(2Nh + c_N)$. Set $c = 0$, so that all the c_N vanish. The Gram matrix in the basis $(L_{-2N}|h\rangle,\ L_{-N}^2|h\rangle)$ and its determinant are

$$\begin{aligned}
\det\begin{pmatrix} 4Nh & 6N^2h \\ 6N^2h & 2Nh(4Nh + 2N^2)\end{pmatrix} &\overset{(1)}{=} 8N^2h^2(4Nh + 2N^2) - 36N^4h^2\\
&\overset{(2)}{=} 32N^3h^3 - 20N^4h^2 \overset{(3)}{=} 4N^3h^2\,(8h - 5N).
\end{aligned}$$

(1) $ad - b^2$.
(2) Expand: $8N^2h^2 \cdot 4Nh = 32N^3h^3$ and $8N^2h^2 \cdot 2N^2 - 36N^4h^2 = -20N^4h^2$.
(3) Factor out $4N^3h^2$.

For any $h > 0$, choose an integer $N > \frac{8h}{5}$. The determinant is then negative, so this 2×2 block has one negative eigenvalue. *At $c = 0$ every $h > 0$ is excluded.* What remains is $h = 0$. But at $c = 0$, $\|L_{-2}|0\rangle\|^2 = 0$ as well, so $T(0)|0\rangle = 0$: the stress tensor vanishes. The only unitary $c = 0$ theory is the trivial one, with one state. (For $N = 1$ the determinant $4h^2(8h-5)$ is the level-2 Kac determinant at $c = 0$, $2h\big(16h^2 - 10h\big)$, as it should be.)

Watch out: non-unitary is not the same as unphysical

The $c = 0$ result does not say that $c = 0$ CFTs are useless. Two-dimensional percolation and self-avoiding polymers are critical, conformally invariant and have $c = 0$. Their CFTs are non-unitary: the transfer matrix of these lattice models is not a positive operator. Likewise the Yang–Lee edge singularity is described by a CFT with $c = -\frac{22}{5}$ and a primary of weight $h = -\frac{1}{5}$. Unitarity is the right requirement for a quantum field theory whose states are physical particles. It is a genuine extra assumption for statistical models.

$c \geq 1$: no further obstruction

For $c \geq 1$ we show that $h \geq 0$ is the only condition. The argument uses the Kac formula (11.140) and a continuity principle.

Key idea: continuity principle

The entries of $M^{(N)}(c, h)$ are polynomials in (c, h), so its eigenvalues depend continuously on (c, h). An eigenvalue can change sign only by passing through zero, and there $\det M^{(N)} = 0$. Hence *on a connected region of the (c, h) plane that contains no zero of the Kac determinant, the number of negative eigenvalues of $M^{(N)}$ is constant.*

So we need two facts: that there are no zeros in the region $c > 1$, $h > 0$, and that somewhere in that region there is no negative eigenvalue.

Where the zeros are. First rewrite $h_{r,s}$ from (11.140) so that its dependence on t is visible:

$$h_{r,s} \overset{(1)}{=} \frac{r^2t^2 - 2rs\,t + s^2 - t^2 + 2t - 1}{4t} \overset{(2)}{=} \frac{1}{4}\Big[(r^2-1)\,t + \frac{s^2-1}{t} - 2(rs-1)\Big]. \tag{11.145}$$

(1) Expand $(rt - s)^2 - (t - 1)^2$.
(2) Group by powers of t: $(r^2 - 1)t^2 - 2(rs - 1)t + (s^2 - 1)$, then divide by $4t$.

Next, which t belongs to which c? From $c = 13 - 6(t + 1/t)$ we get $t + \frac{1}{t} = \frac{13-c}{6}$. Three cases:

- $c < 1$: $t + \frac{1}{t} > 2$, so t is real and positive (and $t \neq 1$).
- $1 < c < 25$: $-2 < t + \frac{1}{t} < 2$. A real t has $|t + 1/t| \geq 2$, so t is complex. Since t and $1/t$ are the two roots of $t^2 - \frac{13-c}{6}t + 1 = 0$ with real coefficients, they are complex conjugates, and $t\bar{t} = t \cdot \frac{1}{t} = 1$. So $t = e^{i\theta}$ with $0 < \theta < \pi$.
- $c \geq 25$: $t + \frac{1}{t} \leq -2$, so t is real and negative.

Now look at $h_{r,s}$ in each case with $c > 1$.

Case $1 < c < 25$, $t = e^{i\theta}$. By (11.145),

$$\operatorname{Im} h_{r,s} \overset{(1)}{=} \frac{1}{4}\big[(r^2-1)\sin\theta - (s^2-1)\sin\theta\big] = \frac{(r^2-s^2)\sin\theta}{4},$$
$$h_{r,r} \overset{(2)}{=} \frac{1}{4}\big[(r^2-1)(e^{i\theta}+e^{-i\theta}) - 2(r^2-1)\big] \overset{(3)}{=} -\frac{(r^2-1)(1-\cos\theta)}{2} \leq 0.$$

(1) $\operatorname{Im} e^{\pm i\theta} = \pm\sin\theta$; the constant term is real.
(2) Put $s = r$ in (11.145).
(3) $e^{i\theta} + e^{-i\theta} = 2\cos\theta$, so the bracket is $2(r^2 - 1)(\cos\theta - 1)$.

For $r \neq s$ the imaginary part is nonzero ($\sin\theta > 0$), so $h_{r,s}$ is not real. For $r = s$ it is real but ≤ 0. Either way, no zero lies at real $h > 0$.

Case $c \geq 25$, $t < 0$. All three terms in (11.145) are ≤ 0: $(r^2-1)t \leq 0$, $(s^2-1)/t \leq 0$ and $-2(rs-1) \leq 0$. So $h_{r,s} \leq 0$.

Hence for $c > 1$ the Kac determinant has no zero anywhere in $h > 0$. The region $\{c > 1,\ h > 0\}$ is connected.

A point with no negative eigenvalue. Take h very large at fixed c. As we noted after (11.139), the diagonal entry of $M^{(N)}$ belonging to $L_{-i_1}\cdots L_{-i_k}|h\rangle$ grows like h^k with a positive coefficient, while the off-diagonal entries in its row grow more slowly. A symmetric matrix dominated by a positive diagonal is positive definite. So for $h \gg 1$ there is no negative eigenvalue. The continuity principle then gives:

Key idea: the region $c \geq 1$

For $c > 1$ and $h > 0$, every Gram matrix $M^{(N)}(c,h)$ is positive definite. The Verma module $V(c,h)$ is irreducible and its completion is a Hilbert space: every such (c,h) gives a unitary representation of *Vir*. At $c = 1$ the zeros $h_{r,s} = \frac{(r-s)^2}{4}$ are real and ≥ 0. By continuity from $c > 1$, the Gram matrices at $c = 1$ are positive *semi*-definite, and after quotienting the null states the representation is unitary for all $h \geq 0$. This is the first line of Nash's (6.58): "$c \geq 1$, $h \geq 0$".

The $c = 1$ free boson of Section 11.4.5 realises this explicitly: its Fock space is manifestly positive (the a_{-n} are ordinary creation operators) and it contains primaries of every weight $h = \frac{\alpha^2}{4} \geq 0$, the vertex operators of Example 11.23.

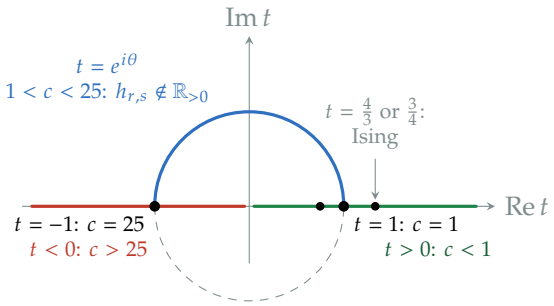

Figure 11.23: The parameter t of the Kac formula, $c = 13 - 6(t + 1/t)$. Values of c below 1 put t on the positive real axis (green), and there the zeros $h_{r,s}$ are real and many of them positive. For $1 < c < 25$, t lies on the unit circle (blue), and the zeros are either non-real or ≤ 0. For $c > 25$, t is negative (red) and all zeros are ≤ 0. The replacement $t \to 1/t$ (reflection in the unit circle) gives the same c and swaps $h_{r,s} \leftrightarrow h_{s,r}$. Only on the green half-line can the Kac determinant vanish at positive h, so only there can unitarity fail beyond $h \geq 0$.

$0 < c < 1$: the sieve

Below $c = 1$ everything changes. Now $t > 0$ is real and the curves $h_{r,s}(c)$ of Figure 11.22 run through the physical region $h > 0$. Crossing a curve can flip the sign of an eigenvalue. We look first at level 2, where everything can be done by hand.

Level 2. By (11.136) and (11.139), $\det M^{(2)} = 32\,h\,(h - h_{1,2})(h - h_{2,1})$. For $0 < c < 1$ both roots are real and positive, with $h_{1,2} < h_{2,1}$. If $h_{1,2} < h < h_{2,1}$, one factor is negative and the

others positive, so $\det M^{(2)} < 0$. A real symmetric 2×2 matrix with negative determinant has eigenvalues $\lambda_1\lambda_2 < 0$, i.e. one of each sign. So the entire band between the two level-2 curves is excluded. (It is the shaded region of Figure 11.22.)

Worked example 11.47: An explicit negative-norm state at $c = \frac{1}{2}$, $h = \frac{1}{4}$

At $c = \frac{1}{2}$ we have $h_{1,2} = \frac{1}{16}$ and $h_{2,1} = \frac{1}{2}$ (Example 11.43). The value $h = \frac{1}{4}$ lies between them. Take the simplest combination $|\psi\rangle = (L_{-2} - L_{-1}^2)|h\rangle$. With the level-2 entries $M_{11} = 4h + \frac{c}{2}$, $M_{12} = 6h$, $M_{22} = 4h(2h+1)$ of (11.136),

$$\langle\psi|\psi\rangle \overset{(1)}{=} M_{11} - 2M_{12} + M_{22} \overset{(2)}{=} 4h + \frac{c}{2} - 12h + 8h^2 + 4h = 8h^2 - 4h + \frac{c}{2}$$
$$\overset{(3)}{=} 8\cdot\frac{1}{16} - 4\cdot\frac{1}{4} + \frac{1}{4} = \frac{1}{2} - 1 + \frac{1}{4} = -\frac{1}{4}.$$

(1) Bilinearity: $\langle\psi|\psi\rangle = \langle L_{-2}h|L_{-2}h\rangle - 2\langle L_{-2}h|L_{-1}^2h\rangle + \langle L_{-1}^2h|L_{-1}^2h\rangle$ (the entries are real).
(2) Insert the entries.
(3) $h = \frac{1}{4}$, $c = \frac{1}{2}$.
