So a CFT with $c = \frac{1}{2}$ cannot contain a primary of weight $\frac{1}{4}$. The same formula shows how narrow the window is: $8h^2 - 4h + \frac{1}{4} < 0$ exactly for $\frac{2-\sqrt{2}}{8} < h < \frac{2+\sqrt{2}}{8}$, i.e. $0.073 < h < 0.427$. This vector alone does not see the whole band $(\frac{1}{16}, \frac{1}{2})$. The eigenvector of the negative eigenvalue does. At $h = \frac{1}{4}$ the matrix is $\left(\begin{smallmatrix} 5/4 & 3/2 \\ 3/2 & 3/2 \end{smallmatrix}\right)$, with $\det = \frac{15}{8} - \frac{9}{4} = -\frac{3}{8}$ and eigenvalues $\frac{11\pm\sqrt{145}}{8} \approx 2.88,\ -0.13$.

Level 3 and beyond. At level 3 the new factor $3h^2 + (c-7)h + c + 2 = 3(h - h_{1,3})(h - h_{3,1})$ of (11.138) is negative between $h_{1,3}$ and $h_{3,1}$. Where the level-2 factor is positive, $\det M^{(3)} < 0$ there. The determinant of a 3×3 matrix is the product of three eigenvalues, so an odd number of them are negative, and at least one is. A second band is excluded. At level 4 the factors $h - h_{2,2}$, $h - h_{1,4}$ and $h - h_{4,1}$ bring more bands, and so on. Each level carves the (c, h) region further, like a sieve.

To see what survives, we computed the Gram matrices exactly up to level 12 ($p(12) = 77$ states), using the same commutation rules we used by hand for levels 2 and 3. For each point of a fine grid we recorded the first level with a negative eigenvalue. The result is Figure 11.24.

c	h	first negative level	comment
0.5	0.25	2	inside the level-2 band (Example 11.47)
0.7	0.2	2	inside the level-2 band
0.9	0.3	2	the band is narrow near $c = 1$, but 0.3 is in it
0.6	0.02	4	below $h_{1,2}$; caught by the $h_{2,2}$ factor
0.1	0.01	4	likewise
0.8	0.1	6	between the $c = \frac{4}{5}$ Kac values $\frac{1}{15}$ and $\frac{1}{8}$
0.6	0.5	6	just above $h_{2,1}(0.6) \approx 0.43$
0.95	0.05	none up to 9	not a minimal model: excluded at a higher level
0.7	0.1	none	$= (c_4, h_{1,2})$, a minimal model (tricritical Ising)
0.5	0.0625	none	$= (c_3, h_{1,2})$, the Ising spin field

Table 11.3: Sample points from the computation behind Figure 11.24. The first two columns are the point, the third is the lowest level with a negative eigenvalue of $M^{(N)}$. Points near $c = 1$ survive to high level: the sieve's holes get finer as $c \to 1$.

The picture suggests, and Friedan, Qiu and Shenker proved, the following.

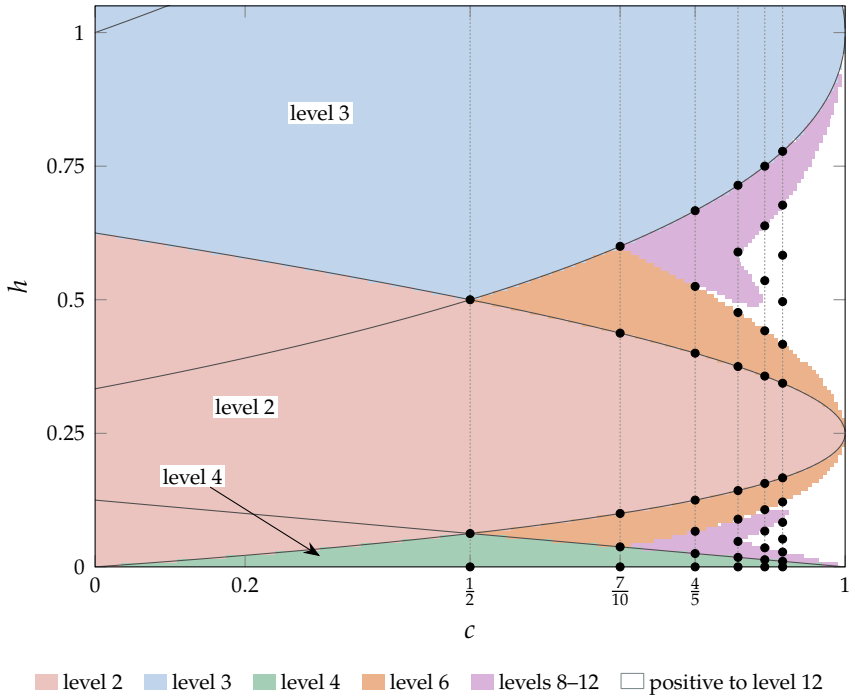

Figure 11.24: The unitarity sieve for $0 < c < 1$, computed from the exact Gram matrices $M^{(N)}(c, h)$ for $N \leq 12$. The colour of a point is the first level at which a negative-norm state appears. The thin black curves are the Kac curves $h_{r,s}(c)$ with $rs \leq 4$. The boundaries of the level-2, 3 and 4 regions run exactly along them, as the continuity principle demands; the higher-level regions are bounded in the same way by curves with $rs = 6, 8, 9, 12$, not drawn. Level 2 removes the band between $h_{1,2}$ and $h_{2,1}$, level 3 everything above $h_{2,1}$ in view, level 4 a thin wedge at small h, and higher levels bite ever closer to $c = 1$. The white region shrinks as the level grows. The black dots are the unitary minimal models $c = \frac{1}{2}, \frac{7}{10}, \frac{4}{5}, \frac{6}{7}, \frac{25}{28}, \frac{11}{12}$ (dotted lines) with $h = h_{r,s}$: they sit exactly on crossings of the curves, and they survive every level. The white area near $c = 1$ that is still uncoloured at level 12 is removed at higher levels, except for these dots.

Key idea: the Friedan–Qiu–Shenker theorem; Nash's (6.58)

For $0 \le c < 1$, the Virasoro module $L(c,h)$ is unitary *only* if

$$c = c_m := 1 - \frac{6}{m(m+1)}, \qquad h = h_{r,s} = \frac{\big((m+1)r - ms\big)^2 - 1}{4m(m+1)}, \tag{11.146}$$
$$m = 2,3,4,\dots, \qquad 1 \le r \le m-1, \quad 1 \le s \le m.$$

Together with the region $c \ge 1$, $h \ge 0$ this is the complete list of unitary highest-weight representations of *Vir*.

Some remarks on why this is plausible.

- *Why the special lines $c = c_m$.* The values c_m are exactly those for which $t = \frac{m+1}{m}$ is rational with numerator and denominator differing by 1. Then $h_{r,s} = h_{r+m,s+m+1}$, and the curves $h_{r,s}$ cross each other at the points (11.146). At a crossing the determinant vanishes to higher order, and sign changes coming from different curves can cancel. At a generic point between curves, FQS show that at some level an odd number of factors in (11.139) is negative.
- *Why they accumulate at $c = 1$.* As $m \to \infty$, $c_m \to 1$ and the table (11.146) fills in more and more of the half-line $h \ge 0$, in the limit giving the $c = 1$ values $h = \frac{(r-s)^2}{4}$ and everything in between.
- *Why $m = 2$ is trivial.* $c_2 = 0$ and the only entry is $h_{1,1} = h_{1,2} = 0$: the trivial theory, as we showed by hand above.

Existence: the coset construction. The FQS theorem is a list of *necessary* conditions. That each point on the list really carries a unitary representation was shown by Goddard, Kent and Olive (Nash's Chapter 6 cites them). They build *Vir* with $c = c_m$ inside a manifestly unitary theory, namely a product of SU(2) Kac–Moody representations (these appear in Section 11.4.14). By the Sugawara construction, the level-k SU(2) current algebra has a stress tensor with $c(k) = \frac{3k}{k+2}$. The difference of the stress tensors of $\mathrm{SU}(2)_k \times \mathrm{SU}(2)_1$ and of the diagonal $\mathrm{SU}(2)_{k+1}$ is again a Virasoro generator, commuting with the diagonal currents, with central charge

$$c \overset{(1)}{=} \frac{3k}{k+2} + \frac{3\cdot 1}{1+2} - \frac{3(k+1)}{k+3} \overset{(2)}{=} 1 + \frac{3\big[k(k+3) - (k+1)(k+2)\big]}{(k+2)(k+3)} \overset{(3)}{=} 1 - \frac{6}{(k+2)(k+3)}.$$

(1) The coset (difference) of Sugawara central charges, with $c(1) = 1$.
(2) Common denominator $(k+2)(k+3)$ for the first and third terms.
(3) $k^2 + 3k - (k^2 + 3k + 2) = -2$.

With $m = k+2$ this is c_m. The space of states of the coset theory is a subspace of a positive Hilbert space, so the representations are unitary, and one checks that all the weights $h_{r,s}$ of (11.146) occur. For $k = 1$ ($m = 3$) we get $c = \frac{1}{2}$, the Ising model.

Reading Nash (p. 310 and Chapter 6, pp. 186–187, (6.57)–(6.58))

In Chapter 6 Nash defines a highest-weight representation by (6.57), $L_0|h\rangle = h|h\rangle$, $L_n|h\rangle = 0$ for $n \ge 1$ (the same as his (11.37)), and quotes the unitary values (6.58):

$$c \ge 1,\ h \ge 0, \qquad \text{or} \qquad c = 1 - \frac{6}{(m+1)(m+2)}, \quad h = \frac{\big((m+2)p - (m+1)q\big)^2 - 1}{4(m+1)(m+2)},$$

with $m = 1, 2, \ldots$, $p = 1, \ldots, m$, $q = 1, \ldots, p$. His m is our $m - 1$: put $m_{\text{Nash}} = m - 1$, $p = r$, $q = s$ and one gets (11.146). His ranges $1 \le q \le p \le m_{\text{Nash}}$ pick one representative from each pair identified by the symmetry (11.147) below, so they list each distinct weight once. His $m = 1$ is our $m = 2$: $c = 0$, $h = 0$, the trivial theory. On p. 310 he adds that negative-norm states "are disallowed" and that positivity selects the allowed (c, h); in this subsection we derived $h \ge 0$, $c \ge 0$, the triviality of $c = 0$, the absence of obstructions for $c \ge 1$, and the level-2 and level-3 bands, and we displayed the rest of the sieve by computation.

11.4.12 The unitary minimal models

The discrete series has a striking property. At $c = c_m$ only finitely many values of h are allowed. So a unitary CFT with $c < 1$ can contain only finitely many conformal families. Such a theory is called a **minimal model**, and it is labelled by m. These are the simplest interacting quantum field theories that exist, and they are solvable: every correlation function can be computed exactly. Nash's §4 (the next part of these notes) takes the $m = 3$ model as its central example.

Working definition 11.20 (Kac table and minimal model $\mathcal{M}_m$)

Fix an integer $m \ge 3$. The **Kac table** is the rectangle of weights $h_{r,s}$ in (11.146) [$h_{r,s} = \frac{((m+1)r - ms)^2 - 1}{4m(m+1)}$], with $1 \le r \le m-1$ and $1 \le s \le m$. The **unitary minimal model** $\mathcal{M}_m$ is the CFT with $c = c_m$ [$c_m = 1 - \frac{6}{m(m+1)}$, so $c_3 = \frac{1}{2}$] whose primary fields are $\phi_{r,s}$ of weights $(h_{r,s}, h_{r,s})$, one for each distinct entry of the table. (We describe the "diagonal" model, with $\bar{h} = h$; other combinations are possible, see the pitfall below.) *How to use it:* to find the spectrum, evaluate $h_{r,s}$ on the rectangle and identify equal entries using the symmetry (11.147) [$h_{m-r,\,m+1-s} = h_{r,s}$, so each weight appears exactly twice].

The symmetry of the table. The table is symmetric under a half-turn:

$$h_{m-r,\,m+1-s} \overset{(1)}{=} \frac{\big((m+1)(m-r) - m(m+1-s)\big)^2 - 1}{4m(m+1)} \overset{(2)}{=} \frac{\big(-(m+1)r + ms\big)^2 - 1}{4m(m+1)} \overset{(3)}{=} h_{r,s}. \tag{11.147}$$

(1) (11.146) with $(r, s) \to (m - r, m + 1 - s)$.
(2) $(m+1)m - (m+1)r - m(m+1) + ms = -(m+1)r + ms$.
(3) The square does not see the overall sign.

No entry is fixed by the half-turn: that would need $r = \frac{m}{2}$ and $s = \frac{m+1}{2}$, but m and $m+1$ are not both even. So the $(m-1)m$ entries pair up, and $\mathcal{M}_m$ has

$$\#\{\text{primaries of } \mathcal{M}_m\} = \frac{m(m-1)}{2}. \tag{11.148}$$

The identity is always $\phi_{1,1} = \phi_{m-1,m}$, with $h_{1,1} = \frac{(m+1-m)^2 - 1}{4m(m+1)} = 0$.

Worked example 11.48: The Ising model, $m = 3$

For $m = 3$, $c_3 = 1 - \frac{6}{12} = \frac{1}{2}$ and $h_{r,s} = \frac{(4r-3s)^2 - 1}{48}$. The first row of the table is

$$h_{1,1} \overset{(1)}{=} \frac{(4-3)^2 - 1}{48} = 0, \quad h_{1,2} \overset{(1)}{=} \frac{(4-6)^2 - 1}{48} = \frac{3}{48} = \frac{1}{16}, \quad h_{1,3} \overset{(1)}{=} \frac{(4-9)^2 - 1}{48} = \frac{24}{48} = \frac{1}{2},$$

(1) (11.146) with $m = 3$, $r = 1$.

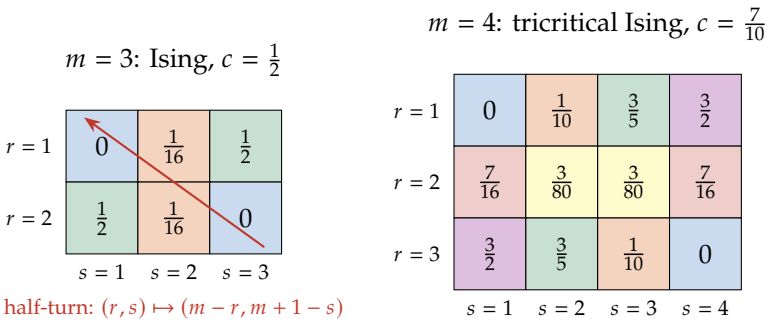

Figure 11.25: Kac tables of the first two unitary minimal models. Rows are r, columns are s. Equal colours mark entries identified by the half-turn symmetry (11.147), which rotates the rectangle about its centre (red arrow). The Ising table has $3 = \frac{3\cdot 2}{2}$ distinct weights $0, \frac{1}{16}, \frac{1}{2}$; the tricritical Ising table has $6 = \frac{4\cdot 3}{2}$ weights $0, \frac{3}{80}, \frac{1}{10}, \frac{7}{16}, \frac{3}{5}, \frac{3}{2}$.

and the second row is the first reversed, by (11.147). So the Ising CFT has three primaries:

$$\mathbb{1}\ (h=0), \qquad \sigma\ (h=\tfrac{1}{16}), \qquad \varepsilon\ (h=\tfrac{1}{2}).$$

The field σ is the continuum limit of the lattice spin, and ε is the energy density $\sigma_i\sigma_j$ on a bond. We already know one realisation: the free Majorana fermion of Section 11.3.7 has $c=\frac{1}{2}$, and $\varepsilon = i\psi\bar\psi$ has weights $(\frac{1}{2},\frac{1}{2})$. The spin field σ is not a polynomial in ψ: it is a twist field around which ψ changes sign.

Counting the states. Computing the rank of $M^{(N)}$ at the three points $(\frac{1}{2},0)$, $(\frac{1}{2},\frac{1}{16})$, $(\frac{1}{2},\frac{1}{2})$ gives the number of states of the irreducible module at each level:

level N	0	1	2	3	4	5	6	7	8	9
Verma $p(N)$	1	1	2	3	5	7	11	15	22	30
$L(\frac{1}{2},0)$	1	0	1	1	2	2	3	3	5	5
$L(\frac{1}{2},\frac{1}{16})$	1	1	1	2	2	3	4	5	6	8
$L(\frac{1}{2},\frac{1}{2})$	1	1	1	1	2	2	3	4	5	6

The irreducible modules are far smaller than the Verma module: at level 9 the vacuum module keeps 5 of 30 states. The free fermion confirms the first and third rows. Its Fock space is built by ψ_{-k}, $k\in\{\frac{1}{2},\frac{3}{2},\frac{5}{2},\dots\}$, each used at most once (Pauli). An even number of fermions gives integer level: at level 4 there are $\psi_{-7/2}\psi_{-1/2}|0\rangle$ and $\psi_{-5/2}\psi_{-3/2}|0\rangle$, i.e. 2 states, as in the row $L(\frac{1}{2},0)$. An odd number of fermions gives the module of ε, starting with $\psi_{-1/2}|0\rangle$ at weight $\frac{1}{2}$. (The chiral half of $\varepsilon = i\psi\bar\psi$ is ψ, of weight $\frac{1}{2}$.)

Worked example 11.49: Critical exponents of the Ising model from the Kac table

In Example 11.3 we went from Onsager's exponents to scaling dimensions. Now we run the argument backwards and *predict* the exponents from the Kac table. Recall from Section 11.1.2 that η is defined by the power law of the spin-spin correlation at T_c, $\langle\sigma(x)\sigma(0)\rangle \sim |x|^{-(d-2+\eta)}$, and ν by $\xi\sim|T-T_c|^{-\nu}$. A spinless primary of weights (h,h) has scale dimension $\Delta=2h$ and two-point function $|x|^{-2\Delta}$ (by the two-point function of Section 11.3.6). In $d=2$:

$$\eta \overset{(1)}{=} 2\Delta_\sigma \overset{(2)}{=} 2\cdot 2\cdot\frac{1}{16} = \frac{1}{4},$$
$$\nu \overset{(3)}{=} \frac{1}{2-\Delta_\varepsilon} \overset{(4)}{=} \frac{1}{2-1} = 1,$$

$$\beta \overset{(5)}{=} \frac{\nu\,(d-2+\eta)}{2} = \frac{1\cdot\frac{1}{4}}{2} = \frac{1}{8}.$$

(1) Compare $|x|^{-2\Delta_\sigma}$ with $|x|^{-(d-2+\eta)}$ at $d=2$.
(2) $\Delta_\sigma = h + \bar{h} = 2h_{1,2}$.
(3) Moving off T_c adds $\delta S = g\int \mathrm{d}^2x\,\varepsilon(x)$ with $g \propto T - T_c$. Since d^2x has dimension -2 and ε has Δ_ε, the coupling g has mass dimension $2-\Delta_\varepsilon$. The only length is then $\xi \sim g^{-1/(2-\Delta_\varepsilon)}$.
(4) $\Delta_\varepsilon = 2h_{1,3} = 1$.
(5) The scaling relation between the magnetisation exponent β and ν, η (from $\langle\sigma\rangle \sim \xi^{-\Delta_\sigma}$, so $\beta = \nu\Delta_\sigma$).

These are exactly Onsager's exact values for the square-lattice Ising model: $\eta = \frac{1}{4}$, $\nu = 1$, $\beta = \frac{1}{8}$. A lattice computation that took Onsager a tour de force comes out of (11.146) in three lines. The same recipe for the tricritical Ising model ($m = 4$) uses the leading energy field $\varepsilon = \phi_{1,2}$, $h = \frac{1}{10}$, so $\Delta_\varepsilon = \frac{1}{5}$ and $\nu = \frac{1}{2-1/5} = \frac{5}{9}$, the known tricritical value.

m	c_m	primaries	statistical model at criticality and weights h
2	0	1	trivial theory
3	$\frac{1}{2}$	3	Ising: $0,\ \frac{1}{16},\ \frac{1}{2}$
4	$\frac{7}{10}$	6	tricritical Ising: $0,\ \frac{3}{80},\ \frac{1}{10},\ \frac{7}{16},\ \frac{3}{5},\ \frac{3}{2}$
5	$\frac{4}{5}$	10	tetracritical Ising: $0, \frac{1}{40}, \frac{1}{15}, \frac{1}{8}, \frac{2}{5}, \frac{21}{40}, \frac{2}{3}, \frac{7}{5}, \frac{13}{8}, 3$; the 3-state Potts model uses the subset $0, \frac{1}{15}, \frac{2}{5}, \frac{2}{3}, \frac{7}{5}, 3$

Table 11.4: The first unitary minimal models. The number of primaries is $\frac{m(m-1)}{2}$ from (11.148).

Watch out: diagonal and non-diagonal models, and non-unitary ones

Two cautions. First, the Kac table fixes which *holomorphic* weights may occur. A full CFT must also say which pairs $(h, \bar{h})$ occur and how often. The diagonal choice $\bar{h} = h$ is always consistent. Sometimes there are others; the 3-state Potts model at $c = \frac{4}{5}$ is one. Which combinations are allowed is decided by modular invariance on the torus, Nash's §4 (next part). Second, the FQS list assumes unitarity. Dropping it gives the non-unitary minimal models $\mathcal{M}(p,p')$ with coprime p, p' and $c = 1 - \frac{6(p-p')^2}{pp'}$. The Yang–Lee model $\mathcal{M}(5,2)$ has $c = -\frac{22}{5}$ and a primary with $h = -\frac{1}{5} < 0$, which our condition $h \geq 0$ forbids in a unitary theory.

Why "minimal": null vectors force the operator algebra to close

A CFT has an operator product expansion. If $\phi_{r,s}$ and $\phi_{r',s'}$ are in $\mathcal{M}_m$, their product must again be a sum of fields in $\mathcal{M}_m$. There are only finitely many to choose from, so the product must close on a finite set. What enforces this? The null vectors. In $L(c,h)$ a singular vector is *zero*, so the corresponding descendant field is the zero operator. Setting it to zero inside a correlation function gives a differential equation. We show how this works for the simplest case, a field with a level-2 null vector. (The full theory of fusion rules is in Nash's §5, the next part.)

Let $\phi := \phi_{1,2}$ with weight $h_\phi = h_{1,2}$. By (11.127) and (11.130) its level-2 null vector is $(L_{-2} + \alpha L_{-1}^2)|h_\phi\rangle$ with $\alpha = -\frac{3}{2(2h_\phi+1)}$. In the t parametrisation $h_{1,2} = \frac{3-2t}{4t}$, so $2h_\phi + 1 = \frac{3}{2t}$ and

$\alpha = -t$. Therefore the field equation is

$$\big(L_{-2}\phi\big)(z) = t\,\partial^2\phi(z), \tag{11.149}$$

using $L_{-1}\phi = \partial\phi$. Now sandwich $\phi(z)$ between two highest-weight states $|h\rangle = \phi_h(0)|0\rangle$ and $\langle h'|$ and define $G(z) \coloneqq \langle h'|\phi(z)|h\rangle$. This is a three-point function with the third field at infinity.

The z-dependence of G. By (11.101) with $m = 0$, $[L_0, \phi(z)] = (z\partial + h_\phi)\phi(z)$. Take the matrix element:

$$(h' - h)\,G(z) \overset{(1)}{=} \langle h'|\big(L_0\phi(z) - \phi(z)L_0\big)|h\rangle \overset{(2)}{=} (z\partial_z + h_\phi)\,G(z),$$

(1) $\langle h'|L_0 = h'\langle h'|$ (L_0 is Hermitian) and $L_0|h\rangle = h|h\rangle$.
(2) The commutator formula.

so $zG' = \kappa\,G$ with $\kappa \coloneqq h' - h - h_\phi$, and $G(z) = C\,z^\kappa$. The constant C is the OPE coefficient: $C \neq 0$ exactly when $[\phi_{h'}]$ appears in the product $\phi \times \phi_h$.

The descendant $L_{-2}\phi$ inside G. By Nash's (11.41) ((11.124)),

$$(L_{-2}\phi)(z) = \oint_z \frac{\mathrm{d}w}{2\pi i}(w - z)^{-1}T(w)\phi(z).$$

$$\begin{aligned}\langle h'|(L_{-2}\phi)(z)|h\rangle &\overset{(1)}{=} \oint_{|w|>|z|}\frac{\mathrm{d}w}{2\pi i}\frac{\langle h'|T(w)\phi(z)|h\rangle}{w-z} - \oint_{|w|<|z|}\frac{\mathrm{d}w}{2\pi i}\frac{\langle h'|\phi(z)T(w)|h\rangle}{w-z}\\ &\overset{(2)}{=} \sum_{k\geq 0} z^k\,\langle h'|L_{-k-2}\,\phi(z)|h\rangle + \sum_{k\geq 0} z^{-k-1}\langle h'|\phi(z)\,L_{k-1}|h\rangle\\ &\overset{(3)}{=} z^{-1}\langle h'|\phi(z)L_{-1}|h\rangle + h\,z^{-2}\,G(z) \overset{(4)}{=} -z^{-1}\,\partial_z G(z) + h\,z^{-2}\,G(z).\end{aligned}$$

(1) A small circle around z is the difference of a circle $|w| > |z|$ and a circle $|w| < |z|$ (both around 0), and radial ordering (11.99) puts $T(w)$ to the left when $|w| > |z|$ (Section 11.4.3).
(2) For $|w| > |z|$, $\frac{1}{w-z} = \sum_{k\geq 0} z^k w^{-k-1}$, and $\oint \frac{\mathrm{d}w}{2\pi i} w^{-k-1}T(w) = L_{-k-2}$ by the mode formula (11.94). For $|w| < |z|$, $\frac{1}{w-z} = -\sum_{k\geq 0} w^k z^{-k-1}$ and $\oint \frac{\mathrm{d}w}{2\pi i} w^k T(w) = L_{k-1}$; the two minus signs cancel.
(3) $\langle h'|L_{-n} = \big(L_n|h'\rangle\big)^\dagger = 0$ for $n \geq 1$, so the first sum vanishes. In the second, $L_{k-1}|h\rangle = 0$ for $k \geq 2$, and $L_0|h\rangle = h|h\rangle$ for $k = 1$.
(4) $\phi(z)L_{-1} = L_{-1}\phi(z) - [L_{-1}, \phi(z)] = L_{-1}\phi(z) - \partial\phi(z)$, and $\langle h'|L_{-1} = 0$.

The equation and its solutions. Insert this and $\langle h'|\partial^2\phi(z)|h\rangle = G''$ into (11.149):

$$0 \overset{(1)}{=} \Big(\frac{h}{z^2} - \frac{1}{z}\,\partial_z - t\,\partial_z^2\Big)C\,z^\kappa \overset{(2)}{=} \big(h - \kappa - t\,\kappa(\kappa-1)\big)\,C\,z^{\kappa-2}. \tag{11.150}$$

(1) The null-vector equation between $\langle h'|$ and $|h\rangle$.
(2) $\partial z^\kappa = \kappa z^{\kappa-1}$ and $\partial^2 z^\kappa = \kappa(\kappa-1)z^{\kappa-2}$.

So either $C = 0$, or κ solves the quadratic $t\kappa^2 + (1-t)\kappa - h = 0$. For a given h there are exactly two allowed values $h' = h + h_\phi + \kappa_\pm$. The product of $\phi_{1,2}$ with any primary contains *at most two* conformal families. With $h = h_{r,s}$ one checks (by inserting (11.140); we verified it by computer algebra) that the two roots are $h' = h_{r,s-1}$ and $h' = h_{r,s+1}$:

$$\phi_{1,2} \times \phi_{r,s} = \phi_{r,s-1} + \phi_{r,s+1}. \tag{11.151}$$

Worked example 11.50: Ising fusion rules from the null vector

In the Ising model $t = \frac{m+1}{m} = \frac{4}{3}$ and $\sigma = \phi_{1,2}$ with $h_\phi = \frac{1}{16}$. (Check: $\alpha = -\frac{3}{2(2/16+1)} = -\frac{3}{9/4} = -\frac{4}{3}$.)
$\sigma \times \sigma$. Put $h = \frac{1}{16}$:

$$\tfrac{4}{3}\kappa^2 - \tfrac{1}{3}\kappa - \tfrac{1}{16} = 0 \overset{(1)}{=} 64\kappa^2 - 16\kappa - 3 = 0 \overset{(2)}{=} \kappa = \frac{16 \pm \sqrt{256+768}}{128} = \frac{16 \pm 32}{128} = \frac{3}{8} \text{ or } -\frac{1}{8},$$

(1) Multiply by 48.
(2) Quadratic formula; $\sqrt{1024} = 32$.

and $h' = \frac{1}{16} + \frac{1}{16} + \kappa = \frac{1}{8} + \kappa \in \{\frac{1}{2}, 0\}$. So $\sigma \times \sigma = \mathbb{1} + \varepsilon$: two spins fuse into the identity (they can annihilate) or into the energy density (a bond). This is (11.151) with $(r, s) = (1, 2)$: $\phi_{1,1} + \phi_{1,3}$.
$\sigma \times \varepsilon$. Put $h = \frac{1}{2}$:

$$\tfrac{4}{3}\kappa^2 - \tfrac{1}{3}\kappa - \tfrac{1}{2} = 0 \overset{(1)}{=} 8\kappa^2 - 2\kappa - 3 = 0 \overset{(2)}{=} \kappa = \frac{2 \pm 10}{16} = \frac{3}{4} \text{ or } -\frac{1}{2},$$

(1) Multiply by 6.
(2) Quadratic formula; $\sqrt{4+96} = 10$.

so $h' = \frac{9}{16} + \kappa \in \{\frac{21}{16}, \frac{1}{16}\}$. The value $\frac{21}{16} = h_{1,4}$ is outside the Kac table. It is eliminated by the second null vector: ε is $\phi_{2,1}$ as well as $\phi_{1,3}$, so it has its own level-2 null vector, with $\alpha = -\frac{3}{2(2\cdot\frac{1}{2}+1)} = -\frac{3}{4}$, and the same computation with the roles of the two fields exchanged ($\varepsilon(z)$ between $\langle h'|$ and $|\sigma\rangle$) gives $\frac{3}{4}\kappa^2 + \frac{1}{4}\kappa - \frac{1}{16} = 0$, i.e. $\kappa \in \{\frac{1}{6}, -\frac{1}{2}\}$ and $h' = \frac{1}{16} + \frac{1}{2} + \kappa \in \{\frac{35}{48}, \frac{1}{16}\}$. The coupling $\langle \phi_{h'} \sigma \varepsilon \rangle$ must satisfy both equations, so $h' = \frac{1}{16}$: $\sigma \times \varepsilon = \sigma$. Truncation of (11.151) to the Kac table is exactly what makes the model minimal.

Try it: $\varepsilon \times \varepsilon$

Use the level-2 null vector of ε ($\alpha = -\frac{3}{4}$) with $h = \frac{1}{2}$ to find the families in $\varepsilon \times \varepsilon$.
Answer: $\frac{3}{4}\kappa^2 + \frac{1}{4}\kappa - \frac{1}{2} = 0$, i.e. $3\kappa^2 + \kappa - 2 = 0$, so $\kappa \in \{\frac{2}{3}, -1\}$ and $h' = 1 + \kappa \in \{\frac{5}{3}, 0\}$. The value $\frac{5}{3} = h_{3,1}$ lies outside the table (it is removed by the level-3 null vector of $\varepsilon = \phi_{1,3}$), leaving $\varepsilon \times \varepsilon = \mathbb{1}$. In the free fermion this is $\psi(z)\psi(w) \sim \frac{1}{z-w}$: two fermions fuse only into the identity family.

Physical picture: the whole story in one sentence

A null vector is a relation among the states of a family. As a field equation it becomes a differential equation for correlators, and differential equations have only finitely many solutions (here, two exponents $\kappa_\pm$). This finiteness, imposed at every null vector, is what cuts the operator algebra down to the $\frac{m(m-1)}{2}$ families of the Kac table.

11.4.13 The global subalgebra $\mathfrak{sl}(2, \mathbb{C})$ and the vacuum

The Virasoro algebra has infinitely many generators. Which of them are symmetries in the everyday sense, i.e. leave the vacuum unchanged? Nash answers in two lines, (11.46)–(11.47): exactly the three generators L_{-1}, L_0, L_1. In this subsection we explain why, what these three generators do, and what they buy us: the two-point functions, the $\langle TT \rangle$ correlator, and the behaviour of T at infinity that we used in Section 11.3.12.

The subalgebra. For $m, n \in \{-1, 0, 1\}$ the central term $\frac{c}{12} m(m^2-1)\delta_{m+n,0}$ of (11.102) vanishes, because $m(m^2-1) = (m-1)m(m+1)$ is zero for $m = 0, \pm 1$. So L_{-1}, L_0, L_1 close among themselves, as in (11.103):

$$[L_0, L_{-1}] = L_{-1}, \qquad [L_0, L_1] = -L_1, \qquad [L_1, L_{-1}] = 2L_0.$$

We have met this algebra in three guises already. It is worth putting them side by side, since each is a different *representation* of the same three commutators.

Dictionary: three faces of $\mathfrak{sl}(2,\mathbb{C})$

vector fields on the sphere	$\ell_{-1} = -\partial_z$ (translation), $\ell_0 = -z\partial_z$ (dilation and rotation), $\ell_1 = -z^2\partial_z$ (special conformal), from Section 11.3.3
2×2 matrices	the traceless matrices generating $\mathrm{SL}(2,\mathbb{C})$ acting by $z \mapsto \frac{az+b}{cz+d}$, Section 11.3.4
operators on states	L_{-1}, L_0, L_1 acting on the space of states; L_{-1} is the momentum P, L_0 the dilation (energy on the cylinder), L_1 the special conformal generator K

The angular momentum algebra is a useful comparison. Put $J_3 = L_0$, $J_+ = L_{-1}$, $J_- = L_1$. Then $[J_3, J_\pm] = \pm J_\pm$, and $[J_-, J_+] = 2J_3$. This is $[J_+, J_-] = 2J_3$ with the opposite sign: it is the algebra of $\mathrm{SU}(1,1) \cong \mathrm{SL}(2,\mathbb{R})$, the non-compact real form, not of $\mathrm{SU}(2)$. That sign has a visible consequence in the next example.

Worked example 11.51: The $\mathfrak{sl}(2)$ tower on a primary

Let $|h\rangle$ be a highest-weight state and $e_k := L_{-1}^k |h\rangle$, $k = 0, 1, 2, \dots$ These are the states $\partial^k \phi(0)|0\rangle$. First,

$$L_1 e_k \overset{(1)}{=} \sum_{j=0}^{k-1} L_{-1}^j \, [L_1, L_{-1}] \, L_{-1}^{k-1-j} |h\rangle \overset{(2)}{=} \sum_{j=0}^{k-1} L_{-1}^j \, 2L_0 \, L_{-1}^{k-1-j} |h\rangle$$

$$\overset{(3)}{=} \sum_{j=0}^{k-1} 2\,(h + k - 1 - j)\, e_{k-1} \overset{(4)}{=} k\,(2h + k - 1)\, e_{k-1}.$$

(1) Move L_1 to the right through the k factors, one commutator at a time; at the end $L_1|h\rangle = 0$.

(2) $[L_1, L_{-1}] = 2L_0$.

(3) L_0 acts on $L_{-1}^{k-1-j}|h\rangle$ with eigenvalue $h + k - 1 - j$; the remaining L_{-1}^j makes the total e_{k-1}.

(4) $\sum_{j=0}^{k-1}(h + k - 1 - j) = kh + \frac{k(k-1)}{2}$; doubling gives $k(2h + k - 1)$.

In the basis $(e_0, e_1, e_2, \dots)$ the three generators are the infinite matrices

$$L_0 = \begin{pmatrix} h & & & \\ & h+1 & & \\ & & h+2 & \\ & & & \ddots \end{pmatrix}, \quad L_{-1} = \begin{pmatrix} 0 & & & \\ 1 & 0 & & \\ & 1 & 0 & \\ & & \ddots & \ddots \end{pmatrix}, \quad L_1 = \begin{pmatrix} 0 & 2h & & \\ & 0 & 2(2h+1) & \\ & & 0 & \ddots \\ & & & \ddots \end{pmatrix}.$$

The norms follow by induction:

$$\|e_k\|^2 \overset{(1)}{=} \langle h | L_1^k L_{-1}^k | h \rangle \overset{(2)}{=} k(2h + k - 1)\, \|e_{k-1}\|^2 \overset{(3)}{=} k!\,(2h)(2h+1)\cdots(2h+k-1).$$

(1) $(L_{-1}^k)^\dagger = L_1^k$.

(2) $\|e_k\|^2 = \langle e_{k-1}|L_1 e_k\rangle$ and the formula for $L_1 e_k$.
(3) Iterate down to $\|e_0\|^2 = 1$.

For $h > 0$ every norm is positive and the tower never ends: an infinite-dimensional unitary representation, as it must be for a non-compact group. (For SU(2) the analogous coefficient is $k(2j - k + 1)$, with a minus sign, and it vanishes at $k = 2j + 1$: the tower ends and the representation is finite, with $2j + 1$ states.) For $h = 0$ the tower stops immediately, $\|e_1\|^2 = 2h = 0$: this is the vacuum, next.

The vacuum is an $\mathfrak{sl}(2)$ singlet. Regularity of $T(z)|0\rangle$ at $z = 0$ gave $L_n|0\rangle = 0$ for all $n \geq -1$ in (11.117). Nash obtains the L_{-1} part differently, and his argument is instructive because it uses only the Hilbert-space structure. Start from (11.46),

$$L_0|0\rangle = L_1|0\rangle = 0, \tag{11.152}$$

which says that the vacuum has zero energy and is a highest-weight state with $h = 0$. Then (11.47):

$$\|L_{-1}|0\rangle\|^2 \overset{(1)}{=} \langle 0|L_1 L_{-1}|0\rangle \overset{(2)}{=} \langle 0|[L_1, L_{-1}]|0\rangle \overset{(3)}{=} 2\langle 0|L_0|0\rangle \overset{(4)}{=} 0. \tag{11.153}$$

(1) $L_{-1}^\dagger = L_1$, (11.119).
(2) $L_1|0\rangle = 0$, so $L_1 L_{-1}|0\rangle = [L_1, L_{-1}]|0\rangle$.
(3) $[L_1, L_{-1}] = 2L_0$.
(4) $L_0|0\rangle = 0$.

In a Hilbert space a vector of zero norm is zero, so $L_{-1}|0\rangle = 0$. The vacuum is annihilated by the whole of $\mathfrak{sl}(2,\mathbb{C})$ and is invariant under the Möbius group. Taking adjoints of $L_n|0\rangle = 0$ ($n \geq -1$) gives $\langle 0|L_n = 0$ for $n \leq 1$. So:

$$L_n|0\rangle = 0 \ \ (n \geq -1), \qquad \langle 0|L_n = 0 \ \ (n \leq 1), \qquad \text{both for } n \in \{-1, 0, 1\}. \tag{11.154}$$

The in-vacuum and the out-vacuum are invariant under exactly the same three generators. Figure 11.26 shows the bookkeeping.

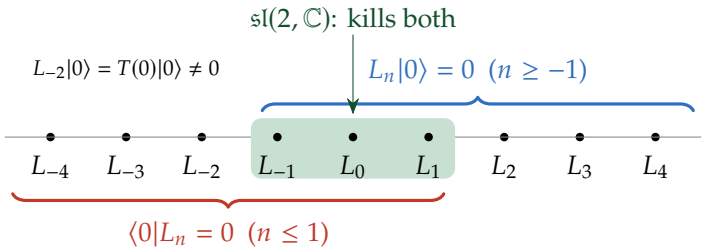

Figure 11.26: Which Virasoro modes annihilate the vacuum. The blue brace marks the modes that kill the in-vacuum $|0\rangle$ (regularity of $T(z)|0\rangle$ at $z = 0$); the red brace marks those that kill the out-vacuum $\langle 0|$ (regularity at $z = \infty$). Only the overlap $\{L_{-1}, L_0, L_1\}$ (green) kills both, so only the global conformal transformations are symmetries of vacuum correlators. The modes $L_{n\leq -2}$ create states, starting with the stress-tensor state $L_{-2}|0\rangle$.

The global Ward identities. Take a correlator of primaries $G = \langle 0|\phi_1(z_1)\cdots\phi_k(z_k)|0\rangle$ (suppressing $\bar z$). For $n \in \{-1, 0, 1\}$,

$$0 \overset{(1)}{=} \langle 0|L_n\,\phi_1\cdots\phi_k|0\rangle - \langle 0|\phi_1\cdots\phi_k\,L_n|0\rangle \overset{(2)}{=} \sum_{i=1}^{k}\langle 0|\phi_1\cdots[L_n,\phi_i(z_i)]\cdots\phi_k|0\rangle$$
$$\overset{(3)}{=} \sum_{i=1}^{k}\Big(z_i^{n+1}\partial_{z_i} + (n+1)h_i\,z_i^n\Big)G.$$

(1) Both terms vanish by (11.154).
(2) The commutator of L_n with a product is the sum of commutators with each factor (Leibniz rule).
(3) (11.101): $[L_n,\phi(z)] = \big(z^{n+1}\partial + (n+1)hz^n\big)\phi(z)$ for a primary; this operator does not act on the other fields.

Written out, these are three first-order differential equations:

$$\sum_i \partial_i G = 0, \qquad \sum_i \big(z_i\partial_i + h_i\big)G = 0, \qquad \sum_i \big(z_i^2\partial_i + 2h_i z_i\big)G = 0. \tag{11.155}$$

They are the statements that G is invariant under translations, under dilations (with the weights h_i as scaling dimensions) and under special conformal transformations. The first two hold in any scale-invariant theory. The third is the new constraint of conformal symmetry.

Worked example 11.52: The two-point function from the global Ward identities

Take $k = 2$. The first equation says G depends only on $z_{12} = z_1 - z_2$. The second then says $(z_1 - z_2)G'(z_{12}) + (h_1 + h_2)G = 0$, so $G = C\,z_{12}^{-(h_1+h_2)}$. Insert this into the third:

$$\big(z_1^2\partial_1 + z_2^2\partial_2 + 2h_1z_1 + 2h_2z_2\big)G \overset{(1)}{=} \Big(-(h_1+h_2)\frac{z_1^2 - z_2^2}{z_{12}} + 2h_1z_1 + 2h_2z_2\Big)G$$
$$\overset{(2)}{=} \big(-(h_1+h_2)(z_1+z_2) + 2h_1z_1 + 2h_2z_2\big)G$$
$$\overset{(3)}{=} (h_1 - h_2)(z_1 - z_2)\,G.$$

(1) $\partial_1 G = -(h_1+h_2)G/z_{12}$ and $\partial_2 G = +(h_1+h_2)G/z_{12}$.
(2) $z_1^2 - z_2^2 = (z_1+z_2)z_{12}$.
(3) Collect: the coefficient of z_1 is $h_1 - h_2$, that of z_2 is $h_2 - h_1$.

This must vanish. So either $C = 0$ or $h_1 = h_2$:

$$\langle\phi_1(z_1)\phi_2(z_2)\rangle = \frac{C\,\delta_{h_1h_2}}{z_{12}^{2h_1}}.$$

Scale invariance alone gave only $z_{12}^{-(h_1+h_2)}$, as in Nash's (11.9); the special conformal generator adds that *fields of different weights are uncorrelated*. This is the field-theory version of the orthogonality of L_0 eigenspaces. The same three equations fix the three-point function up to one constant, $\langle\phi_1\phi_2\phi_3\rangle = C_{123}\,z_{12}^{h_3-h_1-h_2}z_{23}^{h_1-h_2-h_3}z_{13}^{h_2-h_1-h_3}$; the next part of these notes develops it.

Try it: the dilation equation for the three-point function

Check that the three-point function just quoted satisfies $\sum_i (z_i\partial_i + h_i)G = 0$.
Answer: G is homogeneous in the z_i of degree $(h_3-h_1-h_2)+(h_1-h_2-h_3)+(h_2-h_1-h_3) = -(h_1+h_2+h_3)$. Euler's theorem for homogeneous functions gives $\sum_i z_i\partial_i G = -(h_1+h_2+h_3)G$, which cancels $\sum_i h_i G$.

Worked example 11.53: The TT two-point function from the modes

The stress tensor is not primary, so the example above does not apply directly. The modes do the job. For $|z| > |w|$,

$$\begin{aligned}\langle 0|T(z)T(w)|0\rangle &\overset{(1)}{=} \sum_{m,n\in\mathbb{Z}} z^{-m-2}w^{-n-2}\langle 0|L_mL_n|0\rangle \overset{(2)}{=} \sum_{m\geq 2} z^{-m-2}w^{m-2}\langle 0|L_mL_{-m}|0\rangle \\ &\overset{(3)}{=} \frac{c}{12}\sum_{m\geq 2} m(m^2-1)\,z^{-m-2}w^{m-2} \overset{(4)}{=} \frac{c}{2}z^{-4}\sum_{j\geq 0}\binom{j+3}{3}\left(\frac{w}{z}\right)^j \\ &\overset{(5)}{=} \frac{c}{2}z^{-4}\left(1-\frac{w}{z}\right)^{-4} = \frac{c/2}{(z-w)^4}.\end{aligned}$$

(1) The mode expansion (11.94), with $T(z)$ to the left because $|z| > |w|$.
(2) $L_n|0\rangle = 0$ unless $n \leq -2$, and $\langle 0|L_m = 0$ unless $m \geq 2$; also $\langle 0|L_mL_n|0\rangle = 0$ unless $m+n = 0$ (the state $L_mL_n|0\rangle$ has L_0 eigenvalue $-(m+n)$, and it must be 0 to overlap $\langle 0|$).
(3) $\langle 0|L_mL_{-m}|0\rangle = \langle 0|[L_m, L_{-m}]|0\rangle = \frac{c}{12}m(m^2-1)$ as in (11.143) with $h = 0$.
(4) Put $m = j+2$: $\frac{c}{12}(j+3)(j+2)(j+1) = \frac{c}{2}\binom{j+3}{3}$, and $z^{-m-2}w^{m-2} = z^{-4}(w/z)^j$.
(5) The binomial series $\sum_{j\geq 0}\binom{j+3}{3}x^j = (1-x)^{-4}$ (differentiate the geometric series three times and divide by 3!).

Also $\langle 0|T(z)|0\rangle = \sum_n z^{-n-2}\langle 0|L_n|0\rangle = 0$, since $\langle 0|L_n|0\rangle$ vanishes for $n \leq 1$ by (11.154) and for $n \geq -1$ by (11.117). On the plane the vacuum energy density is zero; on the cylinder it is $-\frac{c}{24}$ (Section 11.3.14). The coefficient $\frac{c}{2}$ is the one in the TT OPE (11.89), as it must be: the leading term of the OPE is the two-point function.

The stress tensor at infinity. In Section 11.3.12 we used that correlators of $T(z)$ decay like z^{-4} as $z \to \infty$. Here is why. The point $z = \infty$ of the sphere is an ordinary point, with local coordinate $w = -1/z$. The map $z \mapsto w = -1/z$ is Möbius, so its Schwarzian derivative vanishes (Nash's (11.32), proved in Section 11.3.14), and T transforms as an honest weight-2 tensor:

$$\tilde{T}(w) \overset{(1)}{=} \left(\frac{\mathrm{d}z}{\mathrm{d}w}\right)^2 T(z) + \frac{c}{12}\{z,w\} \overset{(2)}{=} \left(\frac{1}{w^2}\right)^2 T(z) \overset{(3)}{=} z^4\,T(z).$$

(1) The finite transformation law (11.91) of T under the change of coordinate $z = z(w) = -1/w$.
(2) $\frac{\mathrm{d}z}{\mathrm{d}w} = \frac{1}{w^2}$, and the Schwarzian of a Möbius map is zero.
(3) $w^{-4} = z^4$.

The field $\tilde{T}(w)$ is the stress tensor in the coordinate chart around ∞. If nothing is inserted at ∞ (the out-state is the vacuum), then $\tilde{T}(w)$ must be regular at $w = 0$. That is, $z^4T(z)$ stays bounded as $z \to \infty$, so $T(z) = O(z^{-4})$. In modes: $z^4T(z) = \sum_n L_n z^{2-n}$ is bounded at large z inside $\langle 0|\cdots$ precisely when $\langle 0|L_n = 0$ for $n \leq 1$, which is (11.154) again. (The Ward identity check in Example 11.30 showed the same w^{-4} falloff directly.)

The true symmetry group. Nash concludes (p. 311) that "the true invariance of the theory is that of the Möbius group $\mathrm{SL}(2,\mathbb{C})/\{\mp I\}$." Three facts combine here.

1. *Only the Möbius maps are global.* A conformal (holomorphic) map of the whole Riemann sphere to itself which is invertible is a rational function of degree one, i.e. Möbius (Section 11.3.4). The other ℓ_n, such as $\ell_2 = -z^3\partial_z$, generate vector fields with poles at 0 or ∞; they do not exponentiate to maps of the sphere.

2. *Only the Möbius generators fix the vacuum*, by (11.154). The remaining L_n are still useful: they give the local Ward identities and organise the states into representations. But they do not leave $|0\rangle$ alone.

3. *Under Möbius maps T is a true tensor.* The Schwarzian term in (11.91) vanishes exactly for Möbius maps (Nash's (11.32), Section 11.3.14), so under the global group T transforms like a primary of weight $(2,0)$, even though it is not primary under the full local algebra. The central charge is invisible to the global group.

Watch out: "infinite-dimensional symmetry" does not mean infinitely many conserved charges of the vacuum

It is tempting to read the Virasoro algebra as an infinite set of symmetries under which everything is invariant. It is not. The L_n with $|n| \geq 2$ are generated by $\oint \epsilon(z)T(z)$ with $\epsilon(z) = z^{n+1}$ singular somewhere on the sphere. They are symmetries of the *local* structure: they produce Ward identities that relate correlators with and without T insertions. The vacuum is not invariant under them; in fact they create the whole vacuum module $L_{-2}|0\rangle, L_{-3}|0\rangle, L_{-2}^2|0\rangle, \dots$ out of it.

11.4.14 Other sources of conformal field theories

Every CFT carries a representation of $Vir \oplus \overline{Vir}$, so any construction of such representations is a potential source of CFTs. Nash (p. 311) names two: representations of Kac–Moody algebras (studied as CFTs by Gepner and Witten), and superconformal algebras (Friedan, Martinec and Shenker). We describe both concretely. The mechanism in each case is the same: a bigger chiral algebra, containing $T(z)$, whose representations are easier to build and control.

Current algebras and the Sugawara construction

Currents. Suppose a CFT has a continuous internal symmetry with a compact Lie group G. Noether's theorem gives conserved currents. In two dimensions, as for T_{ab}, conservation and tracelessness split a current into a holomorphic part $J^a(z)$ and an antiholomorphic part. The J^a, $a = 1, \dots, \dim G$, are primaries of weight $(1,0)$. Their OPE is fixed by symmetry up to one number k:

$$J^a(z)J^b(w) = \frac{k\,\delta^{ab}}{(z-w)^2} + \frac{i f^{abc} J^c(w)}{z-w} + \text{reg.} \tag{11.156}$$

Here f^{abc} are the structure constants of $\mathfrak{g}$, $[T^a, T^b] = i f^{abc} T^c$, normalised by $f^{acd} f^{bcd} = 2h^\vee \delta^{ab}$, where $h^\vee$ is the dual Coxeter number ($h^\vee = N$ for $\mathrm{SU}(N)$, and $h^\vee = 0$ for $\mathrm{U}(1)$). The simple pole says that the charges rotate the currents into each other as the adjoint representation; the double pole is the Schwinger term, the analogue of the central term in TT. The integer k is the **level**. (Why an integer: see the WZW remark below.)

Worked example 11.54: The affine Kac–Moody algebra from the JJ OPE

Expand $J^a(z) = \sum_n J^a_n z^{-n-1}$, so $J^a_n = \oint_0 \frac{\mathrm{d}z}{2\pi i} z^n J^a(z)$. As for the oscillators in Example 11.37,

$$[J^a_m, J^b_n] \overset{(1)}{=} \oint_0 \frac{\mathrm{d}z}{2\pi i} z^n \oint_z \frac{\mathrm{d}w}{2\pi i} w^m \Big(\frac{k\delta^{ab}}{(w-z)^2} + \frac{i f^{abc} J^c(z)}{w-z} \Big)$$
$$\overset{(2)}{=} \oint_0 \frac{\mathrm{d}z}{2\pi i} \Big(k\delta^{ab}\, m\, z^{m+n-1} + i f^{abc} z^{m+n} J^c(z) \Big) \overset{(3)}{=} i f^{abc} J^c_{m+n} + k\, m\, \delta^{ab} \delta_{m+n,0}.$$

(1) The contour commutator (11.100) and the OPE (11.156) with the roles $w \leftrightarrow z$ (the OPE is symmetric after relabelling $a \leftrightarrow b$, c).
(2) Residues at $w = z$: of $w^m/(w-z)^2$ it is $m z^{m-1}$, of $w^m/(w-z)$ it is z^m.
(3) $\oint z^{m+n-1} = \delta_{m+n,0}$ and $\oint z^{m+n} J^c = J^c_{m+n}$.

This is the **affine Kac–Moody algebra** $\hat{\mathfrak{g}}_k$, the central extension of the loop algebra $\mathfrak{g} \otimes \mathbb{C}[z, z^{-1}]$ met in Chapter 6. The zero modes J^a_0 obey $[J^a_0, J^b_0] = i f^{abc} J^c_0$: the ordinary Lie algebra, the global charges. For $G = \mathrm{U}(1)$ we recover the oscillators $[a_m, a_n] = m\delta_{m+n,0}$ of (11.104)–(11.105) with $k = 1$.

The Sugawara construction. Given the currents, there is a stress tensor built out of them:

Key idea: Sugawara stress tensor

$$T(z) = \frac{1}{2(k+h^\vee)} \sum_a :J^a J^a:(z), \qquad c = \frac{k\ \dim G}{k+h^\vee}. \tag{11.157}$$

With this T each J^a is primary of weight 1, and a primary transforming in the representation R of G has $h = \frac{C_2(R)}{k+h^\vee}$, with C_2 the quadratic Casimir.

The shift $k \to k + h^\vee$ is a quantum effect. Classically one would guess the prefactor $\frac{1}{2k}$, as for the free boson. But in computing the OPE $T(z)J^b(w)$ one must contract J^b with each J^a inside $:J^aJ^a:$. The double pole of (11.156) gives k and the simple pole, used twice, gives $f^{acd}f^{bcd} = 2h^\vee\delta^{ab}$. Requiring the coefficient of $J^b(w)/(z-w)^2$ to be 1 forces the prefactor $\frac{1}{2(k+h^\vee)}$. The central charge then follows from the fourth-order pole of TT.

For U(1) ($\dim G = 1$, $h^\vee = 0$, $k = 1$): $T = \frac{1}{2}:jj:$ and $c = 1$, which is (11.104). For SU(2) at level k: $\dim G = 3$, $h^\vee = 2$, so

$$c\big(\mathrm{SU}(2)_k\big) = \frac{3k}{k+2}, \qquad h_j = \frac{j(j+1)}{k+2}, \quad j = 0, \tfrac{1}{2}, \dots, \tfrac{k}{2}. \tag{11.158}$$

These are the central charges used in the coset construction of Section 11.4.11. At $k = 1$ we get $c = 1$, and indeed:

Worked example 11.55: $\mathrm{SU}(2)_1$ out of one free boson

With the free boson of Section 11.4.5, put

$$J^3 = j = i\sqrt{2}\,\partial\varphi, \qquad J^\pm = :e^{\pm 2i\varphi}:, \qquad J^1 = \tfrac{1}{\sqrt{2}}(J^+ + J^-), \quad J^2 = \tfrac{1}{i\sqrt{2}}(J^+ - J^-).$$

The vertex operators $e^{\pm 2i\varphi}$ have weight $\frac{\alpha^2}{4} = 1$ (Example 11.23), exactly right for currents. Their OPE follows from the chiral propagator $\langle\varphi(z)\varphi(w)\rangle = -\frac{1}{2}\ln(z-w)$:

$$:e^{2i\varphi(z)}::e^{-2i\varphi(w)}: \overset{(1)}{=} e^{(2i)(-2i)\langle\varphi(z)\varphi(w)\rangle}\, :e^{2i\varphi(z)-2i\varphi(w)}: \overset{(2)}{=} (z-w)^{-2}\, :e^{2i(\varphi(z)-\varphi(w))}:$$

$$\overset{(3)}{=} \frac{1}{(z-w)^2} + \frac{2i\,\partial\varphi(w)}{z-w} + \text{reg.} = \frac{1}{(z-w)^2} + \frac{\sqrt{2}\,J^3(w)}{z-w} + \text{reg.}$$

(1) Wick's theorem for exponentials: $:e^A::e^B: = e^{\langle AB\rangle}:e^{A+B}:$ for A, B linear in the free field (Section 11.3.9).
(2) $4\cdot\left(-\frac{1}{2}\ln(z-w)\right) = -2\ln(z-w)$.
(3) Taylor expand $\varphi(z)-\varphi(w) = (z-w)\partial\varphi(w)+\dots$ in the exponent. Finally $2i\partial\varphi = \sqrt{2}\,j$.

From this one gets $J^1J^1 \sim \frac{1}{2}(J^+J^- + J^-J^+) \sim \frac{1}{(z-w)^2}$, the double pole with $k=1$, and simple poles reproducing $f^{abc} = \sqrt{2}\,\epsilon^{abc}$ (for which $f^{acd}f^{bcd} = 4\delta^{ab}$, i.e. $h^\vee = 2$). The Sugawara tensor $\frac{1}{6}\sum_a :J^aJ^a:$ coincides with the boson's $\frac{1}{2}:jj:$, with $c=1$. The spin-$\frac{1}{2}$ primary has $h_{1/2} = \frac{3/4}{3} = \frac{1}{4}$, the weight of $:e^{\pm i\varphi}:$. One free boson at this special radius has an enhanced SU(2) symmetry.

WZW models. The CFTs whose chiral algebra is $\hat{\mathfrak{g}}_k$ are the Wess–Zumino–Witten models. Their field is a map $g:\Sigma\to G$ and their action is a sigma-model term plus k times the Wess–Zumino term $\frac{1}{12\pi}\int_B \operatorname{tr}(g^{-1}\mathrm{d}g)^3$, an integral over a 3-manifold B with boundary Σ. Different choices of B change this term by 2π times an integer (the integral of the closed 3-form over a closed 3-manifold, a degree in $\pi_3(G)=\mathbb{Z}$), so e^{iS} is well defined only if k is an integer. This is the topological origin of the quantised level, and of Nash's "level k representations". Gepner and Witten determined the spectrum of these models: the primaries are the integrable highest-weight representations of $\hat{\mathfrak{g}}_k$, finitely many for each k; for $\mathrm{SU}(2)_k$ they are the spins $j \le \frac{k}{2}$ of (11.158). Like the minimal models, they are rational CFTs, and their fusion rules are the subject of Nash's §5.

Superconformal field theories

The second source is supersymmetry. Add to $T(z)$ a fermionic current $G(z)$ of weight $\frac{3}{2}$, the supercurrent. The $\mathcal{N}=1$ **superconformal algebra** is defined by the OPEs

$$T(z)G(w) = \frac{\frac{3}{2}G(w)}{(z-w)^2} + \frac{\partial G(w)}{z-w}, \qquad G(z)G(w) = \frac{2c/3}{(z-w)^3} + \frac{2T(w)}{z-w}, \tag{11.159}$$

plus regular terms. The first says G is primary of weight $\frac{3}{2}$; the second says that G is a "square root" of T. Because G is a fermion it may be periodic or antiperiodic around the origin: $G(z) = \sum_r G_r z^{-r-3/2}$ with $r\in\mathbb{Z}+\frac{1}{2}$ (Neveu–Schwarz) or $r\in\mathbb{Z}$ (Ramond). The same contour computation as for the Virasoro algebra, with anticommutators for G, gives

$$\{G_r, G_s\} = 2L_{r+s} + \frac{c}{3}\Big(r^2-\frac{1}{4}\Big)\delta_{r+s,0}, \qquad [L_m, G_r] = \Big(\frac{m}{2}-r\Big)G_{m+r}.$$

The anticommutator $\{G_{-1/2}, G_{1/2}\} = 2L_0$ is the two-dimensional version of "$\{Q,Q^\dagger\}=2H$".

Worked example 11.56: The free superconformal multiplet: $c=\frac{3}{2}$

Take one free boson and one free Majorana fermion, with $T = -(\partial\varphi)^2 - \frac{1}{2}\psi\partial\psi$ and $c = 1+\frac{1}{2} = \frac{3}{2}$. Try $G = a\,\psi\,\partial\varphi$. The contractions are $\psi(z)\psi(w)\sim\frac{1}{z-w}$ and $\partial\varphi(z)\partial\varphi(w)\sim -\frac{1}{2(z-w)^2}$.

$$G(z)G(w) \overset{(1)}{=} a^2\Big[\frac{1}{z-w}\cdot\frac{-1}{2(z-w)^2} + \frac{:\partial\varphi(z)\partial\varphi(w):}{z-w} - \frac{:\psi(z)\psi(w):}{2(z-w)^2}\Big] + \dots$$

$$\overset{(2)}{=} a^2\Big[-\frac{1}{2(z-w)^3}+\frac{(\partial\varphi)^2(w)}{z-w}-\frac{:\partial\psi\,\psi:(w)}{2(z-w)}\Big]+\text{reg.}$$
$$\overset{(3)}{=} -\frac{a^2}{2}\Big[\frac{1}{(z-w)^3}+\frac{2\big(-(\partial\varphi)^2-\frac{1}{2}\psi\partial\psi\big)(w)}{z-w}\Big]+\text{reg.}$$

(1) Wick's theorem: both pairs contracted, the fermions only, or the bosons only ($\partial\varphi(z)$ commutes past $\psi(w)$, so there is no sign).
(2) Taylor expand: $:\partial\varphi(z)\partial\varphi(w):\,=(\partial\varphi)^2(w)+O(z-w)$ and $:\psi(z)\psi(w):\,=(z-w):\partial\psi\,\psi:(w)+O((z-w)^2)$, since $\psi(w)^2=0$.
(3) Factor out $-\frac{a^2}{2}$, and use $:\partial\psi\,\psi:\,=-:\psi\partial\psi:$ (fermions anticommute).

Compare with (11.159): we need $-\frac{a^2}{2}=1$, and then the triple pole is $1=\frac{2c}{3}$ with $c=\frac{3}{2}$, and the simple pole is $2T$. Both work with $a=i\sqrt{2}$: $G=i\sqrt{2}\,\psi\,\partial\varphi$. The boson and fermion are superpartners.

The superconformal algebra has its own Kac determinant and its own unitary discrete series (Friedan, Qiu and Shenker again),

$$c=\frac{3}{2}\Big(1-\frac{8}{m(m+2)}\Big),\qquad m=3,4,\ldots$$

The first member, $m=3$, has $c=\frac{3}{2}\cdot\frac{7}{15}=\frac{7}{10}$: the tricritical Ising model of Section 11.4.12 is supersymmetric. In string theory the superconformal algebra is the gauge symmetry of the worldsheet of the superstring: ten free multiplets give $c=10\cdot\frac{3}{2}=15$, which cancels the -15 of the superconformal ghosts (Chapter 9).

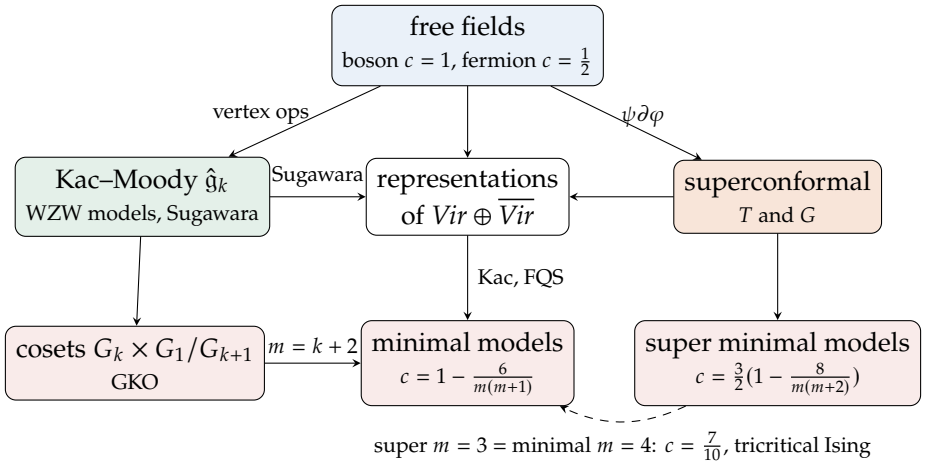

Figure 11.27: Where conformal field theories come from. Everything flows into representations of $Vir\oplus\overline{Vir}$ (centre). Free fields give the simplest ones; currents built from them (vertex operators) give Kac–Moody algebras, whose Sugawara stress tensors give Virasoro representations; differences of Sugawara tensors (cosets) realise the whole unitary minimal series; supercurrents give the superconformal series, whose first member coincides with the $m=4$ minimal model.

Reading Nash (pp. 310–311, (11.46)–(11.47))

Nash identifies the Möbius subalgebra $\mathfrak{sl}(2,\mathbb{C})=\{L_{-1},L_0,L_1\}$, states that the vacuum is annihilated by L_0 and L_1 (11.46), and shows $\|L_{-1}|0\rangle\|^2=0$ (11.47); we reproduced that chain, noted that it forces $L_{-1}|0\rangle=0$ only because we are in a Hilbert space, and gave the independent argument from regularity. He concludes that the true invariance is

$\mathrm{SL}(2,\mathbb{C})/\{\mp I\}$, that these are the only invertible conformal maps of the Riemann sphere, and that T is a true tensor under them because the Schwarzian vanishes. We added the $\mathfrak{sl}(2)$ tower, the global Ward identities and the two-point function, $\langle TT\rangle = \frac{c/2}{(z-w)^4}$ from modes, and the z^{-4} falloff of T. His closing paragraph of §3 lists Kac–Moody algebras (Gepner–Witten) and superconformal symmetry (Friedan–Martinec–Shenker) as further sources of CFTs; we derived the affine algebra from the JJ OPE, stated the Sugawara construction with the $\mathrm{SU}(2)_1$ example, and built the free $c = \frac{3}{2}$ superconformal multiplet. His §4 then turns to statistical mechanics, which is the next part of these notes.

Recap: Section 11.4

- The local conformal algebra is two copies of the Witt algebra (the complexified $\mathrm{Vect}(S^1)$); quantum mechanically each becomes the Virasoro algebra $[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12}m(m^2-1)\delta_{m+n,0}$, with $L_n = \oint \frac{\mathrm{d}z}{2\pi i} z^{n+1}T(z)$. The central term follows from the $\frac{c/2}{(z-w)^4}$ term of the TT OPE; for the free boson $c = 1$.
- Radial quantisation: time is $\ln|z|$, the Hamiltonian is $L_0 + \bar{L}_0$ (minus $\frac{c}{12}$ on the cylinder), $L_n^\dagger = L_{-n}$, and states correspond to fields: $|h\rangle = \phi(0)|0\rangle$ with $L_0|h\rangle = h|h\rangle$, $L_{n>0}|h\rangle = 0$.
- Descendants $L_{-n_1}\cdots L_{-n_k}|h\rangle$ form the Verma module $V(c,h)$, graded by level with $p(N)$ states. Singular vectors generate the null submodule N, and the physical representation is $L(c,h) = V/N$. For generic (c,h), $V = L$.
- The Gram matrices and the Kac determinant $\det M^{(N)} \propto \prod_{rs\le N}(h-h_{r,s})^{p(N-rs)}$ locate the singular vectors.
- Unitarity requires $h \ge 0$ and $c \ge 0$, allows everything with $c \ge 1$, $h \ge 0$, and for $c < 1$ only the discrete series $c = 1 - \frac{6}{m(m+1)}$, $h = h_{r,s}$ (Nash's (6.58), Friedan–Qiu–Shenker); the coset construction realises each point.
- The minimal models have $\frac{m(m-1)}{2}$ primaries; $m = 3$ is the Ising model with $h = 0, \frac{1}{16}, \frac{1}{2}$, giving $\eta = \frac{1}{4}$, $\nu = 1$. Null vectors become differential equations and truncate the fusion rules, e.g. $\sigma \times \sigma = \mathbb{1} + \varepsilon$.
- Only L_{-1}, L_0, L_1 annihilate both $|0\rangle$ and $\langle 0|$: the Möbius group is the true symmetry of the vacuum, and gives the global Ward identities.
- Further CFTs come from Kac–Moody algebras (Sugawara, $c = \frac{k\dim G}{k+h^\vee}$, WZW models) and superconformal algebras (the $c = \frac{3}{2}$ free multiplet, the super minimal series).

11.5 Critical phenomena and the two-dimensional Ising model

The first three sections of this chapter built an abstract machine. A two-dimensional conformal field theory has a holomorphic energy–momentum tensor $T(z)$, whose modes L_n obey the Virasoro algebra with central charge c. Its primary fields ϕ carry weights $(h, \bar{h})$, and every primary generates a tower of descendants. That is a lot of structure. A physicist is entitled to ask two blunt questions.

- *Where do such theories occur in nature?*

- *What do the numbers c and h measure?*

Nash's answer, in his §4, is statistical mechanics. A magnet at its Curie point, a liquid–gas mixture at its critical point, or a binary alloy at its ordering temperature has fluctuations on all length scales. Its long-distance physics is scale invariant, and in two dimensions it is conformally invariant. The conformal weights of the primary fields then *are* the measured critical exponents. The simplest example, the two-dimensional Ising model, turns out to be the CFT with $c = \frac{1}{2}$ and exactly three primary fields.

This section supplies the statistical-mechanics background Nash assumes: the lattice model, its phase transition, the critical exponents, and the dictionary between exponents and scaling dimensions. The next section (Section 11.6) identifies the Ising model with the $c = \frac{1}{2}$ representation theory. The two after that put the theory on a torus and check modular invariance, which is Nash's actual topic.

Watch out: Page numbers

Throughout this part, [Nash p. n] is the *printed* page number of Nash. The PDF page is printed +10. Our Nash range is printed pp. 311–321.

11.5.1 Where Section 3 leaves us: the Möbius group

Nash opens our page range by tidying up one point. The Virasoro algebra has infinitely many generators L_n, $n \in \mathbb{Z}$. Yet only three of them, L_{-1}, L_0, L_1, exponentiate to honest, globally defined, invertible transformations of the Riemann sphere $\hat{\mathbb{C}} = \mathbb{C} \cup \{\infty\}$. The others are only infinitesimal symmetries: they are holomorphic near a point, but they cannot be extended to invertible maps of the whole sphere.

Recall that L_n is represented on functions by the vector field

$$\ell_n = -z^{n+1}\frac{\partial}{\partial z}. \tag{11.160}$$

At $z = 0$ this is regular only for $n \geq -1$. To look at $z = \infty$, use the coordinate $w = -1/z$. Then $\partial_z = w^2\partial_w$ and $z^{n+1} = (-1)^{n+1}w^{-n-1}$, so

$$\begin{aligned} \ell_n &\overset{(1)}{=} -z^{n+1}\,\frac{\mathrm{d}w}{\mathrm{d}z}\,\frac{\partial}{\partial w} \\ &\overset{(2)}{=} -(-1)^{n+1}w^{-n-1}\,w^2\,\frac{\partial}{\partial w} \\ &= (-1)^n\,w^{1-n}\,\frac{\partial}{\partial w}. \end{aligned}$$

(1) Chain rule: a vector field $f(z)\partial_z$ becomes $f(z)(\mathrm{d}w/\mathrm{d}z)\partial_w$ in the new coordinate.
(2) $w = -1/z$ gives $\mathrm{d}w/\mathrm{d}z = 1/z^2 = w^2$ and $z = -1/w$.

This is regular at $w = 0$ (that is, at $z = \infty$) only for $n \leq 1$. So the vector fields regular on the *whole* sphere are exactly $\ell_{-1}, \ell_0, \ell_1$:

$$\underbrace{\ell_{-1} = -\partial_z}_{\text{translation}}, \qquad \underbrace{\ell_0 = -z\partial_z}_{\text{dilation, rotation}}, \qquad \underbrace{\ell_1 = -z^2\partial_z}_{\text{special conformal}}.$$

They generate the **Möbius group**.

Working definition 11.21 (Möbius transformation)

A Möbius transformation is a map of the Riemann sphere [the plane $\mathbb{C}$ with one point ∞ added, so that $m_M(-d/c)=\infty$ and $m_M(\infty)=a/c$] of the form

$$z \longmapsto m_M(z)=\frac{az+b}{cz+d}, \qquad M=\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}(2,\mathbb{C}), \quad ad-bc=1.$$

How to use it: to compose two Möbius maps, multiply their matrices. The matrices M and $-M$ give the same map, so the group of maps is $\mathrm{SL}(2,\mathbb{C})/\{\pm I\}=\mathrm{PSL}(2,\mathbb{C})$. It has three complex (six real) parameters, one for each of ℓ_{-1},ℓ_0,ℓ_1 [they integrate to the translations $z+b$, the rescalings with rotations λz, and the special conformal maps $z/(cz+1)$].

The composition rule is the reason for writing the map with a matrix. Let $M=\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ and $N=\left(\begin{smallmatrix} \alpha & \beta \\ \gamma & \delta \end{smallmatrix}\right)$. Then

$$\begin{aligned} m_M\big(m_N(z)\big) &\overset{(1)}{=} \frac{a\,\frac{\alpha z+\beta}{\gamma z+\delta}+b}{c\,\frac{\alpha z+\beta}{\gamma z+\delta}+d} \\ &\overset{(2)}{=} \frac{a(\alpha z+\beta)+b(\gamma z+\delta)}{c(\alpha z+\beta)+d(\gamma z+\delta)} \\ &\overset{(3)}{=} \frac{(a\alpha+b\gamma)z+(a\beta+b\delta)}{(c\alpha+d\gamma)z+(c\beta+d\delta)} = m_{MN}(z). \end{aligned}$$

(1) Substitute $m_N(z)$ for z in m_M.
(2) Multiply numerator and denominator by $\gamma z+\delta$.
(3) Collect powers of z; the coefficients are the entries of the matrix product MN.

Physical picture: Why only Möbius maps are global

A holomorphic bijection f of the sphere onto itself is a meromorphic function that takes the value ∞ exactly once, with multiplicity one. A meromorphic function on the sphere is a rational function $P(z)/Q(z)$, and it takes each value as many times as its degree. Degree one means $f=(az+b)/(cz+d)$. The infinitely many other "conformal transformations" generated by L_n, $|n|\geq 2$, are only local: $z\mapsto z+\varepsilon z^{n+1}$ is invertible near $z=0$ but not on all of $\hat{\mathbb{C}}$.

Nash's second remark concerns the energy–momentum tensor. Under a finite conformal map $z\mapsto z'$, [Nash p. 307, (11.31)] gives

$$T(z)=\left(\frac{\mathrm{d}z'}{\mathrm{d}z}\right)^2 T'(z')+\frac{c}{12}\{z',z\}, \qquad \{f,z\}=\frac{f'''}{f'}-\frac{3}{2}\left(\frac{f''}{f'}\right)^2. \tag{11.161}$$

The **Schwarzian derivative** $\{f,z\}$ is the obstruction to T being a tensor of weight 2. For a Möbius map it vanishes. Nash proves the converse; here is the direct check. Take $f(z)=(az+b)/(cz+d)$ with $ad-bc=1$:

$$\begin{aligned} f'(z) &\overset{(1)}{=} \frac{a(cz+d)-c(az+b)}{(cz+d)^2}=\frac{1}{(cz+d)^2}, \\ f''(z) &\overset{(2)}{=} \frac{-2c}{(cz+d)^3}, \qquad f'''(z)=\frac{6c^2}{(cz+d)^4}, \\ \{f,z\} &\overset{(3)}{=} \frac{6c^2}{(cz+d)^2}-\frac{3}{2}\left(\frac{-2c}{cz+d}\right)^2=\frac{6c^2-6c^2}{(cz+d)^2}=0. \end{aligned}$$

(1) Quotient rule, then $ad - bc = 1$.
(2) Differentiate $(cz + d)^{-2}$ twice more.
(3) $f'''/f' = 6c^2/(cz + d)^2$ and $f''/f' = -2c/(cz + d)$.

So *with respect to Möbius maps, $T(z)$ is a true tensor of weight* $(2, 0)$. This is the global statement behind the fact, proved in §3, that the vacuum is annihilated by L_{-1}, L_0, L_1 [Nash p. 310, (11.46)–(11.47)]: the vacuum is Möbius invariant, although it is not invariant under the whole Virasoro algebra. We will use Möbius invariance repeatedly in Section 11.9 to fix two- and three-point functions.

Watch out: Two different "conformal groups"

In the physics literature "the conformal group in two dimensions" means either the global group $\mathrm{PSL}(2, \mathbb{C})$ (finite dimensional, acts on the whole sphere) or the local algebra $\mathrm{Vir} \oplus \overline{\mathrm{Vir}}$ (infinite dimensional, acts only near a point, and centrally extended). The correlation functions on the sphere are exactly invariant under the first. They obey Ward identities, not invariance, under the second.

Where conformal field theories come from

Nash then observes that a CFT is, at heart, a collection of representations of $\mathrm{Vir} \oplus \overline{\mathrm{Vir}}$. Anything that produces Virasoro representations can therefore produce CFTs. He lists three sources, and his §4 adds a fourth. We collect them in Figure 11.28.

- **Kac–Moody (affine Lie) algebras.** In chapter 6 we met the loop group LG and its central extension. A representation of its Lie algebra at level k yields a Virasoro representation through the **Sugawara construction** $T(z) = \frac{1}{2k + c(G)} \sum_a : J^a(z) J^a(z) :$ in Nash's normalisation, with central charge $c = 2k \dim G/(2k + c(G))$ [Nash p. 187, (6.60)]. In the common normalisation where the level is written k and the dual Coxeter number $h^\vee$, this reads $c = k \dim G/(k + h^\vee)$; for SU(2), $c = 3k/(k + 2)$. The CFTs built this way are the **Wess–Zumino–Witten (WZW) models**; Gepner and Witten studied them as string backgrounds. They reappear in chapter 12, where their conformal blocks become the state spaces of Chern–Simons theory.

- **Superconformal symmetry.** Add a fermionic current $G(z)$ of weight $\frac{3}{2}$ to $T(z)$. The resulting super-Virasoro algebra gives two-dimensional superconformal field theories (Friedan, Martinec and Shenker), the world-sheet theories of the superstring. The simplest example is a free boson plus a free Majorana fermion, with $c = 1 + \frac{1}{2} = \frac{3}{2}$.

- **Strings.** The bosonic string is a CFT with $c = 26$ on every Riemann surface (chapter 9, and Section 11.11 below).

- **Critical statistical mechanics.** The subject of §4. Nash promises "an example of a conformal field theory of genus one". He means that the natural observable, the partition function with periodic boundary conditions, lives on a torus.

11.5.2 The Ising model on a square lattice

The Ising model is a cartoon of a uniaxial magnet. Put a spin $s_i \in \{+1, -1\}$ at every site i of a square lattice with N sites. Each spin likes to be aligned with its four nearest neighbours. The

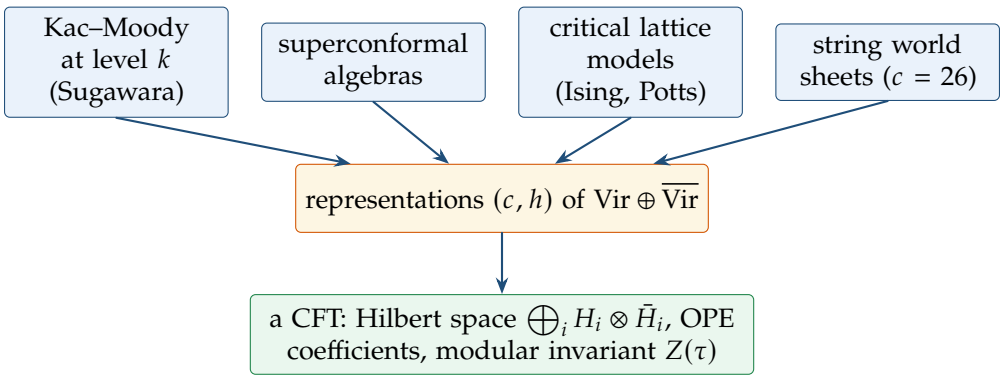

Figure 11.28: Four routes to a conformal field theory. Each source on top produces representations of two commuting Virasoro algebras; a CFT is a consistent way of assembling them. What to see: the Virasoro representation theory of §3 is the common currency, and statistical mechanics is only one of its customers.

energy of a configuration $\{s\}$ is

$$\mathcal{H}[s] = -J \sum_{\langle ij \rangle} s_i s_j \; - \; B \sum_i s_i, \tag{11.162}$$

where $\langle ij \rangle$ runs over nearest-neighbour pairs (bonds), $J > 0$ is the ferromagnetic coupling and B an external magnetic field. At temperature T the probability of a configuration is $e^{-\beta \mathcal{H}}/Z$ with $\beta = 1/k_B T$, and

$$Z(\beta, B) = \sum_{\{s\}} e^{-\beta \mathcal{H}[s]} \tag{11.163}$$

is the **partition function**. It is a finite sum of 2^N terms. All thermodynamics follows from it: the free energy per site is $f = -(k_B T/N) \ln Z$, the magnetisation per site is $M = \langle s_i \rangle = -\partial f / \partial B$, and so on. We write $K = \beta J$ for the dimensionless coupling.

Physical picture: Two competing tendencies

At low temperature (K large) energy wins. Almost all spins point the same way, and $M \neq 0$ even at $B = 0$: the system has spontaneously chosen a direction. At high temperature (K small) entropy wins. Spins fluctuate nearly independently and $M = 0$. Somewhere in between, at a critical temperature T_c, the order disappears. In two dimensions this happens continuously: $M \to 0$ as $T \to T_c^-$ with no latent heat. This is a **second-order** (continuous) phase transition.

Periodic boundary conditions put the model on a torus

A finite lattice has edges, and edge spins have fewer neighbours. The standard cure is to identify the right edge with the left one and the top edge with the bottom one. Then every site has four neighbours. But a rectangle with opposite sides identified is a *torus* (Figure 11.29). This innocent choice is the reason Nash's section on statistical mechanics is about modular invariance: the Ising partition function with periodic boundary conditions is a partition function on a torus.

High- and low-temperature expansions, and where T_c is

We can locate T_c exactly, without Onsager's full solution, by a beautiful argument of Kramers and Wannier. It also introduces the key idea that configurations of the model are *loops*, a picture that the continuum theory inherits.

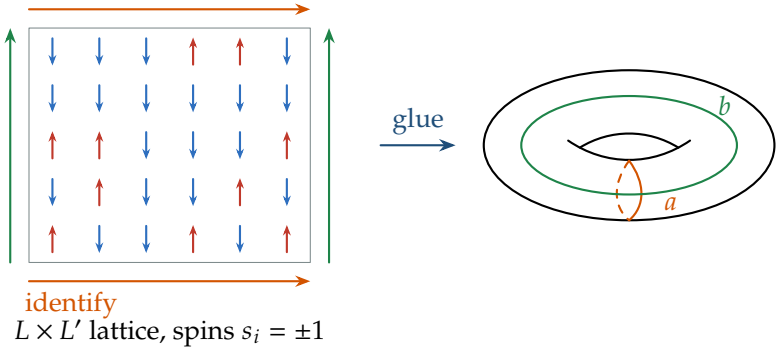

Figure 11.29: Periodic boundary conditions. Identifying the opposite edges of the lattice (orange with orange, green with green) makes every site equivalent and turns the rectangle into a torus with two independent cycles a and b. What to see: the lattice partition function is secretly a partition function on a torus, and its continuum limit will depend on the torus's shape through a single complex number τ (Section 11.7).

High-temperature expansion. Set $B = 0$ and $t_K = \tanh K$. Because $s_i s_j = \pm 1$, the Boltzmann weight of one bond is

$$\begin{aligned} e^{K s_i s_j} &\overset{(1)}{=} \cosh K + s_i s_j \sinh K \\ &= \cosh K \left(1 + s_i s_j \, t_K\right). \end{aligned}$$

(1) For $x = \pm 1$, $e^{Kx} = \cosh K + x \sinh K$: check $x = 1$ and $x = -1$ separately.

Now multiply over all $2N$ bonds (a periodic square lattice with N sites has $2N$ bonds) and sum over spins:

$$\begin{aligned} Z &\overset{(1)}{=} (\cosh K)^{2N} \sum_{\{s\}} \prod_{\langle ij \rangle} (1 + s_i s_j \, t_K) \\ &\overset{(2)}{=} (\cosh K)^{2N} \sum_{G \subseteq \text{bonds}} t_K^{|G|} \sum_{\{s\}} \prod_{\langle ij \rangle \in G} s_i s_j \\ &\overset{(3)}{=} 2^N (\cosh K)^{2N} \sum_{G \text{ closed}} t_K^{|G|}. \end{aligned} \tag{11.164}$$

(1) Pull the factor $\cosh K$ out of every bond.

(2) Expand the product: each bond contributes either 1 or $t_K s_i s_j$. A term is labelled by the set G of bonds that contributed $t_K s_i s_j$; $|G|$ is the number of such bonds.

(3) In $\prod_G s_i s_j$ the spin s_i appears once for every bond of G touching i. Since $\sum_{s=\pm 1} s = 0$ and $\sum_{s=\pm 1} s^2 = 2$, the spin sum is 2^N if every site touches an even number of bonds of G, and zero otherwise. Such G are unions of closed loops: "closed graphs".

Low-temperature expansion. Start from the all-up configuration, with weight e^{2NK}. Any other configuration is described by its domain walls: the set of bonds with $s_i \neq s_j$. Draw each such wall as the segment of the *dual* lattice (the lattice of plaquette centres) that crosses the broken bond. The walls form closed loops on the dual lattice, because every plaquette has an even number of broken bonds around it. Each broken bond changes $K s_i s_j$ from K to $-K$, a factor e^{-2K}. The configuration and its global flip have the same walls, so

$$Z = 2\, e^{2NK} \sum_{G^* \text{ closed on dual lattice}} \left(e^{-2K}\right)^{|G^*|}. \tag{11.165}$$

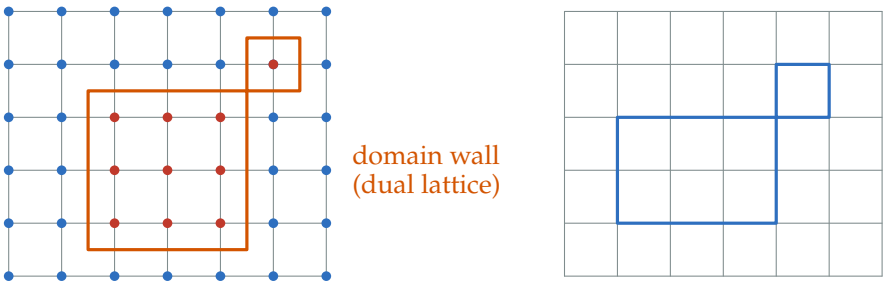

Figure 11.30: The two loop expansions of the Ising partition function. Left: at low temperature, a configuration is a sea of up spins (blue) with islands of down spins (red); the islands are bounded by closed domain walls on the dual lattice, each unit of wall costing e^{-2K}. Right: at high temperature the expansion (11.164) is a sum over closed graphs on the original lattice, each bond costing $\tanh K$. What to see: the two sums are the *same* sum over closed graphs, so the model at coupling K and at the dual coupling K^* are the same model.

The square lattice is its own dual. So (11.164) and (11.165) are the same loop sum if the weights per unit length agree. Define the dual coupling K^* by

$$e^{-2K^*} = \tanh K. \tag{11.166}$$

Then the high-temperature model at K and the low-temperature model at K^* have proportional partition functions (up to analytic prefactors and boundary effects from non-contractible loops on the torus). Small K maps to large K^*: the map exchanges the ordered and disordered phases. If there is a single critical point, it must be at the fixed point $K^* = K$.

Worked example 11.57: The critical coupling of the square-lattice Ising model

Solve $e^{-2K_c} = \tanh K_c$:

$$\begin{aligned} e^{-2K_c} = \frac{e^{K_c} - e^{-K_c}}{e^{K_c} + e^{-K_c}} &\overset{(1)}{=} e^{-K_c} + e^{-3K_c} = e^{K_c} - e^{-K_c} \\ &\overset{(2)}{=} 1 + e^{-2K_c} = e^{2K_c} - 1 \\ &\overset{(3)}{=} \sinh 2K_c = 1. \end{aligned}$$

(1) Cross-multiply by $e^{K_c} + e^{-K_c}$.
(2) Multiply by e^{K_c}.
(3) Rearrange to $e^{2K_c} - e^{-2K_c} = 2$.

So $K_c = \frac{1}{2}\ln(1+\sqrt{2}) \approx 0.4407$, that is $k_B T_c/J = 2/\ln(1+\sqrt{2}) \approx 2.269$. The general duality relation can be written symmetrically as $\sinh 2K \sinh 2K^* = 1$: from (11.166), $\sinh 2K^* = 2\tanh K^*/(1-\tanh^2 K^*)$ with $\tanh K^* = (1-e^{-2K^*})/(1+e^{-2K^*})$, and a two-line computation gives $1/\sinh 2K$.

11.5.3 Critical exponents

Near T_c thermodynamic quantities have power-law singularities. Let

$$t = \frac{T - T_c}{T_c}$$

be the reduced temperature. The two-point function $G(r) = \langle s(x)s(0)\rangle - \langle s\rangle^2$ at separation $r = |x|$ decays exponentially, $G \sim e^{-r/\xi}$, where ξ is the **correlation length**. As $t \to 0$ the

correlation length diverges. Six exponents summarise the singular behaviour [QFT notes §16.2.1, Table 16.2.1]:

exponent	definition	quantity	2D Ising (exact)
ν	$\xi \sim \lvert t\rvert^{-\nu}$	correlation length	1
η	$G(r) \sim r^{-(d-2+\eta)}$ at $t=0$	two-point function	$\frac{1}{4}$
α	$C \sim \lvert t\rvert^{-\alpha}$	specific heat	0 (log)
β	$M \sim (-t)^{\beta}$, $B=0$	spontaneous magnetisation	$\frac{1}{8}$
γ	$\chi \sim \lvert t\rvert^{-\gamma}$	susceptibility	$\frac{7}{4}$
δ	$M \sim B^{1/\delta}$ at $t=0$	critical isotherm	15

Here d is the space dimension ($d=2$ for us), C the specific heat and $\chi = \partial M/\partial B$ the susceptibility. The last column comes from Onsager's exact solution (1944), Yang's magnetisation (1952) and later work. The exponents are **universal**: any two-dimensional system with a two-fold degenerate ordered phase and short-range interactions (triangular lattice, anisotropic couplings, lattice gases, some adsorbed monolayers) has the same six numbers, although T_c changes. Universality is the first hint that the exponents are properties of a continuum field theory, not of the lattice.

Worked example 11.58: Reading off $\beta = \frac{1}{8}$ from Yang's formula

For $T < T_c$, Yang showed $M = \left(1 - \sinh^{-4} 2K\right)^{1/8}$. Near K_c, write $K = K_c + \delta K$ with $\delta K > 0$ small:

$$\sinh 2K \overset{(1)}{=} \sinh 2K_c + 2\cosh(2K_c)\,\delta K + O(\delta K^2) \overset{(2)}{=} 1 + 2\sqrt{2}\,\delta K + O(\delta K^2),$$

$$1 - \sinh^{-4} 2K \overset{(3)}{=} 1 - (1 - 8\sqrt{2}\,\delta K) + O(\delta K^2) = 8\sqrt{2}\,\delta K + O(\delta K^2),$$

$$M \overset{(4)}{=} (8\sqrt{2})^{1/8}\,(\delta K)^{1/8}\big(1 + O(\delta K)\big) \;\propto\; (-t)^{1/8}.$$

(1) Taylor expansion of $\sinh 2K$ about K_c.
(2) $\sinh 2K_c = 1$, so $\cosh 2K_c = \sqrt{1+1} = \sqrt{2}$.
(3) $(1+x)^{-4} \approx 1 - 4x$ with $x = 2\sqrt{2}\,\delta K$.
(4) $K = J/k_B T$, so $\delta K \approx -K_c\, t$ is proportional to $-t$.

The magnetisation vanishes with the strikingly small exponent $\frac{1}{8}$: it drops almost vertically at T_c (Figure 11.31). Mean-field theory would give $\frac{1}{2}$.

Worked example 11.59: $\nu = 1$ from Kramers–Wannier duality

For $T > T_c$ Onsager's solution gives the correlation length along a lattice axis as $\xi^{-1} = 2(K^* - K)$, with K^* the dual coupling (11.166). Near K_c the dual map is $K^* \approx K_c - (K - K_c)$ (it is an involution with fixed point K_c, so its derivative there is -1). Hence

$$\xi^{-1} \overset{(1)}{=} 2\big(K_c - (K - K_c) - K\big) = 4(K_c - K)$$
$$\overset{(2)}{=} 4K_c\, t + O(t^2),$$

(1) Insert the linearised dual map.
(2) $K = K_c/(1+t) \approx K_c(1-t)$.

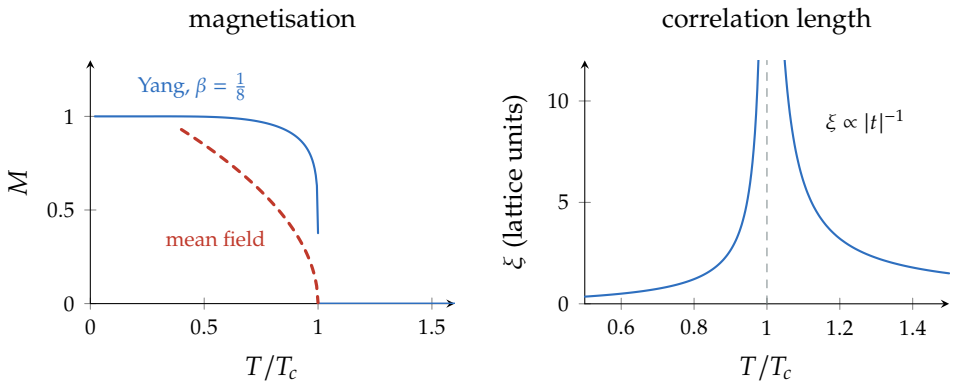

Figure 11.31: Left: the exact spontaneous magnetisation of the square-lattice Ising model (blue) against the mean-field square-root law (red, schematic). The exponent $\frac{1}{8}$ makes M fall off a cliff at T_c. Right: the correlation length $\xi^{-1} \propto |K - K^*|$ diverges linearly on both sides ($\nu = 1$). What to see: at $T = T_c$ there is no length scale left in the problem, which is the precondition for scale and conformal invariance.

so $\xi \propto t^{-1}$ and $\nu = 1$. The derivative of the involution is -1 because differentiating $(K^*)^* = K$ at the fixed point gives $(\mathrm{d}K^*/\mathrm{d}K)^2 = 1$, and the map is decreasing.

Scaling and the renormalisation group

Why power laws? The modern answer is the renormalisation group (RG). Coarse grain the lattice by a factor b (replace blocks of $b \times b$ spins by one effective spin). The couplings change, $(t, B) \mapsto (t', B')$. At the critical point $(0, 0)$ the model looks the same at every scale: it is a **fixed point** of the RG. Near the fixed point the flow is linear,

$$t' = b^{\,y_t}\, t, \qquad B' = b^{\,y_h}\, B, \tag{11.167}$$

with **RG eigenvalues** $y_t, y_h > 0$ (both perturbations grow under coarse graining: they are **relevant**). Lengths shrink by b, so $\xi(t', B') = \xi(t, B)/b$. The free energy per unit area, f, has dimension (length)$^{-d}$, so its singular part obeys

$$f(t, B) = b^{-d}\, f\left(b^{y_t} t,\; b^{y_h} B\right). \tag{11.168}$$

Every exponent follows from (11.168) by choosing b cleverly. We do that below, after seeing where y_t and y_h come from in a field theory.

11.5.4 Why the critical point is conformally invariant

Nash asserts that "at a second order phase transition the conformal invariance of the theory means…". Let us see where the conformal invariance comes from. At T_c the correlation length is infinite, so the continuum limit is a Euclidean field theory with no length scale. It is therefore invariant under translations and rotations (inherited from the lattice at long distance) and under dilations $x \mapsto \lambda x$ (no scale). The claim is that it is then invariant under the larger group of local conformal maps.

The mechanism is the energy–momentum tensor. For a local field theory the response of the action to any infinitesimal change of coordinates $x^\mu \mapsto x^\mu + \varepsilon^\mu(x)$ is

$$\delta S = -\frac{1}{2\pi} \int \mathrm{d}^2x\; T^{\mu\nu}\, \partial_\mu \varepsilon_\nu \tag{11.169}$$

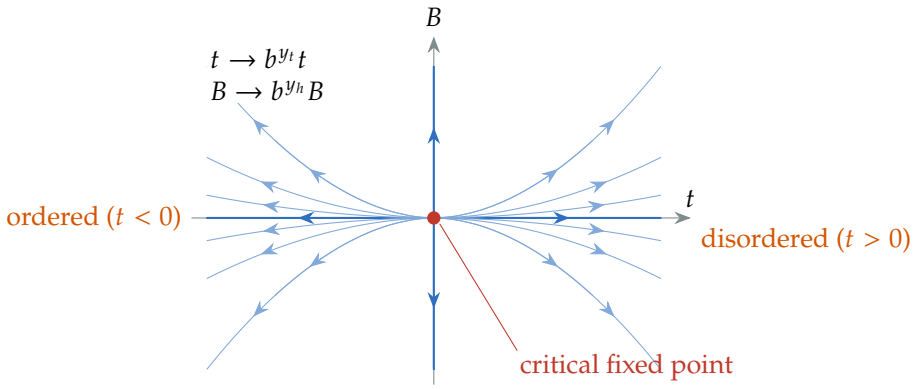

Figure 11.32: Renormalisation-group flow near the Ising critical point. Coarse graining pushes every point away from the origin along the relevant directions t (temperature) and B (magnetic field); since $y_h > y_t$ the B direction grows faster. What to see: the critical theory is the fixed point itself, and the two RG eigenvalues y_t, y_h encode all six critical exponents.

(the normalisation $1/2\pi$ is the one standard in two-dimensional CFT; Nash's (11.16) is the same statement for correlation functions). Rotation invariance makes $T^{\mu\nu}$ symmetric. Scale invariance forces $T^{\mu}{}_{\mu} = 0$: for $\varepsilon^\mu = \lambda x^\mu$ we have $\partial_\mu \varepsilon_\nu = \lambda \delta_{\mu\nu}$ and $\delta S = -(\lambda/2\pi)\int T^{\mu}{}_{\mu}$, which must vanish for every region, so (for a theory without scale) the trace vanishes as an operator, up to contact terms. This is Nash's (11.11), $T_{11} + T_{22} = 0$.

Now take a general ε and split $\partial_\mu \varepsilon_\nu$ into its symmetric traceless part, its trace, and its antisymmetric part:

$$\begin{aligned} \delta S &\overset{(1)}{=} -\frac{1}{2\pi}\int T^{\mu\nu}\,\tfrac{1}{2}\big(\partial_\mu\varepsilon_\nu + \partial_\nu\varepsilon_\mu\big) \\ &\overset{(2)}{=} -\frac{1}{2\pi}\int T^{\mu\nu}\,\tfrac{1}{2}\Big(\partial_\mu\varepsilon_\nu + \partial_\nu\varepsilon_\mu - \delta_{\mu\nu}\,\partial\cdot\varepsilon\Big) \;-\; \frac{1}{4\pi}\int T^{\mu}{}_{\mu}\,\partial\cdot\varepsilon \\ &\overset{(3)}{=} -\frac{1}{2\pi}\int T^{\mu\nu}\,\tfrac{1}{2}\Big(\partial_\mu\varepsilon_\nu + \partial_\nu\varepsilon_\mu - \delta_{\mu\nu}\,\partial\cdot\varepsilon\Big). \end{aligned}$$

(1) $T^{\mu\nu}$ is symmetric, so only the symmetric part of $\partial_\mu\varepsilon_\nu$ survives.
(2) Add and subtract the trace part $\frac{1}{2}\delta_{\mu\nu}\partial\cdot\varepsilon$.
(3) $T^{\mu}{}_{\mu} = 0$.

So the action is invariant under every ε that satisfies the **conformal Killing equation**

$$\partial_\mu\varepsilon_\nu + \partial_\nu\varepsilon_\mu = \delta_{\mu\nu}\,\partial\cdot\varepsilon. \tag{11.170}$$

In two dimensions, with $\varepsilon = \varepsilon^1 + i\varepsilon^2$ and $z = x^1 + ix^2$, the $(\mu\nu) = (11)$ and (12) components of (11.170) read $\partial_1\varepsilon^1 = \partial_2\varepsilon^2$ and $\partial_1\varepsilon^2 = -\partial_2\varepsilon^1$. These are the Cauchy–Riemann equations: $\varepsilon(z)$ is *any* holomorphic function. That is the infinite-dimensional conformal symmetry of §1–§3. In $d > 2$ the same equation allows only a finite-dimensional family (translations, rotations, dilations and special conformal maps).

Watch out: Scale invariance does not always imply conformal invariance

The argument needs $T^{\mu}{}_{\mu} = 0$ *as an operator*. Scale invariance alone only gives $T^{\mu}{}_{\mu} = \partial_\mu K^\mu$ for some local current K^μ (the "virial current"). In two dimensions, for unitary theories with a discrete spectrum, Zamolodchikov and Polchinski showed that K^μ can always be removed by improving $T^{\mu\nu}$, so scale plus rotation invariance gives conformal invariance. Critical lattice models satisfy these hypotheses; this is the quiet assumption behind Nash's

sentence.

11.5.5 Critical exponents are conformal weights

In the continuum theory at T_c the lattice spin becomes a local field $\sigma(x)$ and the local energy density $s_i s_j - \langle s_i s_j \rangle$ becomes a field $\varepsilon(x)$. Both are scaling fields: under $x \mapsto \lambda x$ they pick up factors $\lambda^{-\Delta}$. In a CFT they are primary fields with weights $(h, \bar{h})$, scaling dimension $\Delta = h + \bar{h}$ and spin $h - \bar{h} = 0$ (they are scalars). By [Nash p. 303, (11.9)], their two-point functions at T_c are

$$\langle \phi(z,\bar{z})\,\phi(0,0)\rangle = \frac{C}{z^{2h}\bar{z}^{2\bar{h}}} = \frac{C}{|z|^{2\Delta}} \qquad (h = \bar{h}). \tag{11.171}$$

(Nash's (11.9) writes $z^h \bar{z}^{\bar{h}}$; the exponent $2h$ is forced by the L_0 Ward identity, see Section 11.9.)

Away from T_c the critical theory is perturbed. Changing the temperature couples to the energy density and changing B couples to the spin:

$$S = S_{\mathrm{CFT}} + g_t \int \mathrm{d}^2x\ \varepsilon(x) + g_h \int \mathrm{d}^2x\ \sigma(x), \qquad g_t \propto t,\ \ g_h \propto B. \tag{11.172}$$

Each term in the action must be dimensionless. Under $x \mapsto bx$, the measure d^2x scales as b^d and the field as $b^{-\Delta}$, so the coupling must scale as $b^{\,d-\Delta}$. Comparing with (11.167):

$$y_t = d - \Delta_\varepsilon, \qquad y_h = d - \Delta_\sigma. \tag{11.173}$$

A perturbation is relevant exactly when $\Delta < d$.

Key idea: The dictionary between exponents and dimensions

All six critical exponents follow from the two scaling dimensions $\Delta_\sigma = 2h_\sigma$ and $\Delta_\varepsilon = 2h_\varepsilon$:

$$\nu = \frac{1}{d-\Delta_\varepsilon}, \quad \eta = 2\Delta_\sigma + 2 - d, \quad \alpha = 2 - \frac{d}{d-\Delta_\varepsilon}, \quad \beta = \frac{\Delta_\sigma}{d-\Delta_\varepsilon}, \quad \gamma = \frac{d-2\Delta_\sigma}{d-\Delta_\varepsilon}, \quad \delta = \frac{d-\Delta_\sigma}{\Delta_\sigma}.$$

For the Ising CFT, $h_\sigma = \frac{1}{16}$ and $h_\varepsilon = \frac{1}{2}$ (Section 11.6), so $\Delta_\sigma = \frac{1}{8}$, $\Delta_\varepsilon = 1$, and with $d = 2$ these give exactly the Onsager–Yang values $\nu = 1$, $\eta = \frac{1}{4}$, $\alpha = 0$, $\beta = \frac{1}{8}$, $\gamma = \frac{7}{4}$, $\delta = 15$.

We now derive each formula. Throughout, d is general; set $d = 2$ at the end.

ν. Iterate the RG until t' is of order one: choose $b = |t|^{-1/y_t}$. At that scale the correlation length is some number ξ_0 of order one, so

$$\xi(t) \overset{(1)}{=} b\,\xi(b^{y_t}t) \overset{(2)}{=} |t|^{-1/y_t}\,\xi(\pm 1) \overset{(3)}{=} \xi_0\,|t|^{-1/(d-\Delta_\varepsilon)}.$$

(1) Lengths measured in coarse-grained units are b times smaller.
(2) Choose $b = |t|^{-1/y_t}$, so the rescaled temperature is ± 1.
(3) $y_t = d - \Delta_\varepsilon$ from (11.173).

Hence $\nu = 1/(d - \Delta_\varepsilon)$. For Ising: $\nu = 1/(2-1) = 1$.

η. At T_c, $G(r) = \langle \sigma(r)\sigma(0)\rangle \propto r^{-2\Delta_\sigma}$ by (11.171). The definition $G \sim r^{-(d-2+\eta)}$ gives $d - 2 + \eta = 2\Delta_\sigma$, so $\eta = 2\Delta_\sigma + 2 - d$. For Ising: $\eta = 2 \cdot \frac{1}{8} = \frac{1}{4}$.

α. Put $B = 0$ and choose $b = |t|^{-1/y_t}$ in (11.168):

$$f(t,0) \overset{(1)}{=} |t|^{d/y_t}\,f(\pm 1, 0), \qquad C \propto \frac{\partial^2 f}{\partial t^2} \overset{(2)}{=} |t|^{d/y_t - 2},$$

(1) $b^{-d} = |t|^{d/y_t}$.
(2) The specific heat is the second temperature derivative of the free energy (up to a smooth factor T).

so $\alpha = 2 - d/y_t = 2 - d\nu$ (the **hyperscaling** relation). For Ising $\alpha = 2 - 2 = 0$. An exponent zero here means a logarithm: $f \propto t^2 \ln|t|$, which is Onsager's famous logarithmic specific heat.

β. The magnetisation is $M = -\partial f/\partial B$ at $B = 0$. Differentiating (11.168) with respect to B brings down a factor b^{y_h}:

$$M(t) \overset{(1)}{=} b^{\,y_h - d}\, M(b^{y_t} t, 0) \overset{(2)}{=} |t|^{(d-y_h)/y_t}\, M(-1, 0),$$

(1) Chain rule on $f(b^{y_t}t, b^{y_h}B)$.
(2) Choose $b = |t|^{-1/y_t}$, $t < 0$.

so $\beta = (d - y_h)/y_t = \Delta_\sigma/(d - \Delta_\varepsilon)$. For Ising $\beta = \frac{1}{8}/1 = \frac{1}{8}$, as Yang found.

γ. Differentiate twice with respect to B: $\chi(t) = b^{2y_h - d}\chi(b^{y_t}t, 0)$, so $\gamma = (2y_h - d)/y_t = (d - 2\Delta_\sigma)/(d - \Delta_\varepsilon)$. For Ising $\gamma = (2 - \frac{1}{4})/1 = \frac{7}{4}$.

δ. Now put $t = 0$ and choose $b = B^{-1/y_h}$: $M(0, B) = b^{y_h - d}M(0, 1) = B^{(d-y_h)/y_h}M(0, 1)$, so $1/\delta = (d - y_h)/y_h$ and $\delta = y_h/(d - y_h) = (d - \Delta_\sigma)/\Delta_\sigma$. For Ising $\delta = (2 - \frac{1}{8})/\frac{1}{8} = 15$.

Worked example 11.60: Checking the scaling relations for the Ising model

Because six exponents come from two numbers, there must be four relations among them. With the Ising values:

$$\begin{aligned} \alpha + 2\beta + \gamma &= 0 + \tfrac{1}{4} + \tfrac{7}{4} = 2 && \text{(Rushbrooke)},\\ \gamma &= \beta(\delta - 1) = \tfrac{1}{8}\cdot 14 = \tfrac{7}{4} && \text{(Widom)},\\ \gamma &= \nu(2 - \eta) = 1 \cdot \tfrac{7}{4} = \tfrac{7}{4} && \text{(Fisher)},\\ d\nu &= 2 - \alpha = 2 && \text{(Josephson)}. \end{aligned}$$

All four hold. They hold for *any* values of $\Delta_\sigma, \Delta_\varepsilon$: for instance Fisher's relation is $\nu(2 - \eta) = \frac{1}{d-\Delta_\varepsilon}(d - 2\Delta_\sigma) = \gamma$. For comparison, mean-field theory ($\beta = \frac{1}{2}, \gamma = 1, \delta = 3, \nu = \frac{1}{2}, \eta = 0, \alpha = 0$) violates Josephson's relation in $d = 2$ ($d\nu = 1 \neq 2$): mean-field theory is wrong in two dimensions.

Dictionary: Statistical mechanics ↔ conformal field theory

lattice at $T = T_c$, $B = 0$	CFT (fixed point of the RG)
lattice spin s_i	primary field σ, weights $(\frac{1}{16}, \frac{1}{16})$
energy density $s_i s_j - \langle s_i s_j\rangle$	primary field ε, weights $(\frac{1}{2}, \frac{1}{2})$
constant function 1	identity $\mathbf{1}$, weights $(0, 0)$
temperature deviation t	coupling of $\int \varepsilon$, RG eigenvalue $2 - \Delta_\varepsilon = 1$
magnetic field B	coupling of $\int \sigma$, RG eigenvalue $2 - \Delta_\sigma = \frac{15}{8}$
critical exponents	functions of h_σ, h_ε (key idea above)
universality class	the CFT (its c and its operator content)
periodic $L \times L'$ lattice	torus with modulus τ (Section 11.7)

Reading Nash (p. 311, top of §4)

Nash spends two lines on the physics we have just laid out: "In statistical mechanics the imposition of periodic boundary conditions leads to partition functions Z defined on a

torus; at a second order phase transition the conformal invariance of the theory means that Z should be invariant under the modular transformations". The periodic boundary conditions are Figure 11.29; the second-order transition is the Kramers–Wannier point $\sinh 2K_c = 1$; its conformal invariance is the argument of Section 11.5.4. The link between critical exponents and conformal weights is not stated by Nash at all, but it is the reason the weights $(\frac{1}{16}, \frac{1}{16})$ and $(\frac{1}{2}, \frac{1}{2})$ of his next paragraph are physically meaningful. The preceding paragraph (end of his §3) is our Section 11.5.1.

Recap

- Only L_{-1}, L_0, L_1 generate global maps of the sphere: the Möbius group $\mathrm{SL}(2,\mathbb{C})/\{\pm I\}$. The Schwarzian vanishes on it, so $T(z)$ is a genuine weight-2 tensor under Möbius maps.
- CFTs come from Kac–Moody algebras (Sugawara), superconformal algebras, strings and critical statistical mechanics.
- The 2D Ising model has a continuous transition at $\sinh 2K_c = 1$, located by Kramers–Wannier duality between two loop expansions.
- At T_c, $\xi = \infty$; scale, rotation and locality give $T^{\mu}{}_{\mu} = 0$, hence invariance under all holomorphic $\varepsilon(z)$.
- Perturbing couplings scale with RG eigenvalues $y = d - \Delta$; all six exponents are functions of $\Delta_\sigma, \Delta_\varepsilon$. The Ising values $\Delta_\sigma = \frac{1}{8}, \Delta_\varepsilon = 1$ reproduce Onsager's exact exponents.

11.6 The Ising model as the $c = \frac{1}{2}$ conformal field theory

The last section ended with a promise. If the critical Ising model is a CFT, and if its spin and energy fields have weights $h_\sigma = \frac{1}{16}$ and $h_\varepsilon = \frac{1}{2}$, then all six Onsager exponents follow. Nash states the needed facts in one sentence:

> "if we choose the two dimensional Ising model it turns out that the conformal field theory has $c = 1/2$ and contains only three primary fields whose conformal weights are $(0,0)$, $(1/16, 1/16)$ and $(1/2, 1/2)$."

His footnote adds that this can be checked from the Virasoro representation formula (6.58) with $m = 2$. This section does that check, and more. We want to see *why* $c = \frac{1}{2}$ forces exactly these three weights, what the states in each representation look like, and how the whole theory can be built from one free fermion. The question we answer is:

Given only the Virasoro algebra with $c = \frac{1}{2}$ and unitarity, which weights h are allowed, and what do their representations contain?

11.6.1 From one state to a whole representation: Verma modules

We recall the algebra of §3 and of Chapter 6. The Virasoro algebra is spanned by L_n, $n \in \mathbb{Z}$, and a central element acting as the number c:

$$[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12}\, m(m^2-1)\,\delta_{m+n,0}. \tag{11.174}$$

L_0 measures energy (in radial quantisation, the dilation generator). Since $[L_0, L_{-n}] = nL_{-n}$, the operator L_{-n} raises the L_0 eigenvalue by n and L_n lowers it by n. So $L_{n>0}$ are *lowering* (annihilation-like) operators and $L_{n<0}$ are *raising* (creation-like) operators, exactly as a and $a^\dagger$ for the harmonic oscillator.

A vector space, or a module?

A physicist starts with a Hilbert space of states and asks how symmetry operators act on it. Here we reverse the logic. We start with a single state $|h\rangle$ and *build* the space by acting on it with the algebra. What comes out is not just a vector space: it is a vector space together with a rule for how every L_n acts on every vector. The algebraists' name for that pair is a **module**.

Working definition 11.22 (module = representation space)

A **module** over the Virasoro algebra is a complex vector space V together with linear maps $L_n : V \to V$ (one for each n) that satisfy the commutation relations (11.174) with c acting as a number [the central element acts as c times the identity on all of V]. "Module" and "representation space" mean the same thing. *How to specify one:* give a basis and the matrix of every L_n in it. A **submodule** is a subspace $N \subseteq V$ that every L_n maps into itself. A module is **irreducible** if its only submodules are $\{0\}$ and V [starting from any nonzero vector, repeated action of the L_n and linear combinations reach all of V].

Notice what this definition does *not* contain: an inner product. The Hilbert-space structure is extra data, and it enters at a separate step below (the Shapovalov form). Keeping the two apart is what makes null states understandable. The whole construction is a three-stage pipeline (Figure 11.33).

Key idea: The highest-weight pipeline

$$|h\rangle \xrightarrow{\text{descendants}} V(c,h) = U(\text{vir}_-)|h\rangle \xrightarrow{\text{quotient by } N} L(c,h) = V(c,h)/N.$$

$V(c,h)$ is the **Verma module**: everything the algebra can produce from $|h\rangle$, with no relations beyond the highest-weight conditions. $L(c,h)$ is the **irreducible** module: the actual space of states of a conformal family in a CFT. We quotient by the *entire submodule* generated by the singular vectors, never by a single vector.

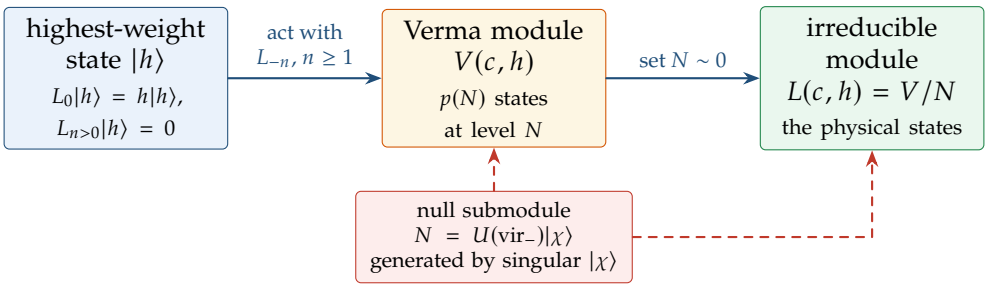

Figure 11.33: The highest-weight pipeline. One state generates the Verma module; the singular vectors inside it generate a submodule N (red), and dividing it out gives the irreducible module. What to see: N is removed as a whole; for generic (c,h) it is $\{0\}$ and the second arrow does nothing.

Step 1: the highest-weight state and its descendants

A **highest-weight state** $|h\rangle$ obeys

$$L_0|h\rangle = h|h\rangle, \qquad L_n|h\rangle = 0 \quad (n \geq 1) \tag{11.175}$$

[Nash p. 186, (6.57)]. It is the lowest-energy state of its family: the lowering operators have nowhere to go. In a CFT it is the state created by a primary field at the origin, $|h\rangle = \phi(0)|0\rangle$. The raising operators produce the **descendants** $L_{-n_1}L_{-n_2}\cdots L_{-n_k}|h\rangle$, with $n_1 \geq n_2 \geq \cdots \geq n_k \geq 1$. Such a state has L_0 eigenvalue $h + N$, where $N = n_1 + \cdots + n_k$ is its **level**. We may order the L_{-n} decreasingly because any other order can be rewritten with the commutators (11.174). The number of such monomials at level N is $p(N)$, the number of partitions of N:

level N	basis of $V(c,h)$ at level N	$p(N)$
0	$\|h\rangle$	1
1	$L_{-1}\|h\rangle$	1
2	$L_{-2}\|h\rangle,\ L_{-1}^2\|h\rangle$	2
3	$L_{-3}\|h\rangle,\ L_{-2}L_{-1}\|h\rangle,\ L_{-1}^3\|h\rangle$	3
4	$L_{-4},\ L_{-3}L_{-1},\ L_{-2}^2,\ L_{-2}L_{-1}^2,\ L_{-1}^4$ (on $\|h\rangle$)	5

In the Verma module these monomials are declared linearly independent. The span is

$$V(c,h) = U(\mathrm{vir}_-)|h\rangle = \mathrm{span}\{L_{-n_1}\cdots L_{-n_k}|h\rangle\}, \tag{11.176}$$

where $U(\mathrm{vir}_-)$, the **universal enveloping algebra** of the raising operators, simply means "all polynomials in the L_{-n}, $n \geq 1$, with products reordered by the commutators".

Worked example 11.61: The Verma module as explicit matrices, levels 0–2

A module is specified by how the operators act. On the basis above we compute the action of L_{-1}, L_1, L_{-2}, L_2 between levels 0, 1, 2. The raising operators are trivial: $L_{-1}|h\rangle$ is basis vector 1 of level 1, $L_{-1}(L_{-1}|h\rangle) = L_{-1}^2|h\rangle$ is basis vector 2 of level 2, and $L_{-2}|h\rangle$ is basis vector 1 of level 2. The lowering operators need the algebra. The three building blocks are

$$L_1L_{-1}|h\rangle \overset{(1)}{=} [L_1, L_{-1}]|h\rangle = 2L_0|h\rangle = 2h|h\rangle,$$
$$L_2L_{-2}|h\rangle \overset{(2)}{=} \big(4L_0 + \tfrac{c}{12}\cdot 2\cdot 3\big)|h\rangle = \big(4h + \tfrac{c}{2}\big)|h\rangle,$$
$$L_1L_{-2}|h\rangle \overset{(3)}{=} 3L_{-1}|h\rangle,$$
$$L_1L_{-1}^2|h\rangle \overset{(4)}{=} \big(2L_0 + L_{-1}L_1\big)L_{-1}|h\rangle \overset{(5)}{=} \big(2(h+1) + 2h\big)L_{-1}|h\rangle = (4h+2)L_{-1}|h\rangle,$$
$$L_2L_{-1}^2|h\rangle \overset{(6)}{=} \big([L_2, L_{-1}]L_{-1} + L_{-1}L_2L_{-1}\big)|h\rangle \overset{(7)}{=} 3L_1L_{-1}|h\rangle = 6h|h\rangle.$$

(1) $L_1|h\rangle = 0$; (11.174) with $m = 1, n = -1$ gives $[L_1, L_{-1}] = 2L_0$ (the central term has $m(m^2-1) = 0$).
(2) $[L_2, L_{-2}] = 4L_0 + \frac{c}{12}2(4-1)$, and $L_2|h\rangle = 0$.
(3) $[L_1, L_{-2}] = 3L_{-1}$, and $L_1|h\rangle = 0$.
(4) $L_1L_{-1} = [L_1, L_{-1}] + L_{-1}L_1 = 2L_0 + L_{-1}L_1$.
(5) $L_{-1}|h\rangle$ has $L_0 = h + 1$, and $L_1L_{-1}|h\rangle = 2h|h\rangle$ by the first line.
(6) Commute L_2 once past L_{-1}.
(7) $[L_2, L_{-1}] = 3L_1$; the second term dies because $L_2L_{-1}|h\rangle = 3L_1|h\rangle + L_{-1}L_2|h\rangle = 0$. Then the first line.

So, as matrices between the levels (columns labelled by the basis of the source level, rows by the basis of the target level),

$$L_1\big|_{1\to 0} = \begin{pmatrix} 2h \end{pmatrix}, \qquad L_1\big|_{2\to 1} = \begin{pmatrix} 3 & 4h+2 \end{pmatrix}, \qquad L_2\big|_{2\to 0} = \begin{pmatrix} 4h+\frac{c}{2} & 6h \end{pmatrix}, \qquad L_{-1}\big|_{1\to 2} = \begin{pmatrix} 0 \\ 1 \end{pmatrix}. \tag{11.177}$$

This is the Verma module "as a representation": a graded vector space with explicit matrices. Every higher level works the same way, with bigger matrices.

Step 2: where the inner product comes in (the Shapovalov form)

So far there is no notion of length. A quantum theory needs one. Physical input fixes it: $T(z)$ is Hermitian in radial quantisation, which gives $L_n^\dagger = L_{-n}$; and we normalise $\langle h|h\rangle = 1$. These two rules determine the inner product of any two descendants. To compute $\langle h|L_{n_k}\cdots L_{n_1}L_{-m_1}\cdots L_{-m_j}|h\rangle$, move the lowering operators to the right with (11.174) until they hit $|h\rangle$ and die. The resulting Hermitian form on $V(c,h)$ is the **Shapovalov form** (in physics usually just "the Kac form"). Different levels are orthogonal, because L_0 is Hermitian and they have different L_0 eigenvalues. Within level N the form is the $p(N)\times p(N)$ **Gram matrix** $G^{(N)}$.

Working definition 11.23 (Gram matrix and unitarity test)

List the $p(N)$ basis descendants [the vectors $L_{-n_1}\cdots L_{-n_k}|h\rangle$ with $n_1 \geq \cdots \geq n_k \geq 1$ and $n_1+\cdots+n_k = N$] at level N as $|v_1\rangle,\ldots,|v_{p(N)}\rangle$ and compute $G^{(N)}_{ab} = \langle v_a|v_b\rangle$ as just described. *Test:* the representation can be **unitary** (live in a Hilbert space) only if every $G^{(N)}$ is positive semi-definite [all eigenvalues ≥ 0, so no combination of the $|v_a\rangle$ has negative norm squared]. A zero eigenvalue signals a **null vector**: a nonzero element of $V(c,h)$ orthogonal to everything. A negative eigenvalue forbids the pair (c,h) outright.

Worked example 11.62: The Gram matrix at levels 1 and 2

Level 1. One state, $L_{-1}|h\rangle$, and $\langle h|L_1L_{-1}|h\rangle = 2h$ from the first building block. So unitarity needs $h \geq 0$, and $h = 0$ gives a null vector $L_{-1}|0\rangle$. For the vacuum this is welcome: L_{-1} generates translations, and the vacuum is translation invariant.

Level 2. Take $|v_1\rangle = L_{-2}|h\rangle$, $|v_2\rangle = L_{-1}^2|h\rangle$.

$$\begin{aligned} G_{11} &= \langle h|L_2L_{-2}|h\rangle = 4h+\tfrac{c}{2}, \\ G_{12} &\overset{(1)}{=} \langle h|L_2L_{-1}^2|h\rangle \overset{(2)}{=} 6h, \\ G_{22} &\overset{(3)}{=} \langle h|L_1L_1L_{-1}^2|h\rangle \overset{(4)}{=} (4h+2)\,\langle h|L_1L_{-1}|h\rangle = (4h+2)\,2h. \end{aligned}$$

(1) $\langle v_1| = (L_{-2}|h\rangle)^\dagger = \langle h|L_2$.
(2) The last building block. ($G_{21} = G_{12}^* = 6h$ as well.)
(3) $(L_{-1}^2|h\rangle)^\dagger = \langle h|L_1^2$.
(4) The fourth building block, then level 1.

Hence

$$G^{(2)} = \begin{pmatrix} 4h+\frac{c}{2} & 6h \\ 6h & 4h(2h+1) \end{pmatrix}, \qquad \det G^{(2)} = 2h\big(16h^2+2(c-5)h+c\big). \tag{11.178}$$

The determinant: $(4h+\frac{c}{2})(8h^2+4h) - 36h^2 = 32h^3+(4c-20)h^2+2ch$, which factorises as shown.

The determinant vanishes at $h = 0$ (the level-1 null vector, now seen again as $L_{-1}^2|0\rangle$) and at the two roots

$$h_\pm(c) = \frac{(5-c) \pm \sqrt{(1-c)(25-c)}}{16}. \tag{11.179}$$

These are the first two nontrivial **Kac curves**, usually written $h_{2,1}$ and $h_{1,2}$ (Figure 11.34).

Worked example 11.63: The Ising weights from one quadratic equation

Put $c = \frac{1}{2}$ in (11.179):

$$h_\pm\left(\tfrac{1}{2}\right) \overset{(1)}{=} \frac{\frac{9}{2} \pm \sqrt{\frac{1}{2}\cdot\frac{49}{2}}}{16} = \frac{\frac{9}{2} \pm \frac{7}{2}}{16} \overset{(2)}{=} \left\{\tfrac{1}{2},\ \tfrac{1}{16}\right\}.$$

(1) $5 - \frac{1}{2} = \frac{9}{2}$, $1 - \frac{1}{2} = \frac{1}{2}$ and $25 - \frac{1}{2} = \frac{49}{2}$, so the square root is $\frac{7}{2}$.
(2) $8/16 = \frac{1}{2}$ and $1/16$.

So at $c = \frac{1}{2}$ the only weights with a null vector at level ≤ 2 are exactly Nash's 0, $\frac{1}{16}$ and $\frac{1}{2}$. These are the dimensions of the identity, the spin field and the energy field.

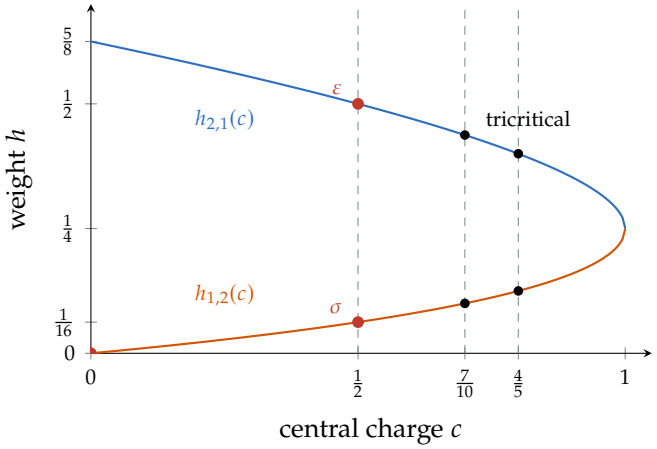

Figure 11.34: The two level-2 Kac curves (11.179). A highest-weight representation with (c, h) on one of the curves has a null vector at level 2. The dashed verticals are the first unitary minimal models $c = \frac{1}{2}$ (Ising, red dots: $h = \frac{1}{2}, \frac{1}{16}$), $c = \frac{7}{10}$ (tricritical Ising) and $c = \frac{4}{5}$ (tetracritical Ising / three-state Potts). What to see: the two curves meet at $c = 1$, $h = \frac{1}{4}$; below $c = 1$ they cut out a discrete list of weights at each allowed c.

Step 3: a singular vector appears

A zero of the Gram determinant means some level-2 combination is special. We now find it directly, without the determinant. Call a descendant $|\chi\rangle$ **singular** if it is itself a highest-weight state: $L_n|\chi\rangle = 0$ for all $n \ge 1$. At level 2 try

$$|\chi\rangle = \left(L_{-2} + \alpha L_{-1}^2\right)|h\rangle. \tag{11.180}$$

It is enough to impose $L_1|\chi\rangle = 0$ and $L_2|\chi\rangle = 0$: every L_n with $n \ge 3$ is a commutator of these two ($L_3 = [L_2, L_1]$, $L_4 = \frac{1}{2}[L_3, L_1]$, and so on), and a commutator of two operators that kill $|\chi\rangle$

also kills it. Using the building blocks,

$$L_1|\chi\rangle \overset{(1)}{=} L_1L_{-2}|h\rangle + \alpha L_1L_{-1}^2|h\rangle \overset{(2)}{=} \big(3 + \alpha(4h+2)\big)L_{-1}|h\rangle,$$
$$L_2|\chi\rangle \overset{(3)}{=} L_2L_{-2}|h\rangle + \alpha L_2L_{-1}^2|h\rangle \overset{(4)}{=} \big(4h + \tfrac{c}{2} + 6h\alpha\big)|h\rangle.$$

(1) Linearity.
(2) Third and fourth building blocks: $3L_{-1}|h\rangle$ and $(4h+2)L_{-1}|h\rangle$.
(3) Linearity.
(4) Second and fifth building blocks: $(4h + \frac{c}{2})|h\rangle$ and $6h|h\rangle$.

Both brackets must vanish. The first fixes α, the second then fixes a relation between h and c:

$$\alpha = -\frac{3}{2(2h+1)},$$
$$c \overset{(1)}{=} -2(4h + 6h\alpha) \overset{(2)}{=} -8h + \frac{18h}{2h+1} = \frac{2h(5-8h)}{2h+1}. \tag{11.181}$$

(1) Solve $4h + \frac{c}{2} + 6h\alpha = 0$ for c.
(2) Insert α: $-12h\alpha = 18h/(2h+1)$; then $-8h(2h+1) + 18h = 2h(5-8h)$.

Solving (11.181) for h gives back $16h^2 + 2(c-5)h + c = 0$, the quadratic factor of $\det G^{(2)}$: the singular vector exists exactly on the Kac curves. At $h = \frac{1}{16}$ we get $\alpha = -\frac{4}{3}$ and $c = \frac{1}{8}\cdot\frac{9}{2}\cdot\frac{8}{9} = \frac{1}{2}$; at $h = \frac{1}{2}$ we get $\alpha = -\frac{3}{4}$ and $c = 1\cdot 1/2 = \frac{1}{2}$. So the Ising model has the two singular vectors

$$|\chi_\sigma\rangle = \Big(L_{-2} - \tfrac{4}{3}L_{-1}^2\Big)|\sigma\rangle, \qquad |\chi_\varepsilon\rangle = \Big(L_{-2} - \tfrac{3}{4}L_{-1}^2\Big)|\varepsilon\rangle. \tag{11.182}$$

In Section 11.9.7 these two equations, set to zero, become differential equations for correlation functions, and they produce the fusion rule $\sigma \times \sigma = \mathbf{1} + \varepsilon$.

Worked example 11.64: A singular vector is a null vector

Why does "singular" (killed by lowering operators) imply "null" (zero norm, orthogonal to everything)? Take any level-2 state $|v\rangle = X|h\rangle$ with X a combination of L_{-2} and L_{-1}^2. Then $X^\dagger$ is a combination of L_2 and L_1^2, and

$$\langle v|\chi\rangle \overset{(1)}{=} \langle h|X^\dagger|\chi\rangle \overset{(2)}{=} \langle h|\big(a\,L_2 + b\,L_1L_1\big)|\chi\rangle \overset{(3)}{=} 0.$$

(1) $\langle v| = (X|h\rangle)^\dagger = \langle h|X^\dagger$.
(2) Write $X^\dagger = aL_2 + bL_1^2$ for some numbers a, b.
(3) $L_2|\chi\rangle = 0$ and $L_1|\chi\rangle = 0$.

States at other levels are orthogonal to $|\chi\rangle$ automatically. So $|\chi\rangle$ is orthogonal to the whole Verma module, itself included: $\langle\chi|\chi\rangle = 0$. As a numerical check at $h = \frac{1}{16}$, $c = \frac{1}{2}$, (11.178) is $G^{(2)} = \left(\begin{smallmatrix} 1/2 & 3/8 \\ 3/8 & 9/32 \end{smallmatrix}\right)$, and with the coefficient vector $v = (1, -\frac{4}{3})$ of $|\chi_\sigma\rangle$,

$$\langle\chi_\sigma|\chi_\sigma\rangle = v^{\mathsf{T}}G^{(2)}v \overset{(1)}{=} \tfrac{1}{2} - 2\cdot\tfrac{4}{3}\cdot\tfrac{3}{8} + \tfrac{16}{9}\cdot\tfrac{9}{32} = \tfrac{1}{2} - 1 + \tfrac{1}{2} = 0.$$

(1) $v^{\mathsf{T}}Gv = G_{11} + 2v_2G_{12} + v_2^2G_{22}$ with $G_{11} = \frac{1}{4} + \frac{1}{4}$, $G_{12} = \frac{6}{16}$, $G_{22} = \frac{4}{16}\cdot\frac{9}{8}$.

The other eigenvalue of $G^{(2)}$ is its trace, $\frac{25}{32} > 0$.

Step 4: one singular vector generates a whole submodule

$|\chi\rangle$ is a highest-weight state of weight $h+2$. So the raising operators act on it just as they act on $|h\rangle$, and generate a copy of a Verma module sitting inside $V(c,h)$:

$$N_\chi = U(\mathrm{vir}_-)|\chi\rangle = \mathrm{span}\{|\chi\rangle,\ L_{-1}|\chi\rangle,\ L_{-2}|\chi\rangle,\ L_{-1}^2|\chi\rangle,\ L_{-3}|\chi\rangle,\ \dots\}. \tag{11.183}$$

It has $p(N-2)$ states at level N: one at levels 2 and 3, two at level 4, three at level 5, and so on. For instance, in the level-3 basis of the table,

$$L_{-1}|\chi\rangle \overset{(1)}{=} L_{-1}L_{-2}|h\rangle + \alpha L_{-1}^3|h\rangle \overset{(2)}{=} L_{-3}|h\rangle + L_{-2}L_{-1}|h\rangle + \alpha L_{-1}^3|h\rangle,$$

(1) Apply L_{-1} to (11.180).
(2) $L_{-1}L_{-2} = L_{-2}L_{-1} + [L_{-1}, L_{-2}]$ and $[L_{-1}, L_{-2}] = (-1+2)L_{-3} = L_{-3}$.

a definite nonzero vector with coordinates $(1, 1, \alpha)$.

Two facts make N_χ the right thing to remove.

- **It is a submodule.** Raising operators keep us in N_χ by construction. A lowering operator L_n acting on $L_{-m_1}\cdots L_{-m_k}|\chi\rangle$ can be commuted to the right; every commutator produces another L, and when the lowering operators reach $|\chi\rangle$ they kill it. What survives is again of the form (raising operators)$|\chi\rangle$.
- **It is entirely null.** Any element of N_χ is $Y|\chi\rangle$ with $Y \in U(\mathrm{vir}_-)$. For any $|v\rangle \in V(c,h)$, $\langle v|Y|\chi\rangle = \langle Y^\dagger v|\chi\rangle$, and $Y^\dagger v$ is some vector of $V(c,h)$ (at level 2, if the level is to match). We showed $|\chi\rangle$ is orthogonal to all of those, so $\langle v|Y\chi\rangle = 0$.

Watch out: Why not throw away only $|\chi\rangle$?

Suppose we divided by the one-dimensional subspace $\mathbb{C}|\chi\rangle$ only. In the quotient $|\chi\rangle \sim 0$, so linearity demands $L_{-1}|\chi\rangle \sim L_{-1}\,0 = 0$. But $L_{-1}|\chi\rangle$ is a nonzero level-3 vector not in $\mathbb{C}|\chi\rangle$, so in that quotient it is *not* zero. The action of L_{-1} would give two different answers on the same equivalence class: it is not well defined. The subspace we divide by must be closed under the algebra. The smallest such subspace containing $|\chi\rangle$ is exactly N_χ.

Step 5: the quotient, and why it is still a module

Let N be the maximal proper submodule of $V(c,h)$: the sum of the submodules generated by all its singular vectors (there can be more than one, as the Ising σ example below shows). Define

$$L(c,h) = V(c,h)/N, \qquad v \sim v' \iff v - v' \in N. \tag{11.184}$$

An element of $L(c,h)$ is an equivalence class $[v] = v + N$. In particular $|\chi\rangle \sim 0$, $L_{-1}|\chi\rangle \sim 0$, $L_{-2}|\chi\rangle \sim 0$, and so on: the whole null tower is set to zero. Define the action on classes by $L_n[v] := [L_n v]$. This is well defined, because if $v \sim v'$ then

$$L_n v - L_n v' \overset{(1)}{=} L_n(v - v') \overset{(2)}{\in} L_n N \overset{(3)}{\subseteq} N \quad\Longrightarrow\quad [L_n v] = [L_n v'].$$

(1) L_n is linear.
(2) $v - v' \in N$ by the definition of $\sim$.
(3) N is a submodule: every L_n maps it into itself.

The commutation relations survive because they hold on representatives: $[L_m, L_n][v] = [(L_m L_n - L_n L_m)v] = [((m-n)L_{m+n} + \frac{c}{12}m(m^2-1)\delta_{m+n,0})v]$. So $L(c,h)$ is a Virasoro module. The inner product also descends, because N is orthogonal to everything: for $n, n' \in N$,

$$\langle v + n \,|\, v' + n' \rangle \overset{(1)}{=} \langle v|v'\rangle + \langle v|n'\rangle + \langle n|v'\rangle + \langle n|n'\rangle \overset{(2)}{=} \langle v|v'\rangle.$$

(1) Sesquilinearity.
(2) Every element of N is orthogonal to all of $V(c,h)$.

On the quotient the form has no null vectors left. If in addition it has no negative directions, $L(c,h)$ is a genuine (pre-)Hilbert space: this is the physical conformal family $[\phi]$ of Nash's §5.

Physical picture: Why unitarity needs the null states removed

In a Hilbert space the only vector of zero length is the zero vector: $\langle\psi|\psi\rangle = 0 \Rightarrow |\psi\rangle = 0$. A null state in $V(c,h)$ has zero norm and zero overlap with every state, so no measurement can ever detect it: every amplitude involving it vanishes. Keeping it would make the inner product degenerate; removing it costs nothing physical. The quotient is the precise way of saying "these states are zero". For the correlation functions this becomes a strong statement: inserting the field of a null state gives zero, which yields differential equations (Section 11.9.7).

Key idea: Generic weights have no null states

If (c,h) lies on none of the Kac curves $h = h_{r,s}(c)$, every Gram determinant is nonzero, $N = \{0\}$, and $V(c,h) = L(c,h)$ is already irreducible. Null states are the exception, and the exceptions are exactly where the interesting (minimal, rational) CFTs live.

	what it is	dimension at level N
Verma module $V(c,h)$	all formally generated descendants $L_{-n_1}\cdots L_{-n_k}\|h\rangle$	$p(N)$
null submodule N	descendants of the singular vectors; zero norm, orthogonal to everything	$p(N-2)$ for one level-2 singular vector (more if there are more)
irreducible $L(c,h)$	V/N: the physical states of a conformal family	$p(N) - \dim N_N$; equals $p(N)$ for generic (c,h)

Worked example 11.65: The weight diagram of the Ising spin module

Take $c = \frac{1}{2}$, $h = \frac{1}{16}$. In the Kac table of Figure 11.36, σ has two labels, $\phi_{1,2}$ and $\phi_{2,2}$, and the null vector of $\phi_{r,s}$ sits at level rs. So there are two singular vectors, at levels 2 and 4. Counting states level by level:

level N	0	1	2	3	4
Verma V: $p(N)$	1	1	2	3	5
generated by $\|\chi_\sigma\rangle$ (level 2): $p(N-2)$	0	0	1	1	2
generated by the level-4 singular vector: $p(N-4)$	0	0	0	0	1
irreducible L	1	1	1	2	2

The last row is confirmed independently by the free-fermion construction of Section 11.6.3, which gives $1, 1, 1, 2, 2$ states for the Ramond ground state tower. (The two null submodules first overlap at higher level, which the inclusion–exclusion character formula of Section 11.7 accounts for.) Figure 11.35 draws the same count.

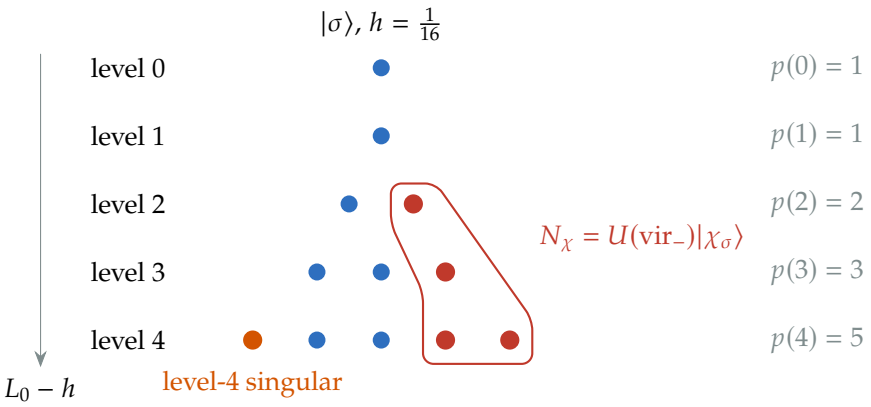

Figure 11.35: The weight diagram of the Verma module $V(\frac{1}{2}, \frac{1}{16})$ by level: $1, 1, 2, 3, 5$ states at levels 0–4 (dots). The red dots and the red outline are the submodule generated by the level-2 singular vector $|\chi_\sigma\rangle$ ($1, 1, 2$ states at levels $2, 3, 4$); the orange dot is a second singular vector at level 4. What to see: removing all coloured dots leaves $1, 1, 1, 2, 2$ blue dots, the states of the irreducible module $L(\frac{1}{2}, \frac{1}{16})$, i.e. of the physical spin field's family.

11.6.2 The Kac formula and the unitary series

Level 2 was a lucky shortcut. The general answer is Kac's determinant formula: $\det G^{(N)}$ is, up to a positive constant, a product of factors $(h - h_{r,s}(c))^{p(N-rs)}$ over positive integers r, s with $rs \le N$. For $c < 1$ Friedan, Qiu and Shenker showed that positivity at *all* levels leaves only a discrete set of (c, h). This is Nash's (6.58):

Key idea: The unitary discrete series [Nash p. 186, (6.58)]

For $c < 1$ a unitary highest-weight representation exists only if

$$c = 1 - \frac{6}{(m+1)(m+2)}, \qquad h = \frac{\big((m+2)p - (m+1)q\big)^2 - 1}{4(m+1)(m+2)}, \tag{11.185}$$

with $m = 1, 2, 3, \ldots$, $p = 1, \ldots, m$, $q = 1, \ldots, p$. For each m the list of h is finite. The corresponding CFTs are the **unitary minimal models**.

Physical picture: Why a discrete list

Each level adds more Kac curves $h_{r,s}(c)$. Between the curves the Gram determinant changes sign. Below $c = 1$ the curves accumulate, and at a generic point some level already has a negative-norm state. Only at the special points where many curves cross simultaneously do all the determinants stay non-negative. These are the points (11.185). Above $c = 1$ the curves have complex h and no longer cut the positive quadrant, so every $h \ge 0$ is allowed.

Worked example 11.66: Nash's footnote 4: $m = 2$ is the Ising model

For $m = 2$: $c = 1 - \frac{6}{3\cdot 4} = \frac{1}{2}$, and $4(m+1)(m+2) = 48$, so $h = \big((4p-3q)^2 - 1\big)/48$ with $1 \le q \le p \le 2$:

$$\begin{aligned}(p,q) = (1,1): &\quad h \overset{(1)}{=} \tfrac{(4-3)^2-1}{48} = 0,\\ (p,q) = (2,1): &\quad h = \tfrac{(8-3)^2-1}{48} = \tfrac{24}{48} = \tfrac{1}{2},\\ (p,q) = (2,2): &\quad h = \tfrac{(8-6)^2-1}{48} = \tfrac{3}{48} = \tfrac{1}{16}.\end{aligned}$$

(1) Substitute into (11.185); the other two lines are the same substitution.

Exactly three weights: $0, \frac{1}{2}, \frac{1}{16}$. This is Nash's claim.

Worked example 11.67: The next model: $m = 3$, the tricritical Ising model

For $m = 3$: $c = 1 - \frac{6}{20} = \frac{7}{10}$, and $h = \big((5p-4q)^2 - 1\big)/80$:

(p,q)	$(1,1)$	$(2,1)$	$(2,2)$	$(3,1)$	$(3,2)$	$(3,3)$
$(5p-4q)^2-1$	0	35	3	120	48	8
h	0	$\frac{7}{16}$	$\frac{3}{80}$	$\frac{3}{2}$	$\frac{3}{5}$	$\frac{1}{10}$

Six primaries. The level-2 ones, $h_{\pm}(\frac{7}{10}) = \frac{7}{16}, \frac{1}{10}$, lie on the curves of Figure 11.34. This theory describes the Ising model with vacancies at its tricritical point, and it is also the simplest superconformal minimal model. In general the m-th model has $m(m+1)/2$ primaries.

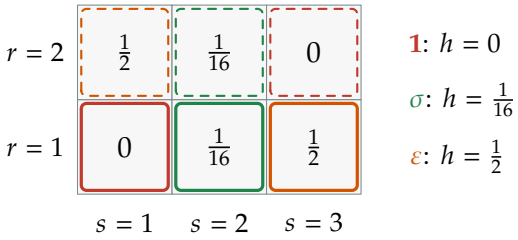

Figure 11.36: The Kac table of the Ising model in the modern labelling $h_{r,s} = \big((4r-3s)^2-1\big)/48$, $1 \le r \le 2$, $1 \le s \le 3$. The table is symmetric under $(r,s) \mapsto (3-r, 4-s)$ (a rotation by 180°), so each weight appears twice; boxes of the same colour are the same field. What to see: six entries, three distinct primaries. Nash's labels (p,q) with $q \le p$ pick one representative of each pair.

Watch out: Two labellings of the Kac table

Nash writes the weights with (p,q), $1 \le q \le p \le m$. Most CFT texts write $h_{r,s} = \frac{(r(m+2)-s(m+1))^2-1}{4(m+1)(m+2)}$ with $1 \le r \le m$, $1 \le s \le m+1$, and identify $h_{r,s} = h_{m+1-r,\,m+2-s}$. Both give the same list. In the modern labels, $\sigma = \phi_{1,2} = \phi_{2,2}$ and $\varepsilon = \phi_{2,1} = \phi_{1,3}$. The null vector of $\phi_{r,s}$ appears at level rs, which is why σ and ε both have level-2 null vectors.

Matching the lattice

Which lattice quantities are these three fields? The lattice model has a global $\mathbb{Z}_2$ symmetry $s_i \mapsto -s_i$. The identity $\mathbf{1}$ and the energy density ε are even; the spin σ is odd. A scalar primary

of weight (h, h) has dimension $\Delta = 2h$, so

$$\Delta_{\mathbf{1}} = 0, \qquad \Delta_\sigma = \tfrac{1}{8}, \qquad \Delta_\varepsilon = 1,$$

which are exactly the values that reproduced Onsager's exponents in Section 11.5.5. The most relevant $\mathbb{Z}_2$-odd operator is the spin, and the most relevant nontrivial $\mathbb{Z}_2$-even operator is the energy. Nothing else is needed: the critical Ising model *is* the $m = 2$ minimal model, with the diagonal combination $(h, \bar{h}) = (h, h)$ of left and right weights.

Watch out: There is a fourth lattice field with $h = \frac{1}{16}$

Kramers–Wannier duality maps σ to the **disorder operator** μ, which creates a domain-wall line ending at a point. It has the same weights $(\frac{1}{16}, \frac{1}{16})$ but is not local with respect to σ: taking one around the other gives a sign. It does not appear as a separate primary in the partition function below, which counts only fields local with respect to the spin. Nash's list of three is the list for the spin (order) description.

11.6.3 The Ising model is a free Majorana fermion

Abstract representation theory tells us which weights occur. A concrete model tells us what the states *are*. Onsager's solution, as reformulated by Kaufman and by Schultz, Mattis and Lieb, shows that the transfer matrix of the Ising model is the exponential of a quadratic form in fermions. At the critical point these fermions become massless. So the critical Ising model is the theory of one free Majorana fermion, the example of [Nash p. 303, (11.5)–(11.6)].

In part 11a we met this fermion. Its holomorphic component $\psi(z)$ has weight $(\frac{1}{2}, 0)$ and two-point function $\langle \psi(z)\psi(w)\rangle = 1/(z-w)$. Its energy–momentum tensor $T = -\frac{1}{2}\psi\partial\psi$ has central charge $c = \frac{1}{2}$. The antiholomorphic partner $\bar{\psi}(\bar{z})$ has weight $(0, \frac{1}{2})$. The product

$$\varepsilon(z, \bar{z}) = i\,\psi(z)\bar{\psi}(\bar{z}) \tag{11.186}$$

has weight $(\frac{1}{2}, \frac{1}{2})$: it is the energy field. (It is the mass term $im\psi\bar{\psi}$ of the fermion action. Moving off T_c gives the fermion a mass proportional to t, which is (11.172) with $g_t \propto t$.)

Modes and the two sectors

On the plane expand

$$\psi(z) = \sum_r \psi_r\, z^{-r-1/2}, \qquad \{\psi_r, \psi_s\} = \delta_{r+s,0}. \tag{11.187}$$

The exponent $-r - \frac{1}{2}$ is the usual $-r - h$ with $h = \frac{1}{2}$, so that ψ_r lowers L_0 by r. There are two consistent choices of the mode labels:

- **Neveu–Schwarz (NS)** sector: $r \in \mathbb{Z} + \frac{1}{2}$. Then $\psi(z)$ is single valued on the plane.
- **Ramond (R)** sector: $r \in \mathbb{Z}$. Then $\psi(z)$ changes sign when z goes once around the origin: $z^{-r-1/2}$ picks up $e^{-2\pi i(r+1/2)} = -1$.

The origin of the plane is the far past of a cylinder. Map $z = e^w$, $w = \tau_E + i\theta$, with $\theta \sim \theta + 2\pi$. A weight-$\frac{1}{2}$ field transforms with $(\mathrm{d}z/\mathrm{d}w)^{1/2} = z^{1/2}$:

$$\psi_{\mathrm{cyl}}(w) \overset{(1)}{=} \left(\frac{\mathrm{d}z}{\mathrm{d}w}\right)^{1/2} \psi(z) \overset{(2)}{=} \sum_r \psi_r\, z^{-r} \overset{(3)}{=} \sum_r \psi_r\, e^{-r\tau_E}\, e^{-ir\theta}.$$

(1) Primary-field transformation law with $h = \frac{1}{2}$.
(2) $z^{1/2} \cdot z^{-r-1/2} = z^{-r}$.
(3) $z = e^{\tau_E + i\theta}$.

So on the cylinder the roles swap: NS fermions ($r \in \mathbb{Z} + \frac{1}{2}$) are *antiperiodic* in θ, and R fermions ($r \in \mathbb{Z}$) are *periodic*. These are the two spin structures on a circle (Chapter T4). Figure 11.37 shows both pictures.

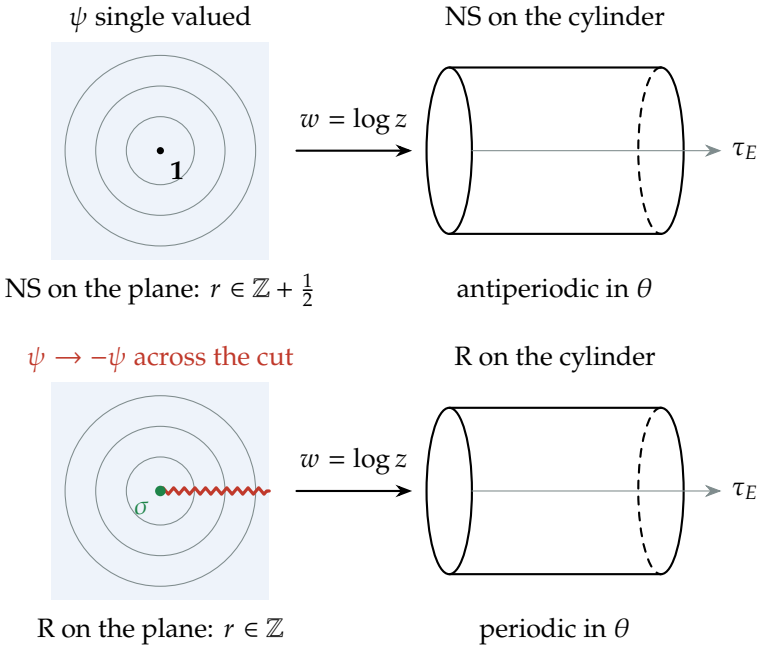

Figure 11.37: The two sectors of the Majorana fermion, one per row. On the plane (left column) the NS fermion is single valued, and the state at the origin is the vacuum; the R fermion changes sign around the origin, so a branch cut (zigzag) must end on an operator there, the spin field σ. Under $z = e^w$ (right column) the plane becomes a cylinder and the boundary conditions around the circle swap: NS is antiperiodic, R is periodic. What to see: inserting σ is the same as changing the spin structure around the insertion point.

The NS sector contains 1 and ε

The NS vacuum $|0\rangle$ obeys $\psi_r|0\rangle = 0$ for $r > 0$. States are created by ψ_{-r}, $r = \frac{1}{2}, \frac{3}{2}, \ldots$. Each can be used at most once, because $\psi_{-r}^2 = \frac{1}{2}\{\psi_{-r}, \psi_{-r}\} = 0$. A state $\psi_{-r_1} \cdots \psi_{-r_k}|0\rangle$ with $r_1 > \cdots > r_k > 0$ has $L_0 = r_1 + \cdots + r_k$. The fermion number $(-1)^F$ splits the NS space into an even part (containing $|0\rangle$) and an odd part (containing $\psi_{-1/2}|0\rangle$, with $L_0 = \frac{1}{2}$). Since T is bilinear in ψ, the Virasoro generators preserve $(-1)^F$, so each part is a Virasoro representation:

L_0	even states (**1** module)	odd states (ε module)
0	$\|0\rangle$	
$\frac{1}{2}$		$\psi_{-1/2}\|0\rangle$
$\frac{3}{2}$		$\psi_{-3/2}\|0\rangle$
2	$\psi_{-3/2}\psi_{-1/2}\|0\rangle$	
$\frac{5}{2}$		$\psi_{-5/2}\|0\rangle$
3	$\psi_{-5/2}\psi_{-1/2}\|0\rangle$	
$\frac{7}{2}$		$\psi_{-7/2}\|0\rangle$
4	$\psi_{-7/2}\psi_{-1/2}\|0\rangle,\ \psi_{-5/2}\psi_{-3/2}\|0\rangle$	
$\frac{9}{2}$		$\psi_{-9/2}\|0\rangle,\ \psi_{-5/2}\psi_{-3/2}\psi_{-1/2}\|0\rangle$

Compare the Virasoro count. In the vacuum module, level 1 is empty ($L_{-1}|0\rangle = 0$), level 2 has only $L_{-2}|0\rangle$, level 3 only $L_{-3}|0\rangle$, level 4 has $L_{-4}|0\rangle$ and $L_{-2}^2|0\rangle$. That is $1, 0, 1, 1, 2$: the even column. In the ε module, levels $0, 1, 2, 3, 4$ above $h = \frac{1}{2}$ contain $1, 1, 1, 1, 2$ states. A generic Verma module would have $1, 1, 2, 3, 5$; the null vector $(L_{-2} - \frac{3}{4}L_{-1}^2)|\varepsilon\rangle$ of (11.182) removes one state at level 2, and a second null vector at level 3 (the $rs = 1 \cdot 3$ one of $\phi_{1,3}$) removes more. The fermion does the bookkeeping for us.

The R sector contains σ

In the Ramond sector there is a zero mode ψ_0 with $\psi_0^2 = \frac{1}{2}$. The ground state $|\sigma\rangle$ obeys $\psi_n|\sigma\rangle = 0$ for $n > 0$. Its weight is the conformal weight of the operator that sits at the end of the branch cut in Figure 11.37. We can compute it exactly.

Worked example 11.68: $h_\sigma = \frac{1}{16}$ from the Ramond propagator

Step 1: the propagator in the R ground state. Only $\langle\psi_n\psi_{-n}\rangle$ with $n \geq 0$ survive, with $\langle\psi_n\psi_{-n}\rangle = \{\psi_n, \psi_{-n}\} = 1$ for $n > 0$ and $\langle\psi_0\psi_0\rangle = \frac{1}{2}$. So, for $|w| < |z|$,

$$\begin{aligned}\langle\sigma|\psi(z)\psi(w)|\sigma\rangle &\overset{(1)}{=} \sum_{n\geq 0}\langle\psi_n\psi_{-n}\rangle\, z^{-n-1/2}w^{n-1/2} \\ &\overset{(2)}{=} (zw)^{-1/2}\Big(\tfrac{1}{2} + \sum_{n\geq 1}\big(\tfrac{w}{z}\big)^n\Big) \overset{(3)}{=} (zw)^{-1/2}\,\frac{z+w}{2(z-w)} \\ &= \frac{\sqrt{z/w} + \sqrt{w/z}}{2\,(z-w)}.\end{aligned}$$

(1) Insert the mode expansion (11.187) with $r \in \mathbb{Z}$; $\psi_n|\sigma\rangle = 0$ for $n > 0$ kills all other terms.
(2) Pull out $(zw)^{-1/2}$; the $n = 0$ term gives $\frac{1}{2}$.
(3) Geometric series: $\frac{1}{2} + \frac{w/z}{1-w/z} = \frac{1}{2} + \frac{w}{z-w} = \frac{z+w}{2(z-w)}$.

(The same computation in the NS sector, $r \in \mathbb{Z} + \frac{1}{2}$, gives exactly $1/(z-w)$.)

Step 2: expand near $z = w$. Put $z = w(1+u)$:

$$\frac{\sqrt{z/w} + \sqrt{w/z}}{2} \overset{(1)}{=} \frac{2+u}{2\sqrt{1+u}} \overset{(2)}{=} \big(1 + \tfrac{u}{2}\big)\big(1 - \tfrac{u}{2} + \tfrac{3u^2}{8} + O(u^3)\big) = 1 + \frac{u^2}{8} + O(u^3).$$

(1) $\sqrt{1+u} + 1/\sqrt{1+u} = (2+u)/\sqrt{1+u}$.

(2) Binomial series $(1+u)^{-1/2} = 1 - \frac{u}{2} + \frac{3}{8}u^2 - \cdots$.

With $z - w = wu$ the propagator is $\frac{1}{z-w} + \frac{z-w}{8w^2} + O\big((z-w)^2\big)$.

Step 3: the expectation value of T. Normal ordering subtracts the singular part $1/(z-w)$, so

$$\langle\sigma|{:}\psi(w)\partial\psi(w){:}|\sigma\rangle \overset{(1)}{=} \lim_{z\to w} \partial_w\Big(\frac{z-w}{8w^2}\Big) = -\frac{1}{8w^2},$$
$$\langle\sigma|T(w)|\sigma\rangle \overset{(2)}{=} -\tfrac{1}{2}\Big(-\frac{1}{8w^2}\Big) = \frac{1}{16\,w^2}.$$

(1) $\langle\psi(z)\partial_w\psi(w)\rangle = \partial_w$ of the propagator; the regular part's derivative at $z = w$ is $-1/(8w^2)$ (the other terms vanish as $z \to w$).

(2) $T = -\frac{1}{2}{:}\psi\partial\psi{:}$.

Step 4: read off h. For any highest-weight state, $\langle h|T(w)|h\rangle = \sum_n w^{-n-2}\langle h|L_n|h\rangle = h/w^2$, because only L_0 has a diagonal matrix element. Comparing: $h_\sigma = \frac{1}{16}$.

Physical picture: Zero-point energies

The same number comes out of the Casimir energy. Each fermion mode of frequency ω contributes $-\omega/2$ to the ground-state energy. On the unit circle, NS modes have $\omega = r \in \mathbb{N} - \frac{1}{2}$ and R modes have $\omega = n \in \mathbb{N}$. With zeta-function regularisation, $\sum_{n\geq 1} n = -\frac{1}{12}$ and $\sum_{r\in\mathbb{N}-1/2} r = \frac{1}{24}$. So $E_{\mathrm{NS}} = -\frac{1}{48}$ and $E_{\mathrm{R}} = +\frac{1}{24}$. The first is $-c/24$ for $c = \frac{1}{2}$ (the vacuum Casimir energy); the difference is $E_{\mathrm{R}} - E_{\mathrm{NS}} = \frac{1}{24} + \frac{1}{48} = \frac{1}{16} = h_\sigma$.

Above $|\sigma\rangle$ the R states are $\psi_{-n_1}\cdots\psi_{-n_k}|\sigma\rangle$ with $n_1 > \cdots > n_k \geq 1$. Their counting at levels $0, 1, 2, 3, 4$ is $1, 1, 1, 2, 2$ (for level 3: ψ_{-3} and $\psi_{-2}\psi_{-1}$). The zero mode ψ_0 maps the R ground state to a state of the same weight; for a single Majorana fermion the two can be identified up to the choice of $(-1)^F$, a subtlety that shows up as the factor $\sqrt{2}$ in (11.204) below.

Dictionary: Ising model ↔ free Majorana fermion

identity $\mathbf{1}$, $h = 0$	NS states with $(-1)^F = +1$
energy ε, $h = \frac{1}{2}$	NS states with $(-1)^F = -1$; $\varepsilon = i\psi\bar{\psi}$
spin σ, $h = \frac{1}{16}$	R ground state; end point of a branch cut
$T \neq T_c$	mass $m \propto t$ for the fermion
$c = \frac{1}{2}$	one real fermion (half a complex one)
periodic/antiperiodic on the torus	the four spin structures (Section 11.7)

Reading Nash (p. 311–312, (11.49)–(11.50) and footnote 4)

Nash asserts $c = \frac{1}{2}$ and the three weights and cites (6.58). We have checked (6.58) at $m = 2$, and derived the same weights independently from the level-2 Gram determinant (11.178) and from the fermion (11.187). Nash's weights are the pairs $(h, \bar{h})$; the Ising model uses only the diagonal pairs (h, h), which will be the content of his formula (11.50).

Recap

- Unitarity is positivity of the Gram matrices. At level 2, $\det G^{(2)} = 2h(16h^2 + 2(c-5)h + c)$.

- At $c = \frac{1}{2}$ its roots are $h = 0, \frac{1}{16}, \frac{1}{2}$; the null vectors are $(L_{-2} - \frac{4}{3}L_{-1}^2)|\sigma\rangle$ and $(L_{-2} - \frac{3}{4}L_{-1}^2)|\varepsilon\rangle$.
- The Kac formula (6.58) at $m = 2$ gives the same list; $m = 3$ is the tricritical Ising model with six primaries.
- The Ising model is a free Majorana fermion. The NS sector splits into the **1** and ε modules by $(-1)^F$; the R sector is the σ module, with $h_\sigma = \frac{1}{16}$ computed from the Ramond propagator.

11.7 Partition functions on the torus

We now have a CFT, the $c = \frac{1}{2}$ theory with three primaries, and a lattice model that it describes. Nash's §4 asks a global question about it. Put the critical Ising model on a periodic lattice. Its partition function is a single number for each lattice shape. What does that number depend on, and what symmetry must it have?

The answer has three parts, and this section derives each one.

1. In the continuum limit, a periodic lattice is a flat torus, and a CFT only sees its *shape*: one complex number τ with $\operatorname{Im}\tau > 0$, the **modular parameter**.
2. Different τ can describe the same torus. They are related by $\tau \mapsto (a\tau + b)/(c\tau + d)$ with integer entries and $ad - bc = 1$: Nash's (11.48). So $Z(\tau)$ must be invariant under this **modular group**.
3. Computing Z in the operator language gives a trace over the Hilbert space, which organises itself into a sum of products of Virasoro characters: Nash's (11.49). For Ising it is (11.50).

11.7.1 A torus is a lattice in the complex plane

Take two complex numbers ω_1, ω_2 that are not real multiples of each other. They generate a lattice

$$\Lambda = \{\, m\omega_1 + n\omega_2 : m, n \in \mathbb{Z} \,\} \subset \mathbb{C}, \tag{11.188}$$

and the quotient $\mathbb{C}/\Lambda$ (identify $z \sim z + \omega_1 \sim z + \omega_2$) is a torus. It inherits the flat metric $|\mathrm{d}z|^2$ and, more importantly for us, the complex coordinate z up to translations: it is a Riemann surface of genus one. The fundamental parallelogram with corners $0, \omega_1, \omega_2, \omega_1 + \omega_2$ is one copy of the torus (Figure 11.38).

The Ising lattice of Figure 11.29 with L columns and L' rows, in units of the lattice spacing, is $\omega_1 = L$, $\omega_2 = iL'$. If we glue the top edge to the bottom edge with a shift by s columns (a "helical" boundary condition), $\omega_2 = s + iL'$.

A CFT cannot tell apart two tori related by a conformal map. The map $z \mapsto z/\omega_1$ is conformal: a rotation and a dilation. It takes Λ to the lattice generated by 1 and

$$\tau = \frac{\omega_2}{\omega_1}. \tag{11.189}$$

We order the generators so that $\operatorname{Im}\tau > 0$ (swap them if necessary). So the conformal class of the torus is fixed by the single number τ in the upper half plane $\mathbb{H}$.

Working definition 11.24 (modular parameter)

For a torus $\mathbb{C}/(\mathbb{Z}\omega_1 + \mathbb{Z}\omega_2)$ [the plane with z, $z+\omega_1$ and $z+\omega_2$ counted as the same point], the **modular parameter** is $\tau = \omega_2/\omega_1$ with the labelling chosen so that $\operatorname{Im}\tau > 0$. *How to read it:* rescale and rotate so that one period is 1; the other period is τ. For an $L \times L'$ rectangular lattice $\tau = iL'/L$; a twist by s sites [top edge glued to bottom edge after a shift by s columns] adds s/L to $\operatorname{Re}\tau$.

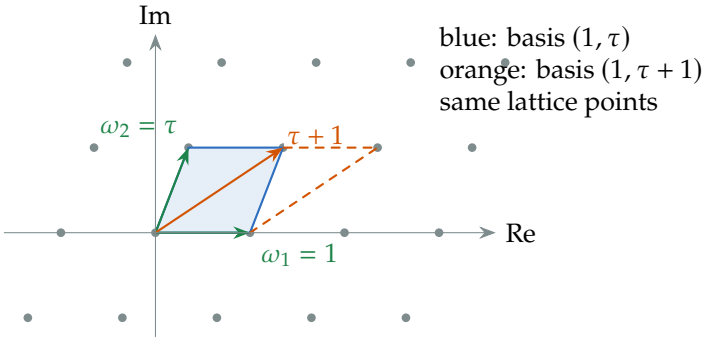

Figure 11.38: A torus is the plane modulo a lattice. The blue parallelogram, spanned by 1 and τ, is one fundamental domain. The orange one, spanned by 1 and $\tau+1$, contains the same area and tiles the plane with the *same* lattice points. What to see: τ and $\tau+1$ describe the same torus; this is the generator T of the modular group.

11.7.2 The modular group

The lattice Λ does not determine its generators. Any other pair

$$\begin{pmatrix}\omega_2'\\ \omega_1'\end{pmatrix} = \begin{pmatrix}a & b\\ c & d\end{pmatrix}\begin{pmatrix}\omega_2\\ \omega_1\end{pmatrix}, \qquad a,b,c,d \in \mathbb{Z}, \tag{11.190}$$

generates a sublattice of Λ. It generates all of Λ exactly when the matrix can be inverted *with integer entries*, which means $ad - bc = \pm 1$ (the inverse matrix has $1/(ad-bc)$ in front). Then the new modular parameter is

$$\tau' \overset{(1)}{=} \frac{\omega_2'}{\omega_1'} \overset{(2)}{=} \frac{a\omega_2 + b\omega_1}{c\omega_2 + d\omega_1} \overset{(3)}{=} \frac{a\tau + b}{c\tau + d}. \tag{11.191}$$

(1) Definition (11.189) in the new basis.
(2) The basis change (11.190).
(3) Divide numerator and denominator by ω_1.

This is Nash's (11.48). The sign of the determinant is fixed by the upper half plane:

$$\operatorname{Im}\frac{a\tau+b}{c\tau+d} \overset{(1)}{=} \operatorname{Im}\frac{(a\tau+b)(c\bar\tau+d)}{|c\tau+d|^2} \overset{(2)}{=} \frac{\operatorname{Im}\left(ad\,\tau + bc\,\bar\tau\right)}{|c\tau+d|^2} \overset{(3)}{=} \frac{(ad-bc)\operatorname{Im}\tau}{|c\tau+d|^2}.$$

(1) Multiply top and bottom by the complex conjugate of the denominator.
(2) The numerator is $ac|\tau|^2 + ad\,\tau + bc\,\bar\tau + bd$; the first and last terms are real.
(3) $\operatorname{Im}\bar\tau = -\operatorname{Im}\tau$.

So $\operatorname{Im}\tau' > 0$ requires $ad - bc = +1$: the basis change must preserve orientation. The matrices form $\mathrm{SL}(2,\mathbb{Z})$. Finally M and $-M$ give the same τ', so the group that acts on $\mathbb{H}$ is

$$\mathrm{PSL}(2,\mathbb{Z}) = \mathrm{SL}(2,\mathbb{Z})/\{\pm I\}, \tag{11.192}$$

which is Nash's $\mathrm{SL}(2,\mathbb{Z})/\{\mp I\}$. Composition of the maps is matrix multiplication, exactly as for Möbius maps (Section 11.5.1): $\mathrm{SL}(2,\mathbb{Z})$ is the subgroup of $\mathrm{SL}(2,\mathbb{C})$ with integer entries.

Working definition 11.25 (the generators S and T)

$$T = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} : \ \tau \mapsto \tau + 1, \qquad S = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} : \ \tau \mapsto -\frac{1}{\tau}.$$

Every element of $\mathrm{PSL}(2,\mathbb{Z})$ [a change of period basis, acting as $\tau \mapsto \frac{a\tau+b}{c\tau+d}$ with integers a,b,c,d and $ad-bc=1$] is a product of S's and T's. *Consequence (Nash's (11.51)):* to show that a function $Z(\tau)$ is modular invariant [unchanged under every such change of basis, so it depends only on the torus and not on the chosen periods] it suffices to check $Z(\tau+1) = Z(\tau)$ and $Z(-1/\tau) = Z(\tau)$.

Geometrically (Figure 11.39): T keeps the cycle a (along ω_1) and replaces the cycle b by $b + a$. This is a **Dehn twist**: cut the torus along a, rotate one edge by a full turn, and glue back. S exchanges the two cycles (with an orientation flip), which for a rectangular torus $\tau = i\beta$ exchanges space and time: $-1/(i\beta) = i/\beta$.

Worked example 11.69: The relations $S^2 = (ST)^3 = 1$

Multiply the matrices:

$$S^2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix} = -I,$$

$$ST \overset{(1)}{=} \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix},$$

$$(ST)^2 = \begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix}\begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix}, \qquad (ST)^3 = \begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix} = -I.$$

(1) ST means "first T, then S" as maps: $\tau \mapsto \tau+1 \mapsto -1/(\tau+1)$, which is indeed $(0\cdot\tau - 1)/(\tau+1)$.

In $\mathrm{PSL}(2,\mathbb{Z})$, $-I$ is the identity, so $S^2 = (ST)^3 = 1$. These are the only relations: $\mathrm{PSL}(2,\mathbb{Z})$ is the free product $\mathbb{Z}_2 * \mathbb{Z}_3$. Check on a point: ST sends $\tau = e^{2\pi i/3} \mapsto -1/(e^{2\pi i/3}+1) = -1/e^{i\pi/3} = e^{2\pi i/3}$, a fixed point of order 3; S fixes $\tau = i$.

Worked example 11.70: Writing a modular transformation as a word in S and T

Take $M = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, $\tau \mapsto (2\tau+1)/(\tau+1)$. The algorithm is Euclid's: use $T^{\pm 1}$ to reduce $|a|$ against $|c|$, and S to swap them.

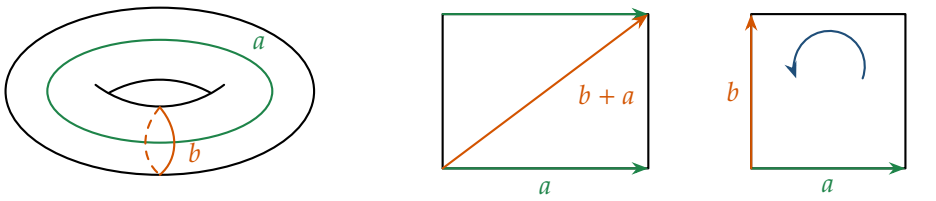
$$T^{-1}M \overset{(1)}{=} \begin{pmatrix} 1 & -1 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix},$$

$$S\,T^{-1}M \overset{(2)}{=} \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix} = (ST)^2.$$

(1) Subtract row 2 from row 1: $a \to a - c$.

(2) Swap the rows (with a sign).

So $M = T\,S^{-1}(ST)^2 = T\,S^{-1}STST = T^2ST$ (using $S^{-1} = S$ in PSL and cancelling). Check on the map: $\tau \overset{T}{\mapsto} \tau+1 \overset{S}{\mapsto} -\frac{1}{\tau+1} \overset{T^2}{\mapsto} 2 - \frac{1}{\tau+1} = \frac{2\tau+1}{\tau+1}$. ✓



cycles a (ω_1) and b (ω_2) T: $b \mapsto b + a$ (Dehn twist) S: $(a, b) \mapsto (b, -a)$

Figure 11.39: The two generators of the modular group acting on the cycles of the torus. T cuts along a and re-glues with a full twist, so the new b cycle is the old $b + a$; S rotates the fundamental square by 90°, exchanging the cycles. What to see: neither changes the torus itself, only our choice of cycles. For a rectangular torus, S exchanges the "space" and "time" directions.

The fundamental domain

Every $\tau \in \mathbb{H}$ can be moved by $\mathrm{PSL}(2,\mathbb{Z})$ into

$$\mathcal{F} = \left\{\tau \in \mathbb{H} : \ |\mathrm{Re}\,\tau| \le \tfrac{1}{2},\ |\tau| \ge 1\right\}, \tag{11.193}$$

and two interior points of $\mathcal{F}$ are never related. The reason is a one-line calculation: $\mathrm{Im}(M\tau) = \mathrm{Im}\,\tau/|c\tau + d|^2$, and only finitely many pairs (c, d) make $|c\tau + d| < 1$. So in any orbit there is a point of maximal $\mathrm{Im}\,\tau$. Translate it by T^n into the strip $|\mathrm{Re}\,\tau| \le \frac{1}{2}$. If it had $|\tau| < 1$, then S would raise its imaginary part to $\mathrm{Im}\,\tau/|\tau|^2$, contradicting maximality. So $\mathcal{F}$ is the **moduli space of tori**: each conformal class of torus appears once. It is the genus-one case of the moduli spaces $\mathcal{M}_p$ that come back in Section 11.11.

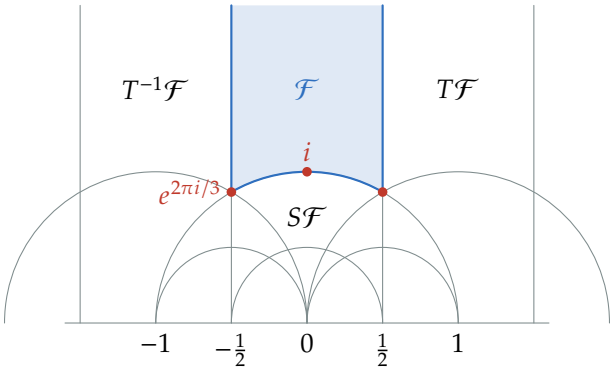


Figure 11.40: The fundamental domain $\mathcal{F}$ of $\mathrm{PSL}(2,\mathbb{Z})$ (blue) and some of its images: $T^{\pm 1}\mathcal{F}$ beside it and $S\mathcal{F}$ inside the unit circle. The vertical edges are glued by T, the arc to itself by S ($\tau \mapsto -\bar{\tau}$ on it). The red points are the orbifold points $\tau = i$ (fixed by S) and $\tau = e^{2\pi i/3}$ (fixed by ST). What to see: $\mathcal{F}$ is the space of shapes of tori; a modular invariant $Z(\tau)$ is really a function on $\mathcal{F}$.

Watch out: The modular group is not a symmetry of the lattice model

For a finite lattice, $\tau = iL'/L$ and $\tau \mapsto -1/\tau$ just means "turn the page by 90°", a trivial symmetry. The nontrivial content of modular invariance appears only when we write Z in the operator language, where the two cycles play very different roles (space and Euclidean time). Then $Z(-1/\tau) = Z(\tau)$ says that the spectrum of the Hamiltonian on a circle of length L determines, and is determined by, the spectrum on a circle of length L'. That is a strong constraint on the spectrum.

11.7.3 The Hamiltonian on a circle

To write Z as a trace we need the Hamiltonian of the CFT on a spatial circle of length L. Take the infinite cylinder with coordinate $w = t + ix$, $x \sim x + L$, $t \in \mathbb{R}$ Euclidean time, and map it to the plane by

$$z = e^{2\pi w/L}. \tag{11.194}$$

The far past $t \to -\infty$ is the origin $z = 0$, where the in-state sits in radial quantisation (§3). Circles of constant t are circles $|z| = e^{2\pi t/L}$. So time translation $t \mapsto t + \delta t$ is the dilation $z \mapsto e^{2\pi\delta t/L} z$, generated by $L_0 + \bar{L}_0$; translation in x is the rotation $z \mapsto e^{2\pi i \delta x/L} z$, generated by $L_0 - \bar{L}_0$.

The constant term comes from the Schwarzian. Apply the transformation law (11.161) with the cylinder coordinate w in the role of z and the plane coordinate z in the role of z'. With $k = 2\pi/L$ we have $z' = kz$, $z'' = k^2 z$, $z''' = k^3 z$ (primes are $\mathrm{d}/\mathrm{d}w$), so

$$\begin{aligned} T_{\mathrm{cyl}}(w) &\overset{(1)}{=} \left(\frac{\mathrm{d}z}{\mathrm{d}w}\right)^2 T(z) + \frac{c}{12}\{z, w\} \overset{(2)}{=} k^2 z^2 T(z) + \frac{c}{12}\left(k^2 - \tfrac{3}{2}k^2\right) \\ &\overset{(3)}{=} \left(\frac{2\pi}{L}\right)^2 \Big(\sum_{n\in\mathbb{Z}} L_n z^{-n} - \frac{c}{24}\Big). \end{aligned} \tag{11.195}$$

(1) Transformation law of T, [Nash p. 307, (11.31)].
(2) $\{z, w\} = z'''/z' - \frac{3}{2}(z''/z')^2 = k^2 - \frac{3}{2}k^2 = -\frac{1}{2}k^2$.
(3) Mode expansion $T(z) = \sum_n L_n z^{-n-2}$, so $z^2 T(z) = \sum_n L_n z^{-n}$.

The Hamiltonian is $H = \frac{1}{2\pi}\int_0^L \mathrm{d}x\, \big(T_{\mathrm{cyl}} + \bar{T}_{\mathrm{cyl}}\big)$ at fixed t (this normalisation is the one for which H generates unit time translations, as the next line confirms), and the momentum is $P = \frac{1}{2\pi}\int_0^L \mathrm{d}x\, (T_{\mathrm{cyl}} - \bar{T}_{\mathrm{cyl}})$ up to a factor i. Since $z^{-n} = e^{-2\pi n(t+ix)/L}$, the x-integral kills every $n \neq 0$:

$$\begin{aligned} H &\overset{(1)}{=} \frac{1}{2\pi} L \left(\frac{2\pi}{L}\right)^2 \Big(L_0 - \frac{c}{24} + \bar{L}_0 - \frac{c}{24}\Big) = \frac{2\pi}{L}\Big(L_0 + \bar{L}_0 - \frac{c}{12}\Big), \\ P &= \frac{2\pi}{L}\big(L_0 - \bar{L}_0\big). \end{aligned} \tag{11.196}$$

(1) $\int_0^L \mathrm{d}x\, e^{-2\pi i n x/L} = L\,\delta_{n,0}$; the same for the antiholomorphic half with $\bar{c} = c$.

Worked example 11.71: The Casimir energy measures c

The ground state is the vacuum, $L_0 = \bar{L}_0 = 0$. Its energy on a circle of length L is

$$E_0(L) = -\frac{2\pi}{L}\,\frac{c}{12} = -\frac{\pi c}{6L}. \tag{11.197}$$

This is a Casimir energy: it exists only because the circle is finite, and it is negative. On a lattice (or for the quantum Ising chain, whose transfer matrix is the lattice Hamiltonian) one measures $E_0(L) = e_\infty L - \pi c\, v/(6L) + \dots$, where e_∞ is a non-universal energy density and v the "speed of light" of the chain. Fitting the $1/L$ term gives c. Numerically this gives $c = 0.500$ for the Ising chain, $c = 0.700$ for the tricritical Ising chain and $c = 0.800$ for the three-state Potts chain (Blöte, Cardy, Nightingale; Affleck, 1986). The excited states give the weights: $E_i - E_0 = \frac{2\pi v}{L}(h_i + \bar{h}_i + N + \bar{N})$, a tower above each primary. So the entire operator content of §5 is visible in the spectrum of a finite chain. For the free Majorana fermion on a circle of length $L = 2\pi$, the zero-point sums of the intuition box in Section 11.6.3 gave $E_{\mathrm{NS}} = -\frac{1}{48}$ per chirality, i.e. total $-\frac{1}{24} = -c/12$ with $c = \frac{1}{2}$: the same answer.

11.7.4 The torus partition function as a trace

Now close the cylinder into a torus. Propagate for a Euclidean time t, translate in space by x, and identify the final circle with the initial one. The result is the torus with periods $\omega_1 = L$ (space) and $\omega_2 = x + it$, i.e.

$$\tau = \frac{x + it}{L}. \tag{11.198}$$

In quantum mechanics, "evolve and identify" is a trace. So the path integral on the torus is

$$\begin{aligned} Z(\tau) &\overset{(1)}{=} \operatorname{Tr}\, e^{-tH}\, e^{ixP} \\ &\overset{(2)}{=} \operatorname{Tr}\, \exp\!\left[-\frac{2\pi t}{L}\left(L_0 + \bar{L}_0 - \frac{c}{12}\right) + \frac{2\pi i x}{L}\left(L_0 - \bar{L}_0\right)\right] \\ &\overset{(3)}{=} \operatorname{Tr}\, \exp\!\left[2\pi i\tau\left(L_0 - \frac{c}{24}\right) - 2\pi i\bar{\tau}\left(\bar{L}_0 - \frac{c}{24}\right)\right] \\ &\overset{(4)}{=} \operatorname{Tr}\, q^{\,L_0 - c/24}\, \bar{q}^{\,\bar{L}_0 - c/24}, \qquad q = e^{2\pi i\tau}. \end{aligned} \tag{11.199}$$

(1) Periodic Euclidean time gives a trace (as $\operatorname{Tr} e^{-\beta H}$ in statistical mechanics); the spatial shift inserts the translation operator e^{ixP} before the trace closes.
(2) Insert (11.196).
(3) Collect the coefficient of L_0: $-2\pi t/L + 2\pi i x/L = 2\pi i(x + it)/L = 2\pi i\tau$; the coefficient of $\bar{L}_0$ is its complex conjugate $-2\pi i\bar{\tau}$. The constants: $-\frac{2\pi t}{L}\cdot(-\frac{c}{12}) = 2\pi \operatorname{Im}\tau\, \frac{c}{12}$, and $2\pi i\tau(-\frac{c}{24}) - 2\pi i\bar{\tau}(-\frac{c}{24}) = 2\pi \operatorname{Im}\tau\, \frac{c}{12}$ too.
(4) Write the exponentials as powers of q and $\bar{q} = e^{-2\pi i\bar{\tau}}$.

Here $\bar{q}$ is the complex conjugate of q, so $|q| = e^{-2\pi \operatorname{Im}\tau} < 1$ and the trace converges. The $-c/24$ shifts are the Casimir energy: they are exactly what makes Z modular invariant, as we will see.

Watch out: Lattice versus continuum partition function

The lattice Z at T_c is $e^{-f_\infty A}\, Z_{\mathrm{CFT}}(\tau)\,(1 + \dots)$, where $A = LL'$ is the area, f_∞ a non-universal bulk free energy, and the dots are corrections that vanish as the lattice spacing goes to zero. Only the universal factor $Z_{\mathrm{CFT}}(\tau)$ is modular invariant and depends only on τ. It is what Nash calls Z.

Characters

The Hilbert space of a CFT is a sum of products of irreducible representations of the two Virasoro algebras [Nash p. 311]:

$$\mathcal{H} = \bigoplus_{h,\bar{h}} m_{h,\bar{h}}\, L(c,h) \otimes \overline{L(c,\bar{h})}. \tag{11.200}$$

The trace (11.199) factorises on each summand, because L_0 acts only on the first factor and $\bar{L}_0$ only on the second. Each factor gives a **character**.

Working definition 11.26 (Virasoro character)

The character of the irreducible module $L(c,h)$ [the Verma module $V(c,h)$ with all its null vectors removed] is

$$\chi_h(\tau) = \operatorname{Tr}_{L(c,h)}\, q^{\,L_0 - c/24} = q^{\,h - c/24} \sum_{N \geq 0} d_N\, q^N,$$

where d_N is the number of independent states at level N [states with L_0 eigenvalue $h+N$]. *How to compute it:* count the states of the irreducible module level by level (the weight diagram of Figure 11.35) and put them into a power series.

Then

$$Z(\tau) \overset{(1)}{=} \sum_{h,\bar{h}} m_{h,\bar{h}} \, \mathrm{Tr}_{L(c,h)} \, q^{L_0 - c/24} \, \mathrm{Tr}_{\overline{L(c,\bar{h})}} \, \bar{q}^{\bar{L}_0 - c/24} \overset{(2)}{=} \sum_{h,\bar{h}} m_{h,\bar{h}} \, \chi_h(\tau) \, \bar{\chi}_{\bar{h}}(\bar{\tau}), \tag{11.201}$$

(1) The trace over a direct sum is the sum of traces; the trace over a tensor product of an operator $A \otimes B$ is $\mathrm{Tr}\, A \cdot \mathrm{Tr}\, B$.
(2) Definition of the character; the barred one is the complex conjugate function of τ.

which is Nash's (11.49). The multiplicities $m_{h,\bar{h}}$ are non-negative integers (they count copies of a representation), and $m_{0,0} = 1$ if the vacuum is unique.

Worked example 11.72: The Verma character and the partition generating function

For generic (c,h), $L(c,h) = V(c,h)$ has $p(N)$ states at level N, so

$$\chi_h^{\text{Verma}}(\tau) = q^{h-c/24} \sum_{N \geq 0} p(N) \, q^N \overset{(1)}{=} q^{h-c/24} \prod_{n=1}^{\infty} \frac{1}{1-q^n} \overset{(2)}{=} \frac{q^{\,h-(c-1)/24}}{\eta(\tau)}. \tag{11.202}$$

(1) Expand each factor: $\frac{1}{1-q^n} = \sum_{k_n \geq 0} q^{n k_n}$. A term of the product is a choice of $k_1, k_2, \ldots$, i.e. "use the part n exactly k_n times", and contributes $q^{\sum n k_n}$. So the coefficient of q^N counts partitions of N. (Equivalently: the state $L_{-1}^{k_1} L_{-2}^{k_2} \cdots |h\rangle$ is the partition with k_n parts equal to n.)
(2) Dedekind's function $\eta(\tau) = q^{1/24} \prod_n (1-q^n)$, Nash's (11.52), studied in the next section.

For the vacuum at generic c the only null state is $L_{-1}|0\rangle$ and its descendants, a Verma module starting at level 1, so $\chi_0 = q^{-c/24}(1-q)\prod_n (1-q^n)^{-1}$: the factor $(1-q)$ removes $p(N-1)$ states at level N.

Worked example 11.73: Spin must be an integer: T-invariance

Under $\tau \mapsto \tau + 1$, $q = e^{2\pi i \tau}$ is unchanged, but $q^{h-c/24}$ is multiplied by a phase:

$$\chi_h(\tau+1) \overset{(1)}{=} e^{2\pi i (h-c/24)} \, q^{h-c/24} \sum_N d_N q^N = e^{2\pi i (h-c/24)} \chi_h(\tau),$$

$$Z(\tau+1) \overset{(2)}{=} \sum_{h,\bar{h}} m_{h,\bar{h}} \, e^{2\pi i (h-c/24)} e^{-2\pi i (\bar{h}-c/24)} \chi_h(\tau) \bar{\chi}_{\bar{h}}(\bar{\tau}) = \sum_{h,\bar{h}} m_{h,\bar{h}} \, e^{2\pi i (h-\bar{h})} \chi_h \bar{\chi}_{\bar{h}}.$$

(1) $e^{2\pi i(\tau+1)a} = e^{2\pi i a} e^{2\pi i \tau a}$, and $e^{2\pi i N} = 1$ for integer levels N.
(2) Apply the first line to both factors; the antiholomorphic one gets the complex-conjugate phase.

So $Z(\tau+1) = Z(\tau)$ iff $h - \bar{h} \in \mathbb{Z}$ whenever $m_{h,\bar{h}} \neq 0$. The number $h - \bar{h}$ is the spin of the field (its eigenvalue under rotations, generated by $L_0 - \bar{L}_0$). T-invariance says: *every local field has integer spin*. It is the operator form of the statement that the Dehn twist of Figure 11.39 does nothing.

11.7.5 The Ising partition function

For the Ising model Nash writes

$$Z_{\text{Ising}} = \chi_0\bar{\chi}_0 + \chi_{1/2}\bar{\chi}_{1/2} + \chi_{1/16}\bar{\chi}_{1/16} = |\chi_0|^2 + |\chi_{1/2}|^2 + |\chi_{1/16}|^2, \tag{11.203}$$

his (11.50): $m_{h,\bar{h}} = \delta_{h,\bar{h}}$ for $h \in \{0, \frac{1}{2}, \frac{1}{16}\}$. Each primary appears once, paired with itself, so all three fields are spinless: $\mathbf{1} = (0,0)$, $\varepsilon = (\frac{1}{2}, \frac{1}{2})$, $\sigma = (\frac{1}{16}, \frac{1}{16})$. This is the **diagonal modular invariant**. To check its modular invariance we need the three characters explicitly. The free fermion gives them.

Worked example 11.74: The Ising characters from the Majorana fermion

NS sector. The NS Fock space is built by the modes ψ_{-r}, $r = \frac{1}{2}, \frac{3}{2}, \ldots$, each either empty or occupied. The trace factorises mode by mode:

$$\mathrm{Tr}_{\text{NS}}\, q^{L_0 - c/24} \overset{(1)}{=} q^{-1/48} \prod_{r \in \mathbb{N} - \frac{1}{2}} (1 + q^r), \qquad \mathrm{Tr}_{\text{NS}}\, (-1)^F q^{L_0 - c/24} \overset{(2)}{=} q^{-1/48} \prod_{r \in \mathbb{N} - \frac{1}{2}} (1 - q^r).$$

(1) $c/24 = 1/48$; an occupied mode ψ_{-r} adds r to L_0, so each mode contributes $1 + q^r$ (empty + occupied).

(2) An occupied mode also flips the sign of $(-1)^F$.

The projector onto even (odd) fermion number is $\frac{1}{2}(1 \pm (-1)^F)$, and by Section 11.6.3 the even part is the $\mathbf{1}$ module and the odd part the ε module. Hence

$$\chi_0 \pm \chi_{1/2} = q^{-1/48} \prod_{n=1}^{\infty} (1 \pm q^{n-1/2}), \qquad \chi_{1/16} = q^{1/24} \prod_{n=1}^{\infty} (1 + q^n). \tag{11.204}$$

R sector. The modes ψ_{-n}, $n \geq 1$, give $\prod_n (1 + q^n)$, and the ground state has $L_0 = \frac{1}{16}$, so the prefactor is $q^{1/16 - 1/48} = q^{1/24}$.

Watch out: The $\sqrt{2}$ of a single Majorana zero mode

The Ramond zero mode obeys $\psi_0^2 = \frac{1}{2}$. A Clifford algebra with one generator has no irreducible representation of dimension "1 with a fermion number": the smallest module with a $(-1)^F$ anticommuting with ψ_0 is two dimensional. For *two* Majorana fermions (one Dirac fermion) the two zero modes act on $\mathbb{C}^2$ like $\sigma_1/\sqrt{2}$ and $\sigma_2/\sqrt{2}$ (Chapter T4), and the R ground state is doubly degenerate. For one Majorana fermion the "degeneracy" is formally $\sqrt{2}$, which is why the full Ramond trace is $\sqrt{2}\,\chi_{1/16}$. The Ising model has a single spin field σ, and $\chi_{1/16}$ itself is the character that appears in Z.

Worked example 11.75: Checking the characters against the Verma-module count

Expand (11.204) (a short computer or hand expansion) and strip the prefactors $q^{h-1/48}$:

level N	0	1	2	3	4	5	6	7	8
χ_0: d_N	1	0	1	1	2	2	3	3	5
$\chi_{1/2}$: d_N	1	1	1	1	2	2	3	4	5
$\chi_{1/16}$: d_N	1	1	1	2	2	3	4	5	6
Verma: $p(N)$	1	1	2	3	5	7	11	15	22

The Verma-module picture predicts these numbers. The null vectors of $\phi_{r,s}$ sit at levels rs and $(2-r+1)(3-s+1)$, i.e. at levels $1, 6$ for $\mathbf{1} = \phi_{1,1}$, levels $2, 3$ for $\varepsilon = \phi_{2,1}$ and levels $2, 4$ for $\sigma = \phi_{1,2}$. Removing their submodules,

$$d_N^{(\mathbf{1})} = p(N) - p(N-1) - p(N-6) + \dots, \qquad d_6^{(\mathbf{1})} \overset{(1)}{=} 11 - 7 - 1 = 3,$$
$$d_N^{(\varepsilon)} = p(N) - p(N-2) - p(N-3) + \dots, \qquad d_4^{(\varepsilon)} \overset{(2)}{=} 5 - 2 - 1 = 2,$$
$$d_N^{(\sigma)} = p(N) - p(N-2) - p(N-4) + \dots, \qquad d_6^{(\sigma)} \overset{(3)}{=} 11 - 5 - 2 = 4,$$

(1) $p(6) = 11$, $p(5) = 7$, $p(0) = 1$.
(2) $p(4) = 5$, $p(2) = 2$, $p(1) = 1$.
(3) $p(6) = 11$, $p(4) = 5$, $p(2) = 2$.

all matching the fermion table. The dots are the inclusion–exclusion corrections from the overlap of the two submodules; they start at level 11 for $\mathbf{1}$, 7 for ε and 10 for σ. The full answer is the **Rocha-Caridi formula** $\chi_{r,s} = \eta(\tau)^{-1} \sum_{k\in\mathbb{Z}} \left(q^{(24k+4r-3s)^2/48} - q^{(24k+4r+3s)^2/48} \right)$ for the Ising model. So the free fermion and the abstract representation theory agree to every order we care to check.

Spin structures: why the fermion knows about modular invariance

The fermion picture explains *why* this particular combination of characters is modular invariant. A Majorana fermion on a torus needs a spin structure: a choice of periodic (P) or antiperiodic (A) boundary condition around each of the two cycles, four choices in all. Label them by (space, time). The traces we just computed are path integrals with definite spin structures:

- antiperiodic in space is the NS sector (on the cylinder, NS fermions are antiperiodic, Section 11.6.3);
- a plain trace gives *antiperiodic* time, because fermion path integrals with a trace have an extra sign; inserting $(-1)^F$ makes time periodic.

So, for the chiral fermion, $\mathrm{Tr}_{\mathrm{NS}}\, q^{L_0 - c/24} \leftrightarrow (A, A)$, $\mathrm{Tr}_{\mathrm{NS}} (-1)^F q^{L_0 - c/24} \leftrightarrow (A, P)$, $\mathrm{Tr}_{\mathrm{R}}\, q^{L_0 - c/24} \leftrightarrow (P, A)$, and $\mathrm{Tr}_{\mathrm{R}} (-1)^F q^{L_0 - c/24} \leftrightarrow (P, P)$, which vanishes because of the zero mode. A modular transformation relabels the cycles, so it permutes the spin structures (Figure 11.41): S swaps $(A, P) \leftrightarrow (P, A)$, and T swaps $(A, A) \leftrightarrow (A, P)$. An honest theory of the lattice spins must *sum over all spin structures*, and a sum over all of them is automatically modular invariant. Summing |fermion partition function| over the four spin structures gives

$$\tfrac{1}{2}\left(\left|\chi_0 + \chi_{1/2}\right|^2 + \left|\chi_0 - \chi_{1/2}\right|^2 + \left|\sqrt{2}\,\chi_{1/16}\right|^2 + 0 \right) \overset{(1)}{=} |\chi_0|^2 + |\chi_{1/2}|^2 + |\chi_{1/16}|^2 = Z_{\mathrm{Ising}}. \tag{11.205}$$

(1) $|a+b|^2 + |a-b|^2 = 2|a|^2 + 2|b|^2$, and $|\sqrt{2}\chi_{1/16}|^2 = 2|\chi_{1/16}|^2$.

This is the physical reason behind Nash's "routine" check. The factor $\frac{1}{2}$ is the projector $\frac{1}{2}(1 + (-1)^F)$ that keeps only states local with respect to the spin. We verify the modular invariance explicitly, with theta functions, in the next section.

Reading Nash (pp. 311–312, (11.48)–(11.51))

Nash's §4 is a single page: periodic boundary conditions give a torus; conformal invariance gives invariance under (11.48); the Hilbert space $\bigoplus_i H_i \otimes \bar{H}_i$ gives the character sum (11.49); the Ising model gives (11.50); and invariance under the generators S, T suffices

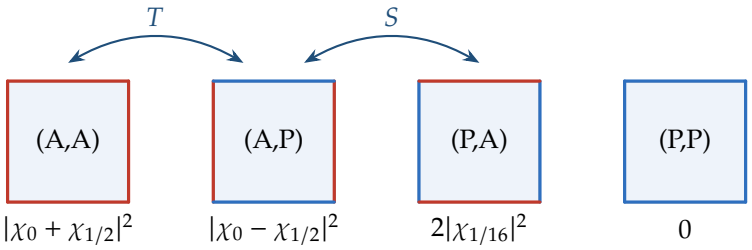

Figure 11.41: The four spin structures on a torus and the (left×right) fermion partition functions they give, in terms of Ising characters. The modular group permutes them: T exchanges (A,A) and (A,P), S exchanges (A,P) and (P,A), and (P,P) is invariant (its partition function vanishes by the zero mode). What to see: summing over all spin structures is modular invariant by construction, and the sum is $2Z_{\text{Ising}}$.

(11.51). We have derived each step: τ as the shape of the lattice (Section 11.7.1), (11.48) as a change of lattice basis (11.191), (11.49) from the cylinder Hamiltonian (11.199)–(11.201), and the three Ising characters from the free fermion (11.204). Note that Nash's $\chi_h(\tau)$ is our χ_h including the factor $q^{-c/24}$; without that factor Z would not be modular invariant.

Recap

- A torus is $\mathbb{C}/(\mathbb{Z}+\mathbb{Z}\tau)$; its conformal class is $\tau \in \mathbb{H}$ modulo $\mathrm{PSL}(2,\mathbb{Z})$, generated by $T:\tau\mapsto\tau+1$ and $S:\tau\mapsto -1/\tau$, with $S^2=(ST)^3=1$. The fundamental domain $\mathcal{F}$ is the moduli space of tori.
- On a circle of length L: $H=\frac{2\pi}{L}(L_0+\bar L_0-\frac{c}{12})$; the $-\frac{c}{12}$ is the Casimir energy from the Schwarzian, and it lets one measure c on a lattice.
- $Z(\tau)=\mathrm{Tr}\, q^{L_0-c/24}\bar q^{\bar L_0-c/24}=\sum m_{h,\bar h}\chi_h\bar\chi_{\bar h}$. T-invariance forces integer spins.
- The Ising characters are fermion traces (11.204); they agree with the Verma-module counting; Z_{Ising} is the sum over the four spin structures, hence modular invariant.

11.8 Modular forms and the modular invariance of Z

We have reduced Nash's claim to two equations, $Z(\tau+1)=Z(\tau)$ and $Z(-1/\tau)=Z(\tau)$. The first was easy: it only asks that every field have integer spin (Section 11.7.4). The second is hard. Under $\tau\mapsto -1/\tau$ the variable $q=e^{2\pi i\tau}$ goes to $\tilde q=e^{-2\pi i/\tau}$, and a power series in q has no obvious relation to a power series in $\tilde q$. If $\tau=it$ is purely imaginary, $q=e^{-2\pi t}$ and $\tilde q=e^{-2\pi/t}$: a long thin torus becomes a short fat one. Physically, S exchanges "a long time on a short circle" with "a short time on a long circle".

So the question of this section is:

Which functions of q have a known behaviour under $\tau\mapsto -1/\tau$, and how do we write the characters in terms of them?

The answer is the classical theory of modular forms, which Nash sketches in (11.52)–(11.59). We need three tools: the Dedekind η function, the Jacobi θ functions, and one piece of Fourier analysis, the Poisson summation formula. With these we prove the invariance of Z_{Ising} (Nash

calls this "a routine matter"), compute the free boson partition function, and see how modular invariance classifies theories.

11.8.1 The Dedekind eta function

Working definition 11.27 (Dedekind η function [Nash p. 312, (11.52)])

For τ in the upper half plane $\mathbb{H}$ and $q = e^{2\pi i\tau}$,

$$\eta(\tau) = e^{\pi i\tau/12}\prod_{n=1}^{\infty}(1-e^{2\pi in\tau}) = q^{1/24}\prod_{n=1}^{\infty}(1-q^n). \tag{11.206}$$

How to use it: $1/\eta(\tau)$ is "$q^{-1/24}$ times the generating function of partitions" [$\prod_n(1-q^n)^{-1} = \sum_N p(N)\,q^N = 1+q+2q^2+3q^3+5q^4+\cdots$]. It is the character of one free boson's oscillators [the states $a_{-n_1}\cdots a_{-n_k}|0\rangle$, of which there are $p(N)$ with $n_1+\cdots+n_k = N$]. Since $|q|<1$ the product converges, and η has no zeros in $\mathbb{H}$.

We already met $1/\eta$ in (11.202): the Verma module has $p(N)$ states at level N, and $\sum_N p(N)q^N = \prod_n(1-q^n)^{-1}$. The same function counts the states of a free boson. Its oscillators a_{-n}, $n\geq 1$, each raise L_0 by n, and each can be applied any number of times. A state $a_{-1}^{k_1}a_{-2}^{k_2}\cdots|0\rangle$ has level $\sum nk_n$, so

$$\mathrm{Tr}_{\text{oscillators}}\; q^{L_0-1/24} \overset{(1)}{=} q^{-1/24}\prod_{n=1}^{\infty}\Big(\sum_{k_n=0}^{\infty}q^{nk_n}\Big) \overset{(2)}{=} q^{-1/24}\prod_{n=1}^{\infty}\frac{1}{1-q^n} \overset{(3)}{=} \frac{1}{\eta(\tau)}. \tag{11.207}$$

(1) $c=1$ for one boson, so the shift is $q^{-1/24}$. The oscillators for different n are independent, so the trace is a product over n of traces over the occupation number k_n.
(2) Geometric series.
(3) Definition (11.206).

Worked example 11.76: The first terms of η, and Euler's pentagonal numbers

Multiply out the first few factors:

$$\begin{aligned}&(1-q)(1-q^2)(1-q^3)(1-q^4)(1-q^5)(1-q^6)(1-q^7)\cdots\\ &\quad = 1-q-q^2+q^5+q^7-q^{12}-q^{15}+\cdots.\end{aligned}$$

Almost everything cancels. Euler found the pattern: the surviving exponents are the **pentagonal numbers** $n(3n-1)/2$ for $n\in\mathbb{Z}$ $(0,1,2,5,7,12,15,\ldots)$, with sign $(-1)^n$. Including the prefactor,

$$\eta(\tau) \overset{(1)}{=} \sum_{n\in\mathbb{Z}}(-1)^n\,q^{\,n(3n-1)/2+1/24} \overset{(2)}{=} \sum_{n\in\mathbb{Z}}(-1)^n\,q^{\,(6n-1)^2/24}. \tag{11.208}$$

(1) Euler's pentagonal number theorem, times $q^{1/24}$.
(2) $(6n-1)^2/24 = (36n^2-12n+1)/24 = n(3n-1)/2+1/24$.

Check: $n=0,1,-1,2,-2$ give $(6n-1)^2 = 1,25,49,121,169$, that is $q^{1/24}$ times q^0,q^1,q^2,q^5,q^7 with signs $+,-,-,+,+$. The form (11.208), a Gaussian sum over a lattice, is what makes an S-transformation law possible: Gaussians are the functions that the Fourier transform maps to Gaussians.

The T law

This one is immediate:

$$\eta(\tau+1) \overset{(1)}{=} e^{\pi i(\tau+1)/12}\prod_n\left(1-e^{2\pi i n\tau}e^{2\pi i n}\right) \overset{(2)}{=} e^{\pi i/12}\,e^{\pi i\tau/12}\prod_n\left(1-e^{2\pi i n\tau}\right) = e^{\pi i/12}\,\eta(\tau). \quad (11.209)$$

(1) Substitute $\tau+1$ in (11.206).
(2) $e^{2\pi i n}=1$ for integer n; only the prefactor sees the shift.

This is Nash's (11.58). So η is *not* invariant: it picks up a 24th root of unity. The S law, Nash's (11.59),

$$\eta(-1/\tau) = (-i\tau)^{1/2}\,\eta(\tau), \quad (11.210)$$

needs "some additional work". We do that work in Section 11.8.3 after building the θ functions. Here $(-i\tau)^{1/2}$ is the branch that is positive for $\tau = it$, $t>0$; this is well defined because $-i\tau$ lies in the right half plane.

Watch out: Why η and not $\prod(1-q^n)$

The prefactor $q^{1/24}$ looks like decoration. It is not. Without it, $\prod(1-q^n)$ has no simple S law at all. With it, η transforms by the simple factor (11.210). This is the same $-c/24$ that the Casimir energy (11.197) put into the characters, for $c=1$. The zero-point energy of the cylinder is exactly what the torus needs to be modular invariant.

11.8.2 Modular forms

Nash now digresses to define modular forms. The idea is simple: we want functions on $\mathbb{H}$ that are not invariant under $\mathrm{PSL}(2,\mathbb{Z})$, but change by a *known, simple* factor.

Working definition 11.28 (modular form of weight k, Nash's convention [Nash p. 312, (11.54)])

A holomorphic function f on $\mathbb{H}$ is a **modular form of weight k** (or "dimension $-2k$") if the object

$$F(\tau) = f(\tau)\,(d\tau)^k$$

is invariant under every $m\in\mathrm{PSL}(2,\mathbb{Z})$ [every map $m(\tau)=\frac{a\tau+b}{c\tau+d}$ with integers a,b,c,d and $ad-bc=1$]. Nash calls F an **automorphic form** of weight k. *How to test it:* check $f(m(\tau))=(c\tau+d)^{2k}f(\tau)$ [since $dm(\tau)=d\tau/(c\tau+d)^2$, the factor f must make up $(c\tau+d)^{2k}$] for the two generators S and T (and require f to stay bounded as $\mathrm{Im}\,\tau\to\infty$).

The transformation law comes from how $d\tau$ transforms. For $m(\tau)=(a\tau+b)/(c\tau+d)$ with $ad-bc=1$, the derivative $m'(\tau)=(c\tau+d)^{-2}$ (we computed exactly this for Möbius maps in Section 11.5.1). Invariance of F means

$$\begin{aligned} F(m(\tau)) = F(\tau) &\overset{(1)}{=} f(m(\tau))\,\big(m'(\tau)\big)^k(d\tau)^k = f(\tau)(d\tau)^k \\ &\overset{(2)}{=} f(m(\tau)) = (c\tau+d)^{2k}f(\tau). \end{aligned} \quad (11.211)$$

(1) Pull back: $d(m(\tau)) = m'(\tau)\,d\tau$.
(2) $m'(\tau)^k=(c\tau+d)^{-2k}$; cancel $(d\tau)^k$.

This is Nash's (11.55).

Watch out: Nash's weight is half the usual weight

In almost every modern text, a modular form of weight w obeys $f(m(\tau)) = (c\tau + d)^w f(\tau)$. Nash's "weight k" is the modern weight $w = 2k$: he counts powers of $\mathrm{d}\tau$, which carries $(c\tau + d)^{-2}$. So Nash's "η^{24} is a modular form of weight 6" is the modern "$\Delta = \eta^{24}$ is the cusp form of weight 12". Both say (11.213) below.

Why is this consistent, that is, why does it suffice to check S and T? Write $j(M,\tau) = c\tau + d$ for $M = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$. Then j is a **cocycle**:

$$j(MN,\tau) \overset{(1)}{=} \frac{\mathrm{d}\tau}{\mathrm{d}(MN\tau)}\Big|^{1/2} \overset{(2)}{=} \left(\frac{\mathrm{d}\tau}{\mathrm{d}(N\tau)} \cdot \frac{\mathrm{d}(N\tau)}{\mathrm{d}(MN\tau)}\right)^{1/2} \overset{(3)}{=} j(N,\tau)\, j(M,N\tau), \tag{11.212}$$

(1) $\mathrm{d}(M\tau)/\mathrm{d}\tau = j(M,\tau)^{-2}$, so $j = (\mathrm{d}\tau/\mathrm{d}(M\tau))^{1/2}$ (up to a sign, which one checks directly by multiplying the matrices).
(2) Chain rule for the composite map $\tau \mapsto N\tau \mapsto M(N\tau)$.
(3) Each factor is the corresponding j^2; take square roots.

So if $f(M\tau) = j(M,\tau)^{2k} f(\tau)$ and $f(N\tau) = j(N,\tau)^{2k} f(\tau)$, then $f(MN\tau) = j(M,N\tau)^{2k} f(N\tau) = j(M,N\tau)^{2k} j(N,\tau)^{2k} f(\tau) = j(MN,\tau)^{2k} f(\tau)$. The law for generators implies the law for every word in them.

Worked example 11.77: η^{24} is a modular form: Nash's (11.56)–(11.57)

Raise the two laws (11.209) and (11.210) to the 24th power:

$$\eta^{24}(\tau+1) \overset{(1)}{=} \left(e^{\pi i/12}\right)^{24} \eta^{24}(\tau) = e^{2\pi i} \eta^{24}(\tau) = \eta^{24}(\tau),$$
$$\eta^{24}(-1/\tau) \overset{(2)}{=} (-i\tau)^{12}\, \eta^{24}(\tau) \overset{(3)}{=} \tau^{12}\, \eta^{24}(\tau).$$

(1) The T law.
(2) The S law; $\left((-i\tau)^{1/2}\right)^{24} = (-i\tau)^{12}$, with no branch ambiguity left since the exponent is an integer.
(3) $(-i)^{12} = \left((-i)^4\right)^3 = 1$.

These are Nash's (11.57). T has $c = 0, d = 1$, so $(c\tau + d)^{12} = 1$; S has $c = 1, d = 0$, so $(c\tau + d)^{12} = \tau^{12}$. By the cocycle argument,

$$\eta^{24}\big(m(\tau)\big) = (c\tau + d)^{12}\, \eta^{24}(\tau) \qquad \text{for all } m \in \mathrm{PSL}(2,\mathbb{Z}), \tag{11.213}$$

which is Nash's (11.56): η^{24} has Nash-weight 6 ($12 = 2 \cdot 6$). Its expansion begins

$$\eta^{24}(\tau) \overset{(1)}{=} q\,(1-q)^{24}(1-q^2)^{24}\cdots \overset{(2)}{=} q\Big(1 - 24q + \big[\tbinom{24}{2} - 24\big]q^2 + \dots\Big)$$
$$= q - 24q^2 + 252q^3 - \cdots.$$

(1) $(q^{1/24})^{24} = q$.
(2) From $(1-q)^{24}$: $1 - 24q + \binom{24}{2}q^2$; from $(1-q^2)^{24}$: $-24q^2$. $\binom{24}{2} = 276$ and $276 - 24 = 252$.

The coefficients $1, -24, 252, -1472, \dots$ are Ramanujan's $\tau(n)$.

Physical picture: Why 24 is the bosonic string's number

$1/\eta^{24}$ is the partition function of 24 free bosons' oscillators, $q^{-1}(1 + 24q + 324q^2 + \dots)$. These are the 24 transverse oscillators of the bosonic string in 26 dimensions (Chapter 9). The

leading q^{-1} is the tachyon, and $-c/24 = -24/24 = -1$ is the famous intercept. The fact that η^{24} is a modular form, while η alone is not, is one way of seeing why the light-cone string needs exactly 24 transverse directions for its one-loop amplitude to be modular invariant.

11.8.3 Poisson summation and the theta functions

Everything in the S law comes from one fact of Fourier analysis.

Key idea: Poisson summation

For a smooth, rapidly decaying $f:\mathbb{R}\to\mathbb{C}$ with Fourier transform $\hat f(k)=\int_{\mathbb{R}} f(x)e^{-2\pi i k x}\,dx$,

$$\sum_{n\in\mathbb{Z}} f(n) = \sum_{k\in\mathbb{Z}} \hat f(k). \tag{11.214}$$

A sum over a lattice equals the sum of the Fourier transform over the dual lattice.

Why it is true: periodise f. The function $P(x)=\sum_n f(x+n)$ has period 1, so it has a Fourier series $P(x)=\sum_k c_k e^{2\pi i k x}$. Its coefficients are

$$c_k \overset{(1)}{=} \int_0^1 P(x)e^{-2\pi i k x}dx \overset{(2)}{=} \sum_{n\in\mathbb{Z}}\int_0^1 f(x+n)e^{-2\pi i k(x+n)}dx \overset{(3)}{=} \int_{\mathbb{R}} f(y)e^{-2\pi i k y}dy = \hat f(k).$$

(1) Fourier coefficient of a period-1 function.
(2) Insert P; $e^{-2\pi i k n}=1$, so we may add n to x in the exponent.
(3) Substitute $y=x+n$; the intervals $[n,n+1]$ tile $\mathbb{R}$.

Now set $x=0$: $\sum_n f(n)=P(0)=\sum_k c_k=\sum_k \hat f(k)$.

The functions we need are Gaussians. For $\operatorname{Im}\tau>0$ and $f(x)=e^{i\pi\tau x^2}$,

$$\hat f(k) \overset{(1)}{=} \int_{\mathbb{R}} e^{i\pi\tau x^2-2\pi i k x}dx \overset{(2)}{=} e^{-i\pi k^2/\tau}\int_{\mathbb{R}} e^{i\pi\tau(x-k/\tau)^2}dx \overset{(3)}{=} (-i\tau)^{-1/2}\,e^{-i\pi k^2/\tau}. \tag{11.215}$$

(1) Definition of $\hat f$.
(2) Complete the square: $\tau x^2-2kx=\tau(x-k/\tau)^2-k^2/\tau$.
(3) Shift the contour back to the real axis (the integrand decays in the strip in between), then $\int e^{-\pi a y^2}dy=a^{-1/2}$ with $a=-i\tau$, $\operatorname{Re} a=\operatorname{Im}\tau>0$.

A narrow Gaussian has a wide Fourier transform and vice versa (Figure 11.42). This is the uncertainty principle, and it is exactly the exchange of a thin torus with a fat one.

Working definition 11.29 (Jacobi theta functions)

With $q=e^{2\pi i\tau}$ (so $q^{n^2/2}=e^{i\pi\tau n^2}$),

$$\theta_3(\tau)=\sum_{n\in\mathbb{Z}} q^{n^2/2},\qquad \theta_4(\tau)=\sum_{n\in\mathbb{Z}}(-1)^n q^{n^2/2},\qquad \theta_2(\tau)=\sum_{n\in\mathbb{Z}} q^{(n+1/2)^2/2}. \tag{11.216}$$

How to think of them: each is a Gaussian summed over a one-dimensional lattice ($\mathbb{Z}$ or $\mathbb{Z}+\tfrac12$), possibly with a sign [$e^{i\pi\tau n^2}$ is a Gaussian in n, decaying because $\operatorname{Im}\tau>0$]. They are partition functions of a particle on a circle [the state of momentum n has energy proportional to n^2 and contributes $q^{n^2/2}$ to the trace], with momentum quantised in $\mathbb{Z}$ or in $\mathbb{Z}+\tfrac12$.

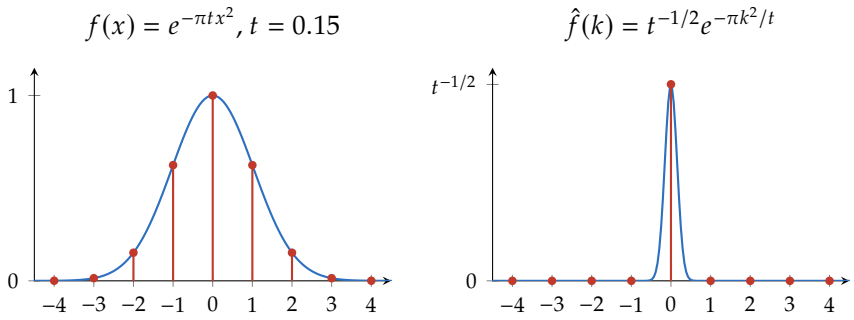

Figure 11.42: Poisson summation for a Gaussian, $\tau = it$. Left: a wide Gaussian sampled at the integers; many samples contribute, so $\theta_3(it)$ is large and slowly converging. Right: its Fourier transform is a narrow, tall Gaussian; only the $k = 0$ sample matters, giving $t^{-1/2}$. The two red sums are equal. What to see: $\theta_3(it) = t^{-1/2}\theta_3(i/t)$ trades a slowly converging sum for a rapidly converging one, which is the whole content of the S transformation.

S and T laws of the theta functions

Worked example 11.78: The S laws by Poisson summation

θ_3. Apply (11.214) to $f(x) = e^{i\pi\tau x^2}$:

$$\theta_3(\tau) \overset{(1)}{=} \sum_n e^{i\pi\tau n^2} \overset{(2)}{=} (-i\tau)^{-1/2} \sum_k e^{-i\pi k^2/\tau} \overset{(3)}{=} (-i\tau)^{-1/2}\, \theta_3(-1/\tau).$$

(1) Definition (11.216).
(2) Poisson summation with (11.215).
(3) $e^{-i\pi k^2/\tau} = e^{i\pi(-1/\tau)k^2}$ is the θ_3 summand at $-1/\tau$.

$\theta_4 \to \theta_2$. Now $f(x) = e^{i\pi\tau x^2} e^{i\pi x}$, so that $f(n)$ carries $(-1)^n$. The extra phase shifts the Fourier variable by $\frac{1}{2}$: $\hat{f}(k) = (-i\tau)^{-1/2} e^{-i\pi(k-1/2)^2/\tau}$ (repeat (11.215) with $k \to k - \frac{1}{2}$). Hence

$$\theta_4(\tau) \overset{(1)}{=} \sum_n e^{i\pi\tau n^2} e^{i\pi n} \overset{(2)}{=} (-i\tau)^{-1/2} \sum_k e^{-i\pi(k-1/2)^2/\tau} \overset{(3)}{=} (-i\tau)^{-1/2}\, \theta_2(-1/\tau).$$

(1) $(-1)^n = e^{i\pi n}$.
(2) Poisson summation.
(3) $k - \frac{1}{2}$ runs over $\mathbb{Z} + \frac{1}{2}$ as k runs over $\mathbb{Z}$.

Replacing τ by $-1/\tau$ in the last line, and using $(i/\tau)^{-1/2} = (-i\tau)^{1/2}$, gives the partner law. Altogether:

$$\theta_3(-\tfrac{1}{\tau}) = (-i\tau)^{1/2}\theta_3(\tau), \quad \theta_2(-\tfrac{1}{\tau}) = (-i\tau)^{1/2}\theta_4(\tau), \quad \theta_4(-\tfrac{1}{\tau}) = (-i\tau)^{1/2}\theta_2(\tau). \tag{11.217}$$

The T laws are one-liners. Since $n^2 \equiv n \pmod 2$, $e^{i\pi n^2} = (-1)^n$; and $(n + \frac{1}{2})^2 = n(n+1) + \frac{1}{4}$ with $n(n+1)$ even. So

$$\theta_3(\tau + 1) = \theta_4(\tau), \qquad \theta_4(\tau + 1) = \theta_3(\tau), \qquad \theta_2(\tau + 1) = e^{i\pi/4}\, \theta_2(\tau). \tag{11.218}$$

S swaps $\theta_2 \leftrightarrow \theta_4$ and T swaps $\theta_3 \leftrightarrow \theta_4$. Compare Figure 11.41: this is the same permutation as the spin structures $(A, P) \leftrightarrow (P, A)$ and $(A, A) \leftrightarrow (A, P)$. That is no accident, as we now see.

Product formulas: the Jacobi triple product

To connect the θ's with the fermion characters we need them as products. The bridge is Jacobi's identity, valid for $|q|<1$ and $y\neq 0$:

$$\sum_{n\in\mathbb{Z}} q^{n^2/2}y^n = \prod_{n=1}^{\infty}(1-q^n)\big(1+yq^{n-1/2}\big)\big(1+y^{-1}q^{n-1/2}\big). \tag{11.219}$$

Physical picture: The triple product is bosonisation

Read the right side as a trace over the NS Fock space of a complex (Dirac) fermion: modes $\psi^\dagger_{-r}$ (charge $+1$) and ψ_{-r} (charge -1), $r\in\mathbb{N}-\frac12$, each empty or occupied, with y counting charge. That gives $\prod(1+yq^r)(1+y^{-1}q^r)$. Read the left side as a compact boson: a sector of charge n has lowest weight $n^2/2$ (the lowest state of charge n fills the n lowest levels $\frac12+\frac32+\cdots+\frac{2n-1}{2}=\frac{n^2}{2}$), and on top of it sits a tower of neutral excitations counted by $\prod(1-q^n)^{-1}$. Multiplying both sides by $\prod(1-q^n)^{-1}$, the identity says: *the Dirac fermion Fock space equals* $\bigoplus_n$(*charge* n) $\otimes$ (*boson Fock space*). This is the boson–fermion correspondence of [Nash p. 303] in its sharpest form.

Worked example 11.79: Checking the triple product at charge 0 and 1

Expand the right side of (11.219), divided by $\prod(1-q^n)$, and collect the coefficient of y^0 up to q^2. The neutral states are: nothing (1); $\psi^\dagger_{-1/2}\psi_{-1/2}$ (q); $\psi^\dagger_{-3/2}\psi_{-1/2}$ and $\psi^\dagger_{-1/2}\psi_{-3/2}$ $(2q^2)$. So the fermion count is $1+q+2q^2+\cdots$. The boson count is $\prod(1-q^n)^{-1}=1+q+2q^2+\cdots$: the same. At y^1: the lowest state is $\psi^\dagger_{-1/2}$ with weight $\frac12=1^2/2$, then $\psi^\dagger_{-3/2}$ $(q^{3/2})$, then $\psi^\dagger_{-5/2}$ and $\psi^\dagger_{-1/2}\psi^\dagger_{-3/2}\psi_{-1/2}$ $(2q^{5/2})$: so $q^{1/2}(1+q+2q^2+\dots)$, again matching.

Setting $y=1$, $y=-1$ and $y=q^{1/2}$ in (11.219) gives

$$\theta_3(\tau)\overset{(1)}{=}\prod_{n\geq1}(1-q^n)(1+q^{n-1/2})^2,\qquad \theta_4(\tau)\overset{(2)}{=}\prod_{n\geq1}(1-q^n)(1-q^{n-1/2})^2,$$
$$\theta_2(\tau)\overset{(3)}{=}2q^{1/8}\prod_{n\geq1}(1-q^n)(1+q^n)^2. \tag{11.220}$$

(1) $y=1$: the left side is θ_3.
(2) $y=-1$: the left side is θ_4.
(3) $y=q^{1/2}$: the left side is $\sum q^{(n^2+n)/2}=q^{-1/8}\sum q^{(n+1/2)^2/2}=q^{-1/8}\theta_2$. On the right, $(1+q^n)(1+q^{n-1})$; the $n=1$ factor $1+q^0=2$ gives the 2, and the rest reassembles to $\prod_n(1+q^n)^2$.

Worked example 11.80: The S law of η: Nash's "additional work"

First, a product identity:

$$\theta_2\theta_3\theta_4\overset{(1)}{=}2q^{1/8}\prod_n(1-q^n)^3\Big[(1+q^n)(1+q^{n-1/2})(1-q^{n-1/2})\Big]^2$$
$$\overset{(2)}{=}2q^{1/8}\prod_n(1-q^n)^3\Big[(1+q^n)(1-q^{2n-1})\Big]^2\overset{(3)}{=}2q^{1/8}\prod_n(1-q^n)^3\overset{(4)}{=}2\eta^3. \tag{11.221}$$

(1) Multiply the three products (11.220).
(2) $(1+x)(1-x)=1-x^2$ with $x=q^{n-1/2}$.
(3) Euler: $\prod_n(1+q^n)=\prod_n\frac{1-q^{2n}}{1-q^n}=\frac{\prod_{\text{even }m}(1-q^m)}{\prod_{\text{all }m}(1-q^m)}=\prod_{\text{odd }m}\frac{1}{1-q^m}$, so the bracket is 1.

(4) $\eta^3 = q^{1/8}\prod(1-q^n)^3$.

Now apply S to both sides, using (11.217):

$$2\eta^3(-1/\tau) \overset{(1)}{=} \theta_2(-\tfrac{1}{\tau})\theta_3(-\tfrac{1}{\tau})\theta_4(-\tfrac{1}{\tau}) \overset{(2)}{=} (-i\tau)^{3/2}\,\theta_4\theta_3\theta_2(\tau) \overset{(3)}{=} (-i\tau)^{3/2}\,2\eta^3(\tau).$$

(1) (11.221) at $-1/\tau$.
(2) Each θ gives a factor $(-i\tau)^{1/2}$; θ_2 and θ_4 swap.
(3) (11.221) at τ.

So $\eta(-1/\tau) = \omega\,(-i\tau)^{1/2}\eta(\tau)$ with $\omega^3 = 1$. Both sides are holomorphic and nonzero on $\mathbb{H}$, so ω is a continuous function with values in $\{1, e^{\pm 2\pi i/3}\}$: it is constant. At $\tau = i$, $-1/\tau = i$ and $(-i\cdot i)^{1/2} = 1$, so $\eta(i) = \omega\,\eta(i)$ and $\omega = 1$. This proves (11.210), Nash's (11.59). A numerical check at $\tau = 0.23 + 0.91i$ agrees to 30 digits.

11.8.4 The Ising model is modular invariant

Compare the fermion characters (11.204) with the products (11.220):

$$\frac{\theta_3}{\eta} \overset{(1)}{=} \frac{\prod(1-q^n)(1+q^{n-1/2})^2}{q^{1/24}\prod(1-q^n)} = \Big(q^{-1/48}\prod(1+q^{n-1/2})\Big)^2 \overset{(2)}{=} (\chi_0+\chi_{1/2})^2,$$
$$\frac{\theta_4}{\eta} \overset{(3)}{=} (\chi_0-\chi_{1/2})^2, \qquad \frac{\theta_2}{2\eta} \overset{(4)}{=} \frac{q^{1/8}\prod(1+q^n)^2}{q^{1/24}} = \Big(q^{1/24}\prod(1+q^n)\Big)^2 = \chi_{1/16}^2. \tag{11.222}$$

(1) Insert the product formulas; the $\prod(1-q^n)$ cancel, and $q^{-1/24} = (q^{-1/48})^2$.
(2) The NS character (11.204) with the + sign.
(3) The same with − signs.
(4) $q^{1/8-1/24} = q^{1/12} = (q^{1/24})^2$; then the R character.

So the three Ising characters are square roots of theta functions over η:

$$\chi_0 = \tfrac{1}{2}\Big(\sqrt{\tfrac{\theta_3}{\eta}} + \sqrt{\tfrac{\theta_4}{\eta}}\Big), \qquad \chi_{1/2} = \tfrac{1}{2}\Big(\sqrt{\tfrac{\theta_3}{\eta}} - \sqrt{\tfrac{\theta_4}{\eta}}\Big), \qquad \chi_{1/16} = \sqrt{\tfrac{\theta_2}{2\eta}}. \tag{11.223}$$

(The square roots are the branches that are positive for $\tau = it$.)

The partition function in closed form

$$\begin{aligned} Z_{\text{Ising}} &\overset{(1)}{=} \tfrac{1}{2}\big|\chi_0+\chi_{1/2}\big|^2 + \tfrac{1}{2}\big|\chi_0-\chi_{1/2}\big|^2 + |\chi_{1/16}|^2 \\ &\overset{(2)}{=} \frac{1}{2}\Big|\frac{\theta_3}{\eta}\Big| + \frac{1}{2}\Big|\frac{\theta_4}{\eta}\Big| + \frac{1}{2}\Big|\frac{\theta_2}{\eta}\Big| = \frac{|\theta_2|+|\theta_3|+|\theta_4|}{2\,|\eta|}. \end{aligned} \tag{11.224}$$

(1) Parallelogram law $|a|^2+|b|^2 = \tfrac{1}{2}|a+b|^2 + \tfrac{1}{2}|a-b|^2$.
(2) (11.222): $|\chi_0 \pm \chi_{1/2}|^2 = |\theta_{3,4}/\eta|$ and $|\chi_{1/16}|^2 = |\theta_2|/(2|\eta|)$.

Worked example 11.81: The routine verification: $Z(-1/\tau) = Z(\tau+1) = Z(\tau)$

S. From (11.210) and (11.217), every $|\theta_i|$ and $|\eta|$ gets the same factor $|-i\tau|^{1/2} = |\tau|^{1/2}$:

$$Z(-\tfrac{1}{\tau}) \overset{(1)}{=} \frac{|\tau|^{1/2}\big(|\theta_4|+|\theta_3|+|\theta_2|\big)}{2|\tau|^{1/2}|\eta|} \overset{(2)}{=} Z(\tau).$$

(1) S laws; θ_2 and θ_4 are exchanged.
(2) The factor cancels, and the sum is symmetric in θ_2, θ_4.

T. From (11.209) and (11.218), $|\eta|$ and $|\theta_2|$ are unchanged (phases), and $\theta_3 \leftrightarrow \theta_4$. The sum is symmetric, so $Z(\tau+1) = Z(\tau)$. That is all: the Ising partition function is modular invariant. Numerically, at $\tau = 0.23 + 0.91i$ all three of $Z(\tau)$, $Z(-1/\tau)$, $Z(\tau+1)$ equal $1.894632739812\ldots$.

Nash's formula (11.53)

Nash writes the squared moduli with η alone, at the arguments $\tau/2$, τ and 2τ. To get there, express the half-integer products through η:

$$\eta(\tau/2) \overset{(1)}{=} q^{1/48}\prod_{m\geq 1}(1-q^{m/2}) \overset{(2)}{=} q^{1/48}\prod_{n}(1-q^{n})\prod_{n}(1-q^{n-1/2}) \overset{(3)}{=} q^{1/48-1/24}\,\eta(\tau)\prod_{n}(1-q^{n-1/2}),$$
$$\eta(2\tau) \overset{(4)}{=} q^{1/12}\prod_{n}(1-q^{2n}) \overset{(5)}{=} q^{1/12}\prod_{n}(1-q^{n})(1+q^{n}) = q^{1/24}\,\eta(\tau)\prod_{n}(1+q^{n}).$$

(1) (11.206) at $\tau/2$: $q \to q^{1/2}$.
(2) Split m into even ($m = 2n$) and odd ($m = 2n-1$).
(3) $\prod(1-q^n) = q^{-1/24}\eta(\tau)$.
(4) (11.206) at 2τ: $q \to q^2$.
(5) $1 - q^{2n} = (1-q^n)(1+q^n)$.

So $\prod(1-q^{n-1/2}) = q^{1/48}\eta(\tau/2)/\eta(\tau)$ and $\prod(1+q^n) = q^{-1/24}\eta(2\tau)/\eta(\tau)$. With Euler's identity, $\prod(1+q^{n-1/2}) = \prod(1-q^{2n-1})/\prod(1-q^{n-1/2})$, and $\prod(1-q^{2n-1}) = \prod(1-q^n)/\prod(1-q^{2n}) = q^{1/24}\eta(\tau)/\eta(2\tau)$. Inserting into (11.204) and (11.224):

$$|\chi_0|^2 + |\chi_{1/2}|^2 = \frac{1}{2}\left\{\left|\frac{\eta^2(\tau/2)}{\eta^2(\tau)}\right| + \left|\frac{\eta^4(\tau)}{\eta^2(2\tau)\,\eta^2(\tau/2)}\right|\right\}, \qquad |\chi_{1/16}|^2 = \left|\frac{\eta^2(2\tau)}{\eta^2(\tau)}\right|. \tag{11.225}$$

The first is Nash's (11.53) exactly: the two terms are $|\theta_4/\eta|$ and $|\theta_3/\eta|$.

Watch out: A stray factor of 2 in Nash's (11.53)

Nash writes $|\chi_{1/16}|^2 = 2\,|\eta^2(2\tau)/\eta^2(\tau)|$. The factor 2 is a misprint. From (11.204), $\chi_{1/16} = q^{1/24}(1+q+\ldots)$, so $|\chi_{1/16}|^2 \to |q|^{1/12}$ as $q \to 0$, while $|\eta^2(2\tau)/\eta^2(\tau)| = |q|^{2/12-1/12}(1+\ldots) = |q|^{1/12}(1+\ldots)$ with coefficient 1. A numerical check confirms it: at $\tau = 0.23 + 0.91i$ both sides of our (11.225) equal $0.6214738\ldots$. With Nash's factor 2 the partition function would contain the spin field twice and would *fail* the S test.

The modular group acts on the characters: the S and T matrices

The S law does more than prove invariance. It says that the *vector* of characters transforms linearly. Using (11.217), $\sqrt{\theta_3/\eta} \mapsto \sqrt{\theta_3/\eta}$, $\sqrt{\theta_4/\eta} \mapsto \sqrt{\theta_2/\eta} = \sqrt{2}\,\chi_{1/16}$ and $\sqrt{\theta_2/2\eta} \mapsto \sqrt{\theta_4/2\eta}$ (the factors $(-i\tau)^{1/2}$ cancel between numerator and denominator). So, in the basis $(\chi_0, \chi_{1/2}, \chi_{1/16})$,

$$\chi_0(-\tfrac{1}{\tau}) \overset{(1)}{=} \tfrac{1}{2}\left(\sqrt{\tfrac{\theta_3}{\eta}} + \sqrt{2}\,\chi_{1/16}\right) \overset{(2)}{=} \tfrac{1}{2}\chi_0 + \tfrac{1}{2}\chi_{1/2} + \tfrac{1}{\sqrt{2}}\chi_{1/16},$$
$$\chi_{1/2}(-\tfrac{1}{\tau}) = \tfrac{1}{2}\chi_0 + \tfrac{1}{2}\chi_{1/2} - \tfrac{1}{\sqrt{2}}\chi_{1/16}, \qquad \chi_{1/16}(-\tfrac{1}{\tau}) \overset{(3)}{=} \tfrac{1}{\sqrt{2}}(\chi_0 - \chi_{1/2}). \tag{11.226}$$

(1) (11.223) and the S images just listed.
(2) $\sqrt{\theta_3/\eta} = \chi_0 + \chi_{1/2}$.
(3) $\sqrt{\theta_4/2\eta} = (\chi_0 - \chi_{1/2})/\sqrt{2}$.

That is, $\chi_i(-1/\tau) = \sum_j S_{ij}\chi_j(\tau)$ and $\chi_i(\tau+1) = \sum_j T_{ij}\chi_j(\tau)$ with

$$S = \frac{1}{2}\begin{pmatrix} 1 & 1 & \sqrt{2} \\ 1 & 1 & -\sqrt{2} \\ \sqrt{2} & -\sqrt{2} & 0 \end{pmatrix}, \qquad T = \begin{pmatrix} e^{-2\pi i/48} & 0 & 0 \\ 0 & e^{2\pi i\,23/48} & 0 \\ 0 & 0 & e^{2\pi i/24} \end{pmatrix}. \tag{11.227}$$

The entries of T are $e^{2\pi i(h-c/24)}$ with $h = 0, \frac{1}{2}, \frac{1}{16}$ and $c/24 = \frac{1}{48}$.

Worked example 11.82: The characters carry a representation of the modular group

S is real and symmetric, and $S^2 = 1$:

$$(S^2)_{11} = \tfrac{1}{4}(1+1+2) = 1, \qquad (S^2)_{12} = \tfrac{1}{4}(1+1-2) = 0, \qquad (S^2)_{13} = \tfrac{1}{4}(\sqrt{2}-\sqrt{2}+0) = 0,$$
$$(S^2)_{33} = \tfrac{1}{4}(2+2+0) = 1,$$

and the others by symmetry. So S is also orthogonal, i.e. unitary. Multiplying the matrices (numerically is quickest) gives $(ST)^3 = 1$ exactly. So S and T satisfy the defining relations of PSL$(2,\mathbb{Z})$ (Section 11.7.2): *the characters of a rational CFT carry a finite-dimensional unitary representation of the modular group.* Modular invariance of a combination $Z = \sum_{ij} M_{ij}\chi_i\bar{\chi}_j$ is then the matrix statement

$$S^{\mathsf{T}} M\, \bar{S} = M, \qquad T^{\mathsf{T}} M\, \bar{T} = M, \tag{11.228}$$

i.e. M commutes with S and T (both are unitary and symmetric). For Ising, $M = I$ works because S is unitary and T is diagonal. This matrix S is the protagonist of Verlinde's formula in Section 11.10.5.

11.8.5 The free boson on a circle

The brief promised the free boson's partition function, and it is the best illustration of modular invariance: we can compute it both in the operator language and in the path-integral language, and modular invariance is the statement that the two agree.

Conventions

We take the action $S = \frac{1}{4\pi}\int \mathrm{d}^2x\,(\partial_\mu\varphi)^2$, which gives $\langle\varphi(x)\varphi(0)\rangle = -\ln|x| = -\frac{1}{2}\ln|z|^2$, the stress tensor $T = -(\partial\varphi)^2$ with $c = 1$, and vertex operators $:e^{ip\varphi}:$ of weight $(p^2/4, p^2/4)$ as in Nash's §5. Now make the target a circle: $\varphi \sim \varphi + 2\pi R$.

On a spatial circle of length 2π two kinds of zero modes appear.

- **Momentum.** The wave function $e^{ip\varphi_0}$ of the centre of mass must be single valued under $\varphi_0 \to \varphi_0 + 2\pi R$, so $p = n/R$, $n \in \mathbb{Z}$.
- **Winding.** The field may wind around the target: $\varphi(x+2\pi) = \varphi(x) + 2\pi R w$, $w \in \mathbb{Z}$. This is a topological sector that a non-compact boson does not have.

The zero-mode energy is kinetic plus gradient energy. With canonical momentum $\Pi = \frac{1}{2\pi}\partial_t\varphi$ and total momentum $\int \Pi = n/R$, and $\partial_x\varphi = Rw$ for the winding,

$$H_0 \overset{(1)}{=} \int_0^{2\pi} \mathrm{d}x \left[\pi\,\Pi^2 + \frac{1}{4\pi}(\partial_x\varphi)^2\right] \overset{(2)}{=} 2\pi\left[\pi\frac{(n/R)^2}{4\pi^2} + \frac{R^2w^2}{4\pi}\right] = \frac{1}{2}\Big(\frac{n^2}{R^2} + R^2w^2\Big).$$

(1) The Hamiltonian density of $\mathcal{L} = \frac{1}{4\pi}(\dot\varphi^2 - \varphi'^2)$ is $\pi\Pi^2 + \frac{1}{4\pi}\varphi'^2$.
(2) Constant zero modes: $\Pi = (n/R)/2\pi$, $\varphi' = Rw$; the integral gives a factor 2π.

Since $H = L_0 + \bar L_0 - \frac{1}{12}$ on this circle, the zero modes contribute $h + \bar h = \frac{1}{2}(n^2/R^2 + R^2w^2)$, and the momentum $P = L_0 - \bar L_0$ is nw (the product of the two quantum numbers). Both are reproduced by

$$h = \tfrac{1}{4}p_L^2, \quad \bar h = \tfrac{1}{4}p_R^2, \qquad p_L = \frac{n}{R} + wR, \quad p_R = \frac{n}{R} - wR. \tag{11.229}$$

Indeed $\frac{1}{4}(p_L^2 + p_R^2) = \frac{1}{2}(n^2/R^2 + w^2R^2)$ and $\frac{1}{4}(p_L^2 - p_R^2) = \frac{1}{4}\cdot 4nw = nw$.

The partition function, Hamiltonian form

Each sector (n, w) carries a Fock space of left and right oscillators, contributing $1/\eta$ and $1/\bar\eta$ by (11.207). Hence

$$Z(\tau; R) = \frac{1}{|\eta(\tau)|^2}\sum_{n,w\in\mathbb{Z}} q^{\,p_L^2/4}\,\bar q^{\,p_R^2/4} = \frac{1}{|\eta(\tau)|^2}\sum_{n,w\in\mathbb{Z}} \exp\Big[-\pi\tau_2\Big(\frac{n^2}{R^2} + w^2R^2\Big) + 2\pi i\tau_1 nw\Big], \tag{11.230}$$

with $\tau = \tau_1 + i\tau_2$. (The second form: $q^a\bar q^b = e^{2\pi i\tau_1(a-b)}e^{-2\pi\tau_2(a+b)}$ with $a + b = \frac{1}{2}(n^2/R^2 + w^2R^2)$, $a - b = nw$.)

T-invariance is immediate: $\tau_1 \to \tau_1 + 1$ multiplies each term by $e^{2\pi i nw} = 1$, and $|\eta|$ is invariant. The spins $h - \bar h = nw$ are integers, as they must be.

The partition function, path-integral form

For S we Poisson-resum over the momentum n. At fixed w, the n-sum is a Gaussian sum:

$$\sum_{n\in\mathbb{Z}} e^{-\pi\tau_2 n^2/R^2 + 2\pi i\tau_1 wn} \overset{(1)}{=} \sum_{m\in\mathbb{Z}}\int_{\mathbb{R}} \mathrm{d}x\; e^{-\pi\tau_2 x^2/R^2 + 2\pi i x(\tau_1 w - m)} \overset{(2)}{=} \frac{R}{\sqrt{\tau_2}}\sum_{m\in\mathbb{Z}} e^{-\pi R^2(m-\tau_1 w)^2/\tau_2}. \tag{11.231}$$

(1) Poisson summation (11.214); we relabelled $k \to m$.
(2) The Gaussian integral $\int e^{-\pi a x^2 + 2\pi i b x}\mathrm{d}x = a^{-1/2}e^{-\pi b^2/a}$ with $a = \tau_2/R^2$ and $b = \tau_1 w - m$.

Multiply by the winding factor $e^{-\pi\tau_2 w^2R^2}$ and combine the exponents: $(m - \tau_1 w)^2 + \tau_2^2 w^2 = |m - w\tau|^2$. So

$$Z(\tau; R) = \frac{R}{\sqrt{\tau_2}\,|\eta(\tau)|^2}\sum_{m,w\in\mathbb{Z}} \exp\Big[-\frac{\pi R^2}{\tau_2}\,|m - w\tau|^2\Big]. \tag{11.232}$$

This form has a direct meaning. On the torus $\mathbb{C}/(\mathbb{Z} + \mathbb{Z}\tau)$, a classical solution can wind m times around the target as we go around one cycle and w times around the other: $\varphi = 2\pi R(\dots)$ linear in the coordinates. Its action is $\pi R^2|m - w\tau|^2/\tau_2$. The factor $R/(\sqrt{\tau_2}|\eta|^2)$ is the fluctuation determinant and the zero-mode volume. So (11.232) is "sum over classical windings × one-loop determinant", the path integral done exactly.

Worked example 11.83: Modular invariance of the compact boson

Under a general $m(\tau) = (a\tau + b)/(c\tau + d)$:

$$\frac{|m - w\,\tau'|^2}{\tau_2'} \overset{(1)}{=} \frac{|m(c\tau + d) - w(a\tau + b)|^2}{|c\tau + d|^2} \cdot \frac{|c\tau + d|^2}{\tau_2} \overset{(2)}{=} \frac{\big|(md - wb) - (wa - mc)\tau\big|^2}{\tau_2}.$$

(1) $m - w\tau' = \big(m(c\tau + d) - w(a\tau + b)\big)/(c\tau + d)$, and $\tau_2' = \tau_2/|c\tau + d|^2$ (Section 11.7.2).
(2) Collect the constant and the τ terms.

The map $(m, w) \mapsto (md - wb,\ wa - mc)$ is given by an integer matrix of determinant $ad - bc = 1$, so it is a bijection of $\mathbb{Z}^2$: the double sum is just reordered. Meanwhile the prefactor $\sqrt{\tau_2}|\eta|^2$ is invariant: under S, $\sqrt{\tau_2} \to \sqrt{\tau_2}/|\tau|$ and $|\eta|^2 \to |\tau||\eta|^2$ by (11.210); under T both are unchanged. So $Z(\tau; R)$ is modular invariant *for every radius* R. (Numerically, at $R = 1.37$ and $\tau = 0.23 + 0.91i$: $Z = 2.3375179\ldots$ for τ, $-1/\tau$ and $\tau + 1$.)

Worked example 11.84: The non-compact boson

As $R \to \infty$ only $w = 0$ survives in (11.230), and the momentum sum becomes an integral, $\sum_n \to R \int \mathrm{d}p$ with $p = n/R$:

$$Z(\tau; R) \overset{(1)}{=} \frac{R}{|\eta|^2} \int_{\mathbb{R}} \mathrm{d}p\ q^{p^2/4} \bar{q}^{p^2/4} \overset{(2)}{=} \frac{R}{|\eta|^2} \int_{\mathbb{R}} \mathrm{d}p\ e^{-\pi\tau_2 p^2} \overset{(3)}{=} \frac{R}{\sqrt{\tau_2}\,|\eta(\tau)|^2}.$$

(1) Riemann sum with spacing $1/R$.
(2) $q^{p^2/4}\bar{q}^{p^2/4} = e^{2\pi i(\tau - \bar{\tau})p^2/4} = e^{-\pi\tau_2 p^2}$.
(3) Gaussian integral.

The factor R is the volume of the target, an overall normalisation. The function $1/(\sqrt{\tau_2}|\eta|^2)$ is modular invariant, which is the $m = w = 0$ term of (11.232). This is the torus partition function of the free field of [Nash p. 303, (11.7)–(11.8)].

T-duality and the moduli space of $c = 1$ theories

Look at (11.229) again. Exchanging $n \leftrightarrow w$ and $R \leftrightarrow 1/R$ sends $p_L \to p_L$ and $p_R \to -p_R$. Since only p_R^2 enters, the spectrum and hence Z are unchanged:

$$Z(\tau; R) = Z(\tau; 1/R). \tag{11.233}$$

This is **T-duality**: a boson on a circle of radius R is indistinguishable from one on radius $1/R$, with momentum and winding exchanged. (Numerically: $Z(\tau; 1.37) = Z(\tau; 1/1.37)$ to 30 digits.) In the path-integral form it is far from obvious; in the Hamiltonian form it is a relabelling. Figure 11.43 shows the lattice of (p_L, p_R).

So the compact bosons form a one-parameter family of CFTs, all with $c = 1$, labelled by $R \in [1, \infty)$ (the half-line, after T-duality). This is our first example of a **moduli space of conformal field theories**. Some points on it are special (Figure 11.44).

Worked example 11.85: Two special radii

$R = 1$, the self-dual point. Look for states with $(h, \bar{h}) = (1, 0)$: holomorphic currents. $h = p_L^2/4 = 1$ and $p_R = 0$ need $n/R = wR$ and $n/R + wR = \pm 2$. At $R = 1$ this is $n = w = \pm 1$. So two extra currents $J^\pm = :e^{\pm 2i\varphi_L}:$ appear, alongside $J^3 = i\partial\varphi$. Together they form SU(2) at level 1, whose Sugawara central charge $c = 3k/(k + 2) = 1$ matches (Section 11.5.1).

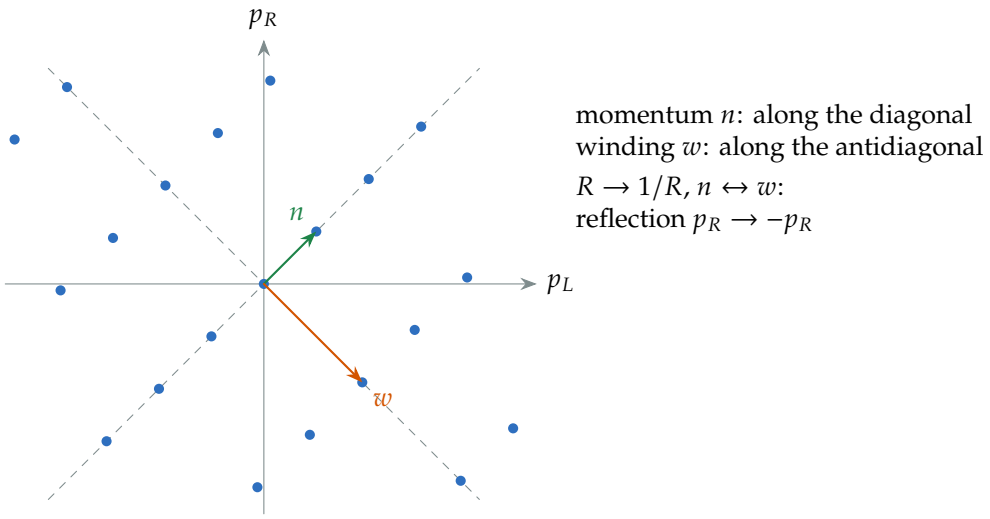

Figure 11.43: The charge lattice of the compact boson at $R = 1.37$: points $(p_L, p_R) = (n/R + wR,\ n/R - wR)$. Momentum steps (green) have length $\sqrt{2}/R$ along the diagonal, winding steps (orange) length $\sqrt{2}R$ along the antidiagonal. What to see: the lattice for radius $1/R$ is the mirror image in the p_L axis, and the spectrum depends only on p_L^2, p_R^2, so the two theories are identical. The lattice is even ($\frac{1}{4}(p_L^2 - p_R^2) = nw \in \mathbb{Z}$) and self-dual, which is the lattice version of T- and S-invariance.

T-duality is part of this enhanced SU(2) symmetry.

$R = \sqrt{2}$, the Dirac fermion. A complex fermion is two Majorana fermions with a common spin structure. Summing over the four spin structures as in (11.205), but now with $c = 1$,

$$Z_{\text{Dirac}} = \frac{|\theta_2|^2 + |\theta_3|^2 + |\theta_4|^2}{2|\eta|^2}. \tag{11.234}$$

This is modular invariant by exactly the argument for Ising (now with $|\theta_i|^2$ and $|\eta|^2$). Numerically it equals $Z(\tau;\sqrt{2})$ (and $Z(\tau;1/\sqrt{2})$): at $\tau = 0.1 + 1.3i$ both are $2.4914614645\ldots$. The two theories are the same: this is bosonisation on the torus, including all spin structures. The triple product (11.219) is the charge-resolved version of this equality.

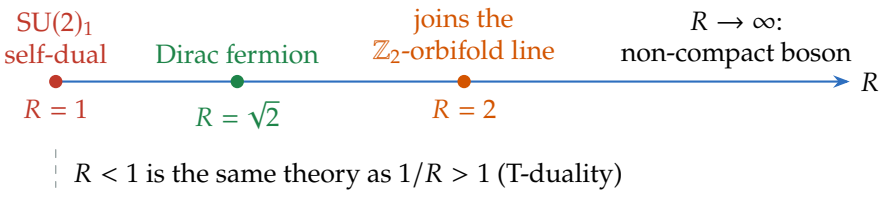

Figure 11.44: The moduli space of compact $c = 1$ bosons is the half-line $R \geq 1$. Every point is a modular-invariant CFT; the partition function varies continuously with R. Marked: the self-dual radius with enhanced $SU(2)_1$ symmetry, the Dirac point, and the point $R = 2$ where this line meets a second $c = 1$ line, the bosons on the orbifold $S^1/\mathbb{Z}_2$ (the circle at $R = 2$ equals the orbifold at $R = 1$). Two decoupled Ising models are not on this line: Z_{Ising}^2 is the orbifold at the Dirac radius $R = \sqrt{2}$. What to see: modular invariance alone does not fix a CFT; there can be continuous families.

Watch out: Two Majoranas are not always a Dirac fermion

The product Z_{Ising}^2 is modular invariant, but it is *not* Z_{Dirac}. In Z_{Ising}^2 the two Majorana fermions sum over their spin structures independently; in Z_{Dirac} they share one. At $\tau = 0.1 + 1.3i$, $Z_{\text{Ising}}^2 = 3.657\ldots$ while $Z_{\text{Dirac}} = 2.491\ldots$. Different sums over spin structures give different (but each consistent) theories. This is the simplest example of the freedom that the classification problem below has to control.

11.8.6 What modular invariance buys: Cardy's constraints

Nash remarks that modular invariance is "a considerable restriction on Z" and cites Cardy. Here are the two most famous consequences.

The high-temperature limit is controlled by the vacuum

Take a rectangular torus, $\tau = it$, and let $t \to 0$: the time circle is much shorter than the space circle, a high temperature. Directly, every state contributes and the sum is hard. After S, $\tilde\tau = i/t$ and $\tilde q = e^{-2\pi/t} \to 0$, so the sum is dominated by its lowest term, the vacuum:

$$Z(it) \overset{(1)}{=} Z(i/t) \overset{(2)}{=} \tilde q^{-c/24}\,\bar{\tilde q}^{-c/24}\big(1 + O(\tilde q^{h_{\min}})\big) \overset{(3)}{=} e^{\pi c/(6t)}\big(1 + O(e^{-2\pi h_{\min}/t})\big). \tag{11.235}$$

(1) S-invariance.
(2) In $\operatorname{Tr} \tilde q^{L_0 - c/24}\bar{\tilde q}^{\bar L_0 - c/24}$ the lowest state is the vacuum ($L_0 = \bar L_0 = 0$, unique); every other state is suppressed by at least $|\tilde q|^{h_{\min}}$, with $h_{\min}$ the lowest nonzero weight.
(3) $\tilde q^{-c/24} = e^{2\pi c/(24t)}$, squared.

For Ising, $c = \frac{1}{2}$ and $h_{\min} = \frac{1}{16}$:

t	$Z_{\text{Ising}}(it)$ (exact, from (11.224))	$e^{\pi c/6t}$	ratio
0.2	3.7754	3.7025	1.020
0.1	13.7135	13.7082	1.0004
0.05	187.9147	187.9146	1.0000002

Put units back: space circle L, inverse temperature $\beta = tL$ (with the velocity set to 1). Then $\ln Z = \pi c L/(6\beta)$, i.e. the free energy per unit length is

$$f(T) = -\frac{\pi c}{6}\,T^2, \qquad C(T) = \frac{\pi c}{3}\,T. \tag{11.236}$$

The low-temperature specific heat of a critical chain measures c. This is the finite-temperature twin of the Casimir energy (11.197), and modular invariance is what makes them twins: S swaps the circle of length L with the circle of length β.

Cardy's formula for the density of states

Write $Z(it) = \int \rho(\Delta) e^{-2\pi t(\Delta - c/12)}\mathrm{d}\Delta$, with $\Delta = L_0 + \bar L_0$ and ρ the density of states. For small t the integral is dominated by large Δ, and a saddle point must reproduce (11.235). Assume $\rho(\Delta) \approx e^{S(\Delta)}$ and maximise the exponent $S(\Delta) - 2\pi t\Delta$; then $\ln Z \approx S - 2\pi t\Delta$ at the saddle, a Legendre transform. Inverting it:

$$S(\Delta) \overset{(1)}{=} \min_t\Big(\frac{\pi c}{6t} + 2\pi t\Delta\Big) \overset{(2)}{=} \frac{\pi c}{6t_*} + 2\pi t_*\Delta\Big|_{t_* = \sqrt{c/12\Delta}} \overset{(3)}{=} 2\pi\sqrt{\frac{c\,\Delta}{3}}.$$

(1) Inverse Legendre transform of $\ln Z(t) = \pi c/6t$.
(2) Stationarity: $-\pi c/(6t^2) + 2\pi\Delta = 0$.
(3) At the stationary point both terms equal $\pi\sqrt{c\Delta/3}$.

This is **Cardy's formula**: $\rho(\Delta) \sim \exp\!\left(2\pi\sqrt{c\Delta/3}\right)$. The growth of the number of high-energy states is fixed by the central charge alone. (For the non-chiral string, the same argument gives the Hagedorn growth of the spectrum; for black holes it counts microstates in Strominger–Vafa.) The lesson is Nash's: a single symmetry of Z ties the ultraviolet (many states) to the infrared (the vacuum energy).

11.8.7 Classifying modular invariants: the ADE pattern

Modular invariance can be used as a classification tool. Fix a chiral algebra and its characters χ_i with S and T matrices. Look for all matrices M with

$$M_{ij} \in \mathbb{Z}_{\geq 0}, \qquad M_{00} = 1, \qquad [M, S] = [M, T] = 0. \tag{11.237}$$

Each solution is a candidate partition function $\sum M_{ij}\chi_i\bar{\chi}_j$ of a consistent theory. For Ising, the only solution is $M = I$: the lattice model is the *only* CFT built from $c = \frac{1}{2}$ Virasoro modules. (Try it: T-invariance forbids off-diagonal terms because the three T-phases differ, so M is diagonal; then $S^{\mathsf{T}}MS = M$ with $M = \mathrm{diag}(1, a, b)$ forces $a = b = 1$ from the first row.)

The richest test case is SU(2) at level k (the WZW models of Figure 11.28). There are $k+1$ primaries, labelled by $a = 2j \in \{0, 1, \ldots, k\}$, with

$$h_a = \frac{a(a+2)}{4(k+2)}, \qquad c = \frac{3k}{k+2}, \qquad S_{ab} = \sqrt{\frac{2}{k+2}}\,\sin\frac{\pi(a+1)(b+1)}{k+2}. \tag{11.238}$$

Cappelli, Itzykson and Zuber found *all* solutions of (11.237) (1987). Writing χ_λ with $\lambda = a+1 \in \{1, \ldots, k+1\}$ (the dimension of the SU(2) representation), the list is:

name	level	partition function
A_{k+1}	all k	$\sum_{\lambda=1}^{k+1} \lvert\chi_\lambda\rvert^2$
$D_{2\rho+2}$	$k = 4\rho$	$\sum_{\lambda\ \text{odd},\ \lambda<2\rho+1} \lvert\chi_\lambda + \chi_{k+2-\lambda}\rvert^2 + 2\lvert\chi_{2\rho+1}\rvert^2$
$D_{2\rho+1}$	$k = 4\rho - 2$	$\sum_{\lambda\ \text{odd}} \lvert\chi_\lambda\rvert^2 + \sum_{\lambda\ \text{even}} \chi_\lambda\bar{\chi}_{k+2-\lambda}$
E_6	$k = 10$	$\lvert\chi_1 + \chi_7\rvert^2 + \lvert\chi_4 + \chi_8\rvert^2 + \lvert\chi_5 + \chi_{11}\rvert^2$
E_7	$k = 16$	$\lvert\chi_1 + \chi_{17}\rvert^2 + \lvert\chi_5 + \chi_{13}\rvert^2 + \lvert\chi_7 + \chi_{11}\rvert^2 + \lvert\chi_9\rvert^2 + \left[(\chi_3 + \chi_{15})\bar{\chi}_9 + \text{c.c.}\right]$
E_8	$k = 28$	$\lvert\chi_1 + \chi_{11} + \chi_{19} + \chi_{29}\rvert^2 + \lvert\chi_7 + \chi_{13} + \chi_{17} + \chi_{23}\rvert^2$

(We checked each of D_4, D_5, E_6, E_7, E_8 numerically against (11.228).)

Worked example 11.86: Why the labels are Dynkin diagrams

Take E_6 at $k = 10$. The labels λ that appear on the diagonal of M (with multiplicity) are $1, 4, 5, 7, 8, 11$. These are exactly the **exponents** of the Lie algebra E_6, and $k + 2 = 12$ is its **Coxeter number**. The same holds for every entry:

invariant	$k+2$	diagonal labels in M	Lie algebra: Coxeter number, exponents
A_{k+1}	$k+2$	$1, 2, \ldots, k+1$	A_{k+1}: $h = k+2$, $1, \ldots, k+1$
D_4 ($k=4$)	6	$1, 3, 3, 5$	D_4: $h = 6$, $1, 3, 3, 5$
E_6 ($k=10$)	12	$1, 4, 5, 7, 8, 11$	E_6: $h = 12$, $1, 4, 5, 7, 8, 11$
E_8 ($k=28$)	30	$1, 7, 11, 13, 17, 19, 23, 29$	E_8: $h = 30$, same list

For D_4: $M = |\chi_1 + \chi_5|^2 + 2|\chi_3|^2$ has diagonal entries $M_{11} = M_{55} = 1$ and $M_{33} = 2$, i.e. the labels $1, 5, 3, 3$. Nobody has a fully satisfying explanation of why modular invariance "knows" the simply laced Dynkin diagrams; it is one of the correspondences Nash calls "intriguing". The same ADE list classifies finite subgroups of SU(2), simple singularities $\mathbb{C}^2/\Gamma$, and quivers of finite type.

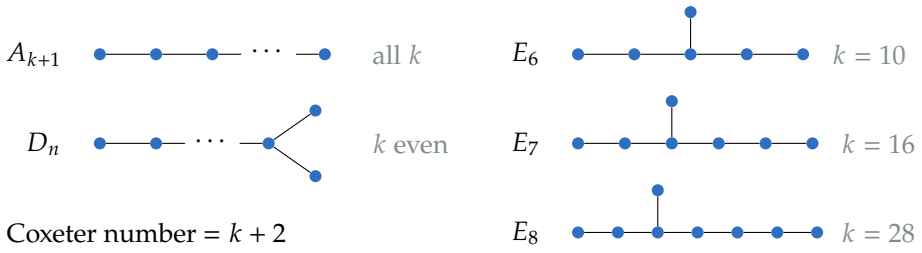

Figure 11.45: The simply laced Dynkin diagrams and the levels at which the corresponding $SU(2)_k$ modular invariants occur. What to see: the classification of modular-invariant partition functions, a purely analytic problem about q-series, reproduces the ADE list; the Virasoro minimal models are then classified by *pairs* (A_m, G) with Coxeter numbers $m+1$ and $m+2$, e.g. Ising = (A_2, A_3) and three-state Potts = (A_4, D_4).

Why pairs of Lie algebras, as Nash says? The minimal models can be built as cosets $SU(2)_k \times SU(2)_1/SU(2)_{k+1}$, so their invariants are products of an $SU(2)_{m-1}$ invariant and an $SU(2)_m$ invariant, one of each type. The Coxeter numbers of the pair are $m+1$ and $m+2$, the two integers in $c = 1 - 6/((m+1)(m+2))$. The Ising model, $m = 2$, is (A_2, A_3) and has only the diagonal invariant: that is the statement "$M = I$ is the only solution" above. The first model with a non-diagonal invariant is $m = 5$, $c = \frac{4}{5}$, where (A_4, D_4) is the three-state Potts model: a genuinely different lattice model from the tetracritical Ising model (A_4, A_5) at the same c.

Reading Nash (pp. 312–313, (11.52)–(11.59))

Nash defines η (11.52), relates the Ising $|\chi|^2$ to η at $\tau/2, \tau, 2\tau$ (11.53), defines modular forms of weight k via $f(\tau)\mathrm{d}\tau^k$ (11.54)–(11.55), states η^{24}'s law (11.56)–(11.57) and η's laws (11.58)–(11.59), and leaves the invariance of Z as "a routine matter". We derived (11.53) from the fermion products (correcting the factor 2 in its second line), proved (11.59) through $2\eta^3 = \theta_2\theta_3\theta_4$ and Poisson summation, and did the routine matter in (11.224). Note Nash's "weight 6" for η^{24} is weight 12 in modern language. His last paragraph (Cardy; Cappelli–Itzykson–Zuber and the A, D, E series) is our Sections 11.8.6 and 11.8.7.

Recap

- $\eta = q^{1/24}\prod(1-q^n)$: $\eta(\tau+1) = e^{i\pi/12}\eta$, $\eta(-1/\tau) = (-i\tau)^{1/2}\eta$. Modular forms change by $(c\tau+d)^{2k}$ (Nash's weight k); η^{24} has Nash-weight 6.
- Poisson summation turns a Gaussian lattice sum at τ into one at $-1/\tau$: $\theta_3 \to \theta_3$,

$\theta_2 \leftrightarrow \theta_4$. The triple product (bosonisation) gives θ's as products and $2\eta^3 = \theta_2\theta_3\theta_4$.

- $Z_{\text{Ising}} = (|\theta_2| + |\theta_3| + |\theta_4|)/2|\eta|$ is manifestly S- and T-invariant. The characters carry a unitary representation (S, T) of $\mathrm{PSL}(2,\mathbb{Z})$.
- Compact boson: $Z = |\eta|^{-2} \sum q^{p_L^2/4} \bar{q}^{p_R^2/4}$; Poisson resummation gives the winding (path-integral) form, which is manifestly invariant. $Z(R) = Z(1/R)$; a line of $c = 1$ theories.
- Cardy: $Z \approx e^{\pi c/6t}$ at high temperature; $\rho \sim e^{2\pi\sqrt{c\Delta/3}}$. CIZ: modular invariants of $\mathrm{SU}(2)_k$ follow the ADE classification.

11.9 Operator products and correlation functions

The torus taught us which representations a CFT contains. It did not tell us how the fields *interact*: what happens when two of them come close, and what the correlation functions are. Nash's §5 turns to this question. Its message is that conformal symmetry is so strong that a whole CFT is fixed by a small, finite amount of data:

the list of primary fields with their weights $(h_i, \bar{h}_i)$, the central charge c, and one number C_{ij}^{k} for each triple of primaries.

Everything else (every correlation function of every field, at any number of points) is then determined by symmetry and by a consistency condition, crossing symmetry. This section shows how, step by step:

1. a conformal family is a primary field plus its descendants, and correlators of descendants reduce to correlators of primaries;
2. two- and three-point functions of primaries are fixed up to constants;
3. the four-point function is fixed up to a function of one complex variable, the cross ratio;
4. the operator product expansion (OPE) of two primaries is fixed by the C_{ij}^{k};
5. inserting the OPE into the four-point function splits it into *conformal blocks*;
6. for the Ising model we compute everything explicitly: the blocks of $\langle\sigma\sigma\sigma\sigma\rangle$, the fusion $\sigma \times \sigma = \mathbf{1} + \varepsilon$, and the constant $C_{\sigma\sigma\varepsilon} = \tfrac{1}{2}$.

Figure 11.46 shows how the pieces feed into each other.

Conventions for this section

We use the holomorphic language of §§2–3. A primary field $\phi(z, \bar{z})$ of weights $(h, \bar{h})$ has the operator product with the energy–momentum tensor

$$T(z)\,\phi(w,\bar{w}) = \frac{h\,\phi(w,\bar{w})}{(z-w)^2} + \frac{\partial_w \phi(w,\bar{w})}{z-w} + \text{regular}, \tag{11.239}$$

Nash's (11.26). The Virasoro modes are $L_n = \oint \frac{\mathrm{d}z}{2\pi i}\, z^{n+1} T(z)$, and (11.239) is equivalent to the commutator

$$[L_n, \phi(z)] = z^n \big(z\partial_z + (n+1)h\big)\phi(z), \tag{11.240}$$

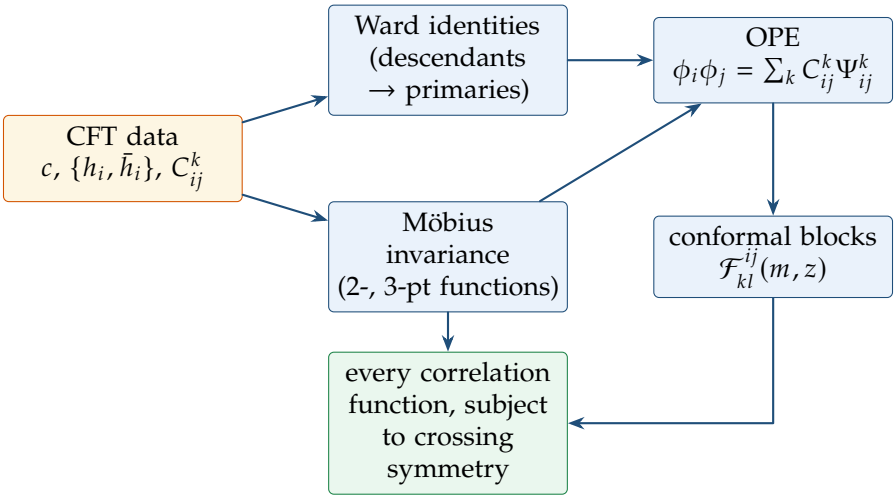

Figure 11.46: The logic of this section. What to see: the only inputs are the spectrum and the three-point constants; symmetry does the rest, and crossing symmetry is the one remaining condition that the data must satisfy.

where we suppress $\bar{z}$. The in-state of a primary is $|h\rangle = \phi(0)|0\rangle$ and its out-state is $\langle h| = \lim_{w\to\infty} w^{2h}\bar{w}^{2\bar{h}}\langle 0|\phi(w,\bar{w})$. Throughout, a formula written for the holomorphic side has an identical antiholomorphic partner, and we write only the first.

11.9.1 Conformal families and descendant fields

Nash starts with a theory that has finitely many primary fields $\phi_1, \dots, \phi_F$. Each generates a **conformal family** $[\phi_i]$: the primary together with everything the Virasoro raising operators make from it. A theory with finitely many families is a **rational conformal field theory** (RCFT). The Ising model is rational with $F = 3$; the non-compact free boson is not (it has a continuum of primaries V_p). The Hilbert space is Nash's

$$\mathcal{H} = \bigoplus_{i=1}^{F} H_i \otimes \bar{H}_i,$$

where $H_i = L(c, h_i)$ is the irreducible Virasoro module of Section 11.6.1 and $\bar{H}_i$ its antiholomorphic partner. (This is (11.200) with the diagonal multiplicities $m_{h,\bar{h}} = \delta_{h\bar{h}}$.)

Multi-index notation

A descendant state is a string of raising operators acting on $|h_i\rangle$. Nash packs the string into a multi-index. For $I = (i_1, \dots, i_s)$ with $i_1 \geq \cdots \geq i_s \geq 1$ he writes

$$L^I = L_{-i_1}\cdots L_{-i_s}, \qquad |I| = i_1 + \cdots + i_s, \qquad \bar{L}^J = \bar{L}_{-j_1}\cdots\bar{L}_{-j_t}, \tag{11.241}$$

Nash's (11.60). Then $L^I\bar{L}^J|h_i\rangle$ has weights $(h_i + |I|, \bar{h}_i + |J|)$. The multi-indices at level N are the partitions of N, so the table in Section 11.6.1 is also the list of multi-indices: $I = (1)$; $I = (2), (1,1)$; $I = (3), (2,1), (1,1,1)$; and so on.

From descendant states to descendant fields

In radial quantisation every state is created by a field at the origin (the state–field correspondence). So each descendant state must be created by a **descendant field**. Nash denotes it

$$\Phi_i^{I,J}(z,\bar z) = L^I(z)\,\bar L^J(\bar z)\,\phi_i(z,\bar z), \tag{11.242}$$

his (11.61). What does $L_{-n}(z)$ acting on a field at z mean? It is the same contour integral as L_{-n}, but centred on z instead of on the origin.

Working definition 11.30 (descendant field)

For a field $A(w)$ and $n \geq 1$,

$$(L_{-n}A)(w) := \oint_w \frac{\mathrm{d}z}{2\pi i}\,(z-w)^{1-n}\,T(z)A(w),$$

where the small contour encircles w and no other insertion. *How to compute it:* write the OPE $T(z)A(w)$ [for a primary A of weight h it begins $\frac{hA(w)}{(z-w)^2} + \frac{\partial A(w)}{z-w}$, followed by nonsingular terms] as a Laurent series in $z-w$; then $(L_{-n}A)(w)$ is the coefficient of $(z-w)^{n-2}$. Iterating gives $L^I(w)\phi(w)$ for any multi-index.

At $w=0$ the definition is literally L_{-n} acting on the state:

$$(L_{-n}A)(0)|0\rangle = \oint \frac{\mathrm{d}z}{2\pi i}\,z^{1-n}T(z)A(0)|0\rangle = L_{-n}A(0)|0\rangle,$$

since $z^{1-n} = z^{(-n)+1}$ is the weight in the definition of L_{-n}.

Worked example 11.87: The first descendants of a primary and of the identity

Read off coefficients from (11.239):

$$(L_{-1}\phi)(w) \overset{(1)}{=} \oint_w \frac{\mathrm{d}z}{2\pi i}\Big(\frac{h\phi(w)}{(z-w)^2} + \frac{\partial\phi(w)}{z-w} + \dots\Big) \overset{(2)}{=} \partial\phi(w),$$
$$(L_0\phi)(w) \overset{(3)}{=} \oint_w \frac{\mathrm{d}z}{2\pi i}\,(z-w)\,T(z)\phi(w) = h\,\phi(w),$$
$$(L_{-2}\phi)(w) \overset{(4)}{=} \oint_w \frac{\mathrm{d}z}{2\pi i}\,\frac{T(z)\phi(w)}{z-w} \overset{(5)}{=} :T\phi:(w).$$

(1) The definition with $n=1$, so $(z-w)^{1-n}=1$.
(2) Residue theorem: only the simple pole contributes.
(3) $n=0$: now the double pole becomes a simple pole with residue $h\phi$.
(4) $n=2$.
(5) The integrand's residue is the $(z-w)^0$ term of the OPE, which is by definition the normal-ordered product.

So L_{-1} is differentiation: the family $[\phi]$ contains all derivatives $\partial^k\phi$. For the identity field $\mathbf{1}$ the OPE $T(z)\mathbf{1} = T(z)$ is regular, so $L_{-1}\mathbf{1}=0$ (the vacuum is translation invariant) and $(L_{-2}\mathbf{1})(w) = T(w)$. *The energy–momentum tensor is a descendant of the identity*, at level 2. This is why T is not a primary field (its transformation law has the Schwarzian term) and yet belongs to the theory with no new label: it lives in the family $[\mathbf{1}]$.

Figure 11.47 draws a conformal family as a tower of fields, next to the contour that defines a descendant.

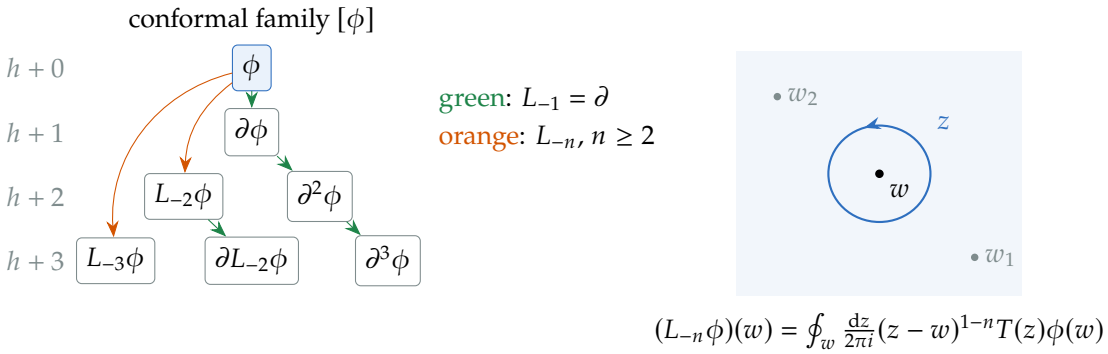

Figure 11.47: Left: the conformal family of a primary ϕ up to level 3, as fields (compare the states of Figure 11.35). Each level is a weight $h+N$; the green arrows are derivatives. Right: the contour that defines a descendant field encloses only w. What to see: a descendant is the primary "dressed" by a loop of T; the other insertions w_1, w_2 lie outside the loop, which is what lets us move the loop onto them.

11.9.2 Correlators of descendants reduce to primaries

Nash's most general correlation function (11.62) is

$$\left\langle \Phi_{i_1}^{I_1,J_1}(z_1,\bar z_1)\cdots\Phi_{i_n}^{I_n,J_n}(z_n,\bar z_n)\right\rangle, \tag{11.243}$$

and he asserts that the Ward identities express it through the correlators $\langle\phi_{i_1}\cdots\phi_{i_n}\rangle$ of primaries alone. Here is the mechanism, in one line and then in detail: *a descendant is a contour of T around a primary; deform the contour until it wraps the other insertions, and there the $T\phi$ OPE turns it into derivatives.*

Key idea: Descendant Ward identity

For primaries ϕ_i of weights h_i at points w_i, and any field ϕ at w (primary or not),

$$\left\langle (L_{-n}\phi)(w)\,\phi_1(w_1)\cdots\phi_N(w_N)\right\rangle = \mathcal{L}_{-n}\left\langle \phi(w)\,\phi_1(w_1)\cdots\phi_N(w_N)\right\rangle, \tag{11.244}$$

with the differential operator

$$\mathcal{L}_{-n} = \sum_{i=1}^{N}\left[\frac{(n-1)h_i}{(w_i-w)^n} - \frac{1}{(w_i-w)^{n-1}}\frac{\partial}{\partial w_i}\right], \qquad n\geq 1. \tag{11.245}$$

Let $X=\phi_1(w_1)\cdots\phi_N(w_N)$. As a function of z, the correlator $\langle T(z)\phi(w)X\rangle$ is meromorphic on the sphere, with poles only at w and the w_i, and it falls off like z^{-4} at infinity (because T is regular at $z=\infty$ in the coordinate $u=1/z$, where $T(z)=u^4T'(u)$). Then

$$\begin{aligned}\left\langle (L_{-n}\phi)(w)X\right\rangle &\overset{(1)}{=} \oint_w \frac{dz}{2\pi i}(z-w)^{1-n}\left\langle T(z)\phi(w)X\right\rangle \\ &\overset{(2)}{=} -\sum_{i=1}^{N}\oint_{w_i}\frac{dz}{2\pi i}(z-w)^{1-n}\left\langle T(z)\phi(w)X\right\rangle \\ &\overset{(3)}{=} -\sum_{i=1}^{N}\oint_{w_i}\frac{dz}{2\pi i}(z-w)^{1-n}\left[\frac{h_i}{(z-w_i)^2}+\frac{1}{z-w_i}\frac{\partial}{\partial w_i}\right]\left\langle\phi(w)X\right\rangle\end{aligned}$$

$$\overset{(4)}{=} -\sum_{i=1}^{N}\Big[(1-n)(w_i-w)^{-n}h_i + (w_i-w)^{1-n}\frac{\partial}{\partial w_i}\Big]\big\langle\phi(w)X\big\rangle \overset{(5)}{=} \mathcal{L}_{-n}\big\langle\phi(w)X\big\rangle. \tag{11.246}$$

(1) The definition of the descendant field.
(2) On the sphere the sum of all residues of a meromorphic 1-form is zero (Stokes' theorem on the sphere minus small discs). The 1-form $(z-w)^{1-n}\langle T\phi X\rangle\,\mathrm{d}z$ decays like $z^{-3-n}\mathrm{d}z$ at infinity, so there is no residue there for $n \geq 1$. Hence the contour around w equals minus the sum of contours around the w_i (Figure 11.48).
(3) Near w_i only the singular part of the OPE $T(z)\phi_i(w_i)$, (11.239), has a residue; the other fields are spectators.
(4) Residues: $\oint_{w_i}\frac{f(z)}{(z-w_i)^2} = f'(w_i)$ and $\oint_{w_i}\frac{f(z)}{z-w_i} = f(w_i)$, with $f(z) = (z-w)^{1-n}$.
(5) Rearranged, this is (11.245).

Since $\mathcal{L}_{-n}$ only involves the positions and weights of the *other* fields, we can iterate: a field $L_{-n_1}L_{-n_2}\phi$ gives $\mathcal{L}_{-n_1}\mathcal{L}_{-n_2}$ acting on $\langle\phi X\rangle$ (with care about the order: the inner operator is applied first, and the outer one also acts on the w-dependence through the $(w_i - w)$ factors). Descendants of the *other* fields are handled by the same argument, one at a time. That is Nash's claim: all of (11.243) follows from the primary correlators.

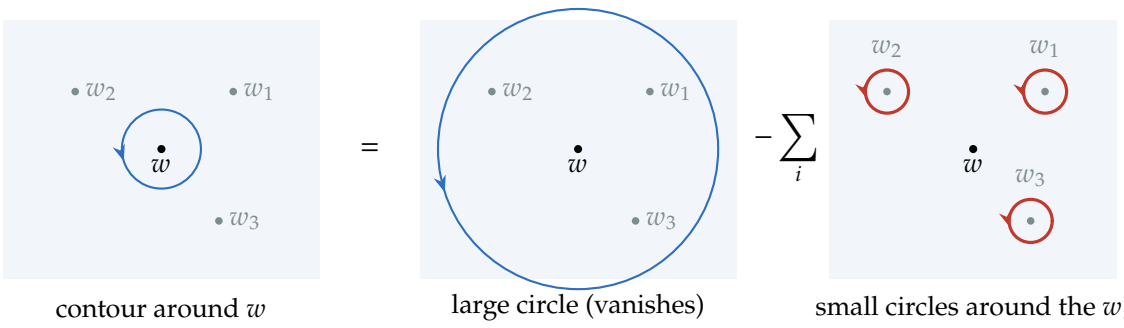

Figure 11.48: Contour deformation behind the Ward identity (11.246). The small loop around w is blown up into a large circle (which contributes nothing because $T \sim z^{-4}$ at infinity) minus loops around every other insertion (red). What to see: the action of T on one field is traded for its action on all the others, where the OPE (11.239) turns it into h_i's and derivatives.

Worked example 11.88: Two checks of the Ward operator

$n = 1$. (11.245) gives $\mathcal{L}_{-1} = -\sum_i \partial_{w_i}$. On the other hand $L_{-1}\phi = \partial_w\phi$. So the identity says $\partial_w\langle\phi X\rangle = -\sum_i \partial_{w_i}\langle\phi X\rangle$, i.e.

$$\Big(\partial_w + \sum_i \partial_{w_i}\Big)\langle\phi(w)X\rangle = 0,$$

which is translation invariance. Good.
$n = 2$ **on the identity.** Take $\phi = \mathbf{1}$, so $(L_{-2}\mathbf{1})(w) = T(w)$ and $\langle\mathbf{1}X\rangle = \langle X\rangle$:

$$\begin{aligned}\langle T(w)\,\phi_1(w_1)\cdots\phi_N(w_N)\rangle &\overset{(1)}{=} \sum_i\Big[\frac{h_i}{(w_i-w)^2} - \frac{1}{w_i-w}\partial_{w_i}\Big]\langle X\rangle \\ &\overset{(2)}{=} \sum_i\Big[\frac{h_i}{(w-w_i)^2} + \frac{1}{w-w_i}\partial_{w_i}\Big]\langle X\rangle.\end{aligned}$$

(1) (11.244) with $n = 2$.

(2) $(w_i - w)^2 = (w - w_i)^2$ and $-1/(w_i - w) = 1/(w - w_i)$.

This is the conformal Ward identity of §2 (Nash's (11.17)–(11.19) in correlator form): the singular behaviour of T near each insertion is exactly (11.239), and nothing else.

Watch out: Descendants of the identity are not zero

Since $\langle \mathbf{1} \rangle = 1$ and $\mathcal{L}_{-n}$ acts on the other fields, correlators like $\langle T(w)T(w') \rangle$ are not given by (11.244) with primaries only: T is not primary, and its OPE with itself has the extra $\frac{c/2}{(z-w)^4}$ term. So for descendants of $\mathbf{1}$ one must keep the central term; for example $\langle T(w)T(w') \rangle = \frac{c/2}{(w-w')^4}$. The reduction still works, but c now enters. This is how the central charge gets into every correlator.

11.9.3 Two- and three-point functions

Among all Ward identities, three are special. They come from the global conformal transformations, the Möbius maps generated by L_{-1}, L_0, L_1 (Section 11.5.1). Their statement is that correlators of primaries are *exactly* invariant, with no contour needed.

Working definition 11.31 (global Ward identities)

For primaries ϕ_i of weights h_i [fields for which $\phi_i \, \mathrm{d}z^{h_i} \mathrm{d}\bar{z}^{\bar{h}_i}$ is invariant under conformal maps] at points z_i, the function $G = \langle \phi_1(z_1) \cdots \phi_n(z_n) \rangle$ obeys

$$\sum_i \partial_i G = 0, \qquad \sum_i \big(z_i \partial_i + h_i\big) G = 0, \qquad \sum_i \big(z_i^2 \partial_i + 2h_i z_i\big) G = 0, \tag{11.247}$$

with $\partial_i = \partial/\partial z_i$ (and the same with bars). *How to use it:* three linear PDEs in n variables; they cut the number of free variables from n to $n - 3$ [for $n \geq 3$ a Möbius map can move z_1, z_2, z_3 to $0, 1, \infty$, so only the positions of the others remain free].

Where do they come from? The previous example gives $\langle T(z)X \rangle = \sum_i [h_i (z - z_i)^{-2} + (z - z_i)^{-1} \partial_i] \langle X \rangle$. Expand at large z:

$$\langle T(z)X \rangle \overset{(1)}{=} \frac{1}{z} \sum_i \partial_i \langle X \rangle + \frac{1}{z^2} \sum_i \big(z_i \partial_i + h_i\big) \langle X \rangle + \frac{1}{z^3} \sum_i \big(z_i^2 \partial_i + 2h_i z_i\big) \langle X \rangle + O(z^{-4}).$$

(1) $\frac{1}{z - z_i} = \frac{1}{z} + \frac{z_i}{z^2} + \frac{z_i^2}{z^3} + \cdots$ and $\frac{1}{(z-z_i)^2} = \frac{1}{z^2} + \frac{2z_i}{z^3} + \cdots$; collect powers.

Since $\langle T(z)X \rangle = O(z^{-4})$, the coefficients of z^{-1}, z^{-2}, z^{-3} vanish: that is (11.247). They are the statements that L_{-1}, L_0, L_1 annihilate both $|0\rangle$ and $\langle 0|$.

Worked example 11.89: The two-point function, Nash's (11.63) first line

Let $G(z_1, z_2) = \langle \phi_i(z_1) \phi_j(z_2) \rangle$. The first identity makes G a function of $z_{12} = z_1 - z_2$ only. The second:

$$0 \overset{(1)}{=} \big(z_1 \partial_1 + z_2 \partial_2 + h_i + h_j\big) G(z_{12}) \overset{(2)}{=} \big(z_{12} G'(z_{12}) + (h_i + h_j) G\big) \quad \Longrightarrow \quad G \overset{(3)}{=} \frac{C_{ij}}{z_{12}^{\,h_i + h_j}}.$$

(1) The L_0 identity.
(2) Chain rule: $\partial_1 G = G'$, $\partial_2 G = -G'$.
(3) The solution of $xG' = -aG$ is $G = Cx^{-a}$.

The third identity now gives a condition on the weights:

$$\big(z_1^2\partial_1 + z_2^2\partial_2 + 2h_i z_1 + 2h_j z_2\big)G \overset{(1)}{=} \Big[-(h_i+h_j)\frac{z_1^2 - z_2^2}{z_{12}} + 2h_i z_1 + 2h_j z_2\Big]G$$
$$\overset{(2)}{=} \big[-(h_i+h_j)(z_1+z_2) + 2h_i z_1 + 2h_j z_2\big]G = (h_i - h_j)\, z_{12}\, G.$$

(1) $\partial_1 G = -(h_i+h_j)G/z_{12}$ and $\partial_2 G = +(h_i+h_j)G/z_{12}$.
(2) $z_1^2 - z_2^2 = (z_1+z_2)z_{12}$.

So $C_{ij} = 0$ unless $h_i = h_j$ (and $\bar h_i = \bar h_j$). Including the antiholomorphic side,

$$\langle \phi_i(z_1,\bar z_1)\phi_j(z_2,\bar z_2)\rangle = \frac{C_{ij}}{z_{12}^{\,h_i+h_j}\,\bar z_{12}^{\,\bar h_i+\bar h_j}} = \frac{C_{ij}}{z_{12}^{\,2h_i}\,\bar z_{12}^{\,2\bar h_i}},$$

which is Nash's formula. One usually chooses a basis of primaries with $C_{ij} = \delta_{ij}$.

Worked example 11.90: The three-point function, Nash's (11.63) second line

Try $G = C\, z_{12}^a z_{13}^b z_{23}^d$; it already obeys the L_{-1} identity. With $\partial_1 = \frac{a}{z_{12}} + \frac{b}{z_{13}}$, $\partial_2 = -\frac{a}{z_{12}} + \frac{d}{z_{23}}$, $\partial_3 = -\frac{b}{z_{13}} - \frac{d}{z_{23}}$ (acting on $\log G$):

$$\frac{1}{G}\sum_i z_i^2\partial_i G \overset{(1)}{=} a\frac{z_1^2 - z_2^2}{z_{12}} + b\frac{z_1^2 - z_3^2}{z_{13}} + d\frac{z_2^2 - z_3^2}{z_{23}} \overset{(2)}{=} a(z_1+z_2) + b(z_1+z_3) + d(z_2+z_3).$$

(1) Collect the terms with the same z_{ij}.
(2) Difference of squares, as before.

Adding $2h_1z_1 + 2h_2z_2 + 2h_3z_3$ and demanding that the coefficient of each z_i vanish:

$$a+b = -2h_1, \qquad a+d = -2h_2, \qquad b+d = -2h_3$$
$$\Longrightarrow \quad a = -(h_1+h_2-h_3),\ \ b = -(h_1+h_3-h_2),\ \ d = -(h_2+h_3-h_1).$$

(The L_0 identity, $a+b+d = -(h_1+h_2+h_3)$, is then automatic.) So

$$\langle \phi_i(z_1)\phi_j(z_2)\phi_k(z_3)\rangle = \frac{C_{ijk}}{z_{12}^{\,h_i+h_j-h_k}\, z_{13}^{\,h_i+h_k-h_j}\, z_{23}^{\,h_j+h_k-h_i}} \times (\text{same with bars}), \tag{11.248}$$

Nash's (11.63). *One number C_{ijk} per triple* is all the freedom.

Worked example 11.91: Checking (11.248) on vertex operators

For the free boson, Wick's theorem (the Coulomb-gas formula of §2) gives, for $\alpha_1+\alpha_2+\alpha_3 = 0$, $\langle V_{\alpha_1}(z_1)V_{\alpha_2}(z_2)V_{\alpha_3}(z_3)\rangle = \prod_{i<j}|z_{ij}|^{\alpha_i\alpha_j}$. With $h_i = \alpha_i^2/4$, the predicted exponent of z_{12} is

$$-(h_1+h_2-h_3) \overset{(1)}{=} -\tfrac14\big(\alpha_1^2+\alpha_2^2-(\alpha_1+\alpha_2)^2\big) = \tfrac12\alpha_1\alpha_2,$$

(1) $\alpha_3 = -(\alpha_1+\alpha_2)$.

and $|z_{12}|^{\alpha_1\alpha_2} = z_{12}^{\alpha_1\alpha_2/2}\bar z_{12}^{\alpha_1\alpha_2/2}$ has exactly this exponent. Similarly for z_{13}, z_{23}. Here $C_{123} = 1$ if the charges add to zero and 0 otherwise.

Physical picture: Why three points and not four

A Möbius map has three complex parameters and can send any three distinct points to any other three. So there is nothing Möbius invariant to build from three points: the three-point function has no room for an arbitrary function. With four points there is exactly one invariant left over, the cross ratio. With n points there are $n-3$.

11.9.4 Four points and the anharmonic ratio

Working definition 11.32 (cross ratio)

For four distinct points of the Riemann sphere [$\mathbb{C}$ with the one point ∞ added], the **anharmonic (cross) ratio** is

$$z_{12,34} = \frac{(z_1 - z_2)(z_3 - z_4)}{(z_1 - z_3)(z_2 - z_4)}, \tag{11.249}$$

Nash's (11.64), and similarly $\bar{z}_{12,34}$. *Test:* it is unchanged by every Möbius map [$z \mapsto \frac{az+b}{cz+d}$ with $ad - bc = 1$, applied to all four points at once], and it takes every value in $\mathbb{C} \setminus \{0, 1\}$ as the points vary.

Worked example 11.92: The cross ratio is Möbius invariant

It suffices to check the generators: translations $z \mapsto z + b$ and scalings $z \mapsto az$ obviously leave (11.249) alone. For the inversion $z \mapsto -1/z$,

$$z_i - z_j \;\mapsto\; -\frac{1}{z_i} + \frac{1}{z_j} \overset{(1)}{=} \frac{z_i - z_j}{z_i z_j}, \qquad \text{so} \qquad z_{12,34} \;\mapsto\; \frac{\frac{z_{12}}{z_1 z_2}\,\frac{z_{34}}{z_3 z_4}}{\frac{z_{13}}{z_1 z_3}\,\frac{z_{24}}{z_2 z_4}} \overset{(2)}{=} z_{12,34}.$$

(1) Common denominator.

(2) Numerator and denominator both carry $1/(z_1 z_2 z_3 z_4)$.

Every Möbius map is a composition of these (Section 11.5.1).

Now use the invariance to move three of the points to $\infty, 1, 0$. The Möbius map $f(\zeta) = \frac{(\zeta - z_4)(z_2 - z_1)}{(\zeta - z_1)(z_2 - z_4)}$ sends $z_1 \mapsto \infty$, $z_2 \mapsto 1$, $z_4 \mapsto 0$, and $z_3 \mapsto z_{12,34}$. (Check: $f(z_3) = \frac{z_{34} z_{21}}{z_{31} z_{24}} = \frac{z_{12} z_{34}}{z_{13} z_{24}}$.) This is why Nash places the four fields at $(\infty, 1, z, 0)$: the one remaining position z *is* the cross ratio. Figure 11.49 shows it.

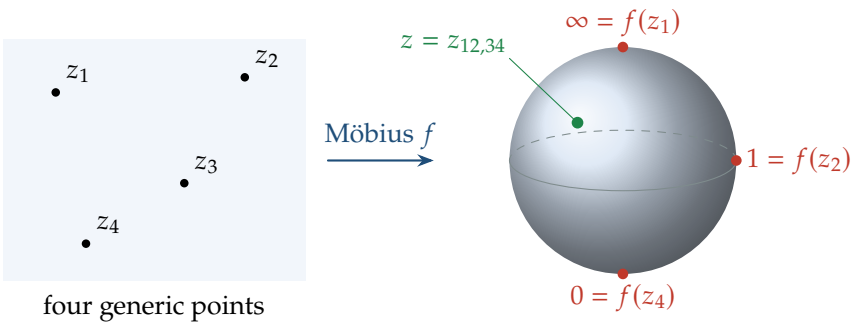

Figure 11.49: Using the three complex parameters of PSL(2, $\mathbb{C}$) to fix three of four points at $\infty, 1, 0$. What to see: the one point that remains free (green) is exactly the cross ratio, so a four-point function is a function of one complex variable z and its conjugate.

Key idea: The four-point function

Global conformal invariance fixes the four-point function of primaries up to one function of the cross ratio:

$$\langle\phi_1(z_1)\phi_2(z_2)\phi_3(z_3)\phi_4(z_4)\rangle = \prod_{i<j} z_{ij}^{h/3-h_i-h_j}\,\bar{z}_{ij}^{\bar{h}/3-\bar{h}_i-\bar{h}_j}\,Y\big(z_{12,34},\bar{z}_{12,34}\big), \tag{11.250}$$

with $h=\sum_i h_i$. Nash's arbitrary function F is Y. It is not determined by symmetry alone.

Why this prefactor? Any product $\prod z_{ij}^{\gamma_{ij}}$ with $\sum_{j\neq i}\gamma_{ij}=-2h_i$ for each i solves (11.247) (the same computation as for three points, with each z_i's coefficient giving one condition). The choice $\gamma_{ij}=h/3-h_i-h_j$ is symmetric and works: $\sum_{j\neq i}\gamma_{ij}=3\cdot\frac{h}{3}-3h_i-(h-h_i)=-2h_i$. Any other choice differs by a power of the cross ratio, which can be absorbed into Y. So "$n\geq 4$ needs further information": symmetry has used up its three parameters, and what remains is dynamics.

Worked example 11.93: A four-point function with no free function at all

For vertex operators with charges $(\alpha,-\alpha,\alpha,-\alpha)$ at $(\infty,1,z,0)$, the Coulomb-gas formula gives, after the factor $|z_1|^{4h_1}$ that defines the out-state has removed the dependence on z_1,

$$G(z,\bar{z})=\big\langle V_\alpha(\infty)V_{-\alpha}(1)V_\alpha(z,\bar{z})V_{-\alpha}(0)\big\rangle \overset{(1)}{=} |1-z|^{-\alpha^2}\,|1-0|^{\alpha^2}\,|z-0|^{-\alpha^2}=\big|z(1-z)\big|^{-\alpha^2}.$$

(1) Only the pairs not involving $z_1=\infty$ survive: $\alpha_2\alpha_3=-\alpha^2$, $\alpha_2\alpha_4=\alpha^2$, $\alpha_3\alpha_4=-\alpha^2$.

It factorises as $|z^{-\alpha^2/2}(1-z)^{-\alpha^2/2}|^2$: a single holomorphic function times its conjugate. As $z\to 0$ it behaves as $z^{-\alpha^2/2}=z^{h_p-h_3-h_4}$ with $h_p=0$: the two vertex operators fuse into the identity (and its descendants, from expanding $(1-z)^{-\alpha^2/2}$). The symmetry $G(z)=G(1-z)$ is the crossing symmetry discussed next.

Crossing symmetry and associativity

The four-point function of four *identical* fields must not care how we label the points. Permuting (z_1,z_2,z_3,z_4) changes the cross ratio by one of six maps,

$$z\;\mapsto\; z,\quad 1-z,\quad \frac{1}{z},\quad \frac{1}{1-z},\quad \frac{z-1}{z},\quad \frac{z}{z-1}, \tag{11.251}$$

the **anharmonic group** ($\cong S_3$). For example, swapping z_2 and z_4 sends $\frac{z_{12}z_{34}}{z_{13}z_{24}}\mapsto\frac{z_{14}z_{32}}{z_{13}z_{42}}$, and $1-z_{12,34}=\frac{z_{13}z_{24}-z_{12}z_{34}}{z_{13}z_{24}}=\frac{z_{14}z_{23}}{z_{13}z_{24}}$ by the identity $z_{13}z_{24}=z_{12}z_{34}+z_{14}z_{23}$. So $z\mapsto 1-z$. Invariance of the correlator under these maps (with the prefactors adjusted) is **crossing symmetry**.

Nash, following Belavin, Polyakov and Zamolodchikov, notes that crossing symmetry is equivalent to *associativity of the operator algebra*. Here is why. We can evaluate $\langle\phi_1\phi_2\phi_3\phi_4\rangle$ by first fusing ϕ_3 with ϕ_4 (as $z\to 0$) and then pairing the result with $\phi_1\phi_2$; or by first fusing ϕ_2 with ϕ_3 (as $z\to 1$). These are the two bracketings $\phi_1\phi_2(\phi_3\phi_4)$ and $\phi_1(\phi_2\phi_3)\phi_4$ of an operator product. If the OPE is associative the two must agree wherever both converge; and this agreement, written out, is the crossing relation between the expansions around $z=0$ and $z=1$ (Figure 11.50).

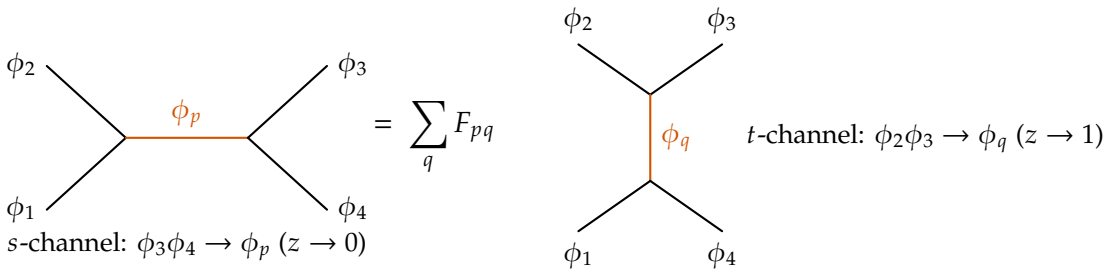

Figure 11.50: Crossing symmetry as associativity. The same four-point function can be expanded by fusing $\phi_3\phi_4$ first (left) or $\phi_2\phi_3$ first (right). Each tree is a sum over intermediate families (orange), and the two sums are related by a constant matrix F_{pq}. What to see: the diagram is the CFT version of $(ab)c = a(bc)$; demanding it is a strong constraint on the C_{ij}^{k}.

11.9.5 The operator product expansion of two primaries

To use associativity we need the OPE itself. Nash writes the general OPE of two primaries as

$$\phi_i(z,\bar z)\,\phi_j(0,0) = \sum_k \sum_{L,\bar L} \frac{C_{ij}^{k,L,\bar L}}{z^{\,h_i+h_j-h_k-|L|}\,\bar z^{\,\bar h_i+\bar h_j-\bar h_k-|\bar L|}}\,\Phi_k^{L,\bar L}(0,0), \tag{11.252}$$

his (11.65). The powers of z are forced by scaling: the left side has total weight $h_i + h_j$, a descendant $\Phi_k^{L,\bar L}$ has weight $h_k + |L|$, and z^a has weight $-a$. So $a = h_k + |L| - h_i - h_j$, the exponent shown.

The key claim is Nash's (11.66): the coefficient factorises,

$$C_{ij}^{k,L,\bar L} = C_{ij}^{k}\,\beta_{ij}^{kL}\,\bar\beta_{ij}^{k\bar L}, \tag{11.253}$$

where C_{ij}^{k} is the coefficient of the primary itself ($\beta^{k,\emptyset} = 1$) and the β's are *determined by conformal symmetry*, i.e. by c, h_i, h_j, h_k alone. With the β's Nash packages the family's contribution into

$$\Psi_{ij}^{k}(z,\bar z;0,0) = \sum_{L,\bar L} \frac{\beta_{ij}^{kL}\,\bar\beta_{ij}^{k\bar L}}{z^{\,h_i+h_j-h_k-|L|}\,\bar z^{\,\bar h_i+\bar h_j-\bar h_k-|\bar L|}}\,\Phi_k^{L,\bar L}(0,0),$$
$$\phi_i(z,\bar z)\phi_j(0,0) = \sum_k C_{ij}^{k}\,\Psi_{ij}^{k}(z,\bar z;0,0), \tag{11.254}$$

his (11.67)–(11.68). Ψ_{ij}^{k} is "the contribution of the family $[\phi_k]$ to the product $\phi_i\phi_j$".

Why the β's are fixed: the level-one coefficient

Apply the OPE to the vacuum: $\phi_j(0)|0\rangle = |h_j\rangle$, so (holomorphic part)

$$\phi_i(z)|h_j\rangle = \sum_k C_{ij}^{k}\,z^{\,h_k-h_i-h_j}\Big(|h_k\rangle + z\,\beta^{(1)}L_{-1}|h_k\rangle + z^2\big(\beta^{(2)}L_{-2} + \beta^{(1,1)}L_{-1}^2\big)|h_k\rangle + \cdots\Big). \tag{11.255}$$

Now act with L_1 on both sides and compare the coefficients of $z^{h_k-h_i-h_j+1}|h_k\rangle$.

$$\text{left: } L_1\phi_i(z)|h_j\rangle \overset{(1)}{=} [L_1,\phi_i(z)]|h_j\rangle \overset{(2)}{=} \big(z^2\partial_z + 2h_i z\big)\phi_i(z)|h_j\rangle$$
$$\overset{(3)}{=} \sum_k C_{ij}^k \big(h_k - h_i - h_j + 2h_i\big) z^{h_k-h_i-h_j+1}|h_k\rangle + \cdots,$$

$$\text{right: } \sum_k C_{ij}^k z^{h_k-h_i-h_j}\, z\,\beta^{(1)} L_1 L_{-1}|h_k\rangle \overset{(4)}{=} \sum_k C_{ij}^k\, 2h_k\,\beta^{(1)}\, z^{h_k-h_i-h_j+1}|h_k\rangle.$$

(1) $L_1|h_j\rangle = 0$, since $|h_j\rangle$ is a highest-weight state.
(2) (11.240) with $n = 1$.
(3) Insert (11.255) and differentiate the leading term: $(z^2\partial_z + 2h_i z)z^a = (a + 2h_i)z^{a+1}$.
(4) $L_1|h_k\rangle = 0$ kills the leading term, and $L_1L_{-1}|h_k\rangle = 2h_k|h_k\rangle$.

Hence

$$\beta_{ij}^{k,(1)} = \frac{h_k + h_i - h_j}{2h_k}. \tag{11.256}$$

A pure number built from weights. At level 2 the same trick with L_1^2 and L_2 gives two equations for $(\beta^{(2)}, \beta^{(1,1)})$, whose matrix is the Gram matrix $G^{(2)}$ of (11.178).

Worked example 11.94: Level 2, and what a null vector does to the OPE

Pair both sides of (11.255) with the level-2 bras $\langle h_k|L_2$ and $\langle h_k|L_1^2$. The right side gives $G^{(2)}\beta$, with $\beta = (\beta^{(2)}, \beta^{(1,1)})$. The left side is computed with (11.240): in general $\langle h_k|L_n\phi_i(z)|h_j\rangle = \langle h_k|[L_n,\phi_i(z)]|h_j\rangle = (h_k + nh_i - h_j)\,C_{ij}^k\, z^{h_k-h_i-h_j+n}$, because $z^n(z\partial_z + (n+1)h_i)z^a = (a + (n+1)h_i)z^{a+n}$ with $a = h_k - h_i - h_j$. Applying this twice for L_1^2:

$$G^{(2)}\begin{pmatrix}\beta^{(2)}\\ \beta^{(1,1)}\end{pmatrix} = \begin{pmatrix} h_k + 2h_i - h_j \\ (h_k + h_i - h_j)(h_k + h_i - h_j + 1)\end{pmatrix}.$$

Generic h_k: $G^{(2)}$ is invertible and β is unique. *Ising*, $\sigma\times\sigma \to \varepsilon$: $h_i = h_j = \frac{1}{16}$, $h_k = \frac{1}{2}$, $c = \frac{1}{2}$. Then

$$G^{(2)} \overset{(1)}{=} \begin{pmatrix}\frac{9}{4} & 3\\ 3 & 4\end{pmatrix}, \qquad \text{right side} \overset{(2)}{=} \begin{pmatrix}\frac{9}{16}\\ \frac{3}{4}\end{pmatrix} = \frac{3}{16}\begin{pmatrix}3\\4\end{pmatrix}.$$

(1) (11.178) at $h = \frac{1}{2}$, $c = \frac{1}{2}$: $4h + \frac{c}{2} = \frac{9}{4}$, $6h = 3$, $4h(2h+1) = 4$. Its determinant is $9 - 9 = 0$: the null vector $|\chi_\varepsilon\rangle$ of (11.182).
(2) $\frac{1}{2} + \frac{1}{8} - \frac{1}{16} = \frac{9}{16}$ and $\frac{1}{2}\cdot\frac{3}{2} = \frac{3}{4}$.

The matrix is singular, but the right side lies in its range (both rows of $G^{(2)}$ are multiples of $(3,4)$, and so is the right side). So a solution exists, for instance $\beta = (\frac{1}{4}, 0)$, and it is unique up to adding the null vector $(1, -\frac{3}{4})$, which is zero in the irreducible module anyway. This is not an accident: the OPE $\sigma\times\sigma$ is allowed to contain ε precisely because this consistency condition holds. If it failed, $C_{\sigma\sigma}^{\varepsilon}$ would have to vanish. *Null vectors restrict which families may appear in an OPE*: this is the seed of the fusion rules.

Watch out: The OPE is not a Taylor series

(11.252) is an exact operator statement inside correlators, convergent for $|z|$ smaller than the distance to the next insertion. It is not an asymptotic expansion: in a CFT the OPE converges. The non-integer powers $z^{h_k-h_i-h_j}$ make the correlator multivalued as a function of z for fixed k, even though the full correlator (summed over holomorphic and antiholomorphic

parts) is single valued.

11.9.6 Conformal blocks

Insert the OPE into the four-point function, with the points at Nash's positions $(\infty, 1, z, 0)$:

$$\begin{aligned}\left\langle \phi_i(\infty)\phi_j(1)\phi_k(z,\bar z)\phi_l(0)\right\rangle &\overset{(1)}{=} \sum_m C_{kl}^m \left\langle \phi_i(\infty)\phi_j(1)\,\Psi_{kl}^m(z,\bar z;0,0)\right\rangle \\ &\overset{(2)}{=} \sum_m C_{kl}^m \sum_{L,\bar L} \frac{\beta_{kl}^{mL}\bar\beta_{kl}^{m\bar L}}{z^{h_k+h_l-h_m-|L|}\bar z^{h_k+h_l-h_m-|\bar L|}} \left\langle \phi_i(\infty)\phi_j(1)\Phi_m^{L,\bar L}(0,0)\right\rangle \\ &\overset{(3)}{=} \sum_m C_{kl}^m\, C_{ijm}\, \mathcal{F}_{kl}^{ij}(m,z)\,\bar{\mathcal{F}}_{kl}^{ij}(m,\bar z). \end{aligned} \tag{11.257}$$

(1) The OPE (11.254) of $\phi_k(z)\phi_l(0)$, valid for $|z|<1$.
(2) The definition of Ψ.
(3) Each three-point function of descendants is, by the Ward identities of Section 11.9.2, a number times C_{ijm}; the sum factorises into a holomorphic sum times an antiholomorphic one.

The functions

$$\begin{aligned}\mathcal{F}_{kl}^{ij}(m,z) &= \sum_L \frac{\beta_{kl}^{mL}}{z^{\,h_k+h_l-h_m-|L|}} \frac{\left\langle \phi_i(\infty)\phi_j(1)L^L\phi_m(0)\right\rangle}{C_{ijm}} \\ &= z^{\,h_m-h_k-h_l}\left(1+\frac{(h_m+h_k-h_l)(h_m+h_j-h_i)}{2h_m}\,z+O(z^2)\right)\end{aligned} \tag{11.258}$$

are the **conformal blocks**: Nash's (11.69). (Nash normalises with $\sqrt{C_{ij}}$ factors and writes $C_{kl}^m C_{ij}^m$; with $C_{ij}=\delta_{ij}$ these are the same.) Each block depends only on the six numbers $c, h_i, h_j, h_k, h_l, h_m$, and is a power series in z times a leading power.

Worked example 11.95: The level-one coefficient of a block

The coefficient of z in (11.258) is $\beta^{(1)}\times\frac{\langle h_i|\phi_j(1)L_{-1}|h_m\rangle}{C_{ijm}}$. The first factor is (11.256) with $(i,j,k)\to(k,l,m)$. For the second, move L_{-1} to the left:

$$\begin{aligned}\langle h_i|\phi_j(1)L_{-1}|h_m\rangle &\overset{(1)}{=} \langle h_i|\big(L_{-1}\phi_j(1)-[L_{-1},\phi_j(1)]\big)|h_m\rangle \overset{(2)}{=} -\partial_w\langle h_i|\phi_j(w)|h_m\rangle\big|_{w=1} \\ &\overset{(3)}{=} -\partial_w\big(C_{ijm}\,w^{h_i-h_j-h_m}\big)\big|_{w=1} = (h_m+h_j-h_i)\,C_{ijm}.\end{aligned}$$

(1) Commutator.
(2) $\langle h_i|L_{-1}=(L_1|h_i\rangle)^\dagger=0$, and $[L_{-1},\phi_j(w)]=\partial_w\phi_j(w)$.
(3) $\langle h_i|\phi_j(w)|h_m\rangle$ is the three-point function with points at $\infty, w, 0$, which by (11.248) is $C_{ijm}w^{h_i-h_j-h_m}$.

Multiplying by $\beta^{(1)}=(h_m+h_k-h_l)/2h_m$ gives (11.258). For the identity family ($h_m=0$) this coefficient must be dropped: $L_{-1}|0\rangle=0$, and the block begins $z^{-h_k-h_l}(1+\frac{2h_kh_j}{c}z^2+\cdots)$ when $h_k=h_l$, $h_i=h_j$, from the level-2 state $L_{-2}|0\rangle$ with norm $c/2$.

More points; blocks as holomorphic objects

For $n \geq 4$ points the same procedure (fuse pairs repeatedly) writes the correlator as

$$\langle \phi_{i_1}(z_1,\bar z_1)\cdots\phi_{i_n}(z_n,\bar z_n)\rangle = \sum_{I,J} \mathcal{F}^I(z_1,\dots,z_{n-3})\, h_{IJ}\, \bar{\mathcal{F}}^J(\bar z_1,\dots,\bar z_{n-3}), \tag{11.259}$$

Nash's (11.70). The indices I, J label the choices of intermediate families in a chosen tree of fusions, and h_{IJ} is a Hermitian matrix made of the C_{ij}^k. After three points are fixed by Möbius invariance, the blocks depend on $n-3$ coordinates: the coordinates on the moduli space $\mathcal{M}_{0,n}$ of the n-punctured sphere.

The correlator is single valued on the configuration space (it is a physical quantity). The blocks are *not*: $\mathcal{F}(m,z) \sim z^{h_m - h_k - h_l}$ picks up a phase $e^{2\pi i(h_m-h_k-h_l)}$ when z circles 0. Circling $z=1$ mixes the blocks among themselves, by the crossing matrix of Figure 11.50. So the blocks form a vector-valued multivalued holomorphic function whose **monodromy** is a representation of the fundamental group of $\mathcal{M}_{0,n}$, and (11.259) is single valued because h_{IJ} is an invariant Hermitian form for that representation. Equivalently: the blocks are holomorphic sections of a flat vector bundle over $\mathcal{M}_{0,n}$, with the h_{IJ} giving a flat Hermitian metric. Nash will return to this picture for surfaces of any genus in Section 11.10.

11.9.7 The Ising four-spin function

Everything so far is general. We now compute one four-point function exactly, from nothing but the null vector (11.182) of the spin field. This is the classic BPZ computation, and it produces the fusion rule $\sigma \times \sigma = \mathbf{1} + \varepsilon$ and the constant $C_{\sigma\sigma\varepsilon}$.

Step 1: the null vector becomes a differential equation

In the irreducible module $|\chi_\sigma\rangle = (L_{-2} - \frac{4}{3}L_{-1}^2)|\sigma\rangle = 0$. By the state–field correspondence, the field $(L_{-2}\sigma)(w) - \frac{4}{3}\partial_w^2\sigma(w)$ is zero, so its correlators vanish. The descendant Ward identity (11.244) converts this into a PDE for $G = \langle\sigma(w)\sigma(w_1)\sigma(w_2)\sigma(w_3)\rangle$:

$$\Big[\tfrac{4}{3}\partial_w^2 - \sum_{i=1}^{3}\Big(\frac{h_\sigma}{(w_i-w)^2} - \frac{1}{w_i-w}\partial_{w_i}\Big)\Big]G = 0. \tag{11.260}$$

For a general level-2 null vector $(L_{-2} - aL_{-1}^2)\phi$ with $a = \frac{3}{2(2h+1)}$ the same holds with $\frac{4}{3} \to a$.

Step 2: reduce to an ODE in the cross ratio

Put $w = x$, $w_1 = 0$, $w_2 = 1$, $w_3 \to \infty$, and write $f(x) = \lim w_3^{2h_3} G$. We need $\partial_{w_1}G$ and $\partial_{w_2}G$ in terms of $\partial_x G$. For large w_3, $G \propto w_3^{-2h_3}$, so $\partial_{w_3}G \to 0$ and $w_3\partial_{w_3}G \to -2h_3 G$. The first two global Ward identities (11.247) then read

$$\partial_{w_1}f + \partial_{w_2}f \overset{(1)}{=} -\partial_x f,$$
$$0\cdot\partial_{w_1}f + 1\cdot\partial_{w_2}f \overset{(2)}{=} -x\partial_x f - (h + h_1 + h_2 - h_3)f,$$

(1) L_{-1} identity, with $\partial_{w_3} \to 0$.
(2) L_0 identity at $w_1 = 0$, $w_2 = 1$, with $w_3\partial_{w_3} \to -2h_3$; h is the weight of the field at x.

so $\partial_{w_2} f = -xf' - \kappa f$ and $\partial_{w_1} f = (x-1)f' + \kappa f$, with $\kappa = h + h_1 + h_2 - h_3$. Insert into the $\mathcal{L}_{-2}$ operator (the $i = 3$ term vanishes as $w_3 \to \infty$):

$$\begin{aligned}\mathcal{L}_{-2} f &\overset{(1)}{=} \frac{h_1}{x^2} f + \frac{1}{x}\partial_{w_1} f + \frac{h_2}{(1-x)^2} f - \frac{1}{1-x}\partial_{w_2} f \\ &\overset{(2)}{=} \left[\frac{h_1}{x^2} + \frac{h_2}{(1-x)^2} + \frac{\kappa}{x(1-x)}\right] f + \left[\frac{x-1}{x} + \frac{x}{1-x}\right] f' \\ &\overset{(3)}{=} \left[\frac{h_1}{x^2} + \frac{h_2}{(1-x)^2} + \frac{\kappa}{x(1-x)}\right] f + \frac{2x-1}{x(1-x)}\, f'.\end{aligned}$$

(1) (11.245) with $n = 2$: $w_1 - w = -x$, $w_2 - w = 1 - x$.
(2) Insert the two derivatives; $\frac{\kappa}{x} + \frac{\kappa}{1-x} = \frac{\kappa}{x(1-x)}$.
(3) $\frac{(x-1)(1-x)+x^2}{x(1-x)} = \frac{2x-1}{x(1-x)}$.

So the null-vector equation $a f'' = \mathcal{L}_{-2} f$ becomes the ordinary differential equation

$$a\, f''(x) + \frac{1-2x}{x(1-x)}\, f'(x) - \left[\frac{h_1}{x^2} + \frac{h_2}{(1-x)^2} + \frac{h + h_1 + h_2 - h_3}{x(1-x)}\right] f(x) = 0. \tag{11.261}$$

For four spins: $a = \frac{4}{3}$ and $h = h_1 = h_2 = h_3 = \frac{1}{16}$, so the last numerator is $\frac{1}{8}$.

Step 3: the indicial equation gives the fusion rule

Near $x = 0$ try $f \sim x^\lambda$. The most singular terms are of order $x^{\lambda-2}$:

$$\begin{aligned}a\lambda(\lambda-1) + \lambda - h_1 = 0 \quad &\xrightarrow{a=\frac{4}{3},\ h_1=\frac{1}{16}} \quad \tfrac{4}{3}\lambda^2 - \tfrac{1}{3}\lambda - \tfrac{1}{16} = 0 \\ &\overset{(1)}{=} 64\lambda^2 - 16\lambda - 3 = 0 \quad \Longrightarrow \quad \lambda \overset{(2)}{=} \tfrac{16 \pm 32}{128} = \left\{-\tfrac{1}{8},\ \tfrac{3}{8}\right\}.\end{aligned} \tag{11.262}$$

(1) Multiply by 48.
(2) Quadratic formula: $\sqrt{256 + 768} = 32$.

(The coefficient of f' is $\frac{1-2x}{x(1-x)} \approx \frac{1}{x}$ near 0, which gives the $+\lambda$.) Compare with the block (11.258), which starts as $x^{h_m - h_\sigma - h_\sigma} = x^{h_m - 1/8}$:

$$h_m - \tfrac{1}{8} = -\tfrac{1}{8} \;\Rightarrow\; h_m = 0, \qquad h_m - \tfrac{1}{8} = \tfrac{3}{8} \;\Rightarrow\; h_m = \tfrac{1}{2}.$$

Only the identity and the energy field can appear in $\sigma \times \sigma$. *A second-order ODE has exactly two solutions, and they are the two families*: $\sigma \times \sigma = \mathbf{1} + \varepsilon$. Notice that σ itself cannot appear (it would need $\lambda = -\frac{1}{16}$), which is the $\mathbb{Z}_2$ symmetry $\sigma \to -\sigma$ derived from scratch.

Step 4: solve the ODE

Remove the leading power by $f = (x(1-x))^{-1/8} u(x)$. The resulting equation is solved by $u = \sqrt{1 \pm \sqrt{1-x}}$ (one checks this by direct substitution; we verified it symbolically). The two solutions with the normalisation $x^{h_m - 1/8}(1 + O(x))$ are

$$\mathcal{F}_{\mathbf{1}}(x) = \frac{\sqrt{\frac{1}{2}\left(1 + \sqrt{1-x}\right)}}{(x(1-x))^{1/8}}, \qquad \mathcal{F}_{\varepsilon}(x) = \frac{\sqrt{2\left(1 - \sqrt{1-x}\right)}}{(x(1-x))^{1/8}}. \tag{11.263}$$

Worked example 11.96: The blocks have the predicted expansions

With $\sqrt{1-x} = 1 - \frac{x}{2} - \frac{x^2}{8} - \cdots$:

$$x^{1/8}\mathcal{F}_{\mathbf{1}} \overset{(1)}{=} (1-x)^{-1/8}\Big(1 - \tfrac{x}{4} - \tfrac{x^2}{16} + \cdots\Big)^{1/2} \overset{(2)}{=} 1 + \tfrac{x^2}{64} + O(x^3),$$
$$x^{-3/8}\mathcal{F}_{\varepsilon} \overset{(3)}{=} (1-x)^{-1/8}\Big(1 + \tfrac{x}{4} + \cdots\Big)^{1/2} \overset{(4)}{=} 1 + \tfrac{x}{4} + \tfrac{9x^2}{64} + O(x^3).$$

(1) $\frac{1}{2}(1+\sqrt{1-x}) = 1 - \frac{x}{4} - \frac{x^2}{16} - \cdots$.
(2) Multiply out the series; the $O(x)$ terms cancel.
(3) $2(1-\sqrt{1-x}) = x(1 + \frac{x}{4} + \cdots)$, and $x^{1/2}\cdot x^{-1/8} = x^{3/8}$.
(4) Multiply out.

Check against the general theory. For the identity block the $O(x)$ term is absent ($L_{-1}|0\rangle = 0$) and the x^2 coefficient is $2h_\sigma^2/c = 2\cdot\frac{1}{256}\cdot 2 = \frac{1}{64}$. For the ε block (11.258) predicts $\frac{(h_\varepsilon + h_\sigma - h_\sigma)^2}{2h_\varepsilon} = \frac{1/4}{1} = \frac{1}{4}$. Both agree.

Step 5: crossing symmetry fixes $C_{\sigma\sigma\varepsilon}$

The full correlator must be a single-valued combination

$$G(x,\bar{x}) = |\mathcal{F}_{\mathbf{1}}(x)|^2 + C_{\sigma\sigma\varepsilon}^2\,|\mathcal{F}_{\varepsilon}(x)|^2.$$

(No cross terms: the left and right families must match, since σ has $h = \bar{h}$ and the Ising model is diagonal.) Around $x = 0$ each term is single valued. Around $x = 1$ the blocks behave like $\sqrt{1 \pm \sqrt{1-x}}$, which mix when $\sqrt{1-x}$ changes sign. To find the mixing, parametrise $x = \sin^2 2\varphi$, so $\sqrt{1-x} = \cos 2\varphi$ and $\sqrt{x} = \sin 2\varphi$. Then (dropping the common prefactor $(x(1-x))^{-1/8}$, which is symmetric under $x \leftrightarrow 1-x$)

$$\sqrt{\tfrac{1}{2}(1+\cos 2\varphi)} = \cos\varphi, \qquad \sqrt{2(1-\cos 2\varphi)} = 2\sin\varphi,$$
$$\sqrt{\tfrac{1}{2}(1+\sin 2\varphi)} \overset{(1)}{=} \tfrac{1}{\sqrt{2}}(\cos\varphi + \sin\varphi), \qquad \sqrt{2(1-\sin 2\varphi)} \overset{(2)}{=} \sqrt{2}(\cos\varphi - \sin\varphi).$$

(1) $1 + \sin 2\varphi = (\cos\varphi + \sin\varphi)^2$.
(2) $1 - \sin 2\varphi = (\cos\varphi - \sin\varphi)^2$.

The first row is the blocks at x; the second row is the blocks at $1-x$. Solving the linear system,

$$\mathcal{F}_{\mathbf{1}}(x) = \tfrac{1}{\sqrt{2}}\mathcal{F}_{\mathbf{1}}(1-x) + \tfrac{1}{2\sqrt{2}}\mathcal{F}_{\varepsilon}(1-x), \qquad \mathcal{F}_{\varepsilon}(x) = \sqrt{2}\,\mathcal{F}_{\mathbf{1}}(1-x) - \tfrac{1}{\sqrt{2}}\mathcal{F}_{\varepsilon}(1-x). \tag{11.264}$$

Now rescale the ε block by the constant we are looking for: with $\tilde{\mathcal{F}}_\varepsilon = \frac{1}{2}\mathcal{F}_\varepsilon$ the relations become

$$\begin{pmatrix}\mathcal{F}_{\mathbf{1}}\\ \tilde{\mathcal{F}}_\varepsilon\end{pmatrix}(x) = \frac{1}{\sqrt{2}}\begin{pmatrix}1 & 1\\ 1 & -1\end{pmatrix}\begin{pmatrix}\mathcal{F}_{\mathbf{1}}\\ \tilde{\mathcal{F}}_\varepsilon\end{pmatrix}(1-x),$$

an *orthogonal* matrix. So $|\mathcal{F}_{\mathbf{1}}|^2 + |\tilde{\mathcal{F}}_\varepsilon|^2$ is crossing symmetric, and any other ratio is not. Hence

$$C_{\sigma\sigma\varepsilon}^2 = \tfrac{1}{4}, \qquad C_{\sigma\sigma\varepsilon} = \tfrac{1}{2}. \tag{11.265}$$

The matrix $\frac{1}{\sqrt{2}}\left(\begin{smallmatrix}1 & 1\\ 1 & -1\end{smallmatrix}\right)$ is the **fusion** (or crossing) **matrix** F_{pq} of Figure 11.50 for four spins.

Worked example 11.97: The four-spin function in closed form

Add the two terms:

$$G(x,\bar{x}) \overset{(1)}{=} \frac{\left|1+\sqrt{1-x}\right|+\left|1-\sqrt{1-x}\right|}{2\,|x(1-x)|^{1/4}} \overset{(2)}{=} \frac{1}{|x(1-x)|^{1/4}}\sqrt{\frac{1+|x|+|1-x|}{2}}.$$

(1) $|\mathcal{F}_1|^2 = \frac{1}{2}|1+s|\,|x(1-x)|^{-1/4}$ and $\frac{1}{4}|\mathcal{F}_\varepsilon|^2 = \frac{1}{2}|1-s|\,|x(1-x)|^{-1/4}$, with $s=\sqrt{1-x}$.
(2) Square: $(|1+s|+|1-s|)^2 = |1+s|^2+|1-s|^2+2|1-s^2| = 2+2|s|^2+2|x|$, and $|s|^2=|1-x|$.

The last form is manifestly symmetric under $x \leftrightarrow 1-x$, and it is single valued (only absolute values appear). Under $x \to 1/x$, which swaps $\sigma(0)$ with $\sigma(\infty)$, it obeys $G(1/x) = |x|^{1/4}G(x)$, the correct covariance. Numerically, at $x = 0.3+0.4i$ both $G(x)$ and $G(1-x)$ equal $1.34766\ldots$. On the real segment $0<x<1$ the square root is 1 and $G = (x(1-x))^{-1/4}$ (Figure 11.51).

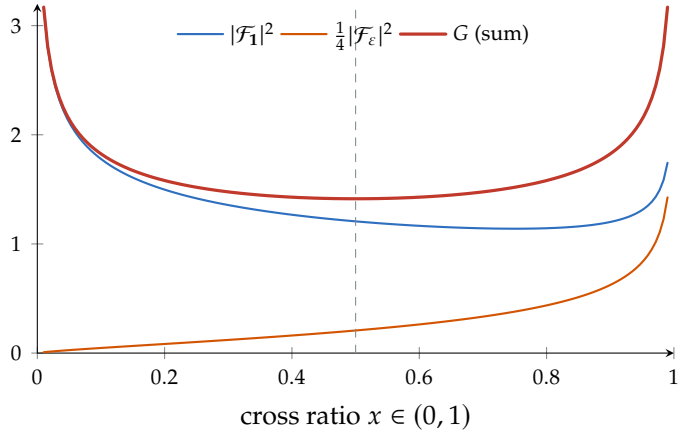

Figure 11.51: The Ising four-spin function on the real segment $0<x<1$. The identity block (blue) dominates near $x=0$, where $\sigma(x)$ approaches $\sigma(0)$ and the leading singularity $x^{-1/4} = |x|^{-2\Delta_\sigma}$ is the two-point function. The ε block (orange) grows towards $x=1$. What to see: neither block is symmetric about $x=\frac{1}{2}$, but their sum with the weight $C^2_{\sigma\sigma\varepsilon} = \frac{1}{4}$ (red) is: crossing symmetry fixes the OPE coefficient.

Physical picture: What the lattice sees

G is the correlation of four spins at criticality, in units where the two-point function is $|z|^{-1/4}$. The exponent $\frac{1}{4} = 2\Delta_\sigma$ is η of Section 11.5.3. The constant $C_{\sigma\sigma\varepsilon} = \frac{1}{2}$ is a universal amplitude: it says how strongly two nearby spins look like an energy density. On the lattice it is measured by comparing $\langle s_1 s_2\, E_3\rangle$ with $\langle s_1 s_2\rangle\langle E_3 E_4\rangle^{1/2}$. It is a prediction of the CFT with no free parameters.

Try it: The other Ising fusions from indicial equations

Use (11.262) in the general form $a\lambda(\lambda-1)+\lambda-h_1=0$, with $h_m = \lambda+h+h_1$. (a) For the σ null vector ($a=\frac{4}{3}$, $h=\frac{1}{16}$) fusing with ε ($h_1=\frac{1}{2}$), show $\lambda \in \{-\frac{1}{2},\frac{3}{4}\}$, hence $h_m \in \{\frac{1}{16},\frac{21}{16}\}$. (b) For the ε null vector ($a=\frac{3}{4}$, $h=\frac{1}{2}$) fusing with ε, show $h_m \in \{0,\frac{5}{3}\}$. *Answer:* $\frac{21}{16}$ and $\frac{5}{3}$ are not Ising weights, so their coefficients vanish, and $\sigma\times\varepsilon=\sigma$, $\varepsilon\times\varepsilon=\mathbf{1}$. (In (a), $8\lambda^2-2\lambda-3=0$; in (b), $3\lambda^2+\lambda-2=0$.)

Reading Nash (pp. 313–315, (11.60)–(11.70))

Nash introduces the families $[\phi_i]$, the notation L^I, $\Phi_i^{I,J}$ (11.60)–(11.61), the general correlator (11.62), and states that the Ward identities reduce it to primaries; we derived the reducing operators (11.245). His (11.63) is our (11.248) with its two-point companion; his (11.64) is the cross ratio. (11.65)–(11.68) are the OPE and its factorisation, for which we computed the level-one β (11.256) and the level-two system. (11.69) defines the blocks with the points at $(\infty, 1, z, 0)$, and (11.70) is the n-point form. The Ising computation of Section 11.9.7 is not in Nash; it is the standard illustration of all of these formulas at once, and it shows concretely what "crossing symmetry implies associativity" means.

Recap

- A descendant field is a loop of T around a primary; $L_{-1} = \partial$, $L_{-2}\mathbf{1} = T$. Contour deformation turns descendant insertions into the operators $\mathcal{L}_{-n}$, so all correlators reduce to those of primaries.
- Möbius invariance fixes $\langle\phi_i\phi_j\rangle = C_{ij}\delta_{h_ih_j}z_{12}^{-2h_i}\cdots$ and $\langle\phi_i\phi_j\phi_k\rangle$ up to C_{ijk}; the four-point function up to a function of the cross ratio.
- The OPE coefficients factorise as $C_{ij}^k\beta\bar{\beta}$, with $\beta^{(1)} = (h_k + h_i - h_j)/2h_k$; the four-point function is a sum over families of blocks $\mathcal{F}(m,z)\bar{\mathcal{F}}(m,\bar{z})$.
- Blocks are multivalued; the correlator is a monodromy-invariant Hermitian combination. Crossing symmetry = associativity of the OPE.
- Ising: the null vector gives a second-order ODE; its two exponents give $\sigma\times\sigma = \mathbf{1} + \varepsilon$; crossing fixes $C_{\sigma\sigma\varepsilon} = \frac{1}{2}$ and $G = |x(1-x)|^{-1/4}\sqrt{(1+|x|+|1-x|)/2}$.

11.10 Fusion rules and the Verlinde formula

The operator product expansion of Section 11.9 is a rich object: it contains the full set of constants C_{ij}^k and all the descendant coefficients β. Very often we do not need all of that. We only want to know *which* conformal families can appear when two fields collide, and how many independent ways there are for this to happen. That coarse information is a table of non-negative integers N_{ij}^k, the **fusion rules**. This section answers three questions about them.

1. *What are they, and what algebra do they obey?* They define a commutative, associative product $\phi_i \times \phi_j = \sum_k N_{ij}^k\phi_k$ on the set of families. Associativity is crossing symmetry again, now at the level of counting.
2. *How do they generalise to curved worldsheets?* On a surface of genus p with n punctures the conformal blocks form a vector space $V(\Sigma_{p,n})$. The fusion number N_{ij}^k is its dimension for the three-punctured sphere, and by cutting a surface into three-punctured spheres every $\dim V(\Sigma_{p,n})$ is computed from the N_{ij}^k alone.
3. *How do we compute them?* Verlinde's formula: the modular transformation $S : \tau \mapsto -1/\tau$ of the torus characters diagonalises the fusion rules, so the N_{ij}^k are read off from the matrix S of Section 11.8.4.

At the end we meet the constraints that Riemann surfaces of genus $p > 0$ impose on the singularities of fields: the Weierstrass gap theorem.

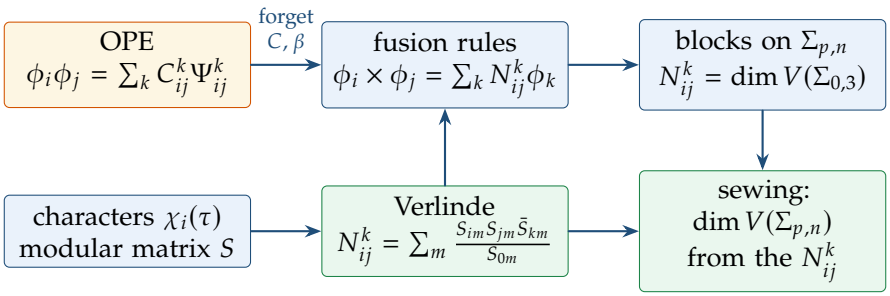

Figure 11.52: The logic of this section. What to see: the fusion rules sit in the middle. They come from the OPE by forgetting the continuous data, they are computed from the torus (the matrix S), and they determine the dimensions of the spaces of conformal blocks on every surface.

11.10.1 Which families appear in an operator product

Take two primaries ϕ_i and ϕ_j. Their OPE (11.255) is a sum over families $[\phi_k]$, each with coefficient C_{ij}^k. Nash's question (p. 316) is: *which k actually occur?* The answer is read off from three-point functions. Pair the OPE with ϕ_k at infinity:

$$\big\langle \phi_k(\infty)\,\phi_i(z)\,\phi_j(0)\big\rangle \overset{(1)}{=} \sum_l C_{ij}^l\, z^{h_l-h_i-h_j}\bar{z}^{\bar{h}_l-\bar{h}_i-\bar{h}_j}\big\langle \phi_k(\infty)\,\big(\phi_l(0)+\text{descendants}\big)\big\rangle$$
$$\overset{(2)}{=} C_{ij}^{k'}\,C_{k'k}\; z^{h_{k'}-h_i-h_j}\bar{z}^{\bar{h}_{k'}-\bar{h}_i-\bar{h}_j},$$

(1) Insert the OPE (11.255) of $\phi_i(z)\phi_j(0)$.

(2) The two-point function $\langle\phi_k\phi_l\rangle$ vanishes unless ϕ_l is the conjugate $\phi_{k'}$ of ϕ_k (the field with $C_{k'k}\neq 0$, Section 11.9.3); descendants of ϕ_l have zero two-point function with the primary ϕ_k (they are orthogonal to it, being at a different L_0 level).

So $[\phi_{k'}]$ occurs in $\phi_i\phi_j$ exactly when the three-point function $\langle\phi_k\phi_i\phi_j\rangle$ is non-zero. Nash's phrase is that a non-vanishing three-point function is "a fusing together of three representations of the conformal group".

Working definition 11.33 (fusion rules)

For each ordered pair of primaries, the **fusion coefficient** N_{ij}^k is the number of independent ways in which the family $[\phi_k]$ [ϕ_k together with all its descendants $L^I\bar{L}^J\phi_k$] appears in the operator product $\phi_i\phi_j$. Equivalently, it is the number of linearly independent chiral three-point couplings [holomorphic halves of three-point functions, depending on z_1, z_2, z_3 only] $\langle\phi_{k'}\phi_i\phi_j\rangle$ allowed by the chiral algebra [the holomorphic symmetry generators, whose modes act on each family] (the Virasoro algebra, or a larger algebra such as a Kac–Moody algebra). Verlinde packages them into the formal product (Nash (11.71))

$$\phi_i \times \phi_j = \sum_k N_{ij}^k\,\phi_k. \tag{11.266}$$

Operational test: N_{ij}^k is the number of conformal blocks [independent holomorphic functions into which a correlator splits, one for each family that can be exchanged] with $[\phi_k]$ in the intermediate channel. For a Virasoro minimal model it is 0 or 1 and can be read off from the null-vector differential equations [setting a null vector to zero inside a correlator gives a differential equation in the positions], as in (11.262).

Watch out: The fusion product is not a product of fields, nor a tensor product

$\phi_i \times \phi_j$ is a *formal* product. It forgets the positions z, the constants C_{ij}^k and the descendant coefficients: only the integers survive. It is also not the tensor product of Virasoro representations. If L_n acts on H_i and on H_j with central charge c, then $L_n \otimes 1 + 1 \otimes L_n$ acts on $H_i \otimes H_j$ with central charge $2c$, so $H_i \otimes H_j$ is not even a module of the same algebra. Fusion is the right replacement: it builds a module with the *same* c out of two modules, using the geometry of two points on the sphere.

The fusion algebra

The integers N_{ij}^k obey four rules. Each has a one-line reason.

1. **Commutativity:** $N_{ij}^k = N_{ji}^k$. The OPE $\phi_i(z)\phi_j(0)$ and $\phi_j(0)\phi_i(z)$ are the same product of commuting (bosonic, Euclidean) fields; the families that appear cannot depend on the order.
2. **Identity:** $N_{0j}^k = \delta_j^k$. The identity field $\phi_0 = \mathbf{1}$ multiplies nothing: $\mathbf{1} \times \phi_j = \phi_j$.
3. **Conjugation:** $N_{ij}^0 = \delta_{j,i'}$, where i' labels the conjugate family, the unique one with $\langle \phi_i \phi_{i'} \rangle \neq 0$. The identity appears in $\phi_i \phi_j$ only if the two-point function is non-zero.
4. **Associativity:** $\sum_m N_{ij}^m N_{mk}^l = \sum_m N_{jk}^m N_{im}^l$, i.e. $(\phi_i \times \phi_j) \times \phi_k = \phi_i \times (\phi_j \times \phi_k)$.

The last rule is crossing symmetry. Consider the four-point function $\langle \phi_{l'}(\infty)\phi_i(1)\phi_j(z)\phi_k(0)\rangle$. In the channel $z \to 0$ we first fuse $\phi_j\phi_k \to \phi_m$, then $\phi_i\phi_m \to \phi_l$: the number of blocks is $\sum_m N_{jk}^m N_{im}^l$. In the channel $z \to 1$ we first fuse $\phi_i\phi_j \to \phi_m$, then $\phi_m\phi_k \to \phi_l$: the number of blocks is $\sum_m N_{ij}^m N_{mk}^l$. The crossing matrix of Figure 11.50 is an invertible change of basis between the two sets of blocks, so the two counts must agree.

Working definition 11.34 (fusion matrices)

For each primary ϕ_i define the $F \times F$ matrix [F is the number of primary families] N_i with entries $(N_i)_j{}^k = N_{ij}^k$. It is "multiplication by ϕ_i", written as a matrix in the basis $\phi_0, \ldots, \phi_{F-1}$ of the fusion algebra [formal sums of the ϕ_k with integer coefficients, multiplied by (11.266)]. The four rules become

$$N_0 = \mathbb{1}, \qquad N_i N_j = N_j N_i, \qquad N_i N_j = \sum_k N_{ij}^k N_k. \tag{11.267}$$

So the matrices N_i *represent the fusion algebra*: this is the statement of Nash (p. 317) that "the N_{ij}^k form a representation of the fusion algebra 11.71".

Let us check the third relation in (11.267) from the associativity rule, entry by entry:

$$(N_i N_j)_a{}^b \overset{(1)}{=} \sum_m (N_i)_a{}^m (N_j)_m{}^b \overset{(2)}{=} \sum_m N_{ia}^m N_{jm}^b \overset{(3)}{=} \sum_m N_{ji}^m N_{ma}^b \overset{(4)}{=} \sum_k N_{ij}^k (N_k)_a{}^b.$$

(1) Matrix multiplication.
(2) The definition $(N_i)_a{}^m = N_{ia}^m$.
(3) Associativity in the form $\phi_j \times (\phi_i \times \phi_a) = (\phi_j \times \phi_i) \times \phi_a$, with commutativity used to write $N_{jm}^b = N_{mj}^b$ and so on.

(4) Rename $m \to k$, use $N_{ji}^{k} = N_{ij}^{k}$, and $(N_k)_a{}^b = N_{ka}^{b} = N_{ak}^{b}$.

In words: multiplying by ϕ_i and then by ϕ_j is the same as multiplying by the product $\phi_i \times \phi_j$.

Worked example 11.98: The Ising fusion algebra and its matrices

The Ising model has $F = 3$ families, ordered $(\mathbf{1}, \varepsilon, \sigma)$. From Section 11.9.7 and its exercise,

$$\sigma \times \sigma = \mathbf{1} + \varepsilon, \qquad \sigma \times \varepsilon = \sigma, \qquad \varepsilon \times \varepsilon = \mathbf{1}, \tag{11.268}$$

plus the identity rules. Every field is self-conjugate. The fusion matrices (row j, column k) are

$$N_{\mathbf{1}} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad N_{\varepsilon} = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad N_{\sigma} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}.$$

For instance the third row of N_σ says $\sigma \times \sigma = \mathbf{1} + \varepsilon$. Now check that they represent (11.268):

$$N_\sigma N_\sigma \overset{(1)}{=} \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 2 \end{pmatrix} \overset{(3)}{=} N_{\mathbf{1}} + N_{\varepsilon},$$

$$N_\sigma N_\varepsilon \overset{(4)}{=} \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix} \overset{(5)}{=} N_\sigma, \qquad N_\varepsilon N_\varepsilon \overset{(6)}{=} N_{\mathbf{1}}.$$

(1) The matrix of "multiply by σ", applied twice.
(2) Row times column: e.g. the $(3,3)$ entry is $1 \cdot 1 + 1 \cdot 1 + 0 = 2$.
(3) Add the matrices $N_{\mathbf{1}}$ and N_ε above.
(4) Multiply by ε first, then by σ.
(5) Right-multiplying by the permutation N_ε swaps the first two columns, which are equal.
(6) N_ε is a transposition, so it squares to the identity.

The entry 2 in N_σ^2 is the statement that $\sigma \times \sigma \times \sigma$ contains σ twice: there are *two* conformal blocks for $\langle\sigma\sigma\sigma\sigma\rangle$, as we found in (11.263). The algebra is also $\mathbb{Z}_2$-graded: give $\mathbf{1}$, ε charge 0 and σ charge 1; charges add under fusion. This is the spin-flip symmetry $\sigma \to -\sigma$ of the lattice.

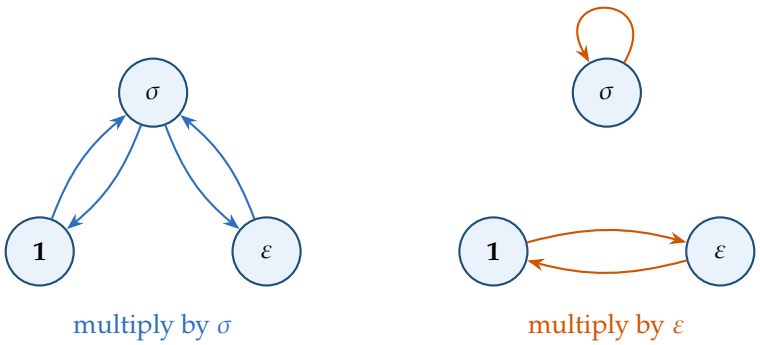

Figure 11.53: Fusion graphs of the Ising model: an arrow $a \to b$ for every occurrence of ϕ_b in $\phi_i \times \phi_a$. The graphs are the fusion matrices N_σ and N_ε drawn as adjacency matrices. What to see: the σ-graph is the Dynkin diagram A_3 (a path $\mathbf{1} - \sigma - \varepsilon$); the number of paths of length n from $\mathbf{1}$ to ϕ_b counts the blocks of $\langle\sigma \cdots \sigma\, \phi_b\rangle$ with n spins.

Worked example 11.99: Associativity checked by counting blocks

Count the blocks of $\langle\sigma\sigma\sigma\sigma\rangle$ in two ways, with $i=j=k=l=\sigma$:

$$\sum_m N_{\sigma\sigma}^{m} N_{m\sigma}^{\sigma} \overset{(1)}{=} N_{\sigma\sigma}^{\mathbf{1}} N_{\mathbf{1}\sigma}^{\sigma} + N_{\sigma\sigma}^{\varepsilon} N_{\varepsilon\sigma}^{\sigma} + N_{\sigma\sigma}^{\sigma} N_{\sigma\sigma}^{\sigma} \overset{(2)}{=} 1\cdot 1 + 1\cdot 1 + 0\cdot 0 = 2,$$

(1) Sum over the intermediate family $m \in \{\mathbf{1}, \varepsilon, \sigma\}$.
(2) The Ising fusion rules (11.268); in particular $\sigma \notin \sigma\times\sigma$.

and $\sum_m N_{\sigma\sigma}^{m} N_{\sigma m}^{\sigma}$ gives the same 2 by commutativity. Now a mixed case, $\langle \varepsilon\,\sigma\,\sigma\,\varepsilon\rangle$ (the family l at infinity is $\varepsilon' = \varepsilon$): in the s-channel we fuse $\sigma\times\varepsilon = \sigma$ first, and $\sigma\times\sigma \ni \varepsilon$ once: one block. In the t-channel we fuse $\varepsilon\times\sigma = \sigma$, then $\sigma\times\sigma \ni \varepsilon$ once: one block. They agree, as they must.

11.10.2 Vertex operators: fusion is momentum conservation

Nash's simple example (p. 316) is the free scalar field. We recall from §2 (Nash's (11.8)) that φ itself is not primary: its two-point function is a logarithm, $\langle\varphi(z,\bar z)\varphi(0)\rangle = -\frac{1}{2}\ln|z|^2$ in the normalisation of Section 11.8.5, and a logarithm is not a power. Its exponentials are primary.

Working definition 11.35 (vertex operator)

For $p\in\mathbb{R}$ the **vertex operator** is

$$V_p(z,\bar z) = :\exp\big(ip\varphi(z,\bar z)\big): = \sum_{n\ge 0}\frac{(ip)^n}{n!}:\varphi^n:(z,\bar z),$$

with all contractions inside the exponential removed. It is a primary field of weights $(h,\bar h) = (p^2/4, p^2/4)$ [read off from $\langle V_p(z,\bar z)V_{-p}(0)\rangle = |z|^{-p^2} = z^{-2h}\bar z^{-2\bar h}$]. *Operational meaning:* it creates a state of momentum p in the φ direction, i.e. it shifts the zero mode [the constant part of φ, whose conjugate momentum is $\hat p$]: $V_p|0\rangle \propto |p\rangle$ with $\hat p|p\rangle = p|p\rangle$.

To compute the OPE we need one identity for free fields: if A and B are linear in φ, then

$$:e^{A}::e^{B}: = :e^{A+B}:\, e^{\langle AB\rangle}. \tag{11.269}$$

It follows from Wick's theorem (the free-field toolkit of §2): each term of the product with n contractions between A's and B's gives $\langle AB\rangle^n/n!$ times the normal-ordered rest, and the sum over n is the exponential. (It is the field-theory version of the Baker–Campbell–Hausdorff formula $e^Ae^B = e^{A+B}e^{[A,B]/2}$ for operators with a central commutator.) Now take $A = ip\varphi(z,\bar z)$ and $B = iq\varphi(0)$:

$$\begin{aligned} V_p(z,\bar z)V_q(0) &\overset{(1)}{=} :e^{ip\varphi(z,\bar z)+iq\varphi(0)}:\, e^{(ip)(iq)\langle\varphi(z,\bar z)\varphi(0)\rangle} \\ &\overset{(2)}{=} :e^{ip\varphi(z,\bar z)+iq\varphi(0)}:\, e^{\frac{pq}{2}\ln|z|^2} \\ &\overset{(3)}{=} |z|^{pq}\Big(:e^{i(p+q)\varphi(0)}: + ip\,z\,:\partial\varphi\, e^{i(p+q)\varphi}:(0) + \cdots\Big) \\ &\overset{(4)}{=} z^{pq/2}\,\bar z^{pq/2}\,V_{p+q}(0) + \cdots . \end{aligned} \tag{11.270}$$

(1) The identity (11.269).
(2) $(ip)(iq) = -pq$ and $\langle\varphi\varphi\rangle = -\frac{1}{2}\ln|z|^2$, so the exponent is $+\frac{pq}{2}\ln|z|^2$.

(3) $e^{\frac{pq}{2}\ln|z|^2} = |z|^{pq}$; Taylor expand $\varphi(z,\bar z) = \varphi(0) + z\partial\varphi(0) + \bar z\bar\partial\varphi(0) + \cdots$ inside the normal ordering.

(4) The leading term is the vertex operator of momentum $p+q$; the dots are its descendants, with extra powers of z and $\bar z$.

Check the exponent against the general OPE (11.255), which says the leading power is $z^{h_{p+q}-h_p-h_q}$:

$$h_{p+q} - h_p - h_q = \frac{(p+q)^2 - p^2 - q^2}{4} = \frac{pq}{2}.$$

It agrees. So the only family in $V_p \times V_q$ is $[V_{p+q}]$ (Nash's (11.73)):

$$\phi_p \times \phi_q = \phi_{p+q}, \qquad N_{pq}^r = \delta_{r,p+q}. \tag{11.271}$$

Watch out: The exponent in Nash's (11.72)

Nash writes the prefactor as $|z|^{pq/2} = z^{pq/4}\bar z^{pq/4}$. With the weights $(p^2/4, p^2/4)$ that he states, the exponent must be $h_{p+q} - h_p - h_q = pq/2$, i.e. the prefactor is $|z|^{pq}$ as in (11.270). The two are consistent only if the propagator were $-\frac{1}{4}\ln|z|^2$, which would make the weight $p^2/8$. The fusion rule (11.271) is unaffected.

Worked example 11.100: Momentum conservation from the zero-mode integral

Why must the charges in a correlator of vertex operators add to zero? Split $\varphi = \varphi_0 + \tilde\varphi$ into the constant zero mode and the rest. In the path integral the zero mode appears only through the vertex operators, so

$$\Big\langle \prod_{a=1}^{n} V_{p_a}(z_a) \Big\rangle \overset{(1)}{=} \int \mathrm{d}\varphi_0\, e^{i(p_1+\cdots+p_n)\varphi_0} \Big\langle \prod_a :e^{ip_a\tilde\varphi(z_a)}: \Big\rangle_{\tilde\varphi}$$
$$\overset{(2)}{=} 2\pi\,\delta\Big(\sum_a p_a\Big) \prod_{a<b} |z_{ab}|^{p_a p_b}.$$

(1) The action does not depend on φ_0 (it contains only derivatives), and $V_p = e^{ip\varphi_0}{:}e^{ip\tilde\varphi}{:}$.

(2) $\int \mathrm{d}\varphi_0\, e^{ik\varphi_0} = 2\pi\delta(k)$; the remaining Gaussian integral is (11.269) applied repeatedly.

The δ-function is translation invariance of the target: shifting $\varphi \to \varphi + a$ is a symmetry with conserved charge $\hat p$. For the three-point function this says $\langle V_{-r}V_pV_q\rangle \neq 0$ only for $r = p+q$: that is $N_{pq}^r = \delta_{r,p+q}$ again. For the compact boson of Section 11.8.5, $p = n/R$ is quantised and the δ-function becomes a Kronecker delta.

Nash's extension (p. 316) is to d scalar fields X^μ, $\mu = 1,\dots,d$, the string embedding coordinates of Chapter 9. The vertex operator $V_p = {:}e^{ip_\mu X^\mu}{:}$ has weight $p^2/4$ with $p^2 = p_\mu p^\mu$, the OPE prefactor is $|z|^{p\cdot q}$, and the fusion rule $V_p \times V_q = V_{p+q}$ is the conservation of d-momentum at a vertex of a string diagram. For the closed bosonic string V_p with $h = \bar h = 1$, i.e. $p^2 = 4$ in these units, is the tachyon vertex operator.

Physical picture: Group-like fusion

When every $\phi_i \times \phi_j$ contains a single family, the fusion algebra is the group ring of an abelian group: the momentum lattice for free bosons, $\mathbb{Z}_2$ for the spin-flip sector of Ising's $\{\mathbf{1}, \varepsilon\}$, $\mathbb{Z}_N$ for the parafermion-like vertex operators of a boson at a rational radius. Families with several outputs, like $\sigma \times \sigma = \mathbf{1} + \varepsilon$, are *non-abelian*; they are what makes rational CFT (and the anyons of Chapter 12) interesting.

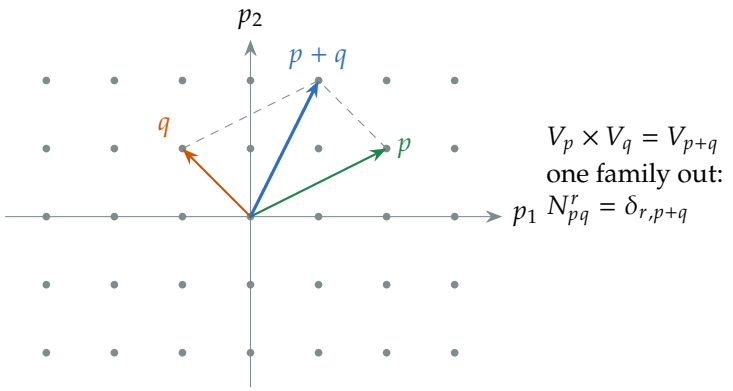

Figure 11.54: Fusion of vertex operators for two compact bosons: the charges live on a lattice (grey), and fusion is vector addition. What to see: the fusion algebra of a free boson is the group algebra of the charge lattice. A group-like fusion rule has exactly one output, so every block space is one- or zero-dimensional.

11.10.3 Conformal blocks on a surface of genus p

In string theory the worldsheet can be any Riemann surface. So we need to say what a conformal block is on a surface Σ of genus p. Nash's answer (p. 317) has three steps.

1. All the local formulas of Section 11.9 (OPEs, Ward identities, null-vector equations) hold near any point of Σ, in a local holomorphic coordinate z. They are statements about neighbourhoods, and every neighbourhood of a Riemann surface looks like a disc in $\mathbb{C}$.

2. A **conformal block** on Σ with n punctures $P_1, \dots, P_n$ carrying primaries $\phi_{i_1}, \dots, \phi_{i_n}$ is a (multivalued) function of the complex structure of Σ and the positions of the punctures, satisfying all the local Ward identities and glued consistently. Write $\Sigma_{p,n}$ for a genus-p surface with n distinct punctures.

3. The blocks form a vector space $V(\Sigma_{p,n})$. Its dimension counts the independent chiral "channels".

The simplest case is the sphere with three punctures. Its blocks are the chiral three-point couplings, one for each occurrence of ϕ_k in $\phi_i \times \phi_j$, so (Nash (11.74))

$$N_{ij}^{k} = \dim V\big(\Sigma_{0,3}\big) \quad \text{with punctures labelled } i,\ j,\ k'. \tag{11.272}$$

Working definition 11.36 (moduli space $\mathcal{M}_{p,n}$)

$\mathcal{M}_{p,n}$ is the set of all complex structures [choices of which local coordinates z count as holomorphic, which fixes angles but not lengths] on a genus-p surface with n marked points, where two are identified if a biholomorphic map [an invertible holomorphic map with holomorphic inverse] carries one to the other (and the marked points to the marked points). A point of $\mathcal{M}_{p,n}$ is "a shape" of the punctured surface [for $p = 1$, $n = 0$ it is a modular parameter $\tau \in \mathbb{H}$, with τ and $\frac{a\tau+b}{c\tau+d}$ counted as the same point]. *Operational meaning:* its complex coordinates are the parameters a conformally invariant quantity can depend on after all the Möbius, translation and rescaling freedom has been used up.

Nash's footnote 5 gives $\dim_{\mathbb{C}} \mathcal{M}_{p,n} = 3p-3+n$. Here is where it comes from. An infinitesimal change of complex structure that fixes the punctures is a class in $H^1(\Sigma, T\Sigma(-P_1 - \cdots - P_n))$

(vector fields vanishing at the punctures), and the holomorphic sections H^0 of the same bundle are the infinitesimal automorphisms, which do not change the shape. So

$$\begin{aligned}\dim \mathcal{M}_{p,n} &\overset{(1)}{=} h^1\big(T\Sigma(-\textstyle\sum P_a)\big) - h^0\big(T\Sigma(-\textstyle\sum P_a)\big)\\ &\overset{(2)}{=} -\operatorname{index}\bar\partial_{T\Sigma(-\sum P_a)}\\ &\overset{(3)}{=} -\Big(\deg T\Sigma(-\textstyle\sum P_a) + 1 - p\Big)\\ &\overset{(4)}{=} -\big((2-2p-n)+1-p\big) = 3p-3+n. \end{aligned} \tag{11.273}$$

(1) Deformations minus automorphisms (the stacky dimension; it is the honest dimension whenever the surface has no continuous automorphisms, i.e. whenever $3p-3+n \geq 0$ and $(p,n) \neq (1,0)$).
(2) The index of the $\bar\partial$ operator on sections of a holomorphic line bundle is $h^0 - h^1$ (Chapter 4).
(3) Riemann–Roch: $\operatorname{index}\bar\partial_L = \deg L + 1 - p$ (Chapter 5).
(4) $\deg T\Sigma = \chi(\Sigma) = 2-2p$ (a vector field has $2-2p$ zeros counted with sign), and each forced zero at a puncture lowers the degree by one.

Worked example 11.101: The first few moduli spaces

- $\mathcal{M}_{0,3}$: $3\cdot 0 - 3 + 3 = 0$. A point. Any three points of the sphere can be moved to $(0,1,\infty)$ by a Möbius map, so there is no shape to vary. This is why three-point functions contain only constants (Section 11.9.3).
- $\mathcal{M}_{0,4}$: dimension 1. The shape of four points is the cross ratio z of (11.249), with $z \neq 0,1,\infty$. So $\mathcal{M}_{0,4} = \mathbb{CP}^1 \setminus \{0,1,\infty\}$, and four-point blocks are functions of z.
- $\mathcal{M}_{1,1}$: dimension 1. A torus with one marked point is fixed by τ modulo $\mathrm{SL}(2,\mathbb{Z})$: $\mathcal{M}_{1,1}$ is the fundamental domain of Figure 11.40. (Without the marked point, translations are automorphisms and (11.273) gives 0, the "1 − 1" of one modulus minus one automorphism.)
- $\mathcal{M}_{2,0}$: dimension 3. A genus-2 surface is a double cover of the sphere branched at 6 points, $y^2 = \prod_{a=1}^{6}(x-e_a)$; three of the e_a can be fixed by Möbius, leaving $6-3=3$ parameters. This matches $3p-3$.

In general $\dim \mathcal{M}_p = 3p-3$ for $p \geq 2$ is Nash's result (5.99) from Chapter 5.

As the surface changes shape, the space of blocks moves with it: $V(\Sigma_{p,n})$ varies holomorphically with the point of $\mathcal{M}_{p,n}$, and its dimension does not jump (it is a count of channels, an integer that cannot change continuously). So the spaces fit together into a holomorphic vector bundle

$$\mathcal{V}_{p,n} \longrightarrow \mathcal{M}_{p,n}, \qquad \text{fibre over } [\Sigma] \;=\; V(\Sigma_{p,n}),$$

and a conformal block is a holomorphic section of it. For $p=0$ this is the remark of Section 11.9.6: the blocks are holomorphic on $\mathcal{M}_{0,n}$, and their monodromy is the flat structure of the bundle. In general $\mathcal{V}_{p,n}$ carries a *projectively* flat connection (flat up to a scalar curvature proportional to c), which we meet again in the Friedan–Shenker picture of Section 11.11.

11.10.4 Sewing: every block space from three-punctured spheres

The final sentence of Nash's p. 317 contains a powerful idea: "any punctured Riemann surface $\Sigma_{p,n}$ can be assembled by joining together $\Sigma_{0,3}$'s". Physically, it is the statement that every

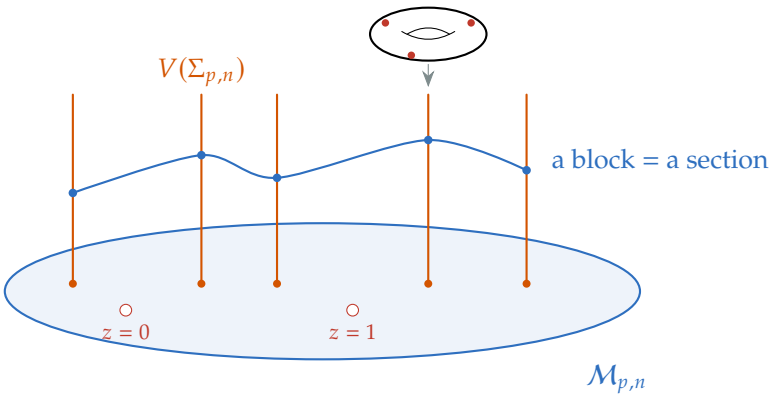

Figure 11.55: Conformal blocks as a vector bundle over moduli space. Each point of the base $\mathcal{M}_{p,n}$ is a shape of the punctured surface (one is drawn above its fibre); the fibre is the space of blocks $V(\Sigma_{p,n})$ for that shape. What to see: a block is a holomorphic section, and going round a hole of the base (for $\mathcal{M}_{0,4}$ the removed points $z = 0, 1$) returns it to a different vector of the same fibre: monodromy.

string diagram is built from cubic vertices and propagators.

Key idea: Pants decomposition

Cut a surface $\Sigma_{p,n}$ along $3p - 3 + n$ disjoint simple closed curves. The pieces are $2p - 2 + n$ **pairs of pants**: spheres with three holes (or punctures). Every $\Sigma_{p,n}$ with $2p - 2 + n > 0$ can be cut this way.

The counting is Euler characteristic bookkeeping. A pair of pants has $\chi = 2 - 3 = -1$; gluing along circles ($\chi = 0$) adds Euler characteristics; so the number of pants is $-\chi(\Sigma_{p,n}) = 2p - 2 + n$. Each pant has three boundary circles, giving $3(2p - 2 + n)$ circles; n of them are the punctures and the rest are glued in pairs, so the number of cuts is $\frac{1}{2}\big(3(2p - 2 + n) - n\big) = 3p - 3 + n$, the dimension of $\mathcal{M}_{p,n}$. This is no coincidence: each cut has a length and a twist, which together form one complex modulus (the plumbing parameter of Section 11.11).

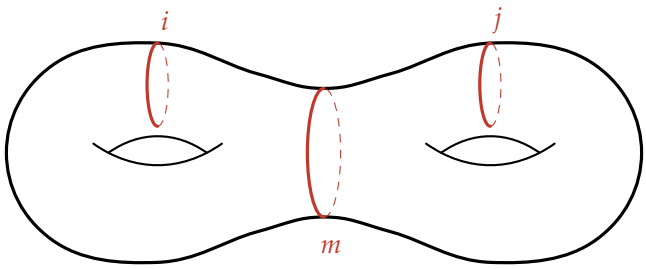
Key idea: The sewing rule for dimensions

Cut Σ along a circle C into Σ_1 and Σ_2 (or, if C does not separate, into one surface Σ' with two new punctures). Then

$$\dim V(\Sigma) = \sum_m \dim V(\Sigma_1;\, m)\, \dim V(\Sigma_2;\, m') \qquad \Big(\text{or} \sum_m \dim V(\Sigma';\, m, m')\Big), \tag{11.274}$$

where m runs over the primaries and the new punctures carry m and its conjugate m'.

Why is this true? Near the circle C the surface looks like a long thin cylinder. Every state crossing the cylinder decomposes into families: by (11.200) the Hilbert space on a circle is $\bigoplus_m H_m \otimes \bar{H}_m$. The chiral blocks sort themselves according to which H_m flows through C: this is the insertion of a complete set of states, the "$\sum_m$", and it is the same mechanism that expanded the four-point function into blocks in (11.257). For each m the blocks factorise as (blocks of Σ_1 with m at the new puncture) $\otimes$ (blocks of Σ_2 with m'), and dimensions multiply.



$$\dim V(\Sigma_{2,0}) = \sum_m \Big(\sum_i N_{im}^{\,i}\Big)\Big(\sum_j N_{jm'}^{\,j}\Big) = \sum_m \operatorname{tr} N_m \ \operatorname{tr} N_{m'}$$

Figure 11.56: A pants decomposition of a closed genus-2 surface: $3p-3=3$ cuts (red) and $2p-2=2$ pairs of pants. The waist cut m separates two one-holed tori; the cut i (resp. j) on each handle turns a one-holed torus into a pair of pants whose three boundaries carry i, i' and m. What to see: summing over the labels of the cuts, with one fusion number per pair of pants, gives the dimension of the space of genus-2 blocks.

Worked example 11.102: Dimensions from the Ising fusion rules

(a) Four spins on the sphere. Cut $\Sigma_{0,4}$ into two pants joined along one circle with label m:

$$\dim V(\Sigma_{0,4};\sigma,\sigma,\sigma,\sigma) \overset{(1)}{=} \sum_m N_{\sigma\sigma}^{m} N_{m\sigma}^{\sigma} \overset{(2)}{=} 2,$$

(1) (11.274) with (11.272) for each pant (all fields are self-conjugate).
(2) The count of the associativity example.

the two blocks $\mathcal{F}_{\mathbf{1}}$, $\mathcal{F}_{\varepsilon}$ of (11.263).

(b) The torus without punctures. Cut along one non-separating circle; the result is a sphere with two punctures labelled m and m':

$$\dim V(\Sigma_{1,0}) \overset{(1)}{=} \sum_m N_{mm'}^{\mathbf{1}} \overset{(2)}{=} \sum_m 1 = F = 3.$$

(1) (11.274); a sphere with two punctures is a sphere with three punctures, one of them the identity.
(2) The conjugation rule: $N_{mm'}^{\mathbf{1}} = 1$ for every m.

These three blocks are the three characters $\chi_0, \chi_{1/2}, \chi_{1/16}$: the torus blocks are the characters, and the torus partition function $\sum_m |\chi_m|^2$ is the Hermitian combination (11.259) at genus one.

(c) The torus with one puncture ϕ_j. Cut the handle: a sphere with punctures m, m', j, so $\dim V(\Sigma_{1,1};j) = \sum_m N_{jm}^{m} = \operatorname{tr} N_j$. For Ising: $\operatorname{tr} N_{\mathbf{1}} = 3$, $\operatorname{tr} N_{\varepsilon} = 1$, $\operatorname{tr} N_{\sigma} = 0$ (read off the diagonals of the matrices above). So $\langle\sigma\rangle_{\text{torus}} = 0$, the $\mathbb{Z}_2$ symmetry again, and $\langle\varepsilon\rangle_{\text{torus}}$ has exactly one block (with σ circulating round the handle).

(d) Genus two. Use Figure 11.56:

$$\dim V(\Sigma_{2,0}) \overset{(1)}{=} \sum_m \operatorname{tr} N_m \ \operatorname{tr} N_{m'} \overset{(2)}{=} 3^2 + 1^2 + 0^2 = 10.$$

(1) Two one-punctured tori glued along the waist, each contributing (c).
(2) The traces from (c), with $m = \mathbf{1}, \varepsilon, \sigma$.

The answer must not depend on how we cut. For $\Sigma_{0,4}$ the s- and t-channel decompositions

give the two sides of the associativity rule, so this independence *is* associativity. A theorem of Moore and Seiberg says that for genus zero and genus one the relations between different pants decompositions are generated by a handful of moves (the fusion move on $\Sigma_{0,4}$, the S move on $\Sigma_{1,1}$, and braiding), so consistency on those surfaces is enough for every surface.

Working definition 11.37 (the handle operator)

Attaching one handle to a surface is a sum over the family circulating through it [cutting the handle leaves two new punctures labelled i and i', and one sums over i]. As a matrix acting on the label of a puncture, it is

$$\mathcal{H} = \sum_i N_i N_{i'}, \qquad \dim V(\Sigma_{p,1}; j) = (\mathcal{H}^p)_j{}^{\mathbf{1}}, \qquad \dim V(\Sigma_{p,0}) = (\mathcal{H}^p)_{\mathbf{1}}{}^{\mathbf{1}}. \tag{11.275}$$

with N_i the fusion matrices [$(N_i)_j{}^k = N_{ij}^k$] and $V(\Sigma_{p,1}; j)$ [the space of conformal blocks on a genus-p surface with one puncture carrying ϕ_j]. *Operational meaning:* to add a handle next to a puncture labelled a, fuse a with a pair i, i' in all possible ways.

For the Ising model the handle operator can be computed in closed form:

$$\mathcal{H} \overset{(1)}{=} N_{\mathbf{1}}^2 + N_\varepsilon^2 + N_\sigma^2 \overset{(2)}{=} \mathbb{1} + \mathbb{1} + (\mathbb{1} + N_\varepsilon) = 3\,\mathbb{1} + N_\varepsilon,$$
$$\mathcal{H}^2 \overset{(3)}{=} 9\,\mathbb{1} + 6N_\varepsilon + N_\varepsilon^2 \overset{(4)}{=} 10\,\mathbb{1} + 6N_\varepsilon, \qquad \mathcal{H}^3 \overset{(5)}{=} 36\,\mathbb{1} + 28N_\varepsilon.$$

(1) All Ising fields are self-conjugate, $i' = i$.
(2) $N_{\mathbf{1}} = \mathbb{1}$, $N_\varepsilon^2 = \mathbb{1}$ and $N_\sigma^2 = \mathbb{1} + N_\varepsilon$ from Example 11.98.
(3) Square: $N_{\mathbf{1}}$ commutes with everything.
(4) $N_\varepsilon^2 = \mathbb{1}$.
(5) $(10\,\mathbb{1} + 6N_\varepsilon)(3\,\mathbb{1} + N_\varepsilon) = 30\,\mathbb{1} + 10N_\varepsilon + 18N_\varepsilon + 6\,\mathbb{1}$.

Since $(N_\varepsilon)_{\mathbf{1}}{}^{\mathbf{1}} = 0$, the numbers of blocks on closed surfaces of genus $1, 2, 3$ are $3, 10, 36$. Genus 2 agrees with part (d) of the example, obtained by cutting differently.

11.10.5 The Verlinde formula

The fusion rules so far came from hard work: null vectors, differential equations and indicial exponents. Verlinde (1988) found that they are hidden in something much simpler, the behaviour of the torus characters under $\tau \mapsto -1/\tau$. This is Nash's p. 317: "the matrix representing the action of S on the characters can be used to diagonalise the fusion algebra".

Key idea: The Verlinde formula

Let $\chi_i(-1/\tau) = \sum_j S_{ij}\chi_j(\tau)$ define the modular S matrix of a rational CFT, with 0 the label of the identity. Then S is symmetric and unitary, the fusion matrices are simultaneously diagonalised by S,

$$N_i = S\,\Lambda_i\,S^{-1}, \qquad \Lambda_i = \operatorname{diag}\!\left(\frac{S_{im}}{S_{0m}}\right)_m, \tag{11.276}$$

and therefore

$$N_{ij}^k = \sum_m \frac{S_{im}\,S_{jm}\,\bar{S}_{km}}{S_{0m}}. \tag{11.277}$$

We explain the formula in three steps: why the N_i can be diagonalised at all, why S is the diagonalising matrix, and why the eigenvalues are ratios of entries of S.

Step 1: one basis that diagonalises all the N_i at once

By (11.267) the N_i commute. They are also normal: $N_i^{\mathsf{T}} = N_{i'}$ (because $N_{ij}^{k} = N_{ik'}^{j'}$, a relabelling of the three punctures of $\Sigma_{0,3}$), and $N_{i'}$ is again one of the commuting family, so $N_i N_i^{\mathsf{T}} = N_i N_{i'} = N_{i'} N_i = N_i^{\mathsf{T}} N_i$. A family of commuting normal matrices can be **diagonalised simultaneously**: there is *one* unitary change of basis U such that $U^{-1} N_i U$ is diagonal for *every* i.

Watch out: What "commuting matrices share eigenvectors" does and does not say

It does *not* say the matrices are diagonal. In the basis of primary fields the N_i are full matrices of non-negative integers. What commutation (plus normality) buys is the *existence* of some other basis, the common eigenvectors $\psi^{(m)}$, in which all of them become diagonal together. Normality matters. Without it, commuting matrices are only guaranteed to share *one* eigenvector, and may not be diagonalisable at all. For example, $\left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$ commutes with $\mathbb{1}$, and both have the eigenvector $(1, 0)$, but the first has no basis of eigenvectors. So "simultaneously diagonalisable" is a statement about a basis that exists, not about the matrices as written.

Let $\psi^{(m)}$, $m = 0, \ldots, F-1$, be the common eigenvectors and $\lambda_i^{(m)}$ the eigenvalue of N_i on $\psi^{(m)}$. Applying (11.267) to $\psi^{(m)}$ gives

$$\lambda_i^{(m)} \lambda_j^{(m)} = \sum_k N_{ij}^{k} \lambda_k^{(m)}. \tag{11.278}$$

So for each m the numbers $\phi_i \mapsto \lambda_i^{(m)}$ are a one-dimensional representation of the fusion algebra: a way of replacing each field by a number that respects the fusion rules. There are F of them.

Step 2: why S diagonalises (Verlinde's loop operators)

Think of the torus as a cylinder, of circumference 2π in the space direction, whose ends have been glued after a Euclidean time $2\pi \operatorname{Im}\tau$. Call the space circle the a-cycle and the time circle the b-cycle (Figure 11.57). The torus blocks are the characters: in $\chi_j(\tau) = \operatorname{Tr}_{H_j} q^{L_0 - c/24}$ the family j propagates around the b-cycle.

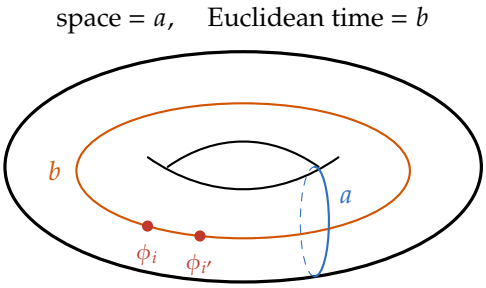
Now define an operation on blocks: create the pair ϕ_i, $\phi_{i'}$ out of the vacuum at some point (allowed, since $\mathbf{1} \in \phi_i \times \phi_{i'}$), carry ϕ_i once around a closed curve C, and let the pair annihilate back into the vacuum. The result is again a torus block, so this defines a linear map $\phi_i(C)$ on the F-dimensional space $V(\Sigma_{1,0})$.

- $C = a$ (around space, at fixed time). The whole operation happens on one time slice, so it is an operator on each H_j. The loop can be slid past any insertion of T (the stress tensor is single valued), so the operator commutes with all L_n. By Schur's lemma it is a number on the irreducible module H_j: $\phi_i(a)\chi_j = \lambda_i^{(j)} \chi_j$. *Diagonal.*

- $C = b$ (around time). On every time slice between creation and annihilation, the state is ϕ_i fused with the family j that was circulating: it lies in $\bigoplus_k N_{ij}^{k} H_k$. When the pair annihilates, family k is circulating instead of j: $\phi_i(b)\chi_j = \sum_k N_{ij}^{k} \chi_k$. *The fusion matrix.*

- The modular transformation $S : \tau \mapsto -1/\tau$ exchanges the two cycles. In the basis of characters it is the matrix S, so $\phi_i(b) = S\, \phi_i(a)\, S^{-1}$.

Putting the three together: $N_i = S\Lambda_i S^{-1}$, with Λ_i diagonal. The columns of S are the common eigenvectors $\psi^{(m)}$ of Step 1.



$$\phi_i(a)\,\chi_j = \frac{S_{ij}}{S_{0j}}\,\chi_j$$

$$\phi_i(b)\,\chi_j = \textstyle\sum_k N_{ij}^k\,\chi_k$$

$$S:\ a \leftrightarrow b$$

Figure 11.57: Verlinde's loop operators on the torus. A pair ϕ_i, $\phi_{i'}$ is created, ϕ_i travels round a cycle, and the pair annihilates. What to see: round the space cycle a the operation acts inside one module and is a number; round the time cycle b it changes the circulating family by fusion. The modular transformation S swaps the cycles, so S turns the diagonal matrices into the fusion matrices.

Step 3: the eigenvalues

The identity family is special: $\phi_i \times \mathbf{1} = \phi_i$. Use it to find the eigenvalues. Take the $(0, m)$ entry of $N_i S = S\Lambda_i$:

$$(N_i S)_{0m} \overset{(1)}{=} \sum_k (N_i)_0{}^k\, S_{km} \overset{(2)}{=} \sum_k N_{i0}^k\, S_{km} \overset{(3)}{=} S_{im},$$

$$(S\Lambda_i)_{0m} \overset{(4)}{=} S_{0m}\,\lambda_i^{(m)}.$$

(1) Matrix multiplication.
(2) The definition of the fusion matrix, row 0.
(3) The identity rule $N_{i0}^k = N_{0i}^k = \delta_i^k$.
(4) Λ_i is diagonal with entries $\lambda_i^{(m)}$.

Therefore $\lambda_i^{(m)} = S_{im}/S_{0m}$. (For a unitary theory $S_{0m} > 0$ for all m, so the division is allowed; this positivity is the statement that the vacuum character dominates as $\tau \to 0$, Cardy's argument of Section 11.8.6.) Now write out $N_i = S\Lambda_i S^{-1}$ entry by entry:

$$N_{ij}^k \overset{(1)}{=} \sum_m S_{jm}\,\lambda_i^{(m)}\,(S^{-1})_{mk} \overset{(2)}{=} \sum_m S_{jm}\,\frac{S_{im}}{S_{0m}}\,\bar{S}_{km} = \sum_m \frac{S_{im}S_{jm}\bar{S}_{km}}{S_{0m}},$$

(1) Matrix product, with $(N_i)_j{}^k = N_{ij}^k$.
(2) Step 3 for λ; S unitary and symmetric, so $(S^{-1})_{mk} = \bar{S}_{km}$.

which is (11.277). (Had the orientation conventions given $S^{-1}\Lambda_i S$ instead, the result would be the complex conjugate of (11.277); since N_{ij}^k is real, nothing changes.)

Watch out: What was proved, and when

Step 2 is a physical argument: it assumes that the loop operators are well defined and behave as described, which Verlinde conjectured. The formula was derived from the axioms of rational CFT by Moore and Seiberg (1988–89) and proved rigorously for rational vertex operator algebras by Huang (2005). In every example we can check, it works; the

next examples check it.

Worked example 11.103: Verlinde for Ising: $\sigma \times \sigma = \mathbf{1} + \varepsilon$ from the torus

The Ising S matrix of (11.227), in the order $(\mathbf{1}, \varepsilon, \sigma)$, is real, with $S_{0m} = (\frac{1}{2}, \frac{1}{2}, \frac{\sqrt{2}}{2})$. Compute $N_{\sigma\sigma}^k$ for each k:

$$N_{\sigma\sigma}^{\mathbf{1}} \overset{(1)}{=} \frac{S_{\sigma\mathbf{1}}S_{\sigma\mathbf{1}}S_{\mathbf{11}}}{S_{\mathbf{11}}} + \frac{S_{\sigma\varepsilon}S_{\sigma\varepsilon}S_{\mathbf{1}\varepsilon}}{S_{\mathbf{1}\varepsilon}} + \frac{S_{\sigma\sigma}S_{\sigma\sigma}S_{\mathbf{1}\sigma}}{S_{\mathbf{1}\sigma}} \overset{(2)}{=} \tfrac{1}{2} + \tfrac{1}{2} + 0 = 1,$$

$$N_{\sigma\sigma}^{\varepsilon} \overset{(3)}{=} \frac{(\frac{\sqrt{2}}{2})^2 \cdot \frac{1}{2}}{\frac{1}{2}} + \frac{(-\frac{\sqrt{2}}{2})^2 \cdot \frac{1}{2}}{\frac{1}{2}} + 0 = 1,$$

$$N_{\sigma\sigma}^{\sigma} \overset{(4)}{=} \frac{(\frac{\sqrt{2}}{2})^2 \cdot \frac{\sqrt{2}}{2}}{\frac{1}{2}} + \frac{(-\frac{\sqrt{2}}{2})^2 \cdot (-\frac{\sqrt{2}}{2})}{\frac{1}{2}} + 0 = \frac{\sqrt{2}}{2} - \frac{\sqrt{2}}{2} = 0.$$

(1) (11.277) with $i = j = \sigma$, $k = \mathbf{1}$, summing over $m = \mathbf{1}, \varepsilon, \sigma$.

(2) $S_{\sigma\mathbf{1}} = \frac{\sqrt{2}}{2}$, $S_{\sigma\varepsilon} = -\frac{\sqrt{2}}{2}$, $S_{\sigma\sigma} = 0$; the first two terms are $\frac{1}{2}$ each.

(3) Now $\bar{S}_{km} = S_{\varepsilon m} = (\frac{1}{2}, \frac{1}{2}, -\frac{\sqrt{2}}{2})$; the third term has the factor $S_{\sigma\sigma}^2 = 0$.

(4) $S_{\sigma m} = (\frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{2}, 0)$; the two surviving terms cancel.

So $\sigma \times \sigma = \mathbf{1} + \varepsilon$: the result of the four-spin differential equation of Section 11.9.7, now obtained from nothing but the modular properties of the characters. The eigenvalues of N_σ are $S_{\sigma m}/S_{0m} = (\sqrt{2}, -\sqrt{2}, 0)$; indeed $\det(N_\sigma - \lambda) = -\lambda^3 + 2\lambda$ for the matrix of Example 11.98.

Working definition 11.38 (quantum dimension)

The **quantum dimension** of ϕ_i is $d_i = S_{i0}/S_{00}$ [S is the matrix with $\chi_i(-1/\tau) = \sum_j S_{ij}\chi_j(\tau)$. For Ising $d_\varepsilon = 1$ and $d_\sigma = \sqrt{2}$], the eigenvalue of N_i on the column $m = 0$ [the eigenvector $(S_{k0})_k$, all of whose entries are positive]. By (11.278) $d_i d_j = \sum_k N_{ij}^k d_k$, and since N_i has non-negative entries, d_i is its largest eigenvalue (Perron–Frobenius [if a matrix with non-negative entries has an eigenvector with all entries positive, that eigenvalue is the largest]). *Operational meaning:* the number of blocks with n copies of ϕ_i grows like d_i^n.

For Ising $d_{\mathbf{1}} = d_\varepsilon = 1$ and $d_\sigma = \sqrt{2}$; check $d_\sigma^2 = 2 = d_{\mathbf{1}} + d_\varepsilon$. A system of $2n$ spin fields has 2^{n-1} blocks, i.e. $(\sqrt{2})^{2n}/2$: this is the degeneracy of $2n$ Majorana zero modes (the non-abelian anyons of the $p + ip$ superconductor, whose edge theory is the chiral Ising model).

The dimension of block spaces from S

Combine the handle operator (11.275) with the diagonal form (11.276):

$$\dim V(\Sigma_{p,0}) \overset{(1)}{=} (\mathcal{H}^p)_0{}^0 \overset{(2)}{=} \Big(S\Big(\sum_i \Lambda_i \Lambda_{i'}\Big)^p S^{-1}\Big)_0^{\ 0}$$

$$\overset{(3)}{=} \sum_m S_{0m}\Big(\sum_i \frac{|S_{im}|^2}{S_{0m}^2}\Big)^p \bar{S}_{0m} \overset{(4)}{=} \sum_m S_{0m}^{2-2p}. \tag{11.279}$$

(1) The handle operator applied p times to the identity label.

(2) Each $N_i = S\Lambda_i S^{-1}$; the $S^{-1}S$ in between cancel.

(3) The diagonal entries: $\lambda_{i'}^{(m)} = S_{i'm}/S_{0m} = \bar{S}_{im}/S_{0m}$ (charge conjugation is complex conjugation of S).

(4) $\sum_i |S_{im}|^2 = 1$ by unitarity, and S_{0m} is real positive.

This is the **Verlinde dimension formula**. For Ising: $\sum_m S_{0m}^{2-2p} = 2 \cdot 2^{2p-2} + 2^{p-1}$, which is $1, 3, 10, 36$ for $p = 0, 1, 2, 3$, exactly the numbers found by sewing.

Worked example 11.104: $\mathbb{Z}_N$ fusion: Verlinde is Fourier analysis

Take $F = N$ fields ϕ_a, $a \in \mathbb{Z}_N$, with group-like fusion $\phi_a \times \phi_b = \phi_{a+b \bmod N}$. (A compact boson at radius $R^2 = 2N$ in suitable units, or SU(N) at level 1, realises it.) The S matrix is the discrete Fourier transform, $S_{ab} = N^{-1/2} e^{2\pi i ab/N}$. Verlinde gives

$$N_{ab}^c \overset{(1)}{=} \sum_{m=0}^{N-1} \frac{N^{-1/2} e^{2\pi i am/N}\, N^{-1/2} e^{2\pi i bm/N}\, N^{-1/2} e^{-2\pi i cm/N}}{N^{-1/2}}$$
$$\overset{(2)}{=} \frac{1}{N} \sum_{m=0}^{N-1} e^{2\pi i (a+b-c)m/N} \overset{(3)}{=} \delta_{c,\, a+b \bmod N}.$$

(1) (11.277) with $S_{0m} = N^{-1/2}$.
(2) Collect the phases.
(3) A geometric sum of N-th roots of unity is N if the exponent is a multiple of N and 0 otherwise.

The Verlinde formula is the statement that the characters of the group $\mathbb{Z}_N$ (the columns of S) turn convolution into multiplication. For a non-abelian fusion algebra the same thing happens, with the columns of S playing the role of a character table. The block dimensions are $\sum_m S_{0m}^{2-2p} = N \cdot N^{p-1} = N^p$ at genus p.

Worked example 11.105: $\mathrm{SU}(2)_k$: truncated Clebsch–Gordan

For SU(2) at level k the primaries are the spins $j = 0, \frac{1}{2}, \ldots, \frac{k}{2}$ and S is given in (11.238). Evaluating (11.277) with trigonometric sums gives

$$j_1 \times j_2 = \sum_{j=|j_1-j_2|}^{\min(j_1+j_2,\, k-j_1-j_2)} j \qquad \text{(step 1)}. \tag{11.280}$$

This is the Clebsch–Gordan rule of angular momentum, cut off at the top by $j \le k - j_1 - j_2$. Three cases (all checked numerically from S):

- $k = 1$: $\frac{1}{2} \times \frac{1}{2} = 0$. The spin 1 of ordinary angular momentum is removed. The algebra is $\mathbb{Z}_2$, and the block dimensions are 2^p.
- $k = 2$: $\frac{1}{2} \times \frac{1}{2} = 0 + 1$, $\frac{1}{2} \times 1 = \frac{1}{2}$, $1 \times 1 = 0$. This is the Ising fusion algebra with $\sigma \leftrightarrow \frac{1}{2}$, $\varepsilon \leftrightarrow 1$. In the order $(0, 1, \frac{1}{2})$ the S matrix of (11.238) with $k = 2$ is *identical* to the Ising S of (11.227). The theories are different ($c = \frac{3}{2}$ versus $\frac{1}{2}$, and $h_{1/2} = \frac{3}{16}$ versus $h_\sigma = \frac{1}{16}$): fusion rules and S do not determine the theory; the T matrix distinguishes them. ($\mathrm{SU}(2)_2$ is three Majorana fermions, $3 \times \frac{1}{2} = \frac{3}{2}$.)
- $k = 3$: $1 \times 1 = 0 + 1$. The pair $\{0, 1\}$ closes under fusion; with $d_1 = S_{10}/S_{00} = \sin\frac{3\pi}{5} / \sin\frac{\pi}{5} = \frac{1+\sqrt{5}}{2}$, the golden ratio, and $d_1^2 = 1 + d_1$. This is the "Fibonacci" fusion rule, whose block spaces have Fibonacci-number dimensions.

The level-k dimension formula is $\dim V(\Sigma_{p,0}) = \left(\frac{k+2}{2}\right)^{p-1} \sum_{a=1}^{k+1} \left(\sin\frac{\pi a}{k+2}\right)^{2-2p}$, the famous Verlinde formula for the dimension of the space of non-abelian theta functions (holomorphic

sections of the k-th power of a line bundle over the moduli space of flat SU(2) connections on Σ). For $k = 2$ it gives $1, 3, 10, 36, \ldots$, the Ising numbers again.

11.10.6 Kac–Moody theories and the dimensions (11.75)

Nash recalls (p. 317) that CFTs can be built from representations of the loop group $\widetilde{LG}$, i.e. of the Kac–Moody algebra $\hat{\mathfrak{g}}_k$ (the WZW models of Figure 11.28). A primary is then labelled by an irreducible representation R of G (with a level-dependent upper bound), and a primary field $\phi_R(z)$ is a vector of fields transforming in R:

$$[J_0^a, \phi_R(z)] = -\, t_R^a\, \phi_R(z),$$

where t_R^a are the representation matrices of the generators and J_0^a is the zero mode of the current, the global G charge. For the next chapter Nash needs only spheres, so he writes $V(S^2_{R_1,\ldots,R_n})$ for the space of blocks on the sphere with punctures carrying $R_1, \ldots, R_n$.

Key idea: Nash (11.75)

$$\dim V(S^2_R) = \begin{cases} 1, & R \text{ trivial}, \\ 0, & \text{otherwise}, \end{cases} \qquad \dim V(S^2_{R_i,R_j}) = g_{ij} \equiv N_{ij}^0 = \begin{cases} 1, & R_i = R_j^*, \\ 0, & \text{otherwise}, \end{cases} \tag{11.281}$$

where R^* is the **dual** (complex conjugate) representation.

Both statements follow from the global G symmetry and Schur's lemma. The vacuum is G-invariant, $J_0^a|0\rangle = 0$ and $\langle 0|J_0^a = 0$. So for one puncture

$$0 \overset{(1)}{=} \langle 0|\,[J_0^a, \phi_R(z)]\,|0\rangle \overset{(2)}{=} -\, t_R^a\, \langle 0|\phi_R(z)|0\rangle,$$

(1) J_0^a annihilates the vacuum on both sides.
(2) The transformation law of ϕ_R.

The one-point function is a vector $v \in R$ killed by every generator: a G-invariant vector. In an irreducible R the invariant vectors form a subrepresentation, which is either 0 or all of R; it is all of R only if G acts trivially. Hence $\dim V(S^2_R) = 1$ for R trivial and 0 otherwise. For two punctures the same argument shows that $\langle \phi_{R_i}\phi_{R_j}\rangle$ is an invariant vector in $R_i \otimes R_j$, i.e. an invariant bilinear pairing, i.e. a G-map $R_j \to R_i^*$. By Schur's lemma such a map is zero unless $R_j \cong R_i^*$, and then it is unique up to a constant. That is g_{ij}.

Worked example 11.106: Duals for SU(2) and SU(3)

SU(2). Every representation is self-dual. For the doublet, the invariant pairing is the antisymmetric tensor $\epsilon = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$: for $U \in \mathrm{SU}(2)$,

$$U^{\mathsf{T}} \epsilon\, U \overset{(1)}{=} (\det U)\, \epsilon \overset{(2)}{=} \epsilon,$$

(1) For any 2×2 matrix, $U^{\mathsf{T}}\epsilon U = (\det U)\epsilon$ (multiply out with $U = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$: the $(1,2)$ entry is $ad - bc$).
(2) $\det U = 1$.

So $\langle \phi_{1/2}\phi_{1/2}\rangle \propto \epsilon_{\alpha\beta}$, the spin singlet $\frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle)$, and $g_{\frac{1}{2}\frac{1}{2}} = 1$.

SU(3). The triplet $\mathbf{3}$ is not self-dual. Take $U = \mathrm{diag}(e^{i\theta}, e^{i\theta}, e^{-2i\theta})$. Its character in $\mathbf{3}$ is $\mathrm{tr}\, U = 2e^{i\theta} + e^{-2i\theta}$ and in $\mathbf{3}^*$ it is $\mathrm{tr}\, \bar{U} = 2e^{-i\theta} + e^{2i\theta}$; these differ for generic θ, so $\mathbf{3} \not\cong \mathbf{3}^* = \bar{\mathbf{3}}$.

Hence $g_{\mathbf{33}} = 0$ and $g_{\mathbf{3\bar{3}}} = 1$: a quark two-point function needs an antiquark. At level 1 the three primaries $\mathbf{1}, \mathbf{3}, \bar{\mathbf{3}}$ have $\mathbb{Z}_3$ fusion, $\mathbf{3} \times \mathbf{3} = \bar{\mathbf{3}}$, and their S matrix is the $N = 3$ Fourier matrix of the previous example.

With three punctures the same argument gives, at large level, the number of invariants in $R_1 \otimes R_2 \otimes R_3$: the Clebsch–Gordan multiplicity of R_3^* in $R_1 \otimes R_2$. At finite level there is an additional constraint from a null vector of the affine algebra (for $\mathrm{SU}(2)_k$ it is $(J_{-1}^{+})^{k+1-2j}|j\rangle = 0$), and it produces the truncation in (11.280): $j_1 + j_2 + j_3 \le k$. The metric g_{ij} lowers indices, $N_{ijk} = \sum_l N_{ij}^{l} g_{lk}$, and the lowered symbol N_{ijk} is totally symmetric in its three labels: it is the dimension of the space of blocks on a sphere with three punctures, and the punctures can be listed in any order. These spaces $V(S^2_{R_1,\dots,R_n})$ are exactly the Hilbert spaces of Chern–Simons theory on a sphere with n marked points that Chapter 12 uses to build knot invariants.

$\mathrm{SU}(2)_3$: $j_1 \times j_2$	0	$\frac{1}{2}$	1	$\frac{3}{2}$
0	0	$\frac{1}{2}$	1	$\frac{3}{2}$
$\frac{1}{2}$	$\frac{1}{2}$	$0+1$	$\frac{1}{2}+\frac{3}{2}$	1
1	1	$\frac{1}{2}+\frac{3}{2}$	$0+1$	$\frac{1}{2}$
$\frac{3}{2}$	$\frac{3}{2}$	1	$\frac{1}{2}$	0

Every entry follows from (11.280) with $k = 3$: for example 1×1 would contain $0, 1, 2$ by angular momentum, but $2 > k - 1 - 1 = 1$ is cut. In the table the field $\frac{3}{2}$ acts as a simple current: $\frac{3}{2} \times j = \frac{3}{2} - j$.

11.10.7 Higher genus: the Weierstrass gap theorem

Nash ends his discussion of blocks with a single sentence: “the Weierstrass gap theorem is a constraint on the nature of the meromorphic singularities when $p > 0$. This is also a constraint on the properties of some of the correlation functions”. Let us unpack both halves.

The theorem

On the Riemann sphere, for any point P and any $n \ge 1$ there is a meromorphic function with a pole of order exactly n at P and no other poles: $1/(z - P)^n$. On a surface of higher genus this fails.

Key idea: Weierstrass gap theorem

Let Σ have genus $p \ge 1$ and let $P \in \Sigma$. Among the integers $n = 1, 2, 3, \dots$ there are exactly p values, all in the range $1 \le n \le 2p - 1$, for which *no* meromorphic function on Σ has a pole of order exactly n at P and is holomorphic elsewhere. These are the **gaps** at P. For generic P the gaps are $\{1, 2, \dots, p\}$; the finitely many points with a different gap sequence are the **Weierstrass points**.

The proof is Riemann–Roch. Let $\ell(nP)$ be the dimension of the space of meromorphic functions with at most an n-fold pole at P, and K the canonical bundle (holomorphic 1-forms,

degree $2p-2$). Then

$$\ell(nP) \overset{(1)}{=} n+1-p+\ell(K-nP),$$
$$\ell(nP) \overset{(2)}{=} n+1-p \qquad \text{for } n \geq 2p-1,$$

(1) Riemann–Roch for the divisor nP (Chapter 5): $\ell(D)-\ell(K-D)=\deg D+1-p$.
(2) If $n>2p-2$ then $K-nP$ has negative degree, and a line bundle of negative degree has no non-zero holomorphic sections.

Now count. $\ell(0)=1$ (the constants) and $\ell((2p-1)P)=p$. Going from $n-1$ to n, ℓ grows by 0 or 1 (a new function is fixed, up to lower-order ones, by the coefficient of its leading pole). In the $2p-1$ steps from $n=0$ to $n=2p-1$ it grows by $p-1$ in total. So it stays constant at exactly $(2p-1)-(p-1)=p$ steps: those n are the gaps. For $n \geq 2p$ it grows at every step: no more gaps.

Worked example 11.107: Gaps on the torus and on genus two

Torus ($p=1$). The only gap is $n=1$: there is no meromorphic function on a torus with a single simple pole. Reason: a meromorphic function f on the torus gives a meromorphic 1-form $f\,\mathrm{d}z$, and the sum of the residues of a 1-form on a compact surface is zero (Stokes' theorem on the surface minus small discs, Chapter T2). A single simple pole would have non-zero residue. At $n=2$ there is the Weierstrass function $\wp(z)=z^{-2}+O(z^2)$, and $\wp'$ has a triple pole; all $n \geq 2$ occur. Every point of a torus looks the same (translations), so there are no Weierstrass points.
Genus two. Write Σ as $y^2=\prod_{a=1}^{6}(x-e_a)$, a double cover of the x-sphere branched over the six points e_a. At a branch point $P_a=(e_a,0)$ the local coordinate is y, and $x-e_a \sim y^2$. The function $1/(x-e_a)$ has a double pole at P_a and nothing else. So $n=2$ is not a gap at P_a, and the gaps there are $\{1,3\}$. At a generic point the gaps are $\{1,2\}$. The six branch points are the Weierstrass points of a genus-2 surface.

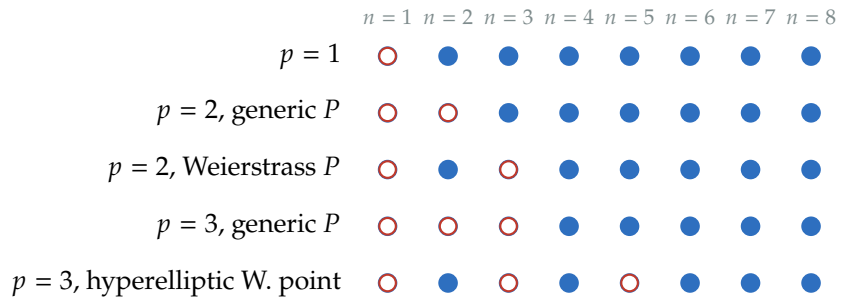


Figure 11.58: Gap sequences. A filled dot at n means a meromorphic function with a pole of order exactly n at P (and no other poles) exists; an open red circle is a gap. What to see: there are always exactly p gaps, all below $2p$; on the sphere ($p=0$) the row would be all filled; the pattern can change only at special points, the Weierstrass points.

Why a field theorist cares

A correlation function on Σ in which a chiral field $A(z)$ of weight h appears, with all other insertions at the single point P, is, as a function of z, a meromorphic section of K^h with poles only at P. The local OPE of A with the fields at P specifies the singular terms. On the plane every choice of singular terms is realised by some global function. On Σ, Riemann–Roch decides which are, and the answer depends on h and on p.

Worked example 11.108: Charge conservation on any surface

Let $J(z)$ be a U(1) current ($h = 1$) and put one charged field $\phi_q(P)$ on Σ, so $J(z)\phi_q(P) \sim \frac{q}{z-P}\phi_q(P)$. Then $\langle J(z)\phi_q(P)\rangle$ is a meromorphic 1-form with at most a simple pole at P. Riemann–Roch for $K + nP$:

$$\ell(K+nP) \overset{(1)}{=} (2p-2+n) + 1 - p + \ell(-nP) \overset{(2)}{=} p - 1 + n \quad (n \geq 1),$$

(1) Riemann–Roch with $\deg(K + nP) = 2p - 2 + n$ and $K - (K + nP) = -nP$.

(2) $\ell(-nP) = 0$: a holomorphic function vanishing at P is zero.

At $n = 1$ this is $p = \ell(K)$: there is no 1-form with a genuine simple pole at one point. So the residue $q\langle\phi_q\rangle$ must vanish: a single charged field has zero expectation value, on every surface. This "gap" at $n = 1$ for 1-forms is the residue theorem, and physically it is charge conservation. For the stress tensor ($h = 2$) the same count gives $\ell(2K + nP) = 3p - 3 + n$ for $p \geq 2$: no gaps, so T can have singularities of every order, and the $3p - 3$ holomorphic quadratic differentials that exist without any pole are the cotangent vectors to $\mathcal{M}_p$ that we meet in Section 11.11.

These constraints are the higher-genus version of the Ward identities. In the operator formalism developed by Alvarez-Gaumé, Gomez, Moore, Reina and Vafa, a genus-p surface with a disc removed around P is represented by a state $\langle\Sigma, P|$ in the Hilbert space of the boundary circle, and that state must be annihilated by exactly those modes of each chiral field that extend holomorphically over $\Sigma \setminus P$. Which modes extend is the Riemann–Roch count above, with its gaps. Vafa used this circle of ideas, together with consistency of sewing at genus two, to show that in a rational CFT the phases $e^{2\pi i(h_i - c/24)}$ are roots of unity: the central charge and the conformal weights are rational numbers.

Reading Nash (pp. 316–318, (11.71)–(11.75))

Nash defines the fusion rules through Verlinde's formal product (11.71), gives the vertex-operator example (11.72)–(11.73) (our (11.270), with the corrected exponent), and states $N_{ij}^k = \dim V(\Sigma_{0,3})$ (11.74). His footnote 5, $\dim \mathcal{M}_{p,n} = 3p - 3 + n$, is our (11.273). The paragraph on Verlinde's work (S diagonalises the fusion algebra; N_{ij}^k in terms of S; sewing gives $\dim V(\Sigma_{p,n})$) is expanded in Sections 11.10.4 and 11.10.5. (11.75) is (11.281), with the Schur's-lemma derivation. The gap theorem is only mentioned by Nash; the proof and the charge-conservation example are ours.

Recap

- N_{ij}^k counts the occurrences of $[\phi_k]$ in $\phi_i\phi_j$. The fusion algebra is commutative and associative with unit $\mathbf{1}$; associativity is crossing symmetry. The matrices $(N_i)_j{}^k$ represent it.
- Vertex operators: $V_p \times V_q = V_{p+q}$, momentum conservation; the OPE prefactor is $|z|^{pq}$.
- Blocks on $\Sigma_{p,n}$ form a vector bundle over $\mathcal{M}_{p,n}$, $\dim \mathcal{M}_{p,n} = 3p - 3 + n$; $N_{ij}^k = \dim V(\Sigma_{0,3})$; sewing along pants decompositions computes every $\dim V(\Sigma_{p,n})$.
- Verlinde: $N_i = S\Lambda_i S^{-1}$, $N_{ij}^k = \sum_m S_{im}S_{jm}\bar{S}_{km}/S_{0m}$, $\dim V(\Sigma_{p,0}) = \sum_m S_{0m}^{2-2p}$. Ising: $\sigma \times \sigma = \mathbf{1} + \varepsilon$ and $1, 3, 10, 36$ blocks at genus $0, 1, 2, 3$.

- Kac–Moody theories: $\dim V(S^2_R) = \delta_{R,\mathrm{triv}}$, $\dim V(S^2_{R_i,R_j}) = \delta_{R_i,R_j^*}$ (Schur's lemma); $\mathrm{SU}(2)_k$ fusion is Clebsch–Gordan truncated at $j_1 + j_2 + j_3 \le k$.
- Weierstrass: at each point of a genus-p surface exactly p pole orders are impossible; for currents the gap at $n = 1$ is charge conservation.

11.11 Axiomatic approaches I: conformal field theory as geometry on moduli space

So far we have met a conformal field theory in three guises. On the sphere it is a list of primary fields with weights $(h_i, \bar{h}_i)$ and operator product coefficients C_{ij}^k that obey crossing symmetry (Section 11.9). On the torus it is a partition function $Z(\tau)$, a sum of products of characters that is invariant under the modular group (Sections 11.7 and 11.8). On a surface of genus p with n punctures it is a finite-dimensional space of conformal blocks $V(\Sigma_{p,n})$ that varies holomorphically with the shape of the surface (Section 11.10). These are three views of one object. We now ask the question that ties them together:

What is a conformal field theory, if we are not allowed to start from a Lagrangian?

Every answer so far has had the same shape. A CFT *assigns numbers (or operators) to Riemann surfaces*, and the assignment is compatible with cutting a surface into pieces and gluing it back. Two ways of making this precise are mentioned by Nash.

1. *Friedan and Shenker* (this section) look at *all closed surfaces at once*. The partition functions of all genera, and of disconnected surfaces, are one object living on one big space, the **universal moduli space** $\mathcal{R}$. The axioms are statements about the analytic geometry of $\mathcal{R}$: which line bundle the partition function is a section of, and how it behaves where surfaces degenerate.

2. *Segal* (Section 11.12) looks at *surfaces with boundary*. A surface with incoming and outgoing boundary circles is a "spacetime history" of closed strings, and the CFT assigns to it an operator between Hilbert spaces. The axioms say that gluing surfaces corresponds to composing operators.

The first is natural for string theory, whose vacuum amplitude is an integral over moduli spaces. The second is the ancestor of the axioms for topological field theory in Chapter 12.

11.11.1 The string vacuum amplitude as a sum over moduli spaces

The motivating example is the closed bosonic string (Chapter 9). Its vacuum amplitude is Polyakov's path integral over worldsheet metrics g and embeddings $X : \Sigma \to \mathbb{R}^{26}$, summed over the topology of Σ:

$$Z = \sum_{p=0}^{\infty} g_s^{2p-2} \int \frac{\mathcal{D}g\,\mathcal{D}X}{\mathrm{Vol}(\mathrm{Diff} \ltimes \mathrm{Weyl})}\, e^{-S[g,X]}. \tag{11.282}$$

Here p is the genus, g_s is the string coupling (each handle costs a factor g_s^2, and the Euler characteristic is $\chi = 2-2p$), and we divide by the volume of the gauge group of diffeomorphisms

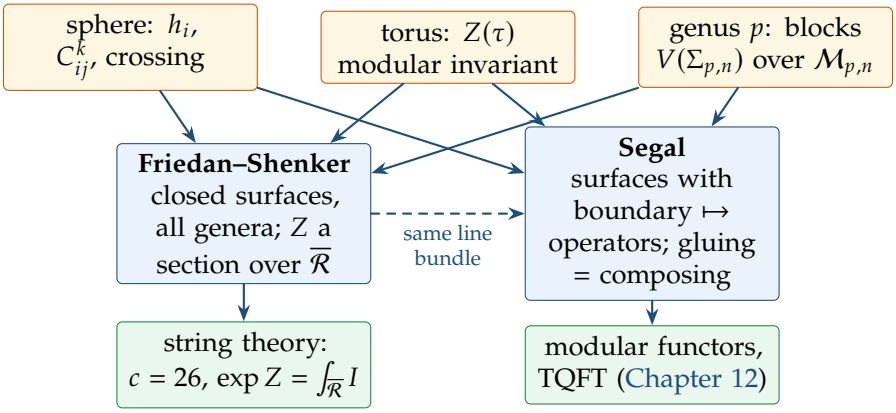

Figure 11.59: The logic of the two axiomatic approaches. What to see: the three concrete pictures of a CFT (top row) are all special cases of "amplitudes assigned to Riemann surfaces, compatible with gluing". Friedan and Shenker package the closed surfaces into one space; Segal uses surfaces with boundary. Both find that the amplitudes are not functions but sections of a line bundle fixed by c.

and Weyl rescalings $g \mapsto e^{2\omega} g$. In chapter 9 we saw that after gauge fixing the infinite-dimensional integral over metrics collapses to a finite-dimensional integral. What survives is exactly the set of metrics that cannot be reached from each other by a diffeomorphism and a Weyl rescaling. A metric up to Weyl rescaling is a complex structure. So what survives is the set of complex structures up to diffeomorphism.

Working definition 11.39 (Moduli space $\mathcal{M}_p$)

$\mathcal{M}_p$ is the set of Riemann surfaces of genus p [surfaces with p handles, with holomorphic coordinates z chosen patch by patch], where two surfaces are the same if a holomorphic bijection maps one onto the other. *Operationally:* $\mathcal{M}_p$ is the list of parameters in the shape of a genus-p surface that no change of coordinates can remove.

- $p = 0$: there is one Riemann sphere; $\mathcal{M}_0$ is a point.
- $p = 1$: a torus is $\mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$ with τ in the upper half plane $\mathbb{H}$, and τ, τ' give the same torus iff they differ by $\mathrm{PSL}(2,\mathbb{Z})$ [$\tau' = \frac{a\tau+b}{c\tau+d}$ with integers a, b, c, d and $ad - bc = 1$] (Section 11.7.2). So $\mathcal{M}_1 = \mathbb{H}/\mathrm{PSL}(2,\mathbb{Z})$, one complex parameter, pictured as the fundamental domain (11.193) [$|\operatorname{Re}\tau| \le \frac{1}{2}$, $|\tau| \ge 1$, which holds one τ for each torus, up to edge identifications].
- $p \ge 2$: $\mathcal{M}_p$ has complex dimension $3p - 3$.

Where does $3p - 3$ come from? An infinitesimal change of complex structure is a **Beltrami differential** $\mu = \mu_{\bar z}{}^{z}\, \mathrm{d}\bar z \otimes \partial_z$: it deforms the holomorphic coordinate by $\mathrm{d}z \mapsto \mathrm{d}z + \mu\, \mathrm{d}\bar z$. Changes that come from an infinitesimal diffeomorphism $z \mapsto z + v(z,\bar z)$ have $\mu = \partial_{\bar z} v$, and they do not change the surface. So the tangent space to $\mathcal{M}_p$ is "Beltrami differentials modulo $\bar\partial$ of vector fields", which is the Dolbeault cohomology group $H^1(\Sigma, K^{-1})$ (K is the canonical line bundle, whose sections are 1-forms $f(z)\mathrm{d}z$; K^{-1} is the tangent bundle). Its dimension is computed by Riemann–Roch (Chapter 5): for a line bundle L of degree d on a genus-p surface, $\dim H^0(L) - \dim H^1(L) = d + 1 - p$. Serre duality says $H^1(L) \cong H^0(K \otimes L^{-1})^*$. Then

$$\dim_{\mathbb{C}} T_{[\Sigma]}\mathcal{M}_p \overset{(1)}{=} \dim H^1(\Sigma, K^{-1}) \overset{(2)}{=} \dim H^0(\Sigma, K^2)$$
$$\overset{(3)}{=} \deg(K^2) + 1 - p + \dim H^0(\Sigma, K^{-1}) \overset{(4)}{=} (4p - 4) + 1 - p + 0 = 3p - 3. \qquad (11.283)$$

(1) Tangent vectors to $\mathcal{M}_p$ are Beltrami differentials modulo $\bar\partial v$.
(2) Serre duality with $L = K^{-1}$: $K \otimes L^{-1} = K^2$. Elements of $H^0(K^2)$ are **holomorphic quadratic differentials** $\varphi(z)\,\mathrm{d}z^2$.
(3) Riemann–Roch for $L = K^2$, with $H^1(K^2) \cong H^0(K^{-1})^*$ by Serre duality again.
(4) $\deg K = 2p-2$ (a 1-form has $2p-2$ zeros), so $\deg K^2 = 4p-4$; K^{-1} has negative degree for $p \geq 2$, so it has no holomorphic sections: there are no holomorphic vector fields.

Two facts from this chain are used below. First, the cotangent space to $\mathcal{M}_p$ is the space of holomorphic quadratic differentials, $T^*_{[\Sigma]}\mathcal{M}_p \cong H^0(\Sigma, K^2)$. The stress tensor $T(z)\mathrm{d}z^2$ is a quadratic differential, so it is naturally a cotangent vector to moduli space. Second, for $p = 0, 1$ the last term is not zero: the sphere has three holomorphic vector fields (the Möbius generators L_{-1}, L_0, L_1) and the torus has one (translation), and the formula $\dim H^0(K^2) - \dim H^0(K^{-1}) = 3p-3$ gives $0-3=-3$ and $1-1=0$. The negative count is the number of conformal Killing vectors that must be fixed by fixing the positions of punctures, which is why a sphere needs three punctures before it has any moduli ($\dim \mathcal{M}_{0,n} = n-3$, (11.273)).

After gauge fixing, (11.282) becomes Nash's formula

$$Z = \sum_{p=0}^{\infty} \int_{\mathcal{M}_p} I_p, \tag{11.284}$$

[Nash p. 318, (11.76)], where I_p is a density on $\mathcal{M}_p$ (a top-degree form of real degree $2(3p-3)$), built from the partition function of the matter CFT on Σ, the Faddeev–Popov (ghost) determinant, and the power g_s^{2p-2}, which Nash absorbs into I_p. Each term is one *connected* closed surface. The job of a CFT, from this point of view, is to supply the integrand.

Worked example 11.109: The one-loop integrand of the bosonic string

At $p = 1$ everything is explicit. The integrand is, up to a τ-independent constant (see Polchinski, *String Theory*, §7.3),

$$I_1 = \frac{\mathrm{d}^2\tau}{\tau_2^2}\left(\tau_2^{-12}\,|\eta(\tau)|^{-48}\right), \qquad \tau = \tau_1 + i\tau_2, \quad \mathrm{d}^2\tau = \mathrm{d}\tau_1\,\mathrm{d}\tau_2. \tag{11.285}$$

The factor in brackets is the partition function of the 24 transverse bosons $X^2, \dots, X^{25}$; the ghosts cancel the oscillators of the other two, and the leftover powers of τ_2 combine into the measure $\mathrm{d}^2\tau/\tau_2^2$. We check the two ingredients.
One non-compact boson. Its states are a momentum $k \in \mathbb{R}$ times the oscillator Fock space, with $L_0 = \bar L_0 = k^2/4 + (\text{levels})$ (the normalisation of Section 11.8.5, in which $e^{ik\phi}$ has weight $k^2/4$). The trace (11.199), per unit length of the target line, is

$$Z_{\mathbb{R}}(\tau) \overset{(1)}{=} \int_{-\infty}^{\infty} \frac{\mathrm{d}k}{2\pi}\,(q\bar q)^{k^2/4}\,\frac{1}{|\eta(\tau)|^2} \overset{(2)}{=} \int_{-\infty}^{\infty} \frac{\mathrm{d}k}{2\pi}\,e^{-\pi\tau_2 k^2}\,\frac{1}{|\eta(\tau)|^2} \overset{(3)}{=} \frac{1}{2\pi\sqrt{\tau_2}}\,\frac{1}{|\eta(\tau)|^2}.$$

(1) A continuum of momentum states replaces the sum over (n, w) of the compact boson; the oscillators give $\left|q^{-1/24}\prod_n (1-q^n)^{-1}\right|^2 = |\eta|^{-2}$ as in (11.207).
(2) $q\bar q = \left|e^{2\pi i\tau}\right|^2 = e^{-4\pi\tau_2}$.
(3) Gaussian integral $\int \mathrm{d}k\, e^{-ak^2} = \sqrt{\pi/a}$ with $a = \pi\tau_2$.

Twenty-four copies give $\tau_2^{-12}\,|\eta|^{-48}$, up to constants.
Modular invariance. Under $\tau \mapsto \tau' = (a\tau+b)/(c\tau+d)$ with $ad-bc=1$:

$$\tau_2' \overset{(1)}{=} \mathrm{Im}\,\frac{(a\tau+b)(c\bar\tau+d)}{|c\tau+d|^2} \overset{(2)}{=} \frac{(ad-bc)\,\tau_2}{|c\tau+d|^2} = \frac{\tau_2}{|c\tau+d|^2},$$

$$\mathrm{d}^2\tau' \overset{(3)}{=} \left|\frac{\mathrm{d}\tau'}{\mathrm{d}\tau}\right|^2 \mathrm{d}^2\tau \overset{(4)}{=} \frac{\mathrm{d}^2\tau}{|c\tau+d|^4},$$
$$|\eta(\tau')|^{48} \overset{(5)}{=} |c\tau+d|^{24}\,|\eta(\tau)|^{48}.$$

(1) Multiply numerator and denominator by $c\bar\tau + d$.
(2) $\mathrm{Im}\big[(a\tau+b)(c\bar\tau+d)\big] = \mathrm{Im}\big[ac\,|\tau|^2 + ad\tau + bc\bar\tau + bd\big] = (ad-bc)\tau_2$.
(3) A holomorphic map $\tau \mapsto \tau'$ scales areas by $|\mathrm{d}\tau'/\mathrm{d}\tau|^2$ (its real Jacobian).
(4) $\mathrm{d}\tau'/\mathrm{d}\tau = \big(a(c\tau+d) - c(a\tau+b)\big)/(c\tau+d)^2 = 1/(c\tau+d)^2$.
(5) η^{24} is a modular form of weight 12, (11.213).

So $\mathrm{d}^2\tau/\tau_2^2$ is invariant (it is the hyperbolic area element of $\mathbb{H}$), and $\tau_2^{12}\,|\eta|^{48} \mapsto |c\tau+d|^{-24}\,\tau_2^{12}\,|c\tau+d|^{24}\,|\eta|^{48}$ is invariant too. Hence I_1 is a well-defined density on $\mathcal{M}_1$, and $\int_{\mathcal{M}_1} I_1$ may be computed over the fundamental domain. Modular invariance is not a luxury: without it the integral over $\mathcal{M}_1$ would not even be defined.

Reading the spectrum. Expand in q:

$$|\eta|^{-48} = (q\bar q)^{-1}\big(1 + 24q + 324q^2 + \dots\big)\big(1 + 24\bar q + 324\bar q^2 + \dots\big). \tag{11.286}$$

A term $q^{m-1}\bar q^{n-1}$ is a string state with left and right oscillator levels m, n. In the part of the fundamental domain with $\tau_2 > 1$ the τ_1 integral runs over a full period:

$$\int_{-1/2}^{1/2} \mathrm{d}\tau_1\; q^{m-1}\bar q^{n-1} \overset{(1)}{=} e^{-2\pi\tau_2(m+n-2)} \int_{-1/2}^{1/2} \mathrm{d}\tau_1\, e^{2\pi i\tau_1(m-n)} \overset{(2)}{=} e^{-4\pi\tau_2(m-1)}\,\delta_{mn}.$$

(1) $q^a\bar q^b = e^{2\pi i\tau_1(a-b)}e^{-2\pi\tau_2(a+b)}$.
(2) The integral of $e^{2\pi ik\tau_1}$ over one period is δ_{k0}.

Only states with equal left and right levels survive. This is **level matching**: $L_0 = \bar L_0$, the statement that a closed string has no preferred point. The surviving terms are the tachyon ($m = n = 0$, growing like $e^{4\pi\tau_2}$), then $24\times 24 = 576$ massless states ($m = n = 1$: the graviton, the antisymmetric tensor and the dilaton, in light-cone gauge), then massive levels. The tachyon makes the integral diverge at $\tau_2 \to \infty$. We will see below that $\tau_2 \to \infty$ is a *degenerate* torus, a point we must add to $\mathcal{M}_1$ to compactify it.

11.11.2 Disconnected surfaces and the universal moduli space

The sum (11.284) contains only connected surfaces. In quantum field theory the sum of *all* vacuum diagrams, connected or not, is the exponential of the sum of the connected ones. This is the **linked-cluster theorem**, and the $1/n!$ in the exponential series is the symmetry factor for permuting n identical connected pieces.

Worked example 11.110: Linked clusters in a zero-dimensional field theory

Take one real variable x with "action" $\frac12 x^2 - Jx$. The generating function is

$$\mathcal{Z}(J) \overset{(1)}{=} \frac{\int_{-\infty}^{\infty}\mathrm{d}x\, e^{-x^2/2+Jx}}{\int_{-\infty}^{\infty}\mathrm{d}x\, e^{-x^2/2}} \overset{(2)}{=} e^{J^2/2} \overset{(3)}{=} \sum_{n=0}^{\infty}\frac{1}{n!}\Big(\frac{J^2}{2}\Big)^n.$$

(1) Normalised Gaussian integral with a source J.
(2) Complete the square: $-\frac12 x^2 + Jx = -\frac12(x-J)^2 + \frac12 J^2$, and shift $x \mapsto x + J$.

(3) Exponential series.

The only connected diagram is one propagator joining two sources, with value $W = J^2/2$ (the $\frac{1}{2}$ is its symmetry factor: swapping its two ends). A diagram with n disjoint propagators is W^n, divided by $n!$ because the n identical pieces can be permuted. As a check, the coefficient of J^{2n} is $1/(2^n n!)$, and $\langle x^{2n}\rangle = (2n)!/(2^n n!) = (2n-1)!!$, which is the number of ways of pairing $2n$ points: Wick's theorem. So $\mathcal{Z} = e^W$: *all diagrams* = exp(connected diagrams), with $1/n!$ as the symmetry factor of n identical components.

The string version of this is Nash's

$$\exp[Z] \overset{(1)}{=} \exp\Big[\sum_{p=0}^{\infty}\int_{\mathcal{M}_p} I_p\Big] \overset{(2)}{=} \prod_{p=0}^{\infty}\exp\Big[\int_{\mathcal{M}_p} I_p\Big] \overset{(3)}{=} \prod_{p=0}^{\infty}\sum_{n=0}^{\infty}\frac{1}{n!}\Big\{\int_{\mathcal{M}_p} I_p\Big\}^n, \tag{11.287}$$

[Nash p. 318, (11.77)].

(1) Insert (11.284).
(2) $e^{a+b} = e^a e^b$, applied to every term (formally, for infinitely many terms).
(3) Exponential series for each factor.

The term $\frac{1}{n!}\{\int_{\mathcal{M}_p} I_p\}^n$ is the contribution of n disjoint surfaces, all of genus p. Choosing one term from each factor of the product gives a surface with n_0 spheres, n_1 tori, n_2 genus-two components, and so on. So $\exp Z$ is the sum over *all* closed surfaces, connected or not.

Now comes the geometric idea. Can we write each such term as an integral over one space, the space of all possibly disconnected surfaces? A set of n surfaces of genus p is an *unordered* list of n points of $\mathcal{M}_p$. The space of such lists is the **symmetric product**

$$\mathrm{Sym}^n(\mathcal{M}_p) = \underbrace{\mathcal{M}_p \times \cdots \times \mathcal{M}_p}_{n} \big/ S_n, \tag{11.288}$$

where the permutation group S_n permutes the factors. (By convention Sym^0 is one point: the empty surface.) The integrand on a disconnected surface is the product of the integrands of its components: amplitudes of independent pieces multiply. Then

$$\int_{\mathrm{Sym}^n(\mathcal{M}_p)} I_p \cdots I_p \overset{(1)}{=} \frac{1}{n!}\int_{\mathcal{M}_p\times\cdots\times\mathcal{M}_p} I_p(\Sigma_1)\cdots I_p(\Sigma_n) \overset{(2)}{=} \frac{1}{n!}\Big\{\int_{\mathcal{M}_p} I_p\Big\}^n. \tag{11.289}$$

(1) The map $\mathcal{M}_p^n \to \mathrm{Sym}^n \mathcal{M}_p$ is $n!$-to-one away from the diagonals (where two surfaces coincide), and the diagonals have measure zero. So the integral upstairs counts every point $n!$ times.
(2) Fubini: the integrand is a product of functions of separate variables.

So the $1/n!$ of the linked-cluster theorem is the $1/n!$ of the symmetric product. Friedan and Shenker collect everything into the **universal moduli space**

$$\mathcal{R} = \prod_{p=0}^{\infty}\Big\{\bigcup_{n=0}^{\infty}\mathrm{Sym}^n(\mathcal{M}_p)\Big\}, \tag{11.290}$$

[Nash p. 319, (11.78)]. A point of $\mathcal{R}$ is a choice, for each p, of a finite unordered set of genus-p surfaces (almost all of them empty): that is, one closed Riemann surface with any number of components. With I the product integrand, the full vacuum amplitude is one integral:

$$\int_{\mathcal{R}} I \overset{(1)}{=} \prod_{p=0}^{\infty}\sum_{n=0}^{\infty}\int_{\mathrm{Sym}^n(\mathcal{M}_p)} I_p\cdots I_p \overset{(2)}{=} \prod_{p=0}^{\infty}\sum_{n=0}^{\infty}\frac{1}{n!}\Big\{\int_{\mathcal{M}_p} I_p\Big\}^n \overset{(3)}{=} \exp[Z]. \tag{11.291}$$

(1) An integral over a product of spaces of a product integrand is the product of integrals; an integral over a disjoint union is the sum.
(2) (11.289).
(3) (11.287).

This is Nash's (11.79), $\exp[Z] = \int_{\mathcal{R}} I$. Its content is a change of viewpoint: the basic object is not the sequence of numbers $\int_{\mathcal{M}_p} I_p$ but a single integrand I on the single space $\mathcal{R}$, which is *multiplicative*: on a disconnected surface $\Sigma = \Sigma_1 \sqcup \Sigma_2$ it satisfies $I(\Sigma) = I(\Sigma_1)I(\Sigma_2)$.

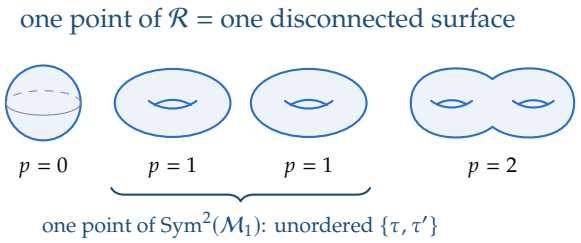

Figure 11.60: A point of the universal moduli space $\mathcal{R}$. What to see: it is a closed surface with several components, here one sphere, two tori and one genus-two surface. The two tori form an unordered pair, a point of $\mathrm{Sym}^2(\mathcal{M}_1)$; the $\frac{1}{2!}$ in $\exp Z$ is the statement that swapping them gives the same point. The integrand I is the product of the integrands of the components.

Watch out: Formal products

The product over p in (11.290) is infinite, and the series in p does not converge (see Section 11.11.6). Equations (11.287)–(11.291) are identities of formal power series in the coupling g_s, hidden inside I_p. They organise the perturbation series; they do not by themselves define a number.

11.11.3 Nodes, stable curves and the compactified moduli space

The moduli spaces $\mathcal{M}_p$ are not compact. The fundamental domain of $\mathcal{M}_1$ runs off to $\tau_2 \to \infty$, and we saw that the string integrand misbehaves exactly there. What does a surface look like near such an "end" of moduli space? The torus with $\tau = i\tau_2$ is a cylinder of circumference 1 and length τ_2 with its ends glued. As $\tau_2 \to \infty$ the cylinder becomes infinitely long and thin *relative to its length*; conformally, a long thin tube is the same as a short tube whose waist shrinks to a point. In the limit a circle on the surface has been pinched to a point. The result is a surface with a **node**.

Working definition 11.40 (Node; plumbing)

A **node** is a point near which the surface looks like two discs glued at their centres: locally $\{(x, y) \in \mathbb{C}^2 : xy = 0\}$, the union of the x-axis and the y-axis. Its smoothing is the **plumbing** $xy = t$ with a small complex number $t \neq 0$: remove the disc $|x| < |t|$ from one side and $|y| < |t|$ from the other, and identify the annuli $|t| < |x| < 1$ and $|t| < |y| < 1$ by $y = t/x$. The **plumbing parameter** t is a local complex coordinate on moduli space transverse to the degenerate surfaces [those with a node. For the torus $t = q = e^{2\pi i\tau}$, so $t \to 0$ is $\tau_2 \to \infty$], and $t = 0$ is the node.

The neck created by plumbing is the annulus $|t| < |x| < 1$. In the coordinate $w = \ln x = u + i\theta$ it is a cylinder of circumference 2π and length $\ell = \ln(1/|t|)$: small t means a long neck. A state propagating down the neck evolves by the cylinder Hamiltonian (11.196) with $L = 2\pi$, $H = L_0 + \bar{L}_0 - \frac{c}{12}$, and the phase of t twists one end relative to the other by the angle $\theta_0 = \arg t$,

which is the momentum operator $P = L_0 - \bar{L}_0$. So the plumbing operator is

$$\begin{aligned} e^{-\ell H}\, e^{i\theta_0 P} &\overset{(1)}{=} \exp\Big[\ln|t|\,\Big(L_0 + \bar{L}_0 - \frac{c}{12}\Big) + i\arg t\,\big(L_0 - \bar{L}_0\big)\Big] \\ &\overset{(2)}{=} \exp\Big[(\ln|t| + i\arg t)\Big(L_0 - \frac{c}{24}\Big) + (\ln|t| - i\arg t)\Big(\bar{L}_0 - \frac{c}{24}\Big)\Big] \\ &\overset{(3)}{=} t^{\,L_0 - c/24}\;\bar{t}^{\,\bar{L}_0 - c/24}. \end{aligned} \tag{11.292}$$

(1) $\ell = -\ln|t|$ and $\theta_0 = \arg t$; the operators commute, so the exponentials combine.
(2) Split $\frac{c}{12} = \frac{c}{24} + \frac{c}{24}$ and regroup the L_0 and $\bar{L}_0$ terms.
(3) $\ln|t| + i\arg t = \ln t$ and $\ln|t| - i\arg t = \ln\bar{t}$.

This is the same operator as $q^{L_0 - c/24}\bar{q}^{\bar{L}_0 - c/24}$ in the torus trace (11.199), and that is no accident.

Worked example 11.111: The torus is a plumbed sphere; q is the plumbing parameter

Take the Riemann sphere with the two points 0 and ∞, with local coordinates $x = z$ near 0 and $y = 1/z$ near ∞. Plumb them with parameter $t = q$: the relation $xy = q$ identifies z (near 0) with the point $1/y = z/q$ (near ∞). The result is the annulus $|q| < |z| < 1$ with its two boundary circles identified by $z \sim z/q$, i.e. the quotient $\mathbb{C}^\times/(z \sim qz)$. Writing $z = e^{2\pi i u}$,

$$\mathbb{C}^\times/(z \sim qz) \overset{(1)}{=} \mathbb{C}\Big/\Big(u \sim u + 1,\; u \sim u + \tfrac{\ln q}{2\pi i}\Big) \overset{(2)}{=} \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z}), \qquad q = e^{2\pi i\tau}.$$

(1) $z = e^{2\pi i u}$ maps $\mathbb{C}$ onto $\mathbb{C}^\times$ with $u \sim u + 1$; multiplying z by q shifts u by $\ln q/(2\pi i)$.
(2) Definition of τ by $q = e^{2\pi i\tau}$.

So the torus with modulus τ is the sphere with 0 and ∞ plumbed together with parameter $q = e^{2\pi i\tau}$. The end of $\mathcal{M}_1$, $\tau_2 \to \infty$, is $q \to 0$: the torus becomes a sphere with 0 and ∞ glued to each other, a *nodal* torus. Its partition function is dominated by the lowest state through the node. For the Ising model the characters of Section 11.7.5 give

$$\begin{aligned} (q\bar{q})^{1/48} Z_{\text{Ising}} &\overset{(1)}{=} \big|1 + q^2 + \ldots\big|^2 + \big|q^{1/2}(1 + q + \ldots)\big|^2 + \big|q^{1/16}(1 + q + \ldots)\big|^2 \\ &\overset{(2)}{=} 1 + (q\bar{q})^{1/16}\big(1 + q + \bar{q} + \ldots\big) + (q\bar{q})^{1/2}\big(1 + q + \bar{q} + \ldots\big) + q^2 + \bar{q}^2 + \ldots \end{aligned}$$

(1) $\chi_h = q^{h - 1/48}(1 + \ldots)$ with the expansions $q^{1/48}\chi_0 = 1 + q^2 + q^3 + 2q^4 + \ldots$, $q^{1/48}\chi_{1/2} = q^{1/2}(1 + q + q^2 + q^3 + 2q^4 + \ldots)$, $q^{1/48}\chi_{1/16} = q^{1/16}(1 + q + q^2 + 2q^3 + \ldots)$ (Section 11.7.5).
(2) Multiply out and order by powers of $|q|$.

As $q \to 0$: the prefactor $(q\bar{q})^{-c/24}$ is the Casimir energy of the long neck; the coefficient 1 of the leading term is the partition function of the nodal surface (a sphere, normalised to 1); and the corrections $q^h\bar{q}^{\bar{h}}$ list the states that flow through the node: σ at $|q|^{1/8}$, then its descendants, ε at $|q|$, the stress tensor $T = L_{-2}\mathbf{1}$ at q^2.

We can now say precisely what Nash means by the **factorisation condition**. Suppose the pinched circle separates Σ into two pieces Σ_1 (genus p_1) and Σ_2 (genus $p_2 = p - p_1$). Cut along the neck. Each piece, with a disc removed, defines a state in the Hilbert space of the circle: $|\Sigma_2\rangle$, and dually $\langle\Sigma_1|$ (this is Segal's point of view, Section 11.12; on the sphere it is the state–operator correspondence). Inserting a complete orthonormal set of $L_0, \bar{L}_0$ eigenstates $|k\rangle$ between them,

$$\begin{aligned} Z(\Sigma_t) &\overset{(1)}{=} \langle\Sigma_1|\, t^{L_0 - c/24}\,\bar{t}^{\bar{L}_0 - c/24}\,|\Sigma_2\rangle \overset{(2)}{=} |t|^{-c/12}\sum_k t^{h_k}\bar{t}^{\bar{h}_k}\,\langle\Sigma_1|k\rangle\langle k|\Sigma_2\rangle \\ &\overset{(3)}{=} |t|^{-c/12}\Big(Z(\Sigma_1)\,Z(\Sigma_2) + O\big(|t|^{2h_{\min}}\big)\Big). \end{aligned} \tag{11.293}$$

(1) The plumbed surface is Σ_1 and Σ_2 joined by the neck operator (11.292).
(2) Insert $\sum_k |k\rangle\langle k| = \mathbb{1}$; $L_0|k\rangle = h_k|k\rangle$.
(3) For a unitary theory all weights are ≥ 0 and only the vacuum has $h = \bar{h} = 0$, so it dominates as $t \to 0$. The vacuum is the state made by an empty disc, so $\langle \Sigma_1 | 0 \rangle$ is the partition function of Σ_1 with the hole filled in: the closed surface Σ_1. Here $h_{\min}$ is the smallest non-zero value of $(h + \bar{h})/2$.

In words: *the partition function of a surface with a node is the product of the partition functions of the surfaces obtained by pinching*, once the universal factor $|t|^{-c/12}$ (which depends only on c and on the choice of metric near the neck) is stripped off. If the pinched circle does not separate Σ, the same argument gives a trace instead of a matrix element, and the leading term is the partition function of the genus $p-1$ surface obtained by cutting and filling in the two holes; the torus example above is the case $p = 1$. Notice what the singular terms record: the powers t^{h_k} are the conformal weights. The singular behaviour at the node is the spectrum of the theory.

Worked example 11.112: The four-punctured sphere and its three boundary points

Fix four points on the sphere at Nash's positions $(\infty, 1, z, 0)$. The only modulus is the anharmonic ratio z, so $\mathcal{M}_{0,4} = \mathbb{CP}^1 \setminus \{0, 1, \infty\}$. The three missing points are where two punctures collide: $z \to 0$ (the fields at z and 0), $z \to 1$ (at z and 1), $z \to \infty$ (at z and ∞). Colliding punctures is not allowed on a smooth surface. The stable-curve picture replaces the collision by a new sphere that "bubbles off": the two colliding points sit on a small sphere attached by a node to the original one, which keeps the other two points. Each of the two spheres now carries three special points (two punctures and the node). The four-point function near $z = 0$ is, by the block expansion (11.257) with (11.258), for scalar fields,

$$\langle \phi_i(\infty)\phi_j(1)\phi_k(z,\bar{z})\phi_l(0)\rangle \overset{(1)}{=} \sum_m C_{kl}^m C_{ijm}\, \mathcal{F}_{kl}^{ij}(m,z)\, \bar{\mathcal{F}}_{kl}^{ij}(m,\bar{z})$$
$$\overset{(2)}{=} \sum_m C_{kl}^m C_{ijm}\; |z|^{2(h_m - h_k - h_l)} \big(1 + O(z,\bar{z})\big).$$

(1) The OPE of $\phi_k(z)\phi_l(0)$, summed over families m.
(2) Each block starts as $z^{h_m - h_k - h_l}$ times a power series in z.

Two features are Nash's two remarks about the compactification divisor. First, the blocks are singular there, with exponents fixed by the weights h_m of the intermediate families: the boundary is "a locus of singularities". Second, the coefficient of each singular term is the product $C_{kl}^m \cdot C_{ijm}$ of the two three-point functions of the two component spheres of the nodal curve: this is factorisation again. The plumbing parameter at $z = 0$ is z itself. Adding the three points gives the compact space $\overline{\mathcal{M}}_{0,4} = \mathbb{CP}^1$.

Working definition 11.41 (Stable curve; $\overline{\mathcal{M}}_p$)

A **stable curve** of genus p is a connected compact complex curve whose only singularities are nodes, such that every component [a piece left over when every node is pulled apart into two separate points] that is a sphere contains at least three *special points* (nodes or marked points), and every component that is a torus contains at least one. *Operational test:* for each component, remove its special points; the result must have negative Euler characteristic, $2 - 2g_i - n_i < 0$ [g_i is the genus of the component and n_i its number of special points]. Equivalently it has only finitely many automorphisms [holomorphic bijections

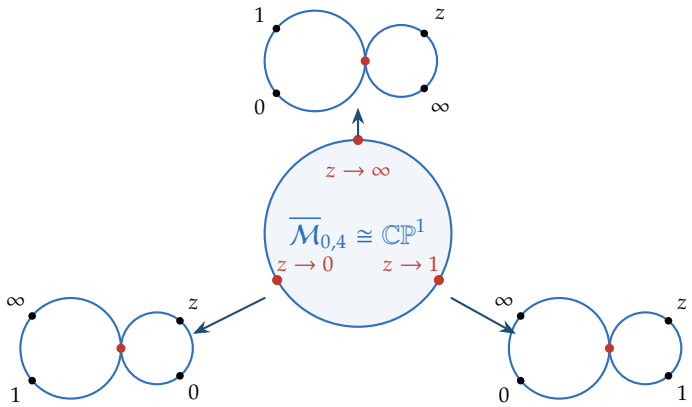

Figure 11.61: The compactified moduli space of four points on a sphere. What to see: the smooth surfaces fill $\mathbb{CP}^1$ minus three points (red). At each red point two punctures would collide; instead a small sphere bubbles off, carrying the two colliding punctures and attached at a node (red dot) to a sphere with the other two. Every component has three special points, so the nodal curves are *stable*. The three points are the three OPE channels (kl), (jk), (ik) of the four-point function, and crossing symmetry relates their expansions.

of the component onto itself that fix each special point], so no continuous symmetries (unfixed conformal Killing vectors) are left over. The **genus** is the genus of any smoothing [the surface obtained by replacing each node $xy = 0$ with a plumbing $xy = t$, $t \neq 0$]. Deligne and Mumford showed that stable curves of genus $p \geq 2$ form a compact space $\overline{\mathcal{M}}_p \supset \mathcal{M}_p$ of the same dimension $3p - 3$, the **moduli space of stable curves**.

The stability condition is exactly the one that makes the plumbing coordinates work: a sphere with fewer than three special points could be rescaled or rotated for free, and it would contribute a spurious continuous symmetry. The added set $\overline{\mathcal{M}}_p \setminus \mathcal{M}_p$ is where at least one plumbing parameter vanishes, one complex equation $t = 0$, so it has complex codimension one. A codimension-one subvariety is a **divisor**; this one is the **compactification divisor** D (often written $\partial\mathcal{M}_p$). It has components labelled by the topology of the pinched circle:

- Δ_0: a non-separating circle is pinched; the generic point is an irreducible curve with one node, whose normalisation has genus $p - 1$ with two points identified;
- Δ_i, $1 \leq i \leq \lfloor p/2 \rfloor$: a separating circle is pinched; the generic point is a genus-i and a genus-$(p - i)$ surface meeting at one node.

Conformal blocks and partition functions are generically singular along D, with singularities $t^{h_k - c/24}$ controlled by the spectrum, as in (11.293). So D is the locus of singularities of the theory, and the singularities are not a nuisance: they encode the spectrum, and their coefficients encode factorisation.

Worked example 11.113: Compactifying $\mathcal{M}_1$: the cusp and the discriminant

The modular function $j(\tau) = q^{-1} + 744 + 196884\,q + \ldots$ is invariant under $\mathrm{PSL}(2,\mathbb{Z})$ and takes every complex value exactly once on the fundamental domain, so $j : \mathcal{M}_1 \to \mathbb{C}$ is a bijection. The missing point $j = \infty$ is $q = 0$, the nodal torus of the plumbing example. So $\overline{\mathcal{M}}_1 = \mathcal{M}_1 \cup \{q = 0\} \cong \mathbb{CP}^1$: we add one point, the *cusp* $\tau = i\infty$ of the fundamental domain. In algebraic terms a torus is a cubic curve $y^2 = 4x^3 - g_2 x - g_3$; it is smooth exactly when

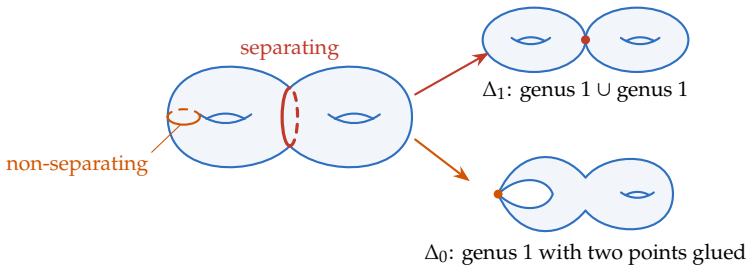

Figure 11.62: The two ways a genus-two surface can degenerate. What to see: pinching the separating circle (red) gives two tori meeting at a node, a point of the boundary component Δ_1; pinching a non-separating circle (orange) gives a torus with two of its points glued, a point of Δ_0. In each case one plumbing parameter t has gone to zero, so the boundary has complex codimension one in $\overline{\mathcal{M}}_2$.

the discriminant $g_2^3 - 27g_3^2$ is non-zero, and that discriminant is $(2\pi)^{12}\eta(\tau)^{24}$. Since

$$\eta(\tau)^{24} = q\prod_{n\geq 1}(1-q^n)^{24}$$

has a simple zero at $q = 0$ and no other zeros, the function η^{24} "detects" the compactification divisor. The string integrand (11.285) contains $|\eta|^{-48}$: it has a pole on the divisor, and (11.286) shows that the pole is the tachyon, the state of negative weight flowing through the node. In a unitary CFT all weights are non-negative, and the only singularity at the node is the universal factor $|q|^{-c/12}$.

When nodes are allowed everywhere, the universal moduli space is replaced by its **stable** version $\overline{\mathcal{R}}$, built from the $\overline{\mathcal{M}}_p$ exactly as in (11.290), and the vacuum amplitude becomes

$$\exp[Z] = \int_{\overline{\mathcal{R}}} I, \tag{11.294}$$

[Nash p. 319, (11.80)]. The gain is conceptual. A nodal surface is on the boundary between connected and disconnected surfaces: pinching a separating circle of a connected genus-p surface produces, after the node is resolved, a disconnected pair. So $\overline{\mathcal{R}}$ glues the pieces $\mathrm{Sym}^n\,\mathcal{M}_p$ of $\mathcal{R}$ together along their boundaries, and the factorisation condition (11.293) says that the integrand I is *continuous* across the gluing (after stripping the universal factor). Multiplicativity on disconnected surfaces and factorisation at nodes become one condition on one integrand on one space.

11.11.4 The stress tensor as a connection on moduli space

So far we have treated the partition function as a *function* on moduli space. For $c \neq 0$ it is not one. To define $Z(\Sigma)$ we must pick a metric in the conformal class of Σ, and the conformal anomaly (Chapter 10; chapter 9 for the string) says that a Weyl rescaling $g \mapsto e^{2\omega}g$ multiplies Z by $\exp\left(\frac{c}{24\pi}S_L[\omega, g]\right)$, where $S_L = \int \mathrm{d}^2x\sqrt{g}\,(g^{ab}\partial_a\omega\partial_b\omega + R\,\omega)$ is the Liouville action. There is no canonical metric on a general Riemann surface that varies holomorphically with moduli. So Z is defined only after a choice, and changing the choice multiplies it by a non-zero factor. An object "defined up to a non-zero factor that depends on local choices" is a *section of a line bundle*. To compare its values at nearby points of moduli space we need a *connection*. The stress tensor supplies it.

Step 1: T is the response to a change of moduli. By definition T_{ab} is the response of the theory to a change of metric. A change of complex structure by a Beltrami differential μ ($\mathrm{d}z \mapsto \mathrm{d}z + \mu\,\mathrm{d}\bar{z}$) is a change of the metric component $g_{z\bar{z}}$, and it couples to $T = T_{zz}$:

$$\delta_\mu \ln Z = \frac{1}{2\pi}\int_\Sigma \mathrm{d}^2 z\,\big(\mu\,\langle T(z)\rangle + \bar{\mu}\,\langle \bar{T}(\bar{z})\rangle\big), \qquad \mathrm{d}^2 z = 2\,\mathrm{d}x\,\mathrm{d}y, \tag{11.295}$$

with the normalisation in which $T(z)\phi(0) \sim h\phi(0)/z^2$.

Worked example 11.114: The torus: $\partial_\tau \ln Z$ is the zero mode of T

On the torus the trace formula (11.199) makes this a one-line computation, treating τ and $\bar{\tau}$ as independent:

$$\partial_\tau \ln Z \overset{(1)}{=} \frac{1}{Z}\,\mathrm{Tr}\Big[2\pi i\Big(L_0 - \frac{c}{24}\Big) q^{L_0 - c/24}\bar{q}^{\bar{L}_0 - c/24}\Big] \overset{(2)}{=} 2\pi i\,\Big\langle L_0 - \frac{c}{24}\Big\rangle_\tau \overset{(3)}{=} \frac{i}{2\pi}\int_0^1 \mathrm{d}x\,\langle T_{\mathrm{cyl}}\rangle_\tau .$$

(1) $\partial_\tau q^a = 2\pi i\, a\, q^a$ with $q = e^{2\pi i \tau}$.
(2) Thermal expectation value on the torus.
(3) (11.195) with $L = 1$: $\int_0^1 \mathrm{d}x\, T_{\mathrm{cyl}} = (2\pi)^2(L_0 - \frac{c}{24})$, all modes $n \neq 0$ integrating to zero.

The change $\tau \mapsto \tau + \delta\tau$ is produced by the constant Beltrami differential $\mu \propto \delta\tau/\tau_2$, and the right-hand side is the integral of $\langle T\rangle$ against it, as (11.295) says. For the Ising model at large τ_2, $\langle L_0 - \frac{c}{24}\rangle \to -\frac{1}{48}$: the Casimir energy.

Step 2: the pairing with Beltrami differentials. Tangent vectors to $\mathcal{M}_p$ are Beltrami differentials modulo $\bar{\partial} v$ (Section 11.11.1). If $\varphi = \varphi(z)\mathrm{d}z^2$ is a *holomorphic quadratic differential*, then $\int \mu\varphi$ depends only on the class of μ:

$$\int_\Sigma \mathrm{d}^2 z\,(\mu + \partial_{\bar{z}} v)\,\varphi \overset{(1)}{=} \int_\Sigma \mathrm{d}^2 z\,\mu\varphi - \int_\Sigma \mathrm{d}^2 z\, v\,\partial_{\bar{z}}\varphi \overset{(2)}{=} \int_\Sigma \mathrm{d}^2 z\,\mu\,\varphi. \tag{11.296}$$

(1) Integrate by parts. $v\varphi\,\mathrm{d}z$ is a globally defined 1-form ($v\partial_z$ is a vector field, $\varphi\,\mathrm{d}z^2$ a quadratic differential), so by Stokes the total derivative integrates to zero on the closed surface Σ.
(2) φ is holomorphic: $\partial_{\bar{z}}\varphi = 0$.

This is the Serre duality pairing between $H^1(\Sigma, K^{-1}) = T\mathcal{M}_p$ and $H^0(\Sigma, K^2) = T^*\mathcal{M}_p$. Each holomorphic quadratic differential is a cotangent vector, i.e. the value at $[\Sigma]$ of a $(1,0)$-form on $\mathcal{M}_p$. So if $\langle T(z)\rangle \mathrm{d}z^2$ were a holomorphic quadratic differential, (11.295) would say that $\partial \ln Z$ is a well-defined 1-form, and Z would be a function.

Step 3: it is not, because of the Schwarzian. Away from insertions $\langle T(z)\rangle$ is holomorphic, but by Nash's (11.81),

$$T'(z')(\mathrm{d}z')^2 = T(z)\,\mathrm{d}z^2 + \frac{c}{12}\{z, z'\}(\mathrm{d}z')^2, \tag{11.297}$$

(our (11.161) with the primes exchanged), it changes by an inhomogeneous term under a change of chart. Now look at the *difference* of two stress tensors T_1, T_2 obeying the same law (for instance $\langle T\rangle$ at two different points of moduli space, written in the same chart, or two different reference choices):

$$\begin{aligned}\big(T_1'(z') - T_2'(z')\big)(\mathrm{d}z')^2 &\overset{(1)}{=} \Big(T_1\mathrm{d}z^2 + \tfrac{c}{12}\{z,z'\}(\mathrm{d}z')^2\Big) - \Big(T_2\mathrm{d}z^2 + \tfrac{c}{12}\{z,z'\}(\mathrm{d}z')^2\Big)\\ &\overset{(2)}{=} \big(T_1(z) - T_2(z)\big)\mathrm{d}z^2.\end{aligned} \tag{11.298}$$

(1) (11.297) for each of T_1 and T_2.
(2) The Schwarzian terms are the same (they depend only on the change of chart and on c), so they cancel.

So the difference is a genuine quadratic differential, a tensor. This is word for word the situation of gauge potentials. With Nash's convention (Chapter T3) $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$, so for two connections

$$A_1' - A_2' \overset{(1)}{=} \left(g^{-1}A_1 g + g^{-1}\mathrm{d}g\right) - \left(g^{-1}A_2 g + g^{-1}\mathrm{d}g\right) \overset{(2)}{=} g^{-1}(A_1 - A_2)\, g,$$

(1) Gauge transformation of each potential.
(2) The inhomogeneous terms $g^{-1}\mathrm{d}g$ cancel.

and $A_1 - A_2$ is a tensor (a 1-form with values in the adjoint bundle), while each A_i on its own is only a connection. By Serre duality (11.296), a difference $T_1 - T_2$ is a 1-form on $\overline{\mathcal{M}}_p$; therefore $\langle T\rangle \mathrm{d}z^2$ itself is a *connection* 1-form on $\overline{\mathcal{M}}_p$, and Z is a section of the line bundle on which it acts. This is Nash's statement on p. 320.

Dictionary: Stress tensor ↔ gauge potential

gauge theory	CFT over moduli space
potential A	$\langle T(z)\rangle\, \mathrm{d}z^2$
gauge transformation g	change of holomorphic chart $z \mapsto z'$
inhomogeneous term $g^{-1}\mathrm{d}g$	$\frac{c}{12}\{z, z'\}(\mathrm{d}z')^2$
$A_1 - A_2$ is a tensor	$T_1 - T_2$ is a quadratic differential
tensor ↔ 1-form	Serre duality: $H^0(K^2) = T^*\mathcal{M}_p$
section of a bundle	partition function Z
curvature	a $(1,1)$-form on $\overline{\mathcal{M}}_p$ proportional to c

The object that transforms like $\frac{c}{12}\{z, z'\}$ has a name.

Working definition 11.42 (Projective connection)

A **projective connection** on a Riemann surface is a choice, in every holomorphic chart z_α, of a holomorphic function $S_\alpha(z_\alpha)$, such that on overlaps

$$S_\beta(z_\beta)\,(\mathrm{d}z_\beta)^2 = S_\alpha(z_\alpha)\,(\mathrm{d}z_\alpha)^2 + \{z_\alpha, z_\beta\}(\mathrm{d}z_\beta)^2.$$

Here $\{z_\alpha, z_\beta\}$ is the Schwarzian derivative [$\frac{z_\alpha'''}{z_\alpha'} - \frac{3}{2}\left(\frac{z_\alpha''}{z_\alpha'}\right)^2$, with primes meaning $\mathrm{d}/\mathrm{d}z_\beta$. It vanishes for Möbius changes of chart]. *Operationally:* it transforms like $\frac{12}{c}T$. The difference of two projective connections is a holomorphic quadratic differential [$q(z)\,\mathrm{d}z^2$ with q holomorphic, changing between charts with no extra term], so on a surface of genus $p \geq 2$ the projective connections form an affine space [fix one of them. Every other one is that one plus a quadratic differential] of complex dimension $\dim H^0(K^2) = 3p - 3$. By (11.297), $\frac{12}{c}\langle T\rangle$ is a projective connection.

For the definition to be consistent, the rule must compose correctly: going from chart z to z' and then to z'' must agree with going directly. The law (11.297) applied twice gives

$$T''(\mathrm{d}z'')^2 \overset{(1)}{=} T'(\mathrm{d}z')^2 + \tfrac{c}{12}\{z', z''\}(\mathrm{d}z'')^2 \overset{(2)}{=} T\mathrm{d}z^2 + \tfrac{c}{12}\Big[\{z, z'\}(\mathrm{d}z')^2 + \{z', z''\}(\mathrm{d}z'')^2\Big],$$

(1) (11.297) for the change $z' \to z''$.

(2) (11.297) for the change $z \to z'$.

while the direct change gives $T\mathrm{d}z^2 + \frac{c}{12}\{z,z''\}(\mathrm{d}z'')^2$. So consistency is the **cocycle identity** of the Schwarzian,

$$\{z,z''\} = \{z,z'\}\Big(\frac{\mathrm{d}z'}{\mathrm{d}z''}\Big)^2 + \{z',z''\}, \qquad \text{i.e.} \qquad \{f\circ g,x\} = \big(\{f,y\}\circ g\big)\,g'(x)^2 + \{g,x\}, \tag{11.299}$$

which is true: it follows from the chain rule by differentiating $f(g(x))$ three times (we checked it symbolically for several f, g). It is the analogue of $(gh)^{-1}\mathrm{d}(gh) = h^{-1}(g^{-1}\mathrm{d}g)h + h^{-1}\mathrm{d}h$, the identity that makes gauge transformations compose. A special case: if g is Möbius, $\{g,x\} = 0$, and the Schwarzian is invariant under Möbius changes of the inner variable.

Worked example 11.115: The same vacuum, two values of $\langle T\rangle$

In the plane the vacuum has $\langle T(z)\rangle = 0$ (rotation and scale invariance forbid anything else for a field of weight 2). Map to the cylinder of circumference L by $z = e^{2\pi w/L}$, as in (11.194). With $k = 2\pi/L$,

$$\langle T_{\mathrm{cyl}}(w)\rangle \overset{(1)}{=} \Big(\frac{\mathrm{d}z}{\mathrm{d}w}\Big)^2\langle T(z)\rangle + \frac{c}{12}\{z,w\} \overset{(2)}{=} 0 + \frac{c}{12}\Big(k^2 - \frac{3}{2}k^2\Big) = -\frac{c}{24}\Big(\frac{2\pi}{L}\Big)^2.$$

(1) (11.161) with the cylinder coordinate w as the new chart.
(2) $z' = kz$, $z'' = k^2 z$, $z''' = k^3 z$ (primes are $\mathrm{d}/\mathrm{d}w$), so $\{z,w\} = k^2 - \frac{3}{2}k^2$.

The state is the same; the number $\langle T\rangle$ is not. It depends on the chart, exactly as a gauge potential depends on the gauge. The physical content is in differences: the energy density $-\frac{\pi c}{6L^2}$ on the cylinder, i.e. the Casimir energy (11.197), is $\frac{1}{2\pi}$ times the constant $\langle T_{\mathrm{cyl}}\rangle + \langle \bar{T}_{\mathrm{cyl}}\rangle$ relative to the plane, and it is measurable.

Worked example 11.116: Canonical projective structures by uniformisation

Is there a natural reference projective connection? Choose charts in which all transition functions are Möbius maps. Then $S_\alpha = 0$ in every chart is consistent, because $\{z_\alpha, z_\beta\} = 0$ for Möbius transitions. Such charts exist on every surface:

- $p = 0$: the charts z and $w = 1/z$ of $\mathbb{CP}^1$; the transition $1/z$ is Möbius.
- $p = 1$: $\mathbb{C}/(\mathbb{Z}+\tau\mathbb{Z})$ with the flat coordinate z; transitions are translations $z \mapsto z+m+n\tau$.
- $p \geq 2$: the uniformisation theorem writes $\Sigma = \mathbb{H}/\Gamma$ with $\Gamma \subset \mathrm{PSL}(2,\mathbb{R})$; the coordinate of $\mathbb{H}$ is a chart with Möbius transitions.

In such a chart $\frac{12}{c}\langle T\rangle$ is a genuine holomorphic quadratic differential, i.e. a cotangent vector to $\mathcal{M}_p$, and (11.295) turns it into the 1-form $\partial \ln Z$ *in the trivialisation defined by the chart*. On the torus this is what we did in the previous example: $\partial_\tau \ln Z$ in the flat chart. Change the family of charts, and $\partial \ln Z$ shifts by a 1-form: a gauge transformation.

The connection is not flat. Its curvature is a $(1,1)$-form on $\overline{\mathcal{M}}_p$ proportional to c, so that Z can be made a *function* only when the relevant power of the line bundle is trivial. Nash phrases this by saying that T is a projective connection and gives rise to a **projective line bundle** E_c over $\mathcal{R}$: "projective" because its transition functions are fixed only up to the c-dependent anomaly factors. Since T is obtained by varying moduli, Z can be viewed as obtained by integrating this variation over $\overline{\mathcal{R}}$: $\ln Z$ is a "potential" whose derivative is the connection 1-form $\langle T\rangle$.

11.11.5 Which line bundle: E_c, holomorphic factorisation and $c = 26$

Friedan and Shenker identify the bundle and state the structure of Z:

Key idea: Friedan–Shenker

The anomaly line bundle is a power of a determinant line bundle, $E_c = (\det)^{c/2}$, and the partition function is the norm squared of a holomorphic section,

$$Z = h(\Psi, \Psi), \qquad \Psi \text{ a holomorphic section of } \mathcal{V} = E_c \otimes W,$$

where W is a vector bundle over $\overline{\mathcal{R}}$ with a projectively flat hermitian metric h. The fibre of W is the space of conformal blocks of the theory (Section 11.10.3), and its projectively flat connection is the one mentioned there.

Here is what the ingredients are, and how to see them in examples.

Determinant lines and modular forms. On a surface of genus p the holomorphic 1-forms form a p-dimensional space $H^0(\Sigma, K)$. Its top exterior power is a complex line, and as Σ varies these lines form the **Hodge line bundle** $\lambda = \det H^0(\Sigma, K)$ over $\mathcal{M}_p$; similarly $\lambda_n = \det H^0(\Sigma, K^n)$. (It is also the determinant line bundle of the $\bar\partial$ operator, the bundle of Chapter 4.) At genus one we can see sections of λ explicitly. The torus $\mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$ has the 1-form $\mathrm{d}z$. Under $\tau \mapsto \tau' = (a\tau + b)/(c\tau + d)$, the same torus is $\mathbb{C}/(\mathbb{Z} + \tau'\mathbb{Z})$ with coordinate $z' = z/(c\tau + d)$:

$$\mathbb{Z} + \tau'\mathbb{Z} \overset{(1)}{=} \frac{1}{c\tau + d}\big((c\tau + d)\mathbb{Z} + (a\tau + b)\mathbb{Z}\big) \overset{(2)}{=} \frac{1}{c\tau + d}\big(\mathbb{Z} + \tau\mathbb{Z}\big), \qquad \text{so} \qquad \mathrm{d}z' = \frac{\mathrm{d}z}{c\tau + d}.$$

(1) Put τ' over the common denominator.
(2) $(c\tau + d)m + (a\tau + b)n = (cm + an)\tau + (dm + bn)$, and $\left(\begin{smallmatrix} d & b \\ c & a \end{smallmatrix}\right)$ is invertible over $\mathbb{Z}$, so these run over all of $\mathbb{Z} + \tau\mathbb{Z}$.

So the generator $\mathrm{d}z$ of the fibre of λ rescales by $(c\tau + d)^{-1}$. A section $f(\tau)(\mathrm{d}z)^k$ of λ^k is well defined iff $f(\tau') = (c\tau + d)^k f(\tau)$: *sections of λ^k over $\mathcal{M}_1$ are modular forms of weight k* (modern convention). For example η^{24} is a section of λ^{12}. Since $\mathrm{d}\tau' = \mathrm{d}\tau/(c\tau + d)^2$, Nash's invariant $f(\tau)\mathrm{d}\tau^k$ of (11.54) needs f of modern weight $2k$: that is why η^{24} has "weight 6" in Nash's convention (the pitfall in Section 11.8.2). Nash's modular forms of weight k are sections of $K_{\mathcal{M}_1}^k$, the k-th power of the canonical bundle of $\mathcal{M}_1$.

Worked example 11.117: Holomorphic factorisation of the one-loop string

The integrand (11.285) is, up to a constant,

$$I_1 = \left|\frac{\mathrm{d}\tau}{\eta(\tau)^{24}}\right|^2 \tau_2^{-14}.$$

The first factor is $|F|^2$ with $F = \mathrm{d}\tau/\eta^{24}$ holomorphic (away from the cusp). The second is a positive "metric". Under a modular transformation

$$F(\tau') \overset{(1)}{=} \frac{(c\tau + d)^{-2}\mathrm{d}\tau}{(c\tau + d)^{12}\eta(\tau)^{24}} = (c\tau + d)^{-14}F(\tau),$$
$$\tau_2'^{-14} \overset{(2)}{=} |c\tau + d|^{28}\,\tau_2^{-14},$$

(1) $\mathrm{d}\tau' = (c\tau + d)^{-2}\mathrm{d}\tau$ and η^{24} has weight 12.
(2) $\tau_2' = \tau_2/|c\tau + d|^2$.

so the holomorphic section F and the hermitian metric τ_2^{-14} transform oppositely and $I_1 = h(F,F)$ is invariant. This is the simplest instance of "Z is the norm squared of a holomorphic section". At higher genus the same structure is the theorem of Belavin and Knizhnik: the bosonic string measure on $\mathcal{M}_p$ is $|F_p|^2 (\det \operatorname{Im}\Omega)^{-13}$, with Ω the period matrix and F_p a holomorphic, nowhere-vanishing section of $K_{\mathcal{M}_p} \otimes \lambda^{-13}$.

Why $c = 26$. Why should $K_{\mathcal{M}_p} \otimes \lambda^{-13}$ have a nowhere-vanishing holomorphic section? Two facts.

$$K_{\mathcal{M}_p} = \det T^*\mathcal{M}_p \overset{(1)}{=} \det H^0(\Sigma, K^2) = \lambda_2 \overset{(2)}{=} \lambda^{6\cdot 2^2 - 6\cdot 2 + 1} = \lambda^{13}. \tag{11.300}$$

(1) (11.283): the cotangent space is the space of quadratic differentials, so the top power of $T^*\mathcal{M}_p$ is λ_2.

(2) Mumford's isomorphism $\lambda_n \cong \lambda^{6n^2-6n+1}$ on $\mathcal{M}_p$, $p \geq 2$ (a consequence of Grothendieck–Riemann–Roch applied to the family of curves; Chapter 4 for the index-theoretic viewpoint).

So $K_{\mathcal{M}_p} \otimes \lambda^{-13}$ is trivial, and a trivial bundle has a nowhere-vanishing section. Now count powers. The integrand of a string theory must be a density on $\mathcal{M}_p$, i.e. a section of $K_{\mathcal{M}_p} \otimes \bar{K}_{\mathcal{M}_p}$: a $(3p-3, 3p-3)$-form, which is what one integrates over a complex $(3p-3)$-dimensional space. The ghosts supply the $K_{\mathcal{M}_p}$ (their zero modes are the quadratic differentials). The matter CFT of central charge c contributes a section of the anomaly bundle, a fixed power $\lambda^{-c/2}$. The two combine into something with no leftover anomaly exactly when $c/2 = 13$, i.e. $c = 26$. At $c = 26$, E_c is (up to duality) $\lambda^{13} \cong K_{\mathcal{M}_p}$, the determinant of the cotangent bundle: the partition function has become a density that can be integrated. This is the geometric meaning of the critical dimension.

Watch out: The exponent in $E_c = (\det T^*\mathcal{R})^{c/2}$

Nash writes $E_c = (\det T^*\mathcal{R})^{c/2}$. Read literally, with $\det T^*\mathcal{R}$ the canonical bundle K, this would give K^{13} at $c = 26$, which is not what the argument needs. The consistent reading is that "det" denotes the determinant (Hodge) line bundle λ of the $\bar\partial$ operator, so $E_c = \lambda^{c/2}$ (or its dual, depending on conventions). By Mumford's isomorphism (11.300) this is the same as $E_c = K^{c/26}$, and at $c = 26$ it is the canonical bundle $\det T^*\mathcal{R}$ itself. Keep the formula $E_c \cong \lambda^{c/2}$, and $E_{26} \cong \det T^*\mathcal{R}$.

Worked example 11.118: The Ising model: W, h, and why "projectively" flat

At genus one the blocks of the Ising model are the three characters, and the vector $\chi = (\chi_0, \chi_{1/2}, \chi_{1/16})$ is a holomorphic section of a rank-3 bundle over $\mathcal{M}_1$: modular transformations act on it by the constant matrices S and T of (11.227). With the hermitian metric $h_{ij} = \delta_{ij}$,

$$Z_{\text{Ising}} = h(\chi,\chi) = |\chi_0|^2 + |\chi_{1/2}|^2 + |\chi_{1/16}|^2,$$

Nash's (11.50). Constant transition matrices mean a flat connection, and S, T unitary means h is parallel. Where is the "projective"? The phases of T are $e^{2\pi i(h_i - c/24)}$: the part $e^{2\pi i h_i}$ belongs to the blocks, and the part $e^{-2\pi i c/24}$ belongs to the anomaly bundle E_c (it is the phase of η^{-c} under $\tau \mapsto \tau + 1$, by (11.209)). Strip off E_c by using $T_{\text{top}} = \operatorname{diag}(e^{2\pi i h_i}) = e^{2\pi i c/24}\, T$ instead. Then

$$(ST_{\text{top}})^3 \overset{(1)}{=} e^{2\pi i c/8}\, (ST)^3 \overset{(2)}{=} e^{2\pi i c/8}\, S^2 \overset{(3)}{=} e^{2\pi i/16}\, \mathbb{1}.$$

(1) $T_{\text{top}} = e^{2\pi i c/24} T$ and scalars commute; three factors give $e^{2\pi i c/8}$.

(2) The characters carry a genuine representation of $\mathrm{SL}(2,\mathbb{Z})$, so $(ST)^3 = S^2$ (checked numerically with (11.227)).
(3) For Ising $S^2 = \mathbb{1}$ (every field is self-conjugate) and $c = \frac{1}{2}$.

The relation $(ST)^3 = S^2$ of the modular group now holds only up to the phase $e^{2\pi i c/8}$: after removing E_c, the blocks W carry a *projective* representation, and the connection on W is only projectively flat. The obstruction is a function of c alone. This phase reappears as the framing anomaly of Chern–Simons theory in Chapter 12.

11.11.6 Infinite genus and non-perturbative effects

Nash closes the Friedan–Shenker discussion with a speculation: if $\overline{\mathcal{R}}$ is extended to a space $\overline{\mathcal{R}}_\infty$ that includes surfaces of infinite genus, then non-perturbative effects might be incorporated, by studying $p \to \infty$ and expanding in inverse powers of p. Why would one want this? Because the sum over genera is a power series in g_s^2, and it does not converge. For closed strings the genus-p term grows like $(2p)!$ (Gross and Periwal; Shenker). A series whose terms grow factorially is asymptotic, and its ambiguity is non-perturbative in the coupling.

Worked example 11.119: How small is the ambiguity of a factorially divergent series?

Take $a_n = n!\, g^n$ with $0 < g \ll 1$. The terms decrease while $a_{n+1}/a_n = (n+1)g < 1$, i.e. up to $n_* \approx 1/g$, and increase afterwards. The best one can do is to stop at the smallest term, and the error is of the size of that term:

$$a_{n_*} \overset{(1)}{=} n_*!\, g^{n_*} \overset{(2)}{=} \sqrt{2\pi n_*}\left(\frac{n_*}{e}\right)^{n_*} n_*^{-n_*} \overset{(3)}{=} \sqrt{\frac{2\pi}{g}}\, e^{-1/g}.$$

(1) Stop at $n_* = 1/g$.
(2) Stirling's formula $n! \approx \sqrt{2\pi n}\,(n/e)^n$, and $g = 1/n_*$.
(3) $(n_*/e)^{n_*} n_*^{-n_*} = e^{-n_*} = e^{-1/g}$.

The error $e^{-1/g}$ vanishes faster than any power of g: no finite order of perturbation theory can see it. For strings $a_p \sim (2p)!\, g_s^{2p}$ gives, by the same argument with $n = 2p$, an ambiguity of order e^{-C/g_s}. Such effects are the ones that a large-p analysis of $\overline{\mathcal{R}}_\infty$ was meant to capture; in modern string theory they are produced by D-branes. In the quantum-mechanical double well the analogous effects are the instantons of Chapter 8, with action $\propto 1/g$.

Reading Nash (pp. 318–320, (11.76)–(11.81))

Nash introduces the axiomatic approaches of Friedan–Shenker and Segal, and Friedan–Shenker's *gauge system*: a CFT as analytic geometry on the universal moduli space $\mathcal{R}$, with string theory as the case $c = 26$. (11.76) is our (11.284); (11.77) is (11.287), the exponential of connected diagrams; (11.78) and (11.79) are (11.290) and (11.291), with the $1/n!$ explained by (11.289). The nodes, the factorisation condition, the stable compactification $\overline{\mathcal{M}}_p$, the compactification divisor and (11.80) are in Section 11.11.3, where the plumbing formula (11.292) and the factorisation formula (11.293) are ours. (11.81) is (11.297); the tensor property of differences is (11.298), with the Serre-duality step spelled out in (11.296). The projective connection, E_c, Z as a norm squared of a section of $E_c \otimes W$, and the remark on $\overline{\mathcal{R}}_\infty$ are in Sections 11.11.5 and 11.11.6; see the pitfall there on the exponent of E_c. Nash's footnote 6 says the compactification is the natural one; it is the Deligne–Mumford

compactification by stable curves.

Recap

- The string vacuum amplitude is $Z = \sum_p \int_{\mathcal{M}_p} I_p$, with $\dim_{\mathbb{C}} \mathcal{M}_p = 3p - 3$ (Riemann–Roch for K^2). At genus one the integrand $\tau_2^{-14} \left| \mathrm{d}\tau / \eta^{24} \right|^2$ is modular invariant, and its q-expansion lists the string spectrum with level matching.
- All vacuum diagrams: $\exp Z = \int_{\mathcal{R}} I$ with $\mathcal{R} = \prod_p \bigcup_n \mathrm{Sym}^n \mathcal{M}_p$; the $1/n!$ of the exponential is the $1/n!$ of the symmetric product.
- Ends of moduli space are nodes, reached by plumbing $xy = t$. The neck propagates by $t^{L_0 - c/24} \bar{t}^{\bar{L}_0 - c/24}$; so partition functions factorise at nodes, and the singular exponents are the conformal weights. Stable curves compactify $\mathcal{M}_p$ to $\overline{\mathcal{M}}_p$; the boundary is a divisor, and $\exp Z = \int_{\overline{\mathcal{R}}} I$.
- $\langle T \rangle \mathrm{d}z^2$ transforms with a Schwarzian, so it is a projective connection and, via Serre duality, a connection 1-form on $\overline{\mathcal{M}}_p$; differences are tensors, as for gauge potentials.
- $Z = h(\Psi, \Psi)$ for a holomorphic section Ψ of $E_c \otimes W$; $E_c \cong \lambda^{c/2}$; with Mumford's $K_{\mathcal{M}_p} \cong \lambda^{13}$ the string integrand is a density exactly at $c = 26$. After removing E_c the blocks carry a projective representation, with phase $e^{2\pi i c/8}$.

11.12 Axiomatic approaches II: Segal's definition

Friedan and Shenker look at closed surfaces. But a physicist's first instinct about a quantum theory is Hamiltonian: there is a space of states on a slice of space, and time evolution is an operator. Segal's definition of a conformal field theory takes this instinct seriously for *every* Riemann surface, not only for the cylinder. The question this section answers is:

If a closed string can split and join, what is the "time-evolution operator" of an arbitrary worldsheet, and what rules must these operators obey?

The answer: a surface Σ whose boundary consists of q incoming and r outgoing circles defines an operator $U_\Sigma : H^{\otimes q} \to H^{\otimes r}$, and gluing surfaces along circles composes the operators. That is all. Everything we have met (the Hamiltonian, the vacuum, the OPE, the torus partition function, modular invariance, the conformal blocks) is a special case, and the rules of the game are those of a *functor* between two categories. We build up to this in steps, starting with ordinary quantum mechanics.

11.12.1 Warm-up: quantum mechanics as a rule for intervals

In Euclidean quantum mechanics, a time interval of length t is turned into the operator $U_t = e^{-tH}$ on the Hilbert space H. Three properties make this assignment work.

1. *Gluing is composition.* Putting an interval of length s after one of length t gives an interval of length $s + t$, and $U_s U_t = U_{s+t}$.
2. *Closing is a trace.* Gluing the two ends of an interval of length β gives a circle, and the circle is assigned the number $\mathrm{Tr}\, U_\beta = \mathrm{Tr}\, e^{-\beta H}$: the thermal partition function.

3. *Kernels are path integrals.* In the position basis U_t has a kernel $K_t(x_0, x_t) = \langle x_t | e^{-tH} | x_0 \rangle$, and Feynman's formula writes it as an integral over paths $x(s)$, $0 \le s \le t$, with fixed endpoints: $K_t(x_0, x_t) = \int_{[x_0, x_t]} e^{-S[x]} \mathcal{D}x$.

Worked example 11.120: Gluing two free-particle intervals

For a free particle ($m = \hbar = 1$, $H = -\frac{1}{2}\partial_x^2$) the Euclidean kernel is the heat kernel $K_t(x, y) = (2\pi t)^{-1/2} e^{-(x-y)^2/2t}$. Gluing means integrating over the position y at the junction:

$$\begin{aligned}\int_{-\infty}^{\infty} \mathrm{d}y\, K_s(x,y) K_t(y,z) &\overset{(1)}{=} \frac{1}{2\pi\sqrt{st}} \int \mathrm{d}y\, \exp\Big[-\frac{(x-y)^2}{2s} - \frac{(y-z)^2}{2t}\Big] \\ &\overset{(2)}{=} \frac{1}{2\pi\sqrt{st}}\, e^{-\frac{(x-z)^2}{2(s+t)}} \int \mathrm{d}y\, \exp\Big[-\frac{s+t}{2st}\big(y - y_*\big)^2\Big] \\ &\overset{(3)}{=} \frac{1}{2\pi\sqrt{st}}\, e^{-\frac{(x-z)^2}{2(s+t)}} \sqrt{\frac{2\pi st}{s+t}} = K_{s+t}(x,z).\end{aligned}$$

(1) Insert the kernels.
(2) Complete the square in y, with $y_* = (tx + sz)/(s+t)$; the y-independent remainder is $-(x-z)^2/2(s+t)$.
(3) Gaussian integral $\int \mathrm{d}y\, e^{-a(y-y_*)^2} = \sqrt{\pi/a}$ with $a = (s+t)/2st$.

The composition law $U_s U_t = U_{s+t}$ holds kernel by kernel: gluing intervals is integrating over the field at the junction.

Worked example 11.121: Closing the interval: the oscillator on a circle

For the harmonic oscillator $H = \frac{1}{2}(p^2 + x^2)$ the kernel is Mehler's

$$K_t(x,y) = \frac{1}{\sqrt{2\pi \sinh t}} \exp\Big[-\frac{(x^2+y^2)\cosh t - 2xy}{2\sinh t}\Big].$$

Gluing the ends means setting $y = x$ and integrating:

$$\begin{aligned}\operatorname{Tr} e^{-tH} &\overset{(1)}{=} \int \mathrm{d}x\, K_t(x,x) \overset{(2)}{=} \frac{1}{\sqrt{2\pi\sinh t}} \int \mathrm{d}x\, \exp\Big[-x^2\,\frac{\cosh t - 1}{\sinh t}\Big] \\ &\overset{(3)}{=} \frac{1}{\sqrt{2\pi\sinh t}} \sqrt{\frac{\pi \sinh t}{\cosh t - 1}} \overset{(4)}{=} \frac{1}{2\sinh(t/2)}.\end{aligned} \tag{11.301}$$

(1) The trace of an operator with kernel K is $\int K(x,x)\,\mathrm{d}x$.
(2) At $y = x$ the exponent is $-(2x^2\cosh t - 2x^2)/(2\sinh t)$.
(3) Gaussian integral with $a = (\cosh t - 1)/\sinh t$.
(4) $\cosh t - 1 = 2\sinh^2(t/2)$.

Compare the sum over the spectrum $E_n = n + \frac{1}{2}$: $\sum_n e^{-t(n+1/2)} = e^{-t/2}/(1 - e^{-t}) = 1/(2\sinh(t/2))$. The same number, computed once as a path integral on a circle and once as a trace over states. We will use (11.301) mode by mode for the free boson below.

11.12.2 Surfaces with boundary and their operators

A closed string at an instant is a circle. So in string theory the analogue of an endpoint of an interval is a boundary circle, and the analogue of an interval is a Riemann surface Σ with

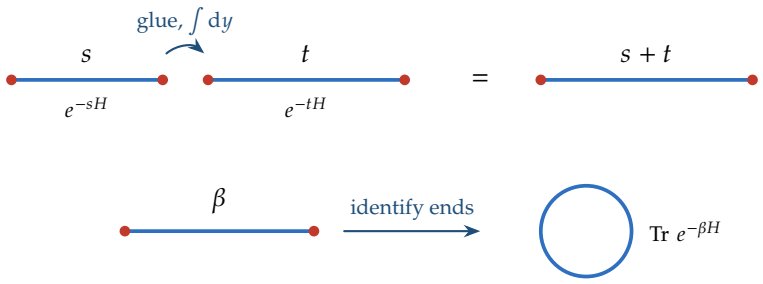

Figure 11.63: Quantum mechanics as a rule for intervals. What to see: an interval of length t is assigned the operator e^{-tH}; gluing endpoints (integrating over the position at the junction) composes operators; gluing the two ends of one interval into a circle takes the trace. Segal's axioms are the same three rules with intervals replaced by Riemann surfaces and endpoints replaced by boundary circles.

boundary $\partial\Sigma = S^1 \sqcup \cdots \sqcup S^1$, n circles in all. Each boundary circle comes with a *parametrisation*, an identification with the standard circle $\{|z| = 1\}$ (this is what lets us glue two circles in a definite way), and with a label: *incoming* or *outgoing*, fixed by whether the orientation induced from Σ agrees or disagrees with the standard one.

Physical picture: Punctures versus boundary circles

Nash remarks that a surface with n boundary circles is, up to homotopy, a surface with n punctures. Topologically: Σ minus an open disc deformation-retracts onto Σ minus a point, since the punctured disc $\{0 < |z| \le 1\}$ retracts onto its boundary circle, so the two have the same topology. Physically: a puncture at which a local operator ϕ sits, together with a local coordinate z vanishing there, is the same thing as a boundary circle $\{|z| = 1\}$ carrying the state $|\phi\rangle = \phi(0)|0\rangle$. This is the state–operator correspondence of radial quantisation (Nash §3, earlier in this chapter). A local coordinate at a puncture is exactly the data needed to parametrise the small circle around it.

From the string point of view q of the circles are strings coming in and $r = n - q$ are strings going out, and the history in between should be described by an operator

$$U_{\Sigma,\partial\Sigma} : \underbrace{H \otimes \cdots \otimes H}_{q \text{ factors}} \longrightarrow \underbrace{H \otimes \cdots \otimes H}_{r \text{ factors}}, \tag{11.302}$$

[Nash p. 320, (11.82)]. Here H is the Hilbert space of one closed string (the space of states of the CFT on one circle). For a CFT the operator depends only on the conformal structure of Σ and on the boundary parametrisations, not on a metric; but because of the anomaly, only up to a scalar factor, as we will see in Section 11.12.5.

11.12.3 The Hilbert space of a string, and the kernel of U

What is H, concretely? Nash follows the path-integral picture. Take the simplest surface with boundary, $\Sigma_{p,2}$: genus p with two boundary circles, one incoming and one outgoing. A moment in the history of the string is a loop, so the configuration space is a space of loops, and a history is a path of loops,

$$\alpha : [0, t] \longrightarrow L\Sigma_{p,2} = \mathrm{Map}(S^1, \Sigma_{p,2}), \tag{11.303}$$

with $\alpha(0) = \alpha_0$ and $\alpha(t) = \alpha_t$ the two boundary circles and t the duration of the evolution, [Nash p. 320, (11.83)]. The quantum states are wave functions on the configuration space,

$$H = L^2(L\Sigma_{p,2}), \tag{11.304}$$

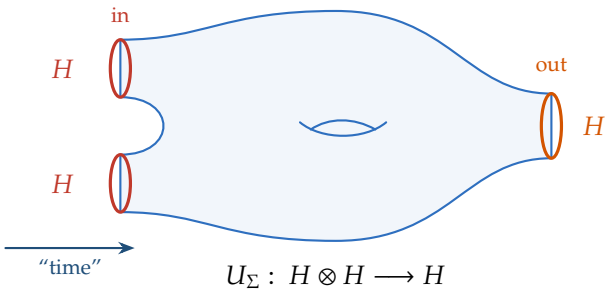

Figure 11.64: A Segal morphism. What to see: a genus-one surface with two incoming boundary circles (red) and one outgoing circle (orange). Two closed strings come in, join, and one leaves, with a loop (the handle) in between. The CFT assigns to it a linear map $H \otimes H \to H$. With no handle this surface is the "pair of pants", and its map is the operator product expansion.

(11.84). If S is a conformally invariant action (for example the string action), the propagation kernel from the loop α_0 to the loop α_t is the path integral over all histories with those ends,

$$K(\alpha_0, \alpha_t) = \int_{[\alpha_0, \alpha_t]} e^{-S(\alpha)}\, \mathcal{D}\alpha, \tag{11.305}$$

(11.85), and the operator acts on wave functions by

$$\big(U_{\Sigma_{p,2}}\psi\big)(\alpha_t) = \int K(\alpha_0, \alpha_t)\, \psi(\alpha_0)\, \mathcal{D}\alpha_0, \tag{11.306}$$

(11.86). These are the formulas of the quantum-mechanics warm-up, with a point x replaced by a loop α: (11.305) is Feynman's kernel and (11.306) is "multiply by the kernel and integrate".

Watch out: What the loops are, and what L^2 means

Two cautions. (i) In a sigma model with target X (spacetime, for the string) the field on a circle is a loop *in* X, $x : S^1 \to X$, and the wave functions live on the loop space LX; the surface $\Sigma_{p,2}$ is what the moving loop sweeps out. Nash's $L\Sigma_{p,2}$ should be read in this spirit: an element records how a circle sits in the history. For a general CFT there is no target at all, and "the field configuration on a circle" is replaced by an abstract state. (ii) There is no Lebesgue measure on an infinite-dimensional loop space, so neither L^2 nor $\mathcal{D}\alpha$ is literally defined. Segal's axioms are designed to avoid both: they postulate the space H and the operators U_Σ directly, and (11.304)–(11.306) become a heuristic for constructing examples. For free fields the heuristic can be made exact, because every integral is Gaussian, as the next example shows.

Worked example 11.122: The disc amplitude is the vacuum wave functional

Take a free boson ϕ with action $S = \frac{1}{2}\int \mathrm{d}^2x\, |\nabla\phi|^2$, and let the unit disc D have its boundary circle outgoing. Expand the boundary value in Fourier modes,

$$\phi(\sigma) = \frac{1}{\sqrt{2\pi}} \sum_{n\in\mathbb{Z}} \phi_n\, e^{in\sigma}, \qquad \phi_{-n} = \overline{\phi_n}.$$

The disc defines a state: a wave functional of the boundary loop, $\Psi_D[\phi] = \int_{\phi|_{\partial D}=\phi} e^{-S}$. The integral is Gaussian, so up to a constant it is $e^{-S_{\mathrm{cl}}}$, where S_{cl} is the action of the classical solution with the given boundary value. That solution is harmonic, $\phi_{\mathrm{cl}} = \frac{1}{\sqrt{2\pi}} \sum_n \phi_n r^{|n|} e^{in\sigma}$,

so

$$S_{\mathrm{cl}} \overset{(1)}{=} \frac{1}{2}\int_D \big(\nabla\cdot(\phi_{\mathrm{cl}}\nabla\phi_{\mathrm{cl}}) - \phi_{\mathrm{cl}}\nabla^2\phi_{\mathrm{cl}}\big) \overset{(2)}{=} \frac{1}{2}\oint_{\partial D}\phi_{\mathrm{cl}}\,\partial_r\phi_{\mathrm{cl}}\,\mathrm{d}\sigma$$
$$\overset{(3)}{=} \frac{1}{2}\int_0^{2\pi}\mathrm{d}\sigma\,\frac{1}{2\pi}\sum_{m,n}\phi_m\phi_n\,|n|\;e^{i(m+n)\sigma} \overset{(4)}{=} \frac{1}{2}\sum_{n\in\mathbb{Z}}|n|\,\big|\phi_n\big|^2. \tag{11.307}$$

(1) $\big|\nabla\phi\big|^2 = \nabla\cdot(\phi\nabla\phi) - \phi\nabla^2\phi$.
(2) Stokes (the divergence theorem) on the disc, and $\nabla^2\phi_{\mathrm{cl}} = 0$; the outward normal is ∂_r.
(3) At $r = 1$, $\partial_r r^{|n|} = |n|$.
(4) $\int_0^{2\pi} e^{i(m+n)\sigma}\mathrm{d}\sigma = 2\pi\delta_{m,-n}$ and $\phi_{-n} = \overline{\phi_n}$.

So $\Psi_D[\phi] \propto \exp\big(-\sum_{n\geq 1} n\,\big|\phi_n\big|^2\big)$. Compare the Hamiltonian on the circle: $H = \frac{1}{2}\int_0^{2\pi}\mathrm{d}\sigma\,\big(\Pi^2 + (\partial_\sigma\phi)^2\big) = \frac{1}{2}\sum_n\big(|\Pi_n|^2 + n^2\,\big|\phi_n\big|^2\big)$. Each mode $n \neq 0$ is a harmonic oscillator of frequency $|n|$, whose ground state is $\exp(-\frac{1}{2}\,|n|\,\big|\phi_n\big|^2)$ per real degree of freedom; the pair $\pm n$ gives $\exp(-n\,\big|\phi_n\big|^2)$. This is Ψ_D. *The disc is the vacuum*: an empty disc creates $|0\rangle$, the state–operator correspondence for the identity operator. The ground energy is the sum of zero-point energies,

$$E_0 = \sum_{n\neq 0}\frac{|n|}{2} = \sum_{n\geq 1} n \;\to\; \zeta(-1) = -\frac{1}{12} = -\frac{c}{12}, \qquad c = 1,$$

with the zeta-function value $\zeta(-1) = -\frac{1}{12}$ (the regularisation that respects the conformal symmetry). This is the Casimir energy (11.197) for $L = 2\pi$.

11.12.4 Gluing the ends: the trace condition and modular invariance

Join the two boundary circles of $\Sigma_{p,2}$ to each other. The result is a closed surface $\tilde{\Sigma}_{p,2}$ of genus $p+1$. Exactly as closing an interval gave a trace, Segal requires

$$\mathrm{tr}\big(U_{\Sigma_{p,2}}\big) = U_{\tilde{\Sigma}_{p,2}}, \tag{11.308}$$

[Nash p. 321, (11.87)], where the operator of a closed surface is a map $\mathbb{C}\to\mathbb{C}$, i.e. a number: its partition function. For this to make sense $U_{\Sigma_{p,2}}$ must be trace class, which it is whenever the surface has non-zero area (the factor q^{L_0} below damps high-energy states).

The case $p = 0$ is the one we know. $\Sigma_{0,2}$ is a cylinder, or conformally an annulus $A_q = \{|q| \leq |z| \leq 1\}$, with $|z| = 1$ incoming and $|z| = |q|$ outgoing, the outgoing circle parametrised by $\sigma \mapsto q e^{i\sigma}$. Evolution from the outer to the inner circle is the plumbing operator (11.292):

$$U_{A_q} = q^{\,L_0 - c/24}\,\bar{q}^{\,\bar{L}_0 - c/24}. \tag{11.309}$$

Gluing the two circles of A_q (with the rotation by $\arg q$ built into the parametrisation) gives the torus with modulus τ, $q = e^{2\pi i\tau}$, exactly as in the plumbing example of Section 11.11.3. So (11.308) is

$$Z(\tau) = \mathrm{tr}\;U_{A_q} = \mathrm{Tr}\;q^{L_0 - c/24}\bar{q}^{\bar{L}_0 - c/24},$$

the trace formula (11.199). The trace condition *is* the statement "periodic Euclidean time gives a trace".

Worked example 11.123: The free-boson annulus, mode by mode

For the free boson and $\tau = i\tau_2$ (so $q = e^{-t}$ with $t = 2\pi\tau_2$ the length of a cylinder of circumference 2π), the annulus operator is e^{-tH}, and H is a sum of independent oscillators of frequency n, two for each $n \geq 1$ (the modes $\pm n$), plus the zero mode. The trace factorises into Mehler traces (11.301):

$$\mathrm{Tr}_{\mathrm{osc}}\, e^{-tH} \overset{(1)}{=} \prod_{n\geq 1}\Big(\frac{1}{2\sinh(nt/2)}\Big)^2 \overset{(2)}{=} \prod_{n\geq 1}\frac{e^{-nt}}{(1-e^{-nt})^2} \overset{(3)}{=} e^{-t\sum_{n\geq 1} n}\prod_{n\geq 1}\frac{1}{(1-q^n)^2}$$
$$\overset{(4)}{=} q^{-1/12}\prod_{n\geq 1}\frac{1}{(1-q^n)^2} \overset{(5)}{=} \frac{1}{|\eta(i\tau_2)|^2}.$$

(1) Independent modes: the trace of a tensor product is the product of traces; each oscillator of frequency n evolves for time t, i.e. (11.301) with $t \to nt$.
(2) $2\sinh(x/2) = e^{x/2}(1-e^{-x})$, squared.
(3) Collect the prefactors; $e^{-nt} = q^n$.
(4) $\sum_{n\geq 1} n = \zeta(-1) = -\frac{1}{12}$, so $e^{t/12} = q^{-1/12}$.
(5) For real q, $|\eta|^2 = \eta^2 = q^{1/12}\prod(1-q^n)^2$.

The zero mode adds the factor $(2\pi\sqrt{\tau_2})^{-1}$ of the example in Section 11.11.1. So Segal's trace condition, evaluated by gluing Mehler kernels, reproduces the partition function of the free boson.

Modular invariance now comes out as a *consistency condition*. The axioms say that $U_{\tilde{\Sigma}}$ depends only on the closed surface, not on how it was cut open. A torus can be cut along either of its two cycles. Cutting along the a-cycle gives the annulus A_q, $q = e^{2\pi i\tau}$; cutting along the b-cycle gives an annulus $A_{\tilde{q}}$ with $\tilde{q} = e^{-2\pi i/\tau}$, because the roles of space and time are exchanged and the modulus becomes $-1/\tau$. The two traces must agree:

$$\mathrm{Tr}\; q^{L_0 - c/24}\bar{q}^{\bar{L}_0 - c/24} = \mathrm{Tr}\; \tilde{q}^{\,L_0 - c/24}\bar{\tilde{q}}^{\,\bar{L}_0 - c/24}, \qquad \text{i.e.} \qquad Z(\tau) = Z(-1/\tau). \tag{11.310}$$

Similarly, cutting along the a-cycle but choosing a different parametrisation (a Dehn twist) replaces τ by $\tau + 1$. So Segal's axioms imply Nash's (11.51). The same mechanism at higher genus is the requirement that $U_{\tilde{\Sigma}}$ be invariant under the mapping class group, the large diffeomorphisms of $\tilde{\Sigma}$.

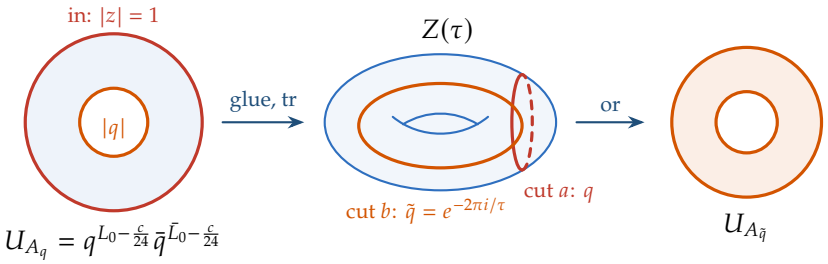

Figure 11.65: Why Segal's axioms imply modular invariance. What to see: the torus (middle) can be cut open along the a-cycle (red), giving the annulus A_q (left), or along the b-cycle (orange), giving the annulus $A_{\tilde{q}}$ with $\tilde{q} = e^{-2\pi i/\tau}$ (right). The trace condition applied to the two annuli must give the same number, since it is the same torus: that is $Z(\tau) = Z(-1/\tau)$.

11.12.5 Sewing surfaces and the multiplier λ

The trace condition glues two circles of *one* surface. The other basic operation glues two *different* surfaces. If $\Sigma_{p,2}$ and $\Sigma'_{p,2}$ each have one incoming and one outgoing circle, sew the outgoing circle of Σ' to the incoming circle of Σ (using the parametrisations to match points). The result is a surface $\Sigma_{p,2} \cup \Sigma'_{p,2}$ with again two boundary circles, and Segal requires

$$U_{\Sigma_{p,2}} \circ U_{\Sigma'_{p,2}} = \lambda\, U_{\Sigma_{p,2} \cup \Sigma'_{p,2}}, \tag{11.311}$$

[Nash p. 321, (11.88)], with λ a non-zero scalar. Why not simply $\lambda = 1$? In quantum mechanics $U_s U_t = U_{s+t}$ exactly. Here the answer is the central charge.

Worked example 11.124: Round annuli compose exactly

The round annuli form a semigroup: sewing $A_{q'}$ (outer circle $|z| = 1$, inner $|z| = |q'|$) to A_q by rescaling the second one by q' gives the annulus $\{|qq'| \le |z| \le 1\} = A_{qq'}$. And

$$U_{A_q}\, U_{A_{q'}} \overset{(1)}{=} q^{L_0 - c/24} \bar{q}^{\bar{L}_0 - c/24}\, q'^{L_0 - c/24} \bar{q}'^{\bar{L}_0 - c/24} \overset{(2)}{=} (qq')^{L_0 - c/24} (\overline{qq'})^{\bar{L}_0 - c/24} = U_{A_{qq'}}.$$

(1) (11.309) for each annulus.
(2) L_0 and $\bar{L}_0$ commute with each other and with themselves, so the powers add.

Here $\lambda = 1$, because the normalisation $-c/24$ was chosen consistently (it is the Casimir energy of the flat cylinder metric, which is additive in the length).

For general surfaces there is no such preferred normalisation. Deform the boundary parametrisations of an annulus by diffeomorphisms of the circle. The "annuli with arbitrary boundary parametrisation" form a semigroup $\mathcal{A}$ which contains, as its boundary, the group $\mathrm{Diff}(S^1)$ (the infinitely thin annuli), and $\mathcal{A}$ is a kind of complexification of $\mathrm{Diff}(S^1)$. Segal's axioms give a map $A \mapsto U_A$, and (11.311) says it is a representation up to scalars: $U_A U_{A'} = \lambda(A, A') U_{AA'}$. Infinitesimally, $\mathrm{Diff}(S^1)$ is generated by the vector fields $\ell_n = -z^{n+1}\partial_z$ (Section 11.5.1), represented by the L_n, and the projective factor becomes the central term of the Virasoro algebra (11.174). Can a clever choice of phases remove it? Try shifting L_0 by a constant a, which is all the freedom one has (the central term only appears in $[L_m, L_{-m}]$):

$$[L_m, L_{-m}] \overset{(1)}{=} 2mL_0 + \frac{c}{12}(m^3 - m) \overset{(2)}{=} 2m\,(L_0 + a) + \Big(\frac{c}{12}(m^3 - m) - 2ma\Big). \tag{11.312}$$

(1) The Virasoro algebra (11.174) with $n = -m$.
(2) Add and subtract $2ma$.

In terms of $L'_0 = L_0 + a$ the central term is $\frac{c}{12}m^3 - (\frac{c}{12} + 2a)m$. The part linear in m can be removed by $a = -c/24$ (and this is exactly the shift to $L_0 - c/24$ that appears on the cylinder). The cubic part $\frac{c}{12}m^3$ cannot be removed by any choice. So for $c \neq 0$ the representation of $\mathrm{Diff}(S^1)$, and hence of the annulus semigroup, is genuinely projective, and $\lambda \neq 1$ in general. For $m = 0, \pm 1$ the central term $m^3 - m$ vanishes: the Möbius subgroup is represented honestly, as we knew.

Key idea: The multiplier is the anomaly

The scalar λ in (11.311) is the finite, global form of the central charge. In Segal's precise formulation each surface carries a complex line Det_Σ (built from determinant lines, raised to a power fixed by c), sewing multiplies these lines, and U_Σ is an element of $\mathrm{Hom}(H^{\otimes q}, H^{\otimes r}) \otimes \mathrm{Det}_\Sigma$. Choosing a trivialisation of each line produces the numbers λ. As Σ varies over moduli space the lines Det_Σ form a line bundle: the anomaly bundle E_c of Friedan and Shenker (Section 11.11.5). The two axiom systems meet here.

11.12.6 The category of circles and surfaces

All the rules so far are instances of one structure. Segal organises them as follows [Nash p. 321].

Working definition 11.43 (The Segal category C)

- *Objects:* finite disjoint unions of parametrised circles [each circle comes with a chosen identification with the standard circle $|z| = 1$], $S^1 \sqcup \cdots \sqcup S^1$, including the empty union $\varnothing$.
- *Morphisms* from X to Y: Riemann surfaces Σ whose boundary is X (incoming) together with Y (outgoing), with the parametrisations, up to biholomorphisms that respect them [invertible holomorphic maps between surfaces that match the boundary parametrisations point by point].
- *Composition:* if $\Sigma' : X \to Y$ and $\Sigma : Y \to Z$, then $\Sigma \circ \Sigma' : X \to Z$ is the surface obtained by sewing Σ to Σ' along their common boundary Y [each outgoing circle of Σ' is glued to the matching incoming circle of Σ, point by point through the parametrisations].
- *Disjoint union* $\sqcup$ of objects and of morphisms makes C a *monoidal* category [circles and surfaces can be placed side by side, and adding $\varnothing$ changes nothing], with unit $\varnothing$.

A **conformal field theory** in Segal's sense is then a (projective, monoidal) **functor** U from C to a category $\mathcal{H}$ of topological vector spaces:

- to k circles it assigns $U(S^1 \sqcup \cdots \sqcup S^1) = H^{\otimes k}$, and to $\varnothing$ the ground field $\mathbb{C}$;
- to a morphism $\Sigma : X \to Y$ it assigns the operator $U_\Sigma : U(X) \to U(Y)$ of (11.302);
- it respects composition up to the multiplier, $U_{\Sigma\circ\Sigma'} = \lambda^{-1} U_\Sigma U_{\Sigma'}$, as in (11.311);
- it respects disjoint union, $U_{\Sigma\sqcup\Sigma'} = U_\Sigma \otimes U_{\Sigma'}$ (independent systems have tensor-product state spaces and amplitudes);
- gluing an outgoing circle of Σ to an incoming circle of the same surface is a partial trace, as in (11.308).

Nash calls such a functor a **modular functor**. (In later usage that name is reserved for the chiral structure of Section 11.12.7; the full theory is "a CFT in Segal's sense".) A closed surface is a morphism $\varnothing \to \varnothing$, so U_Σ is a linear map $\mathbb{C} \to \mathbb{C}$: a number, the partition function. The multiplicativity of Friedan and Shenker on disconnected surfaces is the disjoint-union axiom.

Worked example 11.125: The Ising pair of pants

Take the pants of Figure 11.66 with round boundary circles in standard position (the three-punctured sphere with punctures at $0, 1, \infty$ and the unit-disc coordinates there). Its operator $U_P : H \otimes H \to H$ is known once we know its matrix elements between primaries, because the descendants are fixed by the Virasoro Ward identities (Section 11.9.2). With the unit-normalised primaries $\mathbf{1}, \sigma, \varepsilon$ of the Ising model,

$$\langle \varepsilon | U_P | \sigma \otimes \sigma \rangle \overset{(1)}{=} \langle \varepsilon(\infty)\sigma(1)\sigma(0)\rangle \overset{(2)}{=} C_{\sigma\sigma\varepsilon} = \tfrac{1}{2},$$
$$\langle \mathbf{1} | U_P | \sigma \otimes \sigma \rangle \overset{(3)}{=} C_{\sigma\sigma\mathbf{1}} = 1, \qquad \langle \sigma | U_P | \sigma \otimes \sigma \rangle \overset{(4)}{=} 0.$$

(1) Matrix elements of the pants between primary states are three-point functions with

surface (morphism)	operator U_Σ	physics
disc, boundary outgoing: $\varnothing \to S^1$	$\mathbb{C} \to H$, $1 \mapsto \lvert 0\rangle$	the vacuum (example of Section 11.12.3)
disc with ϕ at the centre	$1 \mapsto \lvert\phi\rangle = \phi(0)\lvert 0\rangle$	state–operator correspondence
disc, boundary incoming: $S^1 \to \varnothing$	$H \to \mathbb{C}$, $\psi \mapsto \langle 0\rvert\psi\rangle$	the vacuum bra
annulus A_q: $S^1 \to S^1$	$q^{L_0 - c/24}\bar{q}^{\bar{L}_0 - c/24}$	Hamiltonian and momentum; plumbing
pair of pants: $S^1 \sqcup S^1 \to S^1$	$H \otimes H \to H$	the OPE; matrix elements C_{ijk}
sphere with four holes	$H^{\otimes 3} \to H$	four-point function; its two cuttings give crossing
torus: $\varnothing \to \varnothing$	tr U_{A_q}	$Z(\tau)$, modular invariant
closed genus p: $\varnothing \to \varnothing$	a number	$Z(\Sigma)$, integrand I_p of (11.284)

Table 11.5: The Segal functor on the basic surfaces. What to see: every object of the earlier sections (vacuum, states, evolution, OPE, correlation functions, partition functions) is the operator of some surface.

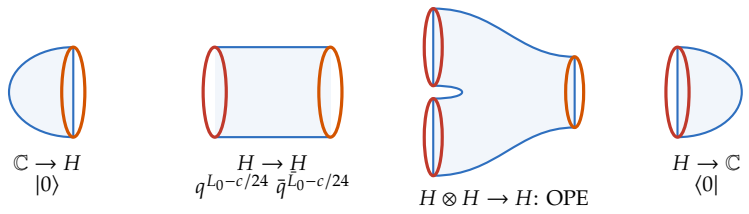

Figure 11.66: The building blocks of the Segal category. What to see: the disc with outgoing boundary (orange) creates the vacuum, the cylinder evolves, the pair of pants multiplies two states (the OPE), and the cap with incoming boundary (red) projects on the vacuum. Every Riemann surface with boundary can be sewn from these pieces (a pants decomposition plus discs), so the whole functor is determined by H, the annulus operators and the pants operator, subject to consistency.

the punctures at $\infty, 1, 0$ (the out-state at ∞).

(2) (11.248) at these points is the constant C_{ijk}; $C^2_{\sigma\sigma\varepsilon} = \frac{1}{4}$ from the exact four-point function, (11.265), with the sign convention $C > 0$.

(3) The two-point normalisation $\langle\sigma\sigma\rangle = 1$.

(4) The $\mathbb{Z}_2$ symmetry $\sigma \to -\sigma$: an odd number of spins has zero correlator; equivalently $N^{\sigma}_{\sigma\sigma} = 0$.

The non-zero pattern of the pants matrix elements is exactly the fusion rule $\sigma \times \sigma = \mathbf{1} + \varepsilon$ of (11.268). So the fusion rules are the "support" of the pants operator.

Worked example 11.126: Associativity of sewing is crossing symmetry

A sphere with four holes can be sewn from two pairs of pants in two ways: glue along a circle separating holes $\{3,4\}$ from $\{1,2\}$, or along a circle separating $\{2,3\}$ from $\{1,4\}$ (Figure 11.67). The functor axioms say both give the same operator. Evaluating each one by inserting a complete set of states in the sewn circle,

$$\sum_{m} C^{m}_{kl}\, C_{ijm}\, \left|\mathcal{F}^{ij}_{kl}(m,z)\right|^2 = \sum_{m'} C^{m'}_{jk}\, C_{il\,m'}\, \left|\mathcal{F}^{il}_{jk}(m',1-z)\right|^2,$$

(for scalar fields) which is the crossing relation of Section 11.9.4, checked for the Ising spin four-point function in (11.264). *Functoriality contains the bootstrap.* Moore and Seiberg showed that, conversely, consistency of sewing on the four-holed sphere and on the one-holed torus is enough to guarantee consistency on every surface.

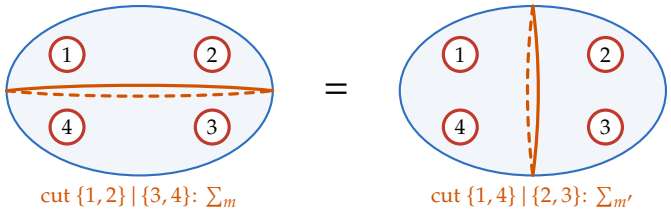

Figure 11.67: The four-holed sphere sewn from two pairs of pants in two ways. What to see: the orange circle is where the two pants are sewn, and where a complete set of intermediate states m (left) or m' (right) is inserted. Since both give the same surface, the two sums are equal: crossing symmetry is associativity of sewing.

Watch out: No identity morphism

A category needs identity morphisms, and $\mathcal{C}$ has none: the identity would be an annulus of zero width, which is not a Riemann surface. The annuli A_q with $q \to 1$ approximate it, and $U_{A_q} \to \mathbb{1}$ strongly (on each state, $q^{L_0} \to 1$). Strictly $\mathcal{C}$ is a "category without units", or one adds the thin annuli by hand. This is a technical point; it does not affect anything above.

11.12.7 Modular functors: where blocks and fusion rules live

Nash ends with the remark that in Segal's framework concrete notions such as conformal blocks and fusion rules can be identified. They live in the *chiral* half of the theory. The full amplitudes U_Σ are real-analytic in the moduli; but, as the block decomposition (11.257) showed, they are sums of products of holomorphic and antiholomorphic pieces. The holomorphic pieces, for a surface whose boundary circles are *labelled* by primaries, span finite-dimensional vector spaces.

The rules they obey define a (chiral) modular functor.

Working definition 11.44 (Modular functor (chiral data of a rational CFT))

Fix the finite set of primaries $\{0 = \mathbf{1}, 1, \dots, F-1\}$ with the conjugation $i \mapsto i^*$ [ϕ_{i^*} is the unique primary with $\langle \phi_i \phi_{i^*} \rangle \neq 0$]. A **modular functor** assigns to each surface Σ with boundary circles labelled $i_1, \dots, i_n$ a finite-dimensional vector space $V(\Sigma; i_1, \dots, i_n)$ (the conformal blocks), such that:

1. *Disjoint union:* $V(\Sigma \sqcup \Sigma') = V(\Sigma) \otimes V(\Sigma')$.
2. *Gluing:* if Σ is cut along a circle into Σ_{cut} with two new boundary circles, $V(\Sigma) \cong \bigoplus_m V(\Sigma_{\text{cut}}; m, m^*)$ ((11.274)).
3. *Normalisation:* $\dim V(S^2; i) = \delta_{i0}$ and $\dim V(S^2; i, j) = \delta_{ij^*}$: Nash's (11.75), (11.281).
4. *Holomorphy:* as Σ varies, the spaces form a holomorphic vector bundle over moduli space with a projectively flat connection [a rule for carrying blocks along paths in moduli space. Around a small closed loop a block comes back multiplied by a number]; its monodromy [what carrying the blocks once around a non-contractible loop does to them] gives a projective action of the mapping class group [diffeomorphisms of Σ modulo those that can be deformed to the identity, $\mathrm{SL}(2,\mathbb{Z})$ for the torus] on each $V(\Sigma)$.

The fusion numbers are $N_{ij}^k = \dim V(S^2; i, j, k^*)$, (11.272).

Worked example 11.127: The torus has one block per primary

Cut the torus along a non-separating circle. What is left is an annulus, i.e. a sphere with two holes, with labels m and m^*:

$$\dim V(T^2) \overset{(1)}{=} \sum_{m=0}^{F-1} \dim V(S^2; m, m^{**}) \overset{(2)}{=} \sum_{m=0}^{F-1} \delta_{m,m} = F.$$

(1) The gluing axiom, with the new circles labelled m and m^*.
(2) The normalisation axiom: $\dim V(S^2; i, j) = \delta_{ij^*}$ with $i = m$, $j = m^*$, and $m^{**} = m$.

So $V(T^2)$ has dimension equal to the number of primaries, and a basis is given by the characters $\chi_m(\tau)$: for the Ising model, $F = 3$ and $V(T^2) = \mathrm{span}(\chi_0, \chi_{1/2}, \chi_{1/16})$. The mapping class group of the torus is $\mathrm{SL}(2,\mathbb{Z})$, and it acts on $V(T^2)$ by the matrices S and T of (11.227), projectively after the c-dependent phase is removed (the example at the end of Section 11.11.5). The same gluing rule with Verlinde's formula gave $\dim V(\Sigma_2) = 10$ for the Ising model at genus two, (11.279).

The full CFT is recovered from the modular functor by "gluing the two halves": the Hilbert space is $H = \bigoplus_i H_i \otimes \bar{H}_i$ (11.200), and each amplitude is a hermitian pairing of a holomorphic block with an antiholomorphic one, $U_\Sigma = \sum h^{I\bar{J}} \mathcal{F}_I \bar{\mathcal{F}}_{\bar{J}}$, as $Z_{\text{Ising}} = \sum_i |\chi_i|^2$ and (11.257). This is the same statement as Friedan–Shenker's $Z = h(\Psi, \Psi)$.

Forget the complex structure altogether and keep only the topology. What remains is a rule that assigns finite-dimensional vector spaces to topological surfaces and linear maps to three-dimensional cobordisms between them: a **topological quantum field theory**. Atiyah's axioms for it (Chapter 12) are Segal's with "Riemann surface" replaced by "manifold" and with no anomaly multiplier, up to framing. Witten showed that Chern–Simons theory with

gauge group G at level k is such a theory, and that its state space on a surface Σ is the space of conformal blocks $V(\Sigma)$ of the G Kac–Moody (WZW) model at level k: the modular functor of this chapter is the Hilbert space of the next.

	quantum mechanics	Segal CFT / modular functor	Atiyah TQFT (Chapter 12)
space	a point	a circle (parametrised)	closed surface Σ
spacetime	interval $[0,t]$	Riemann surface with boundary	3-manifold with $\partial M = \Sigma$
state space	H (∞-dim.)	$H = \bigoplus_i H_i \otimes \bar{H}_i$ (CFT); $V(\Sigma)$ finite-dim. (chiral)	$V(\Sigma)$, finite-dim.
amplitude	e^{-tH}	U_Σ; blocks $\mathcal{F} \in V(\Sigma)$	vector $Z(M) \in V(\Sigma)$
gluing	$U_s U_t = U_{s+t}$	sewing, (11.311); trace, (11.308)	gluing 3-manifolds
anomaly	none	multiplier λ, central charge c	framing phase $e^{2\pi i c/24}$
closed case	Tr $e^{-\beta H}$	$Z(\Sigma)$, e.g. $Z(\tau)$	$Z(M)$, knot invariants

Table 11.6: Three "functorial" quantum theories. What to see: the same three rules (spacetimes give operators, gluing composes, closing traces) organise quantum mechanics, conformal field theory and topological field theory; only the geometry of "space" and "spacetime" changes.

Reading Nash (pp. 320–321, (11.82)–(11.88))

Segal's approach: a surface whose boundary is n circles (homotopically, n punctures), q incoming and r outgoing, gives $U_{\Sigma,\partial\Sigma} : H^{\otimes q} \to H^{\otimes r}$, (11.82) = (11.302). For $\Sigma_{p,2}$ Nash describes H as L^2 of the loop space, with the history α (11.83), H (11.84), the kernel (11.85) and the action of U (11.86): our (11.303)–(11.306), with the caveats of the pitfall in Section 11.12.3 and the exactly solvable free-boson examples added. The trace condition (11.87) is (11.308); for $p = 0$ it gives the torus partition function and modular invariance, which we derived from cutting the torus two ways. The sewing condition (11.88) is (11.311), with λ explained by the Virasoro central term. The category C, the functor to topological vector spaces, and the identification of blocks and fusion rules are in Sections 11.12.6 and 11.12.7.

Recap

- Segal's CFT is quantum mechanics with intervals replaced by Riemann surfaces: a surface with q incoming and r outgoing parametrised circles gives $U_\Sigma : H^{\otimes q} \to H^{\otimes r}$.
- Heuristically $H = L^2(\text{loops})$ and U has a path-integral kernel; for free fields this is exact: the disc gives the vacuum functional $e^{-\sum n|\phi_n|^2}$, and gluing Mehler kernels gives $|\eta|^{-2}$.
- Closing a surface is a trace (11.87); for the annulus $U = q^{L_0 - c/24}\bar{q}^{\bar{L}_0 - c/24}$ this is $Z(\tau)$, and cutting the torus two ways gives $Z(\tau) = Z(-1/\tau)$.
- Sewing composes operators up to a scalar λ (11.88); λ is the global form of the Virasoro central term, whose m^3 part cannot be removed.

- The whole structure is a projective monoidal functor from the category of circles and surfaces; disc = vacuum, pants = OPE, associativity of sewing = crossing.
- The chiral data form a modular functor: finite-dimensional block spaces $V(\Sigma)$ with gluing and normalisation axioms (11.75); $\dim V(T^2) = F$, and the mapping class group acts by S, T. Its topological shadow is the TQFT of Chapter 12.

11.13 The c-theorem: the flow runs downhill

The renormalisation group was built in the toolkit chapter Chapter T5. Recall its picture in three sentences. Lowering the cutoff moves a theory through the space of all couplings; the fixed points of this flow have no length scale, and in two dimensions (for unitary theories with a discrete spectrum) they are conformal field theories (Section T5.5.4). Near a fixed point the flow leaves along relevant directions and comes in along irrelevant ones (Figure T5.11), and a quantum field theory is a trajectory from one fixed point to another (Section T5.6). This section adds the one global fact about the flow that is special to conformal field theory: it runs downhill.

Integrating out throws information away (Section T5.1.1), so one expects a long-distance theory to have "fewer degrees of freedom" than the short-distance theory it came from. For a two-dimensional CFT there is a natural count of degrees of freedom: the central charge. A free boson has $c = 1$ and a free Majorana fermion $c = \frac{1}{2}$ (Section 11.3.13); n decoupled copies of anything have n times the central charge; and c fixes the Casimir energy $-\pi c/6L$ of a system on a circle of length L and the growth of the number of high-energy states (Cardy's formula, $\ln \rho(E) \simeq 2\pi\sqrt{cLE/6\pi}$ at large E, Section 11.8.6). Zamolodchikov (1986) turned the expectation into a theorem: there is a function on theory space that equals c at every fixed point and decreases along every RG flow. Sources: Nakayama (arXiv:1302.0884, §5.1) for the construction, Komargodski (arXiv:1112.4538, eq. (1.8)) for the sum rule, and Komargodski–Schwimmer (arXiv:1107.3987) for the four-dimensional analogue.

What we take from Chapter T5. In complex coordinates $z = x^1 + ix^2$ put $T = -2\pi T_{zz}$ and $\Theta = -2\pi T_{z\bar{z}} = -\frac{\pi}{2} T^{\mu}{}_{\mu}$ (Eq. (T5.94)); at a fixed point $\Theta = 0$ and $T = T(z)$ is the holomorphic stress tensor of Eq. (11.76). Conservation reads $\bar{\partial} T + \partial \Theta = 0$. Rotation invariance fixes the two-point functions up to three functions of $r^2 = z\bar{z}$,

$$\langle T(z,\bar{z})T(0)\rangle = \frac{F}{z^4}, \qquad \langle T(z,\bar{z})\Theta(0)\rangle = \frac{G}{z^3\bar{z}}, \qquad \langle \Theta(z,\bar{z})\Theta(0)\rangle = \frac{H}{z^2\bar{z}^2}$$

(Eq. (T5.96)), and conservation, inserted in these correlators, gives (Eqs. (T5.97) and (T5.98)), with dots meaning $\mathrm{d}/\mathrm{d}\ln r^2$,

$$\dot{F} = -\dot{G} + 3G, \qquad \dot{G} - G = -\dot{H} + 2H.$$

At a scale-invariant point F, G, H are constants, these force $G = H = 0$, and reflection positivity turns $\langle \Theta\Theta \rangle = 0$ into $\Theta = 0$ (Section T5.5.4). Away from a fixed point the same two equations contain more.

11.13.1 Zamolodchikov's C-function

Keep this notation, now in a theory that is *not* at a fixed point, so that F, G, H depend on $r^2 = z\bar{z}$. Dots denote $\mathrm{d}/\mathrm{d}\ln r^2$. The conservation equations (T5.97) and (T5.98) are two first-order

equations for three functions. Look for a combination whose derivative contains no G and no $\dot{H}$.

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}\ln r^2}\big(2F + aG + bH\big) &\overset{(1)}{=} 2(-\dot{G} + 3G) + a\dot{G} + b\dot{H} = (a-2)\dot{G} + 6G + b\dot{H} \\ &\overset{(2)}{=} (a-2)(G - \dot{H} + 2H) + 6G + b\dot{H} \\ &= (a+4)\,G + (b - a + 2)\,\dot{H} + 2(a-2)\,H. \end{aligned} \tag{11.313}$$

(1) (T5.97): $\dot{F} = -\dot{G} + 3G$.
(2) (T5.98): $\dot{G} = G - \dot{H} + 2H$.

The G term vanishes for $a = -4$, and then the $\dot{H}$ term vanishes for $b = a - 2 = -6$. The last coefficient is $2(-6) = -12$.

Key idea: Zamolodchikov's c-theorem

Define

$$C := 2F - 4G - 6H. \tag{11.314}$$

Then

$$\frac{\mathrm{d}C}{\mathrm{d}\ln r^2} = -12\,H = -12\,r^4\langle\Theta(x)\Theta(0)\rangle \;\le\; 0. \tag{11.315}$$

At a fixed point $C = c$, the central charge. Along an RG flow from a CFT with central charge c_{UV} (reached as $r \to 0$) to one with c_{IR} (reached as $r \to \infty$), C decreases monotonically, so

$$c_{\mathrm{UV}} \;\ge\; c_{\mathrm{IR}},$$

with equality only if $\Theta = 0$ throughout, that is, if there is no flow.

Three ingredients make this work, and each is something we have already proved.

- *The sign.* $H = r^4\langle\Theta\Theta\rangle \ge 0$ by reflection positivity, (T5.99). This is where unitarity enters.
- *The fixed-point value.* At a fixed point $\Theta = 0$, so $G = H = 0$, and $\langle T(z)T(0)\rangle = \frac{c/2}{z^4}$ (Eq. (11.89)) gives $F = \frac{c}{2}$ and $C = 2F = c$.
- *A function on theory space.* C is dimensionless, so it can depend on r only through dimensionless combinations of r and the couplings: $C = C(\hat{g}_i(r))$, the couplings measured in units of the distance r at which the correlators are evaluated. (The stress tensor is conserved, so it needs no renormalisation and has no anomalous dimension; Nakayama eqs. (5.8)–(5.10) show that the Callan–Symanzik equation then removes any other r dependence.) So (11.315) says C decreases along the flow in theory space.

Physical picture: why "fewer degrees of freedom"

$C(r)$ measures the strength of the TT correlation at separation r, that is, how many independent fluctuating fields carry energy and momentum at that scale. A field of mass m contributes at $r \ll 1/m$ and stops contributing at $r \gg 1/m$, where its correlations die exponentially. So $C(r)$ counts the modes that are still "light" at scale r, and that number can only go down as r grows. The next example shows this happening explicitly.

Trace and β-function. Let the theory be a fixed point perturbed by one operator, $S = S_{\mathrm{CFT}} + g\int \mathrm{d}^2x\,\Phi(x)$, with Φ of dimension $\Delta = 2 - y$, so g has mass dimension y. The trace

of the stress tensor is the response of the action to a uniform stretch of all lengths (this is the two-dimensional case of Eq. (T5.91), repeated here with the normalisation of this chapter). With the stress tensor defined by the response to the metric, $\delta S = \frac{1}{2}\int \sqrt{g}\, T_{\mu\nu}\delta g^{\mu\nu}$ (for the free boson this reproduces Example 11.24), a stretch $g_{\mu\nu} \to (1+2\sigma)g_{\mu\nu}$ gives $\delta S = -\sigma \int T^{\mu}{}_{\mu}$. The CFT part does not respond (in flat space), while in the perturbation $\sqrt{g} \to (1+2\sigma)\sqrt{g}$ and the primary $\Phi \to (1-\Delta\sigma)\Phi$:

$$-\sigma \int T^{\mu}{}_{\mu} \overset{(1)}{=} g\,(2-\Delta)\,\sigma \int \mathrm{d}^2x\,\Phi \quad\Longrightarrow\quad T^{\mu}{}_{\mu} \overset{(2)}{=} -y\,g\,\Phi = -\beta(g)\,\Phi, \qquad \Theta \overset{(3)}{=} \frac{\pi}{2}\,\beta(g)\,\Phi.$$

(1) Collect the factors of $1+\sigma$ from the measure and from Φ.
(2) $2-\Delta = y$; and $y\,g$ is the classical β-function (T5.6) of g ($\beta = \mathrm{d}\hat{g}/\mathrm{d}t$ with t the logarithm of the length scale). In the quantum theory the full β appears; this is the operator form of the Callan–Symanzik equation.
(3) $\Theta = -\frac{\pi}{2}T^{\mu}{}_{\mu}$.

Check on the massive free boson $S = \frac{1}{4\pi}\int[(\partial\varphi)^2 + m^2\varphi^2]$: here $\Phi = \varphi^2$, $g = m^2/4\pi$, $y = 2$, so $T^{\mu}{}_{\mu} = -m^2\varphi^2/2\pi$. Directly, $T_{\mu\nu} = \frac{1}{2\pi}\big[\partial_\mu\varphi\partial_\nu\varphi - \frac{1}{2}\delta_{\mu\nu}((\partial\varphi)^2 + m^2\varphi^2)\big]$ has trace $\frac{1}{2\pi}[(\partial\varphi)^2 - (\partial\varphi)^2 - m^2\varphi^2] = -m^2\varphi^2/2\pi$. They agree.

So $H = \frac{\pi^2}{4}\beta^2 r^4\langle\Phi(x)\Phi(0)\rangle$. Write $r^4\langle\Phi\Phi\rangle =: \mathsf{G}(\hat{g})$, the (dimensionless) **Zamolodchikov metric**, normalised so that $\mathsf{G} = 1$ at the UV fixed point when $\langle\Phi(x)\Phi(0)\rangle = |x|^{-2\Delta}$ and g is measured in units of r. With $t = \ln r$ (so $\mathrm{d}\ln r^2 = 2\,\mathrm{d}t$), (11.315) becomes

$$\frac{\mathrm{d}C}{\mathrm{d}t} = -24H = -6\pi^2\,\mathsf{G}(\hat{g})\,\beta(\hat{g})^2. \tag{11.316}$$

Along the flow $\mathrm{d}t = \mathrm{d}\hat{g}/\beta$, so

$$c_{\mathrm{UV}} - c_{\mathrm{IR}} = 6\pi^2 \int_{\hat{g}_{\mathrm{UV}}}^{\hat{g}_{\mathrm{IR}}} \mathsf{G}(\hat{g})\,\beta(\hat{g})\,\mathrm{d}\hat{g}. \tag{11.317}$$

11.13.2 The sum rule, and a free massive boson

Integrating (11.315) over all scales gives a formula for the total drop that needs no knowledge of the couplings:

$$\begin{aligned} c_{\mathrm{UV}} - c_{\mathrm{IR}} &\overset{(1)}{=} 12\int_0^\infty H\;\mathrm{d}\ln r^2 \overset{(2)}{=} 24\int_0^\infty \frac{\mathrm{d}r}{r}\,r^4\,\frac{\pi^2}{4}\,\langle T^{\mu}{}_{\mu}(x)T^{\mu}{}_{\mu}(0)\rangle \\ &\overset{(3)}{=} \frac{6\pi^2}{2\pi}\int \mathrm{d}^2x\;|x|^2\langle T^{\mu}{}_{\mu}(x)T^{\mu}{}_{\mu}(0)\rangle = 3\pi\int \mathrm{d}^2x\;|x|^2\,\langle T^{\mu}{}_{\mu}(x)T^{\mu}{}_{\mu}(0)\rangle. \end{aligned} \tag{11.318}$$

(1) Integrate (11.315) from $r = 0$ ($C = c_{\mathrm{UV}}$) to $r = \infty$ ($C = c_{\mathrm{IR}}$).
(2) $\mathrm{d}\ln r^2 = 2\mathrm{d}r/r$ and $\Theta = -\frac{\pi}{2}T^{\mu}{}_{\mu}$.
(3) $\mathrm{d}^2x = 2\pi r\,\mathrm{d}r$ for a rotation-invariant integrand, so $\int r^3\mathrm{d}r\,f = \frac{1}{2\pi}\int \mathrm{d}^2x\,|x|^2 f$.

This is Cardy's sum rule; Komargodski derives it (his (1.8)) from the dilaton effective action, a different route to the same formula.

Worked example 11.128: A massive boson flows from $c = 1$ to $c = 0$

Take $S = \frac{1}{4\pi}\int[(\partial\varphi)^2 + m^2\varphi^2]$. At short distances it is the free boson ($c = 1$); at long distances nothing is left ($c = 0$). So the sum rule must give exactly 1. We found $T^{\mu}{}_{\mu} = -\frac{m^2}{2\pi}\varphi^2$. The

kinetic operator is $\frac{1}{2\pi}(k^2+m^2)$ in momentum space, so the propagator is $\tilde G(k) = 2\pi/(k^2+m^2)$ (in position space $K_0(m|x|)$, which tends to the massless $-\ln|x|$ of Eq. (11.69) as $m \to 0$, up to a constant). By Wick's theorem $\langle\varphi^2(x)\varphi^2(0)\rangle_{\text{conn}} = 2\,G(x)^2$, so

$$\mathcal{F}(x) := \langle T^{\mu}{}_{\mu}(x) T^{\mu}{}_{\mu}(0)\rangle = \frac{m^4}{4\pi^2}\cdot 2G(x)^2.$$

It is easiest in momentum space, since $\int \mathrm{d}^2x\,|x|^2\mathcal{F}(x) = -\nabla_p^2\tilde{\mathcal{F}}(p)\big|_{p=0}$ (differentiate $\tilde{\mathcal{F}}(p) = \int \mathrm{d}^2x\, e^{-ip\cdot x}\mathcal{F}(x)$ twice). The product G^2 becomes a convolution:

$$\tilde{\mathcal{F}}(p) \overset{(1)}{=} \frac{m^4}{2\pi^2}\int \frac{\mathrm{d}^2k}{(2\pi)^2}\,\frac{2\pi}{k^2+m^2}\,\frac{2\pi}{(p-k)^2+m^2} \overset{(2)}{=} \frac{m^4}{2\pi^2}\int_0^1 \mathrm{d}x \int \mathrm{d}^2\ell\,\frac{1}{\big(\ell^2+m^2+x(1-x)p^2\big)^2}$$
$$\overset{(3)}{=} \frac{m^4}{2\pi}\int_0^1 \frac{\mathrm{d}x}{m^2+x(1-x)p^2} \overset{(4)}{=} \frac{m^2}{2\pi} - \frac{p^2}{2\pi}\int_0^1 x(1-x)\,\mathrm{d}x + O(p^4) = \frac{m^2}{2\pi} - \frac{p^2}{12\pi} + O(p^4).$$

(1) The Fourier transform of a product is the convolution of the transforms (with $\int \mathrm{d}^2k/(2\pi)^2$).

(2) Feynman's parameter formula $\frac{1}{AB} = \int_0^1 \frac{\mathrm{d}x}{[xA+(1-x)B]^2}$ with $A = (p-k)^2+m^2$, $B = k^2+m^2$. Then $xA+(1-x)B = (k-xp)^2 + x(1-x)p^2 + m^2$; shift $\ell = k - xp$.

(3) $\int \mathrm{d}^2\ell\,(\ell^2+D)^{-2} = \pi\int_0^\infty \mathrm{d}(\ell^2)\,(\ell^2+D)^{-2} = \pi/D$.

(4) Expand $1/(m^2+ap^2) = m^{-2} - ap^2m^{-4} + \cdots$; $\int_0^1 x(1-x)\mathrm{d}x = \frac{1}{6}$.

In two dimensions $\nabla_p^2 p^2 = 4$, so $\int \mathrm{d}^2x\,|x|^2\mathcal{F} = -(-\frac{4}{12\pi}) = \frac{1}{3\pi}$, and the sum rule (11.318) gives

$$c_{\text{UV}} - c_{\text{IR}} = 3\pi\cdot\frac{1}{3\pi} = 1.$$

Exactly one degree of freedom has been lost, as it must.

We can even write down C at every scale. With $\Theta = \frac{m^2}{4}\varphi^2$, $H = r^4\langle\Theta\Theta\rangle = \frac{m^4r^4}{8}K_0(mr)^2$, and integrating (11.315) from 0 to r,

$$C(r) = 1 - 24\int_0^r \frac{\mathrm{d}r'}{r'}H(r') = 1 - 3\int_0^{mr} u^3K_0(u)^2\,\mathrm{d}u. \tag{11.319}$$

The integral $\int_0^\infty u^3K_0(u)^2\mathrm{d}u = \frac{1}{3}$ (the position-space version of the calculation above), so $C(\infty) = 0$. Figure 11.68 plots it.

11.13.3 Short flows: conformal perturbation theory

Now a flow between two non-trivial CFTs. Perturb a CFT by a primary Φ that is only *slightly* relevant, $\Delta = 2-y$ with $0 < y \ll 1$, normalised by $\langle\Phi(x)\Phi(0)\rangle = |x|^{-2\Delta}$, and with OPE

$$\Phi(x)\Phi(0) = \frac{1}{|x|^{2\Delta}} + \frac{C}{|x|^{\Delta}}\Phi(0) + \cdots \tag{11.320}$$

(the OPE rule Eq. (11.8) fixes the power $|x|^{\Delta-2\Delta}$). The number $C = C_{\Phi\Phi}{}^{\Phi}$ is an OPE coefficient of the CFT.

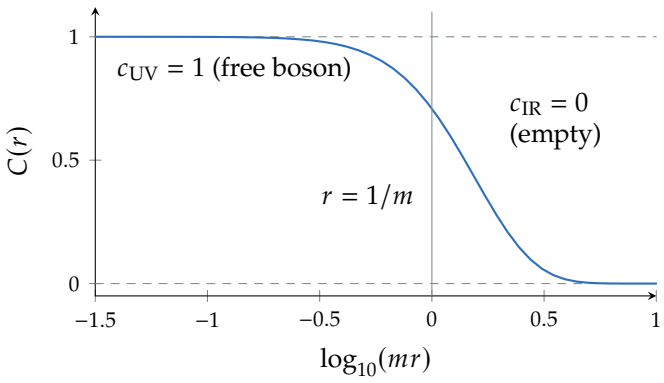

Figure 11.68: Zamolodchikov's C-function for a free boson of mass m, (11.319), computed numerically. What to see: at distances well below the Compton wavelength $1/m$ the boson is effectively massless and $C \approx 1$; near $r \sim 1/m$ it drops; beyond a few Compton wavelengths the field no longer fluctuates and $C \to 0$. The curve is monotonic, as (11.315) requires.

Worked example 11.129: The β-function to second order

Regularise with a short-distance cutoff a: in the expansion of $e^{-g\int\Phi}$, no two operators may come closer than a. Increase the cutoff to $a(1+\delta t)$. In the second-order term $\frac{g^2}{2}\iint\Phi\Phi$ we lose the pairs with separation between a and $a(1+\delta t)$. By the OPE, their contribution is

$$\frac{g^2}{2}\int \mathrm{d}^2x \int_{a<|y|<a(1+\delta t)} \mathrm{d}^2y\ \Phi(x+y)\Phi(x) \overset{(1)}{=} \frac{g^2}{2}\, C\, a^{-\Delta}\,(2\pi a\cdot a\,\delta t)\int \mathrm{d}^2x\,\Phi(x)+\cdots$$
$$= \pi C g^2 a^{2-\Delta}\,\delta t\int \mathrm{d}^2x\,\Phi(x)+\cdots .$$

(1) Use (11.320) (the identity term only shifts the free energy); the thin annulus has area $2\pi a\cdot a\delta t$ and on it $|y|^{-\Delta}=a^{-\Delta}$.

To keep all correlation functions unchanged we must put this contribution back into the first-order term, $-g\int\Phi$: the coupling becomes $g' = g - \pi C g^2 a^{2-\Delta}\delta t$. In the dimensionless coupling $\hat g = g\,a^y$ (measured in units of the cutoff), which also picks up the canonical factor $(1+y\,\delta t)$,

$$\beta(\hat g) = \frac{\mathrm{d}\hat g}{\mathrm{d}t} = y\,\hat g - \pi C\,\hat g^2 + O(\hat g^3). \tag{11.321}$$

For $C > 0$ there is a fixed point at $\hat g^* = y/(\pi C)$, of order y, so it is within reach of perturbation theory.

At the new fixed point the slope is $\beta'(\hat g^*) = y - 2\pi C\hat g^* = -y$: the operator that was relevant with eigenvalue $+y$ at the UV point is irrelevant with eigenvalue $-y$ at the IR point, so its dimension there is $\Delta_{\mathrm{IR}} = 2 + y + O(y^2)$.

Worked example 11.130: How much c is lost

Insert (11.321) in (11.317) with $\mathsf{G} = 1 + O(\hat g)$:

$$c_{\mathrm{UV}} - c_{\mathrm{IR}} \overset{(1)}{=} 6\pi^2\int_0^{\hat g^*}\left(y\,\hat g - \pi C\hat g^2\right)\mathrm{d}\hat g \overset{(2)}{=} 6\pi^2\left(\frac{y\,\hat g^{*2}}{2} - \frac{\pi C\,\hat g^{*3}}{3}\right) \overset{(3)}{=} 6\pi^2\left(\frac{y^3}{2\pi^2C^2} - \frac{y^3}{3\pi^2C^2}\right) = \frac{y^3}{C^2}.$$

(1) (11.317); corrections from $\mathsf{G}-1$ and from the $\hat g^3$ term of β are of relative order y.
(2) Integrate the polynomial.

(3) $\hat{g}^* = y/\pi C$.

So $c_{\mathrm{IR}} = c_{\mathrm{UV}} - y^3/C^2 + O(y^4)$: positive, as the theorem demands, and small, of third order in the distance y from marginality.

11.13.4 Flows between minimal models

The unitary minimal models $\mathcal{M}_m$ (Section 11.4.12) have $c_m = 1 - \frac{6}{m(m+1)}$, increasing towards 1 as $m \to \infty$. Their primaries $\phi_{r,s}$ have weights given by the Kac formula Eq. (11.146). Take $\phi_{1,3}$:

$$h_{1,3} \overset{(1)}{=} \frac{\big((m+1)-3m\big)^2 - 1}{4m(m+1)} = \frac{(2m-1)^2-1}{4m(m+1)} \overset{(2)}{=} \frac{m-1}{m+1}, \qquad \Delta_{1,3} = 2h_{1,3} = 2 - \frac{4}{m+1}.$$

(1) Eq. (11.146) with $r = 1$, $s = 3$.

(2) $(2m-1)^2 - 1 = (2m-2)(2m) = 4m(m-1)$.

So $\phi_{1,3}$ is relevant with $y = 4/(m+1)$, small when m is large: exactly the situation of Section 11.13.3. (For the Ising model, $m = 3$, $\phi_{1,3}$ is the energy operator ε with $\Delta = 1$; the perturbation is not small, and the flow goes to a massive theory, $c = 0 = c_2$.)

Worked example 11.131: $\mathcal{M}_m \to \mathcal{M}_{m-1}$

Zamolodchikov (1987) computed $C_{(1,3)(1,3)}{}^{(1,3)} = \frac{4}{\sqrt{3}}\big(1 + O(1/m)\big)$ from the Coulomb-gas construction. Then Example 11.130 predicts

$$c_{\mathrm{UV}} - c_{\mathrm{IR}} \overset{(1)}{=} \frac{y^3}{C^2} \overset{(2)}{=} \frac{64}{(m+1)^3} \cdot \frac{3}{16} = \frac{12}{(m+1)^3} \approx \frac{12}{m^3}.$$

(1) Example 11.130.

(2) $y = 4/(m+1)$, $C^2 = 16/3$.

Compare with the drop from $\mathcal{M}_m$ to the next model down:

$$c_m - c_{m-1} \overset{(1)}{=} \frac{6}{(m-1)m} - \frac{6}{m(m+1)} \overset{(2)}{=} \frac{6\big((m+1)-(m-1)\big)}{(m-1)m(m+1)} = \frac{12}{m(m^2-1)} \approx \frac{12}{m^3}.$$

(1) $c_m = 1 - 6/(m(m+1))$ and $c_{m-1} = 1 - 6/((m-1)m)$.

(2) Common denominator.

They agree at leading order in $1/m$. The dimension check agrees too. The IR fixed point should have an irrelevant operator with $\Delta_{\mathrm{IR}} = 2 + y = 2 + \frac{4}{m+1}$. In $\mathcal{M}_{m-1}$ (replace m by $m-1$ in the Kac formula),

$$h_{3,1} = \frac{(3m-(m-1))^2 - 1}{4(m-1)m} = \frac{(2m+1)^2-1}{4m(m-1)} = \frac{m+1}{m-1}, \qquad \Delta_{3,1} = 2 + \frac{4}{m-1},$$

which matches at leading order. So the perturbation $\phi_{1,3}$ of $\mathcal{M}_m$ flows to $\mathcal{M}_{m-1}$, arriving along its irrelevant operator $\phi_{3,1}$. Numerically (with $y = 4/(m+1)$):

m	c_m	$c_m - c_{m-1}$ (exact)	y^3/C^2	ratio
5	0.8000	0.1000	0.0556	0.56
10	0.9455	0.01212	0.00902	0.74
20	0.9857	0.001504	0.001296	0.86
50	0.99765	9.60×10^{-5}	9.05×10^{-5}	0.94

The ratio tends to 1 with $O(1/m)$ corrections, as expected from the neglected terms. The exact statement (confirmed by the exact S-matrix and numerical methods) is that the flow ends precisely at $\mathcal{M}_{m-1}$.

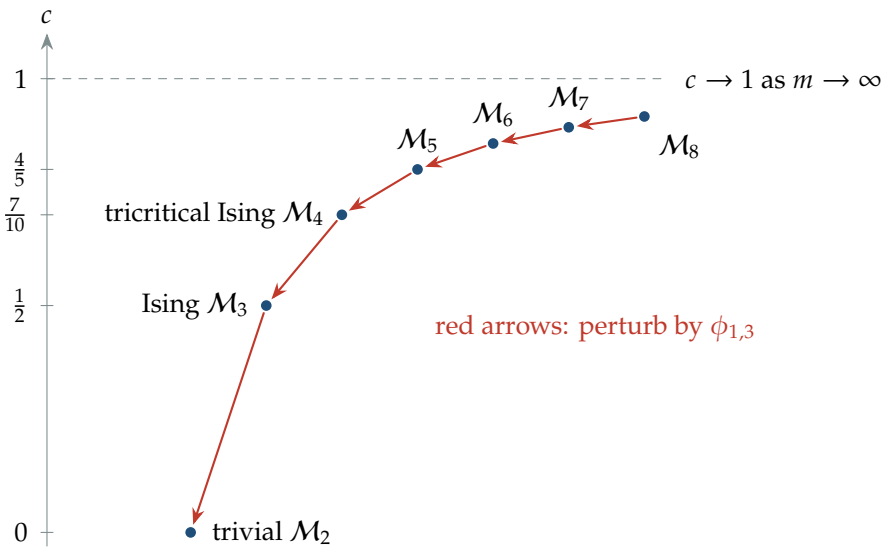

Figure 11.69: The staircase of flows between unitary minimal models. Each dot is $\mathcal{M}_m$ at height $c_m = 1 - 6/(m(m+1))$; each red arrow is the flow generated by the relevant operator $\phi_{1,3}$, which lands on $\mathcal{M}_{m-1}$. The last step, Ising $\to$ trivial, is the thermal perturbation that makes the Ising model massive. What to see: every arrow goes down in c, and the steps shrink like $12/m^3$ as the models accumulate below $c = 1$.

11.13.5 The RG as a gradient flow; the Morse picture

With several couplings $\hat{g}^i$ and $\Theta = \frac{\pi}{2}\beta^i\Phi_i$, the same steps give $H = \frac{\pi^2}{4}\beta^i \mathsf{G}_{ij}\beta^j$ with the **Zamolodchikov metric**

$$\mathsf{G}_{ij}(\hat{g}) = r^4\langle\Phi_i(x)\Phi_j(0)\rangle\big|_{|x|=r}, \qquad \frac{\mathrm{d}C}{\mathrm{d}t} = -6\pi^2\,\beta^i\mathsf{G}_{ij}\beta^j. \tag{11.322}$$

The metric is positive definite: for any real vector v, $v^i\mathsf{G}_{ij}v^j = r^4\langle(v\cdot\Phi)(x)\,(v\cdot\Phi)(0)\rangle \geq 0$ by reflection positivity, with equality only for $v = 0$ when the Φ_i are independent. In conformal perturbation theory one checks more: to the order computed, $C(\hat{g}) = c_{\mathrm{UV}} - 6\pi^2\big(\frac{y}{2}\hat{g}^2 - \frac{\pi C}{3}\hat{g}^3\big)$ satisfies

$$\frac{\partial C}{\partial \hat{g}^i} = -6\pi^2\,\mathsf{G}_{ij}\,\beta^j, \qquad \text{that is} \qquad \beta^i = -\mathsf{G}^{ij}\,\partial_j\Big(\frac{C}{6\pi^2}\Big). \tag{11.323}$$

(For one coupling: $\partial_{\hat{g}}C = -6\pi^2(y\hat{g} - \pi C\hat{g}^2) = -6\pi^2\beta$.) This is the **gradient-flow** property: the RG flows down the gradient of $C/6\pi^2$ with respect to the metric G, which is exactly the gradient flow of Morse theory, [Nash Ch. VII], $\dot{x}^i = -g^{ij}\partial_j f$ (Chapter 7). In general two-dimensional theories (11.323) holds up to extra terms that vanish at fixed points (Nakayama eq. (5.11)); the monotonicity (11.322) holds exactly.

Key idea: the Morse index of C counts relevant operators

Fixed points are critical points of C ($\beta = 0 \Leftrightarrow \partial C = 0$ when G is invertible). Differentiating (11.323) at a fixed point, where $\beta = 0$,

$$\partial_i \partial_j C = -6\pi^2\, \mathsf{G}_{ik}\, \partial_j \beta^k = -6\pi^2\, (\mathsf{G}M)_{ij},$$

with M the stability matrix of Section T5.3.1. So $M = -\mathsf{G}^{-1}\mathrm{Hess}(C)/6\pi^2$. Since G is positive, M is similar to $-\mathsf{G}^{-1/2}\mathrm{Hess}(C)\,\mathsf{G}^{-1/2}/6\pi^2$, which is congruent to $-\mathrm{Hess}(C)$; by Sylvester's law of inertia (Chapter 7) the number of positive eigenvalues y_a of M equals the number of negative eigenvalues of the Hessian:

$$\text{Morse index of } C \text{ at a CFT} = \text{number of relevant operators.}$$

UV fixed points are maxima or saddles of C; an IR-stable fixed point (no relevant operators) is a local minimum.

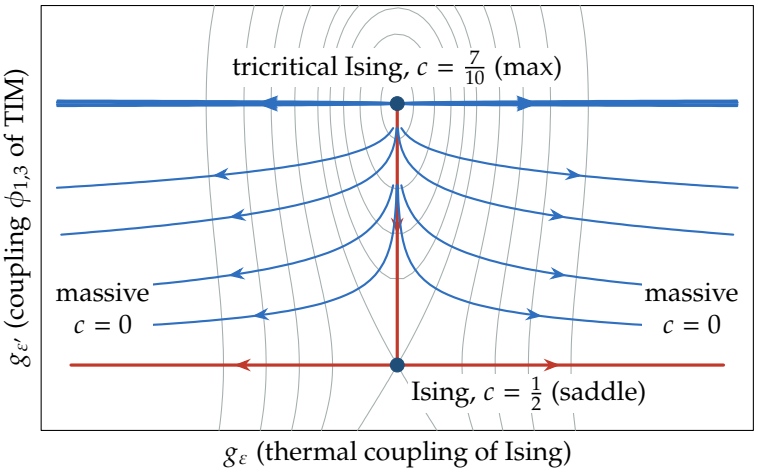

Figure 11.70: The RG as gradient flow on a two-parameter slice of theory space (a schematic height function $C = h(g_{\varepsilon'})e^{-g_\varepsilon^2}$ with the correct values at the fixed points; flow lines computed as its gradient flow). Grey: level sets of C. Blue: flows leaving the tricritical Ising point, a maximum of C with two relevant $\mathbb{Z}_2$-even directions. Thick red: the special flows along $\phi_{1,3}$ from tricritical to Ising, and from the Ising saddle (one relevant direction, ε) down to the two massive phases. What to see: every flow crosses the level sets downwards, fixed points are the critical points of C, and the number of downhill directions at each is its number of relevant operators, its Morse index.

Watch out: what the gradient picture does and does not give

Two consequences are solid: there are no limit cycles (a function that strictly decreases along the flow cannot return to its starting value), and there is no "chaotic" RG in unitary 2D theories. The analogy with Chapter 7 should not be pushed further without care: theory space is infinite-dimensional, not compact, and G can degenerate, so there is no established set of "Morse inequalities" relating the numbers of CFTs of each index. The flows between fixed points are the analogue of the flow lines between critical points that build the Morse–Witten complex.

11.13.6 Four dimensions: the a-theorem

In four dimensions the two-point function of T does not produce a monotonic function; the right quantity turned out to be a coefficient of the trace anomaly. On a curved background a 4D CFT has

$$\langle T^{\mu}{}_{\mu} \rangle = a\, E_4 - c\, W_{\mu\nu\rho\sigma} W^{\mu\nu\rho\sigma}$$

(the convention of Komargodski–Schwimmer; signs vary in the literature), where W is the Weyl tensor and E_4 the Euler density, whose integral is $32\pi^2\chi(M)$ by Gauss–Bonnet–Chern (the four-dimensional version of the Gauss–Bonnet theorem of Chapter T2). Cardy conjectured in 1988 that a, not c, decreases.

Key idea: the a-theorem (Komargodski and Schwimmer, 2011)

For any unitary RG flow in four dimensions between a UV CFT and an IR CFT, $a_{\rm UV} > a_{\rm IR}$. The proof couples the theory to a background "dilaton" $\tau(x)$ by replacing every mass scale $M \to M e^{-\tau}$. Anomaly matching forces the low-energy effective action of τ to contain the Wess–Zumino term $2(a_{\rm UV} - a_{\rm IR}) \int \mathrm{d}^4x\, [2(\partial\tau)^2 \Box\tau - (\partial\tau)^4]$. Its coefficient appears in the forward $2 \to 2$ "dilaton scattering" amplitude as $A(s) \propto (a_{\rm UV} - a_{\rm IR}) s^2$, and a dispersion relation gives

$$a_{\rm UV} - a_{\rm IR} = \frac{1}{4\pi} \int_{s>0} \frac{\mathrm{Im}\, A(s)}{s^3}\, \mathrm{d}s > 0,$$

positive by the optical theorem (Komargodski, eq. (1.15)). The 2D analogue of this argument, with a two-dilaton term $\frac{c_{\rm UV}-c_{\rm IR}}{24\pi} \int (\partial\tau)^2$, reproduces the sum rule (11.318).

Worked example 11.132: Counting with free fields: QCD and pions

For free fields, in units of $1/(90(8\pi)^2)$, a real scalar has $a = 1$, a Weyl fermion $a = \frac{11}{2}$ and a gauge field $a = 62$ (Komargodski–Schwimmer, app. A). QCD with N_c colours and N_f massless quarks is free in the UV (asymptotic freedom): $N_c^2 - 1$ gluons and $2N_cN_f$ Weyl fermions. In the IR, chiral symmetry breaking leaves $N_f^2 - 1$ free massless pions. So

$$a_{\rm UV} \overset{(1)}{=} 62(N_c^2 - 1) + \tfrac{11}{2} \cdot 2N_cN_f = 62(N_c^2 - 1) + 11N_cN_f, \qquad a_{\rm IR} \overset{(2)}{=} N_f^2 - 1.$$

(1) Each Dirac quark of each colour is two Weyl fermions.
(2) Each pion is a real scalar.

For $N_c = 3$, $N_f = 2$: $a_{\rm UV} = 496 + 66 = 562$ and $a_{\rm IR} = 3$. The theorem holds with room to spare. It would fail only for $N_f \gtrsim 44$ at $N_c = 3$, far beyond the $N_f < 16.5$ required for asymptotic freedom. In three dimensions the analogous monotonic quantity is the free energy on the three-sphere (F-theorem, Casini–Huerta).

Recap

- From the conservation equations, $C = 2F - 4G - 6H$ obeys $\mathrm{d}C/\mathrm{d}\ln r^2 = -12r^4\langle\Theta\Theta\rangle \le 0$; $C = c$ at fixed points, so $c_{\rm UV} \ge c_{\rm IR}$.
- $\Theta = \frac{\pi}{2}\beta^i\Phi_i$ gives $\mathrm{d}C/\mathrm{d}t = -6\pi^2\beta\mathsf{G}\beta$ with the positive Zamolodchikov metric G.
- Sum rule $c_{\rm UV} - c_{\rm IR} = 3\pi \int \mathrm{d}^2x\, x^2 \langle T^{\mu}{}_{\mu} T^{\nu}{}_{\nu} \rangle$; a massive boson gives exactly 1.
- Near-marginal flows: $\beta = y\hat{g} - \pi C\hat{g}^2$, $\Delta c = y^3/C^2$; for $\phi_{1,3}$ in $\mathcal{M}_m$ this is $12/m^3$, the drop to $\mathcal{M}_{m-1}$.

- The RG is (to the order checked) the gradient flow of C; the Morse index of C at a CFT is its number of relevant operators.
- In 4D the a-anomaly decreases (Komargodski–Schwimmer).

Chapter summary

This chapter asked what a quantum field theory looks like when it has no length scale at all, and found that in two dimensions the answer is astonishingly rigid. The story in five steps:

1. *Why conformal* (Nash §1). At a second-order phase transition the correlation length diverges, so no length scale is left; scale invariance plus rotations and locality (a traceless stress tensor) give conformal invariance. Short-distance limits of massive theories, and RG fixed points, are conformal. The operator product expansion $A(x)B(0) = \sum_n C_n(x)O_n(0)$ is the organising tool, and scale invariance fixes the powers in $C_n(x)$ by the scaling dimensions.

2. *Two dimensions* (Nash §2). Conformal maps of the plane are holomorphic maps, so the local conformal algebra is infinite dimensional (the Witt algebra), while the global group is the Möbius group $\mathrm{SL}(2,\mathbb{C})/\{\pm\mathbb{1}\}$. Primary fields transform with weights $(h,\bar{h})$. The stress tensor splits into $T(z)$ and $\bar{T}(\bar{z})$; the Ward identity turns into the OPE $T(w)\phi(z) \sim h\phi/(w-z)^2 + \partial\phi/(w-z)$, and $T(w)T(z)$ contains the central charge c, which makes T transform with a Schwarzian.

3. *Virasoro* (Nash §3). The modes L_n of T obey the Virasoro algebra. Radial quantisation turns primaries into highest-weight states; descendants fill a Verma module; null vectors are removed; unitarity restricts (c,h), and for $c<1$ only the discrete series (Kac table) survives.

4. *Statistical mechanics* (Nash §4, Sections 11.5 to 11.8). The critical Ising model is the $c=\frac{1}{2}$ minimal model with primaries of weights $0, \frac{1}{16}, \frac{1}{2}$, and its critical exponents are conformal weights. On the torus the partition function is a sum of products of characters, and modular invariance under $\tau \mapsto (a\tau+b)/(c\tau+d)$ is a strong constraint, verified through the theta and eta functions and classified (ADE).

5. *Operator products, fusion, axioms* (Nash §5, Sections 11.9 to 11.12). Correlators reduce to primaries; two- and three-point functions are fixed up to constants; four-point functions are sums of conformal blocks; the fusion rules N_{ij}^{k} count blocks and are diagonalised by the modular S matrix (Verlinde). The axiomatic approaches of Friedan–Shenker and Segal repackage all of this as amplitudes on Riemann surfaces compatible with gluing, which leads directly to the topological field theories of Chapter 12.

Formula sheet

Key idea: The formulas to remember

primary: $$\phi'(z',\bar{z}') = \left(\frac{\mathrm{d}z'}{\mathrm{d}z}\right)^{-h}\left(\frac{\mathrm{d}\bar{z}'}{\mathrm{d}\bar{z}}\right)^{-\bar{h}}\phi(z,\bar{z})$$

$T\phi$ OPE: $$T(w)\phi(z) \sim \frac{h\,\phi(z)}{(w-z)^2} + \frac{\partial\phi(z)}{w-z}$$

TT OPE: $$T(w)T(z) \sim \frac{c/2}{(w-z)^4} + \frac{2T(z)}{(w-z)^2} + \frac{\partial T(z)}{w-z}$$

Schwarzian: $$T(z) = \left(\tfrac{\mathrm{d}z'}{\mathrm{d}z}\right)^2 T'(z') + \tfrac{c}{12}\{z',z\}$$

Virasoro: $$[L_m, L_n] = (m-n)L_{m+n} + \tfrac{c}{12}m(m^2-1)\delta_{m+n,0}$$

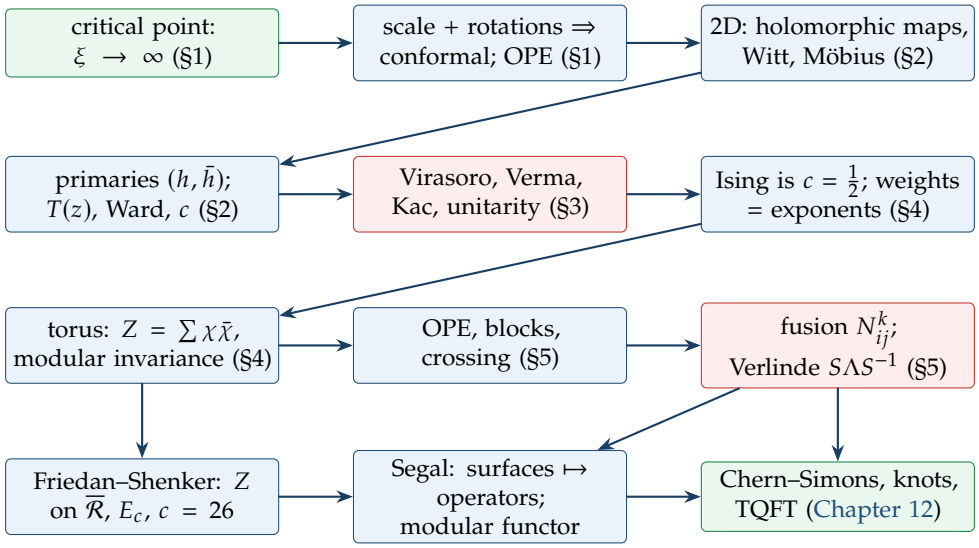

Figure 11.71: The logic of Chapter 11. What to see: the physics of critical points (green, top left) forces conformal invariance; in two dimensions this gives the Virasoro algebra and its representations (red, the algebraic core); the torus and the sphere give two sets of consistency conditions (modular invariance, crossing), which meet in the fusion rules and the Verlinde formula (red); the axiomatic approaches package everything as amplitudes on Riemann surfaces, which is the starting point of topological field theory (green, bottom right).

minimal (6.58):	$c = 1 - \frac{6}{(m+1)(m+2)}, \quad h = \frac{((m+2)p-(m+1)q)^2-1}{4(m+1)(m+2)}$, Ising: $m = 2$
cylinder:	$H = \frac{2\pi}{L}\left(L_0 + \bar{L}_0 - \frac{c}{12}\right), \quad E_0 = -\frac{\pi c}{6L}$
torus:	$Z(\tau) = \mathrm{Tr}\; q^{L_0 - c/24}\bar{q}^{\bar{L}_0 - c/24} = \sum M_{h\bar{h}}\chi_h(\tau)\overline{\chi_{\bar{h}}(\tau)}$
eta:	$\eta(\tau+1) = e^{i\pi/12}\eta(\tau), \quad \eta(-1/\tau) = \sqrt{-i\tau}\,\eta(\tau)$
Ising:	$Z = \frac{\lvert\theta_2\rvert + \lvert\theta_3\rvert + \lvert\theta_4\rvert}{2\lvert\eta\rvert}, \quad \sigma \times \sigma = \mathbf{1} + \varepsilon$
2-, 3-point:	$\langle\phi_i\phi_j\rangle = \frac{C_{ij}}{z_{12}^{2h}\bar{z}_{12}^{2\bar{h}}}, \quad \langle\phi_1\phi_2\phi_3\rangle = \frac{C_{123}}{z_{12}^{h_1+h_2-h_3} z_{23}^{h_2+h_3-h_1} z_{13}^{h_1+h_3-h_2}} \times \text{c.c.}$
Verlinde:	$N_{ij}^k = \sum_m \frac{S_{im}S_{jm}\bar{S}_{km}}{S_{0m}}, \quad \dim V(\Sigma_p) = \sum_m S_{0m}^{2-2p}$
moduli:	$\dim_{\mathbb{C}} \mathcal{M}_{p,n} = 3p - 3 + n, \quad T^*\mathcal{M}_p = H^0(K^2)$
plumbing:	$xy = t \;\Rightarrow$ neck operator $t^{L_0 - c/24}\bar{t}^{\bar{L}_0 - c/24}$
Segal:	$U_\Sigma : H^{\otimes q} \to H^{\otimes r}, \quad U_\Sigma U_{\Sigma'} = \lambda\, U_{\Sigma\cup\Sigma'}, \quad \mathrm{tr}\; U_{\Sigma_{p,2}} = U_{\bar{\Sigma}_{p,2}}$

Concepts, what they mean operationally, and where they are used

concept	operational meaning	where it is used
Nash §1: conformal invariance and QFT		
scaling dimension d_A	$A(\lambda x) \mapsto \lambda^{-d_A} A$; read off from $\langle AA \rangle \propto \lvert x \rvert^{-2d_A}$	critical exponents (§4); OPE powers
anomalous dimension	$\gamma_A = d_A - d_A^{\mathrm{c}}$, from the Callan–Symanzik equation at a fixed point	RG language of §4
RG fixed point	$\beta(g_*) = 0$; necessary, not sufficient, for conformal invariance	critical points; string backgrounds (Chapter 9)
Wilson OPE	$A(x)B(0) = \sum_n C_n(x) O_n(0)$, $C_n \propto \lvert x \rvert^{d_{O_n} - d_A - d_B}$	§5 OPE, fusion rules
conformal group in d dim.	solutions of the conformal Killing equation, $\mathrm{SO}(d+1,1)$, dim. $\frac{(d+1)(d+2)}{2}$	contrast with $d = 2$
Nash §2: conformal field theories in two dimensions		
conformal = holomorphic	f with $\partial_{\bar z} f = 0$ preserves angles, scales lengths by $\lvert f' \rvert$	everything in 2D
Witt algebra	$\ell_n = -z^{n+1}\partial_z$, $[\ell_m, \ell_n] = (m-n)\ell_{m+n}$	Virasoro; $\mathrm{Diff}(S^1)$ (Chapter 6)
Möbius group	$z \mapsto \frac{az+b}{cz+d}$, generated by $\ell_{-1}, \ell_0, \ell_1$; kills $\{f, z\}$	fixing three points; 2-, 3-point functions
primary field $(h, \bar h)$	transforms by $(f')^h (\bar f')^{\bar h}$; OPE with T stops at $(w-z)^{-2}$	all of §3–§5
free fermion, free boson	$c = \frac{1}{2}$ and $c = 1$; ψ primary $(\frac{1}{2}, 0)$, $\partial\phi$ primary $(1,0)$, $e^{ip\phi}$ primary $(\frac{p^2}{4}, \frac{p^2}{4})$	Ising (§4); vertex-operator fusion (§5); strings
stress tensor $T(z)$	$T = T_{zz}$, holomorphic; generates conformal maps via $\oint \varepsilon(z) T(z)$	Ward identities, L_n, moduli connection
central charge c	coefficient of $(w-z)^{-4}$ in TT; Casimir energy $-\pi c/6L$	Virasoro, modular T-phase, $c = 26$, anomaly
Schwarzian $\{f, z\}$	$f'''/f' - \frac{3}{2}(f''/f')^2$; zero iff f Möbius	cylinder shift $-c/24$; projective connection

concept	operational meaning	where it is used
Nash §3: relation to the Virasoro algebra		
Virasoro algebra	modes $L_n = \oint \frac{dz}{2\pi i} z^{n+1} T(z)$; central term $\frac{c}{12} m(m^2-1)$	representations (Chapter 6); Segal's λ
radial quantisation	time $= \ln\lvert z\rvert$, $H = L_0 + \bar{L}_0$; state $\lvert h\rangle = \phi(0)\lvert 0\rangle$	state–operator; Segal's discs
highest-weight state	$L_0\lvert h\rangle = h\lvert h\rangle$, $L_{n>0}\lvert h\rangle = 0$	Verma modules, characters
Verma module $V(c,h)$	span of $L_{-n_1}\cdots L_{-n_k}\lvert h\rangle$; $p(N)$ states at level N	characters $q^{h-c/24}/\prod(1-q^n)$
null vector / singular vector	descendant annihilated by L_1, L_2; zero norm; generates a submodule N	irreducible $L = V/N$; BPZ equations
Gram matrix, Kac determinant	matrix of inner products at level N; zeros at $h = h_{r,s}(c)$	unitarity; Ising weights
unitary minimal models	$c = 1 - \frac{6}{(m+1)(m+2)}$ (Nash's (6.58)), weights $h_{p,q}$	Ising ($m=2$), tricritical Ising ($m=3$), Potts
$\mathfrak{sl}(2,\mathbb{C})$ vacuum	L_{-1}, L_0, L_1 annihilate $\lvert 0\rangle$	Möbius covariance of correlators
Kac–Moody, Sugawara	currents J^a at level k; $T \propto \sum :J^a J^a:$; WZW	$SU(2)_k$ fusion; Chern–Simons (Chapter 12)
Nash §4: statistical mechanics (Sections 11.5 to 11.8)		
Ising model	$H = -J\sum \sigma_i\sigma_j$ on $\mathbb{Z}^2$; T_c from Kramers–Wannier	the prototype critical CFT
critical exponents	$\alpha, \beta, \gamma, \delta, \nu, \eta$; $\nu = 1/(2-2h_\varepsilon)$, $\eta = 4h_\sigma$	universality classes
Ising = minimal model	$c = \frac{1}{2}$; $\mathbf{1}, \sigma, \varepsilon$ with $h = 0, \frac{1}{16}, \frac{1}{2}$	fusion, Verlinde, blocks (§5)
torus, modulus τ	$\mathbb{C}/(\mathbb{Z}+\tau\mathbb{Z})$; $\tau \sim \frac{a\tau+b}{c\tau+d}$; fundamental domain	$\mathcal{M}_1$; one-loop strings
torus partition function	$Z = \mathrm{Tr}\, q^{L_0-c/24}\bar{q}^{\bar{L}_0-c/24} = \sum M_{h\bar{h}}\chi_h\bar{\chi}_{\bar{h}}$	modular invariance; Cardy; Segal's trace
character χ_h	$\mathrm{Tr}_{H_h}\, q^{L_0-c/24}$; a vector in the block space $V(T^2)$	Verlinde's S; modular functor
Dedekind η, theta functions	$\eta = q^{1/24}\prod(1-q^n)$; θ_i via Poisson summation	all explicit modular checks
modular form of weight k	$f(\frac{a\tau+b}{c\tau+d}) = (c\tau+d)^k f(\tau)$; a section of λ^k	η^{24}, discriminant; string measure
compact boson, T-duality	$Z(R) = \lvert\eta\rvert^{-2}\sum q^{p_L^2/4}\bar{q}^{p_R^2/4}$; $Z(R) = Z(2/R)$	strings on circles; $c=1$ moduli
ADE classification	modular invariants of $SU(2)_k \leftrightarrow$ ADE diagrams	classification of CFTs

Table 11.8: Chapter 11 concepts, part 2 (Nash §3–§4).

concept	operational meaning	where it is used
Nash §5: operator products and fusion rules (Sections 11.9 and 11.10)		
conformal family $[\phi]$	ϕ and all $L^I\bar{L}^J\phi$; closes under OPE with T	rational CFT
Ward reduction	$\langle (L_{-n}\phi)\cdots\rangle = \mathcal{L}_{-n}\langle\phi\cdots\rangle$, a differential operator	descendants from primaries
2-, 3-, 4-point functions	fixed by Möbius up to C_{ij}, C_{ijk}, and a function of the cross-ratio z	OPE coefficients; blocks
OPE of primaries	$\phi_i\phi_j = \sum_k C_{ij}^k \Psi_{ij}^k$, descendant coefficients β fixed by Virasoro	crossing, bootstrap
conformal block $\mathcal{F}(m,z)$	contribution of one family m to a four-point function; $z^{h_m-h_k-h_l}(1+\dots)$	monodromy; braid group (Chapter 12)
crossing symmetry	the s- and t-channel block expansions agree; associativity of the OPE	bootstrap; Moore–Seiberg
BPZ equation	a null vector gives a differential equation for correlators	exact Ising $\langle\sigma\sigma\sigma\sigma\rangle$
fusion rules N_{ij}^k	multiplicity of $[\phi_k]$ in $\phi_i\phi_j$; $\dim V(\Sigma_{0,3})$	Verlinde; knot invariants
block spaces $V(\Sigma_{p,n})$	finite-dim. spaces over $\mathcal{M}_{p,n}$, $\dim \mathcal{M}_{p,n} = 3p-3+n$; sewing rule	Hilbert spaces of Chern–Simons (Chapter 12)
Verlinde formula	S diagonalises fusion: $N_i = S\Lambda_i S^{-1}$	dimension formulas; quantum dimensions
dual rep., (11.75)	$\dim V(S_R^2) = \delta_{R,0}$, $\dim V(S_{R_i,R_j}^2) = \delta_{R_i,R_j^*}$	normalisation axiom of TQFT
Weierstrass gaps	exactly p impossible pole orders at a point of Σ_p	higher-genus Ward identities
Nash §5: axiomatics (Sections 11.11 and 11.12)		
genus sum, $\mathcal{R}$	$\exp Z = \int_{\mathcal{R}} I$, $\mathcal{R} = \prod_p \bigcup_n \mathrm{Sym}^n \mathcal{M}_p$	string perturbation theory
node, plumbing, stable curve	$xy = t$; neck operator $t^{L_0-c/24}\bar{t}^{\bar{L}_0-c/24}$; $\overline{\mathcal{M}}_p$	factorisation; degenerations
projective connection	transforms like $\frac{12}{c}T$; differences are quadratic differentials	T as a connection on E_c
anomaly bundle E_c	$E_c \cong \lambda^{c/2}$; $Z = h(\Psi,\Psi)$, $\Psi \in \Gamma(E_c \otimes W)$	$c = 26$ via Mumford; framing
Segal functor	surfaces with boundary $\mapsto$ operators; sewing = composition up to λ	Atiyah's TQFT axioms (Chapter 12)
modular functor	block spaces with gluing and normalisation axioms; projective mapping-class action	Chern–Simons, Jones polynomial (Chapter 12)

Table 11.9: Chapter 11 concepts, part 3 (Nash §5).

Which tool answers which question

- *What are the critical exponents of a 2D transition?* Identify the CFT by its central charge (Casimir energy of a finite chain) and its primaries; then $\nu = 1/(2 - 2h_\varepsilon)$, $\eta = 4h_\sigma$, and the others by scaling relations.
- *Which operators can a CFT contain?* Unitarity and the Kac determinant for $c < 1$; modular invariance of the torus partition function for the combinations $(h, \bar{h})$ and their multiplicities.
- *What is a correlation function?* Möbius invariance for two and three points; conformal blocks and crossing for four; null vectors for exact differential equations.
- *Which fields appear in a product?* The fusion rules, computed from the modular S matrix by Verlinde's formula, or from the indicial exponents of a BPZ equation.
- *How many independent amplitudes on a surface of genus p?* Sew three-punctured spheres: $\dim V(\Sigma_p) = \sum_m S_{0m}^{2-2p}$.
- *What is a CFT without a Lagrangian?* A section of a line bundle over the (stable, universal) moduli space (Friedan–Shenker), or a functor from surfaces to operators (Segal). Forgetting the complex structure gives a TQFT, the subject of Chapter 12.

Chapter 12

Topological Quantum Field Theories

Where this chapter is going

Every quantum field theory we have met so far needs a metric. The Yang–Mills action contains $F \wedge \star F$, and the Hodge star needs a metric. The string and conformal field theories of Chapters 9 and 11 need a little less: only the conformal class of a metric on a Riemann surface. This last chapter asks what happens if we throw away even that. Can we build a quantum field theory whose only input is the bare smooth manifold? Such a theory is a **topological quantum field theory** (TQFT). Its partition function is a number attached to a manifold that does not change when we deform the metric, so it is a *topological invariant*. Its Hilbert spaces are finite-dimensional, and every state has zero energy.

This sounds like a theory in which nothing happens. The surprise of the chapter is the opposite. TQFTs turn out to be machines for producing the deepest invariants known in low-dimensional topology, and the machines are built from ingredients we already have: Morse theory and its supersymmetric quantum mechanics (Chapter 7), instantons and their moduli spaces (Chapter 8), spectral flow and the index theorem (Chapters 4 and 10), and conformal field theory (Chapter 11).

The chapter has three strands.

- **Floer theory (§2).** Witten's Morse complex of Chapter 7 is rebuilt on the infinite-dimensional space $\mathcal{A}/\mathcal{G}$ of gauge orbits of SU(2) connections on a 3-manifold. The Morse function is the Chern–Simons functional. Its critical points are flat connections and its gradient flow lines are instantons on $M \times \mathbb{R}$. The result is Floer homology, a new invariant of homology 3-spheres, graded by $\mathbb{Z}_8$.
- **Donaldson theory (§3).** Moduli spaces of instantons on a 4-manifold carry cohomology classes. Integrating them gives Donaldson's polynomial invariants, which can tell apart 4-manifolds that are homeomorphic but not diffeomorphic. Witten showed that they are correlation functions of a topological field theory, and cutting a 4-manifold along a 3-manifold expresses them through Floer groups.
- **Chern–Simons theory and knots (§§4–7).** The Chern–Simons functional, used as an action, defines a TQFT in three dimensions. Expectation values of Wilson loops in it are knot invariants: the linking number in the abelian theory, the Jones polynomial in the SU(2) theory. Surgery and the modular data of a conformal field theory make the computation explicit.

This part of the notes covers §§1–3. Figure 12.1 shows how the ideas feed into each other.

One idea runs through the whole chapter, and it is worth stating now. In Chapter 7 the cohomology of a finite-dimensional manifold X was computed as the space of *zero-energy*

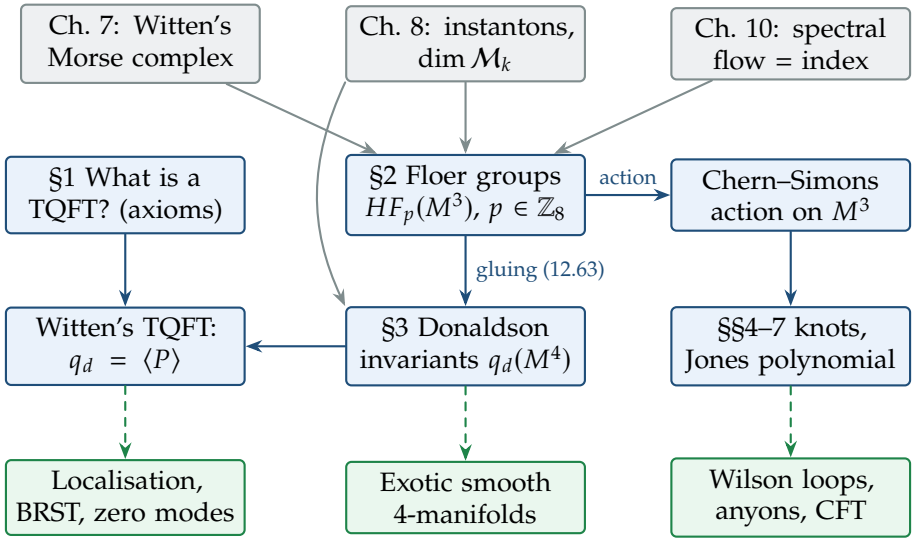

Figure 12.1: The logic of Chapter XII. Grey boxes are earlier chapters that feed in, blue boxes are this chapter, green boxes are the physics or mathematics that comes out. Read the middle column top to bottom: Morse theory on the space of gauge orbits gives Floer homology, and Floer homology is the "space of states" that glues Donaldson's 4-manifold invariants together. This part covers §§1–3.

states of a supersymmetric quantum mechanics on X. Classical vacua sat at the critical points of a function f, and instantons (steepest-descent paths) tunnelling between them decided which classical vacua survived as true quantum ground states. Floer theory is the same story with X replaced by $\mathcal{A}/\mathcal{G}$. Donaldson theory is its four-dimensional "relativistic" completion. Chern–Simons theory takes the Morse function itself and uses it as an action. In each case, a topological invariant is a *count* (of vacua, instantons or flat connections) done in a way that no deformation of the metric can change.

12.1 Introduction: quantum field theory without a metric

What is the least amount of structure on which one can build a quantum field theory? In the previous chapter the data were a Riemann surface Σ and its complex structure. Once those are fixed, the Hilbert space of the conformal field theory can be constructed. Nash's opening move is to discard the complex structure too, and with it every trace of a metric. A quantum field theory built from Σ alone (or from a manifold M of any dimension alone) is a topological quantum field theory.

This section explains what such a theory is, why its dynamics is "trivial" and yet its content is not, and how one axiomatises it. Nash gives the physical description in one paragraph (printed p. 322) and mentions at the end of the chapter that "an axiomatic approach, somewhat analogous to that introduced for conformal field theories, can be given, cf. Atiyah". We give those axioms here, with pictures and small examples, because they are the cleanest way to see what the later sections are computing.

12.1.1 No metric, no dynamics

Start with ordinary quantum mechanics or field theory on a spacetime M with metric $g_{\mu\nu}$. Time evolution is generated by the Hamiltonian H, and H is the integral over space of the energy

density T_{00}, a component of the energy–momentum tensor

$$T_{\mu\nu} = \frac{2}{\sqrt{g}} \frac{\delta S}{\delta g^{\mu\nu}}. \tag{12.1}$$

(We use the Euclidean sign conventions; the overall normalisation will not matter.) Now suppose the action S does not depend on the metric at all. Then $\delta S/\delta g^{\mu\nu} = 0$, so $T_{\mu\nu} = 0$, and

$$H \overset{(1)}{=} \int_{\text{space}} T_{00}\, \mathrm{d}^{d-1}x \overset{(2)}{=} 0. \tag{12.2}$$

(1) The Hamiltonian is the charge of time translations, and the conserved current of translations is the energy–momentum tensor.
(2) A metric-independent action has vanishing energy–momentum tensor, by (12.1).

So every state has energy zero. There is nothing like a particle moving from one place to another, because "distance" and "speed" do not exist without a metric. There are no forces. This is what Nash means by "no conventional dynamics".

A second consequence is that the Hilbert space is usually *finite-dimensional*. Here is the heuristic. In an ordinary field theory the Hilbert space is infinite-dimensional because there are infinitely many excitations (particles with any momentum). Each excitation costs energy. If all states have zero energy there is nowhere for the infinitely many excitations to live; what is left is a finite set of "vacua", typically labelled by topological data (flat connections, homology classes, conformal blocks). We will see this explicitly in the examples below.

Physical picture: Where the non-triviality lives: tunnelling between vacua

If $H = 0$, what can such a theory possibly compute? The answer is that it still has *several* vacua, and the quantum amplitudes between them are non-trivial numbers that depend only on the topology. In the Morse-theory language of Chapter 7: perturbation theory around each critical point of a function f produces one candidate ground state, but instantons tunnelling between critical points can pair some of them up and lift them. The surviving ground states count the cohomology. The information is in *which* vacua are connected by tunnelling, and with what sign. That is Nash's sentence "the non-triviality of the theory is reflected in the existence of tunnelling between vacua".

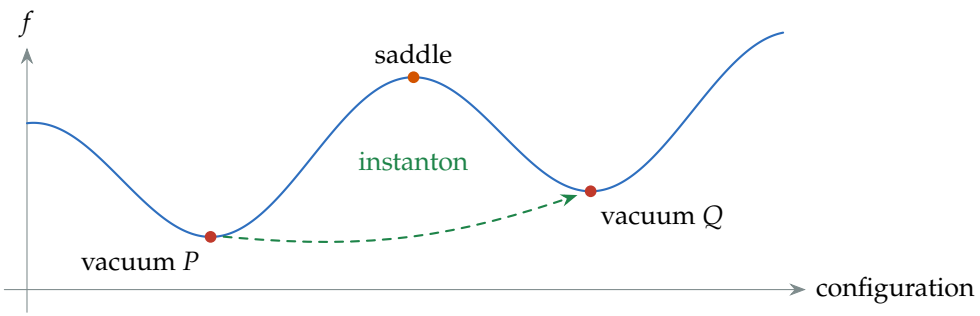

Figure 12.2: Two classical vacua (red) separated by a barrier. With $H = 0$ nothing moves classically, but the Euclidean path integral contains instantons (green) that tunnel from one vacuum to another. A topological theory is controlled entirely by the pattern and signs of such tunnelling events.

12.1.2 Two ways to be topological

There are two ways to make the physics independent of the metric, and this chapter uses both.

Working definition 12.1 (Schwarz-type and Witten-type TQFTs)

A quantum field theory is **topological** if its correlation functions (including the partition function) do not change when the metric is varied [the answers depend only on the shape of the manifold up to smooth deformation, not on any lengths or angles]. *Test:* vary $g_{\mu\nu}$ inside a correlator and show the answer is zero.

- **Schwarz type**: the action contains no metric at all, so $T_{\mu\nu} = 0$ identically [$T_{\mu\nu} = \delta S/\delta g^{\mu\nu}$, the response of the action to a change of metric]. Example: the Chern–Simons action $\int \mathrm{tr}(A \wedge \mathrm{d}A + \frac{2}{3} A \wedge A \wedge A)$ on a 3-manifold (Section 12.5).
- **Witten type** or **cohomological**: the action does contain a metric, but there is a fermionic symmetry Q [a symmetry that turns bosonic fields into fermionic ones and back, like a BRST operator] with $Q^2 = 0$ (on gauge-invariant quantities) such that both the action and $T_{\mu\nu}$ are Q-exact [equal to Q acting on something. The vacuum expectation value of any such term is zero]: $S = \{Q, V\}$, $T_{\mu\nu} = \{Q, V_{\mu\nu}\}$. Example: Witten's theory of Donaldson invariants (Section 12.7).

In a Witten-type theory, H is not zero as an operator, but it is Q-exact, and the physical states are Q-cohomology classes. On them H acts as zero. The supersymmetric quantum mechanics of Chapter 7 is the prototype: $H = \{Q, Q^\dagger\}$, and the ground states represent the cohomology.

12.1.3 Atiyah's axioms: a TQFT is a machine on cobordisms

The cleanest way to say what a TQFT *is* goes back to Atiyah (1988), following Segal's axioms for conformal field theory. The idea is to write down the structure that a path integral would have, if it existed, and take that structure as the definition.

Think of a d-dimensional Euclidean spacetime M whose boundary is a disjoint union of $(d-1)$-dimensional "space slices". In a path integral:

- a closed space slice Σ has a space of states $Z(\Sigma)$ (wave functionals of the fields on Σ);
- a spacetime M with boundary $\partial M = \Sigma$ produces a state $Z(M) \in Z(\Sigma)$: the path integral over fields on M with prescribed boundary values on Σ, viewed as a function of those boundary values;
- a spacetime M running from an "in" slice Σ_0 to an "out" slice Σ_1 gives a linear map $Z(M) : Z(\Sigma_0) \to Z(\Sigma_1)$, the Euclidean evolution operator.

Such an M is called a **cobordism** from Σ_0 to Σ_1. Orientation matters: $\bar{\Sigma}$ denotes Σ with the opposite orientation.

Working definition 12.2 (Atiyah's axioms for a d-dimensional TQFT)

A TQFT Z assigns

- to every closed oriented $(d-1)$-manifold Σ [a space slice, compact with no boundary], a finite-dimensional complex vector space $Z(\Sigma)$;
- to every compact oriented d-manifold M with $\partial M = \Sigma$ a vector $Z(M) \in Z(\Sigma)$ [the state on Σ prepared by the path integral over M],

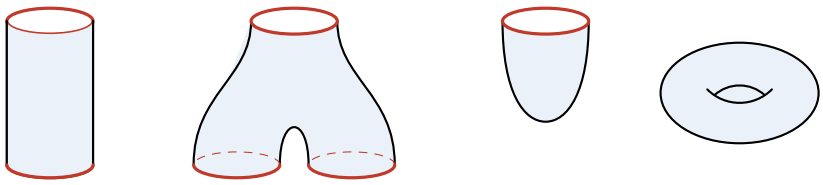

Figure 12.3: Cobordisms in two dimensions and what a TQFT assigns to them. Time runs upward: the bottom circles are "in", the top circles are "out". Red circles are boundaries, each carrying the vector space $V = Z(S^1)$. The cylinder is the identity map, whatever its length. The disc with its circle on top is the unit $1 \in V$; turned upside down it is the trace $\theta : V \to \mathbb{C}$. A closed surface has no boundary, so it is a map $\mathbb{C} \to \mathbb{C}$, that is, a number.

such that:

(A1) *Naturality.* A diffeomorphism $\Sigma \to \Sigma'$ induces an isomorphism $Z(\Sigma) \to Z(\Sigma')$, compatible with the vectors $Z(M)$.

(A2) *Orientation reversal.* $Z(\bar{\Sigma}) = Z(\Sigma)^*$ (the dual space).

(A3) *Multiplicativity.* $Z(\Sigma_1 \sqcup \Sigma_2) = Z(\Sigma_1) \otimes Z(\Sigma_2)$, and $Z(\varnothing) = \mathbb{C}$.

(A4) *Gluing.* If M_1 has boundary $\bar{\Sigma}_0 \sqcup \Sigma_1$ and M_2 has boundary $\bar{\Sigma}_1 \sqcup \Sigma_2$, then $Z(M_1 \cup_{\Sigma_1} M_2) = Z(M_2) \circ Z(M_1)$, where by (A2), (A3) we read $Z(M_i)$ as linear maps $Z(\Sigma_{i-1}) \to Z(\Sigma_i)$.

(A5) *Identity.* $Z(\Sigma \times [0,1]) = \mathrm{id}_{Z(\Sigma)}$.

Operational reading: to compute Z of anything, cut it into simple pieces, compute each piece as a vector or matrix, and multiply the matrices. *Formally*, a TQFT is a symmetric monoidal functor from the cobordism category [objects are closed $(d-1)$-manifolds, arrows are the d-manifolds joining them, and "monoidal" means $\sqcup$ goes to $\otimes$] to the category of vector spaces.

Let us see what these axioms buy us.

Closed manifolds give numbers. A closed d-manifold M has $\partial M = \varnothing$, so $Z(M) \in Z(\varnothing) = \mathbb{C}$. This number is the partition function. Axiom (A1) says it depends only on the diffeomorphism class of M: it is an invariant.

The Hamiltonian vanishes. The cylinder $\Sigma \times [0,T]$ is the Euclidean evolution operator e^{-TH}. Axiom (A5) says it is the identity, for every T (a cylinder of length T is diffeomorphic to one of length 1). So

$$\begin{aligned} -H &\overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}T} e^{-TH}\Big|_{T=0} \\ &\overset{(2)}{=} \frac{\mathrm{d}}{\mathrm{d}T} \mathrm{id} \\ &= 0. \end{aligned}$$

(1) Differentiate the evolution operator at $T = 0$.
(2) $Z(\Sigma \times [0,T]) = \mathrm{id}$ for all T, by (A5) and (A1).

This is the axiomatic form of (12.2).

The dimension of the space of states is a partition function. Glue the two ends of the cylinder $\Sigma \times [0,1]$ together. The result is $\Sigma \times S^1$. Gluing an in-boundary to an out-boundary is taking

a trace (it is the "sum over intermediate states" of the path integral with periodic boundary conditions). So

$$\begin{aligned} Z(\Sigma \times S^1) &\overset{(1)}{=} \mathrm{Tr}_{Z(\Sigma)}\big(Z(\Sigma \times [0,1])\big) \\ &\overset{(2)}{=} \mathrm{Tr}_{Z(\Sigma)}\,\mathrm{id} \\ &= \dim Z(\Sigma). \end{aligned} \tag{12.3}$$

(1) Gluing the out-end to the in-end contracts the $Z(\Sigma)$ and $Z(\Sigma)^*$ indices of the cylinder, which is a trace.
(2) Axiom (A5).

Physically, (12.3) is the statement $\mathrm{Tr}\, e^{-\beta H} = \mathrm{Tr}\,\mathrm{id} = \dim \mathcal{H}$ when $H = 0$: the thermal partition function counts ground states. The same formula will turn up in the knot sections of the chapter, and it is the reason finite-dimensionality is forced: $\dim Z(\Sigma)$ is a (finite) number.

Worked example 12.1: The simplest TQFT: $d = 1$

In one dimension the closed 0-manifolds are finite sets of oriented points. Let $Z(+) = V$, a vector space of dimension n, so $Z(-) = V^*$ by (A2). Pick a basis e_i of V and the dual basis e^i of V^*.
An interval bent into a "cap" has boundary $\{+\} \sqcup \{-\}$ as an in-boundary; it is a map $\mathrm{ev} : V \otimes V^* \to \mathbb{C}$, the evaluation $v \otimes \alpha \mapsto \alpha(v)$. Bent the other way (a "cup") it is a map $\mathrm{coev} : \mathbb{C} \to V \otimes V^*$, $1 \mapsto \sum_i e_i \otimes e^i$. The circle is a cup followed by a cap. So

$$\begin{aligned} Z(S^1) &\overset{(1)}{=} \mathrm{ev} \circ \mathrm{coev}(1) \\ &\overset{(2)}{=} \textstyle\sum_{i=1}^{n} e^i(e_i) \\ &\overset{(3)}{=} n. \end{aligned}$$

(1) Cut the circle into two arcs and use the gluing axiom (A4).
(2) Definitions of coev and ev.
(3) $e^i(e_j) = \delta^i_j$.

This is (12.3) with $\Sigma =$ point. Physically it is quantum mechanics of a system with an n-dimensional Hilbert space and $H = 0$: the partition function on a circle of any circumference β is $\mathrm{Tr}\, e^{-\beta \cdot 0} = n$.

Worked example 12.2: Two dimensions: a commutative Frobenius algebra

In two dimensions the only closed connected 1-manifold is the circle, so the theory is determined by the single space $V = Z(S^1)$ and by what the basic cobordisms of Figure 12.3 do. The pair of pants (two circles in, one out) is a product $m : V \otimes V \to V$. The disc read as "one circle in, nothing out" is a linear functional $\theta : V \to \mathbb{C}$ (the "trace"). The disc read the other way is a unit $1 \in V$. Because pants can be deformed into each other in the ways drawn by topologists, m is associative and commutative, and $\langle a, b\rangle = \theta(ab)$ is a non-degenerate pairing. Such a structure is a **commutative Frobenius algebra**.
Take the simplest one: $V = \mathbb{C}^n$ with basis $e_1, \dots, e_n$ of idempotents, $e_i e_j = \delta_{ij} e_i$, unit $1 = \sum_i e_i$, and $\theta(e_i) = \theta_i \neq 0$. The pairing is $\langle e_i, e_j\rangle = \delta_{ij}\theta_i$, so the copairing (the cylinder bent into a U with two out-circles) is $\sum_i e_i \otimes e_i/\theta_i$. A handle is "copairing then multiply":

$$h \overset{(1)}{=} m\Big(\textstyle\sum_i \theta_i^{-1}\, e_i \otimes e_i\Big)$$

$$\overset{(2)}{=} \textstyle\sum_i \theta_i^{-1}\, e_i .$$

(1) A handle is a tube that splits and rejoins: copairing followed by the product.
(2) $e_i e_i = e_i$.

A closed genus-g surface is a disc (the unit 1), then g handles, then a cap (θ):

$$\begin{aligned} Z(\Sigma_g) &\overset{(1)}{=} \theta\big(h^g \cdot 1\big) \\ &\overset{(2)}{=} \theta\Big(\textstyle\sum_i \theta_i^{-g} e_i\Big) \\ &= \textstyle\sum_{i=1}^{n} \theta_i^{1-g}. \end{aligned}$$

(1) Cut Σ_g into a disc, g one-holed tori, and a disc, and glue with (A4).
(2) Idempotents multiply diagonally, so $h^g = \sum_i \theta_i^{-g} e_i$, and $h^g \cdot 1 = h^g$.

Check: for the torus $g = 1$ we get $\sum_i 1 = n = \dim V$, exactly as (12.3) demands for $\Sigma \times S^1 = S^1 \times S^1$.

Worked example 12.3: Gauge theory with a finite gauge group counts flat connections

Here is a physical 2d TQFT. Let G be a finite group and do "lattice gauge theory" on a surface with gauge group G. Since G is discrete, there is no curvature to integrate: every connection is flat, and a flat connection is determined up to gauge by its holonomies, a homomorphism $\rho : \pi_1(\Sigma) \to G$ up to conjugation. The path integral, with the natural normalisation (divide by the volume $|G|$ of the gauge group at a base point), is

$$Z(\Sigma_g) \;=\; \frac{\#\operatorname{Hom}\big(\pi_1(\Sigma_g), G\big)}{|G|}. \tag{12.4}$$

One can show it is the Frobenius algebra of class functions on G, with $\theta_R = (\dim R/|G|)^2$ for the irreducible representations R, so that $Z(\Sigma_g) = \sum_R (\dim R/|G|)^{2-2g}$. Let us test this on $G = S_3$ (order 6; irreducible representations of dimensions $1, 1, 2$; three conjugacy classes).
Sphere. $\pi_1(S^2) = 1$, so only the trivial homomorphism exists:

$$Z(S^2) \overset{(1)}{=} \tfrac{1}{6} \overset{(2)}{=} \tfrac{1^2+1^2+2^2}{6^2} = \tfrac{6}{36}.$$

(1) Formula (12.4) with one homomorphism.
(2) Frobenius formula at $g = 0$; the numbers agree because $\sum_R (\dim R)^2 = |G|$.

Torus. $\pi_1(T^2) = \mathbb{Z}^2$, so a homomorphism is a commuting pair (a, b). For each a the number of b commuting with it is the order of the centraliser of a: 6 for the identity, 2 for each of the 3 transpositions, 3 for each of the 2 three-cycles. So

$$Z(T^2) \overset{(1)}{=} \tfrac{1}{6}\,(6 + 3\cdot 2 + 2\cdot 3) = \tfrac{18}{6} = 3 \overset{(2)}{=} 1 + 1 + 1.$$

(1) Count commuting pairs using centralisers.
(2) Frobenius formula at $g = 1$: one term per irreducible representation.

And $3 = \dim Z(S^1)$, the number of class functions, as (12.3) requires.

Physical picture: The same set will come back

The partition function of a gauge theory whose only field configurations are flat connections *counts* $\mathrm{Hom}(\pi_1, G)/G$. Keep this in mind: in §2 the critical points of the Chern–Simons functional on a 3-manifold are exactly the flat SU(2) connections, $\mathrm{Hom}(\pi_1(M), \mathrm{SU}(2))/\mathrm{Ad}\,\mathrm{SU}(2)$, and Casson's invariant is a *signed* count of them.

Watch out: Axioms are not a construction

Atiyah's axioms tell us what structure a TQFT has. They do not tell us how to find one in dimension 3 or 4. The theories of this chapter are constructed from physics: an action, a path integral, and a lot of analysis (Floer, Donaldson) to make the resulting counts rigorous. In dimension 4, Floer homology is only a partial fit to the axioms: it is defined only for homology 3-spheres and is $\mathbb{Z}_8$-graded rather than a plain vector space.

12.1.4 Where the first TQFT comes from

Topological field theories are not restricted to two dimensions. In three dimensions (Chern–Simons theory) they compute knot invariants; in four dimensions (Witten's theory) they compute Donaldson invariants. Nash's plan is to find the first one by *generalising a quantum-mechanical construction we already understand*: the supersymmetric quantum mechanics whose ground states are the de Rham cohomology of a manifold. Replacing the manifold by the infinite-dimensional space of gauge orbits, and the Morse function by the Chern–Simons functional, leads to Floer homology, and at the very end, to the Chern–Simons TQFT. This is the subject of the next four sections of these notes.

Dictionary: TQFT words

Mathematics	Physics
closed $(d-1)$-manifold Σ	a space slice
$Z(\Sigma)$	Hilbert space of states on Σ
cobordism $M : \Sigma_0 \to \Sigma_1$	Euclidean spacetime history
$Z(M) : Z(\Sigma_0) \to Z(\Sigma_1)$	path integral with fixed boundary values; evolution operator
$Z(\Sigma \times I) = \mathrm{id}$	$H = 0$
$Z(M)$, M closed	partition function; topological invariant
$Z(\Sigma \times S^1) = \dim Z(\Sigma)$	$\mathrm{Tr}\, e^{-\beta H}$ counts ground states
gluing axiom	inserting a complete set of states

Reading Nash (p. 322, §1)

Nash's §1 is one paragraph. He says: a CFT needs Σ plus a complex structure; drop the complex structure and the metric and you get a TQFT; without a metric there are no distances, forces or conventional dynamics; the Hamiltonian has only zero eigenstates and the Hilbert space is usually finite-dimensional; the theory is non-trivial because of tunnelling between vacua; there is an axiomatic approach (Atiyah) analogous to the one for CFTs; and the first example will arise from a field-theory version of the Morse theory of his Chapter 7. We have expanded each clause: $H = 0$ from $T_{\mu\nu} = 0$ or from the cylinder axiom; finite-dimensionality from $Z(\Sigma \times S^1) = \dim Z(\Sigma)$; and explicit TQFTs in dimensions 1 and 2.

Recap

- A TQFT is a quantum field theory whose correlation functions do not depend on the metric. Closed manifolds get numbers (invariants), space slices get finite-dimensional state spaces.
- Schwarz type: metric-free action (Chern–Simons). Witten type: action and $T_{\mu\nu}$ are Q-exact (Donaldson–Witten).
- Atiyah's axioms: cut, compute pieces, compose. Consequences: $H = 0$ and $Z(\Sigma\times S^1) = \dim Z(\Sigma)$.
- 2d TQFTs are commutative Frobenius algebras; $Z(\Sigma_g) = \sum_i \theta_i^{1-g}$. Finite-group gauge theory counts flat connections.
- The content of a TQFT is in tunnelling between its vacua.

12.2 Floer's programme and the Chern–Simons function

In Chapter 7 a function f on a finite-dimensional manifold X was enough to rebuild the cohomology of X: critical points of f became basis vectors of a complex, and gradient flow lines (instantons of a supersymmetric quantum mechanics) became the matrix elements of its coboundary. Floer asked: what if X is the space of all gauge fields on a 3-manifold, and f is the most natural gauge-theory function there is? This section sets up the stage: which space, which bundle, which gauge group and which function. The key discovery is that the natural function, the Chern–Simons functional, is not quite gauge invariant: it shifts by *integers*. That integer shift will eventually produce the $\mathbb{Z}_8$ grading of Floer homology.

Nash's §2 is long. We split it into four sections of these notes: this one (the function), Section 12.3 (critical points, Hessian, relative index), Section 12.4 (gradient flow and instantons, the number 8) and Section 12.5 (Floer groups, Casson's invariant, Chern–Simons theory and Floer's Hamiltonian).

12.2.1 Reminder: Witten's Morse complex

Here is what we need from Chapter 7, in one place. Let X be a compact Riemannian manifold of dimension n and $f : X \to \mathbb{R}$ a Morse function (all critical points non-degenerate). At a critical point x the Hessian $\partial^2 f/\partial x^i \partial x^j$ is a symmetric matrix; its number of negative eigenvalues is the **Morse index** λ_x.

The supersymmetric quantum mechanics on X has Hilbert space

$$\mathcal{H} \;=\; \bigoplus_{p\geq 0} \Omega^p(X), \tag{12.5}$$

the space of all differential forms (Nash's (12.1)). A p-form is a state with p fermions, so even p are bosonic and odd p are fermionic. The supercharge is the exterior derivative d, and the Hamiltonian is the Hodge Laplacian $\mathrm{d}\mathrm{d}^* + \mathrm{d}^*\mathrm{d}$, whose zero-energy states (harmonic forms) represent $H^*_{\mathrm{dR}}(X)$.

Witten deformed d to $\mathrm{d}_t = e^{-tf}\,\mathrm{d}\,e^{tf}$. For large t the low-energy states localise at the critical points of f: one approximate ground state per critical point, a p-form if the index is p. So the

approximate ground states span

$$C^p \;=\; \bigoplus_{\text{crit. pts } x,\ \lambda_x = p} \mathbb{R}\cdot x. \tag{12.6}$$

Tunnelling (instantons) between critical points lifts some of them. The exact statement is that there is a **coboundary**

$$\cdots \xrightarrow{\delta} C^p \xrightarrow{\delta} C^{p+1} \xrightarrow{\delta} \cdots, \qquad \delta x \;=\; \sum_{\lambda_y = \lambda_x + 1} n(x,y)\, y, \tag{12.7}$$

where $n(x,y)$ is the number of gradient flow lines running between y and x, counted with signs from orientations. Then $\delta^2 = 0$ and $\operatorname{Ker}\delta/\operatorname{Im}\delta \cong H^*_{\mathrm{dR}}(X)$. This is Nash's (12.12).

Worked example 12.4: The Morse complex of a circle with four critical points

Let $X = S^1$ with angle ϑ, and $f = \cos 2\vartheta$. Then $f' = -2\sin 2\vartheta$ vanishes at $\vartheta = 0, \pi/2, \pi, 3\pi/2$, and $f'' = -4\cos 2\vartheta$ is -4 at $0, \pi$ (maxima, index 1) and $+4$ at $\pi/2, 3\pi/2$ (minima, index 0). Call the minima m_1, m_2 and the maxima M_0, M_π. So $C^0 = \mathbb{R}m_1 \oplus \mathbb{R}m_2$ and $C^1 = \mathbb{R}M_0 \oplus \mathbb{R}M_\pi$.

Each minimum is joined to each maximum by exactly one flow line (an arc of the circle). Orient S^1 anticlockwise and give a flow line from a minimum up to a maximum the sign $+1$ if it runs anticlockwise, -1 if clockwise. From m_1 ($\vartheta = \pi/2$) the arc to M_π is anticlockwise and the arc to M_0 is clockwise. From m_2 ($\vartheta = 3\pi/2$) the arc to M_0 ($= 2\pi$) is anticlockwise and the arc to M_π clockwise. Hence

$$\delta m_1 = M_\pi - M_0, \qquad\qquad \delta m_2 = M_0 - M_\pi.$$

The kernel of δ on C^0 is spanned by $m_1 + m_2$, and the image is spanned by $M_0 - M_\pi$. So

$$H^0 \overset{(1)}{=} \operatorname{Ker}\delta|_{C^0} = \mathbb{R}(m_1 + m_2) \cong \mathbb{R},$$
$$H^1 \overset{(2)}{=} C^1/\operatorname{Im}\delta = \frac{\mathbb{R}M_0 \oplus \mathbb{R}M_\pi}{\mathbb{R}(M_0 - M_\pi)} \cong \mathbb{R}.$$

(1) There is no C^{-1}, so H^0 is the kernel alone.
(2) There is no C^2, so everything in C^1 is closed.

These are the Betti numbers $b_0 = b_1 = 1$ of the circle, although f has four critical points. The two "extra" vacua have been paired off by tunnelling.

Floer's idea is to run exactly this machine with X infinite-dimensional:

	Chapter 7	Floer
space X	compact manifold M	gauge orbits $\mathcal{A}/\mathcal{G}$ over a 3-manifold
function f	any Morse function	the Chern–Simons functional
critical points	$\mathrm{d}f = 0$	flat connections
flow lines	$\dot{x} = -\nabla f$	instantons on $M \times \mathbb{R}$
index	finite, λ_x	infinite; only differences defined, mod 8
output	$H^*_{\mathrm{dR}}(M)$	Floer groups $HF_p(M)$, $p \in \mathbb{Z}_8$

With an arbitrary f on an arbitrary $\mathcal{A}/\mathcal{G}$ this would be hopeless. Floer made very specific choices, which we now describe.

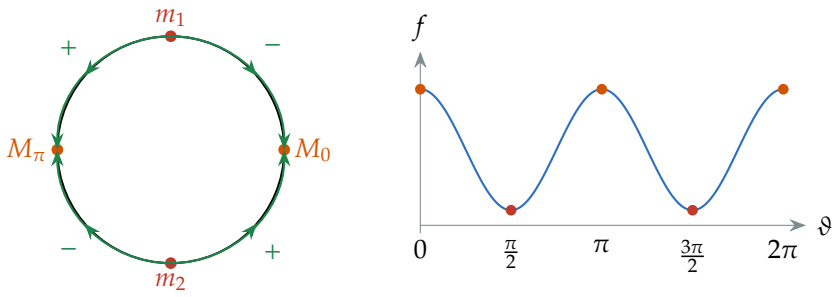

Figure 12.4: Left: the circle with $f = \cos 2\vartheta$, two minima (red) and two maxima (orange). Green arrows are the four flow lines from minima up to maxima, with the orientation signs used in the coboundary. Right: the graph of f. Each minimum sees the two maxima with opposite signs, so $\delta(m_1 + m_2) = 0$ and one combination of maxima is exact.

12.2.2 The stage: SU(2) connections on a homology 3-sphere

Floer's choice (Nash's (12.2)) is

$$\mathcal{A} \;=\; \{\text{SU(2) connections on a closed orientable 3-manifold } M\}. \tag{12.8}$$

Throughout the Floer part of this chapter M is three-dimensional. (In the Donaldson sections, Section 12.6 onwards, M will be four-dimensional; we will warn again.)

Connections as matrices of 1-forms

Recall the conventions (see Chapter T3). Over a region where the bundle is trivial, an SU(2) connection is a 2×2 matrix of 1-forms

$$A = A^a_\mu \, T_a \, \mathrm{d}x^\mu, \qquad T_a = -\tfrac{i}{2}\sigma_a, \tag{12.9}$$

with the Pauli matrices

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

The T_a are anti-Hermitian and traceless, so they span $\mathfrak{su}(2)$. From $\sigma_a\sigma_b = \delta_{ab} + i\varepsilon_{abc}\sigma_c$ we get

$$[T_a, T_b] \overset{(1)}{=} -\tfrac{1}{4}[\sigma_a, \sigma_b] \overset{(2)}{=} -\tfrac{1}{4} \cdot 2i\varepsilon_{abc}\sigma_c \overset{(3)}{=} \varepsilon_{abc} T_c,$$
$$\operatorname{tr}(T_a T_b) \overset{(4)}{=} -\tfrac{1}{4}\operatorname{tr}(\sigma_a\sigma_b) = -\tfrac{1}{2}\delta_{ab}.$$

(1) $T_aT_b = (-\frac{i}{2})^2\sigma_a\sigma_b = -\frac{1}{4}\sigma_a\sigma_b$.
(2) The symmetric part δ_{ab} cancels in the commutator.
(3) $-\frac{1}{4}\cdot 2i\,\varepsilon_{abc}\sigma_c = \varepsilon_{abc}\big(-\frac{i}{2}\sigma_c\big)$, and $-\frac{i}{2}\sigma_c = T_c$.
(4) $\operatorname{tr}\sigma_a\sigma_b = 2\delta_{ab}$.

So $-\operatorname{tr}(XY)$ is a positive-definite inner product on $\mathfrak{su}(2)$: for $X = X^aT_a$, $-\operatorname{tr}(X^2) = \frac{1}{2}\sum_a (X^a)^2$. The curvature is $F = \mathrm{d}A + A \wedge A$, and a gauge transformation $g : M \to \mathrm{SU}(2)$ acts by

$$A \mapsto A^g = g^{-1}Ag + g^{-1}\mathrm{d}g, \qquad F \mapsto F^g = g^{-1}Fg. \tag{12.10}$$

Dictionary: Gauge-field conventions

Nash and these notes use anti-Hermitian A. A physicist writes $A_{\text{math}} = -i\, g_{\text{YM}}\, A^a_{\text{phys}}\, \frac{\sigma_a}{2}$ with real A^a_{phys} and coupling g_{YM}; then $F_{\text{math}} = -i\, g_{\text{YM}}\, F^a_{\text{phys}}\, \frac{\sigma_a}{2}$ and $-\operatorname{tr}(F_{\text{math}} \wedge \star F_{\text{math}}) = \frac{g_{\text{YM}}^2}{2} F^a_{\text{phys}} \wedge \star F^a_{\text{phys}}$, a positive energy density. For SU(2) the physicist's A^a and our A^a of (12.9) are related by $A^a = g_{\text{YM}} A^a_{\text{phys}}$.

Homology 3-spheres

Nash adds an assumption in a footnote: $H_1(M;\mathbb{Z}) = 0$.

Working definition 12.3 (homology 3-sphere)

A closed oriented 3-manifold M is a **homology 3-sphere** if it has the same integer homology as S^3 [$H_k(M;\mathbb{Z})$ records the closed k-dimensional cycles in M that are not boundaries, counted with integer coefficients]:

$$H_0(M;\mathbb{Z}) = \mathbb{Z}, \quad H_1(M;\mathbb{Z}) = 0, \quad H_2(M;\mathbb{Z}) = 0, \quad H_3(M;\mathbb{Z}) = \mathbb{Z}.$$

Test: compute $H_1(M;\mathbb{Z})$, which is the abelianisation $\pi_1(M)/[\pi_1,\pi_1]$ of the fundamental group [the loop group $\pi_1(M)$ with every commutator $aba^{-1}b^{-1}$ set equal to 1]. If it vanishes, M is a homology sphere; the other groups follow automatically.

Why do the others follow? $H_0 = H_3 = \mathbb{Z}$ for any closed connected oriented 3-manifold. For H_2 we use Poincaré duality and the universal coefficient theorem:

$$\begin{aligned} H_2(M;\mathbb{Z}) &\overset{(1)}{=} H^1(M;\mathbb{Z}) \\ &\overset{(2)}{=} \operatorname{Hom}\big(H_1(M;\mathbb{Z}),\mathbb{Z}\big) \\ &\overset{(3)}{=} 0. \end{aligned}$$

(1) Poincaré duality in dimension 3: $H_k \cong H^{3-k}$.
(2) H^1 is always torsion-free and equals the homomorphisms from H_1 to $\mathbb{Z}$ (a class in H^1 is "what you get when you integrate a closed 1-form around 1-cycles").
(3) $H_1 = 0$.

In words: a homology sphere has no non-contractible surfaces and no *abelian* loops, but it may have a highly non-abelian fundamental group.

Worked example 12.5: Homology spheres that are not spheres

- S^3 itself, with $\pi_1 = 1$.
- The **Poincaré homology sphere** $\Sigma(2,3,5)$. It can be built by gluing opposite faces of a solid dodecahedron with a $\pi/5$ twist, or as the quotient $\mathrm{SU}(2)/I^*$, where $I^* \subset \mathrm{SU}(2)$ is the binary icosahedral group of order 120. Then $\pi_1 = I^*$, which has the presentation $\langle x, y \mid (xy)^2 = x^3 = y^5 \rangle$. This group is *perfect*: every element is a product of commutators, so $H_1 = I^*/[I^*,I^*] = 0$ even though π_1 has 120 elements.
- The **Brieskorn spheres** $\Sigma(p,q,r) = \{z_1^p + z_2^q + z_3^r = 0\} \cap S^5 \subset \mathbb{C}^3$ for pairwise coprime $p,q,r \geq 2$. The case $(2,3,5)$ is the Poincaré sphere. Their fundamental groups are $\langle x,y,z \mid x^p = y^q = z^r = xyz \rangle$ (the element xyz is central).

Let us check $H_1(\Sigma(2,3,5)) = 0$ from the presentation. To abelianise, let x, y commute and write the group additively. The relations $(xy)^2 = x^3 = y^5$ become two linear equations for the two generators x, y:

$$\begin{aligned} 2x + 2y = 3x \ \text{ and } \ 3x = 5y &\overset{(1)}{=} x = 2y \ \text{ and } \ 3x = 5y \\ &\overset{(2)}{=} 6y = 5y \\ &\overset{(3)}{=} y = 0, \ \ x = 0. \end{aligned}$$

(1) Rearranging the first equation, $x = 2y$.
(2) Substitute $x = 2y$ into the second.
(3) Subtract; then $x = 2y = 0$.

So both generators die: $H_1 = 0$. The same computation in matrix form: the relation matrix has rows $(1, -2)$ and $(3, -5)$, with determinant $-5 + 6 = 1$, and an integer matrix of determinant ± 1 presents the trivial group. For a general Brieskorn sphere, the analogous determinant is ± 1 precisely because p, q, r are pairwise coprime.

Watch out: Presentations and abelianisation

Abelianising is a mechanical recipe: write each relation additively, put the coefficients into an integer matrix, and read off $\mathbb{Z}^{\#\text{gens}}$ modulo the row lattice. The order of the result (when finite) is the gcd of the maximal minors. A small slip in a presentation changes the answer completely: $\langle a, b \mid a^2 = b^3 = (ab)^5 \rangle$, which looks similar, has abelianisation $\mathbb{Z}_{19}$, not 0. Always use a presentation you have checked against a known invariant.

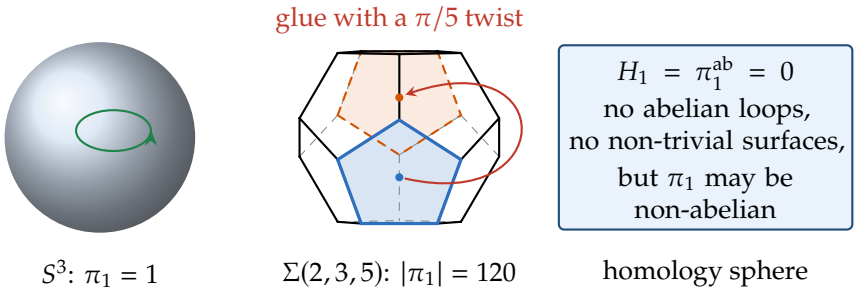

Figure 12.5: Two homology 3-spheres. Left: S^3, where every loop contracts. Middle: the Poincaré sphere, obtained from a dodecahedron by gluing each face to the opposite one after a twist by $\pi/5$; the red arrow shows one such pair, the front face (blue) and the back face (dashed orange). Its fundamental group has 120 elements but no abelian quotient. Floer theory detects exactly this kind of non-abelian topology, through flat SU(2) connections.

Why impose $H_1 = 0$? Nash says: "to avoid difficulties with reducible connections". We will see the reason in Section 12.3.2: on a homology sphere, the only flat connection with a large stabiliser is the trivial one.

12.2.3 Every SU(2) bundle over a 3-manifold is trivial

Before writing down f, Nash digresses to show that there is only one SU(2) bundle over M, the product $M \times \text{SU}(2)$. This matters because then a connection is a single global matrix of 1-forms, and gauge transformations are simply maps $M \to \text{SU}(2)$.

Picture 1: $\mathrm{SU}(2)$ is the 3-sphere of unit quaternions

Every $g \in \mathrm{SU}(2)$ has the form

$$g = \begin{pmatrix} \alpha & -\bar{\beta} \\ \beta & \bar{\alpha} \end{pmatrix}, \qquad |\alpha|^2 + |\beta|^2 = 1, \tag{12.11}$$

since the columns must be orthonormal and $\det g = 1$. Writing $\alpha = x^4 + ix^3$, $\beta = x^2 + ix^1$ (one convenient choice), $g = x^4\,\mathbf{1} + i(x^1\sigma_1 + x^2\sigma_2 + x^3\sigma_3)$ and the condition is $\sum_\mu (x^\mu)^2 = 1$. So $\mathrm{SU}(2)$ is the unit sphere $S^3 \subset \mathbb{R}^4$. The matrices $1, i\sigma_1, i\sigma_2, i\sigma_3$ multiply like the quaternions $1, \mathbf{k}, \mathbf{j}, \mathbf{i}$ (up to ordering), so $\mathrm{SU}(2)$ is the group of unit quaternions.

Picture 2: the classifying space $B\mathrm{SU}(2) = \mathbb{H}P^\infty$

Principal G-bundles over M are classified by homotopy classes of maps $[M, BG]$ into the classifying space (Chapter 1). In Chapter 7 we saw $B\mathrm{U}(1) = \mathbb{C}P^\infty$: $\mathrm{U}(1)$ acts freely on the unit sphere $S^\infty \subset \mathbb{C}^\infty$ by scalar multiplication, S^∞ is contractible, and the quotient is $\mathbb{C}P^\infty$. Replace $\mathbb{C}$ by the quaternions $\mathbb{H}$: the unit quaternions $\mathrm{SU}(2)$ act freely on the unit sphere $S^\infty \subset \mathbb{H}^\infty$ by right multiplication, and the quotient is quaternionic projective space. Hence

$$B\mathrm{SU}(2) = \mathbb{H}P^\infty.$$

$\mathbb{H}P^n$ has a cell decomposition with one cell in each dimension $0, 4, 8, \dots, 4n$ (the quaternionic analogue of $\mathbb{C}P^n = \mathbb{C}P^{n-1} \cup e^{2n}$: a point of $\mathbb{H}P^n$ not in $\mathbb{H}P^{n-1}$ is $[q_0 : \cdots : q_{n-1} : 1]$, a copy of $\mathbb{H}^n = \mathbb{R}^{4n}$). Since all cells are in dimensions divisible by 4, no boundary map can connect two of them, and each contributes one Betti number:

$$\begin{aligned} P_t(B\mathrm{SU}(2)) &\overset{(1)}{=} \sum_k b_k\, t^k \\ &\overset{(2)}{=} 1 + t^4 + t^8 + \cdots \\ &\overset{(3)}{=} \frac{1}{1 - t^4}. \end{aligned} \tag{12.12}$$

(1) Definition of the Poincaré polynomial (series).
(2) One cell, hence one Betti number, in each dimension $4j$; the cellular boundary maps vanish because adjacent cells differ in dimension by 4, not 1.
(3) Geometric series in t^4.

This is Nash's (12.3).

Picture 3: cellular approximation

The **n-skeleton** of a cell complex is the union of its cells of dimension at most n. The **cellular approximation theorem** (Whitehead) says that any map from an n-dimensional cell complex into a cell complex Y is homotopic to one landing in the n-skeleton of Y. Apply it to M (dimension 3) and $Y = \mathbb{H}P^\infty$: the 3-skeleton of $\mathbb{H}P^\infty$ is just the 0-cell, a point. So every map $M \to B\mathrm{SU}(2)$ is homotopic to a constant map, and the constant map classifies the trivial bundle. Hence every $\mathrm{SU}(2)$ bundle over M is isomorphic to $M \times \mathrm{SU}(2)$.

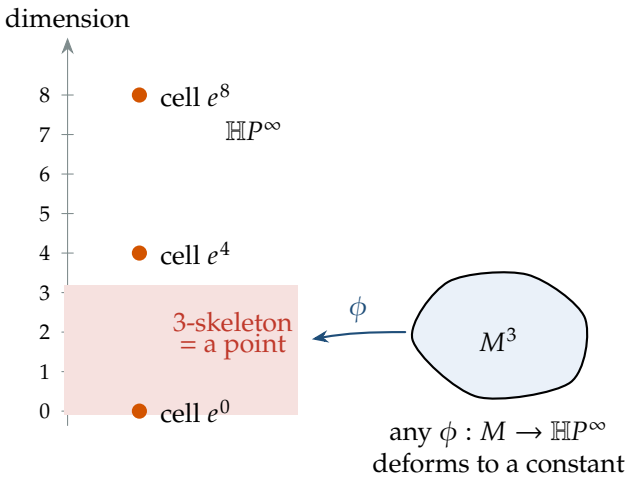

Figure 12.6: Why SU(2) bundles over a 3-manifold are trivial. The classifying space $\mathbb{H}P^\infty$ has cells only in dimensions $0, 4, 8, \dots$. A map from a 3-dimensional M can be pushed down into the 3-skeleton (shaded), which is a single point. The constant map classifies the trivial bundle.

Physical picture: The same fact, by hand

Here is a more hands-on version. Build M out of cells of dimension $0, 1, 2, 3$. Over each cell the bundle is trivial (cells are contractible). Try to extend a global trivialisation cell by cell. On a k-cell D^k we already have a trivialisation over its boundary S^{k-1}, and on the cell itself another one; they differ by a map $S^{k-1} \to \mathrm{SU}(2) = S^3$. We can adjust the trivialisation on D^k to match if that map extends over D^k, i.e. if it is null-homotopic. For $k \le 3$ the sphere S^{k-1} has dimension at most 2, and every map $S^j \to S^3$ with $j \le 2$ is null-homotopic ($\pi_j(S^3) = 0$ for $j < 3$). So the extension never fails. The first possible obstruction lives on 4-cells and is measured by $\pi_3(S^3) = \mathbb{Z}$: that is the instanton number, which is exactly why SU(2) bundles over 4-manifolds are labelled by an integer k.

Consequences

Because the bundle is trivial:

- a connection is a global $\mathfrak{su}(2)$-valued 1-form A on M, and $\mathcal{A}$ is an affine space: any two connections differ by an $\mathfrak{su}(2)$-valued 1-form. Its tangent space at any point is

$$T_A\mathcal{A} = \Omega^1(M) \otimes \mathfrak{su}(2), \tag{12.13}$$

  which Nash writes as $\Omega^1(M) \times \mathfrak{su}(2)$;

- the gauge group is the group of all smooth maps,

$$\mathcal{G} = \mathrm{Map}(M, \mathrm{SU}(2)), \tag{12.14}$$

  with pointwise multiplication, acting by (12.10). Nash calls this the "untwisted" form: over a non-trivial bundle, gauge transformations would be sections of a twisted bundle of groups.

12.2.4 The Chern–Simons function

Now the function. Floer's choice is the integral of the Chern–Simons secondary characteristic class of Chapter 8 (Nash's (12.4)):

$$\boxed{f : \mathcal{A} \to \mathbb{R}, \qquad f(A) = -\frac{1}{8\pi^2}\int_M \operatorname{tr}\Big(A\wedge \mathrm{d}A + \tfrac{2}{3}A\wedge A\wedge A\Big).} \tag{12.15}$$

We will also write $\mathrm{CS}(A) = \operatorname{tr}(A\wedge \mathrm{d}A + \frac{2}{3}A^3)$ for the 3-form in the integrand, so $f(A) = -\frac{1}{8\pi^2}\int_M \mathrm{CS}(A)$. (Wedge products of matrix-valued forms are understood; $A^3 = A\wedge A\wedge A$.)

Why this function: it is a "potential" for $\operatorname{tr} F\wedge F$

Where does (12.15) come from? From four dimensions. The instanton-number density $\operatorname{tr}(F\wedge F)$ is closed, and locally exact:

$$\begin{aligned}
\mathrm{d}\,\mathrm{CS}(A) &\overset{(1)}{=} \operatorname{tr}(\mathrm{d}A\wedge \mathrm{d}A) + \tfrac{2}{3}\operatorname{tr}\,\mathrm{d}(A\wedge A\wedge A)\\
&\overset{(2)}{=} \operatorname{tr}(\mathrm{d}A\wedge \mathrm{d}A) + 2\operatorname{tr}(A\wedge A\wedge \mathrm{d}A)\\
&\overset{(3)}{=} \operatorname{tr}(\mathrm{d}A\wedge \mathrm{d}A) + \operatorname{tr}(\mathrm{d}A\wedge A^2) + \operatorname{tr}(A^2\wedge \mathrm{d}A) + \operatorname{tr}(A^4)\\
&\overset{(4)}{=} \operatorname{tr}(F\wedge F).
\end{aligned} \tag{12.16}$$

(1) $\mathrm{d}\operatorname{tr}(A\wedge \mathrm{d}A) = \operatorname{tr}(\mathrm{d}A\wedge \mathrm{d}A) - \operatorname{tr}(A\wedge \mathrm{d}\mathrm{d}A)$ and $\mathrm{d}\mathrm{d} = 0$.

(2) $\mathrm{d}(A^3) = \mathrm{d}A\,A^2 - A\,\mathrm{d}A\,A + A^2\,\mathrm{d}A$; under the trace, moving a p-form past a q-form costs $(-1)^{pq}$, so $\operatorname{tr}(\mathrm{d}A\,A^2) = \operatorname{tr}(A^2\mathrm{d}A)$ and $\operatorname{tr}(A\,\mathrm{d}A\,A) = -\operatorname{tr}(A^2\mathrm{d}A)$; the three terms add to $3\operatorname{tr}(A^2\mathrm{d}A)$.

(3) Split $2\operatorname{tr}(A^2\mathrm{d}A)$ as $\operatorname{tr}(\mathrm{d}A\,A^2) + \operatorname{tr}(A^2\mathrm{d}A)$ and add $\operatorname{tr}(A^4)$, which is zero: $\operatorname{tr}(A\cdot A^3) = (-1)^{1\cdot 3}\operatorname{tr}(A^3\cdot A) = -\operatorname{tr}(A^4)$.

(4) Expand $F\wedge F = (\mathrm{d}A + A^2)\wedge(\mathrm{d}A + A^2)$.

So on a 4-manifold W with boundary $\partial W = M$, Stokes gives $\int_W \operatorname{tr}(F\wedge F) = \int_M \mathrm{CS}(A)$. With the normalisation of the instanton number $k = \frac{1}{8\pi^2}\int \operatorname{tr}(F\wedge F)$ (conventions of Chapter 8; see §12.4.2 for the sign), $-f(A)$ is "the instanton number of W read off from its boundary". That is why the $\frac{1}{8\pi^2}$ is there.

Worked example 12.6: The abelian Chern–Simons functional is magnetic helicity

For a U(1) gauge field write $A = -i\,a$ with a real 1-form $a = a_i\mathrm{d}x^i$ on $\mathbb{R}^3$ (or T^3). Then $A\wedge A = 0$ and

$$\begin{aligned}
\mathrm{CS}(A) &\overset{(1)}{=} (-i)^2\, a\wedge \mathrm{d}a\\
&\overset{(2)}{=} -\,\vec{a}\cdot(\nabla\times\vec{a})\,\mathrm{d}^3x = -\,\vec{a}\cdot\vec{B}\,\mathrm{d}^3x.
\end{aligned}$$

(1) The cubic term vanishes for an abelian field, and there is no trace to take.

(2) In $\mathbb{R}^3$, $a\wedge \mathrm{d}a = \epsilon^{ijk}a_i\partial_j a_k\,\mathrm{d}^3x$, which is $\vec{a}\cdot(\nabla\times\vec{a})\,\mathrm{d}^3x$ (Dray's dictionary between forms and vector calculus, Chapter T1).

The integral $\int \vec{a}\cdot\vec{B}\,\mathrm{d}^3x$ is the **magnetic helicity** of plasma physics. For two thin closed flux tubes with fluxes Φ_1, Φ_2 it equals $2\,\Phi_1\Phi_2\,\mathrm{Lk}(C_1, C_2)$, twice the product of fluxes times the Gauss linking number of their core curves. So the Chern–Simons functional measures *how field lines are linked*. This is the seed of the knot theory in the later sections of the chapter.

Note that it involves no metric: $a \wedge \mathrm{d}a$ is a 3-form, which can be integrated without a volume element.

12.2.5 The Chern–Simons function is gauge invariant only modulo integers

Would f descend to a function on $\mathcal{A}/\mathcal{G}$? Only if $f(A^g) = f(A)$ for every gauge transformation. The truth (Nash's (12.5)) is

$$\boxed{f(A^g) = f(A) + n, \qquad n = \deg g \in \mathbb{Z}.} \tag{12.17}$$

Nash quotes this from Nash and Sen. We now derive it.

Step 1: how CS changes

Write $\theta = g^{-1}\mathrm{d}g$ (the pull-back of the Maurer–Cartan form) and $\eta = \mathrm{d}g\, g^{-1}$. Two identities do all the work:

$$\mathrm{d}\eta \overset{(1)}{=} -\mathrm{d}g \wedge \mathrm{d}(g^{-1}) \overset{(2)}{=} \mathrm{d}g\, g^{-1} \wedge \mathrm{d}g\, g^{-1} = \eta \wedge \eta, \tag{12.18}$$
$$\operatorname{tr}(\eta^3) \overset{(3)}{=} \operatorname{tr}\big(g\,\theta^3 g^{-1}\big) = \operatorname{tr}(\theta^3).$$

(1) $\mathrm{d}(\mathrm{d}g\, g^{-1}) = \mathrm{d}\mathrm{d}g\, g^{-1} - \mathrm{d}g \wedge \mathrm{d}g^{-1}$, and $\mathrm{d}\mathrm{d}g = 0$.
(2) Differentiate $g\, g^{-1} = 1$: $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\, g^{-1}$.
(3) $\eta = g\,\theta\, g^{-1}$, and the trace is conjugation invariant.

Now $A^g = g^{-1}(A + \eta)g$. Put $\tilde{A} = A + \eta$, so $A^g = g^{-1}\tilde{A}g$. Differentiating,

$$\begin{aligned}\mathrm{d}A^g &\overset{(1)}{=} \mathrm{d}(g^{-1})\,\tilde{A}\,g + g^{-1}\mathrm{d}\tilde{A}\,g - g^{-1}\tilde{A} \wedge \mathrm{d}g \\ &\overset{(2)}{=} g^{-1}\big(\mathrm{d}\tilde{A} - \eta \wedge \tilde{A} - \tilde{A} \wedge \eta\big)g.\end{aligned}$$

(1) Leibniz rule; the minus sign appears because d passes the 1-form $\tilde{A}$ before hitting g.
(2) $\mathrm{d}(g^{-1}) = -g^{-1}\mathrm{d}g\, g^{-1} = -g^{-1}\eta$ and $\mathrm{d}g = \eta\, g$.

Therefore, using the cyclicity of the trace (for 1-forms $\operatorname{tr}(\alpha\beta\gamma) = \operatorname{tr}(\gamma\alpha\beta)$),

$$\begin{aligned}\mathrm{CS}(A^g) &\overset{(1)}{=} \operatorname{tr}\big(\tilde{A}\,\mathrm{d}\tilde{A} - \tilde{A}\eta\tilde{A} - \tilde{A}^2\eta\big) + \tfrac{2}{3}\operatorname{tr}\tilde{A}^3 \\ &\overset{(2)}{=} \mathrm{CS}(\tilde{A}) - 2\operatorname{tr}(\tilde{A}^2\eta).\end{aligned}$$

(1) The conjugation by g drops out of every trace.
(2) $\operatorname{tr}(\tilde{A}\eta\tilde{A}) = \operatorname{tr}(\tilde{A}^2\eta)$ by cyclicity.

Now expand $\tilde{A} = A + \eta$ in both terms. Using $\mathrm{d}\eta = \eta^2$ and cyclicity repeatedly:

$$\begin{aligned}\mathrm{CS}(\tilde{A}) &= \mathrm{CS}(A) + \operatorname{tr}(A\,\mathrm{d}\eta) + \operatorname{tr}(\eta\,\mathrm{d}A) + \operatorname{tr}(\eta\,\mathrm{d}\eta) + 2\operatorname{tr}(A^2\eta) + 2\operatorname{tr}(A\eta^2) + \tfrac{2}{3}\operatorname{tr}\eta^3, \\ -2\operatorname{tr}(\tilde{A}^2\eta) &= -2\operatorname{tr}(A^2\eta) - 4\operatorname{tr}(A\eta^2) - 2\operatorname{tr}\eta^3.\end{aligned}$$

(In the first line the cube $\operatorname{tr}(A+\eta)^3$ gives $\operatorname{tr}A^3 + 3\operatorname{tr}A^2\eta + 3\operatorname{tr}A\eta^2 + \operatorname{tr}\eta^3$, multiplied by $\frac{2}{3}$. In the second, $\operatorname{tr}(A+\eta)^2\eta = \operatorname{tr}A^2\eta + \operatorname{tr}A\eta^2 + \operatorname{tr}\eta A\eta + \operatorname{tr}\eta^3$ and $\operatorname{tr}\eta A\eta = \operatorname{tr}A\eta^2$.) Adding, and using $\operatorname{tr}(A\,\mathrm{d}\eta) = \operatorname{tr}(A\eta^2)$ and $\operatorname{tr}(\eta\,\mathrm{d}\eta) = \operatorname{tr}\eta^3$,

$$\begin{aligned}\mathrm{CS}(A^g) &\overset{(1)}{=} \mathrm{CS}(A) + \operatorname{tr}(\eta\,\mathrm{d}A) - \operatorname{tr}(A\eta^2) - \tfrac{1}{3}\operatorname{tr}\eta^3 \\ &\overset{(2)}{=} \mathrm{CS}(A) + \mathrm{d}\,\operatorname{tr}(A \wedge \eta) - \tfrac{1}{3}\operatorname{tr}(\theta^3).\end{aligned} \tag{12.19}$$

(1) Collect: $\operatorname{tr} A\eta^2$ appears with coefficient $1+2-4=-1$, $\operatorname{tr} A^2\eta$ with $2-2=0$, $\operatorname{tr}\eta^3$ with $1+\frac{2}{3}-2=-\frac{1}{3}$.
(2) $\mathrm{d}\operatorname{tr}(A\eta)=\operatorname{tr}(\mathrm{d}A\,\eta)-\operatorname{tr}(A\,\mathrm{d}\eta)=\operatorname{tr}(\eta\,\mathrm{d}A)-\operatorname{tr}(A\eta^2)$, and $\operatorname{tr}\eta^3=\operatorname{tr}\theta^3$ by (12.18).

Step 2: integrate

On a closed M the exact term integrates to zero (Stokes, $\partial M=\varnothing$):

$$\begin{aligned} f(A^g) &\overset{(1)}{=} -\frac{1}{8\pi^2}\int_M \mathrm{CS}(A)+\frac{1}{8\pi^2}\cdot\frac{1}{3}\int_M \operatorname{tr}(\theta^3) \\ &\overset{(2)}{=} f(A)+\frac{1}{24\pi^2}\int_M \operatorname{tr}\big((g^{-1}\mathrm{d}g)^3\big). \end{aligned} \tag{12.20}$$

(1) Integrate (12.19) and multiply by $-\frac{1}{8\pi^2}$; the total derivative drops out.
(2) Definition (12.15) of f.

The last term depends only on the map $g: M\to \mathrm{SU}(2)=S^3$, and it is its **degree**.

Step 3: the integral is the degree

The 3-form $\frac{1}{24\pi^2}\operatorname{tr}(\theta^3)$ is the pull-back by g of a 3-form ω on $\mathrm{SU}(2)$, namely $\omega=\frac{1}{24\pi^2}\operatorname{tr}((h^{-1}\mathrm{d}h)^3)$ with h the coordinate on the group. For any map g between closed oriented 3-manifolds, $\int_M g^*\omega=\deg(g)\int_{S^3}\omega$ (the degree counts preimages with orientation signs; Chapter 1). So we only need $\int_{\mathrm{SU}(2)}\omega=1$.

Worked example 12.7: The identity map has winding number one

Take $M=S^3=\mathrm{SU}(2)$ and $g=\mathrm{id}$, i.e. $g=x^4\mathbf{1}+ix^a\sigma_a$. At the identity element ($x^4=1$, $x^a=0$) the tangent directions are $\mathrm{d}x^a$ and $\theta=g^{-1}\mathrm{d}g=i\sigma_a\,\mathrm{d}x^a$. Then

$$\begin{aligned} \theta^3 &\overset{(1)}{=} i^3\,\sigma_a\sigma_b\sigma_c\,\mathrm{d}x^a\wedge\mathrm{d}x^b\wedge\mathrm{d}x^c \\ &\overset{(2)}{=} i^3\sum_{a,b,c}\varepsilon_{abc}\,\sigma_a\sigma_b\sigma_c\,\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3 \\ &\overset{(3)}{=} i^3\cdot 6i\cdot\mathbf{1}\,\mathrm{d}x^1\wedge\mathrm{d}x^2\wedge\mathrm{d}x^3=6\cdot\mathbf{1}\,\mathrm{d}x^{123}, \\ \operatorname{tr}\theta^3 &= 12\,\mathrm{d}x^{123}. \end{aligned}$$

(1) Expand the matrix product of three matrix-valued 1-forms.
(2) $\mathrm{d}x^a\wedge\mathrm{d}x^b\wedge\mathrm{d}x^c=\varepsilon_{abc}\,\mathrm{d}x^{123}$.
(3) For a,b,c a permutation of $1,2,3$, $\sigma_a\sigma_b\sigma_c=\varepsilon_{abc}\,\sigma_1\sigma_2\sigma_3=\varepsilon_{abc}\,i\mathbf{1}$; so the sum is $\sum\varepsilon_{abc}^2\,i=6i$.

The form $\operatorname{tr}\theta^3$ is invariant under left translation ($(hg)^{-1}\mathrm{d}(hg)=g^{-1}\mathrm{d}g$), so it equals 12 times the round volume form everywhere on the unit S^3, oriented so that $\mathrm{d}x^{123}>0$ at $\mathbf{1}$ (this is the boundary orientation of the unit ball in $\mathbb{H}=\mathbb{R}^4$ with ordered basis $1,i,j,k$). The volume of the unit S^3 is $2\pi^2$. Hence

$$\frac{1}{24\pi^2}\int_{S^3}\operatorname{tr}\theta^3\overset{(1)}{=}\frac{12\cdot 2\pi^2}{24\pi^2}=1.$$

(1) $\operatorname{tr}\theta^3=12\,\mathrm{vol}$ and $\mathrm{vol}(S^3)=2\pi^2$.

Putting the three steps together proves (12.17), with $n = \deg g$. For a general closed M, $[M, S^3] \cong \mathbb{Z}$ via the degree (Hopf's theorem), so $\mathcal{G} = \mathrm{Map}(M, \mathrm{SU}(2))$ has one connected component for each integer: gauge transformations are "large" or "small" according to their degree, and only small ones leave f unchanged.

Worked example 12.8: A gauge transformation of degree one on $\mathbb{R}^3 \cup \{\infty\}$

On $\mathbb{R}^3$ with $r = |\vec{x}|$, set

$$g(\vec{x}) = \frac{(r^2 - 1)\mathbf{1} + 2i\,\vec{x}\cdot\vec{\sigma}}{r^2 + 1}.$$

It is a unit quaternion: $\big((r^2-1)^2 + 4r^2\big)/(r^2+1)^2 = 1$. It tends to $\mathbf{1}$ as $r \to \infty$, so it extends to $S^3 = \mathbb{R}^3 \cup \{\infty\}$, and $g(\vec{0}) = -\mathbf{1}$. Every $h \in \mathrm{SU}(2)$ other than $\mathbf{1}$ is hit exactly once (this is inverse stereographic projection), so $\deg g = \pm 1$, with the sign fixed by orientations. Physicists know this as the **hedgehog**: the direction $\hat{x}\cdot\vec{\sigma}$ in the Lie algebra points radially outward. Applying it to $A = 0$ gives the pure-gauge field $g^{-1}\mathrm{d}g$, whose Chern–Simons number is $f = \pm 1$ although its curvature vanishes. In the temporal-gauge quantisation of Yang–Mills theory the classical vacua $A = g^{-1}\mathrm{d}g$ are labelled by this integer, and the instanton tunnels between neighbouring ones (Chapter 1).

Step 4: descend to $\mathcal{A}/\mathcal{G}$ with values in a circle

Since f changes by integers, compose it with $\mathbb{R} \to \mathbb{R}/\mathbb{Z}$:

$$\bar{f} : \mathcal{A}/\mathcal{G} \longrightarrow \mathbb{R}/\mathbb{Z}, \qquad \bar{f}([A]) = f(A) \bmod 1.$$

This is well defined. Its derivative $\mathrm{d}\bar{f}$ is an honest 1-form on $\mathcal{A}/\mathcal{G}$, so critical points and gradient flow make sense. Think of the angle ϑ on a circle: not a function, but $\mathrm{d}\vartheta$ is a perfectly good 1-form.

Worked example 12.9: Climbing from one flat connection to its gauge copy

Let g have degree 1 on M and $\theta = g^{-1}\mathrm{d}g$. Both $A = 0$ and $A = \theta$ are flat (the second is a gauge transform of the first). Walk along the straight line $A_s = s\,\theta$, $0 \le s \le 1$, in $\mathcal{A}$. Then

$$\mathrm{d}A_s \overset{(1)}{=} s\,\mathrm{d}\theta \overset{(2)}{=} -s\,\theta^2, \qquad F_s = \mathrm{d}A_s + A_s^2 = (s^2 - s)\,\theta^2,$$

$$\mathrm{CS}(A_s) \overset{(3)}{=} \mathrm{tr}\big(s\theta \wedge (-s\theta^2)\big) + \tfrac{2}{3}s^3\,\mathrm{tr}\,\theta^3 = \big(-s^2 + \tfrac{2}{3}s^3\big)\,\mathrm{tr}\,\theta^3,$$

$$f(A_s) \overset{(4)}{=} -\frac{1}{8\pi^2}\big(-s^2 + \tfrac{2}{3}s^3\big)\cdot 24\pi^2 = 3s^2 - 2s^3.$$

(1) θ does not depend on s.
(2) Maurer–Cartan: $\mathrm{d}(g^{-1}\mathrm{d}g) = -g^{-1}\mathrm{d}g \wedge g^{-1}\mathrm{d}g$ (differentiate g^{-1} as in (12.18)).
(3) Substitute into $\mathrm{CS} = \mathrm{tr}(A\mathrm{d}A + \frac{2}{3}A^3)$.
(4) $\int_M \mathrm{tr}\,\theta^3 = 24\pi^2 \deg g = 24\pi^2$.

So f rises smoothly from 0 to 1. The endpoints are critical ($\frac{\mathrm{d}}{\mathrm{d}s}(3s^2 - 2s^3) = 6s(1-s)$ vanishes at $s = 0, 1$), matching the fact that they are flat, and in between the connection is not flat ($F_s \neq 0$ for $0 < s < 1$). In $\mathcal{A}/\mathcal{G}$ the two endpoints are the same point, so this path is a closed loop, and going once around it raises f by 1.

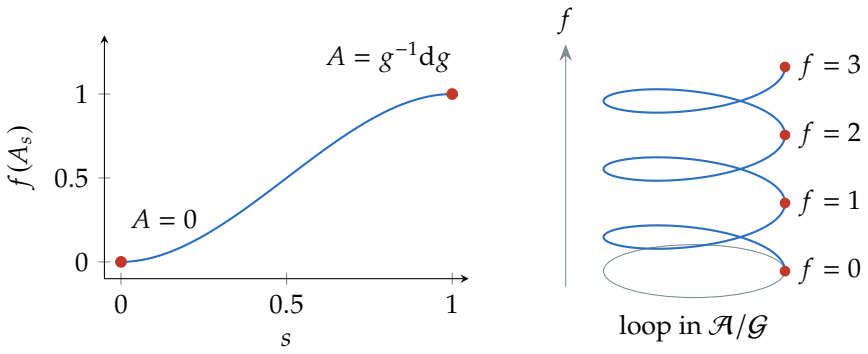

Figure 12.7: Left: the Chern–Simons function along the straight path $A_s = s\, g^{-1}\mathrm{d}g$ with $\deg g = 1$ rises from 0 to 1; both ends are flat connections (red), hence critical points. Right: the same fact globally. The loop in $\mathcal{A}/\mathcal{G}$ lifts to a spiral staircase in $\mathcal{A}$; each turn climbs by one unit of f. So f is well defined only as an angle, f mod 1.

Watch out: A function with integer ambiguity is not a sickness

Physicists meet this all the time. The action of a charged particle in a monopole field, the θ-term, and the Wess–Zumino term are all defined only modulo a constant. What must be single valued is e^{iS}, or here the 1-form $\mathrm{d}f$. For Floer theory $\mathrm{d}f$ is all we need; for the Chern–Simons *quantum* theory we will need $e^{2\pi i k f}$ to be single valued, which forces $k \in \mathbb{Z}$ (Section 12.5.4).

Reading Nash (pp. 322–324, (12.1)–(12.5))

Nash recalls the supersymmetric Morse complex of his Chapter 7 (our (12.5), (12.7)); states Floer's choice (12.2) with the footnote defining homology 3-spheres; shows that all SU(2) bundles over M^3 are trivial via $B\mathrm{SU}(2) = \mathbb{H}P^\infty$, the Poincaré series (12.3) and cellular approximation; notes $\mathcal{G} = \mathrm{Map}(M, \mathrm{SU}(2))$ and $T_A\mathcal{A} = \Omega^1(M) \times \mathfrak{su}(2)$; defines f in (12.4); and quotes (12.5), $f(A_g) = f(A) + n$. We derived (12.5) in full, identified n as the degree of g and computed it for the identity map. Note that Nash writes A_g for our A^g.

Recap

- Floer's plan: Witten's Morse complex with $X = \mathcal{A}/\mathcal{G}$ and f = Chern–Simons.
- M is a homology 3-sphere: $H_1(M;\mathbb{Z}) = 0$, hence $H_2 = 0$; π_1 can still be large (Poincaré sphere).
- SU(2) bundles over 3-manifolds are trivial (cells of $\mathbb{H}P^\infty$ start in dimension 4). So A is a global matrix of 1-forms, $\mathcal{G} = \mathrm{Map}(M, \mathrm{SU}(2))$, $T_A\mathcal{A} = \Omega^1 \otimes \mathfrak{su}(2)$.
- $f(A) = -\frac{1}{8\pi^2}\int \mathrm{tr}(A\mathrm{d}A + \frac{2}{3}A^3)$ satisfies $\mathrm{d}\,\mathrm{CS} = \mathrm{tr}\, F \wedge F$ and $f(A^g) = f(A) + \deg g$, with $\deg g = \frac{1}{24\pi^2}\int \mathrm{tr}(g^{-1}\mathrm{d}g)^3$.
- So f is an $\mathbb{R}/\mathbb{Z}$-valued function on $\mathcal{A}/\mathcal{G}$; $\mathrm{d}f$ is a genuine 1-form.

12.3 Critical points, the Hessian and the relative Morse index

We now have a function f on $\mathcal{A}$, defined on $\mathcal{A}/\mathcal{G}$ up to integers. A Morse theorist asks three questions about any function. Where are its critical points? What does the Hessian

look like at each one? How many negative eigenvalues does the Hessian have? For the Chern–Simons function the first two questions have beautiful answers: the critical points are the flat connections, and the Hessian is the "curl" operator $\star \mathrm{d}_A$. The third question has a shocking answer: *infinitely many*. Floer's way out, the relative Morse index defined by spectral flow, is the subject of the second half of the section.

12.3.1 The first variation: $\mathrm{d}f = -F/4\pi^2$

To find critical points we differentiate f along a straight line in $\mathcal{A}$ (Nash's (12.6)–(12.7)). Since $\mathcal{A}$ is an affine space, every tangent vector $a \in T_A\mathcal{A} = \Omega^1(M) \otimes \mathfrak{su}(2)$ gives a line

$$A_t = A + t\,a, \qquad t \in \mathbb{R}, \tag{12.21}$$

and $\mathrm{d}f(A)$ applied to a is $\frac{\mathrm{d}}{\mathrm{d}t} f(A_t)|_{t=0}$. The condition for a critical point is

$$\mathrm{d}f(A) = 0, \quad \text{i.e.} \quad \frac{\mathrm{d}}{\mathrm{d}t} f(A + ta)\Big|_{t=0} = 0 \ \text{ for every } a. \tag{12.22}$$

Here d is the exterior derivative *on the infinite-dimensional space* $\mathcal{A}$, not on M. We shall be careful to say which one we mean.

Two rules of the matrix-valued form calculus will be used over and over. For a p-form α and a q-form β with values in matrices,

$$\operatorname{tr}(\alpha \wedge \beta) = (-1)^{pq} \operatorname{tr}(\beta \wedge \alpha), \qquad \mathrm{d} \operatorname{tr}(\alpha \wedge \beta) = \operatorname{tr}(\mathrm{d}\alpha \wedge \beta) + (-1)^p \operatorname{tr}(\alpha \wedge \mathrm{d}\beta). \tag{12.23}$$

The first holds because the trace is cyclic on the matrix indices and reordering the forms costs $(-1)^{pq}$. The second is the Leibniz rule.

Expand the integrand of $f(A_t)$ in powers of t. The quadratic piece is

$$\operatorname{tr}\big(A_t \wedge \mathrm{d}A_t\big) = \operatorname{tr}(A\,\mathrm{d}A) + t\big[\operatorname{tr}(a\,\mathrm{d}A) + \operatorname{tr}(A\,\mathrm{d}a)\big] + t^2 \operatorname{tr}(a\,\mathrm{d}a),$$

and the cubic piece is

$$\begin{aligned} \tfrac{2}{3}\operatorname{tr}(A_t^3) = \tfrac{2}{3}\operatorname{tr}(A^3) &+ \tfrac{2}{3}t\big[\operatorname{tr}(aAA) + \operatorname{tr}(AaA) + \operatorname{tr}(AAa)\big] \\ &+ \tfrac{2}{3}t^2\big[\operatorname{tr}(aaA) + \operatorname{tr}(aAa) + \operatorname{tr}(Aaa)\big] + \tfrac{2}{3}t^3 \operatorname{tr}(a^3). \end{aligned}$$

(All products are wedge products.) This is Nash's middle line of (12.7). Now simplify the linear terms:

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\operatorname{CS}(A_t)\Big|_{t=0} &\overset{(1)}{=} \operatorname{tr}(a\,\mathrm{d}A) + \operatorname{tr}(A\,\mathrm{d}a) + 2\operatorname{tr}(a\,A^2) \\ &\overset{(2)}{=} \operatorname{tr}(a\,\mathrm{d}A) + \operatorname{tr}(\mathrm{d}A\,a) - \mathrm{d}\operatorname{tr}(A\,a) + 2\operatorname{tr}(a\,A^2) \\ &\overset{(3)}{=} 2\operatorname{tr}\big(a \wedge (\mathrm{d}A + A \wedge A)\big) - \mathrm{d}\operatorname{tr}(A \wedge a) \\ &\overset{(4)}{=} 2\operatorname{tr}(F \wedge a) - \mathrm{d}\operatorname{tr}(A \wedge a). \end{aligned} \tag{12.24}$$

(1) The three cubic terms are equal: $\operatorname{tr}(AaA) = \operatorname{tr}(a\,A^2)$ and $\operatorname{tr}(A^2a) = \operatorname{tr}(a\,A^2)$ by the graded cyclicity (12.23) (moving a 1-form past a 2-form costs $(-1)^2 = +1$), so $\frac{2}{3}\cdot 3 = 2$.
(2) Leibniz (12.23): $\mathrm{d}\operatorname{tr}(A\,a) = \operatorname{tr}(\mathrm{d}A\,a) - \operatorname{tr}(A\,\mathrm{d}a)$.
(3) $\operatorname{tr}(\mathrm{d}A \wedge a) = \operatorname{tr}(a \wedge \mathrm{d}A)$ (2-form past 1-form, sign $+1$).
(4) $F = \mathrm{d}A + A \wedge A$ and $\operatorname{tr}(a \wedge F) = \operatorname{tr}(F \wedge a)$.

Integrate over the closed manifold M; the exact term drops out by Stokes, and multiplying by $-1/8\pi^2$,

$$f(A+ta) = f(A) - \frac{t}{4\pi^2}\int_M \operatorname{tr}(F\wedge a) + O(t^2). \tag{12.25}$$

This is the last line of Nash's (12.7). Reading off the linear term gives Nash's (12.8):

$$\boxed{\mathrm{d}f(A) = -\frac{F(A)}{4\pi^2}} \qquad \text{meaning} \qquad \mathrm{d}f_a(A) = -\frac{1}{4\pi^2}\int_M \operatorname{tr}\big(F(A)\wedge a\big). \tag{12.26}$$

Working definition 12.4 (the curvature as a 1-form on $\mathcal{A}$ (Nash's footnote 3))

On M^3 the curvature $F(A)$ is an $\mathfrak{su}(2)$-valued 2-form. It becomes a 1-form on the space $\mathcal{A}$ [the space of all SU(2) connections A on M, infinite-dimensional] by the rule

$$a \longmapsto F_a(A) := \int_M \operatorname{tr}\big(F(A)\wedge a\big), \qquad a \in T_A\mathcal{A}.$$

Here $a \in T_A\mathcal{A}$ is a tangent vector [a small change $A \to A + ta$ of the connection, itself an $\mathfrak{su}(2)$-valued 1-form on M]. *Why this works:* a 2-form wedged with a 1-form on a 3-manifold is a 3-form, which can be integrated; the result is linear in a. So a field strength on space is the same thing as a covector on configuration space. The finite-dimensional analogue is $\sum_i F_i\,\mathrm{d}x^i$, with the index i replaced by the pair (point of M, Lie algebra direction, form index).

Physical picture: Electric and magnetic fields

In a Hamiltonian formulation of Yang–Mills theory on space M, the configuration variable is $A_i(\vec{x})$. The magnetic field is $B^i = \frac{1}{2}\varepsilon^{ijk}F_{jk}$, which is $(\star F)^i$. Equation (12.26) says the gradient of the Chern–Simons function is the magnetic field:

$$\frac{\delta f}{\delta A_i^a(\vec{x})} \;\propto\; B_a^i(\vec{x}).$$

The critical points are the *magnetic vacua*, configurations with no magnetic field anywhere. This will be exactly the potential energy of Floer's Hamiltonian in Section 12.5.5.

12.3.2 Critical points are flat connections

From (12.26), $\mathrm{d}f(A) = 0$ for all a precisely when $F(A) = 0$. (Take $a = \star F$: then $\int \operatorname{tr}(F\wedge\star F) = -\|F\|^2$, which vanishes only if $F = 0$.) So:

Key idea: critical points of Chern–Simons

The critical points of the Chern–Simons function are the **flat connections**, $F(A) = 0$. Modulo gauge, they are in one-to-one correspondence with representations of the fundamental group,

$$\{\text{flat } A\}/\mathcal{G} \;\longleftrightarrow\; \operatorname{Hom}\big(\pi_1(M), \mathrm{SU}(2)\big)\,/\,\mathrm{Ad}\,\mathrm{SU}(2). \tag{12.27}$$

Nash states (12.27) as (12.9)–(12.10). Here is where it comes from.

Holonomy of a flat connection

Pick a base point $x_0 \in M$. For a loop γ based at x_0, the **holonomy** is the path-ordered exponential (Chapter T3)

$$\mathrm{hol}_A(\gamma) = \mathcal{P}\exp\Big(-\oint_\gamma A\Big) \in \mathrm{SU}(2),$$

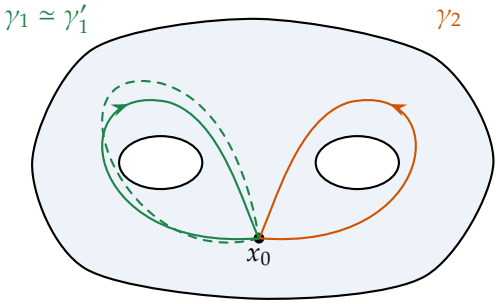
the matrix by which parallel transport around γ rotates the fibre over x_0. (The sign in the exponent is convention; nothing below depends on it.) For a general connection, deforming γ changes its holonomy, and the rate of change is the curvature: by the non-abelian Stokes theorem, the holonomy around a small loop bounding an area element $\Delta S^{\mu\nu}$ is $1 - F_{\mu\nu}\Delta S^{\mu\nu} + \cdots$. If $F = 0$ the holonomy does not change under deformation, so it depends only on the homotopy class $[\gamma] \in \pi_1(M, x_0)$. Composing loops composes parallel transports, so

$$\rho_A : \pi_1(M, x_0) \to \mathrm{SU}(2), \qquad \rho_A([\gamma_1][\gamma_2]) = \rho_A([\gamma_1])\,\rho_A([\gamma_2]) \tag{12.28}$$

is a homomorphism (up to an ordering convention).

A gauge transformation g changes parallel transport by $g(x_0)^{-1}$ at the start and $g(x_0)$ at the end, so it conjugates the whole representation: $\rho_{A^g} = g(x_0)^{-1}\rho_A\, g(x_0)$. That is the quotient by $\mathrm{Ad}\,\mathrm{SU}(2)$ in (12.27). Conversely, given ρ, build the flat bundle $\tilde{M} \times_\rho \mathrm{SU}(2)$ from the universal cover $\tilde{M}$: the product connection on $\tilde{M} \times \mathrm{SU}(2)$ descends, and its holonomy is ρ. So the correspondence is one-to-one.

$$F = 0\text{: } \mathrm{hol}(\gamma_1) = \mathrm{hol}(\gamma_1') = \rho(a), \quad \mathrm{hol}(\gamma_2) = \rho(b)$$



flat connection $\iff$ $\rho : \pi_1(M, x_0) \to \mathrm{SU}(2)$, up to conjugation

Figure 12.8: A flat connection assigns an SU(2) matrix to every loop through the base point x_0. Because $F = 0$, sliding a loop (green solid to green dashed) does not change its holonomy, so only the homotopy class matters. Different loops that cannot be deformed into each other (green and orange) can have different, even non-commuting, holonomies. (The surface drawn is a 2d cartoon of a 3-manifold with non-trivial π_1.)

Worked example 12.10: Flat connections on S^3 and on the 3-torus

S^3. $\pi_1(S^3) = 1$, so $\mathrm{Hom}(1, \mathrm{SU}(2))$ is a single point: the only flat connection up to gauge is $A = 0$. (The pure-gauge fields $g^{-1}\mathrm{d}g$ of Example 12.9 are all gauge equivalent to 0; they are the same point of $\mathcal{A}/\mathcal{G}$, with values of f differing by integers.) So f has exactly one critical point on $\mathcal{A}/\mathcal{G}$ over S^3.

T^3 (not a homology sphere, but instructive). $\pi_1(T^3) = \mathbb{Z}^3$, generated by three commuting loops. A homomorphism sends them to three *commuting* matrices $U_1, U_2, U_3 \in \mathrm{SU}(2)$.

Commuting elements of SU(2) lie in a common maximal torus, so after conjugation

$$U_j = \begin{pmatrix} e^{i\phi_j} & 0 \\ 0 & e^{-i\phi_j} \end{pmatrix}, \qquad \phi_j \in [0, 2\pi),$$

and the remaining freedom is the Weyl reflection $\phi_j \to -\phi_j$ (conjugation by $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$). A representing flat connection on $T^3 = \mathbb{R}^3/(2\pi\mathbb{Z})^3$ is the constant one

$$A = -\frac{i}{2\pi}\,\sigma_3 \sum_j \phi_j \, \mathrm{d}x^j,$$

whose holonomy round the j-th circle is $\exp(-2\pi A_j) = \exp(i\phi_j\sigma_3) = U_j$. It is constant, so $\mathrm{d}A = 0$, and diagonal, so $A \wedge A = 0$; hence $F = 0$. The space of flat connections is

$$\mathrm{Hom}(\mathbb{Z}^3, \mathrm{SU}(2))/\mathrm{Ad}\,\mathrm{SU}(2) \;=\; T^3/\mathbb{Z}_2,$$

a 3-dimensional orbifold. The critical points of f are *not isolated*, and every one of them is reducible (it commutes with the U(1) of diagonal matrices). This is exactly the kind of degenerate situation Floer's homology-sphere condition is designed to avoid.

Reducible and irreducible flat connections

A connection is **reducible** if some gauge transformations other than the centre $\pm\mathbf{1}$ leave it fixed. For a flat connection, $A^g = A$ means $g(x_0)$ commutes with every holonomy, i.e. with the whole image of ρ. So:

Working definition 12.5 (irreducible flat connection)

A flat SU(2) connection with holonomy ρ [the map $\rho : \pi_1(M) \to \mathrm{SU}(2)$ sending each loop to the parallel-transport matrix round it] is **irreducible** if the only matrices commuting with all of $\rho(\pi_1)$ are $\pm\mathbf{1}$. *Test:* the image of ρ is non-abelian. (If the image is abelian it lies in a maximal torus $\mathrm{U}(1) \subset \mathrm{SU}(2)$ [after conjugation, the diagonal matrices $\mathrm{diag}(e^{i\phi}, e^{-i\phi})$], and that whole U(1) commutes with it; if it is non-abelian, two non-commuting elements have only $\pm\mathbf{1}$ as common centraliser [the matrices that commute with both].)

Now Nash's argument. Suppose ρ is reducible. Then $\rho(\pi_1)$ lies in a $\mathrm{U}(1) \subset \mathrm{SU}(2)$, which is abelian. A homomorphism into an abelian group kills all commutators, so it factors through the abelianisation:

$$\pi_1(M) \;\longrightarrow\; \pi_1(M)/[\pi_1, \pi_1] = H_1(M; \mathbb{Z}) \;\longrightarrow\; \mathrm{U}(1).$$

On a homology sphere $H_1 = 0$, so ρ is trivial. Hence:

Key idea: the only reducible is the trivial connection

On a homology 3-sphere, every non-trivial flat SU(2) connection is irreducible, and the trivial connection $\theta = 0$ is the unique reducible one.

Watch out: Nash's "all irreducible"

Nash writes that the flat connections "are also all irreducible". That is true of all *non-trivial* ones. The trivial connection is always there and is maximally reducible (its stabiliser is all of SU(2)). In Floer's construction it is treated separately: the Floer complex is built from

the irreducible flat connections, and the trivial connection enters only as a reference point and as a possible end of flow lines, handled by extra analysis. On a homology sphere at least it is isolated, since $H^1(M;\mathfrak{su}(2)) = H^1(M)\otimes\mathfrak{su}(2) = 0$.

Worked example 12.11: The Poincaré sphere has two irreducible flat connections

$\pi_1(\Sigma(2,3,5)) = I^*$, the binary icosahedral group, which is itself a subgroup of SU(2). The inclusion $I^* \hookrightarrow \mathrm{SU}(2)$ is therefore a homomorphism, and it is irreducible because I^* is non-abelian. Composing with the outer automorphism of I^* (which exchanges the two classes of elements of order 5, i.e. swaps $e^{2\pi i/5}$ with $e^{4\pi i/5}$ in the eigenvalues) gives a second, inequivalent one: an element of order 10 has trace $2\cos(\pi/5) = \frac{1+\sqrt{5}}{2}$ in one and $2\cos(3\pi/5) = \frac{1-\sqrt{5}}{2}$ in the other, and conjugation cannot change a trace. A theorem of Fintushel and Stern shows these are all. So

$$\mathrm{Hom}(I^*, \mathrm{SU}(2))/\mathrm{Ad}\,\mathrm{SU}(2) = \{\theta,\ \rho_1,\ \rho_2\},$$

the trivial connection plus two irreducible ones. The function $\bar{f}$ on $\mathcal{A}/\mathcal{G}$ has exactly three critical points, and two of them are the building blocks of the Floer complex.

12.3.3 The Hessian is the curl operator $\star \mathrm{d}_A$

At a critical point, the second-order term of $f(A + ta)$ defines the Hessian. We expand to order t^2 (Nash's (12.11)); the coefficient of $t^2/2$ is the quadratic form $\mathrm{Hess}_A(a,a)$.

First we need the covariant derivative on $\mathfrak{su}(2)$-valued 1-forms. For a p-form ω with values in the adjoint representation,

$$\mathrm{d}_A\omega = \mathrm{d}\omega + A\wedge\omega - (-1)^p\,\omega\wedge A, \qquad \text{so} \qquad \mathrm{d}_A a = \mathrm{d}a + A\wedge a + a\wedge A \ \text{ for a 1-form } a. \tag{12.29}$$

(For $p = 1$ the "commutator" is an anticommutator of matrix-valued 1-forms, because the forms themselves anticommute.)

$$\begin{aligned}
\mathrm{Hess}_A(a,a) &\overset{(1)}{=} 2\times\Big(-\frac{1}{8\pi^2}\Big)\int_M \Big\{\mathrm{tr}(a\wedge\mathrm{d}a) + \tfrac{2}{3}\big[\mathrm{tr}(aaA) + \mathrm{tr}(aAa) + \mathrm{tr}(Aaa)\big]\Big\} \\
&\overset{(2)}{=} -\frac{1}{4\pi^2}\int_M \mathrm{tr}\big\{a\wedge(\mathrm{d}a + 2\,a\wedge A)\big\} \\
&\overset{(3)}{=} -\frac{1}{4\pi^2}\int_M \mathrm{tr}\big\{a\wedge\mathrm{d}a + a\wedge A\wedge a + a\wedge a\wedge A\big\} \\
&\overset{(4)}{=} -\frac{1}{4\pi^2}\int_M \mathrm{tr}\big(a\wedge\mathrm{d}_A a\big) \\
&\overset{(5)}{=} \frac{1}{4\pi^2}\,\big\langle a, \star\mathrm{d}_A a\big\rangle.
\end{aligned} \tag{12.30}$$

(1) The t^2 terms of $f(A_t)$ collected above, multiplied by 2 because the Hessian is the coefficient of $t^2/2$.

(2) The three cubic terms are all equal to $\mathrm{tr}(a\wedge a\wedge A)$ by graded cyclicity (moving a 1-form past a 2-form is free), so $\frac{2}{3}\cdot 3 = 2$.

(3) Split $2\,\mathrm{tr}(aaA)$ as $\mathrm{tr}(aAa) + \mathrm{tr}(aaA)$, again by cyclicity.

(4) $a\wedge\mathrm{d}_A a = a\wedge(\mathrm{d}a + Aa + aA)$ by (12.29).

(5) The L^2 inner product on $\mathfrak{su}(2)$-valued forms is $\langle\alpha,\beta\rangle = -\int_M \mathrm{tr}(\alpha\wedge\star\beta)$, and $\star\star = 1$ on forms on a Riemannian 3-manifold, so $\langle a, \star\mathrm{d}_A a\rangle = -\int \mathrm{tr}(a\wedge\mathrm{d}_A a)$.

Nash's (12.11) has the same content; his first line keeps the $\frac{2}{3}$ and the three cubic terms visible, and the simplification in his second line uses exactly step (2).

Note that we did not use flatness to get (12.30): it is the second-order term at any A. At a critical point it is the honest Hessian. Using the metric to turn the quadratic form into an operator,

$$\mathrm{Hess}_A(a,b) = \langle a, H(A)b\rangle, \qquad \boxed{4\pi^2\, H(A) = \star \mathrm{d}_A} \qquad \text{acting on } \Omega^1(M)\otimes \mathfrak{su}(2). \tag{12.31}$$

Working definition 12.6 (the Hessian of Chern–Simons)

$H(A)$ takes an $\mathfrak{su}(2)$-valued 1-form a, differentiates it covariantly [$\mathrm{d}_A a = \mathrm{d}a + A\wedge a + a\wedge A$] to a 2-form, and turns the 2-form back into a 1-form with the Hodge star [in orthonormal coordinates on the 3-manifold, $\star$ sends $\mathrm{d}x^1\wedge\mathrm{d}x^2$ to $\mathrm{d}x^3$, and cyclically]. *In vector-calculus language*, for $A=0$ and one colour component, it is the curl: $\star\mathrm{d}a \leftrightarrow \nabla\times\vec{a}$ (Dray's dictionary, Chapter T1). It is symmetric: $\langle a, \star\mathrm{d}_A b\rangle = \langle \star\mathrm{d}_A a, b\rangle$ (integrate by parts on the closed M).

Why the Hessian is a disaster for ordinary Morse theory

The Morse index is the number of negative eigenvalues of the Hessian. The operator $\star\mathrm{d}_A$ is *first order*. Like the Dirac operator, and unlike the Laplacian, a first-order self-adjoint operator typically has spectrum unbounded in *both* directions. So the "Morse index" of every critical point is infinite. The following example shows this in the simplest case.

Worked example 12.12: The spectrum of curl on the 3-torus

Take $M = T^3 = \mathbb{R}^3/(2\pi\mathbb{Z})^3$, $A=0$, and one Lie-algebra component, so $H \propto \star\mathrm{d}$ acting on ordinary real 1-forms, i.e. curl acting on vector fields $\vec{a}(\vec{x})$. Fourier-expand: $\vec{a} = \vec{\varepsilon}\, e^{i\vec{k}\cdot\vec{x}}$ with $\vec{k}\in\mathbb{Z}^3$. Then

$$\nabla\times\left(\vec{\varepsilon}\, e^{i\vec{k}\cdot\vec{x}}\right) \overset{(1)}{=} i\,\vec{k}\times\vec{\varepsilon}\, e^{i\vec{k}\cdot\vec{x}}.$$

(1) $\partial_j e^{i\vec{k}\cdot\vec{x}} = ik_j e^{i\vec{k}\cdot\vec{x}}$ and $\vec{\varepsilon}$ is constant.

So on each Fourier mode curl is the 3×3 matrix $C_{\vec{k}}\,\vec{\varepsilon} = i\vec{k}\times\vec{\varepsilon}$. For $\vec{k} = (0,0,\kappa)$, $\kappa>0$,

$$C_{\vec{k}} = i\kappa\begin{pmatrix} 0 & -1 & 0\\ 1 & 0 & 0\\ 0 & 0 & 0\end{pmatrix}, \qquad \text{eigenvalues } +\kappa,\ -\kappa,\ 0,$$

with eigenvectors $\vec{\varepsilon}_\pm = (1,\pm i,0)/\sqrt{2}$ (the two circular polarisations, i.e. the two helicities) and $\vec{\varepsilon}_0 = (0,0,1)$ (the longitudinal direction, $\vec{a} = \nabla(\text{something})$). Check one:

$$C_{\vec{k}}\,\vec{\varepsilon}_+ \overset{(1)}{=} \frac{i\kappa}{\sqrt{2}}(-i,\,1,\,0) \overset{(2)}{=} \frac{\kappa}{\sqrt{2}}(1,\,i,\,0) = +\kappa\,\vec{\varepsilon}_+.$$

(1) The matrix sends $(\varepsilon_1,\varepsilon_2,\varepsilon_3)$ to $i\kappa(-\varepsilon_2,\varepsilon_1,0)$, and $\varepsilon_2 = i$, $\varepsilon_1 = 1$.
(2) $i\cdot(-i) = 1$ and $i\cdot 1 = i$.

The same computation gives $C_{\vec{k}}\vec{\varepsilon}_- = -\kappa\,\vec{\varepsilon}_-$ and $C_{\vec{k}}\vec{\varepsilon}_0 = 0$. By rotation invariance the same holds for every $\vec{k}$ with $\kappa = |\vec{k}|$. The full spectrum is

$$\mathrm{Spec}(\star\mathrm{d}) = \{+|\vec{k}|,\,-|\vec{k}| : \vec{k}\in\mathbb{Z}^3\setminus 0\}\ \cup\ \{0 \text{ (longitudinal and constant modes)}\}.$$

There are infinitely many positive *and* infinitely many negative eigenvalues: $|\vec{k}|$ grows without bound in both helicities. The Morse index at $A=0$ is $+\infty$, and so is the "co-index".

Worked example 12.13: Curl on the round 3-sphere

On the unit $S^3 = \mathrm{SU}(2)$ use the left-invariant coframe. From the Maurer–Cartan equation $\mathrm{d}\theta = -\theta \wedge \theta$ for $\theta = g^{-1}\mathrm{d}g = \theta^a T_a$ we get

$$\mathrm{d}\theta^c\, T_c \overset{(1)}{=} -\theta^a \wedge \theta^b\, T_a T_b \overset{(2)}{=} -\tfrac{1}{2}\theta^a \wedge \theta^b\, [T_a, T_b] \overset{(3)}{=} -\tfrac{1}{2}\varepsilon_{abc}\, \theta^a \wedge \theta^b\, T_c,$$

(1) Expand $\theta \wedge \theta$ in components.
(2) $\theta^a \wedge \theta^b$ is antisymmetric in a, b, so only the antisymmetric part of $T_a T_b$ survives.
(3) $[T_a, T_b] = \varepsilon_{abc} T_c$.

so $\mathrm{d}\theta^1 = -\theta^2 \wedge \theta^3$ and cyclically. At the identity $g = \mathbf{1} + ix^a\sigma_a$, so $\theta = i\sigma_a \mathrm{d}x^a = -2T_a\,\mathrm{d}x^a$, i.e. $\theta^a = -2\,\mathrm{d}x^a$. Hence $e^a := -\tfrac{1}{2}\theta^a$ is an orthonormal coframe for the round metric (it is at the identity, and everything is left-invariant), and

$$\star\mathrm{d}e^1 \overset{(1)}{=} \star\big(\tfrac{1}{2}\theta^2 \wedge \theta^3\big) \overset{(2)}{=} \star\big(2\,e^2 \wedge e^3\big) \overset{(3)}{=} 2\,e^1.$$

(1) $\mathrm{d}e^1 = -\tfrac{1}{2}\mathrm{d}\theta^1 = \tfrac{1}{2}\theta^2 \wedge \theta^3$.
(2) $\theta^a = -2e^a$, so $\theta^2 \wedge \theta^3 = 4e^2 \wedge e^3$.
(3) $\star(e^2 \wedge e^3) = e^1$ for an oriented orthonormal coframe.

So the three left-invariant 1-forms are eigenvectors of curl with eigenvalue $+2$. The same computation with right-invariant forms gives -2. In general the eigenvalues of $\star\mathrm{d}$ on co-closed 1-forms on the unit S^3 are $\pm(n+1)$, $n = 1, 2, 3, \ldots$, each with multiplicity $n(n+2)$: a spectrum symmetric about zero and unbounded both ways. (The $n = 1$ case is what we just computed: ± 2, multiplicity 3.)

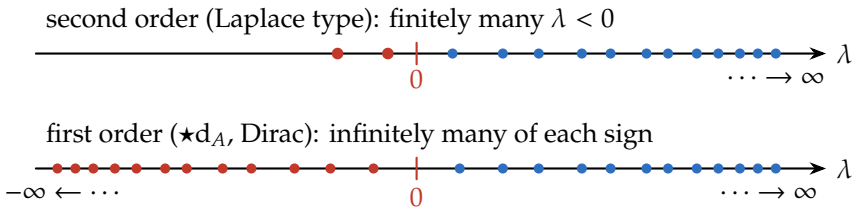


Figure 12.9: Why the Chern–Simons Hessian has infinite Morse index. Top: a Laplace-type operator (Hessian of the energy of paths, or of the Yang–Mills action) is bounded below, so only finitely many eigenvalues (red) are negative. Bottom: the first-order operator $\star\mathrm{d}_A$ has eigenvalues accumulating at both $+\infty$ and $-\infty$, like the curl on T^3 or S^3. Counting the red dots gives ∞.

Physical picture: Why geodesics and Yang–Mills were fine

In Chapter 7 the infinite-dimensional Morse functions were the energy $E(\gamma) = \frac{1}{2}\int |\dot\gamma|^2 \mathrm{d}t$ of paths, and the Yang–Mills action. Their Hessians are $-\frac{\mathrm{d}^2}{\mathrm{d}t^2} + (\text{curvature})$ and $\mathrm{d}_A^*\mathrm{d}_A + \cdots$: second order, like $p^2 + V$ in quantum mechanics. Such an operator has a lowest eigenvalue; only finitely many eigenvalues lie below zero, and the Morse index is finite. The Chern–Simons Hessian is first order, like $\vec\sigma \cdot \vec p$ for a Weyl fermion: its spectrum is a "Dirac sea", filled with infinitely many negative states.

12.3.4 The relative Morse index

How does one do Morse theory when every index is infinite? Floer's observation is that the complex of Chapter 7 never uses the index itself. Look at the coboundary (12.7) (Nash's (12.12)):

$$\cdots \xrightarrow{\delta} C^{p} \xrightarrow{\delta} C^{p+1} \xrightarrow{\delta} \cdots$$

It only needs to know *which pairs* of critical points have indices differing by one. That is, it only uses *differences* of indices. And while $\infty - \infty$ is meaningless as arithmetic, it can be made meaningful as a count of eigenvalues that *cross zero*.

Finite dimensions: index difference = eigenvalue crossings

Let X be finite-dimensional, P, Q critical points of f, and $A(t)$ a path from P to Q. Extend the Hessian to a family of symmetric matrices $H(t)$ along the path (any interpolation will do). At $t = 0$ it has λ_P negative eigenvalues; at $t = 1$ it has λ_Q. Eigenvalues move continuously, so the only way the count can change is by eigenvalues passing through zero. Hence

$$\lambda_P - \lambda_Q \;=\; \#\{\text{eigenvalues crossing } - \to + \} - \#\{\text{eigenvalues crossing } + \to - \} \;=:\; \mathrm{SF}\big(H(t)\big). \tag{12.32}$$

The right side is the **spectral flow** of the family. In finite dimensions both sides make sense and agree. In infinite dimensions only the right side makes sense, and it is still a finite integer, because only finitely many eigenvalues can cross zero along a compact path (the spectrum near zero is discrete for an elliptic operator).

Working definition 12.7 (spectral flow and the relative Morse index)

Let $H(t)$, $0 \le t \le 1$ (or $-\infty < t < \infty$), be a continuous family of self-adjoint operators with discrete spectrum and invertible ends [H has no zero eigenvalue at the two endpoints of the path]. The **spectral flow** σ is the net number of eigenvalues that cross zero from negative to positive as t increases (Chapter 10, where it was the mechanism of the anomaly). *To compute:* draw the eigenvalues as curves $\lambda_j(t)$ and count the signed zero crossings.
For Chern–Simons, choose a steepest-descent path $A(t)$ from A_P to A_Q (Nash's (12.13)) [$A(t)$ runs downhill in f as fast as possible, with grad f the vector dual to $\mathrm{d}f = -F/4\pi^2$ under the L^2 metric],

$$\frac{\mathrm{d}A(t)}{\mathrm{d}t} = -\operatorname{grad} f\big(A(t)\big), \qquad A(-\infty) = A_P,\; A(+\infty) = A_Q, \tag{12.33}$$

consider the family $4\pi^2 H(A(t)) = \star \mathrm{d}_{A(t)}$, and define the **relative Morse index** (Nash's (12.14))

$$\lambda_{A_P, A_Q} := \sigma(A_P, A_Q) = \mathrm{SF}\big(\star \mathrm{d}_{A(t)}\big). \tag{12.34}$$

In finite dimensions this is $\lambda_P - \lambda_Q$.

Nash describes it as "the net number of negative eigenvalues of $H(A_P)$ which flow into positive eigenvalues of $H(A_Q)$", and calls it a "renormalised" measure of the difference of Morse indices. The renormalisation is literal: we subtract two infinite numbers by pairing their eigenvalues along a path, exactly as one renormalises the charge of the Dirac sea by counting only level crossings.

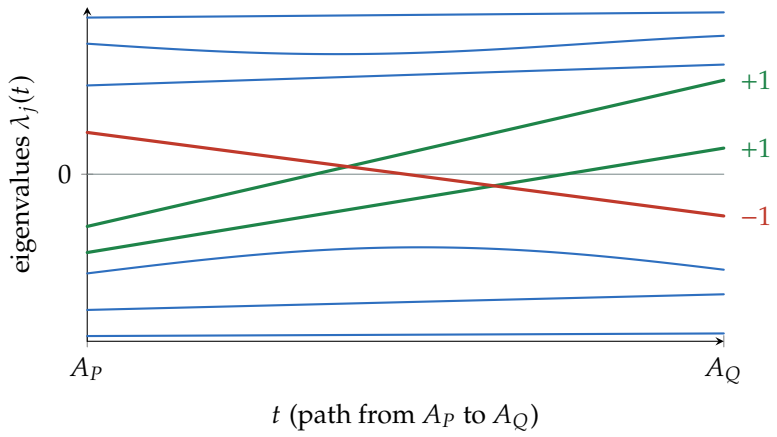

Figure 12.10: Spectral flow. The eigenvalues of $\star \mathrm{d}_{A(t)}$ along a path from A_P to A_Q extend infinitely far up and down (only a window is drawn). Blue curves never cross zero and do not count. The two green curves cross upward (+1 each), the red curve crosses downward (−1). The spectral flow is $1 + 1 - 1 = 1$: the relative Morse index $\lambda_{A_P,A_Q} = 1$, although both Morse indices are infinite.

Worked example 12.14: Spectral flow of the Dirac operator on a circle

The simplest infinite-dimensional case. On S^1 with angle ϑ, consider the family of self-adjoint operators

$$D_s = -i\frac{\mathrm{d}}{\mathrm{d}\vartheta} + s, \qquad s \in \mathbb{R},$$

(the Dirac operator coupled to a constant U(1) gauge field s). The eigenfunctions are $e^{in\vartheta}$, $n \in \mathbb{Z}$, with eigenvalues

$$D_s\, e^{in\vartheta} \overset{(1)}{=} (n+s)\, e^{in\vartheta}.$$

(1) $-i\,\partial_\vartheta e^{in\vartheta} = n\, e^{in\vartheta}$.

The spectrum $\{n + s\}$ is unbounded both ways: each D_s has infinitely many negative eigenvalues. Now move s from $-\frac{1}{2}$ to $\frac{1}{2}$. Every eigenvalue moves up by one unit; exactly one of them ($n = 0$) crosses zero, upward. So

$$\mathrm{SF}\big(D_s,\ s \in [-\tfrac{1}{2}, \tfrac{1}{2}]\big) = +1.$$

Also note that $D_{s+1} = e^{-i\vartheta} D_s\, e^{i\vartheta}$: shifting s by 1 is a (large) gauge transformation, so $s \in [0, 1]$ is a *closed loop* in the space of gauge orbits, and the spectral flow round it is 1. This is the toy model for the statement below that the spectral flow round a loop in $\mathcal{A}/\mathcal{G}$ is not zero but 8.

Spectral flow is an index

Why is spectral flow an *integer invariant*, independent of the details of the path? Because it equals the index of an operator in one dimension more. This is the bridge Nash uses to compute it.

Worked example 12.15: $\operatorname{index}(\frac{\mathrm{d}}{\mathrm{d}t}+\lambda(t))$ counts one crossing

Take one eigenvalue: a smooth function $\lambda(t)$ on $\mathbb{R}$ with limits $\lambda_\pm = \lambda(\pm\infty) \neq 0$, and the operator $D = \frac{\mathrm{d}}{\mathrm{d}t} + \lambda(t)$ on $L^2(\mathbb{R})$. Its kernel:

$$Du = 0 \overset{(1)}{=} u(t) = u(0)\exp\Big(-\int_0^t \lambda(s)\,\mathrm{d}s\Big) \sim \begin{cases} e^{-\lambda_+ t}, & t \to +\infty, \\ e^{-\lambda_- t} = e^{+\lambda_-|t|}, & t \to -\infty. \end{cases}$$

(1) Separate variables in $u' = -\lambda u$; at large $|t|$, $\int_0^t \lambda \approx \lambda_\pm t$.

So $u \in L^2$ iff $\lambda_+ > 0$ and $\lambda_- < 0$. The adjoint $D^* = -\frac{\mathrm{d}}{\mathrm{d}t} + \lambda(t)$ has solutions $\exp(+\int\lambda)$, in L^2 iff $\lambda_+ < 0$ and $\lambda_- > 0$. Therefore

$$\operatorname{index} D = \dim\operatorname{Ker} D - \dim\operatorname{Ker} D^* = \begin{cases} +1 & \lambda : - \longrightarrow + \ \text{(upward crossing)}, \\ -1 & \lambda : + \longrightarrow - \ \text{(downward crossing)}, \\ 0 & \text{no net crossing.} \end{cases}$$

For a family $H(t)$ with many eigenvalues, decompose (approximately) into eigenvalue curves and add: $\operatorname{index}\big(\frac{\mathrm{d}}{\mathrm{d}t} + H(t)\big) = \mathrm{SF}(H(t))$. (This is the Atiyah–Patodi–Singer theorem; the diagonal case above is its whole mechanism.)

So: the relative Morse index is the index of the four-dimensional operator $\frac{\mathrm{d}}{\mathrm{d}t} + \star\mathrm{d}_{A(t)}$ on $M \times \mathbb{R}$. In the next section we shall see that this operator is precisely the deformation operator of instantons, and its index is computed by the Atiyah–Singer formula of Chapter 8.

12.3.5 Path dependence and the fundamental group of $\mathcal{A}/\mathcal{G}$

Is $\sigma(A_P, A_Q)$ independent of the chosen path? Take two paths $A(t)$ and $A'(t)$ from A_P to A_Q. Running along A and back along A' is a loop ℓ, and

$$\mathrm{SF}(A) - \mathrm{SF}(A') = \mathrm{SF}(\ell).$$

Spectral flow round a loop is the index of $\frac{\mathrm{d}}{\mathrm{d}t} + \star\mathrm{d}_{A(t)}$ on $M \times S^1$ (the t-direction closed up into a circle), an Atiyah–Singer index. An index is a deformation invariant, so $\mathrm{SF}(\ell)$ depends only on the homotopy class of ℓ. Two possibilities:

- In $\mathcal{A}$, which is an affine space (contractible), every loop is contractible, so $\mathrm{SF}(\ell) = 0$ and $\sigma(A_P, A_Q)$ is well defined for points of $\mathcal{A}$.
- But the critical points are really points of $\mathcal{A}/\mathcal{G}$, and paths there can wind around non-contractible loops.

Key idea: Nash's footnote 4: $\pi_1(\mathcal{A}/\mathcal{G}) = \mathbb{Z}$

For SU(2) on a closed 3-manifold,

$$\pi_1(\mathcal{A}/\mathcal{G}) \;\cong\; \pi_0(\mathcal{G}) \;\cong\; [M, S^3] \;\cong\; \mathbb{Z}, \tag{12.35}$$

the integer being the degree of a gauge transformation.

Here is the argument, with the steps Nash compresses.

1. $\mathcal{G}$ acts on $\mathcal{A}$ and (after removing the few points with large stabilisers, or using the based gauge group of maps with $g(x_0) = \mathbf{1}$) freely, so $\mathcal{G} \to \mathcal{A} \to \mathcal{A}/\mathcal{G}$ is a fibration: a principal $\mathcal{G}$-bundle.

2. A fibration has a long exact sequence of homotopy groups; its end is

$$\pi_1(\mathcal{A}) \to \pi_1(\mathcal{A}/\mathcal{G}) \xrightarrow{\partial} \pi_0(\mathcal{G}) \to \pi_0(\mathcal{A}).$$

   The map ∂ takes a loop in $\mathcal{A}/\mathcal{G}$, lifts it to a path in $\mathcal{A}$ from A to some A^g, and returns the component of g.

3. $\mathcal{A}$ is contractible (it is an affine space: shrink everything to a chosen A_0 along straight lines). So $\pi_1(\mathcal{A}) = \pi_0(\mathcal{A}) = 0$ and ∂ is an isomorphism.

4. $\pi_0(\mathcal{G}) = \pi_0(\mathrm{Map}(M, \mathrm{SU}(2)))$ is the set of homotopy classes of maps $M^3 \to S^3$. By Hopf's theorem these are classified by the degree, an integer.

The generating loop is precisely the one in Example 12.9: the straight path from A to A^g with $\deg g = 1$, closed up in $\mathcal{A}/\mathcal{G}$.

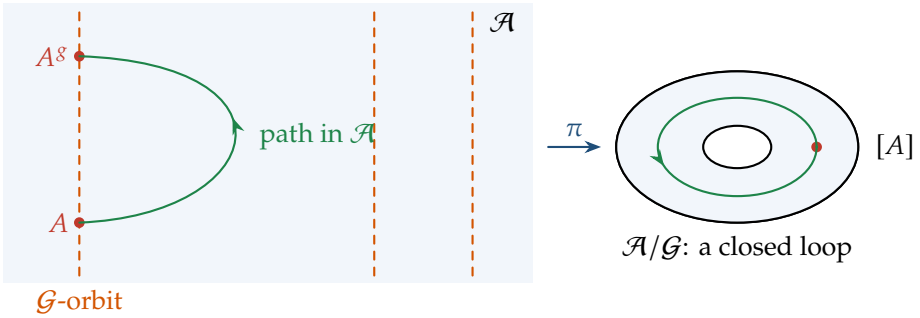

Figure 12.11: Why $\pi_1(\mathcal{A}/\mathcal{G}) = \pi_0(\mathcal{G})$. Left: the contractible space $\mathcal{A}$, with gauge orbits drawn as dashed fibres. A path from A to its gauge copy A^g projects to a closed loop in $\mathcal{A}/\mathcal{G}$ (right). The loop is non-contractible exactly when g lies in a non-trivial component of $\mathcal{G}$, i.e. has non-zero degree. The "hole" is a cartoon of that non-contractibility.

Consequently $\sigma(A_P, A_Q)$ on $\mathcal{A}/\mathcal{G}$ is defined only modulo the spectral flow round the generating loop: if that number is N, then σ is well defined in $\mathbb{Z}/N\mathbb{Z}$. Computing N is an index computation on $M \times S^1$, and it is done in the next section. The answer will be $N = 8$.

Watch out: Chern–Simons values and the grading

Going once round the generating loop changes f by 1 (Example 12.9) and the relative index by $N = 8$. So the pair (f mod 1, σ mod 8) is well defined, while $f \in \mathbb{R}$ and $\sigma \in \mathbb{Z}$ are defined only on $\mathcal{A}$. In more refined versions of Floer theory one keeps track of both at once, using $\mathcal{A}/\mathcal{G}_0$ with $\mathcal{G}_0$ the degree-zero gauge transformations; then the grading is a genuine integer.

Reading Nash (pp. 324–327, (12.6)–(12.14))

Nash expands $f(A + ta)$ to first order to get $\mathrm{d}f = -F/4\pi^2$ (12.7)–(12.8) and explains in footnote 3 how F is a 1-form on $\mathcal{A}$. He identifies the critical points with flat connections, i.e. with $\mathrm{Hom}(\pi_1(M), \mathrm{SU}(2))$ modulo conjugation (12.9)–(12.10), and argues irreducibility from $H_1 = 0$. He expands to second order to get the Hessian $4\pi^2 H(A) = \star \mathrm{d}_A$ (12.11), observes that it is first order with infinite Morse index, and contrasts it with the geodesic

and Yang–Mills cases. He recalls the coboundary (12.12) and defines the relative Morse index by the spectral flow along a steepest-descent path (12.13)–(12.14), discussing path dependence and $\pi_1(\mathcal{A}/\mathcal{G}) = \mathbb{Z}$ in footnote 4. We added the graded-trace details, the holonomy construction, the T^3 and Poincaré-sphere examples, the explicit curl spectra, the circle example of spectral flow, and the one-dimensional computation showing that spectral flow is an index.

Recap

- $\mathrm{d}f(A) = -F(A)/4\pi^2$: the gradient of Chern–Simons is the magnetic field. Critical points = flat connections = $\mathrm{Hom}(\pi_1, \mathrm{SU}(2))/\mathrm{Ad}$.
- On a homology sphere every non-trivial flat connection is irreducible; the trivial one is the unique reducible.
- Hessian: $4\pi^2 H(A) = \star \mathrm{d}_A$, a first-order "curl" operator with spectrum unbounded in both directions; Morse indices are infinite.
- Relative index λ_{A_P, A_Q} = spectral flow of $\star \mathrm{d}_{A(t)}$ = $\mathrm{index}\big(\frac{\mathrm{d}}{\mathrm{d}t} + \star \mathrm{d}_{A(t)}\big)$; finite.
- $\pi_1(\mathcal{A}/\mathcal{G}) = \mathbb{Z}$, so the relative index is defined modulo the spectral flow round the generating loop.

12.4 Gradient flow lines are instantons

In Witten's Morse complex the coboundary counts gradient flow lines between critical points. So to build Floer's complex we need to understand the gradient flow of the Chern–Simons function. The remarkable fact, and the reason Floer theory is a gauge theory rather than a piece of abstract analysis, is that a gradient flow line of Chern–Simons on a 3-manifold M *is* an instanton on the 4-manifold $M \times \mathbb{R}$. Once we see this, the missing number from the last section, the spectral flow round a loop, is an instanton-moduli dimension, and we know how to compute those (Chapter 8). The answer is 8.

12.4.1 A metric on $\mathcal{A}$ and the gradient of f

A gradient needs a metric. The flow (Nash's (12.15)) is

$$\frac{\mathrm{d}A(t)}{\mathrm{d}t} = -\operatorname{grad} f\big(A(t)\big), \tag{12.36}$$

and "grad" converts the 1-form $\mathrm{d}f$ into a vector using an inner product on $T_A\mathcal{A}$. The tangent vectors are $\mathfrak{su}(2)$-valued 1-forms on M, so the natural choice (Nash's (12.16)) is the L^2 inner product built from the metric on M and the trace:

$$\langle a, b\rangle = -\int_M \operatorname{tr}(a \wedge \star b), \qquad a, b \in T_A\mathcal{A} \cong \Omega^1(M) \otimes \mathfrak{su}(2). \tag{12.37}$$

Let us check that it is positive. Write $a = a^i_\mu\, T_i\, \mathrm{d}x^\mu$ with $\operatorname{tr}(T_iT_j) = -\frac{1}{2}\delta_{ij}$ (from (12.9)). Then

$$\begin{aligned} -\operatorname{tr}(a \wedge \star a) &\overset{(1)}{=} -\operatorname{tr}(T_iT_j)\, a^i_\mu a^j_\nu\, \mathrm{d}x^\mu \wedge \star \mathrm{d}x^\nu \\ &\overset{(2)}{=} \tfrac{1}{2}\,\delta_{ij}\, a^i_\mu a^j_\nu\, g^{\mu\nu}\,\mathrm{vol} \end{aligned}$$

$$= \tfrac{1}{2}\sum_i |a^i|^2 \,\mathrm{vol} \;\geq 0.$$

(1) Pull the Lie-algebra generators out of the wedge product.
(2) $\mathrm{tr}(T_iT_j) = -\tfrac{1}{2}\delta_{ij}$, and $\mathrm{d}x^\mu \wedge \star \mathrm{d}x^\nu = g^{\mu\nu}\,\mathrm{vol}$ (the defining property of $\star$, Chapter T1).

So $\langle a, a\rangle = \tfrac{1}{2}\int_M \sum_i |a^i|^2 \mathrm{vol}$, the sum of the squared lengths of the colour components: the obvious "kinetic" metric.

The gradient is defined by $\langle \mathrm{grad}\, f, a\rangle = \mathrm{d}f_a$ for every a (Nash's (12.17)). Using (12.26):

$$\begin{aligned} \mathrm{d}f_a &\overset{(1)}{=} -\frac{1}{4\pi^2}\,F_a(A) \\ &\overset{(2)}{=} -\frac{1}{4\pi^2}\int_M \mathrm{tr}(F\wedge a) \\ &\overset{(3)}{=} -\frac{1}{4\pi^2}\int_M \mathrm{tr}\big(a\wedge\star(\star F)\big) \\ &\overset{(4)}{=} \left\langle a, \frac{\star F}{4\pi^2}\right\rangle \;=\; \left\langle \frac{\star F}{4\pi^2}, a\right\rangle. \end{aligned} \tag{12.38}$$

(1) Equation (12.26), written with Nash's notation $F_a(A)$ of footnote 3.
(2) Definition of $F_a(A)$.
(3) $\mathrm{tr}(F\wedge a) = \mathrm{tr}(a\wedge F)$ (2-form past 1-form), and $F = \star\star F$ because $\star\star = 1$ on 2-forms on a Riemannian 3-manifold. Here $\star F$ is an $\mathfrak{su}(2)$-valued 1-form.
(4) Definition (12.37) of the inner product, with $b = \star F/4\pi^2$; it is symmetric.

This is Nash's (12.18), and it gives (12.19):

$$\boxed{\mathrm{grad}\, f(A) = \frac{\star F(A)}{4\pi^2}}. \tag{12.39}$$

The gradient flow is $\mathrm{d}A/\mathrm{d}t = -\star F/4\pi^2$. Rescale time, $t \to 4\pi^2 t$, to absorb the constant; the flow equation (Nash's (12.20)) is

$$\boxed{\frac{\mathrm{d}A}{\mathrm{d}t} = -\star F(A)}. \tag{12.40}$$

In components on M with $A = A_i\,\mathrm{d}x^i$ and $B^i = (\star F)^i = \tfrac{1}{2}\varepsilon^{ijk}F_{jk}$ (the non-abelian magnetic field), (12.40) reads $\dot{A}_i = -B_i$: *the connection flows against its own magnetic field.*

How does f change along the flow? It decreases, at a rate set by the magnetic energy:

$$\frac{\mathrm{d}}{\mathrm{d}t}f(A(t)) \overset{(1)}{=} \mathrm{d}f_{\dot{A}} \overset{(2)}{=} \left\langle \frac{\star F}{4\pi^2}, \dot{A}\right\rangle \overset{(3)}{=} -\frac{1}{4\pi^2}\,\|\star F\|^2 \;\leq 0. \tag{12.41}$$

(1) Chain rule: the derivative of f along a curve is $\mathrm{d}f$ applied to the velocity.
(2) Equation (12.38) with $a = \dot{A}$.
(3) The flow (12.40): $\dot{A} = -\star F$.

So f is strictly decreasing except at flat connections, where the flow stops.

Worked example 12.16: The abelian flow on the 3-torus is not an initial-value problem

Take one abelian component on T^3, so the flow is linear: $\dot{\vec{a}} = -\nabla\times\vec{a}$. Expand in the curl eigenmodes found in Example 12.12: a mode of helicity $\pm$ and wavenumber $\kappa = |\vec{k}|$ has

$\nabla \times \vec{a} = \pm\kappa\, \vec{a}$, so

$$\dot{\vec{a}}_{\vec{k},\pm} = \mp\kappa\, \vec{a}_{\vec{k},\pm} \overset{(1)}{=} \vec{a}_{\vec{k},\pm}(t) = e^{\mp\kappa t}\, \vec{a}_{\vec{k},\pm}(0).$$

(1) Solve the scalar linear ODE for each mode separately.

Positive-helicity modes decay forward in time; negative-helicity modes *grow* like $e^{\kappa t}$, faster and faster as $\kappa \to \infty$. So for generic initial data the forward flow does not exist even for a short time, and neither does the backward flow. Contrast the heat equation $\dot{u} = \Delta u$, whose modes all decay forward. The Chern–Simons flow is not a parabolic evolution; it behaves like the Cauchy–Riemann equations $\partial_t u + i\partial_x u = 0$, where one cannot choose initial data freely. The right way to pose it is as a *boundary value problem* in t, with conditions at $t = \pm\infty$. The only finite-energy solutions linking two flat connections are those in which each growing mode is present only for $t < 0$ and each decaying mode only for $t > 0$, glued smoothly. This is exactly the setting of elliptic equations in four dimensions, and it leads to instantons.

12.4.2 The flow equation is the anti-self-duality equation on $M \times \mathbb{R}$

Now think of the path $A(t)$ as a single object on the 4-manifold $M \times \mathbb{R}$, with coordinates (x^1, x^2, x^3, t) and $x^4 \equiv t$. Define a connection $\mathbf{A}$ on $M \times \mathbb{R}$ by

$$\mathbf{A} = A(t), \qquad \text{i.e.} \qquad \mathbf{A}_i(x,t) = A_i(x,t), \quad \mathbf{A}_4 = 0. \tag{12.42}$$

Physicists call $\mathbf{A}_4 = 0$ **temporal gauge**: covariant differentiation in the t-direction is just $\partial/\partial t$. (Any connection on $M \times \mathbb{R}$ can be put in this gauge by solving an ODE in t for the gauge transformation.) Give $M \times \mathbb{R}$ the product metric $g_M + \mathrm{d}t^2$ and the orientation $\mathrm{d}t \wedge \mathrm{vol}_M$, i.e. the ordered coframe $(e^4, e^1, e^2, e^3) = (\mathrm{d}t, e^1, e^2, e^3)$.

Step 1: the four-dimensional curvature

Write $\mathbf{d} = \mathrm{d}_M + \mathrm{d}t \wedge \partial_t$ for the exterior derivative on $M \times \mathbb{R}$, with d_M the derivative along M. Then

$$\begin{aligned} \mathbf{F} &\overset{(1)}{=} \mathbf{dA} + \mathbf{A} \wedge \mathbf{A} \\ &\overset{(2)}{=} \mathrm{d}_M A + \mathrm{d}t \wedge \partial_t A + A \wedge A \\ &\overset{(3)}{=} F(t) + \mathrm{d}t \wedge \dot{A}(t), \end{aligned} \tag{12.43}$$

(1) Definition of curvature on $M \times \mathbb{R}$.
(2) $\mathbf{A} = A(t)$ has no $\mathrm{d}t$ component, so the only extra term in $\mathbf{dA}$ is the t-derivative.
(3) $F(t) = \mathrm{d}_M A + A \wedge A$ is the curvature of $A(t)$ on the slice $M \times \{t\}$.

In components, $\mathbf{F}_{ij} = F_{ij}$ and $\mathbf{F}_{4i} = \partial_t A_i$. This is Nash's remark that "the curvature components $\mathbf{F}_{4i}$ reduce to $\mathbf{F}_{4i} \equiv \mathrm{d}A/\mathrm{d}t$". Physically $\mathbf{F}_{4i}$ is the (Euclidean) electric field E_i, so (12.43) is the familiar $\mathbf{F} = \vec{E} \wedge \mathrm{d}t + \vec{B}$ split, with $\vec{E} = \dot{\vec{A}}$ in temporal gauge.

Step 2: the Hodge star on $M \times \mathbb{R}$

For a 1-form α on M (independent of how it varies in t), the four-dimensional star of the two kinds of 2-forms is

$$\star_4(\mathrm{d}t \wedge \alpha) = \star_3 \alpha, \qquad \star_4(\star_3 \alpha) = \mathrm{d}t \wedge \alpha. \tag{12.44}$$

Check on the coframe, with $\alpha = e^1$: $\star_3 e^1 = e^2 \wedge e^3$. The defining property $\omega \wedge \star\omega = |\omega|^2 \,\mathrm{vol}_4$ with $\mathrm{vol}_4 = e^4 \wedge e^1 \wedge e^2 \wedge e^3$ gives

$$(e^4 \wedge e^1) \wedge \star_4(e^4 \wedge e^1) = \mathrm{vol}_4 \overset{(1)}{=} \star_4(e^4 \wedge e^1) = e^2 \wedge e^3 = \star_3 e^1,$$
$$(e^2 \wedge e^3) \wedge \star_4(e^2 \wedge e^3) = \mathrm{vol}_4 \overset{(2)}{=} \star_4(e^2 \wedge e^3) = e^4 \wedge e^1.$$

(1) $e^4 \wedge e^1 \wedge e^2 \wedge e^3 = \mathrm{vol}_4$ exactly.
(2) $e^2 \wedge e^3 \wedge e^4 \wedge e^1 = e^4 \wedge e^1 \wedge e^2 \wedge e^3$, since moving the 2-form $e^4 \wedge e^1$ past the 2-form $e^2 \wedge e^3$ costs $(-1)^{2\cdot 2} = +1$.

The other components follow by cyclic permutation of $1, 2, 3$.

Step 3: compare

Apply (12.44) to (12.43), with $F = \star_3(\star_3 F)$:

$$\star_4 \mathbf{F} = \mathrm{d}t \wedge \star_3 F + \star_3 \dot{A}.$$

So the anti-self-duality equation $\mathbf{F} = -\star_4 \mathbf{F}$ reads

$$\begin{aligned} & F + \mathrm{d}t \wedge \dot{A} \overset{(1)}{=} -\mathrm{d}t \wedge \star_3 F - \star_3 \dot{A} \\ \iff \quad & \dot{A} \overset{(2)}{=} -\star_3 F \quad \text{and} \quad F = -\star_3 \dot{A} \\ \iff \quad & \dot{A} \overset{(3)}{=} -\star_3 F. \end{aligned} \tag{12.45}$$

(1) Substitute (12.43) and the formula for $\star_4 \mathbf{F}$.
(2) Match the parts containing $\mathrm{d}t$ and the parts tangent to M separately; a 2-form on $M \times \mathbb{R}$ splits uniquely this way.
(3) The second equation is the first with $\star_3$ applied to both sides ($\star_3 \star_3 = 1$): the two halves are the same equation.

Key idea: flow lines are instantons

With the product metric and the orientation $\mathrm{d}t \wedge \mathrm{vol}_M$, the Chern–Simons gradient flow $\dot{A} = -\star F$ on M is *exactly* the anti-self-duality equation

$$\mathbf{F} = -\star \mathbf{F} \quad \text{on } M \times \mathbb{R} \tag{12.46}$$

for the connection $\mathbf{A} = A(t)$ in temporal gauge. With the opposite orientation (or the flow run backwards) one gets the self-duality equation; this is Nash's (12.21), $\mathbf{F} = \mp \star \mathbf{F}$.

12.4.3 Boundary conditions and the energy identity

$M \times \mathbb{R}$ is not compact, so (12.46) needs boundary conditions at the two ends. The natural ones (Nash's (12.22)) are that the flow starts and ends at critical points:

$$A(-\infty) = A_P, \qquad A(+\infty) = A_Q, \qquad A_P, A_Q \text{ flat}. \tag{12.47}$$

Nash remarks that this is consistent with the usual requirement of finite Yang–Mills action: finite action forces $\mathbf{F} \to 0$ at the ends, i.e. the slices become flat. Let us compute the action and see that it is not only finite but *determined* by the endpoints.

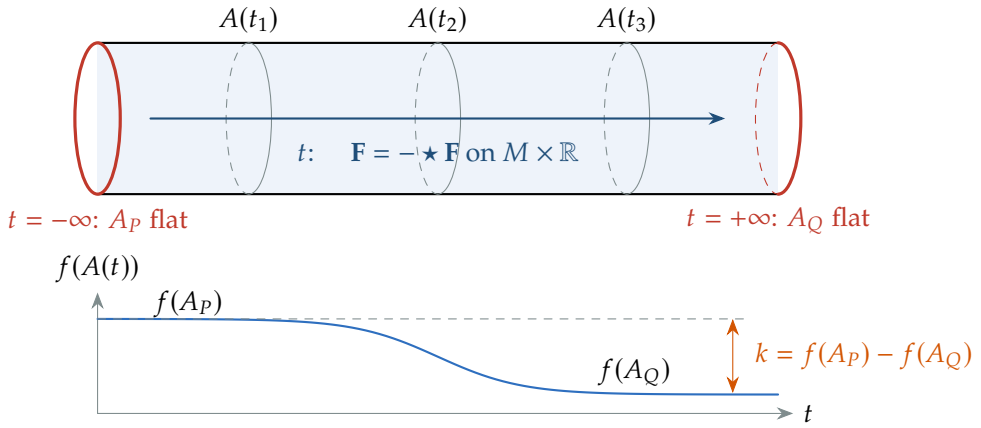

Figure 12.12: Top: a flow line of the Chern–Simons function is a 1-parameter family of connections $A(t)$ on the slices $M \times \{t\}$. Stacked together they form a connection on the infinite cylinder $M \times \mathbb{R}$, and the flow equation is the anti-self-duality equation there. The ends are flat connections (red). Bottom: along the flow, f decreases monotonically; the total drop is the instanton number k, a sum of the energy on all the slices.

$$\begin{aligned} S_{\mathrm{YM}} &:= -\int_{M\times\mathbb{R}} \operatorname{tr}(\mathbf{F}\wedge\star\mathbf{F}) \overset{(1)}{=} \int_{M\times\mathbb{R}} \operatorname{tr}(\mathbf{F}\wedge\mathbf{F}) \\ &\overset{(2)}{=} \int_{M\times\mathbb{R}} \mathbf{d}\,\mathrm{CS}(\mathbf{A}) \\ &\overset{(3)}{=} \int_M \mathrm{CS}(A_Q) - \int_M \mathrm{CS}(A_P) \\ &\overset{(4)}{=} 8\pi^2\big(f(A_P) - f(A_Q)\big). \end{aligned} \tag{12.48}$$

(1) Anti-self-duality: $\star\mathbf{F} = -\mathbf{F}$.
(2) The transgression formula (12.16), $\operatorname{tr}(F\wedge F) = \mathrm{d}\,\mathrm{CS}(A)$, which holds in any dimension.
(3) Stokes on $M \times [-T, T]$, $T \to \infty$. With the orientation $\mathrm{d}t \wedge \mathrm{vol}_M$ the outward normal at $t = +T$ is $+\partial_t$ and the boundary orientation is $+\mathrm{vol}_M$; at $t = -T$ it is $-\mathrm{vol}_M$. The 3-form $\mathrm{CS}(\mathbf{A})$ restricted to a slice is $\mathrm{CS}(A(t))$ since $\mathbf{A}$ has no $\mathrm{d}t$ component.
(4) Definition (12.15): $\int_M \mathrm{CS} = -8\pi^2 f$.

With the instanton number normalised as $k = \frac{1}{8\pi^2}\int \operatorname{tr}(\mathbf{F}\wedge\mathbf{F})$,

$$\boxed{\,k = f(A_P) - f(A_Q) \geq 0, \qquad S_{\mathrm{YM}} = 8\pi^2 k\,}. \tag{12.49}$$

The inequality is (12.41): f only goes down along a flow. The action of a flow line is its height drop.

Physical picture: Instantons as tunnelling, again

In Chapter 7 instantons were steepest-descent paths between critical points, and the Euclidean action of an instanton equalled the height difference $f(P) - f(Q)$: that was the Bogomolny trick $\frac{1}{2}\int |\dot{x} \pm \nabla f|^2 \geq \mp\int \dot{x}\cdot\nabla f$. Equation (12.48) is literally the same computation one dimension up. The famous Yang–Mills bound $S_{\mathrm{YM}} \geq 8\pi^2|k|$ is the Bogomolny bound of the supersymmetric quantum mechanics on $\mathcal{A}/\mathcal{G}$ whose "potential" is the Chern–Simons function.

Worked example 12.17: The BPST instanton is a flow line on $S^3 \times \mathbb{R}$

Remove the origin from $\mathbb{R}^4$ and use polar coordinates $r > 0$ and a point of the unit S^3. Put $\tau = \ln r$. Then

$$\mathrm{d}r^2 + r^2\, g_{S^3} \overset{(1)}{=} e^{2\tau}\mathrm{d}\tau^2 + e^{2\tau} g_{S^3} = e^{2\tau}\big(\mathrm{d}\tau^2 + g_{S^3}\big).$$

(1) $r = e^\tau$, so $\mathrm{d}r = e^\tau \mathrm{d}\tau$.

So $\mathbb{R}^4 \setminus \{0\}$ is *conformal* to the cylinder $S^3 \times \mathbb{R}$ with the product metric. The Hodge star on 2-forms in four dimensions is conformally invariant (rescaling $g \to \Omega^2 g$ multiplies $\omega \wedge \star\omega$ and vol by the same Ω^0 factor on 2-forms), so an anti-self-dual connection on $\mathbb{R}^4$ is an anti-self-dual connection on $S^3 \times \mathbb{R}$, i.e. a Chern–Simons flow line on S^3 with time $\tau = \ln r$. The orientation $\mathrm{d}\tau \wedge \mathrm{vol}_{S^3}$ is the standard one of $\mathbb{R}^4$ (radial direction first, then the boundary orientation of the sphere).

Take the BPST instanton of instanton number $k = 1$ centred at the origin (Chapter 8). In regular gauge it is smooth at $r = 0$, where $A \to 0$; as $r \to \infty$ it approaches a pure gauge $h^{-1}\mathrm{d}h$ with $h : S^3 \to \mathrm{SU}(2)$ of degree ± 1. So as a flow line on $S^3 \times \mathbb{R}$:

- $\tau \to -\infty$: $A \to A_P = 0$, with $f(A_P) = 0$;
- $\tau \to +\infty$: $A \to A_Q = h^{-1}\mathrm{d}h$, and (12.49) forces $f(A_Q) = f(A_P) - k = -1$.

Both ends are the *same* point of $\mathcal{A}/\mathcal{G}$, the trivial connection θ. The flow line descends the spiral staircase of Figure 12.7 by one full turn: it is a closed loop in $\mathcal{A}/\mathcal{G}$ representing the generator of $\pi_1(\mathcal{A}/\mathcal{G})$. Its scale parameter ρ is the time-translation of the flow line ($\rho \to e^c\rho$ is $\tau \to \tau + c$), and its centre gives four more parameters, so these flow lines form the 5-dimensional moduli space of $k = 1$ instantons on $\mathbb{R}^4$. The number $5 = 8 - 3$ is the index $8k$ computed below, minus $3 = \dim \mathrm{SU}(2)$ because both ends sit at the reducible connection θ whose stabiliser is all of SU(2).

12.4.4 Linearising the flow

To count flow lines we need their deformation theory: how many independent directions can one move a flow line and stay a flow line? Perturb a solution $A(t)$ to $A(t) + \varepsilon a(t)$ and keep first order in ε (Nash's (12.23)):

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\big(A + \varepsilon a\big) &\overset{(1)}{=} -\star F(A + \varepsilon a) \\ \frac{\mathrm{d}A}{\mathrm{d}t} + \varepsilon\frac{\mathrm{d}a}{\mathrm{d}t} &\overset{(2)}{=} -\star F(A) - \varepsilon\ \star \mathrm{d}_{A(t)}a + O(\varepsilon^2) \\ \frac{\mathrm{d}a}{\mathrm{d}t} &\overset{(3)}{=} -\star\, \mathrm{d}_{A(t)}a. \end{aligned} \tag{12.50}$$

(1) The perturbed path must satisfy the flow equation.
(2) $F(A + \varepsilon a) = F(A) + \varepsilon\, \mathrm{d}_A a + \varepsilon^2 a \wedge a$: the linear term is $\mathrm{d}a + A \wedge a + a \wedge A = \mathrm{d}_A a$ by (12.29).
(3) Subtract the unperturbed equation and divide by ε.

So a tangent vector to the space of flow lines is a solution of (Nash's (12.24))

$$\Big(\frac{\mathrm{d}}{\mathrm{d}t} + \star\mathrm{d}_{A(t)}\Big)a(t) = 0. \tag{12.51}$$

This is the same operator whose index is the spectral flow (Example 12.15): $\frac{\mathrm{d}}{\mathrm{d}t} + 4\pi^2 H(A(t))$. So

$$\dim\{\text{flow lines near } A(t)\} = \mathrm{index}\Big(\frac{\mathrm{d}}{\mathrm{d}t} + \star\mathrm{d}_{A(t)}\Big) = \sigma(A_P, A_Q), \tag{12.52}$$

exactly as in finite dimensions, where the space of flow lines from P to Q has dimension $\lambda_P - \lambda_Q$ (Figure 12.13). The relative Morse index is the dimension of the space of instantons connecting the two flat connections (when the relevant cokernel vanishes, which holds for generic data).

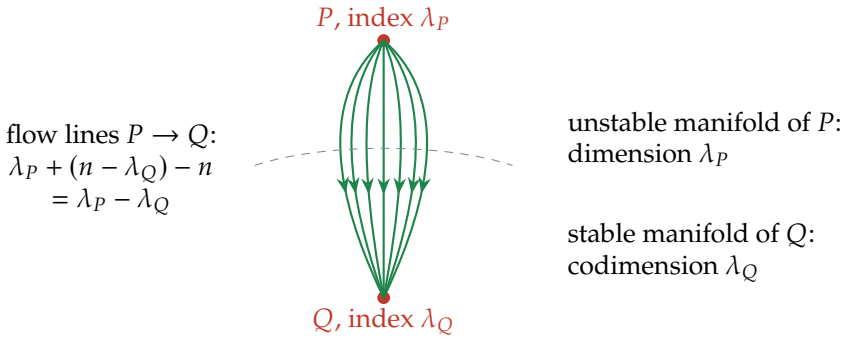

Figure 12.13: Finite-dimensional picture of (12.52). Flow lines from P leave along the λ_P-dimensional unstable manifold of P and must arrive in the stable manifold of Q, which has codimension λ_Q. Generic intersection has dimension $\lambda_P - \lambda_Q$. In Floer theory both numbers are infinite, but their difference is the index of $\frac{\mathrm{d}}{\mathrm{d}t} + \star \mathrm{d}_{A(t)}$.

The operator is the instanton deformation operator

Nash says that "after taking proper account of gauge equivalent a's", (12.51) is the deformation problem for instantons. Here is the proper account. A general perturbation of the 4d connection is $\mathbf{a} = a_0\,\mathrm{d}t + a$, with $a_0(x,t) \in \Omega^0(M) \otimes \mathfrak{su}(2)$ and $a(t) \in \Omega^1(M) \otimes \mathfrak{su}(2)$. The instanton deformation complex of Chapter 8 (Nash's (8.104), with self-dual and anti-self-dual exchanged because we linearise $\mathbf{F}^+ = 0$) asks for

$$\mathbf{d}_{\mathbf{A}}^+ \mathbf{a} = 0 \quad \text{(linearised ASD)}, \qquad \mathbf{d}_{\mathbf{A}}^* \mathbf{a} = 0 \quad \text{(gauge fixing)}.$$

Using $\mathbf{d}_{\mathbf{A}}\mathbf{a} = \mathrm{d}_A a + \mathrm{d}t \wedge (\dot{a} - \mathrm{d}_A a_0)$ and (12.44), the self-dual part of a 2-form $\beta + \mathrm{d}t \wedge \gamma$ is determined by $\gamma + \star_3 \beta$. So the two equations become

$$\begin{aligned} \dot{a} - \mathrm{d}_A a_0 + \star \mathrm{d}_A a &= 0, \\ -\dot{a}_0 + \mathrm{d}_A^* a &= 0, \end{aligned}$$

i.e.

$$\left(\frac{\mathrm{d}}{\mathrm{d}t} + L_{A(t)}\right)\begin{pmatrix} a_0 \\ a \end{pmatrix} = 0, \qquad L_A = \begin{pmatrix} 0 & -\mathrm{d}_A^* \\ -\mathrm{d}_A & \star \mathrm{d}_A \end{pmatrix} \text{ on } (\Omega^0 \oplus \Omega^1)(M) \otimes \mathfrak{su}(2). \tag{12.53}$$

L_A is self-adjoint (the off-diagonal entries are adjoints of each other). It is the **extended Hessian**: the curl operator $\star \mathrm{d}_A$ of (12.31) bordered by the gauge directions $\mathrm{d}_A a_0$. At an irreducible, non-degenerate flat connection L_A is invertible, and on the gauge-fixed slice $\mathrm{d}_A^* a = 0$ it reduces to $\star \mathrm{d}_A$. This is the precise sense of Nash's statement that $\frac{\mathrm{d}}{\mathrm{d}t} + \star \mathrm{d}_{A(t)}$ is the instanton deformation operator.

Worked example 12.18: The extended Hessian at $A = 0$ on the 3-torus

Return to Example 12.12. On a Fourier mode $e^{i\vec{k}\cdot\vec{x}}$ the bordered operator acts on $(a_0, \vec{a})$, with $\mathrm{d}_A = \nabla$ on functions, $\mathrm{d}_A^* = -\nabla\cdot$ on 1-forms, and $\star\mathrm{d} = \nabla\times$:

$$L_{\vec{k}} = \begin{pmatrix} 0 & i\vec{k}^{\mathsf{T}} \\ -i\vec{k} & i\vec{k}\times \end{pmatrix} \quad \text{on} \quad \mathbb{C} \oplus \mathbb{C}^3.$$

On the transverse helicity modes it gives $\pm|\vec{k}|$ as before. The longitudinal mode $\vec{a} = \hat{\vec{k}}$ and the scalar a_0 now mix: on the pair (a_0, $\hat{\vec{k}}$-component) the matrix is $\left(\begin{smallmatrix} 0 & i|\vec{k}| \\ -i|\vec{k}| & 0 \end{smallmatrix}\right)$, with eigenvalues $\pm|\vec{k}|$. So the zero eigenvalues that came from the gauge directions have become $\pm|\vec{k}|$: gauge fixing removes the spurious kernel. What remains at $\vec{k} = 0$ is a 4-dimensional kernel (constant a_0 and constant $\vec{a}$), reflecting that on T^3 the flat connection 0 is reducible ($H^0 \neq 0$) and degenerate ($H^1 \neq 0$). On a homology sphere $H^1 = 0$, and away from the trivial connection $H^0 = 0$ too.

12.4.5 The spectral flow round a loop is $8k$

We can now compute the missing number. Close up the t-direction: a loop in $\mathcal{A}/\mathcal{G}$ is a path $A(t)$, $0 \le t \le 1$, with $A(1) = A(0)^g$. Glue the ends of $M \times [0,1]$ using g. The result is an SU(2) bundle P over $M \times S^1$, and $\mathbf{A}$ is a connection on it. The bundle is non-trivial when $\deg g \neq 0$: g is the clutching function, and its degree is the instanton number,

$$k = \frac{1}{8\pi^2}\int_{M\times S^1} \operatorname{tr}(\mathbf{F}\wedge\mathbf{F}) = f(A(0)) - f(A(1)) = f(A(0)) - f(A(0)^g) = -\deg g,$$

by the same Stokes computation as (12.48) and the gauge shift (12.17). (The sign just reflects our orientation choice; what matters is $|k| = |\deg g|$.)

The spectral flow round the loop is the index of $\frac{\mathrm{d}}{\mathrm{d}t} + \star\mathrm{d}_{A(t)}$ on the closed 4-manifold $M \times S^1$, which is the dimension of the moduli space of instantons there. From Chapter 8 (Nash's (8.115) and (8.124)):

$$\operatorname{index}\Big(\frac{\mathrm{d}}{\mathrm{d}t} + \star\mathrm{d}_{A(t)}\Big) = \dim \mathcal{M}_k = p_1(\mathrm{ad}_{\mathbb{C}}P) - \frac{\dim G}{2}\big(\chi(M\times S^1) - \tau(M\times S^1)\big). \tag{12.54}$$

This is Nash's (12.25). We need three numbers.

(i) The Pontryagin number. For $G = \mathrm{SU}(2)$, in Nash's normalisation (Chapter 8, (8.127)–(8.131)),

$$p_1(\mathrm{ad}_{\mathbb{C}}P) = 8k, \qquad \dim G = 3. \tag{12.55}$$

(ii) The signature. The signature τ of a 4-manifold is the signature of the intersection form on H_2. Use the Künneth formula:

$$\begin{aligned} H_2(M\times S^1) &\overset{(1)}{=} \big(H_2(M)\otimes H_0(S^1)\big) \oplus \big(H_1(M)\otimes H_1(S^1)\big) \\ &\overset{(2)}{=} 0 \oplus 0 = 0 \quad\Longrightarrow\quad \tau(M\times S^1) = 0. \end{aligned} \tag{12.56}$$

(1) Künneth: $H_n(X\times Y) = \bigoplus_{p+q=n} H_p(X)\otimes H_q(Y)$ (plus torsion terms, which vanish here); $H_2(S^1) = 0$ kills the third term.
(2) M is a homology sphere: $H_1(M) = H_2(M) = 0$.

(Nash writes this as $H_2(M\times S^1) = H_2(M) = 0$, which is the same thing once one notes $H_1(M) = 0$; this is Nash's (12.26).) With no 2-cycles there is no intersection form at all, so its signature is 0.

(iii) The Euler characteristic. The Euler characteristic is multiplicative (Nash's (12.27)):

$$\chi(M\times S^1) \overset{(1)}{=} \chi(M)\,\chi(S^1) \overset{(2)}{=} (1-0+0-1)(1-1) = 0. \tag{12.57}$$

(1) Künneth again: the Poincaré polynomial of a product is the product of the Poincaré polynomials, and $\chi = P_{-1}$.

(2) Betti numbers of a homology 3-sphere are $1,0,0,1$; of the circle, $1,1$. (Either factor alone would do: every closed odd-dimensional manifold has $\chi = 0$ by Poincaré duality, $b_j = b_{n-j}$.)

Putting (i)–(iii) into (12.54):

$$\operatorname{index}\Big(\frac{\mathrm{d}}{\mathrm{d}t} + \star \mathrm{d}_{A(t)}\Big) \overset{(1)}{=} 8k - \frac{3}{2}(0-0) = 8k. \tag{12.58}$$

(1) Equations (12.55), (12.56) and (12.57).

This is Nash's (12.28). Back in three dimensions it says (Nash's (12.29)):

Key idea: the magic number 8

The spectral flow of $\star \mathrm{d}_{A(t)}$ round a loop in $\mathcal{A}/\mathcal{G}$ of degree k is $8k$. The generating loop ($k = 1$) has spectral flow 8. Hence the relative Morse index of the Chern–Simons function is well defined only modulo 8:

$$\lambda_{A_P, A_Q} \in \mathbb{Z}/8\mathbb{Z}.$$

Watch out: Normalisations of p_1 and the sign of k

Nash's (12.25) uses his normalisation $p_1(\mathrm{ad}_{\mathbb{C}}P) = 8k$ from Chapter 8; in the most common modern convention one writes $\dim \mathcal{M}_k = 8c_2(E) - 3(1 - b_1 + b_2^+)$ for an SU(2) bundle E with $c_2(E) = k$. On $M \times S^1$ with M a homology sphere, $b_1 = 1$ and $b_2^+ = 0$, so this also gives $8k - 3(1 - 1 + 0) = 8k$. The formulae agree; only the bookkeeping of p_1 differs (see the corresponding warning in Chapter 8). The sign of k is fixed by the orientation; with ours, instantons have $k \geq 0$ and flow lines go downhill in f.

Worked example 12.19: Betti numbers of $\Sigma(2,3,5) \times S^1$

Poincaré polynomials multiply:

$$P_t(\Sigma \times S^1) \overset{(1)}{=} (1 + t^3)(1 + t) = 1 + t + t^3 + t^4.$$

(1) $P_t(\Sigma) = 1 + t^3$ for any homology 3-sphere, $P_t(S^1) = 1 + t$.

So $b_0 = b_1 = b_3 = b_4 = 1$ and $b_2 = 0$. Then $\chi = 1 - 1 + 0 - 1 + 1 = 0$ and $\tau = 0$ (no H_2). Compare S^4 ($1 + t^4$, $\chi = 2$) where the same formula gives $\dim \mathcal{M}_k = 8k - \frac{3}{2} \cdot 2 = 8k - 3$: the -3 that appeared at the end of Example 12.17. On $M \times S^1$ there is no such correction; all of $8k$ is spectral flow.

Physical picture: Where 8 comes from

Why eight and not one? The index of the instanton deformation operator counts real parameters of instantons, and for SU(2) each unit of instanton number carries eight: on $\mathbb{R}^4$ they are the four coordinates of the instanton's centre, its size, and three SU(2) orientation angles (the global gauge rotation). The three orientation angles are "lost" on S^4 and $\mathbb{R}^4$ because the endpoint is reducible, leaving $8k - 3$; on $M \times S^1$ nothing is lost and all $8k$ are counted. So one trip round $\mathcal{A}/\mathcal{G}$ passes eight eigenvalues of the curl operator through zero.

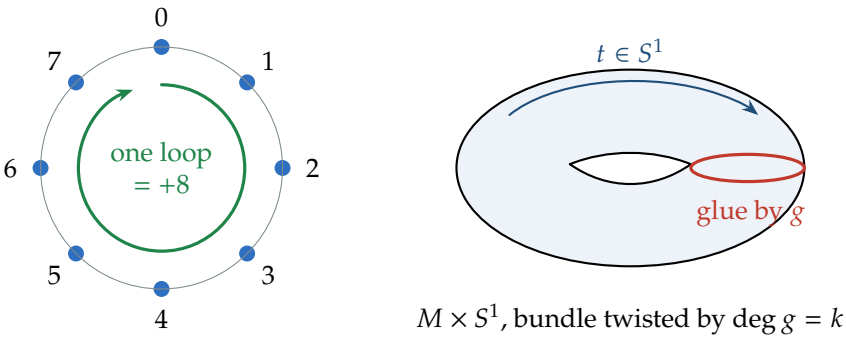

Figure 12.14: Left: because the spectral flow round the generating loop of $\pi_1(\mathcal{A}/\mathcal{G}) = \mathbb{Z}$ is 8, relative Morse indices live on a clock with eight hours. Right: the loop closes $M \times [0,1]$ into $M \times S^1$, glued by the gauge transformation g; the resulting bundle has instanton number $k = \pm \deg g$, and the index theorem on this closed 4-manifold gives $8k$.

Reading Nash (pp. 327–330, (12.15)–(12.29))

Nash introduces the metric (12.16) on $T_A\mathcal{A}$, computes grad $f = \star F/4\pi^2$ (12.17)–(12.19) and the flow $\dot{A} = -\star F$ (12.20). He extends $A(t)$ to $M \times \mathbb{R}$ with $\mathbf{A}_4 = 0$ and product metric and states that the flow is the (anti-)self-duality equation (12.21), with boundary conditions (12.22). He linearises (12.23)–(12.24) and computes the index via Chapter 8's (8.115), (8.124) (12.25), using $p_1 = 8k$, $\tau = 0$ (12.26), $\chi = 0$ (12.27), to get $8k$ (12.28), the spectral flow round a loop (12.29). We added: positivity of the metric; the monotonicity of f; the ill-posedness of the flow as an initial value problem; the full Hodge-star verification of anti-self-duality with our orientation; the energy identity $S_{\mathrm{YM}} = 8\pi^2(f(A_P) - f(A_Q))$; the BPST instanton as a flow line; the gauge-fixed extended Hessian; and the Künneth computations.

Recap

- With the L^2 metric, grad $f = \star F/4\pi^2$; the flow (rescaled) is $\dot{A} = -\star F$, and f decreases along it.
- In temporal gauge on $M \times \mathbb{R}$, $\mathbf{F} = F + \mathrm{d}t \wedge \dot{A}$, and the flow equation is exactly $\mathbf{F} = -\star\mathbf{F}$: flow lines are instantons with flat limits A_P, A_Q.
- Energy identity: $S_{\mathrm{YM}} = 8\pi^2 k$, $k = f(A_P) - f(A_Q)$.
- The linearised flow is $\left(\frac{\mathrm{d}}{\mathrm{d}t} + \star \mathrm{d}_A\right) a = 0$, the gauge-fixed instanton deformation operator; its index is the dimension of the space of flow lines and equals the relative index.
- On $M \times S^1$: $\tau = \chi = 0$, index $= 8k$. The relative Morse index is defined mod 8.

12.5 Floer homology, Casson's invariant and the Chern–Simons theory

We now have every ingredient of a Morse complex on $\mathcal{A}/\mathcal{G}$: critical points (irreducible flat connections), relative indices (spectral flow, defined mod 8), and flow lines (instantons on $M \times \mathbb{R}$). This section assembles them. We build the complex and its homology, the Floer groups $HF_p(M)$; we see why they are invariants of the 3-manifold; we compute them in the simplest non-trivial case; and we take their Euler characteristic, which turns out to be twice a classical invariant of Casson. Then we look at the Chern–Simons function from two more angles that

Nash raises at the end of his §2: as the *action* of a quantum field theory in three dimensions, and as the potential in a supersymmetric Hamiltonian whose ground states are the Floer groups.

12.5.1 The Floer complex

The chain groups

Let M be a homology 3-sphere, and suppose (after a small perturbation if necessary) that every irreducible flat connection is non-degenerate, i.e. the curl operator $\star \mathrm{d}_\alpha$ has no kernel on the gauge slice. Write

$$\mathcal{R}^*(M) = \{\alpha_1, \dots, \alpha_N\} \subset \mathrm{Hom}(\pi_1(M), \mathrm{SU}(2))/\mathrm{Ad}\,\mathrm{SU}(2)$$

for the irreducible ones. The trivial connection θ is the only reducible one (Section 12.3); it is *left out* of the complex, because its stabiliser SU(2) makes the flow lines into and out of it behave differently. It is still useful as a reference point for the grading.

Each α_i gets a degree in $\mathbb{Z}_8$: its relative Morse index with respect to θ,

$$\mu(\alpha) := \sigma(\alpha, \theta) \bmod 8, \tag{12.59}$$

the spectral flow of $\star \mathrm{d}_{A(t)}$ along any path from α to θ (Section 12.3.4). Different paths change it by multiples of 8 (Section 12.4.5), so $\mu(\alpha) \in \mathbb{Z}_8$ is well defined. (Conventions differ by a constant shift, usually $3 = \dim \mathrm{SU}(2)$, coming from the stabiliser of θ. Only differences matter for the complex.) The **Floer chain groups** are the free abelian groups

$$C_p := \bigoplus_{\alpha \in \mathcal{R}^*(M),\ \mu(\alpha) = p} \mathbb{Z} \cdot \alpha, \qquad p \in \mathbb{Z}_8. \tag{12.60}$$

This is (12.6) with "critical point of index p" replaced by "irreducible flat connection of relative index p mod 8".

The boundary operator

For $\alpha, \beta \in \mathcal{R}^*(M)$ let $\mathcal{M}(\alpha, \beta)$ be the space of flow lines from α to β modulo gauge, i.e. instantons on $M \times \mathbb{R}$ with limits α at $t = -\infty$ and β at $t = +\infty$ (Section 12.4). By (12.52) its dimension is the relative index $\sigma(\alpha, \beta)$. Time translation $t \mapsto t + c$ acts on it freely (a non-constant flow line is not translation invariant), so

$$\dim\big(\mathcal{M}(\alpha, \beta)/\mathbb{R}\big) = \sigma(\alpha, \beta) - 1.$$

When $\mu(\alpha) - \mu(\beta) = 1$, the quotient is a finite set of points: a finite number of *unparametrised* instantons. Each carries a sign ± 1 (the orientation of the moduli space at that point; physically, the sign of a fermion determinant). Their signed count is

$$n(\alpha, \beta) := \#\big(\mathcal{M}(\alpha, \beta)/\mathbb{R}\big) \in \mathbb{Z}, \tag{12.61}$$

and the **Floer boundary operator** is

$$\partial \alpha := \sum_{\mu(\beta) = \mu(\alpha) - 1} n(\alpha, \beta)\, \beta. \tag{12.62}$$

It lowers the degree by one. Unlike (12.7), which counted flow lines *up* and raised the degree (a coboundary), this counts flow lines *down* and lowers it (a boundary). The two are transposes of each other; Nash, following Floer, uses the boundary version.

Because degrees live in $\mathbb{Z}_8$, the complex closes up on itself (Nash's (12.30)):

$$\cdots \xrightarrow{\partial} C_7 \xrightarrow{\partial} C_6 \xrightarrow{\partial} \cdots \xrightarrow{\partial} C_1 \xrightarrow{\partial} C_0 \xrightarrow{\partial} C_7 \xrightarrow{\partial} \cdots \tag{12.63}$$

Watch out: The complex is cyclic, not finite

Nash draws (12.30) as $0 \to C_7 \to C_6 \to \cdots \to C_0 \to 0$, with zeros at both ends. Read literally, that would mean no flow lines from degree 0 to degree 7. But $7 \equiv 0 - 1 \pmod 8$, so there is in general a map $\partial : C_0 \to C_7$, and the complex is a *cycle* of eight groups, as in (12.63). What Nash means by "length 8" is that there are only eight distinct groups, however many critical points and however infinite the index.

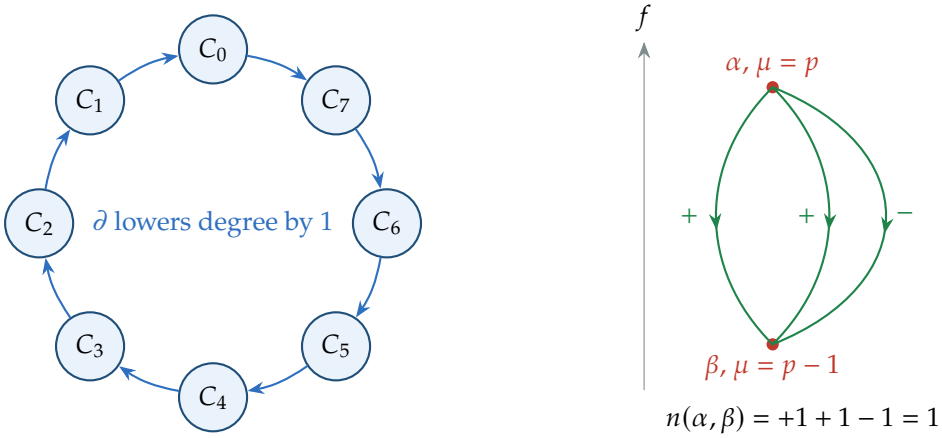

Figure 12.15: Left: the Floer complex has one group for each residue mod 8, and the boundary operator goes once round the clock. Right: the matrix element $n(\alpha, \beta)$ is the signed number of instantons on $M \times \mathbb{R}$ (flow lines modulo time translation) from α down to β, when their relative index is 1.

Why $\partial^2 = 0$: broken flow lines

Nash says that $\partial^2 = 0$ "can be done (formally) with exactly the same instanton tunnelling method" as in Chapter 7. Here is that method, as a Stokes-type argument. Take α and γ with $\mu(\alpha) - \mu(\gamma) = 2$. The coefficient of γ in $\partial^2\alpha$ is

$$\begin{aligned}(\partial^2\alpha)_\gamma &\overset{(1)}{=} \sum_\beta n(\alpha,\beta)\, n(\beta,\gamma) \\ &\overset{(2)}{=} \#\{\text{broken flow lines } \alpha \to \beta \to \gamma\} \\ &\overset{(3)}{=} \#\,\partial\big(\overline{\mathcal{M}(\alpha,\gamma)/\mathbb{R}}\big) \\ &\overset{(4)}{=} 0. \end{aligned} \tag{12.64}$$

(1) Apply (12.62) twice; β runs over generators of degree $\mu(\alpha) - 1$.

(2) A pair (flow line $\alpha \to \beta$, flow line $\beta \to \gamma$) is a **broken flow line**; its sign is the product of the two signs.

(3) $\mathcal{M}(\alpha,\gamma)/\mathbb{R}$ has dimension $2 - 1 = 1$. The *gluing theorem* says it can be compactified to a compact 1-manifold whose boundary points are exactly the broken flow lines, with the product orientation.

(4) A compact 1-manifold is a finite union of closed intervals and circles; each interval has two ends with opposite orientations, so the signed count of boundary points is zero.

Step (4) is the one-dimensional case of "$\int_M \mathrm{d}\alpha = \int_{\partial M} \alpha$": the fundamental theorem of calculus, $\int_a^b h' = h(b) - h(a)$, applied to the constant function $h = 1$ on each interval.

Watch out: Why no bubbles in the 1-dimensional moduli space

In four dimensions a sequence of instantons can concentrate curvature at a point and "bubble off" an instanton on S^4 (Section 12.6.5). Could this add extra ends in step (3)? A bubble carries away instanton number 1, hence (by Section 12.4.5) index 8. What is left is a flow line of index $2 - 8 = -6 < 0$, and for generic data there are none. So bubbling cannot happen in the moduli spaces that define ∂ and ∂^2. This is the same number 8 that made the grading cyclic.

Worked example 12.20: A dented sphere: tunnelling cancels a pair

Let $X = S^2$ be dented like a kidney bean standing on end, with height function f. It has two maxima a_1, a_2 (index 2), a saddle s between them (index 1) and one minimum m (index 0). The chain groups are $C_2 = \mathbb{Z}a_1 \oplus \mathbb{Z}a_2$, $C_1 = \mathbb{Z}s$, $C_0 = \mathbb{Z}m$.
From each maximum exactly one flow line runs down to the saddle, and from the saddle two flow lines run down to the minimum, one on each side. Orienting the unstable manifolds gives

$$\partial a_1 = s, \qquad \partial a_2 = -s, \qquad \partial s = m - m = 0, \qquad \partial m = 0.$$

Then

$$H_2 \overset{(1)}{=} \operatorname{Ker} \partial|_{C_2} = \mathbb{Z}(a_1 + a_2) \cong \mathbb{Z},$$
$$H_1 \overset{(2)}{=} \operatorname{Ker} \partial|_{C_1} / \operatorname{Im} \partial|_{C_2} = \mathbb{Z}s / \mathbb{Z}s = 0,$$
$$H_0 \overset{(3)}{=} C_0 / \operatorname{Im} \partial|_{C_1} = \mathbb{Z}m \cong \mathbb{Z}.$$

(1) There is no C_3, so H_2 is the kernel; $\partial(xa_1 + ya_2) = (x - y)s$ vanishes iff $x = y$.
(2) $\partial s = 0$, and $\operatorname{Im} \partial|_{C_2} = \mathbb{Z}s$.
(3) $\partial s = 0$, so nothing in C_0 is a boundary.

These are the Betti numbers of S^2. The pair (a_2, s) has been "cancelled by tunnelling". Now check $\partial^2 a_1 = 0$ geometrically: the flow lines from a_1 to m form a 1-parameter family (they sweep out the cap of a_1). At the two ends of the family the flow line breaks at s, once on each side, giving the two broken lines $a_1 \to s \to m$ with signs $+1$ and -1. They cancel, as (12.64) says they must.

12.5.2 The Floer groups

With $\partial^2 = 0$ we can take homology (Nash's (12.31)):

$$\boxed{HF_p(M) = \frac{\operatorname{Ker}\big(\partial : C_p \to C_{p-1}\big)}{\operatorname{Im}\big(\partial : C_{p+1} \to C_p\big)}, \qquad p \in \mathbb{Z}_8.} \tag{12.65}$$

(Nash labels the map $C_{p+1} \to C_p$ as ∂_p, so his formula reads $\operatorname{Ker} \partial_{p-1} / \operatorname{Im} \partial_p$; it is the same thing.) These are the **Floer homology groups** of M.

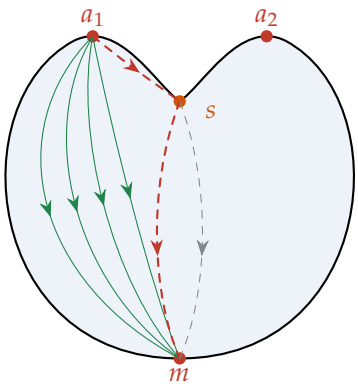

Figure 12.16: The dented sphere of Example 12.20, seen from the front. Flow lines from the maximum a_1 to the minimum m come in a 1-parameter family. As the parameter runs to its ends, the flow line is pulled onto the saddle s and breaks into two pieces. The two broken lines (front and back) have opposite signs, which is why $\partial^2 a_1 = 0$. The same picture, with instantons on $M \times \mathbb{R}$ in place of flow lines, proves $\partial^2 = 0$ in Floer's complex.

Working definition 12.8 (Floer homology of a homology 3-sphere)

To compute $HF_*(M)$:

1. List the irreducible flat SU(2) connections, i.e. the irreducible representations $\pi_1(M) \to \mathrm{SU}(2)$ up to conjugation. Perturb if any is degenerate [its Hessian $\star \mathrm{d}_A$ has a nonzero zero mode a that is not a gauge direction].
2. Give each one a degree $\mu \in \mathbb{Z}_8$ by the spectral flow of the curl operator $\star \mathrm{d}_{A(t)}$ from it to the trivial connection.
3. For each pair with degrees differing by one, count the instantons on $M \times \mathbb{R}$ [anti-self-dual connections, the same as steepest-descent paths $A(t)$ of the Chern–Simons function] running between them, modulo time translation, with signs. This is the matrix of ∂.
4. Take kernel modulo image in each of the eight degrees.

Formally $HF_*(M)$ is the Morse homology [chains are the critical points, and ∂ counts the flow lines between them] of the Chern–Simons function on the irreducible part of $\mathcal{A}/\mathcal{G}$ [gauge classes of irreducible connections].

Why it is an invariant

The construction used a metric on M (to define $\star$, hence the curl operator and the flow), the product metric on $M \times \mathbb{R}$ (to define instantons), and the L^2 metric (12.37) on $\mathcal{A}$ (to define the gradient). Nash stresses that $HF_*(M)$ does not depend on these choices. The mechanism is again the one we know from Chapter 7. Take two metrics g_0, g_1 on M and a path g_s between them. Put the metric $g_{s(t)}$ on the slice $M \times \{t\}$, with $s(t) = 0$ for $t \ll 0$ and $s(t) = 1$ for $t \gg 0$. Counting instantons on this cylinder from a generator of the g_0-complex to one of the same degree of the g_1-complex defines a map

$$\Phi : C_*(M; g_0) \to C_*(M; g_1), \qquad \Phi \partial_0 = \partial_1 \Phi,$$

the second equation by another broken-flow-line argument. Running the path backwards gives Ψ in the other direction, and a homotopy of homotopies shows that $\Psi\Phi$ and $\Phi\Psi$ induce the

identity on homology. So Φ induces an isomorphism $HF_*(M; g_0) \cong HF_*(M; g_1)$.

Physical picture: Invariance is the cylinder axiom

In the language of Section 12.1.3, the Floer groups are the state space $Z(M)$ attached to the 3-manifold M, and the instanton counts on the cylinder $M \times \mathbb{R}$ with varying metric are the operator $Z(M \times I)$. Atiyah's cylinder axiom $Z(M \times I) = \mathrm{id}$ is precisely the statement that changing the metric does not change the state space. Floer's invariance proof is that axiom, verified by analysis.

Key idea: Floer homology

For a homology 3-sphere M, the Floer groups $HF_p(M)$, $p \in \mathbb{Z}_8$, are topological invariants of M. They are built from the infinite-dimensional space $\mathcal{A}/\mathcal{G}$, yet there are only eight of them and each is finitely generated. They are the Morse homology of the Chern–Simons function, and physically the zero-energy states of a supersymmetric gauge theory on $M \times \mathbb{R}$ (Section 12.5.5).

Worked example 12.21: The 3-sphere and the Poincaré sphere

$M = S^3$. Here $\pi_1 = 1$, so the only flat connection is θ, which is excluded. Every chain group is zero:

$$HF_p(S^3) = 0 \quad \text{for all } p.$$

This vanishing is used in Section 12.8.4 to show that Donaldson invariants of connected sums vanish.

$M = \Sigma(2,3,5)$. By Example 12.11 there are exactly two irreducible flat connections, ρ_1 and ρ_2. Fintushel and Stern computed their degrees: with the standard orientation and grading convention, $\mu(\rho_1) = 1$ and $\mu(\rho_2) = 5$. Then

$$\partial\rho_1 \in C_0 \overset{(1)}{=} 0, \qquad \partial\rho_2 \in C_4 \overset{(1)}{=} 0,$$

(1) C_0 and C_4 are zero: no generator has degree 0 or 4.

So the boundary operator vanishes for degree reasons, without counting a single instanton, and

$$HF_*(\Sigma(2,3,5)) = \big(0,\ \mathbb{Z},\ 0,\ 0,\ 0,\ \mathbb{Z},\ 0,\ 0\big) \qquad (p = 0, 1, \dots, 7).$$

A non-zero Floer group proves at once that $\Sigma(2,3,5)$ is not S^3, which is no surprise since $\pi_1 \neq 1$. More interesting is the general pattern found by Fintushel and Stern: for every Brieskorn sphere $\Sigma(p,q,r)$ all irreducible flat connections have *odd* degree, so $\partial = 0$ always and HF_* is free on the flat connections.

Worked example 12.22: Degree reasons in general

The argument above is worth isolating. If every generator of a $\mathbb{Z}_8$-graded complex has degree of the same parity, then

$$\partial(C_{\mathrm{odd}}) \subset C_{\mathrm{even}} \overset{(1)}{=} 0 \quad \Longrightarrow \quad \partial = 0 \quad \Longrightarrow \quad HF_p = C_p.$$

(1) ∂ changes the degree by one, hence changes the parity, and the even chain groups are zero.

So $\operatorname{rank} HF_* = \#\mathcal{R}^*(M)$: every flat connection survives as a quantum ground state. Tunnelling can only lift pairs of vacua whose degrees differ by one; if all vacua are "fermionic",

none can be lifted. This is the Floer analogue of the statement that a Morse function with critical points only of even index (like the height on $\mathbb{CP}^n$) is *perfect*.

12.5.3 The Euler characteristic and Casson's invariant

The Euler characteristic of a $\mathbb{Z}_8$-graded complex

A $\mathbb{Z}$-graded complex has an Euler characteristic $\sum(-1)^p \operatorname{rank} H_p$. With only a $\mathbb{Z}_8$ grading, is $(-1)^p$ still meaningful? Yes, because 8 is even: p and $p+8$ have the same parity. So define

$$\chi_F(M) := \sum_{p=0}^{7} (-1)^p \operatorname{rank} HF_p(M). \tag{12.66}$$

As in finite dimensions it can be computed from the chains, with no knowledge of ∂:

$$\begin{aligned}\sum_p (-1)^p \operatorname{rank} HF_p &\overset{(1)}{=} \sum_p (-1)^p \left(\operatorname{rank} Z_p - \operatorname{rank} B_p\right) \\ &\overset{(2)}{=} \sum_p (-1)^p \left(\operatorname{rank} C_p - \operatorname{rank} B_{p-1} - \operatorname{rank} B_p\right) \\ &\overset{(3)}{=} \sum_p (-1)^p \operatorname{rank} C_p \;=\; \sum_{\alpha \in \mathcal{R}^*(M)} (-1)^{\mu(\alpha)}.\end{aligned} \tag{12.67}$$

(1) $Z_p = \operatorname{Ker}(\partial|_{C_p})$, $B_p = \operatorname{Im}(\partial|_{C_{p+1}}) \subset C_p$, and $HF_p = Z_p/B_p$.
(2) Rank–nullity for $\partial : C_p \to C_{p-1}$: $\operatorname{rank} C_p = \operatorname{rank} Z_p + \operatorname{rank} B_{p-1}$.
(3) In the sum over the cycle $p \in \mathbb{Z}_8$, the term B_{p-1} appears with sign $(-1)^p$ and again (as $B_{p'}$ with $p' = p-1$) with sign $-(-1)^{p'} = (-1)^p \ldots$ with opposite total sign; the B's cancel in pairs. This uses only that $(-1)^p$ is well defined mod 8.

So $\chi_F(M)$ is a signed count of irreducible flat connections, the sign of each being the parity of its spectral flow. For $\Sigma(2,3,5)$, $\chi_F = (-1)^1 + (-1)^5 = -2$.

The finite-dimensional model: Poincaré–Hopf

Nash explains (12.67) through a classical theorem. Let X be a compact manifold and ω a 1-form (equivalently, via a metric, a vector field v) with isolated non-degenerate zeros. At a zero x, write $\omega = \omega_i \, \mathrm{d}x^i$ and form the matrix $J_{ij} = \partial_j \omega_i(x)$. The **index** of the zero is $\operatorname{sgn} \det J$.

Key idea: Poincaré–Hopf

The sum of the indices of the zeros of any 1-form (or vector field) with isolated non-degenerate zeros on a compact manifold X is the Euler characteristic:

$$\sum_{\omega(x)=0} \operatorname{sgn} \det\big(\partial_j \omega_i(x)\big) = \chi(X).$$

For $\omega = \mathrm{d}f$, J is the Hessian, $\operatorname{sgn}\det J = (-1)^{\lambda_x}$, and the theorem is $\sum_x (-1)^{\lambda_x} = \chi(X)$: the Euler characteristic of the Morse complex.

Why it is true (sketch). The sum of indices does not change when ω is deformed: zeros can move, and can be created or annihilated only in pairs of opposite index (a fold $\omega = x^2 - \varepsilon$ has

two zeros with slopes $\pm 2\sqrt{\varepsilon}$ that merge and vanish as $\varepsilon \to 0^-$). So the sum is an invariant of X, and computing it for one Morse function identifies it with $\sum (-1)^p b_p$ by the Morse complex.

Worked example 12.23: Poincaré–Hopf on the sphere and the torus

Sphere. The height $f = z$ on the unit S^2 has a minimum at the south pole and a maximum at the north pole. Near either pole use (x, y) as coordinates, $f = \pm\sqrt{1 - x^2 - y^2} \approx \pm(1 - \tfrac{1}{2}(x^2 + y^2))$, so the Hessian is $\mp \mathbf{1}_2$ and

$$\sum (-1)^{\lambda_x} \overset{(1)}{=} \det(-\mathbf{1}_2)^{\mathrm{sgn}} + \det(+\mathbf{1}_2)^{\mathrm{sgn}} = (+1) + (+1) = 2 = \chi(S^2).$$

(1) $\operatorname{sgn}\det(-\mathbf{1}_2) = (-1)^2 = +1$ at the maximum (index 2) and $\operatorname{sgn}\det \mathbf{1}_2 = +1$ at the minimum (index 0).

Torus. On the square torus $T^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$ take $f = \cos x + \cos y$. Then $\omega = \mathrm{d}f = -\sin x\,\mathrm{d}x - \sin y\,\mathrm{d}y$ vanishes at the four points with $x, y \in \{0, \pi\}$, and $J = \operatorname{diag}(-\cos x, -\cos y)$:

(x, y)	$(0,0)$	(π,π)	$(0,\pi)$	$(\pi,0)$
J	$\operatorname{diag}(-1,-1)$	$\operatorname{diag}(1,1)$	$\operatorname{diag}(-1,1)$	$\operatorname{diag}(1,-1)$
type	max	min	saddle	saddle
$\operatorname{sgn}\det J$	$+1$	$+1$	-1	-1

The sum is $1 + 1 - 1 - 1 = 0 = \chi(T^2)$. Figure 12.17 shows the vector field.

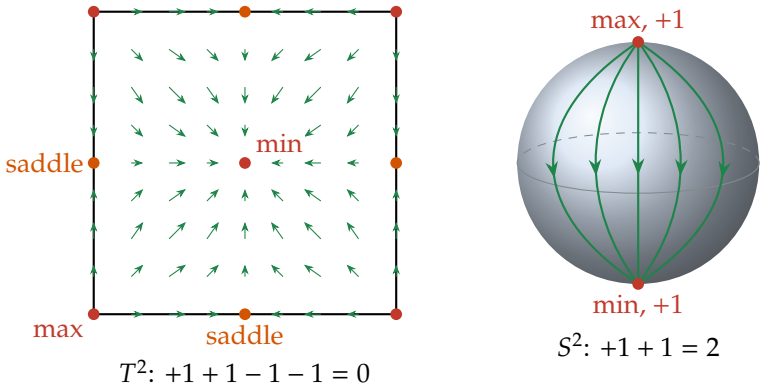

Figure 12.17: Poincaré–Hopf. Left: the downhill vector field $-\nabla f$ for $f = \cos x + \cos y$ on the square torus (opposite edges identified, so the four corners are one point). Its four zeros have indices $+1$ (maximum and minimum) and -1 (the two saddles), summing to $\chi(T^2) = 0$. Right: on the sphere the height function has only a maximum and a minimum, each of index $+1$: $\chi(S^2) = 2$. In Floer theory the vector field is $-\star F$ on $\mathcal{A}/\mathcal{G}$, its zeros are the flat connections, and the index of each is the parity of its spectral flow.

The infinite-dimensional version

Now carry this over (Nash's (12.33)). By (12.26) the curvature F is, up to the factor $-1/4\pi^2$, the 1-form $\mathrm{d}f$ on $\mathcal{A}$. It is gauge covariant, $F(A^g) = g^{-1}F(A)g$, and the pairing $\int \operatorname{tr}(F \wedge a)$ is gauge invariant, so it descends to a 1-form on $\mathcal{A}/\mathcal{G}$ (on the part where $\mathcal{G}$ acts freely). Its zeros are the flat connections modulo gauge,

$$\operatorname{Hom}\big(\pi_1(M), \mathrm{SU}(2)\big) \,/\, \operatorname{Ad}\mathrm{SU}(2),$$

and the "index" of each irreducible zero is sgn det of the Hessian, which in infinite dimensions has to be defined as $(-1)^{\text{spectral flow}}$, i.e. $(-1)^{\mu(\alpha)}$. The signed count of zeros is therefore exactly (12.67). Taubes made this precise: he perturbed F by a small Fredholm perturbation (if needed) to make all zeros non-degenerate, and used spectral flow to decide whether a zero's sign changes as the perturbation or the metric is varied. The result is Taubes' theorem (Nash's (12.32)):

$$\boxed{\chi_F(M) = 2\lambda(M)}, \tag{12.68}$$

where $\lambda(M)$ is the **Casson invariant**. In particular $\chi_F(M)$ is always even.

Casson's invariant

Casson defined $\lambda(M)$ in the mid-1980s by a finite-dimensional intersection count, long before the gauge theory reading was available. Nash calls the definition complicated; its idea is simple and pretty.

1. *Split M.* Every closed 3-manifold is a union of two handlebodies H_1, H_2 of some genus g (solid "pretzels") glued along their common boundary surface Σ_g: a **Heegaard splitting** $M = H_1 \cup_\Sigma H_2$.

2. *Represent.* Let $\mathcal{R}(X) = \mathrm{Hom}(\pi_1(X), \mathrm{SU}(2))/\text{conj}$. Van Kampen's theorem says $\pi_1(M)$ is generated by $\pi_1(H_1)$ and $\pi_1(H_2)$ with the relations coming from $\pi_1(\Sigma)$. So a representation of $\pi_1(M)$ is a pair of representations of the handlebodies that agree on Σ:

$$\mathcal{R}(M) = \mathcal{R}(H_1) \cap \mathcal{R}(H_2) \;\subset\; \mathcal{R}(\Sigma).$$

3. *Count dimensions.* $\pi_1(\Sigma_g)$ has $2g$ generators and one relation; $\pi_1(H_i)$ is free on g generators. For irreducible representations,

$$\dim \mathcal{R}^*(\Sigma_g) \overset{(1)}{=} 3 \cdot 2g - 3 - 3 = 6g - 6,$$
$$\dim \mathcal{R}^*(H_i) \overset{(2)}{=} 3g - 3.$$

   (1) Each generator gives an element of SU(2) (3 parameters); the relation is an SU(2)-valued equation (3 conditions); conjugation removes 3 more.
   (2) g free elements of SU(2), minus conjugation.

   So each $\mathcal{R}^*(H_i)$ is half-dimensional in $\mathcal{R}^*(\Sigma)$, and two half-dimensional submanifolds meet generically in isolated points. (In fact $\mathcal{R}^*(\Sigma)$ is symplectic, with form $\int_\Sigma \mathrm{tr}(a \wedge b)$, and the $\mathcal{R}^*(H_i)$ are Lagrangian.)

4. *Intersect.* Casson's invariant is

$$\lambda(M) = \tfrac{1}{2}\,\#\big(\mathcal{R}^*(H_1) \cap \mathcal{R}^*(H_2)\big), \tag{12.69}$$

   the signed intersection number, with orientations from a fixed orientation of M. The factor $\frac{1}{2}$ is part of the definition; Casson proved the result is an integer independent of the splitting.

The intersection points are exactly the irreducible flat connections on M, the same points that generate the Floer complex. So (12.68) is the statement that two ways of signing them (by intersection orientation, and by the parity of spectral flow) agree up to the overall factor.

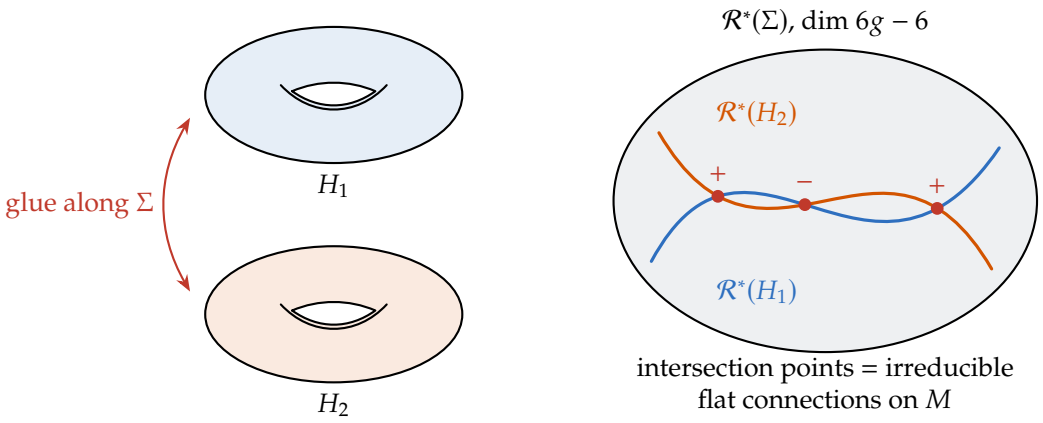

Figure 12.18: Casson's construction. Left: a Heegaard splitting of genus 1 (two solid tori glued along a torus; genus 1 gives only S^3, $S^1\times S^2$ and lens spaces, so real examples need higher genus). Right: in the space of irreducible representations of the surface group, the representations that extend over H_1 and those that extend over H_2 are two half-dimensional submanifolds. They meet at the irreducible representations of $\pi_1(M)$. Half the signed count is $\lambda(M)$; here it would be $\frac{1}{2}(+1-1+1)$, so the three points drawn are only a cartoon: a real example has an even signed count.

Worked example 12.24: Properties and values of Casson's invariant

- $\lambda(S^3)=0$: there are no irreducible representations of the trivial group.
- $\lambda(-M)=-\lambda(M)$: reversing the orientation of M reverses all intersection signs. The Floer version: reversing orientation replaces f by $-f$, the curl operator by its negative, and the degree μ by $-\mu$ up to a shift of 3, which flips every parity.
- For the Poincaré sphere, oriented as the link of the singularity $z_1^2+z_2^3+z_3^5=0$, $\lambda(\Sigma(2,3,5))=-1$, consistent with $\chi_F=-2$ in Example 12.21 and (12.68).
- $\lambda(M)$ mod 2 is the Rokhlin invariant of M (the signature of any spin 4-manifold bounded by M, divided by 8, mod 2). For $\Sigma(2,3,5)$ it bounds the E_8 plumbing, of signature ∓ 8, so the Rokhlin invariant is 1, matching $\lambda=-1$ mod 2.

Casson's *surgery formula* makes λ computable. If M_n is obtained from S^3 by $1/n$ surgery on a knot K (cut out a tubular neighbourhood of K and glue it back with a twist), then

$$\lambda(M_{n+1})-\lambda(M_n)=\tfrac{1}{2}\Delta_K''(1),$$

where Δ_K is the symmetrised Alexander polynomial of K (see the knot sections of this chapter). For the trefoil, $\Delta(t)=t-1+t^{-1}$:

$$\Delta''(t)\overset{(1)}{=}\frac{\mathrm{d}}{\mathrm{d}t}\bigl(1-t^{-2}\bigr)=2t^{-3},\qquad \tfrac{1}{2}\Delta''(1)\overset{(2)}{=}1.$$

(1) $\Delta'(t)=1-t^{-2}$, then differentiate again.
(2) Evaluate at $t=1$.

Since $M_0=S^3$ has $\lambda=0$, the manifolds $M_{\pm1}$ obtained by ±1 surgery on the trefoil have $\lambda=\pm1$. One of them is the Poincaré sphere (which one, and with which orientation, is a matter of conventions for the handedness of the trefoil).

12.5.4 The Chern–Simons function as an action

Nash ends his §2 by turning the Morse function into an action. This is the seed of the second half of the chapter (Witten's knot invariants), so we set it up carefully here.

A metric-free action

Define (Nash's (12.34))

$$S(A) = -\frac{1}{8\pi^2}\int_M \operatorname{tr}\Big(A\wedge \mathrm{d}A + \tfrac{2}{3}A\wedge A\wedge A\Big), \tag{12.70}$$

which is our $f(A)$ of (12.15), now for any closed oriented 3-manifold M and any compact gauge group. Look at what went into it: A, the wedge product, d, a trace, and the integral of a 3-form over an oriented 3-manifold. *No metric*, no Hodge star, no $\sqrt{g}$. So S is automatically invariant under all orientation-preserving diffeomorphisms of M, and the stress tensor $T_{\mu\nu} = \delta S/\delta g^{\mu\nu}$ is identically zero. This is the Schwarz type of TQFT of Section 12.1.2.

The classical equations of motion are the critical points of S, already found in (12.26) (Nash's (12.35)):

$$F(A) = 0.$$

Unlike in Yang–Mills theory, the classical solutions are not just the trivial connection: on a 3-manifold with $\pi_1(M) \neq 1$ there are flat connections with non-trivial holonomy (Example 12.11), and these are the classical vacua.

Quantisation of the level

S is gauge invariant only modulo integers (12.17): $S(A^g) = S(A) + \deg g$. Classically this is harmless, because the equations of motion only see δS. Quantum mechanically, the path integral in $2+1$ Lorentzian dimensions weights each configuration with $\exp(iS)$ (Nash's (12.36)), and $\exp(iS)$ changes by $e^{i\deg g}$ under a large gauge transformation. So $\exp(iS)$ is not a function on $\mathcal{A}/\mathcal{G}$. The cure (Nash's (12.37)) is to multiply the action by $2\pi k$ with k an integer:

$$\begin{aligned}\exp\big(2\pi i k\, S(A)\big) &\overset{(1)}{=} \exp\Big[2\pi i k\cdot\Big(-\frac{1}{8\pi^2}\Big)\int_M \operatorname{tr}\Big(A\wedge \mathrm{d}A + \tfrac{2}{3}A^3\Big)\Big]\\ &\overset{(2)}{=} \exp\Big[-\frac{ik}{4\pi}\int_M \operatorname{tr}\Big(A\wedge \mathrm{d}A + \tfrac{2}{3}A\wedge A\wedge A\Big)\Big],\end{aligned} \tag{12.71}$$

(1) Definition (12.70).
(2) $2\pi\cdot\frac{1}{8\pi^2} = \frac{1}{4\pi}$.

and under a gauge transformation

$$\exp\big(2\pi i k\, S(A^g)\big) \overset{(1)}{=} \exp\big(2\pi i k\, S(A)\big)\,\exp\big(2\pi i k\deg g\big) \overset{(2)}{=} \exp\big(2\pi i k\, S(A)\big).$$

(1) The shift formula (12.17).
(2) $k\deg g \in \mathbb{Z}$, and $e^{2\pi i\cdot\text{integer}} = 1$.

The integer k is the **level** of the Chern–Simons theory. With $k\notin\mathbb{Z}$ the weight is multivalued on $\mathcal{A}/\mathcal{G}$; with $k\in\mathbb{Z}$ the theory makes sense. This is the same logic as Dirac's quantisation condition: $e^{ie\oint A}$ must be single-valued, so $eg\in 2\pi\mathbb{Z}$.

Watch out: Lorentzian or Euclidean?

Nash puts the theory in $2+1$ Lorentzian dimensions to get e^{iS}. For a topological term the distinction is immaterial: S contains no metric, so nothing changes under Wick rotation, and the weight stays e^{iS} (a phase) even on a Euclidean 3-manifold. Topological terms such as Chern–Simons and the θ-term are "imaginary" in Euclidean signature. That is why their path integrals are oscillatory, not damped.

Worked example 12.25: Level quantisation seen on a single gauge transformation

Take $M = S^3$, $A = 0$ and g of degree 1 (Example 12.7). Then $A^g = g^{-1}\mathrm{d}g$, and

$$S(g^{-1}\mathrm{d}g) \overset{(1)}{=} S(0) + 1 = 1, \qquad e^{iS(g^{-1}\mathrm{d}g)} \overset{(2)}{=} e^{i} \neq e^{iS(0)} = 1,$$

(1) The shift formula with $\deg g = 1$ and $S(0) = 0$.
(2) The unnormalised weight differs on two gauge-equivalent configurations.

while $e^{2\pi i k S(g^{-1}\mathrm{d}g)} = e^{2\pi i k} = 1 = e^{2\pi i k S(0)}$ for $k \in \mathbb{Z}$. So the weight of the pure-gauge configuration $g^{-1}\mathrm{d}g$, which is physically the same as $A = 0$, agrees with it only at integer level.

Worked example 12.26: Abelian Chern–Simons on a torus has a k-dimensional Hilbert space

Here is the promise of Section 12.1, a finite-dimensional Hilbert space, made explicit. Take $G = \mathrm{U}(1)$, write $A = ia$ with a a real 1-form (the physicists' potential), so $\mathrm{tr}(A \wedge \mathrm{d}A) = -a \wedge \mathrm{d}a$ and the cubic term vanishes. The level-k action (12.71) is $\frac{k}{4\pi}\int a \wedge \mathrm{d}a$. Put it on $\Sigma \times \mathbb{R}$ with $\Sigma = T^2$, coordinates $x^1, x^2 \in [0, 2\pi)$ and time t, in the gauge $a_0 = 0$.
The equation of motion from varying a_0 (Gauss's law) is that a is flat on Σ. Flat connections on T^2, modulo small gauge transformations, are constant: $a = \frac{1}{2\pi}(\theta_1\,\mathrm{d}x^1 + \theta_2\,\mathrm{d}x^2)$, with $\theta_j = \oint_{\gamma_j} a$ the holonomy round the jth cycle. Large gauge transformations $e^{i(n_1x^1+n_2x^2)}$ shift $\theta_j \to \theta_j + 2\pi n_j$, so the θ_j are angles. Substituting into the action,

$$\begin{aligned}\frac{k}{4\pi}\int a \wedge \mathrm{d}a &\overset{(1)}{=} \frac{k}{4\pi}\int a \wedge \mathrm{d}t \wedge \dot{a} \\ &\overset{(2)}{=} -\frac{k}{4\pi}\int \mathrm{d}t \wedge \frac{(\theta_1\dot{\theta}_2 - \theta_2\dot{\theta}_1)}{4\pi^2}\,\mathrm{d}x^1 \wedge \mathrm{d}x^2 \\ &\overset{(3)}{=} -\frac{k}{4\pi}\int \mathrm{d}t\,(\theta_1\dot{\theta}_2 - \theta_2\dot{\theta}_1) \overset{(4)}{=} -\frac{k}{2\pi}\int \mathrm{d}t\,\theta_1\dot{\theta}_2 + (\text{boundary term}).\end{aligned}$$

(1) The θ_j depend only on t, so $\mathrm{d}a = \mathrm{d}t \wedge \dot{a}$.
(2) Move $\mathrm{d}t$ to the front past the 1-form a (one sign), and $a \wedge \dot{a} = \frac{1}{4\pi^2}(\theta_1\dot{\theta}_2 - \theta_2\dot{\theta}_1)\mathrm{d}x^1 \wedge \mathrm{d}x^2$.
(3) $\int_{T^2} \mathrm{d}x^1 \wedge \mathrm{d}x^2 = 4\pi^2$ with orientation $\mathrm{d}t \wedge \mathrm{d}x^1 \wedge \mathrm{d}x^2$.
(4) $\theta_2\dot{\theta}_1 = \frac{\mathrm{d}}{\mathrm{d}t}(\theta_1\theta_2) - \theta_1\dot{\theta}_2$.

The Lagrangian $L = -\frac{k}{2\pi}\theta_1\dot{\theta}_2$ has the form $p\dot{q}$ with $q = \theta_2$, $p = -\frac{k}{2\pi}\theta_1$. It is first order in time: the two holonomies are canonically conjugate, and the phase space is the torus of flat connections itself, of finite area. Canonical quantisation $[q, p] = i$ gives

$$[\theta_1, \theta_2] = \frac{2\pi i}{k}$$

(the overall sign depends on the orientation and does not matter). Only the periodic operators $W_j = e^{i\theta_j}$, the Wilson loops, are well defined. Using $e^X e^Y = e^Y e^X e^{[X,Y]}$ when

$[X, Y]$ is a number,

$$W_1 W_2 \overset{(1)}{=} W_2 W_1 \, e^{[i\theta_1,\, i\theta_2]} \overset{(2)}{=} W_2 W_1 \, e^{-2\pi i/k} \;=:\; q\, W_2 W_1.$$

(1) Baker–Campbell–Hausdorff with a central commutator.
(2) $[i\theta_1, i\theta_2] = -[\theta_1, \theta_2] = -2\pi i/k$.

Its irreducible representation is the *clock and shift* pair on $\mathbb{C}^k$ with basis $e_0, \dots, e_{k-1}$:

$$W_1 e_j = q^j e_j, \qquad W_2 e_j = e_{j+1} \text{ (indices mod } k).$$

Check: $W_1 W_2 e_j = q^{j+1} e_{j+1}$ and $q W_2 W_1 e_j = q \cdot q^j e_{j+1}$, equal. No smaller representation exists: if $W_1 v = \mu v$, then $W_1(W_2 v) = q\mu\, W_2 v$, so $\mu, q\mu, q^2\mu, \dots$ are all eigenvalues, and q is a primitive kth root of unity, so there are k distinct ones. For $k = 2$: $q = -1$, $W_1 = \sigma_3$, $W_2 = \sigma_1$, and indeed $\sigma_3\sigma_1 = -\sigma_1\sigma_3$. So

$$\dim Z(T^2) = k, \qquad Z(T^3) = Z(T^2 \times S^1) = \dim Z(T^2) = k$$

by the trace axiom of Section 12.1.3. The Hilbert space is finite because the classical phase space (flat connections on T^2) is compact, with symplectic area proportional to k: one quantum state per unit of area $2\pi\hbar$.

12.5.5 Floer's supersymmetric Hamiltonian

In Chapter 7, Morse theory was the large-t limit of a supersymmetric quantum mechanics with Hamiltonian H_t, and the cohomology was its space of exact ground states. Nash's last point in §2 is that Floer homology has the same interpretation, with the Chern–Simons function as the "superpotential" of a quantum mechanics on $\mathcal{A}$, i.e. a quantum field theory on M.

Finite dimensions: the deformed Laplacian

Let $X = \mathbb{R}^n$ with the flat metric (the general case adds curvature terms that do not change the structure). Introduce fermion operators $a^{i*} = \mathrm{d}x^i \wedge$ (creates a form index) and $a^i = \iota_{\partial_i}$ (removes one), with

$$\{a^i, a^{j*}\} = \delta^{ij}, \qquad \{a^i, a^j\} = \{a^{i*}, a^{j*}\} = 0.$$

Then $\mathrm{d} = a^{i*}\partial_i$ and $\mathrm{d}^* = -a^i \partial_i$ on forms. Witten's deformation is $\mathrm{d}_t = e^{-tf}\,\mathrm{d}\, e^{tf}$ and $\mathrm{d}_t^* = e^{tf}\mathrm{d}^* e^{-tf}$, i.e.

$$\mathrm{d}_t = a^{i*} D_i, \quad D_i = \partial_i + t f_i; \qquad \mathrm{d}_t^* = -a^j \bar{D}_j, \quad \bar{D}_j = \partial_j - t f_j,$$

with $f_i = \partial_i f$, $f_{ij} = \partial_i \partial_j f$. The Hamiltonian is

$$\begin{aligned} H_t = \{\mathrm{d}_t, \mathrm{d}_t^*\} &\overset{(1)}{=} -\big(a^{i*} a^j D_i \bar{D}_j + a^j a^{i*} \bar{D}_j D_i\big) \\ &\overset{(2)}{=} -a^{i*} a^j \big[D_i, \bar{D}_j\big] - \bar{D}_i D_i \\ &\overset{(3)}{=} 2t\, f_{ij}\, a^{i*} a^j - \partial_i \partial_i - t\, f_{ii} + t^2 f_i f_i \\ &\overset{(4)}{=} -\partial_i \partial_i + t^2\, |\nabla f|^2 + t\, f_{ij}\, [a^{i*}, a^j]. \end{aligned} \tag{12.72}$$

(1) Expand the anticommutator; the a's commute with the differential operators $D, \bar{D}$.
(2) Write $a^j a^{i*} = \delta^{ij} - a^{i*} a^j$; the $a^{i*} a^j$ terms combine into a commutator of D's.

(3) $[D_i, \bar{D}_j] = [\partial_i, -tf_j] + [tf_i, \partial_j] = -2tf_{ij}$, and $\bar{D}_i D_i = \partial_i\partial_i + tf_{ii} - t^2 f_i f_i$ (the cross terms $\pm tf_i\partial_i$ cancel).
(4) $f_{ij}[a^{i*}, a^j] = f_{ij}(2a^{i*}a^j - \delta^{ij}) = 2f_{ij}a^{i*}a^j - f_{ii}$.

This is the second line of Nash's (12.38): Laplacian $+ t^2\langle \operatorname{grad} f, \operatorname{grad} f\rangle + t$ (Hessian)$\times$ (fermion bilinear).

Watch out: The first line of Nash's (12.38)

Nash writes $H_t = \mathrm{d}_t\mathrm{d}_t^* + \mathrm{d}_t^*\mathrm{d}_t = e^{-ft}(\mathrm{dd}^* + \mathrm{d}^*\mathrm{d})e^{ft}$. The first equality is the definition; the second is not right. Since $\mathrm{d}_t^* = e^{+tf}\,\mathrm{d}^* e^{-tf}$ has the opposite exponent, $\mathrm{d}_t\mathrm{d}_t^* = e^{-tf}\,\mathrm{d}\,e^{2tf}\,\mathrm{d}^* e^{-tf}$, which is not a conjugate of dd^*. Indeed, if H_t were conjugate to H_0 it would have the same spectrum for all t, and Witten's localisation would never happen. What *is* conjugate is the complex: $\mathrm{d}_t = e^{-tf}\,\mathrm{d}\,e^{tf}$, which is why $\operatorname{Ker}\mathrm{d}_t/\operatorname{Im}\mathrm{d}_t$ (hence the number of zero modes of H_t) is independent of t. The correct explicit form is the second line, (12.72).

Worked example 12.27: The harmonic oscillator is the simplest Witten Laplacian

Take $n = 1$ and $f = \frac{1}{2}x^2$. The form degrees are 0 and 1, and $[a^*, a] = a^*a - aa^*$ equals -1 on 0-forms (a kills them, $aa^* = 1$) and $+1$ on 1-forms (a^* kills them, $a^*a = 1$). So

$$H_t\big|_{\Omega^0} \overset{(1)}{=} -\partial_x^2 + t^2x^2 - t, \qquad H_t\big|_{\Omega^1} \overset{(1)}{=} -\partial_x^2 + t^2x^2 + t.$$

(1) (12.72) with $f_x = x$, $f_{xx} = 1$.

The oscillator $-\partial_x^2 + t^2x^2$ has levels $t(2m+1)$, $m = 0, 1, \dots$. So the spectrum on 0-forms is $\{0, 2t, 4t, \dots\}$ with ground state $e^{-tx^2/2} = e^{-tf}$, and on 1-forms it is $\{2t, 4t, \dots\}$. There is exactly one zero-energy state, in degree 0 = the Morse index of the minimum. Every excited level is paired between degrees 0 and 1 by the supercharge: this is the boson–fermion degeneracy that will make fermion and boson determinants cancel in Section 12.7.4.

Infinite dimensions: the Floer Hamiltonian

On $\mathcal{A}$ the coordinates are the field values $A_i^a(x)$, one for each point $x \in M$, each direction i and each colour a. The exterior derivative on $\mathcal{A}$ is a functional derivative (Nash's (12.39)):

$$\mathrm{d} = \int_M \operatorname{tr}\Big(a \wedge \frac{\delta}{\delta A}\Big), \tag{12.73}$$

where $a = a_i^a(x)\,T_a\,\mathrm{d}x^i$ is the fermionic analogue of a^{i*}: it multiplies a form on $\mathcal{A}$ by the 1-form $\delta A_i^a(x)$ (that is what the tangent vector a in (12.21) becomes when promoted to an operator). Its adjoint a^* removes such a factor. The operators satisfy canonical anticommutation relations, schematically $\{a_i^a(x), a_j^{b*}(y)\} = \delta^{ab}\delta_{ij}\delta^3(x-y)$.

Now substitute the Chern–Simons function into (12.72), term by term.

- *Laplacian.* $\mathcal{A}$ is an affine space with the flat metric (12.37), so $-\partial_i\partial_i$ becomes $-\int_M \operatorname{tr}(\delta/\delta A)^2$, the functional Laplacian.
- *Potential.* By (12.39),

$$\langle \operatorname{grad} f, \operatorname{grad} f\rangle \overset{(1)}{=} -\frac{1}{16\pi^4}\int_M \operatorname{tr}\big(\star F \wedge \star\star F\big) \overset{(2)}{=} -\frac{1}{16\pi^4}\int_M \operatorname{tr}\big(F \wedge \star F\big),$$

(1) The metric (12.37) with $a = b = \star F/4\pi^2$.

(2) $\star\star = 1$ on a Riemannian 3-manifold, and $\operatorname{tr}(\star F \wedge F) = \operatorname{tr}(F \wedge \star F)$ (1-form past 2-form).

which is the magnetic energy $\frac{1}{2}\int \sum_a |\vec{B}^a|^2$ up to normalisation.

- *Fermion term.* The Hessian is $4\pi^2 H(A) = \star \mathrm{d}_A$ (12.31), so $f_{ij}[a^{i*}, a^j]$ becomes a curl sandwiched between a and a^*: $\int_M \operatorname{tr}(a \wedge \mathrm{d}_A a^*)$, a Dirac-like (first-order) coupling of the fermions to the gauge field.

Absorbing the constants into t and the normalisation of a, one gets Nash's (12.40):

$$\mathcal{H}_t = \int_M \Big\{ -\operatorname{tr}\Big(\frac{\delta}{\delta A}\Big)^2 - 2t\ \operatorname{tr}\big(a \wedge \mathrm{d}_A a^*\big) - t^2\ \operatorname{tr}\big(F \wedge \star F\big) \Big\}. \tag{12.74}$$

Physical picture: It is a Yang–Mills Hamiltonian

In temporal gauge the canonical momentum of A_i is the electric field, $E_i = -i\,\delta/\delta A_i$, so $-\operatorname{tr}(\delta/\delta A)^2$ is the electric energy $\frac{1}{2}\vec{E}^2$ (with our sign of the trace), and $-\operatorname{tr}(F \wedge \star F)$ is the magnetic energy $\frac{1}{2}\vec{B}^2$. So (12.74) is

$$\mathcal{H}_t \sim \int_M \big(\vec{E}^2 + t^2 \vec{B}^2\big) + \text{fermions},$$

the Hamiltonian of Yang–Mills theory on M with coupling $\sim t^{-1/2}$, coupled to adjoint fermions. The states are functionals $\Psi[A]$ which must be gauge invariant (Gauss's law), i.e. functions on $\mathcal{A}/\mathcal{G}$. Large t is weak coupling, where the low-lying states localise on the classical vacua $F = 0$: the flat connections.

The fermions a, a^* are 1-forms on M, i.e. they carry a vector index, and yet they anticommute. Nash notes this "unconventional property of possessing integral spin". In a relativistic theory spin and statistics are tied together, but here there is no Lorentz symmetry forcing the connection: these are exactly the *twisted* fermions of topological field theory, which look like ghosts. The Fock space is graded by fermion number, and the grading that survives in infinite dimensions is the spectral-flow one (Nash's (12.41)):

$$\mathcal{H}_t = \bigoplus_{p=0}^{7} \Delta_p, \tag{12.75}$$

where Δ_p is the restriction of $\mathcal{H}_t$ to states of degree p mod 8. Hodge theory ("harmonic representatives") then suggests

$$HF_p(M) \ \cong\ \operatorname{Ker} \Delta_p = \{\text{ground states of degree } p\}.$$

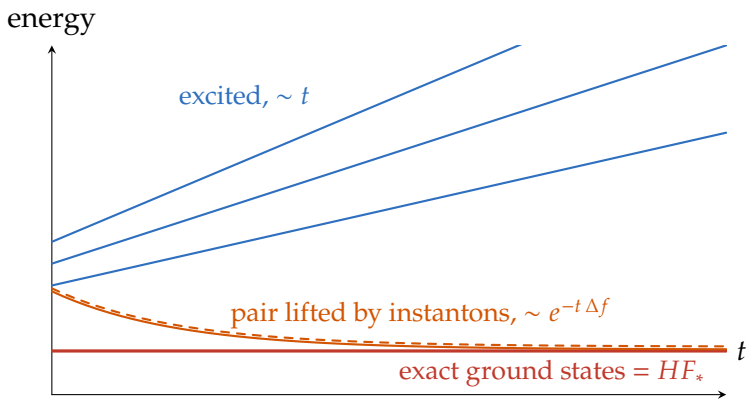

Figure 12.19: Schematic spectrum of Floer's Hamiltonian $\mathcal{H}_t$ as t grows. The excited levels rise like t (oscillator frequencies around each vacuum). One approximate ground state sits at each flat connection; pairs of them in adjacent degrees joined by an instanton are split away from zero by an energy of order $e^{-t\,\Delta f}$, where $\Delta f = S_{\mathrm{YM}}/8\pi^2$ is the instanton action. What stays exactly at zero is Floer homology.

Dictionary: Floer theory as supersymmetric quantum mechanics

Floer theory	Supersymmetric quantum mechanics / gauge theory
$\mathcal{A}/\mathcal{G}$	configuration space (gauge-invariant wavefunctionals)
Chern–Simons f	superpotential
flat connection α	classical vacuum
relative index $\mu(\alpha)$ mod 8	fermion number of the vacuum
instanton on $M \times \mathbb{R}$	tunnelling path
$n(\alpha,\beta)$	tunnelling amplitude, signed
∂	supercharge Q at large t
$HF_p(M)$	exact zero-energy states of degree p
$\chi_F(M) = 2\lambda(M)$	Witten index $\mathrm{Tr}(-1)^F e^{-\beta\mathcal{H}}$
metric independence	$\mathcal{H}_t = \{Q, Q^*\}$ is Q-exact

The Witten-index line deserves a remark. $\mathrm{Tr}(-1)^F e^{-\beta\mathcal{H}_t}$ receives no contribution from the paired excited states (a boson and a fermion with the same energy cancel), so it equals the number of bosonic minus fermionic ground states, $\chi_F(M)$, for all β and t. Casson's invariant is (half) the Witten index of Floer's quantum mechanics. Nash's closing remark, that this non-relativistic system has a relativistic four-dimensional generalisation (Witten), is the subject of the next two sections: the partition function of that 4d theory on a closed 4-manifold computes Donaldson's invariants.

Reading Nash (pp. 330–332, (12.30)–(12.41))

From the relative index mod 8 Nash gets a complex with eight groups (12.30) and defines $HF_p(M)$ (12.31); he states that $\partial^2 = 0$ follows by the instanton-tunnelling argument of his Chapter 7 and that the Floer groups are metric independent, and quotes Casson's invariant and Taubes' theorem $\chi_F = 2\lambda$ (12.32), explained via zeros of the 1-form F on $\mathcal{A}/\mathcal{G}$ (12.33). He then introduces the Chern–Simons action (12.34), its field equation $F = 0$ (12.35), the weight e^{iS} (12.36) and the level (12.37); finally he writes Floer's supersymmetric Hamiltonian (12.38)–(12.41). We have filled in: the grading convention, the explicit boundary operator,

the broken-flow-line proof of $\partial^2 = 0$ and the absence of bubbles, the invariance argument, HF of S^3 and $\Sigma(2,3,5)$, the rank-nullity computation of χ_F, Poincaré–Hopf with examples, Casson's Heegaard construction and surgery formula, the level-quantisation check, the k-dimensional Hilbert space of abelian Chern–Simons on T^2, and the derivation of the Witten Laplacian. Note that Nash's complex (12.30) is really cyclic, and that the first line of his (12.38) should be replaced by the second.

Recap

- Floer chains: irreducible flat connections, graded mod 8 by spectral flow from θ. Boundary: signed count of instantons on $M \times \mathbb{R}$ between generators of adjacent degree, modulo translation.
- $\partial^2 = 0$ because broken flow lines are the ends of 1-dimensional moduli spaces; no bubbling since a bubble costs index 8.
- $HF_p(M)$, $p \in \mathbb{Z}_8$, is a topological invariant; $HF(S^3) = 0$; $HF(\Sigma(2,3,5)) = \mathbb{Z}$ in degrees 1 and 5.
- $\chi_F(M) = \sum(-1)^{\mu(\alpha)} = 2\lambda(M)$ (Taubes), with λ Casson's intersection count on a Heegaard splitting.
- The Chern–Simons functional as an action is metric-free; its weight $e^{2\pi i k S}$ is gauge invariant for integer level k. Abelian Chern–Simons on T^2 has a k-dimensional Hilbert space.
- Floer homology is the space of ground states of $\mathcal{H}_t = -\int \mathrm{tr}(\delta/\delta A)^2 - 2t \int \mathrm{tr}(a \wedge \mathrm{d}_A a^*) - t^2 \int \mathrm{tr}(F \wedge \star F)$, a Yang–Mills Hamiltonian with twisted fermions.

12.6 Donaldson's polynomial invariants

From here on M is a four-dimensional manifold. In the Floer sections it was three-dimensional; the switch matters for every Hodge star below.

Here is the question this section answers. Suppose two closed 4-manifolds are *homeomorphic*: there is a continuous bijection between them with a continuous inverse. Are they *diffeomorphic*, that is, can the homeomorphism be chosen smooth? In every dimension except four the answer is understood and is "usually yes, and when no, for reasons one can list". In dimension four it is wildly false, and the first tool that could see the difference was built out of instantons.

A physicist should care for two reasons. First, the tool is a gauge theory: the invariants are integrals over the moduli space of Yang–Mills instantons, the same objects that dominate the Euclidean path integral of QCD. Second, Witten showed that the tool *is* a quantum field theory: Donaldson's invariants are correlation functions of a twisted supersymmetric Yang–Mills theory. That is the prototype of a Witten-type TQFT (Section 12.1.2).

Physical picture: Why instantons can see smooth structure

The anti-self-duality equation $F = -\star F$ needs a metric, and a metric needs a smooth structure (it is a smooth tensor field). So the space $\mathcal{M}_k$ of solutions knows about the smooth structure. The homeomorphism type does not enter the equation at all. If we can extract from $\mathcal{M}_k$ numbers that do not depend on the metric we chose, those numbers are

invariants of the *smooth* manifold, and they have a chance of distinguishing two smooth structures on the same topological manifold.

We first recall what Nash did in Chapter 1 with the first moduli space $\mathcal{M}_1$ (Chapter 1). There M had a positive definite intersection form. The moduli space $\mathcal{M}_1$ of SU(2) instantons of charge 1 is then a 5-manifold. Near its "end", where instantons shrink to zero size, it looks like $M \times (0, \epsilon)$: an infinitely concentrated instanton is labelled by the point where it sits. It has finitely many singular points, cones on $\mathbb{CP}^2$, one for each reducible connection. So $\mathcal{M}_1$ is a cobordism between M and a disjoint union of copies of $\mathbb{CP}^2$, and that forces the intersection form to be diagonal. Donaldson's later insight, which is what Nash's §3 describes, is that *all* the moduli spaces $\mathcal{M}_k$, $k = 1, 2, \ldots$, contain information, and that one can package it into polynomials on the second homology.

12.6.1 The stage: simply connected four-manifolds

Nash's setting is: M a smooth, simply connected, oriented, closed 4-manifold with a Riemannian metric g. Let us collect what we need to know about such an M.

Homology

Simply connected means $\pi_1(M) = 1$, so $H_1(M;\mathbb{Z}) = 0$ (it is the abelianisation of π_1). By Poincaré duality $H_3(M;\mathbb{Z}) \cong H^1(M;\mathbb{Z}) = 0$ as well. The only interesting group is $H_2(M;\mathbb{Z})$. It has no torsion: by the universal coefficient theorem its torsion equals that of H_1, which is zero. So

$$H_2(M;\mathbb{Z}) \cong \mathbb{Z}^{b_2}, \qquad b_0 = b_4 = 1, \quad b_1 = b_3 = 0.$$

Elements of $H_2(M;\mathbb{Z})$ can be pictured as closed oriented surfaces $\Sigma \subset M$ (every class is represented by an embedded surface in a 4-manifold).

The intersection form

Two surfaces in a 4-manifold generically meet in isolated points: two 2-dimensional objects in 4 dimensions have $2 + 2 - 4 = 0$ dimensional intersection, just as two lines in a plane meet in points.

Working definition 12.9 (intersection form)

For $\Sigma_1, \Sigma_2 \in H_2(M;\mathbb{Z})$, the **intersection form** $Q(\Sigma_1, \Sigma_2) = \Sigma_1 \cdot \Sigma_2 \in \mathbb{Z}$ is computed by either of:

- *counting:* move Σ_1, Σ_2 to meet transversally [at each meeting point the two tangent planes together span the 4-dimensional tangent space of M] and count intersection points, each with sign $+1$ if the orientation of Σ_1 followed by that of Σ_2 is the orientation of M, and -1 otherwise;
- *integrating:* with α_i closed 2-forms Poincaré dual to Σ_i [$\int_{\Sigma_i} \beta = \int_M \alpha_i \wedge \beta$ for every closed 2-form β] (Section 12.6.3), $Q(\Sigma_1, \Sigma_2) = \int_M \alpha_1 \wedge \alpha_2$.

Q is symmetric (2-forms commute), bilinear, and *unimodular*: its matrix in a basis of $H_2(M;\mathbb{Z})$ has determinant ± 1 (this is Poincaré duality over $\mathbb{Z}$). Formally: the cup product [the integer-coefficient version of the wedge product of closed forms] pairing $H^2(M;\mathbb{Z}) \times H^2(M;\mathbb{Z}) \to H^4(M;\mathbb{Z}) = \mathbb{Z}$.

Diagonalise Q over $\mathbb{R}$. The number of positive eigenvalues is b_2^+, the number of negative ones is b_2^-, and

$$b_2 = b_2^+ + b_2^-, \qquad \tau(M) = b_2^+ - b_2^- \ \text{(the signature)}, \qquad \chi(M) = \sum_j (-1)^j b_j = 2 + b_2.$$

Q is **even** if $Q(\Sigma, \Sigma)$ is even for every Σ, and **odd** otherwise. Freedman's theorem (Chapter 1) says that a simply connected closed topological 4-manifold is determined up to homeomorphism by Q (plus one $\mathbb{Z}_2$ invariant when Q is odd), and that every unimodular form occurs. So Q is the *whole* topology. Anything the instantons see beyond Q is smooth structure.

$b_2^\pm$ from the Hodge star

The numbers $b_2^\pm$ have a direct meaning in terms of forms, which is how they enter the instanton equations. On a Riemannian 4-manifold the Hodge star maps 2-forms to 2-forms and squares to one:

$$\star\star\,\omega \overset{(1)}{=} (-1)^{p(n-p)}\,\omega \overset{(2)}{=} (-1)^{2\cdot 2}\,\omega = \omega.$$

(1) The general rule for a p-form in n Riemannian dimensions (Chapter T1).
(2) $p = 2$, $n = 4$.

So $\star$ has eigenvalues ± 1 on 2-forms, and splits them into **self-dual** ($\star\omega = \omega$) and **anti-self-dual** ($\star\omega = -\omega$) parts: $\Lambda^2 = \Lambda^2_+ \oplus \Lambda^2_-$, each of rank 3. The star commutes with the Laplacian, so it preserves the harmonic 2-forms, $\mathcal{H}^2 = \mathcal{H}^2_+ \oplus \mathcal{H}^2_-$. For a harmonic self-dual form ω,

$$Q(\omega, \omega) = \int_M \omega \wedge \omega \overset{(1)}{=} \int_M \omega \wedge \star\omega \overset{(2)}{=} \|\omega\|^2 > 0, \tag{12.76}$$

(1) $\omega = \star\omega$.
(2) $\omega \wedge \star\omega = |\omega|^2\,\mathrm{vol}$ defines the pointwise norm; $\|\cdot\|^2$ is its integral.

and for an anti-self-dual one the same chain gives $-\|\omega\|^2 < 0$. Since $\mathcal{H}^2 \cong H^2_{\mathrm{dR}}(M)$ (Hodge's theorem), Q is positive on $\mathcal{H}^2_+$ and negative on $\mathcal{H}^2_-$, and these are Q-orthogonal. Hence

$$b_2^+ = \dim \mathcal{H}^2_+(g), \qquad b_2^- = \dim \mathcal{H}^2_-(g).$$

The *numbers* do not depend on g, but the *subspaces* do: as the metric varies, the plane $\mathcal{H}^2_+(g)$ moves around inside $H^2_{\mathrm{dR}}(M) \cong \mathbb{R}^{b_2}$. This will matter when we discuss reducible connections.

Worked example 12.28: $S^2 \times S^2$: the hyperbolic form

Take two round unit spheres with coordinates (θ_1, ϕ_1) and (θ_2, ϕ_2) and the product metric. An oriented orthonormal coframe is

$$e^1 = \mathrm{d}\theta_1, \quad e^2 = \sin\theta_1\,\mathrm{d}\phi_1, \quad e^3 = \mathrm{d}\theta_2, \quad e^4 = \sin\theta_2\,\mathrm{d}\phi_2, \qquad \mathrm{vol} = e^1 \wedge e^2 \wedge e^3 \wedge e^4.$$

The area forms are $\omega_1 = e^1 \wedge e^2$ and $\omega_2 = e^3 \wedge e^4$, each with total area 4π on its own factor. Their stars:

$$\star\omega_1 \overset{(1)}{=} e^3 \wedge e^4 = \omega_2, \qquad \star\omega_2 \overset{(2)}{=} e^1 \wedge e^2 = \omega_1.$$

(1) $e^{12} \wedge e^{34} = \mathrm{vol}$, so $\star e^{12} = e^{34}$.
(2) $e^{34} \wedge e^{12} = e^{12} \wedge e^{34} = \mathrm{vol}$ (2-forms commute).

Both forms are closed and co-closed, hence harmonic, and

$$\omega_1 + \omega_2 \text{ is self-dual}, \qquad \omega_1 - \omega_2 \text{ is anti-self-dual}.$$

So $b_2^+ = b_2^- = 1$. Now the intersection form. Let $S_1 = S^2 \times \{p\}$ and $S_2 = \{p\} \times S^2$. The form $\omega_2/4\pi$ is Poincaré dual to S_1: for any closed 2-form $\alpha = a_1\omega_1/4\pi + a_2\omega_2/4\pi$ (plus exact),

$$\int_M \alpha \wedge \frac{\omega_2}{4\pi} \overset{(1)}{=} \frac{a_1}{16\pi^2} \int_M \omega_1 \wedge \omega_2 \overset{(2)}{=} a_1 \overset{(3)}{=} \int_{S_1} \alpha.$$

(1) $\omega_2 \wedge \omega_2 = 0$ (it is a 4-form built only from the second factor's 2-dimensional coframe).
(2) $\int_M \omega_1 \wedge \omega_2 = (4\pi)(4\pi)$ by Fubini.
(3) On S_1 only ω_1 survives the restriction, and it integrates to 4π.

Similarly $\omega_1/4\pi$ is dual to S_2. Therefore

$$Q = \begin{pmatrix} S_1 \cdot S_1 & S_1 \cdot S_2 \\ S_2 \cdot S_1 & S_2 \cdot S_2 \end{pmatrix} = \frac{1}{16\pi^2} \begin{pmatrix} \int \omega_2^2 & \int \omega_2\omega_1 \\ \int \omega_1\omega_2 & \int \omega_1^2 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} =: H.$$

The counting picture agrees: $S^2 \times \{p\}$ and $S^2 \times \{q\}$ are disjoint for $p \neq q$, so $S_1 \cdot S_1 = 0$; and S_1 meets S_2 in the single point (p, p). The eigenvalues of H are ± 1, with eigenvectors $S_1 \pm S_2$, matching the harmonic forms $\omega_1 \pm \omega_2$. H is even: $(xS_1 + yS_2)^2 = 2xy$.

Worked example 12.29: $\mathbb{CP}^2$: the form $(+1)$

$H_2(\mathbb{CP}^2;\mathbb{Z}) = \mathbb{Z}$, generated by a complex projective line $L = \{z_2 = 0\} \cong \mathbb{CP}^1$. Two distinct lines in the projective plane meet in exactly one point, and complex submanifolds always meet positively (the complex orientation of L_1 followed by that of L_2 at a transverse intersection is the complex orientation of $\mathbb{CP}^2$). So $Q = (L \cdot L) = (+1)$: $b_2^+ = 1$, $b_2^- = 0$. The self-dual harmonic form is the Fubini–Study Kähler form (Kähler forms are self-dual; we check this on $\mathbb{C}^2$ in Example 12.39). Reversing the orientation gives $\overline{\mathbb{CP}}^2$ with $Q = (-1)$.

Connected sums

Nash's footnote 6 defines the **connected sum** $X\#Y$ of two n-manifolds: remove a small open n-ball from each, and glue the two resulting boundary spheres S^{n-1} together (with an orientation-reversing identification, so that the orientations of X and Y extend over the sum). The removed balls carry no second homology, so

$$H_2(X\#Y) = H_2(X) \oplus H_2(Y), \qquad Q_{X\#Y} = Q_X \oplus Q_Y, \qquad b_2^\pm(X\#Y) = b_2^\pm(X) + b_2^\pm(Y).$$

(Surfaces in X can be pushed off the ball, so they never meet surfaces in Y.)

12.6.2 Instantons and the dimension of $\mathcal{M}_k$

The equation and the conventions

Let $P \to M$ be a principal G-bundle with a connection A, and use the metric to define $\star$. Nash's instantons are now the **anti-self-dual** (ASD) connections (Nash's (12.42)):

$$F = -\star F. \tag{12.77}$$

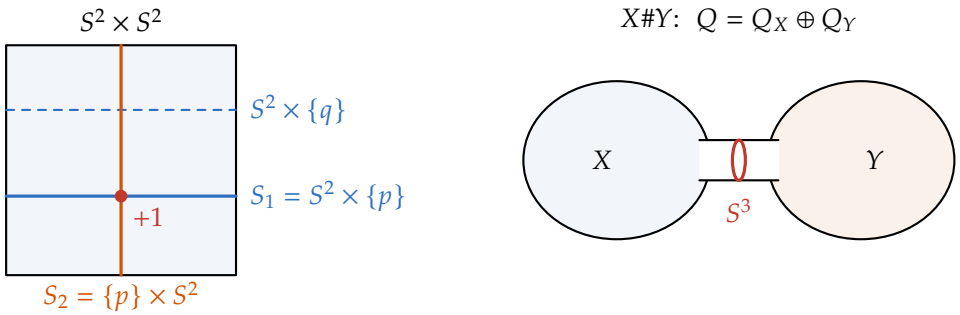

Figure 12.20: Left: in $S^2 \times S^2$ (drawn schematically as a square, one factor horizontal and one vertical) the sphere S_1 can be pushed to the disjoint parallel copy $S^2 \times \{q\}$, so $S_1 \cdot S_1 = 0$; it meets S_2 once, positively. Right: a connected sum is two manifolds joined by a thin tube whose cross-section is a 3-sphere. Surfaces live on one side or the other, so the intersection form is block diagonal.

M	b_2	b_2^+	b_2^-	τ	χ	Q
S^4	0	0	0	0	2	(empty)
$\mathbb{CP}^2$	1	1	0	1	3	(1)
$\overline{\mathbb{CP}}^2$	1	0	1	−1	3	(−1)
$S^2 \times S^2$	2	1	1	0	4	H (even)
$\mathbb{CP}^2\#\overline{\mathbb{CP}}^2$	2	1	1	0	4	(1) ⊕ (−1) (odd)
K3 surface	22	3	19	−16	24	$3H \oplus 2(-E_8)$ (even)
elliptic surface $E(3)$	34	5	29	−24	36	$5(1) \oplus 29(-1)$ (odd)
$5\mathbb{CP}^2\#29\overline{\mathbb{CP}}^2$	34	5	29	−24	36	$5(1) \oplus 29(-1)$ (odd)

Table 12.1: Simply connected 4-manifolds used in this section. E_8 is the positive definite even form of rank 8 (Chapter 1). The last two rows have the same Q, so by Freedman they are homeomorphic; we will see in Section 12.6.6 that Donaldson's invariants tell them apart.

This is the same equation as the flow equation on $M^3 \times \mathbb{R}$ (Eq. (12.46)), now on a closed 4-manifold. Our conventions are those of the Floer sections: A is anti-Hermitian, $F = \mathrm{d}A + A \wedge A$, and the instanton number is

$$k = \frac{1}{8\pi^2} \int_M \operatorname{tr}(F \wedge F). \tag{12.78}$$

For an ASD connection $k \geq 0$:

$$8\pi^2 k = \int_M \operatorname{tr}(F \wedge F) \overset{(1)}{=} -\int_M \operatorname{tr}(F \wedge \star F) \overset{(2)}{=} \tfrac{1}{2} \int_M \textstyle\sum_a |F^a|^2 \,\mathrm{vol} \;\geq 0,$$

(1) $F = -\star F$.

(2) Expand $F = F^a T_a$ with $\operatorname{tr}(T_a T_b) = -\frac{1}{2}\delta_{ab}$ (Eq. (12.9)); the same computation as the positivity of the metric (12.37).

with equality only for $F = 0$. In the physicists' dictionary ($A_{\text{math}} = -igA^a_{\text{phys}} \frac{\sigma^a}{2}$) this is the familiar statement that an anti-instanton or instanton (depending on one's orientation convention) saturates the bound $S_{\text{YM}} \geq 8\pi^2 |k|/g^2$.

The **moduli space** is

$$\mathcal{M}_k = \{A \text{ on } P_k \;:\; F_A = -\star F_A\} / \mathcal{G},$$

with P_k the bundle of instanton number k and $\mathcal{G}$ its gauge group. For $G = \mathrm{SU}(2)$ the bundle is classified by k alone (over a 4-dimensional complex, the only obstruction to triviality of an SU(2) bundle lives in $H^4(M; \pi_3(\mathrm{SU}(2))) = H^4(M; \mathbb{Z}) = \mathbb{Z}$, compare Section 12.2.3 where H^4 vanished for a 3-manifold).

The deformation complex

The dimension of $\mathcal{M}_k$ is the number of independent ways to deform an instanton and stay an instanton, not counting gauge directions. Perturb $A \to A + a$ with $a \in \Omega^1(\mathrm{ad}P)$. Then $F_{A+a} = F_A + \mathrm{d}_A a + a \wedge a$, so the linearised equation says the self-dual part of $\mathrm{d}_A a$ vanishes. Gauge directions are $a = \mathrm{d}_A \xi$ for $\xi \in \Omega^0(\mathrm{ad}P)$; we remove them by asking a to be L^2-orthogonal to them, $\mathrm{d}_A^* a = 0$. So the tangent space is the kernel of

$$D_A = \mathrm{d}_A^* \oplus \mathrm{d}_A^+ : \Omega^1(\mathrm{ad}P) \longrightarrow \Omega^0(\mathrm{ad}P) \oplus \Omega^2_+(\mathrm{ad}P), \qquad \mathrm{d}_A^+ a = \tfrac{1}{2}\big(\mathrm{d}_A a + \star \mathrm{d}_A a\big). \tag{12.79}$$

Equivalently, it is the middle cohomology H^1_A of the **deformation complex**

$$0 \longrightarrow \Omega^0(\mathrm{ad}P) \xrightarrow{\mathrm{d}_A} \Omega^1(\mathrm{ad}P) \xrightarrow{\mathrm{d}_A^+} \Omega^2_+(\mathrm{ad}P) \longrightarrow 0. \tag{12.80}$$

It is a complex because $\mathrm{d}_A^+ \mathrm{d}_A \xi = [F_A^+, \xi] = 0$ when A is ASD. This is Nash's complex (8.104) with self-dual and anti-self-dual exchanged: Chapter 8 studied self-dual instantons, whose linearisation lands in Ω^2_-. The three cohomology groups mean:

$$H^0_A = \{\xi : \mathrm{d}_A \xi = 0\} = \text{stabiliser of } A, \qquad H^1_A = T_{[A]}\mathcal{M}_k, \qquad H^2_A = \text{obstructions}.$$

If A is irreducible, $H^0_A = 0$; for generic metrics (and $b_2^+ > 0$), $H^2_A = 0$. Then $\dim \mathcal{M}_k = \dim H^1_A =$ − index of the complex, and the index theorem computes it.

Worked example 12.30: The symbol of D_A is a quaternion

Look at the simplest case: flat $\mathbb{R}^4$, one abelian component, orientation $\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3 \wedge \mathrm{d}x^4$. A basis of self-dual 2-forms is

$$\eta^1 = \mathrm{d}x^{12} + \mathrm{d}x^{34}, \quad \eta^2 = \mathrm{d}x^{13} - \mathrm{d}x^{24}, \quad \eta^3 = \mathrm{d}x^{14} + \mathrm{d}x^{23},$$

(check one: $\mathrm{d}x^{13} \wedge \mathrm{d}x^{24} = -\mathrm{vol}$, so $\star \mathrm{d}x^{13} = -\mathrm{d}x^{24}$). With $f_{\mu\nu} = \partial_\mu a_\nu - \partial_\nu a_\mu$, the four equations $Da = 0$ are

$$\begin{aligned} -\mathrm{d}^* a &= \partial_1 a_1 + \partial_2 a_2 + \partial_3 a_3 + \partial_4 a_4 = 0, \\ f_{12} + f_{34} &= \partial_1 a_2 - \partial_2 a_1 + \partial_3 a_4 - \partial_4 a_3 = 0, \\ f_{13} - f_{24} &= \partial_1 a_3 - \partial_3 a_1 - \partial_2 a_4 + \partial_4 a_2 = 0, \\ f_{14} + f_{23} &= \partial_1 a_4 - \partial_4 a_1 + \partial_2 a_3 - \partial_3 a_2 = 0. \end{aligned}$$

Four equations for four unknowns: the system is square, which is why an index can be finite. Replace ∂_μ by $i\xi_\mu$ (and drop the i) to get the **symbol**, the matrix acting on (a_1, a_2, a_3, a_4):

$$\sigma(\xi) = \begin{pmatrix} \xi_1 & \xi_2 & \xi_3 & \xi_4 \\ -\xi_2 & \xi_1 & -\xi_4 & \xi_3 \\ -\xi_3 & \xi_4 & \xi_1 & -\xi_2 \\ -\xi_4 & -\xi_3 & \xi_2 & \xi_1 \end{pmatrix}.$$

Multiply it by its transpose. The diagonal entries are $\xi_1^2 + \xi_2^2 + \xi_3^2 + \xi_4^2$; the off-diagonal ones vanish, e.g.

$$\begin{aligned} (\sigma\sigma^{\mathsf{T}})_{12} &\overset{(1)}{=} \xi_1(-\xi_2) + \xi_2\xi_1 + \xi_3(-\xi_4) + \xi_4\xi_3 = 0, \\ (\sigma\sigma^{\mathsf{T}})_{34} &\overset{(2)}{=} (-\xi_3)(-\xi_4) + \xi_4(-\xi_3) + \xi_1\xi_2 + (-\xi_2)\xi_1 = 0. \end{aligned}$$

(1) Row 1 dotted with row 2.
(2) Row 3 dotted with row 4; the other four pairs work the same way.

So $\sigma(\xi)\sigma(\xi)^{\mathsf{T}} = |\xi|^2\, \mathbb{1}_4$: $\sigma(\xi)$ is $|\xi|$ times an orthogonal matrix, invertible for every $\xi \neq 0$. This is the definition of an **elliptic** operator (Chapter 2). The matrix is right multiplication by the quaternion $\xi_1 - \xi_2\mathbf{i} - \xi_3\mathbf{j} - \xi_4\mathbf{k}$ in the basis $1, \mathbf{i}, \mathbf{j}, \mathbf{k}$ of $\mathbb{H} = \mathbb{R}^4$ (a unit quaternion times $|\xi|$): D is a "quaternionic Cauchy–Riemann operator", a Dirac operator in disguise. Its ellipticity is why $\mathcal{M}_k$ is finite-dimensional.

The dimension formula

Chapter 8 computed the index of the complex for *self-dual* instantons (Nash's (8.124)): $\dim \mathcal{M}_k = p_1(\mathrm{ad}_{\mathbb{C}}P) - \frac{\dim G}{2}(\chi - \tau)$. Our ASD connections on M are self-dual connections on $\overline{M}$, the same manifold with the opposite orientation. Reversing orientation leaves χ alone, flips τ, and swaps $b_2^+ \leftrightarrow b_2^-$. The instanton number is, by construction, the positive number k in both descriptions. So

$$\begin{aligned} \dim \mathcal{M}_k &\overset{(1)}{=} p_1(\mathrm{ad}_{\mathbb{C}}P) - \frac{\dim G}{2}\big(\chi(\overline{M}) - \tau(\overline{M})\big) \\ &\overset{(2)}{=} p_1(\mathrm{ad}_{\mathbb{C}}P) - \frac{\dim G}{2}\big(\chi(M) + \tau(M)\big) \\ &\overset{(3)}{=} p_1(\mathrm{ad}_{\mathbb{C}}P) - \frac{\dim G}{2}\big(2 + b_2^+ + b_2^- + b_2^+ - b_2^-\big) \\ &= p_1(\mathrm{ad}_{\mathbb{C}}P) - \dim G\,(1 + b_2^+). \end{aligned} \tag{12.81}$$

(1) Nash's (8.124) applied on $\overline{M}$, where A is self-dual.
(2) $\chi(\overline{M}) = \chi(M)$ and $\tau(\overline{M}) = -\tau(M)$.
(3) $\chi = 2 + b_2$ for a simply connected closed 4-manifold, and $\tau = b_2^+ - b_2^-$.

This is Nash's (12.43). The combination $1 + b_2^+$ has a direct meaning: it is $b_0 - b_1 + b_2^+$, the Euler characteristic of the *untwisted* complex $\Omega^0 \to \Omega^1 \to \Omega^2_+$ (the cohomologies are the constants, the harmonic 1-forms and the self-dual harmonic 2-forms). The index theorem says: twisted index = (curvature term) − dim $G\times$ (untwisted index).

Specialising to SU(2)

Nash next writes $p_1(\mathrm{ad}_{\mathbb{C}}P) = -2c_2(\mathrm{ad}_{\mathbb{C}}P)$ (his (12.44)), and for $G = \mathrm{SU}(2)$, $c_2(\mathrm{ad}_{\mathbb{C}}P) = -4k$. Let us check the factor 4 by splitting principle. Let E be the rank-2 complex vector bundle of P (fundamental representation), with formal Chern roots $\pm x$ (they sum to zero because SU(2) has $c_1 = 0$). The complexified adjoint bundle is $\mathrm{ad}_{\mathbb{C}}P = \mathrm{Sym}^2 E$, the spin-1 representation, whose weights are the sums of pairs of weights of E: $2x, 0, -2x$. Then

$$\begin{aligned} c_2(\mathrm{ad}_{\mathbb{C}}P) &\overset{(1)}{=} (2x)(0) + (2x)(-2x) + (0)(-2x) \\ &= -4x^2 \overset{(2)}{=} 4\,c_2(E). \end{aligned} \tag{12.82}$$

(1) c_2 is the second elementary symmetric function of the Chern roots.
(2) $c_2(E) = (x)(-x) = -x^2$.

With Nash's orientation convention (Chapter 8's (8.127)) $c_2(E) = -k$, so $c_2(\mathrm{ad}_{\mathbb{C}}P) = -4k$ and $p_1(\mathrm{ad}_{\mathbb{C}}P) = 8k$. Also $\dim \mathrm{SU}(2) = 3$. Hence Nash's (12.45):

$$\boxed{\dim \mathcal{M}_k = 8k - 3\,(1 + b_2^+)} \tag{12.83}$$

Watch out: Normalisations of p_1 and c_2

The standard definition is $p_1(V) = -c_2(V \otimes \mathbb{C})$ for a real bundle V, not $-2c_2$; and in the most common convention the instanton number of an ASD SU(2) connection is $c_2(E) = +k$. With those conventions one writes

$$\dim \mathcal{M}_k = -2p_1(\mathrm{ad}P) - 3(1 - b_1 + b_2^+) = 8c_2(E) - 3(1 + b_2^+).$$

Nash's letters differ (see the matching warning in Chapter 8), but the formula a reader should remember is convention-free: *eight real parameters per unit of instanton number, minus three for each of* $1 + b_2^+$.

Parity and Nash's condition that b_2^+ be odd

$8k$ is even, so $\dim \mathcal{M}_k$ is even exactly when $3(1 + b_2^+)$ is even, i.e. when b_2^+ is odd. Nash insists on this because the invariants will be integrals of products of *2-forms* over $\mathcal{M}_k$, which can only fill up an even-dimensional space (Section 12.6.4). For complex algebraic surfaces, the most important examples, the condition holds automatically: $b_2^+ = 1 + 2p_g$ is always odd (Example 12.39).

Worked example 12.31: Counting dimensions

Using (12.83) and Table 12.1:

- S^4: $b_2^+ = 0$, so $\dim \mathcal{M}_k = 8k - 3$; for $k = 1$ it is 5, the centre (4) and scale (1) of the BPST instanton (Chapter 8). It is odd, consistent with $b_2^+ = 0$ being even: S^4 has no Donaldson polynomials (it has no H_2 anyway).

- $\mathbb{CP}^2$, $S^2 \times S^2$: $b_2^+ = 1$, $\dim \mathcal{M}_k = 8k - 6$: $2, 10, 18, \ldots$
- K3: $b_2^+ = 3$, $\dim \mathcal{M}_k = 8k - 12$. For $k = 1$ this is -4: generically there are no charge-1 instantons at all. For $k = 2$ it is 4, for $k = 3$ it is 12.
- $E(3)$: $b_2^+ = 5$, $\dim \mathcal{M}_k = 8k - 18$: $6, 14, 22, \ldots$ for $k = 3, 4, 5, \ldots$
- $b_2^+ = 7$: $\dim \mathcal{M}_k = 8k - 24$, which is *zero* for $k = 3$. Then $\mathcal{M}_3$ is a finite set of points and the invariant is a signed count (Nash's (12.64); Section 12.8.5).

The dimension grows by 8 with each unit of k, the same 8 that made the Floer grading periodic (Section 12.4.5).

Reducible connections and the role of b_2^+

Irreducibility is what made $H^0_A = 0$. When can an SU(2) instanton be reducible? A reducible SU(2) connection has stabiliser containing a U(1), so the bundle splits, $E = L \oplus L^{-1}$, and $A = \operatorname{diag}(\alpha, -\alpha)$ with α a U(1) connection on the line bundle L. Let $e = c_1(L) \in H^2(M;\mathbb{Z})$. Then

$$\begin{aligned} k = \frac{1}{8\pi^2}\int_M \operatorname{tr}(F \wedge F) &\overset{(1)}{=} \frac{1}{8\pi^2}\int_M 2\,F_\alpha \wedge F_\alpha \\ &\overset{(2)}{=} \frac{1}{8\pi^2}\int_M 2(-2\pi i)^2\, c \wedge c \\ &\overset{(3)}{=} -Q(e,e). \end{aligned} \tag{12.84}$$

(1) $F = \operatorname{diag}(F_\alpha, -F_\alpha)$ and $F_\alpha \wedge F_\alpha$ appears twice in the trace.
(2) $c = \frac{i}{2\pi}F_\alpha$ is the Chern–Weil representative of $e = c_1(L)$, so $F_\alpha = -2\pi i\, c$.
(3) $(-2\pi i)^2 = -4\pi^2$, and $\int_M c \wedge c = Q(e,e)$.

F is ASD if and only if F_α is, and a closed ASD 2-form is automatically co-closed ($\mathrm{d} \star F_\alpha = -\mathrm{d}F_\alpha = 0$), hence harmonic. So:

Key idea: reducibles and b_2^+

Reducible ASD SU(2) connections of charge k correspond to classes $e \in H^2(M;\mathbb{Z})$ with $Q(e,e) = -k$ whose harmonic representative is anti-self-dual, i.e. e lies in $\mathcal{H}^2_-(g)$, i.e. e is Q-orthogonal to the b_2^+-dimensional subspace $\mathcal{H}^2_+(g)$. That is b_2^+ conditions on the metric. For a generic metric there are none when $b_2^+ \geq 1$; along generic *paths* of metrics there are none when $b_2^+ \geq 2$.

Watch out: The case $b_2^+ = 1$

When $b_2^+ = 1$ the metrics with reducibles form walls of codimension 1. Two metrics on opposite sides of a wall cannot be joined without passing through a reducible, and the invariants can jump there (**wall-crossing**). The invariants of $\mathbb{CP}^2$ and $S^2 \times S^2$ are therefore defined only relative to a chamber. Nash's statement that the invariants are metric-independent is correct for $b_2^+ > 1$ ($b_2^+ \geq 3$, given oddness). When $b_2^+ = 0$ reducibles are unavoidable; that is precisely the situation of Donaldson's diagonalisation theorem in Chapter 1, where the reducibles were the cone points of $\mathcal{M}_1$.

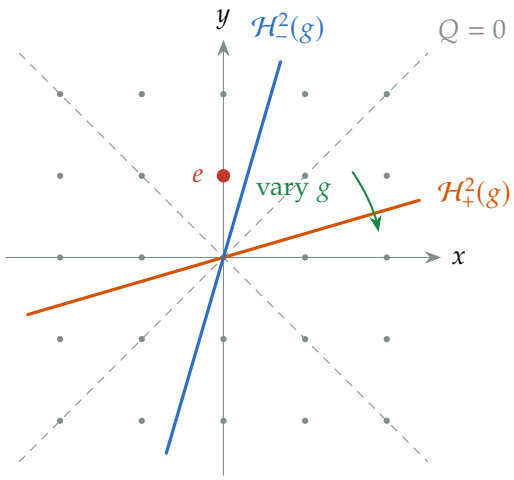

Figure 12.21: $H^2(M;\mathbb{R})$ for $M = \mathbb{CP}^2\#\overline{\mathbb{CP}}^2$, with $Q = x^2 - y^2$. The dashed light cone is $Q = 0$; lattice points are integral classes. The metric determines a positive line $\mathcal{H}^2_+(g)$ (orange) and its Q-orthogonal negative line $\mathcal{H}^2_-(g)$ (blue); they rotate like a Lorentz boost as g varies. A reducible instanton with $k = 1$ appears exactly when $\mathcal{H}^2_-(g)$ passes through a class e with $e^2 = -1$ (red). With $b_2^+ = 1$ this happens on a *wall* of codimension one in the space of metrics, so a path of metrics can be forced to cross it.

Reading Nash (pp. 332–333, (12.42)–(12.45))

Nash recalls that Chapter 1 used $\mathcal{M}_1$ for smoothability questions, and that Donaldson used all $\mathcal{M}_k$ to build invariants of simply connected 4-manifolds, also reachable by Witten's relativistic version of Floer's quantum mechanics. He takes M smooth, simply connected, oriented and closed with a metric, writes the ASD equation (12.42), quotes $\dim \mathcal{M}_k = p_1(\mathrm{ad}_{\mathbb{C}}P) - \dim G(1 + b_2^+)$ (12.43) "in the notation of chapter 8", rewrites it with $p_1 = -2c_2$ (12.44), remarks that it is even when b_2^+ is odd, and for SU(2) uses $c_2(\mathrm{ad}_{\mathbb{C}}P) = -4k$ to get $8k - 3(1 + b_2^+)$ (12.45). We have supplied: the homology of simply connected 4-manifolds, the intersection form and $b_2^\pm$ via $\star$, the examples $S^2 \times S^2$ and $\mathbb{CP}^2$, the deformation complex and its elliptic symbol, the orientation-reversal derivation of (12.43) from Chapter 8's (8.124), the splitting-principle check of the factor 4, and the role of b_2^+ in excluding reducibles.

12.6.3 From surfaces in M to 2-forms on $\mathcal{M}_k$

We now know that $\mathcal{M}_k$ is a manifold of dimension $8k - 3(1 + b_2^+)$. The next question is: *what number can we extract from it?* A manifold by itself gives only crude numbers (its dimension, its Euler characteristic), and $\mathcal{M}_k$ is not even compact. Donaldson's idea is to integrate differential forms over $\mathcal{M}_k$. To integrate, we need top-degree forms on $\mathcal{M}_k$, and to build those we need a supply of lower-degree forms that are natural, i.e. that come from the geometry of M and not from arbitrary choices.

The supply comes from the surfaces in M. Nash states the result as a map (his (12.47))

$$m : H_2(M) \longrightarrow H^2(\mathcal{M}_k), \tag{12.85}$$

which turns a surface $\Sigma \subset M$ into a 2-form $m(\Sigma)$ on the moduli space. (Most of the literature writes μ for this map; we use Nash's m and μ interchangeably.) Building m takes three ingredients: Poincaré duality, which turns surfaces into forms on M; the universal bundle, which turns forms on M into forms on $M \times \mathcal{M}_k$; and integration over M, which removes the M-dependence. We take them in turn.

Ingredient 1: Poincaré duality

A surface Σ is a place to integrate 2-forms. A 2-form is a thing to integrate. Poincaré duality says that, on a closed oriented manifold, these two kinds of object carry the same information: integrating over Σ is the same as wedging with a fixed form and integrating over all of M. Nash gives the definition in his footnote 5.

Working definition 12.10 (Poincaré dual of a submanifold)

Let M be closed and oriented of dimension n, and let $i : X \hookrightarrow M$ be a closed oriented submanifold of dimension r. The **Poincaré dual** of X is the class $X^* = [\omega] \in H^{n-r}_{\mathrm{dR}}(M)$ [a closed $(n-r)$-form ω, with two such forms counted as the same when they differ by an exact form] such that

$$\int_X i^*\alpha = \int_M \alpha \wedge \omega \qquad \text{for every closed } r\text{-form } \alpha. \tag{12.86}$$

Here $i^*\alpha$ is the pull-back [α restricted to X, fed only vectors tangent to X]. *How to find it:* take a thin tubular neighbourhood of X [the points of M within a small distance of X, shaped like X times a small normal disc], and let ω be a closed $(n-r)$-form supported in it whose integral over every small normal disc (oriented so that "X followed by the normal disc" is the orientation of M) equals 1. Then ω represents X^*. Nash writes a^* for the dual of a class $a \in H_2(M)$.

The degrees are forced. The left side of (12.86) integrates an r-form over an r-manifold. On the right, $\alpha \wedge \omega$ must be an n-form, so ω has degree $n-r$. For a surface in a 4-manifold, $n - r = 4 - 2 = 2$: *the Poincaré dual of a surface is again a 2-form*. This coincidence is special to the middle dimension, and it is why H_2 of a 4-manifold carries a symmetric form.

Why does the bump form work? Near X, split coordinates into r along X and $n-r$ normal to it. A closed form α is nearly constant across a thin normal disc. So integrating $\alpha \wedge \omega$ over the tube is integrating α along X and ω across the disc, and the second factor is 1. Figure 12.22 shows this for a circle on the torus.

Worked example 12.32: Poincaré duals of circles on the torus

Let $T^2 = \mathbb{R}^2/\mathbb{Z}^2$ with coordinates $x, y \in [0,1)$ and orientation $\mathrm{d}x \wedge \mathrm{d}y$. Let $a = \{y = y_0\}$, oriented by ∂_x, and $b = \{x = x_0\}$, oriented by ∂_y. Every closed 1-form is cohomologous to $\alpha = p\,\mathrm{d}x + q\,\mathrm{d}y$ with constants p, q. We look for $\omega_a = c\,\mathrm{d}y$:

$$\int_{T^2} \alpha \wedge \omega_a \overset{(1)}{=} \int_{T^2} (p\,\mathrm{d}x + q\,\mathrm{d}y) \wedge c\,\mathrm{d}y \overset{(2)}{=} pc \int_{T^2} \mathrm{d}x \wedge \mathrm{d}y = pc,$$

(1) Insert the two forms.
(2) $\mathrm{d}y \wedge \mathrm{d}y = 0$; the torus has unit area.

and this must equal $\int_a \alpha = p$. So $c = 1$ and $a^* = [\mathrm{d}y]$. The bump version is $\omega_a = \rho(y - y_0)\,\mathrm{d}y$ with $\int \rho = 1$ and ρ supported in $|y - y_0| < \epsilon$: it is cohomologous to $\mathrm{d}y$ because the difference $(\rho - 1)\mathrm{d}y = \mathrm{d}\big(\int^y (\rho - 1)\big)$ is exact (the integral of $\rho - 1$ over a full period vanishes, so the primitive is periodic).
For b, try $\omega_b = c\,\mathrm{d}x$:

$$\int_{T^2} \alpha \wedge \omega_b \overset{(1)}{=} qc \int_{T^2} \mathrm{d}y \wedge \mathrm{d}x \overset{(2)}{=} -qc,$$

(1) Only the $q\,\mathrm{d}y$ term survives against $\mathrm{d}x$.

(2) $\mathrm{d}y \wedge \mathrm{d}x = -\mathrm{d}x \wedge \mathrm{d}y$.

and this must equal $\int_b \alpha = q$. So $b^* = [-\mathrm{d}x]$. Now intersect:

$$\int_{T^2} a^* \wedge b^* \overset{(1)}{=} \int_{T^2} \mathrm{d}y \wedge (-\mathrm{d}x) \overset{(2)}{=} +1,$$

(1) The two duals just found.
(2) $-\mathrm{d}y \wedge \mathrm{d}x = \mathrm{d}x \wedge \mathrm{d}y$.

The geometric count agrees: a and b meet once, at (x_0, y_0), and there "∂_x followed by ∂_y" is the orientation of T^2, so the sign is $+1$. The minus sign in b^* is not a nuisance; it is what makes wedge product and signed counting agree.

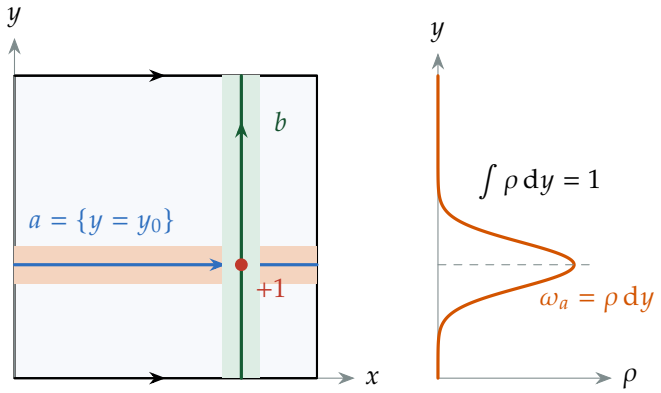

Figure 12.22: The Poincaré dual of a curve is a form concentrated on a thin tube around it. The circle a (blue) on the torus (a square with opposite sides identified) has dual $\omega_a = \rho(y)\,\mathrm{d}y$, a bump across the orange strip with unit total weight (profile on the right). Wedging with ω_a and integrating over the torus is therefore the same as integrating along a. The product of the two bump forms of a and b is concentrated on the small square where the strips cross, and integrates to the intersection sign $+1$.

Key idea: Wedge product of duals counts intersections

For closed oriented submanifolds $X, Y \subset M$ of complementary dimension meeting transversally,

$$\int_M X^* \wedge Y^* = \#(X \cap Y) \quad \text{(counted with signs)}.$$

Why: the product of the bump forms of X and Y is supported near the intersection points; near each one the two tubes cross like the two strips in Figure 12.22, and the integral is ± 1 depending on orientations. For surfaces in a 4-manifold this is the statement, used in Section 12.6.1, that $Q(\Sigma_1, \Sigma_2) = \int_M \Sigma_1^* \wedge \Sigma_2^*$.

Worked example 12.33: The line in $\mathbb{CP}^2$ and the Fubini–Study form

On $\mathbb{CP}^2$ with affine coordinates (z_1, z_2) (the chart $[1 : z_1 : z_2]$, which misses only a line at infinity, a set of measure zero), consider

$$\omega = \frac{i}{2\pi}\,\partial\bar\partial \log(1 + |z|^2) = \frac{i}{2\pi} \sum_{j,l} g_{j\bar l}\,\mathrm{d}z_j \wedge \mathrm{d}\bar z_l, \qquad g_{j\bar l} = \frac{(1 + |z|^2)\delta_{jl} - \bar z_j z_l}{(1 + |z|^2)^2}.$$

This is the (normalised) Fubini–Study Kähler form. It is closed because $\mathrm{d} = \partial + \bar\partial$ and $\partial^2 = \bar\partial^2 = 0$, $\partial\bar\partial = -\bar\partial\partial$.
Its integral over a line. Restrict to the line $L = \{z_2 = 0\}$, with coordinate $z = z_1 = re^{i\theta}$. There $\omega|_L = \frac{i}{2\pi}\,\mathrm{d}z \wedge \mathrm{d}\bar z/(1+r^2)^2$, and

$$\int_L \omega \overset{(1)}{=} \frac{1}{2\pi}\int_{\mathbb{R}^2} \frac{2\,\mathrm{d}x\wedge\mathrm{d}y}{(1+r^2)^2} \overset{(2)}{=} \frac{1}{\pi}\cdot 2\pi\int_0^\infty \frac{r\,\mathrm{d}r}{(1+r^2)^2} \overset{(3)}{=} 2\cdot\frac{1}{2} = 1.$$

(1) $i\,\mathrm{d}z\wedge\mathrm{d}\bar z = i(\mathrm{d}x + i\mathrm{d}y)\wedge(\mathrm{d}x - i\mathrm{d}y) = 2\,\mathrm{d}x\wedge\mathrm{d}y$.
(2) Polar coordinates.
(3) $\int_0^\infty r(1+r^2)^{-2}\mathrm{d}r = \left[-\frac{1}{2}(1+r^2)^{-1}\right]_0^\infty = \frac{1}{2}$.

So ω integrates to 1 on the generator L of $H_2(\mathbb{CP}^2) = \mathbb{Z}$. Since $H^2_{\mathrm{dR}}(\mathbb{CP}^2) = \mathbb{R}$, this says $[\omega] = L^*$ (both pair to 1 with L, and the pairing is non-degenerate).
Its square. First the determinant of g: the matrix $(1+|z|^2)\mathbb{1} - \bar z z^{\mathsf T}$ has eigenvalue $1+|z|^2$ on vectors orthogonal to $\bar z$ and eigenvalue $(1+|z|^2) - |z|^2 = 1$ on $\bar z$ itself, so $\det g = (1+|z|^2)(1+|z|^2)^{-4} = (1+|z|^2)^{-3}$. Then

$$\int_{\mathbb{CP}^2}\omega\wedge\omega \overset{(1)}{=} \left(\frac{i}{2\pi}\right)^2\int 2\det g\;\mathrm{d}z_1\wedge\mathrm{d}\bar z_1\wedge\mathrm{d}z_2\wedge\mathrm{d}\bar z_2$$
$$\overset{(2)}{=} \frac{1}{4\pi^2}\int_{\mathbb{R}^4}\frac{2\cdot 4\,\mathrm{d}^4x}{(1+r^2)^3} \overset{(3)}{=} \frac{2}{\pi^2}\cdot 2\pi^2\int_0^\infty\frac{r^3\,\mathrm{d}r}{(1+r^2)^3} \overset{(4)}{=} 4\cdot\frac{1}{4} = 1.$$

(1) Expanding the wedge square, only terms with $\{j,k\} = \{l,m\} = \{1,2\}$ survive; reordering the four 1-forms gives $2(g_{1\bar1}g_{2\bar2} - g_{1\bar2}g_{2\bar1}) = 2\det g$ times $\mathrm{d}z_1\mathrm{d}\bar z_1\mathrm{d}z_2\mathrm{d}\bar z_2$.
(2) $(i\,\mathrm{d}z_1\wedge\mathrm{d}\bar z_1)\wedge(i\,\mathrm{d}z_2\wedge\mathrm{d}\bar z_2) = 4\,\mathrm{d}^4x$ with the complex orientation, and $\det g = (1+r^2)^{-3}$.
(3) The integrand is radial; the unit 3-sphere has volume $2\pi^2$.
(4) With $u = r^2$: $\int_0^\infty r^3(1+r^2)^{-3}\mathrm{d}r = \frac{1}{2}\int_0^\infty u(1+u)^{-3}\mathrm{d}u = \frac{1}{2}\cdot\frac{1}{2}$.

So $\int L^*\wedge L^* = 1 = L\cdot L$, matching the geometric count in Example 12.29: two lines meet in one point. We will use this computation twice more: as the model of a "positive" class in Section 12.6.6, and as the simplest instance of the integrals that define q_d.

Ingredient 2: the space of gauge orbits as a classifying space

Nash writes "let $E_{\mathcal G}$ be the universal $\mathcal G$-bundle over $B\mathcal G$" and, a line later, "$\mathcal M_k \subset B\mathcal G$". Both statements hide a construction, which we now supply.

Classifying spaces, in one paragraph. For a group H, a **universal bundle** is a principal H-bundle $EH \to BH$ whose total space EH is contractible. BH is the **classifying space**. Its defining property: every principal H-bundle over any (reasonable) space Y is the pullback of EH along a map $Y \to BH$, unique up to homotopy. So characteristic classes of H-bundles are pulled back from $H^*(BH)$. We met two examples in Section 12.2.3: $S^\infty \to \mathbb{CP}^\infty$ for U(1), and $S^\infty \to \mathbb{H}P^\infty$ for SU(2).

The gauge group version. Let $\mathcal A_k$ be the space of all connections on P_k, and $\mathcal A_k^*$ the irreducible ones. Then:

1. $\mathcal A_k$ is contractible: it is an affine space, and $A_t = (1-t)A_0 + tA_1$ joins any two connections.

2. $\mathcal A_k^*$ is still (weakly) contractible: the reducibles form a subset of infinite codimension, and removing a subset of infinite codimension from an infinite-dimensional contractible space does not create any homotopy (just as $\mathbb{R}^N$ minus a point has $\pi_j = 0$ for $j < N-1$,

and $N = \infty$).

3. The gauge group acts freely on $\mathcal{A}_k^*$ *except* for the central elements $\pm\mathbb{1}$, which fix every connection (for constant $g = \pm\mathbb{1}$, $g^{-1}Ag + g^{-1}\mathrm{d}g = A$). So $\bar{\mathcal{G}} = \mathcal{G}/\{\pm\mathbb{1}\}$ acts freely.

A free action of $\bar{\mathcal{G}}$ on a contractible space is exactly the data of a universal bundle. Hence

$$\mathcal{A}_k^* \longrightarrow \mathcal{B}_k^* := \mathcal{A}_k^*/\mathcal{G} \quad \text{is the universal } \bar{\mathcal{G}}\text{-bundle, and} \quad \mathcal{B}_k^* \simeq B\bar{\mathcal{G}}. \tag{12.87}$$

Nash's "$B\mathcal{G}$" is this $\mathcal{B}_k^*$, and his (12.49), $\mathcal{M}_k \subset B\mathcal{G}$, is the obvious inclusion of the irreducible instantons into all irreducible gauge orbits.

Ingredient 3: the universal bundle over $M \times \mathcal{B}^*$

A point of $\mathcal{B}_k^*$ is a gauge orbit $[A]$. Each connection A lives on the same bundle P over M. So we have a *family* of bundles-with-connection parametrised by $\mathcal{B}_k^*$. Families of bundles over M parametrised by Y are bundles over $M \times Y$. Here is the bundle.

Working definition 12.11 (the universal bundle over $M \times \mathcal{B}^*$)

The gauge group acts on $\mathcal{A}_k^*$ (by gauge transformations) and on the adjoint bundle $\mathrm{ad}P$ [a copy of $\mathfrak{su}(2)$ over each point x of M, where the Lie-algebra-valued fields live] (a gauge transformation is a bundle automorphism, so it acts fibrewise on $\mathrm{ad}P$ by Ad_g). Let it act on both at once and form the quotient [a pair $(A,(x,v))$ and its gauge transform $(A^g,(x,g^{-1}vg))$ become the same point]

$$\mathbb{E} := \big(\mathcal{A}_k^* \times \mathrm{ad}P\big)/\mathcal{G} \longrightarrow \mathcal{B}_k^* \times M, \qquad [A,\,(x,v)] \mapsto ([A],\,x). \tag{12.88}$$

It is a real rank-3 vector bundle (an SO(3)-bundle). Its fibre over $([A],x)$ is "the Lie algebra at x, as seen by the connection A". Its restriction to $\{[A]\} \times M$ is $\mathrm{ad}P$ itself.

Why $\mathrm{ad}P$ *and not* P*?* The central element $-\mathbb{1}$ acts trivially on $\mathcal{A}_k^*$ but as -1 on the fibres of P (or of the rank-2 bundle E). The quotient $(\mathcal{A}^* \times E)/\mathcal{G}$ would then not be a vector bundle: the fibre over $([A],x)$ would be $E_x/\{\pm1\}$. On the adjoint bundle $-\mathbb{1}$ acts as $\mathrm{Ad}_{-\mathbb{1}} = +1$, so the problem disappears. The price is that $\mathbb{E}$ is an SO(3)-bundle, and its natural characteristic class is $p_1(\mathbb{E})$. On any subspace where the SU(2) lift exists, $p_1(\mathrm{ad}E) = -4c_2(E)$ (a real form of (12.82)). So Nash's "$c_2(E_{\mathcal{G}})$" is to be read as

$$c_2 := -\tfrac{1}{4}\,p_1(\mathbb{E}) \;\in H^4(\mathcal{B}_k^* \times M;\mathbb{Q}). \tag{12.89}$$

The $\frac{1}{4}$ is why careful authors say the invariants are rational numbers which turn out to be integers (or integers up to a known power of 2).

The map m

We have a 4-class $c_2(\mathbb{E})$ on the ∞-dimensional space $\mathcal{B}_k^* \times M$. Split it by bidegree, (p,q) meaning p directions along $\mathcal{B}_k^*$ and q along M. By the Künneth theorem,

$$H^4(\mathcal{B}_k^*\times M) = \bigoplus_{p+q=4} H^p(\mathcal{B}_k^*)\otimes H^q(M) = H^4(\mathcal{B}^*)\otimes H^0(M) \oplus H^2(\mathcal{B}^*)\otimes H^2(M) \oplus H^0(\mathcal{B}^*)\otimes H^4(M), \tag{12.90}$$

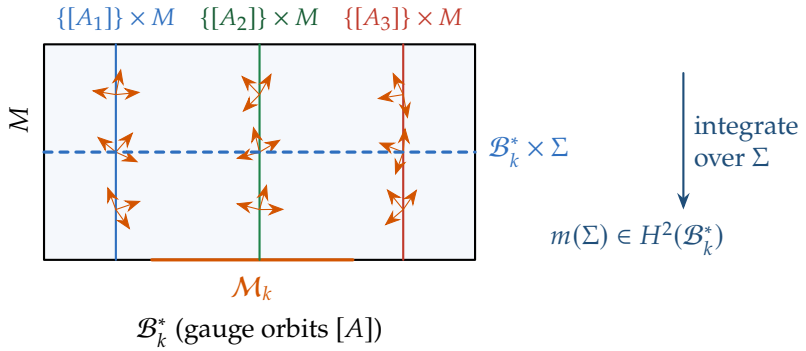

Figure 12.23: The universal bundle. The rectangle is $\mathcal{B}^*_k \times M$; each vertical slice $\{[A]\} \times M$ is a copy of M carrying the bundle $\mathrm{ad}P$ (orange triads) with the connection A. As $[A]$ moves horizontally the internal frames twist, and $c_2(\mathbb{E})$ measures that twisting. Restricting to $\mathcal{B}^*_k \times \Sigma$ (dashed) and integrating out the two Σ-directions leaves a 2-form on $\mathcal{B}^*_k$, and hence on $\mathcal{M}_k$ (orange segment).

where we used $H^1(M) = H^3(M) = 0$ for simply connected M (and the odd cohomology of $\mathcal{B}^*$ plays no role below). Nash's construction (12.48)–(12.51) extracts the middle piece. In a chain:

$$\begin{aligned} m(a) &\overset{(1)}{=} \int_M c_2(\mathbb{E}) \wedge a^* \\ &\overset{(2)}{=} \int_M c_2(\mathbb{E})^{(2,2)} \wedge a^* \\ &\overset{(3)}{=} \int_\Sigma c_2(\mathbb{E})^{(2,2)}\Big|_{\mathcal{B}^*\times\Sigma} \in H^2(\mathcal{B}^*_k), \qquad a = [\Sigma]. \end{aligned} \tag{12.91}$$

(1) Nash's definition (12.51): wedge with the Poincaré dual a^* (a form on M, pulled back to $\mathcal{B}^* \times M$), which gives a 6-form (12.48), then integrate over the four M-directions (12.50). Integration over the fibre M of the projection $\mathcal{B}^* \times M \to \mathcal{B}^*$ lowers the degree by 4: $6 - 4 = 2$.

(2) Only components with exactly two M-directions survive: a^* already supplies two, and the integral needs four in total.

(3) The defining property (12.86) of the Poincaré dual, applied slice by slice in $\mathcal{B}^*$.

Finally restrict from $\mathcal{B}^*_k$ to the submanifold $\mathcal{M}_k$ (Nash's (12.49)): $m(a)|_{\mathcal{M}_k} \in H^2(\mathcal{M}_k)$. The map is linear in a, because $a \mapsto a^*$ is linear and integration is linear.

Physical picture: What $m(\Sigma)$ measures

A 2-form on $\mathcal{M}_k$ assigns a number to every small 2-dimensional family of instantons, or, after integrating, to every closed surface S of instantons in $\mathcal{M}_k$. Take such a family $S \subset \mathcal{M}_k$. It gives a bundle $\mathbb{E}|_{S\times\Sigma}$ over the 4-manifold $S \times \Sigma$, and $\langle m(\Sigma), S\rangle = \int_{S\times\Sigma} c_2(\mathbb{E})$ is its instanton number. So $m(\Sigma)$ asks: *as the instanton moves around the family S, how much do its internal frames over Σ twist?*

A formula for the representative

It is worth having an explicit form, because the same expression will reappear in Witten's field theory as an observable. The bundle $\mathbb{E}$ carries a natural connection, whose curvature $\mathbb{F}$ at a point $([A], x)$ has three pieces (Atiyah–Singer, Donaldson):

- bidegree $(0,2)$ (two M-directions): $\mathbb{F}^{(0,2)} = F_A(x)$, the curvature of A itself;

- bidegree $(1,1)$: for a tangent vector $a \in T_{[A]}\mathcal{B}^*$, represented by a 1-form $a \in \Omega^1(\mathrm{ad}P)$ in Coulomb gauge $\mathrm{d}_A^* a = 0$, and a tangent vector v to M, $\mathbb{F}^{(1,1)}(a, v) = a(v)$: *the mixed curvature is the tangent vector itself*;
- bidegree $(2,0)$: for two tangent vectors a, b, $\mathbb{F}^{(2,0)}(a,b) = \Phi(a,b)$, where $\Phi(a,b) \in \Omega^0(\mathrm{ad}P)$ solves the Laplace equation $\mathrm{d}_A^* \mathrm{d}_A \Phi = -2 \star [a \wedge \star b]$ (up to a normalisation constant depending on conventions). It exists because A is irreducible, so $\mathrm{d}_A^* \mathrm{d}_A$ is invertible.

(The $(2,0)$ piece is the curvature of the Coulomb-gauge "connection" on $\mathcal{A}^* \to \mathcal{B}^*$: two horizontal directions a, b fail to commute by an infinitesimal gauge transformation, and $\Phi(a,b)$ is its generator.) Then Chern–Weil (Chapter 8) gives $c_2(\mathbb{E}) = \frac{1}{8\pi^2}\operatorname{tr}(\mathbb{F} \wedge \mathbb{F})$ in our conventions, and its $(2,2)$ part is

$$\begin{aligned} \operatorname{tr}(\mathbb{F} \wedge \mathbb{F})^{(2,2)} &\overset{(1)}{=} \operatorname{tr}\big(\mathbb{F}^{(0,2)}\mathbb{F}^{(2,0)} + \mathbb{F}^{(2,0)}\mathbb{F}^{(0,2)} + \mathbb{F}^{(1,1)} \wedge \mathbb{F}^{(1,1)}\big) \\ &\overset{(2)}{=} 2\operatorname{tr}\big(F_A\,\Phi\big) + \operatorname{tr}\big(\mathbb{F}^{(1,1)} \wedge \mathbb{F}^{(1,1)}\big). \end{aligned} \tag{12.92}$$

(1) Expand $\mathbb{F} = \mathbb{F}^{(0,2)} + \mathbb{F}^{(1,1)} + \mathbb{F}^{(2,0)}$ and keep the products whose bidegrees add to $(2,2)$.
(2) The trace is cyclic, and the $(2,0)$ piece Φ is a 0-form on M, so it commutes past F_A under the trace.

Evaluated on two tangent vectors a, b of $\mathcal{M}_k$ and integrated over Σ, this gives

$$m(\Sigma)(a,b) = \frac{1}{4\pi^2}\int_\Sigma \operatorname{tr}\big(\Phi(a,b)\,F_A + a \wedge b\big) \qquad \text{(up to an overall sign fixed by orientations).} \tag{12.93}$$

Keep an eye on the two terms, "ΦF" and "$a \wedge b$". In Witten's theory they will be ϕF and $\frac{1}{2}\psi \wedge \psi$ (Section 12.7.5).

Worked example 12.34: A toy universal bundle: flat $\mathrm{U}(1)$ connections on T^2

Everything above can be seen in a finite-dimensional abelian model, one dimension lower. Let $M = T^2 = \mathbb{R}^2/\mathbb{Z}^2$ and consider flat U(1) connections on the trivial line bundle,

$$A_\theta = i(\theta_1\,\mathrm{d}x + \theta_2\,\mathrm{d}y), \qquad \theta \in \mathbb{R}^2.$$

(Anti-Hermitian, so U(1) connections are i times real 1-forms.) A gauge transformation $g = e^{2\pi i(mx+ny)}$, $m, n \in \mathbb{Z}$, is well defined on T^2 and sends

$$A_\theta \mapsto g^{-1}A_\theta g + g^{-1}\mathrm{d}g \overset{(1)}{=} A_\theta + 2\pi i(m\,\mathrm{d}x + n\,\mathrm{d}y) \overset{(2)}{=} A_{\theta + 2\pi(m,n)}.$$

(1) U(1) is abelian, so $g^{-1}Ag = A$; and $g^{-1}\mathrm{d}g = 2\pi i(m\,\mathrm{d}x + n\,\mathrm{d}y)$.
(2) Read off the new θ.

So the moduli space of flat connections is the *dual torus* $\hat{T} = \mathbb{R}^2/(2\pi\mathbb{Z})^2$, with coordinates θ_1, θ_2. The universal line bundle over $\hat{T} \times T^2$ (the **Poincaré line bundle**) carries the "universal connection" $\mathbb{A} = i(\theta_1 \mathrm{d}x + \theta_2 \mathrm{d}y)$, viewed as a 1-form on the product (it is defined on $\mathbb{R}^2 \times T^2$ and glued by the gauge transformations above). Its curvature is

$$\mathbb{F} = \mathrm{d}\mathbb{A} \overset{(1)}{=} i\big(\mathrm{d}\theta_1 \wedge \mathrm{d}x + \mathrm{d}\theta_2 \wedge \mathrm{d}y\big),$$

(1) d on the product acts on the θ's too; $\mathrm{d}(\mathrm{d}x) = 0$.

This is purely of mixed bidegree $(1,1)$: $F_A = 0$ since the connections are flat, and $\Phi = 0$ since the group is abelian. The mixed term is the tangent vector: moving θ_1 by $\delta\theta_1$ changes A by $i\,\delta\theta_1\,\mathrm{d}x$, which is what $\mathbb{F}$ pairs with ∂_{θ_1}. The first Chern class is

$c_1 = \frac{i}{2\pi}\mathbb{F} = -\frac{1}{2\pi}(\mathrm{d}\theta_1 \wedge \mathrm{d}x + \mathrm{d}\theta_2 \wedge \mathrm{d}y)$. Now slant with the circle $a = \{y = y_0\}$, which has dual $a^* = \mathrm{d}y$ (Example 12.32). Integrating over T^2 (the x, y directions, placed on the right):

$$m(a) = \int_{T^2} c_1 \wedge a^* \overset{(1)}{=} -\frac{1}{2\pi}\int_{T^2} \mathrm{d}\theta_1 \wedge \mathrm{d}x \wedge \mathrm{d}y \overset{(2)}{=} -\frac{\mathrm{d}\theta_1}{2\pi}.$$

(1) The $\mathrm{d}\theta_2 \wedge \mathrm{d}y$ term dies against $\mathrm{d}y$.
(2) $\int_{T^2} \mathrm{d}x \wedge \mathrm{d}y = 1$, with the $\hat{T}$-form $\mathrm{d}\theta_1$ pulled out to the left.

So a 1-cycle of M produced a 1-form on moduli space, whose integral round the θ_1-circle of $\hat{T}$ is -1. Likewise $b = \{x = x_0\}$, with $b^* = -\mathrm{d}x$, gives $m(b) = -\frac{1}{2\pi}\int \mathrm{d}\theta_2 \wedge \mathrm{d}y \wedge (-\mathrm{d}x) = -\mathrm{d}\theta_2/2\pi$ (since $\mathrm{d}y \wedge \mathrm{d}x = -\mathrm{d}x \wedge \mathrm{d}y$). The "toy invariant" is then

$$\int_{\hat{T}} m(a) \wedge m(b) = \frac{1}{4\pi^2}\int_{\hat{T}} \mathrm{d}\theta_1 \wedge \mathrm{d}\theta_2 = 1,$$

a number built from cycles in M and the geometry of the moduli space. In Donaldson theory the cycles are surfaces, the forms have degree 2, and the integral is over $\mathcal{M}_k$; the logic is identical.

Try it: Degrees in the toy model

In the toy model M had dimension 2 and the curvature class had degree 2. Show that a j-cycle of M gives a $(2-j)$-form on $\hat{T}$, and check that the 0-cycle "a point p" gives $m(p) = c_1|_{\hat{T}\times\{p\}} = 0$. *Answer:* $c_1 \wedge$ (dual of a j-cycle) has degree $2 + (2-j)$; integrating over the 2-dimensional M leaves $2 - j$. For a point the dual is the volume form of T^2, which kills both terms of c_1 (each contains a T^2-direction), so $m(p) = 0$: the Poincaré bundle is trivial on each slice $\hat{T} \times \{p\}$. In Donaldson theory the analogous point class is *not* zero; it is the degree-4 class of Section 12.7.5.

12.6.4 The polynomials q_d

Now we can integrate. Choose d surfaces $a_1, \dots, a_d \in H_2(M;\mathbb{Z})$. Each gives a 2-form $m(a_i)$ on $\mathcal{M}_k$. Their wedge product is a $2d$-form. It can be integrated over $\mathcal{M}_k$ exactly when it has top degree:

$$2d = \dim \mathcal{M}_k \qquad \Longleftrightarrow \qquad d = \tfrac{1}{2}\dim \mathcal{M}_k = 4k - \tfrac{3}{2}(1 + b_2^+). \tag{12.94}$$

This is why Nash insisted that $\dim \mathcal{M}_k$ be even: products of 2-forms have even degree, so on an odd-dimensional moduli space no product of m's has top degree and every integral of the kind below is zero.

Working definition 12.12 (Donaldson's polynomial invariant)

For $d = \frac{1}{2}\dim \mathcal{M}_k$ (Nash's (12.52)),

$$q_d(M)(a_1, \dots, a_d) = \int_{\overline{\mathcal{M}}_k} m(a_1) \wedge \cdots \wedge m(a_d) \ \in \mathbb{Z}, \tag{12.95}$$

where $\overline{\mathcal{M}}_k$ is a compactification of $\mathcal{M}_k$ [$\mathcal{M}_k$ with the limits added in which instantons shrink to points] (Section 12.6.5) and the metric is generic [chosen so that $\mathcal{M}_k$ is a smooth manifold of the expected dimension]. *How to compute, geometrically:* represent each $m(a_i)$ by a codimension-2 submanifold $V_{a_i} \subset \mathcal{M}_k$ (its Poincaré dual in $\mathcal{M}_k$), put them in general position [moved slightly so that they meet transversally, in finitely many isolated points],

and count the points of $V_{a_1} \cap \cdots \cap V_{a_d}$ with signs. Formally, q_d is a symmetric d-linear form on $H_2(M;\mathbb{Z})$, i.e. an element of $\mathrm{Sym}^d(H^2(M))$, or equivalently a homogeneous polynomial of degree d on $H_2(M)$ (Nash's (12.46)).

Let us unpack each property.

Multilinear: each $m(a_i)$ is linear in a_i and the wedge product is linear in each factor.

Symmetric: 2-forms commute. For two of them,

$$m(a_1) \wedge m(a_2) \overset{(1)}{=} (-1)^{2\cdot 2}\, m(a_2) \wedge m(a_1) = m(a_2) \wedge m(a_1),$$

(1) $\alpha \wedge \beta = (-1)^{pq}\beta \wedge \alpha$ for a p-form and a q-form (Chapter T1).

so swapping any two arguments leaves the integrand, hence q_d, unchanged.

A polynomial: a symmetric multilinear form is determined by its values on the diagonal, $q_d(a) \coloneqq q_d(a,\dots,a)$, which is a homogeneous polynomial of degree d in the coordinates of a with respect to a basis of $H_2(M;\mathbb{Z}) \cong \mathbb{Z}^{b_2}$. The multilinear form is recovered by **polarisation**. For $d = 2$:

$$q_2(a+b) \overset{(1)}{=} q_2(a,a) + q_2(a,b) + q_2(b,a) + q_2(b,b) \overset{(2)}{=} q_2(a) + 2q_2(a,b) + q_2(b),$$

(1) Bilinearity.
(2) Symmetry.

so $q_2(a,b) = \frac{1}{2}\big(q_2(a+b) - q_2(a) - q_2(b)\big)$. The same trick, with more terms, works for every d. This is the same relation as between a quadratic form and its bilinear form: q_2 "looks like" an intersection form, and q_d is a degree-d generalisation.

Integer valued: the geometric definition as a signed point count makes this plausible. Behind it lie two technical facts. (i) $\mathcal{M}_k$ is orientable, and an orientation is fixed by choosing an orientation of $H^2_+(M)$ (a **homology orientation**); reversing it flips the sign of q_d. This is why Nash later says the invariants are defined "up to a sign". (ii) The classes $m(a)$ are integral after the correct normalisation of (12.89); with other normalisations one gets rational numbers with bounded denominators.

Worked example 12.35: Toy polynomials from simple moduli spaces

Suppose, purely to see how a polynomial arises, that the moduli space were a compact complex manifold on which the m-classes are combinations of a few standard 2-forms.

1. *Moduli* $= \mathbb{CP}^2$, $m(a) = \lambda(a)\,h$ with $h = L^*$ the hyperplane class and $\lambda : H_2(M) \to \mathbb{Z}$ linear. Then, by Example 12.33,

$$q_2(a) = \int_{\mathbb{CP}^2} m(a)^2 \overset{(1)}{=} \lambda(a)^2 \int_{\mathbb{CP}^2} h \wedge h \overset{(2)}{=} \lambda(a)^2.$$

   (1) Linearity: $m(a)^2 = \lambda(a)^2 h^2$.
   (2) $\int h^2 = 1$: two lines meet in one point.

   A perfect square of a linear form.

2. *Moduli* $= \mathbb{CP}^1 \times \mathbb{CP}^1$, $m(a) = \lambda_1(a)h_1 + \lambda_2(a)h_2$, with h_i the area form of the i-th factor, normalised to $\int_{\mathbb{CP}^1} h_i = 1$. Then

$$q_2(a) \overset{(1)}{=} \int \big(\lambda_1^2 h_1^2 + 2\lambda_1\lambda_2\, h_1 \wedge h_2 + \lambda_2^2 h_2^2\big) \overset{(2)}{=} 2\lambda_1(a)\lambda_2(a).$$

(1) Expand the square; the 2-forms commute.
(2) $h_i \wedge h_i = 0$ (a 4-form built from a 2-dimensional factor), and $\int h_1 \wedge h_2 = 1$ by Fubini, exactly as in Example 12.28.

The polynomial is now *indefinite*, like the hyperbolic form H.

The geometry of the moduli space, through the intersection numbers of its 2-forms, determines the shape of the polynomial. Real Donaldson polynomials are built in this way, but from moduli spaces that are (usually) far from explicit.

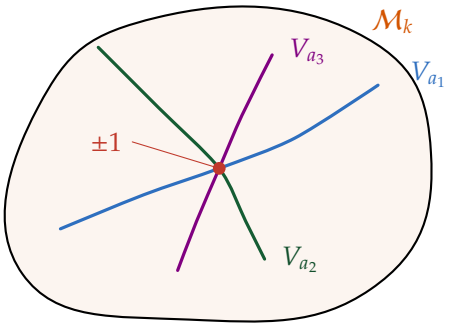

Figure 12.24: The geometric meaning of q_d. Each surface $a_i \subset M$ defines a codimension-2 "divisor" V_{a_i} in the moduli space (drawn as curves in a schematic picture). In a $2d$-dimensional $\mathcal{M}_k$, d divisors in general position meet in finitely many points, and q_d counts them with signs. The same picture with $\mathcal{M}_k = \mathbb{CP}^n$ and V's hyperplanes gives $\int h^n = 1$.

The divisors V_Σ

Donaldson constructs V_Σ concretely. Restrict each instanton A to a small tubular neighbourhood $\nu(\Sigma)$ of the surface. The restricted connections define a family of Dirac-type operators on Σ (a $\bar\partial$-operator coupled to $A|_\Sigma$), and the determinant of such a family is a complex line bundle $\mathcal{L}_\Sigma$ over the space of connections on $\nu(\Sigma)$, with $c_1(\mathcal{L}_\Sigma) = m(\Sigma)$ up to a factor. A generic section of $\mathcal{L}_\Sigma$ vanishes on a real codimension-2 set: this is V_Σ, the instantons for which the coupled Dirac operator on Σ has a zero mode. The key feature is *locality*: V_Σ is defined by what the instanton does near Σ. That locality is what makes the cutting-and-gluing arguments of Section 12.8 work, and it is the geometric counterpart of the fact that $m(\Sigma)$ in (12.93) is an integral over Σ.

12.6.5 Compactness: bubbles and the compactification $\overline{\mathcal{M}}_k$

Nash's (12.52) integrates over "a compactification $\overline{\mathcal{M}}_k$". Integrals of top-degree forms over non-compact manifolds are not topological (think of $\int_{\mathbb{R}} \mathrm{d}f = f(\infty) - f(-\infty)$). So we need to know how $\mathcal{M}_k$ fails to be compact, and what to add.

How a sequence of instantons can escape

In a sequence of connections in $\mathcal{M}_k$ the total action is fixed, $\int \frac{1}{2}|F|^2 = 8\pi^2 k$. The only way a sequence can fail to converge (after gauge transformations) is by **bubbling**: the action density piles up at finitely many points, each carrying a quantised amount $8\pi^2$ (a whole unit of instanton number), while away from these points the connections converge to an instanton of lower charge. This is **Uhlenbeck's compactness theorem**. It is the non-abelian cousin of a familiar phenomenon: a family of Gaussians of fixed area converging to a delta function.

Worked example 12.36: A BPST instanton shrinking to a point

The BPST instanton of Chapter 8 with centre 0 and scale ρ has action density

$$e_\rho(x) = \tfrac{1}{2}\sum_a |F^a|^2 = \frac{48\,\rho^4}{(|x|^2+\rho^2)^4} \qquad (x \in \mathbb{R}^4).$$

Its total is independent of ρ:

$$\int_{\mathbb{R}^4} e_\rho \,\mathrm{d}^4x \overset{(1)}{=} 48\rho^4 \cdot 2\pi^2 \int_0^\infty \frac{r^3\,\mathrm{d}r}{(r^2+\rho^2)^4} \overset{(2)}{=} 48\rho^4 \cdot \pi^2 \int_0^\infty \frac{u\,\mathrm{d}u}{(u+\rho^2)^4}$$
$$\overset{(3)}{=} 48\rho^4\pi^2 \cdot \frac{1}{6\rho^4} = 8\pi^2.$$

(1) Radial integrand; $\mathrm{vol}(S^3) = 2\pi^2$.
(2) $u = r^2$, $r^3\mathrm{d}r = \frac{1}{2}u\,\mathrm{d}u$.
(3) $\int_0^\infty u(u+c)^{-4}\mathrm{d}u = c^{-2}B(2,2) = c^{-2}/6$ with $c = \rho^2$ (substitute $u = cs$ and use $B(2,2) = \Gamma(2)^2/\Gamma(4) = 1/6$).

So e_ρ always carries exactly $8\pi^2 = 8\pi^2 \cdot 1$. The peak value is $e_\rho(0) = 48/\rho^4$, and at a fixed $x \neq 0$, $e_\rho(x) \approx 48\rho^4/|x|^8 \to 0$ as $\rho \to 0$. Hence, as distributions,

$$e_\rho \xrightarrow{\rho\to 0} 8\pi^2\,\delta^4(x).$$

The connection itself converges, away from 0, to a flat (pure gauge) connection: all the curvature has gone into the "bubble" at the origin. On a compact M the same happens in a small coordinate ball: a charge-k instanton can converge to a charge-$(k-1)$ instanton plus a delta function of weight $8\pi^2$ at a point $x \in M$.

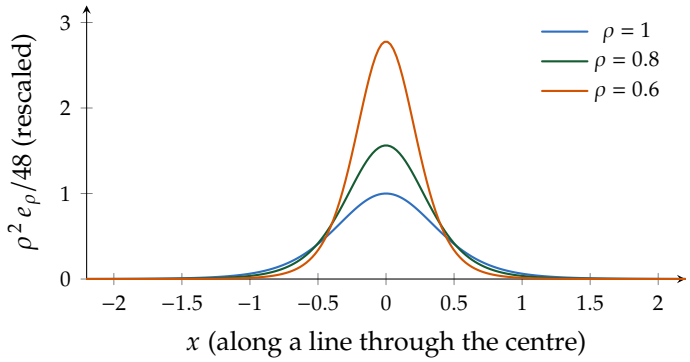

Figure 12.25: Bubbling. The action density of a BPST instanton of scale ρ, along a line through its centre (plotted as $\rho^6/(x^2+\rho^2)^4$, i.e. e_ρ times $\rho^2/48$, to keep the curves on one scale). As ρ decreases the profile narrows and its height grows like ρ^{-2} in this normalisation (ρ^{-4} unnormalised), while the four-dimensional integral stays $8\pi^2$. In the limit the density is $8\pi^2\delta^4$: a unit of instanton number concentrated at a point.

The Uhlenbeck compactification

The limits just described are "ideal instantons": a pair $(A', \{x_1, \dots, x_l\})$ with $A' \in \mathcal{M}_{k-l}$ and l points of M (possibly repeated), unordered. Adding them gives

$$\overline{\mathcal{M}}_k = \mathcal{M}_k \cup \mathcal{M}_{k-1} \times M \cup \mathcal{M}_{k-2} \times \mathrm{Sym}^2 M \cup \cdots \cup \mathcal{M}_0 \times \mathrm{Sym}^k M, \tag{12.96}$$

where $\mathrm{Sym}^l M = M^l/S_l$ is the space of unordered l-tuples. This space is compact. Its lower strata are small. Count dimensions using (12.83):

$$\dim\bigl(\mathcal{M}_{k-l}\times \mathrm{Sym}^l M\bigr) \overset{(1)}{=} 8(k-l) - 3(1+b_2^+) + 4l \\ \overset{(2)}{=} \dim \mathcal{M}_k - 4l. \tag{12.97}$$

(1) Each lost unit of charge removes 8 parameters from the moduli space and adds 4 (the position of the bubble in the 4-manifold).
(2) $\dim \mathcal{M}_k = 8k - 3(1+b_2^+)$.

So every lower stratum has codimension at least 4. (Where did the other four parameters go? A bubble on S^4 has 8 parameters: 4 for its centre, 1 for its scale and 3 for its SU(2) orientation relative to the background. In the limit only the centre survives; scale and orientation collapse.)

Key idea: Why codimension 4 is enough

A top-degree form integrated over $\overline{\mathcal{M}}_k$ does not see subsets of codimension ≥ 2 (they have measure zero), and more importantly the divisors V_{a_i} can be chosen to avoid the lower strata in the intersection count as long as those strata have codimension large enough. Donaldson shows that for k large compared with b_2^+ (the **stable range**, roughly $4k > 3(1+b_2^+)$+const) the cut-down moduli spaces $V_{a_1}\cap\cdots\cap V_{a_j}$ meet the ends in codimension at least two, and q_d is well defined and metric independent. Outside the stable range one must work harder.

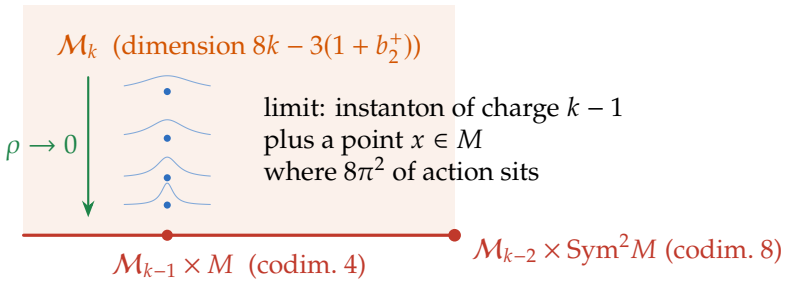

Figure 12.26: The Uhlenbeck compactification, schematically. A sequence in the top stratum $\mathcal{M}_k$ (blue dots, each with its narrowing density profile) runs to the edge as one bubble shrinks. The limit is a point of the stratum $\mathcal{M}_{k-1}\times M$ (red edge), four dimensions smaller. Two simultaneous bubbles land in a stratum of codimension 8 (red corner). The ends are thin, so a count of intersection points in the interior is not disturbed by them.

Worked example 12.37: $\mathcal{M}_1(S^4)$: the five-ball and its boundary

On S^4 with the round metric every charge-1 instanton is a BPST instanton, labelled by a centre $x_0\in\mathbb{R}^4\cup\{\infty\}=S^4$ and a scale $\rho>0$; conformal symmetry lets us trade (x_0,ρ) for a point of the open unit ball $B^5\subset\mathbb{R}^5$. The centre of the ball is the most spread out, SO(5)-symmetric instanton; points near the boundary sphere are instantons concentrated near the corresponding point of S^4. So

$$\mathcal{M}_1(S^4) = B^5, \qquad \overline{\mathcal{M}}_1(S^4) = \bar{B}^5 = B^5\cup(\mathcal{M}_0\times S^4),$$

with $\mathcal{M}_0=\{\theta\}$ the trivial connection. The boundary stratum is S^4 itself, of dimension $4 = 5-1$: here the codimension is only 1, not 4, because $\mathcal{M}_0$ is the reducible trivial connection, whose stabiliser SU(2) has absorbed the three orientation parameters. This is the "collar" $M\times(0,\epsilon)$ of Chapter 1: a manifold bounding its own moduli space. Donaldson's

diagonalisation proof used precisely this kind of boundary, while the polynomial invariants are built in the opposite regime, where the ends are thin.

Watch out: Where $\mathcal{M}_k$ sits versus where we integrate

The forms $m(a)$ are defined on $\mathcal{B}_k^*$, which contains only irreducible connections, and on $\mathcal{M}_k$. Integrating over $\overline{\mathcal{M}}_k$ requires extending them over the ideal points, where $\mathcal{B}_k^*$ gives no guidance. Donaldson's solution is the geometric one of Figure 12.24: define q_d as an intersection number of divisors V_{a_i} chosen, using their locality, to stay away from the bubbling points. So "$\int_{\overline{\mathcal{M}}_k}$" in (12.52) is best read as a count of points in the interior $\mathcal{M}_k$.

Reading Nash (pp. 333–334, (12.46)–(12.52), footnote 5)

Nash states that $q_d(M)$ is a symmetric integer polynomial of degree d on $H_2(M;\mathbb{Z})$ (12.46), built from a map $m : H_2(M) \to H^2(\mathcal{M}_k)$ (12.47). To construct m he takes the universal $\mathcal{G}$-bundle $E_{\mathcal{G}}$ over $B\mathcal{G}$, forms $c_2(E_{\mathcal{G}}) \wedge a^* \in H^6(M \times B\mathcal{G})$ (12.48), uses $\mathcal{M}_k \subset B\mathcal{G}$ (12.49), and integrates over M (12.50)–(12.51). Then q_d is the integral of $m(a_1) \wedge \cdots \wedge m(a_d)$ over a compactification $\overline{\mathcal{M}}_k$ with $d = \dim \mathcal{M}_k/2$ (12.52). Footnote 5 defines the Poincaré dual. We have supplied: Poincaré duals as bump forms with the torus and $\mathbb{CP}^2$ computed; $\mathcal{B}^* = \mathcal{A}^*/\mathcal{G}$ as a classifying space and the explicit universal bundle (with the $\pm\mathbb{1}$ issue that forces ad$P$ and p_1); the Künneth bookkeeping behind (12.50); the explicit curvature representative of $m(\Sigma)$; the Poincaré line bundle toy model; symmetry, polarisation and toy polynomials; the divisor picture; and Uhlenbeck's compactification with the BPST bubbling computation. Nash's "$E_{\mathcal{G}}$ over $B\mathcal{G}$" should be read as the bundle $\mathbb{E}$ over $\mathcal{B}^* \times M$ of (12.88): the universal bundle of the gauge group lives over $\mathcal{B}^*$, but c_2 needs the M-directions too.

12.6.6 Two theorems: algebraic surfaces and connected sums

We have defined the numbers $q_d(M)(a_1, \ldots, a_d)$. Nash is candid about them: they "are, a priori, not very easy to calculate since they require detailed knowledge of the instanton moduli space". For a general 4-manifold nobody can write down $\mathcal{M}_k$. But two *general* statements can be made without knowing $\mathcal{M}_k$ in detail, and they point in opposite directions:

- on a *complex algebraic surface*, the q_d are *non-zero* once d is large (Nash's (12.53));
- on a *connected sum* $M_1 \# M_2$ with $b_2^+(M_i) > 0$ on both sides, all the q_d *vanish* (Nash's (12.54)–(12.55)).

A manifold of the first kind and one of the second kind can have the same intersection form. Freedman then says they are homeomorphic, and Donaldson's invariants say they are not diffeomorphic. That is the promised payoff. We take the two theorems in turn and then put them together.

Complex surfaces in one page

A **complex surface** is a 4-manifold covered by charts with complex coordinates (z_1, z_2), the transition functions being holomorphic. It is **algebraic** if it can be embedded in some $\mathbb{CP}^N$ as the common zero set of homogeneous polynomials (Chapter 5). The examples to keep in mind are the smooth surfaces of degree d in $\mathbb{CP}^3$,

$$X_d = \{[z_0 : z_1 : z_2 : z_3] \in \mathbb{CP}^3 : \; z_0^d + z_1^d + z_2^d + z_3^d = 0\}.$$

They are all simply connected (Lefschetz), and their topology is fixed by d. We quote the standard formulas (they follow from the adjunction formula and the Hirzebruch signature theorem of Chapter 4):

$$\chi(X_d) = d\,(d^2 - 4d + 6), \qquad \tau(X_d) = -\tfrac{1}{3}\,d\,(d^2 - 4), \qquad p_g(X_d) = \binom{d-1}{3}. \tag{12.98}$$

Here p_g, the **geometric genus**, is the number of independent holomorphic 2-forms $f(z_1, z_2)\,\mathrm{d}z_1 \wedge \mathrm{d}z_2$ on the surface.

Worked example 12.38: The hypersurfaces X_d: b_2^+ is always odd

For simply connected M, $b_2 = \chi - 2$ and $b_2^\pm = \tfrac{1}{2}(b_2 \pm \tau)$. For the quartic $d = 4$:

$$b_2^+(X_4) \overset{(1)}{=} \tfrac{1}{2}\big(\chi - 2 + \tau\big) \overset{(2)}{=} \tfrac{1}{2}\big(4 \cdot 6 - 2 - \tfrac{1}{3} \cdot 4 \cdot 12\big) = \tfrac{1}{2}(24 - 2 - 16) = 3.$$

(1) $b_2 = \chi - 2$ and $b_2^+ = \tfrac{1}{2}(b_2 + \tau)$.

(2) (12.98) with $d = 4$: $\chi = 4(16 - 16 + 6) = 24$ and $\tau = -\tfrac{4}{3}(16 - 4) = -16$.

This is the K3 surface of Table 12.1. Doing the same for the first few degrees:

d	χ	τ	b_2^+	b_2^-	p_g	surface
1	3	1	1	0	0	$\mathbb{CP}^2$
2	4	0	1	1	0	quadric $\cong S^2 \times S^2$
3	9	−5	1	6	0	cubic $\cong \mathbb{CP}^2 \# 6\overline{\mathbb{CP}}^2$
4	24	−16	3	19	1	K3
5	55	−35	9	44	4	quintic
6	108	−64	21	85	10	sextic

In every row $b_2^+ = 1 + 2p_g$, which is odd. The cubic is the surface containing the famous 27 lines of Chapter 5. We now explain why $b_2^+ = 1 + 2p_g$ holds for every Kähler surface.

The Kähler form is self-dual

An algebraic surface inherits a metric from the Fubini–Study metric of $\mathbb{CP}^N$, and with it a **Kähler form** ω: a closed real 2-form which, in suitable local holomorphic coordinates at any given point, looks like the flat one on $\mathbb{C}^2$. So everything about how ω sits inside Λ^2 can be read off in flat $\mathbb{C}^2$.

Worked example 12.39: Self-dual and anti-self-dual forms on $\mathbb{C}^2$

Write $z_1 = x^1 + ix^2$, $z_2 = x^3 + ix^4$, and orient $\mathbb{C}^2 = \mathbb{R}^4$ by $\mathrm{vol} = \mathrm{d}x^{1234}$ (the complex orientation). Recall the self-dual basis η^1, η^2, η^3 of Example 12.30. First the Kähler form:

$$\omega := \frac{i}{2}\big(\mathrm{d}z_1 \wedge \mathrm{d}\bar{z}_1 + \mathrm{d}z_2 \wedge \mathrm{d}\bar{z}_2\big) \overset{(1)}{=} \frac{i}{2}\big(-2i\,\mathrm{d}x^{12} - 2i\,\mathrm{d}x^{34}\big) = \mathrm{d}x^{12} + \mathrm{d}x^{34} = \eta^1.$$

(1) $\mathrm{d}z \wedge \mathrm{d}\bar{z} = (\mathrm{d}x + i\mathrm{d}y) \wedge (\mathrm{d}x - i\mathrm{d}y) = -i\,\mathrm{d}x \wedge \mathrm{d}y + i\,\mathrm{d}y \wedge \mathrm{d}x = -2i\,\mathrm{d}x \wedge \mathrm{d}y$.

Next the holomorphic 2-form $\Omega = \mathrm{d}z_1 \wedge \mathrm{d}z_2$:

$$\begin{aligned}\Omega &\overset{(1)}{=} (\mathrm{d}x^1 + i\mathrm{d}x^2) \wedge (\mathrm{d}x^3 + i\mathrm{d}x^4) \\ &\overset{(2)}{=} \big(\mathrm{d}x^{13} - \mathrm{d}x^{24}\big) + i\big(\mathrm{d}x^{14} + \mathrm{d}x^{23}\big) = \eta^2 + i\,\eta^3.\end{aligned}$$

(1) Definitions of z_1, z_2.

(2) Multiply out: $i \cdot i\, dx^2 \wedge dx^4 = -dx^{24}$, and the two cross terms are $i\, dx^{14}$ and $i\, dx^{23}$.

So the three self-dual forms are exactly ω, $\operatorname{Re}\Omega$ and $\operatorname{Im}\Omega$. The anti-self-dual forms are the other three, and they are all of type $(1,1)$ and orthogonal to ω:

$$\tfrac{i}{2}\big(dz_1 \wedge d\bar{z}_1 - dz_2 \wedge d\bar{z}_2\big) \overset{(1)}{=} dx^{12} - dx^{34},$$
$$dz_1 \wedge d\bar{z}_2 \overset{(2)}{=} \big(dx^{13} + dx^{24}\big) - i\big(dx^{14} - dx^{23}\big).$$

(1) The same computation as for ω, with a relative minus sign.
(2) $(dx^1 + i dx^2) \wedge (dx^3 - i dx^4) = dx^{13} - i dx^{14} + i dx^{23} + dx^{24}$.

Check one anti-self-duality directly: $dx^{13} \wedge dx^{24} = -\text{vol}$ gives $\star dx^{13} = -dx^{24}$, so $\star(dx^{13} + dx^{24}) = -(dx^{13} + dx^{24})$. In one line:

$$\Lambda^2_+ \otimes \mathbb{C} = \mathbb{C}\,\omega \;\oplus\; \Lambda^{2,0} \oplus \Lambda^{0,2}, \qquad \Lambda^2_- \otimes \mathbb{C} = \Lambda^{1,1}_0 \;\text{ (the } (1,1)\text{-forms orthogonal to } \omega).$$

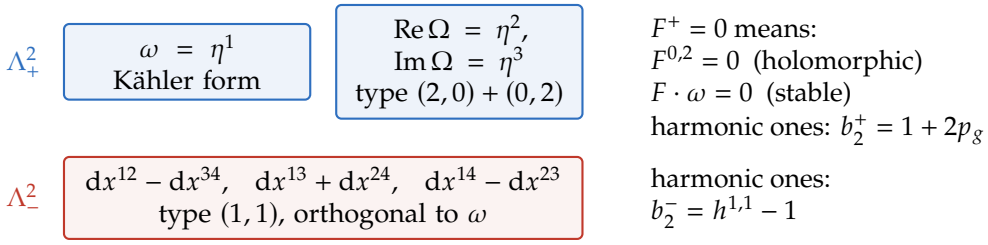

Figure 12.27: How the complex structure of $\mathbb{C}^2$ splits the six 2-forms. The three self-dual forms (blue) are the Kähler form and the real and imaginary parts of $dz_1 \wedge dz_2$; the three anti-self-dual forms (red) are the $(1,1)$-forms perpendicular to ω. Read off: an ASD curvature has no $(0,2)$ part and no ω-component, and the self-dual harmonic forms are ω plus the holomorphic 2-forms.

Two consequences follow at once from Example 12.39.

First, $b_2^+ = 1 + 2p_g$. The self-dual harmonic forms on a compact Kähler surface are spanned by the (harmonic) Kähler form and by the real and imaginary parts of the holomorphic 2-forms, which are automatically harmonic. Counting real dimensions,

$$b_2^+ \overset{(1)}{=} \dim_{\mathbb{R}} \mathcal{H}^2_+ \overset{(2)}{=} 1 + \dim_{\mathbb{R}} \big(\mathcal{H}^{2,0} \oplus \mathcal{H}^{0,2}\big)_{\mathbb{R}} \overset{(3)}{=} 1 + 2p_g. \tag{12.99}$$

(1) b_2^+ is the dimension of the self-dual harmonic 2-forms (Section 12.6.1).
(2) The pointwise splitting of Λ^2_+ in Example 12.39 passes to harmonic forms: the ω-direction contributes only multiples of ω itself, and the other two directions contribute the real forms $\operatorname{Re}\alpha$, $\operatorname{Im}\alpha$ for holomorphic 2-forms α.
(3) The holomorphic 2-forms form a complex vector space of dimension p_g, which is $2p_g$ real dimensions.

So b_2^+ is odd, and Nash's parity requirement is met by every algebraic surface.

Second, ASD connections are holomorphic bundles. Split the curvature by type, $F = F^{2,0} + F^{1,1} + F^{0,2}$. For an SU(2) connection $F^{2,0} = -(F^{0,2})^\dagger$, so the reality of F ties the two. Then

$$F = -\star F \quad\Longleftrightarrow\quad F^{0,2} = 0 \;\text{ and }\; \omega \cdot F^{1,1} = 0, \tag{12.100}$$

because F^+ has exactly the components along ω, $\Lambda^{2,0}$ and $\Lambda^{0,2}$. Now $F^{0,2}$ is the square of the $(0,1)$-part of the covariant derivative: $F^{0,2} = (\bar{\partial}_A)^2$. An operator $\bar{\partial}_A$ with $\bar{\partial}_A^2 = 0$ is precisely what it takes to define holomorphic sections, so it makes E a *holomorphic* vector bundle. The second condition in (12.100), the "Hermitian–Yang–Mills" condition, turns out to be equivalent

to an algebraic condition called **stability**. This is the theorem of Donaldson (for surfaces) and Uhlenbeck–Yau (in general), sometimes called the Kobayashi–Hitchin correspondence:

$$\mathcal{M}_k(M, g_{\text{Kähler}}) \;\cong\; \big\{\text{stable holomorphic rank-2 bundles } E \to M \\ \text{with } c_1(E) = 0,\; c_2(E) = k\big\}\big/\text{iso}.$$

The right side is a problem in algebraic geometry, and algebraic geometers know a great deal about it. For example, it is a complex (quasi-projective) variety, and its complex dimension can be computed by the Riemann–Roch theorem.

Worked example 12.40: Riemann–Roch reproduces $\dim \mathcal{M}_k$

Deformations of a holomorphic bundle E are measured by the sheaf cohomology of the trace-free endomorphisms $\operatorname{End}_0 E$ (Chapter 3): $H^1(\operatorname{End}_0 E)$ is the tangent space and $H^2(\operatorname{End}_0 E)$ the obstructions, while $H^0(\operatorname{End}_0 E) = 0$ for a stable bundle. Riemann–Roch for a rank-3 bundle $V = \operatorname{End}_0 E$ with $c_1(V) = 0$ on a surface gives $\chi(V) = 3\,\chi(\mathcal{O}_M) - c_2(V)$, and $c_2(\operatorname{End}_0 E) = 4c_2(E)$ by (12.82). Hence

$$\begin{aligned}\dim_{\mathbb{R}} \mathcal{M}_k &\overset{(1)}{=} 2\big(h^1(\operatorname{End}_0 E) - h^2(\operatorname{End}_0 E)\big) \overset{(2)}{=} -2\,\chi(\operatorname{End}_0 E)\\ &\overset{(3)}{=} 2\big(4k - 3\,\chi(\mathcal{O}_M)\big) \overset{(4)}{=} 8k - 6\,(1 + p_g)\\ &\overset{(5)}{=} 8k - 3\,(1 + b_2^+).\end{aligned}$$

(1) The expected complex dimension is $h^1 - h^2$; real dimension is twice that.
(2) $\chi = h^0 - h^1 + h^2$ and $h^0 = 0$.
(3) Riemann–Roch as quoted, with $c_2(E) = k$.
(4) $\chi(\mathcal{O}_M) = 1 - q + p_g$ with $q = \dim H^1(\mathcal{O}_M) = \tfrac{1}{2}b_1 = 0$ for simply connected M.
(5) $b_2^+ = 1 + 2p_g$ from (12.99).

This is Nash's (12.45), obtained this time by algebraic geometry rather than by the Atiyah–Singer index theorem. The agreement is no accident: Riemann–Roch is the index theorem for the Dolbeault complex (Chapter 4).

Why the invariants are non-zero: positivity

Here is the mechanism behind Nash's (12.53). It rests on one elementary fact.

Key idea: Complex things intersect positively

If two complex submanifolds of a complex manifold meet transversally, every intersection point counts $+1$, never -1. If V is a compact complex submanifold of complex dimension n in a Kähler manifold, then $\int_V \omega^n > 0$. So a count of intersections of complex objects cannot cancel.

Worked example 12.41: Complex linear maps preserve orientation

The sign of a transverse intersection point is the sign of a real determinant: the determinant of the real matrix whose columns are the oriented tangent vectors of the two submanifolds. For complex submanifolds these columns come in complex pairs, and the matrix is the real form of a complex matrix. Take first a 1×1 complex matrix, multiplication by $c = a + ib$ on

$\mathbb{C} = \mathbb{R}^2$:

$$\det_{\mathbb{R}}(c) \overset{(1)}{=} \det \begin{pmatrix} a & -b \\ b & a \end{pmatrix} = a^2 + b^2 \overset{(2)}{=} |c|^2 \ \geq 0.$$

(1) $(a+ib)(x+iy) = (ax-by)+i(bx+ay)$, so in the basis $(1, i)$ the real matrix is as shown.
(2) Definition of the modulus.

For an $n \times n$ complex matrix C, bring it to upper triangular form by a complex change of basis (which changes $\det_{\mathbb{R}}$ by $|\det_{\mathbb{C}}|^2$ of the change, a positive number). The real form of a triangular matrix is block triangular with 2×2 diagonal blocks of the kind above, so

$$\det_{\mathbb{R}} C \overset{(1)}{=} \prod_{j=1}^{n} \det_{\mathbb{R}}(\lambda_j) \overset{(2)}{=} \prod_{j=1}^{n} |\lambda_j|^2 = |\det_{\mathbb{C}} C|^2 \ \geq 0.$$

(1) The determinant of a block triangular matrix is the product of the determinants of the diagonal blocks; λ_j are the diagonal entries (eigenvalues).
(2) The 1×1 case, applied to each block.

For the two coordinate lines $\{z_2 = 0\}$ and $\{z_1 = 0\}$ in $\mathbb{C}^2$ the tangent vectors $(\partial_{x^1}, \partial_{x^2})$ followed by $(\partial_{x^3}, \partial_{x^4})$ give the identity matrix: sign $+1$. Any other transverse pair of complex lines is obtained by a complex linear map, so has sign $+1$ as well. This is why $L \cdot L = +1$ in $\mathbb{CP}^2$ (Example 12.29), and why a degree-n curve meets a line in exactly n points counted positively.

With this fact the non-vanishing argument runs as follows.

1. Choose the Kähler metric. By the Kobayashi–Hitchin correspondence, $\mathcal{M}_k$ is a complex variety.
2. Take $a = [H]$, the class of a hyperplane section $H = M \cap \mathbb{CP}^{N-1}$ (a complex curve in M). Donaldson shows that the divisor $V_H \subset \mathcal{M}_k$ of Figure 12.24 can be chosen to be a *complex* hypersurface, and that for k large $m(H)$ is represented by a positive $(1,1)$-form on $\mathcal{M}_k$, playing the role of a Kähler form on the moduli space.
3. For k large the moduli space is non-empty and has the expected dimension $2d$ (Gieseker, Taubes).
4. Then $q_d(H, \dots, H) = \int_{\mathcal{M}_k} m(H)^d$ is, up to a positive factor $d!$, the volume of $\mathcal{M}_k$ in this Kähler-like form: a sum of $+1$'s, one for each point of $V_{H_1} \cap \cdots \cap V_{H_d}$. It is strictly positive.

Key idea: Donaldson's non-vanishing theorem (Nash's (12.53))

If M is a simply connected complex algebraic surface, there is a d_0 such that

$$q_d(M) \neq 0 \qquad \text{for all } d \geq d_0,$$

and in fact $q_d(M)(H, \dots, H) > 0$ for the hyperplane class H. The mechanism is positivity: intersections of complex divisors in a complex moduli space all count $+1$.

Physical picture: A toy version of positivity

On $\mathbb{CP}^n$ with hyperplane class h, $\int_{\mathbb{CP}^n} h^n = 1$: n hyperplanes meet in one point, and it counts $+1$. On any complex projective variety $V \subset \mathbb{CP}^N$ of dimension n, $\int_V h^n = \deg V$, the

number of points in which V meets a generic linear subspace of complementary dimension, all counted +1. The Donaldson invariant of an algebraic surface is essentially the "degree" of its instanton moduli space.

The wedge computation in Example 12.39 also shows the volume form of the moduli-space picture in miniature. On $\mathbb{C}^2$,

$$\tfrac{1}{2}\,\omega\wedge\omega \overset{(1)}{=} \tfrac{1}{2}\big(\mathrm{d}x^{12}+\mathrm{d}x^{34}\big)\wedge\big(\mathrm{d}x^{12}+\mathrm{d}x^{34}\big) \overset{(2)}{=} \tfrac{1}{2}\cdot 2\,\mathrm{d}x^{12}\wedge\mathrm{d}x^{34} = \mathrm{vol}\ > 0,$$

(1) $\omega = \mathrm{d}x^{12}+\mathrm{d}x^{34}$.
(2) $\mathrm{d}x^{12}\wedge\mathrm{d}x^{12}=0$, and the two cross terms are equal because 2-forms commute.

so $\omega^n/n!$ is the Riemannian volume form on a Kähler manifold of complex dimension n (here $n=2$), and its integral over any complex submanifold is that submanifold's volume: positive.

Connected sums: the vanishing theorem

Now the opposite statement. Let $M = M_1\#M_2$ (Nash's (12.54); the connected sum was described in Figure 12.20). The two pieces are joined by a tube whose cross-section is S^3. Since we may choose any metric, choose one in which the tube is a very long cylinder $S^3\times[-T,T]$. What do instantons look like as $T\to\infty$?

Step 1: the energy splits. An instanton has finite action $8\pi^2 k$. On a very long cylinder most of the slices $S^3\times\{t\}$ must carry almost no curvature, otherwise the action would grow with T. So in the middle of the neck the connection is almost flat. The only flat SU(2) connection on S^3 is the trivial one ($\pi_1(S^3)=1$; see Example 12.10). The instanton therefore splits into an instanton A_1 of charge k_1 concentrated in M_1 and an instanton A_2 of charge k_2 concentrated in M_2, with $k_1+k_2=k$ and both asymptotically trivial on the neck.

Step 2: gluing needs a parameter. Conversely, given A_1 and A_2 we can glue them back into an approximate instanton on M and then correct it to an exact one (Taubes' gluing). But to glue we must identify the fibre of P_1 over the neck with the fibre of P_2. Both connections are trivial there, so any constant SU(2) matrix u will do. Replacing u by $-u$ changes nothing, since $-\mathbb{1}$ is central and acts trivially on connections. So the gluing data is a point of

$$\mathrm{SU}(2)/\{\pm\mathbb{1}\} = \mathrm{SO}(3), \qquad \dim \mathrm{SO}(3) = 3.$$

Physically, u is the relative colour orientation of the two instantons. The same three parameters appeared as the "orientations" of a BPST instanton in Example 12.37.

Step 3: the dimensions add up, with three to spare. For irreducible A_1, A_2 we get, near the long-neck limit,

$$\mathcal{M}_k(M_1\#M_2) \;\approx\; \mathcal{M}_{k_1}(M_1)\times\mathcal{M}_{k_2}(M_2)\times\mathrm{SO}(3). \tag{12.101}$$

Check the dimension with (12.83):

$$\begin{aligned}\dim\mathcal{M}_{k_1}(M_1)+\dim\mathcal{M}_{k_2}(M_2)+3 &\overset{(1)}{=} \big(8k_1-3-3b_2^+(M_1)\big)+\big(8k_2-3-3b_2^+(M_2)\big)+3\\ &\overset{(2)}{=} 8k-3-3\big(b_2^+(M_1)+b_2^+(M_2)\big)\\ &\overset{(3)}{=} 8k-3\big(1+b_2^+(M)\big) \overset{(4)}{=} \dim\mathcal{M}_k(M).\end{aligned}$$

(1) (12.83) on each piece.
(2) $k_1+k_2=k$, and $-3-3+3=-3$.
(3) b_2^+ is additive under connected sum (Section 12.6.1).

(4) (12.83) on M.

The count closes. The picture (12.101) is therefore consistent, and it is the whole moduli space near the long-neck limit.

Step 4: cutting down. By multilinearity it is enough to evaluate q_d on classes each of which lies on one side, say $a_1, \dots, a_r \in H_2(M_1)$ and $a_{r+1}, \dots, a_d \in H_2(M_2)$. The divisors V_{a_i} are *local* (Section 12.6.4): V_{a_i} for $a_i \subset M_1$ only looks at the connection near a_i, i.e. at A_1. So in (12.101) the cut-down moduli space is

$$\Big(\mathcal{M}_{k_1}(M_1) \cap V_{a_1} \cap \cdots \cap V_{a_r}\Big) \times \Big(\mathcal{M}_{k_2}(M_2) \cap V_{a_{r+1}} \cap \cdots \cap V_{a_d}\Big) \times \mathrm{SO}(3).$$

Write $D_i = \dim \mathcal{M}_{k_i}(M_i)$. The three factors have dimensions $D_1 - 2r$, $D_2 - 2(d-r)$ and 3, and they must add up to 0 for a point count:

$$(D_1 - 2r) + \big(D_2 - 2(d-r)\big) \overset{(1)}{=} (D_1 + D_2) - 2d \overset{(2)}{=} (2d-3) - 2d = -3.$$

(1) Collect terms.
(2) Step 3: $D_1 + D_2 + 3 = \dim \mathcal{M}_k(M) = 2d$.

Two integers summing to -3 cannot both be ≥ 0. So one of the two cut-down factors has negative expected dimension, which means it is empty for generic choices. The cut-down moduli space of M is empty, and the count is zero. Put differently: the three SO(3) directions can never be cut down by divisors coming from either side, because every V_{a_i} is pulled back from one of the factors, and a top-degree form pulled back from a space of smaller dimension vanishes.

Where $b_2^+ > 0$ is used. Step 3 assumed A_1 and A_2 irreducible. The dangerous case is $k_2 = 0$: then A_2 is the trivial connection, whose stabiliser is all of SO(3), so the gluing parameter is used up by the stabiliser and no spare dimensions remain. However, the trivial connection on M_2 has obstruction space $H^2_A = \mathcal{H}^2_+(M_2) \otimes \mathfrak{su}(2)$, of dimension $3b_2^+(M_2)$. When $b_2^+(M_2) > 0$ these obstructions cut the glued family down by $3b_2^+(M_2)$ dimensions, below what is needed, and again nothing survives. When $b_2^+(M_2) = 0$, as for $M_2 = \overline{\mathbb{CP}}^2$, there are no obstructions and the argument fails, correctly so, as the next pitfall explains. The same caution applies to reducible A_1 or A_2 with $k_i > 0$, which are excluded by $b_2^+(M_i) > 0$ and a generic metric (Section 12.6.2).

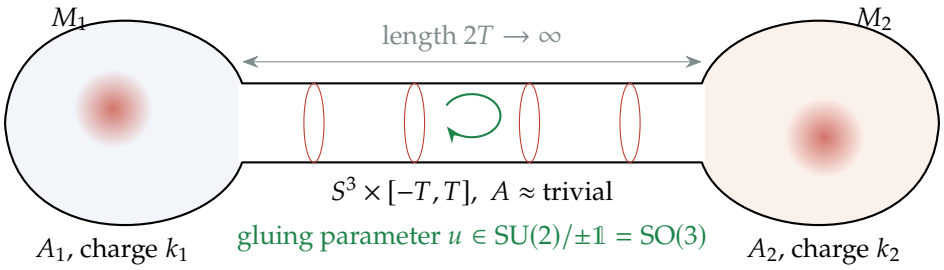

Figure 12.28: Stretching the neck of a connected sum. The instanton's action cannot live on the long neck, where the connection becomes flat, hence trivial (S^3 is simply connected). What remains are an instanton A_1 in M_1 and A_2 in M_2, glued with a relative colour rotation u. These three extra parameters can never be cut down by surfaces from either side, so every Donaldson invariant vanishes.

Key idea: Donaldson's vanishing theorem (Nash's (12.55))

If $M = M_1 \# M_2$ with $b_2^+(M_1) > 0$ and $b_2^+(M_2) > 0$, then

$$q_d(M) = 0 \qquad \text{for all } d.$$

The mechanism: near a long neck the moduli space is (moduli of M_1) $\times$ (moduli of M_2) $\times$SO(3), and the three gluing directions cannot be cut down by any product of m-classes.

Watch out: The condition $b_2^+ > 0$ on *both* sides is essential

Blowing up a point of a complex surface X gives $X\#\overline{\mathbb{CP}}^2$, which is again an algebraic surface. By the non-vanishing theorem its invariants are non-zero, although it is a connected sum. There is no contradiction: $b_2^+(\overline{\mathbb{CP}}^2) = 0$. Indeed the invariants of $X\#\overline{\mathbb{CP}}^2$ are computed from those of X by a "blow-up formula". The exceptional sphere e with $e \cdot e = -1$ supports reducible instantons on the $\overline{\mathbb{CP}}^2$ side (Figure 12.21), and these contribute.

Worked example 12.42: The dimension bookkeeping on a concrete sum

Take $M = \mathbb{CP}^2\#(4\mathbb{CP}^2\#29\overline{\mathbb{CP}}^2)$, so $M_1 = \mathbb{CP}^2$ with $b_2^+ = 1$ and $M_2 = 4\mathbb{CP}^2\#29\overline{\mathbb{CP}}^2$ with $b_2^+ = 4$. Then $b_2^+(M) = 5$ and $\dim \mathcal{M}_k(M) = 8k - 18$. For $k = 3$: $\dim \mathcal{M}_3(M) = 6$ and $d = 3$. The possible splittings $k = k_1 + k_2$ with both pieces irreducible include $(k_1, k_2) = (1, 2)$:

$$\dim \mathcal{M}_1(\mathbb{CP}^2) + \dim \mathcal{M}_2(M_2) + 3 \overset{(1)}{=} (8 - 6) + (16 - 15) + 3 = 2 + 1 + 3 = 6.$$

(1) $\dim \mathcal{M}_k = 8k - 3(1 + b_2^+)$ with $b_2^+ = 1$ and $b_2^+ = 4$ respectively.

Three divisors must cut the six dimensions down to points. With r of them from $\mathbb{CP}^2$ and $3 - r$ from M_2, the first factor has dimension $2 - 2r$ and the second $1 - 2(3 - r) = 2r - 5$; their sum is -3 for every r. For $r = 0$: $(2, -5)$; $r = 1$: $(0, -3)$; $r = 2$: $(-2, -1)$; $r = 3$: $(-4, 1)$. Each row has a negative entry, so the cut-down space is empty. (Note that the moduli space of M_2 has odd dimension here: nothing forbids that for the pieces, only for M.)

Putting the two theorems together: exotic smooth structures

Now the punchline, which Nash states at the end of §3 ("they have the potential to distinguish homeomorphic manifolds which have distinct diffeomorphic structures"). We need a manifold of each kind with the same intersection form.

Worked example 12.43: The elliptic surface $E(3)$ and $5\mathbb{CP}^2\#29\overline{\mathbb{CP}}^2$

The **elliptic surfaces** $E(n)$ are simply connected algebraic surfaces fibred over $\mathbb{CP}^1$ with generic fibre a torus; $E(1) = \mathbb{CP}^2\#9\overline{\mathbb{CP}}^2$ and $E(2) = \text{K3}$. Their Chern numbers are $c_1^2 = 0$ and $c_2 = \chi = 12n$. The signature theorem for surfaces gives $\tau = \frac{1}{3}(c_1^2 - 2c_2)$. So

$$\begin{aligned}
\tau(E(n)) &\overset{(1)}{=} \tfrac{1}{3}(0 - 24n) = -8n, \\
b_2^+(E(n)) &\overset{(2)}{=} \tfrac{1}{2}\big(\chi - 2 + \tau\big) = \tfrac{1}{2}(12n - 2 - 8n) = 2n - 1, \\
b_2^-(E(n)) &\overset{(3)}{=} \tfrac{1}{2}\big(\chi - 2 - \tau\big) = \tfrac{1}{2}(12n - 2 + 8n) = 10n - 1.
\end{aligned}$$

(1) Hirzebruch's signature theorem written in Chern numbers.
(2) $b_2 = \chi - 2$ and $b_2^+ = \frac{1}{2}(b_2 + \tau)$.
(3) $b_2^- = \frac{1}{2}(b_2 - \tau)$.

For $n = 3$: $b_2^+ = 5$, $b_2^- = 29$, and the form is odd (the $E(n)$ with n odd are not spin). An odd indefinite unimodular form is determined by its rank and signature and is diagonal, so

$$Q_{E(3)} \cong 5\,(+1) \oplus 29\,(-1) = Q_{5\mathbb{CP}^2\#29\overline{\mathbb{CP}}^2}.$$

Now compare:

- $E(3)$ is algebraic: $q_d(E(3)) \neq 0$ for large d (12.53).
- $X = 5\mathbb{CP}^2\#29\overline{\mathbb{CP}}^2 = \mathbb{CP}^2\#(4\mathbb{CP}^2\#29\overline{\mathbb{CP}}^2)$ is a connected sum of two pieces with $b_2^+ = 1$ and $b_2^+ = 4$, both positive: $q_d(X) = 0$ for all d (12.55).

Freedman's theorem says $E(3)$ and X are homeomorphic (same odd form, and both have the same $\mathbb{Z}_2$ invariant, since both are smooth). If they were diffeomorphic, the diffeomorphism would carry $q_d(E(3))$ to $\pm q_d(X) = 0$. It cannot. So $E(3)$ and X are homeomorphic but *not* diffeomorphic: the topological manifold underlying X carries at least two smooth structures.

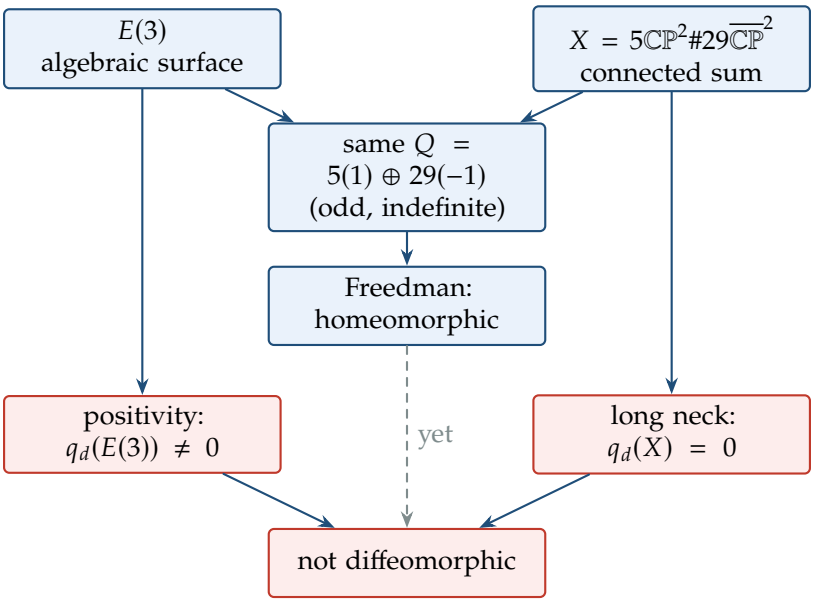

Figure 12.29: The logic of an exotic pair. The top half is topology: equal intersection forms force a homeomorphism. The bottom half is gauge theory: the Donaldson invariants, which are diffeomorphism invariants, are non-zero on one side and zero on the other.

Physical picture: What the invariants "see"

The vanishing theorem says that q_d detects whether a manifold can be pulled apart along an S^3 into two pieces that each carry a self-dual harmonic form. The non-vanishing theorem says that complex surfaces cannot be pulled apart in this way, although their intersection forms would allow it. The invariants measure a kind of smooth "irreducibility" that the intersection form, and hence the topology, cannot see. The same argument gives many more exotic pairs, e.g. $E(n)$ against $(2n-1)\mathbb{CP}^2\#(10n-1)\overline{\mathbb{CP}}^2$ for every odd $n \geq 3$; Nash

cites Ebeling for further examples.

Try it: Why not the K3 surface?

K3 has $Q = 3H \oplus 2(-E_8)$, even. Is there a connected sum of standard pieces with the same form, to play the role of X?
Answer: the candidate would be $3(S^2 \times S^2)\#2$ (a manifold with form $-E_8$), but by Donaldson's diagonalisation theorem (Chapter 1) there is no smooth closed simply connected manifold with definite form $-E_8$. So K3 has no "obvious" connected-sum rival, and the exotic pair argument is run instead with $E(n)$, n odd, where the diagonal rival $(2n-1)\mathbb{CP}^2\#(10n-1)\overline{\mathbb{CP}}^2$ exists.

Reading Nash (pp. 334–335, (12.53)–(12.55), footnote 6)

Nash remarks that the q_d are hard to compute because they need detailed knowledge of $\mathcal{M}_k$; that for a complex algebraic surface "a positivity argument shows" $q_d \neq 0$ for $d \geq d_0$ (12.53); and that if $M = M_1\#M_2$ (12.54) with $b_2^+(M_i) > 0$ for both, then $q_d(M) = 0$ for all d (12.55). Footnote 6 defines the connected sum (remove a disc from each manifold and sew along the new boundaries). He gives no argument for either statement. We have supplied: the hypersurfaces X_d and their Betti numbers; the self-duality of the Kähler form and the splitting of Λ^2 on $\mathbb{C}^2$; $b_2^+ = 1 + 2p_g$; the holomorphic reading of the ASD equation and the Riemann–Roch check of (12.45); positivity of complex intersections; the neck-stretching argument with its SO(3) gluing parameter and dimension count; the role of $b_2^+ > 0$ and the blow-up caveat; and the exotic pair $E(3)$ versus $5\mathbb{CP}^2\#29\overline{\mathbb{CP}}^2$ that realises Nash's closing remark on p. 339.

Recap

- The stage is a smooth, simply connected, closed, oriented 4-manifold. Its topology is the unimodular intersection form Q on $H_2(M;\mathbb{Z})$; $b_2^\pm$ are the dimensions of self-dual and anti-self-dual harmonic 2-forms.
- For SU(2), $\dim \mathcal{M}_k = 8k - 3(1 + b_2^+)$: eight parameters per unit charge, minus three for each of $1 + b_2^+$. It is even exactly when b_2^+ is odd. Generic metrics avoid reducible instantons when $b_2^+ \geq 1$, and paths of metrics avoid them when $b_2^+ \geq 2$.
- Surfaces $\Sigma \subset M$ give 2-forms $m(\Sigma)$ on $\mathcal{M}_k$ via Poincaré duality, the universal bundle and integration over M. Geometrically, $m(\Sigma)$ is dual to a divisor V_Σ of instantons with a zero mode on Σ.
- $q_d(a_1, \dots, a_d) = \int_{\mathcal{M}_k} m(a_1) \wedge \cdots \wedge m(a_d)$ with $2d = \dim \mathcal{M}_k$, a symmetric integer polynomial on $H_2(M)$. It counts the points of $V_{a_1} \cap \cdots \cap V_{a_d}$. The integral makes sense because bubbling happens in high codimension.
- Algebraic surfaces: positivity of complex intersections makes $q_d \neq 0$ for large d. Connected sums with $b_2^+ > 0$ on both sides: the SO(3) gluing parameter makes all $q_d = 0$.
- Together with Freedman's theorem this gives homeomorphic but not diffeomorphic pairs, e.g. $E(3)$ and $5\mathbb{CP}^2\#29\overline{\mathbb{CP}}^2$.

12.7 Witten's topological field theory

Donaldson's invariants are integrals over moduli spaces of instantons. Instantons are what dominate a Euclidean path integral at weak coupling. So it is natural to ask: *is there a quantum field theory whose correlation functions are exactly Donaldson's integrals?* Atiyah posed the question in 1987, with a hint: Floer's supersymmetric quantum mechanics on $\mathcal{A}/\mathcal{G}$ (Section 12.5.5) should be the Hamiltonian version of a four-dimensional theory on $M^3 \times \mathbb{R}$. Witten answered it in 1988. His theory is Nash's "relativistic generalisation" of Floer's Hamiltonian, and it is the prototype of a Witten-type (cohomological) TQFT (Section 12.1.2).

The logic of this section is the one of Chapter 7, where Witten's supersymmetric quantum mechanics computed Morse homology. Four facts do all the work:

1. there is a fermionic symmetry Q with $Q^2 = 0$ (up to gauge);
2. the action and the energy-momentum tensor are Q-exact;
3. hence the correlation functions of Q-invariant observables do not depend on the metric or on the coupling;
4. hence they can be computed at infinitesimal coupling, where the path integral collapses onto the classical minima: the instantons.

We first meet the fields, then establish 1–4, then do the whole computation in a zero-dimensional toy model, and finally identify the observables that produce q_d.

Watch out: Conventions in this section

Nash's (12.56) is written in the physicists' way: the trace is positive-definite on the fields and factors of i sit in front of the fermion terms. Reading it with our anti-Hermitian fields, replace tr by $-\operatorname{tr}$ (i.e. use the positive inner product $\langle X, Y\rangle = -\operatorname{tr} XY$ of (12.37)). None of the arguments below depends on these normalisations: they only use which terms are present and how Q acts. Instantons are anti-self-dual, $F^+ = 0$, as in the rest of this part.

12.7.1 The fields and the action

The field content

All fields take values in the Lie algebra $\mathfrak{su}(2)$, i.e. they are sections of $\mathrm{ad}P$. There are three bosons and three fermions:

field	type	form degree	statistics	U	geometric role
A_μ	gauge field	1	boson	0	point of $\mathcal{A}$
ψ_μ	fermion	1	fermion	+1	tangent vector to $\mathcal{A}$
ϕ	scalar	0	boson	+2	curvature of $\mathcal{A} \to \mathcal{A}/\mathcal{G}$
λ	scalar	0	boson	−2	partner of ϕ
η	scalar	0	fermion	−1	gauge directions
$\chi_{\mu\nu}$	self-dual 2-form	2, $\chi = \star\chi$	fermion	−1	the equation $F^+ = 0$

ϕ and λ are "spinless" (Nash's word): they are scalars, not spinors, even though λ comes from a gaugino of the supersymmetric theory we start from. The fermions $(\eta, \psi_\mu, \chi_{\mu\nu})$ are a 0-form, a 1-form and a self-dual 2-form. Nash's key observation is that this is exactly the

anti-instanton deformation complex (8.104), which in our ASD conventions is (12.80):

$$\underbrace{\Omega^0(\mathrm{ad}P)}_{\eta} \xrightarrow{\mathrm{d}_A} \underbrace{\Omega^1(\mathrm{ad}P)}_{\psi_\mu} \xrightarrow{\mathrm{d}_A^+} \underbrace{\Omega^2_+(\mathrm{ad}P)}_{\chi_{\mu\nu}}.$$

So the fermions are a copy of the three spaces that control the moduli space: ψ lives where the deformations live, χ where the equation lives, and η where the gauge transformations live. This is not a coincidence; it is how the theory was designed.

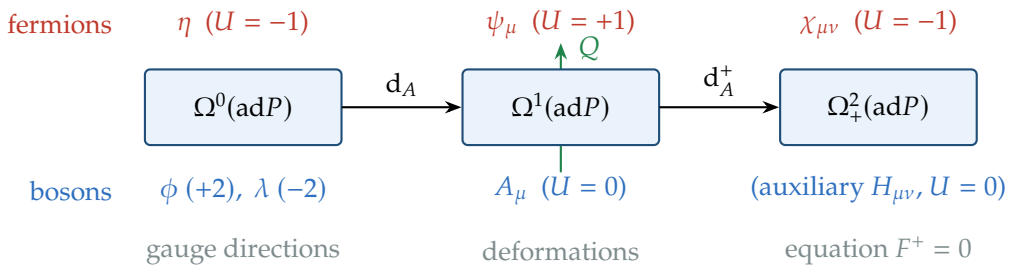

Figure 12.30: The fields of Witten's theory sit on top of the instanton deformation complex. Each fermion (red) lives in one of the three spaces; Q maps the gauge field A_μ to its fermionic partner ψ_μ, a tangent vector to $\mathcal{A}$. The zero modes of ψ are the tangent vectors to $\mathcal{M}_k$; the would-be zero modes of η and χ are H^0_A and H^2_A, which vanish for irreducible, unobstructed instantons.

Worked example 12.44: Where the fields come from: twisting $N=2$ super Yang–Mills

Witten obtained the theory by "twisting" the $N=2$ supersymmetric Yang–Mills theory in four Euclidean dimensions. The rotation group is $\mathrm{SO}(4)=\big(\mathrm{SU}(2)_L\times\mathrm{SU}(2)_R\big)/\mathbb{Z}_2$, and representations are labelled by two spins (j_L,j_R): a vector is $(\frac12,\frac12)$ and the two kinds of 2-forms $\Lambda^2_\pm$ are $(1,0)$ and $(0,1)$. The $N=2$ theory also has an internal symmetry $\mathrm{SU}(2)_I$ rotating its two supercharges, and a $\mathrm{U}(1)_R$ symmetry. Its fields, with their (j_L,j_R,j_I):

$$A_\mu:(\tfrac12,\tfrac12,0),\qquad \lambda^A_\alpha:(\tfrac12,0,\tfrac12),\qquad \bar\lambda_{A\dot\alpha}:(0,\tfrac12,\tfrac12),\qquad B,\bar B:(0,0,0),$$

with B a complex scalar of $\mathrm{U}(1)_R$ charge ±2. The **twist** declares the new rotation group to be $\mathrm{SU}(2)_L\times\mathrm{SU}(2)'_R$ with $\mathrm{SU}(2)'_R$ the diagonal subgroup of $\mathrm{SU}(2)_R\times\mathrm{SU}(2)_I$. So we simply combine j_R and j_I with the Clebsch–Gordan rule $\frac12\otimes\frac12=0\oplus1$, $0\otimes\frac12=\frac12$:

$$\begin{aligned}\lambda:(\tfrac12,\,0\otimes\tfrac12)&\overset{(1)}{=}(\tfrac12,\tfrac12)\;\longrightarrow\;\psi_\mu,\\ \bar\lambda:(0,\,\tfrac12\otimes\tfrac12)&\overset{(2)}{=}(0,0)\oplus(0,1)\;\longrightarrow\;\eta\oplus\chi_{\mu\nu},\\ B,\bar B:(0,0\otimes0)&=(0,0)\;\longrightarrow\;\phi,\lambda.\end{aligned}$$

(1) Spin 0 times spin $\frac12$ is spin $\frac12$; $(\frac12,\frac12)$ is the vector representation.
(2) $\frac12\otimes\frac12=0\oplus1$: a scalar and a 2-form of one chirality (which we call self-dual).

Counting components per colour: λ and $\bar\lambda$ have $2\times2+2\times2=8$ real fermionic components after the Euclidean reality conditions, and ψ,η,χ have $4+1+3=8$. The $\mathrm{U}(1)_R$ charge becomes Nash's U-number. The supercharges transform like the gauginos, so one of them, the $(0,0)$ piece of $\bar Q_{A\dot\alpha}$, becomes a *scalar* after the twist. That scalar supercharge is Q. Because it is a scalar, it survives on any curved M: no covariantly constant spinors are needed.

The action

Nash's (12.56) is

$$S = \int_M d^4x\sqrt{g}\ \mathrm{tr}\Big\{\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} + \tfrac{1}{4}F_{\mu\nu}{}^*F^{\mu\nu} + \tfrac{1}{2}\phi D_\mu D^\mu\lambda + iD_\mu\psi_\nu\chi^{\mu\nu} - i\eta D_\mu\psi^\mu \\ - \tfrac{i}{8}\phi[\chi_{\mu\nu},\chi^{\mu\nu}] - \tfrac{i}{2}\lambda[\psi_\mu,\psi^\mu] - \tfrac{i}{2}\phi[\eta,\eta] - \tfrac{1}{8}[\phi,\lambda]^2\Big\}, \tag{12.102}$$

with ${}^*F_{\mu\nu} = \frac{1}{2}\varepsilon_{\mu\nu\rho\sigma}F^{\rho\sigma}$. Let us read it term by term.

The gauge terms. The first two terms together are the square of the self-dual part of F. Split $F = F^+ + F^-$ with ${}^*F^\pm = \pm F^\pm$, and write $X\cdot Y = X_{\mu\nu}Y^{\mu\nu}$ (summed, with the trace understood). Self-dual and anti-self-dual 2-forms are orthogonal: $F^+\cdot F^- = {}^*F^+\cdot F^- = F^+\cdot{}^*F^- = -F^+\cdot F^-$, so $F^+\cdot F^- = 0$ (we used that $\star$ is symmetric, $X\cdot{}^*Y = {}^*X\cdot Y$). Then

$$\begin{aligned}\tfrac{1}{4}F\cdot F + \tfrac{1}{4}F\cdot{}^*F &\overset{(1)}{=} \tfrac{1}{4}\big(F^+\cdot F^+ + F^-\cdot F^-\big) + \tfrac{1}{4}\big(F^+ + F^-\big)\cdot\big(F^+ - F^-\big)\\ &\overset{(2)}{=} \tfrac{1}{4}\big(F^+\cdot F^+ + F^-\cdot F^-\big) + \tfrac{1}{4}\big(F^+\cdot F^+ - F^-\cdot F^-\big)\\ &= \tfrac{1}{2}\,F^+\cdot F^+.\end{aligned} \tag{12.103}$$

(1) Expand $F\cdot F$ using $F^+\cdot F^- = 0$, and use ${}^*F = {}^*F^+ + {}^*F^- = F^+ - F^-$.
(2) Multiply out; the cross terms vanish by orthogonality.

So the bosonic gauge action is $\frac{1}{2}\int|F^+|^2 \geq 0$, and its minima are exactly the configurations with $F^+ = 0$: the anti-self-dual instantons, Nash's (12.57), $F_{\mu\nu} = -{}^*F_{\mu\nu}$. Equivalently: the second term is topological, $\int\sqrt{g}\ \mathrm{tr}\,F_{\mu\nu}{}^*F^{\mu\nu}\,d^4x = 2\int\mathrm{tr}\,F\wedge F$, which is a fixed multiple of the instanton number, so within a fixed topological sector the gauge part of S is the ordinary Yang–Mills action plus a constant. Yang–Mills with a θ-term tuned so that the action vanishes on instantons.

The fermion kinetic terms. $iD_\mu\psi_\nu\chi^{\mu\nu}$ pairs χ with the self-dual part of $D\psi$ (only that part survives contraction with a self-dual χ), i.e. with $\mathrm{d}_A^+\psi$. $-i\eta D_\mu\psi^\mu$ pairs η with $\mathrm{d}_A^*\psi$. Together they are $\langle(\eta,\chi), D_A\psi\rangle$ with $D_A = \mathrm{d}_A^*\oplus\mathrm{d}_A^+$, the operator (12.79) whose kernel is $T\mathcal{M}_k$.

The scalar terms. $\frac{1}{2}\phi D_\mu D^\mu\lambda$ is a kinetic term for the pair (ϕ,λ) built from the covariant Laplacian $\mathrm{d}_A^*\mathrm{d}_A$ on Ω^0. The Yukawa-like terms couple ϕ to $\chi\chi$ and $\eta\eta$, and λ to $\psi\psi$. The last term is a potential $\propto|[\phi,\lambda]|^2$.

The U-number

Assign $U = (2,-2,-1,0,1,-1)$ to $(\phi,\lambda,\eta,A_\mu,\psi_\mu,\chi_{\mu\nu})$ (derivatives carry $U=0$). Every term of (12.102) has total $U = 0$:

term	$\phi DD\lambda$	$D\psi\,\chi$	$\eta D\psi$	$\phi\chi\chi$	$\lambda\psi\psi$	$\phi\eta\eta$	$[\phi,\lambda]^2$
U	$2-2$	$1-1$	$-1+1$	$2-1-1$	$-2+1+1$	$2-1-1$	0

So U is a classical symmetry, a "ghost number". Quantum mechanically it is anomalous, exactly like the axial charge of QCD in an instanton background (Chapter 10): the path-integral measure is not U-invariant when there are fermion zero modes. We compute the anomaly in Section 12.7.4: it is $\dim\mathcal{M}_k = 8k - 3(1+b_2^+)$. For fixed M this depends on k only through $8k$, so, as Nash says, U is not conserved but is conserved *mod* 8. This is the same 8 as the $\mathbb{Z}_8$ grading of Floer homology (Section 12.4.5), and for the same reason.

12.7.2 The BRST symmetry

The action is invariant under a fermionic symmetry. Following Witten, with a Grassmann parameter ε of $U = -1$,

$$\begin{aligned} \delta A_\mu &= i\varepsilon\psi_\mu, & \delta\phi &= 0, & \delta\lambda &= 2i\varepsilon\eta, \\ \delta\eta &= \tfrac{1}{2}\varepsilon[\phi,\lambda], & \delta\psi_\mu &= -\varepsilon D_\mu\phi, & \delta\chi_{\mu\nu} &= \varepsilon\big(F_{\mu\nu} + {}^*F_{\mu\nu}\big). \end{aligned} \tag{12.104}$$

Write $\delta X = \varepsilon\, QX$; then Q is an odd derivation that raises U by one ($A \to \psi$: $0 \to 1$; $\psi \to D\phi$: $1 \to 2$; $\lambda \to \eta$: $-2 \to -1$; $\eta \to [\phi,\lambda]$: $-1 \to 0$; $\chi \to F^+$: $-1 \to 0$). Physicists call such a symmetry a BRST symmetry, after the symmetry of gauge-fixed Yang–Mills theory, because it too is fermionic and squares to zero on the gauge-invariant quantities.

Worked example 12.45: Q^2 is a gauge transformation generated by ϕ

Recall that an infinitesimal gauge transformation with parameter $\xi \in \Omega^0(\mathrm{ad}P)$ acts by $\delta_\xi A = -D\xi$ and $\delta_\xi X = [\xi, X]$ on adjoint fields (Chapter T3). Apply Q twice, using $QA = i\psi$, $Q\psi = -D\phi$, $Q\phi = 0$, $Q\lambda = 2i\eta$, $Q\eta = \frac{1}{2}[\phi,\lambda]$:

$$\begin{aligned} Q^2 A_\mu &\overset{(1)}{=} Q(i\psi_\mu) = -iD_\mu\phi \overset{(2)}{=} \delta_{i\phi}A_\mu, \\ Q^2\psi_\mu &\overset{(3)}{=} -Q(D_\mu\phi) = -[QA_\mu,\phi] = -i[\psi_\mu,\phi] = [i\phi,\psi_\mu] \overset{(4)}{=} \delta_{i\phi}\psi_\mu, \\ Q^2\lambda &\overset{(5)}{=} Q(2i\eta) = 2i\cdot\tfrac{1}{2}[\phi,\lambda] = [i\phi,\lambda] = \delta_{i\phi}\lambda, \\ Q^2\phi &= 0 = [i\phi,\phi] = \delta_{i\phi}\phi. \end{aligned}$$

(1) $QA = i\psi$ and $Q\psi = -D\phi$.
(2) Gauge transformation with $\xi = i\phi$: $\delta_\xi A = -D(i\phi)$.
(3) $D_\mu\phi = \partial_\mu\phi + [A_\mu,\phi]$ and $Q\phi = 0$, so only A is varied.
(4) $\delta_\xi\psi = [\xi,\psi]$ for an adjoint field.
(5) $Q\lambda = 2i\eta$, $Q\eta = \frac{1}{2}[\phi,\lambda]$.

So $Q^2 = \delta_{\text{gauge}}(i\phi)$. On gauge-invariant functionals $Q^2 = 0$, and the Q-cohomology ("Q-closed modulo Q-exact") is well defined. The field ϕ is thus the generator of the gauge transformation that Q^2 produces. In the mathematical language, Q is the differential of the Cartan model of $\mathcal{G}$-equivariant cohomology of $\mathcal{A}$, with $\psi \leftrightarrow$ "$\mathrm{d}A$" (1-forms on $\mathcal{A}$) and $\phi \leftrightarrow$ the curvature of $\mathcal{A} \to \mathcal{A}/\mathcal{G}$; its cohomology is the de Rham cohomology of $\mathcal{A}/\mathcal{G}$. This is the precise sense in which the field theory computes the topology of the space of gauge orbits.

Dictionary: Witten's supersymmetric quantum mechanics versus Witten's TQFT

Chapter 7: SUSY QM on a manifold X	Donaldson–Witten theory on M^4
coordinates x^i	gauge field $A_\mu(x)$
fermions $\psi^i \leftrightarrow \mathrm{d}x^i$	$\psi_\mu \leftrightarrow$ "$\mathrm{d}A_\mu$"
supercharge $Q = \mathrm{d} + t\,\mathrm{d}f\wedge$	BRST charge Q
fermion number	U-number
Morse critical points	instantons $F^+ = 0$
wave functions = forms on X	observables = forms on $\mathcal{A}/\mathcal{G}$
$\ker\Delta \cong H^*(X)$	Q-cohomology $\cong H^*(\mathcal{A}/\mathcal{G})$

12.7.3 Why the answers do not depend on the metric or the coupling

The Ward identity

Everything rests on one identity. If the measure $\mathcal{DF}$ (all fields) and the action are Q-invariant, then for every functional X,

$$\langle QX \rangle = \int \mathcal{DF}\, e^{-S}\, QX = 0. \tag{12.105}$$

The reason is that Q acts on the fields as a vector field, and the integral of a derivative is zero. (We check this explicitly in the toy model of Section 12.7.4.) Physically: Q annihilates the vacuum, so a Q-exact operator has zero expectation value, as in any theory with unbroken supersymmetry.

S and $T_{\mu\nu}$ are Q-exact

Witten showed that, up to the topological term $\int \operatorname{tr} F \wedge F$,

$$S = \{Q, V\}, \qquad T_{\mu\nu} \coloneqq \frac{\delta S}{\delta g^{\mu\nu}} = \{Q, V_{\mu\nu}\}, \qquad V_{\mu\nu} = \frac{\delta V}{\delta g^{\mu\nu}}, \tag{12.106}$$

for a functional V of $U = -1$. (Here $\{Q, V\}$ means QV; the anticommutator notation recalls that in the operator formalism Q acts on operators by graded commutator.) The topological term does not depend on the metric at all. The toy model in Section 12.7.4 shows how such a V looks: schematically $V = \int \operatorname{tr}\big(\chi \cdot (F^{+} - \tfrac{1}{4}H) + \dots\big)$ with an auxiliary field $H_{\mu\nu}$, the dots being terms built from λ, η, ψ that produce the scalar part of S.

Metric independence

Let P be a Q-invariant observable ($QP = 0$) that does not depend on the metric. Vary the metric, $g \to g + \delta g$. Then

$$\begin{aligned}
\delta_g \langle P \rangle &\overset{(1)}{=} \int \mathcal{DF}\, \big(-\delta_g S\big)\, e^{-S}\, P \\
&\overset{(2)}{=} -\int \mathcal{DF}\, e^{-S}\, \{Q, \delta_g V\}\, P \\
&\overset{(3)}{=} -\int \mathcal{DF}\, e^{-S}\, Q\big(\delta_g V\, P\big) \\
&\overset{(4)}{=} -\big\langle Q(\delta_g V\, P) \big\rangle \overset{(5)}{=} 0.
\end{aligned} \tag{12.107}$$

(1) Only the action depends on g; P does not, and (for the natural measure) neither does $\mathcal{DF}$.
(2) $\delta_g S = \int \delta g^{\mu\nu} T_{\mu\nu} = \{Q, \delta_g V\}$ by (12.106).
(3) Q is a derivation and $QP = 0$, so $(Q\delta_g V)P = Q(\delta_g V\, P)$.
(4) Definition of $\langle\cdot\rangle$.
(5) The Ward identity (12.105).

So $\langle P \rangle$ is a smooth invariant: it depends on the smooth structure (through the existence of metrics and of the action) but not on the metric. In the Hamiltonian picture, the Hamiltonian $H = \int T_{00}$ is Q-exact, so it vanishes on Q-cohomology: every physical state has zero energy, as promised in Section 12.1.1.

Coupling independence

Put a coupling constant in front: $S_e = \frac{1}{e^2}\{Q, V\}$. The same chain with $\frac{\mathrm{d}}{\mathrm{d}(1/e^2)}$ in place of δ_g:

$$\frac{\mathrm{d}}{\mathrm{d}(1/e^2)}\langle P\rangle_e \overset{(1)}{=} -\big\langle \{Q,V\}\,P\big\rangle_e \overset{(2)}{=} -\big\langle Q(VP)\big\rangle_e \overset{(3)}{=} 0.$$

(1) Differentiate e^{-S_e}.
(2) $QP = 0$.
(3) The Ward identity.

So we may take $e \to 0$. There the path integral is dominated by the minima of S, and the semiclassical (Gaussian) approximation around them is *exact*. This is the step Nash describes as "we can evaluate them in a small coupling limit".

Physical picture: Why a theory with $\hbar$-independent answers is "topological"

In an ordinary QFT, the loop expansion in e^2 (or $\hbar$) generates an infinite series of corrections. Here all corrections beyond one loop cancel between bosons and fermions, because Q pairs them. The one-loop answer is exact, and it is a count: a sum over classical solutions of determinant ratios that are ± 1.

12.7.4 Localisation: the path integral becomes an integral over $\mathcal{M}_k$

Before the infinite-dimensional case, here is the entire mechanism in a model with one bosonic variable. It is the zero-dimensional ancestor of both Witten's theory and the Morse theory of Chapter 7.

Worked example 12.46: A zero-dimensional TQFT counts zeros with signs

Let $s : \mathbb{R} \to \mathbb{R}$ be a smooth function with $|s(x)| \to \infty$ as $|x| \to \infty$. The "fields" are two bosons x, H and two Grassmann variables ψ, χ, with $U(x) = U(H) = 0$, $U(\psi) = 1$, $U(\chi) = -1$. The BRST operator is

$$Qx = \psi, \quad Q\psi = 0, \quad Q\chi = H, \quad QH = 0; \qquad \text{i.e. } Q = \psi\frac{\partial}{\partial x} + H\frac{\partial}{\partial \chi},$$

and plainly $Q^2 = 0$. Take $V = \chi\big(\frac{1}{2}H - i\,s(x)\big)$ and $S_t = t\,QV$:

$$\begin{aligned} QV &\overset{(1)}{=} (Q\chi)\big(\tfrac{1}{2}H - is\big) - \chi\,Q\big(\tfrac{1}{2}H - is\big) \\ &\overset{(2)}{=} \tfrac{1}{2}H^2 - iHs(x) + i\,\chi\,s'(x)\,\psi. \end{aligned}$$

(1) Q is an odd derivation: it picks up a sign when it passes the odd variable χ.
(2) $Q\chi = H$, and $Q\,s(x) = s'(x)\,Qx = s'(x)\psi$, $QH = 0$.

Define $Z_t = i\int \frac{\mathrm{d}x\,\mathrm{d}H}{2\pi}\,\mathrm{d}\psi\,\mathrm{d}\chi\; e^{-S_t}$ (the factor i fixes the overall normalisation). Do the integrals one at a time. The Grassmann integral, with $\int \mathrm{d}\psi\,\psi = \int \mathrm{d}\chi\,\chi = 1$:

$$\int \mathrm{d}\psi\,\mathrm{d}\chi\; e^{-it\chi s'\psi} \overset{(1)}{=} \int \mathrm{d}\psi\,\mathrm{d}\chi\,\big(1 - it\,s'\,\chi\psi\big) \overset{(2)}{=} -it\,s'(x).$$

(1) The exponential series stops after the linear term, because $(\chi\psi)^2 = 0$.
(2) $\int \mathrm{d}\chi\,\chi\psi = \psi$ and then $\int \mathrm{d}\psi\,\psi = 1$; the constant term integrates to zero.

The H integral is a Gaussian:

$$\int \frac{\mathrm{d}H}{2\pi}\, e^{-t(\frac{1}{2}H^2 - iHs)} \overset{(1)}{=} \int \frac{\mathrm{d}H}{2\pi}\, e^{-\frac{t}{2}(H-is)^2}\, e^{-\frac{t}{2}s^2} \overset{(2)}{=} \frac{1}{\sqrt{2\pi t}}\, e^{-\frac{t}{2}s(x)^2}.$$

(1) Complete the square: $\frac{1}{2}H^2 - iHs = \frac{1}{2}(H-is)^2 + \frac{1}{2}s^2$.

(2) $\int e^{-tu^2/2}\mathrm{d}u = \sqrt{2\pi/t}$ (shifting the contour by is is harmless).

Putting the pieces together, with $\Phi(u) = \int_{-\infty}^{u} e^{-v^2/2}\mathrm{d}v/\sqrt{2\pi}$ the normal distribution function:

$$\begin{aligned} Z_t &\overset{(1)}{=} \int \mathrm{d}x\, \sqrt{\frac{t}{2\pi}}\, s'(x)\, e^{-\frac{t}{2}s(x)^2} \\ &\overset{(2)}{=} \int \mathrm{d}x\, \frac{\mathrm{d}}{\mathrm{d}x}\Phi\big(\sqrt{t}\, s(x)\big) \\ &\overset{(3)}{=} \Phi\big(\sqrt{t}\, s(+\infty)\big) - \Phi\big(\sqrt{t}\, s(-\infty)\big). \end{aligned} \tag{12.108}$$

(1) $i \cdot (-it\, s') \cdot (2\pi t)^{-1/2} = \sqrt{t/2\pi}\, s'$.

(2) Chain rule: $\frac{\mathrm{d}}{\mathrm{d}x}\Phi(\sqrt{t}\, s) = \sqrt{t}\, s'\, e^{-ts^2/2}/\sqrt{2\pi}$.

(3) Fundamental theorem of calculus.

Since $\Phi(+\infty) = 1$ and $\Phi(-\infty) = 0$:

$$Z_t = \begin{cases} +1, & s(-\infty) = -\infty,\ s(+\infty) = +\infty, \\ -1, & s(-\infty) = +\infty,\ s(+\infty) = -\infty, \\ 0, & s(\pm\infty) \text{ of the same sign.} \end{cases}$$

Three observations, each a piece of Nash's p. 336.

1. *Z_t is independent of t.* This is the coupling independence ($t = 1/e^2$). Directly from the Ward identity: $\frac{\mathrm{d}Z_t}{\mathrm{d}t} = -i\int (QV)e^{-tQV} = -i\int Q\big(Ve^{-tQV}\big) = 0$, because $Q = \psi\partial_x + H\partial_\chi$ is a sum of derivatives: $\int \mathrm{d}x\, \partial_x(\cdots) = 0$ by the Gaussian decay, and $\int \mathrm{d}\chi\, \partial_\chi(\cdots) = 0$ because a χ-derivative contains no χ.

2. *Z_t counts zeros of s with signs.* For s with only simple zeros x_j, $Z = \sum_j \operatorname{sgn} s'(x_j)$: going from $-\infty$ to $+\infty$, s crosses zero upwards once more than downwards. For $s = x^3 - x$: zeros at $-1, 0, 1$ with $s' = 2, -1, 2$, so $Z = 1 - 1 + 1 = 1$. For $s = x^2 - 1$: $s'(\mp 1) = \mp 2$, so $Z = -1 + 1 = 0$, in agreement with (12.108).

3. *As $t \to \infty$ the integrand localises*, and each zero contributes a ratio of determinants equal to ± 1. Near x_j, $s \approx s'_j\, y$ with $y = x - x_j$. The bosonic integrals (x and H) give $\int \mathrm{d}y\, (2\pi t)^{-1/2} e^{-ts_j'^2 y^2/2} = 1/(t|s'_j|)$: one over the bosonic "determinant". The fermionic integral gives $i \cdot (-its'_j) = ts'_j$: the fermionic determinant. The ratio is $s'_j/|s'_j| = \pm 1$.

Worked example 12.47: Zero modes must be soaked up: observables are forms

Now take two bosons $(x, y) \in \mathbb{R}^2$ but still one equation, $s(x, y) = y$. The zero set $\{y = 0\}$ is a line: a "moduli space" of dimension 1. There are fermions $\psi^x = Qx$, $\psi^y = Qy$ and one χ,

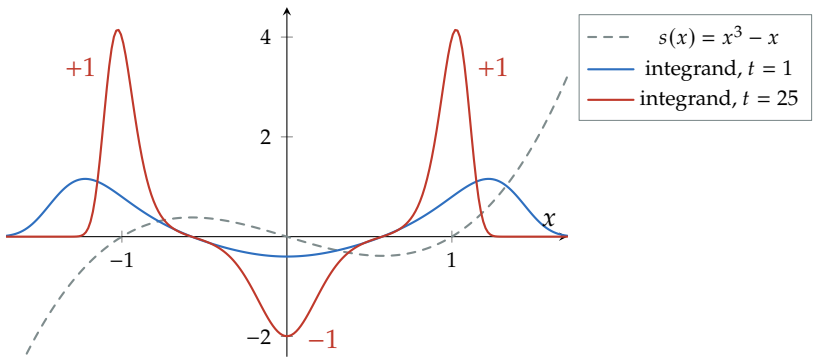

Figure 12.31: Localisation in the toy model. The integrand $\sqrt{t/2\pi}\, s'(x) e^{-t s(x)^2/2}$ has total integral 1 for every t. At $t = 1$ (blue) it is spread out; at $t = 25$ (red) it has collapsed onto narrow peaks at the zeros of s (dashed), each of area $\operatorname{sgn} s'(x_j)$: $+1 - 1 + 1 = 1$. In Witten's theory the zeros of s become the instantons and the peaks become the contributions of $\mathcal{M}_k$.

so the action $S_t = t\,Q\big(\chi(\tfrac{1}{2}H - iy)\big) = t\big(\tfrac{1}{2}H^2 - iHy + i\chi\psi^y\big)$ contains no ψ^x at all. Then

$$Z = \int \mathrm{d}\psi^x \,(\text{something independent of } \psi^x) = 0.$$

The unpaired ψ^x is a *fermion zero mode*, pointing along the moduli space. To get a non-zero answer we must insert an observable that contains ψ^x, for instance $\mathcal{O} = f(x)\,\psi^x$. It is Q-closed: $Q\mathcal{O} = f'(x)\psi^x\psi^x = 0$. Its expectation value is

$$\begin{aligned}\langle f(x)\psi^x\rangle &\overset{(1)}{=} \int \mathrm{d}x\, f(x) \int \mathrm{d}\psi^x\, \psi^x \;\times\; i\int \frac{\mathrm{d}y\,\mathrm{d}H}{2\pi}\mathrm{d}\psi^y\mathrm{d}\chi\; e^{-t(\frac{1}{2}H^2 - iHy + i\chi\psi^y)} \\ &\overset{(2)}{=} \int \mathrm{d}x\, f(x)\cdot 1\cdot 1 = \int_{\{y=0\}} f(x)\,\mathrm{d}x.\end{aligned}$$

(1) The integrand factorises into an (x, ψ^x) part and a (y, H, ψ^y, χ) part.

(2) $\int \mathrm{d}\psi^x\psi^x = 1$, and the second factor is the one-dimensional model (12.108) with $s(y) = y$, which equals 1.

The observable $f(x)\psi^x$ is really the 1-form $f(x)\,\mathrm{d}x$ ($\psi^x \leftrightarrow \mathrm{d}x$), and the answer is its integral over the zero set. The U-numbers match: the measure $\mathrm{d}\psi^x\mathrm{d}\psi^y\mathrm{d}\chi$ has $U = -1 - 1 + 1 = -1$ (a Grassmann measure $\mathrm{d}\psi$ carries the opposite charge of ψ), which is minus the dimension of the zero set, so only an observable of $U = +1$, a 1-form, can have a non-zero expectation value.

Dictionary: From the toy model to Donaldson–Witten theory

toy model	Witten's theory on M^4
x	A_μ (modulo gauge: ϕ, λ, η do the dividing)
$\psi = Qx$	ψ_μ, with $QA_\mu = i\psi_\mu$
the equation $s(x)$	F^+, a section of Ω^2_+ over $\mathcal{A}/\mathcal{G}$
χ, H	$\chi_{\mu\nu}$ and an auxiliary self-dual $H_{\mu\nu}$
$\frac{t}{2}s^2$ after integrating out H	$\frac{1}{2}\lvert F^+\rvert^2$, i.e. $\frac{1}{4}F\cdot F + \frac{1}{4}F\cdot {}^*F$
$i\chi s'\psi$	$iD_\mu\psi_\nu\chi^{\mu\nu}$, i.e. $\chi\, \mathrm{d}_A^+\psi$
zeros of s	instantons, $\mathcal{M}_k$
$\operatorname{sgn} s'(x_j)$	orientation sign of an instanton $((-1)^{n_i})$
$t \to \infty$	weak coupling $e \to 0$
$f(x)\psi^x$	$P(\mathcal{F})$, a form on $\mathcal{M}_k$

The real computation, step by step

Now repeat the three observations with Nash's (12.58),

$$\langle P\rangle = \int \mathcal{D}\mathcal{F}\; e^{-S}\, P(\mathcal{F}), \tag{12.109}$$

where $\mathcal{F}$ denotes all the fields and P is a polynomial in them.

Step 1: the minima. At $e \to 0$ we need S minimal. The bosonic part of S is a sum of squares: $\frac{1}{2}|F^+|^2$, the kinetic term of (ϕ, λ) and $|[\phi, \lambda]|^2$ (with Euclidean reality conditions making them positive). They vanish exactly when

$$F^+ = 0, \qquad D_\mu\phi = 0, \qquad D_\mu\lambda = 0.$$

These are also the fixed points of Q ($\delta\chi = 0$ and $\delta\psi = 0$ in (12.104)): the path integral localises on Q-fixed points, exactly as the toy model localised on $s = 0$. A covariantly constant ϕ generates a gauge transformation fixing A ($\delta_\phi A = -D\phi = 0$), so it lies in H^0_A, the Lie algebra of the stabiliser. For irreducible A this is zero. Hence Nash's remark "we also need ϕ and λ to vanish for irreducible connections": the minima are $\phi = \lambda = 0$ and $A \in \mathcal{M}_k$.

Step 2: the non-zero modes cancel. Expand all fields to quadratic order around a minimum. The bosonic fluctuation a of A (in a gauge $\mathrm{d}_A^* a = 0$) has quadratic action $\frac{1}{2}\langle a, D_A^* D_A a\rangle$, the expansion of $\frac{1}{2}|F^+|^2$ plus gauge fixing. The fermions ψ and (η, χ) have quadratic action $\langle(\eta, \chi), D_A\psi\rangle$. The key fact is that $D_A^* D_A$ and $D_A D_A^*$ have the same non-zero eigenvalues:

$$D_A^* D_A\, v = \mu v,\ \mu \neq 0 \overset{(1)}{=} D_A D_A^*\,(D_A v) = D_A(D_A^* D_A v) = \mu\,(D_A v), \qquad D_A v \overset{(2)}{=\!\!\!\neq} 0.$$

(1) Apply D_A to the eigenvalue equation.
(2) If $D_A v = 0$ then $\mu v = D_A^* D_A v = 0$, contradicting $\mu \neq 0$, $v \neq 0$.

(and symmetrically in the other direction, so the non-zero spectra coincide with multiplicities, as in the proof of the McKean–Singer formula, Chapter 4). Therefore

$$\frac{\text{fermions}}{\text{bosons}} \overset{(1)}{=} \frac{\det'(D_A)}{\det'(D_A^* D_A)^{1/2}} \overset{(2)}{=} \frac{\pm\prod_j \sqrt{\mu_j}}{\prod_j \sqrt{\mu_j}} = \pm 1.$$

(1) A Grassmann Gaussian gives a determinant; a bosonic one gives an inverse square root of a determinant. Primes: zero modes omitted.

(2) The singular values of D_A are the square roots $\sqrt{\mu_j}$ of the common non-zero eigenvalues; the sign depends on orientation conventions, exactly the $\operatorname{sgn} s'$ of the toy model.

The scalars (ϕ, λ) and the remaining fermions cancel in the same way. This is Nash's "Boson–Fermion ratio of determinants, a ratio which supersymmetry constrains to be ∓ 1 since Bosonic and Fermionic eigenvalues are equal in pairs".

Step 3: the zero modes remain. The zero modes of the bosonic fluctuation a are $\ker D_A = H^1_A = T_{[A]}\mathcal{M}_k$: moving along them costs no action, so they are not Gaussian integrals but an honest integral over $\mathcal{M}_k$. The fermionic zero modes are: for ψ, again $\ker D_A$ ($n = \dim \mathcal{M}_k$ of them); for η and χ, $\ker D_A^* = H^0_A \oplus H^2_A = 0$ (none, for irreducible unobstructed instantons). The n Grassmann zero modes $\psi_0^1, \dots, \psi_0^n$, like ψ^x in Example 12.47, must be soaked up by P. Expanding $P(\mathcal{F})$ and keeping the term with exactly n factors of ψ_0 gives

$$\langle P \rangle = \int_{\mathcal{M}_k} P_n, \tag{12.110}$$

Nash's (12.59), where P_n is an n-form on $\mathcal{M}_k$ ($\psi_0^i \leftrightarrow \mathrm{d}x^i$ on $\mathcal{M}_k$).

Step 4: the selection rule. Each zero mode ψ_0^i has $U = 1$, so each measure factor $\mathrm{d}\psi_0^i$ has $U = -1$:

$$\begin{aligned} U(\text{measure}) &\overset{(1)}{=} -\#(\psi \text{ zero modes}) + \#(\eta \text{ zero modes}) + \#(\chi \text{ zero modes}) \\ &\overset{(2)}{=} -\dim H^1_A + \dim H^0_A + \dim H^2_A \overset{(3)}{=} -\dim \mathcal{M}_k = -\big(8k - 3(1 + b_2^+)\big). \end{aligned} \tag{12.111}$$

(1) ψ has $U = +1$; η, χ have $U = -1$; the non-zero modes come in pairs of opposite U and contribute nothing net.
(2) The zero modes are the cohomology groups of the deformation complex (Figure 12.30).
(3) $H^0_A = H^2_A = 0$, and the index theorem (12.83). (In general the alternating sum is the index, which is still the expected dimension.)

So $\langle P \rangle \neq 0$ requires $U(P) = \dim \mathcal{M}_k$. Since the dimension changes by 8 when k changes by 1, the net U-violation is fixed mod 8 on a given M. With the right choice of P, (12.110) is literally Donaldson's integral (12.95). Which P? That is the subject of the next subsection.

12.7.5 Observables and the descent equations

We need Q-invariant, gauge-invariant, metric-independent observables with the right U-number. Start from the only gauge-invariant polynomial in ϕ of lowest degree:

$$W_0 = \tfrac{1}{2} \operatorname{tr} \phi^2, \qquad U(W_0) = 4.$$

It is Q-invariant because $Q\phi = 0$. It is a function on M, so it depends on the point x where it is inserted. But its derivative is Q-exact. With $W_1 \coloneqq \operatorname{tr}(\phi\, \psi)$, a 1-form on M of $U = 3$:

$$\mathrm{d}W_0 \overset{(1)}{=} \operatorname{tr}(\phi\, \mathrm{d}\phi) \overset{(2)}{=} \operatorname{tr}(\phi\, D\phi) \overset{(3)}{=} -\operatorname{tr}(\phi\, Q\psi) \overset{(4)}{=} -Q \operatorname{tr}(\phi\, \psi) = -QW_1.$$

(1) $\mathrm{d}\frac{1}{2} \operatorname{tr} \phi^2 = \frac{1}{2} \operatorname{tr}(\mathrm{d}\phi\, \phi + \phi\, \mathrm{d}\phi)$, and the trace is cyclic.
(2) $D\phi = \mathrm{d}\phi + [A, \phi]$ and $\operatorname{tr}(\phi[A, \phi]) = 0$ (cyclicity).
(3) $Q\psi = -D\phi$.
(4) $Q\phi = 0$, so Q passes ϕ and acts only on ψ.

The pattern continues. Define

$$W_2 = \operatorname{tr}\big(\tfrac{1}{2}\psi \wedge \psi + i\phi F\big), \qquad W_3 = i \operatorname{tr}(\psi \wedge F), \qquad W_4 = -\tfrac{1}{2} \operatorname{tr}(F \wedge F), \tag{12.112}$$

with $U(W_k) = 4 - k$. They obey Witten's **descent equations**

$$QW_0 = 0, \qquad \mathrm{d}W_k = -QW_{k+1} \ \ (k = 0,1,2,3), \qquad \mathrm{d}W_4 = 0. \tag{12.113}$$

Let us verify the next step, $\mathrm{d}W_1 = -QW_2$. Here Q commutes with $\mathrm{d}x^\mu$ and anticommutes with the Grassmann-odd components ψ_μ. First,

$$\begin{aligned} Q\ \mathrm{tr}(\tfrac{1}{2}\psi\wedge\psi) &\overset{(1)}{=} \tfrac{1}{2}\,\mathrm{tr}\big((Q\psi_\mu)\psi_\nu - \psi_\mu(Q\psi_\nu)\big)\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu \\ &\overset{(2)}{=} -\tfrac{1}{2}\,\mathrm{tr}\big(D_\mu\phi\,\psi_\nu - \psi_\mu D_\nu\phi\big)\mathrm{d}x^{\mu\nu} \overset{(3)}{=} -\,\mathrm{tr}(D\phi\wedge\psi), \end{aligned}$$

(1) Q is an odd derivation acting on the Grassmann components.
(2) $Q\psi_\mu = -D_\mu\phi$.
(3) $\mathrm{tr}(\psi_\mu D_\nu\phi)\mathrm{d}x^{\mu\nu} = \mathrm{tr}(D_\nu\phi\,\psi_\mu)\mathrm{d}x^{\mu\nu} = -\,\mathrm{tr}(D\phi\wedge\psi)$ (cyclicity, $D\phi$ Grassmann-even, then $\mathrm{d}x^{\mu\nu} = -\mathrm{d}x^{\nu\mu}$).

and $Q\ \mathrm{tr}(\phi F) = \mathrm{tr}(\phi\,QF) = \mathrm{tr}(\phi\,D(QA)) = i\,\mathrm{tr}(\phi\,D\psi)$, using $\delta F = D\,\delta A$. So

$$-QW_2 \overset{(1)}{=} \mathrm{tr}(D\phi\wedge\psi) - i\cdot i\ \mathrm{tr}(\phi\,D\psi) = \mathrm{tr}(D\phi\wedge\psi + \phi\,D\psi) \overset{(2)}{=} \mathrm{d}\ \mathrm{tr}(\phi\,\psi) = \mathrm{d}W_1.$$

(1) The two computations just made.
(2) Leibniz rule; the $[A,\cdot]$ terms cancel inside the trace.

This fixes the coefficient i in W_2.

Try it: The last two descent equations

Check $\mathrm{d}W_2 = -QW_3$ and $\mathrm{d}W_3 = -QW_4$, using $DF = 0$ (Bianchi), $QF = iD\psi$ and $\mathrm{tr}(\psi\wedge D\psi) = -\,\mathrm{tr}(D\psi\wedge\psi)$.
Answer: $\mathrm{d}W_2 = \mathrm{tr}(D\psi\wedge\psi) + i\,\mathrm{tr}(D\phi\wedge F)$ and $QW_3 = i\,\mathrm{tr}(Q\psi\wedge F) - i\,\mathrm{tr}(\psi\wedge QF) = -i\,\mathrm{tr}(D\phi\wedge F) - \mathrm{tr}(D\psi\wedge\psi)$. For the last one, $\mathrm{d}W_3 = i\,\mathrm{tr}(D\psi\wedge F)$ and $QW_4 = -\,\mathrm{tr}(QF\wedge F) = -i\,\mathrm{tr}(D\psi\wedge F)$.

Key idea: Observables from cycles

For a k-dimensional closed submanifold (cycle) $\gamma\subset M$ define $I(\gamma) = \int_\gamma W_k$. Then:

$$Q\,I(\gamma) \overset{(1)}{=} \int_\gamma QW_k \overset{(2)}{=} -\int_\gamma \mathrm{d}W_{k-1} \overset{(3)}{=} -\int_{\partial\gamma} W_{k-1} \overset{(4)}{=} 0,$$

(1) Q acts on fields, not on the point of integration.
(2) Descent equation (12.113).
(3) Stokes' theorem (Chapter T2).
(4) γ is closed: $\partial\gamma = \varnothing$.

so $I(\gamma)$ is Q-invariant. If $\gamma = \partial\beta$ is a boundary, the same steps in reverse give $I(\gamma) = \int_\beta \mathrm{d}W_k = -Q\int_\beta W_{k+1}$, which is Q-exact and so has zero expectation value by (12.105). Hence $\langle I(\gamma_1)\cdots I(\gamma_r)\rangle$ depends only on the *homology classes* of the γ_i: the field theory turns homology of M into observables.

Matching with Donaldson's classes

For a surface Σ, $I(\Sigma) = \int_\Sigma \mathrm{tr}(\tfrac{1}{2}\psi\wedge\psi + i\phi F)$ has $U = 2$. In the localised theory, ψ is replaced by its zero modes, which are tangent vectors a, b to $\mathcal{M}_k$, and ϕ by its value forced by the λ

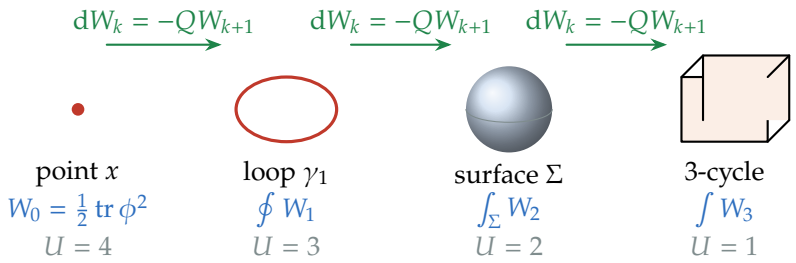

Figure 12.32: The descent ladder. Each W_k is a k-form on M of U-number $4-k$, and its exterior derivative is Q of the next one. Integrated over a k-cycle it gives a Q-invariant observable that depends only on the homology class. For simply connected M only points and surfaces matter ($b_1 = b_3 = 0$): they give the classes of degree 4 and 2 on $\mathcal{M}_k$.

equation of motion, $\mathrm{d}_A^* \mathrm{d}_A \phi \propto [\psi, \star\psi]$, which is the $\Phi(a,b)$ of Section 12.6.3. So

$$I(\Sigma) \longrightarrow \int_\Sigma \operatorname{tr}\big(a\wedge b + \Phi(a,b)F_A\big) \;\propto\; m(\Sigma)(a,b),$$

exactly the two terms of (12.93): the field theory's observable *is* Donaldson's 2-form. Therefore, when $2d = \dim \mathcal{M}_k$,

$$\big\langle I(\Sigma_1)\cdots I(\Sigma_d)\big\rangle \overset{(1)}{=} \int_{\mathcal{M}_k} m(\Sigma_1)\wedge\cdots\wedge m(\Sigma_d) \overset{(2)}{=} q_d(M)(\Sigma_1,\ldots,\Sigma_d), \tag{12.114}$$

(1) Localisation (12.110) with $P = \prod I(\Sigma_i)$, whose U-number $2d$ equals $\dim \mathcal{M}_k$ as the selection rule demands.
(2) Definition (12.95).

up to normalisation. Similarly $W_0(x)$ becomes a 4-form ν on $\mathcal{M}_k$ (the "point class", independent of x by descent), and the general Donaldson invariant is $\langle I(\Sigma_1)\cdots I(\Sigma_r)\, W_0^s\rangle$ with $2r + 4s = \dim \mathcal{M}_k$. Nash's q_d are the $s = 0$ ones.

Watch out: What the field theory does and does not prove

Witten's derivation is a physicist's argument: it assumes the path integral exists, is Q-invariant and localises. It explains *why* Donaldson's integrals are metric-independent and *what* they are (correlation functions), and it reproduces their structural properties. It does not by itself handle compactness of $\mathcal{M}_k$ or reducible connections; those are the hard analysis of Section 12.6.5. Its real power appeared later, when Seiberg and Witten used the physical *strong-coupling* description of the same theory to compute the invariants.

Reading Nash (pp. 335–336, (12.56)–(12.59))

Nash says Witten obtained the $q_d(M)$ as correlation functions of a BRST-supersymmetric TQFT, the relativistic generalisation of Floer's theory, and describes only its principal features. He writes the action (12.56), lists the fields $(\phi, \lambda, \eta, \psi_\mu, \chi_{\mu\nu})$, notes that ϕ, λ are spinless and that (η, ψ, χ) are a 0-form, a 1-form and a self-dual 2-form matching the anti-instanton deformation complex (8.104), and assigns $U = (2, -2, -1, 0, 1, -1)$, conserved only mod 8. Metric independence follows from $S = \{Q, V\}$, $T = \{Q, V'\}$; coupling independence lets one take weak coupling, where the minima are instantons (12.57) with $\phi, \lambda = 0$ for irreducibles. For $\langle P\rangle = \int \mathcal{D}\mathcal{F}\, \exp(-S)P$ (12.58) the zero modes are tangent to $\mathcal{M}_k$, the non-zero modes give a boson–fermion ratio ∓ 1, and $\langle P\rangle = \int_{\mathcal{M}_k} P_n$ (12.59), non-zero only when $U(P) = \dim \mathcal{M}_k$. We have supplied: the twisting origin of the fields; the F^+

form of the gauge action; the U-check of every term; the BRST transformations and $Q^2 =$ gauge; the metric- and coupling-independence chains; the complete zero-dimensional toy model, with and without zero modes; the spectral pairing behind the determinant ratio; the U-anomaly as an index; and the descent equations that produce the observables and match them to Donaldson's $m(\Sigma)$.

Recap

- Witten's theory has fields $A, \psi, \phi, \lambda, \eta, \chi$; the fermions (η, ψ, χ) fill the deformation complex $\Omega^0 \to \Omega^1 \to \Omega^2_+$. It is the twist of $N = 2$ super Yang–Mills, which makes one supercharge Q a scalar.
- The gauge action is $\frac{1}{2}|F^+|^2$, minimised by instantons. U is a classical symmetry, broken by $\dim \mathcal{M}_k$ units by zero modes, hence conserved mod 8.
- Q^2 is a gauge transformation generated by ϕ; S and $T_{\mu\nu}$ are Q-exact. The Ward identity $\langle QX \rangle = 0$ then gives independence of the metric and of the coupling.
- At weak coupling the path integral localises on Q-fixed points: $F^+ = 0$, $\phi = \lambda = 0$. Non-zero modes cancel to ± 1 because D^*D and DD^* share their non-zero spectrum; zero modes turn the integrand into a form on $\mathcal{M}_k$: $\langle P \rangle = \int_{\mathcal{M}_k} P_n$.
- The toy model $Z = \int \sqrt{t/2\pi}\, s' e^{-ts^2/2} \mathrm{d}x = \sum \operatorname{sgn} s'(x_j)$ contains the whole mechanism.
- The descent equations $\mathrm{d}W_k = -QW_{k+1}$ turn k-cycles into observables; $\int_\Sigma W_2$ is Donaldson's $m(\Sigma)$, and $\langle \prod I(\Sigma_i) \rangle = q_d$.

12.8 Cutting along homology spheres: Floer meets Donaldson

We now have two theories that look as if they were made for each other. Floer's theory (Section 12.5) attaches to a closed oriented homology 3-sphere N a $\mathbb{Z}_8$-graded group $HF_*(N)$, built from flat connections and the instantons on the cylinder $N \times \mathbb{R}$. Donaldson's theory (Section 12.6) attaches to a closed oriented 4-manifold M a list of numbers $q_d(M)$, built from the instantons on M. Atiyah's axioms (Section 12.1.3) tell us what a TQFT in $3+1$ dimensions should do: to a closed 3-manifold it assigns a vector space $Z(N)$, to a 4-manifold with boundary N it assigns a vector in $Z(N)$, and when a closed 4-manifold is cut into two pieces its number is the pairing of the two vectors.

So the question of this section is:

If we cut M along a homology 3-sphere N, can we compute $q_d(M)$ from the two halves, with the Floer group $HF_*(N)$ playing the role of $Z(N)$?

The answer is yes, and it is Nash's formula (12.63),

$$[C^+] \bullet [C^-] = q_d(M).$$

To understand it we need four things, which are the four subsections below: how to cut a 4-manifold along a homology sphere and what this does to the intersection form; what an instanton on a manifold with boundary is, and why its "boundary value" is a flat connection; why the set of such instantons defines a *Floer homology class*; and why pairing two such classes reproduces the count of instantons on the closed manifold. After that (Section 12.8.5 onwards)

we look at the simplest case, $d = 0$, read the formula in both directions, and set up the relative invariants.

Throughout, N is a closed oriented homology 3-sphere ($H_1(N;\mathbb{Z}) = 0$), the gauge group is SU(2), and instantons are anti-self-dual, $F^+ = 0$. We use the conventions of Section 12.4: on a cylinder $N \times \mathbb{R}$ with orientation $\mathrm{d}t \wedge \mathrm{vol}_N$ the ASD equation is the downward gradient flow $\dot{A} = -\star F_A$ of the Chern–Simons function f, and a flow line from α (at $t = -\infty$) to β (at $t = +\infty$) has charge $k = f(\alpha) - f(\beta) \geq 0$ (12.49).

12.8.1 Splitting a 4-manifold along a homology sphere

The operation $M = M^+ \cup_h M^-$

Take two compact oriented 4-manifolds M^+ and M^- with boundaries

$$\partial M^+ = N, \qquad \partial M^- = \overline{N},$$

where $\overline{N}$ is N with the opposite orientation. Glue them along the common boundary with an orientation-reversing identification. The result is a closed oriented 4-manifold, which Nash writes (12.60)

$$M = M^+ \cup_h M^-. \tag{12.115}$$

The subscript h is a reminder that the gluing surface is a *homology* sphere, not an ordinary one. Nash calls the two copies of the boundary N^+ and N^-. They are the same 3-manifold N; what differs is the orientation each inherits from its side (Figure 12.33).

Watch out: Why the two boundaries have opposite orientations

The rule for the orientation of a boundary is *outward normal first* (Chapter T2): an ordered basis (v_1, v_2, v_3) of $T\partial X$ is positive if $(n_{\text{out}}, v_1, v_2, v_3)$ is positive in X. Near the gluing surface, write $M \supset N \times (-\varepsilon, \varepsilon)$ with coordinate t and orientation $\mathrm{d}t \wedge \mathrm{vol}_N$, with M^+ at $t < 0$ and M^- at $t > 0$. The outward normal of M^+ is $+\partial_t$, so ∂M^+ carries $+\mathrm{vol}_N$: it is N. The outward normal of M^- is $-\partial_t$, so ∂M^- carries $-\mathrm{vol}_N$: it is $\overline{N}$. This is the same reason that the two ends of an interval $[a, b]$ come with opposite signs in $\int_a^b g'\,\mathrm{d}t = g(b) - g(a)$.

The simplest example is the **connected sum** (Section 12.6.6). Remove a small ball from each of two closed manifolds M_1, M_2 and glue along the two boundary 3-spheres:

$$M_1 \# M_2 = (M_1 \setminus B^4) \cup_{S^3} (M_2 \setminus B^4).$$

Here $N = S^3$, which is certainly a homology sphere. The operation $\cup_h$ generalises this by allowing any homology sphere, such as the Poincaré sphere $\Sigma(2,3,5)$ or the Brieskorn spheres $\Sigma(2,3,6n-1)$.

What the splitting does to H_2 and to Q

Nash says the decomposition exists when the intersection form splits, $Q(M) = Q(M^+) \oplus Q(M^-)$. Let us first see the easy direction: if M is split along a homology sphere, then Q splits.

The tool is the **Mayer–Vietoris sequence**. It is the homology version of the inclusion–exclusion principle: if $X = U \cup V$, a cycle in X can be cut into a piece in U and a piece in V whose boundaries agree on $U \cap V$. The precise statement is that the sequence

$$\cdots \to H_p(U \cap V) \xrightarrow{(i_*, -j_*)} H_p(U) \oplus H_p(V) \to H_p(X) \xrightarrow{\partial} H_{p-1}(U \cap V) \to \cdots \tag{12.116}$$

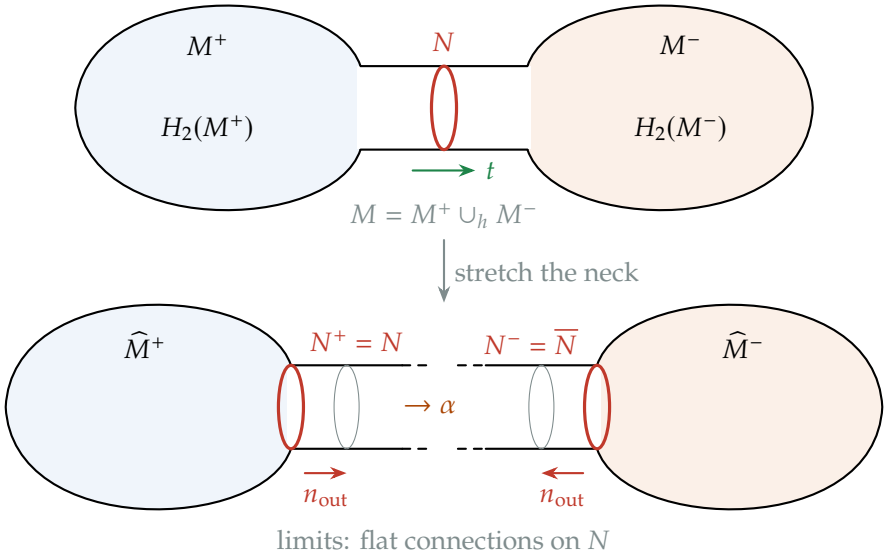

Figure 12.33: Cutting a closed 4-manifold along a homology sphere N. Top: M is the union of M^+ and M^- along N. Bottom: stretching the neck to infinite length turns each half into a manifold with a cylindrical end. See the outward normals point in opposite t-directions, which is why $\partial M^+ = N$ but $\partial M^- = \overline{N}$. On each end an instanton tends to a flat connection α on N.

is exact: at each spot the image of the incoming map equals the kernel of the outgoing map. The middle arrow adds a cycle in U and a cycle in V; the map ∂ takes a cycle in X, cuts it along $U \cap V$, and returns the boundary of the U-piece. We take $U \simeq M^+$, $V \simeq M^-$ (thickened slightly) and $U \cap V \simeq N$.

Two facts about N are needed:

$$H_1(N) \overset{(1)}{=} 0, \qquad H_2(N) \overset{(2)}{=} H^1(N) \overset{(3)}{=} \operatorname{Hom}\big(H_1(N), \mathbb{Z}\big) = 0. \tag{12.117}$$

(1) N is a homology sphere.
(2) Poincaré duality on the closed oriented 3-manifold N: $H_p \cong H^{3-p}$.
(3) H^1 is the dual of H_1 (a 1-cocycle is determined by its values on loops; the universal coefficient theorem), and $H_1 = 0$.

This is Nash's footnote 1 of Section 12.2 again, now doing real work. Put $p = 2$ in (12.116):

$$\underbrace{H_2(N)}_{=0} \longrightarrow H_2(M^+) \oplus H_2(M^-) \longrightarrow H_2(M) \longrightarrow \underbrace{H_1(N)}_{=0}. \tag{12.118}$$

Exactness at $H_2(M^+) \oplus H_2(M^-)$ says the middle map has kernel equal to the image of 0, so it is injective. Exactness at $H_2(M)$ says its image is the kernel of the map to 0, i.e. everything, so it is surjective. Hence

$$\boxed{H_2(M) \cong H_2(M^+) \oplus H_2(M^-)} \tag{12.119}$$

which is the decomposition Nash uses in (12.67).

The intersection form splits too. A class $a^+ \in H_2(M^+)$ is represented by a surface inside M^+, and $a^- \in H_2(M^-)$ by a surface inside M^-. These surfaces are disjoint, so

$$\begin{aligned} Q(a^+ + a^-,\, b^+ + b^-) &\overset{(1)}{=} Q(a^+, b^+) + Q(a^+, b^-) + Q(a^-, b^+) + Q(a^-, b^-) \\ &\overset{(2)}{=} Q^+(a^+, b^+) + Q^-(a^-, b^-), \end{aligned} \tag{12.120}$$

(1) Q is bilinear.
(2) Surfaces on opposite sides do not meet, so their intersection number is zero; surfaces on the same side meet only inside that side, so Q restricted to $H_2(M^\pm)$ is the intersection form $Q^\pm$ of $M^\pm$.

In matrix language: in a basis adapted to (12.119), the matrix of Q is block diagonal, $Q = \begin{pmatrix} Q^+ & 0 \\ 0 & Q^- \end{pmatrix}$. Each block is itself unimodular ($\det Q^\pm = \pm 1$), because $\det Q = \det Q^+ \det Q^- = \pm 1$ with integer factors. Consequently b_2^+ and b_2^- add:

$$b_2^\pm(M) = b_2^\pm(M^+) + b_2^\pm(M^-). \tag{12.121}$$

The converse: Freedman and Taylor

Nash quotes the converse: *if $Q(M) = Q_1 \oplus Q_2$ is any splitting of the intersection form of a closed simply connected smooth 4-manifold, then $M = M^+ \cup_h M^-$ along some homology sphere, with $Q(M^\pm) = Q_{1,2}$* (Freedman and Taylor, 1977). The point to appreciate is the contrast with connected sums. Every splitting of Q is realised by cutting along a homology sphere, but *not* by cutting along an honest S^3. We saw why in Example 12.43: $E(3)$ has $Q = 5(1) \oplus 29(-1)$, which splits into pieces with $b_2^+ > 0$, yet $E(3)$ is not a connected sum of two such pieces, because it has non-zero Donaldson invariants. The homology spheres are the extra room that smooth 4-manifolds need.

Worked example 12.48: Splitting the elliptic surfaces: nucleus and Milnor fibre

The elliptic surfaces $E(n)$ (with $E(1) = \mathbb{CP}^2 \# 9\overline{\mathbb{CP}}^2$ and $E(2) = \mathrm{K3}$) contain a torus fibre F and a sphere section S with

$$F \cdot F = 0, \qquad F \cdot S = 1, \qquad S \cdot S = -n.$$

A neighbourhood of $F \cup S$ is a 4-manifold with boundary, the **nucleus** $N(n)$. Its boundary is the Brieskorn sphere $\Sigma(2,3,6n-1)$, and its complement is the **Milnor fibre** $M(2,3,6n-1)$ of the singularity $z_1^2 + z_2^3 + z_3^{6n-1} = 0$. So

$$E(n) = N(n) \cup_{\Sigma(2,3,6n-1)} M(2,3,6n-1)$$

is a splitting of exactly Nash's kind. Let us check that the forms fit.

The nucleus. In the basis (F, S) the form is $Q_{N(n)} = \begin{pmatrix} 0 & 1 \\ 1 & -n \end{pmatrix}$, with determinant -1: unimodular, as it must be for a manifold bounded by a homology sphere. For $n = 2$ change basis to $e_1 = F$, $e_2 = S + F$:

$$e_2 \cdot e_2 \overset{(1)}{=} S \cdot S + 2\,S \cdot F + F \cdot F \overset{(2)}{=} -2 + 2 + 0 = 0,$$
$$e_1 \cdot e_2 \overset{(1)}{=} F \cdot S + F \cdot F \overset{(2)}{=} 1,$$

(1) Bilinearity and symmetry of the intersection form.
(2) The values $F^2 = 0$, $F \cdot S = 1$, $S^2 = -2$.

so $Q_{N(2)} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = H$, the hyperbolic form of $S^2 \times S^2$ (Example 12.28), with $b_2^+ = b_2^- = 1$. For $n = 1$ the same change of basis gives $e_2 \cdot e_2 = -1 + 2 = 1$ and $S \cdot e_2 = -1 + 1 = 0$, so in the basis $(S, S + F)$ one finds $Q_{N(1)} = \mathrm{diag}(-1, 1)$.

The Milnor fibre. Its rank is the Milnor number $\mu = (p-1)(q-1)(r-1)$. For $(2,3,11)$ this is $1 \cdot 2 \cdot 10 = 20$, and for $(2,3,5)$ it is $1 \cdot 2 \cdot 4 = 8$.

The bookkeeping for K3. $b_2(\mathrm{K3}) = 22 = 2+20$, and the signature is $-16 = 0+\tau(M(2,3,11))$, so the Milnor fibre has $b_2^+ = 2$, $b_2^- = 18$, and (being even) $Q_{M(2,3,11)} = 2H \oplus 2(-E_8)$. Altogether

$$Q(\mathrm{K3}) = \underbrace{H}_{N(2)} \oplus \underbrace{2H \oplus 2(-E_8)}_{M(2,3,11)} = 3H \oplus 2(-E_8),$$

in agreement with Table 12.1, and by (12.121) $b_2^+ = 1+2 = 3$. *Both sides have* $b_2^+ > 0$: this is a splitting of the type Nash needs, along $N = \Sigma(2,3,11)$.
The bookkeeping for $E(1)$. Here $(1) \oplus 9(-1) = \mathrm{diag}(-1,1) \oplus (-E_8)$ over the integers (both are odd, indefinite, unimodular, of rank 10 and signature -8), with the $-E_8$ carried by $M(2,3,5)$, the E_8 plumbing bounded by the Poincaré sphere. The Milnor-fibre side now has $b_2^+ = 0$, so this splitting does *not* satisfy Nash's hypothesis.

12.8.2 Instantons on a manifold with a cylindrical end

Nash says that on $M^\pm$ "boundary conditions are required since the $M^\pm$ are not closed. The boundary conditions are just the specifying of a connection on the boundaries." Let us make this precise, because the precise version is what makes everything work.

Stretch the neck

The Donaldson invariants do not depend on the metric (Section 12.7.3 and Section 12.8.8). So we may choose a metric on M that is a product $\mathrm{d}t^2 + g_N$ on a long neck $N \times [-T, T]$, and let $T \to \infty$. In the limit each half acquires an infinite cylindrical end (bottom of Figure 12.33):

$$\widehat{M}^+ = M^+ \cup_N \big(N \times [0,\infty)\big), \qquad \widehat{M}^- = \big(N \times (-\infty, 0]\big) \cup_N M^-.$$

On the cylindrical part of $\widehat{M}^+$ everything is as in Section 12.4.2: in temporal gauge an ASD connection is a path $A(t)$ of connections on N with

$$\frac{\mathrm{d}A}{\mathrm{d}t} = -\star_N F_{A(t)} = -4\pi^2 \operatorname{grad} f\big(A(t)\big) \tag{12.122}$$

by (12.45) and (12.39). So an instanton on $\widehat{M}^+$ is "an instanton on M^+ with a Chern–Simons gradient flow line attached".

Finite action forces a flat limit

Finite Yang–Mills action on the end means $\int_0^\infty \|\dot{A}\|^2 \,\mathrm{d}t < \infty$. Along a gradient flow the action on $[t_1, t_2]$ is the drop of f (the same chain as (12.48)), so $f(A(t))$ decreases and converges. Then $\|\dot{A}\|^2 = \|\star F\|^2 \to 0$ along a sequence of times, and with the compactness of the space of flat connections one shows

$$\lim_{t\to\infty} A(t) = \alpha, \qquad \alpha \text{ a flat connection on } N. \tag{12.123}$$

This is the four-dimensional statement "finite action forces the field strength to vanish at infinity", which for $\mathbb{R}^4$ gave the pure-gauge boundary condition of the BPST instanton (Chapter 8). Here the "sphere at infinity" is N, and "pure gauge" is replaced by "flat", because N has non-trivial flat connections.

So Nash's "boundary condition" is: *choose the limiting flat connection*. For each $\alpha \in \mathcal{R}^*(N)$ (the irreducible flat connections of (12.27), perturbed if necessary so that each is non-degenerate) define

$$\mathcal{M}(M^+;\alpha) := \big\{A \text{ ASD on } \widehat{M}^+,\ \ \|F_A\| < \infty,\ \ A(t) \to \alpha \text{ as } t \to \infty\big\}/\mathcal{G}, \tag{12.124}$$

and similarly $\mathcal{M}(M^-;\alpha)$ with $A(t) \to \alpha$ as $t \to -\infty$ on $\widehat{M}^-$. These are Nash's solution sets $C^{\pm}$: more precisely, C^+ is the collection of all the $\mathcal{M}(M^+;\alpha)$ as α varies.

Working definition 12.13 (The moduli space of a manifold with a cylindrical end)

To describe $\mathcal{M}(M^+;\alpha)$:

1. Attach $N \times [0,\infty)$ to M^+ and use a product metric there [$g_N + \mathrm{d}t^2$, the same metric on every slice $N \times \{t\}$].
2. Solve $F_A^+ = 0$ [the self-dual part of the curvature vanishes, so A is an instanton] with finite action. On the end, the solution is a Chern–Simons flow line (12.122).
3. Record its limit $\alpha = \lim_{t\to\infty} A(t)$, a flat connection on N. Group the solutions by their limit.
4. The dimension of $\mathcal{M}(M^+;\alpha)$ is the index of the linearised operator [independent solutions of the linearised instanton equation, minus independent obstructions] (Section 12.4.4) with decay at the end; it depends on α through its Floer degree [the $\mathbb{Z}_8$ grading $\mu(\alpha)$ fixed by spectral flow], as in (12.127) below.

The charge becomes fractional

On a closed manifold the instanton number k is an integer. On $\widehat{M}^+$ it is not, and the Chern–Simons function tells us exactly what it is. Recall the local identity $\operatorname{tr}(F\wedge F) = \mathrm{d}\operatorname{tr}\big(A\wedge\mathrm{d}A + \frac{2}{3}A\wedge A\wedge A\big)$ ((12.16)), and $f(A) = -\frac{1}{8\pi^2}\int_N \operatorname{tr}\big(A\mathrm{d}A + \frac{2}{3}A^3\big)$. Suppose first that the bundle over $\widehat{M}^+$ is trivialised, so that A is a global 1-form. Truncating the end at $t = T$,

$$\begin{aligned}\frac{1}{8\pi^2}\int_{M^+\cup N\times[0,T]} \operatorname{tr}(F\wedge F) &\overset{(1)}{=} \frac{1}{8\pi^2}\int_{\partial(M^+\cup N\times[0,T])} \operatorname{tr}\big(A\mathrm{d}A + \tfrac{2}{3}A^3\big)\\ &\overset{(2)}{=} \frac{1}{8\pi^2}\int_{N\times\{T\}} \operatorname{tr}\big(A\mathrm{d}A + \tfrac{2}{3}A^3\big) \overset{(3)}{=} -f\big(A(T)\big) \xrightarrow{T\to\infty} -f(\alpha).\end{aligned} \tag{12.125}$$

(1) Stokes' theorem applied to the transgression formula.
(2) The only boundary is $N \times \{T\}$, with the orientation $+N$ (outward normal $+\partial_t$, as in the pitfall above).
(3) Definition of f.

In general the bundle over $\widehat{M}^+$ need not be trivial, and trivialising it near the end changes f by an integer ((12.17)). So the charge on $\widehat{M}^+$ satisfies

$$k^+ \equiv -f(\alpha) \pmod 1, \qquad \text{and likewise} \qquad k^- \equiv +f(\alpha) \pmod 1, \tag{12.126}$$

the sign flipping because $\partial\widehat{M}^- = \overline{N}$. When we glue, the total charge $k = k^+ + k^-$ is an integer again, as it must be.

Worked example 12.49: Fractional instantons ending on the Poincaré sphere

The Poincaré sphere $\Sigma(2,3,5)$ has two irreducible flat connections, ρ_1 and ρ_2 (Example 12.11). Their Chern–Simons values were computed by Fintushel and Stern; in one common normalisation

$$f(\rho_1) \equiv \tfrac{1}{120}, \qquad f(\rho_2) \equiv \tfrac{49}{120} \pmod 1.$$

(The denominators are $120 = |\pi_1(\Sigma(2,3,5))|$, the order of the binary icosahedral group, which is no accident: a flat connection is a representation of π_1, and $120\,f$ is an integer invariant of it.) So by (12.126) an instanton on a manifold with a $\Sigma(2,3,5)$-end limiting to ρ_1 carries charge $k^+ \in -\frac{1}{120} + \mathbb{Z}$, e.g. $k^+ = \frac{119}{120}$. Gluing it to an instanton on the other side with $k^- \in \frac{1}{120} + \mathbb{Z}$ gives an integer total. The Chern–Simons function on the gluing surface tells the two halves how to share the charge.

Dimensions: the Floer grading reappears

What is $\dim \mathcal{M}(M^+;\alpha)$, and how does it depend on α? The cleanest way to see it is to glue a flow line onto the end. Suppose $u \in \mathcal{M}(M^+;\alpha)$ and γ is a flow line on $N \times \mathbb{R}$ from α to β. Placing γ far down the end of $\widehat{M}^+$, after u has settled down to α, gives an approximate instanton limiting to β, which can be corrected to an exact one (this is the gluing construction of Section 12.5.1). So families glue, and dimensions add (the index is additive under gluing along a non-degenerate irreducible α):

$$\dim \mathcal{M}(M^+;\beta) = \dim \mathcal{M}(M^+;\alpha) + \sigma(\alpha,\beta), \tag{12.127}$$

where $\sigma(\alpha,\beta) = \dim \mathcal{M}(\alpha,\beta)$ is the relative Morse index ((12.52)), i.e. the spectral flow of the curl operator $\star \mathrm{d}_A$. Since $\sigma(\alpha,\beta) \equiv \mu(\alpha) - \mu(\beta) \pmod 8$ (12.59), we get

$$\dim \mathcal{M}(M^+;\alpha) + \mu(\alpha) \equiv \text{a constant} \pmod 8,$$

the constant depending only on M^+. *The limiting flat connections of the zero-dimensional moduli spaces all have the same Floer degree mod 8.* This is why the class we are about to build is homogeneous.

On the closed manifold, the same additivity gives the dimension of the glued moduli space. The general formula for gluing along a flat connection α is

$$\dim \mathcal{M}_k(M) = \dim \mathcal{M}(M^+;\alpha) + \dim \mathcal{M}(M^-;\alpha) + \dim H^0_\alpha + \dim H^1_\alpha, \tag{12.128}$$

where $H^0_\alpha = \operatorname{Ker} \mathrm{d}_\alpha$ on $\Omega^0(\mathfrak{su}(2))$ is the Lie algebra of the stabiliser of α, and $H^1_\alpha = \operatorname{Ker}(\star \mathrm{d}_\alpha)$ on $\operatorname{Ker} \mathrm{d}^*_\alpha$ is the space of flat deformations. The two corrections count the gluing parameters: a rotation of one half relative to the other by an element of the stabiliser, and a flat deformation of the neck.

Worked example 12.50: The two extreme cases: irreducible α and S^3

Irreducible, non-degenerate α. Irreducible means the stabiliser is the centre $\{\pm\mathbb{1}\}$, which is discrete, so $H^0_\alpha = 0$. Non-degenerate means the Hessian $\star \mathrm{d}_\alpha$ has no kernel on $\operatorname{Ker} \mathrm{d}^*_\alpha$, so $H^1_\alpha = 0$ (Section 12.3.3). Then (12.128) reads

$$\dim \mathcal{M}_k(M) = \dim \mathcal{M}(M^+;\alpha) + \dim \mathcal{M}(M^-;\alpha)\,:$$

no gluing parameters. The two halves lock together rigidly.
The connected sum, $N = S^3$. The only flat connection is the trivial one, θ. Its stabiliser is all of SU(2), so $H^0_\theta = \mathfrak{su}(2)$ has dimension 3; and $H^1_\theta = H^1(S^3) \otimes \mathfrak{su}(2) = 0$. Writing

$D_i = \dim \mathcal{M}_{k_i}(M_i)$ for the closed pieces,

$$\dim \mathcal{M}_k(M_1 \# M_2) \overset{(1)}{=} D_1 + D_2 + \dim H^0_\theta + \dim H^1_\theta$$
$$\overset{(2)}{=} D_1 + D_2 + 3.$$

(1) (12.128), with $\mathcal{M}(M_i \setminus B^4; \theta) \cong \mathcal{M}_{k_i}(M_i)$ (an instanton on a punctured manifold with finite action extends over the puncture, by removable singularities).
(2) $\dim \mathfrak{su}(2) = 3$ and $H^1(S^3) = 0$.

This is exactly the count of (12.101): the "+3" there is the SO(3) of gluing parameters, and it is the reason the invariants of a connected sum vanish. In Floer's language the same fact appears as $HF_*(S^3) = 0$, because the reducible θ is not a generator of the Floer complex (Example 12.21).

12.8.3 The Floer classes $[C^\pm]$

Nash writes (12.62): "The boundary conditions allow us to construct two Floer homology classes $[C^\mp] \in HF(N^\mp)$." Here is the construction, in the simplest case where no surfaces are used to cut down ($d = 0$). The general case is in Section 12.8.6.

Counting the rigid instantons on $\widehat{M}^+$

For each generator α of the Floer complex (12.60) of N, consider the moduli spaces $\mathcal{M}(M^+; \alpha)$ that are zero-dimensional. For generic metrics they are finite sets of points, each with a sign ± 1 from an orientation (the same signs as in (12.61)). Let $\#\mathcal{M}(M^+; \alpha)^0$ be the signed count, taken to be 0 when the moduli space is not zero-dimensional. Define the Floer chain

$$\psi^+ := \sum_{\alpha \in \mathcal{R}^*(N)} \#\mathcal{M}(M^+; \alpha)^0 \, \alpha \ \in C_*(N). \tag{12.129}$$

By the dimension formula (12.127), all the α that appear have the same degree, so $\psi^+ \in C_p(N)$ for one $p \in \mathbb{Z}_8$.

Key idea: The rigid instantons form a cycle

$\partial\psi^+ = 0$. So ψ^+ defines a Floer homology class

$$[C^+] := [\psi^+] \in HF_p(N).$$

It does not depend on the metric on M^+ (or on the other choices), because changing them changes ψ^+ by a boundary.

Why $\partial\psi^+ = 0$. This is the same mechanism as $\partial^2 = 0$ in Section 12.5.1: *a compact 1-manifold has an even number of ends, which cancel in pairs when counted with orientation*. Fix a generator β one degree below the α's, and look at the one-dimensional moduli space $\mathcal{M}(M^+; \beta)^1$. It is a 1-manifold, not compact, and its non-compactness is completely described: a sequence of instantons in it can only break by sending energy down the end. The limit is a *broken configuration*: a rigid instanton $u \in \mathcal{M}(M^+; \alpha)^0$ followed by a rigid flow line $\gamma \in \widehat{\mathcal{M}}(\alpha, \beta)$ on $N \times \mathbb{R}$ (Figure 12.34). (Bubbling is excluded in such low dimensions; the dimension count is the one of Section 12.6.5.) Conversely every broken configuration is the end of exactly one

component, by gluing. So

$$\begin{aligned} 0 &\overset{(1)}{=} \#\big(\text{oriented ends of } \mathcal{M}(M^+;\beta)^1\big) \\ &\overset{(2)}{=} \sum_{\alpha} \#\mathcal{M}(M^+;\alpha)^0 \cdot n(\alpha,\beta) \\ &\overset{(3)}{=} \big(\text{coefficient of } \beta \text{ in } \partial\psi^+\big). \end{aligned} \tag{12.130}$$

(1) A compact oriented 1-manifold with boundary is a disjoint union of closed intervals and circles; each interval has one end counted +1 and one counted −1.

(2) The ends are the broken configurations (u,γ), and the sign of an end is the product of the signs of u and γ; for fixed α there are $\#\mathcal{M}(M^+;\alpha)^0$ choices of u and $n(\alpha,\beta)$ (signed) choices of γ.

(3) By (12.62), $\partial\psi^+ = \sum_\alpha \psi^+_\alpha\,\partial\alpha = \sum_\beta\big(\sum_\alpha \psi^+_\alpha n(\alpha,\beta)\big)\beta$.

Every coefficient vanishes, so $\partial\psi^+ = 0$.

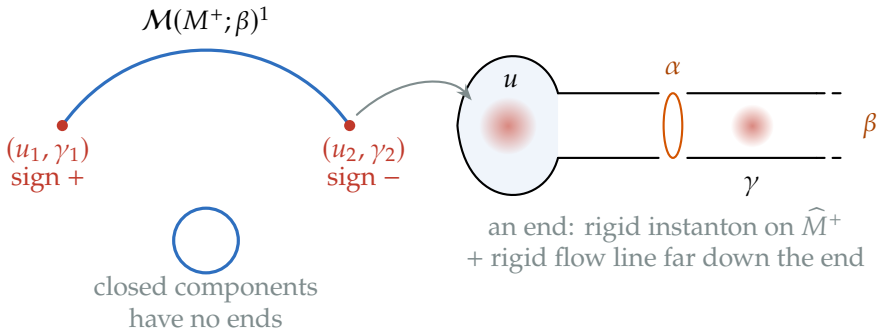

Figure 12.34: Why ψ^+ is a Floer cycle. The one-dimensional moduli space $\mathcal{M}(M^+;\beta)^1$ is a union of arcs and circles. Each end of an arc is a broken configuration: a rigid instanton u on $\widehat{M}^+$ limiting to α, followed by a rigid flow line γ from α to β that has slid infinitely far down the end. The ends of each arc cancel, and the total count of ends is the coefficient of β in $\partial\psi^+$.

Worked example 12.51: A cycle condition in numbers

Suppose N had three generators, α_1,α_2 in degree p and β in degree $p-1$, with instanton counts $n(\alpha_1,\beta)=1$ and $n(\alpha_2,\beta)=2$. The Floer complex in these degrees is

$$C_p = \mathbb{Z}\alpha_1 \oplus \mathbb{Z}\alpha_2 \xrightarrow{\partial=(1\ \ 2)} C_{p-1} = \mathbb{Z}\beta.$$

Then $\operatorname{Ker}\partial$ is spanned by $2\alpha_1-\alpha_2$. The rigid-instanton chain $\psi^+ = a\,\alpha_1 + b\,\alpha_2$ of *any* manifold M^+ bounded by N (with these degrees) is forced by (12.130) to satisfy $a+2b=0$: the instanton counts on the two halves are not independent, they are constrained by the counts on the neck. For instance $\psi^+ = 2\alpha_1-\alpha_2$ is allowed, and $\psi^+=\alpha_1$ is not.

Independence of choices

Change the metric on M^+ along a path g_s, $s\in[0,1]$. The parametrised moduli space $\bigcup_s \mathcal{M}_{g_s}(M^+;\alpha)\times\{s\}$ is one dimension bigger. Its zero-dimensional part consists of isolated instantons that occur at special values of s with limit α' of degree $p+1$; count them to get a chain $\chi\in C_{p+1}(N)$. Counting the ends of the one-dimensional parametrised moduli spaces as above gives

$$\psi^+_{g_1} - \psi^+_{g_0} = \pm\,\partial\chi. \tag{12.131}$$

The ends are now of three kinds: the endpoints at $s = 0$ and $s = 1$ (contributing $\psi^+_{g_1} - \psi^+_{g_0}$) and the broken configurations at intermediate s (contributing $\partial\chi$). So the class $[\psi^+]$ is unchanged. This is the Floer-theoretic version of the metric independence of q_d, and it is the same "count the ends" argument once more.

The other half: a cocycle

On $\widehat{M}^-$ the end points the other way: the connection comes *from* α as $t \to -\infty$. A broken configuration now consists of a flow line γ from β to α *followed* by a rigid instanton on $\widehat{M}^-$ limiting to α. Define

$$\phi^- := \sum_\alpha \#\mathcal{M}(M^-;\alpha)^0 \; \alpha^*,$$

a linear function on $C_*(N)$ ($\alpha^*(\beta) = \delta_{\alpha\beta}$). The count of ends of $\mathcal{M}(M^-;\beta)^1$ gives $\sum_\alpha n(\beta,\alpha)\,\phi^-_\alpha = 0$ for every β, i.e.

$$\phi^- \circ \partial = 0 : \tag{12.132}$$

ϕ^- is a *cocycle*, and defines a class in Floer *cohomology* $HF^*(N)$. Reversing the orientation of N turns the flow of f into the flow of $-f$ and exchanges "down" with "up", so $HF^*(N)$ is the same thing as the Floer homology of $\overline{N}$ up to a shift of the grading (Example 12.24). This is Nash's remark that $N^\pm$ "inherit opposite orientations from M and so the $HF(N^\mp)$ are dual to one another":

$$[C^+] \in HF_*(N), \qquad [C^-] \in HF_*(\overline{N}) \cong HF^*(N) \;\text{ (up to a grading shift).} \tag{12.133}$$

12.8.4 The pairing formula

We can now read Nash's (12.61) and (12.63).

$C^+ \cap C^- = \mathcal{M}_k$

An instanton on the closed manifold M with a very long neck looks, on each half, like an instanton on $\widehat{M}^\pm$, and on the neck like a nearly flat connection $\approx \alpha$. Conversely, if $u^+ \in \mathcal{M}(M^+;\alpha)$ and $u^- \in \mathcal{M}(M^-;\alpha)$ have the *same* limit α, they can be glued across the neck into an instanton on M. So, for a long enough neck,

$$\mathcal{M}_k(M) \;\cong\; \bigcup_\alpha \mathcal{M}(M^+;\alpha) \times \mathcal{M}(M^-;\alpha) \qquad (\text{with } k^+ + k^- = k). \tag{12.134}$$

This is what Nash's (12.61), $C^+ \cap C^- = \mathcal{M}_k$, means: restrict each instanton on M^+ to the neck, and each on M^-; the instantons on M are the pairs whose restrictions *match*. If we think of $C^\pm$ as subsets of the space $\mathcal{B}^*(N)$ of connections on N modulo gauge (the boundary values), then $\mathcal{M}_k$ is literally their intersection. By Example 12.50 there are no extra gluing parameters, because α is irreducible.

The count

Take the case $\dim \mathcal{M}_k(M) = 0$. By (12.128) with $H^0_\alpha = H^1_\alpha = 0$, the only contributions come from α with $\dim \mathcal{M}(M^+;\alpha) + \dim \mathcal{M}(M^-;\alpha) = 0$. Generically a moduli space of negative dimension

is empty, so both must be zero-dimensional. Then

$$\begin{aligned} q_0(M) &\overset{(1)}{=} \#\mathcal{M}_k(M) \\ &\overset{(2)}{=} \sum_\alpha \#\mathcal{M}(M^+;\alpha)^0 \cdot \#\mathcal{M}(M^-;\alpha)^0 \\ &\overset{(3)}{=} \sum_\alpha \phi^-_\alpha \psi^+_\alpha \overset{(4)}{=} \phi^-(\psi^+) \overset{(5)}{=} \langle [C^-], [C^+] \rangle. \end{aligned} \tag{12.135}$$

(1) For $\dim \mathcal{M}_k = 0$ the invariant is the signed count of instantons (Section 12.8.5).
(2) The bijection (12.134), and the sign of a glued instanton is the product of the signs of its halves (orientations multiply under gluing).
(3) Definitions of ψ^+ (12.129) and ϕ^-.
(4) $\alpha^*(\beta) = \delta_{\alpha\beta}$.
(5) ψ^+ is a cycle and ϕ^- a cocycle, and the evaluation of a cocycle on a cycle depends only on their classes (next paragraph).

This is Nash's (12.63), $[C^+]\bullet[C^-] = q_d(M)$, with the pairing $\bullet$ being the evaluation of cohomology on homology, i.e. the Poincaré-duality pairing between $HF_*(N)$ and $HF_*(\overline{N})$.

Why the pairing is well defined on classes. If we change ψ^+ by a boundary and ϕ^- by a coboundary $\eta \circ \partial$,

$$\begin{aligned} (\phi^- + \eta\circ\partial)(\psi^+ + \partial\chi) &\overset{(1)}{=} \phi^-(\psi^+) + \phi^-(\partial\chi) + \eta(\partial\psi^+) + \eta(\partial\partial\chi) \\ &\overset{(2)}{=} \phi^-(\psi^+). \end{aligned}$$

(1) Linearity.
(2) $\phi^- \circ \partial = 0$ (12.132), $\partial\psi^+ = 0$ (12.130), and $\partial^2 = 0$.

This is the same algebra that made the Morse-theoretic pairing between cycles and cocycles well defined in Chapter 7.

Physical picture: The pairing as a transition amplitude

In the Hamiltonian picture of Section 12.5.5, the Floer groups are the zero-energy states of a supersymmetric theory on N. Then $[C^+]$ is the state that the path integral on M^+ prepares on its boundary, $|M^+\rangle \in \mathcal{H}_N$, and $[C^-]$ is the dual state $\langle M^-|$ prepared by the other half. The number of the closed manifold is the overlap,

$$q(M) = \langle M^-|M^+\rangle,$$

exactly as a Euclidean path integral over a spacetime cut along a time slice is $\langle \text{out}|(\text{evolution})|\text{in}\rangle$. With a long neck the evolution operator e^{-TH} projects onto $H = 0$, which is why only Floer homology (the zero-energy states) survives.

Worked example 12.52: Only one degree can contribute

Take $N = \Sigma(2,3,5)$ with $HF_* = \mathbb{Z}\rho_1 \oplus \mathbb{Z}\rho_2$ in degrees 1 and 5 (Example 12.21). Suppose $M = M^+ \cup_{\Sigma(2,3,5)} M^-$ and the rigid instantons on $\widehat{M}^+$ limit to degree-1 connections, with $\psi^+ = a\,\rho_1$ for an integer a. For the rigid instantons of $\widehat{M}^-$ to pair non-trivially with ψ^+ they must also limit to ρ_1: $\phi^- = c\,\rho_1^* + (\text{terms in } \rho_2^*)$. Then

$$q_0(M) \overset{(1)}{=} \phi^-(\psi^+) \overset{(2)}{=} c\,a\,\rho_1^*(\rho_1) = ac.$$

(1) (12.135).
(2) $\rho_2^*(\rho_1) = 0$.

The whole global count has become a product of two local counts, one on each side. If M^+ had only produced instantons ending on ρ_2, the invariant would vanish. (This example only illustrates the bookkeeping; we do not claim a specific M realising given a and c.)

The rest of Nash's discussion is about what this formula means: the simplest case $d = 0$, the two directions in which it can be read, and the generalisation to $d > 0$ with surfaces on both sides. We take these in turn.

12.8.5 The simplest case: $d = 0$ and a signed count of instantons

When is the moduli space a finite set?

The invariant q_d is a polynomial of degree $d = \frac{1}{2}\dim \mathcal{M}_k$ (12.94). The lowest possible degree is $d = 0$: a polynomial of degree zero is a constant, so $q_0(M)$ is a single integer. Nash's (12.64) is the condition for this to happen:

$$\dim \mathcal{M}_k = 8k - 3(1 + b_2^+) = 0. \tag{12.136}$$

Which manifolds allow it? Solve for b_2^+:

$$8k = 3(1 + b_2^+) \overset{(1)}{\Longrightarrow} 8 \mid 3(1 + b_2^+) \overset{(2)}{\Longrightarrow} 8 \mid (1 + b_2^+)$$
$$\overset{(3)}{\Longrightarrow} b_2^+ = 8j - 1, \qquad k = \tfrac{3(1+b_2^+)}{8} = 3j, \qquad j = 1, 2, 3, \ldots$$

(1) $8k$ is divisible by 8.
(2) $\gcd(3, 8) = 1$, so 8 divides the other factor.
(3) Write $1 + b_2^+ = 8j$ and solve for k.

So $b_2^+ \in \{7, 15, 23, \ldots\}$ with charges $k \in \{3, 6, 9, \ldots\}$. As a check, b_2^+ is odd, as it must be for $\dim \mathcal{M}_k$ to be even (Section 12.6.4).

Worked example 12.53: Which surfaces have a q_0?

For a simply connected complex surface $b_2^+ = 2p_g + 1$, where p_g is the number of independent holomorphic 2-forms (Section 12.6.6). The elliptic surfaces $E(n)$ have $p_g = n - 1$, hence

$$b_2^+\big(E(n)\big) = 2(n - 1) + 1 = 2n - 1,$$

which gives $1, 3, 5$ for $E(1) = \mathbb{CP}^2\#9\overline{\mathbb{CP}}^2$, $E(2) = \mathrm{K3}$ and $E(3)$, in agreement with Table 12.1 and Example 12.43. The condition $b_2^+ = 8j - 1$ becomes $2n - 1 = 8j - 1$, i.e. $n = 4j$. So:

manifold	b_2^+	k with $\dim \mathcal{M}_k = 0$	next dimensions
$E(4)$	7	3	$\dim \mathcal{M}_4 = 8$, $\dim \mathcal{M}_5 = 16$
$E(8)$	15	6	$\dim \mathcal{M}_7 = 8, \ldots$
$E(12)$	23	9	$\dim \mathcal{M}_{10} = 8, \ldots$

For $E(4)$ at $k = 3$ the "polynomial" $q_0(E(4))$ is a number: the signed number of charge-3 instantons for a generic metric. By the positivity theorem of Section 12.6.6 (for large enough k) the invariants of algebraic surfaces are non-zero; the number at $k = 3$ is not guaranteed by that theorem, which is why Nash writes "$q_d \neq 0$ for $d \geq d_0$".

The count, and the partition function

When $\dim \mathcal{M}_k = 0$ (and the metric is generic, and there are no reducibles), $\mathcal{M}_k$ is a finite set of points $\{A_1, \dots, A_r\}$; it is compact because bubbling would need 8 dimensions to spare (Section 12.6.5). The invariant is

$$q_0(M) = \sum_{i=1}^{r} \varepsilon_i, \qquad \varepsilon_i = (-1)^{n_i} \in \{\pm 1\}, \tag{12.137}$$

where ε_i is the orientation of $\mathcal{M}_k$ at A_i. Orienting a point means choosing a sign. Here it is the sign of the determinant of the linearised operator $D_{A_i} = \mathrm{d}^*_{A_i} \oplus \mathrm{d}^+_{A_i}$ of (12.79), measured against a reference, and the reference is fixed once and for all by orienting the space $H^2_+(M)$ of self-dual harmonic forms (a **homology orientation**).

From the field-theory side this is the partition function. In Witten's theory a correlation function $\langle P \rangle$ is non-zero only when $U(P) = \dim \mathcal{M}_k$ (12.111). For $\dim \mathcal{M}_k = 0$ the observable is $P = 1$, and $\langle 1 \rangle$ is the partition function Z. Localisation (12.110) sums over the classical minima, and each isolated minimum contributes the ratio of the fermion determinant to the square root of the boson determinant, which is ± 1 because the non-zero eigenvalues pair up. This gives Nash's (12.65):

$$Z = \sum_i (-1)^{n_i}, \qquad n_i \in \{0, 1\}. \tag{12.138}$$

This is the four-dimensional version of the toy model of Example 12.46, $Z = \sum_j \operatorname{sgn} s'(x_j)$ (12.108): there the sign was the sign of the "fermion determinant" $s'(x_j)$, here it is the sign of $\det D_{A_i}$.

Watch out: Why the answer is a signed count, not a count

The unsigned number r of instantons does depend on the metric: as the metric moves, pairs of instantons can be born or annihilate, exactly as a pair of zeros of $s(x)$ in the toy model can appear when a local minimum of s dips below the axis. At such a birth the two new instantons have opposite signs. So r jumps by 2 while $\sum \varepsilon_i$ does not change. Only the signed count is an invariant.

Middle-dimensional intersections

Nash's formula (12.63) at $d = 0$ says that the signed sum (12.137) is also the *intersection pairing* of the two Floer classes, and he concludes that the Floer groups behave like the "middle-dimensional" homology of $\mathcal{A}/\mathcal{G}$. Here is a finite-dimensional model of what this means.

On a closed oriented manifold X of dimension $2m$, two cycles of the middle dimension m generically meet in isolated points. Each point gets a sign: $+1$ if a positive basis of the first cycle's tangent space followed by a positive basis of the second's is a positive basis of TX, and -1 otherwise. The signed count is the **intersection number** $a \cdot b$, which depends only on the homology classes. The intersection form of a 4-manifold (Section 12.6.1) is the case $m = 2$.

Worked example 12.54: Curves on the torus

Take $X = T^2 = \mathbb{R}^2/\mathbb{Z}^2$, $m = 1$. A closed curve of homology class (p, q) winds p times in the x-direction and q times in the y-direction; the straight line of slope q/p represents it. Two

straight curves of classes (p,q) and (r,s) meet in $|ps-qr|$ points, all with the same sign, so

$$(p,q)\cdot(r,s) \overset{(1)}{=} \det\begin{pmatrix} p & r \\ q & s \end{pmatrix} = ps - qr.$$

(1) At each crossing the sign compares the ordered pair of tangent vectors $\big((p,q),(r,s)\big)$ with the standard orientation (∂_x,∂_y), which is the sign of this determinant; the number of crossings is $|\det|$ because the linear map with these columns has degree det on the torus.

For $a=(1,0)$ and $b=(0,1)$ this is 1. Now wiggle a into the curve a' of Figure 12.35: it now crosses b three times, with signs $+,-,+$. The count of points went from 1 to 3, but

$$a'\cdot b = (+1)+(-1)+(+1) = 1 = a\cdot b.$$

The wiggle created a cancelling pair, exactly as in the pitfall above.

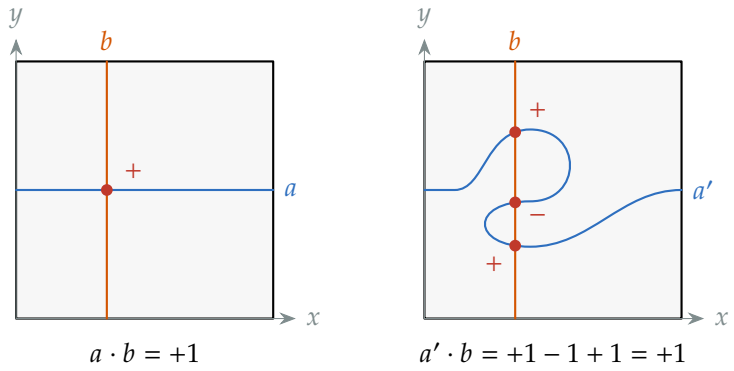

Figure 12.35: The finite-dimensional model of (12.63) at $d=0$. On the torus (opposite sides identified), two middle-dimensional cycles meet in isolated points with signs. Deforming a into a' creates two new crossings of opposite sign; the signed count is unchanged. In gauge theory the cycles are the boundary values $C^{\pm}$ of instantons on the two halves, the ambient space is $\mathcal{A}/\mathcal{G}$ of the gluing surface, and the crossings are the instantons on the closed manifold.

In the gauge-theory problem, C^+ and C^- are sets of boundary values on N, i.e. subsets of $\mathcal{B}^*(N)=\mathcal{A}^*/\mathcal{G}$ of the gluing surface, and $\mathcal{M}_k = C^+\cap C^-$ (12.134). Both $C^{\pm}$ are infinite-dimensional *and* of infinite codimension: roughly, C^+ contains the connections on N that extend as instantons over M^+, which is "half" of all connections, in the sense that the Hessian of f has infinitely many positive and infinitely many negative directions and C^+ is tangent to one half. Ordinary homology cannot measure such "semi-infinite" cycles. Floer homology can: its grading is a *relative* index (Section 12.3.4), exactly what is needed to say which semi-infinite cycles can intersect in points. That is the sense in which $HF_*(N)$ is the middle-dimensional homology of $\mathcal{A}/\mathcal{G}$.

Physical picture: The Atiyah–Floer picture

There is a finite-dimensional version of this which one can actually draw. Casson's construction (Section 12.5.3) splits N along a surface Σ_g into two handlebodies. The flat SU(2) connections on Σ_g form a space $\mathcal{R}(\Sigma_g)$ of dimension $6g-6$, and those extending over each handlebody form two subspaces of dimension $3g-3$: *exactly half*. Their intersection points are the flat connections on N, and half their signed count is the Casson invariant (12.69). The **Atiyah–Floer conjecture** says that the Floer homology of N is the

Floer homology of this pair of half-dimensional (Lagrangian) submanifolds. The same "half-dimensional cycles and their intersections" structure appears one dimension up, in (12.63).

Reading (12.63) in both directions

Nash stresses that $[C^+] \bullet [C^-] = q_d(M)$ carries information both ways.

From Donaldson to Floer. Suppose $q_d(M) \neq 0$ for some d, and $M = M^+ \cup_h M^-$ with $b_2^+(M^\pm) > 0$. Then

$$0 \neq q_d(M) \overset{(1)}{=} \langle [C^-], [C^+] \rangle \quad \Longrightarrow \quad [C^+] \neq 0 \quad \Longrightarrow \quad HF_*(N) \neq 0.$$

(1) Nash's (12.63), in the form (12.135) (and its generalisation (12.142) below for $d > 0$).

So every homology sphere along which one can cut an algebraic surface (into pieces with $b_2^+ > 0$) has non-zero Floer homology. The hypothesis $b_2^+(M^\pm) > 0$ is there for the same reason as on closed manifolds: it keeps reducible instantons out of the moduli spaces of the pieces, so that the relative invariants are defined.

Worked example 12.55: K3 and the Brieskorn sphere $\Sigma(2,3,11)$

By Example 12.48, K3 $= N(2) \cup_{\Sigma(2,3,11)} M(2,3,11)$ with $b_2^+ = 1$ and 2 on the two sides. The Donaldson invariants of K3 are non-zero (it is an algebraic surface; the first one, at $k = 2$, has $\dim \mathcal{M}_2 = 4$ and $d = 2$). So the argument above predicts $HF_*(\Sigma(2,3,11)) \neq 0$. Check it independently with Casson's invariant. For Brieskorn spheres Fintushel and Stern showed $\lambda(\Sigma(p,q,r)) = \frac{1}{8}\tau\big(M(p,q,r)\big)$, the signature of the Milnor fibre over 8. Then

$$\chi_F\big(\Sigma(2,3,11)\big) \overset{(1)}{=} 2\lambda\big(\Sigma(2,3,11)\big) \overset{(2)}{=} 2 \cdot \tfrac{1}{8}\tau\big(M(2,3,11)\big) \overset{(3)}{=} 2 \cdot \tfrac{-16}{8} = -4 \neq 0.$$

(1) Taubes' theorem (12.68).
(2) The Fintushel–Stern formula quoted above.
(3) $\tau(M(2,3,11)) = -16$ from Example 12.48.

A non-zero Euler characteristic forces a non-zero group. (The same formula for $\Sigma(2,3,5)$ gives $\chi_F = 2 \cdot (-8)/8 = -2$, matching Example 12.21.) In fact all four irreducible flat connections of $\Sigma(2,3,11)$ have odd degree, so by Example 12.22 $HF_*(\Sigma(2,3,11))$ is free of rank 4.

From Floer to Donaldson. Suppose instead that the gluing surface is a genuine 3-sphere, so $M^+ \cup_h M^- = \widehat{M}^+ \# \widehat{M}^-$ with $\widehat{M}^\pm$ the closed manifolds obtained by capping off with balls. Then

$$q_d(M) \overset{(1)}{=} \langle [C^-], [C^+] \rangle \overset{(2)}{=} \langle 0, 0 \rangle = 0.$$

(1) Nash's (12.63).
(2) $HF_*(S^3) = 0$ (Example 12.21): there are no irreducible flat connections on S^3, so every Floer class is zero.

This recovers the connected-sum vanishing theorem (12.55) of Section 12.6.6. The two proofs are the same proof: in (12.101) the obstruction was the SO(3) of gluing parameters of the reducible θ; here it is the absence of θ from the Floer complex (Example 12.50).

12.8.6 Relative invariants and the evaluation rule

For $d > 0$ we must cut the moduli spaces down by the divisors V_a, $a \in H_2(M)$ (Section 12.6.4), and it matters on which side of N each surface lies.

Polynomials on $H_2(M^+)$ with values in $HF_*(N)$

The key property is locality: V_a is defined by what the connection does near a surface representing a (Section 12.6.3). If $a \in H_2(M^+)$, pick the surface inside M^+; then V_a only constrains the M^+-half of a glued instanton. So for $a_1, \dots, a_i \in H_2(M^+)$ define, generalising (12.129),

$$q^i(M^+)(a_1, \dots, a_i) := \sum_{\alpha} \#\big(\mathcal{M}(M^+;\alpha) \cap V_{a_1} \cap \cdots \cap V_{a_i}\big)\, \alpha, \tag{12.139}$$

where only the α with $\dim \mathcal{M}(M^+;\alpha) = 2i$ contribute (each divisor cuts down 2 dimensions, so the intersection is a finite set of signed points). The same "count the ends" argument as in (12.130), now applied to the one-dimensional cut-down moduli spaces, shows that (12.139) is a cycle. Its class

$$q^i(M^+)(a_1, \dots, a_i) \in HF_*(N)$$

is symmetric and multilinear in the a's. These are Nash's **relative Donaldson invariants**. They are polynomials in the variables (12.68)

$$\underbrace{H_2(M^+) \times \cdots \times H_2(M^+)}_{i \text{ factors}},$$

but their values are *not* numbers: they are Floer homology classes of the boundary. This is the precise meaning of Nash's statement that "the relative Donaldson invariants for a non-closed manifold are not integer valued, but rather take values in the Floer groups of its boundary". The $d = 0$ class $[C^+]$ of Section 12.8.3 is $q^0(M^+)$. Similarly $q^j(M^-)$ takes values in the dual group $HF^*(N)$.

Symmetric powers split: (12.66)–(12.67)

A symmetric multilinear function of d arguments in $H = H_2(M)$ is the same as a linear function on the **symmetric power** $\mathrm{Sym}^d H$. Concretely: if $x_1, \dots, x_n$ are coordinates on H (a basis of the dual), Sym^d is the space of homogeneous polynomials of degree d in the x's, with basis the monomials $x_1^{e_1} \cdots x_n^{e_n}$, $e_1 + \cdots + e_n = d$. Counting monomials ("d stars and $n-1$ bars"):

$$\dim \mathrm{Sym}^d(\mathbb{R}^n) = \binom{n+d-1}{d}. \tag{12.140}$$

Nash applies the splitting (12.119) $H = V \oplus W$, with $V = H_2(M^+)$ and $W = H_2(M^-)$, to the d-fold product (12.66). Every monomial in the coordinates x on V and y on W factors uniquely as (a monomial of degree i in x)×(a monomial of degree $d-i$ in y). So (Nash's (12.67))

$$\mathrm{Sym}^d(V \oplus W) = \bigoplus_{i=0}^{d} \mathrm{Sym}^i(V) \otimes \mathrm{Sym}^{d-i}(W). \tag{12.141}$$

Nash writes the sum as $\sum_i \mathrm{Sym}^i \mathrm{Sym}^{d-i}$; the product of the two factors is a tensor product.

Worked example 12.56: Checking the splitting by counting

Take $V = \mathbb{R}^2$ with coordinates x_1, x_2, $W = \mathbb{R}$ with coordinate y, and $d = 2$. The left side of (12.141) has the basis $x_1^2,\ x_1x_2,\ x_2^2,\ x_1y,\ x_2y,\ y^2$, six monomials, in agreement with (12.140): $\binom{3+2-1}{2} = \binom{4}{2} = 6$. Sorting them by their degree i in the x's:

$$\begin{aligned}\dim \mathrm{Sym}^2(V\oplus W) &\overset{(1)}{=} \dim\big(\mathrm{Sym}^2V\otimes\mathrm{Sym}^0W\big) + \dim\big(\mathrm{Sym}^1V\otimes\mathrm{Sym}^1W\big)\\ &\quad + \dim\big(\mathrm{Sym}^0V\otimes\mathrm{Sym}^2W\big)\\ &\overset{(2)}{=} 3\cdot 1 + 2\cdot 1 + 1\cdot 1 = 6.\end{aligned}$$

(1) (12.141); dim of a direct sum adds, of a tensor product multiplies.
(2) $\{x_1^2, x_1x_2, x_2^2\}$, $\{x_1y, x_2y\}$, $\{y^2\}$, with (12.140) for each factor.

In general the count is the identity $\binom{m+n+d-1}{d} = \sum_i \binom{m+i-1}{i}\binom{n+d-i-1}{d-i}$ (a form of Vandermonde's identity), which is (12.141) with $\dim V = m$, $\dim W = n$.

The evaluation rule (12.69)

Now evaluate $q_d(M)$ on a class $x = x^+ + x^-$ with $x^\pm \in H_2(M^\pm)$. As a homogeneous polynomial, $q_d(M)(x)$ means the symmetric multilinear form with all d arguments equal to x. Then

$$\begin{aligned}q_d(M)(x^+ + x^-) &\overset{(1)}{=} \sum_{S\subset\{1,\dots,d\}} q_d(M)\big(y_1^S,\dots,y_d^S\big), \qquad y_j^S = \begin{cases} x^+, & j\in S\\ x^-, & j\notin S\end{cases}\\ &\overset{(2)}{=} \sum_{i=0}^{d}\binom{d}{i}\, q_d(M)(\underbrace{x^+,\dots,x^+}_{i},\underbrace{x^-,\dots,x^-}_{d-i})\\ &\overset{(3)}{=} \sum_{i=0}^{d}\binom{d}{i}\Big\langle q^{d-i}(M^-)(x^-,\dots,x^-),\ q^i(M^+)(x^+,\dots,x^+)\Big\rangle. \end{aligned}\tag{12.142}$$

(1) Multilinearity: expand each of the d slots into its x^+ and x^- parts, giving 2^d terms, one for each subset S of slots filled with x^+.
(2) Symmetry: the term depends only on $i = |S|$, and there are $\binom{d}{i}$ subsets of size i.
(3) The gluing argument of Section 12.8.4, with the divisors for x^+ inside M^+ and those for x^- inside M^- (locality); the cut-down moduli spaces glue exactly as the zero-dimensional ones did in (12.135).

This is Nash's (12.69), $q_d(M) = \sum_{i=0}^{d} q_d^i(M^+)\bullet q_d^{d-i}(M^-)$: each term of the splitting (12.141) of the symmetric power is computed as a Floer pairing of a relative invariant of one side with a relative invariant of the other.

Watch out: Binomial coefficients and degrees

Nash's (12.69) has no binomial coefficients. That is a matter of normalisation: if the relative invariants are regarded as elements of $\mathrm{Sym}^i(V)^*\otimes HF$ (as polynomials rather than multilinear forms), the $\binom{d}{i}$ is absorbed. Also, not every term can be non-zero: $q^i(M^+)$ lands in one degree of $HF_*(N)$ and $q^{d-i}(M^-)$ in one degree of $HF^*(N)$, determined by the dimension formula (12.127), and the pairing vanishes unless these degrees match.

Worked example 12.57: A degree-2 invariant cut in half

Suppose $H_2(M^+) = \mathbb{Z}x$ and $H_2(M^-) = \mathbb{Z}y$ (one generator each) and $d = 2$. For a general class $ax + by$,

$$q_2(M)(ax+by) \overset{(1)}{=} a^2 \left\langle q^0(M^-), q^2(M^+)(x,x)\right\rangle + 2ab \left\langle q^1(M^-)(y), q^1(M^+)(x)\right\rangle + b^2 \left\langle q^2(M^-)(y,y), q^0(M^+)\right\rangle.$$

(1) (12.142) with $x^+ = ax$, $x^- = by$, $d = 2$, and multilinearity to pull out the powers of a and b.

The three coefficients of the quadratic form $q_2(M)$ are three separate Floer pairings. The a^2 coefficient uses only moduli spaces on M^+ cut down by two copies of V_x, glued to rigid instantons on M^-; the ab coefficient cuts down once on each side; and so on. If the Floer degrees of $q^1(M^\pm)$ do not match, the mixed coefficient is forced to be zero, and $q_2(M)$ has no ab term: the cutting has told us something about the shape of the polynomial.

12.8.7 The Floer–Donaldson theory as a TQFT

We can now put the chapter's opening axioms (Section 12.1.3) next to what Floer and Donaldson built. The comparison is the real content of the phrase "Donaldson theory is a topological quantum field theory".

Dictionary: Atiyah's axioms and the Floer–Donaldson theory

Axiom / TQFT datum	Floer–Donaldson realisation
space of states $Z(N)$ of a closed 3-manifold	$HF_*(N;\mathbb{Q})$, N a homology 3-sphere
$Z(\overline{N}) = Z(N)^*$	$HF_*(\overline{N}) \cong HF^*(N)$ (grading shifted) (12.133)
vector $Z(X) \in Z(\partial X)$	relative invariants $q^i(X) \in HF_*(\partial X)$ (12.139)
number $Z(M)$ of a closed 4-manifold	$q_d(M)$ (or its generating function)
gluing $Z(M^+ \cup M^-) = \langle Z(M^-), Z(M^+)\rangle$	Nash's (12.63), (12.135), (12.142)
cobordism $W : N_1 \to N_2$ gives $Z(W) : Z(N_1) \to Z(N_2)$	count rigid instantons on W with two cylindrical ends
$Z(N \times [0,1]) = \mathrm{id}$	only constant flow lines are rigid (Example 12.58)
$Z(N \times S^1) = \dim Z(N)$	$\chi_F(N) = 2\lambda(N)$ (Example 12.59)

Cobordisms act on Floer groups

Let W be a compact oriented 4-manifold with $\partial W = \overline{N_1} \sqcup N_2$: a cobordism from N_1 to N_2. Attach an incoming end $N_1 \times (-\infty, 0]$ and an outgoing end $N_2 \times [0, \infty)$. For flat connections α_1 on N_1 and α_2 on N_2 let $\mathcal{M}(W; \alpha_1, \alpha_2)$ be the finite-action instantons with these limits, and define

$$Z(W)\alpha_1 := \sum_{\alpha_2} \#\mathcal{M}(W;\alpha_1,\alpha_2)^0 \, \alpha_2. \tag{12.143}$$

Counting the ends of the one-dimensional moduli spaces now gives broken configurations of two kinds, a flow line on the incoming end or one on the outgoing end, and the count says $Z(W)\partial = \partial Z(W)$: $Z(W)$ is a chain map and so acts on HF_*. Gluing two cobordisms along N_2 gives, by the same argument as (12.134), $Z(W_2 \cup_{N_2} W_1) = Z(W_2) \circ Z(W_1)$ on homology (Figure 12.36). A manifold M^+ with $\partial M^+ = N$ is a cobordism from the empty set to N, and $Z(M^+)$ applied to $1 \in Z(\varnothing) = \mathbb{Q}$ is the class $[C^+]$.

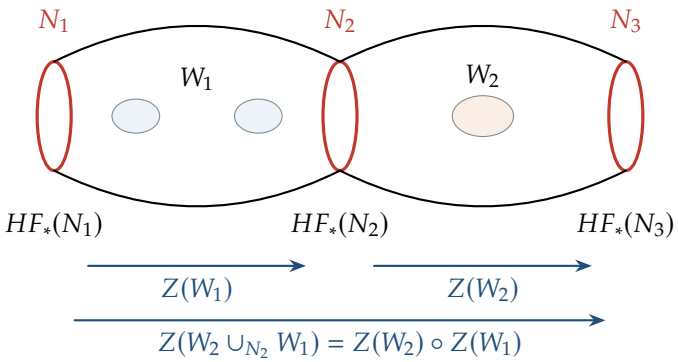

Figure 12.36: Cobordisms act on Floer groups. A 4-manifold W_1 from N_1 to N_2 induces a map $HF_*(N_1) \to HF_*(N_2)$ by counting rigid instantons with prescribed limits on its two ends; gluing cobordisms composes the maps. This is Atiyah's gluing axiom realised by instantons, and (12.63) is the special case in which the two outer boundaries are empty.

Worked example 12.58: The cylinder acts as the identity

Take $W = N \times [0,1]$ with its ends attached: this is the infinite cylinder $N \times \mathbb{R}$. The instantons on it with limits α and β are the Chern–Simons flow lines from α to β, a space of dimension $\sigma(\alpha,\beta)$ (12.52). Time translation $t \mapsto t + c$ maps flow lines to flow lines. On a non-constant flow line it acts freely, so a non-constant flow line comes in a family of dimension ≥ 1 and is never rigid. The only rigid instantons are the constant ones, $A(t) \equiv \alpha$, which exist only for $\beta = \alpha$ and count +1. Hence

$$Z(N \times \mathbb{R})\,\alpha \overset{(1)}{=} \sum_{\beta} \#\mathcal{M}(\alpha,\beta)^0\,\beta \overset{(2)}{=} \alpha.$$

(1) Definition (12.143).
(2) Only $\beta = \alpha$ contributes, with the constant flow line counted once.

So $Z(N \times \mathbb{R}) = \mathrm{id}$, which is axiom (A5) of Section 12.1.3. The non-rigid flow lines are not wasted: after dividing by translations they are what the boundary operator ∂ counts.

Worked example 12.59: The partition function on $N \times S^1$ is Casson's invariant

In a TQFT, closing the cylinder into a circle takes a trace, $Z(N \times S^1) = \mathrm{Tr}_{Z(N)}\,\mathrm{id} = \dim Z(N)$ (12.3). When the space of states is graded into bosons and fermions, as the Floer groups are (even and odd degrees, following the Morse-theory dictionary of Section 12.2.1), the path integral on a circle with periodic boundary conditions for the fermions computes the *supertrace* $\mathrm{Tr}(-1)^F$, the Witten index. So Witten's theory predicts

$$Z(N \times S^1) \overset{(1)}{=} \mathrm{Tr}_{HF_*(N)}(-1)^F \overset{(2)}{=} \sum_{p=0}^{7} (-1)^p \,\mathrm{rank}\, HF_p(N) \overset{(3)}{=} \chi_F(N) \overset{(4)}{=} 2\lambda(N).$$

(1) The trace axiom, with the fermion-parity sign that periodic fermions produce.
(2) $(-1)^F = (-1)^p$ on HF_p.
(3) Definition of the Floer Euler characteristic (Section 12.5.3).
(4) Taubes' theorem (12.68).

For the Poincaré sphere this is $2 \cdot (-1) = -2$, the two fermionic ground states ρ_1, ρ_2 of Example 12.21. This is a physicist's statement: $N \times S^1$ has $b_2^+ = 0$ (its H_2 is $H_2(N) \oplus H_1(N) \otimes$

$H_1(S^1) = 0$), so it has no Donaldson polynomials in the sense of Section 12.6. The field theory nevertheless assigns it a number, and the number it assigns is Casson's invariant, a result of Taubes that the TQFT picture makes natural.

Watch out: A partial TQFT

The Floer–Donaldson theory satisfies Atiyah's axioms only partially. The 3-manifolds are restricted (homology spheres, so that the only reducible flat connection is θ and it can be discarded); the 4-manifolds need $b_2^+ > 0$ on each piece (to avoid reducible instantons) and $b_2^+ > 1$ for metric independence of the closed invariants; the grading is only mod 8; and the vector "$Z(M)$" of a closed manifold is really a whole polynomial (or a generating function of all the q_d) rather than one number. What survives is the essential structure: local pieces, states on the cuts, and gluing by pairing.

12.8.8 What kind of invariants are the q_d?

Nash closes the section with a list of properties. Each deserves an explanation.

There are infinitely many, with relations

For each k with $8k - 3(1 + b_2^+) \geq 0$ we get one polynomial q_d, with $d = 4k - \frac{3}{2}(1 + b_2^+)$ (12.94); as k grows, d grows by 4 each time. So there are infinitely many q_d for each M. Nash remarks that there may be relations among them. There are, and for a large class of manifolds (those of **simple type**) they are strong enough to determine every q_d from finitely many numbers. The result, due to Kronheimer and Mrowka, packages all the invariants into a generating function of the form

$$\mathbb{D}_M(x) = e^{Q(x)/2} \sum_r c_r \, e^{K_r \cdot x},$$

with finitely many *basic classes* $K_r \in H^2(M;\mathbb{Z})$ and rational coefficients c_r. For K3 there is a single basic class $K = 0$, and the formula says that every q_d(K3) is, up to normalisation, a power of the intersection form. In particular the first one, at $d = 2$, is proportional to $Q(x) = x \cdot x$ itself (Donaldson's computation). The basic classes turned out to be the Seiberg–Witten classes, which is where the physics of this chapter eventually led.

They do not depend on the metric

Nash: "the Donaldson invariants are independent of the metric required to define the instantons". The physics argument was Q-exactness (Section 12.7.3). The mathematical argument is Stokes' theorem on a cobordism of moduli spaces, and it is worth writing out. Join two generic metrics by a path g_t, $t \in [0,1]$, and form the parametrised moduli space

$$\mathcal{W} = \bigcup_{t \in [0,1]} \overline{\mathcal{M}}_k(g_t) \times \{t\},$$

of dimension $2d + 1$. For a generic path it is a manifold with boundary

$$\partial \mathcal{W} = \overline{\mathcal{M}}_k(g_1) \sqcup \overline{\overline{\mathcal{M}}_k(g_0)}$$

(the bar on the second copy meaning reversed orientation), provided no reducible connection is met along the path (Figure 12.37). The classes $m(a)$ are defined on the whole space of

connections, so they are closed 2-forms $\mu(a)$ on $\mathcal{W}$ restricting to $m(a)$ on each end. Then

$$\begin{aligned} q_d(g_1) - q_d(g_0) &\overset{(1)}{=} \int_{\overline{\mathcal{M}}_k(g_1)} \mu(a_1) \wedge \cdots \wedge \mu(a_d) - \int_{\overline{\mathcal{M}}_k(g_0)} \mu(a_1) \wedge \cdots \wedge \mu(a_d) \\ &\overset{(2)}{=} \int_{\partial \mathcal{W}} \mu(a_1) \wedge \cdots \wedge \mu(a_d) \\ &\overset{(3)}{=} \int_{\mathcal{W}} \mathrm{d}\big(\mu(a_1) \wedge \cdots \wedge \mu(a_d)\big) \overset{(4)}{=} 0. \end{aligned} \tag{12.144}$$

(1) Definition (12.95) for each metric.
(2) $\partial\mathcal{W}$ is the g_1 end minus the g_0 end (outward normal first: at $t = 1$ it is $+\partial_t$, at $t = 0$ it is $-\partial_t$).
(3) Stokes' theorem on the $(2d + 1)$-dimensional $\mathcal{W}$.
(4) Each $\mu(a_i)$ is closed, so their wedge product is closed.

This is the most basic use of Stokes' theorem: an exact form integrates to zero over something with no boundary, and a difference of two boundary integrals is an integral of d of something closed. (The compactification adds lower strata of codimension at least 2, which do not affect Stokes' theorem; this is part of the analysis of Section 12.6.5.)

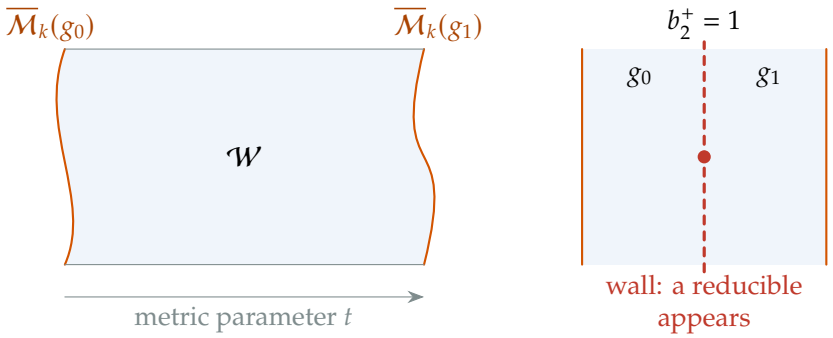

Figure 12.37: Metric independence by Stokes' theorem. Left: as the metric moves from g_0 to g_1 the moduli spaces sweep out a manifold $\mathcal{W}$ whose boundary is the two ends, so the two integrals agree. Right: reducible connections occur in codimension b_2^+ in the space of metrics; when $b_2^+ = 1$ a path of metrics can be forced across such a wall, $\mathcal{W}$ acquires an extra boundary there, and the invariant jumps (compare Figure 12.21).

They are invariant under orientation-preserving diffeomorphisms, up to sign

Let $\varphi : M \to M'$ be an orientation-preserving diffeomorphism and g' a metric on M'. Pull back the metric to $g = \varphi^* g'$. Then φ is an isometry $(M, g) \to (M', g')$, and pulling back connections $A' \mapsto \varphi^* A'$ maps g'-instantons to g-instantons (the ASD condition only uses the metric and the orientation, and both are preserved). So $\varphi^* : \mathcal{M}_k(M', g') \to \mathcal{M}_k(M, g)$ is a diffeomorphism, and it carries the divisor of $\varphi_* a$ to the divisor of a. Therefore

$$\begin{aligned} q_d(M')(\varphi_* a_1, \ldots, \varphi_* a_d) &\overset{(1)}{=} \int_{\mathcal{M}_k(M', g')} m(\varphi_* a_1) \wedge \cdots \wedge m(\varphi_* a_d) \\ &\overset{(2)}{=} \pm \int_{\mathcal{M}_k(M, g)} m(a_1) \wedge \cdots \wedge m(a_d) \overset{(3)}{=} \pm q_d(M)(a_1, \ldots, a_d). \end{aligned}$$

(1) Definition (12.95) on M'.

(2) Change of variables under the diffeomorphism φ^* of moduli spaces, which pulls $m(\varphi_* a)$ back to $m(a)$; the sign is $+1$ if φ^* preserves the orientations of the moduli spaces and -1 otherwise.
(3) Metric independence on M.

The orientation of $\mathcal{M}_k$ is fixed by the homology orientation (an orientation of H^2_+). So the sign is $+1$ or -1 according as φ preserves or reverses the chosen orientation of $H^2_+(M)$: it is $\det(\varphi^*|_{H^2_+})$.

Worked example 12.60: Complex conjugation on $\mathbb{CP}^2$

Let $c : \mathbb{CP}^2 \to \mathbb{CP}^2$ be complex conjugation of the homogeneous coordinates. In local coordinates $(z_1, z_2) = (x_1 + iy_1, x_2 + iy_2)$ it is $(x_1, y_1, x_2, y_2) \mapsto (x_1, -y_1, x_2, -y_2)$, with Jacobian determinant $(+1)(-1)(+1)(-1) = +1$: orientation-preserving. It maps the line $L = \mathbb{CP}^1$ to itself reversing its orientation, so $c_*[L] = -[L]$; and it is antiholomorphic, so it sends the Kähler form ω, which spans $H^2_+(\mathbb{CP}^2)$, to $-\omega$. The sign in the rule above is therefore -1, and the rule predicts

$$q_d(c_* a) = -q_d(a).$$

Check it against homogeneity. With $a = [L]$, $c_* a = -a$ and

$$q_d(c_* a) \overset{(1)}{=} q_d(-a) \overset{(2)}{=} (-1)^d q_d(a) \overset{(3)}{=} -q_d(a).$$

(1) $c_*[L] = -[L]$.
(2) q_d is homogeneous of degree d.
(3) For $\mathbb{CP}^2$, $b_2^+ = 1$ and $2d = 8k - 6$, so $d = 4k - 3$ is odd.

The two computations agree: the sign from the homology orientation is exactly what the parity of d requires. (Conjugation is an isometry of the Fubini–Study metric, so the chamber subtleties of $b_2^+ = 1$ do not enter.)

No relation under orientation reversal

Reversing the orientation of M gives $\overline{M}$ with

$$Q(\overline{M}) = -Q(M), \qquad b_2^+(\overline{M}) = b_2^-(M), \qquad b_2^-(\overline{M}) = b_2^+(M),$$

and the Hodge star changes sign, so anti-self-dual on $\overline{M}$ means self-dual on M. The instantons of $\overline{M}$ are the anti-instantons of M: a different equation with differently sized moduli spaces, $\dim \mathcal{M}_k(\overline{M}) = 8k - 3(1 + b_2^-(M))$. There is no reason for the two sets of invariants to be related, and in general they are not.

Worked example 12.61: K3 and $\mathbb{CP}^2$ with both orientations

For K3, $(b_2^+, b_2^-) = (3, 19)$. Then

$$\dim \mathcal{M}_k(\mathrm{K3}) = 8k - 12, \qquad \dim \mathcal{M}_k(\overline{\mathrm{K3}}) = 8k - 3(1 + 19) = 8k - 60.$$

The first invariant of K3 appears at $k = 2$, that of $\overline{\mathrm{K3}}$ at $k = 8$: they are unrelated polynomials. For $\mathbb{CP}^2$ the contrast is even starker. $\overline{\mathbb{CP}}^2$ has $b_2^+ = 0$, so $\dim \mathcal{M}_k = 8k - 3$ is odd and $\overline{\mathbb{CP}}^2$ has no Donaldson polynomials at all, while $\mathbb{CP}^2$ ($b_2^+ = 1$) has them in every dimension $8k - 6$.

Differential, not topological, invariants

The last point is the reason anyone cares. The ASD equation involves derivatives, so it needs a *smooth* structure; a mere homeomorphism cannot transport instantons from one manifold to another. So the q_d are invariants of the smooth manifold, and two manifolds that are homeomorphic (same Q, by Freedman's theorem, in the simply connected case) may have different q_d. When that happens they are not diffeomorphic. We saw one such pair in Example 12.43: $E(3)$ and $5\mathbb{CP}^2\#29\overline{\mathbb{CP}}^2$. Nash cites Ebeling, who used the q_d to show that certain pairs of complex surfaces (complete intersections in projective space) are homeomorphic but not diffeomorphic. In each case the mechanism is the contrast of Section 12.6.6: one member has non-zero invariants (positivity), the other has them all equal to zero (a splitting along S^3, or along a homology sphere with trivial Floer groups), or both are non-zero but different polynomials.

Reading Nash (pp. 336–339, (12.60)–(12.69))

Nash says: cut $M = M^+ \cup_h M^-$ along homology spheres (12.60), which is possible when Q splits with $b_2^+(M^\pm) > 0$ (Freedman–Taylor). With boundary conditions given by connections on $N^\pm$, the instanton sets $C^\pm$ on the two halves satisfy $C^+ \cap C^- = \mathcal{M}_k$ (12.61) and define Floer classes $[C^\mp] \in HF(N^\mp)$ (12.62); since $N^\pm$ have opposite orientations the groups are dual, and Donaldson shows that $[C^+] \bullet [C^-] = q_d(M)$ (12.63). For $d = 0$ one needs $8k - 3(1 + b_2^+) = 0$ (12.64); $\mathcal{M}_k$ is a finite set, q_0 a signed count, and in the field theory it is the partition function $Z = \sum_i (-1)^{n_i}$ (12.65). The Floer groups are like the middle-dimensional homology of $\mathcal{A}/\mathcal{G}$. Read one way, (12.63) shows that the gluing spheres of algebraic surfaces have non-trivial HF; read the other way, gluing along S^3 forces $q_d = 0$, recovering (12.55). Relative invariants take values in Floer groups; splitting the product (12.66) and the symmetric powers (12.67) leads to polynomials $q_d^i(M^+)$ in the variables (12.68) and the evaluation rule (12.69). Finally the q_d are infinite in number, metric independent, invariant up to sign under orientation-preserving diffeomorphisms, unrelated under orientation reversal, and differential rather than topological (Ebeling). We have supplied: the boundary-orientation rule; the Mayer–Vietoris proof that H_2 and Q split; the nucleus/Milnor-fibre splitting of $E(n)$ and K3 with explicit forms; the cylindrical-end moduli spaces and the flat limit; the fractional charge $k^\pm \equiv \mp f(\alpha)$; the gluing dimension formula with the H^0, H^1 corrections and its S^3 case; the construction of $[C^+]$ as a cycle by counting ends; the cocycle $[C^-]$; the derivation of the pairing and its well-definedness; the $b_2^+ = 8j - 1$ analysis of (12.64); the torus model of middle-dimensional intersections; the Casson check for $\Sigma(2,3,11)$; the binomial form of (12.69); the dictionary with Atiyah's axioms, the cylinder, and $Z(N \times S^1) = 2\lambda$; and the Stokes proof of metric independence, the diffeomorphism sign with the $\mathbb{CP}^2$ check, and the orientation-reversal examples.

Recap

- Cutting M along a homology sphere N splits H_2 and Q (Mayer–Vietoris, using $H_1(N) = H_2(N) = 0$). Every splitting of Q is realised this way (Freedman–Taylor), though not always along S^3.
- On a half with a cylindrical end an instanton is an instanton on $M^\pm$ with a Chern–Simons flow line attached; finite action makes it converge to a flat connection α, and its charge is $\mp f(\alpha)$ mod 1.
- Counting rigid instantons on $\widehat{M}^+$ by their limits gives a Floer cycle ψ^+ (the ends of 1-dimensional moduli spaces cancel), hence a class $[C^+] \in HF_*(N)$; the other half

gives a cocycle, i.e. a class of $\overline{N}$.

- Gluing along irreducible α has no gluing parameters, so $q_d(M) = \langle [C^-], [C^+] \rangle$. Along S^3 the only flat connection is the reducible θ: $HF(S^3) = 0$, and $q_d = 0$.
- For $d = 0$ ($b_2^+ = 8j - 1$, $k = 3j$) the invariant is the signed count of instantons, the partition function $Z = \sum (-1)^{n_i}$ of Witten's theory, and an intersection number of "middle-dimensional" cycles.
- For $d > 0$ the relative invariants $q^i(M^+)$ are HF-valued polynomials; $\mathrm{Sym}^d(V \oplus W) = \bigoplus \mathrm{Sym}^i V \otimes \mathrm{Sym}^{d-i} W$ and $q_d(x^+ + x^-) = \sum \binom{d}{i} \langle q^{d-i}(M^-), q^i(M^+) \rangle$.
- This is Atiyah's axiom system in $3 + 1$ dimensions: $Z(N) = HF_*(N)$, the cylinder is the identity, $Z(N \times S^1) = \chi_F = 2\lambda$.
- The q_d are metric independent (Stokes on a cobordism of moduli spaces, for $b_2^+ > 1$), diffeomorphism invariant up to the sign $\det \varphi^*|_{H^2_+}$, unrelated under orientation reversal, and sensitive to the smooth structure.

The Floer groups entered this story as the space of states of a three-dimensional slice. The same question can be asked of the three-dimensional Chern–Simons theory whose action is the function f of Section 12.2: quantise it, and ask what its states on a surface and its path integral over a 3-manifold compute. The answer involves knots, and that is where the chapter goes next.

12.9 Knots, links and when two of them are the same

Here is the question that drives the next two sections. A Wilson loop is the trace of the holonomy of a gauge field around a closed curve C in space-time. In an ordinary gauge theory its expectation value depends on the length of C, the area it spans, the metric, and so on. In a *topological* field theory in three dimensions, such as the Chern–Simons theory of Chapter 12, nothing depends on the metric. So $\langle W(C) \rangle$ can only depend on how C sits inside the three-manifold, up to smooth deformation. It depends only on the *knot type* of C. If we have several loops, it depends on how they are tangled with one another: on the *link type*.

So the correlation functions of a topological gauge theory in three dimensions are *knot invariants*. To recognise what the path integral computes, we first need to know what knots are, when two of them count as "the same", and which invariants mathematicians already had. That is the content of Nash's §4. He gives it in three pages. We take it slowly, because everything in the Chern–Simons calculation of Sections 12.12 and 12.13 is checked against these invariants.

The physicist has met knot theory before, perhaps without the name. Gauss invented the linking number while doing magnetostatics (Section 12.10). Kelvin's "vortex atom" theory of 1867 proposed that atoms are knotted vortex tubes in the ether, and it was Tait's attempt to tabulate atoms that produced the first knot tables. A charged particle going round a solenoid feels the Aharonov–Bohm phase: this is the simplest knot invariant, a winding number, measured by a phase.

12.9.1 What a knot is

Working definition 12.14 (knot, link)

A **knot** is a smooth closed curve in $\mathbb{R}^3$ that does not cross itself. Concretely, it is a smooth map

$$\gamma : [0, 2\pi] \to \mathbb{R}^3, \qquad \gamma(0) = \gamma(2\pi),$$

with $\gamma'(t) \neq 0$ everywhere [the point never stops moving, so the curve has no cusps] and $\gamma(s) \neq \gamma(t)$ for $s \neq t$ in $[0, 2\pi)$. We usually identify the knot with its image $K = \gamma([0, 2\pi])$. A **link** with p **components** is p such curves that are disjoint from one another. A knot is a link with one component.
Operational test: to specify a knot, write down a periodic parametrisation and check that it never revisits a point.
Formal version: a knot is an embedding $S^1 \hookrightarrow \mathbb{R}^3$ (or into $S^3 = \mathbb{R}^3 \cup \{\infty\}$).

Nash works in $\mathbb{R}^3$ or its one-point compactification S^3. For knots the two are interchangeable: a knot is compact, so it misses a neighbourhood of ∞, and every deformation in S^3 can be pushed off the point ∞. The reason to prefer S^3 is that it is a *closed* three-manifold, which is where Chern–Simons theory is defined without boundary terms.

Worked example 12.62: Three explicit knots

1. The **unknot**: $\gamma(t) = (\cos t, \sin t, 0)$, the round circle.

2. The **trefoil** (Nash's "clover leaf"):

$$\gamma(t) = \big(\sin t + 2\sin 2t,\ \cos t - 2\cos 2t,\ \sin 3t\big). \tag{12.145}$$

   Its projection to the xy-plane is the three-lobed curve of Figure 12.38. The height $z = \sin 3t$ decides, at each of the three points where the projection crosses itself, which strand is on top.

3. The **torus knots**. Draw a doughnut of core radius 2 and tube radius 1. The curve that winds p times around the z-axis while winding q times around the tube,

$$\gamma_{p,q}(t) = \big((2 + \cos qt)\cos pt,\ (2 + \cos qt)\sin pt,\ -\sin qt\big), \tag{12.146}$$

   is the torus knot $T(p, q)$ when $\gcd(p, q) = 1$. $T(2, 3)$ is the trefoil again. When $\gcd(p, q) = d > 1$ the curve closes up after $1/d$ of the way round and the formula gives a link $T(p, q)$ with d components (shift t by $2\pi j/q$ for the j-th one).

Why is $\gamma_{p,q}$ injective when $\gcd(p, q) = 1$? Suppose $\gamma_{p,q}(s) = \gamma_{p,q}(t)$. The point lies on the torus, and $(pt \bmod 2\pi,\ qt \bmod 2\pi)$ are its two angles on the torus. So $p(s - t) \in 2\pi\mathbb{Z}$ and $q(s - t) \in 2\pi\mathbb{Z}$. With $\gcd(p, q) = 1$ there are integers a, b with $ap + bq = 1$, so $s - t = a\,p(s - t) + b\,q(s - t) \in 2\pi\mathbb{Z}$, and $s = t$ on the circle.

The first thing Nash stresses is this.

Key idea: The knottedness is in the embedding

As topological spaces all knots are the same: each is homeomorphic to S^1 (use the parameter t). What distinguishes a trefoil from a circle is not the curve but *how it sits in the surrounding*

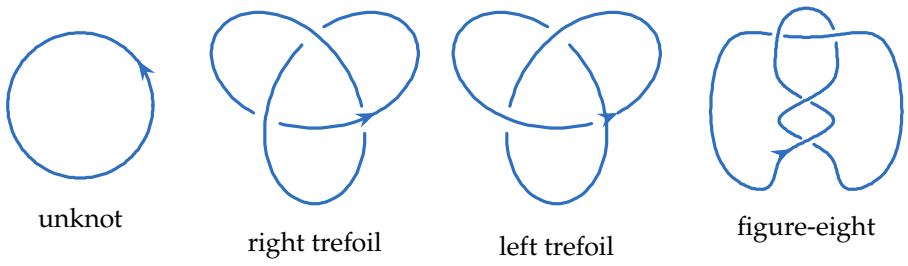

Figure 12.38: The first few knots. Each is a copy of the circle; what differs is how it sits in space. At a crossing the gap marks the strand that passes underneath. The two trefoils are mirror images: every crossing has been switched. The figure-eight knot has four crossings.

space. The information lives in the *complement* $\mathbb{R}^3 \setminus K$, not in K.

This is exactly the situation of a physicist who measures a curve from outside. You cannot walk along a knot and discover it is knotted; every point looks like a line. You discover it by walking *around* it: measuring holonomies, phases, fluxes. That is why the invariants below are built from the complement (the knot group), from loops around the knot (Wilson loops) and from fields sourced by currents on it (the Gauss integral).

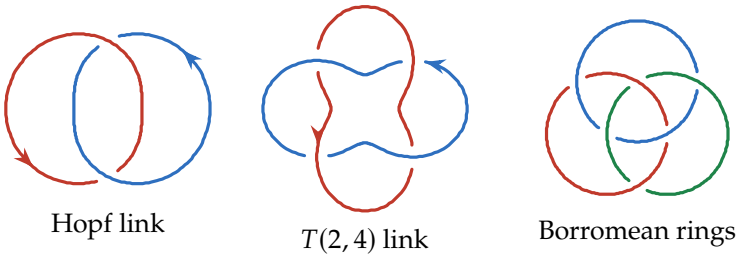

Figure 12.39: Three links. The Hopf link is two circles through each other once. The $T(2,4)$ link winds twice. In the Borromean rings no two rings are linked (remove any one and the other two fall apart), yet the three together cannot be separated.

12.9.2 Why three dimensions: all knots untie in four

Why is knot theory a subject about $\mathbb{R}^3$? Look at the other dimensions.

In the plane. A closed curve in $\mathbb{R}^2$ without self-crossings is, by the Jordan–Schoenflies theorem, always deformable to a round circle. There is no room to tangle.

In four dimensions. In $\mathbb{R}^3$ a knot cannot be untied because one strand would have to pass through another. Think of a crossing: strand a passes over strand b. To change it into an under-crossing we must move a down, and in $\mathbb{R}^3$ it has to go through b. In $\mathbb{R}^4 = \{(x, y, z, w)\}$ we can do this instead:

1. lift a short piece of a near the crossing into $w = 1$ (the rest of the knot stays at $w = 0$);
2. move that piece down in z, past the height of b; this does not hit b, because b is at $w = 0$ and the moving piece is at $w = 1$;
3. lower the piece back to $w = 0$.

The net effect is a crossing change, obtained without any collision. It is the same trick as in one lower dimension. Two strands crossing in the plane must meet; in space one simply goes over the other.

Any knot diagram can be turned into an unknot by changing some of its crossings. (Walk along the knot from a starting point and make each crossing an over-crossing the first time you reach it. The result, a "descending" diagram, lies like a spiral staircase that can be lifted off from the top.) So every knot in $\mathbb{R}^3$ becomes the unknot inside $\mathbb{R}^4$.

Nash quotes the general statement: an m-sphere embedded in $\mathbb{R}^n$ can always be unknotted if

$$n > \tfrac{3}{2}(m+1). \tag{12.147}$$

For $m = 1$ this is $n > 3$, so knotted circles need exactly $n = 3$. There is a cruder count that shows where such bounds come from. Deforming an m-dimensional sphere sweeps out an $(m+1)$-dimensional track. The track generically meets the m-dimensional sphere itself in a set of dimension $(m+1) + m - n$. If this is negative, collisions can be avoided, so all knots untie once $n \geq 2m+2$. The true bound (12.147) is sharper.

m	crude count $n \geq 2m+2$	bound (12.147)	knots exist in
1	4	$n \geq 4$	$\mathbb{R}^3$
2	6	$n \geq 5$	$\mathbb{R}^4$ ("2-knots")
3	8	$n \geq 7$	$\mathbb{R}^5, \mathbb{R}^6$

Nash also notes that other spaces can be knotted in $\mathbb{R}^3$: for example, a knotted torus is the boundary of a thickened knot. We will not need this.

12.9.3 When are two knots the same? Equivalence and isotopy

We need a precise notion of "the same knot". Nash gives two, and the difference between them is the difference between a knot and its mirror image.

Working definition 12.15 (equivalent knots, Nash (12.70))

Knots K_1 and K_2 are **equivalent** if there is a homeomorphism $\alpha : \mathbb{R}^3 \to \mathbb{R}^3$ (a continuous bijection with continuous inverse) that carries one onto the other:

$$\alpha K_1 = K_2. \tag{12.148}$$

Operational test: find a continuous invertible change of coordinates of all of space that moves one curve onto the other. The equivalence classes [each class collects all the knots equivalent to one given knot] are the **knot types**.

Examples of such α: translations, rotations, rescalings $x \mapsto \lambda x$ ($\lambda > 0$), any smooth invertible "stretching" of space, and also reflections, such as

$$\rho(x, y, z) = (x, y, -z). \tag{12.149}$$

The **mirror image** of a knot K is $\bar{K} = \rho K$. Applying ρ to the trefoil (12.145) replaces $\sin 3t$ by $-\sin 3t$. The projection is unchanged, but at every crossing the strand that was on top is now below. That is the left trefoil of Figure 12.38. By definition, K and $\bar{K}$ are always equivalent.

This is too coarse for a physicist who cares about handedness, like a chemist distinguishing a molecule from its mirror image. A reflection is not a motion you can perform on a piece of string. What you can do continuously is captured by the second definition.

Working definition 12.16 (isotopic knots, Nash (12.71))

K_1 and K_2 have the same **isotopy type** if there is a family of homeomorphisms

$$\{\alpha_t\}, \qquad t \in [0,1], \tag{12.150}$$

of $\mathbb{R}^3$, with $\alpha_t(x)$ continuous in t and x together, $\alpha_0 = \mathrm{id}$ and $\alpha_1 K_1 = K_2$. *Operational meaning:* a film, starting from "do nothing", in which all of space flows continuously and at the end K_1 sits where K_2 is. Moving a piece of string about on a table, without cutting it, is an isotopy.

Isotopic knots are equivalent: just take $\alpha = \alpha_1$. The converse fails, and the reason is orientation.

Key idea: Isotopies preserve orientation

Every α_t of an isotopy preserves orientation. For smooth α_t this is a one-line continuity argument:

$$\begin{aligned} \det D\alpha_1 &\overset{(1)}{=} \det D\alpha_0 \cdot \frac{\det D\alpha_1}{\det D\alpha_0} \\ &\overset{(2)}{=} (+1) \cdot (\text{a number that never passes through } 0) \\ &\overset{(3)}{=} \text{positive.} \end{aligned}$$

(1) Trivial rewriting, with $D\alpha_t$ the Jacobian matrix of α_t at a fixed point x.

(2) $\alpha_0 = \mathrm{id}$ has Jacobian $\mathbb{1}$, with determinant 1. Each α_t is invertible, so $\det D\alpha_t \neq 0$ for all t.

(3) A continuous real function of t that starts at $+1$ and is never zero stays positive (intermediate value theorem).

The reflection ρ of (12.149) has Jacobian $\mathrm{diag}(1,1,-1)$, with determinant -1. So ρ is never the end of an isotopy. Conversely, one can show that every orientation-preserving homeomorphism of $\mathbb{R}^3$ is the end of some isotopy. So:

$$\text{isotopic} \iff \text{equivalent through an orientation-preserving homeomorphism.}$$

A knot isotopic to its own mirror image is **amphichiral**. The figure-eight knot is amphichiral (try it with a piece of string, or see Example 12.79). The trefoil is not: the right and left trefoils are equivalent but not isotopic. Nash states this; the proof needs an invariant that can tell the two apart, and the Alexander polynomial and the knot group cannot (Section 12.11.2). The Jones polynomial can (Section 12.11.5).

Watch out: Isotopy is not homotopy (Nash's footnote 7)

The definition of isotopy looks like the definition of a homotopy. The crucial difference is that in an isotopy *every* α_t is invertible, so the curve $\alpha_t K_1$ is an embedded knot at every moment. A homotopy of the curve only requires a continuous family of maps $S^1 \to \mathbb{R}^3$, and these may pass through self-intersections. Under homotopy all knots are trivial: at a self-intersection a strand passes through itself, which changes a crossing (Figure 12.40), and we saw above that crossing changes can untie anything. Indeed $\pi_1(\mathbb{R}^3) = 0$, so every loop is homotopic to a constant. Homotopy forgets exactly the information knot theory is about.

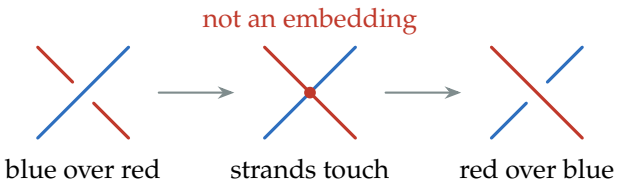

Figure 12.40: A crossing change. A homotopy may pass one strand through another (middle frame); an isotopy may not, because every intermediate curve must be embedded. In $\mathbb{R}^4$ the middle frame can be avoided by lifting the blue strand into the fourth dimension.

Tame and wild knots. Nash separates off a pathology. A knot is **tame** if it is equivalent to a **polygonal** knot, one made of finitely many straight segments. Otherwise it is **wild**. The standard wild knot ties infinitely many smaller and smaller trefoils into a string, with sizes 2^{-n}, so that they accumulate at a point (Figure 12.41). Near the accumulation point the curve is continuous but has no tangent line, and no finite polygon captures it. Every *smooth* knot is tame: approximate it by a fine inscribed polygon; when the polygon is fine enough, straightening each small arc into a chord is an isotopy. From now on, like Nash, we consider only smooth, and hence tame, knots.

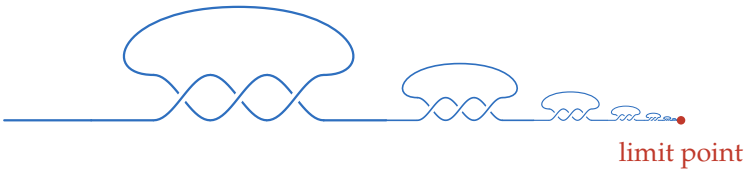

Figure 12.41: A wild knot: infinitely many ever smaller trefoils tied end to end in one string, accumulating at a point (sizes halving each time). The curve is continuous, but at the red point it has no tangent and cannot be replaced by a finite polygon. Smooth knots never do this.

Orientations. An **oriented** knot comes with a direction of travel (the direction of increasing t). Several invariants below (crossing signs, linking numbers, the Jones polynomial of a link) need orientations. Reversing the orientation of a *knot* does not change any of the polynomials we meet. For a link, reversing one component can change them. A knot isotopic to itself with the orientation reversed is **invertible**; all knots with fewer than eight crossings are, and the first non-invertible one has eight crossings.

12.9.4 Knot diagrams and the Reidemeister moves

Nobody computes with parametrisations like (12.145). One computes with pictures. Nash mentions that knot calculations use projections to two dimensions, and that one must then prove the answer does not depend on the projection. Here is the machinery that makes this precise.

Working definition 12.17 (knot diagram)

Project the knot to a plane, for instance by $(x, y, z) \mapsto (x, y)$. The projection is **regular** if it has only finitely many self-intersection points, each a transverse crossing [the two strands cross at a nonzero angle, they do not just touch] of exactly two strands. A **knot diagram** is a regular projection together with the information, at each crossing, of which strand is on top: we break the lower strand.

Operational fact: almost every direction of projection is regular. If a projection has a triple point or a tangency, tilt the plane slightly.

Different diagrams can represent the same knot. How do we know when?

Key idea: Reidemeister's theorem

Two diagrams represent isotopic knots if and only if one can be turned into the other by a finite sequence of

- planar isotopies (sliding the picture about in the plane without creating or destroying crossings), and
- the three **Reidemeister moves** R1, R2, R3 of Figure 12.42.

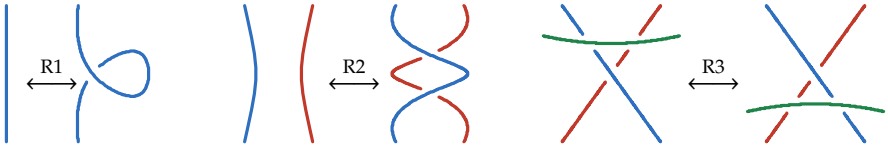

Figure 12.42: The Reidemeister moves. R1 adds or removes a kink. R2 slides one strand entirely over another, creating or removing two crossings. R3 slides a strand (green) over a crossing of the other two. Only the part of the diagram inside a small disc changes; outside it everything is fixed.

Why these three moves? Here is the physicist's argument. An isotopy is a film of knots K_t. Look at the film projected to the plane. At most moments the projection is regular, and it changes only by planar isotopy. The diagram changes type only at isolated moments when the projection is *not* regular. A generic one-parameter family meets only the simplest (codimension-one) failures of regularity, and there are exactly three:

1. a strand is viewed edge-on and its projection has a cusp: a small kink is born or dies (R1);
2. two strands become tangent in the projection and then pass through each other there, one staying on top: two crossings are born or die (R2);
3. three strands pass through a common point of the projection: a triple point, across which a strand slides over a crossing (R3).

Worse coincidences (a tangency at a triple point, say) need two parameters to arrange, and a generic film avoids them, just as a generic path in the plane avoids a given point.

Key idea: How to build a knot invariant

Define a quantity from a diagram. Check that it is unchanged by R1, R2 and R3. Then it is an invariant of the isotopy type of the knot. Every invariant in Sections 12.10 and 12.11 is checked this way. The Chern–Simons definition in Section 12.12 is different: it is manifestly three-dimensional and needs no diagram at all.

Crossing signs and the writhe. Give the knot an orientation. At each crossing the two strands then have directions, and there are two kinds of crossing (Figure 12.43). The **sign** of a crossing is

$$\varepsilon = \left(\hat{t}_{\text{over}} \times \hat{t}_{\text{under}}\right) \cdot \hat{z} \quad \text{(normalised to } \pm 1\text{)}, \tag{12.151}$$

where $\hat{t}$ are the unit tangents, $\hat{z}$ points towards the viewer, and the diagram lies in the xy-plane. Equivalently (right-hand rule): point the thumb of the right hand along the over-strand; if the fingers curl in the direction of the under-strand, the crossing is positive.

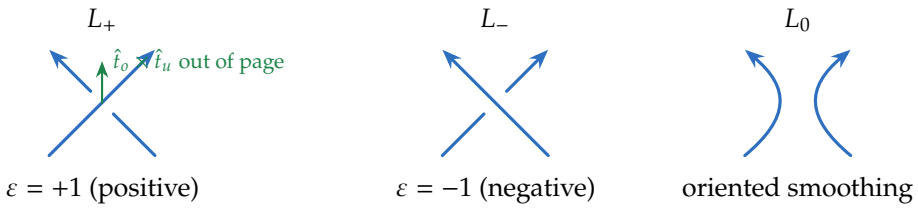

Figure 12.43: The two kinds of oriented crossing and the oriented smoothing. Both strands point upwards. In L_+ the over-strand runs south-west to north-east; in L_- it runs south-east to north-west. L_0 reconnects the four ends without a crossing, respecting the arrows. These are the three local pictures in every skein relation of Section 12.11.

Check (12.151) on L_+ of Figure 12.43. The over-strand has direction $\hat{t}_o \propto (1,1,0)$ and the under-strand $\hat{t}_u \propto (-1,1,0)$. Then $(\hat{t}_o \times \hat{t}_u)_z \propto 1\cdot 1 - 1\cdot(-1) = 2 > 0$, so $\varepsilon = +1$.

Working definition 12.18 (writhe)

The **writhe** of an oriented diagram D is the sum of all its crossing signs [$\varepsilon = +1$ for an L_+ crossing, -1 for an L_- crossing], $w(D) = \sum_{\text{crossings}} \varepsilon$. *Test for invariance:* an R2 move [sliding one strand over another] creates two crossings of opposite sign; R3 [sliding a strand across a crossing] moves crossings about without changing their signs; R1 [adding or removing a kink] creates a single crossing of sign ± 1. So w is invariant under R2 and R3 but *not* under R1: it is a property of the diagram, not of the knot.

For the trefoil drawn in Figure 12.38 with the orientation of increasing t, all three crossings are positive for the right trefoil and negative for the left one: $w = +3$ and $w = -3$. (Mirroring switches every over/under, and switching the over/under at a crossing flips its sign.) The figure-eight diagram has two positive and two negative crossings: $w = 0$. The failure of R1-invariance is not a nuisance to be discarded. We will meet it again as the *framing* of a Wilson loop (Section 12.12.8): w is the self-linking number of the knot thickened into a ribbon lying flat in the page.

12.9.5 A first invariant: tricolouring

Before the heavy machinery, a toy invariant that already proves the trefoil is knotted.

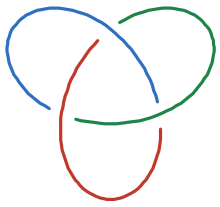
Working definition 12.19 (tricolouring)

An **arc** of a diagram is a piece of the curve running from one under-crossing to the next. A **tricolouring** assigns one of three colours to every arc such that at each crossing the three arcs meeting there (the over-arc and the two halves of the under-strand) are either *all the same colour* or *all different*. Let $\tau(D)$ be the number of tricolourings.

Worked example 12.63: Tricolourings of the unknot and the trefoil

The round circle has one arc and no crossings, so any of the 3 colours works: $\tau = 3$. These three constant colourings exist for every diagram; call a colouring *non-trivial* if it uses more than one colour.

The trefoil diagram has three arcs a, b, c and three crossings, and each crossing involves all three arcs. So the rule says: a, b, c are all equal or all different. All equal: 3 ways. All different: $3! = 6$ ways. So $\tau(\text{trefoil}) = 9$ (Figure 12.44).



at each crossing: over-arc and both under-arcs are all equal or all different.

Here: red, blue, green meet at every crossing, so this is a valid colouring.

Figure 12.44: A non-trivial tricolouring of the trefoil. The three arcs meet at each of the three crossings, and they carry three different colours. The round circle has no non-trivial tricolouring, so the trefoil is not the unknot.

Why is τ an invariant? Check the moves.

- *R1.* The kink has one crossing whose over-arc and one under-arc are the same arc. So all three arcs must be equal: the kink carries the colour of the strand, with nothing new.
- *R2.* Two strands, one over the other. If the lower strand's outer ends have the same colour as the upper strand, the middle piece must share it. If they have colour x and the upper strand has $y \neq x$, the middle piece must be the third colour z at both crossings, consistently. Either way colourings before and after correspond one to one.
- *R3.* A case check (there are only a few colour patterns for the three incoming strands); in each case the outgoing colours can be matched, one to one.

So τ is a knot invariant, and $\tau(\text{trefoil}) = 9 \neq 3 = \tau(\text{unknot})$: *the trefoil is really knotted*. For the figure-eight knot the same count gives $\tau = 3$, so tricolouring cannot distinguish the figure-eight from the unknot. We need stronger invariants.

Colourings as linear algebra. Label the colours by $\mathbb{Z}_3 = \{0, 1, 2\}$. For three elements $x, y, z \in \mathbb{Z}_3$, "all equal or all different" is the same as $x + y + z \equiv 0 \pmod 3$ (check: $0+1+2 = 3$ and $3x \equiv 0$; any other pattern, like $0, 0, 1$, gives a non-zero sum). Since $3 \equiv 0$, this is also $2x_{\text{over}} \equiv x_{\text{under},1} + x_{\text{under},2} \pmod 3$. So tricolourings are the solutions of a linear system mod 3, with one equation per crossing. For the trefoil,

$$\begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{pmatrix} \begin{pmatrix} a \\ b \\ c \end{pmatrix} \equiv 0 \pmod 3.$$

Mod 3 every entry of this matrix is $\equiv -1 \equiv 2$ times the all-ones matrix, whose rank is 1. So the solution space is 2-dimensional over $\mathbb{Z}_3$, with $3^2 = 9$ elements, as counted. Replacing 3 by another prime p gives **Fox p-colourings**. They are controlled by one integer, the *determinant* of the knot, which we will meet again as $|\Delta(-1)|$ in Section 12.11.2.

12.9.6 The knot group

Nash says the classification of knots proceeds by constructing invariants, and the first one he names is the fundamental group of the complement. It is the most direct way to "walk around" the knot.

Reminder: the fundamental group. For a space X and a base point x_0, $\pi_1(X, x_0)$ is the set of loops starting and ending at x_0, where two loops are identified if one can be continuously deformed into the other (keeping x_0 fixed). Loops are multiplied by doing one after the other; the inverse is the loop run backwards; the identity is the constant loop. See Chapter 1.

Working definition 12.20 (knot group, Nash (12.72))

The **knot group** of K is

$$\pi_1(\mathbb{R}^3 \setminus K). \tag{12.152}$$

Operational meaning: the group of ways of travelling around the knot and coming home, up to deformation. Equivalent knots have homeomorphic complements [the map α carries $\mathbb{R}^3 \setminus K_1$ onto $\mathbb{R}^3 \setminus K_2$], hence isomorphic groups.

Worked example 12.64: The unknot: the Aharonov–Bohm group

Let K be the unit circle in the xy-plane. A loop in the complement can wind any integer number of times through the disc bounded by K, and the winding number is the only thing that survives deformation. So $\pi_1(\mathbb{R}^3 \setminus K) \cong \mathbb{Z}$, generated by a small loop μ that links K once (a **meridian**).

Physically: run a steady current I around K. For a loop ℓ in the complement, Ampère's law gives

$$\oint_\ell \vec{B} \cdot \mathrm{d}\vec{l} = \mu_0 I \, n(\ell),$$

with $n(\ell)$ the number of times ℓ threads K. The integer $n(\ell)$ is precisely the element of $\pi_1 \cong \mathbb{Z}$ represented by ℓ. A charged particle carried around ℓ picks up an Aharonov–Bohm phase that depends only on $n(\ell)$. This is the abelian version of the Wilson loops of Section 12.12.

For a knotted K the group is non-abelian, and a direct recipe computes a presentation of it from any diagram.

Working definition 12.21 (Wirtinger presentation)

Take an oriented diagram with arcs $x_1, \dots, x_n$ (and n crossings; for a knot diagram each crossing ends one arc and starts another). Put the base point high above the page, towards the viewer.

- *Generators.* To each arc x_i associate the loop that comes down from the base point, passes once under x_i from right to left (with respect to the arc's direction), and goes back up. We call this loop x_i too.
- *Relations.* At a crossing where the over-arc is x_k and the under-strand goes from x_i into x_j, there is one relation:

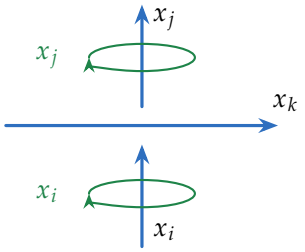
$$x_j = x_k^{\varepsilon} \, x_i \, x_k^{-\varepsilon}, \tag{12.153}$$

  where $\varepsilon = \pm 1$ is the crossing sign.

Then $\pi_1(\mathbb{R}^3 \setminus K)$ is generated by $x_1, \dots, x_n$ subject to these n relations [every element is a product of the $x_i^{\pm 1}$, and two products are equal exactly when the relations force it], and any one of the relations follows from the others.

Why the relation holds (Figure 12.45): a loop passing under the arc x_i just before the crossing can be slid along the under-strand, underneath the over-arc x_k, to a loop under x_j. Sliding

it under x_k drags it around x_k, and that is conjugation by x_k. The sign ε records which way round x_k goes. (With other conventions for the generators, the exponent is $-\varepsilon$; this changes nothing below.)



Slide the loop around x_i up the under-strand. To get past the over-arc it must go round x_k once: $x_j = x_k^{\pm 1} x_i\, x_k^{\mp 1}$.

Figure 12.45: The Wirtinger relation at one crossing. The green loops encircle the arcs just below and just above the over-arc x_k. They differ by conjugation by the loop around x_k.

Worked example 12.65: The trefoil group and a representation by matrices

Label the three arcs of the trefoil x, y, z so that at the three crossings the over-arcs are x, y, z in turn. With all crossings of the same sign, the Wirtinger relations are, in a suitable labelling,

$$z = x\,y\,x^{-1}, \qquad x = y\,z\,y^{-1}, \qquad y = z\,x\,z^{-1}.$$

Eliminate z using the first relation and substitute into the second:

$$\begin{aligned} x &\overset{(1)}{=} y\,z\,y^{-1} \\ &\overset{(2)}{=} y\,(xyx^{-1})\,y^{-1}, \end{aligned}$$

(1) The second Wirtinger relation.
(2) Substitute $z = xyx^{-1}$ from the first relation.

so $x\,y\,x = y\,x\,y$ after multiplying on the right by $y\,x$. (The third relation then follows automatically, as promised.) Hence

$$\pi_1(\mathbb{R}^3 \setminus \text{trefoil}) = \langle x, y \mid xyx = yxy \rangle. \tag{12.154}$$

This is the braid group on three strands. With $a = xyx$ and $b = xy$ one finds $b^3 = xyxyxy = (xyx)(yxy) = (xyx)(xyx) = a^2$, which gives the other common form $\langle a, b \mid a^2 = b^3 \rangle$, the torus-knot presentation for $T(2,3)$.

Is this group really different from $\mathbb{Z}$? We prove it is non-abelian by exhibiting a representation with non-commuting matrices. Send x and y to the transpositions (12) and (23) of three objects, written as permutation matrices:

$$x \mapsto P_x = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad y \mapsto P_y = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}.$$

Check the relation:

$$\begin{aligned} P_x P_y P_x &\overset{(1)}{=} \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix} P_x \overset{(2)}{=} \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}, \\ P_y P_x P_y &\overset{(3)}{=} \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix} P_y \overset{(4)}{=} \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}. \end{aligned}$$

(1) Row i of P_xP_y is row i of P_x times P_y: rows $(0,1,0)$, $(1,0,0)$, $(0,0,1)$ of P_x pick out rows $2,1,3$ of P_y.
(2) Multiplying by P_x on the right swaps the first two columns.
(3) Similarly, P_yP_x has rows $1,3,2$ of P_x.
(4) Multiplying by P_y on the right swaps the last two columns.

Both products equal the matrix of (13), so $xyx = yxy$ holds in the image and we have a genuine representation of the knot group. But $P_xP_y \neq P_yP_x$ (the first is the cycle (123), the second (132)). The image is the whole permutation group S_3, which is non-abelian. Therefore the trefoil group is not $\mathbb{Z}$, and the trefoil is not the unknot, a second proof.
The two proofs are the same proof. A homomorphism $\pi_1 \to S_3$ sending every Wirtinger generator to a transposition is a choice of one of the three transpositions (12), (23), (13) for each arc, subject to (12.153). Conjugating one transposition by another gives the third one, unless they are equal. That is exactly the tricolouring rule, with colours = transpositions.

Physical picture: Representations of the knot group are flat connections

A homomorphism $\rho : \pi_1(\mathbb{R}^3 \setminus K) \to G$ assigns a group element to each loop in the complement, compatibly with composition. That is exactly the holonomy of a *flat* G-connection on the complement: the Wilson loop $P \exp \oint A$ of a connection with $F = 0$ depends only on the homotopy class of the loop (Chapter T3). So "counting representations of the knot group" means "counting flat gauge fields on the knot complement". Flat connections are exactly the classical solutions of Chern–Simons theory (Section 12.13.3); this is the first hint of why a gauge theory computes knot invariants.

What the knot group cannot see. All Wirtinger generators of a knot are conjugate to each other (at each crossing x_j is conjugate to x_i, and the diagram is connected). Abelianising (setting all commutators to 1) therefore sends them all to one generator t:

$$H_1(\mathbb{R}^3 \setminus K) = \pi_1/[\pi_1, \pi_1] \cong \mathbb{Z} = \{t^n\}$$

for every knot. The abelian part sees nothing; all the information is in the non-abelian structure. The Alexander polynomial of Section 12.11.2 extracts some of that information and packages it as a Laurent polynomial in this t. Also, the complements of K and of its mirror image $\bar{K}$ are homeomorphic (by ρ), so the knot group can never detect chirality.

Reading Nash (pp. 339–340, (12.70)–(12.72))

Nash defines knots as embeddings of S^1 in $\mathbb{R}^3$ or S^3, notes that they are all homeomorphic to S^1, and quotes the unknotting criterion $n > 3(m+1)/2$ (his reference is Kyle; the smooth statement is due to Haefliger). He defines links with p components, equivalence by a homeomorphism $\alpha K_1 = K_2$ (12.70) and isotopy through a family α_t with $\alpha_0 = \mathrm{id}$ (12.71). His footnote 7 is our pitfall on homotopy versus isotopy. His "isotopic knots are equivalent, but the converse is false, because the α_t all preserve orientation" is our determinant argument. "Tame" and "wild" are as above, and his first invariant is the knot group (12.72). Diagrams, Reidemeister moves, crossing signs, the writhe, tricolourings and the Wirtinger presentation are not in Nash; they are the standard tools that make his statements checkable, and we use them throughout.

Recap

- A knot is an embedded circle in $\mathbb{R}^3$ or S^3; the knottedness is in the complement, not in the circle.
- All knots untie in $\mathbb{R}^4$: an extra dimension lets strands pass each other. Knotted m-spheres need $n \le \tfrac{3}{2}(m+1)$.
- Equivalence uses any homeomorphism of space; isotopy uses a continuous film starting at the identity, which preserves orientation. A knot and its mirror image are equivalent, but need not be isotopic (trefoil).
- Homotopy allows self-crossing and trivialises every knot. We consider smooth, hence tame, knots.
- Diagrams represent the same knot iff they are related by R1, R2, R3. An invariant is anything unchanged by the three moves. The writhe is invariant under R2, R3 but not R1.
- Tricolourings and the knot group $\langle x, y \mid xyx = yxy \rangle$ (with its S_3 representation) both prove the trefoil is knotted. Representations of the knot group are flat connections on the complement.

12.10 The linking number: Gauss, Ampère and a degree

The simplest question about two disjoint closed curves C_1 and C_2 is: *how many times does one wind around the other?* The answer is an integer, the **linking number** $L(C_1, C_2)$. It is the oldest knot invariant. Gauss wrote down an integral formula for it in 1833, and it is exactly the quantity that the abelian Chern–Simons path integral will produce in Section 12.12 (Nash's (12.89)–(12.90)). So before the polynomials of Section 12.11, we take the linking number apart completely. We shall meet it in four guises:

1. a *count of crossings* in a diagram;
2. a *flux*: the current through one loop measured by Ampère's law around the other;
3. the *Gauss double integral*, which is Biot–Savart in disguise;
4. the *degree* of a map from a torus to a sphere.

That the four agree is the whole content of this section. Each guise explains a different feature. The crossing count makes it computable. The flux makes it obviously an integer. The Gauss integral makes it obviously independent of any projection. The degree makes it obviously unchanged by deformations.

Throughout, C_1 and C_2 are oriented, disjoint, smooth closed curves in $\mathbb{R}^3$, parametrised as $x(s)$ and $y(t)$ with $s, t \in [0, 2\pi]$. We write $\dot{x} = \mathrm{d}x/\mathrm{d}s$ and $\dot{y} = \mathrm{d}y/\mathrm{d}t$.

12.10.1 Counting crossings

Working definition 12.22 (linking number from a diagram)

Draw a diagram of the two-component link $C_1 \cup C_2$. Look only at the crossings *between* C_1 and C_2 (ignore the self-crossings of each component). Each has a sign $\varepsilon = \pm 1$ given by (12.151) [$+1$ for an L_+ crossing, -1 for an L_- crossing]. Then

$$L(C_1, C_2) = \frac{1}{2} \sum_{\substack{\text{crossings of} \\ C_1 \text{ with } C_2}} \varepsilon = \sum_{\substack{\text{crossings where} \\ C_1 \text{ is over } C_2}} \varepsilon. \tag{12.155}$$

Why are the two sums in (12.155) equal? Walk along C_2 in the diagram. Each time C_2 passes under C_1 and then later back out, the total number of crossings between the two is even, and the "C_1 over" and "C_2 over" signed counts are equal. This is not obvious from the diagram alone; it follows from the degree picture of Section 12.10.4, where the two counts are the degree of the same map computed at two antipodal points of the sphere. We use the symmetric form $\frac{1}{2}\sum$ when we want to check invariance, and the one-sided form when we want to compute quickly.

Invariance under the Reidemeister moves.

- R1 creates or removes a self-crossing of one component. It does not enter the sum.
- R2 between C_1 and C_2 creates two inter-component crossings. The two strands are the same two directed strands at both, and one of them is over at both. Reversing which of the two crossings we look at reverses the relative direction of the under-strand, so their signs are opposite. The sum is unchanged. (R2 between a component and itself does not enter.)
- R3 moves one strand across a crossing of two others. The three crossings survive with the same over/under information and the same directions, so the same signs.

So L is a link invariant. Because every crossing has sign ± 1 and the one-sided count is a sum of such signs, $L \in \mathbb{Z}$.

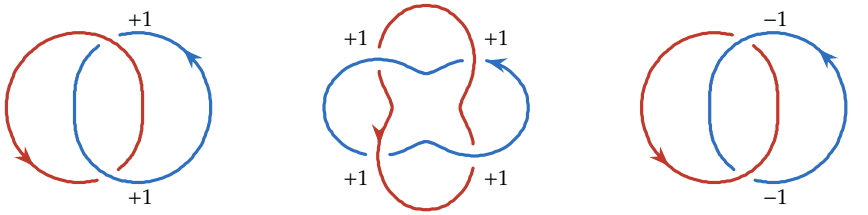


Figure 12.46: Counting crossings. Only crossings between the blue and the red component count, each with its sign. The Hopf link has two, both $+1$, so $L = \frac{1}{2}(1+1) = 1$. The $T(2,4)$ link has four positive crossings: $L = 2$. The mirror image switches every crossing and flips every sign.

Worked example 12.66: Linking numbers of simple links

1. *The unlink* (two circles far apart) has no crossings between the components: $L = 0$.
2. *The Hopf link* of Figure 12.46 (left). Two inter-component crossings, both positive:

$$L = \tfrac{1}{2}(+1 + 1) = 1.$$

The one-sided count agrees: blue passes over red exactly once (at the bottom), with sign +1.

3. *The torus links* $T(2, 2n)$, two parallel strands twisted n full times around each other. The diagram has $2n$ crossings, all between the two components, all of the same sign: $L = \pm n$.

4. *The Whitehead link*. One round circle, and one component that clasps it: it goes under, over, then back under and over in the reverse direction. There are four inter-component crossings with signs $+1, +1, -1, -1$, so $L = 0$. Yet the two components cannot be pulled apart. The linking number does not see this.

5. *The Borromean rings* (Figure 12.39). Each pair of rings has two crossings with opposite signs, so every pairwise linking number is 0, even though the three rings are linked.

Three properties follow at once from (12.155).

$$\begin{aligned} L(C_2, C_1) &= L(C_1, C_2) && \text{(the symmetric sum does not care which is first),} \\ L(-C_1, C_2) &= -L(C_1, C_2) && \text{(reversing one strand flips the sign of every crossing it is in),} \\ L(\rho C_1, \rho C_2) &= -L(C_1, C_2) && \text{(the mirror (12.149) switches every crossing).} \end{aligned}$$

The last line means that the linking number, unlike the knot group, *does* detect chirality of links: the Hopf link with $L = +1$ is not isotopic to its mirror image with $L = -1$ (as oriented links).

12.10.2 Ampère's law: why the linking number is an integer

Now forget diagrams and think about magnetostatics. Let a steady unit current $I = 1$ flow along C_2. We use units with $\mu_0 = 1$. The magnetic field is given by the Biot–Savart law,

$$\vec{B}(x) = \frac{1}{4\pi} \oint_{C_2} \frac{d\vec{y} \times (x - y)}{|x - y|^3}. \tag{12.156}$$

Ampère's law says that the circulation of $\vec{B}$ around any closed loop equals the current threading the loop:

$$\oint_{C_1} \vec{B} \cdot d\vec{x} = (\text{current through a surface bounded by } C_1). \tag{12.157}$$

Let us see why the right side is an integer, and which integer it is.

Working definition 12.23 (linking number as a flux)

Choose any oriented surface S with boundary $\partial S = C_1$ (orient S so that C_1 runs anticlockwise when S is seen from the tip of its normal $\hat{n}$). Count the points where C_2 pierces S, with sign $+1$ if C_2 crosses in the direction of $\hat{n}$ and -1 otherwise. The signed count is $L(C_1, C_2)$.

Such a surface always exists. If C_1 is a round circle, S is the flat disc. For any knot, Seifert's algorithm (Section 12.11.2) constructs an orientable surface with boundary C_1, a **Seifert surface**. The surface may be pierced by C_2 many times, but the signed count is independent of the choice of S. Two choices S and S' together bound a region of space (glue S to S' with the orientation of S' reversed); C_2 enters that region as often as it leaves, so the counts through S and S' agree.

Now apply Stokes' theorem. Because the current is a sum of delta functions along C_2,

$$\oint_{C_1} \vec{B} \cdot \mathrm{d}\vec{x} \overset{(1)}{=} \int_S (\nabla \times \vec{B}) \cdot \hat{n}\, \mathrm{d}A \overset{(2)}{=} \int_S \vec{j} \cdot \hat{n}\, \mathrm{d}A \overset{(3)}{=} \sum_{\text{piercings } p} \varepsilon_p \overset{(4)}{=} L(C_1, C_2). \tag{12.158}$$

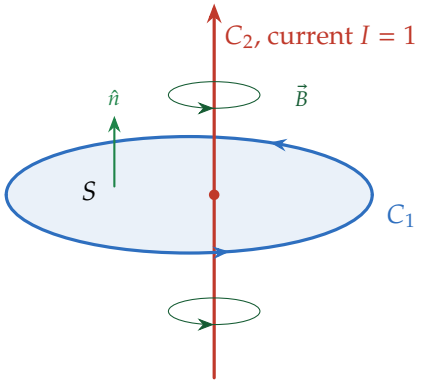
(1) Stokes' theorem for the surface S with $\partial S = C_1$ (Chapter T2). $\vec{B}$ is smooth on S except where C_2 pierces it, where it has an integrable $1/\rho$ singularity; cutting out tiny discs around the piercings and letting them shrink gives the same result.

(2) The magnetostatic Maxwell equation $\nabla \times \vec{B} = \vec{j}$ (with $\mu_0 = 1$), which Biot–Savart solves.

(3) $\vec{j}$ is concentrated on C_2, a unit current along the curve. Each piercing contributes ± 1 according to the direction of crossing: the flux of a unit current through a surface it crosses once.

(4) The flux description of the linking number.

The left side is a continuous function of the curves (as long as they do not touch). The right side is an integer. So the left side cannot change under deformation: it is a topological invariant, and an integer. This is Nash's remark "from Ampère's law, where precisely this integral occurs, it follows that $L(C_l, C_m)$ is an integer".



one piercing, along $\hat{n}$:

$$\oint_{C_1} \vec{B} \cdot \mathrm{d}\vec{x} = \int_S \vec{j} \cdot \hat{n}\, \mathrm{d}A = +1$$

Figure 12.47: The linking number as a flux. The disc S spans C_1; its normal $\hat{n}$ is fixed by the right-hand rule from the arrow on C_1. The current on C_2 pierces S once along $\hat{n}$, so Ampère's law gives circulation $+1$. Deform the curves and the piercing may move, but it cannot disappear without C_2 crossing C_1.

12.10.3 The Gauss integral

Substituting Biot–Savart into Ampère turns the linking number into a double integral over the two curves, with no surface and no diagram in sight:

$$L(C_1, C_2) \overset{(1)}{=} \oint_{C_1} \vec{B} \cdot \mathrm{d}\vec{x} \overset{(2)}{=} \frac{1}{4\pi} \oint_{C_1} \oint_{C_2} \frac{\mathrm{d}\vec{x} \cdot \left(\mathrm{d}\vec{y} \times (x - y)\right)}{|x - y|^3} \overset{(3)}{=} \frac{1}{4\pi} \oint_{C_1} \oint_{C_2} \frac{(x - y) \cdot (\mathrm{d}\vec{x} \times \mathrm{d}\vec{y})}{|x - y|^3}$$

$$\overset{(4)}{=} \frac{\varepsilon_{ijk}}{4\pi} \oint_{C_1} \mathrm{d}x^i \oint_{C_2} \mathrm{d}y^j \, \frac{(x-y)^k}{|x-y|^3}. \tag{12.159}$$

(1) Ampère's law (12.158).
(2) Insert the Biot–Savart field (12.156) of a unit current on C_2.
(3) Cyclic symmetry of the triple product, $\vec{a}\cdot(\vec{b}\times\vec{c}) = \vec{c}\cdot(\vec{a}\times\vec{b})$, with $\vec{a} = \mathrm{d}\vec{x}$, $\vec{b} = \mathrm{d}\vec{y}$, $\vec{c} = x - y$.
(4) In components, $\vec{c}\cdot(\vec{a}\times\vec{b}) = \varepsilon_{ijk}a^i b^j c^k$.

The last line is exactly Nash's (12.90). In parametrised form, which is what one feeds to a computer,

$$L(C_1, C_2) = \frac{1}{4\pi} \int_0^{2\pi} \mathrm{d}s \int_0^{2\pi} \mathrm{d}t \, \frac{\big(x(s) - y(t)\big)\cdot\big(\dot{x}(s)\times\dot{y}(t)\big)}{|x(s) - y(t)|^3}. \tag{12.160}$$

Worked example 12.67: The Gauss integral for a circle and a line

Take C_1 the unit circle in the xy-plane, anticlockwise seen from above, and C_2 the z-axis traversed upwards. The z-axis is not a closed curve in $\mathbb{R}^3$, but it is one in $S^3 = \mathbb{R}^3 \cup \{\infty\}$: it closes up through the point at infinity. (Equivalently, think of a huge circle, most of which is far away and contributes nothing.) Parametrise

$$x(s) = (\cos s, \sin s, 0), \qquad y(u) = (0, 0, u), \quad u \in \mathbb{R}.$$

Then $\dot{x} = (-\sin s, \cos s, 0)$, $\dot{y} = (0, 0, 1)$ and $x - y = (\cos s, \sin s, -u)$. Compute the integrand piece by piece:

$$\begin{aligned} \dot{x}\times\dot{y} &\overset{(1)}{=} (\cos s\cdot 1 - 0,\ 0 - (-\sin s)\cdot 1,\ 0) = (\cos s, \sin s, 0), \\ (x-y)\cdot(\dot{x}\times\dot{y}) &\overset{(2)}{=} \cos^2 s + \sin^2 s + 0 = 1, \\ |x-y|^3 &\overset{(3)}{=} (1+u^2)^{3/2}. \end{aligned}$$

(1) $(\vec{a}\times\vec{b})_x = a_y b_z - a_z b_y$, and cyclically, with $\vec{a} = \dot{x}$, $\vec{b} = \dot{y}$.
(2) Dot product with $x - y = (\cos s, \sin s, -u)$.
(3) $|x-y|^2 = \cos^2 s + \sin^2 s + u^2$.

So

$$\begin{aligned} L(C_1, C_2) &\overset{(1)}{=} \frac{1}{4\pi} \int_0^{2\pi} \mathrm{d}s \int_{-\infty}^{\infty} \frac{\mathrm{d}u}{(1+u^2)^{3/2}} \\ &\overset{(2)}{=} \frac{1}{4\pi}\cdot 2\pi \cdot \left[\frac{u}{\sqrt{1+u^2}}\right]_{-\infty}^{\infty} \\ &\overset{(3)}{=} \frac{1}{4\pi}\cdot 2\pi\cdot 2 = 1. \end{aligned}$$

(1) The parametrised Gauss formula (12.160) with the integrand just computed.
(2) The s-integral is trivial. For the u-integral, $\frac{\mathrm{d}}{\mathrm{d}u}\frac{u}{\sqrt{1+u^2}} = \frac{(1+u^2)-u^2}{(1+u^2)^{3/2}}$.
(3) $u/\sqrt{1+u^2} \to \pm 1$ as $u \to \pm\infty$.

The z-axis goes up through the disc spanned by the circle, which is the direction of the circle's right-hand normal: one positive piercing, and the integral agrees. Physically, $2\pi\cdot\frac{1}{2\pi\rho}\big|_{\rho=1} = 1$ is the circulation of the field $B_\phi = 1/(2\pi\rho)$ of an infinite wire.

Worked example 12.68: Two coplanar circles

Let C_1 and C_2 be any two disjoint closed curves lying in the plane $z = 0$. Then $\dot{x}$ and $\dot{y}$ lie in the plane, so $\dot{x} \times \dot{y}$ points along $\hat{z}$. But $x - y$ also lies in the plane, so $(x - y) \cdot (\dot{x} \times \dot{y}) = 0$ at every point. The integrand vanishes identically: $L = 0$. Two curves in a plane are never linked, as the crossing count (no crossings at all) also says.

Watch out: The integrand is not a total derivative

The Gauss integrand is not zero and not constant for a general link; only its integral is topological. For the Hopf link of Figure 12.46 the integrand is large where the curves come close and small elsewhere. Deform the curves and the integrand changes everywhere, but the integral stays at 1. A numerical evaluation of (12.160) on the torus-link parametrisations (12.146) with 400×400 points gives 1.0001 for the Hopf link $T(2, 2)$ and 2.0002 for $T(2, 4)$.

12.10.4 The Gauss integral as a degree

Why is the Gauss integral unchanged by deformations, directly and without Ampère? Because it is the *degree* of a map, and degrees are integers that cannot jump.

Working definition 12.24 (the Gauss map)

The **Gauss map** of the pair (C_1, C_2) assigns to each pair of parameters the unit vector pointing from the point on C_1 to the point on C_2:

$$\Psi : T^2 \to S^2, \qquad \Psi(s, t) = \frac{y(t) - x(s)}{|y(t) - x(s)|}. \tag{12.161}$$

Here $T^2 = S^1 \times S^1$ is the torus of pairs (s, t), oriented by $\mathrm{d}s \wedge \mathrm{d}t$ [s counts as the first direction and t as the second, which fixes the sign of the degree]. It is well defined because the curves never meet.

The **degree** of a map between closed oriented surfaces of the same dimension counts, with signs, how many times it covers the target (Chapter 1). Operationally there are two ways to compute it:

- *by integration:* $\deg \Psi = \frac{1}{4\pi} \int_{T^2} \Psi^* \omega$, where ω is the area form of the unit sphere, with total area 4π;
- *by counting:* pick a point $\hat{n} \in S^2$ that is a regular value; then $\deg \Psi = \sum_{\Psi(p)=\hat{n}} \pm 1$, with $+1$ where Ψ preserves orientation near p and -1 where it reverses it.

Step 1: the integral is the Gauss integral. The area form of the unit sphere at the point $u \in S^2$, evaluated on two tangent vectors $\vec{a}, \vec{b}$, is the signed area $u \cdot (\vec{a} \times \vec{b})$. Put $\vec{r} = x - y$, so $\Psi = -\vec{r}/|\vec{r}|$. Then

$$\partial_s \Psi \overset{(1)}{=} -\frac{\dot{x}}{|\vec{r}|} + (\dots)\,\vec{r}, \qquad \partial_t \Psi \overset{(2)}{=} \frac{\dot{y}}{|\vec{r}|} + (\dots)\,\vec{r},$$

$$\Psi^* \omega(\partial_s, \partial_t) \overset{(3)}{=} \Psi \cdot (\partial_s \Psi \times \partial_t \Psi)$$

$$\overset{(4)}{=} \left(-\frac{\vec{r}}{|\vec{r}|}\right) \cdot \left(-\frac{\dot{x}}{|\vec{r}|} \times \frac{\dot{y}}{|\vec{r}|}\right) = \frac{\vec{r} \cdot (\dot{x} \times \dot{y})}{|\vec{r}|^3}.$$

(1) $\partial_s \vec{r} = \dot{x}$ and $\partial_s (1/|\vec{r}|) \propto \vec{r}$; only the first term will matter.

(2) $\partial_t \vec{r} = -\dot{y}$, so $\partial_t \Psi = +\dot{y}/|\vec{r}| + (\ldots)\vec{r}$.
(3) Definition of the area form, and of pullback: $\Psi^*\omega$ evaluated on ∂_s, ∂_t is ω evaluated on their images (Chapter T1).
(4) Any term proportional to $\vec{r}$ inside the cross product is killed by the dot product with $\vec{r}$ (a triple product with a repeated vector vanishes).

So $\frac{1}{4\pi}\int_{T^2} \Psi^*\omega$ is exactly the Gauss integral (12.160):

$$L(C_1, C_2) = \deg \Psi. \tag{12.162}$$

Step 2: why the degree is invariant. Deform the curves. Ψ changes continuously, so $\frac{1}{4\pi}\int \Psi^*\omega$ changes continuously. But it is always an integer (the counting description). A continuous integer-valued function is constant. The only way to change the degree is to make Ψ undefined, which happens exactly when $y(t) = x(s)$ for some s, t: the curves pass through each other.

Step 3: counting gives the crossing formula. Choose $\hat{n} = -\hat{z}$, pointing away from a viewer who looks down on the xy-plane. Then $\Psi(s,t) = -\hat{z}$ means that $y(t)$ lies directly *below* $x(s)$: in the diagram, C_1 crosses over C_2 there. So the preimages of $-\hat{z}$ are exactly the crossings where C_1 is over C_2, and the local sign of Ψ at such a point is the crossing sign ε. (Check it on the Hopf link: one such crossing, sign +1, and $L = +1$.) If instead we choose $\hat{n} = +\hat{z}$, the preimages are the crossings where C_2 is over C_1. Both counts compute the same degree, which proves that the two sums in (12.155) agree.

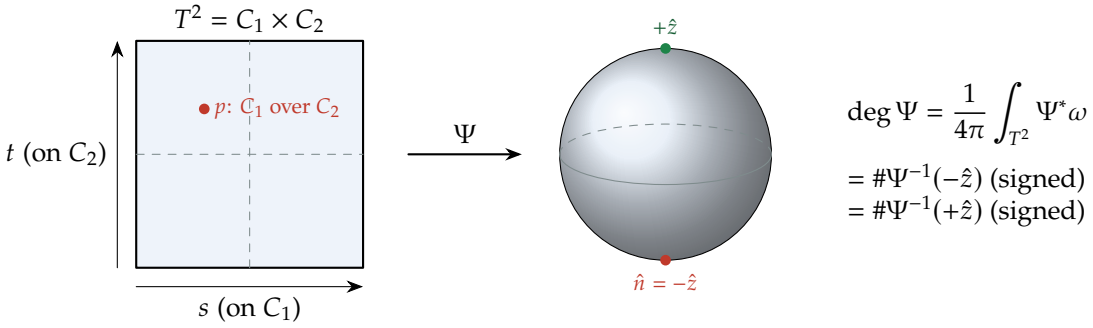


Figure 12.48: The Gauss map sends a pair of points, one on each curve, to the direction from the first to the second. The torus of pairs wraps around the sphere L times. Pairs mapped to the south pole are the crossings where C_1 lies over C_2; pairs mapped to the north pole are those where C_2 lies over C_1.

Worked example 12.69: The degree for the circle and the line

Return to Example 12.67. There $\Psi(s,u) = \big(-\cos s, -\sin s, u\big)/\sqrt{1+u^2}$. As u runs from $-\infty$ to ∞ the third component runs from -1 to $+1$: from the south pole to the north pole. As s goes once round, Ψ goes once round the z-axis. So Ψ covers every point of the sphere (apart from the poles, which are limits) exactly once, and $|\deg \Psi| = 1$. The sign is +1 by Step 1, because the integrand is positive.

12.10.5 Homology and physics: what the linking number measures

Two more ways to see the same integer, both important later.

Homology of the complement. In Example 12.64 we saw that the first homology of the complement of a knot is $H_1(\mathbb{R}^3 \setminus C_2) \cong \mathbb{Z}$, generated by a small meridian loop μ_2 around C_2.

The curve C_1 lies in this complement, so it defines a class

$$[C_1] = L(C_1, C_2)\,[\mu_2] \in H_1(\mathbb{R}^3 \setminus C_2) \cong \mathbb{Z}. \tag{12.163}$$

The integer is the linking number: the homomorphism $H_1(\mathbb{R}^3 \setminus C_2) \to \mathbb{Z}$ is "circulation of the field of a unit current on C_2", which is 1 on μ_2. In gauge-theory words: a particle of charge q transported around C_1 in the field of a unit magnetic flux tube along C_2 picks up the Aharonov–Bohm phase

$$\exp\Big(iq \oint_{C_1} \vec{A} \cdot \mathrm{d}\vec{x}\Big) = \exp\big(iq\, L(C_1, C_2)\big).$$

The Wilson loop of a $U(1)$ field with a flux tube measures the linking number. The abelian Chern–Simons theory of Section 12.12 is a theory in which each Wilson loop *is* such a flux tube for the others.

Magnetic helicity. The abelian Chern–Simons action is, up to a constant, the integral $\int A \wedge \mathrm{d}A$. For a real $U(1)$ field in $\mathbb{R}^3$ in the vector-calculus dictionary of Chapter T1, $A \leftrightarrow \vec{A}$, $\mathrm{d}A \leftrightarrow \vec{B} = \nabla \times \vec{A}$, and

$$\int_{\mathbb{R}^3} A \wedge \mathrm{d}A = \int_{\mathbb{R}^3} \vec{A} \cdot \vec{B}\, \mathrm{d}^3x,$$

which is the **magnetic helicity** of plasma physics (Woltjer, Moffatt). It measures linking of field lines.

Worked example 12.70: Helicity of two linked flux tubes

Let the magnetic field be concentrated in two thin, untwisted flux tubes along closed curves C_1, C_2 carrying fluxes Φ_1 and Φ_2. So $\vec{B} = \Phi_1 \vec{\delta}_{C_1} + \Phi_2 \vec{\delta}_{C_2}$, where $\int \vec{v} \cdot \vec{\delta}_C\, \mathrm{d}^3x = \oint_C \vec{v} \cdot \mathrm{d}\vec{x}$. Write $\vec{A} = \Phi_1 \vec{A}_1 + \Phi_2 \vec{A}_2$ with $\nabla \times \vec{A}_i$ the field of a unit tube along C_i. Then

$$\begin{aligned} \int \vec{A} \cdot \vec{B}\, \mathrm{d}^3x &\overset{(1)}{=} \sum_{i,j} \Phi_i \Phi_j \oint_{C_i} \vec{A}_j \cdot \mathrm{d}\vec{x} \\ &\overset{(2)}{=} \sum_{i \neq j} \Phi_i \Phi_j\, L(C_i, C_j) + (\text{self terms}) \\ &\overset{(3)}{=} 2\,\Phi_1 \Phi_2\, L(C_1, C_2) + (\text{self terms}). \end{aligned}$$

(1) Insert $\vec{B}$ as delta functions and expand $\vec{A}$.

(2) By Stokes, $\oint_{C_i} \vec{A}_j \cdot \mathrm{d}\vec{x}$ is the flux of the unit tube j through a surface spanning C_i, which is the signed number of piercings: $L(C_i, C_j)$ (the flux description, with the roles of $\vec{B}$ and $\vec{j}$ exchanged).

(3) Symmetry $L(C_1, C_2) = L(C_2, C_1)$.

The "self terms" $i = j$ measure how each tube is twisted and coiled around itself. They are exactly the self-linking numbers that force the framing of Section 12.12.8. Nash's formula (12.92), $\exp\big(\frac{i\pi}{k} \sum_{l,m} n_l n_m L(C_l, C_m)\big)$, is this helicity with fluxes $\Phi_l \propto n_l$ put into the exponent.

12.10.6 Self-linking: the first sign of framing

What if $C_1 = C_2 = C$? The Gauss formula (12.160) with both parameters on the same curve,

$$\mathrm{Wr}(C) = \frac{1}{4\pi} \oint_C \oint_C \frac{(x-y)\cdot(\mathrm{d}\vec{x}\times\mathrm{d}\vec{y})}{|x-y|^3}, \tag{12.164}$$

is called the **writhe** of the space curve C. (Its relative, the writhe $w(D)$ of a diagram, was defined in Section 12.9.4.) Near the diagonal $s = t$ both numerator and denominator vanish. Expand $x = x(s)$, $y = x(t)$ with $h = t - s$ small:

$$\begin{aligned} x - y &\overset{(1)}{=} -\dot{x}\,h - \tfrac{1}{2}\ddot{x}\,h^2 + O(h^3), \\ \dot{x}(s)\times\dot{x}(t) &\overset{(2)}{=} \dot{x}\times\ddot{x}\,h + O(h^2), \\ (x-y)\cdot\big(\dot{x}(s)\times\dot{x}(t)\big) &\overset{(3)}{=} -\tfrac{1}{2}\,\ddot{x}\cdot(\dot{x}\times\ddot{x})\,h^3 + O(h^4) = O(h^4), \\ |x-y|^3 &\overset{(4)}{=} |\dot{x}|^3\,|h|^3 + O(h^4). \end{aligned}$$

(1) Taylor expansion of $x(t) = x(s+h)$ about s.
(2) $\dot{x}(s+h) = \dot{x} + \ddot{x}\,h + \ldots$, and $\dot{x}\times\dot{x} = 0$.
(3) The term $-\dot{x}h\cdot(\dot{x}\times\ddot{x})h$ vanishes (repeated vector); the term $-\frac{1}{2}\ddot{x}h^2\cdot(\dot{x}\times\ddot{x})h$ vanishes for the same reason. What survives is of order h^4 (it involves the third derivative, i.e. the torsion of the curve).
(4) $|x-y| = |\dot{x}|\,|h| + O(h^2)$.

So the integrand is bounded near the diagonal and $\mathrm{Wr}(C)$ is a finite number. But it is *not* an integer and *not* an invariant. The degree argument fails, because the Gauss map $\Psi(s,t) = (x(t)-x(s))/|x(t)-x(s)|$ is undefined on the whole diagonal $s = t$: the torus now has a circle cut out of it, and the counting argument has a boundary to leak through. Deform a curve smoothly and Wr changes smoothly. A flat curve in a plane has $\mathrm{Wr} = 0$ (by Example 12.68); lift part of it into a helix and Wr takes any real value you like.

In quantum field theory the trouble is worse: the self-term involves the propagator $\langle A_i(x)A_j(y)\rangle$ at coincident points, which is singular. Nash states the difficulty this way: $L(C_l, C_l)$ has singularities at $x = y$. The cure, framing, keeps the answer topological at the price of one extra integer per component. We return to it in Section 12.12.8.

Try it: Orientation and mirror

Compute L for the Hopf link with the red component reversed, and for the $T(2,6)$ link. *Answer:* reversing one component flips all crossing signs: $L = -1$. $T(2,6)$ has six positive inter-component crossings: $L = 3$.

Reading Nash (pp. 344–345, (12.89)–(12.90))

Nash meets the linking number as the output of the abelian Chern–Simons path integral (12.89), written with $\varepsilon_{ijk}\oint \mathrm{d}x^i \oint \mathrm{d}y^j\,(x-y)^k/|x-y|^3$, and identifies it as Gauss's linking number $L(C_l, C_m)$ (12.90), "one of the oldest invariants in knot theory". He notes that it arose from Ampère's law and that this makes it an integer. Our chain (12.159) is exactly his (12.90); the diagram count, the degree of the Gauss map and the helicity are not in Nash, but they explain why the integral is an invariant and why a gauge theory produces it. His remark that $L(C_l, C_l)$ is singular is our Section 12.10.6.

Recap

- $L(C_1, C_2)$ is half the signed number of crossings between the two components in any diagram; it is an integer and a link invariant.
- Ampère: $L = \oint_{C_1} \vec{B} \cdot \mathrm{d}\vec{x}$ for the field of a unit current on C_2, equal to the signed number of times C_2 pierces a surface spanning C_1.
- Gauss: $L = \frac{1}{4\pi} \oint \oint (x - y) \cdot (\mathrm{d}x \times \mathrm{d}y)/|x - y|^3$, which is Biot–Savart inserted into Ampère (Nash (12.90)).
- The Gauss integral is the degree of the map $T^2 \to S^2$ giving the direction between the two points; this is why it is invariant, and counting preimages of a pole recovers the crossing count.
- L is symmetric, flips sign under reversing one component or under mirroring, and misses the Whitehead link and Borromean rings.
- The same integral for one curve, the writhe, is finite but not invariant. This is the origin of framing.

12.11 Knot polynomials: Alexander, Jones and their skein relations

The tricolouring number and the knot group proved that the trefoil is knotted. Neither can tell the right trefoil from the left one, and the knot group is hard to compare between two knots: deciding whether two presentations give the same group is, in general, hopeless. We want invariants that are *numbers we can compute and compare*. The answer found by Alexander in 1928, and in a much stronger form by Jones in 1984, is to attach to every knot a polynomial.

This section answers three questions.

1. Where does the variable t come from, and what does the Alexander polynomial measure? (The abelian shadow of the knot group, seen by an infinite "crystal" built from the knot complement.)

2. How do we compute these polynomials in practice? (By cutting the problem into smaller problems with *skein relations*, or by a state sum like a partition function in statistical mechanics.)

3. Why is the Jones polynomial the one a physicist should care about? (Because it sees chirality, and because Section 12.12 and Chapter 12 show it is a Wilson-loop expectation value in Chern–Simons theory.)

Nash states the results in two pages, [Nash pp. 340–342, (12.73)–(12.83)], and says the properties "can be easily checked". We check all of them.

12.11.1 Laurent polynomials, and what "defined up to $\pm t^n$" means

Working definition 12.25 (Laurent polynomial)

A **Laurent polynomial** (Nash: an *L*-**polynomial**) in t is a finite sum $\sum_{k=m}^{M} a_k t^k$ in which negative powers are allowed. We write $\mathbb{Z}[t, t^{-1}]$ for the Laurent polynomials with integer coefficients. When half-integer powers $t^{1/2}$ occur (for links with an even number of components) we work in $\mathbb{Z}[t^{1/2}, t^{-1/2}]$.

Examples: $t^2 - t + 1$, $t^{-1} - 1 + t$ and $t + t^3 - t^4$ are Laurent polynomials; $t^{-1/2} + t^{1/2}$ is one in $t^{1/2}$.

The **units** of $\mathbb{Z}[t, t^{-1}]$, the elements with an inverse inside $\mathbb{Z}[t, t^{-1}]$, are exactly $\pm t^n$: indeed $(\pm t^n)(\pm t^{-n}) = 1$, and a product of two Laurent polynomials with more than one term has more than one term. The Alexander polynomial will turn out to be defined only up to multiplication by a unit. This is the same kind of ambiguity as an overall phase of a wavefunction, and it is removed by a normalisation convention.

Working definition 12.26 (span and normalised form)

The **span** of a non-zero Laurent polynomial is (largest power) − (smallest power). It is unchanged by multiplying by $\pm t^n$, so it is a well-defined invariant of anything defined up to units. The **normalised form** is the unique representative with no negative powers and a positive constant term.

For $t^{-1} - 1 + t$: span $= 1 - (-1) = 2$, normalised form $t^2 - t + 1$.

12.11.2 The Alexander polynomial

Where the variable t comes from. At the end of Section 12.9.6 we saw that abelianising the knot group always gives $\mathbb{Z} = \{t^n\}$: the only abelian information is how many times a loop winds around the knot. Here t stands for "one meridian", one loop around the knot. The Alexander polynomial is the first-order non-abelian information, written in the language of this t.

Physical picture: The Alexander polynomial is a Bloch determinant

Cut the knot complement open along a surface bounded by the knot. We get a "unit cell" with two faces, a top copy and a bottom copy of the surface. Stack infinitely many unit cells, gluing the top of each to the bottom of the next. The result is the **infinite cyclic cover**: a one-dimensional "crystal" whose lattice translation is t (going once around the knot moves us up one cell). Loops in this crystal (its first homology) form a module over the translations, just as the states of an electron in a crystal form representations of the lattice translations. In Bloch's language $t = e^{ik}$ is the phase acquired per cell. The Alexander polynomial is the determinant of the matrix that presents this module, the analogue of $\det H(k)$ for a tight-binding Hamiltonian. Its zeros are the "Bloch phases" at which the crystal has an extra loop. The two recipes below compute this determinant: the Fox calculus from the knot group, and the Seifert matrix from the surface.

Recipe 1: from the knot group (Fox calculus)

The Fox derivative is a way of differentiating words in a group. It is the discrete analogue of the product rule.

Working definition 12.27 (Fox derivative)

For words in generators $x_1, \dots, x_n$ [products such as $x_1 x_2^{-1} x_1$ of generators and their inverses], the **Fox derivative** $\partial/\partial x_j$ [its values are integer combinations of words, such as $1 - x_1 x_2$] is fixed by three rules:

$$\frac{\partial x_i}{\partial x_j} = \delta_{ij}, \qquad \frac{\partial (uv)}{\partial x_j} = \frac{\partial u}{\partial x_j} + u\,\frac{\partial v}{\partial x_j}, \qquad \frac{\partial x_j^{-1}}{\partial x_j} = -x_j^{-1}.$$

(The third follows from the first two applied to $x_j x_j^{-1} = 1$: $0 = 1 + x_j\,\partial x_j^{-1}/\partial x_j$.) In words: scan the word from left to right; every time you meet x_j, write down the prefix before it with a plus sign; every time you meet x_j^{-1}, write the prefix *including* x_j^{-1} with a minus sign. *Recipe for* Δ. Take a Wirtinger presentation [one generator per arc of the diagram, one relation per crossing] with n generators and $n-1$ relations $r_i = 1$ (one relation can always be dropped). Form the $(n-1)\times n$ **Alexander matrix** $\partial r_i/\partial x_j$ and then set every generator equal to t. Delete any one column. The determinant of the remaining square matrix is $\Delta(t)$, up to a unit $\pm t^n$.

Worked example 12.71: Alexander polynomial of the trefoil from its group

From (12.154) the trefoil group has generators x, y (both Wirtinger generators, both mapping to t) and one relation $xyx = yxy$, i.e. $r = xyx\,y^{-1}x^{-1}y^{-1} = 1$. Differentiate with respect to x. The letter x appears in position 1 (prefix: empty word 1) and position 3 (prefix xy); x^{-1} appears in position 5 (prefix including it: $xyxy^{-1}x^{-1}$):

$$\begin{aligned}\frac{\partial r}{\partial x} &\overset{(1)}{=} 1 + xy - xyxy^{-1}x^{-1}\\ &\overset{(2)}{=} 1 + t^2 - t^{1+1+1-1-1}\\ &= t^2 - t + 1.\end{aligned}$$

(1) The scanning rule.
(2) Abelianise: every generator becomes t, and exponents add.

Now with respect to y: y in position 2 (prefix x), y^{-1} in positions 4 and 6 (prefixes $xyxy^{-1}$ and $xyxy^{-1}x^{-1}y^{-1}$):

$$\begin{aligned}\frac{\partial r}{\partial y} &\overset{(1)}{=} x - xyxy^{-1} - xyxy^{-1}x^{-1}y^{-1}\\ &\overset{(2)}{=} t - t^2 - t^0\\ &= -(t^2 - t + 1).\end{aligned}$$

(1) The scanning rule again.
(2) Abelianise; the last word is r itself, which becomes $t^0 = 1$.

The Alexander matrix is the 1×2 matrix $\big(t^2 - t + 1,\ -(t^2 - t + 1)\big)$. Delete either column: $\Delta(t) = t^2 - t + 1$, up to sign. This is Nash's (12.74).

Consistency check. There is a "fundamental formula" of the Fox calculus, $\sum_j (\partial r/\partial x_j)(x_j - 1) = r - 1$, which is the discrete version of $\sum_j \mathrm{d}x_j\,\partial_j f = \mathrm{d}f$. Abelianised, with $r = 1$, it

says $(t-1)\sum_j(\partial r/\partial x_j) = 0$: *the columns of the Alexander matrix add to zero.* Ours do: $(t^2-t+1)-(t^2-t+1)=0$. This is why deleting different columns gives the same answer.

Recipe 2: from a surface (the Seifert matrix)

The second recipe is geometric and makes the properties of Δ transparent.

Working definition 12.28 (Seifert surface and Seifert matrix)

A **Seifert surface** for an oriented knot K is a compact, connected, oriented surface S in $\mathbb{R}^3$ with boundary $\partial S = K$. If S has genus g [S is a disc with g handles attached], its first homology has a basis of $2g$ loops [every closed loop on S is, up to deformation on S, an integer combination of these $2g$] $a_1, \dots, a_{2g}$ on S. Let a_j^+ be the loop a_j pushed slightly off S in the direction of the positive normal. The **Seifert matrix** is the $2g \times 2g$ integer matrix

$$V_{ij} = L\big(a_i, a_j^+\big),$$

with L the linking number of Section 12.10. Then

$$\Delta_K(t) = \det\big(V - tV^T\big). \tag{12.165}$$

How to find S (Seifert's algorithm). In an oriented diagram, replace every crossing by its oriented smoothing L_0 [cut both strands and reconnect the four ends without a crossing, following the arrows] (Figure 12.43). The result is a set of disjoint oriented circles, the **Seifert circles**. Fill each with a disc (stacking nested discs at different heights). At each old crossing attach a small band with a half-twist joining the two discs there. The result is an oriented surface bounded by K.

A useful fact, which we will use: for any two loops a, b on the oriented surface,

$$L(a, b^+) - L(a^+, b) = a \cdot b, \tag{12.166}$$

the signed number of intersection points of a and b on S. The reason: pushing b up versus pushing a up differs, near each intersection point, by moving one strand from one side of the other to the other side, which changes the linking number by ± 1. Since $L(a^+, b) = L(a, b^-) = L(b^-, a)$ and pushing b down is the same as pushing a up, $L(a^+, b) = V_{ji}$. So $V - V^T = J$, the matrix of intersection numbers of the basis loops.

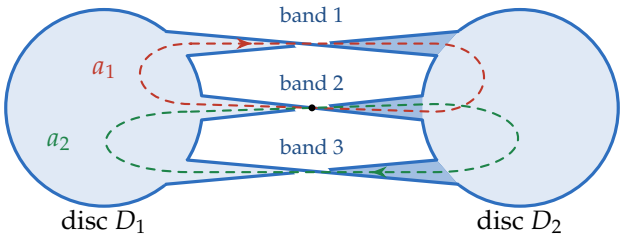

Figure 12.49: A Seifert surface for the trefoil, from Seifert's algorithm applied to the closed braid $\widehat{\sigma_1^3}$: two discs (one for each Seifert circle) joined by three bands, each with a half-twist (light shading: the front face of the band, dark: its back face, which the twist brings into view). The boundary of the surface is the trefoil. The loop a_1 (red) runs through bands 1 and 2, the loop a_2 (green) through bands 2 and 3; they meet once, at the dot in band 2. These two loops are the basis used for the Seifert matrix in Example 12.72.

Worked example 12.72: Seifert matrices of the trefoil and the figure-eight

Trefoil. Draw the trefoil as the closure of the two-strand braid σ_1^3 (Figure 12.51). The oriented smoothings give two Seifert circles, so the surface is two discs joined by three half-twisted bands (Figure 12.49). Its Euler characteristic is $\chi = (\text{discs}) - (\text{bands}) = 2 - 3 = -1$, and a surface with one boundary circle has $\chi = 1 - 2g$, so $g = 1$. A basis of loops: a_1 runs through bands 1 and 2, a_2 through bands 2 and 3.

The entries come from two facts. A loop running once through a band with a (right-handed) half-twist links its own push-off by $-\frac{1}{2}$ for that band; a_1 uses two bands, so $V_{11} = -1$, and likewise $V_{22} = -1$. The loops a_1, a_2 cross once (in band 2), so by (12.166) $V_{12} - V_{21} = \pm 1$; pushing a_2 up lifts it over a_1, which links once, while pushing a_1 up does not. So

$$V = \begin{pmatrix} -1 & 1 \\ 0 & -1 \end{pmatrix}, \qquad V - V^T = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}.$$

Then

$$\begin{aligned} \Delta(t) &\overset{(1)}{=} \det \begin{pmatrix} -1+t & 1 \\ -t & -1+t \end{pmatrix} \\ &\overset{(2)}{=} (t-1)^2 + t \\ &= t^2 - t + 1. \end{aligned}$$

(1) $V - tV^T$ entry by entry: the $(1,2)$ entry is $1 - t \cdot 0$, the $(2,1)$ entry is $0 - t \cdot 1$.
(2) 2×2 determinant: $(t-1)^2 - (1)(-t)$.

The same answer as the Fox calculus, as it must be.

Figure-eight. Seifert's algorithm on the standard diagram gives a genus-one surface with, in a suitable basis, $V = \begin{pmatrix} 1 & 1 \\ 0 & -1 \end{pmatrix}$ (one loop twists one way, the other the opposite way, which is the amphichirality of 4_1 in miniature). Then

$$\begin{aligned} \Delta_{4_1}(t) &\overset{(1)}{=} \det \begin{pmatrix} 1-t & 1 \\ -t & -1+t \end{pmatrix} \overset{(2)}{=} -(1-t)^2 + t \\ &= -(t^2 - 3t + 1) \;\doteq\; t^2 - 3t + 1, \end{aligned}$$

(1) $V - tV^T$ entry by entry.
(2) $(1-t)(t-1) - (1)(-t)$.

where $\doteq$ means "equal up to a unit". So $\Delta_{4_1} \neq \Delta_{3_1}$: the figure-eight knot is not a trefoil.

The properties Nash lists, (12.73). Nash says Δ is only determined up to $\mp t^n$, that $\Delta(1) = \mp 1$, that $\Delta(1/t) = t^n \Delta(t)$ for some even n, and that the coefficients are integers. All four follow from (12.165).

Integer coefficients. V is an integer matrix, so $\det(V - tV^T)$ is a polynomial in t with integer coefficients.

Only up to units. Different Seifert surfaces and bases give different matrices V. A change of basis $V \mapsto PVP^T$ with $\det P = \pm 1$ changes the determinant by $(\det P)^2 = 1$. Adding a tube to the surface (the other move relating two Seifert surfaces) enlarges V by a block and multiplies the determinant by $\pm t$. Hence Δ is well defined up to $\pm t^n$.

Value at $t = 1$.

$$\begin{aligned}\Delta(1) &\overset{(1)}{=} \det(V - V^T)\\ &\overset{(2)}{=} \det J\\ &\overset{(3)}{=} \det\begin{pmatrix} 0 & 1\\ -1 & 0\end{pmatrix}^{g} = 1.\end{aligned}$$

(1) Set $t = 1$ in (12.165).
(2) By (12.166), $V - V^T$ is the intersection matrix J of the loops on S.
(3) On a genus-g surface one can choose loops $a_1, b_1, \ldots, a_g, b_g$ with a_i meeting only b_i, once: J is block diagonal with g blocks $\left(\begin{smallmatrix} 0 & 1\\ -1 & 0\end{smallmatrix}\right)$, each of determinant 1.

After multiplying by an arbitrary unit $\pm t^n$ we get Nash's $\Delta(1) = \mp 1$.

Symmetry.

$$\begin{aligned}\Delta(t) &\overset{(1)}{=} \det\big((V - tV^T)^T\big) \overset{(2)}{=} \det\big(V^T - tV\big)\\ &\overset{(3)}{=} \det\big(-t\,(V - t^{-1}V^T)\big) \overset{(4)}{=} (-t)^{2g}\det\big(V - t^{-1}V^T\big)\\ &\overset{(5)}{=} t^{2g}\,\Delta(1/t).\end{aligned} \tag{12.167}$$

(1) A matrix and its transpose have the same determinant.
(2) $(V - tV^T)^T = V^T - tV$.
(3) Factor out $-t$: $-t(V - t^{-1}V^T) = -tV + V^T$.
(4) The matrix is $2g \times 2g$, so pulling a scalar out of the determinant gives its $2g$-th power.
(5) Definition (12.165) at t^{-1}, and $2g$ is even.

So $\Delta(1/t) = t^{-2g}\Delta(t)$: Nash's (12.73) with the even integer $n = -2g$. The coefficients read the same forwards and backwards (for $t^2 - t + 1$: $1, -1, 1$; for $t^2 - 3t + 1$: $1, -3, 1$). The chain also shows that the degree of Δ is at most $2g$: *the Alexander polynomial bounds the genus of the knot from below*. For the trefoil, degree 2 means no Seifert surface of genus 0 (a disc) exists, which is a third proof that it is knotted.

Normalisations, (12.74)–(12.75). Since Δ is defined up to $\pm t^n$, these are all the same invariant of the trefoil:

$$t^2 - t + 1, \qquad \frac{1}{t^2} - \frac{1}{t} + 1 = t^{-2}(t^2 - t + 1), \qquad t - 1 + \frac{1}{t} = t^{-1}(t^2 - t + 1).$$

The first is the normalised form (no negative powers, positive constant term). Its degree is 2, which equals the span. The last is the **symmetric** or **Conway** normalisation Δ^{Sym}: it is invariant under $t \leftrightarrow t^{-1}$ and has $\Delta^{\mathrm{Sym}}(1) = +1$. By (12.167) every knot has one: multiply by t^{-g} and fix the sign so that $\Delta(1) = 1$.

Watch out: Two misprints in Nash (12.75)

Nash prints the symmetric form of the trefoil polynomial as "$t - 1 - \frac{1}{t}$", and says it satisfies "$\Delta(0) = 1$". Both are misprints. Multiplying $t^2 - t + 1$ by t^{-1} gives $t - 1 + \frac{1}{t}$ (a plus sign); and a Laurent polynomial with a t^{-1} term is not even defined at $t = 0$. The property meant is $\Delta^{\mathrm{Sym}}(1) = 1$: indeed $1 - 1 + 1 = 1$.

Mirror images. Under the reflection ρ of (12.149), linking numbers change sign and the positive side of the surface is exchanged with the negative side, so the Seifert matrix becomes $\bar{V} = -V^T$. Then

$$\Delta_{\bar{K}}(t) \overset{(1)}{=} \det\!\left(-V^T + tV\right) \overset{(2)}{=} \det\!\left((-V + tV^T)^T\right) \overset{(3)}{=} (-1)^{2g} \det\!\left(V - tV^T\right) = \Delta_K(t).$$

(1) Formula (12.165) with $\bar{V} = -V^T$, whose transpose is $-V$.
(2) Write the matrix as a transpose.
(3) Transpose-invariance of the determinant, and pull out -1 from a $2g \times 2g$ matrix.

So, as Nash says, the right and left trefoils have the same Alexander polynomial. The Alexander polynomial cannot see chirality, just like the knot group it came from.

The determinant and colourings. The integer $|\Delta(-1)|$ is called the **determinant** of the knot. For the trefoil $|1 + 1 + 1| = 3$; for the figure-eight $|1 + 3 + 1| = 5$. A knot has a non-trivial Fox p-colouring (for p an odd prime) exactly when p divides its determinant. So the trefoil is tricolourable and the figure-eight is not (it is 5-colourable instead), in agreement with Section 12.9.5. The toy invariant of the last section is the Alexander polynomial evaluated at $t = -1$ and reduced mod 3.

12.11.3 Skein relations: computing by cutting and reconnecting

Fox calculus and Seifert matrices work, but for a big diagram they are laborious. Conway (1969) found that the Alexander polynomial obeys a local *recursion* which Nash quotes. It is the idea that later made the Jones polynomial computable, and it is the relation that Chern–Simons theory must reproduce.

Working definition 12.29 (skein triple, Nash (12.79))

Three oriented links L_+, L_-, L_0 form a **skein triple** if their diagrams are identical except inside one small disc, where they look like the three pictures of Figure 12.43: a positive crossing, a negative crossing, and the oriented smoothing [the two strands cut and reconnected without a crossing, following the arrows]. If $L_\pm$ have n crossings, L_0 has $n - 1$.

The number of components changes in a definite way: if the two strands at the crossing belong to the same component of $L_\pm$, smoothing cuts that component into two; if they belong to different components, smoothing joins them into one. So L_0 has one component more or one fewer than $L_\pm$.

Key idea: The Alexander–Conway skein relation, Nash (12.80)

With Δ in its symmetric (Conway) normalisation,

$$\Delta_{L_+}(t) - \Delta_{L_-}(t) = \left(t^{1/2} - t^{-1/2}\right) \Delta_{L_0}(t), \qquad \Delta_{\text{unknot}} = 1. \tag{12.168}$$

It is convenient to write $z = t^{1/2} - t^{-1/2}$; then Δ becomes a polynomial in z, the **Conway polynomial** $\nabla(z)$.

Why these two rules determine Δ for every link. Pick a crossing. Either L_+ or L_- is the link we want; the relation expresses it through the other one (same number of crossings, one crossing changed) and L_0 (one crossing fewer). Recall from Section 12.9.2 that changing suitable

crossings turns any diagram into a "descending" diagram of an unlink. So by induction (on the number of crossings, and for a fixed number, on the number of crossing changes needed), everything reduces to the values on unlinks. This is Nash's remark that "iteration of this relation expresses any $\Delta_L(t)$ in terms of the Alexander polynomial of a finite number of unlinked, unknotted circles".

Figure 12.50: The skein triple at a kink. Both L_+ and L_- are unknots (an R1 move removes the kink), while the oriented smoothing L_0 splits off a small circle, giving the two-component unlink. Feeding this triple into a skein relation computes the value of the invariant on unlinks.

Worked example 12.73: The unlink, the Hopf link and the trefoil by skein

The two-component unlink. Apply the skein relation to the kink in Figure 12.50. L_+ and L_- are both unknots (an R1 move removes the kink), and L_0 is two separate circles, the unlink U_2:

$$\begin{aligned} z\,\Delta_{U_2} &\overset{(1)}{=} \Delta_{L_+} - \Delta_{L_-} \\ &\overset{(2)}{=} 1 - 1 = 0. \end{aligned}$$

(1) Skein relation (12.168).
(2) Both are the unknot.

So $\Delta_{U_2} = 0$, and the same argument with extra circles gives $\Delta_{U_p} = 0$ for all $p \geq 2$. (Geometrically: two disjoint circles bound a disconnected surface; tubing it together produces a Seifert matrix with a zero row.)

The positive Hopf link H_+ is the closure of σ_1^2. At either crossing, $L_+ = H_+$, switching gives $L_- = U_2$, and smoothing gives $L_0 =$ the closure of σ_1, an unknot:

$$\begin{aligned} \Delta_{H_+} &\overset{(1)}{=} \Delta_{U_2} + z\,\Delta_{\text{unknot}} \\ &\overset{(2)}{=} 0 + z = t^{1/2} - t^{-1/2}. \end{aligned}$$

(1) Skein relation solved for Δ_{L_+}.
(2) The two values just found.

The trefoil is the closure of σ_1^3. At one crossing, $L_+ = 3_1$, switching gives the closure of $\sigma_1^2\sigma_1^{-1} = \sigma_1$, an unknot, and smoothing gives the closure of σ_1^2, the Hopf link:

$$\begin{aligned} \Delta_{3_1} &\overset{(1)}{=} \Delta_{\text{unknot}} + z\,\Delta_{H_+} \\ &\overset{(2)}{=} 1 + z^2 \\ &\overset{(3)}{=} 1 + t - 2 + t^{-1} = t - 1 + t^{-1}. \end{aligned}$$

(1) Skein relation.
(2) $\Delta_{H_+} = z$ from above.

(3) $z^2 = (t^{1/2} - t^{-1/2})^2 = t - 2 + t^{-1}$.

This is Δ^{Sym} of the trefoil once more, now in half a dozen lines. The Conway polynomial is $\nabla_{3_1} = 1 + z^2$.

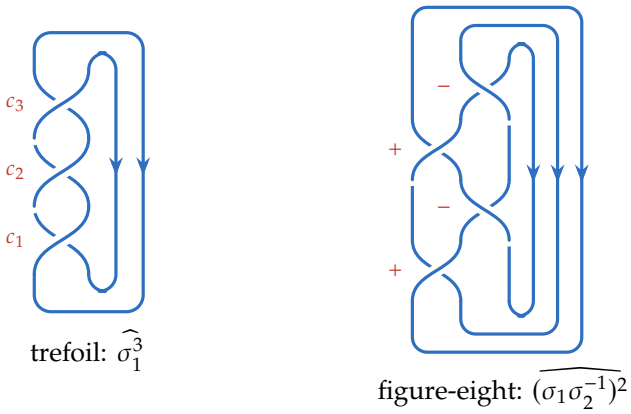

Figure 12.51: Knots as closed braids. Left: the right trefoil as the closure of σ_1^3, three positive crossings c_1, c_2, c_3 between two strands, the ends joined round the back. Right: the figure-eight knot as the closure of $\sigma_1\sigma_2^{-1}\sigma_1\sigma_2^{-1}$ on three strands; the crossing signs alternate $+, -, +, -$ from the bottom up, so the writhe is 0.

Worked example 12.74: The figure-eight knot by skein

Write 4_1 as the closure of the three-strand braid $\sigma_1\sigma_2^{-1}\sigma_1\sigma_2^{-1}$ (Figure 12.51). Apply the skein relation at the first (positive) crossing (Figure 12.52).

- $L_+ = 4_1$.
- L_- is the closure of $\sigma_1^{-1}\sigma_2^{-1}\sigma_1\sigma_2^{-1}$. It is an unknot (its Jones polynomial, computed below by the same method, is 1, and one can untangle it by hand).
- L_0 is the closure of $\sigma_2^{-1}\sigma_1\sigma_2^{-1}$. By cyclically moving the last letter to the front (conjugation, which does not change the closure) it is the closure of $\sigma_2^{-2}\sigma_1$. The strand that passes through σ_1 only once can be pulled straight (a Markov move, the braid version of R1), leaving the closure of σ^{-2} on two strands: the *negative* Hopf link H_-, with $\Delta_{H_-} = -z$ (switch both crossings of H_+: the skein computation above with every sign reversed).

Then

$$\begin{aligned}\Delta_{4_1} &\overset{(1)}{=} \Delta_{\text{unknot}} + z\,\Delta_{H_-}\\ &\overset{(2)}{=} 1 - z^2\\ &\overset{(3)}{=} 1 - t + 2 - t^{-1} = -t + 3 - t^{-1},\end{aligned}$$

(1) Skein relation, solved for Δ_{L_+}.
(2) $\Delta_{H_-} = -z$.
(3) $z^2 = t - 2 + t^{-1}$.

in agreement with the Seifert matrix (up to the unit $-t^{-1}$).

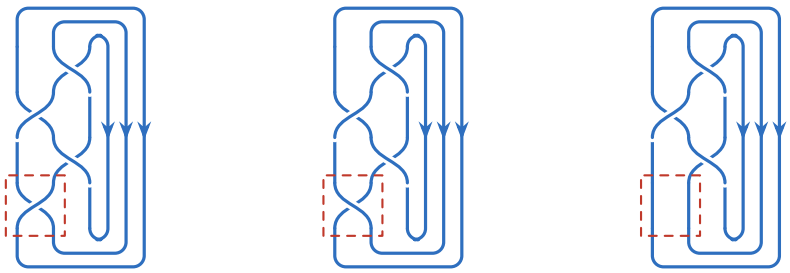

Figure 12.52: The skein triple used for the figure-eight knot, at the lowest crossing (dashed box). Switching it gives an unknot L_-; smoothing it gives the closure of $\sigma_2^{-1}\sigma_1\sigma_2^{-1}$, which is the negative Hopf link.

Watch out: Sign conventions in skein relations

Nash writes (12.80) as $\Delta_{L_+} - \Delta_{L_-} + (t^{1/2} - t^{-1/2})\Delta_{L_0} = 0$, which is (12.168) with $z \to -z$, i.e. $t^{1/2} \to -t^{1/2}$ (or $L_+ \leftrightarrow L_-$). Nash's pictures of $L_\pm$ carry no arrows, so his convention cannot be read off. For *knots* nothing depends on it: $\nabla_K(z)$ contains only even powers of z (a knot has an odd number, one, of components, and each skein step changes the number of components by one and the power of z by one). For links with an even number of components the overall sign of Δ depends on the convention. We use (12.168) with the crossing signs of Figure 12.43 throughout.

12.11.4 The Kauffman bracket: a knot polynomial as a partition function

The Jones polynomial was discovered inside von Neumann algebras, but the quickest honest route to it is Kauffman's (1987). It is a *state sum*, built exactly like the partition function of a lattice model in statistical mechanics: sum over configurations of local choices, each weighted by a Boltzmann-like factor. The "spins" are the ways of resolving each crossing.

Working definition 12.30 (Kauffman bracket)

The **Kauffman bracket** assigns to every unoriented link diagram D [no arrows on the strands] a Laurent polynomial $\langle D \rangle$ in a variable A, fixed by three rules:

$$\begin{aligned} \langle \bigcirc \rangle &= 1, \\ \langle D \sqcup \bigcirc \rangle &= d\,\langle D \rangle, \qquad d := -A^2 - A^{-2}, \\ \left\langle \text{crossing} \right\rangle &= A \left\langle \text{A-smoothing} \right\rangle + A^{-1} \left\langle \text{B-smoothing} \right\rangle. \end{aligned} \tag{12.169}$$

The **A-smoothing** at a crossing joins the two regions that the over-strand sweeps out when rotated anticlockwise until it meets the under-strand; the B-smoothing joins the other two (Figure 12.53). A disjoint circle [an extra circle drawn apart from D, crossing nothing] multiplies by d.

Closed formula (state sum). A **state** s is a choice of A or B at every crossing. Smoothing every crossing according to s gives a collection of $|s|$ disjoint circles. With $a(s)$ and $b(s)$ the numbers of A's and B's,

$$\langle D \rangle = \sum_{\text{states } s} A^{a(s)-b(s)}\, d^{\,|s|-1}. \tag{12.170}$$

For a crossing drawn with the over-strand from south-west to north-east, rotating it

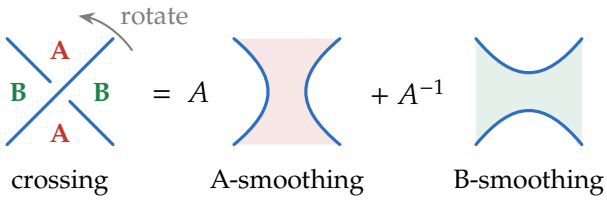

Figure 12.53: The Kauffman bracket rule. Rotate the over-strand anticlockwise: the two regions it sweeps are labelled A, the other two B. The A-smoothing opens a channel joining the two A regions (here: the vertical smoothing), the B-smoothing joins the two B regions (the horizontal one). The weights are A and A^{-1}.

anticlockwise sweeps the regions above and below the crossing. The A-smoothing therefore opens a channel between the top and bottom regions and gives the vertical smoothing ") (". If both strands point upwards this is a *positive* crossing L_+, and its A-smoothing is the oriented smoothing L_0. For a negative crossing the A-smoothing is the horizontal one. We use this constantly.

Dictionary: State sum ↔ partition function

crossing	lattice site
choice A/B at a crossing	spin up/down
weight $A^{\pm 1}$ per crossing	local Boltzmann weight
factor d per closed loop	fugacity of a loop (loop models)
$\langle D \rangle$	partition function $Z = \sum_s e^{-\beta E(s)}$

Kauffman showed that at special values of A the bracket of a planar graph is the partition function of the Potts model on it. The algebra that multiplies the smoothings (below) is the Temperley–Lieb algebra, first found in the transfer matrices of that model.

Invariance under R2 and R3. Take two strands forming an R2 configuration and expand both crossings. Of the four states, one gives the two strands passing straight by each other (") (", with weight $A \cdot A^{-1} = 1$. The other three give the turned-back picture "≍": two of them (AA and BB) directly, with weights A^2 and A^{-2}, and the remaining mixed state with an extra little circle in the middle, weight $A^{-1} A\, d = d$. Therefore

$$\begin{aligned} \big\langle \text{R2 tangle} \big\rangle &\overset{(1)}{=} \big\langle\,)\,(\,\big\rangle + \big(A^2 + A^{-2} + d\big)\big\langle \asymp \big\rangle \\ &\overset{(2)}{=} \big\langle\,)\,(\,\big\rangle. \end{aligned} \tag{12.171}$$

(1) The four states just listed; the small circle is removed by the rule $\langle D \sqcup \bigcirc \rangle = d\langle D \rangle$.

(2) $d = -A^2 - A^{-2}$: *this is why d has the value it has*. The loop fugacity is chosen precisely to cancel the unwanted term.

R3 then follows from R2. Expand the crossing of the two lower strands in both sides of the R3 move. The A-terms on the two sides are equal diagrams outright, and the B-terms are related by two R2 moves, which we just showed are harmless. So $\langle D \rangle$ is unchanged by R2 and R3.

R1 and the writhe. A kink is not harmless. For the positive kink of Figure 12.50 (left), the A-smoothing is the oriented one and splits off a small circle, while the B-smoothing just

straightens the strand:

$$\begin{aligned}\big\langle \text{positive kink} \big\rangle &\overset{(1)}{=} A\, d \,\big\langle \,\big|\, \big\rangle + A^{-1} \big\langle \,\big|\, \big\rangle \\ &\overset{(2)}{=} \big(-A^3 - A^{-1} + A^{-1}\big)\big\langle \,\big|\, \big\rangle = -A^3 \,\big\langle \,\big|\, \big\rangle . \end{aligned} \tag{12.172}$$

(1) Bracket rule at the kink's crossing; the A-state has an extra circle.
(2) $Ad = -A^3 - A^{-1}$.

A negative kink gives $-A^{-3}$ in the same way (A and B exchange roles). So each R1 move multiplies $\langle D \rangle$ by $-A^{\pm 3}$ and changes the writhe $w(D)$ of Section 12.9.4 by ± 1. The two defects cancel in

$$f_L(A) \coloneqq \big(-A^3\big)^{-w(D)} \langle D \rangle , \tag{12.173}$$

for any oriented diagram D of L. f_L is unchanged by R1, R2 and R3, so it is an invariant of oriented links.

Physical picture: The bracket is an invariant of ribbons

$\langle D \rangle$ on its own is invariant under R2 and R3 only ("regular isotopy"). Think of the knot as a flat ribbon lying in the page. R2 and R3 moves slide the ribbon about; an R1 move puts a full twist into it. So $\langle D \rangle$ is an invariant of *framed* knots, and $-A^3$ is the price of one unit of framing. We shall meet exactly this structure in Chern–Simons theory: Wilson loops need a framing, and changing it multiplies $\langle W \rangle$ by a phase (Section 12.12.8). The writhe correction (12.173) is the knot theorist's way of choosing the canonical framing.

Worked example 12.75: The Hopf link

H_+ is the closure of σ_1^2, two positive crossings. Both crossings are positive, so A-smoothing = oriented smoothing = two vertical strands "$\|$", and B-smoothing = cup-cap "$\asymp$". The four states:

state	loops $\lvert s \rvert$	$a - b$	$A^{a-b} d^{\lvert s \rvert - 1}$
AA	2	2	$A^2 d$
AB	1	0	1
BA	1	0	1
BB	2	−2	$A^{-2} d$

(AA: two parallel strands closed up, two circles. One B: the cup-cap joins the two strands into one circle. BB: the cap of one box and the cup of the next close off a small circle, and the rest forms a second one.)

$$\begin{aligned}\langle H_+ \rangle &\overset{(1)}{=} A^2 d + 2 + A^{-2} d \\ &\overset{(2)}{=} -A^4 - 1 + 2 - 1 - A^{-4} \\ &= -A^4 - A^{-4} .\end{aligned}$$

(1) Sum of the table.
(2) $A^{\pm 2} d = -A^{\pm 4} - 1$.

With $w(H_+) = +2$, $f_{H_+} = (-A^3)^{-2}(-A^4 - A^{-4}) = -A^{-2} - A^{-10}$.

Worked example 12.76: The trefoil: the full state sum

Take the right trefoil as the closure of σ_1^3, with crossings c_1, c_2, c_3 (Figure 12.51). All three are positive, so again A = "$\|$" and B = "$\asymp$" in each box. There are $2^3 = 8$ states, drawn in Figure 12.54. Counting loops:

- AAA: three identity boxes; the closure gives 2 circles.
- One B (three states): the single cup-cap connects the two strands: 1 circle.
- Two B's (three states): between two cup-caps there is either a small circle trapped (if they are adjacent) or, going around the closure, a second circle (if not). Either way 2 circles.
- BBB: two small circles between the three cup-caps and one big one: 3 circles.

So

$$\begin{aligned}\langle 3_1\rangle &\overset{(1)}{=} A^3 d + 3A + 3A^{-1} d + A^{-3} d^2 \\ &\overset{(2)}{=} \left(-A^5 - A\right) + 3A + \left(-3A - 3A^{-3}\right) + \left(A + 2A^{-3} + A^{-7}\right) \\ &\overset{(3)}{=} -A^5 - A^{-3} + A^{-7}. \end{aligned} \tag{12.174}$$

(1) State sum (12.170): the weight A^{a-b} is A^3, A, A^{-1}, A^{-3} for 0, 1, 2, 3 B's, and the loop counts are 2, 1, 2, 3.
(2) Expand: $A^3 d = -A^5 - A$; $3A^{-1} d = -3A - 3A^{-3}$; $A^{-3} d^2 = A^{-3}(A^4 + 2 + A^{-4})$.
(3) Collect: the A terms cancel, $-1 + 3 - 3 + 1 = 0$; the A^{-3} terms give $-3 + 2 = -1$.

The writhe is $w = +3$, so

$$\begin{aligned} f_{3_1}(A) &\overset{(1)}{=} (-A^3)^{-3}\left(-A^5 - A^{-3} + A^{-7}\right) \\ &\overset{(2)}{=} -A^{-9}\left(-A^5 - A^{-3} + A^{-7}\right) \\ &= A^{-4} + A^{-12} - A^{-16}. \end{aligned} \tag{12.175}$$

(1) Definition (12.173).
(2) $(-A^3)^{-3} = -A^{-9}$.

12.11.5 The Jones polynomial

Working definition 12.31 (Jones polynomial)

The **Jones polynomial** of an oriented link L is

$$V_L(t) = f_L(A)\Big|_{A=t^{-1/4}} = \left[\left(-A^3\right)^{-w(D)}\langle D\rangle\right]_{A=t^{-1/4}}. \tag{12.176}$$

Recipe: draw a diagram, compute the bracket by the state sum, multiply by $(-A^3)^{-w}$ [w is the writhe, the sum of the crossing signs. This factor cancels the change of $\langle D\rangle$ under R1], substitute $A = t^{-1/4}$. For a knot only integer powers of t survive; for links with an even number of components, half-integer powers appear.

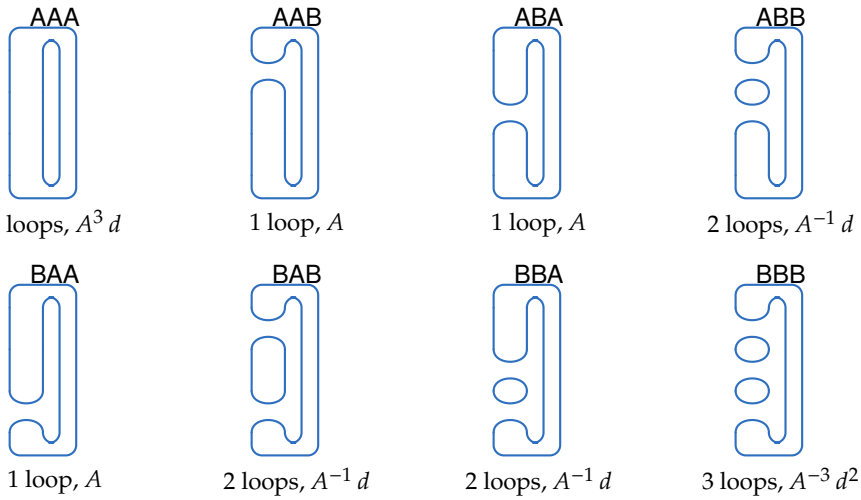

Figure 12.54: The eight states of the trefoil diagram $\widehat{\sigma_1^3}$. Each crossing is replaced by its A-smoothing (two vertical strands) or its B-smoothing (a cup and a cap); the letters list the choices from the bottom crossing c_1 to the top crossing c_3. Under each state: the number $|s|$ of loops and the weight $A^{a-b}d^{|s|-1}$. Summing the weights gives (12.174).

Worked example 12.77: The trefoil and its mirror image, Nash (12.76)

From (12.175), with $A^{-4} = t$:

$$V_{3_1}(t) = t + t^3 - t^4. \tag{12.177}$$

This is Nash's V_L for the clover leaf; our right trefoil (positive crossings) is his.
For the mirror image, every crossing is switched. Switching a crossing exchanges its A- and B-smoothings (rotate the over-strand the other way), so the state sum (12.170) is the same with $A \leftrightarrow A^{-1}$; and d is symmetric under this. The writhe changes sign. Hence

$$f_{\bar{L}}(A) \overset{(1)}{=} \left(-A^3\right)^{+w(D)} \langle D \rangle \big|_{A \to A^{-1}} \overset{(2)}{=} f_L(A^{-1}),$$

(1) Bracket with $A \to A^{-1}$ and writhe $-w$.
(2) $(-A^3)^w = \left(-(A^{-1})^3\right)^{-w}$, so this is (12.173) evaluated at A^{-1}.

and $A \to A^{-1}$ means $t \to t^{-1}$:

$$V_{\bar{L}}(t) = V_L(1/t), \qquad V_{\bar{3}_1}(t) = \frac{1}{t} + \frac{1}{t^3} - \frac{1}{t^4}.$$

This is the second half of Nash's (12.76) and the third property in his (12.77).

Key idea: The Jones polynomial detects chirality

$t + t^3 - t^4 \neq t^{-1} + t^{-3} - t^{-4}$. So the right and left trefoils are *not isotopic*, although they are equivalent (via the reflection ρ) and have the same knot group and the same Alexander polynomial. This settles the claim of Section 12.9.3. A knot with $V_K(t) \neq V_K(1/t)$ can never be amphichiral.

The Jones skein relation, derived. Nash quotes (12.81). We derive it from the bracket. At a crossing, let L_∞ denote the *unoriented* smoothing ("$\asymp$" when the strands point up). From the

A/B rule of the previous subsection:

$$\langle L_+\rangle = A\langle L_0\rangle + A^{-1}\langle L_\infty\rangle,$$
$$\langle L_-\rangle = A^{-1}\langle L_0\rangle + A\langle L_\infty\rangle.$$

Multiply the first by A, the second by A^{-1} and subtract: L_∞ drops out and

$$A\langle L_+\rangle - A^{-1}\langle L_-\rangle = (A^2 - A^{-2})\langle L_0\rangle. \tag{12.178}$$

Now convert to f. Let w_0 be the writhe of L_0; since the other crossings are the same, $w(L_\pm) = w_0 \pm 1$. Using $\langle D\rangle = (-A^3)^{w(D)} f$:

$$\begin{aligned} A(-A^3)^{w_0+1} f_{L_+} - A^{-1}(-A^3)^{w_0-1} f_{L_-} &\overset{(1)}{=} (A^2 - A^{-2})(-A^3)^{w_0} f_{L_0} \\ \Longrightarrow \quad -A^4 f_{L_+} + A^{-4} f_{L_-} &\overset{(2)}{=} (A^2 - A^{-2}) f_{L_0} \\ \Longrightarrow \quad t^{-1} V_{L_+} - t\, V_{L_-} &\overset{(3)}{=} \left(t^{1/2} - t^{-1/2}\right) V_{L_0}. \end{aligned} \tag{12.179}$$

(1) Substitute $\langle D\rangle = (-A^3)^w f$ into (12.178).
(2) Divide by $(-A^3)^{w_0}$: $A(-A^3) = -A^4$ and $A^{-1}(-A^3)^{-1} = -A^{-4}$.
(3) Put $A = t^{-1/4}$, so $A^4 = t^{-1}$, $A^{-4} = t$, $A^{\pm 2} = t^{\mp 1/2}$, and multiply by -1.

Together with $V_{\text{unknot}} = 1$ this determines V on all links, by the same induction as for Δ.

Watch out: Nash's (12.81) is the mirror convention

Nash prints $tV_{L_+} - t^{-1}V_{L_-} + (t^{1/2} - t^{-1/2})V_{L_0} = 0$. This is (12.179) with $t \to t^{-1}$ (equivalently with $L_+ \leftrightarrow L_-$). With his relation read literally in our crossing convention, the trefoil with positive crossings would get $t^{-1} + t^{-3} - t^{-4}$. Since his pictures of $L_\pm$ have no arrows, the two statements are consistent once L_+ and L_- are exchanged. What is convention-independent: the trefoil and its mirror get $t + t^3 - t^4$ and $t^{-1} + t^{-3} - t^{-4}$, one each.

Unlinks, Nash (12.83). Apply (12.179) to the kink of Figure 12.50: $L_\pm$ are unknots and $L_0 = U_2$:

$$\begin{aligned} \left(t^{1/2} - t^{-1/2}\right) V_{U_2} &\overset{(1)}{=} t^{-1}\cdot 1 - t\cdot 1 \\ \Longrightarrow \quad V_{U_2} &\overset{(2)}{=} -\frac{t - t^{-1}}{t^{1/2} - t^{-1/2}} \overset{(3)}{=} -\left(t^{1/2} + t^{-1/2}\right). \end{aligned}$$

(1) Skein relation with $V_{\text{unknot}} = 1$.
(2) Divide.
(3) $t - t^{-1} = (t^{1/2} - t^{-1/2})(t^{1/2} + t^{-1/2})$.

The same argument with $p-1$ extra circles present (they are spectators) shows that each additional split unknotted component multiplies V by this factor:

$$V_{U_p}(t) = \left\{-\frac{t - t^{-1}}{t^{1/2} - t^{-1/2}}\right\}^{p-1} = \left(-t^{1/2} - t^{-1/2}\right)^{p-1}, \tag{12.180}$$

which is Nash's (12.83). It is also immediate from the bracket: p disjoint circles have $\langle U_p\rangle = d^{p-1}$ and $w = 0$, and $d = -A^2 - A^{-2} = -t^{-1/2} - t^{1/2}$.

Worked example 12.78: Hopf link and trefoil by the Jones skein relation

For H_+ at one crossing, $L_+ = H_+$, $L_- = U_2$, $L_0 =$ unknot:

$$\begin{aligned} t^{-1}V_{H_+} &\overset{(1)}{=} t\,V_{U_2} + \left(t^{1/2} - t^{-1/2}\right) \\ &\overset{(2)}{=} -t^{3/2} - t^{1/2} + t^{1/2} - t^{-1/2} = -t^{3/2} - t^{-1/2}, \end{aligned}$$

(1) Skein relation (12.179) solved for $t^{-1}V_{L_+}$.
(2) $V_{U_2} = -(t^{1/2} + t^{-1/2})$.

so $V_{H_+} = -t^{1/2} - t^{5/2}$. (Check with the bracket: $f_{H_+} = -A^{-2} - A^{-10}$ and $A^{-2} = t^{1/2}$, $A^{-10} = t^{5/2}$. It agrees.)
For the trefoil, $L_+ = 3_1$, $L_- =$ unknot, $L_0 = H_+$:

$$\begin{aligned} t^{-1}V_{3_1} &\overset{(1)}{=} t + \left(t^{1/2} - t^{-1/2}\right)\left(-t^{1/2} - t^{5/2}\right) \\ &\overset{(2)}{=} t - t - t^3 + 1 + t^2 \\ \Longrightarrow \quad V_{3_1} &= t + t^3 - t^4. \end{aligned}$$

(1) Skein relation with $V_{L_-} = 1$ and $V_{L_0} = V_{H_+}$.
(2) Multiply out: $t^{1/2}\cdot(-t^{1/2}) = -t$, $t^{1/2}\cdot(-t^{5/2}) = -t^3$, $-t^{-1/2}\cdot(-t^{1/2}) = 1$, $-t^{-1/2}\cdot(-t^{5/2}) = t^2$.

The state sum and the skein relation agree, as they must.

Worked example 12.79: The figure-eight knot is amphichiral

Use the skein triple of Figure 12.52: $L_+ = 4_1$, $L_- =$ unknot, $L_0 = H_-$. The negative Hopf link is the mirror of H_+, so $V_{H_-}(t) = V_{H_+}(1/t) = -t^{-1/2} - t^{-5/2}$. Then

$$\begin{aligned} t^{-1}V_{4_1} &\overset{(1)}{=} t + \left(t^{1/2} - t^{-1/2}\right)\left(-t^{-1/2} - t^{-5/2}\right) \\ &\overset{(2)}{=} t - 1 - t^{-2} + t^{-1} + t^{-3} \\ \Longrightarrow \quad V_{4_1}(t) &\overset{(3)}{=} t^2 - t + 1 - t^{-1} + t^{-2}. \end{aligned}$$

(1) Skein relation (12.179).
(2) Multiply out the four products.
(3) Multiply by t.

The answer is symmetric under $t \leftrightarrow t^{-1}$, consistent with the figure-eight being isotopic to its mirror image (it is: a string model can be rearranged into its mirror in a few moves). A direct state sum over the $2^4 = 16$ states of the braid-closure diagram gives $\langle 4_1\rangle = A^8 - A^4 + 1 - A^{-4} + A^{-8}$ with $w = 0$, the same polynomial. The same skein method applied to L_- itself returns $V_{L_-} = 1$, as claimed in Example 12.74.

The special values, Nash (12.77) and (12.78). Nash says these "can be easily checked for the clover leaf". Let us check them for the trefoil, and then see why they hold for every link.

For the trefoil, $V = t + t^3 - t^4$:

- $V(1) = 1 + 1 - 1 = 1 = (-2)^0$.
- $V(-1) = -1 - 1 - 1 = -3$, and $\Delta^{\mathrm{Sym}}(-1) = -1 - 1 - 1 = -3$.

- With $\omega = e^{2\pi i/3}$, $\omega^3 = 1$ and $\omega^4 = \omega$: $V(\omega) = \omega + 1 - \omega = 1$.
- $V'(t) = 1 + 3t^2 - 4t^3$, so $V'(1) = 1 + 3 - 4 = 0$.

Why $V_L(1) = (-2)^{p-1}$. At $t = 1$ the skein relation (12.179) becomes $V_{L_+}(1) - V_{L_-}(1) = 0$: crossing changes are free. Undo crossings until L becomes the unlink U_p with the same number of components. Then $V_L(1) = V_{U_p}(1) = (-1-1)^{p-1} = (-2)^{p-1}$ by (12.180).

Why $V_K(\omega) = 1$ for knots. Put $t = \omega$, $t^{1/2} = e^{i\pi/3}$. Then $t^{1/2} - t^{-1/2} = 2i\sin\frac{\pi}{3} = i\sqrt{3}$, $t^{-1} - t = -2i\sin\frac{2\pi}{3} = -i\sqrt{3}$, and $V_{U_2}(\omega) = -2\cos\frac{\pi}{3} = -1$. Claim: $V_L(\omega) = (-1)^{p-1}$ for every p-component link. It holds for unlinks. If it holds for L_0 (with $p \pm 1$ components) and for one of $L_\pm$, it holds for the other: if, say, $V_{L_-}(\omega) = (-1)^{p-1}$, then

$$\omega^{-1}V_{L_+}(\omega) \overset{(1)}{=} \omega\,(-1)^{p-1} + i\sqrt{3}\,(-1)^p \overset{(2)}{=} (-1)^{p-1}\big(\omega - i\sqrt{3}\big) \overset{(3)}{=} (-1)^{p-1}\,\omega^{-1},$$

(1) Skein relation, with the hypothesis for L_- and for L_0 (which has $p \pm 1$ components, so its sign is $(-1)^p$).
(2) Factor out $(-1)^{p-1}$.
(3) $\omega - i\sqrt{3} = -\frac{1}{2} + \frac{\sqrt{3}}{2}i - i\sqrt{3} = -\frac{1}{2} - \frac{\sqrt{3}}{2}i = \omega^{-1}$.

so $V_{L_+}(\omega) = (-1)^{p-1}$. By induction it holds for all links, and for knots ($p = 1$) it is Nash's $V_K(e^{2\pi i/3}) = 1$.

Why $V_K'(1) = 0$ for knots. Differentiate (12.179) with respect to t and set $t = 1$:

$$-V_{L_+}(1) + V'_{L_+}(1) - V_{L_-}(1) - V'_{L_-}(1) \overset{(1)}{=} \big(\tfrac{1}{2} + \tfrac{1}{2}\big)V_{L_0}(1)$$
$$\Longrightarrow \quad -1 + V'_{K_+}(1) - 1 - V'_{K_-}(1) \overset{(2)}{=} -2$$
$$\Longrightarrow \quad V'_{K_+}(1) = V'_{K_-}(1).$$

(1) Product rule on the left; on the right the derivative of $t^{1/2} - t^{-1/2}$ at 1 is $\frac{1}{2} + \frac{1}{2}$, and the term with V'_{L_0} is multiplied by $t^{1/2} - t^{-1/2} = 0$ at $t = 1$.
(2) For knots $K_\pm$, $V(1) = 1$; and L_0 then has two components, so $V_{L_0}(1) = -2$.

Crossing changes do not change $V'(1)$; unknotting, $V'_K(1) = V'_{\text{unknot}}(1) = 0$.

Why $V_L(-1) = \Delta_L(-1)$. At $t = -1$ both skein relations become the same recursion. With $t^{1/2} = i$, (12.179) reads $-V_{L_+} + V_{L_-} = 2i\,V_{L_0}$, i.e. $V_{L_+} - V_{L_-} = -2i\,V_{L_0}$, and Nash's form of the Alexander relation (12.80) at $t^{1/2} = i$ reads $\Delta_{L_+} - \Delta_{L_-} = -2i\,\Delta_{L_0}$. The initial values also agree: $V = \Delta = 1$ on the unknot, and on split links $V_{U_p}(-1) = (-i - i^{-1})^{p-1} = 0 = \Delta_{U_p}$. Two functions obeying the same recursion with the same initial values are equal. For knots the choice of square root is irrelevant, as in the trefoil check above.

Where the Jones polynomial came from: a representation of the braid group. Nash mentions that the Jones polynomial "originated in the theory of finite dimensional von Neumann algebras". Here is the part of that story we can make completely explicit, in the spirit of exhibiting representations.

Every link is the closure of a braid (Alexander's theorem), as in Figure 12.51. On two strands, the bracket rule says that a positive crossing is a linear combination of two pictures: the identity $\mathbb{1}$ (two vertical strands) and the cup-cap e:

$$\sigma = A\,\mathbb{1} + A^{-1}e, \qquad \sigma^{-1} = A^{-1}\mathbb{1} + A\,e.$$

Stacking pictures is multiplication. Stacking e on e traps one small circle: $e^2 = d\,e$. This two-dimensional algebra with basis $\{\mathbb{1}, e\}$ is the **Temperley–Lieb algebra** TL_2. Check that σ^{-1} really is the inverse:

$$\begin{aligned}\sigma\sigma^{-1} &\overset{(1)}{=} \mathbb{1} + A^2 e + A^{-2} e + e^2 \\ &\overset{(2)}{=} \mathbb{1} + \bigl(A^2 + A^{-2} + d\bigr)e \overset{(3)}{=} \mathbb{1}.\end{aligned}$$

(1) Multiply out $(A\mathbb{1} + A^{-1}e)(A^{-1}\mathbb{1} + Ae)$.
(2) $e^2 = d\,e$.
(3) $d = -A^2 - A^{-2}$.

This is the R2 computation (12.171) as algebra. Closing a picture up is a linear functional, the **Markov trace**: closing $\mathbb{1}$ gives two circles, weight d; closing e gives one circle, weight 1. So $\mathrm{tr}(\mathbb{1}) = d$, $\mathrm{tr}(e) = 1$, and $\langle\hat{\beta}\rangle = \mathrm{tr}(\beta)$.

Worked example 12.80: All $(2, n)$ torus links from a 2×2 matrix

Left multiplication by σ on TL_2, in the basis $(\mathbb{1}, e)$:

$$\sigma \cdot \mathbb{1} = A\,\mathbb{1} + A^{-1}e, \qquad \sigma \cdot e = Ae + A^{-1}d\,e = -A^{-3}e, \qquad [\sigma] = \begin{pmatrix} A & 0 \\ A^{-1} & -A^{-3} \end{pmatrix}.$$

(We used $A + A^{-1}d = A - A - A^{-3} = -A^{-3}$.) The eigenvalues are A and $-A^{-3}$. The eigenvector for $-A^{-3}$ is e, and the one for A is $\mathbb{1} - e/d$ (check: $\sigma(\mathbb{1} - e/d) = A\mathbb{1} + A^{-1}e + A^{-3}e/d = A\mathbb{1} + \bigl(A^{-1}d + A^{-3}\bigr)e/d = A\mathbb{1} - Ae/d$). Writing $\mathbb{1} = (\mathbb{1} - e/d) + e/d$, the braid σ^n acts on each piece by its eigenvalue, and closing up:

$$\begin{aligned}\bigl\langle T(2,n)\bigr\rangle &\overset{(1)}{=} \mathrm{tr}\bigl(\sigma^n\bigr) \overset{(2)}{=} A^n\,\mathrm{tr}\bigl(\mathbb{1} - e/d\bigr) + (-A^{-3})^n\,\mathrm{tr}(e)/d \\ &\overset{(3)}{=} A^n\Bigl(d - \frac{1}{d}\Bigr) + \frac{(-A^{-3})^n}{d}. \qquad (12.181)\end{aligned}$$

(1) The closure of σ^n is the torus link $T(2, n)$, and closing is the Markov trace.
(2) $\sigma^n\mathbb{1} = A^n(\mathbb{1} - e/d) + (-A^{-3})^n e/d$ by the eigen-decomposition.
(3) $\mathrm{tr}\,\mathbb{1} = d$, $\mathrm{tr}\,e = 1$.

Checks: $n = 0$ gives d, the two-component unlink. $n = 1$ gives $Ad - (A + A^{-3})/d = Ad + A^{-1} = -A^3$, a kinked unknot, as in (12.172). $n = 3$ gives $A^3 d - (A^3 + A^{-9})/d$; since $A^6 + A^{-6} = (A^2 + A^{-2})(A^4 - 1 + A^{-4})$, $(A^3 + A^{-9})/d = -A + A^{-3} - A^{-7}$, and the total is $-A^5 - A - (-A + A^{-3} - A^{-7}) = -A^5 - A^{-3} + A^{-7}$, which is (12.174). The trefoil state sum of eight terms has been replaced by diagonalising a 2×2 matrix.

Physical picture: Transfer matrices

This is the transfer-matrix method of statistical mechanics. The braid direction is "time"; σ is the transfer matrix of one time step; the closure is the trace that imposes periodic boundary conditions; the bracket is $\mathrm{tr}(T^n)$, dominated by eigenvalues. Jones's original construction is the same with TL_n on n strands, realised as operators on a Hilbert space (a von Neumann algebra), and with the trace normalised by $\mathrm{tr}(\mathbb{1}) = 1$. In Chapter 12 these Hilbert spaces reappear as the state spaces of Chern–Simons theory on a punctured sphere, with σ the operator that exchanges two punctures.

12.11.6 HOMFLY, and what polynomials cannot see

Both skein relations have the same shape: $x\,P_{L_+} + y\,P_{L_-} + z\,P_{L_0} = 0$ with some coefficients. Nash mentions that Freyd, Yetter, Hoste, Lickorish, Millett and Ocneanu ("HOMFLY") showed that one can keep the coefficients *free*: there is a unique invariant, homogeneous of degree zero in three variables x, y, z, satisfying this with $P_{\text{unknot}} = 1$. Dividing out the homogeneity leaves two variables. In the common normalisation:

$$a\,P_{L_+} - a^{-1}P_{L_-} = z\,P_{L_0}, \qquad P_{\text{unknot}} = 1. \tag{12.182}$$

Comparing with (12.168) and (12.179):

$$\Delta_L(t) = P_L\big(a = 1,\ z = t^{1/2} - t^{-1/2}\big), \qquad V_L(t) = P_L\big(a = t^{-1},\ z = t^{1/2} - t^{-1/2}\big). \tag{12.183}$$

Worked example 12.81: HOMFLY polynomial of the trefoil

Unlink. From the kink: $aP_{\text{unknot}} - a^{-1}P_{\text{unknot}} = zP_{U_2}$, so $P_{U_2} = (a - a^{-1})/z$.
Hopf link. $L_+ = H_+$, $L_- = U_2$, $L_0 =$ unknot:

$$\begin{aligned} aP_{H_+} &\overset{(1)}{=} a^{-1}P_{U_2} + z \\ \Longrightarrow \quad P_{H_+} &\overset{(2)}{=} a^{-2}\frac{a - a^{-1}}{z} + a^{-1}z = \big(a^{-1} - a^{-3}\big)z^{-1} + a^{-1}z. \end{aligned}$$

(1) Skein relation (12.182).
(2) Divide by a and insert P_{U_2}.

Trefoil. $L_+ = 3_1$, $L_- =$ unknot, $L_0 = H_+$:

$$\begin{aligned} aP_{3_1} &\overset{(1)}{=} a^{-1} + z\,P_{H_+} \overset{(2)}{=} a^{-1} + a^{-1} - a^{-3} + a^{-1}z^2 \\ \Longrightarrow \quad P_{3_1} &= 2a^{-2} - a^{-4} + a^{-2}z^2. \end{aligned}$$

(1) Skein relation.
(2) Insert P_{H_+} and multiply by z.

Now specialise. $a = 1$: $2 - 1 + z^2 = 1 + z^2$, the Conway polynomial of Example 12.73. $a = t^{-1}$, $z^2 = t - 2 + t^{-1}$: $2t^2 - t^4 + t^2(t - 2 + t^{-1}) = t + t^3 - t^4$, the Jones polynomial. One calculation, both of Nash's polynomials.

What polynomials cannot see. Nash ends §4 with a warning: "for the Jones and Homfly polynomials there exist distinct links on which these polynomials have the same values" (Birman; Kanenobu). Examples:

- *Mutants.* Cut a diagram along a circle meeting it in four points, rotate the inside by 180° and reglue. The result (a **mutant**) has the same Alexander, Jones and HOMFLY polynomials, because every skein computation can be done outside the circle first. The Kinoshita–Terasaka and Conway knots (11 crossings) are mutants, and are distinct.
- *Kanenobu's knots.* An infinite family of distinct knots with the same HOMFLY polynomial.
- Whether $V_K(t) = 1$ forces K to be the unknot is still an open question.

This is why a more general machine is desirable, and Chern–Simons theory provides one: each gauge group G and representation R gives an invariant, and the Jones polynomial is only the SU(2), spin-$\tfrac{1}{2}$ member of the family.

	unknot	H_+	3_1 (right)	$\bar{3}_1$ (left)	4_1
components p	1	2	1	1	1
tricolourings τ	3	9	9	9	3
Δ^{Sym}	1	$t^{1/2}-t^{-1/2}$	$t-1+t^{-1}$	$t-1+t^{-1}$	$-t+3-t^{-1}$
$\lvert\Delta(-1)\rvert$	1	2	3	3	5
$V(t)$	1	$-t^{1/2}-t^{5/2}$	$t+t^3-t^4$	$t^{-1}+t^{-3}-t^{-4}$	$t^2-t+1-t^{-1}+t^{-2}$
writhe of diagram used	0	+2	+3	−3	0

Invariants of the smallest knots and links. Only the Jones row separates the two trefoils. (For H_+, $\tau = 9$: the two circles may be coloured independently.)

Reading Nash (pp. 340–342, (12.72)–(12.83))

Nash lists, without derivation: the Alexander polynomial as an integer Laurent polynomial defined up to $\mp t^n$, with $\Delta(1) = \mp 1$ and $\Delta(1/t) = t^n\Delta(t)$, n even (12.73); the trefoil value (12.74) and its other normalisations (12.75), including Δ^{Sym}; the equality of Δ for mirror images; the Jones polynomial and its trefoil values (12.76); the special values (12.77)–(12.78); HOMFLY; the skein triple (12.79); the Alexander skein relation (12.80); the Jones skein relation (12.81)–(12.82) and the unlink formula (12.83). We have derived each of these: the properties of Δ from the Seifert matrix (12.167), the Jones polynomial and its skein relation from the Kauffman bracket (12.179), and the special values by induction on skein relations. Watch Nash's misprint in (12.75) and his sign conventions in (12.80)–(12.81), discussed in the pitfalls above. The Fox calculus, Seifert matrices, the bracket, the Temperley–Lieb matrix and the HOMFLY trefoil computation are not in Nash.

Recap

- The Alexander polynomial $\Delta(t)$ is a Laurent polynomial defined up to $\pm t^n$. Compute it by Fox calculus on the knot group or as $\det(V - tV^T)$ from a Seifert matrix. Trefoil: $t^2 - t + 1$; figure-eight: $t^2 - 3t + 1$.
- From the Seifert matrix: $\Delta(1) = \pm 1$, $\Delta(1/t) = t^{-2g}\Delta(t)$, $\deg\Delta \le 2g$, and Δ is blind to mirror images.
- Skein relations reduce any link to unlinks: $\Delta_+ - \Delta_- = (t^{1/2}-t^{-1/2})\Delta_0$ and $t^{-1}V_+ - tV_- = (t^{1/2}-t^{-1/2})V_0$, with $V_{U_p} = (-t^{1/2}-t^{-1/2})^{p-1}$.
- The Kauffman bracket is a state sum with loop fugacity $d = -A^2 - A^{-2}$, invariant under R2, R3; R1 costs $-A^{\pm 3}$, the framing factor. $V_L(t) = (-A^3)^{-w}\langle D\rangle$ at $A = t^{-1/4}$.
- Right trefoil: $\langle 3_1\rangle = -A^5 - A^{-3} + A^{-7}$, $V = t + t^3 - t^4$; mirror: $V(1/t)$. Jones detects chirality.
- $V(1) = (-2)^{p-1}$, $V(-1) = \Delta(-1)$, $V_K(e^{2\pi i/3}) = 1$, $V_K'(1) = 0$, all by skein induction.
- Temperley–Lieb: $\sigma = A\mathbb{1} + A^{-1}e$, $e^2 = de$; the bracket is a transfer-matrix trace. HOMFLY unifies Δ and V; no polynomial is complete.

12.12 Wilson loops and abelian Chern–Simons theory

We now have a stock of knot invariants: the linking number, the Alexander polynomial and the Jones polynomial. Every one of them was defined from a *picture*, a projection of the knot onto a plane, and every one had to be checked against the three Reidemeister moves. Nash's §5 turns

to Witten's discovery that the Jones polynomial is also a *correlation function* of a quantum field theory in three dimensions, the Chern–Simons theory. This section does the first, fully explicit, part of that story: the abelian theory, where the path integral is Gaussian and we can evaluate it exactly. The answer is the linking number, and along the way we shall meet the one subtlety, framing, that survives in the non-abelian case.

12.12.1 Witten's programme

Nash lists the reasons why a field-theoretic definition is valuable [Nash pp. 342–343]. Let us spell them out.

1. *An intrinsically three-dimensional definition.* A knot lives in $\mathbb{R}^3$ (or S^3), not in a plane. A definition from a diagram depends a priori on the direction of projection, and different knots can even have the same projection if we forget the over/under information. Every diagrammatic invariant therefore needs a proof that it does not depend on the projection: the Reidemeister check of Section 12.9.4. A path integral over gauge fields on the three-manifold, with the knot entering as a Wilson loop, uses no projection at all. If the integral makes sense and is diffeomorphism invariant, then it is automatically an isotopy invariant.

2. *Generalisation.* The same definition works in any closed oriented three-manifold M, not only S^3, and for any compact gauge group G and any choice of representations on the components. The Jones polynomial becomes one member ($G = \mathrm{SU}(2)$, spin $\frac{1}{2}$) of a large family.

3. *The price.* Evaluating the non-abelian path integral is not a Gaussian integral. Witten did it by cutting M into pieces and using the Hilbert spaces of the theory on surfaces, which turn out to be the spaces of conformal blocks of a two-dimensional *conformal field theory*. As Nash remarks, the machinery of conformal field theory is an indispensable part of the construction. That calculation is the business of the next section of this chapter (see Chapter 12).

Key idea: The strategy for proving that $\langle W \rangle$ is the Jones polynomial

By Section 12.11.5, the Jones polynomial is the *unique* function of oriented links that obeys the skein relation (12.179) and takes the value 1 on the unknot (and then $V_{U_p} = (-t^{1/2} - t^{-1/2})^{p-1}$ on unlinks). So to identify a Chern–Simons correlation function with $V_L(t)$ one must show two things: (i) it obeys the skein relation, for a suitable identification of t with the level k; (ii) it takes the right values on unlinked, unknotted circles. Nothing else needs checking.

In the present section we test the idea where everything can be computed: the gauge group U(1). We shall see that the abelian correlation function obeys a skein relation of its own, a degenerate one, and that comparing it with the Jones relation shows exactly what non-abelian structure has to add.

12.12.2 Conventions: two ways of writing a gauge field

As in the rest of these notes, a connection is a Lie-algebra-valued one-form $A = A_\mu \, \mathrm{d}x^\mu$ whose values are *anti-Hermitian* matrices, with curvature $F = \mathrm{d}A + A \wedge A$ and gauge transformation $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$. Physicists usually write a Hermitian field with a coupling g and generators T^a (Hermitian, $[T^a, T^b] = if^{abc}T^c$).

Dictionary: Mathematicians' and physicists' gauge fields

mathematicians (Nash)	physicists
A_μ anti-Hermitian	$A_\mu^{\text{phys}} = A_\mu^a T^a$ Hermitian
A_μ	$-i\,g\,A_\mu^a T^a$
$D_\mu = \partial_\mu + A_\mu$	$D_\mu = \partial_\mu - igA_\mu^a T^a$
$F = \mathrm{d}A + A \wedge A$	$F = -\frac{i}{2}\,g\,F_{\mu\nu}^a T^a\,\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$
U(1): $A = i\,a$, a real	a_μ = the electromagnetic potential (with $e = 1$)
$\operatorname{tr} P \exp \oint_C A$	$\operatorname{tr} P \exp\bigl(-ig \oint_C A_\mu^a T^a \mathrm{d}x^\mu\bigr)$

For U(1) the Lie algebra is $i\mathbb{R}$, so an anti-Hermitian A is i times a real one-form a. Nash, in the abelian formulas (12.87)–(12.88), writes the *real* field and calls it A again; the Wilson line appears as $\exp(in \oint A)$ with an explicit i. We follow him: in Sections 12.12.6 to 12.12.8 A denotes a real one-form, the ordinary electromagnetic vector potential.

12.12.3 Wilson loops: the holonomy made into a number

Parallel transport as a product of small steps. Take a closed curve C, parametrised by $x(s)$, $0 \le s \le 1$, with $x(0) = x(1) = x_0$. Chop it into N short steps $x_j = x(j/N)$ with displacements $\Delta x_j = x_{j+1} - x_j$. Along each step, attach the matrix

$$V_j = \exp\bigl(A_\mu(x_j)\,\Delta x_j^\mu\bigr) \approx \mathbb{1} + A_\mu(x_j)\,\Delta x_j^\mu, \tag{12.184}$$

which lies in the gauge group G because $A_\mu(x_j)$ lies in its Lie algebra. (In lattice gauge theory V_j is the "link variable".) The **holonomy** of A around C is the ordered product

$$\mathrm{Hol}_C(A) = P \exp \oint_C A \coloneqq \lim_{N\to\infty} V_0 V_1 \cdots V_{N-1}. \tag{12.185}$$

The symbol P (path ordering) records that the factors are *not* combined into $\exp(\sum_j A(x_j)\Delta x_j)$: the matrices $A(x_j)$ need not commute, and the order in which they are multiplied is the order of the points along the curve.

Working definition 12.32 (Wilson loop, Nash (12.84))

For a closed curve C, a connection A and an irreducible representation R of G [a rule turning each $g \in G$ into an $n \times n$ matrix, with no proper subspace of $\mathbb{C}^n$ left invariant, such as spin j for SU(2)], the **Wilson loop** is

$$W(R, C) = \operatorname{tr}_R\, P \exp \oint_C A, \tag{12.186}$$

the trace, in the representation R, of the holonomy. *To compute it:* solve the parallel-transport equation (or multiply the link variables) around the loop to get a matrix in G, represent the matrix in R, and take the trace.

Why the trace: gauge invariance. Under $A \mapsto A^g = g^{-1}Ag + g^{-1}\mathrm{d}g$ each link variable transforms as

$$\begin{aligned} g(x_j)^{-1}\,V_j\,g(x_{j+1}) &\overset{(1)}{=} g^{-1}\bigl(\mathbb{1} + A_\mu \Delta x_j^\mu\bigr)\bigl(g + \partial_\mu g\,\Delta x_j^\mu\bigr) + O(\Delta x^2) \\ &\overset{(2)}{=} \mathbb{1} + \bigl(g^{-1}A_\mu g + g^{-1}\partial_\mu g\bigr)\Delta x_j^\mu + O(\Delta x^2) \end{aligned}$$

$$\overset{(3)}{=} V_j^{\,g} + O(\Delta x^2). \tag{12.187}$$

(1) Expand V_j to first order and Taylor expand $g(x_{j+1}) = g(x_j) + \partial_\mu g\, \Delta x_j^\mu$; all functions at x_j.
(2) Multiply out and keep first-order terms; $g^{-1}g = \mathbb{1}$.
(3) The bracket is A_μ^g, so this is the link variable of the transformed connection.

So $V_j^g = g_j^{-1} V_j g_{j+1}$ with $g_j = g(x_j)$. In the ordered product the inner factors cancel in pairs,

$$V_0^g V_1^g \cdots V_{N-1}^g = g_0^{-1} V_0\, g_1 g_1^{-1}\, V_1\, g_2 \cdots g_{N-1}^{-1} V_{N-1} g_N = g_0^{-1} (V_0 \cdots V_{N-1}) g_0,$$

using $g_N = g(x_0) = g_0$ on a closed loop. The holonomy is conjugated by the gauge transformation at the base point, and its trace is invariant: $W(R, C)$ is a gauge-invariant function of A. It also does not depend on the base point, since moving x_0 along C cyclically permutes the factors.

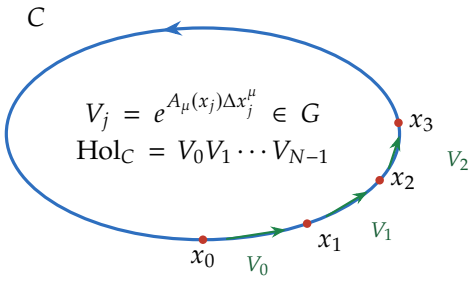

Figure 12.55: The holonomy as an ordered product. The loop C is cut into short steps; the step from x_j to x_{j+1} carries the group element $V_j \approx \mathbb{1} + A_\mu(x_j)\Delta x_j^\mu$ (the link variable of lattice gauge theory). The holonomy is the product in the order of the steps, starting at the base point x_0; a gauge transformation replaces it by $g(x_0)^{-1}\,\mathrm{Hol}_C\; g(x_0)$, so its trace, the Wilson loop, is gauge invariant.

Watch out: Ordering conventions

With Nash's sign, $\exp(+\oint A)$, the earlier points along the curve stand to the *left*, as in (12.185); this is what made (12.187) work. Many physics texts write $P\exp(-\oint A)$ with later points to the left, like the time-ordered exponential $T\exp(-i\int H\,\mathrm{d}t)$ of the Dirac picture. The two holonomies are inverse to each other, and for a unitary matrix $\mathrm{tr}\,U^{-1} = \overline{\mathrm{tr}\,U}$. For SU(2), whose representations are all equivalent to their complex conjugates, the traces agree.

Worked example 12.82: U(1): the Aharonov–Bohm phase

For $G = \mathrm{U}(1)$, write $A = i\,a$ with a real. All the $V_j = e^{ia(x_j)\cdot\Delta x_j}$ commute, so path ordering is empty:

$$W(C) \overset{(1)}{=} \exp\Big(i \oint_C a_\mu\, \mathrm{d}x^\mu\Big) \overset{(2)}{=} \exp\Big(i \int_S (\nabla \times \vec{a}) \cdot \hat{n}\, \mathrm{d}S\Big) \overset{(3)}{=} e^{i\Phi_S},$$

(1) Commuting factors: the product of exponentials is the exponential of the sum, which becomes the line integral.
(2) Stokes' theorem, for any surface S bounded by C.
(3) $\nabla \times \vec{a} = \vec{b}$ is the magnetic field, and its flux through S is Φ_S.

This is the phase an electron of unit charge picks up when carried around C: the Aharonov–Bohm effect. It is non-trivial even where $\vec{b} = 0$ on C itself. A Wilson loop measures the flux

of the gauge field that it encloses.

Worked example 12.83: SU(2): path ordering matters

Take $G = \mathrm{SU}(2)$, the fundamental representation, and the constant connection $A = i\alpha\,\sigma_1\,\mathrm{d}x + i\beta\,\sigma_2\,\mathrm{d}y$ in the plane (σ_i the Pauli matrices). Let C be the boundary of the unit square, traversed $(0,0)\to(1,0)\to(1,1)\to(0,1)\to(0,0)$. On each edge A is constant, so the link variables along the four edges are $e^{i\alpha\sigma_1}$, $e^{i\beta\sigma_2}$, $e^{-i\alpha\sigma_1}$, $e^{-i\beta\sigma_2}$ (the last two edges run in the $-x$ and $-y$ directions). If the matrices commuted the product would be $\mathbb{1}$ and $W = 2$. They do not. First conjugate σ_2 by $e^{i\alpha\sigma_1} = \cos\alpha + i\sigma_1\sin\alpha$ (write $c = \cos\alpha$, $s = \sin\alpha$):

$$\begin{aligned} e^{i\alpha\sigma_1}\sigma_2 e^{-i\alpha\sigma_1} &\overset{(1)}{=} c^2\sigma_2 + isc\,(\sigma_1\sigma_2 - \sigma_2\sigma_1) + s^2\sigma_1\sigma_2\sigma_1 \\ &\overset{(2)}{=} c^2\sigma_2 + isc\,(2i\sigma_3) - s^2\sigma_2 \\ &\overset{(3)}{=} \cos 2\alpha\;\sigma_2 - \sin 2\alpha\;\sigma_3 \equiv m. \end{aligned}$$

(1) Multiply out $(c + is\sigma_1)\sigma_2(c - is\sigma_1)$.
(2) $[\sigma_1,\sigma_2] = 2i\sigma_3$ and $\sigma_1\sigma_2\sigma_1 = -\sigma_2$ (anticommute, then $\sigma_1^2 = \mathbb{1}$).
(3) Double-angle formulas.

m is again a unit Pauli vector, so $m^2 = \mathbb{1}$ and $e^{i\beta m} = \cos\beta + i\sin\beta\, m$. Now

$$\begin{aligned} W &\overset{(1)}{=} \mathrm{tr}\big(e^{i\alpha\sigma_1}e^{i\beta\sigma_2}e^{-i\alpha\sigma_1}e^{-i\beta\sigma_2}\big) \overset{(2)}{=} \mathrm{tr}\big(e^{i\beta m}\,e^{-i\beta\sigma_2}\big) \\ &\overset{(3)}{=} \mathrm{tr}\big[(\cos\beta + i\sin\beta\, m)(\cos\beta - i\sin\beta\,\sigma_2)\big] \\ &\overset{(4)}{=} 2\cos^2\beta + \sin^2\beta\;\mathrm{tr}(m\sigma_2) \overset{(5)}{=} 2\cos^2\beta + 2\sin^2\beta\cos 2\alpha. \end{aligned}$$

(1) The ordered product of the four link variables.
(2) $e^{i\alpha\sigma_1}e^{i\beta\sigma_2}e^{-i\alpha\sigma_1} = \exp(i\beta\, e^{i\alpha\sigma_1}\sigma_2 e^{-i\alpha\sigma_1})$.
(3) Expand both exponentials.
(4) $\mathrm{tr}\,\mathbb{1} = 2$; the terms linear in Pauli matrices are traceless.
(5) $\mathrm{tr}(m\sigma_2) = \cos 2\alpha\;\mathrm{tr}\,\sigma_2^2 = 2\cos 2\alpha$.

For small α,β: $W \approx 2 - 4\alpha^2\beta^2$. Compare the curvature: $F = \mathrm{d}A + A\wedge A = [A_x, A_y]\,\mathrm{d}x\wedge\mathrm{d}y = (i\alpha)(i\beta)[\sigma_1,\sigma_2]\,\mathrm{d}x\wedge\mathrm{d}y = -2i\alpha\beta\,\sigma_3\,\mathrm{d}x\wedge\mathrm{d}y$. A small loop has holonomy $\approx \exp(F_{xy}\times\text{area})$, whose trace is $2\cos(2\alpha\beta) \approx 2 - 4\alpha^2\beta^2$. It agrees: the deviation of a Wilson loop from $\dim R$ measures the non-abelian flux inside it, and that flux here comes *entirely* from the commutator term $A\wedge A$, since $\mathrm{d}A = 0$.

Wilson loops in other representations. Every element of SU(2) is conjugate to $\mathrm{diag}(e^{i\theta}, e^{-i\theta})$. In the spin-$j$ representation (dimension $2j+1$) this element acts on the basis $|j,m\rangle$ by $e^{2im\theta}$, so

$$W(j,C) = \sum_{m=-j}^{j} e^{2im\theta} = \frac{\sin\big((2j+1)\theta\big)}{\sin\theta}, \tag{12.188}$$

the **character** of spin j (geometric series). For $j = \frac{1}{2}$: $2\cos\theta$. For $j = 1$: $1 + 2\cos 2\theta$. A Wilson loop in representation R is the character χ_R evaluated on the holonomy.

Trace normalisations. Nash warns, before (12.87), that different representations have "traces" whose normalisations differ by rational factors. Concretely: for generators T^a of a simple Lie

algebra, $\mathrm{tr}_R(T^aT^b) = x_R\,\delta^{ab}$ with a number x_R (the Dynkin index) that depends on R. For SU(2) with $T^a = J^a$ in spin j,

$$\mathrm{tr}_j\big(J_3^2\big) = \sum_{m=-j}^{j} m^2 = \frac{j(j+1)(2j+1)}{3}: \qquad x_{1/2} = \tfrac{1}{2}, \quad x_1 = 2, \quad x_{3/2} = 5.$$

The ratios are rational. The Chern–Simons action is defined with the trace in one fixed representation (for SU(N), the fundamental), and this normalisation fixes what "level k" means; the Wilson loops can then carry any R. For U(1) with charge n the analogue of x_R is n^2, and that n^2 is exactly what will appear in the exponent of our answer.

12.12.4 The correlation functions and why they are topological

Let L be a link with components $C_1, \dots, C_p$, and assign an irreducible representation R_l to each C_l. The object of interest is the normalised correlation function, Nash's (12.85),

$$\big\langle W(R_1, C_1)\cdots W(R_p, C_p)\big\rangle = \frac{1}{Z(M)}\int \mathcal{D}A\; W(R_1, C_1)\cdots W(R_p, C_p) \\ \times \exp\Big[-\frac{ik}{4\pi}\int_M \mathrm{tr}\big(A\wedge \mathrm{d}A + \tfrac{2}{3}A\wedge A\wedge A\big)\Big], \tag{12.189}$$

with $Z(M)$ the same integral without the Wilson loops. The integral is over all connections on M modulo gauge transformations.

Key idea: No metric anywhere

Look at what enters (12.189).

- The Chern–Simons three-form $\mathrm{tr}(A\,\mathrm{d}A + \frac{2}{3}A^3)$ is built from wedge products and d alone. It is integrated over the oriented M without a volume form. There is no metric and no Hodge star.
- The Wilson loops are integrals of one-forms along curves: again no metric.

Compare Yang–Mills theory, $\int \mathrm{tr}\,F\wedge\star F$, where the Hodge star needs a metric; there a Wilson loop has an "area law" $\langle W\rangle \sim e^{-\sigma\cdot\mathrm{Area}}$, a geometric answer. In Chern–Simons theory the correlation function can only depend on the topology of the pair (M, L). A diffeomorphism of M carrying L to L' can be used to change variables in the integral, so $\langle W(L)\rangle = \langle W(L')\rangle$: the correlator is an isotopy invariant, with no Reidemeister moves to check.

Two caveats make this a "chance", in Nash's word, rather than a theorem. First, to define $\mathcal{D}A$ modulo gauge transformations one must fix a gauge, and gauge fixing does use a metric. The metric dependence must cancel; in the abelian case we shall watch it cancel. Second, the self-linking of a component will turn out to need one extra piece of topological data, a framing (Section 12.12.8). Also, of course, a topological invariant may be trivial; the computation below shows that it is not.

12.12.5 Gaussian integrals with sources: the finite-dimensional rehearsal

The abelian theory is a Gaussian integral with a linear source. Here is everything we need, in finite dimensions first.

One variable. For $\lambda > 0$ the Gaussian integral and its oscillatory cousin, the Fresnel integral, are

$$\int_{-\infty}^{\infty} e^{-\lambda x^2/2}\mathrm{d}x = \sqrt{\frac{2\pi}{\lambda}}, \qquad \int_{-\infty}^{\infty} e^{\mp i\lambda x^2/2}\mathrm{d}x = \sqrt{\frac{2\pi}{\lambda}}\, e^{\mp i\pi/4}. \tag{12.190}$$

(The second follows from the first by rotating the contour through $\mp 45°$, i.e. by setting $\lambda \to \pm i\lambda$ and taking the principal root.) The phase $e^{\mp i\pi/4}$ depends only on the *sign* of the quadratic form. Now add a source J and complete the square:

$$\frac{\int e^{-i\lambda x^2/2 + iJx}\,\mathrm{d}x}{\int e^{-i\lambda x^2/2}\,\mathrm{d}x} \overset{(1)}{=} \frac{\int e^{-i\lambda (x - J/\lambda)^2/2}\,\mathrm{d}x}{\int e^{-i\lambda x^2/2}\,\mathrm{d}x}\, e^{iJ^2/2\lambda} \overset{(2)}{=} e^{iJ^2/2\lambda}. \tag{12.191}$$

(1) $-\frac{\lambda}{2}x^2 + Jx = -\frac{\lambda}{2}\left(x - \frac{J}{\lambda}\right)^2 + \frac{J^2}{2\lambda}$.
(2) Shift the integration variable $x \to x + J/\lambda$; the two integrals cancel.

Two lessons. The normalised answer is $e^{i\Phi_{\mathrm{cl}}}$, the phase evaluated at the stationary point $x_{\mathrm{cl}} = J/\lambda$; and all the awkward prefactors (the $\sqrt{2\pi/\lambda}$ and the Fresnel phase) cancel against the normalisation.

Many variables. For a real symmetric invertible $n \times n$ matrix K and a source vector J, the same completion of the square with $x_{\mathrm{cl}} = K^{-1}J$ gives

$$\left\langle e^{iJ^T x} \right\rangle := \frac{\int \mathrm{d}^n x\; e^{-\frac{i}{2}x^T K x + iJ^T x}}{\int \mathrm{d}^n x\; e^{-\frac{i}{2}x^T K x}} = \exp\!\left(\frac{i}{2}\, J^T K^{-1} J\right). \tag{12.192}$$

Differentiating twice with respect to J at $J = 0$ gives the **propagator** $\langle x_i x_j \rangle = -i(K^{-1})_{ij}$, and (12.192) can be rewritten as $\langle e^X \rangle = e^{\langle X^2 \rangle/2}$ for the linear function $X = iJ^T x$: for a Gaussian distribution the exponential of a linear function is determined by the two-point function. *The whole abelian Chern–Simons calculation is this formula with K^{-1} replaced by a Green's function.*

Zero modes and sources that do not see them. Gauge symmetry makes K degenerate: the action does not change along gauge directions. Here is the finite-dimensional model. Let

$$K = \begin{pmatrix} \lambda & 0 \\ 0 & 0 \end{pmatrix}, \qquad J = \begin{pmatrix} j \\ 0 \end{pmatrix}.$$

The direction x_2 is a "gauge direction": neither the action nor the source depends on it. Then

$$\frac{\int \mathrm{d}x_1 \mathrm{d}x_2\; e^{-i\lambda x_1^2/2 + ijx_1}}{\int \mathrm{d}x_1 \mathrm{d}x_2\; e^{-i\lambda x_1^2/2}} \overset{(1)}{=} \frac{\left(\int \mathrm{d}x_2\right) \int \mathrm{d}x_1\, e^{-i\lambda x_1^2/2 + ijx_1}}{\left(\int \mathrm{d}x_2\right) \int \mathrm{d}x_1\, e^{-i\lambda x_1^2/2}} \overset{(2)}{=} e^{ij^2/2\lambda}.$$

(1) The integrand does not depend on x_2, so the integral factorises; $\int \mathrm{d}x_2$ is infinite, the "volume of the gauge group".
(2) The infinite volumes cancel in the ratio, and the x_1 integral is (12.191).

So the rule is: *restrict to a slice transverse to the gauge directions and invert K there* ("gauge fixing"). This is legitimate because the source has no component along the zero mode. If it had one, the integral would be ill-defined, which is the finite-dimensional shadow of the fact that a gauge-*non*-invariant observable has no expectation value. The choice of slice does not matter: any other slice $x_2 = f(x_1)$ gives the same ratio. In field theory the slice is a gauge condition such as $\nabla \cdot A = 0$, and the Jacobian that appears for a curved slice is the Faddeev–Popov determinant; for the abelian theory it does not depend on A and cancels between numerator and denominator. We shall need it in earnest in Section 12.13.

12.12.6 Abelian Chern–Simons theory: action and Wilson loops

The action, Nash (12.86) and (12.88). For $G = \mathrm{U}(1)$ the cubic term vanishes ($A \wedge A = 0$ for a one-form with values in a commutative algebra), so the action is quadratic. With the real field $A = A_i \,\mathrm{d}x^i$ on $\mathbb{R}^3$ we have

$$\begin{aligned} A \wedge \mathrm{d}A &\overset{(1)}{=} A_i \,\mathrm{d}x^i \wedge \partial_j A_k \,\mathrm{d}x^j \wedge \mathrm{d}x^k \\ &\overset{(2)}{=} \varepsilon^{ijk} A_i \,\partial_j A_k \,\mathrm{d}^3x \overset{(3)}{=} \vec{A} \cdot (\nabla \times \vec{A}) \,\mathrm{d}^3x. \end{aligned} \tag{12.193}$$

(1) $\mathrm{d}A = \partial_j A_k \,\mathrm{d}x^j \wedge \mathrm{d}x^k$.
(2) $\mathrm{d}x^i \wedge \mathrm{d}x^j \wedge \mathrm{d}x^k = \varepsilon^{ijk} \,\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \mathrm{d}x^3$ for the standard orientation.
(3) $(\nabla \times \vec{A})^i = \varepsilon^{ijk} \partial_j A_k$.

So the abelian Chern–Simons action is the **magnetic helicity** $\int \vec{A} \cdot \vec{B} \,\mathrm{d}^3x$ of the field $\vec{B} = \nabla \times \vec{A}$, which we met as a linking number in Example 12.70.

Gauge invariance. Under $A \mapsto A + \mathrm{d}\lambda$,

$$\begin{aligned} \int_M (A + \mathrm{d}\lambda) \wedge \mathrm{d}(A + \mathrm{d}\lambda) &\overset{(1)}{=} \int_M A \wedge \mathrm{d}A + \int_M \mathrm{d}\lambda \wedge \mathrm{d}A \\ &\overset{(2)}{=} \int_M A \wedge \mathrm{d}A + \int_M \mathrm{d}(\lambda \,\mathrm{d}A) \overset{(3)}{=} \int_M A \wedge \mathrm{d}A, \end{aligned}$$

(1) $\mathrm{d}\mathrm{d}\lambda = 0$.
(2) $\mathrm{d}(\lambda \,\mathrm{d}A) = \mathrm{d}\lambda \wedge \mathrm{d}A + \lambda \,\mathrm{d}\mathrm{d}A$ and $\mathrm{d}\mathrm{d}A = 0$.
(3) Stokes' theorem on the closed manifold M ($\partial M = \varnothing$).

The representations and the Wilson loops, Nash (12.87). The irreducible representations of $\mathrm{U}(1) = \{e^{i\theta}\}$ are one-dimensional, $e^{i\theta} \mapsto e^{in\theta}$ with $n \in \mathbb{Z}$ (the charge). The integer condition is needed for the map to be well defined on the circle: θ and $\theta + 2\pi$ are the same group element. Path ordering is empty and the trace of a 1×1 matrix is its entry, so

$$W(n, C) = \exp\Bigl(in \oint_C A \Bigr), \qquad n \in \mathbb{Z}. \tag{12.194}$$

The same integrality shows up as gauge invariance. A gauge transformation $g = e^{i\lambda}$ need only be single valued as a group element, so going once round C the function λ may jump by $2\pi w$ with $w \in \mathbb{Z}$ (for example $\lambda = \varphi$, the azimuthal angle round a line). Then $\oint_C \mathrm{d}\lambda = 2\pi w$ and $W(n, C)$ is multiplied by $e^{2\pi i n w} = 1$ precisely because $n \in \mathbb{Z}$.

Wilson loops are currents. The line integral along C can be written as a volume integral with a delta-function current:

$$\oint_C A = \int \mathrm{d}^3x \; J_C^i(x) A_i(x), \qquad J_C^i(x) := \oint_C \mathrm{d}y^i \,\delta^3(x - y). \tag{12.195}$$

J_C is the current density of a unit current flowing along the wire C. It is conserved: for any test function f,

$$\int \mathrm{d}^3x \; f \,\partial_i J_C^i \overset{(1)}{=} -\int \mathrm{d}^3x \; J_C^i \,\partial_i f \overset{(2)}{=} -\oint_C \mathrm{d}y^i \,\partial_i f(y) \overset{(3)}{=} 0.$$

(1) Integrate by parts.
(2) Insert (12.195) and do the x integral with the delta function.
(3) The integral of a gradient round a closed curve vanishes.

So $\nabla \cdot \vec{J}_C = 0$: a closed loop of current has no sources or sinks. This is the field-theory form of gauge invariance of the Wilson loop, and it is exactly the condition, from the finite-dimensional rehearsal, that the source not couple to the zero modes $A = \mathrm{d}\lambda$.

The integral to be done. For a link with charges $n_1, \dots, n_p$ put $\vec{J} = \sum_l n_l \vec{J}_{C_l}$. The abelian correlation function (12.88) is

$$\big\langle W(n_1, C_1) \cdots W(n_p, C_p) \big\rangle = \frac{1}{Z} \int \mathcal{D}A \; \exp\Big[-\frac{ik}{4\pi} \int \vec{A} \cdot (\nabla \times \vec{A}) \, \mathrm{d}^3x + i \int \vec{J} \cdot \vec{A} \, \mathrm{d}^3x \Big]. \tag{12.196}$$

It has exactly the form (12.192), with the index i of x_i replaced by the pair (vector index, point of space), and with

$$K = \frac{k}{2\pi} \nabla \times \qquad \Big(\text{so that } \tfrac{1}{2} A \cdot KA = \tfrac{k}{4\pi} A \cdot \nabla \times A \Big). \tag{12.197}$$

Following Nash we take $M = S^3$, which for a link is the same as $\mathbb{R}^3$: S^3 is $\mathbb{R}^3$ plus one point at infinity, a link can always be isotoped to miss that point, and fields that fall off at infinity see no difference. On S^3 there are also no non-trivial flat U(1) connections ($H^1(S^3) = 0$), so the only zero modes of K are the gauge directions.

12.12.7 Doing the integral: the propagator of Chern–Simons theory

By (12.192) the answer is $\exp\big(\frac{i}{2} \iint J^i(x) \, G_{ij}(x, y) \, J^j(y)\big)$, where $G = K^{-1}$ on the gauge-fixed slice. We find G in Fourier space, where K becomes a 3×3 matrix we can simply look at.

The curl as a matrix. With $f(x) = \int \frac{\mathrm{d}^3p}{(2\pi)^3} e^{ip\cdot x} \tilde{f}(p)$ the derivative ∂_j becomes multiplication by ip_j, so $(\nabla \times \vec{A})_i = \varepsilon_{ijk} \partial_j A_k$ becomes $P_{ik}(p) \tilde{A}_k$ with

$$P_{ik}(p) = i \, \varepsilon_{ijk} \, p_j, \qquad \tilde{K}(p) = \frac{k}{2\pi} P(p). \tag{12.198}$$

Take $\vec{p} = p \, \hat{z}$. Then only $j = 3$ contributes: $P_{12} = i\varepsilon_{132} p = -ip$, $P_{21} = i\varepsilon_{231} p = ip$, and every other entry vanishes:

$$P(p\hat{z}) = p \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = p \, \big(\sigma_2 \oplus 0 \big). \tag{12.199}$$

This is a Pauli matrix. Its eigenvectors and eigenvalues:

eigenvector	eigenvalue of P	meaning
$\hat{z}$ (along $\vec{p}$)	0	longitudinal, $\tilde{A} \propto \vec{p}$, i.e. $A = \nabla\lambda$: pure gauge
$(1, i, 0)/\sqrt{2}$	$+p$	circular polarisation, helicity $+1$
$(1, -i, 0)/\sqrt{2}$	$-p$	circular polarisation, helicity -1

(Check: $\sigma_2 (1, i)^T = (-i \cdot i, \; i \cdot 1)^T = (1, i)^T$.) Three facts can be read off. The zero mode is exactly the gauge direction, as promised. The operator is first order, so its eigenvalues grow like p

rather than p^2. And the eigenvalues come with *both* signs, so the Gaussian is not damped in any direction: the Chern–Simons "kinetic term" is a Fresnel integral whose phases $e^{\mp i\pi/4}$, one per mode, depend on the spectral asymmetry of the curl. That phase is the origin of the η-invariant in Section 12.13. For the normalised correlator it cancels.

Inverting on the transverse modes. The square of P is the projector onto the transverse plane, times p^2:

$$\begin{aligned}(P^2)_{il} &\overset{(1)}{=} i^2\,\varepsilon_{ijm}p_j\,\varepsilon_{mnl}p_n \overset{(2)}{=} -\big(\delta_{in}\delta_{jl}-\delta_{il}\delta_{jn}\big)p_jp_n\\ &\overset{(3)}{=} p^2\delta_{il}-p_ip_l = p^2\,(\Pi_T)_{il}.\end{aligned} \tag{12.200}$$

(1) Matrix product of (12.198) with itself.
(2) $\varepsilon_{ijm}\varepsilon_{mnl}=\varepsilon_{mij}\varepsilon_{mnl}=\delta_{in}\delta_{jl}-\delta_{il}\delta_{jn}$.
(3) Contract; $\Pi_T=\mathbb{1}-\hat p\hat p^{\,T}$ projects out the longitudinal direction.

(In (12.199): $\sigma_2^2=\mathbb{1}$ on the first two components, 0 on the third.) Hence P/p^2 inverts P on transverse vectors, and the propagator in momentum space, in the gauge $\nabla\cdot\vec A=0$ (i.e. $\vec p\cdot\tilde A=0$), is

$$\tilde G_{il}(p)=\frac{2\pi}{k}\,\frac{P_{il}(p)}{p^2}=\frac{2\pi}{k}\,\frac{i\,\varepsilon_{ijl}\,p_j}{p^2},\qquad \tilde K\tilde G=\Pi_T. \tag{12.201}$$

Back to position space. We need one Fourier transform, that of $1/p^2$. Since $-\nabla^2\frac{1}{4\pi r}=\delta^3(x)$ and $-\nabla^2\to p^2$,

$$\int\frac{\mathrm{d}^3p}{(2\pi)^3}\,\frac{e^{ip\cdot r}}{p^2}=\frac{1}{4\pi\,|r|}. \tag{12.202}$$

Then

$$\begin{aligned}G_{il}(x,y) &\overset{(1)}{=} \frac{2\pi}{k}\int\frac{\mathrm{d}^3p}{(2\pi)^3}\,e^{ip\cdot(x-y)}\,\frac{i\,\varepsilon_{ijl}\,p_j}{p^2}\\ &\overset{(2)}{=} \frac{2\pi}{k}\,\varepsilon_{ijl}\,\frac{\partial}{\partial x^j}\,\frac{1}{4\pi\,|x-y|}\\ &\overset{(3)}{=} -\frac{1}{2k}\,\varepsilon_{ijl}\,\frac{(x-y)_j}{|x-y|^3}\overset{(4)}{=}\frac{1}{2k}\,\varepsilon_{ilj}\,\frac{(x-y)^j}{|x-y|^3}.\end{aligned} \tag{12.203}$$

(1) Inverse Fourier transform of (12.201).
(2) $ip_j\,e^{ip\cdot(x-y)}=\partial_{x^j}e^{ip\cdot(x-y)}$; pull the derivative out and use (12.202).
(3) $\partial_j\,|r|^{-1}=-r_j/|r|^3$, and $\frac{2\pi}{4\pi k}=\frac{1}{2k}$.
(4) $\varepsilon_{ijl}=-\varepsilon_{ilj}$; indices are Euclidean, so up and down are the same.

This is the Chern–Simons propagator, $\langle A_i(x)A_l(y)\rangle=-iG_{il}(x,y)$. It is the Biot–Savart kernel.

The same thing, the physicist's way: Ampère's law. There is a quicker route which shows what is going on. The stationary point of the exponent in (12.196) satisfies

$$\begin{aligned}0 &\overset{(1)}{=} \frac{\delta}{\delta A_i(x)}\Big[-\frac{k}{4\pi}\int\vec A\cdot(\nabla\times\vec A)+\int\vec J\cdot\vec A\Big]\\ &\overset{(2)}{=} -\frac{k}{2\pi}\,(\nabla\times\vec A)_i(x)+J_i(x)\quad\Longrightarrow\quad \nabla\times\vec A_{\mathrm{cl}}=\frac{2\pi}{k}\,\vec J.\end{aligned} \tag{12.204}$$

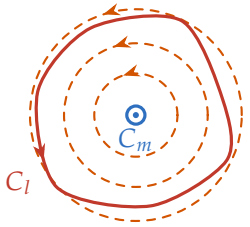
(1) Stationary phase: the classical solution dominates a Gaussian exactly, as in (12.191).

(2) $\int \delta\vec{A}\cdot\nabla\times\vec{A} = \int \vec{A}\cdot\nabla\times\delta\vec{A}$ (integrate by parts; the curl is symmetric), so the variation of the quadratic term is twice $\int \delta\vec{A}\cdot\nabla\times\vec{A}$.

This is Ampère's law $\nabla\times\vec{B} = \vec{J}$ for the field $\vec{B} = (k/2\pi)\vec{A}_{\mathrm{cl}}$. In the gauge $\nabla\cdot\vec{A} = 0$ its solution is the Biot–Savart field (12.156):

$$\vec{A}_{\mathrm{cl}} = \frac{2\pi}{k}\sum_m n_m\,\vec{B}_{C_m}, \qquad \vec{B}_{C_m}(x) = \frac{1}{4\pi}\oint_{C_m}\frac{\mathrm{d}\vec{y}\times(x-y)}{|x-y|^3}. \tag{12.205}$$

In words: *the Chern–Simons field produced by a Wilson loop is the magnetic field of a wire carrying the current n along the loop*, scaled by $2\pi/k$. Equivalently, the Chern–Simons equation of motion $F = \mathrm{d}A = (2\pi/k)\star J$ attaches a flux $2\pi n/k$ to each charge n. This flux attachment is what makes Chern–Simons theory the effective theory of the fractional quantum Hall effect.



field lines of $\vec{A}_{\mathrm{cl}} = \frac{2\pi}{k}\,n_m\vec{B}_{C_m}$

$$\oint_{C_l}\vec{A}_{\mathrm{cl}}\cdot\mathrm{d}\vec{x} = \frac{2\pi}{k}\,n_m\,L(C_l,C_m)$$

Figure 12.56: Flux attachment. Seen end on, a Wilson loop C_m of charge n_m acts as a wire carrying current n_m; the stationary Chern–Simons field $\vec{A}_{\mathrm{cl}}$ is its Biot–Savart field scaled by $2\pi/k$. A second Wilson loop C_l measures its circulation, which by Ampère's law is $2\pi n_m/k$ times the number of times C_l winds around C_m.

The result, Nash (12.89)–(12.92). Evaluate the exponent at the stationary point:

$$\begin{aligned}\Phi_{\mathrm{cl}} &\overset{(1)}{=} -\frac{k}{4\pi}\int\vec{A}_{\mathrm{cl}}\cdot\frac{2\pi}{k}\vec{J} + \int\vec{J}\cdot\vec{A}_{\mathrm{cl}} \overset{(2)}{=} \frac{1}{2}\int\vec{J}\cdot\vec{A}_{\mathrm{cl}}\,\mathrm{d}^3x\\ &\overset{(3)}{=} \frac{\pi}{k}\sum_{l,m} n_l n_m\oint_{C_l}\vec{B}_{C_m}\cdot\mathrm{d}\vec{x} \overset{(4)}{=} \frac{\pi}{k}\sum_{l,m} n_l n_m\,L(C_l,C_m).\end{aligned} \tag{12.206}$$

(1) Use the equation of motion (12.204) to replace $\nabla\times\vec{A}_{\mathrm{cl}}$.
(2) $-\frac{1}{2}+1 = \frac{1}{2}$.
(3) Insert $\vec{J} = \sum_l n_l\vec{J}_{C_l}$ and (12.205), and do the volume integral with the delta functions (12.195).
(4) Ampère's law in the form (12.158): the circulation round C_l of the field of a unit current on C_m is $L(C_l,C_m)$.

Writing out step 3 with the Biot–Savart integral instead of step 4 gives

$$\begin{aligned}\big\langle W(n_1,C_1)\cdots W(n_p,C_p)\big\rangle &\overset{(1)}{=} e^{i\Phi_{\mathrm{cl}}} \overset{(2)}{=} \exp\Big[\frac{i}{4k}\,\varepsilon_{ijk}\sum_{l,m=1}^{p} n_l n_m\oint_{C_l}\mathrm{d}x^i\oint_{C_m}\mathrm{d}y^j\,\frac{(x-y)^k}{|x-y|^3}\Big]\\ &\overset{(3)}{=} \exp\Big[\frac{i\pi}{k}\sum_{l,m} n_l n_m\,L(C_l,C_m)\Big].\end{aligned} \tag{12.207}$$

(1) The Gaussian formula (12.192): the normalised integral is the phase at the stationary point. The fluctuation determinant is independent of J and cancels against Z.
(2) $\frac{\pi}{k}\cdot\frac{1}{4\pi} = \frac{1}{4k}$, and $\oint\vec{B}_{C_m}\cdot\mathrm{d}\vec{x} = \frac{1}{4\pi}\oint\oint\mathrm{d}\vec{x}\cdot\big(\mathrm{d}\vec{y}\times(x-y)\big)/|x-y|^3$ with $\mathrm{d}\vec{x}\cdot(\mathrm{d}\vec{y}\times\vec{r}) = \varepsilon_{ijk}\mathrm{d}x^i\mathrm{d}y^j r^k$. This is Nash's (12.89), and the same as $\frac{i}{2}\iint JGJ$ with the propagator (12.203).

(3) Gauss's formula (12.159), which is Nash's (12.90).

This is Nash's (12.92). The Gaussian path integral of abelian Chern–Simons theory computes the Gauss linking numbers of the Wilson loops: *a topological quantum field theory produces a knot invariant*, exactly as advertised.

Watch out: Two things that look metric dependent but are not

(1) The propagator (12.203) was derived in the gauge $\nabla \cdot \vec{A} = 0$, which uses the flat metric. In another gauge G_{il} changes by terms of the form $\partial_i \Lambda_l(x, y)$ or $\partial_{y^l} \Lambda_i$, and these integrate to zero against the conserved current J (the chain after (12.195)). (2) On S^3 with its round metric the Green's function is a different function, but the Gauss integral is a degree (Section 12.10.4) and any kernel inverting $\nabla\times$ gives the same integer. Only the diagonal terms $l = m$ are delicate; they are the subject of Section 12.12.8.

Watch out: The sign of k

Nash's (12.86) carries tr and an anti-Hermitian A, his (12.88) carries the real A. With $A_{\text{anti-Herm}} = iA_{\text{real}}$, $\operatorname{tr}(A \wedge \mathrm{d}A) \to -A \wedge \mathrm{d}A$, which flips the sign of k. We used (12.88) as printed; with the opposite sign every k in (12.207) becomes $-k$, i.e. the answer is complex conjugated, which is the same as replacing the link by its mirror image. Nash's (12.89) agrees with our sign.

Worked example 12.84: The Hopf link and the unlink

For two components the double sum in (12.207) has two off-diagonal terms, $(l, m) = (1, 2)$ and $(2, 1)$, equal by symmetry of L:

$$\big\langle W(n_1, C_1) W(n_2, C_2) \big\rangle = \exp\Big[\frac{2\pi i}{k}\, n_1 n_2\, L(C_1, C_2)\Big] \times (\text{self-linking factors}).$$

For the Hopf link, $L = \pm 1$ and the cross term is $e^{\pm 2\pi i n_1 n_2/k}$. For the two-component unlink it is 1. For the Whitehead link it is also 1 (Section 12.10: $L = 0$), although the Whitehead link is not split: the abelian theory is as blind as the linking number itself.

Physical picture: Anyons

In $2 + 1$ dimensions a Wilson line in space-time is the world-line of a charged particle, and the Chern–Simons term attaches flux $2\pi n/k$ to charge n. Take two particles of unit charge and let one circle the other: the world-lines form a Hopf link, and the amplitude picks up $e^{2\pi i/k}$, an Aharonov–Bohm phase from the attached flux. Half a circuit, an exchange, gives $e^{i\pi/k}$: the particles are **anyons** with statistics angle $\theta = \pi/k$, neither bosons ($\theta = 0$) nor fermions ($\theta = \pi$). In the Laughlin state of the fractional quantum Hall effect at filling $\nu = 1/k$ the quasiparticles are exactly such anyons, and the low-energy theory is abelian Chern–Simons at level k.

12.12.8 Self-linking and framing

The trouble with $l = m$. The diagonal terms of (12.207) ask for $L(C_l, C_l)$, the Gauss integral of a curve with itself. In Section 12.10.6 we saw that this integral converges (the integrand is bounded on the diagonal) and defines the writhe $\operatorname{Wr}(C)$; but it is not an integer and not an isotopy invariant, because the degree argument breaks down on the diagonal $x = y$. In quantum field theory the problem is sharper: the term involves the propagator $\langle A_i(x) A_j(y) \rangle$ at

$x = y$, the product of two field operators at the same point, which has no unique meaning. Any definition requires a regularisation, and the answer depends on it. This is Nash's remark that $L(C_l, C_l)$ "has singularities due to points where $x - y = 0$".

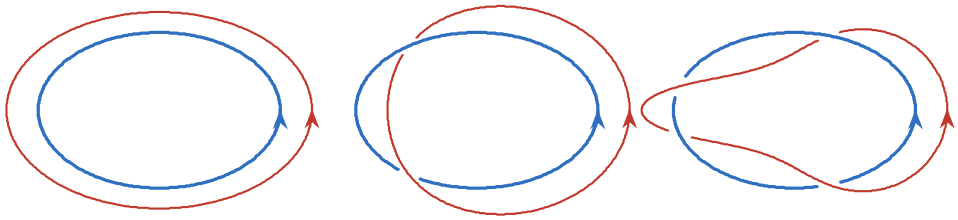
Point splitting. The standard cure for a coincident-point singularity is point splitting: evaluate one of the two fields at a nearby point. For a Wilson loop this means replacing one copy of C by a nearby parallel curve C'. Then $L(C, C')$ is a linking number of two *disjoint* curves, an honest integer and an isotopy invariant of the pair. But there are many choices of C'.

Working definition 12.33 (Framing, Nash (12.91))

A **framing** of a knot C is a choice of a nowhere-vanishing normal vector field $\vec{v}$ along C [at each point of C, a nonzero vector perpendicular to the tangent, varying smoothly], or equivalently a thin ribbon with C as one edge. The other edge, $C' = C + \varepsilon\vec{v}$, is the **push-off**. The **self-linking number** of the framed knot is defined to be

$$L(C, C) := L(C, C'). \tag{12.208}$$

To compute it: draw C and C' and count half the signed crossings between them (Section 12.10.1).



$t = 0$: $L(C, C') = 0$ $t = 1$: $L(C, C') = 1$ $t = 2$: $L(C, C') = 2$

Figure 12.57: Framings of the unknot. The blue curve is C, the red curve its push-off $C' = C + \varepsilon\vec{v}$, drawn in perspective. With the flat framing ($t = 0$) C' is a parallel circle and $L(C, C') = 0$. Each full twist of $\vec{v}$ about the tangent makes C' wind once more around C: two more crossings of the same sign in the picture, one more unit of linking.

How much freedom. Twisting the ribbon once more around C (a full 360° turn of $\vec{v}$ about the tangent) makes C' wind once more around C, so $L(C, C')$ changes by ± 1 (Figure 12.57). Every integer occurs. So a framing is, up to deformation, exactly an integer's worth of extra data per component. "A little thought", as Nash says, shows that this is the only ambiguity: two normal fields along C can be deformed into each other if and only if they give the same $L(C, C')$.

Where the non-integer writhe went. The Călugăreanu–White formula says that for a ribbon,

$$L(C, C') = \mathrm{Wr}(C) + \mathrm{Tw}(C, \vec{v}), \tag{12.209}$$

where $\mathrm{Wr}(C)$ is the writhe integral (12.164) and $\mathrm{Tw} = \frac{1}{2\pi}\oint (\hat{t} \times \vec{v}) \cdot \frac{\mathrm{d}\vec{v}}{\mathrm{d}s}\,\mathrm{d}s$ (for unit $\vec{v} \perp \hat{t}$) is the total rotation of the ribbon about its core, in units of full turns. Neither term on the right is an integer or an invariant; their sum is. As $\varepsilon \to 0$ the Gauss integral $L(C, C'_\varepsilon)$ does *not* tend to $\mathrm{Wr}(C)$: the integrand develops a spike near the diagonal whose integral is exactly Tw. This is the "singularity" at $x = y$: a delta-function-like contribution whose weight depends on how the limit is taken. DNA biophysicists use (12.209) daily, since a closed DNA loop is a ribbon: twisting it (Tw) makes it supercoil (Wr).

Worked example 12.85: Two framings of a round circle

Let C be the unit circle in the xy-plane. It lies in a plane, so $\mathrm{Wr}(C) = 0$ (Example 12.68). (a) The radial framing $\vec{v} = \hat{r}$ keeps the ribbon flat in the plane: C' is a larger concentric circle, disjoint from the disc bounded by C, so $L(C, C') = 0 = \mathrm{Tw}$. (b) The framing $\vec{v} = \cos(ts)\,\hat{r} - \sin(ts)\,\hat{z}$, with s the angle along C, rotates t times round the tangent: C' pierces the flat disc spanning C once for each full turn, always in the same direction, so $L(C, C') = t = \mathrm{Tw}$. Figure 12.57 shows $t = 0, 1, 2$.

The blackboard framing. Given a diagram D of C, there is a natural framing: take $\vec{v}$ lying in the plane of the paper (the blackboard), so that C' is drawn parallel to C everywhere in the picture. Away from crossings C and C' do not cross. At each crossing of D the two strands and their two parallel copies make four crossings (Figure 12.58), all with the same sign ε as the original one; exactly two of them are between C and C'. Hence

$$L(C, C'_{\mathrm{bb}}) \overset{(1)}{=} \frac{1}{2} \sum_{\substack{\text{crossings of} \\ C \text{ with } C'}} \varepsilon \overset{(2)}{=} \frac{1}{2} \sum_{\text{crossings } c \text{ of } D} 2\,\varepsilon_c \overset{(3)}{=} w(D). \tag{12.210}$$

(1) The crossing formula (12.155) for the linking number.
(2) Each crossing c of D produces two crossings between C and C', both of sign ε_c.
(3) Definition of the writhe of the diagram.

The blackboard self-linking number is the writhe of the diagram. This explains why the writhe appeared in the Kauffman bracket: an R1 move changes $w(D)$ by ± 1, i.e. it changes the blackboard framing by one twist (flatten a kink in a ribbon and you get a twisted ribbon), and the bracket is an invariant of framed knots.

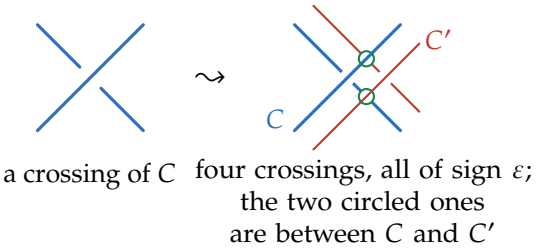


Figure 12.58: The blackboard framing. The push-off C' (red) is drawn parallel to C (blue) in the plane of the diagram. Each crossing of the diagram becomes four crossings of the same sign; two of them are between C and C', so each crossing contributes $\frac{1}{2} \cdot 2\varepsilon = \varepsilon$ to $L(C, C')$, and $L(C, C'_{\mathrm{bb}}) = w(D)$.

The canonical framing in S^3. For a knot in S^3 (or any homology sphere) there is a preferred framing: push C off along a Seifert surface S (Section 12.11.2). The push-off C' lies on a parallel copy of S, which C does not meet, so the signed count of piercings is 0 and $L(C, C') = 0$. This **Seifert** (or zero) framing is why the self-linking ambiguity is harmless for knots in S^3: one always knows how to convert to the canonical choice. In a general three-manifold no such canonical choice need exist, and one must carry the framing along as data.

The correlation function in terms of framed links, Nash (12.92)–(12.94). With each component framed, all the $L(C_l, C_m)$ in (12.207) are integers, and

$$\big\langle W(n_1, C_1) \cdots W(n_p, C_p) \big\rangle = \exp\Big[\frac{i\pi}{k} \sum_{l,m} n_l n_m\, L(C_l, C_m)\Big] \tag{12.211}$$

is an invariant of *framed* links. Change the framing of C_l by t extra twists. Then $L(C_l, C_l) \to L(C_l, C_l) + t$, the diagonal term $l = m$ of the double sum changes by $n_l^2 t$, and nothing else changes:

$$\begin{aligned}\big\langle W(n_1, C_1) \cdots W(n_p, C_p) \big\rangle &\overset{(1)}{=} \exp\Big[\frac{i\pi}{k}\Big(\sum_{l,m} n_l n_m L(C_l, C_m) + n_l^2 t\Big)\Big] \\ &\overset{(2)}{=} \exp\Big[\frac{i\pi}{k} n_l^2 t\Big] \exp\Big[\frac{i\pi}{k} \sum_{l,m} n_l n_m L(C_l, C_m)\Big].\end{aligned} \tag{12.212}$$

(1) Only the (l, l) entry of the matrix of linking numbers changes.
(2) Split the exponential. This is Nash's (12.93).

So under a change of framing,

$$\langle W \rangle \longmapsto \exp\Big[\frac{2\pi i\, t\, n_l^2}{2k}\Big] \langle W \rangle, \tag{12.213}$$

Nash's (12.94): each twist costs a phase, not a new unknown, and one can always translate between framings.

Key idea: Framing phases are conformal weights

Write the phase per twist in (12.213) as $e^{2\pi i h_n}$ with $h_n = n^2/2k$. In the two-dimensional conformal field theory of a compact boson at level k (the one Witten's construction associates with U(1) Chern–Simons), the primary field of charge n has conformal weight exactly $h_n = n^2/2k$. A full twist of a ribbon is a 2π rotation of the particle whose world-line it is, and $e^{2\pi i h}$ is the phase of a spin-h object under a 2π rotation. In the SU(2) theory the same argument gives $e^{2\pi i h_j}$ with $h_j = j(j+1)/(k+2)$, and for the Kauffman bracket the corresponding factor is $-A^3$. This is the first of many places where Nash's remark about conformal field theory being indispensable comes true.

Worked example 12.86: The framed unknot and the framed trefoil

A single unknot of charge n with framing f (self-linking f) has $\langle W \rangle = e^{i\pi n^2 f/k}$. With the canonical framing $f = 0$ it is 1.
Draw the right trefoil in the standard way; $w(D) = +3$, so in the blackboard framing $L(C, C'_{\mathrm{bb}}) = 3$ and $\langle W(n, 3_1) \rangle_{\mathrm{bb}} = e^{3i\pi n^2/k}$. Converting to the canonical framing with $t = -3$ gives $\langle W(n, 3_1) \rangle_0 = 1$, the same as the unknot. *For a single knot in S^3 with canonical framing the abelian theory always gives* 1: it sees linking between components, but nothing of the knotting of a single component.

12.12.9 The abelian skein relation, and what is missing

Let every component carry charge $n = 1$ and use the blackboard framing of a diagram D of L. The double sum in (12.211) then collects every crossing of D exactly once with its sign:

$$\begin{aligned}\sum_{l,m} L(C_l, C_m) &\overset{(1)}{=} \sum_l w(D_l) + 2 \sum_{l<m} L(C_l, C_m) \\ &\overset{(2)}{=} \sum_l \sum_{c \in D_l} \varepsilon_c + \sum_{\substack{c \text{ between} \\ \text{different components}}} \varepsilon_c \overset{(3)}{=} w(D).\end{aligned} \tag{12.214}$$

(1) Diagonal terms by (12.210); off-diagonal terms in pairs by symmetry.
(2) The writhe of the sub-diagram D_l counts the self-crossings of C_l; twice the linking number counts the crossings between two components.
(3) Together these are all crossings of D.

So, with $q := e^{i\pi/k}$,

$$\langle W(L)\rangle_{\mathrm{bb}} = q^{\,w(D)}. \tag{12.215}$$

Now take a skein triple. Switching one crossing from L_+ to L_- lowers w by 2:

$$q^{-1}\langle W(L_+)\rangle - q\,\langle W(L_-)\rangle = 0. \tag{12.216}$$

Compare the Jones relation (12.179), $t^{-1}V_{L_+} - tV_{L_-} = (t^{1/2} - t^{-1/2})V_{L_0}$. The left-hand sides have the same shape; the abelian theory has *no* L_0 *term*. Also, for split unlinks the abelian theory gives $\langle W(U_p)\rangle = 1$, where Jones has $(-t^{1/2} - t^{-1/2})^{p-1}$: each extra circle is worth 1 rather than the "quantum dimension" $-(t^{1/2} + t^{-1/2})$.

Key idea: Where the L_0 term comes from

In the non-abelian theory the propagator carries group indices, $\langle A_i^a(x)A_j^b(y)\rangle \propto \delta^{ab}$, and each propagator joining two strands inserts $\sum_a T^a \otimes T^a$ acting on the two strands' representation spaces. For SU(2) in the spin-$\frac{1}{2}$ representation, $T^a = \sigma^a/2$, this operator can be written with the *swap* $\mathsf{P}|u\rangle \otimes |v\rangle = |v\rangle \otimes |u\rangle$:

$$\sum_{a=1}^{3} \sigma^a \otimes \sigma^a = 2\mathsf{P} - \mathbb{1}, \qquad \sum_a T^a \otimes T^a = \tfrac{1}{2}\big(\mathsf{P} - \tfrac{1}{2}\mathbb{1}\big). \tag{12.217}$$

(Check on $|\uparrow\uparrow\rangle$: $\sigma^3 \otimes \sigma^3$ gives $+1$, $\sigma^1 \otimes \sigma^1$ and $\sigma^2 \otimes \sigma^2$ give $|\downarrow\downarrow\rangle$ and $i^2|\downarrow\downarrow\rangle$, which cancel; so the sum is $1 = 2 \cdot 1 - 1$. On the singlet $\mathsf{P} = -1$ and the sum is $\vec{\sigma}_1 \cdot \vec{\sigma}_2 = -3 = 2(-1) - 1$.) The identity $\mathbb{1}$ acts like the abelian theory: it lets the two strands go straight through. The swap P *reconnects* them, and reconnecting the four ends at a crossing without the crossing is exactly the smoothing L_0. So the extra term in the Jones skein relation is the footprint of non-commutativity. The honest derivation of the Jones relation, with the exact coefficients as functions of k, uses the conformal-field-theory machinery of Chapter 12; the identity (12.217) is its leading-order shadow.

Try it: Charges mod k

Show that in (12.211) replacing n_1 by $n_1 + 2k$ changes nothing, for any framed link. (Cross terms change by $e^{2\pi i \cdot 2n_m L} = 1$; the diagonal term changes by $e^{i\pi(4kn_1+4k^2)L_{11}/k} = 1$.) So the abelian theory at level k has only finitely many distinct Wilson lines, a first glimpse of the finiteness of the state spaces of a topological field theory.

Reading Nash (pp. 342–345, (12.84)–(12.94))

Nash introduces Witten's programme (an intrinsically three-dimensional definition of the Jones polynomial, needing conformal field theory, and to be verified through the skein relation and the unlink values), defines the Wilson line (12.84) and the normalised correlation functions (12.85), and observes that they need no non-topological data. He then specialises to U(1) (12.86)–(12.88), and states that completing the square on S^3 gives (12.89), i.e. the Gauss linking numbers (12.90), integers by Ampère's law. The self-linking singularity is cured by framing (12.91); the correlator is (12.92), and a change of framing by

t twists multiplies it by $e^{i\pi n_l^2 t/k}$ (12.93)–(12.94). We have supplied: the construction of the holonomy and its gauge invariance, the Gaussian integral with sources and zero modes, the propagator (in Fourier space, where the curl is a Pauli matrix, and via Ampère's law), the blackboard and Seifert framings, the Călugăreanu–White formula, the abelian skein relation and its comparison with Jones, and the physics of flux attachment and anyons.

Recap

- The Wilson loop $W(R,C) = \mathrm{tr}_R\, P \exp \oint_C A$ is the trace of the holonomy, an ordered product of link variables; gauge transformations conjugate the holonomy, so the trace is invariant. For U(1) it is the Aharonov–Bohm phase $e^{in\oint A}$, $n \in \mathbb{Z}$.
- Chern–Simons correlators contain no metric; they are candidate isotopy invariants. Gauge fixing uses a metric, but the answer does not depend on it.
- Abelian theory: Gaussian integral with the conserved source $J = \sum n_l J_{C_l}$. The kernel is $\frac{k}{2\pi}\nabla\times$; in Fourier space the curl is $p\,\sigma_2$ with eigenvalues 0 (gauge), $\pm p$ (helicities).
- The classical field of a Wilson loop is its Biot–Savart field times $2\pi/k$ (flux attachment). The correlator is $\exp\left[\frac{i\pi}{k}\sum_{l,m} n_l n_m L(C_l, C_m)\right]$.
- Self-linking needs a framing: $L(C,C) := L(C,C')$, with $L = \mathrm{Wr} + \mathrm{Tw}$. Blackboard framing gives the writhe $w(D)$; Seifert framing gives 0. A change by t twists multiplies $\langle W\rangle$ by $e^{i\pi n^2 t/k} = e^{2\pi i h_n t}$, $h_n = n^2/2k$.
- With unit charges, $\langle W\rangle_{\mathrm{bb}} = q^{w(D)}$ and $q^{-1}W_+ - qW_- = 0$: the Jones relation without the L_0 term. The L_0 term comes from $\sum_a T^a \otimes T^a = \frac{1}{2}(\mathsf{P} - \frac{1}{2})$.

12.13 Chern–Simons theory at weak coupling: flat connections and torsion

The abelian theory was Gaussian, so it could be done exactly. For a non-abelian group the cubic term $\frac{2}{3}A \wedge A \wedge A$ spoils this. Nash's second piece of evidence for the topological nature of the theory is the *weak-coupling*, or large-k, limit: expand the path integral around its stationary points, do the resulting Gaussian integral, and look at what comes out. The stationary points are the flat connections, and the Gaussian integral produces a ratio of determinants of Laplacians that turns out to be a classical topological invariant, the Ray–Singer analytic torsion. This section fills in every step of that argument [Nash pp. 346–350, (12.95)–(12.113)].

The ingredients are standard tools of quantum field theory, each of which we first rehearse in finite dimensions:

1. the method of stationary phase (Section 12.13.2);
2. the expansion of the action to second order about a flat connection (Section 12.13.3);
3. gauge fixing with a Lagrange multiplier and Faddeev–Popov ghosts (Section 12.13.4);
4. Gaussian integrals as determinants, regularised with the zeta function, and the phase given by the eta invariant (Section 12.13.6);
5. the recognition of the answer as the analytic torsion (Section 12.13.7).

Figure 12.59 shows how these steps feed into one another.

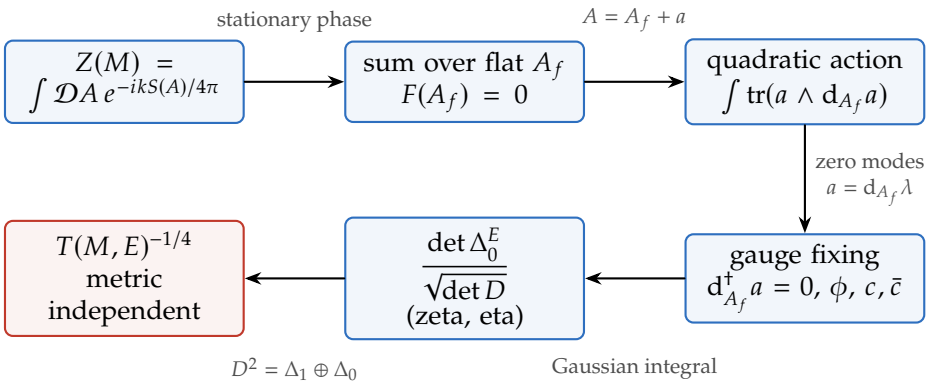

Figure 12.59: The logic of the weak-coupling computation. Read it clockwise from the top left: stationary phase localises the path integral on flat connections; the action is expanded to second order about each; the gauge zero modes are removed with a multiplier and ghosts; the resulting Gaussian is a ratio of determinants; and because D squares to the Laplacians the ratio is a power of the Ray–Singer torsion, from which the metric has disappeared.

12.13.1 The coupling constant is $1/k$

In physics notation the gauge coupling g sits in the commutator term of the curvature. With Hermitian generators $[T^a, T^b] = i f^{abc} T^c$ and the dictionary of Section 12.12.2, Nash's (12.95) reads

$$F(A) = \tfrac{1}{2} F^a_{\mu\nu} T^a \, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu, \qquad F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g\, f^{abc} A^b_\mu A^c_\nu. \tag{12.218}$$

In the language of forms: if $F = \mathrm{d}A + g\, A \wedge A$ then the Chern–Simons form that goes with it is $\mathrm{tr}(A \wedge \mathrm{d}A + \frac{2}{3} g\, A \wedge A \wedge A)$. Rescale $A = \tilde{A}/g$:

$$\begin{aligned} \mathrm{tr}\Big(A \wedge \mathrm{d}A + \tfrac{2}{3} g\, A \wedge A \wedge A\Big) &\overset{(1)}{=} \mathrm{tr}\Big(\frac{\tilde{A} \wedge \mathrm{d}\tilde{A}}{g^2} + \frac{2}{3}\, g\, \frac{\tilde{A} \wedge \tilde{A} \wedge \tilde{A}}{g^3}\Big) \\ &\overset{(2)}{=} \frac{1}{g^2}\, \mathrm{tr}\Big(\tilde{A} \wedge \mathrm{d}\tilde{A} + \tfrac{2}{3} \tilde{A} \wedge \tilde{A} \wedge \tilde{A}\Big). \end{aligned} \tag{12.219}$$

(1) Substitute $A = \tilde{A}/g$: the quadratic term gets g^{-2}, the cubic term $g \cdot g^{-3}$.
(2) Both terms now carry the same factor g^{-2}.

(Nash writes the quadratic term of (12.95) as $i g\, f^{abc} A^b_\mu A^c_\nu$. The factor of i depends on whether the generators are taken Hermitian or anti-Hermitian and on how A is normalised; with our Hermitian T^a and $[T^a, T^b] = i f^{abc} T^c$ the component form above has no i. What matters here is only that g multiplies the part of F quadratic in A.) So the rescaled field has the standard curvature $\tilde{F} = \mathrm{d}\tilde{A} + \tilde{A} \wedge \tilde{A}$ and the action becomes Nash's (12.96),

$$-\frac{ik}{4\pi g^2} \int_M \mathrm{tr}\Big(\tilde{A} \wedge \mathrm{d}\tilde{A} + \tfrac{2}{3} \tilde{A} \wedge \tilde{A} \wedge \tilde{A}\Big).$$

Only the combination k/g^2 occurs. Small coupling $g \to 0$ is therefore the same as large level $k \to \infty$, and from now on we set $g = 1$ and let k be large. The analogy is exact: in $\int \mathcal{D}A\, e^{iS/\hbar}$ the classical limit is $\hbar \to 0$, and here the exponent is $ik\, S_{\mathrm{CS}}/4\pi$, so

$$\hbar_{\mathrm{eff}} = \frac{4\pi}{k}.$$

(There is no freedom to vary k continuously: invariance under large gauge transformations forces $k \in \mathbb{Z}$. But large integers are allowed, and the large-k expansion is the semiclassical expansion.)

12.13.2 Stationary phase: the finite-dimensional model

Working definition 12.34 (Stationary phase)

For a smooth real function f on $\mathbb{R}^n$ with isolated non-degenerate critical points x_c (where $\nabla f = 0$ and the Hessian $H_c = \partial^2 f(x_c)$ is invertible),

$$\int \mathrm{d}^n x \; g(x)\, e^{ikf(x)} \xrightarrow{k\to\infty} \sum_{x_c} g(x_c)\, e^{ikf(x_c)} \left(\frac{2\pi}{k}\right)^{n/2} \frac{e^{i\pi\, \mathrm{sgn}(H_c)/4}}{|\det H_c|^{1/2}}, \tag{12.220}$$

where $\mathrm{sgn}(H_c)$ (the **signature**) is the number of positive minus the number of negative eigenvalues of H_c. *Recipe:* find the critical points; at each, evaluate the phase; expand f to second order and do the Fresnel integral (12.190) [$\int \mathrm{d}x\, e^{ik\lambda x^2/2} = (2\pi/k\,|\lambda|)^{1/2} e^{i\pi\,\mathrm{sgn}(\lambda)/4}$ for real $\lambda \neq 0$], one eigenvalue at a time.

Why: away from critical points e^{ikf} oscillates faster and faster as k grows and the integral cancels itself out; near x_c, $f \approx f(x_c) + \frac{1}{2}(x-x_c)^T H_c (x-x_c)$, and the Gaussian width is $\sim k^{-1/2}$. This is exactly how the classical path is singled out in Feynman's path integral: the paths near the stationary one add up in phase, and all the others cancel.

Worked example 12.87: The Bessel function

Take $f(x) = \cos x$ on the circle $0 \le x < 2\pi$. The exact integral is a Bessel function, $\int_0^{2\pi} e^{ik\cos x}\mathrm{d}x = 2\pi J_0(k)$. Critical points: $x = 0$ ($f = 1$, $f'' = -1$) and $x = \pi$ ($f = -1$, $f'' = +1$). Then

$$\int_0^{2\pi} e^{ik\cos x}\mathrm{d}x \overset{(1)}{=} \sqrt{\frac{2\pi}{k}}\left(e^{ik}e^{-i\pi/4} + e^{-ik}e^{+i\pi/4}\right)$$
$$\overset{(2)}{=} 2\sqrt{\frac{2\pi}{k}}\cos\left(k - \frac{\pi}{4}\right).$$

(1) Formula (12.220): $n = 1$, $|f''| = 1$ at both points, signatures -1 and $+1$.
(2) $e^{i\theta} + e^{-i\theta} = 2\cos\theta$ with $\theta = k - \pi/4$.

This is the textbook asymptotic form $J_0(k) \approx \sqrt{2/\pi k}\,\cos(k - \pi/4)$: multiply by 2π and compare. Two things to notice for later. The *phases* $e^{\pm i\pi/4}$ come from the signs of the Hessian eigenvalues, and they matter: they produce the $-\pi/4$ shift. And the *power* $k^{-1/2}$ counts the dimension of the integral.

12.13.3 Flat connections and the expansion of the action

The partition function and its stationary points, Nash (12.97)–(12.98). The partition function is

$$Z(M) = \int \mathcal{D}A \; \exp\left[-\frac{ik}{4\pi}\, S(A)\right], \qquad S(A) = \int_M \mathrm{tr}\left(A\wedge \mathrm{d}A + \tfrac{2}{3} A\wedge A\wedge A\right). \tag{12.221}$$

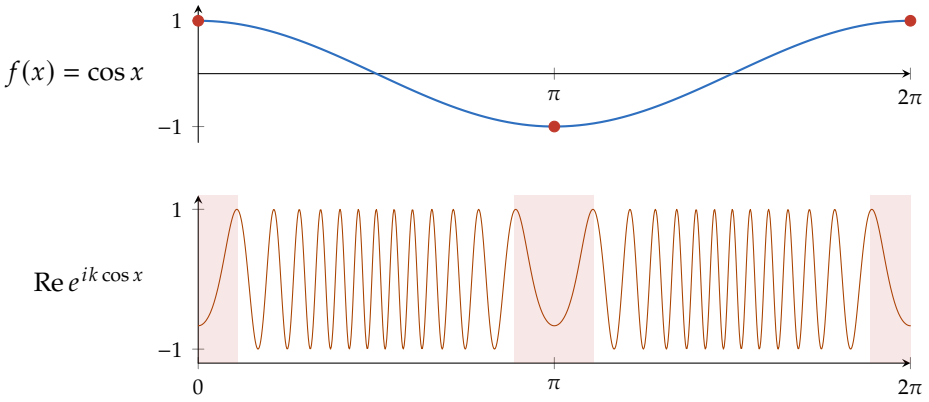

Figure 12.60: Stationary phase for $\int_0^{2\pi} e^{ik\cos x}\,dx$ at $k = 40$. Top: the phase function $f = \cos x$ with its critical points (red). Bottom: the real part of the integrand. Away from the critical points it oscillates rapidly and its positive and negative lobes cancel; only the shaded windows of width $\sim k^{-1/2}$ around $x = 0$ and $x = \pi$ contribute. In the path integral the same mechanism picks out the flat connections.

To find its stationary points, vary $A \to A + \delta A$. We need two facts about traces of matrix-valued forms: for a p-form α and a q-form β, $\operatorname{tr}(\alpha \wedge \beta) = (-1)^{pq} \operatorname{tr}(\beta \wedge \alpha)$ (cyclicity of the trace combined with the sign for moving forms past each other), and $\mathrm{d}\operatorname{tr}(\alpha \wedge \beta) = \operatorname{tr}(\mathrm{d}\alpha \wedge \beta) + (-1)^p \operatorname{tr}(\alpha \wedge \mathrm{d}\beta)$. Then

$$\begin{aligned} \delta S &\overset{(1)}{=} \int_M \operatorname{tr}\Big(\delta A \wedge \mathrm{d}A + A \wedge \mathrm{d}\delta A + \tfrac{2}{3}\big(\delta A \wedge A \wedge A + A \wedge \delta A \wedge A + A \wedge A \wedge \delta A\big)\Big) \\ &\overset{(2)}{=} \int_M \operatorname{tr}\big(2\,\delta A \wedge \mathrm{d}A + 2\,\delta A \wedge A \wedge A\big) \overset{(3)}{=} 2\int_M \operatorname{tr}\big(\delta A \wedge F\big). \end{aligned} \tag{12.222}$$

(1) First-order terms of $S(A + \delta A)$.

(2) $\int \operatorname{tr}(A \wedge \mathrm{d}\delta A) = \int \operatorname{tr}(\mathrm{d}A \wedge \delta A) - \int \mathrm{d}\operatorname{tr}(A \wedge \delta A) = \int \operatorname{tr}(\delta A \wedge \mathrm{d}A)$, using Stokes on closed M and then moving the 1-form δA past the 2-form $\mathrm{d}A$ (sign $(-1)^2 = +1$). The three cubic terms are equal: moving a 1-form past a 2-form inside the trace costs no sign.

(3) $F = \mathrm{d}A + A \wedge A$.

So $\delta S = 0$ for all δA exactly when

$$F(A) = 0\,: \tag{12.223}$$

the classical solutions of Chern–Simons theory are the **flat connections**. By stationary phase, for large k the partition function should become a sum over flat connections, each weighted by $e^{-ikS(A_f)/4\pi}$ and by a Gaussian fluctuation integral.

Working definition 12.35 (Flat connections as representations of π_1)

A flat connection has holonomy that depends only on the homotopy class of the loop [two loops at the base point count as the same if one can be deformed into the other]: by the non-abelian Stokes theorem the holonomy round a small contractible loop is $\mathbb{1} + F \cdot (\text{area}) + \cdots = \mathbb{1}$. So a flat connection defines a homomorphism $\rho : \pi_1(M) \to G$ [going round one loop and then another gives the product of the two holonomies], well defined up to conjugation [$\rho \to h\rho h^{-1}$ for one fixed $h \in G$] (the choice of base point and of gauge), and conversely every such homomorphism comes from a flat connection. *To list the flat connections, list the homomorphisms $\pi_1(M) \to G$ up to conjugation.*

Worked example 12.88: Flat connections on some three-manifolds

- $M = S^3$: $\pi_1 = 1$, so the only flat connection is the trivial one, $A_f = 0$ (up to gauge).
- $M = S^1 \times S^2$, $G = \mathrm{U}(1)$: $\pi_1 = \mathbb{Z}$, so the flat connections are labelled by one holonomy $e^{i\theta}$ round the S^1, a whole circle's worth. They are not isolated; this is the situation with zero modes that Nash excludes at the end.
- $M = L(p, q)$, a lens space (S^3 divided by the $\mathbb{Z}_p$ action $(z_1, z_2) \mapsto (e^{2\pi i/p} z_1, e^{2\pi i q/p} z_2)$), $G = \mathrm{U}(1)$: $\pi_1 = \mathbb{Z}_p$, so there are p flat connections, with holonomies $e^{2\pi i m/p}$, $m = 0, \dots, p-1$. They are isolated points.
- M = the Poincaré homology sphere, $G = \mathrm{SU}(2)$: π_1 is the binary icosahedral group of order 120, and apart from the trivial one there are exactly two irreducible flat SU(2) connections.

The expansion about a flat connection, Nash (12.99). Put $A = A_f + a$. We need the covariant derivative on Lie-algebra-valued forms, $\mathrm{d}_{A_f} a = \mathrm{d}a + A_f \wedge a + a \wedge A_f$ for a 1-form a (the graded commutator $[A_f, a]$). Collect powers of a:

$$\begin{aligned} S(A_f + a) &\overset{(1)}{=} S(A_f) + 2\int_M \mathrm{tr}\big(a \wedge F(A_f)\big) + \int_M \mathrm{tr}\big(a \wedge \mathrm{d}a + 2\,A_f \wedge a \wedge a\big) + \tfrac{2}{3}\int_M \mathrm{tr}(a \wedge a \wedge a) \\ &\overset{(2)}{=} S(A_f) + 2\int_M \mathrm{tr}\big(F(A_f) \wedge a\big) + \int_M \mathrm{tr}\big(a \wedge \mathrm{d}_{A_f} a\big) + \tfrac{2}{3}\int_M \mathrm{tr}(a \wedge a \wedge a) \\ &\overset{(3)}{=} S(A_f) + \int_M \mathrm{tr}\big(a \wedge \mathrm{d}_{A_f} a\big) + O(a^3). \end{aligned} \tag{12.224}$$

(1) The term linear in a is (12.222) with $\delta A = a$ (the two linear pieces $\mathrm{tr}(A_f \wedge \mathrm{d}a) + \mathrm{tr}(a \wedge \mathrm{d}A_f)$ of $\mathrm{tr}(A \wedge \mathrm{d}A)$ become $2\,\mathrm{tr}(a \wedge \mathrm{d}A_f)$ after the same integration by parts). The quadratic piece of $\mathrm{tr}(A \wedge \mathrm{d}A)$ is simply $\mathrm{tr}(a \wedge \mathrm{d}a)$. From the cubic term come the three orderings $A_f aa$, $aA_f a$, aaA_f, which are equal by cyclicity (moving a 1-form past a 2-form inside the trace costs no sign), so $\frac{2}{3} \cdot 3 = 2$ copies of $\mathrm{tr}(A_f \wedge a \wedge a)$.

(2) $\mathrm{tr}(a \wedge \mathrm{d}_{A_f} a) = \mathrm{tr}(a \wedge \mathrm{d}a) + \mathrm{tr}(a \wedge A_f \wedge a) + \mathrm{tr}(a \wedge a \wedge A_f) = \mathrm{tr}(a \wedge \mathrm{d}a) + 2\,\mathrm{tr}(A_f \wedge a \wedge a)$, again by cyclicity; and $\mathrm{tr}(a \wedge F) = \mathrm{tr}(F \wedge a)$.

(3) $F(A_f) = 0$.

The expansion *terminates* at third order: the action is a cubic polynomial in A. Nash writes the first two lines as (12.99).

The quadratic form $\int \mathrm{tr}(a \wedge \mathrm{d}_{A_f} a)$ is the non-abelian version of the helicity $\int \vec{a} \cdot \nabla \times \vec{a}$ of (12.193). It is invariant under infinitesimal gauge transformations $a \to a + \mathrm{d}_{A_f}\lambda$ precisely because A_f is flat: $\mathrm{d}_{A_f}\mathrm{d}_{A_f}\lambda = [F(A_f), \lambda] = 0$. So once more the kernel has zero modes along the gauge directions, and we must fix a gauge.

12.13.4 Gauge fixing: Lagrange multipliers and ghosts

Faddeev–Popov in two dimensions. The whole procedure can be seen in an ordinary double integral with a rotation symmetry. Let $I = \int \mathrm{d}^2x\, e^{-V(r)}$ with $r = |x|$. The "gauge group" is the rotation group SO(2); the "gauge orbits" are circles; a "gauge condition" is a curve $G(x) = 0$ meeting each orbit, say $G(x) = x_2$ (the x_1-axis). Insert 1 in the form

$$1 = \frac{1}{2}\int_0^{2\pi} \mathrm{d}\theta\; \delta\big(G(R_\theta x)\big)\left|\frac{\partial G(R_\theta x)}{\partial \theta}\right|, \qquad x \neq 0, \tag{12.225}$$

where R_θ is rotation by θ. This is the formula $\int \mathrm{d}\theta\, \delta(h(\theta))\,|h'(\theta)| = \#\{\text{zeros of } h\}$ applied to $h(\theta) = G(R_\theta x) = (R_\theta x)_2$, which vanishes at the two angles that rotate x onto the positive and the negative x_1-axis; hence the $\frac{1}{2}$. Then

$$I \overset{(1)}{=} \frac{1}{2}\int_0^{2\pi} \mathrm{d}\theta \int \mathrm{d}^2x\ \delta(x_2)\ |x_1|\ e^{-V(r)}$$
$$\overset{(2)}{=} \frac{1}{2}\cdot 2\pi \int_{-\infty}^{\infty} \mathrm{d}x_1\ |x_1|\ e^{-V(|x_1|)} \overset{(3)}{=} 2\pi \int_0^{\infty} r\, e^{-V(r)}\, \mathrm{d}r. \tag{12.226}$$

(1) Insert (12.225), change variables $x \to R_{-\theta}x$ (the integrand and d^2x are rotation invariant), and evaluate the Jacobian on the slice: $\partial_\theta(R_\theta x)_2 = x_1$ at $x_2 = 0$ (the derivative of a rotation is $\partial_\theta R_\theta x = J\, R_\theta x$ with $J = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$, whose second component is the first component of $R_\theta x$). The $\frac{1}{2}$ is the one in (12.225): each circle meets the x_1-axis *twice*, at $\pm r$.
(2) The θ integral gives the "volume of the gauge group", 2π; the delta function sets $x_2 = 0$.
(3) The integrand is even in x_1.

This is polar coordinates. The **Faddeev–Popov determinant** is the Jacobian $|x_1| = r$, the size of the orbit through the slice; the factor 2π is the gauge-group volume that we divide out in field theory; and the double intersection is a toy **Gribov ambiguity**. Both the δ-function and the determinant are now written as integrals, so that everything becomes an exponent.

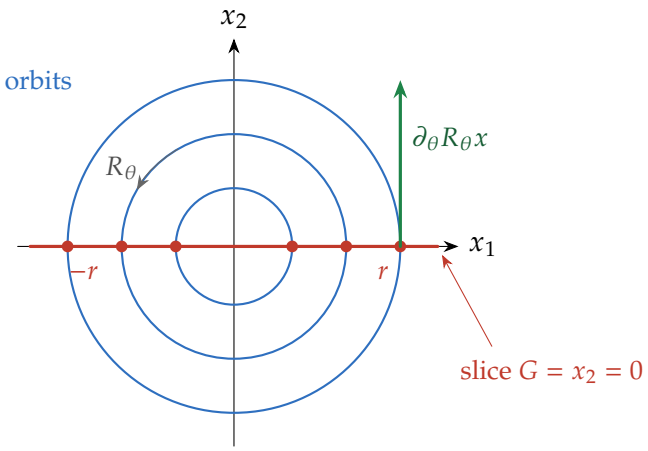

Figure 12.61: Faddeev–Popov in the plane. The "gauge orbits" of rotations are the blue circles; the gauge slice $x_2 = 0$ (red) meets each orbit twice, at $\pm r$ (a toy Gribov copy). The Faddeev–Popov determinant is the speed with which the orbit crosses the slice, the green vector $\partial_\theta(R_\theta x)_2 = x_1$ of length r: integrating over the slice with weight r and multiplying by the orbit "volume" 2π is just polar coordinates.

The delta function as a Lagrange multiplier. $\delta(G) = \int \frac{\mathrm{d}\phi}{2\pi}\, e^{i\phi G}$. Enforcing the gauge condition is the same as adding $\phi\, G$ to the action and integrating over the new field ϕ.

The determinant as a Grassmann integral. Grassmann variables $\theta_1, \bar\theta_1, \ldots$ anticommute ($\theta_i\theta_j = -\theta_j\theta_i$, so $\theta_i^2 = 0$). A function of one Grassmann variable is $a + b\theta$, and integration is defined by $\int \mathrm{d}\theta\, 1 = 0$, $\int \mathrm{d}\theta\, \theta = 1$; with pairs we use the convention $\int \mathrm{d}\bar\theta\, \mathrm{d}\theta\ \theta\bar\theta = 1$. Then for a 1×1 "matrix" b:

$$\int \mathrm{d}\bar\theta\, \mathrm{d}\theta\ e^{-\bar\theta b\theta} = \int \mathrm{d}\bar\theta\, \mathrm{d}\theta\ (1 - \bar\theta b\theta) = \int \mathrm{d}\bar\theta\, \mathrm{d}\theta\ (1 + b\,\theta\bar\theta) = b.$$

The series stops because $\theta^2 = 0$. For an $n \times n$ matrix B the same computation gives $\det B$, *not* $(\det B)^{-1/2}$ as for a real bosonic Gaussian. Here is $n = 2$ in full. Only the second-order term $\frac{1}{2}(\bar\theta B\theta)^2$ contains all four variables:

$$\begin{aligned}\tfrac{1}{2}(\bar\theta B\theta)^2 &\overset{(1)}{=} B_{11}B_{22}\,\bar\theta_1\theta_1\bar\theta_2\theta_2 + B_{12}B_{21}\,\bar\theta_1\theta_2\bar\theta_2\theta_1 \\ &\overset{(2)}{=} \big(-B_{11}B_{22} + B_{12}B_{21}\big)\,\bar\theta_1\theta_1\theta_2\bar\theta_2 \overset{(3)}{=} \det B\;\theta_1\bar\theta_1\,\theta_2\bar\theta_2 .\end{aligned}$$

(1) In $\sum B_{ij}B_{kl}\bar\theta_i\theta_j\bar\theta_k\theta_l$ we need $\{i,k\} = \{j,l\} = \{1,2\}$; the terms with $i = 2, k = 1$ repeat those with $i = 1, k = 2$ (the bilinears $\bar\theta_i\theta_j$ are even and commute), cancelling the $\frac{1}{2}$.
(2) $\bar\theta_2\theta_2 = -\theta_2\bar\theta_2$; and in the second term move θ_1 two places left, past $\bar\theta_2$ and θ_2 (sign $(+1)$).
(3) $\bar\theta_1\theta_1 = -\theta_1\bar\theta_1$.

Integrating with $\int \mathrm{d}\bar\theta_1\mathrm{d}\theta_1\mathrm{d}\bar\theta_2\mathrm{d}\theta_2\;\theta_1\bar\theta_1\theta_2\bar\theta_2 = 1$ gives $\det B$.

Try it: Bosons against fermions

For a complex variable $z = x + iy$ and $b > 0$ show that $\int \frac{\mathrm{d}x\,\mathrm{d}y}{\pi}\, e^{-b\bar z z} = \frac{1}{b}$, and hence that an n-component complex Gaussian gives $(\det B)^{-1}$. (Polar coordinates: $\int_0^\infty 2r\, e^{-br^2}\mathrm{d}r = 1/b$.) So a pair of commuting fields $\bar z, z$ gives $\det^{-1}$, a pair of anticommuting fields $\bar\theta, \theta$ gives $\det^{+1}$, and one real field gives $\det^{-1/2}$.

So a determinant in the numerator is a Gaussian integral over anticommuting **ghost** fields $c, \bar c$. The ghosts are the Faddeev–Popov Jacobian in disguise; they are not physical particles.

The gauge-fixed partition function, Nash (12.100)–(12.101). Pick a metric on M and impose the covariant Lorenz gauge

$$\mathrm{d}^\dagger_{A_f} a = 0, \tag{12.227}$$

where $\mathrm{d}^\dagger_{A_f}$ is the adjoint of d_{A_f} with respect to the metric ($\mathrm{d}^\dagger = -\star\,\mathrm{d}\star$ on 1-forms in three dimensions; Nash writes $\mathrm{d}^*_{A_f}$). For $A_f = 0$ on $\mathbb{R}^3$ this is $\nabla\cdot\vec a = 0$, the gauge used in Section 12.12.7. The infinitesimal gauge transformation $a \to a + \mathrm{d}_{A_f}\lambda$ changes the gauge function by $\mathrm{d}^\dagger_{A_f}\mathrm{d}_{A_f}\lambda$, so the Faddeev–Popov operator is $\mathrm{d}^\dagger_{A_f}\mathrm{d}_{A_f} = \Delta_0$, the covariant Laplacian on Lie-algebra-valued functions. Assembling the pieces,

$$\begin{aligned}Z(M) = \sum_{A_f} e^{-ikS(A_f)/4\pi} \int \mathcal{D}a\,\mathcal{D}\phi\,\mathcal{D}c\,\mathcal{D}\bar c \\ \times \exp\Big[-\frac{ik}{4\pi}\int_M \Big\{\mathrm{tr}\big(a\wedge \mathrm{d}_{A_f}a\big) + 2\,\mathrm{tr}\big(\phi\wedge\star\mathrm{d}^\dagger_{A_f}a\big) + \mathrm{tr}\big(\mathrm{d}_{A_f}\bar c\wedge\star\mathrm{d}_{A_f}c\big)\Big\}\Big].\end{aligned} \tag{12.228}$$

Here ϕ is the Lagrange multiplier, a Lie-algebra-valued function (Nash uses the equivalent 3-form $\star\phi$), and $c, \bar c$ are Lie-algebra-valued Grassmann functions. We have scaled the gauge-fixing and ghost terms by the same factor $ik/4\pi$ for convenience; this only changes the overall constant.

Sections of the flat bundle. The fields $a, \phi, c, \bar c$ are matrix-valued forms. At a flat connection A_f they are best viewed as forms with values in the vector bundle E (the adjoint bundle, with fibre the Lie algebra) on which A_f acts: Nash's

$$\Omega^p(M, E) = \Gamma\big(M, E\otimes\Lambda^p T^*M\big).$$

The operator d_{A_f} maps $\Omega^p(M,E) \to \Omega^{p+1}(M,E)$ and, because $F(A_f)=0$, it squares to zero. So $\Omega^0(M,E) \to \Omega^1(M,E) \to \Omega^2(M,E) \to \Omega^3(M,E)$ is a complex, the de Rham complex twisted by the flat bundle E, with cohomology $H^p(M;E)$. For $A_f = 0$ it is the ordinary de Rham complex tensored with the Lie algebra.

12.13.5 The operator D and its square

Nash packages the bosonic fields into $v = (a, \phi)$, a 1-form and a function (or 3-form), and writes the quadratic part of the bosonic action as $\langle v, Dv\rangle$ for a single operator D. The inner product on E-valued forms is

$$\langle \alpha, \beta\rangle = -\int_M \mathrm{tr}(\alpha \wedge \star\beta), \tag{12.229}$$

which is positive definite because $-\mathrm{tr}(X^2) = \mathrm{tr}(X^\dagger X) \geq 0$ for an anti-Hermitian matrix X.

Working definition 12.36 (The operator D, Nash (12.102)–(12.103))

On $\Omega^1(M,E) \oplus \Omega^0(M,E)$ define

$$D = \begin{pmatrix} \star\mathrm{d}_{A_f} & \mathrm{d}_{A_f} \\ \mathrm{d}^\dagger_{A_f} & 0 \end{pmatrix}, \qquad D\begin{pmatrix} a \\ \phi \end{pmatrix} = \begin{pmatrix} \star\mathrm{d}_{A_f} a + \mathrm{d}_{A_f}\phi \\ \mathrm{d}^\dagger_{A_f} a \end{pmatrix}. \tag{12.230}$$

Here $\mathrm{d}^\dagger_{A_f}$ is the adjoint of d_{A_f} [taken with the inner product (12.229). Setting $\mathrm{d}^\dagger_{A_f} a = 0$ is the covariant Lorenz gauge]. It is first order and self-adjoint: $\star\mathrm{d}_{A_f}$ is self-adjoint on 1-forms in three dimensions (this is the curl), and the off-diagonal entries are adjoints of each other. Replacing the function ϕ by the 3-form $\star\phi$ gives Nash's version on $\Omega^1 \oplus \Omega^3$. D is (a twisted form of) the **odd signature operator** [its eta invariant is what fixes the phase of the one-loop answer below].

The quadratic form:

$$\begin{aligned} \langle v, Dv\rangle &\overset{(1)}{=} \langle a, \star\mathrm{d}_{A_f} a\rangle + \langle a, \mathrm{d}_{A_f}\phi\rangle + \langle \phi, \mathrm{d}^\dagger_{A_f} a\rangle \\ &\overset{(2)}{=} -\int_M \mathrm{tr}\big(a \wedge \star\star\, \mathrm{d}_{A_f} a\big) + 2\langle \phi, \mathrm{d}^\dagger_{A_f} a\rangle \\ &\overset{(3)}{=} -\int_M \mathrm{tr}\big(a \wedge \mathrm{d}_{A_f} a\big) - 2\int_M \mathrm{tr}\big(\phi \wedge \star\mathrm{d}^\dagger_{A_f} a\big). \end{aligned} \tag{12.231}$$

(1) Expand with (12.230).
(2) Definition (12.229) for the first term; the second equals the third by the definition of the adjoint.
(3) $\star\star = 1$ on every form in a three-dimensional Riemannian manifold, and (12.229) again.

This is (minus) the bosonic exponent of (12.228), Nash's (12.104). Likewise the ghost term is $-\langle \bar c, \mathrm{d}^\dagger_{A_f}\mathrm{d}_{A_f} c\rangle$.

Watch out: Signs in D

Nash writes both off-diagonal entries of D as "$\mathrm{d}_{A_f}\star$". Read literally (the composite of $\star$ and d), the two entries are *minus* each other's adjoints: for $A_f = 0$ on $\mathbb{R}^3$ they are $\nabla\phi$ and $\nabla\cdot\vec a$, and $\int \vec a\cdot\nabla\phi = -\int \phi\,\nabla\cdot\vec a$. Then $\langle v, Dv\rangle$ would lose its gauge-fixing term altogether. The intended operator is the self-adjoint one (12.230), which uses $\mathrm{d}^\dagger = -\star\,\mathrm{d}\star$ in one entry; this is what makes the cross term come out doubled, as in his (12.104).

Watch out: A missing star in the ghost term

Nash's (12.101) and (12.104) write the ghost term as $\mathrm{tr}(\mathrm{d}_{A_f}\bar{c}\wedge\mathrm{d}_{A_f}c)$. That is a 2-form, which cannot be integrated over a three-manifold. The intended term is $\mathrm{tr}(\mathrm{d}_{A_f}\bar{c}\wedge\star\mathrm{d}_{A_f}c)$, the covariant version of $\int\nabla\bar{c}\cdot\nabla c\,\mathrm{d}^3x$, as in (12.228). With the star it equals $-\langle\bar{c},\mathrm{d}^\dagger_{A_f}\mathrm{d}_{A_f}c\rangle$ after one integration by parts, which is what (12.104)–(12.105) use.

Worked example 12.89: D as a 4×4 matrix

Take $A_f=0$ and one Lie-algebra direction, on $\mathbb{R}^3$ (or a large torus). In Fourier space $\mathrm{d}\phi\to ip\,\tilde{\phi}$, $\mathrm{d}^\dagger a=-\nabla\cdot\vec{a}\to -ip\cdot\tilde{a}$, and $\star\mathrm{d}a\to P(p)\tilde{a}$ with the curl matrix (12.198). For $\vec{p}=p\,\hat{z}$, in the basis (a_1,a_2,a_3,ϕ),

$$D(p\hat{z})=p\begin{pmatrix}0&-i&0&0\\ i&0&0&0\\ 0&0&0&i\\ 0&0&-i&0\end{pmatrix}=p\,\big(\sigma_2\oplus(-\sigma_2)\big). \tag{12.232}$$

Compare the curl alone, (12.199), which had a zero eigenvalue on the longitudinal mode a_3. In D the longitudinal mode is paired with the Lagrange multiplier ϕ by the block $-p\sigma_2$, and the zero eigenvalue is gone: *the gauge-fixed operator is invertible*. Its eigenvalues are $+p,-p$ (transverse helicities) and $+p,-p$ (the longitudinal–multiplier pair). And

$$D(p\hat{z})^2=p^2\,\mathbb{1}_4\,:$$

D^2 is the Laplacian p^2 on each of the four components, three from the 1-form and one from the function.

Try it: Helicity eigenvectors

Find the eigenvectors of the transverse block $p\sigma_2$ of (12.232). (Answer: $(1,\pm i)/\sqrt{2}$ with eigenvalues $\pm p$; as 3-vectors $(1,\pm i,0)/\sqrt{2}$, the circular polarisations of a photon moving along $\hat{z}$.) Check also $D(p\hat{z})^2=p^2\mathbb{1}_4$ from $\sigma_2^2=\mathbb{1}$.

D^2 in general, Nash (12.111).

$$\begin{aligned}D^2&\overset{(1)}{=}\begin{pmatrix}\star\mathrm{d}_{A_f}\star\mathrm{d}_{A_f}+\mathrm{d}_{A_f}\mathrm{d}^\dagger_{A_f}&\star\mathrm{d}_{A_f}\mathrm{d}_{A_f}\\ \mathrm{d}^\dagger_{A_f}\star\mathrm{d}_{A_f}&\mathrm{d}^\dagger_{A_f}\mathrm{d}_{A_f}\end{pmatrix}\\ &\overset{(2)}{=}\begin{pmatrix}\mathrm{d}^\dagger_{A_f}\mathrm{d}_{A_f}+\mathrm{d}_{A_f}\mathrm{d}^\dagger_{A_f}&0\\ 0&\mathrm{d}^\dagger_{A_f}\mathrm{d}_{A_f}\end{pmatrix}=\begin{pmatrix}\Delta_1^E&0\\ 0&\Delta_0^E\end{pmatrix}.\end{aligned} \tag{12.233}$$

(1) Multiply the block matrices (12.230).

(2) On 2-forms in three dimensions $\mathrm{d}^\dagger=\star\mathrm{d}\star$, so $\star\mathrm{d}_{A_f}\star\mathrm{d}_{A_f}=\mathrm{d}^\dagger_{A_f}\mathrm{d}_{A_f}$ on 1-forms. The off-diagonal blocks contain $\mathrm{d}_{A_f}\mathrm{d}_{A_f}=[F(A_f),\cdot\,]=0$ *because A_f is flat* (for the lower one, $\mathrm{d}^\dagger_{A_f}\star\mathrm{d}_{A_f}=\pm\star\mathrm{d}_{A_f}\mathrm{d}_{A_f}$).

So D is a square root of the Laplacian on $\Omega^1\oplus\Omega^0$, a Dirac-type operator. Nash writes Δ_3^E in place of Δ_0^E, which is the same operator after the Hodge star identifies 3-forms with functions. Taking determinants,

$$(\det D)^2=\det\Delta_1^E\cdot\det\Delta_0^E. \tag{12.234}$$

12.13.6 Gaussian integrals as determinants: zeta and eta

The formal answer, Nash (12.105)–(12.106). With $\mu = ik/4\pi$ the fluctuation integral is

$$\int \mathcal{D}v\,\mathcal{D}c\,\mathcal{D}\bar{c}\;\exp\!\big[\mu\big(\langle v, Dv\rangle + \langle \bar{c}, \mathrm{d}_{A_f}^{\dagger}\mathrm{d}_{A_f} c\rangle\big)\big].$$

The bosonic integral is a (Fresnel) Gaussian and gives $\det(\mu D)^{-1/2}$; the ghost integral gives $\det(\mu\Delta_0^E)$ with no square root, because c and $\bar{c}$ are independent (as for complex variables). Formally, therefore,

$$\int \mathcal{D}v\,\mathcal{D}c\,\mathcal{D}\bar{c}\;e^{\mu(\dots)} = C\,\frac{\det\!\big(\mathrm{d}_{A_f}^{\dagger}\mathrm{d}_{A_f}\big)}{\sqrt{\det D}}, \tag{12.235}$$

where the constant C collects the μ-dependence and the phase. Both determinants are infinite products and need to be defined.

Working definition 12.37 (Zeta-function determinant)

For a positive elliptic operator A [an operator such as Δ_0^E on the compact M, whose eigenvalues are discrete and grow without bound, so their product diverges] with eigenvalues $\lambda_j > 0$, define

$$\zeta_A(s) = \sum_j \lambda_j^{-s}, \qquad \det A := e^{-\zeta_A'(0)}. \tag{12.236}$$

The sum converges for $\operatorname{Re} s$ large and is continued analytically [there is exactly one function, analytic except at isolated poles, that equals the sum wherever the sum converges] to $s = 0$. *Why this definition:* for a finite matrix, $-\zeta'(0) = \sum_j \ln\lambda_j = \ln\prod_j \lambda_j$, since $\frac{\mathrm{d}}{\mathrm{d}s}\lambda^{-s} = -\lambda^{-s}\ln\lambda$.

The scaling rule Nash quotes follows at once:

$$\begin{aligned}\zeta_{\mu A}(s) = \mu^{-s}\zeta_A(s) \;&\Longrightarrow\; \zeta_{\mu A}'(0) \overset{(1)}{=} -\ln\mu\;\zeta_A(0) + \zeta_A'(0)\\ &\Longrightarrow\; \det(\mu A) \overset{(2)}{=} \mu^{\zeta_A(0)}\det A.\end{aligned} \tag{12.237}$$

(1) Product rule at $s = 0$, with $\frac{\mathrm{d}}{\mathrm{d}s}\mu^{-s} = -\mu^{-s}\ln\mu$.
(2) Exponentiate $-\zeta_{\mu A}'(0)$.

For an $n\times n$ matrix, $\zeta(0) = n$ and this is $\det(\mu A) = \mu^n \det A$. For an operator $\zeta(0)$ is a finite number, the "regularised dimension". For positive μ this is harmless and $\mu^{\zeta(0)}$ goes into C. For $\mu = ik/4\pi$ it is not: $i^{\zeta(0)}$ has no meaning until we say how the phases of the individual eigenvalues are to be combined.

Worked example 12.90: A determinant on a circle with a flat bundle

Let $M = S^1$ of length 2π and E the flat U(1) bundle with holonomy $e^{2\pi i\alpha}$, $0 < \alpha < 1$. Its sections are functions with $\psi(x + 2\pi) = e^{2\pi i\alpha}\psi(x)$; a basis is $e^{i(n+\alpha)x}$, $n \in \mathbb{Z}$, and the Laplacian $\Delta_0^E = -\mathrm{d}^2/\mathrm{d}x^2$ has eigenvalues $(n+\alpha)^2$. Using the Hurwitz zeta function $\zeta_H(s,a) = \sum_{m\ge 0}(m+a)^{-s}$, with the classical values $\zeta_H(0,a) = \frac{1}{2} - a$ and $\partial_s\zeta_H(0,a) = \ln\Gamma(a) - \frac{1}{2}\ln 2\pi$:

$$\zeta_\Delta(s) \overset{(1)}{=} \sum_{n\ge 0}(n+\alpha)^{-2s} + \sum_{m\ge 0}(m+1-\alpha)^{-2s} = \zeta_H(2s,\alpha) + \zeta_H(2s,1-\alpha),$$

$$\zeta'_\Delta(0) \overset{(2)}{=} 2\big[\ln\Gamma(\alpha)+\ln\Gamma(1-\alpha)-\ln 2\pi\big] \overset{(3)}{=} 2\ln\frac{\pi}{2\pi\sin\pi\alpha} = -2\ln\big(2\sin\pi\alpha\big),$$
$$\det\Delta_0^E \overset{(4)}{=} \big(2\sin\pi\alpha\big)^2 = \big|1-e^{2\pi i\alpha}\big|^2.$$

(1) Split $n\geq 0$ and $n=-m-1<0$; then $|n+\alpha| = m+1-\alpha$.
(2) Differentiate: the chain rule gives the factor 2; use the value of $\partial_s\zeta_H(0,a)$.
(3) The reflection formula $\Gamma(\alpha)\Gamma(1-\alpha)=\pi/\sin\pi\alpha$.
(4) $\det = e^{-\zeta'(0)}$; and $\big|1-e^{i\theta}\big|^2 = 2-2\cos\theta = 4\sin^2(\theta/2)$.

Three lessons. The regularised infinite product is a finite, explicit function of the holonomy. As $\alpha\to 0$ it vanishes: the constant function becomes a zero mode, which is the zero-mode problem Nash mentions at the end. And $\zeta_\Delta(0) = (\frac12-\alpha)+(\frac12-(1-\alpha)) = 0$, so by (12.237) the determinant does not change if we rescale the circle (all eigenvalues scale by the same factor): it does not depend on the metric.

The phase: the eta invariant. For a real Gaussian with eigenvalue λ, (12.190) gives a phase $e^{i\pi\,\mathrm{sgn}(\lambda)/4}$ (with $e^{+i\lambda x^2/2}$ in the exponent). For infinitely many eigenvalues of both signs the total phase is $\exp\big(\frac{i\pi}{4}\sum_j \mathrm{sgn}\,\lambda_j\big)$, a divergent sum which is regularised in the same spirit as the determinant:

$$\eta_D(s) = \sum_j \mathrm{sgn}(\lambda_j)\,|\lambda_j|^{-s}, \qquad \text{phase} = \exp\Big(\frac{i\pi}{4}\,\eta_D(0)\Big) \quad \text{for } e^{+i\langle v,Dv\rangle/2}. \tag{12.238}$$

$\eta_D(0)$, the **eta invariant** of Atiyah, Patodi and Singer, measures the *spectral asymmetry* of D: how many more positive than negative eigenvalues it has. For the matrix (12.232) the spectrum is symmetric and $\eta=0$; on a curved M, or with a non-trivial flat bundle, it is not.

Worked example 12.91: An eta invariant on the circle

The first-order operator $-i\,\mathrm{d}/\mathrm{d}x$ on the same twisted circle has eigenvalues $n+\alpha$, $n\in\mathbb{Z}$: positive for $n\geq 0$, negative for $n<0$. Then

$$\eta(s) \overset{(1)}{=} \sum_{n\geq 0}(n+\alpha)^{-s} - \sum_{m\geq 0}(m+1-\alpha)^{-s} = \zeta_H(s,\alpha)-\zeta_H(s,1-\alpha),$$
$$\eta(0) \overset{(2)}{=} \big(\tfrac12-\alpha\big)-\big(\tfrac12-(1-\alpha)\big) = 1-2\alpha.$$

(1) Positive and negative eigenvalues separately, as in Example 12.90.
(2) $\zeta_H(0,a)=\frac12-a$.

At $\alpha=\frac12$ the spectrum $\{\pm\frac12,\pm\frac32,\dots\}$ is symmetric and $\eta=0$. As $\alpha\to 0^+$, $\eta\to 1$: the eigenvalue α is about to cross zero, and η jumps by 2 when it does. So the phase of a Chern–Simons one-loop integral depends on the flat connection through such spectral asymmetries.

Nash (following Witten) absorbs the μ-dependence and this phase into the constant C, noting that the phase is of the form $\exp[i\pi\eta(0)/2]$. The precise coefficient depends on conventions (the sign of the exponent, whether η is taken for D or for the operator on all odd forms); the structure is what matters: a modulus given by determinants, and a phase given by the eta invariant. Witten showed that the eta-invariant phase, combined with a gravitational Chern–Simons term needed to cancel its metric dependence, is what shifts k to $k+2$ in the exact SU(2) answers. The shift is derived from the eta invariant in Section T5.7.2.

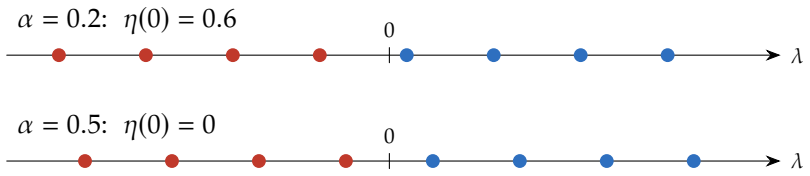

Figure 12.62: Spectral asymmetry. The eigenvalues $n+\alpha$ of $-i\,\mathrm{d}/\mathrm{d}x$ on a circle with holonomy $e^{2\pi i\alpha}$: positive ones blue, negative ones red. For $\alpha = 0.2$ the whole lattice is shifted to the right, so there are "more" positive eigenvalues and $\eta(0) = 1-2\alpha = 0.6$. For $\alpha = \frac{1}{2}$ the spectrum is symmetric about 0 and $\eta(0) = 0$. As $\alpha \to 0$ the eigenvalue α approaches zero, which is where the determinant $\left|1-e^{2\pi i\alpha}\right|^2$ vanishes.

The result, Nash (12.107).

$$Z(M) \approx \sum_{A_f} C\, e^{-ikS(A_f)/4\pi}\, \frac{\det\!\left(\mathrm{d}^\dagger_{A_f}\mathrm{d}_{A_f}\right)}{\sqrt{\det D}}. \tag{12.239}$$

This is the one-loop (first semiclassical) approximation. Now we look at the ratio of determinants.

12.13.7 The Ray–Singer analytic torsion

Working definition 12.38 (Analytic torsion, Nash (12.108))

For a closed oriented Riemannian n-manifold M and a flat bundle E [here the adjoint bundle, with the flat connection A_f] with $H^p(M;E) = 0$ for all p [every d_{A_f}-closed E-valued form is d_{A_f}-exact, so no Δ^E_p has a zero mode], let $\Delta^E_p = \mathrm{d}^\dagger_{A_f}\mathrm{d}_{A_f} + \mathrm{d}_{A_f}\mathrm{d}^\dagger_{A_f}$ on $\Omega^p(M,E)$. The **analytic torsion** $T(M,E)$ is defined by

$$\ln T(M,E) = \sum_{p=0}^{n} (-1)^p\, p\, \ln\det\Delta^E_p. \tag{12.240}$$

(Ray and Singer include a factor $\frac{1}{2}$; Nash omits it, and we follow Nash.) *Recipe:* compute the zeta-determinant of the Laplacian in each degree and combine them with the weights $(-1)^p p$.

Three dimensions, Nash (12.109)–(12.110). For $n = 3$ the weights are $0, -1, +2, -3$, so

$$T(M,E) = \left(\det\Delta^E_1\right)^{-1}\left(\det\Delta^E_2\right)^{2}\left(\det\Delta^E_3\right)^{-3}. \tag{12.241}$$

Now use Hodge duality. The star $\star : \Omega^p \to \Omega^{n-p}$ is an isometry and commutes with the Laplacian, $\star\Delta_p = \Delta_{n-p}\star$; hence if $\Delta_p\omega = \lambda\omega$ then $\Delta_{n-p}(\star\omega) = \lambda\,\star\,\omega$, the spectra agree, and

$$\det\Delta^E_p = \det\Delta^E_{n-p}. \tag{12.242}$$

With $n = 3$: $\det\Delta_2 = \det\Delta_1$ and $\det\Delta_3 = \det\Delta_0$. Therefore

$$T(M,E) \overset{(1)}{=} \left(\det\Delta^E_1\right)^{-1}\left(\det\Delta^E_1\right)^{2}\left(\det\Delta^E_0\right)^{-3} \overset{(2)}{=} \left(\det\Delta^E_0\right)^{-3}\det\Delta^E_1, \tag{12.243}$$

(1) Formula (12.241) with (12.242).
(2) Combine the powers of $\det\Delta_1$: $-1+2 = 1$.

which is Nash's (12.110).

The Chern–Simons ratio is a power of the torsion, Nash (12.112).

$$\frac{\det\left(\mathrm{d}_{A_f}^{\dagger}\mathrm{d}_{A_f}\right)}{\sqrt{\det D}} \overset{(1)}{=} \frac{\det\Delta_0^E}{\left(\det\Delta_1^E\,\det\Delta_0^E\right)^{1/4}} \overset{(2)}{=} \frac{\left(\det\Delta_0^E\right)^{3/4}}{\left(\det\Delta_1^E\right)^{1/4}} \overset{(3)}{=} T(M,E)^{-1/4}. \tag{12.244}$$

(1) The ghost operator is $\mathrm{d}_{A_f}^{\dagger}\mathrm{d}_{A_f} = \Delta_0^E$ on functions (there $\mathrm{d}^{\dagger}$ of a function is zero); and $\sqrt{\det D} = \left((\det D)^2\right)^{1/4}$ with (12.234), up to the phase already put into C.

(2) $\det\Delta_0 \big/ (\det\Delta_0)^{1/4} = (\det\Delta_0)^{3/4}$.

(3) Raise (12.243) to the power $-\frac{1}{4}$: $T^{-1/4} = (\det\Delta_0)^{3/4}(\det\Delta_1)^{-1/4}$.

Hence Nash's (12.113):

$$Z(M) \approx \sum_E C\, e^{-ikS(E)/4\pi}\, T(M,E)^{-1/4}, \tag{12.245}$$

the sum running over flat bundles E (flat connections up to gauge equivalence), $S(E)$ being the Chern–Simons invariant of the flat connection.

Key idea: Why this is evidence of topological invariance

Each factor in (12.245) is topological. $S(A_f)$ is the Chern–Simons invariant of a flat connection: it is unchanged by small deformations (its variation is $2\int \mathrm{tr}(\delta A \wedge F) = 0$ at a flat connection) and depends only on the flat bundle. And the analytic torsion, although built from the metric-dependent Laplacians, is *independent of the metric*: this is the theorem of Ray and Singer (for acyclic E). Schwarz observed that exactly this combination appears in the quadratic Chern–Simons integral, and established the relation explicitly in the abelian case, where the action is exactly quadratic and the one-loop formula is exact. The metric we introduced to fix the gauge has dropped out, as a topological theory requires. (The remaining metric dependence sits in the eta-invariant phase inside C, and is cancelled as described above.)

Worked example 12.92: Torsion of a circle

For $M = S^1$ ($n = 1$) the formula (12.240) has one term, $\ln T = -\ln\det\Delta_1^E$. On a circle the 1-forms $f\,\mathrm{d}x$ have the same spectrum as the functions f, so by Example 12.90,

$$T(S^1,E) = \left|1 - e^{2\pi i\alpha}\right|^{-2}.$$

It depends only on the holonomy, not on the length of the circle (the metric), as promised. Up to the power (fixed by Ray and Singer's factor $\frac{1}{2}$ and by orientation conventions) this is $|1-u|^{\pm 1}$ for holonomy u, which is the combinatorial (Reidemeister) torsion of the circle computed from its cell structure: one 0-cell e_0 and one 1-cell e_1, with twisted boundary map $\partial e_1 = (u-1)e_0$. Ray and Singer conjectured, and Cheeger and Müller proved, that analytic torsion equals Reidemeister torsion in general.

Physical picture: The Alexander polynomial is a torsion too

Apply the same combinatorial recipe to the complement of a knot in S^3, with the flat U(1) bundle whose holonomy round a meridian is t. The cell structure comes from a Wirtinger presentation, the boundary maps are the Fox derivatives of Example 12.71, and the torsion is (Milnor)

$$\tau\left(S^3 \setminus K; t\right) = \frac{\Delta_K(t)}{t-1}.$$

So the determinants of the Chern–Simons one-loop integral and the Alexander polynomial of Section 12.11.2 are the same kind of object, a regularised determinant of a twisted boundary (or Laplace) operator, and the Alexander polynomial is the torsion of the knot complement with a flat U(1) bundle. The circle example above is the case of the unknot, whose complement is homotopic to a circle: $\tau = 1/(t-1)$, $\Delta = 1$.

Zero modes. Nash ends with a caveat. By Hodge theory, the kernel of Δ_p^E is isomorphic to the twisted cohomology $H^p(M;E)$. If some $H^p(M;E) \neq 0$ then Δ_p^E has zero eigenvalues and $\det \Delta_p^E = 0$, and the formulas above break down (as in Example 12.90 at $\alpha \to 0$). Physically: $H^0(M;E) \neq 0$ means the flat connection has a non-trivial stabiliser (constant gauge transformations that leave it fixed), and $H^1(M;E) \neq 0$ means it can be deformed through flat connections (a moduli space, as for $S^1 \times S^2$ in Example 12.88). Both happen for the trivial connection on S^3, where $H^0 = H^3 = \mathfrak{g}$. Nash restricts to acyclic E; the general case requires integrating over the moduli space and dividing by the stabiliser volume. Each zero mode also changes the power of k in the stationary phase formula, one factor $k^{-1/2}$ per missing Gaussian direction (Example 12.87).

Worked example 12.93: The trivial connection on S^3 and the exact answer

For $G = \mathrm{SU}(2)$ on S^3 the only flat connection is trivial, and its stabiliser is all of SU(2), three dimensions of constant gauge transformations. The zero modes of Δ_0 are the three constant Lie-algebra-valued functions, which are gauge directions we may not integrate over as if they were fluctuations. Treating them correctly leaves $Z(S^3) \propto k^{-3/2}$ for large k, one $k^{-1/2}$ per stabiliser dimension. Witten's exact answer, derived with the conformal field theory methods of Chapter 11 as applied to Chern–Simons theory later in this chapter, is

$$Z(S^3) = \sqrt{\frac{2}{k+2}}\,\sin\frac{\pi}{k+2} \;\approx\; \sqrt{2}\,\pi\,k^{-3/2} \qquad (k \to \infty),$$

which indeed decays like $k^{-3/2}$. The weak-coupling analysis correctly predicts the leading behaviour of the exact result, and the shift $k \to k+2$ is the eta-invariant effect mentioned above.

Reading Nash (pp. 346–350, (12.95)–(12.113))

Nash introduces the coupling (12.95), rescales it into the level (12.96) so that small coupling means large k, and argues by stationary phase that $Z(M)$ (12.97) is dominated by flat connections (12.98). He expands the action about a flat connection (12.99), fixes the gauge $\mathrm{d}_{A_f}^* a = 0$ (12.100) with a multiplier and ghosts (12.101), packages the bosons into the operator D (12.102)–(12.104), rewrites Z (12.105), evaluates the Gaussian as a ratio of zeta-function determinants with the μ-dependence and an eta-invariant phase absorbed into C (12.106)–(12.107), and identifies the ratio as $T(M,E)^{-1/4}$ via the Ray–Singer torsion (12.108)–(12.113), metric independent by Schwarz. He assumes all $H^p(M;E)$ vanish. We have added: the stationary-phase formula and the Bessel example; the proof that $\delta S = 2\int \mathrm{tr}(\delta A \wedge F)$ and the exact expansion; flat connections as representations of π_1 with examples; Faddeev–Popov in two dimensions; Grassmann integration; the explicit 4×4 matrix of D; the computation of D^2 and where flatness enters; zeta and eta functions on a twisted circle; the torsion of a circle and its relation to the Alexander polynomial; the zero-mode count and the comparison with $Z(S^3)$. Note the sign issue in Nash's D (pitfall above).

Recap

- The coupling appears only as k/g^2; weak coupling is large k, with $\hbar_{\text{eff}} = 4\pi/k$.
- $\delta S_{\text{CS}} = 2\int \operatorname{tr}(\delta A \wedge F)$: the stationary points are flat connections, i.e. homomorphisms $\pi_1(M) \to G$. $S(A_f + a) = S(A_f) + \int \operatorname{tr}(a \wedge \mathrm{d}_{A_f} a) + \frac{2}{3}\int \operatorname{tr} a^3$.
- Gauge fixing $\mathrm{d}^\dagger_{A_f} a = 0$: a Lagrange multiplier ϕ and ghosts $c, \bar{c}$ (a Grassmann Gaussian gives det, not $\det^{-1/2}$). Ghost operator Δ_0^E.
- $D = \left(\begin{smallmatrix} \star\mathrm{d} & \mathrm{d} \\ \mathrm{d}^\dagger & 0 \end{smallmatrix}\right)$ is self-adjoint, invertible after gauge fixing, and $D^2 = \Delta_1^E \oplus \Delta_0^E$ because $F(A_f) = 0$.
- Determinants by zeta functions, $\det A = e^{-\zeta'(0)}$, $\det(\mu A) = \mu^{\zeta(0)} \det A$; phases by the eta invariant. Twisted circle: $\det \Delta = \left|1 - e^{2\pi i \alpha}\right|^2$, $\eta = 1 - 2\alpha$.
- $\det \Delta_0 / \sqrt{\det D} = T(M,E)^{-1/4}$ with $T = (\det \Delta_0)^{-3} \det \Delta_1$ in three dimensions, so $Z(M) \approx \sum_E C\, e^{-ikS(E)/4\pi} T(M,E)^{-1/4}$: metric independent, as a topological theory must be.

12.14 Chern–Simons theory and the Jones polynomial

In the previous sections we met two faces of Chern–Simons theory. With the abelian group U(1) the path integral is Gaussian, and a pair of Wilson loops gives back the Gauss linking number. With a non-abelian group and a weak coupling, the path integral localises on flat connections and produces the Ray–Singer torsion. Neither computation tells us what the *exact* non-abelian answer is. For $G = \mathrm{SU}(2)$ we would like to know

$$\left\langle W(R_1, C_1) \cdots W(R_p, C_p) \right\rangle = ?$$

at finite level k, for an arbitrary link $C_1 \cup \cdots \cup C_p$ in S^3. The integrand is not Gaussian, so we cannot just complete the square.

Witten's way out is a piece of "cut and paste" physics. He never evaluates the path integral directly. Instead he

(i) cuts the 3-manifold along surfaces Σ;

(ii) quantises the theory on $\Sigma \times \mathbb{R}$, obtaining a Hilbert space $\mathcal{H}_\Sigma$ that turns out to be *finite-dimensional*;

(iii) recognises $\mathcal{H}_\Sigma$ as the space of conformal blocks of a two-dimensional conformal field theory (the WZW model of Chapter 11), which is already fully understood;

(iv) glues the pieces back together, using only linear algebra in these small vector spaces.

The payoff is spectacular. Step (iv), applied to a 2-dimensional Hilbert space, produces the skein relation of the Jones polynomial with no knot diagrams in sight. Section 12.15 pushes the same idea further: cutting out solid tori and regluing them (surgery) computes invariants of 3-manifolds themselves. Figure 12.63 shows the logic of this part.

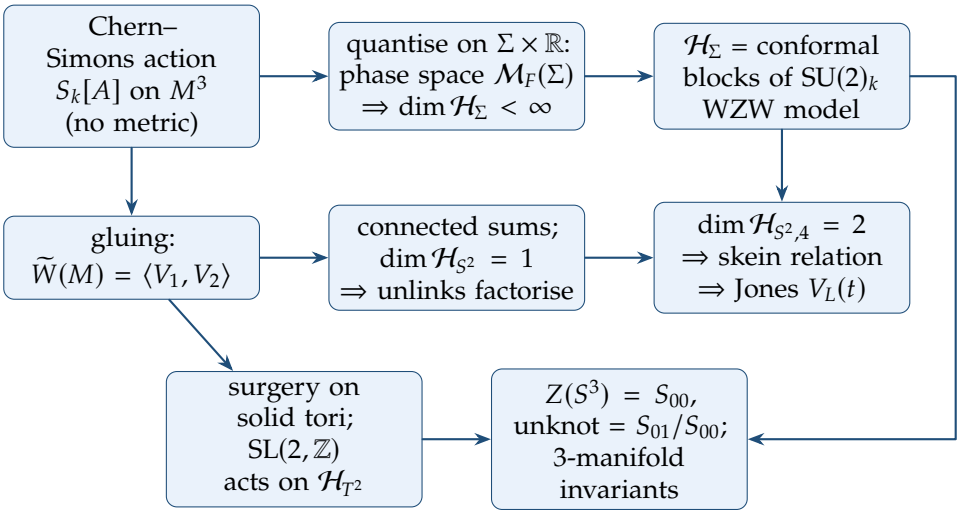

Figure 12.63: The logic of Nash's §6–§7. Read the top row first: the quantisation of Chern–Simons theory on a surface gives finite-dimensional Hilbert spaces, identified with conformal blocks. The middle row uses only gluing and dimension counting to get the skein relation. The bottom row replaces spheres by tori and gets 3-manifold invariants.

12.14.1 Conventions for this part

We keep the conventions of this chapter. The gauge field A is a $\mathfrak{su}(2)$-valued 1-form with anti-Hermitian values, $F = \mathrm{d}A + A \wedge A$, and gauge transformations act as $A \mapsto g^{-1}Ag + g^{-1}\mathrm{d}g$. The Chern–Simons function is

$$f(A) \;=\; -\frac{1}{8\pi^2}\int_M \mathrm{tr}\Big(A \wedge \mathrm{d}A + \tfrac{2}{3}A \wedge A \wedge A\Big), \tag{12.246}$$

which jumps by the integer $\deg g$ under a large gauge transformation. The Chern–Simons **action at level** k is

$$S_k[A] \;=\; 2\pi k\, f(A) \;=\; -\frac{k}{4\pi}\int_M \mathrm{tr}\Big(A \wedge \mathrm{d}A + \tfrac{2}{3}A \wedge A \wedge A\Big), \qquad k \in \mathbb{Z}, \tag{12.247}$$

and the path integral weight is $e^{iS_k[A]}$, which is gauge invariant because $e^{2\pi i k \deg g} = 1$.

Dictionary: anti-Hermitian versus Hermitian gauge fields

Physicists write $A = -iA^a_{\text{phys}}T^a$ with Hermitian generators $T^a = \sigma^a/2$, so $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$. Then $\mathrm{tr}(A \wedge \mathrm{d}A) = -\frac{1}{2}A^a_{\text{phys}} \wedge \mathrm{d}A^a_{\text{phys}}$, and (12.247) becomes the familiar

$$S_k = \frac{k}{4\pi}\int \mathrm{tr}_{\text{phys}}\Big(A \wedge \mathrm{d}A - \tfrac{2i}{3}A \wedge A \wedge A\Big) = \frac{k}{8\pi}\int \Big(A^a \wedge \mathrm{d}A^a + \tfrac{1}{3}\varepsilon^{abc}A^a \wedge A^b \wedge A^c\Big).$$

For U(1) we simply write $S_k = \frac{k}{4\pi}\int A \wedge \mathrm{d}A$ with a real 1-form A, as in the abelian calculation of the previous section.

Two numbers will appear everywhere:

$$q \;:=\; \exp\Big(\frac{2\pi i}{k+2}\Big), \qquad [n]_q \;:=\; \frac{q^{n/2} - q^{-n/2}}{q^{1/2} - q^{-1/2}} \;=\; \frac{\sin\big(n\pi/(k+2)\big)}{\sin\big(\pi/(k+2)\big)}. \tag{12.248}$$

The **quantum integer** $[n]_q$ tends to the ordinary integer n as $k \to \infty$ (so $q \to 1$). For example $[2]_q = q^{1/2} + q^{-1/2} = 2\cos\big(\pi/(k+2)\big)$ and $[3]_q = q + 1 + q^{-1}$. The shift $k \to k+2$ is the famous quantum correction: 2 is the dual Coxeter number of SU(2) (for SU(N) it is N).

12.14.2 Why a surface, and why punctures

Suppose M is a 3-manifold with knots inside it, and pick a surface $\Sigma \subset M$. Near Σ the manifold looks like a slab $\Sigma \times (-\varepsilon, \varepsilon)$. Call the second factor "time". Then the knots are *worldlines*: each time a knot crosses Σ it leaves a mark, a point of Σ where a charged particle sits at that instant (Figure 12.64).

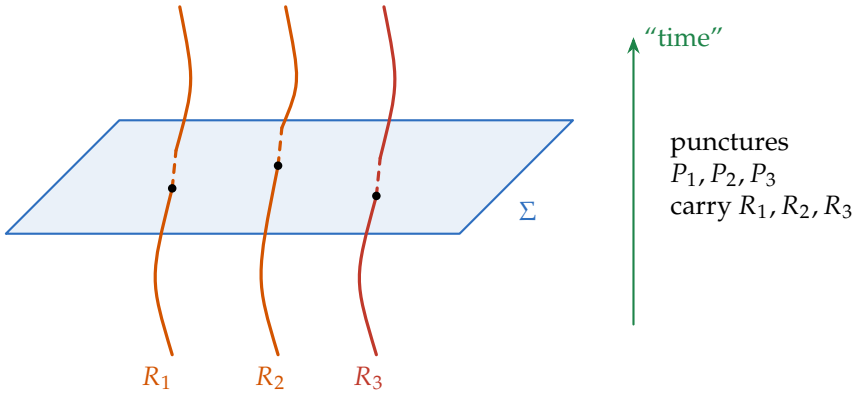

Figure 12.64: A surface Σ inside a 3-manifold, pierced by three Wilson lines. Near Σ the 3-manifold is $\Sigma \times$ time and the Wilson lines are worldlines of static charges. What we should quantise is Σ *together with* its marked points, each labelled by the representation of the line that passes through it.

So the natural objects are Riemann surfaces with marked points, each marked point labelled by a representation of G. These are exactly the data on which a conformal field theory is defined: a CFT assigns a space of conformal blocks $V(\Sigma_{p,n})$ to a genus-p surface with n punctures carrying primary fields (Chapter 11). This coincidence of data is the first hint that the two theories are secretly one.

Physical picture: Anyons

In $2+1$ dimensions a Wilson line is the worldline of a heavy charged particle. The Chern–Simons term attaches magnetic flux to charge, so moving one particle around another produces an Aharonov–Bohm-like phase, or, in the non-abelian case, a *matrix*. Particles whose exchange is a matrix rather than ± 1 are called non-abelian anyons. Knot invariants are the bookkeeping of these exchange matrices along the worldlines.

12.14.3 Canonical quantisation on $\Sigma \times \mathbb{R}$

We now quantise the theory on $M = \Sigma \times \mathbb{R}$ in the ordinary Hamiltonian way. Split the gauge field into a time component and a spatial part,

$$A = A_0\,\mathrm{d}t + \tilde{A}, \qquad \tilde{A} = A_1 \mathrm{d}x^1 + A_2 \mathrm{d}x^2,$$

and split the exterior derivative the same way, $\mathrm{d} = \mathrm{d}t\,\partial_t + \tilde{\mathrm{d}}$, where $\tilde{\mathrm{d}}$ differentiates along Σ only. Write $\tilde{F} = \tilde{\mathrm{d}}\tilde{A} + \tilde{A} \wedge \tilde{A}$ for the curvature of $\tilde{A}$ on the slice.

The action in $2+1$ form

Only the terms containing exactly one $\mathrm{d}t$ survive in a 3-form on $\Sigma \times \mathbb{R}$. Collecting them:

$$\operatorname{tr}(A \wedge \mathrm{d}A)\big|_{\mathrm{d}t} \overset{(1)}{=} \operatorname{tr}\big(A_0\,\mathrm{d}t \wedge \tilde{\mathrm{d}}\tilde{A} + \tilde{A} \wedge \tilde{\mathrm{d}}A_0 \wedge \mathrm{d}t + \tilde{A} \wedge \mathrm{d}t \wedge \partial_t \tilde{A}\big)$$

$$\overset{(2)}{=} \mathrm{d}t \wedge \mathrm{tr}\big(A_0\,\tilde{\mathrm{d}}\tilde{A} + \tilde{A}\wedge\tilde{\mathrm{d}}A_0 - \tilde{A}\wedge\partial_t\tilde{A}\big)$$

$$\overset{(3)}{=} \mathrm{d}t \wedge \mathrm{tr}\big(2A_0\,\tilde{\mathrm{d}}\tilde{A} - \tilde{A}\wedge\partial_t\tilde{A}\big) - \mathrm{d}t\wedge\tilde{\mathrm{d}}\ \mathrm{tr}(\tilde{A}A_0), \tag{12.249}$$

$$\tfrac{2}{3}\,\mathrm{tr}(A\wedge A\wedge A)\big|_{\mathrm{d}t} \overset{(4)}{=} \tfrac{2}{3}\cdot 3\,\mathrm{d}t\wedge\mathrm{tr}\big(A_0\,\tilde{A}\wedge\tilde{A}\big) = 2\,\mathrm{d}t\wedge\mathrm{tr}\big(A_0\,\tilde{A}\wedge\tilde{A}\big). \tag{12.250}$$

(1) $\mathrm{d}A = \tilde{\mathrm{d}}A_0\wedge\mathrm{d}t + \mathrm{d}t\wedge\partial_t\tilde{A} + \tilde{\mathrm{d}}\tilde{A}$; multiply by $A = A_0\mathrm{d}t + \tilde{A}$ and keep the terms with a single $\mathrm{d}t$.
(2) Move $\mathrm{d}t$ to the front: past a 2-form it costs nothing, past the 1-form $\tilde{A}$ it costs a sign.
(3) Leibniz: $\tilde{\mathrm{d}}\ \mathrm{tr}(\tilde{A}A_0) = \mathrm{tr}(\tilde{\mathrm{d}}\tilde{A}\,A_0) - \mathrm{tr}(\tilde{A}\wedge\tilde{\mathrm{d}}A_0)$, so the middle term equals $\mathrm{tr}(A_0\tilde{\mathrm{d}}\tilde{A})$ minus an exact form.
(4) The cube $(A_0\mathrm{d}t + \tilde{A})^3$ has three terms with one $\mathrm{d}t$; after moving $\mathrm{d}t$ to the front and using graded cyclicity of the trace, all three equal $\mathrm{d}t\wedge\mathrm{tr}(A_0\tilde{A}\wedge\tilde{A})$.

Adding the two pieces and dropping the exact term (it integrates to zero on a closed Σ), we find

$$S_k[A] \overset{(1)}{=} -\frac{k}{4\pi}\int \mathrm{d}t\int_\Sigma \mathrm{tr}\big(2A_0(\tilde{\mathrm{d}}\tilde{A} + \tilde{A}\wedge\tilde{A}) - \tilde{A}\wedge\partial_t\tilde{A}\big)$$

$$\overset{(2)}{=} \underbrace{\frac{k}{4\pi}\int \mathrm{d}t\int_\Sigma \mathrm{tr}\big(\tilde{A}\wedge\partial_t\tilde{A}\big)}_{\text{“}p\,\dot{q}\text{”}} \underbrace{-\frac{k}{2\pi}\int \mathrm{d}t\int_\Sigma \mathrm{tr}\big(A_0\,\tilde{F}\big)}_{\text{constraint}}. \tag{12.251}$$

(1) Insert (12.249) and (12.250) into (12.247), with orientation $\mathrm{d}t\wedge\mathrm{vol}_\Sigma$.
(2) Recognise $\tilde{\mathrm{d}}\tilde{A} + \tilde{A}\wedge\tilde{A} = \tilde{F}$.

Read (12.251) like a mechanics Lagrangian. There is a term of the form $p\,\dot{q}$, first order in time. There is a term linear in A_0, which has no time derivative at all: A_0 is a **Lagrange multiplier**. There is *no* term of the form $-H(p,q)$. So

Key idea: The Chern–Simons phase space

(a) Varying A_0 imposes the **Gauss law** $\tilde{F} = 0$: the spatial connection must be flat.

(b) The constraint generates gauge transformations on Σ, so physical configurations are flat connections modulo gauge,

$$\mathcal{M}_F(\Sigma) = \{\tilde{A}\text{ on }\Sigma:\ \tilde{F} = 0\}/\mathcal{G}.$$

(c) The Hamiltonian vanishes, $\mathcal{H} = 0$: nothing evolves, as befits a topological theory.

Choosing the gauge $A_0 = 0$ (Nash's choice) removes the multiplier; the Gauss law is then imposed on states, and we are left with the space $\mathcal{M}_F(\Sigma)$ of flat connections modulo gauge as phase space.

Worked example 12.94: Abelian Chern–Simons: the commutator of A_1 and A_2

Take $G = \mathrm{U}(1)$ and $S_k = \frac{k}{4\pi}\int A\wedge\mathrm{d}A$ with a real 1-form A. In components $A\wedge\mathrm{d}A = \varepsilon^{\mu\nu\rho}A_\mu\partial_\nu A_\rho\,\mathrm{d}^3x$, with $\varepsilon^{012} = 1$. The terms with a time derivative are

$$\frac{k}{4\pi}\varepsilon^{i0j}A_i\partial_0A_j \overset{(1)}{=} -\frac{k}{4\pi}(A_1\dot{A}_2 - A_2\dot{A}_1)$$

$$\overset{(2)}{=} \frac{k}{2\pi}A_2\dot{A}_1 - \frac{k}{4\pi}\partial_t(A_1A_2).$$

(1) $\varepsilon^{i0j} = -\varepsilon^{0ij}$, and ε^{0ij} is $+1$ for $(i,j) = (1,2)$.

(2) $-A_1\dot{A}_2 = A_2\dot{A}_1 - \partial_t(A_1A_2)$.

Dropping the total time derivative, the Lagrangian is $p\dot{q}$ with $q = A_1(x)$ and $p = \frac{k}{2\pi}A_2(x)$ at each point of Σ. Canonical quantisation $[q,p] = i$ then gives

$$\big[A_1(x), A_2(y)\big] = \frac{2\pi i}{k}\,\delta^2(x-y).$$

The two spatial components of the gauge field are conjugate to each other, like x and p of a particle. The effective Planck constant is $2\pi/k$: large k is the classical limit. This is the same algebra as the guiding-centre coordinates of an electron in the lowest Landau level, which is why Chern–Simons theory describes the quantum Hall effect.

For a non-abelian group the same computation, with tr in the dictionary normalisation, gives $[A_1^a(x), A_2^b(y)] = \frac{4\pi i}{k}\delta^{ab}\delta^2(x-y)$ (the extra factor 2 comes from $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$). On the phase space $\mathcal{M}_F(\Sigma)$ the corresponding **symplectic form** is

$$\omega(a,b) \;=\; -\frac{k}{2\pi}\int_\Sigma \mathrm{tr}(a\wedge b), \qquad a,b \in T_{[\tilde{A}]}\mathcal{M}_F \subset \Omega^1(\Sigma;\mathfrak{su}(2)), \tag{12.252}$$

the minus sign making it positive for anti-Hermitian fields. It is non-degenerate on $\mathcal{M}_F$ because the directions it would miss (the gauge directions) have been divided out; this is the Atiyah–Bott construction of the symplectic structure on the moduli space of flat connections.

Counting states: phase-space volume

The semiclassical rule of thumb is

$$\dim\mathcal{H} \;\approx\; \frac{\text{phase-space volume}}{(2\pi\hbar)^d} \;=\; \int_{\mathcal{M}_F}\frac{\omega^d}{d!\,(2\pi)^d}, \qquad 2d = \dim\mathcal{M}_F. \tag{12.253}$$

Since $\omega \propto k$ and $\mathcal{M}_F$ is *compact* (it is built from holonomies in the compact group G), the right-hand side is finite and grows like k^d. This is the reason the Hilbert spaces are finite-dimensional, in sharp contrast with ordinary field theories.

Worked example 12.95: U(1) Chern–Simons on a torus has k states

Let $\Sigma = T^2$ with periodic coordinates $x, y \in [0,1)$. A flat U(1) connection is gauge equivalent to a constant one, $\tilde{A} = \theta_1\mathrm{d}x + \theta_2\mathrm{d}y$, and large gauge transformations $e^{2\pi i(mx+ny)}$ shift $\theta_1 \to \theta_1 + 2\pi m$, $\theta_2 \to \theta_2 + 2\pi n$. So $\mathcal{M}_F$ is the torus of holonomies $(e^{i\theta_1}, e^{i\theta_2})$. The Lagrangian of the previous example restricted to these modes is

$$L \overset{(1)}{=} \frac{k}{2\pi}\int_{T^2} A_2\dot{A}_1\,\mathrm{d}x\,\mathrm{d}y = \frac{k}{2\pi}\,\theta_2\,\dot{\theta}_1,$$

$$\text{volume} \overset{(2)}{=} \int_0^{2\pi}\mathrm{d}\theta_1\int_0^{2\pi}\mathrm{d}p_1 = 2\pi\cdot\frac{k}{2\pi}\cdot 2\pi = 2\pi k,$$

$$\dim\mathcal{H}_{T^2} \overset{(3)}{=} \frac{2\pi k}{2\pi} = k.$$

(1) The fields are constant and the torus has unit area.
(2) The momentum is $p_1 = \frac{k}{2\pi}\theta_2$, which ranges over an interval of length $\frac{k}{2\pi}\cdot 2\pi = k$.
(3) One state per cell of area $2\pi\hbar = 2\pi$.

Here the semiclassical count is exact. The k wavefunctions are theta functions: in the representation where θ_1 is diagonal, periodicity of θ_1 quantises p_1 to integers, periodicity

of θ_2 (i.e. of p_1 modulo k) then leaves the k values $p_1 \in \mathbb{Z}_k$.

Worked example 12.96: SU(2) on a torus: the pillowcase and $k+1$ states

Flat SU(2) connections on T^2 are determined by two holonomies U_1, U_2 around the two cycles. Because $\pi_1(T^2) = \mathbb{Z}^2$ is abelian, they commute: $U_1 U_2 U_1^{-1} U_2^{-1} = 1$ (the holonomy round the boundary of the square). Commuting unitaries can be diagonalised together:

$$U_1 = \begin{pmatrix} e^{i\theta_1} & 0 \\ 0 & e^{-i\theta_1} \end{pmatrix}, \qquad U_2 = \begin{pmatrix} e^{i\theta_2} & 0 \\ 0 & e^{-i\theta_2} \end{pmatrix}.$$

The only remaining freedom is the Weyl element $\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$, which swaps the diagonal entries and sends $(\theta_1, \theta_2) \to (-\theta_1, -\theta_2)$. So $\mathcal{M}_F(T^2) = T^2/\mathbb{Z}_2$, a sphere with four corners, the "pillowcase" of Figure 12.65. The SU(2) theory restricted to the diagonal is a U(1) theory at level $2k$ (the trace of σ_3^2 is 2), which has $2k$ states labelled by $n \in \mathbb{Z}_{2k}$. The Weyl group identifies $n \sim -n$ and keeps only even combinations:

$$\dim \mathcal{H}_{T^2} \overset{(1)}{=} \underbrace{2}_{n=0,\,k} + \underbrace{\tfrac{2k-2}{2}}_{\text{pairs } \{n,-n\}} \overset{(2)}{=} k+1.$$

(1) $n = 0$ and $n = k$ are their own images under $n \to -n$ modulo $2k$; the other $2k-2$ values pair up.
(2) Arithmetic.

A more careful treatment (which includes the one-loop shift $k \to k+2$ and uses Weyl-*odd* theta functions at level $2(k+2)$) gives the same count, $(2(k+2)-2)/2 = k+1$, and identifies the wavefunctions with the numerators of the $SU(2)_k$ characters. Either way the answer is $k+1$, the number of integrable representations of SU(2) at level k (Section 12.14.6). This is our first glimpse of the dictionary with conformal field theory.

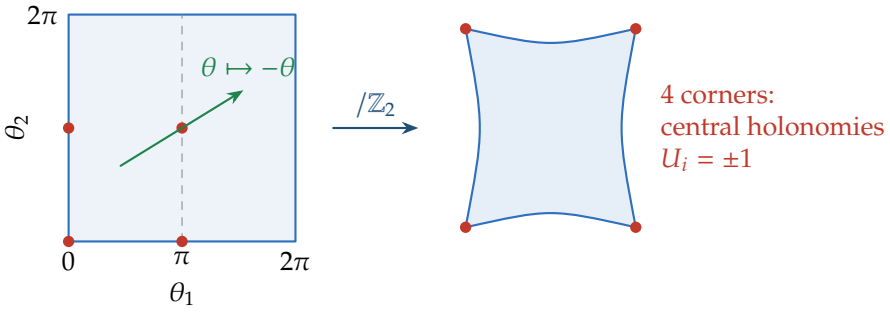

Figure 12.65: The moduli space of flat SU(2) connections on a torus. Left: the torus of angles (θ_1, θ_2) of the two commuting holonomies. The Weyl group acts by $\theta \mapsto -\theta$, whose fixed points are the four red dots. Right: the quotient is a "pillowcase", a sphere with four conical corners. Quantising it at level k gives $k+1$ states.

Worked example 12.97: The sphere: exactly one state

On $\Sigma = S^2$ every loop is contractible, $\pi_1(S^2) = 0$, so every flat connection has trivial holonomy and is gauge equivalent to $\tilde{A} = 0$. Hence $\mathcal{M}_F(S^2)$ is a single point. Quantising a

point gives a one-dimensional Hilbert space:

$$\dim \mathcal{H}_{S^2} = 1.$$

This humble fact, which Nash quotes from the CFT side as (11.75), is the engine behind the factorisation of connected sums in Section 12.14.9.

12.14.4 Kähler quantisation, line bundles and Wilson lines

Nash says that $\mathcal{M}_F$ is "a compact Kähler manifold" and that the Hilbert spaces are "the sections of the kth power of the determinant line bundle". Let us unpack both statements.

Geometric quantisation in one paragraph

To quantise a phase space (P, ω) that is not a cotangent bundle, one needs three things.

(a) A **prequantum line bundle** $L \to P$ with a connection whose curvature is $-i\omega$. Such an L exists only if $\omega/2\pi$ has integer periods: this is the Dirac quantisation condition in disguise, and for Chern–Simons theory it is the quantisation of the level k.

(b) A **polarisation**, i.e. a choice of "half of the coordinates" on which wavefunctions depend. On a Kähler manifold the natural choice is: wavefunctions are *holomorphic*.

(c) Then $\mathcal{H} = H^0(P, L)$, the holomorphic sections of L. For compact P this is finite-dimensional, and for large k its dimension is the volume (12.253) (Riemann–Roch).

For $P = \mathcal{M}_F(\Sigma)$ the Kähler structure comes from a complex structure on Σ: the Hodge star on 1-forms of a Riemann surface squares to -1, so $a \mapsto \star a$ is a complex structure J on $T\mathcal{M}_F$, compatible with ω. The line bundle is $\mathcal{L}^k$, where $\mathcal{L}$ is Quillen's **determinant line bundle** of the family of operators $\bar\partial_{\tilde A}$; its curvature is the basic symplectic form. So

$$\mathcal{H}_\Sigma \;=\; H^0\big(\mathcal{M}_F(\Sigma),\, \mathcal{L}^k\big). \tag{12.254}$$

Notice what has happened. To define $\mathcal{H}_\Sigma$ we chose a complex structure on Σ, although the theory is topological. The resolution is that the spaces for different complex structures form a vector bundle over the moduli space of Riemann surfaces with a projectively flat connection (Hitchin's connection, the Knizhnik–Zamolodchikov connection in CFT language), so they are canonically identified up to a phase. That phase is the **framing anomaly** that will reappear in Section 12.15.7.

Worked example 12.98: Quantising the sphere gives spin $n/2$ (Borel–Weil)

The simplest compact Kähler phase space is $P = \mathbb{CP}^1 = S^2$ with ω equal to $n/2$ times the area form of the unit sphere, so the total area is $2\pi n$. The prequantum line bundle is $\mathcal{O}(n)$, whose holomorphic sections in the affine coordinate z are polynomials of degree at most n:

$$\mathcal{H} = \operatorname{span}\{1, z, z^2, \dots, z^n\}, \qquad \dim \mathcal{H} = n + 1 = \frac{2\pi n}{2\pi} + 1.$$

(The $+1$ is the Riemann–Roch correction to the volume count.) SU(2) acts on these polynomials by the differential operators

$$J_+ = z^2\partial_z - nz, \qquad J_- = -\partial_z, \qquad J_3 = z\partial_z - \tfrac{n}{2}.$$

Check the algebra on a test function $f(z)$:

$$[J_3, J_+]f \overset{(1)}{=} [z\partial_z, z^2\partial_z]f - n[z\partial_z, z]f = z^2 f' - nzf = J_+ f,$$
$$[J_+, J_-]f \overset{(2)}{=} -[z^2\partial_z, \partial_z]f + n[z, \partial_z]f = 2zf' - nf = 2J_3 f.$$

(1) $z\partial_z(z^2 f') - z^2\partial_z(zf') = z^2 f'$ and $z\partial_z(zf) - z\,(zf)'$ reduces to zf.
(2) $z^2 f'' - (z^2 f')' = -2zf'$ and $zf' - (zf)' = -f$.

On the basis, $J_3 z^m = (m - \frac{n}{2})z^m$, so the weights run from $-\frac{n}{2}$ to $+\frac{n}{2}$: this is the spin-$\frac{n}{2}$ representation. The lesson: *quantising a sphere of area $2\pi n$ produces the irreducible representation of dimension $n+1$*. Such a sphere is a coadjoint orbit of SU(2).

This example explains how Wilson lines enter the Hamiltonian picture. A Wilson line $W(R, C) = \mathrm{tr}_R\, P \exp \oint_C A$ can be rewritten as a path integral over an auxiliary "spin" living on the curve, whose phase space is the coadjoint orbit that quantises to R (Kirillov's orbit method). When C pierces Σ at a point P, the spin at P couples to the gauge field, and the Gauss law becomes $\tilde{F} = (\text{charge})\,\delta_P$. Classically this means the holonomy around P is no longer trivial but is fixed to lie in a definite conjugacy class, determined by the representation. Quantum mechanically, the physical Hilbert space $\mathcal{H}_{\Sigma; R_1, \dots, R_n}$ is built from the flat connections on $\Sigma \setminus \{P_1, \dots, P_n\}$ with these prescribed holonomies, tensored with the spins. It is again finite-dimensional.

Physical picture: Gauss law = gauge invariance of the total state

For a large level k the prescribed holonomies are close to 1, and the only remnant of the Gauss law is that the total state of all the spins must be *gauge invariant*: $\mathcal{H}_{S^2; R_1, \dots, R_n} \approx \mathrm{Inv}(R_1 \otimes \cdots \otimes R_n)$, the space of singlets. This is Nash's remark that "the physical Hilbert space must be SU(2)-invariant". At finite k some singlets are lost (Section 12.14.6).

12.14.5 The Hilbert spaces are conformal blocks

The WZW model of Chapter 11 built from the loop group LG at level k has, on each punctured Riemann surface, a finite-dimensional space of conformal blocks $V(\Sigma_{p,n})$, and these form a vector bundle over the moduli space of punctured Riemann surfaces. Witten's claim, which Nash states, is

$$\mathcal{H}_{\Sigma_{p,n}; R_1, \dots, R_n} \;\cong\; V\big(\Sigma_{p,n}; R_1, \dots, R_n\big). \tag{12.255}$$

Why the Gauss law is the WZW Ward identity

Here is the mechanism, at the physicist level (normalisations suppressed). Give Σ a complex coordinate z and use the holomorphic polarisation: wavefunctions are functionals $\Psi[A_{\bar z}]$ of the $(0,1)$ part of the connection. The canonical commutator of Example 12.94 makes A_z act as a derivative,

$$A_z \;\longrightarrow\; \frac{2\pi}{k}\,\frac{\delta}{\delta A_{\bar z}}.$$

The Gauss law $F_{z\bar z} = \partial_z A_{\bar z} - \partial_{\bar z} A_z + [A_z, A_{\bar z}] = 0$ then becomes a first-order functional differential equation,

$$\Big(\frac{k}{2\pi}\,\partial_z A_{\bar z} - \partial_{\bar z}\frac{\delta}{\delta A_{\bar z}} - \Big[A_{\bar z}, \frac{\delta}{\delta A_{\bar z}}\Big]\Big)\Psi[A_{\bar z}] = 0. \tag{12.256}$$

Now look at the WZW model with a background field $A_{\bar z}$ coupled to its holomorphic current $J(z)$: its generating functional $Z[A_{\bar z}] = \langle \exp \int \mathrm{tr}(J A_{\bar z}) \rangle$ obeys exactly this equation, which is

the Ward identity expressing $\bar\partial J + [A_{\bar z}, J] = \frac{k}{2\pi}\partial A_{\bar z}$, the anomalous conservation of the current. So the Chern–Simons physical states *are* WZW generating functionals, i.e. conformal blocks. With punctures the same argument produces the blocks with primary fields inserted at the punctures.

Watch out: Chiral, not full, CFT

The conformal blocks of a CFT are *chiral* (holomorphic) objects. The full correlation functions of the 2d CFT are sesquilinear combinations $\sum h_{IJ}\mathcal{F}_I\bar{\mathcal{F}}_J$ of blocks. Chern–Simons theory sees only one chirality: $\mathcal{H}_\Sigma$ is the space of blocks itself, not the space of full correlators.

12.14.6 The data of SU(2) at level k

From now on $G = \mathrm{SU}(2)$. Everything we need from the CFT side fits in one box.

Working definition 12.39 ($\mathrm{SU}(2)_k$ modular data)

- *Labels.* The integrable representations [the only spins that give consistent primary fields at level k] of the level-k current algebra are the spins $j = 0, \frac12, 1, \dots, \frac{k}{2}$. There are $k+1$ of them. Nash labels them by $i = 2j \in \{0, 1, \dots, k\}$, so $i = 0$ is the trivial representation and $i = 1$ the defining (2-dimensional) one.
- *Conformal weights* [$\phi_j(z)$ picks up a factor λ^{-h_j} under $z \to \lambda z$] of the primary fields, and the central charge c:
$$h_j = \frac{j(j+1)}{k+2} = \frac{i(i+2)}{4(k+2)}, \qquad c = \frac{3k}{k+2}.$$
(Sugawara: $h = C_2(j)/(k+h^\vee)$ with $C_2(j) = j(j+1)$, $h^\vee = 2$.)
- *Fusion rules* [which spins j can appear when ϕ_{j_1} and ϕ_{j_2} are brought together]. $j_1 \times j_2 = \sum_j j$ where j runs in integer steps from $|j_1 - j_2|$ to $\min(j_1 + j_2,\ k - j_1 - j_2)$. The lower limit is the Clebsch–Gordan rule; the upper limit is the level-k truncation.
- *Modular S-matrix* [the matrix, on the blocks of the torus, of the swap of its two circles] (Nash (12.157); derived in Section 12.15.6):
$$S_{ij} = \sqrt{\frac{2}{k+2}}\,\sin\frac{(i+1)(j+1)\pi}{k+2}, \qquad i, j = 0, \dots, k.$$
- *Dimensions.* $\dim \mathcal{H}_\Sigma$ for any punctured surface is computed by cutting Σ into pairs of pants [spheres with three holes] and summing over the labels of the cuts, with $N_{j_1 j_2}^{\ j} \in \{0, 1\}$ from the fusion rules at each pair of pants. Equivalently, Verlinde's formula:
$$\dim \mathcal{H}_{\Sigma_g; j_1, \dots, j_n} = \sum_{m=0}^{k} S_{0m}^{2-2g-n} \prod_{r=1}^{n} S_{i_r m}. \tag{12.257}$$

Worked example 12.99: Four spin-$\frac{1}{2}$ punctures on a sphere

This is the Hilbert space behind the skein relation. First the classical count (large k): we need the number of singlets in $R^{\otimes 4}$ with $R = \frac{1}{2}$.

$$\begin{aligned}\tfrac{1}{2}\otimes\tfrac{1}{2}\otimes\tfrac{1}{2}\otimes\tfrac{1}{2} &\overset{(1)}{=} (0\oplus 1)\otimes(0\oplus 1)\\ &\overset{(2)}{=} (0\otimes 0)\oplus(0\otimes 1)\oplus(1\otimes 0)\oplus(1\otimes 1)\\ &\overset{(3)}{=} 0\oplus 1\oplus 1\oplus(0\oplus 1\oplus 2).\end{aligned}$$

(1) Pair the factors: $\frac{1}{2}\otimes\frac{1}{2} = 0\oplus 1$ (singlet plus triplet); dimension check $2\cdot 2 = 1+3$.
(2) Distribute.
(3) $1\otimes 1 = 0\oplus 1\oplus 2$; dimension check $16 = 1+3+3+(1+3+5)$.

The spin 0 appears twice, so $\dim \mathrm{Inv}(R^{\otimes 4}) = 2$: this is Nash's "the trivial representation occurs precisely twice". A basis is labelled by the spin $j \in \{0,1\}$ of the pair (P_1, P_2) (Figure 12.66).

Now at level k. The intermediate spin $j = 1$ is allowed only if $1 \le k/2$, i.e. $k \ge 2$; the fusion $\frac{1}{2}\times\frac{1}{2}$ at $k = 1$ has upper limit $\min(1, 1-1) = 0$. So

$$\dim \mathcal{H}_{S^2;\frac{1}{2},\frac{1}{2},\frac{1}{2},\frac{1}{2}} = \begin{cases} 2, & k \ge 2,\\ 1, & k = 1.\end{cases}$$

Verlinde's formula agrees: for $k = 2$, with $S_{0m} = \frac{1}{2}(1,\sqrt{2},1)$ and $S_{1m} = \frac{1}{2}(\sqrt{2},0,-\sqrt{2})$,

$$\sum_m S_{0m}^{-2} S_{1m}^{4} \overset{(1)}{=} 4\cdot\tfrac{1}{4} + 2\cdot 0 + 4\cdot\tfrac{1}{4} = 2.$$

(1) $S_{00}^{-2} = 4$, $S_{10}^{4} = (\sqrt{2}/2)^4 = \frac{1}{4}$; the middle term vanishes; the last term equals the first.

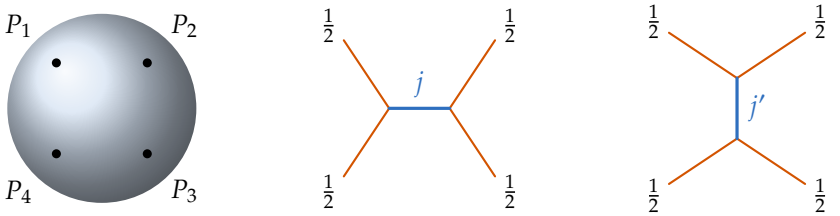

Figure 12.66: The two-dimensional Hilbert space of a sphere with four spin-$\frac{1}{2}$ punctures. A basis is obtained by choosing which pair of punctures to fuse first and labelling the intermediate line by its spin, 0 or 1. Two such choices give two bases, related by a 2×2 "fusion matrix" F that we write down in Section 12.14.12.

Worked example 12.100: Higher genus: Verlinde numbers

With no punctures, (12.257) reads $\dim \mathcal{H}_{\Sigma_g} = \sum_m S_{0m}^{2-2g}$.

- $g = 0$: $\sum_m S_{0m}^2 = 1$, because the rows of the orthogonal matrix S are unit vectors. This is Example 12.97 again.

	$n=0$	$n=1$	$n=2$	$n=3$	$n=4$	$n=5$	$n=6$
$k=1$	1	0	1	0	1	0	1
$k=2$	1	0	1	0	2	0	4
$k=3$	1	0	1	0	2	0	5
$k\to\infty$: $\dim \mathrm{Inv}(R^{\otimes n})$	1	0	1	0	2	0	5

Table 12.2: $\dim \mathcal{H}_{S^2}$ with n punctures, each carrying spin $\frac{1}{2}$, from Verlinde's formula (12.257). Odd n gives zero (no singlet in an odd number of spin-$\frac{1}{2}$'s). At large k the numbers are the Catalan numbers $1,1,2,5,\dots$ counting singlets; small k truncates them. The $n=0$ entry is Example 12.97; $n=2$ gives Nash's $\dim V(S^2_{R_i,R_j}) = g_{ij}$; $n=4$ gives the skein relation.

- $g=1$: $\sum_m S_{0m}^0 = k+1$, matching the pillowcase count of Example 12.96.
- $g=2$, $k=1$: $S_{0m} = \frac{1}{\sqrt{2}}(1,1)$, so $\dim = 2\cdot(\frac{1}{\sqrt{2}})^{-2} = 4 = 2^g$. In general $k=1$ gives 2^g.
- $g=2$, $k=2$: $S_{0m} = (\frac{1}{2}, \frac{1}{\sqrt{2}}, \frac{1}{2})$, so $\dim = (\frac{1}{2})^{-2} + (\frac{1}{\sqrt{2}})^{-2} + (\frac{1}{2})^{-2} = 4+2+4 = 10$.

For large k and $g \geq 2$ the growth is $\dim \sim k^{3g-3}$, in agreement with the semiclassical count (12.253), since $\dim_{\mathbb{R}} \mathcal{M}_F(\Sigma_g) = 6g-6$.

Reading Nash (pp. 350–351, §6 opening)

Nash compresses this whole section into one paragraph: choose $A_0 = 0$ on $\Sigma\times\mathbb{R}$; the phase space is the moduli space $\mathcal{M}_F$ of flat connections, which is compact Kähler; its quantisation gives finite-dimensional $\mathcal{H}_\Sigma$ or $\mathcal{H}_{\Sigma_{p,n}}$, spaces of sections of the kth power of the determinant line bundle; these coincide with the conformal blocks $V(\Sigma)$ of chapter 11 (see Witten, Hitchin). The dimension facts he later uses are his (11.75): $\dim V(S^2_{R_i}) = \delta_{i0}$ and $\dim V(S^2_{R_i,R_j}) = g_{ij}$, with $g_{ij}=1$ if $R_i = R_j^*$ and 0 otherwise. For SU(2) every representation is self-conjugate, so $g_{ij} = \delta_{ij}$. Both follow from (12.257) and the orthogonality of S.

Recap

- Chern–Simons theory on $\Sigma\times\mathbb{R}$ is first order in time, has $\mathcal{H}=0$, and its Gauss law forces flat spatial connections.
- Phase space $= \mathcal{M}_F(\Sigma)$, compact, symplectic form $\propto k$, so $\dim\mathcal{H}_\Sigma < \infty$: U(1) on T^2 gives k, SU(2) on T^2 gives $k+1$, S^2 gives 1.
- Wilson lines piercing Σ are punctures carrying representations; at large k the Hilbert space is the space of singlets.
- $\mathcal{H}_\Sigma$ = space of conformal blocks of the $\mathrm{SU}(2)_k$ WZW model, because the Gauss law is the WZW Ward identity.
- Four spin-$\frac{1}{2}$ punctures on S^2: $\dim = 2$ for $k \geq 2$.

12.14.7 Notation for Wilson-line correlators

Before we cut anything we need a compact way to write the quantities we are after. Recall that a **Wilson line** along an oriented closed curve C, in a representation R of G, is

$$W(R,C) \;=\; \operatorname{tr}_R\, P\exp\oint_C A,$$

the trace, in the representation R, of the holonomy of A around C (Chapter T3). A link $L = C_1 \cup \cdots \cup C_p$ with a representation R_a attached to each component C_a gives a product of p Wilson lines. Its path-integral average is

$$\Big\langle W(R_1,C_1)\cdots W(R_p,C_p)\Big\rangle \;=\; \frac{\widetilde{W}\big(M,\{R\}\big)}{Z(M)}, \qquad \{R\} = R_1,\dots,R_p, \tag{12.258}$$

where the numerator and denominator are the *unnormalised* path integrals

$$\widetilde{W}\big(M,\{R\}\big) \coloneqq \int_{\mathcal{A}/\mathcal{G}} \mathcal{D}A\; e^{iS_k[A]} \prod_{a=1}^{p} W(R_a,C_a), \tag{12.259}$$

$$Z(M) \coloneqq \int_{\mathcal{A}/\mathcal{G}} \mathcal{D}A\; e^{iS_k[A]}. \tag{12.260}$$

The symbol $\{R\}$ records the whole "representation content" of the link: which curves, and which representation on each. When we want to be explicit we write the representations out, for instance

$$\widetilde{W}(M,R_1,R_2) \qquad (p=2), \tag{12.261}$$

and when there are no Wilson lines at all ($p=0$) we write

$$\widetilde{W}(M) \;=\; Z(M), \tag{12.262}$$

because with no insertions (12.259) is just the partition function. Finally the **normalised correlation function** is

$$W\big(M,\{R\}\big) \;\coloneqq\; \frac{\widetilde{W}\big(M,\{R\}\big)}{Z(M)}. \tag{12.263}$$

Working definition 12.40 (unnormalised and normalised correlators)

- $\widetilde{W}(M,\{R\})$: the path integral over connections on M of e^{iS_k} times the product of Wilson lines. It depends on M, on the link (up to isotopy), on the representations and on a framing of each component [a thin ribbon with the curve as one edge, which fixes its self-linking number] (Section 12.14.16).
- $W(M,\{R\}) = \widetilde{W}/Z(M)$: the same, divided by the value with no Wilson lines. This is the "expectation value" a physicist would quote. For $M = S^3$ it will be a Laurent polynomial in $q^{1/4}$ [with $q = e^{2\pi i/(k+2)}$].
- Operationally we never do the integrals. We compute both $\widetilde{W}$ and Z by cutting M into pieces and gluing vectors in the finite-dimensional spaces $\mathcal{H}_\Sigma$ [the space of states on a cut surface Σ, the space of conformal blocks].

From now on $G = \mathrm{SU}(2)$ and, unless stated otherwise, every Wilson line carries the defining 2-dimensional representation, spin $j = \frac{1}{2}$, which Nash calls R (and labels $i = 1$).

12.14.8 A path integral on a manifold with boundary is a vector

The whole method rests on one principle, which every physicist already knows from quantum mechanics.

The quantum-mechanical prototype

The propagator of a particle, $K(x_f,t_f;x_i,t_i)=\langle x_f|e^{-iH(t_f-t_i)}|x_i\rangle$, is a path integral over paths from x_i to x_f. If we stop the paths at an intermediate time t and record where they are, $y=x(t)$, the integral splits:

$$\begin{aligned} K(x_f,t_f;x_i,t_i) &\overset{(1)}{=} \int_{x(t_i)=x_i}^{x(t_f)=x_f} \mathcal{D}x\; e^{iS[x]} \\ &\overset{(2)}{=} \int \mathrm{d}y \int_{x(t)=y}^{x(t_f)=x_f} \mathcal{D}x_2\, e^{iS[x_2]} \int_{x(t_i)=x_i}^{x(t)=y} \mathcal{D}x_1\, e^{iS[x_1]} \\ &\overset{(3)}{=} \int \mathrm{d}y\; K(x_f,t_f;y,t)\,K(y,t;x_i,t_i). \end{aligned} \tag{12.264}$$

(1) Definition of the propagator as a sum over histories.

(2) Every path is a path x_1 up to time t followed by a path x_2 after it, joined at $y=x(t)$; the action is an integral of a local Lagrangian, so $S[x]=S[x_1]+S[x_2]$ and e^{iS} factorises; finally we integrate over the joining point y.

(3) Each inner integral is again a propagator.

In words: the path integral over the *first half* of spacetime, with the fields on the cut held fixed, is a *wavefunction* of those fields, $\psi_1(y)=K(y,t;x_i,t_i)$. The second half gives another function $\psi_2(y)=K(x_f,t_f;y,t)$. The full answer is the pairing $\int \mathrm{d}y\,\psi_2(y)\psi_1(y)$.

The same statement for a 3-manifold

Now let M be a closed 3-manifold and $\Sigma\subset M$ a closed surface that separates it into two pieces, $M=\widetilde{M}_1\cup_\Sigma\widetilde{M}_2$. The Chern–Simons action is the integral of a local 3-form, so it is additive, $S_k[A]=S_k[A|_{\widetilde{M}_1}]+S_k[A|_{\widetilde{M}_2}]$ (the boundary terms cancel between the two sides). Repeat (12.264) with y replaced by the connection a on Σ:

$$\begin{aligned} Z(M) &\overset{(1)}{=} \int \mathcal{D}a \underbrace{\int_{A|_\Sigma=a} \mathcal{D}A_2\; e^{iS_k[A_2]}}_{\Psi_2[a]} \underbrace{\int_{A|_\Sigma=a} \mathcal{D}A_1\; e^{iS_k[A_1]}}_{\Psi_1[a]} \\ &\overset{(2)}{=} \big\langle \Psi_1,\Psi_2\big\rangle. \end{aligned} \tag{12.265}$$

(1) Split every connection on M into its pieces on $\widetilde{M}_1$ and $\widetilde{M}_2$, agreeing on Σ; use additivity of the action; integrate over the common boundary value a.

(2) The integral over a is the natural pairing of a wavefunction on the boundary of $\widetilde{M}_1$ with one on the boundary of $\widetilde{M}_2$.

Gauge invariance (the Gauss law of Section 12.14.3) forces each Ψ_i to lie in the physical Hilbert space, so

$$\Psi_1=V_1\in\mathcal{H}_\Sigma,\qquad \Psi_2=V_2\in\mathcal{H}_{\bar\Sigma}.$$

If Wilson lines run inside $\widetilde{M}_1$ or $\widetilde{M}_2$ they are simply included in the corresponding integral, and V_1, V_2 depend on them. If they cross Σ, the surface acquires punctures and the vectors live in $\mathcal{H}_{\Sigma;R_1,\dots,R_n}$.

Watch out: What is "held fixed" on the boundary

The Chern–Simons action is first order in derivatives, like $p\dot{q}$. In quantum mechanics with $L = p\dot{q} - H$ one cannot fix both q and p at the final time; one fixes q (or p, or $q + ip$). Likewise on Σ we cannot fix both components of a. In the holomorphic polarisation of Section 12.14.5 we fix $a_{\bar{z}}$, and $\Psi[a_{\bar{z}}]$ is a conformal block. Nash's "heuristically a wave function" is this.

Why the other side gives the dual space

The two pieces induce *opposite* orientations on the common surface. If we orient Σ as the boundary of $\widetilde{M}_1$ (outward normal first), then as the boundary of $\widetilde{M}_2$ it is $\bar{\Sigma}$, the same surface with the opposite orientation. The Chern–Simons action is odd under orientation reversal, because it is the integral of a 3-form with no metric in it:

$$\begin{aligned} S_k^{-M}[A] &\overset{(1)}{=} -\frac{k}{4\pi}\int_{-M}\operatorname{tr}\Big(A\wedge \mathrm{d}A + \tfrac{2}{3}A^3\Big) \\ &\overset{(2)}{=} +\frac{k}{4\pi}\int_{M}\operatorname{tr}\Big(A\wedge \mathrm{d}A + \tfrac{2}{3}A^3\Big) = -S_k^{M}[A], \end{aligned} \tag{12.266}$$

(1) Definition (12.247) on the reversed manifold $-M$.
(2) Integrating a top form over $-M$ gives minus the integral over M.

So reversing orientation replaces e^{iS} by $e^{-iS} = \overline{e^{iS}}$, and wavefunctions by their complex conjugates. The Hilbert space of $\bar{\Sigma}$ is the complex conjugate of that of Σ, and with the inner product this is the dual space: $\mathcal{H}_{\bar{\Sigma}} \cong \mathcal{H}_\Sigma^*$. That is why the pairing in (12.265) is the dual pairing of a vector with a covector. It is the axiom "orientation reversal $\mapsto$ dual space" of Atiyah's TQFT axioms, met at the start of this chapter.

Key idea: Gluing

If $\partial\widetilde{M}_1 = \Sigma$ and $\partial\widetilde{M}_2 = \bar{\Sigma}$, the path integrals over the pieces are vectors $V_1 \in \mathcal{H}_\Sigma$ and $V_2 \in \mathcal{H}_\Sigma^*$, and the path integral over the glued manifold is their pairing:

$$\widetilde{W}\big(M, \{R\}\big) = \big\langle V_1, V_2 \big\rangle. \tag{12.267}$$

This is Nash's (12.121). He compares it to the factorisation of string amplitudes on intermediate states (Chapter 9): cutting a world sheet along a circle and inserting a complete set of states.

Worked example 12.101: Two consistency checks: the cylinder and the circle

(a) Take $\widetilde{M} = \Sigma \times [0,1]$. It has two boundary components, $\bar{\Sigma}\times\{0\}$ and $\Sigma\times\{1\}$, so its path integral is a vector in $\mathcal{H}_\Sigma^* \otimes \mathcal{H}_\Sigma = \operatorname{End}(\mathcal{H}_\Sigma)$, i.e. an operator. Since the Hamiltonian vanishes, this operator is $e^{-i\mathcal{H}\cdot 1} = \mathrm{id}$. Gluing a cylinder onto anything therefore changes nothing, as it must: $\Sigma\times[0,1]\cup_\Sigma \widetilde{M}_1 \cong \widetilde{M}_1$.
(b) Glue the two ends of the cylinder to each other. The result is $\Sigma \times S^1$, and gluing the two ends of an operator is taking its trace:

$$Z(\Sigma\times S^1) \overset{(1)}{=} \sum_a \big\langle e_a,\ \mathrm{id}\, e_a\big\rangle \overset{(2)}{=} \dim \mathcal{H}_\Sigma.$$

(1) The identity operator written in a basis e_a of $\mathcal{H}_\Sigma$ with dual basis e^a; gluing the outgoing

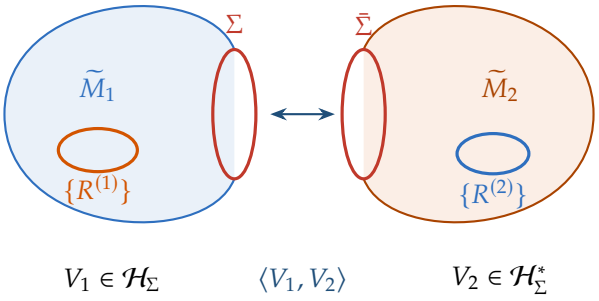

Figure 12.67: Cutting a closed 3-manifold along a surface Σ. The path integral over the left piece, with all Wilson lines inside it, is a vector V_1 in the Hilbert space of Σ; the right piece sees Σ with the opposite orientation and gives a covector V_2. Gluing is pairing. When no Wilson line crosses Σ, the surface has no punctures.

end to the incoming end contracts the upper index with the lower one.

(2) $\mathrm{tr}\ \mathrm{id} = \dim$.

This is Nash's (12.151), which we meet again in Section 12.15.5. With $\Sigma = S^2$ it gives $Z(S^2 \times S^1) = 1$.

12.14.9 Connected sums factorise

What a connected sum is

Given two closed oriented 3-manifolds M_1 and M_2, remove a small open 3-ball from each. What is left, $\widetilde{M}_1$ and $\widetilde{M}_2$, has a 2-sphere as boundary. Glue the two boundary spheres together by an orientation-reversing identification. The result is the **connected sum**

$$M \;=\; M_1 \# M_2 . \tag{12.268}$$

Up to diffeomorphism it does not depend on where the balls were removed. Two simple facts to keep in mind: $M \# S^3 \cong M$ (removing a ball from S^3 leaves a ball, and gluing a ball back into the hole of $\widetilde{M}$ gives M again), and $\pi_1(M_1 \# M_2) = \pi_1(M_1) * \pi_1(M_2)$, the free product, by van Kampen's theorem, because the joining sphere is simply connected.

Conversely, given M and an embedded 2-sphere that separates it, we can *decompose* M as a connected sum by cutting along the sphere and capping each half with a ball. For the first half of the argument we insist that *no knot crosses the joining sphere*. The link then splits into two sets, $\{R^{(1)}\}$ inside M_1 and $\{R^{(2)}\}$ inside M_2 (Figure 12.68).

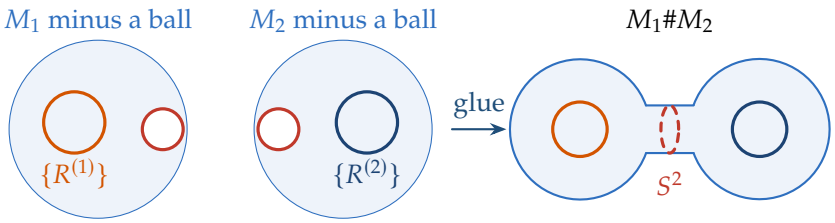

Figure 12.68: The connected sum. Remove a ball (red boundary sphere) from each manifold and glue along the spheres. The knots stay on their own sides: no Wilson line crosses the joining S^2, so the joining sphere carries no punctures and its Hilbert space is one-dimensional.

The factorisation argument

Our goal is Nash's (12.120):

$$Z(S^3)\,\widetilde{W}\big(M,\{R\}\big) \;=\; \widetilde{W}\big(M_1,\{R^{(1)}\}\big)\,\widetilde{W}\big(M_2,\{R^{(2)}\}\big). \tag{12.269}$$

We need four vectors in $\mathcal{H}_{S^2}$ or its dual.

- $V_1 \in \mathcal{H}_{S^2}$: the path integral over $\widetilde{M}_1$ with the Wilson lines $\{R^{(1)}\}$ inside.
- $V_2 \in \mathcal{H}^*_{S^2}$: the path integral over $\widetilde{M}_2$ with $\{R^{(2)}\}$ inside.
- $U_1 \in \mathcal{H}_{S^2}$ and $U_2 \in \mathcal{H}^*_{S^2}$: the path integrals over two empty 3-balls B_1, B_2, with the boundary orientations of $\widetilde{M}_1$ and $\widetilde{M}_2$ respectively.

Now glue these four pieces in the four possible ways. Each gluing is an instance of (12.267):

$$\begin{aligned}
\widetilde{M}_1 \cup \widetilde{M}_2 = M &\;\Longrightarrow\; \widetilde{W}(M,\{R\}) = \langle V_1, V_2\rangle,\\
B_1 \cup B_2 = S^3 &\;\Longrightarrow\; Z(S^3) = \langle U_1, U_2\rangle,\\
\widetilde{M}_1 \cup B_2 = M_1 &\;\Longrightarrow\; \widetilde{W}(M_1,\{R^{(1)}\}) = \langle V_1, U_2\rangle,\\
B_1 \cup \widetilde{M}_2 = M_2 &\;\Longrightarrow\; \widetilde{W}(M_2,\{R^{(2)}\}) = \langle U_1, V_2\rangle.
\end{aligned} \tag{12.270}$$

The second line uses that two balls glued along their boundary make a 3-sphere, the 3-dimensional version of two hemispheres making S^2 (Figure 12.69). The last two lines say that capping the hole of $\widetilde{M}_i$ with a ball gives M_i back.

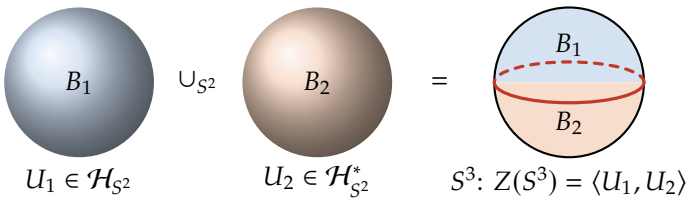

Figure 12.69: Two 3-balls glued along their boundary 2-spheres form S^3. The picture shows the analogy one dimension down: two discs (hemispheres) glued along their boundary circle (red equator) form S^2. Each empty ball defines a vector in the one-dimensional space $\mathcal{H}_{S^2}$ or its dual.

The whole argument now rests on $\dim \mathcal{H}_{S^2} = 1$ (Example 12.97; Nash's (11.75) with no marked points, which corresponds to the trivial representation). In a one-dimensional space every vector is a multiple of any nonzero one. Since $Z(S^3) = \langle U_1, U_2\rangle \neq 0$ (we will find $Z(S^3) = S_{00} > 0$), both U_1 and U_2 are nonzero, so we may write $V_1 = aU_1$ and $V_2 = bU_2$ for some numbers a, b. Then

$$\begin{aligned}
\langle U_1, U_2\rangle\langle V_1, V_2\rangle &\overset{(1)}{=} \langle U_1, U_2\rangle\, ab\, \langle U_1, U_2\rangle\\
&\overset{(2)}{=} \big(a\langle U_1, U_2\rangle\big)\big(b\langle U_1, U_2\rangle\big)\\
&\overset{(3)}{=} \langle V_1, U_2\rangle\, \langle U_1, V_2\rangle.
\end{aligned} \tag{12.271}$$

(1) Substitute $V_1 = aU_1$, $V_2 = bU_2$ and use bilinearity of the pairing.
(2) Regroup the numbers.
(3) Again by bilinearity, $\langle V_1, U_2\rangle = a\langle U_1, U_2\rangle$ and $\langle U_1, V_2\rangle = b\langle U_1, U_2\rangle$.

Reading each factor off (12.270), the left side is $Z(S^3)\widetilde{W}(M,\{R\})$ and the right side is

$$\widetilde{W}\big(M_1,\{R^{(1)}\}\big)\,\widetilde{W}\big(M_2,\{R^{(2)}\}\big) \tag{12.272}$$

so we have shown

$$Z(S^3)\,\widetilde{W}\big(M,\{R\}\big) = \widetilde{W}\big(M_1,\{R^{(1)}\}\big)\,\widetilde{W}\big(M_2,\{R^{(2)}\}\big), \tag{12.273}$$

which after dividing by $Z(S^3)^2$ is the symmetric form

$$\frac{\widetilde{W}\big(M,\{R\}\big)}{Z(S^3)} = \frac{\widetilde{W}\big(M_1,\{R^{(1)}\}\big)}{Z(S^3)}\,\frac{\widetilde{W}\big(M_2,\{R^{(2)}\}\big)}{Z(S^3)}. \tag{12.274}$$

Physical picture: Why a one-dimensional space forces factorisation

A one-dimensional Hilbert space means the joining sphere can carry only one state: "nothing" passes through it. Whatever happens in $\widetilde{M}_1$ can influence $\widetilde{M}_2$ only through that single state, so the two halves are statistically independent, up to the overall normalisation $Z(S^3)$ that measures the "amplitude of the empty sphere". It is the topological version of cluster decomposition.

Reading Nash (pp. 351–352, (12.119)–(12.126))

Nash writes the key identity as $\langle U_1,U_2\rangle\langle V_1,V_2\rangle = \langle V_1,U_1\rangle\langle U_2,V_2\rangle$ and then says "$\langle V_1,U_1\rangle$ corresponds to $\widetilde{M}_1$ 'evolving' into M_1". Read literally this pairs two vectors of the same space. The intended meaning is: pair V_1 with the *ball that caps off* $\widetilde{M}_1$. With our labels, where U_2 is the capping ball for $\widetilde{M}_1$ (it carries the orientation of $\widetilde{M}_2$'s side), this is (12.271). The content is unchanged.

Worked example 12.102: A finite-group check of the factorisation

The factorisation (12.273) holds in *any* TQFT with $\dim\mathcal{H}_{S^2}=1$, so we can test it on a theory where we can do the path integral exactly. Take gauge theory with a *finite* gauge group Γ (the untwisted Dijkgraaf–Witten theory). A connection is then flat automatically and is determined by its holonomies, and the path integral is a finite sum over homomorphisms $\pi_1(M)\to\Gamma$ divided by the size of the gauge group:

$$Z(M) = \frac{\big|\mathrm{Hom}(\pi_1(M),\Gamma)\big|}{|\Gamma|}.$$

Then $Z(S^3)=1/|\Gamma|$ (only the trivial homomorphism from $\pi_1=1$), and for a connected sum

$$\begin{aligned} Z(M_1\#M_2) &\overset{(1)}{=} \frac{\big|\mathrm{Hom}(\pi_1(M_1)*\pi_1(M_2),\Gamma)\big|}{|\Gamma|} \\ &\overset{(2)}{=} \frac{\big|\mathrm{Hom}(\pi_1(M_1),\Gamma)\big|\,\big|\mathrm{Hom}(\pi_1(M_2),\Gamma)\big|}{|\Gamma|} \\ &\overset{(3)}{=} \frac{Z(M_1)\,Z(M_2)}{Z(S^3)}. \end{aligned}$$

(1) Van Kampen: π_1 of a connected sum is the free product.
(2) A homomorphism out of a free product is the same as an independent choice of homomorphism out of each factor.

(3) Multiply and divide by $|\Gamma|$ and use $Z(S^3) = 1/|\Gamma|$.

This is exactly (12.273) with no Wilson lines. For a concrete number take $\Gamma = \mathbb{Z}_2$ and $M_1 = M_2 = \mathbb{RP}^3$ ($\pi_1 = \mathbb{Z}_2$): $Z(\mathbb{RP}^3) = 2/2 = 1$ and $Z(\mathbb{RP}^3\#\mathbb{RP}^3) = |\mathrm{Hom}(\mathbb{Z}_2 * \mathbb{Z}_2, \mathbb{Z}_2)|/2 = 4/2 = 2 = 1 \cdot 1/(1/2)$.

12.14.10 Iterating: unlinks

Nothing stops us from decomposing again. If

$$M = M_1 \# M_2 \# \cdots \# M_p \tag{12.275}$$

with no knot crossing any of the $p-1$ joining spheres, then applying (12.274) once splits off M_1, and applying it to the rest repeatedly gives, by induction on p,

$$\frac{\widetilde{W}(M, \{R\})}{Z(S^3)} = \frac{\widetilde{W}(M_1, \{R^{(1)}\})}{Z(S^3)} \cdots \frac{\widetilde{W}(M_p, \{R^{(p)}\})}{Z(S^3)}. \tag{12.276}$$

The case that matters most is $M = S^3$ and $\{R\}$ a collection of p **unlinked, unknotted circles** (the p-component **unlink**). The circles can be separated by $p-1$ disjoint 2-spheres, one enclosing each circle (Figure 12.70). Cutting along these spheres and capping writes $S^3 = S^3\# \cdots \# S^3$ with exactly one unknot in each copy. Every factor on the right of (12.276) is then the same number, and since $M_i = M = S^3$ we can replace $Z(S^3)$ by the normalisation of each factor:

$$\frac{\widetilde{W}(S^3, \{R\})}{Z(S^3)} = \frac{\widetilde{W}(S^3, R_1)}{Z(S^3)} \cdots \frac{\widetilde{W}(S^3, R_p)}{Z(S^3)}, \qquad \text{i.e.} \qquad W(S^3, \{R\}) = W(S^3, R_1) \cdots W(S^3, R_p). \tag{12.277}$$

The normalised expectation value of an unlink is the product of the expectation values of its components. With all R_a equal to the fundamental representation, and writing $W(\bigcirc) := W(S^3, R)$ for one unknot,

$$W(S^3, \text{unlink of } p) \;=\; W(\bigcirc)^p. \tag{12.278}$$

We still do not know the number $W(\bigcirc)$. The skein relation will give it in Section 12.14.14, and surgery will give it again, independently, in Section 12.15.6.

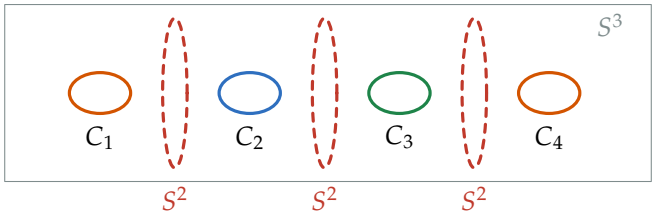

Figure 12.70: A 4-component unlink in S^3. Three 2-spheres (red, dashed) that meet no circle cut S^3 into four pieces, each containing one unknot. By (12.276) the normalised expectation value is the product of the four single-circle values.

Worked example 12.103: Connected sums of 3-manifolds: Z is multiplicative up to $Z(S^3)$

With no Wilson lines, (12.273) reads $Z(M_1\#M_2) = Z(M_1)Z(M_2)/Z(S^3)$. Two quick consequences.

(a) $M_2 = S^3$: $Z(M_1\#S^3) = Z(M_1)Z(S^3)/Z(S^3) = Z(M_1)$, consistent with $M_1\#S^3 \cong M_1$.

(b) $M_1 = M_2 = S^2 \times S^1$, for which $Z = \dim \mathcal{H}_{S^2} = 1$ (Example 12.101):

$$Z\big(\#^g (S^2 \times S^1)\big) \overset{(1)}{=} \frac{Z(S^2 \times S^1)^g}{Z(S^3)^{g-1}} \overset{(2)}{=} Z(S^3)^{1-g} = S_{00}^{1-g}.$$

(1) Apply (12.273) $g-1$ times.
(2) $Z(S^2 \times S^1) = 1$, and $Z(S^3) = S_{00}$, which we derive in Section 12.15.6.

Compare the Verlinde formula $\dim \mathcal{H}_{\Sigma_g} = \sum_m S_{0m}^{2-2g}$ of Example 12.100: the *dominant* term $m = 0$ has the same shape. This is not an accident; both are sums over the labels running round cycles, and here only the trivial label contributes.

Worked example 12.104: Connected sum of knots: the Jones polynomial is multiplicative

Now let the joining sphere be pierced by a knot *twice*. Given knots K_1 and K_2 in S^3, their **connected sum** $K_1 \# K_2$ is made by cutting each open at one point and splicing the loose ends together (Figure 12.71). A 2-sphere separates the two "halves" and meets the knot in two points, carrying R and (because the orientation of the curve runs in on one side and out on the other) R^*, which is R again for SU(2).
The Hilbert space of a sphere with two marked points has dimension $\dim V(S^2_{R_i,R_j}) = g_{ij}$ (Nash's (11.75)), which is 1 for $R_i = R_j$. So the whole argument above goes through verbatim, with U_1, U_2 now the path integrals over balls containing a single *unknotted* arc. Gluing two such balls gives an unknot in S^3, so $\langle U_1, U_2 \rangle = \widetilde{W}(S^3, \bigcirc)$ replaces $Z(S^3)$:

$$\widetilde{W}(S^3, \bigcirc)\, \widetilde{W}(S^3, K_1 \# K_2) \overset{(1)}{=} \widetilde{W}(S^3, K_1)\, \widetilde{W}(S^3, K_2),$$
$$\frac{W(S^3, K_1 \# K_2)}{W(\bigcirc)} \overset{(2)}{=} \frac{W(S^3, K_1)}{W(\bigcirc)} \frac{W(S^3, K_2)}{W(\bigcirc)}.$$

(1) The four-vector identity (12.271) in the one-dimensional space $\mathcal{H}_{S^2;R,R}$.
(2) Divide by $Z(S^3)^2 W(\bigcirc)^2$ and use $\widetilde{W} = Z(S^3)\, W$ on S^3.

The ratio $W(S^3, K)/W(\bigcirc)$ will turn out to be the Jones polynomial $V_K(t)$ (Section 12.14.14). So we have derived, from $\dim \mathcal{H}_{S^2;R,R} = 1$ alone, the known property

$$V_{K_1 \# K_2}(t) = V_{K_1}(t)\, V_{K_2}(t).$$

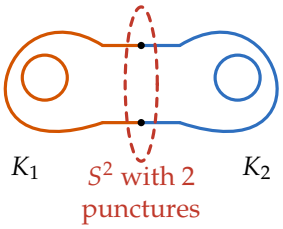
For instance, with the right-handed trefoil $V = t + t^3 - t^4$ and its mirror image $V = t^{-1} + t^{-3} - t^{-4}$ (Example 12.109), the **granny knot** (trefoil # trefoil) and the **square knot** (trefoil # mirror trefoil) have

$$V_{\text{granny}} = (t + t^3 - t^4)^2 = t^2 + 2t^4 - 2t^5 + t^6 - 2t^7 + t^8,$$
$$V_{\text{square}} = (t + t^3 - t^4)(t^{-1} + t^{-3} - t^{-4}) = -t^{-3} + t^{-2} - t^{-1} + 3 - t + t^2 - t^3.$$

The Jones polynomial tells these two apart, while the Alexander polynomial, $(t^2 - t + 1)^2$ for both, does not.

Try it: Three punctures

Why can a sphere never be pierced by a single Wilson line of a closed link (or by three spin-$\frac{1}{2}$ lines)? What does $\dim \mathcal{H}$ say?
Answer. A closed curve crosses a separating sphere an even number of times (it must come



$$\dim \mathcal{H}_{S^2;R,R} = 1 \Rightarrow V_{K_1\#K_2} = V_{K_1} V_{K_2}$$

Figure 12.71: The connected sum of two knots. A sphere meeting the knot in two points separates the two summands. The small circles stand for whatever knotting each summand contains. Because the twice-punctured sphere has a one-dimensional Hilbert space, the same argument that factorised unlinks factorises the Jones polynomial.

back). Algebraically: $\dim \mathcal{H}_{S^2;\frac{1}{2}} = \delta_{\frac{1}{2},0} = 0$ and $\dim \mathcal{H}_{S^2;\frac{1}{2},\frac{1}{2},\frac{1}{2}} = 0$ (Table 12.2), so such configurations would have vanishing amplitude anyway. There is no singlet in an odd tensor power of spin $\frac{1}{2}$.

Recap

- $\widetilde{W}(M,\{R\})$ is the unnormalised path integral with Wilson lines, $Z(M) = \widetilde{W}(M)$, and $W = \widetilde{W}/Z$.
- Path integral over a manifold with boundary Σ = vector in $\mathcal{H}_\Sigma$; the other side gives the dual; gluing = pairing (Nash's (12.121)). Cylinder = identity, $\Sigma \times S^1$ = trace.
- $\dim \mathcal{H}_{S^2} = 1$ forces $Z(S^3)\widetilde{W}(M_1\#M_2) = \widetilde{W}(M_1)\widetilde{W}(M_2)$.
- Unlink of p circles: $W = W(\bigcirc)^p$.
- $\dim \mathcal{H}_{S^2;R,R} = 1$ gives $V_{K_1\#K_2} = V_{K_1} V_{K_2}$.

12.14.11 Knots through the joining sphere

So far no knot was allowed to cross the joining sphere, and the result was factorisation. Now we do the opposite: we let the link cross the joining sphere, and extract the *skein relation*. Recall its shape (Nash's (12.118), in the standard normalisation of the Jones polynomial):

$$t^{-1} V_{L_+}(t) - t\, V_{L_-}(t) \;=\; \left(t^{1/2} - t^{-1/2}\right) V_{L_0}(t), \tag{12.279}$$

where L_+, L_-, L_0 are three links that are identical except inside a small ball, where they look like a positive crossing, a negative crossing and no crossing (Figure 12.72). Nash's version has L_+ and L_- interchanged; we come back to this in Section 12.14.13. His summary of the quantum field theory content is striking: the skein relation "amounts to the statement that any three vectors in a two-dimensional vector space are linearly dependent". Let us see exactly how.

The set-up

Take a link L in M and choose a crossing of some diagram of it. Surround the crossing by a small ball $\widetilde{M}_2$; call the rest $\widetilde{M}_1$. Now $M = \widetilde{M}_1 \cup_{S^2} \widetilde{M}_2$, but the joining sphere is pierced at *four* points, where the two strands enter and leave the ball. Each puncture carries the fundamental representation R (as a point of S^2 it carries R or R^* according to whether the strand enters or

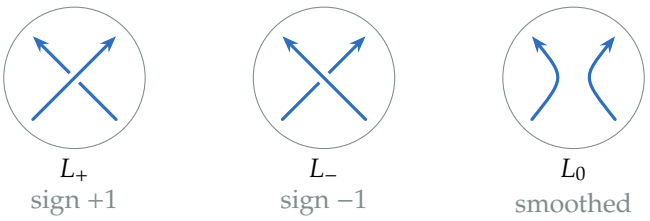


Figure 12.72: The skein triple. Both strands point upwards. In L_+ the strand going from lower left to upper right passes over; in L_- it passes under; in L_0 the crossing is replaced by two parallel arcs, respecting the orientations. Outside the grey ball the three links agree. Each picture is the inside of the ball $\widetilde{M}_2$, whose boundary sphere is pierced at four points.

leaves; for SU(2) these agree). By the gluing rule,

$$\widetilde{W}\big(M,\{R\}\big) = \big\langle V_1, V_2\big\rangle, \qquad V_1 \in \mathcal{H}_{S^2;R,R,R,R}, \quad V_2 \in \mathcal{H}^*_{S^2;R,R,R,R}. \tag{12.280}$$

Reading Nash (p. 353, footnote 8)

Why four punctures rather than two? In a skein relation the two strands in the ball may belong to two different components of the link, or to the same one. To be completely general we allow each of the two strands to belong to its own Wilson loop. Each loop must enter and leave the ball, so there are two entry points and two exit points on the sphere: a 4-punctured S^2.

The Hilbert space of this 4-punctured sphere is the one we computed in Example 12.99:

$$\mathcal{H}_{S^2;R,R,R,R} \equiv \mathcal{H}_{S^2,4}, \qquad \dim \mathcal{H}_{S^2,4} = 2 \quad (k \geq 2),$$

because the trivial representation occurs exactly twice in $R \otimes R \otimes R \otimes R$ (the physical Hilbert space must be SU(2)-invariant).

Three links, three vectors

Do the decomposition three times, for the three links L_+, L_-, L_0 that differ only inside the ball. The outside $\widetilde{M}_1$, with everything in it, is the same each time, so it gives the *same* vector V_1. Only the inside changes, giving three vectors $V_2^+, V_2^-, V_2^0 \in \mathcal{H}^*_{S^2,4}$. Nash's (12.131) is

$$\widetilde{W}\big(M,\{R^+\}\big) = \langle V_1, V_2^+\rangle, \quad \widetilde{W}\big(M,\{R^-\}\big) = \langle V_1, V_2^-\rangle, \quad \widetilde{W}\big(M,\{R^0\}\big) = \langle V_1, V_2^0\rangle, \tag{12.281}$$

where $\{R^\pm\}, \{R^0\}$ denote the Wilson-line content of $L_\pm, L_0$. Three vectors in a two-dimensional space are linearly dependent: there are numbers $\alpha^+, \alpha^-, \alpha^0$, not all zero, with

$$\begin{aligned} &\alpha^+ V_2^+ + \alpha^- V_2^- + \alpha^0 V_2^0 = 0 \\ \Longrightarrow \quad &\alpha^+ \widetilde{W}\big(M,\{R^+\}\big) + \alpha^- \widetilde{W}\big(M,\{R^-\}\big) + \alpha^0 \widetilde{W}\big(M,\{R^0\}\big) = 0, \end{aligned} \tag{12.282}$$

the second line following from the first by pairing with V_1. This is already a skein relation. Two questions remain: what are the α's, and why are they the *same* for every link (that is, why do they not depend on the vectors V_2, which depend on how the ball sits in the link)? Both are answered by the braiding matrix.

Worked example 12.105: Three vectors in $\mathbb{C}^2$: the coefficients are determinants

Here is an explicit formula for the dependence. For $u, v, w \in \mathbb{C}^2$ write $[u, v] := u_1 v_2 - u_2 v_1$. Then

$$[v, w]\, u + [w, u]\, v + [u, v]\, w = 0. \tag{12.283}$$

To see it, look at the i-th component ($i = 1, 2$):

$$[v, w]u_i + [w, u]v_i + [u, v]w_i \overset{(1)}{=} \det \begin{pmatrix} u_i & v_i & w_i \\ u_1 & v_1 & w_1 \\ u_2 & v_2 & w_2 \end{pmatrix} \overset{(2)}{=} 0.$$

(1) Expand the 3×3 determinant along its first row; the three cofactors are $[v, w]$, $-[u, w] = [w, u]$ and $[u, v]$.

(2) The first row equals row $i + 1$, and a determinant with two equal rows vanishes.

For example, $u = (1, 0)$, $v = (1, 1)$, $w = (2, 3)$ give $[v, w] = 1$, $[w, u] = 3$, $[u, v] = 1$, and indeed $(1, 0) + 3(1, 1) - \ldots$ wait: $1 \cdot (1, 0) + 3 \cdot (1, 1) + 1 \cdot (2, 3)$ is not zero. The signs matter: $[w, u] = w_1 u_2 - w_2 u_1 = 0 - 3 = -3$, so the correct combination is $(1, 0) - 3(1, 1) + (2, 3) = (0, 0)$. The lesson for the skein relation is that the α's are not arbitrary: they are built from the vectors themselves, and we must find a reason for them to be universal.

12.14.12 The braiding matrix

Diffeomorphisms of the punctured sphere act on the Hilbert space

Look again at the three pictures in Figure 12.72. Each is a ball containing two arcs, attached to the same four points on the boundary. Take L_0 and grab the two upper endpoints on the boundary sphere. Rotate them around each other by half a turn, anticlockwise as seen from above, dragging the arcs along. The two parallel arcs acquire a crossing: we get L_+. Another half turn in the same direction gives two full twists; a half turn in the opposite direction gives L_-. So

$$L_+ = \sigma(L_0), \qquad L_- = \sigma^{-1}(L_0),$$

where σ is the **half-twist** diffeomorphism of the ball that exchanges two of the punctures on the boundary (Figure 12.73).

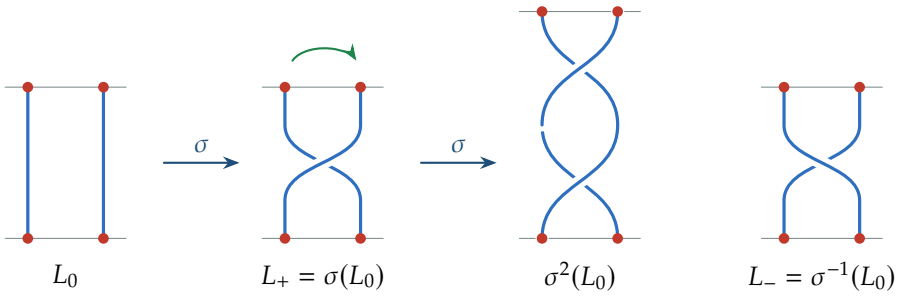

Figure 12.73: The half-twist. Draw the ball as a cylinder with the four punctures (red) on the top and bottom discs. Rotating the two top punctures around each other by half a turn turns the parallel arcs L_0 into L_+; doing it again gives a full twist $\sigma^2(L_0)$; rotating the other way gives L_-. Because these are diffeomorphisms of the punctured sphere, they act on $\mathcal{H}_{S^2,4}$ as 2×2 matrices.

A diffeomorphism ϕ of a punctured surface maps the Hilbert space to itself: it is a symmetry of the classical phase space (it maps flat connections to flat connections, respecting the punctures and their labels), so after quantisation it is a linear operator $\rho(\phi)$ on $\mathcal{H}_\Sigma$. Diffeomorphisms

isotopic to the identity act trivially (the theory is topological), so only the **mapping class group** (diffeomorphisms modulo isotopy) acts. Applied to the half-twist: the vector of the ball containing $\sigma(L_0)$ is the operator σ applied to the vector of the ball containing L_0,

$$V_2^+ = \sigma\, V_2^0, \qquad V_2^- = \sigma^{-1} V_2^0. \tag{12.284}$$

(Strictly, σ acts on the dual space $\mathcal{H}^*_{S^2,4}$ in which the V_2's live; we use the same letter.) Nash writes this as

$$V_2^0 = B V_2^+, \qquad V_2^- = B V_2^0 = B^2 V_2^+, \tag{12.285}$$

with his **braiding matrix** $B = \sigma^{-1}$ (his (12.133)–(12.134)). It is the same statement read in the other direction.

The braid group

The half-twists of adjacent punctures generate the **braid group**. For n strands it has generators $\sigma_1, \dots, \sigma_{n-1}$ (σ_i crosses strand i over strand $i+1$) and relations

$$\sigma_i \sigma_{i+1} \sigma_i = \sigma_{i+1} \sigma_i \sigma_{i+1}, \qquad \sigma_i \sigma_j = \sigma_j \sigma_i \quad (|i-j| \geq 2). \tag{12.286}$$

The first is the **braid relation** (Figure 12.74), the third Reidemeister move in disguise. Unlike the permutation group, there is *no* relation $\sigma_i^2 = 1$: twisting twice is not the same as doing nothing.

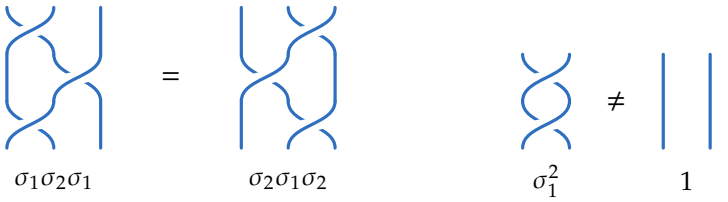

Figure 12.74: Left: the braid relation $\sigma_1\sigma_2\sigma_1 = \sigma_2\sigma_1\sigma_2$ (read from bottom to top). The two braids are isotopic: slide the middle crossing across. Right: a full twist of two strands is *not* isotopic to the trivial braid with the ends fixed, so $\sigma^2 \neq 1$ in the braid group, and its matrix need not be the identity.

The eigenvalues come from the operator product expansion

Choose the basis of $\mathcal{H}_{S^2,4}$ adapted to the pair of punctures that the half-twist exchanges: basis vector e_j means "the two exchanged strands fuse into total spin j", with $j \in \{0, 1\}$ (the s-channel basis of Figure 12.66). Exchanging two particles does not change their total spin, so σ is *diagonal* in this basis, $\sigma e_j = \lambda_j e_j$. To find λ_j we use the conformal blocks. Near each other, two primary fields of spin $\frac{1}{2}$ and weight $h := h_{1/2}$ have the operator product expansion

$$\phi_{1/2}(z_1)\,\phi_{1/2}(z_2) \;\sim\; \sum_{j=0,1} (z_1 - z_2)^{h_j - 2h} \left[\phi_j(z_2) + \dots\right],$$

so the block e_j behaves like $(z_1 - z_2)^{h_j - 2h}$. Half an anticlockwise turn of z_1 around z_2 sends $z_1 - z_2 \mapsto e^{i\pi}(z_1 - z_2)$, and multiplies the block by $e^{i\pi(h_j - 2h)}$. The exchange also swaps the two spin-$\frac{1}{2}$ labels, which costs the Clebsch–Gordan symmetry sign ε_j: the singlet is antisymmetric ($\varepsilon_0 = -1$), the triplet symmetric ($\varepsilon_1 = +1$). With $h_j = j(j+1)/(k+2)$ and $q = e^{2\pi i/(k+2)}$, so that

$e^{i\pi x/(k+2)} = q^{x/2}$:

$$\lambda_0 \overset{(1)}{=} \varepsilon_0\, e^{i\pi(h_0 - 2h_{1/2})} \overset{(2)}{=} -\exp\!\left(i\pi\left(0 - \frac{2\cdot\frac{3}{4}}{k+2}\right)\right) \overset{(3)}{=} -q^{-3/4},$$
$$\lambda_1 \overset{(4)}{=} \varepsilon_1\, e^{i\pi(h_1 - 2h_{1/2})} \overset{(5)}{=} \exp\!\left(i\pi\,\frac{2-\frac{3}{2}}{k+2}\right) = q^{1/4}. \tag{12.287}$$

(1) Phase of the block under the half-exchange, times the symmetry sign.
(2) $h_0 = 0$ and $h_{1/2} = \frac{1}{2}\cdot\frac{3}{2}/(k+2) = \frac{3}{4}/(k+2)$; $\varepsilon_0 = -1$.
(3) $e^{-i\pi\,(3/2)/(k+2)} = q^{-3/4}$.
(4) The same rule for the triplet.
(5) $h_1 = 2/(k+2)$, $\varepsilon_1 = +1$; then $e^{i\pi(1/2)/(k+2)} = q^{1/4}$.

Which sense of rotation is the "positive" crossing is a convention; we fix it by the framing check in Example 12.112, which requires this choice. So in the s-channel basis

$$\sigma \;=\; \begin{pmatrix} -q^{-3/4} & 0 \\ 0 & q^{1/4} \end{pmatrix}, \qquad \det\sigma = -q^{-1/2}, \qquad \operatorname{tr}\sigma = q^{1/4} - q^{-3/4}. \tag{12.288}$$

Physical picture: The classical limit is the permutation of two spins

As $k \to \infty$, $q \to 1$ and $\sigma \to \operatorname{diag}(-1,+1)$. On $\mathbb{C}^2 \otimes \mathbb{C}^2$ the operator that is -1 on the singlet and $+1$ on the triplet is the *swap* $P(u\otimes v) = v\otimes u$. So at infinite level a crossing just exchanges the two spins, $\sigma^2 = 1$, and the theory cannot tell over from under. The quantum deformation $q \neq 1$ splits the two eigenvalues apart by the phases $q^{-3/4}$ and $q^{1/4}$; that splitting is what makes over and under different, and it vanishes like $1/k$.

The second generator and the fusion matrix

With four punctures there are two independent half-twists: σ_1 exchanging punctures 1 and 2, and σ_2 exchanging 2 and 3. In the basis adapted to $(1,2)$, σ_1 is diagonal; σ_2 is diagonal in the basis adapted to $(2,3)$. The change of basis between the two "channels" is the **fusion matrix** F (Moore–Seiberg). For four spin-$\frac{1}{2}$ punctures it is

$$F = \frac{1}{[2]}\begin{pmatrix} 1 & \sqrt{[3]} \\ \sqrt{[3]} & -1 \end{pmatrix}, \qquad F^2 = \mathrm{id}, \qquad \det F = -1, \tag{12.289}$$

the quantum version of the $6j$ symbols of the rotation group, and $\sigma_2 = F\sigma_1 F$. The check $F^2 = \mathrm{id}$ uses $[2]^2 = [3] + 1$ (true for all q: $(q^{1/2} + q^{-1/2})^2 = q + 2 + q^{-1}$).

Worked example 12.106: The braid relation holds

We verify $\sigma_1\sigma_2\sigma_1 = \sigma_2\sigma_1\sigma_2$ with $D := \sigma_1 = \operatorname{diag}(a,b)$, $a = -q^{-3/4}$, $b = q^{1/4}$ and $\sigma_2 = FDF$. First reduce the braid relation to a statement about the single matrix $M := DF$:

$$\sigma_1\sigma_2\sigma_1 = \sigma_2\sigma_1\sigma_2 \overset{(1)}{=} \iff DFDFD = FDFDFDF$$
$$\overset{(2)}{=} \iff (DF)^3F = F(DF)^3$$
$$\overset{(3)}{=} \impliedby (DF)^3 = c\,\mathrm{id} \;\text{ for some number } c.$$

(1) Substitute $\sigma_2 = FDF$; on the right, $FDF\cdot D\cdot FDF$.
(2) Multiply the left side on the right by $F^2 = \mathrm{id}$: $DFDFD = DFDFDF\cdot F = (DF)^3F$; the

right side is $F(DF)^3$.

(3) A multiple of the identity commutes with F.

A 2×2 matrix with eigenvalues μ and $\mu\omega$, $\omega = e^{\pm 2\pi i/3}$, cubes to $\mu^3\mathrm{id}$. Its trace and determinant satisfy $(\operatorname{tr} M)^2 = \mu^2(1+\omega)^2 = \mu^2\omega = \det M$, using $1+\omega+\omega^2 = 0$. So it is enough to check $(\operatorname{tr} M)^2 = \det M$:

$$(\operatorname{tr} DF)^2 \overset{(4)}{=} \left(\frac{a-b}{[2]}\right)^2 \overset{(5)}{=} \left(\frac{-q^{-1/4}(q^{-1/2}+q^{1/2})}{[2]}\right)^2 = q^{-1/2},$$
$$\det(DF) \overset{(6)}{=} ab\,\det F = -ab \overset{(7)}{=} q^{-1/2}.$$

(4) The diagonal of DF is $(aF_{11}, bF_{22}) = (a,-b)/[2]$.

(5) $a-b = -q^{-3/4}-q^{1/4} = -q^{-1/4}(q^{-1/2}+q^{1/2}) = -q^{-1/4}[2]$.

(6) $\det(DF) = \det D\,\det F$ and $\det F = -1$.

(7) $ab = -q^{-3/4}q^{1/4} = -q^{-1/2}$.

They agree, so the braid relation holds for every k. Notice that it is the *specific* eigenvalues (12.287) that make this work: the ratio $b/a = -q$ and the entries of F conspire.

Worked example 12.107: Level $k=2$: Hadamard and phase gates

At $k=2$, $q = e^{2\pi i/4} = i$, $[2] = \sqrt{2}$, $[3] = 1$. Then $a = -q^{-3/4} = -e^{-3\pi i/8} = e^{i\pi/8}\cdot i$ and $b = e^{i\pi/8}$, so

$$\sigma_1 = e^{i\pi/8}\begin{pmatrix} i & 0\\ 0 & 1\end{pmatrix}, \qquad F = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1\\ 1 & -1\end{pmatrix}, \qquad \sigma_2 = F\sigma_1 F = \frac{e^{i\pi/8}}{2}\begin{pmatrix} 1+i & i-1\\ i-1 & 1+i\end{pmatrix}.$$

F is the Hadamard matrix, and σ_1 is (up to a phase) the "phase gate" of quantum computing. The check of the previous example is $(\operatorname{tr} DF)^2 = \big((i-1)/\sqrt{2}\big)^2 = -i = i\cdot(-1) = \det(DF)$ (with the common phase $e^{i\pi/8}$ stripped off). These are the braiding matrices of the Ising anyons that appear in the $\nu = 5/2$ quantum Hall state: particles whose exchange acts by a matrix on a degenerate ground state.

12.14.13 The skein relation, derived

Cayley–Hamilton does the work

Every 2×2 matrix satisfies its own characteristic equation, $\sigma^2 - (\operatorname{tr}\sigma)\,\sigma + (\det\sigma)\,\mathrm{id} = 0$. Multiply by σ^{-1} and apply the result to V_2^0:

$$\begin{aligned} 0 &\overset{(1)}{=} \sigma V_2^0 - (\operatorname{tr}\sigma)V_2^0 + (\det\sigma)\,\sigma^{-1}V_2^0\\ &\overset{(2)}{=} V_2^+ - (q^{1/4}-q^{-3/4})V_2^0 - q^{-1/2}V_2^-\\ &\overset{(3)}{=} q^{1/4}V_2^+ - q^{-1/4}V_2^- - (q^{1/2}-q^{-1/2})V_2^0. \end{aligned} \tag{12.290}$$

(1) Cayley–Hamilton divided by σ, applied to V_2^0.

(2) (12.284) and the trace and determinant (12.288).

(3) Multiply by $q^{1/4}$: $q^{1/4}(q^{1/4}-q^{-3/4}) = q^{1/2}-q^{-1/2}$ and $q^{1/4}q^{-1/2} = q^{-1/4}$.

Pair with V_1:

$$q^{1/4}\,\widetilde{W}_{\mathrm{bb}}(L_+) - q^{-1/4}\,\widetilde{W}_{\mathrm{bb}}(L_-) = \big(q^{1/2}-q^{-1/2}\big)\widetilde{W}_{\mathrm{bb}}(L_0). \tag{12.291}$$

The subscript "bb" is explained in Section 12.14.16: it means the links carry the "blackboard" framing of the diagram.

Key idea: Why the coefficients are universal

The coefficients in (12.290) are the trace and determinant of σ, i.e. symmetric functions of its eigenvalues. They depend only on the representation labels on the four punctures and on k, *not* on the vectors V_2^0, V_1, and so not on the rest of the link. This is what turns "three vectors in $\mathbb{C}^2$ are dependent" into a *universal* skein relation. It also means the relation holds in *any* 3-manifold M, not only S^3.

From blackboard framing to Nash's coefficients

In L_+ and L_- the local crossing contributes ± 1 to the writhe of the diagram, relative to L_0. The framing of a Wilson line (below) multiplies $\widetilde{W}$ by $\theta := e^{2\pi i h_{1/2}} = q^{3/4}$ per unit of framing, and the blackboard framing of a diagram D has total framing equal to its writhe $w(D)$. Define the **writhe-normalised** quantity

$$X(D) := \theta^{-w(D)}\,\widetilde{W}_{\mathrm{bb}}(D),$$

which is independent of the diagram. Then $w(L_\pm) = w(L_0) \pm 1$ and (12.291) becomes

$$\begin{aligned} 0 &\overset{(1)}{=} q^{1/4}\theta^{w_0+1}X(L_+) - q^{-1/4}\theta^{w_0-1}X(L_-) - (q^{1/2}-q^{-1/2})\theta^{w_0}X(L_0) \\ &\overset{(2)}{=} q\,X(L_+) - q^{-1}X(L_-) - (q^{1/2}-q^{-1/2})X(L_0). \end{aligned} \tag{12.292}$$

(1) Substitute $\widetilde{W}_{\mathrm{bb}}(D) = \theta^{w(D)}X(D)$, with $w_0 = w(L_0)$.
(2) Divide by θ^{w_0} and use $q^{1/4}\theta = q^{1/4}q^{3/4} = q$.

Compare Nash's coefficients (12.135),

$$\begin{aligned} \alpha^+ &= -\exp\!\left[\frac{2\pi i}{k+2}\right] = -q, \qquad \alpha^- = \exp\!\left[-\frac{2\pi i}{k+2}\right] = q^{-1}, \\ \alpha^0 &= \exp\!\left[\frac{\pi i}{k+2}\right] - \exp\!\left[-\frac{\pi i}{k+2}\right] = q^{1/2}-q^{-1/2}. \end{aligned} \tag{12.293}$$

Then $\alpha^+X(L_+) + \alpha^-X(L_-) + \alpha^0X(L_0) = 0$ is exactly -1 times (12.292). The "inessential overall constant" Nash mentions is this -1, and the "change of framing" in his footnote 9 is our passage from $\widetilde{W}_{\mathrm{bb}}$ to X. Now introduce Nash's variable

$$t := \exp\!\left[-\frac{2\pi i}{k+2}\right] = q^{-1}, \qquad t^{1/2} := -q^{-1/2} = -e^{-\pi i/(k+2)}. \tag{12.294}$$

With this square root, $t^{1/2} - t^{-1/2} = -q^{-1/2} + q^{1/2} = \alpha^0$, and (12.292) reads

$$\boxed{\,t^{-1}X(L_+) - t\,X(L_-) = \left(t^{1/2}-t^{-1/2}\right)X(L_0).\,} \tag{12.295}$$

This is the Jones skein relation (12.279), now for the path integral.

Watch out: Nash's (12.137): which crossing is which, and which square root

Nash writes the final relation as $t\widetilde{W}(M,\{R^+\}) - t^{-1}\widetilde{W}(M,\{R^-\}) + (t^{1/2}-t^{-1/2})\widetilde{W}(M,\{R^0\}) = 0$, with t multiplying L_+. Substituting his own (12.293) and (12.294) gives $-t^{-1}X_+ + tX_- + \alpha^0X_0 = 0$, i.e. t multiplies L_-. The two versions differ by the exchange $L_+ \leftrightarrow L_-$, equivalently by replacing every link by its mirror image, or t by t^{-1}. His (12.118) has the same interchange

relative to the standard (12.279). Since the unknot is its own mirror image, none of this affects the unknot and unlink values below; it does decide whether the right-handed trefoil gets $t + t^3 - t^4$ or $t^{-1} + t^{-3} - t^{-4}$. Separately, $t^{1/2}$ must be the square root $-e^{-\pi i/(k+2)}$, *not* the principal root $e^{-\pi i/(k+2)}$, for $\alpha^0 = t^{1/2} - t^{-1/2}$ to hold and for the unknot value (12.138) to agree with the surgery value (12.158).

The same relation as a Kauffman bracket

There is a second way to read σ. Let U be the operator that projects the two exchanged strands onto their singlet and multiplies by [2]: in the s-channel basis, $U = \mathrm{diag}([2], 0)$. Pictorially U is a "cap" followed by a "cup": the two strands annihilate into the vacuum and are recreated, and $U^2 = [2]\,U$ because the closed loop in the middle is an unknot, worth [2]. Then

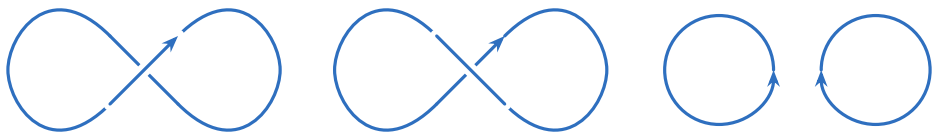
$$\sigma \overset{(1)}{=} q^{1/4}\,\mathrm{id} - q^{-1/4}\,U, \tag{12.296}$$

(1) Check on the basis: on the triplet $U = 0$ and the right side is $q^{1/4} = \lambda_1$; on the singlet it is $q^{1/4} - q^{-1/4}(q^{1/2} + q^{-1/2}) = -q^{-3/4} = \lambda_0$.

In words: *a crossing equals $q^{1/4}$ times the vertical smoothing minus $q^{-1/4}$ times the horizontal smoothing.* With $A := q^{1/4}$ and $U_K := -U$ this is Kauffman's bracket relation $\langle\sigma\rangle = A\langle\,)(\,\rangle + A^{-1}\langle\asymp\rangle$ with loop value $\delta = -A^2 - A^{-2} = -[2]$, met in the discussion of knot polynomials earlier in this chapter. The standard dictionary $t = A^{-4}$ then gives $t = q^{-1}$, in agreement with (12.294). So Chern–Simons theory at level k *is* the Kauffman bracket evaluated at $A = e^{\pi i/(2(k+2))}$.

12.14.14 The unknot and the Jones polynomial

We now compute $W(S^3, \{R\})$ when $\{R\}$ is a single unknotted circle, following Nash (12.138). Draw the unknot with one crossing, a single kink (Figure 12.75). Then L_+ is the unknot, L_- is again the unknot (a kink the other way), and L_0 is two unlinked circles.



L_+: unknot L_-: unknot L_0: two circles

Figure 12.75: The skein triple for the unknot. A figure-of-eight curve with one crossing is an unknot whichever strand is on top (Reidemeister I untwists it). Smoothing the crossing according to the orientation splits it into two disjoint circles. So $L_+ = L_- = \bigcirc$ and $L_0 = \bigcirc\,\bigcirc$.

Divide the skein relation by $Z(S^3)$, so that it holds for the normalised correlators $W = \widetilde{W}/Z$, and use the unlink rule (12.278): $W(L_0) = W(\bigcirc)^2$. In Nash's form (12.137) (where $L_\pm$ are interchanged, which does not matter here because $L_+ = L_-$):

$$\begin{aligned} 0 &\overset{(1)}{=} t\,W(\bigcirc) - t^{-1}W(\bigcirc) + \big(t^{1/2} - t^{-1/2}\big)W(\bigcirc)^2 \\ &\overset{(2)}{=} W(\bigcirc)\Big[(t - t^{-1}) + \big(t^{1/2} - t^{-1/2}\big)W(\bigcirc)\Big], \\ W(\bigcirc) &\overset{(3)}{=} -\frac{t - t^{-1}}{t^{1/2} - t^{-1/2}} \overset{(4)}{=} -\big(t^{1/2} + t^{-1/2}\big) \overset{(5)}{=} q^{1/2} + q^{-1/2} = [2]_q. \end{aligned} \tag{12.297}$$

(1) The skein relation with $L_+ = L_- = \bigcirc$, $L_0 = \bigcirc\,\bigcirc$, and (12.278) with $p = 2$.

(2) Factor out $W(\bigcirc)$.
(3) $W(\bigcirc) \neq 0$ (a vanishing unknot would make every link vanish), so the bracket vanishes.
(4) $t - t^{-1} = (t^{1/2} - t^{-1/2})(t^{1/2} + t^{-1/2})$.
(5) $t^{1/2} = -q^{-1/2}$ from (12.294), so $-(t^{1/2} + t^{-1/2}) = q^{-1/2} + q^{1/2}$.

So the unknot has

$$W(\bigcirc) = [2]_q = 2\cos\frac{\pi}{k+2} \xrightarrow{k\to\infty} 2.$$

At infinite level this is the dimension of the representation: a Wilson loop in a weakly fluctuating field is $\mathrm{tr}_R(\mathrm{id}) = \dim R = 2$. The **quantum dimension** $[2]_q$ is its finite-k deformation.

For a p-component unlink, (12.278) gives Nash's (12.139):

$$W\big(S^3, \text{unlink of } p\big) = \left\{-\frac{t - t^{-1}}{t^{1/2} - t^{-1/2}}\right\}^p = [2]_q^p. \tag{12.298}$$

Dividing by one unknot factor defines the knot polynomial:

$$V_L(t) \;:=\; -\frac{t^{1/2} - t^{-1/2}}{t - t^{-1}}\, W(S^3, \{R\}) \;=\; \frac{W(S^3, \{R\})}{W(\bigcirc)}. \tag{12.299}$$

(For links with framing, W here means the writhe-normalised $X/Z(S^3)$.)

Key idea: Witten's theorem (Nash's (12.140))

$V_L(t)$ satisfies the Jones skein relation (it is W divided by a constant, and the skein relation is linear), and it takes the value $V_{\text{unlink of } p} = [2]^{p-1} = \big(-(t^{1/2} + t^{-1/2})\big)^{p-1}$ on unlinks, which is Nash's (12.83). Since the skein relation and the unlink values determine the Jones polynomial uniquely (any link can be reduced to unlinks by crossing changes and smoothings), $V_L(t)$ *is* the Jones polynomial, evaluated at $t = e^{-2\pi i/(k+2)}$. Knowing it at infinitely many roots of unity, we may "analytically continue" to all t: a Laurent polynomial is determined by its values at infinitely many points.

Worked example 12.108: The Hopf link by the skein relation

The positive Hopf link H_+ is two circles linked once, with both crossings positive. Change one crossing: the circles come apart, $L_- =$ unlink of 2. Smooth it instead: the two circles merge into one unknot, $L_0 = \bigcirc$. With $V(\bigcirc) = 1$ and $V(\bigcirc\,\bigcirc) = \delta := -(t^{1/2} + t^{-1/2})$:

$$\begin{aligned} t^{-1}V(H_+) &\overset{(1)}{=} t\,\delta + (t^{1/2} - t^{-1/2})\cdot 1 \\ &\overset{(2)}{=} -t^{3/2} - t^{1/2} + t^{1/2} - t^{-1/2} = -t^{3/2} - t^{-1/2}, \\ V(H_+) &\overset{(3)}{=} -t^{5/2} - t^{1/2}. \end{aligned}$$

(1) The skein relation (12.295) for V, solved for the L_+ term.
(2) Expand $t\delta = -t^{3/2} - t^{1/2}$.
(3) Multiply by t.

In terms of q (with $t^{1/2} = -q^{-1/2}$): $V(H_+) = q^{-1/2} + q^{-5/2}$. We will reproduce this from the modular S-matrix in Example 12.127.

Worked example 12.109: The right-handed trefoil by the skein relation

The right-handed trefoil T is the closure of the braid σ_1^3 (Figure 12.76); all three crossings are positive. Pick one. Changing it gives $\sigma_1^2\sigma_1^{-1} = \sigma_1$, whose closure is an unknot; smoothing it gives the closure of σ_1^2, the positive Hopf link. So $L_+ = T$, $L_- = \bigcirc$, $L_0 = H_+$:

$$\begin{aligned} t^{-1}V(T) &\overset{(1)}{=} t\cdot 1 + (t^{1/2} - t^{-1/2})\bigl(-t^{5/2} - t^{1/2}\bigr) \\ &\overset{(2)}{=} t - t^3 - t + t^2 + 1 = 1 + t^2 - t^3, \\ V(T) &\overset{(3)}{=} t + t^3 - t^4. \end{aligned}$$

(1) Skein relation with $V(\bigcirc) = 1$ and the Hopf value from Example 12.108.
(2) $(t^{1/2} - t^{-1/2})(-t^{5/2} - t^{1/2}) = -t^3 - t + t^2 + 1$.
(3) Multiply by t.

This is Nash's (12.76). The mirror image (left-handed trefoil) has all crossings negative and gives $V(t^{-1}) = t^{-1} + t^{-3} - t^{-4}$: the Jones polynomial detects chirality.

Try it: The figure-eight knot

In the standard 4-crossing diagram of the figure-eight knot 4_1, pick a positive crossing. Changing it unknots the knot; smoothing it gives the *negative* Hopf link, with $V(H_-) = -t^{-1/2} - t^{-5/2}$ (the mirror of Example 12.108). Find V_{4_1}.
Answer. $t^{-1}V = t + (t^{1/2} - t^{-1/2})(-t^{-1/2} - t^{-5/2}) = t - 1 + t^{-1} - t^{-2} + t^{-3}$, so $V_{4_1} = t^2 - t + 1 - t^{-1} + t^{-2}$. It is symmetric under $t \to t^{-1}$, as it must be: the figure-eight knot is isotopic to its mirror image.

12.14.15 A second route: eigenvalues and closed braids

The skein relation reduces everything to unlinks, but there is a more direct computation for links that are closures of 2-strand braids, which uses the eigenvalues themselves. Close up the braid σ^n by joining the top ends to the bottom ends (Figure 12.76). For $n = 0$ we get two unlinked circles, for $n = \pm 1$ an unknot with a kink, for $n = 2$ the Hopf link, $n = 3$ the trefoil, $n = 5$ the cinquefoil (the $(2, 5)$ torus knot). In general the closure of σ^n is the $(2, n)$ **torus link** $T(2, n)$, a knot for n odd and a two-component link for n even.

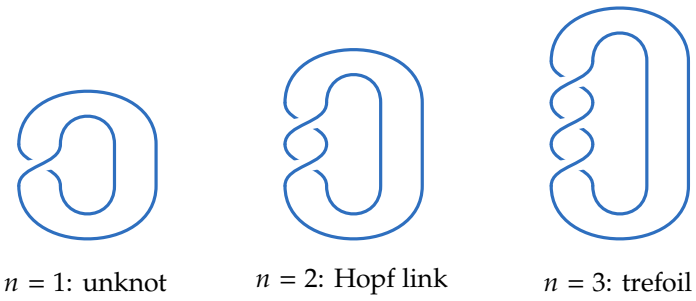


Figure 12.76: Closures of the 2-strand braids σ^n (crossings stacked vertically, closing strands on the right). $n = 1$ is an unknot with one kink, $n = 2$ the Hopf link, $n = 3$ the right-handed trefoil. The link lies inside a solid torus (a thickened circle around which both strands wind), and the braid acts diagonally on the fusion channels of the two strands.

The quantum trace

The closed braid lies inside a solid torus, the neighbourhood of the circle around which it winds. Think of the two strands as a single composite line. In the fusion channel j the pair behaves as one Wilson line of spin j running round the solid torus, and the braid σ^n merely multiplies that channel by λ_j^n. Summing over channels and closing up,

$$W_{\mathrm{bb}}\big(\widehat{\sigma^n}\big) \;=\; \sum_{j=0,1} \lambda_j^{\,n}\, W\big(\bigcirc_j\big) \;=\; \lambda_0^{\,n} + [3]\,\lambda_1^{\,n}, \tag{12.300}$$

where $W(\bigcirc_j)$ is the unknot carrying spin j. We will show in Section 12.15.6 that $W(\bigcirc_j) = S_{0,2j}/S_{00} = [2j+1]$, so $W(\bigcirc_0) = 1$ and $W(\bigcirc_1) = [3]$. This formula is a **quantum trace**: an ordinary trace $\sum_j (\dim j)\lambda_j^n$ with the dimensions replaced by quantum dimensions. At $q = 1$ it is the trace of P^n on $\mathbb{C}^2 \otimes \mathbb{C}^2$, which is 4 for n even and 2 for n odd.

Worked example 12.110: Checks: $n = 0$ and $n = 2$

For $n = 0$ the closure is two unlinked unknots:

$$W_{\mathrm{bb}}(\widehat{\sigma^0}) \overset{(1)}{=} 1 + [3] \overset{(2)}{=} [2]^2 = W(\bigcirc)^2.$$

(1) (12.300) with $n = 0$.
(2) $[2]^2 = q + 2 + q^{-1} = [3] + 1$.

In agreement with the unlink rule. For $n = 2$ (the Hopf link; the two crossings are between different components, so each component has zero self-writhe and the blackboard framing is the zero framing):

$$W_{\mathrm{bb}}(\widehat{\sigma^2}) \overset{(3)}{=} q^{-3/2} + [3]\,q^{1/2} \overset{(4)}{=} q^{-3/2} + q^{3/2} + q^{1/2} + q^{-1/2} \overset{(5)}{=} [4].$$

(3) $\lambda_0^2 = q^{-3/2}$, $\lambda_1^2 = q^{1/2}$.
(4) $[3]q^{1/2} = (q + 1 + q^{-1})q^{1/2}$.
(5) $[4] = (q^2 - q^{-2})/(q^{1/2} - q^{-1/2}) = q^{3/2} + q^{1/2} + q^{-1/2} + q^{-3/2}$.

So the zero-framed Hopf link has $W = [4]$; we will meet this again as S_{11}/S_{00}.

Worked example 12.111: All $(2, n)$ torus knots at once

Let n be odd. The diagram of $\widehat{\sigma^n}$ has writhe n, so the writhe-normalised value is $\theta^{-n} W_{\mathrm{bb}}$ with $\theta = q^{3/4}$. Write $x := q^{-1} = t$. Then

$$\begin{aligned} V_{T(2,n)} &\overset{(1)}{=} \frac{\theta^{-n}\big(\lambda_0^n + [3]\lambda_1^n\big)}{[2]} \overset{(2)}{=} \frac{-q^{-3n/2} + [3]\,q^{-n/2}}{[2]} \\ &\overset{(3)}{=} \frac{x^{1/2}\big[\,x^{n/2}(x^{-1} + 1 + x) - x^{3n/2}\big]}{1 + x} \overset{(4)}{=} x^{\frac{n-1}{2}}\,\frac{1 + x + x^2 - x^{n+1}}{1 + x}. \end{aligned}$$

(1) $V = W/W(\bigcirc)$ with $W(\bigcirc) = [2]$, after writhe normalisation.
(2) $\theta^{-n}\lambda_0^n = q^{-3n/4}(-1)^n q^{-3n/4} = -q^{-3n/2}$ for n odd; $\theta^{-n}\lambda_1^n = q^{-3n/4}q^{n/4} = q^{-n/2}$.
(3) Substitute $q = x^{-1}$; $[3] = x^{-1} + 1 + x$ and $[2] = x^{-1/2}(1 + x)$, so dividing by $[2]$ brings a factor $x^{1/2}$.
(4) Collect powers: $x^{1/2}x^{n/2}x^{-1} = x^{(n-1)/2}$.

Since $1-x^{n+1}=(1+x)(1-x+x^2-\cdots-x^n)$ for n odd, the fraction is a polynomial:

$$\frac{1+x+x^2-x^{n+1}}{1+x}=\frac{(1-x^{n+1})+x(1+x)}{1+x}=1+x^2-x^3+x^4-\cdots-x^n.$$

Hence

$$V_{T(2,3)}=t+t^3-t^4,\qquad V_{T(2,5)}=t^2+t^4-t^5+t^6-t^7,\qquad V_{T(2,n)}=t^{\frac{n-1}{2}}\left(1+t^2-t^3+\cdots-t^n\right).$$

The trefoil agrees with the skein computation of Example 12.109: two independent routes through the same Hilbert space.

12.14.16 Framing

Why Wilson lines need a framing

In the abelian theory we saw that the self-linking of a Wilson loop is ill-defined: the Gauss integral $\oint\oint$ over the same curve twice is singular at coincident points, and has to be regularised by pushing one copy off the curve along a normal vector field. The choice of push-off is a **framing**: a ribbon whose core is the knot. Different framings differ by an integer, the number of full twists of the ribbon around the core (Figure 12.77). The same singularity occurs in the non-abelian theory, so $\widetilde{W}(M,\{R\})$ is really an invariant of *framed* links.

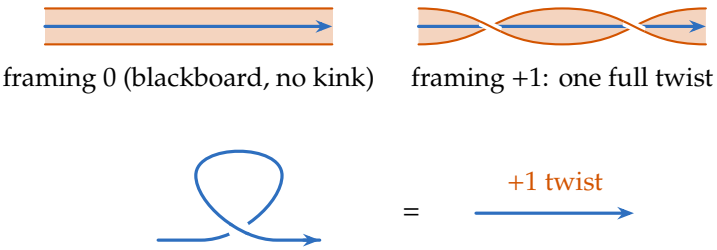

Figure 12.77: Framings. A framed knot is a thin ribbon; framings are counted by full twists. Drawing a knot on paper gives it the "blackboard" framing (the ribbon lies flat on the page); a kink in the drawing then contributes one full twist. This is why Reidemeister move I changes the blackboard framing, and why the writhe correction θ^{-w} is needed.

How the correlator changes: Nash's Dehn twist argument

Nash's argument is short and beautiful. Cut M along a surface Σ that the Wilson line C crosses at a single point P, so that $M=M_1\cup_\Sigma M_2$. Before regluing, apply to ∂M_1 a **Dehn twist** by 2π around P: rotate a small disc around P by a full turn, interpolating to the identity on an annulus around it. The knot is unchanged as a curve, but its ribbon has been twisted once around the core: the framing has changed by 1. Doing it τ times changes the framing by τ.

On the Hilbert space this twist acts as a linear map on $\mathcal{H}_{\Sigma;\ldots,R,\ldots}$. In conformal field theory a 2π rotation around the insertion point of a primary field of weight h_R is generated by $L_0-\bar{L}_0$ and, on the chiral blocks, multiplies by $e^{2\pi i h_R}$: the primary field transforms as $\phi(e^{2\pi i}z)=e^{2\pi i h_R}\phi(z)$ under the rotation, a consequence of ϕ having spin h_R. So

$$\widetilde{W}\big(M,\{R\}\big)\;\longmapsto\;e^{2\pi i\tau h_R}\,\widetilde{W}\big(M,\{R\}\big)\qquad\text{(framing of }C\text{ changed by }\tau).\tag{12.301}$$

For the fundamental representation,

$$\theta := e^{2\pi i h_{1/2}} = \exp\!\Big(2\pi i\,\frac{3/4}{k+2}\Big) = q^{3/4}.$$

In the classical limit $\theta \to 1$: framing dependence is a quantum effect, of order $1/k$, exactly like the self-linking ambiguity in the abelian theory.

Worked example 12.112: The kink: eigenvalues and conformal weights agree

Here is a strong consistency check between two pieces of CFT data that we used independently. The closure of σ^1 is an unknot with a single positive kink, i.e. an unknot with framing +1. By the framing rule its value should be $\theta\, W(\bigcirc) = q^{3/4}[2]$. By the quantum trace (12.300),

$$\begin{aligned} W_{\mathrm{bb}}(\widehat{\sigma}) &\overset{(1)}{=} \lambda_0 + [3]\lambda_1 \overset{(2)}{=} -q^{-3/4} + q^{1/4}(q+1+q^{-1}) \\ &\overset{(3)}{=} q^{5/4} + q^{1/4} \overset{(4)}{=} q^{3/4}\big(q^{1/2}+q^{-1/2}\big) = \theta\,[2]. \end{aligned}$$

(1) (12.300) with $n = 1$.
(2) The eigenvalues (12.287) and $[3] = q + 1 + q^{-1}$.
(3) The terms $-q^{-3/4}$ and $q^{1/4}q^{-1}$ cancel.
(4) Factor out $q^{3/4}$.

The braiding eigenvalues (fusion channels) and the twist (conformal weight of a single line) are consistent. Had we chosen the opposite sense of rotation for the positive crossing, we would have found $\theta^{-1}[2]$: this is the check that fixed the convention in (12.287). It is an instance of the general **ribbon** identity $\sum_j \lambda_j\,[2j+1] = \theta_{1/2}\,[2]$.

Worked example 12.113: The unknot again, in blackboard framing

In (12.297) we treated L_+ and L_- as the same unknot. In blackboard framing they are not the same framed knot: $L_\pm$ is the unknot with framing ± 1, worth $\theta^{\pm 1}W(\bigcirc)$. Nash's footnote 9 warns that the calculation "involves changing the framing". Let us redo it with (12.291), which is valid for blackboard framings:

$$\begin{aligned} 0 &\overset{(1)}{=} q^{1/4}\theta\, W(\bigcirc) - q^{-1/4}\theta^{-1}W(\bigcirc) - (q^{1/2}-q^{-1/2})W(\bigcirc)^2 \\ &\overset{(2)}{=} W(\bigcirc)\big[(q-q^{-1}) - (q^{1/2}-q^{-1/2})W(\bigcirc)\big], \\ W(\bigcirc) &\overset{(3)}{=} \frac{q-q^{-1}}{q^{1/2}-q^{-1/2}} = q^{1/2}+q^{-1/2} = [2]. \end{aligned}$$

(1) (12.291) divided by $Z(S^3)$, with the framed values of $L_\pm$ and the unlink rule for L_0 (two zero-framed circles).
(2) $q^{1/4}\theta = q$ and $q^{-1/4}\theta^{-1} = q^{-1}$.
(3) Divide by $W(\bigcirc) \neq 0$.

The same answer: the framing bookkeeping and the writhe normalisation are equivalent.

Dictionary: framed invariants and the Jones polynomial

Chern–Simons, $\mathrm{SU}(2)_k$, spin $\frac{1}{2}$	Knot theory
$q = e^{2\pi i/(k+2)}$, $t = q^{-1}$	Jones variable t; Kauffman $A = q^{1/4}$
$W(\bigcirc) = [2]_q$	loop value $-(t^{1/2} + t^{-1/2}) = -A^2 - A^{-2}$ (up to sign)
twist $\theta = e^{2\pi i h_{1/2}} = q^{3/4}$	$-A^3$ up to sign: Reidemeister I factor
$\widetilde{W}_{\mathrm{bb}}(D)/Z(S^3)$	framed invariant (Kauffman bracket)
$\theta^{-w(D)}\widetilde{W}_{\mathrm{bb}}(D)/(Z(S^3)[2])$	$V_L(t)$
zero-framed W of a link	$V_L(t)\cdot[2]\cdot\theta^{2\sum_{a<b}\mathrm{lk}(C_a,C_b)}$

Reading Nash (pp. 353–355, (12.130)–(12.140) and the framing paragraph)

Nash's route: four punctures, three configurations (12.130), three pairings (12.131), linear dependence (12.132); the braiding matrix B with $V_2^0 = BV_2^+$, $V_2^- = B^2V_2^+$ (12.133)–(12.134), with the α's (12.135) taken from Moore–Seiberg; $t = e^{-2\pi i/(k+2)}$ (12.136); the skein relation for $\widetilde{W}$ (12.137); the unknot (12.138), unlinks (12.139), and the identification with the Jones polynomial (12.140). The framing paragraph at the end of §6 says that a $2\pi\tau$ Dehn twist around P changes the framing by τ and multiplies $\widetilde{W}$ by $e^{2\pi i\tau h_R}$. We have supplied: the eigenvalues from the OPE, explicit σ and F matrices, the braid-relation check, Cayley–Hamilton as the source of the α's, the framing correction that turns our coefficients into Nash's, the Kauffman-bracket form, and the Hopf link, trefoil, figure-eight and $(2,n)$ torus knot computations.

Recap

- A crossing sits in a ball whose boundary is a 4-punctured sphere, $\dim \mathcal{H}_{S^2,4} = 2$; three vectors in $\mathbb{C}^2$ are dependent.
- The half-twist σ acts on $\mathcal{H}_{S^2,4}$ with eigenvalues $-q^{-3/4}$ (singlet) and $q^{1/4}$ (triplet), read off from the OPE; Cayley–Hamilton gives $q^{1/4}\widetilde{W}_{\mathrm{bb}}(L_+) - q^{-1/4}\widetilde{W}_{\mathrm{bb}}(L_-) = (q^{1/2} - q^{-1/2})\widetilde{W}_{\mathrm{bb}}(L_0)$.
- Writhe normalisation ($\theta = q^{3/4}$ per unit framing) turns this into the Jones skein relation with $t = q^{-1}$, $t^{1/2} = -q^{-1/2}$.
- $W(\bigcirc) = [2]$, unlinks $[2]^p$; $V_L = W/W(\bigcirc)$ is the Jones polynomial: Hopf $-t^{1/2} - t^{5/2}$, trefoil $t + t^3 - t^4$, 4_1: $t^2 - t + 1 - t^{-1} + t^{-2}$.
- Closed 2-braids: $W_{\mathrm{bb}}(\widehat{\sigma^n}) = \lambda_0^n + [3]\lambda_1^n$.
- Changing the framing by τ multiplies $\widetilde{W}$ by $e^{2\pi i\tau h_R}$ (Dehn twist around the puncture).

12.15 Surgery and the Jones polynomial

Jones defined his polynomial for links in $\mathbb{R}^3$ or S^3. The knot diagram on a sheet of paper is a picture in $\mathbb{R}^2$, and the whole combinatorial machinery of Reidemeister moves lives there. Quantum field theory does not care about the paper. The Chern–Simons path integral

$$\widetilde{W}\big(M,\{R\}\big) = \int_{\mathcal{A}/\mathcal{G}} \mathcal{D}A\; e^{iS_k[A]} \prod_a W(R_a, C_a)$$

makes sense for a link in *any* closed oriented 3-manifold M. So we immediately get a generalisation of the Jones polynomial to links in M, and, taking the empty link, a number $Z(M)$ attached to M itself. The question of this section is: *how do we compute these numbers?*

The gluing rules of Section 12.14.8 reduce the question to two things: a supply of simple pieces whose vectors we know, and a way of assembling an arbitrary M from them. The pieces will be *solid tori*; the assembly instruction is **surgery**. Topologists proved long ago that every closed oriented 3-manifold can be obtained from S^3 by removing a few solid tori and gluing them back differently. Witten used this in two ways, both of which Nash describes: to define and compute the invariants on any M, and to recompute the Jones polynomial in S^3 itself, this time from the modular S-matrix rather than from the braiding.

In this section G can be any compact simple Lie group; we return to SU(2) when we need explicit numbers.

12.15.1 Solid tori, meridians and longitudes

A **solid torus** is $D^2 \times S^1$: a disc swept round a circle, the shape of a doughnut or an inner tube including the rubber. Its boundary is the ordinary torus $T^2 = S^1 \times S^1$. On the boundary there are two distinguished kinds of closed curve (Figure 12.78).

Working definition 12.41 (meridian and longitude)

Let $V = D^2 \times S^1$, with $D^2 = \{|z| \le 1\}$ and $S^1 = \{e^{i\phi}\}$.

- A **meridian** is the curve $m = \partial D^2 \times \{\text{pt}\}$. Test: it bounds a disc *inside* V, so it is contractible in V [it can be shrunk to a point without leaving V]. Up to orientation and isotopy it is the unique such curve.
- A **longitude** is a curve $l = \{\text{pt}\} \times S^1$ on ∂V. Test: it meets the meridian exactly once, and it is homotopic in V to the core circle $\{0\} \times S^1$ [it can be deformed into the core circle without leaving V], which generates $\pi_1(V) = \mathbb{Z}$.

The meridian is intrinsic to V. The longitude is *not* unique: $l + n\,m$ (go once along, and n times around) is an equally good longitude for every $n \in \mathbb{Z}$. Choosing a longitude is exactly the same as choosing a **framing** of the core circle: the longitude is the edge of the ribbon.

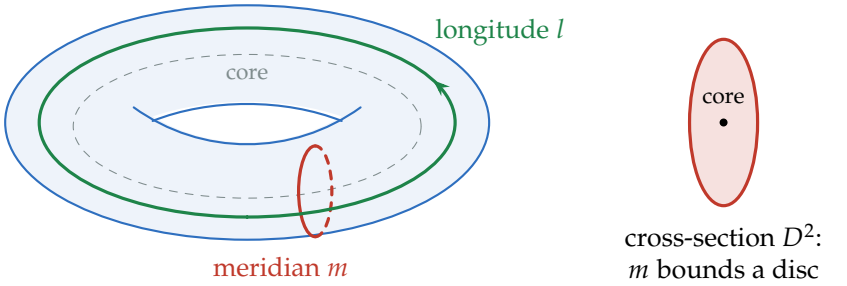

Figure 12.78: A solid torus $V = D^2 \times S^1$. The red meridian m goes once around the tube and bounds a disc inside V (right). The green longitude l goes once along the tube, parallel to the dashed core circle. In V the meridian is contractible and the longitude generates $\pi_1(V) = \mathbb{Z}$. Any closed curve on ∂V is homologous to $a\,m + b\,l$ for integers a, b.

Diffeomorphisms of the torus are $\mathrm{SL}(2,\mathbb{Z})$ matrices

Every closed curve on T^2 is homologous to $a\,m + b\,l$ with $a, b \in \mathbb{Z}$: $H_1(T^2;\mathbb{Z}) = \mathbb{Z}^2$ with basis (m, l). A diffeomorphism K of T^2 maps curves to curves, hence acts on H_1 by an integer 2×2 matrix. It has an integer inverse and it preserves orientation, so its determinant is $+1$. Conversely, every such matrix is realised by a linear map of the square $\mathbb{R}^2/\mathbb{Z}^2$, and two diffeomorphisms that induce the same matrix are isotopic. So

$$\{\text{orientation-preserving diffeos of } T^2\}/\text{isotopy} \;=\; \mathrm{SL}(2,\mathbb{Z}), \tag{12.302}$$

where

$$\mathrm{SL}(2,\mathbb{Z}) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} : \; a,b,c,d \in \mathbb{Z},\; ad - bc = 1 \right\}.$$

This is the **mapping class group** of the torus. It is the same $\mathrm{SL}(2,\mathbb{Z})$ that acts on the modular parameter τ of a torus in Chapter 5 and Chapter 11, via $\tau \mapsto (a\tau + b)/(c\tau + d)$; the matrix $-\mathbb{1}$ acts trivially on τ, which is why Nash writes $\mathrm{SL}(2,\mathbb{Z})/\{\pm\mathbb{1}\}$.

Working definition 12.42 (the generators S and T)

Acting on column vectors of coefficients in the basis (m, l):

$$S = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} : \; m \mapsto l,\; l \mapsto -m; \qquad T = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} : \; m \mapsto m,\; l \mapsto l + m.$$

S is a quarter turn of the square: it swaps the two cycles (up to a sign that keeps the orientation). T is a **Dehn twist** along the meridian: cut the torus along m, twist one side by a full turn, reglue. Curves crossing m pick up an extra copy of m. On τ they act as $S : \tau \mapsto -1/\tau$ and $T : \tau \mapsto \tau + 1$. They generate $\mathrm{SL}(2,\mathbb{Z})$ [every matrix in $\mathrm{SL}(2,\mathbb{Z})$ is a product of S, T and their inverses] and obey

$$S^2 = (ST)^3 = -\mathbb{1}, \qquad S^4 = \mathbb{1}. \tag{12.303}$$

Let us check the relations by multiplying out; this is the first place where the framing anomaly of Section 12.15.7 will later hide.

$$S^2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \overset{(1)}{=} \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix},$$

$$ST = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix}, \qquad (ST)^2 \overset{(3)}{=} \begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix},$$

$$(ST)^3 \overset{(4)}{=} \begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix}.$$

(1) Row times column: the $(1,1)$ entry is $0 \cdot 0 + (-1) \cdot 1 = -1$, and so on.
(2) $(1,1)$: 0; $(1,2)$: $0 \cdot 1 + (-1) \cdot 1 = -1$; $(2,1)$: 1; $(2,2)$: $1 + 0 \cdot \ldots = 1$.
(3) Square the previous matrix: $(1,1) = 0 \cdot 0 + (-1) \cdot 1 = -1$, $(1,2) = 0 \cdot (-1) + (-1) \cdot 1 = -1$, $(2,1) = 0 + 1 = 1$, $(2,2) = -1 + 1 = 0$.
(4) Multiply once more.

An element of order six (ST has $(ST)^6 = \mathbb{1}$) is a rotation of the hexagonal lattice; S, of order four, is a rotation of the square lattice. These are the two special tori with extra symmetry, $\tau = i$ and $\tau = e^{2\pi i/3}$ (Figure 12.79).

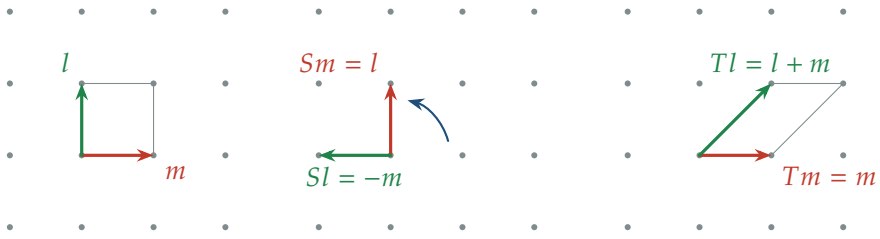

Figure 12.79: How S and T act on the lattice $H_1(T^2) = \mathbb{Z}^2$. The torus is the plane modulo this lattice; a closed curve is a lattice vector. S rotates the basis by a quarter turn, exchanging the roles of meridian and longitude. T shears it, adding one meridian to the longitude: this is the Dehn twist, and it is also a change of framing of the core by one unit. Both preserve the area of the fundamental cell (determinant 1).

Physical picture: A Dehn twist is a change of framing

Take the longitude l of a solid torus and apply T^n: it becomes $l + nm$, a curve that goes once along the tube while winding n times around it. As an edge of a ribbon around the core, this ribbon has n full twists. So *T acting on the boundary of a solid torus is the change of framing of its core circle by one unit.* This is the same Dehn twist that Nash used at the end of §6 to change the framing of a Wilson line (Section 12.14.16); now it acts on a whole solid torus.

12.15.2 Gluing two solid tori

The simplest closed 3-manifolds are made of two solid tori V_1, V_2 glued along their boundaries by a diffeomorphism $K : \partial V_2 \to \partial V_1$. The result depends only on the class of K in $\mathrm{SL}(2,\mathbb{Z})$, and in fact only on *where the meridian m_2 goes*: once the meridian disc of V_2 is glued in, what remains of V_2 is a 3-ball, and there is only one way to fill a spherical hole.

Working definition 12.43 (genus-one gluings)

Glue V_2 to V_1 so that $m_2 \mapsto q\, m_1 + p\, l_1$ with coprime integers p, q [no common factor other than ± 1, which is what lets $q\, m_1 + p\, l_1$ be drawn as one curve that does not cross itself]. Then $M = V_1 \cup_K V_2$ is

- $S^2 \times S^1$ if $m_2 \mapsto m_1$ ($p = 0$);
- S^3 if $m_2 \mapsto l_1$ ($p = 1$, $q = 0$), i.e. $K = S$;
- the **lens space** $L(p, q)$ in general.

Test: $\pi_1(M) = \mathbb{Z}_p$. Indeed $\pi_1(V_1) = \mathbb{Z}$ is generated by l_1 (the meridian m_1 is contractible in V_1), and gluing in the meridian disc of V_2 kills the class of $q\, m_1 + p\, l_1 = p\, l_1$ [that loop now bounds a disc, so it becomes the identity in $\pi_1(M)$]. So $\pi_1(M) = \mathbb{Z}/p\mathbb{Z}$.

S^3 is two solid tori

Nash's description of S^3 as two solid tori "linked together, as if belonging to a chain" becomes very concrete in complex coordinates. Write

$$S^3 = \{(z_1, z_2) \in \mathbb{C}^2 : \ |z_1|^2 + |z_2|^2 = 1\}$$

and split it according to which coordinate is larger:

$$V_1 = \{|z_1| \le |z_2|\}, \qquad V_2 = \{|z_1| \ge |z_2|\}, \qquad V_1 \cap V_2 = \{|z_1| = |z_2| = \tfrac{1}{\sqrt{2}}\} = T^2.$$

Each piece is a solid torus. In V_1 we have $|z_2|^2 \ge \frac{1}{2}$, so $z_2 \neq 0$ and $\arg z_2 \in S^1$ is a good circle coordinate, while $w = z_1/|z_2|$ ranges over the disc $|w| \le 1$:

$$V_1 \overset{(1)}{=} \left\{\left(w\, r,\ \sqrt{1 - r^2\,|w|^2}\ e^{i\phi_2}\right)\right\} \ \cong\ D^2_w \times S^1_{\phi_2},$$

(1) Here $r = |z_2|$ is fixed by $|z_1|^2 + |z_2|^2 = 1$ and $z_1 = wr$: $r^2(1 + |w|^2) = 1$. Every point of V_1 is given uniquely by (w, ϕ_2) with $|w| \le 1$.

The same with $1 \leftrightarrow 2$ for V_2. Now read off the curves on the common boundary torus $\{(e^{i\phi_1}, e^{i\phi_2})/\sqrt{2}\}$:

- the meridian of V_1 bounds the disc D^2_w, so it is the circle in which ϕ_1 varies: $m_1 = \{\phi_2 = \text{const}\}$;
- the meridian of V_2 is the circle in which ϕ_2 varies: $m_2 = \{\phi_1 = \text{const}\} = l_1$.

So the gluing identifies the meridian of each torus with the longitude of the other: $S^3 = V_1 \cup_S V_2$. The swap $(z_1, z_2) \mapsto (z_2, z_1)$ is an isometry of S^3 exchanging V_1 and V_2. Stereographic projection to $\mathbb{R}^3$ turns it into Nash's "inversion which interchanges the interior of T with its exterior": a round torus with radii (a, b) goes to one with radii (b, a). The two core circles $\{z_1 = 0\}$ and $\{z_2 = 0\}$ are the cores of the two tori, and they form a Hopf link (Figure 12.80).

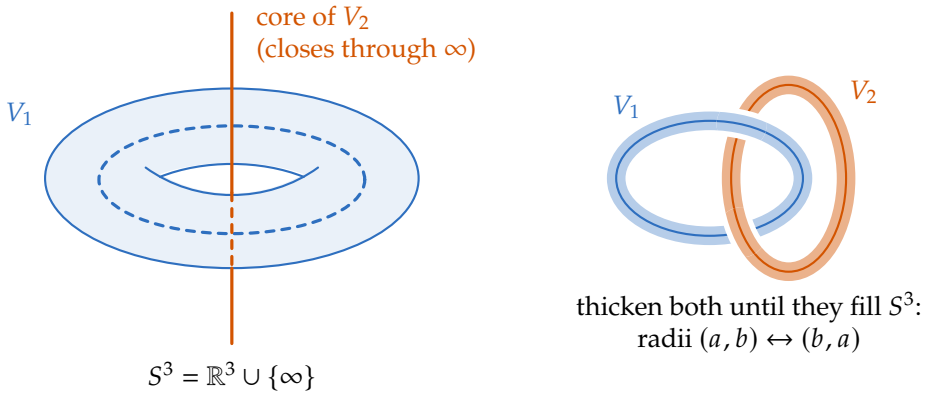

Figure 12.80: S^3 as two solid tori. Left: in $\mathbb{R}^3 \cup \{\infty\}$ the complement of a standard solid torus V_1 is another solid torus V_2 whose core (orange) runs through the hole and closes up through the point at infinity. Right: Nash's "chain" picture. The cores of V_1 and V_2 form a Hopf link; the meridian of each torus is the longitude of the other, so the gluing map is S.

$S^2 \times S^1$ is two solid tori

Take two discs D and D' and glue them along their boundary circles by the identity: the result is a sphere S^2 (two hemispheres). Multiply everything by a circle:

$$(D \times S^1) \cup_{\mathrm{id}} (D' \times S^1) = (D \cup D') \times S^1 = S^2 \times S^1.$$

Here the gluing map is the identity on $\partial D \times S^1$: it sends the meridian $\partial D'$ to the meridian ∂D (Figure 12.81). The cores $\{0\} \times S^1$ and $\{0'\} \times S^1$ are the circles $\{N\} \times S^1$ and $\{S\} \times S^1$ through the north and south poles; they are parallel and unlinked.

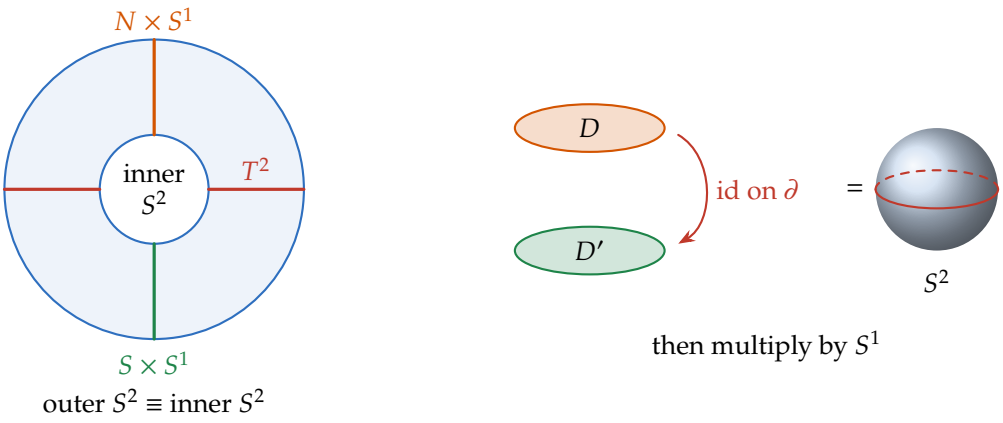

Figure 12.81: $S^2 \times S^1$ as two solid tori. Left: draw $S^2 \times S^1$ as a thick spherical shell whose inner and outer spheres are identified (the radial direction is the S^1). The red torus T^2 = equator $\times S^1$, which this slice cuts in two horizontal segments, splits it into $D \times S^1$ (containing the orange circle $N \times S^1$) and $D' \times S^1$ (containing the green circle $S \times S^1$). Right: $D \cup D'$ glued by the identity on their rims is a sphere. The gluing map on T^2 is the identity, so meridian goes to meridian.

Worked example 12.114: The fundamental groups tell the three apart

Use the test in the working definition.

- $S^2 \times S^1$: $m_2 \mapsto m_1$, which is already trivial in V_1, so nothing new is killed: $\pi_1 = \mathbb{Z}$, generated by the S^1 factor. Correct, since $\pi_1(S^2) = 0$.
- S^3: $m_2 \mapsto l_1$, the generator; $\pi_1 = \mathbb{Z}/1 = 0$.
- $L(2,1)$: $m_2 \mapsto m_1 + 2l_1$, so $\pi_1 = \mathbb{Z}_2$. This lens space is $\mathbb{RP}^3 = \mathrm{SO}(3)$: the famous fact that a 2π rotation is not contractible in SO(3) but a 4π rotation is.

More generally $L(p,1)$ is $S^3/\mathbb{Z}_p$, with $\mathbb{Z}_p$ acting by $(z_1, z_2) \mapsto (e^{2\pi i/p} z_1, e^{2\pi i/p} z_2)$, a free action; its π_1 is $\mathbb{Z}_p$ because S^3 is simply connected.

12.15.3 Dehn surgery

Now take *any* closed 3-manifold M and a knot C inside it. Nash's recipe (Figure 12.82):

(1) Thicken C into a tubular neighbourhood $M_2 \cong D^2 \times S^1$, a solid torus with core C.

(2) Cut it out. What is left, $M_1 = M \setminus \operatorname{int} M_2$, has boundary $\partial M_1 = \partial M_2 \cong T^2$.

(3) Glue M_2 back in, but first act on its boundary with a diffeomorphism K of T^2.

The result is a new closed 3-manifold,

$$M^K \;=\; M_1 \cup_{T^2} M_2^K. \tag{12.304}$$

This is Nash's (12.141). If K extends to a diffeomorphism of the solid torus (for instance if $K = T^n$, which only twists the tube), then $M^K \cong M$: nothing has changed. The interesting surgeries move the meridian.

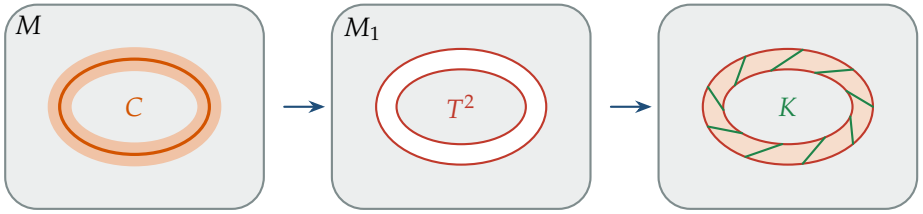

Figure 12.82: Surgery along a knot C (Nash's (12.141)). Remove a solid-torus neighbourhood of C, leaving M_1 with a torus boundary; glue the solid torus back after applying a diffeomorphism K of T^2 (the green "twisted" identification). The new manifold M^K depends only on where K sends the meridian of M_2.

Working definition 12.44 (Dehn surgery on a knot in S^3)

Let $C \subset S^3$ be a knot, μ the meridian of its neighbourhood [a small circle round C that bounds a disc pierced once by C] and λ the **Seifert longitude**: the longitude that has linking number 0 with C (the "zero framing"). For coprime integers p, q, the p/q **surgery** on C glues the solid torus back so that its meridian goes to $p\,\mu + q\,\lambda$. When $q = 1$ this is **integer surgery** with framing $n = p$: the meridian of the new solid torus goes to the framing curve $\lambda + n\mu$ of C. So an integer surgery is specified by a **framed knot**, and a surgery on a link by a **framed link**.

Worked example 12.115: Surgeries on the unknot

For the unknot $U \subset S^3$ the complement of the neighbourhood is the *other* solid torus V_1 of Figure 12.80, and its meridian is $m_1 = \lambda$ (the Seifert longitude of U bounds a disc in the complement) while its longitude is $l_1 = \mu$. The new meridian goes to

$$p\,\mu + q\,\lambda \overset{(1)}{=} q\,m_1 + p\,l_1,$$

(1) Substitute $\mu = l_1$, $\lambda = m_1$.

so, by the genus-one working definition, p/q surgery on the unknot is $L(p, q)$. Special cases:

- 0-surgery ($p = 0$, $q = 1$): $S^2 \times S^1$;
- ± 1-surgery: $L(\pm 1, 1) = S^3$; more generally $1/n$ surgery gives S^3 for every n;
- n-surgery: $L(n, 1)$, e.g. $\mathbb{RP}^3$ for $n = 2$.

The case 0 reversed is Nash's calculation: *starting* from $S^2 \times S^1$ and doing surgery with $K = S$ on the circle $\{N\} \times S^1$ produces S^3.

Worked example 12.116: The Poincaré sphere from the trefoil

Integer surgery with framing -1 on the left-handed trefoil produces the Poincaré homology sphere $\Sigma(2, 3, 5)$, the manifold met in the discussion of Floer homology earlier in this chapter. Why it has trivial homology is a one-line calculation: for integer surgery on a knot with framing n, $H_1(M) = \mathbb{Z}/n\mathbb{Z}$, because the only relation imposed on the meridian class μ

(which generates H_1 of the knot complement) is

$$0 \overset{(1)}{=} [\lambda + n\mu] \overset{(2)}{=} n[\mu] \quad \text{in } H_1,$$

(1) The new meridian disc kills the framing curve.
(2) The Seifert longitude bounds a surface in the complement, so $[\lambda] = 0$.

With $n = \pm 1$ we get $H_1 = 0$: *every* ± 1 surgery on *any* knot is a homology sphere. The trefoil is special in that π_1 is the binary icosahedral group of order 120, not trivial. We shall compute its Chern–Simons invariant in Example 12.133.

Every 3-manifold is surgery on a link

Nash quotes the key fact from surgery theory: "after enough surgery any manifold M can be transformed into S^3".

Key idea: Lickorish–Wallace theorem

Every closed, connected, oriented 3-manifold is obtained from S^3 by integer surgery on a framed link $L \subset S^3$. One may even take every component unknotted with framing ± 1.

Why it is plausible. Every closed oriented 3-manifold has a **Heegaard splitting**: it is two handlebodies of some genus g glued along their common boundary surface Σ_g by a diffeomorphism ϕ (the genus-one case is the lens spaces above). S^3 itself has a splitting of every genus. So M and S^3 differ only in the gluing map, ϕ_M versus ϕ_{S^3}. Lickorish proved that every diffeomorphism of Σ_g is, up to isotopy, a product of Dehn twists along a finite list of curves. A Dehn twist on the gluing surface can be undone by a ± 1 surgery on a copy of the twisting curve pushed slightly into the 3-manifold (cutting out a neighbourhood of the curve and regluing with $T^{\pm 1}$ relative to its surface framing is exactly a twist of the two sides against each other). So M is S^3 with finitely many ± 1 surgeries, one per Dehn twist.

When do two surgeries give the same manifold? Kirby moves

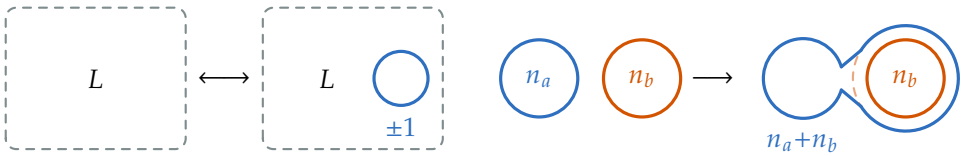
Different framed links can give the same 3-manifold. Kirby found the complete list of moves relating them (Figure 12.83).

Working definition 12.45 (Kirby moves)

Two framed links in S^3 give homeomorphic 3-manifolds if and only if they are related by a sequence of isotopies and the moves

- **K1 (blow-up/down):** add or delete an unknot with framing ± 1 [its push-off links it $+1$ or -1 times] that is unlinked from everything else;
- **K2 (handle slide):** replace a component C_a by the band sum [join the two curves by a thin band and replace the band's two short ends by its two long edges] $C_a \# _b C_b'$ of C_a with a parallel copy C_b' of another component C_b, the copy being pushed off along the framing of C_b. Framings and linking numbers change according to $n_a \mapsto n_a + n_b \pm 2\,\mathrm{lk}(C_a, C_b)$.

A **3-manifold invariant** computed from a framed link must be unchanged by both moves.



K1: add an isolated ±1 unknot K2: slide C_a over C_b

Figure 12.83: The two Kirby moves. K1: an isolated ±1-framed unknot can be added or removed (surgery on it is S^3, and taking a connected sum with S^3 changes nothing). K2: a component C_a can be band-summed with a parallel push-off (dashed) of another component C_b; the new blue component follows C_a, then runs around the push-off of C_b. For unlinked components the framing becomes $n_a + n_b$. Any 3-manifold invariant computed from a framed link must be unchanged by these moves.

Worked example 12.117: The slam-dunk: a Hopf link with framings $(n, 0)$ is S^3

Take a Hopf link $C_1 \cup C_2$ with framings n on C_1 and 0 on C_2. Surgery on C_2 alone (with framing 0) gives $S^2 \times S^1$ (Example 12.115), and in it C_1 becomes the circle $\{\text{pt}\} \times S^1$, a core of one of the two solid tori. Surgery on a core of a genus-one splitting just changes the gluing map: the new meridian goes to $\lambda_1 + n\mu_1$, which in the $S^2 \times S^1$ picture is the curve $m + n\,l$ on the splitting torus with respect to the other torus … and a curve that meets the meridian of the other torus exactly once always gives S^3 (genus one, $p = 1$). So the answer is S^3 for every n. As a Kirby calculus exercise: slide C_1 over C_2 repeatedly to reduce n to 0 or ±1, then use K1. We will check that the Chern–Simons invariant knows this (Example 12.131).

12.15.4 The surgery formula

Now bring in the quantum theory. Surgery is cutting and regluing, and in Section 12.14.8 we learned what the path integral does under cutting and regluing. Cut M along the torus $T^2 = \partial M_2$. The path integral over M_1, with its Wilson lines, is a vector V_1 in (the dual of) $\mathcal{H}_{T^2}$; the path integral over the solid torus M_2, with its Wilson lines, is a vector V_2; and

$$\widetilde{W}\big(M, \{R\}\big) = \langle V_1, V_2 \rangle.$$

When we reglue after applying K to ∂M_2, the vector V_2 is moved by the operator that represents K on $\mathcal{H}_{T^2}$ (Section 12.14.12 explained why diffeomorphisms of a surface act on its Hilbert space). We call this operator K too. Hence Nash's (12.142):

$$\widetilde{W}\big(M^K, \{R\}\big) = \big\langle V_1,\, K\,V_2 \big\rangle. \tag{12.305}$$

Everything now depends on knowing $\mathcal{H}_{T^2}$, a basis of it, and the matrices of K.

A basis of $\mathcal{H}_{T^2}$: Wilson lines along the core

From Example 12.96, $\dim \mathcal{H}_{T^2}$ equals the number of integrable representations of the loop group at level k: for SU(2) it is $k + 1$. Nash writes $\dim \mathcal{H}_{T^2} = n + 1$ for a general group, $n + 1$ being the number of primary fields of the WZW model. There is a natural basis:

Working definition 12.46 (the basis V_2^i)

Let $V_2^i \in \mathcal{H}_{T^2}$ be the vector given by the path integral over the solid torus M_2 with one Wilson line in the representation R_i running once along its core [the central circle $\{0\} \times S^1$]

(parallel to the boundary):

$$V_2^i = \text{(solid torus with core Wilson line } R_i\text{)}, \qquad i = 0, 1, \ldots, n.$$

R_0 is the trivial representation. For it the Wilson line is $\mathrm{tr}_{R_0} P \exp \oint A = 1$: the line is absent. So V_2^0 is the empty solid torus.

Why are these a basis? The quick argument is by counting and by the CFT dictionary. In the holomorphic picture, the path integral on the solid torus with boundary modulus τ gives a conformal block on T^2; with a line R_i along the core it gives the **character**

$$\chi_i(\tau) = \mathrm{Tr}_{\mathcal{H}_i}\, e^{2\pi i\tau(L_0 - c/24)} = e^{2\pi i\tau(h_i - c/24)}\big(\dim R_i + O(e^{2\pi i\tau})\big) \tag{12.306}$$

of the WZW representation $\mathcal{H}_i$ with highest weight R_i (Chapter 11). Characters with different h_i have different leading powers of $e^{2\pi i\tau}$, so they are linearly independent, and there are $n+1$ of them. Physically: in the Hamiltonian picture on the solid torus, the circle direction is time, the disc is space, and a line along the core is a static charge at the centre of the disc; the trace over states with that charge is the character.

Physical picture: What a vector in $\mathcal{H}_{T^2}$ "is"

A state on the boundary torus of a solid torus is the same as "what is running along the core". The vacuum V_2^0 is nothing; V_2^i is a charge R_i. The meridian of the solid torus surrounds the core, so an observer who measures the holonomy around the meridian sees the charge R_i: in the V_2^i basis, Wilson loops along the meridian are *diagonal*. Wilson loops along the longitude instead *add* charge to the core, i.e. act by fusion.

Any operator on $\mathcal{H}_{T^2}$ has a matrix in this basis. Following Nash (12.143), write

$$K\, V_2^i = K^i{}_j\, V_2^j \qquad \text{(sum over } j\text{)}. \tag{12.307}$$

Three consequences

(a) No Wilson lines. If M contains no Wilson lines at all, then $\widetilde{W}(M, \{R\}) = Z(M)$ and V_2 is the empty solid torus, $V_2 = V_2^0$ (Nash's (12.144)–(12.145)):

$$Z(M) = \langle V_1, V_2^0 \rangle. \tag{12.308}$$

Do the surgery:

$$Z(M^K) \overset{(1)}{=} \langle V_1,\, KV_2^0 \rangle \overset{(2)}{=} \langle V_1,\, K^0{}_j V_2^j \rangle \overset{(3)}{=} K^0{}_j \langle V_1, V_2^j \rangle \tag{12.309}$$

$$\overset{(4)}{=} K^0{}_j\, \widetilde{W}\big(M, R_j\big). \tag{12.310}$$

(1) The general surgery formula (12.305) with $V_2 = V_2^0$.
(2) Expand KV_2^0 in the basis, (12.307).
(3) The pairing is bilinear.
(4) $\langle V_1, V_2^j \rangle$ glues back the *original* solid torus, now containing a Wilson line R_j along its core, i.e. along the knot C (Nash's (12.147)).

Read (12.310) (Nash's (12.148)) carefully. The left side is a partition function without Wilson lines on the *new* manifold M^K. The right side is a sum of correlation functions with one Wilson line on the *old* manifold M. Surgery trades topology for Wilson lines.

(b) A Wilson line parallel to the core. If the solid torus M_2 already contains an unknotted Wilson line R_i running parallel to its boundary, then $V_2 = V_2^i$ and (Nash's (12.149))

$$\widetilde{W}(M^K, R_i) \overset{(1)}{=} \langle V_1,\, K V_2^i \rangle \overset{(2)}{=} K^i{}_j \langle V_1, V_2^j \rangle \overset{(3)}{=} K^i{}_j\, \widetilde{W}(M, R_j). \tag{12.311}$$

(1) (12.305) with $V_2 = V_2^i$.
(2) (12.307) and bilinearity.
(3) As in the previous chain.

(c) Lines in M_1 too. Nothing changes if M_1 contains Wilson lines $\{R\}$: they are part of V_1, and $\widetilde{W}(M^K, \{R\}, R_i) = K^i{}_j \widetilde{W}(M, \{R\}, R_j)$.

The matrices of S and T

To use these formulas we need $K^i{}_j$ for $K = S$ and $K = T$. The CFT supplies them, because $\mathrm{SL}(2,\mathbb{Z})$ acts on the characters (12.306) by changing the modular parameter.

Working definition 12.47 (S and T on $\mathcal{H}_{T^2}$)

$$T:\ \chi_i(\tau+1) = e^{2\pi i(h_i - c/24)}\chi_i(\tau), \qquad S:\ \chi_i(-1/\tau) = \sum_j S_{ij}\,\chi_j(\tau).$$

Here $\chi_i(\tau)$ [the vector V_2^i written as a function of the modular parameter τ of the boundary torus] is the character, h_i the conformal weight and c the central charge. So in the basis V_2^i, $T = \mathrm{diag}\big(e^{2\pi i(h_i - c/24)}\big)$ and S is the modular S-matrix. For $\mathrm{SU}(2)_k$, $h_i = \frac{i(i+2)}{4(k+2)}$, $c = \frac{3k}{k+2}$ and

$$S_{ij} = \sqrt{\frac{2}{k+2}}\,\sin\frac{(i+1)(j+1)\pi}{k+2} \qquad \text{(Nash's (12.157)).}$$

S is real, symmetric and orthogonal, $S^2 = \mathbb{1}$, and $(ST)^3 = \mathbb{1}$.

The T rule is immediate from (12.306): every term in χ_i is $e^{2\pi i\tau(h_i - c/24 + N)}$ with integer N, and shifting $\tau \to \tau + 1$ multiplies it by $e^{2\pi i(h_i - c/24)}e^{2\pi i N}$. The S rule is Poisson resummation. Here it is in the simplest case.

Worked example 12.118: The S-matrix of $\mathrm{SU}(2)_1$ by Poisson resummation

At level 1 there are two representations, $j = 0$ and $j = \frac{1}{2}$, with $h = 0$ and $h = \frac{1}{4}$, and $c = 1$. The WZW model is a free boson at the self-dual radius, and its characters are theta functions over the eigenvalues of J_3 (integers for $j = 0$, half-integers for $j = \frac{1}{2}$):

$$\chi_0(\tau) = \frac{1}{\eta(\tau)}\sum_{n\in\mathbb{Z}} e^{2\pi i\tau n^2}, \qquad \chi_{1/2}(\tau) = \frac{1}{\eta(\tau)}\sum_{n\in\mathbb{Z}} e^{2\pi i\tau(n+\frac{1}{2})^2}.$$

Take $\tau = it$ with $t > 0$, so $-1/\tau = i/t$. The Poisson summation formula $\sum_n f(n) = \sum_m \hat{f}(m)$, with $\hat{f}(m) = \int f(x)e^{-2\pi i m x}\mathrm{d}x$, applied to the Gaussian $f(x) = e^{-2\pi t x^2}$ gives

$$\sum_n e^{-2\pi t n^2} \overset{(1)}{=} \frac{1}{\sqrt{2t}}\sum_m e^{-\pi m^2/(2t)} \overset{(2)}{=} \frac{1}{\sqrt{2t}}\Big[\sum_p e^{-2\pi p^2/t} + \sum_p e^{-2\pi(p+\frac{1}{2})^2/t}\Big].$$

(1) The Fourier transform of $e^{-2\pi t x^2}$ is $(2t)^{-1/2}e^{-\pi m^2/(2t)}$ (complete the square).

(2) Split m into even $m = 2p$ and odd $m = 2p+1$: $\pi m^2/(2t) = 2\pi p^2/t$ or $2\pi(p+\frac{1}{2})^2/t$.

The bracket is $\eta(i/t)\big[\chi_0(i/t)+\chi_{1/2}(i/t)\big]$, and the Dedekind function obeys $\eta(i/t) = \sqrt{t}\,\eta(it)$. Dividing by $\eta(it)$:

$$\chi_0(it) \overset{(3)}{=} \frac{\sqrt{t}}{\sqrt{2t}}\big[\chi_0(i/t)+\chi_{1/2}(i/t)\big] = \frac{1}{\sqrt{2}}\big[\chi_0(-1/\tau)+\chi_{1/2}(-1/\tau)\big].$$

(3) Combine the previous chain with $\eta(i/t) = \sqrt{t}\,\eta(it)$.

The same computation with $n+\frac{1}{2}$ gives $\chi_{1/2} = \frac{1}{\sqrt{2}}[\chi_0 - \chi_{1/2}]$ (the half-shift produces the sign $e^{-2\pi i m/2} = (-1)^m$). Since $S^2 = \mathbb{1}$ we can invert, and

$$S = \frac{1}{\sqrt{2}}\begin{pmatrix}1 & 1\\ 1 & -1\end{pmatrix} = \sqrt{\tfrac{2}{3}}\begin{pmatrix}\sin\frac{\pi}{3} & \sin\frac{2\pi}{3}\\ \sin\frac{2\pi}{3} & \sin\frac{4\pi}{3}\end{pmatrix},$$

in agreement with the general formula at $k = 1$.

Worked example 12.119: $(ST)^3 = \mathbb{1}$ at level 1, and where the $c/24$ matters

At $k = 1$, $T = \mathrm{diag}\big(e^{-2\pi i/24}, e^{2\pi i(1/4-1/24)}\big) = e^{-i\pi/12}\,\mathrm{diag}(1,i)$. Put $N = \begin{pmatrix}1 & i\\ 1 & -i\end{pmatrix}$, so that $ST = \frac{e^{-i\pi/12}}{\sqrt{2}}N$.

$$N^2 \overset{(1)}{=} \begin{pmatrix}1+i & 1+i\\ 1-i & -1+i\end{pmatrix}, \qquad N^3 \overset{(2)}{=} \begin{pmatrix}2+2i & 0\\ 0 & 2+2i\end{pmatrix},$$

$$(ST)^3 \overset{(3)}{=} \frac{e^{-i\pi/4}}{2\sqrt{2}}(2+2i)\,\mathbb{1} \overset{(4)}{=} e^{-i\pi/4}\,e^{i\pi/4}\,\mathbb{1} = \mathbb{1}.$$

(1) Row 1: $(1\cdot 1 + i\cdot 1,\ 1\cdot i + i\cdot(-i)) = (1+i, 1+i)$; row 2: $(1-i,\ i-1)$.

(2) Row 1 times N: $(1+i)+(1+i) = 2+2i$ and $(1+i)i-(1+i)i = 0$; row 2: $(1-i)+(-1+i) = 0$ and $(1-i)i+(-1+i)(-i) = 2+2i$.

(3) Cube the prefactor: $(e^{-i\pi/12})^3/(\sqrt{2})^3$.

(4) $2+2i = 2\sqrt{2}\,e^{i\pi/4}$.

Now drop the $-c/24$, i.e. use $T' = \mathrm{diag}(e^{2\pi i h_i}) = \mathrm{diag}(1,i)$, which is what the framing rule (12.301) alone would suggest. The same computation gives $(ST')^3 = e^{i\pi/4}\mathbb{1} = e^{2\pi i c/8}\mathbb{1}$. So T' and S satisfy the $\mathrm{SL}(2,\mathbb{Z})$ relations only *up to a phase*: the action on $\mathcal{H}_{T^2}$ is a **projective** representation. The phase $e^{2\pi i c/8}$ is the germ of the framing anomaly of Section 12.15.7. (Numerically, $(ST)^3 = \mathbb{1}$ and $(ST')^3 = e^{2\pi i c/8}\mathbb{1}$ hold at every level; we checked $k = 1,2,3,4,10$.)

Worked example 12.120: Level 2 in full

At $k = 2$: labels $i = 0,1,2$ (spins $0, \frac{1}{2}, 1$), $h = (0, \frac{3}{16}, \frac{1}{2})$, $c = \frac{3}{2}$, and

$$S = \frac{1}{2}\begin{pmatrix}1 & \sqrt{2} & 1\\ \sqrt{2} & 0 & -\sqrt{2}\\ 1 & -\sqrt{2} & 1\end{pmatrix}, \qquad T = e^{-i\pi/8}\,\mathrm{diag}\big(1,\ e^{3\pi i/8},\ -1\big).$$

Check $S^2 = \mathbb{1}$ on one entry: $(S^2)_{00} = \frac{1}{4}(1+2+1) = 1$, and $(S^2)_{01} = \frac{1}{4}(\sqrt{2}+0-\sqrt{2}) = 0$. The rows of S are orthonormal. This is the modular data of the Ising model tensored with a

free fermion (Example 12.107): the zero in the middle, $S_{11} = 0$, says that the spin-$\frac{1}{2}$ Hopf link vanishes at $k = 2$, since $[4]_q = \sin(4\pi/4)/\sin(\pi/4) = 0$.

Reading Nash (pp. 355–357, (12.141)–(12.149))

Nash's §7 begins by observing that nothing in QFT restricts us to S^3, and that surgery theory lets us reach every M from S^3. He defines the surgery $M^K = M_1 \cup_{T^2} M_2^K$ (12.141), notes that K acts linearly on $\mathcal{H}_{T^2}$, so $\widetilde{W}(M^K, \{R\}) = \langle V_1, KV_2\rangle$ (12.142), introduces the basis $V_2^0, \dots, V_2^n$ of $\mathcal{H}_{T^2}$ labelled by primaries (Wilson lines along the core; V_2^0 trivial because the Wilson line collapses to the identity) and the matrix $K^i{}_j$ (12.143), and derives $Z(M^K) = K^0{}_j \widetilde{W}(M, R_j)$ (12.144)–(12.148) and $\widetilde{W}(M^K, R_i) = K^i{}_j \widetilde{W}(M, R_j)$ (12.149). Nash writes K_i^j with the indices placed differently; only the order "row = old label, column = new label" matters. We have supplied: the meridian/longitude, $\mathrm{SL}(2,\mathbb{Z})$ and its relations, the three genus-one gluings with the explicit $S^3 \subset \mathbb{C}^2$ decomposition, Dehn surgery and framings, Lickorish–Wallace and Kirby moves, the character argument for the basis, and explicit S, T matrices with the Poisson derivation and the $(ST)^3$ check.

Recap

- Curves on $\partial(D^2 \times S^1)$: the meridian bounds a disc, the longitude is defined up to framing; diffeos of T^2 form $\mathrm{SL}(2,\mathbb{Z})$, generated by S (swap) and T (Dehn twist = unit change of framing).
- Two solid tori glued with $m_2 \mapsto q m_1 + p l_1$ give $L(p, q)$; S^3 uses S, $S^2 \times S^1$ uses the identity.
- Dehn surgery: remove a solid torus around a knot, reglue with K. Every 3-manifold is integer surgery on a framed link in S^3; Kirby moves K1, K2 relate different presentations.
- Quantum surgery formula: $\widetilde{W}(M^K, \{R\}) = \langle V_1, KV_2\rangle$; basis V_2^i = core Wilson line R_i; $Z(M^K) = K^0{}_j \widetilde{W}(M, R_j)$.
- $T = \mathrm{diag}\, e^{2\pi i(h_i - c/24)}$, S = modular S-matrix; without the $c/24$ the representation is only projective.

12.15.5 The Hamiltonian formalism: partition functions are traces

To carry out a complete surgery calculation we must pick a definite M and a definite K. Before doing so Nash inserts "a useful piece of Hamiltonian formalism". It answers the question: *what is the path integral on a 3-manifold that is a surface times a circle?* The answer is short, and we will use it at every step that follows: it is a trace, and because the Hamiltonian vanishes, it counts states.

Periodic time gives a trace

Start with ordinary quantum mechanics of one particle, position x, Hamiltonian H. Feynman's formula writes the propagator as a path integral over paths with fixed ends:

$$\langle x_f|\, e^{-iHt}\, |x_i\rangle = \int_{x(0)=x_i}^{x(t)=x_f} \mathcal{D}x\; e^{iS[x]}.$$

Now make time periodic. Set $x_f = x_i$ and integrate over the common endpoint. The paths are then loops, i.e. maps of the circle $S^1 = [0,t]/(0 \sim t)$ into configuration space, and

$$\int_{\text{loops}} \mathcal{D}x\; e^{iS[x]} \overset{(1)}{=} \int \mathrm{d}x\; \langle x|\, e^{-iHt}\, |x\rangle \overset{(2)}{=} \sum_n \int \mathrm{d}x\; \langle x|e^{-iHt}|n\rangle\langle n|x\rangle$$
$$\overset{(3)}{=} \sum_n \langle n|e^{-iHt}|n\rangle \overset{(4)}{=} \operatorname{Tr}\, e^{-iHt}. \tag{12.312}$$

(1) Split the loop integral into "paths from x back to x" followed by an integral over the base point x; the inner integral is the propagator with $x_f = x_i = x$.
(2) Insert a complete set of energy eigenstates $\sum_n |n\rangle\langle n| = \mathbb{1}$.
(3) Move $\langle n|x\rangle$ to the front and use $\int \mathrm{d}x\, |x\rangle\langle x| = \mathbb{1}$.
(4) The sum of diagonal matrix elements in any basis is the trace.

The same argument works for any field theory: the space is Σ, the fields on Σ play the role of x, and the path integral over fields on $\Sigma \times S^1$ that are periodic in time is the trace of the evolution operator over $\mathcal{H}_\Sigma$. Nash writes $\operatorname{tr} \exp(i\mathcal{H}t)$; the sign in the exponent depends on which way round the circle we call "forward", and will not matter.

Worked example 12.121: The harmonic oscillator: a trace weights each state

Rotate to imaginary time, $t = -i\beta$. For the oscillator $H = \omega(a^\dagger a + \frac{1}{2})$,

$$\operatorname{Tr}\, e^{-\beta H} \overset{(1)}{=} \sum_{n=0}^{\infty} e^{-\beta\omega(n+\frac{1}{2})} \overset{(2)}{=} \frac{e^{-\beta\omega/2}}{1-e^{-\beta\omega}} \overset{(3)}{=} \frac{1}{2\sinh(\beta\omega/2)}.$$

(1) The eigenvalues of H are $\omega(n+\frac{1}{2})$, $n = 0, 1, 2, \ldots$
(2) Geometric series with ratio $e^{-\beta\omega} < 1$.
(3) Multiply numerator and denominator by $e^{\beta\omega/2}$.

This is the partition function of statistical mechanics. Each state is counted with the weight $e^{-\beta E_n}$. If *every* energy were zero, each state would be counted with weight 1 and the trace would be the number of states. That is exactly the situation in a topological theory. (With fermions and periodic boundary conditions the same trace becomes the supertrace, the Witten index of Chapter 7.)

Chern–Simons theory: $Z(\Sigma \times S^1) = \dim \mathcal{H}_\Sigma$

In Section 12.14.3 we split the Chern–Simons action on $\Sigma \times \mathbb{R}$ into a "$p\dot{q}$" term plus A_0 times the Gauss-law constraint $\tilde{F} = 0$. There is no other term. So the canonical Hamiltonian $\mathcal{H} = p\dot{q} - L$ is A_0 times the constraint, and it vanishes on the physical Hilbert space: $\mathcal{H} = 0$. (Physically: no metric, so no energy density to write down; the stress tensor $T_{\mu\nu} = \delta S/\delta g^{\mu\nu}$ vanishes identically.) Hence Nash's (12.150)–(12.151):

$$Z(\Sigma \times S^1) \overset{(1)}{=} \operatorname{Tr}_{\mathcal{H}_\Sigma} \exp(i\mathcal{H}t) \overset{(2)}{=} \operatorname{Tr}_{\mathcal{H}_\Sigma}(\mathbb{1}) \overset{(3)}{=} \dim \mathcal{H}_\Sigma. \tag{12.313}$$

(1) Periodic time gives a trace, (12.312), with space Σ and time circle of length t.
(2) $\mathcal{H} = 0$, so $\exp(i\mathcal{H}t) = \mathbb{1}$ for every t. In particular Z does not depend on the length of the circle, as a topological answer must not.
(3) The trace of the identity on a finite-dimensional space is its dimension.

We met this already as the "glue the cylinder to itself" check of Example 12.101; the Hamiltonian argument says the same thing in the language of operators.

Now let Σ carry marked points $P_1, \dots, P_n$ labelled by representations $R_1, \dots, R_n$: Wilson lines piercing Σ. As Σ evolves round the time circle, each P_a traces out the circle $\{P_a\} \times S^1$. These circles are parallel copies of the time direction. They are unknotted and unlinked from one another, each running once round the S^1 factor (Figure 12.84). The trace is now over the Hilbert space of the punctured surface, and Nash's (12.152) follows by the same chain:

$$\widetilde{W}\big(\Sigma \times S^1, \{R\}\big) = \dim \mathcal{H}_{\Sigma,\{R\}}. \tag{12.314}$$

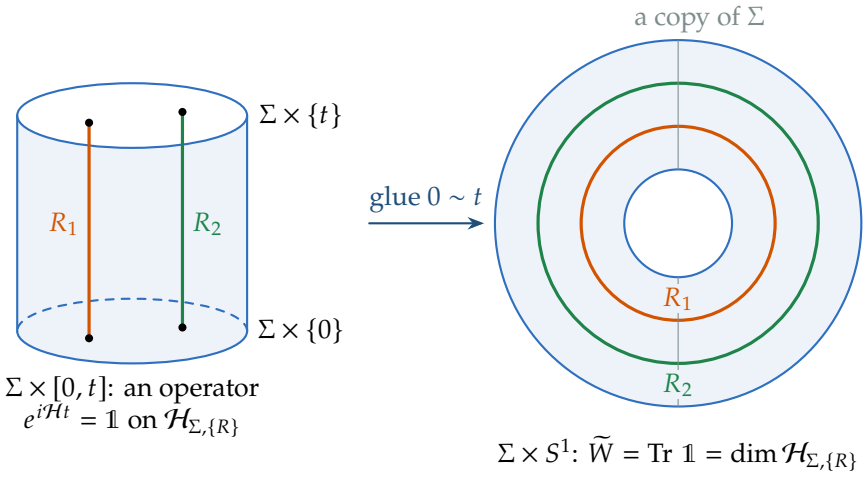


Figure 12.84: Nash's (12.150)–(12.152). Left: the path integral on $\Sigma \times [0, t]$ is the evolution operator on $\mathcal{H}_{\Sigma,\{R\}}$, which is the identity because $\mathcal{H} = 0$. Right: identifying the two ends turns time into a circle (drawn as the angular direction of the ring; each radial slice is a copy of Σ) and the operator into its trace. The marked points trace out parallel, unknotted, unlinked circles $\{P_a\} \times S^1$.

Worked example 12.122: The whole Hilbert-space dictionary of $S^2 \times S^1$

Take $\Sigma = S^2$ with 0, 1, 2 or 3 marked points. The dimensions come from the fusion rules of $\mathrm{SU}(2)_k$ (Section 12.14.6), and (12.314) turns them into correlation functions of parallel circles $\{P_a\} \times S^1$ in $S^2 \times S^1$. Label representations by Nash's $i = 2j$.

$$Z(S^2 \times S^1) \overset{(1)}{=} \dim \mathcal{H}_{S^2} = 1,$$

$$\widetilde{W}(S^2 \times S^1; R_i) \overset{(2)}{=} \dim \mathcal{H}_{S^2;R_i} = \delta_{i0},$$

$$\widetilde{W}(S^2 \times S^1; R_i, R_j) \overset{(3)}{=} \dim \mathcal{H}_{S^2;R_i,R_j} = \delta_{ij},$$

$$\widetilde{W}(S^2 \times S^1; R_i, R_j, R_m) \overset{(4)}{=} \dim \mathcal{H}_{S^2;R_i,R_j,R_m} = N_{ijm}.$$

(1) The sphere with no punctures has a one-dimensional Hilbert space (Example 12.97).
(2) A single charge on a closed sphere violates Gauss's law unless it is neutral: the only invariant in R_i is in R_0. This is Nash's (11.75), $\dim V(S^2_{R_i}) = \delta_{i0}$.
(3) Two charges: $\mathrm{Inv}(R_i \otimes R_j)$ is one-dimensional if $R_j = R_i^*$ and zero otherwise; for SU(2), $R_i^* = R_i$. This is Nash's $g_{ij} = \delta_{ij}$.

(4) Three charges: the number of ways $R_i \otimes R_j$ contains R_m at level k, the **fusion coefficient** $N_{ijm} \in \{0, 1\}$.

At $k = 2$ (spins $0, \frac{1}{2}, 1$) the non-zero fusion coefficients are those with $\frac{1}{2} \times \frac{1}{2} \ni 0, 1$, $\frac{1}{2} \times 1 \ni \frac{1}{2}$ and $1 \times 1 \ni 0$. The level-2 truncation removes $1 \times 1 \to 1$ (allowed classically), so *three parallel spin-1 circles in* $S^2 \times S^1$ *have* $\widetilde{W} = 0$ *at* $k = 2$ *but* 1 *for* $k \geq 3$. A topological amplitude sees the level.

Worked example 12.123: The three-torus and other products

With $\Sigma = T^2$, (12.313) and the pillowcase count of Example 12.96 give

$$Z(T^3) = Z(T^2 \times S^1) = \dim \mathcal{H}_{T^2} = k + 1 \qquad (\mathrm{SU}(2)_k),$$

and $Z(T^3) = k$ for $\mathrm{U}(1)_k$ (Example 12.95). For a surface of genus g, $Z(\Sigma_g \times S^1) = \sum_m S_{0m}^{2-2g}$, the Verlinde numbers of Example 12.100: $Z(\Sigma_2 \times S^1) = 10$ at $k = 2$. Note the pattern: Z of a product with a circle is always a non-negative *integer*, while $Z(S^3)$ will turn out to be an irrational number. The integrality is the fingerprint of a trace over a genuine vector space.

Twisted time: mapping tori

The space-time need not be a product globally. Let Σ evolve for one unit of time and then, before closing time up, apply a diffeomorphism K of Σ: the point $(x, 0)$ is glued to $(Kx, 1)$. The result is the **mapping torus**

$$\Sigma \times_K S^1 = \Sigma \times [0, 1] \big/ \big((x, 0) \sim (Kx, 1)\big),$$

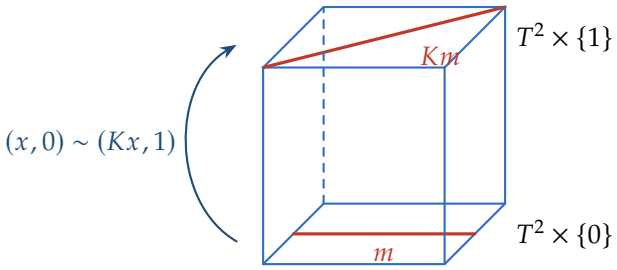
a bundle over the circle with fibre Σ and monodromy K (Figure 12.85). The path integral over $\Sigma \times [0, 1]$ is the identity operator, the twisted gluing inserts the operator $\rho(K)$ that represents K on $\mathcal{H}_\Sigma$ (Section 12.14.12), and gluing the ends takes the trace. So (Nash's (12.153))

$$Z(\Sigma \times_K S^1) \overset{(1)}{=} \mathrm{Tr}\big(\rho(K) \exp(i\mathcal{H}t)\big) \overset{(2)}{=} \mathrm{Tr}\ \rho(K). \tag{12.315}$$

(1) Evolve with $e^{i\mathcal{H}t}$, then apply $\rho(K)$, then trace: the same chain as (12.312) with $\rho(K)$ inserted before the ends are identified.

(2) $\mathcal{H} = 0$.

With $K = \mathrm{id}$ we recover $\Sigma \times S^1$ and $\mathrm{Tr}\ \mathbb{1} = \dim$.



$K = \mathbb{1}$: T^3, $\quad Z = k + 1$
$K = -\mathbb{1}$: $Z = \mathrm{Tr}\ C = k + 1$
$K = S$: $Z = \mathrm{Tr}\ S \in \mathbb{Z}$
general: $Z = \mathrm{Tr}\ \rho(K)$

Figure 12.85: A mapping torus of T^2. Take the slab $T^2 \times [0, 1]$ and glue the bottom to the top after applying K. Here K is the Dehn twist T: the horizontal meridian m on the bottom is glued to the sheared curve Km on the top. The partition function is the trace of the operator that represents K on $\mathcal{H}_{T^2}$ (Nash's (12.153)).

Worked example 12.124: Mapping tori of the torus

On $\mathcal{H}_{T^2}$ we know the operators of S and T in the basis V^i of core Wilson lines (Section 12.15.4).

- $K = -\mathbb{1}$, the involution $(x, y) \mapsto (-x, -y)$ of the square torus. It is S^2 in $\mathrm{SL}(2, \mathbb{Z})$, and it reverses the direction of the core, so it maps a Wilson line R_i to one in the conjugate representation: $\rho(-\mathbb{1}) = C$, the **charge conjugation** matrix $C_{ij} = \delta_{i,j^*}$. For SU(2) every representation is self-conjugate, $C = \mathbb{1}$, and $Z = \mathrm{Tr}\, C = k + 1$.
- $K = S$. Since $S^2 = \mathbb{1}$ on $\mathcal{H}_{T^2}$, the eigenvalues of S are ± 1, and $\mathrm{Tr}\, S = n_+ - n_-$ is an integer. At $k = 2$:

$$\mathrm{Tr}\, S \overset{(1)}{=} S_{00} + S_{11} + S_{22} \overset{(2)}{=} \tfrac{1}{2} + 0 + \tfrac{1}{2} = 1.$$

  (1) The trace is the sum of diagonal entries.
  (2) The level-2 matrix of Example 12.120.

  So S has eigenvalues $(+1, +1, -1)$ at $k = 2$. At $k = 1$, $\mathrm{Tr}\, S = \frac{1}{\sqrt{2}}(1 - 1) = 0$; at $k = 3$ the diagonal entries are $\sqrt{\frac{2}{5}} \sin \frac{\pi}{5}\, (1, 1, -1, -1)$ and again $\mathrm{Tr}\, S = 0$.

For $K = T$ the trace $\sum_i e^{2\pi i (h_i - c/24)}$ is a sum of phases whose overall phase depends on the conventions discussed in Example 12.119: it is only defined up to the framing anomaly. The traces of $\pm\mathbb{1}$ and S are free of this ambiguity.

Watch out: Which Hilbert space do the marked points live in?

In (12.314) the Wilson lines must run *parallel to the time circle*, once round. A Wilson line that winds around the S^1 twice, or that is knotted inside $\Sigma \times S^1$, is not a set of marked points on a single copy of Σ, and the formula does not apply. Likewise, a Wilson loop lying inside one copy $\Sigma \times \{t_0\}$ is not a marked point at all: it is an *operator* acting on $\mathcal{H}_\Sigma$ (for example, a loop around a cycle of T^2; see Example 12.128).

12.15.6 From $S^2 \times S^1$ to S^3: the unknot from the S-matrix

We now have everything needed for Nash's showcase calculation. We take

$$M = S^2 \times S^1, \qquad K = S, \qquad M^K = S^3,$$

and use the surgery formulas (12.310) and (12.311). The inputs on $S^2 \times S^1$ are the counting results of Example 12.122; the output will be the partition function of S^3 and the value of the unknot, obtained this time with no skein relation and no braiding.

The surgery

In Section 12.15.2 we saw both manifolds as two solid tori glued together:

$$S^2 \times S^1 = (D \times S^1) \cup_{\mathrm{id}} (D' \times S^1), \qquad S^3 = (D \times S^1) \cup_S (D' \times S^1).$$

The first piece and the second piece are the same in both; only the gluing differs, by S. So: start from $S^2 \times S^1$, cut out the solid torus $M_2 = D \times S^1$ (a neighbourhood of the circle $C = \{N\} \times S^1$ through the north pole), apply S to its boundary, and glue it back. The result is S^3. This is exactly Nash's description "cutting $S^2 \times S^1$ into two solid tori and then acting with the inversion

on one of them before gluing the pieces back together". In the language of Example 12.115, it is the inverse of 0-surgery on the unknot.

Follow the other core circle, $\{S\} \times S^1$ through the south pole. It lies in $M_1 = D' \times S^1$ and is untouched by the surgery. In S^3 it is the core of one of the two Heegaard solid tori: an *unknot*. So if we place a Wilson line R_i on $\{S\} \times S^1$ before the surgery, we obtain an unknotted Wilson line R_i in S^3 after it (Figure 12.86).

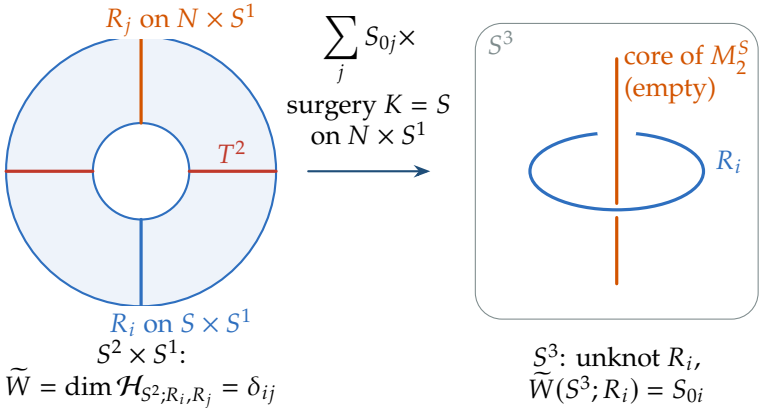


Figure 12.86: Nash's surgery from $S^2 \times S^1$ to S^3. Left: $S^2 \times S^1$ as a spherical shell with inner and outer spheres identified; the two radial segments are the circles through the poles. The red torus (the equator times S^1, seen in this slice as two horizontal segments) cuts it into two solid tori, the upper and lower halves. The surgery formula expands the reglued solid torus as a sum over Wilson lines R_j on its core (orange) with weights S_{0j}. Right: after the surgery the blue circle, which never moved, is an unknot in S^3; the orange circle is the core of the reglued torus, which carries no Wilson line. It runs through the blue unknot and closes through the point at infinity.

The calculation

Apply (12.310) with no Wilson lines, and the variant (c) of Section 12.15.4 with a line R_i in M_1. The matrix of $K = S$ in the basis V_2^j is the modular S-matrix, $K^0_{\ j} = S_{0j}$. This is Nash's (12.154):

$$Z(S^3) \overset{(1)}{=} S_{0j}\, \widetilde{W}\big(S^2 \times S^1, R_j\big) \overset{(2)}{=} S_{0j}\, \delta_{j0} = S_{00}, \tag{12.316}$$

$$\widetilde{W}(S^3, R_i) \overset{(3)}{=} S_{0j}\, \widetilde{W}\big(S^2 \times S^1, R_i, R_j\big) \overset{(4)}{=} S_{0j}\, \delta_{ij} = S_{0i}, \tag{12.317}$$

$$W(S^3, R_i) \overset{(5)}{=} \frac{\widetilde{W}(S^3, R_i)}{Z(S^3)} \overset{(6)}{=} \frac{S_{0j} \dim \mathcal{H}_{S^2;R_i,R_j}}{S_{0j} \dim \mathcal{H}_{S^2;R_j}} \overset{(7)}{=} \frac{S_{0i}}{S_{00}}. \tag{12.318}$$

(1) Nash's (12.148) with $K = S$, $M = S^2 \times S^1$, $M^K = S^3$; the sum over j puts a line R_j on the core $N \times S^1$ of the removed solid torus.
(2) The single circle $N \times S^1$ is a marked point on S^2 carried round the time circle: $\widetilde{W} = \dim \mathcal{H}_{S^2;R_j} = \delta_{j0}$ by (12.314) and (11.75).
(3) The same with the extra line R_i on $S \times S^1$, which lies in M_1 and is carried along unchanged (Nash's (12.149) in the form (c)).
(4) Two marked points: $\dim \mathcal{H}_{S^2;R_i,R_j} = g_{ij} = \delta_{ij}$ (Nash's (12.155)).
(5) Definition of the normalised correlation function.
(6) Nash's way of writing the two previous results, with the dimensions of (12.151)–(12.152) kept visible.
(7) The dimensions are δ_{ij} and δ_{j0}; the sums over j collapse. This is Nash's (12.156).

Three remarks.

- $Z(S^3)$ *is not* 1. The simplest closed 3-manifold has partition function S_{00}, which equals $\sqrt{2/(k+2)}\,\sin(\pi/(k+2))$: a small irrational number. This is why Nash always divides by $Z(M)$.
- *No knot diagram was used.* The unknot value came from the gluing of two solid tori and from counting states on a sphere.
- *A direct route.* Since $S^3 = V_1 \cup_S V_2$ with V^i the solid torus containing a core line R_i, the same numbers are $Z(S^3) = \langle V^0, SV^0\rangle = S_{00}$ and $\widetilde{W}(S^3, R_i) = \langle V^i, SV^0\rangle = S_{i0}$, using $\langle V^i, V^j\rangle = \widetilde{W}(S^2\times S^1; R_i, R_j) = \delta_{ij}$. Nash's surgery calculation is this statement read in a different order.

Where the sines come from

Nash quotes the matrix elements of S from Gepner and Witten (his (12.157)):

$$S_{ij} = \sqrt{\frac{2}{k+2}}\,\sin\!\Big(\frac{(i+1)(j+1)\pi}{k+2}\Big), \qquad i,j = 0,1,\dots,k. \tag{12.319}$$

We verified this at $k=1$ by Poisson resummation in Example 12.118. For general k the derivation has the same shape, and it is worth seeing because it explains *why* a sine appears: the sine is the Weyl character formula of SU(2).

Step 1: the Weyl character formula. The character of the spin-j representation of SU(2) on the rotation $e^{i\theta J_3}$ is

$$\chi_j(\theta) \overset{(1)}{=} \sum_{m=-j}^{j} e^{im\theta} \overset{(2)}{=} e^{-ij\theta}\,\frac{e^{i(2j+1)\theta}-1}{e^{i\theta}-1} \overset{(3)}{=} \frac{e^{i(j+\frac12)\theta}-e^{-i(j+\frac12)\theta}}{e^{i\theta/2}-e^{-i\theta/2}} \overset{(4)}{=} \frac{\sin\big((2j+1)\theta/2\big)}{\sin(\theta/2)}. \tag{12.320}$$

(1) J_3 has eigenvalues $m = -j, -j+1, \dots, j$ on the spin-j multiplet.
(2) Factor out the first term and sum the geometric series of $2j+1$ terms with ratio $e^{i\theta}$.
(3) Multiply numerator and denominator by $e^{-i\theta/2}$.
(4) $e^{ix} - e^{-ix} = 2i\sin x$ in numerator and denominator.

The numerator is an *antisymmetrised* exponential (odd under $\theta\to-\theta$, the Weyl reflection), and the denominator is the same expression for $j=0$ shifted by $\frac12$: the **Weyl vector** $\rho = \frac12$.

Step 2: the affine version. For the level-k current algebra the sum over m becomes a sum over a lattice that also contains the momentum modes of the currents. The result (the Weyl–Kac character formula) replaces each exponential by a theta function

$$\Theta_{m,K}(\tau,z) := \sum_{n\in\mathbb{Z}+\frac{m}{2K}} e^{2\pi iK\tau n^2}\,e^{2\pi iKnz}, \qquad m\in\mathbb{Z}/2K\mathbb{Z},$$

and reads, with $K = k+2$ and i Nash's label,

$$\chi_i(\tau,z) = \frac{\Theta_{i+1,k+2}(\tau,z) - \Theta_{-i-1,k+2}(\tau,z)}{\Theta_{1,2}(\tau,z) - \Theta_{-1,2}(\tau,z)}. \tag{12.321}$$

Here z is the chemical potential for J_3, which we need to keep the antisymmetric numerator from vanishing identically. We can check this formula against what we know. The leading term of $\Theta_{m,K}$ is $n = m/2K$, with $e^{2\pi i\tau\, m^2/4K}$. So the leading power of $e^{2\pi i\tau}$ in χ_i is

$$\frac{(i+1)^2}{4(k+2)} - \frac18 \overset{(1)}{=} \frac{2(i+1)^2-(k+2)}{8(k+2)} \overset{(2)}{=} \frac{i(i+2)}{4(k+2)} - \frac{k}{8(k+2)} \overset{(3)}{=} h_i - \frac{c}{24},$$

(1) Common denominator $8(k+2)$.
(2) $2(i+1)^2 - 2 = 2i(i+2)$; split off $-k/(8(k+2))$.
(3) $h_i = i(i+2)/4(k+2)$ and $c/24 = 3k/(24(k+2)) = k/(8(k+2))$.

exactly as (12.306) demands; and the coefficient of that leading power is $(y^{(i+1)/2} - y^{-(i+1)/2})/(y^{1/2} - y^{-1/2})$ with $y = e^{2\pi i z}$, the Weyl character (12.320) of spin $i/2$ with $e^{i\theta} = y$: the ground states form one copy of the representation R_i.

Step 3: modular transformation of one theta function. Poisson resummation, exactly as in Example 12.118 but with the extra linear term $2\pi i K n z$ (completing the square produces a Gaussian in z), gives

$$\Theta_{m,K}\Big(-\frac{1}{\tau}, \frac{z}{\tau}\Big) = A_K(\tau, z) \sum_{m'=0}^{2K-1} e^{-i\pi m m'/K}\, \Theta_{m',K}(\tau, z), \qquad A_K = \sqrt{\frac{-i\tau}{2K}}\, e^{i\pi K z^2/(2\tau)}.$$

The phases $e^{-i\pi m m'/K}$ are a *discrete Fourier transform* on $\mathbb{Z}/2K\mathbb{Z}$: Poisson resummation exchanges a lattice with its dual, and the finite group of cosets with its group of characters.

Step 4: antisymmetrise. Write $N_m := \Theta_{m,K} - \Theta_{-m,K}$ for the numerator.

$$N_m\Big(-\frac{1}{\tau}, \frac{z}{\tau}\Big) \overset{(1)}{=} A_K \sum_{m'=0}^{2K-1} \big(e^{-i\pi m m'/K} - e^{+i\pi m m'/K}\big)\Theta_{m',K} \overset{(2)}{=} -2i\, A_K \sum_{m'=0}^{2K-1} \sin\frac{\pi m m'}{K}\, \Theta_{m',K}$$
$$\overset{(3)}{=} -2i\, A_K \sum_{m'=1}^{K-1} \sin\frac{\pi m m'}{K}\, \big(\Theta_{m',K} - \Theta_{-m',K}\big) = -2i\, A_K \sum_{m'=1}^{K-1} \sin\frac{\pi m m'}{K}\, N_{m'}. \quad (12.322)$$

(1) Step 3 for $\Theta_{m,K}$ and for $\Theta_{-m,K}$ (replace m by $-m$).
(2) $e^{-ix} - e^{ix} = -2i \sin x$.
(3) Pair the term m' with the term $2K - m' \equiv -m'$: since $\sin(\pi m(2K - m')/K) = -\sin(\pi m m'/K)$ for integer m, the pair is $\sin(\pi m m'/K)(\Theta_{m'} - \Theta_{-m'})$. The terms $m' = 0$ and $m' = K$ have $\sin = 0$.

The denominator of (12.321) is the case $K = 2$, $m = 1$, for which the sum has the single term $m' = 1$ with $\sin(\pi/2) = 1$: it transforms into $-2iA_2$ times itself. Dividing, and writing $m = i + 1$, $m' = j + 1$:

$$\chi_i\Big(-\frac{1}{\tau}, \frac{z}{\tau}\Big) \overset{(4)}{=} \frac{A_{k+2}}{A_2} \sum_{j=0}^{k} \sin\frac{\pi(i+1)(j+1)}{k+2}\, \chi_j(\tau, z) \overset{(5)}{=} e^{i\pi k z^2/(2\tau)} \sum_{j=0}^{k} S_{ij}\, \chi_j(\tau, z).$$

(4) (12.322) for numerator ($K = k + 2$) and denominator ($K = 2$); the factors $-2i$ cancel.
(5) $A_{k+2}/A_2 = \sqrt{2/(k+2)}\, e^{i\pi(k+2-2)z^2/(2\tau)}$. The z-dependent phase disappears at $z = 0$ and is the standard anomaly factor of current-algebra characters; the number in front of the sine is Nash's normalisation.

This is (12.319). (We also checked it numerically, by summing the theta series at a random τ, for $k = 1, 2, 3, 5$.)

Worked example 12.125: S is orthogonal: the discrete sine transform

Set $K = k + 2$ and $a = i + 1$, $b = j + 1 \in \{1, \dots, K - 1\}$. Then

$$\sum_{m=1}^{K-1} \sin\frac{\pi a m}{K} \sin\frac{\pi b m}{K} \overset{(1)}{=} \frac{1}{2} \sum_{m=0}^{2K-1} \sin\frac{\pi a m}{K} \sin\frac{\pi b m}{K}$$

$$\overset{(2)}{=} \frac{1}{4}\sum_{m=0}^{2K-1}\Big[\cos\frac{\pi(a-b)m}{K} - \cos\frac{\pi(a+b)m}{K}\Big] \overset{(3)}{=} \frac{1}{4}\big[2K\,\delta_{ab} - 0\big] = \frac{K}{2}\,\delta_{ab}.$$

(1) The summand is unchanged under $m \to 2K - m$ (both sines flip sign) and vanishes at $m = 0$ and $m = K$; so the sum over a full period $0 \le m < 2K$ is twice the sum over $1 \le m \le K-1$.
(2) $\sin x \sin y = \frac{1}{2}[\cos(x-y) - \cos(x+y)]$.
(3) $\sum_{m=0}^{2K-1} e^{i\pi nm/K}$ is a sum of all powers of the $2K$-th root of unity $e^{i\pi n/K}$: it is $2K$ if $n \equiv 0 \pmod{2K}$ and 0 otherwise. Now $|a-b| < K$ vanishes only for $a = b$, and $2 \le a+b \le 2K-2$ is never $\equiv 0$.

Multiplying by the prefactor $(\sqrt{2/K})^2 = 2/K$ gives $\sum_m S_{im}S_{jm} = \delta_{ij}$: S is orthogonal. It is also symmetric, so $S^2 = SS^{\mathsf{T}} = \mathbb{1}$, the relation we used for the mapping torus of S. Taking $i = j = 0$, $\sum_m S_{0m}^2 = 1$: this was the genus-zero Verlinde count $\dim \mathcal{H}_{S^2} = 1$ of Example 12.100.

The unknot, once more

For the Jones polynomial the Wilson line carries the defining representation, $i = 1$ in Nash's labels. Then (12.318) and (12.319) give Nash's (12.158):

$$W(S^3, R_1) \overset{(1)}{=} \frac{S_{01}}{S_{00}} \overset{(2)}{=} \frac{\sin\big(2\pi/(k+2)\big)}{\sin\big(\pi/(k+2)\big)} \overset{(3)}{=} q^{1/2} + q^{-1/2} \overset{(4)}{=} -\frac{t - t^{-1}}{t^{1/2} - t^{-1/2}}. \tag{12.323}$$

(1) (12.318) with $i = 1$.
(2) (12.319): the common prefactor $\sqrt{2/(k+2)}$ cancels.
(3) $\sin 2x/\sin x = 2\cos x$ with $x = \pi/(k+2)$, and $2\cos x = q^{1/2} + q^{-1/2}$ for $q = e^{2\pi i/(k+2)}$.
(4) With $t = q^{-1}$ and $t^{1/2} = -q^{-1/2}$ (our convention (12.294)): $-(t - t^{-1})/(t^{1/2} - t^{-1/2}) = -(t^{1/2} + t^{-1/2}) = q^{-1/2} + q^{1/2}$.

This is the unknot value $[2]_q$ that the skein relation gave in (12.297): the braiding route and the surgery route agree.

Watch out: The minus sign in Nash's (12.158)

If one reads $t^{1/2}$ in (12.158) as $e^{-i\pi/(k+2)}$, the obvious square root of Nash's $t = e^{-2\pi i/(k+2)}$, then $(t - t^{-1})/(t^{1/2} - t^{-1/2}) = t^{1/2} + t^{-1/2} = 2\cos(\pi/(k+2)) > 0$ and the second line of (12.158) is *minus* the first. The two lines agree only with the other branch, $t^{1/2} = -e^{-i\pi/(k+2)} = -q^{-1/2}$, which is the branch that makes the Chern–Simons skein relation coincide with Jones's (Section 12.14.13). The sign of $t^{1/2}$ is not cosmetic: it is the sign that makes a circle count $+2$ (not -2) at $k = \infty$.

Worked example 12.126: Coloured unknots: quantum dimensions

For a Wilson line in the spin-j representation ($i = 2j$), (12.318) gives

$$W(S^3, R_i) \overset{(1)}{=} \frac{\sin\big((i+1)\pi/(k+2)\big)}{\sin\big(\pi/(k+2)\big)} \overset{(2)}{=} [i+1]_q \overset{(3)}{=} \chi_{i/2}\Big(\frac{2\pi}{k+2}\Big).$$

(1) (12.319) with $j = 0$ in both numerator and denominator.
(2) The quantum integer (12.248) with $n = i + 1$.
(3) The Weyl character (12.320) at the angle $\theta = 2\pi/(k+2)$.

This is the **quantum dimension** d_i of R_i, the number we assumed in the quantum trace (12.300): $d_0 = 1$, $d_1 = [2]$, $d_2 = [3]$. As $k \to \infty$, $d_i \to i+1 = \dim R_i$. At finite level (Figure 12.87):

- $d_i = d_{k-i}$, because $\sin((k+2-(i+1))\pi/(k+2)) = \sin((i+1)\pi/(k+2))$;
- $d_k = 1$: the top representation $j = k/2$ is a **simple current**, whose fusion with anything gives a single representation;
- the **total quantum dimension** is fixed by orthogonality:

$$\mathcal{D}^2 := \sum_{i=0}^{k} d_i^2 \overset{(4)}{=} \frac{1}{S_{00}^2} \sum_i S_{0i}^2 \overset{(5)}{=} \frac{1}{S_{00}^2} \overset{(6)}{=} \frac{k+2}{2\sin^2\bigl(\pi/(k+2)\bigr)}.$$

(4) $d_i = S_{0i}/S_{00}$.
(5) Row 0 of the orthogonal matrix S is a unit vector (Example 12.125).
(6) (12.319) with $i = j = 0$.

So $Z(S^3) = S_{00} = 1/\mathcal{D}$. At $k = 1$: $d = (1,1)$, $\mathcal{D}^2 = 2$; at $k = 2$: $d = (1,\sqrt{2},1)$, $\mathcal{D}^2 = 4$; at $k = 3$: $d = (1,\phi,\phi,1)$ with $\phi = 2\cos(\pi/5) = \frac{1+\sqrt{5}}{2}$ the golden ratio, $\mathcal{D}^2 = 2+2\phi^2 = 5+\sqrt{5} \approx 7.236$.

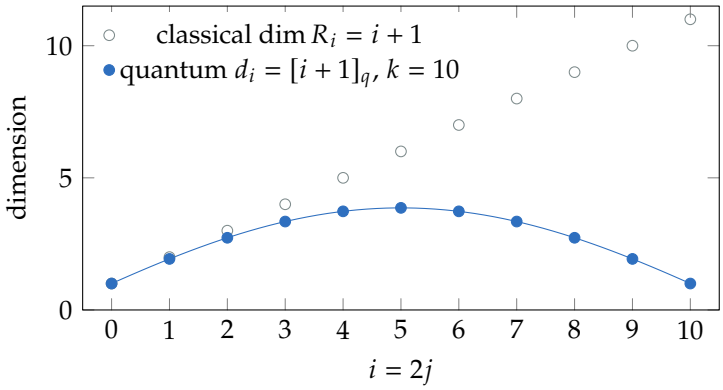

Figure 12.87: Quantum dimensions $d_i = S_{0i}/S_{00}$ at level $k = 10$ (filled) against the classical dimensions $i+1$ (open). For small spins they agree closely. Then they bend over, reach a maximum $1/\sin(\pi/12) \approx 3.86$ in the middle, and come back to $d_{10} = 1$. The quantum dimensions lie on a sine curve, because they are the Weyl character evaluated at the angle $2\pi/(k+2)$.

Physical picture: Why the character is evaluated at a special angle

The ratio $S_{ij}/S_{0j} = \chi_{i/2}\bigl(2\pi(j+1)/(k+2)\bigr)$ is a Wilson loop in the representation R_i, evaluated on a *fixed* holonomy $\exp\bigl(2\pi i\,\frac{j+1}{k+2}\,\sigma_3\bigr)$. Classically, on a solid torus containing a charge R_j on its core, the flat connection on the complement has meridian holonomy $\exp(2\pi i\,\frac{j}{k}\sigma_3)$: a charge j is a magnetic flux $\propto j/k$ in Chern–Simons theory, which ties charge to flux. The quantum corrections shift $j \to j+1$ (the Weyl vector) and $k \to k+2$ (the dual Coxeter number). The unknot, $j = 0$, sees the smallest possible flux $2\pi/(k+2)$.

The Hopf link from the S-matrix

The same splitting $S^3 = V_1 \cup_S V_2$ computes the first non-trivial link. Put a Wilson line R_i on the core of V_1 and R_j on the core of V_2. The two cores $\{z_1 = 0\}$ and $\{z_2 = 0\}$ form a Hopf link (Figure 12.80), and the gluing rule gives it at once.

Worked example 12.127: The coloured Hopf link

$$\widetilde{W}\big(S^3;\mathrm{Hopf}_{ij}\big) \overset{(1)}{=} \big\langle V^i,\, S\,V^j\big\rangle \overset{(2)}{=} \sum_m S_{jm}\big\langle V^i, V^m\big\rangle \overset{(3)}{=} \sum_m S_{jm}\delta_{im} = S_{ij},$$

$$W\big(S^3;\mathrm{Hopf}_{ij}\big) \overset{(4)}{=} \frac{S_{ij}}{S_{00}} \overset{(5)}{=} \frac{\sin\big((i+1)(j+1)\pi/(k+2)\big)}{\sin\big(\pi/(k+2)\big)} = \big[(i+1)(j+1)\big]_q.$$

(1) The gluing formula (12.305): $V_1 = V^i$ is the solid torus with core line R_i, $V_2 = V^j$ likewise, glued by S.
(2) Expand SV^j in the basis, (12.307).
(3) $\langle V^i, V^m\rangle$ glues two solid tori by the identity: two parallel lines in $S^2 \times S^1$, i.e. δ_{im} by Example 12.122.
(4) Divide by $Z(S^3) = S_{00}$.
(5) (12.319); the prefactors cancel.

Each core is pushed off along the longitude of its own solid torus, which is the meridian of the other; that curve bounds a meridian disc disjoint from the first core, so the framing is the zero framing. Now compare with the braiding calculations of Section 12.14.15:

- spin $\frac{1}{2}$ on both, $i = j = 1$: $W = [4]_q$, the value of the zero-framed Hopf link found from the eigenvalues in Example 12.110;
- converting to the Jones polynomial with the dictionary of Section 12.14.16 (divide by one unknot [2], and by $\theta^{2\,\mathrm{lk}} = q^{3/2}$ because the zero framing is not the blackboard framing of the standard 2-crossing diagram, which has writhe 2):

$$V(H_+) \overset{(6)}{=} q^{-3/2}\,\frac{[4]}{[2]} \overset{(7)}{=} q^{-3/2}\big(q + q^{-1}\big) = q^{-1/2} + q^{-5/2},$$

  (6) Normalisation of Section 12.14.16.
  (7) $[4]/[2] = (q^2 - q^{-2})/(q - q^{-1}) = q + q^{-1}$.

  exactly the skein answer of Example 12.108;
- as $k \to \infty$, $W \to (i+1)(j+1) = \dim R_i \dim R_j$: at infinite level linked and unlinked circles cannot be told apart, as for the abelian theory at zero coupling.

At $k = 2$ the spin-$\frac{1}{2}$ Hopf link vanishes, $[4]_{q=i} = \sin\pi/\sin(\pi/4) = 0$, the zero in the middle of the level-2 S-matrix of Example 12.120.

The Verlinde formula from surgery

The S-matrix also produces the fusion rules, i.e. the dimensions of all the Hilbert spaces we have been using. The argument uses Wilson loops as *operators* on $\mathcal{H}_{T^2}$.

Worked example 12.128: Fusion coefficients from S

Let $W_i(\gamma)$ be the operator on $\mathcal{H}_{T^2}$ obtained by inserting a Wilson loop R_i along a curve γ on a copy of the boundary torus, pushed slightly into the solid torus. Act on the basis V^j (a solid torus with core line R_j).

- *Longitude l.* The loop runs parallel to the core. Push it onto the core: the two parallel lines R_i and R_j fuse into $R_i \otimes R_j = \bigoplus_m N_{ij}^{\ m} R_m$, so $W_i(l)\, V^j = \sum_m N_{ij}^{\ m} V^m$.
- *Meridian m.* The loop encircles the core once. A small ball around the loop meets the core in a line segment, so its boundary is a sphere with two punctures R_j, R_j, whose Hilbert space is one-dimensional. The loop can therefore only multiply by a number: $W_i(m)\, V^j = c_{ij} V^j$. To find c_{ij}, glue in the complementary solid torus with S: the core closes into an unknot R_j in S^3 and the meridian loop becomes a Hopf-linked unknot R_i. So $S_{ij} = c_{ij} S_{0j}$, i.e. $c_{ij} = S_{ij}/S_{0j}$.

S exchanges meridian and longitude, so $W_i(l) = S\, W_i(m)\, S^{-1}$. In components, with $S^{-1} = S$ real symmetric:

$$N_{ij}^{\ m} \overset{(1)}{=} \big(S\, W_i(m)\, S\big)_{jm} \overset{(2)}{=} \sum_l S_{jl}\, \frac{S_{il}}{S_{0l}}\, S_{lm}. \tag{12.324}$$

(1) The matrix of $W_i(l)$ in the basis V^j is $N_{ij}^{\ m}$; conjugate the diagonal matrix $W_i(m)$ by S.

(2) $W_i(m) = \mathrm{diag}_l\big(S_{il}/S_{0l}\big)$.

This is the **Verlinde formula**: the S-matrix diagonalises the fusion rules. Check at $k = 2$, with the matrix of Example 12.120 (rows $S_{1l} = \frac{\sqrt{2}}{2}(1, 0, -1)$, $S_{0l} = \frac{1}{2}(1, \sqrt{2}, 1)$, $S_{2l} = \frac{1}{2}(1, -\sqrt{2}, 1)$):

$$N_{11}^{\ 0} \overset{(3)}{=} \sum_l S_{1l}^2\, \frac{S_{0l}}{S_{0l}} = \tfrac{1}{2} + 0 + \tfrac{1}{2} = 1,$$

$$N_{11}^{\ 1} \overset{(4)}{=} \sum_l S_{1l}^2\, \frac{S_{1l}}{S_{0l}} = \tfrac{1}{2}\cdot\sqrt{2} + 0 + \tfrac{1}{2}\cdot(-\sqrt{2}) = 0,$$

$$N_{11}^{\ 2} \overset{(5)}{=} \sum_l S_{1l}^2\, \frac{S_{2l}}{S_{0l}} = \tfrac{1}{2}\cdot 1 + 0 + \tfrac{1}{2}\cdot 1 = 1.$$

(3) (12.324) with $i = j = 1$, $m = 0$; $S_{l0} = S_{0l}$.

(4) $S_{1l}/S_{0l} = (\sqrt{2},\, 0,\, -\sqrt{2})$; the middle term has $S_{11}^2 = 0$.

(5) $S_{2l}/S_{0l} = (1, -1, 1)$.

So $\frac{1}{2} \times \frac{1}{2} = 0 + 1$, and spin $\frac{1}{2}$ is not in $\frac{1}{2} \times \frac{1}{2}$ (it could not be: $\frac{1}{2} \otimes \frac{1}{2}$ contains only integer spins). Gluing pairs of pants with these coefficients gives the dimension formula (12.257) that we used from the start.

Dictionary: the S-matrix, four ways

Viewpoint	What S_{ij} is
2d CFT	modular transformation of characters, $\chi_i(-1/\tau) = \sum_j S_{ij}\chi_j(\tau)$
3d topology	gluing map of the genus-one splitting of S^3 (meridian $\leftrightarrow$ longitude)
knots	unnormalised Hopf link coloured (i, j); S_{0i} is the unknot, $S_{00} = Z(S^3)$
algebra	diagonalises fusion: $N_{ij}^{\ m} = \sum_l S_{jl}S_{il}S_{lm}/S_{0l}$

Reading Nash (pp. 357–360, (12.150)–(12.158))

Nash introduces the Hamiltonian formalism in one paragraph: $Z(\Sigma \times S^1) = \operatorname{tr}\exp(i\mathcal{H}t)$ (12.150), $\mathcal{H} = 0$ so $Z = \dim \mathcal{H}_\Sigma$ (12.151), marked points give unlinked unknotted circles with $\widetilde{W} = \dim \mathcal{H}_{\Sigma,\{R\}}$ (12.152), and a twisted product $\Sigma \times_K S^1$ has $Z = \operatorname{tr}(K)$ (12.153). He then chooses $M = S^2 \times S^1$, describes the inversion of $\mathbb{R}^3$ that swaps the inside and outside of a solid torus, identifies it with $S \in \mathrm{SL}(2,\mathbb{Z})/\{\pm\mathbb{1}\}$ from chapter 5, and obtains (12.154)–(12.156). The S-matrix (12.157) is quoted from Gepner and Witten, and (12.158) is the unknot, "in agreement with 12.138". We have added: the derivation of the trace formula; the $S^2 \times S^1$ dictionary including fusion and level truncation; mapping tori of T^2 with explicit traces; the derivation of (12.157) from the Weyl–Kac formula; orthogonality; quantum dimensions; the Hopf link; the Verlinde formula; and the branch issue in (12.158).

12.15.7 Invariants of 3-manifolds: the Reshetikhin–Turaev formula

Nash's surgery calculation used one surgery, on one very simple circle. The Lickorish–Wallace theorem of Section 12.15.3 says that *every* closed oriented 3-manifold is integer surgery on some framed link in S^3. So the question is now: *given a framed link $L \subset S^3$, what is the partition function of the manifold M_L that surgery on L produces?* If we can answer it, we have a formula for $Z(M)$ for every M, in terms of coloured link invariants in S^3, which the skein relation and the braiding already compute.

The answer was found by Witten on the physics side and by Reshetikhin and Turaev on the mathematics side (who built it rigorously from the quantum group $U_q(\mathfrak{sl}_2)$ at $q = e^{2\pi i/(k+2)}$). The result is often called the **Witten–Reshetikhin–Turaev** (WRT) invariant. We derive it in three steps: a single integer surgery is always the matrix S; many surgeries multiply; and a phase must be fixed.

Step 1: an integer surgery is always S

Let $C \subset M$ be a knot with a framing n. Its solid-torus neighbourhood M_2 has a meridian $m = \mu$ and, because of the framing, a preferred longitude $l = \lambda + n\mu$ (the edge of the ribbon; see Section 12.15.1). Integer surgery with framing n glues the new solid torus so that its meridian goes to exactly this curve l. In the basis (m, l) of ∂M_2 that is the map

$$m \mapsto l, \qquad \text{i.e.} \qquad K = S \quad (\text{possibly followed by } T^a).$$

Why "possibly followed by T^a"? Only the image of the meridian matters (Section 12.15.2), and ST^a also sends $m \mapsto l$, because T fixes m. On the Hilbert space T^a acts on the empty solid torus by the phase $e^{-2\pi i ac/24}$, since V^0 has $h_0 = 0$. So the choice of K is unique up to such phases, and we postpone them to Step 3.

Now apply Nash's surgery formula (12.310):

$$Z(M_C) \overset{(1)}{=} \langle V_1,\, S\,V^0 \rangle \overset{(2)}{=} \sum_j S_{0j} \langle V_1, V^j \rangle \overset{(3)}{=} \sum_j S_{0j}\; \widetilde{W}\big(M; C_j^{(n)}\big). \tag{12.325}$$

(1) (12.305) with $K = S$ and $V_2 = V^0$, the empty solid torus.
(2) Expand $SV^0 = \sum_j S^0{}_j V^j$ with $S^0{}_j = S_{0j}$ (Section 12.15.4).
(3) $\langle V_1, V^j \rangle$ glues back the *original* solid torus with a Wilson line R_j on its core. The core line of V^j is pushed off along the longitude l of M_2, so as a framed knot it is C with framing n; we write $C_j^{(n)}$.

So one integer surgery replaces the knot by a sum over all colours, weighted by the first row of S. This combination deserves a name.

Working definition 12.48 (the Kirby colour Ω)

The **Kirby colour** is the vector

$$\Omega := S\,V^0 = \sum_{j=0}^{k} S_{0j}\, V^j \;\in \mathcal{H}_{T^2}.$$

"Colouring a component C of a link by Ω" means: compute the coloured link invariant with C in each representation R_j, multiply by S_{0j}, and sum over j. Physically, Ω is the state on the boundary of a solid torus that is *empty* as seen from the other side of the gluing: it is the vacuum of the dual solid torus, rewritten as a superposition of all charges on the core. For $\mathrm{SU}(2)_k$, $S_{0j} = S_{00}\, d_j$ with $d_j = [j+1]_q$ the quantum dimension [$d_j = \sin\frac{(j+1)\pi}{k+2} / \sin\frac{\pi}{k+2}$, which tends to the ordinary dimension $j+1$ of R_j as $k \to \infty$] (Example 12.126), so each colour is weighted by its quantum dimension.

Worked example 12.129: The Kirby colour kills every charge that threads it

Take any link containing a strand of colour R_i, and add a small 0-framed unknot U encircling that strand once. Colour U by Ω. From Example 12.128, a meridian loop of colour R_j around a line of colour R_i multiplies the correlator by S_{ji}/S_{0i}. Summing with the Kirby weights:

$$\sum_j S_{0j}\,\frac{S_{ji}}{S_{0i}} \overset{(1)}{=} \frac{(S^2)_{0i}}{S_{0i}} \overset{(2)}{=} \frac{\delta_{0i}}{S_{0i}} = \frac{\delta_{i0}}{S_{00}}.$$

(1) Matrix multiplication: $\sum_j S_{0j} S_{ji} = (S^2)_{0i}$.
(2) $S^2 = \mathbb{1}$ for SU(2) (Example 12.125).

An Ω-coloured unknot acts as a *projector onto zero total charge* through its disc (Figure 12.88). The topology says the same thing. Surgery on a 0-framed unknot that bounds a disc meeting the strand once takes a connected sum with $S^2 \times S^1$, and the strand now pierces the sphere $S^2 \times \{\mathrm{pt}\}$ exactly once. A single charge on a closed sphere violates Gauss's law unless it is neutral, i.e. $\dim \mathcal{H}_{S^2;R_i} = \delta_{i0}$ (Nash's (11.75)). For $i = 0$ the factor $1/S_{00}$ is the connected-sum rule $Z(M\#N) = Z(M)Z(N)/Z(S^3)$ of Section 12.14.9, with $Z(S^2 \times S^1) = 1$.

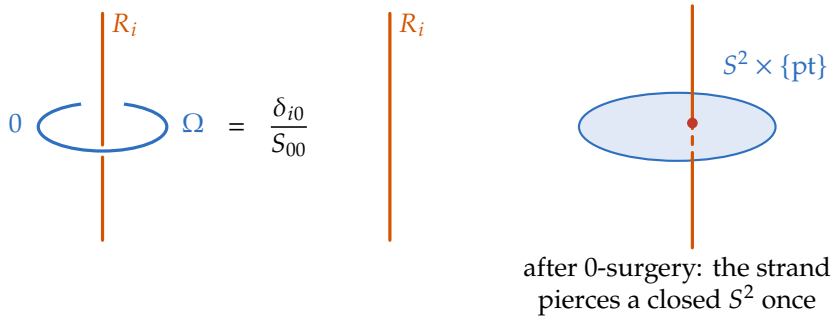

Figure 12.88: The killing property of the Kirby colour (Example 12.129). Left: a strand of colour R_i threading a 0-framed, Ω-coloured unknot equals δ_{i0}/S_{00} times the strand alone. Right: why. Surgery on that unknot creates an $S^2 \times S^1$ summand, and the strand pierces its sphere once (red dot). The sphere is drawn as the disc the unknot bounded, which the surgery caps off; it does not separate $S^2 \times S^1$, so a single piercing is possible. Gauss's law on a closed sphere allows only zero total charge.

Step 2: many components

Let $L = C_1 \cup \cdots \cup C_m$ be a framed link in S^3. The solid-torus neighbourhoods of the components are disjoint, so we can do the surgeries one at a time. After the first surgery, the other components are Wilson lines in the part M_1 that is carried along unchanged (variant (c) of Section 12.15.4). Repeating (12.325) m times,

$$Z_{\text{naive}}(M_L) = \sum_{j_1,\dots,j_m=0}^{k} \Big(\prod_{a=1}^{m} S_{0j_a}\Big)\, \widetilde{W}\big(S^3; L_{j_1\dots j_m}\big), \tag{12.326}$$

where $L_{j_1\dots j_m}$ is the link with component C_a in the representation R_{j_a} and with its framing n_a, and $\widetilde{W}$ is the *unnormalised* correlator (so the empty link gives $\widetilde{W}(S^3;\varnothing) = Z(S^3) = S_{00}$). In words: *colour every component by* Ω.

The framings and the linkings of L are collected in one matrix.

Working definition 12.49 (the linking matrix and its signature)

For a framed link $L = C_1 \cup \cdots \cup C_m$, the **linking matrix** is the symmetric integer matrix

$$B_{aa} = n_a \ (\text{framing of } C_a), \qquad B_{ab} = \text{lk}(C_a, C_b)\ (a \neq b).$$

Here n_a is the framing [the linking number of C_a with its push-off] of C_a. Its **signature** $\sigma(B)$ is the number of positive eigenvalues minus the number of negative ones. Two useful facts: $|\det B|$ is the order of $H_1(M_L)$ [the number of elements of the group $H_1(M_L;\mathbb{Z})$] when it is finite (and $\det B = 0$ exactly when $H_1(M_L)$ is infinite), and B is the intersection form of the 4-manifold W_L obtained by attaching a 2-handle [a copy of $D^2 \times D^2$, glued onto $\partial B^4 = S^3$ along a thickened C_a with framing n_a] to the 4-ball along each C_a, whose boundary is M_L.

For example, the Hopf link with framings $(n, 0)$ has $B = \left(\begin{smallmatrix} n & 1 \\ 1 & 0 \end{smallmatrix}\right)$, with $\det B = -1$, so $H_1 = 0$. Its eigenvalues are $\frac{1}{2}\big(n \pm \sqrt{n^2+4}\big)$, one positive and one negative, and $\sigma = 0$. A single unknot with framing p has $B = (p)$ and $\sigma = \operatorname{sgn} p$.

Step 3: the Kirby test and the framing anomaly

A formula for $Z(M)$ must give the same answer for two framed links related by Kirby moves (Figure 12.83). Test (12.326) on the simplest move, K1: add an isolated unknot $U_\pm$ with framing ± 1. Surgery on it gives back S^3, and a connected sum with S^3 does nothing, so Z should not change. What does (12.326) say? An isolated component factorises by the connected-sum rule of Section 12.14.9: $\widetilde{W}(L \sqcup U_j^{(\pm 1)}) = \widetilde{W}(L)\,\widetilde{W}(U_j^{(\pm 1)})/S_{00}$. The framing rule (12.301) gives $\widetilde{W}(U_j^{(\pm 1)}) = \theta_j^{\pm 1} S_{0j}$ with $\theta_j := e^{2\pi i h_j}$. So adding $U_\pm$ multiplies Z_{naive} by

$$\frac{1}{S_{00}} \sum_j S_{0j}^2\, \theta_j^{\pm 1}. \tag{12.327}$$

This is a **Gauss sum**, and we can evaluate it exactly.

Worked example 12.130: The Gauss sum is a phase times S_{00}

In Example 12.119 we found that S and $T' = \mathrm{diag}(\theta_j)$ obey $(ST')^3 = e^{2\pi i c/8}\,\mathbb{1}$ rather than $\mathbb{1}$. Rearranging,

$$ST'ST'ST' = e^{2\pi i c/8}\,\mathbb{1} \overset{(1)}{=} ST'S = e^{2\pi i c/8}\,T'^{-1}S^{-1}T'^{-1} \overset{(2)}{=} e^{2\pi i c/8}\,T'^{-1}ST'^{-1}.$$

(1) Multiply on the right by $T'^{-1}S^{-1}T'^{-1}$.
(2) $S^{-1} = S$ because $S^2 = \mathbb{1}$.

Take the $(0,0)$ entry of both sides:

$$\sum_j S_{0j}\,\theta_j\,S_{j0} \overset{(3)}{=} e^{2\pi i c/8}\,\theta_0^{-1} S_{00}\,\theta_0^{-1} \overset{(4)}{=} e^{2\pi i c/8}\,S_{00}. \tag{12.328}$$

(3) T' is diagonal, so $(ST'S)_{00} = \sum_j S_{0j}\theta_j S_{j0}$ and $(T'^{-1}ST'^{-1})_{00} = \theta_0^{-1}S_{00}\theta_0^{-1}$.
(4) $h_0 = 0$, so $\theta_0 = 1$.

The complex conjugate gives $\sum_j S_{0j}^2\theta_j^{-1} = e^{-2\pi i c/8}S_{00}$. Check at $k=1$, where $S_{0j}^2 = \frac{1}{2}$, $\theta = (1, i)$ and $c = 1$: $\sum_j S_{0j}^2\theta_j = \frac{1+i}{2} = \frac{e^{i\pi/4}}{\sqrt{2}} = e^{2\pi i/8}S_{00}$. Figure 12.89 shows the sum at $k=3$ as a chain of arrows in the complex plane.

So K1 fails, but only by a phase: adding $U_\pm$ multiplies Z_{naive} by $e^{\pm 2\pi i c/8}$. The fix is to find a quantity built from the framed link that also changes by ± 1 under K1 and does not change under K2. The signature does exactly this.

- *K1.* Adding $U_\pm$ adds a block (± 1) to the linking matrix, $B \mapsto B \oplus (\pm 1)$, so $\sigma \mapsto \sigma \pm 1$.
- *K2.* Sliding C_a over C_b replaces the homology class $[C_a]$ by $[C_a] + [C_b]$. With new basis vectors $f_a = e_a + e_b$, $f_b = e_b$,

$$B'_{aa} \overset{(1)}{=} (e_a + e_b)^{\mathsf{T}} B\,(e_a + e_b) = n_a + n_b + 2\,\mathrm{lk}(C_a, C_b),$$
$$B'_{ab} \overset{(2)}{=} (e_a + e_b)^{\mathsf{T}} B\,e_b = \mathrm{lk}(C_a, C_b) + n_b.$$

(1) The framing of a band sum is the self-intersection of the sum of the classes: expand the bilinear form.
(2) The pushed-off copy of C_b links C_b exactly n_b times; this is what the framing means.

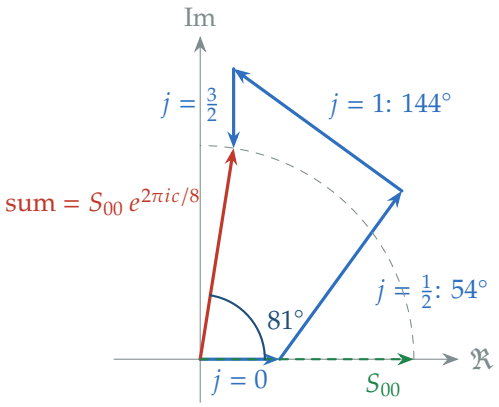

Figure 12.89: The Gauss sum $\sum_j S_{0j}^2 \theta_j$ at level $k = 3$, drawn as a chain of arrows: arrow j has length S_{0j}^2 and direction $2\pi h_j$ ($h_j = 0, \frac{3}{20}, \frac{8}{20}, \frac{15}{20}$). The red resultant has exactly the length $S_{00} \approx 0.372$ that an invariant would need (dashed circle), but it points at $81° = 2\pi c/8$ with $c = \frac{9}{5}$ instead of along the green real axis. Adding a +1-framed unknot therefore rotates the naive surgery sum by $e^{2\pi i c/8}$: this is the framing anomaly.

This is the rule quoted in Section 12.15.3. In matrix form $B' = P^{\mathsf{T}} B P$ with P an integer matrix of determinant 1. By Sylvester's law of inertia a congruence does not change the numbers of positive and negative eigenvalues: $\sigma(B') = \sigma(B)$.

Topologically: K2 is just an isotopy inside M_L (the strand of C_a is pushed across the meridian disc of the new solid torus glued in along C_b), so the path integral cannot see it, and the only thing that can go wrong is the phase. K1 changes the 4-manifold W_L by a connected sum with $\pm\mathbb{CP}^2$, which changes its signature by ± 1.

Key idea: The Witten–Reshetikhin–Turaev invariant

Let M_L be integer surgery on a framed link $L = C_1 \cup \cdots \cup C_m \subset S^3$ with linking matrix B. Then

$$Z(M_L) = e^{-2\pi i\, c\, \sigma(B)/8} \sum_{j_1,\dots,j_m=0}^{k} \Big(\prod_{a=1}^{m} S_{0 j_a}\Big)\, \widetilde{W}\big(S^3; L_{j_1 \dots j_m}\big), \qquad c = \frac{3k}{k+2}, \tag{12.329}$$

is independent of the choice of L: it is an invariant of the 3-manifold. It is normalised so that $Z(S^3) = S_{00}$ and $Z(S^2 \times S^1) = 1$.

Physical picture: The phase is a gravitational Chern–Simons counterterm

Witten found the same phase from the path integral. To define the Chern–Simons theory at the quantum level, one must choose a metric for the gauge fixing. The metric dependence cancels *except* for a phase $\exp\big(\frac{ic}{24} \cdot \frac{1}{4\pi} \int \operatorname{tr}(\omega\, \mathrm{d}\omega + \frac{2}{3}\omega^3)\big)$, with ω the Levi-Civita connection: the gravitational Chern–Simons term, with the coefficient $c/24$ that is the central charge of the boundary CFT. The phase is removed by choosing a framing of the tangent bundle of M (a **2-framing** in Atiyah's sense), and changing the framing by s units multiplies Z by $e^{2\pi i c s/24}$. Atiyah showed that every M has a *canonical* 2-framing. If $M = \partial W$, the gravitational Chern–Simons term of the canonical framing is fixed by the first Pontryagin number of W, and $\int_W p_1 = 3\sigma(W)$ (Hirzebruch). So the phase is $e^{2\pi i\,(c/24)\cdot 3\sigma(W)} = e^{2\pi i c\sigma/8}$, which is exactly the factor in (12.329). The $c/24$ of the Virasoro algebra, the $c/8$ of $(ST')^3$ and the signature of a 4-manifold are one and the same anomaly.

Worked example 12.131: Kirby checks of the formula

We check (12.329) on the surgeries of Section 12.15.3.

(i) The empty link and the 0-framed unknot. With no components the sum is $\widetilde{W}(S^3;\varnothing) = S_{00} = Z(S^3)$. With one 0-framed unknot ($\sigma = 0$),

$$Z \overset{(1)}{=} \sum_j S_{0j}\,\widetilde{W}(S^3;U_j^{(0)}) \overset{(2)}{=} \sum_j S_{0j}^2 \overset{(3)}{=} 1 = Z(S^2\times S^1).$$

(1) (12.329) with $m = 1$, $B = (0)$.
(2) The zero-framed unknot is S_{0j} (Section 12.15.6).
(3) Row 0 of the orthogonal matrix S is a unit vector.

(ii) The ±1-framed unknot. With $B = (\pm1)$, $\sigma = \pm1$:

$$Z \overset{(4)}{=} e^{\mp 2\pi i c/8}\sum_j S_{0j}^2\theta_j^{\pm1} \overset{(5)}{=} e^{\mp 2\pi i c/8}\,e^{\pm 2\pi i c/8}S_{00} = S_{00} = Z(S^3).$$

(4) (12.329); the framing ±1 contributes $\theta_j^{\pm1}$.
(5) The Gauss sum (12.328) and its conjugate.

(iii) Blowing down a linked $+1$ unknot. This is the general form of K1: a $+1$-framed unknot U that links one strand of colour R_i once. Kirby calculus says we may delete U provided we lower the framing of the strand by $\mathrm{lk}^2 = 1$. Colour U by Ω. The meridian loop R_j with framing $+1$ multiplies by $\theta_j S_{ji}/S_{0i}$, so the sum over j is

$$\sum_j S_{0j}\,\theta_j\,\frac{S_{ji}}{S_{0i}} \overset{(6)}{=} \frac{(ST'S)_{0i}}{S_{0i}} \overset{(7)}{=} \frac{e^{2\pi i c/8}\,\theta_0^{-1}S_{0i}\,\theta_i^{-1}}{S_{0i}} = e^{2\pi i c/8}\,\theta_i^{-1}.$$

(6) The sum is the $(0,i)$ entry of $ST'S$.
(7) $ST'S = e^{2\pi i c/8}T'^{-1}ST'^{-1}$ from Example 12.130.

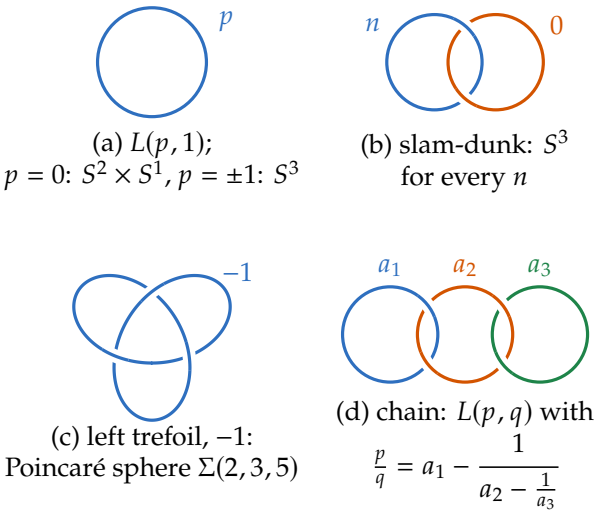
The factor θ_i^{-1} lowers the framing of the strand by one, exactly as Kirby's rule demands, and the phase $e^{2\pi i c/8}$ is cancelled by the change of signature: the linking matrix loses one positive eigenvalue. For instance the chain of two unknots with framings $(a,1)$ must give $L(a-1,1)$. We checked numerically at $k = 1,2,3$ and $a = 2,3,4$ that (12.329) gives identical values for both presentations.

(iv) The slam-dunk. For the Hopf link with framings $(n,0)$ ($\sigma = 0$), the zero-framed Hopf link is S_{ij} (Example 12.127), and the framing n on the first component gives θ_i^n:

$$Z \overset{(8)}{=} \sum_{i,j} S_{0i}S_{0j}\,S_{ij}\,\theta_i^n \overset{(9)}{=} \sum_i S_{0i}\,\theta_i^n\,(S^2)_{i0} \overset{(10)}{=} S_{00}\,\theta_0^n = S_{00}.$$

(8) (12.329) with two components.
(9) Do the sum over j first: $\sum_j S_{ij}S_{j0} = (S^2)_{i0}$.
(10) $(S^2)_{i0} = \delta_{i0}$ and $\theta_0 = 1$.

This is $Z(S^3)$ for every n, as the slam-dunk of Example 12.117 says it must be. The 0-framed component acts as the projector of Example 12.129 on the other one.



(a) $L(p,1)$; $p=0$: $S^2\times S^1$, $p=\pm1$: S^3

(b) slam-dunk: S^3 for every n

(c) left trefoil, -1: Poincaré sphere $\Sigma(2,3,5)$

(d) chain: $L(p,q)$ with $\frac{p}{q}=a_1-\dfrac{1}{a_2-\frac{1}{a_3}}$

Figure 12.90: A gallery of surgery diagrams; the numbers are the framings. (a) One unknot gives a lens space. (b) A Hopf link with framings $(n,0)$ gives S^3 (the 0-framed circle "dunks" the other). (c) -1 surgery on the left-handed trefoil gives the Poincaré homology sphere. (d) A linear chain of unknots gives the lens space whose p/q is the continued fraction of the framings (up to orientation). Every closed oriented 3-manifold has such a picture, and (12.329) turns the picture into a number.

Worked example 12.132: Lens spaces $L(p,1)$

$L(p,1)$ is p-surgery on the unknot (Example 12.115). For $p>0$, $\sigma=1$ and

$$Z\big(L(p,1)\big)=e^{-2\pi i c/8}\sum_{j=0}^{k}S_{0j}^2\,\theta_j^{\,p}. \tag{12.330}$$

(For $p<0$ take the complex conjugate: $L(-p,1)$ is $L(p,1)$ with the orientation reversed.) In operator language this is $\langle V^0, ST'^{\,p}S\,V^0\rangle$ up to the phase: the manifold is two solid tori glued by ST^pS, in agreement with Section 12.15.2.

Level 1. Here $S_{0j}^2=\frac12$, $\theta=(1,i)$, $c=1$:

$$Z\big(L(p,1)\big)\overset{(1)}{=}e^{-i\pi/4}\,\tfrac12\big(1+i^{\,p}\big),$$

(1) (12.330) with $e^{-2\pi i/8}=e^{-i\pi/4}$ and $\theta_{1/2}^{\,p}=i^p$.

which gives $\frac{1}{\sqrt2}$, 0, $-\frac{i}{\sqrt2}$, $e^{-i\pi/4}$ for $p=1,2,3,4$. The value at $p=1$ is $Z(S^3)$, as it must be.

Level 2, $p=2$ ($\mathbb{RP}^3=\mathrm{SO}(3)$). Here $S_{0j}^2=(\frac14,\frac12,\frac14)$, $h=(0,\frac{3}{16},\frac12)$, $c=\frac32$:

$$Z(\mathbb{RP}^3)\overset{(2)}{=}e^{-3\pi i/8}\Big(\tfrac14+\tfrac12e^{3\pi i/4}+\tfrac14e^{2\pi i}\Big)\overset{(3)}{=}\tfrac12\big(e^{-3\pi i/8}+e^{3\pi i/8}\big)\overset{(4)}{=}\cos\frac{3\pi}{8}\approx0.383.$$

(2) $\theta_j^2=e^{4\pi i h_j}=(1,e^{3\pi i/4},e^{2\pi i})$ and $e^{-2\pi i c/8}=e^{-3\pi i/8}$.

(3) $\frac14+\frac14=\frac12$; distribute the prefactor.

(4) $e^{ix}+e^{-ix}=2\cos x$.

A table of (12.330) (computed numerically):

	$p=1$ (S^3)	$p=2$ ($\mathbb{RP}^3$)	$p=3$	$p=4$
$k=1$	0.7071	0	$-0.7071\,i$	$0.7071-0.7071\,i$
$k=2$	0.5	0.3827	$-0.3536+0.3536\,i$	$-0.2706-0.6533\,i$
$k=3$	0.3717	0	$0.5721+0.1859\,i$	$-0.4684+0.2387\,i$

Two features are worth noticing. First, $Z(\mathbb{RP}^3) = 0$ at odd level (we checked $k = 1, 3, 5, 7, 9$). In the Gauss sum the terms with j and $\frac{k}{2} - j$ cancel in pairs. Second, Z distinguishes the lens spaces, even though at level 1 it only takes the few values allowed by an abelian Gauss sum.

The Poincaré sphere

Here is a manifold that is not a lens space. The Poincaré homology sphere $\Sigma(2, 3, 5)$ has the homology of S^3 but a fundamental group of order 120 (Example 12.116). It is -1 surgery on the left-handed trefoil (Figure 12.90(c)).

We need the *coloured* trefoil. The left trefoil is the closure of the 2-braid σ^{-3}. Colour both strands (they are one knot) by spin j. The two strands can fuse into total spin $l \in \{0, 1, \dots, 2j\}$, with $l \le k - 2j$ at level k. In each channel the half-twist σ acts by the number

$$\lambda_l^{(j)} = (-1)^{2j-l}\, e^{i\pi(h_l - 2h_j)} = (-1)^{2j-l}\, q^{\,l(l+1)/2 - j(j+1)}, \tag{12.331}$$

which is (12.287) with the same two ingredients: the exchange phase read off from the operator product (Section 12.14.12), and the symmetry sign of channel l in $j \otimes j$ (the top channel $l = 2j$ is symmetric, and the sign alternates downwards). For $j = \frac{1}{2}$ it gives $\lambda_0 = -q^{-3/4}$ and $\lambda_1 = q^{1/4}$ as before. The quantum trace (12.300) then gives the blackboard-framed value (writhe -3), and we raise the framing from -3 to -1 with θ_j^2:

$$\widetilde{W}\big(S^3; \mathrm{LT}_j^{(-1)}\big) = S_{00}\, \theta_j^2 \sum_l [2l+1]\, \big(\lambda_l^{(j)}\big)^{-3}. \tag{12.332}$$

Worked example 12.133: $Z(\Sigma(2,3,5))$ at levels 1 and 2

With $B = (-1)$, $\sigma = -1$, and (12.329) reads $Z = e^{+2\pi i c/8} \sum_j S_{0j}\, \widetilde{W}(S^3; \mathrm{LT}_j^{(-1)})$.

Level 1 ($q = e^{2\pi i/3}$, $c = 1$). The colour $j = 0$ contributes $S_{00}^2 = \frac{1}{2}$. For $j = \frac{1}{2}$ only the channel $l = 0$ survives ($l \le k - 2j = 0$), with $\lambda_0 = -q^{-3/4}$ and $[1] = 1$:

$$\theta_{1/2}^2\, \lambda_0^{-3} \overset{(1)}{=} q^{3/2} \cdot \big(-q^{9/4}\big) \overset{(2)}{=} -q^{15/4} \overset{(3)}{=} -e^{2\pi i \cdot 5/4} = -i,$$

$$Z\big(\Sigma(2,3,5)\big) \overset{(4)}{=} e^{i\pi/4}\Big(\tfrac{1}{2} + \tfrac{1}{2}(-i)\Big) \overset{(5)}{=} e^{i\pi/4}\, \frac{e^{-i\pi/4}}{\sqrt{2}} = \frac{1}{\sqrt{2}}.$$

(1) $\theta_{1/2} = q^{3/4}$ and $(-q^{-3/4})^{-3} = -q^{9/4}$.
(2) Add the exponents.
(3) $q^{15/4} = e^{2\pi i \cdot 15/12}$.
(4) $S_{0,1/2} S_{00} = \frac{1}{2}$ and $e^{2\pi i c/8} = e^{i\pi/4}$.
(5) $1 - i = \sqrt{2}\, e^{-i\pi/4}$.

So $Z(\Sigma(2,3,5)) = Z(S^3)$ at level 1. That is expected: at $k = 1$ the theory is equivalent to an abelian one, which only sees H_1, and $H_1 = 0$ for both manifolds.

Level 2 ($q = i$, $c = \frac{3}{2}$, $S_{0j} = (\frac{1}{2}, \frac{\sqrt{2}}{2}, \frac{1}{2})$, $[3]_{q=i} = 1$). Colour by colour:

- $j = 0$: $S_{00} \cdot S_{00} = \frac{1}{4}$.
- $j = \frac{1}{2}$: channels $l = 0, 1$. Using $\theta^2(\lambda_0^{-3} + [3]\lambda_1^{-3}) = q^{3/2}(-q^{9/4} + q^{-3/4}) = e^{3\pi i/8} - e^{15\pi i/8} = \sqrt{2}\, e^{5\pi i/8}$, the contribution is $\frac{\sqrt{2}}{2} \cdot \frac{1}{2} \cdot \sqrt{2}\, e^{5\pi i/8} = \frac{1}{2} e^{5\pi i/8}$.

- $j = 1$: only $l = 0$ ($l \le k - 2j = 0$), $\lambda_0^{(1)} = q^{-2} = -1$, $\theta_1^2 = q^4 = 1$: contribution $\frac{1}{2} \cdot \frac{1}{2} \cdot (-1) = -\frac{1}{4}$.

The first and last cancel, and

$$Z\big(\Sigma(2,3,5)\big) \overset{(6)}{=} e^{3\pi i/8} \cdot \tfrac{1}{2} e^{5\pi i/8} \overset{(7)}{=} -\tfrac{1}{2}.$$

(6) $e^{2\pi i c/8} = e^{3\pi i/8}$ times the sum.
(7) $e^{i\pi} = -1$.

Now $Z(S^3) = +\frac{1}{2}$ at $k = 2$: the invariant distinguishes the Poincaré sphere from S^3 although their homology is the same. At higher levels the values (numerically) are

k	3	4	5	6
$Z(\Sigma(2,3,5))$	$-0.3008 + 0.9256\,i$	0.2887	$-0.8460 + 0.0448\,i$	$0.7325\,i$
$Z(S^3)$	0.3717	0.2887	0.2319	0.1913

+1 surgery on the right-handed trefoil gives $\Sigma(2,3,5)$ with the opposite orientation, and the complex-conjugate values. The invariant is *chiral*: it knows the orientation of M.

Physical picture: What $|Z|$ remembers: flat connections

Why is $|Z(\Sigma(2,3,5))|$ so much larger than $Z(S^3)$? At large k the path integral localises on flat connections, as in the weak-coupling analysis of the previous section (Nash's (12.107)–(12.113)). S^3 has only the trivial one. The Poincaré sphere has in addition two irreducible flat SU(2) connections, coming from the two irreducible 2-dimensional representations of its fundamental group (the binary icosahedral group). Their Chern–Simons invariants are $-\frac{1}{120}$ and $-\frac{49}{120}$ mod 1. Each irreducible connection contributes a term of size $O(1)$ (no zero modes) with phase $e^{2\pi i(k+2)\,\mathrm{CS}}$, while the trivial connection contributes only $O(k^{-3/2})$. So $|Z|$ oscillates at order 1, and its oscillation frequencies are the Chern–Simons invariants. The Floer and Casson story of the start of this chapter counts the same irreducible flat connections.

Worked example 12.134: Large k: $Z(S^3)$ and the zero modes of the trivial connection

The exact answer is $Z(S^3) = S_{00} = \sqrt{2/(k+2)}\,\sin(\pi/(k+2))$. For large k,

$$Z(S^3) \overset{(1)}{=} \sqrt{\frac{2}{k+2}}\left(\frac{\pi}{k+2} - \frac{\pi^3}{6(k+2)^3} + \dots\right) \overset{(2)}{=} \sqrt{2}\,\pi\,(k+2)^{-3/2}\Big(1 + O(k^{-2})\Big).$$

(1) Taylor expansion $\sin x = x - x^3/6 + \dots$ with $x = \pi/(k+2)$.
(2) Collect the powers of $k+2$.

Numerically, at $k = 10, 50, 100$ the exact values are 0.10566, 0.011841, 0.0043122, and $\sqrt{2}\pi(k+2)^{-3/2}$ gives 0.10688, 0.011848, 0.0043129; with k in place of $k+2$ the approximation is much worse (0.1405, 0.01257, 0.00444).
The power $k^{-3/2}$ is exactly what the weak-coupling formula predicts, once the assumption stated at the end of Nash's §5 is dropped. S^3 is simply connected, so the only flat connection is $A = 0$, and at $A = 0$ the cohomology of the flat bundle is

$$H^0(S^3; \mathfrak{su}(2)) = \mathfrak{su}(2) \text{ (constant gauge transformations)}, \qquad H^1(S^3; \mathfrak{su}(2)) = 0.$$

Nash's Gaussian formula assumed all H^p vanish. Here the ghost operator $\mathrm{d}^*\mathrm{d}$ on Ω^0 has

dim $H^0 = 3$ zero modes: the constant gauge transformations that leave $A = 0$ fixed, i.e. the stabiliser SU(2). They must be removed from the determinant and replaced by the volume of the stabiliser. A Gaussian mode of the action $\frac{k}{4\pi}\int \ldots$ contributes a factor $\propto k^{-1/2}$. After the regularised count the net power is $k^{-(\dim H^0 - \dim H^1)/2} = k^{-3/2}$, and the constant in front ($\sqrt{2}\pi$) comes from the volume of SU(2) and the Ray–Singer torsion of S^3. The shift $k \to k+2$ is the one-loop correction (the η-invariant phase of Nash's (12.106)), and the exact sin is what the one-loop answer cannot see. The shift is derived in Section T5.7.2.

Watch out: Normalisations of $Z(M)$ differ by phases

Different books multiply (12.329) by different phases and powers of S_{00}. For instance, some normalise $Z(S^3) = 1$ by dividing by S_{00} once per component and once overall, and some use a different framing of M and so a different power of $e^{2\pi i c/24}$. Two things are convention-independent: $|Z(M)|$, and ratios $Z(M)/Z(M')$ computed in one convention. Reversing the orientation of M always complex-conjugates Z.

Reading Nash (pp. 355–360: the invariant $Z(M)$)

Nash states the aim of §7 in one sentence: surgery lets Witten "generalise V_L to an arbitrary 3-manifold M" and gives "a new way to compute V_L for S^3". He works out the surgery on $S^2 \times S^1$ and does not write the general formula. The general formula (12.329) and its checks are therefore additions here. They use only Nash's (12.142)–(12.149), the S-matrix (12.157), and the framing rule at the end of §6. The Kirby-colour sum is the many-component version of Nash's (12.148), and the signature phase is the framing anomaly that Nash's footnote 9 anticipates.

12.15.8 Beyond SU(2): the HOMFLY polynomial

Everything in Section 12.14 was done for $G = \mathrm{SU}(2)$ and Wilson lines in the 2-dimensional representation. Nash ends his account with one sentence: for $G \neq \mathrm{SU}(2)$ we obtain a generalisation of the Jones polynomial, and for $G = \mathrm{SU}(N)$ with N allowed to vary, a *two-variable* polynomial, which is the HOMFLY polynomial of Freyd et al. once the Wilson lines carry the defining representation. The question of this subsection is: *what exactly changes when* SU(2) *becomes* SU(N), *and why does the answer depend on two variables?*

The strategy of Section 12.14.11 was a chain of four steps:

(a) count the dimension of the Hilbert space of a sphere with four punctures: it was 2;

(b) compute the two eigenvalues of the half-twist σ from the conformal weights;

(c) a 2×2 matrix satisfies a quadratic equation, and that equation is the skein relation;

(d) correct for framing with the twist phase $\theta = e^{2\pi i h}$.

We now run exactly these four steps for SU(N). Only the numbers change.

The data of $\mathrm{SU}(N)$ at level k

Working definition 12.50 ($\mathrm{SU}(N)_k$ data needed for knots)

- *Deformation parameter.* The dual Coxeter number [the integer $h^\vee$ that is added to k in the exact formulas, $h^\vee = 2$ for SU(2)] of $\mathrm{SU}(N)$ is $h^\vee = N$, and the quantum shift is $k \to k + N$. We set

$$q := \exp\Big(\frac{2\pi i}{k+N}\Big), \qquad [n]_q = \frac{q^{n/2} - q^{-n/2}}{q^{1/2} - q^{-1/2}}.$$

  For $N = 2$ this is the q of (12.248). The quantum integer $[n]_q$ [equals $\sin\frac{n\pi}{k+N} / \sin\frac{\pi}{k+N}$, and tends to n as $k \to \infty$].

- *Integrable representations.* A representation of $\mathrm{SU}(N)$ is labelled by a Young diagram [left-justified rows of boxes, each row no longer than the one above. One box is the defining representation] with at most $N-1$ rows. At level k it is integrable if its first row has at most k boxes.

- *Conformal weights* (Sugawara, as in Chapter 11): $h_\lambda = C_2(\lambda)/(k+N)$, with the quadratic Casimir C_2 [the number with $\sum_a T^a T^a = C_2(\lambda)\,\mathbb{1}$ in the representation λ] normalised so that $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ in the fundamental representation.

- *Central charge*: $c = k(N^2-1)/(k+N)$.

We need the Casimir of three representations: the fundamental $V = \mathbb{C}^N$, and the two pieces of $V \otimes V$. Write $\mathrm{Sym}^2 V$ (symmetric tensors, Young diagram $\square\square$, dimension $N(N+1)/2$) and $\Lambda^2 V$ (antisymmetric tensors, Young diagram $\begin{smallmatrix}\square\\\square\end{smallmatrix}$, dimension $N(N-1)/2$). For $N = 2$ these are the triplet and the singlet.

Worked example 12.135: Casimirs from the Fierz identity

The N^2 matrices $\mathbb{1}/\sqrt{N}$ and $\sqrt{2}\,T^a$ ($a = 1, \dots, N^2-1$) are an orthonormal basis of all $N \times N$ matrices for the inner product $\langle X, Y\rangle = \mathrm{tr}(X^\dagger Y)$. Completeness of an orthonormal basis, $\sum_B B_{ij}\overline{B_{lk}} = \delta_{il}\delta_{jk}$, reads

$$\frac{1}{N}\,\delta_{ij}\delta_{kl} + 2\sum_a (T^a)_{ij}(T^a)_{kl} = \delta_{il}\delta_{kj}$$

(we used that T^a is Hermitian, so $\overline{(T^a)_{lk}} = (T^a)_{kl}$). As an operator on $V \otimes V$, the right side is the swap $P(u \otimes v) = v \otimes u$. So

$$\sum_a T^a \otimes T^a = \frac{1}{2}\Big(P - \frac{1}{N}\,\mathbb{1}\Big). \tag{12.333}$$

This is the $\mathrm{SU}(N)$ version of $\vec{S}_1 \cdot \vec{S}_2 = \frac{1}{2}(P - \frac{1}{2})$ for two spins $\frac{1}{2}$. Now compute Casimirs. On the fundamental,

$$C_2(V)\,\mathbb{1} \overset{(1)}{=} \sum_a (T^a T^a)_{ij} \overset{(2)}{=} \frac{1}{2}\Big(N\,\delta_{ij} - \frac{1}{N}\delta_{ij}\Big) = \frac{N^2-1}{2N}\,\delta_{ij}.$$

(1) Definition of the Casimir: $C_2 = \sum_a T^a T^a$, a multiple of $\mathbb{1}$ on an irreducible representation (Schur).

(2) Set $j = k$ in the index form of the Fierz identity and sum over j: $\delta_{il}\delta_{jj} \to N\delta_{il}$ and $\delta_{ij}\delta_{jl} \to \delta_{il}$, then divide by 2.

On $V \otimes V$ the generators are $T^a \otimes \mathbb{1} + \mathbb{1} \otimes T^a$, so

$$C_2(V \otimes V) \overset{(1)}{=} C_2(V) \otimes \mathbb{1} + \mathbb{1} \otimes C_2(V) + 2\sum_a T^a \otimes T^a \overset{(2)}{=} \frac{N^2-1}{N} + P - \frac{1}{N}.$$

(1) Square the sum of the two generators and collect the cross terms.

(2) $C_2(V) = \frac{N^2-1}{2N}$ on each factor, and (12.333).

The swap is $P = +1$ on symmetric and $P = -1$ on antisymmetric tensors. Hence

$$C_2(\mathrm{Sym}^2 V) = \frac{N^2-1}{N} + 1 - \frac{1}{N} = \frac{(N-1)(N+2)}{N},$$
$$C_2(\Lambda^2 V) = \frac{N^2-1}{N} - 1 - \frac{1}{N} = \frac{(N+1)(N-2)}{N}.$$

For $N = 2$: $C_2(V) = \frac{3}{4}$, $C_2(\mathrm{Sym}^2) = 2 = 1 \cdot 2$ and $C_2(\Lambda^2) = 0$, the spin values $j(j+1)$ for $j = \frac{1}{2}, 1, 0$. Dividing by $k + N$ gives the conformal weights h_V, h_S, h_A.

Step (a): the four-punctured sphere is still 2-dimensional

For SU(2) all four punctures of the sphere around a crossing carried the same representation, because the 2-dimensional representation is equivalent to its dual. For SU(N) with $N \geq 3$ it is not: the fundamental V and the antifundamental $\bar{V}$ are different. So we must look at orientations. Two strands of a crossing both enter the ball through the lower pair of points and leave through the upper pair (Figure 12.72). A strand leaving the ball is a puncture labelled V; a strand entering it is a puncture labelled $\bar{V}$ (or the other way round; only consistency matters). The Hilbert space is therefore $\mathcal{H}_{S^2;V,V,\bar{V},\bar{V}}$. At large k its dimension is the number of invariants:

$$\dim \mathrm{Inv}\big(V \otimes V \otimes \bar{V} \otimes \bar{V}\big) \overset{(1)}{=} \dim \mathrm{Hom}_G\big(V \otimes V,\, V \otimes V\big)$$
$$\overset{(2)}{=} \dim \mathrm{Hom}_G\big(S \oplus A,\, S \oplus A\big) \overset{(3)}{=} 1 + 1 = 2.$$

(1) $\bar{V} \otimes \bar{V} \cong (V \otimes V)^*$, and an invariant in $X \otimes Y^*$ is the same thing as a G-equivariant linear map $Y \to X$.

(2) $V \otimes V = S \oplus A$ with $S = \mathrm{Sym}^2 V$, $A = \Lambda^2 V$.

(3) Schur's lemma: an equivariant map sends $S \to S$ and $A \to A$ by multiples of the identity and cannot mix the inequivalent S and A. So there are exactly two independent maps, for example $\mathbb{1}$ and P, or the projectors $\frac{1}{2}(\mathbb{1} \pm P)$.

At finite level we must also keep only integrable intermediate states: $\Lambda^2 V$ (one column of two boxes) is integrable for $k \geq 1$, but $\mathrm{Sym}^2 V$ (one row of two boxes) only for $k \geq 2$. So for $k \geq 2$ the space is 2-dimensional, exactly as for SU(2), and the "three vectors in a 2-dimensional space" argument of (12.283) goes through unchanged. (At $k = 1$ it is 1-dimensional; see Example 12.138.)

Step (b): the braiding eigenvalues

The half-twist exchanging the two outgoing punctures acts diagonally in the basis labelled by the fusion channel (S or A). Its eigenvalue is the phase of the conformal block, times the

exchange sign $\varepsilon_S = +1$, $\varepsilon_A = -1$, as in (12.287):

$$\lambda_S \overset{(1)}{=} \varepsilon_S\, e^{i\pi(h_S - 2h_V)} \overset{(2)}{=} \exp\!\Big(\frac{i\pi}{k+N}\Big[\frac{(N-1)(N+2)}{N} - \frac{N^2-1}{N}\Big]\Big) \overset{(3)}{=} q^{\frac{N-1}{2N}},$$
$$\lambda_A \overset{(4)}{=} \varepsilon_A\, e^{i\pi(h_A - 2h_V)} \overset{(5)}{=} -\exp\!\Big(\frac{i\pi}{k+N}\Big[\frac{(N+1)(N-2)}{N} - \frac{N^2-1}{N}\Big]\Big) \overset{(6)}{=} -q^{-\frac{N+1}{2N}}. \tag{12.334}$$

(1) Half a turn of one field around the other in the symmetric channel (same rule as for SU(2)).
(2) The Casimirs of Example 12.135 divided by $k+N$.
(3) The bracket is $\frac{(N-1)(N+2-N-1)}{N} = \frac{N-1}{N}$, and $e^{i\pi x/(k+N)} = q^{x/2}$.
(4) The same rule in the antisymmetric channel, with the exchange sign -1.
(5) The Casimirs again.
(6) The bracket is $\frac{(N+1)(N-2-N+1)}{N} = -\frac{N+1}{N}$.

For $N = 2$ these are $\lambda_S = q^{1/4} = \lambda_1$ and $\lambda_A = -q^{-3/4} = \lambda_0$, the SU(2) values of (12.287): the triplet is the symmetric channel and the singlet the antisymmetric one. The framing phase of a single fundamental line is

$$\theta_V := e^{2\pi i h_V} = \exp\!\Big(2\pi i\,\frac{N^2-1}{2N(k+N)}\Big) = q^{\frac{N^2-1}{2N}}, \tag{12.335}$$

which is $q^{3/4}$ for $N = 2$, as in Section 12.14.16.

Step (c): the Hecke relation

On a 2-dimensional space with eigenvalues $\lambda_S \neq \lambda_A$ the matrix σ obeys its characteristic equation $(\sigma - \lambda_S)(\sigma - \lambda_A) = 0$. This is the **Hecke relation**. Rewrite it with σ^{-1}:

$$\begin{aligned} 0 &\overset{(1)}{=} \sigma - (\lambda_S + \lambda_A)\mathbb{1} + \lambda_S\lambda_A\,\sigma^{-1} \\ &\overset{(2)}{=} \sigma - q^{-\frac{1}{2N}}\big(q^{\frac12} - q^{-\frac12}\big)\mathbb{1} - q^{-\frac{1}{N}}\,\sigma^{-1}, \\ \text{so}\quad q^{\frac{1}{2N}}\,\sigma - q^{-\frac{1}{2N}}\,\sigma^{-1} &\overset{(3)}{=} \big(q^{\frac12} - q^{-\frac12}\big)\mathbb{1}. \end{aligned} \tag{12.336}$$

(1) Expand $(\sigma - \lambda_S)(\sigma - \lambda_A) = 0$ and multiply by σ^{-1}.
(2) $\lambda_S + \lambda_A = q^{\frac{N-1}{2N}} - q^{-\frac{N+1}{2N}} = q^{-\frac{1}{2N}}(q^{\frac12} - q^{-\frac12})$, and $\lambda_S\lambda_A = -q^{\frac{(N-1)-(N+1)}{2N}} = -q^{-\frac{1}{N}}$.
(3) Move the $\mathbb{1}$ term to the right and multiply by $q^{\frac{1}{2N}}$.

Apply this operator identity to the vector V_0 of the smoothed crossing, as in Section 12.14.13: $\sigma V_0 = V_+$ and $\sigma^{-1}V_0 = V_-$. Pairing with the vector V_1 of the outside of the ball gives, for blackboard-framed correlators,

$$q^{\frac{1}{2N}}\,W_{\mathrm{bb}}(L_+) - q^{-\frac{1}{2N}}\,W_{\mathrm{bb}}(L_-) = \big(q^{\frac12} - q^{-\frac12}\big)\,W_{\mathrm{bb}}(L_0).$$

Step (d): framing, and the result

The framing-independent invariant is $X(L) := \theta_V^{-w(L)} W_{\mathrm{bb}}(L)$, where w is the writhe of the diagram (Section 12.14.16). The three diagrams have writhes $w(L_\pm) = w(L_0) \pm 1$. Substitute $W_{\mathrm{bb}}(L) = \theta_V^{w(L)} X(L)$ and divide by $\theta_V^{w(L_0)}$:

$$\big(q^{\frac{1}{2N}}\theta_V\big)X(L_+) - \big(q^{\frac{1}{2N}}\theta_V\big)^{-1}X(L_-) \overset{(1)}{=} \big(q^{\frac12} - q^{-\frac12}\big)X(L_0),$$

$$\boxed{a\,X(L_+) - a^{-1}X(L_-) = z\,X(L_0), \qquad a = q^{N/2}, \quad z = q^{1/2} - q^{-1/2}.} \tag{12.337}$$

(1) The writhe bookkeeping just described.
The exponent is $\frac{1}{2N} + \frac{N^2-1}{2N} = \frac{N}{2}$, so $q^{\frac{1}{2N}}\theta_V = q^{N/2}$.

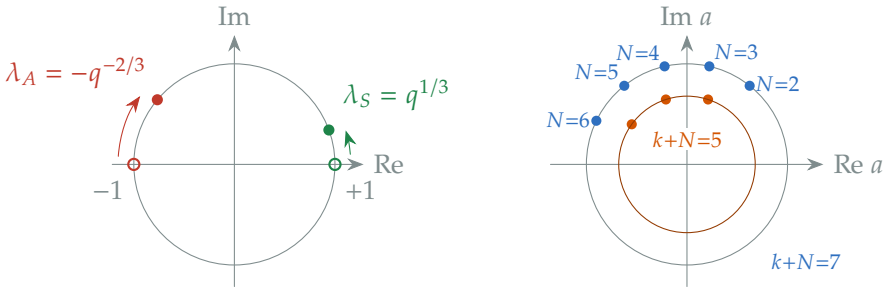
This is the **HOMFLY skein relation** (named after Hoste, Ocneanu, Millett, Freyd, Lickorish and Yetter; also called HOMFLY-PT, after Przytycki and Traczyk). Its two variables are

$$a = \exp\Big(\frac{i\pi N}{k+N}\Big), \qquad z = 2i\sin\Big(\frac{\pi}{k+N}\Big). \tag{12.338}$$

These are Nash's "variables determined by N and k".

Key idea: The HOMFLY polynomial from $\mathrm{SU}(N)$ Chern–Simons theory

Wilson lines in the defining representation of SU(N) at level k obey the skein relation (12.337). With the normalisation $P(\text{unknot}) = 1$, the ratio $P_L = X(L)/X(\bigcirc)$ is the two-variable HOMFLY polynomial $P_L(a,z)$ evaluated at (12.338). For $N = 2$ it is the Jones polynomial. The mechanism is the same as for SU(2): a 2-dimensional space of conformal blocks, and a quadratic relation for the braiding.



(a) SU(3), $k = 3$: $q = e^{2\pi i/6}$ (b) points $a = e^{i\pi N/(k+N)}$

Figure 12.91: (a) The two braiding eigenvalues of SU(3) at level 3 on the unit circle. Open circles are the classical values ±1 (the swap P); the arrows show how the quantum corrections $q^{(N-1)/2N}$ and $-q^{-(N+1)/2N}$ move them apart. (b) For fixed $k+N = n$ the variable $z = 2i\sin(\pi/n)$ is fixed, and the admissible $N = 2, \dots, n-1$ give $n-2$ points a on the upper unit semicircle (drawn on circles of different radii only to separate the two values of n). As n grows these sets become dense; this is why the SU(N) invariants for all N and k determine a genuinely two-variable polynomial.

Worked example 12.136: The unknot and the quantum dimension $[N]_q$

Take the one-crossing diagram of the unknot with a positive kink. Then L_+ is the kinked unknot, L_- the unknot with a negative kink, and L_0 is two disjoint circles. X ignores framing, so $X(L_\pm) = X(\bigcirc)$, and X of two unlinked circles is $X(\bigcirc)^2$ (connected sums, Section 12.14.9). The skein relation gives

$$\big(a - a^{-1}\big)X(\bigcirc) \overset{(1)}{=} z\,X(\bigcirc)^2 \quad\Longrightarrow\quad X(\bigcirc) \overset{(2)}{=} \frac{a-a^{-1}}{z} \overset{(3)}{=} \frac{q^{N/2}-q^{-N/2}}{q^{1/2}-q^{-1/2}} = [N]_q.$$

(1) (12.337) for this triple.
(2) Divide by $zX(\bigcirc) \neq 0$.
(3) Insert $a = q^{N/2}$, $z = q^{1/2} - q^{-1/2}$.

As $k \to \infty$, $[N]_q \to N = \dim V$: the classical Wilson loop of the trivial connection, $\mathrm{tr}_V \mathbb{1} = N$. The surgery side (Section 12.15.6) gives the same thing as S_{0V}/S_{00}, the quantum dimension of V. For $N = 2$ it is $[2] = W(\bigcirc)$ of (12.323).
Two more checks, which test step (b) against step (d). A single strand of V with a positive

kink closes to $\widehat{\sigma}$, and the quantum trace (12.300) with the SU(N) data is

$$W_{\mathrm{bb}}(\widehat{\sigma}) = \lambda_S\, d_S + \lambda_A\, d_A, \qquad d_S = \frac{[N][N+1]}{[2]}, \quad d_A = \frac{[N][N-1]}{[2]},$$

where d_S, d_A are the quantum dimensions of $\mathrm{Sym}^2 V$ and $\Lambda^2 V$ (they reduce to $N(N\pm1)/2$ at $q=1$). With n crossings, $W_{\mathrm{bb}}(\widehat{\sigma^n}) = \lambda_S^n d_S + \lambda_A^n d_A$. For $n=0$, $d_S + d_A = [N]([N+1]+[N-1])/[2] = [N]^2$, using $[N+1]+[N-1] = [2][N]$: two unlinked circles. For $n=1$ one finds $\theta_V[N]$, the kinked unknot. (Both are easy to check numerically for any N and k; the $N=2$ case is Example 12.112.)

Worked example 12.137: The Hopf link and the trefoil, for all N at once

Normalise $P_L = X(L)/X(\bigcirc)$, so $P(\bigcirc)=1$ and the unlink of two has $P = [N]_q = (a-a^{-1})/z$.
Hopf link. Take the positive Hopf link H_+ and change one crossing (as in Example 12.108): $L_+ = H_+$, $L_- =$ unlink, $L_0 = \bigcirc$.

$$a\,P(H_+) \overset{(1)}{=} a^{-1}\,\frac{a-a^{-1}}{z} + z \quad\Longrightarrow\quad P(H_+) \overset{(2)}{=} \frac{a^{-1}-a^{-3}}{z} + a^{-1}z.$$

(1) (12.337) solved for the L_+ term, with the unlink and unknot values.
(2) Divide by a.

Trefoil. The right-handed trefoil is the closure of σ^3. Change one crossing: $L_- = \widehat{\sigma}$ is an unknot, $L_0 = \widehat{\sigma^2} = H_+$.

$$P(T) \overset{(1)}{=} a^{-2}\cdot 1 + a^{-1}z\,P(H_+) \overset{(2)}{=} a^{-2} + a^{-1}z\Big(\frac{a^{-1}-a^{-3}}{z} + a^{-1}z\Big) \overset{(3)}{=} 2a^{-2} - a^{-4} + z^2a^{-2}.$$

(1) Skein relation divided by a.
(2) The Hopf result.
(3) Multiply out: $a^{-2} + a^{-2} - a^{-4} + a^{-2}z^2$.

Specialisations. Put $N=2$: $a = q = t^{-1}$ and, with the square root $t^{1/2} = -q^{-1/2}$ of (12.294), $z = q^{1/2} - q^{-1/2} = t^{1/2} - t^{-1/2}$ so that $z^2 = t - 2 + t^{-1}$. Then

$$P(T)\big|_{N=2} \overset{(1)}{=} 2t^2 - t^4 + t^2\big(t - 2 + t^{-1}\big) = t + t^3 - t^4,$$

(1) Substitute $a^{-2} = t^2$, $a^{-4} = t^4$ and z^2.

which is Nash's (12.76), the Jones polynomial of the trefoil (and agrees with Example 12.109). Put instead $a=1$: the skein relation becomes Conway's $X_+ - X_- = zX_0$, and with $z = t^{1/2} - t^{-1/2}$, $P(T)|_{a=1} = 1 + z^2 = t - 1 + t^{-1}$, the Alexander polynomial of the trefoil (Nash's (12.74), up to the factor t). Formally $a = q^{N/2} = 1$ is "$N=0$"; the unknot value $[0]_q = 0$ then vanishes, which is why only the normalised P survives this limit. (The supergroup U(1|1), whose defining representation has superdimension $1-1=0$, realises it.)

Worked example 12.138: Level 1: $\mathrm{SU}(N)_1$ is secretly abelian

At $k=1$ the symmetric channel is not integrable. The quantum dimension knows this: $q = e^{2\pi i/(N+1)}$ and $[N+1]_q = \sin\pi/\sin\frac{\pi}{N+1} = 0$, so $d_S = 0$. The 4-punctured sphere is 1-dimensional and $\sigma = \lambda_A$ is a number. Every fundamental line has $[N]_q = \sin\frac{N\pi}{N+1}/\sin\frac{\pi}{N+1} =$

1: all quantum dimensions are 1, the hallmark of an abelian theory. For a 2-strand closure,

$$X\left(\widehat{\sigma^n}\right) \overset{(1)}{=} \theta_V^{-n}\lambda_A^n\, d_A \overset{(2)}{=} \left(-q^{-\frac{N^2-1}{2N}-\frac{N+1}{2N}}\right)^n \overset{(3)}{=} \left(-q^{-\frac{N+1}{2}}\right)^n \overset{(4)}{=} 1.$$

(1) The quantum trace with only the antisymmetric channel.
(2) At this q, $[N] = 1$ and $[N-1] = [2]$ (because $\sin\frac{(N-1)\pi}{N+1} = \sin\frac{2\pi}{N+1}$), so $d_A = [N][N-1]/[2] = 1$; then insert (12.335) and (12.334).
(3) $\frac{N^2-1+N+1}{2N} = \frac{N+1}{2}$.
(4) $q^{(N+1)/2} = e^{i\pi} = -1$.

So in the writhe-normalised form the Hopf link and the trefoil are both trivial. The information sits in the framing: the zero-framed Hopf link is $\theta_V^2 X(H_+) = e^{-2\pi i/N}$ (for $N = 3$: $e^{-2\pi i/3}$). This is a pure phase, the exponential of a linking number, exactly the kind of answer the abelian theory of the previous section gave through Gauss's formula. The lines of $\mathrm{SU}(N)_1$ are abelian anyons with statistics $e^{-2\pi i/N}$.

Worked example 12.139: Why all N and k together determine a two-variable polynomial

One $\mathrm{SU}(N)$ theory at one level gives one number $P_L(a,z)$. Why does Nash say the answer is a polynomial in two variables? Write the HOMFLY polynomial as $P_L(a,z) = \sum_{m=-M}^{M} a^m\, p_m(z)$ with Laurent polynomials p_m. Fix $n = k+N$. Then $z_n = 2i\sin(\pi/n)$ is fixed, while $N = 2,\dots,n-1$ gives the $n-2$ distinct values $a = e^{i\pi N/n}$ (Figure 12.91(b)). The function $a \mapsto a^M P_L(a, z_n)$ is a polynomial of degree at most $2M$, so once $n-2 > 2M$ its values at those points fix all its coefficients (Vandermonde). Thus every $p_m(z_n)$ is known, for infinitely many distinct z_n; a Laurent polynomial is fixed by infinitely many values. Conversely, for a single N the values only see the one-variable specialisation $a = q^{N/2}$, $z = q^{1/2} - q^{-1/2}$. So a single group gives a one-variable invariant, and the family $\mathrm{SU}(N)$, $N = 2,3,\dots$, gives the two-variable one.

Watch out: Many conventions for HOMFLY

The HOMFLY polynomial appears in the literature as $P(l,m)$ with $lP_+ + l^{-1}P_- + mP_0 = 0$, as $P(v,z)$ with $v^{-1}P_+ - vP_- = zP_0$, and as $P(x,y,z)$ with $xP_+ + yP_- + zP_0 = 0$ (the original homogeneous form of Freyd et al., which Nash cites). They differ by $a \leftrightarrow a^{-1}$, by signs and by i's, and by the exchange $L_+ \leftrightarrow L_-$, which is reflection of the link. Always test a convention on the trefoil: with ours, the right-handed trefoil has only non-positive powers of a.

Other groups and other representations

The number of terms in the skein relation equals the dimension of the space of conformal blocks on the 4-punctured sphere, which at large k is the number of irreducible pieces of $R \otimes R$ (when each occurs once). A d-dimensional space makes σ obey a polynomial equation of degree d, so a relation among $\sigma^{-1}, \mathbb{1}, \sigma, \dots$ with $d+1$ terms.

group and representation R	$R \otimes R$	channels	polynomial
U(1), charge n	charge $2n$	1	$e^{i\cdot\text{linking}}$ (previous section)
SU(2), spin $\frac{1}{2}$	$0 \oplus 1$	2	Jones $V_L(t)$
SU(N), $V = \mathbb{C}^N$	$\mathrm{Sym}^2 V \oplus \Lambda^2 V$	2	HOMFLY $P_L(a,z)$
SO(N), $V = \mathbb{R}^N$	$\mathbf{1} \oplus \Lambda^2 V \oplus \mathrm{Sym}^2_0 V$	3	Kauffman $F_L(a,z)$
Sp($2n$), $V = \mathbb{C}^{2n}$	$\mathbf{1} \oplus \Lambda^2_0 V \oplus \mathrm{Sym}^2 V$	3	Kauffman (other branch)
SU(2), spin 1	$0 \oplus 1 \oplus 2$	3	coloured Jones / Kauffman
G_2, $\mathbf{7}$	$\mathbf{1} \oplus \mathbf{7} \oplus \mathbf{14} \oplus \mathbf{27}$	4	G_2 invariant (Kuperberg)

A new diagram appears when R is equivalent to its dual (real or pseudo-real). Then a strand may turn back, and the invariant $\mathbf{1} \subset R \otimes R$ is a "cup": two outgoing punctures joined to each other. The fourth diagram L_∞ of Figure 12.92 is allowed, and the Kauffman relation reads $L_+ - L_- = z(L_0 - L_\infty)$ (for framed links). For SU(N) with $N \geq 3$ the fundamental is complex, orientation forbids joining two outgoing punctures, and L_∞ is absent: two channels, three terms. For SU(2) the fundamental is pseudo-real, and indeed the Jones polynomial has an unoriented version, the Kauffman bracket of the previous section, in which L_∞ appears as the second smoothing. There, however, the space is still 2-dimensional, and L_∞ can be eliminated in favour of L_0 and the crossings.

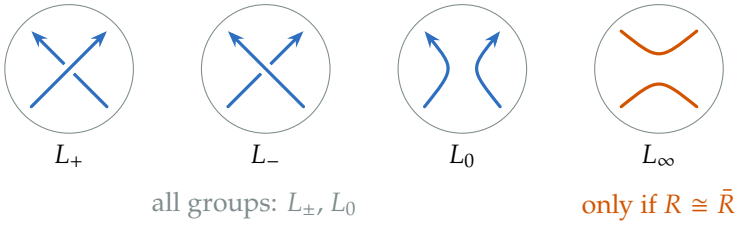


Figure 12.92: The diagrams that can appear in a skein relation. The first three respect the orientation of the strands, and are all that SU(N) with its complex defining representation allows. The fourth joins the two lower punctures to each other and the two upper ones to each other. It needs an invariant pairing $R \otimes R \to \mathbb{C}$, so it exists for SO($N$) and Sp($2n$) (and for SU(2)), and it gives the Kauffman polynomial.

Physical picture: Why the answer is a polynomial

Why are all these invariants *polynomials* (in $q^{\pm 1/2}$ or in a, z) and not arbitrary functions of k? Because the skein relation reduces any link, crossing by crossing, to unlinks, and each step multiplies by a Laurent monomial in the eigenvalues. The eigenvalues are powers of q because the conformal weights are rational multiples of $1/(k + h^\vee)$. The only non-polynomial ingredient, the unknot value $[N]_q$, is removed by the normalisation $P(\bigcirc) = 1$. Physics supplies the relation; the polynomial structure is combinatorics.

12.15.9 Other topological field theories

Nash closes the chapter by observing that Chern–Simons theory is far from the only topological field theory. He mentions two more: a topological sigma model in two dimensions (Witten, Floer, Gromov), whose ground states are "like Floer groups", and a Chern–Simons theory of gravity in $2+1$ dimensions with gauge group ISO$(2,1)$ (Witten), whose Hilbert spaces are infinite-dimensional and which has topology-changing amplitudes. Finally he points to the axiomatic approach of Atiyah. We take them in turn, each time with the same questions: *what are the fields, why is the theory topological, and what does it compute?*

The two-dimensional topological sigma model

The fields and the energy bound. A **sigma model** is a field theory whose field is a map $\phi : \Sigma \to X$ from a surface (the worldsheet) to a target manifold X, with action the Dirichlet energy $E(\phi) = \frac{1}{2}\int_\Sigma |\mathrm{d}\phi|^2 \, \mathrm{d}A$. (For $X = \mathbb{R}^n$ these are n free massless scalars; for a curved X it is the string worldsheet theory of Chapter 9.) Take X to be a **Kähler manifold**: it carries a metric g, a complex structure J (a linear map on each tangent space with $J^2 = -\mathbb{1}$, "multiplication by i"), and the 2-form $\omega(u, v) = g(Ju, v)$, which is closed.

The key identity is a Bogomolny-type completion of the square, exactly as for instantons (Chapter 8). Work first with $X = \mathbb{C}$, $\phi = u + iv$, and local coordinates (x, y) on Σ:

$$\begin{aligned} \tfrac{1}{2}|\mathrm{d}\phi|^2 &\overset{(1)}{=} \tfrac{1}{2}(u_x^2 + u_y^2 + v_x^2 + v_y^2) \\ &\overset{(2)}{=} \tfrac{1}{2}\big[(u_x - v_y)^2 + (u_y + v_x)^2\big] + (u_x v_y - u_y v_x) \\ &\overset{(3)}{=} 2\,|\partial_{\bar w}\phi|^2 + \frac{\phi^*(\mathrm{d}u \wedge \mathrm{d}v)}{\mathrm{d}x \wedge \mathrm{d}y}. \end{aligned} \tag{12.339}$$

(1) The Euclidean norm of the four partial derivatives.

(2) Add and subtract $u_x v_y - u_y v_x$: the squares produce $-2u_x v_y$ and $+2u_y v_x$, which the last bracket cancels.

(3) With $w = x + iy$, $\partial_{\bar w} = \frac{1}{2}(\partial_x + i\partial_y)$ gives $2\partial_{\bar w}\phi = (u_x - v_y) + i(u_y + v_x)$; and the Jacobian $u_x v_y - u_y v_x$ is the pull-back of the area form $\omega = \mathrm{d}u \wedge \mathrm{d}v$ divided by $\mathrm{d}x \wedge \mathrm{d}y$.

The same pointwise identity holds for any Kähler X (it is linear algebra in one tangent space):

$$E(\phi) = \int_\Sigma |\bar\partial_J \phi|^2 \, \mathrm{d}A \; + \; \int_\Sigma \phi^*\omega \;\geq\; \int_\Sigma \phi^*\omega. \tag{12.340}$$

Since $\mathrm{d}\omega = 0$, the last integral depends only on the homology class $\phi_*[\Sigma] \in H_2(X)$ (Stokes, Chapter T2: changing ϕ by a homotopy changes $\int \phi^*\omega$ by $\int \mathrm{d}(\dots) = 0$). It is a topological charge. The bound is saturated exactly by the **holomorphic maps**, $\bar\partial_J \phi = 0$: these are the **worldsheet instantons**.

Dictionary: Instantons in four dimensions and in two

Yang–Mills on M^4	sigma model on Σ^2
$\frac{1}{2}\int \lvert F\rvert^2 = \frac{1}{2}\int \lvert F \pm \star F\rvert^2 \mp \int \operatorname{tr} F \wedge F$	$E = \int \lvert\bar\partial\phi\rvert^2 + \int \phi^*\omega$
self-duality $F = \pm \star F$	Cauchy–Riemann $\bar\partial_J \phi = 0$
instanton number k	degree $d = \phi_*[\Sigma]$
weight $e^{-8\pi^2 k/g^2}$	weight e^{-td}, $t = \int_{\text{line}} \omega$
moduli space $\mathcal{M}_k$	moduli space of holomorphic curves
Donaldson invariants (§3)	Gromov–Witten invariants

Why it is topological. Witten's construction adds fermions and a BRST-type charge Q with $Q^2 = 0$ (up to symmetries), exactly as in the Donaldson theory of §3. The action becomes $S = \{Q, V\} + \int \phi^*\omega$ for some V. The first term has metric-independent correlators by the argument of §3 (its variation with respect to the worldsheet metric is Q-exact); the second is topological by (12.340). The coupling in front of $\{Q, V\}$ can be sent to infinity, and the path integral localises on the zeros of $\bar\partial_J \phi$: the holomorphic maps. Gromov's contribution was the analysis of these maps (the **pseudo-holomorphic curves**, allowed also for non-integrable J) and in particular their compactness: sequences can only degenerate by "bubbling" off spheres, the 2-dimensional analogue of Uhlenbeck's bubbling of instantons.

The observables are labelled by cohomology classes $\alpha \in H^*(X)$: pick a point $z \in \Sigma$ and a cycle Poincaré dual to α, and ask that $\phi(z)$ lie on that cycle. A correlation function counts the holomorphic maps satisfying all such conditions, each weighted by e^{-td}.

How many conditions? The dimension of the moduli space. The tangent space to the moduli space at a holomorphic ϕ is the kernel of the linearised operator, a $\bar\partial$ operator on sections of ϕ^*TX. Its index is given by Riemann–Roch (Chapter 4): for Σ of genus g and $\dim_{\mathbb{C}} X = n$,

$$\dim_{\mathbb{C}} \mathcal{M}_d = n(1-g) + \int_\Sigma \phi^* c_1(TX) \qquad \text{(when there is no cokernel).} \tag{12.341}$$

This is the "selection rule" (the ghost-number anomaly): a correlator can be non-zero only if the total complex codimension of the conditions equals $\dim_{\mathbb{C}} \mathcal{M}_d$.

Worked example 12.140: The three-point function of $\mathbb{CP}^1$ and quantum cohomology

Let $\Sigma = X = \mathbb{CP}^1$, the Riemann sphere, with $c_1(T\mathbb{CP}^1)$ equal to 2 on the fundamental class (Euler characteristic 2). A holomorphic map of degree d is a rational function $\phi(z) = f(z)/g(z)$ with $\deg f, \deg g \le d$ and no common root. Let $x \in H^2(\mathbb{CP}^1)$ be the class of a point; the condition "$\phi(z_i) = p_i$" has complex codimension 1.

$$\dim_{\mathbb{C}} \mathcal{M}_d \overset{(1)}{=} 1\cdot(1-0) + 2d = 2d+1.$$

(1) (12.341) with $n=1$, $g=0$ and $\int \phi^* c_1 = d\cdot 2$. Directly: f and g have $2(d+1)$ coefficients, minus one for the overall scale, giving $2d+1$.

Three point conditions need $2d+1=3$, so $d=1$. Degree-1 maps are the Möbius transformations $\phi(z) = (\alpha z+\beta)/(\gamma z+\delta)$, which form $\mathrm{PSL}(2,\mathbb{C})$, of complex dimension 3. Now require $\phi(0)=p_1$, $\phi(1)=p_2$, $\phi(\infty)=p_3$ for three distinct points. There is exactly one such Möbius map (it is fixed by the cross-ratio). Hence

$$\langle \mathcal{O}_x(0)\,\mathcal{O}_x(1)\,\mathcal{O}_x(\infty)\rangle = 1\cdot e^{-t},$$

a one-instanton effect: at $d=0$ (constant maps) three distinct points can never be hit, so classically this correlator vanishes. The correlators with the unit $1 \in H^0$ are $\langle \mathcal{O}_1\mathcal{O}_1\mathcal{O}_x\rangle = 1$ (at $d=0$; total codimension $1 = \dim \mathcal{M}_0$) and $\langle \mathcal{O}_1\mathcal{O}_x\mathcal{O}_x\rangle = 0$ (it would need $2d+1=2$). Define a product by $\langle x*y,\, z\rangle = \langle \mathcal{O}_x\mathcal{O}_y\mathcal{O}_z\rangle$, using the classical pairing $\langle 1,x\rangle = 1$, $\langle 1,1\rangle = \langle x,x\rangle = 0$. Then $\langle x*x, x\rangle = e^{-t}$ and $\langle x*x, 1\rangle = 0$ give

$$x * x = e^{-t}\,\mathbf{1},$$

the **quantum cohomology** ring of $\mathbb{CP}^1$. Classically $x\cup x = 0$ (two points on a sphere do not meet); the instanton deforms the ring, and the classical ring returns as $t\to\infty$ (a very large sphere, where instantons are infinitely suppressed).

Floer-like ground states. Now take the worldsheet to be a cylinder $S^1\times\mathbb{R}$, with $t\in S^1$ the space direction and $s\in\mathbb{R}$ the Euclidean time. A state is a functional on the space LX of loops $\gamma : S^1 \to X$. The structure is that of §2 of this chapter, with $\mathcal{A}/\mathcal{G}$ replaced by LX and the Chern–Simons function replaced by the **symplectic action** $\mathcal{A}(\gamma) = \int_D \bar\gamma^*\omega$, the ω-area of a disc $\bar\gamma$ bounded by γ (defined up to the periods of ω, just as the Chern–Simons function is defined up to integers). Let us compute its gradient in the simplest target, $X = \mathbb{C} = \mathbb{R}^2$ with $\omega = \mathrm{d}x\wedge\mathrm{d}y$ and $J(\xi_x,\xi_y) = (-\xi_y,\xi_x)$.

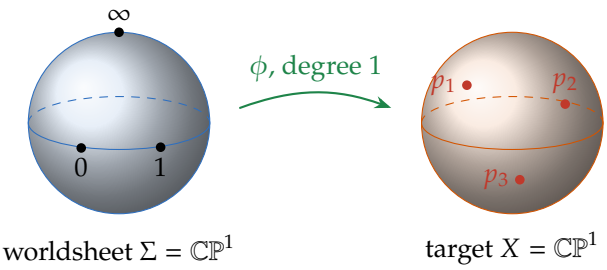

Figure 12.93: The three-point function of the $\mathbb{CP}^1$ sigma model. Constant maps cannot send three points of the worldsheet to three different points of the target. Degree-1 holomorphic maps (Möbius transformations) form a 3-dimensional family, and exactly one of them sends $0, 1, \infty$ to p_1, p_2, p_3. So the correlator is a pure one-instanton effect, e^{-t}.

$$\begin{aligned}
\mathcal{A}(\gamma) &\overset{(1)}{=} \frac{1}{2}\oint (x\,\mathrm{d}y - y\,\mathrm{d}x),\\
\delta\mathcal{A} &\overset{(2)}{=} \frac{1}{2}\oint \big(\xi_x\dot{y} + x\dot{\xi}_y - \xi_y\dot{x} - y\dot{\xi}_x\big)\mathrm{d}t \overset{(3)}{=} \oint \big(\xi_x\dot{y} - \xi_y\dot{x}\big)\mathrm{d}t = \oint \omega(\xi,\dot{\gamma})\,\mathrm{d}t,\\
\operatorname{grad}\mathcal{A} &\overset{(4)}{=} -J\dot{\gamma}.
\end{aligned} \tag{12.342}$$

(1) Green's theorem (Stokes in the plane): the area enclosed is $\frac{1}{2}\oint(x\,\mathrm{d}y - y\,\mathrm{d}x)$.
(2) Vary $\gamma \to \gamma + \xi$ to first order.
(3) Integrate by parts round the closed loop: $\oint x\dot{\xi}_y = -\oint \dot{x}\xi_y$ and $-\oint y\dot{\xi}_x = \oint \dot{y}\xi_x$.
(4) The gradient is defined by $\delta\mathcal{A} = \oint g(\xi, \operatorname{grad}\mathcal{A})$ with $g(a,b) = \omega(a,Jb) = a\cdot b$. We need $J\operatorname{grad} = \dot{\gamma}$, so $\operatorname{grad} = -J\dot{\gamma}$.

The gradient flow $\partial_s u = \operatorname{grad}\mathcal{A}$ for a family of loops $u(s,t)$ is therefore

$$\partial_s u + J\,\partial_t u = 0, \tag{12.343}$$

which for $u = x + iy$ and $w = s + it$ is $2\partial_{\bar{w}} u = 0$: the flow lines of the symplectic action are *holomorphic cylinders*. This is Floer's equation, the exact analogue of "gradient flow of the Chern–Simons function = instanton on $M\times\mathbb{R}$" in §2. The critical points are the loops with $\dot{\gamma} = 0$: constant loops (or, after adding a Hamiltonian term, the periodic orbits of a Hamiltonian flow).

Worked example 12.141: Infinite index in both directions, again

Expand a loop in $\mathbb{C}$ in Fourier modes, $\gamma(t) = \sum_n c_n e^{int}$. Then

$$\mathcal{A}(\gamma) \overset{(1)}{=} \frac{1}{2}\operatorname{Im}\oint \bar{\gamma}\,\mathrm{d}\gamma \overset{(2)}{=} \frac{1}{2}\operatorname{Im}\sum_{m,n}\bar{c}_m c_n\, in\int_0^{2\pi} e^{i(n-m)t}\mathrm{d}t \overset{(3)}{=} \pi\sum_n n\,|c_n|^2.$$

(1) With $\gamma = x + iy$: $\bar{\gamma}\,\mathrm{d}\gamma = (x\,\mathrm{d}x + y\,\mathrm{d}y) + i(x\,\mathrm{d}y - y\,\mathrm{d}x)$, and the real part integrates to zero round a loop.
(2) Insert the Fourier series, $\mathrm{d}\gamma = \sum_n in\,c_n e^{int}\mathrm{d}t$.
(3) Orthogonality: the integral is $2\pi\delta_{mn}$; and $\operatorname{Im}(2\pi in\,|c_n|^2) = 2\pi n\,|c_n|^2$.

So $\mathcal{A}$ is a quadratic form with infinitely many positive directions ($n > 0$, loops winding anticlockwise) and infinitely many negative ones ($n < 0$). Its Morse index is infinite, exactly like the Hessian $\star\mathrm{d}_A$ of the Chern–Simons function in §2, whose eigenvalues on S^3 or T^3 also run to $\pm\infty$. The cure is the same: only *relative* indices, computed by spectral flow,

are used, and the Floer groups are built from critical points and holomorphic cylinders between them.

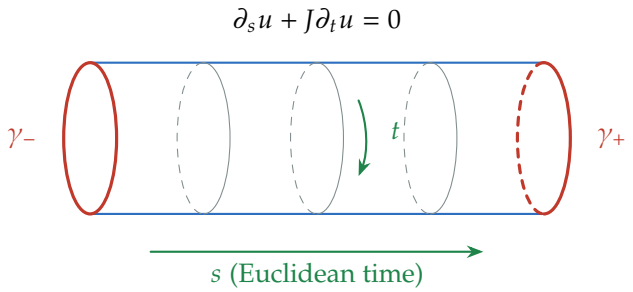

Figure 12.94: A Floer trajectory: a holomorphic cylinder $u(s,t)$ that flows from one critical loop γ_- at $s = -\infty$ to another γ_+ at $s = +\infty$. The grey circles are the intermediate loops $u(s,\cdot)$. This is the 2-dimensional counterpart of an instanton on $M \times \mathbb{R}$ joining two flat connections; counting such cylinders defines the boundary operator of the Floer complex, and the supersymmetric ground states of the sigma model on the circle are its homology.

Dictionary: Two Floer theories side by side

	instanton Floer theory (§2)	symplectic Floer theory
configuration space	$\mathcal{A}/\mathcal{G}$ over a 3-manifold M	loop space LX
Morse function	Chern–Simons $f(A)$, mod $\mathbb{Z}$	action $\mathcal{A}(\gamma)$, mod periods
critical points	flat connections	constant loops / periodic orbits
flow lines	instantons on $M \times \mathbb{R}$	holomorphic cylinders
Hessian	$\star \mathrm{d}_A$, index $\pm\infty$	$-J\,\mathrm{d}/\mathrm{d}t$, index $\pm\infty$
field theory	3d $\to$ 4d Donaldson TQFT	1d $\to$ 2d sigma model
ground states	$HF_*(M)$	$HF_*(X) \cong H_*(X)$

For a compact symplectic X (under technical conditions that exclude holomorphic spheres of negative index) Floer proved that the symplectic Floer groups are isomorphic to the ordinary homology of X. Since the chain complex is generated by the fixed points of a Hamiltonian symplectomorphism (the periodic orbits), this gives the **Arnold conjecture**: such a map has at least $\sum_i b_i(X)$ fixed points (when they are non-degenerate). This was Floer's original motivation, and it is the sense of Nash's phrase "quantum ground states that are like Floer groups".

Chern–Simons gravity in $2+1$ dimensions

General relativity in three spacetime dimensions is a remarkable test case: the vacuum Einstein equations say that spacetime is *flat*. (In three dimensions the Riemann tensor is determined by the Ricci tensor, and $R_{\mu\nu} = 0$ forces $R_{\mu\nu\rho\sigma} = 0$. The number of graviton polarisations in d dimensions is $d(d-3)/2$, which is 0 for $d = 3$.) So the theory has no local degrees of freedom; everything is global, just as in Chern–Simons theory. Witten showed that it *is* a Chern–Simons theory.

The gauge group. Use the first-order (frame) formalism: a **dreibein** $e^a = e^a_\mu \mathrm{d}x^\mu$ ($a = 0,1,2$, with $g_{\mu\nu} = \eta_{ab} e^a_\mu e^b_\nu$ and $\eta = \mathrm{diag}(-1,1,1)$) and a spin connection, which in three dimensions we dualise to a vector of 1-forms $\omega^a = \frac{1}{2}\varepsilon^{abc}\omega_{bc}$. Indices are raised with η, and $\varepsilon_{012} = 1$. The Poincaré group $\mathrm{ISO}(2,1)$ has generators J_a (Lorentz) and P_a (translations). Exhibit them

concretely as 4×4 matrices acting on $(x^0,x^1,x^2,1)$, the affine representation:

$$J_a=\begin{pmatrix} j_a & 0\\ 0 & 0\end{pmatrix},\quad (j_a)^b{}_c=\varepsilon^b{}_{ac},\qquad P_a=\begin{pmatrix} 0 & e_a\\ 0 & 0\end{pmatrix},$$

where e_a is the a-th unit column vector. A translation matrix has its only entries in the last column and a zero last row, so the product of two of them vanishes: $[P_a,P_b]=0$ at once. Multiplying out the other products gives

$$[J_a,J_b]=\varepsilon_{abc}J^c,\qquad [J_a,P_b]=\varepsilon_{abc}P^c,\qquad [P_a,P_b]=0. \tag{12.344}$$

(For $[J_a,P_b]$: the commutator has last column $j_a e_b$, whose c-th entry is $\varepsilon^c{}_{ab}$, so it is $\varepsilon^c{}_{ab}P_c=\varepsilon_{abc}P^c$.)

The invariant form. Chern–Simons theory needs an invariant, non-degenerate bilinear form on the Lie algebra; for SU(2) it was $-\operatorname{tr}$. For $\mathfrak{iso}(2,1)$ the Killing form $K(X,Y)=\operatorname{tr}(\operatorname{ad}_X\operatorname{ad}_Y)$ is *degenerate*: a direct computation gives $K(J_a,J_b)=4\eta_{ab}$ and $K(P_a,\cdot)=0$, because ad_{P_a} maps everything into the abelian ideal spanned by the P's. There is, however, another invariant form,

$$\langle J_a,P_b\rangle=\eta_{ab},\qquad \langle J_a,J_b\rangle=\langle P_a,P_b\rangle=0, \tag{12.345}$$

which is non-degenerate. Invariance, $\langle[X,Y],Z\rangle+\langle Y,[X,Z]\rangle=0$, is checked on basis elements; for instance with $X=J_a$, $Y=J_b$, $Z=P_c$ it reads $\varepsilon_{abd}\eta^{de}\eta_{ec}+\varepsilon_{acd}\eta^{de}\eta_{be}=\varepsilon_{abc}+\varepsilon_{acb}=0$.

The action is Einstein–Hilbert. Form the $\mathfrak{iso}(2,1)$ connection $A=e^aP_a+\omega^aJ_a$. With $[A\wedge A]:=A^i\wedge A^j[X_i,X_j]$ (so that $A\wedge A=\frac12[A\wedge A]$ in a matrix representation), the curvature is

$$F=\mathrm{d}A+\tfrac12[A\wedge A]\overset{(1)}{=}\big(\mathrm{d}e^a+\varepsilon^a{}_{bc}\,\omega^b\wedge e^c\big)P_a+\big(\mathrm{d}\omega^a+\tfrac12\varepsilon^a{}_{bc}\,\omega^b\wedge\omega^c\big)J_a=:T^aP_a+R^aJ_a.$$

(1) Using (12.344): the $\omega\omega$ terms give $\omega^b\wedge\omega^c\varepsilon_{bca}J^a$; the two mixed terms $\omega^b\wedge e^c[J_b,P_c]$ and $e^c\wedge\omega^b[P_c,J_b]$ are equal and give $2\,\omega^b\wedge e^c\varepsilon_{bca}P^a$; $[P,P]=0$.

Here T^a is the *torsion* and R^a the (dualised) *Riemann curvature*. The Chern–Simons 3-form built with (12.345) is

$$\begin{aligned}\operatorname{CS}(A):=\Big\langle A\wedge\mathrm{d}A+\tfrac13 A\wedge[A\wedge A]\Big\rangle&\overset{(1)}{=}\big(e_a\wedge\mathrm{d}\omega^a+\omega_a\wedge\mathrm{d}e^a\big)+\varepsilon_{abc}\,e^a\wedge\omega^b\wedge\omega^c\\&\overset{(2)}{=}2\,e_a\wedge\mathrm{d}\omega^a+\varepsilon_{abc}\,e^a\wedge\omega^b\wedge\omega^c+\mathrm{d}\big(e_a\wedge\omega^a\big)\\&\overset{(3)}{=}2\,e_a\wedge R^a+\mathrm{d}\big(e_a\wedge\omega^a\big).\end{aligned} \tag{12.346}$$

(1) $\langle A\wedge\mathrm{d}A\rangle$ pairs e with $\mathrm{d}\omega$ and ω with $\mathrm{d}e$ through (12.345). In $\langle A\wedge[A\wedge A]\rangle$, e^aP_a pairs with the J-part $\varepsilon_{bcd}\omega^b\wedge\omega^cJ^d$ of $[A\wedge A]$, giving $\varepsilon_{abc}e^a\wedge\omega^b\wedge\omega^c$, and ω^aJ_a pairs with the P-part, giving twice that; the total $3\varepsilon_{abc}e^a\omega^b\omega^c$ times $\frac13$.
(2) $\mathrm{d}(e_a\wedge\omega^a)=\mathrm{d}e_a\wedge\omega^a-e_a\wedge\mathrm{d}\omega^a$, and $\omega_a\wedge\mathrm{d}e^a=\mathrm{d}e^a\wedge\omega_a$ (a 1-form and a 2-form commute).
(3) $e_a\wedge R^a=e_a\wedge\mathrm{d}\omega^a+\frac12\varepsilon_{abc}e^a\wedge\omega^b\wedge\omega^c$.

So, up to a boundary term, $\frac12\int\operatorname{CS}(A)=\int e_a\wedge R^a$. In components, $e_a\wedge R^a=\frac12\varepsilon_{abc}e^a\wedge R^{bc}$ equals $\pm\frac12\sqrt{|g|}\,R\,\mathrm{d}^3x$ (the determinant of e comes from $e^a_\rho e^d_\mu e^e_\nu\varepsilon^{\rho\mu\nu}=\det(e)\,\varepsilon^{ade}$, and $\varepsilon_{abc}\varepsilon^{ade}$ contracts $R^{bc}{}_{de}$ to twice the Ricci scalar; the sign is fixed by orientation and signature). This is the Einstein–Hilbert Lagrangian. Hence

$$S_{\mathrm{EH}}=\frac{1}{8\pi G}\int_M e_a\wedge R^a=\frac{k}{4\pi}\int_M\operatorname{CS}(A),\qquad k=\frac{1}{4G}, \tag{12.347}$$

a Chern–Simons action for ISO(2,1) with the form (12.345) in place of the trace.

Field equations and gauge symmetry. The Chern–Simons equation of motion is $F = 0$, i.e. $T^a = 0$ and $R^a = 0$: the spin connection is torsion-free (so it is the Levi-Civita connection of e) and its curvature vanishes: spacetime is flat, which is the vacuum Einstein equation in three dimensions. The gauge transformations with parameter $u = \rho^a P_a + \tau^a J_a$ act as $\delta A = \mathrm{d}u + [A, u]$: the τ's are local Lorentz rotations, and the ρ's are "local translations" $\delta e^a = \mathrm{d}\rho^a + \varepsilon^a{}_{bc}\omega^b\rho^c$, $\delta\omega = 0$. These are the diffeomorphisms, on shell. Indeed, for a vector field ξ,

$$\mathcal{L}_\xi A \overset{(1)}{=} \iota_\xi \mathrm{d}A + \mathrm{d}(\iota_\xi A) \overset{(2)}{=} \iota_\xi F - [\iota_\xi A, A] + \mathrm{d}(\iota_\xi A) \overset{(3)}{=} \iota_\xi F + D(\iota_\xi A),$$

(1) Cartan's formula $\mathcal{L}_\xi = \iota_\xi \mathrm{d} + \mathrm{d}\iota_\xi$ on forms (Chapter T1).
(2) $\iota_\xi F = \iota_\xi \mathrm{d}A + \frac{1}{2}\iota_\xi[A \wedge A]$ and $\frac{1}{2}\iota_\xi[A \wedge A] = [\iota_\xi A, A]$.
(3) $D\lambda = \mathrm{d}\lambda + [A, \lambda]$ for a Lie-algebra-valued function λ, and $-[\lambda, A] = [A, \lambda]$.

On shell $F = 0$, so a diffeomorphism acts as a gauge transformation with parameter $u = \iota_\xi A = \xi^\mu e^a_\mu P_a + \xi^\mu \omega^a_\mu J_a$. The theory is *generally covariant*, yet its action contains no metric: the metric $g_{\mu\nu} = \eta_{ab} e^a_\mu e^b_\nu$ is one of the fields, not a background. This is the sense of Nash's "a gravity theory which is generally covariant but possesses no metric".

Worked example 12.142: A point particle is a Wilson line: the conical deficit

Put a static particle of mass m at the origin of space. The metric $\mathrm{d}s^2 = -\mathrm{d}t^2 + h_{ij}\mathrm{d}x^i\mathrm{d}x^j$ is ultrastatic, and then $R_{00} = 0$ and the scalar curvature is that of the spatial metric h. The 00 Einstein equation reads

$$G_{00} \overset{(1)}{=} R_{00} - \tfrac{1}{2}g_{00}R \overset{(2)}{=} \tfrac{1}{2}R^{(2)} \overset{(3)}{=} K \overset{(4)}{=} 8\pi G\, m\, \delta^2(x),$$

(1) Definition of the Einstein tensor.
(2) $R_{00} = 0$, $g_{00} = -1$ and $R = R^{(2)}$ for an ultrastatic metric.
(3) On a surface the scalar curvature is twice the Gauss curvature K.
(4) Einstein's equation $G_{\mu\nu} = 8\pi G T_{\mu\nu}$ with energy density $T_{00} = m\,\delta^2(x)$.

So space is flat except at the particle, where all the curvature sits: it is a *cone*. By Gauss–Bonnet (Chapter T2), the total curvature $\int K\,\mathrm{d}A = 8\pi G m$ equals the deficit angle of the cone. Cut a wedge of angle $8\pi G m$ out of the plane and glue the edges (Figure 12.95). In gauge-theory language, the holonomy of the flat connection A around a loop encircling the particle is a Lorentz rotation by $8\pi G m$, i.e. $\exp(8\pi G m\, J_0)$. A particle is a Wilson line of ISO(2, 1), labelled by a representation (mass and spin), just as knots were Wilson lines of SU(2).

Why the Hilbert spaces are infinite-dimensional. For compact G, the phase space of Chern–Simons theory on Σ is the moduli space $\mathcal{M}_F(\Sigma)$ of flat connections, which is compact, and a compact phase space of volume $\mathcal{V}$ carries about $\mathcal{V}/(2\pi\hbar)^n$ states (Example 12.95). For ISO(2, 1) the moduli space of flat connections is *non-compact*. On a closed surface of genus $g \geq 2$, the component that describes spacetimes $\Sigma \times \mathbb{R}$ is the cotangent bundle $T^*\mathcal{T}_g$ of the Teichmüller space $\mathcal{T}_g$ (the flat SO(2, 1) part ω gives the hyperbolic structure of the spatial slice, and the translation part e gives a cotangent vector). For the torus $\mathcal{T}_1$ is the upper half plane of modular parameters τ. The quantisation of a cotangent bundle T^*N is the space of wave functions $L^2(N)$, exactly as $T^*\mathbb{R}$ (phase space (x, p)) gives $L^2(\mathbb{R})$ in ordinary quantum mechanics. That space is infinite-dimensional. So in Nash's words, "the Hilbert spaces are no longer finite dimensional".

There is a second difference. For SU(2) the level k had to be an integer because $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$ allows large gauge transformations that shift the action by $2\pi k$ (Section 12.14.1). The group

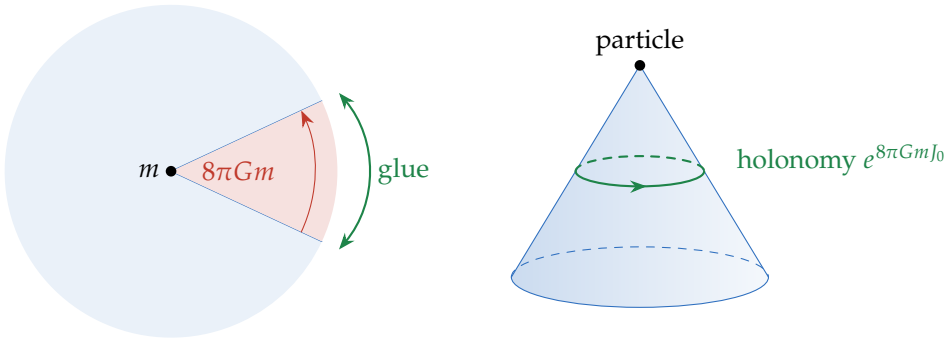

Figure 12.95: A massive particle in 2 + 1 gravity. Left: remove a wedge of angle $8\pi Gm$ from flat space and identify the two edges. Right: the result is a cone, flat everywhere except at the tip. A vector carried round the green loop comes back rotated by the deficit angle: the particle is a Wilson line of the flat ISO(2, 1) connection, and the rotation is its holonomy.

ISO(2, 1) retracts onto its maximal compact subgroup SO(2), which has $\pi_3 = 0$. There are no large gauge transformations of this kind, and the coupling $1/G$ is not quantised.

Topology change. In the Atiyah framework (below), a 3-manifold M with $\partial M = \bar{\Sigma}_1 \sqcup \Sigma_2$ gives a linear map $Z(M) : \mathcal{H}_{\Sigma_1} \to \mathcal{H}_{\Sigma_2}$. If Σ_1 and Σ_2 are different surfaces, this is an *amplitude for space to change its topology*. In Einstein's theory in metric form such processes are hard even to formulate, since a Lorentzian metric on a topology-changing cobordism must degenerate somewhere. In the Chern–Simons form the dreibein e is allowed to be degenerate (it is just a component of a connection), and Witten found that these amplitudes can be non-zero. Figure 12.96 shows the simplest picture.

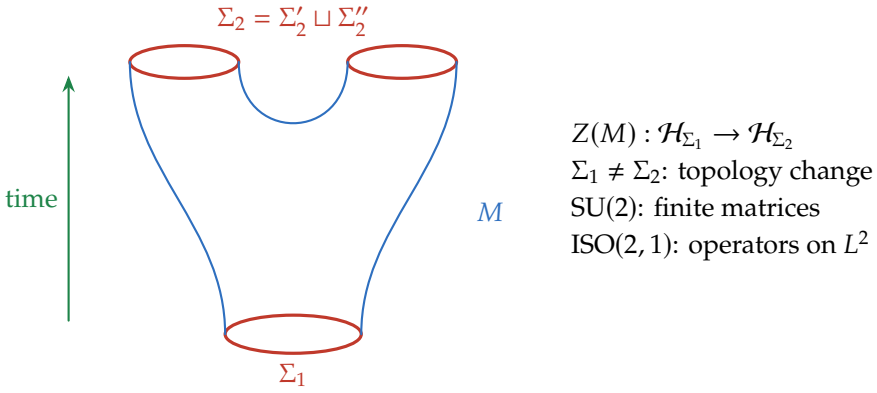

Figure 12.96: A cobordism M from one spatial slice Σ_1 to two. Each red circle stands for a whole closed surface (one dimension is suppressed). The path integral over M is a linear map between the Hilbert spaces of the initial and final slices. When the slices are topologically different, this is a topology-changing amplitude; in 2 + 1 gravity written as a Chern–Simons theory it can be computed and need not vanish.

Physical picture: Adding a cosmological constant

With a cosmological constant Λ the vacuum solutions have constant curvature instead of zero curvature, and the gauge group changes: it is SO(3, 1) for $\Lambda > 0$ (de Sitter) and $\mathrm{SO}(2,2) \cong (\mathrm{SL}(2,\mathbb{R}) \times \mathrm{SL}(2,\mathbb{R}))/\mathbb{Z}_2$ for $\Lambda < 0$ (anti-de Sitter). In the second case the action splits into two $\mathrm{SL}(2,\mathbb{R})$ Chern–Simons actions of opposite levels. The Poincaré group is the

contraction $\Lambda \to 0$ of both, in which the translations P_a stop failing to commute.

The common language: Atiyah's axioms

Nash's last sentence points to the axiomatic approach of Atiyah, analogous to that of Segal for conformal field theories. The axioms were stated at the start of this chapter: a TQFT assigns a vector space $Z(\Sigma)$ to each closed oriented surface and a vector $Z(M) \in Z(\partial M)$ to each oriented 3-manifold, compatibly with gluing. Looking back, every calculation of §6–§7 was an application of one of them. The table records where each axiom was used.

axiom	Chern–Simons realisation	used in
$\Sigma \mapsto Z(\Sigma)$, finite-dim.	$\mathcal{H}_\Sigma$ = conformal blocks of $\mathrm{SU}(2)_k$	Sections 12.14.3 and 12.14.5
$Z(\bar\Sigma) = Z(\Sigma)^*$	$S_k \to -S_k$ under orientation reversal	(12.266)
$Z(\Sigma_1 \sqcup \Sigma_2) = Z(\Sigma_1) \otimes Z(\Sigma_2)$	path integral factorises over pieces	Section 12.14.8
$Z(M) \in Z(\partial M)$; gluing = pairing	$\widetilde{W}(M) = \langle V_1, V_2 \rangle$	(12.267), connected sums
$Z(\Sigma \times I) = \mathbb{1}$	no Hamiltonian, $H = 0$	Example 12.101
$Z(\Sigma \times S^1) = \dim Z(\Sigma)$	$\mathrm{tr}\, e^{iHt} = \mathrm{tr}\, \mathbb{1}$	(12.313)
$\mathrm{Diff}(\Sigma)$ acts on $Z(\Sigma)$	braid group σ; $\mathrm{SL}(2,\mathbb{Z})$ via S, T	Sections 12.14.12 and 12.15.4
(extra structure) framings	twist $e^{2\pi i h}$; anomaly $e^{2\pi i c/24}$	Sections 12.14.16 and 12.15.7
(extra structure) marked points	Wilson lines $\leftrightarrow$ punctures with labels R	Example 12.99

Two lessons stand out. First, the representation of the mapping class group is only *projective*: this is the framing anomaly, which forced the signature phase in (12.329). Chern–Simons theory is a TQFT for 3-manifolds with a little extra structure (a 2-framing, or a choice of signature). Second, the axioms by themselves say nothing about which vector spaces occur; the physics (quantisation of flat connections, conformal field theory) is what supplies the actual $\mathcal{H}_\Sigma$, the matrices S and T, and the braiding. The gravity example shows that relaxing finite-dimensionality leads to theories that are topological but not of Atiyah's finite type.

Reading Nash (p. 360: other groups and other theories)

[Nash p. 360] "When $G \neq \mathrm{SU}(2)$ we obtain a generalisation of the original Jones polynomial. If $G = \mathrm{SU}(N)$ and N is allowed to vary we obtain a two variable polynomial whose variables are determined by N and k." Translation: the whole of §6 goes through with the $\mathrm{SU}(N)$ conformal weights; the Hecke relation (12.336) gives the HOMFLY skein relation (12.337) with $a = q^{N/2}$, $z = q^{1/2} - q^{-1/2}$ and $q = e^{2\pi i/(k+N)}$. "On adjusting the representations of the Wilson lines to be the defining representation of $\mathrm{SU}(N)$ we can recover the Homfly polynomial of Freyd et al." This is Example 12.137; other representations give more terms (Figure 12.92).

Nash then mentions "a topological sigma model (cf. Witten, Floer and Gromov) which, when quantised, exhibits quantum ground states that are like Floer groups": this is Eq. (12.343) and the dictionary of the two Floer theories. Next, "a Chern–Simons topological theory of gravity ... where the group $G = \mathrm{ISO}(2,1)$ ... the moduli space of flat $\mathrm{ISO}(2,1)$-connections is non-compact and the Hilbert spaces are no longer finite dimensional ... non-trivial amplitudes which change the topology of space": this is (12.347), the cotangent-bundle phase space and Figure 12.96. Finally "an axiomatic approach, somewhat analogous to

that introduced for conformal field theories, can be given, cf. Atiyah": the table above.

Recap: Section : surgery and the Jones polynomial

- A solid torus neighbourhood of a knot can be cut out and reglued by a diffeomorphism K of its boundary torus; this is surgery, and by Lickorish–Wallace every closed oriented 3-manifold arises by integer surgery on a link in S^3. Kirby moves say when two links give the same manifold.
- $\mathcal{H}_{T^2}$ has the basis $V^0, \dots, V^k$ (Wilson lines of spin $j = i/2$ on the core), and $\mathrm{SL}(2,\mathbb{Z})$ acts on it through S and T. Surgery changes correlators by $\widetilde{W}(M^K, R_i) = K^i{}_j \widetilde{W}(M, R_j)$ (Nash (12.149)).
- The Hamiltonian is zero, so $Z(\Sigma \times S^1) = \dim \mathcal{H}_\Sigma$ and a mapping torus gives $\operatorname{tr} K$.
- Gluing two solid tori by S turns $S^2 \times S^1$ into S^3. Hence $Z(S^3) = S_{00}$ and the unknot is $S_{0i}/S_{00} = [i+1]_q$; the Hopf link is S_{ij}/S_{00}. This reproduces the skein-relation answer from the modular S-matrix alone.
- For many surgeries, each component is coloured by the Kirby colour $\Omega = \sum_j S_{0j} V^j$; the framing anomaly adds the phase $e^{-2\pi i c\, \sigma(L)/8}$. The result, $Z(M)$, is the Witten–Reshetikhin–Turaev invariant (lens spaces, Poincaré sphere).
- For $\mathrm{SU}(N)$ the same four steps give the HOMFLY polynomial, with $a = q^{N/2}$, $z = q^{1/2} - q^{-1/2}$; groups with self-dual representations give the Kauffman polynomial.
- Other TQFTs: the topological sigma model (holomorphic maps, Gromov–Witten invariants, symplectic Floer homology), and $2+1$ gravity as $\mathrm{ISO}(2,1)$ Chern–Simons theory (no local degrees of freedom, infinite-dimensional Hilbert spaces, topology change). All of them fit Atiyah's axioms, possibly with extra structure.

Chapter summary

This chapter asked one question in three settings: *what can a quantum field theory compute if it never uses a metric?* The answer each time is a topological invariant of the space on which the theory lives, and the mechanism each time is the same pair of tools from the earlier chapters: the path integral localises on the solutions of a first-order equation (flat connections, instantons, holomorphic maps), and the answer is a count of those solutions with signs or phases, or a trace over a finite-dimensional Hilbert space.

1. *What a TQFT is* (Nash §1). Remove the metric from a field theory. Then the stress tensor vanishes (or is Q-exact), the Hamiltonian is zero, the states are all ground states, and the amplitudes depend only on topology. Atiyah's axioms turn this into linear algebra: a vector space for each closed surface, a vector for each 3-manifold bounding it, and gluing by pairing.

2. *Floer homology* (Nash §2). The Chern–Simons function $f(A)$ on the space of SU(2) connections on a homology 3-sphere is a Morse function whose critical points are flat connections and whose gradient lines are instantons on $M \times \mathbb{R}$. Witten's Morse theory of Chapter 7, with relative indices from spectral flow, gives the $\mathbb{Z}_8$-graded groups $HF_*(M)$; their Euler characteristic is twice Casson's invariant.

3. *Donaldson invariants* (Nash §3). Integrating products of 2-dimensional classes over the instanton moduli space $\mathcal{M}_k$ of a 4-manifold gives polynomials q_d on $H_2(M)$. Witten wrote them as correlators of a BRST-exact (cohomological) field theory. Cutting along a homology sphere expresses them as pairings in Floer homology.

4. *Knots* (Nash §4). Knots, links, isotopy, and the classical and modern polynomials (Alexander, Jones, HOMFLY), all characterised by skein relations and the unknot value.

5. *Chern–Simons theory and knots* (Nash §5). Wilson loops in the Chern–Simons theory are knot invariants. For U(1) the path integral is Gaussian and gives the Gauss linking number, with a framing ambiguity for self-linking. At weak coupling the non-abelian theory localises on flat connections, with a one-loop factor given by the Ray–Singer torsion and a phase from the η-invariant.

6. *Chern–Simons theory and the Jones polynomial* (Nash §6, Section 12.14). Quantising on $\Sigma \times \mathbb{R}$ gives finite-dimensional Hilbert spaces, identified with the conformal blocks of the $\mathrm{SU}(2)_k$ WZW model. Gluing and connected sums give unlinks; the 2-dimensional space of the four-punctured sphere forces a three-term linear relation, which is the Jones skein relation with $q = e^{2\pi i/(k+2)}$.

7. *Surgery* (Nash §7, Section 12.15). Cutting out solid tori and regluing them by $\mathrm{SL}(2,\mathbb{Z})$ builds every 3-manifold. The modular matrices S, T act on $\mathcal{H}_{T^2}$, giving $Z(S^3) = S_{00}$, the unknot as S_{01}/S_{00}, the Hopf link as S_{ij}/S_{00}, and the Witten–Reshetikhin–Turaev invariant of any 3-manifold. The same scheme with $\mathrm{SU}(N)$ gives HOMFLY. Other TQFTs: the topological sigma model and 2 + 1 gravity.

Figure 12.97 draws the logic. After it come a formula sheet, two examples that tie the chapter together, the concept tables, and a guide to which tool answers which question.

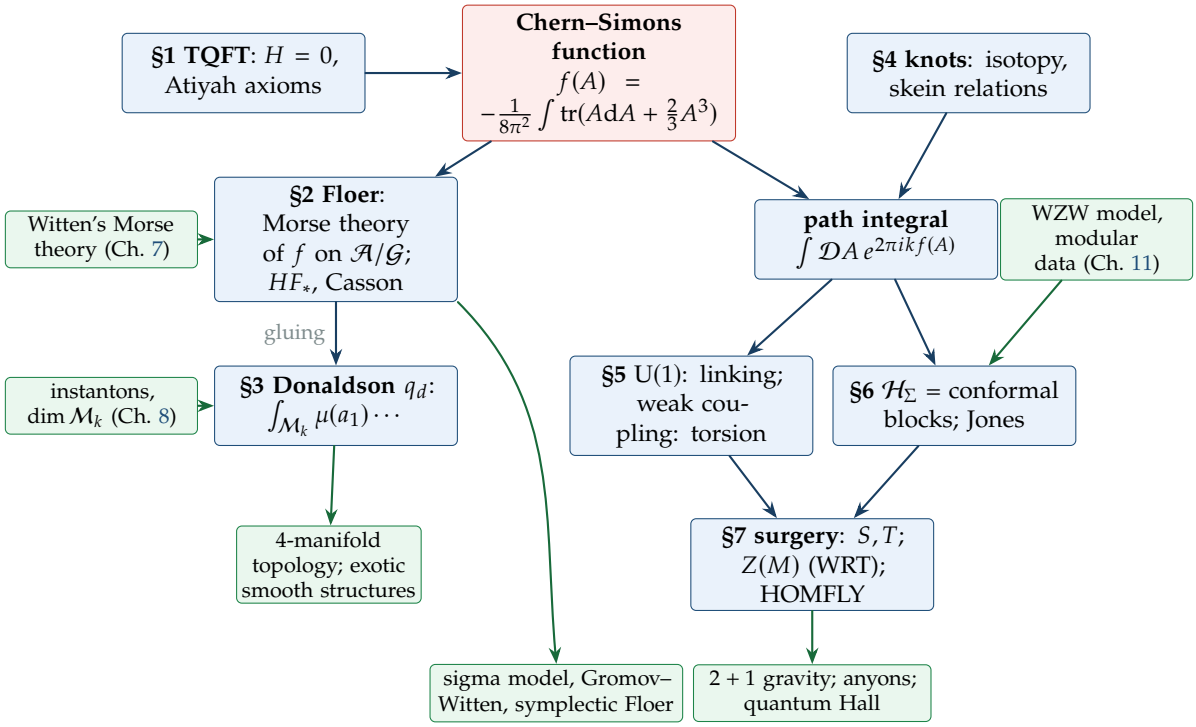

Figure 12.97: Chapter 12 in one picture. The red box, the Chern–Simons function, is used in two ways. On the left it is a Morse function on the space of connections (§2), whose gradient lines are the instantons behind Donaldson's invariants (§3). On the right it is an action, $2\pi k f$, and its path integral with Wilson loops computes knot polynomials (§4–§6) and 3-manifold invariants (§7). Green boxes: the earlier chapters that feed in, and the directions in which these ideas continue.

The formula sheet

The Chern–Simons function and action. With anti-Hermitian A,

$$f(A) = -\frac{1}{8\pi^2}\int_M \mathrm{tr}\Big(A\wedge \mathrm{d}A + \tfrac{2}{3}A\wedge A\wedge A\Big), \qquad f(A^g) = f(A) + \deg g, \qquad S_k = 2\pi k\, f(A),\ k\in\mathbb{Z}.$$

Its variation and flow (§2): $\mathrm{d}f(a) = -\frac{1}{4\pi^2}\int \mathrm{tr}(F\wedge a)$, so critical points are flat connections; $\mathrm{grad}\, f = \star F/4\pi^2$ and the flow $\dot A = -\star F$ is the anti-self-duality equation on $M\times\mathbb{R}$. The spectral flow round a loop in $\mathcal{A}/\mathcal{G}$ is $8k$, whence the $\mathbb{Z}_8$ grading of $HF_*(M)$, and $\chi(HF_*) = 2\lambda(M)$ (Taubes).

Instanton moduli and Donaldson (§3): for SU(2), $\dim \mathcal{M}_k = 8k - 3(1+b_2^+)$ and $q_d(a_1,\dots,a_d) = \int_{\mathcal{M}_k}\mu(a_1)\wedge\cdots\wedge\mu(a_d)$ with $\mu(a) = \int_a c_2(\mathbb{E})$ and $d = \frac{1}{2}\dim\mathcal{M}_k$.

Knot polynomials (§4): the Jones skein $t^{-1}V_+ - tV_- = (t^{1/2}-t^{-1/2})V_0$ with $V(\bigcirc) = 1$; right-handed trefoil $V = t + t^3 - t^4$; HOMFLY $aP_+ - a^{-1}P_- = zP_0$ (Section 12.15.8).

Abelian Chern–Simons (§5): for $S = \frac{k}{4\pi}\int A\wedge \mathrm{d}A$, $\langle\prod_l W(n_l, C_l)\rangle = \exp\big(\frac{i\pi}{k}\sum_{l,m} n_l n_m\, L(C_l, C_m)\big)$ (the overall sign of the exponent depends on the orientation convention), with the Gauss linking number $L(C_1,C_2) = \frac{1}{4\pi}\oint\oint \frac{(\vec x-\vec y)\cdot(\mathrm{d}\vec x\times\mathrm{d}\vec y)}{|\vec x-\vec y|^3}$ and the self-linking fixed by a framing.

Weak coupling (§5): $Z(M) \approx \sum_{\text{flat } A_f} C\, e^{iS_k(A_f)}\, T_{A_f}^{-1/4}$ for isolated, acyclic A_f (Nash (12.113)), with T the Ray–Singer torsion and a further phase fixed by the η-invariant.

Exact $\mathrm{SU}(2)_k$ *data* (§6–§7): $q = e^{2\pi i/(k+2)}$, $h_j = \frac{j(j+1)}{k+2}$, $c = \frac{3k}{k+2}$, $S_{ij} = \sqrt{\frac{2}{k+2}}\sin\frac{(i+1)(j+1)\pi}{k+2}$, $T_{ij} = \delta_{ij}e^{2\pi i(h_i - c/24)}$, braiding eigenvalues $\lambda_0 = -q^{-3/4}$, $\lambda_1 = q^{1/4}$, framing phase $\theta = q^{3/4}$.

Gluing and surgery (§6–§7):

$$\widetilde{W}(M) = \langle V_1, V_2 \rangle, \qquad Z(M_1 \# M_2) = \frac{Z(M_1) Z(M_2)}{Z(S^3)}, \qquad \widetilde{W}(M^K, R_i) = K^i{}_j \, \widetilde{W}(M, R_j),$$

$$Z(S^3) = S_{00}, \qquad W(\bigcirc_i) = \frac{S_{0i}}{S_{00}} = [i+1]_q, \qquad W(\mathrm{Hopf}_{ij}) = \frac{S_{ij}}{S_{00}}, \qquad Z(\Sigma \times S^1) = \dim \mathcal{H}_\Sigma.$$

The WRT invariant of the manifold M_L obtained by integer surgery on a framed link $L = L_1 \cup \cdots \cup L_n$ with linking matrix of signature $\sigma(L)$:

$$Z(M_L) = e^{-2\pi i c\, \sigma(L)/8} \sum_{j_1, \ldots, j_n} \prod_{r=1}^{n} S_{0 j_r} \, \widetilde{W}\big(S^3; L_{j_1 \ldots j_n}\big) \qquad \text{(Eq. (12.329))}.$$

Two examples that tie the chapter together

Worked example 12.143: One family of flat connections, seen by four invariants

Take the Poincaré homology sphere $\Sigma(2,3,5)$ (Example 12.116). Its fundamental group is the binary icosahedral group of order 120, and $\mathrm{Hom}(\pi_1, \mathrm{SU}(2))/\text{conjugation}$ consists of the trivial connection and two irreducible flat connections A_1, A_2. Every invariant of the chapter reads off the same list.

- *Floer* (§2): the chain complex has one generator for each irreducible flat connection. Their relative index is even (they sit in degrees 1 and 5 in the usual grading), so the boundary operator, which changes the degree by one, vanishes and HF_* has rank 2.
- *Casson* (§2): $\chi(HF_*) = (-1)^1 + (-1)^5 = -2$, and Taubes' $\chi(HF_*) = 2\lambda$ gives $\lambda(\Sigma(2,3,5)) = -1$.
- *Chern–Simons values*: $f(A_1) = -\frac{1}{120}$ and $f(A_2) = -\frac{49}{120}$ modulo 1. These are the phases $e^{2\pi i (k+2) f(A_i)}$ that make $|Z|$ oscillate at large k (Example 12.133).
- *WRT* (§7): surgery on the left-handed trefoil with framing -1 gives $Z(\Sigma(2,3,5))$ exactly, e.g. $Z = -\frac{1}{2}$ at $k = 2$, and the large-k asymptotics are a sum of one term per flat connection: the trivial one contributing $O(k^{-3/2})$, the irreducible ones $O(1)$.

The pattern (flat connections as critical points, weighted by $e^{2\pi i k f}$ and a one-loop determinant, or counted with signs) is the whole chapter in miniature. The sum over critical points is the stationary phase version of the path integral; the signed count is its supersymmetric version.

Worked example 12.144: The unknot three ways

The Wilson loop of an unknotted circle in the spin-$\frac{1}{2}$ representation of SU(2), computed by the three methods of the chapter.

$$\begin{aligned}
\text{classical } (k \to \infty): \quad & W(\bigcirc) \overset{(1)}{=} \mathrm{tr}_{\mathbb{C}^2} \mathbb{1} = 2, \\
\text{skein relation (§6)}: \quad & W(\bigcirc) \overset{(2)}{=} -\frac{t - t^{-1}}{t^{1/2} - t^{-1/2}} \overset{(3)}{=} q^{1/2} + q^{-1/2}, \\
\text{surgery and } S \text{ (§7)}: \quad & W(\bigcirc) \overset{(4)}{=} \frac{S_{01}}{S_{00}} \overset{(5)}{=} \frac{\sin\big(2\pi/(k+2)\big)}{\sin\big(\pi/(k+2)\big)} \overset{(6)}{=} 2\cos\frac{\pi}{k+2}.
\end{aligned}$$

(1) At $k \to \infty$ the path integral is dominated by the trivial flat connection $A = 0$, whose

holonomy is $\mathbb{1}$.

(2) The unknot value from the skein relation, Nash's (12.138) (and the second line of (12.158)).

(3) $t = q^{-1}$ and $t^{1/2} = -q^{-1/2}$: numerator $-(q^{-1} - q)$, denominator $-(q^{-1/2} - q^{1/2})$, and $(q - q^{-1})/(q^{1/2} - q^{-1/2}) = q^{1/2} + q^{-1/2}$.

(4) Nash's (12.156): gluing two solid tori by S.

(5) Nash's (12.157) with $i = 1$ and $i = 0$.

(6) $\sin 2x = 2 \sin x \cos x$.

All three agree, since $q^{1/2} + q^{-1/2} = 2 \cos \frac{\pi}{k+2}$, which tends to 2 as $k \to \infty$. The quantum correction is $W(\bigcirc) - 2 \approx -\pi^2/(k+2)^2$.

Concepts of the chapter

In the tables, "operational meaning" says how to compute or recognise the thing; "used in" says where it reappears within the chapter, and, since this is the last chapter of the book, where it leads beyond it.

Topological field theory in general (§1)

concept	operational meaning	used in
TQFT	correlators independent of the metric: check that $T_{\mu\nu} = \delta S/\delta g^{\mu\nu}$ vanishes or is $\{Q,\cdot\}$-exact	every section
Schwarz vs Witten type	metric absent from S (Chern–Simons) vs $S = \{Q, V\}$ (Donaldson, sigma model)	§3, §5, Section 12.15.9
Atiyah axioms	$\Sigma \mapsto Z(\Sigma)$, $M \mapsto Z(M) \in Z(\partial M)$, gluing = pairing, $Z(\Sigma \times S^1) = \dim Z(\Sigma)$	§6–§7 (table in Section 12.15.9)
$H = 0$	time evolution trivial; states are ground states; $Z(\Sigma \times S^1)$ counts them	(12.313)
2d TQFT	commutative Frobenius algebra; $Z(\Sigma_g) = \sum_i \theta_i^{1-g}$	Verlinde formula (12.257)

Floer theory and the Chern–Simons function (§2)

concept	operational meaning	used in
homology 3-sphere	closed 3-manifold with $H_1 = 0$ (so $H_2 = 0$); only reducible flat connection is trivial	§2, §3 gluing; $\Sigma(2,3,5)$
trivial SU(2) bundles over M^3	$B\mathrm{SU}(2) = \mathbb{H}P^\infty$ has cells only in dimensions $4m$	$\mathcal{G} = \mathrm{Map}(M, \mathrm{SU}(2))$
Chern–Simons function f	integrate the CS 3-form; $\mathbb{R}/\mathbb{Z}$-valued on $\mathcal{A}/\mathcal{G}$; jumps by $\deg g$	§5 action, §6–§7
flat connections	$F = 0$; $= \mathrm{Hom}(\pi_1 M, \mathrm{SU}(2))/\mathrm{conj}$ via holonomy	§5 stationary phase; Example 12.143
Hessian $\star \mathrm{d}_A$	first-order, spectrum unbounded both ways; infinite Morse index	relative index; Example 12.141
spectral flow	net number of eigenvalues crossing 0 along a path; = index of $\partial_t + \star \mathrm{d}_{A(t)}$	Floer grading; Chapter 10
gradient flow = instantons	$\dot{A} = -\star F$ on $M \times \mathbb{R}$ is $F = -\star_4 F$	§3 gluing; Floer equation (12.343)
Floer homology $HF_*(M)$	complex on irreducible flat connections, boundary counts instantons, $\mathbb{Z}_8$-graded	§3 pairing $[C^+]\cdot[C^-]$
Casson invariant λ	signed count of irreducible flat connections; $\chi(HF_*) = 2\lambda$	Example 12.143
Floer's Hamiltonian	Witten Laplacian of $\mathrm{d}_t = e^{-tf}\,\mathrm{d}\,e^{tf}$ on $\mathcal{A}/\mathcal{G}$; ground states = HF_*	sigma-model ground states

Donaldson invariants (§3)

concept	operational meaning	used in
intersection form, $b_2^{\pm}$	symmetric matrix of H_2 pairings; count its positive/negative eigenvalues	dim $\mathcal{M}_k$; signature $\sigma(L)$ in (12.329)
dim $\mathcal{M}_k$	index of the ASD deformation complex: $8k - 3(1 + b_2^+)$	selection rules, §3
μ-map	slant product of c_2 of the universal bundle with $a \in H_2(M)$	q_d
Donaldson polynomial q_d	integrate $\mu(a_1)\cdots\mu(a_d)$ over compactified $\mathcal{M}_k$	smooth structures; beyond: Seiberg–Witten
cohomological TQFT	fields $(A, \psi, \phi, \dots)$ with Q^2 = gauge; $S = \{Q, V\}$; localise at Q-fixed points	sigma model, Section 12.15.9
ghost number U	selection rule: $\sum U(\mathcal{O}_i) = \dim \mathcal{M}_k$	(12.341)
Floer gluing	$M = M^+ \cup_N M^-$; $q_d(M) = \langle [C^+], [C^-] \rangle$ in $HF_*(N)$	Atiyah axioms; $\widetilde{W} = \langle V_1, V_2 \rangle$

Knots and knot invariants (§4)

concept	operational meaning	used in
knot, link, isotopy	embedded circles; same if related by Reidemeister moves on a diagram	§5–§7
knot group	$\pi_1(S^3 \setminus K)$ from the Wirtinger presentation	Alexander; flat connections on the complement
linking number	half the signed count of crossings between two components; Gauss integral	§5 abelian CS; framing
framing, writhe	choice of a parallel push-off; writhe = signed crossing count of a diagram	Section 12.14.16, (12.337)
skein triple $L_\pm, L_0$	three links differing inside one ball at one crossing	Section 12.14.13
Alexander $\Delta(t)$	$\Delta_+ - \Delta_- = (t^{1/2} - t^{-1/2})\Delta_0$, or Seifert/Fox matrices	$a = 1$ of HOMFLY
Jones $V(t)$	skein relation plus $V(\bigcirc) = 1$; Kauffman bracket	§6 derivation; Example 12.144
HOMFLY $P(a, z)$	$aP_+ - a^{-1}P_- = zP_0$	SU(N) Chern–Simons, Section 12.15.8
braid, closure	strands going up; closing gives every link (Alexander)	quantum trace (12.300)

Chern–Simons theory and knots (§5)

concept	operational meaning	used in
Wilson loop $W(R, C)$	$\mathrm{tr}_R\ P \exp \oint_C A$: holonomy in representation R	every knot computation
level quantisation	e^{iS_k} gauge invariant iff $k \in \mathbb{Z}$ (large gauge transformations)	§6; contrast ISO(2, 1)
abelian CS	Gaussian integral with sources; propagator = Biot–Savart kernel; answer $e^{i\cdot\text{linking}}$	$\mathrm{SU}(N)_1$, Example 12.138
weak coupling	stationary phase at flat connections; gauge fixing with ghosts	large-k checks Example 12.134
ζ- and η-regularisation	$\det A = e^{-\zeta'_A(0)}$; phase of $\det^{-1/2}$ from $\eta(0)$	shift $k \to k+2$; framing
Ray–Singer torsion	a ratio of ζ-determinants of the Laplacians on forms of each degree (Nash (12.108)); metric-independent	one-loop $Z(M)$

Chern–Simons theory and the Jones polynomial (§6)

concept	operational meaning	used in
phase space $\mathcal{M}_F(\Sigma)$	flat connections on Σ mod gauge, symplectic form $\frac{k}{4\pi}\int \mathrm{tr}\,\delta A \wedge \delta A$	quantisation; gravity (non-compact)
$\mathcal{H}_\Sigma$	holomorphic sections of $\mathcal{L}^k$ over $\mathcal{M}_F$; = conformal blocks; dimension by Verlinde	§7 everywhere
Wilson lines = punctures	a line crossing Σ is a marked point with label R (Borel–Weil)	skein, surgery
$\dim \mathcal{H}_{S^2} = 1$	sphere with no punctures carries one state	connected sums, unlinks
$\dim \mathcal{H}_{S^2,\frac{1}{2}^4} = 2$	two fusion channels (spin 0, 1)	skein relation
braiding matrix	half-twist on the 4-punctured sphere; eigenvalues $-q^{-3/4}, q^{1/4}$	skein; $\mathrm{SU}(N)$ Hecke
fusion matrix F	change of channel basis (quantum $6j$)	braid relation check
quantum dimension	$[n]_q = \sin(n\pi/(k+2))/\sin(\pi/(k+2))$	unknot, Kirby colour
framing anomaly	twist of a line multiplies by $e^{2\pi i h_R}$	writhe normalisation; T-matrix

Surgery and 3-manifold invariants (§7)

concept	operational meaning	used in
solid torus, meridian, longitude	$D^2 \times S^1$; meridian bounds a disc, longitude runs along the core	surgery
mapping class group of T^2	$\mathrm{SL}(2,\mathbb{Z})$ acting on $H_1(T^2)$; generators S, T	$\mathcal{H}_{T^2}$ representation
Heegaard/genus-1 gluing	two solid tori glued by K: S^3 ($K = S$), $S^2 \times S^1$ ($K = \mathbb{1}$), lens spaces	$Z(S^3) = S_{00}$
Dehn surgery p/q	remove a knot neighbourhood, reglue so the meridian goes to $p\mu + q\lambda$	Lickorish–Wallace; Poincaré sphere
Kirby moves	blow-up/down (± 1 unknots) and handle slides relate links giving the same M	invariance test of $Z(M)$
surgery formula	$\widetilde{W}(M^K, R_i) = K^i{}_j \widetilde{W}(M, R_j)$	every closed M
mapping torus	$\Sigma \times_K S^1$; $Z = \mathrm{tr}\, K$	$Z(T^3) = k + 1$
modular S, T	S_{ij} of Nash (12.157); $T = e^{2\pi i(h - c/24)}$; $(ST)^3 = S^2$	unknot, Hopf, Verlinde, WRT
Kirby colour Ω	$\sum_j S_{0j} V^j$ on each surgery component	WRT formula
WRT invariant $Z(M)$	(12.329): coloured link invariant, Gauss-sum phase correction	lens spaces, $\Sigma(2,3,5)$
Hecke relation	$(\sigma - \lambda_S)(\sigma - \lambda_A) = 0$ gives HOMFLY with $a = q^{N/2}$	Section 12.15.8
topological sigma model	localises on holomorphic maps; counts them (Gromov–Witten)	quantum cohomology, Example 12.140
ISO(2,1) Chern–Simons	$A = eP + \omega J$; $S_{\mathrm{CS}} = S_{\mathrm{EH}}$; non-compact phase space	$2+1$ gravity

Which tool answers which question

question	tool
Are two homology 3-spheres different?	Floer groups HF_*, Casson λ, or $Z(M)$ at several k
Are two smooth 4-manifolds (homeomorphic) diffeomorphic?	Donaldson polynomials q_d
Are two knots isotopic?	Jones/HOMFLY/Kauffman polynomials; different values $\Rightarrow$ different knots
Is a knot equivalent to its mirror image?	$V(t)$ vs $V(1/t)$ (the trefoil is chiral)
Linking of two curves, without a diagram	Gauss integral, or abelian Chern–Simons
Exact non-abelian Wilson loops at level k	skein relation from the 4-punctured sphere; or S_{ij}/S_{00}
Partition function of a closed 3-manifold	surgery presentation plus (12.329)
Number of states on a surface	Verlinde formula (12.257) or $Z(\Sigma \times S^1)$
Large-k behaviour, flat connections, torsion	stationary phase (Nash §5), Example 12.134
Counts of holomorphic curves	topological sigma model, Example 12.140
Quantum gravity without local degrees of freedom	ISO(2, 1) Chern–Simons, (12.347)

Physical picture: Where this goes next

The ideas of this chapter did not stop in 1991. In four dimensions, Donaldson's invariants were largely replaced by the Seiberg–Witten invariants, which count solutions of an abelian monopole equation and come from the low-energy limit of the same supersymmetric theory. The Jones polynomial was "categorified" by Khovanov: it is the Euler characteristic of a homology theory, just as Casson's invariant is the Euler characteristic of Floer homology. The topological sigma model became the A-model of mirror symmetry. Abelian Chern–Simons theory at level k is the effective theory of the fractional quantum Hall effect, and the non-abelian theories describe anyons; $SU(2)_3$ (whose anyons have quantum dimension $[2]_q = 2\cos(\pi/5)$, the golden ratio) is universal for topological quantum computation. And $2+1$ gravity with negative cosmological constant, written as two $SL(2,\mathbb{R})$ Chern–Simons theories, is the simplest setting of the AdS/CFT correspondence. Each of these starts from a calculation in this chapter: a metric-independent action, a localisation, and a gluing rule.

Chapter 13

The Mass Gap

Where this chapter is going

The strong nuclear force has a range of about 1.4×10^{-15} m. The electromagnetic force has no range at all: the Coulomb field of a charge falls off as a power of the distance, never exponentially. Both forces come from gauge theories. Why is one short-ranged and the other long-ranged? The answer is a single property of the spectrum of the Hamiltonian, the **mass gap**: an energy $\Delta > 0$ below which there are no excitations of any kind. A theory with a gap has short-range correlations, with range $1/\Delta$. A theory without one has correlations that decay only as a power.

The chapter has three movements. First we say precisely what a gap is and why it forces correlations to decay exponentially (Sections 13.1 and 13.2). Then we collect the ways a gap can be produced. The elementary ones are a mass term, the Higgs mechanism and dimensional transmutation (Section 13.3). The deeper ones are topological: instantons that screen a photon (Section 13.4), a Chern–Simons term that gives a photon a mass with no Higgs field (Section 13.5), a θ-term that decides whether a spin chain is gapped (Section 13.6), and anomalies that *forbid* a trivial gap (Section 13.7), with supersymmetry and topological field theory closing the loop (Section 13.8). Last, we state the Yang–Mills mass gap problem carefully and separate what is known from what is not (Section 13.9). Figure 13.1 shows how the pieces fit, and which earlier chapters each piece leans on.

Dictionary: the words of this chapter

word	what it means physically
mass gap Δ	smallest energy of any excitation above the vacuum
gapped / gapless	$\Delta > 0$ / excitations of arbitrarily small energy
correlation length ξ	range of correlations, $\xi = 1/\Delta$ in a relativistic theory
spectral density $\rho(\mu^2)$	how strongly a field creates states of invariant mass μ
dimensional transmutation	a mass $\mu\, e^{-1/(\beta_0 g^2)}$ made from a dimensionless coupling
monopole-instanton	a tunnelling event in 2+1 dimensions that changes magnetic flux
topological mass	a photon mass from a Chern–Simons term
θ-term	$i\theta\times$(integer winding number) in the Euclidean action
't Hooft anomaly	a symmetry that cannot be coupled to background fields consistently
trivially gapped	gapped, one vacuum, no topological order

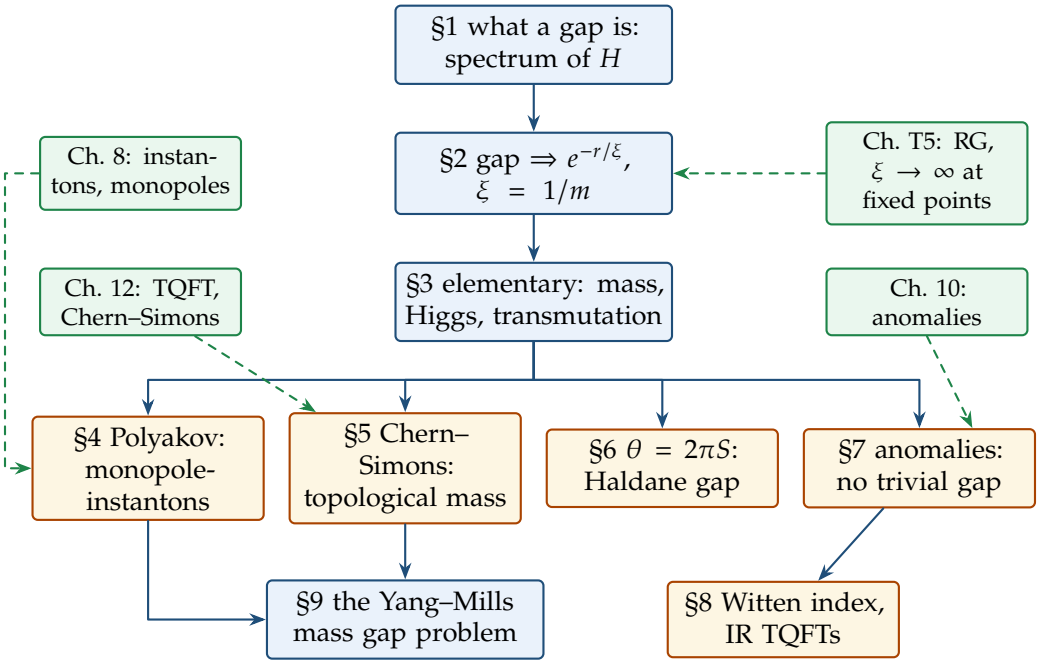

Figure 13.1: The logic of the chapter. The spine (blue) defines the gap and turns it into exponential decay of correlations. The orange boxes are the topological mechanisms, each a different way for topology to open (or to forbid) a gap. The green boxes are the earlier chapters that each piece uses. Everything feeds into the precise statement of the Yang–Mills problem at the bottom.

Reading Nash (no single chapter)

Nash never discusses the spectrum of a Hamiltonian, so there is no "mass gap" in his book. His tools, however, are everywhere in this chapter. Monopoles and their topology are his Chapter VIII, §4 (p. 242 onwards). The Chern–Simons form is his Chapter VIII, §2 (p. 223) and Chapter XII (abelian Chern–Simons theory on S^3, pp. 343–344, (12.86)–(12.89)). Supersymmetric quantum mechanics and Morse theory are Chapter VII, §4 (p. 207, (7.60)–(7.69)). Anomalies are his Chapter X. Here those tools are put to one physical use: deciding whether a theory has a gap.

Conventions. We use natural units $\hbar = c = 1$, except in Section 13.2.6, where $\hbar$ and c are restored to get numbers. Spacetime has dimension d, space has dimension $d-1$. Euclidean signature is the default. When a Minkowski metric is needed we use $\eta = \mathrm{diag}(+1,-1,\ldots,-1)$ and say so. Abelian gauge fields are written in the physicists' real convention, $F = \mathrm{d}A$, with covariant derivative $D_\mu = \partial_\mu - iA_\mu$ on a field of charge one. The dictionary to the anti-Hermitian convention of Chapter T3 is $A_{\text{math}} = -iA$, so $F_{\text{math}} = -iF$.

13.1 What a mass gap is

Here is a question that sounds as if it has an easy answer. *If the mass gap is the mass of the lightest particle, doesn't every theory with massive particles have a gap?* It does not. Quantum electrodynamics has a massive electron, and it has no gap. The reason is that the gap is not about the lightest *particle we care about*. It is about the lightest *excitation of any kind*: massive particles, massless particles, and continua of many-particle states. A single massless particle anywhere in the theory closes the gap. This section makes that precise.

13.1.1 The spectrum of the Hamiltonian

A quantum field theory is, among other things, a Hilbert space $\mathcal{H}$ with two commuting operators: the Hamiltonian H, which generates time translations, and the momentum $\vec{P}$, which generates space translations. Their joint eigenstates $|n\rangle$ obey

$$H|n\rangle = E_n|n\rangle, \qquad \vec{P}|n\rangle = \vec{p}_n|n\rangle.$$

The **vacuum** $|\Omega\rangle$ is the state of lowest energy E_0. It is translation invariant, $\vec{P}|\Omega\rangle = 0$. We may always shift H by a constant so that $E_0 = 0$, and we will often do so.

The set of all energies E_n is the **spectrum** of H. In a finite box the spectrum is a discrete list of numbers. In infinite volume, momenta are continuous and the spectrum contains whole intervals. Picture it as marks on an energy axis: a mark at E_0 for the vacuum, and then marks, or shaded bands, for everything else.

Two remarks keep us out of trouble later.

- In infinite volume a single particle of mass m has energies $\sqrt{m^2 + \vec{p}^2}$ for every $\vec{p}$, so the one-particle states fill the whole interval $[m, \infty)$ of the spectrum of H. To see a particle as an isolated line we look at states of *zero total momentum* (the rest frame), or equivalently at the invariant mass $M = \sqrt{H^2 - \vec{P}^2}$. The gap itself does not care about this distinction, because the bottom of the spectrum is the same either way.

- Positivity of energy, $E_n \geq E_0$, together with Lorentz invariance, forces every state to satisfy $(E_n - E_0)^2 \geq \vec{p}_n^{\,2}$. This is the **spectral condition**: every state lies inside the forward light cone in the $(E, \vec{p})$ plane.

Working definition 13.1 (mass gap)

A quantum system has a **mass gap** $\Delta > 0$ if, in infinite volume, the spectrum of its Hamiltonian H [the list of energies E for which $H|\psi\rangle = E|\psi\rangle$ has a solution] consists of the vacuum energy E_0 [the lowest energy, carried by one state or by finitely many states that no local measurement can tell apart energetically] and then nothing in the open interval $(E_0, E_0 + \Delta)$ [no state at all, whether one particle, many particles or a continuum, has energy strictly between E_0 and $E_0 + \Delta$]. The largest such Δ is the gap. In a Lorentz-invariant theory it equals the smallest invariant mass m of any state other than the vacuum [the mass of the lightest thing that can be created, massless particles included]. *To test for a gap:* put the system in a box of size L, discard the finitely many lowest levels whose splitting from E_0 shrinks exponentially in L, and check that the next level stays at least Δ above E_0 as $L \to \infty$. *Equivalent test in a relativistic theory:* every connected correlation function of local operators decays at least as fast as $e^{-\Delta r}$ at distance r (Section 13.2).

Formal version (as stated by Jaffe and Witten for the Clay problem, with $E_0 = 0$): the theory has a mass gap Δ if H has no spectrum in the interval $(0, \Delta)$; the supremum of such Δ is the mass m, and one requires $m < \infty$ (A. Jaffe and E. Witten, *Quantum Yang–Mills theory*, Clay Mathematics Institute problem description, §4).

13.1.2 The gap is the lightest excitation, not the lightest particle

In a Lorentz-invariant theory, take any state $|n\rangle$ other than the vacuum, with energy E_n and momentum $\vec{p}_n$. Its **invariant mass** M_n is defined by $M_n^2 = (E_n - E_0)^2 - \vec{p}_n^{\,2}$, which is non-negative

by the spectral condition. Let m be the smallest invariant mass that occurs. Then

$$E_n - E_0 \overset{(1)}{=} \sqrt{M_n^2 + \vec{p}_n^{\,2}} \overset{(2)}{\geq} M_n \overset{(3)}{\geq} m. \tag{13.1}$$

(1) Solve the definition of M_n for $E_n - E_0$, taking the positive root because $E_n \geq E_0$.
(2) $\vec{p}_n^{\,2} \geq 0$, and the square root is increasing.
(3) m is the smallest invariant mass in the spectrum, by definition.

The bound is reached: a state of invariant mass m at rest has $E_n - E_0 = m$ exactly. So in a Lorentz-invariant theory

$$\Delta \;=\; m \;=\; \min\{\text{invariant masses of all states other than } |\Omega\rangle\}.$$

The word "all" carries the whole weight. If *any* state has $M_n = 0$, or if invariant masses accumulate at zero, then $\Delta = 0$.

Key idea: gap versus particle mass

A theory is gapped when *every* excitation costs at least a finite energy. "The theory has a massive particle" is not enough. A single massless particle, or a continuum of states reaching down to zero energy, closes the gap, however heavy the other particles are.

Worked example 13.1: the free massive scalar is gapped

A free real scalar of mass m has Hamiltonian (normal ordered, so $E_0 = 0$)

$$H = \int \frac{\mathrm{d}^{d-1}p}{(2\pi)^{d-1}}\, \omega_{\vec{p}}\, a^\dagger_{\vec{p}} a_{\vec{p}}, \qquad \omega_{\vec{p}} = \sqrt{m^2 + \vec{p}^{\,2}},$$

where $a^\dagger_{\vec{p}}$ creates one particle of momentum $\vec{p}$. Every state is built from $n \geq 0$ particles, $a^\dagger_{\vec{p}_1} \cdots a^\dagger_{\vec{p}_n} |0\rangle$. For such a state with $n \geq 1$,

$$E - E_0 \overset{(1)}{=} \omega_{\vec{p}_1} + \cdots + \omega_{\vec{p}_n} \overset{(2)}{\geq} n\, m \overset{(3)}{\geq} m.$$

(1) $[H, a^\dagger_{\vec{p}}] = \omega_{\vec{p}} a^\dagger_{\vec{p}}$, so each creation operator raises the energy by $\omega_{\vec{p}}$, and $H|0\rangle = 0$.
(2) Each $\omega_{\vec{p}_i} = \sqrt{m^2 + \vec{p}_i^{\,2}} \geq m$.
(3) $n \geq 1$.

So $\Delta = m$. At zero total momentum the spectrum is: 0 (the vacuum), m (one particle at rest), and the continuum $[2m, \infty)$ (two particles with momenta $\pm\vec{k}$, energy $2\sqrt{m^2 + \vec{k}^2}$), then $[3m, \infty)$, and so on (Figure 13.2(a)).

Worked example 13.2: QED has a massive electron and no gap

QED contains the electron, $m_e = 0.511\,\mathrm{MeV}$, and the photon, which is massless. A state with two photons of momenta $\vec{k}$ and $-\vec{k}$ has total momentum zero and energy

$$E - E_0 \overset{(1)}{=} |\vec{k}| + |-\vec{k}| \overset{(2)}{=} 2|\vec{k}|.$$

(1) A photon of momentum $\vec{k}$ has energy $|\vec{k}|$, since its mass is zero, and the two photons are (to leading order) free.
(2) $|-\vec{k}| = |\vec{k}|$.

Given any proposed gap $\Delta > 0$, choose $|\vec{k}| < \Delta/2$. This state has energy below Δ. So no $\Delta > 0$ works: QED is gapless, although its only charged particle is massive (Figure 13.2(b)). Physically, the long range of the Coulomb force and the absence of a gap are the same fact.

Worked example 13.3: Goldstone bosons close the gap

When a continuous symmetry is spontaneously broken, there are gapless excitations, the **Goldstone bosons** (Goldstone's theorem). The picture is simple. The vacua form a continuous family (a circle of values of a phase, say). A long-wavelength wave in which the field slowly rotates from one vacuum to a neighbouring one costs almost no energy, and its energy goes to zero as the wavelength goes to infinity: $\omega = c\,|\vec{k}|$ for some speed c. Examples:

- phonons in a crystal (broken translations), $\omega = c_s|\vec{k}|$;
- spin waves in a Heisenberg antiferromagnet in three dimensions (broken spin rotations);
- the pions of QCD (broken chiral symmetry). Here the symmetry is also broken slightly *explicitly* by the quark masses, so the pions have a small mass, $m_\pi \approx 140\,\text{MeV}$, much less than the proton mass 938 MeV. In the limit of massless quarks QCD would be gapless.

In each case there are states of arbitrarily small energy, so $\Delta = 0$ (Figure 13.2(c)). We return to this in Section 13.3.2, where we see that gauging the broken symmetry removes the Goldstone boson and opens a gap.

Watch out: "massive theory"

Physicists say "a massive theory" to mean a theory in which *all* excitations are massive. Such a theory is gapped by (13.1). A theory in which *some* particles are massive, like QED or the Standard Model, need not be gapped. There are also gapless theories with no particles at all: a conformal field theory (Chapter 11) has a continuum of states reaching down to zero energy and no isolated one-particle lines.

13.1.3 Multi-particle continua and the energy–momentum plane

It helps to draw the spectrum in the plane of energy E (with $E_0 = 0$) against momentum $p = |\vec{p}|$. Each state is a point in the forward light cone $E \geq p$. A particle of mass m traces the hyperbola $E = \sqrt{m^2 + p^2}$.

Two particles of mass m with momenta $\vec{k}_1, \vec{k}_2$ have total momentum $\vec{p} = \vec{k}_1 + \vec{k}_2$ and energy $E = \omega_{\vec{k}_1} + \omega_{\vec{k}_2}$. The smallest energy at fixed total momentum is reached when the two particles move together, each carrying half the momentum:

$$E_{\min}(\vec{p}) \overset{(1)}{=} 2\,\omega_{\vec{p}/2} \overset{(2)}{=} 2\sqrt{m^2 + \tfrac{1}{4}\vec{p}^{\,2}} = \sqrt{(2m)^2 + \vec{p}^{\,2}}. \tag{13.2}$$

(1) $\omega_{\vec{k}}$ is a convex function of $\vec{k}$, so for fixed $\vec{k}_1 + \vec{k}_2 = \vec{p}$ the sum $\omega_{\vec{k}_1} + \omega_{\vec{k}_2}$ is smallest at $\vec{k}_1 = \vec{k}_2 = \vec{p}/2$.
(2) Definition of ω.

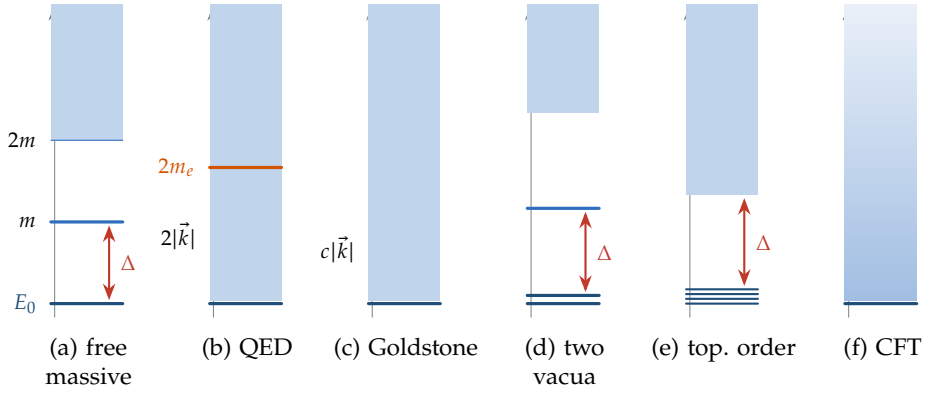

Figure 13.2: Spectra at zero total momentum, energy upwards. Dark lines are vacua, blue lines are one-particle states at rest, shaded bands are continua. (a) A free massive field: a gap $\Delta = m$, then the two-particle continuum at $2m$. (b) QED: the heavy electron pair threshold at $2m_e$ is irrelevant, because two back-to-back photons fill the spectrum down to zero. (c) Goldstone bosons do the same. (d) A spontaneously broken discrete symmetry: two vacua, then a gap. (e) Topological order on a torus: several vacua, split only by an amount exponentially small in the system size, then a gap. (f) A conformal field theory: a continuum from zero, with no particles.

So the two-particle states fill the region above the hyperbola of mass $2m$. They form a continuum: an interval of invariant masses $[2m, \infty)$. A **bound state** of two particles would show up as an extra hyperbola with mass between m and $2m$ (like the deuteron below the proton–neutron threshold). The gap is the lowest of all these curves at $p = 0$ (Figure 13.3).

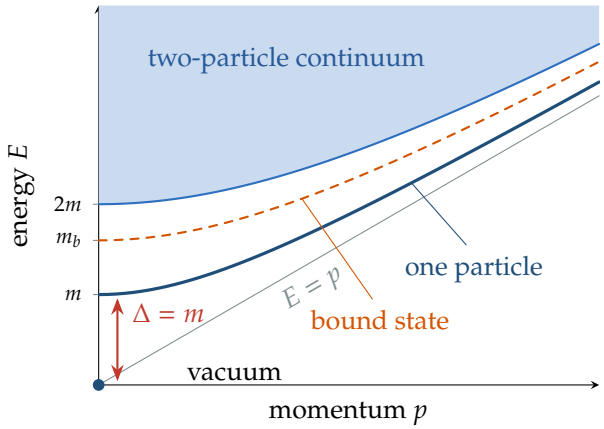

Figure 13.3: The energy–momentum plane of a gapped theory. Every state lies above the light line $E = p$. A particle of mass m is the hyperbola $E = \sqrt{m^2 + p^2}$ (dark blue). A bound state of mass $m_b < 2m$ is another hyperbola (dashed orange). Two-particle states fill the whole region above the hyperbola of mass $2m$ (shaded). The gap is the height of the lowest curve at $p = 0$. In a gapless theory some curve, or some shaded region, touches the origin.

Try it: the $3m$ threshold

In ϕ^4 theory the field ϕ is odd under $\phi \to -\phi$, so acting with ϕ on the vacuum creates only states with an odd number of particles. Where does the continuum seen by the operator ϕ start? *Answer:* one particle at m, then three particles at $3m$. The two-particle continuum at $2m$ is created by even operators such as ϕ^2.

13.1.4 Gapped phases with several vacua

A gap does not require a unique vacuum. The working definition allows finitely many vacua, and two important classes of gapped phases need this.

Broken discrete symmetry. Take a real scalar in the double-well potential $V(\phi) = \frac{\lambda}{4}(\phi^2 - v^2)^2$. It has two classical vacua $\phi = \pm v$, exchanged by $\phi \to -\phi$. In infinite volume the quantum theory also has two vacua $|\Omega_\pm\rangle$, and above each one every excitation is massive: small oscillations have mass $m^2 = V''(\pm v) = 2\lambda v^2$, and in $1+1$ dimensions there are also **kinks**, domain walls interpolating from $-v$ to $+v$, with a finite mass. The spectrum is two vacuum lines and then a gap (Figure 13.2(d)). Jaffe and Witten describe exactly this situation for the rigorously constructed two-dimensional ϕ^4 theory at strong coupling: two phases, each with a mass gap and a unique vacuum. Choosing one vacuum is choosing one "phase".

Topological order. Some gapped phases have several vacua that are not related by any symmetry. Their number depends on the topology of space: one vacuum on a sphere, four on a torus for the simplest example (the $\mathbb{Z}_2$ toric code of Section 13.8.2). No local operator distinguishes these vacua, and in a box of size L they are split only by an amount of order $e^{-L/\xi}$ (Figure 13.2(e)). The low-energy physics is a topological quantum field theory (Chapter 12).

Key idea: three kinds of gapped phase

- *Trivially gapped:* one vacuum on every spatial manifold, and no topological response. This is the phase of a free massive field.
- *Gapped with broken symmetry:* several vacua, permuted by a broken discrete symmetry.
- *Gapped with topological order:* vacua whose number depends on the topology of space, not related by symmetry.

In all three the spectrum above the vacua has a gap. Section 13.7 shows that anomalies can rule out the first kind while allowing the other two.

13.1.5 Finite volume

The definition insists on infinite volume, and for good reason. In a finite box every spectrum is discrete, so every finite system is "gapped" in a trivial sense. What matters is how the lowest gaps behave as the size L grows. There are three typical behaviours.

Worked example 13.4: a massless scalar on a circle

Put a free massless scalar on a circle of circumference L (one space dimension). Periodicity quantises the momenta, $p_n = 2\pi n/L$ with $n \in \mathbb{Z}$. The lowest excitation with nonzero momentum has energy

$$E_1 - E_0 \overset{(1)}{=} |p_{\pm 1}| \overset{(2)}{=} \frac{2\pi}{L} \xrightarrow{L\to\infty} 0.$$

(1) A massless particle has $E = |p|$.
(2) $n = \pm 1$.

In a finite box the gap is $2\pi/L > 0$, but it closes like $1/L$. This $1/L$ closing is the fingerprint of a gapless theory. For a massive scalar the same lowest state (one particle at rest, $p = 0$) has $E_1 - E_0 = m$ for every L, and the gap stays open.

Worked example 13.5: the transverse-field Ising chain shows all three behaviours

Take L spin-$\frac{1}{2}$ sites on a ring with

$$H = -J \sum_{j=1}^{L} \sigma_j^z \sigma_{j+1}^z - h \sum_{j=1}^{L} \sigma_j^x, \qquad J, h > 0,$$

where $\sigma_j^{x,z}$ are Pauli matrices on site j. This model can be solved exactly by turning spins into free fermions (the Jordan–Wigner transformation), and the single-fermion energies are

$$\varepsilon_k = 2\sqrt{J^2 + h^2 - 2Jh\cos k}, \qquad k \in \left\{\tfrac{2\pi n}{L}\right\}.$$

The smallest value is at $k = 0$:

$$\varepsilon_0 \overset{(1)}{=} 2\sqrt{J^2 + h^2 - 2Jh} \overset{(2)}{=} 2\sqrt{(J-h)^2} = 2|J - h|.$$

(1) $\cos 0 = 1$.
(2) Complete the square.

- $h > J$ *(disordered):* a unique vacuum, spins mostly along x, and a gap $2(h - J)$.
- $h < J$ *(ordered):* two nearly degenerate lowest states, close to $|{\uparrow\uparrow}\cdots\rangle \pm |{\downarrow\downarrow}\cdots\rangle$. To connect $|{\uparrow\uparrow}\cdots\rangle$ to $|{\downarrow\downarrow}\cdots\rangle$ the term $-h\sigma^x$ must flip all L spins, so their splitting appears first at order h^L in perturbation theory and is of order $J(h/J)^L = Je^{-L\ln(J/h)}$, exponentially small in L. Above this pair there is a gap $2(J - h)$.
- $h = J$ *(critical):* $\varepsilon_k = 4J|\sin(k/2)|$, so the lowest excitation with $k = 2\pi/L$ costs about $2\pi J/L$. The gap closes like $1/L$, and the long-distance theory is a conformal field theory (the critical Ising model of Chapter 11).

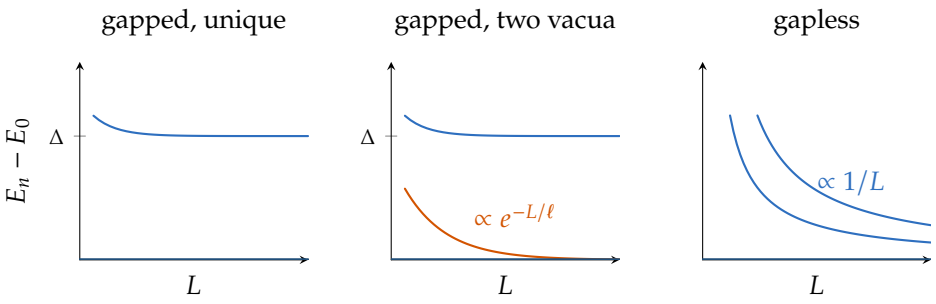

Figure 13.4: How the lowest energy differences behave as the box size L grows. Left: a gapped theory with one vacuum, whose first excitation tends to a finite Δ. Middle: a gapped theory with two vacua. The second level (orange) falls onto the vacuum exponentially fast, and the gap Δ sits above the pair. Right: a gapless theory, where every level falls like $1/L$ and nothing is left in infinite volume.

The exponential splitting in the ordered phase has a general origin. To go from one vacuum to the other, the whole system must tunnel. In Euclidean language the tunnelling event is a domain wall that sweeps across space once, an instanton (Chapter 8) whose action is the wall tension σ times the area of space, L^{d-1}. The splitting is therefore of order $e^{-\sigma L^{d-1}}$, which vanishes as $L \to \infty$. This is why the working definition discards "finitely many levels whose splitting shrinks exponentially". They become exactly degenerate vacua in infinite volume.

Watch out: a finite-volume gap proves nothing

Numerical studies always work in finite volume, and they always find a gap. The question is whether it survives $L \to \infty$. A lattice gauge theory calculation that reports a glueball mass is really reporting that the lowest excitation stays at a fixed value in physical units as both $L \to \infty$ and the lattice spacing $a \to 0$. Jaffe and Witten stress that a gap which is *uniform in the volume* is exactly what current mathematical methods cannot yet prove for Yang–Mills theory (Section 13.9).

theory	lightest excitation	gapped?
free scalar of mass m	particle of mass m	yes, $\Delta = m$
QED	two photons, $E = 2\lvert\vec{k}\rvert$	no
QCD with massless quarks	pions (Goldstone bosons)	no
real QCD	pions, $m_\pi \approx 140\,\text{MeV}$	yes, but only because $m_q \neq 0$
pure Yang–Mills, $d = 4$	glueball (conjectured)	believed yes, unproven
superconductor (Higgs phase)	massive photon	yes
critical Ising model	continuum from 0	no

Recap

- The mass gap is a property of the spectrum of H in infinite volume: nothing between the vacuum energy and $E_0 + \Delta$.
- In a Lorentz-invariant theory Δ is the smallest invariant mass of *any* state. One massless particle, or a continuum reaching zero, closes the gap. QED and theories with Goldstone bosons are gapless.
- Multi-particle states form continua starting at thresholds such as $2m$. Bound states sit below them.
- Gapped phases may have several vacua, from broken discrete symmetry or from topological order.
- In a box of size L, gapped theories keep a finite Δ (after exponentially split vacua are merged). Gapless theories have levels falling like $1/L$.

13.2 The gap makes correlations decay exponentially

We almost never diagonalise a Hamiltonian. What we can compute, on a lattice, in perturbation theory or in an experiment, are *correlation functions*: how much a measurement at one point is correlated with a measurement at another. So we need a bridge between the spectrum and correlations. The bridge is to insert a complete set of energy eigenstates between two field operators. The result is simple and exact: *a gap Δ makes every connected correlation function decay like $e^{-\Delta r}$*. In a relativistic theory the range of correlations is therefore $\xi = 1/\Delta$, which is the Compton wavelength of the lightest particle.

13.2.1 Imaginary time and the spectral sum

In real time, a state of energy E evolves by the phase e^{-iEt}. Phases oscillate and never decay. Replace t by $-i\tau$ (a **Wick rotation**). Then e^{-iEt} becomes $e^{-E\tau}$, and high energies are exponentially

damped. This is also the time variable of the Euclidean path integral, with weight e^{-S_E}. The **Euclidean Heisenberg field** at imaginary time τ and position $\vec{x}$ is

$$\phi(\tau,\vec{x}) = e^{H\tau}\, e^{-i\vec{P}\cdot\vec{x}}\, \phi(0)\, e^{i\vec{P}\cdot\vec{x}}\, e^{-H\tau}, \tag{13.3}$$

where $\phi(0)$ is a Hermitian field operator at the origin. (The sign in the spatial translation makes $\langle\Omega|\phi(0,\vec{x})|\vec{p}\rangle = e^{i\vec{p}\cdot\vec{x}}\langle\Omega|\phi(0)|\vec{p}\rangle$, as for a free field $\phi \ni a_{\vec{p}}e^{i\vec{p}\cdot\vec{x}}$.)

For $\tau > 0$, the **Euclidean two-point function** is $G(\tau,\vec{x}) = \langle\Omega|\phi(\tau,\vec{x})\phi(0,\vec{0})|\Omega\rangle$. Write $c_n = \langle\Omega|\phi(0)|n\rangle$ for the amplitude with which ϕ connects the vacuum to the eigenstate $|n\rangle$. Then

$$\begin{aligned} G(\tau,\vec{x}) &\overset{(1)}{=} \langle\Omega|e^{H\tau}e^{-i\vec{P}\cdot\vec{x}}\phi(0)e^{i\vec{P}\cdot\vec{x}}e^{-H\tau}\,\phi(0)|\Omega\rangle \\ &\overset{(2)}{=} \sum_n \langle\Omega|e^{H\tau}e^{-i\vec{P}\cdot\vec{x}}\phi(0)e^{i\vec{P}\cdot\vec{x}}e^{-H\tau}|n\rangle\langle n|\phi(0)|\Omega\rangle \\ &\overset{(3)}{=} \sum_n e^{E_0\tau}\, e^{-E_n\tau}\, e^{i\vec{p}_n\cdot\vec{x}}\, \langle\Omega|\phi(0)|n\rangle\langle n|\phi(0)|\Omega\rangle \\ &\overset{(4)}{=} \sum_n |c_n|^2\, e^{-(E_n-E_0)\tau + i\vec{p}_n\cdot\vec{x}}. \end{aligned} \tag{13.4}$$

(1) Definition (13.3), and $\phi(0,\vec{0}) = \phi(0)$.

(2) Insert the identity $\mathbb{1} = \sum_n |n\rangle\langle n|$, a sum over all joint eigenstates of H and $\vec{P}$ (it includes integrals over continuous momenta).

(3) Acting to the right, $e^{i\vec{P}\cdot\vec{x}}e^{-H\tau}|n\rangle = e^{i\vec{p}_n\cdot\vec{x}}e^{-E_n\tau}|n\rangle$. Acting to the left, $\langle\Omega|e^{H\tau}e^{-i\vec{P}\cdot\vec{x}} = e^{E_0\tau}\langle\Omega|$ because $\vec{P}|\Omega\rangle = 0$.

(4) $\phi(0)$ is Hermitian, so $\langle n|\phi(0)|\Omega\rangle = \overline{\langle\Omega|\phi(0)|n\rangle} = \overline{c_n}$.

For $\tau < 0$ the operators are ordered the other way (Euclidean time ordering), and the same steps give (13.4) with τ replaced by $|\tau|$.

The term $n = \Omega$ is the constant $|\langle\Omega|\phi|\Omega\rangle|^2 = \langle\phi\rangle^2$. It does not depend on the separation, and it carries no information about excitations. Subtracting it defines the **connected** two-point function

$$G_c(\tau,\vec{x}) = G(\tau,\vec{x}) - \langle\phi\rangle^2 = \sum_{n\neq\Omega} |c_n|^2\, e^{-(E_n-E_0)|\tau| + i\vec{p}_n\cdot\vec{x}}. \tag{13.5}$$

If there are several vacua, we work in one of them. In infinite volume a local operator cannot take one vacuum to another (they differ everywhere in space), so $c_n = 0$ for the other vacua and they do not appear in the sum.

Physical picture: oscillation in real time, decay in imaginary time

Every term in (13.5) is an exponential $e^{-(E_n-E_0)|\tau|}$. At large $|\tau|$ the terms with larger energy die first, and the sum is dominated by the *lowest* state that ϕ can create. Undo the Wick rotation and the same term is a phase $e^{-i(E_n-E_0)t}$: the gap is the lowest frequency at which the vacuum can ring when struck by ϕ.

13.2.2 From a gap to exponential decay

Now assume a gap, $E_n - E_0 \geq \Delta$ for all $n \neq \Omega$. Fix a small reference time $\tau_0 > 0$ (we need $\tau_0 > 0$ because at $\tau = 0$ the sum is $\langle\phi(0)^2\rangle$, which is ultraviolet divergent for a point-like field). For

$\tau \geq \tau_0$ at $\vec{x} = 0$,

$$G_c(\tau, \vec{0}) \overset{(1)}{=} \sum_{n \neq \Omega} |c_n|^2 \, e^{-(E_n - E_0)\tau_0} \, e^{-(E_n - E_0)(\tau - \tau_0)}$$
$$\overset{(2)}{\leq} e^{-\Delta(\tau - \tau_0)} \sum_{n \neq \Omega} |c_n|^2 \, e^{-(E_n - E_0)\tau_0}$$
$$\overset{(3)}{=} e^{-\Delta(\tau - \tau_0)} \, G_c(\tau_0, \vec{0}). \tag{13.6}$$

(1) (13.5) at $\vec{x} = 0$, with the exponent split as $\tau = \tau_0 + (\tau - \tau_0)$.
(2) Every term is non-negative, $\tau - \tau_0 \geq 0$, and $E_n - E_0 \geq \Delta$, so each factor $e^{-(E_n - E_0)(\tau - \tau_0)}$ is at most $e^{-\Delta(\tau - \tau_0)}$.
(3) The remaining sum is (13.5) at $\tau = \tau_0$, $\vec{x} = 0$.

At nonzero $\vec{x}$ the phases can only help:

$$|G_c(\tau, \vec{x})| \overset{(1)}{\leq} \sum_{n \neq \Omega} |c_n|^2 \, e^{-(E_n - E_0)|\tau|} \left| e^{i \vec{p}_n \cdot \vec{x}} \right| \overset{(2)}{=} G_c(\tau, \vec{0}).$$

(1) The triangle inequality, $|\sum a_n| \leq \sum |a_n|$.
(2) $|e^{i\theta}| = 1$, and what is left is (13.5) at $\vec{x} = 0$.

So in *imaginary time* the correlation decays at least as $e^{-\Delta|\tau|}$.

What about two points at the same time, separated in space? In a Lorentz-invariant theory, the Euclidean correlation functions are invariant under rotations of $\mathbb{R}^d$, which mix τ with $\vec{x}$. So $G_c(\tau, \vec{x}) = F\left(\sqrt{\tau^2 + \vec{x}^2}\right)$ for some function F of the Euclidean distance alone. Then

$$G_c(0, \vec{x}) \overset{(1)}{=} F(|\vec{x}|) \overset{(2)}{=} G_c(|\vec{x}|, \vec{0}) \overset{(3)}{\leq} e^{-\Delta(|\vec{x}| - \tau_0)} \, G_c(\tau_0, \vec{0}). \tag{13.7}$$

(1) Rotation invariance at $\tau = 0$.
(2) The same function F evaluated at a purely temporal separation of the same length.
(3) The bound (13.6) with $\tau = |\vec{x}|$.

Key idea: the gap gives clustering

If H has a gap Δ, then every connected two-point function of local operators decays at least as $e^{-\Delta r}$, in imaginary time and, in a Lorentz-invariant theory, also at spacelike separation r. This is the **clustering** property that Jaffe and Witten single out as "an important consequence of the existence of a mass gap": for any $C < \Delta$, $|\langle \Omega, O(\vec{x}) O(\vec{y}) \Omega \rangle| \leq e^{-C|\vec{x} - \vec{y}|}$ for large $|\vec{x} - \vec{y}|$, when $\langle O \rangle = 0$.

Watch out: without Lorentz invariance

Step (1) of (13.7) used rotation invariance of Euclidean spacetime. A lattice magnet has no such symmetry, so the argument above only gives decay in imaginary time. Decay in space is still true for lattice systems with local interactions and a gap, but it needs a separate proof (the Hastings–Koma theorem, which gives equal-time correlations bounded by $e^{-r/\xi}$ with ξ set by the gap and the speed at which information spreads).

Reading off masses. The same formula tells us how masses are measured in lattice simulations. Integrate over space to project onto zero total momentum:

$$C(\tau) = \int \mathrm{d}^{d-1}x \; G_c(\tau, \vec{x}) \overset{(1)}{=} \sum_{n \neq \Omega} |c_n|^2 \, (2\pi)^{d-1} \delta^{d-1}(\vec{p}_n) \, e^{-(E_n - E_0)|\tau|} \tag{13.8}$$

(1) $\int \mathrm{d}^{d-1}x\, e^{i\vec{p}\cdot\vec{x}} = (2\pi)^{d-1}\delta^{d-1}(\vec{p})$.

Only states at rest survive, and their energies are their masses. At large τ the lightest state created by ϕ dominates, $C(\tau) \approx A\, e^{-m\tau}$.

Worked example 13.6: the effective-mass plateau

Suppose ϕ creates two states at rest, of masses $m_1 < m_2$, with weights $A_1, A_2 > 0$, so $C(\tau) = A_1 e^{-m_1\tau} + A_2 e^{-m_2\tau}$. Define the **effective mass** $m_{\text{eff}}(\tau) = -\mathrm{d}\ln C/\mathrm{d}\tau$. Then

$$m_{\text{eff}}(\tau) \overset{(1)}{=} \frac{m_1 A_1 e^{-m_1\tau} + m_2 A_2 e^{-m_2\tau}}{A_1 e^{-m_1\tau} + A_2 e^{-m_2\tau}}$$
$$\overset{(2)}{=} \frac{m_1 + m_2\, r\, e^{-(m_2-m_1)\tau}}{1 + r\, e^{-(m_2-m_1)\tau}}, \qquad r = A_2/A_1,$$
$$\overset{(3)}{=} m_1 + (m_2 - m_1)\, r\, e^{-(m_2-m_1)\tau} + O\big(e^{-2(m_2-m_1)\tau}\big).$$

(1) $-\mathrm{d}\ln C/\mathrm{d}\tau = -C'/C$, and $-\frac{\mathrm{d}}{\mathrm{d}\tau}e^{-m\tau} = m\, e^{-m\tau}$.
(2) Divide numerator and denominator by $A_1 e^{-m_1\tau}$.
(3) Expand $1/(1+\epsilon) = 1 - \epsilon + O(\epsilon^2)$ with $\epsilon = re^{-(m_2-m_1)\tau}$, and collect terms.

The effective mass falls from above onto a *plateau* at m_1, and it approaches the plateau at a rate set by the splitting $m_2 - m_1$ (Figure 13.5). Lattice glueball masses are read off from exactly such plateaux, with ϕ a gauge-invariant operator like $\mathrm{tr}\, F_{ij}F_{ij}$ summed over a time slice.

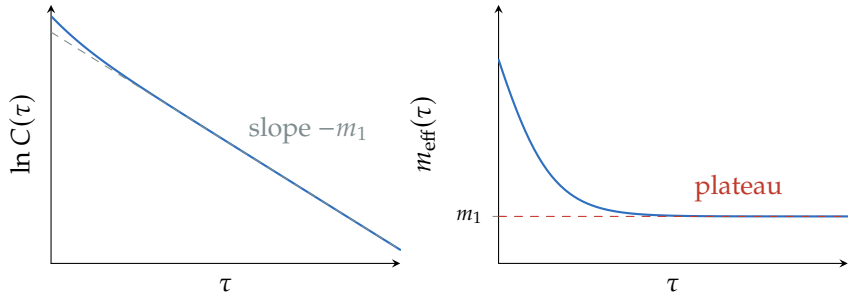

Figure 13.5: Reading a mass off a Euclidean correlator. Left: at zero momentum, $\ln C(\tau)$ becomes a straight line whose slope is minus the lightest mass. Right: the effective mass $-\mathrm{d}\ln C/\mathrm{d}\tau$ falls onto a plateau at m_1. The heavier state only bends the curve at small τ.

The converse. The implication also runs the other way in a relativistic theory. If every connected correlator of local operators decays at least as e^{-mr}, then the zero-momentum projection (13.8) decays at least as $e^{-m\tau}$ for every local operator. Since local operators acting on the vacuum create (a dense set of) all states, no state lies below m. So "gap" and "exponential clustering of all local correlators" are two ways of saying the same thing.

13.2.3 The Källén–Lehmann representation

Lorentz invariance lets us organise the spectral sum by invariant mass. Write $p = (p^0, \vec{p})$ for a d-momentum and $p^2 = (p^0)^2 - \vec{p}^{\,2}$ for its Minkowski square. Each state $|n\rangle$ has $p_n = (E_n - E_0, \vec{p}_n)$. Define the **spectral density** ρ by

$$\sum_{n\neq\Omega} |c_n|^2\, (2\pi)^d\, \delta^d(p - p_n) = 2\pi\, \theta(p^0)\, \rho(p^2). \tag{13.9}$$

The left side is a sum of positive delta functions, so $\rho \geq 0$. It is Lorentz invariant (each Lorentz transformation permutes the states $|n\rangle$ without changing $|c_n|$ for a scalar ϕ), so it can depend on p only through p^2 and the sign of p^0. The spectral condition says it vanishes unless $p^2 \geq 0$ and $p^0 > 0$.

Working definition 13.2 (spectral density)

The **spectral density** $\rho(\mu^2)$ of a field ϕ is the non-negative function defined by (13.9) [how strongly ϕ, acting on the vacuum, creates states of invariant mass μ]. A single particle of mass m shows up as a delta function $Z\,\delta(\mu^2 - m^2)$ [$Z = |c|^2$ is the probability-like weight with which ϕ creates that particle], and many-particle states show up as a continuous part starting at a threshold [the smallest total invariant mass of the particles, for example $2m$]. *To test for a gap:* the gap is the lowest μ at which ρ of some local operator is nonzero.

Now rewrite (13.5) with ρ. For $\tau > 0$,

$$
\begin{aligned}
G_c(\tau,\vec{x}) &\overset{(1)}{=} \int \frac{\mathrm{d}^d p}{(2\pi)^d} \sum_{n\neq\Omega} |c_n|^2 (2\pi)^d \delta^d(p - p_n)\, e^{-p^0\tau + i\vec{p}\cdot\vec{x}} \\
&\overset{(2)}{=} \int \frac{\mathrm{d}^d p}{(2\pi)^{d-1}}\, \theta(p^0)\rho(p^2)\, e^{-p^0\tau + i\vec{p}\cdot\vec{x}} \\
&\overset{(3)}{=} \int_0^\infty \mathrm{d}\mu^2\, \rho(\mu^2) \int \frac{\mathrm{d}^d p}{(2\pi)^{d-1}}\, \theta(p^0)\, \delta(p^2 - \mu^2)\, e^{-p^0\tau + i\vec{p}\cdot\vec{x}} \\
&\overset{(4)}{=} \int_0^\infty \mathrm{d}\mu^2\, \rho(\mu^2) \int \frac{\mathrm{d}^{d-1} p}{(2\pi)^{d-1}\, 2\omega_\mu(\vec{p})}\, e^{-\omega_\mu(\vec{p})\tau + i\vec{p}\cdot\vec{x}} \\
&\overset{(5)}{=} \int_0^\infty \mathrm{d}\mu^2\, \rho(\mu^2)\, G_\mu(\tau,\vec{x}).
\end{aligned}
\tag{13.10}
$$

(1) In each term of (13.5), write the exponential as $\int \mathrm{d}^d p\, \delta^d(p - p_n)\, e^{-p^0\tau + i\vec{p}\cdot\vec{x}}$, and move the sum inside the p integral.

(2) Definition (13.9); the factor 2π cancels one power of 2π.

(3) Insert $1 = \int_0^\infty \mathrm{d}\mu^2\, \delta(p^2 - \mu^2)$, allowed because $p^2 \geq 0$ wherever $\rho(p^2) \neq 0$, and then replace $\rho(p^2)$ by $\rho(\mu^2)$.

(4) Do the p^0 integral. With $\omega_\mu(\vec{p}) = \sqrt{\vec{p}^{\,2} + \mu^2}$, $\delta\big((p^0)^2 - \omega^2\big) = \big[\delta(p^0 - \omega) + \delta(p^0 + \omega)\big]/(2\omega)$, and $\theta(p^0)$ keeps the first term.

(5) The inner integral is the Euclidean propagator G_μ of a free field of mass μ, as we check next.

The check. The free Euclidean propagator is $G_\mu(\tau,\vec{x}) = \int \frac{\mathrm{d}^d k}{(2\pi)^d} \frac{e^{ik_0\tau + i\vec{k}\cdot\vec{x}}}{k_0^2 + \vec{k}^2 + \mu^2}$. Do the k_0 integral first, for $\tau > 0$, with $\omega = \sqrt{\vec{k}^2 + \mu^2}$:

$$
\int_{-\infty}^{\infty} \frac{\mathrm{d}k_0}{2\pi}\, \frac{e^{ik_0\tau}}{k_0^2 + \omega^2} \overset{(1)}{=} \frac{1}{2\pi}\, 2\pi i\, \mathrm{Res}_{k_0 = i\omega} \frac{e^{ik_0\tau}}{(k_0 - i\omega)(k_0 + i\omega)} \overset{(2)}{=} i\, \frac{e^{-\omega\tau}}{2i\omega} = \frac{e^{-\omega\tau}}{2\omega}.
$$

(1) For $\tau > 0$, $e^{ik_0\tau}$ decays in the upper half plane, so we close the contour there. The only pole inside is $k_0 = i\omega$.

(2) The residue is $e^{i(i\omega)\tau}/(2i\omega) = e^{-\omega\tau}/(2i\omega)$.

What remains is exactly the inner integral of step (4) with μ in place of the mass. For a free field of mass m, the only states created by ϕ are one-particle states $|\vec{q}\rangle$ with $c = 1$ and

$\sum_n \to \int \frac{\mathrm{d}^{d-1}q}{(2\pi)^{d-1}2\omega_q}$, and (13.9) gives

$$\int \frac{\mathrm{d}^{d-1}q}{(2\pi)^{d-1}2\omega_q}(2\pi)^d\delta(p^0-\omega_q)\delta^{d-1}(\vec{p}-\vec{q}) \overset{(1)}{=} \frac{2\pi\,\delta(p^0-\omega_p)}{2\omega_p} \overset{(2)}{=} 2\pi\,\theta(p^0)\,\delta(p^2-m^2),$$

(1) The $\vec{q}$ integral sets $\vec{q}=\vec{p}$.
(2) The identity used in step (4) above, read backwards.

so $\rho(\mu^2)=\delta(\mu^2-m^2)$ and (13.10) returns G_m, as it must.

Key idea: Källén–Lehmann

Any two-point function in a unitary Lorentz-invariant theory is a positive superposition of free propagators,

$$G_c(x)=\int_0^\infty \mathrm{d}\mu^2\,\rho(\mu^2)\,G_\mu(x), \qquad \rho\geq 0.$$

If $\rho(\mu^2)=0$ for $\mu<\Delta$, then G_c is a superposition of propagators each of which decays at least as $e^{-\Delta r}$ (next subsection). The gap is the bottom of the support of ρ.

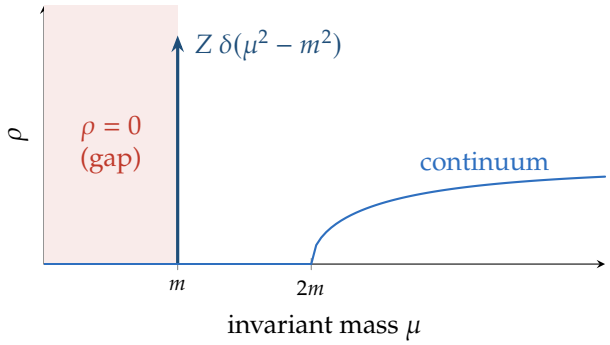

Figure 13.6: A typical spectral density in a gapped theory. Nothing below the lightest mass m (shaded). A delta function at $\mu=m$ for the one-particle state, with weight Z. A continuum from the two-particle threshold $2m$ upwards. In a gapless theory the continuum would reach down to $\mu=0$.

Try it: a gapless spectral density

Take $\rho(\mu^2)=(\mu^2)^a$ for $\mu>0$, with $a>-1$. Show, using the scaling $G_\mu(x)=\mu^{d-2}g(\mu|x|)$ of the free propagator (evident from (13.11) below), that $G_c(x)\propto|x|^{-(d+2a)}$. *Answer:* substitute $\mu=s/|x|$; then $\int \mathrm{d}\mu^2\,\mu^{2a}\mu^{d-2}g(\mu|x|)=|x|^{-(2a+d)}\int \mathrm{d}s^2\,s^{2a+d-2}g(s)$. A continuum reaching down to zero gives a power law, the hallmark of a conformal field theory (Chapter 11), where $2\Delta_\phi=d+2a$.

13.2.4 The free massive propagator: Bessel functions and Yukawa

We now compute $G_m(x)=\int \frac{\mathrm{d}^dk}{(2\pi)^d}\frac{e^{ik\cdot x}}{k^2+m^2}$ in d Euclidean dimensions, with $r=|x|$. The trick is to turn the denominator into a Gaussian.

$$G_m(x) \overset{(1)}{=} \int_0^\infty \mathrm{d}s \int \frac{\mathrm{d}^dk}{(2\pi)^d}\,e^{ik\cdot x-s(k^2+m^2)}$$
$$\overset{(2)}{=} \int_0^\infty \mathrm{d}s\; e^{-sm^2}\,(4\pi s)^{-d/2}\,e^{-r^2/(4s)}$$

$$\overset{(3)}{=} (4\pi)^{-d/2}\, m^{d-2} \int_0^\infty \mathrm{d}t\; t^{-d/2}\, e^{-t-(mr)^2/(4t)}$$
$$\overset{(4)}{=} (4\pi)^{-d/2}\, m^{d-2} \cdot 2\Big(\frac{mr}{2}\Big)^{1-d/2} K_{d/2-1}(mr)$$
$$\overset{(5)}{=} \frac{1}{(2\pi)^{d/2}} \Big(\frac{m}{r}\Big)^{d/2-1} K_{d/2-1}(mr). \tag{13.11}$$

(1) The **Schwinger parametrisation** $1/A = \int_0^\infty \mathrm{d}s\, e^{-sA}$ for $A > 0$, with $A = k^2 + m^2$.
(2) The k integral factorises into d Gaussian integrals. In each, complete the square, $ik_jx_j - sk_j^2 = -s(k_j - ix_j/2s)^2 - x_j^2/4s$, and use $\int \mathrm{d}k\, e^{-sk^2} = \sqrt{\pi/s}$, so $\int \frac{\mathrm{d}k_j}{2\pi} e^{ik_jx_j - sk_j^2} = (4\pi s)^{-1/2} e^{-x_j^2/4s}$. The product over j gives $(4\pi s)^{-d/2} e^{-r^2/4s}$.
(3) Change variable to $t = sm^2$: $\mathrm{d}s = \mathrm{d}t/m^2$, $s^{-d/2} = m^d t^{-d/2}$ and $r^2/4s = (mr)^2/4t$.
(4) The integral representation of the modified Bessel function,

$$K_\nu(z) = \tfrac{1}{2}(z/2)^\nu \int_0^\infty \mathrm{d}t\; t^{-\nu-1} e^{-t-z^2/4t},$$

with $\nu = d/2 - 1$ (so $t^{-\nu-1} = t^{-d/2}$) and $z = mr$. It says that $\int_0^\infty \mathrm{d}t\, t^{-d/2} e^{-t-z^2/4t}$ equals $2(z/2)^{-\nu} K_\nu(z)$.
(5) Collect constants: $2 \cdot 2^\nu (4\pi)^{-d/2} = 2^{d/2}\, 2^{-d}\, \pi^{-d/2} = (2\pi)^{-d/2}$, and $m^{d-2}(mr)^{-\nu} = m^\nu r^{-\nu}$.

Large distances. For $z \gg 1$ the Bessel integral is dominated by the minimum of the exponent $f(t) = t + z^2/4t$, a Laplace (saddle-point) approximation.

$$K_\nu(z) \overset{(1)}{=} \tfrac{1}{2}\big(\tfrac{z}{2}\big)^\nu \int_0^\infty \mathrm{d}t\; t^{-\nu-1} e^{-f(t)} \overset{(2)}{\approx} \tfrac{1}{2}\big(\tfrac{z}{2}\big)^\nu \big(\tfrac{z}{2}\big)^{-\nu-1} e^{-z} \sqrt{\frac{2\pi}{4/z}} \overset{(3)}{=} \sqrt{\frac{\pi}{2z}}\; e^{-z}.$$

(1) The integral representation, with $f(t) = t + z^2/4t$.
(2) $f'(t) = 1 - z^2/4t^2$ vanishes at $t_* = z/2$, where $f(t_*) = z$ and $f''(t_*) = z^2/(2t_*^3) = 4/z$. Laplace's method: $\int g(t) e^{-f(t)} \mathrm{d}t \approx g(t_*) e^{-f(t_*)} \sqrt{2\pi/f''(t_*)}$, with $g = t^{-\nu-1}$ slowly varying on the width $\sqrt{z/4}$ of the peak.
(3) $\frac{1}{2} \cdot \frac{2}{z} \cdot \sqrt{\pi z/2} = \sqrt{\pi/2z}$.

Inserting this into (13.11),

$$G_m(r) \overset{(1)}{\approx} \frac{1}{(2\pi)^{d/2}} \Big(\frac{m}{r}\Big)^{\frac{d-2}{2}} \sqrt{\frac{\pi}{2mr}}\; e^{-mr} \overset{(2)}{=} \frac{1}{2m} \Big(\frac{m}{2\pi r}\Big)^{\frac{d-1}{2}} e^{-mr}, \qquad mr \gg 1. \tag{13.12}$$

(1) The asymptotic form of K_ν.
(2) Collect powers: $m^{(d-2)/2-1/2} = m^{(d-3)/2} = m^{-1} m^{(d-1)/2}$, $r^{-(d-2)/2-1/2} = r^{-(d-1)/2}$, and $(2\pi)^{-d/2}(\pi/2)^{1/2} = \frac{1}{2}(2\pi)^{-(d-1)/2}$.

So the free propagator decays as e^{-mr} times a power $r^{-(d-1)/2}$. At short distances, $mr \ll 1$, the mass is invisible and G_m reduces to the massless power law $G_0 \propto r^{-(d-2)}$ (for $d > 2$). The crossover happens at $r \sim 1/m$ (Figure 13.7).

Worked example 13.7: three dimensions: the Yukawa form, directly

For $d = 3$, $\nu = \frac{1}{2}$ and $K_{1/2}(z) = \sqrt{\pi/2z}\, e^{-z}$ *exactly*, so (13.11) gives $G_m = e^{-mr}/(4\pi r)$ with no approximation. It is worth getting this directly, with spherical coordinates $\vec{k}$ at angle

arccos u to $\vec{x}$:

$$G_m(r) \overset{(1)}{=} \frac{1}{(2\pi)^2}\int_0^\infty \mathrm{d}k\,\frac{k^2}{k^2+m^2}\int_{-1}^{1}\mathrm{d}u\,e^{ikru} \overset{(2)}{=} \frac{1}{(2\pi)^2}\int_0^\infty \mathrm{d}k\,\frac{k^2}{k^2+m^2}\,\frac{2\sin kr}{kr}$$
$$\overset{(3)}{=} \frac{1}{4\pi^2 r}\,\mathrm{Im}\int_{-\infty}^{\infty}\mathrm{d}k\,\frac{k\,e^{ikr}}{k^2+m^2} \overset{(4)}{=} \frac{1}{4\pi^2 r}\,\mathrm{Im}\Big(2\pi i\cdot\frac{im\,e^{-mr}}{2im}\Big) = \frac{e^{-mr}}{4\pi r}.$$

(1) $\mathrm{d}^3k = 2\pi k^2\,\mathrm{d}k\,\mathrm{d}u$; the 2π from the azimuth cancels one of the three factors 2π.
(2) $\int_{-1}^{1} e^{iau}\mathrm{d}u = 2\sin a/a$.
(3) $k\sin kr/(k^2+m^2)$ is even in k, so $\int_0^\infty = \frac{1}{2}\int_{-\infty}^{\infty}$, and $\sin kr = \mathrm{Im}\,e^{ikr}$.
(4) Close the contour in the upper half plane ($r>0$). The pole at $k=im$ has residue $im\,e^{-mr}/(2im) = e^{-mr}/2$.

Worked example 13.8: two and four dimensions

$d=4$: $G_m = \frac{m}{4\pi^2 r}K_1(mr)$. For $mr \ll 1$, $K_1(z)\approx 1/z$ and $G_m \approx 1/(4\pi^2 r^2)$, the massless propagator. For $mr \gg 1$, (13.12) gives $G_m \approx \frac{\sqrt{m}}{2(2\pi r)^{3/2}}e^{-mr}$. $d=2$: $G_m = \frac{1}{2\pi}K_0(mr)$. For $mr \ll 1$, $K_0(z)\approx -\ln(z/2)-\gamma_E$ (γ_E is Euler's constant), a logarithm. The massless propagator in two dimensions is $-\frac{1}{2\pi}\ln r$, which does not even decay. This infrared disaster will force a mass to appear in Section 13.3.4.

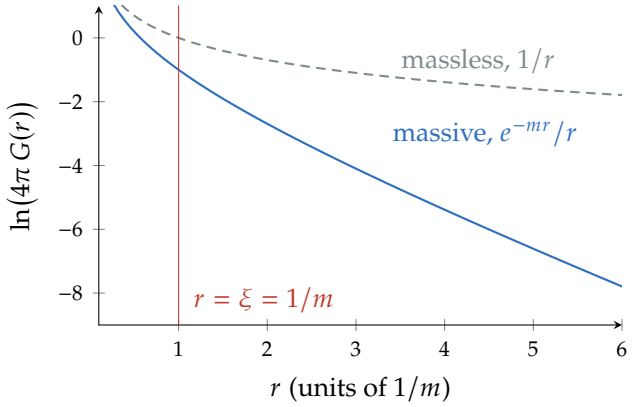

Figure 13.7: The three-dimensional propagator on a logarithmic scale. At distances below $\xi = 1/m$ the massive propagator (blue) follows the massless one (grey, dashed). Beyond ξ it falls exponentially, a straight line of slope $-m$ at large r, while the massless one decays only as a power.

Worked example 13.9: the Yukawa potential and the range of a force

Couple a scalar of mass m to static point sources through $\mathcal{L} \ni g\,\varrho(\vec{x})\phi$. The static field energy is $E[\phi] = \int \mathrm{d}^3x\big[\frac{1}{2}(\nabla\phi)^2 + \frac{1}{2}m^2\phi^2 - g\varrho\phi\big]$, and minimising it gives $(-\nabla^2+m^2)\phi = g\varrho$. For two sources $\varrho = \delta^3(\vec{x}-\vec{x}_1)+\delta^3(\vec{x}-\vec{x}_2)$ at distance r:

$$E_{\min} \overset{(1)}{=} -\tfrac{1}{2}\,g\int \mathrm{d}^3x\,\varrho\,\phi \overset{(2)}{=} -\tfrac{1}{2}\,g^2\int \mathrm{d}^3x\,\mathrm{d}^3y\;\varrho(\vec{x})\,G_m(\vec{x}-\vec{y})\,\varrho(\vec{y})$$
$$\overset{(3)}{=} (\text{self-energies}) \;-\; g^2\,G_m(r) \overset{(4)}{=} (\text{self-energies}) \;-\; \frac{g^2}{4\pi}\,\frac{e^{-mr}}{r}.$$

(1) Integrate $(\nabla\phi)^2$ by parts and use the field equation: the quadratic terms become $\frac{1}{2}g\int\varrho\phi$.

(2) The solution is $\phi = g\, G_m * \varrho$, since G_m is the Green function of $-\nabla^2 + m^2$ in three dimensions.
(3) Of the four terms, the two with $\vec{x}, \vec{y}$ at the same source do not depend on r. The two cross terms are equal.
(4) Example 13.7.

The interaction $V(r) = -\frac{g^2}{4\pi}\frac{e^{-mr}}{r}$ is attractive and has range $1/m$. For $m = 0$ it is Coulomb's (or Newton's) law. This was Yukawa's argument of 1935: the nuclear force has a range of about 1.4 fm, so it must be carried by a particle of mass about $\hbar c/1.4\,\text{fm} \approx 140\,\text{MeV}$. That particle is the pion.

13.2.5 The correlation length and the renormalisation group

The **correlation length** is the decay length of connected correlations,

$$\xi = -\lim_{r\to\infty} \frac{r}{\ln G_c(r)}.$$

By (13.12) and (13.10), in a relativistic theory $\xi = 1/m$, where m is the lightest mass that the operator can create (the power-law prefactor does not change the limit). Taking the lightest over all local operators, $\xi = 1/\Delta$.

Worked example 13.10: the Ising chain: transfer matrix, gap and ξ

The one-dimensional Ising chain at coupling K (weight $\prod_i e^{K s_i s_{i+1}}$, $s_i = \pm 1$) is a Euclidean "quantum mechanics" in which the lattice direction is imaginary time. Its **transfer matrix** is the 2×2 matrix of Boltzmann weights between neighbours,

$$T = \begin{pmatrix} e^{K} & e^{-K} \\ e^{-K} & e^{K} \end{pmatrix}, \qquad T\begin{pmatrix}1\\1\end{pmatrix} = 2\cosh K \begin{pmatrix}1\\1\end{pmatrix}, \quad T\begin{pmatrix}1\\-1\end{pmatrix} = 2\sinh K\begin{pmatrix}1\\-1\end{pmatrix}.$$

Write $T = \lambda_1 e^{-aH}$: H is a Hamiltonian with eigenvalues 0 and $\Delta = a^{-1}\ln(\lambda_1/\lambda_2)$, where a is the lattice spacing. The spin s is the matrix σ^z, which maps the eigenvector $(1,1)$ to $(1,-1)$. For an infinite chain,

$$\langle s_0 s_r\rangle \overset{(1)}{=} \frac{\langle 1|\sigma^z T^r \sigma^z|1\rangle}{\lambda_1^r} \overset{(2)}{=} |\langle 2|\sigma^z|1\rangle|^2 \Big(\frac{\lambda_2}{\lambda_1}\Big)^r \overset{(3)}{=} (\tanh K)^r \overset{(4)}{=} e^{-r\,a\Delta}.$$

(1) For a long chain, $\mathrm{Tr}(\cdots T^N)$ is dominated by the top eigenvector $|1\rangle = (1,1)/\sqrt{2}$, which plays the role of the vacuum.
(2) Insert $|2\rangle\langle 2|$ with $|2\rangle = (1,-1)/\sqrt{2}$, the only state that $\sigma^z|1\rangle$ has overlap with, since $\sigma^z|1\rangle = |2\rangle$.
(3) $|\langle 2|\sigma^z|1\rangle| = 1$ and $\lambda_2/\lambda_1 = \tanh K$.
(4) Definition of Δ.

This is (13.4) in miniature. The correlation length in lattice units is $\xi = 1/(a\Delta) = -1/\ln\tanh K$. At low temperature (large K), $\ln\tanh K \approx -2e^{-2K}$, so $\xi \approx \frac{1}{2}e^{2K}$, which is huge but finite for any $K < \infty$. Under the decimation step of Chapter T5, $\tanh K' = \tanh^2 K$, so $\xi(K') = -1/(2\ln\tanh K) = \xi(K)/2$: the correlation length measured in the new lattice units halves, as it must.

Key idea: gap, correlation length and the RG

In a lattice model the correlation length ξ is measured in lattice units, and the physical mass is $m = 1/(\xi a)$. Under coarse graining by a factor b, $\xi \mapsto \xi/b$ (Chapter T5). So a *fixed point* of the RG has $\xi = 0$ or $\xi = \infty$.

- Away from a critical point ξ is finite. Coarse graining drives $\xi \to 0$: the long-distance limit of a gapped theory has no local degrees of freedom left. It is trivial, or a topological field theory (Section 13.8.2).
- At a critical point $\xi = \infty$, and $m = 0$. Near it, $\xi \propto |t|^{-\nu}$, so the gap closes as $m \propto |t|^{\nu}$, where t is the distance from criticality.
- To define a continuum QFT with a finite mass m from a lattice, we must take $a \to 0$ at fixed m, so $\xi = 1/(ma) \to \infty$: the continuum limit is taken *at* a critical point, approached along a trajectory.

13.2.6 The Compton wavelength

Restore $\hbar$ and c. A mass m becomes an inverse length through

$$\xi = \frac{1}{m} \quad \longrightarrow \quad \lambda\!\!\!^{-}_C = \frac{\hbar}{mc},$$

the (reduced) **Compton wavelength**. So the correlation length of a gapped relativistic theory is the Compton wavelength of its lightest particle. This length has a second meaning: it is the length below which a one-particle description fails and quantum *field* theory becomes unavoidable.

Two wavelengths, two thresholds. Quantum mechanics becomes important when the **de Broglie wavelength** $\lambda_{\mathrm{dB}} = h/p$ of a particle is comparable to the size of the region it moves in. Quantum field theory becomes important when the particle is probed on distances comparable to $\lambda\!\!\!^{-}_C$. The argument is the uncertainty principle plus $E = mc^2$. Suppose a particle is localised within Δx. Then

$$\Delta p \overset{(1)}{\gtrsim} \frac{\hbar}{\Delta x}, \qquad \text{so} \qquad \Delta x < \lambda\!\!\!^{-}_C = \frac{\hbar}{mc} \overset{(2)}{\Longrightarrow} c\,\Delta p > mc^2. \tag{13.13}$$

(1) The Heisenberg uncertainty relation, up to a factor of order one.
(2) Substitute $\Delta x < \hbar/(mc)$ into $\Delta p \gtrsim \hbar/\Delta x$ and multiply by c.

A relativistic particle with momentum spread $\Delta p \gtrsim mc$ has an energy spread $c\Delta p \gtrsim mc^2$, comparable to the threshold $2mc^2$ for creating a particle–antiparticle pair. So an attempt to confine an electron to a region smaller than its Compton wavelength puts enough energy into the region to create electron–positron pairs. The "one electron" is no longer one electron, the particle number is not conserved, and the only consistent description is a field. Correlations of the field extend over $\lambda\!\!\!^{-}_C$ because virtual pairs live that long: $\Delta t \sim \hbar/(2mc^2)$, over which they travel $c\Delta t \sim \lambda\!\!\!^{-}_C/2$.

Worked example 13.11: numbers for the electron and the pion

Use $\hbar c = 197.327\,\mathrm{MeV\,fm}$ ($1\,\mathrm{fm} = 10^{-15}\,\mathrm{m}$).

$$\lambda\!\!\!^{-}_C(e) \overset{(1)}{=} \frac{\hbar c}{m_e c^2} = \frac{197.327\ \mathrm{MeV\,fm}}{0.511\ \mathrm{MeV}} \overset{(2)}{=} 386.2\ \mathrm{fm} = 3.86 \times 10^{-13}\ \mathrm{m},$$
$$\lambda\!\!\!^{-}_C(\pi^{\pm}) \overset{(1)}{=} \frac{\hbar c}{m_\pi c^2} = \frac{197.327\ \mathrm{MeV\,fm}}{139.57\ \mathrm{MeV}} \overset{(2)}{=} 1.414\ \mathrm{fm}.$$

(1) Multiply top and bottom of $\hbar/(mc)$ by c.
(2) Arithmetic. (The unreduced Compton wavelength is 2π times larger, $h/(m_e c) = 2.43 \times 10^{-12}$ m for the electron.)

The pion value is the range of the nuclear force (Example 13.9). Compare with atomic physics. The Bohr radius is $a_0 = \lambda\!\!\!^{-}_C(e)/\alpha = 386.2\,\text{fm} \times 137.04 = 5.29 \times 10^4\,\text{fm} = 0.529\,\text{Å}$, where $\alpha \approx 1/137$ is the fine-structure constant. Atoms are 137 times larger than the electron's Compton wavelength. That is why non-relativistic quantum mechanics describes them so well, and why the effects of the quantum electromagnetic field (the Lamb shift, $g-2$) are small corrections, suppressed by powers of α. By contrast, a 1 eV electron has $p = \sqrt{2m_e E} = 1.01\,\text{keV}/c$ and de Broglie wavelength $\lambda_{\text{dB}} = h/p = 1.23\,\text{nm}$: quantum mechanics matters at the nanometre scale, field theory at the scale of 10^{-13} m.

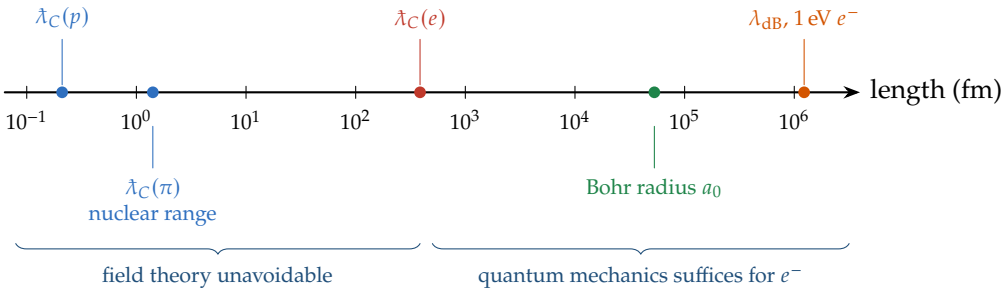

Figure 13.8: Length scales on a logarithmic axis. Each reduced Compton wavelength $\hbar/mc$ is the correlation length of the corresponding field and the range of the force it carries. For the electron, the Bohr radius sits a factor 137 above $\lambda\!\!\!^{-}_C(e)$, so atoms live in the quantum-mechanical regime. Nuclear physics lives at the pion's Compton wavelength, where pair creation of pions is always at hand.

Recap

- Inserting energy eigenstates gives the exact spectral sum $G_c = \sum_{n\neq\Omega} |c_n|^2 e^{-(E_n-E_0)|\tau|+i\vec{p}_n\cdot\vec{x}}$.
- A gap Δ bounds G_c by $e^{-\Delta|\tau|}$, and by Euclidean rotation invariance also by $e^{-\Delta r}$ at spacelike separation. Conversely, clustering of all local correlators implies a gap.
- Källén–Lehmann: $G_c = \int \mathrm{d}\mu^2 \rho(\mu^2) G_\mu$ with $\rho \geq 0$. The gap is the bottom of the support of ρ.
- The free propagator is $(2\pi)^{-d/2}(m/r)^{d/2-1}K_{d/2-1}(mr)$, decaying as $r^{-(d-1)/2}e^{-mr}$. In $d=3$ it is Yukawa's $e^{-mr}/4\pi r$.
- $\xi = 1/\Delta = \hbar/mc$: the correlation length is the Compton wavelength of the lightest particle. It is finite away from critical points and diverges at RG fixed points.
- Probing below $\lambda\!\!\!^{-}_C$ creates pairs. That is the scale where quantum field theory takes over from quantum mechanics.

13.3 Elementary ways to make a gap

A theory is gapless when it has massless excitations. Massless excitations are usually there for a reason: a symmetry forbids their mass. So opening a gap means getting around that protection. There are three elementary ways. Put in a mass by hand, where the symmetries allow it. Let a gauge field "eat" a would-be Goldstone boson (the Higgs mechanism). Or let quantum effects create a mass out of a theory that has none classically (dimensional transmutation). This section treats all three, and solves one theory of the third kind exactly at large N. The topological mechanisms of the later sections are best understood against this background.

Key idea: what keeps things massless

- *Gauge invariance* forbids a photon mass term $m^2 A_\mu A^\mu$, since it changes under $A \to A + \mathrm{d}\alpha$.
- *Chiral symmetry* forbids a fermion mass term $\bar\psi\psi$, since it couples left- and right-handed components that rotate differently.
- *Spontaneously broken continuous symmetry* gives Goldstone bosons, whose mass is forbidden by the shift $\theta \to \theta + c$ of the Goldstone field.

Every gap-generating mechanism in this chapter defeats one of these protections.

13.3.1 An explicit mass

The simplest way is to write a mass into the Lagrangian. For a real scalar in Minkowski signature, $\mathcal{L} = \frac{1}{2}\partial_\mu\phi\partial^\mu\phi - \frac{1}{2}m^2\phi^2$, the field equation and a plane wave give

$$(\partial_t^2 - \nabla^2 + m^2)\phi = 0, \quad \phi = e^{-i\omega t + i\vec{k}\cdot\vec{x}} \overset{(1)}{\Longrightarrow} -\omega^2 + \vec{k}^2 + m^2 = 0 \overset{(2)}{\Longrightarrow} \omega = \sqrt{\vec{k}^2 + m^2} \geq m.$$

(1) $\partial_t \to -i\omega$ and $\nabla \to i\vec{k}$ on the plane wave.

(2) Take the positive root. The minimum over $\vec{k}$ is at $\vec{k} = 0$.

This dispersion relation, quantised, gives the gapped spectrum of Example 13.1. A Dirac mass $m\bar\psi\psi$ does the same for fermions.

Worked example 13.12: the Proca field: a vector with an explicit mass

Take $\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}m^2 A_\mu A^\mu$ in 3+1 dimensions. The field equation is $\partial_\mu F^{\mu\nu} + m^2 A^\nu = 0$. Then

$$0 \overset{(1)}{=} \partial_\nu\partial_\mu F^{\mu\nu} + m^2\partial_\nu A^\nu \overset{(2)}{=} m^2\,\partial_\nu A^\nu,$$
$$0 \overset{(3)}{=} \partial_\mu\partial^\mu A^\nu - \partial^\nu\partial_\mu A^\mu + m^2 A^\nu \overset{(4)}{=} (\Box + m^2)A^\nu.$$

(1) Take ∂_ν of the field equation.

(2) $\partial_\nu\partial_\mu$ is symmetric and $F^{\mu\nu}$ antisymmetric, so the first term vanishes. Hence $\partial_\nu A^\nu = 0$ for $m \neq 0$.

(3) Write out $F^{\mu\nu} = \partial^\mu A^\nu - \partial^\nu A^\mu$ in the field equation.

(4) Use $\partial_\mu A^\mu = 0$ from the first line.

Each component obeys the Klein–Gordon equation, and the constraint $\partial \cdot A = 0$ removes one of the four components, leaving three polarisations of mass m. The price is gauge invariance: $m^2 A_\mu A^\mu$ is not invariant under $A \to A + \partial\alpha$. For the gluons of Yang–Mills theory such a term would destroy the consistency of the quantum theory, so gauge bosons need a subtler mechanism.

Worked example 13.13: a small explicit breaking gives a small gap

Take a complex scalar with a U(1)-symmetric Mexican-hat potential, whose minima form the circle $|\phi| = v/\sqrt{2}$. Write $\phi = \frac{v}{\sqrt{2}} e^{i\theta}$ on the circle. The kinetic term becomes $|\partial\phi|^2 = \frac{v^2}{2}(\partial\theta)^2$, and θ is a massless Goldstone boson. Now tilt the hat with a small term $-\epsilon \operatorname{Re}\phi$, $\epsilon > 0$. On the circle of minima,

$$-\epsilon \operatorname{Re}\phi \overset{(1)}{=} -\frac{\epsilon v}{\sqrt{2}} \cos\theta \overset{(2)}{=} -\frac{\epsilon v}{\sqrt{2}} + \frac{\epsilon v}{2\sqrt{2}}\,\theta^2 + O(\theta^4).$$

(1) $\operatorname{Re} e^{i\theta} = \cos\theta$.
(2) $\cos\theta = 1 - \theta^2/2 + \ldots$

Compare with $\frac{v^2}{2}\left[(\partial\theta)^2 - m_\theta^2\theta^2\right]$ (the canonical form for the field $v\theta$). Matching the θ^2 terms, $\frac{v^2}{2}m_\theta^2 = \frac{\epsilon v}{2\sqrt{2}}$, so $m_\theta^2 = \epsilon/(\sqrt{2}\,v)$. The gap grows like $\sqrt{\epsilon}$. The same mechanism gives the pions their mass, $m_\pi^2 \propto m_u + m_d$ (the Gell-Mann–Oakes–Renner relation): the quark masses tilt the hat of broken chiral symmetry.

13.3.2 The Higgs mechanism

Gauge the U(1) of the previous example. The **abelian Higgs model** is

$$\mathcal{L} = -\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} + |D_\mu\phi|^2 - \lambda\left(|\phi|^2 - \tfrac{v^2}{2}\right)^2, \qquad D_\mu = \partial_\mu - ieA_\mu,$$

in Minkowski signature, with gauge coupling e written explicitly. It is invariant under $\phi \to e^{ie\alpha}\phi$, $A_\mu \to A_\mu + \partial_\mu\alpha$. Without the gauge field, the phase of ϕ would be a Goldstone boson (Figure 13.9). With it, the phase can be removed by a gauge transformation: choose α so that ϕ is real and positive everywhere (the **unitary gauge**), and write $\phi = (v + h)/\sqrt{2}$ with h a real field. Then

$$\begin{aligned} |D_\mu\phi|^2 &\overset{(1)}{=} \tfrac{1}{2}\left|\partial_\mu h - ieA_\mu(v+h)\right|^2 \overset{(2)}{=} \tfrac{1}{2}(\partial_\mu h)^2 + \tfrac{1}{2}e^2(v+h)^2 A_\mu A^\mu \\ &= \tfrac{1}{2}(\partial_\mu h)^2 + \tfrac{1}{2}\,e^2v^2\,A_\mu A^\mu + e^2vh\,A_\mu A^\mu + \tfrac{1}{2}e^2h^2 A_\mu A^\mu, \end{aligned} \tag{13.14}$$

$$\lambda\left(|\phi|^2 - \tfrac{v^2}{2}\right)^2 \overset{(3)}{=} \lambda\left(vh + \tfrac{1}{2}h^2\right)^2 = \lambda v^2h^2 + \lambda vh^3 + \tfrac{1}{4}\lambda h^4. \tag{13.15}$$

(1) Insert $\phi = (v + h)/\sqrt{2}$, which is real.
(2) $|a - ib|^2 = a^2 + b^2$ for real $a = \partial_\mu h$, $b = eA_\mu(v+h)$ (with the Lorentz contraction understood).
(3) $|\phi|^2 - v^2/2 = \frac{1}{2}(v+h)^2 - \frac{1}{2}v^2 = vh + \frac{1}{2}h^2$.

Read off the quadratic terms. $\frac{1}{2}e^2v^2A_\mu A^\mu$ is a Proca mass term with $m_A^2 = e^2v^2$. $\lambda v^2h^2 = \frac{1}{2}m_h^2h^2$ gives $m_h^2 = 2\lambda v^2$. So

$$m_A = ev, \qquad m_h = \sqrt{2\lambda}\,v. \tag{13.16}$$

Count degrees of freedom in 3+1 dimensions. Before: a massless photon (two polarisations) and a complex scalar (two real fields), four in all. After: a massive vector (three polarisations) and one real scalar h, again four. The Goldstone boson has become the longitudinal polarisation of the massive photon. Every excitation is massive: *the Higgs phase is gapped*, with $\Delta = \min(m_A, m_h)$.

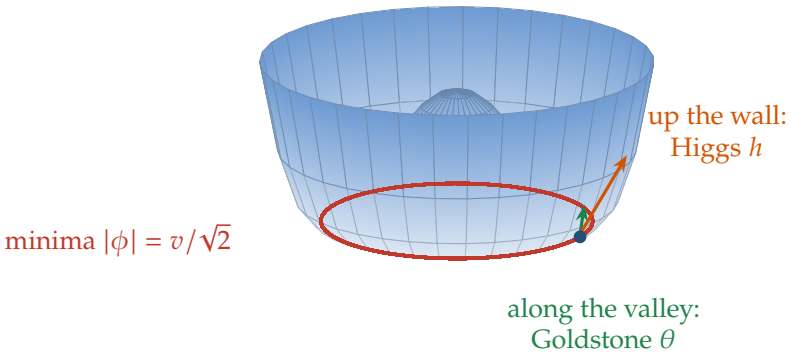

Figure 13.9: The Mexican-hat potential over the complex ϕ plane. The vacua form a circle (red). Moving up the wall costs energy, so the radial mode h is massive. Moving along the valley costs none, so the angular mode is a massless Goldstone boson. When the U(1) is gauged, motion along the valley is a gauge transformation, the Goldstone mode is absorbed by the photon, and the photon becomes massive.

Worked example 13.14: the Meissner effect: a gap seen as screening

A superconductor is a Higgs phase, with ϕ the Cooper-pair field. A static magnetic field inside obeys the Proca equation with $A_0 = 0$. In Coulomb gauge $\nabla \cdot \vec{A} = 0$ it reads $\nabla^2 \vec{A} = m_A^2 \vec{A}$, and taking the curl, $\nabla^2 \vec{B} = m_A^2 \vec{B}$. For a field $\vec{B} = B(x)\hat{\vec{z}}$ entering a superconductor filling $x > 0$,

$$B''(x) = m_A^2 B(x) \overset{(1)}{\Longrightarrow} B(x) = B_0\, e^{-m_A x} + B_1 e^{m_A x} \overset{(2)}{\Longrightarrow} B(x) = B_0\, e^{-x/\lambda_L}, \quad \lambda_L = \frac{1}{m_A}.$$

(1) General solution of a linear ODE with constant coefficients.
(2) B must stay bounded deep inside, so $B_1 = 0$.

The magnetic field is expelled, except for a skin of thickness equal to the Compton wavelength of the massive photon, the **London penetration depth**. For a typical superconductor $\lambda_L \approx 50\,\text{nm}$, so the photon mass inside is $\hbar c/\lambda_L \approx 197\,\text{MeV fm}/(5\times 10^7\,\text{fm}) \approx 4\,\text{eV}$. This is Section 13.2 in action: a gap makes the static response decay exponentially.

Watch out: the Standard Model is not gapped

In the electroweak theory the Higgs mechanism gives the W and Z bosons masses of 80.4 and 91.2 GeV, but it leaves one combination of gauge fields, the photon, massless. So the Standard Model, like QED, is gapless. Also, a "broken gauge symmetry" is a figure of speech: gauge transformations are redundancies of the description and cannot break. The gauge-invariant statement is that the Higgs phase is gapped and screens charges.

13.3.3 Dimensional transmutation

Pure Yang–Mills theory in four dimensions has one parameter, the coupling g, and g is dimensionless. Classically there is no mass anywhere: gluons are massless waves, and the theory is scale invariant. How can it have a gap? A mass needs a scale.

The scale comes from quantum mechanics. To define the quantum theory we must regularise it at some scale, and the coupling then depends on the scale μ at which it is measured

(Chapter T5). Write the running as

$$\mu \frac{\mathrm{d}g^2}{\mathrm{d}\mu} = -\beta_0\, g^4 + O(g^6), \tag{13.17}$$

where $\beta_0 > 0$ means **asymptotic freedom**: g shrinks at high energies and grows at low ones. For SU(N) Yang–Mills, $\beta_0 = \frac{11N}{24\pi^2}$. (The usual form $\mu\,\mathrm{d}g/\mathrm{d}\mu = -\frac{b_0 g^3}{16\pi^2}$ with $b_0 = \frac{11N}{3}$ gives this, since $\mu\,\mathrm{d}g^2/\mathrm{d}\mu = 2g\,\mu\,\mathrm{d}g/\mathrm{d}\mu$.) Solve the leading-order equation:

$$\mu \frac{\mathrm{d}}{\mathrm{d}\mu}\left(\frac{1}{g^2}\right) \overset{(1)}{=} -\frac{1}{g^4}\,\mu\frac{\mathrm{d}g^2}{\mathrm{d}\mu} \overset{(2)}{=} \beta_0 \quad \overset{(3)}{\Longrightarrow} \quad \frac{1}{g^2(\mu)} = \beta_0 \ln\frac{\mu}{\Lambda}. \tag{13.18}$$

(1) Chain rule, $\mathrm{d}(1/u) = -\mathrm{d}u/u^2$ with $u = g^2$.
(2) (13.17) at leading order.
(3) Integrate in $\ln\mu$. The integration constant is written as $-\beta_0 \ln\Lambda$, which defines the scale Λ.

Solving for Λ,

$$\Lambda = \mu\, e^{-1/(\beta_0 g^2(\mu))}. \tag{13.19}$$

The right side contains μ and $g(\mu)$, but the combination does not depend on μ:

$$\mu\frac{\mathrm{d}\Lambda}{\mathrm{d}\mu} \overset{(1)}{=} \Lambda + \mu\, e^{-1/(\beta_0 g^2)}\cdot\left(-\frac{1}{\beta_0}\right)\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\frac{1}{g^2} \overset{(2)}{=} \Lambda - \frac{\beta_0}{\beta_0}\Lambda = 0.$$

(1) Product rule and chain rule on (13.19).
(2) $\mu\,\mathrm{d}(1/g^2)/\mathrm{d}\mu = \beta_0$ by (13.18).

Λ is a renormalisation-group invariant mass. It is the *only* mass in pure Yang–Mills theory, so by dimensional analysis every physical mass is a pure number times Λ:

$$m = c\,\Lambda = c\,\mu\, e^{-1/(\beta_0 g^2(\mu))}. \tag{13.20}$$

A dimensionless coupling has been traded for a mass. This is **dimensional transmutation**.

Worked example 13.15: the gap is invisible in perturbation theory

Let $f(x) = e^{-1/x}$ for $x > 0$, where $x = \beta_0 g^2$. Every derivative of f has the form $f^{(n)}(x) = P_n(1/x)\,e^{-1/x}$ with P_n a polynomial. (Induction: $\frac{\mathrm{d}}{\mathrm{d}x}[P(1/x)e^{-1/x}] = [-x^{-2}P'(1/x) + x^{-2}P(1/x)]e^{-1/x}$, again a polynomial in $1/x$ times $e^{-1/x}$.) With $y = 1/x$,

$$\lim_{x\to 0^+} f^{(n)}(x) \overset{(1)}{=} \lim_{y\to\infty} P_n(y)\,e^{-y} \overset{(2)}{=} 0.$$

(1) Substitute $y = 1/x \to \infty$.
(2) An exponential beats any polynomial.

So the Taylor series of $m(g)$ around $g = 0$ is identically zero, to every order. No finite order of perturbation theory in g can see the mass gap. This is why the gap of Yang–Mills theory is a genuinely non-perturbative problem (Figure 13.10).

Physical picture: instantons and powers of Λ

A Yang–Mills instanton (Chapter 8) has action $8\pi^2/g^2$, so it contributes with weight

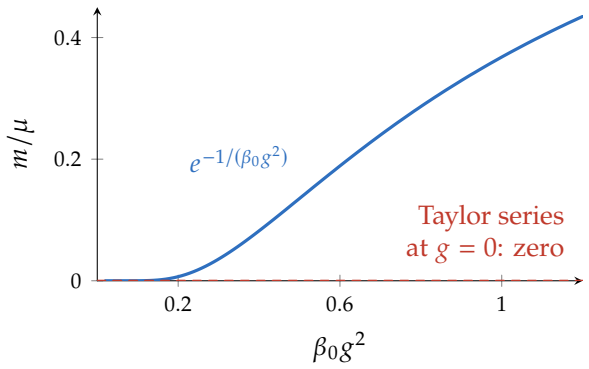

Figure 13.10: The dynamically generated mass as a function of the coupling. The curve leaves zero so flatly that all its derivatives vanish at $g = 0$: the Taylor series (red, dashed) is identically zero. A perturbative expansion in g therefore predicts massless gluons to all orders, although the true theory is (believed to be) gapped.

$e^{-8\pi^2/g^2(\mu)}$. With $1/g^2 = \frac{b_0}{8\pi^2}\ln(\mu/\Lambda)$,

$$e^{-8\pi^2/g^2(\mu)} = e^{-b_0\ln(\mu/\Lambda)} = \left(\frac{\Lambda}{\mu}\right)^{b_0}.$$

Instanton effects are powers of Λ, the same non-analytic scale. This is suggestive, but it does not mean instantons *cause* the gap. The next example shows a theory where they demonstrably do not, while Section 13.4 shows one where they do.

13.3.4 A solvable example: the $\mathbb{CP}^{N-1}$ model at large N

We want a theory that is classically massless, asymptotically free, and in which the gap can actually be computed. The two-dimensional $\mathbb{CP}^{N-1}$ model is such a theory, at large N.

The model. Take N complex fields $z_a(x)$, $a = 1, \dots, N$, on two-dimensional Euclidean space, subject to the constraint $\sum_a |z_a|^2 = N/g^2$ (a sphere S^{2N-1} in $\mathbb{C}^N$). Identify $z_a \sim e^{i\alpha(x)} z_a$ (a local U(1)). The field lives on $S^{2N-1}/\mathrm{U}(1) = \mathbb{CP}^{N-1}$, the space of complex lines in $\mathbb{C}^N$ (for $N = 2$, $\mathbb{CP}^1 = S^2$). The action is

$$S = \int \mathrm{d}^2x \sum_{a=1}^{N} |D_\mu z_a|^2, \qquad D_\mu = \partial_\mu - iA_\mu, \tag{13.21}$$

where A_μ is an auxiliary gauge field with no kinetic term. (Its field equation sets $A_\mu = \frac{i}{2}\frac{\bar{z}\partial_\mu z - \partial_\mu \bar{z}\, z}{\bar{z}z}$, which makes the action invariant under the local phase.) The coupling g is dimensionless in two dimensions, since $[z] = 0$.

Classically gapless. Pick a point on $\mathbb{CP}^{N-1}$, say $z = (\sqrt{N}/g, 0, \dots, 0)$. It breaks the global SU(N) symmetry, and the fluctuations along $\mathbb{CP}^{N-1}$ are $N-1$ massless complex Goldstone fields. But in two dimensions this picture cannot survive. The fluctuation of a massless field at a point is $\langle \delta z^2 \rangle \propto \int \frac{\mathrm{d}^2p}{(2\pi)^2}\frac{1}{p^2} = \frac{1}{2\pi}\int \frac{\mathrm{d}p}{p}$, which diverges logarithmically at small p. The field wanders all over the target space, and the would-be order is destroyed (the **Mermin–Wagner–Coleman theorem**: no spontaneous breaking of a continuous symmetry in two dimensions). Something must give. At large N we can see exactly what.

The Lagrange multiplier. Impose the constraint with a field $\lambda(x)$:

$$Z = \int \mathcal{D}z\,\mathcal{D}\bar{z}\,\mathcal{D}A\,\mathcal{D}\lambda\ \exp\Big[-\int \mathrm{d}^2x\Big(\sum_a |D_\mu z_a|^2 + i\lambda\Big(\sum_a |z_a|^2 - \frac{N}{g^2}\Big)\Big)\Big].$$

(The λ integral of $e^{-i\lambda X}$ is a delta function $\delta(X)$.) Now z appears only quadratically, $\int \bar{z}\,\mathcal{O}\,z$ with $\mathcal{O} = -D^2 + i\lambda$. For one complex field $\int \mathcal{D}z\mathcal{D}\bar{z}\,e^{-\int \bar{z}\mathcal{O}z} \propto (\det\mathcal{O})^{-1}$, the complex Gaussian integral. With N fields,

$$Z \overset{(1)}{=} \int \mathcal{D}A\,\mathcal{D}\lambda\,(\det\mathcal{O})^{-N}\,e^{\,i\frac{N}{g^2}\int\lambda} \overset{(2)}{=} \int \mathcal{D}A\,\mathcal{D}\lambda\ e^{-S_{\text{eff}}},$$
$$S_{\text{eff}} = N\Big[\operatorname{Tr}\ln\big(-D^2 + i\lambda\big) - \frac{i}{g^2}\int \mathrm{d}^2x\,\lambda\Big]. \tag{13.22}$$

(1) The N complex Gaussian integrals, one per z_a, each giving $(\det\mathcal{O})^{-1}$.
(2) $(\det\mathcal{O})^{-N} = e^{-N\ln\det\mathcal{O}}$ and $\ln\det = \operatorname{Tr}\ln$.

The whole effective action is proportional to N. As $N\to\infty$ the remaining integral over A and λ is dominated by its saddle point, exactly as $\int \mathrm{d}x\,e^{-Nf(x)}$ is dominated by the minimum of f. (The fluctuations around the saddle are suppressed by $1/N$.)

The gap equation. Look for a saddle with $A_\mu = 0$ and constant $i\lambda = m^2$. (The saddle lies at imaginary λ. The contour of the λ integral can be deformed to pass through it.) For constant fields Tr ln is the volume V times a momentum integral, so $S_{\text{eff}} = V\,\mathcal{V}(m^2)$ with

$$\frac{\mathcal{V}(m^2)}{N} = \int^{\Lambda} \frac{\mathrm{d}^2p}{(2\pi)^2}\,\ln(p^2+m^2) - \frac{m^2}{g^2}, \tag{13.23}$$

with an ultraviolet cutoff Λ on $|p|$. The saddle point condition is $\mathrm{d}\mathcal{V}/\mathrm{d}m^2 = 0$:

$$\frac{1}{g^2} \overset{(1)}{=} \int^{\Lambda} \frac{\mathrm{d}^2p}{(2\pi)^2}\,\frac{1}{p^2+m^2} \overset{(2)}{=} \frac{1}{2\pi}\int_0^{\Lambda} \frac{p\,\mathrm{d}p}{p^2+m^2} \overset{(3)}{=} \frac{1}{4\pi}\ln\Big(1+\frac{\Lambda^2}{m^2}\Big). \tag{13.24}$$

(1) Differentiate (13.23) under the integral sign.
(2) Polar coordinates, $\mathrm{d}^2p = 2\pi p\,\mathrm{d}p$.
(3) Substitute $u = p^2$: $\int_0^{\Lambda^2} \frac{\mathrm{d}u/2}{u+m^2} = \frac{1}{2}\ln\frac{\Lambda^2+m^2}{m^2}$.

This is the **gap equation**. It has a direct meaning. The constraint says $\langle\sum_a |z_a|^2\rangle = N/g^2$. At the saddle, each z_a is a free field of mass m, so $\langle|z_a|^2\rangle = G_m(0) = \int \frac{\mathrm{d}^2p}{(2\pi)^2}\frac{1}{p^2+m^2}$, and (13.24) is exactly the constraint. With $m = 0$ the right side would diverge at small p: the constraint can be satisfied *only* with a mass. Solving,

$$m \overset{(1)}{=} \frac{\Lambda}{\sqrt{e^{4\pi/g^2}-1}} \overset{(2)}{\approx} \Lambda\,e^{-2\pi/g^2}. \tag{13.25}$$

(1) Exponentiate (13.24): $1 + \Lambda^2/m^2 = e^{4\pi/g^2}$.
(2) For small g, $e^{4\pi/g^2} \gg 1$.

This is (13.20) with $c = 1$, $\mu = \Lambda$ and $\beta_0 = \frac{1}{2\pi}$. Indeed, holding m fixed while changing the cutoff requires $1/g^2(\Lambda) = \frac{1}{2\pi}\ln(\Lambda/m)$, which is (13.18) with $\beta_0 = 1/2\pi$: the $\mathbb{CP}^{N-1}$ model is asymptotically free.

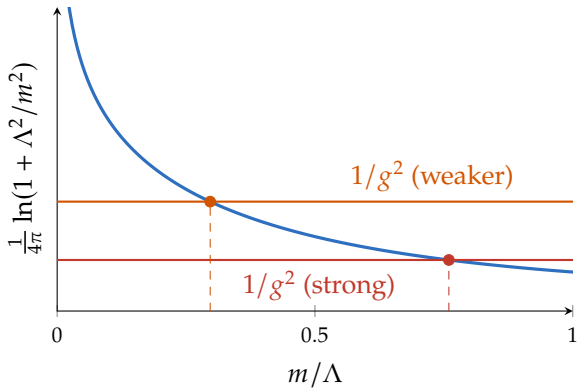

Figure 13.11: Graphical solution of the gap equation (13.24). The blue curve is the fluctuation $\langle|z|^2\rangle$ per field for fields of mass m, which grows without bound as $m \to 0$ because of the infrared logarithm. The horizontal lines are the value $1/g^2$ that the constraint demands. They always cross the curve, so a mass is always generated. Weaker coupling (higher line) gives an exponentially smaller mass.

What the gapped theory looks like. At the saddle, all N fields z_a have the same mass m: the SU(N) symmetry is unbroken, and there are no Goldstone bosons, as Mermin–Wagner demanded. One step beyond the saddle, the loop of z fields generates a kinetic term $\frac{N}{48\pi m^2}F_{\mu\nu}F_{\mu\nu}$ for the gauge field A_μ, so A becomes a genuine two-dimensional photon. In two dimensions the Coulomb potential between charges is linear (the field lines cannot spread), so the z quanta are *confined*. The physical particles are gauge-invariant $\bar{z}z$ bound states, with masses near $2m$. The theory is gapped.

Worked example 13.16: numbers, and why instantons are not the cause

For $g^2 = 2$, (13.25) gives $m = \Lambda/\sqrt{e^{2\pi}-1} = 0.043\,\Lambda$. For $g^2 = 1$ it gives $m = \Lambda/\sqrt{e^{4\pi}-1} = 0.0019\,\Lambda$. Halving g^2 cut the mass by a factor of more than twenty. The $\mathbb{CP}^{N-1}$ model has instantons, labelled by $\pi_2(\mathbb{CP}^{N-1}) = \mathbb{Z}$, with action $S_{\text{inst}} = 2\pi N/g^2$ in our normalisation. So

$$e^{-S_{\text{inst}}} \overset{(1)}{=} \left(e^{-2\pi/g^2}\right)^N \overset{(2)}{=} \left(\frac{m}{\Lambda}\right)^N.$$

(1) $S_{\text{inst}} = N \cdot 2\pi/g^2$.
(2) (13.25).

At large N instanton effects are suppressed by the N-th power of the tiny number m/Λ, while the gap is of order m itself. The gap of the $\mathbb{CP}^{N-1}$ model is *not* caused by instantons: it comes from the collective effect of the N fluctuating fields, the infrared logarithm.

13.3.5 A fermionic example: the Gross–Neveu model

The same logic works for fermions, and shows a gapped phase with two vacua. Take N massless two-component Dirac fermions ψ_i in two Euclidean dimensions, with the attractive four-fermion interaction

$$\mathcal{L}_E = \sum_i \bar{\psi}_i \partial\!\!\!/ \psi_i - \frac{g^2}{2N}\Big(\sum_i \bar{\psi}_i \psi_i\Big)^2.$$

Use the Euclidean gamma matrices $\gamma_1 = \sigma^1$, $\gamma_2 = \sigma^2$ (Hermitian, $\{\gamma_\mu, \gamma_\nu\} = 2\delta_{\mu\nu}$) and $\gamma_5 = \sigma^3$ (Chapter T4). The model has a discrete chiral symmetry $\psi \to \gamma_5\psi$, $\bar{\psi} \to -\bar{\psi}\gamma_5$, under which

$\bar\psi\psi \to -\bar\psi\psi$. It forbids a mass term.

Introduce an auxiliary field σ: $\mathcal{L}_E = \bar\psi_i(\not\partial+\sigma)\psi_i + \frac{N}{2g^2}\sigma^2$. (Completing the square, $\sigma = -\frac{g^2}{N}\bar\psi\psi$, returns the original Lagrangian.) The chiral symmetry now acts as $\sigma \to -\sigma$. Integrate out the fermions: the Grassmann Gaussian integral gives $\det(\not\partial + \sigma)^N$, with a *positive* power. For constant σ, in momentum space $\not\partial \to i\not p$, and the 2×2 determinant is $\det(i\not p + \sigma) = \sigma^2 + p^2$ (the eigenvalues of the Hermitian matrix $\not p$ are $\pm|p|$). The effective potential per unit volume is

$$\frac{\mathcal{V}(\sigma)}{N} = -\int^{\Lambda} \frac{\mathrm{d}^2p}{(2\pi)^2}\,\ln(p^2+\sigma^2) + \frac{\sigma^2}{2g^2}. \tag{13.26}$$

Its extrema:

$$\frac{1}{N}\frac{\mathrm{d}\mathcal{V}}{\mathrm{d}\sigma} \overset{(1)}{=} -\int^{\Lambda} \frac{\mathrm{d}^2p}{(2\pi)^2}\frac{2\sigma}{p^2+\sigma^2} + \frac{\sigma}{g^2} \overset{(2)}{=} \sigma\Big[\frac{1}{g^2} - \frac{1}{2\pi}\ln\Big(1+\frac{\Lambda^2}{\sigma^2}\Big)\Big]. \tag{13.27}$$

(1) Differentiate under the integral.
(2) The integral is twice the one in (13.24).

So either $\sigma = 0$ or $\frac{1}{g^2} = \frac{1}{2\pi}\ln(1+\Lambda^2/\sigma^2)$, that is

$$\sigma = \pm m, \qquad m = \frac{\Lambda}{\sqrt{e^{2\pi/g^2}-1}} \approx \Lambda\, e^{-\pi/g^2}.$$

Which is the minimum? The second derivative at $\sigma = 0$ contains $-2\int \frac{\mathrm{d}^2p}{(2\pi)^2}\frac{1}{p^2}$, which is $-\infty$ from the infrared. So $\sigma = 0$ is a maximum, and the minima are at $\sigma = \pm m$ (Figure 13.12). In either vacuum the fermions have mass m: the gap is generated dynamically, with $\beta_0 = 1/\pi$. The chiral $\mathbb{Z}_2$ is spontaneously broken, so there are *two* vacua, and in two dimensions there are also kinks interpolating between them. This is a gapped phase of the second kind in Section 13.1.4.

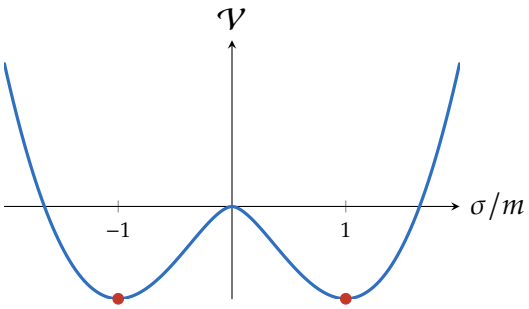

Figure 13.12: The large-N effective potential of the Gross–Neveu model, $\mathcal{V} \propto \sigma^2(\ln(\sigma^2/m^2) - 1)$ (from (13.26) after removing a constant). The symmetric point $\sigma = 0$ is a maximum, for any coupling. The two minima $\sigma = \pm m$ are the two vacua, related by the broken chiral symmetry, and in each the fermions have mass m.

Try it: the potential in closed form

Using $\int_0^{\Lambda^2}\ln(u+\sigma^2)\mathrm{d}u = (\Lambda^2+\sigma^2)\ln(\Lambda^2+\sigma^2) - \Lambda^2 - \sigma^2\ln\sigma^2$ and expanding for $\Lambda \gg \sigma$, show that $\mathcal{V}/N = \frac{\sigma^2}{4\pi}\big[\ln\frac{\sigma^2}{\Lambda^2} - 1\big] + \frac{\sigma^2}{2g^2} + \text{const} = \frac{\sigma^2}{4\pi}\big[\ln\frac{\sigma^2}{m^2} - 1\big] + \text{const}$, with $m = \Lambda e^{-\pi/g^2}$. *Answer:* the Λ dependence of the first form is absorbed exactly by $1/g^2 = \frac{1}{2\pi}\ln(\Lambda/m)^2$, which is the renormalisation of the coupling.

13.3.6 Three dimensions: a gap only beyond a critical coupling

In two dimensions the infrared logarithm forced a gap at any coupling. In three dimensions the massless fluctuation integral $\int \frac{\mathrm{d}^3p}{(2\pi)^3}\frac{1}{p^2}$ converges at small p, and the story changes. Repeat the $\mathbb{CP}^{N-1}$ (or O(N)) calculation in $d = 3$, where g^2 now has dimensions of length. The gap equation is

$$\frac{1}{g^2} \overset{(1)}{=} \int^{\Lambda} \frac{\mathrm{d}^3p}{(2\pi)^3}\frac{1}{p^2+m^2} \overset{(2)}{=} \frac{1}{2\pi^2}\int_0^{\Lambda} \mathrm{d}p\left(1-\frac{m^2}{p^2+m^2}\right) \overset{(3)}{=} \frac{1}{2\pi^2}\left(\Lambda - m\arctan\frac{\Lambda}{m}\right) \overset{(4)}{\approx} \frac{\Lambda}{2\pi^2} - \frac{m}{4\pi}. \tag{13.28}$$

(1) The same saddle-point condition as (13.24), in three dimensions.

(2) $\mathrm{d}^3p = 4\pi p^2\mathrm{d}p$, and $\frac{p^2}{p^2+m^2} = 1 - \frac{m^2}{p^2+m^2}$.

(3) $\int_0^{\Lambda} \frac{\mathrm{d}p}{p^2+m^2} = \frac{1}{m}\arctan\frac{\Lambda}{m}$.

(4) $\arctan(\Lambda/m) \to \pi/2$ for $\Lambda \gg m$.

Define the critical coupling by $1/g_c^2 = \Lambda/(2\pi^2)$. Then

$$m = 4\pi\left(\frac{1}{g_c^2} - \frac{1}{g^2}\right), \tag{13.29}$$

which is positive only for $g > g_c$. For $g < g_c$ the gap equation has no solution with $m > 0$: the constraint is satisfied by a condensate, the symmetry is broken, and the theory has Goldstone bosons. So there are two phases (Figure 13.13): a gapless ordered phase at weak coupling and a gapped symmetric phase at strong coupling, separated by a critical point at $g = g_c$. Near it, $m \propto (g - g_c)$, so the correlation length $\xi = 1/m \propto (g - g_c)^{-\nu}$ with $\nu = 1$. The critical point is an RG fixed point with $\xi = \infty$ (Chapter T5), and the large-N value $\nu = 1$ is the $N \to \infty$ limit of the O(N) Wilson–Fisher exponents.

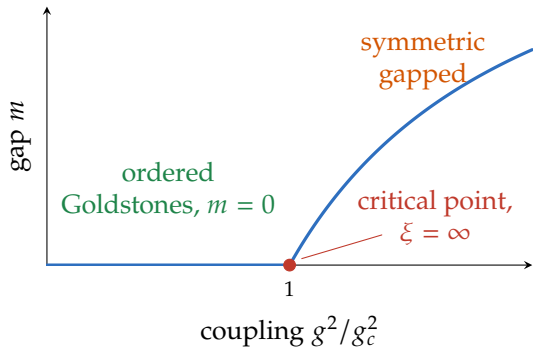

Figure 13.13: The large-N sigma model in three dimensions. Below the critical coupling the symmetry is broken and Goldstone bosons make the theory gapless. Above it the gap (13.29) rises linearly from zero. At the critical point the correlation length diverges: this is an RG fixed point, a conformal field theory.

Recap

- Masslessness is protected by gauge invariance, chiral symmetry or Goldstone's theorem. Opening a gap means evading the protection.
- Explicit masses work where symmetry allows. A small explicit breaking gives a

small gap (pions).

- The Higgs mechanism: the gauge field eats the Goldstone boson, with $m_A = ev$ and $m_h = \sqrt{2\lambda}v$. The Higgs phase is gapped and screens magnetic fields over $1/m_A$.
- Dimensional transmutation: $m = c\,\mu\, e^{-1/(\beta_0 g^2(\mu))}$, an RG invariant that vanishes to all orders in perturbation theory.
- At large N, the $\mathbb{CP}^{N-1}$ gap equation $1/g^2 = \int \frac{\mathrm{d}^2p}{(2\pi)^2}\frac{1}{p^2+m^2}$ forces $m = \Lambda e^{-2\pi/g^2}$ through the infrared logarithm. Gross–Neveu gives $m = \Lambda e^{-\pi/g^2}$ with two vacua. In three dimensions a gap appears only beyond a critical coupling, with $\nu = 1$.

Sources. The large-N solutions of the $\mathbb{CP}^{N-1}$ and Gross–Neveu models follow D. Tong, *Gauge Theory* (lecture notes, Cambridge), §7.3 and §7.4.1, which reproduce the original analyses of D'Adda, Lüscher and Di Vecchia and of Witten (1979) and of Gross and Neveu (1974).

13.4 A gap from instantons: Polyakov's compact QED in 2+1 dimensions

Maxwell theory in $2+1$ dimensions has one photon polarisation, and it is massless. So pure electromagnetism in the plane is gapless, and charges feel a potential that grows only logarithmically with distance. In 1977 Polyakov showed that this changes completely when the gauge group is the *compact* group U(1), for example when electromagnetism arises from SU(2) broken by a Higgs field. Then magnetic monopoles exist as finite-action configurations of Euclidean spacetime. They are instantons (Chapter 8). Summing over a dilute gas of them turns the massless photon into a massive one, with mass proportional to $e^{-S_0/2}$, where S_0 is the monopole action, and turns the logarithmic potential into a linear one. The gap and confinement both come from a topological charge: the degree of a map $S^2 \to S^2$.

This is also the prototype of what Jaffe and Witten call the need for a "non-classical change of variables or duality transformation" to see a mass gap. Here the duality is explicit, and the whole calculation can be done.

13.4.1 Maxwell theory in three dimensions and the dual photon

Work in three-dimensional Euclidean space with action

$$S = \frac{1}{4e^2}\int \mathrm{d}^3x\, F_{\mu\nu}F_{\mu\nu}. \tag{13.30}$$

The coupling is in front of the action, so a charge-one particle couples as $e^{i\oint A}$, and e^2 has dimensions of mass (since $[A]=1$ and $[\mathrm{d}^3x]=-3$). In three dimensions an antisymmetric $F_{\mu\nu}$ has three components, the same number as a vector. Package them as the **dual field strength**

$$B_\mu = \tfrac{1}{2}\epsilon_{\mu\nu\rho}F_{\nu\rho}, \qquad F_{\mu\nu}F_{\mu\nu} = 2B_\mu B_\mu.$$

The Bianchi identity $\mathrm{d}F = 0$ reads $\partial_\mu B_\mu = 0$: the lines of B never end. A magnetic monopole of charge q at a point X is exactly a place where they do end, with total flux $2\pi q$ (Dirac quantisation for charge-one matter):

$$\partial_\mu B_\mu = 2\pi\sum_i q_i\,\delta^3(x - X_i), \qquad q_i \in \mathbb{Z}. \tag{13.31}$$

Worked example 13.17: Maxwell theory is a free scalar in disguise

Without monopoles, integrate over unconstrained fields B_μ and impose $\partial \cdot B = 0$ with a Lagrange multiplier $\sigma(x)$, using $\int \mathcal{D}\sigma\, e^{\frac{i}{2\pi}\int \sigma\, \partial\cdot B} \propto \delta[\partial \cdot B]$:

$$Z = \int \mathcal{D}B\, \mathcal{D}\sigma\ \exp\Big[-\int \mathrm{d}^3x \Big(\frac{1}{2e^2} B_\mu B_\mu + \frac{i}{2\pi} B_\mu \partial_\mu \sigma\Big)\Big],$$

after integrating $\frac{i}{2\pi}\int \sigma\, \partial \cdot B$ by parts. Complete the square in B:

$$\frac{1}{2e^2} B^2 + \frac{i}{2\pi} B \cdot \partial\sigma \overset{(1)}{=} \frac{1}{2e^2}\Big(B + \frac{ie^2}{2\pi}\partial\sigma\Big)^2 + \frac{e^2}{8\pi^2}(\partial\sigma)^2.$$

(1) Expand the square: $\frac{1}{2e^2}\big(B^2 + \frac{ie^2}{\pi} B\cdot\partial\sigma - \frac{e^4}{4\pi^2}(\partial\sigma)^2\big) = \frac{B^2}{2e^2} + \frac{i}{2\pi} B\cdot\partial\sigma - \frac{e^2}{8\pi^2}(\partial\sigma)^2$, so adding back $\frac{e^2}{8\pi^2}(\partial\sigma)^2$ reproduces the left side.

The Gaussian integral over the shifted B is a constant, so

$$Z \propto \int \mathcal{D}\sigma\ \exp\Big[-\frac{e^2}{8\pi^2}\int \mathrm{d}^3x\, (\partial_\mu\sigma)^2\Big], \qquad B_\mu = -\frac{ie^2}{2\pi}\,\partial_\mu\sigma \text{ (on shell)}. \tag{13.32}$$

The field σ is the **dual photon**. It is a free massless scalar: one degree of freedom, as a $2+1$ dimensional photon should have. Why is σ periodic, $\sigma \sim \sigma + 2\pi$? Because with monopoles present, (13.31) turns the multiplier term into $e^{\frac{i}{2\pi}\int \sigma\,\partial\cdot B} = \prod_i e^{iq_i\sigma(X_i)}$, which is unchanged by $\sigma \to \sigma + 2\pi$ exactly when all $q_i \in \mathbb{Z}$.

The free action (13.32) is invariant under the shift $\sigma \to \sigma + c$. This is a genuine global symmetry, called $\mathrm{U}(1)_{\text{top}}$ ("topological" or magnetic), whose conserved current is $J_\mu = \frac{1}{2\pi} B_\mu$ and whose charge is the magnetic flux through space divided by 2π. In the Coulomb phase the vacuum picks a value of σ, so $\mathrm{U}(1)_{\text{top}}$ is spontaneously broken and the photon is its Goldstone boson. That is the symmetry reason the $2+1$ dimensional photon is massless. To give it a mass, something must break $\mathrm{U}(1)_{\text{top}}$ explicitly. The insertion $e^{iq\sigma(X)}$ does exactly that: it shifts by e^{iqc}. So *monopoles are the only thing that can gap the photon*, and the question is whether they occur in the theory.

13.4.2 Monopole-instantons

In pure Maxwell theory with gauge group $\mathbb{R}$ there are no monopoles. They appear when the U(1) is compact and the short-distance theory can smooth out the Dirac singularity. The cleanest example is the three-dimensional **Georgi–Glashow model**: SU(2) gauge theory with a real scalar Φ^a in the adjoint representation, whose potential forces $|\Phi| = v$ at low energies. The vacuum value $\Phi^a = v\,\delta^{a3}$ breaks SU(2) to the U(1) of rotations about the 3-axis. The charged gauge bosons $W^\pm$ get mass $m_W = ev$, and below m_W we are left with compact U(1) electromagnetism.

The topology. A configuration with finite Euclidean action must have $|\Phi| \to v$ on the sphere at infinity, S^2_∞. So $\Phi/|\Phi|$ restricted to S^2_∞ is a map $S^2_\infty \to S^2$ (the vacuum manifold $\mathrm{SU}(2)/\mathrm{U}(1) = S^2$). Such maps are classified by their degree, $\pi_2(S^2) = \mathbb{Z}$, the number of times the image wraps the target sphere. The degree equals the magnetic charge q of the unbroken U(1). The **'t Hooft–Polyakov monopole** is the smooth solution with $q = 1$: the hedgehog $\Phi^a \to v\, x^a/|x|$ (Figure 13.14).

In $3+1$ dimensions this configuration, extended in time, is a particle. In three Euclidean

dimensions the same configuration is localised at a *point* of spacetime: it is an event, an instanton. What does it do? Its flux $2\pi q$ leaves every sphere around it. A spatial slice below the event and a spatial slice above it therefore carry magnetic fluxes differing by $2\pi q$: the monopole-instanton is a tunnelling event that changes the magnetic flux through space by one quantum. Its action is

$$S_0 = \frac{4\pi m_W}{e^2}\,\varepsilon\!\left(\frac{m_H}{m_W}\right), \tag{13.33}$$

where m_H is the mass of the neutral Higgs particle and ε is a slowly varying function of order one ($\varepsilon = 1$ in the limit $m_H \to 0$, where the Bogomolny bound is saturated, rising to about 1.8 as $m_H \to \infty$). The theory is weakly coupled when $e^2 \ll m_W$, and then $S_0 \gg 1$.

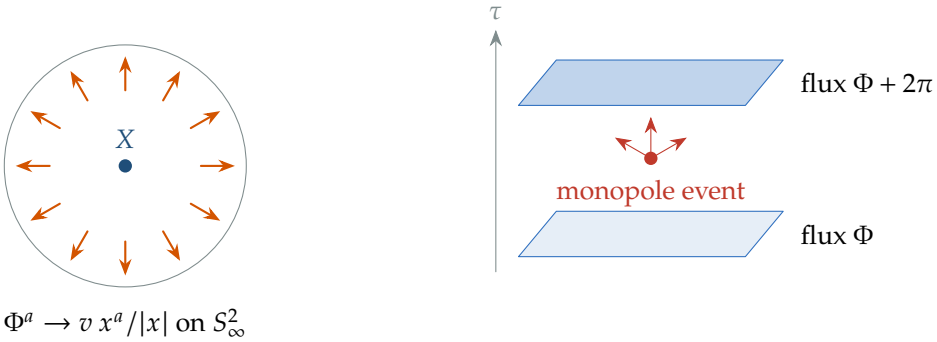

Figure 13.14: Left: the 't Hooft–Polyakov hedgehog. On the sphere at infinity the Higgs field points radially, a map $S^2 \to S^2$ of degree one. Right: in three-dimensional Euclidean spacetime the same configuration is an event (red). The magnetic flux through the spatial slice after the event exceeds the flux before it by one quantum 2π: the monopole is an instanton that tunnels between flux sectors.

Worked example 13.18: monopoles interact through a three-dimensional Coulomb law

Far from its core, a monopole of charge q at X has $B_\mu = \frac{q}{2}\frac{(x-X)_\mu}{|x-X|^3} = -\frac{q}{2}\partial_\mu \frac{1}{|x-X|}$, whose flux through any sphere around X is $\frac{q}{2}\cdot 4\pi = 2\pi q$, as required. For two monopoles the action $\frac{1}{2e^2}\int (B_1+B_2)^2$ contains the self-actions and a cross term:

$$S_{12} \overset{(1)}{=} \frac{1}{e^2}\int \mathrm{d}^3x\, B_1\cdot B_2 \overset{(2)}{=} \frac{q_1q_2}{4e^2}\int \mathrm{d}^3x\, \partial_\mu \frac{1}{|x-X_1|}\,\partial_\mu \frac{1}{|x-X_2|}$$
$$\overset{(3)}{=} -\frac{q_1q_2}{4e^2}\int \mathrm{d}^3x\, \frac{1}{|x-X_1|}\,\nabla^2 \frac{1}{|x-X_2|} \overset{(4)}{=} \frac{\pi\, q_1q_2}{e^2\,|X_1-X_2|}.$$

(1) The cross term of $\frac{1}{2e^2}(B_1+B_2)^2$ is $\frac{1}{e^2}B_1\cdot B_2$.
(2) The far-field form above, for both monopoles.
(3) Integrate by parts. The surface term vanishes because the integrand falls like $1/|x|^3$.
(4) $\nabla^2 \frac{1}{|x-X_2|} = -4\pi\delta^3(x-X_2)$.

Like charges repel and opposite charges attract, with a $1/r$ law: the monopole-instantons form a three-dimensional **Coulomb gas**. The same result comes from the dual photon. The action (13.32) is $\frac{1}{2}\kappa(\partial\sigma)^2$ with $\kappa = e^2/4\pi^2$, so the propagator is $\langle\sigma(x)\sigma(0)\rangle = \frac{1}{\kappa}\frac{1}{4\pi|x|} = \frac{\pi}{e^2|x|}$ (Example 13.7 with $m=0$). For a Gaussian field, $\langle e^{i\sum_i q_i\sigma(X_i)}\rangle = e^{-\frac{1}{2}\sum_{i,j} q_iq_j\langle\sigma(X_i)\sigma(X_j)\rangle}$, and the $i\neq j$ terms give $e^{-\sum_{i<j}\pi q_iq_j/(e^2|X_i-X_j|)} = e^{-\sum_{i<j}S_{ij}}$. Inserting $e^{iq\sigma(X)}$ *is* inserting a monopole.

13.4.3 The dilute gas and the sine-Gordon model

At weak coupling the monopoles are rare and far apart, so the path integral is a sum over configurations of N_+ monopoles and N_- anti-monopoles ($q = \pm 1$) at arbitrary positions. Each one carries the weight e^{-S_0} times a factor K from the Gaussian fluctuations around it (a one-loop determinant with the zero modes traded for the position integrals, exactly as for the instantons of Chapter 8). K has dimensions of (mass)^3, so that $K\,\mathrm{d}^3X$ is dimensionless. Write $\zeta = Ke^{-S_0}$ for the **fugacity**. The $1/N_\pm!$ removes the overcounting of identical objects. Then

$$
\begin{aligned}
Z &\overset{(1)}{=} \sum_{N_+,N_-} \frac{\zeta^{N_++N_-}}{N_+!\,N_-!} \int \prod_i \mathrm{d}^3X_i \; e^{-\sum_{i<j} \pi q_i q_j/(e^2|X_i-X_j|)} \\
&\overset{(2)}{=} \int \mathcal{D}\sigma \, e^{-\frac{e^2}{8\pi^2}\int(\partial\sigma)^2} \sum_{N_+,N_-} \frac{1}{N_+!\,N_-!} \Big(\zeta \int \mathrm{d}^3X \, e^{i\sigma(X)}\Big)^{N_+} \Big(\zeta \int \mathrm{d}^3X \, e^{-i\sigma(X)}\Big)^{N_-} \\
&\overset{(3)}{=} \int \mathcal{D}\sigma \; \exp\Big[-\int \mathrm{d}^3x \, \frac{e^2}{8\pi^2}(\partial\sigma)^2 + \zeta \int \mathrm{d}^3x \, \big(e^{i\sigma} + e^{-i\sigma}\big)\Big] \\
&\overset{(4)}{=} \int \mathcal{D}\sigma \; \exp\Big[-\int \mathrm{d}^3x \Big(\frac{e^2}{8\pi^2}(\partial\sigma)^2 - 2\zeta\cos\sigma\Big)\Big].
\end{aligned}
\tag{13.34}
$$

(1) The dilute monopole gas, with the Coulomb interaction of Example 13.18 (the monopole self-energies are part of S_0).
(2) Example 13.18: the Coulomb factor is the Gaussian average of $\prod_i e^{iq_i\sigma(X_i)}$ over the dual photon.
(3) $\sum_N \frac{x^N}{N!} = e^x$, once for N_+ and once for N_-.
(4) $e^{i\sigma} + e^{-i\sigma} = 2\cos\sigma$.

The Coulomb gas of monopole-instantons is equivalent to the three-dimensional **sine-Gordon model**. This is the duality Jaffe and Witten cite for the rigorous proof of Debye screening in a Coulomb gas.

The photon mass. The potential $-2\zeta\cos\sigma$ has minima at $\sigma \in 2\pi\mathbb{Z}$ (Figure 13.15). Expand about $\sigma = 0$:

$$
\frac{e^2}{8\pi^2}(\partial\sigma)^2 - 2\zeta\cos\sigma \overset{(1)}{=} -2\zeta + \frac{e^2}{8\pi^2}(\partial\sigma)^2 + \zeta\sigma^2 + O(\sigma^4) \overset{(2)}{=} -2\zeta + \frac{e^2}{8\pi^2}\Big[(\partial\sigma)^2 + \frac{8\pi^2\zeta}{e^2}\,\sigma^2\Big] + \dots
$$

(1) $\cos\sigma = 1 - \sigma^2/2 + O(\sigma^4)$.
(2) Factor out the coefficient of the kinetic term.

Comparing with $\frac{\kappa}{2}[(\partial\sigma)^2 + m^2\sigma^2]$, the dual photon has mass

$$
m_\gamma^2 = \frac{8\pi^2\zeta}{e^2} = \frac{8\pi^2 K}{e^2}\, e^{-S_0}, \qquad m_\gamma \propto e^{-S_0/2}. \tag{13.35}
$$

The photon has a mass, and pure compact U(1) gauge theory in $2+1$ dimensions is gapped. The mass is exponentially small at weak coupling, $m_\gamma \ll e^2 \ll m_W$, which is what justifies using the low-energy dual photon theory with the cosine as a small perturbation.

Physical picture: Debye screening by a plasma of instantons

In an ordinary plasma, mobile charges screen an electric field over the Debye length. Here the "plasma" lives in Euclidean spacetime, and its particles are monopole-instantons, with density $n = \langle N_+ + N_-\rangle/V = 2\zeta$ at leading order. They screen *magnetic* field. The Debye

mass of a Coulomb gas is (interaction strength)×(density). Our interaction is $\frac{\pi}{e^2 r} = \frac{4\pi^2}{e^2}\cdot\frac{1}{4\pi r}$, of strength $4\pi^2/e^2$, and indeed $m_\gamma^2 = \frac{4\pi^2}{e^2}\cdot 2\zeta$. The photon mass is the screening mass of the instanton plasma.

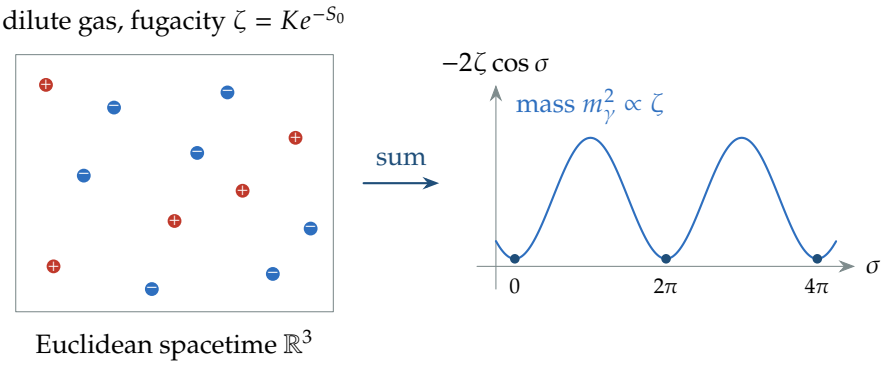

Figure 13.15: Left: a typical configuration in the path integral of compact QED in $2+1$ dimensions, a dilute gas of monopoles (+) and anti-monopoles (−) scattered through Euclidean spacetime, interacting by a $1/r$ Coulomb law. Right: summing over the gas produces a periodic potential for the dual photon. Its minima are the vacua $\sigma \in 2\pi\mathbb{Z}$, and its curvature there is the photon mass squared.

13.4.4 Confinement

A mass gap is not the same thing as confinement, but here both follow from the same potential. Rotate back to Minkowski signature, where the on-shell relation of (13.32) becomes real: $\frac{1}{2}\epsilon^{\mu\nu\rho}F_{\nu\rho} = \frac{e^2}{2\pi}\partial^\mu\sigma$. In components the electric field is $E_i = F_{0i}$, and $E_i = \frac{e^2}{2\pi}\epsilon_{ij}\partial_j\sigma$ (up to an overall sign convention). So an electric field is a *gradient* of σ at right angles to it.

Before the monopoles. The field of two opposite static charges is the two-dimensional Coulomb field: its lines spread out over the plane, and the energy grows as $\frac{e^2}{2\pi}\ln r$ (log confinement). In σ language this is a smooth gradient spread over all of space.

After the monopoles. A spread-out gradient of σ now costs potential energy $-2\zeta\cos\sigma$ everywhere it moves σ off a minimum. The cheaper option is to keep σ at a minimum almost everywhere and let it jump by 2π, from one minimum to the next, across a thin wall. Across such a **kink** the electric flux is

$$\int E_\perp \,\mathrm{d}\ell \overset{(1)}{=} \frac{e^2}{2\pi}\int \partial_\ell\sigma \,\mathrm{d}\ell \overset{(2)}{=} \frac{e^2}{2\pi}\cdot 2\pi = e^2,$$

(1) $E = \frac{e^2}{2\pi}\epsilon\cdot\nabla\sigma$: the flux through a line crossing the wall is the change of σ along the line.
(2) σ changes by 2π across the kink.

which is exactly the flux of one unit of charge (Gauss's law from (13.30) is $\nabla\cdot\vec{E} = e^2\rho$). So the electric flux between the charges is squeezed into a string of width $\sim 1/m_\gamma$: a **flux tube** (Figure 13.16). A string of fixed tension T (energy per unit length) stretched between the charges gives the linear potential $V(r) = T\,r$. Charges are confined.

Worked example 13.19: the string tension

The tension is the minimum energy per unit length of a kink in which σ goes from 0 to 2π along a coordinate y. With $A = e^2/8\pi^2$ and $U(\sigma) = 2\zeta(1-\cos\sigma) \geq 0$ (the potential shifted to vanish at the minima),

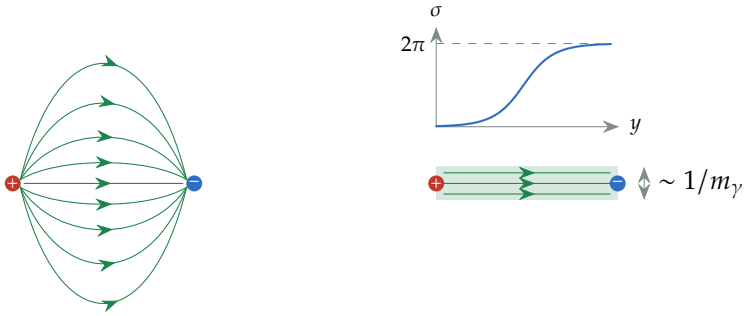
$$T \overset{(1)}{=} \int \mathrm{d}y \left[A\,\sigma'^2 + U(\sigma)\right] \overset{(2)}{=} \int \mathrm{d}y \left[\left(\sqrt{A}\,\sigma' - \sqrt{U}\right)^2 + 2\sqrt{AU}\,\sigma'\right] \overset{(3)}{\geq} 2\sqrt{A}\int_0^{2\pi} \sqrt{U(\sigma)}\,\mathrm{d}\sigma$$
$$\overset{(4)}{=} 2\sqrt{2A\zeta}\int_0^{2\pi} \sqrt{1-\cos\sigma}\,\mathrm{d}\sigma \overset{(5)}{=} 2\sqrt{2A\zeta}\cdot\sqrt{2}\int_0^{2\pi} \sin\frac{\sigma}{2}\,\mathrm{d}\sigma \overset{(6)}{=} 16\sqrt{A\zeta}.$$

(1) Energy per unit length of a static configuration depending on y.
(2) Complete the square: $(a-b)^2 + 2ab = a^2 + b^2$ with $a = \sqrt{A}\sigma'$, $b = \sqrt{U}$.
(3) Drop the non-negative square. The remaining term is $\int 2\sqrt{AU}\,\frac{\mathrm{d}\sigma}{\mathrm{d}y}\mathrm{d}y = \int_0^{2\pi} 2\sqrt{AU}\,\mathrm{d}\sigma$. Equality holds for the kink obeying $\sqrt{A}\sigma' = \sqrt{U}$ (the Bogomolny trick).
(4) $U = 2\zeta(1-\cos\sigma)$.
(5) $1-\cos\sigma = 2\sin^2(\sigma/2)$, and $\sin(\sigma/2) \geq 0$ on $[0, 2\pi]$.
(6) $\int_0^{2\pi} \sin(\sigma/2)\mathrm{d}\sigma = 4$, and $2\sqrt{2}\cdot\sqrt{2}\cdot 4 = 16$.

With $A = e^2/8\pi^2$ and $\zeta = e^2 m_\gamma^2/8\pi^2$ from (13.35),

$$T = 16\sqrt{\frac{e^2}{8\pi^2}\cdot\frac{e^2 m_\gamma^2}{8\pi^2}} = \frac{2\,e^2\,m_\gamma}{\pi^2}.$$

The string tension is proportional to the photon mass: both vanish when the monopoles are switched off. For a large Wilson loop of area $\mathcal{A}$, the same wall spans the loop in Euclidean spacetime, and $\langle W(C)\rangle \sim e^{-T\mathcal{A}}$, the **area law**.



no monopoles: $V \propto \ln r$ monopole plasma: $V = T\,r$

Figure 13.16: Left: without monopoles, the electric field lines of two opposite charges spread over the whole plane, and the energy grows only logarithmically. Right: in the monopole plasma the dual photon σ must sit at a minimum of its cosine potential almost everywhere. It jumps by 2π across a thin wall (inset), and the wall carries exactly one unit of electric flux. The flux is confined to a tube of width about $1/m_\gamma$, and the energy grows linearly with separation.

Try it: how small is the gap?

Take the BPS limit $\varepsilon = 1$ and $e^2/m_W = 0.5$. Compute S_0 and the suppression factor $e^{-S_0/2}$. *Answer:* $S_0 = 4\pi m_W/e^2 = 8\pi \approx 25.1$, so $e^{-S_0/2} = e^{-12.6} \approx 3.5\times 10^{-6}$. The photon mass, and the string tension with it, are some six orders of magnitude below the W mass: an

enormous hierarchy produced by a topological effect.

13.4.5 What was topological, and what is known rigorously

Key idea: Polyakov's mechanism in four lines

1. Non-compact $2+1$ dimensional QED is gapless: the photon is the Goldstone boson of the magnetic symmetry $\mathrm{U}(1)_{\mathrm{top}}$, $\sigma \to \sigma + c$.
2. Compactness of U(1) allows finite-action monopole-instantons, labelled by the degree $q \in \pi_2(S^2) = \mathbb{Z}$.
3. Each monopole inserts $e^{\pm i\sigma}$, which breaks $\mathrm{U}(1)_{\mathrm{top}}$ explicitly. The dilute gas generates $-2\zeta \cos\sigma$, and $m_\gamma^2 = 8\pi^2 K e^{-S_0}/e^2$.
4. The same cosine squeezes electric flux into tubes of tension $T = 2e^2 m_\gamma/\pi^2$: linear confinement.

Watch out: the mechanism is fragile

Three things can switch it off. (i) In $3+1$ dimensions monopoles are particles, not instantons, and compact QED_4 keeps a massless photon (a Coulomb phase) at weak coupling. (ii) Massless charged fermions give each monopole-instanton fermion zero modes (Chapter 4), and then $e^{i\sigma}$ alone has vanishing expectation value; QED_3 with enough massless fermions is believed to be gapless. (iii) At high temperature the Euclidean time direction becomes a small circle, the monopole gas turns into a gas of monopole–anti-monopole pairs, and confinement is lost. The topological charge is always there, but whether it opens a gap depends on dimension, matter content and temperature.

Dictionary: compact QED_3 and a superconductor

superconductor (Example 13.14)	compact QED_3
Cooper pairs condense	monopoles proliferate
photon gets a mass	dual photon gets a mass
magnetic flux expelled or squeezed into tubes	electric flux squeezed into tubes
magnetic charges would be confined	electric charges are confined

Compact QED_3 is a *dual superconductor*: the roles of electric and magnetic are exchanged. The 't Hooft–Mandelstam picture of confinement in four-dimensional Yang–Mills theory is the conjecture that the QCD vacuum is also a dual superconductor, with magnetic monopoles condensing. In four dimensions no one has made this into a controlled calculation for pure Yang–Mills theory. It has been made precise in supersymmetric theories (Seiberg and Witten, 1994), where monopoles become light and their condensation can be followed exactly.

Rigorous status. For the lattice version of compact U(1) gauge theory in three dimensions (with the Villain action), Göpfert and Mack proved in 1982 that static charges are confined and that there is a mass gap, for all values of the coupling. Polyakov's model is therefore one of the few gauge theories in which a gap generated by topology is established mathematically, though on the lattice rather than in the continuum.

Reading Nash (Ch. VIII, §§4–5, pp. 242–257)

Nash treats monopoles as static solutions of the Yang–Mills–Higgs equations in 3 + 1 dimensions: their topological charge, the Bogomolny equations, and their moduli spaces. Everything he says about a single monopole applies unchanged here, because a static monopole in $\mathbb{R}^3$ and a monopole-instanton in Euclidean $\mathbb{R}^3$ are the same field configuration. What changes is its interpretation: here the third coordinate is Euclidean time, the monopole is an event, and the physical question is what a gas of such events does to the spectrum.

Recap

- In 2 + 1 dimensions Maxwell theory is dual to a free periodic scalar, the dual photon, $S = \frac{e^2}{8\pi^2}\int(\partial\sigma)^2$.
- Compact U(1) has monopole-instantons with action $S_0 = 4\pi m_W \varepsilon/e^2$, which insert $e^{\pm i\sigma}$ and interact by a three-dimensional Coulomb law.
- The dilute gas sums to the sine-Gordon model, giving $m_\gamma^2 = 8\pi^2 K e^{-S_0}/e^2$: a gap from instantons, the Debye mass of a plasma of topological events.
- Electric flux is carried by kinks of σ with tension $T = 2e^2 m_\gamma/\pi^2$: linear confinement and an area law.

13.5 A gap from a topological term: the Chern–Simons photon

The Higgs mechanism gives a photon a mass by adding a charged scalar that condenses. Polyakov's mechanism needs a compact gauge group and a gas of instantons. In 2 + 1 dimensions there is a third way, which needs neither extra fields nor instantons. Add to the Maxwell action the Chern–Simons term, a term that knows nothing about the metric. The photon becomes massive, gauge invariance is untouched, and the long-distance theory is a topological quantum field theory (Chapter 12). This is the **topologically massive gauge theory** of Deser, Jackiw and Templeton (1982).

13.5.1 The Chern–Simons term

For an abelian gauge field on a three-manifold M, the Chern–Simons term is

$$S_{\mathrm{CS}} = \frac{k}{4\pi}\int_M A\wedge \mathrm{d}A = \frac{k}{4\pi}\int \mathrm{d}^3x\;\epsilon^{\mu\nu\rho}A_\mu\partial_\nu A_\rho, \tag{13.36}$$

with $\epsilon^{012} = 1$. It has three properties we need.

No metric. The integrand is a 3-form built from A and $\mathrm{d}A$ alone. Neither the wedge product nor d involves the metric (Chapter T1). So S_{CS} is unchanged by any change of the metric, and its stress tensor $T_{\mu\nu} \propto \delta S/\delta g^{\mu\nu}$ vanishes. A pure Chern–Simons theory has zero Hamiltonian: it has no energy to give to anything. That is what "topological" means here.

Gauge invariance up to a boundary. Under $A \to A + \mathrm{d}\alpha$,

$$\delta\big(A \wedge \mathrm{d}A\big) \overset{(1)}{=} \mathrm{d}\alpha \wedge \mathrm{d}A \overset{(2)}{=} \mathrm{d}(\alpha\, \mathrm{d}A),$$

(1) $\mathrm{d}(A + \mathrm{d}\alpha) = \mathrm{d}A$ since $\mathrm{d}^2 = 0$, so only the first factor changes.
(2) $\mathrm{d}(\alpha\, \mathrm{d}A) = \mathrm{d}\alpha \wedge \mathrm{d}A + \alpha\, \mathrm{d}^2 A$ and $\mathrm{d}^2 A = 0$.

So $\delta S_{\mathrm{CS}} = \frac{k}{4\pi}\int_{\partial M} \alpha\, \mathrm{d}A$ by Stokes, which vanishes when M has no boundary and α is single valued. For large gauge transformations on nontrivial manifolds, $e^{iS_{\mathrm{CS}}}$ is invariant only if the **level** k is an integer (Chapter 12). We write $\kappa = k/2\pi$, so the term is $\frac{\kappa}{2}\epsilon^{\mu\nu\rho}A_\mu \partial_\nu A_\rho$.

Odd under parity and time reversal. The ϵ tensor changes sign under a reflection of one coordinate. So a Chern–Simons term can only appear in a theory that breaks parity and time reversal. This is the price of the mechanism.

Working definition 13.3 (topological mass)

A $2+1$ dimensional gauge field has a **topological mass** when its action contains, besides the Maxwell term $-\frac{1}{4e^2}F^2$, a Chern–Simons term $\frac{k}{4\pi}\int A \wedge \mathrm{d}A$ [a term built from A and $\mathrm{d}A$ only, with no metric, so it contributes no energy of its own]. The photon then has mass $m = |k|e^2/2\pi$ [the only mass that can be made from e^2, which carries units of mass in $2+1$ dimensions, and the pure number k], while gauge invariance is kept [the action changes only by a boundary term under $A \to A + \mathrm{d}\alpha$] and no field condenses [there is no Higgs scalar and no vacuum expectation value]. *To test for it:* the photon propagator has a single pole at $p^2 = m^2$, the static field of a charge Q decays as e^{-mr}, and the charge carries magnetic flux $2\pi Q/k$.

13.5.2 The field equation and the mass

Use Minkowski signature $\eta = \mathrm{diag}(+1,-1,-1)$, so that $\epsilon_{012} = +1$ as well. The **Maxwell–Chern–Simons** Lagrangian is

$$\mathcal{L} = -\frac{1}{4e^2}F_{\mu\nu}F^{\mu\nu} + \frac{\kappa}{2}\,\epsilon^{\mu\nu\rho}A_\mu \partial_\nu A_\rho. \tag{13.37}$$

Vary A. For the Maxwell term, $\delta(-\frac{1}{4e^2}F^2) = -\frac{1}{e^2}F^{\mu\nu}\partial_\mu \delta A_\nu$, which after integration by parts is $\frac{1}{e^2}(\partial_\mu F^{\mu\nu})\delta A_\nu$. For the Chern–Simons term,

$$\delta\Big(\frac{\kappa}{2}\epsilon^{\mu\nu\rho}A_\mu\partial_\nu A_\rho\Big) \overset{(1)}{=} \frac{\kappa}{2}\epsilon^{\mu\nu\rho}\big(\delta A_\mu\, \partial_\nu A_\rho + A_\mu\, \partial_\nu \delta A_\rho\big) \overset{(2)}{=} \frac{\kappa}{2}\epsilon^{\mu\nu\rho}\delta A_\mu\, \partial_\nu A_\rho - \frac{\kappa}{2}\epsilon^{\mu\nu\rho}\partial_\nu A_\mu\, \delta A_\rho$$
$$\overset{(3)}{=} \kappa\, \epsilon^{\mu\nu\rho}\delta A_\mu\, \partial_\nu A_\rho \overset{(4)}{=} \kappa\, \tilde{F}^\mu\, \delta A_\mu, \qquad \tilde{F}^\mu := \tfrac{1}{2}\epsilon^{\mu\nu\rho}F_{\nu\rho}.$$

(1) Product rule.
(2) Integrate the second term by parts (dropping a total derivative).
(3) In the second term rename $\rho \to \mu \to \nu \to \rho$ cyclically, using $\epsilon^{\rho\mu\nu} = \epsilon^{\mu\nu\rho}$, and then swap $\mu \leftrightarrow \nu$ inside $\partial_\nu A_\mu$, which costs a sign that cancels the minus. Both terms become equal.
(4) $\epsilon^{\mu\nu\rho}\partial_\nu A_\rho = \frac{1}{2}\epsilon^{\mu\nu\rho}(\partial_\nu A_\rho - \partial_\rho A_\nu) = \frac{1}{2}\epsilon^{\mu\nu\rho}F_{\nu\rho}$.

The field equation is therefore

$$\frac{1}{e^2}\partial_\mu F^{\mu\nu} + \kappa\, \tilde{F}^\nu = 0. \tag{13.38}$$

The dual field $\tilde{F}^\mu$ is gauge invariant and obeys the Bianchi identity $\partial_\mu \tilde{F}^\mu = \frac{1}{2}\epsilon^{\mu\nu\rho}\partial_\mu F_{\nu\rho} = 0$. In $2+1$ dimensions $\tilde{F}$ contains all of F: $F_{\nu\rho} = \epsilon_{\nu\rho\sigma}\tilde{F}^\sigma$ (contract $\tilde{F}^\mu = \frac{1}{2}\epsilon^{\mu\nu\rho}F_{\nu\rho}$ with $\epsilon_{\alpha\beta\mu}$ and use

$\epsilon_{\alpha\beta\mu}\epsilon^{\mu\nu\rho} = \delta^\nu_\alpha\delta^\rho_\beta - \delta^\rho_\alpha\delta^\nu_\beta$). Write the equation in terms of $\tilde{F}$ alone. With $m \coloneqq \kappa e^2$,

$$\frac{1}{e^2}\partial_\mu F^{\mu\nu} \overset{(1)}{=} \frac{1}{e^2}\epsilon^{\mu\nu\sigma}\partial_\mu\tilde{F}_\sigma \overset{(2)}{=} -\frac{1}{e^2}\epsilon^{\nu\mu\sigma}\partial_\mu\tilde{F}_\sigma \quad \overset{(3)}{\Longrightarrow} \quad \epsilon^{\nu\mu\sigma}\partial_\mu\tilde{F}_\sigma = m\,\tilde{F}^\nu. \tag{13.39}$$

(1) $F^{\mu\nu} = \epsilon^{\mu\nu\sigma}\tilde{F}_\sigma$ (raise the indices of $F_{\nu\rho} = \epsilon_{\nu\rho\sigma}\tilde{F}^\sigma$).
(2) $\epsilon^{\mu\nu\sigma} = -\epsilon^{\nu\mu\sigma}$.
(3) Insert into (13.38) and multiply by $-e^2$.

This is a first-order equation. Apply it twice. Lower the indices of (13.39), $\epsilon_{\lambda\alpha\nu}\partial^\alpha\tilde{F}^\nu = m\tilde{F}_\lambda$, and act with $\epsilon_{\lambda\alpha\nu}\partial^\alpha$ on (13.39) itself:

$$\begin{aligned} m^2\tilde{F}_\lambda &\overset{(1)}{=} m\,\epsilon_{\lambda\alpha\nu}\partial^\alpha\tilde{F}^\nu \overset{(2)}{=} \epsilon_{\lambda\alpha\nu}\epsilon^{\nu\mu\sigma}\partial^\alpha\partial_\mu\tilde{F}_\sigma \overset{(3)}{=} \left(\delta^\mu_\lambda\delta^\sigma_\alpha - \delta^\sigma_\lambda\delta^\mu_\alpha\right)\partial^\alpha\partial_\mu\tilde{F}_\sigma \\ &\overset{(4)}{=} \partial_\lambda\left(\partial^\alpha\tilde{F}_\alpha\right) - \partial^\alpha\partial_\alpha\tilde{F}_\lambda \overset{(5)}{=} -\Box\tilde{F}_\lambda. \end{aligned} \tag{13.40}$$

(1) The lowered form of (13.39), multiplied by m.
(2) Replace $m\tilde{F}^\nu$ by the left side of (13.39).
(3) $\epsilon_{\lambda\alpha\nu}\epsilon^{\nu\mu\sigma} = \epsilon_{\nu\lambda\alpha}\epsilon^{\nu\mu\sigma} = \delta^\mu_\lambda\delta^\sigma_\alpha - \delta^\sigma_\lambda\delta^\mu_\alpha$ (cyclic reordering, and $\epsilon_{012}\epsilon^{012} = +1$ in this signature).
(4) Carry out the contractions.
(5) Bianchi identity $\partial^\alpha\tilde{F}_\alpha = 0$, and $\Box = \partial^\alpha\partial_\alpha$.

So $(\Box + m^2)\tilde{F} = 0$: every component of the field strength obeys the Klein–Gordon equation with

$$m_{\text{top}} = |\kappa|\,e^2 = \frac{|k|\,e^2}{2\pi}. \tag{13.41}$$

The dispersion relation is $\omega^2 = \vec{k}^2 + m^2_{\text{top}}$: a gap (Figure 13.17).

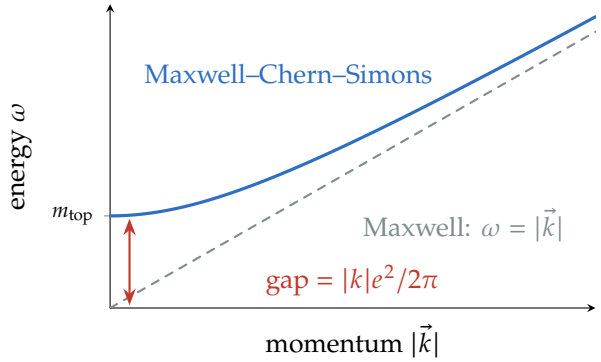

Figure 13.17: Dispersion relations of the 2 + 1 dimensional photon. Pure Maxwell theory (grey, dashed) is gapless, $\omega = |\vec{k}|$. Adding a Chern–Simons term at level k lifts the curve to $\omega = \sqrt{\vec{k}^2 + m^2_{\text{top}}}$ (blue), with a gap set by the level and the coupling, and no other field involved.

13.5.3 One polarisation with a definite spin

How many states does the massive photon have? A Proca photon in 2 + 1 dimensions (Example 13.12 with three spacetime dimensions) has two polarisations, spin +1 and spin −1. The Chern–Simons photon has only one.

Worked example 13.20: the rest frame

Look for a solution at rest, $\tilde{F}^\mu = f^\mu e^{-iEt}$ with constant f^μ and $E > 0$. The Bianchi identity gives $\partial_\mu \tilde{F}^\mu = \partial_0 \tilde{F}^0 = -iE f^0 e^{-iEt} = 0$, so $f^0 = 0$. The spatial components of (13.39) involve only the time derivative ($\mu = 0$):

$$m f^i \overset{(1)}{=} \epsilon^{i0j}(-iE) f_j \overset{(2)}{=} -iE\, \epsilon^{0ij} f^j \overset{(3)}{=} -iE\, \varepsilon_{ij} f^j,$$

(1) $\partial_0 \to -iE$ and the plane wave factor cancels.
(2) $\epsilon^{i0j} = -\epsilon^{0ij}$ and $f_j = -f^j$ (lowering a spatial index costs a sign). The two signs cancel.
(3) Write $\varepsilon_{ij} = \epsilon^{0ij}$, the two-dimensional antisymmetric symbol with $\varepsilon_{12} = 1$.

In matrix form this is

$$-iE \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \begin{pmatrix} f^1 \\ f^2 \end{pmatrix} = m \begin{pmatrix} f^1 \\ f^2 \end{pmatrix}.$$

The matrix $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ has eigenvalues $\pm i$, with eigenvectors $(1, \pm i)$. So $-iE \cdot (\pm i) = \pm E$ must equal m. Since $E > 0$, only *one* eigenvector works, $E = |m|$, with the sign $\pm = \operatorname{sgn} m = \operatorname{sgn} \kappa$. For $\kappa > 0$ the solution is $f \propto (1, i)$, so the real field is $(\cos Et,\ \sin Et)$: it rotates counterclockwise. For $\kappa < 0$ it rotates clockwise. The Chern–Simons photon is a single massive particle of spin $\operatorname{sgn} \kappa = \pm 1$ (Figure 13.18).

The counting matches: the Maxwell photon has one massless state. The Chern–Simons term does not add a state; it gives the existing one a mass and a handedness. The absent partner of opposite spin is the visible sign that parity is broken.

2 + 1 dimensional theory	states	mass	spin
Maxwell	1	0	none (parity even)
Proca, $\frac{1}{2}m^2A^2$	2	m	+1 and −1
Maxwell–Chern–Simons	1	$\lvert k\rvert e^2/2\pi$	$\operatorname{sgn} k$
pure Chern–Simons	0	—	—

Try it: the propagator pole

Add the gauge-fixing term $-\frac{1}{2\xi e^2}(\partial \cdot A)^2$ and invert the quadratic form in momentum space. The result (Dunne, *Aspects of Chern–Simons theory*, eq. (26)) is

$$\Delta_{\mu\nu}(p) = e^2 \frac{p^2 g_{\mu\nu} - p_\mu p_\nu - i\kappa e^2 \epsilon_{\mu\nu\rho} p^\rho}{p^2 (p^2 - \kappa^2 e^4)} + \xi e^2 \frac{p_\mu p_\nu}{(p^2)^2}.$$

Which poles are physical? *Answer:* the pole at $p^2 = \kappa^2 e^4$ is the massive photon. The $1/p^2$ poles multiply $p^2 g_{\mu\nu} - p_\mu p_\nu$ or $p_\mu p_\nu$, which vanish between conserved currents at $p^2 = 0$ (or are gauge artefacts), so there is no massless particle.

13.5.4 Charges carry flux, and their fields are screened

Couple a conserved current, $\mathcal{L} \ni -A_\mu j^\mu$. The field equation becomes $\frac{1}{e^2}\partial_\mu F^{\mu\nu} + \kappa \tilde{F}^\nu = j^\nu$. Its time component is Gauss's law. With $E^i = F^{i0}$ and $B = \tilde{F}^0 = F_{12}$ it reads

$$\frac{1}{e^2} \nabla \cdot \vec{E} + \kappa B = \rho. \tag{13.42}$$

Worked example 13.21: a static charge

Put a charge Q at the origin, $\rho = Q\delta^2(\vec{x})$. The fields are components of $\tilde{F}$, which obeys $(\Box + m^2)\tilde{F} =$ (local source terms), so away from the charge the static fields obey $(-\nabla^2 + m^2)\tilde{F} = 0$ and fall off like the two-dimensional Yukawa function $K_0(mr) \sim e^{-mr}/\sqrt{r}$ (Example 13.8). Integrate (13.42) over a disc of radius $R \gg 1/m$:

$$Q \overset{(1)}{=} \frac{1}{e^2} \oint_{|\vec{x}|=R} \vec{E} \cdot \hat{\vec{n}}\, \mathrm{d}\ell + \kappa \int_{|\vec{x}|<R} B\, \mathrm{d}^2x \overset{(2)}{\longrightarrow} \kappa\, \Phi \overset{(3)}{\Longrightarrow} \Phi = \frac{Q}{\kappa} = \frac{2\pi Q}{k}.$$

(1) Integrate (13.42), using the divergence theorem on the first term.

(2) As $R \to \infty$ the boundary term vanishes because $\vec{E}$ decays exponentially. Φ is the total magnetic flux.

(3) $\kappa = k/2\pi$.

The charge is surrounded by a cloud of magnetic flux $2\pi Q/k$, and its electric field is screened: nothing of the charge is felt beyond $1/m$ by local measurements. What remains at long distances is purely topological. A second charge carried around the first picks up an Aharonov–Bohm phase from the attached flux, and exchanging two unit charges gives the phase $e^{i\pi/k}$: the particles are **anyons** (Chapter 12).

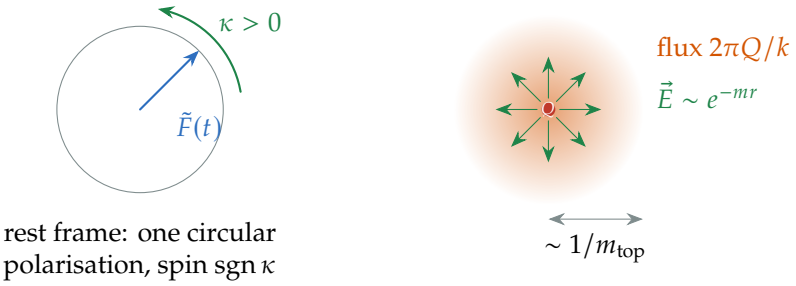

Figure 13.18: Left: at rest, the Chern–Simons photon's field strength rotates in one sense only, fixed by the sign of the level: a single state of spin ±1. Right: a static charge Q is dressed by a cloud of magnetic flux $2\pi Q/k$ (orange) of size $1/m_{\text{top}}$. Its electric field (green) is screened exponentially. At long distances only the attached flux remains, visible through Aharonov–Bohm phases.

13.5.5 The infrared: a topological field theory

Compare the two terms of (13.37) by dimension. In $2+1$ dimensions $[A] = 1$, so F^2 has dimension 4 and needs the coefficient $1/e^2$ of dimension -1, while $A\,\mathrm{d}A$ has dimension 3 and a dimensionless coefficient. At energies $E \ll m_{\text{top}} = \kappa e^2$, the Maxwell term is suppressed by E/m_{top} and drops out. What is left is pure Chern–Simons theory, $\mathrm{U}(1)_k$: a TQFT with no local degrees of freedom and zero Hamiltonian. So Maxwell–Chern–Simons theory is *gapped with topological order* (Section 13.1.4): its vacua are the states of the TQFT, and the massive photon sits a gap m_{top} above them.

Worked example 13.22: k vacua on a torus

Put $\mathrm{U}(1)_k$ Chern–Simons theory on a spatial torus with coordinates $x, y \in [0, 1)$. The low-energy configurations are flat connections, $A = a_1(t)\,\mathrm{d}x + a_2(t)\,\mathrm{d}y$, with holonomies e^{ia_1}, e^{ia_2} around the two cycles, and $a_j \sim a_j + 2\pi$ by large gauge transformations. Then

$$A \wedge \mathrm{d}A \overset{(1)}{=} (a_1\mathrm{d}x + a_2\mathrm{d}y) \wedge (\dot{a}_1\,\mathrm{d}t \wedge \mathrm{d}x + \dot{a}_2\,\mathrm{d}t \wedge \mathrm{d}y) \overset{(2)}{=} (a_2\dot{a}_1 - a_1\dot{a}_2)\,\mathrm{d}t \wedge \mathrm{d}x \wedge \mathrm{d}y,$$

$$S_{\mathrm{CS}} \overset{(3)}{=} \frac{k}{4\pi}\int \mathrm{d}t\,(a_2\dot{a}_1 - a_1\dot{a}_2) \overset{(4)}{=} \frac{k}{2\pi}\int \mathrm{d}t\,a_2\,\dot{a}_1.$$

(1) $\mathrm{d}A = \dot{a}_1\mathrm{d}t\wedge\mathrm{d}x + \dot{a}_2\mathrm{d}t\wedge\mathrm{d}y$.
(2) $\mathrm{d}x\wedge\mathrm{d}t\wedge\mathrm{d}y = -\mathrm{d}t\wedge\mathrm{d}x\wedge\mathrm{d}y$ and $\mathrm{d}y\wedge\mathrm{d}t\wedge\mathrm{d}x = +\mathrm{d}t\wedge\mathrm{d}x\wedge\mathrm{d}y$. Terms with $\mathrm{d}x\wedge\mathrm{d}x$ or $\mathrm{d}y\wedge\mathrm{d}y$ vanish.
(3) The x, y integrals give 1.
(4) Integrate $-a_1\dot{a}_2$ by parts to $+a_2\dot{a}_1$.

This is a first-order action, like $\int p\,\dot{q}$: a_1 is the coordinate and $p_1 = \frac{k}{2\pi}a_2$ its momentum. Quantising, $[a_1, a_2] = \frac{2\pi i}{k}$. The gauge-invariant operators are the holonomies $U = e^{ia_1}$ and $V = e^{ia_2}$, and $e^Xe^Y = e^Ye^Xe^{[X,Y]}$ for a central commutator gives

$$UV = e^{-2\pi i/k}\,VU.$$

The smallest matrices obeying this are $k\times k$: the clock and shift matrices $U = \mathrm{diag}(1,\omega,\omega^2,\ldots,\omega^{k-1})$ and V the cyclic shift, with $\omega = e^{-2\pi i/k}$. So the Hilbert space on the torus is k-dimensional: k degenerate vacua, whose number depends on the topology of space. On a sphere, with no noncontractible loops, there is one.

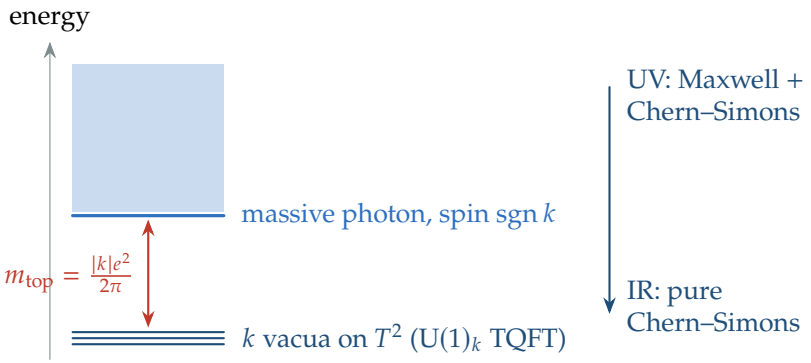

Figure 13.19: The spectrum of Maxwell–Chern–Simons theory on a spatial torus. The photon sits a gap m_{top} above a set of k exactly degenerate vacua. Below the gap only the topological field theory $\mathrm{U}(1)_k$ survives: the Maxwell term fades out along the RG flow (right), leaving a theory with no local excitations and a vacuum degeneracy that counts the topology of space.

Physical picture: where Chern–Simons terms come from

A Chern–Simons term is not an exotic addition. Integrate out a massive two-component Dirac fermion of mass M and charge one in $2+1$ dimensions: the one-loop vacuum polarisation contains a parity-odd piece, which at momenta $\ll |M|$ is a Chern–Simons term at level $\frac{1}{2}\,\mathrm{sgn}\,M$. (The half-integer is the **parity anomaly**, Chapter 10: a single massless Dirac fermion cannot be regularised without breaking parity.) In a quantum Hall system, integrating out the gapped electrons gives a Chern–Simons term whose level is the Hall conductance in units of e^2/h. Gapped matter leaves behind topological terms, and topological terms gap the gauge field.

Key idea: a gap from topology, not from condensation

In Maxwell–Chern–Simons theory the photon mass $|k|e^2/2\pi$ comes from a metric-independent term. No field condenses, no symmetry is spontaneously broken, and

gauge invariance is intact. The only inputs are the integer level k and the coupling e^2. The theory is gapped, parity violating, and at long distances a TQFT whose vacuum degeneracy on a torus is $|k|$.

Reading Nash (Ch. XII, pp. 343–344, (12.86)–(12.89))

Nash computes the correlation functions of Wilson lines in *pure* abelian Chern–Simons theory on S^3. The action is quadratic, the integral is Gaussian, and the answer is an exponential of Gauss linking numbers of the knots. There are no local degrees of freedom at all: only the topology of the knots matters. Adding the Maxwell term, as here, gives the theory exactly one local degree of freedom, a massive photon, and leaves Nash's topological answer as its long-distance limit. His Chern–Simons form (Ch. VIII, §2, p. 223) is the non-abelian version of $A \wedge \mathrm{d}A$.

Recap

- $S_{\mathrm{CS}} = \frac{k}{4\pi}\int A \wedge \mathrm{d}A$ is metric independent, gauge invariant up to boundary terms ($k \in \mathbb{Z}$), and odd under parity.
- Maxwell + Chern–Simons gives $\frac{1}{e^2}\partial_\mu F^{\mu\nu} + \kappa \tilde{F}^\nu = 0$, which squares to $(\Box + m^2)\tilde{F} = 0$ with $m = |k|e^2/2\pi$.
- There is one massive state, of spin $\operatorname{sgn} k$.
- A charge Q binds flux $2\pi Q/k$, and its electric field is screened: charges become anyons.
- Below the gap the theory is the TQFT $\mathrm{U}(1)_k$, with $|k|$ vacua on a torus: gapped with topological order.

13.6 θ-terms and the Haldane gap

Take a chain of quantum spins of size S with antiferromagnetic nearest-neighbour coupling,

$$H = J\sum_j S_j \cdot S_{j+1}, \qquad J > 0. \tag{13.43}$$

Classically, and in spin-wave theory, all values of S behave alike: the spins want to alternate (the **Néel** pattern), and the excitations are gapless spin waves. In 1983 Haldane argued that this is wrong in a way that depends on S in a startling manner. For *integer* S the chain has a gap. For *half-integer* S it is gapless. The difference comes from a term in the effective action that is invisible in the classical equations of motion, a **θ-term**, with $\theta = 2\pi S$. This section builds the idea from the simplest example, derives the θ-term from the spin chain, and explains why $\theta = \pi$ is special.

13.6.1 A θ-term in quantum mechanics: the particle on a ring

A particle of moment of inertia I moves on a circle, angle $\varphi \sim \varphi + 2\pi$. Add a total-derivative term:

$$L = \frac{I}{2}\dot{\varphi}^2 + \frac{\theta}{2\pi}\dot{\varphi}.$$

The added term is $\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\theta}{2\pi}\varphi\right)$, so the Euler–Lagrange equation $I\ddot{\varphi} = 0$ does not see it. Classically θ is irrelevant. Quantum mechanically it is not:

$$p \overset{(1)}{=} \frac{\partial L}{\partial \dot{\varphi}} = I\dot{\varphi} + \frac{\theta}{2\pi}, \qquad H \overset{(2)}{=} p\dot{\varphi} - L = \frac{1}{2I}\left(p - \frac{\theta}{2\pi}\right)^2, \qquad E_n \overset{(3)}{=} \frac{1}{2I}\left(n - \frac{\theta}{2\pi}\right)^2, \quad n \in \mathbb{Z}.$$

(1) Canonical momentum.
(2) Legendre transform: substitute $\dot{\varphi} = (p - \theta/2\pi)/I$.
(3) Wavefunctions $e^{in\varphi}$ must be single valued on the circle, so $p = -i\partial_\varphi$ has integer eigenvalues n.

The spectrum depends on θ, periodically with period 2π (shifting $\theta \to \theta + 2\pi$ relabels $n \to n + 1$). Physically θ is a magnetic flux threading the ring, and this is the Aharonov–Bohm effect. In Euclidean time with period β, a path winds $w \in \mathbb{Z}$ times, and the θ-term contributes

$$-i\frac{\theta}{2\pi}\int_0^\beta \dot{\varphi}\,\mathrm{d}\tau = -i\theta\, w \qquad \Longrightarrow \qquad Z = \sum_{w\in\mathbb{Z}} e^{i\theta w}\, Z_w,$$

a phase that weights each topological sector (Figure 13.20).

Worked example 13.23: the gap closes at $\theta = \pi$

At $\theta = 0$ the ground state is $n = 0$ with $E_0 = 0$, and the first excited states $n = \pm 1$ have $E = 1/2I$: a gap $1/2I$. At $\theta = \pi$,

$$E_0 \overset{(1)}{=} \frac{1}{2I}\left(0 - \frac{1}{2}\right)^2 = \frac{1}{8I}, \qquad E_1 \overset{(2)}{=} \frac{1}{2I}\left(1 - \frac{1}{2}\right)^2 = \frac{1}{8I},$$

(1) $n = 0$, $\theta/2\pi = \frac{1}{2}$.
(2) $n = 1$.

so the two lowest levels are exactly degenerate. Time reversal sends $\theta \to -\theta$. It is a symmetry only at $\theta = 0$ and at $\theta = \pi$ (where $-\pi \equiv \pi \bmod 2\pi$), and at $\theta = \pi$ it exchanges the two ground states, $n = 0 \leftrightarrow n = 1$. In the path-integral language the sectors with even and odd winding enter with opposite signs, $e^{i\pi w} = (-1)^w$, and this destructive interference is what removes the unique ground state.

Working definition 13.4 (θ-term)

A **θ-term** is a contribution $-i\theta\, Q$ to the Euclidean action, where Q is an integer-valued topological charge [a winding number, unchanged by any small deformation of the field, like the number of times a path goes round a ring]. It is a total derivative, so it leaves the classical field equations unchanged [the Euler–Lagrange equations of L and of $L + \frac{\mathrm{d}}{\mathrm{d}t}f$ are the same], but it weights each topological sector by $e^{i\theta Q}$ [paths that wind differently interfere with different phases]. Physics depends on θ only modulo 2π. Time reversal (or parity) sends $\theta \to -\theta$, so it is a symmetry only at $\theta = 0$ and $\theta = \pi$. *To test for one:* find the integer Q of the field configurations (for example $\pi_1(S^1)$, $\pi_2(S^2)$, the instanton number of Chapter 8), and check whether the action contains Q with an imaginary coefficient.

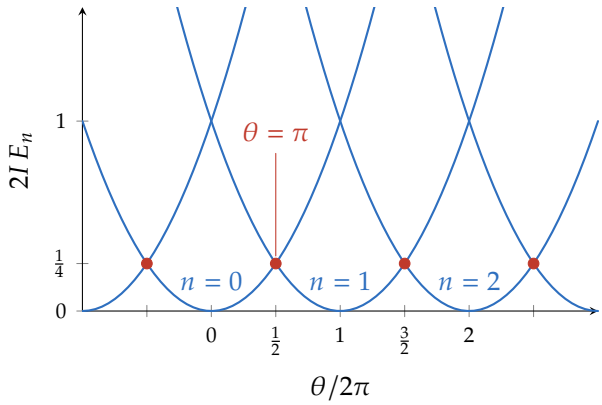

Figure 13.20: Energy levels of a particle on a ring as a function of the θ-angle. Each parabola is one momentum n. The spectrum is periodic in θ with period 2π. At $\theta = 0$ the ground state is unique and gapped. At $\theta = \pi$ (red) two parabolas cross and the ground state is doubly degenerate: a topological term, invisible classically, has closed the gap.

The examples we need are:

- four-dimensional Yang–Mills theory, $\frac{\theta}{8\pi^2}\int \operatorname{tr} F \wedge F$, with Q the instanton number (Chapter 8);
- the two-dimensional O(3) sigma model, a unit vector field $\vec{n}(x,\tau) \in S^2$, with

$$Q = \frac{1}{4\pi}\int \mathrm{d}x\,\mathrm{d}\tau\ \vec{n}\cdot\left(\partial_x\vec{n}\times\partial_\tau\vec{n}\right) \in \mathbb{Z}, \tag{13.44}$$

  the degree of the map from spacetime (compactified to S^2) to the target S^2. The integrand $\vec{n}\cdot(\partial_x\vec{n}\times\partial_\tau\vec{n})\,\mathrm{d}x\,\mathrm{d}\tau$ is the area element of the target sphere pulled back to spacetime, so $4\pi Q$ is the total area covered, counted with orientation.

13.6.2 A single spin: the Berry phase is a solid angle

A spin S can be described by the direction $\vec{n}$ in which it points. The **spin coherent state** $|\vec{n}\rangle$ is the state $|S,S\rangle$ (maximal S_z) rotated so that its axis points along $\vec{n}$, with $\langle\vec{n}|\vec{S}|\vec{n}\rangle = S\vec{n}$. When $\vec{n}(\tau)$ moves round a closed loop, the state acquires a **Berry phase**, and in the path integral for the spin this phase is the whole of the kinetic term. We compute it for a loop at fixed polar angle ϑ_0, with azimuth ϕ going once round.

Worked example 13.24: Berry phase of a spin

Take $|\vec{n}\rangle = e^{iS\phi}e^{-i\phi S_z}e^{-i\vartheta_0 S_y}|S,S\rangle$. (The prefactor $e^{iS\phi}$ makes the state smooth at the north pole.) The Berry phase is $\gamma = i\oint\langle\vec{n}|\partial_\tau\vec{n}\rangle\,\mathrm{d}\tau$:

$$\langle\vec{n}|\partial_\tau|\vec{n}\rangle \overset{(1)}{=} iS\dot\phi - i\dot\phi\,\langle S,S|e^{i\vartheta_0 S_y}S_z e^{-i\vartheta_0 S_y}|S,S\rangle \overset{(2)}{=} iS\dot\phi - i\dot\phi\,S\cos\vartheta_0,$$

$$\gamma \overset{(3)}{=} -S\oint(1-\cos\vartheta_0)\,\mathrm{d}\phi \overset{(4)}{=} -S\cdot 2\pi(1-\cos\vartheta_0) \overset{(5)}{=} -S\,\Omega.$$

(1) Differentiate the two ϕ-dependent factors. The operator $e^{i\phi S_z}\cdots e^{-i\phi S_z}$ from the conjugation leaves S_z unchanged.
(2) Rotating by ϑ_0 about the y axis turns S_z into $S_z\cos\vartheta_0$ + (a component of S_x), and $\langle S,S|S_x|S,S\rangle = 0$.
(3) Multiply by i and integrate.

(4) ϕ increases by 2π.
(5) $\Omega = 2\pi(1 - \cos\vartheta_0)$ is the solid angle of the cap enclosed by the loop.

The phase is S times the solid angle enclosed by the path of $\vec{n}$, as if the spin were a charge moving on the unit sphere in the field of a magnetic monopole of strength S at the centre.

The loop bounds two caps, of solid angles Ω and $4\pi - \Omega$ (with opposite orientation). The two choices give phases differing by $4\pi S$, so the path-integral weight $e^{iS\Omega}$ is unambiguous only if $e^{4\pi iS} = 1$, that is $2S \in \mathbb{Z}$. Spin quantisation is Dirac quantisation for the monopole of strength S (Figure 13.21).

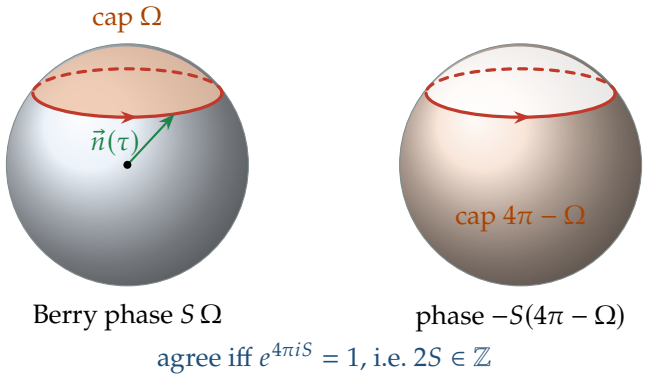

Figure 13.21: The Berry phase of a spin is S times the solid angle swept by its direction $\vec{n}$. The same loop (red) bounds the upper cap (left) and, with the opposite orientation, the rest of the sphere (right). The two answers differ by $4\pi S$, so the quantum amplitude is well defined only for integer or half-integer spin: Dirac's quantisation condition for a monopole of strength S.

We will also need how the solid angle changes when the loop is deformed. Move the loop $\vec{n}(\tau)$ to $\vec{n} + \delta\vec{n}$. The enclosed solid angle changes by the area of the thin strip between the old and the new loop. The strip has sides $\partial_\tau\vec{n}\,\mathrm{d}\tau$ and $\delta\vec{n}$, and its oriented area on the unit sphere (normal $\vec{n}$) is $\vec{n}\cdot(\delta\vec{n}\times\partial_\tau\vec{n})\,\mathrm{d}\tau$. So

$$\delta\Omega = \oint \mathrm{d}\tau\;\vec{n}\cdot\left(\delta\vec{n}\times\partial_\tau\vec{n}\right) \tag{13.45}$$

(with an orientation convention whose overall sign plays no role below).

13.6.3 The spin chain becomes the $\mathrm{O}(3)$ sigma model

For large S the spins of (13.43) stay close to a Néel pattern whose direction varies slowly. Let the lattice spacing be a and write

$$\vec{S}_j \approx S\,(-1)^j\,\vec{n}(x_j) + (\text{small uniform part}),$$

with $\vec{n}$ a slowly varying unit vector, the local Néel direction (Figure 13.22). The Euclidean action is the sum of the Berry phases of all spins and the energy. We compute three pieces.

(a) The staggered Berry phases give the θ-term. The spin at site j points along $(-1)^j\vec{n}_j$. The antipodal loop $-\vec{n}$ encloses the solid angle $-\Omega[\vec{n}]$ (mod 4π), so the total Berry phase is

$S\sum_j(-1)^j\Omega[\vec n_j]$. Pair the sites $(2k,2k+1)$:

$$S\sum_j(-1)^j\Omega[\vec n_j]\overset{(1)}{=}S\sum_k\big(\Omega[\vec n_{2k}]-\Omega[\vec n_{2k+1}]\big)\overset{(2)}{\approx}-S\sum_k a\,\partial_x\Omega\overset{(3)}{\approx}-\frac{S}{2}\int \mathrm{d}x\;\partial_x\Omega$$
$$\overset{(4)}{=}-\frac{S}{2}\int \mathrm{d}x\,\mathrm{d}\tau\;\vec n\cdot(\partial_x\vec n\times\partial_\tau\vec n)\overset{(5)}{=}-2\pi S\,Q. \tag{13.46}$$

(1) Group even and odd sites.
(2) $\vec n_{2k+1}\approx\vec n_{2k}+a\,\partial_x\vec n$, so the difference of solid angles is $a\,\partial_x\Omega$ to first order.
(3) The pairs are spaced by $2a$, so $\sum_k 2a\,f(x_{2k})\to\int \mathrm{d}x\,f$.
(4) (13.45) with $\delta\vec n=\partial_x\vec n\,\mathrm{d}x$.
(5) Definition (13.44) of Q.

So the chain produces a θ-term with

$$\boxed{\theta=2\pi S.} \tag{13.47}$$

(Pairing $(2k-1,2k)$ instead flips the sign, $\theta=-2\pi S$. Since $e^{\pm 2\pi i SQ}$ are equal for $2S\in\mathbb{Z}$, nothing depends on this choice.)

(b) Twisting the Néel direction costs gradient energy. For the Néel part, $\vec S_j\cdot\vec S_{j+1}=-S^2\vec n_j\cdot\vec n_{j+1}$. Expand to second order:

$$\vec n(x)\cdot\vec n(x+a)\overset{(1)}{=}\vec n\cdot\big(\vec n+a\vec n'+\tfrac{a^2}{2}\vec n''\big)\overset{(2)}{=}1+\tfrac{a^2}{2}\,\vec n\cdot\vec n''\overset{(3)}{=}1-\tfrac{a^2}{2}(\vec n')^2,$$

(1) Taylor expansion, $\vec n'=\partial_x\vec n$.
(2) $\vec n\cdot\vec n=1$ and, differentiating, $\vec n\cdot\vec n'=0$.
(3) Differentiating $\vec n\cdot\vec n'=0$ once more gives $\vec n\cdot\vec n''=-(\vec n')^2$.

so each bond costs $\frac{JS^2a^2}{2}(\partial_x\vec n)^2$ above the Néel energy, and the energy per unit length is $\frac{JS^2a}{2}(\partial_x\vec n)^2$.

(c) Canting and the time-derivative term. A spin configuration that moves in time must cant slightly: in each cell of two sites write $\vec S_{2k}\propto S(\vec n+a\vec l)$, $\vec S_{2k+1}\propto -S(\vec n-a\vec l)$, normalised, with $\vec l\perp\vec n$ a small uniform magnetisation. Canting costs energy:

$$\vec S_{2k}\cdot\vec S_{2k+1}\overset{(1)}{=}-S^2\,\frac{(\vec n+a\vec l)\cdot(\vec n-a\vec l)}{1+a^2\vec l^{\,2}}\overset{(2)}{=}-S^2\,\frac{1-a^2\vec l^{\,2}}{1+a^2\vec l^{\,2}}\overset{(3)}{\approx}-S^2\big(1-2a^2\vec l^{\,2}\big),$$

(1) Each vector $\vec n\pm a\vec l$ has length $\sqrt{1+a^2\vec l^{\,2}}$ because $\vec n\perp\vec l$, and we divide by it.
(2) $\vec n\cdot\vec l=0$.
(3) $(1-\epsilon)/(1+\epsilon)\approx 1-2\epsilon$.

so each bond costs $2JS^2a^2\vec l^{\,2}$. With two bonds per cell of length $2a$, the energy per unit length is $2JS^2a\,\vec l^{\,2}$. The canting also changes the Berry phases. The two spins of a cell contribute $S\,\Omega[\vec n+a\vec l]-S\,\Omega[\vec n-a\vec l]\approx S\int \mathrm{d}\tau\,\vec n\cdot(2a\vec l\times\partial_\tau\vec n)$ by (13.45), which per unit length is $S\,\vec l\cdot(\partial_\tau\vec n\times\vec n)$. The Euclidean Lagrangian density for $\vec l$ is therefore $2JS^2a\,\vec l^{\,2}-iS\,\vec l\cdot(\partial_\tau\vec n\times\vec n)$. The field $\vec l$ appears quadratically, so we integrate it out:

$$\int \mathrm{d}^2l\;e^{-\left[A\vec l^{\,2}-i\vec b\cdot\vec l\right]}\overset{(1)}{=}\frac{\pi}{A}\,e^{-\vec b^{\,2}/4A},\qquad \frac{\vec b^{\,2}}{4A}\overset{(2)}{=}\frac{S^2(\partial_\tau\vec n)^2}{8JS^2a}=\frac{(\partial_\tau\vec n)^2}{8Ja},$$

(1) Complete the square, $A\vec{l}^2 - i\vec{b}\cdot\vec{l} = A(\vec{l} - i\vec{b}/2A)^2 + \vec{b}^2/4A$, for the two components of $\vec{l}$ perpendicular to $\vec{n}$.
(2) $A = 2JS^2a$ and $\vec{b} = S\,\partial_\tau\vec{n}\times\vec{n}$, whose square is $S^2(\partial_\tau\vec{n})^2$ because $\partial_\tau\vec{n}\perp\vec{n}$.

The result. Adding (a), (b) and (c), the long-wavelength Euclidean action of the spin chain is

$$S_E = \frac{1}{2g}\int \mathrm{d}x\,\mathrm{d}\tau\left[v\,(\partial_x\vec{n})^2 + \frac{1}{v}(\partial_\tau\vec{n})^2\right] - i\theta\,Q, \qquad g = \frac{2}{S}, \quad v = 2JSa, \quad \theta = 2\pi S. \tag{13.48}$$

To read off g and v, match $\frac{v}{2g} = \frac{JS^2a}{2}$ and $\frac{1}{2gv} = \frac{1}{8Ja}$: multiplying gives $\frac{1}{4g^2} = \frac{S^2}{16}$, and dividing gives $v^2 = 4J^2S^2a^2$. The time direction can be rescaled by v to make the action Lorentz invariant, with v playing the role of the speed of light. This is the O(3) **nonlinear sigma model** with a θ-term. It is also the $\mathbb{CP}^1$ model of Section 13.3.4, since $\mathbb{CP}^1 = S^2$.

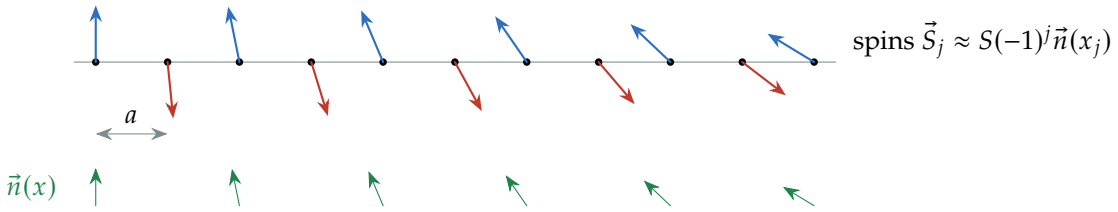

Figure 13.22: The Néel field of an antiferromagnetic chain. Neighbouring spins (blue and red) point in nearly opposite directions. Their common axis, the Néel direction $\vec{n}(x)$ (green, drawn below the chain), rotates slowly along the chain. Slow rotations in space cost gradient energy. Slow rotations in time force a small canting of each pair, and the Berry phases of the alternating spins leave behind the topological term $-2\pi iSQ$.

13.6.4 Integer versus half-integer spin

The weight of a topological sector is

$$e^{i\theta Q} = e^{2\pi iSQ} = \begin{cases} 1 & S\in\mathbb{Z}, \\ (-1)^Q & S\in\mathbb{Z}+\frac{1}{2}. \end{cases}$$

Integer spin: the O(3) model at $\theta = 0$ is gapped. With no phase, (13.48) is the plain two-dimensional O(3) sigma model. Like the $\mathbb{CP}^{N-1}$ model it is asymptotically free, with one-loop running $\mu\,\mathrm{d}g/\mathrm{d}\mu = -g^2/2\pi$ (for O(N) the coefficient is $(N-2)/2\pi$). By the argument of Section 13.3.3, a mass is generated.

Worked example 13.25: estimating the Haldane gap

The bare coupling $g = 2/S$ is defined at the lattice scale, momentum $\mu_0 \sim 1/a$, which corresponds to the energy $v/a = 2JS$. Integrating the running coupling,

$$\frac{1}{g(\mu)} \overset{(1)}{=} \frac{1}{g(\mu_0)} - \frac{1}{2\pi}\ln\frac{\mu_0}{\mu} \quad \overset{(2)}{\Longrightarrow} \quad \mu_* \overset{(3)}{=} \mu_0\,e^{-2\pi/g(\mu_0)} \overset{(4)}{=} \frac{1}{a}\,e^{-\pi S},$$

(1) $\frac{\mathrm{d}}{\mathrm{d}\ln\mu}\frac{1}{g} = -\frac{1}{g^2}\frac{\mathrm{d}g}{\mathrm{d}\ln\mu} = \frac{1}{2\pi}$, integrated from μ up to μ_0.
(2) The coupling becomes strong ($1/g\to 0$) at the scale μ_*.
(3) Solve $1/g(\mu_0) = \frac{1}{2\pi}\ln(\mu_0/\mu_*)$.
(4) $g(\mu_0) = 2/S$ and $\mu_0 \sim 1/a$.

The gap is $\Delta \sim v\mu_* \sim JS\, e^{-\pi S}$ and the correlation length is $\xi \sim a\, e^{\pi S}$. (A two-loop treatment refines the prefactor to $\Delta \sim JS^2 e^{-\pi S}$.) The gap is exponentially small for large spin, consistent with the gapless classical limit, but it is nonzero for every integer S. Numerically, the spin-1 chain has $\Delta = 0.4105\,J$ and $\xi \approx 6$ sites, and the spin-2 chain has $\Delta \approx 0.087\,J$ and $\xi \approx 50$ sites. The gap has been seen by neutron scattering in quasi-one-dimensional spin-1 compounds such as NENP.

Half-integer spin: $\theta = \pi$ and destructive interference. Now sectors of odd Q come with a minus sign. In the integer case the gap is produced by the disordering effect of all the topologically nontrivial fluctuations of $\vec{n}$. At $\theta = \pi$ those fluctuations cancel in pairs, just as the even and odd windings did for the particle on a ring (Example 13.23). The result, established by Affleck and Haldane (1987) using the non-abelian bosonisation of Chapter 11, is that the O(3) model at $\theta = \pi$ flows to a gapless conformal field theory, the $\mathrm{SU}(2)_1$ Wess–Zumino–Witten model. Three independent pieces of evidence support this.

- *Exact solution for $S = \frac{1}{2}$.* Bethe's ansatz solves the spin-$\frac{1}{2}$ chain exactly. Its elementary excitations, spinons, have dispersion $\varepsilon(k) = \frac{\pi J}{2}|\sin k|$, which vanishes at $k = 0, \pi$: gapless.
- *Lieb–Schultz–Mattis.* For every half-integer S, a rigorous theorem (Section 13.7.2) forbids a unique gapped ground state that preserves translation symmetry.
- *An anomaly at $\theta = \pi$.* The O(3) model at $\theta = \pi$ has a mixed 't Hooft anomaly between its SO(3) symmetry and time reversal (or translation, from the lattice point of view). It forbids a trivially gapped phase (Section 13.7).

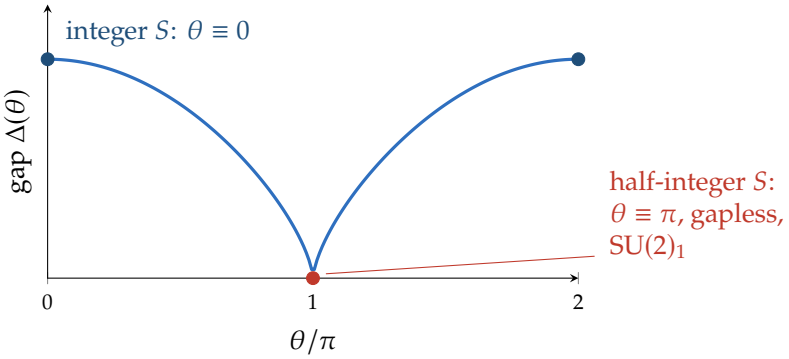

Figure 13.23: Schematic gap of the O(3) sigma model as a function of θ, at the coupling relevant for the Heisenberg chain. The gap is largest at $\theta = 0$ (integer spin, dark dots) and closes at $\theta = \pi$ (half-integer spin, red dot), where the theory is the gapless $\mathrm{SU}(2)_1$ conformal field theory. Only the two time-reversal-invariant values, 0 and π, can be realised by a Heisenberg chain.

The role of $\theta = \pi$. Two facts make $\theta = \pi$ special. First, it is one of only two values compatible with time reversal, so a time-reversal- invariant microscopic model (such as the Heisenberg chain) must land on $\theta = 0$ or $\theta = \pi$. Second, at $\theta = \pi$ the anomaly leaves only two options: the theory is gapless, or a symmetry breaks spontaneously and the ground state is degenerate. Both occur. The Heisenberg chain is gapless. Adding a next-nearest-neighbour coupling J_2 drives it, beyond $J_2/J \approx 0.241$, into a *dimerised* phase: gapped, with two ground states that break translation by one site. At $J_2 = J/2$ (the Majumdar–Ghosh point) the two dimer coverings are exact ground states (Figure 13.24). What cannot happen at $\theta = \pi$ is a unique gapped ground state.

Worked example 13.26: the AKLT chain: an exactly gapped spin-1 chain

Integer spin chains can be made exactly solvable. For spin 1, consider

$$H_{\mathrm{AKLT}} = J\sum_j \Big[\vec{S}_j\cdot\vec{S}_{j+1} + \tfrac{1}{3}(\vec{S}_j\cdot\vec{S}_{j+1})^2\Big].$$

For two spins 1 with total spin $s\in\{0,1,2\}$, $x=\vec{S}_j\cdot\vec{S}_{j+1}=\frac{1}{2}[s(s+1)-4]$ takes the values $-2,-1,1$. The projector onto $s=2$ is $P_2=\frac{(x+2)(x+1)}{(1+2)(1+1)}$ (it vanishes at $x=-2,-1$ and equals 1 at $x=1$). So

$$x+\tfrac{1}{3}x^2 \overset{(1)}{=} \tfrac{1}{3}\big(x^2+3x+2\big)-\tfrac{2}{3} \overset{(2)}{=} 2P_2-\tfrac{2}{3},$$

(1) Add and subtract $\frac{2}{3}$.
(2) $x^2+3x+2=(x+2)(x+1)=6P_2$.

and $H_{\mathrm{AKLT}}=J\sum_j(2P_2^{(j,j+1)}-\frac{2}{3})$: a sum of projectors, minus a constant. Now build a state as in Figure 13.24: write each spin 1 as two spin-$\frac{1}{2}$'s symmetrised, and join neighbouring halves into singlets. On any bond, the two spin-1's share one singlet, so their total spin is at most 1 and P_2 annihilates the state. Since every $P_2\geq 0$, this **valence-bond solid** is an exact ground state, with energy $-\frac{2}{3}J$ per bond. Affleck, Kennedy, Lieb and Tasaki proved that it is the unique ground state on a ring and that there is a gap above it: a rigorous Haldane gap. On an open chain the two unpaired spin-$\frac{1}{2}$'s at the ends give a fourfold ground-state degeneracy, the signature of the **Haldane phase** as a symmetry-protected topological phase: trivially gapped in the bulk, with a topological response at its edges.

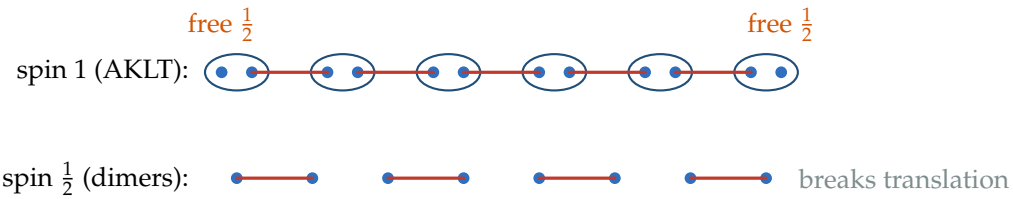

Figure 13.24: Top: the AKLT valence-bond solid. Each spin 1 (ellipse) is two spin-$\frac{1}{2}$'s, and every bond carries one singlet (red). The state is translation invariant, unique on a ring and gapped. On an open chain two spin-$\frac{1}{2}$'s are left free at the ends. Bottom: for spin $\frac{1}{2}$ each site has only one spin-$\frac{1}{2}$, so singlets can cover only every other bond. A gapped state must pick one of two dimer patterns, breaking translation. This is the lattice face of $\theta=2\pi S$.

Key idea: Haldane's conjecture

The Heisenberg antiferromagnetic chain of spin S is, at long distances, the O(3) sigma model with $g=2/S$ and $\theta=2\pi S$. For integer S ($\theta\equiv 0$) the model is gapped, with $\Delta\sim JS^2e^{-\pi S}$. For half-integer S ($\theta\equiv\pi$) the topological sectors interfere destructively and the model is gapless, flowing to the $\mathrm{SU}(2)_1$ conformal field theory. The gap is decided by a term that does not appear in any classical equation of motion.

Recap

- A θ-term $-i\theta Q$ weights topological sectors by $e^{i\theta Q}$. It is invisible classically, periodic in θ, and time-reversal invariant only at $\theta=0,\pi$.

- For the particle on a ring, $E_n = (n - \theta/2\pi)^2/2I$, and the ground state becomes degenerate at $\theta = \pi$.
- A spin's Berry phase is S times a solid angle. Staggering it along a Néel chain produces $\theta = 2\pi S$ for the O(3) model, with $g = 2/S$ and $v = 2JSa$.
- Integer S: gapped (Haldane gap $0.41J$ for $S = 1$, AKLT exactly). Half-integer S: gapless, or gapped only by breaking translation.

13.7 Anomalies forbid a trivial gap

The previous sections were about producing gaps. This one is about the opposite: a topological obstruction that makes a gap *impossible*, unless something else happens. The obstruction is an 't Hooft anomaly. Its lattice version is the Lieb–Schultz–Mattis theorem, which is why half-integer spin chains cannot have a Haldane gap. The logic is short enough to state at once.

Key idea: anomaly matching and gaps

If a theory has an 't Hooft anomaly for a symmetry G, then its low-energy limit must reproduce the same anomaly. A *trivially* gapped phase (one vacuum, no topological order, G unbroken) cannot reproduce any anomaly. So the theory must be

1. gapless, or
2. gapped with G spontaneously broken (several vacua, or Goldstone bosons), or
3. gapped with topological order, a nontrivial TQFT in the infrared (Chapter 12) that carries the anomaly.

13.7.1 't Hooft anomalies

Take a theory with a global symmetry G (not gauged). We may always couple the symmetry currents to a *background* gauge field A, a fixed classical field that we are free to choose, and compute the partition function $Z[A]$. It is a generating function: derivatives with respect to A give correlation functions of the currents. If the symmetry were perfect, $Z[A]$ would be invariant under background gauge transformations $A \to A^\lambda$.

Working definition 13.5 ('t Hooft anomaly)

A global symmetry G has an **'t Hooft anomaly** if the partition function in a background gauge field A [a fixed, non-dynamical field coupled to the conserved currents of G, like an external electromagnetic field] transforms under background gauge transformations as $Z[A^\lambda] = e^{i\alpha[\lambda,A]}\, Z[A]$ with a phase α that cannot be removed by adding a local counterterm to the action [an integral of a polynomial in A and its derivatives, which one is always free to add because it does not change the physics at separated points]. The symmetry itself is exact [currents are conserved when $A = 0$, and states still fall into representations of G].

The anomaly is an obstruction to gauging G, not a breaking of G. *To test for one:* compute the variation of $Z[A]$ in the simplest background, for example from the triangle diagram of massless fermions (Chapter 10) or from spectral flow (Example 13.27).

Why the anomaly is the same at all energies. 't Hooft's argument: add to the theory a set of free massless "spectator" fermions, chosen to have exactly the opposite anomaly. The combined theory has no anomaly, so G can be gauged with a tiny coupling that does not disturb the dynamics. A consistent gauge theory must be consistent at every energy scale, so at low energies the original theory's infrared degrees of freedom, plus the spectators (which are free and do not change), must again cancel the anomaly. The infrared of the original theory therefore has exactly the anomaly of the ultraviolet. The anomaly is an invariant of the renormalisation-group flow.

Why a trivially gapped theory has none. This is where the gap enters. If the theory is gapped with a unique vacuum, every connected correlation function of currents decays exponentially (Section 13.2). Expanding $\ln Z[A]$ in powers of A, each coefficient is a connected correlator of currents, and exponentially decaying kernels can be expanded in derivatives. So

$$-\ln Z[A] = W[A] = \int \mathrm{d}^d x \, \left(c_0 + c_1 A^2 + c_2 (\partial A)^2 + \dots \right) + (\text{topological terms}), \tag{13.49}$$

a *local* functional of the background (up to topological terms such as Chern–Simons terms at integer levels, which are gauge invariant). But an anomaly is, by definition, a variation of $\ln Z$ that is *not* the variation of any local functional. If W is local, its variation is trivially the variation of a local functional. Contradiction: a trivially gapped theory has no 't Hooft anomaly. The contrapositive is the key idea above. In a gapless theory $W[A]$ is nonlocal (for example the $1/p^2$ pole of the two-dimensional anomaly, which is the massless boson of bosonisation). With spontaneous breaking, W depends on which vacuum is chosen and on the Goldstone fields. With topological order, the TQFT coupled to A carries the anomaly.

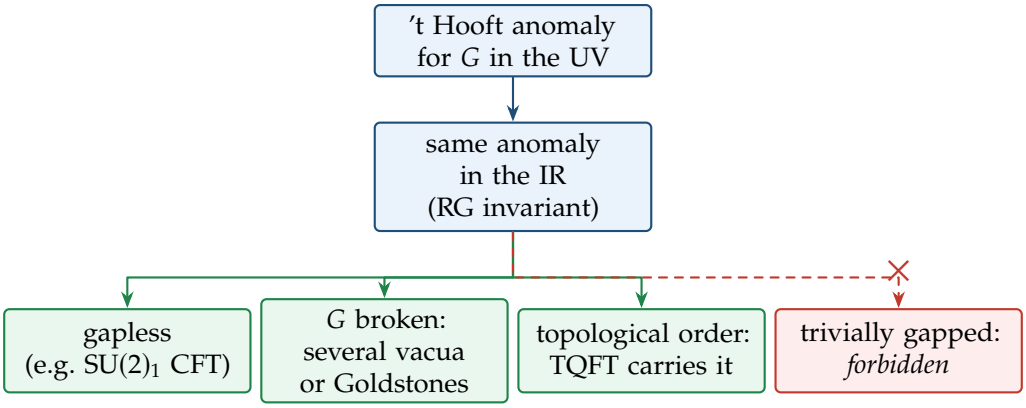

Figure 13.25: The logic of anomaly matching. An anomaly present at short distances is present at long distances. A trivially gapped infrared, whose response to background fields is local, cannot carry it (red). What remains is a gapless theory, a phase with spontaneously broken symmetry, or a topologically ordered phase whose TQFT carries the anomaly (green).

Worked example 13.27: spectral flow: the massless Dirac fermion in two dimensions

A massless Dirac fermion in 1 + 1 dimensions is a right-mover and a left-mover, with $E = +p$ and $E = -p$. It has two U(1) symmetries, the vector charge $Q_V = N_R + N_L$ and the

axial charge $Q_A = N_R - N_L$ ($N_{R,L}$ count particles minus holes). Put it on a ring of length L and thread a flux Φ of the $\mathrm{U}(1)_V$ background field through the ring. With $A_x = \Phi/L$, the covariant momentum is $p - A_x$, and the single-particle levels are

$$E_R(n) = \frac{2\pi}{L}\left(n - \frac{\Phi}{2\pi}\right), \qquad E_L(n) = -\frac{2\pi}{L}\left(n - \frac{\Phi}{2\pi}\right), \qquad n \in \mathbb{Z}.$$

As Φ goes from 0 to 2π, every right-moving level moves down by one spacing and every left-moving level moves up by one spacing (Figure 13.26). One right-moving level crosses $E = 0$ from above to below and becomes filled; one left-moving level crosses from below to above and becomes empty. So

$$\Delta N_R \overset{(1)}{=} +1, \qquad \Delta N_L \overset{(2)}{=} -1, \qquad \Delta Q_A \overset{(3)}{=} \Delta N_R - \Delta N_L = 2, \qquad \Delta Q_V = 0.$$

(1) The Dirac sea of right-movers fills all levels with $E < 0$; one more level has entered it.
(2) One left-moving level has left the sea: a hole.
(3) Definition of Q_A.

The Hamiltonian at $\Phi = 2\pi$ is gauge equivalent to the one at $\Phi = 0$, yet the ground state has become a state with $Q_A = 2$. This is the two-dimensional chiral anomaly, $\partial_\mu j^\mu_A = \frac{1}{\pi}E$ integrated over the process ($\int E\,\mathrm{d}t\,\mathrm{d}x = \Phi = 2\pi$). It is a mixed 't Hooft anomaly between $\mathrm{U}(1)_V$ and $\mathrm{U}(1)_A$. Now suppose the theory could be deformed, keeping both symmetries, into a trivially gapped one with a unique ground state of $Q_A = 0$. Threading the flux slowly would then return the ground state to itself, contradicting $\Delta Q_A = 2$. Indeed, the only mass term, $m\bar\psi\psi$, breaks $\mathrm{U}(1)_A$: to open a gap one must give up a symmetry. The same flux-threading logic, on a lattice, is the Lieb–Schultz–Mattis argument.

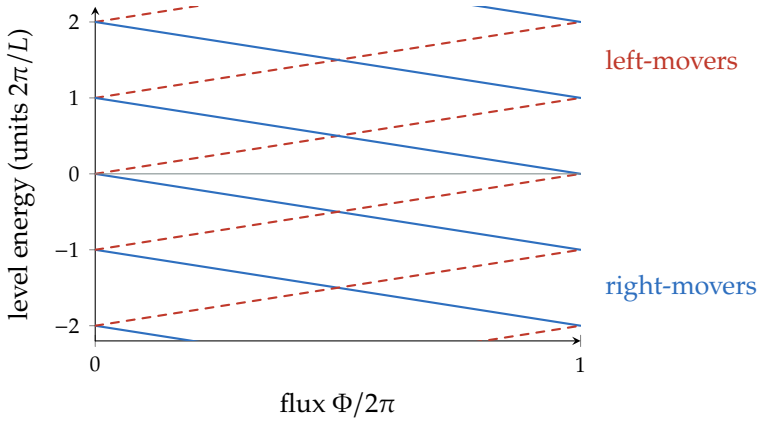

Figure 13.26: Spectral flow of a massless Dirac fermion on a ring as one flux quantum is threaded. Right-moving levels (blue) all slide down by one spacing and left-moving levels (red, dashed) slide up. At the end the spectrum is the same, but one right-mover has sunk into the Dirac sea and one left-mover has left it. The axial charge has changed by two: an anomaly, visible as a level crossing through zero energy.

13.7.2 The Lieb–Schultz–Mattis theorem

Key idea: Lieb–Schultz–Mattis, and Oshikawa's extension

A translation-invariant lattice system with a conserved U(1) charge (for spins, the total S^z), at a filling of ν particles per unit cell, cannot have a unique gapped ground state unless ν is an integer. For $\nu = p/q$ in lowest terms, a gapped phase has at least q degenerate ground states. For spin-S chains at zero magnetisation, $\nu = S$ (count $S + S_j^z$ as the number of bosons at site j), so half-integer spin chains cannot be trivially gapped.

The original argument (one dimension, spin $\frac{1}{2}$). Take the Heisenberg chain (13.43) with $S = \frac{1}{2}$ on a ring of L sites (L even), with ground state $|\Psi_0\rangle$ of energy E_0, total $S^z = 0$ and momentum P_0. Apply a slow twist,

$$U = \exp\Big(\frac{2\pi i}{L}\sum_{j=1}^{L} j\, S_j^z\Big),$$

which rotates spin j about the z axis by the angle $2\pi j/L$. Two facts follow.

(i) The twisted state has low energy. Since $e^{-i\alpha S^z} S^+ e^{i\alpha S^z} = e^{-i\alpha} S^+$, each bond term transforms as $U^\dagger S_j^+ S_{j+1}^- U = e^{2\pi i/L} S_j^+ S_{j+1}^-$ (the angles differ by $2\pi/L$ on every bond, including the bond from L to 1 where they differ by $2\pi/L - 2\pi$). Write $H = J\sum_j \big[\frac{1}{2}(S_j^+ S_{j+1}^- + S_j^- S_{j+1}^+) + S_j^z S_{j+1}^z\big]$ and $c = \langle\Psi_0|S_j^+ S_{j+1}^-|\Psi_0\rangle$, which is real and independent of j by translation and reflection symmetry. Then

$$\begin{aligned}\langle\Psi_0|U^\dagger H U|\Psi_0\rangle - E_0 &\overset{(1)}{=} \frac{J}{2}\sum_{j=1}^{L}\big[(e^{2\pi i/L}-1)+(e^{-2\pi i/L}-1)\big]c \overset{(2)}{=} JLc\Big(\cos\frac{2\pi}{L}-1\Big)\\ &\overset{(3)}{\approx} -\frac{2\pi^2 Jc}{L} = O\Big(\frac{1}{L}\Big).\end{aligned} \tag{13.50}$$

(1) The S^zS^z terms commute with U and cancel. The two hopping terms pick up $e^{\pm 2\pi i/L}$, and both have expectation value c.
(2) L equal terms, and $e^{ix} + e^{-ix} - 2 = 2(\cos x - 1)$.
(3) $\cos x - 1 \approx -x^2/2$ with $x = 2\pi/L$.

(ii) The twisted state is orthogonal to the ground state. Let T translate by one site, $T S_j^z T^{-1} = S_{j+1}^z$. Then

$$\begin{aligned}TUT^{-1} &\overset{(1)}{=} \exp\Big(\frac{2\pi i}{L}\sum_{j=1}^{L} j\, S_{j+1}^z\Big) \overset{(2)}{=} \exp\Big(\frac{2\pi i}{L}\sum_{k=1}^{L}(k-1)S_k^z + 2\pi i S_1^z\Big)\\ &\overset{(3)}{=} U\, e^{-\frac{2\pi i}{L}S_{\text{tot}}^z}\, e^{2\pi i S_1^z} \overset{(4)}{=} -U.\end{aligned} \tag{13.51}$$

(1) Conjugate each S_j^z.
(2) Relabel $k = j + 1$. The last term, $j = L$, is $L\, S_{L+1}^z = L\, S_1^z$ on the ring. The $k = 1$ term of $\sum_k (k-1)S_k^z$ is zero, so the sum equals $\sum_{k=1}^{L}(k-1)S_k^z + L\, S_1^z$, and $\frac{2\pi i}{L}\cdot L = 2\pi i$.
(3) The operators commute, so the exponential splits.
(4) $S_{\text{tot}}^z = 0$, and $e^{2\pi i S_1^z} = e^{\pm i\pi} = -1$ for spin $\frac{1}{2}$.

So $TU|\Psi_0\rangle = -UT|\Psi_0\rangle = e^{i(P_0+\pi)}U|\Psi_0\rangle$: the twisted state has momentum $P_0 + \pi$, and is therefore orthogonal to $|\Psi_0\rangle$.

Together, (i) and (ii) give a state orthogonal to the ground state with energy at most $O(1/L)$ above it. As $L \to \infty$, either there is a second ground state (degeneracy, as in the dimerised phase) or there are excitations of arbitrarily low energy (gaplessness). A unique gapped ground state is impossible. For integer spin, step (4) gives $e^{2\pi i S_1^z} = +1$: no momentum shift, and no conclusion. That is exactly the room the Haldane gap needs.

Oshikawa's flux-threading argument. In higher dimensions the energy estimate (i) fails (the twist costs energy proportional to the cross-section of the system). Oshikawa replaced it by a topological argument borrowed from Laughlin's explanation of the quantum Hall effect. Give the conserved particles a fictitious charge, make the system a ring in the x direction (length L, cross-section of C unit cells), and thread a flux Φ through the ring (Figure 13.27).

1. Increase Φ adiabatically from 0 to 2π. The Hamiltonian stays translation invariant throughout, so the momentum P_x of the evolving state is conserved.
2. At $\Phi = 2\pi$ the Hamiltonian is gauge equivalent to the original one: $H(2\pi) = UH(0)U^{-1}$ with $U = \exp\left(\frac{2\pi i}{L}\sum_{\vec{r}} x_{\vec{r}} n_{\vec{r}}\right)$, the large gauge transformation (the analogue of the twist above).
3. By the same computation as (13.51), undoing the gauge transformation shifts the momentum by $2\pi\nu C$.
4. If the system is gapped, adiabatic evolution takes a ground state to a ground state. If $\nu C \notin \mathbb{Z}$, the final ground state has a different momentum from the initial one, so it is a different ground state.

Repeating, for $\nu = p/q$ with C coprime to q, there are at least q degenerate ground states. Hastings (2004) made the argument rigorous in any dimension.

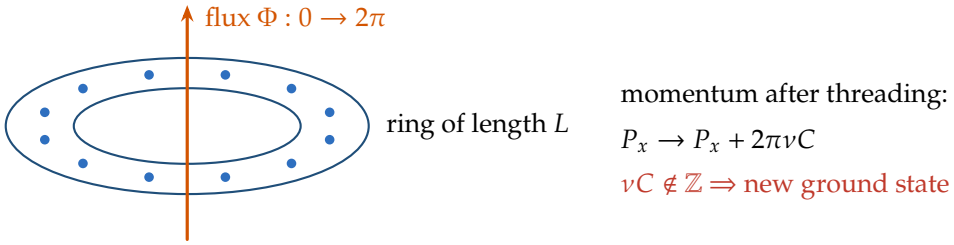

Figure 13.27: Oshikawa's argument. The lattice system (dots) is a ring threaded by a fictitious flux. Adding one flux quantum slowly returns the Hamiltonian to itself up to a gauge transformation, but shifts the crystal momentum of the state by $2\pi\nu C$. At fractional filling the state that comes back is orthogonal to the one that went in, so a gapped system must have several ground states.

Physical picture: LSM is an anomaly

In field-theory language, LSM says that lattice translation and the U(1) (or SO(3)) spin rotations have a mixed 't Hooft anomaly whenever there is a half-integer spin per unit cell. All three escape routes of Figure 13.25 are realised. The spin-$\frac{1}{2}$ Heisenberg chain is gapless (the $SU(2)_1$ CFT, which carries the anomaly). The J_1–J_2 chain dimerises (broken translation). In two dimensions a spin liquid with $\mathbb{Z}_2$ topological order can be gapped and symmetric: its TQFT carries the anomaly, through anyons that carry spin $\frac{1}{2}$ (Section 13.8.2). Oshikawa pointed out that such a state must have a topological ground-state degeneracy on the torus, consistent with the argument above.

Worked example 13.28: Yang–Mills at $\theta = \pi$

Four-dimensional SU(N) Yang–Mills theory has a θ-term $\frac{\theta}{8\pi^2}\int \operatorname{tr} F \wedge F$ (Definition 13.4), and is time-reversal invariant at $\theta = 0$ and $\theta = \pi$. It also has a "one-form" symmetry, the centre $\mathbb{Z}_N$ of SU(N), which acts on Wilson loops rather than on local operators. Gaiotto, Kapustin, Komargodski and Seiberg (2017) showed that at $\theta = \pi$ there is a mixed 't Hooft anomaly between time reversal and the $\mathbb{Z}_N$ centre symmetry. In their words, "at $\theta = \pi$ the vacuum cannot be a trivial non-degenerate gapped state", while at $\theta = 0$ it is believed to be. If the theory is gapped and confining at $\theta = \pi$ (as expected at large N), then time reversal must be spontaneously broken there, with two degenerate vacua and a domain wall between them that carries a Chern–Simons theory. The two-dimensional analogue is the $\mathbb{CP}^{N-1}$ model at $\theta = \pi$: for $N = 2$ it is gapless (Haldane's case), and for $N > 2$ time reversal is broken. So even for the theory of the Clay problem, anomalies tell us something rigorous about where the gap *can* be trivial and where it cannot.

Watch out: what anomalies do not tell you

Anomaly matching is a constraint, not a solution. It says that a trivially gapped phase is impossible, and it lists the alternatives, but it does not say which one is realised. Nor does the *absence* of an anomaly imply a gap: the three-dimensional O(N) model at weak coupling (Section 13.3.6) has no anomaly and is gapless because of spontaneous symmetry breaking.

Recap

- An 't Hooft anomaly is an obstruction to coupling a global symmetry to background gauge fields. It is invariant under the RG.
- A trivially gapped theory has a local response $W[A]$, hence no anomaly. So an anomalous theory is gapless, breaks the symmetry, or is topologically ordered.
- Spectral flow of a Dirac fermion under flux threading exhibits the two-dimensional anomaly: $\Delta Q_A = 2$.
- LSM: a twist U gives a state of energy $O(1/L)$ and momentum shifted by π for half-integer spin. Oshikawa's flux threading extends this to all dimensions: fractional filling forbids a unique gapped ground state.
- SU(N) Yang–Mills at $\theta = \pi$ cannot be trivially gapped.

13.8 Supersymmetry, the Witten index, and gapped phases as TQFTs

Two more ideas complete the picture. The Witten index is a topological count of vacua that cannot change under deformations: it detects, without solving the theory, whether zero-energy vacua exist. And every gapped phase, looked at below its gap, is a topological quantum field theory. Together they explain why the language of Nash's book (Morse theory, TQFT) is the natural language for gapped quantum systems.

13.8.1 Supersymmetric quantum mechanics and the Witten index

Take a particle on a line with a two-state internal space ("fermion number" 0 or 1) and a real function $W(x)$, the **superpotential**. Define

$$Q = \sigma^{-}(p + iW'), \qquad Q^{\dagger} = \sigma^{+}(p - iW'), \qquad \sigma^{+} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \ \sigma^{-} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix},$$

with $p = -i\,\mathrm{d}/\mathrm{d}x$. Then $Q^2 = 0$ (since $(\sigma^{-})^2 = 0$), and

$$\begin{aligned} H \coloneqq \tfrac{1}{2}\{Q, Q^{\dagger}\} &\overset{(1)}{=} \tfrac{1}{2}\big[\sigma^{-}\sigma^{+}(p + iW')(p - iW') + \sigma^{+}\sigma^{-}(p - iW')(p + iW')\big] \\ &\overset{(2)}{=} \tfrac{1}{2}\big(p^2 + W'^2 + W''\,\sigma^3\big). \end{aligned} \tag{13.52}$$

(1) Expand the anticommutator, $QQ^{\dagger} + Q^{\dagger}Q$.

(2) $(p \pm iW')(p \mp iW') = p^2 + W'^2 \mp i[p, W']$ and $[p, W'] = -iW''$, so the products are $p^2 + W'^2 \mp W''$. Also $\sigma^{-}\sigma^{+} = \mathrm{diag}(0, 1)$ and $\sigma^{+}\sigma^{-} = \mathrm{diag}(1, 0)$, which combine into $W''\sigma^3$.

Let $(-1)^F = -\sigma^3$ (the lower component is "bosonic"). It anticommutes with Q and $Q^{\dagger}$.

Worked example 13.29: nonzero energies come in boson–fermion pairs

Let $Q_1 = Q + Q^{\dagger}$. It is Hermitian, anticommutes with $(-1)^F$, and $Q_1^2 = QQ^{\dagger} + Q^{\dagger}Q = 2H$ (using $Q^2 = 0$). Let $|b\rangle$ be bosonic with $H|b\rangle = E|b\rangle$, $E > 0$, and set $|f\rangle = Q_1|b\rangle/\sqrt{2E}$. Then

$$\langle f|f\rangle \overset{(1)}{=} \frac{\langle b|Q_1^2|b\rangle}{2E} = 1, \qquad (-1)^F|f\rangle \overset{(2)}{=} -|f\rangle, \qquad H|f\rangle \overset{(3)}{=} E|f\rangle.$$

(1) Q_1 is Hermitian and $Q_1^2 = 2H$.

(2) $(-1)^F Q_1 = -Q_1(-1)^F$.

(3) $[H, Q_1] = \tfrac{1}{2}[Q_1^2, Q_1] = 0$.

So every positive energy is shared by as many bosons as fermions. Only the zero-energy states can be unpaired. Hence the **Witten index**

$$I = \mathrm{Tr}\,(-1)^F e^{-\beta H} = n_B(E = 0) - n_F(E = 0) \tag{13.53}$$

does not depend on β, and it cannot change under any deformation that keeps the large-x behaviour of W (states can only enter or leave $E = 0$ in boson–fermion pairs). If $I \neq 0$, there are exact zero-energy vacua and supersymmetry is unbroken.

Worked example 13.30: counting vacua with Morse theory

Zero-energy states solve $Q\psi = Q^{\dagger}\psi = 0$. For the upper component, $(p + iW')\psi_{\uparrow} = 0$ gives $\psi_{\uparrow} = e^{W}$. For the lower one, $(p - iW')\psi_{\downarrow} = 0$ gives $\psi_{\downarrow} = e^{-W}$. Only normalisable solutions count.

- $W = \frac{1}{4}x^4 - \frac{1}{2}a^2x^2$: e^{-W} is normalisable, e^{W} is not. Exactly one bosonic vacuum, $I = 1$.
- $W = \frac{1}{3}x^3 - a^2x$: neither e^{W} nor e^{-W} is normalisable (the cubic grows with opposite signs at $\pm\infty$). No vacuum, $I = 0$: supersymmetry is broken.

Now compare with a semiclassical count. Near each critical point x_c of W ($W'(x_c) = 0$), $H \approx \frac{1}{2}[p^2 + W''(x_c)^2(x - x_c)^2] + \frac{1}{2}W''(x_c)\sigma^3$: a harmonic oscillator of frequency $|W''(x_c)|$ with zero-point energy $\frac{1}{2}|W''|$, cancelled by $\frac{1}{2}W''\sigma^3$ in the component with $\sigma^3 = -\operatorname{sgn} W''$. So each critical point gives one perturbative vacuum, bosonic if $W'' > 0$ and fermionic if $W'' < 0$, and

$$I = \sum_{x_c} \operatorname{sgn} W''(x_c).$$

For the quartic, the critical points are 0 ($W'' = -a^2$) and $\pm a$ ($W'' = 2a^2$): $I = -1 + 1 + 1 = 1$. For the cubic, $\pm a$ with $W'' = \pm 2a$: $I = 1 - 1 = 0$. The semiclassical count gives the exact index, although in the cubic case the two perturbative vacua are lifted by instantons tunnelling between $\pm a$, to an energy of order $e^{-2[W(-a)-W(a)]}$. This is Witten's proof of the Morse inequalities in miniature (Chapter 7): on a manifold, $Q = \mathrm{d} + \mathrm{d}^*$ deformed by a Morse function, and the index is the Euler characteristic.

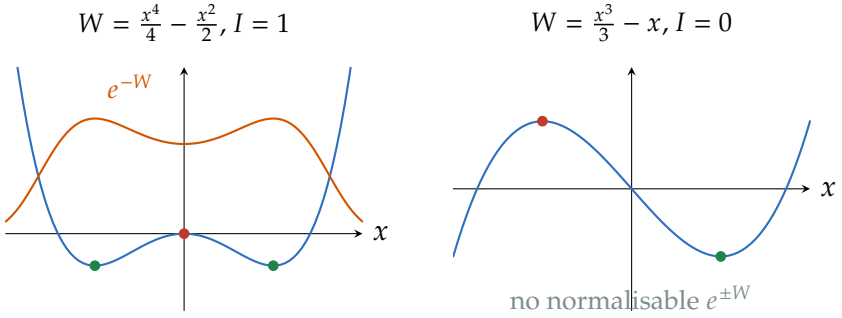

Figure 13.28: Supersymmetric quantum mechanics and Morse theory. The superpotential W is blue. Its minima (green) give bosonic perturbative vacua and its maxima (red) fermionic ones. Left: the signed count is 1, and the exact vacuum e^{-W} (orange) exists. Right: the count is 0, no exact vacuum exists, and the two perturbative vacua are lifted by tunnelling: supersymmetry is broken.

The index and the gap. In a supersymmetric field theory the Witten index, computed in a finite spatial box (where the spectrum is discrete), counts vacua. The four-dimensional $\mathcal{N} = 1$ supersymmetric SU(N) Yang–Mills theory has $\operatorname{Tr}(-1)^F = N$. This matches the expected physics: the theory confines, is gapped, and has N vacua, which spontaneously break a discrete $\mathbb{Z}_{2N}$ chiral symmetry to $\mathbb{Z}_2$ through a gaugino condensate. A nonzero index guarantees exact vacua. It does not by itself guarantee a gap. And if supersymmetry is spontaneously broken in a field theory, Goldstone's theorem gives a massless fermion (the goldstino) and the gap closes.

Reading Nash (Ch. VII, §4, p. 207, (7.60)–(7.69))

Nash introduces supersymmetry generators Q_1, Q_2 with $Q_1^2 = H + P$, $Q_2^2 = H - P$ (7.61), the operator $(-1)^F$ (7.63), and the realisation $Q_1 = \mathrm{d} + \mathrm{d}^*$, $Q_2 = i(\mathrm{d} - \mathrm{d}^*)$ on differential forms (7.68), with even forms bosonic and odd forms fermionic. Then $\operatorname{Tr}(-1)^F$ counts harmonic forms with signs, which is the Euler characteristic. Our one-dimensional example is the case $M = \mathbb{R}$ with a Morse function W, where the "forms" are the two components of ψ.

13.8.2 Gapped phases are topological field theories

Suppose a theory has a gap Δ. Probe it at energies far below Δ (or distances far beyond ξ). Only the vacua are left, and on the vacua the Hamiltonian is a constant, which we set to zero. What remains is: for every spatial manifold Σ, a finite-dimensional space $\mathcal{H}(\Sigma)$ of vacua, and for every spacetime, an amplitude that depends only on its topology (after removing non-universal local terms such as the vacuum energy density times the volume). These are the data of a **topological quantum field theory** in the sense of Atiyah (Chapter 12).

Key idea: the infrared of a gapped phase

The long-distance limit of a gapped phase is a TQFT. The long-distance limit of a gapless phase is a scale-invariant theory (a CFT, or free massless particles). Classifying gapped phases of matter is therefore largely classifying TQFTs, possibly with symmetry.

gapped phase	$\dim \mathcal{H}(\Sigma)$, genus g	example
trivially gapped	1	free massive field
broken $\mathbb{Z}_2$	2 (any Σ)	ordered Ising chain, Gross–Neveu
$\mathbb{Z}_2$ topological order	4^g	toric code, $\mathbb{Z}_2$ spin liquid
$\mathrm{U}(1)_k$ Chern–Simons	$\lvert k\rvert^g$	Maxwell–Chern–Simons, quantum Hall
SPT (e.g. Haldane phase)	1, but edge modes	AKLT chain

Worked example 13.31: the toric code: a gap and a topological degeneracy

Put a spin $\frac{1}{2}$ on every edge of a square lattice drawn on a closed surface Σ. For each vertex v let $A_v = \prod \sigma^x$ over the four edges touching v, and for each face p let $B_p = \prod \sigma^z$ over its four edges. Take

$$H = -\sum_v A_v - \sum_p B_p .$$

Every A_v commutes with every B_p: they share either no edge or exactly two, and $\sigma^x\sigma^z = -\sigma^z\sigma^x$ on each shared edge, so the two signs cancel. All terms can be diagonalised together, with eigenvalues ± 1. A ground state has all $A_v = B_p = +1$. An excitation flips at least one sign, and since the operators that create excitations (σ^z or σ^x on an edge) flip them in pairs, it costs at least 4: an exact gap. Now count the ground states. There are 2^E states for E edges. Each independent constraint $A_v = 1$ or $B_p = 1$ halves the count. The constraints are not all independent: $\prod_v A_v = 1$ and $\prod_p B_p = 1$ identically (each edge appears twice). With V vertices and F faces,

$$\dim \mathcal{H}_0 \overset{(1)}{=} 2^{E-(V-1)-(F-1)} \overset{(2)}{=} 2^{2-\chi(\Sigma)} \overset{(3)}{=} 2^{2g} = 4^g .$$

(1) $V-1$ independent vertex constraints and $F-1$ independent face constraints.
(2) Euler's formula $V - E + F = \chi(\Sigma)$ (Chapter 1).
(3) $\chi = 2 - 2g$ for a surface of genus g.

One ground state on the sphere, four on the torus. The four torus ground states are distinguished by the eigenvalues of $\prod \sigma^z$ along the two noncontractible loops, the elements of $H^1(T^2;\mathbb{Z}_2) = \mathbb{Z}_2^2$ (Figure 13.29). No local operator can tell them apart, which is why in a perturbed model their splitting is only of order $e^{-L/\xi}$.

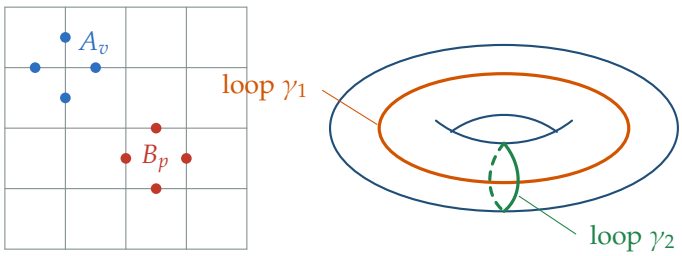

Figure 13.29: The toric code. Left: spins live on edges. The vertex term A_v (blue) acts with σ^x on the four edges at a vertex, and the face term B_p (red) with σ^z on the four edges of a face. Right: on a torus the ground states are labelled by the values of σ^z-strings around the two noncontractible loops. They are four vacua that no local measurement distinguishes: topological order, and a TQFT in the infrared.

Recap

- In supersymmetric theories, nonzero energies pair up, and the Witten index $\mathrm{Tr}(-1)^F = n_B - n_F$ at zero energy is a deformation invariant, computable semiclassically as a Morse count $\sum \operatorname{sgn} W''(x_c)$.
- A nonzero index guarantees exact vacua. Spontaneous supersymmetry breaking in field theory produces a massless goldstino.
- Below its gap, every gapped phase is a TQFT: finite vacuum spaces $\mathcal{H}(\Sigma)$ that depend only on topology. The toric code has $\dim \mathcal{H} = 4^g$, from Euler's formula.

13.9 The Yang–Mills mass gap problem

We can now state the most famous open problem about gaps, and see which parts of this chapter bear on it. Pure Yang–Mills theory in four dimensions is the theory of gluons without quarks. Classically it describes massless waves, like Maxwell theory. Quantum mechanically it is believed to have a mass gap, to confine, and to have as its lightest particles colourless bound states of gluons, the **glueballs**. Nobody has proved any of this. In 2000 the Clay Mathematics Institute made it one of its seven Millennium Prize Problems, with the problem description written by Jaffe and Witten.

13.9.1 The statement

Key idea: Yang–Mills existence and mass gap (Jaffe and Witten)

Prove that for any compact simple gauge group G, a non-trivial quantum Yang–Mills theory exists on $\mathbb{R}^4$ and has a mass gap $\Delta > 0$. Existence includes establishing axiomatic properties at least as strong as those cited in [the Wightman axioms and the Osterwalder–Schrader axioms].

Every phrase carries weight. We unpack them in turn.

"Compact simple gauge group G". For example $\mathrm{SU}(N)$ with $N \geq 2$, $\mathrm{SO}(N)$, $\mathrm{Sp}(N)$, or an exceptional group. The Lie algebra has no abelian factor, so U(1) (Maxwell theory, which is free

and gapless) is excluded. The classical theory is the Yang–Mills action $\frac{1}{4g^2}\int \operatorname{Tr} F \wedge \star F$ with $F = \mathrm{d}A + A \wedge A$ (Chapter T3).

"Exists". The theory must be a quantum field theory in the precise sense of the axioms. In Minkowski form (Wightman), there is a Hilbert space carrying a unitary representation of the Poincaré group, the energy is non-negative, there is a unique Poincaré-invariant vacuum Ω, and there are local field operators that commute at spacelike separation. Jaffe and Witten specify which fields: local operators "in correspondence with the gauge-invariant local polynomials in the curvature F and its covariant derivatives, such as $\operatorname{Tr} F_{ij}F_{kl}(x)$". Their correlation functions must agree at short distances with asymptotic freedom and perturbative renormalisation theory, including the existence of a stress tensor and an operator product expansion.

Working definition 13.6 (Euclidean QFT in the sense of Osterwalder and Schrader)

A **Euclidean quantum field theory** is a collection of correlation functions $S_n(x_1, \dots, x_n)$ of local fields on $\mathbb{R}^d$ [the Euclidean path-integral averages $\langle \phi(x_1) \cdots \phi(x_n) \rangle$, for example of $\operatorname{Tr} F^2$] that are invariant under Euclidean motions, symmetric (or antisymmetric for fermions), clustering [they factorise when two groups of points are pulled far apart, as in (13.7)], and **reflection positive** [reflecting in the plane $\tau = 0$ and complex conjugating gives a non-negative inner product, which is what later becomes the positivity of probabilities in the Hilbert space]. *Why it matters:* the Osterwalder–Schrader reconstruction theorem turns such correlation functions into a Wightman theory, with Hilbert space, Hamiltonian and vacuum. The spectral sum of Section 13.2.1 is exactly this reconstruction, read backwards.

"Non-trivial". Not a free theory. (A free theory of massless fields would exist, but would not be Yang–Mills theory.)

"Has a mass gap $\Delta > 0$". With $H\Omega = 0$, the Hamiltonian has no spectrum in the interval $(0, \Delta)$ (Definition 13.1). Jaffe and Witten note the consequence we derived in Section 13.2: exponential clustering, $|\langle \Omega, \mathcal{O}(\vec{x})\mathcal{O}(\vec{y})\Omega \rangle| \le e^{-C|\vec{x}-\vec{y}|}$ for $C < \Delta$. They also exclude one shortcut: "weak existence (compactness)" of a limit of approximations does not count, unless the properties of the limit (the gap and the axioms) are also established.

Watch out: two problems, not one

The problem has two halves, and both are open. *Existence*: no interacting quantum field theory in four dimensions has ever been constructed to satisfy the axioms. *Mass gap*: even granted existence, the gap must be proved. The gap is also not the same as confinement. A Higgs phase is gapped and not confining (Section 13.3.2). Proving confinement (an area law for Wilson loops) is listed by Jaffe and Witten as a natural *extension* of the problem, not as part of it.

13.9.2 Why it is hard

The gap is invisible classically and perturbatively. Classical Yang–Mills waves are massless. Perturbation theory in g describes massless gluons to every order. The expected gap is $\Delta = c\,\Lambda = c\,\mu\, e^{-1/(\beta_0 g^2(\mu))}$ with $\beta_0 = \frac{11N}{24\pi^2}$ for SU(N) (Section 13.3.3), and this function has a vanishing Taylor series at $g = 0$ (Example 13.15). Jaffe and Witten: "because four-dimensional gauge theory is a theory in which the mass gap is not classically visible, to demonstrate it

may require a non-classical change of variables or duality transformation". Polyakov's model (Section 13.4) is the example where such a change of variables works.

The continuum limit is at weak coupling. On a lattice with spacing a the theory is a well-defined finite-dimensional integral in finite volume. But the continuum limit $a \to 0$ at fixed physical Δ requires $\Delta a \to 0$, that is $\xi \to \infty$ in lattice units, which by (13.20) means $g(1/a) \to 0$ in a precise way.

Worked example 13.32: how the lattice coupling must be tuned

With $\mu = 1/a$ in (13.18), $1/g^2(1/a) = \beta_0 \ln \frac{1}{a\Lambda}$. Halving the lattice spacing changes the coupling by

$$\frac{1}{g^2(2/a)} - \frac{1}{g^2(1/a)} \overset{(1)}{=} \beta_0 \ln 2 \overset{(2)}{=} \frac{33}{24\pi^2} \times 0.693 = 0.097.$$

(1) Difference of (13.18) at $\mu = 2/a$ and $\mu = 1/a$.
(2) $\beta_0 = 11N/24\pi^2$ with $N = 3$.

Lattice practitioners use $\beta_{\text{lat}} = 6/g^2$ for SU(3), so halving a means raising β_{lat} by about 0.58 at one loop. (Simulations near $\beta_{\text{lat}} \approx 6$ find roughly this rate, with corrections from higher loops.) The dimensionless gap Δa must fall by a factor of two at each step, forever, while the physical Δ stays put. A proof must control an infinite sequence of such steps uniformly: this is an RG problem of exactly the type of Chapter T5, in the hardest possible regime.

The volume must go to infinity. Jaffe and Witten stress that even a complete construction on a four-torus would leave open "the existence of a mass gap that is uniform in the volume", and that "no present ideas point the direction" to it. Finite-volume gaps always exist (Section 13.1.5); the whole content is their persistence as $L \to \infty$.

Four dimensions is the borderline. Scalar ϕ^4 theory, the simplest interacting candidate, exists with a mass gap in two and three dimensions but is *trivial* (becomes free in the continuum limit) in five or more dimensions, and, as proved by Aizenman and Duminil-Copin in 2021 for the lattice regularisation, also in four. Asymptotic freedom is what makes Yang–Mills theory the natural candidate for a non-trivial four-dimensional theory. It is also what puts the interesting physics at strong coupling.

13.9.3 What is known and what is not

Numerical evidence. Monte Carlo simulations of lattice Yang–Mills theory, extrapolated to $a \to 0$ and $L \to \infty$, find a gapped spectrum of glueballs and an area law for Wilson loops. For SU(3) the lightest glueball has $J^{PC} = 0^{++}$ and mass about 3.5 times the square root of the string tension, that is about 1.5–1.7 GeV depending on how physical units are assigned. Heavier states include a 2^{++} near 2.4 GeV and a 0^{-+} near 2.6 GeV (Figure 13.30). The ratios approach finite limits as $N \to \infty$. These results are extremely convincing physically. They are not proofs, because they are finite-volume, finite-spacing numerics with statistical errors.

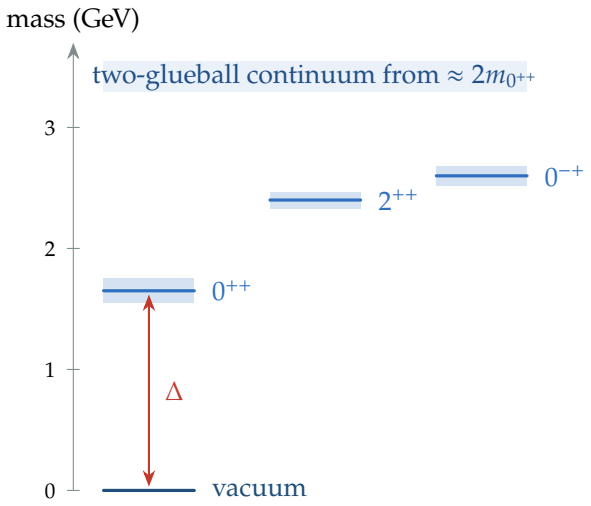

Figure 13.30: Schematic spectrum of pure SU(3) Yang–Mills theory from lattice simulations, at zero momentum. Bands indicate the rough spread between determinations. The lightest state, the scalar 0^{++} glueball, sets the gap. Compare the free massive field in Figure 13.2(a): the shape is the same, but here nothing in the Lagrangian carries a mass.

Worked example 13.33: what a 1.7 GeV gap means for correlations

If the lightest glueball has $m_{0^{++}}c^2 \approx 1.7\,\text{GeV}$, then by Section 13.2.6 the correlation length of pure Yang–Mills theory is

$$\xi \overset{(1)}{=} \frac{\hbar c}{m_{0^{++}}c^2} \overset{(2)}{=} \frac{197.3\ \text{MeV fm}}{1700\ \text{MeV}} \approx 0.12\ \text{fm}.$$

(1) $\xi = 1/\Delta$ with $\hbar$ and c restored.
(2) $\hbar c = 197.3\,\text{MeV fm}$.

So the connected correlator of $\operatorname{Tr} F^2$ at two points 1 fm apart is suppressed by roughly $e^{-1/0.12} = e^{-8.6} \approx 2 \times 10^{-4}$ relative to its value at the scale ξ, while in a gapless theory it would fall only as a power of the distance. A lattice with spacing a must resolve ξ, so $a \ll 0.12\,\text{fm}$, and must contain many correlation lengths, so $L \gg 0.12\,\text{fm}$: modern simulations use $a \approx 0.05$–$0.1\,\text{fm}$ and $L \approx 2$–$4\,\text{fm}$. Proving the Clay statement amounts to proving that this exponential suppression survives $a \to 0$ and $L \to \infty$.

	scalar ϕ^4	abelian gauge	Yang–Mills
$d = 2$	exists, gapped	Higgs: exists, gapped	solvable
$d = 3$	exists, gapped	compact U(1) lattice: gapped, confining	partial (lattice, probabilistic)
$d = 4$	trivial (lattice)	free photon (gapless)	**open**: existence and mass gap

Figure 13.31: A map of what is established, by spacetime dimension (rows) and type of theory (columns). Green cells are constructed with the stated properties, the red cell is proved trivial, yellow cells are partial. The Clay problem is the framed cell: four-dimensional Yang–Mills theory, the only asymptotically free candidate for a non-trivial four-dimensional quantum field theory.

Rigorous results. Here is what has been proved, as surveyed by Jaffe and Witten and in the mathematical literature since.

- *Lattice gauge theory at strong coupling.* For any compact gauge group, the Wilson lattice theory at large g has a mass gap and an area law (Osterwalder and Seiler, 1978). But the continuum limit lives at $g \to 0$, not at large g.
- *Lower dimensions and simpler theories.* ϕ^4 in two and three dimensions (Glimm, Jaffe and others) has a mass gap. The two-dimensional abelian Higgs model was constructed and shown to satisfy the Osterwalder–Schrader axioms (Brydges, Fröhlich and Seiler), with a mass gap proved on the lattice (Balaban, Brydges, Imbrie and Jaffe). Three-dimensional compact U(1) lattice gauge theory confines with a gap (Göpfert and Mack).
- *Balaban's programme.* A renormalisation-group analysis of lattice Yang–Mills theory on three- and four-dimensional tori, establishing ultraviolet stability uniformly in the lattice spacing. It is "an important step toward establishing the existence of the continuum limit on a compactified space-time", but it does not reach gauge invariant correlation functions, infinite volume, or the gap.
- *Two dimensions.* Two-dimensional Yang–Mills theory is exactly solvable, and recent probabilistic work has constructed Yang–Mills measures in two dimensions and made progress in three. The four-dimensional case remains out of reach.

Physics arguments. Each gives strong evidence for a gap, in a setting that differs from pure four-dimensional Yang–Mills theory in one controlled way.

- $2+1$ *dimensions:* Polyakov's compact QED (Section 13.4) and, for non-abelian theories with an adjoint Higgs field, the same monopole mechanism.
- *Two-dimensional analogues:* the $\mathbb{CP}^{N-1}$ model is asymptotically free, classically massless and provably gapped at large N (Section 13.3.4).
- *Supersymmetry:* in $\mathcal{N} = 2$ theories softly broken to $\mathcal{N} = 1$ (Seiberg and Witten), monopole condensation gives a gap and confinement exactly, the dual superconductor of Section 13.4.5; $\mathcal{N} = 1$ super Yang–Mills has N gapped vacua (Section 13.8.1).
- *Large N and holography:* gauge theories dual to gravity in higher dimensions have gapped glueball spectra computable from wave equations in the dual geometry.
- *Anomalies:* at $\theta = \pi$ the theory cannot be trivially gapped (Example 13.28), which constrains how the gap at $\theta = 0$ can evolve with θ.

statement	status	source of confidence
4D YM exists as an axiomatic QFT	open	asymptotic freedom, Balaban
4D YM has a mass gap	open	lattice numerics, analogues
4D YM confines (area law)	open	lattice numerics
lattice YM gapped at strong coupling	proved	cluster expansion
ϕ^4_2, ϕ^4_3 exist with a gap	proved	constructive QFT
compact $\mathrm{U}(1)_3$ (lattice) gapped, confining	proved	Göpfert–Mack
$\mathbb{CP}^{N-1}_2$ gapped at $N = \infty$	derived	saddle point, exact at $N = \infty$
$\mathrm{SU}(N)$ YM at $\theta = \pi$ not trivially gapped	derived	't Hooft anomaly

Physical picture: what the gap would buy

Jaffe and Witten note that clustering "may make it possible to apply mathematical results established on $\mathbb{R}^4$ to any 4-manifold". The reason is locality: in a gapped theory, what happens in one region is independent of what happens a few correlation lengths away, so a theory on a curved four-manifold can be pieced together from flat patches, with only topological information surviving at long distances. Witten's derivation of the Seiberg–Witten invariants from the topologically twisted $\mathcal{N} = 2$ theory (the setting of Donaldson theory in Chapter 12) used exactly this kind of argument, for the supersymmetric extension where the infrared is under control. A gapped theory is one whose long-distance limit is a TQFT (Section 13.8.2): the mass gap is the bridge between quantum field theory and the topology of Nash's book.

Key idea: the chapter in one paragraph

A mass gap is the absence of low-energy excitations of any kind, and it is equivalent to exponential clustering with $\xi = 1/\Delta = \hbar/mc$. Gaps are opened by explicit masses, by the Higgs mechanism and by dimensional transmutation, and, more subtly, by topology: monopole-instantons screen a photon, a Chern–Simons term gives it a mass, and a θ-term decides whether a spin chain is gapped. Topology can also forbid a trivial gap, through 't Hooft anomalies and the Lieb–Schultz–Mattis theorem. Whatever produces it, a gap leaves a TQFT at long distances. For four-dimensional Yang–Mills theory, none of these mechanisms has yet been turned into a proof.

Recap

- The Clay problem: construct 4D Yang–Mills theory for compact simple G satisfying the Wightman or Osterwalder–Schrader axioms, and prove $\operatorname{spec} H \cap (0, \Delta) = \varnothing$ for some $\Delta > 0$.
- The gap is invisible classically and to all orders of perturbation theory, the continuum limit sits at weak coupling, and the gap must be uniform in the volume.
- Lattice numerics give a 0^{++} glueball near 1.5–1.7 GeV. Rigorous results exist only at strong lattice coupling, in lower dimensions or for simpler theories.

correlation length	$\xi = 1/\Delta$, finite off criticality, ∞ at RG fixed points	Section 13.2.5, Chapter T5
Compton wavelength	$\hbar/mc$: range of force, onset of pair creation	Section 13.2.6
Higgs mechanism	$m_A = ev$, $m_h = \sqrt{2\lambda}v$, Meissner screening	Section 13.3.2
dimensional transmutation	$m = c\mu e^{-1/(\beta_0 g^2)}$, zero Taylor series	Section 13.3.3
gap equation	$1/g^2 = \int \frac{\mathrm{d}^d p}{(2\pi)^d}\frac{1}{p^2+m^2}$ ($\mathbb{CP}^{N-1}$, O(N)), GN analogue	Sections 13.3.4 to 13.3.6
dual photon, monopole-instanton	$\frac{e^2}{8\pi^2}(\partial\sigma)^2$, $e^{\pm i\sigma}$ insertions, $\pi_2(S^2)$	Section 13.4, Chapter 8
Polyakov mass, string tension	$m_\gamma^2 = 8\pi^2 K e^{-S_0}/e^2$, $T = 2e^2 m_\gamma/\pi^2$	Sections 13.4.3 and 13.4.4
topological mass	$m = \lvert k\rvert e^2/2\pi$ from $\frac{k}{4\pi}A\,\mathrm{d}A$, one state of spin sgn k	Definition 13.3, Chapter 12
θ-term	$-i\theta Q$, periodic, T-invariant only at $0, \pi$	Definition 13.4
Haldane gap	spin chain = O(3) model with $\theta = 2\pi S$, $g = 2/S$	Section 13.6
't Hooft anomaly	obstruction to gauging; forbids a trivial gap	Definition 13.5, Chapter 10
Lieb–Schultz–Mattis	fractional filling: gapless, degenerate, or topological	Section 13.7.2
Witten index	$\mathrm{Tr}(-1)^F$, Morse count of vacua	Section 13.8.1, Chapter 7
IR TQFT	gapped phase at long distances; toric code $\dim\mathcal{H} = 4^g$	Section 13.8.2, Chapter 12
Yang–Mills problem	existence + gap for compact simple G on $\mathbb{R}^4$	Section 13.9
